Bioconjugate Chemistry

EDITORIAL

We welcome the following distinguished scientists as *new members* of the Editorial Advisory Board, and we look forward to working with them to take the journal in new directions:

Jackie Barton
California Institute of Technology
Pasadena, CA

Mark E. Davis
California Institute of Technology
Pasadena, CA

Gene M. Dubowchik
Bristol-Myers Squibb
Wallingford, CT

Greg Hermanson
Pierce Chemical Company
Rockford, IL

Donald J. Hnatowich
University of Massachusetts Medical Center
Worcester, MA

Thomas Kissel
Philipps-University of Marburg
Marburg, Germany

Chris Leamon
Endocyte Pharmaceuticals, Inc.
West Lafayette, IN

Helmut R. Maecke
University Hospital Basel
Basel, Switzerland

Oleg Melnyk
Biological Institute of Lille
Lille, France

Sherie L. Morrison
University of California, Los Angeles
Los Angeles, CA

Steven L. Regen
Lehigh University
Bethlehem, PA

P. August Schubiger
Paul Scherrer Institute
Villigen, Switzerland

Paul Selvin
University of Illinois
Urbana, IL

David H. Thompson
Purdue University
West Lafayette, IN

Pierre Vierling
Universite de Nice Sophia-Antipolis
Nice, France

Wynn A. Volkert
University of Missouri
Columbia, MO

We are grateful to the following *outgoing members* of the Editorial Advisory Board for their service during the past years, and we wish them well in their future endeavors.

Maciej Adamczyk
Gary Bignami
Daniel J. Coughlin
Masad Damha
Edith Dellacherie
Jean F. Desreux
Raymond Firestone
Alan Fritzberg
Jean Gariepy
Sidney M. Hecht

Element-Coded Affinity Tags for Peptides and Proteins

Paul A. Whetstone, Nathaniel G. Butlin, Todd M. Corneillie, and Claude F. Meares*

Department of Chemistry, University of California, One Shields Avenue, Davis, California 95616. Received August 26, 2003

Isotope-coded affinity tags (ICAT) represent an important new tool for the analysis of complex mixtures of proteins in living systems [Aebersold, R., and Mann, M. (2003) *Nature, 422*, 198−207]. We envisage an alternative protein-labeling technique based on tagging with different *element-coded* metal chelates, which affords affinity chromatography, quantification, and identification of a tagged peptide from a complex mixture. As proof of concept, a synthetic peptide was modified at a cysteine side chain with either a carboxymethyl group or acetamidobenzyl-1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (AcBD) chelates of terbium or yttrium. A mixture of the three modified peptides in a mole ratio of 100:1.0:0.83 carboxymethyl:AcBD-Tb:AcBD-Y was trypsinized, purified on a new affinity column that binds rare-earth DOTA chelates, and analyzed by LC-MS/MS. Chelate-tagged tryptic peptides eluted cleanly from the affinity column; the tagged peptides chromatographically coeluted during LC-MS analysis, were present in the expected ratio as indicated by MS ion intensity, and were sequence-identified by tandem mass spectrometry. DOTA-rare earth chelates have exceptional properties for use as affinity tags. They are highly polar and water-soluble. Many of the rare earth elements are naturally monoisotopic, providing a variety of simple choices for preparing mass tags. Further, the rare earths are heavy elements, whose mass defects give the masses of tagged peptides exact values not normally shared by molecules that contain only light elements.

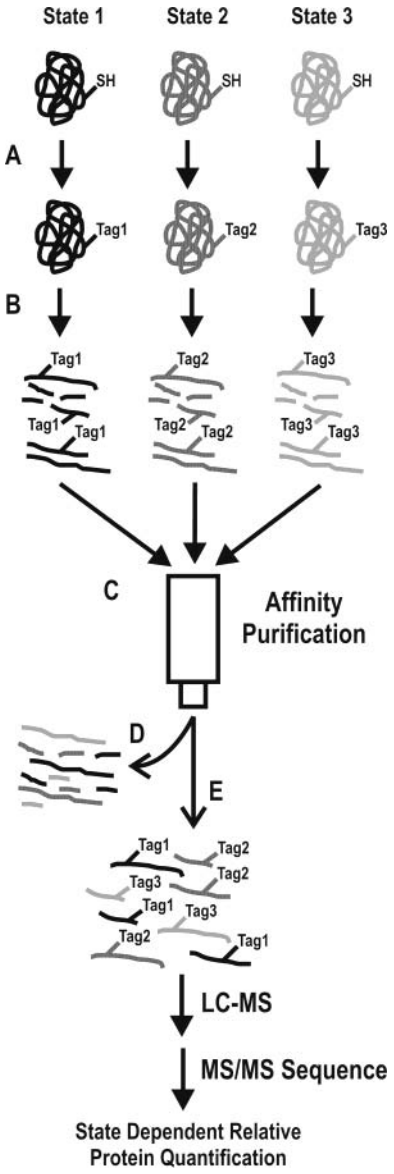
INTRODUCTION

The assessment of protein expression profiles is an important tool for understanding many aspects of cell biology, including the effects of drug treatments. One way of comparing protein expression under different conditions involves chemically modifying the proteins in separate samples with isotopically distinct but otherwise identical reagents, followed by enzymatic fragmentation, chromatographic separation, and combination of the samples for mass spectrometric analysis (*1*−*4*). Chemically equivalent, but isotopically discrete, labeled peptides from the combined samples are detected simultaneously in the mass spectrometer, permitting quantitative analysis of expression levels. A well-established enhancement of this approach is isotope-coded affinity tags (ICAT, Scheme 1) in which ^{2}H- or ^{13}C-isotopes are incorporated within a biotinylated tag, permitting affinity capture and enrichment of tagged peptides on avidin columns (*5*−*17*). ICAT is potentially well suited to the study of complex protein mixtures. However, because typical avidin affinity media bind and release some peptides that do not carry the tag, biotin-based ICAT reagents lead to *enrichment* rather than isolation of the tagged peptides and may therefore have limited sensitivity to rare components of the mixture.

Antibody−antigen interactions are often the basis for preparative affinity chromatography. As an alternative to biotin−avidin, we have explored affinity tags based on the interactions between antibody 2D12.5 and the range of ligands that it binds (*18*). These ligands are metal chelates incorporating any of the rare earth metals bound to the macrocycle DOTA.[1] DOTA-rare earth chelates have exceptional properties for use as affinity tags. Unlike biotin, they have no natural analogues that might interfere with affinity purification. They are highly polar and water-soluble. Many of the rare earth elements are naturally monoisotopic, providing a variety of simple choices for preparing mass tags. As shown in Table 1,

Table 1. Mass Differences between Pairs of Naturally Monoisotopic Rare Earths for Use in Element-Coded Affinity Tags

element	^{89}Y	^{139}La	^{140}Ce[a]	^{141}Pr	^{159}Tb	^{165}Ho	^{169}Tm	^{175}Lu
^{89}Y		50	51	52	70	76	80	86
^{139}La			1	2	20	26	30	36
^{140}Ce[a]				1	19	25	29	35
^{141}Pr					18	24	28	34
^{159}Tb						6	10	16
^{165}Ho							4	10
^{169}Tm								6
^{175}Lu								



[a] Natural abundance ^{140}Ce (88%) and ^{142}Ce (11%). All other isotopes are naturally >97% monoisotopic.

Scheme 1. Generalized Scheme for ICAT and ECAT[a]

[a] (A) Amino acid side chains such as cysteine sulfhydryls are modified with reactive tag molecules. For ICAT, different tags contain different numbers of ^{2}H or ^{13}C; for ECAT, tags contain different rare earth elements. (B) Tagged protein is digested with a protease: e.g., trypsin. (C) The tryptic fragments from multiple labeling experiments are combined and purified on a tag-specific affinity column. (D) Washing removes untagged peptides from the column. (E) Tagged peptides are eluted from the column and analyzed by LC-MS.

naturally occurring mass tags could be used in combinations differing in mass from 1 to 86 amu. Isotopically enriched elements and non-rare earth elements that bind to DOTA could extend the selection dramatically. Further, the rare earths are heavy elements, whose mass defects give the masses of tagged peptides exact values not normally shared by molecules that contain only light elements (*19*).

It appeared to us that these properties of the rare earths could be advantageous; however, data were not available regarding the suitability of metal chelate mass tags to mass spectrometric analysis. Answers to basic questions regarding the feasibility of element-coded affinity tags (ECAT) are addressed in this communication.

It has already been established that protein-tagging DOTA reagents can be prepared (e.g., *20*−*24*). Besides

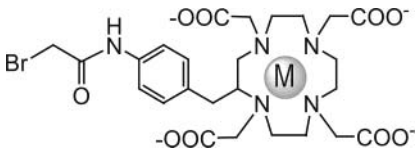

Figure 1. Bromoacetamidobenzyl-DOTA (BAD). Metalation of the chelate with a monoisotopic rare earth (M) provides a unique mass tag. Alkylation of a sulfhydryl group on a protein and protease digestion allow antibody 2D12.5 affinity purification of tagged peptides from complex mixtures, and relative quantification of all tagged peptides in the mixture, as well as sequence identification through tandem mass spectrometric analysis. The bromoacetamido reactive group may be replaced by many others with different chemical properties, e.g., an isothiocyanate that reacts with amines.

demonstrating that these reagents and their protein conjugates are compatible with trypsin digestion conditions, it must be shown that an affinity medium can be prepared, and that the metal chelates are equivalently stable to affinity column binding, washing, and elution. Tagged peptides containing different rare earth elements should also coelute on reverse-phase liquid chromatography. Finally, the tags themselves should not complicate mass spectrometric analysis; preferably, the tags should resist fragmentation under conditions of peptide sequencing by tandem mass spectrometry (MS/MS). We have confirmed these properties, with the results presented below. Experimental details are given in Supporting Information.

Molecules incorporating the macrocyclic polyaminocarboxylate DOTA attached to electrophilic groups can be synthesized by various methods (*20*−*24*). For this work we prepared the reagent BAD[1] (Figure 1). As a trial peptide for tagging, we synthesized the hemagglutinin-based peptide CNSLKLAT-amide using standard solid-phase techniques. Incorporating iodoacetic acid or BAD into the syntheses at appropriate steps led to C(carboxymethyl)-NSLKLAT-amide or C(acetamidobenzyl-DOTA)NSLKLAT-amide. Aliquots of a C(AcBD)NSLKLAT-NH_2 solution were combined with solutions of either $TbCl_3$, YCl_3, or $LuCl_3$ and the chelate-labeled peptides purified.

Metal-labeled C(AcBD)NSLKLAT-NH_2 peptides were examined by LC-MS/MS. Mixed pairs of tagged peptides (chosen from Tb, Y, Lu) were analyzed in triplicate with good reproducibility. In all cases both chelate-labeled peptides in the sample coeluted on reverse phase LC; comparison of relative ion counts yielded expected abundance ratios within 15%. Tandem mass spectrometry of each peptide reproducibly yielded the expected b/y series with no tag fragmentation evident (Figure 2).

A mixture containing carboxymethylated CNSLKLAT-NH_2 peptide as well as Tb- and Y-metalated peptide chelates was prepared in a 100:1.0:0.83 mole ratio. The mixture was completely digested with trypsin (cleaved after the lysine residue) and used to test an affinity column prepared from antibody 2D12.5, which binds all the rare earth−DOTA complexes. The affinity column was prepared using Pierce Amino-link media, and elution protocols were investigated using NBD−rare earth chelates.

To see if the antibody 2D12.5 affinity column could bind different DOTA−rare earth-tagged peptides without significant discrimination while passing untagged peptides, the trypsinized and tagged test peptide mixture was applied to the column, which was washed and eluted. LC-MS analysis of the eluent is shown in Figure 3.

Figure 2 shows that the tags resist fragmentation under conditions of peptide sequencing (MS/MS). Figure

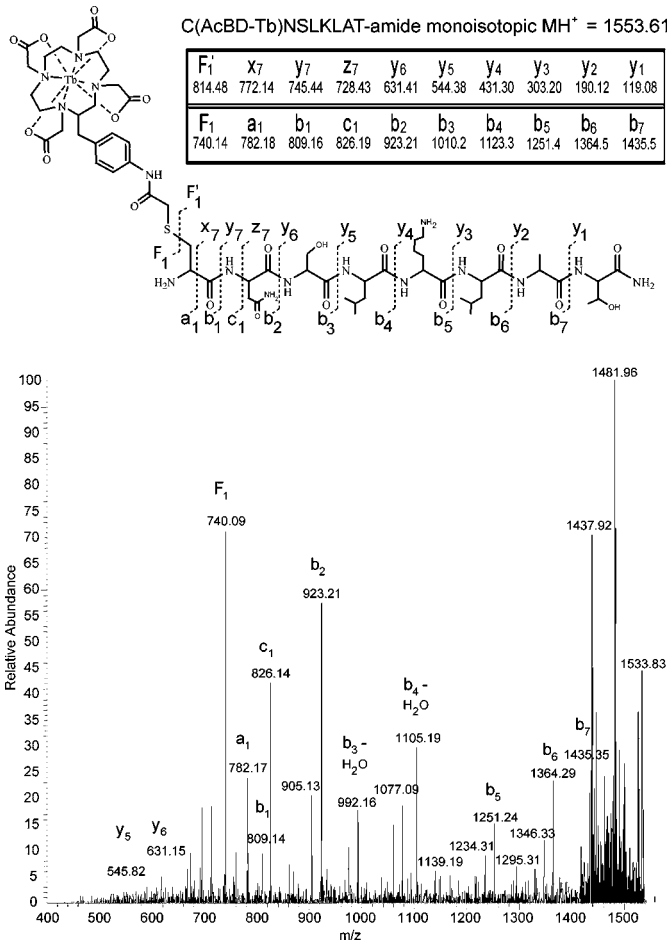

Figure 2. Predicted and observed CID fragment masses of the C(AcBD-Tb)NSLKLAT-NH_2 peptide. Similar results were obtained for peptides with Lu- and Y-metalated mass tags. Because the mass tag is located at the N-terminal end of this peptide, the b-ion series predominates in the observable mass range. Mass spectrometry was performed on an LCQ Deca electrospray ion-trap instrument.

3 shows that tagged peptides containing different rare earth elements coelute by reverse-phase liquid chromatography, and that the affinity column effectively removes untagged peptides. This was confirmed by an additional experiment in which the peptide digest was mixed with a large excess of trypsin-digested human serum albumin before being added to the affinity column; the results were comparable to Figure 3.

Thus element-coded affinity tags based on rare earth−DOTA chelates have the necessary properties for the study of more complicated systems. Element-coded tags also have other properties that may prove useful in applications: all the elements exhibit characteristic X-rays whose energies behave systematically, many have redox potentials accessible under normal conditions, others are paramagnetic or have radioisotopes with useful properties. This alternative to biotin−avidin tags may find applications beyond the study of complex mixtures of proteins.

ACKNOWLEDGMENT

We thank Susan Lee, Sarah Cheal, Carlito Lebrilla, and Nick Young for helpful discussions. This work was supported by Research Grants GM25909 and CA16861 to C.F.M. from the National Institutes of Health. The LCQ mass spectrometer was purchased with support from NIH Shared Instrumentation Grant RR014701.

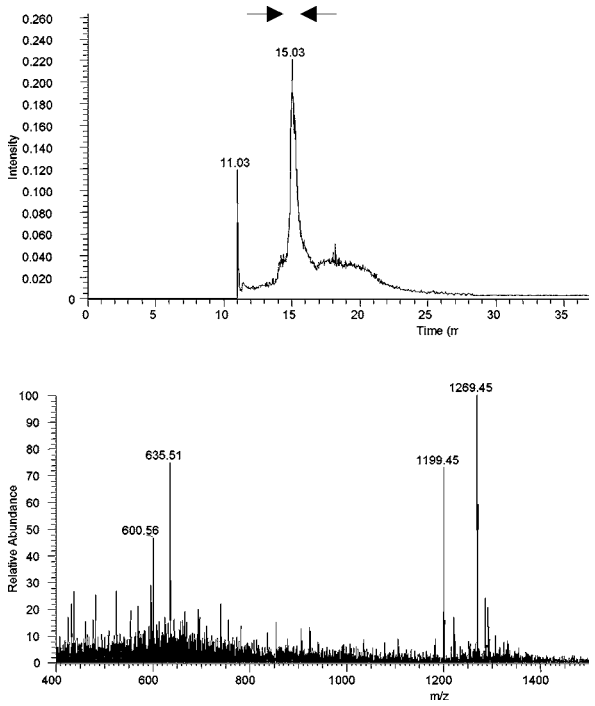

Figure 3. LC-MS of trypsinized, affinity-purified peptide mixture (originally 0.83 Y:1.0 Tb mole ratio in the presence of 100-fold excess untagged peptides, which were removed by the affinity column). The top panel depicts the total ion count versus time; the arrows in the top panel mark the time period over which the one-dimensional mass spectrum in the bottom panel is averaged, indicating that trypsin fragments of the Y- and Tb-labeled peptide, which differ by 70 mass units, coeluted from the LC column. The mass-to-charge ratio (*m*/*z*) of protonated C(AcBD-Tb)NSLK is 1269.45; protonated C(AcBD-Y)NSLK is 1199.45 *m*/*z*. Doubly protonated ions of the Tb- and Y-labeled peptides appear at 635.51 and 600.56 *m*/*z*, respectively.

Element-Coded Affinity Tags for Peptides and Proteins †

Paul A. Whetstone, Nathaniel G. Butlin, Todd M. Corneillie and Claude F. Meares*

Abbreviations: BAD, ((S)-2-(4-(2-bromo-acetamido)-benzyl)-DOTA); C(AcBD)NSLKLAT-amide, peptide CNSLKLAT-amide with acetamidobenzyl-DOTA group attached to cysteine; C(CM)NSLKLAT-amide, C(carboxymethyl)NSLKLAT-amide; CID, collision-induced dissociation; CV, column volume; DIEA, *N,N*-diisopropylethylamine; DOTA, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid; DTPA, diethylenetriaminepentaacetic acid; HOBt, 1-hydroxybenzotriazole; PyBOP, benzotriazole-1-yl-oxytrispyrrolidinophosphonium hexafluorophosphate; TIS, triisopropylsilane.

Reagents

All reagents and solvents were the purest commercially available and used without further purification. Precautions were taken to minimize contamination with adventitious metal ions. All the laboratory glassware was washed with mixed acid solution and rinsed copiously with 18 MΩ cm H_2O. Trace-metal grade HCl was used for acid washing and as a reagent. All plasticware was washed in 3 M HCl overnight and thoroughly rinsed. Glassware was oven dried overnight and cooled under an argon atmosphere.

All buffer reagents were biochemical grade or higher. Glacial acetic acid (EM Scientific) and trifluoroacetic acid (Acros) were used as received. Triethylamine (EM Scientific), sodium chloride and potassium phosphate mono- and dibasic (Fisher Scientific) were >99.5% and used as received. Antibody 2D12.5, purified from hybridoma cell culture, was a gift from Dr David Goodwin, Palo Alto Veterans Administration Hospital (Palo Alto, CA).

Chelate Synthesis

(S)-2-(p-aminobenzyl)-1,4,7,10-tetraazacyclododecane-N,N',N'',N'''-tetraacetic acid tetra-tertbutyl ester (ABD-tBu$_4$) was synthesized as indicated schematically in Supplementary Scheme 1 according to previously published methods[1-3].

(S)-2-(p-bromoacetamidobenzyl)-1,4,7,10-tetraazacyclododecane- N,N',N'',N'''-tetraacetic acid tetra-tertbutyl ester (BAD-tBu$_4$). To remove adventitious metals, all glassware was soaked in mixed acids overnight and rinsed with double-deionized H_2O.

In a fume hood, 136 μL of bromoacetyl bromide (FW 199.85, 0.682 mmol) was added to 2mL of CH_2Cl_2 in a 25 mL round-bottom flask under an argon atmosphere, and the solution was chilled to 0 °C on ice. Under argon, 250 mg of ABD-tBu_4 (FW 733.50, 0.341 mmol) was dissolved in 5 mL of CH_2Cl_2 and cannulated into a 10 mL addition funnel, to which 107 μL of DIEA (FW 129.15, 0.682 mmol) was added. With stirring, the solution of ABD-tBu_4 was added dropwise over 5 min to the bromoacetyl bromide solution. The mixture was stirred for an additional 5 min and then extracted with an aqueous basic solution (0.1% DIEA in H_2O) until the aqueous fractions remained basic. The CH_2Cl_2 layer was then dried over Na_2SO_4 and solvent was removed under reduced pressure to quantitatively yield 290 mg of BAD-tBu_4 as a light orange solid (ESI-MS *m/z* calc'd (MH+): 854.43, 856.43. Found: 854.42, 856.43.

Peptide Synthesis

Synthesis of the hemagglutinin-based peptide CNSLKLAT-amide was carried out using standard Fmoc-amino acid solid phase techniques [4-10]. Briefly, the peptide was extended on Rink Amide AM resin (NovaBiochem, San Diego, CA) in a batch-wise manner; Fmoc was removed from resin-bound N-terminal amines with a 20% piperidine solution in DMF, and amide couplings were subsequently performed by addition of a solution containing 3 molar equivalents of protected amino acid, HOBt, PyBOP and DIEA in DMF.

The N-terminal cysteine was added with methoxytrityl protection of the sulfhydryl, which was later selectively removed with a 1% CF_3COOH solution in CH_2Cl_2. After sulfhydryl deprotection, the resin was washed, dried and divided into two lots. Each lot

was again pre-swollen in CH_2Cl_2, washed with DMF, and then a solution containing 2 molar equivalents of DIEA and either iodoacetic acid or BAD-tBu_4 in DMF was added. The resin was agitated at room temperature by bubbling argon through the reaction bed; after 2 h, the reaction was deemed complete when an aliquot of resin tested negatively for free sulfhydryl[11-13]. The N-terminal Fmoc was removed, the resin washed, dried, and cleaved at room temperature over 2 h with 95% CF_3COOH, 2.5% TIS, 2.5% H_2O. After CF_3COOH removal under reduced pressure, 2 mL of Et_2O was added to the flask, and the solution was sonicated until it resembled a colloidal suspension. The Et_2O slurry was extracted with H_2O four times; H_2O extracts of each peptide were combined and washed with Et_2O four times. The aqueous portions were then solvent reduced, passed through a 5 μm filter to remove particulate contamination, and purified by reverse phase HPLC to yield C(carboxymethyl)NSLKLAT-amide or C(acetamidobenzylDOTA)NSLKLAT-amide in yields >98%. High-performance liquid chromatography was carried out on a Rainin HPXL system (Rainin Instruments,Woburn, MA) equipped with titanium self-washing pump heads. Solvents were mixed using a Dynamax titanium dual-chamber mixer. UV absorbance was measured at 254 or 280 nm. The HPLC system was controlled by Dynamax software on a Macintosh Plus computer. Analytical reversed-phased HPLC was performed at room temperature at 1 mL/min with an Alltech Altima 4.6 × 250 mm column and 4.6 × 7.5 mm guard column (Alltech Associates, Inc, Deerfield, IL). Preparative RP-HPLC was performed at room temperature at 6mL/min with an Alltech Alltima 22 × 250 mm column. The running solvents were CH_3CN containing 0.075% CF_3COOH and H_2O containing 0.1% CF_3COOH.

Metallation of peptide-chelates

Using a 0.1 M NH_4OAc, pH 6.1 buffer, 100 μL aliquots of a 1 mM solution C(AcBD)NSLKLAT-amide peptide were combined with 10 μL of 100 mM solutions of either $TbCl_3$, YCl_3, $EuCl_3$, or $LuCl_3$. All were incubated at 37 °C for 2 h, after which 10 μL of a 0.1 M solution of DTPA in 0.1 M NH_4OAc, pH 6.1 buffer was added to the solution, incubated 30 min at 37 °C and then purified on SepPak Plus C-18 (Waters, Milford, MA) cartridges. SepPak Plus C18 purification was done according to established protocols. Briefly, cartridges were equilibrated with 10 mL CH_3CN followed by 10 mL 0.1 M NH_4OAc buffer, pH 6.1 at approximate flow-rates of 2 mL/min. Metallated peptide-chelate solutions (in aqueous NH_4OAc) were passed through the cartridge and the cartridge was again washed with 10 mL of NH_4OAc buffer, followed by 10 mL of deionized H_2O. The analytes were eluted with 2 mL of a 1:1 CH_3CN/H_2O solution. Using the reported extinction coefficient of the UV absorption maximum at 244 nm[14], the concentration of each metallated peptide-chelate was measured both before and after application to the SepPak cartridge to verify complete elution. Mass spectrometric analysis was done to verify that the peptide-chelates had been fully metallated.

Trypsinization of peptides

A mixture containing carboxymethylated-peptide as well as Tb- and Y-metallated peptide-chelates was prepared according to Table S1. Solvent was removed under reduced pressure, and the residue was resuspended in 100 μL of 50 mM NH_4HCO_3 buffer, pH 8.0. 10 μg sequencing grade modified porcine trypsin was reconstituted in 10 μL of resuspension buffer (Promega), heated at 30 °C for 15 min, and added to the peptide

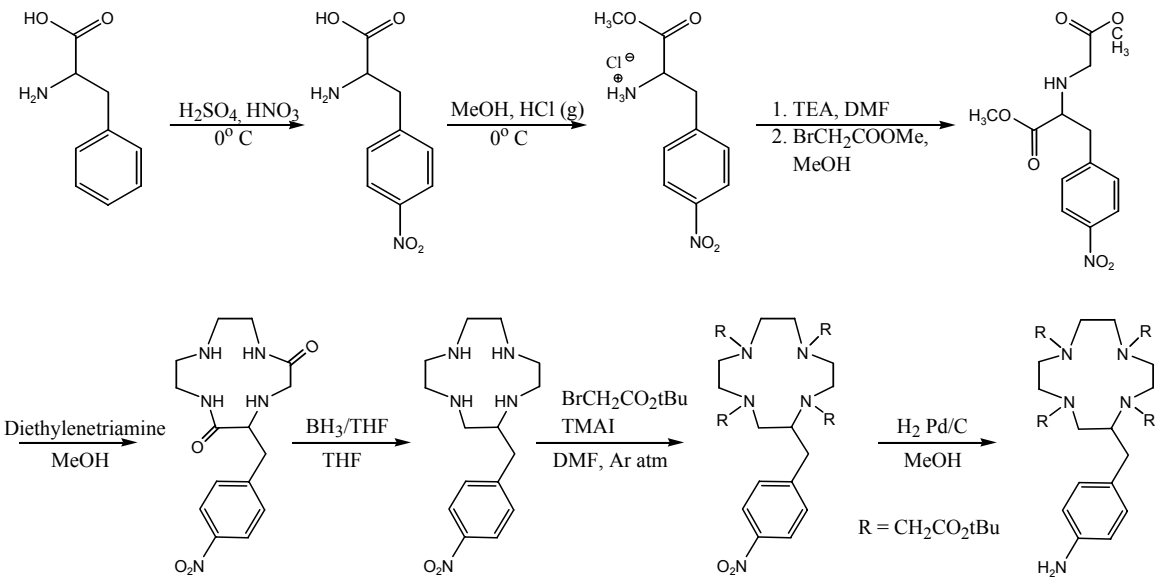
mixture. The solution was mixed by pipetting, and incubated at 37 °C for 8 h, at which time mass spectrometry indicated the complete conversion of the carboxymethylated-peptide parent to the expected tryptic fragments.

Table S1 Stoichiometry of peptide mixture trypsinization reaction.

Peptide	nmol	MW	μg
C(AcBD-Tb)NSLKLAT	1.0	1552.6	1.6
C(AcBD-Y)NSLKLAT	0.8	1482.6	1.2
C(CM)NSLKLAT	100.0	906.4	90.6

Mass Spectroscopy

All mass spectrometry was performed on a ThermoFinnigan LCQ Deca electrospray ion-trap instrument. Before LC-MS experiments were performed, the instrument was calibrated according to the manufacturers protocol, and was tuned to maximize signal of the C(CM)NSLKLAT peptide. LC-MS was performed at room temperature at 20 μL/min with a Vydac microbore 218TP51 column. The running solvents were 0.01% CF_3COOH in H_2O and 0.01% CF_3COOH in CH_3CN. Samples were injected at 3%, gradient ramped to 30% over 20 min, with peptide-chelates eluting at 9% CH_3CN.



Preparation of 2D12.5 Affinity Column

Antibody 2D12.5 (18 mg) was dialyzed into 3 mL of PBS, pH7.2, and combined with 5 mL of Aminolink slurry (Pierce). The antibody and column material were incubated together overnight at 4 °C with end-over-end rocking. The following morning 200 μL of 5 M $NaCNBH_3$ in 0.01 M NaOH was added to the slurry and incubated for 8 h at 4 °C. The coupled gel was then washed with 5 column volumes of PBS and 3 column volumes of 1.0 M Tris-HCl (pH = 7.4), and incubated and reduced with $NaCNBH_3$ in a similar manner. Coupling efficiency was >90% as determined by A_{280nm} measurements for the

antibody (ε = 1.32 mL/mg). The column material was stored in 10 mM TBS (pH = 7.4) with 0.01% NaN_3 and 1 mM EDTA at 4 °C.

Affinity Purification of Tagged Peptides

All buffer solutions were filter sterilized prior to use with the 2D12.5 affinity media. Digested and tagged test peptide (1 nmol) was resuspended with a trypsin-digested solution of human serum albumin (HSA, 10 nmol). The serine protease inhibitor phenylmethylsulfonyl fluoride (PMSF) was added to a final concentration of 1.0 mM. The peptide solution was loaded onto a 500 µL 2D12.5 minicolumn pre-equilibrated with 10 mM Et_3NHOAc, pH = 7.1 (Buffer A). The minicolumn was washed with 6 column volumes (CVs) of Buffer A, 7 CVs of 1 M NaCl in 10 mM Et_3NHOAc, 1 CV of Buffer A, 7 CVs of 0.5% HOAc (pH = 2.8), 1 CV of Buffer A, 7 CVs of 0.1% Et_3N (adjusted to pH = 10.1 with HOAc), 1 CV of Buffer A, and 7 CVs of 30% CH_3CN v/v in Buffer A. The isolated tagged peptide fragment was eluted in 8 column volumes of aqueous 20% CH_3CN containing 0.1% CF_3COOH. LC-MS analysis of the eluent is shown in Figure 3.

N-(3-Trifluoroethanesulfonyloxypropyl)anthraquinone-2-carboxamide: A New Heterobifunctional Reagent for Immobilization of Biomolecules on a Variety of Polymer Surfaces

P. Kumar, S. K. Agarwal, and K. C. Gupta*

Nucleic Acids Research Laboratory, Institute of Genomics and Integrative Biology, Mall Road, Delhi University Campus, Delhi 110 007, India. Received October 28, 2003

A new heterobifunctional reagent, *N*-(3-trifluoroethanesulfonyloxypropyl)anthraquinone-2-carboxamide (NTPAC) has been developed, useful for making bioconjugates and immobilization of biomolecules, viz., oligonucleotides, peptides, proteins, etc., on a variety of carbon-containing solid surfaces. Its trifluoroethanesulfonate ester group reacts with aminoalkyl or mercaptoalkyl functions present in biomolecules, and the anthraquinone structure reacts with a variety of carbon-containing polymers under ultraviolet irradiation (365 nm). The reagent has been used in two ways. First, the reagent, NTPAC, was first brought in contact with the above said supports and exposed to long wavelength ultraviolet light (365 nm), thereby generating active trifluoroethanesulfonate ester functions on the support, which subsequently react with appropriate mercaptoalkyl- or aminoalkyl-containing biomolecules to fix them on the supports. In another route, the proposed reagent was allowed to react first with proteins or 5′-aminoalkyl- or mercaptoalkyl-modified oligonucleotides to form the appropriate biomolecule−anthraquinone conjugate, which was then brought in contact with a variety of carbon-containing polymers, viz., modified controlled pore glass (CPG), modified glass microslides, cross-linked polystyrene, nylon, cross-linked polysaccharides, polypropylene (PP), polyethylene (PE), etc., and exposed to long wavelength ultraviolet light (365 nm), resulting in immobilization of the conjugates on the support. Both of the routes work satisfactorily and we could successfully immobilize a number of enzymes and modified oligonucleotides on a variety of supports.

INTRODUCTION

A large number of homobifunctional and heterobifunctional reagents (*1*−*7*) are known in the literature to introduce modifications in proteins, nucleic acids, and other biomolecules. In the case of homobifunctional reagents, in almost all cases, the two reactive groups are identical, while the two reactive groups are dissimilar in heterobifunctional reagents. These reagents have been shown to induce cross-linking intramolecularly between two locales within a macromolecule and intermolecularly between two molecules. Intramolecular cross-linking has been used to increase the stability of proteins against thermal and mechanical denaturation, to determine the distances between two reactive groups, and to detect different conformational states. Intermolecular cross-linking has been employed to characterize the nature and extent of protein−protein interactions, to couple two or more different proteins. The unique advantage of heterobifunctional reagents having differential reactivity of the two different functional groups is that cross-linking can be controlled both selectively and sequentially. These reagents find a variety of applications in modern molecular biology. In recent years, the high-density oligonucleotide microarrays have emerged as an important tool for molecular biology studies. Arrays of short synthetic oligonucleotides, peptides, and proteins have been used for various applications (*8*−*14*), viz., drug development, DNA sequencing, medical diagnostics, nucleic acid-ligand binding studies, DNA computing, etc. Basically, two approaches are being followed for the construction of oligonucleotide arrays. In one approach, the oligonucleotides are directly synthesized on the plane surface at a preselected position following conventional chemical methods or photolithography or ink-jet methods (*15*). Another method, which is gaining popularity, is based on fixing prefabricated oligonucleotides, peptides, and proteins on a solid surface (*16*). This method offers great flexibility and can accommodate different chemistries as well as surfaces of choice. Two important factors which affect the quality of microarrays (microchip) fabricated by the latter method depend on the solid surface used and chemistry employed for fixing of oligonucleotides and other biomolecules. A large number of chemical methods (*17*−*20*) and surfaces (*21*−*23*) have been reported for this purpose. Usually, the polymer surface is first modified, to have the desired reactive functional groups, using appropriate reagents, and then peptides or proteins and premodified oligonucleotides are immobilized on the activated surface employing suitable reagents or activators. Thus, one would require a number of steps and reagents to immobilize oligonucleotides or peptides/proteins of choice on a solid surface. We describe here a general method for the immobilization of presynthesized modified oligonucleotides or peptides/proteins on a variety of surfaces, e.g., glass, polypropylene (PP), polyethylene (PE), nylon, and polysaccharide (Sepharose CL-4B), in regioselective fashion using a new heterobifunctional reagent, NTPAC. The reagent has been used in two ways.

In the first route, the reagent, NTPAC, is brought in contact with a variety of carbon-containing polymers, viz., modified controlled pore glass (CPG), nylon, cross-linked polysaccharides (Sepharose CL-4B), polypropylene (PP), and polyethylene (PE), and exposed to UV light (365 nm), thereby generating the reactive trifluoroethanesulfonate ester functions on the support, enabling them to react with mercaptoalkyl or aminoalkyl group-containing ligands in the subsequent step. In the second route, the anthraquinone−ligand conjugate is formed by allowing the reagent, NTPAC, to react with an appropriate ligand, viz., peptides (having a free α-amino group), proteins, and 5′-aminoalkyl- or mercaptoalkyl-modified oligonucleotides, and the resulting conjugate in the subsequent step reacts with a carbon-containing support under UV irradiation (365 nm). Both of the routes work satisfactorily, and we could successfully immobilize a number of enzymes or modified oligonucleotides on a variety of supports using the proposed heterobifunctional reagent.

EXPERIMENTAL PROCEDURES

Materials. All the reagents used in the present investigation were purified prior to their use. 2,2,2-Trifluoroethanesulfonyl chloride (tresyl chloride), anthraquinone-2-carboxylic acid, 3-aminopropan-1-ol, and dicyclohexylcarbodiimide (DCC) were procured from Aldrich Chemical Co. (St. Louis, MO). FAM-phosphoramidite was obtained from Applied Biosystems, Inc. (Foster City, CA). All other reagents and chemicals were procured locally. All the reactions were carried out in an inert atmosphere unless otherwise specified.

Photochemical Reactions. Photochemical reaction of anthraquinone was carried out in a photochemical chamber (Gautam Enterprises, Delhi, India) attached with long wavelength tubes (365 nm) and a variable energy regulator.

***N*-(3-Hydroxypropyl)anthraquinone-2-carboxamide 2.** To a solution of anthraquinone-2-carboxylic acid (2.0 mmol) **1** and *N*-hydroxysuccinimide (2.5 mmol) in anhydrous *N*,*N*-dimethylformamide (15 mL) was added dicyclohexylcarbodiimide (DCC) (2.5 mmol). The reaction was allowed to stir for 3 h at room temperature. After completion of reaction, 3-aminopropanol (3.0 mmol) and triethylamine (3.0 mmol) were added dropwise at room temperature. The reaction was further allowed to stir for 6 h at room temperature. Then the reaction mixture was filtered to remove dicyclohexylurea and the filtrate concentrated under vacuum to a syrupy mass. The residual mass was dissolved in ethyl acetate (100 mL) and washed with aq 5% sodium bicarbonate (2 × 25 mL), 5% citric acid (2 × 25 mL), and saturated solution of sodium chloride (1 × 25 mL), respectively. The organic phase was collected, dried over anhydrous sodium sulfate, and after filtration, concentrated under vacuum to obtain *N*-(3-hydroxypropyl)anthraquinone-2-carboxamide **2** as solid material in 90% yield. The compound was further characterized by ^{1}H NMR: $CDCl_3$ δ 1.65 (m, 2H, CH_2), 3.2−3.45 (m, 4H, 2 × CH_2), 7.5−8.5 (m, 8H, ArH).

***N*-(3-Trifluoroethanesulfonyloxypropyl)anthraquinone-2-carboxamide (NTPAC) 3.** *N*-(3-Hydroxypropyl)anthraquinone-2-carboxamide (1.0 mmol) **2** was taken up in anhydrous dichloromethane (10 mL) containing triethylamine (1.2 mmol). The reaction mixture was cooled in an ice-bath and 2,2,2-trifluoroethanesulfonyl chloride (tresyl chloride) (1.2 mmol) added dropwise. After 2 h, the solution was filtered in an inert atmosphere to remove suspended ammonium chloride, and the filtrate was concentrated under vacuum and further dried in a desiccator to obtain the title compound **3** in almost quantitative yield as a syrupy material. Attempts were not made to crystallize the syrupy material. The reagent was characterized by its MALDI-TOF (456, M + H^+; matrix: 2,5-dihydroxybenzoic acid).

Oligonucleotides and Their 5′-Modified Analogues. Oligonucleotides, viz., $H_2N(CH_2)_5O-PO_2$-d(ACG TAG CCT TTA GTA CCT TT), $HS(CH_2)_6O-PO_2$-d(ACG TAG CCT TTA GTA CCT TT), and FAM-d(AAA GGT ACT AAA GGC TAC GT), were synthesized on Pharmacia.LKB Gene Assembler Plus at 0.2 μmol scale following standard protocol (*24*). To introduce a mercaptoalkyl or aminoalkyl group at 5′-end of these oligomers, the last coupling was performed with reagent I (*25*) and II (*26*), respectively, in an analogous manner, the normal nucleoside-phosphoramidites were coupled. During the final deprotection step, oligomers with desired functionality were obtained. In case of reagent I, aq ammonium hydroxide containing 0.1 M DTT was used for 16 h at 55 °C. After concentration, the oligomers were dissolved in water (100 μL) and desalted on a reverse phase silica gel column. The oligomers were eluted with 30% acetonitrile and concentrated in a speed vac. Oligomers with free sulfhydryl groups were obtained. Similarly, oligomers with the last coupling performed with reagent II were deprotected in aq ammonium hydroxide (30%), 16 h at 55 °C. Desalting on RP-silica gel gave 5′-aminoalkylated oligonucleotides.

Immobilization of Ligands via Route A. To demonstrate the utility of the proposed reagent **3** for immobilization of biomolecules on a variety of surfaces, a number of enzymes including 5′-modified oligonucleotides were immobilized on a variety of surfaces. In a typical experiment, a few pieces of polypropylene (PP) film (1 cm^2) were dipped in a solution of the reagent **3** (0.5 mL, 0.1 M in dichloromethane). The solvent was evaporated by keeping the reaction vial in air, and the dried pieces of PP film were exposed to UV light (365 nm) for 30 min in a UV chamber. Then the films were washed several times with dry dichloromethane (5 × 5 mL) and dried under vacuum. The activated PP films were then treated with a solution of alkaline phosphatase solution (1 mL) (prepared by dissolving 10 mg enzyme/mL in 0.1 M phosphate buffer, pH 8.0) for 1 h at 37 °C. After the reaction, the films were washed with 0.1 M phosphate buffer, pH 8.0 (3 × 1 mL), and finally with double-distilled water (2 × 1 mL) followed by drying at room temperature under vacuum. These strips were analyzed by treating them with the substrate of alkaline phosphatase (0.001 M *p*-nitrophenyl phosphate disodium salt in 0.1 M Tris buffer, pH 8.0) and subsequently reading the absorbance of the released chromophore (*p*-nitrophenoxide ion) in the solution taking 0.001 M *p*-nitrophenyl phosphate in 0.1 M Tris buffer, pH 8.0, as control followed by determination of activity of the immobilized enzyme. Similarly, other enzymes were immobilized on a variety of solid surfaces and their activities were calculated.

In the case of oligonucleotides (mercaptoalkyl and aminoalkylated), the immobilized oligomers on modified glass beads were hybridized with fluorescent-labeled complementary oligonucleotide. Subsequently, the beads were analyzed under a fluorescent microscope.

Immobilization of Biomolecules via Route B. In this method, the oligomer, d(ACG TAG CCT TTA GTA CCT TT) (2.0 O.D. A_{260}), with aminoalkyl and mercaptoalkyl groups at the 5′-terminus, in 0.1 M phosphate buffer, pH 8.5, was reacted with an excess of the reagent **3** (0.2 μmol) dissolved in dimethylformamide (100 μL). The suspension was agitated at room temperature for 1

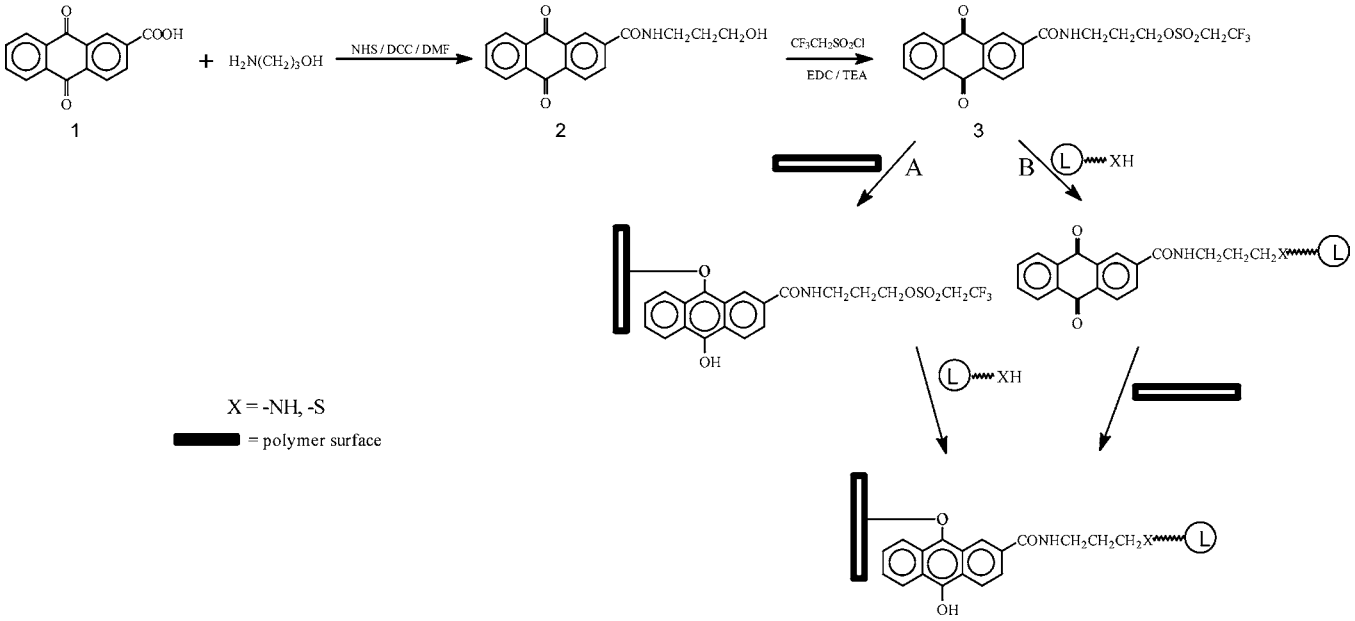
h and then concentrated in a vacuum. The dried residue was dissolved in double-distilled water (25 μL), and the mixture was centrifuged to remove the excess reagent **3**. The decanted solution was charged with lithium chloride to make 0.2 M final concentration and C-8-controlled pore glass beads (500A) (20 mg). Then the suspended beads were kept under UV light (365 nm) for 30 min at room temperature. After being washed with water, the beads were suspended in a solution of complementary oligomer d(AAA GGT ACT AAA GGC TAC GT) (2.0 O.D. A_{260}) labeled with FAM dye at the 5′-terminus dissolved in 0.1 M phosphate buffer, pH 7.1, containing sodium chloride (1 M). The suspension was warmed to 70 °C followed by slow cooling to room temperature and then to 10 °C. Subsequently, the beads were washed several times with 0.1 M phosphate buffer containing 1 M sodium chloride, and the beads were visualized under a fluorescent microscope.

Similarly, enzymes were reacted with the reagent followed by immobilization on a variety of surfaces. Their activity was measured using their respective substrates in solution as described in route A.



RESULTS AND DISCUSSION

The primary aim of this study was to search for a versatile heterobifunctional reagent useful for immobilization of biomolecules, including modified oligonucleotides, on a variety of solid matrixes. The choice of reactive functional groups in the heterobifunctional reagent was carefully made, keeping in mind that one of the functional groups must have reactivity toward aminoalkyl and mercaptoalkyl functions commonly found in biomolecules such as proteins and peptides and must be easy to introduce in oligonucleotides. The choice for other functional groups is critical, as we wanted it to react with a variety of solid matrixes, viz., polypropylene (PP), polyethylene (PE), nylon, C-8-CPG, and Sepharose. To cover a wide spectrum of polymer supports including the inert supports, we decided to look for a general reactive function which could react with all kinds of polymer supports without undertaking prederivatization of the supports. First we screened a range of chemical functional groups, but we found that they have limited reactivity toward functional groups available on polymer supports and may not cover the whole spectrum of commonly used polymer supports and particularly inert polymer supports. Then we decided to look for photoactivatable functional groups and found that they can cover a wide range of polymer supports including inert ones. On further screening the available photoactivatable moieties, we found that azido, carbenes, and substituted quinones may be the potential candidates (*27*, *28*). However, the azido group leads to generation of nitrenes on photoactivation, which is very reactive and reacts in a nonspecific manner with the substrate as well as with the medium, resulting in loss of efficiency of the reaction. Such reagents may be useful for generating functional groups on inert surfaces. The carbenes also behave in the same way as nitrenes and may not be suitable for our purpose. The use of substituted quinones has been demonstrated for immobilization of biomolecules on solid surfaces. Recently, Koch et al. (*29*) have demonstrated the usefulness of anthraquinone as photoactivatable group for making biochemical conjugates for various studies. The same group has prepared phosphoramidites of anthraquinone derivatives for immobilization of oligonucleotides on solid surface. However, it would require the preparation of phosphoramidite, which is usually very time consuming. The immobilization of biomolecules through photoactivation of anthraquinone proceeds fast, clean, and with high yields. However, it would require several chemical manipulations and use of other coupling reagents for making biomolecule-anthraquinone conjugates before immobilization. This has prompted us to use anthraquinone as one of the reactive functions in the proposed reagent, NTPAC. Being heterobifunctional reagent, NTPAC contains one trifluoroethanesulfonate ester function and one anthraquinone moiety. The trifluoroethanesulfonate ester reacts selectively with aminoalkyl and mercaptoalkyl functions present in biomolecules or modified oligonucleotides to give stable imine and thioether linkages, respectively, and the anthraquinone reacts with almost any polymer support exposing C−H groups under photolight, generating stable covalent bonds. Both of these reactions proceed rapidly under mild conditions. NTPAC has good solubility in organic solvents and particularly in water miscible solvents and hence allows one to use its DMF solution with common buffer solutions containing the ligands (biomolecules).

Design and Synthesis of *N*-(3-Trifluoroethanesulfonyloxypropyl)anthraquinone-2-carboxamide (NTPAC). The synthesis of the reagent NTPAC is depicted in Scheme 1. The synthesis of NTPAC is carried out in a two-step process. In the first step, anthraquinone-2-carboxylic acid (1 equiv) is converted to is *N*-hydroxysuccinimide active ester by its reaction with *N*-hydroxysuccinimide (1.25 equiv) in the presence of dicyclohexylcarbodiimide (1.25 equiv) in *N*,*N*-dimethylformamide. The reaction was allowed to proceed to completion, as checked by TLC. Without isolating the *N*-hydroxysuccinimide active ester, it was allowed to react with 3-aminopropanol (1.5 equiv) in the presence of a tertiary amine, triethylamine (TEA), for 6 h at room temperature. The precipitated dicyclohexylurea was removed by filtration, and the filtrate was concentrated to a syrupy mass, which was taken up in ethyl acetate where successively washed with aq 5% sodium bicarbonate, 5% citric acid, and finally with saturated sodium chloride. The organic phase, after drying over sodium sulfate, was concentrated under vacuum to obtain *N*-(3-hydroxypropyl)anthraquinone-2-carboxamide (NHAC) **2** as solid material in 90% yield.

N-(3-Hydroxypropyl)anthraquinone-2-carboxamide (NHAC) (1 equiv) was converted to NTPAC reagent by its reaction with 2,2,2-trifluoroethanesulfonyl chloride (tresyl chloride) (1.2 equiv) in the presence of triethylamine

Scheme 1. Preparation of Reagent NTPAC and Immobilization of Ligands on Polymeric Surfaces[a]

[a] Abbreviations: NHS, *N*-hydroxysuccinimide; DCC, dicyclohexylcarbodiimide; DMF, *N*,*N*-dimethylformamide; EDC, ethylene dichloride; TEA, triethylamine; L, ligand with aminoalkyl or mercaptoalkyl groups.

(TEA) for 2 h at 4 °C. After the completion of the reaction, the reaction mixture was filtered under inert atmosphere to eliminate ammonium chloride formed during the reaction. The filtrate was concentrated under vacuum to obtain a syrupy mass, which was further dried in a desiccator to obtain the desired reagent, NTPAC **3**, in almost quantitative yield.

Immobilization of Biomolecules. *Immobilization via Route A.* Basically this route of immobilization of biomolecules on a variety of surfaces involves the generation of active trifluoroethanesulfonate ester function on the surface of the polymer matrixes followed by the coupling of aminoalkylated or mercaptoalkylated ligands. The reagent, NTPAC, is brought in contact with the desired surface in dichloromethane; after evaporating the solvent, the dried polymer support is exposed to UV light where through the anthraquinone moiety it gets immobilized on the surface of the matrix with active trifluoroethanesulfonate ester functions on it. The desired ligand, enzyme, or modified oligonucleotide, etc., is then allowed to react with the surface where the trifluoroethanesulfonate ester function reacts with the ligand via their mercaptoalkyl or aminoalkyl functions (*30*). A number of enzymes and oligonucleotides were immobilized following this route successfully on a variety of polymer matrixes. The results are summarized in Table 1. This route is of particular importance in that the reactive functionality, trifluoroethanesulfonate ester, can be generated on a variety of surfaces including the inert ones such as polypropylene (PP), polyethylene (PE), nylon, etc., which are otherwise difficult to functionalize. The schematic diagram of immobilization is depicted in Scheme 1.

Immobilization via Route B. In this route, a conjugate of ligand and the reagent is first formed by mixing the appropriate quantity of the ligand in buffer with an excess of the reagent in dimethylformamide. After a brief period of reaction, the conjugate formed is centrifuged where the unreacted reagent settled as a pellet and the conjugate remained in the solution. The solution of the conjugate is mixed with the desired polymer support and exposed to UV light for about 30 min, allowing the conjugate to fix on the surface through the anthraquinone. 5′-Aminoalkyled and 5′-mercaptoalkylated oligonucleotides and a number of enzymes were immobilized on a variety of surfaces. The results are shown in Table 1.

The reagent NTPAC has also been tried for construction of oligonucleotide arrays on glass slides and polypropylene film and would be communicated shortly. The preliminary account of this work has been communicated elsewhere (*31*).

Hybrid Nanoparticles Based on Organized Protein Immobilization on Fullerenes

Pramod Nednoor, Marcello Capaccio, Vasilis G. Gavalas, Mark S. Meier, John E. Anthony, and Leonidas G. Bachas*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506-0055. Received August 28, 2003

Nanoscale carbon materials (i.e., fullerenes and nanotubes) are an attractive platform for applications in biotransformations and biosensors. The interesting properties displayed by nanoparticles demand new strategies for the manipulation of these materials on the nanoscale. Controlled modification of their surface with biomolecules is required to fully realize their potential in bionanotechnology. In this work, immobilization of a fullerene derivative with a mutant subtilisin is demonstrated, and the effect of the fullerene on the protein activity is determined. The fullerene-conjugated enzyme had improved catalytic properties in comparison to subtilisin immobilized on nonporous silica. Further, the pH profile of free and fullerene-conjugated subtilisin were almost identical.

Among the exciting possibilities of nanotechnology is the use of nanosized materials as building blocks to construct higher order supramolecular architectures. Nanomaterials that have been proposed to be suitable as building blocks include inorganic nanoparticles, quantum dots, fullerenes, and nanotubes/nanofibers from carbon or inorganic materials (*1*−*4*). Complementing this is the use of biomolecules as connectors between the various building blocks. Additionally, surface functionalization of nanoparticles for selective molecular attachment has facilitated the development of nanosensors, bioprobes, and other devices (*3*,*5*−*7*). Therefore, development of methodologies to prepare hybrid nanoparticles by controlling the interactions between biomolecules and various nanomaterials should enhance the functionality and range of application of nanoparticles. Although methodologies based on attaching nucleic acids to nanoparticles followed by DNA hybridization have appeared in the literature (*8*−*10*), the controlled conjugation of proteins on nanoscale materials has received less attention. We are interested in binding proteins on nanoparticles from a single site on the protein to yield well-defined hybrid nanomaterials with the protein oriented on the surface. For example, we recently demonstrated the preparation of hybrid alumina nanoparticles with phosphorylated pepsin through the interaction of the single phosphoryl group on serine 68 of pepsin with the alumina surface (*11*). Upon attachment to the alumina nanoparticles the enzyme remained active, while its thermal stability was enhanced. Zhang and Cass proposed a different method to orient proteins: a polyhistidine-tagged alkaline phosphatase was oriented on a titanium dioxide film through the interaction of the polyhistidine tail and surface-immobilized Ni^{2+} ions (*12*).

Fullerenes should be useful as building blocks of nanostructured materials because of their rich chemistry, electronic properties, and small dimensions (*13*). Among fullerene derivatives that have found biological applications, a diamido diphenyl fulleroid derivative was used as inhibitor of HIV protease (*14*), a fullerene carboxylic acid was used as a light sensitive biochemical probe (*15*), a C_{60}−PEG conjugate was used for photodynamic tumor therapy (*16*), a vesicular stomatitis virus was photoinactivated with fullerene-conjugated methoxy poly(ethylene glycol) amine (*17*), and a malonic acid derivative was shown to have antiapoptopic activity (*18*). Additionally, it has been recently shown that fullerenes can be used as electron mediators (*19*), or as coatings on piezoelectric quartz crystals to develop biosensors (*20*). Herein, a strategy to couple fullerenes with biomolecules has been explored that involves direct attachment of a site-specifically functionalized protein on the surface of C_{60}.

The approach undertaken involves the introduction of a unique functional group (a single cysteine residue) in the protein sequence using protein engineering. The point of mutation was selected to be away from the protein's active site to avoid deactivation upon coupling to the nanoparticles. Surfaces with maleimides have been previously used for immobilizing site-specifically a variety of proteins and peptides by taking advantage of the presence of a free sulfhydro group in the amino acid cysteine (*21*−*23*). A stable thioether bond is formed when the double bond of maleimide undergoes an alkylation reaction with sulfhydryl groups. Because of the inherent reactivity of maleimides for sulfhydro groups, *N*-(3-maleimidopropionyl)-3,4-fulleropyrrolidine (Figure 1, left), a maleimide-containing functionalized fullerene was synthesized. To obtain this compound, *N*-triphenylmethyl pyrrolidine−C_{60} was initially prepared according to a previously published procedure (*24*, *25*). To this, trifluoroacetic acid was added to obtain an intermediate fullerene pyrrolidine ammonium salt. An amount of 40 mg of the solid containing the protonated amine (fulleropyrrolidinium salt) was suspended by sonication in 15 mL of dry CH_2Cl_2. Anhydrous pyridine (0.6 mL) was added to the suspension followed by maleimidopropionic acid (17.6 mg, 2 equiv). Dicyclohexylcarbodiimide (21.4 mg, 2 equiv) was added at 0 °C, and the mixture was stirred in an ice bath for 30 min and then overnight at room temperature. The reaction mixture was diluted to a final volume of 60 mL with CH_2Cl_2 and filtered

through a Büchner funnel. The filtered solution was then washed with water (2 × 60 mL), a saturated solution of $CuSO_4$, and with water again. The organic phase was dried over $MgSO_4$ and evaporated under reduced pressure. The crude product was then purified by column chromatography (eluant CH_2Cl_2) yielding 30.8 mg (65%) of pure *N*-(3-maleimidopropionyl)-3,4-fulleropyrrolidine as a brown solid: ^{1}H NMR ($CDCl_3/CS_2$ 2:1, 200 MHz) 6.78 (s, 2H), 5.46 (s, 2H), 5.38 (s, 2H), 4.14 (triplet, J = 7.2 Hz, 2 H), 3.16 (triplet, J = 7.5 Hz, 2 H); *m/z* (MS−FAB$^-$) 914 (M^-, 45%), 720 (C_{60}, 100%).

Subtilisin is a serine protease secreted by members of the genus *Bacillus* that has high specificity for proteinaceous substrates. Subtilisin BPN′ from *Bacillus amyloliquifaciens* has 275 amino acids without any cysteine residues. For this study, a mutant subtilisin was produced in which a serine to cysteine (S145C) mutation was carried out by oligonucleotide-directed mutagenesis generating a single sulfhydro group per enzyme molecule. This mutant also has a nonspecific G98C mutation as a result of the polymerase chain reaction. Because there is only one attachment site on the maleimidofullerene and only one reactive group on subtilisin, a 1:1 coupling reaction is expected (Figure 1, right). The mutated subtilisin gene was inserted into a plasmid, and the protein was expressed in *Bacillus subtilis*. The plasmid was designed to produce a protein that is secreted into the culture medium (*26*). This helps in the purification of the enzyme, as the culture medium is relatively devoid of other proteins in comparison to whole cell lysate. Subtilisin BPN′ was purified using a BioCAD Sprint perfusion chromatography system (PE Biosystems, Framingham, MA) equipped with a POROS HS cation-exchange column (*26*). A volume of 1 mL of subtilisin solution was loaded to the column, and 1-mL fractions were collected and tested for protein concentration. The protein content was determined with the Micro BCA method (Pierce, Rockford, IL) using bovine serum albumin solutions as standards. The purified protein was dialyzed against phosphate buffer, pH 6.2, and stored after lyophilization at −20 °C.

A Reduce-Imm column (Pierce) was used to reduce any formed intermolecular disulfide bonds and generate the free sulfhydryl group immediately prior to reaction with the maleimidofullerene. The conjugation of maleimidofullerene and subtilisin was performed in phosphate buffer, pH 7.0, a pH that favors the reaction of maleimides with thiols over amines. An amount of 1.6 mg of *N*-(3-maleimidopropionyl)-3,4-fulleropyrrolidine was added to 5 mL of phosphate buffer (pH 7.0) containing 0.06 μmol of mutant subtilisin, and the mixture was vortexed to obtain a homogeneous suspension. The reaction was carried out for 5 h at 4 °C on a rotary shaker. The mixture was centrifuged and rinsed three times with 100 mM Tris-HCl, pH 8.6, buffer to separate the unreacted enzyme. The enzymatic activity was determined in the supernatant and the fullerene-containing solid. The enzyme releases *p*-nitroaniline form the substrate succinyl-Ala-Ala-Pro-Phe-*p*-nitroaniline (SAAPF-pNA) (Sigma, St. Louis, MO). The corresponding increase in absorbance at 412 nm was monitored on a HP 8453 Spectrophotometer. To measure the enzymatic activity, immobilized subtilisin was suspended in the buffer (Tris-HCl, pH 8.6), and aliquots of the suspension were transferred to a cuvette containing the substrate and stirred.

Initially, studies were carried out to investigate whether there is physical adsorption of subtilisin on unmodified C_{60}. For this, an excess of C_{60} (2.5 μmol) was added to the mutant subtilisin (0.05 μmol), and the mixture was shaken in a rotary shaker for 5 h as above. After removing from the rotary shaker, the mixture was centrifuged and washed three times. Activity measurement showed that almost the entire enzyme (92%) was present in the supernatant. No enzyme activity was determined on the fullerene fraction indicating the absence of any nonspecific binding on C_{60}. It should be mentioned that a C_{60} derivative was previously found to inhibit HIV-1 protease by blocking its active site (*14*). Therefore, we also evaluated the inhibitory effect of C_{60} on subtilisin. After adding C_{60} to the enzyme solution, the mixture was vortexed to obtain a homogeneous suspension, which was incubated in a rotary shaker. In this way, C_{60} was made available to the enzyme. The activity of the enzyme did not change in the presence of C_{60} indicating the absence of any kind of inhibition.

Kinetic studies were carried out to compare the K_M and k_{cat} values of free and fullerene-conjugated subtilisin. The amount of enzyme coupled was determined using the Micro BCA protein assay. To determine the K_M and k_{cat} values of the homogeneous and immobilized enzyme, the initial rate of the hydrolysis of the substrate SAAPF-pNA for a range of substrate concentrations was measured (Figure 2). The measurements were carried out in 100 mM Tris-HCl buffer (pH 8.6). The values of K_M and k_{cat} were obtained from Lineweaver−Burk reciprocal plots.

The immobilizeded enzyme demonstrated a higher K_M value than the free enzyme, suggesting that there is an influence of coupling on the affinity of the enzyme for the substrate (Table 1); higher K_M indicates lower affinity. Although this could be explained by the substrate having less access to the active site, it is more likely that the active site conformation is changed slightly upon

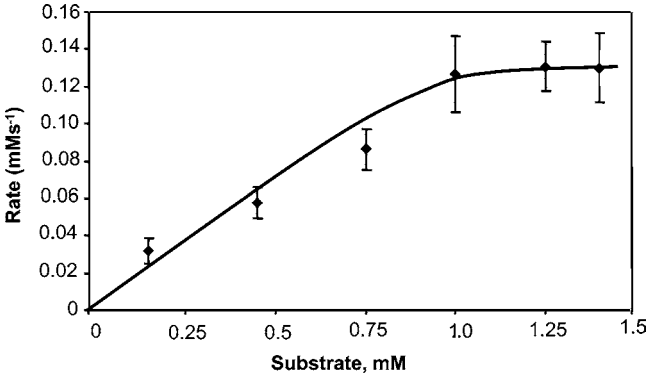

Figure 2. Initial rate (in units of mM of product formed per second) as a function of substrate concentration for the fullerene-conjugated subtilisin. Data shown are average ± standard deviation, $n = 3$. The rates were measured at 25 °C.

Table 1. Comparing the Kinetic Parameters of Free and Conjugated Enzyme

	K_M (mM)	k_{cat} (s^{-1})	k_{cat}/K_M ($M^{-1}\,s^{-1}$)
free subtilisin	0.17 ± 0.01	51 ± 2	$(3.0 \pm 0.2) \times 10^5$
coupled subtilisin with C_{60}	0.76 ± 0.2	37 ± 2	$(4.9 \pm 1.3) \times 10^4$
immobilized subtilisin on derivatized silica (*26*)	0.43 ± 0.02	14 ± 0.4	$(4.2 \pm 0.4) \times 10^4$

coupling to C_{60}. The k_{cat} value of the fullerene-conjugated subtilisin was significantly better when compared to the enzyme immobilized on a nonporous silica support (*26*) from the same amino acid residue. Compared to the free enzyme, the k_{cat} value of the fullerene-conjugated subtilisin was only reduced by 27%, while in the case of the silica support the corresponding reduction was 73%. Both silica and C_{60} are nonporous supports. Despite the hydrophilic nature of silica, which is typically advantageous in immobilized enzyme systems, the silica-conjugated subtilisin had >2.5-fold reduction in activity compared to the fullerene-conjugated subtilisin. C_{60} (0.7 nm) is much smaller in size compared to the silica particles (0.5 μm, average diameter), and it binds to only one enzyme molecule per particle. Thus, crowding effects, which tend to reduce activity at high enzyme loadings (*27*, *28*), are avoided.

The effect of pH on the activity of free and conjugated enzyme was also studied. The enzyme-catalyzed hydrolysis of SAAPF-pNA was investigated at 25 °C under various pH conditions. Buffer solutions composed of 0.0500 M acetic acid and 0.0500 M Bis-Tris propane were adjusted to pH 6.0, 7.0, 8.0, 8.5, and 9.0 with HCl or NaOH solutions. To each of these solutions, a fixed volume of substrate stock solution (40 mM SAAPF-pNA in DMF) was added to reach a concentration of 1 mM. At each pH value, a volume of 2.00 mL of the substrate solution of the corresponding pH was mixed with a fixed amount of the free or immobilized enzyme (60 μL) in a cuvette, and the initial reaction rate (60 s) was determined as described above. Attachment on conventional substrates causes changes in the pH profile of hydrolytic enzymatic reactions that is characterized by a displacement or broadening of the profile toward more acidic or basic values. When either proton exchange groups or diffusional limitation are present, both the limbs of the pH profile can be broadened. It was found that the pH profile curve for the coupled enzyme (Figure 3B) was similar to that of the free enzyme (Figure 3A). This can be explained by the lack of charged groups on the surface of C_{60}. Therefore, there should be no effect of the fullerene surface on the protonation state of the substrate. Broadened pH profiles can also be seen if diffusion on the

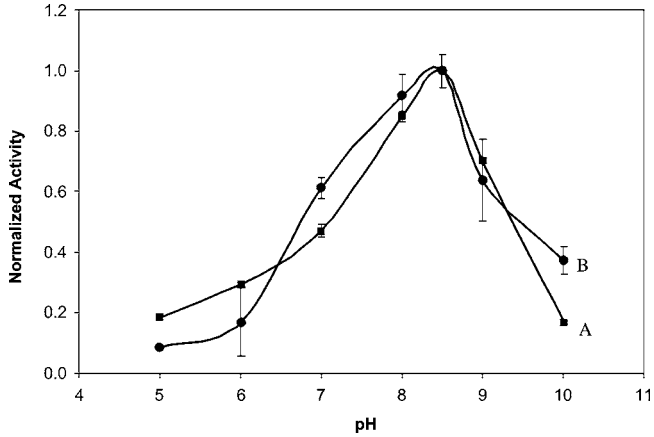

Figure 3. pH profiles of (A) free subtilisin and (B) subtilisin attached to the maleimidofullerene. All measurements were carried out at 25 °C and with a substrate concentration of 1 mM.

substrate to the enzyme is hindered upon immobilization (*29*). The small size of the C_{60} molecule makes the active site of the enzyme accessible to the substrate, and there is no diffusional limitation for the substrate to reach the active site imposed by the C_{60} surface. Thus, with regard to pH sensitivity, the attached enzyme behaves in a similar manner as free enzyme in solution.

In summary, nanotechnology has emerged as a powerful tool in the fabrication of materials having superior and often unique properties. To fully realize the potential of nanotechnology it is essential to control the way by which nanomaterials, such as fullerenes, interact with biomolecules. In this work, a maleimidofullerene was successfully attached to subtilisin through site-specific immobilization. The K_M and k_{cat} values of fullerene-conjugated subtilisin were found to be different from those of the free enzyme, but the k_{cat} was better in comparison to subtilisin immobilized on silica. Thus, the nature of the immobilization support affects the catalytic properties of the enzyme. It was also found that there is a difference in the pH profile of activity between the two supports, which is consistent with the difference in surface ionizable groups.

Production of Soluble ScFvs with C-Terminal-Free Thiol for Site-Specific Conjugation or Stable Dimeric ScFvs on Demand

Huguette Albrecht, Patricia A. Burke, Arutselvan Natarajan, Cheng-Yi Xiong, Mark Kalicinsky, Gerald L. DeNardo, and Sally J. DeNardo*

Radiodiagnosis and Therapy, Molecular Cancer Institute, University of California Davis Medical Center, Sacramento, California 95816 Received April 6, 2003; Revised Manuscript Received October 14, 2003

ScFv recombinant antibody fragments can provide specific tumor binding modules for targeting drugs. In the process of building multimeric tumor targeting pharmaceuticals, a prerequisite is the conservation of functional scFv antigen binding domains, thereby excluding scFv random conjugation to a carrier molecule or to another scFv. The pCANTAB 5E phage display/expression vector was genetically engineered to express any scFv gene as scFv with an additional C-terminal cysteine (scFv-Cys) such that the specific conjugation site is removed from the binding domain. Selected scFvs derived from an anti-MUC-1 scFv phage library were expressed in pCANTAB 5E and its modified version pCANTAB 5E Cys vectors, and compared for key characteristics. Production yields of scFv and scFv-Cys in shaker flask and biofermentor were compared. In the absence of a reducing agent, stable dimers (covalent scFv homodimers $(scFv\text{-}Cys)_2$) were the major form of scFv-Cys. These diabodies provided substantial signal enhancement for immunohistochemical staining of tissues. In the presence of a reducing agent, scFv-Cys molecules remained monomeric, with the free SH available for conjugation to a $PEG(maleimide)_2$ scaffold to form immunoreactive $PEG(scFv)_2$ bioconjugates. ScFv expression from pCANTAB 5E Cys allowed for the production of soluble scFv-Cys protein from *E.coli*, either as stable scFv-Cys or $(scFv\text{-}Cys)_2$. ScFv-Cys can be used for conjugation to PEG to form bivalent PEG $(scFv\text{-}Cys)_2$ molecules or used as $(scFv\text{-}Cys)_2$ for increased sensitivity in IHC.

INTRODUCTION

Radiolabeled monoclonal antibodies (mAb)[1] have proven to be effective therapeutic agents (*1*−*3*). However, their large size decreases tumor uptake and penetration (*4*, *5*). Normal tissue binding of the mAb Fc portion contributes to retention in vital organs, resulting in further decrease in tumor to normal tissue radiation or "therapeutic index". The development of single chain Fv antibody fragments (scFv)[1] in combination with phage display technology offers new avenues for tumor-targeted therapy (*6*−*8*). About 1/6 the size of a native antibody, the 25 kDa scFv retains the specificity of an antibody but has a decreased avidity due to its monovalent nature. Pharmacokinetic studies with scFvs have shown that their small size leads to rapid blood clearance by renal glomerular filtration, leaving little opportunity for extravascular tumor targeting (*9*, *10*). However, their use as modules for new targeting multivalent paradigms is under investigation (*11*, *12*).

ScFv fragments are typically stabilized by joining their VH and VL domains with a 15 amino acids flexible linker composed of $(Gly_4Ser)_3$ (*13*). Occasionally, a disulfide bond has been used to stabilize the VH−VL pairing (dsFv) (*14*, *15*). Reduction of the peptide linker length below 12 amino acid residues favors intermolecular VH−VL associations resulting in the formation of noncovalent dimers or diabodies (50 kDa) (*16*, *17*). Covalent dimers or $(scFv')_2$ molecules have been engineered by C-terminal addition of a peptide (*18*) or a cysteine (*10*, *19*−*21*) or by cross-linking with chemical linkers (*22*). Higher scFv multimers, triabodies (75 kDa) and tetrabodies (100 kDa), have been generated by shortening the linker length to less than five amino acid residues (*23*). At high concentrations, in a sequence-dependent manner, spontaneous scFv oligomerization can also occur (*24*).

Our overall objective is to use tumor-specific scFvs as tumor binding modules attached to multiarmed PEG scaffolds, as the initial targeting molecule in pretargeted strategies for cancer therapy. The covalent attachment of PEG to proteins has been used in many pharmaceuticals to extend plasma half-life, reduce immunogenicity, increase solubility, and decrease proteolysis (*25*−*27*). In nonspecific conjugation of appropriately activated PEG polymers to proteins, the usual targets are primary amines of lysine (*28*). Conjugation by random targeting of lysine residues has been satisfactory with large size molecules such as antibodies (*29*). However, site-specific conjugation is more likely to preserve the active binding site on the small scFv protein. In this respect, site-specific

conjugation, based on thiol chemistry, appears to provide an approach that is generally applicable. Most scFvs are primarily stabilized through the intradomain disulfide bridges formed between the two cysteines present in each VH and VL domain. A free SH can be provided by the insertion of an extra cysteine at a location that causes little or no interference with the scFv binding site. Successful site-specific PEGylation via a free thiol has been reported. For example, di- and tri-scFvs were obtained by cross-linking of hinge cysteine residues, introduced at the COOH end of the B72.3 scFv by addition of a cysteine containing hinge region, using maleimide-based di- and trifunctional reagents (*30*). The scFv−immunotoxin LMB-2 molecule was assembled via maleimide conjugation to a free thiol group introduced through a cysteine inserted in the linker joining the scFv to the toxin (*31*).

Here we report the engineering of the generally available pCANTAB 5E, a vector designed for soluble scFv expression in *E. coli*, such that any scFv cloned in this vector will be expressed with an extra cysteine at its carboxy end. This extra cysteine provides a free SH group that can bind to sulfhydryl affinity reagents or resins, facilitating purification, or can participate in disulfide bond formation by mild oxidation, resulting in covalent $(scFv')_2$ homodimers or dimeric scFv molecules, with increased binding avidity. Using scFv clones selected from an anti-MUC-1 immune scFv phage library (*32*), we show improved in vitro targeting of the tumor antigen by dimeric compared to monomeric anti-MUC-1 scFvs, in ELISA and on tissue sections. This stable dimeric scFv product has facilitated evaluation of initial scFv selections on tumor and normal tissue arrays. Toward the development of tumor targeting pharmaceuticals, the effective conjugation of scFv-SH monomers to bivalent PEG is demonstrated.

EXPERIMENTAL PROCEDURES

Mutagenesis on pCANTAB 5E. The anti-MUC1 12E scFv clone in pCANTAB 5E (*44*) was used for mutagenesis. PCR and subsequent cloning were used to create the mutant clone carrying the extra TGT in pCANTAB 5E. The mutagenic ForNotCys primer (5′GCGGCCGCATGTGGTGCGCCGGTGCCGTAT 3′) and the L_{CANT}-3350 primer (5′ TCACCAGTAGCACCATTACCATTAGCAA 3′) (Operon Technologies, Inc., Alameda, CA) were used on the 12E clone to generate a fragment of about 1 Kb using the Pfu Taq polymerase (Stratagene, La Jolla, CA) in the PCR reaction mixture ($V = 100$ μL). Thirty-five cycles of denaturing 94 °C, 30 s; annealing 60 °C, 1 min; extending 72 °C, 1 min, were run. Verification of PCR reaction was confirmed by running 10 μL of the reaction on a 1.3% agarose gel (*33*). The 1 Kb PCR product was cloned into the pCR2.1 vector using the TOPO cloning kit (Invitrogen, Carlsbad, CA). Recombinant plasmids were extracted from positive colonies (white) using the plasmid midi kit (QIAGEN, Valencia, CA) and were sequenced (DBS sequencing facility, UC Davis) to confirm the presence of the extra TGT codon. To obtain the 12E scFv mutant clone (scFv-Cys clone), a recombinant pCR2.1 clone was double digested with NotI and ClaI. The resulting 971 bp NotI/ClaI fragment was gel isolated using a GFX PCR kit (Amersham Biosciences Corp., Piscataway, NJ) and ligated into the NotI/ClaI double digested 12E scFv clone. Transformants were recovered after electroporation of the *E.coli* HB2151 host (K12 Δ (lac-pro), ara, nal^r, thi/F′ [proAB, $lacI^q$, lacZ Δ M15]).

Selection of Mutant Clones. Potential mutant clones were first screened for scFv expression. Clones were grown in 2YT medium (17 g/L bacto-tryptone, 10 g/L bacto-yeast extract, 5 g/L NaCl) containing 2% glucose and 100 μg/mL ampicillin (2YT + AG) in a 96-well microtiter plate overnight (ON) at 30 °C with shaking at 150 rpm. Two replica plates were made by inoculation of 100 μL of 2YT + AG medium with aliquots of the precultures. After 6 h growth at 30 °C with shaking at 150 rpm, one plate was used for induction of scFv expression, and the other plate was stored at −70 °C after addition of 50 μL of 50% glycerol per well. For induction of scFv expression, the bacteria were pelleted by centrifugation at 2000 rpm (Beckman benchtop centrifuge) for 10 min and resuspended in 2YT medium supplemented with ampicillin (100 μg/mL) and isopropyl-β-D-thiogalactopyranoside (ITPG)[1] (USB, Cleveland, OH) at 1 mM final concentration. Following ON induction at 30 °C with shaking at 150 rpm, the cultures were centrifuged for 10 min at 2000 rpm and their supernatants were transferred to a new microtiter plate. Supernatants were tested for the presence of the 12E scFv by immunodetection on western blots using the anti-E Tag mAb (1:2000) conjugated to horseradish peroxidase (HRP)[1]. Enhanced Chemo Luminescence (Amersham Biosciences Corp.) was used to visualize the reactions. Positive clones were sequenced.

Cloning of scFvs into pCANTAB 5E. Other anti-MUC1 scFvs, namely E1 and G1, were selected from our anti-MUC1 phage display library (*48*) on the basis of binding to BSA-MUC1 100 mer synthetic peptide. The scFv fragments were isolated by SfiI/NotI double digestion and ligated into pCANTAB 5E Cys digested by SfiI/NotI digestion. ScFv-Cys clones were recovered following electropration of the HB2151 bacterial host.

ScFv Production in Shaker Flasks. Two liters of 2YT + AG in a 4 L shaker flask were inoculated with 200 mL of preculture grown ON at 30 °C with shaking at 220 rpm in 2YT + AG. After 3 h to 4 h growth at 30 °C with shaking at 220 rpm, the bacteria were pelleted at 6300*g* for 15 min at 4 °C using a Sorval centrifuge with a GSA rotor and resuspended in 2xYT media containing 0.5 mM ITPG and 100 μg/mL of ampicillin for soluble scFv protein production at 30 °C for 16 h.

ScFv Production in the Biofermentor. A 5 L Bioflo 3000 fermentor (New Brunswick Scientific Co., Inc. Edison, NJ) was used to produce scFv on a larger scale. Four liters of medium described previously (*34*), containing ampicillin as the selective agent, was inoculated with preculture of the clone of interest to an initial OD_{630nm} between 0.03 and 0.05.

Growth was carried out under the following conditions: 30 °C, agitation variable between 200 and 800 rpm, pH at 6.9, and constant aeration to maintain the dissolved O_2 level at or above 30%. After 14 to 16 h of growth, when bacteria had reached the stationary phase, scFv production was induced by addition of ITPG to 0.5 mM final concentration. Induction was performed for 8 h.

ScFv Purification and Storage. ScFvs were purified from bacterial periplasms and from culture supernatants. For periplasmic extract preparation, after induction, bacterial cultures were pelleted and resuspended in 3 mL of TES [0.2 M Tris-HCl (pH 8.0), 0.5 mM EDTA, 0.5 M sucrose] per OD_{630} unit, followed by addition of 4.5 mL per OD_{630} unit of 0.2× TES followed. After 30 min incubation on ice with moderate agitation, the bacterial debris and insoluble periplasmic material were pelleted by centrifugation at 12 000 g for 30 min at 4 °C. The

supernatant fraction containing the soluble periplasmic proteins was filtered (0.45 um) and used for scFv purification. For scFv extraction from the bacterial growth medium, the supernatant was filtered (0.45 μm) and a protease inhibitor cocktail (Roche Diagnostics, Mannheim, Germany) was added.

The scFv proteins were affinity purified from the periplasmic extracts and culture supernatants by anti-E Tag affinity column chromatography using the RPAS purification module (Amersham Biosciences Corp.). Centriprep YM-10 (Millipore, Bedford, MA) was used to buffer exchange the purified scFvs into PBS and concentrate them. Purified scFvs in solution at 1 to 2 mg/mL in phosphate-buffered saline pH 7.4 (PBS)[1] (Sigma Aldrich, St Louis, MO) were stored at 4 °C for short-term storage (not exceeding 3 months) or were frozen in liquid nitrogen and kept at −70 °C for long-term storage.

Reduction of SH Groups and Removal of Reducing Agent. Tris(2-carboxyethyl)phosphine hydrochloride (TCEP)[1] (Molecular Probes, Eugene, OR) was used as a reducing agent. TCEP was added to the scFvs in solution in PBS (pH 7.4) in a 2 -fold molar excess, which was the lowest amount required for near 100% reduction in an ON reaction at 4 °C. This was done regularly at the last buffer exchange step in the purification. TCEP was removed from scFv solutions by filtration through a centricon YM-10 (Millipore).

Protein N-Terminal Sequencing. After separation of the scFv forms by nonreducing SDS−PAGE, (∼9.5 and 19 μg of 12E-Cys nonreduced scFv were loaded into two lanes of a 4−12% NuPAge gel (Invitrogen)), the proteins were electroblotted onto a PVDF membrane (Biorad, Hercules, CA) for direct N-terminal sequencing by Edman's degradation. This protein microsequencing was performed on an ABI Procise HT Edman Sequencer System (Perkin-Elmer/Applied Biosystems, Foster City, CA) at the Molecular Structure Facility at UCDavis.

Cell Lines and Cell Lysate Preparation. MUC-1 positive human breast adenocarcinoma MCF-7 cells (American Type Culture Collection (ATCC) Manassas, VA) were grown to 75% confluence in DMEM (Gibco, Invitrogen Corp., Carlsbad, CA) medium supplemented with 5% fetal calf serum (FCS) (Gibco, Invitrogen Corp.). MUC-1-positive DU145 human prostate cancer cells (ATTC) were grown to 100% confluence in RPMI-1640 medium (Gibco, Invitrogen Corp.) supplemented with 10% FCS.

Cell lysates were prepared by hypotonic lysis in a 10 mM Tris, pH 8, 1 mM $MgCl_2$, 1 mM $CaCl_2$ buffer, followed by three cycles of freeze at −70 °C/thaw at room temperature and a final homogenization in a dounce tissue grinder (Wheaton, Milville, NJ).

Protein Quantitation. The Micro BCA protein assay reagent kit (Pierce Chemical Co., Rockford, IL) was used to quantify purified scFvs and total protein content of cell lysates.

ELISA. Pro-Bind ELISA assay plates (Becton Dickinson Labware, Franklin Lakes, NJ) were coated with 100 μL of MCF7 or DU145 cell lysate at 1 mg/mL. The wells were dried by placing the plates at 37 °C ON. Plates not used immediately were stored at −20 °C in the presence of drierite. Nonspecific binding was blocked with 200 μL/well of PBS/0.1% Tween 20 (Sigma Aldrich) containing 3.0% nonfat dry milk (Bio-Rad, Hercules, CA) for 1 h at 37 °C. Anti-MUC-1 scFv proteins at various concentrations in a total volume of 100 μL/well with PBS/0.01% Tween/0.3% nonfat dry milk were incubated at 37 °C for 1 h. Following each incubation, the plates were washed six times with PBS containing 0.01% Tween 20. One hundred microliters of anti-E-Tag-HRP mAb diluted to 1:4000 in PBS/0.1% Tween/0.3% nonfat milk solution was added. Following the last wash step, the 2,2′-amino-bis-3-ethylbenzthiazoline-6-sulfonic acid (ABTS) substrate (Sigma-Aldrich), containing 0.3% H_2O_2, was added. As soon as the colorimetric reaction had developed, the content of each well was transferred to a new plate to prevent the interference of the coating with the readings. Plates were read at $A_{405\ nm}$ (Dynex microplate reader, Chantilly, VA).

Immunohistopathology. Human prostate cancer tissue (Gleason pattern 3), fixed in formalin and embedded in paraffin, was cut into 5 μm sections onto slides. After warming and deparaffinizing, the sections were rehydrated through alchohols and rinsed in PBS. Endogenous peroxidases were blocked by a 15 min incubation in 0.3% H_2O_2 in methanol. After rinsing in PBS, antigen retrieval was performed in 10 mM citrate buffer, pH 6, by microwaving the slides at 600 W three times for 5 min. The slides were rinsed in PBS and blocked for 30 min in 10% goat serum in PBS. The sections were incubated with scFv at 26 μg/mL overnight at 4 °C. ScFv used for tissue staining included one nonbinding control, 12E, 12E-Cys, E1, E1-Cys, G1, and G1-Cys. ScFv staining was compared to staining by mAb BrE−3 (*8*), performed similarly (5 μg/mL) on sections from the same tissue block. After rinsing in PBS, the sections were incubated for 1 h with biotinylated anti-mouse monoclonal antibody (Molecular Probes, Eugene, OR) diluted 1:250. Following PBS rinsing, ABC reagent (Vector Labs, Burlingame, CA) was added and the slides incubated for 30 min. Staining was visualized with 3,3′-diaminobenzidine (DAB), and the sections were rinsed and dipped in Mayer's Modified hematoxylin before dehydration and mounting. All sections were photographed at magnification 400×.

PEG−$(scFv)_2$ Bioconjugate. *Conjugation.* PEG-2-arm *o*-pyridyl disulfide [2 kDa (PEG-$(OPSS)_2$)] and PEG-2-arm maleimide [10 kDa (PEG-$(Mal)_2$)] were obtained from Sun Bio Inc., Anyang City, S. Korea.

12E and 12E-Cys scFvs, PEG-$(OPSS)_2$ and PEG-$(Mal)_2$ were all in solution in PBS, pH 7.4. A 2 molar excess of TCEP was used to maintain the 12E-Cys scFv in its monomeric form and to reduce the intermediate pyridyl disulfide forms to 12E−S−S−PEG-SH. Molar ratios of scFv, PEG$(OPSS)_2$, and PEG-$(Mal)_2$ of 4:5:10, respectively, were combined at room temperature and left to react overnight. The 12E scFv, the control without an extra cysteine, was reacted under the same conditions The conjugation reactions were analyzed by PAGE.

Purification. Conjugation mixture, estimated to contain about 100 μg of scFv protein, was fractionated by size exclusion HPLC chromatography on a calibrated (gel filtration standard, Biorad) 300 × 7.8 mm BioSep-SEC−S 2000 column (Phenomenex, Torrance, CA). The column was preconditioned in 100mM sodium phosphate buffer pH 7.1 and operated at a flow rate of 0.25 mL/min. Fractions of 125 μL were collected.

Immunoreactivity. The concentration of PEG−$(scFv)_2$ bioconjugate was estimated based on the absorbance at 280 nm using a Beckman DU64 spectrophotometer. The absorbance of monomeric scFv-Cys prior to conjugation was compared to the absorbance of the PEG−$(scFv)_2$ bioconjugate for an estimate of bioconjugate concentration. As two scFvs are attached to each PEG molecule, the concentration of PEG−$(scFv)_2$ bioconjugate was estimated as 1/2 the extrapolated concentration. The bioconjugate was diluted to 25 μg/mL in PBS for use on prostate tissue and MUC-1 expressing BT20 cells (*35*). A mixture of the 10 kDa PEG and the 2 kDa PEG linker

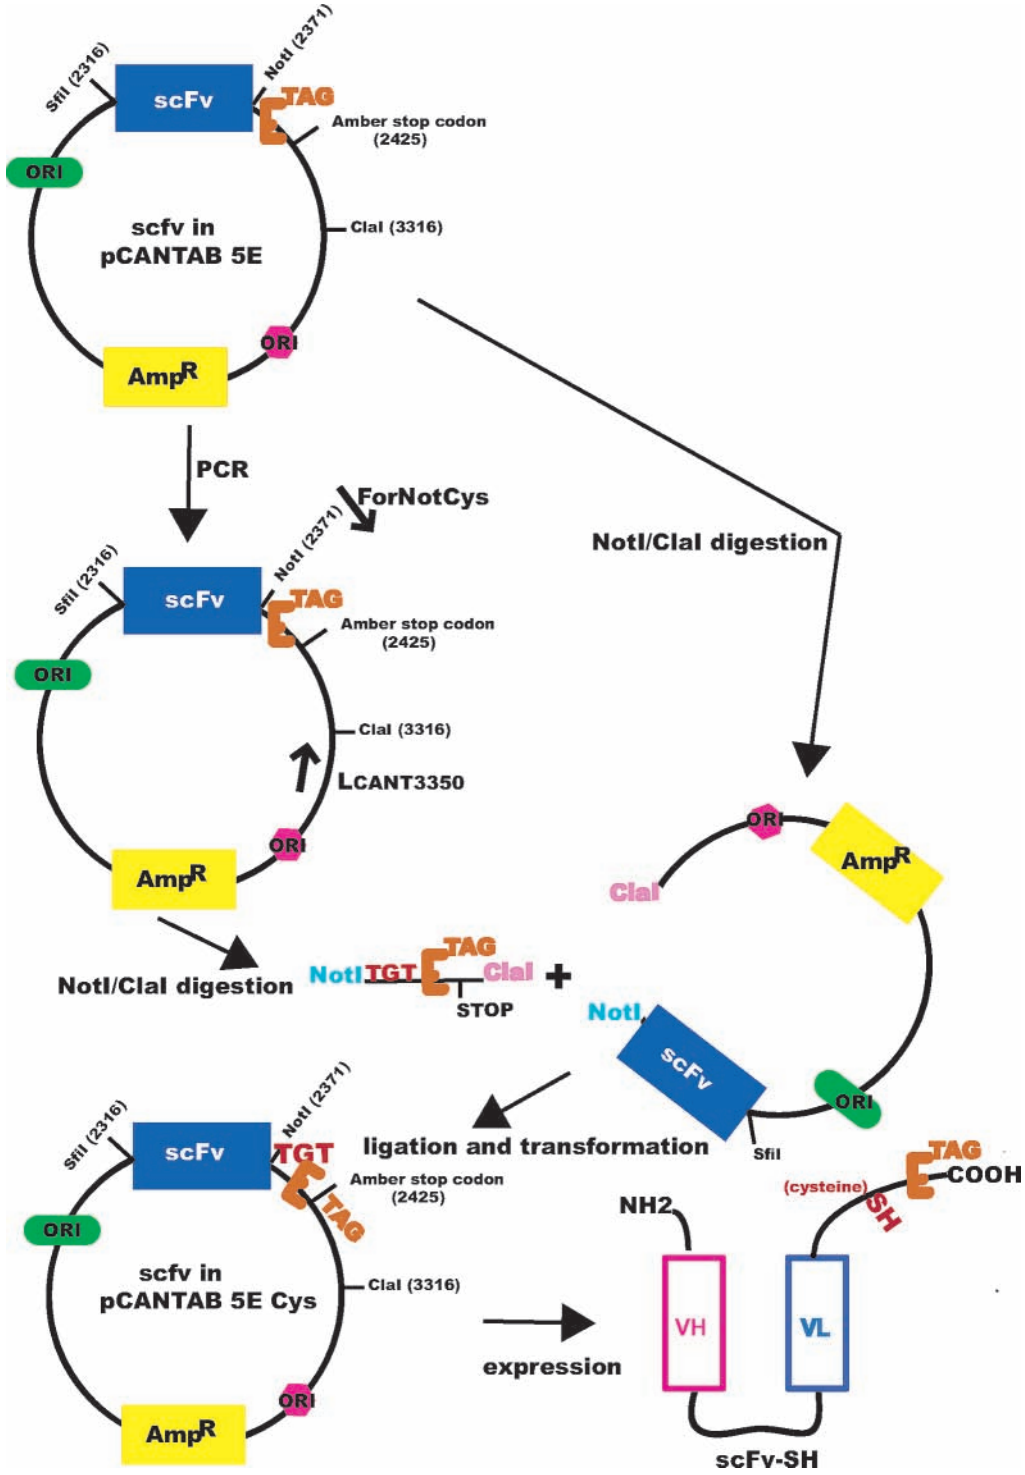

Figure 1. Strategy used to insert a free SH group at the C-terminus of a scFv. PCR on the pCANTAB 5E vector (Amersham Biosciences Inc.); the forward ForNotCys and the reverse $L_{CANT}3350$ primers were used to insert a TGT codon specifying a cysteine, just downstream of the NotI restriction site used for scFv cloning. NotI/ClaI digested PCR fragments and vector were ligated to create the pCANTAB 5E Cys vector. ScFvs expressed from this vector have a cysteine (free SH group) at their C-terminus.

molecules (1:2) was used as a control at the same concentration as in the PEG−$(scFv)_2$ bioconjugate. Prostate tissue slides were treated as described under Immunohistopathology. BT20 cells grown in minimal essential medium with 10% FCS were rinsed, scraped into PBS, and cytospun onto slides. After air-drying, the slides were frozen at −70 °C until use. The cells were fixed for 10 min in 10% buffered formalin and rinsed in PBS. Endogenous peroxidases were quenched by a 15 min incubation in 0.3% H_2O_2 in methanol. After rinsing, PEG−$(scFv)_2$ bioconjugate or control was incubated on cell and tissue slides overnight at 4 °C. After rinsing, slides were treated as described under immunohistopathology. BT20 cells with PEG or PEG−$(scFv)_2$ bioconjugate were photographed at magnification 400×.

RESULTS

Construction of the pCANTAB 5E Cys Vector and Cloning of Other scFvs. PCR site-directed mutagenesis of pCANTAB 5E was used to insert the cysteine-specifying codon at the 3′ end of the scFv gene, downstream of the NotI restriction site and just upstream of the stop

Table 1. Comparison of the Production of Anti-MUC-1 ScFvs in Shaker Flasks and Biofermentor[a]

	anti-MUC-1 scFv	periplasmic extract, mg/L	culture supernatant, mg/L
shaker flask	12E	1.67	not detected
	12E-Cys	0.51	0.57
biofermentor	12E	1.50	not detected
	12E-Cys	2.12	0.69

[a] Shaker flask and biofermentor production yields were determined for the anti-MUC-1 12E and 12E-Cys scFvs. The presence of scFvs in the culture supernatant was determined by immunoblot using the anti-E Tag mAb. ScFvs obtained from bacterial periplasm or culture supernatants were purified and quantified.

codon carried on the vector backbone when NotI is used as a cloning site. From the two codons specifying a cysteine, TGT and TGC, the TGT codon was used in the design of the 30 mer forward mutagenic primer ForNot-Cys with the consideration of the primer T_m. The 28 mer reverse primer, L_{CANT} 3350, hybridizes downstream of the unique ClaI restriction site in pCANTAB 5E and allows for a good size PCR product of 971 bp. As illustrated in Figure 1, the mutation carrying fragment was generated by PCR on the 12E clone in the presence of the proofreading Pfu Taq and subcloned into the pCR2.1 cloning vector. After the presence of the TGT insertion was confirmed by sequencing, the NotI/ClaI mutant fragment was isolated from a recombinant clone and ligated into the 12E clone linearized by NotI/ClaI digestion. Because no unmodified 12E scFv was detected in culture supernatants, we were able to use the secretion of the scFv into the medium as a selection criteria for potential mutant clones. From 32 potential mutant clones tested for their expression by western blot prior to sequence analysis, five expressed scFv in their supernatant at various levels. Sequence analysis of these clones confirmed the presence of the extra TGT codon. The best expressing clone (12E-Cys) was selected for further experiments.

Other selected scFv clones from the anti-MUC-1 scFv library were cloned as SfiI/NotI scFv gene fragments into pCANTAB 5E Cys linearized by SfiI/NotI digestion, e.g. E1-Cys and G1-Cys.

Anti-MUC-1 scFvs Production and Purification. To compare their production yields, both scFv and scFv-Cys were produced in shaker flasks and in a biofermentor. Analyses by western blot were used to test for the distribution of the scFv in the bacterial periplasm and in the culture supernatant. The results, summarized in Table 1, show the distinct behavior of 12E and 12E-Cys scFvs. Whether produced in the shaker flask or the biofermentor, detectable levels of 12E scFv are only present in the bacterial periplasm while 12E-Cys scFv is found in both the periplasm and the culture supernatant. Both scFvs were affinity purified, using the E Tag present at their C-terminus (Figure 1), from periplasmic extracts, and 12E-Cys scFv was also purified from the culture supernatant. Typical yields, shown in Table 1, illustrate that the production of 12E scFv is best in flasks. However, analyses of 12E-Cys scFv indicated that about 1/2 or 1/4 of the total amount of scFv produced was present in the culture supernatant from shaker flask or biofermentor, respectively, and that the production of 12E-Cys scFv was best in the biofermentor.

Other scFv-Cys clones (E1-Cys and G1-Cys) have produced soluble scFvs but secretion into the medium is not a general rule.

Analysis of scFv Expression. PAGE analysis under nonreducing conditions of the purified 12E and 12E-Cys scFvs, illustrated in Figure 2, shows that the two scFvs also have distinct gel profiles. For 12E scFv, shown in lane 1 of Figure 2, two bands were visualized by Coomassie Blue staining. The major band with the highest apparent molecular weight of about 25 kDa corresponds to the monomeric form of the scFv. The 12E-Cys scFv is shown in lane 2 of Figure 2. Two bands are observed with apparent molecular weights of 50 and 25 kDa, corresponding to dimeric and monomeric 12E-Cys scFvs, respectively. Similar profiles were observed for other scFv and scFv-Cys (data not shown).

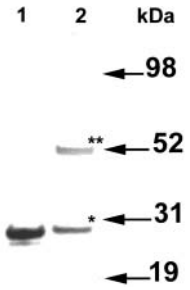

Figure 2. Comparison of the SDS−PAGE profiles of the 12E and 12E-Cys scFvs. Coomassie Blue staining of purified scFvs (8 μg) resolved on a 4−12% gradient polyacrylamide gel by nonreducing SDS−PAGE. The 12E scFv is shown in lane 1 and the 12E-Cys scFv in lane 2. ScFvs monomers (*) and dimers (**) are indicated. Standards for apparent molecular weights are indicated on the right.

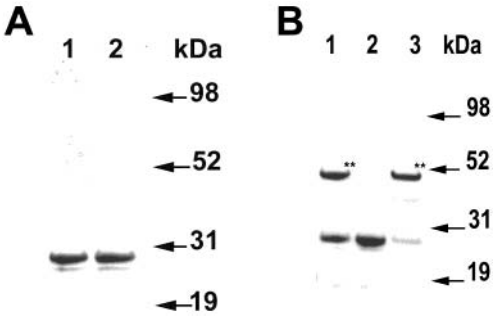

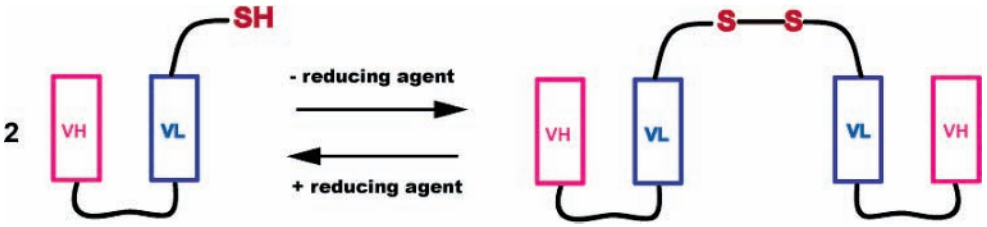

Figure 3. Effect of the reducing agent TCEP on the scFvs forms. Coomassie Blue staining of purified scFvs (8 μg), before and after TCEP treatment and analyzed by 4−12% nonreducing SDS−PAGE is shown. The 12E scFv is illustrated in A and 12E-Cys scFv is shown in B. Lane 1 of Figure 3, A and B, corresponds to untreated scFv. Lane 2 of Figure 3, A and B, illustrates 12E scFv and 12E-Cys scFv, respectively, after addition of a 2-fold molar excess of TCEP. ScFv dimers are indicated by **. Lane 3 of Figure 3B shows the 12E-Cys scFv after removal of TCEP. Standards for apparent molecular weights are indicated on the right.

Reduction of the 12E-Cys Homodimers. Because the extra cysteine is the only difference between the 12E and the 12E-Cys scFvs, the free SH group is most likely involved in the formation of the 12E-Cys dimeric scFv. We used TCEP, a reducing agent which (unlike β-mercaptoethanol and dithiothreitol (DTT)[1]) does not contain any SH group itself and is active in a broad pH range (pH 5 to 8) to compare the scFvs. In the presence of a 2-fold molar excess of TCEP, the 12E-Cys scFv homodimers were reduced to their monomeric counterparts as visualized by nonreducing PAGE analysis (Figure 3B, lane 2). An excess of TCEP was required to observe a reduction near to 100%. Monomeric and dimeric forms, at ~50% each were present in the 12E-Cys scFv control with no TCEP added (Figure 3B, lane 1). Addition of a 2-fold molar excess of TCEP to the 12E scFv left the monomer unchanged (Figure 3A, lane 2) and in comparison to the control without TCEP in lane 1. Removal of

Scheme 1. ScFv-Cys Dual Forms

the reducing agent resulted in the predominance of 12E-Cys scFv dimers (Figure 3B, lane 3). The observation that 12E-Cys scFv homodimers can be reduced is consistent with the free SH involvement in the formation of a covalent dimeric structure. N-Terminal sequencing of both molecular species shows that their N-termini are identical (data not shown). Thus, definite evidence is provided that the protein with an apparent molecular of 50 kDa is formed by dimerization of the protein with an apparent molecular weight of 25 kDa. A schematic representation of the two molecular forms of the 12E-Cys scFv is shown in Scheme 1.

Comparison of scFv and scFv-Cys in Vitro Binding Activities. *ELISA.* Binding of MUC-1 targeting scFvs was tested by ELISA using MCF7 (breast) and DU145 (prostate) cancer cell lysates. 12E-Cys scFv binds 1.4 and 2 times as well, respectively, to these cell lysates compared to 12E scFv (Figure 4, A: MCF7; and B: DU145). Increased binding to MCF7 and DU145 cell lysates was also observed for other anti-MUC-1 scFvs Cys (data not shown).

Immunohistochemistry (IHC)[1]. Binding of the 12E, E1, G1, and 12E-Cys, E1-Cys, and G1-Cys scFvs was compared on sections of malignant prostate tissue (Figure 5). Results show a clear enhancement of specific staining with scFv-Cys compared to unmodified scFvs, consistent with increased avidity associated with the predominance of covalent dimeric scFv form and possible bivalent binding of the second (anti scFv) antibody. In comparison with the negative control (Figure 5A), little or no staining is seen with the 12E and E1 scFvs (Figures 5, C and E), whereas specific tumor cell staining is observed with both scFvs Cys (Figure 5, D and F). G1 scFv staining (Figure 5G) is further enhanced with G1-Cys scFv (Figure 5H). The positive control, with the intact monoclonal anti-MUC1 BrE−3 (*36*), is shown in Figure 5B.

PEG−(scFv)$_2$ Bioconjugate. *Conjugation.* PEGylation in a single reaction mixture and in the presence of TCEP of bifunctional 10 kDa PEG-(Mal)$_2$ and 2 kDa PEG-(OPSS)$_2$ to 12E (without Cys) or 12E-Cys scFvs at respective molar ratios of 4: 5: 10 resulted in three products as visualized by Coomassie Blue staining following nonreducing PAGE (Figure 6A). The product, migrating at about 70 kDa, corresponds to the PEG(10 kDa)−(PEG(2 kDa)−scFv)$_2$ bioconjugate of interest (Figure 6A, lane 4). The broader band at about 50 kDa is thought to represent (PEG(2 kDa)−scFv)$_2$ molecules. Nonconjugated 12E and 12E-Cys scFv monomers are shown in Figure 6A, lanes 1 and 3, respectively. No PEGylated product was visualized with the conjugation control, 12E scFv (without Cys) (Figure 6A, lane 2). Thus, original intramolecular S−S bonds were not available for conjugation to PEG via maleimide.

PEG-(OPSS)$_2$ was added as a spacer between 12E-Cys and PEG-(Mal)$_2$ to increase the reaction yield. Multiple conjugations have confirmed that this approach yields about 40% of PEG(10 kDa)−(PEG(2 kDa)-scFv)$_2$ bioconjugate.

Purification. The PEG−(scFv)$_2$ bioconjugate was isolated from the conjugation mixture (Figure 6A, lane 4) by size exclusion chromatography as illustrated in Figure 6B. Two major peaks were visualized. The first and major peak corresponding to a protein with an apparent molecular weight of 70 kDa was identified as the PEG−(scFv)$_2$ bioconjuagte of interest. The bioconjugate was distributed between four fractions that were pooled and used to test its immunoreactivity. The second peak, with

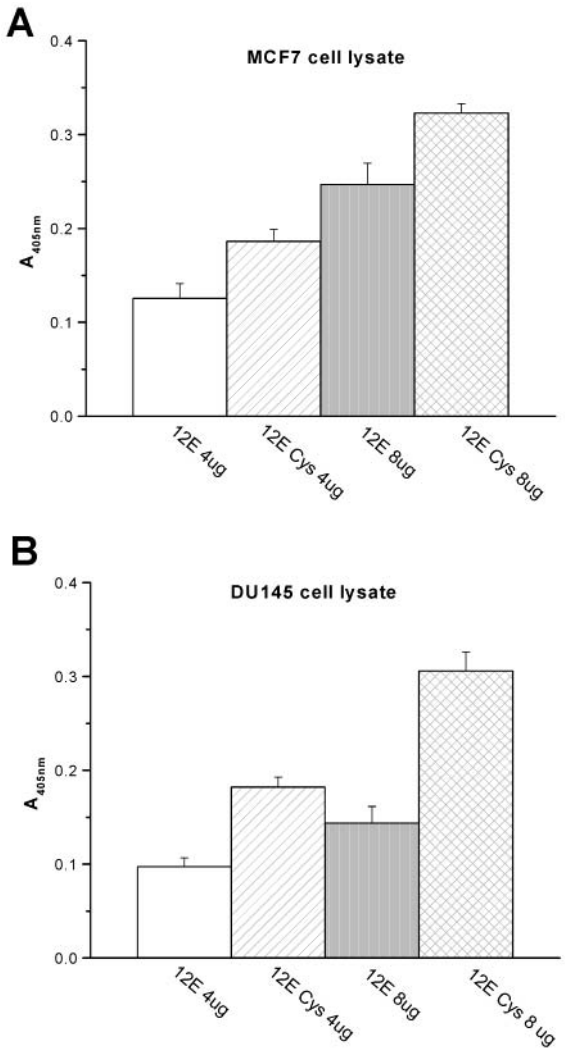

Figure 4. Comparison of MUC-1 binding of 12E and 12E-Cys scFvs to cell lysate. MUC-1 binding 12E and 12E-Cys scFvs, 4 and 8 μg, were tested by ELISA on MCF7 (A) and DU145 (B) cell lysates. Graphs were derived from mean absorbance values normalized to background (no scFv). Corresponding standard errors (SE) from three experiments with triplicates in each experiment are shown. Mean background values and SE were 0.137 (±0.005) for MCF7 cell lysate (A) and 0.154 (±0.010) for DU145 cell lysate (B). 12E-Cys scFv [diagonal (4 μg) and crosshatched (8 μg)] binding was higher compared to 12E scFv [white (4 μg) and gray (8 μg)] on both MCF7 and DU145 cell lysates.

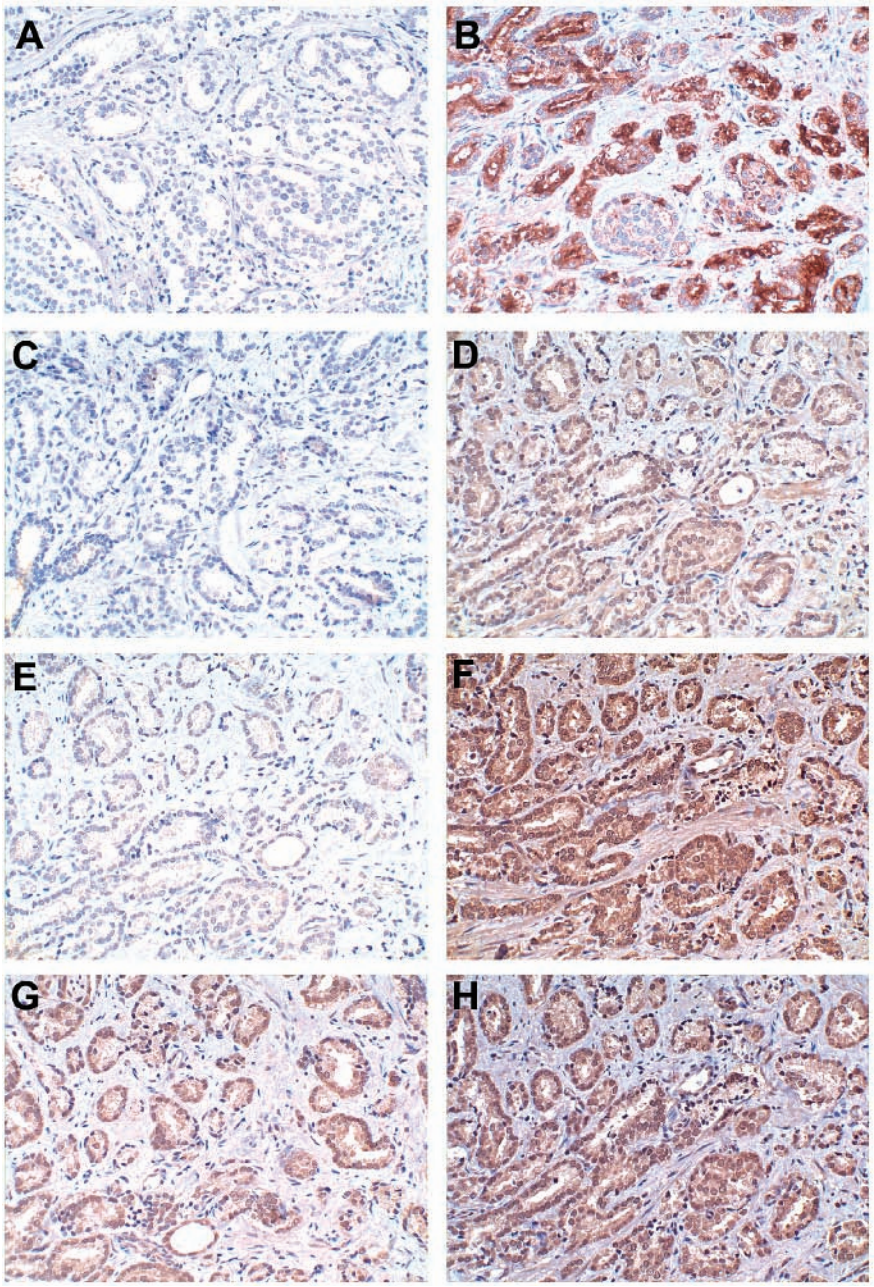

Figure 5. Enhanced specific immunohistochemical staining of MUC-1 on prostate cancer tissue by scFv with extra cysteine. Prostate cancer tissue (Gleason's grade 3) was stained with (A) nonbinding control scFv, (B) mAb BrE−3, (C) scFv 12E, (D) scFv 12E-Cys, (E) scFv E1, (F) scFv E1-Cys, (G) scFv G1, and (H) scFv G1-Cys. The mAb (BrE−3) concentration used was 5 μg/mL, and the scFv concentration used was 26 μg/mL. Tissue was photographed at 400× magnification. The figures illustrate scFv staining of MUC-1 (brown stain) similar to staining by mAb BrE-3, with increased staining observed on tissue stained with scFv containing an extra cysteine (D, F, H) compared to scFv without the additional cysteine (C, E, G), consistent with increased avidity of scFv associated with dimer formation following cysteine insertion.

an apparent molecular weight of 50 kDa, was assumed to represent the scFv-spacer-scFv side product.

Immunoreactivity. Immunoreactivity of the PEG−$(scFv)_2$ bioconjugate was assessed by IHC on MUC-1 expressing cells. The bioconjugate strongly stained MUC-1 expressing BT20 cells (*35*) in comparison to control slides treated with PEG mixture (Figure 6C).

DISCUSSION

The pCANTAB 5E vector was engineered for the addition of a C-terminal cysteine to any scFv expressed from the new pCANTAB 5E Cys vector. Anti-MUC-1 scFvs (*37*) were expressed as scFv-Cys, and production yields, binding activities, and some applications of scFvs with and without a C-terminal cysteine were compared.

The decision to introduce the cysteine at the C-terminus of the scFv was based on several considerations. An initial requirement was to preserve the affinity of antigen binding after conjugation into a larger molecular format. Our 12E anti-MUC-1 scFv 3D model indicated that short N- and C-terminal sequences are flexible and therefore not involved in the structural conformation of the VH and VL domains (*37*). Furthermore, other scFvs with a specific C-terminal cysteine insertion have retained binding activity (*10*, *19*, *20*). Second, the SH group introduced needed to be accessible for intermolecular reactions to facilitate conjugation. Third, the scFvs must be produced in a soluble, properly folded, and active form that can be easily purified. Soluble scFv expression from prokaryotic vectors, such as pCANTAB 5E, involves

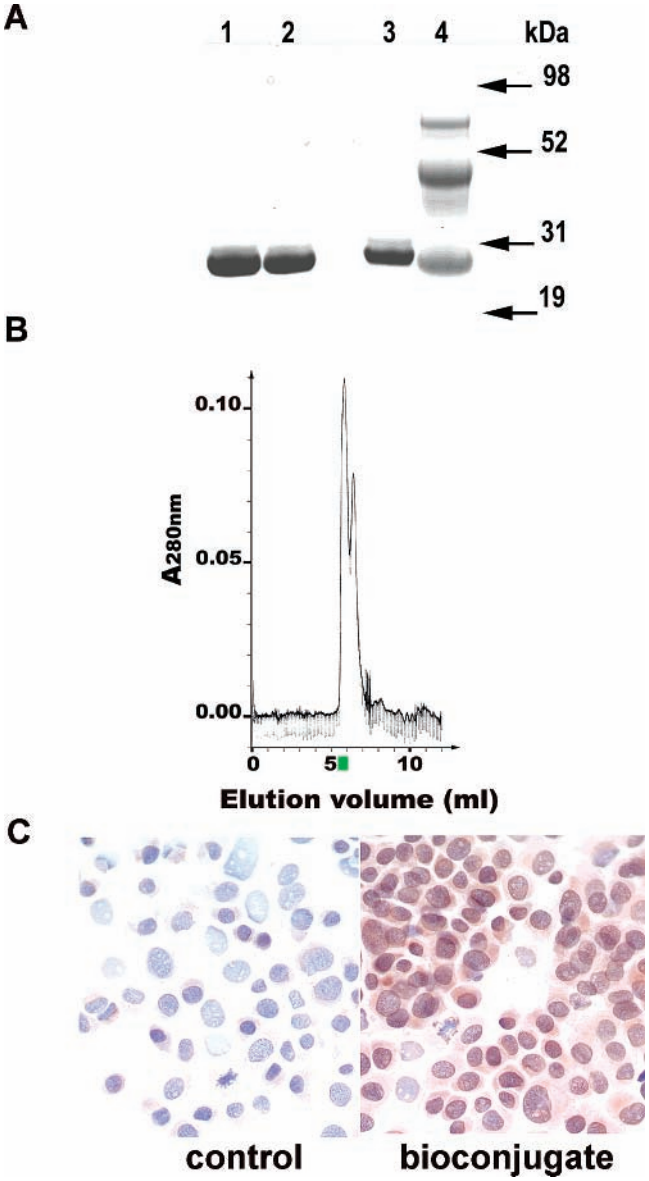

Figure 6. (A) PAGE of the PEG−$(scFv)_2$ bioconjugate. Coomassie blue staining of 12 E (25 μg) and 12E-Cys scFvs (20 μg) in the presence of an excess of TCEP (lanes 1 and 3, respectively), and after conjugation to PEG (lanes 2 and 4 respectively) are shown after separation by nonreducing SDS−PAGE on a 4−12% gradient polyacrylamide gel. Standards for apparent molecular weights are indicated on the right. The (10 kDa)-PEG−(2 kDa)PEG−$(scFv)_2$ product of interest, at ~70 kDa, and the side product of (2 kDa)PEG−$(scFv)_2$, at about 50 kDa, are formed with the 12E-Cys scFv (lane 4) but not with the negative control 12E scFv (lane 3), lacking a free thiol. (B) HPLC purification profile size exclusion HPLC of the PEG−$(scFv)_2$ bioconjugate on a calibrated 300 × 7.8 mm BioSep-SEC−S 2000 column. The column was calibrated in 100 mM sodium phosphate buffer, pH 7.1, and the flow rate was 0.25 mL/min. The fractions corresponding to the PEG−$(scFv)_2$ bioconjugate are underlined in green. (C) Immunoreactivity of the PEG−$(scFv)_2$ bioconjugate MUC-1-expressing BT20 cells were stained with PEG solution (control, left) and the PEG−$(scFv)_2$ bioconjugate (bioconjugate, right), as described in Experimental Procedures. The figure shows staining of BT20 cells incubated with the bioconjugate but not with PEG alone (control), consistent with immunoreactivity of the bioconjugate. Cells were photographed at magnification 400×.

N-terminal maturation of the protein by cleavage of a signal peptide for cytoplasmic export to the periplasm (*38*). Studies of an anti-insulin scFv protein, expressed with a N-terminal cysteine but lacking a signal peptide, demonstrated that it accumulates in inclusion bodies (*39*). Although this provided a useful product, the loss in solubilizing and refolding of the scFvs was substantial. Finally, we did not wish the cysteine addition to be scFv specific; therefore, the modification should be introduced into the vector backbone. This last requirement completely excluded N-terminal addition, as the signal peptide cleavage does not allow for scFv nonspecific modification.

The cysteine specifying codon was added to the vector backbone downstream of the SfiI/NotI restriction sites used for scFv cloning and upstream of the E Tag used for affinity purification.

As illustrated by the yields (50 μg/L to 3 mg/L) obtained for different anti-MUC-1 scFvs produced in shaker flasks and in the biofermentor, scFv production yield was unique to the expressed sequence. An even wider range of scFv production yields, under comparable conditions, have been reported (*40*−*42*). The slightly better biofermentor yields can be accounted for by more optimal growth conditions, achieved by constant aeration, more efficient agitation and pH control of the medium in combination with a shorter induction time. Yields might be increased by changing the linker joining the VH and VL domains (*43*), or by introducing mutations in framework amino acids (*42*, *44*).

Comparison of the shaker flask and biofermentor production yields indicated that the scFv with an extra cysteine (12E-Cys) was produced somewhat better than the original scFv (12E) in the biofermentor. This was unexpected since, according to Blank et al. (*45*), the presence of an unpaired cysteine impairs the periplasmic production of a scFv. Unlike the 12E scFv, the 12E-Cys scFv does not remain exclusively in the periplasmic space but is also released into the culture medium. Thus, even if a negative effect of the unpaired cysteine in the periplasmic space cannot be ruled out, the extra cysteine apparently promoted the secretion of the 12E-Cys scFv into the culture medium. More efficient folding of the 12E-Cys in the bacterial periplasm could be contributing to secretion. The importance of the primary sequence of an antibody is known to play a decisive role in the efficiency of folding in the bacterial environment, and scFv folding in the periplasmic space has also been reported as a limiting factor for its secretion (*44*). Another explanation for the distinct behavior of the 12E-Cys is that, in the oxidizing environment of the periplasm, it engages in an intermolecular disulfide bond. Periplasmic disulfide bond formation was shown to be indispensable for the cellulase secretion by the plant pathogen *Erwinia chrysanthemi* (*46*). Interestingly, as for the scFv-SH, the S−S bond was present in the C-terminal region of the cellulase. However, the formation of such a disulfide bond alone is not enough to account for the 12E-Cys secretion since some of the other scFv-Cys expressed from pCANT-AB 5E Cys remain confined in the periplasmic space (unpublished data). Production and purification from culture supernatant has also been described for scFvs lacking a free C-terminal cysteine (*42*, *47*).

An interesting and important feature of scFv-Cys or scFv-SH, shown here and reported by others (*20*), is its dimerization or stable dimer formation as a result of air oxidation at basic pH. The spontaneous $(scFv')_2$ formation of these scFvs was more efficient than that described by Wang et al. (*20*) for the anti-CD19FVS191 scFv originally produced in an insoluble form. The observation that, by addition in excess or removal of a reducing agent, the homodimers can be reverted to monomers and vice versa, while retaining immunoreactivity, indicates that the SH

group of the extra cysteine is responsible for the formation of a covalent dimer as previously observed for other scFvs (*10*, *19*, *20*). At the concentrations used, the reducing agent (TCEP) reduced the intermolecular disulfide bridge without altering the two intramolecular disulfide bonds, most likely because cysteines were more exposed in complementarity-determining regions (CDR)[1] than they were in the framework regions (*48*). The four native cysteines engaged in intramolecular disulfide bonds in our three anti-MUC-1 scFvs are all part of framework regions, as determined by molecular modeling (*37*), and therefore their inaccessibility might explain why they escape reduction. This conclusion is supported by the identical behavior on PAGE of the 12E scFv (lacking the extra SH) in the absence and presence of TCEP and by the fact that it cannot be PEGylated, even in the presence of TCEP.

The scFv-Cys dual forms have several applications.

In vitro binding of three anti-MUC-1 scFv-Cys, assessed by ELISA or immunohistopathology, showed affinity was not only retained but enhanced, thus supporting the carboxy end choice for the cysteine addition.

The scFv-S−S-scFv dimeric form is useful for immunohistopathological studies of tumor and normal tissues distribution of the scFv antigen target. Undoubtly, the scFv dimerization contributed to improved binding to the MUC-1 antigen. The improved binding of a diabody (antiparallel homodimer), that mimics the higher binding avidity of a bivalent antibody, compared to the univalent scFv is well documented (*49*−*51*). The enhanced immunohistochemical signal observed with the 12E-Cys, E1-Cys, and G1-Cys anti-MUC-1 scFvs was found reproducible with other scFv-Cys (unpublished data). The signal enhancement provided by dimeric scFvs represents the sum of better binding due to the scFv bivalency and of better binding detection since two targets, one on each scFv, are available for the detection antibody. Thus, these scFv-S−S-scFv molecules are a solution to the weak binding signal of monomeric scFvs for scFv binding evaluation on normal and cancer tissues.

The scFv-SH monomeric form provided the free thiol needed for site-specific conjugation to a PEG scaffold, as illustrated here with a biactivated PEG maleimide. The use of PEG-$(OPSS)_2$ as a spacer to boost the PEGylation proved to be beneficial, since a 40% yield was reached for the bioconjugate of interest. The yield was good for a reaction known for its low efficiency. The HPLC-purified ∼70 kDa PEG−$(scFv)_2$ bioconjugate shown here demonstrated binding to MUC-1-expressing BT20 cells. Such a bioconjugate is expected to be a superior in vivo tumor targeting agent compared to monomeric or dimeric svFvs for the following reasons: (i) enhanced bioavailability over the monomeric scFv form should result in increased tumor uptake; (ii) as a consequence of increased molecular size, decreased kidney clearance can be expected since the renal threshold for first pass elimination is about 65 kDa (*52*); (iii) the addition of PEG is likely to prolong circulation time, decrease proteolysis, and lower immunogenicity (*53*).

Finally, the free thiol at the C-terminus of the scFv provides additional choices for affinity purification. For example, the scFv-SH can be directly retained on an activated thiol resin or by avidin or streptavidin after conjugation to maleimide-biotin (*54*). This last bioconjugate can also be used to immobilize scFvs onto a glass surface (*55*) for high-throughput ligand screening.

In conclusion, we have described a way to produce, on demand, a stable dimer or the monomeric form of any scFv expressed from pCANTAB 5E Cys. As shown here, the addition of a cysteine to the C-terminus of a scFv resulted in scFv with improved characteristics for biomedical applications. The scFv-Cys dimer is valuable for in vitro targeting studies, while the scFv-Cys monomer can be conjugated to PEG or other molecules to create tumor targeting pharmaceuticals with improved pharmacokinetics.

Anne de Bellevue, Quebec, Canada H9X 3V9. Received May 16, 2003; Revised Manuscript Received November 26, 2003

Although protein glycation has been implicated in the alteration of protein functionality, both in vivo (in biological systems) and in vitro (in food systems), the effect of the protein-bound glycan moiety on the structure/conformation of proteins that result in the modification of functionality is not clear. In this article, we report a study of the conformational changes of glycated lysozyme using LC-ESI-MSMS peptide mapping, and molecular modeling. A comparison of the RP-HPLC of the tryptic digests of unglycated and glycated lysozyme showed markedly different chromatographic profiles. Analysis of the peptide composition of the chromatographic fractions of the tryptic digests revealed that glycation of lysozyme resulted in the modification of its conformation. Glycation-induced changes in the conformation of lysozyme resulted in the exposure of its active site region to increased proteolytic activity of trypsin. Molecular simulation of triglycated lysozyme also showed that limited glycation of lysozyme caused reorientation of the active site residues (Arg 45, Arg 68, Asn 44, and Trp 62) and increased solvent accessibility into the active site region of the protein. The results of the modeling experiment corroborated the results of the RP-HPLC and ESI-MSMS peptide mapping.

INTRODUCTION

The development of age- and diabetes-related micro- and macrovascular pathologies underlying nephropathy, neuropathy, retinopathy, and sclerosis have been associated, in part, with nonenzymatic glycosylation (glycation) of body proteins and the formation and the accumulation of advanced glycation end products (AGEs) in tissues under chronic hyperglycemia (*1*−*4*). Although the molecular basis of how protein glycation leads to the development of these pathologies is not well understood, it is generally accepted that (1) AGE-modified matrix proteins interact abnormally with other matrix components and with cell surface receptors such as integrins, and (2) age-modified plasma proteins bind to AGE-specific receptors on macrophages and mesangial cells. These interactions induce receptor-mediated production of reactive oxygen species, thereby increasing the oxidative stress status of cells (*4*, *5*).

Alteration of the biological properties of glycated or AGE-modified proteins may derive from changes in their structure and conformation, with a consequent modification to their physicochemical and biochemical properties. The effects of glycation on protein structure and conformation have not been clearly established. Early-stage protein glycation, involving the formation of Amadori rearrangement products, and the initial non-cross-linking reactions of the protein bound sugar moieties, have been reported to enhance the physicochemical properties of several proteins. For example, the emulsifying properties of carp myofibrillar proteins (*6*), whey proteins (*7*), casein (*8*), plasma proteins (*9*), and lysozyme (*10*) have been shown to improve with limited glycation. The gel forming properties of dried egg white (*11*) and bovine serum albumin (*12*) have also been reported to improve with limited glycation. Limited glycation has also been shown to enhance the enzymatic activity of lysozyme (*13*, *14*) and trypsin (*15*). The thermal and conformational stability of several proteins, including bovine β-lactoglobulin (*16*, *17*) and bovine lens Crystallin (*18*) have also been shown to improve with limited glycation. These reports show that the effect of glycation on protein structure and functionality may depend on several factors, including the type of protein, the type of reducing sugar used for glycation, the glycation site on the protein, and the extent of glycation. The reports also suggest that, depending on the protein involved, limited glycation may cause a global conformational change or a localized structural change in the vicinity of the glycation site. Glycation-induced changes in the structure and functional properties of proteins may be due, in part, to the direct covalent attachment of sugar moieties to the basic amino acid residues of proteins, the glyco-oxidative reactions of the protein-bound sugar moieties, and to glycation-induced charge modification of proteins (*19*−*21*). Understanding the nature of the structure and conformational changes that accompany protein glycation will help in elucidating the functional consequences of protein glycation in both food and biological systems. Glycation-induced modification of proteins at the secondary, tertiary, and quaternary structural levels are yet to be elucidated. This paper describes the effect of glycation on conformational changes in the structure of lysozyme.

MATERIALS AND METHODS

Materials. Hen egg white lysozyme (LZM)[1] (Sigma cat. # L-6786), D-glucose, D-fructose, and bovine trypsin (Sigma cat. # T-8003) were obtained from Sigma Chemicals (St. Louis, MO). All other chemicals and reagents were of analytical grade from Fisher Scientific (Nepean, ON, Canada). Ultrapure water from the "Nanopure" water purification system (Barnstead, Thermolyne, Dubuque, IA) was used throughout the study.

Protein Glycation. Glycated lysozyme was prepared according to the method described by Yeboah et al. (*23*). Briefly, lyophilized lysozyme or lyophilized mixtures of lysozyme and D-glucose or D-fructose (1:1 molar ratio of ϵ-amino group:sugar carbonyl groups) were incubated at 50 °C and 65% relative humidity. The temperature and humidity condition were chosen to accelerate the rate of glycation. The incubation temperature of 50 °C is below the denaturation temperature of lysozyme (~76 °C) (*22*), so thermal denaturation of lysozyme was not expected to occur in the incubated samples. Samples were incubated for 1, 2, 5, 10, or 14 days. Lyophilized lysozyme was incubated alone (without any reducing sugar) under the same temperature and humidity conditions as a control. After 1, 2, 5, 10, or 14 days of incubation, samples were taken and immediately dialyzed exhaustively against water for 48 h at 4 °C (1 kDa MW cutoff) to remove free unreacted sugar and other low molecular weight reaction products. After dialysis, the samples were lyophilized and stored at −20 °C prior to further analysis.

Tryptic Hydrolysis. Solutions (25 mL) of lysozyme that had been incubated alone for 14 days (LZM) or lysozyme that had incubated with D-glucose (LZM-G) or D-fructose (LZM-F) (100 mg/mL, pH 8.5), and of bovine trypsin (4 mg/mL, pH 8.5) were mixed together (lysozyme:trypsin; 25:1) and incubated at 37 °C. After 6 h incubation, the hydrolysis reaction was terminated by rapidly heating the reaction mixture to boiling. Samples were then cooled over ice, filtered (0.22 μm Millipore syringe filter), and lyophilized. The lyophilized tryptic digests were stored at −20 °C prior to further analysis.

Reversed Phase HPLC. Quantities (5 mg) of the lyophilized tryptic digest of LZM, LZM-G, or LZM-F (prepared as described above) were dissolved in 0.1% aqueous trifluoroacetic acid (TFA) (1 mL), vortexed, and sonicated for 15 min. The resulting solutions were filtered through 0.22 μm syringe filters, and 50 μL of the filtrate was injected for RP-HPLC analysis. RP-HPLC analysis was performed on a Beckman Gold HPLC system, equipped with a UV diode-array detector (Beckman Instruments, Inc., Fullerton, CA). The mobile phase consisted of 0.1% TFA in water (solvent A) and in acetonitrile (solvent B), and the elution gradient was 0% to 60% solvent B in 40 min. Separation was achieved on a reversed phase analytical column (Vydac C_{18} column, 218TP54) at a flow rate of 1 mL/min. Eluting peaks (monitored 220 nm) were collected for electrospray tandem mass spectrometric analysis.

ESI-Mass Spectrometry. Lyophilized HPLC fractions were reconstituted in 70% aqueous acetic acid and analyzed by ESI-MSMS using an API−III MSMS system (SCIEX, Thornhill, Ontario, Canada). Samples were infused into the electrospray ion source through a fused silica capillary (100 μm i.d.) at a rate of 1 μL/min using a low-pressure infusion pump (Model 22, Harvard Apparatus, South Natick, MA). The sequence of tryptic peptides was determined from their collision-induced dissociation (CID) spectrum. The composition of glycoforms of lysozyme in the incubated samples was determined from the area of their corresponding peaks in the electrospray ionization (ESI) mass spectrum. The relative composition of individual glycoforms in the incubation mixture is proportional to the relative area their corresponding peaks. (*23*)

Molecular Modeling of Glycated Lysozyme. The AMBER force field (*24*, *25*) was used to simulate the effect of glycation on the conformation of lysozyme. The parameters had to be supplemented for glycated lysine residues. Missing equilibrium bond and angle parameters of the lysine-bound glucose moiety (Amadori product of lysine in the pyranose for) were obtained from the model compounds in the Cambridge Structural Database (*26*). Force constants were derived from similar atom types in the AMBER force field, and partial charges for glycated lysine were obtained by fitting to the 6-31G* electrostatic potential as calculated in GAMESS (*27*, *28*).

A triglycated model of chicken egg white lysozyme was developed, by replacing Lys-1, Lys-33, and Lys-97 with glucose-derived Amadori-lysine (in the pyranose form) that is glycated at the ϵ-amino group. These three residues were chosen for modification in the glycated lysozyme model because they were the most reactive residues in the protein. Another reason for using a triglycated model of lysozyme in the molecular modeling studies was that the average sugar load, in the form of Amadori product (average number of Amadori-products molecules per molecule of lysozyme) was approximately 2.4, so the next highest whole number was chosen. Molecular models of native lysozyme and of the triglycated lysozyme model were subjected to conjugate gradient energy minimization using a distance-dependent dielectric function ($\epsilon = 4r$) and an 8 Å nonbonded cutoff. Solvation effects were included, using an implicit solvation model with continuum electrostatics (*29*, *30*).

A conformational search using Monte Carlo minimization (*31*−*33*) was carried out to explore the effect of glycation on the structure of lysozyme. The side chain dihedral angles of glycated Lys 1, 33, 97 and of 18 amino acids (Val 2, Arg 21, Phe 34, Asn 37, Gln 41, Thr 43, Asn 44, Arg 45, Asp 52, Gln 57, Trp 62, Trp 63, Arg 68, Leu 75, Ser 81, Ser 86, Val 109, Trp 123) present in and around the active site of lysozyme were searched for a total of 20 000 Monte Carlo-minimization cycles. During minimization, all atoms in the protein were allowed to move. As a control, a similar conformational search was carried out on the same set of amino acids for native enzyme.

RESULTS

Glycation. Incubation of lysozyme with D-glucose or D-fructose resulted in the formation of a mixture of glycoforms of lysozyme. The ESI-mass spectrum of lysozyme incubated alone for 1 day (A), lysozyme incubated with fructose (B), and lysozyme incubated with glucose (C) for 1 day are presented in Figure 1. The mass spectra show the profile of glycoforms of lysozyme formed after 1 day of incubation. Only one peak, corresponding to lysozyme can be observed when lysozyme was incubated alone for 1 day. Incubation of lysozyme with D-fructose resulted in the formation of two glycoforms, mono- and difructated lysozyme (Figure 1B), while the incubation of lysozyme in the presence of glucose resulted

[1] Abrreviations: ESI/MS, electrospray mass spectrometry; ESI/MS/MS, electrospray tandem mass spectrometry; LZM, lysozyme incubated alone; LZM-F, lysozyme glycated by D-fructose; LZM-G, lysozyme glycated by D-glucose; TFA, trifluoroacetic acid.

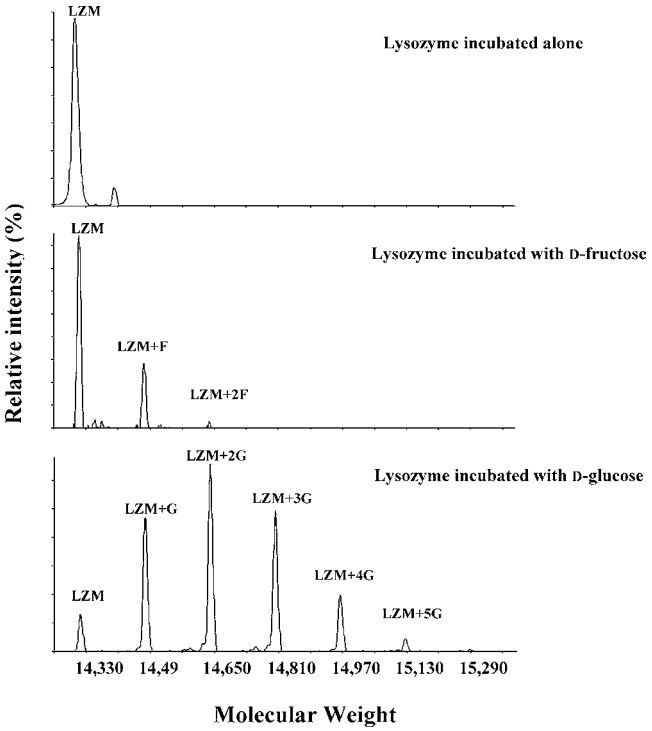

Figure 1. Reconstructed ESI-MS spectra of lysozyme incubated alone for 1 day and of lysozyme incubated with D-fructose and D-glucose for 1 day, showing the distribution of glycoforms of lysozyme formed during incubation.

in extensive glycation, leading to the formation of a mixture of five glycoforms ranging from mono- to pentaglucated lysozyme (Figure 1C). Less than 30% of lysozyme was glycated in the lysozyme−fructose system after the 1st day of incubation, while over 90% of lysozyme was glycated in the lysozyme−glucose system in the same period of incubation. The extent of glycation, determined as the average sugar load per molecule of lysozyme, increased with time of incubation in both sugar systems, but the rate of sugar loading of lysozyme when incubated with glucose was 5 to 6 times higher than when lysozyme was incubated with fructose throughout the incubation period.

Tryptic Digests of Unglycated and Glycated Lysozyme. The chromatographic profiles of the tryptic digest of unglycated and glycated lysozyme are presented in Figures 2 and 3. Figure 2A−D represents the chromatograms of the tryptic digests of lysozyme incubated alone for 14 days, and lysozyme incubated with D-fructose for 1, 5, and 14 days, respectively. Figure 3A−D represents the chromatograms of the tryptic digests of lysozyme incubated alone for 14 days, and lysozyme incubated with D-glucose for 1, 5, and 14 days, respectively. A comparison of the tryptic peptide profile of unglycated lysozyme and that of glycated lysozyme after different periods of incubation reveal marked differences between unglycated and glycated lysozyme. Several peaks (e.g. peaks 3 and 8) that were not observed in the peptide profile of the tryptic digest of unglycated lysozyme appeared in the tryptic digest of glycated lysozyme after only 1 day of incubation with D-fructose. After the 5th day of incubation, other peaks (e.g. peaks 2, 4, and 13) also appeared in the chromatogram in significant amounts. The relative proportion of peaks 7, 12, 14, and 15 decreased sharply after the 1st day of incubation, while at the same time the relative proportions of peaks 5 and 9 increased sharply. The HPLC peptide profile of lysozyme changed progressively with time of incubation. Similar results

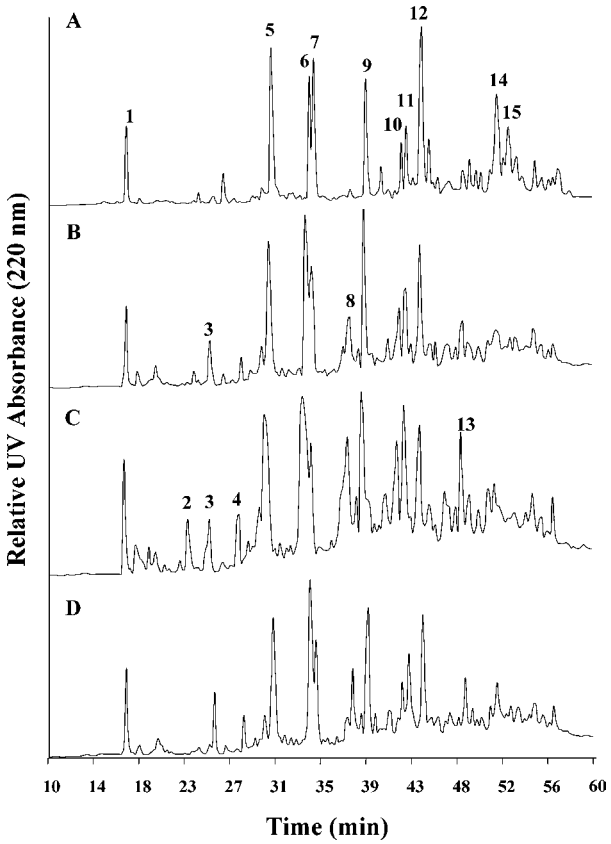

Figure 2. Reversed phase HPLC chromatograms of tryptic digest of unglycated lysozyme incubated alone for 14 days (LZM) (panel A), and lysozyme incubated with D-fructose after 1, 5, and 14 days (panels B, C, and D, respectively), showing peaks (labeled 1 through 15) that were collected and analyzed with ESI-MSMS.

were observed for the tryptic digest of lysozyme glycated with D-glucose as with D-fructose, but the extent of the changes was more pronounced for lysozyme incubated with D-glucose especially after prolonged incubation (Figure 3).

Identification of Tryptic Peptides. Electrospray tandem mass spectrometric was used to identify and sequence the peptide components of the tryptic digests. Table 1A,B shows the m/z $(M + H)^+$ values and the sequence of the peptides identified in the HPLC fractions of the tryptic digests of unglycated and glycated lysozyme after 1, 5, and 14 days of incubation. The symbol "+" or "−" is used to indicated the presence or absence of the designated peptide in the HPLC fraction, and the symbol "++" is used to indicate the major peptide component of an HPLC fraction, if the fraction contains more than one peptide component. The symbol "=" is used to indicate peptide fragments that contain disulfide bonds, and the symbol "*" placed after an amino acid letter code indicates that that amino acid residue is the glycation site. Most of the identified peptides were trypsin-specific peptides (i.e., produced by the cleavage of peptide bonds at the carboxyl end of a lysine or arginine residue). Nontrypsin specific of peptides, such as peptide residues 109−112, 117−123, 97−108, and 98−108 produced by the cleavage of peptide bonds at the carboxyl end of Trp-108 and Trp-123 were also identified.

Residues 117−125 and 98−112, identified in HPLC fractions 12 and 15, respectively, of the tryptic digest of unglycated lysozyme were not detected in the digests of any of the glycated samples. The peptide components of HPLC fractions 2, 3, and 8 of the tryptic digest of glycated

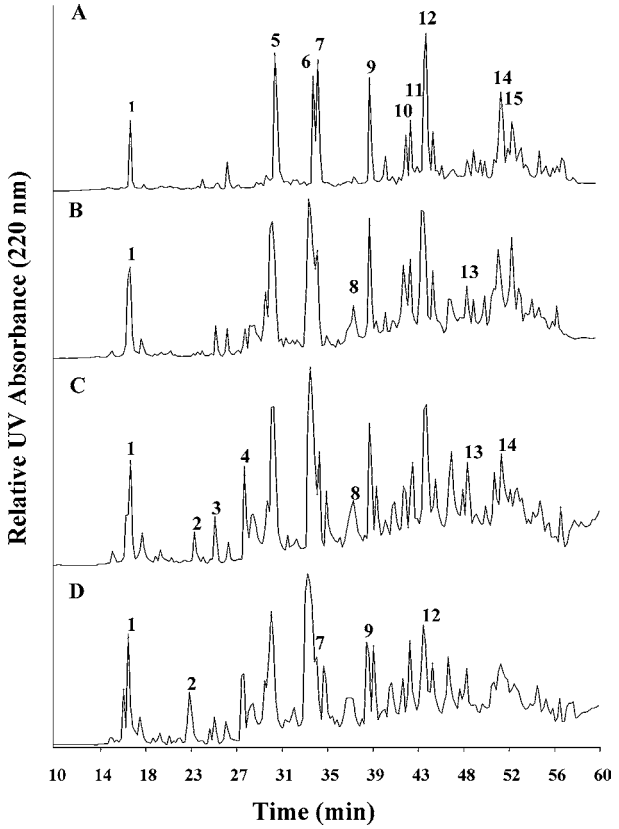

Figure 3. Reversed phase HPLC chromatograms of tryptic digest of unglycated lysozyme incubated alone for 14 days (LZM) (panel A), and lysozyme incubated with D-glucose after 1, 5, and 14 days (panels B, C, and D, respectively), showing peaks (labeled 1 through 15) that were collected and analyzed with ESI-MSMS.

lysozyme (glucated and fructated) were identified as residues 46−53, 35−45, and 60−68, respectively. These peptides were not observed in the tryptic digest of unglycated lysozyme, but they appeared in the digest of glycated lysozyme after the 1st day of incubation. The peptide components of HPLC fraction 13 were identified as residues 22−28, 46−59, 47−61, and 64−84. These peptides were also not released in the digest of unglycated lysozyme. The peptide defined by residues 22−28 was also released in the tryptic digest of glycated lysozyme after the 1st day of incubation in both sugar systems, but residues 46−59, 47−61, and 64−84 were detected in the digest of glucated lysozyme samples after the 5th day of incubation. These peptides were derived by the cleavage of nontrypsin specific bonds.

Glycation of lysozyme with glucose had a more pronounced effect on the peptide composition of the tryptic digest of lysozyme than with fructose. For example, after just 1 day of incubation of LZM with glucose (LZM-G), the peptides defined by residues 1−5, 97−108, 22−23=115−116, 97−112, and 98−112 could not be detected in HPLC fractions 5, 10, 14, and 15, respectively. These peptides were, however, observed in the digest of LZM-F even after the 5th day of incubation. Prolonged incubation of lysozyme with glucose (after 5 days) also resulted in the release of peptides defined by residues 46−59, 47−61, and 64−84 in HPLC fraction 13. These residues were not observed in the tryptic digests of unglycated lysozyme or any of the LZM-F samples. Di- and triglycated peptides ($[M + H]^+ = 936.4$ and 2400.2; see Table 1), and glycated peptides for which the bound sugar moieties had undergone further dehydration (residues with $(M + H)^+ = 750.4$, 1654.8, and 1493) to form deoxyosones were detected in the digests of glycated lysozyme samples (both LZM-F and LZM-G) after the 5th day of incubation. Glycated peptides that had undergone both dehydration and deamination ($[M + H]^+ = 1654.8$ and 1493.6) were only detected in the digest of LZM-G after the 5th day of incubation.

DISCUSSION

Tryptic Peptide Profile. Differences in the chromatographic profile of the tryptic digest of unglycated lysozyme (LZM) and glycated lysozyme (LZM-F or LZM-G) (Figures 2 and 3) suggests that glycation of LZM resulted in changes to its conformation. A comparison of the chromatographic profile of the tryptic digests of unglycated and glycated lysozyme provided information about glycation-induced conformational changes in the structure of lysozyme. Monitoring of the peptide components of chromatographic peaks that appeared only in the tryptic digest of the glycated lysozyme samples also provided information about the regions or domains of unglycated lysozyme that had become more exposed to the proteolytic activity of trypsin after glycation. The peptide profile of peaks that disappeared, or reduced in relative intensity in the chromatogram of the tryptic digest of unglycated lysozyme after glycation provided information about the regions of lysozyme that had become less exposed, or more resistant to the proteolytic activity of trypsin. Information about the glycation sites of lysozyme, and the relative reactivities of the identified glycation sites could also be determined from changes in the chromatographic and peptide profiles of the tryptic digests of lysozyme after glycation.

The detection of peptide residue 46−53, 35−45, 60−68, and 22−28 in HPLC fractions 2, 3, 8, and 13, respectively (Table 1A), of the tryptic digests of glycated lysozyme after the 1st day of incubation indicate that the region(s) or domain(s) of lysozyme that contained these peptide fragments became more exposed to the proteolytic activity of trypsin after limited glycation. An inspection of the 3-D structure of native lysozyme showed that these peptide fragments are all located within or in the vicinity of the active site of lysozyme. A comparison of the chromatographic profile of the tryptic digests (Figures 2 and 3) of unglycated and glycated lysozyme also reveal that the relative chromatographic response of peaks 6, 9, 10, and 11 increased markedly after the 1st day of incubation. The peptide component(s) of these chromatographic fractions were identified as residues 109−112, 117−123, 54−61, and 97−108, respectively. These residues were also found to be located in the vicinity of the active site of lysozyme.

These results show that limited glycation of lysozyme caused an increased exposure of its active site residues to the proteolytic activity of trypsin. It also suggests that limited glycation of lysozyme increased solvent penetration into its active site. This observation may explain the enhanced enzymatic activity of lysozyme after limited glycation (*13, 14*). The active site residues of lysozyme include Phe 34, Glu 35, Ser 36, Asn 37, Asn 44, Asp 52, Leu 56, Gln 57, Trp 62, Trp 63, Leu 75, Asp 101, Asn 103, Ala 107, Trp 108, Val 109, Ala 110, and Arg 114.

The sharp decrease in the relative chromatographic response of peaks 7, 12, 14, and 15 after the 1st day of incubation show that the regions of lysozyme that contain their peptide components had become resistant to the proteolytic activity of trypsin after glycation. The peptide component(s) of fractions 7, 12, 14, and 15 are residues 34−45, 117−125, 97−112, and 98−112 respectively, all

"+" indicates that peptide was identified in fraction, and "++" is used to indicate the Major peptide component in cases where HPLC fraction contained more than one peptide. "−" indicates that peptide was not identified in fraction or is present below the detectable limit, and "=" is used to indicate disulfied bonds. A. unglycated peptides, and B glycated peptides identified in the HPLC fractions of the hydrolysates of the LZM-F and LZM-G systems.

of which are produced by the cleavage of a peptide bond at the carboxyl end of a lysine residue (Lys-33, -96, -97, and -116). The decreased rates of release of these fragments indicate that the ϵ-amino groups of the respective lysine residues had undergone glycation. This does not mean that every molecule of lysozyme is glycated at all four lysine residues, but that different populations of glycoforms of lysozyme with varying degrees of glycation at Lys-33, -96, -97, and -116 had been formed in the glycation mixture (Figure. 1). The major peptide component of fraction 5 of unglycated lysozyme was residue 2−5, which is formed by the cleavage of peptide bonds at the carboxyl end of Lys-1 and Arg-5. After the 1st day incubation of lysozyme with fructose, the major peptide component of fraction 5 was no longer residue 2−5, but residue 15−21. In addition, peptide fragment 1−5 was not observed in any of the tryptic digests of LZM-G samples, even after only 1 day of incubation, due to the extensive nature of the glycation of lysozyme in the when incubated with glucose. These results indicate the glycation of either the N-terminal α-amino group and/or the ϵ-amino group of Lys-1. The fact that the peptide fragments defined by residues 117−125, and 98−112 could not be detected in the tryptic digest of even the least glycated sample (LZM-F after 1 day incubation) also indicates the glycation of Lys-97 and -116. The results of this study show that all seven lysine residues of lysozyme were involved in the glycation reaction and that Lys-1, -33, and -97 were the most susceptible residues to the glycation reaction. The list of identified glycated peptides (Table 1B) show that diglycation occurred at Lys-1 and -33. The diglycation at Lys-1 could be due to glycation of the N-terminal α-amino and ϵ-amino group or diglycation at the ϵ-amino group. The results of this study are consistent with the report of previous studies (where the lysine residues of lysozyme were modified with acetic anhydride) (*33*), where the order of reactivity of the ϵ-amino groups of the lysine residues of lysozyme was reported as Lys-97 > -33 > -1> -13 > -116 > -96.

Effect of Glycation on the Structure Lysozyme. Changes in the chromatographic profile of the tryptic digest of lysozyme, and in the peptide composition of the HPLC fractions after glycation, show that the glycation of lysozyme resulted in a modification of its structure and conformation. Differences between in the chromatographic and peptide profile of the tryptic digests of lysozyme glycated with glucose and fructose (Figures 2 and 3) can be explained by the differences in the extent of glycation in the two sugar systems. The most dramatic change in the peptide profile of the tryptic digest of lysozyme occurred after the 1st day of incubation with either glucose or fructose. These changes were accompanied by the release of new peptides (residues 46−53, 35−45, 54−61, 46−56, and 22−28) that were not

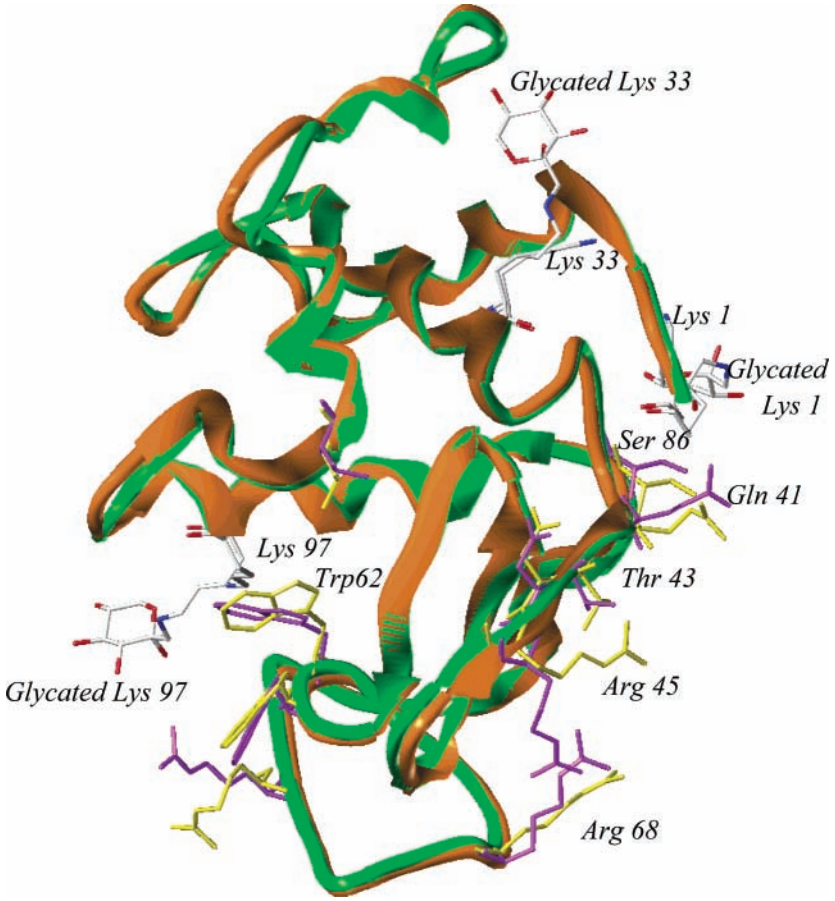

Figure 4. Superimposed structures of native hen egg white lysozyme and its triglycated model. Residues that showed conformational change after glycation are highlighted in yellow (in the glycated model) and purple (in the native enzyme). Secondary structures colored green (in the glycated model) and orange (in the native enzyme) are displayed. Glycated residue Lys 1, Lys 33, and Lys 97 are displayed for clarity.

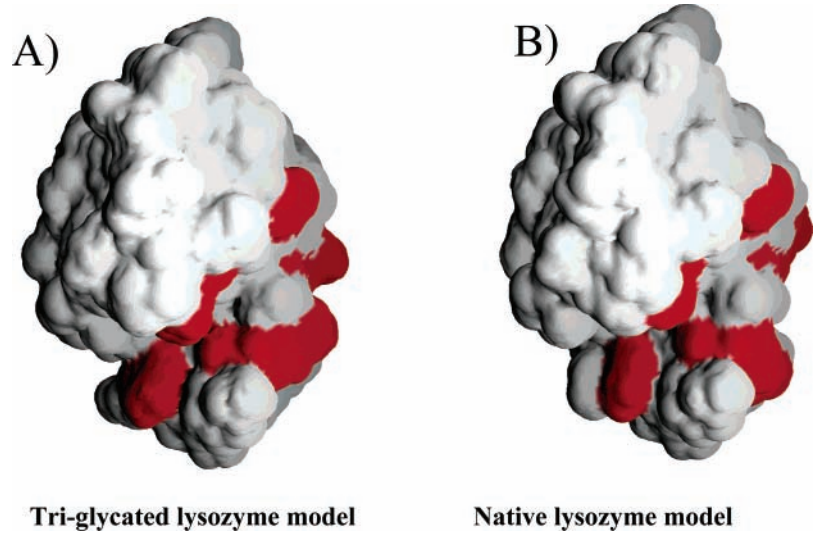

Figure 5. Solvent-accessible surface area of the triglycated model of lysozyme (A) and of the native lysozyme (B). The solvent-accessible surface area of the active site residues is highlighted in red for comparison (see text for detail).

observed in the digest of unglycated lysozyme. The amino acid residue of the peptide fragments defined by residues 46−53, 35−45, 54−61, and 46−56 constitute the active site amino acid residues of lysozyme. The increased rate of release of the peptide fragments from the active site of lysozyme as a result of glycation show that the glycation of lysozyme modified its conformation to expose the active site to the proteolytic activity of trypsin.

It has been reported that reductive methylation of all the ϵ-amino groups of lysozyme resulted in only minor overall structural change of the protein, but caused significant modifications to the surface loops defined by residues 69−72 and 101−103, as well as the C-terminal residues 126−129 (*34*). The minor structural changes effected by the reductive methylation of lysozyme may be due to the small size and hydrophobic nature of the

methyl group. The larger size of D-fructose or D-glucose, with their numerous hydroxyl groups, on the other hand, may cause a more significant change to the structure and hydrodynamic properties of lysozyme as observed in this study.

Modeling. Monte Carlo simulations of models of native and glycated lysozyme were carried out to determine structural perturbation caused by limited glycation, given that limited glycation of lysozyme (after the 1st day of incubation) resulted in significant changes in the chromatographic and peptide profile of the tryptic digest of lysozyme. A superposition of the lowest-energy structures of native lysozyme and a model of triglycated lysozyme is presented in Figure 4. Overall, only minor structural differences were observed between the model of native lysozyme and the triglycated model. However, there was significant reorientation of the side chains of glycated Lys-1, -33, and -97, Gln 41, Thr 43, Asn 44, Arg 45, Arg 68, Trp 62, and Val 109. With the exception of the glycated lysine residues (Lys-1, -33, and -97), the common feature between these amino acid residues is that they are all located in the active site region of lysozyme. A comparison between the solvent-accessible surface area of native lysozyme (6487.11 Å^2) and of the triglycated lysozyme model (6894.38 Å^2) shows a significant net increase of 407.27 Å^2 in the triglycated lysozyme model compared to the native enzyme. The solvent-accessible surface area of the active site region increased from 470 Å^2 in native lysozyme to 550 Å^2 in the triglycated model. This increase of 80 Å^2 is significant, given that it represents ~20% of the total net increase in solvent accessibility of lysozyme (407.27 Å^2), when the contribution of the active site region to the total solvent accessible surface area of native lysozyme is only 7.2%. Figure 5 shows the solvent-accessible surface area of the triglycated lysozyme model (A) and of native lysozyme (B). The solvent-accessible surface area of the active site region is indicated in red for clarity. The reorientation of the side chains of the active site residues, coupled with the increase in the solvent-accessibility of the active site, is consistent with the increased susceptibility of the active site residues in the glycated protein to tryptic digestion.

CONCLUSION

The findings of this study show that limited glycation of lysozyme resulted in conformational changes that increased the susceptibility of its active site region to the proteolytic activity of trypsin. The extent and nature of the conformational change depended on the extent of glycation, as well as the site(s) of glycation. The results also showed that conformational changes could occur at the glycation sites or regions remote from the site of glycation. Although the observed glycation sites of lysozyme in both sugar systems were similar, fructose showed a higher degree of specificity in glycating the ϵ-amino groups of the most reactive lysine residues (Lys-1, -33, and -97) during the early stages of the glycation reaction, due to the lower reactivity of fructose.

The results of this study also show that ESI-MS peptide mapping is a powerful technique for revealing specific and global changes in protein structure due to chemical modifications such as glycation. Glycation-induced changes in the peptide profile of the chromatographic fractions of the tryptic digest of lysozyme at different extends of glycation provided information about the dynamic nature of the changes in the structure and conformation the protein.

Liposomes with Differential Lipid Components Exert Differential Adjuvanticity in Antigen−Liposome Conjugates via Differential Recognition by Macrophages

Yuriko Tanaka,[†] Michiyuki Kasai,[†] Maiko Taneichi,[†] Seishiro Naito,[†] Hiroshi Kato,[†] Masahito Mori,[‡] Mitsuhiro Nishida,[‡] Naoya Maekawa,[‡] Hiroyuki Yamamura,[‡] Katsutoshi Komuro,[†] and Tetsuya Uchida*[,†]

Department of Safety Research on Blood and Biological Products, National Institute of Infectious Diseases, Tokyo 208-0011, Japan and Drug Delivery System Development Division, Nippon Oil and Fat Corporation, Tokyo 150-6019, Japan. Received July 28, 2003; Revised Manuscript Received November 12, 2003

We previously reported that liposomes having differential lipid components displayed differential adjuvant effects when antigen was coupled with liposomes via glutaraldehyde. In the present study, antigen−liposome conjugates prepared using liposomes having differential lipid components were added to the macrophage culture, and phagocytosis and the antigen digest of liposome-coupled antigen by macrophages were then investigated. Antigen presentation by macrophages to an antigen-specific T-cell clone was further investigated using the same conjugates. Antigen−liposome conjugates which induced higher levels of antibody production in vivo were recognized more often, and the liposome-coupled antigen was digested to a greater degree by macrophages than antigen−liposome conjugates which induced lower levels of antibody production. These results correlated closely with those regarding antigen presentation by macrophages; when antigen was coupled to liposomes showing higher adjuvant effect, macrophages cocultured with antigen−liposome conjugates activated antigen-specific T-cells at a higher degree. The concentration of OVA in the macrophage culture added as antigen−liposome conjugates was approximately 32 μg/mL. However, the extent of T-cell activation was almost equal to that when 800 μg/mL of soluble OVA was added to the culture. The results of the present study demonstrated that the adjuvant activity of liposomes observed primary in vivo correlated closely with the recognition of antigen−liposome conjugates and antigen presentation of liposome-coupled antigen by macrophages, suggesting that the adjuvant effects of liposomes are exerted at the beginning of the immune response, i.e., recognition of antigen by antigen-presenting cells.

INTRODUCTION

Adjuvants play a pivotal role in vaccination, especially when the vaccine antigen itself possesses a weak immunogenicity (*1*−*3*). At present, aluminum adjuvant is the only adjuvant that is clinically in use, although a number of candidate adjuvants have beeen reported and examined in a preclinical study (*3*). However, aluminum adjuvants are known to be effective only for the induction of humoral immunity, not for the induction of cell-mediated immunity. In addition, aluminum adjuvants are also known to induce the production of IgE antibodies, which is a cause of allergic response against the vaccine (*4*−*6*). Consequently, the development of a novel vaccine adjuvant is indispensable. Among the candidates for adjuvants, liposomes have garnered recent attention for their capacity as carriers of vaccines (*7*−*14*).

We previously reported that antigens chemically coupled to the surface of liposomes induced antigen-specific IgG but not IgE antibody production (*15*). This IgE-selective unresponsiveness was induced by antigen−liposome conjugates regardless of the coupling procedure of the antigen and liposomes (*16*), of the antigens used for the coupling with liposomes (*17*), or of the route of inoculation (i.e., intraperitoneal (*15*) or intranasal (*18*)). The inducibility of antigen-specific IgG antibody production by antigen−liposome conjugates varied among the liposome preparations used for the production of antigen−liposome conjugates; the greater the membrane mobility in liposomes, the more antibody production induced by antigen−liposome conjugates (*19*). In fact, alteration of lipid composition has been reported to modulate immune responses (*20*−*26*). The aim of this study is to examine if the differential adjuvant effects displayed among liposomes with different lipid components were due to differential recognition of liposomal antigens by antigen-presenting cells. Antigen−liposome conjugates prepared using liposomes with differential lipid components were added to the culture of macrophages, and recognition and digest of liposomal antigen were compared. Further, antigen presentation by macrophages was investigated after coculture of macrophages with antigen−liposome conjugates made using liposomes having different lipid components.

MATERIALS AND METHODS

Mice. BALB/c mice (8 weeks of age, female) were purchased from Charles River (Yokohama, Kanagawa, Japan).

Chemicals. All phospholipids were obtained from NOF Co., Tokyo, Japan. Reagent grades of cholesterol were purchased from Wako Pure Chemical Industries, Osaka, Japan.

Antigens. Ovalbumin (OVA, Grade VII) was purchased from Sigma (St. Louis, MO). For the analysis of the processing of liposome-coupled OVA by macrophages, DQ-OVA, that exhibits green fluorescence upon proteolytic degradation, was purchased from Molecular Probes, Inc. (Eugene, OR).

Fluorescence Labeling of OVA. OVA was labeled with fluorescence using an Alexa Flour 488 protein labeling kit (Molecular Probes, Inc.) following manufacturer's protocol.

Liposomes. Liposomes consisting of two different lipid components were used in this study: "Stearoyl" liposomes composed of distearoyl phosphatidylcholine, distearoyl phosphatidyl ethanolamine, cholesterol, and distearoyl phosphatidyl glycerol acid in 4:3:7:2 molar ratios, and "Oleoyl" liposomes composed of dioleoyl phosphatidylcholine, dioleoyl phosphatidyl ethanolamine, cholesterol, and dioleoyl phosphatidyl glycerol acid in 4:3:7:2 molar ratios. The crude liposome solution was passed through a membrane filter (Nucleopore polycarbonate filter, Coster, Cambridge, MA) with a pore size of 0.2 μm.

Coupling of OVA to Liposomes. Liposomal conjugates with plain OVA, Alexa-labeled OVA, or DQ-OVA were prepared essentially in the same way as described previously (*15*). Briefly, to a mixture of 90 mg of liposomes and 6 mg of OVA in 2.5 mL phosphate buffer (pH 7.2) was added in drops 0.5 mL of 2.5% glutaraldehyde solution. The mixture was stirred gently for 1 h at 37 °C, and then 0.5 mL of 3 M glycine−NaOH (pH 7.2) was added to block excess aldehyde groups. This was followed by incubation overnight at 4 °C. The liposome-coupled OVA and uncoupled OVA in the resulting solution were separated using CL-4B column chromatography (Pharmacia Fine Chemical Co., Upsala, Sweden). The amount of lipid in the liposomal fraction was measured using a Phospholipid-Test-Wako phospholipid content assay kit (Wako Pure Chemical Industries). The OVA−liposome solution was adjusted to 10 mg lipid/mL in RPMI-1640, sterile-filtered using Millex-HA syringe filter unit (0.45 μm, Millipore Corp., Bedford, MA), and kept at 4 °C until use.

Quantification of OVA Coupled to Liposome. For the measurement of OVA coupled to liposome, radiolabeled OVA ([methyl-^{14}C]: purchased from New England Nuclear, Boston, MA) was mixed with cold OVA and used for coupling with liposome and for determining the calibration curve. The radioactivity of the resulting OVA−liposome solution was counted using a calibration curve. The amounts of OVA coupled to "Stealoyl" and "Oleoyl" liposomes were 47.0 and 46.8 μg/mg lipid, respectively.

Immunization. Mice were immunized intraperitoneally (ip) with OVA−liposome at a dose of 2 mg lipid/200 μL/mouse or with 80 μg/200 μL/mouse of plain OVA solution in PBS. Four weeks after primary immunization, mice were boosted in the same manner as that used for primary immunization. For the measurement of serum antibodies, mice were bled from the tail vein.

Measurement of Serum Antibodies. Six weeks after primary immunization, serum anti-OVA IgG and IgG isotypes were determined by ELISA using HRP-labeled goat anti-mouse IgG (Zymed Lab., San Francisco, CA).

Cloned Macrophage Hybridoma. Macrophage hybridoma clone #39, obtained from the fusion of splenic adherent cells from CKB mice and P388D$_1$ (*27*), was used.

Antigen-Specific T-Cell Clone. OVA-specific T-cell clone, 42−6A (*28*), was kindly provided by Dr. T. Kakiuchi, Toho University School of Medicine, Tokyo.

Macrophage Culture. Macrophage hybridoma clone #39 was maintained in RPMI-1640 (Gibco Laboratories, Grand Island, NY) supplemented with 10% heat-inactivated FCS (Hyclone Laboratories, Logan, UT), 100 U/mL of penicillin, and 100 μg/mL of streptomycin (Gibco Laboratories) in a 75 cm^2 flask (No. 3111, Becton Dickinson Labware, Franklin Lakes, NJ).

Flow Cytometry. To investigate the capture of OVA−liposome by macrophages, #39 macrophage clone were incubated for 60 min at 37 °C in the presence of Alexa-labeled OVA−liposome conjugates that contained a final concentration of 4 μg/mL OVA. After the incubation, cells were washed with ice cold PBS. Then they were analyzed on a FACS Calibur flow cytometer (BD Biosciences, Mountain View, CA). The histograms of fluorescence distribution were plotted as the number of cells versus fluorescence intensity on a logarithmic scale.

Confocal Laser Scanning Microscopy To investigate degradation of liposome-coupled OVA by macrophages, #39 macrophage clone were cultured for 18h at 37 °C on eight-hole heavy Teflon-coated slides (Bokusui Brown, New York, NY) and were then incubated with DQ-OVA−liposome conjugates, prepared using "Stearoyl" or "Oleoyl" liposomes, for 60 min at 37 °C. They were washed with MEM and fixed with 4% paraformaldehyde in PBS for 10 min at room temperature. After fixation, they were incubated for 10 min in 0.1 M glycine-HCl, pH 7.0, to block the remaining aldehyde residue. They were then washed two times in PBS. After being washed, these slides were sealed with PBS/glycerin (PBS:glycerin = 1:9). These slides were analyzed under a confocal laser scanning microscope system, LSM410 (Carl Zeiss Co., Germany).

Antigen Presentation by Macrophages Cocultured with OVA−Liposome. OVA−liposome conjugates made using "Stearoyl" or "Oleoyl" liposomes were added to the culture of macrophage clone #39 and incubated overnight. The macrophages were then washed three times in ice-cold media, and 5×10^4 cells were cocultured with 2×10^4 cells of OVA specific T-cell clone, 42−6A, in a 96-well plate (No. 3072, Becton Dickinson Labware). After 18 hours of incubation, IL-2 in the culture supernatants were assayed using a Biotrak mouse ELISA system (Amersham International, Buckinghamshire, UK). The final concentration of OVA−liposome added to the macrophage culture was 800 μg lipid/mL, which included 32 μg OVA/mL. For controls, OVA was added to the macrophage culture continuously at final concentrations of 32 or 800 μg/mL.

RESULTS

Comparison of Anti-OVA Antibody Production in Mice Induced by OVA−Liposome Conjugates Made Using Liposomes of Two Different Lipid Components. Mice were immunized with OVA−liposome conjugates which were made using "Stearoyl" or "Oleoyl" liposomes. Figure 1 shows serum anti-OVA IgG titers six weeks after the primary immunization with OVA−liposome or with plain OVA solution. Levels of anti-OVA IgG antibody production induced by two OVA−liposome conjugates were significantly different; OVA−liposome made using "Oleoyl" liposome induced more than a 10-fold higher level of anti-OVA IgG production than that induced by OVA−liposome made using "Stearoyl" liposome. The same dose of plain OVA solution induced a

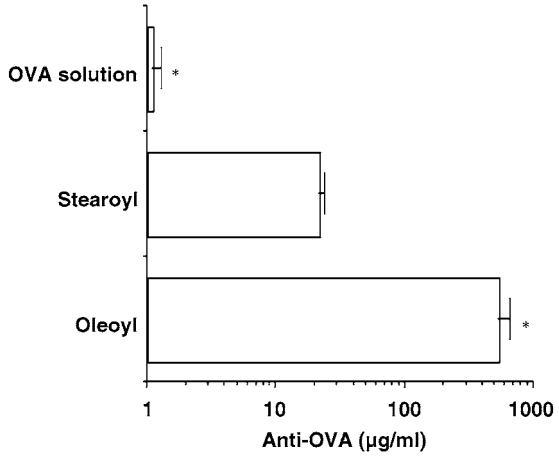

Figure 1. Anti-OVA IgG antibody production in mice immunized with OVA−liposome conjugates. BALB/c mice were immunized with OVA−liposome made using "Stearoyl" or "Oleoyl" liposomes or with plain OVA solution at 0 and 4 weeks. Six weeks after primary immunization, mice were bled from the tail vein, and serum anti-OVA IgG was measured. Data represent mean and SE of five mice per group. Asterisk, significant ($p < 0.01$) difference as compared with "Stearoyl" group.

far lower level of anti-OVA IgG antibody production as compared with that induced by OVA−liposome conjugates.

Phagocytosis of Fluorescence-Labeled OVA by Macrophages. To examine if the differential adjuvant effects between two liposome preparations observed in the above experiment were due to differential recognition of liposomal antigens by antigen-presenting cells, phagocytosis of OVA−liposome by macrophages was investigated by adding fluorescence-labeled OVA coupled with "Stearoyl" or "Oleoyl" liposomes to the macrophage culture. FACS analysis was performed 15, 30, 60, and 120 min after the addition of OVA−liposome conjugates to the macrophage culture, and a maximal incorporation was observed at 60 min. Figure 2a shows the fluorescence intensity of macrophages cultured for 60 min with OVA−liposome conjugates. More OVA was incorporated when OVA was coupled to "Oleoyl" liposomes than when OVA was coupled to "Stearoyl" liposomes. A similar result was observed in the confocal microscopic analysis; more OVA was incorporated by macrophages when OVA coupled to "Oleoyl" liposome was added to the culture (Figure 2b).

Processing of Liposome-Coupled OVA by Macrophages. To compare the processing of OVA coupled either with "Stearoyl" or "Oleoyl" liposomes by macrophages, the fluorescence intensity of the macrophages was investigated by adding DQ-OVA−coupled liposome to the macrophage culture. FACS analysis was performed 15, 30, 60, and 120 min after the addition of OVA−liposome in the macrophage culture, and a maximal processing of OVA was observed at 60 min. Figure 3 shows the results of FACS and confocal microscopic analysis at 60 min after the addition of OVA−liposome in the culture. More OVA appeared to be processed in 60 min by macrophages when OVA was coupled to "Oleoyl" liposome and added to the culture than that when OVA was coupled to "Stearoyl" liposome and added

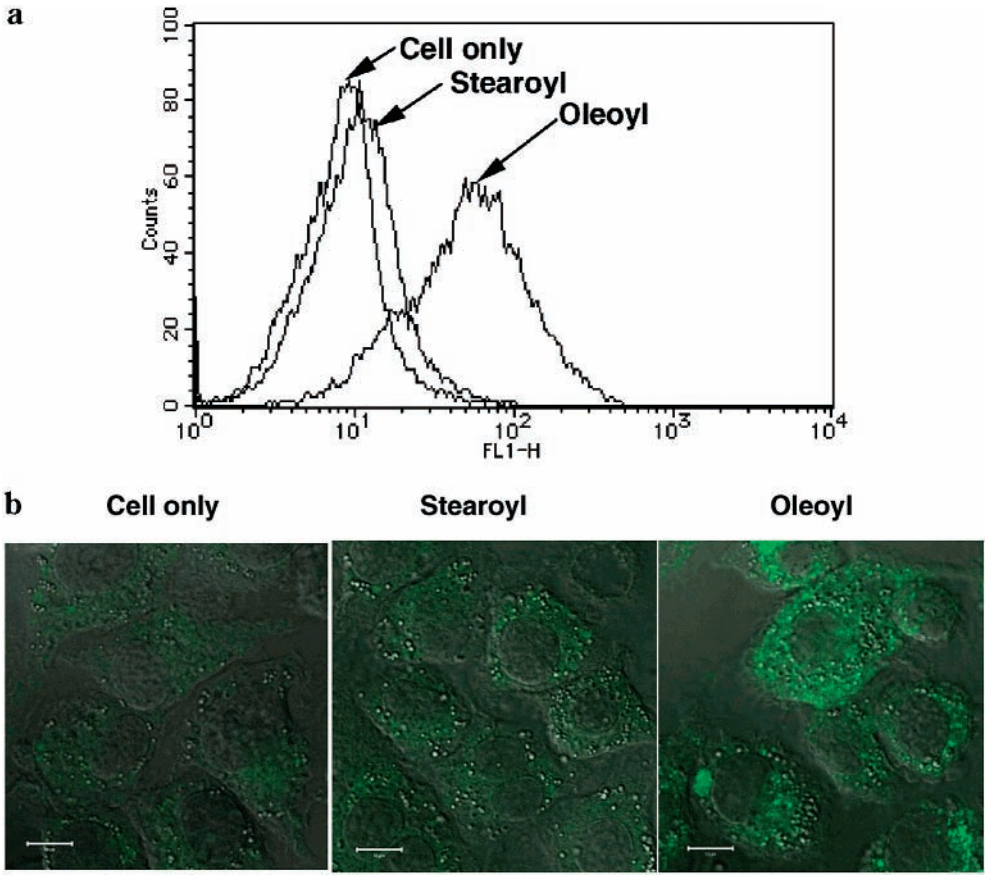

Figure 2. Phagocytosis of OVA−liposome conjugates by macrophages. Fluorescence-labeled OVA was coupled to either "Stearoyl" or "Oleoyl" liposomes and added to the culture of macrophages as described in Materials and Methods. Macrophages recovered from the culture were analyzed using flow cytometry (a) and confocal laser scanning microscopy (b).

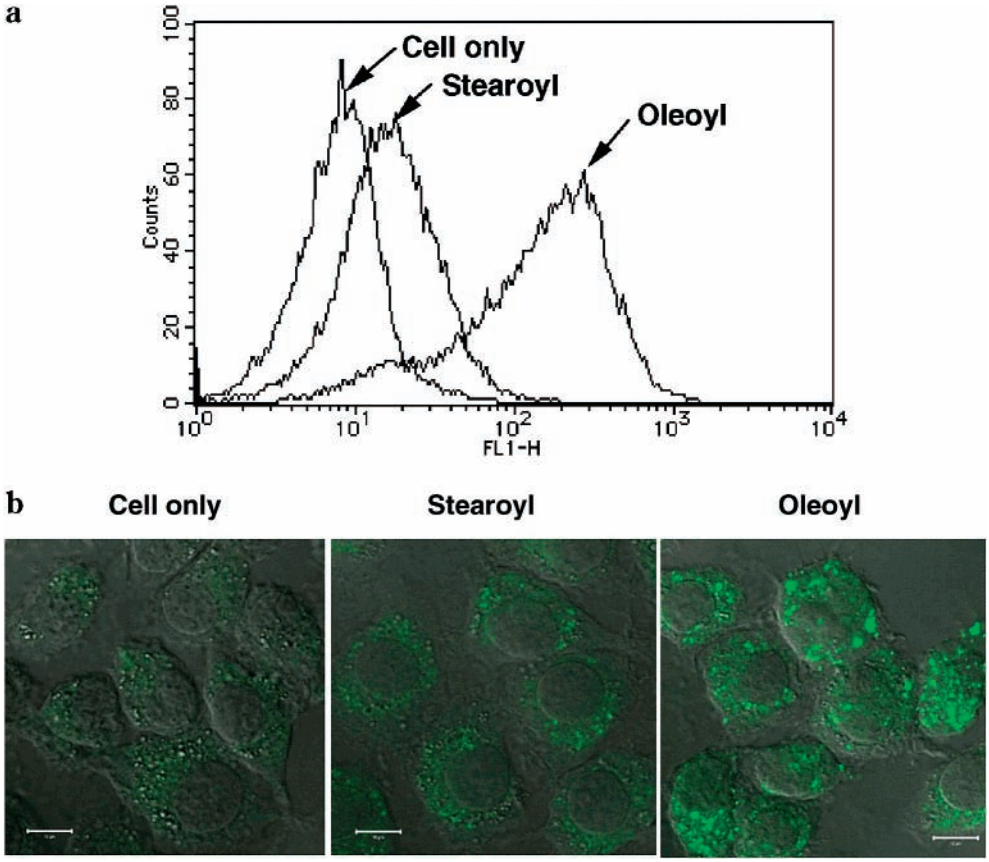

Figure 3. Digestion of liposome-coupled OVA by macrophages. "Stearoyl" or "Oleoyl" liposomes coupled with DQ-OVA were added to the macrophage culture. Sixty minutes after the onset of the culture, macrophages were recovered and analyzed using flow cytometry (a) and confocal laser scanning microscopy (b).

to the culture (Figure 3a). A consistent result was observed by confocal microscopic analysis (Figure 3b).

Antigen-Presentation by Macrophages Cocultured with OVA−Liposome Conjugates. Macrophages were cultured in the presence of OVA−liposome prior to the coculture with OVA-specific T-cell clone, 42−6A, and IL-2 production by the T-cell clone was monitored. Figure 4 shows the amount of IL-2 in the culture supernatant. A significantly high level of IL-2 production was observed when the macrophages were pre-cultured with OVA−liposome made using "Oleoyl" liposomes. The amount of IL-2 was comparable with that when 800 μg/mL of plain OVA was added to the culture. The amount of OVA in the culture to which OVA−liposome conjugates were added was 32 μg/mL. However, the addition of 32 μg of plain OVA to the culture resulted in production of a far lesser amount of IL-2. Although a significant level of IL-2 was produced when macrophages were pre-cultured with OVA−liposome made using "Stearoyl" liposomes, it was more than 10-fold less than that in the "Oleoyl" liposome group.

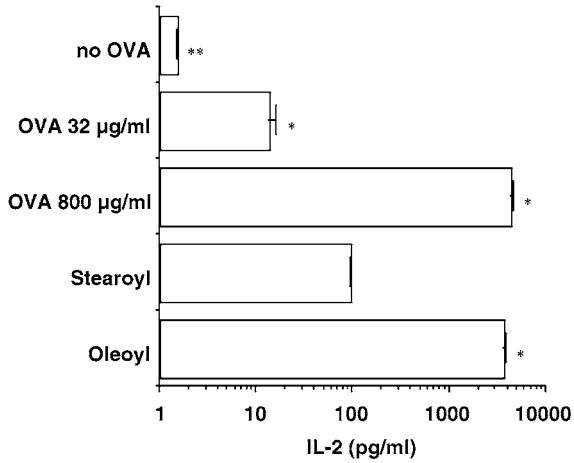

Figure 4. Antigen presentation by macrophages pulsed with OVA−liposomes. Macrophages preincubated with OVA−liposomes were cocultured with OVA−specific T-cell clone as described in Materials and Methods. Data represent mean IL-2 concentration and the SE of the culture supernatant in triplicate cultures. Asterisk, significant ($p < 0.01$) difference as compared with "Stearoyl" group. Two asterisks, significant ($p < 0.01$) difference as compared with the other groups.

DISCUSSION

We previously demonstrated that the adjuvanticity of liposomes in the surface-linked liposomal antigen differs among liposomes of differing lipid compositions (*19*). The results obtained in the present study suggested that the adjuvanticity in liposomes with differential lipid components would correlate with the recognition of liposomal antigens by macrophages, resulting in the differential extent of digestion and antigen presentation. When OVA was coupled to "Oleoyl" liposomes, which expressed high adjuvant activity, OVA was incorporated more efficiently by macrophages than when OVA was coupled to "Stearoyl" liposomes, which expressed lower adjuvanticity. These results further correlated closely with those obtained in the succeeding investigations regarding antigen processing and presentation by macrophages; more OVA was processed in macrophages when OVA was coupled to "Oleoyl" liposomes than when coupled to "Stearoyl" liposomes. Moreover, OVA coupled to "Oleoyl" liposomes was effectively presented to OVA-specific T-cells. When

OVA coupled to "Oleoyl" liposomes was presented to T-cells, the amount of IL-2 released from OVA-specific T-cells was comparable to that when 800 μg/mL of plain OVA was added to the culture, although the amount of OVA added to the culture as OVA−liposome was 32 μg/mL. A significant difference was observed among "Oleoyl"- and "Stearoyl" liposomes in the results, although OVA coupled to "Stearoyl" liposomes was presented even more effectively as compared with that when 32 μg/mL of plain OVA was added to the culture. These results suggest that the adjuvant effect of liposomes correlates well with antigen recognition and presentation by macrophages, at the initiation of immune response.

In the vaccines, adjuvants are indispensable especially for antigens with weak immunogenicity. However, the currently used aluminum adjuvants are known to stimulate only humoral responses (*1*) and are known to induce IgE antibody production, which elicits an allergic response in the vaccinee (*4*). Therefore, the availability of improved adjuvants suitable for clinical use is highly desirable. Among the candidates for adjuvants for novel vaccines, liposomes are garnering attention as antigen carriers (vehicles) because they are known to act as powerful adjuvants when physically associated with a protein antigen (*7*, *10*, *12*, *13*). Most of the liposomal vaccines proposed have been prepared by antigen entrapment within the aqueous lumen of liposomes (*8*). However, it is known that encapsulated and surface-linked liposomal antigens induce differential immune responses in both humoral- (*26*) and cell-mediated (*25*) immunity.

We previously reported that surface-linked liposomal antigen induced IgE-selective unresponsiveness (*15*). The results were consistent even when different procedures for coupling antigen with liposomes (*16*), or for liposomes with different lipid components (*19*), were employed. During the course of an investigation intended to clarify the mechanism of IgE-selective unresponsiveness induced by surface-coupled liposomal antigens, we discovered an alternative approach to regulate the production of IgE, one that is independent of the activity of T-cells (*29*). In the secondary immune response, OVA−liposome enhanced anti-OVA IgG antibody production but it did not enhance ongoing IgE production, suggesting that the IgE-selective unresponsiveness induced by the liposomal antigen involved direct effects on IgE but not IgG switching in vivo. Another advantage of liposomes as an adjuvant is that they are capable of inducing both humoral and cellular immunity. A liposome delivery system could be tailored to induce either a preferential cellular or humoral immune response (*22*, *30*).

The mechanism of action of adjuvants remains unclear. Adjuvants may increase cellular infiltration into the injection site, may directly contribute to the delivery of antigen to the local lymph node, or may directly promote the uptake of antigen into antigen-presenting cells. The results in this study clearly demonstrated that liposomes promote the uptake of liposome-coupled antigen by antigen-presenting cells and enhance antigen presentation to T-cells, which may result in the enhanced induction of systemic immune responses.

MicroPET and Autoradiographic Imaging of Breast Cancer α_v-Integrin Expression Using ^{18}F- and ^{64}Cu-Labeled RGD Peptide

Xiaoyuan Chen, Ryan Park, Michel Tohme, Anthony H. Shahinian, James R. Bading, and Peter S. Conti*

PET Imaging Science Center, University of Southern California Keck School of Medicine, Los Angeles, California 90033. Received August 12, 2003

Cell adhesion molecules $\alpha_v\beta_3$ and $\alpha_v\beta_5$ play a pivotal role in tumor angiogenesis and metastasis. Antiangiogenic therapy by using small peptide antagonists of α_v-integrins slows tumor growth and prevents tumor spread. The ability to visualize and quantify integrin expression will enable selection of appropriate patients for clinical trials, following determination of treatment efficacy and development of new potent drugs. We have previously labeled cyclic RGD peptide c(RGDyK) with ^{125}I and ^{18}F and applied the radiotracers to both subcutaneous and orthotopic brain tumor models. Here we conjugated c(RGDyK) with 1,4,7,10-tetraaza-1,4,7,10-tetradodecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) and labeled the DOTA−RGD conjugate with ^{64}Cu ($t_{1/2}$ = 12.8 h, 19% β^+) in high radiochemical purity and specific activity. The tumor targeting ability and in vivo kinetics of ^{64}Cu-DOTA−RGD was compared with [^{18}F]FB−RGD and ^{125}I-RGD in orthotopic MDA-MB-435 breast cancer model. All three radiotracers revealed fast blood clearance and high tumor-to-blood and tumor-to-muscle ratios. ^{125}I-RGD had higher tumor uptake than the corresponding ^{18}F and ^{64}Cu analogues. [^{18}F]FB−RGD indicated a fast tumor washout rate and an unfavorable hepatobiliary excretion pathway, resulting in significant activity accumulation in gallbladder and intestines. ^{64}Cu-DOTA−RGD had prolonged tumor retention (1.44 ± 0.09 %ID/g at 4 h postinjection) and persistent uptake in the liver. All three tracers revealed receptor specific tumor accumulation which were illustrated by effective blocking via coinjection with a blocking dose of c(RGDyK). Static microPET imaging and whole-body autoradiography showed strong contrast from the contralateral background. In conclusion, overall molecular charge and characteristics of radiolabels have profound effects on tumor accumulation and in vivo kinetics of radiolabeled RGD peptide. Further modification of the RGD peptide and optimization of the tracer for prolonged tumor uptake and improved in vivo kinetics are being explored.

INTRODUCTION

Breast cancer is the most common form of cancer in women (*1*). Despite vigorous efforts to diagnose, treat, and prevent this disease, it remains a leading cause of death among women. To develop new approaches to the treatment of this disease, further knowledge is needed of the basic biology underlying the etiology and progression of the disease. Recent studies have shown that vascularization is significantly higher in node-positive breast tumors than in node-negative tumors, and that a high degree of vascularization is generally associated with a poor prognosis (*2*). This finding has led to the conclusion that inhibition of angiogenesis offers a possible therapeutic modality for a subset of patients (*3*). Antiangiogenic agents that can block the formation of new blood vessels in the body and destroy existing abnormal blood vessels by starving breast tumors and inhibiting the progression of breast tumors have become the new frontiers in the fight against cancer (*4*). Antiangiogenic agents have been shown to increase therapeutic efficacy in conjunction with other chemotherapeutic agents or when used in combination with external radiotherapy (*5*). Since this kind of therapy is primarily cytostatic and not cytotoxic, the established PET imaging criteria based upon metabolic (e.g. FDG) (*6*) or cell proliferation (e.g. FLT) (*7*) tracers for assessing tumor response to chemo- and/or radiotherapy cannot be applied to antiangiogenic therapy (*8*). Molecular imaging of tumor angiogenesis will thus play a pivotal role to visualize and quantify angiogenesis potential and to monitor antiangiogenic treatment efficacy.

Angiogenesis is a complex process involving extensive interplay between cells, soluble factors, and extracellular membrane (ECM) components (*9*). The construction of a vascular network requires different sequential steps including the release of proteases from "activated" endothelial cells with subsequent degradation of basement membrane surrounding the existing vessel, migration of endothelial cells into the interstitial space, endothelial cell proliferation, and differentiation into mature blood vessels. Each of these processes presents a possible target for diagnostic and therapeutic interventions (*10*). We focus here solely on the cell adhesion molecules α_v-integrins, which are responsible for a wide range of cell−extracellular matrix and cell−cell interactions (*11*). Inhibition of α_v-integrins by monoclonal antibodies (mAbs), cyclic RGD peptides, and peptidomimetics has been shown to induce endothelial apoptosis (*12*), to inhibit angiogenesis (*13*−*15*) and to increase endothelial monolayer permeability (*16*). The inhibition of α_v-integrin activity has been associated with decreased tumor growth in breast cancer xenografts (*14*, *17*). Synergy of cylic RGD

peptide EMD 121974 with radioimmunotherapy (RIT) has resulted in increased efficacy of therapy in a murine breast cancer model (*15*).

We recently labeled RGD peptide c(RGDyK) with ^{125}I for brain tumor targeting (*18*). This tracer revealed fast blood clearance and rapid tumor uptake; however, the prolonged kidney retention limited the further application of this tracer. The modification of the lysine ϵ-amino group with a monomethoxy poly(ethylene glycol) moiety (mPEG, MW = 2000) found drastically decreased renal uptake, slightly increased liver accumulation and prolonged tumor retention (*18*). Modification of the lysine residue with a sugar moiety revealed increased water solubility and thus improved pharamacokinetics of the tracer (*19*). The same glycosylated RGD peptide c[RGDyK-(SAA)] was further labeled with ^{18}F through a prosthetic labeling moiety 2-[^{18}F]fluoropropionate (*20*) for positron emission tomography (PET) imaging of $\alpha_v\beta_3$ integrin positive tumors. The proof-of-principle experiment demonstrated the feasibility of this tracer for integrin positive tumor targeting and that the tumor uptake is receptor specific since the uptake of the tracer is dose dependent. We labeled c(RGDyK) with ^{18}F through 4-[^{18}F]fluorobenzoyl group and applied this tracer to both subcutaneous U87MG and orthotopic U251T glioblastoma models. The tracer showed very rapid blood clearance and both hepatobiliary and renal excretion. Tumor-to-muscle uptake ratio at 30 min was approximately 5 ± 1 in the subcutaneous U87MG tumor model. MicroPET imaging with the orthotopic U251T brain tumor model revealed very high tumor-to-brain ratio, with virtually no uptake in the normal brain. Successful blocking of tumor uptake of [^{18}F]FB−RGD in the presence of excess amount of c(RGDyK) revealed receptor specific activity accumulation (*21*). Ogawa et al. (*22*) labeled EMD 121974 with ^{18}F via direct electrophilic radiofluorination and revealed very modest tumor uptake in a colon cancer model, probably due to low specific activity of the carrier-added radiotracer. Van Hagen et al. (*23*) substituted the lysine ϵ-amino group on c(RGDyK) with diethylenetriaminepentaacetic acid (DTPA) and labeled the conjugate with ^{111}In to target rat pancreatic CA20948 tumor model. Janssen et al. (*24*) conjugated dimeric RGD peptide E-[c(RGDfK)]$_2$ with 1,4,7,10-tetraazadodecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) and hydrazinonicotinamide (HYNIC) chelators and labeled the conjugates with ^{111}In/^{90}Y and ^{99m}Tc, respectively, and applied the tracers to NIH:OVCAR-3 sc ovarian carcinoma xenografts. All the metallic radionuclide-labeled RGD peptides revealed significant kidney and liver accumulation. The tracer distribution pattern is markedly affected by the chelator and metal ions. In this study, we conjugated monomeric RGD peptide c(RGDyK) with DOTA and labeled the RGD−DOTA conjugate with ^{64}Cu ($t_{1/2}$ = 12.8 h; 40% β^- (656 keV), 19% β^+ (600 keV), 38% EC) (*25*). The tumor accumulation and in vivo kinetics of this ^{64}Cu-DOTA−RGD is evaluated and compared with ^{125}I-RGD and [^{18}F]-FB−RGD in orthotopic MDA-MB-435 breast cancer xenograft mouse model. In addition, microPET and autoradiographic imaging of breast cancer with ^{64}Cu-DOTA−RGD and [^{18}F]FB−RGD were also assessed.

EXPERIMENTAL PROCEDURES

Materials and Analyses. Cyclic RGD peptide c(RGDyK) was synthetically produced via solution cyclization of fully protected linear pentapeptide H-Gly-Asp(OtBu)-D-Tyr(OtBu)-Lys(Boc)-Arg(Pbf)-OH, followed by trifluoroacetic acid deprotection in the presence of the free radical scavenger triisopropylsilane (*18*, *21*). [^{125}I]-NaI was obtained from Perkin-Elmer Life Sciences Inc. (Boston, MA). No-carrier-added [^{18}F]F$^-$ was produced via the ^{18}O(p,n)^{18}F reaction by bombardment of an isotopically enriched [^{18}O]water target (95% enrichment, Isonics, Golden, CO) with 11 MeV protons using a Siemens RDS-112 negative ion cyclotron. The [^{18}F]F$^-$ was trapped on an anion-exchange resin (Dowex (Cl$^-$) 1X-8, 200−400 mesh), converted to OH$^-$ form and then eluted with K_2CO_3 (0.6 mL 10 mM, 6 μmol) and combined with Kryptofix 2.2.2 (10 mg, 26.6 μmmol). The solvent was evaporated under a stream of argon at 90 °C. Azeotropic drying was repeated twice with 1 mL portions of MeCN. ^{64}Cu was produced on a CS-15 biomedical cyclotron at Washington University School of Medicine by the ^{64}Ni(p,n)^{64}Cu nuclear reaction (*25*).

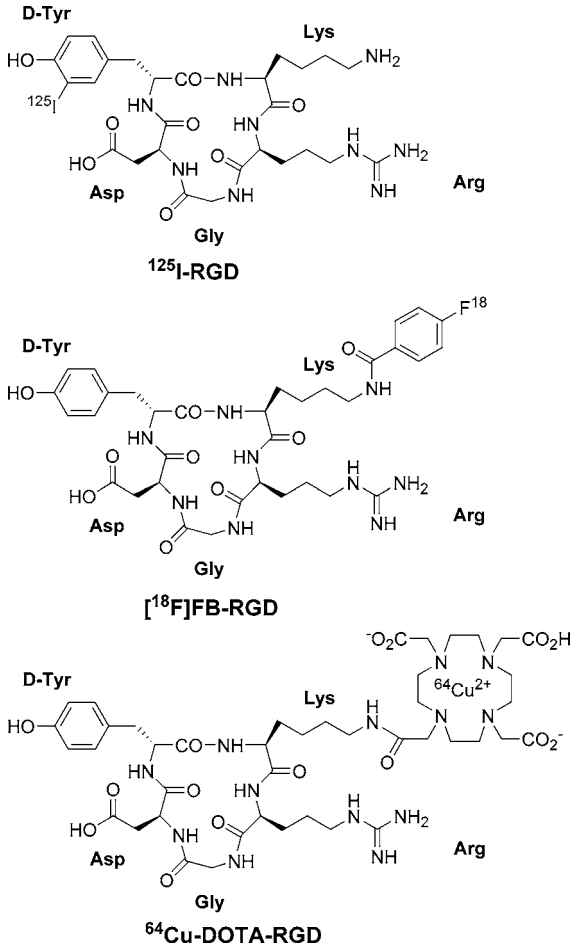

Figure 1. Structures of ^{125}I-RGD, [^{18}F]FB−RGD, and ^{64}Cu-DOTA−RGD.

All reagents, unless otherwise specified, were of analytical grade and commercially available. 1,4,7,10-tetraazadodecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) was purchased from Macrocyclics, Inc. (Dallas, TX). *N*-hydroxysulfonosuccinimide (SNHS), 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC), and Chelex 100 (50−100 mesh) were obtained from Aldrich. 4,7,13,16,21,24-Hexaoxa-1,10-diazabicyclo[8.8.8]hexacosan (Kryptofix 2.2.2) and potassium carbonates (K_2CO_3), as well as sodium phosphate buffer, were obtained from Sigma. Ethyl 4-(dimethylamino)benzoate, methyl trifluoromethanesulfonate, *O*-(*N*-succinimidyl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TSTU), and tetrapropylammonium hydroxide in water (1.0 M) were from Fluka. Water was distilled and then deionized (18 MΩ/cm^2) by passing through a Milli-Q water filtration system (Millipore Corp., Bedford, MA). Water and all buffers were

passed over a Chelex 100 column (1 × 15 cm) before use in radiolabeling procedures. Dimethyl sulfoxide (DMSO) was distilled from barium oxide, dispensed under N_2 into vials containing activated molecular sieves (4 Å), and stored at 4 °C. Anhydrous acetonitrile (MeCN) from a newly opened flask was stored over activated molecular sieves (4 Å) at room temperature (rt). All other solvents were used without further purification. Radio-TLC was performed using MKC18F plates (Whatman, Clifton, NJ), a Bioscan system 200, and Winscan software, version 2.2. Reversed-phase extraction C-18 SepPak cartridges were obtained from Waters (Milford, MA).

Semipreparative reversed-phase HPLC was accomplished on a Waters 515 chromatography system with a 486 tunable absorbance detector and model 1015-DC−P single channel radiation detector from Carroll & Ramsey Associates (Berkeley, CA). Version 7.2.1 Labtech Notebook/XE software (Andover, MA) was used to record chromatograms. Purification was performed on a Vydac protein and peptide column 218TP510, 5 μm, 250 × 10 mm). The flow was 3 mL/min, with the mobile phase starting from 95% solvent A (0.1% TFA in water) and 5% solvent B (0.1% TFA in acetonitrile) (0−2 min) to 35% solvent A and 65% solvent B at 32 min. The analytical HPLC method was performed with the same gradient system, but with a Vydac 218TP54 column (5 μm, 250 × 4.6 mm) and flow= 1 mL/min. The absorbance was monitored at 218 nm.

Preparation of DOTA−RGD Conjugate. DOTA was activated by EDC at pH 5.5 for 30 min (4 °C), with molar ratio of DOTA:EDC:SNHS = 10:5:4. Typically, 12 mg of DOTA (24 μmol) dissolved in 500 μL of water and 2.3 mg of EDC (12 mmol) dissolved in 130 μL of water were mixed, and 0.1 N NaOH (250 μL) was added to adjust the pH to 5. SNHS (2.1 mg, 9.6 μmol) was then added to the stirring mixture on ice-bath, and 0.1 N NaOH (50 μL) was further added to finalize the pH to 5.5. The reaction was allowed for 30 min at 4 °C. The theoretical concentration of active ester DOTA-OSSu was calculated to be 9.1 mM. Cyclic RGD peptide (1.5 mg, 2.4 μmol) dissolved in 300 μL (5 mg/mL) of water was cooled to 4 °C and added to the DOTA-OSSu reaction mixture, and the pH was adjusted to 8.5 with 0.1 N NaOH (280 μL). The reaction was allowed to incubate for overnight at 4 °C. The DOTA−RGD conjugate was purified by semipreparative HPLC. The peak containing the RGD conjugate was collected, lyophilized, and dissolved in H_2O at a concentration of 1 mg/mL for use in radiolabeling reactions.

Radiolabeling. Cyclic RGD peptide c(RGDyK) was labeled with ^{125}I using the chloramine-T method (*18*). 4-[^{18}F]fluorobenzoyl-RGD ([^{18}F]FB−RGD) was produced by conjugating RGD peptide c(RGDyK) with *N*-succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]SFB) under slightly basic condition (*21*). The specific activity of [^{18}F]FB−RGD was estimated to be over 300 GBq/μmol at end of bombardment (EOB)), based on 9.25 GBq (250 mCi) starting [^{18}F]F$^-$ (*21*). DOTA−RGD was labeled with ^{64}Cu by addition of 1−5 mCi of ^{64}Cu (2−5 μg DOTA−RGD per mCi ^{64}Cu) in 0.1 N NaOAc (pH 5.5) buffer followed by 45 min incubation at 50 °C. The reaction was terminated by adding 5 μL of 10 mM EDTA solution and radiochemical yield was determined by Radio-TLC using Whatman MKC18F TLC plates as the stationary phase and 70:30 MeOH:10% NaOAc as the eluent. ^{64}Cu-DOTA−RGD was purified on a C-18 SepPak cartridge, using 85% ethanol as the elution solvent. Radiochemical purity was determined by radio-TLC or radio-HPLC. The ethanol was evaporated and the activity was reconstituted in phosphate-buffered saline and passed through a 0.22 μm Millipore filter into a sterile multidose vial for use in animal experiments.

Animal Models. All animal experiments were performed in compliance with the Guidelines for the Care and Use of Research Animals established by University of Southern California's Animal Studies Committee. MDA-MB-435 estrogen receptor-negative human breast cancer cells were maintained at 37 °C in minimum essential medium (alpha modification) containing 3.7 g of sodium bicarbonate per liter, supplemented with 10% v/v fetal calf serum, in a humidified atmosphere of 5% carbon dioxide. Stock cultures were seeded at a density of 2 × 10^5 cells and allowed to multiply for 48−72 h. Female athymic nude mice (*nu/nu*) obtained from Harlan (Indianapolis, IN) at 4−6 weeks of age were injected orthotopically in the right mammary fat pad with 5 × 10^6 MDA-MB-435 cells suspended in 100 μL of medium. Palpable tumors appeared by the day 10−14 postimplantation. The tumors were allowed to grow 3−4 weeks until 0.5−0.9 g in size.

Biodistribution Studies. When the tumors reached 0.4−0.6 cm in diameter (20 to 25 d after implant), the mice received ^{125}I-RGD (2 μCi), [^{18}F]FB−RGD (20 μCi), or ^{64}Cu-DOTA−RGD (10 μCi). The radiolabeled peptides were injected via the tail vein. Mice (n = 5 per time point) were sacrificed by exsanguinations at different time points postinjection (pi). Blood, tumor and the major organs and tissues were collected, wet-weighed, and counted in a γ-counter (Packard). The percent injected dose per gram (%ID/g) was determined for each sample. For each mouse, radioactivity of the tissue samples was calibrated against a known aliquot of the injectate. Values are quoted as mean ± standard deviation (SD). The receptor-mediated localization of the radiotracers was investigated by determining the biodistribution of radiolabeled peptide in the presence of 15 mg/kg of c(RGDyK). Biodistribution was determined as described above at 1 h pi in 5 mice/group.

MicroPET Imaging. Positron emission tomography (PET) imaging was performed on a microPET R4 rodent model scanner (Concorde Microsystems, Knoxville, TN). The scanner has a computer-controlled bed, 10.8 cm transaxial and 8 cm axial field of view (FOV). The camera has no septa and operates exclusively in 3 D list mode. All raw data were first sorted into 3D sinograms, followed by Fourier rebinning and ordered subsets-expectation maximization (OSEM) reconstruction algorithm using a ramp filter with the Nyquist limit (0.5 cycles/voxel) as the cutoff frequency. For PET imaging of breast cancer tumor-bearing mice, the animal model was injected 200 μCi [^{18}F]FB−RGD or 400 μCi ^{64}Cu-DOTA−RGD via the tail vein. The mouse was then euthanized at 1 h pi and placed near the center of the FOV of the microPET, where the highest image resolution and sensitivity are available. Static imaging was performed for 15 min. To investigated receptor-specific uptake of ^{64}Cu-labeled RGD, one MDA-MB-435 breast cancer-bearing mouse was imaged three times daily apart: (a) without coinjection with c(RGDyK); (b) with 2.5 mg/kg c(RGDyK); and (c) with 7.5 mg/kg c(RGDyK). The mouse was anesthetized with ketamine/xylazine and immobilized in a specially prepared scanner cradle. To assess the tumor uptake of ^{64}Cu-DOTA−RGD, circular regions of interest were placed at the locations of maximum tracer uptake in the tumor and in the corresponding contralateral site (reference region). Relative tracer uptake was expressed as the ratio between mean counts in tumor and the reference region (tumor:background ratio).

Whole-Body Autoradiography. Autoradiography was performed using a Packard Cyclone Storage Phosphor Screen system (Downers Grove, IL) and a Bright 5030/WD/MR cryomicrotome (Hacker Instruments, Fairfield, NJ). Immediately after microPET scanning, the already killed mice were frozen in a dry ice and isopropyl alcohol bath for 2 min. The bodies were then embedded in a 4% carboxymethyl cellulose (CMC) (Aldrich, Milwaukee, WI) in water mixture using a stainless steel mold. The mold was placed in the dry ice and isopropyl alcohol bath for 5 min and then into a −20 °C freezer for 1 h. The walls of the mold were then removed, and the frozen block was mounted in the cryomicrotome. The block was then cut into 50 μM sections, and desired sections were digitally photographed and captured for autoradiography. The sections were transferred into a chilled autoradiography cassette containing a Super Resolution screen (Packard, Meriden, CT) and kept there overnight at −20 °C. Screens were laser-scanned with the Packard Cyclone.

Statistical Analysis. Statistical analysis was performed using GraphPad Prism 3.0 (GraphPad Software, San Diego, CA). The biodistribution data were analyzed using the one-way ANOVA test. The level of significance was set at $P = 0.05$.

RESULTS

Chemistry and Radiochemistry. The DOTA−RGD conjugate was produced in 79% yield after HPLC purification. Analytical HPLC using conditions described in the Methods section found the retention time to be 11.6 min, whereas cyclic RGD peptide c(RGDyK) eluted at 10.7 min under the same condition. MALDI-TOF-MS: $m/z = 1005.3$ for $[M + H]^+$ ($C_{43}H_{65}N_{13}O_{15}$), 1027.3 for $[M + Na]^+$, and 1043.2 for $[M + K]^+$. ^{64}Cu-DOTA−RGD was labeled in ≥90% radiochemical yield and ≥98% radiochemical purity and was used immediately for in vivo assays. Free ^{64}Cu-acetate remained at the origin of the radio-TLC plate and R_f value of ^{64}Cu-DOTA−RGD was about 0.6. Specific activity of ^{64}Cu-DOTA−RGD ranged from 200 to 500 Ci/mmol (7.4−18.5 GBq/μmol). RGD was labeled with ^{125}I with specific activity of 1700 Ci/mmol (*18*) and conjugation labeled with ^{18}F with specific activity of 6000 Ci/mmol at end of synthesis (EOS) (*21*).

Biodistribution Studies. Summaries of the biodistribution data for ^{125}I-RGD, [^{18}F]FB−RGD, and ^{64}Cu-DOTA−RGD in orthotopic MDA-MB-435 human breast cancer-bearing mice were shown in Table 1, Table 2, and Table 3, respectively. Rapid clearance of the radioactivity from the blood circulation was observed for all three compounds. At any time point examined, the tumor uptake followed the order of ^{125}I-RGD > ^{64}Cu-DOTA−RGD > [^{18}F]FB−RGD. Tumor-to-blood (T/B) and tumor-to-muscle (T/M) ratios increased with time elapsed for both ^{125}I-RGD and [^{18}F]FB−RGD. ^{64}Cu-DOTA−RGD showed highest tumor-to-background ratio at 1 h pi (8.1 ± 0.9 for T/B and 7.1 ± 1.3 for T/M) and the contrast slightly decreased at 2 h (6.9 ± 0.5 for T/B and 6.0 ± 0.6 for T/M) and 4 h (6.0 ± 0.1 for T/B and 6.3 ± 1.3 for T/M) pi ^{125}I-RGD excreted through both renal and hepatobiliary pathways which reflected significant uptake in both liver and kidneys. High and persistent retention in the kidneys may be attributed to the electrostatic interaction between overall positively charged ^{125}I-RGD with negatively charged renal proximal tubular cells, which is responsible for reabsorption of glomerularly filtered peptide into renal cells. Significant accumulation of radioactivity in the stomach was found for ^{125}I-RGD but not for [^{18}F]FB−RGD and ^{64}Cu-DOTA−RGD, demonstrating partial deiodination of the ^{125}I-labeled RGD peptide. The fast tumor washout rate for [^{18}F]FB−RGD was due to the increased lipophilicity of compound upon conjugation labeling through a prosthetic 4-[^{18}F]fluorobenzoyl moiety. The liver, kidneys, and intestines were the only organs to have similar or slightly higher uptake of ^{64}Cu-DOTA−RGD than the tumor. All three tracers revealed receptor-specific tumor accumulation as the uptake was inhibited upon coinjection of c(RGDyK) although the extent of blocking of tumor uptake was different for the three tracers. A detailed comparison of activity accumulation in the blood, tumor, liver, and

kidneys for the ^{125}I-, ^{18}F-, and ^{64}Cu-labeled RGD peptides were illustrated in Figure 2.

MicroPET and Autoradiographic Imaging. The localization of [^{18}F]FB−RGD in MDA-MB-435 tumor-bearing mouse as determined by microPET imaging followed by whole-body autoradiography was shown in Figure 3. On the left was a coronal imaging (15 min scan) of tumor-bearing mouse, 1 h postadministration of 200 μCi of [^{18}F]FB−RGD. Whole-body autoradiographic section concord with the microPET image was shown on the right. Regions of interest (ROIs) were placed on tumors as well as other organs of interest. The tumor/muscle ratio was 4.6 ± 0.4 (n = 3) from autoradiography and 5.1 ± 0.8 (n = 3) from microPET, in good agreement with that obtained from direct tissue sampling (4.8 ± 1.4) (n = 5).

Static microPET imaging (15 min scan) 120−135 min after iv administration of ^{64}Cu-DOTA−RGD illustrated in a coronal image of an orthotopically implanted MDA-MB-435 tumor-bearing mouse was shown in Figure 4. Tumor was visualized with clear contrast. PET imaging was further validated by whole-body autoradiography in the same animal. Tumor/muscle ratios measured with microPET and autoradiography were 5.6 ± 0.4 and 6.9 ± 0.8, respectively, which again agreed with the biodistribution experiment in a separate group of mice (6.0 ± 0.6; n = 5) (Table 3). As expected, we did not observe any tumor uptake in the brain for any of the three tracers, suggesting that either the tracer does not penetrate the tight blood−brain barrier (BBB) or the normal brain tissue does not express significant amount of α_v-integrins.

The transaxial image of a MDA-MB-435 tumor-bearing mouse acquired at 1 h pi revealed tumor to contralateral background ratio of 7.5 ± 0.6 (Figure 5). Coinjection of ^{64}Cu-DOTA−RGD with different amounts of c(RGDyK) revealed dose-dependent blocking of tumor uptake. The tumor-to-background ratio decreased to 2.3 ± 0.4 [coinjection with 2.5 mg/kg c(RGDyK)] and 1.8 ± 0.5 [coinjection with 7.5 mg/kg c(RGDyK)].

DISCUSSION

Cyclic RGD peptide antagonists of α_v-integrins have been labeled with different isotopes such as ^{125}I, ^{99m}Tc, ^{111}In, ^{90}Y, and ^{18}F for tumor targeting in various preclinical animal models. However, to the best of our knowledge, this is the first report of ^{64}Cu-labeled RGD for tumor angiogenesis imaging. Copper radioistope offers an attractive basis for the development of diagnostic (^{60}Cu, ^{61}Cu, ^{62}Cu, and ^{64}Cu) and therapeutic (^{64}Cu and ^{67}Cu) radiopharmaceuticals (*26*). ^{64}Cu, in particular, has the

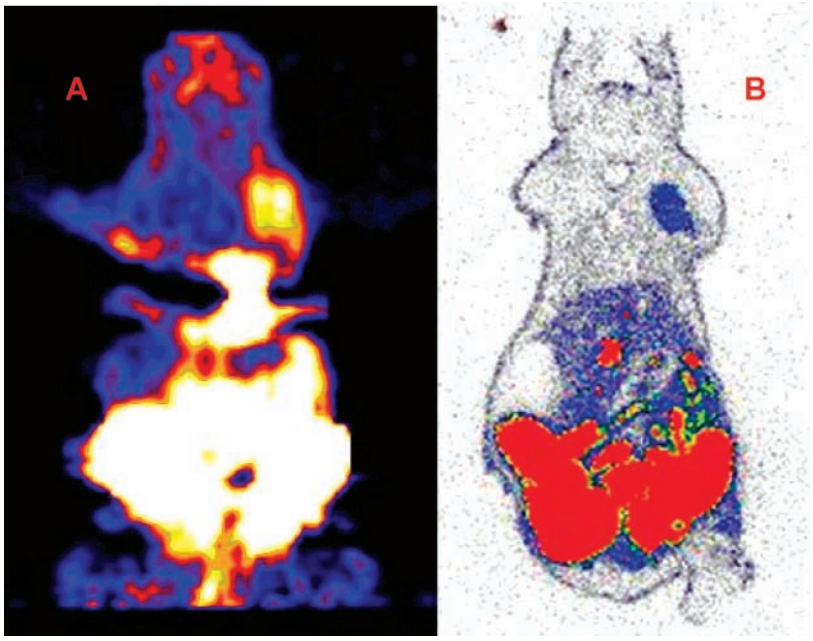

Figure 3. (A) MicroPET scan of mouse administered 200 μCi of [^{18}F]FB−RGD and scanned 60 min after injection (10 min single frame). The mouse carried an orthotopic MDA-MB-435 breast cancer xenograft in the right mammary fat pad. (B) Digital autoradiograph of the section containing tumor after microPET scanning.

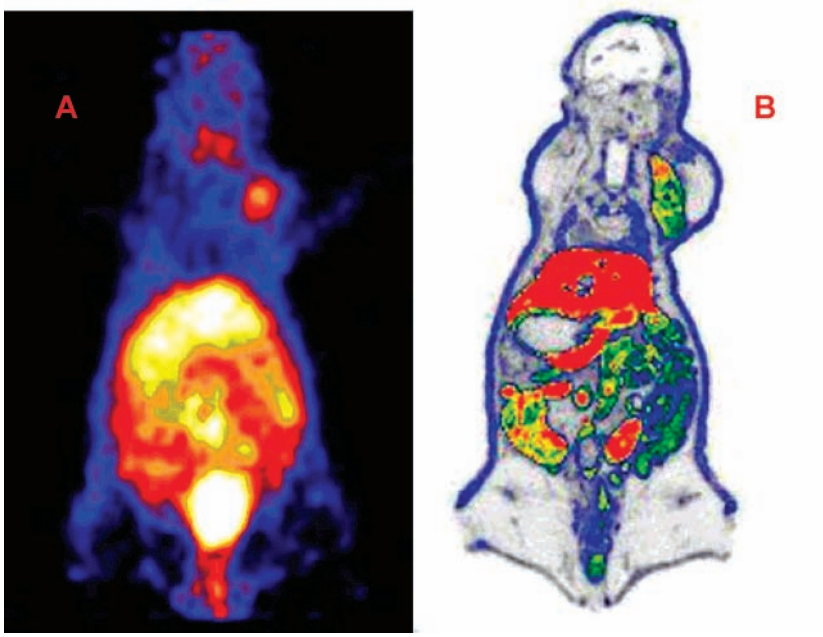

Figure 4. (A) MicroPET scan of mouse administered 400 μCi of ^{64}Cu-DOTA−RGD and scanned 2 h after injection (15 min single frame). The mouse carried an orthotopic MDA-MB-435 breast cancer xenograft in the right mammary fat pad. (B) Digital autoradiograph of the section containing tumor after microPET scanning.

desirable properties for both PET imaging and therapy and can be produced in high yield and high specific activity on a small biomedical cyclotron (*25*, *27*). In this study we would like to compare the tumor targeting ability and in vivo kinetics of ^{125}I-, ^{18}F-, and ^{64}Cu-labeled cyclic RGD peptide c(RGDyK) in murine orthotopic MDA-MB-435 human breast cancer model.

^{125}I-RGD has the highest tumor uptake and slowest tumor washout rate compared to [^{18}F]FB−RGD and ^{64}Cu-DOTA−RGD. The low molecular mass compound c(RGDyK) is optimized in size to fit the binding pocket of the $\alpha_v\beta_3$ integrin receptor. Thus, introduction of any labeling groups is likely to result in a loss of the affinity. Adding ^{125}I label to the ortho-position of the cyclic RGD peptide is expected to have minimal change of geometry and binding characteristics of the peptide and thus allows high receptor-specific tumor uptake. On the other hand, having a bulky 4-[^{18}F]fluorobenzoyl group or ^{64}Cu-DOTA complex (Figure 1) that are not far from the integrin-recognizing RGD moiety decreased receptor binding affinity and specificity of these tracers, which were demonstrated by lowered tumor uptake (Figure 2) and incomplete inhibition of tumor accumulation by applying a blocking dose of c(RGDyK). The blocking experiment indicated tumor-to-muscle ratio of 0.7 ± 0.5, 2.4 ± 0.4, and 2.9 ± 1.1 for ^{125}I-RGD, [^{18}F]FB−RGD, and ^{64}Cu-DOTA−RGD, respectively. Solid-phase receptor binding assay to directly assess the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrin binding affinity and specificity of these tracers is needed to further confirm this.

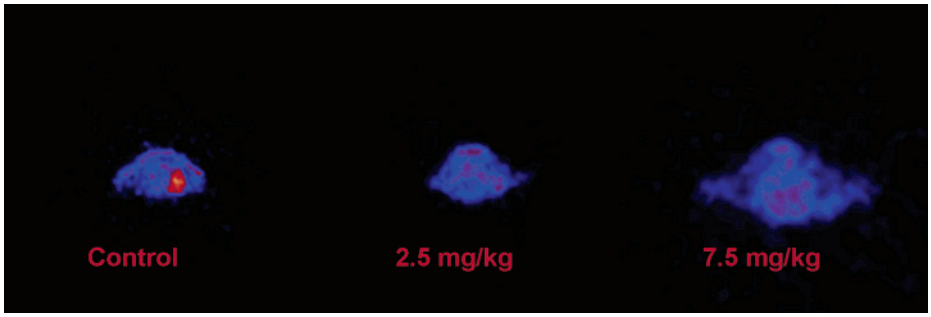

Figure 5. Transaxial microPET images of nude mice bearing MDA-MB-435 xenografts. Images were acquired 60 min after injection of 300 μCi of ^{64}Cu-DOTA−RGD. The three images were obtained from serial ^{64}Cu-DOTA−RGD PET studies on the same mouse. The images illustrate the dose-dependent blockade of tracer uptake by c(RGDyK).

The prolonged liver and blood uptake of ^{64}Cu-DOTA−RGD is problematic for this tracer, suggesting slow dissociation of ^{64}Cu from the DOTA chelator (*28*). It has been demonstrated that ^{64}Cu when bound to DOTA or TETA conjugates tends to transchelate to albumin, superoxide dismutase, ceruloplasmin, and metallothionein, leading to higher blood and liver uptake (*29*−*31*) and that more rapid clearance from the liver is indicative of higher in vivo stability of the ^{64}Cu complex (*32*). Development of more stable chelators for copper radionuclides that have greater kinetic stability and yet fast incorporation rate of ^{64}Cu into the macrocyclic chelating moiety (*32*, *33*) is needed for creation of new copper radiopharmaceuticals for diagnosis and therapy applications. Recent studies to investigate the renal uptake of ^{111}In-DTPA-conjugated octreotide analogues (*34*, *35*) found out that initial kidney uptake is related to the overall molecular charge of the peptide, and that persistent localization of the radioactivity in the kidney would be attributed to the long residence time of the final radiometabolite generated after lysosomal proteolysis in the renal cells. The relatively low renal uptake of ^{64}Cu-DOTA−RGD is probably due to the overall negative charge character of this radiotracer under physiological condition. The sustained low retention of activity in the kidneys may be caused by the metabolites after ^{64}Cu-DOTA-conjugated RGD peptide is internalized, but ^{64}Cu-DOTA−Lys will unlikely be the species which is retained in the lysosomes. Further studies to investigate in vivo transchelation of ^{64}Cu and metabolic stability of the radioconjugate is necessary to fully understand the excretion kinetics of this compound and to further optimize the tracer for potential clinical applications.

MicroPET, a dedicated small animal imaging device, enables real time imaging studies in rodents and forms an invaluable bridge between laboratory and clinical science. The picomolar sensitivity and reasonably good spatial and temporal resolution of microPET makes it play a leading role in molecular imaging (*36*). Depending on the radiotracers used, it allows visualization and quantification of physiological, metabolic, and molecular changes during disease development and upon treatment. Both endogenous protein imaging and exogenous reporter gene imaging are being actively explored. In this study, we demonstrate the feasibility of ^{18}F- and ^{64}Cu-labeled cyclic RGD peptide for breast cancer angiogenesis imaging by targeting cell adhesion molecules, α_v-integrins. Several RGD peptide antagonists have been labeled with ^{111}In and ^{99m}Tc for SPECT imaging of tumor models. Recently Haubner et al. (*20*) labeled a RGD-containing glycopeptide with ^{18}F through a 2-[^{18}F]fluoropropionate moiety for PET imaging of melanoma xenograft. In this study we labeled c(RGDyK) with both ^{18}F and ^{64}Cu for orthotopic breast cancer tumor imaging. MicroPET imaging of [^{18}F]FB−RGD at 1 h postinjection of 200 μCi of activity showed reasonably good tumor-to-background ratio; however, very high uptake in the urinary bladder and intestines was observed, suggesting the unfavorable hepatobiliary excretion pathway due to the lipophilicity of this tracer. This tracer may be able to locate tumors in areas with higher uptake than the liver, such as breast cancer and brain tumors. MicroPET and autoradiographic imaging of ^{64}Cu-DOTA−RGD also gives clear tumor-to-background contrast, but also significant liver and kidney uptake, which correlates well with the distribution pattern found from direct tissue sampling. The successful blocking of tumor uptake of ^{64}Cu-DOTA−RGD in a dose-dependent manner demonstrates that accumulation in the tumor is receptor specific. Further study to correlate the magnitude of tumor uptake with receptor expression level needs to be performed.

High expression and activation of the $\alpha_v\beta_3$ integrin has been correlated with the more metastatic and invasive breast tumors (*37*, *38*). Inhibition of $\alpha_v\beta_3$ integrin activities has been associated with decreased tumor growth in breast cancer xenografts (*14*). The DeNardo group demonstrated increased tumor uptake of ^{90}Y-DOTA−peptide−ChL6 mAb after treatment with cyclic RGD peptide in nude mice bearing HBT 3477 breast cancer xenografts (*39*). The combination of cilengitide and radioimmunotherapy (RIT) significantly increased the efficacy and endothelial cell apoptosis without apparent increase in toxicity, compared with either therapeutic protocol alone (*40*). Recently, Janssen et al. (*24*) labeled DOTA−E[c(RGDfK)]$_2$ with ^{90}Y and applied a therapeutic dose of the radiolabeled compound to a sc ovarian cancer tumor model and induced a significant delay in tumor growth by a single injection. ^{111}In was used as a surrogate for ^{90}Y to obtain dosimetry information. However, the different biodistributions of ^{111}In- and ^{90}Y-labeled compounds may result in inaccurate dosimetry of ^{90}Y-labeled compounds using ^{111}In analogues. A more suitable isotope for accurately imaging the biodistribution of ^{90}Y would be quantitative imaging with the surrogate positron emitter ^{86}Y ($t_{1/2}$ = 14.7 h, 33% β^+) to detect the uptake and dosimetry of ^{90}Y-labeled RGD. Due to the existence of imaging/therapy radionuclide pair (^{64}Cu/^{67}Cu) for diagnosing and treating cancer, ^{64}Cu-DOTA−RGD developed in this study may be able to determine dosimetry and tumor response to the same ligand labeled with therapeutic amounts of ^{67}Cu for $\alpha_v\beta_3$ integrin-mediated internal radiotherapy. Since DOTA-derivatized macrocyclic ligands bind a large number of metal ions with extremely high in vivo stability, the same bioconjugates developed in this study for ^{64}Cu would also be able to bind other imaging radionuclides such as ^{86}Y and therapeutic radionuclides such as ^{90}Y and ^{177}Lu.

CONCLUSIONS

The study presented here demonstrated that [^{18}F]FB−RGD and ^{64}Cu-DOTA−RGD are tracers suitable for PET imaging of α_v-integrin expression in breast cancer. Although the positron emitter-labeled RGD peptide indicated lower tumor uptake than ^{125}I-RGD, they were able to visualize breast cancer tumor in xenograft models with clear contrast and receptor-specific uptake. Unfavorable hepatobiliary excretion and rapid tumor washout rate of [^{18}F]FB−RGD limited its potential clinical applications unless further modification is performed to optimize this tracer. ^{64}Cu-DOTA−RGD, on the other hand, revealed more consistent and sustained blood concentration, prolonged tumor uptake, but also significant amount of liver and kidney retention. The hydrophilicity, overall molecular charge, and characteristics of the radiolabel as well as radiometabolites have profound effects on the tumor targeting and in vivo kinetics of the radiopharmaceuticals derived from cyclic RGD peptides. Modification of the ^{64}Cu-complexing moiety and the systematic investigation of the tethers linking RGD and ^{64}Cu-macrocycle complex will be the future focus to develop a superior ligand for α_v-integrin targeting and for integrin-targeted internal radiotherapy.

ACKNOWLEDGMENT

This work was carried out with partial contributions from NIH grant P20 CA86532 (to P.S.C.), ACS grant ACS-IRG-580007-42 (to X.C.), and the Wright Foundation (to X.C.). The USC cyclotron team, particularly Joseph Cook, is acknowledged for [^{18}F]F$^-$ production. Copper-64 has been provided by Washington University Medical School and partially funded through an NCI grant R24 CA86307.

Nanogels for Oligonucleotide Delivery to the Brain

Serguei V. Vinogradov, Elena V. Batrakova, and Alexander V. Kabanov*

College of Pharmacy, Department of Pharmaceutical Sciences, University of Nebraska Medical Center, 986025 Nebraska Medical Center, Omaha, Nebraska 68198-6025 Received September 10, 2003; Revised Manuscript Received October 15, 2003

Systemic delivery of oligonucleotides (ODN) to the central nervous system is needed for development of therapeutic and diagnostic modalities for treatment of neurodegenerative disorders. Macromolecules injected in blood are poorly transported across the blood−brain barrier (BBB) and rapidly cleared from circulation. In this work we propose a novel system for ODN delivery to the brain based on nanoscale network of cross-linked poly(ethylene glycol) and polyethylenimine ("nanogel"). The methods of synthesis of nanogel and its modification with specific targeting molecules are described. Nanogels can bind and encapsulate spontaneously negatively charged ODN, resulting in formation of stable aqueous dispersion of polyelectrolyte complex with particle sizes less than 100 nm. Using polarized monolayers of bovine brain microvessel endothelial cells as an in vitro model this study demonstrates that ODN incorporated in nanogel formulations can be effectively transported across the BBB. The transport efficacy is further increased when the surface of the nanogel is modified with transferrin or insulin. Importantly the ODN is transported across the brain microvessel cells through the transcellular pathway; after transport, ODN remains mostly incorporated in the nanogel and ODN displays little degradation compared to the free ODN. Using mouse model for biodistribution studies in vivo, this work demonstrated that as a result of incorporation into nanogel 1 h after intravenous injection the accumulation of a phosphorothioate ODN in the brain increases by over 15 fold while in liver and spleen decreases by 2-fold compared to the free ODN. Overall, this study suggests that nanogel is a promising system for delivery of ODN to the brain.

INTRODUCTION

Oligonucleotides (ODN) have attracted significant interest as potential diagnostic and therapeutic agents for diseases that currently have no cure. This includes cancer, neurodegenerative disorders (Alzheimer's and Parkinson's disease), and lethal viral infections (*1*−*7*). However, the use of ODN in the body is hindered by the lack of stability of ODN against enzymatic degradation as well as rapid clearance of ODN through renal excretion. Furthermore, the blood−brain barrier (BBB) severely restricts the entry of ODN to the brain from the periphery, which represents a major obstacle for the use of ODN for diagnostics and therapy of disorders of central nervous system (CNS). The need to improve the pharmacological performance of ODN resulted in development of drug delivery systems for ODN (*8*−*12*). In particular, studies involving nanoparticles demonstrated promise in enhancing delivery of ODN to the brain (*13*). Several major features of nanoparticles make them especially useful for this application. First, they represent an injectable drug delivery system with particle size ca. 100 nm or less. Such particles can easily enter brain capillaries and reach the surface of the brain microvascular endothelial cells (BMVEC) forming the BBB. Second, the surface of the nanoparticles, for example, those prepared from poly(lactide-*co*-glycolide) or poly(butylcyanoacrylate), can be modified by poly(ethylene glycol) (PEG) or PEG-containing surfactants. This can prolong the circulation of the nanoparticles in the blood and enhance exposure of the BBB to the modified nanoparticles. Third, the nanoparticles can be further modified with specific targeting molecules that enhance binding of the nanoparticles with the surface receptors of the BMVEC and promote transport of the nanoparticles across the BBB. In particular, Pardridge and collaborators proposed to use for this purpose insulin and transferrin receptors (*14*−*16*). Importantly, the small size of nanoparticles may allow for their receptor-mediated transcytosis in BBB without violating the integrity of the tight junctions of BMVEC, which are impermeable to macromolecules. Various therapeutic agents including ODN, proteins, and peptides can be encapsulated in the nanoparticles. Following the delivery of the nanoparticles to the disease site in the body, the polymer matrix can slowly degrade resulting in sustained release of the encapsulated therapeutic agents. Thus, the nanoparticles have a dual capacity as drug carriers and sustained drug release systems.

However, the currently used nanoparticles have substantial shortcomings including relatively low drug loading capacities and rather complicated preparation and drug formulation procedures. These procedures require exposure to organic solvents and energy input (e.g. sonication), which often result in inactivation of therapeutic macromolecules. One alternative approach, proposed by our group, is to use, as drug carriers, flexible hydrophilic polymer gels of nanoscale size, termed nanogels (NanoGel) (*17*−*20*). Nanogels can be synthesized in the absence of the drug, equilibrated (swollen) in water, and then loaded with the drug. Drug loading occurs spontaneously and results in decrease of the solvent volume, which is followed by the gel collapse and formation of dense nanoscale particles. We have previously described cationic nanogels consisting of covalently cross-linked PEG and polyethylenimine (PEI) chains, nano-PEG-*cross*-PEI (*18*, *20*). Such nanogels can bind and

encapsulate spontaneously, through ionic interactions, any type of negatively charged ODN, including antisense ODN, ribozymes, siRNAs, etc. Although the charge neutralization results in condensation of polycation and ODN chains, the loaded nanogels remain stable in aqueous dispersion due to the effect of nonionic PEG chains. A key advantage of nanogels is that they allow for high "payloads" of macromolecules, up to 50 wt %, which usually cannot be achieved with conventional nanoparticles. Nanogels are transported in the cells and can release functionally active antisense ODN, which was shown to produce specific effects on gene expression in the cells (*18*). Furthermore, nanogels can carry ODN across cellular barriers, such as monolayers of human intestine epithelial cells and protect ODN from degradation within these cells (*18*). Previous studies also demonstrated that as a result of modification of nanogels with targeting moieties, such as insulin or transferrin, the modified nanogels undergo receptor-mediated transport in the cells (*18*, *20*).

The objective of the present work is to evaluate whether the nano-PEG-*cross*-PEI nanogels can be useful for delivery of ODN to the brain. We describe the synthesis and characterization of nano-PEG-*cross*-PEI nanogels, modified with insulin and transferrin. We use polarized monolayers of bovine brain microvessel endothelial cells (BBMEC) as an in vitro model of the BBB in the transport studies as well as a mouse model for initial studies of the in vivo biodistribution of nanogels and encapsulated ODN. The results suggest successful delivery of nanogel-encapsulated ODN from the apical to basolateral side of the BBMEC monolayers. Furthermore, the data suggest that nanogel protects ODN from enzymatic degradation in the cells. Finally, the in vivo biodistribution study suggests that following intravenous (iv) administration of nanogel-formulated ODN in mice, substantial amounts of nanogel and ODN accumulate in the brain.

MATERIALS AND METHODS

Materials. PEG (MW 8000), ^{3}H-succinimidyl propionate, 96 mCi/mmol, and ^{3}H-mannitol, 50 mCi/mmol, were purchased from Moravek Radiochemicals (Brea, CA) and DuPont Corp. (Boston, MA), respectively. All other reagents and resins for chromatography were obtained from Sigma-Aldrich Co. (St-Louis, MO). The commercial branched PEI (MW 25 000) was fractionated by gel permeation chromatography on the Sepharose CL-2B column (2.5 × 75 cm) in 0.2 M sodium chloride, 0.025% aqueous ammonia, at elution rate 1 mL min^{-1} with refractive index detection. Polymer fractions containing amines were identified by blue color development following treatment of dried aliquots with a 2% solution of ninhydrin in ethanol. The high molecular mass (>ca. 50 000) and low molecular mass (<ca. 5000) fractions were discarded and the main fraction, ca. 50 wt % of the initial sample, was collected and used for the nanogel synthesis. The carbonyldiimidazole-activated PEG was synthesized from commercial PEG (8000), which was first dried in vacuo at 50 °C overnight and then dissolved in 50 mL of anhydrous acetonitrile and reacted with excess of 1,1′-carbonyldiimidazole under argon atmosphere for 4 h at 40 °C. The product was quantitatively precipitated from anhydrous ether (1 L), collected by centrifugation at 2000*g*, and dried in vacuo. Antisense ODN, 5′GT-CAAGCCAATTTGAATAGC, targeting the MDR1 gene with the 3′-amino (C3) linker (Glen Research, CA) was synthesized using phosphorothioate chemistry on a 1 micromolar scale (UNMC Oligonucleotide Core Facility, Omaha, NE). ODN was used without any additional purification except for ODN precipitation from 0.3 M sodium chloride solution in 2-propanol.

Synthesis of Nano-PEG-*cross*-PEI. Nanogel was synthesized using the emulsification−solvent evaporation method with modifications (*18*). The solution of carbonyldiimidazole-activated PEG (3 g) in dichloromethane (10 mL) was added dropwise to the solution of PEI (1 g) in water (180 mL) upon sonication in a Bransonic ultrasonic bath with ice-cold water. Following complete mixing, the resulting emulsion was sonicated for 20 or 30 min at 40 MHz. After that dichloromethane was quickly removed from the resulting milky solution in vacuo using a Buchi rotary evaporator with water bath set at 30 °C until the solution became clear. After that the solution was stirred for a 24 h period at 25 °C, filtered to separate large debris, and then neutralized by hydrochloric acid. The polymeric product was dialyzed through a SpectraPore membrane with the cutoff 25 000 Da against 0.025% aqueous ammonia for 2 days, concentrated in vacuo, and redissolved in 60 mL of 20% ethanol. Nanogel particles were fractionated by gel permeation chromatography on the Sepharose CL-2B column (2.5 × 75 cm) in 20% ethanol at an elution rate 1 mL min^{-1}. PEG-containing fractions were determined by the colorimetric method (*21*), and the fractions containing amines (PEI) were analyzed using the qualitative ninhydrin reaction. Nanogel fractions, containing both PEG and PEI, were collected and lyophilized. About 65−70% of polymeric material was recovered in the form of nanogel.

Nanogel Characterization. For analysis of PEG/PEI ratio in nanogel preparations, 5% solutions of dried nano-PEG-*cross*-PEI samples in D_2O were prepared and filtered. ^{1}H NMR spectra (with integration) were measured in the range 0−6 ppm at ambient temperature using the Varian 300 MHz spectrometer. Elemental analysis (M−H−W Laboratories, Phoenix, AZ) was used to measure total nitrogen content in nanogel preparations. The amount of ionizable groups in nanogel was determined by potentiometric titration of 1% suspension in 0.15 M solution of sodium chloride with hydrochloric acid. Before analysis, nanogel samples were dialyzed in 2% aqueous ammonia for 24 h and then lyophilized.

Biotin-Conjugated Nanogel. Nanogel (0.2 g) suspension in 2 mL of 0.1 M sodium carbonate buffer, pH 9, was treated with 1% solution of biotin *p*-nitrophenyl ester (0.6 mL) in dimethylformamide (DMF) overnight at 25 °C. Biotinylated nanogel was separated from low molecular weight substances by gel filtration on the Sephadex G-25 column (1 × 20 cm) in 20% ethanol at elution rate 0.5 mL min^{-1}, and fractions containing the product were lyophilized. Content of the covalently attached biotin was determined using 2-anilinonaphthalene-6-sulfonic acid (ANS)−avidin titration assay (*22*).

Rhodamine-Labeled Nanogel. Nanogel (0.2 g) suspension in 2 mL of 0.1 M sodium carbonate buffer, pH 9, was treated with 1% solution of rhodamine isothiocyanate (RITC) (0.2 mL) in DMF overnight at 25 °C. The red fraction of RITC-labeled nanogel was separated from low molecular weight substances by gel filtration on the Sephadex G-25 column (1 × 20 cm) in 20% ethanol at elution rate 0.5 mL min^{-1}, and fractions containing the product were lyophilized. Fluorescent spectral characteristics of the RITC-labeled nano-PEG-*cross*-PEI (λ_{ex} 549 nm and λ_{em} 577 nm) were measured in the phosphate-buffered saline, pH 7.4, using a Shimadzu RF5000 spectrofluorimeter.

Fluorescein-Labeled ODN. Solution of 3′-amino-ODN (10 nmol) in 0.2 mL of 0.1 M sodium carbonate

buffer, pH 9.0, was treated with 0.8 mL of 1% solution of fluorescein isothiocyanate (FITC) in DMF overnight at 25 °C. The green fraction of FITC-labeled OND was separated from low molecular weight substances by gel filtration on the Sephadex G-25 column (1 × 20 cm) in 20% ethanol at elution rate 0.5 mL min^{-1}, and fractions containing the product were lyophilized. Fluorescent spectral characteristics of the FITC-labeled ODN (λ_{ex} 489 nm and λ_{em} 513 nm) were measured in the phosphate-buffered saline, pH 7.4, using a Shimadzu RF5000 spectrofluorimeter.

Tritium-Labeled ODN. ODN bearing a 3′-primary amino group were labeled according to ref 23. The procedure for introduction of tritium label consists of the following steps. First, ODN (10 nmol) was precipitated in the form of cetyltrimethylammonium (CTA) salt, which is soluble in organic solvents, dried in vacuo, and redissolved in DMF. This solution was mixed with ^{3}H-succinimidyl propionate (40 μCi, specific activity 96 Ci/mmol), dissolved in toluene−ethyl acetate, and left to stand overnight at 25 °C. After the volatile organic solvents were removed in the flow of nitrogen, 0.04 mL of 50 mM sodium dodecyl sulfate solution was added to convert labeled ODN from CTAB-salt into sodium salt. Finally, tritium-labeled ODN was precipitated twice from sodium acetate solution in ethanol, washed by 70% ethanol, and dried in vacuo. Radioactivity of the precipitate and solutions was analyzed using Beckman LS6000 IC Liquid Scintillation counter. ODN concentration was determined using UV measurements. Efficiency of the labeling procedure was about 75%, and the specific activity of ODN was 3.3 Ci/mmol.

Preparation of Tritium-Labeled Nanogel. Nanogel (0.2 g) suspension in 2 mL of anhydrous acetonitrile containing 2% (v/v) of triethylamine was treated with a solution of ^{3}H-succinimidyl propionate (150 μCi) in toluene−ethyl acetate mixture overnight at 25 °C. Organic solvents were removed in the flow of nitrogen, and tritium-labeled nanogel was separated from low molecular weight substances by gel filtration on the Sephadex G-25 column (1 × 20 cm) in 20% ethanol at elution rate 0.5 mL min^{-1}. Radioactivity of the fractions was analyzed using Beckman LS6000 IC Liquid Scintillation counter. Fractions containing nanogel were collected and lyophilized. Specific activity of the tritium-labeled nanogel measured in 0.01% aqueous solution was equal to 20 μCi/mg. Efficiency of the labeling procedure was about 80%.

Preparation of Nanogel−ODN Complexes. Nanogel dispersion (1% w/v) in phosphate-buffered saline (PBS) was sonicated for 10−15 min at 25 °C and then filtered through the 0.45 μm filter. Total nitrogen (N) concentration was 66 mM. ODN solution (0.05 mM) in PBS (concentration of phosphate (P) groups 0.95 mM) was used as a stock solution for preparation of the complexes. For example, to prepare complexes containing 5 μM of ODN at N/P ratio 8, 0.2 mL of ODN solution was added dropwise upon stirring to the suspension of biotinylated nanogel (0.023 mL) in 1.78 mL of assay buffer (10 mM HEPES, 122 mM sodium chloride, 25 mM sodium bicarbonate, 10 mM glucose, 3 mM potassium chloride, 1.4 mM calcium chloride, 1.2 mM magnesium sulfate, 0.4 mM dibasic potassium phosphate). The resulting slightly opalescent solution was stirred for 1 h at 25 °C and then filtered through the sterile 0.22 μm filter. This solution could be stored at 4 °C at least for a week without any sign of precipitation. To prepare vectorized carriers, the equal volumes (0.1 mL) of white egg avidin (0.1 mM) and biotinylated bovine insulin (0.1 mM) or biotinylated bovine transferrin (0.1 mM) solutions in PBS were mixed in 1.8 mL of assay buffer upon stirring. After 30 min, this solution was supplemented with 2 mL of the preformed nanogel-ODN dispersion. The final solutions (4 mL) were incubated for at least 2 h at 25 °C, filtered through a 0.45 μm syringe filter, and used in further studies. Freshly prepared insulin and transferrin modified nanogel−ODN complexes were stored without freezing at 4 °C and used next day in the cell transport experiments.

Particle Sizing and ξ-Potential Measurements. The electrophoretic mobility (EPM) measurements of the nanogel−ODN complexes were performed in phosphate buffer, pH 7.4, at various N/P ratios, 25 °C with electrical field strength of 15−18 V cm^{-1} by using 'ZetaPlus' Zeta Potential Analyzer (Brookhaven Instruments, Santa Barbara, CA) with 15 mV solid-state laser operated at a laser wavelength of 635 nm. The ξ-potential of the particles was calculated from the EPM values using manufacturer's software. Effective hydrodynamic diameter of free and the ODN-loaded nanogel particles was measured by photon correlation spectroscopy using the same instrument equipped with the Multi-Angle Option at the angle of 90° and ambient temperature. The instrument was tested by standard suspension of polystyrol latex particles. All solutions were prepared in phosphate buffer, pH 7.4, and filtered through 0.45 μm filter.

To study particle size in the presence of bovine serum albumin (BSA), ODN−nanogel complexes were prepared in 2 mL of phosphate-buffered saline (PBS), incubated 30 min at room temperature, mixed with 0.2 mL of 4% BSA solution, and incubated another 30 or 90 min. Samples were filtered through 0.45 μm filter before measurements.

Cell Culture. BBMEC were isolated according to the method (*24*). BBMEC monolayers for transport studies were grown on the fibronectin- and collagen-coated Transwell polycarbonate membrane inserts (Fisher Scientific, Pittsburgh, PA) in MEM:F12 culture medium supplemented with 10% horse serum, heparin sulfate (100 μg/mL), amphotericin B (2.5 μg/mL), and gentamicin (50 μg mL^{-1}) (Gibco BRL, Grand Island, NY) at 5% CO_2 and 37 °C. The isolated cells formed confluent monolayers following 14 days of incubation. Transepithelial electrical resistance (TEER) values were recorded as indexes of cell viability and monolayer integrity. Under basal conditions, mean resistance was 135 ± 13 Ω/cm^2.

Cytotoxicity. Cytotoxicity of free and ODN-loaded nanogel was assessed by the measurement of IC_{50} value in a standard 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) assay (*25*). Briefly, 96-well microtiter plates were seeded with 5000 cells/well and allowed to reattach overnight. Dilutions of the nanogel−ODN dispersion (100 μL) in assay buffer were incubated with the cells for 2 h at 37 °C. Samples were washed three times with 100 μL of Minimum Essential Medium (MEM) and replaced with fresh culture medium (200 μL) daily. After incubation period of 72 h, 25 μL of MTT solution (5 mg/mL) was added to each well and the cells were incubated for 2 h at 37 °C in the dark. Medium and indicator dye were then removed and the cells lysed with 20% sodium dodecyl sulfate in 50% aqueous dimethylformamide (100 μL) overnight at 37 °C. Absorption was measured at 550 nm in Microkinetics reader BT2000, and obtained values were expressed as a percentage of the values obtained for control cells to which no carriers were added. All measurements were repeated eight times.

Transport Experiments. Transport studies were performed as previously described (*26*). Briefly, polycar-

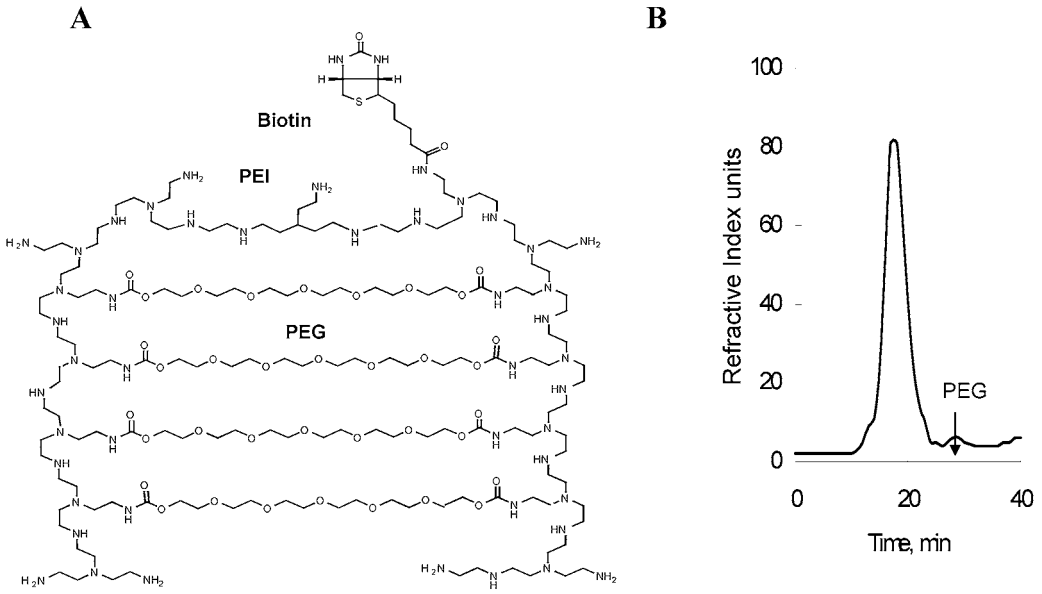

Figure 1. Shematic representing biotinylated nanogel network (A), and the chromatographic profile of GP−HPLC with refractive index (RI) detection of a biotinylated nanogel sample (B). See Material and Methods for chromatography conditions.

bonate membrane inserts with confluent BBMEC monolayers were placed in thermostated Side-By-Side diffusion chambers (Crown BioScientific, Inc.) maintained at 37 °C. Cell monolayers were preincubated for 30 min with the assay buffer added into both donor and receiver chambers. Following the preincubation period, fresh assay buffer was added to the receiver chamber and the buffer in the donor chamber was replaced with nanogel−ODN dispersions containing a paracellular marker for cell monolayers, ^{3}H-labeled mannitol. All experiments were conducted in triplicates. At different time points, solutions in the receiver container were removed and analyzed. Phosphorothioate ODN and nanogel−ODN complexes were quantified by the anion exchange HPLC using Nucleopac PA-100 guard column (0.4 × 5 cm), and gradient elution with buffer A (90% 25 mM Tris, pH 8.0; 10% acetonitrile) and buffer B (90% 2M ammonium chloride in 25 mM Tris, pH 8.0; 10% acetonitrile), at 2 mL min^{-1} and 65 °C with UV detection at 270 nm (*27*). To assess extent of dissociation of the nanogel−ODN complex following the transport across BBMEC monolayer, the samples in receiver chamber were concentrated using Ultrafree-15 Centrifugal Filter Device (5K NMWL, Millipore, Bedford, MA), and then analyzed by the gel permeation HPLC on SigmaChrom GFC-1300 column (0.7 × 30 cm) in 0.1 M sodium phosphate, pH 7.4, at 0.5 mL min^{-1} and 25 °C with UV detection at 270 nm.

Apparent permeability (P_{app}) of the cells with respect to ODN and nanogel−ODN complexes was calculated as follows:

$$P_{app} = (V/AC_o) \times dC/dt \text{ (cm/s)}$$

where $V \times dC/dt$ is the steady-state rate of appearance of ODN at the basolateral side of the monolayers, C_o is the initial ODN concentration at the apical side, and A is the surface area of the membrane.

Confocal Microscopy. Cellular accumulation localization of FITC-labeled ODN, RITC-labeled nanogel, and their complexes was examined using laser confocal fluorescent microscopy. In these studies, BBMEC were grown on chamber slides (Fisher Scientific) and incubated with 0.5 mL of 5 μM ODN or ODN-loaded nanogel for 2 h at 37 °C. After the incubation, cells were washed three times with ice-cold PBS containing 1% bovine serum albumin and scanned with a confocal fluorescence microscopic system ACAS-570 (Meridian Instruments, Okimos, MI) with argon ion laser (excitation wavelength, 488 nm) and corresponding filter set. Digital images were obtained using the CCD camera (Photometrics) and Adobe Photoshop software.

Biodistribution in Mice. All experiments were performed with female FVB wild type mice between 12 and 14 weeks of age (Charles River Laboratories, Wilmington, DE) using procedure analogous to that previously described (*28*). In the initial studies, the nanogel−ODN complex was injected daily in the tail vein to assess tolerated doses. The concentration of the complexes in injected solutions (200 μL) increased daily from 0.5 to 2.5% (w/v) with 0.5% increment. In following experiments, 100 μL of nanogel−ODN (50 μM) complex were injected in the tail vein of FVB mice. In this study we used radioactively labeled compounds, ^{3}H-nanogel or ^{3}H-ODN. There were four animals in each treatment group. Animals were sacrificed 1 h after injection, and their organs (brain, liver, spleen, and lung) were taken and washed with PBS. Blood and organs were weighted, soaked in 4% BSA solution (2 mL g^{-1} of organ), and homogenized. Samples (200 μL) of organ homogenates or 100 μL of blood plasma were added into 4 mL of scintillator solution, and the amount of ^{3}H-nanogel or ^{3}H-ODN was measured using Beckman LS6000 IC liquid scintillation counter. Concentrations of labeled compound in the plasma and brain were expressed as cpm/100 μL of plasma or cpm/200 μL. These concentrations were used to calculate brain/plasma ratios.

RESULTS AND DISCUSSION

Synthesis and Characterization of Nanogel. Figure 1A presents a schematic structure of nano-PEG-*cross*-PEI nanogel synthesized in this work. It was prepared by cross-linking the branched PEI (25 000) with an amino reactive PEG linker (8000), using a modified procedure (*18*). According to this procedure, the solution of the activated PEG in dichloromethane was emulsified in the aqueous solution of PEI by sonication. After completion of the cross-linking reaction, the organic solvent was removed, and nanogel was allowed to maturate in aque-

Table 1. Properties of Nanogel Carriers

batch	PEG/PEI molar ratio	total nitrogen content, μmol/mg	chargeable amino groups, μmol/mg	nanogel effective diameter, nm, and ζ-potential, mV (in brackets)			
				unloaded	N/P = 4	N/P = 8	N/P = 8[a] (+BSA)
batch 1	8.7	6.6	4.0	237 ± 3 (+5)	76 ± 1 (−0.2)	94 ± 2 (+2.3)	54 ± 1
batch 2	8.6	6.9	4.2	148 ± 3 (+4.6)	58 ± 1 (0)	64 ± 2 (+1.9)	50 ± 2

[a] Particle size measured 30 min after addition of 4% BSA solution in phosphate-buffered saline.

ous medium. The maturating stage is important to allow for the completion of the cross-linking reaction, which at high stages of conversion can be decelerated due to the chain entanglements in the forming polymer networks. Nanogel particles of the desired size range were purified using combination of high-speed centrifugation and gel-permeation chromatography. One important modification in the procedure was that we used higher PEG:PEI ratio, 9:1, compared to that reported in our previous studies, 6:1 (*18*). The primary reason for this modification was to increase the stability of nanogel formulations in aqueous dispersion due to increase of the amount of the hydrophilic PEG chains.

We also varied the time of sonication of the dichloromethane−water emulsion during the synthesis of the nanogel and found that this strongly affected the properties of the product, in particular, the particle size. Two major batches of nanogel were obtained following crude fractionation by gel-permeation chromatography: the first one having the particle size 240 nm (sonication time 20 min, "batch 1") and the second one having the particle size 150 nm (sonication time 30 min, "batch 2"). Interestingly, longer sonication time, e.g. 60 min, resulted in formation of macroscopic gel fragments that could not be used in these studies.

The properties of the nanogel batches are listed in Table 1. Generally, 55−70% of the total weight of reacting polymers was recovered in the form of nanogel particles. The absence of the unreacted polymers was verified by gel permeation chromatography with refractive index detection as exemplified in Figure 1B. Contamination of the free PEG (t = 29 min) was less than 5% (the main nanogel peak eluted at t = 17 min). From the NMR data, the proton assignments of nanogel were found to be δ 3.6 ppm (PEG CH_2O) and δ 2.5−3.1 ppm (PEI CH_2NH). The H_{PEG}/H_{PEI} ratios were equal to 2.7 (batch 1) and 2.6 (batch 2), which corresponded to the PEG:PEI molar ratios 8.7 (batch 1) and 8.6 (batch 2). The elemental analysis showed that the total nitrogen content was practically the same for both batches, 6.6−6.9 μmol/mg. The potentiometric titration with hydrochloric acid suggested that approximately 2/3 of the amino groups in nanogel was protonated at pH 4.5, whereas only 1/3 of the amino groups was protonated at pH 7.5. This is typical of branched PEI samples (*29*). We estimated that no more than ca. 3% of amino groups in PEI can be involved in the formation of the cross-links with PEG. Most of the experiments described below (unless stated otherwise) were performed with batch 1.

Biotin-Modified Nanogel. Biotin moiety was introduced in the nanogel (batch 1) by modification of amino groups (1.5% of total) with biotin *p*-nitrophenyl ester. After completion of the reaction, biotin-modified nanogel particles were purified from low-molecular weight products by gel permeation chromatography. The amount of biotin linked to the nanogel was determined by adding the biotin−nanogel to the complex of avidin with a fluorescent probe, ANS. Since biotin has much higher affinity to avidin than ANS, it displaces latter in the complex resulting in the decrease of the probe fluorescence (*22*). The biotin content was found to be equal to 16.5 μg/mg, which is ca. 67% of the theoretical modification degree (24.5 μg/mg) at used reagent combination. The result shows that substantial part of the biotin moieties linked to the nanogel is available for reacting with avidin.

Fluorescent and Radioactive Labeling of the Nanogel. The rhodamine label was introduced into nanogel particles to follow their transport and localization in BBMEC monolayers. For this purpose, the primary amino groups of nanogel were modified with RITC (1% of total amino group). RITC-labeled nanogel was purified by gel permeation chromatography in the dark resulting in a pink-colored dispersion. Spectral characteristics of the labeled carrier were as follows: $\lambda_{excitation}$ = 549 nm, $\lambda_{emission}$ = 577 nm (PBS, pH 7.4). Additionally, a tritium-labeled nanogel was obtained for in vivo biodistribution experiments. The primary amino groups of the nanogel were modified using the ^{3}H-succinimidylpropionate in the presence of 2% triethylamine in anhydrous acetonitrile. ^{3}H-Nanogel with specific activity 20 μCi/mg was separated by gel permeation chromatography on Sephadex G-25. Eighty percent of the radioactive label was found to incorporate into macromolecular fraction.

Complexes of Nanogel and ODN. Mixing of ODN and nanogel solutions in PBS, pH 7.4, resulted in immediate formation of the polyelectrolyte complexes, due to the electrostatic binding of the oppositely charged ODN and PEI chains. This was accompanied by the collapse of the gel and decrease in the particle size. To prepare uniform complexes, ODN solution was typically added to the same volume of stirred nanogel suspension. Although the binding of ODN to nanogel was accompanied by neutralization of electrostatic charges, the overall changes in the ζ-potential of nanogel particles were small. The unloaded nanogel equilibrated in aqueous solution was characterized by low positive ζ-potential values, presumably, because of penetration of the small counterions within the nanogel volume (*30*). Nevertheless, the charge decrease of the nanogel upon binding of ODN was detected. Composition of the polycation−DNA complexes is usually described in terms of N/P ratio, i.e., the ratio of nitrogen (nanogel) to phosphate (ODN) concentrations in the final nanogel and ODN mixture. At N/P = 8 the particles of the complex exhibited small positive charge, while at N/P = 4 these complexes were electroneutral. Table 1 presents the characteristics of unloaded and ODN-loaded nano-PEG-*cross*-PEI nanogels (batches 1 and 2) measured at two N/P ratios, 4 and 8. Binding of ODN to nanogels resulted in 2.6- to 3.1-times size decrease (N/P = 4), which corresponds to ca. 17 to 30 times decrease in the gel volume. Interestingly, the ODN-loaded nanogel formed more uniform particles (polydispersity index 0.05) compared unloaded nanogel, which had much broader particle size distribution (polydispersity index 0.30). Binding of ODN with the RITC-labeled nanogel resulted in almost 10-fold enhancement of the fluorescence (N/P = 4), presumably due to complexation of the charged amino groups of PEI, which, in the absence of ODN, quench the fluorescence.

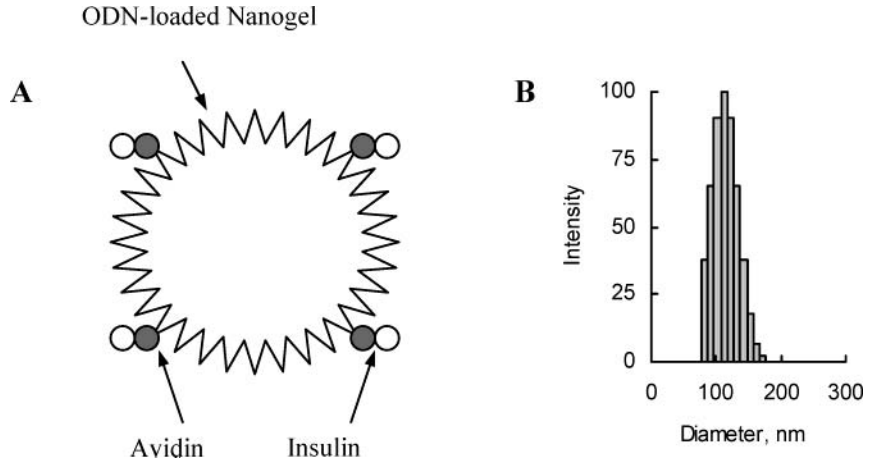

Figure 2. The putative structure (A), and particle size distribution (B) of bovine insulin-vectorized nanogel−ODN complex.

Introduction of BSA into the dispersion of nanogel−ODN complex resulted in an additional 20−40% reduction of the detectable particle size. Although no aggregation was observed following the treatment, stability of the complex might be compromised by extended incubation with the protein. Two hours later both samples of nanogel formed particles with very close mean diameter of 34−39 nm, which showed no more changes. These data could be reasonably explained by the phenomenon of opsonization earlier observed for cationic microcarriers in vivo (*31*).

Modification of ODN-Loaded Nanogel with Insulin and Transferrin. Biotin-modified nanogel was used for further conjugation with transferrin and insulin. First, the biotin-modified nanogel was loaded with ODN at the desired N/P ratio as described above. Second, the ODN-loaded biotin−nanogel complex was reacted with the preformed complex of avidin and biotinylated transferrin or insulin. The schematic showing putative structure of such complex as well as the size distribution diagram of this complex are presented in Figure 2. Importantly, no aggregation of nanogel was observed following the modification procedure, and the particle size increased by only 15% to 20%, e.g., from 94 to 110 nm (N/P = 8). No signs of precipitation have been observed in the formulations for at least 1 day at 4 °C. However, at longer storage periods we observed visible signs of aggregation in these dispersions, most likely induced by interactions of vacant avidin binding sites and excessive biotin residues on vector protein molecules.

Toxicity of Nanogel. Cytotoxicity of nanogel was examined in BBMEC monolayers using MTT assay. Cells were exposed over the period of 2 h to various concentrations of unloaded and ODN-loaded (N/P = 8) nanogel and the cell viability was tested (Figure 3). Nanogel carriers showed little cytotoxicity with respect to the BBMEC. Furthermore, the cytotoxicity was noticeably decreased when the positive charge of nanogel was neutralized by negatively charged ODN. The IC_{50} values were ca. 0.9 mg mL^{-1} and 6 mg mL^{-1} for the free and loaded nanogel, respectively. Nanogel concentrations of about 0.1−0.2 mg mL^{-1} (0.01−0.02%) were relatively nontoxic in both cases, and this concentration range was used in further studies. Preliminary data obtained in animal experiments also revealed no acute toxic effects of nanogel−ODN complexes administered iv in FVB wild-type mice at cumulative dose of up to 15 mg nanogel−ODN per mice.

Transport across BBMEC Monolayers. To evaluate potential effects of nanogel on the delivery of ODN to the brain, we examined ODN permeability using BBMEC monolayers as an in vitro model of BBB. Polarized BBMEC monolayers were grown on membrane filter inserts, which were placed in standard Side-By-Side diffusion chambers. Initial studies characterized the transport of RITC-labeled nanogel from apical (lumenal) to basolateral (ablumenal) side of the monolayers as a function of the composition of the complexes (N/P ratio) as presented in Figure 4. This figure also presents the data on the transport of FITC-labeled ODN for comparison. These data suggest that there is little if any difference in the permeability of unloaded nanogel batches 1 and 2. At the same time the rate of transport of loaded nanogels drastically depended on the composition of the complex. Specifically, the complex prepared at N/P = 8 that displays positive charge (see Table 1) was transported more efficiently than the complex at N/P = 4 having slight negative charge.

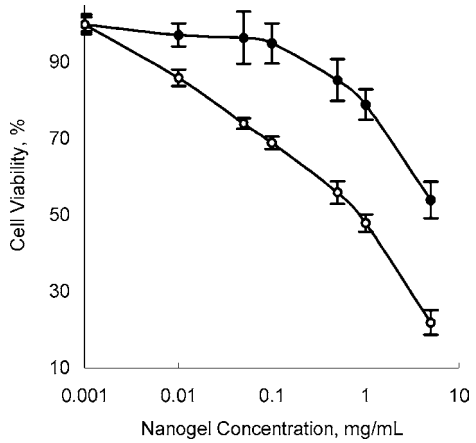

Figure 3. Cell viability based on MTT assay following the incubation of nanogel−ODN complex (black circles), or unloaded nanogel (open circles) with BBMEC monolayers for 2 h at 37 °C. IC_{50} values are equal to 0.9 mg/mL for nanogel alone, and 6 mg/mL for nanogel−ODN complex.

Further study examined whether the ODN transported with nanogel in BBMEC monolayers remains bound to the nanogel or becomes released from it in the receiver chamber. For this purpose the samples from the receiver chamber were analyzed by gel permeation chromatography with UV absorbance at 270 nm. The chromatography profiles are shown in Figure 5. From analysis of the chromatography data it appears that at least ca. 2/3 of ODN detected in the receiver chamber at 2 h time point of the transport study was incorporated in the complex with nanogel (compare peak 3 in Figure 5B with peak 1 in Figure 5A). About 10% appeared to be the free

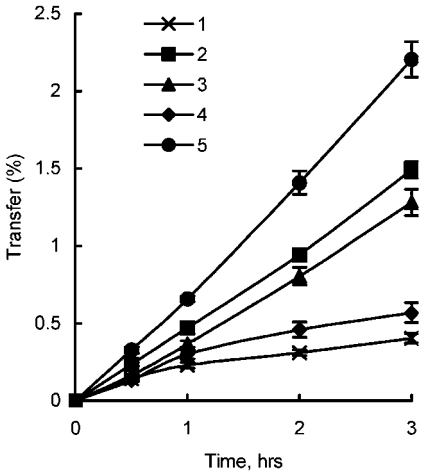

Figure 4. Transport of FITC-labeled ODN and RITC-labeled nanogel particles across BBMEC monolayers: 1, free ODN; 2, unloaded nanogel (batch 1); 3, unloaded nanogel (batch 2); 4, complex of ODN and nanogel (batch 1), N/P = 4; 5, complex of ODN and nanogel (batch 1), N/P = 8. Transport of ODN and nanogel was determined by measuring fluorescence of the corresponding probe (1, FITC; 2−5, RITC) in the receiver chamber. Concentrations of the compounds in the donor chambers were as follows: nanogel, 0.03%, ODN, 2.5−5 μM.

undegraded ODN released from the complex (compare peak 4 in Figure 5B with peak 2 in Figure 5A).

To directly assay the ODN transported through the BBMEC monolayer we used an anion exchange HPLC analysis described previously (*27*). This technique uses highly positively charged chromatography matrix Nucleopac PA-100. When ODN-loaded nanogel particles were applied on the column containing this matrix, the encapsulated ODN was effectively released from the nanogel and eluted with its normal retention time (t = 4.5 min, data not shown). As a result the total ODN in the receiver chamber (both free and nanogel bound) could be easily quantified at the concentrations as low as 5−10 nM. This HPLC technique was used to examine the relative permeability of the free and nanogel−bound ODN in BBMEC monolayers.

Table 2. Permeability Coefficients of ODN and Its Nanogel Formulations in BBMEC Monolayers

ODN formulations	N/P ratio	$P_{app} \times 10^6$, cm s^{-1} [e]
free ODN[a]	−	0.08 ± 0.01
nanogel−ODN[b]	4	0.17 ± 0.02
	8	0.45 ± 0.03
insulin−nanogel−ODN[c]	8	0.96 ± 0.03
transferrin−nanogel−ODN[d]	8	0.86 ± 0.02

[a] ODN concentration was 5 μM in all experiments. [b] Biotinylated nanogel was used at 0.02 wt %, except for N/P = 4, used at 0.01 wt %. [c] Avidin-bovine insulin, 1.25 μM. [d] Avidin-bovine transferrin, 2.5 μM. [e] Data are means ± SEM (n = 3).

In all transport experiment the ODN concentration in the donor chamber was 5 μM. The concentrations of nanogels used in the permeability studies were 0.01−0.02%. A paracellular marker, ^{3}H-mannitol, was also added in the donor chamber to assess possible changes in the integrity of the BBMEC monolayers in the presence of either ODN or its complexes with nanogel. Figure 6 presents the ODN and mannitol permeability data. The ODN permeability coefficients calculated on the base of the transport data are presented in Table 2. Formulation of ODN with nanogel resulted in permeability increases compared to the free ODN. Specifically, at N/P = 4 the permeability increase was only 2-fold (data not shown in Figure 6). At N/P = 8 the increase was almost 6-fold. Therefore, the N/P = 8 was used in experiments to further enhance ODN transport by adding peptide ligands to nanogel formulations. Modification of nanogel with either insulin or transferrin through the avidin−biotin bridges resulted in ca. 11- to 12-fold permeability increases compared to the free ODN. With all ODN formulations used, there were no changes in the permeability of mannitol, which remained the same as its

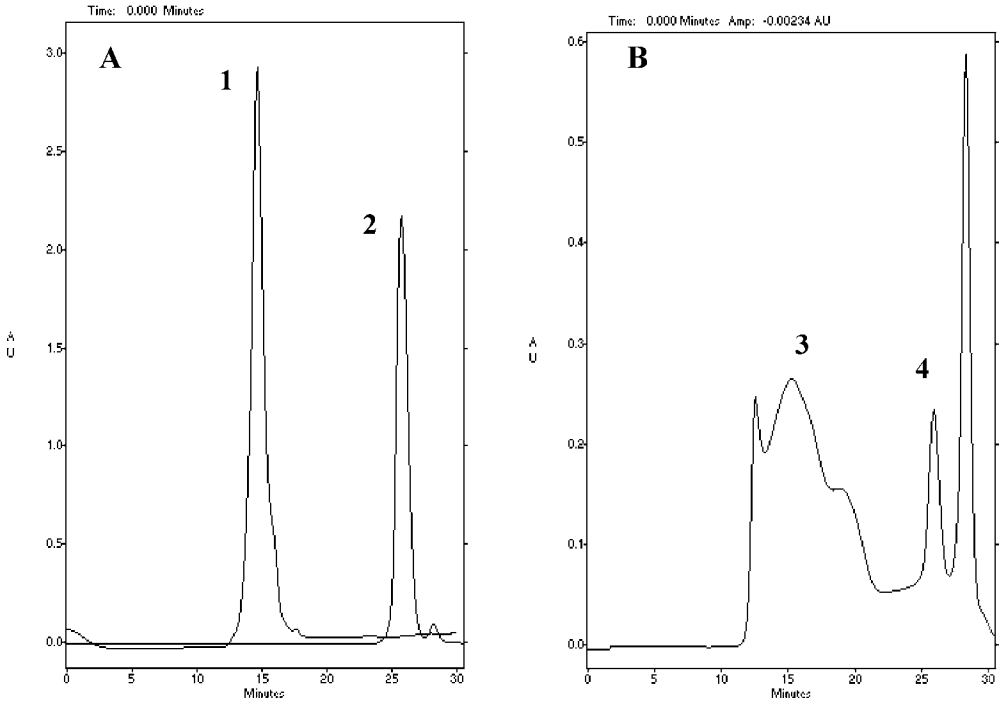

Figure 5. Gel permeation chromatography of ODN and nanogel−ODN complexes. (A) Nanogel−ODN complex (N/P = 8) added in the donor chamber (peak 1) or free ODN added in the donor chamber (peak 2). (B) Nanogel−ODN complex in receiver chamber following transport across the BBMEC monolayers (2 h, 37 °C). The chromatography peaks were assigned as follows: nanogel−ODN complex (peak 3), released ODN (peak 4), last peak relates to UV-absorbing low-molecular weight compounds.

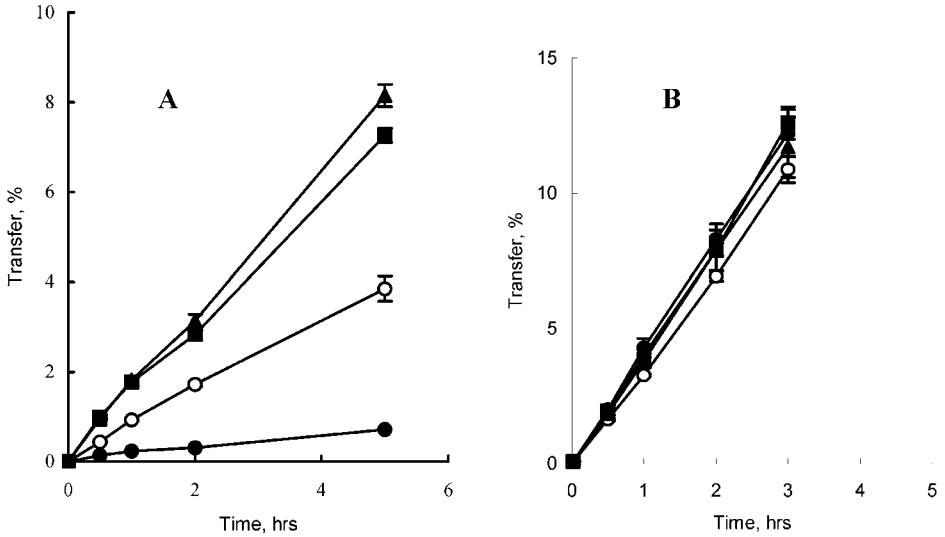

Figure 6. (A) Transport of free ODN and ODN formulated with nanogel across BBMEC monolayers. (B) Transport of paracellular marker, ^{3}H-mannitol, in the presence of the ODN and its formulations with nanogel. The symbols correspond to free ODN (black circles); nanogel−ODN complex (open circles); transferrin-vectorized nanogel−ODN complex ODN (squares); insulin-vectorized nanogel−ODN complex (triangles). All nanogel−ODN complexes are prepared at N/P = 8. Data are means ± SEM (n = 3).

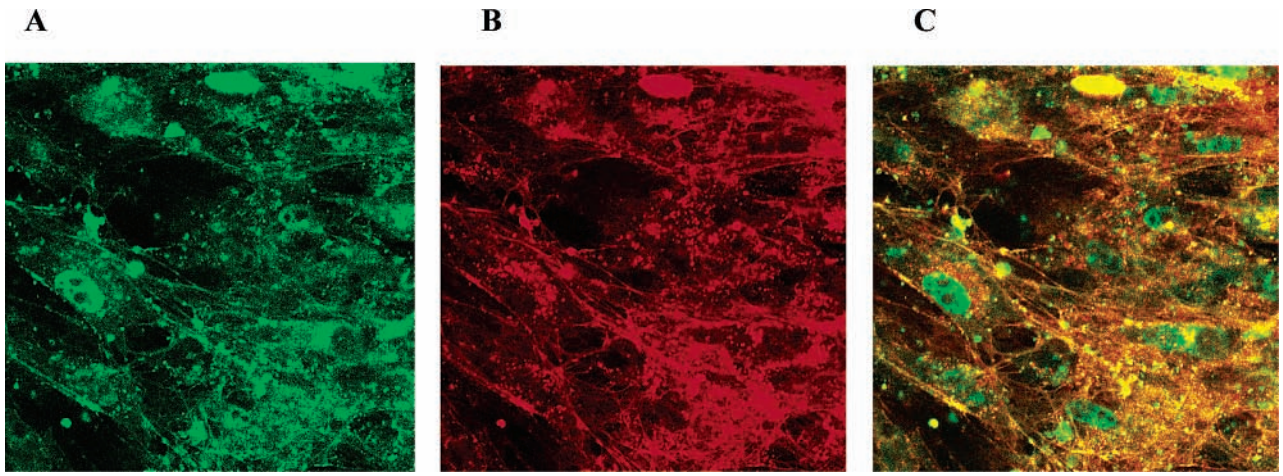

Figure 7. Confocal fluorescent microscopy of BBMEC monolayers after the incubation (2 h) with FITC-labeled ODN loaded into RITC-labeled nanogel. The images were recorded using λ_{ex} 460−500 nm, λ_{ba} 510−560 nm filter for FITC−ODN (A), and λ_{ex} 540−575 nm, λ_{ba} 605−655 nm-filter for RITC-nanogel (B). Panel C is the superposition of images A and B. Magnification ×100.

permeability in the absence of the ODN formulations (2.4×10^{-6}, cm s^{-1}). Therefore, neither free ODN, nor its nanogel formulations, affected the tight junctions in the BBMEC monolayers.

Fluorescence Microscopy Studies. Localization of ODN and nanogel following their uptake in BBMEC monolayers for 2 h was examined by laser confocal fluorescent microscopy. These experiments used FITC-labeled ODN and RITC-labeled nanogel to visualize both components within the cell. Typical micrographs are presented in Figure 7. All three images are recorded from the same sample. Panel A shows the localization of FITC−ODN. Panel B shows the localization of RITC-nanogel. Panel C is the superposition of images A and B displaying localization of both ODN and nanogel. Fluorescein label (ODN) was mainly spread throughout the cells with significant portion displayed in what appears to be cytoplasmic compartments (panel A). Similar cytoplasmic localization was displayed in the case of the rhodamine label (nanogel) (panel B). In the superposed images the areas of colocalization of ODN and nanogel are evident by yellow and orange colors (panel C). However, this panel also clearly shows that in selected cells a portion of fluorescein label is displayed in the nucleus, while practically no rhodamine fluorescence was found in the nucleus.

We have previously speculated that ODN-loaded nanogel can be transported into the cells via endocytosis with some portion crossing the cytoplasmic membrane (*20*). Specifically, despite of the presence of PEO chains, the PEI chains of nanogel are positively charged at endosomal pH, which can destabilize endosomal membrane either by the mechanism similar to that called "proton sponge" (*32*), or by forming cationic patches as a result of interaction of PEI with phospholipid bilayer (*33*). Since ODN chains are relatively short (19 phosphates) and their cooperativity of binding to nanogel is relatively small, some portion of ODN can obviously release in the cytoplasm and then transport into the nucleus through the pores in the nuclear membrane. In contrast, the nanogel particles cannot penetrate through the pores since the size exclusion of these pores is about 20 nm, which is much smaller that even the loaded nanogel particles. (Release of a portion of ODN from nanogel could only result in swelling and increase of the size of the latter). An important result of these studies is that even though a portion of ODN appears to be released in BMVEC a significant portion of it remains bound to the

Table 3. Biodistribution of Free ODN and the Nanogel−ODN Compositions

	radioactivity distribution in tissues, % of injected dose/g[a]				
injected composition	plasma	brain	lung	liver	spleen
nanogel−^{3}H-ODN	3.00 ± 0.16	5.34 ± 0.33	2.26 ± 0.22	4.34 ± 0.28	3.82 ± 0.20
^{3}H-nanogel−ODN	2.81 ± 0.27	2.67 ± 0.13	1.80 ± 0.09	3.80 ± 0.70	3.12 ± 0.16

[a] Injected compositions (0.1 mL) contained 50 μM ODN and 0.12% nanogel in PBS (N/P = 8).

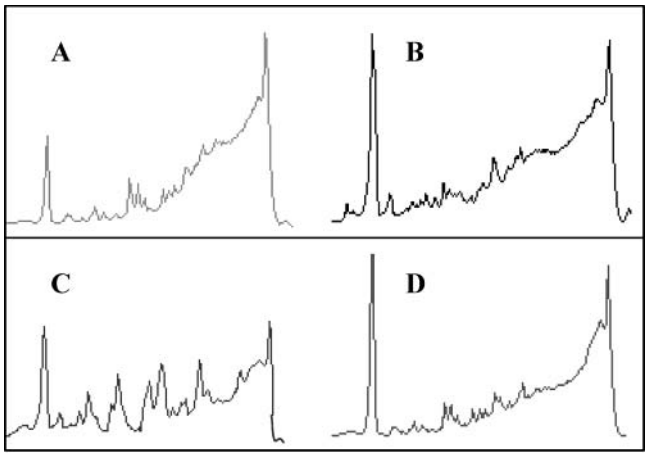

Figure 8. Nuclease resistance of free ODN and ODN incorporated in nanogel in mouse blood serum. The experiment was conducted as follows: Free ODN (5 μM) was added to freshly prepared mouse serum and immediately analyzed by ion-pair reverse phase HPLC (A) or incubated for 1 h at 37 °C and then analyzed by HPLC (C). Similarly, ODN incorporated in nanogel (5 μM, N/P = 8) was added to serum and analyzed immediately (B) or after 1 h incubation (D). In all cases prior to HPLC analysis the samples (200 μL) were mixed with 40 μL of 50 mM sodium dodecyl sulfate solution, proteins were removed by phenol extraction of proteins, and ODN was precipitated by ethanol. The ion-pair reverse phase HPLC was performed on the Spherisorb C18 column (0.4 × 15 cm), elution rate 1 mL/min using 0.2% tetrabutylammonium hydroxide, 50 mM potassium hydrogen phosphate, and 0.1 M sodium chloride in the gradient of acetonitrile 0 to 40%.

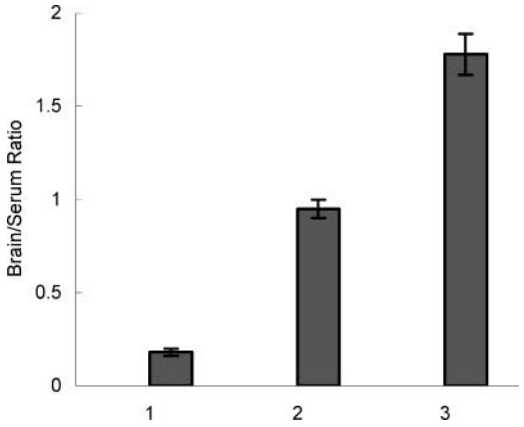

Figure 9. Brain/plasma ratios for the free (1) ^{3}H-ODN and its complexes with nanogel prepared at (2) N/P = 4 and (3) N/P = 8 following iv administration in mice. Animals were sacrificed 1 h after the injection, and the tritium radioactivity in the tissue samples was analyzed. The data represent average values ± SEM (n = 4).

nanogel, a result consistent with the permeability experiments described above.

Stability of Nanogel in Serum. To examine the protection of ODN against nuclease degradation the free ODN or nanogel−ODN complexes were incubated in freshly prepared mouse serum. As is seen in Figure 8 after 1 h incubation in serum substantial amount of free ODN was degraded (compare panels A and C). In contrast ODN incorporated in nanogel displayed little if any degradation (panels B and D).

In Vivo Biodistribution Studies. Finally, in vivo biodistribution of radioactively labeled ODN and nanogel was characterized in mice. The initial studies were conducted using complexes of ODN with ^{3}H-labeled nanogel injected iv. The injected dose contained 120 μg of nanogel. Following 1 h after injection, only 2.8% of injected dose (3.4 μg) of nanogel was detected in 1 g of blood. Significant portion of the injected dose was distributed in the organs (Table 3).

We further used ^{3}H-labeled ODN to assess its biodistribution after iv injection in a free form or as nanogel−ODN formulation. Previous studies reported that the highest levels of ODN are found in liver and spleen, with significantly smaller quantity of ODN accumulating in the brain (~0.3%) (*34*−*36*). As is seen in Table 3, our data for the free ODN were consistent with these observations. However, for nanogel−ODN complexes the amount of the radioactivity in the brain was greatly increased compared to the free ODN. At the same time the accumulation of the radioactivity in the liver and spleen was significantly decreased while plasma and lungs displayed relatively less changes. It was shown that the tritium label introduced into phosphorothioate ODN using the same technique is metabolically stable in blood in vivo for at least 2 h after injection (*23*). Therefore, the results of our experiments strongly suggest that formulation of ODN with nanogel leads to increased brain and decreased liver and spleen accumulations compared to the free phosphorothioate ODN. This effect in the brain is further illustrated in Figure 9 presenting brain/plasma ratios for free ODN and nanogel−ODN formulations 1 h after iv injection. This ratio for the nanogel−ODN formulation increased by as much as 1 order of magnitude compared to the free ODN. It also appears from this study that nanogel formulation at N/P = 8 was more efficacious in brain delivery of ODN than the formulation at N/P = 4.

On the basis of these studies, it appears that nanogel carriers can protect ODN from rapid clearance by peripheral tissues and increase ODN transport to the brain. It was demonstrated that iv-injected phosphorothioate ODNs strongly bind to albumin and other plasma proteins (*37*). Encapsulation of ODN in nanogels may have protective effect reducing the nonspecific interactions. It could also decrease the renal clearance of ODN because the molecular mass of nanogel−ODN complexes exceeds the renal clearance threshold (*38*). However, to fully address this issue, further studies of the in vivo properties of nanogel carriers need to be done.

CONCLUSIONS

A novel ODN delivery system based on positively charged nanosized hydrogel particles, nano-PEG-*cross*-PEI, has been developed. The ODN-loaded nanogel remains stable in dispersion due to the solubilizing effect of nonionic hydrophilic PEG chains resulting in a formation of nanosized particles. Nanogel structure enables easy attachment of vector groups for targeted delivery.

In particular, nanogel carriers vectorized with insulin and transferrin molecules were shown to efficiently deliver antisense ODN across BBB as demonstrated using a cell model, BBMEC. Following transport across the brain microvessel endothelial cells a significant portion of ODN remained associated with nanogel. Nanogel carriers have low toxicity, especially in the loaded form, and show no adverse toxic effect being injected intravenously in mice. Further studies in vivo should reveal the potential for the use of the vectorized nanogel carriers for systemic delivery of antisense ODN into the brain.

ACKNOWLEDGMENT

The studies were supported in parts by grants from National Science Foundation (BES 9986393) and National Institutes of Health (NS 366229) awarded to A.V.K.. NanoGel is a trademark of Supratek Pharma Inc. (Montreal, Canada), who supported part of the work on synthesis of the nanogel material. A.V.K. is a cofounder and consultant for this company. The authors would like to acknowledge the technical assistance of Shu Li in performing of the transport studies on BBMEC monolayers.

Received September 18, 2003

It has been demonstrated in various murine tumor models that radiolabeled RGD-peptides can be used for noninvasive determination of $\alpha v\beta 3$ integrin expression. Introduction of sugar moieties improved the pharmacokinetic properties of these peptides and led to tracer with good tumor-to-background ratios. Here we describe the synthesis, radiolabeling, and the metabolic stability of a glycosylated RGD-peptide ([^{18}F]Galacto-RGD) and give first radiation dose estimates for this tracer. The peptide was assembled on a solid support using Fmoc-protocols and cyclized under high dilution conditions. It was conjugated with a sugar amino acid, which can be synthesized via a four-step synthesis starting from pentaacetyl-protected galactose. For radiolabeling of the glycopeptide, 4-nitrophenyl-2-[^{18}F]fluoropropionate was used. This prosthetic group allowed synthesis of [^{18}F]Galacto-RGD with a maximum decay-corrected radiochemical yield of up to 85% and radiochemical purity >98%. The overall radiochemical yield was 29 ± 5% with a total reaction time including final HPLC preparation of 200 ± 18 min. The metabolic stability of [^{18}F]Galacto-RGD was determined in mouse blood and liver, kidney, and tumor homogenates 2 h after tracer injection. The average fraction of intact tracer in these organs was approximately 87%, 76%, 69%, and 87%, respectively, indicating high in vivo stability of the radiolabeled glycopeptide. The expected radiation dose to humans after injection of [^{18}F]Galacto-RGD has been estimated on the basis of dynamic PET studies with New Zealand white rabbits. According to the residence times in these animals the effective dose was calculated using the MIRDOSE 3.0 program as 2.2×10^{-2} mGy/MBq. In conclusion, [^{18}F]Galacto-RGD can be synthesized in high radiochemical yields and radiochemical purity. Despite the time-consuming synthesis of the prosthetic group 185 MBq of [^{18}F]Galacto-RGD, a sufficient dose for patient studies, can be produced starting with approximately 2.2 GBq of [^{18}F]flouride. Moreover, the fast excretion, the suitable metabolic stability and the low estimated radiation dose allow to evaluate this tracer in human studies.

INTRODUCTION

Integrins are heterodimeric glycoproteins consisting of an α- and a β-subunit, which are involved in cell/cell and cell/matrix interactions (*1*). They possess large extracellular and short cytoplasmatic domains. The C-terminal end of the β-subunit is connected via cytoplasmatic proteins such as talin, vinculin, and α-actinin with the actin filament of the cytoskeleton. This connection allows inside out as well as outside in signaling. Thus, integrins are not only adhesion receptors linking cells with proteins of the extracellular matrix, but are also involved in signal transduction pathways (*2*).

One of the most prominent members of this receptor class is the $\alpha v\beta 3$ integrin which is involved in several pathological processes such as osteoporosis (*3*), restenosis (*4*), inflammation (*5*), rheumatoid arthritis (*6*), metastasis (*7*), and tumor-induced angiogenesis (*8*). Thus, great efforts are being made to develop $\alpha v\beta 3$ antagonists for several therapeutic approaches (*9*, *10*). First, cyclic pentapeptides (*11*, *12*) were introduced which contain the tripeptide sequence arginine-glycine-aspartic acid (RGD[1] in single letter amino acid code). This is a recognition motif used by several extracellular matrix proteins, like fibronectin and vitronectin, to bind to a variety of integrins including $\alpha v\beta 3$ (*13*). It has been demonstrated in model systems that cyclo(-Arg-Gly-Asp-D-Phe-Val-), one member of this peptide class, can block tumor-induced angiogenesis. For example, it has been shown in a chick chorioallontoic membrane model that this RGD-peptide inhibits tumor induced formation of new blood vessels without affecting already existing adjacent vessels (*14*).

Initial clinical trials evaluating the use of $\alpha v\beta 3$ antagonists as antiangiogenic therapy in patients with various malignant tumors have been initiated (*15*) (e.g. Cilengitide, a derivative of cyclo(-Arg-Gly-Asp-D-Phe-Val-) where valine is replaced by NMeVal, is in clinical phase

II studies (*16*)). Thus, radiolabeled RGD-peptides may be of advantage to document $\alpha v\beta 3$ expression of the tumors prior to administration of $\alpha v\beta 3$ antagonists allowing appropriate selection of patients entering clinical trials and determination of the optimal dose of $\alpha v\beta 3$ antagonists. Moreover, $\alpha v\beta 3$ expression has been reported to be an important factor determining the invasiveness and metastatic potential of malignant tumors in experimental tumor models as well as in patient studies (*17*, *18*). Therefore, noninvasive imaging of $\alpha v\beta 3$ expression using radiolabeled RGD-peptides and positron emission tomography may provide a unique means of characterizing the biological aggressiveness of a malignant tumor in an individual patient.

On the basis of cyclo(-Arg-Gly-Asp-D-Phe-Val-), several radiohalogenated and radiometalated RGD-peptides have been synthesized during the past few years (for review see ref 19). First tracers resulted from radioiodination of cyclo(-Arg-Gly-Asp-D-Tyr-Val-) and cyclo(-Arg-Gly-Asp-D-Phe-Tyr-) (*20*). These compounds showed high $\alpha v\beta 3$-affinity and selectivity in vitro and receptor specific tumor uptake in vivo. However, due to their lipophilic character, high activity concentration was found in the liver. To reduce the lipophilicity of the tracer, the peptide was modified allowing conjugation with a sugar amino acid. The resulting radioiodinated glycopeptide Gluco-RGD showed higher initial retention in the blood, higher uptake in the tumor and clearly reduced activity concentration in the liver (*21*). On the basis of these results, a ^{18}F-labeled glycopeptide was synthesized using 4-nitrophenyl-2-[^{18}F]fluoropropionate as prosthetic group. It has already been demonstrated that this compound allows noninvasive determination of $\alpha v\beta 3$-expression in a murine tumor model using a dedicated small animal PET scanner (*22*). Here we describe the detailed synthesis of the precursor including synthesis of the corresponding sugar amino acid, the optimization of the labeling strategy, the metabolic stability, and first radiation dose estimates on [^{18}F]Galacto-RGD.

MATERIALS AND METHODS

All chemicals were used as supplied without further purification. 9-Fluorenylmethoxycarbonyl (Fmoc) amino acids were purchased from Bachem (Heidelberg, Germany) or Novabiochem (Bad Soden, Germany). The trityl chloride polystyrene (TCP) resin was purchased form PepChem (Tübingen, Germany). 1-Hydroxybenzotriazole (HOBt), *O*-(1*H*-benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluoroborate (TBTU), and diphenyl phosphorazidate (DPPA) were purchased from Aldrich (Steinheim, Germany) or Alexis (Grünberg, Germany). 1-Hydroxy-7-azabenzotriazole (HOAt) and *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) were purchased from PerSeptive Biosystems (Hamburg, Germany). All other organic reagents were purchased from Merck (Darmstadt, Germany), Aldrich, or Fluka (Neu-Ulm, Germany). Human M21 melanoma cells were a kind gift of D. A. Cheresh, Departments of Immunology and Vascular Biology, The Scripps Research Institute, La Jolla, CA.

Mass spectra were recorded on the LC-MS system LCQ from Finnigan (Bremen, Germany) using the Hewlett-Packard series 1100 HPLC system. NMR-spectra were recorded on a Bruker AC 250 or Bruker AMX 500 (Karlsruhe, Germany) at 300 K. For all experiments, the solvent signal was used for calibration.

Analytical reversed-phase high-performance liquid chromatography (RP-HPLC), using several acetonitrile/water gradients with 0.1% trifluoroacetic acid, was performed on Sykam equipment (Gilching, Germany) using columns with YMC−Pack ODS-A (5 μm, 250 × 4 mm) (YMC Co., Ltd, Kyoto, Japan). For radioactivity monitoring, the outlet of the UV detector was connected to a well-type NaI(Tl) detector from EG&G (München, Germany). Preparative RP-HPLC was performed with the same system using a YMC−Pack J'sphere H80 (4 μm, 150 × 20 mm) column.

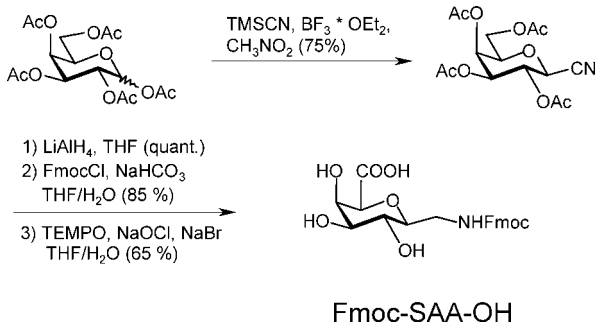

Figure 1. Synthesis of the Fmoc-protected sugar amino acid (Fmoc-SAA-OH). Synthesis starts with the transformation of the anomeric acteyl group of the pentaacetyl-protected galactose into a cyanide group using trimethylsilyl cyanide (TMSCN) under Lewis acidic conditions. The nitrile group is reduced to an aminomethylene unit using lithiumaluminum hydride. Subsequently, Fmoc-protection via standard protocols was carried out. Finally, the primary hydroxyl group is oxidized using a TEMPO-catalyzed oxidation.

Synthesis of the Fmoc-Protected Sugar Amino Acids (Fmoc-SAA-OH) (Figure 1). *2,3,4,6-Tetra-O-acetylgalactosyl-β-D-pyranosyl Cyanide (Ac$_4$GalCN).* Synthesis of the protected pyranosyl cyanide was carried out using a slightly modified protocol compared with literature (*23*). Briefly, to a solution of 42.8 g of penta-*O*-acetylgalacto-β-D-pyranose (110 mmol) in 200 mL of nitromethane were consecutively added 15 mL of trimethylsilyl cyanide (110 mmol) and 3 mL of boron trifluoride etherate (0.33 mmol, 0.3 equiv). After stirring at room temperature for 1 h, an additional 10 mL of trimethylsilyl cyanide (55 mmol, 0.5 equiv) and 2 mL of boron trifluoride etherate (22 mmol, 0.15 equiv) were added. After stirring for a further 30 min, the solvent was evaporated and the residue was dissolved in acetyl acetate (EtOAc). The solution was consecutively washed with a saturated $NaHCO_3$ solution, H_2O, and brine and dried over Na_2SO_4. Evaporation of the solvent and crystallization from EtOAc yielded 32.4 g (83%). R_f (hexane/EtOAc 2:1) = 0.3; ESI-MS: m/z = 710 (2M − HCN + Na^+), 737 (2M + Na^+); Analysis ($C_{15}H_{19}NO_9$) C, H, N; calcd C 50.42, H 5.36, N 3.92; found C 50.39, H 5.14, N 4.05; ^{1}H NMR ($CDCl_3$, 250 MHz): 5.5 (t, 1H, H2); 5.42 (dd, 1H, $^3J_{3,4}$ = 3.3 Hz, $^3J_{4,5}$ = 1.1 Hz, H4); 4.95 (dd, 1H, $^3J_{2,3}$= 10.1 Hz, $^3J_{3,4}$ = 3.3 Hz, H3); 4.15 (d, 1H, $^3J_{1,2}$ = 10.2 Hz, H1), 4.08 (d, 2H, $^3J_{5,6}$ = 6.3 Hz, H6 und H6′); 3.93 (td, 1H, $^3J_{4,5}$ = 1.1 Hz, $^3J_{5.6}$ = 6.3 Hz, H5); 2.12−1.92 (4s, 12H, acetyl-CH_3); ^{13}C NMR (DMSO-d_6, 62.5 MHz): 169.9, 169.8, 169.3, 169.1 (Acetyl-*C*O); 115.6 (CN); 74.5 (C1); 69.7 (C2); 67.3 (C3); 65.9 (C4); 65.0 (C5); 61.6 (C6); 20.5, 20.3, 20.24, 20.19 (acetyl-*C*H$_3$)

β-D-Galactopyranosylmethylamine (GalCH$_2$NH$_2$). Gal-CH_2NH_2 was synthesized according to BeMiller et al. (*24*) using a modified workup procedure. Briefly, to a suspension of 20 g of $LiAlH_4$ (527 mmol, 3.8 equiv) in 100 mL of dry tetrahydrofuran (THF) was slowly added a saturated solution of 50 g of Ac$_4$GalCN (140 mmol) in dry THF. After completion of addition, the resulting suspension was stirred for 3 h at RT. Ethanol was added dropwise

until no further hydrogen evolution was detectable. Subsequently, 100 mL concentrated NH_3 solution was slowly added, and the suspension was stirred for 1.5 h. The suspension was centrifuged, and the remaining solid was washed five times with water. The following steps can be accomplished without further purification although the solid contains large amounts of inorganic salts. ESI-MS: m/z = 194.2 ($M + H^+$); 200.1 ($M + Li^+$)

N-(Fluorenylmethyloxycarbonyl)-β-D-galactopyranosylmethylamine. To a solution of 4.7 g of $GalCH_2NH_2$ (24 mmol) in 70 mL of a 10% $NaHCO_3$ solution was added a solution of 6.93 g FmocCl (26.8 mmol, 1.1 equiv) in 40 mL of THF. After stirring for 1.5 h at RT, the pH of the solution was adjusted to 2 using cationic ion-exchange resin (Amberlyst 15, H^+ form). The resin was filtrated off and washed thoroughly with THF. The organic solvents were removed in vacuo and the remaining emulsion was extracted twice with hexane and five times with EtOAc. The combined EtOAc-fractions were evaporated to dryness and coevaporated with toluene. The resulting crude product (9.6 g) can be used without further purification. R_f (chloroform/methanol 9:1) = 0.45; ESI-MS: m/z = 416.2 ($M + H^+$)

Fmoc-SAA-OH. The reaction was accomplished using a procedure published by de Nooy et al. (*25*). For the workup, the pH of the reaction mixture was adjusted to 1.5 using cationic ion-exchange resin (Amberlyst 15, H^+ form), then the resin was filtered off and washed thoroughly with water. The filtrate was saturated with NH_4Cl and extracted five times with EtOAc. The collected organic layers were evaporated, then coevaporated twice with toluene. The product was purified by crystallization from methanol. Nine grams of *N*-(fluorenylmethyloxycarbonyl)-β-D-galactopyranosyl-methylamine yield 6.7 g (72%) of Fmoc-SAA-OH as white crystalls. R_f (chloroform/methanol 9:1) = 0.15; ESI-MS: m/z = 429.9 ($M + H^+$); 452.2 ($M + Na^+$); 663.6 ($3M + K^+ + Na^+/2$); 858.8 ($2M + H^+$); 880.9 ($2M + Na^+$); 897.0 ($2M + K^+$); 1309.6 ($3M + Na^+$); 1326.7 ($3M + K^+$); ^{1}H NMR (DMSO-d_6, 500 MHz): 7.87 (d, 2H, $^3J_{HH}$ = 7.5 Hz, Fmoc-CH); 7.69 (d, 2H, $^3J_{HH}$ = 7.5 Hz, Fmoc-CH); 7.4 (t, 2H, $^3J_{HH}$ = 7.9 Hz, Fmoc-CH); 7.3 (m, 2H, Fmoc-CH); 7.23 (t, br, 1H, NH); 5.0−4.65 (m, 3H, OH); 4.32 (d, 2H, $^3J_{HH}$ = 6.7 Hz, Fmoc-CHCH_2), 4.24 (t, 1H, $^3J_{HH}$ = 6.6 Hz, Fmoc-CHCH$_2$); 4.05 (s, 1H, H2); 3.97 (s, br, 1H, H3); 3.55 (dd, 1H, $^3J_{HH}$ = 4.4 Hz, $^3J_{HH}$ = 12.7 Hz, H7); 3.38 (m, 1H, H4); 3.30 (m, 1H, H5); 3.19 (m, 1H, H6); 3.05 (m, 1H, H7′); ^{13}C NMR (DMSO-d_6, 125 MHz): 170.2 (COOH); 156.2 (Fmoc-CO); 143.9−120.1 (arom-C); 78.2 (C6); 77.1 (C2); 73.8 (C4); 70.2 (C3); 67.9 (Fmoc-CH_2); 65.4 (C5); 46.8 (Fmoc-CH); 42.2 (C7).

Glycopeptide Synthesis (Figure 2). *Cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys-).* Loading of the TCP-resin, synthesis of the peptide, subsequent cyclization, and selective deprotection of the lysine moiety were carried out following the protocols described elsewhere (*20*, *21*, *26*). Side chain protection was 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (Pbf) for arginine, benzyloxycarbonyl (Z) for lysine, and *tert*-butyl (tBu) for aspartic acid. ESI-MS: $(M + H)^+$ = 912; RP-HPLC: t_R = 13.8 min, K' = 7.6 (30−80% MeCN; 30 min).

Cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys(Fmoc-SAA)-). After dissolving 0.08 mmol cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys-) and 0.24 mmol Fmoc-SAA-OH in 6 mL dimethylformamide (DMF), 0.24 mmol HATU and 0.24 mmol HOAt were added. The pH was adjusted to 8 using *N*-ethyldiisopropylamine. After stirring the solution for 1 h at ambient temperature, the solvent was reduced in vacuo, the residue was triturated with water and the crude peptide was isolated by centrifugation. ESI-MS: $(M + H)^+$ = 1323; RP-HPLC: t_R = 33.0 min, K' = 11.7 (0−80% MeCN; 30 min).

Table 1. Analytical Data for the Labeling Precursor c(RGDfK(SAA)) (0−80% MeCN in 20 min) and the Reference Compound [^{19}F]Galacto-RGD (0−50% MeCN in 30 min)

peptide	formula	MW [g/mol]	HPLC-MS $(M + H)^+$	t_R [min]	K'
c(RGDfK(SAA))	$C_{34}H_{52}N_{10}O_{12}$	792.85	794	10.8	5.0
[^{19}F]Galacto-RGD	$C_{37}H_{55}N_{10}O_{13}F$	866.90	868	23.5	6.8

Cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys(SAA)-). The Fmoc-protected glycopeptide was dissolved in 5 mL of 20% piperidine in DMF and stirred for 20 min at ambient temperature. After concentration of the solvent in vacuo, the glycopeptide was precipitated with diethyl ether. The crude product was isolated by centrifugation and washed 3 times with diethyl ether. ESI-MS: $(M + H)^+$ = 1101; RP-HPLC: t_R = 16.7 min, K' = 6.0 (30−80% MeCN; 30 min).

Cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys(SAA-(FP))-). After dissolving 0.01 mmol cyclo(-Arg(Pbf)-Gly-Asp(OtBu)-D-Phe-Lys(SAA)-) and 0.02 mmol 2-fluoropropionate in 1 mL of DMF, 0.02 mmol of HATU, and 0.02 mmol of HOAt were added. *N*-Ethyldiisopropylamine was used to adjust the pH to 8.5. After stirring the solution for 1 h at ambient temperature, the solvent was reduced in vacuo, and the residue was triturated with water. The crude product was isolated by centrifugation and dried in vacuo. ESI-MS: $(M + H)^+$ = 1174; RP-HPLC: t_R = 19.2 min, K' = 9.1 (30−80% MeCN; 30 min).

Removal of the Side Chain Protection Groups of the Glycopeptides. Glycopeptides were treated with 20 mL of a solution of 95% trifluoroacetic acid (TFA), 2.5% water, and 2.5% triisobutylsilane for 24 h at ambient temperature. The mixture was filtered if necessary, evaporated in vacuo, triturated with diethyl ether, filtered, and washed several times with diethyl ether.

The crude, cyclic glycopeptides were purified by RP-HPLC. Analytical data are given in Table 1.

[^{18}F]Fluoride Production. No carrier added [^{18}F]-fluoride was produced on a RDS-112 cyclotron (Siemens/

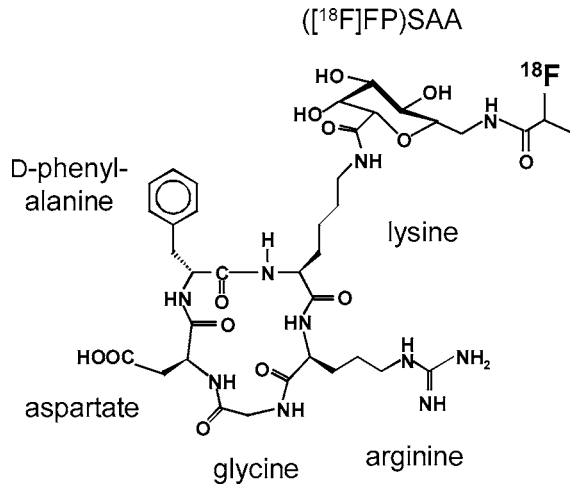

Figure 3. Schematic structure of [^{18}F]Galacto-RGD. Labeling with [^{18}F]NFP was carried out via acylation of the aminomethyl group at the C1-position of the sugar moiety. (This figure is reproduced with permission from the American Association for Cancer Research, Inc.; see ref 22).

CTI, Knoxville, TN) by irradiation of a water target using an 11 MeV proton beam on isotopically enriched [^{18}O]-water (Rotem, Beersheva, Israel). At end of bombardment, the enriched water containing [^{18}F]fluoride was passed through an anion-exchange resin (Dowex, AG1 × 8, 40 mg). The [^{18}F]fluoride was eluted from the resin using 200 to 300 μL of a 5.7 mg/mL aqueous $K_2CO_3 \cdot 1.5H_2O$ solution and collected in a 5 mL conical vial closed with a septum containing 10 mg of Kryptofix 222 in 500 μL of dry MeCN (acetonitrile for DNA synthesis). The resulting solution was concentrated to dryness at 100 °C in vacuo. The azeotropic drying was repeated at least twice with 500 μL portions of acetonitrile.

Synthesis of 4-Nitrophenyl-2-[^{18}F]fluoropropionate. Synthesis of 2-[^{18}F]fluoropropionate was prepared according to literature (*27*−*29*).

Synthesis of [^{18}F]Galacto-RGD. The glycopeptide (0.01−5.0 mg) was dissolved in 200 μL of dimethyl sulfoxide (DMSO) and added to the polypropylene vial containing 4-nitrophenyl-2-[^{18}F]fluoropropionate (185−370 MBq). The reaction mixture was allowed to remain for different times at different temperatures (for details see Figure 4). Purification of the [^{18}F]Galacto-RGD (Figure 3) was performed using RP-HPLC with an acetonitrile/water gradient containing 0.1% trifluoroacetic acid (10−50% acetonitrile in 30 min; flow 10 mL/min, t_R = 11.6 min, K' = 5.1). For animal experiments the solvent was removed in vacuo, and the residue was dissolved in phosphate-buffered saline (PBS) pH 7.4.

Octanol/Water Partition Coefficient. Approximately 2.5 kBq [^{18}F]Galacto-RGD in 10 μL PBS was diluted with 490 μL of PBS and added to 500 μL of octanol in an Eppendorf tube. After vigorous mixing of the suspension for 3 min at room temperature, the caps were centrifuged (10 300 g; 6 min) and 100 μL aliquots of both layers were counted in a gamma counter. The experiment was repeated six times.

Metabolic Stability. *Tumor Xenografts.* Metabolic stability of [^{18}F]Galacto-RGD was evaluated in mice using a xenotransplanted human melanoma model. It has previously been demonstrated that this tumor model shows high expression of the $\alpha v\beta 3$ integrin (*20*, *30*). Human M21 melanoma cells (*30*) were cultured in a humidified atmosphere with 5% CO_2. The cell culture medium was RPMI 1640 (Seromed Biochrom, Berlin, Germany) supplemented with 10% fetal calf serum and gentamycine. Tumor xenografts were obtained by subcutaneous injection 5×10^6 cells. Mice bearing tumors weighing 300−400 mg were used for the studies.

Metabolic Stability. Nude mice bearing tumor xenografts of human melanoma M21 were intravenously injected with 3.7 MBq of [^{18}F]Galacto-RGD. The animals were sacrificed and dissected 120 min after tracer injection. Blood, liver, kidney, and tumor were removed. Blood was immediately centrifuged for 5 min at 1200 g. Organs were frozen with liquid nitrogen, homogenized using a Mikro Dismembranator II (B. Braun, Melsungen, Germany), suspended in 1 mL of PBS pH 7.4, and centrifuged for 3 min at 15 600*g*. After removal of the supernatants, the pellets were washed with 500 μL of PBS. For each sample supernatants of both centrifugation steps were combined and passed through Sep-Pak C18 cartridges. The cartridges were washed with 2 mL of water and eluted with 2 mL of acetonitrile containing 0.1% TFA. Before analysis with RP-HPLC, the acetonitrile was removed in vacuo, and the residues were dissolved in 500 μL of PBS. Aliquots of 350 μL were injected onto a RP-HPLC (Sykam, Gilching, Germany; 150 × 10 mm Multosphere 100 RP-18, 5 μm column, CS Chromatographie Service GmbH, Langerwehe, Germany) using a flow of 3 mL/min (gradient: 10−50% acetonitrile, 20 min). Radioactivity was monitored using a flow scintillation analyzer (Radiomatic 500 TR Series, Packard Canberra Company, Meriden, CT). HPLC analysis was carried out in duplicate and extraction efficiency determination in triplicate.

To verify if the peak eluting approximately 1.5 min before [^{18}F]Galacto-RGD (designated as metabolite 2) is a metabolite of [^{18}F]Galacto-RGD and not [^{18}F]Galacto-RGD in a different protonation status, both peaks were sampled and aliquots were reinjected onto the HPLC. In addition, coinjection of both fractionated samples was carried out.

Dynamic PET Study and Dose Estimates. Anesthetized New Zealand white rabbits underwent dynamic PET studies using a Simens ECAT HR+ scanner (Siemens/CTI, Knoxville, Tennessee). Tracer distribution was followed for 60 min after injection of 18.5 MBq of [^{18}F]Galacto-RGD. Residence times were calculated by monoexponential extrapolation of the time activity curves for the various organ systems. According to the residence times radiation doses were calculated for an adult female patient using the MIRDOSE 3.0 program.

RESULTS

Radiosynthesis. ^{18}F-Fluorination of Galacto-RGD was carried out using 4-nitrophenyl-2-[^{18}F]fluoropropionate. Synthesis of the prosthetic group follows the protocol previously published (*27*−*29*) and resulted in a radiochemical yield of 45.2 ± 10.6% (n = 20) with an average reaction time of 126 ± 10 min. As shown in Figure 3, radiolabeling of the glycopeptide was performed via acylation of the amino methyl group at the C1-position of the sugar moiety. This led to a ^{18}F-labeled glycopeptide with an even more hydrophilic character than found for radioiodinated Gluco-RGD (21) (log P([^{125}I]Gluco-RGD) = −2.45 vs log P([^{18}F]Galacto-RGD) = −3.17).

The dependence of the radiochemical acylation yield on peptide concentration, temperature, and reaction time was investigated (for details see Figure 4). The maximum yield for the acylation step was approximately 85%. This can be reached by either using 0.5 mg of peptide at 70 °C within 10 min, 1 mg of peptide at 45 °C within 10 min, or 1 mg of peptide at 70 °C within 2.5 min. At least

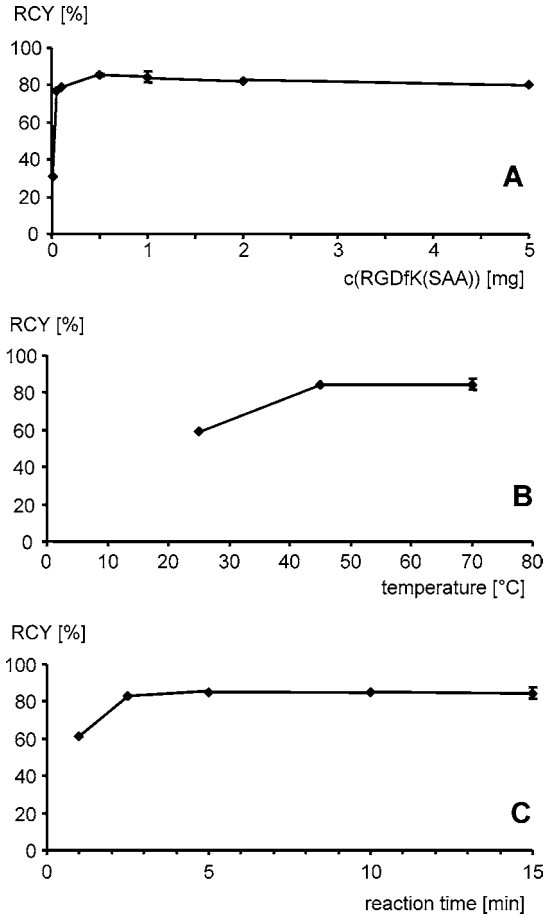

Figure 4. Dependence of the radiochemical acylation yield from (A) peptide concentration (70 °C, 10 min), (B) reaction temperature (6.3 mM peptide, 10 min), and (C) reaction time (6.3 mM peptide, 70 °C).

76% can be reached using 0.5 mg Galacto-RGD at 45 °C within 2.5 min. Final RP-HPLC with a semipreparative column allows preparation of [18F]Galacto-RGD with radiochemical purities >98% and with specific activities ranging from 40 to 100 TBq/mmol. The total radiochemical yield was 29.5 ± 5.1% (EOB) with a total reaction time of 200 ± 18 min including final HPLC purification (calculation based on 1.0 mg of peptide, 70 °C, and 10 min reaction time ($n = 6$)). Typically, starting with 2200 MBq of [18F]F$^-$, 185 MBq of [18F]Galacto-RGD was prepared in a synthesis time compatible with the half-life of 18F-fluorine.

Metabolism of [18F]Galacto-RGD. The metabolic stability of [18F]Galacto-RGD was determined in mouse blood and liver, kidney, and tumor homogenates 2 h after tracer injection. For all organs extraction efficiency was between 60% and 93% (Table 2). The lowest extraction efficiency was found for the liver homogenates and highest was found for the kidneys. Between 2 and 8% of the total activity could not be fixed on the C-18 cartridges, which can correspond with very hydrophilic metabolites or protein bound activity.

HPLC analysis of the soluble fraction of the different samples (Figure 5) allowed detection of two radiolabeled metabolites in tumor, liver, and kidney homogenates. The retention times of metabolite 1 (met 1) and metabolite 2 (met 2) were ~4.0 min and ~9.5 min, respectively. The retention time for [18F]Galacto-RGD was ~11.0 min. In blood samples only one metabolite, corresponding with met 2 in the other samples, was found. Detailed HPLC-analysis of met 2 and [18F]Galacto-RGD showed that both

Table 2. Extraction Efficiency and Data from the HPLC Analysis of the Soluble Fraction of the Organ Homogenates and the Blood Samples 120 min after Tracer Injection

	blood	liver	kidneys	tumor
Extraction Efficiency [%] ($n = 3$)

nonretained fraction[a]	7.8 ± 2.3	5.8 ± 0.1	1.7 ± 0.7	5.4 ± 1.1
soluble fraction[b]	66.6 ± 2.3	60.2 ± 6.9	93.0 ± 3.7	74.8 ± 6.6

	blood	liver	kidneys	tumor
HPLC Analysis [%] ($n = 2$)				
met 1	n.d.[c]	2.4 ± 0.4	3.5 ± 1.3	0.7[d]
met 2	14.4 ± 5.1	21.9 ± 1.8	27.8 ± 1.3	12.3 ± 1.7
intact tracer	85.6 ± 5.2	75.8 ± 2.2	68.7 ± 2.5	87.4 ± 2.2

[a] Amount of activity, which could not be fixed on the C-18 cartridge. [b] Amount of activity, which was eluted from the C-18 cartridge using acetonitrile with 0.1% trifluoroacetic acid. [c] Not detectable. [d] Detectable only in one sample.

peaks represent two different radiolabeled species and not [18F]Galacto-RGD in different protonated forms. The average fraction of intact tracer was between 70% and 87% (Table 2). The average amount of met 1 was between 1% and 4% and of met 2 between 12% and 28%. Highest metabolic stability of [18F]Galacto-RGD was found in tumor (87% intact tracer) and blood (86% intact tracer).

PET Study and Dose Estimates. The dynamic PET study of two New Zealand white rabbits showed fast renal elimination of the tracer with low activity accumulation in almost all organs of the rabbit (Figure 6). One minute after injection of 18.5 MBq of [18F]Galacto-RGD, highest activity concentration was found in heart, kidneys, liver, and large blood vessels. At 15 min pi, most activity could be detected in kidneys and at 60 min pi in the urinary bladder. Calculation of time activity curves demonstrated that there is no tracer retention in any of the investigated organs (Figure 7).

The expected radiation dose to an adult female patient after injection of [18F]Galacto-RGD has been estimated to be of 2.2×10^{-2} mGy/MBq. Only slightly different results were obtained from radiation dose calculations based on the biodistribution data in mice (biodistribution data can be found in (*22*)). An effective radiation dose of 3.8×10^{-2} mGy/MBq was calculated on the basis of the mouse data. The highest radiation doses were found for the urinary bladder wall and the small intestine (1.5×10^{-1} mGy/MBq and 2.2×10^{-1} mGy/MBq, respectively). In rabbits the radiation dose for the gallbladder wall and the small intestine were lower than in the mouse model, probably reflecting slower excretion kinetics in larger animals. Table 3 shows the expected radiation dose for the individual organ systems.

DISCUSSION

It has been shown that sugar derivatives can improve several pharmacological properties of peptides such as bioavailability (*31*), increased stability toward enzymatic degradation (*32*), and solubility under physiological conditions (*33*). Recently, radiolabeled octreotide and octreotate derivatives conjugated with glucose, maltose or maltotriose have been described (*29*, *34*−*36*). These glycosylated tracers showed reduced liver and increased tumor uptake resulting in excellent tumor-to-background ratios which allows imaging of SSTR-positive tumors with high contrast.

We used a similar approach to improve the pharmacokinetic behavior of our first generation compounds and conjugated sugar amino acids with cyclo(-Arg-Gly-Asp-D-Tyr-Lys-) (*21*). An advantage of sugar amino acids,

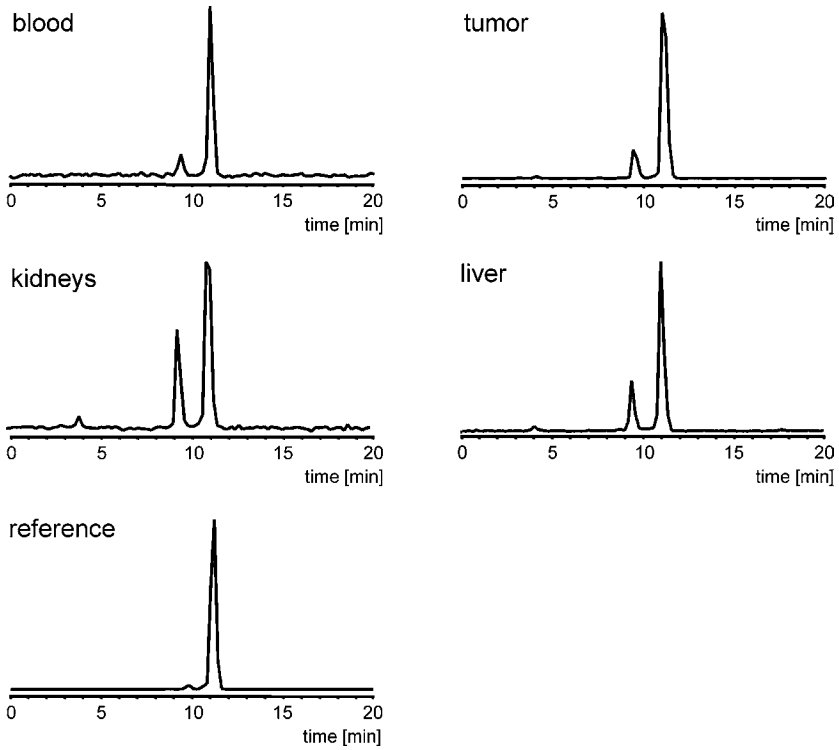

Figure 5. Representative HPLC profiles of the reference compound, and the soluble fraction of blood samples, tumor, kidney, and liver homogenates collected 120 min after tracer injection.

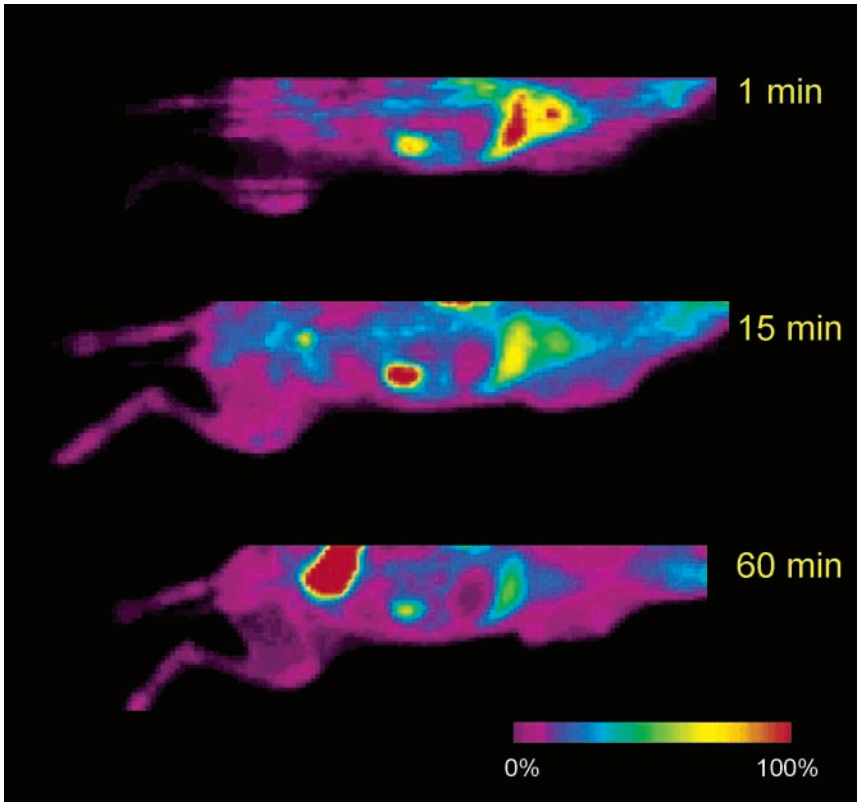

Figure 6. Dynamic PET study of a New Zealand white rabbit over 60 min after injection of [^{18}F]Galacto-RGD. The image 1 min after tracer injection shows blood-pool activity in the heart, liver, right kidney, and large blood vessels. In the image 15 min pi there is accumulation of the tracer in the right kidney and clearance of blood-pool activity. Furthermore, activity is found in the bladder. At 60 min pi the tracer has accumulated in the bladder. Liver and right kidney are only faintly visible. Please note that some parts of the left side of the rabbit including the left kidney were not in the field of view of the PET scanner.

which are sugar derivatives with an amino and a carboxylic function (*37*), is that they can easily be used with standard peptide synthesis protocols. Moreover, due to the carbon−carbon bond at the anomeric center, the resulting glycopeptides are expected to be very stable toward metabolic degradation. For the synthesis of the first radioiodinated glycopeptide, a sugar amino acid based on glucose was used. The resulting radioiodinated

Gluco-RGD showed promising improved pharmacokinetics and increased activity retention in the tumor (*21*). For ^{18}F-labeling with prosthetic groups, another sugar amino acid based on galactose was introduced (*22*) allowing acylation at the amino function at the C1-position of the sugar moiety.

This Fmoc-protected sugar amino acid (Fmoc-SAA-OH, Figure 1) can be synthesized in four steps starting from pentaacetyl protected galactose. The reaction starts with the transformation of the anomeric acetyl into a cyanide group by reaction of the protected galactose with trimethylsilyl cyanide under Lewis acidic conditions. The nitrile group is then reduced to an aminomethylene unit using lithiumaluminum hydride and the newly formed amino group is subsequently Fmoc-protected via standard protocols. In the last step the primary hydroxyl group is oxidized using a TEMPO-catalyzed oxidation which yields the carboxylic acid moiety that enables fast and efficient glycosylation of the partially protected cyclo(-Arg-Gly-Asp-D-Phe-Lys-) via the ϵ-amino function of the lysine. The final deprotection of the peptide side chain functions, as well as the primary amino function at the sugar moiety, offers a RGD-containing glycopeptide which can be labeled with ^{18}F-fluorine by prosthetic groups, such as succinimidyl-4-[^{18}F]fluorobenzoate ([^{18}F]-SFB) (*38*) and 4-nitrophenyl-2[^{18}F]-fluoropropionate ([^{18}F]-NFP) (*27*). To minimize the negative effect of hydrophobic prosthetic groups, such as [^{18}F]SFB, on the optimized hydrophilicity of sugar-conjugated tracer, [^{18}F]NFP was chosen for labeling. Acylation of the glycopeptide with this prosthetic group resulted in the radiolabeled compound with high radiochemical purity and radiochemical yield. By using a peptide concentration of 0.32 mM, radiochemical acylation yields of approximately 76% can already be reached at 45 °C within 2.5 min. Moreover, it is not necessary to add any additional base during the acylation step when the amino function of the sugar is in the deprotonated form. This can be carried out by adding 1 equiv sodium carbonate and subsequent removal of the solvent in vacuo. Although the synthesis of [^{18}F]NFP is a time-consuming three step procedure necessary to be improved, the discussed synthesis route allows the production of [^{18}F]Galacto-RGD in amounts sufficient for clinical trials.

In murine tumor models it has already been demonstrated that [^{18}F]Galacto-RGD shows receptor specific accumulation in the tumor with good tumor-to-background ratios and allows noninvasive determination of $\alpha v\beta 3$-expression using a small animal scanner (*22*). The dynamic PET study using a New Zealand white rabbit confirmed the data from biodistribution studies with tumor-bearing mice indicating fast predominantly renal excretion of the tracer. The radiation dose estimates using the MIRDOSE program resulted in values very similar to that found for [^{18}F]FDG, indicating low radiation doses for patients. The studies concerning the metabolic stability showed that there remains between 5 and 35% of the injected activity in the unsoluble fraction, which could be due to coprecipitation, or especially for the blood sample, also due to some binding to cells. However, this was not verified in more detail in this study. Nevertheless, between 65 and 90% of the tracer in the soluble fraction remains intact during the time frame essential for ^{18}F-PET studies. Especially in tumor and blood, even 2 h after tracer injection more than 85% of the activity found correspond with the intact tracer, indicating that the resulting signal mainly reflects tracer accumulation.

In conclusion, glycosylation of RGD-peptides using a sugar amino acid is easy to accomplish via standard peptide chemistry protocols. Subsequently, radiolabeling with [^{18}F]NFP results in [^{18}F]Galacto-RGD in high radiochemical yields and radiochemical purity. Introduction of the sugar moiety in combination with this prosthetic group leads to a hydrophilic tracer with fast predominantly renal excretion and suitable metabolic stability in vivo which allows noninvasive determination of $\alpha v\beta 3$-expression in different murine tumor models. The route described enables production of a standard amount of [^{18}F]Galacto-RGD sufficient for patient studies, starting with approximately 2.2 GBq of [^{18}F]fluoride. The estimated radiation dose is in the same range as found for [^{18}F]FDG.

ACKNOWLEDGMENT

This work was supported by a grant from the Sander Foundation (grant no. 96.017.3). Wolfgang Linke, Claudia Bodenstein, Gitti Dzewas, and Burghard Cordes are acknowledged for excellent technical assistance and Amy R. Claus for carefully reading the manuscript. We thank

the RDS-cyclotron team, and especially Michael Herz, for providing the ^{18}F-fluorine and initial training at the hot cells. We acknowledge David A. Cheresh, The Scripps Research Institute, La Jolla, CA, for supplying us with M21 melanoma cells. The rabbit was kindly provided by Ivo Buschmann and Emanuelle K. Chorianopoulos, University of Freiburg, Germany.

Structure Property Analysis of Pentamethine Indocyanine Dyes: Identification of a New Dye for Life Science Applications

Oliver Mader,[§] Knut Reiner,[#] Hans-Joachim Egelhaaf,[†] Rainer Fischer,[§] and Roland Brock*[,§]

Institute for Cell Biology, University of Tübingen, Auf der Morgenstelle 15, 72076 Tübingen, Germany, and Institute of Physical and Theoretical Chemistry, University of Tübingen, Auf der Morgenstelle 8, 72076 Tübingen, Germany, and FEW Chemicals GmbH, ChemiePark Bitterfeld Wolfen, Areal A - Technikumstrasse 1, 06766 Wolfen, Germany. Received October 16, 2003; Revised Manuscript Received November 27, 2003

A collection of nine pentamethine indocyanine dyes was synthesized, and the photophysical characteristics relevant to applications in cell biology and single molecule detection were analyzed in detail. Substituents at the aromatic system covering the auxochromic series and substitutions in the polymethine chain were investigated with respect to absorption and emission spectra, fluorescence lifetimes, fluorescence quantum yields, and fluorescence autocorrelations. Substitutions in the polymethine chain increased the nonradiative energy dissipation of the excited singlet state and decreased the fluorescence quantum yield, relative to the unsubstituted compound. For substituents at the aromatic rings the fluorescence quantum yield negatively correlates with the position of the substituents in the auxochromic series $-SO_3^-$, -H, -F, $-CH_3$. Compounds with sulfonic acid groups or halogen atoms attached to the indolenine systems had the highest fluorescence quantum yields. The compound S0387 had nearly 70% of the quantum yield of Cy5 and comparable photostability. The free carboxylic acid of S0387 was attached to peptides in high yield and purity by established procedures of solid-phase synthesis. The dye-labeled peptides did not aggregate or bind to tissue culture cells and proteins unspecifically. The indocyanine dye S0387 is therefore an attractive new fluorophore for in vitro and cell-based detection of receptor ligand interaction at nanomolar concentrations by flow cytometry, fluorescence correlation spectroscopy, and laser scanning microscopy.

INTRODUCTION

Over the past decade, fluorescence has become one of the key detection principles in life sciences and drug discovery. The sensitivity of fluorescence-based detection systems has enabled the miniaturization of assay formats in high-throughput screening for new drug candidates, greatly reducing the consumption of costly assay reagents (*1*).

Spectrally resolved detection modalities, such as fluorescence anisotropy decay, detection of fluorescence lifetimes, and simultaneous detection of different wavelengths (*2*), have greatly increased the information per assay. Depending on the fluorophore used, the spectral characteristics provide valuable information on the chemical environment of a fluorophore (*3*), molecular interactions (*4*), or enzymatic turnover (*5*).

The suitability of a fluorophore for life science applications is determined by its photophysical characteristics and the chemical compatibility with the respective biological application. The key photophysical parameters of a fluorophore are the compatibility of the excitation and emission spectra with available instrumentation, the fluorescence quantum yield, the dependence of the photophysical characteristics on the chemical environment, and its photostability. Moreover, the chemical stability of the fluorophore to labeling conditions, minimum interference with biological activity of the labeled molecules, and the solubility in aqueous buffers are essential prerequisites for applications (*6*).

Detection techniques based on fluorescence emitted from single molecules are gaining significance in miniaturized drug screening and biophysical research. Fluorophores employed for such detection modalities should be free of any tendency to aggregate. In addition, the quantum yield for the transition into electronic states with long lifetimes, such as triplet state transitions, should be minimal for techniques based on the time-resolved analysis of fluorescence fluctuations.

Applications of fluorophores in life sciences include the labeling of small synthetic molecules and of large biomolecules such as proteins in screening applications for drug development, of antibodies for immunofluorescence (*7*), of nucleotides in DNA sequencing (*8*), and of oligonucleotides or proteins as probes in DNA and protein microarrays (*9*). The requirements of chemical stability depend on the molecules to be labeled. To label proteins, an active ester or maleimido group is usually attached to a free carboxyl group of the fluorophore (*10*, *11*). These groups react with primary amines or thiol groups in aqueous buffers and at mildly basic pH, conditions affecting neither the biomolecule nor the dye. In solid-phase synthesis (SPS)[1] (*12*), the in situ activation of carboxylic acids provides a more efficient and cheaper way to label compounds (*13*) than preactivation. Using

dye and coupling reagents in excess, complete formation of the labeled products can be achieved. Unreacted dye can be removed easily by washing the solid-phase resin. However, relatively harsh chemical conditions may be encountered during further on-resin labeling of compounds, such as strong acid for the cleavage of these compounds from the resin. Thus, the reactivity of a fluorophore to the conditions encountered in a particular SPS protocol needs to be evaluated in detail.

Compounds based on the indocyanine scaffold are widely used as fluorophores for labeling biomolecules (*14*−*18*). The spectral characteristics of these compounds depend primarily on the length of the polymethine chain linking the two aromatic systems. As a rule-of-thumb, the wavelength of the excitation and emission maxima shifts to the red by 100 nm with every vinylene unit, rendering the $n = 0$ dyes (n is the number of vinylene units in the polymethine chain) compatible with excitation with argon-ion lasers at 488 nm, the $n = 1$ dyes compatible with excitation by helium−neon lasers at 543 nm, and the $n = 3$ dyes compatible with excitation by helium−neon lasers at 633 nm (*19*, *20*). Dyes with $n = 2$ or $n = 3$ have maximum quantum yields (*21*). A major factor reducing the fluorescence quantum yield of the polymethine dyes is the photoinduced trans−cis isomerization of the polymethine chain. This process, which occurs via a twisted excited singlet state (*22*), leads to a nonradiative dissipation of absorbed energy (Figure 2) (*23*).

Efforts to improve the photophysical characteristics of fluorophores based on a number of different scaffolds have identified sulfonic acid groups and halogen atoms as substituents increasing water solubility (*17*) and fluorescence quantum yield and decreasing the dependence of the fluorescence on the chemical environment. The results of these efforts are exemplified by the difluorinated fluorescein derivatives Oregon Green 488 and Oregon Green 514 (*24*). Early analyses of the structure property relationship of substituted polymethine dyes in benzene solution demonstrated a sensitive dependence of the photophysical properties on the substituents on the aryl rings (*25*). Groups with strong −I effects, e.g., trifluoromethyl groups, increase the fluorescence quantum yield compared with the unsubstituted analogues (*25*).

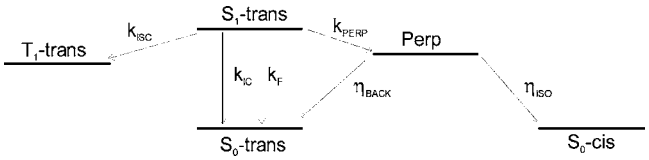

Figure 2. Processes contributing to the dissipation of energy from the excited singlet state. The fluorescence rate constant k_F describes the dissipation by emission of light, k_{ISC} intersystem crossing to the triplet state, k_{IC} internal conversion to the ground state, and k_{PERP} the transition to the partially twisted transition state from where the isomerization or the dissipation to the ground state occurs with efficiencies η_{ISO} and $\eta_{BACK} = 1 - \eta_{ISO}$, respectively.

To assess the effect of substitutions on the photophysical characteristics of pentamethine indocyanines in more detail and to identify new fluorophores for life science applications, a collection of nine pentamethine indocyanine dyes was synthesized and the photophysical properties were determined in aqueous buffers, methanol, and glycerol. Two of these compounds bear a methyl or a chlorine substituent in the polymethine chain to investigate the effect of such substitutions on the tendency to undergo photoinduced trans−cis isomerization.

Absorption, excitation, and emission spectra were recorded and fluorescence lifetimes and quantum yields were measured for each of the new derivatives. Fluorescence correlation spectroscopy (FCS) was employed to assess the suitability of these compounds for single molecule detection. In FCS, information on molecular interactions and molecular concentrations is derived from temporal autocorrelations of time-resolved fluorescence measurements (*26*, *27*). The autocorrelation function responds sensitively to the presence of fluorescent aggregates. Moreover, photophysical transitions into long-lived dark states manifest themselves in the autocorrelation function (*28*). A detailed analysis of the photoinduced trans−cis isomerization of Cy5 by FCS was presented in 2000 (*23*). The compound S0387 had about 70% of the quantum yield of Cy5, had comparable photostability, and did not show any aggregation. For this reason, this compound was further characterized with respect to life science applications. A major histocompatibility complex (MHC) class I binding epitope (SIINFEKL) (*29*, *30*) was labeled with this fluorophore and tested for MHC binding by confocal laser scanning microscopy and flow cytometry. In another experiment, the interaction of an S0387 labeled c-myc peptide (*31*) with a peptide binding antibody was detected by FCS (*32*).

MATERIALS AND METHODS

Synthesis of Fluorophores. *S0387.* (A) 2-(4-Acetanilino-1,3-butadienyl)-3,3-dimethyl-1-(4-sulfobutyl)-indolium inner salt: A mixture of 1-(4-sulfobutyl)-2,3,3-trimethylindolium inner salt (4.75 g, 50 mmol) and malonaldehyde dianil hydrochloride (13.2 g, 51 mmol) in 80 mL of acetic acid anhydride was allowed to react for 1 h at a temperature of 120 °C. After cooling to room temperature, the

reaction mixture was diluted with 300 mL of ethyl acetate. The crude solid was boiled with acetonitrile. Yield: 19.4 g.

(B) 1-(5-Carboxypentyl)-2,3,3-trimethyl-indolium-5-sulfonate: The sodium salt of 2,3,3-trimethyl-indoleninium-5-sulfonate (2.61 g, 10 mmol) and 6-bromohexanoic acid (2.1 g, 11 mmol) were mixed and heated at 110 °C for 2 h with constant stirring. The reaction mixture was cooled to room temperature, and the residue was boiled with acetone until a powder was obtained. Yield: 2.58 g.

^{1}H NMR (DMSO-d_6): δ (ppm) 7.94 (s, 1H, arom. CH), 7.65 (dd, 1H, arom. CH), 7.46 (d, 1H, arom. CH), 4.43 (t, 2H, NCH_2), 2.83 (s, 3H, CH_3), 2.21 (t, 2H, CH_2), 1.84 (b, 2H, CH_2), 1.54(s, 3H, CH_3), 1.32−1.61 (b, 4H, CH_2)

(C) 2-[5-[1-(5-Carboxypentyl)-1,3-dihydro-3,3-dimethyl-5-sulfo-2H-indol-2-ylidene]-penta-1,3-dienyl]-3,3-dimethyl-1-(4-sulfobutyl)-3H-indolium inner salt, sodium salt: Compound A (2.33 g, 5 mmol) and compound B (1.77 g, 5 mmol) were dissolved in 20 mL of ethanol. After sodium acetate (0.82 g, 10 mmol) was added to the sample, the mixture was heated for 20 min to reflux. The solution was cooled to 5−8 °C, and the crude product was collected by filtration and washed with ethyl acetate. After air-drying the crude dye was chromatographed on silica gel (Kieselgel 60, Merck, Darmstadt, Germany) using a methanol/chloroform (4:9, v/v) mixture as eluent. Yield: 0.81 g, λ_{max} (methanol): 646 nm, ϵ = 187 000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.35 (m, 2H, CH), 7.81 (d, 1H, arom. CH), 7.64 (d, 2H, arom. CH), 7.48(m, 1H, arom. CH), 7.30 (m, 2H, arom. CH), 6.62 (t, 1H, CH), 6.36 (q, 2H, CH), 4.08 (b, 4H, NCH_2), 2.55 (b, CH_2), 2.14 (t, 2H, CH_2), 1.75 (b, CH_2), 1.69 (s, 12H, CH_3), 1.55 (b, CH_2), 1.37 (b, CH_2), HPLC: 97.3%.

S0693. (D) 2,3,3,5-Tetramethyl-1-(4-sulfobutyl)-indolium hydroxide inner salt: 2,3,3,5-tetramethylindolenine (8.65 g, 0.05 mol) and 1,4-butanesulfone (9.0 g, 0,06 mol) were mixed and heated to 120 °C for 2 h. The reaction mixture was cooled and triturated with acetone until a purple colored powder was obtained. Yield: 8.1 g.

^{1}H NMR (DMSO-d_6): δ (ppm) 7.91 (d, 1H, arom. CH), 7.66 (s, 1H, arom. CH), 7.43 (d, 1H, arom. CH), 4.76 (t, 2H, NCH_2), 2.83 (s, 3H, CH_3), 2.54 (m, 2H, CH_2), 2.45 (s, 3H, CH_3), 1.98 (m, 2H, CH_2), 1.73 (m, 2H, CH_2), 1.52 (s, 6H, CH_3).

(E) 2-(4-Acetanilino-1,3-butadienyl)-3,3,5-trimethyl-1-(4-sulfobutyl)-indolium inner salt: This compound was prepared by reacting compound D with malonaldehyde dianil hydrochloride following the procedure for compound A. Yield: 15.7 g.

(F) 2-[5-[1-(5-Carboxypentyl)-1,3-dihydro-3,3-dimethyl-5-sulfo-2H-indol-2-ylidene]-penta-1,3-dienyl]-3,3,5-trimethyl-1-(4-sulfobutyl)-3H-indolium inner salt, sodium salt: This dye was prepared by condensing intermediates E and B following the procedure for compound C. Yield: 0.58 g, λ_{max} (methanol): 651 nm, ϵ = 163000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.33 (m, 2H, CH), 7.80 (d, 1H, arom. CH), 7.63 (d, 1H, arom. CH), 7.48 (m, 1H, arom. CH), 7.39 (d, 1H, arom. CH), 7.26 (m, 2H, arom. CH), 6.59 (t, 1H, CH), 6.43 (d, 1H, CH), 6.24 (d, 1H, CH), 4.10 (b, 4H, NCH_2), 2.60 (b, CH_2), 2.39 (s, 3H, CH_3), 2.22 (t, 2H, CH_2), 1.76 (b, CH_2), 1.69 (s, 12H, CH_3), 1.56 (b, CH_2), 1.39 (b, CH_2), HPLC: 95.8%.

S0694. (G) 5-Fluoro-2,3,3,-trimethyl-1-(4-sulfobutyl)-indolium hydroxide inner salt: The compound was prepared following the procedure for compound D. Yield: 13.7 g.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.23 (q, 1H, arom. CH), 7.86 (d, 1H, arom. CH), 7.50 (t, 1H, arom. CH), 4.51 (t, 2H, NCH_2), 2.86 (s, 3H, CH_3), 2.54 (m, 2H, CH_2), 1.99 (m, 2H, CH_2), 1.76 (m, 2H, CH_2), 1.56 (s, 6H, CH_3).

(H) 2-(4-Acetanilino-1,3-butadienyl)-5-fluoro-3,3,-dimethyl-1-(4-sulfobutyl)-indolium inner salt: This compound was prepared by reacting compound G with malonaldehyde dianil hydrochloride following the procedure for compound A. Yield: 16.1 g.

(I) 2-[5-[1-(5-Carboxypentyl)-1,3-dihydro-3,3-dimethyl-5-sulfo-2H-indol-2-ylidene]-penta-1,3-dienyl]-5-fluoro-3,3-dimethyl-1-(4-sulfobutyl)-3H-indolium inner salt, sodium salt: This dye was prepared by condensing intermediates H and B following the procedure for compound C. Yield: 0.41 g, λ_{max} (methanol): 646 nm, ϵ = 140 000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.34 (m, 2H, CH), 7.81 (d, 1H, arom. CH), 7.68 (m, 2H, arom. CH), 7.49 (m, 1H, arom. CH), 7.29 (m, 2H, arom. CH), 6.60 (t, 1H, CH), 6.36 (q, 2H, CH), 4.14 (b, 4H, NCH_2), 2.58 (b, CH_2), 2.07 (t, 2H, CH_2), 1.78 (b, CH_2), 1.71 (s, 12H, CH_3), 1.56 (b, CH_2), 1.35 (b, CH_2), HPLC: 88.1%.

S0436. (J) 2-[5-[1-Carboxypentyl-1,3-dihydro-3,3-dimethyl-2H-indol-2-ylidene]-penta-1,3-dienyl]-3,3-dimethyl-1-(4-sulfobutyl)-3H-indolium hydroxide inner salt: The dye was prepared according to the synthesis of compound C by the reaction of 1-(5-carboxypentyl)-2,3,3-trimethyl-indoleninium bromide with compound A; λ_{max} (methanol): 643 nm, ϵ = 160 000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.35 (m, 2H, CH), 7.63 (d, 2H, arom. CH), 7.39 (m, 4H, arom. CH), 7.23 (m, 2H, arom. CH), 6.60 (t, 1H, CH), 6.33 (q, 2H, CH), 4.09 (b, 4H, NCH_2), 2.57 (b, CH_2), 2.05 (t, 2H, CH_2), 1.76 (b, CH_2), 1.67 (s, 12H, CH_3), 1.52 (b, CH_2), 1.38 (b, CH_2), HPLC: 98.2%.

S0430. (K) 3-Carboxypentyl-2-[5-(1,3-dihydro-3,3-dimethyl-1-(4-sulfobutyl)-2H-indol-2-ylidene)-penta-1,3-dienyl]-1,1-dimethyl-1H-benzo[*e*]indolium hydroxide inner salt: The dye was prepared according to the synthesis of compound C by the reaction of 1-(5-carboxypentyl)-2,3,3-trimethyl-indoleninium bromide with 2-(4-acetanilino-1,3-butadienyl)-1,1-dimethyl-3-(4-sulfobutyl)-H-benzo[*e*]indolium hydroxide inner salt, λ_{max} (methanol): 663 nm, ϵ = 162 000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.43 (t, 1H, arom. CH), 8.33 (t, 1H, arom. CH), 8.22 (d, 1H, arom. CH), 8.05 (dd, 2H, CH), 7.78 (d, 1H, arom. CH), 7.67 (t, 1H, arom. CH), 7.58 (d, 1H, arom. CH), 7.49 (t, 1H, arom. CH), 7.35 (m, 2H, arom. CH), 7.19 (m, 1H, arom. CH), 6.61 (t, 1H, CH), 6.45 (d, 1H, CH), 6.24 (d, 1H, CH), 4.25 (b, 2H, NCH_2), 4.05 (b, 2H, NCH_2), 2.57 (b, CH_2), 2.04 (t, 2H, CH_2), 1.91 (s, 3H, CH_3), 1.81 (b, CH_2), 1.67 (s, 12H, CH_3), 1.55 (b, CH_2), 1.35 (b, CH_2), 1.27 (b, CH_2), HPLC: 95.8%.

S0223. (L) 2-[5-[1-(5-Carboxypentyl)-1,3-dihydro-3,3-dimethyl-2H-indol-2-ylidene]-penta-1,3-dienyl]-1,3,3-trimethyl-3H-indolium bromide: The dye was prepared according to the synthesis of compound C by the reaction of 1-(5-carboxypentyl)-2,3,3-trimethyl-indoleninium bromide with 2-(4-acetanilino-1,3-butadienyl)-1,3,3-trimethyl-indolium bromide; λ_{max} (methanol): 640 nm, ϵ = 184 000 M^{-1} cm^{-1}.

^{1}H NMR (DMSO-d_6): δ (ppm) 8.09 (t, 2H, CH), 7.50−7.00 (b, 8H, arom. CH), 6.85 (t, 1H, CH), 6.36 (d, 2H, CH), 6.30 (d, 1H, CH), 4.06 (t, 2H, NCH_2), 3.68 (s, 3H, CH_3), 2.41 (t, 2H, CH_2), 2.08 (t, 2H, CH_2), 1.73 (s, 12H, CH_3), 1.35 (b, CH_2), HPLC: 95.3%.

The symmetrical dyes S0438 and S0428 were prepared following the procedures described in earlier publications (*33*, *34*). The unsymmetrical dye S0301 was synthesized using a procedure described in the literature (*35*). The purity of all dyes was confirmed using a Merck-Hitachi analytical high performance liquid chromatography

[a] The molar extinction coefficients were determined for fluorophores dissolved in methanol at a concentration of 10 mg/L. The fluorescence lifetime τ_F, the fluorescence quantum yield Φ_F, the rate constant of fluorescence k_F, the nonradiative rate constant k_{NR}, as well as the anisotropy r and the rotational correlation time τ_R were determined as described in the materials and methods section. [b] Values were adopted from ref *17*. [c] Value in PBS was obtained from Amersham Bioscience. [d] Agrees very well with reported lifetime of Cy5 (1.0 ns) (*45*).

(HPLC) unit, equipped with a Purospher RP18e column (Agilent, Waldbronn, Germany) with acetonitrile/water (1:1, v/v) as eluent.

Peptide Synthesis. The SIINFEKL (MHC class I epitope) and EQKLISEEDL (myc-tag) peptides were synthesized using solid-phase Fmoc-chemistry on an automated peptide synthesizer for multiple peptide synthesis (RSP5032, Tecan, Hombrechtlikon, Switzerland). Fmoc-protected amino acids were purchased from Novabiochem (Läufelfingen, Switzerland). Standard chemicals for peptide chemistry were obtained from Fluka (Deisenhofen, Germany) and Merck (Darmstadt, Germany), solvents were p. a. grade. The SIINFEKL peptide was synthesized on Fmoc-Leu preloaded 2-chloro trityl resin (capacity 0.5 mmol/g; Senn Chemicals, Dielsdorf, Switzerland) using Fmoc-Lys(Dde)-OH as an orthogonally deprotectable building block. To protect the N-terminus from the reaction with dye, the resin bound peptide SIINFEK(Dde)L (15 μmol) was reacted with Boc_2O (39.3 mg, 180 μmol) and DIPEA (31 μL, 180 μmol) in DMF for 32 h. The Dde protecting group at the ϵ-amino group of lysine was cleaved off using 2% hydrazine hydrate in DMF (3 × 5 min). S0387 was covalently attached to the deprotected ϵ-amino group using 5 equiv of DIC (11.7 μL, 75 μmol), 5 equiv of HOBt (11.5 mg, 75 μmol) and 1.5 equiv of S0387 (15.9 mg, 22,5 μmol) in DMF twice for 16 h. The peptide was cleaved off the resin by treatment with 92.5% TFA, 2.5% TIS, 2.5% ethanedithiol, and 2.5% H_2O twice for 2 h, each. The crude peptide was precipitated by adding cold diethyl ether (−20 °C). Finally, the peptide was dissolved in tBuOH/H_2O 4:1 and lyophilized.

The c-myc peptide Aca-EQKLISEEDL-Aca-K−NH_2 was synthesized on Rink amide resin (Rapp Polymere, Tübingen, Germany). The dye S0387 was attached to the N-terminus. Coupling conditions as well as cleavage off the resin were performed as described for the SIINFEKL peptide.

The identity and purity of the peptides was determined using Maldi-TOF-MS (G2025A, Hewlett-Packard, Waldbronn, Germany) and by analytical RP-HPLC using a H_2O (0.1% TFA, solvent A)/ACN (0.1% TFA, solvent B) gradient on a Waters 600 System (Eschborn, Germany) with detection at 214 nm. The samples were analyzed on an analytical column (Nucleosil 100, 250 × 2 mm, C18 column, 5 μm particle diameter; Grom, Herrenberg, Germany), using a linear gradient from 10% B to 100% B within 30 min (flow rate: 0.3 mL/min). The calculated masses were 1631.1 and 2222.1 Da, experimental masses 1631.8 and 2222.8 Da [M+H^+] for SIINFEK(S0387)L and S0387-Aca-EQKLISEEDL-Aca-K-NH_2 respectively. The respective purities were >63 and >66%. The peptides were purified using preparative RP-HPLC (Nucleosil 300 C18 column, 10 μm particle diameter, 250 × 20 mm; Grom, Herrenberg, Germany) using H_2O (0.1% TFA)/ACN (0.1% TFA) gradient on a Waters 600 Multisolvent Delivery System (HPLC: >98%).

Photophysical Characterization. Fluorescence spectra were recorded on an LS50B (Perkin-Elmer, Rodgau-Jügesheim, Germany) and a SPEX Fluorolog 222 spectrofluorometer (Jobin Yvon Horiba, Edison, NJ). The spectra were corrected for the sensitivity of the detection system. Absorption spectra were measured with an Ultrospec 2000 (Pharmacia Biotech, Cambridge, UK).

Fluorescence lifetimes were measured on a SPEX Fluorolog 112 fluorometer. Fluorescence was excited by a stabilized HAMAMATSU C4725 diode laser, which provides pulse widths (full width at half-maximum, fwhm) of 64 ps at the excitation wavelength 653 nm. Fluorescence was detected with an R928 photomultiplier tube (Hamamatsu Photonics, Shizuoka, Japan). The resulting signals were fed into an ORTEC 457 time-to-amplitude converter via an ORTEC 454 timing filter amplifier and an ORTEC 937 picosecond timing discriminator (AMETEK, Meerbusch, Germany). The fwhm of the resulting instrument response was Δt = 600 ps. Fluorescence decay times were obtained by fitting the decay curves to single exponential decays. Fitting to sums of exponentials did not improve the quality of the fits.

The quantum yields Φ_{sample} of the dyes in PBS were determined using eq 1

$$\Phi_{sample} = \Phi_{reference} \frac{I_{sample}}{I_{reference}} \frac{[1 - 10^{-E_{reference}}]}{[1 - 10^{-E_{sample}}]} K \quad (1)$$

where E_{sample} and E_{ref} are the absorbencies of sample and reference, respectively. I_{sample} and I_{ref} are the integral fluorescence intensities. K is a correction factor accounting for the difference in the steady-state fluorescence anisotropies of sample and reference, r_{sample} and r_{ref}, respectively (Table 1). K is given by eq 2, where G is the ratio of the sensitivities of the detection system for vertically and horizontally polarized light, $G = S_v/S_h$. A is the ratio of the quantum fluxes of horizontally and vertically polarized components in the exciting light, $A = I_{exc,h}/I_{exc,v}$.

$$K = \frac{r_{\text{ref}}\left[\frac{3G}{1+A} - (G+1)\right] + (G+1)}{r_{\text{sample}}\left[\frac{3G}{1+A} - (G+1)\right] + (G+1)} \qquad (2)$$

Cy5 in PBS served as the reference with $\Phi_{\text{reference}} = 0.27$ (Amersham Bioscience Europe, Freiburg, Germany). Measurements were performed at room temperature (20 °C) under magic angle conditions (polarizer vertical, analyzer at 54.7° from vertical), i.e., $A \approx 0$ and $G = 2G'$, where $G' = 0.30$ is the value obtained without polarizer in the detection system.

Relative photostabilities were determined by irradiating 10 nM dye solutions in closed capillary tubes using the 633 nm HeNe Laser of a ConfoCor2 fluorescence correlation microscope (Carl Zeiss, Jena, Germany). The fluorescence quantum yields of Cy5 and S0387 in glycerol were measured immediately after preparation of the solutions, because both absorbance and fluorescence intensity of the solutions decreased quickly, even in the dark.

Fluorescence Correlation Spectroscopy. FCS measurements were carried out on a ConfoCor2. For excitation, the light of a 633 nm HeNe-laser was reflected into the sample via an HFT633 main beam-splitter, and fluorescence was detected using an LP650 emission filter. The dyes were dissolved in methanol to a concentration of 300 μM and further diluted to working concentrations of 10 nM either in methanol or PBS, pH 7.4. Twenty autocorrelation functions were recorded over 10 s each. The prebleach time was set to zero to include initial photobleaching in the count-trace and the laser power was 84 kW/cm^2. Autocorrelation functions not affected by initial photobleaching were fitted from autocorrelation times of 1 μs to 3.4 s with an algorithm describing one diffusing molecule (*28*) using the ConfoCor2 software (eq 3).

$$G(\tau) = 1 + \frac{1}{N_{\text{App}}} \cdot \frac{1 - T + Te^{-\tau/\tau_{tr}}}{(1-T)} \cdot \frac{1}{\left(1 + \frac{\tau}{\tau_{\text{D}}}\right)\sqrt{1 + \left(\frac{\omega_{xy}}{\omega_z}\right)^2 \frac{\tau}{\tau_{\text{D}}}}} \qquad (3)$$

N_{App} is the apparent number of molecules affected by scattered light, τ_{D} is the diffusional autocorrelation time, and ω_{xy} and ω_z are the radii of the detection volume in the optical plane and along the optical axis, respectively (defined by the isocontour of e^{-2} detection efficiency relative to the center of the confocal detection volume). T denotes the equilibrium molar fraction of fluorophores in a transient nonfluorescent ("dark") state (assumed, to a first approximation, equal for bound and unbound dye-labeled peptide (see below)) and τ_{T} is the triplet lifetime of the dark state. In this work, T and τ_T account for the sum of all intramolecular deactivation processes which lead to a dark state.

Peptide antibody interactions were measured with 8.5 nM c-myc peptide (S0387-Aca-EQKLISSEDL-Aca-K-NH_2) and 260 nM of the monoclonal anti-c-myc antibody (clone 9E10, Dianova, Hamburg, Germany) in HBS using 384-well glass bottom microplates (MMI, Glattburg, Switzerland). To prevent unspecific binding of peptide and antibody, before use every well was blocked with 1% BSA (Sigma, Taufkirchen, Germany) in HBS for 12 h on ice followed by washing with HBS containing 0.2% BSA. The concentration of the antibody was derived from information provided by the supplier. The FCS data obtained for peptide antibody interactions were fitted with an algorithm describing independent species of freely diffusing molecules, assuming that all fluorescent molecules have the same fluorescence efficiency (eq 4).

$$G(\tau) = 1 + \frac{1}{N_{\text{App}}} \cdot \frac{1 - T + Te^{-\tau/\tau_{tr}}}{(1-T)} \cdot \left(\sum_j Y_j \frac{1}{\left(1 + \frac{\tau}{\tau_{\text{D},j}}\right)\sqrt{1 + \left(\frac{\omega_{xy}}{\omega_z}\right)^2 \frac{\tau}{\tau_{\text{D},j}}}} \right) \qquad (4)$$

Y_j is the contribution of the jth fluorescent molecule and $\tau_{D,j}$ is the respective diffusional autocorrelation time.

MHC Peptide Binding. Murine RMA-S cells expressing the H-2k^b MHC class I molecule (obtained from S. Stevanović) (*36*) were grown in a 5% CO_2 humidified atmosphere at 37 °C in RPMI 1640 medium (PAN Biotech, Aidenbach, Germany), supplemented with 10% fetal calf serum (PAN Biotech), 100 U/mL penicillin, and 0.1 mg/mL streptomycin (Biochrom, Berlin, Germany). Cells were passaged every third to fourth day by a 1:5 dilution with fresh medium.

To determine peptide binding to MHC class I molecules, cells were seeded at a density of 40 000 per well in 96-well plates (Nunc, Wiesbaden, Germany) and kept 16 h at room temperature (25 °C) in RPMI 1640 medium containing fetal calf serum to allow the accumulation of peptide free MHC class I molecules on the plasma membrane (*37*, *38*). Cells were then incubated for 1 h with the S0387-labeled SIINFEKL peptide (SIINFEK-(S0387)L) at concentrations of 1 and 10 nM and, alternatively, with a mixture of the labeled peptide and a 100-fold excess of unlabeled peptide in serum free RPMI medium. Cells were washed four times with PBS followed by confocal laser scanning microscopy and flow cytometry. Confocal fluorescence images were recorded on an inverted LSM510 laser scanning microscope (Carl Zeiss, Göttingen, Germany). S0387 was excited with a helium−neon laser at 633 nm and fluorescence detected with an LP650 long-pass filter. Flow cytometry was performed on a FACSCalibur flow cytometer (Becton Dickinson, Heidelberg, Germany) using a 633 nm HeNe-laser for excitation. Vital cells were gated based on forward light and side scatter. Cells, not incubated with any peptide, were used to set the sensitivity of the fluorescence detector to the appropriate level (histogram peak in the first decade of the 4 decade log scale).

RESULTS AND DISCUSSION

Synthesis and General Characterization. The synthesis of the substituted pentamethine indocyanines (Figure 1) followed published protocols with modifications. A quaternary indolium salt having an acidic methyl group was reacted with malonaldehyde dianil hydrochloride followed by condensation of the intermediate with a second indolium salt under basic conditions in ethanol. Two of the compounds were symmetrical (S0428 and S0438), while the remaining dyes were unsymmetrical with respect to the substituents of the indolenine groups. For the asymmetric indocyanines, the second step resulted in the formation of a mixture of the symmetric indocyanine and the desired product which was purified by column chromatography on silica gel. The purity of all compounds was confirmed by analytical HPLC, and

the structures of the dyes were verified using ^{1}H NMR spectroscopy. Except for S0694 (purity, 88%), the purity of all other compounds exceeded 95%. All compounds except S0223 were readily soluble in methanol and no precipitation occurred upon dilution of the methanol stock solutions into water or PBS.

To render these compounds compatible with the labeling of biomolecules, each derivative contained at least one carboxyl group for covalent attachment to primary amines. All compounds except S0223 were substituted with at least one sulfonic acid group to increase water solubility. The compounds S0387, S0436, S0693, and S0694 were synthesized to assess the dependence of the photophysical characteristics on substitutions of the aromatic system with substituents of the auxochromic series. Compounds S0428 and S0438 were prepared to address the effect of substitutions at the meso-position of the pentamethine chain on isomerization. Rotation around one of the bonds of the pentamethine chain is known as an effective mechanism of radiationless loss of excitation energy of the pentamethine compounds. With S0301 and S0430 the effect of extensions of the aromatic systems were investigated.

Photophysical Characteristics. *Absorption, Excitation, and Emission Spectra.* The absorption maxima of the dyes were in a range of 640−666 nm around the absorption maximum of Cy5 at 648 nm (Table 1). Replacement of both sulfonic acid groups on the aryl rings by hydrogen atoms (S0436) led to a hypsochromic shift of 5−8 nm compared to Cy5. Substitution of only one sulfonic acid group by hydrogen (S0387) or fluorine (S0694) caused a weak hypsochromic shift by 2 nm, while substitution by a methyl group (S0693) led to a small bathochromic shift by 3 nm. Introduction of a methyl group at the X_3 position in the polymethine chain (S0438) caused a slight hypsochromic shift, while a significant bathochromic shift was observed for a chlorine substituent (S0428). The extension of the aromatic system shifted the absorption and emission maxima to the red by about 15 nm (S0301 and S0430). The Stokes shifts of all compounds were in the range between 16 and 26 nm, the smallest values being obtained for the dyes that carry a substituent in the X_3 position.

Fluorescence Quantum Yields and Lifetimes. After excitation of the indocyanine dyes to the excited singlet state, deactivation by fluorescence competes with nonradiative dissipation of energy (Figure 2). Internal conversion to the ground state with the rate constant k_{IC}, intersystem crossing to the triplet state (with rate constant k_{ISC}), and transition into a partially twisted transition state with rate constant k_{PERP} (*39*) from where trans−cis isomerization occurs are possible mechanisms for nonradiative deactivation (*23*, *40*) that occurs with the rate constant k_{NR} (eq 5). k_{ISC} is negligible in carbocyanines without heavy atoms ($\Phi_{ISC} < 10^{-3}$) (*40*, *41*).

$$k_{NR} = k_{IC} + k_{PERP} + k_{ISC} \quad (5)$$

The dyes with extended aromatic systems (S0301 and S0430) had the lowest fluorescence quantum yields ($\Phi_F = 0.08$), and S0387 and Cy5 had the highest ones with $\Phi_F = 0.18$ and $\Phi_F = 0.27$, respectively (Table 1). The latter two compounds also had the longest fluorescence lifetimes τ_F of 0.70 and 1.0 ns.

To get a deeper insight into the relationship of structure and photophysics of the dyes, the radiative rate constants k_F and the rate constants of nonradiative deactivation k_{NR} were calculated from the fluorescence quantum yields Φ_F and the fluorescence lifetimes τ_F according to eqs 6 and 7, respectively (Table 1).

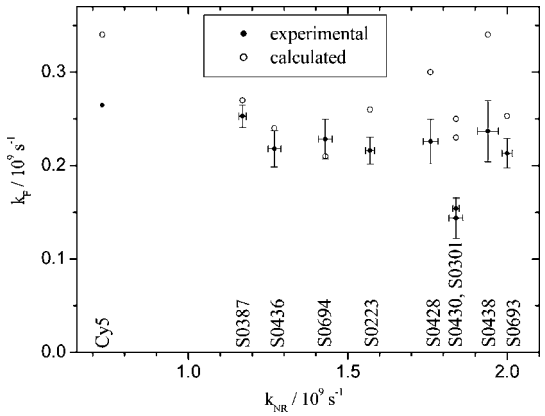

Figure 3. Radiative and nonradiative rate constants for the cyanine dyes in PBS. Experimental values were obtained from fluorescence quantum yields and lifetimes (Table 1) using eqs 6 and 7. Calculated values were obtained from absorption spectra using the Strickler−Berg equation (eq 8).

$$k_F = \frac{\Phi_F}{\tau_F} \quad (6)$$

$$k_{NR} = \frac{1 - \Phi_F}{\tau_F} \quad (7)$$

A plot of k_F vs k_{NR} revealed that the differences in fluorescence quantum yields and decay times between the dyes were mainly due to the variations in k_{NR}, while k_F varied only very little (Figure 3). The values of k_{NR} span a range between 0.73×10^9 and 2.0×10^9 s^{-1}, with Cy5 showing the lowest nonradiative rate constant of all dyes followed by S0387.

To identify the specific nonradiative process leading to this variation in k_{NR}, the effect of solvent viscosity on fluorescence quantum yields and lifetimes of Cy5 and S0387 was investigated. The increase of the viscosity from 1 cPoise in PBS to 1340 cPoise in glycerol should strongly reduce k_{PERP}, the rate constant of photoinduced twisting about the bonds in the polymethine chain (*42*, *43*). In glycerol, the fluorescence quantum yields increased to $\Phi_F = 0.60$ and $\Phi_F = 0.59$ for Cy5 and S0387, respectively. For the fluorescence lifetimes $\tau_F = 1.93$ ns and $\tau_F = 1.90$ ns were obtained. While the radiative rate constants increased less than 20% with respect to the values obtained in PBS (Table 1), the nonradiative rate constants decreased by more than 70% to $k_{NR} = 0.21 \times 10^9$ s^{-1} and $k_{NR} = 0.22 \times 10^9$ s^{-1} for Cy5 and S0387, respectively. From the almost identical values of k_{NR} for both dyes in glycerol, we concluded that the difference in k_{NR} of Cy5 and S0387 in PBS was mainly due to the different rates k_{PERP} of bond twisting in the excited state. Assuming that k_{PERP} in glycerol is negligible for both dyes, values of $k_{PERP} = 5.3 \times 10^8$ s^{-1} and $k_{PERP} = 9.6 \times 10^8$ s^{-1} were calculated for Cy5 and S0387 in PBS, respectively.

This result has important consequences for the application of these dyes. In environments of high viscosity, as they are encountered for fluorophores conjugated to proteins, the differences between the photophysical properties of Cy5 and S0387 are negligible.

In summary, our results provide information on the effect of substitution pattern on k_{NR} for three types of substitutions: (i) k_{NR} increases in the series Cy5 < S0387 < S0436 < S0694 < S0693. Obviously, k_{NR} increases with the position of X_1- and X_5-substituents in the auxochromic

series along $-SO_3^- < -H < -F < -CH_3$. This finding agrees with the results obtained on indocarbocyanine derivatives by Murphy and Schuster (*25*), who found decreasing k_{PERP} values with increasing -M-effect of the terminal substituents as quantified by their Hammett parameters. Originally sulfonic acid groups were introduced into cyanine dyes to increase the water solubility of these compounds (*17*). Our results show that in addition to increasing the solubility these substituents also improve the fluorescent properties by decreasing k_{NR}. (ii) Extension of the aromatic system by annellation of benzene rings increases the nonradiative rate constants. (iii) Introduction of substituents into the polymethine chain at the X_3 position (S0428, S0438) resulted in relatively high nonradiative rate constants of $k_{NR} \geq 1.76 \times 10^9\ s^{-1}$, independent of the auxochromic effect of the substituent. This increase in k_{NR} is propably caused by the enhancement of bond torsion due to steric crowding as described by Khimenko et al. (*40*).

The radiative rate constants k_F of most of the dyes were in the relatively small range between $0.21 \times 10^9\ s^{-1}$ and $0.27 \times 10^9\ s^{-1}$ (Figure 3). Only for the aryl substituted dyes S0430 and S0301 significantly smaller values of $k_F = 0.16 \times 10^9\ s^{-1}$ were obtained. To elucidate the reasons for this anomaly, the radiative rate constants k_F (calc) were calculated from the absorption spectra using the Strickler−Berg relationship (eq 8) and compared with the experimental values.

$$k_F\,(\text{calc}) = 2.8825 \times 10^{-9} \text{cm}^2\ \text{s}^{-1}\text{mol}^{-1} \cdot n^2 \cdot \langle \tilde{\nu}_F^{-3} \rangle^{-1} \cdot \int \epsilon(\tilde{\nu}) d\ln\tilde{\nu} \quad (8)$$

where n is the refractive index of the solution, $\tilde{\nu}_F$ is a wavenumber of the fluorescence spectrum, and $\epsilon(\tilde{\nu})$ is the extinction coefficient.

For most compounds the Strickler−Berg equation resulted in radiative rate constants larger than those determined experimentally. For S0387, S0436, and S0694, the deviation was close to or within the margin of error. For S0223 and S0693, the deviation was less than 20%. Significantly larger deviations were found for the dyes with extended aromatic systems (S0301 and S0430), with substituents in the polymethine chain (S0428 and S0438) and for Cy5. The k_F values calculated for S0301 and S0430 were in the range of most of the other compounds, whereas the values calculated for S0428 and S0438 exceeded those of all other compounds, due to the large extinction coefficients of the X_3-substituted dyes.

The most likely explanation for the discrepancies between calculated and experimental k_F values are fast conformational changes upon excitation of the dyes, which are not accounted for by eq 8. However, although care was taken to avoid any aggregation and adsorption effects in the determination of the fluorescence quantum yields, the presence of nonfluorescent aggregates as another possible reason for this discrepancy cannot be excluded completely. The large difference between the experimental and calculated rate constants of fluorescence observed for Cy5 may be due to a too large extinction coefficient provided by the supplier.

Rotational Diffusion. The rotational correlation times τ_R were calculated from the fluorescence lifetime τ_F and the steady-state anisotropy r according to eq 9.

$$\tau_R = \frac{\tau_F}{\frac{r_0}{r} - 1} \quad (9)$$

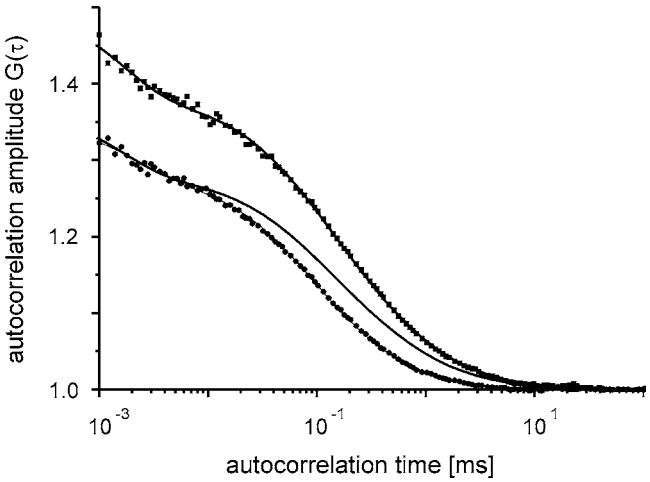

Figure 4. Autocorrelation functions and fits for an S0387 labeled c-myc peptide in the absence (bottom curve, fit for one diffusing species) and presence of an anti-myc-tag antibody (top curve, fit for two diffusing species). Center curve: Fit to the autocorrelation function in the presence of antibody, normalized to the amplitude of the autocorrelation function in the absence in order to better illustrate the shift of the diffusional autocorrelation time. The laser power was 84 kW/cm^2.

where the value observed in glycerol, $r = 0.38$, was inserted for the limiting anisotropy, r_0. The values of τ_R for the free dyes in PBS were in a narrow range of 0.37 ns for S0223 and 0.61 ns for Cy5. They were mainly determined by the hydrodynamic volume of the substituents in the X_1 and X_5 positions.

Applications in FCS, Fluorescence Microscopy, and Flow Cytometry. *Fluorescence Correlation Spectroscopy.* To determine the suitability of the dyes for single molecule detection, fluorescence correlation spectroscopy was applied to fluorophores dissolved in methanol and diluted with PBS. For S0223, aggregates interfered with the acquisition of autocorrelation functions. For all other dyes the autocorrelations could be fitted with a function containing one diffusion term and one exponential term, the latter accounting for the formation of nonfluorescent states by all intramolecular deactivation processes, e.g., intersystem crossing (data not shown). Due to the limited temporal resolution of our instrument, no detailed analysis of this fast process was possible as presented by Widengren and Schwille (*23*). Autocorrelation functions with low noise were obtained for Cy5, S0693, S0694, S0387, S0428, and S0438. In contrast, for S0301, S0430, and S0436 the acquisition of the autocorrelation functions was complicated by the low molecular brightness. An important requirement for the application of fluorescent dyes in fluorescence microscopy and FCS is a high photostability. Therefore, the photostability of S0387 was compared to the photostability of Cy5. Aqueous solutions of both dyes in glass capillaries were illuminated with a focused HeNe laser at 633 nm and fluorescence was recorded over time (data not shown). Both dyes had comparable photostabilities.

Due to its favorable photophysical properties, S0387 was further characterized as a reporter group in biochemical and cellular applications. First S0387 was used in the detection of molecular interactions in vitro by FCS measurements of an S0387 labeled c-myc peptide (S0387-Aca-EQKLISEEDL-Aca-K-NH_2) incubated with an anti-c-myc antibody (Figure 4). From the autocorrelation curve of S0387 and c-myc-S0387 a diffusion coefficient of $1.3 \times 10^{-6}\ cm^2\ s^{-1}$ was calculated for the dye-labeled peptide, assuming a diffusion coefficient of $2.5 \times 10^{-6}\ cm^2\ s^{-1}$ (*44*)

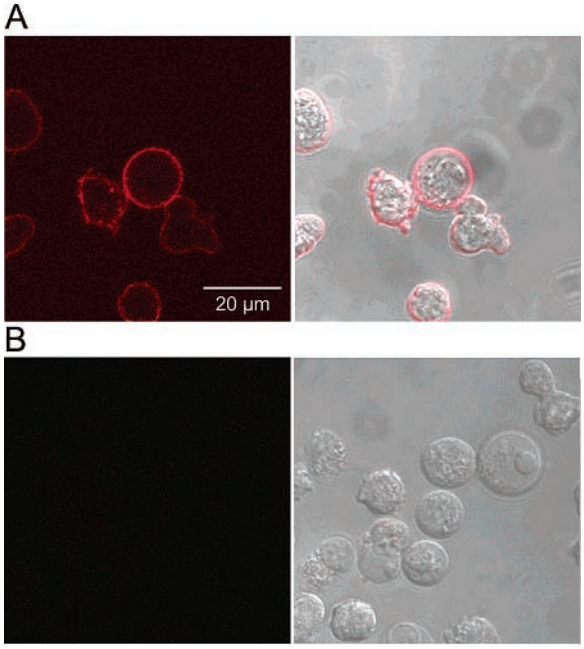

Figure 5. Receptor binding of an S0387 labeled peptide. (A) RMA-S cells were incubated with 10 nM S0387 labeled SIINFEKL for 1 h followed by intensive washing with PBS. Images were acquired by confocal laser scanning microscopy. (B) Cells incubated with 10 nM S0387 labeled SIINFEKL peptide in the presence of a 100-fold excess of unlabeled SIINFEKL peptide. One confocal section is shown in each case.

for the free dye molecule. After incubation of the free c-myc-S0387-peptide with anti-c-myc antibodies, an equilibrium between free and antibody-bound peptide was observed. The antibody bound peptide was detected as a second diffusive component in the autocorrelation function with a longer diffusion time compared to the unbound peptide resulting in a diffusion coefficient of 3.5 $\times$ 10^{-7} cm^2 s^{-1}.

Flow Cytometry and Fluorescence Microscopy. Nonspecific binding of fluorophores to proteins and cellular components is a major concern in the development of new fluorophores for life science applications. The fluorophore was attached to the MHC class I binding peptide SIINFEKL (SIINFEK(S0387)L) by solid-phase chemistry after selective deprotection of the ϵ-amino-group of the lysine side chain. The activation of the carboxyl group was carried out in situ using DIC and HOBt. Complete turnover of the amino group was achieved by coupling twice with only 1.5 times excess of dye. The fluorophore was fully resistant to the acidic conditions during the cleavage of the peptide from the resin and workup procedure. Incubation of RMA-S cells expressing empty MHC class I molecules (H-$2k^b$) on the cell surface with S0387-labeled SIINFEKL resulted in a fluorescence confined to the cell surface (Figure 5). Using flow cytometry fluorescence could be detected from cells incubated in the presence of as little as 1 nM peptide (data not shown). Incubation in the presence of a 100-fold excess of unlabeled competitor peptide reduced the fluorescence to background levels.

ACKNOWLEDGMENT

We thank Günther Jung for excellent facilities in peptide chemistry and instrumental analytics, Nicole Sessler for expert technical assistance in peptide synthesis, Lisa Neumann for proofreading the manuscript, and Manfred Claassen for technical assistance in FCS measurements. Noninvasive Imaging of Quantum Dots in Mice

Byron Ballou,*[,†,‡] B. Christoffer Lagerholm,[†] Lauren A. Ernst,[†] Marcel P. Bruchez,[§] and Alan S. Waggoner[†,‡]

Molecular Biosensor and Imaging Center, and Department of Biological Sciences, Carnegie Mellon University, 4400 Fifth Avenue, Pittsburgh, Pennsylvania 15213 and Quantum Dot Corporation, 26118 Research Road, Hayward, California 94545. Received August 29, 2003; Revised Manuscript Received November 23, 2003

Quantum dots having four different surface coatings were tested for use in in vivo imaging. Localization was successfully monitored by fluorescence imaging of living animals, by necropsy, by frozen tissue sections for optical microscopy, and by electron microscopy, on scales ranging from centimeters to nanometers, using only quantum dots for detection. Circulating half-lives were found to be less than 12 min for amphiphilic poly(acrylic acid), short-chain (750 Da) methoxy-PEG or long-chain (3400 Da) carboxy-PEG quantum dots, but approximately 70 min for long-chain (5000 Da) methoxy-PEG quantum dots. Surface coatings also determined the in vivo localization of the quantum dots. Long-term experiments demonstrated that these quantum dots remain fluorescent after at least four months in vivo.

INTRODUCTION

Quantum dots (QDs) are stable, bright fluorophores that, under ideal conditions, can have high quantum yields, narrow fluorescence emission bands, high absorbency, very long effective Stokes shifts, high resistance to photobleaching, and can provide excitation of several different emission colors using a single wavelength for excitation (*1*). Because QDs have size-tunable narrow emission bands, in addition to single-wavelength excitation, QDs are suitable for detecting multiple ligands in a single experiment. Multiplexing using several colors and intensities of quantum dots to code assay supports ("barcoding") would allow the detection of many distinct ligands in single experiments (*2*−*4*). Moreover, QDs may be readily imaged using two-photon microscopy in vitro and in vivo (*5*). However, commercially available materials do not yet offer many of the potential advantages of QDs. The chief hindrances to routine use have been difficulties in reproducible production of QDs in quantity and the lack of suitable surface coatings that maintain high quantum yields, confer stability in aqueous solution, and can be chemically manipulated for biological applications.

Bruchez et al. (*6*) and Chan and Nie (*7*) first reported the use of quantum dot conjugates for labeling biological specimens. In these experiments, QDs were coated with silica and mercaptoacetic acid layers, respectively. Both groups showed specific labeling by covalent coupling of ligands to these surfaces. Subsequently, several authors have shown labeling of whole cells and tissue sections using several different surface modifications of QDs (*1*, *8*−*11*). A variety of colors of Qdot conjugates for immunospecific labeling are now available commercially from Quantum Dot Corporation (www.qdots.com).

[§] Quantum Dot Corporation.

Quantum dot preparations reported to date have not been optimized for in vivo studies. For in vivo imaging, QDs must have adequate circulating lifetime, must show minimal nonspecific deposition, and must retain their fluorescence for a sufficiently long time. We report that QDs coated using an amphiphilic poly(acrylic acid) polymer are stable in vivo, that changing surface chemistry prolongs circulating lifetime and reduces nonspecific deposition in vivo, that targeting to tissues may be observed by noninvasive whole body fluorescence, and that QDs may be visualized in tissue sections by light and electron microscopy many weeks after injection.

MATERIALS AND METHODS

Quantum Dots. Quantum dots were supplied by Quantum Dot Corporation, Hayward, CA 94545. Core−shell zinc sulfide-cadmium selenide QDs emitting at 606, 635, 645, and 655 nm were coated with an amphiphilic poly(acrylic acid) polymer (amp QDs (*9*)) or the same coating conjugated with methoxy- or carboxy-terminated poly(ethylene glycol) amine (mPEG-750 QDs, mPEG-5000 QDs, COOH−PEG-3400 QDs). Quantum dots have spectra that exhibit an absorption peak at a wavelength slightly shorter than the emission wavelength ("longest wavelength peak.") At wavelengths shorter than this peak, absorbance first declines, then rises steeply at shorter wavelengths, with no definite peak. Absorption and excitation spectra are nearly identical; thus QD's may be excited at any wavelength shorter than the emission maximum (e.g., (*6*)). QD concentration was determined by absorbance using appropriate extinction coefficients (for example, 800 000 M^{-1} cm^{-1} at 638 nm for the 655 materials and 650 000 M^{-1} cm^{-1} at the longest wavelength peak for the 605 materials). These values agree with concentrations measured by a variety of distinct techniques including elemental analysis, stoichiometric gel shift assays, and fluorescence correlation spectroscopy.

Quantum Yield Determination. Quantum yields were measured by comparing integrated fluorescence intensity of absorbance matched solutions in an intensity

calibrated Ocean Optics S2000 fluorimeter. The absorbance of the solutions was fixed at 0.03 ± 0.003 AU at the excitation wavelength. Red QDs (576−655) were compared to Rhodamine 101 in methanol (QY 0.95) with excitation at 530 nm. The integrated fluorescent intensities were scaled according to the absolute absorbance of the sample and the standard, and the ratio of these values multiplied by the reported standard quantum yield gives the absolute sample quantum yield. Properties of the quantum dots used in this paper are shown in Table 1.

PEG Conjugation. Poly(ethylene glycol) derivatives were acquired from Shearwater Polymers Corp (Huntsville, AL 35806; COOH−PEG-3400-amine, mPEG-5000-amine) and from Sigma-Aldrich (Milwaukee, WI 53201; mPEG-750-amine). Other reagents were supplied by Sigma. These reactions have been carried out at a variety of scales, but the 5 mL scale reaction is described here for the mPEG-750 amine. Quantum dots were dispersed at 1.0 uM in 50 mM sodium borate, pH 8.0, with a molar ratio of 2000:1 of PEG-amine (7.5 mg). These materials were then reacted with a 1500:1 molar ratio of *N*-dimethylaminopropyl-*N*′-ethylcarbodiimide (EDC, 1.4 mg) for 2 h followed by purification using a 100 kDa centrifugal ultrafiltration device (Vivascience, Edgewood, NY).

The number of PEG-amine molecules coupled to each quantum dot was determined by conducting the coupling reaction in the presence of an excess of PEG-amine, then reacting the residual amines with fluorescamine reagent. This reagent produced a blue fluorescent species that was monitored at 490 nm and compared to the signal produced from the materials without EDC activation. The % retained signal corresponds to the remaining excess amine that did not react with the quantum dots. The difference was assumed to have completely reacted with the quantum dots, so the concentration of consumed amines (initial concn × (final signal/initial signal)) divided by the concentration of quantum dots yielded the number of amines reacted per quantum dot.

For all PEG-substituents, we attempted to saturate available carboxyl groups. The levels of substitution were approximately 300 residues/QD for mPEG-750, and 100 residues/QD for COOH−PEG-3400 and mPEG-5000.

The final materials were filtered through a 0.2 μm filter unit and prepared at an appropriate concentration for tail vein injection prior to use. Each dose was adjusted to 0.14 M NaCl by addition of 1.4 M NaCl just prior to use.

Mice. Balb/C and athymic nude mice were obtained from Harlan Sprague Dawley (Indianapolis, IN, 46229); mice were used at ages from 6 to 12 weeks without any noticeable effect of age. For all results shown in this paper, QDs (360 pmol) in 200 μL normal saline were injected into the tail veins of mice (typically 18 g; thus 180 nM QD, 20 pmol QD/g animal weight). In other experiments, doses ranging from 50 to 500 pmol in 50−200 μL normal saline were administered, with no significant dose effect on circulating time or distribution. Mice were anesthesized for imaging either by pentobarbital intraperitoneally to effect, or by inhalation anesthesia using isofluorane (*12*). For timed measurements, animals were first anesthetized, then injected while under the camera. To compare whole-blood lifetimes to lifetimes derived from images, mice were bled by saphenous venipuncture (*13*). All operations on animals were in accord with institutional animal use and care regulations.

Macro Imaging. Whole body images were acquired on a Photometrics (Tucson, AR) C258 cooled CCD camera equipped with a custom filter holder and lens adapter (Bioptechs, Butler, PA 16002). Animals were illuminated using four 250-W quartz-halogen illuminators (Cuda Products, Jacksonville, FL 32217) equipped with half-inch fiber optic bundles terminating in filter holders (Edmund Industrial Optics, Barrington, NJ 08007). Excitation filters were 460/50 nm, and emission filters were 20 nm wide band-pass filters, centered on the emission maxima of the QDs. All filters were provided by Chroma Technologies (Brattleboro, VT. 05301). Imaging times varied with time postinjection and were adjusted on the fly to give maximum dynamic range, but were typically 0.5 s; for time series, three images were acquired in rapid succession at 1-min intervals; acquisition times of 0.2, 1.0, and 5 s were normally used to bracket the large range in intensities between different sites of deposition.

Microscopy. Light and fluorescence images were acquired on an inverted Zeiss Axiovert 135TV microscope (Zeiss, Thornwood, NY 10594) equipped with a Hamamatsu ORCA II cooled CCD camera (Hamamatsu, Bridgewater, NJ 08807). Fluorescence images of quantum dots were acquired with a 440/20 nm excitation filter and appropriately selected 20 nm wide band-pass emission filters, centered on the emission maxima of the quantum dots.

Tissue samples for light microscopy were 10 μm frozen sections. Sections were cut on a cryostat, fixed for 10 s in methanol, dipped for 1 min in Gill's 2X hematoxylin, briefly rinsed and then developed in Scott's solution.

Electron Microscopy. Tissue specimens were fixed in 2% glutaraldehyde buffered with 0.1 M sodium cacodylate, pH 7.4. The tissue was washed with 3 changes of 0.1 M sodium cacodylate buffer, pH 7.4, and postfixed for 1 h in a solution containing 1% OsO4 buffered with 0.1 M sodium cacodylate, pH 7.4, then washed in three changes of dH_2O and dehydrated in EtOH. Propylene oxide was used as a transitional solvent. The tissue was infiltrated overnight in a 1:1 mixture of Epon-Araldite and propylene oxide. The following day, the 1:1 mixture was removed and replaced with 100% Epon-Araldite. The specimens were infiltrated an additional 8 h, placed in embedding capsules, and polymerized for 48 h at 60 °C.

The embedded specimens were thin sectioned (0.1 μm), then stained with 1% uranyl acetate and Reynolds lead citrate. The sections were viewed on a Hitachi H-7100 TEM operating at 50 kV. Digital images were obtained using an AMT Advantage 10 CCD Camera System and NIH Image software.

Image Analysis. All image analysis was performed in ImageJ (http://rsb.info.nih.gov/ij/) while curve fitting was done using Mathematica (Wolfram Research, Champaign, IL; 61820; http://www.wolfram.com/). To analyze circulating lifetimes from bleeds, macro fluorescence images were acquired using ~20 μL blood samples in 1 mm × 0.1 mm bore rectangular glass capillary tubes (VitroCom, Mountain Lakes, NJ 07046). Fluorescence intensity was measured using a rectangular region of interest over the body of the capillaries; background was determined using an identical region of interest over an adjacent noncapillary area. The mean fluorescence intensity was determined and the resulting background corrected data was curve fit to single exponentials.

To obtain circulating lifetimes by whole mouse imaging, mice were imaged at 1 min intervals postinjection for 1−3 h (Figure 1). Lifetime data were then generated by selecting nine 2 × 2 pixel regions of interest per mouse, where the regions of interest were selected to coincide with conspicuous blood vessels, and by tracking them through time. Background due to intrinsic fluorescence was normally negligible; subtraction of fluorescence in adjacent tissue made little or no difference to the slope of the intensity versus time plot. The resulting background-corrected data was fitted to one- and two-exponential curves with the two-exponential curve providing a better fit for mPEG-750 QDs, as evidenced by F-statistics. However, mPEG-5000 QD data showed no improvement using a two-exponential fit as compared to a one-exponential fit.

RESULTS

Core−shell cadmium selenide−zinc sulfide quantum dots having maximum emission wavelengths at 606, 630, 645, and 655 nm were supplied by Quantum Dot Corporation. The core−shell size (and hence emission wavelengths) of the QDs had no significant effects on tissue deposition or circulating lifetimes. Four different surface coatings were used: an amphiphilic poly(acrylic acid) primary coat (amp) that stabilizes the quantum dots in aqueous solution (*9*), and quantum dots having the amp coating further coupled to methoxy-terminated poly(ethylene glycol), molecular weight 750 (mPEG-750), carboxy-terminated poly(ethylene glycol), molecular weight 3400 (COOH−PEG-3400), or methoxy-terminated poly(ethylene glycol), molecular weight 5000 (mPEG-5000).

We compared the amp-QDs to the three differently substituted PEG-QDs by noninvasive imaging and repetitive bleeds to determine whether PEG-substitution would affect the circulating lifetime. Immediately after intravenous injection, fluorescence from all QD emission wavelengths and surface coatings is easily seen in the superficial vasculature. Subsequently, QDs are seen to deposit in liver, skin, and bone marrow in a surface coating dependent manner. By 1 h postinjection, QDs having amp-, mPEG-750-, and COOH-PEG-3400 coatings are cleared from the circulation, while mPEG-5000 QDs remain visible in circulation for at least 3 h (Figures 1 and 2, and see Supporting Information, which includes a Quicktime movie of in vivo distribution of the mPEG-750 and mPEG-5000 quantum dots). Circulating lifetimes (Table 1) were 12 min or less for the amp, mPEG-750, and COOH-PEG-3400 QDs, while the mPEG-5000 QDs had a much longer circulating lifetime (50−100 min by venipuncture, 140 min by imaging). There was no statistically significant difference between nude and normal mice in the circulating lifetime of QDs. The circulating lifetime obtained by noninvasive imaging of whole animals was consistently longer than that obtained by venipuncture; this is caused mostly by the presence of extravasated QD's in surrounding tissue (data not shown.) Due to an erratic pattern of early deposition in the skin by amp and COOH−PEG-3400 QDs, only early lifetime data (<5 min) could be derived from images. Deposition in the skin was initially punctate, then spread over most of the surface. Most of the skin fluorescence disappeared by 24 h postinjection.

Necropsy at 24 h corroborated and extended the localization of mPEG-750 (Figure 3) and mPEG-5000 (Figure 4) quantum dots seen by noninvasive imaging. Figures 3A and 4A show noninvasive fluorescence images of living mice, which, compared to the short-term images in Figure 1, show increased deposition in lymph nodes and bone marrow relative to the liver; intestinal contents also show significant fluorescence due mainly to excretion of QDs from the liver. Figure 3 also shows two stages of necropsy (B,C). In addition to sites seen by noninvasive imaging, major sites of fluorescence include the deep lymph nodes and the spleen. Figure 4B,C shows a similar necropsy of an animal injected using mPEG-5000 QDs. The most striking difference from Figure 3 is the very low labeling of the lymph nodes, compared to the liver, spleen, and bone marrow. These results suggest that the longer circulating lifetime of the higher molecular weight mPEG-substituted QDs may be due to lesser uptake by the lymph nodes as well as to the lower rate of uptake by the liver. Uninjected animals showed no comparable fluorescence in any organs.

To determine the long-term stability and tissue deposition of QDs in vivo, a set of normal Balb/C mice were intravenously injected using mPEG-750 QDs. Animals were imaged during necropsy at 15 min, 1 day, 3 days, 7 days, 28 days, and 133 days (>four months) postinjection. QDs remained for at least one month in liver, lymph nodes, and bone marrow. By one month, fluorescence was substantially decreased, but the overall distribution of fluorescence remained similar to that at 24 h after injection. In follow-up experiments at 133 days postinjection, QD fluorescence was still visible on necropsy, though background fluorescence from intestinal contents was now higher than that in lymph nodes. The liver had no grossly visible fluorescence; however, QD's were still grossly visible in lymph nodes and bone marrow (Figure 5), and visible by fluorescence microscopy in liver, lymph nodes, and spleen (data not shown).

Cellular sites of uptake were identified by microscopy of tissue sections. Imaging of whole spleen by fluorescence 24 h postinjection of mPEG-750 QDs showed a freckled pattern of dark centers having bright haloes. Figure 6 shows one frozen section from a spleen taken 24 h postinjection, stained using hematoxylin and visualized in white light and by fluorescence. Deposition is perifollicular, with no accumulation in germinal centers. The QDs are concentrated in internal vacuoles of phagocytic cells. Sections of lymph nodes showed a similar pattern. QDs were further localized by electron microscopy. Figure 7 shows transmission electron microscope images of a mouse spleen cell 24 h postinjection. Localization in endosomes is confirmed by these images, which also demonstrate that QDs deposited in tissues may be imaged easily using standard electron microscopic meth-

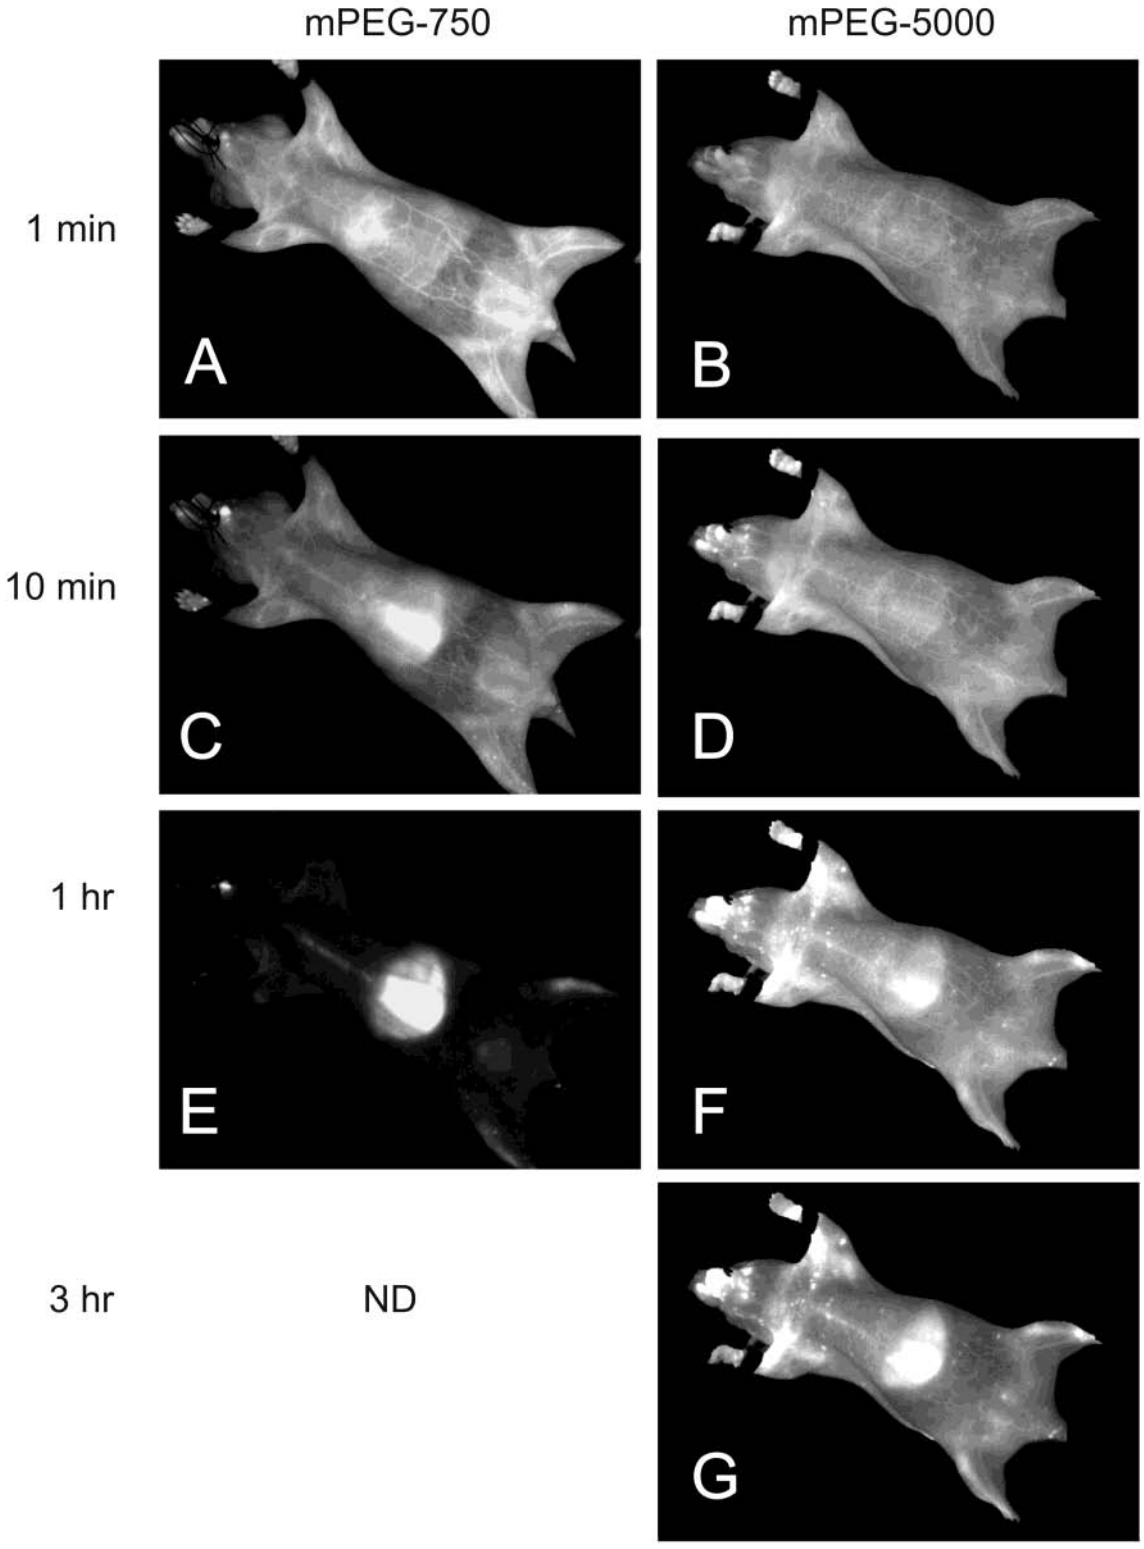

Figure 1. Noninvasive imaging using 645 nm mPEG-750 QDs (left, A, C, E) and 655 nm-emitting mPEG-5000 QDs (right, B, D, F, G). Nude mice were imaged at 1min (A, B), 10 min (C, D) 1 h (E, F), and 3 h (G) postinjection. Note that even at 1 min, significant liver uptake is visible using mPEG-750 QDs (A), while even at 10 min there is little or no visible liver uptake using mPEG-5000 QDs (D). At 1 h, the difference between mPEG-750 QDs (E) and mPEG-5000 QDs is even more marked, with PEG-750 QDs completely cleared from the circulation, while mPEG-5000 QDs persist (F); even 3 h postinjection, mPEG-5000 QDs remain in circulation (G). Since essentially all fluorescence is cleared from the circulation by 1 h, imaging of mPEG-750 QDs was terminated at 1 h after injection. In other experiments, we found that the pattern of deposition of mPEG-750 QDs seen at 1 h remained stable for at least 24 h.

ods. At one month postinjection, electron microscope images show subcellular localization in the spleen similar to that seen 24 h postinjection. Whether QDs remain in the cells that originally took them up is not yet known.

DISCUSSION

We have shown that quantum dots are well suited for fluorescence visualization in whole animals. Because of

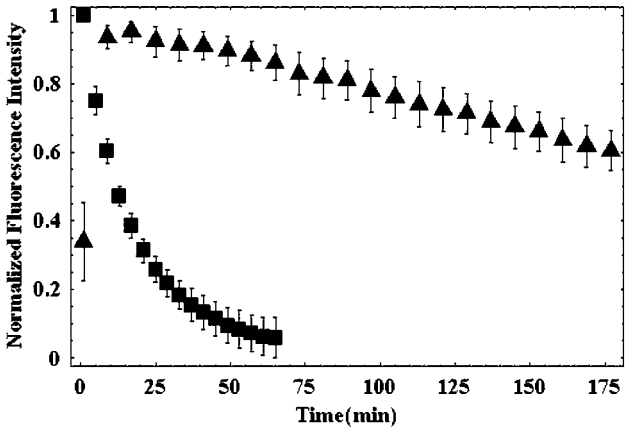

Figure 2. Regions of interest (2 × 2 pixels) over several different surface vessels of the animals in Figure 1 were used to determine the circulating lifetime of the QDs. Mean fluorescence intensities from nine regions of interest on each animal were measured, normalized to maximum initial values, and plotted versus time after injection (triangles, mPEG-5000 QDs; squares, mPEG-750 QDs.) Bars indicate standard deviations. Exponential fits of the fluorescence intensities as a function of time yielded average circulating half-lives of 6.1 ± 2.9 min for mPEG-750 QDs and 141 ± 45 min for mPEG-5000 QDs (Table 1).

their high quantum yields and high absorbency, the fluorescence of QDs in the superficial vasculature was readily visible to the naked eye just after injection; even the orange 605 nm-emitting QDs can be imaged noninvasively in liver and bone marrow. QDs in tissue can be imaged on scales that range from the whole animal to the electron microscope level. Moreover, the QDs used in these experiments are stable and fluorescent in vivo for at least four months. Microscopy showed no signs of localized necrosis at the sites of deposition, and there was no obvious sign of breakdown of the QDs as seen by electron microscopy. This stability is presumably due to the amp coating, which preserves fluorescence and protects the QDs from degradation in vivo. We cannot exclude the possibility that some QDs are no longer fluorescent after prolonged residence in tissue, but their structure is preserved as revealed by electron microscopy.

QDs can be excited by any light wavelength shorter than their emission wavelength. We used blue excitation because of the higher absorbency of QDs in the blue, and the ability to use QDs with emission wavelengths from green through infrared with a single excitation wavelength. Red light excitation should improve visualization and resolution at increased tissue depth, at some cost in efficiency of excitation. Because of the resistance of QDs to photobleaching, higher intensity illumination or a long integration time should make up for any decrease in absorbency in the red. However, in our hands, blue excitation with a wideband filter proved quite satisfactory in mice, and use of red laser illumination produced no significant improvement.

The small size of QDs and their conjugates should allow efficient tissue perfusion and good targeting to specific sites in tissues, provided that the QDs remain in circulation long enough. For many uses in vivo, reducing Qdot uptake by the reticuloendothelial system and increasing circulating lifetime will be essential. PEGylation of nanoparticles and liposomes to prolong serum lifetime and aid in targeting is an area of active research; second-generation PEG derivatives may offer longer lifetimes and enhanced tissue perfusion (*14*−*24*.) Our results recall those of Gref et al. (*23*) and Mosqueria et al. (*24*), who found that increasing PEG density and chain length-reduced nanoparticle binding to cells and

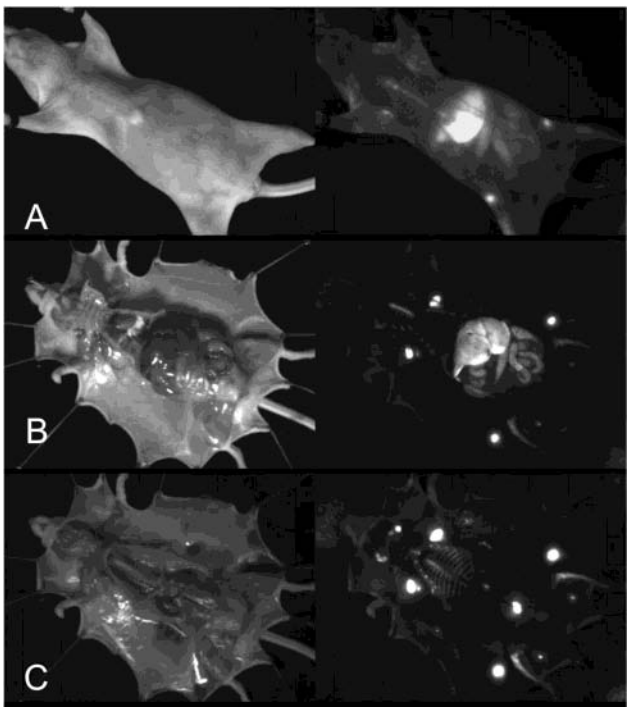

Figure 3. Mouse imaged 24 h postinjection of 645 nm mPEG-750 QDs. Left, light images; Right, fluorescence images. A, whole animal; B, skin and peritoneum removed, sternum pinned back showing marrow staining, but concealing cervical nodes. C, sternum, heart, lungs, liver, and digestive tract removed. Note the visibility of axillary and inguinal lymph nodes through the skin (A), and the retention of QDs by bone marrow as well as by lymph nodes and liver (B, C).

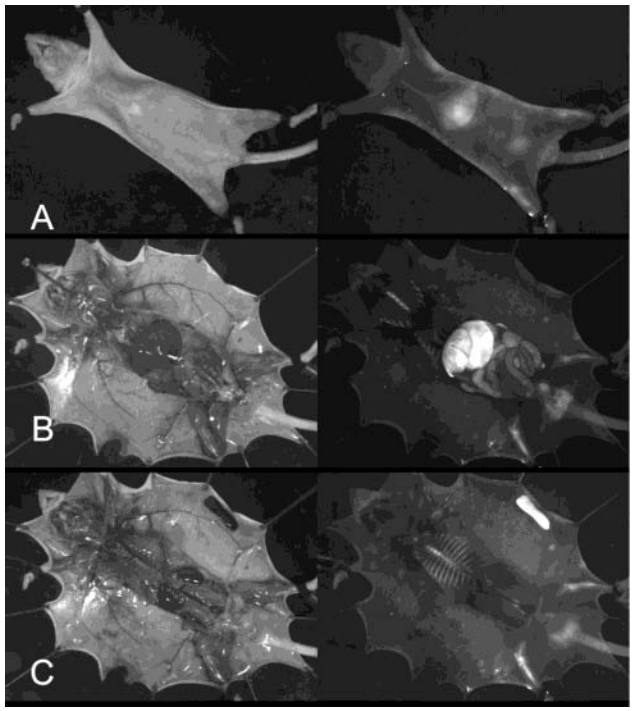

Figure 4. Mouse imaged 24 h postinjection of 655 nm mPEG-5000 QDs. Left, light images; Right, fluorescence images. A, whole animal; B, skin and peritoneum removed, sternum pinned back showing marrow staining, but concealing cervical nodes. C, sternum, heart, lungs, liver, and digestive tract removed. Note the minimal labeling of lymph nodes compared to mPEG-750 (Figure 3). Note the high relative brightness of the spleen, displayed on the upper right of the dissection (C).

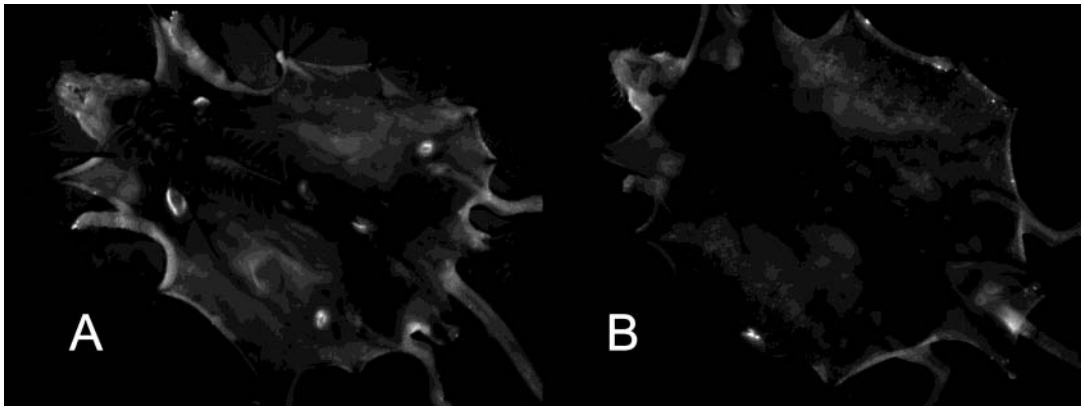

Figure 5. Long-term retention of QD fluorescence in vivo. A. Mouse imaged 133 days postinjection of 360 pmol of 655 nm mPEG-750 QDs. The mouse was dissected, and most internal organs were removed to show continuing fluorescence of axillary, inguinal, and lumbar lymph nodes as well as weak fluorescence of bone marrow. B. Same dissection of control (uninjected) mouse. Mice were imaged under identical conditions, and images are displayed using identical brightness functions.

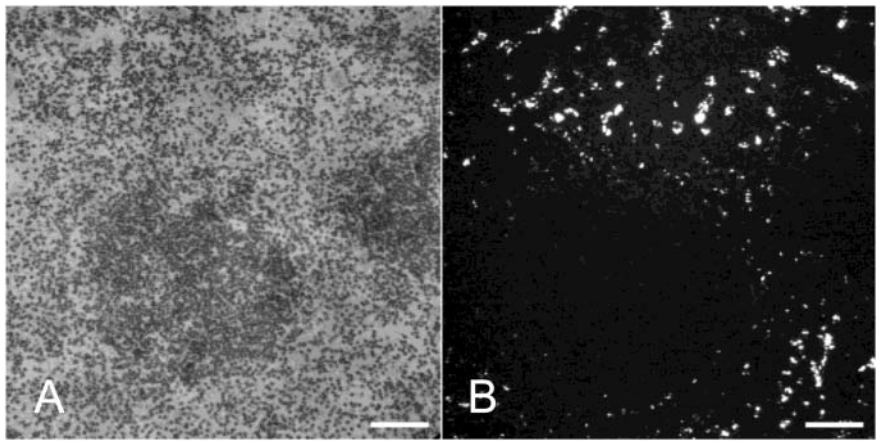

Figure 6. Spleen, frozen section 24 h postinjection of 630 nm-emitting mPEG-750 QDs. A. Section stained using Gill's hematoxylin, white light image; B. Fluorescence image of A. Note concentration of QDs in perifollicular areas, but not in germinal centers. Bar = 200 μm.

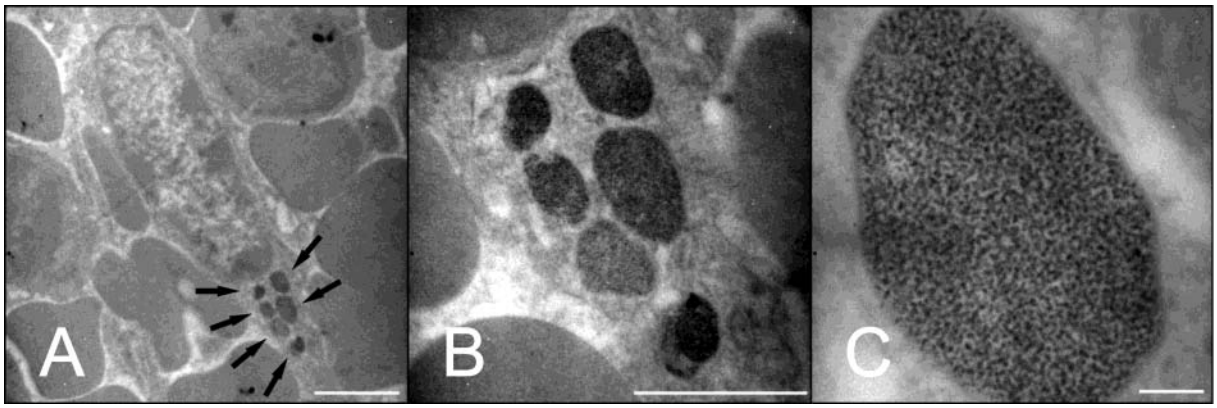

Figure 7. mPEG-750 QDs in mouse spleen imaged by electron microscopy 24 h postinjection. A. Perifollicular cell, presumably macrophage, bar = 10 μm; arrows indicate endosomes. B. Same cell, bar = 1 μm. C, Enlarged single endosome, showing individual QDs, bar = 100 nm. Glutaraldehyde fixation, Epon embedding, osmium stain.

plasma components and increased circulating lifetime. We anticipate that circulating lifetimes will be further improved by adjusting the surface composition of QDs.

Other groups have used QDs in vivo. Dubertret et al. (*25*) microinjected QDs enclosed in PEG-conjugated lecithin micelles; these QDs persisted in Xenopus embryos from blastula at least until tadpole stage, with little or no indication of toxicity. Akerman et al. (*26*) explored the deposition of peptide conjugated and PEGylated QDs in mice using fluorescence microscopy of tissue sections rather than whole-body visualization. By using a high level of PEG-substitution on QD−peptide conjugates directed to vascular and tumor targets, this group found that uptake in RES sites could be reduced, while selective targeting to organ-specific vasculature and to tumors could be achieved. These results, taken with ours, demonstrate the usefulness of QDs for targeting in vivo and whole-body visualization.

Several groups, including ours, have investigated organic fluorochromes as labels for targeting in vivo; all have concluded that far-red and near-infrared fluorophores are more effective than shorter wavelengths (*27*−

33). For good visualization through a significant thickness of tissue (>1 mm), stable near-infrared-emitting QDs will be necessary (*34*). Difficulties in the manufacture and stabilization of infrared-emitting QDs are being resolved; this should enable visualization in whole animals at greater depth and with increased sensitivity.

That QD surfaces can control serum lifetime and pattern of deposition suggests many medical uses. Rapid deposition in the reticuloendothelial system is potentially useful for defining some tumor types and detecting sentinel lymph nodes. Tumor targeting by QD conjugates is an exciting prospect, as tumor sites and margins could be readily imaged during surgery (*26*), provided that heavy-metal toxicity due to the QD's can be appropriately limited or controlled. As with antibody conjugates, the key to good targeting in vivo is the use of surface coatings that reduce nontargeted uptake. We have shown considerable increase in circulating lifetimes and reduction in nonspecific uptake of QDs by the use of long-chain PEG surfaces. At this point, the serum lifetime of mPEG-5000 QDs is similar to that of some of our cyanine fluorochrome antibody conjugates that were successfully used for tumor labeling (*28*, *29*). Finally, thanks to the high stability of amp-coated QDs, experiments using molecules and cells tagged with QDs and injected into animals may permit analysis of antigen trafficking and cellular migration over very long time scales, with unprecedented sensitivity and resolution.

ACKNOWLEDGMENT

We thank Joseph P. Suhan (Department of Biological Sciences, Carnegie Mellon University) for excellent technical assistance in electron microscopy, Joyce Horner and Lisa McGaw (Department of Biological Sciences, Carnegie Mellon University) for assistance with animal handling and anesthesia. This work was supported by NIH grant number R01 EB 000364. The work at Quantum Dot Corporation was partly funded by NIST-ATP 70NANB0H3000.

Received May 1, 2003; Revised Manuscript Received October 15, 2003

Multivalent glycoclusters have the potential to become pharmaceuticals by virtue of their target specificity toward clinically relevant sugar receptors. Their application can also provide fundamental insights into the impact of two spatial factors on binding, i.e., topologies of ligand (branching mode, cluster presentation) and carbohydrate recognition domains in lectins. Persubstituted macrocycles derived from nucleophilic substitution of iodide from heptakis 6-deoxy-6-iodo-β-cyclodextrin by the unprotected sodium thiolate of 3-(3-thioacetyl propionamido)propyl glycosides (galactose, lactose and *N*-acetyllactosamine) were prepared. The produced glycoclusters were first tested as competitive inhibitors in solid-phase assays. A plant toxin from mistletoe and an immunoglobulin G fraction from human serum were markedly susceptible. A nearly 400-fold increase in inhibitory potency of each galactose moiety in the heptavalent form relative to free lactose (217-fold relative to free galactose) was detected. Thus, these glycoclusters can efficiently interfere, for example, with xenoantigen-dependent hyperacute rejection. Among the tested galectins selected from this family of adhesion- and growth-regulatory endogenous lectins, the substituted β-cyclodextrins acted as sensors to delineate topological differences between the two dimeric prototype proteins. The relatively strong reactivity with chimera-type galectin-3, a mediator of tumor metastasis, disclosed selectivity for glycocluster binding among galectins. Equally important, the geometry of ligand display (maxiclusters, bi- or triantennary N-glycans) made its mark on the inhibitory potency. To further determine the sensitivity of a distinct galectin presented on the cell surface and not in solution, we established a stably transfected tumor cell clone. We detected a significant response to presence of the multivalent inhibitor. This type of chemical scaffold with favorable pharmacologic properties might thus be exploited for the design of galectin- and ligand-type-selective glycoclusters.

INTRODUCTION

The emergence of the concept of the sugar code entails an increasing interest in the activities of endogenous lectins (Winterburn and Phelps, 1972; Laine, 1997; Reuter and Gabius, 1999; Rüdiger et al., 2000; Gabius et al., 2002; Kilpatrick, 2002). On account of cell surface presentation and capacity for endocytosis, medical applications are being examined for several C-type lectins (Gabius, 1991, 1997; Rice, 1997; Yamazaki et al., 2000, 2001; Davis and Robinson, 2002), by exploiting glycoligands as a postal code in vectorized drug delivery. Acting as role models for this purpose, the hepatic and macrophage asialoglycoprotein receptors and the tandem-repeat mannose macrophage receptor have already served as proof-of-principle. In fact, the design of multivalent ligands matching the rather rigid topological display of these lectins' carbohydrate recognition domains was the basis for achieving astounding affinity enhancements of custom-made glycoclusters relative to their monovalent form, termed the glycoside cluster effect (Lee and Lee, 1994; Biessen et al., 1996; Grandjean et al., 2001; East and Isacke, 2002; Weigel and Yik, 2002). A similarly impressive example for how rational design of the ligand display accomplishes complementarity to fixed geometry of receptor sites is afforded by starfish and modularly prepared pentavalent inhibitors for bacterial AB_5 toxins (Schengrund, 2003). Thus, there is already ample reason to conclude that the combination of synthetic chemistry with lectin research promises insights into receptor functionality and a clinical perspective (Lee and Lee, 1994; Bovin and Gabius, 1995; Roy, 1996, 2002; Kiessling

et al., 2000; Gabius, 2001a; Cloninger, 2002; Houseman and Mrksich, 2002).

Presently, a major challenge in this area is to figure out how spatial factors and binding avidity toward soluble lectins are correlated. Model studies revealed that sugar surface density is a crucial factor for selectivity of binding, rate of cluster formation, and their stoichiometry (Horan et al., 1999; Cairo et al., 2002). However, increases in epitope density in neoglycoconjugates do not necessarily entail improved capacity as competitive inhibitors in model systems (Zanini and Roy, 1997a,b; Ashton et al., 1998; André et al., 1999a, 2001). Thus, systematic studies are warranted. After the chemistry to graft bioactive carbohydrates onto synthetic/natural scaffolds had been mastered, first studies on molecular interactions were nearly exclusively performed with plant lectins. Of note, the behavior of endogenous lectins cannot be reliably deduced on this experimental basis. As study objects, we consequently included mammalian proteins from a lectin family with adhesion/growth-regulatory activity on normal and malignant cells, i.e., the galectins (Gabius, 1997; Hirabayashi, 1997; Ohannesian and Lotan, 1997; Kaltner and Stierstorfer, 1998; André et al., 1999b; Brewer, 2002; Danguy et al., 2002; Rabinovich et al., 2002). For comparison, we also worked with a galactoside-specific plant lectin with potent signaling activity and—at increased concentration—toxicity on mammalian cells (Endo, 1989; Timoshenko et al., 1999; Gabius, 2001b) and an affinity-purified human immunoglobulin G fraction, a model for auto- or xenoreactive carbohydrate-binding antibodies in serum. Similar to galectins, these two sugar receptors are also cross-linking modules (Gupta et al., 1996). Persubstituted β-cyclodextrins maintaining their C_n-symmetry were chosen as test substance owing to several favorable properties for potential applications.

Cyclodextrins are nonimmunogenic natural macrocycles with inherently low pharmacological activity and high biocompatibility, the capacity to host pharmaceuticals in their truncated cone-shaped hydrophobic cavity coming along as added value. Functionalization with carbohydrate derivatives was accomplished with the long-term aim to devise an "intelligent" drug delivery system (Fulton and Stoddart, 2001a; Houseman and Mrksich, 2002; Ortiz Mellet et al., 2002). Having developed the facile synthesis of persubstituted β-cyclodextrins with galactose (Gal), lactose (Lac), or *N*-acetyllactosamine (LacNAc) as headgroup (Furuike et al., 2000), these glycoclusters (for schematic illustration, please see Figure 1) were introduced to assays with galectins. These endogenous lectins harbor marked intrafamily complexity. It encompasses different modes of spatial orientations of the carbohydrate recognition domains and cross-linking capacity, leading to functional divergence in disease mechanisms such as tumor invasion and spread (Kopitz et al., 2001; Lahm et al., 2001; Brewer, 2002; Camby et al., 2002; Cooper, 2002; Nangia-Makker et al., 2002; Nagy et al., 2003). For this study, we selected two related prototype proteins (galectins-1 and -7) and the chimera-type galectin-3. Because sugar density and topology are emerging as crucial factors modulating lectin binding, we systematically tested the glycoclusters' capacity to inhibit lectin binding to a panel of surface-presented ligands. Toward this end, (neo)glycoproteins presenting either lactose maxiclusters, bi- or triantennary N-glycans, or a complex mixture of N- and O-glycans were used for establishing the model surface. Last but not least, our study design accounted for another parameter of importance: the potency to interfere with multivalent interactions can vary with the nature of the test system (Mann et al., 1998). To address this issue properly, we performed solid-phase, haemagglutination, and cell binding assays. In these experimental settings the lectins were invariably present in solution. To be able to probe galectin behavior when presented on a cell surface, we generated a stable galectin-1-overexpressing colorectal cancer cell clone by transfection as a test model. The presented data reveal (a) efficiency of the substituted cyclodextrins to abolish receptor binding, (b) differential sensitivity of the tested galectins, (c) the improtance of ligand topology, and (d) of lectin presentation either in solution or on the cell surface.

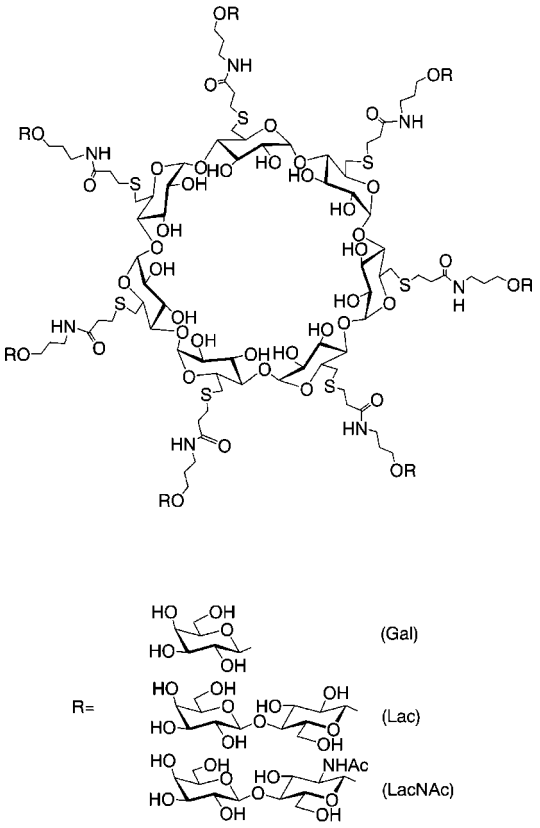

Figure 1. Structural illustration of the perglycosylated β-cyclodextrin derived from coupling 3-(3-thioacetyl propionamido)-propyl glycosides after de-O,S-acetylation to yield unprotected glycosides with a terminal sodium thiolate to heptakis 6-deoxy-6-iodo-β-cyclodextrin.

EXPERIMENTAL PROCEDURES

Reagents. The persubstituted glycoclusters with galactose, lactose, and *N*-acetyllactosamine as headgroup (please see Figure 1 for structural details) were prepared by conjugation of the respective sodium thiolate derived from treatment of 3-(3-thioacetyl propionamido)propyl sugars with NaOMe to heptakis 6-deoxy-6-iodo-β-cyclodextrin at 70 °C for 24 h, as described (Furuike et al., 2000). Following gel filtration on Sephadex G25, concentration of peak fractions, washing of the crude solid and lyophilization analytical procedures (optical rotation, ^{1}H and ^{13}C NMR spectroscopy, and matrix-assisted laser desorption ionization time-of-flight mass spectrometry) checked structure and purity of the products prior to the inhibition studies. Galectin-1 from bovine heart, murine galectin-3 (using the plasmid prCBP35s and *E. coli* JA 221 cells; a kind gift of Dr. J. L. Wang), and human galectin-7 (using the plasmid pQE−60/hGal-7 and *E. coli* M15[pREP4] cells; a kind gift of Dr. F.-T. Liu), the

[a] The assays were performed at the following combinations of lectin and (neo)glycoprotein concentration: VAA/Lac-BSA (1.5 μg/mL/0.05 μg), VAA/SAP (1.5 μg/mL/0.5 μg), VAA/ASF (1.5 μg/mL/1μg), VAA/laminin (3 μg/mL/0.5 μg/mL). [b] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard [c] The assays were performed at the following combinations of IgG and (neo)glycoprotein concentration: Lac-IgG/Lac-BSA (1 μg/mL/0.05 μg), Lac-IgG /SAP (10 μg/mL/0.5 μg), Lac-IgG /ASF (10 μg/mL/1μg); laminin was not tested as matrix. [d] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard.

galactoside-specific agglutinin from *Viscum album* L. (VAA) and the lactoside-binding immunoglobulin G fraction of human serum, subfractionated by removing any α-galactoside-binding activity, were isolated and their purity was checked by one- and two-dimensional gel electrophoresis as described (Gabius, 1990; André et al., 1997). Biotinylation was performed under optimized activity-preserving conditions, and the binding partners for the sugar receptors, i.e., lactosylated bovine serum albumin with an average ligand density of 28 moieties per carrier molecule, human serum amyloid P component, and bovine asialofetuin, were prepared, as described previously (André et al., 2001). Murine Engelbreth-Holm-Swarm laminin was a kind gift by Dr. R. Timpl.

Quaternary Structure Analysis. Aliquots of 100 μg of galectin were run over a prepacked Superose 12 HR 10/30 column (24 mL bed volume) connected to a HPLC system (Hitachi-Merck, Darmstadt, Germany) with 50 mM phosphate-buffered saline (pH 7.2) without/with 100 mM lactose at a flow rate of 0.7 mL/min. Commercial standard proteins (BioRad, Munich, Germany) were used for calibration.

Inhibition Assays. The solid-phase assays were performed in microtiter plate wells (Microlon; Greiner, Nürtingen, Germany). Surface coating of the (neo)-glycoproteins was carried with an optimal concentration based on initial systematic testing (please see Table 1 and Table 2 for details) with 50 μL of 20 mM phosphate-buffered saline (pH 7.2) overnight at 4 °C. Thorough washing, blocking of remaining protein-binding sites with 100 μL of buffer solution containing 1% carbohydrate-free bovine serum albumin for 1 h at 37 °C and again thorough washing preceded the incubation step with the biotinylated sugar receptor in the absence/presence of glycocluster for 1 h at 37 °C. This mixture had been preincubated for 30 min at 37 °C without visible precipitate formation. Signal generation by streptavidin-peroxidase and *o*-phenylenediamine/H_2O_2 and its quantitation followed, as described in detail (André et al., 1997). Carbohydrate-dependent haemagglutination of trypsin-treated, glutaraldehyde-fixed rabbit erythrocytes by lectins was monitored with increasing concentrations of glycoinhibitor to determine the minimal inhibitory concentration, as described (Gabius et al., 1984). Flow cytofluorimetric analysis of binding of labeled galectins or lactosylated neoglycoprotein to tumor cell surfaces (human colon adenocarcinoma line SW480 obtained from the American Type Culture Collection, Rockville, MD, and human B-lymphoblastoid line Croco II established and propagated as described by Gabius et al., 1991) used standard FACScan instrumentation (Becton-Dickinson, Heidelberg, Germany, equipped with the software package CellQuest Pro) and fluorescent streptavidin-*R*-phycoerythrin (Sigma, Munich, Germany) as signal-generating reagent, as described (Kojima et al., 1997).

Generation of Stable Galectin-1-Overexpressing Transfectants. Cells of the human colorectal adenocarcinoma line DLD-1 (American Type Culture Collection, Rockville, MD) were grown in RPMI 1640 medium with 10% fetal calf serum (Biochrom, Berlin, Germany), 2 mM L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin. For transfection full-length cDNA for human galectin-1, kindly provided in the pH14Gal vector by Dr. J. Hirabayashi, was subcloned into the Kpn I restriction site of the pcDNA3.1(+) vector (Invitrogen/Life Technologies, Karlsruhe, Germany). Using 60−80% confluent cultures and the SuperFect reagent (Qiagen, Hilden, Germany; 10 μL/100 μL serum-free medium × 2 μg vector DNA) the cells were transfected and selection with G418 (600 μg/mL) initiated. Mock transfection with insert-free (null) vector was performed in parallel.

Characterization of Stable Transfectants. Insertion of the cDNA-carrying vector into genomic DNA was verified by PCR. Pellets from 2×10^6 cells were treated with 600 μL of nuclear lysis solution (Promega, Mannheim, Germany) and RNase. Following precipitation of proteins the genomic DNA in solution was pelleted by addition of 2-propanol and centrifugation. A 0.5 μg amount of this material was subjected to PCR analysis using the following pair of sense (5′-CGCTAGGGTAC-CATGGCTTGTGGTCTGGTCG-3′) and antisense (5′-CG-TACGGGTACCTCAGTCAAAGGCCACACA-3′; KpnI site underlined) sequences. In parallel, actin gene amplification was run. For the RT-PCR analysis total RNA was extracted with the RNAeasy kit reagents (Quiagen, Hilden, Germany) and reverse transcription used 200 U Superscript II RNase H^- Reverse Transcriptase (Invitrogen/Life Technologies, Karlsruhe, Germany). Western blotting analysis from total cell extracts with non-cross-reactive anti-galectin-1 antibody (1 μg immunoglobulin G/ml) was performed, as described (Gabius et al., 1986; Kaltner et al., 2002). Specifically bound antibody was visualized with an horseradish peroxidase/goat anti-rabbit immunoglobulin G conjugate (0.2 μg/mL) and a

[a] The assays were performed at the following combinations of lectin and (neo)glycoprotein concentration: galectin-1/Lac-BSA (10 μg/mL/1 μg), galectin-1/SAP (15 μg/mL/0.5 μg), galectin-1/ASF (10 μg/mL/1μg), galectin-1/laminin (10 μg/mL/0.5 μg/mL). [b] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard. [c] The assays were performed at the following combinations of lectin and (neo)glycoprotein concentration: galectin-3/Lac-BSA (5 μg/mL/0.25 μg), galectin-3/SAP (10 μg/mL/0.5 μg), galectin-3/ASF (5 μg/mL/1μg), galectin-3/laminin (20 μg/mL/0.5 μg/mL). [d] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard. [e] The assays were performed at the following combinations of lectin and (neo)glycoprotein concentration: galectin-7/Lac-BSA (30 μg/mL/0.05 μg), galectin-7/SAP (30 μg/mL/0.5 μg), galectin-7/ASF (30 μg/mL/1μg), galectin-7/laminin (30 μg/mL/0.5 μg/mL). [f] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard.

chemiluminescence kit system (Amersham/Pharmacia Biotech, Freiburg, Germany). In a second round of probing actin was detected on the same blots by a polyclonal anti-actin antibody (Sigma, Munich, Germany; 3 μg/mL). Cell growth kinetics was analyzed for 10 days starting with a cell density of 10^4 cells/ml in 24-well culture plates loaded with 1 mL at 24 h intervals using an improved Neubauer chamber. Flow cytofluorimetric detection of cell surface galectin-1 was carried out, as described above for cell binding of lectins and lactosylated neoglycoprotein using a goat anti-rabbit immunoglobulin G FTC-conjugate (Sigma, Munich, Germany; 1:100 dilution of commercial solution).

RESULTS

Quaternary Galectin Structure. The three tested mammalian galectins belong to different subgroups within this family of endogenous lectins. Galectins-1 and -7 are prototype family members. They are characterized by the presence of a protomer harboring one carbohydrate recognition domain. In principle, it may or may not associate noncovalently to a dimeric cross-linking module. Galectin-3, in contrast, is the only known chimera-type family member. Its C-terminal carbohydrate recognition domain is linked to a collagenase-sensitive tandem-repeat region and a short N-terminal stretch. To ascertain the quaternary structure of these preparations of galectins-1 and -3 in solution, we performed molecular weight analysis by analytical gel filtration. Using a Superose matrix containing galactose and 3,6-anhydro-*L*-galactose in its repeating unit (agarobiose), the elution profile for galectin-1 confirmed its complete dimerization, whereas galectin-3 was retarded considerably in relation to the expected position (Figure 2, upper panel). Recalling binding capacity of galectin-3 to both nonreducing terminal and internal LacNAc sequences (Ahmad et al., 2002), a weak carbohydrate-specific interaction with the matrix was a reasonable and testable explanation. We therefore repeated the analysis in the presence of 100 mM lactose to block it. Indeed, the elution peak of galectin-3 was shifted to the position of the monomer (calculated MW: 27,384 Da) as predicted (Figure 2, bottom panel). This result underscored the necessity for rigorous specificity controls in the binding assay especially for galectin-3 (please see below).

With these two positions in the elution profile extending the set of molecular weight markers, we next addressed the question on the quaternary structure of human galectin-7. To preclude that weak and transient binding to the matrix might erroneously intimate presence of a monomer, this analysis was likewise performed in the absence and presence of lactose. Irrespective of altering this parameter galectin-7 eluted exclusively at the position of the dimer like galectin-1 (Figure 2). This result is in accord with recent mass spectrometric assessment (Kopitz et al., 2003). Galectin-7 is thus a dimeric prototype galectin in solution. It is noteworthy that its retention time (18.8 min) was longer than that for galectin-1 (16.52 min) despite a molecular weight difference of 546 Da in favor of galectin-7. Evidently, the shape of the two prototype galectins differed in solution. This intragroup variation is a strong argument to include members of the same subclass into our investigation whether and to what extent the tested multivalent inhibitors will affect lectin binding. Two principal types of inhibition assay were performed to answer this ques-

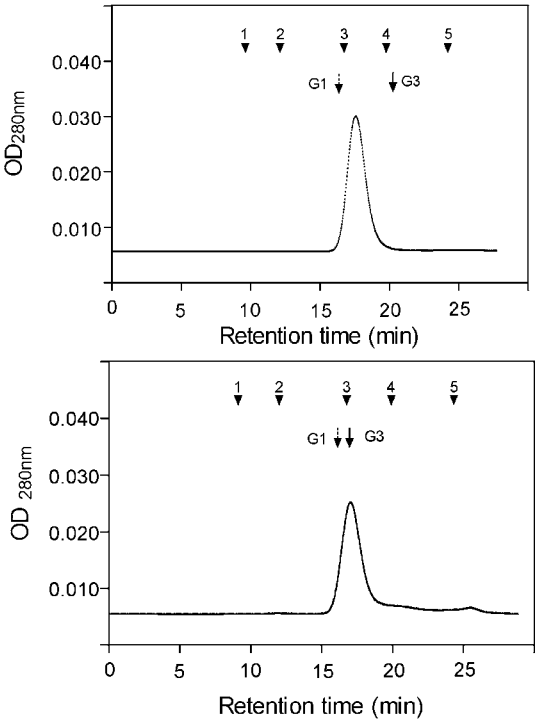

Figure 2. Determination of the molecular weight under native conditions for bovine galectin-1 (G1, arrow), murine galectin-3 (G3, arrow), and human galectin-7 (elution profile) with a Superose 12 HR 10/30 column. The analysis was performed in running buffer without addition of lactose (top) and in the presence of 100 mM lactose (bottom). Positions of molecular weight markers for calibration are given by arrowheads: bovine immunoglobulin (1) at 159 kDa, bovine serum albumin (2) at 66 kDa, carbonic anhydrase (3) at 29 kDa, cytochrome *c* (4) at 12.4 kDa, and aprotinin (5) at 6.5 kDa.

tion: a.) solid-phase binding to a matrix of biochemically defined (neo)glycoproteins mimicking a standardized cell surface and b.) cell-based binding using erythrocytes as laboratory models as well as cultured tumor cells and a lectin-overexpressing cell clone after gene transfection for clinical relevance. We tested persubstituted cyclodextrins to assess their potency to interfere with the protein-carbohydrate interactions.

Cyclodextrins as Inhibitors of Binding to (Neo)-glycoproteins. The adsorption of (neo)glycoproteins to the surface of ELISA plate wells established a matrix with ligand properties of a cell surface. The way the persubstituted β-cyclodextrins meddle with lectin binding to the glycans of the artificial glycocalyx can thus be considered as model situation to measure their influence on extracellular lectin activities. In the first step, the sugar dependence of the interaction between the surface-immobilized (neo)glycoproteins and the sugar receptors was ascertained. Invariably, binding for all sugar receptors was saturable and sensitive to presence of the haptenic sugar but not mannose. We performed our measurements with lactosylated albumin, presenting rather widely spaced ligand sites (maxiclusters), and three glycoproteins with known differences in glycan features: the human pentraxin serum amyloid P component (SAP) with a single complex-type biantennary N-glycan at Asn32 per protomer which -convenient for interaction studies − extends outward from the subunits, asialofetuin with preferentially triantennary N-glycans at its three N-glycosylation sites and murine laminin harboring a complex array of especially bi- and triantennary N-glycans including poly(*N*-acetyllactosamine) elongations distributed over 73 sites for N-glycosylation.

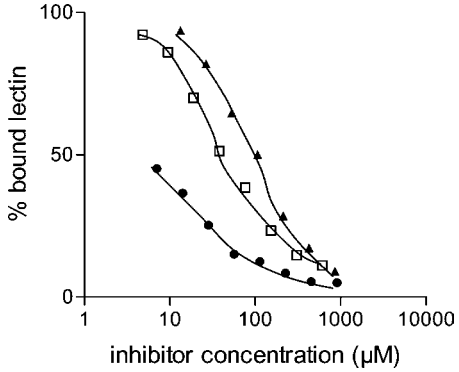

Figure 3. Inhibition curves of binding of biotinylated galactoside-specific *Viscum album* L. agglutinin to surface-immobilized murine laminin using the β-cyclodextrin-based glycoclusters with derivatives of D-galactose (□), lactose (●) and *N*-acetyllactosamine (▲) as headgroup.

Thus, this set enabled us to relate inhibitory capacity to the lectin and also to a defined glycan display, the latter parameter so far not thoroughly evaluated. To exclude that the cyclooligosaccharide carrier itself impaired receptor binding, we performed assays to figure out as to whether presence of unsubstituted β-cyclodextrins affected extent of binding of the biotinylated markers. Even at the very high concentration of 3.52 mM no or only minor (up to 15%) inhibitory activity could generally be picked up under the standard assay conditions. Looking at the data reported in the first section of Results, an expectable exception was galectin-3, with this concentration for example reaching 43.4% inhibition of binding to SAP. Because functionalization improved the inhibitory capacity of the cyclooligosaccharide by up to 2 orders of magnitude, these effects could yet be considered to be minor. Maintaining the overall symmetric geometry of their presentation, we attached three different headgroups to the carrier scaffold, i.e., Gal, Lac, and LacNAc via the same linker structure. Thus, we could determine exclusively the influence of headgroup tailoring under otherwise identical conditions. β-Cyclodextrin-based glycoclusters were then tested as competitive inhibitors to matrix binding of the sugar receptors kept in solution.

By raising the concentration of the glycocluster in the individual experimental series, the percentage of surface-bound receptor was reduced to varying extents, as exemplarily shown in Figure 3. Conjugation of the carbohydrate derivatives to the cyclodextrin scaffold thus did not harm binding properties of the headgroups to lectins and immunoglobulins. To calculate the glycoclusters' efficiency, we set an internal standard by running assays with galactose and lactose as reference substances in parallel. Tables 1 and 2 present the data for the five receptor types and the four (neo)glycoproteins as IC_{50} values. The measurements revealed that the glycoclusters had pronounced activities, the immunoglobulin G fraction and the plant lectin being markedly responsive (Tables 1a,b). Importantly, the topological display of the glycans (maxicluster, bi- or triantennary N-glycan chains) of the surface-presented ligand mattered. Plant lectin binding to maxiclusters and triantennary glycans was preferentially sensitive to glycocluster presence (Table 1a). Galactose-presenting scaffolds impaired binding of the serum immunoglobulin G fraction, too, especially in the presence of triantennary N-glycans of ASF in the artificial glycocalyx (Table 1b). Further synthetic manipulations of the glycoclusters by adding a glucose moiety and then a *N*-acetyl group were apparently not beneficial in this case. Regarding the galectins, there is

Table 3. Determination of the Minimal Inhibitory Concentration (MIC) and the Relative Inhibitory Capacity of Glycosubstances in Lectin-Mediated Haemagglutination

	VAA (0.1 μg/mL)		galectin-1 (1 μg/mL)		galectin-3 (100 μg/mL)	
inhibitor	MIC [μM]	relative potency	MIC [μM]	relative potency	MIC [μM]	relative potency
D-galactose	25000	0.5	6250	0.1	50000	0.06
lactose	12500	1	625	1	3000	1
ASF	10.5	1190 (132)[a]	2.5	250 (27.8)	105	28.6 (3.2)
β-CD	no inhibition up to 3500 μM	<3.6	no inhibition up to 3500 μM	<0.18	no inhibition up to 3500 μM	<0.86
Gal−CD	305	41.0 (5.9)	1218	0.5 (0.07)	no inhibition up to 1218 μM	< 2.5
Lac−CD	452	27.7 (4.0)	226	2.8 (0.4)	452	6.6 (0.9)
LacNAc−CD	850	14.7 (2.1)	106	5.9 (0.8)	106	28.3 (4)

[a] The numbers in parentheses denote the relative potency of each sugar unit in the heptavalent cyclodextrin compared to carrier-free lactose set as internal quality standard.

a general trend that headgroup extension improved the inhibitory efficiency (Table 2a−c). However, the overall sensitivity did often not reach the high level of inhibition detected for the other two sugar receptors. Among the galectins, galectin-3 showed the comparatively best responsiveness (Table 2b). In comparison, the two prototype proteins were generally not very reactive with these glycoclusters, although interindividual differences were apparent between galectins-1 and -7 (Table 2a−c). The inhibition of galectin-3 binding to maxiclusters and biantennary N-glycans showed a stronger dependence on inhibitor multivalency than that to the other two glycoproteins (Table 2b vs Table 2a,c). When calculating the relative potency of each carbohydrate unit of the cyclic glycoclusters, rather modest increases were obtained for the prototype galectins, depending on the nature of the ligand tested, relative to the other two sugar receptor types (Tables 1a,b, Tables 2a,c). Because a potential field of application will entail blocking binding to cell surfaces, not a matrix established by a single (neo)glycoprotein, we next tested the glycoclusters in assays using different cell types.

Cyclodextrins as Inhibitors of Binding to Cells. In the first test system we determined the extent of inhibition of lectin-mediated haemagglutination using trypsin-treated, glutaraldehyde-fixed rabbit erythrocytes as popular cell model. The agglutination was sugar dependent and not affected by the unsubstituted cyclodextrin up to 3.5 mM, as shown by controls (Table 3). The glycoclusters were clearly inhibitory, especially for the plant lectin. In this case, their design led to an improvement of the inhibitory capacity on the level of the individual sugar molecule by the factor of 11.8 in direct comparison to free galactose (Table 3). Corroborating the results of the solid-phase assays, the bridging activity of galectins was also inhibited by the functionalized macrocycles, especially with LacNAc as headgroup. Relative to the plant lectin, their activity toward the tested prototype galectin again was less pronounced. On the other hand, galectin-3, a weak haemagglutinin due to the requirement of aggregation when surface bound as it is monomeric in solution (please see Figure 1), was a rather suitable target (Table 3). To address the issue as to whether the assay design using cell agglutination and not cell binding as endpoint might influence the results, we performed flow cytofluorimetric measurements with two tumor cell lines (the B-lymphoblastoid line Croco II and the colon carcinoma line SW480). We tested the glycoclusters as inhibitors of lectin binding to the cell surface.

The results clearly showed that both assay types monitoring cell binding (haemagglutination or surface binding of labeled lectin) yielded comparable results. As shown in Figure 4 for the Croco II cells, the functionalized β-cyclodextrin was a potent inhibitor for the plant lectin relative to the monovalent sugar (top panel). The inhibition of galectin-3 binding by the Lac/LacNAc-bearing glycoclusters was significant and in the same favorable range, which had been monitored in haemagglutination, compared to the free sugar (middle and bottom panels). Up to this point, the assays were designed with a ligand-exposing surface to which the receptor coming from solution associates. The inhibitor and the receptor were thus both in solution. This situation simulated extracellular activities of galectins. In addition and equally important, they can also exert functions from the cell surface. To further define the extent to which the glycoclusters inhibit interactions mediated by cell surface lectins, it was thus essential to determine their influence on blocking galectin functionality on the cell surface. At this site, the lectin such as galectin-1 can act as a signal sensor or as a cell migration/adhesion molecule directing transient or firm adhesion to other cells and/or extracellular matrix glycoproteins, a step crucial for metastasis. To assign inhibitory potency of the glycoclusters on binding of glycans to a distinct galectin of the cell surface, a tumor cell line with strong surface expression of a certain galectin was required. The two tumor lines used above produce a set of four galectins, namely types 1, 3, 8, and 9 (Gabius et al., 1991; Lahm et al., 2001), confounding the interpretation. For this purpose, we generated a clone by gene transfection, using the human colorectal cancer line DLD-1 and galectin-1 as models.

Stable gene transfection by a galectin-1-cDNA-bearing expression vector and ensuing galectin-1 overexpression on the mRNA and protein levels were verified by PCR analysis of genomic DNA, RT-PCR monitoring, and Western blotting (Figure 5). The primer sequences were chosen to yield an amplification product of 408 bp from the vector-based cDNA in the genomic DNA and the mRNA. The length of the amplification product from the regular galectin-1 gene in the genomic DNA is 8142 bp. Highly efficient reverse transcription and Western blotting revealed traces of galectin-1-specific products in wild-type cells, signal absence in mock-transfected cells, and very strong expression in the sense-transfected cells. The morphological appearance of the three cell populations was rather similar (Figure 6), excluding a detrimental effect caused by this genetic manipulation. Also, the cell growth kinetics of the cell populations gave no indications for a markedly altered behavior with impaired membrane functions (Figure 7). Of interest for our study was the measurement of cell surface presentation of galectin-1. Relative to the control value the anti-galectin-1 antibody binding to the cell surface was clearly increased for the stably transfected cells (Figure 8). Using fluorescent

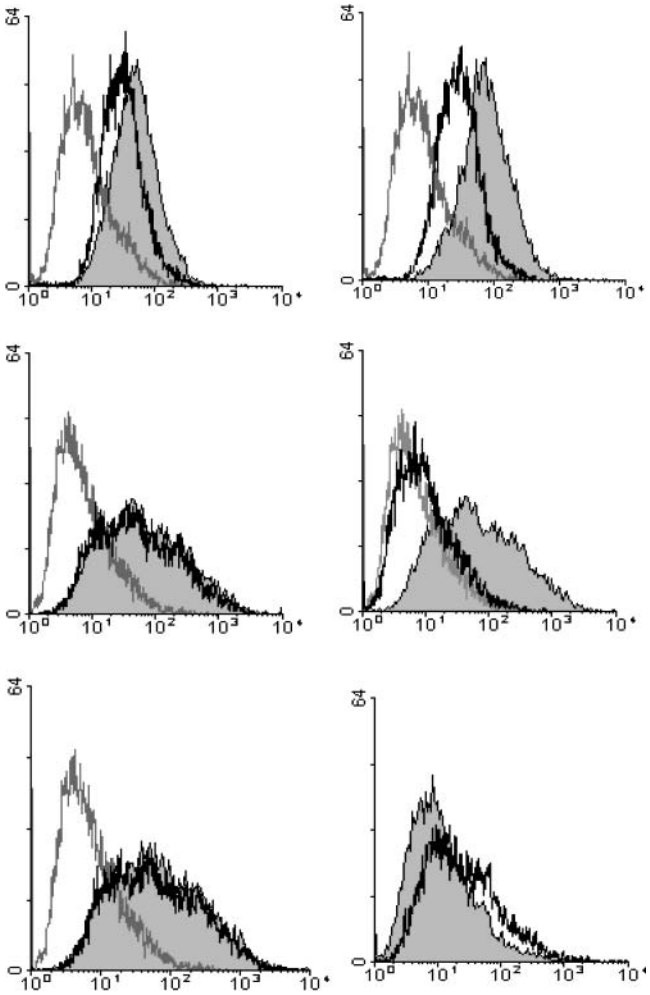

Figure 4. Semilogarithmic representation of fluorescent staining of the surface of human B-lymphoblastoid Croco II cells by biotinylated lectins in the absence and in the presence of glycoinhibitors using streptavidin R-phycoerythrin as second-step reagent. Top panel: cell staining after incubation with the second-step reagent only (gray line), with 0.5 μg mistletoe lectin/ml in the absence of any inhibitor (gray area; left) and in the presence of 6.4 mM lactose (black line; left), 3.5 mM β-cyclodextrin (gray area; right) and 0.9 mM lactose-presenting β-cyclodextrin (equivalent of 6.3 mM lactose in the heptavalent glycoclusters (black line; right)). Middle and bottom panels: cell staining after incubation with the second-step reagent only (gray line), with 10 μg galectin-3/ml in the absence of any inhibitor (gray area; middle panel) and in the presence of 2.2 mM D-galactose (black line in middle panel; left), 1.6 mM lactose (black line in middle panel; right), 180 μM substituent-free β-cyclodextrin and 61 μM galactose-presenting β-cyclodextrin (gray area and black line in bottom panel; left) as well as 43 μM *N*-acetyllactosamine- and lactose-presenting β-cyclodextrin (gray area and black line in bottom panel, right).

lactosylated albumin as probe, the inhibition of its cell surface association by lactose and lactose-bearing β-cyclodextrin was compared in FACScan analysis. Notably, the maxiclusters on the neogycoprotein enabled multivalent contacts to the surface-presented lectin, as already shown for several tumor cell lines and neoglycoenzymes as probes (Gabius et al., 1990). With the lactose concentration set at 6.4 mM, the percentage of positive cells was decreased to 70.5% relative to the control. The β-cyclodextrin derivative used at the same concentration also reduced binding of the neoglycoprotein to the cells, 59.5% of the cells remaining positive. Remarkably, even an increase of the free lactose concentration to 200 mM did not reach this level of competition with multivalent binding. The same tendency was apparent for the mean fluorescence intensity of cells. This result indicates that this galectin was more responsive to the multivalent inhibitor when presented on the cell surface than when in solution.

DISCUSSION

A general feature of protein−carbohydrate interactions is the requirement for establishment of several contacts to generate a sufficiently high affinity for biological activities. Therefore, carbohydrate recognition domains in lectins are often clustered, as recently summarized and illustrated for mammalian lectins (Gabius et al., 2002). A panel of structural motifs gives rise to diverse ways for the relative orientation of the binding sites. "Intelligent" blocking reagents or drug-delivery systems will capitalize on this factor to selectively home in on their targets. Advances in synthetic chemistry to solve problems of convenient carrier functionalization have made it possible to move from the preparative phase to testing the custom-made glycoclusters. In the case of heptaantennated β-cyclodextrins, plant lectins have so far served as model receptors. Respective measurements led to the conclusions that multivalency triggered nonuniform responses for various agglutinins in inhibition assays and that an increase in sugar density will not necessarily entail linear enhancement of inhibitory capacity.

In detail, galactosyl clusters interacted with the peanut lectin leading to a 16-fold increased association constant relative to the monovalent analogue but the individual ligands in two forms of persubstituted β-cyclodextrins (i.e. heptakis[6-*S*-β-D-galactopyranosyl-6-thio]cyclomaltoheptaose and heptakis[6-amino-6-deoxy-6-N−(β-D-galactopyranosyl-1-thiomethyl-carbonyl]cyclomaltoheptaose) failed to retain the level of inhibitory activity of a galactose moiety as internal standard in a solid-phase assay (García-López et al., 1999; Yasuda et al., 2000). The same inhibitor design gave reactivity for the pea lectin, the *Griffonia simplicifolia* I and wheat germ agglutinins but not the lectin from *Galanthus nivalis* (Ichikawa et al., 2000; Yasuda et al., 2000). Wheat germ agglutinin was also found to be remarkably responsive, whereas the dimeric *Erythrina corallodendron* lectin showed a reduced level of sensitivity (Furuike et al., 2000). Interestingly, studies with this lectin or its closely related variant from *Erythrina cristagalli* had not detected a strong effect of multivalency in dendrimers or neoglycopolymers (Zanini and Roy, 1997a; Pohl and Kiessling, 1999). This body of evidence discourages prediction of a priori potent activity of glycoclusters on lectins, although they harbor more than one binding site (Rüdiger and Gabius, 2001; Loris, 2002). It rather advises consideration of systematic experimental work as mandatory. Moving from hepta- to tetradeca-antennated glycoclusters, the apparent binding affinity to concanavalin A was not improved and, of relevance for drug targeting approaches, the ability of the cyclodextrin carrier to form an inclusion complex with 2-naphthalenesulfonate was harmed (Ortega-Caballero et al., 2001). This behavior is evocative of the eventual decrease in inhibitory capacity of Tris-branched dendritic wedges attached by 1,3,5-trisubstitution to a benzenoid core by increasing the number of headgroups from nine, then 18 to finally 36 carbohydrate residues (Ashton et al., 1998). The way the nature of the linker can even drastically influence the inhibition profile was illustrated in the case of heptasubstitution of primary hydroxyls with mannopyranosylthioureido moieties which fail to bind to concanavalin A (Baussanne et al., 2001; Ortiz

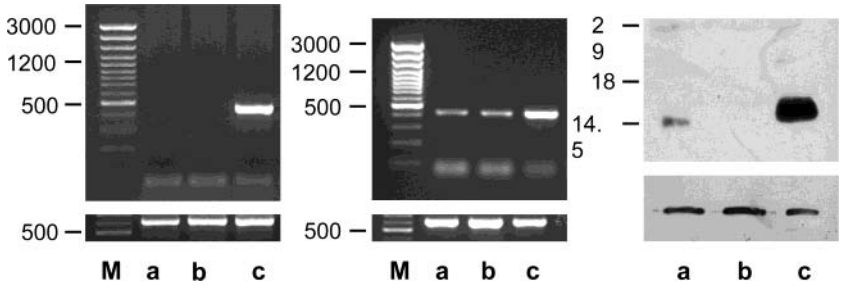

Figure 5. Detection of presence of galectin-1-specific cDNA in genomic DNA (left), of galectin-1-specific mRNA by RT-PCR analysis (middle) and of galectin-1 by Western blotting (right) in material obtained from human colorectal adenocarcinoma DLD-1 cells (a = wild type, b: mock-transfected cells, c: galectin-1 sense transfectant). Numbers on the left side of each panel indicate length of markers (M) or molecular weight of standard proteins. Actin-related parameters were determined as positive quality control (bottom panel).

Mellet et al., 2002). When extending the linker's length to give the supposedly required degree of conformational freedom, as for example documented by García-López et al. (1999), it should not be overlooked that long alkyl spacer arms might find access to the hydrophobic cavity and that carbohydrates might form interresidual hydrogen bonds, impairing their accessibility for lectins (Fulton and Stoddart, 2001b). The strong preference of the

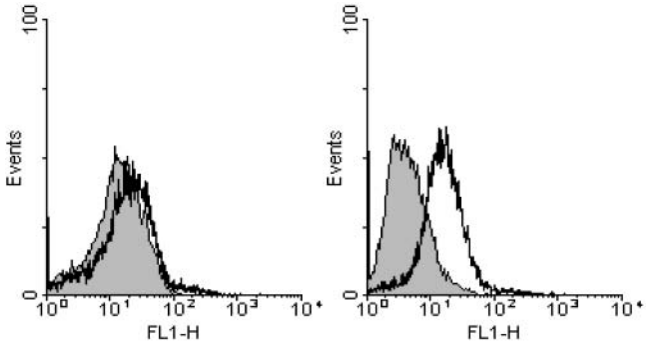

Figure 8. Detection of expression of galectin-1 on the surface of wild-type (left) and sense-transfected DLD-1 cells (right) by flow cytofluorimetry (black line) relative to antigen-independent staining by the fluorescent second-step reagent (gray area) as control.

mistletoe lectin for lactose relative to *N*-acetyllactosamine despite rather similar binding properties in inhibition assays and isothermal titration calorimetry appears to indicate occurrence of such unfavorable events (Lee et al., 1992; Galanina et al., 1997; Bharadwaj et al., 1999). On the other hand, galectin-1, where presence of the *N*-acetyl group accounts for a 0.7 kcal/mol increase of $-\Delta G$ relative to lactose binding (300 K), preferred this ligand in contrast to galectin-7, ΔG in this case decreasing from -4.6 for lactose to -4.4 kcal/mol for LacNAc (Ahmad et al., 2002). With this background, Fulton and Stoddart (2001a) stated that "it is probably fair to conclude that, in the area of saccharide-branched cyclodextrins, and indeed saccharide-branched macrocycles, the research carried out to date only begins to scratch the surface of understanding the subtleties of the relative spatial orientation of carbohydrate ligands, relative to their scaffolds and to each other."

In comparison between the presented reactivity profiles, the plant lectin with its double trefoil structure (Niwa et al., 2003) was prominent for its sensitivity toward glycoinhibitor multivalency. Mitogenic effects on immune and, notably, tumor cells in the ng/mL-range and toxicity at doses above this concentration, seen in vitro for cultured and for peripheral blood cells as well as histotypic tumor cultures (Hajto et al., 1990; Gabius et al., 2001), can thus be abrogated swiftly by these inhibitiors. A similar result can be expected for other plant AB toxins such as ricin. Similarly, the natural β-galactoside-specific immunoglobulin G fraction from human serum was efficiently blocked by hepta-galactosylated β-cyclodextrin. The relative potency on the level of the individual carrier-attached moiety reached the factor of 391 compared to lactose as internal standard. The remarkable sensitivity of the immunoglobulin to these

glycoclusters and also to starburst/wedgelike glycodendrimers and neoglycopolymers might find practical application to protect patients from antibody-dependent hyperacute rejection originating from the immunoreactivity of carbohydrate xenoantigens (André et al., 1999a, 2001; Wang et al., 1999; Baek and Roy, 2002).

In contrast to these two sugar receptors, the prototype galectins with their binding sites on opposing sides of the dimer at a distance of close to 50 Å were less reactive. This result is in line with previous measurements assaying divalent ligands connected by varying linker lengths as well as starburst and wedgelike glycodendrimers (Lee et al., 1990; André et al., 1999a, 2001, 2003). However, our measurements with the gene-transfected cell clone revealed that cell surface presentation can render the prototype galectin-1 more susceptible to a multivalent ligand compared to its behavior in solution. As the k_{off}-rates from *p*-aminophenyl lactoside differed only slightly between the plant lectin and galectin-1 in plasmon resonance monitoring (Dettmann et al., 2000), the impact of the topological aspect is underscored. Also, the differential activity of the substituted β-cyclodextrins against the two prototype galectins, which are both dimeric, can be interpreted to be a sensitive sensor for slight differences in their shape. They might have a bearing on galectin functionality by ligand cross-linking and thus contribute to explain differences in the biological response profile of related galectins (Camby et al., 2001; Kopitz et al., 2001; Sheikholeslam-Zadeh et al., 2001; Brewer, 2002; Cao et al., 2002; Nagy et al., 2002, 2003; Timoshenko et al., 2003). It is thus useful to have a reliable marker in hand to probe these characteristics comparatively.

The most notable difference between the galectins concerned galectin-3 relative to galectins-1 and -7. Monomeric in solution, the chimera-type galectin can form aggregates via its N- and C-terminal domain which are responsive toward multivalent ligands (André et al., 2001 and references therein). The relative potency of the substituted β-cyclodextrins to galectin-3 distinguished this family member from the prototype galectins, a clear indication for subgroup selectivity. This result is in line with the activity profile of wedgelike glycodendrimers, especially after spacer rigidification (André et al., 2001; Vrasidas et al., 2003). The answer to the question as to whether persubstitution is indispensable for this feature can be figured out by testing less than hepta-antennated products obtained by running conjugation with a subsaturating concentration of the carbohydrate derivative. Combining these topological factors, i.e., ligand display and spacer properties, with exploitation of the differences in carbohydrate fine-specificity, among others the 12-fold difference of inhibitory capacity of α2,6-sialylated diLacNAc to galectin-3 vs galectin-1 (Ahmad et al., 2002; Hirabayashi et al., 2002), the discriminatory power is sure to be further enhanced. In this area, combinatorial synthesis of carbohydrates and mimetics thereof is likely to be instrumental to extend the panel of structures, efficiently homing in on a certain lectin (Nishimura, 2001; Ramström et al., 2002).

A further salient finding of this report is the influence of the topology of the lectin's binding partner on the inhibitory profile. To avoid missing this "topological" specificity, it will be essential to routinely test more than one biochemically defined ligand. By using (neo)glycoproteins with precisely known glycan profile (maxiclusters, bi- and/or triantennary N-glycans), we obtained a nonuniform response to the substituted β-cyclodextrins for each tested sugar receptor. Thus, we can in fact conclude that the characteristics of the ligand population (cluster formation, status of branching) matter more than currently appreciated for receptors in solution. Avidity of binding to branched and/or clustered ligands encompasses both a contact and a topology dimension. With chemoenzymatically synthesized glycan chains becoming available, systematic studies of this aspect are clearly warranted. The way the natural N-glycan substitution by core fucosylation modulates lectin affinity to the galactoside termini of complex-type biantennary N-glycans has recently set a precedent for further efforts in this respect (Unverzagt et al., 2002).

In conclusion, this report proves that hepta-antennated β-cyclodextrins present their carbohydrate appendages in bioactive form for galactoside-specific plant and, notably, mammalian lectins as well as immunoglobulin G. Furthermore, discriminatory potency of these glycoclusters between two prototype and between prototype vs chimera-type galectins was evidenced. Beside the topological aspect of binding site arrangement in the receptor part, the geometry of the ligand structure was shown to exert a considerable influence, a result with evident biological implications. In more general terms, our results provide a promising example that substituted β-cyclodextrins, owing to their favorable pharmacologic properties, have potential to find their place in the design of "intelligent" blocking reagents.

ACKNOWLEDGMENT

The skilfull technical assistance of B. Hofer, the kind gifts of reagents from Drs. J. Hirabayashi, F.-T. Liu, R. Timpl, and J. L. Wang, the helpful advice from Drs. B. B. and S. Namirha, and the generous financial support of the Wilhelm Sander-Stiftung (Munich, Germany) are gratefully acknowledged.

Synthesis and Physicochemical Characterization of Gd−DTPA−B(sLe^x)A, a New MRI Contrast Agent Targeted to Inflammation

Sophie Laurent, Luce Vander Elst, Yanjun Fu,† and Robert N. Muller*

NMR Laboratory, Department of Organic Chemistry, University of Mons-Hainaut, B-7000 Mons, Belgium. Received July 8, 2003; Revised Manuscript Received October 8, 2003

A new magnetic resonance imaging (MRI) contrast agent designed to mimic sialyl Lewis X (sLe^X) and to target inflammation has been synthesized and characterized. The evolution of its proton longitudinal relaxivity as a function of the magnetic field (NMRD) and temperature has been studied. The exchange rate of the water coordinated to the metal has been assessed by oxygen-17 relaxometry. The transmetalation by zinc(II) ions and the noncovalent binding to human serum albumin have been evaluated. The results show no limitation by the residence time of the coordinated water molecule above room temperature, a higher stability of the complex versus transmetalation by zinc(II) ions than a parent complex, the clinically used Gd-DTPA-BMA, and negligible interaction with human serum albumin.

INTRODUCTION

The interaction between E-selectin of endothelial cells and sialyl Lewis^x (sLe^x), an oligosaccharide located on the surface of monocytes, neutrophils, basophils, eosinophils, and a specific subset of T lymphocytes, occurs early after tissue injury and leads to inflammation (*1*, *2*). Blocking the sLe^x/selectin interaction has thus been considered as an efficient way to treat inflammatory disease (*3*). Although sLe^x has demonstrated antiinflammatory action, its large-scale synthesis, like that of other oligosaccharides, is difficult. Therefore, efforts to produce mimetics have been attempted. The conformation of sLe^x in solution and the three-dimensional structure of the human E-selectin have been determined (*4*−*7*). Six functional groups of the sLe^x molecule, the 2-, 3- and 4-hydroxyl groups of L-fucose, the 4- and 6-hydroxyl groups of galactose, and the carboxylate group of the sialic acid, are essential for the recognition by E-selectin (*8*, *9*). Compounds containing these functional groups and mimicking the active conformation of sLe^x have been recently designed and synthesized (*10*−*15*).

For the purpose of developing a novel contrast agent targeted to inflammation, we have described a successful and original synthesis of a new DTPA ligand conjugated to a sialyl Lewis^X mimetic, a 3-(2-α-D-mannopyranosyloxyphenyl)phenylacetic acid moiety which is a potent inhibitor for sLe^x-selectin binding (*16*). DTPA was chosen as metal chelator because of its high thermodynamic equilibrium constant with stable paramagnetic or radioactive ions such as gadolinium (*17*, *18*). The coupling of DTPA to the sialyl Lewis^X mimetic is performed through its bicyclic bisanhydride form (*19*, *20*). The DTPA ligand has been subsequently complexed with gadolinium, an ion commonly used as the paramagnetic core of MRI contrast agents (*21*, *22*). In the present work, the specific MRI contrast agent Gd−DTPA−B(sLe^x)A has been submitted to a classical physicochemical characterization encompassing the study of its relaxivity as a function of the magnetic field and temperature, stability in the presence of Zn(II) ions, and the assessment of noncovalent binding to albumin and the determination of water residence time by oxygen-17 relaxometry.

EXPERIMENTAL PROCEDURES

Chemicals. Gd−DTPA (Magnevist) was obtained from Schering AG (Berlin, Germany), and Gd−DTPA−BMA (Omniscan) from Amersham-Nycomed (Oslo, Norway). $GdCl_3$ and $ZnCl_2$ were purchased from Aldrich (Bornem, Belgium). Phosphate buffer pH 7 was from Merck (Overijse, Belgium).

Mass Spectrometry. The mass spectrum was obtained on a Q-tof II mass spectrometer (Micromass, Manchester, UK). Compound (0.5 mg) was dissolved in 1 mL of a mixture MeOH/H_2O (50/50) and infused in the source at a debit of 5 μL/min.

Chromatography. Reverse-phase HPLC was carried out on a system consisting of a Waters 600 controller and a Waters 996 photodiode array detector equipped with a Novapak C18 column for analytical runs (i.d. 4.56 mm × 150 mm) and for semiprep runs (i.d. 25 mm × 100 mm) (Waters, Milford, MA). A gradient of 95:5 to 50:50 (S1/S2, v/v) solvent was run over 20 min at a flow rate of 0.7 mL/min for analysis or 9.0 mL/min for preparation (solvent S1, 5% aqueous CH_3CN with 0.3 mM HCl; solvent S2, 95% aqueous CH_3CN with 0.3 mM HCl). Addition of HCl was necessary to decrease the adsorption of samples on the column materials. UV adsorption of the effluent was monitored at 254 nm.

Dialysis. Dialysis was carried out against deionized water using a cellulose ester tube with cutoff molecular weight of 500 (Spectra/PorCE, diameter 20 mm).

Relaxometry. Proton nuclear magnetic relaxation dispersion (NMRD) profiles were recorded at different temperatures on an IBM Research Field Cycling Relaxometer working between 0.02 and 40 MHz. The samples

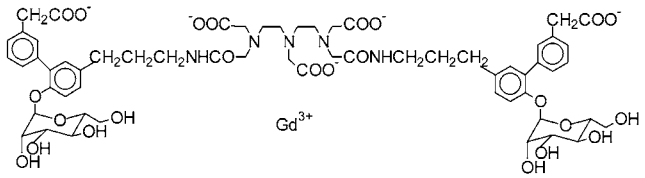

Figure 1. Structure of the Gd−DTPA−B(sLe^x)A.

(0.6 mL) were contained in 10 mm o.d. tubes. The temperature was controlled with a precision of 0.1 °C. Additional points at 20, 40, and 300 MHz were respectively obtained on Minispec systems PC-20 and PC-40 and on an AMX 300 spectrometer (Bruker, Germany). Fitting of the ^{1}H NMRD curves was performed with a previously described software using minimization routines (Minuit, CERN Library) (*23*, *24*), according to the theoretical innersphere (*25*, *26*) and outersphere models (*27*). T_1 measurements at 7.05 T were performed with the inversion recovery Fourier transform technique and a subsequent three parameters fit of the peak height.

The oxygen-17 measurements (*28*) were carried out on 2 mL samples contained in 10 mm o.d. tubes on a Bruker AMX-300 spectrometer equipped with a broadband probe and with a Bruker BVT-2000 unit for temperature control. The temperature was regulated by air or nitrogen flow. Diamagnetic transverse relaxation times of ^{17}O water (pH ≈ 6.5) were measured at natural abundance using a Carr−Purcell−Meiboom−Gill sequence and a two-parameter fit of the data points. ^{17}O transverse relaxation times of water (natural abundance) in solutions containing paramagnetic complexes were calculated directly from the line width measurement. All ^{17}O NMR spectra were proton decoupled. The evaluation of the exchange rate of the water coordinated to the Gd ion was carried out by analyzing the temperature dependence of the oxygen-17 resonance line width in the range of 280−350 K.

Transmetalation. Transmetalation by zinc ions was evaluated by the decrease of the water longitudinal relaxation rate at 310 K and 20 MHz (Bruker Minispec) of buffered phosphate solutions containing 2.5 mM of the gadolinium complex and 2.5 mM of Zn (*29*).

Synthesis. Gadolinium (III) complex, Gd−DTPA−B(sLe^X)A: A solution of $GdCl_3 \cdot 6H_2O$ (0.196 mmol, 72.8 mg) in distilled water (5 mL) was added slowly to the ligand DTPA−B(sLe^X)A solution (0.196 mmol). The complexation was performed at pH 6−6.5 by adding diluted NaOH. The mixture was stirred at 50 °C for 3 h and then submitted to an exhaustive dialysis (membrane cutoff: 500 Da, 4 × 300 mL, 4 × 18 h). The dialyzate, in which the absence of free Gd^{3+} ions was assessed by the arsenazo III test (*30*), was lyophilized to give 230 mg of chromatographically pure complex as a slightly yellow solid. Analytical reverse-phase HPLC: retention time 4.94 min, semiprep HPLC: retention time: 12.14 min. ESI: Gd-isotopes m/z = 1446−1455 $(M + H)^+$. Anal. ($C_{60}H_{72}N_5O_{24}GdNa_2 \cdot 6H_2O$): calcd (found): C 46.21 (46.01); H 5.4 (5.25); N 4.49 (4.45).

RESULTS AND DISCUSSION

The Gd−DTPA−B(sLe^x)A complex obtained by mixing an equimolar amount of ligand (*16*) and gadolinium chloride hexahydrate is shown in Figure 1.

Residence Time of the Coordinated Water Molecule. The possible influence of the residence time of the coordinated water molecule, τ_M, on proton relaxation was evaluated by measuring the proton longitudinal relaxivity r_1 of the Gd complexes at 0.47 T over a temperature range extending from 5 to 45 °C (Figure 2). The continuous increase of r_1 when temperature decreased shows that no drastic limitation of the relaxivity of the complex occurs at low temperatures, even if by comparison to the data obtained for Gd−DTPA there is evidence of a slight limitation at low temperatures.

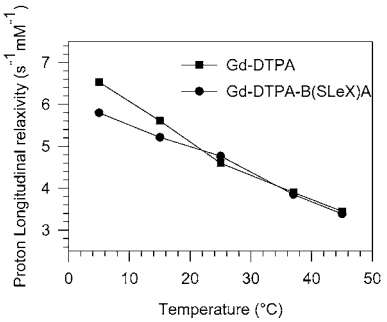

Figure 2. Temperature dependence of the proton longitudinal relaxivity of Gd−DTPA−B(sLe^x)A and Gd−DTPA at 20 MHz.

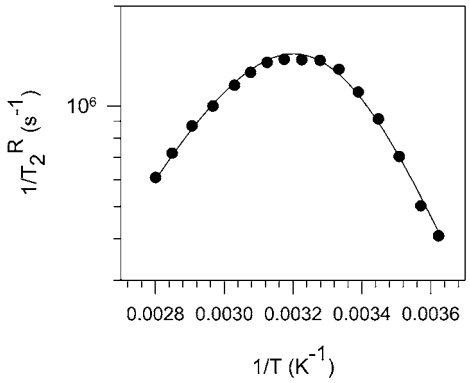

Figure 3. Temperature dependence of the oxygen-17 reduced transverse relaxation rate of Gd−DTPA−B(sLe^x)A (26.3 mM).

The quantitative determination of the residence time of water molecules in the first coordination sphere of the gadolinium complexes (τ_M) was performed as described previously (*28*) by analysis of the temperature dependence of the paramagnetic oxygen-17 transverse relaxation rate of a 26.3 mM solution of the complex (Figure 3). From the theoretical fitting of the data, several parameters are obtained: first, the hyperfine coupling constant between the oxygen-17 nucleus and the electronic spin of Gd^{3+} ($A/\hbar$); second, the parameters related to the electronic relaxation times of the gadolinium ion τ_{S1} and τ_{S2}, i.e., τ_V, the correlation time for the modulation of the zero field splitting, E_V, the activation energy for this process, and B, which depends on the trace of the square of the zero field splitting tensor (Δ^2) and on the electron spin S ($B = \Delta^2\{4S(S + 1) - 3\}/25$); and, third, the parameters of the water exchange rate, i.e., the enthalpy ($\Delta H^{\ddagger}$) and the entropy ($\Delta S^{\ddagger}$) of activation. By analogy with other derivatives of Gd−DTPA, the number of coordinated water molecules (q) was assumed to be equal to one. The theoretical fitting of the reduced transverse relaxation rates ($1/T_2^R = \{1/T_2^{obs} - 1/T_2^{dia}\} \times 55.55/$ [Gd complex]) obtained over a temperature range extending from 276 to 357 K gives a τ_M^{298} value of 525 ± 57 ns. This value is somewhat larger than that reported for Gd−DTPA ($\tau_M^{298} = 331 \pm 60$ ns) (*31*) but much shorter than that of Gd−DTPA−BMA ($\tau_M^{298} = 2130 \pm 80$ ns) (*32*) or other Gd−DTPA bisamides substituted by alkyl chains (*32*). The fitted parameters are shown in Table 1 (the values obtained for Gd−DTPA−BMA are shown for com-

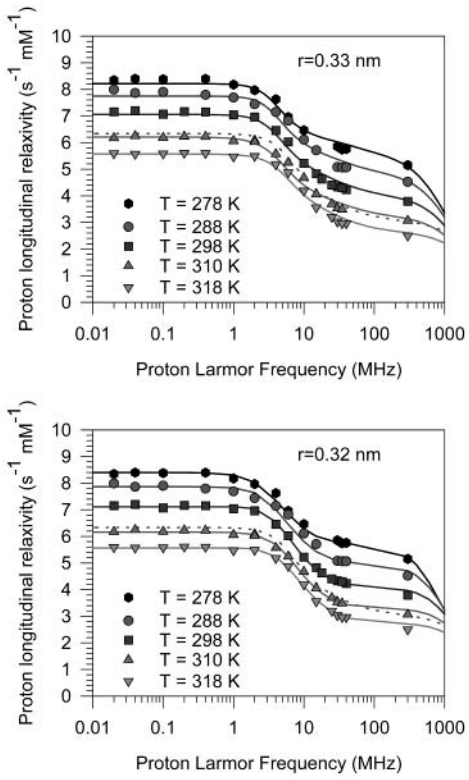

Figure 4. Experimental NMRD profiles of Gd−DTPA−B(sLe^x)A (1.18 mM) in water at different temperatures. Top graph: the lines correspond to the theoretical fitting performed with outer-sphere and inner-sphere interactions. Bottom graph: the lines correspond to the theoretical fitting performed with inner-sphere and second-sphere interactions. Dotted line: Gd−DTPA at 310 K.

Table 1. Parameters Obtained from the Fitting of the Reduced Transverse Relaxation Rate of Oxygen-17

	Gd−DTPA−B(sLe^x)A	Gd−DTPA	Gd−DTPA−BMA
B (10^{20} s^{-2})	1.96 ± 0.64	2.60 ± 0.06	2.04 ± 0.06
τ_V^{298} (ps)	18.5 ± 5.6	12.3 ± 0.3	21.2 ± 0.6
$A/\hbar$ (10^6 rad s^{-1})	−3.0 ± 0.1	−3.4 ± 0.1	−3.2 ± 0.1
$\Delta H^{\ddagger}$(kJ/mol)	42.7 ± 0.1	51.5± 0.3	48.0 ± 0.1
$\Delta S^{\ddagger}$(J/mol K)	18.7 ± 0.5	52.1 ± 0.6	24.9 ± 0.2
E_V (kJ/mol)	15.4 ± 2.2	4.5 ± 4.2	15.0 ± 10.9
τ_M^{310} (ns)	259 ± 27	143 ± 26	967 ± 36

parison). The value obtained for the hyperfine coupling constant confirms the presence of one coordinated water molecule.

The τ_M^{310} value is short enough to enable a fast exchange between coordinated and bulk water molecules. However, at low temperatures, a slight limitation of the inner-sphere proton relaxivity by the water residence time is responsible for the lower relaxivity of Gd−DTPA−B(sLe^x)A as compared to that of Gd−DTPA.

Relaxivity at Various Magnetic Fields and Temperatures. The proton NMRD profiles recorded at five temperatures are shown in Figure 4.

Despite the larger molecular weight of the Gd−DTPA−B(sLe^x)A complex (MW = 1449), its proton relaxivity at 310 K is comparable to that of Gd−DTPA (MW = 547) (*31*) over the whole proton Larmor frequency range. The fittings of the proton NMRD profiles were performed as described in the Experimental Section and include both inner-sphere and outer-sphere interactions (*23*−*27*). The following parameters were fixed during the fitting procedure: *d*, the distance of closest approach for the outersphere contribution which was set at 0.36 nm (*28*, *31*), τ_M values which were those obtained by ^{17}O NMR, and *q*, the number of water molecules in the first coordination sphere of Gd^{3+}, which was set to one. The parameters describing the electronic relaxation times, τ_V and τ_{SO} (the electronic relaxation time at zero field), were optimized for the outer-sphere and the inner-sphere contributions simultaneously. The distance *r* between the protons of the coordinated water molecule and the Gd ion is usually set to 0.3 or 0.31 nm for Gd−DTPA derivatives unsubstituted on the carbon backbone (*32*, *33*, *34*). The rotational correlation time of the complex, τ_R, could not be estimated by the analysis of the deuterium relaxation rates due to the hydrolysis of the amide bonds during the labeling of the α-carbons of carbonyl groups. Its estimation by the Stokes−Einstein law, assuming that the molecular volume is roughly proportional to the molecular weight and that the complex rotates as a rigid structure, gives a value of approximately 145 ns at 310 K. This value and a distance *r* equal to 0.31 nm did not allow a proper fitting of the experimental data. Reasonable fits were obtained either by decreasing the value of τ_R to values even lower than those of Gd−DTPA, which seems unrealistic, or by increasing the distance *r*. In a first approach, this last solution was chosen. The fitting performed with an *r* value of 0.33 nm results in a τ_R^{310} of 93 ps. This value of τ_R seems acceptable since internal motion could lower the effective rotational correlation time. The fittings were thus performed for the five temperatures with this value of *r*. The resulting parameters are given in Table 2.

Table 2. Parameters Obtained from the Fitting of the Proton NMRD Data of Gd−DTPA-B(sLe^x)A

Inner-Sphere and Outer-Sphere Contributions with r = 0.33 nm

temperature	D (10^{-9} m^{2}s^{-1})[a]	τ_R (ps)	τ_{so}[b] (ps)	τ_v (ps)	τ_M (ns)
278 K	1.5	194	95	33	1945
288 K	1.9	146	94	34	988
298 K	2.5	116	97	32	525
310 K	3.3	93	97	24	259
318 K	3.7	71	97	27	166

Inner-Sphere and Second-Sphere Contributions with r = 0.32 nm[c]

temperature	τ_R (ps)	τ_{so}[b] (ps)	τ_v (ps)	τ_M (ns)	τ_{ss} (ps)[d]
278 K	261	119	40	1945	44
288 K	168	104	40	988	35
298 K	120	93	40	525	30
310 K	90	82	30	259	25
318 K	75	85	33	166	20

[a] The relative translational diffusion coefficient was set to the averaged value measured on a series of lanthanum analogues (*37*). [b] τ_{SO} is the electronic relaxation time at very low magnetic field. [c] The number of water molecules in the second sphere was set to 6, and the distance for this second sphere interaction was fixed at 0.4 nm. [d] τ_{ss} is the correlation time modulating the second-sphere interaction.

In a second approach, the hypothesis of a reduced outer-sphere contribution was also considered. With such a hypothesis, good agreement between theoretical and experimental points was found only for frequencies lower than 1 MHz or larger than 40 MHz. Moreover, for an *r* value of 0.31 nm and a τ_R value equal to 92 ps at 310 K, this fitting implies a much larger value of the distance of closest approach (d = 0.85 nm), a value which is quite unrealistic.

In a third approach, given the presence of several hydroxyl groups in the vicinity of the gadolinium ion, a second sphere contribution was included in the fittings (*35*). In this case, the outer-sphere contribution was

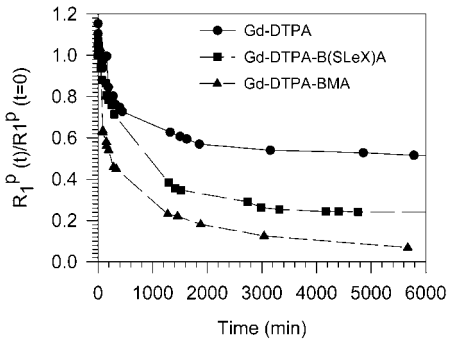

Figure 5. Evolution of the ratio $R_1^p(t)/R_1^p$ ($t = 0$) as a function of time for Gd−DTPA−B(sLe^x)A, Gd−DTPA, and Gd−DTPA−BMA.

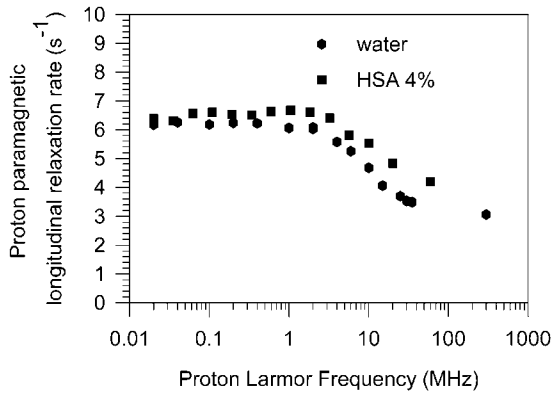

Figure 6. Paramagnetic proton longitudinal relaxation rate of 1 mM solutions of Gd−DTPA−B(sLeX)A in pure water and in a 4% HSA solution.

neglected, the distance *r* for the inner-sphere interaction was set to 0.32 nm, the number of water molecules in the second sphere was fixed to 6, and the distance of interaction for these water molecules was set to 0.4 nm. The results are shown in Table 2.

The first and the third approaches give similar fits. The choice of one fitting procedure is difficult but, based on the recent report of Caravan et al. stating that the distance *r* must be equal to 0.31 ± 0.1 nm (*36*), the model including inner- and second-sphere interactions seems to be better. An accurate determination of the distance *r* would be needed to select the best model.

Kinetics of Transmetalation. Transmetalation was assessed by the time-evolution of the paramagnetic proton longitudinal relaxation rate (R_1^p) of a phosphate buffer solution (pH 7) containing 2.5 mM of the gadolinium complex and 2.5 mM of $ZnCl_2$ (*29*). When transmetalation takes place, the released gadolinium ions form an insoluble complex with phosphate ions. Consequently, the paramagnetic relaxation rate decreases. The measurements were performed at 0.47 T and 310 K. After 5000 min, the paramagnetic relaxation rate had decreased by 90% for Gd−DTPA−BMA, by 48% for Gd−DTPA, and by 76% for Gd−DTPA−B(sLe^x)A (Figure 5). Gd−DTPA−B(sLe^x)A is thus more stable than the commercial bisamide Gd−DTPA−BMA but, as the other bisamide complexes (*29*), less stable than the parent pentacarboxylic compound Gd−DTPA.

Interaction with Albumin. The possible interaction of the complex with human serum albumin was studied through the comparison of the proton paramagnetic relaxation rate of an aqueous 1 mM solution of the complex in the absence and in the presence of 4% of HSA. If an interaction with the protein occurs, a significant increase of the proton paramagnetic relaxation is expected. The ratio of the paramagnetic relaxation rates observed in the presence and in the absence of HSA was equal to 1.3 at 20 MHz and 310 K. The NMRD profiles of the paramagnetic relaxation rate of this solution and of a 1 mM solution in pure water are very similar except at frequencies larger than 10 MHz, where the values of the HSA solution are slightly higher (Figure 6). This behavior is similar to that of Gd−DTPA that does not interact with albumin and markedly different from that of other gadolinium complexes known for their interaction with albumin and for which significant increase of the paramagnetic relaxation rate at low and high magnetic fields are observed. These data agree thus with the absence of marked interaction between the complex and the protein.

CONCLUSION

The new contrast agent potentially targeting inflammation is characterized by an unexpected low proton relaxivity as compared to Gd−DTPA despite a larger molecular weight. This feature does not result from a limitation by the water residence time at and above room temperature, as shown by the τ_M values obtained from the analysis of the oxygen-17 transverse relaxation rate data. Rather, it seems that this peculiarity can be explained by a slightly larger distance between the gadolinium ion and the protons of the coordinated water molecule. The stability of the complex versus transmetalation by zinc(II) ions is larger than that of the commercial contrast agent Gd−DTPA−BMA, and no significant interaction with serum albumin is observed. The study of its efficacy as a contrast agent for the in vivo detection by MRI of pathologies characterized by inflammation is currently under progress. The preliminary results show a prolonged contrast enhancement of blood vessels in livers submitted to fulminant hepatitis (*38*).

ACKNOWLEDGMENT

The authors thank Mrs Patricia de Francisco for her help in preparing the manuscript. This work was supported by the ARC Program (contracts number 95/00-194 and 00-05/258) of the French Community of Belgium.

Potential and Practical Adrenomedullary PET Radiopharmaceuticals as an Alternative to *m*-Iodobenzylguanidine: *m*-(ω-[^{18}F]Fluoroalkyl)benzylguanidines

Byung Chul Lee,[†] Jin-Young Paik,[‡] Dae Yoon Chi,*[,†] Kyung-Han Lee,*[,‡] and Yearn Seong Choe*[,‡]

Department of Chemistry, Inha University, 253 Yonghyundong Namgu, Inchon 402-751, Korea, and Department of Nuclear Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, 50 Ilwon-dong Kangnam-ku, Seoul 135-710, Korea. Received July 8, 2003; Revised Manuscript Received October 26, 2003

To investigate adrenomedullary radiopharmaceuticals for positron emission tomography (PET), we have developed no-carrier-added *m*-(ω-[^{18}F]fluoroalkyl)benzylguanidines. *m*-(ω-[^{18}F]Fluoroalkyl)benzylguanidines were prepared in two steps starting from *N*,*N*′-bis(*tert*-butyloxycarbonyl)-*N*″-(ω-methanesulfonyloxyalkyl)benzylguanidines in 20−30% radiochemical yields (decay corrected for 100 min) and with high radiochemical purity (>97%) and shown to be stable (>90%) in an in vitro metabolic stability assay. The binding of *m*-(3-[^{18}F]fluoropropyl)benzylguanidine (**[^{18}F]3**) to SK-N-SH human neuroblastoma cells was temperature dependent, and binding levels at 4 °C were reduced to half of that at 37 °C, which was similar to the reduction rate observed for [^{123}I]MIBG. Tissue distribution studies in mice showed the highest uptake in the adrenals (%ID/g = 27.2 ± 5.0%) with relatively high uptake in the myocardium (%ID/g = 9.3 ± 0.5%). The results suggest that this radiotracer holds promise as a useful adrenomedullary radiopharmaceutical for PET imaging.

INTRODUCTION

m-Iodobenzylguanidine (MIBG) is a structural analogue of the adrenergic-neuron-blocking agent guanethidine and a functional analogue of the neurotransmitter norepinephrine (*1*, *2*). MIBG shares the same uptake and release mechanism as norepinephrine in neuroendocrine tumors and in myocardial sympathetic nerve endings (*3*, *4*). Radiolabeled [^{123}I]MIBG and [^{131}I]MIBG, therefore, are widely used for the localization and therapy of neuroendocrine tumors such as pheochromocytoma and neuroblastoma, and [^{123}I]MIBG is also applied for assessing the cardiac adrenergic system in cardiomyopathy and myocardial infarction (*5*−*10*). Many laboratories have shown an interest in MIBG analogues for PET, which can probe altered biochemical pathways and can be used to access metabolic levels quantitatively (*11*−*14*). Although MIBG analogues labeled with ^{18}F, ^{124}I, and ^{76}Br have been synthesized, none of them are practically useful as clinical PET tracers, because of either impractical synthetic routes or difficulties in availabilities of radionuclides (*12*−*17*).

On the other hand, fluorine-18 is the most desirable PET radionuclide due to its ideal physical properties (511 keV, $t_{1/2}$ = 110 min) (*18*, *19*). Three fluorine-18-labeled analogues of MIBG have been developed: *para*- and *m*-[^{18}F]fluorobenzylguanidine ([^{18}F]PFBG, [^{18}F]MFBG) and (4-[^{18}F]fluoro-3-iodobenzyl)guanindine ([^{18}F]FIBG) (*12*−*14*, *17*). The synthesis of [^{18}F]PFBG was more facile than that of [^{18}F]MFBG, but [^{18}F]MFBG gave better in vitro cell binding results. Nevertheless both compounds have lower binding affinities than MIBG, which may derive from their low lipophilicities. It is believed that lipophilic aromatic substituents can enhance neuron-blocking potency (*20*). By fluoride ion displacement reaction of the sulfonate group on the side chain of the aromatic system, [^{18}F]fluoroalkyl aromatics could be synthesized very efficiently in short reaction time with good radiochemical yield (*21*). In this report, we describe the preparation and evaluation of 3-(ω-[^{18}F]fluoroalkyl)-benzylguanidines.

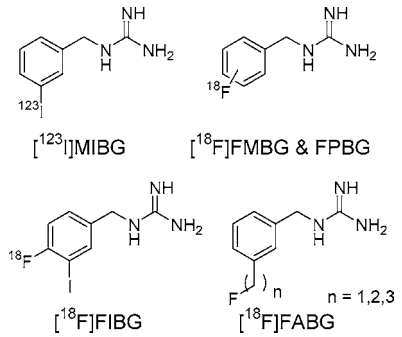

Figure 1. Structures of [^{123}I]MIBG, [^{18}F]FMBG, [^{18}F]FPBG, [^{18}F]FIBG, and [^{18}F]FABG.

MATERIALS AND METHODS

General. Solvents and reagents were purchased from the following commercial sources: Aldrich, Kanto, and Acros. ^{1}H NMR spectra were obtained on a Varian Gemini-200 and 400 (200 and 400 MHz) spectrometer (Palo Alto, CA) and ^{13}C NMR at 50 or 100 MHz. Chemical shifts were reported in parts per million (ppm, δ units) and coupling constants in units of hertz (Hz). Electron impact (EI) and chemical ionization (CI) mass spectra were obtained on a GC/MS QP5050A spectrometer (Shimadzu, Kyoto, Japan). Fast atom bombardment (FAB) mass spectra were obtained on a JMS 700 (JEOL Ltd.,

Tokyo, Japan). [^{18}F]Fluoride ion was produced from [^{18}O]-H_2O (Rotem Industries, Ltd., Israel) by a cyclotron (GEMS, Uppsala, Sweden). High performance liquid chromatography (HPLC) was carried out on a Thermo Separation Products System (Fremont, CA) with a semi-preparative column (Alltech Econosil C18 silica gel, 10 μm, 10 × 250 mm) and analytic column (Alltech Enonosil C18 silica gel, 5 μm, 4.6 × 250 mm). The eluant was simultaneously monitored by a UV detector (215 nm) and a NaI(Tl) radioactivity detector. Thin-layer chromatography (TLC) was performed on Merck F_{254} silica gel or C-18 silica gel plates and analyzed on a Bioscan radio-TLC scanner (Washington DC). In vitro incubation was carried out at 37 °C using a block heater (Digi-Block Laboratory Device Inc., Holliston, MA). Radioactivity was measured in a dose calibrator. All animal experiments were performed in compliance with the rules of Samsung Medical Center Laboratory Animal Care based on NIH guidelines. [^{123}I]MIBG was prepared at the Korea Cancer Center Hospital, Seoul, Korea (The radiochemical purity, over 95%; the activity concentration, about 473.6 MBq/mL; specific activity, 220 GBq/μmol).

General Procedure for the Synthesis of 4a,b. To a mixture of 3-bromobenzonitrile (1.00 g, 5.49 mmol) and lithium chloride (1.67 g, 39.6 mmol) in dry THF (25 mL) under nitrogen atmosphere was added tetrakis(triphenylphosphine)palladium(0) (100 mg, 1.6 mol %). The mixture was stirred at room temperature. After 40 min, a colorless solution was generated and to this was added allyltributyltin (1.87 mL, 6.03 mmol). This mixture was heated at 75 °C for 12 h. The reaction mixture was cooled to room temperature and diluted with ethyl acetate (20 mL), and the LiCl·Pd(II) complex was removed by filtration. The filtrate was washed with 10% NaOH (aq 2 × 15 mL), and the organic layer was dried over Na_2SO_4. After the solvents were removed by vacuum, the residue was purified by silica gel flash column chromatography (hexane/EtOAc =19:1) gave **4b** (634 mg, 81%) as a colorless oil: **3-Allylbenzonitrile (4b).** ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.51−7.35 (m, 4H, Ar), 6.03−5.83 (m, 1H, CH), 5.17−5.05 (m, 2H, CH_2), 3.42 (d, J = 6.6 Hz, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 141.38, 135.70, 133.08, 132.02, 129.80, 129.08, 118.77, 117.05, 112.43, 39.46; MS (CI) m/z 144 (M^+ + H). HRMS calcd for $C_{10}H_{10}N$ 144.0813, found 144.0818.

3-Vinylbenzonitrile (4a). Colorless oil in 81% yield; ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.65−7.38 (m, 4H, Ar), 6.74 (dt, J = 17.6, 10.6 Hz, 1H, CH), 5.63 (d, J = 17.6 Hz, 1H, CH_2), 5.56 (d, J = 15.0 Hz, 1H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 138.53, 134.60, 130.80, 130.44,129.47, 129.15, 118.44, 116.37, 112.58; MS (CI) m/z 130 (M^+ + H). HRMS calcd for C_9H_8N 130.0657, found 130.0656.

3-Cyanobenzyl Alcohol (5a). To a solution of 3-cyanobenzaldehyde (1.00 g, 7.62 mol) in 15 mL of ethanol was added sodium borohydride (346 mg, 9.15 mmol). After 1 h, the reaction was quenched by a piece of ice and diluted with ethanol. The ethanol was evaporated under reduced pressure, and then water was poured into the reaction mixture. The resulting mixture was extracted with dichloromethane (2 × 25 mL). The combined extracts were dried over Na_2SO_4. After removal of the solvent, silica gel flash column chromatography (hexane/EtOAc = 3:2) gave **5a** (993 mg, 98%) as a colorless oil: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.60−7.40 (m, 4H, Ar), 4.67 (s, 2H, CH_2), 3.70 (bs, 1H, OH); ^{13}C NMR (50 MHz, $CDCl_3$) δ 142.36, 130.95, 130.76, 129.87, 129.02, 118.67, 111.79, 63.28; MS (EI) m/z 133 (M^+). Anal. (C_8H_7NO) calcd: C, 72.16; H, 5.30; N, 10.52. found: C, 71.99; H, 5.43; N, 10.74.

General Procedure for the Synthesis of 5b,c. To a stirred solution of **4b** (350 mg, 2.44 mmol) in dry tetrahydrofuran (7 mL) at 0 °C under a nitrogen atmosphere was added 1 M borane−tetrahydrofuran complex (2.92 mL, 2.92 mmol). After 1 h, water (2 mL) was added cautiously to decompose excess hydride. Oxidation was carried out by adding 2.6 mL of 4 N sodium hydroxide, followed by addition of 3.5 mL of 28% hydrogen peroxide. The reaction mixture was stirred for 40 min. The crude product was extracted by EtOAc (3 × 5 mL). The organic layer was dried over Na_2SO_4. After the organic layer was removed by vacuum, the product was obtained by silica gel flash column chromatography (hexane/EtOAc = 7:3) gave **5c** (295 mg, 75%) as a colorless oil: **3-(3-Hydroxypropyl)benzonitrile (5c).** ^{1}H NMR (200 M MHz, $CDCl_3$) δ 7.50−7.34 (m, 4H, Ar), 3.66 (t, J = 6.3 Hz, 2H, CH_2), 2.76 (t, J = 7.7 Hz, 2H, CH_2), 2.42 (bs, 1H, OH), 1.95−1.82 (m, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 143.28, 133.01, 131.82, 129.51, 129.03, 118.844, 112.10, 61.32, 33.53, 31.45; MS (CI) m/z 162 (M^+ + H). HRMS calcd for $C_{10}H_{12}NO$ 162.0919, found 162.0918.

3-(2-Hydroxyethyl)benzonitrile (5b). Colorless oil with 45% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.53−7.36 (m, 4H, Ar), 3.85 (t, J = 7.2 Hz, 2H, CH_2), 2.88 (t, J = 6.4 Hz, 2H, CH_2), 2.39 (bs, 1H, OH); ^{13}C NMR (50 MHz, $CDCl_3$) δ 140.43, 133.56, 132.41, 129.94, 129.08, 118.76, 112.18, 62.632; MS (EI) m/z 147 (M^+). HRMS calcd for C_9H_9NO 147.0684, found 147.0656.

General Procedure for the Synthesis of 6a−c, 11a−c. To a stirred solution of **5a** (1.16 g, 8.71 mmol) and triethylamine (1.33 mL, 9.58 mmol) in 25 mL of methylene chloride was added methanesulfonyl chloride (674 μL, 8.71 mmol) at 0 °C dropwise. After 30 min, the reaction was quenched by the addition of saturated sodium bicarbonate. The resulting mixture was extracted with dichloromethane (3 × 20 mL). The organic layer was dried over Na_2SO_4. After the organic layer was removed by vacuum, the product was obtained by silica gel flash column chromatography (hexane/EtOAc = 3:2) gave **6a** (1.69 g, 92%) as a colorless oil: **3-(Methanesulfonyloxymethyl)benzonitrile (6a).** ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.73−7.55 (m, 4H, Ar), 5.27 (s, 2H, CH_2), 3.06 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ 135.15, 132.57, 132.51, 131.61, 126.66, 117.99, 112.92, 69.22, 36.47; MS (CI) m/z 212 (M^+ + H). HRMS calcd for $C_9H_{10}NO_3S$ 212.0381, found 212.0382.

3-(2-Methanesulfonyloxyethyl)benzonitrile (6b). Colorless oil with 93% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.55−7.41 (m, 4H, Ar), 4.40 (t, J = 6.6 Hz, 2H, CH_2), 3.06 (t, J = 6.6 Hz, 2H, CH_2), 2.91 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ 137.84, 133.47, 132.30, 130.65, 129.38, 118.48, 112.38, 69.10, 37.16, 34.84; MS (CI) m/z 226 (M^+ + H). HRMS(FAB) calcd for $C_{10}H_{11}NO_3SNa$ 248.0357, found 248.0399.

3-(3-Methanesulfonyloxypropyl)benzonitrile (6c). Colorless oil with 97% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.55−7.41 (m, 4H, Ar), 4.25 (t, J = 6.0 Hz, 2H, CH_2), 3.03 (s, 3H, CH_3), 2.81 (t, J = 7.7 Hz, 2H, CH_2), 2.16−2.02 (m, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 141.82, 132.99, 131.87, 130.12, 129.38, 118.67, 112.72, 68.43, 37.46, 31.19, 30.37; MS (FAB) m/z 240 (M^+ + H). HRMS calcd for $C_{11}H_{14}NO_3S$ 240.0694, found 240.0651.

***N,N′*-Bis(*tert*-butyloxycarbonyl)-*N″*-3-(methanesulfonyloxymethyl)benzylguanidine (11a).** Colorless oil with 98% yield; ^{1}H NMR (200 MHz, $CDCl_3$) δ 11.56 (s, 1H, NH), 8.63 (s, 1H, NH), 7.40−7.30 (m, 4H, Ar), 5.24 (s, 2H, CH_2), 4.65 (d, J = 5.0 Hz, 2H, CH_2), 2.92 (s, 3H, CH_3), 1.51 (s, 9H, $3CH_3$), 1.49 (s, 9H, $3CH_3$); ^{13}C NMR (50 MHz, $CDCl_3$) δ 167.40, 156.07, 153.10, 137.80, 133.84,

129.21, 128.62, 127.92, 127.85, 83.21, 79.31, 71.04, 44.37, 38.25, 28.17, 27.93; MS (FAB) *m/z* 458 ($M^+ + H$). HRMS calcd for $C_{20}H_{32}N_3O_7S$ 458.1961, found 458.1962.

***N,N′*-Bis(*tert*-butyloxycarbonyl)-*N″*-3-(2-methanesulfonyloxyethyl)benzylguanidine (11b).** Colorless oil with 98% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 11.54 (s, 1H, NH), 8.59 (s, 1H, NH), 7.31−7.14 (m, 4H, Ar), 4.61 (d, J = 2.5 Hz, 2H, CH_2), 4.41 (t, J = 6.8 Hz, 2H, CH_2), 3.05 (t, J = 6.9 Hz, 2H, CH_2), 2.84 (s, 3H, CH_3), 1.51 (s, 9H, $3CH_3$), 1.48 (s, 9H, $3CH_3$); ^{13}C NMR (50 MHz, $CDCl_3$) δ 163.49, 156.04, 153.13, 137.77, 136.84, 129.10, 128.41, 128.26, 126.53, 83.22, 79.43, 70.10, 44.68, 37.25, 35.43, 28.20, 27.98; MS (FAB) *m/z* 472 ($M^+ + H$). HRMS calcd for $C_{21}H_{34}N_3O_7S$ 472.2117, found 472.2096.

***N,N′*-Bis(*tert*-butyloxycarbonyl)-*N″*-3-(3-methanesulfonyloxypropyl)benzylguanidine (11c).** Colorless oil with 97% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 11.55 (s, 1H, NH), 8.58 (s, 1H, NH), 7.33−7.10 (m, 4H, Ar), 4.61 (d, J = 5.0 Hz, 2H, CH_2), 4.23 (t, J = 6.2 Hz, 2H, CH_2), 3.00 (s, 3H, CH_3), 2.76 (t, J = 7.5 Hz, 2H, CH_2), 2.15−2.01 (m, 2H, CH_2) 1.52 (s, 9H, $3CH_3$), 1.48 (s, 9H, $3CH_3$); ^{13}C NMR (50 MHz, $CDCl_3$) δ 163.53, 156.05, 153.148, 140.78, 137.67, 128.92, 127.89, 127.65, 125.70, 83.12, 79.28, 68.96, 44.84, 37.30, 31.41, 30.48, 28.25, 27.99; MS (FAB) *m/z* 486 ($M^+ + H$). HRMS calcd for $C_{22}H_{36}N_3O_7S$ 486.2274, found 486.2271.

General Procedure for the Synthesis of 7a−c. To a stirred solution of **6a** (1.63 g, 7.72 mmol) in 25 mL of acetonitrile was added tetra-*n*-butylammonium flouride hydrate (2.43 g, 7.72 mmol) at 130 °C. After 40 min, the acetonitrile was evaporated under reduced pressure. The product was obtained by silica gel flash column chromatography (hexane/EtOAc = 19:1) gave **7a** (920 mg, 91%) as a colorless oil: **3-(Fluoromethyl)benzonitrile (7a).** ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.68−7.52 (m, 4H, Ar), 5.42 (d, J = 47.2 Hz, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 139.80 (d, J = 17.8 Hz), 132.05 (d, J = 2.3 Hz), 131.10 (d, J = 6.1 Hz), 130.28 (d, J = 6.8 Hz), 129.43, 118.26, 112.74, 82.93 (d, J = 168.4 Hz); MS (CI) *m/z* 136 ($M^+ + H$). HRMS calcd for C_8H_7NF 136.0563, found 136.0566.

3-(2-Fluoroethyl)benzonitrile (7b). Colorless oil with 15% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.58−7.26 (m, 4H, Ar), 4.65 (dt, J = 46.8, 6.1 Hz, 2H, CH_2), 3.04 (dt, J = 26, 6.0 Hz, 2H, CH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 138.88, 133.51, 132.45, 130.45, 129.30, 118.72, 112.58, 83.19 (d, J = 168.3 Hz), 36.36 (d, J = 19.7 Hz); MS (CI) *m/z* 149 ($M^+ + H$). HRMS calcd for C_9H_8NF 149.0641, found 149.0629.

3-(3-Fluoropropyl)benzonitrile (7c). Colorless oil with 65% yield: ^{1}H NMR (200 MHz, $CDCl_3$) δ 7.47−7.35 (m, 4H, Ar), 4.44 (dt, J = 46.8, 5.7 Hz, 2H, CH_2), 2.78 (t, J = 7.7 Hz, CH_2), 2.13−1.86 (m, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 140.88, 131.38, 130.27, 128.22, 127.59, 117.14, 110.91, 80.87 (d, J = 165.0 Hz), 29.91 (d, J = 20.0 Hz), 29.32 (d, J = 5.0 Hz); MS (CI) *m/z* 164 ($M^+ + H$). HRMS calcd for C_8H_7NF 164.0876, found 164.0873.

General Procedure for the Synthesis of 8a−c. A mixture of **7a** (1.4 g, 10.7 mmol) and 1 M borane−THF complex (40 mL, 40.6 mmol) in dry THF (15 mL) under nitrogen atmosphere was stirred at 75 °C for 12 h. The mixture was diluted with ethanol. After the solvent was removed using an evaporator, the crude mixture was extracted from the aqueous layer with EtOAc (3 × 15 mL). The crude product was dried over sodium sulfate. The solvent was evaporated under reduced pressure. The mixture was dissolved in tetrahydrofuran, and then 1 N HCl in tetrahydrofuran (50 μL) was added dropwise. Filtration of the generated solid gave **8a** (880 mg, 47%) as a granular solid: **3-(Fluoromethyl)benzylamine Hydrochloride (8a).** mp, 149.4−153.5 °C; ^{1}H NMR (200 MHz, CD_3OD) δ 7.49−7.46 (m, 4H, Ar), 5.41 (d, J = 47.6 Hz, 2H, CH_2), 4.10 (s, 2H, CH_2); ^{13}C NMR (50 MHz, CD_3OD) δ 139.20 (d, J = 17.1 Hz), 135.55, 130.60, 130.36 (d, J = 2.7 Hz), 129.22 (d, J = 5.7 Hz), 129.11 (d, J = 4.6 Hz), 85.18 (d, J = 164.3 Hz), 44.40; MS (EI) *m/z* 138 ($M^+ - H$). HRMS calcd for C_8H_9NF 138.0719, found 138.0727.

3-(2-Fluoroethyl)benzylamine Hydrochloride (8b). White solid with 55% yield: mp, 143.8−144.9 °C; ^{1}H NMR (200 MHz, CD_3OD) δ 7.45−7.33 (m, 4H, Ar), 4.64 (dt, J = 47.2, 6.2 Hz, 2H, CH_2), 4.11 (s, 2H, CH_2), 3.04 (dt, J = 25.0, 6.4 Hz, 2H, CH_2); ^{13}C NMR (50 MHz, CD_3OD) δ140.52, 134.79, 131.09, 130.81, 130.53, 128.28, 85.01 (d, J = 166.9 Hz), 44.45, 37.87 (d, J = 20.5 Hz); MS (EI) *m/z* 152 ($M^+ - H$). HRMS calcd for $C_9H_{11}NF$ 152.0876, found 152.0857.

3-(3-Fluoropropyl)benzylamine Hydrochloride (8c). White solid with 61% yield: mp, 105.3−107.1 °C; ^{1}H NMR (200 MHz, CD_3OD) δ 7.41−7.25 (m, 4H, Ar), 4.44 (dt, J = 47.2, 6.0 Hz, 2H, CH_2), 4.07 (s, 2H, CH_2), 2.78 (t, J = 8.4 Hz, 2H, CH_2), 2.14−1.91 (m, 2H, CH_2); ^{13}C NMR (50 MHz, CD_3OD) δ 143.97, 135.47, 130.45, 130.35, 130.14, 127.66, 84.06 (d, J = 163.5 Hz), 44.65, 33.37 (d, J = 19.7 Hz), 32.35 (d, J = 5.3 Hz); MS (EI) *m/z* 167 (M^+). HRMS calcd for $C_{10}H_{14}NF$ 167.1110, found 167.1083.

General Procedure for the Synthesis of 9a−c. To a solution of **8a** (200 mg, 1.40 mmol) in 2.50 mL of dimethylformamide was stirred at 0 °C. To the stirred mixture was added *N,N′*-bis(*tert*-butyloxycarbonyl)-2-methylthiourea and triethylamine. After 5 min, mercury chloride was added. The reaction mixture was stirred at 0 °C for 1 h and then diluted with EtOAc (5 mL). The precipitate was filtered through Celite. The filtrate was washed with saturated ammonium chloride (2 × 10 mL) and aqueous sodium bicarbonate (2 × 10 mL). The organic layer was dried over Na_2SO_4. The product was obtained by silica gel flash column chromatography (hexane/EtOAc = 4:1) gave **9a** (416 mg, 78%) as a white solid: ***N,N′*-Bis(*tert*-butyloxycarbonyl)-*N″*-3-(fluoromethyl)benzylguanidine (9a).** mp, 113.0−114.9 °C; ^{1}H NMR (200 MHz, $CDCl_3$) δ 11.53 (bs, 1H, NH), 8.58 (bs, 1H, NH), 7.39−7.29 (m, 4H, Ar), 5.34 (d, J = 48.0 Hz, 2H, CH_2), 4.62 (d, J = 5.2 Hz, 2H, CH_2), 1.49 (s, 9H, $3CH_3$), 1.45 (s, 9H, $3CH_3$); ^{13}C NMR (50 MHz, $CDCl_3$) δ 163.47, 156.07, 153.13, 137.85, 136.72 (d, J = 17.1 Hz), 128.93, 128.03 (d, J = 2.7 Hz), 126.72 (d, J = 6.1 Hz), 126.51 (d, J = 6.1 Hz), 84.17 (d, J = 165. 8 Hz), 83.14, 79.26, 44.64, 28.22, 27.96; MS (FAB) *m/z* 382 ($M^+ + H$). HRMS calcd for $C_{19}H_{29}N_3O_4F$ 382.2143, found 382.2148.

General Procedure for the Synthesis of 10a−c. A solution of **5a** (151 mg, 1.14 mmol) and lithium borohydride (40 mL, 40.6 mmol) in dry tetrahydrofuran (15 mL) under nitrogen atmosphere was stirred at 75 °C for 12 h. The reaction was quenched with ethanol carefully. After the solvent was removed under reduced pressure, the crude mixture dissolved in dichloromethane (50 mL) was washed with water. The crude product in organic layer was dried over sodium sulfate. The solvent was evaporated under reduced pressure. This crude mixture dissolved in 2.50 mL of dimethylformamide and stirred at 0 °C. To the stirred mixture were added *N*,*N*′-bis(*tert*-butyloxycarbonyl)-2-methylthiourea and triethylamine. After 5 min, mercury chloride was added. The reaction mixture was stirred at 0 °C for 1 h and then diluted with EtOAc (5 mL). The precipitate was filtered through Celite. The filtrate was washed with saturated ammonium chloride (2 × 10 mL) and aqueous sodium bicarbonate (2 × 10 mL). The organic layer was dried over Na_2SO_4. The product was obtained by silica gel flash column chromatography (hexane/EtOAc = 3:2) gave **10a** (335 mg, 78%) as colorless oil: ***N*,*N*′-Bis(*tert*-butyloxycarbonyl)-*N*″-3-(hydroxymethyl)benzylguanidine (10a).** ^{1}H NMR (200 MHz, $CDCl_3$) δ 11.53 (bs, 1H, NH), 8.57 (bs, 1H, NH), 7.36−7.20 (m, 4H, Ar), 4.65 (s, 2H, CH_2), 4.59 (d, J = 5.0 Hz, 2H, CH_2), 2.58 (bs, 1H, OH), 1.51 (s, 9H, $3CH_3$), 1.47 (s, 9H, $3CH_3$); ^{13}C NMR (50 MHz, $CDCl_3$) δ 163.45, 156.02, 153.07, 141.54, 137.43, 128.82, 126.83, 126.31, 126.10, 83.12, 79.33, 64.80, 44.84, 28.22, 27.97; MS (FAB) m/z 380 (M^+ + H). HRMS calcd for $C_{19}H_{30}N_3O_5$ 380.2185, found 380.2189.

HRMS calcd for $C_{21}H_{34}N_3O_5$ 408.2498, found 408.2497.

General Procedure for the Synthesis of 1−3. To a stirred solution of **9a** (50 mg, 0.236 mmol) in EtOAc was added 3 M HCl in EtOAc (4 mL) carefully. The reaction mixture was heated at 65 °C for 30 min, and then solvent was removed under reduced pressure. The crude mixture was dissolved with water (200 μL), loaded on C-18 silica gel in a disposable pipet, and washed with water (2 mL) and ethanol (2 mL) successively. The ethanol rinse contained the product. Removal of solvent under reduced pressure gave **1** (38 mg, 91%) as a pale yellow oil: **3-(Fluoromethyl)benzylguanidine (1).** ^{1}H NMR (200 MHz, CD_3OD) δ 7.48−7.33 (m, 4H, Ar), 5.39 (d, J = 47.6 Hz, 2H, CH_2), 4.66 (s, 1H, NH), 4.44 (s, 2H, CH_2); ^{13}C NMR (100 MHz, DMSO-d_6) δ 158.73, 140.13, 138.80 (d, J = 17.5 Hz), 130.21, 128.62, 128.12 (d, J = 6.1 Hz), 127.57 (d, J = 6.0 Hz), 85.20 (d, J = 163.7 Hz), 46.58; MS (FAB) m/z 182 (M^+ + H). HRMS calcd for $C_9H_{13}N_3F$ 182.1094, found 182.1107.

3-(2-Fluoroethyl)benzylguanidine (2). Colorless oil with 95%: ^{1}H NMR (200 MHz, CD_3OD) δ 7.38−7.20 (m, 4H, Ar), 4.62 (dt, J = 47.0, 6.2 Hz, 2H, CH_2), 4.40 (d, J = 6.0 Hz, 2H, CH_2), 3.01 (dt, J = 25.0, 6.6 Hz, 2H, CH_2); ^{13}C NMR (50 MHz, CD_3OD) δ 159.32, 149.63, 137.79, 130.08, 129.74, 129.11, 126.60, 84.98 (d, J = 166.9 Hz), 46.07, 37.80 (d, J = 20.2 Hz); MS (FAB) m/z 196 (M^+ + H). HRMS calcd for $C_{10}H_{15}N_3F$ 196.1250, found 196.1227.

3-(3-Fluoropropyl)benzylguanidine (3). Colorless oil with 97%: ^{1}H NMR (200 MHz, DMSO-d_6) δ 7.31−7.14 (m, 4H, Ar), 4.43 (dt, J = 47.2, 5.8 Hz, 2H, CH_2), 4.26 (s, 2H, CH_2), 2.64 (t, J = 8.0 Hz, 2H, CH_2), 1.81−2.01 (m, 2H, CH_2); ^{13}C NMR (50 MHz, DMSO-d_6) δ 157.31, 141.65, 137.95, 128.87, 127.64, 127.42, 125.03, 81.34 (d, J = 161.2 Hz), 43.99, 31.9, 31.7 (d, J = 19.4 Hz), 30.96; MS (FAB) m/z 210 (M^+ + H). HRMS calcd for $C_{11}H_{17}N_3F$ 210.1407, found 210.1405.

General Procedure for the Labeling of [^{18}F]1−3. [^{18}F]Fluoride was produced in a cyclotron by the ^{18}O-(p,n)^{18}F reaction. A volume of 100−200 μL of [^{18}F]fluoride (18.5−370 MBq) in water was added to a vacutainer containing n-Bu_4NHCO_3 (40% aq, 2.70 μL, 3.65 μmol). The azeotropic distillations were carried out each time with 200 μL aliquots of CH_3CN at 85 °C under a stream of nitrogen. A fluorine-18 ion displacement reaction of **11c** (2 mg, 4.1 μmol) with n-Bu_4N[^{18}F]F in acetonitrile (200 μL) was carried out in a reaction vial at 75−80 °C for 10 min. After the reaction, the vial was cooled in an ice bath. The solvent was removed under a gentle stream of nitrogen at room temperature. To deprotect two Boc groups, the residue was treated with 3 M HCl in EtOAc (200 μL) at 65 °C for 10 min. The solvent was removed with a gentle stream of nitrogen. The crude compound was injected onto reverse phase HPLC with the help of 5% methanol in 0.2 M $(NH_4)H_2PO_4$ (1 mL) and purified. The desired compound was collected from HPLC (t_R = 23 min; C18 silica gel, 10 μm, 10 × 250 mm; 0.2 M $(NH_4)H_2PO_4/CH_3CN$ = 70:30 (v/v); 215 nm; 1.5 mL/min), and the HPLC solvent was removed on water bath (75−80 °C) using a gentle stream of nitrogen. The resulting residue was further treated with ethanol and passed through a Celite plug for the desalting. After the ethanol was evaporated, 3-(3-[^{18}F]fluoropropyl)benzylguanidine (**[^{18}F]3**) was used for biological study. For the identification of the radioproduct, the collected HPLC fraction was matched with the cold compound. The labeling of **[^{18}F]-1−2** was followed with the same procedure. The total labeling time of **[^{18}F]1−3** was 100 min, and the overall decay-corrected radiochemical yield was about 20−30%. Specific activity at the end of synthesis was calculated by relating radioactivity to the mass associated with the UV absorbance (215 nm) peak of cold compound. Specific radioactivity of **[^{18}F]1−3** (**[^{18}F]1**; 59 GBq/μmol, **[^{18}F]2**; 47 GBq/μmol, **[^{18}F]3**; 51 GBq/μmol) was obtained after purification on HPLC column.

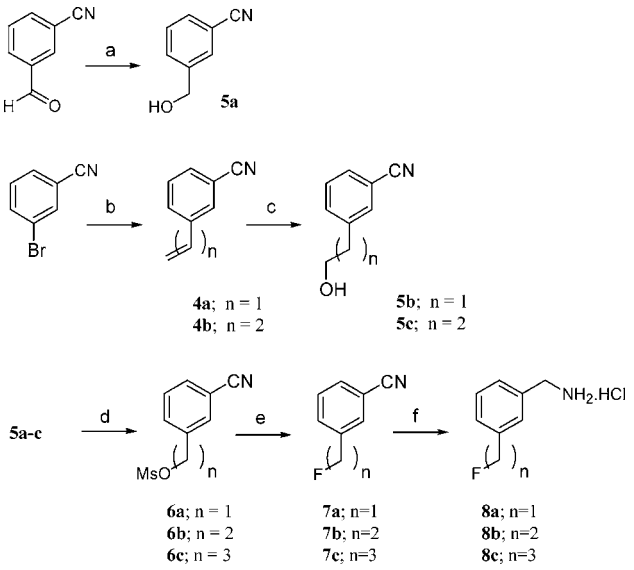
In Vitro Metabolic Stability Studies. Mouse hepatic microsomes (0.5 mg/mL) were placed in five test tubes containing 0.1 M phosphate buffer (pH 7.4, 3 mL) and radiotracer (0.074−0.74 MBq) dissolved in ethanol (50 μL). After each test tube was preincubated at 37 °C for 3 min, the reaction was initiated by addition of NADPH

(0.25 mM), and the mixture was incubated at 37 °C. The volume per sample in the in vitro stability was 500 μL. At the indicated time points (1, 5, 15, 30, and 60 min), the sample was picked out and passed through a Celite plug (2 cm) using 2 mL of absolute ethanol. The obtained mixture was developed on TLC and was analyzed by radio-TLC (*33*).

Cells and Culture Conditions. The human neuroblastoma cells SK-N-SH was obtained from Seoul National University, Seoul, Korea (J. J. Kim, MD). Cells were cultured in RPMI-1640 media supplemented with 10% FBS, glutamine, and antibiotics. Cells that has been seeded into 12-well plates (1×10^5 cells in 1 mL medium per well) 24 h prior to experiments were either 0.74 MBq/well of (**[^{18}F]3**) or [^{123}I]MIBG in paired format to allow comparison. To investigate the effect of temperature on cell binding levels, cells were incubated with the radiotracers at either 4 °C or 37 °C for 30 min or 2 h.

Comparison of [^{18}F]3 and [^{123}I]MIBG Uptake in SK−N−SH Human Neuroblastoma Cells. Cells were incubated with either **[^{18}F]3** (0.74 MBq/well) or [^{123}I]-MIBG for 30 and 120 min at 37 °C. To investigate the effect of temperature on radiotracer uptake, another set of cells were incubated with the radiotracers at 4 °C for 30 and 120 min (*32*). At the end of incubation, media was removed and the cells were washed twice with PBS. The cell bound activity was counted along with standards using a high energy gamma counter.

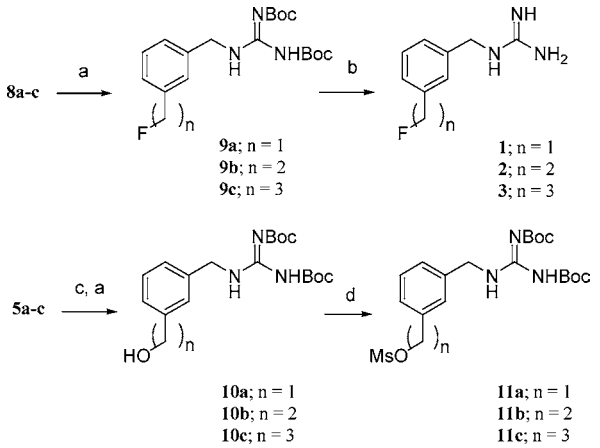
Inhibition of [^{18}F]3 Binding to SK−N−SH Cells by Graded Preincubation Time with Desipramine. **[^{18}F]3** (0.74 MBq/well) uptake measured in SK-N-SH cells after preincubation with 50 μM desipramine for indicated duration of times. At desired time, the medium was removed and cell bound activity was counted after PBS washing.



Tissue Distribution in Normal Mice. Tissue distribution was performed in male ICR mice (n = 3, 26−30 g) with tail vein administration of **[^{18}F]3** (1.1 MBq/mouse) dissolved in phosphate buffered saline to a final volume of 150 mL. After 2 h postinjection, mice were sacrificed by cervical dislocation, and tissues of interest were isolated, weighed, and counted for radioactivity. The injected dose was calculated from standards prepared from the injection solution. The data were expressed as percent injected dose per gram of tissue (%ID/g).

RESULTS AND DISCUSSION

The unlabeled 3-(ω-fluoroalkyl)benzylguanidines (**1**−**3**) were synthesized as shown in Schemes 1 and 2. 3-Cyanobenzyl alcohol (**5a**) was prepared from 3-cyanobenzaldehyde by reduction using sodium borohydride in ethanol in over 96% yield. Stille reaction (*22, 23*) of 3-bromobenzonitrile with either tributylvinyltin or allyltributyltin in the presence of tetrakis(triphenylphosphine palladium(0)) and lithium chloride followed by hydroboration (*24*) provided homologated alcohols **5b**,**c**. Mesylation of the alcohols and subsequent fluorination using tetra-*n*-butylammonium fluoride (TBAF) gave **7a**−**c** in 93, 15, 65% yields, respectively. The big differing yields of fluorinations of three compounds came from the intrinsic properties of aliphatic displacement reactions at benzylic, phenethylic, or plain aliphatic position.



In the case of fluorination of **6b**,**c**, elimination and hydrolyzed byproducts were formed using TBAF in which fluoride was considered as a base. We have developed a new aliphatic fluorination using KF (*25*) as well as [^{18}F]-fluoride (*26*) in ionic liquid, which is expected to provide high yields of fluoroalkyl (especially fluoroethyl) aromatics during the synthesis of **7b**,**c**. Reduction of the nitrile group in **7a**−**c** to aminomethyl moiety was achieved by the treatment with borane−tetrahydrofuran complex. When lithium borohydride was used instead of borane−tetrahydrofuran complex, 3-alkylbenzylamine was obtained as a major product. In the synthesis of **8a** from **7a**, the ratio of **8a** to 3-methylbenzylamine was 2:8. Due to the difficulty of purification of 3-(ω-fluoroalkyl)benzylamines, **8a**−**c** were isolated as HCl salts. Authentic target compounds **1**−**3**, were prepared from **8a**−**c** with *N*,*N*′-bis(*tert*-butyloxycarbonyl)-2-methylthiourea in good yield under mild condition (*27*−*30*) as shown in Scheme 2, followed by deprotection of Boc groups. Parenthetically, we synthesized guanidine from benzylamine using 2-methyl-2-thio-pseudourea sulfate or cyanamide but in very low yield and with difficulty due to its high polarity. The reduction of the nitrile of **5a**−**c** by BH_3-THF did not give good yields, consequently requiring the more powerful reducing reagent. With the use of lithium borohydride (*31, 32*), 3-(ω-hydroxyalkyl)benzylamines were synthe-

Table 1. Yields of the Fluorine-18 Incorporation of 11a−c and the Yields of Deprotection of Boc Groups

compound	1st step:[a] fluorine-18 radiolabeling yields,[c] %	2nd step:[b] deprotection of Boc guanidine,[c] %
11a	35.7 ± 2.1	>90
11b	30.3 ± 3.5	>89
11c	38.1 ± 4.2	>95

[a] An appropriate amount of radioactivity was placed in a Vacutainer containing *n*-Bu_4NHCO_3 (40% aq, 2.70 μL, 3.65 μmol), and three azeotropic distillations were carried out each time with 200 μL aliquots of CH_3CN at 85 °C under a stream of N_2. The resulting *n*-$Bu_4N[^{18}F]F$ was delivered to a reaction vial with CH_3CN. The reaction was heated at 75−80 °C for 10 min. [b] Deprotection was carried out using 3 M HCl in EtOAc (200 μL) at 65 °C for 10 min. [c] Progress of the reaction was analyzed by radio-TLC (1st; hexane/EtOAc = 9: 1 on silica TLC, 2nd; 0.2 M $(NH_4)H_2PO_4/CH_3CN$ = 7:3 on C18 TLC).

sized in about 80% yields. Either BH_3−THF or $LiBH_4$ was used for selective reduction of compounds containing a nitrile group such as **7a−c** and **5a−c**. Because 3-(ω-hydroxyalkyl)benzylamine was unstable when dissolved in solvents, it was difficult to isolate the product by flash column chromatography. After reduction of **5a−c** with $LiBH_4$, the crude mixture was treated with *N*,*N*′-bis(*tert*-butyloxycarbonyl)-2-methylthiourea and mercuric chloride under mild condition to provide **10a−c**. Mesylated products **11a−c** were used as the precursor for the synthesis of [**^{18}F]1−3**.

The process for preparation of 3-(ω-[^{18}F]fluoroalkyl)-benzylguanidines contains only two steps: the displacement of [^{18}F]fluoride and the deprotection of two Boc groups as shown in Scheme 3. The results of the fluoride-18 incorporation and deprotection steps for the preparation of [**^{18}F]1−3** are summarized in Table 1. Based on the analysis by radio-TLC, the radiochemical yields of the Boc-protected compounds [**^{18}F]9a−c** decreased gradually after 10 min. While there was a big difference of chemical yields in the aliphatic nucleophilic fluorination of cold **9a−c**, we have obtained [**^{18}F]9a−c** in 35.7, 30.3, and 38.1% yields, respectively. After deprotection with 3 M HCl, the radiolabeled product was purified by HPLC.

We expected the fluoroalkylated compounds **1−3** to have similar lipophilicities to MIBG. Using retention time on HPLC (5 μm, 4.6 × 250 mm; C18 column; 215 nm; 0.1 M ammonium dihydrogen phosphate:acetonitrile = 50:50 (v/v); 1.0 mL/min), the lipophilicity of each compound is assessed by the capacity factor value which was correlated to the level of binding to SK-N-SH neuroblastoma cells expressed as % binding relative to that of [**^{18}F]-3**. The capacity factor ($k' = (t_R - t_0)/t_0$) of each compound was compared to that of MIBG (k' = 4.26), and cell binding assays were carried out using SK-N-SH human neuroblastoma cells to compare the relative level of cell binding for [**^{18}F]3** (Table 2). The capacity factor of **3** was similar to that of MIBG and [**^{18}F]3** also demonstrated

Table 2. Comparison of Lipophilicities and in Vitro SK-N-SH Human Neuroblastoma Cells of *m*-(ω-[^{18}F]Fluoroalkyl)benzylguanidines

compound	capacity factors (k')[a]	% binding of input activity	% cell binding ratio vs [**^{18}F]3**[b]
[**^{18}F]1**	2.36	3.0 ± 0.4	56 ± 6.7
[**^{18}F]2**	3.23	4.2 ± 0.2	81 ± 1.3
[**^{18}F]3**	3.57	5.3 ± 0.7	100

[a] Using retention time on HPLC (C18 column; 215 nm; 0.1 M ammonium dihydrogen phosphate:acetonitrile = 50:50), the capacity factors were calculated. [b] Measured by γ-counter.

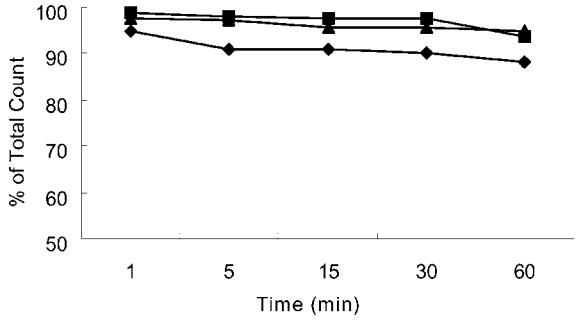

Figure 2. In vitro metabolic stability study of [**^{18}F]1**, [**^{18}F]2**, and [**^{18}F]3**. Using rat hepatic microsomes the radiotracer (0.074−0.74 MBq) was incubated at 37 °C and the obtained mixture was analyzed by radio-TLC at 1, 5, 15 30, and 60 min, respectively. ◆ [**^{18}F]1**; ■ [**^{18}F]2**; ▲ [**^{18}F]3**.

higher binding levels to SK-N-SH cells compared to the other tracers. On the basis of these results, [**^{18}F]3** was used for the remaining in vitro and in vivo studies.

The prospective metabolites of fluoroalkyl compounds would be formed by defluorination, *N*-dealkylation, and hydroxylation. We developed an easy method to check the formation of metabolites by hepatic microsomes (*33*). These polar metabolites could be differentiated by a TLC developing system (0.2 M $(NH_4)H_2PO_4/CH_3CN$ = 7:3 on C18 silica gel TLC). Using a radio-TLC scanner, [**^{18}F]1** (R_f = 0.62), [**^{18}F]2** (R_f = 0.57), and [**^{18}F]3** (R_f = 0.55) were retained with 88, 97, and 95%, respectively (Figure 2), and only a single unknown peak appeared at the starting point on the TLC developed for 60 min. The single unknown peak was matched with free fluorine-18 on C18 silica gel TLC. This demonstrates that the fluoropropyl and fluoroethyl compounds are more stable than the fluoromethyl compound in an in vitro metabolic environment, and that these radiotracers are expected to be highly stable in an in vivo. Magata et al. reported the study of defluorination metabolism of ^{18}F-labeled benzyl fluorides in vivo (*34*), and Welch et al. proposed the mechanism of in vivo stability of fluoroethyl and fluoropropyl group (*35*).

Cell binding assays were carried out using SK-N-SH human neuroblastoma cells in a paired format to compare [**^{18}F]3** and [^{123}I]MIBG uptake. In the in vitro cell uptake study, [**^{18}F]3** and [^{123}I]MIBG showed comparable results as shown in Figure 3. To confirm energy-dependence of uptake, tracer uptake was evaluated by incubation at 37 °C and 4 °C. Incubation at 4 °C decreased cellular binding of [**^{18}F]3** to 44.6 ± 7.0% and 62.4 ± 7.6% of levels obtained at 37 °C, repectively. This result was similar to the change shown for [^{123}I]MIBG uptake (35.9 ± 4.6% and 42.8 ± 5.5%).

The inhibition of [**^{18}F]3** binding to SK-N-SH cells was performed at a increasing preincubation time with 50 μM of desipramine. The time dependent result was shown in Figure 4. After 48 h of incubation with desipramine, uptake in SK-N-SH cell was 24.6 ± 2.8% (p = 0.00114)

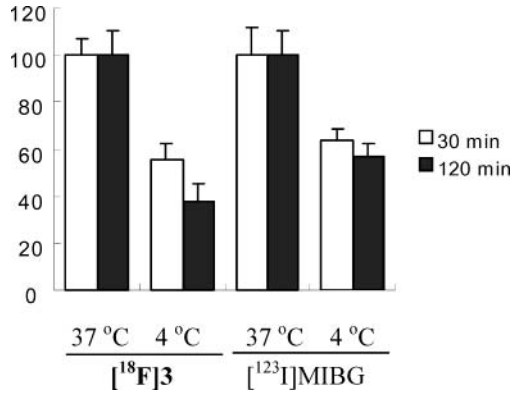

Figure 3. Comparison of temperature-dependent uptake of **[18F]3** and [123I]MIBG in SK-N-SH human neuroblastoma cells. The level of binding to SK-N-SH neuroblastoma cells expressed as % cell binding at 4 °C relative to that of 37 °C. (□) The incubation time is 30 min; (■) the incubation time is 120 min.

Table 3. Tissue Distribution of nca [18F]3[a] in Normal Mice

tissue	%ID/g:[b] 2 h postinjection
blood	1.6 ± 0.4
heart	9.3 ± 0.5
lung	10.6 ± 1.0
liver	12.1 ± 3.5
spleen	9.7 ± 2.0
pancreas	12.3 ± 4.0
muscle	4.4 ± 1.4
adrenal	27.2 ± 5.2
kidney	4.7 ± 0.9

[a] Tracer **[18F]3** was dissolved in saline and injected into normal ICR mice The normal dose per mouse was 1.1 MBq via tail vein. [b] Percent injected dose per gram of tissue; mean ± SD (n = 3).

relative to control levels. However, longer durations of inhibition were required and the magnitude of inhibited binding was smaller than previous reports on desipramine inhibition of MIBG uptake. It thus appears that **[18F]3** has limitations compared to MIBG with respect to specificity of binding, and part of the cellular binding of **[18F]3** may be mediated by systems other than the neuronal pump. This demonstrated that tracer accumulated through the uptake-1 mechanism.

Tissue distribution of **[18F]3** in mice was performed to evaluate whether the radiotracer undergoes an in vivo uptake mechanism similar to that of MIBG. The tissue distribution results of **[18F]3** in mice are summarized in Table 3. After 2 h postinjection, tissue distribution studies showed the uptake of **[18F]3** to be highest in the adrenals (%ID/g = 27.2 ± 5.0%), followed by the myocardium (%ID/g = 9.3 ± 0.5%). The distribution of **[18F]3** in most of the major organs were comparable to previously reported distribution for [125I]MIBG in normal mice, although myocardial uptake levels were somewhat lower for **[18F]3** (*17*).

CONCLUSION

In conclusion, *m*-(*ω*-[18F]fluoroalkyl)benzylguanidines were prepared in two steps with good yields and high stability in vivo. Cell studies of SK-N-SH human neuroblastoma cells and biodistribution data suggest that **[18F]-3** may have potential as a useful PET radiopharmaceutical agent for evaluating adrenomedullary tissue.

A Comparative Study of Different Presentation Strategies for an HIV Peptide Immunogen

Luis J. Cruz,*[,†] Enrique Iglesias,[‡] Julio C. Aguilar,[‡] Luis J. González,[‡] Osvaldo Reyes,[‡] Fernando Albericio,[†,§] and David Andreu[||]

Barcelona Institute of Biomedical Research, Barcelona Science Park, 08028 Barcelona, Spain, Centro de Ingeniería Genética y Biotecnología, Cubanacán, Habana 10600, Cuba, Department of Organic Chemistry, University of Barcelona, 08028 Barcelona, Spain, and Department of Experimental and Health Sciences, Pompeu Fabra University, 08003 Barcelona, Spain. Received July 10, 2003; Revised Manuscript Received October 17, 2003

Different strategies have been used to increase the immunogenicity of an antigenic HIV peptide as a vaccine candidate. The selected B-cell epitope comprises 15 amino acids (317−331) of the V3 region of HIV-1, JY1 isolate (subtype D), in tandem with a T-helper epitope corresponding to the 830−844 region of tetanus toxoid. Several presentations, including oligomerization, multiple antigenic peptide dendrimers, and conjugation to dextran beads or to other macromolecular carriers, have been synthesized and evaluated. Murine sera from the different presentations of the V3 epitope have been compared with regard to antibody titers and cross-reactivity with heterologous HIV subtypes. The dendrimer version of the peptide conjugated to HBsAg protein was a better immunogen than the dendrimer alone and showed a higher immunogenicity than other multimeric presentations or than the peptide alone conjugated to dextran. The dendrimer version, either alone or conjugated to HBSAg, enhanced cross-reactivity toward heterologous V3 sequences relative to monomeric peptide. In addition, fine epitope mapping of the entire JY1 sequence by sera from the different immunization groups was performed by the spot synthesis technique. Results showed that the amino acids involved in molecular recognition were LXQXXY or LXQXLY, with particularly strong recognition of the C-terminal region LGQALY. However, cross-reactivity toward the heterologous sequences did not completely correlate with recognition of particular amino acids in the primary sequences. These results can find application in the development of HIV vaccine candidates.

INTRODUCTION

Although vaccines are widely regarded as the ideal solution for the control of infectious diseases, only a handful of them are currently available and a pressing demand is felt for improvements on existing ones, with particular emphasis on higher efficiency and undisputed safety profiles. In recent years, considerable attention has been focused on the development of peptide-based vaccines as an alternative to conventional formulations. Peptide vaccines have obvious advantages such as high safety, low cost, and easy handling and storage. In contrast to classical vaccines, they can be tailor-made against specific targets including antigenic sites not easily accessible to the immune system. However, they suffer also from limitations such as the usually low immunogenicity of small peptides and the vulnerability to proteolytic degradation. Many of these problems can be addressed by improved forms of presentation of the synthetic epitope to the immune system, including formulations such as multiple antigen peptide systems (MAPs[1]) (*1*), dendrimers (*2*), lipopeptides (*3, 4*), polymerization (*5, 6*), conjugation to carriers such as proteins or synthetic polymers (*7, 8*) or association to particulate systems such as liposomes (*9*), or immunostimulating complexes such as ISCOMs (*10*). Combined approaches such as coupling of MAPs to carrier proteins (*11*) have also been shown to enhance peptide immunogenicity and to induce protective or neutralizing antibody responses for parasitic and viral pathogens.

In HIV-1 infection, the V3 loop is the primary target for neutralizing antibodies (*12, 13*) and is involved in other aspects of infectivity. Thus, sequence changes in V3 can affect chemokine receptor usage and therefore modulate which cell types are infected (*14*). This V3 region includes both T-helper and CTL epitopes (*15*). Antibodies against the principal neutralizing domain (PND) of V3 appear to exert some control over the viral load (*16*−*18*). For the HIV-1 MN (subtype B) isolate, a

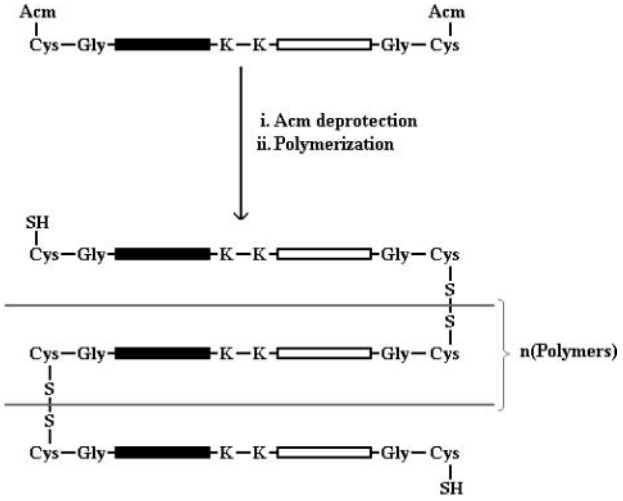

Figure 1. Reaction scheme for the polymerization of a peptide containing the JY1 epitope (filled box) in tandem with a T-epitope of tetanus toxoid (empty box) separated by a cathepsin cleavage site insert. Deprotection of both N- and C-terminal Cys residues gives a dithiol that polymerizes under basic conditions.

high titer against V3 has been correlated to slow progression rates in seropositive hemophilic Japanese patients (*19*). All these findings highlight the immunological relevance of the V3 loop, which has been included in a number of HIV-1 vaccine candidates (*20*). They also underscore the significance of studying how different ways of presentation of the synthetic peptide epitope affect the quality of the immune response.

In the present work we have investigated several presentation strategies for the V3 epitope, with a view to enhance its immunogenicity. Our selected B-cell epitope comprises 15 residues (317−331) of the V3 region from HIV-1 JY1 isolate (*21*), linked through a Lys-Lys cathepsin-like cleavage site (*6*) to a helper T-cell epitope (residues 830−844) from tetanus toxoid (*22*). We have evaluated the anti-peptide antibody response of these presentations and their cross-reactivity toward other V3 sequences and have fine-mapped their recognition of the entire JY1 epitope sequence.

EXPERIMENTAL PROCEDURES

Chemicals and Biologicals. Fmoc- and Boc- protected amino acids were purchased from Bachem (Switzerland). Solvents for peptide synthesis (dichloromethane, 2-propanol, *N*,*N*′-dimethylformamide) were obtained from Merck (Germany). Dextran beads cross-linked with epichlorhydrin (Sephadex G 150) were from Pharmacia Biotech (Sweden). Succinic anhydride and other chemicals were from Sigma (St. Louis, MO). Recombinant hepatitis B virus surface antigen (rHBsAg) and TAB9 protein, a multiepitope polypeptide (MEP) including the V3 region from six divergent HIV-1 isolates (LR150, JY1, RF, MN, BRVA, and IIIB, in this order) fused to the amino terminus (47 amino acids) of P64K protein from *N. meningitidis*, were obtained from CIGB (Cuba).

Synthetic Peptide Antigens and Conjugates. *Peptide Synthesis.* The monomeric form of the immunogen [C(Acm)GRQSTPIGLGQALYTTKKQYIKANSKFIGITELGC(Acm)] (Figure 1) was synthesized by the Boc/Bzl strategy on 4-methylbenzhydryl-amine (MBHA) resin (100−200 mesh, 0.7 mmol/g, Fluka) using the tea bag method (*23*). Side chain protecting groups were acetamidomethyl (Acm) for Cys, benzyl ether for Ser and Thr, benzyl ester for Asp and Glu, tosyl for Arg, dichlorobenzyl for Tyr, and 2-chlorobenzyloxycarbonyl for Lys. Coupling

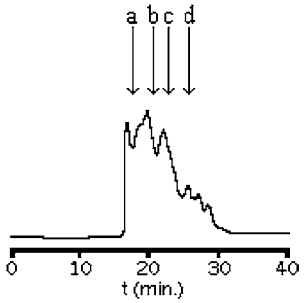

Figure 2. HPLC analysis of the polymerization reaction by gel filtration on TSK G 2000SW in 10% acetonitrile in water. Arrows a−d indicate, respectively, the elution volumes of bovine serum albumin (M_r 67 000), chymotrypsinogen A (M_r 25 000), lysozyme (M_r 14 000), and the monomer peptide (M_r 4000).

of the amino acids was achieved by activation with 1,3-diisopropylcarbodiimide and was monitored by the Kaiser test (*24*). Side-chain deprotection [except for Cys (Acm)] and cleavage from the resin was performed by the low-high HF procedure, using HF-DMS−*p*-cresol (25:65:10) for 2 h at 0 °C followed by HF−DMS−anisole−thiocresol (79.8:10:10:0.2) for 1 h at 0 °C (*25*). The resin was subsequently washed with diethyl ether and dried off under vacuum. The crude peptide was extracted from the resin with 30% acetic acid, diluted with water, and lyophilized.

Polymerization via S-Acm Deprotection/Oxidation with Iodine. The above peptide, with its Cys residues protected with Acm, was dissolved at 25 mmol/L in AcOH/H_2O (3:2, v/v), and 1.5 equiv of 80 mM aqueous HCl and 10 equiv of iodine in DMF were added. The polymerization reaction was stopped after 30 min by addition of L-ascorbic acid. The reaction mixture was purified on a PD10 Sephadex G-25 column (1.5 × 10 cm) equilibrated and eluted with 1% AcOH, to remove excess reagents and to prevent precipitation of polymers. After exhaustive dialysis against 1% AcOH, the solution was lyophilized. The polymer was characterized by HPLC gel filtration using a TSK G 2000SW column (8 × 300 mm) equilibrated and eluted with 10% MeCN (+0.05% TFA) in water (+0.1% TFA). Lysozyme, chymotrypsinogen A, and bovine serum albumin were used as molecular weight markers.

MAP Synthesis. The MAP version of the V3 peptide (see Figure 3 for details) was assembled by stepwise Boc solid-phase methods (*23*), using the protection scheme described above, except that Cys residue at the C-terminus was protected with the 4-methoxybenzyl (Mob) group. The Lys residues responsible for branching (one in the tetravalent, three in the octavalent versions of the MAP, respectively) were incorporated as Boc-Lys(Boc)-OH and coupled with TBTU/DIEA activation. Double couplings with 10-fold excess of Boc-amino acids and DIEA/HOBt were used for most residues of the V3 epitope. When required by the Kaiser test, capping steps were performed with 4% acetic anhydride and 1% DIEA in DMF. After low-high HF cleavage and deprotection as above, the MAPs were extracted into 0.1 M Tris-HCl, pH 8.0, containing 8 M urea, and dimerization of the MAP monomer by disulfide bond formation was allowed to proceed and monitored by the Ellman test (*26*). The homodimeric MAPs were dialyzed against 2 M urea in 0.1 M Tris-HCl buffer, pH 8.0 for 24 h, then dialyzed against 1 M AcOH, to remove all the urea and lyophilized.

Reduction and S-Carboxymethylation. The lyophilized homodimeric MAPs were dissolved at a concentration of 5 mg/mL in 0.3 M Tris.HCl, 6 M guanidinium chloride,

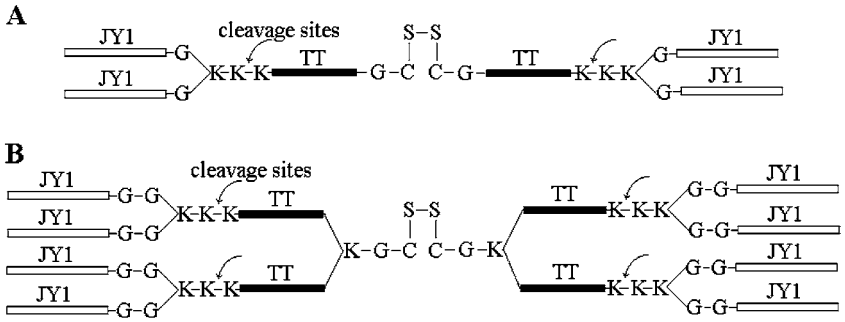

Figure 3. The JY1-MAP4 (A) and JY1-MAP8 (B) dendrimeric immunogens are disulfide dimers of lysine-branched constructs containing the JY1 and TT epitopes in a 2:1 ratio linked through a cathepsin cleavage site.

3 mM EDTA buffer, pH 8.5. A 20-fold molar excess of DTT over Cys residues was added, and the solution was flushed with nitrogen and incubated for 2 h at 37 °C. A 2-fold molar excess of iodoacetic acid over DTT was next added, and the solution was kept at room temperature for 1 h in the dark. Modified MAPs were characterized by RP-HPLC and mass spectrometry as described above.

Assembly of Peptides on Dextran Beads. The dried dextran beads were chemically modified to introduce anchor functions suitable for peptide synthesis. Thus, 1 g of dextran beads was treated for 24 h with 4 mL of a 0.4 M Fmoc-β-alanine solution (activated with 0.48 M DIPC and 0.8 M NMI in DMF) to modify the hydroxyl groups into amine functions. Unreacted hydroxyl sites were acetylated by treatment with 20% acetic anhydride/10% DIPEA/10% NMI in DMF for 30 min. Peptide synthesis was subsequently carried out using Fmoc/tBu chemistry (*27*). Side chain protecting groups were *tert*-butyl for Glu, Thr, Ser, and Tyr; trityl for Gln and Asn; Boc for Lys and 2,2,5,7,8-pentamethylchroman-6-sulfonyl for Arg. Fmoc deprotection was done with 20% piperidine in DMF for 20 min, and the resulting Fmoc-piperidine adduct was quantitated spectrophotometrically to determine resin substitution. Couplings were carried out with 200 μmol each of Fmoc-amino acid, HOBt, and DIPC in DMF for 1 h and monitored by the bromophenol blue (*28*) and Kaiser ninhydrin tests (*24*). When required, recouplings were performed with 300 μmol each of Fmoc-amino acid, TBTU, and HOBt, in the presence of 900 μmol of DIEA, in DMF. Systematic capping after each coupling step was performed with 4% (v/v) acetic anhydride and 1% (v/v) DIEA in DMF.

After the sequence assembly was completed, side chain protecting groups were removed with 50% (v/v) TFA in DCM containing 1% phenol, 2% ethanedithiol, 2% thiophenol, and 2% water (all v/v) for 2 h. Peptide−dextran beads were next washed (4× each) with DCM, DMF, and methanol. Finally, the peptide was cleaved from the dextran beads with 0.1 M NaOH for 15 min, neutralized, and analyzed by RP-HPLC. The main peak was collected and characterized by AAA and mass spectrometry.

Conjugation of Peptides and MAP to Carrier Proteins. Peptides and MAP were coupled to HBsAg as described by Deen et al. (*29*). Briefly, 5 mg of HBsAg was dissolved in 5 mL of 0.2 M K_2HPO_4, pH 8.0, solid succinic anhydride (1 mg) was added, and the solution was stirred until all anhydride was dissolved, adding 3 M NaOH dropwise as required to keep the pH at 8−8.5. The activated protein was next exhaustively dialyzed against dilute HCl (pH 4.5), treated with 7 mg 1-ethyl-3-(dimethylaminopropyl) carbodiimide (EDAC), and stirred for 10 min at 25 °C. Then, 5 mg of peptide or MAP dissolved in 1 mL of 3 M guanidine hydrochloride in PBS was added and the mixture gently stirred for 3 h at 25 °C. The conjugates were purified by gel filtration through Sephadex CL-4B (Pharmacia) eluted with PBS. The front-eluting fractions were pooled and quantitated by the Coomassie method (*30*).

Chromatography. Soluble peptides and MAPs were analyzed by RP-HPLC on Vydac C_{18} (100 × 4.6 mm) and Baker C_8 wide-pore (100 × 4.6 mm) columns, respectively, in a Pharmacia-LKB (Sweden) model 2150 dual pump chromatograph coupled to a Knauer (FRG) variable wavelength UV detector. Linear gradients of acetonitrile (+0.05% TFA) into water containing (+0.1% TFA) were used for the separation, at a 0.8 mL/min flow rate. Optical density was monitored at 226 nm. Data were processed with the BioCrom program (CIGB, Cuba).

Amino Acid Analysis. Samples of S-carboxymethylated MAPs were hydrolyzed with 6 M HCl containing 0.1% phenol and 0.1% 2-mercaptoethanol for 24 h in vacuum-sealed ampules. After evaporation, amino acids in the hydrolyzate were determined in an Alpha Plus 4151 (Pharmacia-LKB, Sweden) analyzer using a sodium buffer system and *o*-phthalaldehyde derivatization for fluorescence detection. All samples were analyzed in triplicate.

Mass Spectrometry. The FAB mass spectrum was recorded in a JMS HX-110HF double-focusing two-sector spectrometer (JEOL, Japan) equipped with a FAB gun, a collision cell, and a DMA-5000 data analysis system, as previously reported (*31*).

Electrospray MS was performed in a hybrid quadrupole-time-of-flight (Q-TOF) instrument (Micromass, UK) fitted with a Z-spray nanoflow ion source (*32*). The mass spectrometer was operated with a source temperature of 80 °C and a drying gas flow rate of 50 L/h. Peptides, polymers, peptides cleaved off dextran beads, and MAP purified by RP-HPLC were dissolved in a 50% (v/v) water/acetonitrile solution containing 1% acetic acid, to an approximate concentration of 5 pmol/μL. The peptide solution was infused at 3 μL/min into the mass spectrometer using a syringe pump (Harvard Apparatus, Holliston, MA). The capillary and cone voltage were set to 3 kV and 35 V, respectively. Data acquisition and processing were performed with the Micromass MassLynx package.

Immunizations. Female Balb/c mice 6−8 weeks old (CENPALAB, Cuba) were inoculated subcutaneously on days 0, 14, 28, and 56 with 100 μL with 40 μg of antigen emulsionated in either CFA (day 0) or IFA (other days) (Sigma). Animals were bled 10 days after the fourth dose. A summary of immunization schedules is shown in Table 1.

Enzyme-Linked Immunosorbent Assay against Synthetic Peptides. ELISA of anti-peptide sera was done as previously described (*33*). Briefly, 96-well polystyrene plates (High binding, Costar) were coated with

100 μL of BSA-coupled V3 peptides (Table 2) at 10 μg/mL and incubated overnight at 4 °C. After three washings with 0.05% Tween 20 in distilled water, plates were blocked with 2% milk in PBS (blocking solution) for 1 h at 37 °C. Samples were diluted with 0.05% Tween 20 and 5% sheep serum in blocking solution and incubated for 2 h at 37 °C. After four washings, an anti-mouse IgG peroxidase conjugate (Amersham, UK) was added and incubated for 1 h at 37 °C. The color reaction with *o*-phenylenediamine was allowed to develop for 10 min and then stopped with 3 M H_2SO_4 solution (50 μL), and the absorbance at 492 nm was determined in a SensIdent Scan (Merck, FRG). Results were expressed as log titer, determined by interpolation of OD values at fixed serum dilutions into a standard curve of a serum with known titer. Titer was defined as the log of the highest dilution giving twice the absorbance of negative control sera. Titers are given as the geometric mean ± SD of the titers of individual sera.

Peptide Synthesis on Cellulose Membranes for Epitope Mapping. Fifteen 15-residue peptides corresponding to the Ala scan of the RQSTPIGLGQALYTT sequence were synthesized as spots on a cellulose membrane. Twenty-five other paper-bound peptides, seven and five residues long, were also synthesized for epitope mapping. The spot synthesis method of Frank et al. (*34*) was used. Functionalition of the paper (Whatman 540) was carried out by esterification of an Fmoc-β-Ala-OH residue, using DIPC and *N*-methylimidazole in DMF. The remaining residues were incorporated by paper synthesis-adapted Fmoc/tBu chemistry (*34*). All peptides were acetylated at the N-terminus at the end of the synthetic program.

Paper-Based Peptide Enzyme Immunoassay. Washing steps and incubations were performed at 25 °C with Tris-buffered saline (TBS) containing 0.05% Tween-20 (T-TBS). Blocking of free binding sites was performed by overnight incubation with 5% skim milk in TBS. Incubation times were 3 h for sera and 2 h for alkaline phosphatase-conjugated anti-mouse IgG (Sigma). Detection of bound antibody was achieved by incubation with 5-bromo-4-chloro-3-indolyl phosphate (Sigma) in substrate buffer (0.1 M Tris, 0.1 M NaCl, 2 mM $MgCl_2$, pH, 8.9). Washing with PBS stopped staining. The peptide-bearing cellulose sheets were regenerated and prepared for the next run as described by Frank (*34*).

Statistical Analysis. Statistical analyses were conducted using Microsoft Excel software. Averages, variance, and standard deviations (SDs) were determined using standard functions. All ELISA OD values were transformed to the natural logarithm to get a normal distribution in the immunized groups. An *F*-test was performed to assess variance homogeneity among groups and a Student's *t*-test was done ($p < 0.05$ was considered statistically significant).

RESULTS AND DISCUSSION

Synthesis of Immunogens. *Free and Oligomeric Versions of the JY1 Peptide.* The primary structure of the monomeric form of the immunogen is shown in Figure 1. It consisted of the JY1 epitope (RQSTPIGLGQALYTT) in tandem with the T-cell epitope of tetanus toxoid (TT, residues 830−844, QYIKANSKFIGITEL), with an intervening Lys pair designed as a cathepsin-like cleavage site and with flanking Cys-Gly and Gly-Cys residues at each end to promote oligomerization. The peptide was synthesized by stepwise solid-phase methods, with the two Cys residues protected with the HF-stable Acm group. After cleavage and characterization, the Acm-protected monomer was treated with iodine to remove the two Acm groups and oligomerization was performed in AcOH:H_2O (3:2, v:v), where the monomer was highly soluble. The reaction proceeded quickly, and a high conversion to oligomer was observed by gel filtration HPLC (Figure 2). ESI-MS analysis of the main fractions of the oligomerization mixture allowed identification of the tetra-, tri-, and dimeric species. In addition, as expected, the monomer underwent intramolecular cyclization. Attempts to reduce the extent of this relatively undesired side reaction by varying the initial concentration of monomer were unsuccessful. Small levels of peptides with masses consistent with the cyclic disulfide forms of the oligomers were also detected. A summary of these findings is shown in Table 3.

Multiple Antigenic Peptide System. Two multivalent (MAP-like) dendrimeric presentations of the JY1 peptide with defined composition and varying number of B- and T-cell epitopes were also designed and synthesized (Figure 3). The JY1-MAP4 immunogen, containing four B and two Th epitopes (Figure 3A), resulted from dimerization of a monomer with a single Lys branching

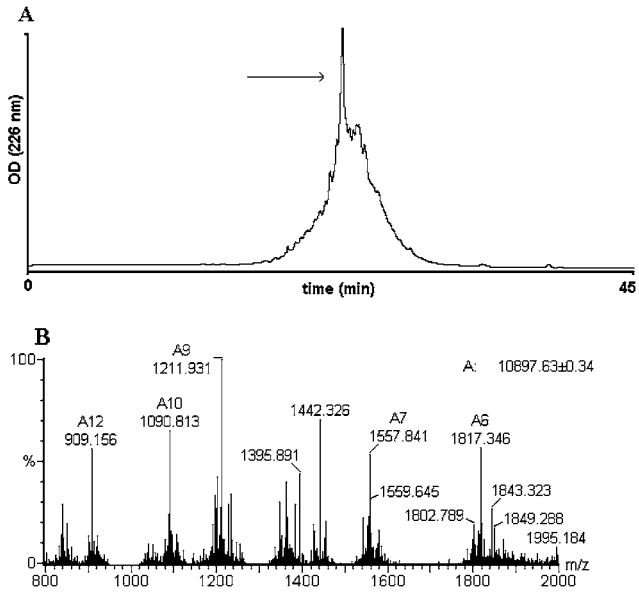

Figure 4. Analytical characterization of JY1-MAP8. A: HPLC analysis after reduction and carboxymethylation; B. ES-MS spectrum of the main HPLC fraction (labeled with an arrow in panel A).

point, while the JY1-MAP8, with eight and four epitopes, respectively (Figure 3B), contained three Lys branching units in each monomer. The monomers were prepared by Boc/benzyl solid-phase chemistry and dimerized as above. To evaluate the quality of each synthesis, an aliquot of each final dimer was reduced and *S*-carboxymethylated and characterized by reverse phase HPLC (Figure 4). The divalent monomer (JY1-MAP2 precursor) was less clean than the tetravalent monomer (JY1-MAP4 precursor), probably due to the use of a resin with too high substitution. In both cases, however, the main fraction of each HPLC profile was identified by ESI-MS as the expected species (Table 4). In conclusion, the dendrimeric approach allowed the preparation of a high molecular weight immunogen of defined composition in a more reproducible form than oligomerization.

Peptide on Dextran Beads. Cross-linked dextran beads were chemically modified with a substoichiometric amount of Fmoc-βAla to give an amine-functionalized support suitable for solid-phase peptide synthesis. The remaining hydroxyl functions of the polymer were blocked by acetylation to avoid the formation of deletion sequences and reduce the substitution to convenient levels. A β-Ala loading of ca. 30 μmol/g of dry resin was determined by spectrophotometric titration of the Fmoc group. On this dextran support, the JY1-LysLys-TT sequence (as in Figure 1, but without the flanking Gly and Cys residues) was assembled by Fmoc chemistry, using HOBt- and DIPC-mediated couplings with relatively high excess of all components (10 equiv) in DMF. Most residues required double couplings with TBTU activation and prolonged reaction times (2 h) until a negative Kaiser test was observed. For additional safety, a capping step with acetic anhydride was performed after incorporation of each residue. The quality of the dextran-bound peptide was evaluated by RP-HPLC analysis of an aliquot cleaved from the support by alkaline hydrolysis (Figure 5). The main product of the chromatogram was satisfactorily characterized as the target peptide by ESI-MS (Table 4).

Peptide and MAP Conjugates. To further enhance the immunogenicity of the anti-peptide response, both the monomeric and the two dendrimeric versions of the JY1-TT peptide were conjugated to recombinant HBsAg protein. HBsAg is a polymeric protein of about 2000 kDa. The 25 kDa monomer contains 14 cysteines which form an uncertain number of intra- and intermolecular disulfide bridges, giving rise to particles of 22 nm average diameter, each containing approximately 100 monomer units (*35*). Our choice of HBsAg was based on its high molecular weight, proven stability, and high immunogenicity and because it is known to act as an effective and safe vaccine in humans.

The conjugations of JY1-TT monomer and JY1-MAP4 and JY1-MAP8 dendrimers to HBsAg were done by means of succinic anhydride, a homobifunctional reagent that allows cross-linking of amino groups. The first step was succinylation of HBsAg under mildly alkaline conditions, followed by dialysis to remove excess succinic anhydride and thus avoid unwanted MAP−MAP and/or

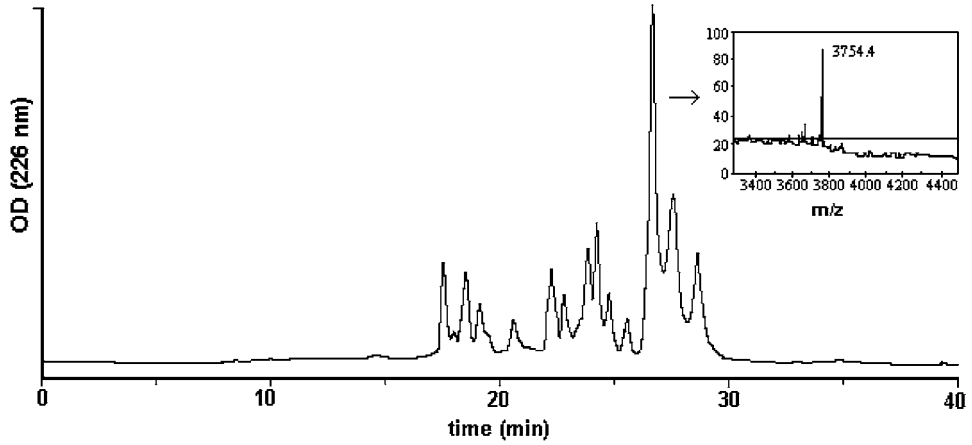

Figure 5. HPLC analysis of crude (after base cleavage) RQSTPIGLGQALYTTKKQYIKANSK-FIGITEL-βAla$_2$ synthesized on dextran beads. The peak labeled with an arrow corresponds to the correct sequence. Inset: FAB-MS of HPLC fractions corresponding to the arrow-labeled peak (see also Table 4).

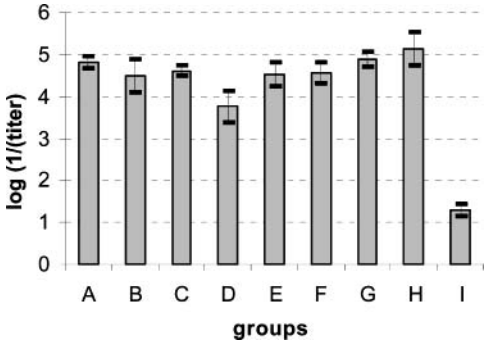

Figure 6. Antibody titers of mice after immunization with four doses of: A, JY1-MAP8, 40 μg; B, JY1-MAP4, 40 μg; C, polymer, 40 μg; D, peptide monomer, 40 μg; E, peptide on dextran beads, 40 μg; F, HBsAg−JY1-peptide, 10 μg; G, HBsAg−JY1-MAP4, 10 μg; H, HBsAg−JY1-MAP8, 10 μg; I, PBS negative control. Titer is defined as the log of the highest dilution giving twice the absorbance of negative control. Titers are the geometric mean ± SD corresponding to eight mice antisera.

peptide−peptide cross-linking. The carboxyl groups on the modified HBsAg were next activated with EDAC (a soluble carbodiimide) and allowed to react with the free amino groups of either linear monomer or JY1-MAP4 or JY1-MAP8. The conjugates were purified by gel filtration to avoid aggregation. For this purpose a Sephadex S300 matrix was selected. This matrix allowed a quick and efficient separation of those conjugates from byproducts such as carbodiimide and MAPs in excess.

Comparison of the Antibody Response in Mice Immunized with Different Presentations of JY1 Peptide. Groups of eight Balb/c mice were inoculated subcutaneously with different presentations of the JY1 peptide antigen and their anti-peptide antibody responses after four doses of the epitope were evaluated by ELISA. Figure 6 shows the titers obtained for the different immunization groups. As can be seen, both HBsAg−JY1-MAP4 and HBsAg−JY1-MAP8 conjugates elicited the highest titers against JY1. The superior immunogenicity of these conjugates may be attributed to the combination of large size and epitope multiplicity, plus the known T-cell response of the carrier protein. The importance of epitope multiplicity was evinced by the fact that the anti-peptide titers elicited by monomeric JY1 conjugated to HBsAg (group F) were significantly lower ($p < 0.01$) than when presented as a MAP dendrimer (groups G and H).

Epitope multiplicity, however, did not provide a simple, uniform pattern in the immune response against JY1. Thus, octameric JY1-MAP8 (group A) was significantly ($p < 0.05$) more immunogenic than monomeric JY1 conjugated to HBSAg (group F), but a similar effect was not observed for tetrameric JY1-MAP4 (group B; $p = 0.893$). On the other hand, the responses to HBsAg−JY1-MAP4 and HBsAg−JY1-MAP8, while the highest among all immunization groups, did not vary significantly ($p = 0.107$) despite the 2-fold difference in multiplicity, nor were there substantial differences between JY1-MAP8 and JY1-MAP4 immunization groups ($p = 0.055$), in contrast to previous results (*36*). In earlier studies, the MAP system has been shown to be more immunogenic than the peptide conjugated to a carrier protein (*37*−*39*). However, the opposite result has also been observed (*40*), a phenomenon that can be related to the nature of the carrier molecule.

The antibody responses generated by immunization with the linear polymer (group C) were significantly lower than those of the JY1-MAP8 dendrimer ($p < 0.05$). However, no significant difference was observed between the linear polymer and the JY1-MAP4 ($p = 0.468$). As for the peptide−dextran conjugate, its anti-JY1 titers were not statistically different from those of the MAP versions or the linear polymer. Finally, as expected, antibody responses of any conjugated or multiple presentation of JY1 were significantly superior to those obtained with the monomeric version.

Analysis of Cross-Reactivity. Pooled sera corresponding to the different immunization groups under study (Table 1) were diluted to an anti-JY1 titer of ca. 10^{-5} and compared with a panel of several V3 peptides from gp 120 HIV-1 (Table 2) for their ability to cross-react. In this experiment, the TAB9 protein, which integrates a number of V3 peptides, was used as a positive control. Results showed that at least three epitopes, MN, IIIB, and JY1, were readily accessible (*36*). As can be seen in Figure 7, the group immunized with the JY1-TT peptide did not exhibit cross-reactivity with other V3 epitopes even after four doses of immunogen. A similar result was found for the same peptide attached to dextran beads, and only marginal recognition was detected for the oligomerized versions of the epitope. On the contrary, when the JY1 sequence was presented as a MAP dendrimer, significant levels of cross-reactivity with the other epitopes were observed after four doses. Similar patterns of cross-reactivity were found for the most immunogenic conjugates HBsAg−JY1-MAP4 and HBsAg−JY1-MAP8. Thus, four 10-μg doses of. the former immunogen sufficed to achieve cross-reactivity with all the variant peptides. Since a substantial proportion of these 10 μg corresponds (in weight) to the HBSAg, not the JY1-MAP4, this means that the carrier has a

Figure 8. Alanine scan (first 15 sequences) and fine epitope mapping (20 sequences) of peptide JY1using the spot synthesis technique. Pooled sera from different immunization groups (after fourth dose) were diluted 1:100 and tested against the peptides. Columns A to J, as in Figure 7. Boxes are coded as follows: white, no recognition; light gray, weak recognition; dark gray, intermediate recognition; black, strong recognition.

significant role in the generation of broadly reactive antibodies. It is important to note that, in most cases, recognition of the heterologous peptides was more than 10 times lower than that of the homologous JY1 peptide. This means that only a minor subset of antibodies were able to react with at least another peptide. Those subsets of antibodies emerged only after repetitive immunizations (data not shown).

To further analyze the cross-reactivity, an alignment analysis of all V3 peptide sequences (Table 2) was performed. The sequence closest to JY1 was MN, with 53.3% homology, followed by RF and BRVA, with 40% homology; LR150 with 33.3%; and the less related IIIB sequence with 26.7%. The ELISA data were in good agreement with this homology. Our results also agreed with previous findings that antibodies for a specific V3 variant provide cross-neutralization for different HIV-1 field isolates (*41*, *42*).

In conclusion, our experiment demonstrated that a certain potential for cross-reactivity is associated to the V3 peptide sequence, but that its intensity strongly depends on the presentation of the epitope to the immune system.

Epitope Mapping. We also examined the effect of the different strategies of immunopeptide presentation on the antibody response to individual residues of the linear JY1 epitope. Our goal was to determine which amino acids in that sequence were more directly involved in the antigen−antibody interaction. For this purpose, we performed fine epitope mapping and an alanine scan of the whole JY1-peptide using the spot synthesis technique.

For epitope mapping, twenty seven- and five-residue peptides covering the JY1 sequence were prepared by simultaneous spot synthesis, as shown in Figure 8. For the alanine scan, fifteen 15-residue peptides with a systematic Ala replacement at each position of the JY1 sequence were similarly synthesized. The cellulose-bound peptides were then assayed by the above protocols against 1:100 dilutions of pooled sera from each immunization group.

The alanine scan (Figure 8) showed that the LXQXXY or LXQXLY sequences were involved in the immune recognition by all sera. This was in good agreement with fine epitope mapping results, in which sera from all immunization groups strongly recognized the C-terminal region (LGQALY) of the JY1-sequence. In addition, mice immunized with either free peptide, peptide oligomers, or MAP also showed weak recognition of the N-terminal region of the JY1-epitope. This region was not recognized when the epitopes were presented as carrier protein

conjugates. On the other hand, this analysis of the antibody response against the linear JY1 epitope did not provide any clues on the different cross-reactivity patterns observed in the above experiments.

SUMMARY AND CONCLUSIONS

In this paper we have described different approaches to improve the immunogenicity of JY1 peptide epitope presentations. These include (i) the JY1-TT construct, where the JY1 epitope is presented in tandem with a well-known T-cell epitope, (ii) oligomeric, disulfide-linked versions of this chimeric sequence, with sizes between 8 and 16 kDa, iii) dendrimeric, MAP-type presentations of the B- and T-cell epitopes, with well-defined structures and masses in the 11−21 kDa range. These immunogens were administered either free or conjugated to HBsAg, an effective carrier protein. In addition, the JY-TT peptide was also administered immobilized on dextran beads, an inexpensive, biocompatible, and biodegradable natural polysaccharide which holds promise as an attractive adjuvant for peptide vaccination (*43*).

This is, as far as we know, one of very few comparative studies on presentation of peptide epitopes to the immune system. We have observed the highest anti-peptide titers in animal groups immunized with MAP−carrier protein conjugates. All dendrimeric versions of the immunogens elicited antibodies that cross-reacted with other V3 HIV-1 sequences. Furthermore, we have shown that cross-recognition can be enhanced by conjugation to a carrier protein, with the advantage that less amount of immunogen is required to achieve a broadly reactive antibody response. This phenomenon of cross-reactivity toward variable regions such as the V3 loop is highly desirable in designing new vaccine candidates against VIH-1. In addition, this approach may be valuable to generate bivalent vaccines when the carrier protein is per se a vaccine immunogen like the HBsAg.

ACKNOWLEDGMENT

This work was supported by the Center for Genetic Engineering and Biotechnology, Havana, Cuba. Work at Barcelona was supported by Spanish CICYT grants (PB97-0873 and BIO2002-04091-C03-01 to D.A., BQ2000-0235 to F.A.), by AECI (Spanish-Cuban cooperation, to D.A.), and by CERBA, Generalitat de Catalunya (to F.A. and D.A.).

8-Cyclopentadienyltricarbonyl ^{99m}Tc 8-oxooctanoic acid (^{99m}Tc−CpTTOA; **1a**) was synthesized for evaluation of medium chain fatty acid metabolism in the liver. ^{99m}Tc−CpTTOA was prepared in high radiochemical yield (50−63%) by a double ligand transfer reaction of methyl 8-ferrocenyl-8-oxooctanoate and $Na^{99m}TcO_4$ in the presence of $CrCl_3$ and $Cr(CO)_6$, followed by hydrolysis. This radiotracer was shown to be stable (>90% at 6 h) when incubated with human serum. Aqueous extraction of the radioactivity from the liver and blood samples of mice suggested that ^{99m}Tc−CpTTOA was mainly metabolized via β-oxidation in the liver, and the radioactivity was retained longer in CCl_4-treated mice than in control mice, possibly due to impaired β-oxidation in the former. Planar images of rats injected with ^{99m}Tc−CpTTOA showed accumulation of the radioactivity in the liver, kidneys, and bladder with rapid hepatic clearance as a function of time. Analysis of the metabolites from the liver and urine samples of rats further supported that ^{99m}Tc−CpTTOA was metabolized to 4-cyclopentadienyltricarbonyl ^{99m}Tc 4-oxobutanoic acid (^{99m}Tc−CpTTBA; **1c**) via β-oxidation. The results suggested that this radiotracer might be of valuable use in the evaluation of fatty acid metabolism in the liver.

INTRODUCTION

Fatty acids are important substrates for energy metabolism, particularly in the heart and liver. In the normal state, glucose and fatty acids are utilized as energy substrates in ATP production. On the other hand, in the fasted state, glucose is synthesized from amino acids (gluconeogenesis) and the rate of fatty acid oxidation is enhanced (*1*, *2*). Therefore, the β-oxidation of fatty acid can be a marker for energy metabolism of the heart and liver. Long chain fatty acids are not only metabolized via β-oxidation but also stored as triglycerides, while medium chain fatty acids are predominantly metabolized via β-oxidation that degrades the fatty acid by the removal of two-carbon units (*3*, *4*). Fatty acid is taken up in many organs, enters the mitochondria, and is metabolized. Unlike long chain fatty acid, medium chain fatty acid enters the mitochondria without the use of carnitine shuttle system (*5*). For past decades, fatty acids were radiolabeled with ^{11}C, ^{18}F, ^{123}I, and ^{99m}Tc (*3*−*4*, *6*−*14*) and utilized for evaluation of fatty acid metabolism using positron emission tomography (PET) and single photon emission computed tomography (SPECT). Among the radionuclides, single photon emitting ^{99m}Tc is desirable due to its ideal physical properties (141 keV, $t_{1/2}$ = 6 h) (*15*, *16*) and ready availability. Therefore, efforts were made to develop ^{99m}Tc-labeled fatty acid analogues (*4*, *7*−*12*). Early attempts included preparation of ^{99m}Tc-labeled fatty acid analogues containing strong chelating groups such as DTPA and EDTA, and these radiotracers were poorly accumulated in the myocardium (*7*, *8*). In other cases, ^{99m}Tc cores such as ^{99m}Tc−N_2S_2 and ^{99m}Tc−N_3S ligand were successfully coordinated to long chain fatty acid analogues, but the radiolabeled analogues showed poor uptake in the myocardium that may be partly due to relatively large size of the ^{99m}Tc cores or inappropriate lipophilicity and thus are not recognized as fatty acids. ^{99m}Tc-labeled iminodiacetic acid was rapidly taken up to the liver and the biliary system and thus applied for hepatobiliary imaging (*11*, *12*). As a same token, radiolabeled medium chain fatty acids have been studied for evaluation of the liver function, based on their rapid accumulation in the liver (*17*). *p*-[^{123}I]Iodophenylenanthic acid and *p*-[^{123}I]iodophenylvaleric acid were studied for assessment of hepatic viability. The results showed that they were taken up to and cleared from the liver rapidly. [1-^{11}C]Octanoate showed the similar pattern of the liver uptake and clearance to other medium chain fatty acid analogues. This radiotracer along with *p*-[^{123}I]-iodophenylenanthic acid were metabolized by β-oxidation in the liver with slower hepatic clearance in CCl_4-treated mice than in control mice due to impaired β-oxidation (*3*, *6*). The results demonstrated that both are promising diagnostic agents for assessment of the liver function. [^{99m}Tc]MAMA−hexanoic acid, a ^{99m}Tc-labeled medium chain fatty acid analogue, was also rapidly accumulated in the liver, and the metabolism via β-oxidation was confirmed by detection of the radiometabolite, [^{99m}Tc]-MAMA−butyric acid (*4*). [^{99m}Tc]MAG−hexanoic acid, a polar analogue, however, showed poor accumulation in the liver and was immediately excreted from the kidneys to the bladder, because of its low lipophilicity. Recent preparation of cyclopentadienyltricarbonyl ^{99m}Tc (^{99m}Tc−CpTT) extended its utilization to the preparation of the various ^{99m}Tc complexes (*18*−*20*). This small lipophilic core is attractive, because the ferrocene with various

substituents can be readily prepared via Friedel−Crafts acylation, and thus biomolecules can be efficiently labeled with ^{99m}Tc−CpTT. Small size of the core is also expected to minimize the perturbation of biological activity of the fatty acid.

In this work, we prepared ^{99m}Tc−CpTTOA (**1a**) by facile incorporation of ^{99m}Tc−CpTT into a medium chain fatty acid analogue. Its metabolism in the liver was evaluated and the metabolite was identified using the proposed radiometabolites, 6-cyclopentadienyltricarbonyl ^{99m}Tc 6-oxohexanoic acid (^{99m}Tc−CpTTHA; **1b**) and ^{99m}Tc−CpTTBA (**1c**).

EXPERIMENTAL SECTION

Materials and Methods. Solvents and reagents were purchased from the following commercial sources: Sigma-Aldrich Company (Milwaukee, WI) and Acros Organics (Geel, Belgium). ^{1}H NMR were obtained on Varian Gemini-200 and 400 (Palo Alto, CA) and a JEOL JNM-LA 300 spectrometer, and ^{13}C NMR at 50 and 100 MHz. Chemical shifts were reported in parts per million (ppm, δ units). Electron impact (EI) and chemical ionization (CI) mass spectra were obtained on a GC/MS QP5050A spectrometer (Shimadzu, Kyoto, Japan). Fast atom bombardment (FAB) mass spectra were obtained on a JMS 700 (JEOL Ltd., Tokyo, Japan). Elemental analyses were performed at the Inha University (CE instrument, Italy). HPLC was carried out on a Thermo Separation Products System (Fremont, CA) with a semipreparative column (Alltech Econosil silica gel, 10 μm, 10 × 250 mm) and an analytical column (YMC C18, 5 μm, 4.6 × 250 mm). The eluant was simultaneously monitored by a UV detector (254 nm) and a NaI(Tl) radioactivity detector. TLC was performed on Merck F_{254} silica plates and analyzed on a Bioscan radio-TLC scanner (Washington DC). $Na^{99m}TcO_4$ was eluted on a daily basis from ^{99}Mo/^{99m}Tc generators (DuPont Pharmaceuticals Co., Wilmington, DE, and Daiichi Radioisotope Labs., Chiba, Japan). Images of rats were obtained on a gamma camera (Trionix Research Lab. Inc., Twinsburg, OH) using a pinhole collimator.

Synthesis of Methyl 8-Ferrocenyl-8-oxooctanoate (3a). The flask was charged with ferrocene (150 mg, 0.806 mmol), methyl 8-chloro-8-oxooctanoate (114 μL, 0.806 mmol), and CH_2Cl_2 (1.5 mL). The solution was then chilled thoroughly in an ice bath. To this solution was added anhydrous aluminum chloride (113 mg, 0.846 mmol) carefully for 20 min using a spatula under N_2. The reaction mixture, which turned to deep violet color, was allowed to stir for 30 min in an ice-bath and for another 2 h at room temperature. At the end of the reaction, the flask was placed again in an ice bath, and water (2 mL) was slowly added. The resulting two-phase mixture was stirred vigorously for 30 min. The organic layer was dried over anhydrous sodium sulfate, and the solvent was removed in vacuo. The residue was purified by flash column chromatography (15:85 ethyl acetate−hexane) to afford **3a** (244 mg, 85%) as a red oil: ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.78 (t, J = 2.0 Hz, 2H, −Fe−Cp-H (α)), 4.49 (t, J = 2.0 Hz, 2H, −Fe−Cp-H (β)), 4.19 (s, 5H, Cp-H), 3.67 (s, 3H, OCH_3), 2.70 (t, J = 7.3 Hz, 2H, CH_2), 2.33 (t, J = 7.6 Hz, 2H, CH_2), 1.74−1.62 (m, 4H), 1.40−1.37 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ 202.030, 171.746, 76.694, 69.669, 67.279, 66.862, 49.020, 37.132, 31.572, 26.694, 26.565, 22.355, 21.907; MS (EI) m/z 356 (M^+). Anal. ($C_{19}H_{24}O_3Fe$) C, H.

Methyl 6-Ferrocenyl-6-oxohexanoate (3b). The flask was charged with ferrocene (500 mg, 2.688 mmol), adipoyl chloride (390 μL, 2.688 mmol), and CH_2Cl_2 (20 mL). The solution was then chilled thoroughly in an ice bath. To this solution was added anhydrous aluminum chloride (394 mg, 2.955 mmol) carefully for 20 min using a spatula under N_2. The reaction mixture, which turned to deep violet color, was allowed to stir for 40 min in an ice-bath and for another 30 min at room temperature. Without further purification, the reaction mixture was heated at 90 °C for 1 h after slow addition of methanol (9 mL) and triethylamine (2 mL). At the end of the reaction, the solvents were removed in vacuo, and the residue was purified by flash column chromatography (20:80 ethyl acetate−hexane) to afford **3b** (389 mg, 44%) as a red oil: ^{1}H NMR (200 MHz, $CDCl_3$) δ 4.76 (t, J = 1.8 Hz, 2H, Fe−Cp-H (α)), 4.48 (t, J = 1.8 Hz, 2H, Fe−Cp-H (β)), 4.18 (s, 5H, Cp-H), 3.67 (s, 3H, OCH_3), 2.72 (t, J = 7.0 Hz, 2H, CH_2), 2.37 (t, J = 7.0 Hz, 2H, CH_2) 1.75−1.68 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ 203.976, 173.918, 78.950, 72.145, 69.717, 69.247, 51.532, 39.181, 33.901, 24.729, 23.848; MS (CI) m/z 329 ($M + H)^+$. Anal. ($C_{17}H_{20}O_3Fe$) C, H.

Methyl 8-Ferrocenyl-8-oxobutanoate (3c). A red oil: ^{1}H NMR (200 MHz, $CDCl_3$) δ 4.79 (t, J = 1.8 Hz, 2H, −Fe−Cp-H (α)), 4.49 (t, J = 1.8 Hz, 2H, −Fe−Cp-H (β)), 4.23 (s, 5H, Cp-H), 3.71 (s, 3H, OCH_3), 3.07 (t, J = 6.6 Hz, 2H, CH_2), 2.68 (t, J = 6.4 Hz, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$) δ 202.027, 173.516, 78.312, 72.167, 69.869, 69.118, 51.767, 34.143, 27.611; MS (CI) m/z 301 ($M + H)^+$. Anal. ($C_{15}H_{16}O_3Fe$) C, H.

Synthesis of 8-Ferrocenyl-8-oxooctanoic Acid (4). A solution of the ester **3a** (70 mg, 0.197 mmol) in 1.5 mL of ethanol and 1.5 mL of 20% NaOH (aq) was heated under reflux for 1 h. The reaction mixture was cooled and acidified with 5 mL of 20% HCl in an ice bath and then stirred vigorously for a few minutes to make free acid from the sodium salt. The product was collected by suction filtration at room temperature, washed with 10 mL of water, and dried. Pure 8-ferrocenyl-8-oxooctanoic acid (**4**) was obtained in 90% yield (60 mg) as a red solid: mp 80.2 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.78 (t, J = 2.0 Hz, 2H, −Fe−Cp-H (α)), 4.49 (t, J = 2.0 Hz, 2H, −Fe−Cp-H (β)), 4.19 (s, 5H, Cp-H), 2.70 (t, J = 7.4 Hz, 2H, CH_2), 2.38 (t, J = 7.6 Hz, 2H, CH_2), 1.74−1.62 (m, 4H), 1.30−1.22 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ 204.628, 179.450, 79.079, 72.145, 69.733, 69.346, 39.570, 33.942, 29.102, 28.904, 24.527, 24.360; MS(FAB) m/z 342 ($M + H)^+$. Anal. ($C_{18}H_{22}O_3Fe$) C, H.

Synthesis of Methyl 8-Cyclopentadienyltricarbonylrhenium-8-oxooctanoate (5a). A mixture of the ester **3a** (52.8 mg, 0.147 mmol), NH_4ReO_4 (13 mg, 0.047 mmol), $Cr(CO)_6$ (58 mg, 0.265 mmol), and $CrCl_3$ (15 mg, 0.094 mmol) was placed in a 4 mL reaction vial containing a magnetic stir bar. Dry methanol (300 μL) was added to the vial that was sealed and heated at 160 °C for 1 h. At the end of the reaction, the mixture was cooled in an ice bath for 15 min and the solvent was removed in vacuo. Flash column chromatography (1:4 ethyl acetate−hexane) of the crude mixture afforded **5a** (26 mg, 35%) as a gray solid: mp 70.2 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ 5.99 (t, J = 2.4 Hz, 2H, Re−Cp-H (α)), 5.40 (t, J = 2.3 Hz, 2H, Re−Cp-H (β)), 3.67 (s, 3H, OCH_3), 2.58 (t, J = 7.3 Hz, 2H, CH_2), 2.31 (t, J = 7.5 Hz, 2H, CH_2), 1.71−1.61 (m, 4H), 1.38−1.33 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ 194.993, 191.777, 174.063, 96.337, 87.765, 85.094, 51.367, 38.645, 33.919, 28.783, 28.631, 24.671, 24.110; MS (FAB) m/z 507 ($M + H)^+$; HRMS calcd for $C_{17}H_{20}O_6{}^{187}$Re 507.0818, found 507.0812.

Methyl 6-Cyclopentadienyltricarbonylrhenium-6-hexanoate (5b). A pale yellow oil: ^{1}H NMR (400 MHz,

$CDCl_3$) δ 5.97 (t, J = 2.0 Hz, 2H, Re−Cp-H (α)), 5.39 (t, J = 2.0 Hz, 2H, Re−Cp-H (β)), 3.66 (s, 3H, OCH_3), 2.61 (t, J = 7.2 Hz, 2H, CH_2), 2.35 (t, J = 7.0 Hz, 2H, CH_2), 1.73−1.64 (m, 4H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 194.689, 191.778, 173.766, 95.786, 87.886, 85.195, 51.590, 38.309, 33.684, 24.239, 23.557; MS (FAB) m/z 479 $(M + H)^+$; HRMS calcd for $C_{15}H_{16}O_6{}^{187}$Re 479.0505, found 479.0515.

Methyl 4-Cyclopentadienyltricarbonylrhenium-4-oxobutanoate (5c). A pale yellow oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.03 (t, J = 2.4 Hz, 2H, Re−Cp-H (α)), 5.40 (t, J = 2.4 Hz, 2H, Re−Cp-H (β)), 3.69 (s, 3H, OCH_3), 2.92 (t, J = 6.8 Hz, 2H, CH_2), 2.31 (t, J = 6.4 Hz, 2H, CH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 193.241, 191.710, 172.857, 95.156, 87.977, 85.217, 51.961, 33.366, 27.635; MS (FAB) m/z 451 $(M + H)^+$; HRMS calcd for $C_{13}H_{12}O_6{}^{187}$Re 451.0192, found 451.0188.

Synthesis of 8-Cyclopentadienyltricarbonylrhenium-8-oxooctanoic Acid (2a). A solution of **5a** (100 mg, 0.197 mmol) in 3 mL of 20% NaOH (aq) and ethanol (1:1) was heated at 80 °C for 1 h. The solution was cooled and acidified with 5 mL of 0.1 N HCl in an ice bath. The reaction mixture was extracted with CH_2Cl_2, and the organic layer was dried over anhydrous sodium sulfate and concentrated. The crude product was purified by flash column chromatography (60:40 ethyl acetate−hexane) to give **2a** (79 mg, 82%) as a pale yellow oil: ^{1}H NMR (200 MHz, $CDCl_3$) δ 5.99 (t, J = 2.4 Hz, 2H, Re−Cp-H (α)), 5.40 (t, J = 2.4 Hz, 2H, Re−Cp-H (β)), 2.59 (t, J = 7.2 Hz, 2H, CH_2), 2.36 (t, J = 7.3 Hz, 2H, CH_2), 1.73−1.62 (m, 4H), 1.39−1.26 (m, 4H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 195.136, 191.816, 179.453, 96.149, 87.863, 85.142, 38.597, 33.715, 28.681, 28.590, 24.391, 24.034; MS (FAB) m/z 493 $(M + H)^+$; HRMS calcd for $C_{16}H_{18}O_6{}^{187}$Re 493.0662, found 493.0616.

6-Cyclopentadienyltricarbonylrhenium-6-oxohexanoic Acid (2b). A pale yellow oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 5.99 (t, J = 2.4 Hz, 2H, Re−Cp-H (α)), 5.40 (t, J = 2.2 Hz, 2H, Re−Cp-H (β)), 2.62 (t, J = 7.0 Hz, 2H, CH_2), 2.39 (t, J = 7.2 Hz, 2H, CH_2), 1.77−1.62 (m, 4H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 194.765, 191.816, 179.316, 95.686, 87.939, 85.255, 38.263, 33.707, 23.966, 23.443; MS (FAB) m/z 465 $(M + H)^+$; HRMS calcd for $C_{14}H_{14}O_6{}^{187}$Re 465.0348, found 465.0356.

4-Cyclopentadienyltricarbonylrhenium-4-oxobutanoic Acid (2c). A pale yellow oil: ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.03 (t, J = 2.4 Hz, 2H, Re−Cp-H (α)), 5.41 (t, J = 2.4 Hz, 2H, Re−Cp-H (β)), 2.90 (t, J = 6.4 Hz, 2H, CH_2), 2.74 (t, J = 6.4 Hz, 2H, CH_2); ^{13}C NMR (100 MHz, $CDCl_3$) δ 195.580, 191.717, 179.305, 94.966, 88.053, 85.263, 33.123, 27.635; MS (FAB) m/z 437 $(M + H)^+$; HRMS calcd for $C_{12}H_{10}O_6{}^{187}$Re 437.0035, found 437.0055.

Radiochemical Synthesis of ^{99m}Tc−CpTTOA (1a). A solution of $Na^{99m}TcO_4$ eluted from a generator was placed in a glass tube and was concentrated to dryness under a stream of N_2 at 75−80 °C. The resulting residue was treated with methanol, and the fraction soluble in methanol was collected in a pressure tube. To this were added the ester **3a** (3 mg, 8.42 μmol), $Cr(CO)_6$ (3.3 mg, 15.16 μmol), and $CrCl_3$ (0.8 mg, 5.39 μmol). The reaction mixture was heated at 160 °C for 1 h. At the end of the reaction, the mixture was cooled in an ice bath and methanol was removed under a stream of N_2. The residue was dissolved in CH_2Cl_2, passed through a short silica plug, and the solvent was removed. The residue was redissolved in methanol (150 μL) and treated with 0.4 N NaOH (50 μL) at 80 °C for 10 min. The solution was cooled, acidified with 50 μL of 0.5 N HCl, and extracted with CH_2Cl_2. ^{99m}Tc−CpTTOA (**1a**) was purified by HPLC at a flow 4 mL/min using a 91:9:0.09 mixture of hexane:methanol:acetic acid. ^{99m}Tc−CpTTOA collected from HPLC was concentrated, redissolved in ethanol, and diluted in saline to give a final solution of 10% ethanol in saline. A portion of the sample was treated with bovine serum albumin to give 5% of the total volume. An aliquot was analyzed by reversed phase HPLC at a flow 1 mL/min using a 70:30 mixture of methanol-0.1% acetic acid (aq). ^{99m}Tc−CpTTHA (**1b**) and ^{99m}Tc−CpTTBA (**1c**) were prepared as in the synthesis of **1a**.

In Vitro Stability Studies. An aliquot (18.5 MBq) of ^{99m}Tc−CpTTOA in 10% ethanol−saline was added to human serum (1 mL) and incubated at 37 °C, and the solution was analyzed at 30, 60, 240, and 360 min by radio-TLC using ethyl acetate−hexane (7:3) as the developing solvents.

Animals. A group of mice (ICR, male, 28 g) was orally administered 30% CCl_4 (1 mL CCl_4/kg) in olive oil after 6 h-long fast, whereas control mice were administered the same volume of olive oil under the same conditions (*3*, *21*). These two groups were fasted for another 2 h and then fed ad libitum for 15 h.

Biological Studies. Control and CCl_4-treated mice were fasted for another 3 h before administration of ^{99m}Tc−CpTTOA (1.5 MBq/mouse) via tail vein. At 2, 30, 60, and 120 min postinjection, both groups of mice (n = 3/time point) were sacrificed by cervical dislocation, and samples of blood and liver were isolated, weighed, and counted. The injected dose was calculated from standards prepared from the injection solution. The data were expressed as percent injected dose per gram of tissue (%ID/g). The 30 min samples of the serum and the liver were homogenized, extracted with a 2:1:1 mixture of $CHCl_3$/MeOH/0.001 N NaOH, and centrifuged (3000 rpm, 30 min) (*22*). The resulting chloroform and aqueous layers (1 mL each) were counted, respectively.

^{99m}Tc−CpTTOA was injected to 6-h-long fasted SD rats and planar images were obtained at 5, 30, and 60 min postinjection. Two sets of experiment were carried out, one with the radiotracer in 10% ethanol−saline and the other with additional 5% bovine serum albumin. In another set of experiment, SD rats (n = 2/time point) were injected with ^{99m}Tc−CpTTOA, and samples of the liver and the bladder were collected at 30 and 60 min postinjection. The liver samples were homogenized and centrifuged as previously, whereas urine samples were filtered through a membrane (MW cutoff 10 000). The samples were analyzed by both HPLC at a flow rate of 1 mL/min using a 70:30 mixture of methanol and 0.1% acetic acid (aq) as the eluants and radio-TLC using a 50:50 mixture of methanol and 0.2% acetic acid (aq) as the developing solvents.

RESULTS AND DISCUSSION

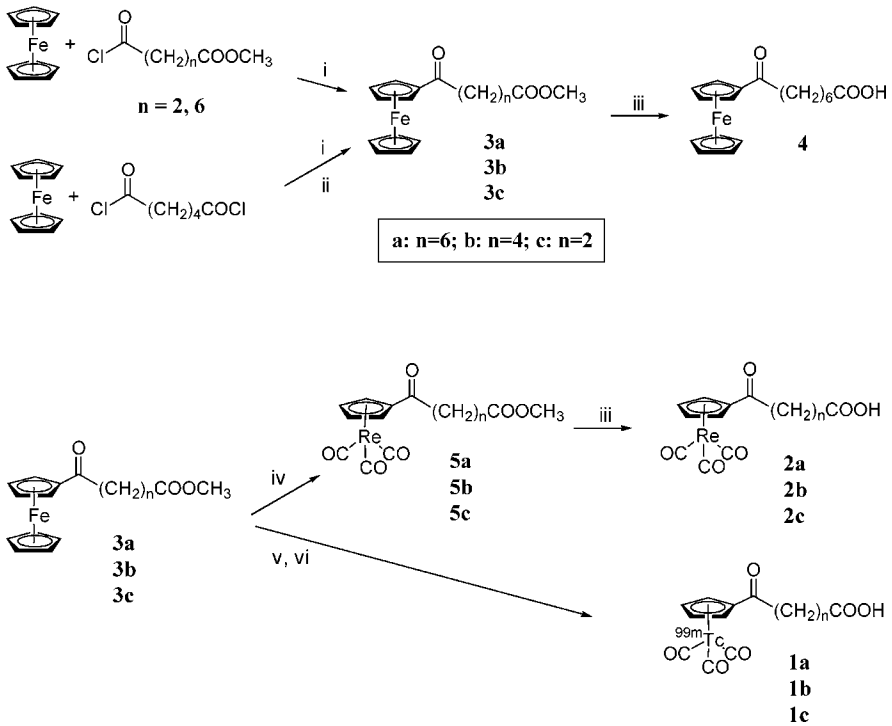
Synthesis of 8-Cyclopentadienyltricarbonylrhenium-8-oxooctanoic Acid (2a). The ester **3a** was prepared by Friedel−Crafts acylation from ferrocene and methyl 8-chloro-8-oxooctanoate in the presence of $AlCl_3$ (*23*). A double ligand transfer reaction of the ester **3a** and NH_4ReO_4 using $CrCl_3$ and $Cr(CO)_6$ was carried out to provide Re compound **5a**. This reaction was well described by Spradau and Katzenellenbogen (*18*), in that ReO_4^- is reduced and carbonylated, which undergoes a Cp ligand transfer reaction with the ferrocenyl precursor. The optimal reaction solvent was methanol among various solvents studied. Hydrolysis of the resulting compound in 0.4 N NaOH (aq) and methanol (1:3) afforded 8-cyclopentadienyltricarbonylrhenium-8-oxooctanoic acid

Table 1. Comparison of Radiochemical Yields Depending on Precursors and Solvents in the Double Ligand Transfer Reaction

precursor	solvent[a]	yield[b] (no. of reacion)
3	methanol	58−82 (8)
4	THF	NR[c] (3)
4	2-propanol	12−15 (2)

[a] A total volume was 200 μL. [b] Yield was based on radio-TLC data. [c] NR: no reaction.

(**2a**). A double ligand transfer reaction of the carboxylic acid **4** in methanol gave the **5a** instead of the **2a** (2−5% yield), possibly due to methyl ester formation of the carboxylic acid by methanol. The ester **3b** was prepared from ferrocene and methyl 6-chloro-6-oxohexanoyl chloride in the presence of $AlCl_3$, followed by methyl ester formation in methanol in the presence of triethylamine. Re complexes **2b** and **2c** were prepared as the synthesis of **2a**.



Radiochemical Synthesis of ^{99m}Tc−CpTTOA (1a). ^{99m}Tc−CpTTOA was synthesized via the same route as the preparation of Re-fatty acid **2a** (*18*−*20*). The ester **3a** was reacted with $^{99m}TcO_4^-$ in the presence of $CrCl_3$ and $Cr(CO)_6$ at 160 °C for 1 h. When either the acid **4** was used as the precursor or THF (or 2-propanol) as the solvent, the radiochemical yield of **1a** was low as shown in Table 1 and some unknown radioactive peaks appeared on radio-TLC. Therefore, the ester **3a** and methanol were employed to produce **1a** as shown in Scheme 1. Hydrolysis of the ^{99m}Tc-labeled compound was attempted in 20% NaOH (aq) and ethanol (*24*) as described for the hydrolysis of the **5a**, but unknown radioactive compounds were detected upon analysis by radio-TLC. Although the unknown peaks were not identified, they were likely to be derived from cleavage of the ^{99m}Tc core. Therefore, hydrolysis conditions were varied to give a maximal yield of the desired product and to minimize the production of the unknown radiochemical impurities. As shown in Table 2, hydrolysis of the methyl ester of ^{99m}Tc−CpTTOA in a 1:3 mixture of 0.4 N NaOH and methanol gave the highest yield (72−77%). The reaction mixture was then purified by HPLC, and the retention time of ^{99m}Tc−CpTTOA was 12.5 min using a 91:9:0.09 mixture of hexane:methanol:acetic acid as the eluants. An aliquot was analyzed by reversed phase HPLC, and ^{99m}Tc−CpTTOA and Re−CpTTOA were eluted at 16.9 and 14.4 min, respectively. Although they were not coeluted on HPLC, ^{99m}Tc−CpTTOA was identified based on the similar chemical properties between Tc and Re complexes. The different retention times of Tc and Re complexes on HPLC have been also reported in other cases (*20*). Synthesis of ^{99m}Tc−CpTTOA gave higher yield than the corresponding Re complex, due to higher reactivity of ^{99m}Tc than Re. Overall radiochemical yield of ^{99m}Tc−CpTTOA was 50−63% (decay-corrected) and radiochemical purity was higher than 99% as determined by HPLC and radio-TLC. ^{99m}Tc−CpTTHA (**1b**) and ^{99m}Tc−CpTTBA (**1c**) were prepared as in the synthesis of **1a** and used as the radiometabolite standards of **1a**. HPLC retention times of **1b** and **1c** were 11.1 and 8.2

Table 2. Comparison of Hydrolysis Conditions of the Methyl Ester of ^{99m}Tc−CpTTOA (1a)

reagent	NaOH/ methanol[a]	ratio of unknown peak to **1a**[b]
20% NaOH/ethanol	1:1	NR[c]
0.1 N NaOH/methanol	1:1	4/1
0.2 N NaOH/methanol	1:1	3/1
0.4 N NaOH/methanol	1:1	3.3/1
0.4 N NaOH/methanol	1:3	1/3
0.5 N NaOH/methanol	1:1	9/1
0.7 N KOH/methanol	1:1	8/1

[a] The reaction was carried out in a total volume of 200 μL (80 °C, 10 min). [b] Measured by radio-TLC. [c] NR: no reaction.

Table 3. In Vitro Stability of ^{99m}Tc−CpTTOA (1a) in Human Serum

time (min)	% of ^{99m}Tc−CpTTOA[a]
30	98
60	98
240	94
360	92

[a] ^{99m}Tc−CpTTOA was incubated with human serum at 37 °C for 6 h and the percentage of the remaining radiotracer was analyzed by radio-TLC.

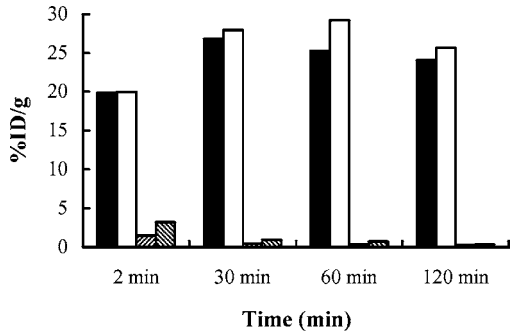

Figure 1. Measurement of the radioactivity in liver and blood samples of control and CCl_4-treated mice. Both groups of mice were injected with ^{99m}Tc−CpTTOA, and the liver and blood were collected at 2, 30, 60, and 120 min postinjection and counted. The injected dose was calculated from standards prepared from the injection solution. The data were expressed as percent injected dose per gram of tissue (%ID/g). Closed bar: liver sample from control mice; open bar: liver sample from CCl_4-treated mice; right-handed striped bar: blood sample from control mice; left-handed striped bar: blood sample from CCl_4-treated mice.

min, respectively, when analyzed in a 70:30 mixture of methanol-0.1% acetic acid (aq) at a flow rate of 1 mL/min.

In Vitro Stability Studies. Percentage of the remaining ^{99m}Tc−CpTTOA was 98% after 1 h and over 90% even after 6 h when the radiotracer was incubated with human serum at 37 °C and analyzed by radio-TLC, indicating high in vitro stability of the radiotracer (Table 3).

Measurement of the Radioactivity in the Liver and Blood Samples of Control and CCl_4-Treated Mice. Control and CCl_4-treated mice were fasted for 3 h before injected with ^{99m}Tc−CpTTOA. Initial uptake of the radioactivity in CCl_4-treated mice was similar to that in control mice at 2 min postinjection of ^{99m}Tc−CpTTOA, as shown in Figure 1. In contrast, the amounts of radioactivity in the liver of CCl_4-treated mice were higher than those of control mice at 30, 60, and 120 min postinjection, reaching a maximum at 60 min. The radioactivity in the samples of blood was slightly higher in CCl_4-treated mice. This was also the case when [1-^{11}C]-octanoate was evaluated in the control and CCl_4-treated mice (*3*), although the difference in the liver uptake of the radioactivity between the two groups of mice was more profound in [1-^{11}C]octanoate than in ^{99m}Tc−CpTTOA. This result demonstrated that the ^{99m}Tc−CpTTOA underwent slower hepatic clearance in CCl_4-treated mice compared to the control mice, probably due to impaired β-oxidation caused by CCl_4 that is known to induce the hepatotoxicity (*21*).

Solubility of the Radioactivity in the Liver and Blood Samples of Control and CCl_4-Treated Mice. Most of the radioactivities obtained from the blood and liver at 30 min postinjection in control and CCl_4-treated mice were extracted into the aqueous layer rather than into the organic layer, indicating that the metabolites are water-soluble (Table 4). The radioactivities produced by esterification should be extracted into chloroform layer. The results therefore indicated that the ^{99m}Tc−CpTTOA was predominately metabolized by β-oxidation in the liver and not esterified as triglycerides, which was consistent with the results of other medium chain fatty acid analogues such as *p*-[^{123}I]iodophenylenanthic acid, *p*-[^{123}I]iodophenylvaleric acid, and [1-^{11}C]octanoate in the liver (*3*, *6*).

Table 4. Solubility of the Radioactivity in Liver and Blood Samples of Control and CCl_4-Treated Mice at 30 min after Administration of ^{99m}Tc−CpTTOA (1a)

	tissue	organic[a]	aqueous[a]
control	liver	1.7	98.3
	serum	14.5	85.5
CCl_4-treated	liver	1.6	98.4
	serum	8.9	91.1

[a] Mean average of three mice.

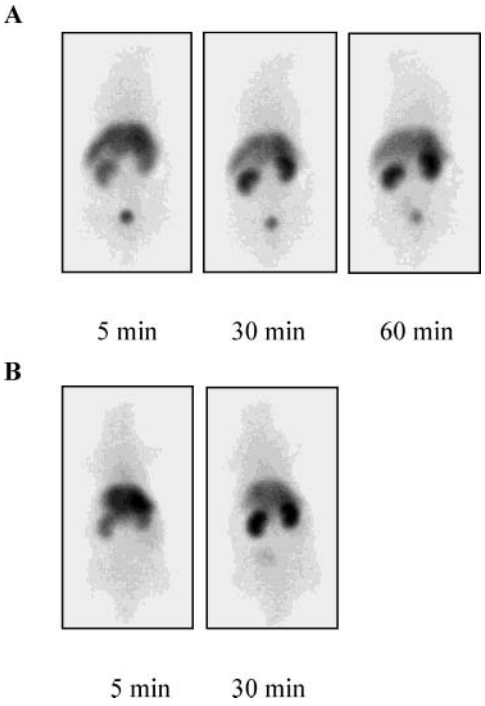

Figure 2. Planar images of ^{99m}Tc−CpTTOA (**1a**) in rats. The radiotracer (11 MBq) was administered to SD rats via tail vein and planar images were obtained at 5, 30, and 60 min postinjection, respectively (A). Another sets of planar images were obtained at 5 and 30 min after administration of the radiotracer containing 5% bovine serum albumin (B).

Imaging Studies. Since fatty acids are predominantly metabolized in the fasted state, the animals were fasted for 6 h prior to the experiments. Planar images of the rats injected with ^{99m}Tc−CpTTOA showed rapid uptake of the radioactivity in the liver, kidneys and bladder at 5 min postinjection with rapid elimination of the radioactivity from the liver as a function of time (Figure 2A). Within 60 min, most of the radioactivity was observed in the kidneys and bladder. This rapid hepatic clearance indirectly suggested that this fatty acid analogue was not esterified, unlike long chain fatty acid. Uptake pattern of the ^{99m}Tc−CpTTOA was not significantly affected by the presence of 5% bovine serum albumin (Figure 2B), even though bovine serum albumin is known to facilitate the penetration of the fatty acid through the cell membranes (*25*). There was no significant uptake in the thyroid or salivary gland, indicating that ^{99m}Tc pertechnetate was not regenerated during the time of the study.

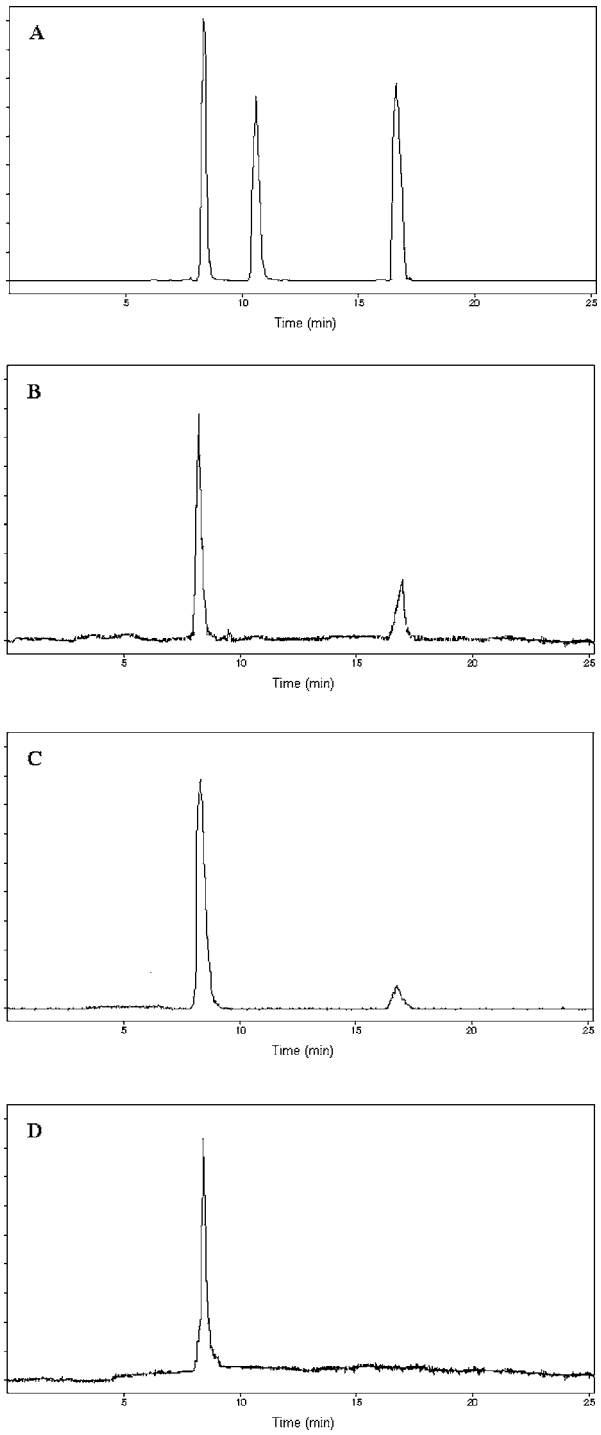

Figure 3. HPLC profile of the standards. (A); t_R = 8.2 min (**1c**), 11.1 min (**1b**), 16.9 min (**1a**). HPLC analysis of the liver and urine samples of the rats injected with ^{99m}Tc−CpTTOA (**1a**); (B): liver, 30 min, (C): urine 30 min, and (D): urine 60 min.

It is likely that the lipophilic properties of ^{99m}Tc−CpTT contributed to rapid uptake of this fatty acid analogue to the liver because medium chain fatty acid does not use carnitine shuttle step when enters the mitochondria, whereas a polar [^{99m}Tc]MAG−hexanoic acid was hardly accumulated in the liver (*4*). Although ^{99m}Tc−CpTT is smaller than ^{99m}Tc−N_2S_2 core, difference in the size of the cores did not significantly affect on the biological activity of the corresponding medium chain fatty acid analogue.

Analysis of Metabolites. When the samples of the liver and urine of rats were analyzed, the sole radiometabolite appeared at the retention time of 8.2 min on HPLC and was identified as ^{99m}Tc−CpTTBA on both radio-TLC and HPLC (Figure 3). ^{99m}Tc−CpTTHA, the metabolite after one cycle of β-oxidation of ^{99m}Tc−CpTTOA, was not detected (Figure 3B-D). Ratios of peak area under ^{99m}Tc−CpTTBA to ^{99m}Tc−CpTTOA were 77:23 and 90:10 in 30 min samples of the liver and urine, respectively (Figure 3B and C). The 60 min samples of the liver were not analyzed because of the insufficient radioactivity. The parent was completely converted to the metabolite in the 60 min sample of the urine (Figure 3D). This indicated that ^{99m}Tc−CpTTOA was metabolized to ^{99m}Tc−CpTTBA via β-oxidation in the liver and excreted to the kidneys and bladder, which was similar to the metabolism of [^{99m}Tc]MAMA−hexanoic acid in the liver (*4*).

CONCLUSION

The labeling method using ^{99m}Tc−CpTT was advantageous, because the precursor was readily prepared by Friedel−Crafts acylation from ferrocene and fatty acid analogue, and ^{99m}Tc labeling via a double ligand transfer reaction was easily achievable. A novel radiotracer, ^{99m}Tc−CpTTOA, was metabolized via β-oxidation in the liver, which supported that the β-oxidation was the main metabolic pathway of this medium chain fatty acid analogue. The results suggest that ^{99m}Tc−CpTTOA may be useful for evaluation of fatty acid metabolism in the liver. This is the first example of the medium chain fatty acid analogue containing ^{99m}Tc−CpTT.

A New Strategy for the Preparation of Peptide-Targeted Radiopharmaceuticals Based on an Fmoc-Lysine-Derived Single Amino Acid Chelate (SAAC). Automated Solid-Phase Synthesis, NMR Characterization, and in Vitro Screening of fMLF(SAAC)G and fMLF[(SAAC−Re(CO)$_3$)$^+$]G

Received July 21, 2003; Revised Manuscript Received October 12, 2003

A tridentate single amino acid chelate (SAAC) derived from N-α-Fmoc-L-lysine was incorporated within a short peptide sequence using an automated peptide synthesizer. Novel derivatives of the chemotactic peptide fMLF were prepared such that the SAAC and its Re complex were selectively placed between a terminal glycine amino acid and the targeting fMLF sequence. The products, which were synthesized in parallel, were characterized by mass spectrometry and multi-NMR spectroscopy. The latter technique demonstrated that the structures of the targeting portions of the peptides are the same in the SAAC and Re−SAAC derivatives. The affinities of the reported compounds for the formyl peptide receptor were subsequently determined using flow cytometry and were found to be comparable to that of the parent peptide. The results of this work demonstrate the feasibility and numerous benefits of using the SAAC system to prepare peptide-targeted Tc(I) and Re(I) radiopharmaceuticals.

INTRODUCTION

Small peptides have proven to be one of the most effective means of targeting radionuclides to specific receptors (*1*). The success of peptides as biological vectors for radioisotopes is a result of their receptor specificity, ease of preparation and modification, ability to target receptors, and clearance from nontarget tissues in a time frame that correlates with the half-life of clinically useful radionuclides such as ^{99m}Tc, ^{111}In, and ^{18}F.

It has been well-documented that several factors influence the receptor binding affinity and biodistribution of technetium-labeled peptides (*2*). These include the site of derivatization, the presence and type of a spacer group between the ligand−metal complex and the peptide, and the nature of the Tc−ligand complex (charge, size, lipophilicity, etc.). As a means of identifying optimal combinations of these factors several groups have begun to employ solid-phase synthesis (SPS) strategies. SPS is attractive because it is a convenient means of preparing analogues of a particular peptide−ligand bioconjugate in parallel (*3*).

The most common SPS strategy used to prepare peptide-targeted Tc radiopharmaceuticals has been to append Tc ligands to the N-termini of peptides bound to a polymeric support. Hoffman et al., for example, reported the synthesis of a series of bombesin derivatives in which a N_3S triamide chelate and its Re complex were linked to the resin-bound peptide through a variety of different spacer groups (*4*). Gariépy and co-workers described a related solid-phase synthesis method for adding a diaminedithiol ligand to the N-terminus of short peptides (*5*). Blower and co-workers recently described a novel SPS approach in which a hydrazinonicotinyl acid (HYNIC) derivative of Fmoc-lysine was used as a metal-binding amino acid analogue (*6*, *7*). The N-protected HYNIC derivative was successfully incorporated within a bioactive peptide using standard Fmoc solid-phase peptide chemistry.

The above-mentioned SPS methods have some limitations including one or more of the following: a lack of flexibility in terms of changing the site of derivatization, the need to employ additional protecting groups on the ligand donor atoms, the inability to prepare the corresponding Re or ^{99}Tc complexes on the solid support and/or in solution and the need to use HPLC to obtain products of sufficient purity. The ideal SPS strategy should be based on a ligand system that forms stable and/or inert complexes with Tc/Re and, like the HYNIC system reported by Blower et al., is able to be incorporated into a peptide at any position using conventional SPS methods. The SPS strategy should also allow the ligand to be incorporated into the peptide without the need for additional protecting groups and isolation of the bioconjugate should be accomplished without the need for extensive HPLC purification. The Re (or ^{99}Tc) complex of the ligand should be sufficiently stable and well-defined to permit the synthesis of the metal complex of

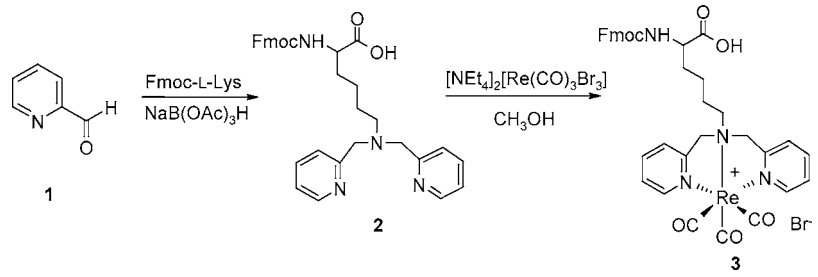
the peptide using the same solid-phase synthetic methodology used to prepare the ligand. At present, Re and ^{99}Tc complexes are often prepared separately for characterization purposes, in vitro screening experiments and to verify the nature of products produced at the tracer level. To consider using combinatorial chemistry and high throughput screening methods as a means of identifying novel radiopharmaceuticals, a viable SPS method should allow for the Re and/or ^{99}Tc peptide complex to be prepared in parallel with the free ligand.

The ability to meet these criteria depends greatly upon the choice of ligand. Zubieta and co-workers recently described the synthesis and structural characterization of a series of Re(I) complexes of tridentate chelates containing two pyridine and one tertiary amine donor groups (*8*). The ligands and their Re(I) complexes, which were prepared in high yield, are stable to a wide range of reaction conditions making them ideal synthons for solid-phase peptide synthesis. With this in mind, an analogous ligand was prepared from Fmoc-lysine, which is herein referred to as a single amino acid chelate (SAAC). The SAAC is a unique Re(I)/Tc(I)-binding amino acid mimic, which has the potential to be incorporated into a peptide at any position using standard automated synthetic protocols. The corresponding Re complex, owing to its stability, inertness, and well-defined structure, should similarly be capable of being incorporated into a peptide using the same basic synthetic procedure. We report herein, the preparation, characterization, and in vitro screening studies of SAAC and Re−SAAC-peptide derivatives prepared using a convenient automated solid-phase synthesis methodology.

EXPERIMENTAL PROCEDURES



Materials. Unless otherwise stated, all reagents and solvents were ACS grade or higher and used without further purification from commercial suppliers. Polystyrene-based *N*-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine loaded SASRIN resin (0.69 mmol g-1, 1% divinylbenzene, 200−400 mesh) was obtained from Bachem Inc. Fmoc-protected amino acids were purchased from NovaBiochem Inc., Bachem Inc., and Advanced ChemTech Inc. Fluorescein-labeled fNLFNTK was purchased from Molecular Probes Inc. (product # F-1314).

Instrumentation. All peptides were prepared on an Advanced ChemTech 348 Ω Peptide Synthesizer using a 40 well reaction vessel. Peptides were analyzed by electrospray mass spectrometry using a Micromass Quattro Ultima instrument in positive ion mode. Samples were dissolved in 50/50 ACN/H_2O prior to analysis. FTIR spectra were acquired on a Bio-Rad FTS-40 FTIR spectrometer. NMR experiments were performed using a Bruker Avance DRX-500 NMR spectrometer. Proton spectra were acquired at 500.13 MHz using a 5-mm broadband inverse probe with triple axis gradient capability. Spectra were obtained in eight scans in 32K data points over a 6.775 kHz spectral width (2.418 s acquisition time). Proton COSY 2-D NMR spectra were recorded in the absolute value mode using the pulse sequence 90°−t1−45°-acq and included pulsed field gradients for coherence selection. During 2-D Fourier transformation a sine-bell squared window function was applied to both dimensions. The transformed data were then symmetrized. Carbon-13 NMR spectra were recorded at 125.771 MHz using the 5 mm broadband inverse probe with triple axis gradient capability. The spectra were acquired over a 28.986 kHz spectral width in 32K data points (0.565 s acquisition time). Inverse detected ^{1}H−^{13}C 2-D chemical shift correlation spectra were acquired in the phase-sensitive mode using the pulsed field gradient version the HSQC pulse sequence. Inverse detected ^{1}H−^{13}C 2-D chemical shift correlation spectra through two- and three-bond coupling interactions were acquired in the absolute value mode using the pulsed field gradient version of the HMBC pulse sequence. ROESY 2-D spectra were acquired in the phase sensitive mode. The data were acquired in 16 scans for each of the 256 FIDs that contained 2K data points in the F2 dimension over a 3.931 kHz spectral width. Zero-filling in the F1 dimension produced a 1K × 1K data matrix with a digital resolution of 3.839 Hz/point in both dimensions. During the real 2-D Fourier transformation, a sine-bell squared window function shifted by $\pi/2$ was applied to both dimensions. The transformed data were not symmetrized. The ROESY 2-D spectrum was plotted displaying negative contours only. Selective 1-D TOCSY ^{1}H NMR spectra were recorded over a 4.006 kHz spectral width in 32K data points (4.089 s acquisition time). Gaussian-shaped pulses were defined by 256 data points with the pulse being truncated at 1% of the maximum pulse amplitude.

Analytical HPLC was performed using a Varian Pro Star model 330 PDA detector, model 230 solvent delivery system and a C-18 Microsorb column (4.6 × 250 mm, 300 Å-5 μm). Semipreparative HPLC was carried out using a Varian Pro Star HPLC fitted with a model 320 UV-detector, a model 215 solvent delivery system and a C-18 Microsorb column (10 × 250 mm, 300 Å-5 μm). The elution protocol for both analytical and semipreparative experiments was a linear gradient of 25% acetonitrile containing 0.1% TFA to 75% acetonitrile containing 0.1% TFA over 15 min. The flow rates were 1.0 mL min^{-1} and 4.2 mL min^{-1} for the analytical and semipreparative experiments, respectively. All analytical HPLC experiments were monitored at $\lambda = 254$ and 214 nm.

Solid-Phase Peptide Synthesis. Fmoc-glycine-loaded SASRIN resin (300 mg, 0.69 mmol/g) was added to two wells of the reaction vessel, suspended in DMF (2 mL/well) and shaken at 900 rpm for 1 min. The wells were subsequently filtered, suspended in THF (2 mL/well), shaken at 900 rpm for 1 min, and drained for 90 s. The THF wash was repeated two more times. The DMF wash was then repeated a final two times to complete the general wash cycle. This procedure was used between every deprotection and coupling step. Fmoc deprotection was brought about through the addition of 25% v/v piperidine−DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 900 rpm. Following filtration, the process was repeated, shaking for 10 min. The deprotected resin-bound amino acid was washed using the general wash procedure and subsequently coupled to the next Fmoc-protected amino acid using a standard HBTU coupling technique. Coupling reactions initially involved adding DMF (200 μL) to the active vessels followed by the addition of a 4-fold excess of the protected amino acid as a 0.5 M solution in DMF. Four equivalents of HBTU as a 0.5 M solution in DMF was then added followed by a 8-fold excess of DIPEA as 2.0 M solution in DMF. The reaction block was subsequently shaken for 80 min at 900 rpm. Following filtration, the resin was washed using the general washing procedure prior to the start of the next cycle. Peptides were cleaved from the resin support using a TFA cocktail containing EDT (2%), water (2%), and TIS (2%). The cleavage cocktail, cooled to 0 °C, was added to the resin and the mixture allowed to warm to room temperature over 60 min. The suspension was filtered into cold diethyl ether and the resulting heterogeneous solution centrifuged at

Scheme 1. Preparation of SAAC (2) and [SAAC−Re(CO)$_3$]$^+$ (3)

3000 rpm and −5 °C for 10 min. The resulting pellet was washed with cold diethyl ether (3 × 25 mL), dissolved in distilled−deionized water, and lyophilized yielding a white solid for both compounds **6** and **8** (Schemes 2 and 3). Compound **6** showed: FT-IR (KBr, cm^{-1}): 1540 (C═O), 1670 (C═O), 2927 (C−H), and 3069 (N−H); ESMS 805 [M + H]$^+$. Compound **8** showed: FT-IR (KBr, cm-^{1}): 1538 (C═O), 1927 and 2032 (C≡O), 2926 (C−H); ESMS 1075 [M + H]$^+$.

Leukocyte Preparation. Whole human blood (10−15 mL) was collected in vacutainer tubes (Becton Dickinson) containing sodium heparin. The red blood cells were lysed using a modified ammonium chloride method (1 part whole blood to 23 parts 0.145 M ammonium chloride solution containing 1.5 mM potassium bicarbonate and 0.1 mM EDTA). Tubes were incubated at room temperature for 15 min and then centrifuged in a Beckman Coulter Allegra 6R centrifuge at 900 rpm (400 g) for 7 min at 5 °C. The supernatant was removed and the pellet of leukocytes subsequently resuspended in HBSS containing 0.1% BSA, 10 mM HEPES, and 1.5 mM $CaCl_2$ (HBSS+). The cells were spun for 7 min at 400*g* at 5 °C, the supernatant removed, and the pellet resuspended in HBSS+. Cell counts were performed using a hemacytometer and a Beckman Coulter Z2 Coulter Particle Count and Size Analyzer. Cell concentrations were adjusted to 2 × 10^6 mL^{-1}.

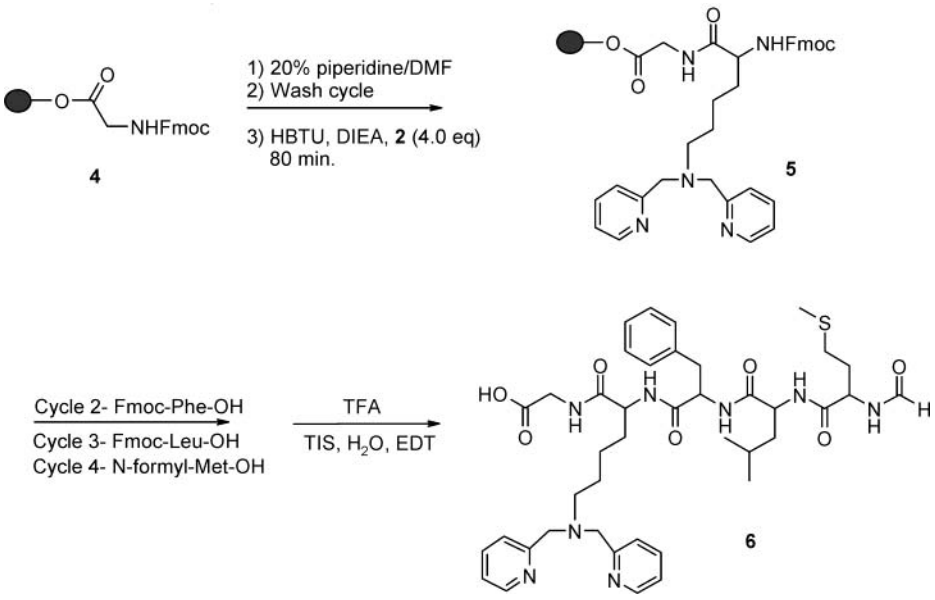
Flow Cytometry. Samples were run on a Beckman Coulter EPICS XL, equipped with an argon laser (488 nm excitation wavelength). Fluorescence was measured using a 525 ± 15 nm band-pass filter. The flow cytometer was calibrated with fluorescein isothiocyanate (FITC)-labeled beads (Quantum 26 Beads, Bangs Laboratories, Inc, Fishers, IN) prior to sample analysis. The fluorescence intensity of the standard was provided by the manufacturer in units of Molecules of Equivalent Soluble Fluorochrome (MESF) and ranged from 5300 to 468 800. A linear fit of MESF versus mean channel number of the beads was used to convert all subsequent mean channel values to MESF values.

Equilibrium Binding Assay. The equilibrium-binding assay was used to determine the number of formyl peptide receptors (FPRs) on the surface of the neutrophils and the dissociation constant (K_d) of the fluorescein-labeled fNLFNTK (Molecular Probes) (1.0 nM) by preparing a saturated binding curve of peptide concentrations verses fluorescence intensity. Peptide stock solutions were made by dissolving the peptide derivatives **6** and **8** in DMSO and then diluting with HBSS+ to the desired concentrations, ensuring the concentration of DMSO was less than 0.1%. Cells at 1 × 10^6 mL^{-1} were equilibrated with 0.25, 0.50. 1.0, 3.0, 5.0, 10.0, and 20.0 nM solutions of the peptide derivatives (U) in duplicate. The samples were incubated for 2 h at 0 °C in the dark and then run on the flow cytometer. Neutrophils were gated on the basis of forward and side scatter parameters using Expo 32 ADC software (Beckman Coulter). All samples were repeated in the presence of 30 μM fMLF to account for nonspecific binding. The number of receptor−ligand complexes per cell (*B*) was determined using the following equation, where *Q* is a normalization factor used by Waller et al. (*14*) and *F* is the total fluorescence per cell:

$$B(\text{in ligand bound per cell}) = F\left(\frac{\text{MESF}}{\text{cell}}\right) \times Q$$

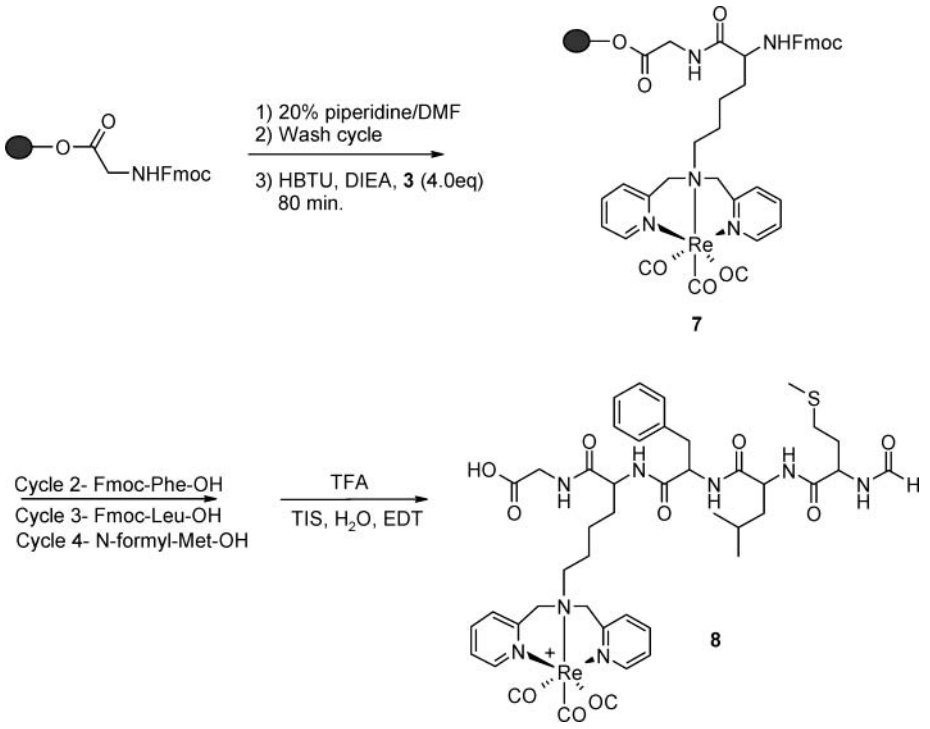
The level of nonspecific binding did not vary significantly with concentration of labeled peptide, thus an average value of nonspecific binding was subtracted from the total fluorescence per cell, *F*, when determining the number of receptor−ligand complexes. The total number of *N*-formyl peptide receptors, R_{tot}, and the equilibrium dissociation constant, K_d, were evaluated by minimizing the squared residual of the equilibrium solution using a one-site binding model (see the following equation). The values of R_{tot} and K_d for each donor were solved simultaneously.

$$[\text{LR}] = \frac{R_{tot}[\text{L}]}{[\text{L}] + K_d}$$



RESULTS

SAAC Synthesis. The synthesis of the Fmoc-protected single amino acid chelate **2** (Scheme 1) will be described elsewhere (*9*). Briefly, Fmoc-L-lysine was reacted with 2-pyridinecarboxaldehyde **1** in the presence of sodium triacetoxyborohydride. The resulting product was isolated in good yield and there was no epimerization of the lysine α proton. The Re complex was prepared in quantitative yield by adding a stoichiometric amount of [NEt$_4$]$_2$[Re(CO)$_3$Br$_3$] in methanol to compound **2**. Using these methods it is possible to produce multigram quantities of the amino acid analogue and its Re complex.



Peptide Synthesis and Characterization. Peptides were prepared on an Advanced ChemTech 348 Ω Peptide Synthesizer using HBTU as the coupling agent (Schemes 2 and 3) (*10*−*12*). The Fmoc protected dipyridyl chelate **2** and its Re complex **3**, as the bromide salt, were dissolved in DMF and coupled to the growing peptide chain using a 4-fold excess of ligand. The duration of the coupling steps to afford complete conversion to compounds **5** and **7** were determined by exposing samples of resin taken from the reaction mixtures to a solution containing ninhydrin (*13*). The time to complete conversion of the amine to the amide in both cases was identical to the conditions used for natural amino acid derivatives. As a result, modification of standard peptide coupling protocols was not necessary.

Peptides were cleaved from the resin using a TFA solution containing ethanedithiol (EDT, 2%), water (2%), and triisopropylsilane (TIS, 2%). Because of the presence of methionine, exclusion of oxygen and the use of freshly

Scheme 2. Solid-Phase Synthesis of fMLF(SAAC)G, 6

Scheme 3. Solid-Phase Synthesis of fMLF[(SAAC−Re(CO)$_3$)$^+$]G, 8

distilled EDT were necessary to avoid oxidation of the thioether to the sulfoxide. Precipitation of the peptide TFA salts was brought about by trituration with cold ether. The resulting solids were collected by centrifugation and washed with cold ether. Following dissolution in distilled water and lyophilization, compounds **6** and **8** were collected as white solids.

LCMS analysis of the crude peptide **6** showed two peaks in a 3:1 ratio. Both peaks exhibit the same *m*/*z* value (805), which corresponds to the mass of the protonated form of the desired peptide. The two components were readily separated by semipreparative HPLC and the analytical trace of the major product is shown in Figure 1a.

HPLC analysis of the crude Re complex **8** similarly showed two peaks possessing the same *m*/*z* value in the electrospray mass spectrum. Semipreparative HPLC again enabled isolation of the major product (Figure 1b), which was a colorless solid. IR analysis of **8** exhibited two distinct metal−CO stretches (1927 and 2032 cm^{-1}) which is consistent with the proposed geometry of the metal complex and similar to the values reported for the Re complex **3**.

NMR Characterization of fMLF(SAAC)G and fMLF[(SAAC−Re(CO)$_3$)$^+$]G. The ^{1}H NMR of HPLC purified **6** was run in 50/50 CF_3CO_2D−CD_3CN at 500 MHz. The spectrum (Figure 2a) shows a downfield singlet at 8.22 pm which is consistent with the presence of the formamide proton. A series of multiplets in the aromatic region were apparent, arising from the protons on the pyridine rings and the phenylalanine aryl group. The α protons of the amino acids, which appear between 4 and 5 ppm, and the side chain residues were readily assigned through the use of COSY and selective TOCSY experi-

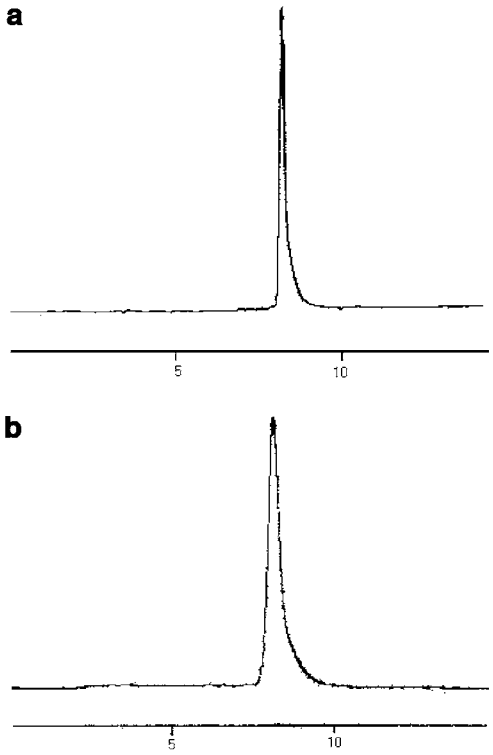


Figure 1. (a) Analytical HPLC of fMLF(SAAC)G, **6**. (b) Analytical HPLC of fMLF[(SAAC−$Re(CO)_3)^+$]G, **8**.

ments (Table 1). The α proton of the dipyridyl chelate appears at 4.37 ppm.

A comparison of the ^{1}H NMR of the Re complex (Figure 2b) with that for compound **6** shows that only the protons associated with the SAAC chelate are influenced by the presence of the Re(I) core. H-23, H-24, H-25, and H-26 shifted downfield with the latter proton moving more than one ppm (Table 1). The protons on the pyridine rings were readily assignable and shifted on average by 0.6 ppm compared to **6** with the exception of H-32 whose chemical shift, somewhat surprisingly, remained unchanged.

The ^{13}C NMR of **6** exhibited the expected number of carbonyl peaks (six) with the formamide carbon appearing at 166.1 ppm. There were numerous signals in the aromatic region corresponding to the pyridine groups and the aryl group of phenylalanine. The remainder of the peptide backbone was assigned using HSQC and HMBC spectra (Table 2).

The ^{13}C NMR of **8** showed two additional peaks downfield at 196.2 and 196.9 ppm arising from the metal−CO ligands. Two peaks are expected given the local symmetry of the complex. The remaining carbonyl groups, which are associated with the amide and acid groups of the peptide backbone, showed no major changes from that for compound **6**. Only the carbon atoms in close proximity to the Re center exhibited significant shifts. C-26 and C-27, for example, were shifted downfield to a similar degree. The carbon atoms on the pyridine groups, not surprisingly, also exhibited significant changes in chemical shift. C-30/36 shifted upfield as did C-29/35 while C-28/34 moved downfield from 154.1 to 161.3 ppm.

In Vitro Screening Studies Using Flow Cytometry. Peptides **6** and **8** were screened on a flow cytometer using a competitive binding assay (*14*−*16*) where the concentration of the competitor was allowed to vary while maintaining the concentration of the fluorescent peptide. Competitive binding data was obtained on the same day using the same blood donor as for the equilibrium binding data, to minimize variability in the number of receptors. Cells at 10^6 mL^{-1} were incubated with 1.0 nM fluorescent peptide (L) and 0.25, 0.5, 1.0, 3.0, 5.0, 10.0, and 15.0 nM competitor (U) in duplicate for 2 h at 0 °C in the dark. Flow cytometry was used to quantify the fluorescence per cell after the incubation. Neutrophils were gated on the basis of forward and side scatter parameters using Expo 32 ADC software (Beckman Coulter). The average value for nonspecific binding, obtained from the equilibrium-

binding assay, was subtracted from the total fluorescence per cell when determining the ligand bound per cell. The equilibrium dissociation constant for the competing unlabeled ligand, K_d, was determined following literature procedures by fitting the specific ligand bound data to the same one-site binding model. The peptide, fMLF was used as a reference standard. Its K_d value was in good agreement with the value reported in the literature (*15*). The K_d values for fMLF and compounds **6** and **8** are given in Table 3.

DISCUSSION

To probe the utility of the single amino acid chelate (SAAC) system, derivatives of the well-studied fMLF peptide were prepared on a commercial automated peptide synthesizer. The fMLF sequence has been used to target a range of different radionuclides, including ^{99m}Tc and ^{111}In, to formyl peptide receptors (FPR) found on the surface of neutrophils as a means of imaging sites of infection and inflammation (*17*−*26*). The traditional approach to preparing these compounds has been to prepare fMLF or fMLFK sequences and to then append, in solution, a Tc ligand to the C-terminus or lysine ϵ-amine groups, respectively. In this study, the SAAC was specifically placed between a terminal glycine amino acid and the fMLF targeting sequence.

The Fmoc-dipyridyl chelate **2** and the Re complex **3** were readily incorporated into the growing peptide linked

to a SASRIN resin, using standard peptide synthesis protocols. Two products were produced in each synthesis. ^{1}H NMR showed that the minor byproducts were the result of epimeriation of the methionine α protons. To determine if the epimerization was caused by the dipyridyl ligand, the peptide was prepared using N-α-Fmoc-N-ϵ-Boc-lysine in place of compounds **2** and **3**. ^{1}H NMR again showed two sets of signals associated with the protons in the methionine backbone. Formation of the second isomer is therefore not related to the incorporation of the ligand or its Re complex but due to the ease with which *N*-formyl amino acid derivatives epimerize (*27*). When the synthesis was repeated using Fmoc-methionine in place of the *N*-formyl derivative, only one product, MLF(SAAC)G, was produced.

As the epimerization issue described previously clearly demonstrates, LCMS studies alone are not always sufficient for characterizing peptide-targeted radiopharmaceuticals. Consequently multi-NMR spectroscopy was used to fully characterize compounds **6** and **8** and to investigate the impact of Re coordination on the structure of the peptide. The ^{1}H and ^{13}C spectra of the peptide−ligand and corresponding Re complex were readily assigned using standard 2-D and selective TOCSY NMR experiments. A comparison of the ^{1}H and ^{13}C spectra for compounds **6** and **8** revealed that metal coordination does not alter the structure of the peptide backbone. The only resonances to undergo significant changes are directly associated with the SAAC. These observations suggest that radiolabeling of **6** will not cause significant structural changes. This hypothesis is supported by the in vitro studies, which showed that compound **6** and **8** have similar affinities for the FPR receptor.

Traditional radioligand displacement methods, which are not particularly suited for evaluating libraries of compounds, are typically used to screen fMLF conjugates. In this study, flow cytometric studies were undertaken as a means of evaluating ligand−receptor interactions. The advantages of using flow cytometry over traditional screening methods are that studies can be performed in real time on single cells (*14*). Flow cytometry also affords the opportunity to look at the binding of ligands to specific subpopulations. The screening studies reported here show that compounds **6** and **8** bind to granulocytes with affinities that are greater than the parent fMLF peptide, which was used as a reference standard. In light of the K_d values, compound **6** is a promising agent for targeting ^{99m}Tc to FPR receptors. Biodistribution studies in animal models of infection are currently underway.

Despite the unavoidable epimerization issue, in a single synthesis run, sufficient quantities of compounds **6** and **8** were produced to carryout characterization studies, including detailed NMR experiments, and in vitro screening studies in parallel. The chelate **2** and its Re complex behaved as typical Fmoc-amino acids and can therefore be incorporated regioselectively into any peptide using commercial peptide synthesizers. The SAAC chelate did not require any additional protecting groups beyond the N-α-Fmoc group, and its metal complex was stable to the conditions used to prepare the peptide and cleave it from the support. The ability to prepare macroscopic quantities of the metal complex, which exists as a single isomer, offers a tremendous advantage over other more commonly employed Tc ligand systems such as HYNIC where purification and detailed characterization of the ^{99}Tc and Re complexes are habitually problematic.

The commercial viability of the [Tc(CO)$_3$]$^+$ core as a synthon for the preparation of radiopharmaceuticals has been queried recently (*28*). Despite the numerous benefits of working with Tc(I), which have been elegantly summarized by Alberto (*29*) and highlighted throughout this paper, intellectual property issues and the increasing clinical use of PET in the United States have brought into question as to whether a clinically useful agent based on the Tc-carbonyl motif will ever be realized.

The current widespread use of technetium in nuclear medicine is not driven solely by the advantages of working with ^{99m}Tc, but by the clinical usefulness of ^{99m}Tc radiopharmaceuticals. The discovery of new imaging agents will determine the future role of ^{99m}Tc in diagnostic nuclear medicine, as is the case for all radionuclides, which places considerable importance on developing new methods that can improve the efficiency of the radiopharmaceutical discovery process. It should also be noted that the opportunity to prepare complementary (i.e. isostructural) Re radiotherapy agents based on ^{186}Re and ^{188}Re will further enhance the future demand for new Tc radiopharmaceuticals.

To develop new Tc and Re radiopharmaceuticals in a reasonable time frame and in a cost-effective manner, researchers must shift to more contemporary drug discovery techniques, like the strategy reported here. Because the Tc(I) and Re(I) core is highly versatile and much more amenable to modern drug discovery techniques than existing Tc/Re (or other radiometal) synthons, commercial matters aside, there is a high prob-

ability that clinically viable diagnostic and/or therapeutic agent based on the Tc(I) or Re(I) carbonyl cores will be discovered.

CONCLUSIONS

The single amino acid chelate used in this study affords the opportunity to incorporate a Tc(I)/Re(I) binding ligand into peptides using standard solid-phase synthesis methods. The derivatization strategy is flexible in that it allows for the chelate to be incorporated at any position in the peptide as an additional amino acid or in place of an existing amino acid that is not involved in receptor binding. In the present study, novel derivatives of a simple chemotactic peptide were prepared and screened using flow cytometry. The use of flow cytometry as a screening strategy creates the opportunity to rapidly identify compounds that are capable of selectively targeting specific types of granulocytes. The focus of our current efforts is to build upon the reported synthesis and screening methods to develop and screen combinatorial libraries of compounds that are capable of targeting specific cell populations that accumulate at sites of infection and inflammation.

ACKNOWLEDGMENT

We thank The Canadian Foundation for Innovation (CFI) and The Ontario Innovation Trust (OIT) and McMaster University for providing the infrastructure used in this project and NSERC of Canada for a scholarship for K.A.S..

Synthesis, Characterization, and Evaluation of Ferrocene−Theophylline Conjugates for Use in Electrochemical Enzyme Immunoassay

Nigel J. Forrow,* Nicola C. Foulds, Jane E. Frew, and John T. Law

MediSense (UK) Ltd., Abbott Laboratories, 14/15 Eyston Way, Abingdon, Oxon OX14 1TR, UK. Received July 22, 2003; Revised Manuscript Received October 20, 2003

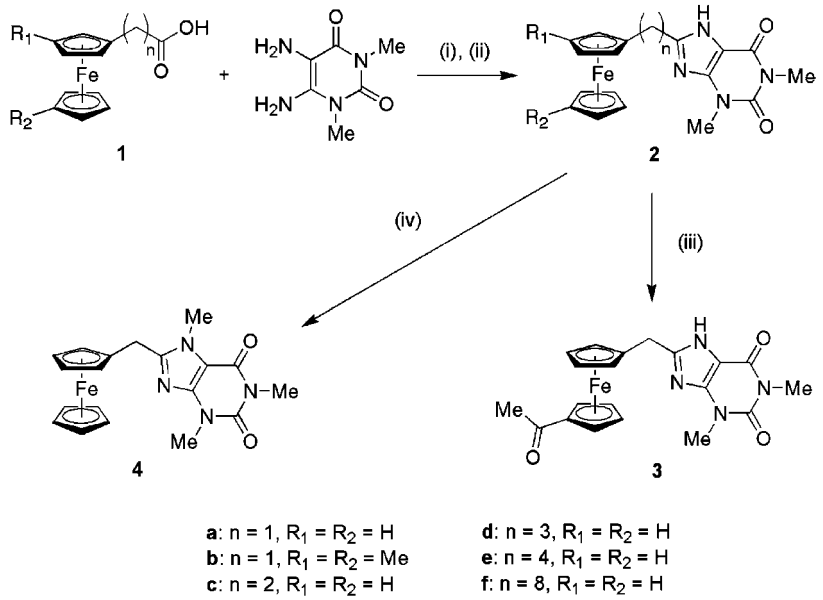
A series of 8-(ferrocenylalkyl)theophylline conjugates were synthesized for evaluation in a homogeneous, competitive electrochemical immunoassay for theophylline with amperometric detection of the ferrocene label at +320 mV. The electrical signal was amplified via redox cycling with the glucose oxidase/glucose system. The resulting catalytic current was strongly inhibited upon binding of the conjugates to anti-theophylline antibodies such that a large excess of theophylline was required to achieve complete reversal leading to an assay with poor sensitivity in the clinical range. A study of the nonspecific interaction of the antibodies with various ferrocene derivatives indicated that this was reduced when a charged functional group was present on the metallocene ring. Consequently, a conjugate was synthesized with a quaternary ammonium group which when incorporated into the assay resulted in improved sensitivity.

INTRODUCTION

Many different types of immunoassays have been developed that avoid the use of radioisotopic labels with their associated problems of short shelf life, disposal, and safety. Fluorescent and chemiluminescent markers along with enzymes have received the most attention as alternative labels for nonisotopic assay systems (*1*). The use of metal complexes as probes was first reported by Cais et al. who described the principle of metalloimmunoassay (MIA) in which, for example, steroid antigens were labeled with ferrocene with detection by flameless atomic absorption spectroscopy (*2*). Recently, this type of immunoassay has been expanded to include the use of metal carbonyl labels which can be detected by Fourier transform infrared spectroscopy (FT-IR). The term carbonylmetalloimmunoassay (CMIA) has been suggested for this class of assay (*3, 4*). Metal complexes, in particular ferrocene, are also of interest for use as electrochemical tracers in immunoassays. Here, the wide variety of substituted derivatives of ferrocene makes it an attractive label for conjugation to antigens. The relative ease of synthesis of ferrocene-labeled molecules, coupled with reversible electrochemistry and the ability to alter redox potential if desired, has led to ferrocene being the first choice for use in electrochemical sensing systems. Thus, ferrocene has also found widespread use as an electrochemical label for oligonucleotides (*5*−*9*) in DNA probes and for host molecules (*10*, *11*) in the detection of neutral and charged guest species. Also, ferrocene−peptide conjugates have been suggested to be useful in electrochemical sensors for the detection of proteins (*12*, *13*).

The use of electrochemical detection offers the possibility of cheap, miniature devices capable of performing rapid assays in cloudy test samples. For example, commercial biosensor devices such as the hand-held MediSense Precision QID glucose meter incorporate a ferrocene derivative in a mass-produced enzyme electrode for use by diabetics to determine their sugar levels in whole blood (*14*).

The potential of ferrocene as an electrochemical label in immunoassays was first explored by Weber and Purdy (*15*) who prepared a ferrocene−morphine conjugate and demonstrated that its electrochemistry was perturbed on binding to the antibody so that a homogeneous competitive assay could, in principle, be configured in which separation of free and antibody-bound label was unnecessary. This procedure has been enhanced using enzyme amplification by exploiting the known (*16*, *17*) ability of ferrocene derivatives to act as electron-transfer mediators to glucose oxidase (GOx). An amperometric immunoassay for lidocaine has been configured using this approach (*18*). Also, brief reports have appeared in a patent application (*19*) and a book (*20*) describing its use for an electrochemical theophylline assay. Here, a detailed report of the synthesis and characterization of some ferrocene−theophylline conjugates and the problems associated with configuring an immunoassay based on them are described.



RESULTS AND DISCUSSION

Synthesis of 8-(Ferrocenylalkyl)theophylline Conjugates. 8-Phenyl and 8-benzyl derivatives of theophylline have been previously prepared by condensation of 5,6-diamino-1,3-dimethyluracil with the respective carboxylic acids in refluxing $POCl_3$ followed by cyclization with NaOH (*21*). The preparation of 8-(ferrocenylmethyl)-theophylline **2a** from ferrocenylacetic acid **1a** using an adaptation of this method has been briefly reported (*19*, *20*). A high boiling solvent, *N*,*N*-dimethylaniline (DMA), is used in place of $POCl_3$. The Experimental Procedures section of this article provides a detailed description of the reaction conditions for the synthesis of **2a** and further applies them to the preparation of a series of ferrocene−theophylline conjugates **2b**−**f** from the corresponding

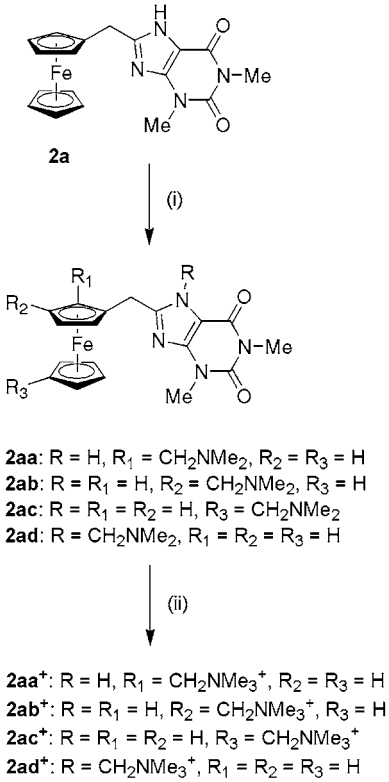
Scheme 1. Synthesis of Ferrocene−Theophylline Conjugates[a]

[a] (i) Δ, DMA; (ii) NaOH; (iii) **2a**, Ac_2O, $AlCl_3$, CH_2Cl_2; (iv) **2a**, MeI, Na_2CO_3, DMF.

ferrocene carboxylic acids **1b**−**f** (Scheme 1). No identifiable conjugate was produced from the reaction of ferrocene carboxylic acid **1** ($n = 0$, $R_1 = R_2 = H$) or ferrocene dicarboxylic acid with 5,6-diamino-1,3-dimethyluracil.



The synthesis of substituted ferrocene−theophylline conjugates was of interest for a number of reasons. In the first instance, the introduction of electron-donating substituents such as methyl groups into the ferrocene cyclopentadienyl rings will alter the redox potential of the conjugate such that a lower operating potential is required in an electrochemical assay. This is advantageous for test media, such as blood or plasma, which may contain oxidizable species. Here, the dimethyl-substituted conjugate **2b** can be synthesized from the readily available (1,1′-dimethylferrocenyl)acetic acid **1b**. However, apart from **1b**, substituted ferrocene carboxylic acids are not easily accessible for use as starting materials in the synthesis of ferrocene−theophylline conjugates.

Direct substitution of a ferrocene ring in a conjugate was explored for the introduction of electron-donating substituents. Here, functional groups of this type were attractive for modifying the hydrophobic nature of the ferrocene−theophylline conjugates. For example, the conjugates **2a**−**f** were almost completely insoluble in aqueous buffer solutions. As such, a carboxylate or amino substituent might be effective in enhancing the aqueous solubility of the conjugates as well as modulating the strength of their binding with anti-theophylline antibodies.

The Friedel−Crafts acetylation of conjugate **2a** proceeded remarkably cleanly to afford the acetyl derivative **3** in moderate yield (Scheme 1). Acetylation was observed to occur only in the unsubstituted ferrocene ring. It was hoped that the acetyl group could be further elaborated into a carboxylate group. However, known procedures for effecting this transformation in acetylated ferrocene derivatives using $NaOH/Br_2$ (*22*) or I_2/pyridine then NaOH (*23*) failed for the conjugate **3**.

The Mannich reaction was considered to be a possible direct route to a tertiary amino derivative of conjugate **2a** which could then be converted simply to a hydrophilic quaternary ammonium compound by alkylation. It appeared feasible that alkylation could be confined to the tertiary amine group since reaction at N-7 of theophylline required the additional use of base to obtain the caffeine conjugate **4** from the corresponding theophylline compound **2a** (Scheme 1). However, we were aware that aminomethylation of **2a** could result in reaction at three different ferrocene ring positions [cf. methylferrocene (*24*)] to yield the isomers **2aa**, **2ab**, **2ac** and also at the N-7 position of theophylline (*25*) to give **2ad** (Scheme 2).

[a] (i) Δ, $(Me_2N)_2CH_2$, H_3PO_4, AcOH; (ii) MeI, MeOH.

Initially, we successfully repeated the known (*25*) Mannich reaction of theophylline itself using Et_2NH/HCHO to yield the unstable 7-(diethylaminomethyl)-

theophylline **5** which displayed a signal at δ 5.2 for the N-7 methylene group in the ^{1}H NMR spectrum. No reac-

5: R = Et
6: R = Me

tion was observed when we applied the exact same reaction conditions to the ferrocene–theophylline conjugate **2a**. This result was encouraging in that it seemed that the ferrocenylmethyl substituent in the 8-position of theophylline had the effect of reducing the acidity of the N-7 hydrogen of **2a** such that it might be possible to restrict aminomethylation to the ferrocene rings of the conjugate. Next, we carried out an aminomethylation reaction on **2a** with the reagents used for methylferrocene (*24*) and ferrocene (*26*), i.e., bis(dimethylamino)methane in the presence of phosphoric acid as a catalyst with glacial acetic acid as the solvent. A brown, water-soluble, oily product was obtained in low yield. The ^{1}H NMR spectrum demonstrated that substitution had occurred at ferrocene to yield **2aa**/**2ab**/**2ac** rather than at theophylline since the expected signal at approximately δ 5 for the N-7 aminomethylene group of **2ad** was not observed. Further examination of the spectrum indicated that only two ferrocene ring isomers were present. These are presumed to be **2aa** and **2ab** by analogy with the isomer distribution seen for aminomethylated methylferrocene (*24*). Latterly, we did note that it was also possible to effect N-7 aminomethylation of theophylline using bis(dimethylamino)methane to afford 7-(dimethylaminomethyl)theophylline **6**. Here, compound **6** displayed a methylene signal at δ 5.1 in the ^{1}H NMR spectrum.

Methylation of **2aa**/**2ab** with MeI proceeds readily at NMe_2 to afford the quaternary ammonium salt **2aa**$^+$/**2ab**$^+$ (Scheme 2) as expected from standard ferrocene chemistry (*24*, *26*). Further support for ferrocene ring substitution was indicated by the apparent stability of **2aa**$^+$/**2ab**$^+$. Thus, attempts to form the quaternary ammonium salt of 7-(dimethylaminomethyl)theophylline **6** resulted only in the isolation of theophylline. No such decomposition to the starting conjugate was observed during the quaternization of the aminomethylated products of conjugate **2a**. Also, it was noted earlier in this article that N-7 methylation of the theophylline unit with MeI to produce a caffeine derivative does not occur in the absence of base.

Despite poor yields and limited characterization data, the water soluble salt **2aa**$^+$/**2ab**$^+$ was nonetheless included in further studies as the only example of a hydrophilic ferrocene–theophylline conjugate. The structural assignments for **2aa**$^+$/**2ab**$^+$ and **2aa**/**2ab** were considered to be sound based on a combination of ^{1}H NMR data and comparative reactions carried out on theophylline itself for the purpose of eliminating N-7 in favor of ferrocene ring substitution.

Electrochemistry of Ferrocene–Theophylline Conjugates. The conjugates **2a**–**f** are practically insoluble in aqueous buffer solution. Polyoxyethylene 9-lauryl ether (5%) was therefore employed to enhance the solubility of **2a**–**f** such that their aqueous electrochemistry could be easily studied by cyclic voltammetry. In contrast, the aminomethylated methiodide conjugate

Table 1. Electrochemical Data for Ferrocene–Theophylline Conjugates

conjugate[a]	no.	$E_{1/2}$, mV[b]

[a] Fc = ferrocene, Me_2Fc = 1,1′-dimethylferrocene, Theo = theophylline, Caff = caffeine. [b] Unless otherwise stated, electrochemical data was obtained in 0.15 M phosphate/0.2 M NaCl buffer (pH 7.0), containing 5% polyoxyethylene 9-lauryl ether. [c] 0.1 M BES/0.15 M NaCl (pH 7.0), containing 1% THF. [d] 0.15 M phosphate/0.2 M NaCl buffer (pH 7.0), no polyoxyethylene 9-lauryl ether.

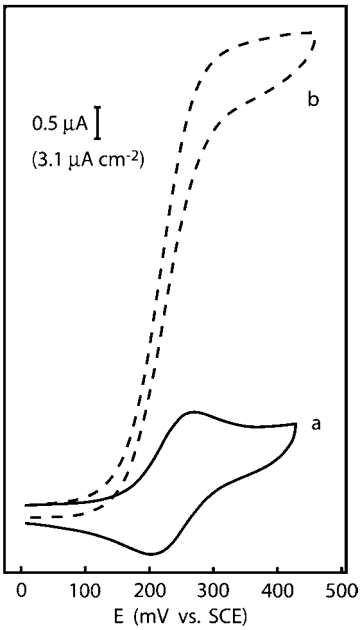

Figure 1. (a) Cyclic voltammogram (at 5 mV s^{-1}) of **2a** (0.25 mM) in a 0.6 mL of 0.15 M phosphate/0.2 M NaCl buffer (pH 7.0), containing 5% polyoxyethylene 9-lauryl ether, at a gold electrode (area 0.16 cm^2); (b) as for a but with the addition of 100 μL of stock glucose oxidase solution at a final concentration of 2.1 μM.

2aa$^+$/**2ab**$^+$ is water soluble. Reversible redox waves due to the ferrocene/ferrocenium couple with midpoint potentials $E_{1/2}$ in the range +135 to +265 mV were recorded for **2a**–**f** and **2aa**$^+$/**2ab**$^+$ (Table 1). In addition, conjugate **2aa**$^+$/**2ab**$^+$ displayed a broad wave in the range +500 to +600 mV due to the oxidation of iodide. This provides further support for the assignment of **2aa**$^+$/**2ab**$^+$ as a methiodide salt. A typical cyclic voltammogram for a ferrocene–theophylline conjugate is displayed in Figure 1a.

As expected from previous work (*17*) on the aqueous electrochemistry of ferrocene derivatives, the dimethyl-substituted conjugate **2b** was observed to have an $E_{1/2}$ value 100 mV lower than the corresponding unsubstituted compound **2a**. There was no clear trend in $E_{1/2}$ value on increasing the number of methylene groups in the ferrocene–theophylline linker from one in **2a** to eight in **2f**. Here, $E_{1/2}$ varied over a narrow range of +205 to +235 mV. The $E_{1/2}$ value for the caffeine conjugate **4** is 30 mV higher than the corresponding to theophylline compound **2a**. The use of 1% THF in place of 5%

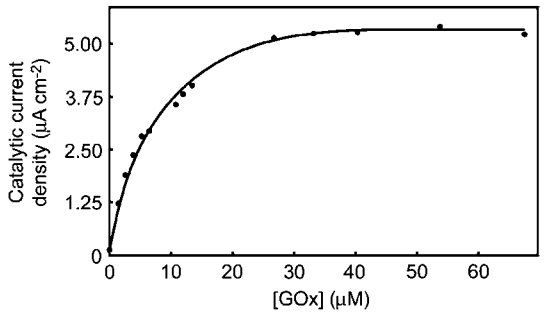

Figure 2. Variation of the catalytic current with glucose oxidase concentration as measured by chronoamperometry. Different amounts of enzyme were added to conjugate **2a** (2 μM) in a cell containing glucose (0.1 M) in BES buffer.

polyoxyethylene 9-lauryl ether did not result in a large shift in the $E_{1/2}$ value for the conjugate **2a**.

Redox mediation of Ferrocene−Theophylline Conjugates with Glucose Oxidase. An enhanced catalytic wave was observed during cyclic voltammetry of the conjugates **2a**−**f** in the presence of glucose oxidase and a nonlimiting excess amount (0.1 M) of glucose substrate. Figure 1b displays a typical voltammogram for **2a** recorded under these conditions. Here, the oxidized ferrocenium form of the conjugate mediated the transfer of electrons from reduced glucose oxidase, produced during oxidation of glucose by the enzyme, to the electrode. This is basis of the signal generation in the proposed immunosensor.

Chronoamperometry is an appropriate electrochemical technique for the exploitation of this signal generation mechanism. A fixed potential ($> E_{1/2}$) was applied to an electrode such that the ferrocenium form of the conjugate was initially generated and then recycled upon reduction by reduced glucose oxidase thereby amplifying the signal. A poise potential of +320 mV was found to be suitable in this respect for the conjugates **2a**−**f**. Each of the compounds **2a**−**f** yielded similar maximum catalytic currents in the region of 0.8 μA (5.0 μA cm^{-2}) for 2 μM solutions in the presence of 0.1 M glucose and a minimum of 35 μM of glucose oxidase (Figure 2).

Inhibition of Conjugate Catalytic Current in the Presence of Antiserum. The redox mediation reaction of conjugates **2a**−**f** with glucose oxidase was inhibited by the anti-theophylline antiserum. For example, this is clearly demonstrated for **2a** in Figure 3a, which was obtained by incubating a fixed amount of conjugate (2 μM) with increasing quantities of undiluted antiserum followed by performing chronoamperometry on the mixture in the presence of glucose oxidase and glucose to determine the catalytic current. Here, it is presumed that the conjugate binds to the antibody and is thereby prevented from interacting with the flavin cofactor inside the active site of glucose oxidase due to the large size of the conjugate−antibody complex. This effect has been reported previously for a ferrocene−lidocaine conjugate in the presence of anti-lidocaine antiserum (*18*). Furthermore, a clear analogy can be drawn with cyclodextrin inclusion complexes of ferrocene derivatives, which are also known not to mediate with glucose oxidase (*27*).

Partial reversal of the inhibition of the catalytic current was achieved upon addition of theophylline to the mixture of conjugate, antiserum, glucose, and glucose oxidase. This is illustrated in Figures 3b and 3c for **2a** for different amounts of theophylline. Here, theophylline competed with the ferrocene−theophylline conjugates

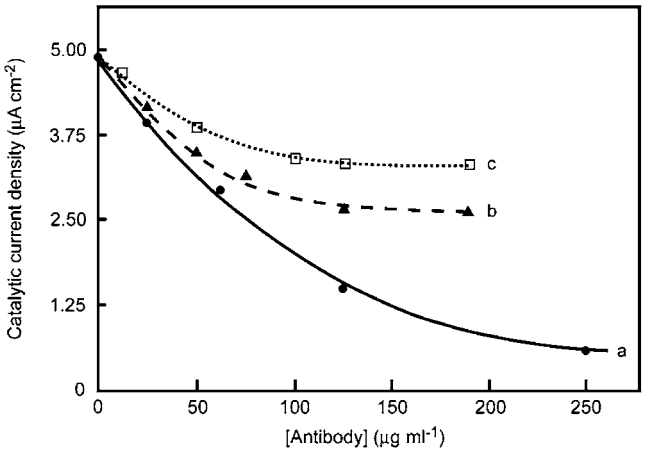

Figure 3. (a) Inhibition of the catalytic current on addition of varying volumes of undiluted anti-theophylline antisera to conjugate **2a** (2 μM) in the presence of glucose (0.1 M) and glucose oxidase (35 μM); (b) as for a but with the addition of theophylline at a final concentration of 25 μM; (c) as for a but with the addition of theophylline at a final concentration of 50 μM.

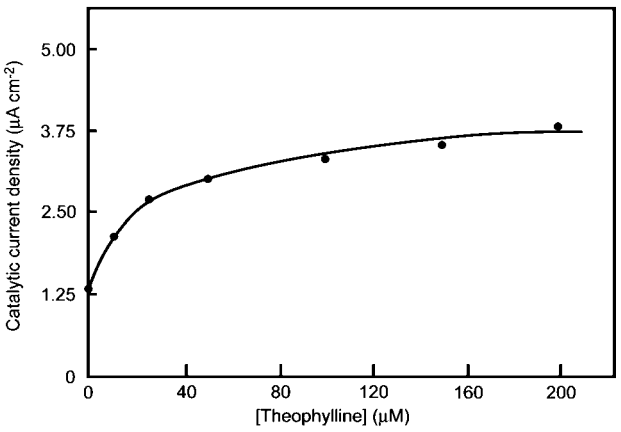

Figure 4. Theophylline calibration curve for electrochemical immunoassay mediated by conjugate **2a** and using an antibody concentration of 125 μg mL^{-1}.

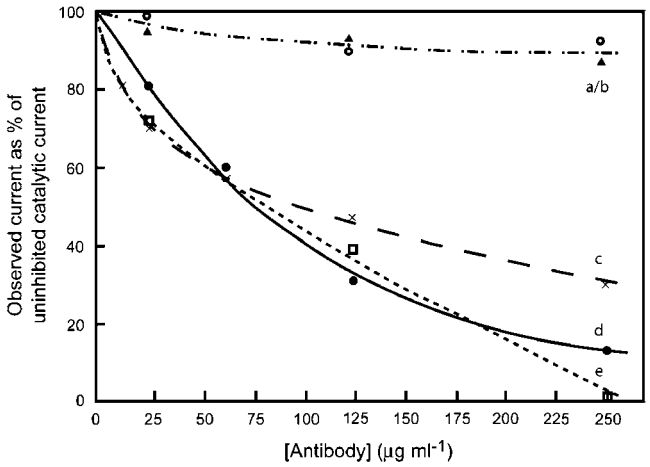
2a−**f** for binding with the antibodies thereby releasing more electroactive label for redox mediation with glucose oxidase. The antibody interaction with the conjugates could not be reversed completely even in the presence of a large excess of theophylline. In this respect, **2a** appeared to be the least antigenic and therefore further work was confined to this particular conjugate. Figure 4 displays a calibration curve for theophylline using **2a**; this spans the therapeutic range for theophylline of 55−100 μM. However, the assay has a low sensitivity in the clinical range due to the poor reversibility of the binding of **2a** with the antibodies.

The Influence of Antiserum on the Redox Mediation of Ferrocene Derivatives with Glucose Oxidase. It appeared unlikely that the ferrocene−theophylline conjugates were more antigenic toward the antiserum than theophylline itself. The nature of the interaction of ferrocene with proteins is unknown but other authors (*13*) have also commented on its strength. In the present system, a possible explanation might be that the hydrophobic nature of the ferrocene group in **2a** leads to nonspecific interactions with the antibody. In this respect, we decided to investigate the influence of anti-theophylline antibodies on the redox mediation of charged



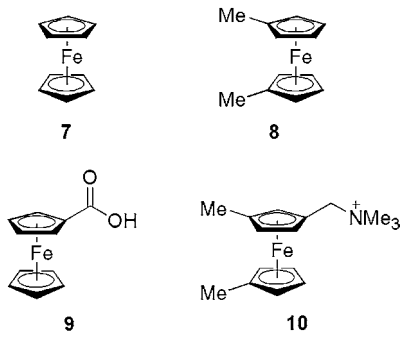


Figure 5. Inhibition of the catalytic current on addition of varying volumes of undiluted anti-theophylline antisera to various ferrocene derivatives (2 μM) in the presence of glucose (0.1 M) and glucose oxidase (35 μM): (a/b) ferrocene carboxylic acid **9** (▲) and dimethylaminomethyl-1,1′-dimethylferrocene methiodide **10** (○); (c) ferrocene **7** (×); (d) conjugate **2a** (●) (for comparison); (e) 1,1′-dimethylferrocene **8** (□).

and uncharged ferrocenes **7**, **8**, **9**, and **10** with glucose oxidase in comparison with the conjugate **2a**.

In a fashion similar to the conjugates **2a**−**f**, the ability of the uncharged ferrocenes **7** and **8** to mediate with glucose oxidase was markedly inhibited in the presence of antiserum (Figures 5c and 5e). Even the addition of an excess (100 μM) of theophylline had no significant effect upon the observed decrease in catalytic current. In contrast, the charged ferrocene derivatives **9** and **10** displayed no such inhibition (Figure 5a/b). These results support the hypothesis that nonspecific hydrophobic interactions between the ferrocene moiety of conjugates **2a**−**f** and the antibody contribute to the observed inhibition.

Attempts to Reduce Nonspecific Interactions in the Assay System. In light of the above results, the charged conjugate **2aa**$^+$/**2ab**$^+$ was synthesized since the ability of the ferrocene quaternary ammonium salt **10** to mediate with glucose oxidase was not inhibited by the presence of antiserum. Nonspecific interactions between the ferrocene unit and anti-theophylline antibodies should then, in theory, be reduced to a minimum. However, as for the uncharged **2a**, the catalytic activity of the charged conjugate **2aa**$^+$/**2ab**$^+$ with glucose oxidase was inhibited by antisera (Figure 6). Complete reversal of this inhibition could only be achieved through the addition of a 50-fold excess of theophylline over **2aa**$^+$/**2ab**$^+$. Therefore, although reducing the hydrophobic nature of the ferrocene moiety of the conjugate improves the reversibility of the inhibition, the sensitivity of the assay over the clinical range remains unsatisfactory (Figure 7).

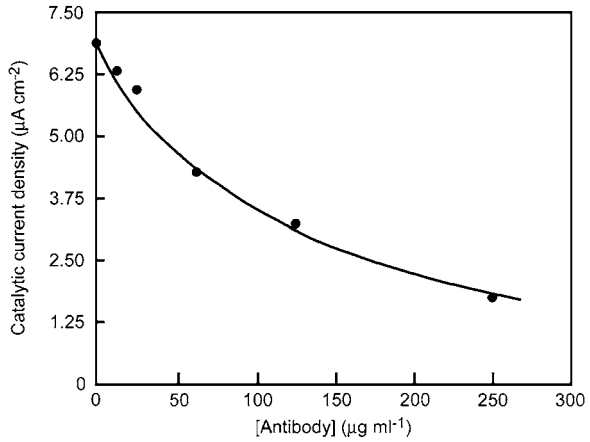

Figure 6. Inhibition of the catalytic current on addition of varying volumes of undiluted anti-theophylline antisera to conjugate **2aa**$^+$/**2ab**$^+$ (2 μM) in the presence of glucose (0.1 M) and glucose oxidase (35 μM).

CONCLUSION

8-(Ferrocenylalkyl)theophylline conjugates, with a range of linker arm chain lengths, were readily synthesized from the corresponding ferrocenylalkanoic acid and 5,6-diamino-1,3-dimethyluracil in moderate yield. However, the conjugates were discovered to bind more strongly to anti-theophylline antibodies than theophylline itself. The resulting competitive, homogeneous immunoassay displayed poor sensitivity in the therapeutic range for theophylline. The nonspecific interaction of the ferrocene moiety with the antibodies was found to be reduced by introducing a charged functional group into the metallocene ring of one conjugate. The assay sensitivity using the modified conjugate was improved but remains unsatisfactory for development into a viable electrochemical immunoassay for theophylline. This work indicates that, unless nonspecific interactions with antibodies can be overcome, ferrocene may be an unsuitable electrochemical label for general use in immunoassays.

EXPERIMENTAL PROCEDURES

Materials. All reactions were carried out under an atmosphere of nitrogen. Anhydrous solvents (Sure Seal grade; Aldrich) were used for reactions when required. All reagents and starting materials for reactions were purchased from Aldrich except for 1,1′-dimethylferrocene

8 (Strem) and were used without further purification. Literature methods were used for the preparation of dimethylaminomethyl-1,1′-dimethylferrocene methiodide **10** (*24*), ferrocenylacetic acid **1a** (*28*), 3-ferrocenylpropanoic acid **1c** (*29*, *30*), 4-ferrocenylbutanoic acid **1d** (*31*), 5-ferrocenylpentanoic acid **1e** (*31*), and 9-ferrocenylnonanoic acid **1f** (*32*, *33*). Dimethylaminomethyl-1,1′-dimethylferrocene methiodide **10** was used as a mixture of the 2- and 3-isomers. Theophylline and polyoxyethylene 9-lauryl ether were obtained from Sigma. Rabbit anti-theophylline antiserum Travenol H113, containing 2.5 mg/mL antibody, was purchased from Clinical Assays.

Glucose oxidase (EC 1.1.3.4 from *Aspergillus niger*) was supplied by Rhodia. The commercial dilute enzyme was concentrated, using tangential flow filtration (30 kDa size exclusion membrane, Millipore), to a protein level of ca. 250 mg/mL (1.5 mM) in 0.2 M BES buffer pH 7.5. The concentration of glucose oxidase was expressed in terms of catalytically active FAD determined spectrophotometrically at 450 nm. A molar extinction coefficient of 1.31×10^4 M^{-1} cm^{-1} was used (*34*). The BES buffer solution of 0.1 M BES (with 0.15 M NaCl as supporting electrolyte), pH 7.0, and containing 0.1 M D-glucose was prepared using AnalaR reagents from VWR in deionized water. The solution was stored overnight at 4 °C prior to use to allow equilibration of the α- and β-anomers. The phosphate buffer (0.15 M, with 0.2 M NaCl), pH 7.0, and containing 0.1 M D-glucose was also prepared employing AnalaR reagents (VWR).

Proton NMR spectra were recorded on Brüker WH 300 (300 MHz) or AM 500 (500 MHz) (external NMR service, University of Oxford) and Hitachi R-24B (60 MHz) instruments. Spectra were referenced internally to either the solvent or $SiMe_4$. Microanalyses were performed by C. H. N. Analysis Ltd., Leicester and Butterworth Laboratories, Teddington. Mass spectra (electron impact) were obtained via the external mass spectrometry service at the University of Oxford.

8-(Ferrocenylmethyl)theophylline (2a). Ferrocenylacetic acid **1a** (20.0 g, 82.3 mmol) and 5,6-diamino-1,3-dimethyluracil hydrate (16.7 g, 88.7 mmol) were dissolved in *N*,*N*-dimethylaniline and refluxed for 5 h using a Dean−Stark water separator. After cooling, NaOH solution (8% w/v, 400 mL) was added and the mixture was stirred for 18 h. The *N*,*N*-dimethylaniline was then removed by steam distillation. A heavy yellow precipitate was observed which partially dissolved upon acidification to pH 3−4 with 6 M HCl. The product was separated from the deep red solution by filtration, and then washed with acetonitrile followed by Et_2O to afford **2a** as an analytically pure yellow powder (11.9 g, 38%). Mp 270−272 °C (dec). Anal. Found: C, 56.93; H, 4.84; N, 14.78%; M^+ 378. $C_{18}H_{18}N_4O_2Fe$ requires C, 57.16; H, 4.80; N, 14.81%; M 378. IR (Nujol, cm^{-1}): 1700, 1650 (υ_{CO}); ^1H NMR (500 MHz; $CDCl_3$): 3.43 (s, 3H, NMe), 3.62 (s, 3H, NMe), 3.94 (s, 2H, CH_2), 4.19 (s, 5H, C_5H_5), 4.21 (m, 2H, C_5H_4), 4.25 (m, 2H, C_5H_4).

8-(Ferrocenylmethyl)caffeine (4). To a mixture of 8-(ferrocenylmethyl)theophylline **2a** (1.25 g, 3.31 mmol) and Na_2CO_3 (0.53 g, 5.0 mmol) in DMF (100 mL) was added iodomethane (0.25 mL). After stirring for 3 d at room temperature, the reaction mixture was filtered and evaporated to dryness. The yellow residue was dissolved in CH_2Cl_2 and then filtered to remove inorganic salts. Removal of the solvent yielded **4** as a yellow solid (1.23 g, 95%). Mp 182−184 °C. ^1H NMR (500 MHz; $CDCl_3$): 3.42 (s, 3H, NMe), 3.62 (s, 3H, NMe), 3.90 (s, 2H, CH_2), 3.92 (s, 3H, NMe), 4.18 (s + m, 9H, C_5H_5 + C_5H_4).

(1,1′-Dimethylferrocenyl)acetonitrile. Dimethylaminomethyl-1,1′-dimethylferrocene methiodide (10.0 g, 24 mmol) was suspended in water (100 mL), and KCN (7.87 g, 121 mmol) was added. The mixture was then refluxed for 2 h. A brown oil separated on cooling. The aqueous layer was decanted from the oil and washed with Et_2O. The oil and the ether extracts were combined and dried ($MgSO_4$). Removal of the solvent in vacuo gave the crude nitrile as an orange oil (6.10 g, 100%). IR (liquid film, cm^{-1}): 2250 (υ_{CN}).

(1,1′-Dimethylferrocenyl)acetic Acid (1b). Unpurified (1,1′-Dimethylferrocenyl)acetonitrile (6.10 g, 24 mmol) was dissolved in EtOH (50 mL), and a solution of KOH (14.0 g, 25 mmol) in water (200 mL) was added. The mixture was refluxed for 7 h. After cooling, the reaction mixture was washed twice with Et_2O before being acidified with 6 M HCl to pH 1. A dark yellow oil was obtained. The oil was dissolved in CH_2Cl_2 (250 mL) and dried ($MgSO_4$). The crude product **1b** was obtained as a brown oil (4.76 g, 73%) after evaporation of the chlorinated solvent. IR (liquid film, cm^{-1}): 1700 (υ_{CO}).

8-[(1,1′-Dimethylferrocenyl)methyl]theophylline (2b). Unpurified (1,1′-Dimethylferrocenyl)acetic acid **1b** (4.76 g, 17.5 mmol) was dissolved in *N*,*N*-dimethylaniline (150 mL), and 1,3-dimethyl-5,6-diamino uracil hydrate (3.57 g, 19 mmol) was added. The reaction mixture was refluxed for 5 h using a Dean−Stark water separator. NaOH solution (8% w/v, 50 mL) was added, and the mixture was stirred for 18 h. *N*,*N*-Dimethylaniline was then removed by steam distillation. Upon cooling, a solid precipitated and this was collected by filtration. The filtrate was acidified with glacial acetic acid to pH 4−5 affording a yellow precipitate. The crude product was dissolved in CH_2Cl_2 and dried ($MgSO_4$). An orange-yellow solid (3.10 g) was thus obtained which was subjected to column chromatography (Florisil). Elution with Et_2O−Me_2CO−MeOH (8:1:1) gave a yellow band from which the product **2b** was obtained as a yellow-green solid (1.46 g, 21%). Mp 220 °C (dec). Anal. Found: C, 59.02; H, 5.44; N, 13.80%; M^+ 378. $C_{20}H_{22}N_4O_2Fe$ requires C, 59.13; H, 5.46; N, 13.79%. ^1H NMR (60 MHz; $CDCl_3$): 1.90 (br m, 6H, C_5H_4*Me* + C_5H_3*Me*), 3.45 (br s, 3H, NMe), 3.55 (br s, 3H, NMe), 3.80 (9H, br m, CH_2 + C_5H_4Me + C_5H_3Me).

Preparation of Ferrocene−Theophylline Conjugates (2c−f). The above procedure for the synthesis of 8-[(1,1′-dimethylferrocenyl)methyl]theophylline **2b** was followed substituting the appropriate ferrocenylalkanoic acid **1c−f** for (1,1′-dimethylferrocenyl)acetic acid **1b**. After column chromatography, the desired ferrocene−theophylline conjugates **2c−f** were isolated as yellow solids in 20−30% yield.

8-(2-Ferrocenylethyl)theophylline (2c). Mp > 200 °C (dec). Anal. Found: C, 58.27; H, 4.55; N, 14.14%. $C_{19}H_{20}N_4O_2Fe$ requires C, 58.18; H, 5.14; N, 14.28%. 8-(8-Ferrocenyloctyl)theophylline (2f). Mp 157−158 °C. Found: C, 63.63; H, 6.82; N, 11.82%. $C_{25}H_{32}N_4O_2Fe$ requires C, 63.03; H, 6.77; N, 11.76%. IR (Nujol, cm^{-1}): 1710, 1625 (υ_{CO}); ^1H NMR (300 MHz; $CDCl_3$): 1.30 (br m, 8H, CH_2), 1.48 (br m, 2H, CH_2), 1.84 (m, J(HH) 7.6 Hz, J(HH) 7.0 Hz, 2H, CH_2), 2.30 (t, J(HH) 7.7 Hz, 2H, CH_2), 2.87 (t, J(HH) 7.7 Hz, 2H, CH_2), 3.48 (s, 3H, NMe), 3.64 (s, 3H, NMe), 4.04 (m, 4H, C_5H_4), 4.09 (s, 5H, C_5H_5), 12.66 (s, 1H, NH).

8-(1′-Acetyl-ferrocenylmethyl)theophylline (3). 8-(Ferrocenylmethyl)theophylline **2a** (3.78 g, 10 mmol) was dissolved in CH_2Cl_2 (600 mL). $AlCl_3$ (6.65 g, 50 mmol) was added followed by the dropwise addition of acetic anhydride (0.94 mL, 1.02 g, 10 mmol). The reaction mixture was stirred for 4 d and then quenched with water. The orange organic layer was separated and dried ($MgSO_4$). Filtration and removal of the solvent afforded an orange solid which was chromatographed (SiO_2). Elution with $Me_2CO-CH_2Cl_2$ (1:4) yielded a small amount of starting material **2a** as a yellow band. The red product band was eluted with $MeOH-CH_2Cl_2$ (1:19) and evaporated to dryness to provide **3** as an orange solid (2.43 g, 58%). Mp 219−220 °C (dec). Anal. Found: C, 57.58; H, 4.88; N, 13.37%. $C_{20}H_{20}N_4O_3Fe$ requires C, 57.16; H, 4.80; N, 13.33%. ^1H NMR (500 MHz; $CDCl_3$): 2.35 (s, 3H, CH_3-CO), 3.46 (s, 3H, NMe), 3.59 (s, 3H, NMe), 3.78 (s, 2H, CH_2), 4.12 (m, 2H, C_5H_4), 4.23 (m, 2H, C_5H_4), 4.41 (t, 2H, C_5H_4), 4.61 (t, 2H, C_5H_4).

8-(2/3-Dimethylaminomethyl-ferrocenylmethyl)-theophylline (2aa/2ab). 8-(Ferrocenylmethyl)theophylline **2a** (1.0 g, 2.65 mmol) was added to a well-stirred solution of bis(dimethylamino)methane (0.51 g, 5 mmol) and H_3PO_4 (10 g) in 100 mL of glacial acetic acid. The resulting mixture was heated for 5 h in an oil bath maintained at 100 °C. A dark amber solution was obtained. This was diluted with water (100 mL) and then extracted with CH_2Cl_2 to remove the starting conjugate **2a**. The aqueous layer was adjusted to pH7 with NaOH pellets and then extracted with CH_2Cl_2. The organic layer was dried (Na_2SO_4), filtered then evaporated to yield a brown oil soluble in $CHCl_3$, CH_2Cl_2, EtOH and water. This oil was passed through a short column of basic Al_2O_3, eluting with $MeOH/CH_2Cl_2$ (1:9), to provide **2aa**/**2ab** as an oil (0.1 g, 9%). ^1H NMR (500 MHz; $CDCl_3$): 2.31 (s, 6H, NMe_2), 3.40 (s, 3H, NMe), 3.58 (s, 3H, NMe), 3.9−4.3 (12H, ferrocene ring protons + 2 × CH_2).

8-(2/3-Dimethylaminomethyl-ferrocenylmethyl)-theophylline Methiodide ($2aa^+/2ab^+$). Crude aminomethylated conjugate **2aa**/**2ab** (0.1 g, 0.23 mmol) from the above reaction was dissolved in MeOH. Iodomethane (0.5 mL) was added and the resulting mixture was stirred for 2 h. After evaporation of the solvent, the residue was redissolved in the minimum volume of MeOH. The methiodide $\mathbf{2aa}^+/\mathbf{2ab}^+$ was precipitated from this solution by the addition of Et_2O. The precipitate was collected, washed with Et_2O and dried to afford 0.11 g (83%) of a beige powder.

Aminomethylation of Theophylline. *(a) Reaction with Diethylamine/Formaldehyde* (*24*). Formaldehyde solution (37%, 0.9 mL, 10 mmol) was added to a well-stirred solution of diethylamine (10 mmol) and theophylline (1.80 g, 10 mmol) in EtOH (30 mL). After 15 min, undissolved starting material was filtered off. The filtrate was evaporated to dryness to yield 7-(diethylaminomethyl)theophylline **5** as a white crystalline solid. The ^1H NMR spectrum of **5** in $CDCl_3$ displayed a singlet at δ 5.2 for the methylene protons.

(b) Reaction with Bis(dimethylamino)methane. Theophylline (1.80 g, 10 mmol) was added to a mixture of bis(dimethylamino)methane (2.04 g, 2.72 mL, 20 mmol), H_3PO_4 (10 g), and glacial acetic acid (150 mL). This mixture was heated at 100 °C on an oil bath for 5 h. Upon cooling, the reaction mixture was diluted with 200 mL of water and then made alkaline with NaOH pellets. Extraction with CH_2Cl_2 followed by separation, drying ($MgSO_4$), and filtration of the organic layer gave a colorless solution. Removal of the solvent provided 7-(dimethylaminomethyl)theophylline **6** as a white solid (0.5 g, 21%). ^1H NMR (500 MHz; $CDCl_3$): 2.45 (s, 6H, NMe_2), 3.37 (s, 3H, NMe), 3.56 (s, 3H, NMe), 5.12 (s, 2H, CH_2).

(c) Attempted Formation of the Methiodide. 7-(Dimethylaminomethyl)theophylline **6** (0.5 g, 1.14 mmol) was dissolved in MeOH and a large excess of iodomethane (1 mL) was added. The resulting solution was stirred for 2 h. Addition of Et_2O produced no precipitate so the solvent was removed under reduced pressure to give a white solid which was washed with CH_2Cl_2. A white solid remained and this was identified as theophylline by ^1H NMR spectroscopy.

Apparatus. Cyclic voltammetry and chronoamperometry experiments were carried out in a two-chamber glass cell of working volume 0.5 cm^3. The cell contained a 1 cm^2 platinum gauze counter electrode and a KCl-saturated calomel electrode as reference. All potentials are referred to SCE. The working electrode was a 4 mm diameter gold disk. An Oxford Electrodes potentiostat was employed.

Solutions of Ferrocene Conjugates. The ferrocene derivatives were only sparingly soluble in the aqueous BES and phosphate buffer solutions. The solubility of the conjugates was enhanced through the use of either 1% tetrahydrofuran (THF) or 5% polyoxyethylene 9-lauryl ether. Generally, THF was employed in chronoamperometry experiments involving anti-theophylline antiserum whereas polyoxyethylene 9-lauryl ether was used during cyclic voltammetry of the conjugates. In the former case, concentrated solutions (0.2 mM) of the ferrocene derivatives were prepared by first dissolving them in THF then mixing with the BES buffer to the desired concentration (2 μM). In the latter case, concentrated solutions (0.25 mM) of the ferrocene derivatives were prepared by first dissolving them in warmed liquid polymer then mixing with the phosphate buffer to the desired percentage (5%). The aminomethylated methiodide conjugate $\mathbf{2aa}^+/\mathbf{2ab}^+$ is water soluble so the use of either THF or polyoxyethylene 9-lauryl ether was unnecessary in the preparation of solutions for electrochemical experiments.

Procedure. Solutions (2 μM) of ferrocene derivatives, including ferrocene−theophylline conjugates, were freshly prepared in the BES buffer solution containing a high level (0.1 M) of D-glucose such that the kinetics of glucose oxidase was saturated. The buffer solution of ferrocene derivative was added to the cell followed by rabbit anti-theophylline antiserum (0−100 μL) and theophylline (0−300 μM). All concentrations are final ones obtained in a total assay volume of 1 mL. The mixture was then stirred for 5 min at room temperature. Finally, glucose oxidase (35 μM) was added then the working electrode was replaced in the cell. A potential of +320 mV was applied and current−time transients were recorded. Catalytic

currents were measured after 3 min and were corrected by subtraction of the background current obtained in the absence of enzyme and antisera.

A Glycopolymer Chaperone for Fibroblast Growth Factor-2

Ran Guan,[†] Xue-Long Sun,[†] Sijian Hou,[†] Peiyi Wu,[†] and Elliot L. Chaikof*[,†,‡]

Departments of Surgery and Biomedical Engineering, Emory University School of Medicine, Atlanta, Georgia 30322, and School of Chemical Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332. Received August 5, 2003; Revised Manuscript Received November 19, 2003

Mono- and disaccharide-containing glycopolymers were synthesized by cyanoxyl-mediated polymerization of acrylamide with acrylate-derivatized mono- and disaccharides. We demonstrate that a glycopolymer bearing pendant, fully sulfated lactose units effectively replaces heparin and heparan sulfate as a molecular chaperone for fibroblast growth factor-2 (FGF-2). Specifically, a compound was identified that protects FGF-2 from proteolytic, acid, and heat-induced degradation, while selectively promoting growth factor and receptor dimerization. Significantly, the capacity of this heparin-mimic to promote an FGF-2 specific proliferative cell response was confirmed and suggests potential applications for this compound and related derivatives in areas related to therapeutic angiogenesis.

INTRODUCTION

Heparan sulfates (HS) influence regenerative responses by acting as cofactors for a variety of cytokines (*1, 2*). For example, heparan sulfates bind fibroblast growth factors (e.g. FGF-1, FGF-2, FGF-7), heparin binding-epidermal growth factor (HB-EGF), platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF), all of which promote endothelial and/or smooth muscle cell motility and proliferation (*3*−*5*). Significantly, the interaction of heparin-binding cytokines and growth factors with heparan sulfates serves to protect these molecules from heat, pH, and protease-related degradation mechanisms, establish high concentration storage sites and may, at times, assist in their appropriate presentation to specific cell-signaling receptors by promoting oligomerization or by altering cytokine or receptor conformation (*6*−*8*). For example, FGF-2 sequestration, dimerization, and stimulation of cell proliferation is dramatically reduced in extracellular matrix produced from chlorate treated cells that are unable to produce fully sulfated glycosaminoglycans (GAG) (*9*).

The diverse biological properties of heparin and heparan sulfate combined with the inherent difficulty associated with the synthesis of these chemically complex natural products have motivated efforts to generate simpler structural mimics as component biomaterials for a variety of applications. In the past five years, significant advances in the synthesis of polymers with pendent saccharides, also known as "glycopolymers", offer one such biomimetic strategy (*10*−*13*). For example, vinyl-, acrylate-, or norbornene-containing saccharide derivatives can be polymerized to yield glycopolymers with biologically active hydrophilic saccharides in the side chains. Moreover, the backbone structure may be altered to modulate both polymer biostability and processability. Significantly, the carbohydrate density of the polymer chain, which appears to affect both ligand binding affinity, as well as polymer physiochemical properties, can be controlled through the choice of polymerizable saccharide, associated comonomers, and dictated chain size. Overall, the potential to stably link bioactive oligosaccharide ligands is an important feature of the glycopolymer approach and presents an opportunity to create GAG mimicking structures that facilitate optimized sequestration and controlled local release of bioactive protein species.

In prior reports, we have examined the applicability of cyanoxyl (•OC≡N)-mediated free-radical polymerization in the synthesis of model glycopolymers from unprotected alkene- and acrylate-derivatized sulfated and unsulfated glycomonomers consisting of a variety of mono- and disaccharide species (*14*−*17*). Significantly, we observed that this polymerization technique can be conducted in aqueous solution, is tolerant of a broad range of functional groups (OH, NH_2, COOH, and OSO_3^-), yields low-polydispersity polymers (PDI < 1.50) with high saccharide content, and can be applied to the synthesis of block and graft copolymers. We have used this approach to generate glycopolymers with pendant monosaccharides, as well as HS- and non-HS-related disaccharides. In this report, we demonstrate that this strategy can yield a novel HS-mimetic that acts as an effective *macromolecular chaperone* for a pro-angiogenic protein growth factor (FGF-2), sequestering and protecting FGF-2 from proteolytic, acid, or heat-induced degradation. In addition, this glycopolymer selectively promotes the interaction of FGF-2 with its receptor, fibroblast growth factor receptor-1 (FGFR-1), as well as the dimerization of both FGF-2 and the FGF-2/FGFR-1 complex. Significantly, all of these features are necessary for receptor activation. The capacity of this glycopolymer to uniquely promote a FGF-2-specific proliferative cell response is confirmed.

MATERIALS AND METHODS

Materials. All solvents and reagents for monomer or polymer synthesis were purchased from commercial sources and were used as received, unless otherwise noted. Deionized water with a resistivity of 18 MΩ·cm was used as a solvent in all polymerization reactions. FGF-2 (human recombinant, 17.2 kDa) was obtained

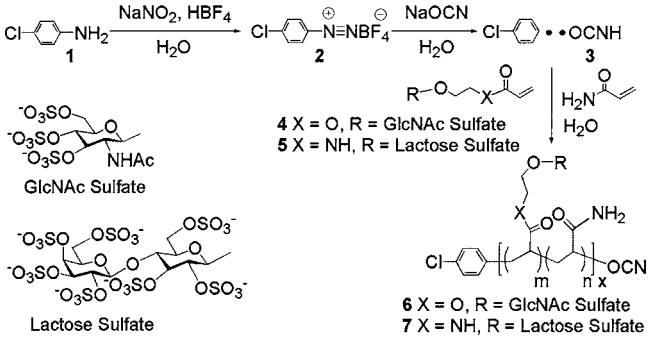
from Pepro Tech Inc (Rocky Hill, NJ), ^{125}I-FGF-2 was purchased from NEN (Boston, MA). Silver stain reagent was obtained from BioRad (Hercules, MA) and disuccinimidyl suberate (DSS) from Pierce (Rockford, IL). RPMI-1640 media, penicillin−streptomycin, L-glutamine, and G418 were all obtained from Mediatech Inc. (Herndon, VA) and bovine calf serum from Hyclone (Logan, UT). Sodium heparin from porcine intestinal mucosa (MW between 12 000 and 20 000, lot 30K0572), heparin sulfate (MW ∼7000, lot 41K1130), and sodium dextran sulfate (MW 5000, 10 000, and 500 000) were obtained from Sigma (St. Louis, MO). Sucrose octasulfate potassium salt was aquired from Toronto Research Chemicals Inc. (Toronto, Canada), and β-mercaptoethanol, protein A sepharose, and [methyl-^{3}H]-thymidine (5 Ci/mmol) were purchased from Amersham Pharmacia Biotech (Piscataway, NJ). FGFR-1 antibody raised against the carboxy terminus of FGFR-1 of human origin (identical to the corresponding mouse sequence) was purchased from Santa Cruz.

General Synthetic Methods. Thin-layer chromatography (TLC) was performed on Whatman silica gel aluminum-backed plates of 250 μm thickness on which spots were visualized with UV light or by charring the plate after dipping in 10% H_2SO_4 in methanol. Mass spectra (MS/FAB) were obtained at an ionizing voltage of 70 eV. ^{1}H NMR spectra were recorded at room temperature with a Varian INOVA 400 spectrometer (magnetic field strengths of 400 and 100 MHz for ^{1}H and ^{13}C NMR analyses, respectively). The size-exclusion chromatography (SEC) equipment comprised a Waters model 510 HPLC pump, a Waters Ultrahydrogel 250 column, and a Wyatt Technology Optilab 903 refractometer. The eluent consisted of a 0.1 mol/L $NaNO_3$ deionized water solution containing 0.05 wt % sodium azide at a flow rate of 0.7 mL/min. The actual molar masses of the glycopolymer samples were determined from the response of the Dawn EOS (Wyatt Technology) multiangle laser light-scattering (LLS) detector that was connected to the outlet of the SEC apparatus.

2-*O*-Acryoylethoxyl-2-acetylamino-3,4,6-trisulfoxy-β-D-glucopyranoside (4) and 2-*N*-Acryoylaminoethoxyl 4-*O*-(2,3,4,6-Tetrasulfoxy-β-D-galatopyranosyl)-2,3,6-trisufoxy-β-D-glucopyranoside (5) were synthesized as previously reported (*14*, *16*).

Homopolymerization of Acrylamide-Derived Glycomonomers Initiated by $ClC_6H_4N{\equiv}N^+BF_4^-$/NaOCN. In a three-neck flask, 3 mg (2.45×10^{-5} mol) of *p*-chloroaniline was reacted with 7 mg of HBF_4 (48 wt % aqueous solution, 3.67×10^{-5} mol) in 2 mL of water at 0 °C and under an Ar atmosphere. The diazonium salt $ClC_6H_4N^+{\equiv}NBF_4^-$ was generated by adding 2 mg (2.93×10^{-5} mol) of $NaNO_2$ to the reaction medium. After 30 min, a degassed mixture of 390 mg (1.22×10^{-3} mol) of glycomonomer **5** (or **4**) and 2 mg (2.45×10^{-5} mol) of sodium cyanate (NaOCN) dissolved in 0.5 mL of water was introduced into the flask containing the arenediazonium salt. The polymerization solution was then heated to 50 °C for 16 h. By varying the [M]/[I] ratio and reaction times resulting glycopolymers **7a** and **7b** (or **6a** and **6b**) were isolated by precipitation in a 10-fold excess of cold methanol and dried to yield white cotton wool-like materials.

Copolymerization of Acylamide-Derived Glycomonomers Initiated by $ClC_6H_4N{\equiv}N^+BF_4^-$/NaOCN. In a three-neck flask, 8 mg (6.03×10^{-5} mol) of *p*-chloroaniline was reacted with 17 mg of HBF_4 (48 wt % aqueous solution, 9.04×10^{-5} mol) in 2 mL of water at 0 °C and under an Ar atmosphere. The diazonium salt $ClC_6H_4N^+{\equiv}NBF_4^-$ was then generated by adding 5 mg (7.2×10^{-5} mol) of sodium nitrite ($NaNO_2$) to the reaction medium. After 30 min, a degassed mixture of 225 mg (6.03×10^{-4} mol) of glycomonomer **5** (or **4**), 171 mg (2.41×10^{-3} mol) of acrylamide, and 4 mg (6.03×10^{-5} mol) of NaOCN dissolved in 1 mL of water were introduced into the flask containing the diazonium salt. The polymerization solution was then heated to 50 °C. The statistical copolymers **7c** and **7d** (or **6c**−**e**) formed after 16 h of reaction were isolated by precipitation in a 10-fold excess of cold methanol and dried. The conversions were determined by weight of the resultant glycopolymer.



Cell Culture. BaF3-FR1C-11 mouse lymphoma cells were kindly provided by Dr. D. Ornitz (Washington University, St. Louis, MO) and were cultured in RPMI 1640 media supplemented with 10% bovine calf serum, 10% WEHI-3 conditioned medium, 100 u/mL penicillin, 100 μg/mL streptomycin, 4 mM L-glutamine, 0.0035% β-mercaptoethanol, and 600 μg/mL G418. FR1C-11 cells were derived from the BaF3 line and have been transfected with a mouse cDNA encoding the 3Ig domain form of FGFR1-IIIc (*18*).

Proliferation Assay. BaF3-FR1C-11 mouse lymphoma cells were washed twice with RPMI 1640 media lacking IL-3 and plated at a concentration of 2.2×10^4 cells/well in a 96-well plate in the presence of 3 ng/mL FGF-2 and increasing concentrations of heparin or various test compounds in a total volume of 150 μL of media (RPMI 1640−10% fetal calf serum without IL-3). After a 36 h incubation period, 1 μCi of ^{3}H-thymidine was added to each well in a volume of 50 μL of RPMI media (without FGF or IL3). Cells were incubated for an additional 5 h and harvested onto glass fiber filters with a TOMTEC cell harvester (Tomtec Co., Orange, CT). Incorporated ^{3}H-thymidine was determined by liquid scintillation counting. Each compound concentration was tested in triplicate.

Dimerization of FGF-2 and FGFR-1. Compound-induced FGF-2 dimerization was assessed, as detailed elsewhere (*19*). Briefly, ^{125}I-FGF-2 (20 ng/mL) was incubated for 1 h at room temperature in the presence and absence of heparin (25 μg/mL) or various concentrations of test glycopolymer in 20 μL buffer containing 150 mM NaCl and 25 mM Hepes, pH 7.5. DSS was then added to a final concentration of 0.3 mM, and the mixture was incubated for an additional 20 min. The cross-linking reaction was quenched with 10 mM ethanolamine-HCl, pH 8.0, for 20 min and diluted with 2 × SDS−PAGE loading buffer. The protein was analyzed on a 15% SDS−PAGE gel, and cross-linked FGF-2 was visualized by autoradiography on XAR film (Eastman Kodak Co., Rochester, NY).

For FGFR cross-linking studies, 10^6 cells were washed with binding buffer (RPMI 1640), 1 mg/mL of bovine serum albumin (BSA), and 20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES, pH 7.5) and incubated with 3 ng/mL ^{125}I-FGF-2 in the absence or presence of either heparin or HS-mimetic compound at 4 °C for 5 h. After three washes with ice cold PBS with 1 mg/mL of BSA, cells were resuspended and incubated in 250 μL of cross-linking solution (PBS, 0.2 mM DSS, 1 mg BSA/mL) for 45 min at room temperature. The reaction was quenched with 500 μL of TN buffer (50 mM tris, pH 7.4, 150 mM NaCl), washed twice with TN, and solubilized in RIPA buffer (PBS, 0.5% deoxycholic acid, 1% Triton X-100, 1 mM EDTA, 1 mM phenylmethylsulfonyl fluoride, 10 μg aprotinin per mL). After 10 min on ice, the nuclei were removed by centrifugation and the supernatants were analyzed by electrophoresis through

Scheme 1. Cyanoxyl-Mediated Free-Radical Copolymerization of Sulfated Glycomonomer with Acrylamide

a 6% SDS−PAGE gel. The cross-linked FGF-2-FGFR was visualized by autoradiography on XAR film (Eastman Kodak Co., Rochester, NY) (*20*).

Proteolytic Digestion of FGF-2. Trypsin-mediated digestion of FGF-2 in the presence of test compound was evaluated as described by Coltrini et al. (*21*). Briefly, 1-μg aliquots of the growth factor were incubated at 37 °C for 5 min in 5 mM Tris/HCl pH 7.6, in the presence of increasing concentrations of the test compound. This was followed by the addition of 100 ng of trypsin with incubation at 37 °C for 3 h. Samples were then supplemented with SDS−PAGE reducing sample buffer, heated to 100 °C for 5 min, and then electrophoresed on a SDS−PAGE (15%) gel. The amount of undigested protein in a given lane was determined by densitometric analysis of silver-stained gels (*21*, *22*).

Acid and Heat Treatment of FGF-2. FGF-2 (100 μg/mL) in 5 mM Tris (pH 7.6) was combined with heparin or test compound and then incubated for 2 h at room temperature in the presence of trifluoroacetic acid (TFA) diluted in water. TFA at a final concentration of 0.05, 0.1, 0.25, 0.5,1, 2.5, and 5% corresponds to a pH of 3.4, 2.37, 1.5, 1.08, 0.4, 0.2, and 0, respectively, which was unaffected by the addition of heparin, test compound, or FGF-2. The reaction mixture was further diluted as indicated with RPMI 1640−10% fetal calf serum. The final pH was neutral, as indicated by a phenol red indicator (*23*). To define the capacity of test compound to protect FGF-2 from heat inactivation, FGF-2 was incubated with heparin or test compound and then heated at 65 °C for 5 min. In both assays, residual FGF-2 activity was determined by measuring the proliferation of BaF3-FR1C-11 cells in response to 1 μL of reaction mixture.

RESULTS AND DISCUSSION

Synthesis of Sulfated Glycopolymers. Polyacrylamide-based neoglycoconjugates have been used as diagnostic reagents, such as in the inhibition of hemagglutination by pathogens (*24*) or as solid-phase coatings in enzyme-linked immunosorbent assays (ELISA) (*25*, *26*). Our prior investigations have confirmed that cyanoxyl (OCN)-mediated free-radical polymerization of acryl-derivatized glycomonomers is a convenient tool to produce water-soluble glycopolymers. In this reaction, cyanoxyl radicals were generated by an electron-transfer reaction between cyanate anions ($^-OC{\equiv}N$), from a NaOCN aqueous solution, and *p*-chlorobenzene-diazonium salts ($ClC_6H_4N{\equiv}N^+BF_4^-$), that were previously prepared in situ through a diazotization reaction of *p*-chloroaniline in water (Scheme 1). In addition to cyanoxyl persistent radicals, aryl-type active radicals were simultaneously produced, and only the latter species is capable of initiating chain growth. As summarized in Tables 1 and 2, cyanoxyl-mediated homopolymerization of sulfated *N*-acetylglucosamine glycomonomer **4** or lactose heptasulfate monomer **5** generated the expected sulfated glycopolymers **6** or **7** in good conversion yield (60−80%) and with relatively low polydispersity ($1.13 < M_w/M_n < 1.62$), respectively. Polymers of varying molecular weight were prepared by altering either monomer conversion or the initial ratio of monomer to initiator concentrations ($[M]_o/[I]_o$). Similarly, copolymers were prepared by copolymerization of sulfated glycomonomer **4** or **5** with acrylamide in low-polydispersity ($1.15 < M_w/M_n < 1.57$). The resultant glycopolymers were characterized by NMR spectroscopy as well as by SEC coupled with both refractive index and multiangle laser-scattered detectors.

Table 1. Sulfated Monosaccharide-Based Glycopolymers

monomer ratio GM/AM (mol)	polymer composition (mol)	glucosamine content (wt %)[a]	M_n (g/mol)	M_w/M_n SEC	glycopolymer
1/0	1/0	100	9900	1.13	**6a** (**SM1**)

Glycopolymers Bearing Lactose Heptasulfate Dissacharides Stimulate FGF-2-Mediated Cell Proliferation. The capacity of selected glycopolymers to potentiate FGF-2 mitogenic activity was measured by [^{3}H]-thymidine incorporation into BaF3-FR1C-11 cells, which express the FGF receptor, FGFR-1, but not cell surface heparan sulfate. In the absence of exogenous heparin or heparan sulfate, FGF-2 is incapable of eliciting cell proliferation. Cells were treated with 3 ng/mL of FGF-2 and increasing concentrations of indicated oligosacharides. Test compounds include a series of glycopolymers ranging in molecular weight, pendant group type, and density, as well as corresponding monomers, sucrose octasulfate (SOS), heparin, and heparan sulfate (Figure 1).

The synthesis of sulfated glycopolymers did not ensure the generation of compounds that mimicked heparin's ability to stimulate FGF-2-dependent cell proliferation. For example, glycopolymers **6** (**SM1**−**SM6**) carrying fully sulfated NAcGlc pendant groups were ineffective in promoting FGF-2-dependent cell proliferation (Figure 1A). However, glycopolymers **7** (**SL3**, **SL4**, **SL5,** and **SL7**) bearing sulfated lactose residues were able to elicit a range of proliferative activity depending upon the structural features of the polymer (Figure 1B−D). Of note, a high level of bioactivity was demonstrated by a glycopolymer designated **SL3** (MW 9300, PDI 1.46) that was a copolymer of sulfated lactose monomers (GM) and acrylamide (AM) (molar ratio AM:GM 1:10, lactose

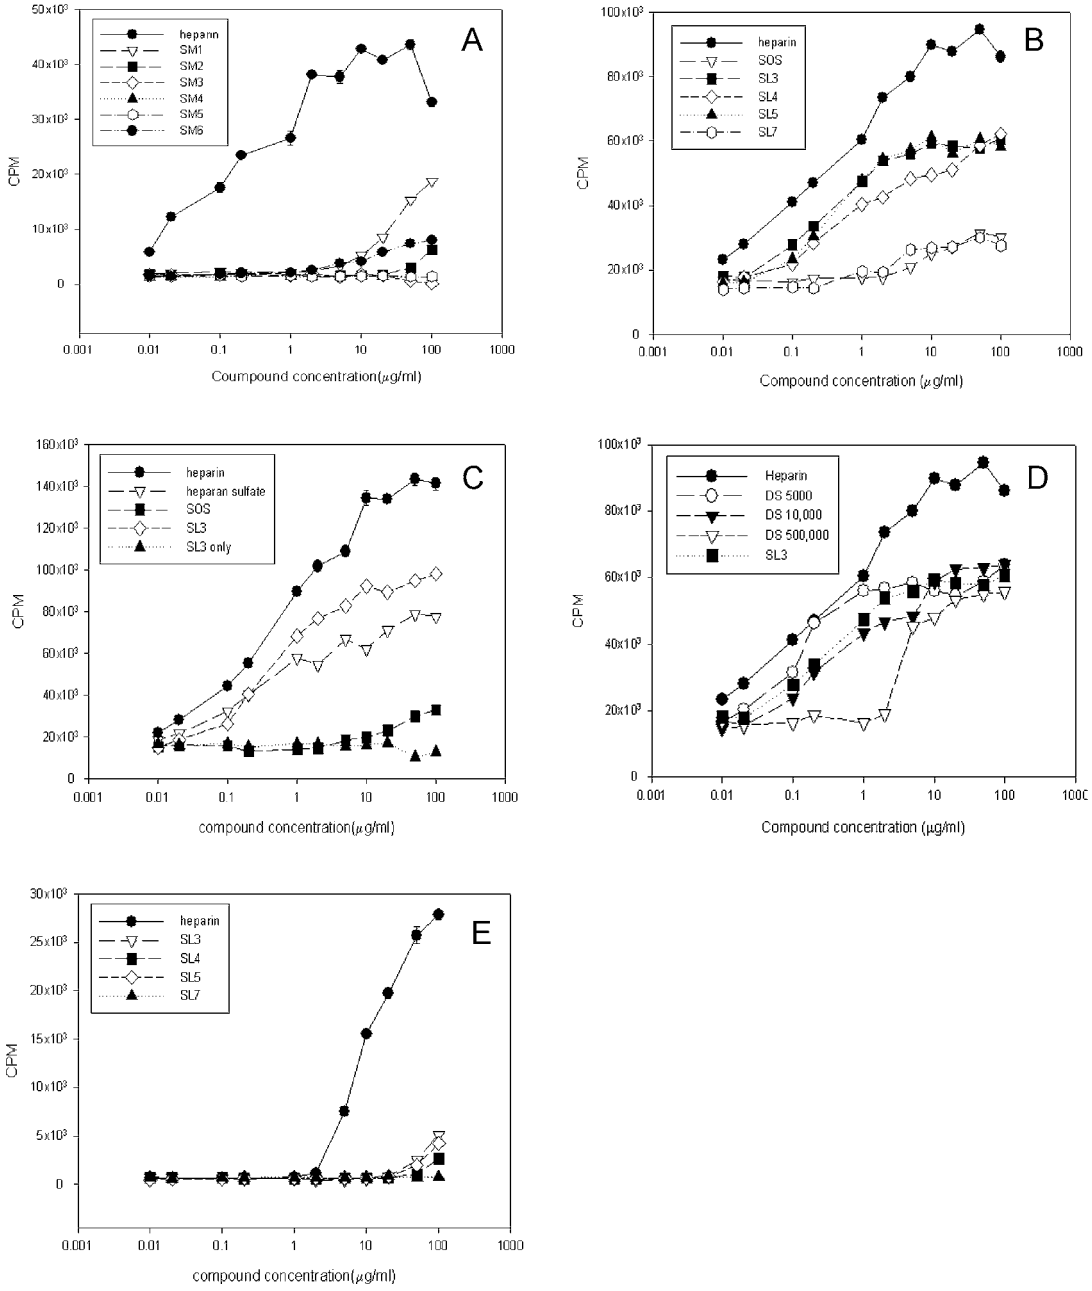

Figure 1. Mitogenic activity of natural and synthetic carbohydrate-based compounds. (A) Mitogenic activity of glycopolymers (**SM1**−**SM6**) in the presence of FGF-2. (B) Comparison of mitogenic activity of glycopolymers (**SL3**−**SL7**) with SOS and heparin. (C) Comparison of mitogenic activity of glycopolymer **SL3** with **SL3** monomer, SOS, and heparan sulfate. (D) Comparison of mitogenic activity of glycopolymer **SL3** with dextran sulfate 5000, 10 000, and 500 000. (E) Mitogenic activity of synthetic glycopolymers in the presence of FGF-1. Activation of FGF-1 mitogenic activity as measured by [^{3}H]-thymidine incorporation into BaF3-FR1C-11 cells treated with 4 ng/mL FGF-1 and increasing concentrations of the indicated compound.

content 57 wt %). **SL3**-mediated proliferative responses to FGF-2 exceeded those observed with heparan sulfate, as well as SOS and free **SL3** monomer **5**. Of interest, the **SL3** effect is selective in that it was not capable of initiating a proliferative response to FGF-1 (Figure 1E).

FGF-2 and FGFR-1 Dimerization Is Mediated by the Mitogenic Glycopolymer SL3. Characteristically, FGF-2 is sequestered in the ECM in a dimerized form only when matrix-producing cells produced fully sulfated GAGs. Significantly, dimerization of both FGF-2 and FGFR-1 are essential for an optimized biological response. To examine the capacity of **SL3** to mediate FGF-2 dimerization, 20 ng/mL of ^{125}I-FGF-2 was incubated with either heparin or **SL3** for 1 h at room temperature. After disuccinimidyl suberate cross-linking, the samples were resolved by electrophoresis and visualized by autoradiography (Figure 2). **SL3** was as effective as heparin in mediating FGF-2 dimerization. Likewise, **SL3**-mediated FGFR-1 dimerization was investigated by incubating BaF3-FGFR-1C-11 cells with ^{125}I-labeled FGF-2 in the presence or absence of either heparin or **SL3**. Cells were treated with disuccinimidyl suberate to cross-link FGF-2 to its receptor. Cross-linked proteins were electrophoresed on an SDS−6% polyacrylamide gel and detected by autoradiography (Figure 3). **SL3** was as effective as heparin in mediating FGFR-1 dimerization.

Glycopolymer SL3 Protects FGF-2 from Protein Degradation Induced by Trypsin, Acidic Condi-

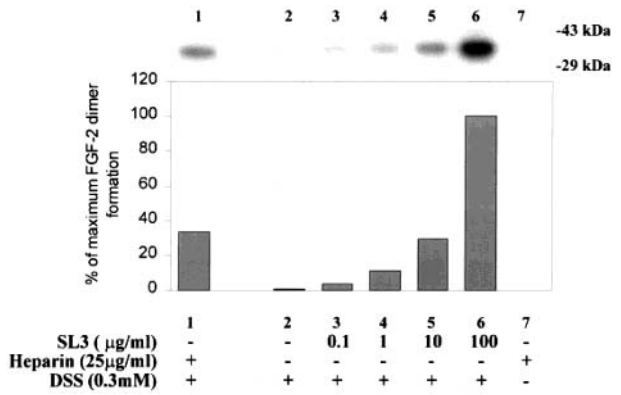

Figure 2. Dimerization of FGF-2 in the presence of **SL3**. ^{125}I-FGF-2 20 (ng/mL) was incubated with either heparin or **SL3** for 1 h at room temperature. After disuccinimidyl suberate cross-linking, samples were resolved by electrophoresis and visualized by autoradiography.

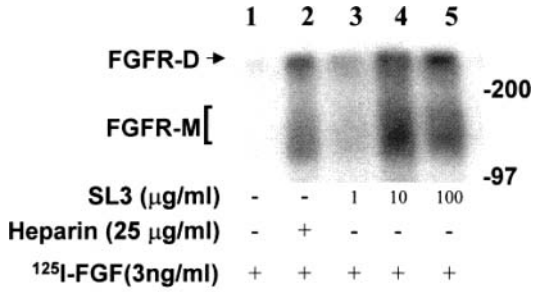

Figure 3. Cross-linking of ^{125}I-FGF-2 to FGFR-1. BaF3-FGFR-1C-11 cells were incubated with ^{125}I -labled FGF-2 in the presence or absence of either heparin or **SL3** and subsequently treated with disuccinimidyl suberate to cross-link FGF to the FGFR-1 receptor. Cross-linked proteins were electrophoresed on an SDS−6% polyacrylamide gel and detected by autoradiography.

tions, and Heat. It has been suggested that once soluble proteins, such as FGF-2, are released into the ECM, their sequestration by heparan sulfate proteoglycans is essential for preservation of bioactivity. In principle, complexation with HS chains should protect heparin-binding proteins from heat-, pH-, and protease-related degradation mechanisms. To assess protection from proteolysis, FGF-2 (1 μg) was incubated with trypsin for 3 h at 37 °C in the presence or absence of 25 μg/mL of heparin or decreasing concentration of glycopolymer **SL3**. Samples were then analyzed by SDS−PAGE and undigested FGF-2 was estimated by densitometry (Figure 4). **SL3** was as effective as heparin in protecting FGF-2 from proteolytic degradation. Protection from acidic conditions was determined by incubation of FGF-2 with or without heparin or glycopolymer **SL3** (25 μg/mL) in varying concentrations of trifluoroacetic acid (0.05 to 5%), corresponding to a pH range of 0 to 3.4. After 2 h incubation at room temperature, samples were diluted 20-fold with RPMI 1640 and incubated with heparin deficient cells (BaF3-FGFR-1) expressing the FGF receptor (FGFR-1). ^{3}H-Thymidine incorporation was determined as an indicator of retained FGF-2 activity (Figure 5). Preservation of biological activity upon heat-treatment of FGF-2 was measured by incubation of FGF-2 at 65 °C for 5 min with or without heparin or glycopolymer **SL3** (25 μg/mL). Samples were diluted in RPMI 1640 and incubated with BaF3-FGFR-1 cells, and ^{3}H-thymidine incorporation was determined (Figure 6). Both heparin and the heparin-mimetic glycopolymer **SL3** provided substantial protection of FGF-2 from trypsin, heat, and acidic conditions.

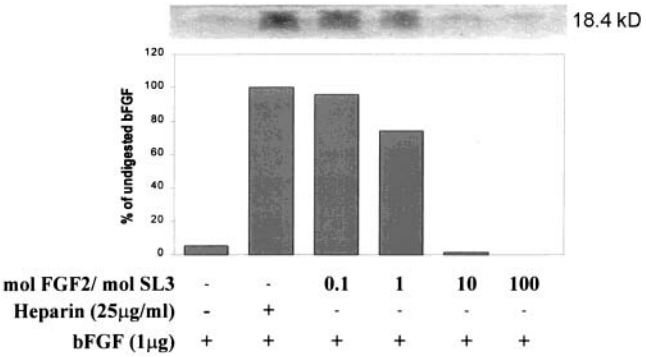

Figure 4. SL3 protects FGF-2 from trypsin digestion. Aliquots (1 μg) of recombinant FGF-2 were incubated at 37 °C with trypsin in the absence or presence of 25 μg/mL heparin or decreasing concentration of **SL3**. Samples were then analyzed by SDS−PAGE and visualized by silver staining. Undigested FGF-2 in each lane of the gel was estimated by densitometry.

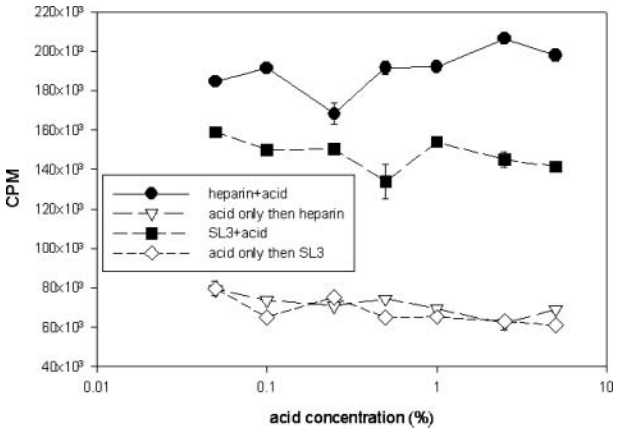

Figure 5. SL3 protects FGF-2 on exposure to acidic conditions. A stock solution of FGF-2 (100 μg/mL in 5 mM tris, pH 7.6) in the presence or absence of either heparin or **SL3** was diluted 10-fold with TFA ranging in concentration from 0.05 to 5%. After 2 h incubation at room temperature, the samples were further diluted 20-fold with RPMI 1640−10% FCS without IL-3 (final FGF-2 concentration 0.5 μg/mL) and added to BaF3-FGFR-1C-11 cells. Heparin or SL3 was added to those test samples that were incubated in TFA in the absence of either compound. The final FGF-2 concentration was 3.3 ng/mL, while that of heparin or SL3 was 25 μg/mL. After 36 h, 1 μCi of [^{3}H]-thymidine was added to each sample. The cells were incubated for an additional 5 h and incorporated thymidine determined by liquid scintillation counting.

Despite recent advances in achieving sustained local delivery of protein growth factors through the use of synthetic or native macromolecules as controlled delivery vehicles, significant limitations remain in achieving optimal control over the degree of growth factor sequestration and maximum preservation of growth factor activity during and after release. For example, while the addition of MgOH to polylactide/glycolide (PLGA) microspheres have led to improvements in protein stabilization during material processing and polymer degradation, the risk of protein inactivation due to proteolytic, thermal, or other mechanisms that are operative at the depot site in the body remains (*27*−*30*). All of this necessitates the delivery of increased quantities of growth factor, with significant added cost, to compensate for its reduced bioavailability. Moreover, variability in the nature, extent, and magnitude of those physiochemical processes, which may degrade or denature protein growth factors, further complicates the goal of predictable uniform drug delivery.

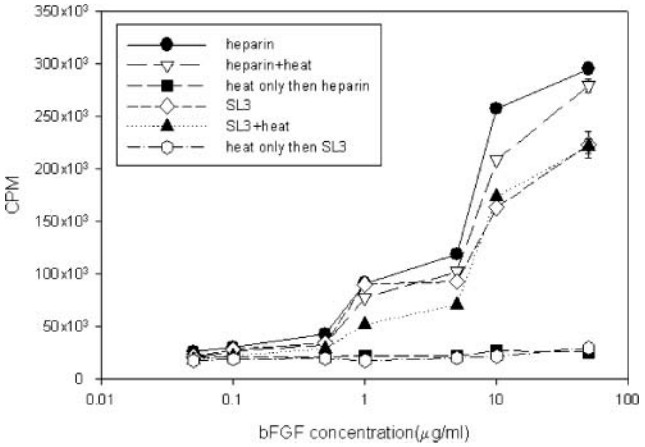

Figure 6. SL3 protects FGF-2 from thermal denaturation. A stock solution of FGF-2 (100 μg/mL, in 5.0 mM tris, pH 7.6) was diluted 10-fold in PBS with or without **SL3** or heparin and heat inactivated. An aliquot was added to BaF3-FGFR-1C-11 cells such that the final FGF-2 concentration was 3.3 ng/mL, while that of heparin or **SL3** was 25 μg/mL. After 36 h, 1 μCi of [^{3}H]-thymidine was added to each sample. The cells were incubated for an additional 5 h and incorporated thymidine determined by liquid scintillation counting.

In this report, we postulate that heparan sulfate proteoglycans, which act as reservoirs for heparin-binding growth factors and cytokines, establishes a useful biomimetic paradigm for the generation of biomaterials for the controlled delivery of proangiogenic proteins or other growth factors. The diverse biological properties of heparin and heparan sulfate combined with the inherent difficulty associated with the synthesis of these chemically complex natural products have motivated efforts to generate simpler structural mimics as component biomaterials for a variety of applications. For example, Cooper et al. (*31*, *32*), and Ito et al. (*33*, *34*) and Onishi (*35*) have all produced sulfonate-functionalized polymers with promising anticoagulant-like properties. Of particular interest have been the efforts of Jozenfowicz and colleagues who have prepared dextrans derivitized with carboxymethyl, carboxymethylbenzamide, and carboxymethylbenzylamide sulfonate functional groups (*36*−*39*). The biological features of these polysaccharides are related to the number and distribution of chemical groups randomly attached along the dextran chain. Indeed, several of these polymers exhibit anticoagulant and anticomplement properties, and in some cases mimic heparin's inhibitory effect on smooth muscle cell growth (*9*, *40*−*41*). Other variants potentiate the activities of FGF-1 and FGF-2 and appear to stimulate the healing responses of a variety of tissue types in vitro and in vivo (*38*, *39*). In this report, we demonstrate that a glycopolymer bearing pendant fully sulfated lactose units effectively replaces heparin and heparan sulfate as a molecular chaperone for FGF-2. A compound was identified that protects FGF-2 from proteolytic, acid, and heat-induced degradation, while selectively promoting its dimerization and interaction with its receptor. Significantly, the capacity of this heparin-mimic to promote an FGF-2 specific proliferative cell response suggests potential applications in areas related to therapeutic angiogenesis, including wound healing, myocardial or lower extremity revascularization, as well as in tissue engineering.

Factors Influencing the Ability of Nuclear Localization Sequence Peptides To Enhance Nonviral Gene Delivery

K. Helen Bremner,[†] Leonard W. Seymour,*[,‡] Ann Logan,[§] and Martin L. Read[§]

Cancer Research UK Institute for Cancer Studies, University of Birmingham, Birmingham, B15 2TH, UK, Department of Clinical Pharmacology, University of Oxford, Oxford, OX2 6HE, UK, and Department of Medicine, University of Birmingham, Birmingham, B15 2TH, UK. Received August 8, 2003; Revised Manuscript Received November 6, 2003

Nonviral gene delivery is limited by inefficient transfer of DNA from the cytoplasm to the nucleus. Nuclear localization sequence (NLS) peptides have been widely used to exploit intracellular transport mechanisms and promote nuclear uptake of DNA. However, the exact conditions to successfully utilize the properties of NLS peptides are still unclear. In the present study a panel of NLS peptides that bind different transport receptors were compared for their ability to enhance nonviral gene transfer. Several factors such as method of incorporating the NLS peptide, type of NLS peptide, DNA morphology, and proper characterization of NLS peptide/DNA conjugates were identified as important considerations in utilizing NLS peptides to enhance gene transfer. In particular, it was shown that a peptide derived from human T cell leukaemia virus type 1 (HTLV) was able to effectively condense DNA into discrete particles and mediate levels of transgene expression up to 32-fold greater than polylysine-based polyplexes. This is the first study to demonstrate efficient transfection mediated by an importin β-binding peptide based on the HTLV sequence. Promising results were also achieved with a 7-fold increase in gene expression using a NLS peptide/DNA conjugate formed by site-specific linkage of an extended SV40 peptide via a peptide nucleic acid (PNA) clamp. Altogether, the results from this study should help to define the requirements for successful NLS-enhanced transfection.

INTRODUCTION

Gene therapy has tremendous potential as either a standalone treatment or adjuvant therapy for many forms of disease such as cancer (*1*). The most efficient methods of delivering genes are those based on viral vectors such as adenovirus and retroviruses. However, safety issues relating to inflammatory and immune responses to adenoviral proteins and malignant transformation due to insertional mutagenesis with retroviral delivery have raised concerns over the use of these vectors (*2*, *3*). A safer alternative is to use nonviral (or synthetic) vectors such as polyplexes and lipoplexes for gene transfer. At present, however, the low levels of gene expression typically observed in vivo restrict the usefulness of nonviral vectors compared to viral vectors. Inefficient transfer of DNA from the cytoplasm to the nucleus has been identified as a major reason for this, particularly in postmitotic and quiescent cells where there is no periodic breakdown of the nuclear membrane (*4*, *5*).

By comparison, cellular and viral proteins enter the nucleus efficiently by means of nuclear localization sequences (NLS[1]), stretches of amino acids that bind to intracellular transport receptors such as importins and facilitate transfer through the nuclear pore. Early experiments showed that NLSs retain their activity when conjugated as a synthetic peptide to otherwise nonnuclear proteins such as bovine serum albumin and transferrin (*6*). The application of NLS peptides for nonviral gene transfer has since been widely investigated (*7*) and results to date have indicated the potential of this approach to improve nuclear delivery of DNA. For example, coupling of streptavidin−NLS conjugates to biotinylated DNA enabled linear DNA fragments of between 310 and 1500 bp to enter the nuclei of digitonin permeabilized cells by an active transport process (*8*). Significant increases in gene expression were also observed following ligation of an oligonucleotide-NLS conjugate to one or both termini of a linear DNA molecule, although no conclusive localization or mechanistic data was given in this study (*9*).

Results have been encouraging using linear DNA fragments but the type of chemistry used to conjugate peptides to circular plasmid DNA often results in loss of transcriptional capability. Two recent studies, for example, used either a photoactivation reaction (*10*) or a cyclopropapyrroloindole group (*11*) to couple NLSs at random locations on the DNA molecule. Sebestyen et al. demonstrated nuclear import in digitonin-permeabilized HeLa cells when >100 NLS peptides were attached to each plasmid, but transgene expression was completely

abolished (*11*). More encouragingly, Ciolina et al. found no decrease in expression until modification reached the level of 43 peptides per plasmid; however, despite binding of the conjugates to importin α, no increase in gene expression was observed (*10*).

A strategy to prevent loss of gene expression is to attach NLS peptides to DNA at specific locations using peptide nucleic acid (PNA) molecules that have a repeating polyamide backbone rather than a repeating sugar−phosphate backbone and hybridize to DNA in a high-affinity and sequence specific manner (*12*). Branden et al. recently demonstrated the utility of this approach with an 8-fold increase in transfection using PNA-NLS and 25-kDa PEI (*13*). The interaction between DNA and mono PNA is weakened under physiological conditions but has been recently overcome by the use of a homopyrimidine J-base containing bis PNA clamp that forms $(PNA)_2$DNA triplexes in a highly stable, pH-independent manner (*14*). PNA clamps have so far been used to label DNA with fluorophores, but there is potential in this approach to attach a wide range of ligands to DNA to provide specific functions without compromising transcriptional capability (*15*).

The exact conditions to successfully utilize the properties of NLS peptides to enhance nonviral gene transfer are, however, still not clear. It is unknown, for example, what type or length of NLS peptide is best suited for this application and NLS sequences that bind to a range of transport receptors, including importin β1 or transportin 1, have not been thoroughly investigated. The aim of the present study was to help define the requirements for successful NLS-enhanced transfection by comparing the ability of a panel of NLS peptides to enhance nonviral gene delivery. Two different strategies for incorporating NLS peptides in nonviral vectors were evaluated. In the first, NLS peptides were linked to DNA in a site-specific manner via an intracellularly stable thioether bond formed between a maleimide-labeled PNA clamp and a cysteine residue at the carboxy terminal of each peptide. The ability of NLS peptide-PNA/DNA conjugates to bind to their intracellular transport receptor and promote levels of gene expression was then examined. In the second strategy, the cationic nature of NLS peptides was utilized by investigating their ability to condense plasmid DNA into discrete particles and mediate transfection.

EXPERIMENTAL PROCEDURES

Materials. Peptides were synthesized by Severn Biotech Ltd (Kidderminster, UK) using standard fmoc chemistry with the following sequences: PKKKRKVEDPYC (SV40 T NLS) and SSDDEATADSQHSTPPKKKRKVEDPYC (Ext SV40 T NLS) containing the wild-type SV40 large T NLS, PKTKRKVEDPYC (mSV40 T NLS) and SSDDEATADSQHSTPPKTKRKVEDPYC (Ext mSV40 T NLS) containing a mutant SV40 large T NLS, MPKTRRRPRRSQRKRPPTPWAHFPGFGQSLC (HTLV) from the human T cell leukaemia virus type 1 Rex protein, GNQSSNFGPMKGGNFGGRSSGPYGGGGQYFAKPRNQGGYC (M9) from heterogeneous ribonucleoprotein A1, and a scrambled version SPGNRMGAGYFKGSGNKSGFQGRNPGSGQGYGPNQGFYGC (Scr M9). Oligonucleotides containing either one, three, or five copies of the PNA binding site (AGAGAGAG) were purchased from Alta Bioscience (University of Birmingham, Birmingham, UK) and inserted into the KpnI-MluI cloning site of pGL3con (Promega). The sequence of oligonucleotides containing PNA-binding sites for pGL3con constructs were 5′-CGATATCCAGCTGTCTCTCTCTCA-3′ (one site), 5′-CGATATCCTTAAGCTCTCTCTCTCTCTCTCTCTCTCTA-3′ (three sites), and 5′-CGATATCCTTAAGCTCTCTCTCTCTCTCTCTCTCTCTCTCTCTCTCTCTA-3′ (five sites). A bis PNA clamp of sequence TCTCTCTC−O−O−O-JTJTJTJT covalently attached at the amino terminus to biotin or maleimide was purchased from Gene Therapy Systems (San Diego, CA). J represents a pseudoisocytosine that is placed in the strand parallel to the DNA forming the "Hoogsteen strand", and O represents an 8-amino-3,6-dioxaoctanoic acid linker.

Preparation of Importin- and Transportin-GST Fusion Proteins. Importin α-GST and importin β-GST were grown from pGEX-2T plasmids (kindly provided by Y. Yoneda, Osaka University, Japan) and transportin 1 from a pGEX-5X plasmid (a kind gift from G. Dreyfuss, University of Pennsylvania) as previously described (*16*, *17*). Proteins were expressed in BL21 (DE3) cells and induced with 1 mM IPTG for 18 h at 20 °C (importins) or 17 °C (transportin 1). Cells were harvested by centrifugation and disrupted by freeze thawing followed by sonication. Fusion proteins were recovered from cleared bacterial lysate using glutathione−sepharose (Pharmacia) according to the manufacturer's instructions. Purified proteins were dialyzed against 20 mM HEPES−NaOH pH 7.3, 100 mM potassium acetate, 2 mM DTT containing 0.5 μg/mL protease inhibitor cocktail (Sigma). Purity of proteins was assessed by Coomassie staining following SDS−PAGE and Western blotting using an anti-GST antibody (Pharmacia).

Interaction of NLS Peptides with Transport Receptors. Binding of NLS peptides to transport receptors was measured by ELISA similar to that previously described (*17*). Maxisorp 96-well plates were coated with peptide (41.9 pmol for SV40 peptide, 41.8 pmol for Ext SV40 peptide, 33.5 pmol for HTLV peptide, and 30.9 pmol for M9 peptide) in 50 mM $NaHCO_3$ pH 9.8 at 4 °C overnight. After blocking with intracellular buffer (IB; 110 mM KCl, 5 mM $NaHCO_3$, 5 mM $MgCl_2$, 1 mM EGTA, 0.1 mM $CaCl_2$, 20 mM HEPES−NaOH pH 7.4, 1 mM DTT, 5 μg/mL protease inhibitor cocktail) containing 5% BSA, plates were incubated at 4 °C overnight with 12.5 nM transport receptor-GST or GST alone in IB/1% BSA. After washing the plate three times, the primary antibody goat anti-GST was applied for 2 h at 1/1000 dilution in IB/1% BSA. The plate was again washed three times and incubated with HRP-labeled rabbit anti-goat antibody (1/1000 in IB/1% BSA) for 2 h. After a further three washes, the plates were incubated with OPD substrate for 20 min and the reaction stopped by addition of 50 μL of 4 M sulfuric acid. The absorbance at 490 nm was measured using a Victor multilabel plate reader and background readings subtracted.

Preparation and Analysis of PNA/DNA Conjugates. PNA-biotin was vortexed for 2 min and heated at 55 °C for 15 min then added to plasmid DNA in PNA binding buffer (10 mM sodium phosphate buffer pH 7, 1 mM EDTA, 20 mM NaCl) and incubated at 37 °C for 24 h. Conjugate formation was assessed using streptavidin-Texas Red (Molecular Probes) to probe for bound PNA-biotin. In brief, PNA-biotin/DNA conjugates were restricted with KpnI and HindIII, purified using Sephadex G-25 spin columns (Pharmacia) and incubated with a 10-fold molar excess of streptavidin-Texas Red in the presence of 200 mM NaCl at room temperature for 30 min. Following gel electrophoresis on a 1.6% agarose gel in ethidium bromide-free conditions, the presence of Texas Red-labeled DNA was detected using a Typhoon gel scanner (Molecular Dynamics, λ_{ex} 633 nm, λ_{em} 610 nm, 800 V). Gels were also stained in ethidium bromide

solution (0.5 μg/mL) for 20 min and DNA fragments visualized using the Typhoon gel scanner (λ_{ex} 532 nm, λ_{em} 526 nm, 550 V). The signal intensity of particular bands was quantified using ImageQuant software. PNA-maleimide was conjugated to plasmid DNA by incubating at 37 °C for 2 h in PNA binding buffer.

Characterization of NLS Peptides. Cysteine-terminated NLS peptides were incubated with Texas-Red maleimide for 3 h in the dark, and reaction products analyzed on 16.5% Tris-Tricine SDS PAGE. Samples (0.5−20 μg of peptide) were loaded in sample buffer (2% SDS, 10% glycerol, 62.5 mM Tris.-HCl pH 6.8, 0.05% bromophenol blue) and were not heated prior to loading. Gels were scanned to detect Texas Red fluorescence using the Typhoon gel scanner (λ_{ex} 633 nm, λ_{em} 610 nm, 800 V).

Preparation of NLS Peptide-PNA/DNA Conjugates and Binding to Transport Receptors. PNA-maleimide/DNA conjugates were purified using Sephacryl S-500HR spin columns and incubated with a 20-fold molar excess of cysteine-terminated NLS peptides in 1 M NaCl for 1 h at room temperature followed by 2 h at 4 °C. The NLS peptide-PNA/DNA conjugates were then purified by ethanol precipitation and resuspended in water, and the amount of DNA was quantified by a fluorimetric assay using Hoechst dye (Sigma). Linear DNA conjugates were prepared by restriction digest using the enzymes KpnI and BamHI and purified by ethanol precipitation, and the amount of DNA was quantified using the Hoechst dye assay.

Binding of NLS/DNA conjugates to transport receptor-GST was measured using an in vitro binding assay similar to that described previously (*10*), whereby transport receptor-GST was immobilized on glutathione−sepharose and the extent of NLS peptide-PNA/DNA binding measured. Briefly, 20 μL of glutathione−sepharose slurry was washed three times in 100 μL of binding buffer (20 mM HEPES−NaOH pH 6.8, 150 mM potassium acetate, 2 mM magnesium acetate, 1 mM EGTA, 5 mM $MgCl_2$) containing 100 μg/mL BSA and incubated with 25 nmol transport receptor-GST in a total volume of 100 μL for 2 h at room temperature with end-over-end rotation. Beads were washed three times in binding buffer containing 1% BSA and then incubated with 0.5 μg of NLS peptide-PNA/DNA or DNA in binding buffer containing 1% BSA, again in a total volume of 100 μL for 2 h at room temperature with rotation. After washing three times, the beads in a volume of 100 μL of binding buffer/1% BSA were assayed for the presence of DNA by addition of 100 μL of PicoGreen (Molecular Probes, 1 in 200 dilution in TE buffer (10 mM Tris-HCl pH 8, 1 mM EDTA)) to samples in 96-well plates. After 2−5 min incubation in the dark, the fluorescence was measured using the Victor plate reader (λ_{ex} 485 nm, λ_{em} 535 nm for 10 s). A DNA standard curve, also containing glutathione−sepharose beads, was included and the amount of DNA bound to the transport receptor was calculated for each sample.

Formation of NLS Peptide/DNA Polyplexes. NLS peptide/DNA polyplexes were formed in water by the addition of the appropriate amount of NLS peptide to 20 μg/mL DNA, mixed and incubated at room temperature for 20 min prior to use. The ethidium bromide condensation and agarose gel retardation assays were used to assess polyplex formation. Briefly, fluorescence of a 10 μg/mL DNA solution with 400 ng/mL ethidium bromide added was measured at λ_{ex} 532 nm, λ_{em} 610 nm using a fluorimeter (PerkinElmer, LS-50B). NLS peptides were added in small increments and the fluorescence measured. Background fluorescence from ethidium bromide alone was subtracted and the N:P ratio of NLS peptide to DNA was plotted as a percentage of the fluorescence in the absence of peptide. In the gel retardation assay DNA was incubated with NLS peptide or PLL in the range N:P of 0 to 10 prior to analysis by agarose gel electrophoresis in the presence of 50 μg/mL ethidium bromide.

Maintenance and Passage of Mammalian Cells in Culture. The human cervical carcinoma cell line HeLa was grown in RPMI containing 1 mM glutamine, glucose (1 g/L) and 10% foetal calf serum (FCS). The PC-3 human prostatic carcinoma cell line was grown in DMEM supplemented with 1 mM glutamine, glucose (1 g/L) and 10% FCS.

Transfection Studies. Cells were seeded at 30 000 cells per well in 48-well plates 24 h prior to transfection. In some experiments, NLS peptide/DNA polyplexes at a N:P ratio of between 1:1 and 10:1 were used to transfect cells and in others, a reducible polycation (RPC) was used in combination with the lipid DOTAP as the transfection agent as previously described (*18*). Briefly, the RPC was added to 50 μg/mL DNA solution at an N:P ratio of 2:1 and incubated at room temperature for 20 min. DOTAP was added at a (w/w) ratio of 5:1 to DNA in 7.5 mM HEPES−NaOH pH 7.4 and complexes incubated at room temperature for a further 30 min before use. Unless stated otherwise, 0.5 μg of DNA was added per well. Cells were incubated in serum-free medium at 37 °C for 2.5 h in the presence or absence of 100 μM chloroquine. The media was replaced with media containing 10% FCS, and the cells were cultured for a total of 8−24 h prior to analysis of reporter gene expression.

Analysis of Reporter Genes. Luciferase expression following transfection was measured by a luminescence assay using cell lysates. The culture media was discarded, and cell lysates were harvested after freeze−thawing cells in 100 μL of lysis buffer. The lysate was gently vortexed, and 20 μL diluted into 100 μL of luciferase reaction buffer (20 mM glycylglycine, 1 mM $MgCl_2$, 0.1 mM EDTA, 3.3 mM DTT, 0.5 mM ATP, 0.27 mM coenzyme A lithium salt). The luminescence was integrated over 10 s on a Lumat LB9507 (Berthold Instruments, UK), and the results were expressed as relative light units (RLU) per mg of cell protein, as determined using the Advanced Protein Assay (Totam Biologicals, Northampton, UK).

MTS Assay for Cell Viability. Cells were seeded at 5000 per well in a flat-bottomed 96-well plate 24 h prior to the experiment. Following transfection (0.25 μg of DNA per well), the medium was changed and 20 μL of MTS reagent (Promega) added per well. Plates were incubated at 37 °C for 5 h prior to measuring the absorbance at 490 nm. Background absorbance was subtracted, and the results were plotted as percentage cell viability.

RESULTS

NLS Peptides Used in Study. Three different types of NLS peptides were used in this study. Peptides SV40 and Ext SV40 were derived from the SV40 T antigen sequence that binds to importin α1, while control peptides mSV40 and Ext mSV40 contained the K128T mutation reported to abolish NLS function (*19*, *20*). The HTLV peptide is a 31 amino acid sequence from the amino terminus of the HTLV Rex posttranscriptional regulatory protein that has previously been identified as mediating nuclear import by direct interaction with importin β1 (*21*). The 38 amino acid peptide M9 was

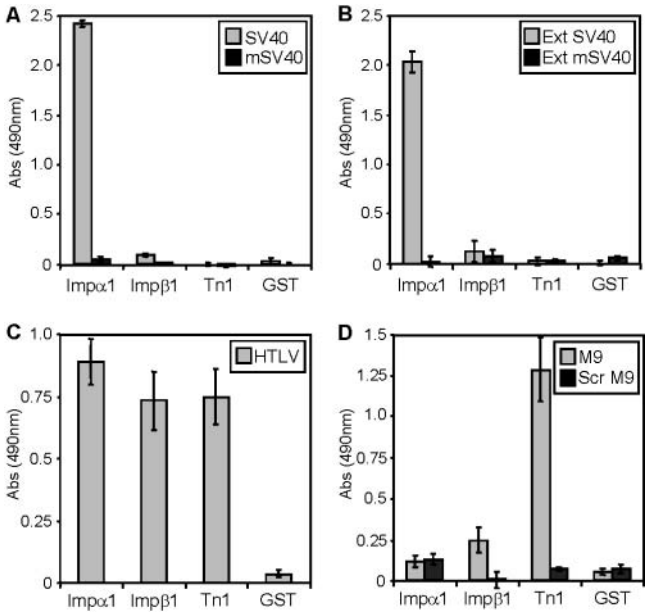

Figure 1. Binding of NLS peptides to transport receptors. 96-well plates were coated with 30−40 pmol/well of the (A) SV40 peptide, (B) Ext SV40 peptide, (C) HTLV peptide, or (D) M9 peptide in 50mM $NaHCO_3$ at 4 °C overnight. After blocking with intracellular buffer containing 5% BSA, plates were incubated with 12.5 nM transport receptor-GST or with GST alone. The presence of the transport receptor was detected using goat anti-GST antibody, HRP-labeled anti-goat and OPD substrate. The absorbance at 490 nm was measured and background subtracted. In panels A, B, and D binding of mutated (mSV40, Ext mSV40) and scrambled (Scr M9) peptides to transport receptors were also determined. Results are shown as a mean and standard deviation from at least three samples.

derived from heterogeneous ribonucleoprotein A1 reported to bind transportin 1, and a scrambled version of this peptide was used as a control peptide. The amino acid sequences of these peptides are shown in Table 1. For all peptides a cysteine residue was included at the carboxy terminus to enable attachment to PNA-maleimide/DNA conjugates.

Binding of NLS Peptides to Intracellular Transport Receptors. The nature of the interaction of NLS peptides with a range of intracellular transport receptors was determined using an ELISA-based assay with purified GST fusion proteins and an anti-GST antibody. Significant binding to importin α1 was observed with the SV40 (Figure 1A) and Ext SV40 (Figure 1B) peptides but not the M9 peptide or the control peptides mSV40 and Ext mSV40. Unexpectedly, the HTLV peptide bound at similar levels to importin α1, importin β1 and transportin 1 (Figure 1C). However, the HTLV peptide bound only weakly to GST alone, indicating some degree of specificity for the interaction. The M9 peptide exhibited a strong interaction with transportin 1, its known receptor, whereas

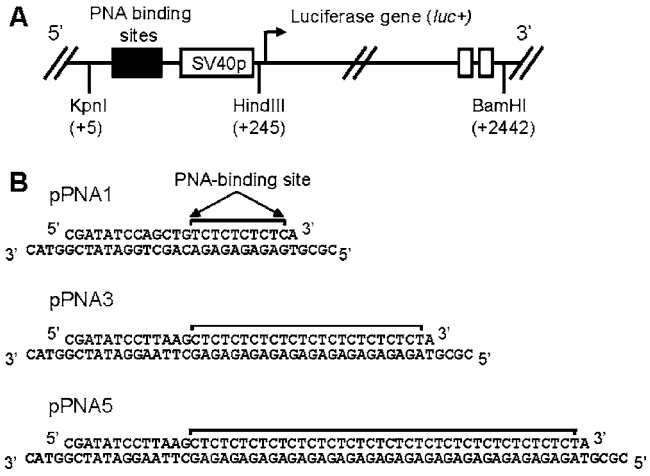

Figure 2. Schematic showing PNA binding sites used in study. (A) Relative location of oligonucleotides containing PNA binding sites inserted into the luciferase expression vector pGL3con (Promega). The relative positions of the SV40 promoter (SV40p), transcription start point and three restriction sites (Kpn1, HindIII, and BamH1) are indicated. (B) Sequences of oligonucleotides containing between one and five PNA binding sites used in study. The sequence of the PNA binding site within each oligonucleotide is highlighted and the name of the resultant plasmid DNA construct given (pPNA1, pPNA3 and pPNA5).

the scrambled peptide control, Scr M9, did not bind (Figure 1D). A significant interaction was also observed between the M9 peptide and importin β1 ($p < 0.05$), although at 5-fold lower than with transportin-1. These data demonstrates that the NLS peptides are capable of binding to intracellular transport receptors in vitro with different degrees of interaction and specificity. The ability of these NLS peptides to enhance delivery of plasmid DNA was therefore next investigated.

Characterization of PNA/DNA Conjugates. In the first strategy to utilize NLS peptides for gene delivery, PNA/DNA conjugates were prepared and characterized prior to attachment of NLS peptides. The requirements for efficient binding of the PNA to DNA were examined using constructs based on the plasmid pGL3con containing one, three, or five copies of the PNA binding sequence AGAGAGAG inserted immediately upstream of the SV40 promoter. Figure 2 shows the relative location and sequence of PNA binding sites inserted into pGL3con. These constructs were incubated with PNA-biotin and the presence of bound PNA-biotin probed using Texas-Red labeled streptavidin. Comigration of streptavidin Texas-Red with DNA following electrophoresis demonstrated significant binding of PNA-biotin to constructs containing three or five copies of the PNA binding site (Figure 3A). By comparison, there was no significant binding of PNA-biotin to DNA without any binding sites (Figure 3A) or to constructs containing only one binding site (data not shown). The interaction between PNA and plasmid DNA was investigated in more detail by restriction of PNA-biotin/DNA conjugates with KpnI and HindIII, generating DNA fragments of either 277 bps (containing three PNA sites) or 293 bps (containing five PNA sites). Probing for PNA-biotin with streptavidin Texas-Red showed that PNA-biotin bound specifically to the PNA binding site, as only short DNA fragments (<300 bps) were labeled with Texas-Red and not the rest of the plasmid DNA (>5 kb) without any known PNA-binding site (data not shown). Binding of streptavidin Texas-Red to PNA-biotin also resulted in retardation of the shorter DNA fragments producing discrete bands. For example, addition of streptavidin Texas-Red to the DNA

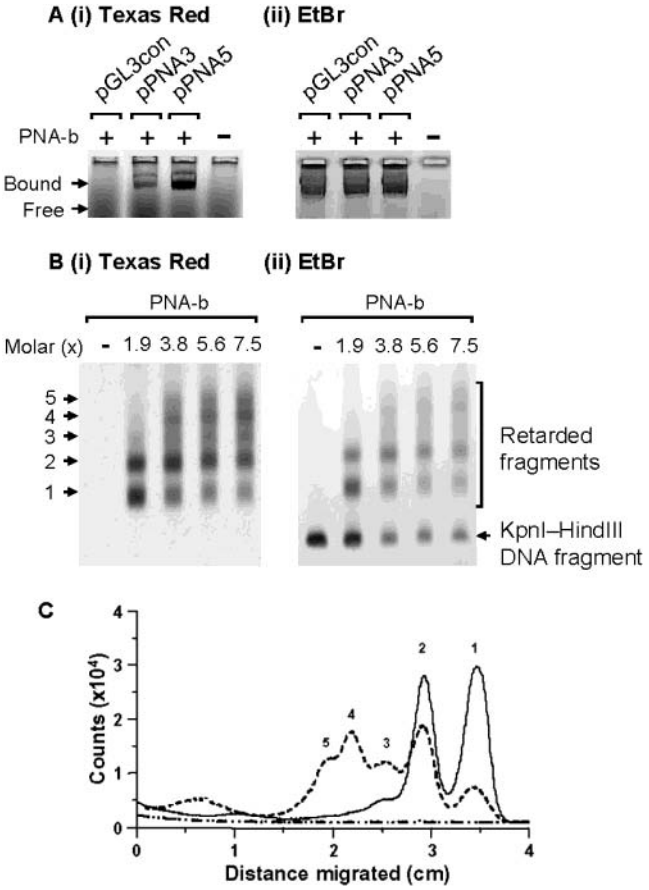

Figure 3. Characterization of PNA/DNA conjugates. (A) PNA-biotin (PNA-b) was added to pGL3con (Lane 1), pPNA3 (Lane 2), and pPNA5 (Lane 3) at a 7.5−12.5 molar excess, incubated at 37 °C for 24 h, and a 10-fold molar excess of streptavidin Texas-Red added in 200 mM NaCl for 30 min. Samples were run on a 0.8% ethidium bromide (EtBr)-free agarose gel and conjugate formation assessed by scanning for (i) Texas Red fluorescence on a Typhoon fluorimager. The gel was then stained in (ii) 50 μg/mL EtBr and scanned for the presence of DNA. Lane 4 (−) contains streptavidin-Texas Red alone with no DNA present. (B) The PNA-b/pPNA5 conjugate was prepared as in (A) using 1.9 to 7.5 molar excess of PNA-b and restricted with KpnI and HindIII prior to addition of streptavidin-Texas Red. Samples were run on a 1.6% agarose gel for 3 h and visualized for (i) Texas Red and (ii) EtBr fluorescence as in (A). Restriction fragment of 293 bp is shown only. (C) Analysis of agarose gel from (B) using ImageQuant software with image density plotted as a function of distance migrated. The peaks numbered 1 to 5 are indicated, and the lines represent using PNA-b at a molar excess of 1.9 (intact) and 7.5 (dashed).

fragment containing five copies of the PNA binding site produced five distinct bands with reduced electrophoretic mobility (Figure 3B and 3C). Similarly, plasmids containing three copies of the PNA binding site gave three retarded bands in the presence of streptavidin Texas-Red (data not shown). These retarded bands most likely indicate that an increasing number of PNA-biotin molecules are bound to each plasmid.

The amount of PNA-biotin used correlated with the intensity of Texas-Red fluorescence in retarded bands, reflecting the level of PNA-biotin bound to the DNA. For example, two major retarded bands were observed using the DNA fragment containing five PNA-binding sites with PNA-biotin at a molar excess of 1.9, whereas five distinct bands of reduced intensity were observed using 4-fold more PNA-biotin (Figures 3B and 3C). The proportion of DNA bound by PNA-biotin was determined by quantifying the ethidium bromide fluorescence of free DNA (Table 2). These results indicated that approximately 80% of plasmid DNA containing five PNA binding sites was bound by PNA-biotin when 7.5 molar excess was used. In contrast, only 25% of plasmid DNA containing three PNA binding sites was bound to PNA-biotin at a molar excess of 12.5. Altogether these results indicate that while PNA bound specifically to plasmids containing three copies of the PNA binding site, at least five binding sites were required to achieve an appropriate level of PNA/DNA conjugation that might prove useful for gene delivery applications.

Table 2. Efficiency of PNA Binding to DNA

construct	PNA-b[a]	%DNA bound[b]
pPNA1	37.5	1.7
pPNA3	3.13	12.1
pPNA3	12.5	18.0
pPNA5	1.88	15.7
pPNA5	7.5	79.4

[a] Molar excess of PNA-biotin added to DNA. [b] Percentage of DNA bound by PNA-b determined by measuring ethidium bromide fluorescence of free DNA.

Preparation and Characterization of NLS Peptide-PNA/DNA Conjugates. To determine the reactivity of terminal cysteine residues the SV40 and Ext mSV40 peptides were incubated with Texas-Red maleimide and reaction products analyzed by Tris-Tricine SDS-PAGE. Two major bands were observed corresponding to the fluorescently labeled NLS peptide and free Texas-Red maleimide (Figure 4A, lane 2i,ii). Increasing the amount of peptide used from 1 to 20-fold molar excess (Figure 4A, lanes 2−4i,ii) resulted in complete loss of free Texas-Red maleimide and more labeled NLS peptide. Similar results were obtained with all of the cysteine terminated NLS peptides (data not shown). On the basis of these results a 20-fold molar excess of NLS peptide to PNA-maleimide was subsequently used in conjugation reactions.

The next step was to attach NLS peptides directly to the PNA/DNA conjugates. However, the NLS peptides used in this study are cationic, containing lysine and arginine residues, and are capable of binding nonspecifically to DNA by electrostatic interaction. To overcome this problem NLS peptide-PNA-maleimide/DNA conjugates were prepared by incubating PNA-maleimide/DNA conjugates with a 20-fold molar excess of each NLS peptide in 1M NaCl. Unreacted peptide was then removed by ethanol precipitation. To verify conjugate formation and removal of free peptide, PNA-maleimide/DNA conjugates were labeled with an N-terminal FITC-labeled HTLV peptide and restricted to release a 293 base pair fragment. Analysis of the restriction fragments by gel electrophoresis demonstrated that fluorescence of the NLS peptide was only associated with DNA fragments containing the PNA binding sites and not with the rest of the plasmid (Figure 4B). Using an agarose gel-based assay to generate a peptide standard curve with FITC-labeled HTLV peptide, it was estimated that on average 1.26 NLS peptides were bound to each plasmid (data not shown). However, as the PNA was bound to 80% of the DNA, this figure was recalculated to an average of 1.6 copies of the NLS peptide bound to 80% of the DNA. These results demonstrate that site-specific conjugation between NLS peptides and the PNA-maleimide/DNA conjugates was achieved.

In Vitro Biological Activity of NLS Peptide-PNA/DNA Conjugates. The biological activity of NLS peptide-PNA/DNA conjugates was evaluated by their ability to bind to intracellular receptors and transfection activity

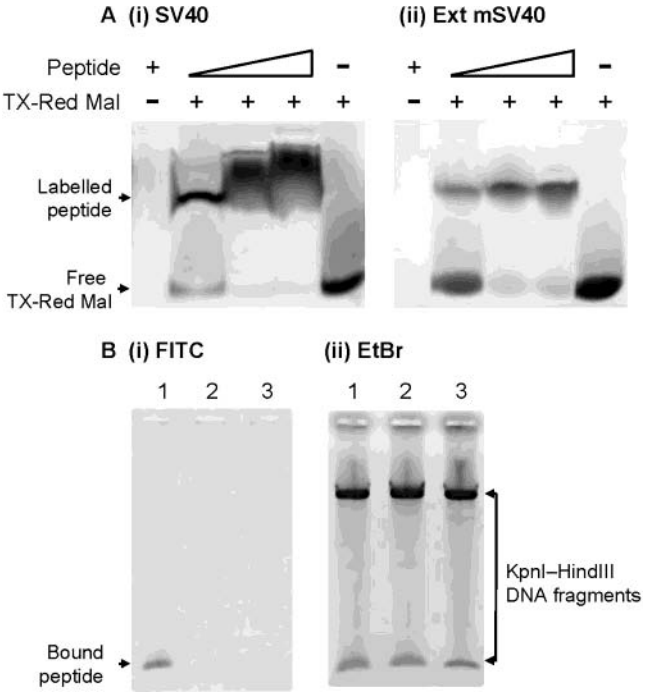

Figure 4. Conjugation of NLS peptides to PNA/DNA. (A) NLS peptides (i) SV40 and (ii) Ext mSV40 were incubated with Texas-Red maleimide (TX-Red mal) for 3 h, analyzed on a 16.5% Tris-Tricine SDS−PAGE gel and scanned using a Typhoon fluorimager at λ_{ex} 633 nm, λ_{em} 610 nm. NLS peptides were added at 1-, 10-, and 20-fold molar excess. Positions of labeled peptides and free TX-Red mal are indicated. (B) NLS peptide-PNA/DNA conjugates were prepared as previously described using either PNA-maleimide (lane 1), PNA-biotin (lane 2) or no PNA (lane 3), and a FITC-tagged HTLV peptide. The conjugates were then restricted with KpnI and HindIII and samples run on a 1.6% ethidium bromide (EtBr)-free agarose gel. The peptide was detected by scanning for (i) FITC using a Typhoon fluorimager at λ_{ex} 532 nm, λ_{em} 526 nm. The gel was stained in (ii) 50 μg/mL EtBr and scanned for the presence of DNA at λ_{ex} 532 nm, λ_{em} 610 nm. Specific conjugate formation was indicated by comigration of the peptide with the DNA fragment containing PNA-binding sites.

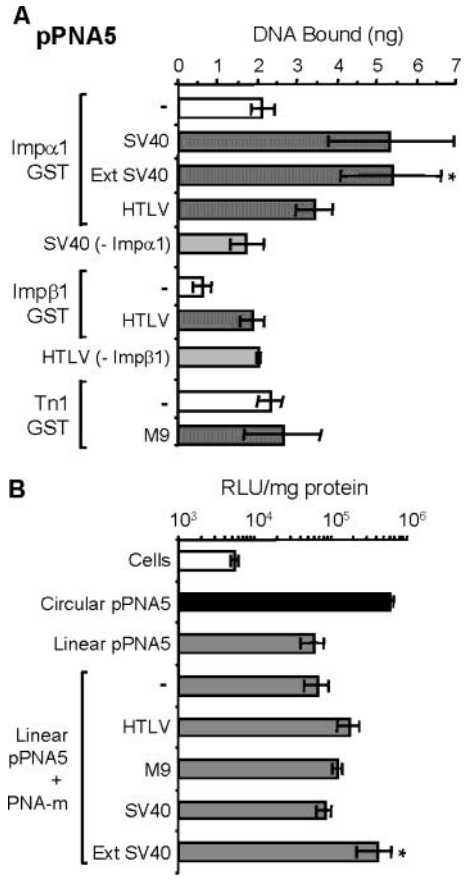

Figure 5. Biological activity of NLS peptide-PNA/DNA conjugates. (A) Binding to intracellular transport receptors. Glutathione−sepharose beads were incubated with 25 nmol of transport receptor-GST (Impα1-importin α1, Impβ1-importin β1, and Tn1-transportin 1) as indicated for 2 h, washed in NLS buffer/1% buffer, and incubated with 0.5 μg of NLS peptide-PNA-maleimide/pPNA5 for 2 h at room temperature. The picogreen assay was used to determine the amount of DNA bound to beads. In control experiments the transport receptor-GST was omitted (−) as indicated. Significant difference was observed between Ext SV40−PNA/DNA conjugates and DNA alone (*p < 0.05). (B) Transfection activity of linear NLS peptide-PNA/pPNA5 conjugates. HeLa cells were transfected with 0.25 μg of 2491 bp linear DNA fragments generated from NLS peptide-PNA/DNA conjugates using RPC/DOTAP as delivery vector. Luciferase expression was assayed after 24 h and normalized to protein concentration. Significant difference was observed between Ext SV40−PNA/DNA conjugates and DNA alone (*p < 0.035). Results are shown as a mean and standard deviation from at least three samples.

in HeLa cells. Using an in vitro binding assay based on GST-receptor fusion proteins bound to glutathione−sepharose beads, approximately 5 ng of SV40 and Ext SV40−PNA/DNA conjugates (p < 0.05) and 3.5 ng of the HTLV−PNA/DNA conjugate (p = 0.0123) bound to importin α1-GST, compared to 2 ng with DNA alone (Figure 5A). In contrast, there was no significant binding observed with the HTLV−PNA/DNA conjugate to importin β1 or the M9-PNA/DNA conjugate to transportin 1-GST. Previous studies have indicated that NLS peptides attached to linear DNA molecules enhance nuclear delivery (*9*). Therefore, NLS peptide-PNA/DNA conjugates were restricted with KpnI and BamHI to generate linear DNA molecules of 2491 base pairs prior and their transfection ability assessed. Transfection of HeLa cells using 0.25 μg of DNA with a reducible polycation/DOTAP delivery system (*18*) showed that reporter gene expression of unmodified linear DNA was 10-fold less than intact circular DNA after 24 h (Figure 5B). Attachment of the Ext SV40 peptide to the PNA/DNA conjugate mediated a significant 7-fold increase in transgene expression (p = 0.035) compared to linear DNA and PNA/DNA controls. There were no significant improvements in gene expression observed using any of the other NLS peptides. These results indicate that biological activity of linear DNA can be enhanced by linkage of NLS peptides using PNA technology but it is dependent on the type of NLS peptide used.

Polyplex Formation Using NLS Peptides. A second strategy to enhance gene delivery was investigated using NLS peptides to condense plasmid DNA into discrete particles and mediate transfection in mammalian cells. The ability of NLS peptides to condense DNA was examined using the ethidium bromide condensation and agarose gel retardation assays. Two different controls were used, an oligolysine peptide consisting of 18 lysine residues (K18) and a 7.5 kDa PLL polymer (PLL). K18 was of similar molecular weight to the smaller NLS peptides such as the SV40 peptide, whereas PLL was used as a control for larger peptides resulting from any dimerization of NLS peptides via disulfide bridges between the terminal cysteine residues. Plasmid DNA was efficiently condensed by PLL (Figure 6A) and K18 (data not shown) with an almost complete loss of fluorescence (~90%) at an N:P ratio of between 1 and 2. The HTLV

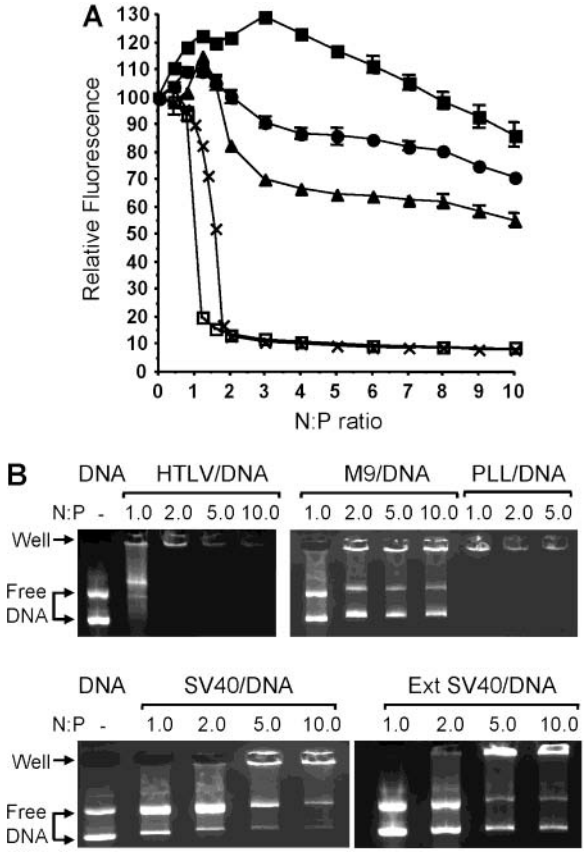

Figure 6. Polyplex formation using NLS peptides. (A) EtBr condensation assay with the following peptides: M9 (filled squares), Ext SV40 (filled circles), SV40 (filled triangles), HTLV (crosses), and PLL 7.5kDa (empty squares). Results are shown as a mean and standard deviation from at least three samples. (B) Agarose gel electrophoresis of plasmid DNA complexed with the indicated NLS peptide at N:P ratios of 1.0, 2.0, 5.0, and 10.0. The control lane (−) contains plasmid DNA alone. The relative locations of wells and free DNA are indicated.

peptide also produced a similar reduction in fluorescence at an N:P ratio of 2 to 3. In contrast, the SV40, Ext SV40 and M9 peptides were relatively poor at condensing DNA with only a 15−40% reduction in fluorescence at an N:P ratio of between 5 and 10. Similar trends were observed using the agarose gel retardation assay where DNA was retained in the wells at an N:P ratio of 1 to 2 with PLL (Figure 6B), K18 (data not shown), and HTLV peptides (Figure 6B), whereas free DNA was still observed with the SV40, Ext SV40, and M9 peptides even at an N:P ratio of 10. These results indicate that the HTLV peptide was the only NLS peptide capable of fully condensing DNA. Photon correlation spectroscopic analysis provided additional evidence that the HTLV peptide efficiently condensed plasmid DNA with polyplexes observed less than 90 nm in diameter at an N:P ratio of 10 (data not shown).

Transfection Activity of NLS Peptide/DNA Polyplexes. PC-3 cells were transfected with NLS peptide/DNA polyplexes formed at an N:P ratio of 10 and luciferase gene expression assayed after 24 h to determine transfection activity (Figure 7A). No significant gene expression was observed using polyplexes formed with the SV40, Ext SV40, or M9 peptides in the presence of 100 μM chloroquine compared to cells alone (Figure 7A). This result was most likely due to the inability of these peptides to condense DNA. In contrast, HTLV/DNA polyplexes mediated levels of gene expression (1.4×10^6 RLU/mg protein) that were approximately 186-fold higher

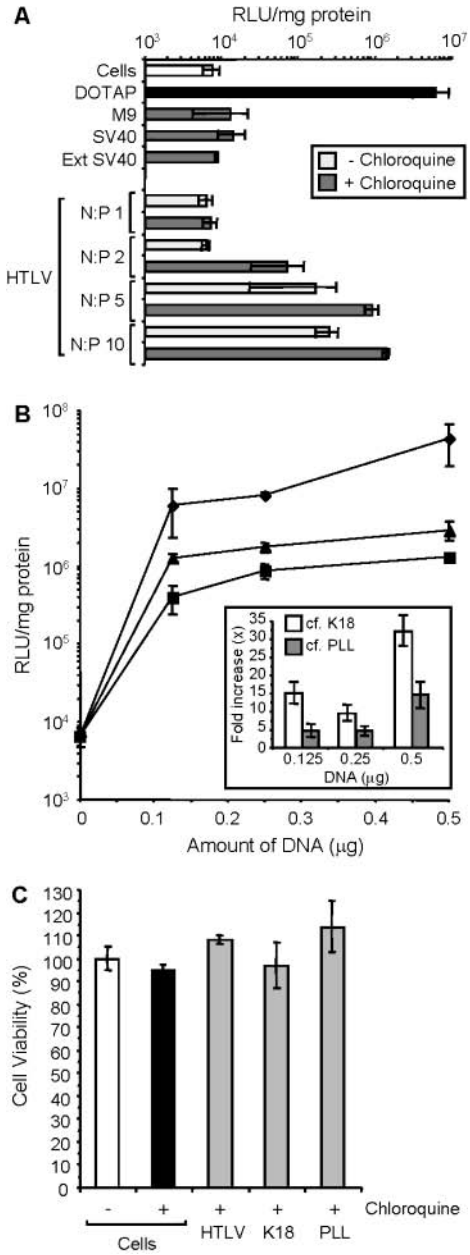

Figure 7. Transfection activity of NLS peptide-based polyplexes. (A) PC-3 cells were transfected with 0.5 μg pGL3con complexed with M9, SV40, Ext SV40, and HTLV peptides at an N:P ratio of 10, unless otherwise indicated, in the absence (light gray bars) or presence (dark gray bars) of 100 μM chloroquine. DOTAP/DNA complexes (black bar) were used as the positive control. (B) PC-3 cells were transfected with either 0, 0.1, 0.25, or 0.5 μg of pGL3con complexed with HTLV peptide (filled diamonds), PLL 7.5 kDa (filled triangles), and K18 (filled squares) at an N:P ratio of 10 in the presence of 100 μM chloroquine. The fold differences in levels of expression achieved using the HTLV peptide compared to PLL (grey bars) or K18 (empty bars) are shown in the inset. Luciferase expression was assayed 24 h after transfection and normalized to protein concentration as in (A). (C) Cytotoxicity of NLS peptide-based polyplexes. PC-3 cells were incubated for 5 h with 0.5 μg of pGL3con complexed with the HTLV peptide, K18, and PLL 7.5 kDa at an N:P ratio of 10 in the presence of 100 μM chloroquine. MTS reagent was then added to the cells and the absorbance at 490 nm measured. Results are shown as a mean and standard deviation from at least three samples.

than cells alone. In the absence of chloroquine, significant levels of reporter gene expression (2.5×10^5 RLU/mg protein) were still observed but were 5.6-fold lower indicating the requirement for the endoosmolytic reagent.

Similar levels of expression were observed using HTLV/DNA polyplexes formed at an N:P ratio of 5. However, no transgene expression was observed at an N:P ratio of 1, reflecting the incomplete condensation of DNA at this N:P ratio.

The transfection activity of HTLV/DNA polyplexes was also compared against those formed with K18 and PLL, which are both capable of condensing DNA efficiently. Measurement of luciferase expression 24 h after transfection demonstrated that the HTLV peptide mediated levels of transgene expression approximately 4.7−14.7-fold greater than PLL and 9.6−32.3-fold greater than K18 depending on the amount of DNA used (Figure 7B). This difference was not due to cellular toxicity as viability assays showed that there was no toxicity observed using any of the NLS peptides (Figure 7C). Altogether these results indicate that HTLV-based polyplexes mediate efficient transfection of cells at levels that are significantly higher than those achieved with polyplexes based on PLL of similar molecular weight.

DISCUSSION

A number of cellular barriers restrict transgene expression but inefficient transfer of DNA from the cytoplasm to the nucleus has been identified as the major contributory factor with only 0.1% of naked DNA or 1% of polyplex DNA reaching the nucleus following microinjection into the cytoplasm (*22*). A common strategy to enhance nuclear delivery of DNA has been to incorporate synthetic NLS peptides into gene delivery vectors that bind intracellular transport receptors, such as importin α, and utilize the highly efficient physiological protein nuclear import pathways. Many of these approaches have however met with limited success (*10*, *11*, *23*, *24*), although one study reported a 10−1000-fold increase in gene expression (*9*). The aim of the present study was to facilitate the development of NLS-based vectors by helping to identify the requirements for NLS-enhanced transfection, including the type of NLS peptide, morphology of DNA and method of incorporating the NLS peptide.

Two different strategies using a range of NLS peptides were evaluated in order to enhance nonviral gene delivery. In the first approach we inserted PNA-binding site oligonucleotides into the plasmid pGL3con and demonstrated site-specific conjugation of NLS peptides via a PNA-maleimide clamp. A major advantage of this approach was that, unlike a number of previous studies (*10*, *11*), NLS peptide-modified DNA did not have diminished transcriptional capacity. In addition, we were able to show in vitro binding of the Ext SV40−PNA/DNA conjugate to an importin α1-GST fusion protein and a corresponding 7-fold increase in reporter gene expression using linear DNA. This increase in gene expression was comparable to the 2−8-fold increases observed in the majority of related studies (*8*, *13*). Whereas, there was no significant improvement in gene expression observed using other NLS peptides such as HTLV or M9.

The number of NLS peptides required to enhance nuclear delivery of DNA, whether circular or linear, is the subject of controversy with some researchers favoring a single NLS and others preferring as great a number of peptides as possible. It has been proposed that a single or cluster of NLS peptides attached to one end of linear DNA is sufficient for nuclear import and that more may actually hinder the process (*8*, *9*). This hindrance could in principle occur through multiple NLSs causing docking of the DNA to several nuclear pore complexes and has been calculated to be physically possible with DNA over 1 kb in size (*25*). In this study, a mixed population of NLS peptide-PNA/DNA conjugates was produced containing a cluster of different numbers of the NLS peptide, and it was estimated using a fluorescently tagged HTLV peptide that on average 1.26−1.6 NLS peptides were bound to each plasmid. Enhanced transfection was only observed, however, when the Ext SV40 peptide was conjugated to DNA, indicating that the type and length as well as the number of NLS peptides play an important role in promoting nuclear delivery.

Initial binding studies demonstrated a strong interaction between the NLS peptides with their corresponding intracellular receptors. In the case of the SV40 and Ext SV40 peptides, for example, this interaction was highly specific as a single mutation from a K to T residue abolished binding. Surprisingly, the HTLV peptide bound with a similar affinity to all of the receptors examined, which may have been a nonspecific interaction as this peptide is highly positively charged. Transportin 1, however, has 24% sequence homology with importin β1 (*26*) and possesses two distinct, nonoverlapping cargo-binding sites, one for M9-like sequences, and one for more basic sequences (*27*). The HTLV peptide may have therefore bound to the second cargo site on transportin 1.

A likely explanation for the lack of NLS activity observed with the HTLV and M9 peptides was their apparent loss in ability to interact with transport receptors following conjugation to DNA. There was also relatively weak binding observed between the Ext SV40−PNA/DNA conjugate and importin α1-GST fusion protein. This lack of binding was most likely due to electrostatic interaction between the negatively charged phosphate groups of DNA with the cationic NLS peptides. The positive charges of the lysine and arginine residues of many NLS peptides are critical for interaction with transport receptors, and their neutralization would likely hinder cargo recognition. Possible ways to overcome this problem include increasing the spacer length separating the NLS peptide from the DNA or to increase the number of NLS peptides attached to the DNA. Ciolina et al., for example, showed that increasing the number of SV40 NLS peptides attached to DNA from 45 to 100 also resulted in enhanced binding of DNA to importin α1-GST (*10*). An advantage of the PNA technology used in this study is the possibility to increase the number of NLS peptides attached to the DNA by insertion of additional PNA-binding sites. However, it is likely that to achieve maximum NLS-mediated transfection a balance will be required between improving the interaction of NLS peptide/DNA conjugates to transport receptors and the proposed hindrance of binding to multiple nuclear pore complexes (*9*).

An important consideration throughout this study was to fully characterize and purify NLS peptide-PNA/DNA conjugates prior to biological evaluation. The presence of unconjugated NLS peptides, for instance, may compete for binding to transport receptors. NLS peptides were therefore attached to PNA/DNA conjugates in the presence of high salt conditions to avoid nonspecific interactions and unreacted peptides removed by ethanol precipitation of the DNA. A fluorescence-based assay was also developed to analyze binding of PNA to DNA indicating that at least five binding sites were required for efficient PNA binding (>80% of DNA bound). No significant PNA binding was observed with plasmids containing just one site or to linear DNA (data not shown). Although some short PNAs can interact stably with their complementary sequence (*28*), weaker binding of PNA to linear DNA compared to circular DNA has been

previously observed by up to two to 3 orders of magnitude (*29*). In addition, secondary structure of the plasmid may hinder binding of PNA to DNA which is dependent on the exact sequence of the plasmid DNA used (*30*).

The morphology of the DNA used was also observed to be an important factor in this study to influence NLS-enhanced transfection. Initial transfection results showed a modest 2-fold increase in gene expression using the SV40 peptide attached to PNA/circular DNA (data not shown). However, the level of gene expression was enhanced to 7-fold compared to unmodified DNA when the NLS peptide-PNA/DNA conjugate was restricted with the enzymes KpnI and BamHI to produce a linear DNA molecule with the cluster of NLS peptides at one end. This is in agreement with previous studies that have shown enhanced gene expression using linear DNA with NLS peptides following ligation of an oligonucleotide−NLS conjugate (*9*) or incorporation of a modified nucleotide for chemical linkage of the NLS peptide (*8*). It is also still not clear what delivery vectors should be used with NLS peptide/DNA conjugates to properly exploit the NLS-transport pathways. Previous studies have observed enhanced gene expression with NLS peptide/DNA conjugates using cationic lipids and PEI (*9*). However, the intracellular trafficking and location of DNA release from these types of vectors are thought to differ greatly, with cationic lipids releasing DNA into the cytoplasm and PEI/DNA polyplexes remaining largely intact (*31*, *32*). PEI might even be expected to hinder NLS activity by masking the peptide and preventing interaction with transport receptors. In this study we used a reducible polycation/lipid combination that has recently been shown to facilitate release of nucleic acids into the cytoplasm and is therefore likely to promote availability of NLS peptides for interaction with transport receptors (*18*).

In the second approach we examined the ability of NLS peptides to condense DNA and mediate transfection. Of all the NLS peptides examined, the HTLV peptide was the most efficient at condensing DNA and mediated transfection at levels 5−32-fold higher than control polyplexes formed with PLL of similar molecular weight. Chloroquine potentiated the transfection activity of HTLV/DNA polyplexes by 5−10-fold, an expected result, as the HTLV peptide does not contain any lytic sequences known to mediate endosomal escape. This is the first study to the best of our knowledge that has demonstrated efficient transfection mediated by a peptide based on the HTLV sequence. The inability of the SV40 and M9 peptides to mediate transfection is probably due to the lack of positively charged amino acids in their sequence since a minimum length of six to eight cationic amino acids are known to be required to compact DNA into structures active in gene delivery (*33*). It still remains to be investigated whether the increased level of transfection observed using the HTLV peptide is NLS-mediated or due to some other mechanism. The arginine-rich sequence of the HTLV peptide is similar to many protein transduction domains (PTDs), such as that in HIV TAT (*34*), which mediate cross-membrane transfer and are also thought to have nuclear homing capacity (*35*). Therefore, it is possible that the HTLV peptide used in this study is functioning as a nuclear homing PTD.

CONCLUSION

Based on these results, a number of factors were identified that directly influence the ability of NLS peptides to enhance nonviral gene transfer. These included the type of NLS peptide, morphology of DNA, and method used to incorporate NLS peptides into nonviral vectors. Highly cationic NLS peptides such as the HTLV sequence were most effective at condensing DNA and enhanced levels of gene expression compared to polylysine controls. Peptides based on the SV40 but not the M9 and HTLV sequences were able to promote gene expression when attached to the ends of linear DNA. Proper characterization of NLS peptide/DNA conjugates was also an important consideration in evaluating the transfection capability of NLS-modified vectors. Further development of NLS-modified vectors is required before they can be used routinely; however, these results help to define the requirements for NLS-modified vector design and construction. It may also prove necessary to include additional components used by viruses to achieve effective nuclear delivery, such as the triple-stranded DNA flap for HIV-1 genome nuclear import (*36*), before more efficient nonviral delivery systems can be developed.

ACKNOWLEDGMENT

We express our gratitude to Dr. Y. Yoneda (Osaka University, Japan) for the pGEX-2T plasmids, Dr. G. Dreyfuss (University of Pennsylvania) for the pGEX-5X plasmid and Dr. L. Haynes (University of Birmingham, UK) for the GST protein. We also thank Dr. R. Grand (University of Birmingham, UK), Dr. G. McNab (University of Birmingham, UK), and Dr. D. Jans (Monash University, Australia) for useful discussions. This work was supported by grants from the Biotechnology and Biological Sciences Research Council (BBSRC) and Cancer Research UK.

Dendritic Polyglycerol Sulfates as New Heparin Analogues and Potent Inhibitors of the Complement System

Holger Türk,[†] Rainer Haag,*[,†] and Susanne Alban*[,‡]

Freiburg Materials Research Center, Albert-Ludwigs-University of Freiburg, Stefan-Meier-Strasse 21, 79104 Freiburg, Germany, and Pharmaceutical Institute, Christian-Albrechts-University of Kiel, 24118 Kiel, Germany. Received March 26, 2003; Revised Manuscript Received October 20, 2003

Due to several limitations of heparin, a widely used antithrombotic drug, there is large interest to develop alternatives. The aim of the presented study was to produce fully synthetic highly branched heparin mimetics. For this purpose, a new type of 'treelike' polysulfated polymers based on dendritic polyglycerol was synthesized. An efficient synthetic approach has been chosen to prepare several polyglycerol sulfates with different molecular weights as well as a polyglycerol carboxylate analogue and to evaluate them for their anticoagulant and anticomplementary activities. In contrast to the nonderivatized and the carboxylated polyglycerols, the polyglycerol sulfates prolong the activated partial thromboplastin time (APTT) and thrombin time (TT) and inhibit both the classical (CCA) and alternative complement activation (ACA). Whereas their anticoagulant activity in the APTT and in the TT amounts to 5.7−8.1% and 15.7−33.6%, respectively, of that of unfractionated heparin (UFH), their CCA and ACA inhibitory activity is 13.4−23.9 and 2.7−3.7 times, respectively, higher. In contrast to sulfated polysaccharides, the activities are not clearly dependent on the molecular weight, which might be due to the globular 3D-structure of the dendritic molecules. Due to the coherence between coagulation, complement activation and inflammation in the pathophysiology of numerous diseases, polyglycerol sulfates with both anticoagulant and anticomplementary activities represent promising candidates for the development of potential drugs.

INTRODUCTION

Although the glycosaminoglycan *heparin* has been the drug of choice in the prevention and treatment of thromboembolic disorders for nearly 70 years, there is large interest to find alternatives to both unfractionated heparin (UFH[1]) and low molecular weight heparins (LMWH). Beside well-documented clinical limitations (*1*), some disadvantages of heparin are based on its natural origin (*2*). It still has to be isolated from mammalian organs, which implies a potential risk of contamination with pathogens such as prions. Because of the increased use of heparin, especially LMWH, there is a growing shortage of the raw material. Moreover, heparin is a polydisperse mixture of molecules with different chain length and chemical structure (*3*, *4*). Numerous parameters, ranging from the animals providing heparin up to the last purification step of the product, influence its respective composition resulting in wide chemical and thus also activity variations between different heparin preparations.

Recent developments such as fondaparinux (*5*), the first selective synthetic factor Xa inhibitor, and ximelagatran (*6*), the first orally available direct thrombin inhibitor, circumvent many problems related to heparin. However, these specifically acting new antithrombotics lack the other biological activities, which are characteristic for heparin and other natural sulfated polysaccharides, e.g., complement inhibiting (*7*), antiinflammatory (*8*, *9*), antiangiogenic (*10*), antimetastatic (*11*), antiatherosclerotic (*12*), antiproliferative (*13*), antiadhesive (*14*), and antiviral effects (*15*). These additional actions can contribute to the overall therapeutic benefit of heparin in some cases (*11*). For example, heparin-coated cardiopulmonary bypass circuits have an improved biocompatibility showing better clinical outcomes (*16*).

Therefore, heparin analogues with a similar or even improved action profile, but lacking the disadvantages of this animal product, are of interest. Beside partial synthetic sulfated linear polysaccharides (*17*), fully synthetic sulfated linear polymers (*18*), which are produced independently of any suitable starting carbohydrate, may represent promising heparin mimetics. Recently, a new type of polysulfated heparin analogue based on branched polysaccharides has been described to possess a much higher anticoagulant activity than their linear counterparts (*19*). However, the accessibility of branched polysaccharides is problematic due to limited natural sources. In the present study, we describe a new synthetic approach to highly branched polysulfated heparin analogues based on dendritic polyglycerol (*20*−*22*). Several polyglycerol sulfates with different molecular weights as

Table 1. Characterization of Polyglycerol Sulfates 2a−c and Polyglycerol Carboxylate 3

polyglycerol derivative	polymer core	DP_n	M_n of the polymer core[a] [g/mol]	degree of functionalization[b] [%]	M_n of the polyglycerol derivative[c] [g/mol]
sulfate **2a**	**1a**	32	2500	85	5500
sulfate **2b**	**1b**	66	5000	79	10 500
sulfate **2c**	**1c**	133	10 000	84	21 700
carboxylate **3**	**1d**	106	8000	26	10 300

[a] Determined from NMR and/or GPC (DMF). [b] **2a−c**: Degree of sulfation (ds) obtained from elemental analysis; **3**: degree of carboxylation (dc) obtained from titration (see Experimental Procedures and Supporting Information). [c] Calculated using the M_n of the polyglycerol core and the experimental degree of functionalization.

well as a polyglycerol carboxylate analogue have been prepared and evaluated for their anticoagulant and anticomplementary activities.

EXPERIMENTAL PROCEDURES

Materials. Polyglycerols (PG) **1a** (M_n = 2500 g/mol, M_w/M_n = 1.6), **1b** (M_n = 5000 g/mol, M_w/M_n = 1.6), **1c** (M_n = 10 000 g/mol, M_w/M_n = 1.8) and **1d** (M_n = 8000 g/mol, M_w/M_n = 2.0) were prepared as described previously, using 1,1,1-tris(hydroxymethyl)propane (TMP) as initiator (*22*). SO_3/pyridine complex and sodium chloroacetate were purchased from Fluka (Buchs, Switzerland). Both reagents were used without further purification. The solvent *N*,*N*-dimethylformamide (DMF, p.a. quality, purchased from Roth, Karlsruhe, Germany) was dried over CaH_2 and stored over molecular sieve 4 Å prior to use. Dialysis (regenerated cellulose tubing, SpectraPore 6/Roth) in distilled water was performed in a 5 L beaker, changing the solvent three times over a period of 48 h.

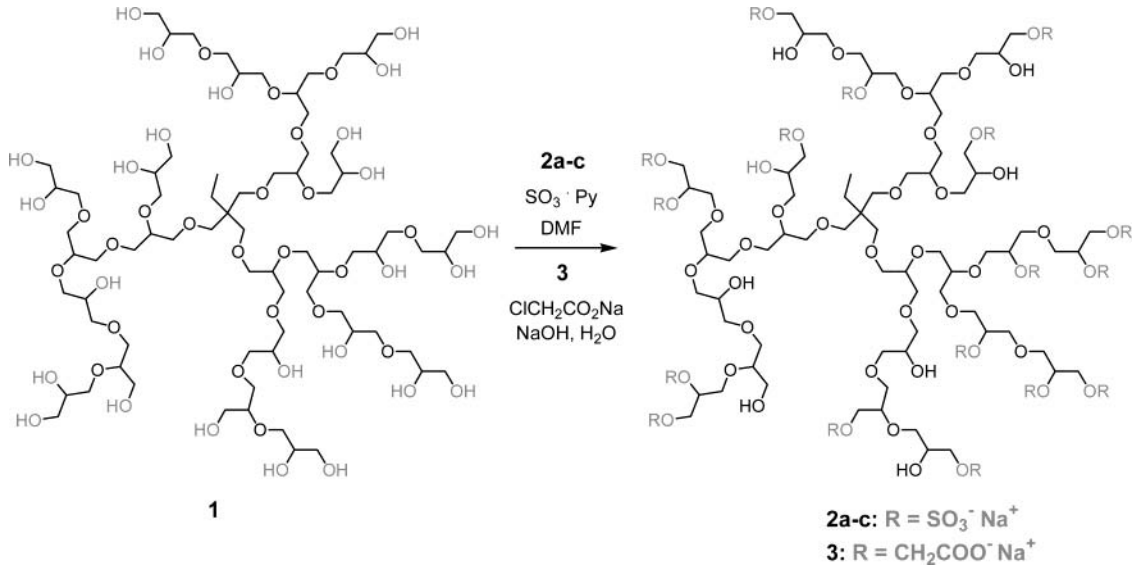
Unfractionated heparin (UFH) of porcine mucosal origin (147 USP−U/mg, purchased from Sigma, Deisenhofen, Germany) was used as reference substance in the coagulation and complement assays.

Analysis. ^{1}H NMR and ^{13}C NMR spectra were recorded in D_2O at concentrations of 100 mg/mL on a Bruker ARX 300 spectrometer operating at 300 and 75.4 MHz, respectively. IR measurements were performed on a Bruker IFS 88 FT-IR spectrometer using a KBr disk.

The degree of sulfation (ds) (Table 1) of compounds **2a−c** was determined by elemental analysis. The amount of carboxylate groups in compound **3** was determined by a common titration method (*23*): 50 mg polyglycerol carboxylate (dried over P_2O_5) dissolved in 20 mL of distilled water was stirred with 2 g of Lewatit K1131 (H^+) resin. The solution of the polyglycerol carboxylic acid was filtered and subsequently titrated with 0.01 N NaOH (1 mL steps), and the pH was recorded by conductivity measurements. The equivalence point was evaluated by extrapolation of the two branches of the titration curve. The degree of carboxylation (dc) (Table 1) was then calculated using the following eq 1 (for derivation, see Supporting Information):

$$dc = \frac{(A \cdot M_n)/(m - AB)}{DP_n + f_c} \times 100\ (\%) \qquad (1)$$

with A = consumption of NaOH (mmol) corresponding to the inflection point; M_n = average molecular weight of the polyglycerol core; m = dry weight of the polyglycerol carboxylate (50 mg); B = equiv weight corresponding to one additional C_2HO_2Na unit (80.02 g/mol); DP_n = degree of polymerization of the polyglycerol core; f_c = functionality of the initiator molecule TMP (f_c = 3).



Synthesis of Polyglycerol Sulfates 2a−c. The sulfation of the polyglycerols was performed according to the method described by Alban et al. (*24*). To a stirred solution of 5.0 g of polyglycerol (**1a**, **1b**, **1c**) (67.5 mmol OH-groups) in 25 mL DMF was added dropwise a solution of 10.75 g (67.5 mmol) SO_3/pyridine complex in 67.5 mL of DMF over 4 h at 60 °C under an argon atmosphere. After the reaction mixture was stirred for additional 2 h at 60 °C and 18 h at room temperature, 50 mL of distilled water was added. To the aqueous solution was added 1 M NaOH immediately until a pH of 11 was reached. Concentration in vacuo gave the crude product which was further purified by dialysis in water. After evaporation of the solvent, the polyglycerol sulfates **2a−c** were obtained as pale yellow solids which were further dried over P_2O_5. Yields: 7.49 g (**2a**); 8.96 g (**2b**); 7.01 g (**2c**). ^{1}H NMR (300 MHz, D_2O): δ (ppm) 0.98 [t, 3H, C*H*$_3$CH$_2$C(CH$_2$O)$_3$-PG-OSO$_3$Na], 1.48 [m, 2H, CH$_3$C*H*$_2$C-(CH$_2$O)$_3$-PG-OSO$_3$Na], 3.40−4.00 [m, CH$_3$CH$_2$C(C*H*$_2$O)$_3$-*PG*-OSO$_3$Na], 4.19, 4.33, 4.38 [*PG*-OSO$_3$Na], 4.72 [PG-OCH$_2$CH(OSO$_3$Na)C*H*$_2$OSO$_3$Na]. ^{13}C NMR (D_2O, 75.4 MHz): δ (ppm) 66.9, 67.6, 68.2, 69.4, 70.3, 75.8, 77.2, 78.3 [*PG*-OSO$_3$Na]. IR (KBr): ν (cm^{-1}) 3470 [OH], 2930 [CH], 1260 [S=O], 780 [C−O−S]. Sulfur content from elemental analysis: **2a**: 15.38% S, **2b**: 14.28% S, **2c**: 15.20% S.

No degradation of the polyglycerol core could be observed by ^{1}H NMR spectroscopy (see Supporting Information).

Synthesis of Polyglycerol Carboxylate 3. To a stirred solution of 23.0 g of polyglycerol **1d** (310.5 mmol OH-groups) in 124.2 g of 30 wt % NaOH (931.5 mmol NaOH) was added dropwise a solution of 108.5 g (931.5 mmol) sodium chloroacetate in 130 mL of distilled water over 30 min. The reaction mixture was heated to 80 °C for 16 h and then cooled to room temperature, neutralized with 2 N hydrochloric acid and concentrated in vacuo. The crude product was purified by dialysis in distilled water. Upon evaporation of the solvent, 12.2 g of the polyglycerol carboxylate **3** were obtained as a colorless solid which was then dried over P_2O_5. ^{1}H NMR (D_2O, 300 MHz): δ (ppm) 0.89 [t, 3H, C*H*$_3$CH$_2$C(CH$_2$O)$_3$-PG-CH$_2$-CO$_2$Na], 1.39 [m, 2H, CH$_3$C*H*$_2$C(CH$_2$O)$_3$-PG-CH$_2$CO$_2$Na], 3.35−3.90 [m, *PG*-CH$_2$CO$_2$Na], 3.98, 4.09 [s, 2H, PG-O$_{prim}$-C*H*$_2$CO$_2$Na, PG-O$_{sec}$-C*H*$_2$CO$_2$Na]. ^{13}C NMR (D_2O, 75.4 MHz): δ (ppm) 60.9, 62.7, 68.9, 70.3, 72.2, 78.0, 79.5 [*PG*-CH$_2$CO$_2$Na], 77.1 [PG-*C*H$_2$CO$_2$Na], 177.8 [PG-CH$_2$*C*O$_2$-Na]. IR (KBr): ν (cm^{-1}) 3500 [OH], 2870 [CH], 1610 [C(=O)O$^-$], 1110 [C−O−C]. Titration of carboxylic acid groups with 0.01 N NaOH (consumption corresponds to the inflection point): 13.7 mL (mean value, which corresponds to a dc of 26%).

Anticoagulant Activity. The anticoagulant activity of the polyglycerol derivatives was evaluated by classical coagulation assays. All assays were performed using citrated human platelet poor pool plasma (PPP) pooled from at least eight healthy adults. PPP was obtained according to the guidelines for preparing citrated plasma for hemostaseological analyses (*25*) and stored at −70 °C until use. Freshly thawed PPP was supplemented with dilution series of the polyglycerols **1**, the polyglycerol derivatives **2**, **3** and UFH in 0.9% sodium chloride resulting in final concentrations ranging between 0.1 and 100 μg/mL. The clotting times in seconds were recorded with a Kugel coagulometer KC 10 (Amelung, Lemgo, Germany). All assays were performed in duplicate and repeated at least three times on different days (n = 6). For comparison with the standard UFH, the concentrations needed for doubling the baseline coagulation time (DC) were determined.

Scheme 1. Synthesis of Polyanionic Polyglycerol Derivatives (sulfates 2a-c, Carboxylate 3)[a]

[a] The depicted structures have a degree of branching of ca. 60% and are only small idealized fragments of the large dendritic polymer cores **1a**−**d**.

Activated Partial Thromboplastin Time (APTT). An amount of 100 μL of supplemented plasma was incubated with 100 μL of Pathromtin (Dade Behring, Marburg, Germany) for 120 s at 37 °C. The coagulation was started by adding 100 μL of 0.025 M calcium chloride solution (Dade Behring, Marburg, Germany).

Thrombin Time (TT). An amount of 100 μL supplemented plasma and 100 μl diethylbarbiturate−acetate buffer solution (pH 7.6) (Dade Behring, Marburg, Germany) was incubated at 37 °C for 60 s. The coagulation was started by adding 100 μL of 3.0 IU/mL Test-Thrombin (bovine) in diethylbarbiturate−acetate buffer solution (pH 7.6) (Dade Behring, Marburg, Germany).

Anticomplementary Activity. The influence of the polyglycerol derivatives on both classical complement activation (CCA) and alternative complement activation (ACA) was determined by complement-induced hemolysis assays using a microtiter plate technique as recently described by Alban et al. (*26*). The assay principle is based on the lysis of antibody-sensitized sheep (for the classical complement activation) and rabbit erythrocytes (for the alternative complement activation) by the remaining active complement proteins contained in human pooled serum and the photometric measurement of the released hemoglobin. All assays were performed in triplicate and repeated at least one time on a different day ($n = 6$). For comparison with the standard UFH, the concentrations reducing the baseline (i.e., in the absence of test compounds) hemolysis by 50% (IC_{50}) were determined.

RESULTS AND DISCUSSION

A. Synthesis and Characterization of Dendritic Polyanions. Polyglycerol **1** is a readily available well-defined polymer with dendritic (treelike) branching obtained by controlled anionic polymerization of glycidol (*20*−*22*). The degree of branching of **1** (60%) is lower than that of perfect glycerol dendrimers (100%) (*27*). Nevertheless, the physicochemical properties are very similar (*28b*). The molecular weight (1000−30 000 g mol^{-1}) and hence the degree of polymerization (DP) can be easily tailored by the monomer/initiator ratio and narrow polydispersities are obtained (typically < 2.0) (*22*). Due to the biocompatible properties of the aliphatic polyether polyols in general (e.g., polysaccharides, poly(ethylene glycol)s), similar properties are expected for polyglycerol (*21*). In addition, oligoglycerols (2−10 monomer units) have been studied in detail with respect to their toxicological properties and have been approved as food and pharma additives (*28, 29*). Dendritic polyglycerol **1** should therefore be well suited as a highly functional support for drugs and for the generation of dendritic polyanions (polysulfates and polycarboxylates) as highly branched heparin analogues.

The synthesis of the polyglycerol sulfates was carried out by modifying a method established for the sulfation of β-1,3-glucans (*24*) using dendritic polyglycerols (*20*) with different molecular weights (**1a**−**c**) as core polymers and the SO_3/pyridine complex as sulfation reagent in dry DMF as solvent (Scheme 1). For all examples the concentration of the SO_3/pyridine complex in DMF as well as its molar ratio (SO_3 per OH groups) were kept constant. The polyglycerol sulfates (**2a**−**c**) were obtained in good yields (50−75%) and high purities (>98% according to ^{1}H NMR) after dialysis in distilled water. Using a SO_3/pyridine concentration equimolar to the OH groups, about 85% of all the free OH groups have been sulfated (Table 1). This high degree of sulfation shows that polyglyerols are much more accessible to sulfation than polysaccharides (*24*).

The synthesis of the polyglycerol carboxylate was performed using the well-known preparation of carboxymethylcellulose from cellulose (*30*). In close analogy to this method, polyglycerol **1d** was treated with aqueous sodium hydroxide solution and the reagent sodium chloroacetate at elevated temperature (80 °C) in order to obtain polyglycerol carboxylate **3** (Scheme 1). Although 3-fold excess of sodium chloroacetate was used, only a moderate carboxylate content (26%) could be achieved (Table 1). However, for biological evaluation this should be sufficient, since most of these carboxylate groups will be on the terminal groups of the dendritic macromolecule.

Detailed analysis (see experimental procedures) of all starting materials **1a**−**d** and products **2a**−**c**, **3** by NMR, IR, elemental analysis, and titration confirmed the structure and degree of functionalization of these dendritic polyanionic heparin analogues. The molecular weights of the unfunctionalized polyglycerols have been

Table 2. Anticoagulant and Anticomplementary Activities of the Polyglycerol Derivatives

polyglycerol derivative	M_n (theoret) [g/mol]	anticoagulant activity, DC [μg/mL][a]		anticompelementary activity, IC_{50} [μg/mL][b]	
		APTT	TT	CCA	ACA
UFH		0.99	1.21	33.9	406
1b	5000	inactive[c]	inactive[c]	inactive[c]	inactive[c]
2a	5500	17.3	7.70	2.53	110
2b	10 500	12.3	3.60	1.42	116
2c	21 700	14.9	5.10	1.56	149
3	10 300	inactive[c]	inactive[c]	inactive[c]	inactive[c]

[a] DC [μg/mL] corresponds to the concentration doubling the baseline coagulation time in the APPT and TT assay. [b] IC_{50} [μg/mL] corresponds to the concentration reducing the baseline hemolysis by 50%. [c] Inactive = not determinable due to missing activity up to 100 μg/mL in APTT and TT and up to 250 μg/mL in CCA and ACA.

calculated from ^{1}H NMR data after precipitation (see Supporting Information). The obtained values agreed with the theoretical adjusted MW in this pseudo-living anionic ring-opening polymerization process (see ref 22). Molecular weights of these highly branched polyglycerols obtained from GPC are systematically lower due to the use of linear calibration standards (e.g. poly(ethylene oxide)). During sulfation, no depolymerization of the polyglycerol backbone has been observed as demonstrated by 2-fold dialysis and ^{1}H NMR analysis of the product **2a**. By comparison of the relative integrals of incorporated starter unit and polyglycerol backbone identical proton ratios were observed as in the starting material **1a** (see Supporting Information). This allowed us to calculate the molecular weight of the products **2a**−**c** and also **3** (degradation is not possible under alkalic reaction conditions) with the functionalization data of elemental analysis or titration measurements, respectively (cf. Table 1).

B. Biological Evaluation (APTT, TT, CCA, ACA). The anticoagulant activity of the polyglycerol derivatives was investigated by the classical coagulation assays APTT and TT using UFH as reference compound. The APTT determines the intrinsic coagulation, i.e., an influence on Factor XIIa, XIa, IXa, VIIIa, kallikrein, and high molecular weight kininogen. Further, effects on FVa and FXa, and moderately also on thrombin and fibrinogen can be detected. The thrombin time, i.e., the coagulation time after adding an excess of thrombin, is the assay for the last step of coagulation, i.e., the thrombin-mediated fibrin formation. Whereas the unfunctionalized polyglycerols (**1a**−**d**) as well as the polyglycerol carboxylate **3** did not influence the coagulation time, the three polyglycerol sulfates **2a**, **2b**, and **2c** concentration-dependently prolonged both APTT and TT. As determined from their DC (Table 2), their APTT-activities amounted to 5.7% (**2a**), 8.1% (**2b**), and 6.6% (**2c**) of that of UFH (Figure 1). Regarding their relative TT-activities of 15.7% (**2a**), 33.6% (**2b**), and 23.7% (**2c**), it appears that the polyglycerol sulfates interfere rather with the last coagulation step than with the intrinsic coagulation activation. However, further studies will be needed to identify their detailed mode of anticoagulant action.

Comparing the three compounds, which actually differ only in their molecular weight, especially in the TT assay, the activity of **2b** with a medium molecular weight is significantly the highest, followed by **2c** and finally **2a** with the lowest molecular weight. These findings are in contrast to the correlation between the anticoagulant activity and the molecular weight of sulfated polysaccharides (*31*−*34*). This might be due to the different

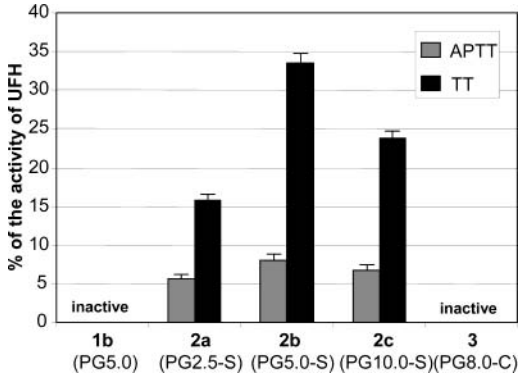


Figure 1. Anticoagulant activities of the polyglycerol derivatives in the APTT and TT assay in relation to UFH as calculated from the DC [μg/mL]. The activity of UFH corresponds to 100%.

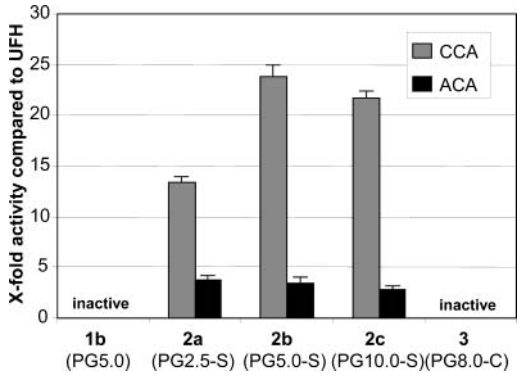

Figure 2. Anticomplementary activities of the polyglycerol derivatives in the CCA and ACA assay in relation to UFH as calculated from the IC_{50} [μg/mL]. The activity of UFH corresponds to 1.0.

three-dimensional structure and the higher density of sulfate groups; whereas a longer chain length of flexible polysaccharide molecules increases the probability of interactions with biomolecules, the globular conformation of polyglycerols may be hindering above a certain size. On the other hand, as demonstrated by **2a**, already a relatively low molecular weight is sufficient for pronounced activity, which is supposed to be advantageous with respect to a potential in vivo application.

Similar to the coagulation assays, both the unfunctionalized polyglycerols **1a**−**d** and the polyglycerol carboxylate **3** were completely inactive in the complement-induced hemolysis assays. They also did not show any complement activating effect as it is known for numerous unsulfated polysaccharides (*26*). All three polyglycerol sulfates, however, concentration-dependently inhibited the hemolysis induced by classical (CCA) as well as alternative (ACA) complement activation. Like some sulfated polysaccharides (*35*), they turned out to be superior to UFH particularly in the CCA assay (Table 2). As calculated from the IC_{50} values, they were 13 (**2a**), 24 (**2b**), and 22 times (**2c**) more active than UFH (Figure 2). In the ACA assay, the factor ranged only between 2.7 and 3.7. In view of the inactivity of polyglycerol carboxylate **3** in both the CCA and ACA assay, sulfate groups are essential to any effect and cannot be replaced by other negatively charged residues (i.e., carboxylates).

In the CCA assay, there is again no clear molecular weight dependency of the activities of **2a**, **2b**, and **2c**, whereby in contrast to the anticoagulant activity **2b** is only slightly more active than **2c**. But in the ACA assay, the inverse order of activities applies: **2c** with the highest molecular weight revealed a considerable weaker effect

than **2b** and **2a**. Consequently, the biological effects of polyglycerol sulfates on diverse biological systems, e.g., CCA and ACA, seem to be favored by different structural characteristics.

In relation to UFH, whose ratio of the anticomplementary to the anticoagulant activity is set to 1.0, the ratio of the anticomplementary- (CAA) to the anticoagulant activity (APTT or TT) of the polyglycerol sulfates amounts to about 300 or 80, respectively. The therapeutic utilization of the relatively weak anticomplementary activity of UFH is limited by the potential bleeding risk (*7*). Referring to this, polyglycerol sulfates exhibit an improved efficacy−risk ratio so that efficient anticomplementary doses may be combined with moderate anticoagulant activities, which do not induce bleeding.

CONCLUSIONS

For the development of synthetic heparin alternatives without the characteristic disadvantages of this animal-derived product, but having a similar activity profile, dendritic polyglycerols have been functionalized with negatively charged sulfate and carboxylate groups. A major advantage of these fully synthetic polyglycerol sulfates is their straightforward preparation, which can be easily scaled up. In contrast to inactive nonderivatized and carboxylated polyglycerols, polyglycerol sulfates turned out to exhibit both anticoagulant and anticomplementary activities. Whereas their anticoagulant activity is lower than that of heparin, they show manyfold stronger anticomplementary effects. A clear molecular weight dependence could not be detected with this limited set of accessible polymer sizes, but the respective activities turned out to depend on the individual structure. Consequently, it should be possible to produce compounds with specific action profiles. Due to the cross-linking between coagulation and inflammation (including complement activation) in the pathophysiology of, for example, sepsis or cardiovascular diseases (*36*, *37*), polyglycerol sulfates with both anticoagulant and antiinflammatory activities represent promising candidates for the development of corresponding drugs. To evaluate the therapeutic potential of this new class of heparin analogues, further studies on the structure−activity-relationships and investigations of the complete action profile and the mechanisms of actions are in progress.

ACKNOWLEDGMENT

H.T. and R.H. would like to acknowledge Prof. Rolf Mülhaupt for his generous support and thank Dr. Béla Oláh, Bernhard Siegel, and Katrin Armbruster for their synthetic support in this project. S.A. is grateful to Gabriele Brunner for her excellent technical assistance at the testing of the compounds. R.H. is indebted to the Deutsche Forschungsgemeinschaft, the Fonds der chemischen Industrie, and Dr. Otto-Röhm Gedächtnisstiftung for financial support.

Synthesis and Characterization of Hapten−Protein Conjugates for Antibody Production against Small Molecules

K. V. Singh, Jasdeep Kaur, Grish C. Varshney, Manoj Raje, and C. Raman Suri*

Institute of Microbial Technology, Sector 39-A, Chandigarh 160 036, India. Received September 5, 2003; Revised Manuscript Received November 4, 2003

For the generation of antibodies against small hapten molecules, the hapten is cross-linked with some carrier protein to make it immunogenic. However, the formation of such conjugates is not always reproducible. This may lead to inconsistent hapten−protein stoichiometries, resulting in large variations in the generation of the desired antibodies. In the study described here the hapten (mercaptopropionic acid derivative of atrazine) was coupled to carrier protein at five different molar ratios. The hapten−protein conjugates prepared were characterized thoroughly by spectrophotometric absorption, fluorescence, matrix-assisted laser desorption ionization (MALDI), and gel electrophoresis methods, before being used for the immunization and assay purposes. Electrophoresis and fluorescence methods were very useful in detecting hapten−protein cross-linking while MALDI-MS and spectrophotometric detection provided qualitatively comparable hapten density. The production of specific antibodies was sought following the generation of appropriate hapten−protein conjugates. A high antibody titer with moderate antibody specificity was obtained with hapten density around 15 molecules per carrier protein. The study proved useful for monitoring the course of hapten−protein conjugation for the production of specific antibodies against small molecules.

INTRODUCTION

Small molecules such as pesticides, drugs, etc. are usually nonimmunogenic and hence do not elicit an immune response unless coupled with some macromolecules such as proteins. It is, therefore, required to modify these small substances (hapten) for coupling with macromolecules (carrier) so as to make a stable carrier−hapten complex. Synthesis of hapten for linking with carrier proteins is the most important aspect of specific antibody generation against small molecules for immunoassay applications (*1*−*3*). The functional group of the hapten governs the selection of the conjugation method to be employed. Common procedures use amine, carboxylic acid, hydroxyl, or sulfhydryl groups on the hapten and the protein (*4*). The most frequently used carrier proteins for conjugation are bovine serum albumin (BSA), ovalbumin (OVA), conalbumin (CONA), thyroglobulin (TG), immunoglobulin (Ig), fibrinogen, or keyhole limpet hemocyanin (KLH). Hapten−protein conjugates made with serum albumin are more frequently used than conjugates of γ-globulin or other carrier proteins. The hapten−protein conjugates of bovine, rabbit, and human serum albumin were found to be soluble above pH 5.5. However, similar conjugates made of γ-globulin and egg albumin precipitated out of solution during preparation (*5*). KLH, even though consisting of a large number of available lysines for hapten conjugation, its use as a carrier protein is restricted because of the problem of its solubility in various buffers due to its high molecular size.

There has been significant progress in recent years in protein−hapten conjugates for the generation of anti-hapten antibodies with applications in immunoassays for environmentally hazardous pollutants (*6*−*8*). An improved method for the microscale preparation and characterization of hapten−protein conjugates for nonchromophore hydroxylated haptens was demonstrated by Naar and co-workers (*9*). In another study, a solid-phase conjugation method utilizing carrier protein bound to an ion exchange matrix was developed, and the conjugation ratio was determined by acid hydrolysis and amino acid analysis (*10*). Verification of the coupling reaction and determination of the hapten density can be accomplished spectrophotometerically, mainly by evaluating the available free amino groups before and after conjugation (*11*, *12*), by matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) to determine the mass change before and after conjugation (*13*, *14*) or by radiolabeled haptens (*15*). To prepare an effective hapten−protein conjugate for the desired immune response, it is important to characterize the resulting hapten−protein conjugates to determine the hapten density on carrier protein. The higher ratio of hapten usually increases the strength and specificity of the immune response. However, there is a risk that a high degree of substitution could adversely affect the activity and specificity of antibodies produced (*16*). Besides, the formations of protein−hapten conjugates are not always reproducible, even in best experimental conditions. This may lead to inconsistent hapten−protein stoichiometries resulting large variation in desired antibodies generation. Careful selection of hapten density for hapten−protein conjugation is therefore an important aspect of antibody generation. In the present study, the binding efficiency of hapten−carrier conjugate (number of hapten molecules per protein molecule) was optimized by taking different hapten: carrier molar ratios. Mercaptopropionic acid derivative of atrazine (MPAD) was synthesized in our laboratory for coupling with carrier protein. Five molar ratios of hapten were used to make hapten−protein conjugates for immunization purpose. The optimum molar ratio of hapten to protein to produce conjugates

for immunization was determined according to a balance between good antibody titers and specific antibodies generated.

MATERIALS AND METHODS

Reagents. Bovine serum albumin (BSA), dicyclohexyl carbodiimide (DCC), *N*-hydroxysuccinimide (NHS) ester, 3-mercaptopropionic acid, 2,4,6-trinitrobenzene 1-sulfonic acid (TNBS), fluorescein isothiocyanate (isomer 1), peroxidase conjugated goat anti-rabbit immunoglobulin, normal anti-rabbit immunoglobulin, and 3,5-dimethoxy-4-hydroxycinnamic acid (Sinapinic acid) were purchased from Sigma Chemical Co., St. Louis, MO. Technical grade atrazine was purchased from Supelco. Peroxidase (POD) and 3,3′,5,5′-tetramethylbenzidine (TMB) substrate were obtained from Bangalore-Genei, India. Affi-gel-102 was purchased from Bio-Rad. All chemicals, reagents, and solvents used in this study were of high purity analytical grade. Buffers were made in Milli-Q double distilled water.

Synthesis of Atrazine Derivative. Mercaptopropionic acid derivative of atrazine (MPAD) was synthesized in our laboratory by the method described by Goodrow and co-workers (*2*). Briefly, in a solution of 5.01 mmol of atrazine (Tech. Grade) in 50 mL of ethanol was added slowly, under constant stirring, a solution of 3-mercaptopropionic acid (5.5 mmol) and 85% KOH (10.8 mmol) in 10 mL of ethanol. The mixture was refluxed for 6 h, and then the solvent was evaporated under reduced pressure. The residue was taken up in 25 mL of 5% $NaHCO_3$ and washed three times with 10 mL of chloroform. The aqueous layer of the solution was acidified (pH 2.0) with 6 N HCl, causing the acidic derivative to precipitate immediately. The supernatant was decanted, and the derivative was dried under mild vacuum. The precipitate was further dissolved in 1 mL of ethanol and then allowed under reduced pressure at 37 °C to form MPAD crystals. The product was stored in a tightly sealed bottle for further use.

Conjugation of Hapten with Protein. Conjugates of atrazine (MPAD derivative) with protein (BSA) at five different molar ratios of protein−hapten (1:5, 1:10, 1:20, 1:40, and 1:100, M1-M5) were prepared. The stock solution of protein (10 mg/mL; 0.15 μmol) was made in pH 9.0 borate buffer, and the final reaction volume of the protein−hapten conjugates was kept constant at 1 mL for each preparation. Stock solution of haptens was made by adding 50 μmol of MPAD derivative of atrazine in 1 mL of DMF along with 125 μmol of DCC and 125 μmol of NHS. The mixture was incubated for 4 h at RT and then centrifuged for 5 min at 10 000 rpm to remove the urea precipitate. The reaction mechanism of MPAD−protein conjugation method is shown in Figure 1. The supernatant was used to prepare conjugates with protein by adding different amounts of hapten to a fixed amount of protein (10 mg) in a final volume of 1 mL to make protein−hapten conjugates of different molar ratios as shown in Table 1. The conjugates were passed through P10 gel filtration column (Pharmacia, Sweden). The fractions with maximum protein concentration were collected, pooled, and checked for the final concentration of protein (hapten−protein) with UV spectrophotometer at 280 nm.

Table 1. Different Molar Ratios of Protein−Hapten Used for Making Conjugates M1 to M5

protein concentration	hapten concentration	protein−hapten ratio
0.15 μmol (10 mg)	0.75 (15 μL)	1:5 (M1)
0.15 μmol (10 mg)	1.50 (30 μL)	1:10 (M2)
0.15 μmol (10 mg)	3.00 (60 μL)	1:20 (M3)
0.15 μmol (10 mg)	6.00 (120 μL)	1:40 (M4)
0.15 μmol (10 mg)	15.0 (300 μL)	1:100 (M5)

Characterization of Conjugates. Protein−hapten conjugates were characterized by following physical techniques to determine the extent of conjugation.

(a) Spectrophotometric Analysis. The available groups of surface lysine present in carrier proteins before and after conjugation (made at different molar ratios of hapten−protein) were determined using 2,4,6-trinitrobenzene-1-sulfonic acid (TNBS) reagent. The amount of amino groups present in the carrier protein before and after coupling with carboxylated hapten was directly quantitated with a UV/vis spectrophotometer (Shimadzu 1601) at 335 nm. Different conjugates were prepared at

Table 2. Determination of Hapten Density on BSA−MPAD Conjugates Using Chemical TNBS and Physical MALDI−TOFF Mass Spectrometric Method[a]

conjugate	carrier−hapten molar ratio used for preparation of conjugates	chemical TNBS method		mass spectrometry MALDI−TOFF		
		% amino groups consumed	approximate no. of amino groups used	observed mass[b] (kDa)	change in mass (ΔM)	$\Delta M/M_h$ (hapten density[c])
control	1:0	0.0	0.0 (0)	67221.0	0	0
M1	1:5	6.0	3.48 (3)	67744.9	523.9	1.84 (2)
M2	1:10	8.0	4.64 (5)	68293.8	1072.8	3.76 (4)
M3	1:20	18.0	10.44 (10)	70288.7	3067.7	10.75 (11)
M4	1:40	24.0	13.92 (14)	71720.8	4499.8	15.77 (16)
M5	1:100	29.0	16.82 (17)	*d*	–	–

[a] The number of lysine groups on protein being utilized for conjugates M1 to M5 before and after conjugation are given in brackets. [b] Mass of hapten (MPAD) $M_h = 285.4$. [c] Number of hapten molecules per BSA molecule. [d] Did not fly.

a concentration of 1 mg/mL and were reacted with 0.1% TNBS solution under alkaline conditions to determine the percentage of NH_2 groups used during conjugation in different conjugates. An amount of 200 μL of conjugate solution was taken and mixed with 200 μL of 4% $NaHCO_3$ solution. An amount of 200 μL of 0.1% TNBS solution was added to the mixture and incubated for 1 h at 37 °C. The color of the solution was read at 335 nm. The amount of NH_2 groups used during conjugation of pesticide residues to the BSA molecules was determined from the difference between the O.D. of the control and the conjugate.

(b) Fluorescence Spectra. The emission spectra of hapten−protein conjugates (M1-M5) were taken in the range of 300−450 nm after excitation at 290 nm (tryptophan excitation) using Kontron spectrofluorometer (SFM 25). The conjugates were also excited at 270 nm to see the effects of both tyrosine and tryptophan amino acids on the conjugates. Spectra were obtained using 1 nm excitation and emission slits, and were recorded at a scan rate of 5 nm s^{-1}.

(c) Gel Electrophoresis. The native and SDS−PAGE of the conjugates (different hapten−protein molar ratio) was performed using Bio-Rad electrophoresis apparatus according to method developed by Laemmli (*17*). Solutions of the conjugates were prepared in SDS−PAGE sample buffer (10 mM Tris, 1 mM EDTA, 2.5% SDS, and 5% mercaptoethanol, pH 8.0) to 1 mg/mL and heated to 100 °C for 5 min. Gels were loaded with 5 μL of sample and run under denaturing conditions for 90 min at 120 V. Coomassie blue staining was done using a standard developing protocol supplied by the manufacturer. The gel was washed three times in Milli-Q water, followed by staining for 1 h with stain reagent followed by washing in Milli-Q water.

(d) MALDI-TOF. The mass analysis of hapten−protein conjugates was done with MALDI spectrometer (Kratos Analytical Systems). Sinapinic acid solution was prepared at a concentration of 15 mg/mL in acetonitrile. Protein conjugates dialyzed against distilled water were used at a concentration of 1.5 mg/mL. The conjugate samples and matrix solution were mixed in equal amounts (1 μL each) and added on the stainless steel probe having 0.5 μL of TFA solution (0.1%). The samples were allowed to dry at room temperature and then kept in the system for MASS analysis. The data were acquired with 50 shots per sample in the linear mode at 30 kV and analyzed using the software provided with the system.

Antibody Generation. The hapten−protein conjugates were used to immunize mice and rabbits subcutaneously by taking 25 μg and 250 μg of each conjugate, respectively, emulsified with Freund's complete adjuvant. This was followed by three secondary boosters of same dose with incomplete Freund adjuvant at intervals of 21 days. The mice and rabbits were bled on the 5th day after the each boost, and the antibody titer was determined. After the confirmation of good titers (checked by ELISA), sufficient amount of sera were prepared and the immunoglobulin fraction was purified using a protein A-sepharose column (Amersham-Pharmacia Biotech). The relative functional affinity of the antibodies was measured by diethylamine dependent displacement of antigen−antibody interaction. Results were expressed as the logarithmic increase in antibody concentration required to obtain the same level of O.D. at 50% of saturation in the absence of diethylamine (*18*).

ELISA Procedure. ELISA plates (96-well polystyrene from Imperial Biomed, India) were coated with 100 μL of each conjugate (25 μg/mL) made in carbonate buffer (pH 9.6) and incubated overnight at 4 °C. After being coated, the plates were washed thoroughly with phosphate buffer saline (50 mM, pH: 7.2). Unbound sites of the plates were blocked with 5% defatted skim milk in PBS for 2 h at 37 °C. The plates were washed three times with PBS containing 0.05% Tween-20 (PBST) and finally with PBS. Primary antibodies (serum) incubation was done for 3 h at 37 °C by adding 100 μL of antibody solution in each well at a dilution of 1:1000 in PBS. After incubation, the plates were thoroughly washed three times with PBST and finally with PBS. The plates were then incubated with 100 μL of HRP conjugated goat anti-mouse immunoglobulin (1:5000 dilution) for 1 h at 37 °C. The plates were washed as before, and the color was developed by adding 100 μL of TMB/H_2O_2 solution. The reaction was stopped with 50 μL of 1 N H_2SO_4. Optical density at 450 nm was measured using an ELISA plate reader (Molecular Devices).

RESULTS

Analysis of Conjugates. TNBS Method. Covalent attachment of carboxylic acid haptens to protein (BSA) via available surface amino groups on BSA (26 surface L-lysine) was confirmed by reacting all the prepared conjugates (M1−M5) with TNBS reagent. The number of amino groups present in the carrier protein before and after conjugation was quantitated with UV/vis spectrophotometer (Shimadzu 1601) at 335 nm and shown in Table 2. The gradual decrease in the available surface lysine on protein after reaction with different molar ratios of hapten confirms the increase in conjugation density (number of hapten molecules per protein molecule) with increasing hapten−protein molar ratio.

Fluorescence Method. The fluorescence emission spectra for each hapten−protein conjugate in the range of 300−450 nm after excitation at 290 nm (excitation of tryptophan residues only) are shown in Figure 2. The combined effects of both tyrosine and tryptophan amino acids in conjugates were also checked by exciting the samples at 270 nm and monitoring the spectra between

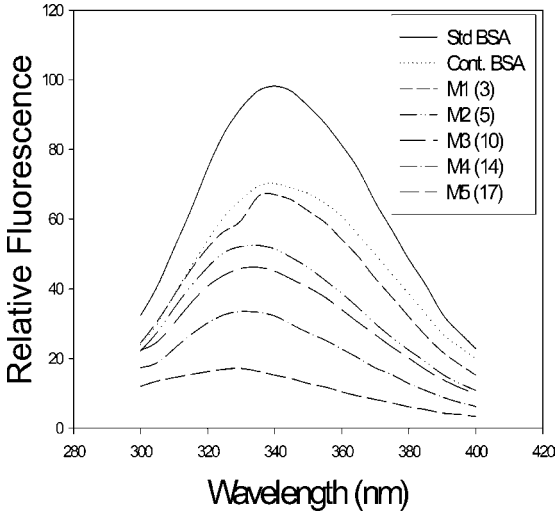

Figure 2. The fluorescence emission spectra (λ_{ex} at 290 nm) of hapten−protein conjugates M1, M2, M3, M4, and M5 having average hapten densities of 3, 5, 10, 14, and 17, respectively.

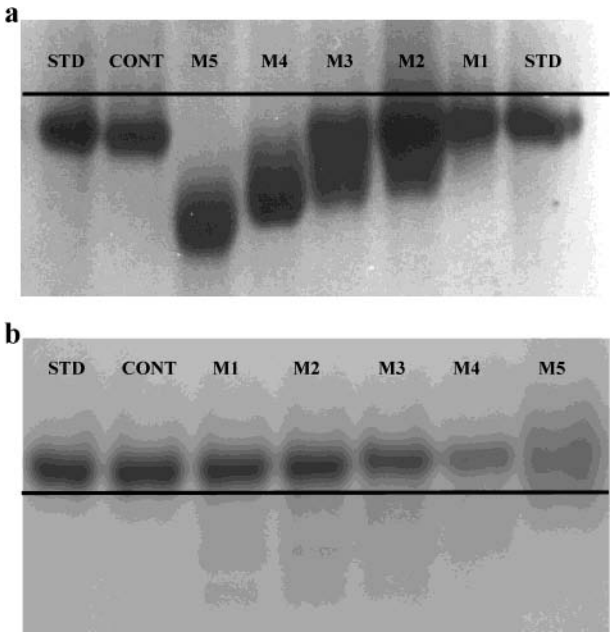

Figure 3. Gel electrophoresis of conjugates (a) native gel and (b) SDS−PAGE. Different BSA-atrazine conjugates M1, M2, M3, M4, and M5 were prepared by reacting activated hapten (MPAD) in molar excess of 1:5, 1:10, 1:20, 1:40, and 1:100, respectively.

300 and 450 nm. No significant change in fluorescent intensity was observed at 270 and 290 nm excitation for the hapten conjugated with protein. The fluorescence spectrum analysis was therefore performed at 290 nm excitation wavelength. Conjugates with increasing molar ratios of protein−hapten (M1−M5) showed linear decrease in fluorescence intensity. The fluorescence intensity of M5 conjugate having protein−hapten molar ratio 1:100 showed almost zero fluorescence intensity.

Gel Electrophoresis and MALDI-MS Analysis. SDS−PAGE and native gel electrophoresis of conjugates are shown in Figure 3. The use of pure protein (BSA) and conjugates made by using different molar ratio of hapten as generated by native gel showed well-defined bands with gradual increments for each hapten with increase in molar ratio (Figure 3a). For the SDS−PAGE (Figure 3b), it was observed that the BSA molecules with higher conjugation density moved further, as this conjugate is more negatively charged in comparison to conjugates prepared with low molar ratio. The SDS−PAGE results correspond to the mass pattern obtained by MALDI-TOF spectrometer. Conjugation density for each hapten in increasing molar ratio (M1−M5) resulted in a detectable increase in the molecular weight of the conjugate as determined by observing the peak shift of mass spectrum (Table 2). The molecular weight of each conjugate was calculated from the peak centroid of the peaks. The incremental change in molecular weight due to incorporation of hapten molecules to protein corresponds to the number of hapten molecules per protein molecule. Apparent coupling efficiency for the MPAD to BSA, at different molar ratios, was nearly same.

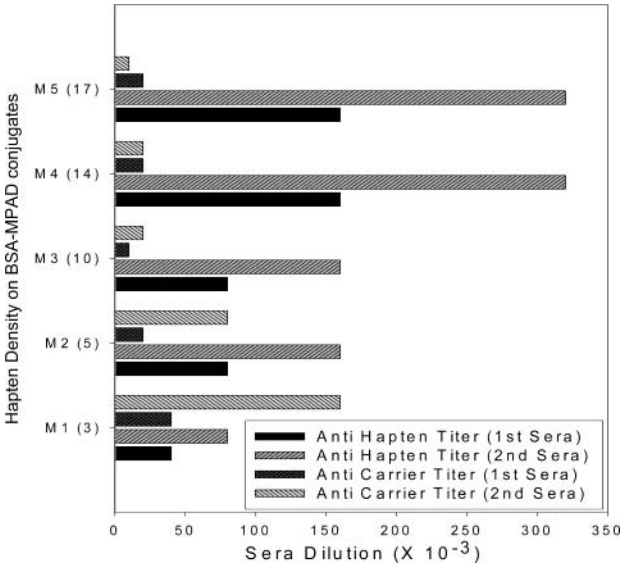

Figure 4. The titer of anti-hapten (atrazine) and anti-carrier (BSA) antibodies in antisera. Rabbits were immunized with various BSA−atrazine conjugates (M1 to M5) having average hapten densities of 3, 5, 10, 14, and 17, respectively.

ELISA Results. All conjugates were tested for their immunogenicity by checking the antibody titers in serum after immunization. The titer of the serum was defined as the dilution giving 50% maximal response by ELISA. Immunization of mice with conjugates (M1 to M5) produced different amount of antibody titers when tested by ELISA (Figure 4). A relatively good titer of anti-hapten antibodies was obtained with M4 conjugate (hapten: protein ratio 1:40). The further increase in conjugational density, i.e., conjugates with hapten−protein ratio of 1:100 (M5), did not show any increase in specific anti-hapten antibodies.

Antibody Characterization. To characterize the antibodies generated against different conjugates, ELISA was done to determine the sensitivity of generated antibodies. The antibody obtained against M4 conjugate, as determined by standard dilution curve analysis, showed very good sensitivity up to the level of ng/mL (Figure 5).

DISCUSSION

For the generation of specific antibodies against small molecules, these molecules are synthesized and conjugated with carrier proteins in such a way that they mimic the structure of the compound and contain a reactive group that can form a covalent linkage with the carrier proteins. The functional group of the hapten governs the selection of the conjugation method to be employed. The method used in this study utilized carbodiimide method

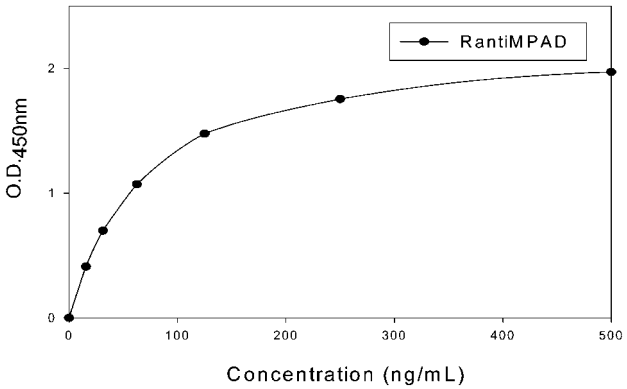

Figure 5. Standard dilution curve for antibody obtained against conjugate M4. Antibody was tested for its sensitivity by dilution curve analysis of data obtained between 12.5 ng/mL to 500 ng/mL of antibody concentration.

(*19*) for carboxy acid haptens (atrazine derivative) to link with BSA. This approach ensured stable cross-linking of haptens with protein along with *N*-acylurea formation. The optimum use of high grade of reagents along with thorough dialysis to remove unbound hapten and *N*-acylurea resulted in good coupling efficiency of haptens to protein as shown by SDS−PAGE and native gel electrophoresis results (Figure 3a,b). Each conjugate generated well-defined bands with low diffusibility. In native gel analysis, the gradual movement of bands with an increase in hapten density is due to a change in net charge of the conjugates, since for each lysine on protein utilized for the conjugation with hapten, one positive charge is lost. Thus, conjugates with more haptens per protein become relatively more negative and move farther than native BSA. Although the electrophoresis analyses of conjugation could not give definite information about the degree of hapten density, its main advantage was in detecting the course of cross-linked conjugation (*21*). In MALDI analysis, the relative increase in the molecular weight of the conjugates is apparent by gradual mass peak shift (Table 2). This corresponds to an increase in hapten density of conjugates, thus determining accurately the number of haptens per protein molecule. A BSA molecule with molecular weight of 66 531 Da (from the manufacturer's data sheet) showed a gradual shift in mass peaks with conjugates made with different molar ratios of hapten (MPAD derivative of atrazine). BSA with 26 available surface lysines can theoretically bind up to 26 hapten molecules. However, the estimated number of hapten molecules linked to BSA could not be more than 17, even at the highest hapten density, i.e., hapten−protein ratio of 1:100. The reason for a lower binding limit of haptens to the protein might be the protein conformational changes induced by haptens. This has also been observed in our analysis of fluorescence spectra for different conjugates (Figure 2) where tryptophan intensity of the hapten−protein conjugates shift toward the blue region for conjugates with higher hapten density, respectively. Due to this compactness of the protein, some surface lysine might actually be in the buried region of the protein, thus allowing fewer lysine groups for linking with the hapten.

The fluorescence spectra for different hapten−protein conjugates showed a linear decrease in fluorescence intensity with increase in hapten−protein molar ratio. The fluorescence signal at 290 nm excitation and 340 nm emission is mainly due to a number of tryptophan residues being available in the protein. The decrease in fluorescence intensity at this wavelength is due to quenching of tryptophan intensity with increase in hapten density, i.e., increase in the number of amide bonds formed between the surface lysine groups of the protein and carboxylated hapten (atrazine derivative). This gradual shift in the fluorescence signal or quenching of tryptophan intensity with different conjugates thus confirms the course of hapten−protein conjugation.

The hapten density of the conjugate is an important parameter which generally defines the quality and quantity of antibody produced. A good antibody titer with higher specificity could be generated with an optimum number of haptens per protein molecule. Higher substitution resulted in an IgM response exceeding that of IgG and produced antibodies of lower affinity. Similar observations have been reported by some other groups (*20*−*21*). It is assumed that high antibody titers with moderate antibody affinities are usually obtained with hapten density of 15−30 molecules per carrier protein while a lower hapten density induces a slower immune response with higher affinity antibodies.

In conclusion, we have characterized different conjugates for getting an optimum molar ratio of protein−hapten conjugate for immunization purposes. The spectrophotometric method using trinitrobenzenesulfonic acid (TNBS) and MALDI-MS were able to quantify the hapten−protein conjugation density accurately. A new fluorescence method has been developed to confirm the course of conjugation by monitoring the relative shift in fluorescence intensity of conjugates. However, the role of many parameters, such as hapten polarity, type of solvent, and the nature of quenching, on the fluorescence signal have to be studied before this method can be used for quantitative determination of conjugation efficiency. This work is undergoing in our laboratory.

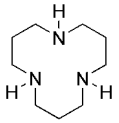
Preparation of Azacrown-Functionalized 2′-*O*-Methyl Oligoribonucleotides, Potential Artificial RNases

Teija Niittymäki, Ulla Kaukinen, Pasi Virta, Satu Mikkola, and Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received September 15, 2003



An improved synthesis for 3-(3-aminopropyl)- and 3-(3-mercaptopropyl)-1,5,9-triazacyclododecane has been developed and alternative methods for their conjugation to oligonucleotides have been described. Accordingly, the 3-aminopropyl azacrown and its *N*-(3-aminopropanoyl)-3-aminopropyl analogue have been tethered to the 3′-terminus of a 2′-*O*-methyloligoribonucleotide by aminolytic cleavage of the thioester linker utilized for the chain assembly. Studies on a monomeric model compound verify that the reaction proceeds solely by the attack of the primary amino group. 5′-Conjugation has been achieved by introducing a 2-benzylthio-2-oxoethyl group to the 5′-terminus as a phosphoramidite reagent and cleaving the thioester bond with the 3-aminopropyl azacrown. For intrachain conjugation, a phosphoramidite reagent derived from 1-deoxy-1-(2-benzylthio-2-oxoethyl)-*β*-D-*erythro*-pentofuranose has been inserted in a desired position within the chain and subjected to on-support aminolysis with the 3-aminopropyl azacrown or its *N*-(3-aminopropanoyl)-3-aminopropyl and *N*-(6-aminohexanoyl)-3-aminopropyl analogues. The 3-mercaptopropyl-derivatized azacrown has been tetherd by a disulfide bond to a 3′-(3-mercaptoalkyl)phosphate-tailed oligonucleotide. The 3′- and intrachain-tethered conjugates have been shown to cleave as their Zn(II) chelate complementary oligoribonucleotide sequences.

INTRODUCTION

Oligonucleotide conjugates that sequence selectively cleave complementary RNA targets have received attention as catalytic antisense oligonucleotides, i.e. as chemical agents with which the expression of a desired gene could be efficiently inhibited in cell lines or even in vivo (*1*−*6*). Unmodified oligodeoxyribonucleotides and their phosphorothioate analogues when hybridized with a complementary mRNA sequence activate an intracellular enzyme, RNase H, which depolymerizes the RNA strand of the duplex leaving the deoxynucleotide strand intact (*7*, *8*). Accordingly, the antisense effect of these oligonucleotides exhibits catalytic turnover. Most of the structurally modified oligonucleotides prepared for antisense purposes do not, unfortunately, have this property. On attempting to increase biological half-life, hybridization efficiency, and cellular uptake by extensive structural modifications, the ability to activate RNase H is often lost (*9*) and the antisense effect is based only on stoichiometric arresting. One may hope that tethering a catalytically active moiety to such an antisense oligonucleotide allows chemical degradation of the target RNA and leads to RNase H-independent turnover. In fact, positive indications of the feasibility of this approach have recently been obtained by in vitro studies on cell lines (*10*, *11*).

The artificial ribonucleases described so far fall in three different categories: (i) oligonucleotide conjugates of redox active chelates or organic molecules that cleave the target RNA by radical induced degradation of a sugar moiety (*12*−*14*), (ii) conjugates of metal ion chelates that catalyze the hydrolysis of a phosphodiester bonds in the target RNA chain (*15*−*30*), and (iii) conjugates of peptidelike oligomers that catalyze the phosphodiester hydrolysis (*31*−*39*). While many of these constructs will undoubtedly find applications as research tools for molecular biology, they do not meet all the requirements of a chemotherapeutic agent and, hence, a wider variety of potential cleaving agents is still desirable. Conjugates cleaving their targets by a radical mechanism, for example, exhibit a reasonably high catalytic activity, but diffusion of radicals creates a risk for deleterious side reactions. It is also worth noting that radical reactions degrade DNA more readily than RNA (*40*). Among the metal ion-dependent nucleases that catalyze the phosphodiester hydrolysis by a polar mechanism, those derived from cationic lanthanide ion chelates are most efficient (*15*−*24*), but they may suffer from leakage of lanthanide ions. The Cu(II) and Zn(II) complexes of aromatic nitrogen bases constitute another group of cleaving agents which deserves attention as a source of drug candidates (*25*−*30*). Also with these cleaving agents, the stability of the chelates may turn out to be the critical parameter. Purely organic conjugates would undoubtedly form the most solid basis for drug development (*31*−*39*). However, only few such conjugates are known and their catalytic activity is low compared to that of the metal ion-dependent cleavers.

Macrocyclic polyamines, the so-called azacrowns, are known to form exceptionally stable complexes with 3d transition metal ions, the log *K* values ranging from 8 to 16 (*41*, *42*), and their chelates have been extensively studied as artificial enzymes (*43*). Among these chelates, the complexes of 1,5,9-triazacyclododecane ([12]aneN$_3$; **1**) have been shown to cleave rather efficiently both mono-

meric (*44*, *45*) and oligomeric (*46*−*48*) phosphodiesters. It is, hence, quite surprising that no azacrown-functionalized oligonucleotides, with the exception of a [12]aneN$_3$ conjugate of a short oligo(T) (*49*), have been prepared, and no such conjugate has been tested as an artificial RNase. We now report on a solid-phase synthesis of 2′-*O*-methyl oligoribonucleotides bearing a 1,5,9-triazacyclododec-3-yl group at the 3′- or 5′-terminus or within the chain has been described. For the attachment of the conjugate group to the oligonucleotide, two different linker chemistries, viz. a peptide and disulfide bond formation, have been applied. Preliminary results on the cleaving activity show that these conjugates really are viable candidates for further development of biocompatible artificial ribonucleases.

EXPERIMENTAL PROCEDURES

General. The NMR spectra were recorded on a JEOL JNM-GX 400 or Bruker 200 NMR spectrometer. The chemical shifts are given in ppm from internal TMS. The mass spectra of small molecular compounds were recorded on a 7070E VG mass spectrometer and those of oligonucleotides and their conjugates on a Finnigan MAT Lasermat, Sciex ABI 365 Triple Quadrupole or ABI Mariner ESI-TOF spectrometer. The 2′-*O*-methylribo oligonucleotides used for conjugation with the functionalized azacrowns and the chimeric 2′-*O*-methylribo/ribo oligonucleotides used as targets in the cleavage experiments were assembled in 1.0 μmol scale on an Applied Biosystems 392 DNA synthesizer from commercially available 5′-*O*-dimethoxytritylated 2′-*O*-methyl- and 2′-*O*-triisopropylsilyloxymethyl ribonucleoside 3′-(2-cyanoethyl)-*N*,*N*-diisopropylphosphoramidites having the base moiety amino groups benzoylated. The HEPES buffer, zinc nitrate, and sodium nitrate used in the cleavage experiments were of reagent grade.

1-Bromo-3-trityloxypropane (2). Trityl chloride (20 g, 72 mmol) was added to a stirred solution of 3-bromo-1-propanol (10 g, 72 mmol) in THF (150 mL). Triethylamine (10 mL, 72 mmol) was slowly added to the mixture, which was allowed to stir in dark for 2 days at room temperature. Volatiles were removed under reduced pressure, and CH_2Cl_2 (250 mL) was added to the residue. The mixture was washed with water and brine, dried over Na_2SO_4, and evaporated to dryness. The crude reaction mixture was purified by silica gel chromatography (50% pentane in CH_2Cl_2) to yield 23 g (82%) of **2** as white solid flakes. MS (EI): *m*/*z* 243 (100%) Tr^+, 380 and 382 (20% and 20%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.49−7.24 (m, 15H, Tr), 3.58 (t,2H, J = 6.8 Hz, CH_2Br), 3.22 (t, 2H, J = 5.8 Hz, TrOCH_2), 2.13 (m, 2H, CH_2CH$_2$Br). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 144.1, 128.6, 127.8, 127.0, 86.5, 61.2, 33.5, 30.7.

Diethyl 2-(3-Trityloxypropyl)malonate (3). Diethyl malonate (28 g, 0.17 mol) was dissolved in ethanolic NaOEt (0.12 mol in 200 mL), tritylated 3-bromopropanol **2** (23 g, 59 mmol) was added, and the mixture was refluxed overnight. Volatiles were removed under reduced pressure, CH_2Cl_2 (250 mL) was added, and the organic phase was washed with water and brine, dried over Na_2SO_4, and evaporated to dryness. The residual oil was purified by silica gel chromatography (50 to 10% pentane in CH_2Cl_2) to yield 23 g (85%) of **3** as a colorless oil. MS (EI): *m*/*z* 383 (100%) $[M - Ph]^+$, 460 (35%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.46−7.22 (m, 15H, Tr), 4.18 (q, 4H, J = 7.1 Hz, 2 × OCH_2CH$_3$), 3.32 [t, 1H, J = 7.5 Hz, CH(COOEt)$_2$], 3.32 (t, 2H, J = 6.3 Hz, TrOCH_2), 1.94−2.05 (m, 2H, TrOCH$_2$CH_2), 1.72−1.57 [m, 2H, TrO(CH$_2$)$_2$CH_2], 1.26 (t, 6H, J = 7.1 Hz, 2 × OCH$_2$CH_3). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 169.4, 144.3, 128.7, 127.7, 126.9, 86.4, 62.9, 61.3, 51.8, 27.7, 25.7, 14.1.

2-(3-Trityloxypropyl)propane-1,3-diol (4). $LiAlH_4$ (7.0 g, 0.18 mol) was added portionwise to a stirred and cooled solution (−20 °C) of **3** (23 g, 50 mmol) in diethyl ether (100 mL). The mixture was allowed to warm to room temperature, and the stirring was continued for additional 2 h. The reaction was carefully quenched by water, which caused slow refluxing. The mixture was concentrated, CH_2Cl_2 (500 mL) was added, and the organic phase was washed several times with water, resulting in formation of an abundant gray precipitation. After this, the organic phase was dried over Na_2SO_4 and evaporated to dryness. The residue was purified by silica gel chromatography (0 to 7% MeOH in CH_2Cl_2) to yield 15 g (79%) of **4** as a colorless oil. MS (EI): *m*/*z* 299 (100%) $[M - Ph]^+$, 376 (6%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.45−7.21 (m, 15H, Tr), 3.78−3.44 [m, 5H, CH(CH_2-OH)$_2$], 3.06 (t, 2H, J = 6.4 Hz, TrOCH_2), 2.64 (br, 2H, 2 × OH), 1.57−1.78 (m, 2H, TrOCH$_2$CH_2), 1.35−1.24 [m, 2H, TrO(CH$_2$)$_2$CH_2]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 144.3, 128.6, 127.7, 126.9, 86.4, 66.2, 63.6, 41.8, 27.6, 24.3.

1,3-Ditosyloxy-2-(3-trityloxypropyl)propane (5). Alcohol **4** (15 g, 40 mmol) was dissolved in pyridine (70 mL), *p*-toluenesulfonyl chloride (23 g, 0.12 mol) was added, and the reaction was allowed to stir at room temperature for 5 h. Volatiles were removed under reduced pressure, and CH_2Cl_2 (200 mL) was added to the residue. The organic phase was washed with saturated $NaHCO_3$ and brine, dried over Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (20 to 0% pentane in CH_2Cl_2) to yield 18 g (66%) of **5** as colorless oil. MS (EI): *m*/*z* 442 (100%) $[M - Tr]^+$, 607 (89%) $[M - Ph]^+$, 685 (30%) M^+. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.69−7.72 (m, 4H, Ts), 7.19−7.36 (m, 19 H, Ts and Tr), 3.93 [dd, 2H, J = 4.9 and 2.2 Hz, CH(CHHOTs)$_2$], 3.87 [dd, 2H, J = 4.9 and 3.1 Hz, CH(CHHOTs)$_2$], 2.94 (t, 2H, J = 3.0 Hz, TrOCH_2), 2.41 (s, 6H, Ts), 1.92 [m, 1H, CH(CH$_2$OTs)$_2$], 1.39−1.46 (m, 2H, TrOCH$_2$CH_2), 1.29−1.35 [m, 2H, TrO(CH$_2$)$_2$CH_2]. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 145.0, 144.1, 132.4, 129.9, 128.6, 127.9, 127.8, 126.9, 86.4, 68.6, 62.8, 37.7, 26.7, 23.8, 21.7.

2-(3-Trityloxypropyl)hexahydro-1*H*,4*H*,7*H*-3a,6a,9a-triazaphenalene (6). TBD (7.4 g, 53 mmol) was added portionwise to a stirred solution of **5** (18 g, 26 mmol) in DME (50 mL). The stirring was continued for 48 h, the mixture was diluted to 100 mL with DME, and $NaBH_4$ (8.0 g, 0.21 mol) was added. The mixture was allowed to stir at ambient temperature overnight. The reaction was carefully quenched with MeOH (100 mL). Volatiles were removed under reduced pressure after the foaming had ceased, and the residue was dissolved in CH_2Cl_2 (150 mL). The resulting organic phase was washed with saturated $NaHCO_3$, dried over Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (5% MeOH and 0.5% Et_3N in CH_2Cl_2) to yield 10 g (79%) of **6** as a colorless oil. MS (EI): *m*/*z* 236 (8%) $[M - Tr]^+$, 480 (100%) M^+. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.40−7.43 (m, 6H, Tr), 7.19−7.30 (m, 9H, Tr), 3.02 (t, 2H, J = 6.7 Hz, TrOCH$_2$), 2.78−2.82 and 1.90−2.14 [m, 6H and m, 7H, 2×CH$_2$(CH_2N)$_2$ and CH$_2$CH(CH_2N)$_2$], 2.25 (br, 1H, CHN$_3$), 1.75 and 1.60 [m, 2H and m, 2H, 2×CH_2(CH$_2$N)$_2$], 1.41 (m, 2H, TrOCH$_2$CH_2), 1.15 [m, 2H, TrO(CH$_2$)$_2$CH_2]. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 144.4, 128.6, 127.7, 126.8, 99.8, 86.3, 63.7, 60.1, 53.7, 53.6, 33.0, 28.3, 27.1, 24.1.

1,5,9-Tris(*tert*-butoxycarbonyl)-3-(3-chloropropyl)-1,5,9-triazacyclododecane (7). Orthoamide **6** (2.4 g, 5 mmol) was refluxed overnight in a mixture of concd aq HCl and dioxane (1:1, *v*/*v*, 30 mL). Volatiles were removed, and the aqueous phase was washed with CH_2Cl_2 and evaporated to dryness. Aqueous HCl (6 mol L^{-1}, 30 mL) was added to the residue. The mixture was refluxed again overnight and evaporated to dryness, and NaOH (1.2 g, 30 mmol) in aq acetonitrile (1:1, *v*/*v*, 60 mL) was added. Bis(*tert*-butyl) dicarbonate (5.5 g, 25 mmol) was added, and the reaction was allowed to stir at room temperature overnight. Volatiles were removed under reduced pressure, and the residue was purified by silica gel chromatography (3% MeOH and 0.5% Et_3N in CH_2Cl_2) to yield 0.85 g (31%) of the desired chloride **7** and 1.2 g (46%) of the corresponding alcohol **8**. **7:** MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 246 (30%) [M − 3×Boc]$^+$, 346 (29%) [M − 2×Boc]$^+$, 446 (22%) [M − Boc]$^+$, 547 (7%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.45−3.84 and 2.83−3.02 [m, 4H and m, 4H, 2×CH_2(CH_2N)$_2$], 3.48 (t, 2H, J = 6.5 Hz, $ClCH_2$), 3.30 [d, 4H, J = 7.1 Hz, CH_2CH(CH_2N)$_2$], 2.14 [m, 1H, CH_2CH(CH_2N)$_2$], 1.71−2.04 [m, 8H, $ClCH_2$-(CH_2)$_2$ and 2×CH_2(CH_2N)$_2$], 1.44 [s, 27H, 3×C(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 156.4, 156.2, 79.8, 79.7, 49.2, 47.6, 45.2, 43.8, 36.3, 29.6, 28.8, 28.7.

1,5,9-Tris(*tert*-butoxycarbonyl)-3-(3-hydroxypropyl)-1,5,9-triazacyclododecane (8). Compound **8** was obtained in 89% yield when orthoamide **6** was hydrolyzed in aq HCl (6 mol L^{-1}) without treatment with concd aq HCl in dioxane. MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 228 (25%) [M − 3×Boc]$^+$, 328 (28%) [M − 2×Boc]$^+$, 428 (25%) [M − Boc]$^+$, 529 (6%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.54−3.75 and 2.84−2.97 (m, 4H and m, 4H, 2×CH_2-(CH_2N)$_2$], 3.29 [d, 4H J = 7.0 Hz, CH_2CH(CH_2N)$_2$], 1.40−2.00 [m, 9H, (CH_2)$_2$CH(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.43 [s, 27H, 3×C(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 156.3, 79.8, 62.8, 53.7,47.7, 43.8, 36.5, 29.9, 28.7, 27.1.

3-(3-Acetylthiopropyl)-1,5,9-tris(*tert*-butoxycarbonyl)-1,5,9-triazacyclododecane (9). Potassium thioacetate (0.82 g, 7.2 mmol) and a catalytic amount of NaI were added to a solution of **7** (0.85 g, 1.6 mmol) in DMF (5.0 mL). The reaction mixture was allowed to stir overnight at 70 °C, and volatiles were then removed under reduced pressure. CH_2Cl_2 (70 mL) was added, and the resulting organic phase was washed with saturated $NaHCO_3$ and brine, dried over Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (20 to 30% EtOAc in petroleum ether) to yield 0.71 g (78%) of **9** as colorless oil. MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 287 (23%) [M − 3×Boc]$^+$, 387 (28%) [M − 2×Boc]$^+$, 487 (27%) [M − Boc]$^+$, 588 (5%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.57−3.70 and 2.81−2.96 [m, 4H and m, 4H, 2×CH_2(CH_2N)$_2$], 3.28 [d, 2H, J = 7.0 Hz, CH_2CH(CH_2N)$_2$)], 2.82 (t, 2H, J = 7.2 Hz, AcSCH_2), 2.30 (s, 3H, AcS), 1.34−2.00 [m, 9H, (CH_2)$_2$CH(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.45 [s, 27H, 3×C(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 191.5, 156.2, 79.7, 49.3, 47.6, 43.6, 36.4, 30.6, 29.8, 29.3, 28.4, 26.7.

1,5,9-Tris(*tert*-butoxycarbonyl)-3-(3-mercaptopropyl)-1,5,9-triazacyclododecane (10). A mixture of **9** (0.80 g, 1.4 mmol) and MeONa (30 mmol) in MeOH (30 mL) was stirred at room temperature overnight. The mixture was neutralized with acetic acid, and volatiles were removed under reduced pressure. CH_2Cl_2 (70 mL) was added, and the organic phase was washed with water and brine, dried over Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography to yield 0.69 g (93%) of **10** as colorless oil. MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 244 (6%) [M − 3×Boc]$^+$, 344 (6%) [M − 2×Boc], 444 (14%) [M − Boc]$^+$, 544 (17%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.63−3.70 and 2.87−2.98 [m, 4H and m, 4H, 2×CH_2(CH_2N)$_2$], 3.32 [d, 4H, J = 6.2 Hz, CH_2CH(CH_2N)$_2$)], 2.62 (t, 2H, J = 7.0 Hz, HSCH_2), 1.26−2.09 [m, 9H, (CH_2)$_2$CH(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.46 [s, 27H, 3×C(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 156.4, 156.2, 79.8, 49.4, 47.8, 43.7, 38.9, 36.6, 30.4, 29.9, 28.5, 26.3.

3-(3-Mercaptopropyl)-1,5,9-triazacyclododecane trihydrochloride (11). Compound **10** (0.67 g, 1.2 mmol) was dissolved in a mixture of EtOH (50 mL) and concd aq HCl (10 mL). The mixture was stirred for 3h at room temperature, and it was then evaporated to dryness. The crude reaction product (0.44 g, a quantitative amount) obtained as a white hygroscopic solid was used without purification for the preparation of the disulfide-tethered oligonucleotide conjugates. MS (EI): *m*/*z* 36 (100%) HCl, 212 (12) [M − SH]$^+$, 245 (10%) M^+. ^{1}H NMR (200 MHz, D_2O): δ = 3.16−3.20 (m, 12H, 6×CH_2N), 2.60 (t, 2H, J = 6.4 Hz, HSCH_2), 2.20 [m, 1H, CH_2CH(CH_2N)$_2$], 2.07 [m, 4H, 2×CH_2(CH_2N)$_2$], 1.66 (m, 2H, HSCH_2CH_2), 1.47 [m, 2H, HS(CH_2)$_2$CH_2]. ^{13}C NMR (50 MHz, D_2O): δ = 42.6, 39.8, 37.3, 34.2, 29.2, 25.8, 22.6, 15.8.

1,5,9-Tris(*tert*-butoxycarbonyl)-3-(3-phthalimidopropyl)-1,5,9-triazacyclododecane (12). DEAD (0.56 mL, 3.6 mmol) was added dropwise to a stirred mixture of **8** (1.7 g, 3.3 mmol), phthalimide (0.49 g, 3.3 mmol), and triphenylphosphine (0.87 g, 3.3 mmol) in THF (15 mL). The mixture was refluxed for 72 h, volatiles were removed under reduced pressure, and CH_2Cl_2 was added. The organic phase was washed two times with saturated $NaHCO_3$, dried over Na_2SO_4, and evaporated to dryness. The crude reaction mixture was purified by silica gel chromatography (50% EtOAc in petroleum ether) to yield 1.92 g (88%) of **12**. MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 357 (27%) [M − 3×Boc]$^+$, 457 (35%) [M − 2×Boc]$^+$, 557 (40%) [M − Boc]$^+$, 658 (5%) M^+. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.84 (q, 2H, J = 3.1 and 5.3 Hz, *o*-Pht), 7.72 (q, 2H, J = 3.1 and 5.6 Hz, M − Pht), 3.66 and 2.97−2.87 [m, 6H and m, 4H, CH_2NPht and 2×CH_2(CH_2N)$_2$], 3.30 [d, 4H, J = 6.9 Hz, CH_2CH(CH_2N)$_2$], 2.05−0.93 [m, 9H, (CH_2)$_2$CH-(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.44 [s, 27H, 3xC(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 167.3, 155.2, 132.9, 131.2, 124.6, 78.8, 73.9, 48.5, 46.6, 42.8, 37.1, 35.5, 28.8, 27.5, 24.7.

3-(3-Aminopropyl)-1,5,9-tris(*tert*-butoxycarbonyl)-1,5,9-triazacyclododecane (13). Compound **12** (1.8 g, 2.7 mmol) was dissolved in EtOH (10 mL), hydrazine hydrate (0.66 mL, 14 mmol) was added, and the reaction mixture was stirred overnight at room temperature. Volatiles were removed under reduced pressure, and CH_2Cl_2 was added. The resulting organic phase was washed with saturated $NaHCO_3$, dried over Na_2SO_4, and evaporated to dryness. The crude product was purified by silica gel chromatography (10% MeOH and 0.5% Et_3N in CH_2Cl_2) to yield 1.0 g (70%) of **13** as white foam. MS (EI): *m*/*z* 57 (100%) *t*Bu^+, 227 (10%) [M − 3×Boc]$^+$, 327 (8%) [M − 2×Boc]$^+$, 427 (6%) [M − Boc]$^+$, 528 (21%) M^+. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 3.61−3.54 and 2.88−2.85 [m, 4H and m, 4H, 2×CH_2(CH_2N)$_2$], 3.26 [d, 4H, J = 6.2 Hz, CH_2CH(CH_2N)$_2$], 2.62 (m, 2H, $CH_2CH_2NH_2$), 1.93 [m, 4H, 2xCH_2(CH_2N)$_2$], 1.77−1.85 [m, 1H, CH_2CH-(CH_2N)$_2$], 1.41 [s, 27H, 3×C(CH_3)$_3$], 1.25−1.31 (m, 2H, $CH_2CH_2CH_2NH_2$), 1.06−1.12 [m, 2H, CH_2(CH_2)$_2$$NH_2$]. ^{13}C NMR (100 MHz, $CDCl_3$): δ = 156.2, 79.6, 49.2, 47.7, 46.0, 43.6, 42.5, 36.5, 30.5, 29.9, 28.4.

3-(3-Aminopropyl)-1,5,9-triazacyclododecane (14). Compound **13** (0.85 g, 1.6 mmol) was dissolved in MeOH (5 mL), and aq HCl (6 mol L^{-1}, 5 mL) was added. The

mixture was stirred for 2 h at room temperature and then evaporated to dryness. The product was converted to the free base by passing it through a Dowex 2 × 8 resin (50/100 mesh, OH^- form) using water as an eluent. Water was removed to yield 0.89 g (80%) of **14** as colorless oil. MS (EI): *m/z* 228 (29%) M^+. ^1H NMR (200 MHz, D_2O): δ = 2.35−2.86 (m, 14H, 6×CH_2N, CH_2NH_2), 1.46−1.62 [m, 5H, 2×CH_2(CH_2N)$_2$ and CH_2CH(CH_2N)$_2$], 1.27−1.38 (m, 2H, C$H_2CH_2NH_2$), 1.03−1.21 [m, 2H, CH_2(CH_2)$_2NH_2$]. ^{13}C NMR (50 MHz, D_2O): δ = 49.5, 44.5, 44.0, 38.4, 32.7, 26.8, 25.6, 22.5.

***N*-{3-[1,5,9-Tris(*tert*-butoxycarbonyl)-1,5,9-triazacyclododec-3-yl]propyl}-3-(*tert*-butoxycarboxamido)-propanamide (15).** *N-tert*-Butoxycarbonyl-β-alanine (0.10 g, 0.50 mmol) and 1-hydroxybenzotriazole (70 mg, 0.50 mmol) were dissolved in 1,4-dioxane (6 mL), *N,N′*-dicyclohexylcarbodiimide was added, and the mixture was stirred for 30 min at room temperature. Compound **13** (0.26 g, 0.50 mmol) was added, and the reaction was allowed to stir for 22 h. Dicyclohexylurea formed was filtered off, and volatiles were removed under reduced pressure. The residue was dissolved in CH_2Cl_2 and washed with saturated $NaHCO_3$, 0.5 M citric acid, and brine. The organic phase was dried over Na_2SO_4 and evaporated to dryness. The crude reaction mixture was purified by silica gel chromatography (10% MeOH and 0.5% Et_3N in CH_2Cl_2) to yield 0.30 g (86%) of **15**. MS (EI): *m/z* 57 (100%) tBu$^+$, 298 (4%) [M − 4×Boc]$^+$, 398 (6%) [M − 3×Boc]$^+$, 498 (8%) [M − 2×Boc]$^+$, 599 (13%) [M − Boc]$^+$, 699 (3%) M^+. ^1H NMR (200 MHz, $CDCl_3$): δ = 3.58−2.80 (m, 16H, 6×CH_2N and BocNHCH_2CH_2-CONHCH_2), 2.20 (t, 2H, J = 7.3 Hz, BocNHCH_2CH_2CO), 1.90−1.11 [m, 9H, CH_2CH(CH_2N)$_2$, 2×CH_2(CH_2N)$_2$ and BocNH(CH_2)$_2$CONHCH_2(CH_2)$_2$], 1.39 [s, 36H, 4×C(CH_3)$_3$]. ^{13}C NMR (50 MHz, $CDCl_3$): δ = 170.0, 155.4, 78.7, 52.0, 48.8, 47.2, 45.5, 43.0, 36.7, 35.7, 29.4, 28.1, 24.4.

***N*-{3-[1,5,9-Tris(*tert*-butoxycarbonyl)-1,5,9-triazacyclododec-3-yl]propyl}-6-(*tert*-butoxycarboxamido)-hexanamide (16).** Compound **13** was conjugated with *N-tert*-butoxycarbonyl-6-aminohexanoic acid to obtain **16**, as described above for the preparation of **15**. Silica gel chromatography (0 to 10% MeOH and 0.5% Et_3N in CH_2Cl_2) gave 0.30 g (58%) of **16**. MS (EI): *m/z* 57 (100%) tBu$^+$, 340 (6%) [M − 4×Boc]$^+$, 440 (8%) [M − 3×Boc]$^+$, 540 (12%) [M − 2×Boc]$^+$, 641 (20%) [M − Boc]$^+$, 741 (2%) M^+. ^1H NMR (400 MHz, DMSO-d_6): δ = 3.49−3.66 and 2.92−3.05 [m, 4H and m, 4H, 2×CH_2(CH_2N)$_2$], 3.08−3.31 [m, 8H, CH_2CH(CH_2N)$_2$ and BocNHCH_2(CH_2)$_4$CONHCH_2], 2.17 [t, 2H, J = 7.5 Hz, BocNH(CH_2)$_4$CH_2], 1.79−2.01 and 1.29−1.37 [m, 10H, BocNHCH_2(CH_2)$_3$CH_2CONHCH_2-(CH_2)$_2$], 1.60−1.68 [m, 1H, CH_2CH(CH_2N)$_2$], 1.46 [s, 36H, 4×C(CH_3)$_3$].

***N*-{3-[1,5,9-Triazacyclododec-3-yl]propyl}-3-amino-propanamide (17).** Compound **15** (0.30 g, 0.43 mmol) was added to a mixture of TFA (5 mL) and CH_2Cl_2 (5 mL). After 1.5 h stirring at room temperature, the mixture was evaporated to dryness and the amino functionalized azacrown was converted to the free base by passing it through a Dowex 2 × 8 resin (50/100 mesh, OH^- form) using water as an eluent. Evaporation of the appropriate fractions gave 0.11 g (85%) of **17**. MS (EI): *m/z* 255 (25%) [M − $H_2NCH_2CH_2$]$^+$, 299 (100%) M^+. ^1H NMR (200 MHz, D_2O): δ = 2.98 [m, 2H, H_2N(CH_2)$_2$-CONHCH_2], 2.63 (m, 12H, 6xCH_2N), 2.39 (m, 2H, H_2NCH_2), 2.14 (m, 2H, $H_2NCH_2CH_2CO$), 1.49 [m, 5H, CH_2CH(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.32 [m, 2H, H_2N-(CH_2)$_2$CONHCH_2CH_2], 1.01 [m, 2H, H_2N(CH_2)$_2$CONH-(CH_2)$_2$CH_2]. ^{13}C NMR (50 MHz, D_2O): δ = 171.9, 49.4, 44.6, 44.3, 36.5, 36.1, 34.9, 32.3, 25.2, 23.3, 22.2.

***N*-{3-[1,5,9-Triazacyclododec-3-yl]propyl}-6-amino-hexanamide (18).** Compound **16** was converted to **18** (0.12 g, 91%), as described above for the conversion of **15** to **17**. MS (EI): *m/z* 255 (41%) [M − $H_2N(CH_2)_5$]$^+$, 341 (100%) M^+. ^1H NMR (200 MHz, D_2O): δ = 2.97 (t, 2H, J = 6.4 Hz, CONHCH_2), 2.54−2.79 (m, 12H, 6×CH_2N), 2.43 (m, 2H, H_2NCH_2), 2.04 (t, 2H, J = 7.2 Hz, CH_2CONH), 1.53 [m, 5H, CH_2CH(CH_2N)$_2$ and 2×CH_2(CH_2N)$_2$], 1.23−1.44 (m, 6H, $H_2NCH_2CH_2CH_2CH_2CH_2CONHCH_2CH_2$), 1.04−1.19 [$H_2N(CH_2)_2CH_2(CH_2)_2CONH(CH_2)_2CH_2$]. ^{13}C NMR (50 MHz, D_2O): δ = 173.9, 49.4, 44.7, 44.3, 38.5, 37.6, 36.4, 33.0, 32.2, 26.6, 25.2, 23.3, 22.6, 22.1.

Disulfide-Tethered Oligonucleotide 3′-Conjugate (22). A 13-mer 2′-*O*-methyl oligoribonucleotide, 5′-UUU CCG CAA UUU U-3′, was assembled by the conventional phosphoramidite chemistry on a polystyrene-anchored disulfide linker, **19**, prepared as described previously. The base moiety protections were removed by normal ammonolysis (concd aq NH_3, 55 °C, 8 h). The deprotected oligonucleotide was then cleaved from the support as a 3′-(3-mercaptopropyl)phosphate (**20**) with slightly alkaline aq dithiotreitol (DTT, 0.5 mol L^{-1}) by using a double-syringe method (Scheme 2) (*50*). The support was washed with water and MeCN, and the solution was evaporated to dryness. DTT was removed by precipitating **20** from EtOH. The terminal mercapto function was activated by conversion to 2-pyridyl disulfide (**21**) with aq bis(2-pyridyl) disulfide (*51*). The activated oligonucleotide (**21**) was purified by RP HPLC (Hypersil ODS, 10 × 250 mm, 5 μm), desalted, and evaporated to dryness. The 3-mercaptopropyl-functionalized azacrown **11** (4.0 mg, 10 μmol), triethylamine (5.7 μL, 40 μmol), and **21** were dissolved in water (1.0 mL), the reaction was allowed to proceed overnight at room temperature, and the mixture was then neutralized with acetic acid. The disulfide-tethered oligonucleotide conjugate **22** was purified by RP HPLC (Hypersil ODS, 10 × 250 mm, 5 μm; 5 min H_2O and then from 0 to 70% MeCN in 20 min, flow rate 1.0 mL min^{-1}, t_R 15−17 min). MS(MALDI): 4579.1 [M + H]$^+$, 2289.8 [(M + 2H)/2]$^+$. M_{calcd} 4578.8.

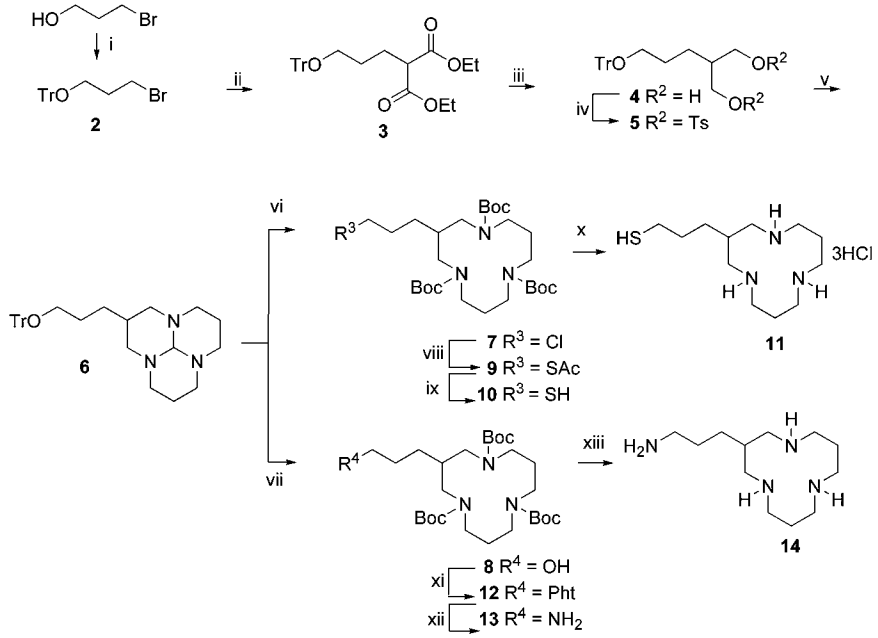
Amide Bond-Tethered Oligonucleotide 3′-Conjugates (24, 25). Two 13-mer 2′-*O*-methyl oligoribonucleotides, 5′-GGG UAG AGU GCG G-3′ and 5′-UUU CCG CAA UUU U-3′, were assembled from commercial 2′-*O*-methylated building blocks on a LCAA-CPG-supported thioester linker (*52*) (**23** in Scheme 3) using standard phosphoramidite RNA-coupling strategy. Upon completion of the chain assembly, the thioester linker was cleaved by shaking the support in 0.5 mol L^{-1} aq solution of the appropriate azacrown derivative, **14** or **17**, overnight at room temperature. To remove the remaining base protections, the solution phase was diluted with concd aq ammonia and kept 8.5 h at 55 °C. All volatile materials were evaporated under reduced pressure, the residue was dissolved in water, and the pH was adjusted to 7 with acetic acid. The oligonucleotide conjugates (**24**, **25**) obtained were purified by ion exchange chromatography on a SynChropak AX-300 column [4.6 × 250 mm, 6.5 μm; buffer A: 0.05 M KH_2PO_4 in 50% aq formamide, pH 5.6; buffer B: buffer A + 0.6 M $(NH_4)_2SO_4$; flow rate: 1 mL min^{-1}; a linear gradient from 10 to 70% B in 35 min] and desalted by RP HPLC (Hypersil ODS, 10 × 250 mm, 5 μm) by applying gradient elution from water to 50% (v/v) aq acetonitrile. The oligonucleotides were characterized by mass spectrometry. The overall isolated yield of both **24** and **25** was about 20%. The authenticity of the conjugates was verified by ESI-MS. MS(ESI) for **24**: *m/z* 685.6 (100%) [M − 7H]$^{7-}$, 800.1 (60%) [M − 6H]$^{6-}$, 960.3 (40%) [M − 5H]$^{5-}$, 1200.6 (31%) [M − 4H]$^{4-}$,

1601.1 (14%) $[M - 3H]^{3-}$. M_{obs} 4806.4, M_{calcd} 4805.0. MS(ESI) for **25**: *m/z* 574.4 (23%) $[M - 8H]^{8-}$, 656.6 (71%) $[M - 7H]^{7-}$, 766.1 (100%) $[M - 6H]^{6-}$, 919.7 (54%) $[M - 5H]^{5-}$, 1149.8 (38%) $[M - 4H]^{4-}$, 1532.9 (22%) $[M - 3H]^{3-}$. M_{obs} 4602.9, M_{calcd} 4604.2.

Amide Bond-Tethered Oligonucleotide 5′-Conjugate (28). The 5′-tethered azacrown conjugate (**28**) of a 13-mer 2′-*O*-methyl oligoribonucleotide, 5′-GGC GUG AGA UGG G-3′, was prepared by the normal phosphoramidite chemistry using a thioester phosphoramidite reagent **26** (0.6 mol L^{-1} in MeCN; coupling time 600 s) in the last coupling cycle to obtain conjugate **27** and cleaving the thioester bond with the 3-aminopropyl derivatized azacrown **14** (Scheme 4). The conjugate was isolated and purified as described above for conjugate **24**.

Amide Bond-Tethered Oligonucleotide Intrachain Conjugates (31−33). A 17-mer 2′-*O*-methyloligoribonucleotide (**30**), 5′-CUC UCC XGC AAG CUU CG-3′, was assembled by the conventional phosphoramidite strategy (Scheme 5). In the sequence, X stands for the abasic building block **29**, which was prepared as described previously (*49*). Upon completion of the oligonucleotide chain assembly, the protected oligonucleotide was treated with an azacrown derivative, either **14**, **17**, or **18** (0.5 mol L^{-1} solution of the free base in water), and then with concd aq ammonia, as described above, to afford the intrachain conjugates **31**, **32**, and **33**, respectively. The conjugates were isolated, purified by ion exchange HPLC and desalted as described above for conjugates **24** and **25.** The overall isolated yields ranged from 7 to14% (10−20 OD). The auhtenticity of the conjugates was verified by ESI-MS. MS(ESI) for **31**: *m/z* 565.7 (28%) $[M - 10H]^{10-}$, 628.7 (88%) $[M - 9H]^{9-}$, 707.6 (96%) $[M - 8H]^{8-}$, 808.4 (100%) $[M - 7H]^{7-}$, 943.7 (31%) $[M - 6H]^{6-}$, 1132.4 (38%) $[M - 5H]^{5-}$, 1415.6 (22%) $[M - 4H]^{4-}$. M_{obs} 5667.2, M_{calcd} 5664.9. MS(ESI) for **32**: *m/z* 572.9 (28%) $[M - 10H]^{10-}$, 636.5 (71%) $[M - 9H]^{9-}$, 716.3 (100%) $[M - 8H]^{8-}$, 818.6 (95%) $[M - 7H]^{7-}$, 955.1 (63%) $[M - 6H]^{6-}$, 1146.2 (55%) $[M - 5H]^{5-}$, 1433.3 (32%) $[M - 4H]^{4-}$, 1912.1 (4%) $[M - 3H]^{3-}$. M_{obs} 5780.3, M_{calcd} 5778.1.

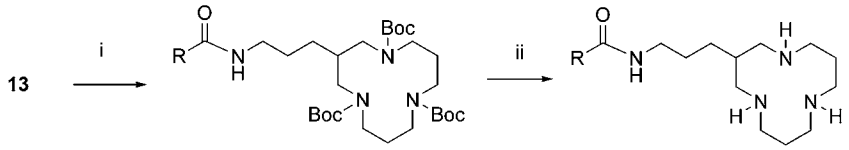
Thymidine 3′-(2-Cyanoethyl, 2-benzylthio-2-oxoethyl)phosphate (34). Carefully dried benzylthio ester of glycolic acid (92 mg, 0.50 mmol) and 5′-*O*-(4,4′-dimethoxytrityl)thymidine 3′-[*O*-(2-cyanoethyl)-*N*,*N*-diisopropyl]phosphoramidite (250 mg, 0.34 mmol, Glenn Research) were dissolved in dry acetonitrile (180 mL), 1*H*-tetrazole (1.36 mmol, 3.0 mL of 0.45 mol L^{-1} solution in acetonitrile) was added, and the mixture was stirred for 2 h at room temperature. The reaction mixture was concentrated under reduced pressure, and 9.5 mL of 0.1 mol L^{-1} solution of iodine in a mixture of THF and water (2:1) was added. After 35 min at room temperature, an aq $NaHCO_3/CH_2Cl_2$ workup was carried out, and the product was treated for 50 min with a mixture of CH_2Cl_2, dichloroacetic acid, and EtOH (10 mL, 85:5:1, v/v) to remove the dimethoxytrityl protection. The crude product obtained by an aq $NaHCO_3/CH_2Cl_2$ workup was purified by silica gel chromatography (5% MeOH in CH_2Cl_2) yielding **34** as a yellow foam (130 mg, 71%). MS(ESI): *m/z* 225.4 (94%) $[Thd\text{-}OH]^+$, 316.1 (100%) $[NC(CH_2)_2OP(OH)_2OCH_2COSBn]^+$, 540.4 (81%) $[MH]^+$, 1079.6 (36%) $[2MH]^+$. ^1H NMR (400 MHz; $CDCl_3$): $\delta = 9.25$ (1H, br s, N*H*), 7.39 (1H, s, *H*6), 7.25 (5H, m, Phe), 6.11 (1H, t, $J =$ 7.5 Hz, *H*1′), 5.18 (1H, m, *H*3′), 4.69 (2H, d, $J = 10.2$ Hz, OCH_2COSBn), 4.30 (2H, m, OCH_2CH_2CN), 4.17 (1H, m, *H*4′), 4.13 (2H, s, SCH_2Ph), 3.82 (2H, m, *H*5′ and *H*5″), 3.14 (1H, br s, 5′-O*H*), 2.73 (2H, t, $J = 6.8$ Hz, OCH_2CH_2CN), 2.47 (2H, m, *H*2′ and *H*2″), 1.83 (3H, s, CH_3). ^{31}P NMR (162 MHz; $CDCl_3$): $\delta = -3.47$ ppm.



Thymidine 3′-{2-[3-(1,5,9-Triazacyclododec-3-yl)-propylamino]-2-oxoethyl}phosphate (35). Equal volumes of a 3.0 mmol L^{-1} solution of **34** in MeCN and a 0.5 mol L^{-1} aq solution of **14** as a free base were mixed. The progress of the reaction was followed by HPLC-ESI-MS on a LiChroCART ODS column (4 × 250 mm, 5 μm) using a gradient elution: isocratic elution with an acetic acid/sodium acetate buffer (pH 3.4) for 5 min was followed by linear increase of the MeCN content from 0% to 100% in 25 min. The starting material **34** disappeared almost immediately, and two products, the desired azacrown derivative **35** and the hydrolysis product of **34** (thymidine 3′-carboxymethyl phosphate), were formed. The retention times were at a flow rate 1 mL min^{-1} 11.3 (*m/z* 589.6) and 14.7 min (*m/z* 379.0), respectively. Compound **35** was isolated on a semipreparative LiChroCART RP-18 column (10 × 250 mm, 5 μm) and characterized by ^1H NMR spectroscopy. MS(ESI): *m/z* 589.6 (100%) M^-. ^1H NMR (500 MHz; CD_2HOD): 7.83 (1H, s, *H*6), 6.28 (1H, dd, $J =$ 7.8 and 6.2 Hz, *H*1′), 4.87 (1H, m, *H*3′), 4.35 (2H, d, $J =$ 9.1 Hz, OCH_2CONH), 4.13 (1H, m, *H*4′), 3.79 (2H, m, *H*5′ and *H*5″), 3.30 (2H, m, $CONHCH_2$), 3.01−3.26 (12H, m, *H*2,*H*4,*H*6,*H*8,*H*10,*H*12 of [12]aneN$_3$), 2.43 (1H, m, *H*2′), 2.31 (1H, m, *H*2″), 2.05 (5H, m, *H*3,*H*7,*H*11 of [12]aneN$_3$), 1.89 (3H, s, CH_3), 1.63 (2H, m, $OCH_2CONHCH_2CH_2$), 1.40 (2H, m, $OCH_2CONHCH_2CH_2CH_2$).

Cleavage Assays. The reactions were carried out in small seal-cap vials immersed in a water bath, the temperature of which was maintained at 35.0 ± 0.1 °C. The volume of the reaction mixture was 200 μL. The pH was adjusted to 7.3 with a HEPES buffer (0.1 mol L^{-1}, $I =$ 0.1 mol L^{-1} with $NaNO_3$). Zinc ions were added as nitrates in 20% excess compared to the azacrown functionalized oligonucleotide, the concentration of which was 4.5 μmol L^{-1} with **22** and 18 μmol L^{-1} with **25**, **32**, and **33**. The concentration of the target was double compared to that of the cleaving agent. *p*-Toluenesulfonate or *p*-nitrobenzenesulfonate ion was used as an internal standard. Aliquots of 20 μL were withdrawn at suitable intervals and immediately cooled to 0 °C. The reaction was quenched by adding aqueous hydrogen chloride (1.0 μL of 1.0 mol L^{-1} solution). The samples were analyzed immediately by capillary zone electrophoresis (CZE; Hewlett-Packard ^{3}DCE or Beckman Coulter P/ACE MDQ CE system) using a fused silica capillary, inverted polarity, and a citrate buffer (0.2 M, pH 3.2) as a background electrolyte. The voltage applied was −30 kV. The temperature of the capillary was kept at 25 °C. Hydrodynamic injection and UV detection were applied.

RESULTS AND DISCUSSION



Preparation of the Functionalized Azacrowns. Azacrowns are usually functionalized for conjugation by attachment of an appropriate sidearm to one of the ring nitrogens. Alkylation of one of the donor atoms may, however, be expected to reduce the binding ability of the relatively small triaza crown (1) employed in the present work. For comparison, methylation of all the nitrogen atoms of 1,4,8,11-tetraazacycotetradecane destabilizes the Zn^{2+} complex by 5 orders of magnitude (*53*). Accordingly, tethering through a carbon atom appears more attractive. Preparation of 3-(3-aminopropyl)-1,5,9-triazacyclododecane (**14**) starting from commercially available

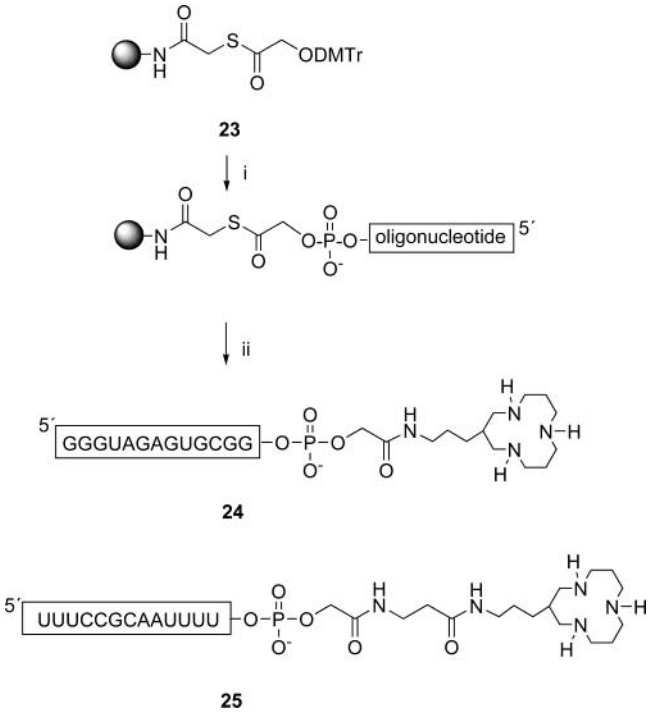
diethyl 2-(2-cyanoethyl)malonate has been described previously (*54*). Scaling up of the reported synthesis is, however, difficult since the first step, viz. reduction of the cyano group to an amino group with borane−dimethyl sulfide, yields the desired 2-(3-aminopropyl)-1,3-propanediol as a minor component (34%), the corresponding monoethyl ether being the major product (59%). A reaction that necessitated a careful chromatographic separation at an early stage of a multistep synthesis proved inconvenient in our hands and, hence, the synthesis was modified to the form depicted in Scheme 1. Accordingly, diethyl 2-(3-trityloxypropyl)malonate (**3**) obtained by alkylation of 3-trityloxypropyl bromide (2) with diethyl malonate carbanion was used as the starting material. $LiAlH_4$ reduction to a diol (**4**) and conversion to a ditosylate (**5**) allowed introduction of the azacrown structure by a nucleophilic displacement with TBD, as originally shown by Alder et al. (*55*) and Kim et al. (*56*) and also utilized in the previous synthesis. Acid-catalyzed hydrolysis of the resulting orthoamide (**6**) and removal of the trityl group in a single step followed by introduction of Boc-protection on the ring nitrogen atoms gave the 3-(3-hydroxypropyl)-functionalized azacrown (**8**). The hydroxy function was displaced with a phthaloyl group by a Mitsunobu reaction **12**, and the amino group was exposed (**13**) by a hydrazine treatment. The Boc-protections were finally removed with aq hydrogen chloride and the product obtained as a hydrochloride salt was converted to a free base (**14**) by passing it through a strong anion-exchange resin (Dowex 2 × 8) in a hydroxy ion form. All the reactions proceeded in a good yield, typically around 80% without optimization, giving the final product in a 15% overall yield.

The 3-(3-mercaptopropyl) derivatized azacrown (**11**) was prepared from the same orthoamide (**6**) as its 3-aminopropyl counterpart. When **6** was treated with concd aq hydrogen chloride in dioxane, the 3-(3-chloropropyl) azacrown (**7**) was obtained in a 31% yield, besides the corresponding alcohol (**8**). Displacement of the chloro substituent with a thioacetate ion (**9**), followed by removal of the acetyl- and Boc-protections by a base-catalyzed transesterification and acid-catalyzed hydrolysis, respectively, gave 3-(3-mercaptopropyl)-1,5,9-triazacyclododecane as a hydrochloride salt in a 73% yield.

The pendant group of 3-(3-aminopropyl)-1,5,9-triazacyclododecane was elongated by acylating the primary amino group of 13 with *N*-Boc-protected *β*-alanine and 6-aminohexanoic acid (Scheme 2). A conventional DCC/HOBt-coupling was applied. Removal of the Boc groups from the products (**15**, **16**) and conversion to a free base gave the *N*-(3-aminopropanoyl)-3-aminopropyl (**17**) and *N*-(6-aminohexanoyl)-3-aminopropyl (**18**) azacrowns in a 73% and 53% yield, rescectively.

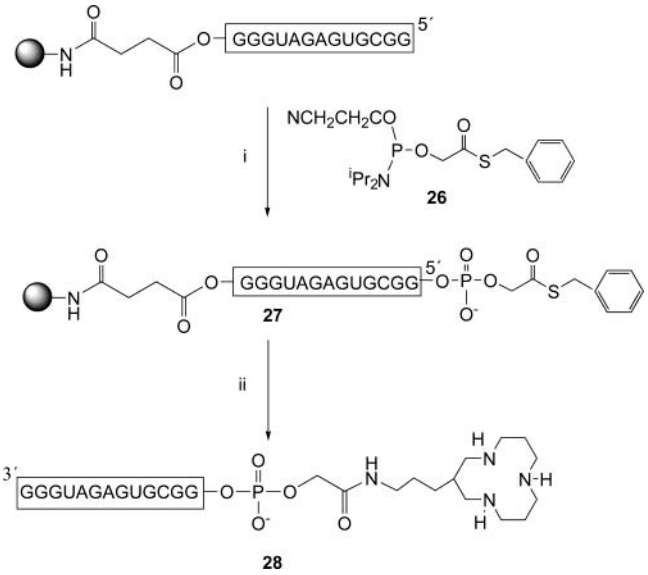
Scheme 3[a]



[a] Reagents and conditions: (i) 1. Oligonucleotide synthesis 2. concd aq NH_3, 3. DTT, aq; (ii) PySSPy; (iii) **11**, Et_3N, H_2O.

Preparation of the disulfide-tethered oligonucleotide conjugate. Conjugation of the 3-(3-mercaptopropyl) azacrown (**11**) to the 3′-terminus of a 13-mer 2′-*O*-methyl oligoribonucleotide is outlined in Scheme 3. Accordingly, the oligonucleotide was first assembled by the conventional phosphoramidite chemistry on a polystyrene-anchored disulfide linker (19), prepared as described previously (*50*). The acyl protections of the base moieties were removed by normal ammonolysis, and the oligonucleotide was then cleaved from the support with slightly alkaline aq dithiotreitol and purified by precipitation from EtOH, as also shown earlier. The terminal mercapto function of the 3′-(3-mercaptopropyl)-tailed oligonucleotide (**20**) was activated by conversion to a 2-pyridyl disulfide (**21**) and reacted with the mercapto-functionalized azacrown (**11**) in silightly basic aq solution. The disulfide-tethered conjugate (**22**) was purified by RP-HPLC and characterized by MALDI-MS.

Preparation of the Amide Bond-Tethered Oligonucleotide Conjugates. The previously developed thioester approach was applied to obtain the oligonucleotide conjugates having the azacrown tethered via an amide bond. Accordingly, the 3′-tethered conjugates were prepared by assembling the desired 2′-*O*-methyl oligoribonucleotide on a LCAA-CPG-supported thioester linker **23** (Scheme 4) and the linker was cleaved by using an appropriate azacrown derivative, viz. **14** or **17**, as the attacking nucleophile. The deprotection of the conjugates (**24**, **25**) was completed by ammonolysis in solution and the conjugates were then purified by ion-exchange HPLC, desalted by RP-HPLC, and characterized by ESI-MS.



Conjugation to the 5′-terminus was achieved by assembling the chain on a standard succinyl-linker using a nonnucleosidic thioester phosphoramidite reagent (26) in the last coupling cycle (Scheme 5). The azacrown derivative (**14**) was then introduced upon the aminolytic cleavage of the conjugate (**27**) from the support, and the

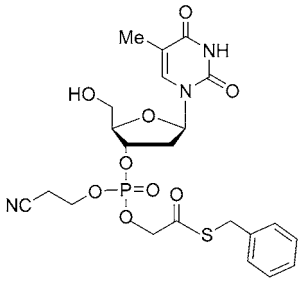
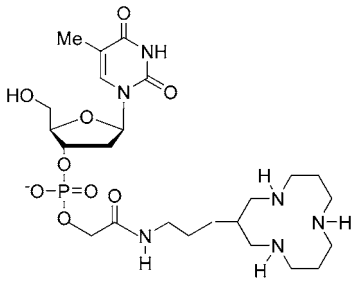
deprotected oligonucleotide conjugate (**28**) was purified and characterized as the 3′-conjugates.



Conjugation to an intrachain position was performed with the aid of an abasic *C*1-(2-benzylthio-2-oxoethyl) building block (**29**) prepared as described previously (*49*). Upon insertion of this unit in a desired position within the chain and completion of the chain assembly to obtain the solid-supported oligonucleotide **30**, the thioester bond was cleaved with three different azacrown derivatives, **14**, **17**, or **18**, bearing 4-, 8-, and 11-atom long pendant aromatics, respectively (Scheme 6). The intrachain conjugates obtained (**31**−**33**) were ammonolyzed, purified, desalted, and characterized as described above the 3′-conjugates.

Scheme 6[a]



[a] Reagents and conditions: (i) Oligonucleotide synthesis; (ii) 1. **14**, **17**, or **18**, aq, 2. concd aq NH_3.

Since the thioester bonds were cleaved with fully deprotected azacrown derivatives (**14**, **17**, **18**), the ring nitrogen atoms could in principle compete with the primary amino group as nucleophiles. To verify that the difference between the nucleophilicity of the primary and secondary amino groups was sufficient to warrant the formation of a single product, the cleavage reaction was studied in more detail with a monomeric model compound (**34**) prepared from a commercial thymidine 3′-phos-

34

phoramidite building block and benzylthio ester of glycolic acid (*52*) by the conventional phosphoramidite chemistry in solution. This compound was treated with 0.5 mol L^{-1} solution of the 3-aminopropyl-functionalized azacrown (**14**) in a 1:1 mixture of water and MeCN and the progress of the reaction was followed by HPLC-ESI-MS. Rapid disappearance of the starting material (**34**) was accompanied by formation of two products, the desired azacrown derivative (**35**; *m*/*z* 589.6) and thymidine 3′-carboxymethyl phosphate (*m*/*z* 379.0), the hydrolysis product of **34**. Compound **35** was isolated by

35

semipreparative RP-HPLC and characterized by NMR spectroscopy. In the heteronuclear multibond correlation spectrum (HMBC), the carbonyl carbon of the amide bond (170 ppm) was coupled to the methylene protons (3.30 ppm) of C3 of the sidearm of the azacrown moiety consistent with bonding to the primary amino group.

Cleavage Experiments. The ability of the 3′-tethered conjugates (**22**, **25**) to cleave, as their Zn^{2+} chelates, a complementary chimeric 2′-*O*-methylribo/ribo oligonucleotide (**36**) was studied. The reactions were carried

3′-**AAA GGC GUU** AAA AUC UUC AU-5′

(2′-*O*-Me-ribonucleosides indicated with

bold and ribonucleosides with normal letters)

36

out in a HEPES buffer (0.1 mol L^{-1}, $I = 0.1$ mol L^{-1} with $NaNO_3$) at 35.0 ± 0.1 °C. The initial concentrations of conjugates **22** and **25** were 4.5 and 18 μmol L^{-1}, respectively. The concentration of the target was double com-

Notation: $T = 35.0$ °C, $I = 0.1$ mol L^{-1} with $NaNO_3$. Filled squares refer to target **36** cleaved by conjugate **22**, filled circles to target **36** cleaved by conjuagate **25**, and filled triangles to target **37** cleaved by conjugate **32**.

pared to that of the conjugate. *p*-Toluenesulfonate or *p*-nitrobenzenesulfonate ion was used as an internal standard. The progress of the reactions was followed by analyzing the content of the aliquots withdrawn at suitable intervals by capillary zone electrophoresis with UV-detection. Both conjugates cleaved the target sequence. The disappearance of the signal of the target was in both cases accompanied by appearance of two product signals. On using **22** as a cleaving agent and a 102 cm capillary, the signal at 21.8 min disappeared and those at 20.5 and 30.5 min appeared, while on using **25** and a 50 cm capillary, the signal at 9.8 min disappeared and those at 10.7 and 11.1 min appeared. Both conjugates also showed turnover without any indication of product inhibition. In other words, the disappearance of the target was complete, and it obeyed first-order kinetics throughout a kinetic run (Figure 1), although the concentration of the target was double compared to that of the cleaving agent. Since the complementary region in duplexes **22**/**36** and **25**/**36** is only 13 nucleotides long and contains only 4 CG pairs, it appears likely that the conjugate remains largely unhybridized under the experimental conditions and, hence, the effective concentration of the cleaving agent remains constant during a kinetic run. Quite unexpectedly, the disulfide-tethered conjugate (**22**) turned out to cleave the target 8 times as fast as the amide bond-tethered conjugate (**25**), although the length of the linker is almost equal, viz. 10 and 12 atoms between the 3′-terminal oxygen atom and *C*3 of the azacrown. Either, the cleaving ability is very susceptible to the length of the linker, or the amide bond present in the linker interacts with the chelated Zn^{2+} ion reducing its catalytic activity. One should also bear in mind that the results obtained with **22** and **25** refer to different concentrations of the cleaving agent, 4.5 and 18 μmol L^{-1}, respectively. Accordingly, the possibility that the cleaving agent tends at higher concentrations to become deactivated by aggragation cannot be excluded. The disulfide-tethered conjugate (**22**) turned out to be an approximately as efficient cleaving agent as the previously reported Zn^{2+}-based artificial RNases. The half-life for the disappearance of the target is about 20 h at 35 °C, while a nuclease derived from a Zn^{2+}/2,9-dimethylphenantroline chelate has been reported to cleave 50% of the target in 60 h at 37 °C (*30*) and a nuclease bearing a dinuclear *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)-3,5-bis(aminomethyl)phenoxy chelate 5% of the target in 3 h at 37 °C (*29*).

Conjugates **32** and **33** bearing a Zn^{2+}/[12]aneN_3 in an intrachain position cleaved target **37**, having a trinucleotide bulge opposite to cleaving agent (Figure 1). Again the cleavage reaction obeyed nicely first-order kinetics. Conjugate **32**, having a shorter linker, turned out to be a more efficient cleaving agent than conjugate **33**. The cleaving activity was comparable to that of the corresponding 3′-tethered conjugate **25**. By contrast, the 5′-tethered conjugate **28** did not show any cleaving activity during 100 h under the same conditions.

Site-Specific Conjugation of Boron-Containing Dendrimers to Anti-EGF Receptor Monoclonal Antibody Cetuximab (IMC-C225) and Its Evaluation as a Potential Delivery Agent for Neutron Capture Therapy

Gong Wu,[†] Rolf F. Barth,[†,*] Weilian Yang,[†] Madhumita Chatterjee,[‡] Werner Tjarks,[‡] Michael J. Ciesielski,[§] and Robert A. Fenstermaker[§]

Department of Pathology and College of Pharmacy, The Ohio State University, Columbus, Ohio 43210 and Department of Neurosurgery, Roswell Park Cancer Institute, Buffalo, New York 14263. Received September 15, 2003; Revised Manuscript Received October 29, 2003

The gene encoding EGFR often is amplified in human gliomas, and the receptor itself has been considered as a potential target for the specific delivery of therapeutic agents to brain tumors. The purpose of the present study was to investigate the use of the chimeric MoAb cetuximab (IMC-C225), which is directed against EGFR and EGFRvIII, as a boron delivery agent for neutron capture therapy (NCT) of brain tumors. As determined by ^{125}I-cetuximab radioligand binding assays, F98 rat glioma cells, which had been transfected with the gene encoding EGFR ($F98_{EGFR}$), expressed $1.60 \pm 0.13 \times 10^5$ receptor sites/cell with a $K_a = 1.64 \pm 0.32 \times 10^8$ M^{-1}. F98 cells transfected with the gene encoding a mutant form of EGFR, designated the $F98_{EGFRvIII}$ glioma, expressed $1.07 \pm 0.10 \times 10^5$ receptor sites/cell with a $K_a = 2.18 \pm 0.54 \times 10^9$ M^{-1} compared to background levels expressed on F98 wild-type cells ($F98_{WT}$). A heavily boronated, fifth generation polyamidoamine (PAMAM or "starburst") dendrimer, G5-B_{1100}, was linked to oligosaccharide moieties, which were distant from antigen binding sites of cetuximab, by means of the heterobifunctional reagents *N*-succinimidyl 3-(2-pyridyldithio)-propionate (SPDP) and *N*-(k-maleimidoundecanoic acid) hydrazide (KMUH). The resulting bioconjugate, designated C225-G5-B_{1100}, was separated from the unconjugated dendrimer using a Sephacryl S-300 column. On the basis of the relative concentration ratios of boron and protein, there were ~1100 boron atoms per molecule of cetuximab with only a slight reduction of K_a. The localization of C225-G5-B_{1100} or G5-B_{1100} in rats bearing intracerebral implants of either $F98_{EGFR}$ or $F98_{WT}$ gliomas was determined 24 h following direct intratumoral (i.t.) injection at which time 92.3 ± 23.3 μg B/g tumor was localized in $F98_{EGFR}$ gliomas versus 36.5 ± 18.8 μg B/g tumor in $F98_{WT}$ gliomas and 13.4 ± 6.1 μg in normal brain. In contrast, only 6.7 ± 3.6 μg B/g tumor of G5-B_{1100} was localized in $F98_{EGFR}$ gliomas following i.t. injection, thereby demonstrating specific molecular targeting of EGFR. Based on these data, BNCT studies will be initiated in $F98_{EGFR}$ glioma bearing rats to evaluate C225-G5-B_{1100} for the treatment of intracerebral brain tumors.

INTRODUCTION

Malignant gliomas are fast growing, highly invasive brain tumors that usually lead to death within 12−18 months following diagnosis (*1*). Despite intensive research over the past several decades, high grade gliomas still are extremely resistant to all current forms of therapy, including surgery, chemotherapy, and radiotherapy (*2*). The long term survival of patients, which is almost 0 % at 5 years, has remained unchanged, and depending upon a number of factors, the 2 year survival is usually less than 10% (*1*). However, significant advances have been made in understanding the molecular genetic events leading to the development and progression of gliomas, and this hopefully will lead to the development of new molecular therapeutic agents designed to specifically inhibit tumor cell proliferation and invasion (*3*, *4*).

The epidermal growth factor receptor (EGFR)[1] or its mutant isoform EGFRvIII are attractive targets for the

treatment of gliomas since they frequently are overexpressed in brain tumors (*5*, *6*). A number of drugs (*7*−*10*) and monoclonal antibodies (*11*−*13*) have been developed to target the EGFR and its signaling pathways (*14*, *15*). Among these is the MoAb cetuximab (IMC-C225), which has been produced by ImClone Systems, Inc., New York, NY. Cetuximab is a chimeric MoAb directed against both wild-type EGFR, and its mutant isoform, EGFRvIII (*16*). This antibody can block the binding of both EGF and TGF-α to their receptors (*16*,*17*), thereby interfering with cell signaling pathways (*14*, *15*) and producing cell cycle arrest and apoptosis (*17*). Phase I clinical trials have shown that cetuximab is well tolerated (*18*, *19*) and preclinical studies (*17*, *18*, *20*), as well as Phase II trials in patients with EGFR positive cancers, have demonstrated that cetuximab had a synergistic effect when administered together with ionizing radiation (*20*, *21*), and cytoreductive chemotherapeutic agents such as cisplatin (*22*), doxorubicin (*23*), gemcitabine (*24*), and docetaxel (*25*).

We previously have reported on the use of heavily boronated "PAMAM" (starburst) dendrimers linked to MoAbs (*26*−*28*) or EGF (*29*) as potential boron delivery agents for neutron capture therapy. Using several different approaches, Carlsson and co-workers have produced a variety of other boron-containing EGF targeting vehicles for boron neutron capture therapy (*30*−*32*). BNCT is based on the nuclear capture and fission reactions that occur when ^{10}B is irradiated with low energy (<0.025 eV) thermal neutrons to produce high LET α particles and recoiling ^{7}Li nuclei, which have path lengths of ∼9 μm and ∼5 μm, respectively. In order for BNCT to be successful for the treatment of brain tumors, ^{10}B concentrations in the tumor should be in the range of 15−20 μg/g, and concomitantly, levels in normal brain should be low. These requirements have been discussed in detail in several recent reviews and monographs (*33*−*36*), and this has been the subject of a recent issue of a neuro-oncology journal (*37*). The use of cetuximab as a boron delivery agent for NCT of gliomas is particularly attractive since not only would the boronated bioconjugate kill tumor cells as a result of the high LET particles produced following neutron irradiation, but it also could block the binding of EGF and TGF-α to EGFR, thereby interfering with critical signal transduction pathways and acting synergistically with BNCT.

We recently have reported on the use of boronated EGF as a molecular targeting agent for BNCT of the F98 rat glioma that had been transfected with the gene encoding human EGFR (*38*). In the present report we describe the preparation and in vitro and in vivo evaluation of cetuximab, which has been site specifically linked to a boronated fifth generation PAMAM dendrimer. This bioconjugate has the capacity to deliver twice the amount of boron compared to that of a previously described (*29*) fourth generation dendrimer/EGF bioconjugate with a minimal reduction in its binding affinity and favorable biodistribution following i.t. delivery.

EXPERIMENTAL PROCEDURES

General Synthetic/Analytical Methods and Materials. A fifth generation PAMAM dendrimer, containing 128 reactive terminal amine groups, was purchased from Sigma-Aldrich Corp., St. Louis, MO; $Na(CH_3)_3NB_{10}H_8NCO$ was prepared from $(CH_3)_3NB_{10}H_8CO$ (Katchem Ltd., Prague, Czech Republic), as previously described (*39*). *N*-Succinimidyl 3-(2-pyridyldithio)propionate and *N*-(κ-maleimidoundecanoic acid) hydrazide both were purchased from Pierce, Rockford, IL. Other chemicals were of reagent grade and were purchased from a number of chemical supply companies. Cetuximab was generously provided by Dr. Daniel Hicklin, ImClone Systems Inc. (New York, NY). Millipore Stirred Cell/Ultrafiltration Membrane (MWCO 100 000) was purchased from Fisher Scientific, Pittsburgh, PA. PD-10 disposable columns, Sephadex G25 and Sephacryl S-300 were purchased from Amersham Pharmacia Biotech, Piscataway, NJ. UV measurements were carried out by means of a Beckman DU6 recording spectrophotometer (Beckman, Fullerton, CA). The protein concentrations of unmodified cetuximab were determined by UV absorption spectrometry at 280 nm, and those of boronated cetuximab were determined at 595 nm using a Coomassie protein assay reagent (Pierce, Rockford, IL). All measurements were made against known concentrations of cetuximab as a reference standard. The concentrations of SPDP in the SPDP-G5-B_{1100} conjugate were determined by UV spectrometry at 343 nm following cleavage of the disulfide bond by DTT. Boron was quantified by means of direct current plasma-atomic emission spectroscopy, using a Spectraspan VB spectrometer (Applied Research Laboratories, La Brea, CA), as previously described by us (*40*). Briefly, 10 μL of the boron containing sample were diluted to 1.0 mL with 0.1 M phosphate buffer, pH 7.5, and the boron concentrations were determined by DCP-AES at 249 nm. The instrument was calibrated using standard boron solutions (VHG Labs, Manchester, NH).

Oxidation of Cetuximab and Conjugation to G5-B_{1100}. A schematic representation of the conjugation chemistry that was used is shown in Figure 1. $NaIO_4$ (**2**, 2.14 mg, 10 μmol) was added to a 1.0 mL of cetuximab (**1**, 2 mg, 13 nmol) in 0.1 M acetate buffer (pH 4.5), and the reaction mixture was kept in the dark for 2 h at ambient temperature. The oxidized cetuximab (C225-CHO, **3**) was desalted on a PD-10 column by elution with 50 mM phosphate buffer (pH 7.4). G5 (**4**, 1.15 g, 5% w/w in methyl alcohol, 2 μmol) and SPDP (**5**, 3.12 mg, 10 μmol) were incubated in 1.0 mL of 0.1 M PBS (pH 7.5) at ambient temperature for 2 h and then applied to a PD-10 column, and the intermediate (SPDP-G5, **6**) was eluted with 0.1 M carbonate buffer (pH 9.0). The number of SPDP molecules linked to G5 was determined by UV spectrometry, as described in a preceding section. The introduction of boron clusters into SPDP-G5 was carried out with minor modifications, as previously described (*39*). Briefly, SPDP-G5 (58 mg, 2 μmol) (**6**) and $Na(CH_3)_3NB_{10}H_8NCO$ (**7**, 117 mg, 250 μmol) were reacted in 1.0 mL of 0.1 M carbonate/bicarbonate buffer, pH 9.0, at ambient temperature for 24 h to yield SPDP-G5-B_{1100} (**8**). The low molecular components of the mixture were separated from SPDP-G5-B_{1100} by PD-10 column chromatography using 50 mM phosphate buffer (10% DMSO, pH 7.5) as the mobile phase. The number of the boron clusters in SPDP-G5-B_{1100} was estimated by comparing the boron concentrations before and after passage through a PD-10 desalting column. The disulfide bond of SPDP-G5-B_{1100} subsequently was cleaved by exposing the bioconjugate to DTT (7.7 mg, 50 μmol) (**9**) in 0.1 M phosphate buffer (pH 7.5) containing 10% DMSO, for 30 min at ambient temperature. Low molecular weight contaminants were removed by passing the mixture through a PD-10 column using the same buffer system. The resulting sulfhydryl-containing HS-G5-B_{1100} bioconjugate (**10**) was mixed with 100 μL solution of KMUH (2.95 mg, 10 μmol) (**11**) in DMSO at a molar ratio of 1:5. The mixture was incubated for 2 h at ambient temper-

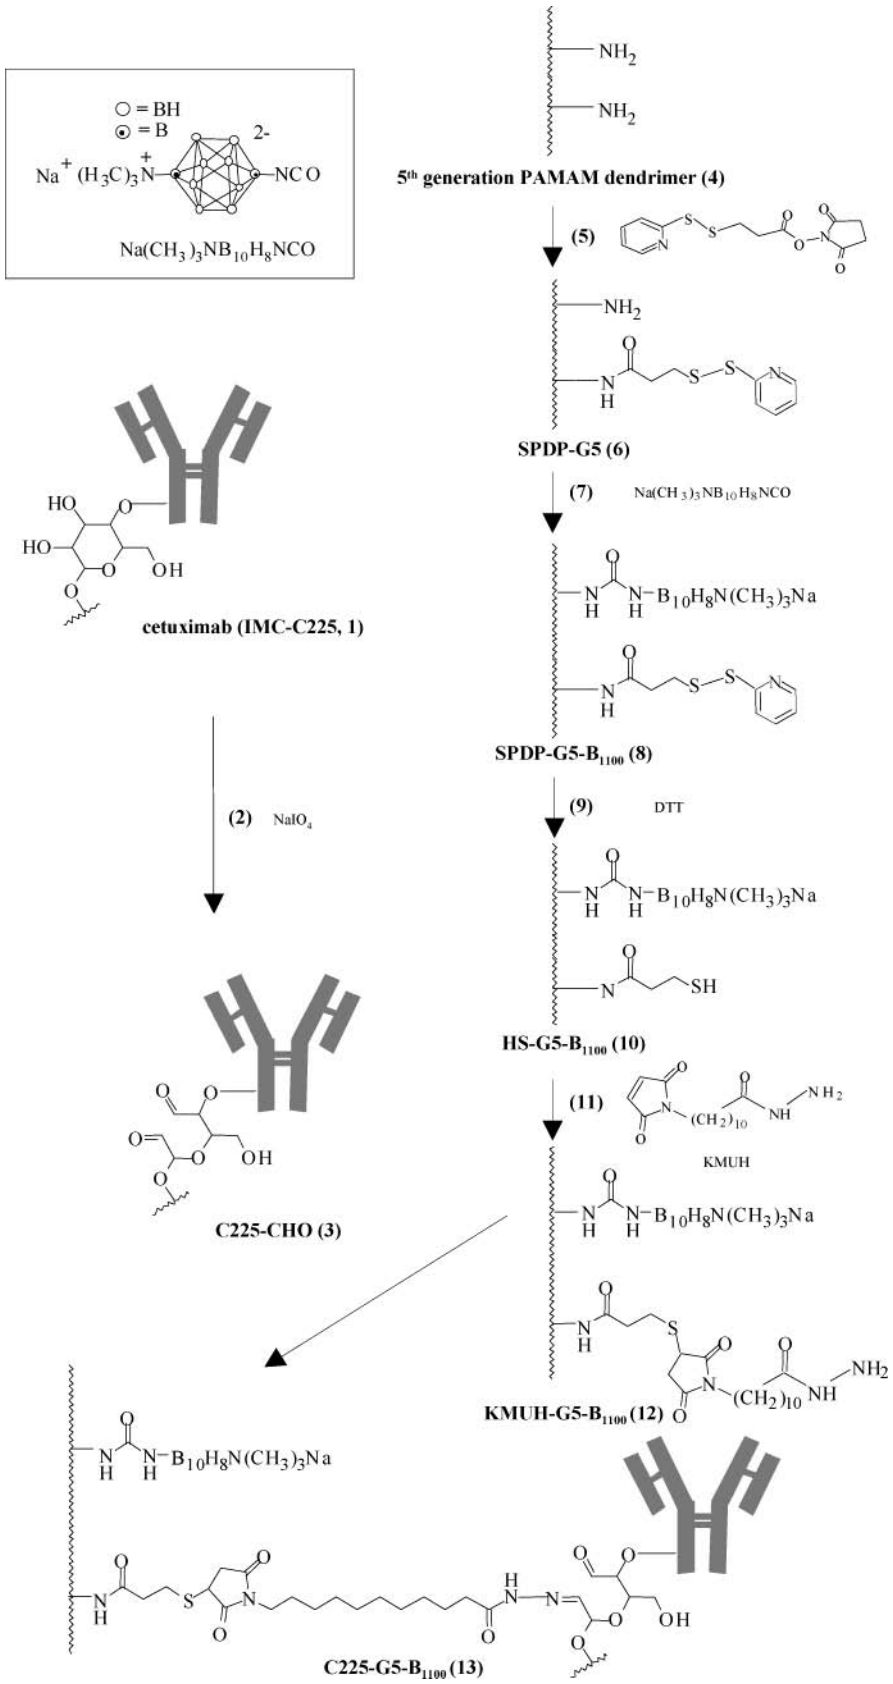

Figure 1. Conjugation scheme for the linkage of boron-containing dendrimer to cetuximab.

ature and then separated from unreacted KMUH by passage through a PD-10 column using PBS as the mobile phase. Following this, the conjugated KMUH-G5-B_{1100} (**12**) was added to the oxidized cetuximab at a molar ratio of 2:1 and mixed overnight at ambient temperature. The final bioconjugate, C225-G5-B_{1100} (**13**), was concentrated to 1−2 mL by ultrafiltration and then applied onto a Sephacryl S-300 gel filtration column, which had been preequilibrated and then eluted with 50 mM phosphate buffer (pH 7.5) containing 10% DMSO. Those fractions containing *both* cetuximab and boron were collected, pooled, and concentrated by ultrafiltration (MWCO, 10K).

Cell Culture. The parental (wild-type) F98 glioma cell line ($F98_{WT}$) has been extensively used by us for studies relating to BNCT (*41*). The $F98_{EGFR}$ glioma cell was produced by transfecting parental F98 glioma cells with an expression vector containing human EGFR cDNA and its production recently has been described by us in detail (*38*). Cells were maintained and propagated in DMEM containing 100 units/mL penicillin, 100 μm/mL streptomycin, 200 mg/mL of G418 and 10% fetal bovine serum (Life Technologies, Inc., Rockville, MD). The $F98_{WT}$ cells were cultured as monolayers in the same media lacking G418 at 37 °C in a humidified atmosphere containing 5% CO_2.

Radiolabeling of Bioconjugate. Radiolabeling of cetuximab with ^{125}I was carried out using IODO-GEN precoated iodination tubes according to the procedure described by the manufacturer (Pierce, Rockford, IL). Briefly, 10 μL (1.0 mCi) of carrier-free $Na^{125}I$ (ICN Biomedicals Inc, Costa Mesa, CA) and 100 μL of 25 mM phosphate buffer (pH 7.5, 0.1 M NaCl) were added to the precoated tubes. After incubation for 6 min at ambient temperature, the activated iodide was removed and added to the antibody solution (50 μg/50μL) and then incubated for an additional 6−9 min. Radiolabeled cetuximab was purified on a Bio-Spin 30 TRIS column (Bio-Rad Laboratories, Hercules, CA) by elution with 25 mM phosphate buffer, pH 7.5. Protein-bound and free ^{125}I were determined by precipitation with TCA and γ-scintillation counting using a well counter (TM Analytic, Des Plaines, IL), as previously described (*29*).

Determination of K_a and Competitive Binding Assay. $F98_{WT}$, $F98_{EGFR}$ and $F98_{EGFRvIII}$ cells were seeded into T-150 flasks and cultured for 3 days to establish a confluent monolayer. Cells were washed 2× with PBS and then harvested by incubating them with 0.5 mM EDTA at 37 °C for 10 min. Following removal of EDTA, 10^6 cells were added to 1.5 mL tubes to which varying amounts of ^{125}I radiolabeled cetuximab or C225-G5-B_{1100} in 0.1% BSA had been added, and these were incubated at 4 °C for 90 min. The cells then were washed 3× with PBS, the cell bound and free radiolabeled antibody or bioconjugate were separated by centrifugation, and radioactivity was determined by γ-scintillation counting. The K_a and the number of receptor sites were derived by nonlinear regression analysis. For the competitive binding assay, $F98_{EGFR}$ cells were incubated at 4 °C for 90 min with 110 ng of ^{125}I-cetuximab and varying amounts of either unmodified cetuximab or C225-G5-B_{1100}. The cells then were washed 3× with PBS, and the cell bound ^{125}I-cetuximab was separated from free ^{125}I-cetuximab by centrifugation following which radioactivity was determined by γ-scintillation counting.

Assay To Detect Internalization of Cetuximab. The procedure of Reist et al. (*42*) was used to determine if cetuximab was internalized following exposure of cells to the antibody. $F98_{EGFR}$ cells were incubated with an excess of ^{125}I-cetuximab for 1 h at 4 °C, following which they were washed 3× with cold PBS (pH 7.4) containing 1% BSA to remove unbound antibody. Then aliquots containing 10^6 cells per/mL were dispensed into 1.5 mL Eppendorf tubes containing DMEM, supplemented with 10% FBS, and incubated at 37 °C for 0, 1, 2, 4, 8, and 24 h. At each time point, cells were sedimented and the supernatants were saved for γ-scintillation counting. Cell pellets were acid washed twice with a solution containing 1% BSA, the pH of which had been adjusted to 2.0 by the addition of HCl in order to remove cell surface bound antibody. Radioactivity of the original supernatants, the acid washes, and the cell pellets was determined by γ-scintillation counting.

Tumor Model and Biodistribution of C225-G5-B_{1100} and G5-B_{1100}. Fischer rats were purchased from the Animal Production Branch, National Cancer Institute, Frederick Research Laboratory, Frederick, MD. Procedures to minimize discomfort, pain, and distress were in accord with guidelines issued by the American Association for Accreditation of Laboratory Animal Care. One million $F98_{WT}$ or $F98_{EGFR}$ cells were stereotactically implanted into the right caudate nucleus of Fischer rats, as previously described by us (*38*). Biodistribution studies were initiated 12 to 14 days following i.t. injection of C225-G5-B_{1100} or G5-B_{1100} via the central entry port of a plastic screw, which had been embedded into the skull at the time of tumor implantation. Rats received an i.t. injection of either C225-G5-B_{1100} or G5-B_{1100}, containing 50 μg of boron/animal, and were euthanized 24 h later. Ten microliters of the test agent were injected over 2 min using a 20 μL Hamilton syringe fitted with a 27 gauge needle. Tumor, normal brain, blood, liver, kidneys, and skin samples were taken, and biodistribution was determined by means of DCP-AES (*40*). Five animals were used per group and the %ID/g was calculated.

RESULTS

Conjugation and Characterization of Boronated Bioconjugate. The bioconjugation scheme, which was used to boronate a fifth generation PAMAM dendrimer, is shown in Figure 1. The heterobifunctional reagent SPDP was easily linked to the dendrimer under mild conditions in aqueous solution and the protected thiol group, which had been introduced, later was cleaved by reduction with DTT. Using a 5:1 molar ratio of SPDP to G5 (**4**), approximately four molecules of SPDP were attached to G5, as determined by measurement of the absorbance of pyridine-2-thione at 343 nm, which was released upon reduction. Boron clusters were conjugated to SPDP-G5 (**6**) via the reaction of a primary amine with an isothiocyanate, which was carried out overnight in carbonate buffer (pH 9.0) and noncovalently associated clusters were removed by PD-10 column chromatography. As determined by quantitation of boron by means of DCP-AES prior to and following PD-10 column chromatography, the amount of boron attached to the dendrimer was ∼1100 boron atoms per molecule of G5 (**4**). The boronated dendrimer (SPDP-G5-B_{1100}, **8**) then was incubated with 50 mM DTT for 30 min. The free sulfhydryl groups, which had been introduced (HS-G5-B_{1100}, **10**), then were reacted with KMUH (**11**), another heterobifunctional reagent that linked aldehyde and sulfhydryl groups with a spacer length of ∼19 Å. The resulting bioconjugate, KMUH-G5-B_{1100} (**12**), then was separated from unreacted KMUH by Sephadex-G25 column chromatography. Different ratios of oxidized cetuximab (C225-CHO, **3**) and boronated dendrimer (KMUH-G5-B_{1100}, **12**) used for the final conjugation of C225-G5-B_{1100} (**13**) have been tested, and as determined from the Sephacryl S-300 elution profile (Figure 2), there were two peaks containing both boron and protein suggesting that either two or more boronated dendrimers were linked to one cetuximab molecule or alternatively, that two or more cetuximab molecules were linked to one molecule of dendrimer. The shift in boron and protein concentrations at the second peak indicated the presence of a small amount of free cetuximab. The contamination of the bioconjugate with free cetuximab was minimized by collecting fractions with high boron to protein concentration ratios.

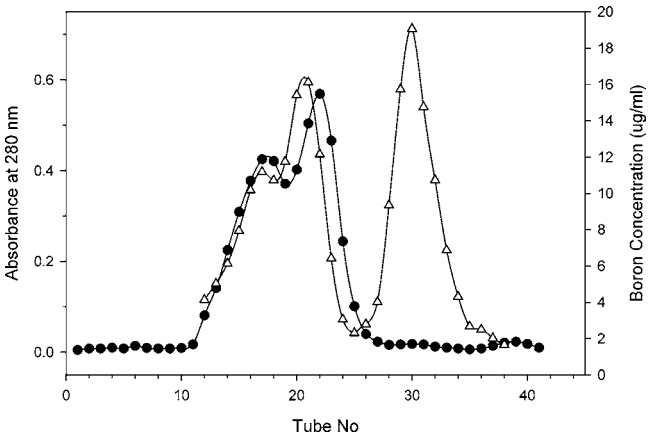

Figure 2. Elution profiles of protein and boron content of samples following completion of the conjugation procedure. The final reaction mixture was concentrated by ultrafiltration and loaded on to a Sephacryl S-300 column and eluted with 50 mM phosphate buffer, pH 7.5 (10% DMSO). Flow rate was 0.5 mL/min. Each fraction contained 1.0 mL. The protein content was measured by UV (●), and the boron concentration was determined by DCP-AES (△).

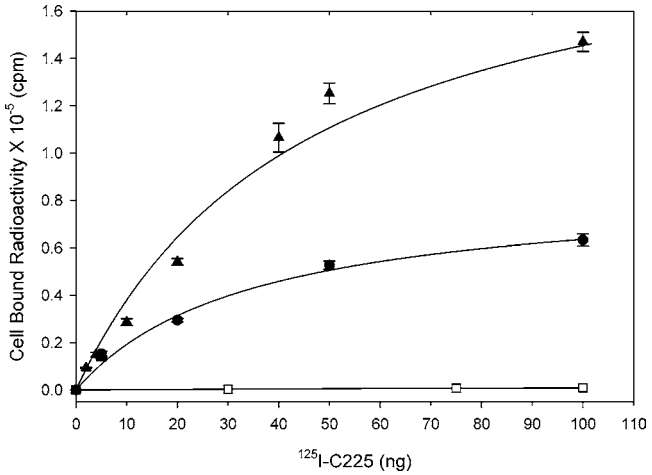

Figure 3. Cellular binding of cetuximab. Varying amounts of ^{125}I-cetuximab ranging from 5 ng to 100 ng were incubated at 4 °C for 90 min with cells expressing wild-type EGF receptors ($F98_{EGFR}$) (▲), mutant EGFRvIII receptors ($F98_{EGFRvIII}$) (●), and receptor negative parental cells ($F98_{WT}$) (□). Cell bound radioactivity was determined by γ-scintillation counting. Mean values ±SD are shown.

Determination of Receptor Sites and Affinity Constants. The binding of cetuximab or the C225-G5-B_{1100} bioconjugate to EGFR was determined by incubating either $F98_{EGFR}$, $F98_{EGFRvIII}$, or $F98_{WT}$ cells with ^{125}I labeled, unmodified MoAb or the bioconjugate. Data from ligand saturation experiments are shown in Figures 3 and 4. The ^{125}I-cetuximab had a very low binding affinity with $F98_{WT}$ cells indicating that the expression of EGFR on F98 wild-type cell was negligible. In contrast, as determined by the binding of ^{125}I-cetuximab, $F98_{EGFR}$ cells expressed $1.60 \pm 0.13 \times 10^5$ receptor sites per cell, as determined from the apparent binding site concentration (B_{max}). The affinity constants (K_a) were $1.64 \pm 0.32 \times 10^8$ M^{-1} for cetuximab and $2.00 \pm 0.22 \times 10^8$ M^{-1} for C225-G5-B_{1100}, respectively, and these also were confirmed by means of a competitive binding assay. The binding of C225-G5-B_{1100} to $F98_{EGFR}$ cells was comparable to that of cetuximab, although the IC_{50} (i.e. the amount required to produce a 50% inhibition of unmodified cetuximab) of C225-G5-B_{1100} was 1.44 nM, which was 2.6-fold greater than that of cetuximab (Figure 5). $F98_{EGFRvIII}$ cells

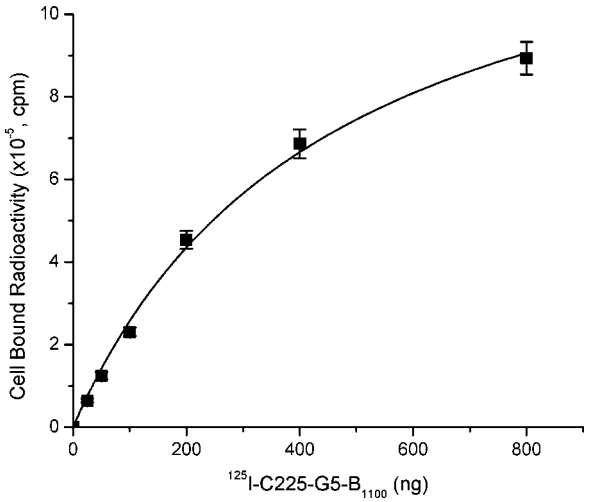

Figure 4. Cellular binding of the conjugate C225-G5-B_{1100}. Varying amounts of ^{125}I-C225-G5-B_{1100} ranging from 25 ng to 800 ng were incubated with $F98_{EGFR}$ cells at 4 °C for 90 min. Cell bound radioactivity was determined by γ-scintillation counting.

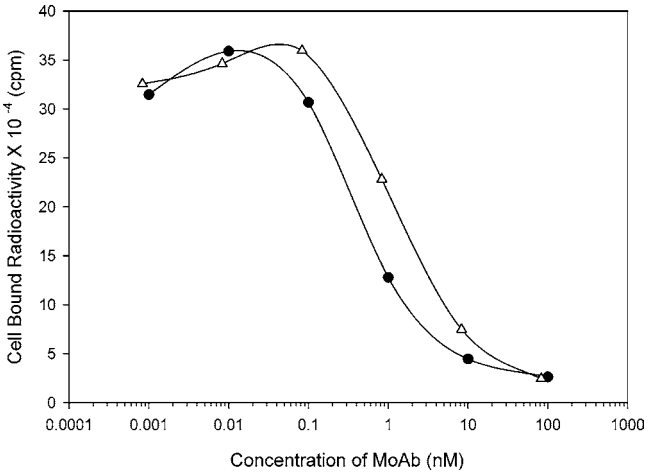

Figure 5. Competitive binding assay. $F98_{EGFR}$ cells were incubated with ^{125}I-cetuximab and varying amounts of nonradiolabeled cetuximab (●) or C225-G5-B_{1100} (△) at 4 °C for 90 min. Cell bound radioactivity was determined by γ-scintillation counting.

expressed $1.07 \pm 0.10 \times 10^5$ receptor sites per cell and the affinity constants (K_a) was $2.18 \pm 0.54 \times 10^9$ M^{-1}, as determined by competitive binding studies with radiolabeled cetuximab.

Internalization of Cetuximab. As shown in Figure 6, the percent cell surface associated radioactivity declined as a function of time from 76.26 ± 1.03% to 48.54 ± 0.88% while the corresponding values in the supernatants increased concomitantly from 12.28 ± 0.07% to 43.96 ± 1.45%. Intracellular radioactivity decreased over the first 8 h from 11.46 ± 0.80% to 3.64 ± 0.34% and then increased over the next 16 h to 7.51 ± 0.16% at 24 h, demonstrating that cetuximab was continuously internalized at the same time as it was being released from the cells.

Biodistribution Following Intratumoral Injection. To determine if C225-G5-B_{1100} could be used to specifically target to EGFR in $F98_{EGFR}$ glioma bearing rats, the bioconjugate was injected i.t. via the entry port of a plastic screw that had been embedded in the calvarium of rats bearing either $F98_{WT}$ or $F98_{EGFR}$ gliomas. After 24 h boron concentrations in tumor and normal brain were measured by DCP-AES. As shown in

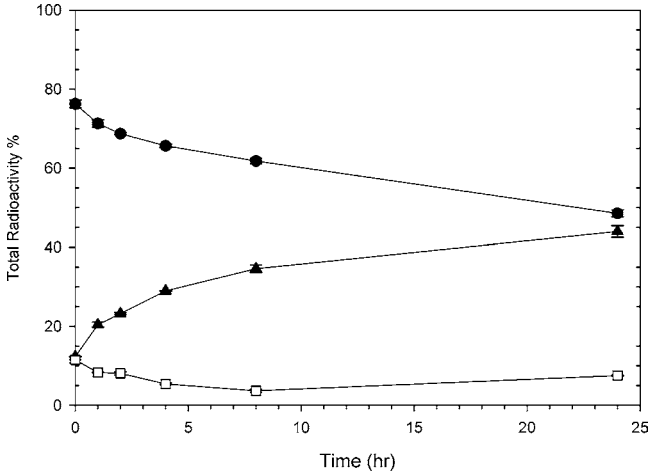

Figure 6. Internalization of cetuximab by $F98_{EGFR}$ cells. Radioactivity was determined by γ-scintillation counting for that associated with the cell culture supernatant before acid wash (▲), and after acid wash (□) and the supernatant from the acid wash (●).

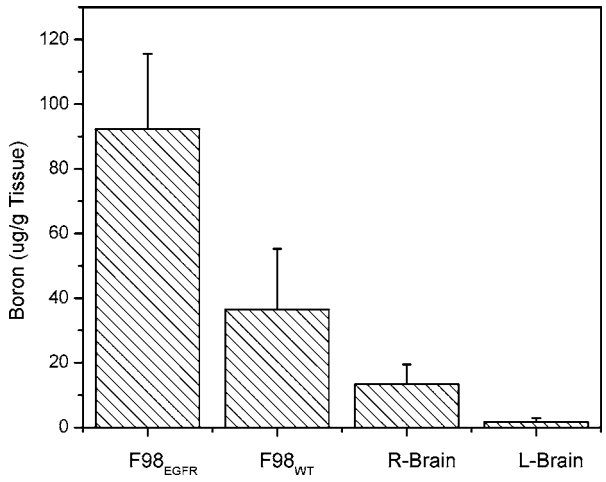

Figure 7. Biodistribution of C225-G5-B_{1100} following i.t administration to rats bearing intracerebral implants of $F98_{EGFR}$ or $F98_{WT}$ gliomas. Animals were euthanized 24 h after injection, the brains were removed and processed for boron determination by means of DCP-AES, the tumor was dissected, and the concentrations of boron in tumor and right (R brain) and left (L brain) cerebral hemispheres was quantified by DCP-AES. Mean values ±SD are shown.

Figure 7, the mean boron concentration was 92.3 ± 23.3 μg/g tumor in rats (n = 4) bearing $F98_{EGFR}$ gliomas compared with 36.5 ± 18.8 μg/g tumor in rats bearing $F98_{WT}$ gliomas. The corresponding boron concentrations of normal brain from the tumor bearing right (ipsilateral) and left (contralateral), nontumor bearing cerebral hemispheres were 13.4 ± 6.1 and 1.7 ± 1.2 μg/g tissue, respectively. Blood, liver, kidneys, spleen, and skin all had nondetectable levels of boron (<0.5 μg/g tissue). Specificity of uptake was further established by injecting either C225-G5-B_{1100} i.t. or nontargeted G5-B_{1100} into rats bearing $F98_{EGFR}$ tumors. As shown in Figure 8, the boronated dendrimer alone without the cetuximab targeting moiety was cleared and the tumor boron content was 6.7 ± 3.6 μg/g at 24 h, which was 13.8-fold less than the cetuximab targeted boronated dendrimer.

DISCUSSION

In the present study, we have site specifically linked a boronated fifth generation PAMAM dendrimer to

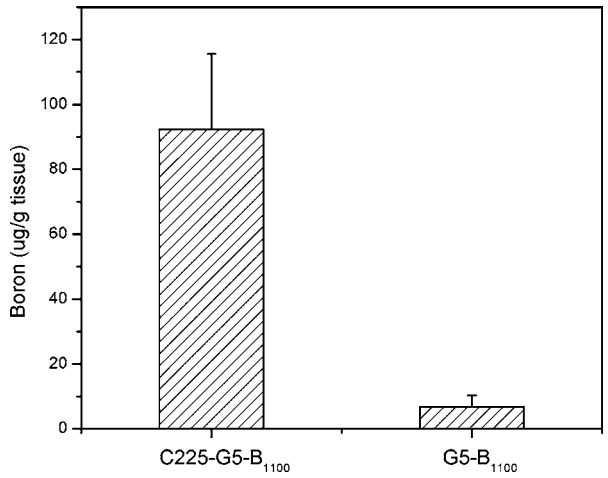

Figure 8. Biodistribution studies of targeted and untargeted conjugates. C225-G5-B_{1100} and untargeted boronated dendrimer G5-B_{1100} were i.t. injected into rats bearing $F98_{EGFR}$ brain tumors and sacrificed 24 h after the injection. Tumor boron concentrations were determined by DCP-AES. Mean values ±SD are shown.

oligosaccharide moieties located in the F_c region of cetuximab. This minimized the loss of binding activity since the covalent linkage sites were specific and distal to the antigen binding site. With minor modifications, this conjugation procedure was based on a recently reported one in which boronated polylysine was linked to an anti-TSH antibody (*43*). Using the improved procedure described in the present report, one reaction step with the antibody was eliminated, but the specific linkage site at the F_c region of the antibody molecule was preserved and the final product was the same. As shown in Figure 1, the maleimide of KMUH first was reacted with SH groups of the boronated fifth generation PAMAM dendrimer, which created stable thioether linkages. After purification, the hydrazide groups of KMUH were reacted with oxidized cetuximab to produce the final bioconjugate by forming hydrazone linkages.

As determined by a binding assay with radiolabeled cetuximab, $F98_{EGFR}$ cells expressed 1.6 ± 0.13 × 10^5 EGFR sites per tumor cell, while the parental $F98_{WT}$ cells expressed <1% of that of $F98_{EGFR}$ cells. The larger number of receptor sties (5.0 × 10^5) determined using the ligand EGF (*38*) may have been due to steric hindrance of the antibody molecule (MW = 150 000Da), whose size was 25× greater that that of EGF (6000 Da), and this also may explain the lower K_a of cetuximab (1.64 × 10^8 M^{-1}), which was 5.7× less than that of EGF (9.1 ± 3.3 ×10^8 M^{-1}) (*38*). Following direct i.t injection, the amount of boron retained in $F98_{EGFR}$ gliomas was 2.5× greater than that of $F98_{WT}$ tumors and 13.8× greater than the nonspecific retention of G5-B_{1100} in $F98_{EGFR}$ gliomas. Boron uptake following administration of C225-G5-B_{1100} was 92.3 μg/g tumor, which was 4.5× higher than the 21.1 μg/g tumor, that we previously reported using EGF-boronated starburst dendrimer as the bioconjugate (*38*). The increased boron uptake and retention, in part, could have been due to the higher generation of the dendrimer that was used to prepare the bioconjugate in the present study. A fifth generation PAMAM dendrimer has 128 amine groups compared to 64 groups in a fourth generation dendrimer. Each molecule of C225-G5-B_{1100} that bound to an EGF receptor had twice the amount of boron than that of the EGF−BSD bioconjugate that we previously have used for in vivo molecular targeting (*38, 44*). Another explanation for the higher tumor retention of C225-G5-B_{1100} could

have been its slower diffusion within the tumor and its prolonged clearance time due to its increased molecular size compared to that of the EGF−BSD bioconjugates. On the basis of the present results, a lower dose of the bioconjugate could be administered to achieve the same therapeutic concentration of boron in the tumor with concomitantly lower boron concentrations in normal brain. It is particularly noteworthy that cetuximab was continuously internalized following receptor binding. This could result in cellular accretion of larger amounts of boronated dendrimer than would have been predicted on the basis of the number of EGFR sites alone.

Approximately 10 years ago, we reported that "starburst", or as they are now referred to, PAMAM dendrimers, could be linked to a MoAb and used as a carrier of ^{10}B for NCT (*26*). These dendrimers are branched, spherical polymers with a unique number of primary amino groups on their surface, which is dependent upon their generation (*45*). They are highly soluble in aqueous solution, which makes them excellent drug carriers because of their high loading capacity (*45*, *46*). They can be precisely synthesized, based on either ammonia as a trivalent initiator core or ethylenediamine as a tetravalent core (*45*). With each new layer or generation, the number of surface amino groups doubles. A fourth generation dendrimer with an ethylenediamine core, such as that which we previously have used (*38*), has a molecular weight of 14215 Da and 64 reactive terminal amino groups. A fifth generation dendrimer, which was used in the present study, has a molecular weight of 28826 Da and the number of reactive functional groups is 128. Their defined structure and large number of surface amine groups recently have led to the use of dendrimers for the delivery of methotrexate (*47*) and 5-flourouracil (*48*). Kobayashi and co-workers (*49*−*51*) have produced indium-111, yttrium-88, and gadolinium-153 dendrimer−monoclonal antibody bioconjugates directed against either Tac (*49*) or murine alkaline phosphatase (*50*) for targeted radioimmunotherapy, Gd NCT, or as an MRI contrast agent (*51*). They were able to attach 49× more ^{111}In and ^{153}Gd atoms to the antibody molecule than was possible using conventional labeling procedures with a minimal loss of immunoreactivity against antigen-expressing tumor cells and with good tumor-localizing properties (*50*). Using an alternative approach, a sixth generation PAMAM dendrimer was biotinylated, chelated, and then reacted with ^{153}Gd citrate, to produce a bioconjugate that had 254 atoms of ^{153}Gd (*51*). This bioconjugate had high in vivo tumor-localizing properties when injected following the i.p. administration of avidin to nude mice bearing i.p. ovarian carcinoma cells, and it was internalized and accumulated within tumor cells in amounts sufficient for Gd NCT.

Very recently, several reports have been published describing drug or radionuclide cetuximab bioconjugates (*23*, *52*, *53*), but dendrimers were not used as the drug carrier. Safavy et al. have directly linked paclitaxel to cetuximab through amide bond formation (*52*). The resulting bioconjugate had increased in vitro cytotoxicity against several EGFR (+) epidermoid carcinoma cell lines compared to cetuximab or paclitaxel alone or a mixture of the two agents. However, there was no difference in the in vivo antitumor activity of the bioconjugate and free paclitaxel, and it was suggested that this might have been due to either the relatively low dose of the bioconjugate that was delivered or a problem relating to its release. On the basis of the data described in the present report, linkage of the drug to a dendrimer might obviate both of these problems. Wen et al. have linked ^{111}In to cetuximab via a pegylated chelator, diethylenetriaminepentacetic acid (*53*). The resulting bioconjugate had better imaging properties than that of its nonpegylated counterpart, and it was concluded that this was a promising strategy to optimize delivery. Since in our study the cetuximab bioconjugate was administered by direct i.t. injection, little would be gained by pegylating it. Finally, and most directly related to what we have described in the present report, Vega et al. have site specifically linked cetuximab to the terminus of a doxorubicin-bound coploymer, poly(L-glutamic acid)-*co*-poly(ethylene glycol) (*23*). The use of this polymer, in a manner similar to that which we have used a fifth generation dendrimer, enhanced the drug payload capacity of the antibody. The resulting bioconjugate had a greater in vitro inhibitory effect on the growth of an EGFR (+) squamous cell carcinoma than that of the free drug. These data, as well as our own, provide a strong argument for using a macromolecular species to enhance the carrying capacity of cetuximab.

The $F98_{EGFR}$ rat glioma that was used in the present study and another F98 transfectant expressing EGFRvIII ($F98_{EGFRvIII}$) are excellent models for investigating localization and in vivo retention of targeting agents (*38*). We recently have established *proof of principle* for the efficacy of BNCT following molecular targeting of EGFR using a fourth generation boronated dendrimer linked to EGF (*38*). To achieve a concentration of ^{10}B capable of producing a lethal $^{10}B(n,\alpha)^{7}Li$ reaction at the cellular level, $\sim 10^9$ boron atoms must be delivered to each tumor cell, or $\sim$15 μg boron/g tumor. Twenty-four hours following i.t injection of the bioconjugate (60 μg ^{10}B/15 μg EGR) to Fischer rats bearing intracerebral implants of $F98_{EGFR}$ cells, the boron concentration was 21.1 ± 4.2 μg/g tumor and the normal brain value was 5.6 ± 1.6 μg/g and blood was <0.5 μg/mL. Based on these data, therapy studies were initiated in $F98_{EGFR}$ glioma bearing rats using boronated EGF either alone or in combination with boronophenylalanine as delivery agents. Following BNCT, the percent increased life span of $F98_{EGFR}$ rats was triple that of animals bearing EGFR negative $F98_{WT}$ gliomas (*38*).

We would like to make some comment concerning our choice of direct i.t. delivery of cetuximab. The major limitation of using anti-EGFR MoAbs, clinically to treat brain tumors, has been that extraordinarily small amounts of the antibody reach the tumor following systemic administration (*54*−*56*). This is attributable to a combination of their rapid clearance by the reticoloendothelial system and the blood−brain barrier, which prevents the passage of hydrophilic agents with a MW in excess of $\sim$250 Da, unless there is an active transport system (*56*). Direct intracerebral delivery will bypass the BBB, minimize toxicity associated with systemic administration, and reduce by orders of magnitude the amount of the agent that would have to be administered by systemic injection. Our previous studies with systemically administered boronated EGF (*57*, *58*) have shown that the amount of the bioconjugate localizing in the tumor following i.v. injection was 0.06% ID/g at 24 h, which was insufficient to deliver the requisite amount of ^{10}B to the tumor. On the other hand, direct i.t. injection resulted in >20 μg of boron/gm tumor, which was therapeutically effective (*38*). Our recent studies indicate that the tumor boron uptake can be further improved by means of convection enhanced delivery (*59*). CED is an innovative method to increase the uptake and distribution of both low and high molecular weight agents to the central nervous system by applying a pressure gradient to

establish bulk flow during interstitial infusion (*60*−*62*). The tumor uptake of ^{125}I-labeled boronated EGF was increased 1.4× following administration by CED compared to i.t. injection (*63*).

We recently have reported preliminary data (*63*) on the potential use of MoAb L8A4 as a boron delivery agent for BNCT using the $F98_{EGFRvIII}$ glioma model. MoAb L8A4 specifically recognizes the EGFRvIII mutant isoform of the receptor (*13*). EGFRvIII has an in frame deletion of 801 base pairs of the coding sequence, which constitutively activates the receptor independent of ligand binding (*64*, *65*). The number of EGFRvIII sites expressed on $F98_{EGFRvIII}$ glioma cells, as determined by a receptor binding assay using cetuximab, was equivalent to that determined with L8A4 ($1.07 \pm 0.10 \times 10^5$ versus $1.20 \pm 0.08 \times 10^5$). However, since cetuximab can target both EGFR and EGFRvIII, it potentially could have significant advantages over either boronated EGF or L8A4 as a receptor targeting agent for BNCT.

Since gliomas contain a heterogeneous population of tumor cells, including EGFR or EGFRvIII (+) and (−) cells, the combination of high molecular weight EGFR targeting agents, administered intracerebrally, together with systemic administration of the low-molecular weight drugs boronophenylalanine (*66*−*69*) and sodium borocaptate (*70*), both of which have been used clinically for BNCT of brain tumors (*37*), would provide a way for targeting the heterogeneous population of cells that are found within glioblastomas. Experimental studies to evaluate this approach using boronated cetuximab, administered by CED, and BPA administered systemically, will be carried out.

ACKNOWLEDGMENT

This work was supported in part by United States Department of Energy grant DE-FG02 98ERG2595 and National Institutes of Health grant 1R01 CA098945-01. We thank Dr. Daniel Hicklin, ImClone Systems, Inc., New York, NY, for a generous gift of cetuximab and Dr. John Mendelsohn, M.D. Anderson Cancer Center, Houston, TX, for facilitating this. We thank Michelle Smith for secretarial assistance in the preparation of this manuscript and Michele R. Smith for technical assistance.

Preparation of No-Carrier-Added Technetium-99m Complexes via Metal-Assisted Cleavage from a Solid Phase

Stefan Mundwiler, Lukas Candreia, Pascal Häfliger, Kirstin Ortner, and Roger Alberto*

Department of Inorganic Chemistry, University of Zürich,
CH-8057 Zürich, Switzerland Received September 18, 2003; Revised Manuscript Received November 7, 2003

A novel method for the preparation of no-carrier-added (nca) complexes [^{99m}Tc(CO)$_3$L] (L = diethylenetriamine or picolylamine-*N*-acetic acid) is described. The ligands were covalently bound to a solid support of organic polymers via formation of a tertiary amine from the chelating unit. This C−N bond to the solid phase is selectively cleaved during the formation of the technetium complexes by intramolecular nucleophilic attack of a remaining hydroxy ligand to the α-carbon. The complex [^{99m}Tc(CO)$_3$L] is released into solution while uncomplexed ligand and uncleaved complex remain solid-phase bound. High specific activity technetium complexes can then be isolated by simple filtration. Cleavage yield depends on temperature, pH, and ligand. Up to 50% release from the solid phase could be achieved under optimized conditions. Corresponding to the ^{99m}Tc concentration, free ligand is present in concentrations lower than 10^{-7} M. If a targeting vector is conjugated to these ligands, no-carrier-added radiopharmaceuticals can be prepared in that way.

INTRODUCTION

For the application of radiolabeled receptor binding biomolecules it is highly desirable that only "hot" compounds are administered. This avoids receptor saturation in vivo or toxic side effects from the cold compounds and gives better resolved images (scintigrams) and, thus, allows a clear diagnosis. High specific activity in a normal homogeneous labeling procedure demands the lowest possible amount (concentration) of chelator−biomolecule conjugate still resulting in quantitative labeling. Depending on chelator and complex precursor, these concentrations are often relatively high since the rate of labeling is slow and accompanied by decomposition of ligand or ^{99m}Tc precursor.

Physical separation of cold from hot compound could conveniently be achieved with solid-phase technology, if the ligand−biomolecule conjugate attached to a solid-phase selectively cleaves during complex formation. Examples for such metal-assisted cleavage from solid phases are rare although solid-phase bound metal complexes are frequently applied in heterogeneous catalysis (*1*) or as artificial peptidases (*2*). In the context of radiopharmaceuticals, it has recently been shown that thiols release the protecting group after coordination to a Tc=O center (*3*). On the basis of this observation, Roe et al. bound a tetradentate chelator via thioether bond to a gold surface. Upon coordination of Tc(V) to the sulfur donor in this ligand the ^{99m}Tc-complex was *selectively* released after S−Au-bond break (*4*). More recently, Ballinger et al. described a similar method. The chelator functionalized with biotin was attached to an organic polymeric support by a covalent C−S bond. This bond cleaved concomitantly to the Tc−S bond formation, affording a labeled biotin derivative with very high specific activity (*5*). Another interesting approach was described by Arterburn et al. (*6*). An estradiol derivative, bound to a solid support via an acetyl hydrazine anchor, was reacted with [ReOCl$_3$(PPh$_3$)$_2$] to selectively release the labeled compound via formation of an organoimido-Re complex.

In this paper, we extend the possibilities for the preparation of very high specific activity radiopharmaceuticals to low valent carbonyl complexes containing the "*fac*-[Tc(CO)$_3$]$^+$" moiety (*7*). This novel method employs highly Lewis acidic [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ for selective hydrolytic cleavage of a C−N bond in a tertiary amine.

Tridentate chelators comprising mutual combinations of aliphatic and aromatic amines and carboxylate groups as donors are excellent ligands for complex formation with [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ even at very low ligand concentration. Biomolecules can easily be conjugated to this ligands via, i.e., formation of a secondary or tertiary amine. We found that biomolecules conjugated through a tertiary amine cleaved from the chelator during complex formation in variable amounts (*8*). Cleavage did not occur in the absence of ^{99m}Tc; thus, is clearly mediated by the Lewis acidity of the Tc(I) center in *fac*-[Tc(CO)$_3$]$^+$. In this work we present a basic study to use this uncommon cleavage for the preparation of nca ^{99m}Tc complexes. The ligand is attached to a solid-phase resin. During complex formation with [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$, the labeled product is released from the solid phase and can be separated from cold ligand by simple filtration (Scheme 1). Ligands investigated for this purpose are depicted in Chart 1.

EXPERIMENTAL PROCEDURES

Materials and Methods. TentaGel S AC resin (90 μm, 0.24 mmol/g) was purchased from Rapp-Polymere, Tübingen, Germany, other chemicals were from Merck, Dietikon (CH), Aldrich, or Fluka, Buchs (CH). Chemicals were of reagent grade and used without further purification. The precursors (NEt$_4$)$_2$[ReBr$_3$(CO)$_3$] and (NEt$_4$)$_2$-[^{99}TcCl$_3$(CO)$_3$] were synthesized according to a previously published method (*9*). Ligand **2** and complexes **5** and **6** were prepared as previously described (*7*).

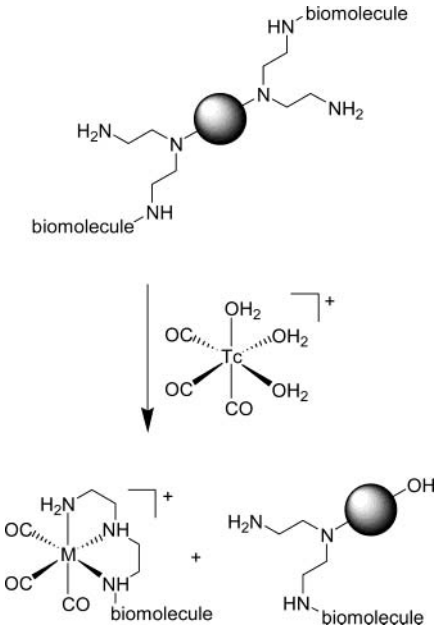
Scheme 1. Preparation of No-Carrier-Added ^{99m}Tc Compounds



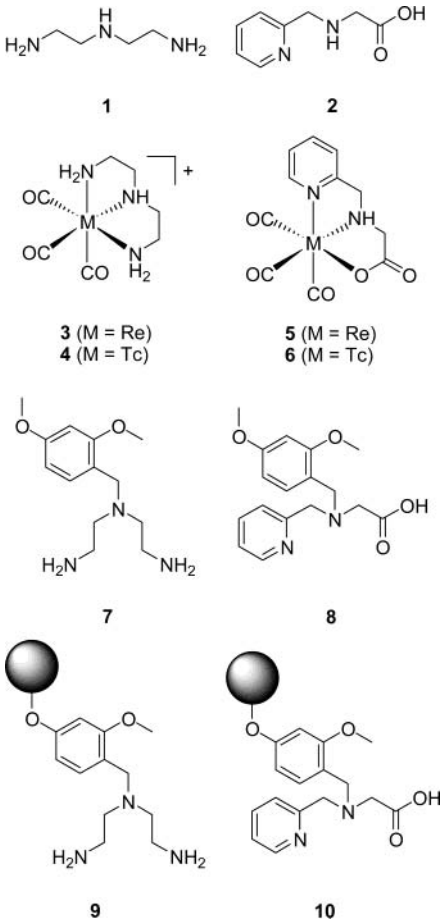


Chart 1. Tridentate Ligands 1,5-Diamino-3-azapentane (diethylenetriamine, diene, 1) and Picolylamine-*N*-acetic Acid (pama, 2), the Corresponding Tc and Re Complexes 3−6, Model Compounds 7 and 8, and Their Solid-Phase Bound Analogues 9 and 10

HPLC analyses were performed on a Merck-Hitachi L-7000 system equipped with a EG&G Berthold LB 508 radiometric detector, using a C-18ec RP column (5 μm particle size, 100 Å pore size, 250 × 3 mm) for separation. HPLC solvents are trifluoroacetic acid, 0.1% in water (A) and methanol (B). Gradient: 0−3 min 100% A, 3.1−9 min 75% A, 9.1 min 66% A, 9.1−20 min 66% A → 0% A, 20−25 min 0% A; 0.5 mL/min. Cleavage yields were calculated by comparing the areas of the product peaks and the corresponding peak of the starting material [^{99m}Tc-$(OH_2)_3(CO)_3]^+$. The activity of the filtered liquids as well as of the resins was measured by a Veenstra Dose Calibrator VDC-304. Semipreparative HPLC separations were performed on LDC Analytical system using a Merck LiChroSpher C-18 reversed-phase column (5 μm particle size, 100 Å pore size, 250 × 10 mm). Electrospray ionization mass spectra (ESI-MS) were recorded on a Merck Hitachi M-8000 spectrometer, GC-MS measurements on a Varian Chrompack Saturn 2000 GC/ion trap MS with splitless injection (1:1) and a CP−Sil 8 CN column. The flow rate was 1 mL/min, the temperature was 70 °C for 5 min, followed by a linear gradient up to 300 °C within 11.5 min, then remaining at 300 °C for 10 min. Free amino groups on the solid-phase resins were visualized by color tests: bromophenol blue solution in water for primary and secondary amino groups and trinitrotoluenesulfonic acid (in DMF/diisopropylethylamin 10:1) and Kaiser's reagent exclusively for primary amines. The loading of chelator to the resins was calculated from the N-content of the resins as determined by elementary analyses.

$[Re(CO)_3$(diethylenetriamine)$]^+(CF_3COO)^-$ (3). An aqueous solution (5 mL) of $(NEt_4)_2[ReBr_3(CO)_3]$ (200 mg, 0.26 mmol) and diethylenetriamine (**1**) (28.3 μL, 0.26 mmol) was refluxed for 12 h. After removal of the solvent, the resulting white powder was purified by preparative HPLC. Subsequent lyophilization yielded 96 mg (76%) of complex **3**. Crystals were obtained by slow diffusion of diethyl ether in a methanolic solution of the Re complex. ^{1}H NMR (D_2O, 300 MHz): δ 2.94−3.05 (*m*, 2H), 2.88 (*p*, 4H, 5.4 Hz), 2.71−2.79 (*m*, 2H).^{13}C NMR (D_2O, 75 MHz): δ, 194.2, 192.9, 50.1, 40.7. ESI-MS: *m*/*z* 372.6 $[M]^+$.

The corresponding ^{99}Tc-complex **4** was formed by mixing solutions of **1** (76 μL, 31 mM in water), [^{99}Tc-$(OH_2)_3(CO)_3]^+$ (1 mL, 2.4 mM in water) and phosphate buffer pH 7.4 (0.1 mL, 1 M), followed by stirring at 90 °C for 30 min (*10*).

***N*′-(2,4-Dimethoxybenzyl)diethylenetriamine (7).** A mixture of 2,4-dimethoxybenzaldehyde (196 mg, 1.18 mmol), *N*,*N*″-bis(*tert*-butyloxycarbonyl)diethylenetriamine (*11*) (357 mg, 1.18 mmol), and sodium triacetoxyborohydride (349 mg, 1.65 mmol) was stirred in dichloromethane (10 mL) for 23 h at room temperature. Excess of sodium triacetoxyborohydride was destroyed by adding aqueous $NaHCO_3$. The BOC-protected intermediate was isolated by extraction into ethyl acetate and purified by column chromatography (silica, methanol/dichloromethane 3:97) to give a viscous, colorless oil (520 mg, 97%). ^{1}H NMR (300 MHz, acetone-d_6): δ 7.21 (d, ^3J = 8.4, 1H); 6.55 (d, ^3J = 2.4, 1H); 6.46 (dd, ^3J = 8.4, ^3J = 2.4, 1H); 5.75 (br s, 2H); 3.87 (s, 3H), 3.78 (s, 3H); 3.53 (s, 2H); 3.13 (td, ^3J = 6.0, ^3J = 6.0, 4H); 2.52 (t, ^3J = 6.0, 4H); 1.40 (s, 18H). ESI-MS: *m*/*z* = 454.4 $[M + H]^+$, *m*/*z* = 150.9 [2,4-dimethoxytoluene]$^+$. Anal. (including one equivalent of acetone) ($C_{26}H_{45}N_3O_7$) C, H, N.

Standard methods for removing of the BOC protecting groups using triflouroacetic acid in dichloromethane or water failed due to the instability of the substrate under these conditions. Deprotection was achieved by stirring a solution of the BOC-protected intermediate (97 mg, 0.21 mmol), chlorotrimethylsilane (230 mg, 2.1 mmol), and phenol (600 mg, 6.4 mmol) in dichloromethane (2.1 mL) for 2.5 h at room temperature. Product **7** was isolated

by extraction into water and purified by semipreparative HPLC to give a colorless, viscous oil (63 mg, 45%), containing traces of water. ^{1}H NMR (300 MHz, Et_2O-d_{10}): δ 7.18 (d, ^3J = 8.1, 1H); 6.59 (s, 1H); 6.52 (d, ^3J = 8.1, 1H); 3.84 (s, 3H), 3.79 (s, 3H); 3.74 (s, 2H); 3.13 (t, ^3J = 6.0, 4H); 2.86 (t, ^3J = 6.0, 4H). ESI-MS: m/z = 253.9 $[M + H]^+$.

***N*-(2,4-Dimethoxybenzyl)-*N*-(2-picolyl)glycine (8).** A mixture of 2,4-dimethoxybenzaldehyde (85 mg, 0.50 mmol), *N*-picolylamineacetic acid ethyl ester (**16**) (99 mg, 0.51 mmol), and sodium triacetoxyborohydride (150 mg, 0.70 mmol) was stirred in dichloromethane (6 mL) for 19 h at room temperature. Excess of sodium triacetoxyborohydride was destroyed by adding aqueous sodium bicarbonate. The ethyl ester intermediate was isolated by extraction into ethyl acetate to give a viscous, colorless oil (171 mg, 97%). ^{1}H NMR (300 MHz, acetone-D_6): δ 8.45 (d, ^3J = 4.8, 1H); 7.73 (dd, ^3J = 8.7, ^3J = 7.8, 1H); 7.63 (d, ^3J = 7.8, 1H); 7.30 (d, ^3J = 8.7, 1H); 7.19 (dd, ^3J = 4.8, ^3J = 7.8, 1H); 6.5 (m, 2H); 4.11 (q, ^3J = 7.2, 2H); 3.94 (s, 2H); 3.7 (m, 8H); 3.33(s, 2H); 1.22 (t, ^3J = 7.2, 3H). ESI-MS: m/z = 344.3 $[M]^+$, m/z = 150.8 [2,4-dimethoxytoluene]$^+$.

The ethyl ester-protected intermediate (111 mg, 0.32 mmol) was stirred in a mixture of ethanol (1 mL), water (3 mL) and aqueous sodium hydroxide (1 M, 0.48 mL) for 24 h at room temperature under a nitrogen atmosphere. Removing of the solvent in vacuo gave the acid **8**. It was used without further purification from the excess of sodium hydroxide.

Preparation of the Solid-Phase Bound Chelator 9. *N*,*N*′′-Bis(1-(4,4-dimethyl-2,6-dioxocyclohexyliden)ethyl)diethylenetriamine (**15**) (101.8 mg, 235.9 μmol) was dissolved in DMF (5 mL), resin **14** (196.6 mg, 47.2 mol) was added, and the mixture was gently stirred at room temperature for 22 h. The reaction mixture was filtered, and the resin was washed with DMF (three times), DMF and methanol (three times alternating), and DMF (five times). The protecting groups were removed by washing the resin 10 times with a solution of hydrazine hydrate, 2% in DMF (1 mL) for 5 min. The reaction mixture was filtered, and the resin was washed with DMF (three times), DMF and methanol (five times alternating), DMF (three times), and diethyl ether (three times). The resin was dried at high vacuum to give product **9** in an yield of 192.3 mg (97.8%; loading 0.236 mmol/g, coupling efficiency 100%).

Preparation of the Solid-Phase Bound Chelator 10. *N*-Picolylamineacetic acid ethyl ester (**16**) (54 mg, 280 μmol) was dissolved in DMF (3 mL), and resin **14** (280 mg, 67 μmol) was added. The mixture was gently stirred at room temperature for 15 h, the reaction mixture was filtered, and the resin was washed with DMF (three times), methanol (three times alternating), and diethyl ether (three times). The protecting groups were removed by gently stirring the resin in a mixture of water (5 mL) and 1 M sodium hydroxide (0.30 mL) for 28 h. Filtration of the resin, washing with DMF (three times), DMF and methanol (three times alternating), DMF (three times), and diethyl ether (three times) and drying at high vacuum gave product **10** in an yield of 268 mg (96%; loading 0.209 mmol/g, coupling efficiency 87.1%).

$[Re(CO)_3$(*N*′-(2,4-dimethoxybenzyl)diethylenetriamine)$]^+Br^-$ (11). Ligand **7** (36 mg, 54 μmol) and $(NEt_4)_2[ReBr_3(CO)_3]$ (50 mg, 65 μmol) were dissolved in water (5 mL), and aqueous $NaHCO_3$ was added until the pH-value reached 8.5. The reaction mixture was stirred at room temperature for 2 h under a nitrogen atmosphere, and a crude product was separated by extraction into dichloromethane. Purification by semipreparative HPLC gave **11** as a white solid in a yield of 16 mg (57%). ^{1}H NMR (300 MHz, Et_2O-D_{10}): δ 7.26 (d, 1H, ^3J = 8.1); 6.58 (s, 1H); 6.55 (d, 1H, ^3J = 8.1); 5.1 (*m*, 2H); 4.50 (s, 2H); 3.8 (*m*, 2H); 3.75 (s, 6H); 3.06 (*m*, 6H); 2.5 (*m*, 2H). ESI-MS: m/z = 523.6 $[M]^+$, m/z = 150.8 [2,4-dimethoxytoluene]$^+$. The corresponding ^{99}Tc-complex **12** was formed by mixing solutions of **7** (1 mL, 2 mM in water), $[^{99}Tc(OH_2)_3(CO)_3]^+$ (0.82 mL, 2.4 mM in water), and phosphate buffer pH 7.4 (0.1 mL, 1 M), followed by stirring at room temperature for 26 h.

Table 1. Homogeneous Reaction of 7 with $[^{99m}Tc(OH_2)_3(CO)_3]^+$: Yield of Cleavage as a Function of Conditions

temp, °C	reaction time, min	pH	[**7**], μM	[Tc], μM	conversion of $[Tc(OH_2)_3(CO)_3]^+$, %	yield of **4**, %	yield of **12**, %

***N*,*N*′′-Bis(1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl)diethylenetriamine (15).** 2-Acetyl-5,5-dimethyl-1,3-cyclohexanedione (695 mg, 3.81 mmol) was dissolved in ethanol (5 mL). Diethylenetriamine (0.197 mL, 1.82 mmol) was added, and the solution was stirred at room temperature for 3 h. The solvent was removed in vacuo, and the crude product was purified by column chromatography (silica, dichloromethane/methanol 92.5: 7.5) to give **15** as a colorless oil. Yield: 714 mg, 90.9%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.60 (m, 4H); 3.02 (t, ^3J = 6.2, 4H); 2.56 (s, 6H); 2.32 (s, 8H); 1.00 (s, 12H). ^{13}C NMR (75 MHz, $CDCl_3$): δ 198.1, 173.7, 108.0, 52.7, 47.6, 43.3, 29.9, 28.1, 18.0. ESI-MS: m/z = 431.6 $[M]^+$.

Labeling Procedure. $Na[^{99m}TcO_4]$ was eluted from a ^{99}Mo/^{99m}Tc generator (Mallinckrodt, Petten, The Netherlands) using 0.9% saline. Solutions of the precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ were prepared out of $[^{99m}TcO_4]^-$ (1 mL eluate) using a borocarbonate kit containing $K_2CO_2BH_3$ (4 mg), disodium tartrate dihydrate (7 mg), and Borax decahydrate (7 mg). After stirring the mixture for 20 min at 95 °C, it was cooled, neutralized with 1 M HCl, and buffered with phosphate buffer 0.1 M, pH 7.4 (1−6 mL) (*12*).

Of the soluble chelators, 0.01 M solutions in aqueous 0.1 M phosphate buffer, pH 7.4, were prepared. 0.10 mL of this solutions were added to 1 mL of the freshly prepared $[^{99m}Tc(OH_2)_3(CO)_3]^+$ solution. The reaction mixture was stirred at 82 °C for 30 min and cooled in an ice bath. HPLC analyses with γ-detection was performed to quantify the conversion of the ^{99m}Tc. Reaction time, concentrations, and temperature were varied. Typical results are given in Table 1.

Of the solid-phase bound chelators, 1 mg (0.2 mmol) was given to the $[^{99m}Tc(OH_2)_3(CO)_3]^+$ solution (1 mL), the mixture was shortly sonicated and then heated to 82 °C for 30 min. The solution was separated from the solid-phase resin by filtration through a 45μm syringe filter and analyzed by HPLC with γ-detection. The pH value of the reaction mixture was varied by adding 1 M HCl or 1 M NaOH. Reaction time, concentrations, and temperature were also varied. Typical yields are given in Table 2.

RESULTS AND DISCUSSION

Complexation of $[Tc(OH_2)_3(CO)_3]^+$ under concomitant cleavage of the tertiary C−N bond to the solid phase was found for the ligands depicted in Chart 1 and Scheme 1, yielding a secondary amine coordinated to the Tc-center.

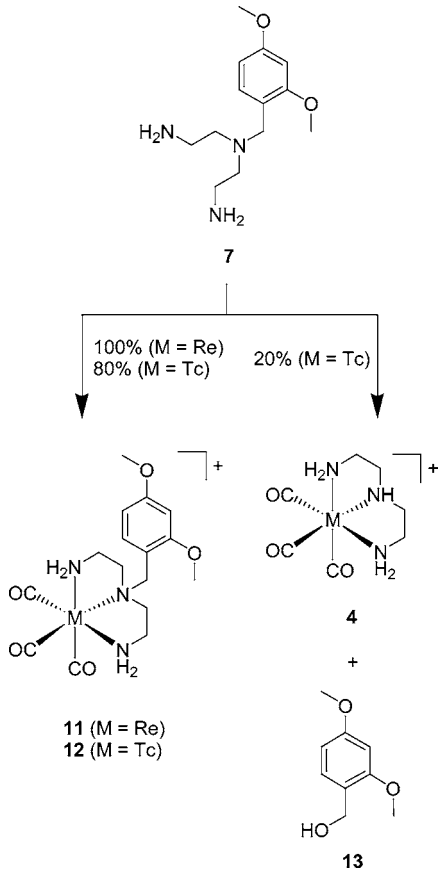
[a] Compound **4.** [b] Compound **6**.



To quantify cleavage, we have chosen two structural frameworks of essential ligands as model compounds. Ligand **1** is a linear triamine and ligand **2** is picolylamine-*N*-acetic acid (pama). Both ligands can potentially be attached to a biomolecule. They form cationic and hydrophilic [M(diethylenetriamine)$(CO)_3]^+$ (**3**: M = Re, **4**: M = Tc) and neutral [M(pama)$(CO)_3$] (**5**: M = Re, **6**: M = Tc) respectively in quantitative yields. For homogeneous studies, **1** and **2** were alkylated at the secondary amine with the same side group as later present on the solid-phase resin. These derivatives **7** and **8** allow studies in homogeneous solution under varying conditions, and possible mechanisms can then be deduced from analytical characterization of the cleavage products. For the heterogeneous studies, **1** and **2** were resin bound to yield **9** and **10** as shown in Chart 1.

Ligand **7** reacted with $(Et_4N)_2[ReBr_3(CO)_3]$ in water to form the corresponding complex [Re(*N*′-(dimethoxybenzyl)-diethylenetriamine)(CO_3)]Br (**11**). It should be emphasize at this point that cleavage never occurred with Re under the conditions where cleavage with $^{99(m)}$Tc was observed. This seems to be one of the rare examples in which Re and Tc behave principally different. The reaction of 4 mM aqueous solutions of $[^{99}Tc(OH_2)_3(CO)_3]^+$ with **7** gave [Tc-(*N*′-(dimethoxybenzyl)-diethylenetrimanine)(CO_3)]Br (**12**) in 80% yield. Two additional peaks in the HPLC were assigned to the cleavage products **4** and 2,4-dimethoxybenzyl alcohol (**13**). This assignment was confirmed by coinjection with the corresponding reference compounds (Scheme 2). To further assess the nature of the two new peaks, they were separatly collected from the HPLC and analyzed by ESI-MS. The M^+ signal of one peak confirmed complex **4**. GC-MS of the second peak showed the mass of methylated **13**. Methylation occurred during the HPLC separation in methanolic solution as confirmed with commercially available 2,4-dimethoxybenzyl alcohol.

The presence of **13** as the primary cleavage product underlines the hypothesis of hydrolytically induced cleavage of the C−N bond. Intermolecular reaction between free hydroxide (or solvent water) and **12** could not be excluded at this stage. Extended reaction time did not improve the yield, and intact complex **12** prepared under mild conditions did not cleave at all. This rationalizes an intramolecular mechanism at a time where not all three coordination sites are occupied by the tridentate chelator. Again, reaction with $[Re(OH_2)_3(CO)_3]^+$ showed no cleavage. Similar experiments with **8** were not possible on the ^{99}Tc level due to complete insolubility of [M$(CO)_3$**8**] (M = Re, Tc) in water.

Homogeneous reaction of **7** with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ confirmed the experimental results found with macroscopic amounts of ^{99}Tc. The yields depend on the conditions and typical cleavage is shown in Table 1.

Scheme 2. Reaction of Ligand 7 with $(Et_4N)_2[ReBr_3(CO)_3]$ and $[^{99}Tc(OH_2)_3(CO)_3]^+$

Complexes **3** and **5**, the rhenium analogues of the cleavage products **4** and **6**, were prepared and the X-ray structure of **3** was elucidated. An ORTEP presentation of the cation is given in Figure 1. The structure has no unusual features but the high hydrophilicity of the complex is worthwhile to mention. The amine donors are not deprotonated. CCDC 219290 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk).

Cleavage from the Solid Support. The two ligands **1** and **2** were covalantly conjugated to the solid-phase resin in order to show that cleavage does not only occur in a homogeneous reaction. The choice of the solid-phase material is crucial since it has to be stable up to 90 °C and to swell in water to allow diffusion of the Tc-species. The polystyrene/poly(ethylene glycol) resin TentaGel S

Scheme 3. Synthesis of the Solid-Phase Bound Chelators 9 and 10

AC is appropriate since its active site, a benzyl alcohol derivative (Scheme 3), can be converted into the bromide **14** (*13*). Alkylation with terminal N-protected dien **15** gave after deprotecting the solid-phase bound chelator **9**. Analogously, a biomolecule derivatized ligand could be bound to the support. Reaction of **14** with **16** produced solid-phase bound ligand **10** after ester hydrolysis. The nitrogen contents of compounds **9** and **10** were determined by elemental analysis. Accordingly, the capacity of the resins in mmols of chelating units per gram of solid-phase material was 0.24 mmol/g for **9** and 0.21 mmol/g for **10**, respectively, corresponding to coupling efficiency of 100% and 88%.

The capacity of resin **9** was also verified by the reaction with $[^{99}Tc(OH_2)_3(CO)_3]^+$. The Tc concentration in solution decreased to an extent as expected from elemental analysis. HPLC analyses confirmed that no cleavage from the solid phase occurred under mild conditions. The resin, once loaded with ^{99}Tc, was heated at 80 °C for 5 h in phosphate buffer pH 7.5. As in case of **12**, only minor amounts (<3%) of ^{99}Tc-complex were released into solution. This is much less than the 11% found when the loading reaction was directly carried out with $[^{99}Tc(OH_2)_3(CO)_3]^+$ at 80 °C for 30 min.

For the heterogeneous reaction with the solid phases **9** and **10**, 1 mL of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared as recently described (*12*), buffered to pH 8.5, and mixed with 1 mg of the solid-phase resins (corresponds to 0.24 mM in ligand). Short ultrasonication ensured good swelling of the resin. The mixtures were incubated for 30 min at 82 °C and cooled to 0 °C, and the solution was separated from the solid-phase resins by filtration. The activities on the solid phase and in solution were measured separately by a γ-counter. Complex **4** was cleaved from the resin **9** in yields up to 23%. During the process, HPLC analysis revealed that an intermediate appeared in strongly condition-dependent amounts. After 30 min it reached 13% but converted completely into product **4** after a further 1 h at 82 °C. This increased the total yield of **4** to 46%. The radiochemical purity after full conversion was >99%, and no $[^{99m}TcO_4]^-$ was observed.

Cleavage of complex **6** from resin **10** and $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was more efficient compared to **4** from **9**. Up to 51% was released at pH 8.5, 82 °C, and after 1 h. The formation of **6** was confirmed by HPLC and coinjection with separately produced **6**. On the nca level it was possible to confirm M^+ of 399 by ESI-MS for the main product which corresponds to $[^{99m}Tc(OH_2)(CO)_2(pama)]^+$. One CO ligand was replaced by water during ionization. As in the case of resin **9**, an intermediate was observed which also converted to **6** after 1 h at 82 °C. The yield as a function of reaction conditions is given in Table 2.

To confirm metal-assisted cleavage from the solid-phase resin, ^{99m}Tc-loaded resin **10** was repeatedly washed with phosphate buffer and reacted with a blank solution as used for the preparation of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ for 1 h and at 82 °C but without any technetium. This afforded less than 2.4% complex release which confirms cleavage takes place during coordination. Subsequently, the resin was reacted again with $[^{99m}Tc(OH_2)_3(CO)_3]^+$, and a yield of 24% was found. Obviously, the predominant process is $[^{99m}Tc(OH_2)_3(CO)_3]^+$-mediated cleavage.

Reaction temperature, pH value, and time were varied to further improve the cleavage yield. Complete conversion of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ and formation of one single product in solution are required for application without the need of purification. The cleavage yield of **6** from resin **10** is strongly pH dependent and ranges from 4% at pH 6 to 52% at pH 8.5. At higher pH the yield decreases again and is about 22% at pH 11. The rest of the activity remains quantitatively bound to the polymer. A strong temperature dependence was observed. At rt, quantitative complex formation on the resin but no cleavage was found. At 45 °C, minor amounts of cleaved products appeared and only at 70 °C did yields increase to 40%. At 85 °C, a maximal yield of 50% was achieved. Stability of the solid-phase resin and of attached biomolecules limits the maximal temperature. For the TentaGel S

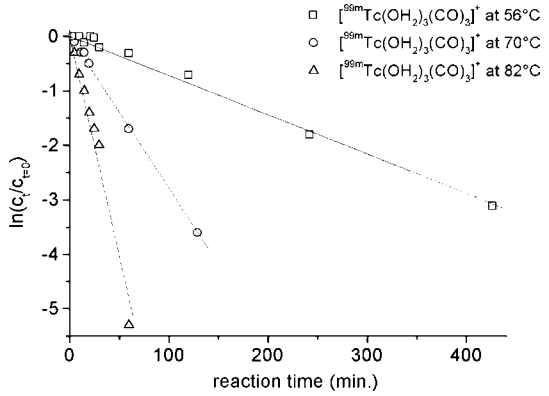

Figure 2. Kinetics of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ conversion at different temperatures, [resin] = 0.25 mM.

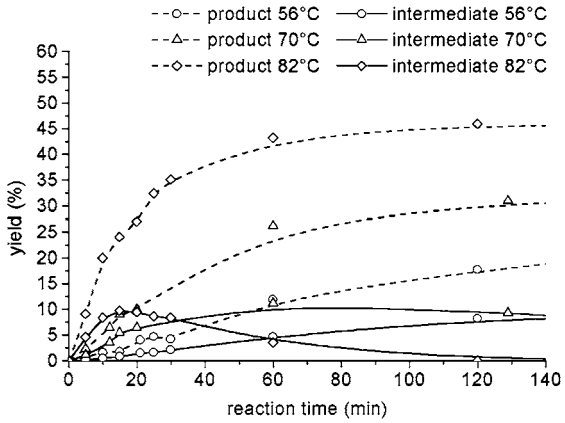

Figure 3. Formation of **6** and the intermediate at 56 °C, 70 °C, and 82 °C.

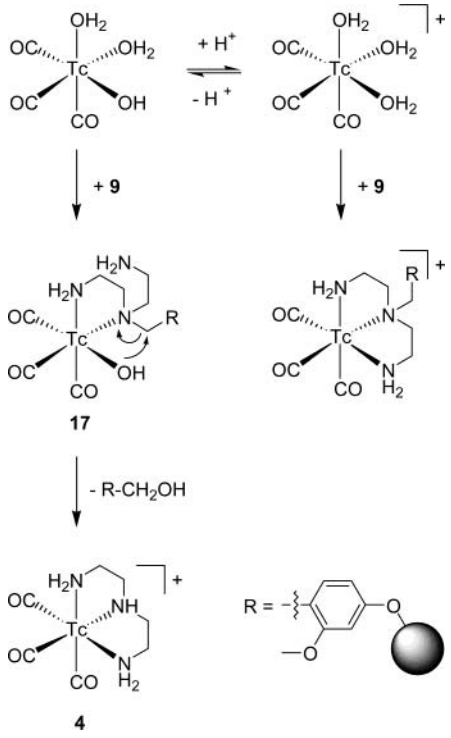


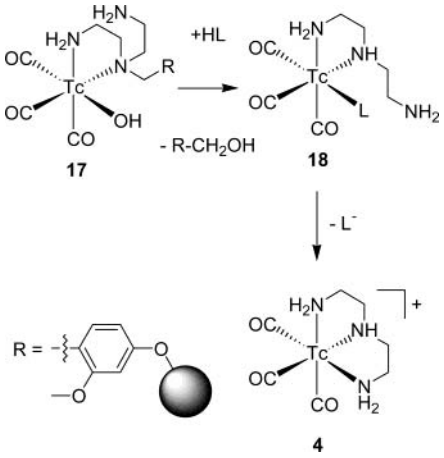
resin, temperatures between 70 °C to 90 °C are preferential to yield radiochemically pure product in good yields.

To get additional insight into the mechanism, the reaction of resin **10** with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was analyzed at distinct time points by HPLC analysis. The amount of $[Tc(OH_2)_3(CO)_3]^+$ was monitored at 56 °C, 70 °C and 82 °C (pH 8.5, [**10**] 0.25 M). Typical curves are shown in Figure 2. From linearization, second-order rate constants for the conversion of $[Tc(OH_2)_3(CO)_3]^+$ were calculated to be 0.48 L mol^{-1} s^{-1} at 56 °C, 1.85 L mol^{-1} s^{-1} at 70 °C, and 5.36 L mol^{-1} s^{-1} at 82 °C. This transforms into an activation energy of the rate-determining step of about 90 kJ mol^{-1} and a preexponential factor of 7.8×10^{13} L mol^{-1} s^{-1}.

In these experiments, the formation of **6** and the above-mentioned intermediate were monitored as well. Typical concentrations as a function of time are depicted in Figure 3. At 82 °C and after 2 h, $[Tc(OH_2)_3(CO)_3]^+$ completely disappeared and the intermediate fully converted into product **6**. At 70 °C after 2 h, no $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was left but the concentration of the intermediate was still high. Conversion was complete after another 2 h. Reaction rates at 56 °C finally are not practical since the intermediate converts too slowly. For all conditions, the "second product" goes through a maximum and is steadily converted into product **6**, clearly showing its intermediate nature rather than a side product. As obvious from Figure 3, only a minor amount of the product is formed through this intermediate; the direct pathway to product formation is still dominant.

The ratio between ^{99m}Tc and ^{99}Tc complex, already present in the eluate, gives the specific activity. More

Scheme 4. Proposed Mechanism of the C−N Bond Cleavage Reaction



practically for application, the specific activity is defined as the ratio between labeled and unlabeled material. Concentrations of ^{99m}Tc-complex after cleavage can be determined from the activity and was typically between 10^{-8} M and 10^{-7} M (depending on the generator). ^{99}Tc "contamination" can be calculated, and the ratio $[^{99}Tc]/[^{99m}Tc]$ is about three 24 h after elution. Due to the very low ligand concentrations expected, the quantification of free chelator is not routine. We developed a radiochemical method in which the yield of complex formation at ligand concentrations between 10 nM and 1000 nM of **2** served as a scale. Filtered solutions of cleavage reactions of **10** were kept in a freezer until complete ^{99m}Tc decay and were then labeled again. Comparison of the yield with the calibration curve then gives an approximate amount of free ligand. It was found for all experiments that the ligand concentration was in the range of the original technetium concentration, confirming no-carrier-added specific activity. Thus, the specific activity of the complex or the labeled bioconjugate is at least between 10 and 100 times higher than what can be obtained in homogeneous labeling procedures under comparable conditions.

Preliminary studies with bioconjugates are currently going on to prove the principle of labeling targeting vectors. Biomolecules of interest to be labeled at very high specific activity are peptides, brain receptor ligands, or other small molecules. We showed previously that pyrene (a DNA intercalator) can be coupled to solid-phase bound **1**, and that the corresponding ^{99m}Tc complex is released in solution in 5−10% yield in very high specific activity (*14*). Cleavage experiments with peptides and biotin coupled to the ligand **1** and bound to the solid phase show that comparable yields can be achieved; however, the synthetic preparation of the solid phase is rather demanding (*15*).

Proposed Mechanism. The proposed mechanism is depicted in Scheme 4. The observation that the free ligands and the fully coordinated complexes are not susceptible for C−N bond cleavage implies an intramo-

Scheme 5. Formation of the Side Product 18

lecular cleavage mechanism during complex formation. Since the ratio between cleaved and resin retained complex is temperature dependent, two competing reactions must occur. The cleavage must have the higher activation energy barrier. The pH dependence is similar as found in enzyme kinetics and implies that deprotonation of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ to $[^{99m}Tc(OH_2)_2(OH)(CO)_3]$ (pK_s for the rhenium analogue: 7.5) (*16*) is relevant for cleavage. The tridentate ligand initially replaces two aquo ligands in $[^{99m}Tc(OH_2)_2(OH)(CO)_3]$, and $[TcL(OH)(CO)_3]$ (**17**) is formed. The strong Lewis acid Tc activates the tertiary amine and the adjacent CH_2 group, respectively, by the formation of a kind of quaternary amine. Then, as the key step, an intramolecular nucleophilic attack of the hydroxo ligand to this methylene group occurs inducing the C−N-bond cleavage and formation of **4** and **13**. The pathway has a counterpart in the Hoffman degradation of tertiary amines. This mechanism is evident from the intramolecular reaction, the pH-dependence, and the hydroxylation of the leaving group. The nucleophilic attack of a hydoxy ligand rationalizes why cleavage occurs exclusively at tertiary aliphatic amines whereas primary and secondary N−C bonds are stable. Unsaturated residues additionally activate nucleophilic substitution. Indeed, benzylic amines cleave much more readily than aliphatic amines which are much less reactive. Metal-bound hydroxo ligands are known as strong nucleophiles in many hydrolytically active enzymes. Solid-phase bound enzyme models with hydroxide ligands coordinating to cobalt, acting as intramolecular nucleophiles, have been described by Suh et al.(*17*). An example of a rhenium-bound hydroxy ligand which acts as a nucleophile was recently described by Pérez et al. (*18*).

The intermediates which converted into **4** or **6** are probably the complexes in which the tridentate ligand is only bidentately bound. After the nucleophilic attack, one coordination site is available. The third donor group of the tridentate might be in a sterically unfavored position for coordination, enabeling a halide to coordinate (Scheme 5). The intermediates already contain the incompletely bound chelator and Tc. The structure is likely to be $[Tc(CO)_3LX]$ **18** where L is the bidentately coordinated ligand and X an additional monodentate ligand, probably Cl^-.

CONCLUSION

A convenient method for the preparation of complexes containing the $^{99m}Tc(CO)_3$ core with very high specific activity has been described. The chelator is bound to a solid-phase support from which the complex cleaves. Uncoordinated ligand and fully coordinated complex remain linked to the solid support. Since exclusively labeled complex is released, very high specific activities can be produced. Although herein shown only with model ligands, biomolecules can be conjugated to the chelators which will allow the production of nca targeting radiopharmaceuticals. Clearly, the bioconjugates must resist relatively high temperatures, but this is not a problem with small molecules such as central nervous system receptor targeting molecules or even peptides. Further studies with bioconjugates bound to the described solid-phase resins are under investigation.

Reagents for Astatination of Biomolecules: Comparison of the in Vivo Distribution and Stability of Some Radioiodinated/Astatinated Benzamidyl and *nido*-Carboranyl Compounds

D. Scott Wilbur,*,† Ming-Kuan Chyan,† Donald K. Hamlin,† Brian B. Kegley,† Reudi Risler,† Pradip M. Pathare,† Janna Quinn,‡ Robert L. Vessella,‡ Catherine Foulon,§ Michael Zalutsky,§ Timothy J. Wedge,# and M. Frederick Hawthorne#

Departments of Radiation Oncology, and Urology, University of Washington, Seattle, Washington 98195, Department of Radiology, Duke University, Durham, North Carolina 27710, and Department of Chemistry and Biochemistry, University of California, Los Angeles, California. Received September 26, 2003; Revised Manuscript Received November 21, 2003

An investigation has been conducted to assess the in vivo stability of a series of astatinated benzamides and astatinated *nido*-carborane compounds in mice. It was hypothesized that the higher bond strength of boron−astatine bonds in the *nido*-carboranes might provide increased stability toward in vivo deastatination. Four tri-*n*-butylstannylbenzamides were prepared for radiohalogenation and evaluation in vivo. Those compounds were *N*-propyl-4-(tri-*n*-butylstannyl)benzamide **1a**, *N*-propyl-3-(tri-*n*-butylstannyl)benzamide **2a**, ethyl 4-tri-*n*-butylstannylhippurate **3a**, and 4-tri-*n*-butylstannyl-hippuric acid **4a**. Seven mono-*nido*-carboranyl derivatives were prepared for radiohalogenation and in vivo evaluation. Four of the seven mono-carboranyl derivatives (**5a**, **6a**, **7a**, **13a**) contained a 3-(*nido*-carboranyl)propionamide functionality, and the remaining compounds (**8a**, **8g**, **10a**) contained a 4-(*nido*-carboranyl)aniline functionality. Two additional derivatives (**11a**, **12a**) were prepared that contained bis-(*nido*-carboranylmethyl)benzene moieties (also referred to as Venus flytrap complexes (VFCs). All benzamide and *nido*-carborane compounds underwent facile iodination and radiohalogenation, except a 4-(*nido*-carboranyl)aniline derivative, **8a**. Iodination of **8a** resulted in a mixture, of which the desired iodinated product was a minor component. Therefore, radiohalogenation was not attempted. It is believed that the mixture of products is due to the presence of a thiourea bond. Previous studies have shown that thiourea bonds can interfere with halogenation reactions. In vivo comparisons of the compounds were conducted by co-injection of dual labeled ($^{125/131}$I and ^{211}At) compounds. Tissue distribution data were obtained at 1 and 4 h postinjection of the radiolabeled compounds, as that was sufficient to determine if astatine was being released. Stability of the astatinated compound was assessed by the difference in concentration of radioiodine and astatine in lung and spleen. All of the benzamides were found to undergo rapid deastatination in vivo. The *nido*-carborane derivatives appeared to be slightly more stable to in vivo deastatination; however, they had long blood residence times. The surprising finding was that the VFC derivatives did not release ^{211}At in vivo, even though they rapidly localized to liver. This finding provides encouragement that stable conjugates of ^{211}At may be attained if appropriate modifications of the VFC can be made to redirect their excretion through the renal system.

INTRODUCTION

Astatine-211 is one of only a few α-particle emitting radionuclides that have properties suitable for application to targeted radionuclide therapy (TRT)[1] of cancer (*5*−*7*). TRT using α-emitting radionuclides (α-TRT) is of particular interest for treatment of micrometastatic disease, cancer contained in compartmental spaces (e.g., ovarian cancer), and cancer that is resistant to other forms of radiation (e.g., melanoma). Aside from the therapeutic radionuclide, a key component in TRT is the cancer cell targeting agent. Fortunately, a large number of cancer cell selective monoclonal antibodies (mAbs) applicable to TRT have been developed (*8*−*12*). In addition to mAbs, there is a rapidly expanding number of other cancer cell targeting agents being identified that might be used in TRT (*13*, *14*). Importantly, to take advantage of the cancer cell targeting provided by mAbs or other agents, the α-emitting radionuclide, e.g., ^{211}At,

must be coupled to the carrier molecule in a manner that is stable toward release of the radionuclide in vivo. Therefore, the method by which a radionuclide is attached to the carrier molecule is of paramount importance in the development of agents used for TRT of cancer.

Direct astatination of the cancer targeting carrier molecule is often problematic. Unlike radioiodine, direct reaction of electrophilic ^{211}At with tyrosine moieties of proteins or peptides does not work well (*15*, *16*), and results in labeled molecules that are not stable to in vivo deastatination (*17*, *18*). To circumvent this problem, deactivated aryl compounds (e.g., benzoates) have been investigated as pendant groups for attaching ^{211}At to carrier molecules (*19*−*23*). Although some biomolecules labeled with astatinated deactivated aryl groups have been found to be stable to in vivo deastatination, other biomolecules labeled using benzoate pendant groups have been found to undergo extensive deastatination in vivo. It is not presently known why large differences in stability are observed, but it may be due to factors such as the rate, or mode, of metabolism of the carrier molecule. Most importantly, the in vivo instability limits the potential for ^{211}At in cancer therapy as it limits which cancer targeting carrier molecules can be used.

The observed in vivo instability of astatinated benzoate conjugated biomolecules prompted investigation of alternate pendant groups to attain higher in vivo stability. Vaidyanathan, Affleck, and Zalutsky (*24*) and Yordanov et al. (*1*) indicated that modifications in the aryl ring of antibody conjugates did not provide high stability,[2] so a very different pendant group was sought. The only criterion set for the pendant group was that it react rapidly and efficiently with ^{211}At as do the organometallic intermediates used for labeling the nonactivated aryl pendant groups (*25*−*27*). This high reactivity was sought so that only a small portion of the ^{211}At ($t_{1/2}$ = 7.2 h) would be lost due to decay during preparation of the radiopharmaceutical. In prior studies by Hawthorne et al. (*28*, *29*), a radioiodinated isothiocyanatophenyl-*nido*-carborane pendant group was used for labeling mAbs. This unique labeling approach involving radioiodinated *nido*-carboranes[3] appeared to have potential for use with ^{211}At. Importantly, radioiodination studies of *nido*-carboranes demonstrated that they could be rapidly and efficiently labeled, and the products were stable to in vivo deiodination (*30*). It was hypothesized that astatinated *nido*-carboranes might be more stable toward in vivo deastatination than the astatinated benzoate derivatives as boron−halogen bonds are generally stronger than carbon−halogen bonds (*31*). On the basis of that hypothesis, an investigation that examined the in vivo stability of four astatinated benzamide derivatives and nine astatinated *nido*-carborane derivatives was conducted. In addition to compounds containing a single *nido*-carboranyl moiety, compounds containing two *nido*-carboranyl moieties, also referred to as Venus flytrap complexes (VFCs) (*32*−*34*), were included in the investigation. To determine the stability of the astatinated compounds, they were labeled with both ^{211}At and radioiodine. Since radioiodinated nonactivated aryl compounds and *nido*-carboranes have previously been shown to be stable in vivo, the differences between the concentrations of ^{211}At and radioiodine in tissues that localize ^{211}At (e.g., lung and spleen) were used to estimate the in vivo stability of the ^{211}At label. Small radiolabeled molecules were employed in this investigation so that stability would be readily determined. The results obtained from the investigation are reported herein.

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were analytical grade or better, and were used without further purification except where noted. 4-Aminobenzyldiethylenetriaminepentaacetic acid (**12d**) was purchased from Macrocyclics (Dallas, TX). 4-Pentynoic acid was obtained from Lancaster (Windham, NC) or Farchan Laboratories (Gainesville, FL). Decaborane was obtained from Alfa Aesar (Ward Hill, MA). Chloramine-T (ChT) and phosphate buffered saline (PBS) were obtained from Sigma (St. Louis, MO). Iodobenzoic acid and most other chemicals were obtained from Aldrich Chemical Co. (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Tetrafluorophenyl trifluoroacetate (TFP−OTFA) was prepared as previously described (*35*).

Radioactivity. Initial ^{211}At labeling studies (involving **5a**) were conducted at Duke University, with later studies being conducted at the University of Washington. All radioactive materials were handled according to approved protocols at Duke University and at the University of Washington. Astatine-211 production at Duke University involved the ^{209}Bi(α,2n)^{211}At reaction, where natural bismuth was irradiated with 28 MeV α-particles on the Duke University Medical Center cyclotron. The ^{211}At activity was distilled from the bismuth target into a cooled $CHCl_3$ trap as previously described (*36*). Production of ^{211}At was also carried out at the University of Washington on a Scandatronix MP-50 cyclotron using the same conditions described above. At the University of Washington, distillation and labeling with ^{211}At were conducted in a glovebox (Innovative Technologies, Inc., radioisotope glovebox) in which the exhaust passes through a charcoal filter. The ^{211}At was distilled from the irradiated bismuth targets into a 0.05 N NaOH solution using the dry distillation apparatus previously described (*37*).

All radiohalogenation reactions were conducted in vials capped with Teflon-coated septa, within a radioactivity approved fume hood. The reaction vials were vented through a 10-mL charcoal filled syringe. Additions of reagents to, or removal of materials from, radiohalogenation vessels were conducted by passing a syringe needle through the septa. All radiohalogenation reactions at the University of Washington were conducted in a charcoal-filtered Plexiglas enclosure (radioiodine fume hood, 20 × 24 × 36 in., Biodex Medical Systems Inc., Shirley, NY) within a radiochemical fume hood.

Na[^{125}I]I was purchased from Perkin-Elmer Life and Analytical Sciences (formerly NEN/Dupont, Billerica,

[2] Interestingly, application of a succinyl-phenethylamide moiety provided increased stability for protein labeling (*1*), and *m*-astatobenzylguanidine ([^{211}At]MABG) displayed a much higher stability in vivo than aryl groups not having the benzyl guanidine moiety (*2*, *3*).

[3] The term "carborane" is used to describe a boron cage moiety that has carbon and boron atoms. There are two carbon atoms in the carborane moieties in these studies. The icosahedral carborane cage moiety containing two carbon atoms and 10 boron atoms is also named as 1,2-dicarba-*closo*-dodecaborane (*4*). The term "*nido*-" (or nest like) signifies a carborane cage molecule that has a boron atom removed from its apex, which is opposed to the "*closo*" (or closed) form of the carborane cage molecule. *nido*-Carboranes are anionic and thus are salts containing cationic counterions. The term *nido*-carboranyl as used herein is simplified from 7-substituted dodecahydro-7,8-dicarba-*nido*-undecaborate(−1).

MA) as a high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I, ^{131}I, and ^{211}At was accomplished in one of three dose calibrators. Measurements at Duke University were accomplished on a Capintec CRC-7 Radioisotope calibrator (Ramsey, NJ). To count ^{211}At on that instrument, the ^{133}Xe setting was used with a multiplication factor of 2.4. Measurements at the University of Washington were conducted on either a Capintec CRC-15R or a Capintec CRC-6A Radioisotope calibrator using calibration #44 (designated by Capintec Technical Services). Tissue samples containing these radionuclides were counted in a LKB 1282 gamma counter (Wallac, Turku, Finland) with the following window settings: channels 35−102 (20−90 keV) and channels 165−185 (300−450 keV) when ^{125}I and ^{131}I were counted together. Spillover of ^{131}I into the ^{211}At window was estimated to be 13.5% and the data were corrected for this. Tissue samples containing ^{211}At and ^{125}I were counted in a Wallac 1480 Wizard gamma counter (EG & G, Wallac, Turku, Finland). In this latter case, the tissue samples were initially counted to obtain both ^{211}At and ^{125}I counts, then they were recounted after 3−5 days (0.1% or less ^{211}At remaining) to obtain ^{125}I counts. Radioactivity counts were imported into an Excel Spreadsheet (Microsoft Corp., Redmond, WA) where calculations were made. The ^{211}At counts were obtained by subtracting ^{125}I counts from total counts. Individual tissue counts for ^{211}At were corrected for decay from the time of counting the first standard (at the beginning of the tissue counting process).

Spectroscopic Data. ^{1}H NMR spectra were obtained on either a Bruker AC-200 (200 MHz), Bruker AF-301 (300 MHz), or AM-500 (500 MHz) instrument. The chemical shifts are expressed as ppm using tetramethylsilane as an internal standard ($\delta = 0.0$ ppm). ^{11}B NMR were obtained at 160 MHz (500 MHz for ^{1}H), and 96 MHz (300 MHz for ^{1}H). The spectra are referenced ($\delta = 0.0$ ppm) to $BF_3{\cdot}O(Et)_2$ as an external standard (insert) in the NMR tube. ^{11}B NMR included ^{1}H coupled and decoupled spectra for all samples examined. Only ^{1}H decoupled resonances are reported. All ^{11}B resonances were split in the coupled spectra except in iodinated samples where one proton was not coupled. IR data were obtained on a Perkin-Elmer 1420 infrared spectrophotometer. Mass spectra were obtained for all new compounds, except for **2f** where several attempts were unsuccessful. Mass spectral data were obtained on a VG 70SEQ mass spectrometer with 11250J data system. Fast atom bombardment (FAB^+) mass spectral data were obtained at 8 kV using a matrix of 90% thioglycerol, 9% DMSO and 1% TFA (DMIX) or propylene glycol 600 containing thioglycolate.

Analytical Chromatography. All reactions were monitored by HPLC. Nonradioactive samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and a Varex ELSD MKIII evaporative light-scattering detector. Analysis of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. The gradient mixture was composed of MeOH (eluant A), 0.1% aqueous HOAc (eluant B) or 0.05 M, pH 5.5 aqueous triethylammonium acetate (eluant C). Two gradient methods were employed: [Method A] This gradient started with 40% MeOH and 60% eluant B for 2 min; then the % MeOH was increased linearly to 100% over a 10 min period; following this the elution continued with 100% MeOH for an additional 8 min. [Method B] This gradient started with 40% MeOH and 60% eluant C for 2 min; then the % MeOH was increased linearly to 100% over a 13 min period; following this the elution continued with 100% MeOH for an additional 5 min. All compounds were evaluated using method A except for compounds **5a**, **5b**, and **7f**, which were evaluated using method B. Retention times (t_R) are provided with the experimental for each compound.

Radioiodinated and astatinated compounds were evaluated for identity and purity, and isolated for animal studies, using reversed-phase radio-HPLC. All radioiodinated compounds were characterized by correlation with nonradioactive standards on the HPLC. Astatinated compounds generally had a slightly longer retention time on reversed-phase HPLC. Radioactive samples were assessed on one of two gradient systems. One system (Duke University) was used for analysis of [^{131}I]**5b**/[^{211}At]-**5c** had two LKB model 2150 pumps, a LKB 2152 controller, a LKB 2138 UV (254 nm), a Beckman 170 Radioisotope detector and PC running Nelson Analytical Data − Chromatography software (v. 3.5) with a 760 interface. A gradient for the elution of the *nido*-carboranes used 50 mM triethylammonium acetate (TEAA) and MeOH. The gradient began with 60% TEAA/40% MeOH and increased to 95% MeOH over 15 min. The second system (University of Washington), used for all other radiolabeled compounds, consisted of two Beckman model 110B pumps (or a HP 1050 quaternary pump), a Beckman 420 controller, a Beckman model 153 UV detector (254 nm), and a Beckman model 170 radioisotope detector. Analysis of the HPLC data were conducted on a PC running Hewlett-Packard HPLC ChemStation software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. Retention times (t_R) are provided with the experimental for each compound.

Preparation of the following compounds was conducted as previously described: 4-iodobenzoic acid TFP ester, **1e** (*38*); 4-(tri-*n*-butylstannyl)benzoic acid TFP ester **1f** (*38*); *tert*-butyldimethylsilyl-1,2-dicarba-*closo*-dodecaborane, **11e** (*39*); 1,2-bis-(*tert*-butyldimethylsilylcarboranylmethyl)benzene, **11f** (*39*); bis-(carboranyl-methyl)-benzene, **11g** (*39*). Iodinated derivatives of compounds containing a *nido*-carborane structure used for HPLC standards were obtained as mixtures containing no iodine, one iodine, or a chlorine (from *N*-chlorosuccinimide); therefore, they were isolated from HPLC and identified by mass spectral analysis only.

***N*-Propyl-4-(tri-*n*-butylstannyl)benzamide, 1a.** A solution containing 0.50 g (0.89 mmol) **1f**, 63 mg (1.07 mmol) of *n*-propylamine and 5 mL of anhydrous DMF was stirred at room temperature for 30 min. The volatile materials were evaporated under vacuum and the residue was purified by silica gel column (30 g), eluting with 10% ethyl acetate/hexanes, to yield 0.30 g (74%) of **1a** as a colorless oil; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.88 (t, J = 8.0, 7.3 Hz, 9H), 0.97 (t, J = 7.3, 7.3 Hz, 3H), 1.07 (t, J = 7.7, 8.1 Hz, 6H), 1.16−1.41 (m, 7H), 1.46−1.72 (m, 7H), 3.41 (q, J = 6.6, 7.0, 6.6 Hz, 2H), 6.24 (s, 1H), 7.53 (d, J = 7.7 Hz, 2H), 7.69 (d, J = 7.7 Hz, 2H); HRMS $(ES)^+$ calcd for $C_{22}H_{40}NOSn$ $(M+H)^+$ 454.2132, found 454.2140. HPLC: t_R = 18.5 min.

4-Iodo-*N*-propylbenzamide, 1b. A 0.09 g quantity (1.51 mmol) of *n*-propylamine in 1 mL of anhydrous DMF was added to a solution containing 0.50 g (1.26 mmol) of **1e** in 4 mL of anhydrous DMF. The solution was stirred at room temperature for 30 min and the DMF was

removed under vacuum. The residue was purified by silica gel column (30 g, 10% ethyl acetate/hexanes) to yield 0.31 g of (85%) of **1b** as a colorless solid, mp 119−120 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.98 (t, J = 7.3, 7.7 Hz, 3 H), 1.54−1.73 (m, 2 H), 3.40 (q, J = 6.6, 7.0, 6.6 Hz, 2 H), 6.16 (s, 1 H), 7.48 (d, J = 8.4 Hz, 2 H), 7.77 (d, J = 8.4 Hz, 2 H); HRMS (ES)$^+$ calcd for $C_{10}H_{13}INO$ $(M+H)^+$ 290.0042, found 290.0040. HPLC: t_R = 11.8 min.

3-Iodobenzoic Acid TFP Ester, 2e. A 11.62 g (44.35 mmol) quantity of 2,3,5,6-tetrafluorophenyl trifluoroacetate (TFP−OTFA) was added dropwise over 5 min to a solution containing 10 g (40.32 mmol) of 3-iodobenzoic acid, **2d**, Et_3N (6.74 mL, 48.38 mmol) and 30 mL of anhydrous DMF at ice−water temperature. After the addition was completed, the reaction mixture was stirred for 30 min, and the volatile materials were evaporated under vacuum. The crude product was purified by silica gel column (100 g) eluting with 5% ethyl acetate/hexanes to give 13.92 g (87%) of **2e** as a colorless solid, mp 67−68 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 7.06 (m, 1 H), 7.30 (t, J = 7.7, 8.1 Hz, 1 H), 8.03 (d, J = 8.1 Hz, 1 H), 8.18 (d, J = 7.7 Hz, 1 H), 8.54 (s, 1 H); HRMS (ES)$^+$ calcd for $C_{13}H_5F_4IO_2$ $(M)^+$ 395.9270, found 395.9283. HPLC: t_R = 15.6 min.

3-Tri-*n*-butylstannylbenzoic Acid TFP Ester, 2f. To a solution containing 1.0 g (2.52 mmol) of **1e** in 30 mL of anhydrous toluene was added 2.55 mL (5.04 mmol) of bis(tributyltin) followed by 29 mg (0.025 mmol) of tetrakis(triphenylphosphine)palladium(0). The reaction mixture was heated to reflux for 4 h, then cooled to room temperature, and the toluene was evaporated under vacuum. The resultant thick oil was purified by silica gel column (40 g, 5% ethyl acetate−hexanes) to give 1.22 g (86%) of **2f** as a colorless oil; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.90 (t, J = 7.3 Hz, 9H), 1.12 (t, J = 8.0 Hz, 6H), 1.28−1.41 (m, 6H), 1.51−1.61 (m, 6H), 6.98−7.09 (m, 1H), 7.48 (t, J = 7.3 Hz, 1H), 7.78 (d, J = 7.3 Hz, 1H), 8.13 (d, J = 8.3 Hz, 1H), 8.28 (s, 1H); HPLC: t_R = 17.1 min.

***N*-Propyl-3-(tri-*n*-butylstannyl)benzamide, 2a.** A 25 mg (0.43 mmol) quantity of *n*-propylamine in 1 mL of anhydrous DMF was added dropwise to a solution containing 200 mg (0.36 mmol) of **2f** in 3 mL of anhydrous DMF. The reaction mixture was stirred at room temperature for 30 min, and was then triturated with water. The water was decanted, the oily product was washed with additional water, then dried under vacuum to yield 154 mg (95%) of **2a** as a colorless oil; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.88 (t, J = 7.3 Hz, 9H), 0.99 (t, J = 7.3 Hz, 3H), 1.08 (t, J = 7.8, 8.3 Hz, 6H), 1.27−1.39 (m, 6H), 1.48−1.71 (m, 14H), 3.39−3.46 (m, 2H), 6.16 (br s, 1H), 7.36 (t, J = 7.8, 7.3 Hz, 1H), 7.57 (d, J = 7.3 Hz, 1H), 7.63 (d, J = 7.8 Hz, 1H), 7.86 (s, 1H); HRMS (ES)$^+$ calcd for $C_{22}H_{40}NOSn$ $(M+H)^+$ 454.2132, found 454.2131. HPLC: t_R = 18.1 min.

3-Iodo-*N*-propylbenzamide, 2b. To a solution containing 0.50 g (1.26 mmol) of **2e** in 4 mL of anhydrous DMF at room temperature was added dropwise 0.09 g of (1.51 mmol) *n*-propylamine in 1 mL of anhydrous DMF. The reaction mixture was stirred at room temperature for 30 min, then DMF was removed under vacuum. The residue was purified by silica gel column (30 g) eluting with 10% ethyl acetate/hexanes to yield 0.24 g (66%) of **2b** as a colorless solid, mp 86−87 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.98 (t, J = 7.7, 7.3 Hz, 3 H), 1.64 (m, 2 H), 3.41 (q, J = 6.6, 7.0, 6.6 Hz, 2 H), 6.15 (s, 1 H), 7.16 (t, J = 8.1, 7.7 Hz, 1 H), 7.71 (d, J = 8.1 Hz, 1 H), 7.81 (d, J = 7.7 Hz, 1 H), 8.09 (s, 1 H); HRMS (FAB$^+$) calcd for $C_{10}H_{12}INO$ $(M)^+$ 288.9963, found 288.9958. HPLC: t_R = 12.7 min.

4-Tri-*n*-butylstannylhippuric Acid Ethyl Ester, 3a. A 0.15 g (1.07 mmol) quantity of glycine ethyl ester hydrochloride was added slowly to a solution containing 0.50 g (0.89 mmol) of **1f** and 0.19 mL (1.34 mmol) of Et_3N in 5 mL of anhydrous DMF at room temperature. The reaction mixture was stirred at room temperature for 30 min, then the volatile materials were removed under vacuum. The crude residue was purified by silica gel column (30 g, 5% ethyl acetate/hexanes) to yield 0.39 g (88%) of **3a** as a colorless oil; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.88 (t, J = 7.3 Hz, 9H), 1.08 (t, J = 7.8, 8.3 Hz, 6H), 1.26−1.39 (m, 9H), 1.48−1.64 (m, 6H), 4.23−4.30 (m, 4H), 6.68 (br s, 1H), 7.55 (d, J = 7.8 Hz, 2H), 7.74 (d, J = 7.8 Hz, 2H); HRMS (ES)$^+$ calcd for $C_{23}H_{40}NO_3Sn$ $(M+H)^+$ 498.2030, found 498.2028. HPLC: t_R = 17.5 min.

4-Iodohippuric Acid Ethyl Ester, 3b. To a solution containing 0.50 g (1.26 mmol) of **1e** and 0.21 g (1.51 mmol) of glycine ethyl ester hydrochloride in 5 mL of anhydrous DMF at room temperature was added 0.26 mL (1.89 mmol) of Et_3N dropwise. The resultant solution was stirred at room temperature for 30 min. The volatile materials were removed under vacuum, then the residue was purified by silica gel column (30 g) eluting with 10% ethyl acetate/hexanes to yield 0.37 g (88%) of **3b** as a colorless solid**,** mp = 123−124 °C; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.32 (t, J = 7.3, 6.7 Hz, 3 H), 4.21−4.30 (m, 4 H), 6.70 (s, 1 H), 7.53 (d, J = 8.3 Hz, 2 H), 7.79 (d, J = 8.3 Hz, 2 H); HRMS (ES)$^+$ calcd for $C_{11}H_{13}NO_3I$ $(M+H)^+$ 333.9940, found 333.9938. HPLC: t_R = 11.8 min.

4-Tri-*n*-butylstannylhippuric Acid, 4a. A 0.30 g quantity (0.60 mmol) of **3a** was dissolved in 5 mL of methanol, then 0.10 g (1.81 mmol) of KOH in 5 mL of water was added. The reaction mixture was stirred at 60 °C for 1 h, then allowed to cool to room temperature. A 60 mL quantity of water was added and the resulting solution was acidified with 3 mL of 1 N HCl. After stirring of the sample at room temperature for additional 10 min, the solution was filtered and washed with 200 mL of water. The remaining oily product (isolated on filter paper) was dissolved in 20 mL of EtOAc, and the EtOAc was evaporated under vacuum to yield 0.26 g (92%) of **4a** as a colorless oil; ^{1}H NMR ($CDCl_3$, 300 MHz) δ 0.88 (t, J = 7.3, 7.3 Hz, 9 H), 1.07 (t, J = 7.8, 8.3 Hz, 6 H), 1.25−1.41 (m, 6 H), 1.47−1.68 (m, 6 H), 4.19 (d, J = 5.2 Hz, 1 H), 6.30 (br s, 1 H), 6.98 (s, 1 H), 7.53 (d, J = 7.8 Hz, 2 H), 7.73 (d, J = 7.8 Hz, 2 H); HRMS (ES)$^+$ calcd for $C_{21}H_{36}NO_3Sn$ $(M+H)^+$ 470.1717, found 470.1737. HPLC: t_R = 16.8 min.

4-Iodohippuric Acid, 4b. A reaction mixture containing 0.20 g (0.60 mmol) of **3b** and 0.10 g (1.81 mmol) of KOH in a mixture of 5 mL of methanol and 5 mL of H_2O was stirred at 60 °C for 1 h. After the solution cooled to room temperature, 60 mL of H_2O and 3 mL of 1 N HCl were added respectively with stirring. The resulting mixture was stirred at room temperature for 10 min, filtered, washed with 500 mL of water, then dried under high vacuum to yield 0.16 g (87%) of **4b** as a colorless solid, mp = 188−189 °C; ^{1}H NMR (CD_3OD, 300 MHz) δ 4.08 (s, 1 H), 7.60 (d, J = 8.3 Hz, 2 H), 7.85 (d, J = 8.3 Hz, 2 H); HRMS (ES)$^+$ calcd for $C_9H_8INO_3$ $(M+Na)^+$ 327.9447, found 327.9448. HPLC: t_R = 10.1 min.

4-Pentynoic Acid TFP Ester, 5e. A 10 g (102 mmol) quantity of 4-pentynoic acid, **5d**, was dissolved in 350 mL of THF. To this solution was added 32 g (155 mmol) of DCC, then shortly thereafter 34 g (205 mmol) of 2,3,5,6-tetrafluorophenol (TFP-OH). A precipitate began forming immediately after the addition of the TFP-OH and the mixture turned light brown. The reaction mixture was stirred overnight at room temperature and 0.5

mL of HOAc was added. This mixture was stirred for 1 h, the precipitate was filtered, then washed with THF. The solvent was removed under vacuum, and the residue was dissolved in 400 mL of hexanes. The resulting precipitate was filtered and washed with 50 mL of hexanes. The hexane was removed under vacuum and the resulting residue was dissolved in 5 mL of EtOAc/120 mL of hexane. That solution was washed 5× with 100 mL of 10% $NaHCO_3$. The hexane solution was dried with $MgSO_4$ and evaporated under vacuum to yield 20.5 g (82%) of **5e**. An analytical sample was prepared by sublimation in a Kugelrohr apparatus to yield a colorless solid, mp 47−49 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 2.36 (t, J = 2.5 Hz, 1H), 2.60−2.63 (m, 2H), 2.95 (t, J = 7.1 Hz, 2H), 7.40−7.47 (m, 1H); LRMS (EI$^+$) calcd for $C_{11}H_6F_4O_2$ (M)$^+$ 246, found, 246. HPLC: t_R = 13.4 min.

3-(*closo*-Carboranyl)propionate TFP Ester, 5f. A 5.0 g (39.0 mmol) quantity of decaborane was dissolved in 40 mL of CH_3CN and refluxed for 30 min. To that solution was added 9.6 g (40.9 mmol) of **5e**, then the reaction mixture was stirred at reflux for 25 h. The mixture was allowed to cool to room temperature and a 2 g quantity of silica gel was added. That mixture was stirred for 1 h and filtered and the CH_3CN was removed under vacuum. The crude product was sublimed (170 °C) on a Kugelrohr apparatus to yield 7.2 g (50%) of **5f** as a colorless solid, mp 135−136 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.46−2.72 (m, 10H), 2.76 (t, J = 7.4 Hz, 2H), 3.00 (t, J = 7.4 Hz, 2H), 7.39−7.46 (m, 1H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) δ −0.91 (1B), −4.12 (1B), −7.85 (2B), −10.03 (4B), −11.26 (2B) (all peaks split in ^{1}H coupled spectrum); LRMS (EI)$^+$ Calcd for $C_{11}H_{16}B_{10}O_2F_4$ (M)$^+$ 364, found 364; HPLC: t_R = 15.2 min.

3-(*closo*-Carboranyl)propionic Acid, 5g. A 2.5 g (6.9 mmol) quantity of **5f** was added to a mixture containing 2.5 g (44.6 mmol) of KOH in 25 mL of EtOH. The resultant mixture was stirred at room temperature for 1 h, and the EtOH was removed under vacuum. The residue was dissolved in H_2O and 1 N HCl was added until a pH of 4 was obtained. The precipitate was filtered, washed with H_2O, and dried over P_2O_5 under high vacuum to yield 1.4 g (94%) of **5g** as a colorless solid, mp 148−149 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.53−2.91 (m, 10H), 2.49−2.53 (m, 2H), 2.57−2.61 (m, 2H), 4.56 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) δ −1.96 (1B), −5.25 (1B), −9.01 (2B), −11.21 (4B), −12.37 (2B) (all peaks split in ^{1}H coupled spectrum); HRMS (EI)$^+$ calcd for $C_5H_{15}B_{10}O_2Na_2$ (M−H+2Na)$^+$ 263.1798, found 263.1798; HPLC: t_R = 13.6 min.

3-(*nido*-Carboranyl)propionic Acid, 5a. A 350 mg quantity (1.62 mmol) of **5g** was dissolved in 1 mL of pyrrolidine at 0 °C, then allowed to come to room temperature. The mixture bubbled vigorously. After stirring of the sample for 30 min at room temperature, the pyrrolidine was removed under vacuum. The pyrrolidine salt was dissolved in H_2O/MeOH and was eluted on an Amberlite IR-120 ion exchange column (2.5 × 15 cm; pretreated with saturated NaCl, washed with H_2O, then MeOH). The effluent was collected and 10 mL of 25% Me_4NCl was added. The MeOH was removed and the precipitate was collected and dried to yield 292 mg (88%) of **5a** as the Me_4N salt, mp 291 °C (dec); ^{1}H NMR (CD_3OD, 500 MHz) δ 0.82−2.29 (m, 13H), 2.47−2.59 (m, 1H), 3.49 (t, J = 6.8 Hz, 1H), 3.68−3.87 (m, 2H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) δ −10.83 (1B), −11.42 (1B), −13.25 (1B), −15.25 (1B), −18.06 (1B), −19.31 (1B), −20.62 (1B), −32.64 (1B), −36.91 (1B) (all peaks split in ^{1}H coupled spectrum); HRMS (EI)$^-$ calcd for $C_5H_{15}B_9O_2$ 206.2024 (M)$^-$, found 206.2039; HPLC: t_R = 11.7 min.

3-(Iodo-*nido*-carboranyl)propionic Acid, 5b. A 20 mg quantity of **5a** (0.116 mmol) was dissolved into 2 mL of 1% HOAc/MeOH. To that solution was added 17 mg (0.114 mmol) of NaI and 17.5 mg (0.131 mmol) of *N*-chlorosuccinimide (NCS) and the reaction mixture was stirred for 5 min. The MeOH was then removed and the crude product was taken up into 4 mL of EtOAc. The organic layer was washed with water (2 × 4 mL), concentrated, and dried under vacuum to yield 28 mg (86%) of **5b** as a tacky solid. ^{1}H NMR (CD_3OD, 500 MHz) δ 1.23 (s, 1H), 1.87−2.23 (m, 6H), 2.67 (t, J = 6.7 Hz, 2H), 3.53−3.62 (m, 1H), 3.68−3.77 (m, 1H), 3.89−3.96 (m, 2H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) δ −6.77 (1B), −13.99 (1B), −16.02 (1B), −17.39 (1B), −20.74 (1B), −23.75 (1B), −29.76 (1B), −36.68 (2B); LRMS (EI)$^-$ calcd for $C_5H_{20}B_9IO_5$ [M+3(H_2O)] 386, found 386; HPLC: t_R = 13.3 min.

3-(*nido*-Carboranyl)-*N*-propyl-propionamide, 6a. To a solution containing 0.20 g (0.55 mmol) of **5f** in 2 mL of anhydrous DMF at room temperature was added dropwise a solution containing 0.09 mL (1.10 mmol) of *n*-propylamine in 1 mL of anhydrous DMF. After the reaction was stirred at room temperature for 30 min, the solution was triturated with H_2O (100 mL), then stirred for additional 10 min. The H_2O was decanted, the residue was washed with water (2 × 100 mL), and subsequently dried under vacuum to yield a residue containing **6d.** The isolated residue was used directly in the subsequent step.

A 5 mL quantity of pyrrolidine was added to dissolve the residue, and the resultant solution was stirred at room temperature for 30 min. Pyrrolidine was evaporated at room temperature under a stream of argon, and the residue was dried under vacuum to yield 150 mg (86%) of **6a** as a tacky solid (pyrrolidine salt). ^{1}H NMR (CD_3OD, 300 MHz) δ 0.92 (t, J = 7.3 Hz, 3H), 1.47−1.59 (m, 2H), 1.66−1.93 (m, 6H), 1.96−2.00 (m, 4H), 2.29 (t, J = 7.8 Hz, 2H), 3.10 (t, J = 7.3 Hz, 2H), 3.18−3.22 (m, 4H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −10.72 (2B), −13.18 (1B), −16.28 (1B), −18.13 (2B), −21.19 (1B), −32.80 (1B), −36.83 (1B); HRMS (ES$^-$) calcd for $C_8H_{23}B_9NO$ (M)$^-$ 248.2617, found 248.2618. HPLC: t_R = 8.1 min.

3-(Iodo-*nido*-carboranyl)-*N*-propyl-propionamide, 6b. A 2.7 mg (0.02 mmol) quantity of *N*-chlorosuccinimide in 0.5 mL of MeOH was added to a mixture containing 3.1 mg (0.02 mmol) of NaI and 6.3 mg (0.02 mmol) of **6a** in 5 mL of 5% HOAc/MeOH. The resulting solution was stirred at room temperature for 30 s, then 3.9 mg (0.02 mmol) of sodium metabisulfite in 0.5 mL of H_2O was added to quench the reaction (HPLC indicated ∼100% yield). As this compound was used only as an HPLC standard, an analytical sample of **6b** was obtained by HPLC purification. HRMS (ES$^-$) calcd for $C_8H_{22}B_9INO$ (M)$^-$ 374.1584, found 374.1579. HPLC: t_R = 10.8 min.

***N*-(3-Aminophenyl)-3-(*closo*-carboranyl)propionamide, 7d.** A 1.0 g (2.72 mmol) quantity of **5f** was dissolved in 20 mL of DMF. In a separate flask, 0.59 g (5.43 mmol) of 1,3-phenylenediamine was dissolved in 20 mL of DMF. The solution containing **5f** was then added dropwise to the solution of 1,3-phenylenediamine over a 1 h period. After addition was complete, reaction was allowed to stir for 2.5 h. The DMF was removed on a Kugelrohr apparatus under vacuum at 50 °C. The residue was dissolved into 50 mL of ether and washed by 1% HOAc/H_2O (2 × 25 mL), then with H_2O (1 × 25 mL). Ether was removed under vacuum, and was dried under vacuum to yield 0.79 g (95%) of **7d** as a colorless solid, mp 105−108 °C; ^{1}H NMR ($CDCl_3$, 500 MHz) δ 1.54−2.81 (m, 10H), 2.18 (s, 2H), 2.57 (t, J = 7.1 Hz, 2H), 2.68 (t, J

= 7.1 Hz, 2H), 3.51 (s,1H), 6.4 (dd, J = 1.8, 8.0 Hz, 1H), 6.5−6.6 (m, 1H), 6.6 (d, J = 8.0 Hz, 1H), 7.0 (t, J = 8.0 Hz, 2H), 7.0 (t, J = 1.8 Hz, 2H), 7.1 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) δ −2.0(1B), −5.2(1B), −9.1(2B), −10.9(4B), −12.3(2B); all peaks split in ^{1}H coupled spectrum; HRMS (ES^+) calcd for $C_{11}H_{22}B_{10}N_2ONa$ $(M+Na)^+$ 331.2560, found 331.2562; HPLC: t_R = 13.5 min.

***N*-(3-Aminophenyl)-3-(*nido*-carboranyl)propionamide, 7e.** A 600 mg (1.95 mmol) quantity of **7d** was dissolved in neat pyrrolidine (2.9 mL) and stirred for 1 h. Excess pyrrolidine was evaporated under a stream of air and the residue was washed with ether (2 × 50 mL), decanting the ether after each washing. Residue was dissolved a minimal amount of H_2O/CH_3CN/MeOH (5:4:1) and that solution was loaded onto preequilibrated ion exchange columns. In the column preparation, two Alltech IC−H ion exchange columns (IC−H, Alltech Associates, Inc.) were connected in series and washed with 10 mL of 1 N NaOH, then with water until the column reached neutral pH, and finally with 20 mL of eluants (H_2O/CH_3CN/MeOH; 5:4:1). The column was eluted in 1 mL fractions of eluant (20×). Fractions containing **7e** were collected and volatile solvents were removed under vacuum. The remaining aqueous solution was washed with CH_2Cl_2 (2 × 25 mL), and then a saturated solution of $(CH_3)_4NCl$ was added. The colorless precipitate was collected by filtration and dried under vacuum to yield 205 mg (36%) of **7e** as the $(CH_3)_4N$ salt: mp 28−30 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.5−2.2 (m, 9H) 2.46 (m, 3H), 3.1 (s, 12H), 3.3 (m, 1H), 6.4 (dd, J = 1.2, 8.0 Hz, 1H), 6.8 (dd, J = 1.2, 8.0 Hz, 1H), 7.0 (t, J = 8.0 Hz, 2H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) −10.2(2B), −12,8(1B), −15.8(1B), −17.5(1B), −18.1(1B), −20.8(1B), −32.4(1B), −36.4(1B); all peaks split in ^{1}H coupled spectrum; HRMS $(ES)^-$ calcd for $C_{11}H_{21}B_9N_2O$ $(M)^-$ 296.2487, found 296.2481; HPLC: t_R = 8.5 min.

3-(*nido*-Carboranyl)-*N*-(3-isothiocyanatophenyl)-propionamide, 7f. A 50 mg (0.16 mmol) quantity of **7e** was dissolved in 2 mL of DMF and 24.3 mg (0.16 mmol) of 1,1-thiocarbonyldiimidazole was added. The reaction was stirred for 0.5 h and the DMF was removed under vacuum. The residue was dissolved in a minimal amount of MeOH, then loaded onto a preparative TLC plate (60 F_{254}, 20 cm × 20 cm × 2 mm, EM Science). The plate was eluted with hexanes/ethyl acetate (9:1). The silica at the origin was removed and washed with MeOH. The MeOH was removed under vacuum and the remaining solid was dried under high vacuum to yield 49 mg (87%) of **7f** as a tacky brown solid, mp 22−24 °C; ^{1}H NMR (CD_3OD, 500 MHz) δ 1.45−1.75 (m, 2H), 1.83 (s, 1H), 1.92−2.00 (m, 2H), 2.03−2.09 (m, 2H), 2.12−2.22 (m, 1H), 2.37−2.49 (m, 1H), 2.52−2.62 (m, 4H), 3.27 (s, 12H), 6.56 (dd, J = 2.2, 8.0 Hz, 1H), 6.91 (d, J = 8.0 Hz, 1H), 7.11 (t, J = 8.0 Hz, 1H), 7.13 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160.46 MHz) −7.8(2B), −12.3(1B), −15.2(1B), −17.1(1B), −17.8(1B), −20.3(1B), −31.9(1B), −35.9(1B); all peaks split in ^{1}H coupled spectrum; LRMS $(ES)^-$ calcd for $C_{12}H_{19}B_9N_2OS$ $(M)^-$ 338.2, found 338.3; HPLC: t_R = 14.8 min.

3-(*nido*-Carboranyl)-*N*-[3-(3-propylthioureido)-phenyl]propionamide, 7a. To a solution containing 48 mg (0.16 mmol) of **7e** in 2 mL of anhydrous DMF at room temperature was added 35 mg (0.20 mmol) of 1,1′-thiocarbonyldiimidazole. The resulting mixture was stirred at room temperature for 30 min, then 28 μL (0.34 mmol) of *n*-propylamine was added and the solution was stirred for another 10 min. A 30 mL quantity of diethyl ether was added to the reaction solution, which was stirred for an additional 30 min at room temperature. The solvents were decanted, the residue was washed with diethyl ether (2 × 30 mL), then dried under high vacuum to yield 60 mg (93%) of **7a** as a colorless tacky solid. ^{1}H NMR (CD_3OD, 300 MHz) δ 0.92 (t, J = 7.3, 7.8 Hz, 3H), 1.18 (t, J = 6.7, 7.3 Hz, 2H), 1.56−1.73 (m, 2H), 1.82−2.30 (m, 6H), 2.49 (t, J = 7.8 Hz, 1H), 2.86−2.95 (m, 1H), 3.29−3.32 (m, 4H), 3.39−3.75 (m, 4H), 7.27 (d, J = 1.0 Hz, 2H), 7.30−7.39 (m, 1H), 8.19 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −10.82 (2B), −13.46 (1B), −16.45 (1B), −18.46 (2B), −21.60 (1B), −33.46 (1B), −37.42 (1B); HRMS $(ES)^-$ calcd for $C_{15}H_{28}B_9N_3OS$ $(M)^-$ 397.2791, found 397.2801. HPLC: t_R = 9.6 min.

3-(Iodo-*nido*-carboranyl)-*N*-[3-(3-propylthioureido)phenyl]propionamide, 7b. To a stirred solution containing 9.3 mg (0.02 mmol) of **7a** in 5 mL of 5% HOAc/MeOH, was added 3.1 mg (0.02 mmol) of NaI and 2.7 mg (0.02 mmol) of *N*-chlorosuccinimide, respectively. The reaction mixture was stirred at room temperature for 30 s, then 3.9 mg (0.02 mmol) of sodium metabisulfite was added to quench the reaction (HPLC indicated that a yield of 41% was obtained). As this compound was used only as an HPLC standard, an analytical sample of **7b** was obtained by HPLC purification; t_R = 11.0 min. HRMS $(ES)^-$ calcd for $C_{15}H_{28}B_9IN_3OS$ $(M)^-$ 524.1835, found 524.1824.

1-Phenylcarborane, 8d. (A modified procedure from that previously reported (*40*) was used.) To 5.0 g (41 mmol) of decaborane in 60 mL of anhydrous CH_3CN was added 4.18 g (41 mmol) of phenylacetylene slowly over a period of 3 h. The resulting solution was refluxed for 24 h. After cooling the samples to room temperature, the CH_3CN was removed and the residue was sublimed to give 6.4 g (71%) of **8d** as a colorless solid, mp = 67−69 °C. HPLC: t_R = 15.3 min.

4-Carboranyl-1-nitrobenzene, 8e. (A modified procedure from that previously reported (*40*) was used.) A 1.50 g (6.81 mmol) quantity of **8d** in 30 mL of CH_2Cl_2 was added to a stirred solution of 15% concentrated HNO_3 in concentrated H_2SO_4. The resultant reaction mixture was stirred at room temperature for 20 h. The CH_2Cl_2 portion was separated and washed with H_2O (2 × 50 mL), dried over anhydrous Na_2SO_4, then evaporated to a solid residue. The crude residue was crystallized from CCl_4 three times to yield 0.83 g (46%) of **8e** as a light yellow solid, mp = 165−167 °C (reported 167−168 °C (*40*)). HPLC: t_R = 15.2 min.

4-Carboranylaniline, 8f. A solution containing 0.5 g (1.88 mmol) **8e** in 30 mL of EtOH was stirred with 50 mg of 10% Pd/C catalyst under 40 psi H_2 pressure (Parr Hydrogenation apparatus) for 16 h at room temperature. After removal of the remaining H_2 and filtration of the catalyst, the EtOH was removed under vacuum to yield 0.42 g (95%) **8f** as a colorless solid, mp = 102−104 °C (reported 104−105 °C (*40*)). HPLC: t_R = 14.3 min.

4-(*nido*-Carboranyl)aniline, 8g. A 100 mg (0.42 mmol) quantity of **8f** was dissolved in 3 mL of neat pyrrolidine and the resultant solution was stirred at room temperature for 30 min. The pyrrolidine was removed under vacuum to yield 125 mg (100%) of **8g** as a light yellow tacky solid (pyrrolidine salt) (reported mp = 155−156 °C as the Me_4N salt (*28*)). HPLC: t_R = 8.3 min.

1-(4-*nido*-Carboranylphenyl)-3-propylthiourea, 8a. A 44.6 mg (0.25 mmol) quantity of 1,1′-thiocarbonyldiimidazole was added to a stirred solution containing 50 mg (0.17 mmol) of **8g** (pyrrolidine salt) in 3 mL of anhydrous DMF, then the reaction mixture was allowed to be stirred at room temperature for 30 min. The 4-(*nido*-

carboranyl)phenylisothiocyanate, **8h**, formed was used without purification in the next reaction step.

A 28 μL (0.34 mmol) quantity of *n*-propylamine was added to the crude reaction mixture containing **8h**, and that resultant mixture was stirred for another 10 min at room temperature. After that time, 30 mL of diethyl ether was added to the reaction mixture, and it was stirred for an additional 30 min. The solvents were decanted, the residue was washed with diethyl ether (2 × 30 mL), and the residue was dried under high vacuum to yield 57 mg (85%) of **8a** as a colorless tacky solid. ^{1}H NMR (CD_3OD, 300 MHz) δ 0.90 (t, J = 7.3 Hz, 2H), 1.01 (t, J = 7.3 Hz, 3H), 1.52−1.74 (m, 6H), 2.17 (s, 1H), 6.98 (d, J = 8.3 Hz, 2H), 7.21 (d, J = 8.8 Hz, 2H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −8.70 (1B), −10.34 (1B), −13.36 (1B), −16.38 (1B), −17.80 (1B), −19.42 (1B), −22.44 (1B), −32.65 (1B), −35.79 (1B); HRMS (ES)$^-$ calcd for $C_{12}H_{24}B_9N_2S$ (M)$^-$ 327.2498, found 327.2535. HPLC: t_R = 8.7 min.

1-(Iodo-4-*nido*-carboranylphenyl)-3-propylthiourea, 8b. A 7.9 mg (0.02 mmol) quantity of **8a** and 3.1 mg (0.02 mmol) of NaI were dissolved in 5 mL of 5% HOAc/MeOH at room temperature. To that solution was added 2.7 mg (0.02 mmol) of *N*-chlorosuccinimide in 0.5 mL of methanol. After the addition was complete, the reaction solution was stirred at room temperature for 30 s, then 3.9 mg (0.02 mmol) of sodium metabisulfite in 0.5 mL of H_2O was added to quench the reaction. The reaction mixture had several products by HPLC analysis with only 35% yield in the peak identified as **8b** by mass spectral analysis. An analytical sample of **8b** was obtained by HPLC purification. HRMS (ES)$^-$ calcd for $C_{12}H_{23}B_9IN_2S$ (M)$^-$ 453.1464, found 453.1476. HPLC: t_R = 11.8 min.

4-(Iodo-*nido*-carboranyl)aniline, 9b. A 5.9 mg (0.02 mmol) quantity of **8g** and 3.1 mg (0.02 mmol) of NaI were dissolved at room temperature in 5 mL of 5% HOAc in MeOH, then 2.7 mg (0.02 mmol) of *N*-chlorosuccinimide in 0.5 mL of MeOH was added. Following the additions, the reaction mixture stirred at room temperature for 30 s, then 3.9 mg (0.02 mmol) of sodium metabisulfite was added to quench the reaction. A quantitative yield was obtained. As this compound was used only as an HPLC standard, an analytical sample of **9b** was obtained by HPLC purification. HRMS (ES)$^-$ calcd for $C_8H_{16}B_9IN$ (M)$^-$ 352.1165, found 352.1180. HPLC: t_R = 10.7 min.

1-(4-*closo*-Carboranylphenyl)-3-propylurea, 10e. To a solution containing 40 mg (0.17 mmol) of **8f** in 2 mL of $CHCl_3$ was added 55 mg (0.34 mmol) of 1,1′-carbonyldiimidazole. The reaction solution was stirred at room temperature for 2 h and 5 mL of H_2O was added. The reaction mixture was stirred for an additional 10 min, then the $CHCl_3$ layer was separated. A 28 μL (0.34 mmol) quantity of *n*-propylamine was added to the crude isocyanate (**10d**) solution, and it was stirred at room temperature for 30 min. The $CHCl_3$ and excess *n*-propylamine were evaporated under a stream of argon, and the crude product was purified on silica gel (12 g) eluted with 30% ethyl acetate−hexanes to provide 45 mg (83%) of colorless solid, mp 101−102 °C. ^{1}H NMR (CD_3OD, 300 MHz) δ 0.94 (t, J = 7.3 Hz, 3H), 1.47−1.59 (m, 2H), 1.71−3.02 (m, br, 10H), 3.14 (t, J = 7.3 Hz, 2H), 7.34 (d, J = 8.8 Hz, 2H), 7.42 (d, J = 8.8 Hz, 2H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −1.75 (1B), −2.36 (1B), −8.16 (2B), −8.85 (2B), −10.14 (3B), −12.01 (1B); HRMS (ES$^+$) calcd for $C_{12}H_{25}B_{10}N_2O$ (M+H)$^+$ 323.2897, found 323.2892. HPLC: t_R = 14.8 min.

1-(4-*nido*-Carboranylphenyl)-3-propylurea, 10a. A 20 mg (0.062 mmol) quantity of **10e** was dissolved in 2 mL of neat pyrrolidine and that solution was stirred at room temperature for 1 h. The pyrrolidine was evaporated under a stream of argon. The residue containing crude *nido*-carborane was washed with diethyl ether (2 × 20 mL), dried under vacuum to give **10a** as a light-yellow tacky solid (pyrrolidine salt). Yield 24 mg (∼100%). ^{1}H NMR (CD_3OD, 300 MHz) δ 0.93 (t, J = 7.3, 7.8 Hz, 3H), 1.48−1.58 (m, 2H), 1.86−1.90 (m, 4H), 2.00−2.28 (m, 4H), 2.87−2.92 (m, 1H), 3.03−3.14 (m, 6H), 3.30 (s, 2H), 3.40−3.71 (m, 3H), 7.04 (d, J = 8.8 Hz, 2H), 7.08 (d, J = 8.8 Hz, 2H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −8.87 (1B), −10.29 (1B), −13.11 (1B), −16.17 (1B), −18.00 (2B), −21.88 (1B), −32.19 (1B), −35.59 (1B); HRMS (ES)$^-$ calcd for $C_{12}H_{24}B_9N_2O$ (M)$^-$ 311.2726, found 311.2725. HPLC: t_R = 10.5 min.

1-(Iodo-4-*nido*-carboranylphenyl)-3-propylurea, 10b. An 83 μL (6.2 μmol) aliquot of a 10 mg/mL solution of *N*-chlorosuccinimide in MeOH was added with stirring to a vial containing 300 μL of a MeOH/5% HOAc solution containing 2.4 mg (6.2 μmol) of **10a** and 10 μL (6.2 μmol) of a solution containing 100 mg/mL NaI in H_2O. After the reaction mixture was stirred at room temperature for 30 s, 119 μL (6.2 μmol) of a 10 mg/mL sodium metabisulfite in H_2O was added to quench the reaction. Pure **10b** was collected from HPLC; t_R = 14.1 min. HRMS (ES)$^-$ calcd for $C_{12}H_{23}B_9IN_2O$ (M)$^-$ 437.1693, found 437.1693.

Bis-(*nido*-Carboranylmethyl)benzene, 11a. [C_6H_4-*bis*-(CH_2-7,8-$C_2B_9H_{10}$)$_2$]$^{2-}$ 2($N(CH_3)_3H$)$^+$, (11a). To a solution containing 3.60 g (9.10 mmol) of **11g** in 85 mL of 95% ethanol was added 3.10 g (54.7 mmol) of KOH pellets. The solution was heated at reflux overnight followed by cooling to ambient temperature and subsequent addition of 4.10 g (93.0 mmol) CO_2. The carbonate was filtered and the solids were washed with 95% ethanol (3 × 100 mL). The extracts were combined and concentrated under vacuum. The crude solids were dissolved in 30 mL water and added to an aqueous solution containing 1.90 g (20.1 mmol) Me_3NHCl. The solids were collected by filtration and dried to give 3.60 g (7.30 mmol) of **11a** (80% yield). IR (Nujol, cm^{-1}) 3139 (s), 3072 (w), 2926 (s), 2505 (s), 1413 (w), 1315 (w), 1256 (w), 1075 (w), 1028 (m), 976 (s), 804 (w), 762 (m), 735 (m); ^{1}H NMR ((CD_3)$_2$CO, 200.13 MHz) δ 8.38 (s, br, 2H), 7.16 (m, 4H), 4.25 (s, 2H), 3.09 (s 18H), 2.88 (m, 4H); ^{13}C NMR ((CD_3)$_2$-CO, 50.32 MHz) δ 141.4, 129.7, 125.8, 46.1, 42.7; ^{11}B NMR ((CH_3)$_2$CO, 160.46 MHz) δ −9.39 (d, 2B), −10.57 (d, 2B), −13.08 (d, 2B), −15.78 (d, 2B), −18.40 (d, 2B), −19.73 (d, 2B), −32.81 (d, 2B), −36.33 (d, 2B); LRMS (FAB$^-$) calcd for $C_{12}H_{30}B_{18}$, 368.97, found 368.34.

[Iodo-bis-(*nido*-Carboranylmethyl)]benzene, 11b. To 4.2 mg (4.9 μmol) of **11a** dissolved in 4.2 mL of 5% HOAc/MeOH, was added 7.3 μL of a 100 mg/mL in H_2O solution of NaI (4.9 μmol), then 65 μL of a 10 mg/mL in MeOH solution of *N*-chlorosuccinimide (4.9 μmol). After the reaction mixture was stirred at room temperature for 30 s, 93 μL of a 10 mg/mL in H_2O solution of sodium metabisulfite was added to quench the reaction. Yield was ∼100%. An analytical sample of **11b** was obtained by collection from HPLC. LRMS (ES)$^-$ calcd for $C_{12}H_{26}B_{18}I$ (M-2H)$^-$ 495.3, found 495.3. HPLC: t_R = 13.6−13.8 min.

3,4-Bis-(*closo*-carboranylmethyl)nitrobenzene, 11h; *m*-NO_2-C_6H_3-*bis*-(CH_2-1,2-$C_2B_{10}H_{11}$)$_2$, (11h). To a solution of 35.1 g (89.8 mmol) of **11g** in 1 L of CH_2Cl_2 was added a mixture of concentrated H_2SO_4 (380 mL) and HNO_3 (70 mL) at 0° C. This solution warmed to ambient temperature and was stirred for 2 days. The aqueous layer was decanted off and extracted with CH_2Cl_2 (3 × 400 mL). The organic phases were combined and con-

centrated under vacuum. The crude product was purified by column chromatography on silica gel with diethyl ether/hexane (1:3) as the eluting solvent. The collected fractions afforded 36.8 g (84.6 mmol) of **11h** as a yellow solid (94% yield), mp 110−112° C. IR (Nujol, cm^{-1}) 3056 (s), 2941 (s), 2570 (s), 1620 (w), 1590 (w), 1513 (s), 1370 (w), 1330 (m), 1090 (w), 1065 (w), 1020 (m), 830 (m), 788 (s), 766 (m), 735 (m), 720 (w); ^{1}H NMR ($(CD_3)_2CO$, 200.13 MHz) δ 8.25 (d, J = 6.5 Hz, 1H), 8.24 (s, 1H), 7.70 (d, J = 9.3 Hz, 1H), 4.98 (s, 1H), 4.89 (s, 1H), 4.02 (s, 2H), 4.00 (s, 2H); ^{13}C NMR ($(CD_3)_2CO$, 50.32 MHz) δ 148.3, 142.0, 137.0, 134.6, 127.7, 123.8, 75.0, 74.7, 63.4, 63.2, 39.9; ^{11}B NMR ($(CH_3)_2CO$, 160.46 MHz) δ −2.18 (d, 2B), −4.98 (d, 2B), −9.00 (d, 4B), −11.34 (d, 8B), −12.24 (d, 4B); LRMS (EI) calcd for $C_{12}H_{29}B_{20}NO_2$, 435.59, found 435.43.

3,4-Bis-(*closo*-carboranylmethyl)aniline, 11i; *m*-NH_2-C_6H_3-*bis*-$(CH_2$-1,2-$C_2B_{10}H_{11})_2$, (11i). To a solution of 26.0 g (59.6 mmol) of **11h** in 1 L of methanol was added 80 mL of concentrated HCl and 14.9 g of (126 mmol) tin metal. The reaction mixture was heated at reflux for 10 h, followed by stirring at ambient temperature overnight. The solvent was removed under vacuum, and to the residue was added 100 mL of diethyl ether. The pH of the mixture was neutralized by slow addition of aqueous sodium bicarbonate. An additional 400 mL of diethyl ether was added and the two-phase mixture was transferred to a separatory funnel. The layers were separated and the aqueous layer was extracted with diethyl ether (2 × 300 mL). The organic phases were combined and dried over $MgSO_4$. The yellow solution was filtered and concentrated under vacuum affording 16.1 g (39.7 mmol) of **11i** as a yellow solid (67% yield), mp 150−152° C. IR (Nujol, cm^{-1}) 3390 (w), 3056 (w), 2951 (s), 2577 (s), 1621 (s), 1583 (s), 1513 (w), 1331 (w), 1291 (w), 1018 (m), 816 (w), 725 (s); ^{1}H NMR ($(CD_3)_2CO$, 200.13 MHz) δ 6.96 (d, J = 8.2 Hz, 1H), 6.62 (dd, J = 8.2 Hz, 2.4 Hz, 2H), 6.55 (d, J = 2.3 Hz, 1H), 4.63 (s, 1H), 4.60 (s, 1H), 3.61 (s, 2H), 3.59 (s, 2H); ^{13}C NMR ($(CD_3)_2CO$, 50.32 MHz) δ 149.1, 135.3, 133.6, 122.6, 117.7, 115.1, 77.2, 76.1, 62.0, 61.9, 40.8, 40.2; ^{11}B NMR ($(CH_3)_2CO$, 160.46 MHz) δ −2.30 (d, 2B), −5.47, (d, 2B), −9.30 (d, 4B), −11.19 (d, 8B), −12.50 (d, 4B); LRMS (EI) calcd for $C_{12}H_{31}B_{20}N$, 405.61, found 406.00.

3,4-Bis-(*nido*-carboranylmethyl)aniline, 11j; [*m*-NH_2-C_6H_3-*bis*-$(CH_2$-7,8-$C_2B_9H_{10})_2]^{2-}$ $2Cs^+$, (11j). To a solution of 24.0 g (59.2 mmol) of **11i** in 550 mL of 95% ethanol was added 20.0 g (357 mmol) of KOH pellets. The solution was heated at reflux overnight followed by cooling to ambient temperature and subsequent addition of 20.0 g (455 mmol) of CO_2. The carbonate was filtered and the solids were washed with 95% ethanol (3 × 100 mL). The extracts were combined and concentrated under vacuum. The crude solids were dissolved in 75 mL of water and that solution was added to an aqueous solution containing 21.0 g (125 mmol) of CsCl. The solids were collected by filtration, dried, and recrystallized from hot water to give 30.8 g (47.4 mmol) of **11j** (80% yield), mp > 200° C (decomposes). IR (Nujol) 3340 (w), 3035 (w), 2951 (s), 2508 (s), 1604 (s), 1070 (w), 1028 (m), 724 (m); ^{1}H NMR (CD_3CN), 200.13 MHz) δ 7.04 (dd, J = 7.0, 1.3 Hz, 1H), 6.74 (s, 1H), 6.67 (dd, J = 8.1, 2.4 Hz, 1H), 2.80 (m, 4H), 1.70 (s, 2H); ^{13}C NMR (CD_3CN), 50.32 MHz) δ 142.9, 140.6, 140.5, 134.8, 134.7, 131.2, 131,1, 119.3, 119.2, 115.6, 60.5, 48.1, 42.6, 41.9; ^{11}B NMR ($(CH_3)_2CO$, 160.46 MHz) δ −9.03 (d, 2B), −10.20 (d, 2B), −12.66 (d, 2B), −15.21 (d, 2B), −17.02 (d, 4B), −20.97 (d, 2B), −32.44 (d, 2B), −35.94 (d, 2B); LRMS (negative ion FAB) calcd for $C_{12}H_{31}B_{18}N$, 383.99, found 384.53.

4-{[3,4-bis-(*nido*-carboranylmethyl)phenyl]ureido}-benzyl-DTPA, 12a. A 7.0 mg (0.043 mmol) of quantity of 1,1′-carbonyldiimidazole was added to a solution containing 20 mg (0.040 mmol) of **11j** $(NMe_3H)_2$ in 2 mL of anhydrous CH_3CN. The reaction mixture was stirred at room temperature for 1 h, and the CH_3CN was evaporated under a stream of argon. The residue containing the isocyanato derivative **11k** was redissolved in 2 mL of anhydrous DMF. To that solution was added 20 mg (0.031 mmol) of 4-aminobenzyl-diethylenetriaminepentaacetic acid hydrochloride salt and 20 μL of anhydrous pyridine, respectively. The resultant reaction mixture was stirred at room temperature for 16 h, and the volatile materials were evaporated under vacuum. The crude **12a** was redissolved in 2 mL of 1 N $NaHCO_3$ and purified by Sephadex G-15 gel column, eluting with water to afford 26 mg (58%) of **12a** as a colorless solid (Na salt). ^{1}H NMR (D_2O, 200 MHz) δ 1.97 (s, 2H), 2.91−2.94 (m, 1H), 3.07 (d, J = 1.8 Hz, 1H), 3.18 (s, 18H), 3.26−3.36 (m, 6H), 3.50−3.71 (m, 6H), 3.87−4.32 (m, 8H), 4.36 (s, 1H), 7.38−7.46 (m, 3H), 7.50 (d, J = 2.2 Hz, 1H), 7.55−7.64 (m, 2H), 7.67 (d, J = 2.2 Hz, 1H); ^{11}B NMR (D_2O, 160.46 MHz) d −12.20 (2B), −13.19 (2B), −15.06 (1B), −18.36 (2B), −20.83 (2B), −22.64 (1B), −34.48 (4B), −38.49 (4B); LRMS (MALDI$^-$) calcd for $C_{34}H_{59}B_{18}N_5O_{11}$ $(M)^-$ 911.6, found 911.7. HPLC: t_R = 9.1−9.3 min.

4-{[3,4-Bis-(iodo-*nido*-carboranylmethyl)phenyl]-ureido}benzyl-DTPA, 12b. A 100 μL (4.4 μmol) quantity of a 10 mg/mL aqueous solution of chloramine-T was added to a solution containing 5 mg (4.4 μmol) of **12a**, 6.6 μL (4.4 μmol) of a 100 mg/mL aqueous solution of NaI, and 5 mL of a 5% HOAc/ H_2O solution. The reaction mixture was stirred at room temperature for 30 s, and 84 μL (4.4 μmol) of a 10 mg/mL aqueous solution of sodium metabisulfite was added to quench the reaction. Pure **12b** was collected from HPLC. Yield was ∼100%. LRMS (MALDI$^-$) calcd for $C_{34}H_{57}B_{18}IN_5O_{11}$ $(M - H)^-$ 1036.5, found 1036.9. HPLC: t_R = 10.9−11.3 min.

3-(*closo*-Carboranyl)-*N*-{3-[(3-benzyl-DTPA)ureido]-phenyl}propionamide, 13e. 1,1′-Carbonyldiimidazole (5.3 mg, 0.033 mmol) was added to a solution containing *N*-(3-aminophenyl)-3-(*closo*-carboranyl)propionamide **7d** (10 mg, 0.033 mmol) and anhydrous chloroform (1 mL), and then the reaction mixture was stirred at room temperature for 1 h. After chloroform was evaporated with a stream of argon, the crude isocyanate **13d** was redissolved in anhydrous DMF (1 mL). 4-Aminobenzyl-diethylenetriaminepentaacetic acid hydrochloride salt (10 mg, 0.016 mmol) and pyridine (20 μL) were added, respectively, and the reaction solution was stirred at room temperature for 16 h. The solution was triturated with $CHCl_3$ (20 mL), filtered, washed with additional $CHCl_3$, and dried under high vacuum to afford **13e** as a colorless solid (57%). ^{1}H NMR (CD_3OD, 200 MHz) δ 2.57 (s, 10H), 2.96−3.34 (m, 6H), 3.39−3.80 (m, 8H), 4.49 (s, 1H), 7.13 (m, 3H), 7.29 (t, J = 8.0 Hz, 1H), 7.46 (s, 2H), 7.67 (m, 1H), 8.76 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 160.4 MHz) δ −1.11 (1B), −4.32 (1B), −8.05 (2B), −10.13 (4B), −11.37 (2B); LRMS (MALDI$^+$) calcd for $C_{33}H_{50}B_{10}N_6O_{12}Na$ $(M+Na)^+$ 855.5, found 855.5. HPLC: t_R = 12.6 min.

3-(*nido*-Carboranyl)-*N*-{3-[(3-benzyl-DTPA)ureido]-phenyl}propionamide, 13a. 20 mg (0.024 mmol) of **13e** was dissolved in neat pyrrolidine (2 mL) and stirred at room temperature for 1 h. After pyrrolidine was evaporated by a stream of argon, the residue was washed with ethyl acetate (2 × 20 mL), and dried under vacuum to give **13a** as a light-yellow tacky solid (quantitative yield). ^{1}H NMR (CD_3OD, 200 MHz) δ 1.96−2.00 (m, 8H), 2.46−

2.53 (m, 1H), 2.89−3.04 (m, 1H), 3.21−3.25 (m, 10H), 3.29−3.32 (m, 4H), 3.36−3.78 (m, 4H), 3.83 (d, J = 3.6 Hz, 1H), 7.19−7.29 (m, 5H), 7.42 (d, J = 8.3 Hz, 2H), 7.64 (s, 1H); ^{11}B NMR (CD_3OD, decoupled, 96.3 MHz) δ −10.62 (1B), −13.23 (1B), −16.10 (1B), −17.92 (1B), −20.86 (1B), −32.80 (2B), −37.04 (2B); LRMS $(ES)^-$ calcd for $C_{33}H_{50}B_9N_6O_{12}$ $(M)^-$ 821.5, found 821.5. HPLC: t_R = 9.7 min.

3-(Iodo-*nido*-carboranyl)-*N*-[3-(3-benzyl-DTPA)-ureido)phenyl]propionamide, 13b. To a solution of **13a** (8.9 mg, 0.01 mmol) in 5% HOAc-MeOH (2.5 mL) sodium iodide (1.5 mg, 0.01 mmol) and *N*-chlorosuccinimide (1.3 mg, 0.01 mmol) were added, respectively, with stirring. After the reaction mixture was stirred at room temperature for 30 s, sodium metabisulfite (1.9 mg, 0.01 mmol) was added to quench the reaction. A quantitative yield was estimated by HPLC. Pure **13b** was collected from HPLC and dried under vacuum to give a light-yellow tacky solid. LRMS ($MALDI^-$) calcd for $C_{33}H_{49}B_9IN_6O_{12}$ $(M-H)^-$ 947.3, found 947.7. HPLC: t_R = 10.8 min.

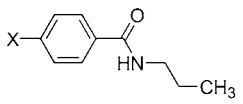
Radiohalogenation of Arylstannanes. A. (Labeling with ^{211}At) To a solution containing 100 μL of 1 mg/mL of arylstannane **1a**, **2a**, **3a**, or **4a** in MeOH/5% HOAc was added 10 μL of Na[^{211}At]astatide in 0.05 N NaOH, or 100 μL of Na[^{211}At]At (100−800 μCi) in MeOH with 10% 0.05N NaOH. To the resultant solution was added 20 μL of a 1 mg/mL solution of *N*-chlorosuccinimide (NCS) in MeOH. The reaction was quenched after 30 s to 2 min with 20 μL of a 1 mg/mL solution of sodium metabisulfite in H_2O. Following the reaction, the bulk of the mixture was injected onto a reversed-phase HPLC column and the peak at the retention time just following the iodo-standard was collected. Radiochemical yields for astatinated compounds were as follows: [^{211}At]**1c**, 55%; [^{211}At]-**2c**, 38%; [^{211}At]**3c** 33%; [^{211}At]**4c**, 42% (yields not optimized).

B. (Labeling with ^{125}I or ^{131}I): The radioiodination reactions were conducted as described for ^{211}At labeling, with the following changes in reagent quantities: Na[*I]I, 1−5 μL of a 0.1 N NaOH solution; NCS, 10 μL; and sodium metabisulfite, 10 μL. Radiochemical yields for radioiodinated compounds ([^{125}I]**1b**, [^{125}I]**2b**, [^{125}I]**3b**, [^{125}I]-**4b**) ranged from 90 to 98%.

Radiohalogenation of *nido*-Carboranyl Compounds. A. (Labeling with ^{211}At): To a solution containing 100 μL of 1 mg/mL of *nido*-carboranyl compound (**5a, 6a, 7a, 8g, 10a, 11a, 12a**, and **13a**) in either H_2O/5%HOAc or 50:50 MeOH/H_2O/5%HOAc, depending on compound solubility, was added 100 μL of Na[^{211}At]At (100−800 μCi) in 0.05 N NaOH. To this solution was added 20 μL of a 1 mg/mL solution of chloramine-T (ChT) in H_2O. The reaction was quenched after 30 s to 2 min with 20 μL of a 1 mg/mL solution of sodium metabisulfite in H_2O. Following the reaction, the bulk of the reaction mixture was injected onto a reversed-phase HPLC column and the peak at the retention time just following the iodo-standard was collected. Radiochemical yields for astatinated compounds were as follows: ([^{211}At]**5c**, 71%; [^{211}At]**6c**, 39%; [^{211}At]**7c**, 61%; [^{211}At]**9c,** 49%; [^{211}At]**10c**, 86%; [^{211}At]**11c**, 72%; [^{211}At]**12c**, 63%; [^{211}At]**13c**, 39% (yields were not optimized).

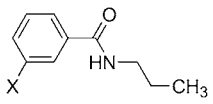
B. (Labeling with ^{125}I or ^{131}I): The radioiodination reactions were conducted as described for ^{211}At labeling of *nido*-carboranes, with the following changes in reagent quantities. The quantity of Na[*I]I used was 1−5 μL of a 0.1 N NaOH solution; 10 μL of ChT solution; and 10 μL of sodium metabisulfite solution. Radiochemical yields for radioiodinated compounds ([^{131}I]**5b**, [^{125}I]**6b**, [^{125}I]**7b**, [^{125}I]**9b**, [^{125}I]**10b**, [^{125}I]**11b**, [^{125}I]**12b**, [^{125}I]**13b**) ranged from 28 to 95%.

Biodistribution Studies. Animal use and procedures were approved by Duke University's Animal Care Committee or the University of Washington's Institutional Animal Care and Use Committee depending on where the study was conducted. In all studies, animal care and use were conducted in accordance with the NIH guidelines.[4] A biodistribution was conducted at Duke University to compare [^{131}I]**5b** and [^{211}At]**5c** in BALB/c mice. All other biodistribution studies were conducted at the University of Washington using BALB/c nu/nu mice. All reagents were administered to mice in a total volume of approximately 100 μL (injectate weighed) via the lateral tail vein. Injections and euthanasia of the animals were done at predetermined times. Blood samples were obtained by cardiac puncture immediately before killing. Urine samples were obtained by syringe bladder tap at the time the tissues were excised. The tissues excised included muscle, lung, kidney, spleen, liver, intestines, neck (with thyroid), and stomach. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (% ID/g) of radioactivity in the tissues was based on internal standards containing 1 μL of the injected dose. The counts obtained were corrected for decay, and where dual radionuclide counting was required, the ^{125}I counts were corrected for spillover counts from ^{131}I activity. Total blood volume was estimated to be 8% of body weight. The data obtained are provided in Tables 1−13 in Supporting Information. The amount of $^{125/131}$I and ^{211}At administered to mice, and the average mouse weight, in each biodistribution are provided in the table legends.



RESULTS

Design and Synthesis of Target Compounds. The goal of this investigation was to prepare and evaluate a series of astatinated benzamide and *nido*-carboranyl compounds to help identify structural features which maximize in vivo stability of an astatine label on a targeting carrier molecule. The compounds prepared for the investigation are shown in Figure 1. Initially, the compounds targeted were simple molecules. However, results obtained during the study led to synthesis of more complex molecules, which incorporated functional groups intended to increase renal excretion and decrease binding with blood components. In a majority of compounds prepared, biomolecule (amine) reactive groups were conjugated with *n*-propylamine to provide simple conjugates, which might be expected to be metabolized readily. Small rapidly metabolized molecules were chosen as they seemed the best candidates to test in vivo stability of the ^{211}At label, and in some cases represented structures that could be useful as prosthetic groups for labeling biomolecules.



To incorporate the radiohalogens into the nonactivated aryl groups, tri-*n*-butylstannyl derivatives were prepared as reactive intermediates. The compounds containing the *nido*-carboranyl functionality were very reactive with radiohalogens, so they were reacted directly with radiohalogens. For evaluation purposes, the prepared compounds have been placed into three groups based on the type of radiohalogenation moiety and on the functional groups conjugated with that moiety. The three groups

Figure 1. Aryl- and *nido*-carboranyl-compounds and their radiohalogenation derivatives prepared for evaluation in the studies. (Note that for simplicity, carborane cage hydrogen atoms, and possible halogenated *nido*-carboranyl regioisomers, are not shown.)

were benzamides, *nido*-carboranes, and *nido*-carboranes conjugated with DTPA. In all compounds studied, nonradioactive iodo derivatives were prepared as HPLC standards. The iodo derivatives were used for comparison of both radioiodinated and astatinated derivatives as there are no nonradioactive astatine nuclides, and the longest lived astatine radionuclide (^{210}At) has a half-life of only 8.3 h.

The *nido*-carborane structures and the structures of their radiohalogenated products shown in Figure 1 and in the synthetic schemes are simplified in that they do not include all of the possible halogenated positional isomers. Some of the possible positional isomers of substituted *nido*-carboranes [i.e., 7-substituted dodecahydro-7,8-dicarba-*nido*-undecaborate(-1)[3]] are shown in Figure 2. While other halogenated positional isomers are possible (i.e., substitution on other cage boron atoms), the positional isomers depicted in Figure 2, where the halogen atom is substituted on the boron atom adjacent to a carbon atom on the rim of the open icosahedron face, seem most likely based on the crystal structures of iodinated *nido*-carboranes previously reported by Hawthorne et al. (*28*, *41*). The figures and schemes have been simplified by not including positional isomers or show carborane cage protons for clarity. It is, however, important to appreciate the fact that the presence of isomers complicates interpretation of the NMR spectra, and can be observed as separate peaks on the HPLC chromato-

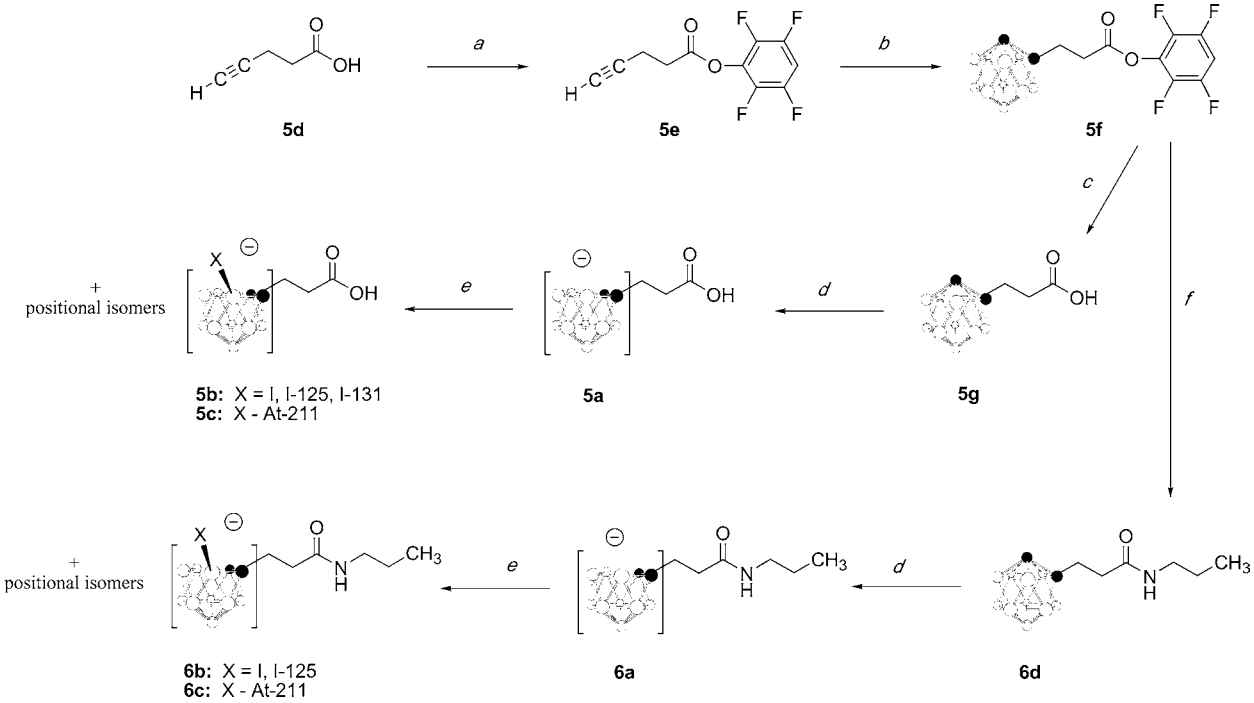
grams in cases in which diastereomeric pairs of isomers are formed.

Benzamide Derivatives. N-Hydroxysuccinimide esters of *p*-astatobenzoic acid and *m*-astatobenzoic acid have been utilized extensively for labeling proteins (*26*, *42*), so benzamide derivatives of these reagents were included in the investigation. The syntheses of the *para*- and *meta*-stannylbenzamides **1a** and **2a**, which are reactive intermediates for the preparation of the [^{211}At]-astatobenzamides **1c** and **2c**, and the iodinated *para*- and *meta*-iodobenzamides **1b** and **2b**, are shown in Scheme 1. The tetrafluorophenyl (TFP) ester of the iodobenzoates, **1e** and **2e**, were readily prepared using 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDC) and tetrafluorophenol (TFP-OH) in EtOAc (*38*), or by using tetrafluorophenyl trifluoroacetate (TFP-OTFA) in anhydrous DMF. Conversion of the iodobenzoate TFP esters to their tri-*n*-butylstannyl derivatives, **1f** and **2f**, was also readily accomplished using hexabutylditin and tetrakis-triphenylphosphine palladium(0) in refluxing toluene. The benzoate TFP esters were reacted with propylamine to provide the targeted stannylbenzoates **1a** and **2a** and the iodobenzoates **1b** and **2b**.

The *para*-astatohippuryl ester **3c** was included in the investigation as previous reports indicated that protein conjugates of an iodohippuryl ester were excreted almost exclusively as the free iodohippuric acid (*43*, *44*). The thought was that rapid renal excretion may decrease the in vivo deastatination. For comparison, *para*-astatohippuric acid **4c** was also prepared and tested. Synthesis of the requisite stannylhippurates **3a/4a** and iodohippurates **3b/4b** is shown in Scheme 2. Reaction of the benzoate TFP esters **1e** and **1f** with glycine ethyl ester provided the targeted hippuryl esters **3a** and **3b**, and base hydrolysis of those compounds gave the targeted hippuric acids **4a** and **4b**.



***nido*-Carborane Derivatives.** Initial studies of *nido*-carboranes involved preparation of *nido*-carboranylpropionic acid **5a** and its propylamine adduct **6a**. The synthesis of these compounds and their astatinated and iodinated derivatives is shown in Scheme 3. In the synthesis, 4-pentynoic acid TFP ester **5e** was prepared using 1,3-dicyclohexylcarbodiimide (DCC) and TFP-OH in THF. The resulting propynoic tetrafluorophenyl (TFP) ester **5e** was reacted with decaborane in refluxing acetonitrile to provide the *closo*-carboranylpropionic acid TFP ester **5f**. Hydrolysis of the TFP ester using KOH in EtOH provided **5g**, which was subsequently treated with pyrrolidine to prepare the *nido*-carborane derivative **5a**. Iodination of **5a** with 0.75 equiv of *N*-chlorosuccinimide (NCS) and NaI in MeOH/1% HOAc provided the monoiodo derivative **5b** (as positional isomers). The adduct **6a**

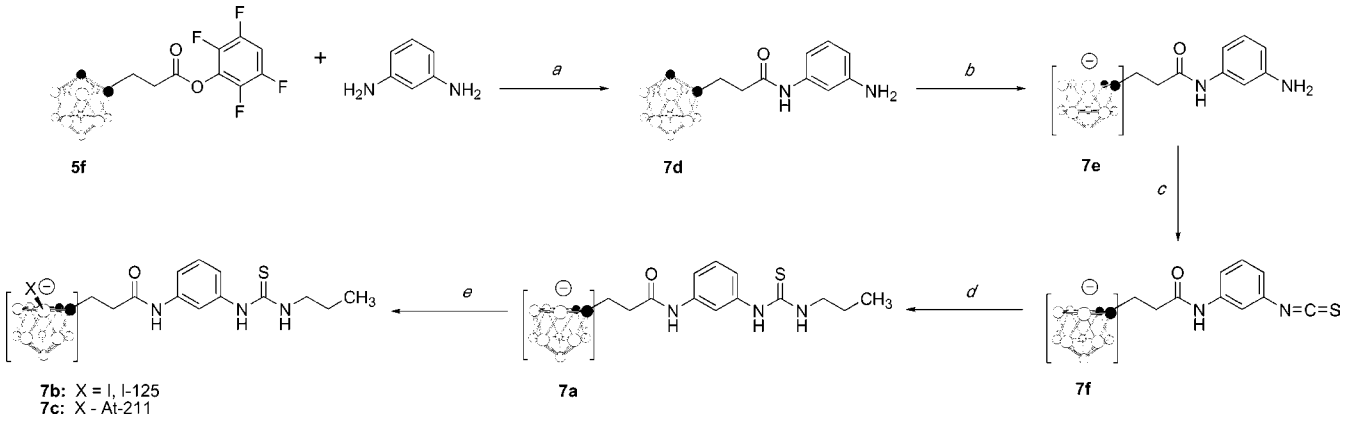
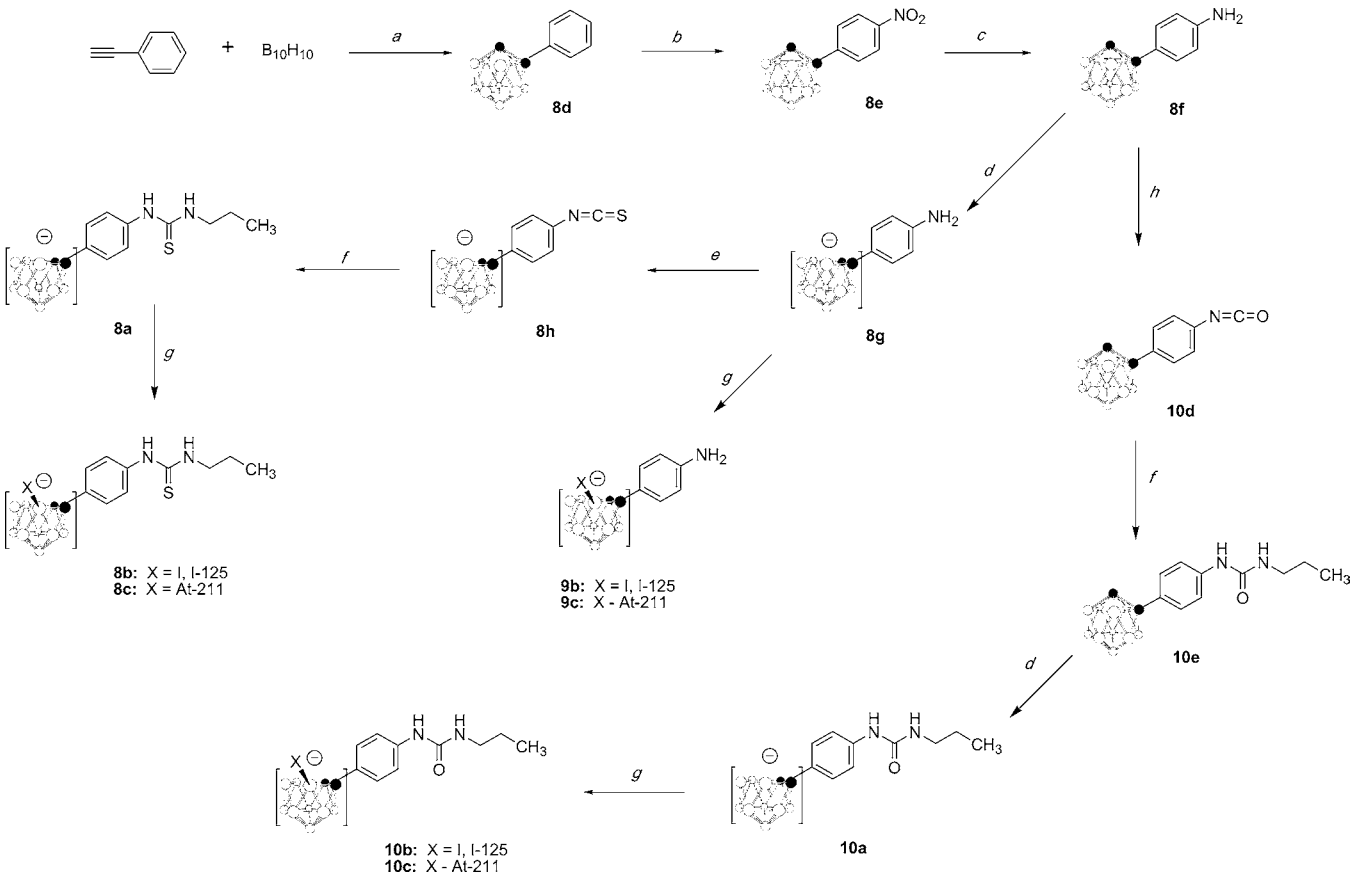
Scheme 3. Synthesis and Radiohalogenation of 3-(*nido*-Carboranyl)propionic Acid, 5a, and Its *n*-Propylbenzamide Adduct, 6a[a]



[a] In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon or C−H atoms. (a) THF, DCC, TFP-OH, rt, 16−24 h, 82%; (b) $B_{10}H_{14}$, CH_3CN, Δ, 25 h, 50%; (c) EtOH, KOH, rt, 1 h, 94%; (d) pyrrolidine, rt, 30 min, 86−88%; (e) NCS, NaX (X = I, ^{125}I or ^{211}At), MeOH/5% HOAc, rt, 30 s − 5 min, 35−39%; (f) *n*-propylamine, DMF, rt, 30 min (not isolated).

and its iodinated derivative **6b** were prepared by reaction of the TFP ester **5f** with propylamine, followed by reaction of pyrrolidine as in the preparation of **5a**. Iodination of **6a** to obtain **6b** employed the same conditions as used to prepare **5b**.

On the basis of the results obtained with the radiohalogenated 3-(*nido*-carboranyl)propionate derivatives **5b/c** and **6b/c**, an additional *nido*-carboranylpropionate derivative **7a**, which incorporated a diaminobenzene moiety, was prepared and evaluated. The thought was that the more complex molecule may have a slower metabolism, and thus decrease the rate of ^{211}At release in vivo. The synthesis of **7a** is shown in Scheme 4. Reaction of an excess of 1,3-diaminobenzene provided the adduct **7d** in high yield. Conversion of **7d** to its *nido*-carborane structure **7e** was accomplished using neat pyrrolidine. The amine reactive isothiocyanate **7f** was readily formed from **7e** by reaction with thiocarbonyldiimidazole (TCDI). Reaction of **7f** with *n*-propylamine gave the targeted 3-(*nido*-carboranyl)propylphenyl derivative **7a**. Iodination of **7a** was accomplished using NCS/NaI in 5% HOAc/MeOH solution to provide the HPLC standard **7b**.



Three compounds that have a phenyl ring bonded the *nido*-carborane structure, **8a**, **8g**, and **10a**, were synthesized in the studies. Synthesis of these compounds and their iodinated and astatinated derivatives is shown in Scheme 5. Compound **8a** was initially targeted for synthesis and evaluation. This compound was included in the investigation to determine if having a phenyl group directly bonded to the *nido*-carborane altered the radiolabeling yields and/or improved the in vivo stability of the astatinated derivative relative to the 3-(*nido*-carboranyl)propionate moiety (e.g., **6a**). Hawthorne et al. had previously reported the synthesis of isothiocyanatophenyl-*nido*-carborane **8h**, and demonstrated that it could be radioiodinated and conjugated with proteins (*28*, *29*). In these studies, reaction of **8h** with *n*-propylamine provided **8a** for radiohalogenation. Iodination of **8a** using

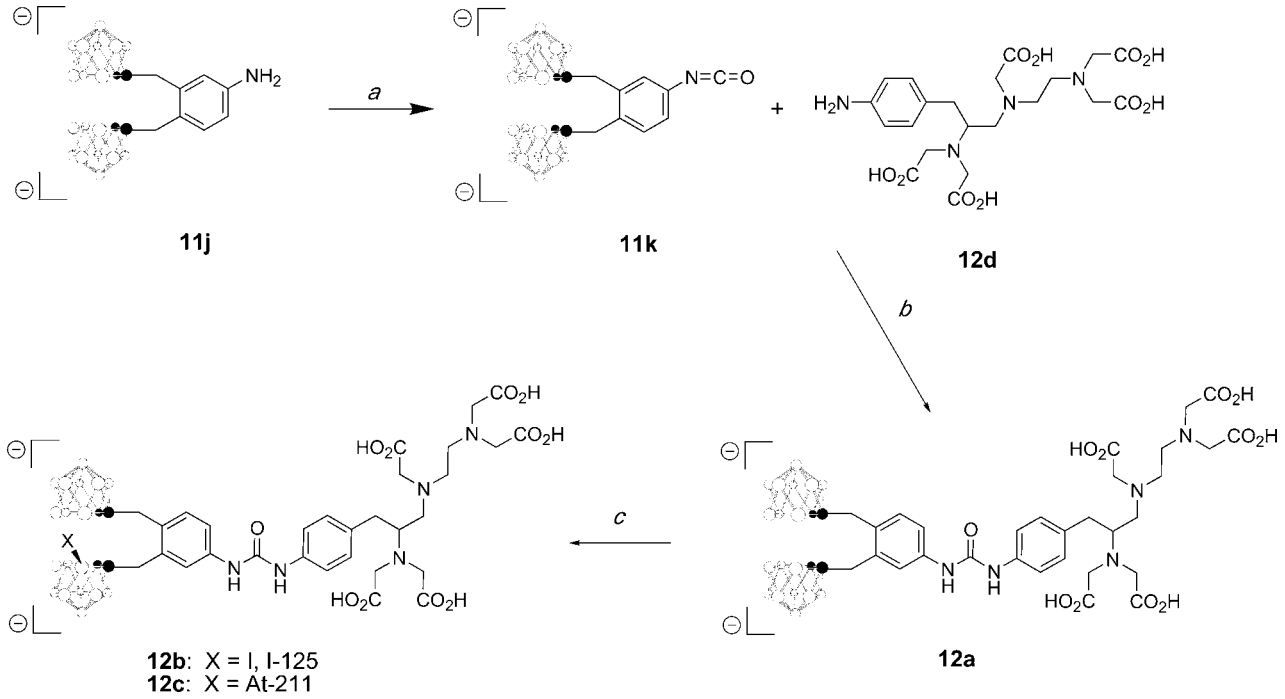
chloramine-T in water gave a mixture of products, of which **8b** was obtained in low yield. The structurally similar **7a** provided higher iodination yields under the same reaction conditions, but also was present in a mixture of compounds by HPLC analysis. This is not surprising as we have previously observed that compounds with thiourea moieties can interfere with radiohalogenation reactions (*45*, *46*). As an alternative, compound **8g** which does not contain an isothiocyanate functionality was iodinated to form **9b**, astatinated to prepare **9c**, and tested in vivo. The fact that **8g** iodinated readily suggested that the difficulty with iodination of **8a** was due to the isothiocyanate functionality. Another phenyl-*nido*-carborane, which did not contain a thiourea functionality, **10a**, was also targeted for synthesis. Initially, the conversion of the aniline derivative **8g** to the isocyanate derivative was studied. However, unlike the phenylisothiocyanate **8h**, the phenylisocyanate was unstable, so another synthetic route was sought. The successful synthesis of **10a** began with the in situ

Scheme 6. Synthesis and Radiohalogenation of Bis-*nido*-carborane Derivatives (Venus Flytrap Complexes), 11a and 11j[a]

[a] In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon or C−H atoms). (a) C_6H_6/Et_2O, 35 °C, 24 h, 74% [39]; (b) THF, $^nBu_4NF$, −76 to 0 °C, 20 min, 71% [39]; (c) KOH, EtOH, H_2O, Δ, 80%; (d) ChT, NaX (X = I, ^{125}I or ^{211}At), rt, 30 s, 72−80%; (e) concentrated H_2SO_4, HNO_3, 0 °C − rt, 2 days, 94%; (f) MeOH, HCl, Sn, Δ, 10 h, 67%.

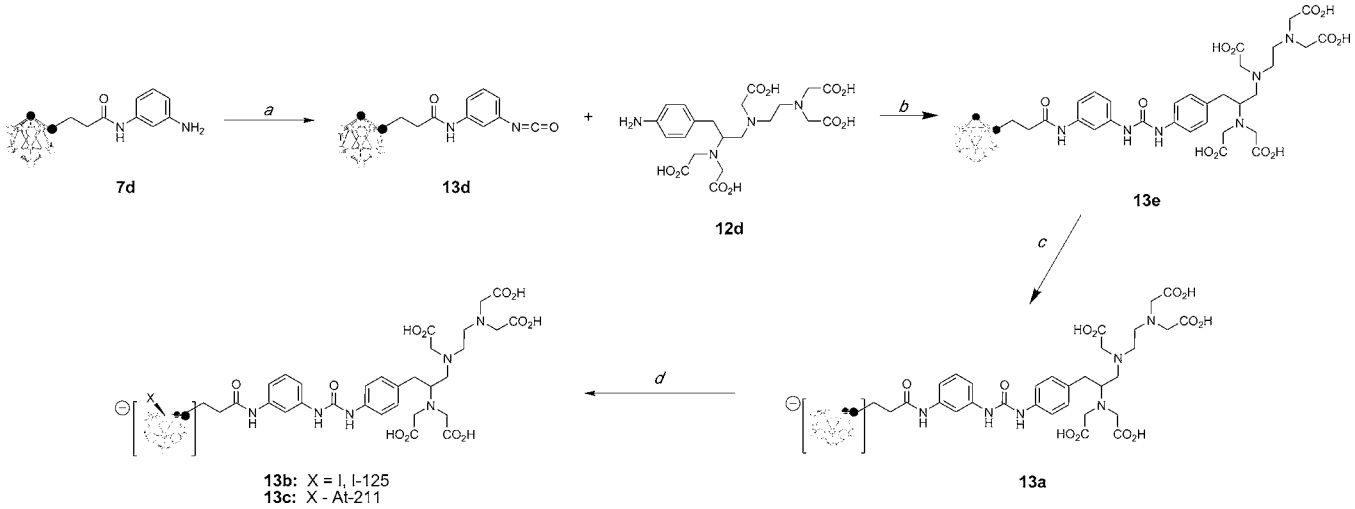
generation of the phenylisocyanate **10d** by reaction of **8f** with carbonyldiimidazole (CDI) in $CHCl_3$. Subsequent reaction of **10d** with *n*-propylamine yielded the *closo*-carboranylphenylpropylurea **10e**. Reaction of **10e** with pyrrolidine provided the targeted **10a**. Iodination of **10a** with NCS/NaI in MeOH/HOAc solution gave a high yield of one major product. It is important to note that the structure of **10a** is identical to that of **9a** except it contains a urea functionality rather than a thiourea functionality. This result further supports the observations that thiourea functionalities can interfere with halogenation reactions.



The seventh *nido*-carborane to be synthesized and evaluated, **11a**, contains two *nido*-carborane functionalities. This structure has been termed a "Venus flytrap complex" by Hawthorne et al., and similar complexes have been used for incorporating radiometals (*34*). Syntheses of **11a** and the iodinated HPLC standard **11b** were accomplished as shown in Scheme 6. Synthesis of the **11a** began with reaction of lithiated *tert*-butyldimethylsilyl-*ortho*-carborane **11e** with 1,2-bis(bromomethyl)benzene as previously described (*39*). Removal of the *tert*-butyldimethylsilyl group to obtain **11g** was accomplished by reaction of **11f** with tetra-butylammonium fluoride in THF. Degradation of the *closo*-carborane cages in **11f** to form the bis-*nido*-carborane **11a** was accomplished by reaction of KOH in EtOH at reflux. Iodination of **11a** to prepare the HPLC standard **11b** was accomplished by reaction with *N*-chlorosuccinimide and NaI in MeOH/HOAc for 30 s at room temperature.

***nido*-Carborane-DTPA Adducts.** In vivo results obtained with the radiohalogenated VFC **11a** led to a decision to prepare an adduct of DTPA. This decision was based on the hypothesis that the radiolabeled VFC was binding with plasma proteins, which increased the serum half-life and led to hepatobiliary excretion. Binding with plasma proteins can cause a radiolabeled compound to be excluded from renal filtration and elimination. DTPA is used to measure renal function when chelated with a radiometal (*47*); thus, we believed that an adduct with the VFC might decrease the serum protein binding (i.e., decrease blood residence time) and increase the renal excretion of the astatinated VFC. Synthesis of a DTPA derivative of the VFC is shown in Schemes 6 and 7. In the synthesis, bis-(1,2-*closo*-carboranylmethyl)benzene, **11g**, was nitrated using concentrated sulfuric and nitric acid to provide the nitro derivative **11h**. Reduction of the nitro group using Sn/HCl in MeOH provided the anilino derivative **11i**, and conversion of **11i** to the bis-*nido* derivative **11j** was accomplished using KOH in EtOH at reflux overnight. The choice was made to avoid incorporation of a thiourea moiety in the targeted compound, **12a** (Scheme 7), to eliminate the possibility that it would interfere with the radiohalogenation reactions. Thus, the bis-*nido*-carboranylaniline, **11j**, was converted to the isocyanate derivative **11k**. Subsequent reaction of the isocyanate **11k** with aminobenzyl-DTPA, **12d**, provided the targeted compound **12a**. Iodination of **12a** was facile using chloramine-T and NaI in H_2O.

As a comparison, a mono-(*nido*-carboranyl)-DTPA derivative **13a** was also prepared as depicted in Scheme 8. The 1,3-diaminobenzene adduct of *closo*-carboranylpropionic acid, **7d**, was converted to the isocyanato derivative **13d**. Again, the isothiocyanate was avoided so that the target compound would not have a thiourea functionality in it. Reaction of **13d** with aminobenzyl-DTPA, **12d**, provided the *closo*-carboranyl adduct **13e**. Neat pyrrolidine was used to prepare the *nido*-carboranyl-DTPA adduct, **13a**. The iodinated HPLC standard was prepared by reaction of **13a** with NCS and NaI in MeOH/HOAc.



Radioiodination and Astatination Reactions of Aryl and *nido*-Carborane Derivatives. Radiohalogenation reactions of arylstannanes have proven to be very facile, and this was found to be the case for reactions with **1a**, **2a**, **3a**, and **4a**. The low aqueous solubility of aryl

Scheme 7. Synthesis and Radiohalogenation of Bis-*nido*-carborane Derivative (Venus Flytrap Complex) with Coupled Benzyl-DTPA, 12a[a]

[a] In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon or C−H atoms). (a) CDI, CH_3CN, rt, 1 h, (not isolated); (b) pyridine, DMF, rt, 16 h, 58%; (c) ChT, NaX (X = I, ^{125}I or ^{211}At), rt, 30 s, 63−76%.

Scheme 8. Synthesis and Radiohalogenation of *nido*-Carborane Derivative Which Has a Benzyl-DTPA Moiety Attached, 13a[a]

[a]In carborane structures, open circles represent boron or B−H atoms and closed circles represent carbon or C−H atoms. (a) CDI, $CHCl_3$, rt, 1 h, (not isolated); (b) DMF, pyridine, rt, 16 h, 57%; (c) pyrrolidine, rt, 1 h, 100%; (d) ChT, NaX (X = I, ^{125}I or ^{211}At), rt, 30 s, 39−70%.

stannanes makes it favorable to conduct the radiohalogenation reactions in MeOH. To offset the addition of base in the radionuclide solution, 5% HOAc was added to the solvent. The astatinations were conducted using the same reaction conditions as used for radioiodinations. The astatination yields (33−55%) were considerably lower than the radioiodination yields (90−95%) under the conditions studied. The reason for this difference has not been established, but it is possible that the amount of H_2O introduced with the Na[^{211}At]At caused the lower yields. Previous studies had demonstrated that a maximum of 10% water was tolerated in radioiodination reactions using the same reaction conditions, and that as the percentage of water increased, the radiochemical yields decreased. It should be noted that none of the radiohalogenation reaction conditions were optimized. It is important to note that free astatide did not elute from the reversed-phase HPLC column under the eluant conditions used. Thus, the yields reported represent the percentages of radioactivity that were isolated as the desired astatinated products from a measured amount of radioactivity (reaction mixture) injected. After isolation, the MeOH and HOAc were removed under a stream of nitrogen (vented through charcoal containing syringe).

Radiohalogenation reactions with *nido*-carboranyl derivative **5a** were conducted in MeOH/HOAc using NCS as oxidant; however, it was more convenient to conduct the reactions in aqueous solution using chloramine-T as the oxidant. Radioiodination and astatination of *nido*-carboranes **6a**, **7a**, **8g**, **10a**, **11a**, **12a**, and **13a** were

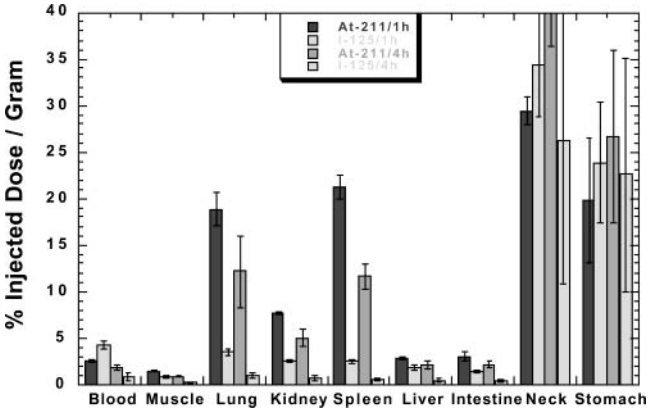


Figure 3. Graph depicting ^{211}At and ^{125}I concentrations (% injected dose/g) in blood and selected tissues of athymic mice at 1 and 4 h postinjection. (Numerical data and additional information on the study are provided in Table 1 of Supporting Information.)

conducted using chloramine-T and Na[^{125}I]I or Na[^{211}At]-At in H_2O for 30 s to 2 min. Radiolabeling of **8a** was not attempted due to the observation that the reaction with stable iodide resulted in a mixture of products using the same reaction conditions. In most reactions, the astatination and radioiodination yields obtained with *nido*-carborane derivatives were similar, with radioiodination yields ranging from 28 to 95**%** and astatination yields ranging from 39 to 72%. Due to the propensity of the *nido*-carborane compounds to adhere to glass surfaces, plastic vials were used for isolating the products. This adherence to glass surfaces appeared to increase with time and with removal of solvent. The radiohalogenated *nido*-carborane derivatives employed in animal studies were diluted with a solution of 1% BSA in PBS to keep the labeled material from adhering to the syringe.

Biodistributions of Radiolabeled Aryl and *nido*-Carborane Derivatives. Our previous studies of astatinated compounds provided data that suggested the best method for determining the in vivo stability of astatinated compounds was to conduct co-injected dual-label experiments with radioiodine. Stability of an astatinated compound can be inferred from the differences in [^{211}At]-astatide and [$^{125/131}$I]iodide concentrations in the tissues where astatide naturally localizes. Although there are literature reports comparing [^{211}At]astatide and [$^{125/131}$I]-iodide, we chose to conduct our own experiment to determine the tissue localization of the free radionuclides by co-injecting them into athymic mice. The biodistribution data from that study are provided in Table 1 in Supplemental Information, and are depicted graphically in Figure 3. As in previous reports involving other animal models (*48*), the primary tissues where [^{211}At]astatide localizes are lung, spleen, neck, and stomach. Importantly, unlike the neck (thyroid) and stomach, low concentrations of iodide are found in the lung and spleen, making the difference between concentrations of ^{211}At and radioiodine in these tissues good indicators of the quantity of free astatide, and thus, the stability of the astatinated compound.

Twelve biodistribution studies were conducted in mice to evaluate the in vivo distributions and stability of the astatinated compounds. All studies, except the one conducted at Duke University, were conducted in athymic mice to provide a baseline for comparison to future studies of astatinated biomolecules in mice bearing human tumor xenografts. The biodistribution study of astatinated *nido*-carborane [^{211}At]**5c** was conducted at Duke University. That study evaluated the distributions of co-injected [^{211}At]**5c** and [^{131}I]**5b** at three time points (1, 3, and 24 h pi). In all other studies, biodistribution data were obtained at 1 and 4 h postinjection as previous studies had shown that instability of ^{211}At could be readily noted during this time period (*23*, *49*). Complete biodistribution data obtained in the investigation are included as tables in Supporting Information (Tables 2−13). Graphs depicting the concentration of astatinated and radioiodinated benzamidyl- and *nido*-carboranyl-derivatives, **1b/c** to **7b/c** and **9b/c** to **13b/c**, are provided as Figures 4A,B and 5A−D. Data from concentration of radionuclides in selected tissues at 4 h postinjection are plotted in pairs of two compounds with similar structures for ease of comparison. All graphs have the same axis values for comparison purposes.

Due to the high stability toward in vivo deiodination of radioiodinated benzamides and *nido*-carboranyl compounds, the concentration of radioiodine in a tissue is indicative of the concentration of the radiolabeled compound(s) in that tissue. However, the concentration of astatine in tissues can be indicative of free astatide, astatinated molecule(s), or a mixture of these due to the lower stability of astatinated molecules in vivo. In molecules that are stable to deastatination, the distribution of ^{211}At and $^{125/131}$I should be very similar. Thus, large differences in tissue concentrations of radionuclides, particularly in lung, spleen, and neck are likely due to release of astatine.

Concentrations (% injected dose/g of tissue) of ^{211}At and ^{125}I in selected tissues of mice at 4 h postinjection of radiolabeled benzamide derivatives **1**−**4** are depicted in Figure 4A,B. As expected, the iodobenzamides **1b**−**4b** are rapidly cleared from the mice, resulting in very low concentrations of radioiodine in tissues by 4 h postinjection. In comparison, a fair amount of astatine is observed in tissues where free astatide localizes. Indeed, comparison of the tissue ^{211}At activity in Figure 4A,B with that in Figure 3 leads to the conclusion that most, if not all, of the ^{211}At observed is present as free astatide. These results, and the data obtained at 1 h postinjection, indicate that the astatinated benzamides studied are unstable, undergoing rapid deastatination in vivo.

Concentrations of ^{211}At and $^{125/131}$I in selected tissues of mice at 4 h postinjection of radiolabeled *nido*-carborane derivatives **5**−**7** and **9**−**13** are depicted in Figure 5A−D. The tissue concentrations of radioactivity for the *nido*-carboranylpropionic acid derivative **5** and its *N*-propylamine adduct **6** are shown in Figure 5A. Large differences in the ^{211}At and ^{131}I or ^{125}I concentrations can be noted in the tissues where astatide localizes (i.e., lung, spleen and thyroid/neck). These data indicate that astatinated structurally simple *nido*-carboranes coupled by a C-alkyl bond are also unstable to in vivo deastatination. Tissue concentrations of the more structurally complex *nido*-carboranylpropionamide derivatives **7** and **13** are provided in Figure 5B. Much higher blood concentrations are noted for this pair of compounds versus the structurally simpler compounds, **5** and **6**. Inspection of the differences in ^{211}At and ^{125}I concentrations in lung, spleen, and neck for compound **7** indicates that this compound undergoes deastatination similar to, but perhaps slower than **6**. Interestingly, conjugation of the benzyl-DTPA appears to greatly diminish the differences in concentration of ^{211}At and ^{125}I in lung, spleen, and neck, suggesting less deastatination occurred. It is unclear why this is the case, but the higher concentrations in blood and lower

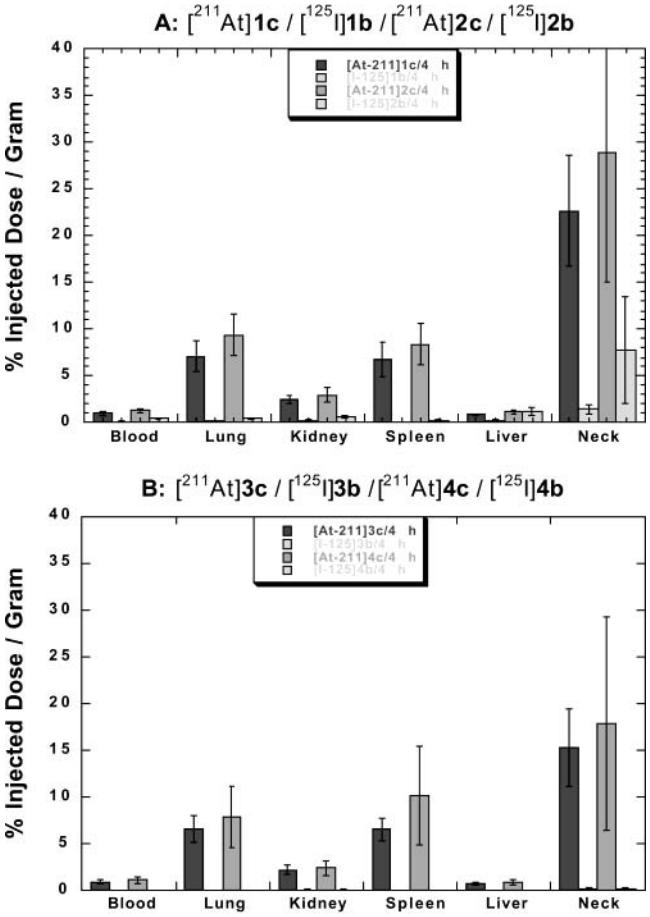

Figure 4. Graphs showing ^{211}At and ^{125}I concentrations (% injected dose/g) of radiolabeled benzamides (**1**−**4**) in selected tissues of athymic mice at 4 h postinjection (Numerical biodistribution data and additional information for the astatinated and iodinated compounds are provided in Tables 2−5 in Supporting Information). Data from two sets of dual labeled compounds are plotted in each panel. Identification of the radiolabeled compound represented by each bar (in the correct order) is provided at the top of the graph with the panel designation (A or B).

concentrations in kidney and liver of **13** may indicate that the difference is simply due to a slower rate of metabolism.

Concentrations of ^{211}At and ^{125}I in selected tissues of mice for the *nido*-carborane derivatives with a phenyl group directly attached to the cage are provided in Figure 5C. It is interesting to note that the zwitterionic derivatives **9b** and **9c** have quite high blood concentrations at 4 h postinjection. Conjugation of the anilino-amine to form **10b** or **10c** results in a dramatic decrease in the blood concentration. Interestingly, inspection of the differences in concentration of radionuclides in lung, spleen, and neck for **9b/c** and **10b/c** suggests that the two molecules are deastatinated at similar rates. Indeed, both are deastatinated, suggesting that there is little difference in stability toward deastatination between the alkyl- and aryl-substituted *nido*-carboranes.

Concentrations of ^{211}At and ^{125}I in selected tissues of mice for the bis-*nido*-carboranyl derivatives **11** and **12** are provided in Figure 5D. In most tissues examined, the concentrations of ^{211}At and ^{125}I are nearly the same. For compounds **11** and **12**, most of the differences between ^{211}At and ^{125}I concentrations in tissues were not significant as measured by a paired Student-t test (see Tables 11 and 12 in Supporting Information). In contrast to this, the differences observed in tissues for the other compounds were highly significant for most tissues when examined in the same analysis. Inspection of the concentrations of ^{211}At and ^{125}I in lung, spleen, and neck leads one to believe that both of these compounds may be quite stable to in vivo deastatination. No differences in concentrations of radionuclides are noted in the spleen. For compound **12**, no significant differences are seen in lung and spleen, but a significant difference is observed in neck. This was also true for data from the 1 h time point. While this may indicate that there is some deastatination, it is likely to be very small quantity as significant differences in the lung and spleen might be expected otherwise. No significant differences were found for concentrations of ^{211}At and ^{125}I in lung, spleen, and neck for compound **12**. Although the difference between the ^{211}At and ^{125}I concentrations in lung for compound **12** appears to be significant by inspection, the difference was not significant when evaluated in the Student-t test. The apparent high stability of the bis-*nido*-carboranyl derivatives **11** and **12** is particularly surprising in that there is a rapid localization to liver and transit to the intestines.

DISCUSSION

The potential for using the alpha-particle emitting radionuclide ^{211}At in TRT of cancer was mentioned in the literature a half-century ago (*50*), and has been the focus of many literature reviews in more recent years (*7*, *51*−*54*). While it is not clear whether alpha-particle emitting radionuclides will be of value in the therapy of solid tumors, their high cytotoxicity and short path length (e.g., 50−80 μm) make them particularly well suited for therapy of metastatic disease, disease in compartmental spaces (e.g., ovarian carcinoma), and cancer cells remaining in surgical tumor resection margins. It is important to note that ^{211}At is one of only a few alpha-emitting radionuclides that are considered appropriate for clinical use (*5*). Although the half-life of ^{211}At is short ($t_{1/2}$ = 7.2 h), there are many cancer cell targeting agents and approaches that are potentially compatible with it. But a key factor in the development and evaluation of ^{211}At-labeled cancer targeting agents is its stability toward deastatination in vivo. Release of ^{211}At from the cancer targeting molecule can be expected to result in accumulation in lung, spleen, stomach, and thyroid as documented previously in mice, rats, and monkeys (*48*, *55*, *56*), and as shown in Figure 3. Dependent on the extent of deastatination, such nontarget tissue localization could completely negate the beneficial effects of the cancer therapy. Therefore, it is imperative that chemical methods for attaching ^{211}At to cancer targeting agents provide high stability in vivo. Without such stability, the application of ^{211}At will be limited.

Since astatine is a member of the halogen group of elements, the chemistry of its nearest neighbor, iodine, is often used to predict astatine chemistry. However, studies have shown that its chemistry can vary significantly from that of iodine (*57*). This difference has been particularly noteworthy when radiolabeling molecules for use in vivo. Early studies of ^{211}At labeled proteins demonstrated that, unlike radioiodine counterparts, direct labeling of proteins with ^{211}At resulted in products that were unstable to deastatination in serum (*17*, *18*). Subsequent investigations found that use of astatinated nonactivated aryl compounds as conjugates for labeling proteins resulted in stabilizing them toward both in vitro and in vivo deastatination (*19*, *20*). Studies in our laboratories, and several other laboratories, have dem-

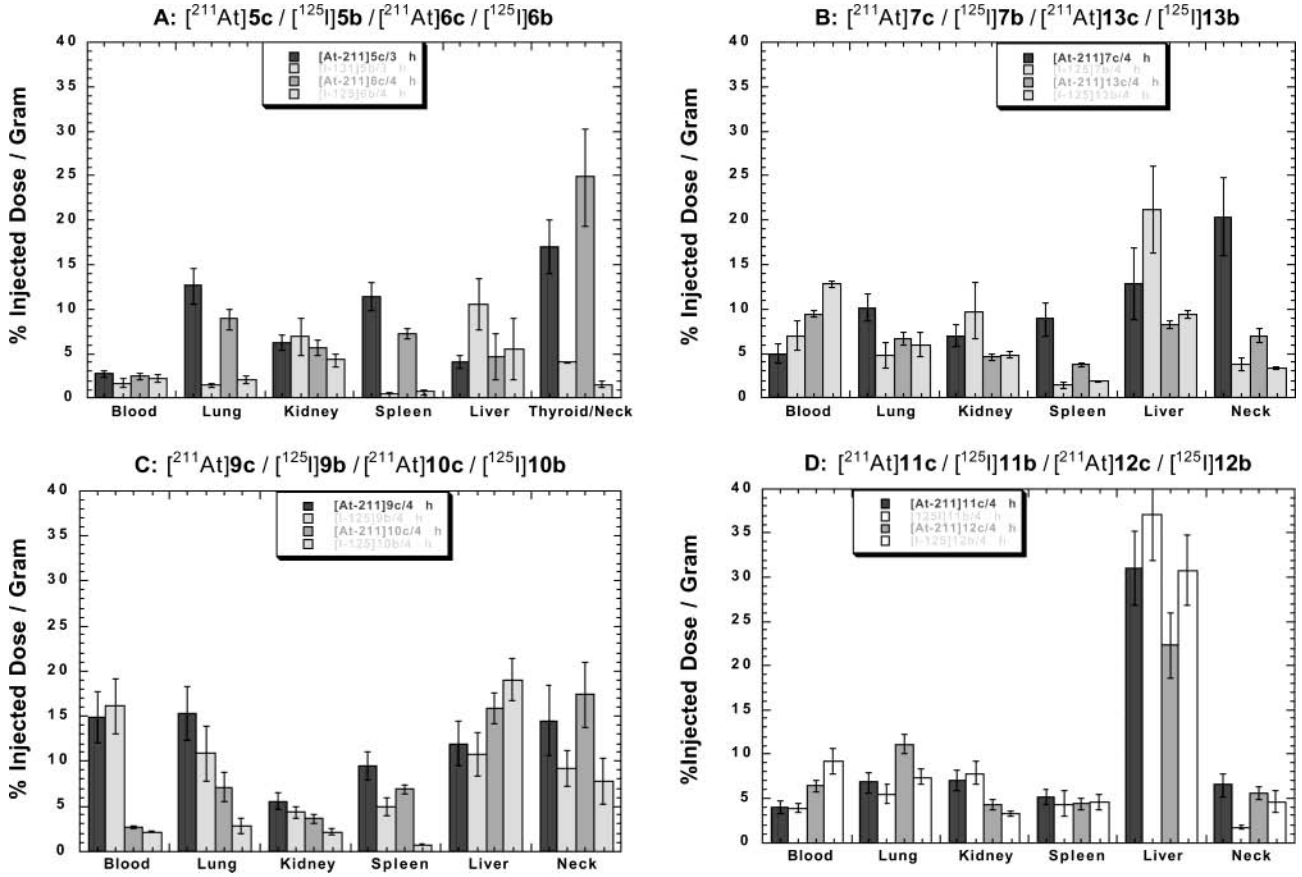

Figure 5. Graphs showing ^{211}At and ^{125}I concentrations (% injected dose/g) of radiolabeled *nido*-carborane derivatives (**5**−**7** and **9**−**13**) in selected tissues of athymic mice at 4 h postinjection (Numerical biodistribution data and additional information for the astatinated and iodinated compounds are provided in Tables 6−12 in Supporting Information). Data from two sets of dual labeled compounds are plotted in each panel. Identification of the radiolabeled compound represented by each bar (in the correct order) is provided at the top of the graph with the panel designation (A−D).

onstrated that astatinated benzoic acid conjugates with reactive functional groups provided a rapid and relatively high yielding method to label monoclonal antibodies (mAbs) for in vivo application (*1*, *22*, *23*, *36*, *37*). In those investigations, it was demonstrated that intact mAbs, and some F(ab′)$_2$ fragments, labeled with ^{211}At were relatively stable to in vivo deastatination. However, the 7.21 h half-life of ^{211}At did not match well with the biological half-lives of the intact mAb and F(ab′)$_2$ fragments, such that most of the radionuclide decayed before good tumor targeting was obtained. To improve in vivo pharmacokinetics, astatinated Fab fragments were evaluated. Even though the ^{211}At was bonded to a stabilizing benzoate derivative, it was not stable to in vivo deastatination when coupled to the more rapidly metabolized Fab fragments (*23*). This was surprising as examination of the in vitro stability of the astatinated Fab indicated that it was quite stable in serum. Thus, it appears that the release of ^{211}At from mAb Fab fragments results from enzymes or other conditions that are present during metabolism of the protein.

Given the fact that the instability of aryl-astatine bond appears to be facilitated by metabolic degradation of the carrier molecule, we hypothesized that there may be two methods of stabilizing astatine on carriers used for in vivo targeting. The first method is to utilize astatinated molecules that are excreted intact, avoiding the metabolic degradation. Because metabolic pathways can vary greatly with the nature of the biomolecule involved, it seems that this approach would not be applicable to most carrier molecules. The second method is to find alternative bonding structures that are not deastatinated under metabolic conditions. On the basis of the expectation that a boron astatine bond might be more stable than the aryl-astatine bond, we became interested in boron cage molecules, and particularly *nido*-carboranes, as pendant groups for astatine labeling. Hawthorne et al. had previously demonstrated that a *nido*-carborane conjugate could be used in the radioiodination of antibodies (*34*). *nido*-Carboranes were also investigated as hydrophilic pendant groups for attaching radionuclides of iodine to biomolecules (*30*). Those investigations showed that *nido*-carborane containing molecules were radioiodinated rapidly (<10 s) in high radiochemical yields (85−99%), and the resultant radioiodinated *nido*-carboranes were stable to in vivo deiodination. Reports of the astatination of *closo*-dodecaborate(2-) have been published (*58*, *59*). However, no previous investigations of astatinated *nido*-carborane derivatives have been reported, so we focused our studies in that area.

The primary goals of the investigation reported herein were to determine if astatinated *nido*-carboranes are more stable to in vivo deastatination than some simple aryl astatine compounds, and to examine the astatinated compounds distribution in vivo to determine if the pendant groups had properties that alter their in vivo characteristics. In addition to those goals, we were interested in (a) determining whether there were differences in the in vivo stability of *meta*- or *para*-substituted benzamide derivatives; (b) comparing the in vivo stability of a *nido*-carboranyl derivative which has a phenyl group attached to a carbon atom on the carborane cage molecule

with a similar *nido*-carborane molecule that has a methylene group attached to the carborane cage, and (c) determining if having two *nido*-carboranyl moieties held in close proximity (e.g., VFCs) would provide increased stability over astatinated compounds that had only one *nido*-carborane moiety. When planning the studies, simple in vitro assays were not included since our previous studies, and studies in other laboratories, had demonstrated that ^{211}At-labeled compounds were generally quite stable in serum and when challenged with a variety of reagents. In vitro assays that mimic organs, such as incubation of astatinated compounds with liver homogenates, were considered as they represented potential methods to predict in vivo ^{211}At stability with a minimal use of animals. However, those in vitro assays did not appear to be practical due to limitations on synthesis of compounds studied and the quantity of ^{211}At produced, which limited the preparation to only one ^{211}At labeled compound at a time. Further, in vitro analyses could not provide information on the differences in tissue distribution that was sought. Thus, we chose to conduct in vivo studies on each astatinated compound. To address the study goals, we decided to examine the biodistributions and in vivo stability of potential astatinated pendant groups by evaluation of simple derivatives that might be readily metabolized. The salient point is that we anticipate pendant groups that are stable to deastatination as simple derivatives will likely be stable in more complex molecules.

The studies conducted required the synthesis and radiolabeling of a number of benzoate and *nido*-carborane derivatives (Figure 1 and Schemes 1−8). The aryl stannanes and aryl halides were readily synthesized as depicted in Schemes 1 and 2 using methods previously described in the literature. Fortunately, the 1,2-carborane derivatives were also readily prepared as depicted in Schemes 3−8 using standard organic synthetic methods. Both the aryl stannanes and the *nido*-carboranes reacted very rapidly with electrophilic astatine to provide good labeling yields under mild conditions. The animal studies conducted were designed to provide limited biodistribution data, which based on previous studies would also provide information on the in vivo stability of astatinated compounds.

The determination of the in vivo stability of astatinated molecules toward deastatination was greatly facilitated by the propensity of astatide to localize to lung and spleen. Examining the tissue distribution data for ^{211}At alone (Figure 4) could lead to the conclusion that the astatinated benzoate derivatives provide the most favorable in vivo characteristics due to the high liver and intestine concentrations of the astatinated *nido*-carborane derivatives. However, dual label experiments provide data (tables in Supporting Information and Figure 5) that indicate the astatinated benzoates are deastatinated rapidly making them unfavorable as pendant groups. Indeed, the large difference between the concentration of ^{211}At- and ^{125}I-labeled benzamides in lung and spleen at 1 and 4 h postinjection (Figure 5) suggests that deastatination is very rapid. We had anticipated that the boron−astatine bond might be more stable toward deastatination than an aryl−astatine bond. While it appears that astatinated *nido*-carboranes are slightly more stable than the benzamides, it is not possible to state that unequivocally. Indeed, the difference in stability is not as large as had been anticipated. Further, the *nido*-carborane containing compounds have long retention in the blood, which could affect biomolecules when they are conjugated. Interestingly, comparison of the in vivo data from **7c** and **10c** indicates that there is very little difference between an astatinated *nido*-carborane containing an alkyl substituent or an aryl substituent. We had anticipated that a larger difference would be obtained based on steric and electronic differences in the *nido*-carborane cages.

The data obtained for the astatinated bis-*nido*-carborane derivatives **11c** and **12c** indicate that they provide high stability toward in vivo deastatination as (relatively) small molecule adducts. However, their propensity to localize to liver is problematic in their use as astatinated pendant groups. Interestingly, the radiohalogenated VFCs do not seem to adhere to glass and syringe needles to the extent that mono-*nido*-carborane derivatives do. This is encouraging as it may be possible through modification of the VFC to diminish the hepatobiliary excretion. It is interesting to consider possible explanations for the differences in stability between the astatinated mono-*nido*-carboranyl derivatives and bis-*nido*-carboranyl derivatives. Although the explanation is unknown, it might be speculated that the ^{211}At could bind with both *nido*-carborane moieties to bridge them. Such a bonding structure would require a higher oxidation state of ^{211}At, but the astatination is conducted under oxidative conditions and the halonium bridged structure would be similar to the well-known iodonium salt structures (*60*, *61*).

The benzyl-DTPA derivatives **12** and **13** were specifically prepared to decrease blood concentrations by inducing a more rapid renal clearance. However, the results indicate that the DTPA adducts did not reduce the blood concentrations; rather, an increased blood concentration was obtained. We had anticipated that the DTPA adducts would be metalated in vivo, which would have increased their hydrophilicity. In future studies, it may be better to chelate the DTPA prior to injection. While the addition of a DTPA did not decrease the blood concentration, it either resulted in more clearance by the renal system or more rapid passage through the liver. Unfortunately, the very high concentrations in liver of the bis-*nido*-carborane (VFC) did not appear to be altered appreciably by the addition of a benzyl-DTPA moiety.

In conclusion, we have prepared a series of astatinated and radioiodinated benzoate and *nido*-carboranyl compounds to examine their in vivo properties. The studies have demonstrated that there are large differences in the in vivo blood concentrations and tissue distributions. However, most of the small molecules labeled with ^{211}At were found to release free astatide via some unknown deastatination process. The exception to this were the astatinated "VFC" containing compounds, which were found to be quite stable to in vivo deastatination. Unfortunately, the VFC containing compounds are highly excreted by the hepatobiliary tract, making them unsuitable as biomolecule conjugates unless they are modified to decrease this propensity.

ACKNOWLEDGMENT

We thank Duke University investigators Susan Slade and Bent Schoultz for their technical assistance in the studies, and Dr. Roy H. Larsen for his discussions on the experiments conducted there. We thank the Department of Energy (DE-FG01-00NE22946) for funding the majority of the studies presented. Some portions of the studies were supported by NIH (CA42324) and the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under Grant Number DE-FG06-95ER62029.

Supporting Information Available: Complete tissue distribution data (Tables 1−13). HPLC chromatograms, ^{1}H NMR spectra, and mass spectra for new compounds (**1a, 1b, 2a, 2b, 2e, 2f, 3a, 3b, 4a, 4b, 5a, 5b, 5e−5g, 6a, 6b, 7a, 7b, 7d−7f, 8a, 8b, 9b, 10a, 10b, 10e, 12a, 12b, 13a, 13b, 13e**) prepared in the research described in this paper. TECHNICAL NOTES

Efficient Synthesis of Isotopically Pure Isotope-Coded Affinity Tagging Reagents

Anupama Patel and David M. Perrin*

Department of Chemistry, 2036 Main Mall, University of British Columbia, Vancouver, B. C. V6T 1Z1 Canada, and PENCE Inc. (Protein Engineering Network of Centers of Excellence), 750 Heritage Medical Research Center, Edmonton, Alberta T6G-2S2 Canada. Received June 3, 2003; Revised Manuscript Received July 23, 2003

Synthesis of an isotopically pure d_8-ICAT linker, *N*-[(5,5,6,6,8,8,9,9-^{2}H)-13-biotinamido-4,7,10-trioxatridecanyl] *tert*-butyloxy carbamide (**12**), has been achieved in seven steps with an overall yield of 33%. Conjugation of exchange-inert d_4-starting materials by classic etherification reaction yielded a pure synthon, carrying eight deuteriums that remained exchange-inert throughout subsequent reactions. This modified synthesis constitutes a significant improvement to the reported syntheses of "heavy" ICAT reagent in terms of expense, yield, and isotopic retention. This synthesis is easily adapted to incorporate additional deuterium atoms and is equally applicable for incorporation of either ^{13}C and/or ^{18}O. In addition, this synthesis allows for the introduction of different orthogonal functionalities and provides for a high yielding series of differentially encoded ICAT tags.

INTRODUCTION

Proteomics is an exciting field in the study of proteins and particularly the study of complex systems involving multiple proteins where each may exert a subtle effect that synergistically gives rise to an identifiable global cellular or physiological state or process. The multiplicity of proteins and effectors increases the difficulty of assigning the cellular and physiological functions to individual proteins as well as complicates the process of drug discovery and target validation. In this growing research field of proteomics, various new approaches have become available to facilitate the identification of many of the proteins in a cell and to generate data that more closely correlate with protein activity levels. However, compared to genomics, proteomics studies face formidable technical challenges due to the structural complexity, the temporal nature of regulation, function, and abundance as well as vast structural variation of different proteins in a cell. To permit a global characterization of the proteome with more rapid and more detailed interrogation, various new strategies are being developed in the research field of proteomics (*1*−*8*). In this context, Aebersold described a creative alternative method dubbed isotope-coded affinity tagging (ICAT)[1] methodology (*9*).

Instead of relying on 2D PAGE and protein-staining methods for quantification, the ICAT method involves utilization of isotopically labeled chemical probes, (ICAT, Figure 1) (*9*) for the quantitative comparison of protein abundances between complex proteomes. Ultimately, this analysis is achieved by some form of mass spectrometry that is being interfaced with robotics and automated sample analysis so as to streamline the discovery process and eliminate human error.

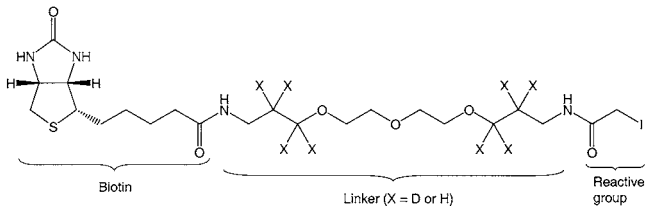

Figure 1. Cysteine-speciic ICAT-reagents for quantitative proteomics studies.[9]

Conceptually, the ICAT reagent is a trifunctional molecule, composed of (a) a specific reactive group capable of reacting covalently with an active site nucleophile (e.g. iodoacetamide for covalent attachment to a cysteinyl thiol); (b) an isotopically coded linker that occurs in a deuterated (isotopically "heavy", X = D) or nondeuterated (isotopically "light", X = H) form and provides the basis for accurate quantification; and (c) a biotin group that enables the isolation of the tagged peptides from complex peptide mixtures via avidin affinity chromatography. This approach makes use of the principle of isotope dilution for analysis. For the quantitative comparison between two proteomes in two different states (e.g. normal and disease state), the 'light' (nondeuterated) ICAT reagent is used to covalently tag proteins of one proteome and the 'heavy' (deuterated) ICAT reagent is used to covalently tag proteins of a second proteome. The two proteomes are then combined for quantitative analysis. Analysis often involves further steps such as digestion of the mixture with a protease (e.g. trypsin), isolation of the ICAT-labeled peptides by affinity purification on avidin, and analysis of the isolated labeled peptide mixture by liquid chromatography−mass spectrometry (LC/MS). Prior mixing of proteins that have been labeled with either light or heavy ICAT reagents eliminates much of the potential experimental error associated with postlabeling analysis. Since the two different physiologi-

cal states are correlated with differential labeling, proteins that are present at very different levels in the two cell states will yield a pair of signals of unequal intensity in the LC-MS (each signal pair differing in mass by the number of deuterium atoms incorporated). Searching for peptide pairs of unequal intensity, followed by tandem MS sequencing, identifies proteins whose levels change as a consequence of the disease.

Although many reports have highlighted the utility of the ICAT methodology for proteomic profiling (*9*−*16*), few have discussed the synthetic methodologies for generating 'heavy' ICAT reagents with respect to the isotopic purity and the cost of the synthesis. As initially reported for the synthesis of the 'heavy' ICAT reagent (*9*, *17*), the d_8-diamine linker was synthesized in two steps: first by Michael addition of diethylene glycol-d_2 (i.e. $O(CH_2CH_2OD)_2$) on the expensive d_3-acrylonitrile, in the presence of catalytic NaOD solution in D_2O, and then subsequent nitrile reduction using Raney nickel, providing an octadeuterodiamine linker. Reacting an excess molar equivalent of the d_8-diamine linker with biotin-pentafluorophenyl ester (*18*) afforded the biotinylated d_8- linker-monoamine, which was then treated with iodoacetic anhydride to give rise to the "heavy" ICAT reagent (Figure 1, X = D).

The problems associated with the reported synthesis of "heavy" ICAT reagent (*9*, *17*) are as follows. (a) The Michael addition reaction results in significant (about 10%) loss of deuterium due to exchange with protium at the carbon α to the nitrile group. Consequently, d_7 and d_6 derivatives contaminate the desired d_8-linker. This gives rise to an inseparable mixture of octa-, hepta-, and hexadeuterodinitrile linkers. (b) The subsequent nitrile reduction to amine groups using Raney nickel results in an increase in the percentage of d_7 and d_6 derivatives due to considerable exchange of the deuteriums with protiums at the α-carbon to the nitrile group. In addition, the yield in this step is very low due to a notable retro-Michael type reaction (*12*). (c) The subsequent amide coupling reaction with biotin pentafluorophenyl ester necessarily requires a large molar excess of d_8-diamine linker (*9*, *12*) to ensure mono-biotinylation and avoid bis-biotinylation. The excess of unreacted diamine, being polar, is difficult to recover from the reaction mixture and results in a significant loss of the diamine. Recently Gelb and co-workers addressed these concerns, as they have described a different reaction strategy that improved the yield of the d_8-diamine linker with respect to deuterium exchange (*12*). However, their process involves a larger number of steps, still requires the use of d_3-acrylonitrile, and moreover does not address the problem of the loss of the diamine in the amide coupling reaction with biotin or other capture ligands. Addressing this problem not only applies to the deuterium-labeled approach, but to other, more recent approaches involving ^{13}C-labeled linkers.

EXPERIMENTAL SECTION

General. Methods And Materials. Flash chromatography was carried out using silica gel 60, 230−400 mesh, supplied by E. Merck Co. TLC was performed on silica gel 60 F_{254} on aluminum sheets (E. Merck, type 5554), and detection was carried out by staining with 8% ammonium molybdate tetrahydrate (Fluka) in 2 M sulfuric acid solution in methanol, and under UV light and by iodine adsorption when applicable. Nuclear magnetic resonance spectra (^1H and ^{13}C) were recorded at 298 K, at 400 MHz (for ^1H) and 100.67 MHz for (^{13}C NMR) using a Bruker AV-400 instrument. Chemical shifts are given in ppm values relative to internal standard TMS (0.00 ppm). Solvent, signal multiplicity, coupling constants (in Hz), and integration ratios are indicated in the experimental procedures. Two-dimensional $^1H-^1H$ and $^1H-^{13}C$ COSY (HMQC) experiments were performed for complete signal assignments wherever necessary. ESI MS spectra were obtained on a Bruker Esquire-LC instrument. HRMS spectra were obtained for final compound **12** in the mass spectrometry laboratory of the Chemistry Department, UBC. Palladium hydroxide (20 wt. %), Raney nickel, *n*-Bu_4NBr, formic acid, anhydrous DMF (99.8%), and DIPEA were purchased from Aldrich, and biotin from Sigma. Toluene was dried over Na metal, DIPEA was distilled over CaH_2, and anhydrous DMF was stored on activated molecular sieves prior to use. Tetradeuterated precursors **1** (*19*) and **2** (*20*) were synthesized from the commercially available (Aldrich) and inexpensive compounds ethylene-d_4 glycol and 2-bromoethanol-1,1,2,2-d_4 according to a known literature procedure. Also following a literature procedure, compound **5** (*22*) from 3-chloropropylamine hydrochloride (Aldrich) and biotin pentaflourophenyl ester (*18*) from biotin have been prepared. As described in the following experimental procedures, all the compounds were easily purified by flash chromatographic methods, and structure of each compound has been characterized and confirmed by NMR and mass spectrometry.

Synthesis. (1,1,2,2,4,4,5,5-^{2}H)-5-Benzyloxy-1-tetrahydropyranyloxy-3-oxapentane (3). (1,1,2,2-^{2}H)-2-Benzyloxyethylene glycol (**1**) (1.1 g, 7.05 mmol) was suspended in NaOH solution (20 mL, 1 g/mL in H_2O) containing *n*-Bu_4NBr (0.1 g, 0.7 mmol) and heated at 80 °C for 30 min. To the hot reaction mixture (1,1,2,2-^{2}H)-1-tetrahydropyranyloxy-2-bromoethanol (**2**) (1.8 g, 8.46 mmol) was added, and the reaction mixture was further stirred at 80 °C for 3 h. Then the reaction mixture was cooled to room temperature and diluted with water (10 mL). The crude product was extracted with diethyl ether (2 × 15 mL) and ethyl acetate (10 mL). The organic layer was successively washed with water and brine and then dried over anhydrous Na_2SO_4. After filtration, the solvent was concentrated in vacuo, and the crude product obtained was purified by flash chromatography (petroleum ether−ethyl acetate, 6:1) to afford the title compound (**3**, 1.9 g, 6.6 mmol, 94%) as a colorless syrup. TLC (petroleum ether−ethyl acetate, 4:1): $R_f = 0.35$ (UV, blue stain in ammonium molybdate). ^1H NMR (400 MHz, $CDCl_3$): δ = 7.35−7.20 (m, 5H, 5 aryl-H), 4.61 (m_c, 1H, OCHO), 4.55 (s, 2H, OCH_2Ph), 3.85 (m_c, 1H, OCH_a), 3.47 (m_c, 1H, OCH_b), 1.91−1.40 (m, 6H, $3CH_2$) ppm; ^{13}C NMR (100.61 MHz, $CDCl_3$): δ = 138.92 (aryl *t*-C), 128.97, 128.89, 128.26, 128.10 (5 aryl-C), 99.47 (OCHO), 73.74 (OCH_2Ph), 70.29, 69.41, 66.43 (3 weak multiplets, 4 OCD_2), 62.75 (OCH_2), 31.14, 26.0, 20.04 (3 CH_2) ppm. ESI-MS: m/z = 311.21 $[M + Na]^+$, 327.21 $[M + K]^+$ observed for $C_{16}H_{16}D_8O_4$ (288.22).

(1,1,2,2,4,4,5,5-^{2}H)-5-Benzyloxy-3-oxapentan-1-ol (4). A solution of **3** (1.8 g, 6.25 mmol) in MeOH (10 mL) was treated with HCl solution (10% in MeOH, 0.5 mL) at 0 °C for 1 h. The acidic reaction mixture was neutralized with aqueous $NaHCO_3$ solution and concentrated in vacuo. The crude product was purified by flash chromatography (petroleum ether−ethyl acetate, 7:3) to afford the alcohol derivative, (**4**, 1.15 g, 5.63 mmol, 90%) as colorless syrup. TLC (petroleum ether−ethyl acetate, 2:1): $R_f = 0.1$ (UV, blue stain in ammonium molybdate). ^1H NMR (400 MHz, $CDCl_3$): δ = 7.35−7.20 (m, 5H, 5 aryl-H), 4.54 (s, 2H, OCH_2Ph), 2.35 (bs, 1H, OH) ppm;

^{13}C NMR (100.61 MHz, $CDCl_3$): δ = 137.98 (aryl *t*-C), 128.39, 127.74 (5 aryl-C), 73.23 (OCH_2Ph), 69.79, 68.28, 60.95 (3 weak multiplets, 4 OCD_2) ppm. ESI-MS: *m*/*z* = 205.18 $[M + H]^+$, 227.20 $[M + Na]^+$ observed for $C_{11}H_8D_8O_3$ (204.16).

***N*-[(5,5,6,6,8,8,9,9-^{2}H)-9-Benzyloxy-4,7-dioxanonanyl]-*tert*-butyloxycarbamide (6).** Following the similar experimental procedure as in case of compound **3**, the title compound **6** was prepared by reacting **4** (1.01 g, 4.95 mmol) and *N*-(3-chloropropyl)-*tert*-butyloxycarbamide (**5**) (1.92 g, 9.92 mmol) in NaOH solution (10 mL, 1 g/mL in H_2O) containing *n*-Bu_4NBr (0.1 g, 0.7 mmol) at 80 °C for 1 h. The crude product obtained was purified by flash chromatography (petroleum ether−ethyl acetate, 4:1) to afford the corresponding conjugate (**6**, 1.31 g, 3.62 mmol, 73%) as colorless syrup. TLC (petroleum ether−ethyl acetate, 2:1): R_f = 0.3 (UV, blue stain in ammonium molybdate). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.36−7.20 (m, 5H, 5 aryl-H), 4.92 (bs, 1H, NHBoc), 4.55 (s, 2H, OCH_2Ph), 3.52 (t, *J* = 5.87 Hz, 2H, OCH_2), 3.20 (m_c, 2H, C*H*$_2$NHBoc), 1.72 (m, 2H, OCH_2CH_2), 1.41 (s, 9H, *t*-Bu) ppm; ^{13}C NMR (100.61 MHz, $CDCl_3$): δ = 156.32 (CONH), 138.56 (aryl *t*-C), 128.63, 128.0, 127.86 (5 aryl-C), 79.17 (*C*(CH_3)), 73.46 (OCH_2Ph), 69.81 (OCH_2, weak multiplet for 4 OCD_2), 38.90 (CH_2NHBoc), 29.92 (OCH_2CH_2), 28.73 (C(*C*H_3)) ppm. ESI-MS: *m*/*z* = 362.29 $[M + H]^+$, 384.3 $[M + Na]^+$, 400.3 $[M + K]^+$ observed for $C_{19}H_{23}D_8NO_5$ (361.27).

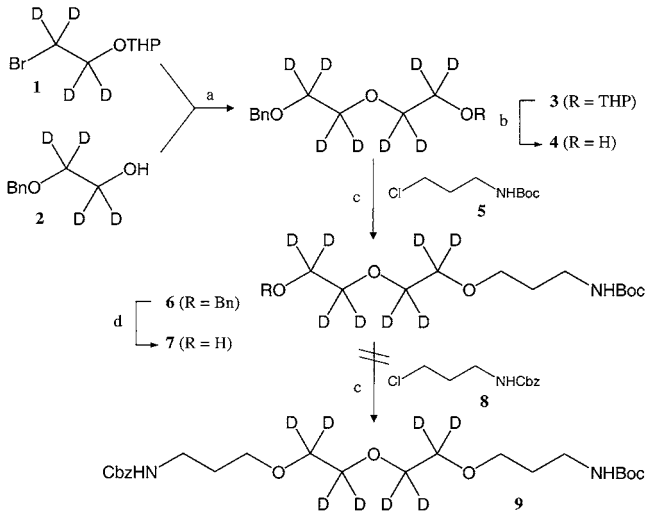
***N*-[(5,5,6,6,8,8,9,9-^{2}H)-9-Hydroxy-4,7-dioxanonanyl]-*tert*-butyloxycarbamide (7).** A mixture of **6** (1.14 g, 3.15 mmol) and $Pd(OH)_2$ (20% on charcoal, 50 mg) in ethyl acetate (10 mL) was hydrogenated under atmospheric pressure for 3 h at RT. Then the reaction mixture was filtered through a thin Celite bed, and the residue was washed with MeOH (10 mL). The filtrate was concentrated in vacuo, and the residue was subjected to flash chromatographic purification on silica gel using neat ethyl acetate as the eluent, yielding the alcohol derivative (**7**, 0.74 g, 2.73 mmol, 87%) as a colorless syrup. For flash column chromatographic purification, neat ethyl acetate was needed to obtain the desired product **7** in pure form. The increased polarity of **7** may be accounted to the free hydroxyl group resulting from the hydrogenolysis. TLC (petroleum ether−ethyl acetate, 1:1): R_f = 0.5 (white patch in ammonium molybdate). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 5.10 (bs, 1H, NHBoc), 3.52 (t, *J* = 5.86 Hz, 2H, OCH_2), 3.20 (t, *J* = 6.37 Hz, 2H, C*H*$_2$NHBoc), 2.78 (bs, 1H, OH), 1.71 (m, 2H, OCH_2CH_2), 1.41 (s, 9H, *t*-Bu) ppm; ^{13}C NMR (100.61 MHz, $CDCl_3$): δ = 156.30 (CONH), 79.31 (*C*(CH_3)), 69.73 (OCH_2, weak multiplet for 3 OCD_2), 61.18 (weak multiplet, CD_2OH), 38.71 (CH_2NHBoc), 29.90 (OCH_2CH_2), 28.69 (C(*C*H_3)) ppm. ESI-MS: *m*/*z* = 294.3 $[M + Na]^+$, 310.25 $[M + K]^+$ observed for $C_{12}H_{17}D_8NO_5$ (271.22).

***N*-[(5,5,6,6,8,8,9,9-^{2}H)-12-Cyano-4,7,10-trioxadidecanyl]-*tert*-butyloxycarbamide (10).** To a suspension of **7** (0.67 g, 2.47 mmol) and solid NaOH (10 mg, 0.24 mmol) in anhydrous toluene (10 mL) was added acrylonitrile (0.21 mL, 3.21 mmpl) under nitrogen atmosphere, and the reaction mixture was stirred for 3 h at RT in the dark. Then the reaction mixture was diluted with ethyl acetate and successively washed with water (5 mL) and brine. After drying over anhydrous Na_2SO_4, the organic layer was filtered and concentrated in vacuo. Purification of the crude product by flash chromatography (petroleum ether−ethyl acetate, 1:1) afforded the nitrile adduct (**10**, 0.77 g, 2.37 mmol, 96%) as colorless syrup. TLC (petroleum ether−ethyl acetate, 1:1): R_f = 0.1 (iodine, white patch in ammonium molybdate). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 4.90 (bs, 1H, NHBoc), 3.70 (t, *J* = 6.44 Hz, 2H, OCH_2), 3.52 (t, *J* = 5.97 Hz, 2H, OCH_2), 3.18 (m_c, 2H, C*H*$_2$NHBoc), 2.58 (t, *J* = 6.45 Hz, 2H, CH_2CN), 1.73 (m, 2H, OCH_2CH_2), 1.41 (s, 9H, *t*-Bu) ppm; ^{13}C NMR (100.61 MHz, $CDCl_3$): δ = 155.97 (CONH), 117.79 (CN), 78.93 (*C*(CH_3)), 69.46 (OCH_2, weak multiplet for 4 OCD_2), 65.86 (OCH_2), 38.68 (CH_2NHBoc), 29.63 (OCH_2CH_2), 28.41 (C(*C*H_3)), 18.84 (CH_2CN) ppm. ESI-MS: *m*/*z* = 325.26 $[M + H]^+$, 347.31 $[M + Na]^+$, 363.31 $[M + K]^+$ observed for $C_{15}H_{20}D_8N_2O_5$ (324.25).

***N*-[(5,5,6,6,8,8,9,9-^{2}H)-13-Amino-4,7,10-trioxatridecanyl]-*tert*-butyloxycarbamide (11).** A mixture of **10** (0.58 g, 1.79 mmol) and Raney nickel (30 mg) in MeOH (8 mL) was hydrogenated under atmospheric pressure for 12 h at RT. Then the reaction mixture was filtered through a thin Celite bed, and the filtrate was concentrated in vacuo which afforded the pure amine derivative **11** (0.6 g) as a colorless oil, in quantitative yield. After filtration of the catalyst, compound **11** was obtained in pure form without any further need for chromatographic purification. TLC (CH_2Cl_2−MeOH, 9:1): R_f = 0.1 (iodine, white patch in ammonium molybdate). ^{1}H NMR (400 MHz, d_4-MeOH): δ = 3.51 (t, *J* = 6.1 Hz, 2H, OCH_2), 3.46 (t, *J* = 6.2 Hz, 2H, OCH_2), 3.08 (t, *J* = 6.76 Hz, 2H, C*H*$_2$NHBoc), 2.52 (t, *J* = 6.82 Hz, 2H, CH_2NH_2), 1.78−1.60 (m, 4H, 2 OCH_2CH_2), 1.38 (s, 9H, *t*-Bu) ppm; ^{13}C NMR (100.61 MHz, d_4-MeOH): δ = 158.45 (CONH), 79.84 (*C*(CH_3)), 70.36 (OCH_2, weak multiplet for 4 OCD_2), 69.81 (OCH_2), 40.10 (CH_2NHBoc), 38.71 (CH_2NH_2), 33.55, 30.92 (2 OCH_2CH_2), 28.80 (C(*C*H_3)) ppm. ESI-MS: *m*/*z* = 329.32 $[M + H]^+$, 351.33 $[M + Na]^+$ observed for $C_{15}H_{24}D_8N_2O_5$ (328.28).

***N*-[(5,5,6,6,8,8,9,9-^{2}H)-13-Biotinamido-4,7,10-trioxatridecanyl]-*tert*-butyloxycarbamide (12).** To a solution of **11** (obtained from the previous reaction without further purification, 0.6 g) in anhydrous DMF (5 mL) was added a solution of the biotin pentaflourophenyl ester (1.12 g, 2.74 mmol) in anhydrous DMF (5 mL) followed by DIPEA (0.3 mL, 1.61 mmol) addition under nitrogen atmosphere. Then the reaction mixture was stirred at RT for 12 h. The reaction mixture was concentrated in vacuo, and the crude product was purified by flash chromatography (CH_2Cl_2−MeOH, 19:1) using neutral silica gel that afforded the pure biotinylated derivative (**12**, 0.64 g, 1.15 mmol, 64% overall yield for two steps) in the form of a white solid (hygroscopic). Compound **12**, being polar due to the presence of amide linkages, could not be purified on commercially available silica gel because of its slightly acidic nature. However, performing the flash column chromatography on neutral silica gel, compound **12** was obtained in pure form with out any loss. To neutralize the commercially available silica gel (230−400 mesh), it was loaded onto a column and washed with CH_2Cl_2 (300 mL), containing 0.1% triethylamine, prior to loading of the crude reaction mixture onto the same column. Then a solvent mixture of CH_2Cl_2 and MeOH in the ratio 19 to 1, without containing any triethylamine, was used for the chromatographic purification of **12**. TLC (CH_2Cl_2−MeOH, 9:1): R_f = 0.6 (iodine, blue stain in ammonium molybdate). ^{1}H NMR (400 MHz, d_4-MeOH): δ = 4.45 (m_c, 1H, CH_2CHNH), 4.26 (dd, J_1 = 4.47 Hz, J_2 = 7.87 Hz, 1H, $CHCHNH$), 3.51−3.42 (m, 4H, 2 OCH_2), 3.20 (t, *J* = 6.8 Hz, 2H, C*H*$_2$CONH), 3.15 (m_c, 1H, SCH), 3.06 (t, *J* = 6.76 Hz, 2H, C*H*$_2$NHBoc), 2.88 (dd, J_1 = 4.99 Hz, J_2 = 12.74 Hz, 1H, SCH_a), 2.66 (d, *J* = 12.72 Hz, 1H, SCH_b), 2.16 (t, *J* = 7.35 Hz, 2H, C*H*$_2$NHCO), 1.77−1.50 (m, 6H, OCH_2CH_2, 2 CH_2), 1.46−1.30 (m, 2H, CH_2), 1.40 (s, 9H, *t*-Bu) ppm; ^{13}C NMR (100.61 MHz, d_4-MeOH): δ = 175.93

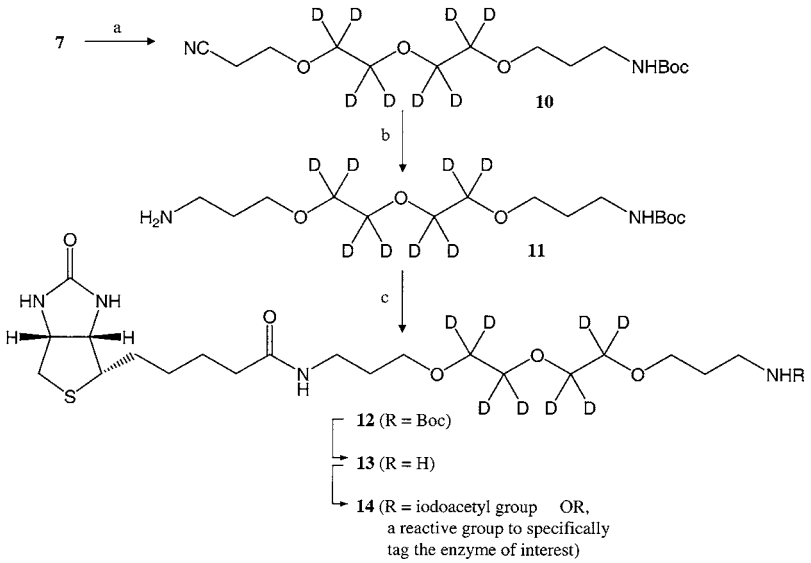
($CH_2NHCOCH_2$), 166.07 (NHCONH), 158.44 ($NHCO_2t$-Bu), 79.85 ($C(CH_3)$), 69.88 (OCH_2, weak multiplet for 4 OCD_2), 69.82 (OCH_2), 63.37, 61.62 (2 CH), 56.99 (SCH), 41.03 (SCH_2), 38.73 (CH_2NHBoc), 37.83 (CH_2CONH), 36.85 (CH_2NHCO), 30.94, 30.43, 29.80, 29.50, 28.81 (5 CH_2), 26.87 ($C(CH_3)$) ppm. ESI-MS: $m/z = 555.37$ $[M + H]^+$, 577.39 $[M + Na]^+$, 593.38 $[M + K]^+$ observed for $C_{25}H_{38}D_8N_4O_7S$ (554.36); HRMS: found 555.3668 $[(M + H)^+]$, $C_{25}H_{39}D_8N_4O_7S$ requires 555.3659.



RESULTS AND DISCUSSION

To overcome all the problems associated with the synthesis of heavy-ICAT linker as discussed in the Introduction, as well as to expand the chemical functionality that may be introduced into ICAT reagents, here we describe an efficient synthesis of the "heavy" ICAT reagent. We contend that the synthesis reported herein is less expensive, facile, and high yielding with no loss of incorporated deuteriums throughout all the subsequent reaction conditions. The synthesis began with the conjugation of the two tetradeutero-precursors **1** (*19*) and **2** (*20*), by classical etherification reaction (*21*) at 80 °C using aqueous NaOH solution and phase-transfer catalyst (n-Bu_4NBr), that gave rise to the orthogonally protected d_8-diethylene glycol (**3**) in 94% yield with no loss of deuterium. Along with ^1H NMR characterization, further evidence for the structure of **3** was obtained by ESI MS that showed signals at $m/z = 311.21$ and 327.21 for $[M + Na]^+$ and $[M + K]^+$, respectively. In the ^{13}C NMR spectrum of **3** instead of singlets, four multiplets with lower intensity have been observed for the four OCD_2 groups arising due to the lack of ^1H broad-band decoupling experiment. Unlike the reported literature method involving simultaneous introduction (*9*), this orthogonally protected glycol linker (**3**) provides for successive introduction of propylamine fragments by chemoselective deprotection of THP and benzyl groups. Thus, chemically differentiable functionalities, including at least one amine, could be further achieved for successive introduction of biotin and a chosen reactive group without the enormous loss of the precious d_8-diamine linker.

The THP group was hydrolyzed in the presence of the acid-stable benzyl group using mild acidic reaction conditions (methanolic HCl solution, 10%) to give the alcohol derivative **4** in 90% yield (Scheme 1). Another etherification reaction between **4** and *N*-(3-chloropropyl)-*tert*-butyloxycarbamide (**5**) (*22*) under similar reaction conditions as used for **3**, provided the Boc derivative **6** in 73% yield, thus installing a propylamine fragment on one end of the linker. In the ^1H and ^{13}C NMR spectra of compound **6**, additional signals due to the extended chain were observed. In the ^{13}C NMR spectrum of **6**, the weak multiplets arising from the four OCD_2 groups were still detectable even though they coincided with the strongly visible singlet corresponding to the newly introduced OCH_2 group. To install the other propylamine fragment, compound **6**, was subjected to hydrogenolysis to give the free alcohol **7** in high yield (87%). In the ^{13}C NMR spectrum of **7**, an upfield shift of the CD_2OH signal (61.18 ppm) was observed, whereas the remaining OCD_2 and OCH_2 signals resonated together at 69.73 ppm.



With an eye to preparing an orthogonally protected d_8-diamine linker **9**, *N*-(3-chloro-propyl)-benzyloxy carbam-

ide (**8**) (*23*) was chosen for the etherification reaction with compound **7**, which would then allow selective cleavage of the Cbz and the Boc groups successively in order to introduce biotin for the affinity purification on avidin and a reactive group to covalently tag the enzyme under study, respectively. Initially, the attempted etherification reaction led to the decomposition of the Cbz functionality in **9** due to the strongly basic medium and high reaction temperature. Thus a different approach was chosen wherein first, Michael addition on **7** gave the nitrile derivative **10** in 96% yield. NMR spectra of **10** showed additional signals corresponding to the newly introduced propylnitrile chain (at 117.79 ppm for CN carbon and a triplet at 2.58 ppm for CH_2CN protons) and in the ^{13}C NMR spectrum the OCD_2 signals appeared as one broad multiplet and overlapping with one of the two OCH_2 signals. Subsequently, Raney nickel reduction of the nitrile to amine **11** was achieved in greater than 80% yield (Scheme 2). A triplet corresponding to the newly formed CH_2NH_2 group at 2.52 ppm in the ^1H NMR spectrum along with ESI mass spectrometry (m/z = 329.32 and 351.33 for $[M + H]^+$ and $[M + Na]^+$) confirmed the amine formation. In this reaction we did not experience yield reduction due to formation of any side products resulting from the retro-Michael type reaction as reported by Gelb and co-workers (*12*).

The monoamine linker **11**, without further purification, was directly coupled to biotin using the activated biotin pentafluorophenyl ester in anhydrous DMF in the presence of DIPEA to give **12** in 64% overall yield for both steps (reduction and biotin coupling). New signals at 4.45 and 4.26 ppm, due to the CH protons of biotin, were well separated from all other signals in the ^1H NMR spectrum of compound **12** and clearly confirmed the introduction of biotin moiety. As observed before, the ^{13}C NMR spectrum revealed weak multiplets corresponding to OCD_2 groups that overlapped one of the two OCH_2 signals. An additional proof of structure and purity of **12** was obtained by HRMS which showed an $[M + H]^+$ signal at m/z = 555.3668 with a deviation of only −0.8 ppm from the required value (Figure 2).

Having established the viability of this synthetic procedure, we envision utility for developing ICAT reagents of high isotopic purity. For instance, the d_8-linker **12** can be readily elaborated into a cysteine specific d_8-ICAT reagent (Figure 1) by deprotection of the Boc group, followed by acylation of the resulting free amine with iodoacetic anhydride. Similarly, any similar d_8-ICAT reagent (**14**, Scheme 2) can be prepared by introducing the reactive group of choice that can specifically tag an enzyme of interest.

Unlike in the previously reported procedures, we incorporated eight deuteriums on the ICAT reagent within the diethylene glycol region in the very first step with no loss of deuteriums through etherification reaction of isotopically pure tetradeutero precursors **1** and **2**. Those incorporated deuteriums are stable throughout the subsequent reaction conditions. Thus, the d_8-ICAT reagent **12** was obtained in 100% isotopic purity and with 33% overall yield. The resultant d_8-ICAT reagent **12** carries deuterium in different positions of the ICAT reagent and is a structural isoform of the original d_8-ICAT reagent (Figure 1). The slight compositional differences between the ICAT linker **12** reported herein, and previously reported ICAT reagents, should not affect the efficiency of the isotopically encoded protein quantification obtained in the ICAT method.

CONCLUSION

In conclusion, we have described an inexpensive and high yielding synthetic strategy to prepare a d_8-ICAT reagent with 100% isotopic purity. A salient aspect of this synthesis is that it allows the synthesis of a wide range of deuterated diamine linkers carrying at least four and potentially any multiple of four deuteriums as the

etherification steps can be repeated to generate longer linkers with a substantially higher isotopic differential. Moreover, this work also enables the synthesis of a class of "heavy, medium, and light" reagents that might be useful for simultaneously probing three cell-based systems; for example (i) uninfected, (ii) infected without treatment, and (iii) infected with treatment. Longer linkers may easily give up to five differentially encoded tags.

Whereas the work herein employed deuterated precursors, other isotopes can be introduced instead of deuterium with minimal alteration to the overall synthetic routes if desired. Indeed, recent reports have underscored slight, yet significant, chromatographic differences due to replacement of protium with deuterium (*24*). Consequently, other stable isotopes, namely ^{13}C, have now been used instead of deuterium. These recent approaches have used ^{13}C-labeled acrylonitrile to address this problem along with undesired exchange of D for H during Michael addition and hydrogenation. The synthetic strategy reported herein can be adapted for (^{13}C or ^{18}O) labeled ICAT reagents by using ^{13}C- or ^{18}O-labeled starting materials (*25*) in the etherification steps. Moreover, *both* carbon *and* oxygen isotopes could be used in tandem to generate an even higher isotopic differential on a relatively shorter linker arm.

In general, this work suggests a modular approach to achieving a high-yielding synthesis of ICAT linkers to give defined isotopic mass differences. Finally, nitrile hydrolysis of **10** with appropriate amine protection, or alternately, Michael addition of **7** to acrylic acid esters is readily envisioned to generate "amino acid" ICAT linkers (carrying an amine at one end and a carboxylic acid at the other end) compatible with automated solid-phase peptide synthesis. Furthermore, Michael addition of **7** to acrolein would give the corresponding aldehyde that could be alternately conjugated to amines, hydrazines, and oximes. In summary, (a) the orthogonal protection strategy obviates extensive loss or tedious recovery steps, (b) allows for effective economy at the level of monobiotinylation, (c) provides options for the introduction of a carboxylate/carbonyl functionality that can be handily converted to an activated ester for the direct attachment to amines, and (d) allows for multiple isotopic labelings through the simultaneous use of ^{13}C or ^{18}O to obtain shorter linkers with higher isotopic density if so desired.

COMMUNICATIONS

A Novel Method for the N-Terminal Modification of Native Proteins

Received May 18, 2003

The formation of structurally defined bioconjugates of proteins hinges on their regioselective modification. Toward this goal a novel method is described here using the commercial IgA protease to attach a nonnatural peptidic moiety to the N-terminus of predisposed proteins by means of a kinetically controlled reverse proteolysis in water. The process requires an H-Ala-Pro N-terminal sequence and then furnishes a selectively modified conjugate under nondenaturing and nondestructive conditions in acceptable yield. The method lends itself to the N-terminal introduction of orthogonal moieties that may be elaborated further.

The regioselective decoration of native proteins with nonnatural structural elements poses an eminently attractive goal, because many possibilities for the tailored modification of their functional properties would be opened which hitherto cannot be implemented by current biological or artificial methods. Particularly interesting options encompass the introduction of atomic markers (isotopes or heavy atoms), reporter groups or therapeutic compounds at well defined positions, the covalent attachment of other biomolecules to form conjugates, the mutually site-selective immobilization to solid supports, or the addition of hydrophobic residues necessary for membrane anchoring. While the chemistry required in manipulation of native proteins is available in quite a variety (*1*−*3*), the major obstacle in the realization of this catalog emerges from the paucity of methods capable to regioselectively address target epitopes in the folded proteins. In principle, two general strategies can be distinguished here. One incorporates the uniquely addressable moiety at the stage of protein synthesis. Peptide segment condensation (*4*−*6*) and protein in vitro biosynthesis (*7*, *8*) provide successful examples using this route. They must, however, rely on the unpredictable chance that the nonnatural moiety does not affect the correct folding pattern.

Alternatively, one can try to regioselectively modify the mature protein in its native folded state, requiring the differentiation of a respectable number of functional groups of quite similar reactivity. Chemical methods in general are devoid of the necessary selectivity unless the reactivity of a certain epitope stands out among all others and thereby paves the way to selective modification (e.g. affinity labels) (*9*, *10*). Better chances may be expected employing protein-modifying enzymes acting in their native role. This approach, however, is blocked by the unavailability of the biocatalyst as well as by their

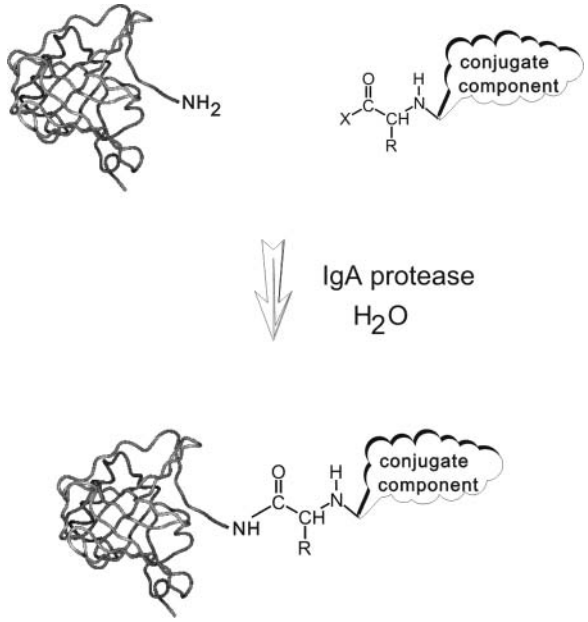

Figure 1. N-Terminal covalent extension of native proteins using the sequence specific restriction endoprotease IgA-protease.

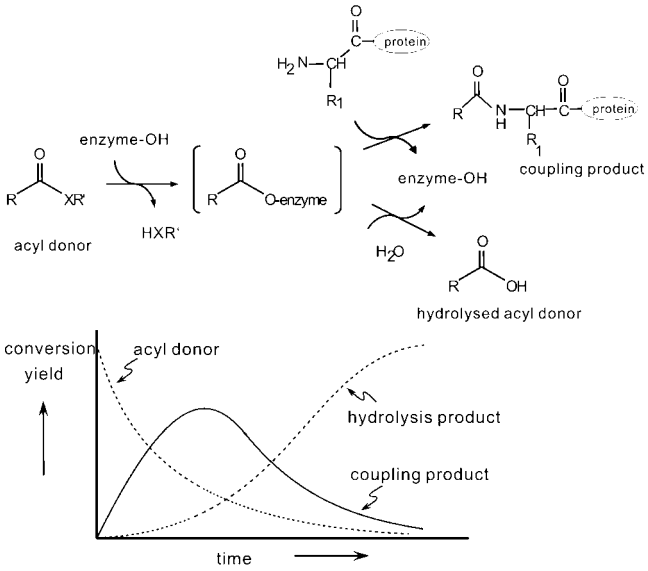

Figure 2. Reverse proteolysis in aqueous buffer depends on the kinetic branching at the stage of a covalent enzyme intermediate between hydrolysis and transamidation. The time dependence of coupling product formation (diagram) shows a maximum at which the reaction must be stopped to obtain an optimal yield (i.e. kinetic control).

substrate specificity that limits the variety of nonnatural groups attachable to the target epitope and undermines generality.

Here, we describe the use of the commercially available protease IgA-Protease to regioselectively elongate the N-terminus of native proteins and peptides with synthetically accessible nonnatural tetrapeptide esters (Figure 1). The novel approach in combination with organometallic aqueous catalyses (*11*) opens a way to introduce a variety of biogenic and abiotic moieties by directed covalent attachment to the N-terminus under nondenaturing conditions without retreat to protective strategies. Conceptually, our method applies a variant of kinetically controlled reverse proteolysis schemes (*12*, *13*). Since all enzymes catalyze the approach to the equilibrium state from the substrate as well as from the product side, proteases will not only cleave but also make peptide bonds. For reactions in water, this facet is invisible, because the position of the equilibrium largely favors the cleavage product. However, shifting of the equilibrium by lowering the water activity (i.e. employing nonaqueous conditions) or avoiding equilibration in total may result in the head-to-tail coupling of peptides subject to the specificity determinants of the enzyme (Figure 2). The kinetic control refers to the exact tuning of the quench process that will stop the enzyme catalysis when the yield of the coupling product arising from the kinetic distribution of an enzyme-bound covalent intermediate between coupling and hydrolysis reaches maximum.

To apply this scheme to the covalent modifications of proteins, serine or cysteine proteases have to be found that do not randomly degrade proteins but will only act on certain primary sequence motifs. One candidate resembling the restriction nucleases in selectivity is the bacterial IgA-protease (*14*−*16*), which recognizes a stretch of at least seven amino acids (*17*) and contains the scissile peptide bond in the middle of the recognition sequence: X-(Ser, Pro) (Arg, Thr) Pro Pro↓(Ala, Gly, Ser) Pro (Ser, Trp, Tyr).

This specificity determinant rarely occurs in globular proteins, thus minimizing the risk of unspecific hydrolysis of protein substrates. For IgA-protease-catalyzed peptide bond formation to occur, two peptidic components are needed: An amino nucleophile representing the N-terminus of the protein to be modified, containing a mandatory proline residue in the penultimate position and preferably an alanine, glycine, or serine residue at the N-terminus. The second component functions as the acyl donor by virtue of its carboxy-terminal ester group that readily acylates the active-site serine residue of IgA-protease, provided at least a tetrapeptide with the correct primary sequence is offered as a substrate. Within generous limits, the chemical nature of the nonnatural group X is uncritical to the success of the reaction (*17*) making this position a good place to implant the desired abiotic moiety.

The principal viability of the approach was probed by peptide fragment coupling of BOC−Pro-Arg-Pro-Pro-OCH_3 as the acyl donor produced by nonmonotonic solution synthesis and carbohydrate-structure-mimicking-peptide, CSMP (H_2N-Ala-Pro-Trp-Leu-Tyr-Gly-Pro-Ala-OH), a commercial octapeptide possessing the mandatory N-terminal sequence and a fluorogenic tryptophane residue that eases the quantitative analysis. The kinetic course of the reverse proteolysis using these substrates under physiological conditions was monitored by HPLC (Figure 3) and revealed the clean formation of a fluorescent product peak in the initial stages of the reaction. Isolation and MALDI-TOF analysis confirmed the identity of the expected coupling product. In continuation of the reaction, this product peak decreases and finally vanishes, completely refurnishing the starting nucleophilic CSMP-peptide, corroborating that IgA-protease strictly follows the assigned specificity pattern. The yield of coupled product at the maximum of its formation is almost 70% based on the CSMP-peptide.

Visualizing the individuality of proteins, the conditions and even the overall outcome of the procedure successful with oligopeptides may not be transferable to the modification of folded proteins. On purpose, we had selected the N-terminus for modification since this epitope is likely to belong to the least structured regions in proteins and in most cases is accessible to enzymatic action from solution because it has been processed by trimming

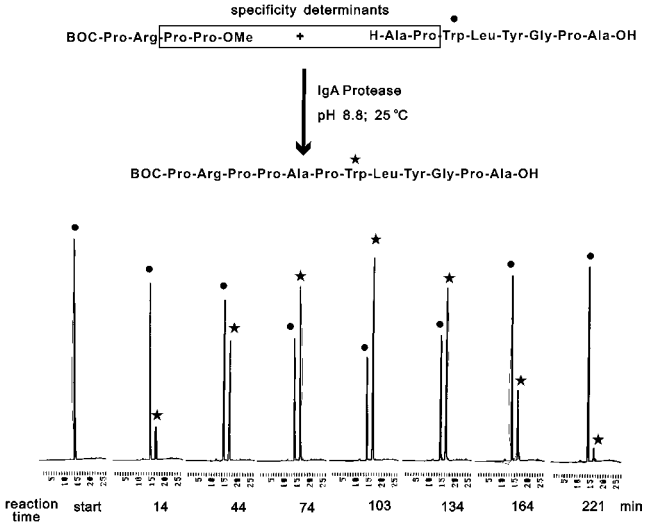

Figure 3. Monitoring peptide fragment coupling of BOC-Pro-Arg-Pro-Pro-OMe with CSMP (●) in aqueous buffer by HPLC fluorescence detection. Only Trp-containing compounds are observable. The formation of the coupling product (★) reaches maximum after 100 min corresponding to a 67% product yield.

enzymes before (cleavage of signal peptides or formylmethionine).

To demonstrate the applicability of our method to native proteins we selected the anticalin FluA (*18*, *19*), a stable, genetically engineered 174-amino acid residue β-barrel protein capable to selectively bind fluorescein with nanomolar affinity. FluA does not contain a sequence motif that would make it susceptible to degradation by IgA-protease, and this inference was fully corroborated by experiment. However, to function as a nucleophile in IgA-protease-catalyzed N-terminal strand extension, the primary sequence had to be altered to include the penultimate Pro residue. Based on the specificity screening (*17*), an Ala-Pro-Ser-Trp tetrapeptide sequence was inserted at the junction of the signal peptide that is lost in the mature FluA-protein and the native N-terminus by established gene-recombinant methods. Expression of the engineered FluA-gene in *E. coli* coding this N-terminally elongated variant furnished the correctly processed FluA protein (H_2N-IgAP1-OH) as proven by MALDI-TOF mass spectral analysis and Edman amino acid sequencing.

IgA-protease-mediated N-terminal elongation of IgAP1 employed the BOC-protected tetrapeptide ester as the unnatural acyl donor that was already used in CSMP-modification. The reaction conditions largely corresponded to those elaborated with the oligopeptides except for the 7-fold lower concentration of the protein nucleophile IgAP1 due to its limited solubility in the reaction medium. The protein modification could be followed by reversed-phase HPLC using fluorescence detection, and the corresponding kinetics are depicted in Figure 4. After 3 h about 30% of the IgAP1 protein was converted into a derivative, and contrary to the analogous experiments with oligopeptides, the yield did not decrease with time again, most likely because the IgA-protease was totally deactivated. The characterization of the product peak after preparative HPLC isolation revealed the correct molecular mass expected from the BOC-tetrapeptide-appended IgAP1 protein. In addition, deblocking the novel N-terminus by treatment with trifluoroacetic acid followed by standard Edman degradation of the initial six amino acids residues unequivocally confirmed that protein modification had occurred in the prospected

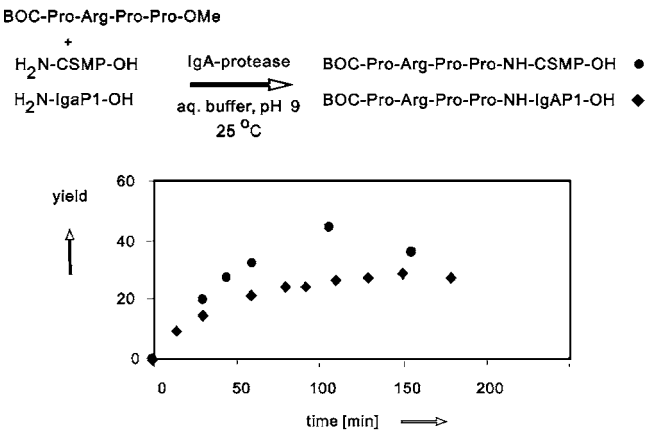

Figure 4. Comparative kinetic runs of the N-terminal modification of CSMP (●) and H_2N-IgaP1-OH (◆) under identical concentration relations. The coupling yield is based on the HPLC-fluorimetric analysis, applying internal standardization. For conditions, see the experimental details.

fashion. To further elucidate the influence imposed by the folded protein structure on the IgA-protease-catalyzed strand extension, IgAP1 and CSMP were compared under identical conditions. The kinetic pattern (Figure 4) shows that the general time course for both substrates is very much alike, but CSMP hits a much higher maximum yield. Since both substrates are very similar in their specificity determining N-terminal sequences, we attribute the difference in derivatization yield to the steric congestion of IgAP1 binding to IgA-protease caused by the bulky 3D-structure of the protein substrate. For the improvement of modification yields, it should be helpful to prolong the N-terminus of the protein to be derivatized rather liberally to arrive at a good substrate for IgA-protease.

The IgA-protease-catalyzed modification of native proteins opens new routes to protein bioconjugates, which are not yet accessible by genetic engineering. Thus, our method (*20*, *21*) complements recombinant methods to generate proteins with a regioselective covalent decoration that may prove vital to their function and use.

(20) Experimental: To a mixture of the IgA-P1 substrate protein (∼100 μM) and acyl donor peptide BOC-Pro-Arg-Pro-Pro-OMe (70 mM) in 100 mM bicine buffer, pH 8.9, containing 2 mM of EDTA and 20 vol % of glycerol was added preconditioned recombinant IgA-protease to make a final concentration of 85 U/100 μL (*11*). The reaction was allowed to proceed at 25 °C for 3 h while adding three 20 μL aliquots of a saturated solution of the acyl donor in the reaction buffer after 20, 50, and 90 min, respectively, to compensate for hydrolysis. Reaction progress was followed by HPLC using a RP-8 column (300 Å, 5 μm) and an acetonitrile/0.1% trifluoroacetic acid gradient at 60 °C (linear from 25% to 45% in 50 min) for elution using fluorescence detection (λ_{ex} = 280 nm; λ_{em} = 350 nm). At the concentration maximum of the product after 3 h, the reaction was quenched by acidification and the product was isolated by HPLC and analyzed by MALDI-TOF mass spectroscopy and Edman degradation.
(21) Recombinant IgA-protease was purchased from MoBiTec, Göttingen, Germany. The enzyme is quite sensitive and was preconditioned in the reaction buffer for 1 h after thawing from the frozen state. The activity was standardized using the hydrolysis of BOC-Pro-Arg-Pro-Pro-*p*-nitroanilide (to be published). According to our procedure, commercial samples of IgA-protease contained 2.5−6 U/μg protein.

^{90}Y and ^{111}In Complexes of a DOTA-Conjugated Integrin $\alpha_v\beta_3$ Receptor Antagonist: Different but Biologically Equivalent

David C. Onthank, Shuang Liu,* Paula J. Silva, John A. Barrett,† Thomas D. Harris, Simon P. Robinson, and D. Scott Edwards

Discovery R & D, Bristol-Myers Squibb Medical Imaging, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received June 26, 2003; Revised Manuscript Received December 15, 2003

^{90}Y-TA138 is a ^{90}Y-labeled nonpeptide integrin $\alpha_v\beta_3$ receptor antagonist that binds with high affinity and specificity to integrin $\alpha_v\beta_3$ receptors overexpressed on both endothelial and tumor cells. ^{90}Y-TA138 has demonstrated significant therapeutic effects in several preclinical tumor-bearing animal models. Since ^{90}Y is a pure β-emitter, ^{111}In-TA138 has been chosen as the imaging surrogate for dosimetry determination of ^{90}Y-TA138. This report describes the synthesis of ^{111}In-TA138 and biological evaluations of both ^{111}In-TA138 and ^{90}Y-TA138 in the c-neu Oncomouse model. The HPLC data shows that ^{111}In-TA138 is more hydrophilic with the retention time ~4.5 min shorter than that of ^{90}Y-TA138 under identical chromatographic conditions. Since the only difference between ^{111}In-TA138 and ^{90}Y-TA138 is the metal ion, the HPLC retention time difference strongly suggests that indium and yttrium chelates do not share the same coordination sphere in solution even though they are coordinated by the same DOTA conjugate. Despite their differences in lipophilicity and solution structure, biodistribution data in the c-neu Oncomouse model clearly showed that ^{111}In-TA138 and ^{90}Y-TA138 are biologically equivalent with respect to their uptake in tumors and other major organs. Therefore, ^{111}In-TA138 is useful as an imaging surrogate for ^{90}Y-TA138 and should be able to predict the radiation dosimetry of ^{90}Y-TA138, a therapeutic radiopharmaceutical for treatment of rapidly growing tumors.

INTRODUCTION

There is currently a considerable interest in radiolabeled biomolecules (BM) as target-specific radiopharmaceuticals for diagnosis and treatment of cancers (*1*−*10*). DOTA and its analogues have been used as bifunctional chelators (BFCs) for the radiolabeling of a variety of biomolecules, including antibodies (*11*−*17*) and small peptides (*18*−*24*). While ^{90}Y-labeled DOTA−BM conjugates are used for tumor radiotherapy, ^{111}In-labeled DOTA−BM conjugates are often used as imaging surrogates for the purpose of dosimetry determination. This is largely based on the assumption that ^{90}Y- and ^{111}In-labeled DOTA−BM conjugates are chemically and biologically equivalent. However, results from recent literature have shown differences in biological properties between ^{90}Y- and ^{111}In-labeled BFC−BM conjugates (*25*−*27*). This causes some concerns about the validity of using ^{111}In-labeled BFC−BM conjugates as imaging surrogates for their ^{90}Y analogues.

We have been interested in developing diagnostic and therapeutic radiopharmaceuticals based on radiolabeled integrin $\alpha_v\beta_3$ receptor antagonists (*23*, *24*, *28*−*33*). In our previous communication (*32*), we reported synthesis of the ^{90}Y complex of a DOTA-conjugated nonpeptide integrin $\alpha_v\beta_3$ receptor antagonist (Figure 1: TA138). ^{90}Y-TA138 has been evaluated as a therapeutic radiopharmaceutical in preclinical tumor-bearing animal models (e.g. c-neu Oncomouse, HCT116, and HT460 xenografts). In all cases, tumor growth was significantly inhibited in mice treated with ^{90}Y-TA138 (30 mCi/kg) on day 7 and 11 after subcutaneous implantation of tumor cells in mice (*33*). As a continuation of these studies, we now present the synthesis of ^{111}In-TA138. To demonstrate the validity of ^{111}In-TA138 as the imaging surrogate for ^{90}Y-TA138, we have evaluated biodistribution characteristics of ^{111}In-TA138 and ^{90}Y-TA138 in the same c-neu Oncomouse model. Results from this study clearly demonstrated that ^{111}In-TA138 and ^{90}Y-TA138 are biologically equivalent with respect to their uptake in tumors and other major organs despite their differences in lipophilicity and solution structures.

EXPERIMENTAL SECTION

Materials. Ammonium acetate, diethylenetriaminepentaacetic acid (DTPA), and sodium gentisate were purchased from Sigma-Aldrich (St. Louis, MO) and were used as received. $^{90}YCl_3$ and $^{111}InCl_3$ (in 0.05 N HCl) were purchased from Perkin-Elmer Life Sciences, North Billerica, MA. Synthesis of TA138 (3-sulfon-*N*-[[4,7,10-tris(carboxymethyl)-1,4,7,10-tetraaza-cyclododec-1-yl]-acetyl]-L-alanyl-*N*-[2-[4-[[[(1*S*)-1-carboxy-2[[[1,4-dihydro-7-[(1*H*-imidazol-2-ylamino]methyl]-1-methyl-4-oxo-3-quinolinyl]carbonyl]amino]ethyl]amino]sulfonyl]-3,5-

dimethylphenoxy]-1-oxobutyl]amino]ethyl]-3-sulfo-L-alaninamide) has been described in our previous communication (*32*).

Analytical Methods. The radio-HPLC method used a HP-1100 HPLC system with an UV/visible detector (λ = 230 nm), an IN−US radio-detector, and a Zorbax C_{18} column (4.6 mm × 250 mm, 80 Å pore size). The flow rate was 1 mL/min with a gradient mobile phase starting from 92% solvent A (25 mM ammonium acetate buffer, pH 6.8) and 8% solvent B (acetonitrile) to 90% solvent A and 10% solvent B at 18 min. The mobile phase was isocratic using 40% of solvent A and 60% solvent B from 19 to 25 min. The TLC method used the C_{18} reverse phase glass plates and a mobile phase containing methanol, acetone, and saline (2:1:1 = v:v:v). By this method, both ^{90}Y-TA138 and ^{111}In-TA138 migrate to the solvent front while unchelated radiometal remains at the origin. The corrected radiochemical purity was calculated by subtracting the percentage of unchelated radiometal obtained by TLC from that obtained by radio-HPLC.

Synthesis of ^{90}Y-TA138. To a clean 10 mL vial containing 775 μg of TA138 were added 15.2 mg sodium gentisate and 7.6 mL of ammonium acetate buffer (0.5 M, pH = 6.0). The solution was immediately degassed under vacuum (<1.0 mmHg) for ~2 min. Upon addition of 175 μL of $^{90}YCl_3$ (~150 mCi) in 0.05 N HCl, the reaction mixture was heated at 95 °C for 5 min. After radiolabeling, a sample of the resulting solution was first diluted 40-fold with the 1.0 mM DTPA solution containing sodium gentisate (10 mg/mL) and was then analyzed by radio-HPLC and TLC. The radiochemical purity was 99.0% for ^{90}Y-TA138. The dose for animal studies was made by diluting part of the kit formulation to a concentration of ~50 μCi/mL with saline.

Synthesis of ^{111}In-TA138. TA138 (100 μg) and sodium gentisate (1.0 mg) were dissolved in 1.5 mL of ammonium acetate buffer (0.5 M, pH = 6.0). The resulting solution was immediately degassed under vacuum (<1 mmHg) for ~2 min. Upon addition of $^{111}InCl_3$ solution (2.2 mCi) in 0.05 N HCl, the reaction mixture was heated at 100 °C for 5 min. After cooling to room temperature, a sample of the resulting solution was analyzed by radio-HPLC and TLC. The radiochemical purity was 99.5% for ^{111}In-TA138. The dose for animal studies was made by diluting the solution above to a concentration of ~15 μCi/mL with saline.

In Vivo Biodistribution Study. The c-neu Oncomouse is a spontaneous tumor-bearing model that carries an activated c-neu oncogene driven by a mouse mammary tumor virus (MMTV) promoter. Transgenic mice uniformly expressing the MMTV/c-neu gene develop mammary adenocarcinomas (4 to 8 months postpartum) that involve the entire epithelium in each gland. The mice used in this study were obtained through an in-house breeding program and were anesthetized intramuscularly with 0.1 mL of a ketamine/acepromazine mixture (1.8 mL saline, 1.0 mL ketamine, and 0.2 mL acepromazine) prior to dosing and tissue sampling. Equal volumes of ^{90}Y-TA138 (50 μCi/mL) and ^{111}In-TA138 (15 μCi/mL) solutions were mixed before injection. The final concentration was 25 μCi/mL for ^{90}Y-TA138 and 7.5 μCi/mL for ^{111}In-TA138. Doses (0.1 mL) were drawn into 0.5 mL insulin syringes for injection.

Eighteen mice (~25 g) were divided into three groups according to the biodistribution time (2, 24, and 48 h) postinjection. Each group had six mice, and each mouse was administered a mixture (0.1 mL) containing ^{90}Y-TA138 at a dose of 2.5 μCi/mouse and ^{111}In-TA138 at a dose of 0.75 μCi/mouse in a single tail vein injection. Biodistributions were performed at the assigned time points (2, 24, and 48 h). Blood, eye, muscle, liver, kidney, bile, spleen, heart, lung, urine, stomach, colon, uterus, bone marrow, bone, and tumors were sampled and assayed for radioactivity. Since the c-neu Oncomouse spontaneously develops tumors in the mammary glands, most mice have more than one tumor. To assess the amount of uptake in the tumors, each tumor was sampled and counted separately. Subsequently, the activity was averaged to obtain an overall representation of tumor uptake. All tissue samples and injected dose aliquots were dissolved in 1 mL of Solvable (Packard Instrument Co., Meriden, CT) and incubated overnight at 37 °C. Each sample was then counted for 15 min on a calibrated Cobra gamma counter (Packard, Instrument Co., Meriden, CT) with dual window settings for counting each isotope. Raw radioactivity data was corrected for background and tested for quantitation limits according to the literature method (*34*). Results are shown in Figures 3−6 and are reported as a percent of the injected dose per gram of the tissue (%ID/g).

Data Analysis. Comparison of ^{90}Y-TA138 and ^{111}In-TA138 tissue uptake was evaluated for bioequivalence based on the 2002 bioequivalence guidance document adopted by the FDA. Briefly, this method describes the estimation of the difference between the means of the logarithms of the data, calculation of the 90% confidence interval for the mean difference, and taking the anti-logs of the limits of the 90% confidence interval. The test compounds are considered bioequivalent if the 90% confidence interval for the ratio of the means is between 0.8 and 1.25. ^{90}Y-TA138 and ^{111}In-TA138 were administered concurrently enabling the ratios of the tissue uptake (%ID/g) to be determined using paired-data analyses. For those organs that only had a single time point available (blood, muscle, bile, bone marrow, and bone), the comparison used the %ID/g. For those organs that had more than one time point available, the comparison used the area under the %ID/g versus time curve (AUC). In the single time point analyses, the paired-difference, log(%ID/g ^{111}In-TA138) − log(%ID/g ^{90}Y-TA138), was calculated for each animal. The mean paired-difference and the 90% confidence limits for the mean were calculated and the antilogarithms obtained to provide the mean and 90% confidence limits for the ratio %ID/g (^{90}Y-TA138)/%ID/g (^{111}In-TA138). The antilog data was necessary in order to express the data on the original scale of measurement. AUCs were estimated using trapezoidal approximations for the multiple time point analyses. The paired-difference, log[AUC(^{90}Y-TA138)] − log[AUC(^{111}In-TA138)], was calculated for each animal. The mean paired-difference and the 90% confidence limits for the mean were calculated and the antilogarithms obtained to provide the mean and 90% confidence limits for the ratio AUC (^{90}Y-TA138)/^{111}In-TA138).

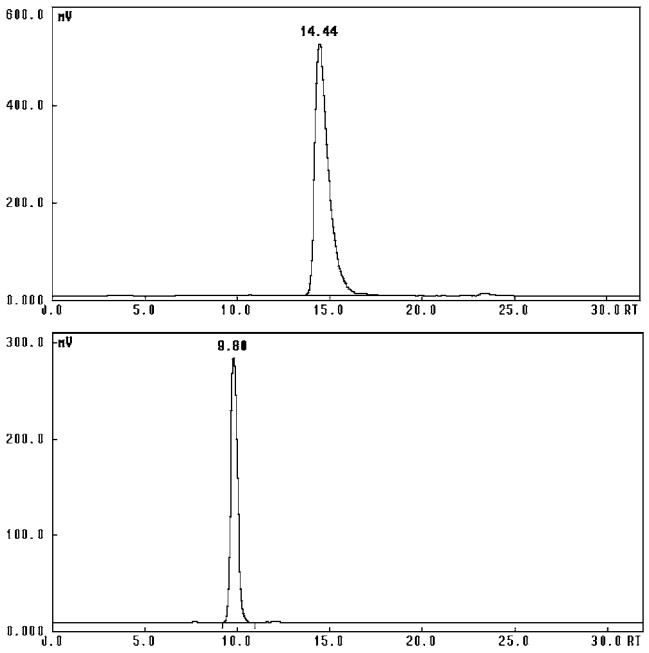

Figure 2. Radio-HPLC chromatograms of ^{90}Y-TA138 (top) and ^{111}In-TA138 (bottom) using a gradient mobile phase (8−10% B over 18 min, A = 25 mM ammonium acetate, B = acetonitrile).

RESULTS

Synthesis of ^{90}Y-TA138 and ^{111}In-TA138. ^{90}Y-TA138 was readily prepared in high yield (RCP > 98%) according to the procedure described in our previous communication (*32*). ^{111}In-TA138 was prepared using a similar procedure with slight modification. In both cases, exclusion of oxygen is required for successful radiolabeling and can be achieved either by degassing under vacuum or by bubbling nitrogen through the mixture before the addition of radiometal. Sodium gentisate was used as a radiolytic stabilizer to prevent radiolysis during the radiolabeling and HPLC analysis. In this study, we used ∼100 μg of TA138 for 20 mCi of $^{90}YCl_3$ (TA138:^{90}Y ∼170:1) for the synthesis of ^{90}Y-TA138, and 2.25 mCi of $^{111}InCl_3$ for preparation of ^{111}In-TA138. The corrected radiochemical purity for ^{90}Y-TA138 and ^{111}In-TA138 was >98% with minimal radiometal colloid formation.

HPLC Characterization of ^{90}Y-TA138 and ^{111}In-TA138. ^{90}Y-TA138 and ^{111}In-TA138 were analyzed by the same reversed phase HPLC method using a gradient mobile phase (8−10% B over 18 min, solvent A = 25 mM ammonium acetate buffer, solvent B = acetonitrile). Figure 2 shows typical radio-HPLC chromatograms of ^{90}Y-TA138 (top) and ^{111}In-TA138 (bottom). There are some small peaks (the void-volume peak at ∼3.0 min and the wash-peak at ∼23 min) due to radioimpurities in ^{90}Y-TA138 and ^{111}In-TA138 preparations. Since these radioimpurities are less than 1.0%, no further characterization was performed. The retention time of ^{111}In-TA138 is ∼4.5 min shorter than that of ^{90}Y-TA138, suggesting that ^{90}Y-TA138 is more lipophilic than that of ^{111}In-TA138. We also tried other reversed phase HPLC methods. It was found that the HPLC retention time difference for ^{90}Y-TA138 and ^{111}In-TA138 depends on the gradient of the mobile phase. Under isocratic conditions (7% B over 30 min, solvent A = 25 mM ammonium acetate buffer, solvent B = acetonitrile), the HPLC retention time difference between ^{90}Y-TA138 and ^{111}In-TA138 was ∼10 min.

Biodistributions of ^{90}Y-TA138 and ^{111}In-TA138 in the c-neu Oncomouse Model. ^{90}Y-TA138 and ^{111}In-TA138 showed rapid blood clearance (Figure 3) primarily via the renal system, and very similar biodistribution patterns (Figures 4−6) in the c-neu Oncomouse model over 48 h postinjection. At 2 h postinjection, the tumor uptake was ∼10% ID/g for ^{90}Y-TA138 and ^{111}In-TA138. The uptake in the eye and bile were below the limit of quantification at 2 h postinjection. Activity levels of ^{90}Y-TA138 and ^{111}In-TA138 were also below the limit of quantification in the blood, muscle, bone, and bone marrow at 24 h postinjection while the uptake in other

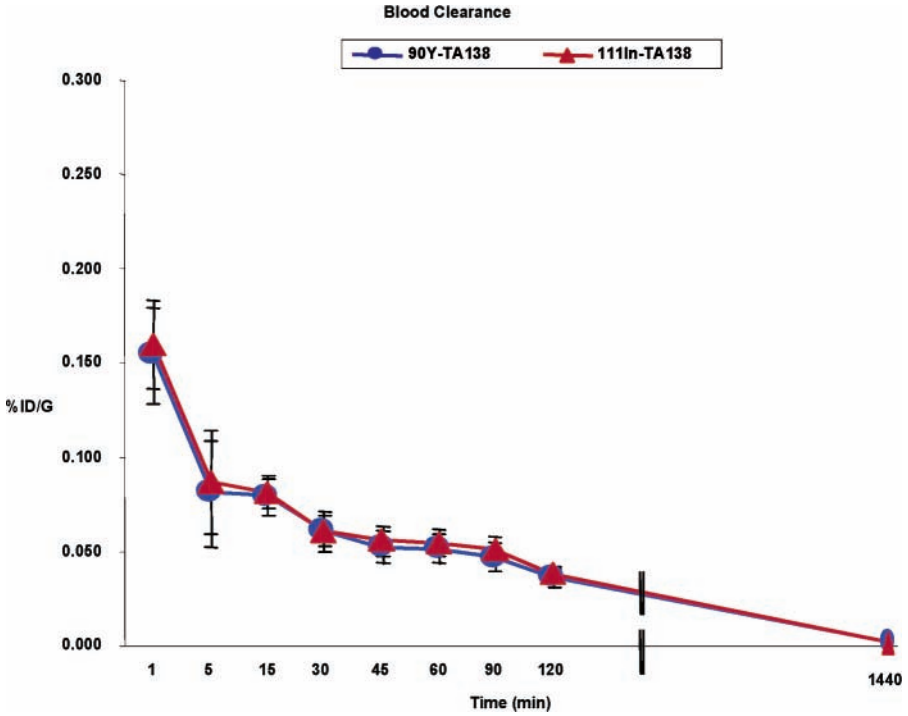

Figure 3. Blood clearance curve for ^{90}Y-TA138 and ^{111}In-TA138 in the c-neu Oncomouse model at 0−24 h postinjection. Each time point is the average ± the standard error of the mean (SEM) (n = 6).

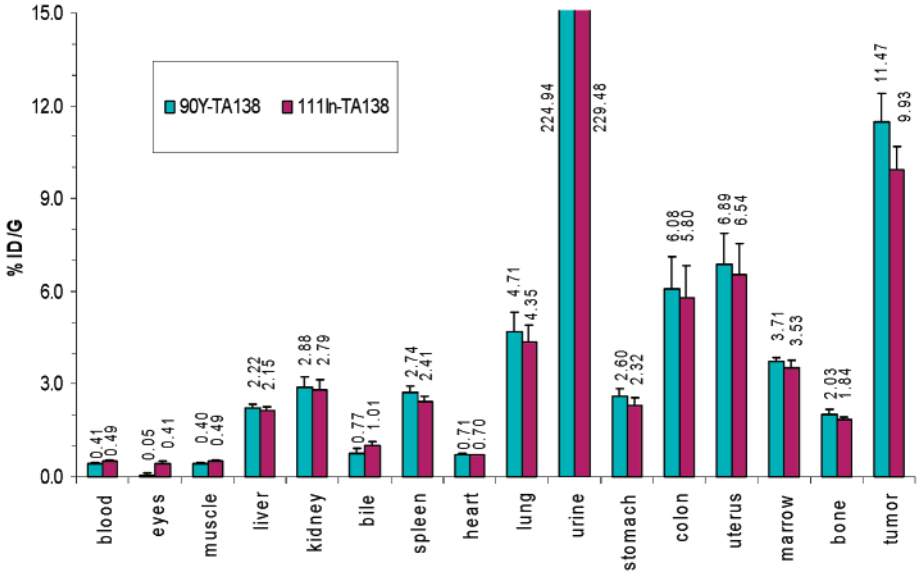

Figure 4. Biodistribution data for ^{90}Y-TA138 (left) and ^{111}In-TA138 (right) in the c-neu Oncomouse model at 2 h postinjection. Each histogram is the average ± the standard error of the mean (SEM) ($n = 6$). The data are decay corrected.

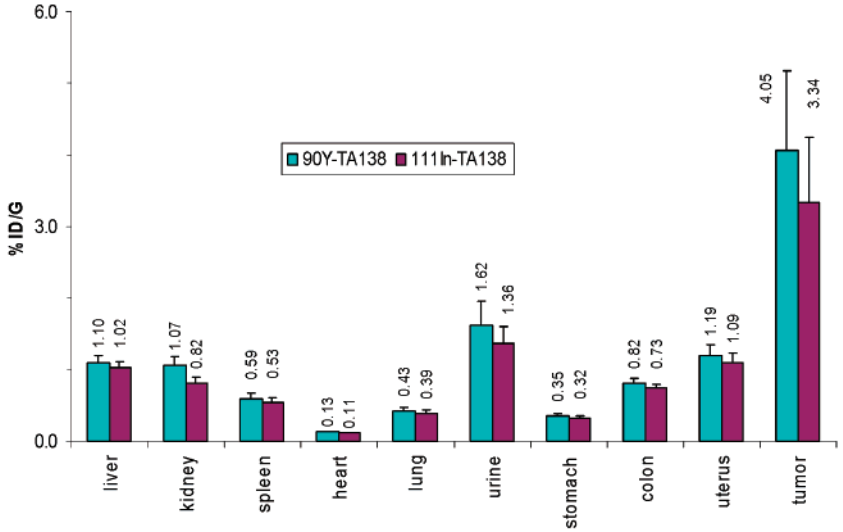

Figure 5. Biodistribution data for ^{90}Y-TA138 (left) and ^{111}In-TA138 (right) in the c-neu Oncomouse model at 24 h postinjection. Each histogram is the average ± the standard error of the mean (SEM) ($n = 6$). The data are decay corrected.

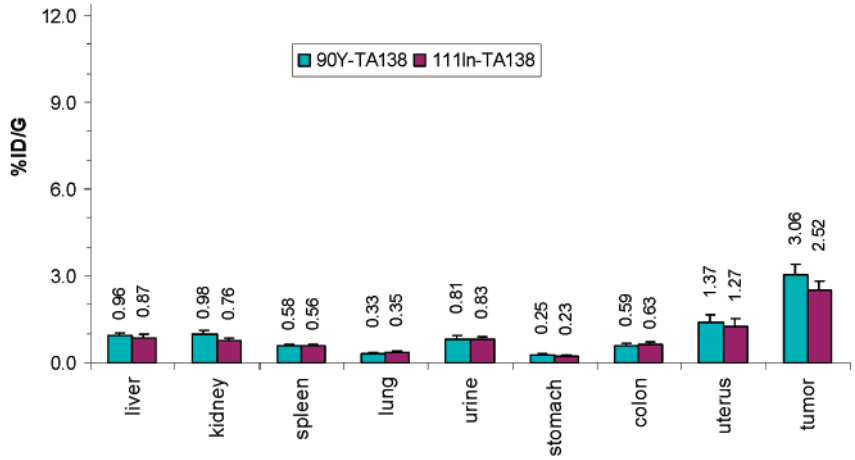

Figure 6. Biodistribution data for ^{90}Y-TA138 (left) and ^{111}In-TA138 (right) in the c-neu Oncomouse model at 48 h postinjection. Each histogram is the average ± the standard error of the mean (SEM) ($n = 6$). The data are decay corrected.

organs were less than 2% ID/g, except the tumor uptake of 3−4%ID/g. At 48 h postinjection, the uptake in all organs except tumor (2−3%) and uterus (1−2%) were less than 1% for ^{90}Y-TA138 and ^{111}In-TA138. At all the time points, there was no significant difference between ^{90}Y-TA138 and ^{111}In-TA138 with respect to their uptake in all organs of interest. HPLC analysis of blood and urine samples at 2 and 24 h postinjection showed no significant metabolism for both ^{90}Y-TA138 and ^{111}In-TA138.

DISCUSSION

^{90}Y-TA138 has demonstrated significant therapeutic effects in several preclinical tumor models, including c-Neu oncomouse, HCT116, and HT460 xenografts (*33*). Since ^{90}Y is a pure β-emitter, ^{111}In-TA138 was chosen as the imaging surrogate for biodistribution and dosimetry determination. Is ^{111}In-TA138 chemically and biologically equivalent to ^{90}Y-TA138? Can ^{111}In-TA138 be used to accurately predict the biodistribution and dosimetry of ^{90}Y-TA138 in animal models? With these questions in mind, we carried out the experiments described in this report.

Difference in Lipophilicity between ^{90}Y-TA138 and ^{111}In-TA138. Radio-HPLC has become a routine method for the characterization of radiolabeled compounds. It is also a powerful tool to compare lipophilicity of two closely related radiolabeled compounds. In this study, we used a reversed phase HPLC method with a gradient mobile phase. It was found that the retention time of ^{111}In-TA138 is ∼4.5 min shorter than that of ^{90}Y-TA138 by the same HPLC method (Figure 2). Similar results were obtained for ^{90}Y and^{111}In complexes of DOTA-BA (BA = benzylamine), a model compound for DOTA−biomolecule conjugates (*35*). Since the only difference in ^{111}In-TA138 and ^{90}Y-TA138 is the metal ion, different retention times strongly suggest that indium and yttrium chelates do not share the same coordination sphere even though they are coordinated by the same DOTA conjugate. If indium and yttrium chelates were to share the same coordination sphere, ^{111}In-TA138 would have had the same retention time as that of ^{90}Y-TA138 under identical chromatographic conditions.

Structural Differences between Y and In Chelates in Solid State. Recently, Mäcke and co-workers (*18*, *36*) described the crystal structures of complexes M(DOTA-D-Phe-NH_2) (M = Y and In) and found that both indium and yttrium in these complexes are eight-coordinated with four amine-nitrogen, one carbonyl-oxygen, and three carboxylate-oxygen atoms bonding to the metal center (*18*, *36*). The difference between these two structures arises from the different conformation of ethylenic bridges and the orientation of sidearms. Y(DOTA-D-Phe-NH_2) exists in solid state as the m-isomer (traditionally designated as the minor isomer) while In(DOTA-D-Phe-NH_2) is observed as the M (major isomer) isomer. The same M isomer is also seen in In(DOTA-AA) (AA = *p*-aminoanilide) (*37*). Since the metal chelate is only one-third of the radiolabeled TA138, the slight difference in solid-state structures of yttrium and indium chelates hardly explains retention time differences between ^{90}Y-TA138 and ^{111}In-TA138 and is not consistent with solution dynamics of In(DOTA-BA) and In(DOTA-AA) as observed in our previous communication (*35*, *37*).

Structural Differences between Y and In Chelates in Solution. The size of Y^{3+} (ionic radius = 0.87 Å) fits perfectly to the coordination cavity of the DOTA-monoamide chelator. It is not surprising that most yttrium complexes of DOTA derivatives are able to maintain their rigid eight-coordinated structure in solution (*18*, *35*, *38*−*41*). In^{3+} has an ionic radius of 0.75 Å, which is smaller than that of Y^{3+} (*42*). As a result, the coordination number for In^{3+} is typically 6 or 7 (*43*−*46*). Only a few eight-coordinated In^{3+} complexes are known (*36*, *37*, *47*−*49*). Due to its smaller size, In^{3+} does not fit to the coordination cavity of the DOTA-monoamide chelator. Although In^{3+} is eight-coordinated in the solid state of In(DOTA-monoamide), the carbonyl-oxygen may become dissociated in solution. This is particularly true for ^{111}In-TA138 at the tracer level (10^{-9} to 10^{-8} M). This explanation is consistent with the HPLC retention time differences between ^{90}Y-TA138 and ^{111}In-TA138, and the fluxionality of In(DOTA-BA) and In(DOTA-AA) in solution (*35*, *37*).

Bioequivalence between ^{90}Y-TA138 and ^{111}In-TA138. There are several factors influencing the bioequivalence of ^{90}Y-TA138 and ^{111}In-TA138. These include solution structures and dissociation kinetics of radiometal chelates, specific activity of radiometals, and the amount of unlabeled TA138 injected into each animal. Since DOTA and its derivatives form eight-coordinated In(III) and Y(III) chelates with extremely high thermodynamic stability and kinetic inertness (*18*, *38*−*41*), the dissociation kinetics may not contribute to the difference, if there is any, in biological properties of ^{90}Y-TA138 and ^{111}In-TA138. In this study we chose to administer ^{90}Y-TA138 and ^{111}In-TA138 concurrently into each animal so that we can eliminate the effect of specific activity and amount of unlabeled TA138 on biodistribution properties of ^{90}Y-TA138 and ^{111}In-TA138. In this way, the only remaining factor that can influence biodistribution properties of ^{90}Y-TA138 and ^{111}In-TA138 would be their structural differences between ^{90}Y and ^{111}In chelates in solution.

In the c-neu Oncomouse model, ^{90}Y-TA138 and ^{111}In-TA138 showed almost identical biodistribution patterns (Figures 4−6) over 48 h. Both ^{90}Y-TA138 and ^{111}In-TA138 are excreted rapidly from blood circulation (Figure 3) via the renal system. There was no significant difference between ^{90}Y-TA138 and ^{111}In-TA138 with respect to their uptake in tumor and other major organs of interest over 48 h postinjection. These results clearly demonstrated that ^{111}In-TA138 and ^{90}Y-TA138 are biologically equivalent despite their differences in solution structure and lipophilicity.

CONCLUSION

This report describes the synthesis and HPLC characterization of ^{111}In-TA138. The HPLC data showed that ^{111}In-TA138 is more hydrophilic, with the retention time being ∼4.5 min shorter than that ^{90}Y-TA138. Since the only difference between ^{111}In-TA138 and ^{90}Y-TA138 is the metal ion, the HPLC retention time difference strongly suggests that indium and yttrium chelates do not share the same coordination sphere in solution even though they are coordinated by the same DOTA conjugate. Despite their differences in lipophilicity and solution structure, biodistribution data in the c-neu Oncomouse model clearly demonstrated that ^{111}In-TA138 and ^{90}Y-TA138 are biologically equivalent with respect to their uptake in tumors and other major organs. Therefore, ^{111}In-TA138 is useful as an imaging surrogate for ^{90}Y-TA138 and should be able to accurately predict the radiation dosimetry of ^{90}Y-TA138, which has the potential as a new therapeutic radiopharmaceutical for the treatment of rapidly growing solid tumors.

BC034108Q

A Dual Fluorochrome Probe for Imaging Proteases

Moritz F. Kircher, Ralph Weissleder, and Lee Josephson*

Center for Molecular Imaging Research, Massachusetts General Hospital and Harvard Medical School, Charlestown, Massachusetts 02129. Received August 27, 2003; Revised Manuscript Received December 12, 2003

Near-infrared fluorescence (NIRF) optical probes have been able to provide a noninvasive assessment of enzyme activity for a number of different enzymes and types of pathology. Here we describe a dual fluorochrome enzyme-activatable probe featuring one NIRF fluorochrome that is activated by protease activity and a second fluorochrome that is protease resistant and serves as an internal standard. The probe was prepared by attaching Cy7 directly to an amino-CLIO, an amine functional cross-linked iron oxide (CLIO) nanoparticle carrier, in a protease resistant manner. Cy5.5 was attached to a protease sensitive polyarginine peptide spacer, also attached to amino-CLIO. In vitro and in vivo the ratio of the Cy5.5 to Cy7 fluorescence was increased by protease, reflecting the increase in Cy5.5 fluorescence by protease in the vicinity of the probe. In vitro and in vivo the absolute values of the Cy5.5 and Cy7 fluorescence reflected lesion size and the distance of lesions from the surface, while the ratio of Cy5.5 to Cy7 fluorescence obtained was constant and independent of lesion size and depth. The dual fluorochrome probe, and related dual wavelength imaging method, represents a novel approach for imaging protease activity in vivo.

INTRODUCTION

In recent years a variety of so-called "smart" probes have been designed that respond to the presence of molecules in their environment with a change in signal. These include calcium indicators (*1*, *2*), sensors of β-galactosidase activity (*3*), and fluorogenic substrates for a variety of hydrolytic enzymes (*4*). Recently, high molecular weight near-infrared fluorescent (NIRF) molecules have been synthesized which are quenched until activated by proteases, and these have been used to image protease activity in vivo (*5*, *6*). These probes consist of a high molecular weight carrier, a cleavable peptide spacer or "stalk" attached through a C-terminal cysteine, and a fluorochrome attached to the N-terminus. These features of probe design are shown in Figure 1. Probes of this design have been used to visualize a variety of proteases including cathepsin D (*7*), MMP-2 (*8*), and thrombin (*9*). The high molecular carrier can be a graft copolymer or a magnetic nanoparticle, the latter serving as combined NIRF/optical and water relaxation enhancing/MR agent, a feature that is sometimes termed a multimodal imaging capability (*10*).

Use of such probes to measure foci of enzyme activity in vivo was initially achieved with surface reflectance-based instrumentation (*11*), but more recent tomographic methods have been used to obtain tissue concentrations of the fluorochrome released as a product of protease activity (*12*). However, the absolute value of fluorescence obtained is a function of the intensity of incident light and the depth and size of the lesion. In addition, the amount of enzyme product produced by protease reflects not only the enzyme activity but also the delivery of substrate (substrate concentration).

We previously reported on a dual probe-based imaging method where an optical probe originally designed for use as a single enzyme-activated probe (*10*) was used together with a second, nondegradable probe employing a second, optically distinct fluorochrome (see ref 13). The nondegradable probe served as a standard for internalization by macrophages; macrophages expressing cathepsin B phagocytosed both probes similarly but could only activate one probe, while macrophages without cathepsin B could not activate either probe. Hence, the ratio of fluorescence provided a measure of cathepsin B activity corrected for variable levels of macrophage internalization. These results indicated the feasibility of using dual fluorochrome ratio imaging methods for the improved

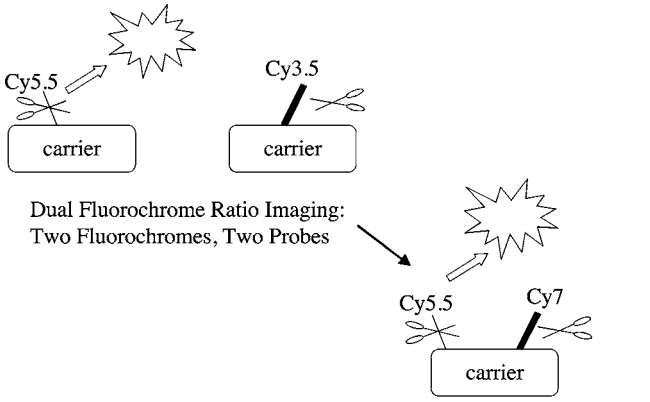

Figure 1. Dual fluorochrome imaging strategies. Dual fluorochrome ratio imaging methods began with two probes with peptide stalks of different proteolytic susceptibility (*13*). Proteolytic cleavage of a peptide by an enzyme (scissors)-activated fluorescence. Here the dual fluorochrome probe consists of a single probe and two fluorochromes. One fluorochrome (Cy5.5) is activatable (cleaved by scissors), while a second (Cy7) serves as an internal standard. The probe is denoted Cy5.5−R4−Cy7−CLIO where the peptide "stalk" is the L-arginyl peptide "R4" and the carrier is amino-CLIO.

quantification of enzyme activity, but the method required the synthesis of two probes and their use as a mixture.

Here we report on an improvement of our previous dual fluorochrome, dual probe method consisting of a single probe that features two fluorochromes. A schematic representation of these different approaches to dual fluorochrome probes is shown in Figure 1. We attached one fluorochrome (Cy5.5) via a cleavable peptide linker while a second fluorochrome (Cy7) was attached directly to a macromolecular carrier and was resistant to proteolytic activation. The amino-CLIO nanoparticle (CLIO = cross-linked iron oxide) was employed as a carrier. The ratio of Cy5.5 to Cy7 fluorescence reflected activation by protease and could be used to correct for differences in the size and depth of a target lesions.

MATERIAL AND METHODS

The dual fluorochrome probe was synthesized by first attaching Cy7 directly to the amino-CLIO carrier and then by attaching Cy5.5 to the N-terminus of a proteolytically cleavable L-polyarginine peptide ("R4"). The probe is denoted Cy5.5−R4−Cy7−CLIO. Attachment of the peptide R4 (R-R-R-R-G-C) to the nanoparticle is through the thiol of the C-terminal cysteine and was accomplished by use of the bifunctional agent succinimidyl iodoacetate (SIA). Cy5.5 is attached to the N-terminal arginine. A more complete synthetic scheme of the probe Cy5.5−R4−CLIO, a probe identical to that used here but lacking the Cy7 attached to the CLIO, has been provided; see refs 10 and 13.

Synthesis of Cy7−CLIO. Amino-CLIO, a magnetic nanoparticle with a coating of cross-linked dextran and primary amino groups was prepared as described (*14*, *15*). To 1 mL of amino-CLIO (10 mg Fe/mL) was added 100 μL of 10x PBS and 2.5 μL 0.5 M EDTA. The mixture was added to one Cy7 dye tube (1 mg) (Amersham-Pharmacica, Piscataway, NJ) and incubated for 1 h at room temperature and then overnight at 4 °C. Unbound Cy7 was then removed by spin-separation over a PD-10 column (Amersham) equilibrated with PBS, 1.25 mM EDTA.

Synthesis of the Peptide−Nanoparticle, R4−Cy7−CLIO. The L-arginyl peptide R-R-R-R-G-C ("R4") was synthesized as described previously (*13*, *14*). To 1 mL Cy7−CLIO (10 mg Fe/mL) were added 330 μL of 0.1 M Na_2HPO_4 and 330 μL of 150 mM succinimidyl iodoacetate in DMSO. The mixture was allowed to sit for 1 h at room temperature and the addition of succinimidyl iodoacetate repeated. Iodoacetyl-CLIO was separated from iodoacetic acid using a Sephadex G-25 column equilibrated with 0.025 M citrate pH 6.5 run at 4 °C. To the void volume (3 mL) was added 10 mg of R4 peptide, and the reaction was incubated overnight at room temperature. Unreacted peptide was removed by dialysis against 3 L of 0.02 M citrate pH 8.2 using a 14 kDa cutoff membrane.

Synthesis of the Dual Fluorochrome Probe, Cy5.5−R4−Cy7−CLIO. To attach Cy5.5, 140 μL of 1 M NaHCO3 (pH 8.3) was added to 3 mL of R4−Cy7−CLIO. The mixture was then distributed to 6 tubes of Cy5.5. After 2 h at room temperature, the tubes were pooled and 10% volume of 1.5 M hydroxylamine was added. The mixture was allowed to sit for an additional 2 h at room temperature and separated using PD-10 columns (equilibrated with 0.02 M citrate buffer, pH 8.2) run in a spin separation mode. One milliliter of sample was added to columns that were spun at 830*g* for 5 min.

Physical Properties of Cy5.5−R4−Cy7−CLIO. Spectra of conjugates were taken using a Hitachi 3500 spectrophotometer. The number of Cy5.5 and Cy7 dyes present was determined spectrophotometrically, using an extinction coefficient of 250 000 M^{-1} cm^{-1} at 675 nm for Cy5.5, and 200 000 M^{-1} cm^{-1} at 747 nm for Cy7. Iron concentration was determined spectrophotometrically (*14*). The ratio of fluorochromes to nanoparticles was obtained assuming 2064 iron atoms per crystal (*16*). R1 and R2 relaxivities were measured using a 0.47T MR relaxometer (*14*). Size was determined by laser light scattering using a Zetasizer 1000 (Malvern, Worcestershire, UK).

Activation of Fluorescence by Trypsin. Cy5.5−R4−Cy7−CLIO fluorescence was determined in a microtiter plate with 0.01 M Na_2HPO_4, pH 7.4, 50 μg Fe/mL of Cy5.5−R4−Cy7−CLIO, and 10 μg/mL trypsin. The plate was incubated at room temperature and Cy7 and Cy5.5 fluorescence determined (ex 747, em 777 and ex 645, em 695, respectively) using a fluorescent microtiter plate reader (SpectraMAXGeminiXS, Molecular Devices, Sunnyvale, CA).

Optical Imaging. To examine the ability of the dual fluorochrome probe to correct for lesion size, a homogenate prepared from the liver from a mouse injected with Cy5.5−R4−Cy7−CLIO was used. Magnetic nanoparticle based probes are internalized by the liver with activation of their fluorescence (*10*, *13*). C57BL/6 mice (National Cancer Institute, Bethesda, MD) were injected via tail vein with 10 mg Fe/mL of Cy5.5−R4−Cy7−CLIO, and 24 h later mice were sacrificed and the livers excised and homogenized. Volumes of homogenate containing activated probe were transferred to 384-well plates to serve as models of enzyme activated "lesions" in vivo. To mimic lesions of different sizes, volumes were chosen to yield wells containing between 2 mm and 10 mm high volumes of homogenate. To demonstrate the ability of the dual fluorochrome probe to correct for lesion depth, liver from a noninjected mouse was transferred to a 384-well plate to achieve heights of 0 to 7 mm in 1 mm increments. Subsequently, 15 μL of 1% agarose containing 10 μg of Cy5.5−R4−Cy7−CLIO was added to each well with liver samples.

To demonstrate the ability of the dual fluorochrome probe to correct for lesion size and depth, the 9L rat gliosarcoma cell line stably transfected to express green fluorescence protein (GFP) (*17*) was cultured at 37 °C in a humidified 5% CO_2 atmosphere in Dulbecco's modified eagle medium (DMEM) supplemented with 10% fetal bovine serum, 1% penicillin and streptomycin and 500 μg/mL geniticine G418 (all products from Cellgro, Herndon, VA). 9L gliosarcomas were induced by means of bilateral injection of 9L glioma cells deep into the mammary fat pad of nude mice ($n = 3$, Charles River, Wilmington, MA). To obtain tumors of different sizes, 0.5×10^6 cells were implanted on the right, and 2×10^6 cells in the left mammary fat pad. After 12 days, animals were anesthetized (ketamine/xylazine, 65/10 mg/kg) and 10 mg Fe/kg body weight Cy5.5−R4−Cy7−CLIO injected by tail vein. Twenty-four hours later, mice were imaged, euthanized by halothane inhalation, and underwent progressive dissection and further NIRF imaging.

Optical imaging of the plates and mice was performed using a whole mouse imaging system as described (*11*). Cy5.5 fluorescence was obtained with an excitation band-pass filter at 630 ± 15 nm (630RDF30; Omega Optical, Brattleboro, VT) and emission band-pass filter at 700 ± 20 nm (700DF40; Omega Optical). Cy7 fluorescence was obtained with an excitation band-pass filter at 736 ± 20 (736AF40; Omega Optical) and emission band-pass filter at 800 ± 20 (800AF40; Omega Optical). Images were

acquired using a cooled CCD camera with 800 × 600-pixel resolution (SenSys; Photometrics, Tucson, AZ). Kodak Digital Science 1D Software (Eastman Kodak; Rochester, NY) was used for acquisition and data analysis.

RESULTS

Properties of the Dual Fluorochrome Probe Cy5.5−R4−Cy7−CLIO. The physical properties of Cy5.5−R4−Cy7−CLIO are summarized in Table 1. The probe uses a thioether linkage and an enzyme-cleavable L-arginine peptide (*10*, *13*). Figure 2A shows the absorption spectrum of Cy5.5−R4−Cy7−CLIO, with a characteristic absorption of the iron oxide in the ultraviolet region of the spectrum and with the absorption maxima of Cy5.5 and Cy7 at 674 and 748 nm, respectively. Figure 2B shows the absorption spectra of Cy5.5−R4−Cy7−CLIO in relation to the excitation and emission filters used. Also shown are the emission maxima for Cy5.5 (694 nm) and Cy7 (737 nm). As shown in Figure 2C an excellent separation of fluorescent signals from Cy5.5 and Cy7 was obtained with the optical imaging system used in this study.

Enzyme Activation of Cy5.5−R4−Cy7−CLIO. Figure 3 shows the effect of treating Cy5.5−R4−Cy7−CLIO with trypsin. Trypsin cleaved the R4 peptide, producing a 700% increase in the Cy5.5 fluorescence after 60 min and 850% increase after 24 h (data not shown). In contrast, Cy7 fluorescence was nearly constant, as expected, because of the direct attachment of Cy7 to the cross-linked dextran coating of CLIO and inability to undergo enzymatic cleavage. The small increase of about 20% in Cy7 fluorescence may reflect a small quenching effect resulting from slight interaction between the two fluorochromes when in close physical proximity to each other (on the same probe). We next performed a series of experiments to determine whether the light associated with Cy5.5 fluorescence and Cy7 fluorescence would be attenuated (or transmitted) similarly in biological tissues. If Cy5.5 fluorescence and Cy7 fluorescence are attenuated similarly, the ratio of their fluorescence should reflect the activation of the probe and be independent of size and depth of the fluorescent lesion.

Imaging with Cy5.5−R4−Cy7-CLIO in Vitro. To assess whether the ratio of Cy5.5 to Cy7 fluorescence depended on the size or magnitude of the fluorescence, we imaged phantoms consisting of a 384-well plate containing variable amounts of liver homogenate (Figure 4). A mouse was injected with 10 mg Fe/kg Cy5.5−R4−Cy7−CLIO and liver homogenate containing probe plus a mixture of naturally occurring proteins and light absorbing materials, was placed in the wells of the plate at different heights (Figure 4A). The fluorescence from Cy5.5 and Cy7 and the ratio of Cy5.5 to Cy7 fluorescence was obtained as shown in Figures 4B and 4C. Cy5.5 and Cy7 fluorescence intensities increased with increasing amounts of homogenate, however, for both fluorochromes fluorescence tended to plateau at higher amounts of homogenate. This reflects the fact that the NIRF signal obtained is strongly surface weighted with this type of instrumentation. However, the ratio of Cy5.5 to Cy7 fluorescence was nearly constant over a 7-fold change in

homogenate height (Cy5.5/Cy7 = 6.43 at 1 mm versus 6.13 at 7 mm). With the liver homogenate the dual fluorochrome probe and ratio imaging method yielded a value of Cy5.5/Cy7 fluorescence of 6 to 7 which was characteristic of the activated probe in vitro, see Figure 3.

We next assessed whether the ratio of Cy5.5 to Cy7 fluorescence could correct for a constant lesion at variable depths from the surface. For this purpose, a constant amount of agar containing unactivated Cy5.5−R4−Cy7−CLIO was placed on top of variable amounts of liver tissue from a noninjected animal (Figure 5A). Figures 5B and 5C show that Cy5.5 and Cy7 fluorescence decreased with increasing depths of liver. However, the ratio of Cy5.5 to Cy7 fluorescence was nearly constant when light passed through 1 to 10 mm of liver (Cy5.5/Cy7 = 1.70 at 1 mm versus 1.64 at 10 mm). The Cy5.5/Cy7 ratio of

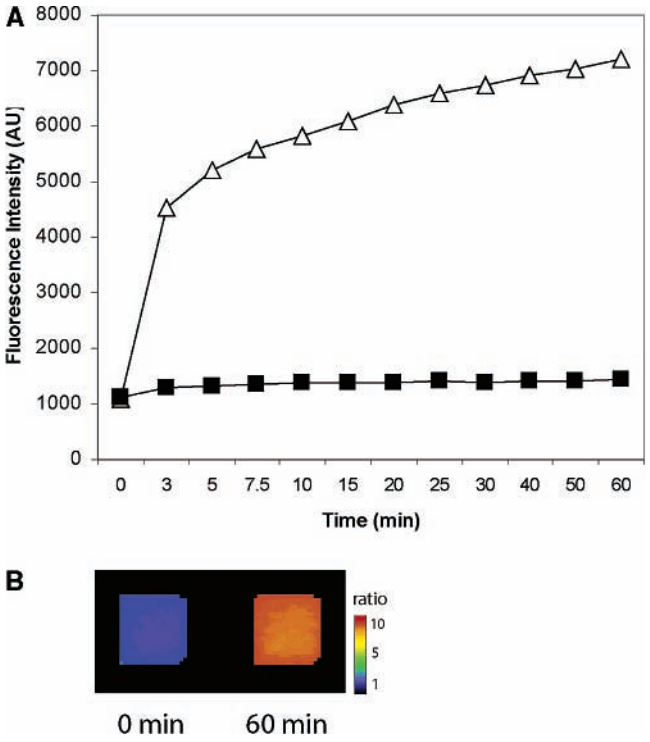

Figure 3. Activation of the dual fluorochrome probe Cy5.5−R4−Cy7−CLIO by trypsin. (A) Time-course measured with fluorescent plate reader. Cy5.5 fluorescence (Δ), Cy7 fluorescence (■). (B) Images representing ratio Cy5.5/Cy7 at 0 and 60 min of activation by trypsin. Orange color corresponds to probe activation or to a Cy5.5/Cy7 fluorescence ratio of about 7. Cy5.5 fluorescence is increased by proteolytic cleavage while Cy7 fluorescence is nearly constant.

about 1.7 was slightly higher than the ratio of native probe (1.0−1.2, see Figure 2). The slight probe activation presumably results from mixing at the interface between native probe (clear solution) with enzymes in liver tissue (brown tissue).

Imaging with Cy5.5−R4−Cy7−CLIO in Vivo. We next tested the ability of the dual fluorochrome probe to correct for differences in tumor size and depth in vivo. Nude mice bearing 9L GFP expressing gliosarcomas of different sizes (Figure 6) were injected with Cy5.5−R4−Cy7−CLIO. Cy5.5 and Cy7 fluorescence from tumors were then determined, where tumor borders (regions of interest) were defined by tumor GFP fluorescence using our previously described technique (*18*). Figure 6 shows white light, fluorescent, and Cy5.5/Cy7 ratio images for an intact animal with tumors of different size as dissection progressed. With the intact animal, the Cy5.5 and Cy7 fluorescence intensities of the two tumors were markedly different, a difference which was not seen on the ratio of Cy5.5/Cy7 image (top row, right image). The ratio of Cy5.5 to Cy7 fluorescence for the two tumors (12 mg and 195 mg) was further independent of dissection level. Results with variable tumor size were similar to in vitro results obtained with variable amounts of homogenate (Figure 4).

DISCUSSION

Here we report on a novel type of multimodal probe that features two fluorochromes covalently linked to an MRI detectable carrier (amino-CLIO), in which each fluorochrome responds differently to proteases. While we have utilized only the optical properties of the Cy5.5−R4−Cy7−CLIO probe, the superparamagnetic iron oxide core of the CLIO nanoparticle has potent relaxation enhancing properties and can be used in conjunction with MRI to determine probe location (*14*, *15*). The feasibility of optical- or magnetic resonance-based imaging in vivo using a probe similar to Cy5.5−R4−Cy7−CLIO but lacking Cy7 has been shown (*10*).

We have shown that fluorescent activation occurs, not by direct interaction between proteases or reducing agents and the fluorochrome, but with the transfer of the fluorochrome from the local environment of the nanoparticle to the bulk solvent (*10*). Cleavage of the bond between a fluorochrome and a nanoparticle has been achieved with proteases such as trypsin or with DTT (dithiothreitol). Use of the latter reagent requires disulfide-linked fluorochromes, synthesized by use of the bifunctional cross-linking agent *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP), in contrast to the bifunctional agent succinimidyl iodoacetate (SIA) used in the current study. DTT could not activate fluorescence when a thioether linkage was used to attach the fluorochrome to the nanoparticle (see Figure 3 of ref 10), and proteases could not activate fluorescence when protease resistant D-arginyl peptides were used to couple the fluorochrome to the nanoparticle (*13*). The activation of Cy5.5 fluorescence by trypsin of (700%, Figure 3A) therefore results from the proteolytic cleavage of the R4 peptide, which transfers Cy5.5 from the local environment of the nanoparticle to the bulk solvent. The much lower activation of Cy7 fluorescence (about 20% Figure 3A) reflects Cy7's direct attachment to the nanoparticle, its resistance to proteolysis, and the inability of the protease to affect a transfer to the bulk solvent.

A second feature of fluorescence quenching by nanoparticles is that when fluorochromes with widely different optical properties (fluorescein, Cy5.5, or Cy3) are attached to CLIO nanoparticles, significant quenching results (see ref 10 and Josephson, unpublished observations). Fluorescence quenching also occurs when fluorochromes are attached to colloidal gold (*19*). In the case of CLIO nanoparticles, quenching reflects two types of effects: interactions between fluorochromes on the nanoparticle, and interactions between fluorochromes and the nanoparticle itself. The effects of quenching due to fluorochrome/nanoparticle interaction, rather than fluorochrome/fluorochrome interaction, were evident from the synthesis of nanoparticles with as little as 0.14 fluorochromes (average per nanoparticle). Such probes still showed greater than 200% activation of fluorescence when treated by DTT, and the fluorochrome was transferred to the bulk solvent (*10*). For colloidal gold and the colloidal CLIO nanoparticle, a major mechanism of quenching is the interaction between the fluorochrome and the nanoparticles, which may reflect collisions of the dye against the nanoparticle surface (collisional or dynamic quenching) (*19*).

The value of the dual fluorochrome probe and related imaging methods is not related to the specific protease(s) responsible for fluorescence activation. As noted above, probes of this general design (high molecular weight carrier, linker peptide, fluorochrome) have been designed to image a wide variety of proteases by varying the structure of the linker peptide. Several factors suggest that the activation of the Cy5.5−R4−Cy7−CLIO probe described here results from cathepsin B activity. First, using specific protease inhibitors and macrophages in vitro, we have shown that the protease activating Cy5.5−R4−CLIO, the single fluorochrome version of the dual fluorochrome probe of the current study, was cathepsin B (*13*). Second, as noted, a nanoparticle probe made with

Liver is from mouse injected with Cy5.5−R4−Cy7−CLIO. (B) NIRF images of wells in A in the Cy5.5 and Cy7 channels and resulting ratio Cy5.5/Cy7 image (color-coded). Orange color corresponds to a Cy5.5/Cy7 ratio of about 7, which is characteristic of the activated probe. (C) Values of fluorescence intensity and the ratio of Cy5.5/Cy7 fluorescence obtained by region of interest analysis from images in B.

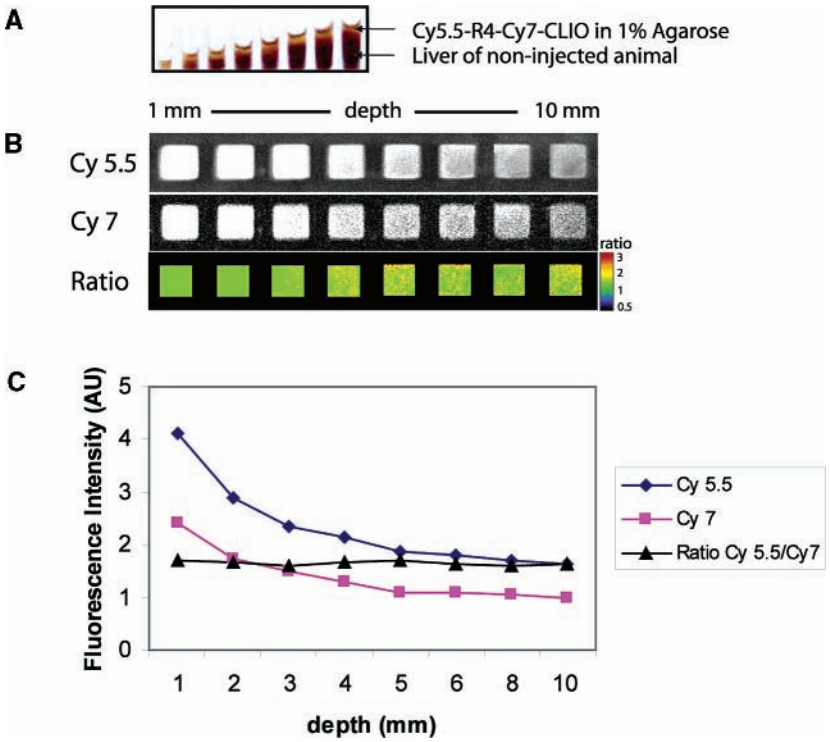

Figure 5. Dual fluorochrome probe imaging through different depths of liver tissue. (A) White light image of wells containing liver from a noninjected animal overlayed with a constant amount of Cy5.5−R4−Cy7−CLIO in 1% agar. (B) NIRF images of wells in A in the Cy5.5 and Cy7 channels and resulting ratio Cy5.5/Cy7 image (color-coded). (C) Values of fluorescence intensity and ratio of Cy5.5/Cy7 fluorescence obtained from images in B.

noncleavable D-arginine peptide spacer could not be activated by macrophages (*13*). Third, macrophages including Kupffer cells of the liver are high in cathepsin B (*20*−*22*). After injection, CLIO nanoparticles are removed by phagocytosis and are concentrated in high cathepsin B activity containing macrophages (*17*, *23*, *24*). Finally, cathepsin B hydrolyzes peptides with arginine in the S2 or S1 subsites of the protease, which are provided by L-polyarginine peptides used to couple the Cy5.5 due to the nanoparticle (*25*, *26*).

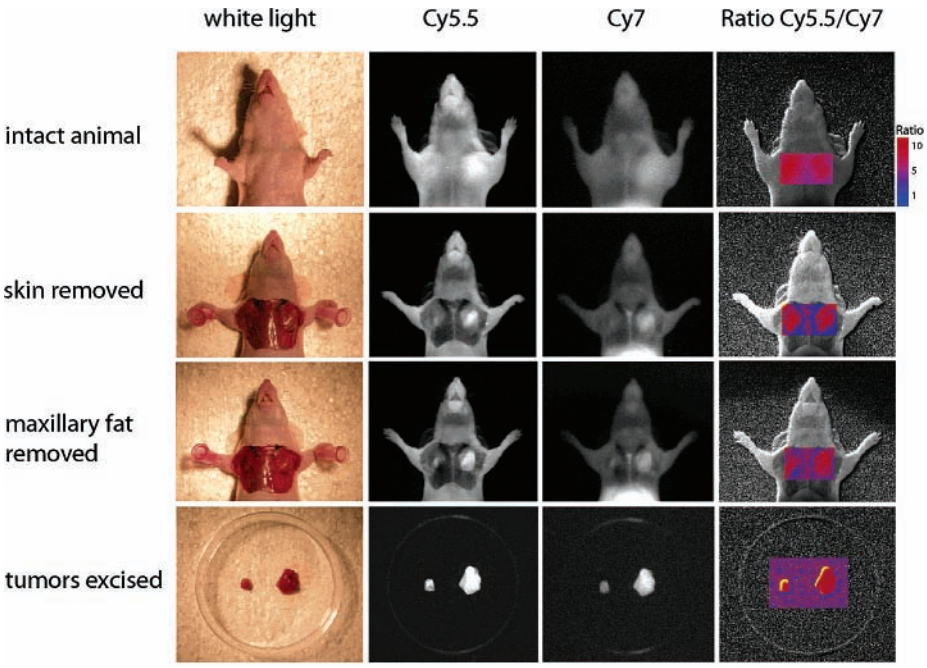

Figure 6. Dual fluorochrome ratio imaging of implanted 9L GFP expressing gliosarcoma tumors. A nude mouse bearing tumors of different sizes (12 mg (left) and 195 mg (right), respectively) implanted in the mammary fat pads was injected with Cy5.5−R4−Cy7−CLIO. From left to right are shown the white light image, the Cy5.5 fluorescent image, the Cy7 fluorescence image and the ratio of Cy5.5 to Cy7 fluorescence (color-coded). Note that despite the variation in signal intensity caused by the differences in tumor size and differences in dissection level (depth), the resulting ratio is similar reflecting the ability of the intenal standard Cy7 to correct for size and depth.

The optical properties of the Cy5.5 (ex 675, em 694) and Cy7 (ex 747, em 777) were found to be well suited to their use in dual fluorochrome probes. First, the fluorescence from each fluorochrome was detected without significant interference from each other (Figure 2). Second, the interaction between the two fluorochromes when attached to the probe was minimal. Proteolytic cleavage and transfer of Cy5.5 to the bulk solvent was associated with a 700% increase in fluorescence, while the increase in Cy7 fluorescence was only about 20% (Figure 3A), which presumably reflects interactions between Cy5.5 and Cy7. If Cy5.5 and Cy7 interacted strongly to quench each other, then both would be dequenched by proteolytic cleavage of either. Third, the ratio of Cy5.5 to Cy7 fluorescence reflected probe activation both in vitro and in vivo. Thus a value of 1 was characteristic of the probe before exposure to proteases but increased to 7 in the presence of protease (Figure 1). A similar value was obtained in liver homogenates after iv injection of the probe (Figure 4). Fourth, the ratio of Cy5.5 to Cy7 fluorescence was independent of sample size (Figures 4 and 6) and tissue depth (Figure 5).

The dual fluorochrome multimodal probe using the Cy5.5/Cy7 fluorochrome pair, and related dual fluorochrome imaging, may permit use of this type of probe to gather a new type of information with in vivo imaging, in addition to the corrections for lesion size and depth demonstrated here. Currently the interaction of a probe with a molecular target, such as a protease, can reflect both the activity of the molecular target enzyme in a specific tissue, and the transport and concentration of the probe in the vicinity of the molecular target. Factors affecting probe transport include blood flow, capillary permeability, capillary blood volume, and other physiological factors. In these studies the dual fluorochrome probe and imaging method provided information on probe activation that is independent of the absolute value of Cy5.5 fluorescence, which depended on parameters such as lesion size and depth. Hence with the dual fluorochrome probe design used here, the Cy7 fluorescence might provide an internal standard for determining probe concentration, allowing Cy5.5 fluorescence to be corrected for variable levels of probe transport. However, proof of this hypothesis that Cy7 fluorescence can yield probe concentration in vivo will require determination of probe concentrations by a suitable reference "gold standard" bioanalytical method. Such studies now appear warranted based on the properties of the Cy5.5−R4−Cy7−CLIO probe described here.

ACKNOWLEDGMENT

This study was funded by the NIH grants P50 CA8635 and R01 EB 001872. M.F.K. was supported by the German Research Foundation (DFG). We thank Edward E. Graves for assistance in computing ratio images.

Received September 30, 2003; Revised Manuscript Received December 23, 2003

Among the various synthetic gene carriers based on biomaterials, cationic polymers with polysaccharide backbones have long been studied as nonviral vectors due to their low immunogenicity and high water solubility. Schizophyllan, a β-(1,3)-glucan, is one of the various polysaccharides that are clinically administered. Furthermore, its safety in the human body has already been confirmed. Various functional groups can be selectively introduced into the side chain, not into the main chain of schizophyllan. Therefore, we have synthesized various oligoamine conjugates from schizophyllan. It was confirmed that their in vitro transfection efficiencies are superior to that of polyethylenimine by adjusting the molecular weight and the degree of amination of cationic schizophyllan. While it was possible to reduce cytotoxicity by adjusting the amount of DNA complex per cell, as seen with poly-L-lysine, polyethylenimine, and chitosan, PEGylation was the most effective means of reducing toxicity. Furthermore, using cationic schizophyllan carriers, it was also possible to express a reporter protein for a long period of time due to a long residence time of plasmid DNA in cells.

INTRODUCTION

Of the various ways of transferring exogenous genes into mammalian cells, biological techniques utilizing viral infectivity are advantageous in terms of high gene transfection efficiency and expression, but disadvantageous in terms of cost, immunogenicity, pathological infection, cancerization, and other virus-related safety issues (*1*). Therefore, safer nonviral vectors are being examined and studied more closely. Nonviral vectors can be roughly divided into two groups: cationic lipids and cationic polymers. In liposome-based gene transfection systems, liposomes are often formed from lipids associated with biological membranes in order to facilitate interactions with cell membranes and organelles, and the degree of antigenicity is low. However, liposome-based gene transfection systems are not suitable for repeated use due to high cytotoxicity. Although it has been reported that using PEGylated liposomes can reduce the degree of cytotoxicity, PEGylation decreases transfection efficiency (*2*). Toxicity is a major obstacle to using cationic lipids in gene therapy, and as a result, the level of interest in cationic polymer-based nonviral vectors shown by researchers is increasing. Research is actively being conducted on the use of dendritic structures (*3*−*6*) and polyethyleneimine (PEI) (*7*−*9*).

However, the transfection efficiency of cationic polymers is generally lower than that of cationic lipids and much lower than that of viral vectors. Moreover, the problem of toxicity is not completely resolved with cationic polymers (*10*), and studies on poly-L-lysine have reported that transfection efficiency and cell membrane toxicity exhibit a positive correlation (*11*). Therefore, when designing cationic polymers, strategies that use biocompatible or biodegradable materials and take cytotoxicity and degradation into account are often employed (*12*, *13*). Of the various biopolymers, cationic polymers with polysaccharide backbones have long been studied as nonviral vectors due to their low immunogenicity and high water solubility (*14*, *15*). However, the cytotoxicity of one such polymer, DEAE−dextran, is very high (*16*). In chitosan, DNA complexation occurs only under certain conditions, and a large amount of DNA is needed to achieve a sufficient level of gene expression (*17*, *18*). Furthermore, the transfection efficiency of chitosan, including chitosan derivatives, is insufficient (*19*).

Schizophyllan (SPG), a β-(1,3)-glucan, is one of the various polysaccharides that are clinically administered by the intramuscular route. The safety of this polysaccharide in the human body has already been confirmed: SPG has been injected intramuscularly as an adjuvant in the treatment of gynecological cancer for over 20 years (*20*, *21*). Moreover, its affinity to antigen-presenting cells in the immune system has been documented (*22*, *23*). Recently, Sakurai and Shinkai discovered that schizophyllan, naturally existing as a triple helix, can form a hetero-triple helix with a single chain of certain nucleotides when it is dissociated into a single chain (*24*, *25*). This characteristic also applies to other β-(1,3)-glucans: for example, molecular weight-dependent single-chain nucleotide affinity has been also confirmed with Curdlan, which does not have a glucose side chain (*26*). Further-

more, by utilizing this triple helix complex formation, β-(1,3)-glucans have been used as oligonucleotide carriers (*27*).

Schizophyllan is a β-(1,3)-glucan in which various functional groups can be selectively introduced into the side chain, but not into the main chain at all. In the present study, the usefulness of this polysaccharide as a backbone of a transfection agent of mammalian cells was investigated by introducing oligoamines into the side chain to increase the amount of its cationic charge, thus enhancing its affinity toward plasmid DNA.

EXPERIMENTAL PROCEDURES

Materials. Triple strand SPG with weight-average molecular weight (M_w) of 1.5×10^5 and the number of repeating units of 231, respectively, was kindly supplied from Taito Co. Ltd., (Kobe, Japan). Methoxy-polyethylenglycol succinimidyl propionates (m-PEG-SPA; M_w 2000 and 5000) were purchased from Shearwater (Huntsville, AL). PEI with molecular weight of 2.5×10^4 was purchased from Aldrich. *N*,*N*′-Bis(3-aminopropyl)-1,3-propanediamine, spermidine, and spermine were purchased from Across Organics (Geel, Belgium), sodium borohydride, 2-aminoethanol, and dextran (M_w 40000) were from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan), and sodium periodate was from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), respectively. Cell counting kit-8 containing WST-8 and 1-methoxyphenazinium methosulfate was purchased from Dojindo (Kumamoto, Japan). The fetal bovine serum (FBS), nonessential amino acids, and penicillin/streptomycin were purchased from Gibco/BRL. Dulbecco's modified Eagle's medium (DEMEM) and RPMI1640 were obtained from Nissui Pharmaceutical Co. Ltd (Tokyo, Japan). Other reagents and solvents were purchased from Aldrich or Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

Plasmids and Cells. pGL3-control was purchased from Promega (Madison, WI). pCMV^{tk}Luc was obtained from the American Type Culture Collection (Manassas, VA). pEGFP-Endo was purchased from Clonetech (Palo Alto, CA). Plasmid DNAs were amplified in *Escherichia coli* and purified by EndoFree Plasmid Kit (Qiagen, Hilden, Germany). Rhodamine-labled pGL3-control was prepared as described in the protocol of Label IT Rhodamine Nucleic Acid Labeling Kit (Mirus, Madison, WI). COS-1, CHO-K1, and HeLa cells were from the American Type Culture Collection. COS-1 and HeLa cells were cultured in DMEM containing 10% FBS, 100 units/mL penicillin, 100 μg/mL streptomycin without or with 0.1 mM nonessential amino acid, respectively. CHO-K1 cells were cultured in Ham's F12K medium, and the other conditions were the same as those of COS-1. The cell incubation was always carried out at 37 °C in a fully humidified air containing 5% CO_2.

Preparation of SPG Having Various Molecular Weights. Hydrolysis of SPG(150K) was carried out in 90% formic acid, and the resultant hydrolyzed mixture was purified by fractionate precipitation according to the reported method (*28*). The molecular weight of the samples obtained by fractionate precipitation was evaluated by gel permeation chromatography (GPC) on an AsahipackGS320-220 column (Asahi Kasei Co., Japan) at a flow rate of 1.0 mL/min in water. The molecular weight was calibrated by a pullulun standard (Hayashibara Biochemical Laboratories, Inc., Okayama, Japan). The molecular weight of the SPG was estimated to be 12000 (12K), 34000 (34K), and 80000 (80K), respectively.

Preparation of Various Amine-Conjugated SPGs. The general synthetic scheme is shown in Chart 1. To 100 mg of SPG(34K) sample dissolved in 100 mL of water was added 165 mg of sodium periodate (5 equiv for the repeating unit of SPG) in 2 mL of water. The mixture was stirred for 2 days at 4 °C. After dialysis with distilled water, the solution was lyophilized. The white solid thus obtained, and 2 mL of *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine was added into 20 mL of dimethyl sulfoxide and stirred for 2 days. After the reaction mixture became clear, 100 mg of sodium borohydride was added to the mixture to reduce the Schiff base formed. Excess sodium borohydride was quenched by acetic acid, and the solution was dialyzed with acidic water, basic water, and distilled water. After the removal of insoluble slug by centrifugation, the supernatant was lyophilized. Thus, we obtained APPD-SPG(34K). The degree of the introduced amine was evaluated as the amount of nitrogen% that determined by elemental analysis. The elemental analysis was carried out at least three times after thoroughly drying with phosphorus oxide, and the degree of amination was estimated to be 40.7 ± 1.2 mol %. Ethanolamine, spermidine, and spermine-conjugated derivatives were synthesized with similar method as mentioned above.

Table 1. Chemical Characterization of SPG Derivatives Conjugated with Various Oligoamines

APPD45(150K)	APPD	150000	6.39	4.56	45

Preparation of SPG with Various Degrees of Amination. When conjugating *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine to SPG with a molecular weight of 34000 Da, the amount of sodium periodate in relation to the glucose side chain was adjusted to 10, 40, 80, 150, or 500 mol %, and the subsequent reductive amination resulted in derivatives with a degree of amination of 3, 9, 18, 28, and 41%, respectively (Table 1). Degree of amination was assessed by an elemental analysis with an assumption that two amine molecules were introduced to the glucose side chain and was defined as the ratio of aminated glucose.

Preparation of Amine-Conjugated Dextran Derivative. To 200 mg of dextran dissolved in 200 mL of water was added 530 mg of sodium periodate (2.0 equiv for the glucose residue) in 2 mL of water. The mixture was stirred for 2 days at 4 °C. After dialysis with distilled water at 4 °C, the solution was lyophilized. The white solid thus obtained, and 2 mL of *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine was added into 20 mL of dimethyl sulfoxide and stirred for 2 days at 20 °C. After the reaction mixture became clear, 100 mg of sodium borohydride was added to the mixture to reduce the Schiff base formed. Excess sodium borohydride was quenched by acetic acid in the ice bath, and the solution was dialyzed with acidic water, basic water, and distilled water at 4 °C. After the removal of insoluble slug by centrifugation, the supernatant was lyophilized. Thus, we obtained APPD-DEX. The degree of the introduced amine was evaluated as the amount of nitrogen% that determined by elemental analysis. The elemental analysis was carried out at least three times after thoroughly

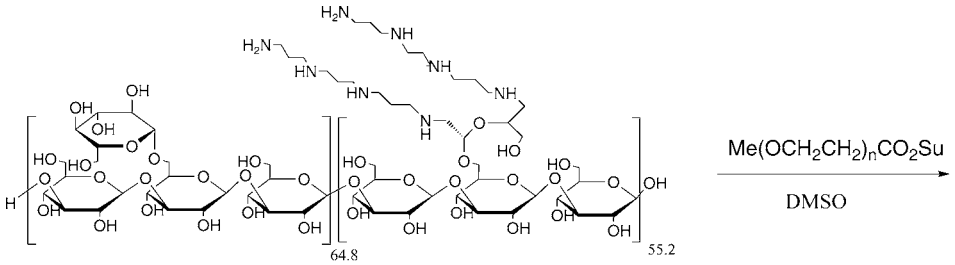
Table 2. Chemical Characterization of PEGlyated Derivatives

conjugates	*M*w of PEG	N% (found)	μmol/mg (protonable N)
2KPEG-APPD46(80K)	2000	3.93	2.21
5KPEG-APPD46(80K)	5000	1.22	0.71
5KPEG-APPDDEX	5000	1.87	1.08

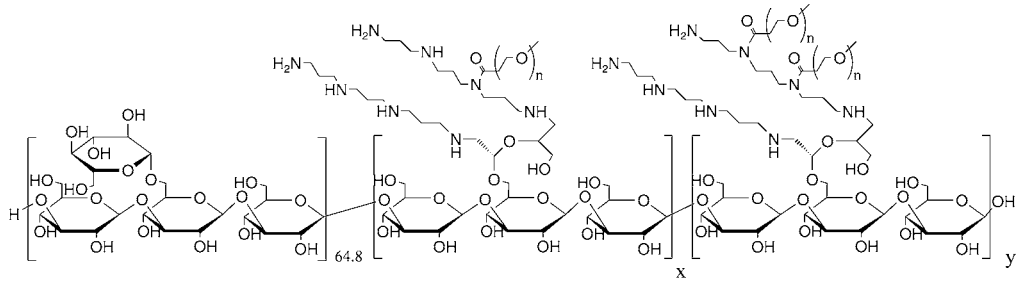
drying with phosphorus oxide, and the degree of amination was estimated to be 34.3 ± 1.3 mol %.

PEGylation of Cationic SPG and Dextran. *N*,*N*′-Bis(3-aminopropyl)-1,3-propanediamine-conjugated polysaccharides (APPD46(80K) and APPD34DEX; 20 μmol of protonable nitrogen atom) were mixed with methoxy-poly(ethylen glycol) succinimidyl propionates (m-PEG-SPA; M_w 2000 or 5000, 2.5 mol % to protonable nitrogen atom) in dry DMSO (1 mL) (Scheme 1). After being gently shaken at room temperature for 24 h, the reaction mixture was poured into Milli-Q (5 mL). PEGylated compounds were purified with ultrafiltration Centricon Plus-20 (nominal molecular weight limit = 10 kDa, Millipore, Bedford, MA) followed by lyophilization. Products were characterized by elemental analyses (Table 2). The yield of 2KPEG-APPD46(80K), 5KPEG-APPD46-(80K), and 5KPEG-APPDDEX was 89%, 81%, and 77%, respectively. The degree of modification of primary amino groups of introduced amine residues of oligoamine-conjugated schizophyllan can be determined by a ninhydrin assay in a manner similar to Wagner's report (*29*). We have confirmed no decrease in free primary amino groups.



Transfection. In general, COS-1 cells (3×10^4 cells for an each well) were grown to just before confluence in a 24-wells culture plates (Techno Plastic Products, Trasadingen, Switzerland) in DMEM with 10% FBS and 100 U/mL penicillin and 100 μg/mL streptomycin in an atmosphere of 5% CO_2 at 37 °C and washed twice with 0.5 mL of PBS. 10% PBS was prepared by dilution of PBS with Milli-Q water to decrease the ionic strength. Transfection was performed with 1 μg plasmid DNA for each well. Basic protocol includes 3 h of transfection time and 48 h of post-transfection time. Luciferase assays were performed as described in the protocol of Steady-Glo Luciferase Assay System (Promega, Madison, WI). Luciferase relative light units (RLU) were analyzed by luminometer Fluoroskan Ascent-FL (Thermo Labsystems, Finland). The protein concentrations of the cell lysates were measured as described in the protocol of NanoOrange Protein Quantitation Kit (Molecular Probes, Eugene, OR) using bovine serum albumin as a standard. The measurement of transfection efficiency was performed in triplicate. To evaluate the effect of backbone on long-term expression, COS-1 cells (1×10^4 cells for an each well) were plated in 12-well culture plates (Techno Plastic Products, Trasadingen, Switzerland), and then the luciferase assay was performed with 4, 7, 14, 21, and 28 days of post-transfection time.

Cytotoxicity. Cells (6×10^3 cells for each well) were seeded in 96-well plates (Techno Plastic Products, Trasadingen, Switzerland) and allowed to attach to the plate for overnight. In the following day, the medium was changed for a fresh medium, and cells were treated with same conditions as transfection. After change of medium, cells were incubated for 48 h before measurement of the cell viability. The viable cell number was estimated by use of Cell Counting Kit-8, called WST assay. WST assays were performed as described in the protocol of Cell Counting Kit-8. Plates were read on microplate reader Multiskan Acent (Thermo Labsystems, Finland). The absorbance was measured at 450 nm. The protein concentrations of the cell lysates were measured as described previously. The measurement of cell viability was performed in sextuplicate.



Agarose Gel Retardation Assay. Plasmid DNA binding was studied by mean of agarose gel retardation assays. Plasmid DNA (1 μg) and increasing amounts of cationic polymer were each diluted in 20 μL of 100 mM NaCl and mixed for complexation in which the amino groups/phosphate groups ratios (N/P ratio) were 0, 0.5, 1, 1.5, 2, 2.5, 3, and 5, respectively. After 20 min of incubation at room temperature, samples (10 μL) with the gel loading buffer (2μL) were electrophoresed through 1% agarose gel for 40 min at 100V. TBE (45 mM Tris-borate and 1 mM EDTA, pH8.0) buffer was used as an electrophoresis buffer. DNA was visualized after ethidium bromide staining.

Ethidium Bromide Competitive Binding Assay. The efficiency of DNA compaction mediated by cationic

2KPEG-APPD46(80K): (x, y) = (16.6, 38.6)
5KPEG-APPD46(80K): (x, y) = (27.6, 27.6)

polymers was evaluated using fluorescence quenching method. It is based on the use of ethidium bromide, a DNA-intercalating agent; its fluorescence is importantly enhanced upon binding to DNA and quenched by the dissociation of complex. Increasing amounts of cationic polymers based on SPG or PEI were added to the complex of 2 μg DNA with 2 μg of ethidium bromide. The fluorescence (λ_{ex} = 485 nm and λ_{em} = 590 nm) is reported relative to the value obtained in the absence of the carrier (after subtraction of the inherent fluorescence of ethidium bromide) using by a fluorescence spectrometer RF-5000 (Shimazu, Kyoto, Japan).

Intracellular Trafficking of Internalized DNA Complex. COS-1 cells were plated at a density of 5 × 10^3 cells/150 μL on a 10-mm glass-bottom dish (Matsunami Glass, Kishiwada, Japan) and cultured overnight to attain complete adhesion. In the first step, COS-1 cells were transfected with 1 μg of pEGFP-Endo gene for 3 h. In the next step, after 12 h of post-transfection period, 1 μg of rhodamine-labled pGL3-control complex with APPD46(80K) at N/P ration of 10 was prepared and added to cells. After 1.5 h of incubation at 37 °C in a 5% CO_2 incubator, the cells were then washed twice with PBS (125 μL), fixed with 4% HCHO (80 μL), and 1 wt% DAPI/methanol (20 μL) at 4 °C for 15 min, and examined by confocal fluorescent microscopy. Images of the samples were collected by fluorescence microscopy on IX-70 (Olympus, Tokyo, Japan), attaching a confocal scan unit CSU-10 (Yokogawa, Tokyo, Japan) with ORCA-ER CCD Camera (Hamamatsu Photonics, Hamamatsu, Japan) using a 40 × Uapo/340 objective with NA 0.9.

Residence Time Measurement of Intact Plasmid in COS-1 Cells. Transfected COS-1 cells with 1 μg of pCMVtkLuc in 12-well plates for long-term expression were used to isolate intact plasmid DNA remaining after long post-transfection time. After 2, 7, 14, 21, and 28 days of post-transfection time, COS-1 cells were trypsinized and collected in microtubes. Isolation of intact plasmid DNA from cell pellets was performed with a QIAprep Spin Plasmid Kit (Quagen, Hilden, Germany) (*30*). Yields of intact plasmid DNA isolated were compared by transforming *E. coli* strain as follows. Isolated plasmid DNA was dissolved in 10 μL of Milli-Q and transformed into 100 μL competent cells of *E. coli JM109* (Nippongene, Toyama, Japan) with a heat shock method. The number of transformants was compared. The measurement of remaining intracellular plasmid DNA was performed in triplicate.

RESULTS

Structural Influence of Amines Introduced into the Side Chain. Schizophyllan has a β-(1,3)-glycoside bond as its backbone and three glucose residues as repeating units. The second residue of the repeating units binds with the glucose side chain via β-(1,6)-glycoside. Periodate oxidation only affects the 1,2-diol groups in the side chain, and as a result, aldehyde groups can be introduced only to the side chain, leaving the main chain intact (*31*, *32*). Furthermore, since various amines can be introduced by reductive amination, it is possible to prepare various amine-modified cationic schizophyllans (*33*). In the present study, amine-conjugated SPG carriers were prepared using the following amines: ethanolamine, spermidine, spermine, and *N,N′*-bis(3-aminopropyl)-1,3-propanediamine (Chart 1, Table 1). Compounds are denoted with the code that represents structure of amine by capital letters, the degree of amination of side chain by percentage, and molecular weight of original SPG in parentheses, in this order. Each amine-conjugated SPG derivative was synthesized according to Chart 1. The transfection efficiency and cytotoxicity of each of these SPG derivatives were assessed (Figure 1). To achieve maximum amination to one part of the glucose side chain, 5 parts of sodium periodate and 100 parts of amine compounds were added as reported previously (*33*). The products were identified by various spectroscopic

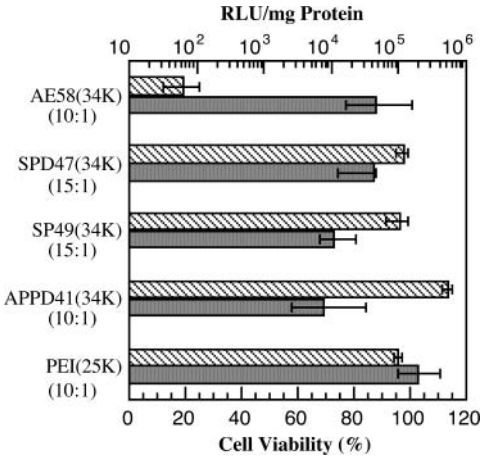

Figure 1. Comparison of transfection efficiency and cytotoxicity of DNA complexes with various oligoamine-conjugated SPG in COS-1 cells at selected N/P ratios. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein on the upper ordinate. Cell viability is shown as percentage of living cells on the lower ordinate.

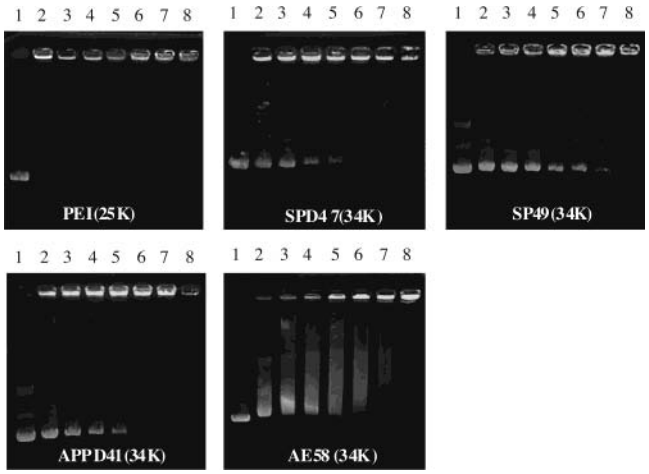

Figure 2. DNA binding was studied by means of an agarose gel retardation assay. Plasmid DNA (1 μg) and increasing amounts of cationic polymer were each diluted in 20 μL of 100 mM NaCl and mixed. After a period of 15 min, samples (10 μL) were electrophoresed through a 1% agarose gel. Lanes 1 to 8: (1) naked DNA, (2−8) cationic polymer/DNA complexes at N/P ratios equal to 0.5, 1, 1.5, 2, 2.5, 3, and 5, respectively.

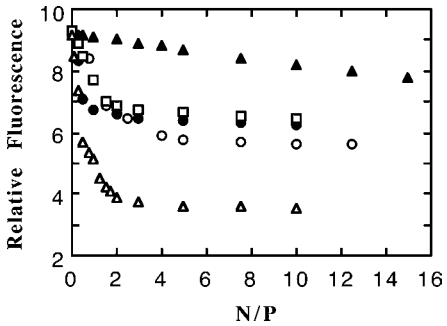

Figure 3. Competitive binding of ethidium bromide toward plasmid DNA in poplyplex with AE58(34K) (closed triangle), APPD41(34K) (open square), SPD47(34K) (closed circle), SP49-(34K) (open circle), and PEI (open triangle). Increasing amounts of cationic polymer were added to 2 μg DNA and to the resulting 2 mL of complex in PBS was added 2 μg of ethidium bromide.

methods. The content of amino groups was estimated with elemental analyses as summarized in Table 1. The results of in vitro transfection efficiency of amine-conjugated SPG showed that when compared to branched PEI with a molecular weight of 25000, a commercially available polycation with high transfection efficiency (*7*), transfection efficiency of the ethanolamine derivative (AE58(34K)) was lower, but those of the oligoamine derivatives, spermidine (SPD47(34K)), spermine (SP49-(34K)), and *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine (APPD41(34K)), were comparable or higher. In particular, the transfection efficiency of APPD41(34K) was about five times greater than that of PEI. We can suppose that all of amino groups are not necessarily protonated at physiological pH. Therefore, we can denote the N/P ratio as the number polymer nitrogen per DNA phosphate and not as a charge ratio. Transfection efficiency was dependent on N/P ratio, with carriers having SPG as the backbone exhibiting the highest transfection efficiency with N/P ratios of 10−15. Under this transfection condition, cytotoxicity was assessed in terms of cell viability with the WST assay (*34*). The results showed that the number of viable cells was high for the ethanolamine derivative, which had low transfection efficiency (about 0.01% of that for APPD41(34K)). Hence, one can recognize the general tendency that the greater the transfection efficiency, the lower the cell viability.

So the question arises: how does the amine structure affect the physical properties of polymers to improve transfection efficiency? To find an answer for this, we examined the affinity of each cationic SPG derivative toward plasmid DNA by agarose gel electrophoresis and ethidium bromide competitive binding. The results of electrophoresis (agarose gel retardation assay) showed the level of DNA affinity to be highest for PEI, followed by SPD47(34K), APPD41(34K), SP49(34K), and AE58-(34K), in this order (Figure 2). Nonetheless, under the transfection conditions with N/P of 10−15, all derivatives formed DNA complexes. Ethidium bromide competitive binding assay can assess plasmid compaction, which reflects polycation and polyanion binding (*35*). The degree of decrease in the fluorescence intensity of ethidium bromide was greatest for PEI, followed by SP49(34 K), SPD47(34 K), APPD41(34 K), and AE58(34 K), in this order (Figure 3). Hence, there was no clear correlation with transfection efficiency.

Molecular Weight Dependence of the SPG Backbone. Using the *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine derivative, we attained the highest transfection efficiency among the different amine derivatives, so that the effects of the molecular weight of the SPG backbone on transfection efficiency and cytotoxicity were investigated with these homologues (Figure 4). Derivatives having backbones with a molecular weight of 12000, 34000, 80000, or 150000 Da were subjected to the maximum amination. The results showed that the transfection efficiency of the APPD37(12K) and APPD45(150K) is lower than that of PEI, while that of the APPD41(34K) and APPD46(80K) is greater than that of PEI. In particular, the transfection efficiency of APPD46(80K) was about eight times greater than that of PEI. Hence, the existence of an optimal range of molecular weight for transfection efficiency was clarified. When cytotoxicity was investigated under the transfection conditions, the tendency appeared that the greater the transfection efficiency, the lower the cell viability: cytotoxicity was the highest for the APPD46(80K), followed by the APPD41(34K), APPD45(150K), and APPD37(12K), in this order, thus confirming the relationship between transfection efficiency and cytotoxicity as reported with poly-L-lysine (*11*).

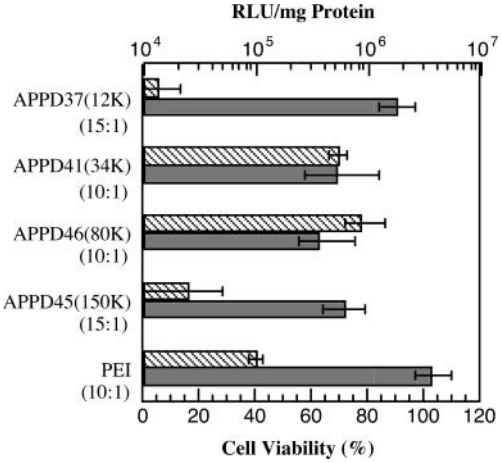

Figure 4. Comparison of transfection efficiency and cytotoxicity of DNA complexes with various molecular weights of based SPG in COS-1 cells at selected N/P ratios. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein on the upper ordinate. Cell viability is shown as percentage of living cells on the lower ordinate.

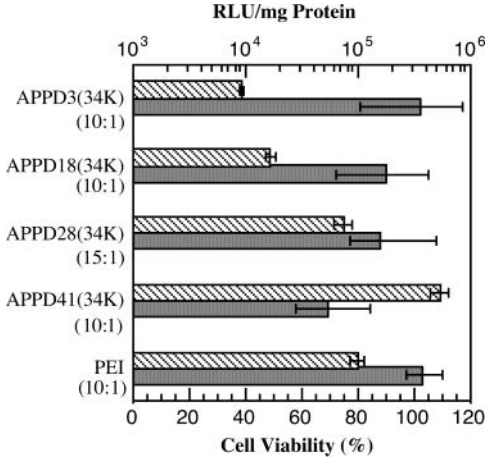

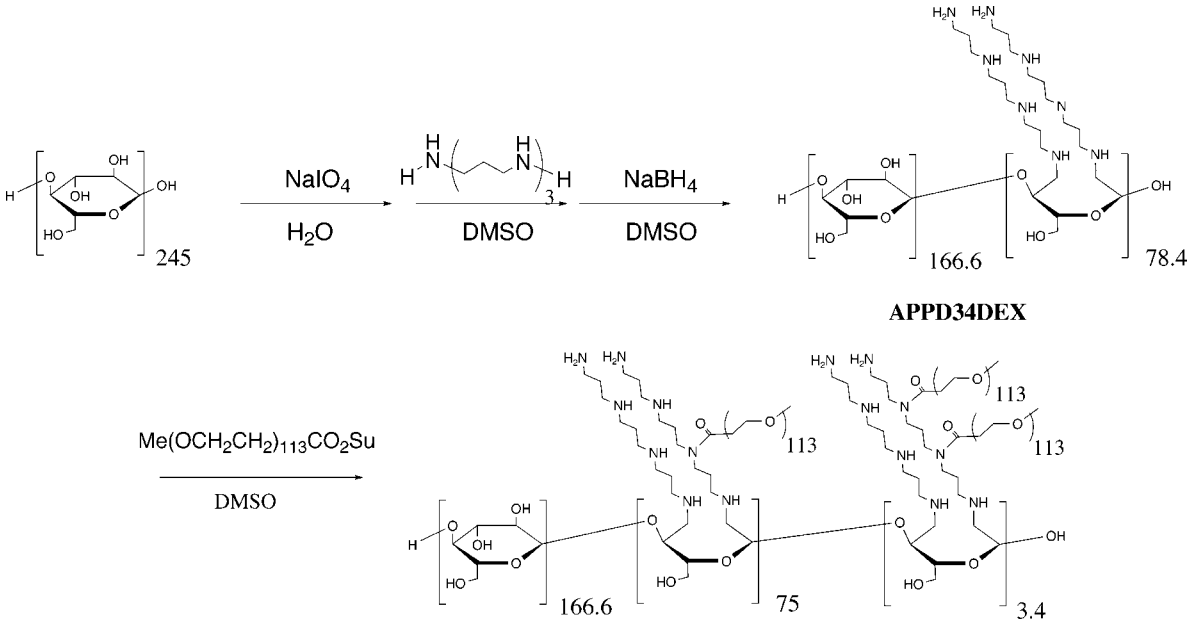

Figure 5. Comparison of transfection efficiency and cytotoxicity of DNA complexes with various degree of amination of side chain of SPG with a molecular weight of 34000 in COS-1 cells at selected N/P ratios. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein on the upper ordinate. Cell viability is shown as percentage of living cells on the lower ordinate.

Influence of Amination Degree. Concerning the influence of the amine structure on transfection efficiency, oligoamine derivatives exhibited greater transfection efficiency than monoamine derivatives, thus suggesting the importance of cation density. The amination degree in the side chain was therefore adjusted by varying the amount of periodic acid, to ascertain the effects of amination on transfection efficiency and cytotoxicity (Figure 5). Degree of amination was assessed by elemental analysis with an assumption that two amine groups were introduced into the glucose side chain and was defined as the ratio of aminated glucose. When conjugating *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine to SPG with a molecular weight of 34000 Da, the amount of sodium periodate with respect to the glucose side chain was adjusted to 10, 40, 80, 150, or 500%, and the subsequent reductive amination resulted in derivatives with a degree of amination of 3, 9, 18, 28, and 41%, respectively (Table 1). The tendency observed here was that the greater the degree of amination, the greater the transfection efficiency. In other words, transfection efficiency for the derivative with 41% amination (APPD41-(34K)) was the highest and was about five times greater than that of PEI. Furthermore, cytotoxicity was assessed under the transfection conditions. The results again showed the tendency that the greater the transfection efficiency, the lower the cell viability.

Comparison to Carriers Possessing a Dextran Backbone. Domb and colleagues synthesized cationic polysaccharides made of dextran, arabinogalactan, or pullulan (*15*), but not schizophyllan, by subjecting the main chain to periodate oxidation and introducing many

Scheme 2. Synthetic Scheme of PEGylated *N*,*N*′-Bis(3-aminopropyl)-1,3-propanediamine-Conjugated Dextran with a Molecular Weight of 40000

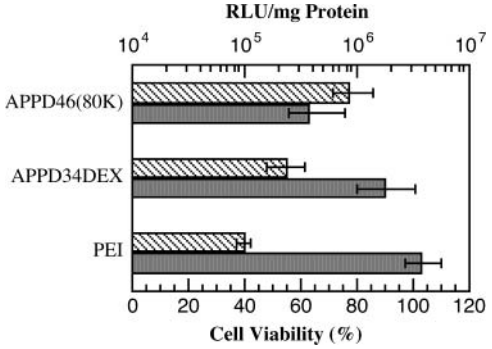

Figure 6. Comparison of transfection efficiency and cytotoxicity of DNA complexes with cationic polymer possessing a backbone consisting of SPG or detran in COS-1 cells at an N/P ratio of 10:1. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein on the upper ordinate. Cell viability is shown as percentage of living cells on the lower ordinate.

oligoamines by reductive amination. They reported that transfection efficiency was high when oligoamines were introduced into dextran. Therefore, in the present study, we compared transfection efficiency between dextran, which has mainly α-(1,6)-glycoside bonds and oligoamines introduced into the main chain, and schizophyllan, which has β-(1,3)-glycoside bonds and oligoamines introduced into the side chain. According to Domb et al., a dextran derivative with ca. 11% N amination with *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine was able to maximize transfection efficiency. So, we synthesized *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine-conjugated dextran according with Scheme 2. The results (Figure 6) showed that when compared to this dextran derivative (APPD34-DEX), transfection efficiency of APPD46(80K) was greater although the cytotoxicity of the schizophyllan derivative was higher.

Conditions for DNA Complexation. The particle size of cationic polymer/DNA complexes usually increased with time (*36*). In addition, a close correlation has been documented between the transfection efficiency of cationic polymers and the particle size of DNA complexes (*37*). Therefore, to ascertain the effects of the duration of DNA complexation on the transfection efficiency of APPD46(80K), which exhibited the highest transfection efficiency, the duration of DNA complexation was set at 30 min or 12 h. With PEI, the transfection efficiency of the longer complexation times was markedly lower (80% decrease), but with APPD46(80K), that of the longer complexation times (12 h) was only slightly decreased (10% decrease).

The complexation of a polyamine compound with polyanionic plasmid DNA is due to polyion complexation based on electrostatic interactions. Therefore, the complexation is largely influenced by the dielectric constant of the medium. Furthermore, solvents used for complexation could contribute to cytotoxicity. Hence, the influence of complexation solvents was examined. The results showed that the transfection efficiency for complexation using 10% PBS without any organic solvent such as DMSO or glycerol was higher than that for complexation using organic solvents. Also, the transfection efficiency of complexation using PBS with a high ionic strength was lower than that for complexation using 10% PBS.

In Vitro Transfection Conditions. Using a 24-well plate, the number of cells per well was increased from the conventional number of 30000 to 50000, 70000, or 90000 in order to reduce cytotoxicity by lowering the

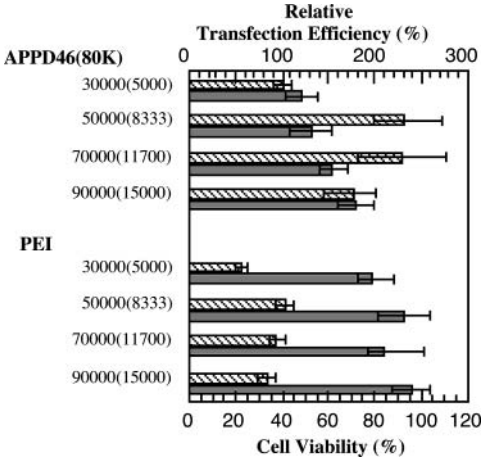

Figure 7. Comparison of transfection efficiency and cytotoxicity of DNA complexes with APPD46(80K) and PEI in COS-1 cells at an N/P ratio of 10:1 and different number of cells per well. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is reported to the efficiency at the number of 30000 (=100%) on the upper ordinate. Cell viability at various numbers in parentheses is shown as percentage of living cells on the lower ordinate.

amount of cations per cell. Also, in a WST assay on toxicity using a 96-well plate, 5000, 8333, 11700, or 15000 cells were placed in each well. As a carrier possessing a schizophyllan backbone, APPD46(80K) was used owing to its high transfection efficiency. The results (Figure 7) showed the tendency that the greater the number of cells, the higher the cell viability under the transfection conditions. However, the level of luciferase expression per unit protein was the highest for 50000 cells.

Furthermore, in transfection, serum proteins such as albumin and globulins strongly interact with cationic compounds. In addition, the presence of serum generally lowers the transfection efficiency of nonviral vectors. However, serum has beneficial effects on cell viability, thus affecting cytotoxicity. Therefore, the influence of serum on transfection was assessed. As expected, the level of cytotoxicity was higher without serum; however, the presence of serum did not markedly lower the transfection efficiency (5% decrease). Moreover, the optimal P/N ratio for transfection with serum was 10, whereas without serum less cation was required (P/N ratio = 5).

Plasmid and Cell Types. In COS-1 cells infected with the SV-40 virus, when pGL3-control possessing an SV-40 promoter is used as an expression vector, the plasmid is replicated inside the cells (*38*), thus making it possible to prepare a more sensitive experimental system. However, a good plasmid vector is one that can efficiently transfer various genes to many different cells. Hence, a comparison was made with the pCMV^{tk}Luc plasmid (*39*), which has a cytomegalovirus promoter, using COS-1, CHO-K1, and HeLa cells (Figure 8). The results showed that the present transfection conditions (N/P ratio, complexation time, solvent usage, plasmid usage, transfection time, and post-transfection time) were optimal for transfecting COS-1 cells with pGL3-control, and that the transfection efficiency is highest for COS-1 cells. Regardless of the plasmid types, the transfection efficiency of APPD46(80K) was higher than that of PEI for COS-1 cell. However, the results varied among the different cell lines, thus clarifying that transfection efficiency is largely dependent on cell/plasmid combinations.

Cellular Uptake Mechanism. It is known that the positively charged polyplexes electrostatically interact

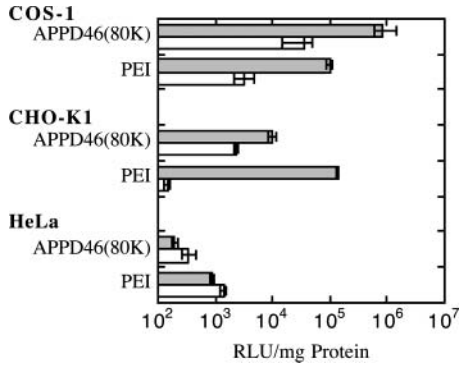

Figure 8. Comparison of transfection efficiency and cytotoxicity of DNA complexes with APPD46(80K) and PEI in various cells at an N/P ratio of 10:1. Gray bars indicate the relative transfection efficiency using pGL3-cntrol and white bars indicate that of pCMV^{tk}Luc. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein.

with negatively charged proteoglycans of the plasma membrane (*40*). Then, endocytosis is generally involved in the cellular uptake of plasmid DNA using nonviral vectors without ligands exhibiting affinity to certain receptors, and this also applied to the cellular uptake of cationic SPG carriers. Therefore, we have confirmed the mechanism of cellular uptakes by previously reported method (*41*). The intracellular trafficking of internalized plasmid DNA was directly observed by confocal fluorescence microscopy. In the first step, COS-1 cells were transfected with pEGFP-Endo gene. It is known that expressed RhoB-fused green fluorescent proteins localize in endosome since RhoB has an endosomal localization signal (*42*). At transfected COS-1 cells, therefore, the lipid membrane of endocytic vesicles can be visualized green. In the next step, a rhodamine-labled DNA complex with APPD46(80K) was prepared and added to cells. As was the case with the transfection, after 1.5 h of incubation, the cells were fixed and examined by confocal fluorescent microscopy. The result in Figure 9 represented that the localization of the red fluorescence for administered plasmid DNA mostly matched the green fluorescence for the lipid membrane of endocytic vesicles. This finding indicates the internalization of the DNA complex by endocytosis.

Reduced Toxicity Due to PEG Modification. The relationship between cytotoxicity and transfection efficiency has been investigated using many cationic polymers, and the tendency that higher transfection efficiency is associated with higher cytotoxicity has been recognized (*11*). One of the important factors for transfection efficiency is cytoplasmic transport of DNA complexes. Carriers with high transfection efficiency is first adsorbed electrostatically to a cell membrane, and their cell membrane toxicity causes instability in the membrane structure, thus increasing the cellular uptake. As a result, the subsequent research has been directed toward the reduction of cytotoxicity by shielding cationic charges with poly(ethylene glycol) chains (*29*, *35*).

In the present study, after PEGylation of the amino groups of cationic schizophyllan and dextran, cytotoxicity and transfection efficiencies were estimated (Schemes 1 and 2, Table 2, Figure 10). When a poly(ethylene glycol) chain with a molecular weight of 2000 or 5000 was introduced into APPD46(80K), cytotoxicity was reduced as expected, but transfection efficiency was also decreased. Nonetheless, the cytotoxicity of the derivative with 5000 Da PEG (5KPEG-APPD46(80K)) was almost nonexistent, and its transfection efficiency was still greater than that for PEI and PEGlyated dextran derivative (5KPEG-APPDDEX).

Long-Term Expression. One of the factors influencing the expression efficiency of nonviral vectors is intracellular DNA release. If a carrier is biodegradable, DNA release should occur efficiently (*43*−*45*). The backbone of cationic schizophyllan carriers is β-(1,3)-glucan; however, β-(1,3)-glucanase does not exist in animal cells (*46*). In other words, β-(1,3)-glucan is decomposed simply by hydrolysis, and as a result, the rate of decomposition is expected to be much slower than those catalyzed by enzymes. In the present study, the expression of a reporter protein was measured by extending the length of the post-transfection period from 2 days to 7, 14, 21, and 28 days in order to assess long-term protein expression.

In relation to the level of luciferase expression at 2 days after transfection, those at 7 14, 21, and 28 days after transfection were determined for each carrier (Figure 11). When compared to dextran derivatives (PEG-APPDDEX) which are biodegraded enzymatically in animal cells (*47*), the transfection efficiency of PEG-APPD46(80K) was obviously higher for 7−28 days after transfection, thus clarifying the ability of SPG carriers to express a target protein for a long period of time.

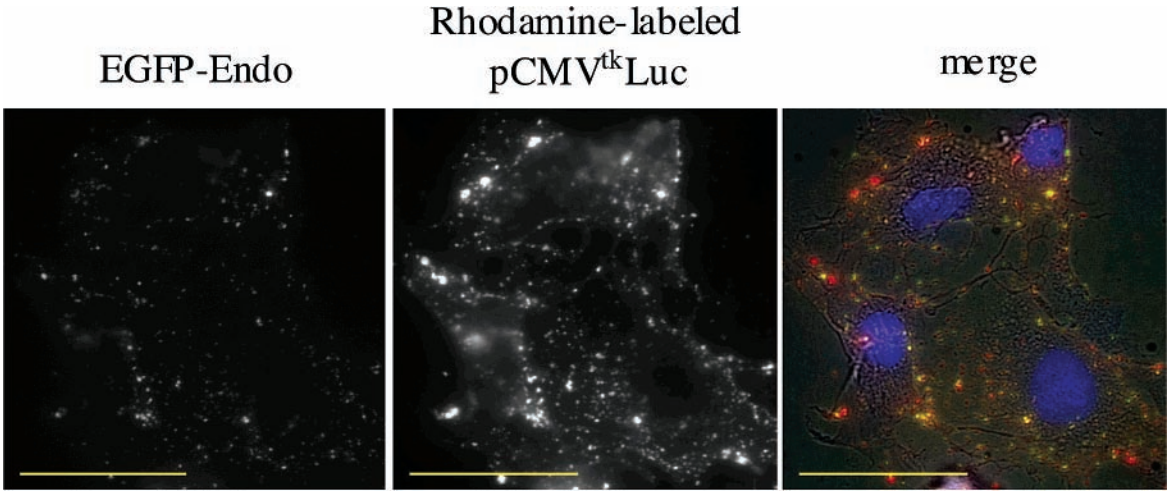

Figure 9. Rhodamine-labeled pCMV^{tk}Luc DNA (red) was internalized with APPD46(80K) into COS-1 cells transfected with pEGFP-Endo. Nuclei are post-stained with DAPI (blue) and endocytic vesicles are visualized by membrane-localized EGFP (green). Bar: 50 μm.

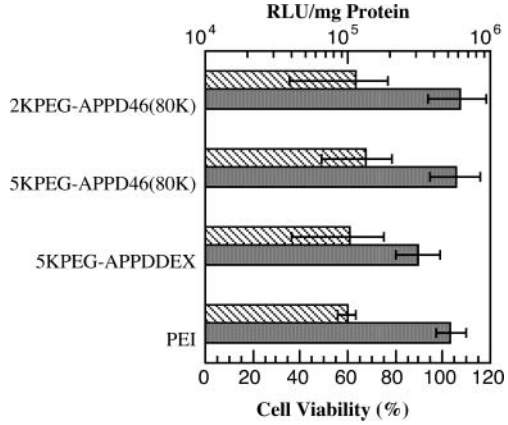

Figure 10. Comparison of transfection efficiency and cytotoxicity of DNA complexes with PEGlyated cationic polymers in COS-1 cells at an N/P ratio of 10:1. Slashed bars indicate the relative transfection efficiency and shaded bars indicate the cell viability. Relative transfection efficiency is shown as relative light units (RLU)/mg of protein on the upper ordinate. Cell viability is shown as percentage of living cells on the lower ordinate.

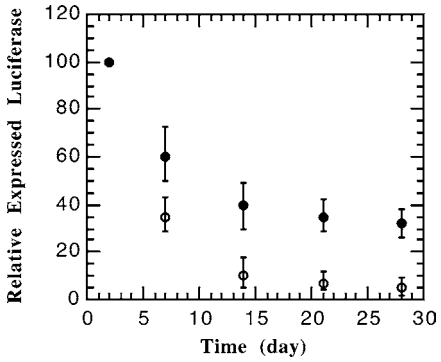

Figure 11. Comparison of long-term transfection efficiency in COS-1 cells at an N/P ratio of 10:1 with PEG-APPD46(80K) (closed circle) and PEG-APPD-DEX (open circle). Relative transfection efficiency is reported to the amounts of expressed luciferase with post-transfection time of 2 days (=100%).

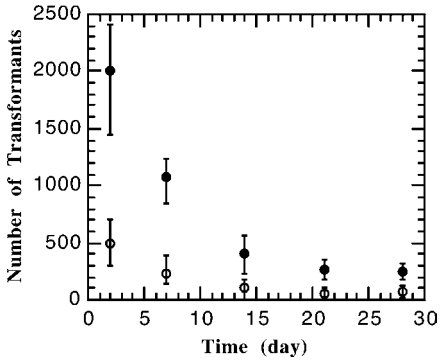

Figure 12. Comparison of the number of transformants using long-residence time plasmid DNA in COS-1 cells (1×10^4) transfected with pCMV^{tk}Luc (1 μg) complexes with PEG-APPD46(80K) (closed circle) and PEG-APPD-DEX (open circle).

Residence Time Measurement of Intact Plasmind in COS-1 Cells. We determined the time course of remaining intracellular plasmid DNA in transfected COS-1 cells with 1 μg of pCMVtkLuc (Figure 12). Number of transformants due to isolated plasmid DNA after long-term post-transfection indicated that amounts of remaining plasmid DNA decreased rapidly with dextran derivatives (PEG-APPD-DEX). In contrast, when compared to this dextran derivative, more than 4-fold amount of plasmid DNA remained intact with PEG-APPD46(80K) after 4 weeks of post-transfection time.

DISUCUSSION

Of the various polyamines, the transfection efficiency for PEI is higher than that for PAMAM dendrimers (*48*). With PEI, genes can be efficiently transferred to various cells both in vitro and in vivo (*7*−*9*). In PEI, nitrogen accounts for one in every three main-chain atoms, and the polyamine consists of 25% primary amine, 50% secondary amine, and 25% tertiary amine. Furthermore, PEI forms homogeneous and condensed DNA complexes, thus contributing to efficient cellular uptake (*8*). The proton sponge hypothesis has been proposed to explain the high gene expression exhibited by PEI (*7*, *49*); however, while escape of DNA from lysosomal DNA decomposition might play a role, no conclusive evidence has been found. In any case, it appears certain that in PEI the high cation charge density (5.3 μmol N/mg) plays an important role. Therefore, when developing a polyamine transfection agent, it is important to increase the amount of protonable nitrogen atoms. In the present study, among the derivatives with a molecular weight of 34000 Da, the degree of modification of the glucose side chain was high (58%) for AE58(34K), an ethanolamine (monoamine) derivative, but its nitrogen content was not particularly high at 1.7 μmol of nitrogen atom per mg. An agarose gel retardation assay showed that, under the transfection condition (N/P = 10), all DNA fragments formed complexes with AE58(34K), but their ion pair formation was very loose, and a competitive binding assay using ethidium bromide suggested the absence of compaction. On the other hand, with oligoamines such as spermidine, spermine, and *N*,*N*′-bis(3-aminopropyl)-1,3-propanediamine, the nitrogen content was high at 3.7, 4.8, and 4.2 μmol N/mg, respectively, and these figures were closer to that for PEI. In addition, the transfection efficiency for these derivatives was high. Interestingly, of the various derivatives with a molecular weight of 34000 Da, the transfection efficiency was highest for the APPD41(34K) derivative. The result of an ethidium bromide competitive binding assay showed that the degree of compaction with DNA for this derivative was not so high as that observed for PEI. After entering the nucleus in the form of a DNA complex, strong complexation is disadvantageous for transcription. This could explain the higher transfection efficiency for APPD41-(34K) with respect to PEI. The correlation between amination and transfection efficiency confirms the correlation between nitrogen contents and transfection efficiency.

As far as the molecular weight of the backbone was concerned, transfection efficiency was low with both low and high molecular weights, thus confirming that the transfection efficiency of cationic polymers is high within a certain range of molecular weight. Using poly-L-lysine, it has been confirmed that the size and particle distributions of DNA complexes are dependent on the molecular weight of the polymer (*11*). Hence, the difference in the characteristics of DNA complexes influences transfection efficiency, and transfection efficiency thus becomes higher in the polymers with certain molecular weights.

In the present study, internalized DNA complexes with cationic polymers made from a schizophyllan backbone and a side chain modified by oligoamines localized in endocytic vesicles. This indicates that the cellular uptake of cationic polymer/DNA complexes is mediated by en-

docytosis. In other words, the interaction between a DNA complex and a cell membrane is the first step of cellular uptake. However, a strong interaction leads to high cytotoxicity. Of the various carriers prepared in the present study, polyamine carriers with high transfection efficiency exhibited higher degrees of cytotoxicity: in fact, APPD46(80K) demonstrated both the highest transfection efficiency and the highest cytotoxicity. The cytotoxicity of polymeric carriers thus appears to be based on cell membrane instability. While it was possible to reduce cytotoxicity by adjusting the amount of DNA complex per cell, as seen with poly-L-lysine (*50*, *51*), PEI (*35*), and chitosan (*19*), PEGylation was the most effective means of reducing toxicity. It appears that increased water solubility of DNA complexes and shielding of cation charge reduce the level of interaction with the cell membrane.

The transfection efficiency of APPD46(80K) without FBS was not much higher than that with FBS, and while the optimal N/P for the transfection without FBS was 10, that for the transfection with FBS was lower (at 5). Without FBS, DNA complexes do not interact with serum proteins, and as a result, efficient transfection can be achieved with a smaller amount of DNA complexes.

In the present study, cationic schizophyllan carriers with a chemically modified glucose side chain and an intact main chain of β-(1,3)-glucan showed higher transfection efficiency than cationic dextran carriers with a chemically modified backbone of α-(1,6)-glucan. Furthermore, the most important characteristic of the β-(1,3)-glucan backbone is its usefulness in long-term expression. In animal cells, β-(1,3)-glucanase does not exist and β-(1,3)-glucan might be degraded slowly by hydrolysis at a speed much slower than enzymatic degradation. Hence, cationic polymers could be gradually degraded over a long period of time, and DNA is released slowly to achieve long-term protein expression. In fact, the long residence time of plasmid DNA in cells supports this phenomenon.

In conclusion, it was possible to achieve transfection efficiency superior to that of PEI by adjusting the molecular weight and amination of cationic schizophyllan with a chemically modified glucose side chain. We also succeeded in the reduction of cytotoxicity and the development of a safe schizophyllan-based gene carrier by the modification with poly(ethylene glycol) chains. Furthermore, using the cationic schizophyllan carrier, it was possible to express a reporter protein for a long period of time due to the long residence time of plasmid DNA in cells. Cationic schizophyllan-based carriers with a natural β-(1,3)-glucan backbone will be useful in certain forms of gene therapy where it is necessary to safely express a particular therapeutic protein over a long period of time. We are now proceeding to evaluate the transfection efficiency and the safty of cationic schizophyllan carriers in vivo.

Received October 22, 2003; Revised Manuscript Received February 3, 2004

The intercalating nucleic acid (INA) presented in this paper is a novel 1-*O*-(1-pyrenylmethyl)glycerol DNA intercalator that induces high thermal affinity for complementary DNA. The duplex examined contained two INA intercalators, denoted X, inserted directly opposite each other: d($C_1T_2C_3A_4A_5C_6$-$\mathbf{X_7}C_8A_9A_{10}G_{11}C_{12}T_{13}$):d($A_{14}G_{15}C_{16}T_{17}$-$T_{18}G_{19}\mathbf{X_{20}}G_{21}T_{22}T_{23}G_{24}A_{25}G_{26}$). Unlike most other nucleotide analogues, DNA with INA inserted has a lower affinity for hybridizing to complementary DNA with an INA inserted directly opposite than to complementary unmodified DNA. In this study we used two-dimensional ^{1}H NMR spectroscopy to determine a high-resolution solution structure of the weak INA−INA duplex. A modified ISPA approach was used to obtain interproton distance bounds from NOESY cross-peak intensities. These distance bounds were used as restraints in molecular dynamics (rMD) calculations. Twenty final structures were generated for the duplex from a B-type DNA starting structure. The root-mean-square deviation (RMSD) of the coordinates for the 20 structures of the complex was 1.95 Å. This rather large value, together with broad lines in the area of insertion, reflect the high degree of internal motion in the complex. The determination of the structure revealed that both intercalators were situated in the center of the helix, stacking with each other and the neighboring nucleobases. The intercalation of the INAs caused an unwinding of the helix in the insertion area, creating a ladderlike structure. The structural changes observed upon intercalation were mainly of local character; however, a broadening of the minor groove was found throughout the helix.

INTRODUCTION

There has been a long search for new oligonucleotide analogues having different properties than natural DNA and RNA. This search has resulted in a very large selection of nucleotide analogues such as PNA (*1*), LNA (*2*), α-L-LNA (*3*), HNA (*4*), ANA (*5*), CNA (*6*), and CeNA (*7*). For a recent review see Leumann (*8*). Many of these analogues bind with improved affinity to DNA and/or RNA, but all of them bind even stronger to a complementary strand of the same type of analogue, i.e., they have a high affinity for self-hybridization. This is a large problem if you want to target both strands of a DNA duplex or a secondary structure of RNA like a hairpin (*9*, *10*). To overcome this problem there has been an intensive search for analogues that bind preferentially to the target and not to the analogue itself, which has resulted in a few new analogues (*11*, *12*).

In this paper we present a novel intercalating nucleotide analogue (INA). The concept of intercalation was proposed in 1961 by Lerman (*13*) and have since been subject for intense investigation (*14*). Some intercalators can be used as fluorescent labels and are applied universally in biology, biotechnology, and medicine (*15*−*17*). The pyrene moiety is one of the most heavily investigated molecules in terms of base stacking, thermal stabilization, and fluorescent abilities in DNA oligonucleotides (*18*−*27*). It has been suggested as an artificial nucleobase in DNA (*28*), attached to modified nucleotides such as LNA (*29*), and inserted in DNA with a glycerol backbone (*30*). These investigations showed a loss of stability upon hybridization except for the last example where a minor stabilization was observed when hybridized to DNA.

Pyrene has also been tested as an intercalator covalently attached to the O2′ in a uracil nucleotide through a methylene linker. The investigations showed a promising stabilization when inserted in and hybridized to DNA whereas hybridization to RNA caused destabilization (*31*). Insertion in RNA caused destabilization when hybridized to both RNA and DNA (*32*).

Recently, very promising results were presented, for a new intercalating nucleic acid (INA), consisting of a 1-*O*-(1-pyrenylmethyl)glycerol (*33*, *34*) (Scheme 1). These results showed that when INA is inserted as a bulge and hybridized to DNA, large thermal stabilizations are observed, whereas hybridization to RNA gives minor destabilizations. This makes INA highly promising as one of a few modifications that are able to discriminate between DNA and RNA. Fluorescent measurements show a decrease in fluorescence emission upon excitation at 340 nm after hybridization (*33*). This indicates that the pyrene moiety intercalates into the DNA double helix (*27*, *35*).

[a] "INA" indicates that an INA pesudo nucleotide has been incorporated and "−" indicates a normal DNA strand with no insertions.

In the present investigation, the objective was to explore the structural implications of two INAs placed directly opposite each in a dsDNA duplex and to determine whether INAs possess highest affinity for self-hybridization or for hybridization to complementary DNA.

EXPERIMENTAL PROCEDURES

Sample Preparation. Samples of duplex **1** and **4** were prepared for NMR investigations (Scheme 2). The two modified strands were synthesized as described elsewhere (*33*). The unmodified oligonucleotides were purchased from DNA Technology, Århus, Denmark. The samples were made by dissolving the two single strands in equivalent amounts in 0.5 mL of 10 mM sodium phosphate buffer (pH 7.0), 100 mM NaCl, and 0.05 mM EDTA. The samples were heated to 80 °C and slowly cooled to achieve hybridization. The final concentrations of the duplexes were 1.9 mM. For experiments in D_2O, the solid sample was lyophilized three times from D_2O and redissolved in 99.96% D_2O (Cambridge Isotope Laboratories). For experiments involving exchanging protons, the sample was dissolved in 90% H_2O and 10% D_2O. The numbering scheme used for the duplexes is shown in Scheme 2.

Thermal Stability Studies. The thermal stability was measured of duplexes **1**−**4** (Scheme 2). The thermal stability was determined spectrophotometrically on a Perkin-Elmer spectrophotometer equipped with a thermoregulated Peltier element. Hybridization mixtures were prepared by dissolving equimolar amounts (2.5−3.5 μM) of the oligonucleotides in 10 mM $Na_2HPO_4 \cdot H_2O$ (pH 7.0), 140 mM NaCl, and 1 mM EDTA. Measurements were done at pH ranging from 4 to 10 in steps of one unit. The pH was regulated using NaOH and HCl. The melting temperature was monitored while the temperature was changed linearly from 20 to 70 °C (1 °C min^{-1}) and then back to 20 °C. The melting temperatures were obtained as the average between the maxima/minima of the first derivatives of the melting curves.

NMR Experiments. The NMR experiments were performed on a Varian INOVA 600 spectrometer at 25 °C unless otherwise stated. For duplex **1**, a NOESY spectrum in D_2O was acquired using 2048 complex points in t_2 and a spectral width of 6000 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling scheme. The residual signal of HOD was removed by low-power presaturation. A NOESY spectrum in H_2O was obtained using the watergate pulse sequence. The spectrum was acquired with 2048 complex points in t_2 and a spectral width of 12000 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling. A DQF−COSY spectrum and TOCSY spectra with mixing times of 30 and 70 ms were obtained using the States phase cycling scheme.

For duplex **4**, two NOE buildup curves were obtained, one in D_2O and one in H_2O. In D_2O, the NOESY spectra were acquired using 2048 complex points in t_2 and a spectral width of 6000 Hz. A total of 512 t_1 experiments were recorded using the States phase cycling scheme. The NOESY spectra with mixing times of 50, 100, 150, and 200 ms were obtained sequentially without removing the sample from the magnet. 64 scans were acquired for each t_1 value with a repetition delay of 4.0 s between each scan. The residual signal of HOD was suppressed by low-power presaturation. In H_2O, the watergate-NOESY spectra were acquired using 2048 complex points in t_2 and a spectral width of 12000 Hz. A total of 680 t_1 experiments were recorded using the States phase cycling scheme. Spectra with mixing times of 100, 200, and 300 ms were obtained sequentially without removing the sample from the magnet. 64 scans were acquired for each t_1 value with a repetition delay of 2.0 s between each scan. A DQF−COSY spectrum and TOCSY spectra with mixing times of 30 and 70 ms were obtained using the States phase cycling scheme. An inversion recovery experiment was recorded to estimate the T_1 relaxations rates.

All the acquired data were processed using FELIX (Version 98, MSI, San Diego, CA). All spectra were apodized by a skewed sinebell squared in F1 and F2. The four spectra used in the D_2O NOE build up were linear predicted in F1 from 340 up to 400 points and baseline-corrected in F2 using the Flatt algorithm. The three spectra used in the build up in H_2O were linear-predicted in F1 from 420 up to 600 points and baseline corrected using the Flatt algorithm in F2.

Distance Restraints. The upper and lower diagonal part of each of the four NOESY buildup spectra in D_2O were separately integrated with FELIX, yielding a total of eight peak intensity sets which were corrected for minor saturation effects using the T_1 relaxations rates determined. A modified ISPA approach, as suggested by Wijmenga and Van Buuren, was used to calculate inter-proton distance bounds from the eight intensity sets (*36*). Bound widths were set to ±10% of the distances obtained. The same procedure was used for the buildup spectra in H_2O, but here the bounds were set to ±15% of the distances. Base planarity restraints and backbone torsion angle restraints were added for the two terminal base pairs: C1:G26, T2:A25, C12:G15, and T13:A14. The values of the 27 backbone angles included were: $-90° < \alpha < -30°$, $-210 < \beta < -150°$, $30° < \gamma < 90°$, $150° < \epsilon < 210°$, and $-150 < \zeta < -90°$. These values encompass both A- and B-type duplex structures.

Restrained molecular Dynamics. Two starting structure for the structure calculations were generated: an A-type and a B-type duplex. These were built with the *nucgen* and *nukit* modules of AMBER 6 (*37*). The INA nucleotides were added using the *xleap* module and

Table 1. Melting Temperatures of INA and DNA Duplexes Measured at Different pH Values[a]

	strand		pH						
duplex	1	2	4.2	5.0	6.1	7.0	8.0	9.0	10.0

4	INA	INA	-	36.1	46.0	46.5	48.5	46.5	40.9

[a] The measurements were done in 1 mM EDTA, 10 mM $Na_2HPO_4 \cdot H_2O$, and 140 mM NaCl.

atomic charges for the INA nucleotides were calculated using the RESP procedure as described by Bayly *et al.*, (*38*).

All distance restraints were incorporated into an rMD procedure for structure refinement. An initial energy minimization was followed by 28 ps of restrained molecular dynamics: at 600 K for 4 ps, followed by cooling to 200 K in 50 K steps of 3 ps each. The final structure was then energy minimized to a final derivative of 0.01 Å. A distance dependent dielectric constant ($\epsilon = r$) was employed to account for solvent effects. The pseudo-energy term used to enforce the distance restraints was:

$$E_{NOE} = \begin{cases} k_1(r - r_1)^2 & \text{when } r_1 > r \\ 0 & \text{when } r_2 \geq r \leq r_1 \\ k_2(r - r_2)^2 & \text{when } r_{2>} r \end{cases}$$

r_1 and r_2 are the lower and upper distance bounds, and k_1 and k_2 are the force constants. A force constant of 50 kcal mol^{-1} $Å^{-2}$ for lower and upper bounds was assigned to all distance restraints.

Helix parameters were calculated with the program CURVES 5.2 (*39*, *40*).

RESULTS

Thermal Stability. The thermal stabilities of the four duplexes shown in Scheme 2 were determined and compared (Table 1). Sharp monophasic transitions were obtained with hypochromicities of 1.1−1.2. No indications of biphasic transitions were detected. The measurements were performed at different pH values to investigate the pH dependency of INAs thermostability, and it can be noted that both DNA and INA duplexes are most stable in slightly basic environments.

Incorporation of one INA modification in either of the strands (duplex **2** and **3**) creates an increase in melting temperature of up to 6.6 °C. The difference in melting temperature reveals a small sequence dependency of the stabilization created by INA. Incorporation of INA modifications in both strands (duplex **4**) creates a decrease in melting temperature of up to 7.2 °C compared to the duplexes with INA in one only of the strands (duplexes **2** and **3**) and 0.6 °C compared to the unmodified duplex (duplex **1**). These results suggest that INA does *not* have a high affinity for self-hybridization; on the contrary, insertion of two INAs directly opposite each other creates a significant thermal destabilization of the duplex compared to when one INA is inserted in one of the strands. The degree of destabilization when INA modifications are inserted opposite each other is increasing when going to acidic pH values.

Spectral Analysis. The 1D ^1H NMR spectrum of the INA:INA duplex exhibits only lines from the expected duplex, and there were no signs of alternative hybridizations. The NOESY spectra of the INA:INA duplex exhibit the characteristic features of right-handed dsDNA sequential connectivities. The assignment of the nonexchangeable DNA protons in the INA:INA duplex was performed using standard methods (*41*−*44*). Both aromatic (H6, H8, and H2) and sugar protons (H1′, H2′, H2″, H3′, H4′, H5′, and H5″) were assigned. The NOESY spectrum recorded with short mixing time (50 ms) allowed unambiguous assignments of the H2′ and H2″ resonances. The H6/H8−H1′ cross-peaks were all weak, suggesting that the glycosidic angle is in the anti-position. The assignment of the exchangeable protons was obtained from the NOESY spectra in H_2O (*45*). The chemical shift values and the NOE connectivity pattern of the imino protons observed were in accordance with normal Watson−Crick base pairing. The unmodified duplex was assigned using the same strategy as for the INA:INA duplex; all determined chemical shift values of the unmodified DNA duplex indicated a canonical B-type helix structure. A selection of the chemical shift values of the DNA nucleotides in the INA:INA duplex are given in Table 2 and compared to the corresponding values of the unmodified duplex.

The assignment of the INA protons was performed using NOESY, DQF−COSY, and TOCSY spectra. The NOESY spectra showed that both INA nucleotides are intercalated, resulting in a large number of NOEs involving both of the aliphatic linkers and the pyrene moieties. The lines arising from INA and from the neighboring nucleotides are broader than other DNA lines, indicating more dynamics in the insertion area. The chemical shift values of the INA intercalators are given in Table 3.

Structure Calculations. More than 1000 NOE cross-peaks were observed in the NOESY spectra obtained with a 200 ms mixing time in D_2O. The accuracy of the integration of some cross-peaks was hampered by spectral overlap. These cross-peaks were not included in the modified ISPA calculations. The integration of the cross-peaks in the four buildup spectra was done separately for each side of the diagonal, resulting in two times four sets of 406 and 415 NOE cross-peaks intensities, respectively. This gives a total of 3284 integrated cross-peaks intensities used in the modified ISPA calculation. Cross-peak intensities that correspond to covalently fixed distances in the dsDNA were used for internal calibration and were therefore not converted into distance restraints. As the number of covalently fixed distances in DNA is rather limited, some internal sugar distances that are fairly independent of the sugar conformation were used for calibration as well. There are 19 internal proton−proton distances in a deoxyribose; these distances were determined at five different pseudorotation angles in the area of the two low energy conformations C3′-endo and C2′endo. In each of the 10 sets, NOESY cross-peaks corresponding to 77 deoxyribose distances and 19 covalently fixed distances were observed and thus yielded 96 distances used in calibration of unknown distances. The final bounds used in the rMD calculations were the average distances from the 10 distance sets ± 10%. The calculations returned 443 interproton distances; of those, 39 involved an INA proton.

Evaluation of the NOESY spectra in H_2O showed normal Watson−Crick bonding in the DNA parts of the duplex except between A9:T18, justifying inclusion of 28 hydrogen bond distance restraints. Three hydrogen bonds were included for each of the six GC base pairs and two hydrogen bonds for each of the five AT base pairs with upper and lower bounds of 1.74 and 2.10 Å, respectively. From the NOESY buildup in H_2O, a total of 36 distance restraints were determined using the same method as in D_2O. But here only covalent fixed distances were used

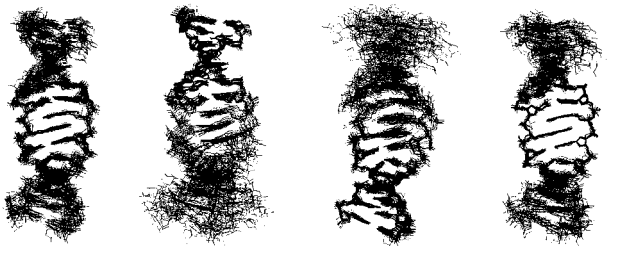
for calibration, and bounds were set to the average distances ±15%. None of the restraints from the spectra acquired in H_2O involved an INA proton. Thus, a total



Scheme 3 Dispersion of the Distance Restraints Used in the RMD Calculations[a]

[a] Dashed lines are distances derived from NOESY spectra in H_2O; solid lines are distances from NOESY spectra in both D_2O and H_2O.

of 479 interproton restraints were used in the rMD calculations. The dispersion of the distance restraints used in the rMD calculation is shown in Scheme 3.

Twenty final structures starting from both A- and B-type starting structures, respectively, were generated. All the structures converged to one family of conformations, but the RMSD between structures generated from A- and B-types were slightly larger than internally in each of the two families. Since no A-type properties are

Ensemble	A	B	C	D
residues superimposed	[1-13;14-26]	[1-6;21-26]	[8-13;14-19]	[5-9;18-22]
RMSD	1.95	0.91	0.86	0.75

Figure 1. Four different views of 20 superimposed structures. (A) All residues are superimposed. (B) Residues [1−6;21−26] are superimposed. (C) Residues [8−13;14−19] are superimposed. (D) Residues [5−9;18−21] are superimposed. Hydrogens have been omitted for clarity.

observed in the final structure, only the 20 structures generated from the B-type structure are further analyzed. Four different views of the duplex are shown in Figure 1, with the RMSD for each ensemble indicated. The average all atom RMSD of the coordinates of the 20 B-type structures was 1.95 Å (Figure 1A). This rather high value, along with line broadening of the INA protons as well as the protons from the neighboring nucleotides, reflects the dynamics of the duplex. Segments of the duplex all had RMSDs below 1.0 Å (Figure 1B−D). The average sum of violations was 12.9 Å for the B-type starting structure. Just eight violations greater than 0.2 Å were observed and none greater than 0.3 Å.

The reliability of the structure calculation was carefully evaluated. rMD calculations were performed with distance restraints force constants changed to either 25 or 100 kcal mol^{-1} $Å^{-2}$, respectively. The generated structures all converged to the same family of structures as with the force constants set to 50 kcal mol^{-1} $Å^{-2}$. The structure obtained is not strongly dependent on the exclusion of any of the restraints. In particular, calculations performed without the Watson−Crick restraints yielded the same structure but with a slightly larger RMSD.

Helix Parameters. Helical parameters for the 20 final structures were analyzed with the program CURVES 5.2 (*39*, *40*). Plots of some global helical parameters for the INA:INA duplex are shown in Figure 5. The coordinates for the twenty final structures are deposited in the RSCB Protein Data Bank under pdb ID 1S88 (*46*).

DISCUSSION

Spectral Data. The NOESY cross-peaks shows that the duplex has a right-handed helix conformation with all nucleotides in the anti conformation. The sequential pathway is broken at the INA modifications due to their unusual backbone. The H6/H8−H1′ region of the 200 ms NOSEY spectrum is shown in Figure 2. It shows some of the sequential connectivities, and examples of INA−DNA cross-peaks.

The chemical shift values displayed in Table 2 demonstrate a close agreement between the modified and the unmodified duplex except for the protons near the INA modifications. The differences in chemical shift are primarily displayed at C6, C8, T18, G19, and G21. The changes in chemical shift can largely be explained by enhanced ring current effects induced by the pyrene moieties. It is difficult to make a pattern in the changes in chemical shifts observed, but it seems as if the nucleotides on the 5′-site of the intercalators (G6 and G19) obtains an upfield shift whereas the nucleotides on the 3′-site (C8 and G21) shift downfield. The chemical shifts of the intercalators are rather difficult to discuss,

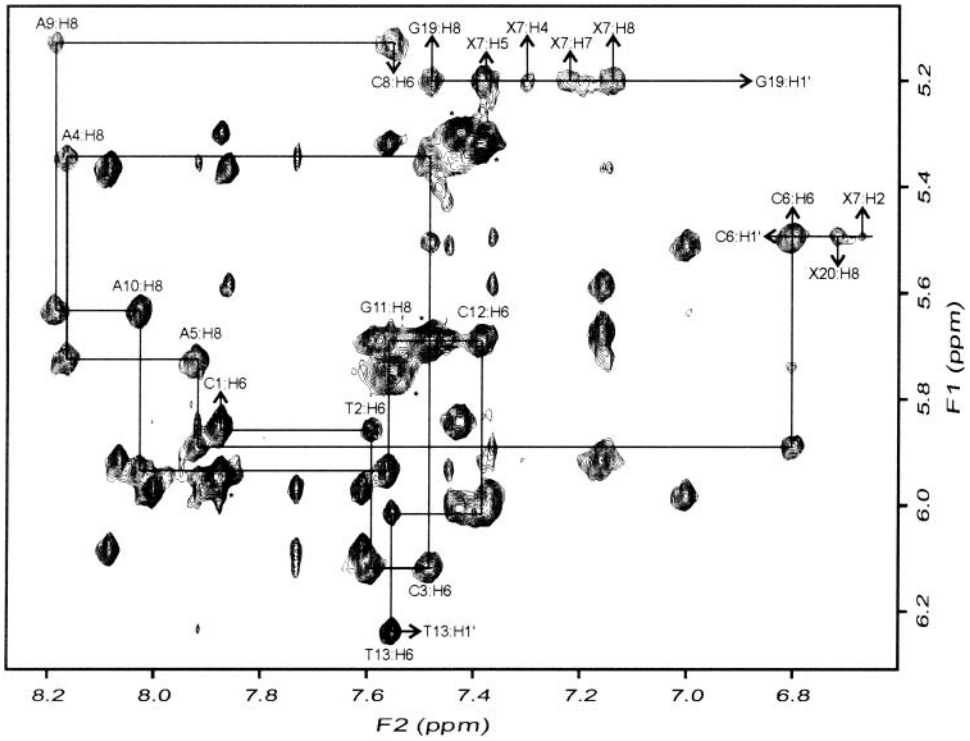


Figure 2. A section of the 200 ms NOESY spectrum displaying the H6/H8−H1′ region. The sequential connectivities for the C1−T13 strand are shown. Note that the connectivity is broken between C6 and C8, due to the missing sugar ring in INA. Cross-peaks between the DNA protons C6:H1′ and C19:H1′ and some of the aromatic protons on the intercalators, X7 and X20, are shown. Cytosine H6−H5 cross-peaks are marked with an asterisk. The C6:H6−C6:H5 cross-peak is not present, due to an upfield shift of C6:H5 induced by the pyrene moiety of X20.

but compared to pyrene, the aromatic protons in the pyrene moieties are shifted approximately 1 ppm upfield. This is probably due to ring current effects from one INA to the other and vice versa, indicating that both pyrene moieties are intercalated. These findings are supported by calculations of ring current effects, which display a similar trend (*47*, *48*)

The imino protons of G19 and G21 are shifted upfield 1.61 and 2.16 ppm, respectively. Such a dramatic upfield shift has been observed before in the literature for imino protons in guanines stacking with pyrenyl ring systems (*21*). Upfield shift of imino protons can be caused by two things: imino protons, with sharp and narrow lines, shifted upfield indicate significant ring current effects due to stacking interactions, whereas, imino protons,with broad lines due to rapid exchange, indicate disruption of the base pair hydrogen bonding (*21*). The reason for the dramatic upfield shift observed for G19:H1 and G21:H1 are probably a combination of the two. They have broad lines and G21:H1 can only be observed in the NOESY spectrum in H_2O at 5 °C, but the characteristic cross-peaks defining Watson−Crick hydrogen bonding are present in the spectra, indicating that base pairing does occur between G19:C8 and G21:C6. The broad lines are presumably due to internal motion rather than disruption of the base paring.

It is interesting that the chemical shift changes observed at T18 are greater than at G19, especially T18: H2′ is shifted 0.58 ppm upfield. Also no Watson−Crick base pairing is observed in the base pair A9:T18. This could be due to necessary structural compensations induced by the intercalation of the INA modfications. The reason it occurs at the A9:T18 base pair rather than at one of the flanking G:C base pairs is that A:T base pairs are more prone to disruption than G:C base pairs. This could explain why the chemical shift changes at T18 are greater than at G19, even though G19 is a neighbor to the intercalator ×20.

Description of the Structure. Qualitatively, the NOESY spectra of the INA:INA duplex indicate that it adopts a right-handed B-type helix conformation, with all the bases in the anti conformation and all forming normal Watson−Crick base pairs. However, Figure 3A reveals that even though the ends of the duplex looks like normal right-handed B-type helixes, some major changes occur in the area of the inserted intercalators. One obvious consequence of the intercalators is a dramatic unwinding of the helix in the insertion area creating a ladderlike structure. Unwinding of the helix as a consequence of intercalation is a common phenomenon for noncovalent bound intercalators (*49*). However, in this case where the INA nucleotide provides its own backbone, unwinding was not necessarily expected.

INA is designed to intercalate in the opposite strand, but Figure 4 reveals that when two INA are inserted opposite to each other they prefer to stack with each other, and X7 is therefore intercalated in the opposite strand as expected whereas X20 intercalates more or less in the strand where it is inserted. Thus both pyrene moieties stack in the same DNA strand, creating good stacking between G19, X7, X20, and G21, whereas stacking with C6 and C8 is less predominant. This shows that INA prefers to stack with G rather than C, due to the larger aromatic system of guanine. Due to the difference in intercalation, the conformation of the linker of the two INA nucleotides is different. The linker of X7 is quite extended whereas the linker of X20 is rather compact. Figure 4 shows that both intercalators are oriented the same way in the duplex relative to the strand direction. This could indicate that the pyrene moieties of the INA nucleotides have a preferred orientation when they intercalate.

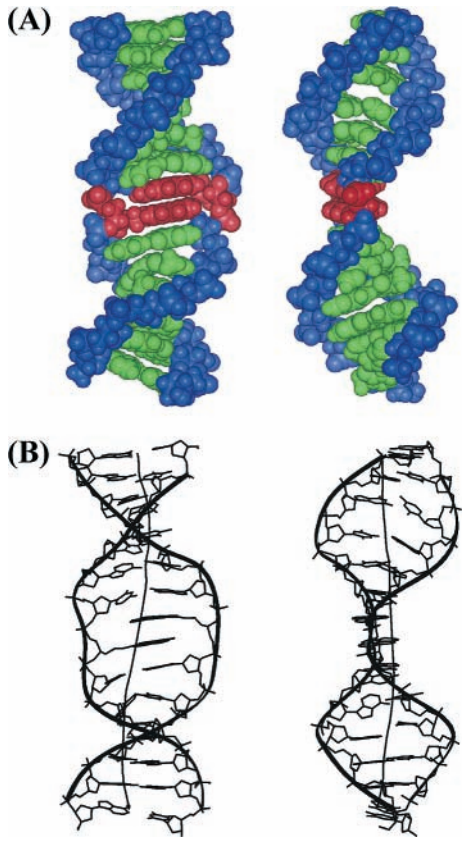

Figure 3. (A) Space-filling representations of the structure viewed from the minor groove (left) and turned 90° (right). (B) Stick representations of the structure. The helix axis calculated with CURVES is shown, and a ribbon has been added to emphasize the backbone. Hydrogens have been omitted for clarity.

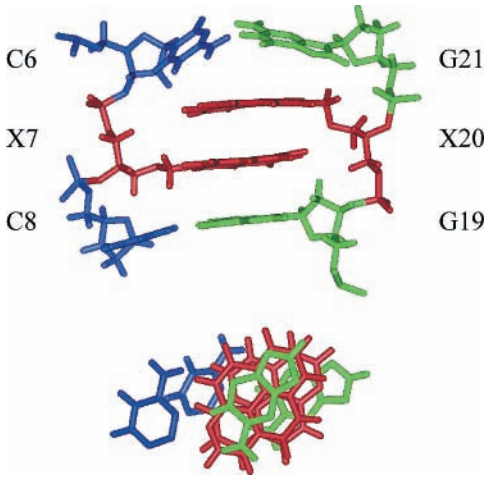

Figure 4. Top: Base pair stacking in the central part of the INA:INA duplex viewed from the major groove. Bottom: Same picture viewed along the helix axis, the backbone is not shown. There seems to be good stacking between G19, X7, X20, and G21, whereas the stacking of the pyrenes with C6 and C8 is rather limited.

Dynamic Considerations. The structure of the INA:INA duplex (duplex **4**) shows that both pyrene moieties are intercalated. This observation is supported by chemical shift values observed for the protons in the pyrene moiety. They are shifted approximately 1 ppm compared to pyrene, indicating ring current effects from one pyrene

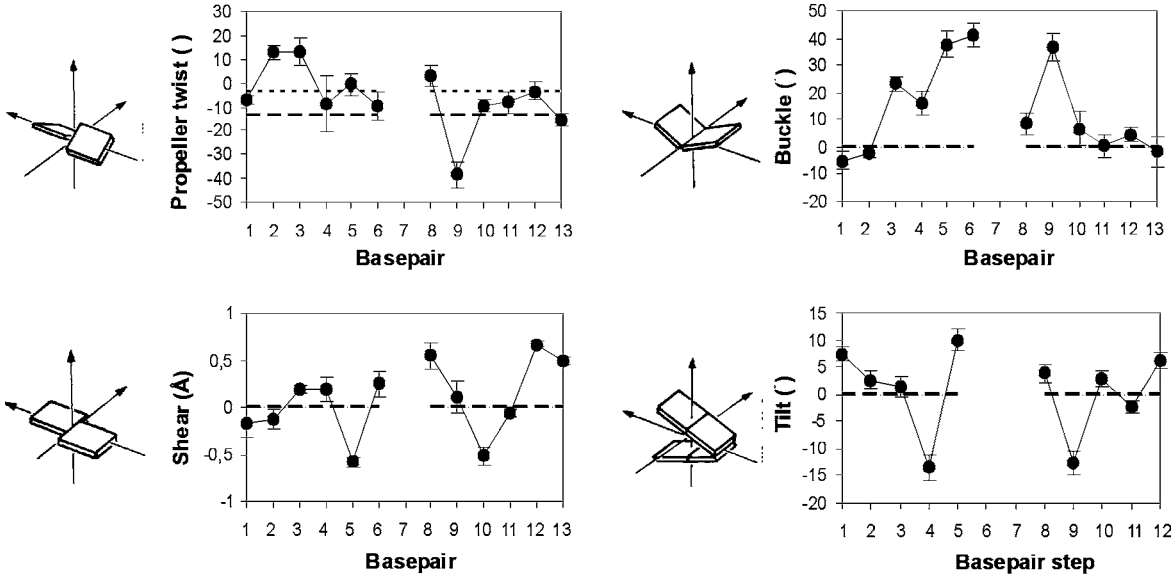

Figure 5. A selection of the helix parameters calculated for the INA:INA duplex. The parameters were calculated using CURVES 5.2 and are compared to values of canonical A-type duplex (- ─ -) and B-type duplex (- ─ -) parameters. No values are calculated for the intercalators X7 and X20.

moiety affecting the other and vice versa. However, all INA protons, as well as the protons from the neighboring nucleotides, have line widths broader than normal, indicating intermediate dynamics in this area. These dynamics have to occur on a fast time scale since only one set of peaks can be observed in any of the acquired spectra.

The observed dynamics of the duplex could have its origin in several different patterns of movement by the pyrenes. They could be intercalated alternately and only briefly be intercalated both at the same time, they could simultaneously move in and out of the helix, or they could be sliding on top of each other either sideways or back and forth. Considering the amount of cross-peaks identified between X7 and X20, the two first models do not seem likely. If the pyrenes only were stacking with each other for a short time, the number of cross-peaks and their intensities would probably be lower. To distinguish between the two other possibilities is more problematic, but since the minor groove has been shown to be extensively widened in the duplex, the last option where the two pyrene moieties are sliding back and forth does seem more appealing. Unfortunatly, no definitive answer can be given.

Helix Parameters. There are three major categories of helical parameters: axis-base pair, intrabase pair and interbase pair parameters (*50*). For the INA:INA duplex some of these parameters are shown in Figure 5. However, no data are available for the intercalators, and the data for the terminal base pairs are probably less reliable due to dynamic processes and a lower density of restraints and are only included for completeness.

The global helix axis is fairly straight (Figure 3B), but it should be noted that the axis does not pass through the intercalators, as they seem to be shifted toward the minor groove. The width of the minor groove, measured as the shortest interstrand phosphorus distance (reduced by 5.8 Å to account for the van der Waals radius of two phosphate groups), is reported in Figure 6. For classical B-type helices, a value of approximately 5.7 Å is expected (*51*), but in the INA structure, a remarkable widening of the minor groove is observed throughout the duplex. The widening is most dramatic in the insertion area where enlargements up to 10.1 Å are observed. This remarkable

Figure 6. The minor groove width measured as the smallest distance between two interstrand phosphorus atoms reduced by 5.8 Å to account for the van der Waals radius of two phosphate groups. A greatly enlarged minor groove width in the central part of the helix is observed.

result indicates that even though the two INAs seemingly are stacking well, they also push the two strands of the duplex apart and hence have a pronounced influence on the minor groove width of the entire duplex.

The calculated values of the intrabase pair parameters shear, buckle, and propeller twist all deviate from normal A- and B-type DNA in the central part of the helix. Changes in buckle have been reported earlier to be connected to changes in the sugar conformations (*52*, *53*), but values of the pseudorotation angle show a majority of S-type conformation in all nucleotides except C6 (results not shown). Even though propeller twist for structures of oligonucleotides determined by NMR normally are more negative than for canonical B-type helixes

(*54*−*57*), the large negative value for the A9:T18 base pair is noteworthy. Together with the large positive buckle, it explains why no Watson−Crick hydrogen bonding could be observed for this base pair. The unusually large positive values of buckle and the large changes in shear, combined with the large changes in the interbase pair parameter tilt in the insertion area, demonstrate the dramatic adaptations the structure has to perform due to the insertion of the two INAs.

Stability of INA Duplexes. The thermal stability measurements displayed in Table 1 shows that one INA nucleotide inserted in either of the strands increases the affinity for the complementary ssDNA. This increase in melting temperature was expected from previous results (*33*). We have shown that even though INA has the very high affinity for its target DNA, it has a lower affinity for complementary INA, when the two INA insertions are placed opposite each other. By adjusting pH to 5.0 (see Table 1), it is possible to optimize the difference in thermal stability between the INA:DNA hybrid and the INA:INA duplex to 13.6 °C. However, thermal stability measurements of duplexes with INA molecules inserted in each strand, displaced with one to three base pairs, show a stabilizing effect of up to 7.0 °C, indicating that INA in general have a high affinity for other sequences with INA inserted (unpublished results).

Even though the intercalation of the two pyrene moieties makes a severe pertubation to the duplex structure, the thermostability of the INA:INA duplex is only slightly lower than that of the unmodified dsDNA duplex. One possible explanation of this could be that even though two intercalators inserted directly opposite each other distort the duplex, they also create an area with an increased flexibility due to the greater mobility of the backbone of the intercalators compared to a normal nucleotide. This enables the duplex to make major changes in the insertion area without having to rearrange the rest of the duplex, thereby creating independent helixes on each side of the intercalators. Another factor minimizing the degree of destabilization is the strong stacking of the INAs, contributing to the stability of the duplex, an effect observed previously with bipyridyl C-nucleotides (*58*). This enhanced stacking in the duplex induced by the pyrene moieties is probably the reason insertion of INAs displaced by one to three base pairs stabilizes the duplex. Such an INA arrangement would intuitively destabilize the duplex even further because the structural adaptations necessary to fit both intercalators in the helix would spread over a greater part of in the duplex. However, due to the enhanced stacking abilities of the pyrene moieties compared to the natural nucleobases, insertion of INAs creates an enhanced stacking in the duplex in a larger area, thereby stabilizing the duplex.

One of the conclusions obtained in this investigation is that insertion of two INA intercalators opposite each other creates a minor thermal destabilization of the duplex. This destabilization is founded in an unwinding of the helix in the insertion area, where the pyrene moieties exhibit good stacking abilities but also push the two strands apart, creating an extensively widened minor groove. Thermal stability measurements suggest that the destabilizing effect of inserting INA in both strands is specific for the case where they are inserted directly opposite each other; otherwise insertion of INA in both strands have a stabilizing effect. The measurements also show that by adjusting pH it is possible to optimize INA affinity for a complementary DNA target over a complementary INA target.

Intercalating nucleic acid is thus one of the first nucleotide analogues that have reduced affinity for hybridization to a complementary strand of its own kind, while still processing a highly increased affinity for hybridizing to its complementary DNA strands, making targeting of both of the complementary strands of a DNA duplex possible. On the basis of the high-affinity, high specificity and low self-affinity, we believe that INA can be used with great advantage in a versatile range of applications where hybridization to single- as well as double-stranded targets is desired.

ACKNOWLEDGMENT

We would like to thank Professor Michael P. Williamson at the University of Sheffield for calculating the ring current values for the duplexes. We thank the Danish National Research Foundation, The Danish Natural Science Research Foundation, and the Danish Technical Research Foundation for financial support.

Antigenic Prenylated Peptide Conjugates and Polyclonal Antibodies To Detect Protein Prenylation

Xiao-hui Liu,[†] Dae-Yeon Suh,[†] Jeffrey Call,[‡] and Glenn D. Prestwich*[,†]

Department of Medicinal Chemistry and the Center for Cell Signaling, The University of Utah, 419 Wakara Way, Suite 205, Salt Lake City, Utah 84108-1257, and Biotechnology & Genomic Research Center, Utah State University, 4700 Old Main Hill, Logan, Utah 84322. Received October 30, 2003

Posttranslational modification of proteins with farnesyl and geranylgeranyl groups is a required modification for signaling proteins that includes the small GTPases in the Ras, Rho, and Rab families, heterotrimeric G proteins, and nuclear lamin proteins. To develop antibodies capable of detecting and distinguishing prenylated proteins, we synthesized two antigens, succinylglycine-(geranylgeranyl)-cysteine methyl ester (SuccG-(gg)CMe, **1**) and succinylglycine-(farnesyl)cysteine methyl ester (SuccG-(f)CMe, **2**). These prenylated peptides were covalently coupled to bovine serum albumin (BSA) and to keyhole limpet hemocyanin (KLH) to produce polyvalent, immunogenic bioconjugates. Immunization of rabbits with these immunogens generated polyclonal antisera that contained significant titers of anti-geranylgeranyl and anti-farnesyl antibodies. The selectivity of the polyclonal antisera was examined using ELISA and dot blotting methods. The anti-farnesyl and anti-geranylgeranyl antisera crossreacted with both antigens. Attempts to purify the polyclonal antisera by either positive or negative immunoaffinity selection protocols failed to produce selective anti-geranylgeranyl and anti-farnesyl antibodies. Moreover, both crude antisera and purified antibodies also crossreacted with myristoylated and palmitoylated BSA conjugates. Immunofluorescence staining of EYFP-CVLL or EYFP-CVIM transfected CHO-K1 cells with rabbit polyclonal antisera showed colocalized membrane fluorescence. Thus, an important caveat for the use of antibodies raised against aliphatic antigens is that extensive controls must be performed to determine selectivity.

INTRODUCTION

Antibodies are synthesized predominantly by plasma cells, which are terminally differentiated cells of the B-lymphocyte lineage and constitute a crucial line of defense against foreign antigens (*1*). The unique specificities of the antibodies have made them indispensable tools in cell and developmental biology, therapeutic medicine, and pathology (*2*). While the majority of antigens used for immunization are proteins, peptides, nucleic acid, carbohydrates, or cell-surface antigens, small molecules can be immunogenic if delivered in a polyvalent form with an appropriate adjuvant. This often requires covalent linkage to a carrier protein such as keyhole limpet hemocyanin (KLH), bovine serum albumin (BSA), or thyroglobulin. Recent studies revealed that some antigenic nonpeptide molecules can stimulate a strong T-cell response in humans and in mouse models. These molecules include aliphatic glycolipids, phosphoantigens, aromatic glycolipids, alkylamines, and lipids (*3*−*11*).

Some anti-lipid antibodies can occur naturally. For example, anti-phospholipid antibodies (αPL) are an important clinical problem (*12*), occurring in autoimmune diseases (e.g., lupus erythematosus) and in infectious diseases such as tuberculosis, hepatitis, Lyme disease, malaria, and bacterial septicemia (*13*). Stereospecific antibodies against phosphatidylserine have been generated using liposomes (*14*) and acyl-linked antigens (*15*); these antigens have been employed for immunolocalization in human placenta (*16*) and other tissues (*17*). In recent studies of lipid signaling, selective antibodies against the phosphoinositides PI(4,5)P_2 and PI(3,4,5)P_3 have been developed (*18, 19*) and used to visualize changes in subcellular phosphoinositides in stimulated cells and in tissue sections (*20*).

Prenylation is a required posttranslational modification of most small GTPases and a variety of other proteins (*21*−*26*). In particular, Ras, Rho, and Rab proteins play important roles in cell proliferation and signal transduction. Aberrant signaling is responsible for the growth and proliferation of cancer cells. Each of these mature small GTPases have isoprenyl moieties (farnesyl or geranylgeranyl) linked to a common cysteine methyl ester via a thioether bond. Proteins are prenylated by the transfer of a farnesyl (C-15) or geranylgeranyl (C-20) unit from farnesyl diphosphate (FPP) or geranylgeranyl diphosphate (GGPP) to the cysteine of a C-terminal motif. Three carboxyl terminal motifs specify the type of prenylation: CA_1A_2X, CC, and CAC, where A is an aliphatic amino acid and X is any amino acid. Generally, the CA_1A_2X (X = Ser, Met, Ala or Gln) sequence is a substrate for farnesylation unless X = Leu or Phe, in which case geranylgeranylation occurs. The CC and CAC sequences are substrates for bisgeranylgeranylation and are found exclusively in the Rab family of small GTPases.

Two groups have reported a polyclonal anti-farnesyl antibody to identify farnesylated proteins in cells (*27, 28*), developed using *N*-acetyl-*S*-farnesyl-L-cysteine, which was coupled to KLH using carbodiimide chemistry. However, the reported polyclonal antibodies crossreacted

with geranylgeranyl moieties. Since selective anti-geranylgeranyl and anti-farnesyl antibodies could be very useful tools for the study of prenylated proteins in cells, we designed and synthesized two new antigens: SuccG-(gg)CMe **1** and SuccG-(f)CMe **2**. (To avoid confusion with single letter amino acid abbreviations, geranylgeranyl is abbreviated as "gg" and farnesyl as "f".) The introduction of a succinylglycine spacer was selected to enhance immunogenicity and to increase the likelihood of obtaining prenyl selective antibodies. Antisera that contained polyclonal antibodies were obtained from immunized rabbits. Antibodies were purified by affinity and size exclusion chromatography and were characterized using ELISA, dot blots, and immunofluorescence.

EXPERIMENTAL PROCEDURES

General. All reactions were conducted using oven-dried glassware. Column chromatography was performed on silica gel (60 Å, 240−400 mesh ASTM) from Whatman Co. BSA and KLH were from Sigma. Affigel-10 was from Bio-Rad. Dot blotting and western blotting reagents were from Amersham. Myristoyl-Gly was from BACHEM, and all other organic reagents were from Sigma-Aldrich Chemical Co. CHO-K1 cells were from ATCC. Lipofectamine and cell culture medium were from Invitrogen Life Technologies. G418 (Geneticin) was from Gibco. L-(Trityl)-Cys **3** was prepared from L-cysteine as described (*29*). The synthetic compounds were visualized on TLC with anisaldehyde−H_2SO_4−AcOH solution.

Vector pcDNA3.1 encoding YFP-KMSKDGKKKKK-KSKTKCVIM was the generous gift of Dr. Tamas Balla (Endocrinology and Reproduction Research Branch, National Institutes of Health). EYFP-CVLL was constructed by site-directed mutagenesis from the EYFP-CVIM, using QuickChange mutagenesis kit (Invitrogen). The mutagenesis primers were sense, 5′-ACAAAGTGTGTACT-TCTTTAAAGATCTCGG-3′; antisense, 5′-CCGAGATCTT-TAAAGAAGTACACACTTTGT-3′. The PCR conditions were 95 °C for 45 s, followed by 18 cycles at 95 °C for 45 s, 55 °C for 1 min, and 68 °C for 13 min.

2-Amino-3-(tritylsulfanyl)propionic Acid Methyl Ester (L-(trityl)-CysMe, 4). A mixture containing concentrated HCl (1.25 mL) and L-(trityl)-Cys **3** (1 g, 2.75 mmol) in 20 mL of methanol was heated to reflux for 15 h. Then the solution was diluted with water, neutralized with Na_2CO_3, and extracted with EtOAc. The organic layer was concentrated and then purified on SiO_2 (EtOAc) to afford a thick colorless oil, 560 mg (54%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.41−7.44 (m, 6H, ArH), 7.19−7.31 (m, 9H, ArH), 3.66 (s, 3H, OCH_3), 3.21 (br s, CH), 2.62 (m, 1H, CHS), 2.52 (m, 1H, CHS), 1.71 (br s, NH_2).

2-(2-(*tert*-Butoxycarbonylamino)acetylamino)-3-(tritylsulfanyl)propionic Acid Methyl Ester (Boc-Gly-(trityl)-CysMe, 5). A solution of L-(trityl)-CysMe **4** (377 mg, 1 mmol), *N*-(*tert*-butoxycarbonyl)glycine (210 mg, 1.2 mmol), and DCC (247 mg, 1.2 mmol) in CH_2Cl_2 (50 mL) was stirred at room temperature for 3 h. The mixture was filtered and concentrated. Chromatography on SiO_2 (EtOAc/hexanes 3:2) afforded 480 mg (90%) of a white solid. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.39−7.36 (m, 5H, ArH), 7.31−7.20 (m, 10H, ArH), 5.01 (br s, 1H, NH), 6.38 (d, J = 7.6 Hz, 1H, NH), 4.54 (m, 1H, CH), 3.76 (m, 2H, CH_2), 3.71 (s, 3H, OCH_3), 2.66 (m, 2H, CH_2), 2.04 (s, 1H, CH), 1.48 (s, 9H, $3CH_3$). ^{13}C NMR ($CDCl_3$, 400 MHz) δ 170.8, 169.2, 144.4, 129.7, 128.2, 127.1, 67.2, 60.6, 52.9, 51.3, 33.8, 28.5. EI-MS *m*/*z* 478, 434.1, 316.1, 243, 239, 165, 101, 57. HRMS (EI) (*m*/*z*) calcd for $C_{30}H_{34}SN_2O_5$ (M^+) 534.66744; found 534.2176.

2-(2-Aminoacetylamino)-3-(tritylsulfanyl)propionic Acid Methyl Ester (Gly-(trityl)-Cys-Me, 6). A solution of Boc-Gly-(trityl)-CysMe **5** (400 mg, 0.748 mmol) in 4 mL of TFA/CH_2Cl_2 (1:1) was stirred at room temperature for 1 h. The mixture was concentrated and evaporated 3× with ether. Filtration with ether afforded 494 mg of a white solid. ^{1}H NMR (CD_3OD, 400 MHz) δ 7.38−7.20 (m, 15H, 3Ph), 3.86 (s, 2H, CH_2), 3.61 (s, 3H, OCH_3), 2.69−2.51 (m, 3H), 2.00 (4H, $2CH_2$). ^{13}C NMR (CD_3OD, 400 MHz) δ 170.8, 166, 144, 129.5, 127.9, 126.9, 110, 52.2, 51.8, 40.2, 33.2. EI-MS *m*/*z* 434, 357, 309.8, 243, 239, 165, 117.9, 68.9, 44.9. HRMS (EI) (*m*/*z*) calcd for $C_{25}H_{26}SN_2O_3$ (M^+) 434.55162; found 434.1663.

***N*-[(1-(Methoxycarbonyl)-2-(tritylsulfanyl)ethylcarbamoyl)methyl]succinamic Acid (Succ-Gly-(trityl)-CysMe, 7).** A mixture containing Gly-(trityl)-CysMe **6** (420 mg, 0.966 mmol) and succinic anhydride (146 mg, 1.45 mmol) in 25 mL of HOAc was stored at room temperature for 2 days. The mixture was concentrated under vacuum and purified on SiO_2 (EtOAc/HOAc 100:3). Pale yellow oil (414 mg, 80%) was obtained. ^{1}H NMR (CD_3OD, 400 MHz) δ 7.38−7.20 (m, 15H, 3Ph), 3.86 (s, 2H, CH_2), 3.61 (s, 3H, OCH_3), 2.69−2.51 (m, 3H), 2.00 (4H, $2CH_2$). ^{13}C NMR (CD_3OD, 400 MHz) δ 175.2, 174.0, 173.9, 171.8, 170.8, 170.4, 144.6, 129.5, 127.8, 126.8, 67.0, 60.4, 52.0, 51.7, 42.1, 33.2, 30.3, 29.0, 19.7, 19.6, 13.3. FAB-MS *m*/*z* 533, 470, 437, 356.9, 311.1, 291, 275, 239, 205, 183, 167, 113. HRMS (FAB) (*m*/*z*) calcd for $C_{29}H_{30}SN_2O_6$ $(M-1)^+$ 533.17463; found 533.17565

***N*-[(2-Mercapto-1-(methoxycarbonyl)ethylcarbamoyl)methyl]succinamic Acid (Succ-Gly-CysMe, 8).** To a solution of Succ-Gly-(trityl)-CysMe **7** (55 mg, 102.8 μmol) in 4 mL of 50% TFA/CH_2Cl_2 was added triethylsilane (66 μL, 411 μmol). The mixture was stored at room temperature overnight. After evaporation to remove solvent, the residue was purified on SiO_2 (EtOAc/MeOH 4:1) to afford 57.7 mg (71%) of Succ-Gly-CysMe **8**. ^{1}H NMR (CD_3OD, 400 MHz) δ 3.90 (s, 2H, CH_2), 3.73 (s, 3H, OCH_3), 2.67−2.50 (m, 3H), 2.00 (4H, $2CH_2$). ^{13}C NMR (CD_3OD, 400 MHz) δ 174.3, 171.9, 170.6, 60.4, 55.0, 51.8, 42.4, 30.2, 29.0, 19.7, 19.6, 13.2. EI-MS *m*/*z* 244, 207, 167, 165, 152, 115, 91, 71, 57.

***N*-{[2-(3,15-Dimethylhexadeca-2*E*,6*E*,10*E*,14-tetraenylsulfanyl)-1-(methoxycarbonyl)ethylcarbamoyl]methyl}succinamic Acid (SuccG-(gg)CMe, 1).** A solution that contained geranylgeranyl chloride (35 mg, 113 μmol), Succ-Gly-CysMe **8** (33 mg, 113 μmol), and $Zn(OAc)_2{\cdot}2H_2O$ (37 mg, 169 μmol) in 4 mL of DMF/CH_3CN/0.025% TFA (2:1:1) was stirred at 0 °C and then brought to room-temperature overnight. The mixture was concentrated and purified on SiO_2 (EtOAc/HOAc 100:3) to afford 36.7 mg (57.5%) of pale yellow oil. ^{1}H NMR (CD_3OD, 400 MHz) δ 5.20 (m, 1H), 5.12 (m, 2H), 4.64 (m, 1H), 3.90 (d, J = 2 Hz, 2H), 3.7 (s, 3H, OCH_3), 3.24 (m, 1H), 3.13 (m, 1H), 2.95 (m, 1H), 2.74 (m, 1H), 2.63 (t, J = 6.4 Hz, 2H), 2.50 (t, J = 6.4 Hz, 2H), 2.14−1.98 (m, 18H), 1.69, 1.66, 1.60, 1.59 (5s, 15H). ^{13}C NMR (CD_3OD, 400 MHz) δ 174.2, 139.5, 124.3, 120.2, 52.4, 51.7, 42.2, 39.7, 32.0, 30.3, 29.1, 26.6, 26.2, 19.6, 15.0.

***N*-{[1-Methoxycarbonyl-2-(3,7,11-trimethyl-dodeca-2*E*,6*E*,10-trienylsulfanyl)ethylcarbamoyl]methyl}-succinamic Acid (SuccG-(f)CMe, 2).** A solution containing farnesyl bromide (29 mg, 97.5 μmol), Succ-Gly-CysMe **8** (57 mg, 195 μmol), and $Zn(OAc)_2{\cdot}2H_2O$ (66 mg, 292.5 μmol) in 4 mL of DMF/CH_3CN/0.025% TFA (2:1:1) was stirred at 0 °C overnight. The mixture was condensed and purified on SiO_2 (EtOAc) to afford 56 mg (∼100%) of pale yellow oil. ^{1}H NMR (CD_3OD, 400 MHz) δ 5.21 (m,

1H), 5.11 (m, 2H), 4.62 (m, 1H), 3.90 (d, $J = 2$ Hz, 2H), 3.71 (s, 3H, OCH_3), 3.22 (m, 1H), 3.12 (m, 1H), 2.78 (m, 1H), 2.65 (t, $J = 6.8$ Hz, 2H), 2.53 (t, $J = 6.8$ Hz, 2H), 2.13−1.96 (m, 8H), 1.69, 1.66, 1.60, 1.59 (4s, 12H). ^{13}C NMR (CD_3OD, 400 MHz) δ 222.0, 163.9, 124.3, 123.9, 120.2, 72.6, 52.4, 51.8, 42.2, 39.7, 39.6, 36.0, 32.0, 30.6, 30.3, 29.0, 26.6, 26.2, 24.8, 19.6, 16.6, 15.1, 15.0. 2-[2-(2,5-Dioxopyrrolidin-1-yl)acetylamino]-3-(3,7,-11,15-tetramethylhexadeca-2,6,10,14-tetraenylsulfanyl)propionic Acid Methyl Ester (Succinimide-G-(gg)CMe, 11). SuccG-(gg)-CMe **1** (36.7 mg, 65 μmol), SDPP (33 mg, 97.4 μmol), and triethylamine (37 μL, 260 μmol) were dissolved in 10 mL of CH_3CN. The mixture was stored at room temperature for 16 h and then concentrated and purified on SiO_2 (EtOAc) to afford 14.7 mg (41%) of oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.52 (s, 1H), 5.19 (t, $J = 8$ Hz, 1H), 5.09 (s, $J = 6$ Hz, 2H), 4.76 (m, 1H), 4.23 (m, 2H), 3.76 (s, 3H, OCH_3), 3.2−2.97 (m, 2H), 2.97−2.78 (m, 6H), 2.09 (m, 8H), 1.98(m, 4H), 1.67, 1.65 (2s, 6H, $2CH_3$), 1.59 (s, 9H, $3CH_3$). ^{13}C NMR ($CDCl_3$, 400 MHz) δ 176.4, 170.9, 169.1, 168.2, 165.5, 165.2, 140.2, 135.4, 134.9, 131.2, 126.1, 124.4, 124.2, 123.7, 120.3, 119.4, 52.7, 52.0, 41.1, 39.7, 39.6, 33.2, 30.0, 28.2, 26.7, 26.6, 26.4, 25.7, 25.6, 25.3, 17.7, 17.5, 16.1, 16.0.

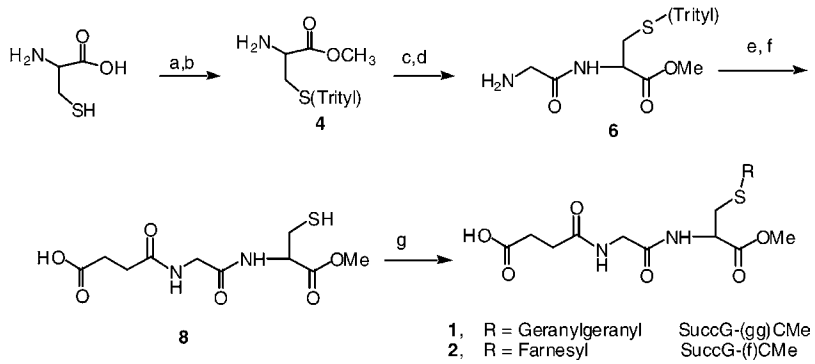
2-[2-(2,5-Dioxopyrrolidin-1-yl)acetylamino]-3-(3,7,-11-trimethyldodeca-2,6,10-trienylsulfanyl)propionic Acid Methyl Ester (Succinimide-G-(f)CMe, 12). SuccG-(f)-CMe **2** (47 mg, 94.6 μmol), SDPP (47.7 mg, 142 μmol), and triethylamine (53 μL, 378 μmol) were dissolved in 10 mL of CH_3CN. The mixture was stored at room temperature for 4 h and then concentrated and purified on SiO_2 to afford 10 mg (22%) of a colorless oil. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 5.19 (t, $J = 8.4$ Hz, 1H), 5.09 (t, $J = 6$ Hz, 2H), 4.77 (m, 1H), 4.23 (m, 2H), 3.77 (s, 3H, OCH_3), 3.2−3.0 (m, 2H), 2.98−2.86 (m, 2H), 2.80 (s, 4H, $2CH_2$), 2.10−1.95 (m, 8H), 1.68, 1.66, 1.60, 1.54 (4s, 12H, $4CH_3$). ^{13}C NMR ($CDCl_3$, 400 MHz) δ 184.4, 176.7, 171.1, 165.4, 140.4, 135.6, 131.5, 130.0, 126.3, 124.5, 123.9, 120.5, 120.4, 119.6, 60.6, 52.9, 52.3, 41.3, 39.9, 39.8, 33.5, 30.3, 28.4, 26.9, 26.4, 25.9, 25.5, 17.9, 16.3, 16.2.

***N*-(2-Methoxyethyl)succinamic Acid (13).** A solution containing 2-methoxyethylamine (100 mg, 1.33 mmol) and succinic anhydride (134 mg, 1.33 mmol) in HOAc (2 mL) was stored at room temperature overnight. The solvent was evaporated, and the residue was recrystallized in EtOAc to afford needles, 185 mg (79%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 6.18 (br s, NH), 3.46 (m, 4H), 3.36 (s, 3H), 2.70 (m, 2H), 2.53 (m, 2H).

1-(2-Methoxyethyl)pyrrolidine-2,5-dione (14). To a solution of acid **13** (5 mg, 28.5 μmol) in 0.5 mL of CH_3CN were added SDPP (14.2 mg, 28.5 μmol) and triethylamine (16 μL). The reaction was allowed to proceed overnight, and the residue was purified on SiO_2 (EtOAc) to give 2 mg of succinimide. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.74 (m, 2H), 3.56 (m, 2H), 3.32 (s, 3H), 2.72 (s, 4H).

2-Amino-3-(3,7,11-trimethyldodeca-2,6,10-trienylsulfanyl)propionic Acid Methyl Ester (Farnesyl-CysMe, 20). A solution containing farnesyl bromide (30 mg, 105 μmol), L-cysteine methyl ester hydrochloride (36 mg, 210 μmol), and $Zn(OAc)_2 2H_2O$ (71.4 mg, 315 μmol) in 6 mL of DMF/CH_3CN/ 0.025%TFA (2:1:1) was stirred at 0 °C for 2 h. The mixture was concentrated and purified on SiO_2 (EtOAc) to afford 57.8 mg (91.6%) of pale yellow oil. ^{1}H NMR (CD_3OD, 400 MHz) δ 5.24 (t, $J = 7.2$ Hz, 1H), 5.13 (m, 2H), 3.78 (s, 3H, OCH_3), 3.16 (m, 1H), 3.03 (m, 1H) 2.82 (m, 1H), 2.16−2.04 (m, 8H), 1.96 (m, 2H), 1.70 (m, 3H), 1.66 (s, 3H), 1.61 (s, 3H), 1.59 (s, 3H). ^{13}C NMR (CD_3OD, 400 MHz) δ 172.8, 141.1, 135.6, 131.5, 124.5, 123.9, 119.1, 53.6, 53.4, 39.9, 34.3, 29.6, 26.9, 26.7, 25.9, 17.9, 16.6, 16.2, 14.3.

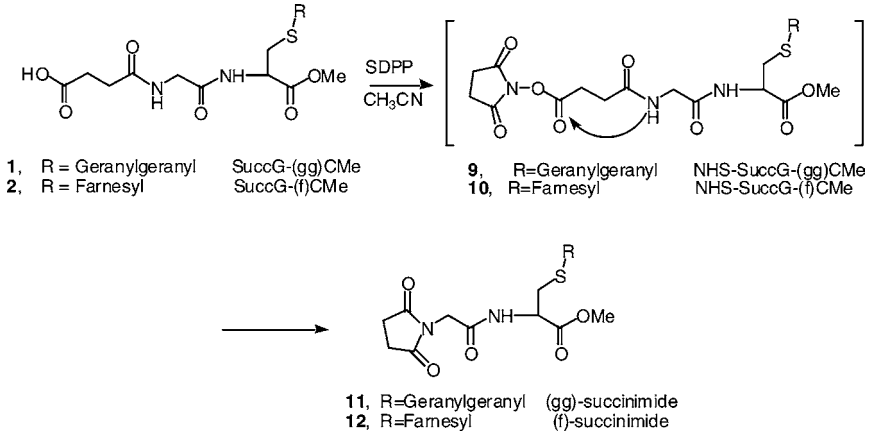
2-(Acetylamino)-3-(hexadecanoylsulfanyl)propionic Acid (Palm-AcCysOH, 21). A mixture containing *N*-acetylcysteine (16.3 mg, 0.1 mmol), palmitoyl chloride (36.4 μL, 0.12 mmol), and DIEA (52 μL, 0.3 mmol) in 1 mL of DMF was stirred at room temperature overnight. The product was purified with silica gel (EtOAc/HOAc 100:2) to afforded 8.88 mg (21.4%) of Palm-AcCysOH. ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.20 (s, 1H), 6.72 (m, 1H), 4.62 (m, 1H), 4.14 (m, 2H), 3.37 (m, 1H), 2.85 (s, 2H), 2.05 (s, 3H), 1.90−1.30 (m, 30H).



Coupling of SuccG-(gg)-CMe 1, SuccG-(f)-CMe 2, (gg)-CysMe 19, (f)-CysMe 20, Palm-AcCysOH 21, and Myr-GlyOH to BSA with EDCI. To a solution of haptens (1.2 μmol, 33 equiv to BSA) and BSA (0.36 μmol) in 30% DMSO buffer (10 mM NaH_2PO_4, 200 mM NaCl, pH 7.2) was added EDCI (4.5 mg, 23.4 μmol). The mixture was stirred at room temperature for 2 h and then purified (Sephadex G-25) by elution with 10 mM NaH_2PO_4, 200 mM NaCl, pH 7.2. Sample concentrations were measured using the Bradford reagent.

Coupling of SuccG-(gg)-CMe 1, SuccG-(f)-CMe 2 to KLH with EDCI. To a solution containing prenylated peptides **1** and **2** (0.8 μmol, 833 eq. to KLH) and KLH (0.96 μmol) in 30% DMSO buffer (31 mM NaH_2PO_4, 0.96 M NaCl, pH 7.4) was added EDCI (2 mg, 10.4 μmol). The mixture was stirred at room temperature for 2 h and then purified (Sephadex G-25) by elution with with 10 mM NaH_2PO_4, 200 mM NaCl, pH 7.2. Sample concentrations were measured using the Bradford reagent.

ELISA. A Maxisorp plate (Nunc) was washed twice with PBS 200 μL/well and then coated with BSA−SuccG-(gg/f)CMe 1 μg/well in the amount of 50 μL and incubated at room temperature for 1 h. The plate was rinsed 3× with 100 μL/well of PBS. Blocking solution (100 μL/well, 5% BSA/TBST) was added, and the plate was shaken for 1 h at room temperature. Blocking solution was removed, and the plate was washed 3× with 100 μL/well of TBST. Next, 50 μL/well of primary antibody (1:300) was added to the plate and shaken at room temperature for 1 h. The plate was washed 4× with 100 μL/well of TBST. Then 50 μL/well of anti-rabbit IgG-HRP at 1:2000 in TBST was applied and shaken for 1 h at room temperature. Antibodies were removed and washed 4× with 100 μL/well of TBST; TMB (Sigma) was added (100 μL/well). The plate was placed in a dark drawer for 15−20 min as the blue color developed. The reaction was stopped with 50 μL/well of 0.5 M H_2SO_4 to yield a yellow color. Absorbance at 430 nm was measured by a UV spectrometer.



CHO-K1 Cell Culture and Transfection. CHO-K1 epithelial cells (1×10^5) were seeded in a 6-well plate and incubated at 37 °C for 19 h to reach 30% confluence. Vector EYFP-CVLL (6 μg) was dissolved in 60 μL of serum-free medium. Lipofectamine (30 μL) was dissolved into 180 μL of serum-free medium, mixed at room temperature for 30 min, and then diluted with 1.6 mL of serum-free medium. Cells were treated with 1 mL of this mixture after aspiration of the original medium. The transfection continued for 6 h at 37 °C and was stopped by addition of medium containing G418 (0.5 mg/mL). The transfected cells were visualized by fluorescence microscopy. In the blank cell cultures, most cells were killed with G 418 antibiotic by day 9. Cell colonies could be seen in the Petri dishes.

Purification of Anti-gg/f from Rabbit Sera with Positive Immunoaffinity Chromatography. Rabbit antisera (1 mL, 26.7 mg/mL, serum-15, immunized with KLH−SuccG-(gg)CMe **15**) was diluted in 4 mL of NaOAc (60 mM, pH 4.0). Caprilic acid (125 μL) was added dropwise, and the mixture was stirred gently at room temperature for 30 min. The mixture was centrifuged to remove precipitate at 10 000 × *g* at room temperature for 30 min. The supernatant was dialyzed against 20 mM Tris-Cl (pH 7.5) overnight (protein concentration was 1.01 mg/mL, total 6.5 mg). Affigel-10 (Bio-Rad, 0.3 mL) was mixed with 0.5 mL of BSA−(gg)CMe **22** (0.54 mg/mL) or BSA−(f)CMe **23** (0.79 mg/mL) and incubated at 4 °C overnight. The Affigel beads were centrifuged at 5000 × *g*. The beads were washed twice with 0.4 mL of 10 mM Na_3PO_4/200 mM NaCl (pH 7.0) and then incubated with 0.2 mL of 7 M urea/1 M NaCl at room temperature for 1 h. The beads were further washed 3× with 0.4 mL of 10 mM Na_3PO_4/200 mM NaCl (pH 7.0) and then once with 0.4 mL of 0.2 M glycine, pH 7.2. Next, the beads were washed 3× with 0.4 mL of 10 mM Na_3PO_4/200 mM NaCl (pH 7.0) and then incubated with 0.4 mL of pretreated antibody solution at room temperature for 1 h. The beads were washed 3× with 0.4 mL of 10 mM Na_3PO_4/200 mM NaCl (pH 7.0). The beads were transferred to a column and eluted with 0.2 M glycine buffer (pH 2.0), and 150 μL of each fraction was collected into 150 μL of 2 M Tris-Cl, pH 8.8. The diluted antibodies were dialyzed against PBS and concentrated to about 1 mg/mL by ultrafiltration.

Fluorescence Imaging of CHO-K1 and EYFP-CVLL CHO-K1 Cells with Rabbit Antiserum. Cells were seeded on cover slips for 10 h to reach ~30% confluence. The localization of EYFP was visualized by fluorescence microscopy. The medium was aspirated, and then cells were washed with 2 × 1 mL of PBS. The cells were fixed with 4% paraformaldehyde for 10 min at room temperature. The cells were washed with 2 × 1 mL of PBS and permeabilized by addition of 0.8 mL of 0.2% Triton X-100 in PBS for 5 min at room temperature. The cells were washed with 3 × 1 mL of 0.2% Triton X-100 in PBS. The cover slips were blocked with 3% BSA/0.2% Triton X-100 in PBS 25 μL/each for 0.5 h. After adding serum-15 (1:150, 25 μL, 3% BSA/0.2% Triton X-100 in PBS), incubation continued for 1 h. The cells were washed with 3 × 1 mL of 0.2% Triton X-100 in PBS, 5 min/each and then incubated with 25 μL of anti-rabbit IgG-Texas Red (1:500, 3% BSA/0.2% Triton X-100 in PBS) for 1 h. Next, the cells were washed with 3 × 1 mL of 0.2% Triton X-100 in PBS, 5 min/each, followed by dehydration with 2 × 1 mL of ethanol, and 10 mL of xylene. Cover slips were mounted on glass slides.

RESULTS AND DISCUSSION

The haptens for coupling to BSA or KLH were synthesized from L-cysteine (Scheme 1). The free thiol of L-cysteine was protected with triphenylmethanol, and the S-protected cysteine was then converted to the methyl ester and coupled to *N*-Boc glycine (*29*, *30*). Subsequent removal of the Boc group afforded dipepetide **6**, which was converted to compound **8** by reaction with succinic anhydride, followed by deprotection of the trityl group (*31*, *32*). Compound **8** is a common intermediate used to synthesize the desired farnesylated and geranylgeranylated haptens SuccG-(gg)CMe **1** and SuccG-(f)CMe **2** (*33*).

Scheme 3. Model Reaction To Form Succinimide[a]

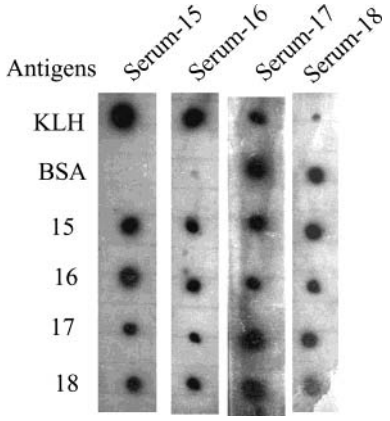
[a] Reagents and conditions: (a) Succinic anhydride, HOAc, 79%; (b) SDPP, CH_3CN.

Table 1. Haptens, Carrier Proteins, and Immunogens for Preparation and Characterization of Anti-Isoprenyl Antibodies

haptens	carrier	conjugates
SuccG-(gg)CMe **1**	KLH	KLH−SuccG-(gg)CMe **15**
SuccG-(f)CMe **2**	KLH	KLH−SuccG-(f)CMe **16**
SuccG-(gg)CMe **1**	BSA	BSA−SuccG-(gg)CMe **17**
SuccG-(f)CMe **2**	BSA	BSA−SuccG-(f)CMe **18**
(gg)-CMe **19**	BSA	BSA−(gg)CMe **22**
(f)-CMe **20**	BSA	BSA−(f)CMe **23**
Palm-AcCys **21**	BSA	BSA−Palm-AcCys **24**
Myr-Gly	BSA	BSA−Myr-Gly **25**

Originally, we planned on using the *N*-hydroxysuccimidyl (NHS) esters **9** and **10** of compounds **1** and **2** as active haptens ready for coupling to BSA or KLH (Scheme 2). Pure products were obtained when **1** and **2** were treated with SDPP in CH_3CN (*34*). However, immunization of chickens with their BSA or KLH conjugates did not produce any anti-isoprenyl reactivity in the IgY fractions. After careful examination of the chemistry of the immunogen preparation, we discovered an unexpected side reaction. When SDPP is added to SuccG-(gg)CMe **1** or SuccG-(f)CMe **2**, the NHS esters **9** and **10**, respectively, appear to form as unstable intermediates that rapidly undergo intramolecular cyclization to the more stable succinimide side products **11** and **12**. To confirm this hypothesis, a model reaction using methoxyethylamine was conducted, and 1-(2-methoxyethyl)-pyrrolidine-2,5-dione **14** was isolated as the main product (Scheme 3).

Successful preparation of immunogens was achieved by conjugation of SuccG-(gg)CMe **1** or SuccG-(f)CMe **2** to BSA and KLH using EDCI (Table 1) (*35*). The reactions were complete in 2 h as determined by TLC. Longer reaction times resulted in the formation of the succinimide byproducts. Four immunogens, KLH−SuccG-(gg)-CMe **15**, KLH−SuccG-(f)CMe **16**, BSA−SuccG-(gg)CMe **17**, and BSA−SuccG-(f)CMe **18** were obtained and then used to immunize both rabbits and mice. Six weeks later the animals were bled and sacrificed to collect antisera.



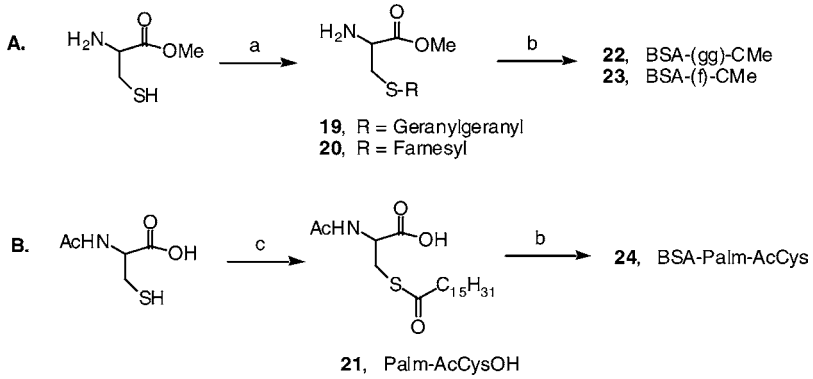


Figure 1. Dot blotting of antisera from rabbits; dilution 1:500.

Rabbit and mouse antisera containing polyclonal antibodies were checked with dot blotting. Figure 1 shows that the rabbit antisera contained antibodies against all four immunogens (**15**, **16**, **17**, **18**). None of the mouse-derived antisera contained sufficiently high titers of either anti-farnesyl or antigeranylgeranyl antibodies to allow us to proceed further with fusion and cloning (data not shown). Antisera from rabbits immunized with KLH−SuccG-(gg)CMe **15** (designated serum-15) or KLH−SuccG-(f)CMe **16** (serum-16) had the same patterns and did not recognize unmodified BSA. In contrast, antisera from rabbits immunized with BSA−SuccG-(gg)CMe **17** (serum-17) and BSA−SuccG-(f)CMe **18** (serum-18) were similar and showed a cross reaction with KLH. We thus selected serum-15 as the starting material for subsequent studies using BSA conjugates.

To determine whether serum-15 could recognize (gg)-CMe and (f)CMe epitopes, two additional immunogens, BSA−(gg)-CMe **22** and BSA−(f)-CMe **23**, were synthesized from geranygeranylated or farnesylated cysteine methyl esters **19** and **20** (Scheme 4A) (*36*). ELISA on Maxisorp plate (Figure 2) further showed that serum-15 recognized both farnesylated and geranylgeranylated immunogens (**17**, **18**, **22**, **23**) and that the selectivity was low.

We also asked whether, given the lack of selectivity between the farnesyl and geranylgeranyl groups, the serum-15 antibodies could distinguish prenylation from simple fatty acid modifications such as *S*-palmitoylation and *N*-terminal myristoylation. To test this hypothesis, first, we synthesized BSA−Palm-AcCys **24** and BSA−

Scheme 4. Synthesis of Immunogens for Characterization of Polyclonal Antibodies[a]

[a] Reagents and conditions: (a) farnesyl bromide or geranylgeranyl chloride, $Zn(OAc)_2 \cdot 2H_2O$, DMF/CH_3CN/TFA; (b) EDCI; (c) palmitoyl chloride, Et_3N, 21%.

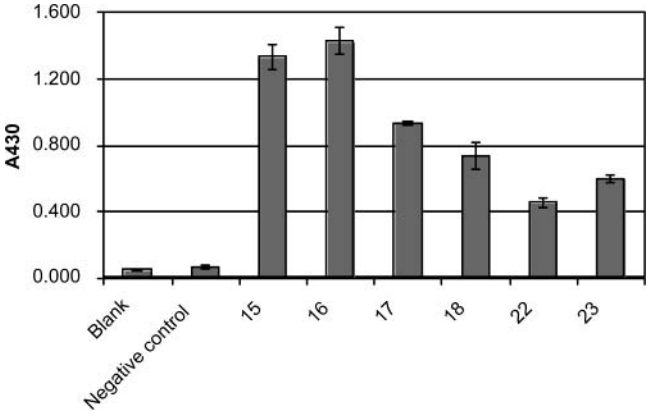

Figure 2. ELISA of rabbit serum-15 on Maxisorp plate. Immunogens (1 μg/well) were added to 96-well plate. In the negative control, no antiserum was added. See text for experiment details.

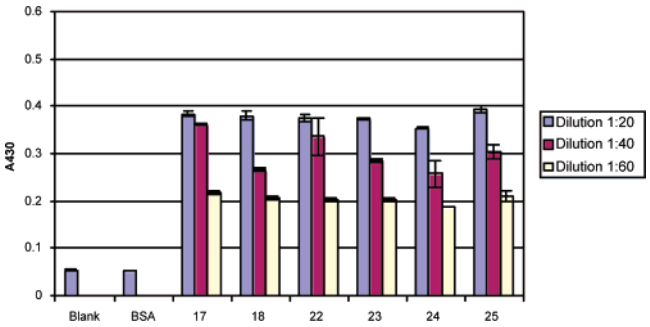

Figure 3. ELISA of BSA conjugates (**17**, **18**, **22**, **23**, **24**, and **25**) using immunoaffinity purified anti-gg antisera in a series of concentration (anti-f antisera gave similar results). Aliquots (1 μg) of BSA and BSA conjugates were added into each well on 96-well plate.

Myr-Gly **25** (Scheme 4B and Table 1). Second, we attempted to obtain selective polyclonal anti-gg or anti-f antibodies from serum-15 by positive immunoaffinity chromatography. Thus, BSA−SuccG-(gg)CMe (**17**) or BSA−SuccG-(f)CMe (**18**) was coupled to Affigel-10, and these resins were then incubated with pretreated serum-15 to bind the desired specific antibodies. After washing the resin beads with sodium phosphate buffer, followed by elution with glycine buffer, pH 2.0, putative anti-gg- or anti-f-containing fractions were collected in Tris-Cl buffer (2 M, pH 8.8). To our surprise, both the anti-gg and the anti-f fractions showed strong cross-reactivity with these aliphatic modifications as well (Figure 3).

It is apparent that rabbit polyclonal antibodies poorly distinguish aliphatic-modified peptides. One future opportunity will be exploring the use of these antibodies as "universal" detectors of lipidated proteins in cells for a proteomic approach to identify differentially expressed lipidated proteins in cells (*37*−*40*).

To address whether serum-15 could be used to stain isoprenylated proteins in cells, we transfected CHO-K1 cells with EYFP-CVLL (*41*−*43*), a fluorescent protein with a C-terminal CAAX sequence for geranylgeranylation. In the G1 phase of the cell cycle, tranasfected cells overexpressed and geranylgeranylated EYFP-CVLL, thus facilitiating movement of the EYFP transport to cell plasma membrane (Figure 4A). When the cells were fixed and treated with serum-15 followed by anti-rabbit IgG-Texas Red, red fluorescence was observed, which indicated colocalization with EYFP in the cell plasma membrane (Figure 4B). As a control, staining of native CHO-K1 cells with the same protocols gave dim red fluorescence in cytosol (Figure 4C). When the cells were treated with lovastatin, which blocks HMG CoA reductase and thus stops the production of FPP and GGPP, EYFP-CVLL could not be geranylgeranylated and thus remained localized in cytosol (Figure 4D) (*44*−*48*). Only dim red fluorescence could be observed in transfected and native CHO-K1 cells (Figure 4E, 4F). Taken together, these results demonstrate that serum-15 could be used to visualize overexpressed isoprenylated proteins in cells. The background fluorescence can be attributed either to nonspecific binding or to low-abundance of naturally occurring prenylated proteins.

In summary, the synthetic immunogens KLH−SuccG-(gg)CMe (**15**), KLH−SuccG-(f)CMe (**16**), BSA−SuccG-(gg)CMe (**17**), and BSA−SuccG-(f)CMe (**18**) stimulated strong immune responses in rabbits, affording antisera containing high titers of polyclonal anti-lipid antibodies. The lack of selectivity of these antisera suggest that distinguishing among specific lipidated proteins in cells would not be feasible. However, the antisera can visualize overexpressed isoprenylated cell proteins localized to the cell membrane, suggesting that perhaps a more universal

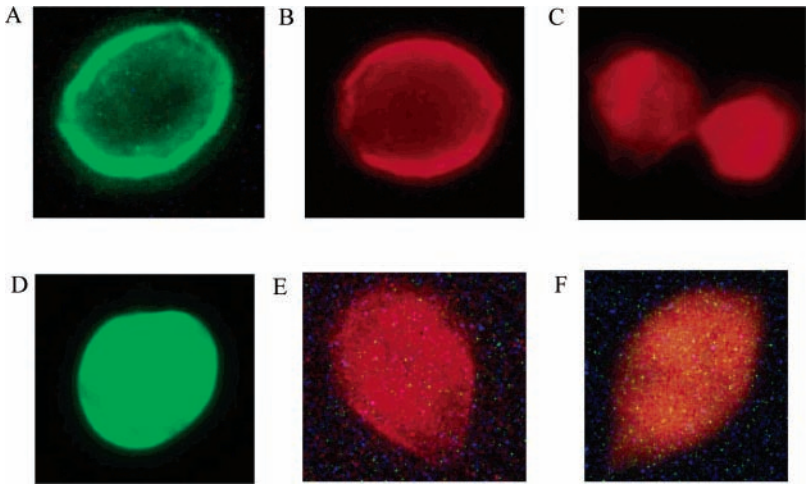

Figure 4. Immunofluorescence of EYFP-CVLL CHO-K1 cells and native CHO-K1 cells. Panel A: EYFP-CVLL cell, 10 h after seeding; Panel B: EYFP-CVLL cells stained with serum-15 (1:150), 10 h after seeding; Panel C: Native CHO-K1 cells stained with serum-15 (1:150), 10 h after seeding; Panel D: EYFP-CVLL cells was treated with 20 μM lovastatin for 24 h; Panel E: EYFP-CVLL cells were treated with 20 μM lovastatin for 24 h and then stained with serum-15 1:150; Panel F: Native CHO-K1 cells were treated with 20 μM lovastatin for 24 h and then stained with serum-15 (1:150).

tool for identification of electrophoretically separated lipidated proteins could be developed (*37*−*40*).

ACKNOWLEDGMENT

Vector pcDNA3.1 encoding EYFP-CVIM was the generous gift provided by Dr. Tamas Balla (Endocrinology and Reproduction Research Branch, National Institutes of Health). Mr. Hyo-Young Chung helped to prepare EYFP-CVLL vectors. This work was supported by the Center for Cell Signaling and NIH grant GM 44836 to G.D.P.

Dimers of D-*myo*-Inositol 1,4,5-Trisphosphate: Design, Synthesis, and Interaction with Ins(1,4,5)P_3 Receptors

Andrew M. Riley,[†] Alex J. Laude,[‡] Colin W. Taylor,[‡] and Barry V. L. Potter*[,†]

Wolfson Laboratory of Medicinal Chemistry, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath BA2 7AY, UK, and Department of Pharmacology, Tennis Court Road, University of Cambridge, CB2 1PD, UK. Received November 18, 2003; Revised Manuscript Received January 23, 2004

The design and synthesis of dimeric versions of the intracellular signaling molecule D-*myo*-inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3] are reported. Ins(1,4,5)P_3 dimers in a range of sizes were constructed by conjugation of a partially protected 2-*O*-(2-aminoethyl)-Ins(1,4,5)P_3 intermediate with activated oligo- and poly(ethylene glycol) (PEG) tethers, to give benzyl-protected dimers with amide or carbamate linkages. After deprotection, the resulting water-soluble Ins(1,4,5)P_3 dimers were purified by ion-exchange chromatography. The interaction of the Ins(1,4,5)P_3 dimers with tetrameric Ins(1,4,5)P_3 receptors was explored, using equilibrium [^{3}H]Ins(1,4,5)P_3-binding to membranes from cerebellum, and $^{45}Ca^{2+}$-release from permeabilized hepatocytes. The results showed that dimers, even when they incorporate large PEG tethers, interact potently with Ins(1,4,5)P_3 receptors, and that the shorter dimers are more potent than Ins(1,4,5)P_3 itself. A very small dimer, consisting of two Ins(1,4,5)P_3 motifs joined by a short *N*,*N*′-diethylurea spacer, was synthesized. Preliminary studies of $^{45}Ca^{2+}$ release from the intracellular stores of permeabilized hepatocytes showed this shortest dimer to be almost as potent as adenophostin A, the most potent Ins(1,4,5)P_3 receptor ligand known. Possible interpretations of this result are considered in relation to the recently disclosed X-ray crystal structure of the type 1 Ins(1,4,5)P_3 receptor core binding domain.

INTRODUCTION

D-*myo*-inositol 1,4,5-trisphosphate [Ins(1,4,5)P_3, **1**, Figure 1] is a hydrophilic intracellular signaling molecule that mediates the release of Ca^{2+} from intracellular stores by binding to Ins(1,4,5)P_3-gated Ca^{2+} channels [Ins(1,4,5)P_3 receptors, InsP_3Rs] located on the endoplasmic reticulum (*1*). Two naturally occurring glyconucleotides, adenophostins A and B (Figure 1), have been shown to activate InsP_3Rs with higher potency than Ins(1,4,5)P_3 itself (*2*, *3*), and work with synthetic adenophostin analogues suggests that this property is directly related to the presence of the aromatic base, which may interact with residues close to the Ins(1,4,5)P_3-binding site (*2*−*5*). An alternative approach to the development of novel and potent InsP_3R ligands may be to exploit the possibility of multivalent binding. InsP_3Rs are tetramers, composed of four subunits, each with a single Ins(1,4,5)P_3-binding site, surrounding the central ion channel, and this oligomeric structure of InsP_3Rs suggests that it may be possible to construct multivalent InsP_3R ligands that could simultaneously occupy more than one Ins(1,4,5)P_3-binding site in the tetramer.

Multivalent binding can lead to enhanced affinity and selectivity for the target protein (*6*, *7*); successful applications of this approach in recent years include multivalent inhibitors of selectins (*8*) and bacterial toxins (*9*), and the development of highly potent and selective inhibitors for the proteasome (*10*), *β*-tryptase (*11*), and glutathione *S*-transferases (*12*) using bivalent ligands. In addition, multivalent InsP_3R ligands could potentially be used as tools with which to study the relationship between Ins(1,4,5)P_3-binding and activation of InsP_3Rs (*13*).

In the first attempt to develop multivalent ligands for InsP_3Rs, bivalent and tetravalent clustered disaccharide analogues related to the adenophostins were synthesized (*13*) in which two or four molecules of a synthetic carbohydrate-based Ins(1,4,5)P_3 mimic were directly attached to a small hydrophobic hub (Figure 1). Although these analogues showed Ca^{2+}-releasing potencies comparable to Ins(1,4,5)P_3, no significant enhancement of binding affinity for InsP_3Rs was found when the multivalent ligands were compared with their monomeric equivalent, suggesting that only monovalent binding occurred (*13*). As electron microscopy studies (*14*−*18*) have shown that InsP_3Rs are large (about 20 nm across) and the locations of the Ins(1,4,5)P_3-binding sites are unknown, we considered that a more promising and versatile approach might be to use bivalent ligands with polymeric tethers in a wide range of lengths. This strategy has been successfully employed to produce super-potent dimeric ligands for tetrameric cyclic nucleotide gated (CNG) channels of photoreceptor and olfactory neurons by using a series of dimers of the 8-thio derivative of the natural ligand (cGMP) linked by poly(ethylene glycol) (PEG) chains of various lengths (*19*). Here we describe the design, synthesis, and biological activities of Ins(1,4,5)P_3 dimers containing poly- and oligo(ethylene glycol) tethers, and of a novel dimeric analogue containing two Ins(1,4,5)P_3 motifs joined by a short *N*,*N*′-diethylurea spacer. Some of this work has previously been reported in preliminary form (*20*), and

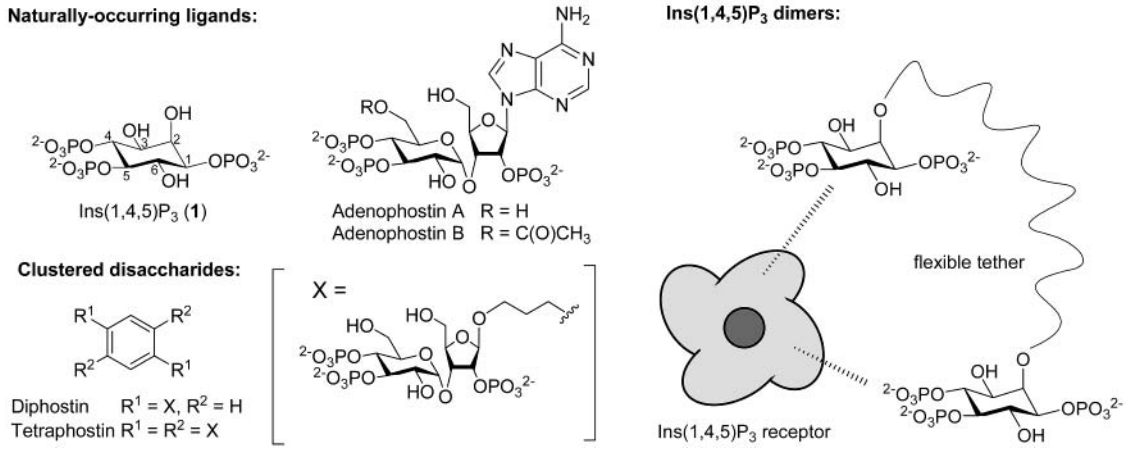

Figure 1. Structures of InsP_3R ligands: D-*myo*-inositol 1,4,5-trisphosphate (**1**), adenophostins A and B, clustered disaccharide analogues diphostin and tetraphostin, and Ins(1,4,5)P_3 dimers.

we have reported in depth on the first findings of biological activity (*21*).

MATERIALS AND METHODS

General Methods. Tetrahydrofuran (THF) was distilled from sodium and benzophenone under a nitrogen atmosphere. Dimethylformamide (DMF), acetonitrile, dichloromethane, and *N*,*N*-diisopropylethylamine (DIPEA) were purchased in anhydrous form and used without further purification. Poly(ethylene glycol)s (PEGs) were dried under vacuum at 60 °C or by azeotropic distillation from toluene prior to use. PEG3350 bis(4-nitrophenyl carbonate) was obtained from Sigma and used without further purification. "NH_4OH" refers to an approximately 28% w/w solution of NH_3 in water. Thin-layer chromatography (TLC) was performed on precoated plates (Merck TLC aluminum sheets silica 60 F_{254}) with detection by UV light or with phosphomolybdic acid in methanol or alkaline aqueous $KMnO_4$, followed by heating. Flash chromatography was carried out on silica gel (particle size 40−63 μm). Ion-exchange chromatography was performed on an LKB−Pharmacia medium-pressure ion exchange chromatograph using Q-Sepharose Fast Flow resin and gradients of triethylammonium bicarbonate (TEAB) as eluent. Quantitative analysis of phosphate was performed using a modification of the Briggs phosphate assay (*22*) or the Ames phosphate assay (*23*). ^{31}P NMR shifts were measured in ppm relative to external 85% phosphoric acid and are positive when downfield from this reference. FAB mass spectra were recorded at the University of Bath using 3-nitrobenzyl alcohol (NBA) as the matrix. Microanalysis was carried out by the Microanalysis Service, University of Bath. Melting points (uncorrected) were determined using a Reichert-Jung hot stage microscope apparatus.

Biological Assays. Equilibrium competition binding assays using [^{3}H]Ins(1,4,5)P_3 (New England Nuclear, 30 Ci/mmol) and membranes prepared from rat cerebellum were performed in medium (50 mM Tris, 1 mM EDTA, pH 8.3 at 2 °C) and using a final concentration of 1.5 nM [^{3}H]Ins(1,4,5)P_3 as previously described (*21*). Functional assays measured the effects of the Ins(1,4,5)P_3 analogues on release of $^{45}Ca^{2+}$ from the intracellular stores of permeabilized rat hepatocytes loaded with $^{45}Ca^{2+}$ in a cytosol-like medium. The methods were reported previously (*21*). The analogues were added (with 1 μM thapsigargin to inhibit further Ca^{2+} uptake) to cells loaded to steady-state with $^{45}Ca^{2+}$, and their effects on the $^{45}Ca^{2+}$ content of the stores were assessed after a further 60 s incubation.

Molecular Docking of Dimer 18. This was carried out using GOLD (*24*) (Version 2.0) running on a Silicon Graphics Octane2 workstation, and the X-ray crystal structure of the Ins(1,4,5)P_3-binding core of mouse type 1 InsP_3R in complex with Ins(1,4,5)P_3 [1N4K, (*25*)] according to methods previously described (*5*). Briefly, a docking protocol was first established that accurately reproduced the crystallographically observed position and conformation of Ins(1,4,5)P_3 in the site. This required that some of the crystallographically observed water molecules involved in the interactions of the 4,5-bisphosphate of Ins(1,4,5)P_3 with the binding site were included in the docking experiments. A model of dimer **18** was then built using Sybyl 6.8 (Tripos Associates) molecular modeling software and docked using the same protocol. Docked solutions were scored using the GoldScore (*24*) fitness function. In the highest scoring "fittest" solutions found, one Ins(1,4,5)P_3 component of **18** interacted with the Ins(1,4,5)P_3-binding site in a similar way to that revealed by the crystal structure, while the second Ins(1,4,5)P_3 interacted with residues close to the Ins(1,4,5)P_3-binding site. However, it was not possible to identify a definitive binding mode for **18**.

(2′*S*,3′*S*)-D-3,6-Di-*O*-benzyl-4,5-*O*-(2′,3′-dimethoxybutane-2′,3′-diyl)-1-*O*-(4-methoxybenzyl)-*myo*-inositol (4). To a solution of diol **3** (*26*) (4.00 g, 8.43 mmol) in MeOH (150 mL) was added dibutyltin oxide (2.12 g, 8.52 mmol). The suspension was heated at reflux for 16 h with removal of formed water using a Soxhlet apparatus containing 3 Å molecular sieves. The resulting clear solution was allowed to cool and then concentrated to dryness by evaporation under reduced pressure. CsF (2.56 g, 16.9 mmol, previously dried in vacuo over P_2O_5), was added, and the flask was fitted with a rubber septum and nitrogen line. Anhydrous DMF (30 mL) was injected, followed by 4-methoxybenzyl chloride (1.45 mL, 10.7 mmol), and the mixture was stirred at 50 °C under N_2 for 5 h, after which time TLC (chloroform/acetone 30:1) showed almost total conversion of diol (R_f 0.15) into a product (R_f 0.40). The solvents were removed by evaporation in vacuo at 50 °C, and the residue was taken up in Et_2O (200 mL) and washed with water (200 mL). The organic layer was dried over $MgSO_4$, filtered through Celite, and concentrated by evaporation under reduced pressure to give an oily residue. Purification by flash chromatography (Et_2O/hexane 1:2, then 1:1) gave the

alcohol **4** as a colorless oil which became a white foam on drying overnight in vacuo (4.22 g, 84%); $[\alpha]^{20}_D = +69$ ($c = 1.3$, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 270 MHz) δ 1.36 (s, 3H, CH_3), 1.38 (s, 3H, CH_3), 2.51 (br s, 1H, D_2O exch. 2-OH), 3.30 (s, 3H, OCH_3), 3.33 (s, 3H, OCH_3), 3.30−3.36 (m, 1H, buried, 1/3-H), 3.42 (dd, 1H, $J = 10.1$, 2.9 Hz, 1/3-H), 3.62 (dd, 1H, $J = 10.1$, 9.9 Hz, 5-H), 3.80 (s, 3H, OCH_3), 3.96 (dd, 1H, $J = 9.5$, 9.5 Hz, 4/6-H), 4.16 (br s, 1H, D_2O exch. gives dd, $J = 2.9$, 2.9 Hz, 2-H), 4.19 (dd, 1H, $J = 9.9$, 9.9 Hz, 4/6-H), 4.58−4.95 (m, 6H, AB systems of CH_2Ar), 6.81−6.88 (m, 2H, *meta*-H of PMB), 7.22−7.41 (m, 12H, ArH); ^{13}C NMR ($CDCl_3$, 68 MHz) 17.76 (2 × CH_3), 47.83, 47.92 (2 × OCH_3), 55.22 ($C_6H_4OCH_3$), 69.13, 69.30, 71.29 (C-2, C-4 and C-5), 72.77, 73.21, 75.65 (3 × OCH_2Ar), 76.55, 78.31, 79.47 (C-1, C-3 and C-6), 99.20, 99.28 (2 × BDA quaternary C), 113.73 (*meta*-C of PMB), 127.45, 127.55, 127.94, 128.20, 128.28, 129.48 (aromatic CH), 130.11 (*ipso*-C of PMB), 138.45 and 139.03 (2 × *ipso*-C of Ph), 159.24 (*para*-C of PMB); MS *m*/*z* (+ve ion FAB, relative intensity); 617 [$(M + Na)^+$, 64%], 593 [$(M - H)^+$, 40%], 563 [$(M - CH_3O)^+$, 16%], 121 (100), 91 [$(C_7H_7)^+$, 44%]; MS *m*/*z* (−ve ion FAB, relative intensity); 1188 (80), 747 [$(M + NBA)^-$, 100%], 593 [$(M - H)^-$, 64%]; Anal. (2′*S*,3′*S*)-D-3,6-Di-*O*-benzyl-2-*O*-cyanomethyl-4,5-*O*-(2′,3′-dimethoxybutane-2′,3′-diyl)-1-*O*-(4-methoxybenzyl)-*myo*-inositol (5). To a solution of **4** (2.63 g, 4.42 mmol) in dry acetonitrile (15 mL) was added sodium hydride (0.90 g of a 60% dispersion in mineral oil, 23 mmol). The suspension was stirred under N_2 at room temperature for 1 h and then cooled to −30 °C. Bromoacetonitrile (2.0 mL, 29 mmol) was added dropwise, and stirring was continued at −40 °C to −20 °C for 5 h. The suspension was then allowed to warm to room temperature, and stirring was continued overnight. The resulting brown liquid was concentrated by evaporation under reduced pressure, and the residue was suspended in water (100 mL) and extracted with Et_2O (2 × 100 mL). The combined organic extracts were dried over $MgSO_4$ and concentrated to give a brown residue. Purification by flash chromatography (Et_2O/hexane 2:3) gave the product **5** as a white solid (2.33 g, 83%); mp 120−121 °C (from ethyl acetate/hexane); $[\alpha]^{18}_D = +56$ ($c = 1.0$, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 270 MHz) δ 1.35 (s, 3H, CH_3), 1.37 (s, 3H, CH_3), 3.295 (s, 3H, OCH_3), 3.30 (s, 3H, OCH_3), 3.30−3.36 (m, 1H, buried, 1/3-H), 3.47 (dd, 1H, dd, $J = 10.3$, 2.6 Hz, 1/3-H), 3.62 (dd, 1H, $J = 9.9$, 9.9 Hz, 5-H), 3.86 (s, 3H, s, OCH_3), 3.89 (dd, 1H, $J = 9.5$, 9.5 Hz, 4/6-H), 4.07 (dd, 1H, $J = 2.6$, 2.6 Hz, 2-H), 4.11 (dd, 1H, $J = 10.1$, 9.9 Hz, 4/6-H), 4.52−4.93 (m, 8H, 4 × AB systems of OCH_2), 6.83−6.89 (m, 2H, *meta*-H of PMB), 7.24−7.40 (m, 12H, ArH); ^{13}C NMR ($CDCl_3$, 68 MHz) 17.74 (2 × CH_3), 47.84 and 47.94 (2 × OCH_3), 55.22 ($C_6H_4OCH_3$), 57.38 (CH_2CN), 69.57 and 71.45 (C-4 and C-5), 73.45, 73.85, 75.70 (3 × OCH_2Ar), 77.10, 77.41, 78.36, 79.47 (C-1, C-2, C-3 and C-6), 99.35, 99.41 (2 × BDA quaternary C), 113.81 (*meta*-C of PMB), 127.50, 127.66, 127.94, 128.22, 128.38, 129.72 (aromatic CH), 129.82 (*ipso*-C of PMB), 138.29 and 138.90 (2 × *ipso*-C of Ph), 159.34 (*para*-C of PMB); MS *m*/*z* (+ve ion FAB, relative intensity); 656 [$(M + Na)^+$, 50%], 632 [$(M - H)^+$, 76%], 602 [$(M - CH_3O)^+$, 16%], 394(76), 121 (100), 91 [$(C_7H_7)^+$, 54%]; MS *m*/*z* (−ve ion FAB, relative intensity); 786 [$(M + NBA)^-$, 100%], 679 (40), 512 (40); Anal. ($C_{36}H_{43}NO_9$) C, H, N.

D-3,6-Di-*O*-benzyl-2-*O*-[2-(2,2,2-trifluoroacetylamino)ethyl]-*myo*-inositol (6). To a solution of $LiAlH_4$ in THF (3.5 mL of a 1 M solution, 3.5 mmol) under N_2 at room temperature was added a solution of **5** (2.00 g, 3.16 mmol) in dry THF (5 mL) dropwise over 10 min. The reaction was stirred at room temperature for a further 1 h and then quenched by careful addition of water. Aqueous 15% NaOH (50 mL) was added, and the resulting solution was extracted with CH_2Cl_2 (3 × 50 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated to give the crude amine (∼2 g) as a colorless oil. The crude amine was taken up in dry THF (10 mL), and ethyl trifluoroacetate (0.5 mL, 4.2 mmol) was added. The solution was stirred at room temperature with exclusion of moisture overnight and then concentrated by evaporation under reduced pressure to give an oil, which was redissolved in CH_2Cl_2 (10 mL). Aqueous trifluoroacetic acid (95%, 10 mL) was added, and the solution was stirred at room temperature for 30 min. The solvents were removed by evaporation under reduced pressure, and the residue was purified by flash chromatography (EtOAc/hexane 2:1) to give triol **6** as a white solid (1.22 g, 77% yield over three steps); mp 130−131 °C (from ethyl acetate/hexane); $[\alpha]^{18}_D = +3$ ($c = 1.0$, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 2.85 (br s, 1H, D_2O exch. OH), 2.97 (br s, 1 H, D_2O exch. OH), 2.98 (br s, 1 H, D_2O exch. OH), 3.21 (dd, 1 H, $J = 9.8$, 2.4 Hz, 3-H), 3.33−3.48 (m, 3H, 1-H, 5-H, OCH_2CHCHN), 3.50−3.57 (m, 1 H, OCH_2CHCHN), 3.61 (dd, 1H, $J = 9.8$, 9.3 Hz, 6-H), 3.65 (ddd, 1 H, $J = 11.2$, 7.8, 2.9 Hz, $OCHCHCH_2N$), 3.81−3.87 (m, 2H, 2-H, 4-H), 3.96 (ddd, 1H, $J = 11.2$, 5.9, 3.4 Hz, $OCHCHCH_2N$), 4.65, 4.69 (AB, 2H, $J_{AB} = 11.7$ Hz, OCH_2Ph), 4.71, 4.97 (AB, 2H, $J_{AB} = 11.2$ Hz, OCH_2Ph), 7.28−7.38 (m, 10H, Ph), 8.08 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 40.38 ($CH_2CH_2NHC(O)CF_3$), 71.56 ($CH_2CH_2NHC(O)CF_3$), 71.74, 72.99 and 74.93 (C-1, C-4 and C-5), 73.13, and 75.27 (2 × OCH_2Ph), 78.46, 79.66 and 81.05 (C-2, C-3 and C-6), 115.99 ($^1J_{CF} = 289$ Hz, CF_3), 128.00, 128.03, 128.11, 128.38, 128.67, 128.75 (Ph CH), 137.23 and 138.29 (2 × *ipso*-C of Ph), 157.31 ($^2J_{CF} = 36.8$ Hz, C=O); MS *m*/*z* (+ve ion FAB, relative intensity); 500 [$(M + H)^+$, 76%], 498 (50), 408 (20), 320 (48), 91 [$(C_7H_7)^+$, 100%]; MS *m*/*z* (−ve ion FAB, relative intensity); 652 [$(M + NBA)^-$, 36%], 498 [$(M - H)^-$, 100%]; Anal. ($C_{24}H_{28}F_3NO_7$) C, H, N.

D-3,6-Di-*O*-benzyl-2-*O*-[2-(2,2,2-trifluoroacetylamino)ethyl]-*myo*-inositol 1,4,5-Tris(dibenzyl phosphate) (7). To a suspension of 1*H*-tetrazole (588 mg 8.39 mmol) and triol **6** (700 mg, 1.40 mmol) in dry CH_2Cl_2 (10 mL) under N_2 was added bis(benzyloxy)diisopropylaminophosphine (2.18 g, 6.31 mmol). The mixture was stirred at room temperature for 1.5 h and then cooled to −78 °C, before MCPBA (57%, 2.5 g, 8.3 mmol) was added in portions over 1 min. The mixture was allowed to warm to room temperature and then diluted with CH_2Cl_2 (100 mL). The clear solution was washed with 10% aq Na_2SO_3 solution (100 mL), dried over $MgSO_4$, and concentrated by evaporation under reduced pressure. The residue was purified by flash chromatography eluting with EtOAc/hexane 1:1 then 2:1 to give the title compound as an oil which slowly crystallized (1.72 g, 96%); mp 85−87 °C (from diisopropyl ether); $[\alpha]^{20}_D = -6$ ($c = 1.0$, $CHCl_3$); ^{1}H NMR ($CDCl_3$, 400 MHz, COSY) δ 3.33−3.42 (m, 3H, 3-H and OCH_2CH_2NH), 3.64−3.74 (m, 2H, OCH_2CH_2NH), 3.96−4.02 (m, 2H, 2-H and 6-H), 4.16 (ddd, 1H, $J = 9.4$, 6.6 and 2.3 Hz, 1-H), 4.39, 4.59 (AB, $J_{AB} = 11.3$ Hz, OCH_2Ph), 4.45 (ddd, 1H, $J = 9.8$, 9.4 and 9.4 Hz, 5-H), 4.62−5.04 (m, 15H, 4-H and 7 × CH_2Ph), 6.94−6.98 (m, 2H, Ph), 7.06−7.32 (m, 38H, Ph), 7.64 (br t, 1H, $J \sim 5$ Hz, OCH_2CH_2NH); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 39.83 (OCH_2CH_2NH), 69.03−69.46 (with couplings, 6 × $OPOCH_2Ph$), 70.78, 73.21 and 74.47 (OCH_2), 76.10 and 77.33 (inositol ring *C*H), 77.35−78.51 (with $^2J_{CP}$ cou-

plings, inositol ring *C*H), 115.62 ($^1J_{CF}$ = 287 Hz, CF_3), 126.72 and 126.95 (Ph *C*H), 127.52−128.46 (Ph *C*H), 134.90−135.64 (*ipso-C* of $POCH_2$*Ph*), 136.37 and 137.68 (*ipso*-C of Ph), 156.99 ($^2J_{CF}$ = 36 Hz, C=O); ^{31}P NMR ($CDCl_3$, 109 MHz) δ −1.17 (1P), −0.95 (1P) and −0.77 (1P); MS *m/z* (+ve ion FAB, relative intensity); 1280 [$(M + H)^+$, 90%], 91 [$(C_7H_7)^+$, 100%]; Anal. ($C_{66}H_{67}F_3NO_{16}P_3$) C, H, N.

D-2-*O*-(2-Aminoethyl)-3,6-di-*O*-benzyl-*myo*-inositol 1,4,5-Tris(dibenzyl phosphate) (2). To a solution of **7** (300 mg, 0.234 mmol) in THF (4 mL) was added a solution of $LiOH·H_2O$ (98 mg, 2.34 mmol) in MeOH (4 mL) and water (2 mL). The mixture was stirred at room temp for 1 h, after which TLC (CH_2Cl_2−MeOH−NH_4OH, 200:20:1) showed complete conversion of starting material (R_f 0.90) into a more polar product (R_f 0.36). The mixture was then diluted with Et_2O (40 mL) and washed with brine (40 mL). The organic layer was dried over $MgSO_4$ and concentrated to give crude **2** as an oil (266 mg, >90% pure by TLC, >86%); ^{1}H NMR ($CDCl_3$, 270 MHz) δ 2.74 (t, 2H, J = 5.0 Hz, $OCH_2CH_2NH_2$), 3.39 (dd, 1H, J = 9.7, 2.3 Hz, 3-H), 3.60−3.75 (m, 2H, OCH_2-CH_2NH), 4.05 (dd, 1 H, J = 9.7, 9.4 Hz, 6-H), 4.12 (dd, 1H, J = 2.3, 2.3 Hz, 2-H), 4.20 (ddd, 1H, J = 9.7, 7.9, 2.3 Hz, 1-H), 4.45−5.08 (m, 18H, 4-H, 5-H and 8 × CH_2Ph), 6.94−7.00 (m, 2H, Ph), 7.06−7.38 (m, 38H, Ph). Amine **2** was found to be unstable, and in subsequent experiments it was freshly prepared from **7**, immediately before use.

Dimer 9. To a solution of crude amine **2** (277 mg, 0.236 mmol) in dry DMF (1 mL) under N_2 was added a solution of **8** (*27*) (33 mg, 0.079 mmol) in dry DMF (1 mL). The solution was stirred at under N_2 at room temperature for 16 h. The solvents were removed by evaporation under reduced pressure, and the residue was purified by flash chromatography (CH_2Cl_2/MeOH 30:1). This procedure removed excess amine and *N*-hydroxysuccinimide, but the product was only ∼60 to 80% pure as judged by TLC. The crude product was taken up in MeOH (20 mL), and deionized water (5 mL) was added, followed by Pd−C (10%, 50% water, 200 mg). The mixture was shaken in a Parr hydrogenator under H_2 (50 psi) for 20 h. The catalyst was removed by filtration through a PTFE syringe filter and 1.0 M TEAB (1 mL) was added. The solvents were removed by evaporation under reduced pressure, and the residue was purified by ion-exchange chromatography on Q-Sepharose Fast Flow resin eluting with a gradient of TEAB (0 to 2 M). Fractions containing the target compound were identified by a modification of the Briggs phosphate test (*22*). The combined fractions were concentrated by evaporation in vacuo, and methanol was repeatedly added and evaporated, eventually leaving the triethylammonium salt of **9** as a colorless glass, which was accurately quantified using a modification of the Briggs phosphate assay (*22*) (15.4 μmol, 19%); $[\alpha]^{20}_D$ = −16 (c = 0.5, MeOH); ^{1}H NMR (D_2O, 400 MHz, COSY) δ 3.26−3.38 (m, 4H, OCH_2CH_2N), 3.58 (dd, 2H, J = 9.7, 2.3 Hz, 3-H), 3.62 (br s, 8H, 2 × OCH_2CH_2O), 3.62−3.68 (m, 2H, $OCHCH_2N$), 3.75 (dd, 2H, J = 9.7, 9.7 Hz, 6-H), 3.80−3.94 (m, 8H, 1-H, 2-H, 5-H and $OCHCH_2N$), 3.96 (br s, 4H, $NHC(O)CH_2O$), 4.14 (ddd, 2H, J = 9.1, 9.1, 9.1 Hz, 4-H); ^{31}P NMR (D_2O, 100 MHz) δ 0.31 (2P), 1.17 (2P), 1.55 (2P); MS *m/z* (−ve ion FAB, relative intensity); 1111 [M^-, 100%]; Accurate mass FAB− calcd for $C_{24}H_{49}N_2O_{35}P_6^-$, 1111.0548; found 1111.0542.

Hexa(ethylene glycol) Bis(4-nitrophenyl carbonate) (10a). To a solution of hexa(ethylene glycol) (564 mg, 2.00 mmol) in dry DMF (10 mL) under N_2 was added bis(4-nitrophenyl) carbonate (1.83 g, 6.00 mmol) followed by DIPEA (1.0 mL, 5.7 mmol). The solution was stirred at room temperature for 20 h, and the solvents were removed by evaporation in vacuo. The residue was purified by flash chromatography on silica gel (EtOAc/hexane 2:1 then EtOAc) to give **10a** as a pale yellow oil (1.17 g, 96%); ^{1}H NMR ($CDCl_3$, 270 MHz) δ 3.67 (br s, 8H, 4 × OCH_2), 3.69 (m, 8H, 4 × OCH_2), 3.78−3.84 (m, 4H, OCH_2CH_2OCO) 4.42−4.48 (m, 4H, OCH_2CH_2OCO), 7.36−7.42 (m, 4H, 2-H and 6-H of 4-nitrophenyl), 8.25−8.31 (m, 4H, 3-H and 5-H of 4-nitrophenyl); MS *m/z* (+ve ion FAB, relative intensity); 613 [$(M + H)^+$, 70%], 210 (100); Anal. Calcd for ($C_{26}H_{32}N_2O_{15}$) C, H, N.

PEG1450 Bis(4-nitrophenyl carbonate) (10b). Synthesized as for **10a** from PEG1450 (1.45 g, approximately 1.0 mmol) using bis(4-nitrophenyl) carbonate (1.83 g, 6.00 mmol) and DIPEA (1.0 mL, 5.7 mmol) in dry DMF (10 mL). Purification by flash chromatography (CH_2Cl_2, then CH_2Cl_2/MeOH 20:1) gave **10b** as a pale yellow waxy solid (1.09 g, 61%); δ 3.60−3.82 (m, approximately 130H, PEG-CH_2), 3.80−3.86 (m, 4H, OCH_2CH_2OCO) 4.40−4.50 (m, 4H, OCH_2CH_2OCO), 7.41 (d, 4H, J = 9.2 Hz, 2-H and 6-H of 4-nitrophenyl), 8.24 (d, 4H, J = 9.2 Hz, 3-H and 5-H of 4-nitrophenyl).

PEG8000 Bis(4-nitrophenyl carbonate) (10d). Synthesized as for **10a** from PEG8000 (4.0 g, approximately 0.5 mmol) using bis(4-nitrophenyl) carbonate (915 mg, 3.00 mmol) and DIPEA (0.5 mL, 2.9 mmol) in dry DMF (40 mL, heating initially required to dissolve). Purification by flash chromatography (CH_2Cl_2, then CH_2Cl_2/MeOH 50:1 to 5:1) gave **10d** as a white solid (2.06 g, 49%) δ 3.50−3.85 (m, approximately 700H, PEG-CH_2), 4.42−4.48 (m, 4H, OCH_2CH_2OCO), 7.40 (d, 4H, J = 9.2 Hz, 2-H and 6-H of 4-nitrophenyl), 8.29 (d, 4H, J = 9.2 Hz, 3-H and 5-H of 4-nitrophenyl).

Methoxyhexa(ethylene glycol) 4-Nitrophenyl Carbonate (12). To a solution of methoxyhexa(ethylene glycol) (**11**) (*28*) (550 mg, 1.86 mmol) in dry DMF (5 mL) under N_2 was added bis(4-nitrophenyl) carbonate (913 mg, 3.00 mmol) followed by DIPEA (0.5 mL, 2.9 mmol). The solution was stirred at room temperature for 20 h, and the solvents were removed by evaporation in vacuo. The residue was purified by flash chromatography (EtOAc/hexane 1:1; then EtOAc) to give **12** as a pale yellow oil (710 mg, 83%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.37 (s, 3H, OMe), 3.53−3.57 (m, 2H, CH_2OMe), 3.62−3.72 (m, 18H, 9 × OCH_2), 3.79−3.82 (m, 2H, OCH_2CH_2OCO), 4.43−4.45 (m, 2H, OCH_2CH_2OCO), 7.37−7.42 (m, 2H, 2-H and 6-H of 4-nitrophenyl), 8.26−8.31 (m, 2H, 3-H and 5-H of 4-nitrophenyl); MS *m/z* (+ve ion FAB, relative intensity); 462 [$(M + H)^+$, 100%], 210 (50), 103(30); Anal. ($C_{20}H_{31}NO_{11}$) C, H, N.

Benzyl-Protected Dimer 13a. To a solution of **7** (300 mg, 0.234 mmol) in THF (4 mL) was added a solution of $LiOH·H_2O$ (98 mg, 2.34 mmol) in MeOH (4 mL) and water (2 mL). The mixture was stirred at room temp for 1 h and then diluted with Et_2O (40 mL). The resulting suspension was washed with brine (40 mL). The organic layer was separated, dried over $MgSO_4$, and concentrated to give amine **2**, which was further dried by addition and evaporation of DMF (3 × 5 mL). Dry DMF (2 mL) was then added under N_2, followed by a solution of **10a** (36 mg, 0.059 mmol) in dry DMF (1 mL). The mixture was stirred under N_2 at room temperature for 16 h. TLC (EtOAc) showed a product at R_f 0.58, and 4-nitrophenol at R_f 0.66. TLC (CH_2Cl_2/MeOH/NH_4OH, 200:20:1) confirmed the presence of excess unreacted amine **2**. Water (2 mL) was added, and the mixture was stirred for a further 1 h, before the solvents were removed by evaporation in vacuo. The residue was purified by flash

chromatography, eluting with CH_2Cl_2/MeOH 50:1 to give **13a** as a colorless oil (93 mg, 58% yield); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.24−3.30 (m, 4H, OCH_2CH_2N), 3.38 (dd, 2H, J = 10.0, 2.1 Hz, 3-H), 3.50−3.70 (m, 24H, 10 × OCH_2 and OCH_2CH_2N), 4.00 (dd, 2H, J = 9.7, 9.4 Hz, 6-H), 4.04 (br s, 2H, 2-H), 4.10−4.16 (m, 4H, 2 × $CH_2OC(O)NH$), 4.18 (ddd, 2H, J = 9.7, 7.3, 2.3 Hz, 1-H), 4.48 (ddd, 2H, J = 9.4, 9.4, 9.1 Hz, 5-H), 4.47, 4.57 (AB_q, 4H, J_{AB} = 11.7 Hz, 2 × OCH_2Ph), 4.62−4.68 (0.5 of AB_q with $^3J_{HP}$ coupling, 2H, J_{AB} 11.7 Hz, J_{HP} 8.5 Hz, $POCH_2Ph$), 4.74−5.07 (m, 28H, 4-H and 6.5 AB systems of OCH_2Ph), 5.60 (br t, 2H, J = 5.3 Hz, NH), 6.96−6.98 (m, 4H, Ph), 7.08−7.36 (m, 76H, Ph); ^{31}P NMR ($CDCl_3$, 162 MHz) δ −0.56 (2P), −0.60 (2P), −0.63 (2P).

Benzyl-Protected Dimer 13b. Synthesized as for **13a** from **7** (300 mg) and **10b** (112 mg, 0.063 mmol) in dry DMF (3 mL). Purification by flash chromatography CH_2Cl_2/MeOH (50:1 then 30:1 and finally 10:1) gave the product **13b** as a colorless glass (147 mg, 0.038 mmol, 60% based on linker); ^{1}H NMR ($CDCl_3$, 400 MHz) was almost identical to that for **13a** except δ 3.55−3.70 (m, approx 130H, CH_2 of PEG); ^{31}P NMR ($CDCl_3$, 162 MHz) δ −0.63 (broad, 4P), −0.59 (broad 2P).

Benzyl-Protected Dimer 13c. Synthesized as for **13a** from **7** (300 mg) and **10c** (Sigma, 248 mg, 0.067 mmol) in dry DMF (4 mL). Purification by flash chromatography using a gradient of CH_2Cl_2/MeOH (20:1 then 10:1 and finally 5:1) gave the product **13c** as a colorless glass (191 mg, 0.033 mmol, 49% based on linker); ^{1}H NMR ($CDCl_3$, 270 MHz) was almost identical to that for **13a** except δ 3.55−3.70 (m, approx 300H, CH_2 of PEG); ^{31}P NMR ($CDCl_3$, 109 MHz) δ approximately −0.9 (broad).

Benzyl-Protected Dimer 13d. Synthesized as for **13a** from **7** (300 mg) and **10d** (450 mg, 0.055 mmol) in dry DMF (5 mL). Purification by flash chromatography eluting with a gradient of CH_2Cl_2/MeOH (20:1 then 10:1 and finally 5:1) to give the product **13d** as a colorless glass (180 mg, 0.017 mmol, 31% based on linker). ^{1}H NMR ($CDCl_3$, 270 MHz) was almost identical to that for **13a** except δ 3.55−3.70 (m, approx 700H, CH_2 of PEG); ^{31}P NMR ($CDCl_3$, 109 MHz) δ approximately −0.9 (broad).

Dimer 14a. To a solution of **13a** (28 mg, 10 μmol) in MeOH (20 mL) and water (5 mL) was added Pd−C (10%, 50% water, 200 mg). The mixture was shaken in a Parr hydrogenator under H_2 (50 psi) for 48 h. The catalyst was removed by filtration through a PTFE syringe filter, and 1.0 M TEAB (1 mL) was added. The solvents were removed by evaporation under reduced pressure, and the residue was purified by ion-exchange chromatography on Q-Sepharose Fast Flow resin, eluting with a gradient of TEAB (0 to 2 M). Fractions containing the target compound were identified by a modification of the Briggs phosphate test (*22*). The combined fractions were concentrated by evaporation in vacuo, and methanol was repeatedly added and evaporated, eventually leaving the triethylammonium salt of **14a** as a colorless glass, which was accurately quantified using the Ames total phosphate assay (*23*) (5.2 μmol, 52%); ^{1}H NMR (CD_3OD, 400 MHz) δ ~3.3 (m, 4H, (buried), OCH_2CH_2N), 3.61−3.70 (m, 22H, 3-H and 10 × OCH_2), 3.77−3.85 (m, 2H, $OCHHCH_2N$), 3.92−4.00 (m, 6H, 5-H, 6-H and $OCHHCH_2N$), 4.01−4.06 (m, 4H, 1-H and 2-H), 4.14−4.20 (m, 4H, 2 × $CH_2OC(O)NH$), 4.32 (ddd, 2H, J = 9.4, 8.9, 8.6 Hz, 4-H); ^{31}P NMR (CD_3OD, 162 MHz) δ 2.06 (2P), 3.19 (2P) and 3.66 (2P); MS *m*/*z* (−ve ion FAB, relative intensity); 1281 (90), 1259 [M^-, 80%], 97 [$H_2PO_4^-$, 100]; Accurate mass FAB− calcd for $C_{30}H_{61}N_2O_{39}P_6^-$, 1259.1277; found 1259.1221.

Dimer 14b. Hydrogenolysis of **13b** (147 mg, 38 μmol) and purification as for **14a** gave the triethylammonium salt of **14b** as a colorless glass which crystallized on standing (21 μmol, 55%). ^{1}H NMR (CD_3OD, 400 MHz) was similar to that for **14a** except δ 3.62−3.66 (m, approx 130H, CH_2 of PEG); ^{31}P NMR (CD_3OD, 109 MHz) δ 1.53 (2P) 2.36 (2P) and 2.85 (2P).

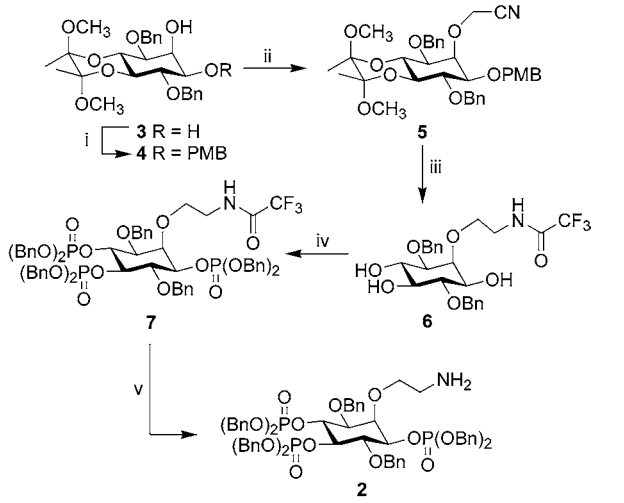
Dimer 14c. Hydrogenolysis of **13c** (191 mg, 33 μmol) and purification as for **14a** gave the triethylammonium salt of **14c** as a colorless glass which crystallized on standing (21 μmol, 64%). ^{1}H NMR (CD_3OD, 400 MHz) was similar to that for **14a** except δ 3.5−3.7 (m, approx 300H, CH_2 of PEG); ^{31}P NMR (CD_3OD, 109 MHz) δ 1.41 (2P) 2.18 (2P) and 2.67 (2P).

Dimer 14d. Hydrogenolysis of **13d** (180 mg, 17 μmol) and purification as for **14a** gave the triethylammonium salt of **14d** as a colorless glass which crystallized on standing (11 μmol, 65%). ^{1}H NMR (CD_3OD, 400 MHz) was similar to that for **14a** except δ approximately 3.5−3.7 (m, approx 700H, CH_2 of PEG); ^{31}P NMR (CD_3OD, 109 MHz) δ 2.02 (2P), 2.70 (2P) and 3.20 (2P).

Benzyl-Protected Methoxyhexa(ethylene glycol)−Ins(1,4,5)P$_3$ Conjugate 15. To a solution of the crude amine **2** (90 mg, 76 μmol, prepared from **7** as in the synthesis of **13a**) in dry DMF (1 mL) under N_2 was added a solution of **12** (115 mg, 250 μmol) in DMF (1 mL). The yellow solution was stirred at room temperature for 16 h and then concentrated by evaporation under reduced pressure. The residue was taken up in THF (5 mL), and NH_4OH (5 drops) was added to destroy excess **12**. After 20 min, the solvents were removed by evaporation under reduced pressure, and the residue was purified by flash chromatography ($CHCl_3$/MeOH 100:1 then 50:1) to give **15** as a colorless oil (67 mg, 58%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.24−3.30 (m, 2H, OCH_2CH_2N), 3.37 (s, 3H, OMe), 3.38 (dd, 1H, partially buried, 3-H), 3.50−3.70 (m, 24H, 11 × OCH_2 and OCH_2CH_2N), 4.01 (dd, 1H, J = 9.7, 9.8 Hz, 6-H), 4.04 (br s, 1H, 2-H), 4.10−4.16 (m, 2H, $CH_2OC(O)NH$), 4.18 (ddd, 1H, J = 9.7, 7.3, 2.3 Hz, 1-H), 4.48 (ddd, 1H, J = 9.4, 9.4, 9.1 Hz, 5-H), 4.47, 4.57 (AB_q, 2H, J_{AB} = 11.7, OCH_2Ph), 4.62−4.68 (0.5 of AB_q with $^3J_{HP}$ coupling, 1H, J_{AB} = 11.7 Hz, J_{HP} = 8.5 Hz, $POCH_2Ph$), 4.73−5.06 (m, 14H, 4-H and 6.5 AB systems of OCH_2Ph), 5.60 (br t, 1H, J ~ 5.3 Hz, NH), 6.95−6.98 (m, 2H, Ph), 7.08−7.36 (m, 38H, Ph); ^{31}P NMR ($CDCl_3$, 162 MHz) δ −0.59 (1P), −0.63 (2P); MS *m*/*z* (+ve ion FAB, relative intensity); 1507 [$(M + H)^+$, 80%], 181 (10), 91 (100); *m*/*z* (−ve ion FAB, relative intensity); 1659 [$(M + NBA)^-$, 40%], 1415 [$(M - C_7H_7)^-$, 90%], 277 (100); accurate mass FAB^+ calcd for $C_{78}H_{95}NO_{23}P_3^+$, 1506.5508; found 1506.5552.

Methoxyhexa(ethylene glycol)−Ins(1,4,5)P$_3$ Conjugate 16. Hydrogenolysis of **15** (47 mg, 31 μmol), and purification by ion exchange chromatography on Q-Sepharose Fast Flow resin eluting with a gradient of TEAB (0 to 1 M) gave the triethylammonium salt of **16** as a colorless glass (29 μmol, 94%). ^{1}H NMR (CD_3OD, 400 MHz) δ ~3.3 (m, 2H, (buried), OCH_2CH_2N), 3.35 (s, 3H, OMe), 3.51−3.56 (m, 2H, PEG CH_2OMe), 3.57−3.70 (m, 21H, 3-H and 10 × CH_2 of PEG), 3.76−3.83 (m, 1H, $OCHHCH_2N$), 3.92−4.08 (m, 5H, 1-H, 2-H, 5-H, 6-H and $OCHHCH_2N$), 4.13−4.17 (m, 2H, CH_2 of PEG), 4.34 (ddd, 1H, J = 9.4, 8.9, 8.6 Hz, 4-H); ^{31}P NMR (CD_3OD, 162 MHz) δ 1.86, 2.65 and 3.10; MS *m*/*z* (−ve ion FAB, relative intensity); 1569 [(2M−H)-, 80%], 784 (M^-, 100%); accurate mass FAB− calcd for $C_{22}H_{45}NO_{23}P_3^-$, 784.1995; found 784.1603.

Benzyl-Protected Dimer 17. To a solution of the crude amine **2** (205 mg, 0.173 mmol, freshly prepared

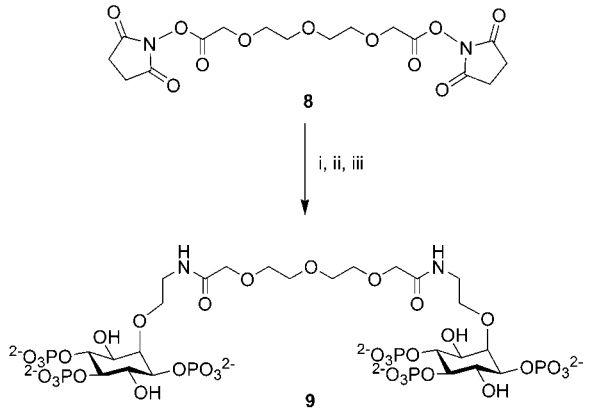


from **7** as in the synthesis of **13a**) in dry DMF (3 mL) under N_2 was added bis(4-nitrophenyl) carbonate (recrystallized from CH_2Cl_2/hexane, 24 mg, 0.079 mmol). The mixture was stirred overnight at room temp. The solvents were removed by evaporation in vacuo to give a residue, which was purified by flash chromatography (CH_2Cl_2 then CH_2Cl_2/MeOH 100:1 to 30:1) to give **17** as a colorless oil (134 mg, 56.0 μmol 71%); ^{1}H NMR ($CDCl_3$, 400 MHz) δ 3.21−3.43 (m, 6H, OCH_2CH_2N and H-3), 3.65−3.72 (m, 2 H, $OCHCH_2N$), 3.72−3.80 (m, 2H, $OCHCH_2N$), 4.04 (dd, 2H, J = 9.8, 9.4 Hz, 6-H), 4.10 (br s, 2H, 2-H), 4.18 (ddd, 2H, J = 9.8, 9.4, 1.6 Hz, 1-H), 4.42−4.51 (m, 6H, OCH_2Ph and 5-H), 4.57−4.63 (0.5 of AB_q with $^3J_{HP}$ coupling, 2H, J_{AB} = 11.7, J_{HP} = 8.6 Hz, $POCHHPh$), 4.70−5.02 (m, 28H, 4-H and 6.5 AB systems of OCH_2Ph), 5.99 (br t, 2H, J = 5.3 Hz, NHC(O)), 6.90−6.94 (m, 4H, Ph), 7.02−7.34 (m, 76H, Ph); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 40.15 (OCH_2CH_2NH), 68.99−69.35 (with $^3J_{CP}$ couplings, $OPOCH_2Ph$), 72.14, 73.40 and 74.44 (OCH_2CH_2NH and OCH_2Ph), 75.38 (inositol ring *C*H), 77.19−78.53 (with J_{CP} couplings, inositol ring *C*H), 126.80−128.23 (Ph *C*H), 135.11−135.59 (*ipso-C* of $POCH_2Ph$), 136.62 and 137.85 (*ipso*-C of Ph), 158.29 (urea C=O); ^{31}P NMR (CD_3Cl_3, 162 MHz) δ −0.69 (2 P), −0.52 (2 P), −0.46 (2 P). MS *m/z* (+ve ion FAB, relative intensity); 2394 [$(M + H)^+$, 80%], 181 (100).

Dimer 18. Hydrogenolysis of **17** (48 mg, 20 μmol) and purification as for **14a** gave the triethylammonium salt of **18** as a colorless glass (12.5 μmol, 63%); $[\alpha]^{20}_D$ = −14 (*c* = 0.40, MeOH); ^{1}H NMR (CD_3OD, 400 MHz) δ ~3.3 (m, 4H, (buried), OCH_2CH_2N), 3.60 (dd, 2H, J = 9.8, 2.3 Hz, 3-H), 3.80−3.87 (m, 2H, $OCHCH_2N$), 3.88−3.96 (m, 2H, $OCHCH_2N$), 3.96−4.07 (m, 8H, 1-H, 2-H, 5-H and 6-H), 4.35 (ddd, 2H, J = 9.4, 9.09, 8.6 Hz, 4-H); ^{31}P NMR (CD_3OD, 162 MHz) δ 2.08 (2P), 3.42 (2P) and 3.79 (2P); MS *m/z* (−ve ion FAB, relative intensity); 951 (M^-, 100%), accurate mass FAB− calcd for $C_{17}H_{37}N_2O_{31}P_6^-$, 950.9806; found 950.9789.

RESULTS

Synthetic Strategy. Structure−activity studies using synthetic Ins(1,4,5)P_3 analogues (*29*, *30*) have demonstrated that large groups can be attached to the axial 2-oxygen atom of Ins(1,4,5)P_3 with minimal reduction in affinity for InsP_3Rs. This suggested that, at the Ins(1,4,5)P_3-binding sites of InsP_3Rs, this area may be open to solvent. This hypothesis has subsequently been confirmed with the publication of the X-ray crystal structure of the Ins(1,4,5)P_3-binding core (*25*). We therefore envisaged a strategy in which a 2-*O*-aminoalkyl-modified Ins(1,4,5)P_3 headgroup would be conjugated with a range of linkers to give dimers of Ins(1,4,5)P_3. These dimers would then be used to conduct a distance scan to identify the separation of Ins(1,4,5)P_3-binding sites. If bivalent binding to InsP_3Rs could be achieved then this should be signaled by an increase in potency for dimers with a particular range of lengths. The same Ins(1,4,5)P_3 headgroup could then be conjugated with more rigid spacers or scaffolds in the appropriate size range. For the linkers, we chose activated derivatives of PEGs and their shorter oligo(ethylene glycol) equivalents. While highly flexible linkers such as PEG may not be ideal in terms of enhancement of potency (*6*), the facts that PEGs are water-soluble irrespective of size, and available in a range of lengths make them an attractive starting point when the locations of the binding sites are unknown and their separation is possibly large, as in the case of InsP_3Rs. For installation of the Ins(1,4,5)P_3 headgroups, we identified **2** (Scheme 1) as a key intermediate. In **2**, a selectively protected derivative of Ins(1,4,5)P_3, the phosphate monoesters and hydroxyl groups are masked with benzyl groups, leaving a primary amine group exposed for reaction with electrophilically activated linkers. A major advantage of this approach, as opposed to using a simple aminoalkyl derivative of Ins(1,4,5)P_3 itself, is that the coupling reactions can be carried out in organic solvents under anhydrous conditions, and the product can be purified to homogeneity by chromatography on silica gel before a final deprotection step. This strategy avoids any hydrolysis of reactive end-groups on the spacer and minimizes the possibility of contamination of the final product with monomeric linker-Ins(1,4,5)P_3 conjugates.



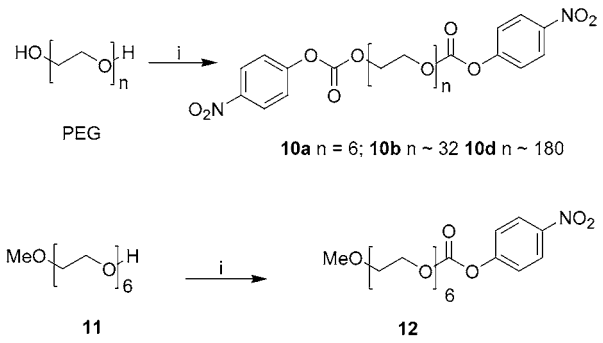
Scheme 1. Preparation of Protected 2-*O*-(2-Aminoethyl)-Ins(1,4,5)P_3 (2)[a]

[a] Reagents and conditions: i, (*a*) Bu_2SnO, MeOH, reflux, 16 h; (*b*) PMBCl, CsF, DMF, 50 °C, 5 h, ii, NaH, $BrCH_2CN$, CH_3CN, −20 °C to −40 °C 5 h then room temp, 16 h; iii, (*a*) $LiAlH_4$, THF, room temp, 1 h, (*b*) ethyl trifluoroacetate, THF, room temp, 1 h, (*c*) TFA/CH_2Cl_2/H_2O 19:20:1, room temp, 30 min; iv, $(BnO)_2PNPr^i_2$, 1*H*-tetrazole, CH_2Cl_2, room temp, 1 h, then MCPBA, −78 °C to room temp, 30 min; v, LiOH·H_2O (10 equiv) in THF/MeOH/H_2O 2:2:1, room temp, 1 h. Bn = benzyl, PMB = 4-methoxybenzyl.

Preparation of a Selectively Protected 2-*O*-(2-Aminoethyl)−Ins(1,4,5)P_3 for Cross-Linking. The required amine **2** was synthesized from diol **3** (*26*) (Scheme 1). Regioselective stannylene-mediated alkylation of the equatorial 1-OH group with 4-methoxybenzyl chloride gave the alcohol **4** in 80% yield. Alkylation of the free 2-OH group in **4** with bromoacetonitrile and sodium hydride at reduced temperatures in acetonitrile (*31*) then gave the crystalline 2-*O*-cyanomethyl derivative **5** in 83% yield. Higher temperatures and alternative solvents gave much-reduced yields. The nitrile group of **4** was smoothly reduced with $LiAlH_4$ in THF to give the primary amine, which was not isolated but temporarily protected as the trifluoroacetamide. This was conveniently achieved by reaction of the crude amine, after standard aqueous workup, with ethyl trifluoroacetate in THF (*32*). Finally, the acid-labile butanediacetal (BDA) and PMB protecting groups were cleaved using TFA, exposing the hydroxyl groups at positions 1, 4, and 5. The trifluoracetyl protection was not affected under these conditions, and the crystalline triol **6** was obtained in 77% overall yield over three steps from **5**. Phosphitylation using bis(benzyloxy)diisopropylaminophosphine and 1*H*-tetrazole followed by in situ oxidation with MCPBA gave crystalline **7** in 96% yield.

Scheme 2. Synthesis of a Short Oligo(ethylene glycol)-Linked Ins(1,4,5)P_3 Dimer[a]

[a] Reagents and conditions: i, **2**, DMF, room temp, 16 h; ii, H_2, Pd−C, MeOH/H_2O, 50 psi, room temp, 16 h; iii, Ion-exchange chromatography on Q Sepharose Fast Flow resin.



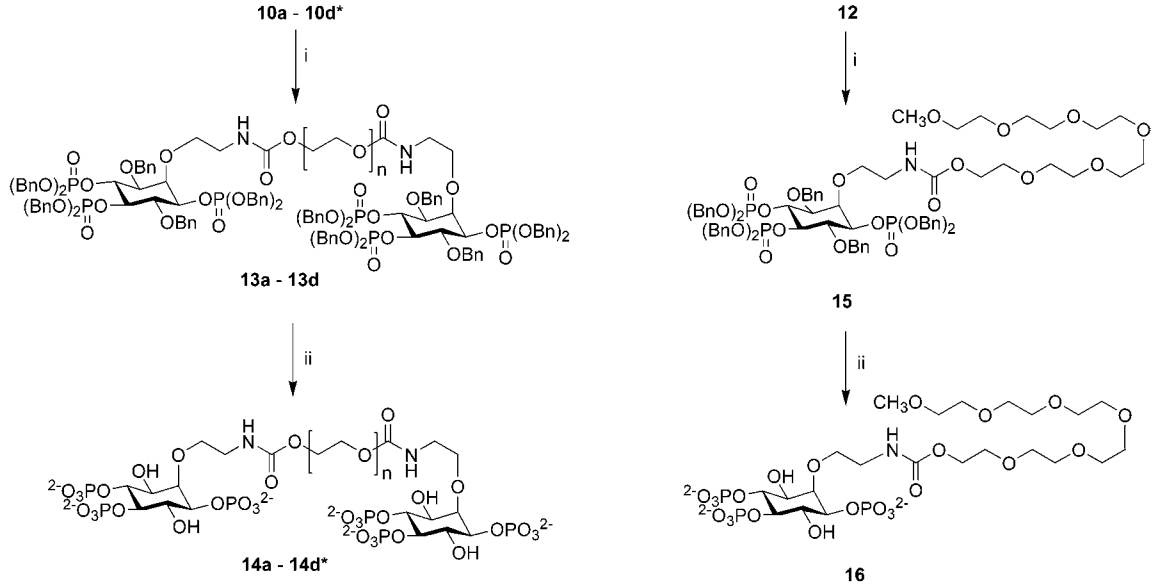
It was now necessary to expose the primary amine by selective removal of the trifluoroacetyl group from **7**. Treatment of **7** with methanolic ammonia or K_2CO_3 in aqueous methanol was only partially successful; long reaction times were required, leading to the formation of various polar products, presumably from partial cleavage of benzyl phosphate esters. However, it was found that the trifluoroacetyl group could cleanly be removed by treatment using LiOH in THF/MeOH/H_2O (*33*) for 1 h. Within this time there was little effect on the benzyl phosphate groups. Amine **2** was found to be an unstable oil and was therefore prepared freshly for each cross-linking reaction from **7**, which can conveniently be stored in crystalline form at room temperature for at least a year without deterioration.

Synthesis of a Small Oligo(ethylene glycol)-Linked Ins(1,4,5)P_3 Dimer. Our first attempt at cross-linking molecules of **2** employed the disuccinimidyl ester **8** (*27*) of 3,6,9-trioxaundecane-1,11-dioic acid (Scheme 2). The reaction of **8** with 3 equiv of **2** gave a complex mixture of products, but after careful chromatography on silica it was possible to obtain the required benzyl-protected dimeric intermediate with amide linkages in about 60 to 80% purity as judged by TLC. The mixture was deprotected by hydrogenolysis over Pd−C, and the product was purified by ion-exchange chromatography on Q Sepharose Fast Flow resin, eluting with a gradient of TEAB buffer. Phosphate-containing fractions were identified by a modification of the Briggs phosphate test (*22*), and the pure triethylammonium salt of the target dimer **9** was isolated in low overall yield. The dimeric structure of **9** was clearly apparent from integration of signals in its ^{1}H NMR spectrum, and from its FAB mass spectrum.

The reaction of **2** with longer PEG diacid linkers activated as disuccinimidyl esters was less satisfactory. The coupling reactions were difficult to follow, and the highly reactive disuccinimidyl esters had to be synthesized from their respective PEG diacids immediately before use to avoid the possibility of partial hydrolysis on storage, which could lead to complications from the formation of monomeric conjugates. Although we successfully isolated a longer Ins(1,4,5)P_3 dimer of this type, with a PEG600 spacer (*21*) in low yield (details not shown), we decided to investigate an alternative strategy for cross-linking of **2**.

Synthesis of Homobifunctional PEG−Carbonate Linkers. As an alternative to the disuccinimidyl esters, we now explored the use of activated carbonate esters of PEGs, which would give carbamate rather than amide linkages on reaction with **2**. Activated carbonate esters are more stable than their activated carboxylic ester equivalents and also have the advantage that they can be prepared directly from commercially available PEGs (*34*). We found that either succinimidyl carbonates (*35*, *36*) or 4-nitrophenyl carbonates were suitable, but we eventually chose 4-nitrophenyl carbonates because the coupling reactions were more easily followed by TLC (see below). The PEG−bis(4-nitrophenyl carbonate) esters were easily prepared by reaction of the appropriate PEG with bis(4-nitrophenyl) carbonate, and they could be purified to homogeneity by flash chromatography on silica. Thus, reaction of hexa(ethylene glycol) with bis-(4-nitrophenyl) carbonate in DMF in the presence of DIPEA (Scheme 3) gave the required bis(4-nitrophenyl carbonate) ester **10a** in 96% yield after chromatography, and similar reactions between PEG1450 and PEG8000 gave the corresponding homobifunctional linkers. The bis(4-nitrophenyl carbonate) ester of PEG3350 (**10c**) is commercially available. The mono(4-nitrophenyl carbonate) ester **12**, for use in the construction of a monofunctional version of **10a** was also synthesized in a similar way from methoxyhexa(ethylene glycol) **11** (*28*).

Scheme 3. Synthesis of Homobifunctional Linkers 10a, 10b, and 10d and Mono(4-nitrophenyl carbonate) Ester 12[a]



[a] Reagents and conditions: i, Bis(4-nitrophenyl)carbonate, DMF, DIPEA, 20 h.

Synthesis of PEG−Ins(1,4,5)P_3 Conjugates with Carbamate Linkages to PEG. The reaction of **10a** with an excess of freshly prepared **2** (Scheme 4) proceeded smoothly, and the benzyl-protected dimer **13a** was isolated in 58% yield after flash chromatography on silica. The reaction could conveniently be monitored using TLC by the appearance of 4-nitrophenol (yellow, UV-active spot) and the disappearance of amine (polar, UV-active spot, stains with phosphomolybdic acid) and activated PEG (UV-active spot, stains yellow on heating) and the concomitant appearance of the required product **13a** (UV-active, no yellow on heating, stains with phosphomolybdic acid). The ^{1}H NMR spectrum of **13a** showed a characteristic signal (broad triplet, ^3J = 5.3 Hz) at 5.60 ppm corresponding to the two carbamate NH protons, while the ^{31}P spectrum of **13a** showed three well-resolved signals, each corresponding to two equivalent phosphorus atoms of the protected Ins(1,4,5)P_3 headgroups. Hydrogenolytic deprotection as in the synthesis of **9**, followed by purification as before, gave pure **14a**, isolated as its triethylammonium salt.

The much larger protected dimeric intermediates **13b−d** were now synthesized by reaction of homobifunctional linkers **10b−d** with freshly prepared amine **2**, and in each case, the protected dimeric intermediate was isolated by flash chromatography on silica. For these

Scheme 4. Synthesis of PEG-Linked Ins(1,4,5)P_3 Dimers 14a to 14d, with Carbamate Linkages to PEG, and of a Monomeric Control (16)[a]

[a] Reagents and Conditions: i, **2**, DMF, room temp, 16−24 h; ii, H_2, Pd−C, MeOH/H_2O, 50 psi, room temp, 24 h, then ion-exchange chromatography on Q Sepharose Fast Flow resin. ***a**, $n = 6$; **b**, n ∼ 32; **c**, n ∼ 75; **d**, n ∼ 180. Bn = benzyl.

larger PEG-linked dimers, the ^{1}H NMR spectra of intermediates **13b**−**d** were invaluable in confirming the structures of the dimers. Because each molecule of **13a**−**d** contains 16 benzyl groups, the large aromatic proton signal in the ^{1}H NMR spectrum of each intermediate (integrating to eighty protons) could be accurately integrated and compared with the PEG-CH_2 signal at approximately 3.5 to 3.7 ppm, allowing the dimeric structure to be verified in each case. This was particularly important for the two largest dimers, whose ^{1}H NMR spectra after deprotection were dominated by the PEG-CH_2 signal. Signals in the ^{31}P NMR spectra of the protected dimeric intermediates became broader with increasing PEG size, and for **13c** and **13d**, they coalesced into a single broad peak. Hydrogenolytic deprotection of **13b** to **13d** and purification of the products by ion exchange chromatography as before gave dimers **14b** to **14d**, each of whose ^{31}P NMR spectra in CD_3OD showed three well-resolved signals, irrespective of PEG size. Finally, a monomeric version of **14a** was synthesized for use as a control in biological experiments. Thus, the reaction of **2** with excess methoxyhexa(ethylene glycol) 4-nitrophenyl carbonate ester **12** (Scheme 4) gave the protected mPEG-Ins(1,4,5)P_3 conjugate **15**, isolated in 58% yield after flash chromatography. Deprotection and purification as before gave pure **16**.

Binding of Ins(1,4,5)P_3 Dimers to Cerebellar Membranes. Equilibrium competition binding studies of the monomeric conjugate **16** using cerebellar membranes showed that the oligo(ethylene glycol) structure alone slightly reduced binding affinity (Table 1 and ref 21); the K_d for **16** (23.6 ± 2 nM) was slightly higher than that for Ins(1,4,5)P_3 (11.52 ± 1.98 nM). However, similar experiments using the equivalent dimer **14a** showed that the K_d of **14a** (3.17 ± 0.08 nM) was three to four times *lower* than that of Ins(1,4,5)P_3. The fact that the affinity of **14a** for cerebellar InsP_3Rs was more than 7-fold higher than its monomeric equivalent **16**, confirmed that the enhanced affinity of the short oligo(ethylene glycol)-linked dimers resulted from the second molecule of Ins(1,4,5)P_3 and was not related to the presence of the oligo(ethylene glycol) tether. The short dimer with amide linkages (**9**) showed activity close to that of the similarly sized dimer **14a**, with a K_d some 6-fold lower than that measured for Ins(1,4,5)P_3. The longer dimers **14b** and **14c** bound with affinities slightly higher than Ins(1,4,5)P_3 itself, but lower than the short dimers, although the longest dimer (**14d**) also appeared to show a significant gain in binding affinity relative to Ins(1,4,5)P_3 (*21*). The demonstration that even dimers with very large tethers (PEG8000 in **14d**) can bind to InsP_3Rs with high affinity confirmed our expectation that, at the Ins(1,4,5)P_3-binding site, the area close to the 2-oxygen atom of Ins(1,4,5)P_3 must be open to solvent.

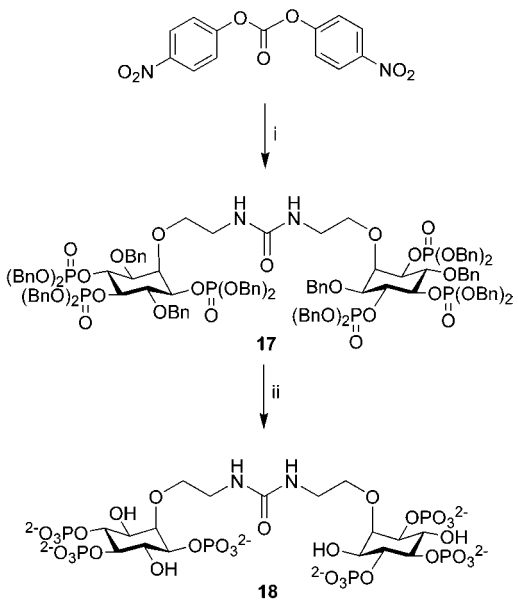


Table 1. Effects of Ins(1,4,5)P_3 Dimers on Ca^{2+} Release from Permeabilized Hepatocytes and [^{3}H]Ins(1,4,5)P_3 Binding to Membranes from Cerebellum[a]

	EC_{50} relative to Ins(1,4,5)P_3 (hepatocytes)	K_d relative to Ins(1,4,5)P_3 (cerebellum)
Ins(1,4,5)P_3	1	1
adenophostin A	13.3 ± 2.5	6.44 ± 1.06
16 (monomer)	ND	0.49 ± 0.09[b]
9	2.9 ± 0.4[b]	6.19 ± 1.24[b]

14b	0.9 ± 0.1[b]	1.76 ± 0.45[b]
14c	1.7 ± 0.4[b]	1.41 ± 0.41[b]
14d	1.4 ± 0.3[b]	3.67 ± 0.64[b]
18	12.7 ± 4.9	ND

[a] Results (means ± SE from at least three experiments) show the ability of the analogues to stimulate $^{45}Ca^{2+}$ release from permeabilized hepatocytes (EC_{50}) and to displace specific binding of [^{3}H]Ins(1,4,5)P_3 from cerebellar membranes (K_d). In both cases, results are expressed relative to the effect of Ins(1,4,5)P_3 measured in parallel, with numbers greater than unity denoting analogues with greater potency (or affinity) than Ins(1,4,5)P_3. ND, not determined. At maximally effective concentrations, each analogue displaced all specifically bound [^{3}H]Ins(1,4,5)P_3 and released a similar fraction of the intracellular Ca^{2+} stores as that released by Ins(1,4,5)P_3 (54 ± 3%, $n = 20$). [b] Calculated from data published in (*21*).

Synthesis of a Short, Urea-Linked Ins(1,4,5)P_3 Dimer. As the equilibrium binding experiments showed that dimers with short linkers had the highest affinities for InsP_3Rs, a further logical step was to synthesize a

Scheme 5. Synthesis of Urea-Linked Ins(1,4,5)P_3 Dimer 18

[a] Reagents and Conditions: i, **2**, DMF, room temp, 16h; ii, H_2, Pd−C, MeOH/H_2O, 50 psi, 24 h, then ion-exchange chromatography on Q Sepharose Fast Flow resin. Bn = benzyl.

dimer having the shortest possible (one carbon) linker. It has previously been demonstrated that reaction of bis(4-nitrophenyl) carbonate with amines provides a convenient method for the synthesis of ureas (*37*), and we found that this method could be applied to the dimerization of amine **2**. Thus, the reaction of 3 equiv of **2** with pure bis(4-nitrophenyl) carbonate (recrystallized from CH_2Cl_2/hexane) in DMF gave the benzyl-protected symmetrical urea-linked dimer **17**, which could be isolated by flash chromatography in 71% yield (Scheme 5).

The ^{1}H NMR spectrum of **17** in $CDCl_3$ showed a signal at 5.99 ppm (broad triplet, ^3J approximately 5 Hz) corresponding to the two urea NH protons, and the ^{13}C NMR spectrum of **17** showed the signal of a quaternary carbon atom resonating at 158.3 p.p.m, corresponding to the urea carbonyl carbon atom. The ^{31}P NMR spectrum showed three signals corresponding to the three pairs of equivalent phosphorus atoms in the symmetrical molecule. Total deprotection of **17** as for the PEG-linked dimers gave the divalent Ins(1,4,5)P_3 analogue **18** as its triethylammonium salt, which, like the PEG-linked dimers, was freely soluble in water or methanol.

Stimulation of Ca^{2+} Release from Permeabilized Hepatocytes. When tested for their ability to release Ca^{2+} from the intracellular stores of permeabilized hepatocytes, all the dimers potently stimulated the release of intracellular Ca^{2+}, with maximally effective concentrations of each dimer releasing similar fractions of the intracellular Ca^{2+} stores. In agreement with the results from equilibrium binding experiments in cerebellum (see above), all the dimers had EC_{50} values similar to, or lower than that of Ins(1,4,5)P_3, with the shorter dimers showing the lowest EC_{50} values (Table 1 and ref 21). Surprisingly, the new urea-linked dimer **18**, in which the two Ins(1,4,5)P_3 motifs are held closest together, was by far the most potent of the series, with an EC_{50} value more than 12-fold lower than Ins(1,4,5)P_3 (Table 1 and Figure 2). The potency of **18** in these experiments approached that of adenophostin A (Table 1) the most potent known agonist of InsP_3Rs.

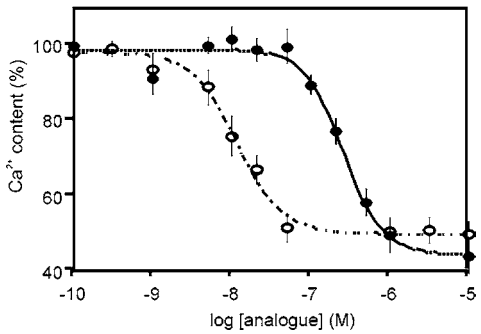

Figure 2. The effects of the indicated concentrations of Ins(1,4,5)P_3 (filled circles) or **18** (open circles) on the intracellular stores of permeabilized hepatocytes. Results are means ± SE from 10 [Ins(1,4,5)P_3] or 19 (**18**) independent experiments.

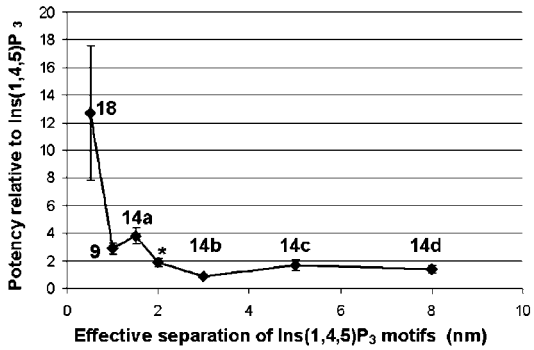

Figure 3. Relative potencies of Ins(1,4,5)P_3 dimers in evoking Ca^{2+} release from permeabilized hepatocytes plotted as a function of effective (rms) separation of the two component Ins(1,4,5)P_3 structures in each dimer. *Measured using an Ins(1,4,5)P_3 dimer synthesized from PEG600 diacid in a similar way to dimer **9** (*21*).

DISCUSSION

To estimate the separation of the two Ins(1,4,5)P_3 structures in each dimer, we followed the approach described by Kramer and Karpen (*19*) in which the effective separation is taken as the average (rms) length of the flexible PEG linker. The rms length can be calculated from previous determinations of the lengths of specific PEGs (*38*) assuming that the rms length is proportional to the square root of the number of ethylene glycol monomers. This method predicts rms lengths of approximately 1 and 1.5 nm, respectively, for the linkers in the two smallest oligo(ethylene glycol)-linked dimers (**9** and **14a**), increasing to 8 nm for the largest dimer (**14d**). It should be remembered, however, that more extended conformations of the longer dimers are capable of spanning much greater distances than 8 nm. This method of estimating separation is difficult to apply to the very short dimer **18**, in which the PEG is replaced by a single atom linker. However, molecular models show that even in the most extended conformations of **18**, the distance between the two O-2 atoms of the two Ins(1,4,5)P_3 motifs cannot be greater than 1 nm. For **18**, the linker between Ins(1,4,5)P_3 motifs contains only six rotatable bonds, and its rigidity relative to the other dimers may also be an important factor, even though the effective separation of its two component Ins(1,4,5)P_3 structures may be only slightly less than the rms separation in **9**. Figure 3 compares the Ca^{2+}-releasing potencies of the dimers in permeabilized hepatocytes measured relative to that of Ins(1,4,5)P_3, plotted as a function of the effective (rms) separation of the two component Ins(1,4,5)P_3 motifs in each dimer. Clearly the potency decreases steeply as effective separation increases, falling

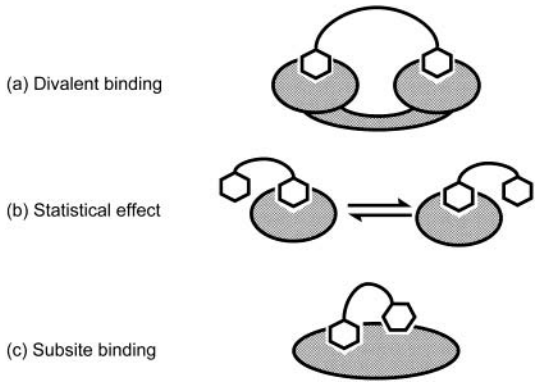

Figure 4. Schematic representations of three possible modes of interaction of Ins(1,4,5)P_3 dimers with binding sites of InsP_3Rs.

to Ins(1,4,5)P_3-like levels beyond an effective separation of around 2 nm.

We have suggested elsewhere (*21*) that dimers **9** and **14a** may be able to bridge equivalent Ins(1,4,5)P_3 binding sites within tetrameric InsP_3Rs. This interpretation is supported by more detailed experiments, which showed that long (**14d**) and short (**9** and **14a**) dimers bound to monomeric Ins(1,4,5)P_3-binding domains with similar affinities to Ins(1,4,5)P_3, so that high-affinity binding for **9** and **14a** (Table 1) appears to require that the receptors are in the tetrameric state. We also suggested that the increased affinity of the longest dimer (**14d**) for cerebellar membranes, where the receptors are densely packed, may result from the linked Ins(1,4,5)P_3 molecules binding to sites on adjacent receptors, because **14d** binds to purified tetrameric cerebellar receptors with similar affinity to Ins(1,4,5)P_3 (*21*). However, the unexpectedly high potency of the very short dimer **18** may be difficult to reconcile with either explanation (intratetramer or intertetramer binding).

Three possible explanations for the high potency of **18** are summarized schematically in Figure 4:

(a) Divalent binding (Figure 4a). In this explanation, the two Ins(1,4,5)P_3 structures in **18** can occupy equivalent Ins(1,4,5)P_3-binding sites. However, molecular models show that even in the most extended conformations of **18**, the distance between the two O-2 atoms of the two Ins(1,4,5)P_3 motifs cannot be greater than 1 nm. It seems very unlikely that the Ins(1,4,5)P_3-binding sites could be so close, little more than the width of a single Ins(1,4,5)P_3 molecule.

(b) A statistical effect (Figure 4b). The high local concentration of the Ins(1,4,5)P_3 motif in **18** may favor rebinding (*39*−*41*) and thereby enhance apparent affinity for InsP_3Rs. Against this analysis, however, it has been shown that the small clustered disaccharide analogues (Figure 1) did not show enhanced affinity for InsP_3Rs over their monomeric equivalent (*13*). It is not obvious why a statistical effect, arising from a simple effect on local concentration, could enhance the affinity of **18**, but not the affinities of diphostin and tetraphostin (Figure 1) for InsP_3Rs, although **18** is likely to be smaller and more rigid than the clustered disaccharides.

(c) Subsite binding (Figure 4c). This interpretation is based on the idea that elements of the second Ins(1,4,5)P_3 motif in **18** may be able to interact with residues close to the Ins(1,4,5)P_3-binding site to enhance binding of the dimer. While this work was nearing completion, the X-ray crystal structure of the core binding domain (residues 224−604) of the mouse type 1 receptor (InsP_3R1) was reported (*25*). This allowed us to explore the possibility of subsite binding for **18** using a molecular modeling approach.

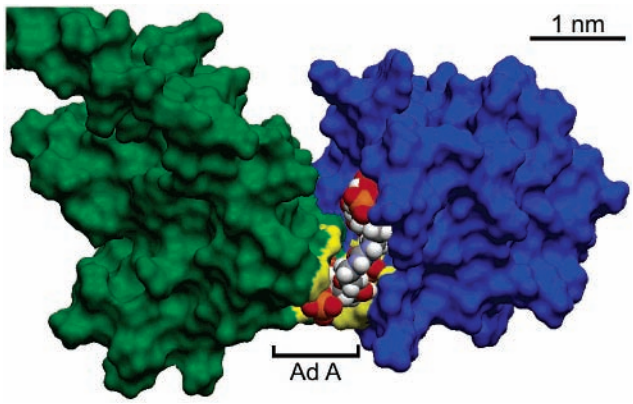

Figure 5. Representative result from molecular docking experiments of **18** and the X-ray crystal structure (*25*) of the type 1 InsP_3R Ins(1,4,5)P_3-binding core. While one Ins(1,4,5)P_3 motif occupies the Ins(1,4,5)P_3-binding site (colored yellow), components of the second motif could interact with other residues elsewhere within the cleft between the α-domain (green) and *β*-domain (blue). The proposed subsite for interaction with the adenosine component of adenophostin A (*5*) is indicated by a bracket.

In the X-ray structure, the bound molecule of Ins(1,4,5)P_3 occupies one end of a deep cleft between two domains. As expected, the area of the binding site around the 2-hydroxyl group of the bound Ins(1,4,5)P_3 molecule is open to solvent. This validates our choice of the 2-oxygen atom of Ins(1,4,5)P_3 for the attachment of linkers in the design of the dimers (see above) and is in agreement with the high affinity of the dimers for the InsP_3Rs of cerebellum, which are primarily type 1. Although the Ca^{2+}-release experiments described here were carried out using hepatocytes, which express mainly type 2 InsP_3Rs, the high homology between the Ins(1,4,5)P_3-binding domains of InsP_3R1 and InsP_3R2 in the Ins(1,4,5)P_3-binding region justifies our use of the InsP_3R1 crystal structure in the analysis of the Ca^{2+}-release results. We therefore carried out molecular docking experiments using **18** and this structure. In the highest-scored docking results, one Ins(1,4,5)P_3 motif of **18** consistently docked into the Ins(1,4,5)P_3-binding site in a similar way to the crystallographically observed position of bound Ins(1,4,5)P_3, while the second motif interacted with other residues within the cleft (Figure 5). It was not possible to identify a single definitive binding mode for **18** because different positions were observed for the second Ins(1,4,5)P_3 according to the details of the docking procedure used, and different residues were involved. Nevertheless, these experiments support the idea that the surprisingly high potency of **18** could result from subsite binding.[1]

[1] After this manuscript was submitted, a three-dimensional electron microscopy study (*44*) was published in which the cytosolic domains of type 1 InsP_3Rs were sometimes observed to be in head-to-head contact such that analogous regions of each might be in close proximity. This led the authors to suggest that our short dimers (**9** and **14a**) may be linking the Ins(1,4,5)P_3-binding domains of different receptors, and that the longest dimer (**14d**) may link Ins(1,4,5)P_3-binding domains within a receptor. While it is not impossible for the two Ins(1,4,5)P_3 motifs in the new dimer **18** to span two Ins(1,4,5)P_3 binding sites in this head-to head mode, we still consider that subsite binding is the most likely explanation for the high potency of **18**. Further investigations are underway.

Adenophostin A, the most potent known agonist of $InsP_3Rs$, has also been proposed to interact with residues close to the Ins(1,4,5)P_3-binding site (Figure 5) (*5*). It would be particularly interesting if **18** could derive its similar enhanced potency by accessing a different subsite, as proposed here. Further investigations to identify the mode of action of **18** are in progress. If **18** does achieve its higher potency by a nonspecific interaction of one Ins(1,4,5)P_3 motif with residues close to the Ins(1,4,5)P_3-binding site then it is likely that only some elements of this second Ins(1,4,5)P_3 component are involved, and also that the interactions involved are not optimal. In that case it might be possible to create even more potent ligands by replacing the second Ins(1,4,5)P_3 motif in **18** with other structures. This suggests a new, divergent strategy for synthesizing potent Ins(1,4,5)P_3 analogues by conjugating 2-*O*-(2-aminoethyl)-Ins(1,4,5)P_3 with a range of molecular fragments chosen to interact with other regions of the $InsP_3R$ that lie close to the Ins(1,4,5)P_3-binding site.

In conclusion, we have presented a synthetic strategy for the construction of divalent analogues of Ins(1,4,5)P_3, examined the effects of Ins(1,4,5)P_3 dimers on Ins(1,4,5)P_3 receptors, and discussed possible interpretations of the results. The synthetic approach described here is equally applicable to the synthesis of multivalent forms of other inositol phosphates. Modular phosphoinositide binding domains such as PH (*42*) and FYVE (*43*) domains may form oligomers, for example, and these small proteins could be attractive targets for synthetic multivalent inositol phosphate ligands. In some cases the appropriate size of linker could be estimated directly from available X-ray structures, allowing rigid scaffolds of well-defined geometry and size to be employed in place of flexible PEG tethers where necessary. Finally, the short urea-linked Ins(1,4,5)P_3 dimer **18** is the most potent inositol-based $InsP_3R$ ligand yet identified, providing a basis for the development of a potential new class of high-affinity synthetic probes for $InsP_3Rs$.

Cellular Uptake of Antisense Morpholino Oligomers Conjugated to Arginine-Rich Peptides

Hong M. Moulton,* Michelle H. Nelson, Susie A. Hatlevig, Muralimohan T. Reddy, and Patrick L. Iversen

AVI BioPharma, Inc., Corvallis, Oregon 97333. Received December 5, 2003; Revised Manuscript Received January 14, 2004

Although the sequence specificity, biostability, and low toxicity of PMO (phosphorodiamidate morpholino oligomers) make them good antisense agents to study gene function, their limited ability to cross cell membranes limits their use in cell culture. In this paper we show that conjugation to arginine-rich peptides significantly enhanced the cellular uptake of PMO. The factors that affect the conjugate's cellular uptake and its antisense activity toward a targeted mRNA were investigated. Factors studied include the number of arginines in the peptide, the choice of cross-linker, the peptide conjugation position, the length of the PMO, and the cell culture conditions. Delivery of PMO to the cell nucleus and cytosol required conjugation rather than complexation of peptides to PMO. R_9F_2C was best suited to deliver a PMO to its target RNA resulting in the strongest antisense effect. By simply adding the R_9F_2C−PMO conjugate into the cell culture medium at low μM concentration, missplicing of pre-mRNA was corrected. This particular peptide-conjugated PMO was more effective than the PMO conjugated to the transmembrane transport peptides of HIV-1 Tat protein, *Drosophila* antennapedia protein, or to peptides with fewer arginines. Length of PMO did not affect a peptide's delivery efficacy, but all other factors were important. R_9F_2C peptide provided a simple and efficient delivery of PMO to a RNA target. Conjugation of peptide to PMO enhances the opportunities to evaluate gene functions in cell cultures.

INTRODUCTION

Phosphorodiamidate morpholino oligomers (PMO) (*1*, *2*) are antisense molecules that inhibit gene expression by preventing translation or interfering with pre-mRNA splicing. The antisense specificity and efficacy of PMO have been well demonstrated in cells and in embryos (*3*−*12*). PMO are similar to DNA with two major structural differences: the negatively charged phosphorodiester internucleoside linkage in DNA is replaced by the neutral phosphorodiamidate linkage; the five-membered ring of deoxyribose in DNA is replaced by the six-membered ring of morpholine (Figure 1). The uncharged and hydrophilic PMO are highly resistant to enzymes and biological fluids (*13*).

To bind to an RNA target, PMO must access the cytoplasm and/or nucleus. The typical length for a PMO to achieve effective antisense activity is between 18 and 25 bases. However, at this size, passive diffusion through cell membranes is slow. When using PMO to study gene function in cultured cells, delivery techniques such as scrape-loading (*14*) and using cationic lipid complexed with heteroduplexes of PMO/DNA (*15*) are generally required. Peptide-based delivery systems offer an attractive alternative to current delivery methods, being much simpler and relevant to in vivo applications.

Some naturally occurring proteins, such as *Drosophila* antennapedia (Ant) and HIV-1 Tat, easily transport macromolecules into cells. The motifs within the transport proteins responsible for membrane "penetration" have been identified and characterized as cationic in nature (*16*−*19*). The cationic transport peptides are especially useful for delivering uncharged antisense oligomers due to lack of the problematic electrostatic interactions which may occur with anionic antisense oligomers. The electrostatic interactions between cationic peptides and anionic oligomers mask the positive charges of the peptide that are important for its delivery ability, subsequently decreasing the delivery efficacy of the peptide. Tat or Ant peptides have been used to deliver uncharged peptide nucleic acids (PNA) (*19*−*22*). PTD4 is an analogue of pTat peptide and was designed to have

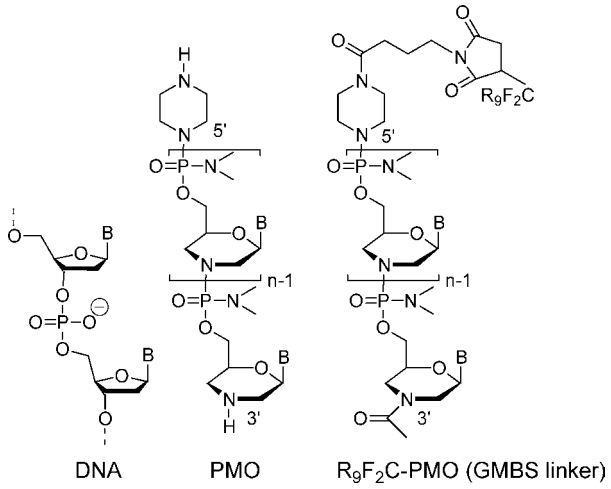

Figure 1. Structure of DNA, PMO, and R_9F_2C−PMO conjugate. The structure of the conjugate is shown with R_9F_2C peptide conjugated at the 5′-end of PMO by the GMBS linker. "B" represents a base.

705-FL[d]	CCT CTT ACC TCA GTT ACA-fluorescein	18
705(12)-FL	CTT ACC TCA GTT-fluorescein	12
705(24)-FL	CCT CTT ACC TCA GTT ACA ATT TAT-fluorescein	24

[a] The sequences of peptides are written using the standard one letter amino acid symbols from N to C terminus. [b] PMO sequences are written using the standard genetic code from 5′ to 3′-end. [c] The antisense PMO was targeted to a mutant splice site at the nucleotide 705 of human β-globin intron 2. [d] 705 had carboxylfluorescein attached at the 3′-end.

more α helical structure than pTat to improve cellular uptake (*23*). It has been reported that Jurkat cells take up the fluorescein-tagged PTD-4 33 times more than fluorescein-tagged pTat (*23*). We have previously shown that Tat peptide enhances cellular uptake of PMO in cultured cells (*24*) as well. But this requires high μM concentration to achieve antisense activity. Therefore, a more effective delivery peptide than the Tat peptide is needed.

We designed a peptide containing nine arginines (R), two phenylalanines (F), and one cysteine (C) with the sequence of NH_2-RRRRRRRRRFFC-$CONH_2$ (R_9F_2C). Arginine residues in the Tat peptide are found to be crucial for the cell delivery; substitution of nonarginine residues in the Tat peptide sequence with arginines increases the cellular uptake of a fluorescein tag (*25*). We added two phenylalanines to R_9 to increase hydrophobicity, enhancing interaction with cell membranes and improving purification by reverse phase chromatography. Adding a hydrophobic moiety onto an arginine-rich peptide has also been shown to increase uptake of the cargo (*26*, *27*). A final cysteine residue provided a sulfhydryl group for conjugation to PMO.

The effectiveness of a peptide to deliver PMO to the targeted mRNA was tested using a positive readout assay rather than conventional "knockdown" assays. Traditionally, decreasing gene expression of cells treated with antisense oligomers has been interpreted as the result of the antisense activity; however, other potential causes of decreased expression must be considered. For example, general suppression of gene expression in the target cells may result if an oligomer causes toxicity, if its degradation products are toxic, or if a delivery method causes toxicity. The toxicity may be misinterpreted as the antisense effect. To remedy these problems, an approach based on the ability of steric-blocking oligomers to alter mRNA splice site selection has been developed to evaluate antisense activity (*28*−*30*).

Sensitive assays that give positive readout of antisense action, in the form of production of functional reporter protein, have been devised in both cell culture (*31*, *32*) and in mice (*33*). These assays exploit mutations in intron 2 of human β-globin pre-mRNAs that lead to missplicing. The mutated intron cannot be properly excised resulting in an in-frame stop codon in the luciferase coding sequence. Two conditions must be met to produce the functional reporter protein at 37 °C. First, an antisense oligomer must enter the cell nucleus to block the mutated splice site, thus restoring normal splicing and read through of the reporter message. The result is mRNA-encoding functional reporter protein. Second, but equally important, the cells must be viable to carry out RNA processing and translation so that reporter protein activity is produced.

Using the splice correction assay, we assessed the necessity of covalent attachment verses complexation of the peptide and PMO and compared the effectiveness of R_9F_2C to other peptides for delivery of PMO to the targeted pre-mRNA. We further determined the effects of conjugation chemistry, conjugation position, length of PMO, and cell culture conditions on the cellular uptake and antisense activity of peptide−PMO conjugates. The linker effects on intracellular distribution and concentration of the peptide conjugated PMO were also examined by fluorescent microscopy and flow cytometry. The cellular toxicity of the conjugates was evaluated.

EXPERIMENTAL PROCEDURES

Peptides, PMO, and Cross-Linkers. The nomenclature and the sequences of peptides and PMO are listed in Table 1. All peptides were synthesized by Global Peptide Services (Ft. Collins, CO) and purified to >90% purity. PMO were synthesized at AVI BioPharma as described elsewhere (*1*, *34*). Cross-linkers: Sulfo-EMCS (*N*-[ϵ-maleimidocaproyloxyl]sulfosuccinimide ester) was obtained from Molecular Bioscience (Boulder, CO). GMBS (*N*-[γ-maleimidobutyryloxy]succinimide ester), sulfo-KMUS (*N*-[κ-maleimidoundecanoyloxy]sulfosuccinimide ester), SBAP (succinimidyl 3-[bromoacetamido]propionate), SPDP (*N*-succinimidyl 3-[2-pyridyldithio]propionate), and sulfo-LCSPDP (sulfosuccinimidyl 6-[3′-(2-pyridyldithio)propionamido]hexanoate were acquired from Pierce (Rockford, IL).

3′-End Acetylated or Fluoresceinated PMO. Acetic anhydride (0.1 M), dissolved in *N*-methyl-2-pyrrolidinone (NMP) containing 1% *N*-ethylmorpholine (v:v) was added to PMO while the oligomer was still attached to the synthesis resin via the 5′-end. The PMO was incubated at 25 °C for 90 min, washed with NMP, cleaved off from the synthesis resin, and purified as described previously (*24*). The product was analyzed by MALDI time-of-flight mass spectrometry (MALDI TOF MS) and high-pressure liquid chromatography (HPLC). Seventy percent of the product corresponded to full-length sequence with acetyl at its 3′-end and a piperazine group at the 5′-end. 5-(and 6-) Carboxyfluorescein was attached to the 3′-end of PMO as described previously (*24*).

Addition of a Cross-Linker to 5′-End of PMO. A cross-linker (Figure 2) predissolved in 50 μL of DMSO was mixed with a PMO (2−5 mM) dissolved in sodium phosphate buffer (50 mM, pH 7.2) containing 20% CH_3-CN at 1:2 PMO:cross-linker molar ratio. The mixture was

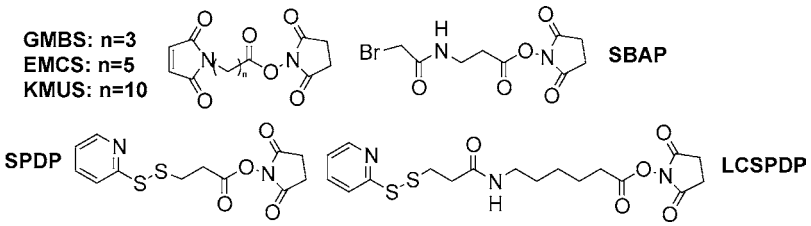

Figure 2. Names and structures of the bifunctional cross-linkers.

stirred at 25 °C in the dark for 30 min, and the product was precipitated in 30-fold excess of cold acetone. The PMO−linker was lyophilized and analyzed by MALDI-TOF MS and HPLC. The conversion from PMO to PMO−linker was >90%.

Peptide and PMO Conjugation. PMO−linker (2−5 mM) was dissolved in sodium phosphate buffer (50 mM, pH 6.5, 5 mM EDTA) containing 20% CH_3CN. The peptide was added to the PMO−cross-linker solution at 2:1 peptide:PMO molar ratio. The reaction was stirred at 25 °C in the dark for 2 h. The conjugate was purified first by CM-sepharose (Sigma, St. Louis, MO) ion exchange chromatography to remove unconjugated PMO and then by reverse phase chromatography (HLB, Waters, Milford, MA) and lyophilized. The concentration calculation used for all conjugates was based on the total absorbance at 260 nm of a sample. As analyzed by MALDI-TOF MS and capillary electrophoresis, the final product contained about 60% peptide conjugated to the full length PMO with the balance composed of conjugates of shorter PMO, a small amount of unconjugated full, and shorter length PMO, and about 2% of unconjugated peptide.

Conjugating a Peptide onto 3′-End of PMO. Addition of a cross-linker and conjugation to a peptide to 3′-end of PMO is described previously (*24*).

Cell Culture. HeLa pLuc705 (*32*) cell line was obtained from Gene Tools (Philomath, OR). NIH3T3 cells were obtained from ATCC (Manassas, VA). Both cell lines were cultured in RPMI 1640 supplemented with 2mM glutamine, 100 μg/mL streptomycin, 100 U/mL penicillin, and 10% fetal bovine serum (FBS) (Hyclone, Ogden, UT) unless specified in the figure legends. Cell lysis buffer contained 10 mL of cell lysis reagent (Promega, Madison, WI) and one proteinase inhibitor cocktail tablet (Roche Diagnostics, Mannheim, Germany).

Fluorescent Microscopy. Exponentially growing cells were plated in a 48-well plate. The next day the conditioned medium was removed, and a test substance, in fresh medium, was added to the well. After a designated time, the cells were washed with phosphate-buffered saline (PBS) three times and imaged directly in the culture medium with a Nikon Diaphot 300 inverted microscope. Images were captured with an Olympus digital camera connected to a computer using MagnaFire software (Optronics, Goleta, CA). Dihydroethidium, a nucleic acid stain, was obtained from Molecular Probes (Eugene, OR).

Flow Cytometry. HeLa pLuc705 cells, plated at 80 000 cells per well in a 24-well plate 20 h before the treatment, were treated with medium containing a test substance for various times at a specified concentration. After each treatment, cells were washed with PBS three times. To measure the internalized conjugate, the membrane-bound conjugate was removed by trypsinization (*21*, *35*). Trypsin (100 μL) (0.25%, Hyclone, Logan, UT) was added to each well and incubated for 6 min at 37 °C, followed by addition of 300 μL of culture media. The cells were spun down and washed with PBS one time then resuspended in 200 μL of a buffer containing PBS, 1% FBS, and 0.2% NaN_3. The flow data (10 000 events) was collected using a BD FACSCalibur cytometer, and data was analyzed using FCS Express 2 (De Novo Software, Thornhill, Ontario, Canada).

Correction of Misspliced Pre-mRNA. HeLa pLuc705 cells, plated in a 48-well plate 20 h before the treatment, were treated with medium containing a test substance at a specified concentration. At designated times, the cells were washed with PBS twice and the cell lysate was collected. Luciferase produced was determined by mixing 30 μL of cell lysate and 50 μL of luciferase assay reagent (Promega, Madison,WI) followed by measuring the light production using the Flx 800 microplate fluorescence/luminescence reader (Bio-tek, Winooski, Vermont). The relative light units were normalized to μg of protein determined by the bicinchoninic acid method following the manufacturer's procedure (Pierce, Rockford, IL).

Cytotoxicity. Cell viability was determined by an MTT (methylthiazoletetrazolium, Sigma, MO) assay. HeLa pLuc705 cells were incubated with or without a test substance for 24 h in a 96-well plate, the conditioned medium in each well was replaced with 100 μL of fresh medium containing 500 μg/mL MTT, and the cells were incubated for 4 h. The medium was removed, and DMSO was added to each well and mixed thoroughly. The absorbance was measured at 540 nm. The percent cell viability was calculated by normalizing absorbance of treated cells to the untreated cells.

Statistical Analysis. Data were plotted and analyzed using GraphPad Prism 3.0 software (GraphPad Software, San Diego, CA).

RESULTS AND DISCUSSION

Peptide−PMO Conjugates. The chemical structures of DNA, PMO, and R_9F_2C−705 conjugate are shown in Figure 1. The nomenclature, the linkers used, conjugation position, and calculated and observed mass and purity are tabulated (Table 2). Peptides and PMO were conjugated by bifunctional cross-linkers. The structures of cross-linkers are illustrated in Figure 2. The conjugate with the GMBS linker is designated as peptide−PMO, otherwise the name of a specific linker is included in the nomenclature. For example, the conjugate of R_9F_2C and 705-FL by GMBS or SPDP linker are designated as R_9F_2C−705-FL or R_9F_2C−SPDP−705-FL, respectively.

Conjugation to R_9F_2C Peptide Was Required To Deliver PMO to the Targeted mRNA. The effect of R_9F_2C peptide on delivering PMO was first determined by comparing fluorescent images of HeLa pLuc705 and NIH3T3 cells treated with a fluorescein tagged PMO (705-FL), a mixture of free R_9F_2C and 705-FL (R_9F_2C +705-FL), and the conjugate of R_9F_2C and 705-FL (R_9F_2C−705-FL). To avoid artifacts that may be caused by cell fixation techniques (*21*, *35*), all fluorescent images were taken of live cells where no fixative agent or mounting medium was used. Very little fluorescence was

[a] Observed mass accuracy ± 0.05% of calculated protonated mass. [b] All peptides were added to the PMO 5′-end except for 705−R_9F_2C for which R_9F_2C was added to the 3′-end of PMO.

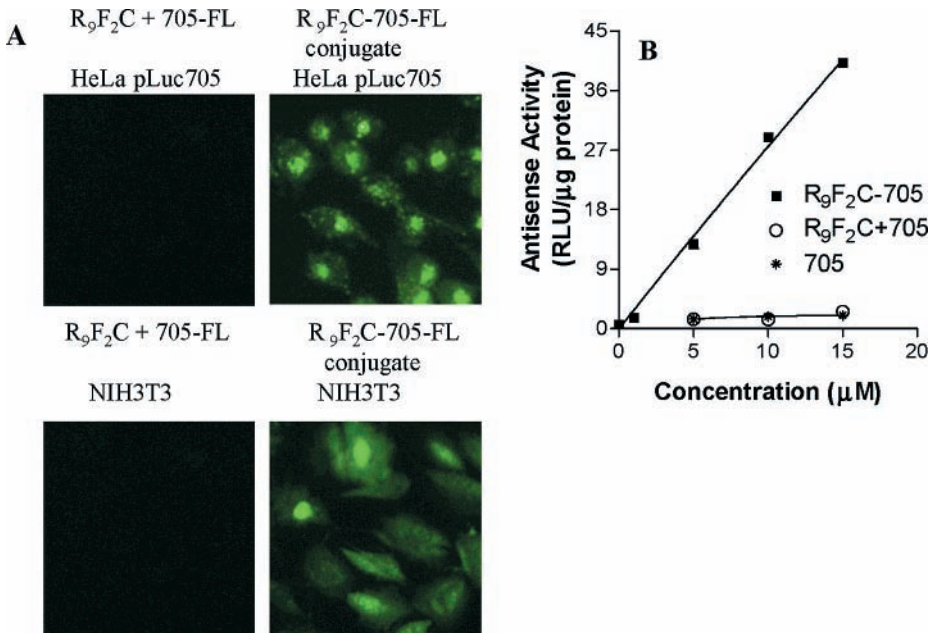

Figure 3. Conjugation to R_9F_2C peptide was required to deliver PMO to the targeted mRNA. (A) Fluorescent images (200× magnification) of live HeLa pLuc705 or NIH3T3 cells treated with test substance at 10 μM for 20 h. The test substances, as indicated above the images, were a mixture of free R_9F_2C peptide and fluorescein tagged 705 (R_9F_2C + 705-FL) (1:1 molar ratio) and R_9F_2C−705-FL conjugate. (B) R_9F_2C−705 conjugate corrected misspliced pre-mRNA and upregulated the expression of luciferase reporter gene while R_9F_2C + 705 (1:1 molar ratio) or 705 alone did not. HeLa pLuc705 cells were treated with the test substance at indicated concentrations in medium containing 10% FBS for 24 h. Antisense activity is represented by luciferase activity, expressed as the relative light units (RLU) per μg protein. Each data point is an average ± the range of means of two independent experiments each consisting of a triplicate sample.

observed with 705-FL (image not shown) or R_9F_2C + 705-FL (Figure 3A). Mixed diffused/punctate cytosolic and nuclear fluorescence was seen in 100% of the cells treated with the R_9F_2C−705-FL conjugate (Figure 3A), suggesting successful delivery of PMO to the cytosol and nucleus in both cell lines.

The necessity of the covalent attachment of R_9F_2C to PMO was evaluated in the splice correction assay, which measures antisense activity of PMO in the nucleus and gives a positive luciferase reporter signal using the HeLa pLuc705 cell line. This cell line (*32*) is stably transfected with a plasmid carrying the luciferase coding sequence interrupted by a mutated human β-globin intron 2. Cells treated with PMO (705) alone or with a mixture of free R_9F_2C and 705 showed the same level of luciferase as cells treated with vehicle control (H_2O). However, cells treated with the R_9F_2C−705 conjugate produced luciferase in a dose-dependent manner (Figure 3B), indicating successful nuclear delivery of PMO. The results show that conjugation of R_9F_2C peptide to PMO was required for delivery to the nucleus.

R_9F_2C Was More Effective in Delivering PMO Than pTat, PTD4, pAnt, and Peptides with Fewer Arginines. Using the splice correction assay and flow cytometry, we compared the effectiveness of R_9F_2C to pTat, PTD4, and pAnt to deliver PMO to the nucleus. PMO conjugated to R_9F_2C corrected splicing 4, 14, or 19 times more effectively than the PMO conjugated to pTat, pAnt, or PTD4, respectively (Figure 4A). Cells treated with R_9F_2C−705-FL had 3, 12, or 17 times more fluorescence than the ones treated with pTat−705-FL, pAnt−705-FL, or PTD4−705-FL (Figure 4B), respectively.

R_9F_2C, pTat, and PTD4 are peptides with the same length but differ in their sequences and number of arginines. pTat, pAnt, or PTD4 contains six, three, or three arginines, respectively, while R_9F_2C has nine

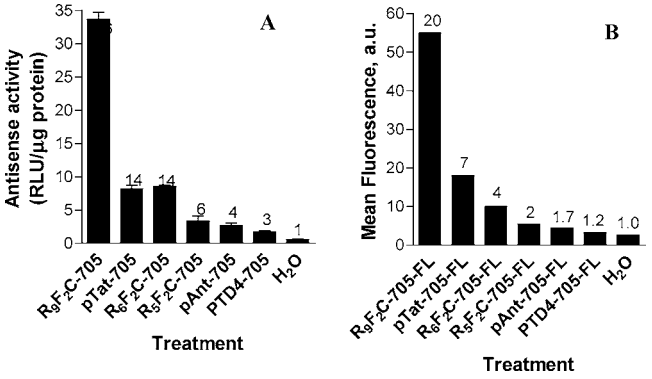

Figure 4. R_9F_2C was more effective to deliver PMO than pTat, PTD4, pAnt, and peptides with fewer arginines. (A). Luciferase activity of HeLa pLuc705 cells treated with the 705 conjugated to R_9F_2C, pTat, R_6F_2C, R_5F_2C, pAnt, or PTD4 by the GMBS linker at 15 μM in the medium containing 10% FBS for 24 h. Each data point is an average ± the range of means of two independent experiments each consisting of a triplicate sample. (B). Flow cytometry measurement of mean fluorescence of HeLa pLuc705 cells treated with 2 μM of a conjugate for 3 h. The antisense activity or mean fluorescence of each conjugate relative to the vehicle control (H_2O) is quantified above each bar.

arginines (Table 1). It has been suggested that arginine-rich peptides with different primary and secondary structures have a similar uptake mechanism (*36*). The number of arginines appears to be more important (*25*), and the structural variations have less effect on cellular uptake (*37*, *38*). These reports are based on studies using fluorescein-tagged peptides; a quantitative comparison using a functional assay has not yet been reported until this study.

To directly verify whether reducing the number of arginines decreases the peptide's delivery efficacy, the cellular uptake of R_9F_2C−705-FL was compared to R_6F_2C−705-FL and R_5F_2C−705-FL by both flow cytometry and the splice correction assay. The mean fluorescence decreased as the number of arginines decreased (Figure 4B). Relative to the vehicle control (H_2O) treated cells, the cells treated with R_9F_2C−705, R_6F_2C−705, or R_5F_2C−705 gave 56, 14, or 5.6-fold increase in luciferase production, respectively (Figure 4A). Lower mean fluorescence given by the conjugates with fewer arginines indicated less PMO delivered by the peptide, which correlated well with their lower antisense activity. We show here, for the first time by an antisense functional assay, that the number of arginines greatly influences the delivery effectiveness of the peptide.

Antisense Activity Was Affected by Linker Length and Not by the Conjugation Chemistry. We examined the effects of linker length (bond length) and connectivity between PMO and R_9F_2C on PMO antisense activity. All linkers used in this study (Figure 2) were bifunctional cross-linkers, containing an amine-reactive *N*-hydroxysuccinimide (NHS) and a sulfhydryl-reactive moiety. To have a meaningful comparison of the linkers, the PMO or R_9F_2C peptide used was from one synthesis batch. The 5′-end of the PMO was conjugated at one end of a cross-linker through NHS chemistry. The opposite end of the cross-linker was conjugated to the sulfhydryl group of R_9F_2C by maleimide, bromoacetyl, or pyridyl disulfide chemistry.

The effect of the linker length was determined by the splice correction assay, and the results are summarized in Table 3. The effect was explored by comparing R_9F_2C−705-FL, R_9F_2C−EMCS−705-FL, and R_9F_2C−KMUS−705-FL and by comparing R_9F_2C−SPDP−705-FL to

Table 3. Effect of the Linker and Linking Chemistry on the Antisense Activity of the R_9F_2C and 705-FL Conjugates[a]

treatment	linker type	linker spacer (Å)	antisense activity RLU/μg protein (range)
vehicle control (H_2O)	N/A	N/A	1 (0.1)
R_9F_2C−705-FL	thiomaleimide	6.8	102 (4.9)
R_9F_2C−EMCS−705-FL	thiomaleimide	9.4	141 (4.3)
R_9F_2C−KMUS−705-FL	thiomaleimide	15.7	171(14.3)
R_9F_2C−SMPB−705-FL	thiomaleimide	11.6	123 (2.1)
R_9F_2C−SMCC−705-FL	thiomaleimide	11.6	86 (1.4)
R_9F_2C−SBAP−705-FL	thioether	6.2	98 (3.2)
R_9F_2C−SPDP−705-FL	disulfide	6.8	109 (2.9)
R_9F_2C−LCSPDP−705-FL	disufide	15.6	181 (7.8)

[a] HeLa pLuc705 cells were treated with 10 μM of an indicated conjugate in the serum free medium for 6 h. The antisense activity was indicated by luciferase activity, expressed as RLU/μg protein. Each data point is an average ± range of means from two independent experiments each consisting of a triplicate sample.

R_9F_2C−LCSPDP−705-FL. The first three conjugates contained a thiomaleimide bond, but differed in spacing between the peptide and PMO. R_9F_2C−KMUS−705-FL (15.7 Å spacer) and R_9F_2C−EMCS−705-FL (9.7 Å) had 1.7 or 1.4-fold higher antisense activity, respectively, than R_9F_2C−705-FL (6.8 Å) (Table 3). The pyridyl disulfide chemistry was used to make R_9F_2C−SPDP−705-FL and R_9F_2C−LCSPDP−705-FL, resulting in each conjugate containing a disulfide bond. LCSPDP (15.6 Å spacer) is about 8.8 Å longer than the SPDP (6.8 Å) linker, and R_9F_2C−LCSPDP−705-FL was almost twice as effective in splice correction as R_9F_2C−SPDP−705-FL. Overall, the conjugates with longer linker length had greater antisense activity.

The effect of conjugation chemistry was determined by comparing three conjugates, R_9F_2C−SBAP−705-FL, R_9F_2C−705-FL, and R_9F_2C−SPDP−705-FL, in the splice correction assay. The three conjugates each had the same linker spacing but differed in linking chemistry: thioether in R_9F_2C−SBAP−705-FL, thiomaleimide in R_9F_2C−705-FL and disulfide in R_9F_2C−SPDP−705-FL. These conjugates had the same antisense activity despite their difference in conjugation chemistry.

The above results show that the antisense activity of the PMO was increased with longer linkers but not affected by the conjugation chemistry. Increasing the backbone and side chain flexibility (*37*) of an arginine-rich peptide or an addition of a hydrophobic moiety (*26*, *27*) onto a peptide have both shown to give better delivery of a fluorescein cargo. The higher antisense activity of the conjugates with longer chains of $(CH_2)_n$ moieties may be the result of their greater flexibility and/or hydrophobicity than those with shorter linkers. It is also possible that a longer linker reduces steric interference for PMO binding to the targeted pre-mRNA.

Effect of Linker Type on Intracellular Distribution and Concentration of the Peptide−PMO Conjugates. The intracellular distribution of the fluorescein-tagged PMO (705-FL), conjugated to R_9F_2C via different linkers, was determined by fluorescent microscopy. All conjugates containing thiomaleimide or thioether bonds gave a similar fluorescent pattern: a bright fluorescent spot in addition to a dimmer diffused fluorescence throughout the cells, as represented by the image of cells treated with R_9F_2C−705-FL (Figure 5A). Green and red dual fluorescence staining (Figure 5B and 5C) reveals that the bright fluorescent spot was located outside of the nucleus as shown by cotreatment of cells with the conjugate and dihydroethidium, a cell-permeable nucleic stain that fluoresces red upon DNA intercalation. This

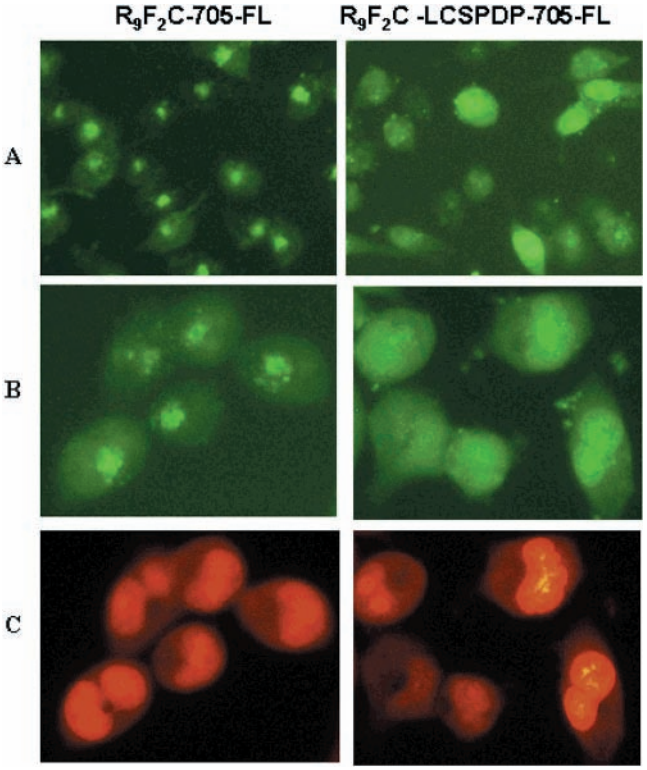

Figure 5. Effect of the linker type on intracellular distribution of the peptide−PMO conjugates. (A). Fluorescent image (200× magnification) of live HeLa pLuc705 cells treated with 10 μM of R_9F_2C−705FL or R_9F_2C−LCSPDP−705-FL for 20 h in RPMI with 10% FBS medium. (B and C). Dual fluorescence staining of HeLa pLuc705 cells treated with 2 μM of either R_9F_2C−705-FL or R_9F_2C−LCSPDP−705-FL in opti-MEM medium for 24 h. 10 μM of dihydroethidium, a nucleic acid stain, was added to the cells during the last 90 min incubation period of the conjugate. The same field image of cells was taken (400× magnification) through the green channel (B) or the red channel (C) of the microscope.

bright fluorescent spot seen using R_9F_2C−GMBS−705-FL was not observed with either disulfide-containing conjugates, R_9F_2C−LCSPDP−705-FL (Figure 5A and 5B) or R_9F_2C−SPDP−705-FL. Instead, the latter conjugates gave dimmer but more diffused fluorescence throughout the cytoplasm and nucleus than the thiomaleimide- or thioether-containing conjugates.

The effect of thiomaleimide or disulfide linker on cellular uptake was measured quantitatively by flow cytometry. Cells treated with R_9F_2C−KMUS−705-FL exhibited significantly higher fluorescence than R_9F_2C−LCSPDP−705-FL (Figure 6). Uptake of R_9F_2C−LCSPDP−705-FL was comparable to R_9F_2C−KMUS−705-FL at the 30 min timepoint but did not increase with longer treatment as did R_9F_2C−KMUS−705-FL. This could be explained by the intrinsic instability of the disulfide bond of R_9F_2C−LCSPDP−705-FL in the serum and/or the cleavage of the disulfide bond by glutathione at the cell surface (*39*). Cleavage of PMO from the peptide outside of the cell membrane would decrease the amount of PMO delivered.

Despite the significant difference in intracellular concentration between R_9F_2C−KMUS−705-FL and R_9F_2C−LCSPDP−705-FL, both conjugates gave nearly identical antisense activities (Table 3) in a dose dependent manner (data not shown). This suggests that the amount of internalized PMO available for the targeted pre-mRNA in the cell nucleus was similar. These interesting results can be analyzed in light of the difference in their linker types. R_9F_2C−LCSPDP−705-FL contained a disulfide bond that can be cleaved by cellular reducing agents such as glutathione in the golgi apparatus (*39*, *40*), releasing PMO from the peptide. R_9F_2C−KMUS−705-FL contained a thiomaleimide bond that does not have known cleavage enzymes and so the PMO likely remained bonded to the peptide. If this is the case, the positive charges of R_9F_2C may make it easier for R_9F_2C−KMUS−705-FL to bind anionic cellular components other than the targeted pre-mRNA. The result would be a decrease in effective PMO concentration, despite its higher intracellular concentration than that of R_9F_2C−LCSPDP−705-FL.

The above explanation was supported by fluorescent images (Figure 5A and 5C). PMO delivered by the peptide with the disulfide linker diffused throughout the cells, similar to the distribution of scrape-loaded unconjugated PMO (*14*). PMO delivered by the peptide with the thiomaleimide linker gave more distinct and localized fluorescence outside nucleus (Figure 5A), similar to the fluorescent image of fluorescein-tagged R_9F_2C (data not shown). These results indicate that the delivery peptide had greater influence on subcellular distribution of PMO with a noncleavable linker compared to a cleavable linker.

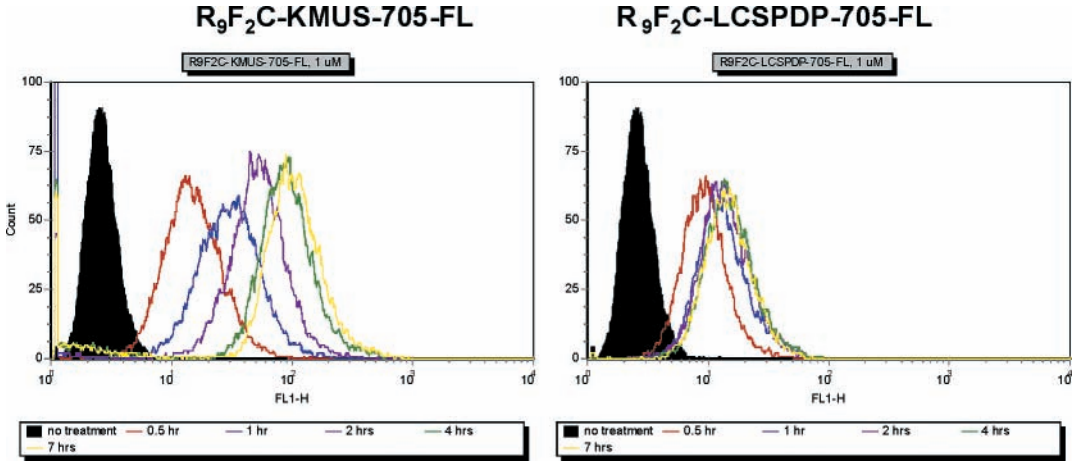

Figure 6. Effect of the linker type on intracellular concentration of the peptide−PMO conjugates. Flow cytometry diagram of the Hela pLuc705 cells treated with 1 μM of R_9F_2C−KMUS−705FL or R_9F_2C−LCSPDP−705-FL for 0.5 (red line), 1 (blue line), 2 (purple line), 4 (green line), or 7 (yellow line) h. The black filled histogram represented the background fluorescence of vehicle control (H_2O) treated cells.

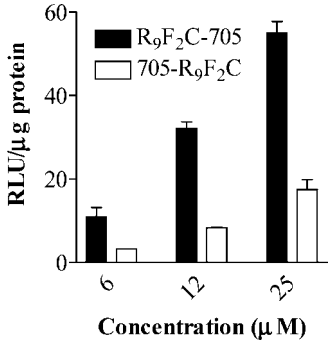

Figure 7. PMO with R_9F_2C at its 5′-end had greater antisense activity than PMO with R_9F_2C at its 3′-end. Luciferase activity of HeLa pLuc705 cells treated with the 705 conjugated to R_9F_2C either at the 5′-end (R_9F_2C−705) or the 3′-end (705-R_9F_2C) at indicated concentrations in the medium containing 10% FBS for 24 h. Each data point is an average ± the range of means of two independent experiments each consisting of a triplicate sample.

PMO with R_9F_2C at the 5′-End Had Higher Antisense Activity Than the PMO with R_9F_2C at the 3′-End. Either the 3′-end or the 5′-end of the PMO can be conjugated to the peptide. The effect of position of the peptide on PMO was determined by comparing two conjugates of 705 with R_9F_2C either at the 3′-end (705−R_9F_2C) or at the 5′-end (R_9F_2C−705). R_9F_2C−705 produced nearly four times as much as luciferase as 705−R_9F_2C (Figure 7).

The data indicate that the 5′-end of PMO is preferred for conjugation and can be understood in terms of PMO−RNA binding. PMO interrupt mRNA processes by steric blocking the access of other biomolecules to the target region (*2*). Addition of bulky moieties such as carboxylfluorescein or cholesterol to the 3′-end of a PMO decreases its antisense activity (data not shown), probably due to steric interference of the PMO/mRNA binding. We hypothesize that the positively charged linear peptide at the 3′-end may have a similar effect.

Length of PMO Did Not Affect Delivery Ability of R_9F_2C but Affects the Antisense Activity of PMO. Tat peptide has been used to deliver various-sized cargos, ranging from small fluorescein (*41*) to large magnetic beads (*42*). The effect of cargo size on cellular delivery by an arginine-rich peptide has not been determined quantitatively. The effect of PMO length on delivery of R_9F_2C conjugate was determined by flow cytometry and splice correction assay. PMO 705(12)-FL, 705-FL and 705(24)-FL are fluorescein-tagged and consist of 12, 18, and 24 bases (Table 1), respectively. R_9F_2C was conjugated to the 5′-end of each PMO using the GMBS linker.

HeLa pLuc/705 cells treated with R_9F_2C−705 (12)-FL, R_9F_2C−705 -FL or R_9F_2C−705 (24)-FL exhibited identical fluorescence (Figure 8A), indicating the same amount of PMO was delivered to the cells. However, the antisense activity of the three conjugates increased with the length of PMO (Figure 8B). A longer PMO is known to have greater antisense activity than shorter ones (*2*), and the higher activity of longer PMO is most likely due to its higher RNA binding affinity, rather than uptake differences. To verify this, each free PMO was delivered into cells by scrape-loading, which is a mechanical method that creates transient pores in the cell membrane, allowing extracellular macromolecules to enter into the cytoplasm directly (*14*). The result from scrape-loading showed a similar trend as R_9F_2C-mediated delivery (Figure 8C) with higher antisense activity for longer PMO. Taken together, the results indicate that the length of PMO does not affect the delivery effectiveness of the R_9F_2C peptide but affects the antisense activity.

Culture Conditions Affected the Cellular Uptake of R_9F_2C−PMO Conjugate. The effect of cell density, type of medium, and the serum concentration within the medium were examined by the splice correction assay. All were found to greatly influence the uptake of the conjugates. Cells treated with R_9F_2C−705 at cell confluence of 40−50%, 70−80%, or 90−100% produced 52, 40, or 28 RLU/μg protein, respectively (Figure 9A). Therefore, lower cell density was ideal when testing the peptide−PMO conjugates. The choice of culture media was examined by adapting the HeLa pLuc705 cells in RPMI, DME/F12, or MEM media for at least two weeks prior to treatment with the R_9F_2C−705 conjugate. Cells treated with the conjugate in RPMI medium had the highest luciferase production (40 RLU/μg protein) compared to those treated in DME/F12 (28 RLU/μg protein) or MEM (11 RLU/μg protein) (Figure 9B). The type and concentration of components vary among these culture media. Therefore, the difference in cellular uptake of the conjugate may be the result of differential interaction between the positively charged conjugate and components of the medium.

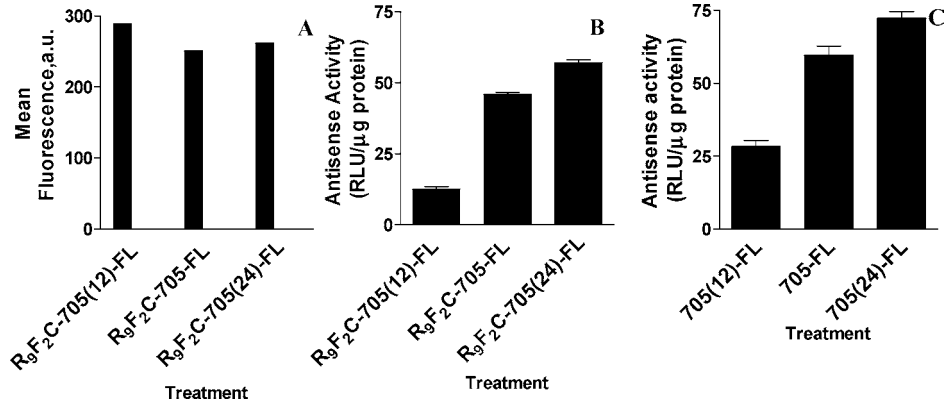

Figure 8. Length of PMO did not affect the delivery ability of R_9F_2C but affects the antisense activity. (A). Mean fluorescence of HeLa pLuc705 cells treated with 1 μM R_9F_2C conjugated to fluorescein-tagged PMO with 12 bases (R_9F_2C−705(12)-FL), 18 bases (R_9F_2C−705-FL), or 24 bases (R_9F_2C−705(24)-FL), determined by flow cytometry. The cells were treated with the test substance for 7 h in serum-free medium. (B). Luciferase activity of cells treated with the 1 μM conjugate for 7 h in serum-free RPMI medium. (C). Luciferase activity of cells treated with the 5 μM unconjugated PMO for 7 h. The unconjugated PMO was delivered by the scrape-loading method (*14*). Each data point is an average ± the range of means of two independent experiments and each consisting of a triplicate sample.

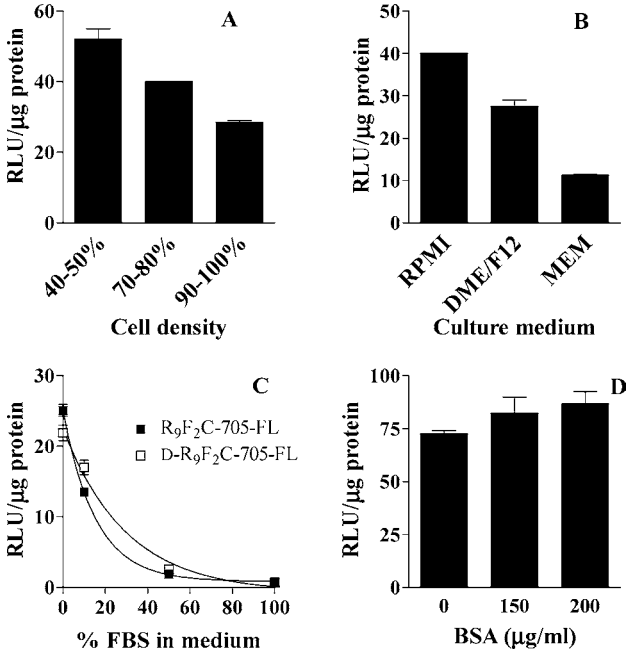

Figure 9. Cell culture conditions affected the cellular uptake of R_9F_2C-PMO conjugate. Luciferase activity of HeLa pLuc705 cells treated with the test substances. Each data point represents the mean of a triplicate sample ± SEM. (A). Cells at indicated cell density treated with 10 μM R_9F_2C-705 for 24 h in RPMI medium with 10% FBS. (B). Cells treated with 10 μM R_9F_2C-705 in indicated culture medium for 24 h in 10% FBS. (C). Cells treated with 5 μM of R_9F_2C-705-FL or D-R_9F_2C-705-FL for 24 h in RPMI medium containing indicated % of FBS. (D). Cells treated with 10 μM R_9F_2C-705 for 6 h in RPMI medium containing 1% FBS and indicated amount of additional BSA.

The effect of serum concentration in the culture medium was determined by incubating the cells with concentrations of FBS from 0% to 100%. Cells produced less luciferase as the concentration of FBS increased. Luciferase production was near background when the percentage of serum in the cultured media was >50% (Figure 9C). Positively charged molecules are known to bind to serum components. R_9F_2C is a highly positively charged peptide made of L-amino acids and may bind to serum components and/or be cleaved by proteinases in the serum. These two factors would decrease the peptide's delivery effectiveness resulting in decreased antisense activity.

To explore whether serum binding and/or serum proteinases were the cause of a decrease in antisense activity, a R_9F_2C peptide made of D-amino acids (D-R_9F_2C) was used in a side-by-side experiment against R_9F_2C. D-R_9F_2C cannot be degraded by FBS proteinase. The result from D-R_9F_2C-705 conjugate was nearly identical to that from R_9F_2C-705 (Figure 9C), indicating that the FBS proteinases did not affect the antisense activity. This points to the binding of serum components as the main cause for reduced antisense activity of a conjugate. Bovine serum albumin (BSA) is one of the major serum proteins. Whether it inhibits cellular uptake of the conjugate was examined in the splice correction assay. The splice correction was not inhibited by addition of BSA to the medium (Figure 9D), showing BSA is not the component that inhibits the function of the conjugate.

Cellular Toxicity. The conjugates of arginine-rich peptide and PMO exhibited dose-dependent toxicity (data not shown). The degree of toxicity depended on cell-type and was influenced by the number of arginines, with

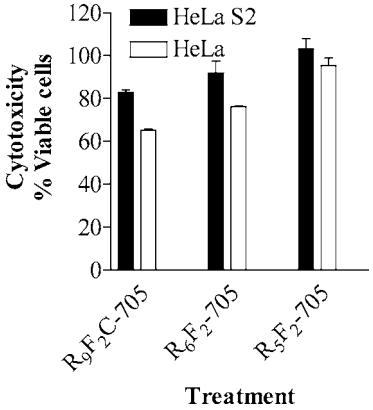

Figure 10. Cellular toxicity of the conjugate. Percentage viable HeLa S2(HeLa pLuc705) or HeLa cells treated with the indicated conjugate at 10 μM for 24 h, determined by MTT assay. Each data point represents the mean of a triplicate sample ± SEM.

greater number of arginines being more toxic (Figure 10). The difference in cellular toxicity was seen even within the subtypes of the HeLa cell line. The HeLa S2 cells (HeLa pLuc705) or HeLa cells treated with 10 μM of R_9F_2C-705 exhibited 83% (±1.4 SEM) or 65% (±0.61 SEM) cell viability (Figure 10). Increasing serum concentrations in the media decreases cellular toxicity of the conjugate (data not shown). The nature of this cytotoxicity is not well understood. Formation of transmembrane pores is not the cause of the toxicity because cells treated with the conjugate did not have elevated extracellular lactate dehydrogenase levels (data not shown). It is observed that adherent cells treated with the conjugate at high concentrations detached more readily from the culture wells compared to untreated cells.

In summary, the conjugation of R_9F_2C peptide to a PMO provided a simple and efficient delivery of the PMO to the RNA target. The length of PMO did not affect the delivery efficacy of the peptide while other factors did. When using the conjugate to study gene function in cell culture, the 5′-end of PMO is the preferred end for conjugation and a flexible linker of 15 Å was the best length of these tested. We have found that R_9F_2C peptide delivers PMO effectively into many different cell lines; however, the cell culture conditions greatly affect the antisense activity of the conjugate. Cell density, type of medium, and serum concentration along with their relationships with cytotoxicity in the specific cell type studied are important considerations when using the conjugate of an arginine-rich peptide and an uncharged antisense oligomer to study gene function in cell culture.

ACKNOWLEDGMENT

We thank Drs. Bruce Geller and Jon Moulton for editing this paper. We are grateful to Candace Lovejoy for synthesizing the PMO used in this study.

Molecular Binding Behavior of Pyridine-2,6-dicarboxamide-Bridged Bis(*β*-cyclodextrin) with Oligopeptides: Switchable Molecular Binding Mode

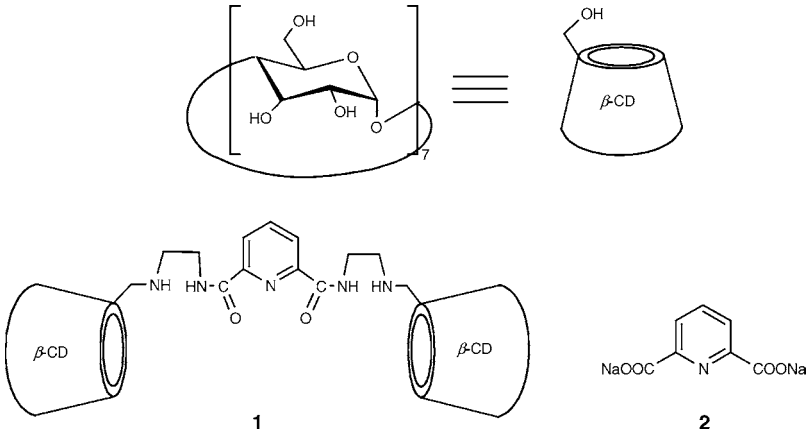
Yu Liu,* Guo-Song Chen, Yong Chen, Fei Ding, Tao Liu, and Yan-Li Zhao

Department of Chemistry, State Key Laboratory of Elemento-Organic Chemistry, Nankai University, Tianjin 300071, P. R. China. Received December 20, 2003; Revised Manuscript Received January 30, 2004

Bridged bis(*β*-cyclodextrin) **1** with a pyridine-2,6-dicarboxamide linker was synthesized, and its inclusion complexation behavior with some aliphatic oligopeptides was investigated in aqueous buffer solution of pH 2.0 and 7.2 at 25 °C by means of circular dichroism, fluorescence, and 2D NMR techniques. The results show that the resulting inclusion complexes of **1** with oligopeptides adopt a cooperative "cyclodextrin−guest−cyclodextrin" sandwich binding mode in a neutral media, but a "guest−linker−cyclodextrin" coinclusion binding mode in an acidic media. These switchable binding modes consequently rationalize the binding ability of bis(*β*-cyclodextrin) **1** at different pH values; that is, **1** shows the stronger association with oligopeptides in a neutral media. Because of the simultaneous contributions of hydrophobic, hydrogen bond, and electrostatic interactions, bis(*β*-cyclodextrin) **1** affords length-selectivity up to 4.7 for the Gly-Gly/Gly-Gly-Gly pair at pH 2.0 and sequence-selectivity up to 4.2 for the Gly-Leu/Leu-Gly pair at pH 7.2. These phenomena are discussed from the viewpoint of the size−fit concept and the multipoint recognitions between host and guest.

INTRODUCTION

Cyclodextrins are a class of cyclic oligosaccharides consisting, for the most common representatives, of six to eight D-glucose units linked by α-1,4-glucose bonds. They are well-known to encapsulate various organic guests within their hydrophobic cavities to afford host−guest complexes or supramolecular species in aqueous solution (*1*). This fascinating property enables them to be successfully utilized as drug carriers (*2*−*4*), separation reagents (*5*), enzyme mimics (*6*), and photochemical sensors (*7*), etc. Bis-cyclodextrin derivatives can greatly enhance the original binding ability and molecular recognition of parent cyclodextrins through the cooperative binding of two adjacent hydrophobic cavities. In addition, the functional linker group introduced in bridged bis-cyclodextrins can not only adjust the distance and orientation of two cyclodextrin cavities in cyclodextrin dimers to affect the penetration depth of guest molecules but also supply additional binding ability toward accommodated guest upon inclusion complexation. Owing to these potential advantages, a variety of dimeric cyclodextrins with different functional linkers have been designed and synthesized to understand the multiple recognition mechanisms of cyclodextrin dimers and to mimic the "multimode, multipoint" binding often observed in the biological systems (*8*−*10*). Among the various families of organic and biological guests for these studies, oligopeptides have attracted considerable interest because they represent an intermediate step toward the recognition of protein surfaces, and the short peptide sequences are themselves worthwhile targets for recognition due to their potential applications in separation, diagnostic, or biological areas (*11*, *12*). Recently, a number of works on the recognition and separation of peptides by cyclodextrins have been published (*13*−*16*). Schneider reported a detailed analysis on the inclusion complexation of some di- and tripeptides with amino cyclodextrins, demonstrating the simultaneous presence of complexes with a peptide phenyl unit approaching from both the narrow and the wide side of the cyclodextrin cavity (*17*). Breslow et al. reported a series of elegant works on the molecular recognition of oligopeptides by cyclodextrin cavities, which showed that the cyclodextrin dimers could strongly associate with the oligopeptides through the cooperative binding of two hydrophobic cavities (*18*). Inoue et al. reported the chiral recognition thermodynamics of dipeptides with native *γ*-cyclodextrin and discussed the effects of the length, size, and flexibility of the tether connecting the two aromatic moieties in a peptide on the molecular recognition (*19*). More recently, synthetic receptors bearing a 2,6-disubstituted pyridine group were proven to be one type of effective host compound for the recognition of peptide guests with a carboxylic acid terminus, since the pyridine unit can specifically bind to the carboxylic acid fragment of the peptide (*20*, *21*). However, most of the studies on the molecular recognition of peptides by cyclodextrins are carried in the neutral media, and the corresponding investigations in the acidic media are less involved (*17*, *22*). Herein, we wish to report the synthesis of a bis(*β*-cyclodextrin) with a fluorescent pyridine-2,6-dicarboxamide linker (Chart 1) and its inclusion complexation behavior with six aliphatic oligopeptides at different pH values. These studies will help us to gain a deeper insight into the recognition process of peptides in different biological environments, such as serum (pH ca. 7.3) or gastric acid (pH ca. 1.5), and consequently meet their potential applications as drug carriers.



EXPERIMENTAL PROCEDURES

Materials. All guest oligopeptides, i.e., Glu-Glu, Gly-Gly, Gly-Leu, Leu-Gly, Met-Met, and Gly-Gly-Gly (Chart 2), were commercially available and used without further

purification. Pyridine-2,6-dicarboxylic acid was purchased from Alfa Aesar. β-Cyclodextrin of reagent grade was recrystallized twice from water and dried in vacuo at 95 °C for 24 h prior to use. *N*,*N*-Dimethylformamide (DMF) was dried over calcium hydride for 2 days and then distilled under reduced pressure prior to use. Mono-[6-*O*-(*p*-toluenesulfonyl)]-β-cyclodextrin (6-OTs-β-cyclodextrin) was prepared by the reaction of tosyl chloride with β-cyclodextrin in an alkaline aqueous solution according to the literature reports (*23*). Then, 6-OTs-β-cyclodextrin was converted to mono[6-(2-aminoeythylamino)-6-deoxy]-β-cyclodextrin in 70% yield on heating in excess ethylenediamine at 70 °C for 7 h (*24*).

Measurements. Elemental analyses were performed on a Perkin-Elmer-2400C instrument. NMR spectra were recorded on a Varian Mercury VX300 instrument. UV and circular dichroism (CD) spectra were performed on a Shimadzu UV 2401 spectrophotometer and a JASCO J-715S spectropolarimeter, respectively. Fluorescence spectra were measured in a conventional rectangular quartz cell (10 × 10 × 45 mm) at 25 °C on a JASCO FP-750 spectrometer equipped with a constant-temperature water bath, with the excitation and emission slits width of 10 nm. In the spectral measurements, disodium hydrogen phosphate dodecahydrate (25.79 g) and sodium dihydrogen phosphate dihydrate (4.37 g) were dissolved in 1000 mL of deionized water to make a 0.10 M aqueous phosphate buffer solution of pH 7.2, whereas 20 mM potassium chloride was adjusted to pH 2.0 with 1 M hydrochloric acid to give an acidic buffer solution (*25*), which were used as solvent for all measurements.

Synthesis of Pyridine-2,6-dicarboxamide-Bridged Bis(β-cyclodextrin) (1). To a solution of DMF (50 mL) containing 2.6 g of mono[6-(2-aminoeythylamino)-6-deoxy]-β-cyclodextrin and 1.24 g of dicyclohexylcarbodiimide (DCC) was added 0.16 g of pyridine-2,6-dicarboxylic acid in the presence of a small amount of 4 Å molecular sieves. The reaction mixture was stirred for 3 d in an ice bath and another 4 d at room temperature. The precipitate was removed by filtration, and the filtrate was poured into 300 mL of acetone. The white precipitate was collected and subsequently purified on a Sephadex G-25 column with deionized water as eluent. After drying in vacuo, a pure sample was obtained in 4% yield. ^{1}H NMR (D_2O, TMS, ppm) δ 2.5−3.0 (m, 8H), 3.1−4.0 (m, 84H), 4.9 (m, 14H), 7.9 (m, 3H); FT-IR (KBr) ν/cm^{-1} 3330, 3064, 2928, 1702, 1615, 1573, 1434 1368, 1301, 1239, 1155, 1079, 1031, 945, 847, 757, 707, 580, 529, 504, 411. Anal. Calcd for $C_{95}H_{153}O_{70}N_5 \cdot 8H_2O$: C, 43.40; H, 6.48; N, 2.66. Found: C, 43.53; H, 6.27; N, 2.94.

RESULTS AND DISCUSSION

Conformational Analysis. Over the past decades, circular dichroism (CD) spectrometry has become a convenient and widely employed method for the elucidation of the absolute conformation of chiral compounds (*26*). Moreover, achiral compounds can also show the induced circular dichroism (ICD) signal in the corresponding transition band in cases where there is a chiral microenvironment. Possessing an inherent chiral cavity, cyclodextrins can certainly provide such a microenvironment for the attached achiral moiety. In this context, we have measured the CD spectra of **1** at 1.0 × 10^{-4} mol dm^{-3} concentration in aqueous buffer solutions (Figure 1) to investigate the conformation of this β-cyclodextrin dimer with a chromophoric pyridine linker.

As shown in Figure 1a, host **1** displays quite different CD spectra in the two buffer solutions of different pH values considered in this study, which indicates that there should exist significant but different degrees of interaction between the linker group and the cyclodextrin cavity. The CD spectrum of **1** shows a strong positive Cotton effect peak around 213 nm ($\Delta\epsilon$ = 3.91 dm^3 mol^{-1} cm^{-1}) in a pH 7.2 buffer but displays a moderate negative Cotton effect peak around 220 nm ($\Delta\epsilon$ = −1.54 dm^3 mol^{-1} cm^{-1}) and a weak negative Cotton effect peak around 270 nm ($\Delta\epsilon$ = −0.14 dm^3 mol^{-1} cm^{-1}) in a pH 2.0 buffer. In the control experiment, the UV spectrum of the reference compound **2**, disodium pyridine-2,6-dicarboxylate, shows a peak around 272 nm and a shoulder around 220 nm, while the CD spectrum of **2** only exhibits a weak positive Cotton effect peak around 219 nm ($\Delta\epsilon$ = 0.1 dm^3 mol^{-1} cm^{-1}) assigned to the ^1L_a transition of the pyridine chromophore. According to the empirical rule proposed

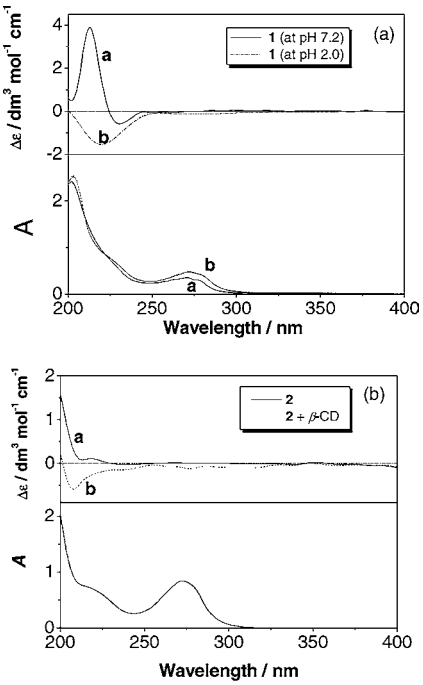

Figure 1. (a) Circular dichroism and UV spectra of host **1** (1.0×10^{-4}mol dm^{-3}) in the pH 7.2 and 2.0 buffers at 25 °C. (b) Circular dichroism and UV spectra of **2** (1×10^{-4}mol dm^{-3}) in the absence and presence of β-cyclodextrin (20 equiv.) in the pH 7.2 buffer at 25 °C.

by Kajtár (*27*), and Harata (*28*), the sign of ICD signal depends on the orientation of the transition dipole moment of the chromophore with respect to the dipole moment of the cyclodextrin. For the chromophore located inside the cyclodextrin cavity, its electronic transition parallel to the cyclodextrin axis gives a positive ICD signal, whereas the perpendicular transitions gives a negative signal, but this situation is reversed for the chromophore located outside the cyclodextrin cavity. So we can deduce that the pyridine group in the linker of host **1** may be located outside the cyclodextrin cavity in a pH 7.2 buffer, where the transition moment of ^1L_a band around 213 nm is nearly perpendicular to the cyclodextrin axis and thus induces the positive CD signal. On the other hand, in a pH 2.0 buffer, the pyridine chromophore may be shallowly included in the cyclodextrin cavity, where both the ^1L_a and ^1L_b transition moments around 220 and 270 nm are nearly perpendicular to the cyclodextrin axis, resulting in the two negative Cotton effect peaks. As a good reference system, the CD spectrum of **2** in the presence of excess amount of β-cyclodextrin is also measured. As can be seen in Figure 1b, compound **2** displays similar, but weak, CD signals to those of bis(β-cyclodextrin) **1** in a pH 7.2 buffer. However, in the presence of β-cyclodextrin, the CD spectrum of **2** shows two negative Cotton effect peaks around 208 and 277 nm, respectively, which is like the spectrum of **1** in a pH 2.0 buffer. In addition, the fluorescence spectra of **1** in the pH 7.2 and 2.0 buffers also provide some useful information. As can be seen in Figure 2, bis(β-cyclodextrin) **1** emits stronger fluorescence in a pH 2.0 buffer than in a pH 7.2 buffer, which indicates that the pyridine chromophore in **1** is certainly located in a more hydrophobic environment in the pH 2.0 buffer. The results of the CD and fluorescence experiments jointly indicate that there exist some interactions between the pyridine chromophore in the linker group and the cyclodextrin cavity, which consequently supports our hypothesis about the self-inclusion conformation of **1** in an acidic media.

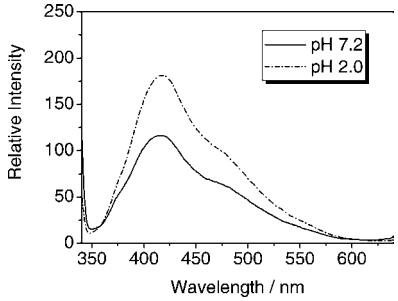

Figure 2. Fluorescence spectra of **1** (1.0×10^{-4} mol dm^{-3}) in the pH 7.2 and 2.0 buffers.

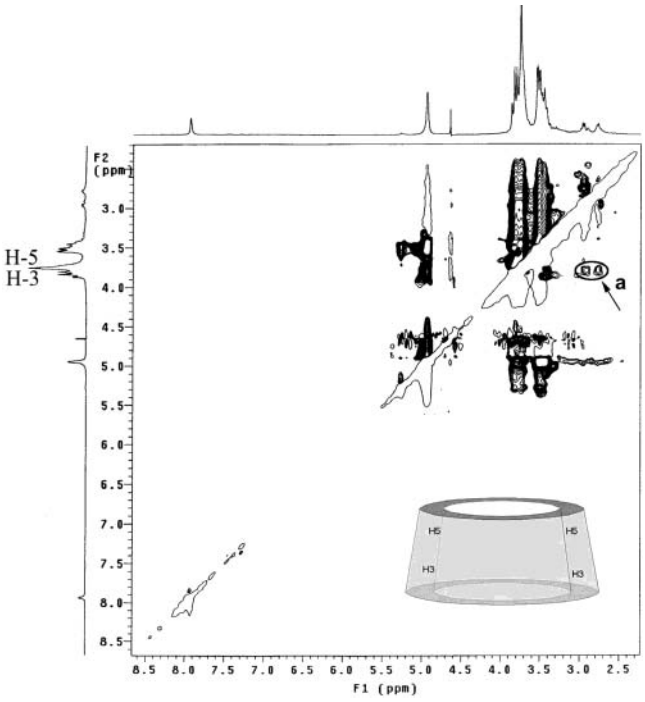

Figure 3. 2D ROESY spectra of host **1** (5 mM) in pD 7.2 buffer at 298 K with a mixing time of 400 ms.

2D NMR experiment provides reliable information about the conformation of bis(β-cyclodextrin) **1** in a pH 7.2 buffer. As illustrated in Figure 3, the ROSEY spectrum of **1** displays clear NOE cross-peaks between the H-5 protons of cyclodextrin and the ethylene protons of the linker group (peaks a). On the other hand, no NOE correlations between the inner protons (H-3 and H-5) of the cyclodextrin moieties and the pyridine protons can be observed. These phenomena indicate that only the ethylene unit of the linker group is shallowly embedded in the cyclodextrin cavity, but the pyridine group is located at the exterior. From the above CD, fluorescence, and NMR results, we can draw the conclusion that the conformation of **1** switches according to the pH value of the buffer solution as represented in Figure 4. Unfortunately, the ROSEY signals of **1** at pD 2.0 are too ambiguous to examine the NOE correlations between the pyridine unit and the H-3/H-5 protons of cyclodextrin, which may be due to the protonation of the pyridine unit, although the mechanism is still unclear. However, we can still get some useful information about the self-inclusion conformation of host **1** at pH 2.0 from the ^{1}H NMR spectra. Seen from the structure of host **1**, one can deduce that its self-inclusion conformation at pH 2.0 should result in the existence of a degenerated chemical-exchange process, i.e. the pyridinium ring included in one or the other cyclodextrin cavity, which would result in

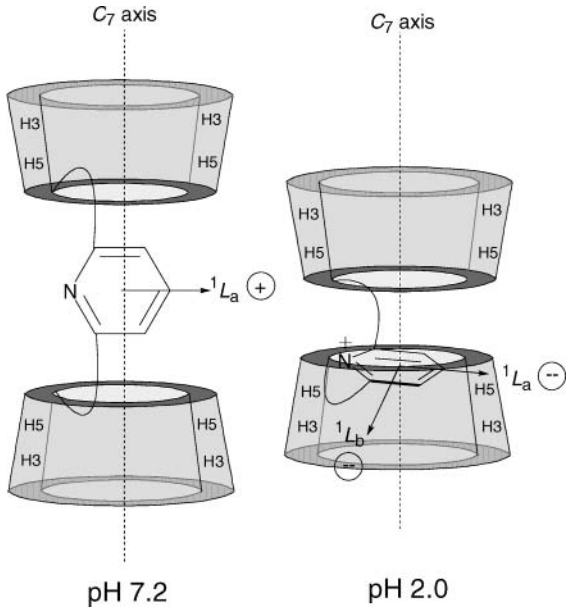

Figure 4. Possible conformation of bis(β-cyclodextrin) **1** in pH 7.2 and 2.0 buffers.

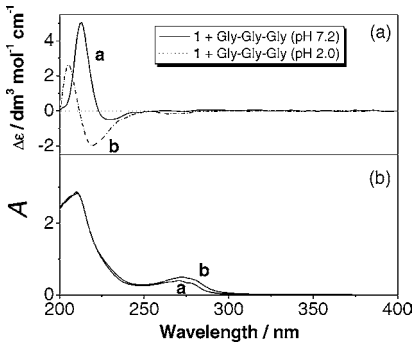

Figure 5. Circular dichroism (a) and UV (b) spectra of host **1** (1.0×10^{-4} mol dm^{-3}) in the presence of Gly-Gly-Gly (6.0×10^{-4} mol dm^{-3}) in the pH 7.2 and 2.0 buffers at 25 °C.

the significant line broadening in the ^{1}H NMR spectra unless this exchange is very rapid. Therefore, the obvious line broadening of the pyridinium protons in **1** at pD 2.0 clearly indicates the self-inclusion conformation of **1** in the acidic media.

Binding Mode. In our previous researches, we found that bridged bis(β-cyclodextrin) hosts could adopt different binding modes upon cooperative association with a given guest molecule, leading to either a sandwich or a coinclusion complex (*29*). In this work, we examine the CD spectra of bis(β-cyclodextrin) **1** in the presence of Gly-Gly-Gly to investigate its binding mode at different pH values. The reason for choosing Gly-Gly-Gly as guest molecule is that it displays no appreciable CD signals in the range of 200−400 nm. As seen from Figure 5, in either the pH 7.2 or the pH 2.0 buffer, the CD spectrum of **1** remains unchanged upon addition of Gly-Gly-Gly, but the Cotton effect intensities increase significantly. The enhanced Cotton effects ($\Delta\Delta\epsilon = 1.13$ dm^3 mol^{-1} cm^{-1} for pH 7.2 buffer and $\Delta\Delta\epsilon = 0.43$ dm^3 mol^{-1} cm^{-1} for pH 2.0 buffer) indicate that **1** has associated with Gly-Gly-Gly to form a host−guest complex. The fact that **1** exhibits similar pH dependent CD signals in the absence and in the presence of Gly-Gly-Gly supports that it adopts binding modes upon inclusion complexation that are compatible with the above-discussed host conformations. In a pH 7.2 buffer, bis(β-cyclodextrin) **1** may adopt a sandwich binding mode, where the guest molecule is cooperatively bound by two cyclodextrin cavities (Figure 6). However, in a pH 2.0 buffer, bis(β-cyclodextrin) **1** probably adopts a coinclusion binding mode; that is, the linker group is partly self-included in one of the hydrophobic cavities, while the guest molecule penetrates into the other cavity (Figure 6).

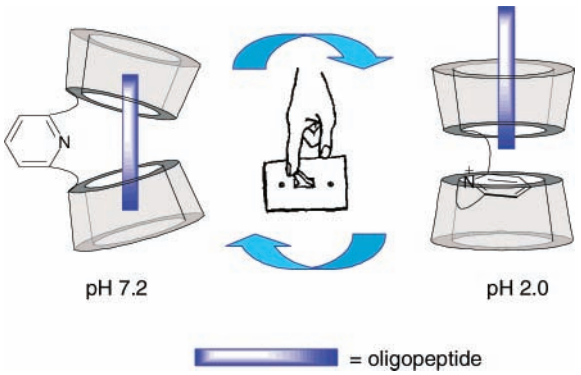

Figure 6. Possible binding mode of bis(β-cyclodextrin) **1** with oligopeptides.

The NMR data further reveal these binding modes in more detail. Since the chemical shifts of the isopropyl protons in Leu fragment are distant from those of the protons in bis(β-cyclodextrin) **1** and can be easily recognized in NMR spectra, we select Gly-Leu as guest to examine the binding geometry of the bridged bis(cyclodextrin) **1** with the guest oligopeptides. As illustrated in Figure 7, the ROESY spectrum of an equimolar mixture of **1** with Gly-Leu displays clear NOE cross-peaks between the H-3 protons of cyclodextrin and the methyl protons (H-5′) in Gly-Leu (peak a) as well as those between the H-5 protons of cyclodextrin and the methine proton (H-4′) of Gly-Leu (peak b). In addition, the initial strong correlation between the ethylene protons in the linker group of bis(cyclodextrin) **1** and the H-5 protons of cyclodextrin (peak a in Figure 3) disappears after the addition of guest oligopeptide. These results jointly indicate that the guest Gly-Leu is accommodated in the cyclodextrin cavity and the linker group is entirely driven out after the guest inclusion, which confirms the cooperative sandwich binding mode between host and guest. On the other hand, the appreciable line broadening of the pyridinium protons in **1** at pD 2.0 in the presence of Gly-Leu indicates that the pyridinium group is still self-included in the cyclodextrin cavity even after host−guest complexation, which consequently verifies the coinclusion binding mode as illustrated in Figure 6.

Spectral Titration. Quantitative investigation of the complexation behavior of **1** with the selected oligopeptides has been examined at pH 7.2 and 2.0 by means of titration fluorimetry. The fluorescence intensity of **1** gradually increases with the stepwise addition of oligopeptides (Figure 8). As expected, all of the continuous variation (Job) plots show the maximum at a molar fraction of 0.5, confirming the formation of 1:1 host−guest inclusion complexes for either the sandwich or the coinclusion binding mode. (Figure 9)

Using a nonlinear least squares curve-fitting method (*30*), we obtain the complexation stability constant for each host−guest combination. The excellent curve fits support the reliability of the stability constants obtained. The stability constant (K_s) and Gibbs free energy change ($-\Delta G°$) for the inclusion complexation of host bis(β-cyclodextrin) **1** with a series of oligopeptide guests are listed in Table 1.

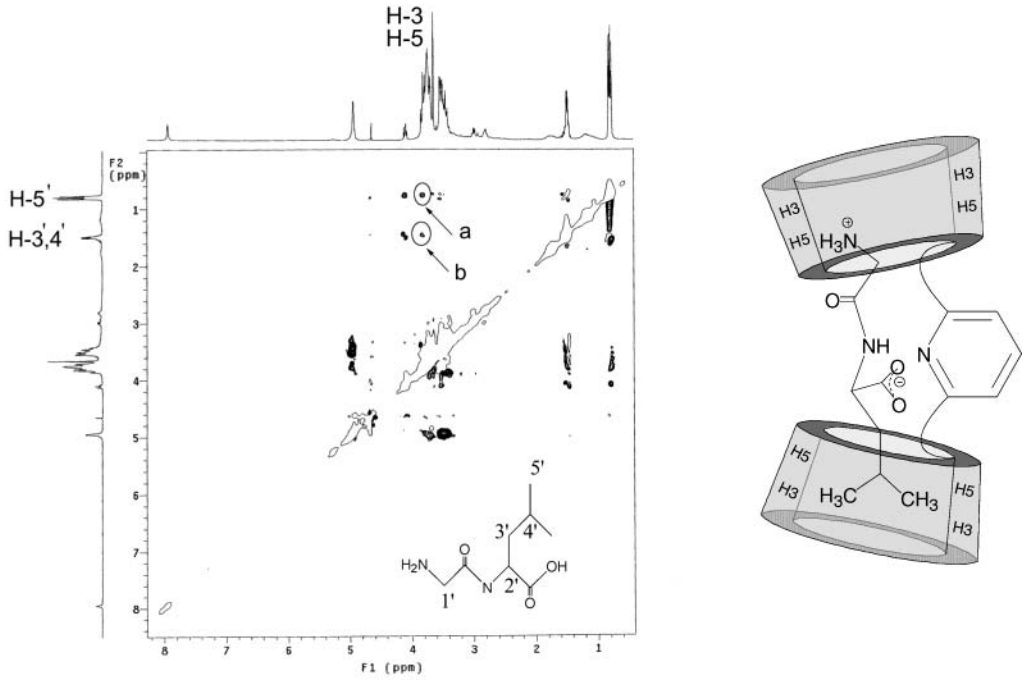

Figure 7. (left) 2D ROESY spectrum of mixture of host **1** (5 mM) and Gly-Leu (5 mM) in pD 7.2 buffer at 298 K with a mixing time of 400 ms, (right) possible binding mode of host **1** with Gly-Leu.

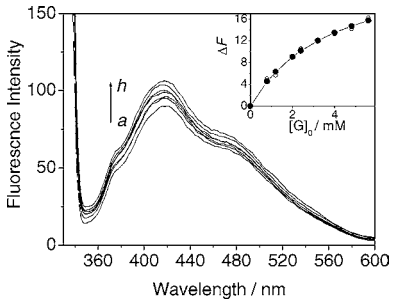

Figure 8. Fluorescence spectral changes bis(*β*-cyclodextrin) **1** (0.08 mM) upon addition of guest Gly-Gly-Gly (0−5.6 mM from *a* to *h*) at pH 7.2 and the nonlinear least-squares analysis (inset) of the differential intensity (Δ*F*) to calculate the complex stability constant (K_s). The excitation wavelength is 330 nm.

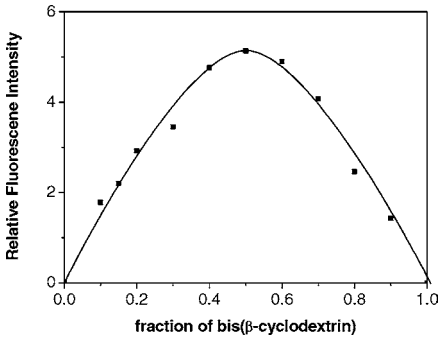

Figure 9. Continuous variation plot of the **1**/Gly-Gly system ([bis(*β*-cyclodextrin)] + [Gly-Gly] = 1.0×10^{-4} mol dm^{-3}) in a pH 2.0 buffer.

Molecular Binding Ability and Molecular Selectivity. It is well-known that several weak interactions, including van der Waals, hydrophobic, and hydrogen bond interactions, simultaneously contribute to the inclusion complexation of cyclodextrins with guest molecules. Additionally, other intermolecular interactions, such as electrostatic interaction and electron transfer, can also affect the binding behavior of cyclodextrins to some extent. In the present case, we find that the host−guest size/shape matching and induced fit dominate the stability of the complexes formed between host **1** and the assayed oligopeptides.

Table 1. Complex Stability Constant (K_s) and Gibbs Free Energy Change ($-\Delta G°$) for 1:1 Inclusion Complexation of Host 1 with Various Oligopeptide Guests in Aqueous Buffer Solution (pH 7.2 and 2.0) at 25 °C

pH	oligopeptide	Ks/M^{-1}	log K_s	$-\Delta G°$/kJ mol^{-1}
7.2	Glu-Glu	320 ± 10	2.50	14.3
2.0	Glu-Glu	153 ± 3	2.18	12.5
7.2	Gly-Gly	832 ± 30	2.92	16.7
2.0	Gly-Gly	339 ± 10	2.53	14.4
7.2	Gly-Leu	1208 ± 40	3.08	17.6
2.0	Gly-Leu	517 ± 20	2.71	15.5
7.2	Leu-Gly	356 ± 10	2.55	14.6
2.0	Leu-Gly	330 ± 10	2.52	14.4
7.2	Met-Met	700 ± 30	2.84	16.2
2.0	Met-Met	641 ± 20	2.81	16.0
7.2	Gly-Gly-Gly	263 ± 10	2.42	13.8
2.0	Gly-Gly-Gly	72 ± 3	1.86	10.6

From Table 1, we can see that the corresponding K_s value for a given oligopeptide guest at pH 7.2 is higher than that at pH 2.0. This observation is consistent with the cooperative contributions of two cyclodextrin cavities on binding with one guest. On the other hand, for the coinclusion mode, the guest molecule is only bound by one cyclodextrin, which will inevitably lead to weaker interactions between host and guest. Among the guest oligopeptides, bis(*β*-cyclodextrin) **1** displays the strongest binding ability toward Gly-Leu and Met-Met, both of which possess a carboxyl group located in the middle of the peptide chain. It is known that the diamidopyridine group can interact with the carboxyl group and thus effectively recognizes complementary peptide guests (*20*, *31*). In our case, this interaction rationalize not only the strong associations of bis(*β*-cyclodextrin) **1** with guest Gly-Leu and Met-Met but also the high sequence selectivity of **1** for Gly-Leu as compared with Leu-Gly ($K_s^{Gly-Leu}/K_s^{Leu-Gly} = 4.2$ at pH 7.2). On the other hand, although Glu-Glu has a similar structure to Met-Met, its poor hydrophobicity arising from the presence of three hydrophilic carboxyl groups in the molecule reduces the

hydrophobic interactions upon complexation with the cyclodextrin cavities and thus results in the moderate K_s value. Another interesting point is that, although possessing a relatively long linker group, bis(β-cyclodextrin) **1** exhibits a higher K_s value for the shorter Gly-Gly than for the longer Gly-Gly-Gly ($K_s^{Gly-Gly}/K_s^{Gly-Gly-Gly} = 4.7$ at pH 2.0), which may be attributed to the size−fit relationship between host and guest. That is, for a coinclusion mode in which the guest is only associated with one cyclodextrin cavity, the shorter guest Gly-Gly (skeleton length 7.246 Å, estimated by MM2) is fits better to the height of the cyclodextrin cavity (7.9 Å) than Gly-Gly-Gly (skeleton length 10.87 Å, estimated by MM2).

Protonation Effect. Because of the relatively low pK_a value of the pyridine group (pK_a ca. 5.4) and the ethylenediamino group (pK_a ca. 3.2), all of the N atoms in the linker group of **1** should be protonated in a pH 2.0 buffer. On the other hand, for the selected guest oligopeptides, the pK_a values of the carboxyl groups are around 3 (*22a*), while the corresponding values for the amino terminus are around 8 (*32*), which indicates that the C-terminals of the guests should exist as COOH the N-terminals as NH_3^+ at pH 2.0. That is to say, in an acidic media (pH 2.0), both host **1** and oligopeptide are positively charged, which will inevitably lead to unfavorable electrostatic repulsions between host and guest. However, this negative contribution will be partly compensated by the hydrogen bonds between the carboxyl, amino, and/or sulfydryl groups of guest peptides and the hydroxyl groups of the cyclodextrin. As a cumulative result of the hydrophobic, electrostatic and hydrogen bond interactions, the differential Gibbs energy changes for the complexation of bis(β-cyclodextrin) at different pH values ($\Delta\Delta G° = \Delta G°_{pH\ 7.2} - \Delta G°_{pH\ 2.0}$) vary in a narrow range (0.2−3.2 kJ/mol). This phenomenon indicates that the protonation effect can only affects the binding ability of bis(β-cyclodextrin) **1** with oligopeptides to a limited extent.

Received July 10, 2003; Revised Manuscript Received December 12, 2003

We describe novel peptide−protein microarrays, which were fabricated using semicarbazide glass slides that permitted the immobilization of glyoxylyl peptides by site-specific ligation and the immobilization of proteins by physisorption. The arrays permitted the simultaneous serodetection of antibodies directed against hepatitis C virus (HCV core p21 15−45 peptide, NS4 1925−1947 peptide, core, NS3, NS4, and mixture of core, NS3, NS4, and NS5 antigens), hepatitis B virus (HBc, HBe, and HBs), human immunodeficiency virus (Gp41 and Gp120 for HIV-I and Gp36 for HIV-II), Epstein−Barr virus (VCAp18 153-176 peptide), and syphilis (rTpN47 and rTpN17) antigens using an immunofluorescence assay. Peptide−protein microarrays displayed high signal-to-noise ratios, sensitivities, and specificities for the detection of antibodies as revealed by the analysis of a collection of human sera referenced against these five pathogens.

INTRODUCTION

The parallel detection of different antibodies in complex biological samples have a wide range of potential applications in the diagnosis of allergies and autoimmune and infectious diseases, as well as in epitope mapping studies and the development of vaccines (*1*−*3*). Actually, the detection of antibodies is usually performed using ELISA-based assays, which are time-consuming and require large quantities of both reagents and biological samples. These limitations have stimulated the development of high-throughput screening systems based on microfabricated analytical devices.

Several reports have demonstrated that peptide microarrays could be utilized for the detection of antibodies (*4*, *5*). On the other hand, the application of protein microarrays in this context has lagged because of poor stability, cross-reactivities, complex coupling chemistries and low sensitivities (*6*−*10*).

Very recently, we have shown that peptide microarrays fabricated by site-specific ligation of glyoxylyl peptides onto semicarbazide glass slides (Figure 1) displayed high levels of sensitivity and specificity for the detection of antibodies in human sera. The detection, based on an immunofluorescent assay, required very small blood samples from infected individuals (typically 1 μL) (*11*). Encouraged by these detection results, we examined the possibility of extending the methodology to the fabrication of protein or of peptide−protein microarrays.

We show in this article that proteins can be efficiently immobilized on semicarbazide glass slides by physisorption, whereas formation of a covalent bond between small peptidic antigens and the surface was found to be necessary to prevent the loss of material. Interestingly, the printing step and the whole process used for peptide microarrays in an antibody detection experiment were found to be applicable to proteins. Thus, peptide−protein microarrays could be prepared and used to detect antibodies directed against viral or bacterial antigens. In particular, we used antigens derived from HCV (core p21 15−45 peptide (*12*), NS4 1925−1947 peptide (*13*), core, NS3, NS4 and mixture of core, NS3, NS4, and NS5 antigens), HBV (HBc, HBe, and HBs), HIV (Gp41 and Gp120 for HIV-I and Gp36 for HIV-II), EBV (VCA p18 153−176 peptide (*14*)), and *Treponema pallidum* (rTpN47 and rTpN17 (*15*)). The performance of this miniaturized assay in terms of sensitivity and specificity was examined using a collection of sera referenced against HIV (245 sera), HCV (300 sera), HBV (220 sera), EBV (90 sera), or *Treponema pallidum* (30 sera) with commercially available tests. The possibility of detecting simultaneously HCV, HBV, HIV, and EBV antibodies with a high level of sensitivity and specificity was demonstrated using a collection of 90 sera referenced against these 4 pathogens.

In the accompanying article, we report other interesting properties of semicarbazide glass slides (chemical

stability of the functional layer, stability of printed antigens, reproducibility), which complement the data presented here and confirm the usefulness of semicarbazide microarrays.

MATERIALS AND METHODS

Peptide Synthesis. HCV core p21 15−45, HCV NS4 1925−1947, and EBV VCA p18 153−176 glyoxylyl peptides (Figure 2) were synthesized in an automated peptide synthesizer (model Pioneer, Perseptive Biosystems Inc., MA) using the Fmoc/*tert*-butyl strategy (*16*). The synthesis of these peptides was already described elsewhere (*17*−*19*).

Proteins. HBc (10 mg/mL), HBs (5 mg/mL), HBe (10 mg/mL), HCV core (1.5 mg/mL), HCV NS3 (0.5 mg/mL), HCV NS4 (0.4 mg/mL), HCV mixture of core, NS3, NS4, and NS5 antigens (1/1/1/1 by weight, 2 mg/mL overall), HIV-I Gp120 (0.5 mg/mL), HIV-I Gp41 (2 mg/mL), HIV-II Gp36 (1 mg/mL), syphilis rTpN47 (1 mg/mL), and rTpN17 (1 mg/mL) were purchased from Beijing Hepatitis Research Institute or from Henan Lily Bio-Products Company (Beijing, China). All these proteins were dissolved in a pH 9.6 0.05 M carbonate/bicarbonate buffer.

Printing of the Arrays. The preparation of semicarbazide glass slides was reported in detail elsewhere (*20*). The slides were printed using a 4-pin Affymetrix 417 arrayer (MWG, Santa Clara, CA) or a 32-pin manual arrayer (Microarray Printer XMM 47832, Xenopore, Hawthorne). Similar results were obtained using these two printing methods. The printed slides were incubated overnight at 37 °C in a humid chamber (60% relative humidity) and stored until use at room temperature. The number of replicates is indicated in the figures and tables.

Glyoxylyl peptides were printed in 0.1 M pH 5.5 sodium acetate buffer, whereas proteins were printed in the buffer used for their storage (pH 9.6 0.05 M carbonate/bicarbonate buffer).

Human Sera. Sera were collected from the clinical laboratory of the Centre Hospitalier Régional (Lille, France).

HCV. The reactivity of HCV referenced sera was determined with the AxSYM HCV version 3.0 Abbott ELISA kit (30 HCV-negative and 100 HCV-positive individuals). For some sera an additional RIBA HCV 3.0 SIA test (Ortho-Clinical Diagnostics) or a DECISCAN HCV PLUS test (BIORAD) was performed.

HBV. The reactivity of HBc referenced sera (40 HBc-negative and 60 HBc-positive individuals) was determined with the BIORAD MONOLISA anti-HBc PLUS test. The reactivity of HBe referenced sera (16 HBe-negative and 16 HBe-positive individuals) was determined with the BIORAD MONOLISA anti-HBe PLUS test. The reactivity of HBs referenced sera (40 HBs-negative and 60 HBs-positive individuals) was determined with the BIORAD MONOLISA anti-HBs PLUS test.

HIV. The reactivity of HIV referenced sera (90 HIV-positive and 20 HIV-negative individuals) was determined with DADE BEHRING Enzygnost HIV Integral and with BIORAD GENSCREEN PLUS HIV tests. The positivity was confirmed with BIORAD New Lav Blot I and II.

EBV. The reactivity of EBV referenced sera (70 EBV-positive and 20 EBV-negative individuals) was determined using an immunofluorescence assay (anti-VCA IFA, Immunoconcept).

Panels and Required Specifications. Panels used in this study (HIV 24+/20−, HCV 40+/40−, and syphilis 10+/20−) were from the National Institute for Drugs and Bio-products Quality Control (Beijing, China). The composition of the panels was as following.

HCV: 40 positive sera and 40 negative sera (anti-HCV and anti-HIV negative). Required ELISA specifications for HCV: less than one false positive and less than two false negatives.

HIV: 20 HIV positive sera (P1−20), 4 HIV-I positive sera with a concentration of anti-Gp41 antibodies close to the detection limit (S21−24), and 20 HIV negative sera (N1−20). Required ELISA specifications for HIV: (1) no false negative; (2) at least three S21−24 sera must be detected as positive; (3) less than two false positives.

Syphilis: 10 positive and 20 negative sera. Required ELISA specifications for syphilis: no false positives or negatives.

Detection of Antibodies. The phosphate-buffered saline (PBS) used for the preparation of the saturation, incubation, and washing solutions was 0.01 M, pH 7.2. PBS-A contained 0.1% of Tween 20 (by volume) and 2.5% of half-fat milk (by weight). PBS-B contained 0.05% of Tween 20 (by volume).

The saturation of the printed slides was performed under sonication in PBS-A during 60 min. After four washings with PBS-B, 1 μL of human serum diluted in 49 μL of PBS-A was incubated for 45 min at 37 °C under cover-glass. After four washings with PBS-B, 50 μL of tetramethylrhodamine-conjugated goat antibodies to human IgG-A-M (Jackson ImmunoResearch Laboratories, Baltimore, MD) diluted $^1/_{100}$ in PBS-A were incubated for 45 min at 37 °C under cover-glass. The slides were then washed three times with PBS-B, with distilled water, and with absolute ethanol (ACROS Organics, Geel, Belgium), and dried in air.

Data Collection and Analysis. The slides were scanned with an Affymetrix 418 array scanner (MWG, Santa Clara, CA). The scanner sensitivity is indicated in the figures and tables. The data were analyzed using the Scanalyse software (Stanford University, CA) or the Affymetrix Jaguar software (MWG, Santa Clara, CA). The background was subtracted from the spot fluores-

cence intensity. This subtraction was performed automatically by the Affymetrix Jaguar software. For all HCV, HIV, and EBV antigens except HCV mixture, the spots after incubation with negative sera were found to be indistinguishable from the background and led to a zero output value. In this case, the cutoff value of positivity was set to zero. For the HCV mixture and HBV and *Treponema pallidum* antigens, the cutoff value of positivity was calculated as the mean of negative sera fluorescence values ± 3 SD.

RESULTS AND DISCUSSION

The development of a microarray for the serodiagnostic of multiple pathogen infections requires a collection of epitopes allowing the highly sensitive and specific detection of antibodies directed against the selected pathogens. However, if there is no doubt about the interest of synthetic peptides for the detection of antibodies, some epitopes of diagnostic value can hardly be represented by linear synthetic peptides and necessitate the whole protein antigen. In this context, the possibility of combining linear synthetic peptidic epitopes and recombinant proteins was found to be attractive. Thus, we engaged in a project devoted to the fabrication of peptide−protein microarrays. The semicarbazide glass slide surface was selected owing to its usefulness for peptide microarray preparation (*11*).

Peptide and Protein Immobilization. The peptidic antigens used in this study are presented in Figure 2 and are derived from HCV (HCV core p21 15−45 (*12*) antigen for peptide **1**, HCV NS4 1925−1947 (*13*) antigen for peptide **2**) or EBV (VCA p18 153−176 (*14*) antigen for peptide **3**) pathogens. The glyoxylyl group was easily generated by periodate oxidation of an N-terminal seryl precursor in solution as described by Geoghegan et al. (*21*) for the EBV VCA p18 peptide or of an isopropylidene tartrate based linker on a solid support for HCV p21 and NS4 peptides (Figure 2) (*18*, *19*). In this latter case, the glyoxylyl group was situated at the C-terminus and separated from the backbone by a flexible spacer. The peptides were dissolved in a pH 5.5 acetate buffer to favor the site-specific ligation to the surface.

For peptides, the presence of a glyoxylyl group is important to avoid the loss of probe during the different incubation or washing steps. This aspect was easily demonstrated using biotinylated peptides **4** and **5**, which were synthesized as described elsewhere (*20*). Peptides **4** and **5** were printed at different concentrations (10^{-3}−10^{-6} M) in acetate buffer, and the slides were incubated with tetramethylrhodamine labeled goat antibiotin antibodies with a competitor for nonspecific adsorption (5% BSA). As shown in Figure 3, the signal displayed by the glyoxylyl peptide **5** at 10^{-4} M was about 7-fold higher than those given by the control peptide **4**.

On the other hand, the chemical modification of proteins by aldehyde groups without altering their recognition properties can be a difficult task and can lead to the loss of material and to additional costs. Thus, we examined the possibility of immobilizing proteins on semicarbazide glass slides by physisorption, as has been done by Haab and co-workers on amine-type cationic surfaces (*9*). Indeed, and to the contrary of small peptides, proteins can adsorb strongly on various surfaces because they are able to establish multiple interactions with accessible functional groups (*22*).

In a first approach, protein A was selected as a model protein for the physisorption studies and was printed at 1 mg/mL on semicarbazide glass slides using a pin-and-ring type printing robot. The microarrays were stored overnight at room temperature and then incubated with diluted human sera. Detection of antibodies captured through interaction with Fc (*23*) was performed following incubation with tetramethylrhodamine-labeled goat antihuman antibodies as described in Figure 4. The microarrays were analyzed using the Cy3 channel of a confocal fluorescence scanner. Figure 5 shows the results for five human sera. For the control experiment without human serum, the protein A spots were found to be indistinguishable from the background of the slide, showing that the high fluorescence observed with human sera was due to captured human antibodies. These data demonstrate that the semicarbazide surface can be used for the immobilization of proteins by simple adsorption.

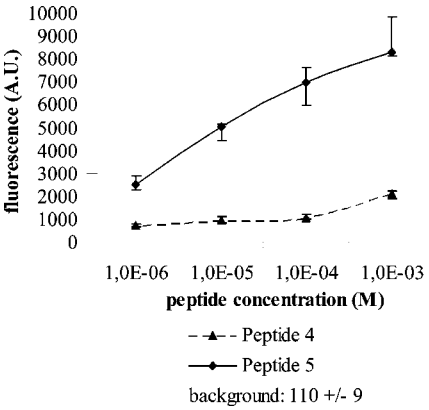

Figure 3. Printing of peptides **4** and **5** on semicarbazide slides and incubation of the arrays with tetramethylrhodamine labeled goat anti-biotin antibodies (10^{-2} mg/mL). Incubations were performed in the presence of 5% (w/v) BSA, using an Affymetrix 418 scanner, Cy3 channel, L35, PMT50. The fluorescence is expressed in arbitrary units (AU). The data were analyzed using ScanAlyse Sofware (Stanford University). The data represent the median and the interquartile range (n = 6).

We next examined the possibility of adsorbing HBs glycoprotein antigen and of using the arrays for the detection of anti-HBs antibodies in human sera. In this experiment, we have printed also HBs protein oxidized with periodate. Indeed, the polysaccharide moieties of HBs can be oxidized with sodium periodate using well-established protocols for generating aldehyde groups on the surface of glycoproteins (*24*). These aldehyde groups are able to react with the semicarbazide moieties to give a covalent semicarbazone linkage (*25*). Thus, this experiment allowed us to compare the physisorption and the covalent immobilization of the same protein antigen on the semicarbazide surface. As shown in Figure 6, similar results were obtained for these two immobilization methods. The largest difference in fluorescence intensity between oxidized and unmodified HBs proteins was found to be 8% (serum 11 in Figure 6B). These results confirm that proteins can be immobilized efficiently on semicarbazide slides by physisorption without the need for chemical modifications.

Peptide−Protein Antigen Microarrays, HCV Serodetection. The possibility of preparing peptide−protein microarrays useful for the serodiagnostic of pathogen infections was first examined with HCV antigens. The antigens used in this study were core p21 15−45 peptide, NS4 1925−1947 peptide, recombinant core, NS3 and NS4 protein antigens, and a mixture of core, NS3, NS4, and NS5 antigens (HCV mixture). Detection of antibodies was performed again as described in Figure 4 using adapted protocols from ref 11.

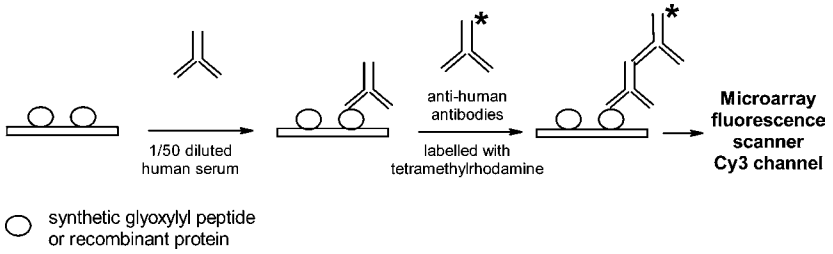

Figure 4. Detection of antibodies using the peptide−protein microarrays. Glyoxylyl peptides were immobilized by site-specific α-oxo semicarbazone ligation. Recombinant protein antigens were immobilized by simple adsorption.

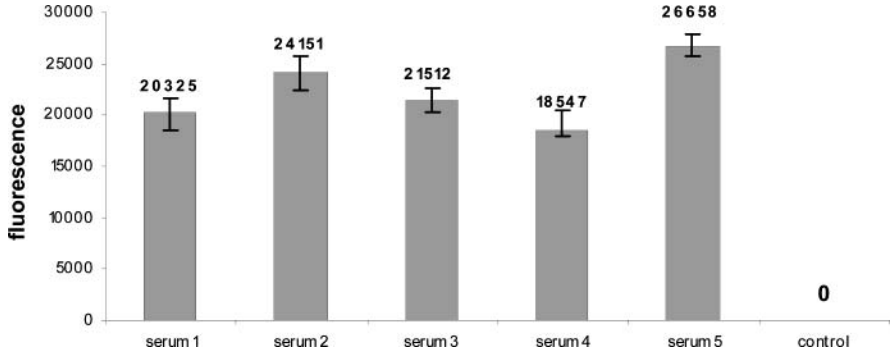

Figure 5. Detection of antibodies captured by protein A (1 mg/mL, $n = 12$) printed on semicarbazide glass slides. Five human sera were used in this experiment. The control experiment was performed by incubating one printed slide with the buffer. The slides were analyzed with an Affymetrix 418 scanner, Cy3 channel, sensitivity L35, PMT50. The fluorescence is expressed in arbitrary units. The data represent the median and the interquartile range.

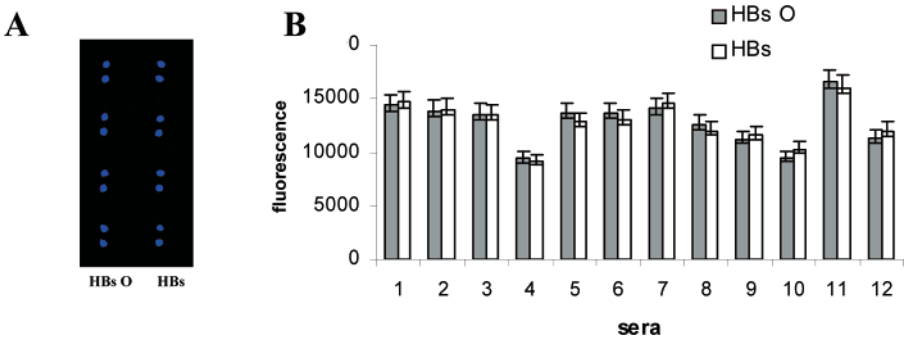

Figure 6. Detection of specific antibodies with physisorbed or oxidized HBs glycoprotein antigen on semicarbazide slides. Oxidized HBs (HBs, ○) and nonoxidized HBs were printed at 0.1 mg/mL: (A) image obtained with serum 11; (B) fluorescence data values for 12 HBs ELISA positive sera, using L35, PMT50. The data represent the median and the interquartile range ($n = 8$).

2	6	+	−	−	false positive ELISAs
3	30	−	−	nd	

[a] 130 ELISA referenced sera (100+/30−, AxSYM HCV version 3.0 Abbott ELISA). [b] HCV mixture is core/NS3/NS4/NS5, 1/1/1/1, by weight, 0.5 mg/mL (n=6). [c] RIBA HCV 3.0 SIA test. Scanner sensitivity L35, PMT50. Cutoff value of positivity (mean ± 3 SD of the 30 negative sera presented in entry 3) was 115. nd: not determined.

The collection of 30 HCV sera allowed us to determine the cutoff of positivity for all the HCV antigens (mean fluorescence ± 3 SD of negative sera). For the mixture of HCV antigens, a low signal arising from nonspecific binding could be observed and resulted in a cutoff of 115 at L35, PMT50 scanner sensitivity. For comparison, the lowest fluorescence signal observed with this mixture of antigens for an HCV positive serum was 331 (Table 2, group 4, serum 36). Table 1 describes the serodetection results obtained with this HCV mixture for 130 HCV sera referenced with a commercially available ELISA test (100 HCV+, 30 HCV−). Microarrays and ELISA assays were in agreement for 94 HCV+ and 30 HCV− sera. A Western blot assay recognized as the most specific assay for HCV antibodies detection was carried out for the six sera where discrepancies were observed (Table 1, entry 2). The Western blot assays were negative and thus in accord with the microarray data. In such a situation where ELISA tests are positive and Western blot assays negative, the sera are considered as false positive (*26*). At this stage, our results demonstrated that at least for the collection of tested sera microarrays displayed high levels of sensitivity and specificity.

These data in hand, we next examined the specificity and sensitivity of HCV serodetection using the different peptide or protein antigens considered separately. A collection of sera composed of the 6 previous false positive ELISA (Table 1, entry 2) and 34 new sera (HCV positive ELISA) were analyzed using a recombinant immunoblot assay that permitted the detection of specific antibodies directed against HCV core, NS3, and NS4 antigens.

Western blot negative sera are collected in group 1 of Table 2. The first six sera (sera 1−6) corresponded to the

false positive ELISA of Table 1. Two sera (sera 7 and 8) among the 34 new sera were found to be also false positive ELISA. Interestingly, the sera of group 1 were also found to be negative for all the HCV antigens in the microarray format. Western blot core, NS3, and NS4 positive sera are collected in group 2. In this case, all the microarray HCV antigens displayed high fluorescence signals. Group 3 includes the sera that displayed one or two Western blot negative reactivities. The same sensitivity and specificity were observed with the arrayed antigens. Group 4 collects the sera, which displayed at least one Western blot 0.5+ intensity for core, NS3, or NS4 antigens. These sera were particularly useful because they permitted us to evaluate the performance of peptide−protein microarrays in a context where the limit of sensitivity of the Western blot was attained for at least one antigen. Interestingly, antibodies that led to a Western blot 0.5+ intensity were easily detected using the corresponding microarray HCV antigens, illustrating the ability of the miniaturized device to detect specifically low levels of antibodies in human sera.

HBV and HIV Serodetection. These encouraging results obtained with HCV antigens led us to examine the possibility of detecting antibodies directed against other pathogens such as HBV (HBc, HBe and HBs antigens) and HIV (Gp41 and Gp120 antigens).

For the HBV serodetection study, a collection of sera referenced against HBc, HBs, or HBe by ELISA was used to document the sensitivity and specificity of the microarrays (Figure 7). As for the HCV mixture of antigens described above, some nonspecific binding could be observed with these antigens. The cutoff values for the three antigens corresponded to about 10-fold the background of the slides. Nevertheless, all the ELISA positive sera were detected without difficulty. The lowest positive signal observed with HBc, HBs, or HBe antigens corresponded to 12-, 6.5-, or 5.9-fold the cutoff of positivity, respectively. Alternatively, all the ELISA negative sera gave a fluorescence value below the cutoff of positivity. Taken together, these data highlight the utility of semicarbazide antigen microarrays for the sensitive and specific detection of antibodies directed against HBc, HBe, and HBs.

For the HIV serodetection study, we used a collection of 110 sera referenced against Gp120 and Gp41 antigens by ELISA. Here, as for HCV core, NS3 and NS4 recom-

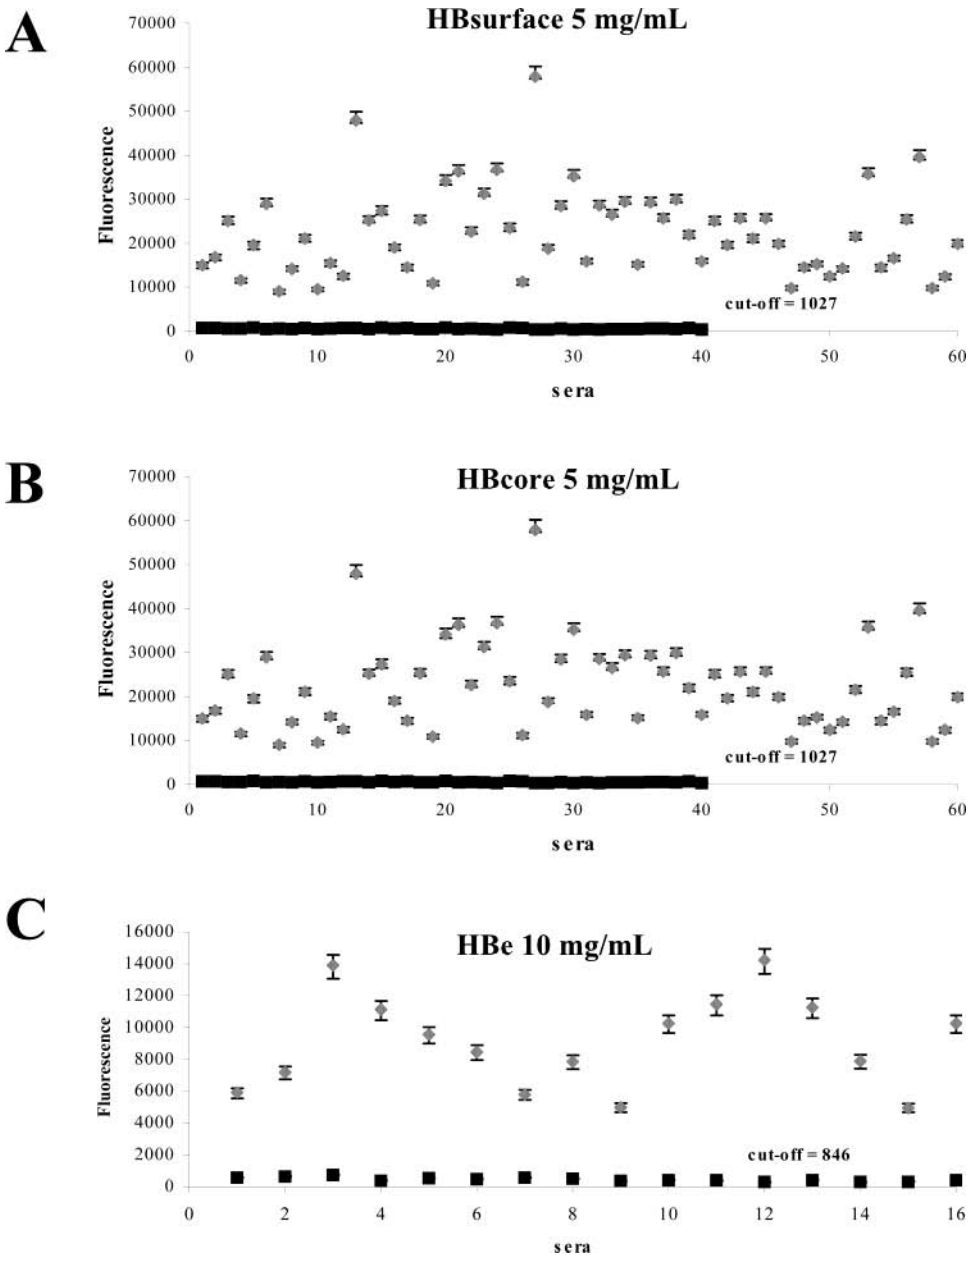

Figure 7. HBV serodetection study. The data were obtained after incubation of the microarrays with ELISA positive (open squares) or ELISA negative (filled squares) sera for (A) HBs 60+/40−, (B) HBc 60+/40−, (C) HBe 16+/16−. The fluorescence values (arbitrary units) represent the median and the interquartile range for six spots at L35, PMT 50 scanner sensitivity.

binant antigens and Gp41 and Gp120 spots were found to be indistinguishable from the background of the slide for all negative referenced sera, leading to a cutoff value of positivity equal to zero. No false positive sera were observed whatever the concentration tested (Gp120 0.5−0.01 mg/mL, Gp41 2−0.1 mg/mL). Both Gp41 and Gp120 antigens displayed 100% of sensitivity for the concentrations above 0.05 mg/mL. The printing of Gp120 at 0.01 mg/mL resulted in a loss of sensitivity (89%). Figure 8 details the fluorescence data obtained for the highest Gp120 or Gp41 concentrations.

These encouraging results led us to evaluate the performance of the device in a simultaneous serodetection study of multiple pathogen infections.

Simultaneous Detection of Multiple Pathogen Infections. Model Study with HCV, HBV, HIV, and EBV Antigens. For this study, the antigens selected for HCV serodetection were core p21 15−45 and NS4 1925−1947 peptides, the HCV mixture, and NS3 recombinant protein. For HIV, we used Gp120 and Gp41. HBc was selected for HBV serodetection, and finally EBV VCAp18 153−176 peptide was used for the serodetection of EBV infections. Protein A was printed as a positive control.

Ninety sera referenced against these four pathogens were used in this study. Twenty sera were negative for all the pathogens (entry 1), whereas 70 sera were positive for one (entry 2), two (entries 3−6), three (entries 7−9), or all pathogens (entry 10). The data collected in Table 3 show that there was usually a good correspondence between the reference tests and the microarray serodetection results except for entries 2 and 6, which corresponded to HCV false positive ELISAs, as confirmed by the Western blot assays. These sera were found to be HCV negative using the microarrays. No cross-reactivity was observed in this study. Figure 9 shows microarray images obtained using a serum positive (Figure 9A) or negative (Figure 9B) for all the pathogens.

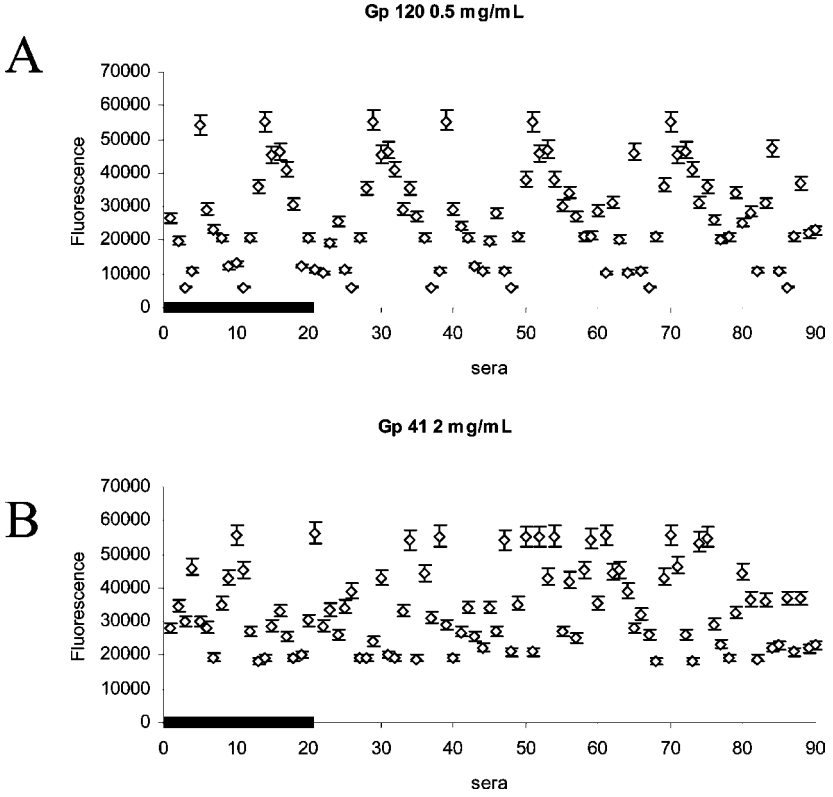

Figure 8. HIV serodetection study. The data were obtained after incubation of the microarrays with ELISA positive (open squares) or ELISA negative (filled squares) sera for (A) Gp120 90+/20− and (B) Gp41 90+/20−. The fluorescence values (arbitrary units) represent the median and the interquartile range for six spots at L35, PMT 50 scanner sensitivity.

Screening of HCV, HIV, and Syphilis Panels. To confirm the utility of semicarbazide microarrays for the serodiagnostic of pathogen infections, HCV, HIV, and syphilis panels of referenced sera from the Chinese National Institute for Drugs and Bio-products Quality Control were studied. These panels, combining sera with low levels of antibodies or sera known to give cross-reactivity problems, are used to select ELISA tests that are sensitive and specific enough to merit further evaluation. The microarray data will be discussed in light of ELISA specifications (see Materials and Methods) because no specifications were available for microarray-based serodiagnostic assays.

For the three panels (Figures 10−12), microarrays displayed 100% of specificity and sensitivity. For HCV (Figure 10B), the lowest positive signal was 3.8-fold the cutoff value of positivity. For the HIV panel (Figure 11), the specifications were imposed to detect at least three S21−24 sera, which contained low levels of antibodies and were close to the detection limit in ELISA. Interestingly, these four sera were detected as positive. Taken together, these results highlight the high sensitivity and specificity of peptide−protein microarrays on semicarbazide glass slides for the parallel detection of antibodies in complex biological samples.

CONCLUSION

In conclusion, we have described in this article a peptide−protein microarray methodology that was found to be useful for the serodetection of antibodies directed against different pathogens. Microarrays were prepared using semicarbazide functionalized glass slides. Peptidic antigens were functionalized by a glyoxylyl group and anchored to the glass surface by site-specific α-oxo

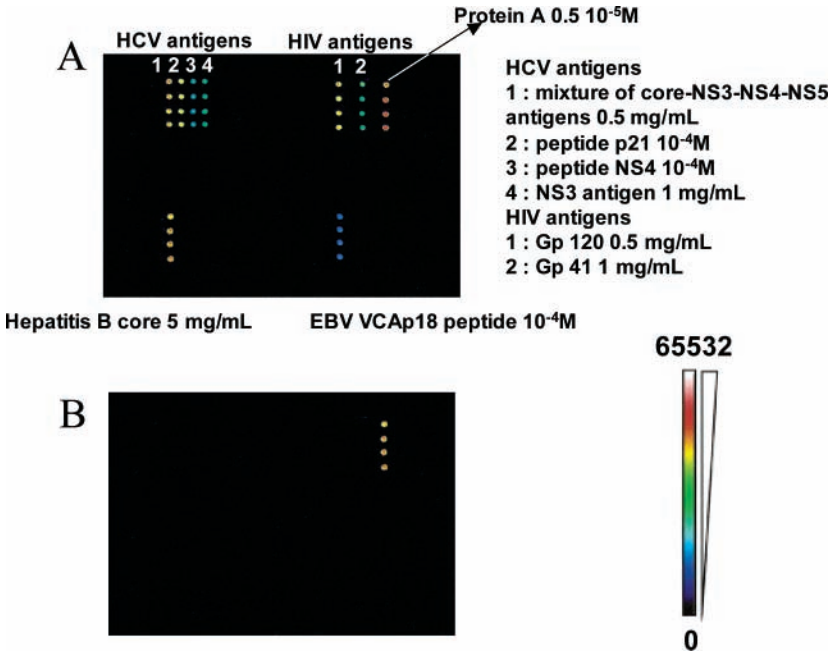

Figure 9. Microarray images obtained during the multiple serodetection study of HIV, HBV, HCV, and EBV infections: (A) referenced serum positive for all the pathogens; (B) referenced serum negative for all the pathogens. Scanner sensitivity was L35, PMT50. Protein A was used as a positive control.

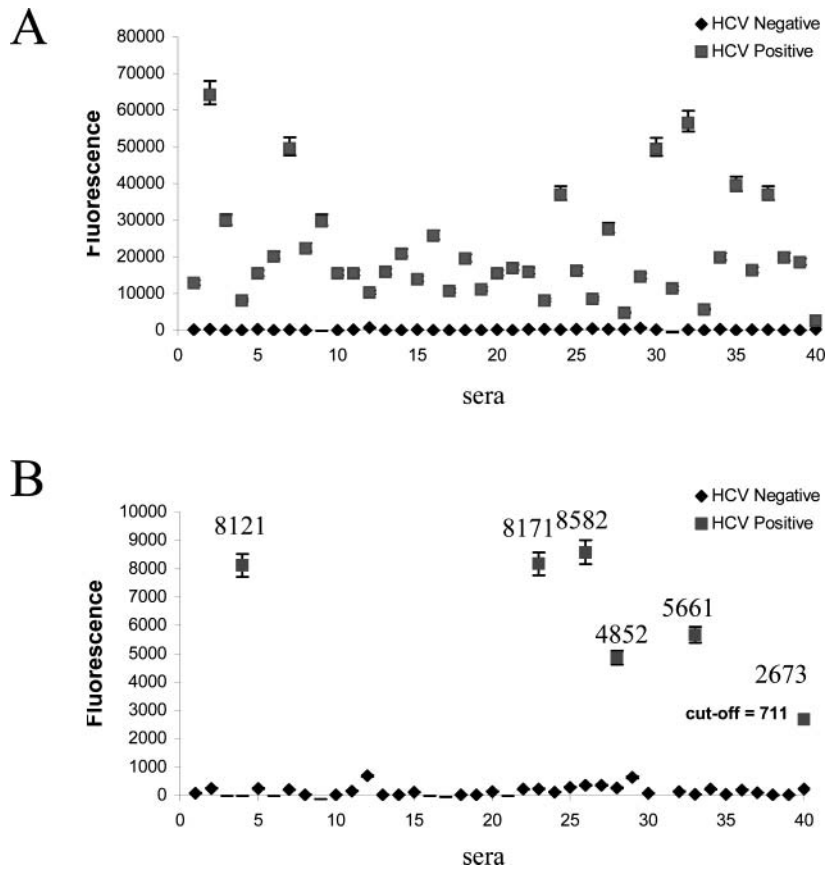

Figure 10. HCV serodetection results using the mixture of HCV core-NS3-NS4 and NS5 antigens, 1.5 mg/mL overall: (A) whole HCV panel; (B) sera that displayed the lowest fluorescence signals. The fluorescence values (arbitrary units) represent the median and the interquartile range for nine spots at L35, PMT 50 scanner sensitivity.

semicarbazone ligation, whereas recombinant proteins were adsorbed on the substrate. The microarrays, used in an immunofluorescence assay, displayed high levels of sensitivity and specificity for the detection of antibodies directed against HIV, HCV, HBV, and EBV pathogens. The performance of the device was further confirmed using referenced HIV, HCV, and syphilis panels. These promising results open the way for further validation studies on a larger scale. In the accompanying paper, we present a comparative study with amine glass slides and other data concerning the characterization of semicarbazide microarrays using chemical and physical methods.

Received July 10, 2003; Revised Manuscript Received December 12, 2003

We have described in the accompanying article the preparation of peptide−protein semicarbazide microarrays and their use for the simultaneous serodetection of antibodies directed against different pathogens. Here, we present a comparative study between semicarbazide and amine glass slides in an immunofluorescent serodetection assay using HIV (Gp120, Gp41), HCV (mix-HCV, core, NS3, and NS4), and HBV (HBs) recombinant antigens. Amine and semicarbazide surfaces displayed the same sensitivity for antibodies detection just after printing. However, the reactivity of protein antigens changed rapidly upon aging on amine slides but not on semicarbazide slides. Peptide or protein semicarbazide microarrays were found to be remarkably stable for months. Additional data concerning the characterization of the semicarbazide surface (homogeneity of the slides, chemical stability, contact angle measurements, atomic force microscopy studies, reproducibility of serodetection results) are also presented and discussed.

INTRODUCTION

The parallel detection of antibodies in complex biological samples have a wide range of potential applications in the diagnosis of allergies, autoimmune, and infectious diseases as well as in epitope mapping studies and vaccines development. The need for high-throughput screening systems have stimulated the development of microfabricated analytical devices.

In the preceding paper, we have described the preparation of novel peptide−protein microarrays based on the utilization of glass slides functionalized by a semicarbazide layer. This surface can be used for the site-specific immobilization of glyoxylyl-peptidic antigens through α-oxo semicarbazone ligation or for the immobilization of recombinant proteins through physisorption. These peptide−protein arrays could be used for the capture of antibodies in the sera of infected individuals using an immunofluorescent assay. Owing to the miniaturization, very small quantities of antigens, of sera (1 μL), and of tetramethylrhodamine labeled secondary antibodies (1 μg) could be used. The microarrays displayed high levels of sensitivity and specificity for the detection of HIV, HCV, HBV, EBV, and syphilis antibodies as revealed by the screening of a collection of sera referenced against these pathogens.

We disclose in this article a comparative study between semicarbazide and amine microarray glass slides, the later surface being often used for the preparation of protein microarrays (*1*, *2*). In particular, we have examined the performance of the two surfaces in the serodetection of HBV, HIV, and HCV infections and the evolution of the serodetection results during an accelerated aging of the arrays. The reproducibility of antibody detection with semicarbazide microarrays was documented. We have also carried out contact angle measurements with reference liquids to determine the sensitivity of both surfaces to air pollution. Finally, the semicarbazide glass slides were analyzed by atomic force microscopy to give a picture of the surface topography and to measure the height of the silane layer.

MATERIALS AND METHODS

Peptide Synthesis. HCV core p21 15−45, HCV NS4 1925−1947, and EBV VCA p18 153−176 glyoxylyl peptides were synthesized in an automated peptide synthesizer (Pioneer, Perseptive Biosystems Inc., MA) using the Fmoc/*tert*-butyl strategy (*3*) and an isopropylidene tartrate based linker (*4*−*6*) as described elsewhere (*7*).

Proteins. HCV core (1.5 mg/mL), HCV NS3 (0.5 mg/mL), HCV NS4 (0.4 mg/mL), HCV mixture of core, NS3, NS4, and NS5 antigens (1/1/1/1 by weight, 2 mg/mL overall), HIV-I Gp120 (0.5 mg/mL), and HIV-I Gp41 (2 mg/mL) were purchased from Beijing Hepatitis Research Institute or from Henan Lily Bio-Products Company (Beijing, China). All these proteins were supplied in a pH 9.6 0.05 M carbonate/bicarbonate buffer. HBs antigen (1 mg/mL) was purchased from Advanced ImmunoChemical (Long Beach, CA) and was supplied in a 0.01 M pH 7.2 PBS solution. All these proteins were diluted before printing in the buffer used for their storage.

Protein A (51 mg/mL) was purchased from Sigma-Aldrich (Saint Quentin Fallavier, France) and was supplied in water. Protein A was diluted with a 0.1 M pH 5.5 sodium acetate buffer before printing.

[a] The surface tension parameters of diiodomethane (dim), water (w), and formamide (fad) were taken from the literature (*20*). [b] Interfacial interaction free energy of the surface in water. [c] Free energy of binding of water to the surface.

Preparation of the Glass Slides. Amine Glass Slides. Microscope slides (ESCO precleaned microslide, frosted) were cleaned using a freshly prepared piranha solution (H_2SO_4/H_2O_2, 1/1 by volume, overnight). The slides were washed with water (3 × 3 min) and methanol (3 min) and treated with 3% 3-aminopropyltrimethoxysilane in methanol/water, 95/5 by volume (30 min, under sonication). The slides were then washed with methanol, water (two times), and methanol and annealed for 15 min at 110 °C.

Semicarbazide glass slides were prepared and characterized as described elsewhere (*8*). Rapidly, the amine slides prepared as described above were treated with triphosgen/diisopropylethylamine in 1,2-dichloroethane and then Fmoc-$NHNH_2$ (*9*) in DMF containing 1% EtOH (by volume) to install the semicarbazide functions. Finally, removal of the Fmoc groups was performed with piperidine/1,8-diaza-bicyclo[5.4.0]undec-7-ene (DBU) in *N*,*N*-dimethylformamide (DMF, 30 min). Four slides were used for the quality control. Three slides were immersed for 1 h at 37 °C in a 10^{-4} M solution of Rho-Lys-Arg-NH-$(CH_2)_3$NH-CO-CHO (synthesized according to refs 7 and 8, where Rho is (5)-6-carboxytetramethylrhodamine). One slide was treated with the control peptide Rho-Lys-Arg-NH_2. The fluorescence intensity of the slides was quantified using an Affymetrix 418 array scanner (MWG, Santa Clara, CA). Amine and semicarbazide slides were stored at room temperature in air in a closed box.

Printing of the Arrays. The slides were printed using a 4-pin Affymetrix 417 arrayer (MWG, Santa Clara, CA) or a 32-pin manual arrayer (Microarray printer XMM 47832, Xenopore, Hawthorne). The printed slides were incubated overnight at 37 °C in a humid chamber (60% relative humidity) and stored until use at room temperature. The number of replicates is indicated in the figures or tables.

Human Sera. Sera were collected from the clinical laboratory of the Centre Hospitalier Régional (Lille, France).

HCV. The reactivity of HCV referenced sera was determined with the AxSYM HCV version 3.0 Abbott ELISA kit (30 HCV-negative and 100 HCV-positive individuals). For some sera an additional RIBA HCV 3.0 SIA test (Ortho-Clinical Diagnostics) or a DECISCAN HCV PLUS test (BIORAD) was performed.

HIV. The reactivity of HIV referenced sera (90 HIV-positive and 20 HIV-negative individuals) was determined with DADE BEHRING Enzygnost HIV Integral and with BIORAD GENSCREENPLUS HIV tests. The positivity was confirmed with BIORAD New Lav Blot I and II.

HBs. The reactivity of HBs referenced sera (40 HBs-negative and 60 HBs-positive individuals) was determined with the BIORAD MONOLISA anti-HBs PLUS test.

Detection of Antibodies. The phosphate-buffered saline (PBS) used for the preparation of the saturation, incubation, and washing solutions was 0.01 M pH 7.2. PBS-A contained 0.1% of Tween 20 (by volume) and 2.5% of half-fat milk (by weight). PBS-B contained 0.05% of Tween 20 (by volume).

The saturation of the printed slides was performed under sonication in PBS-A during 60 min. After four washings with PBS-C, 1 μL of human serum diluted in 49 μL of PBS-A was incubated during 45 min at 37 °C under cover-glass. After four washings with PBS-B, 50 μL of tetramethylrhodamine-conjugated goat antibodies to human IgG-A-M (Jackson ImmunoResearch Laboratories, Baltimore, MD) diluted $^1/_{100}$ in PBS-A were incubated for 45 min at 37 °C under cover-glass. The slides were then washed three times with PBS-B, with distilled water, and with absolute ethanol (ACROS Organics, Geel, Belgium) and dried in air.

Data Collection and Analysis. The slides were scanned with an Affymetrix 418 array scanner (MWG, Santa Clara, CA). The scanner sensitivity is indicated in the figures or tables. The data were analyzed using the Affymetrix Jaguar software (MWG, Santa Clara, CA).

Statistical Analyses. Statistical analyses were performed using the nonparametric Mann−Whitney U-test (two samples) or the Kruskal−Wallis test for more than two samples (*10*).

Contact Angle Measurements. Contact angle measurements were performed at 20 °C with a Digidrop goniometer (GBX, Romans sur Isère, France) and water, formamide, and diiodomethane as reference liquids. For each liquid, at least nine drops of 1 μL were used for the determination of the angle (median, interquartile range). The Lifshitz−van der Waals and Lewis acid and base surface tension parameters (van Oss theory (*22*); see Table 1) were determined using the Young's equation. The interfacial interaction free energy between the surface in water (ΔG_{sws}) and the free energy of binding of water to the surface (ΔG_{sw}) were calculated as described in ref 22.

AFM Studies. The thickness of the amine or semicarbazide silane layer was obtained by local reactive ion etching of the surface followed by atomic force microscopy (AFM) analysis of the step between the silicon oxide and semicarbazide regions.

Reactive Ion Etching (RIE). A 200 nm layer of polystyrene was first deposited on the glass surfaces by spin-coating (v = 3000 rpm, acc = 2500 rpm/s during 10 s). The samples were dried by a rapid thermal annealing (120 °C, 1 min) and covered with a 1.6 μm photolithographic resin layer (S18S18, Chimie Tech Service, Anthony, France). The irradiation of the resin by a UV light (365 nm, 5 mW/cm^2, 12 s) was performed through an optical mask with square-shaped patterns with lateral dimensions of 9 μm. The irradiated regions were removed by a MF319 solution (Chimie Tech Service, Anthony, France). The polystyrene layer in the square-shaped pattern was decomposed with an oxygen plasma (Plasmalab 80 plus, Oxford instrument; 0.1 Torr; 20 sccm; 100 W) during 7 min. The engraving speeds for S18S18 and for polystyrene thickness were 200 and 170 nm/min, respectively (the silicon oxide substrate was not affected by the oxygen plasma). Finally, the samples were soaked with

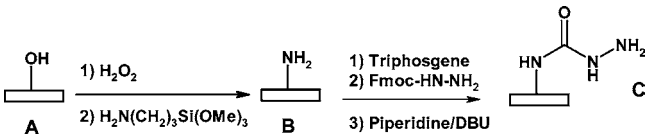

Figure 1. Fabrication of amine and semicarbazide functionalized glass slides used in this study.

sonication in a series of solvents to remove the unreacted parts (toluene, isopropyl alcohol, and water, 10 min each).

AFM Measurements. AFM (atomic force microscopy) was carried out with a Nanoscope IIIa controller (Digital Instrument) using intermittent contact mode at room temperature under ambient conditions. Processing of the AFM images was achieved by removing only local planes to the images. The height of the silane layer was measured from averaged profiles (so-called profile line) obtained along lines that run through the square-shape patterns. To characterize the substrate homogeneity, the root-mean-squared surface roughness (R_{rms}) was measured in the different layers.

RESULTS AND DISCUSSION

Preparation of the Glass Slides. The functionalization of glass slides by a semicarbazide sol−gel layer was discussed in detail elsewhere and is rapidly described in Figure 1 (*8*). Commercially available glass slides were silanized with 3-aminopropyltrimethoxysilane. The amine groups were treated successively with triphosgene and Fmoc protected hydrazine to install the semicarbazide functions. The correct functionalization of the slides is controlled using a glyoxylyl probe labeled with tetramethylrhodamine, which is able to react chemoselectively with the surface through the formation of an α-oxo semicarbazone linkage. This aspect will be discussed later, since this quality control was used to document the chemical stability of the semicarbazide glass slides upon aging.

Amine glass slides used for the comparative study were the same as those utilized for the synthesis of semicarbazide glass slides (Figure 1).

Fabrication of Protein Microarrays on Semicarbazide or Amine Glass Slides. Comparison in a Serodetection Study. The preparation of protein microarrays by adsorption of proteins on surfaces is an appealing strategy because no chemical modification of the proteins is required. As shown in the accompanying paper, recombinant proteins were found to adsorb efficiently on semicarbazide glass slides. The corresponding microarrays permitted the highly sensitive and specific detection of antibodies in human sera and were used for the simultaneous serodetection of multipathogen infections. Alternatively, proteins are known to adsorb on amine-modified surfaces. For this reason, amine glass slides were often utilized for the preparation of protein microarrays (*11*, *12*). For example, Mezzasoma et al. have recently described the fabrication of antigen microarrays for the serodiagnosis of infectious diseases using aminosilane-derivatized slides (*13*). Robinson et al. have printed antigens or antibodies on poly-L-lysine for the detection of their cognate ligands (*14*).

Both semicarbazide and amine glass slides present NH_2 groups on the surface. However, the pK_a values of semicarbazide and alkylamines are completely different (*15*). Indeed, the pK_a of semicarbazide is 3.65 at 25 °C, whereas the pK_a of methylamine is 10.65 at 25 °C. Thus, the semicarbazide surface is expected to be uncharged at physiological pH, whereas in the same conditions amine slides are protonated and thus cationic surfaces. Given the different physicochemical properties of these

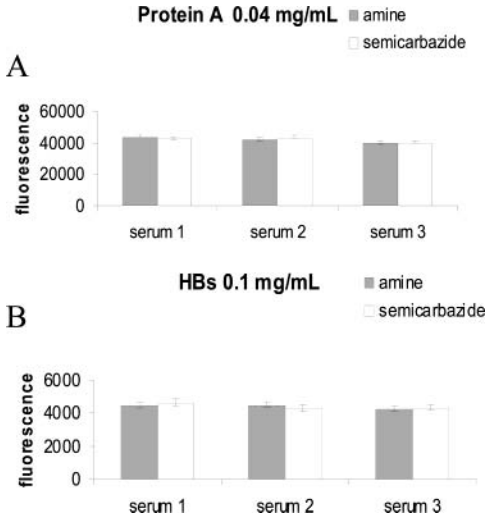

Figure 2. Adsorption of protein A (A) or HBs antigen (B) on amine or semicarbazide slides. For protein A, the arrays were incubated 1 h with a human serum (diluted $^1/_{50}$). For HBs, the arrays were incubated 2 h with a HBs positive referenced serum (diluted $^1/_{50}$). Detection of captured antibodies was performed with tetramethylrhodamine labeled goat antihuman IgG-A-M antibodies. $n = 6$, L35, PMT50. The interquartile range is indicated at the top of the bar (median).

surfaces, we have decided to print recombinant proteins on both surfaces in a microarray format and to evaluate their ability to detect antibodies in sera. In addition, we have studied the stability of the printed arrays upon accelerated aging. Despite the importance of this aspect for the development of protein microarrays, no long-term stability studies have been reported to our knowledge.

In a preliminary study, we have printed protein A and the surface antigen of hepatitis B virus (HBs) at 0.04 and 0.1 mg/mL, respectively (Figure 2). Each printed slide was incubated first with a human serum (ELISA referenced HBV positive serum for HBs microarrays) and then with goat antihuman secondary antibodies labeled with tetramethylrhodamine. The arrays were analyzed using the Cy3 channel of a fluorescence microarray scanner. As shown in Figure 2, both proteins behaved similarly on the two surfaces, both in term of signal intensity and background level. These results show that adsorption of proteins occurs similarly on amine and semicarbazide surfaces, even if the mechanism of immobilization is probably different.

These preliminary data in hand, we have selected other antigens derived from HCV to confirm the previous observations. We used recombinant core, NS3, and NS4 antigens and a mixture of core, NS3, NS4, and NS5 antigens named mix-HCV antigen. The HCV antigen microarrays were incubated with a collection of ELISA referenced HCV sera (16+, 4−) just after the printing step. The determination of the cutoff values of positivity is described in detail elsewhere (*16*). As shown in Figure 3, both types of microarrays displayed 100% of sensitivity and specificity with this collection of sera. Usually, the signal displayed by amine slides was equal or superior to the signal obtained with semicarbazide supports. However, for mix-HCV and core antigens, some sera led to higher signals on semicarbazide slides.

Stability Study of Amine and Semicarbazide Microarrays, Protein Antigens. These data set the stage for the stability study, which was performed using both surfaces. We used the previous HCV antigen microarrays and HIV antigen microarrays composed of two HIV recombinant proteins Gp 120 (0.5−0.05 mg/mL) and

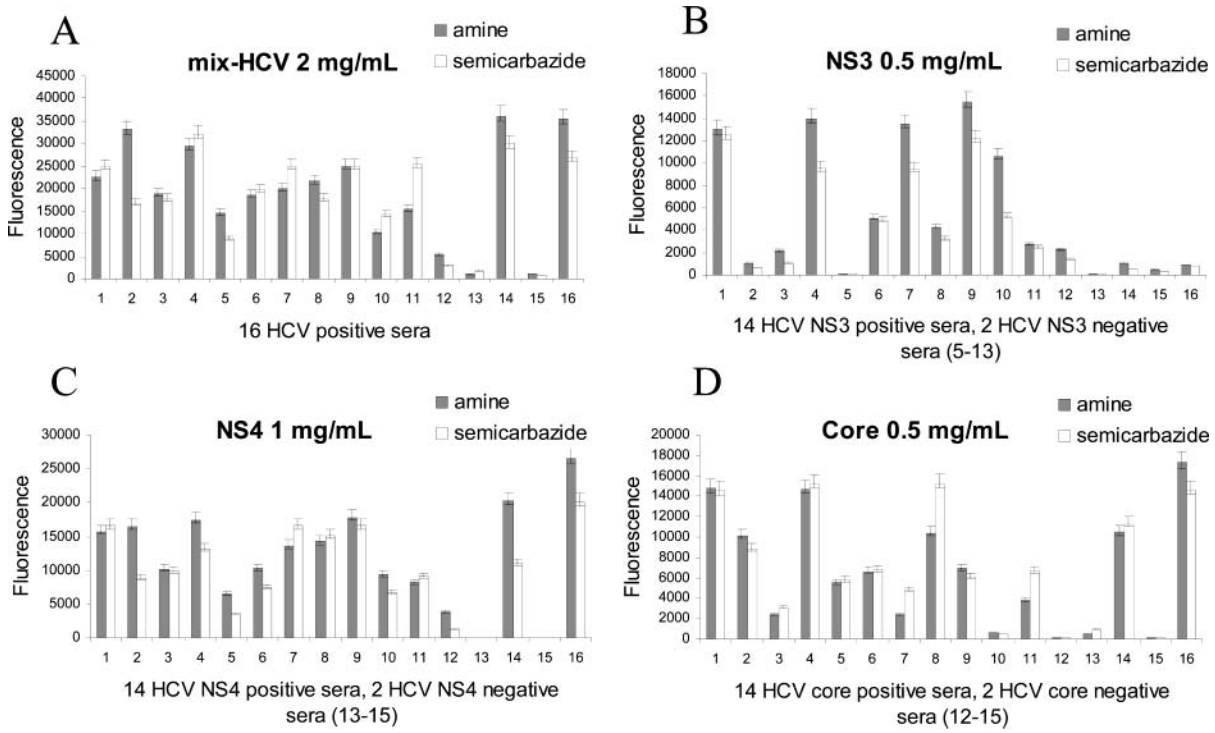

Figure 3. Detection of antibodies using amine or semicarbazide slides and HCV core, NS3, NS4, and mix-HCV antigens. HCV referenced sera (for ELISA, AxSYM HCV version 3.0, Abbott; for Western blot, RIBA, CHIRON RIBA HCV 3.0 SIA, Ortho-Clinical Diagnostics). The cutoff values of positivity (mean ± 3 SD) were determined using a collection of 30 HCV ELISA negative sera. The normality of the distribution was verified using the Shapiro−Wilk test. (A) mix-HCV, cutoff: 161 ± 36. (B) NS3 recombinant protein, cutoff: 28 ± 8. (C) NS4 recombinant protein, cutoff: 31 ± 9. (D) Core recombinant protein, cutoff: 23 ± 7. $n = 6$, L35, PMT50. The interquartile range is indicated at the top of the bar (median).

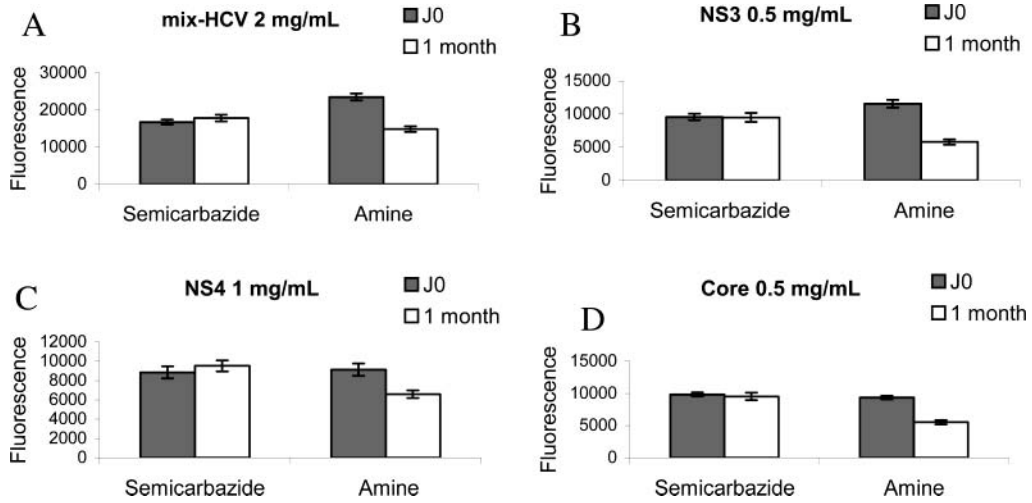

Figure 4. Stability of HCV core, NS3, NS4, and mix-HCV antigens on amine or semicarbazide surfaces. HCV referenced positive serum (for ELISA, AxSYM HCV version 3.0, Abbott; for Western blot, RIBA, CHIRON RIBA HCV 3.0 SIA, Ortho-Clinical Diagnostics). The microarrays were stored at 38 °C in a humid chamber. $n = 9$, L35, PMT50. The interquartile range is indicated at the top of the bar (median).

Gp41 (2−0.1 mg/mL). For each study, one ELISA referenced positive serum was selected. A series of microarrays were used for antibody detection just after printing. The other slides were placed in a humid chamber (60% relative humidity) at 38 °C to accelerate the aging.

The data corresponding to the HCV stability study are presented in Figure 4. The specificity of antibody detection was verified using HCV ELISA negative sera (data not shown). After 1 month, the fluorescence signal was found to drop significantly for all the tested antigens on amine slides: −37% for mix-HCV, −50% for NS3, −16% for NS4, and −44% for core. Alternatively, the largest variation observed with semicarbazide slides was +7.5% for NS4. Interestingly, the signals displayed by NS3 or core antigens were found to be stable on the semicarbazide surface (−0.8% and +2.7%, respectively, nonsignificant at $p < 0.05$), whereas the loss of reactivity on amine slides upon aging was as high as 45−50%. This high difference in stability was confirmed with other sera (data not shown).

The data corresponding to the HIV study are collected in Figures 5 and 6. For amine microarrays (Figure 5), the signals displayed by Gp120 and Gp41 antigens changed significantly ($p < 0.05$) upon aging for all the tested concentrations. The figure for Gp41 was complex and depended on both concentration and time of aging

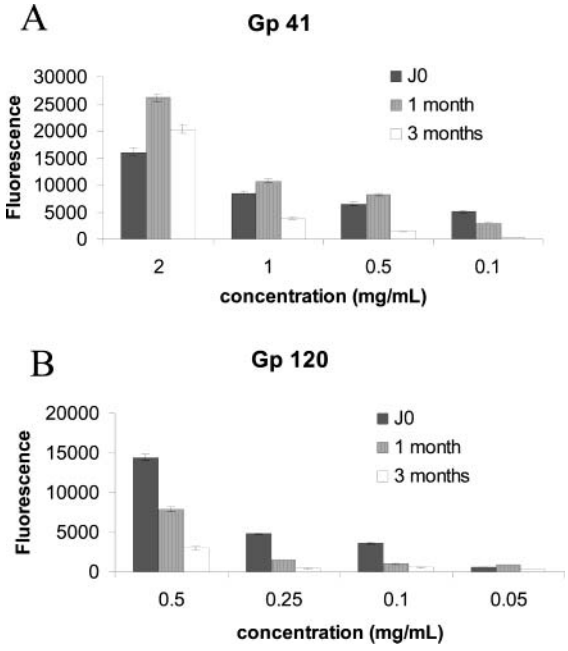

Figure 5. Stability of HIV Gp41 (A) and Gp120 (B) antigens on amine surfaces. HIV positive referenced serum, $n = 9$, L35, PMT 50. The confidence interval ($p = 0.05$, $t = 2.26$) is indicated at the top of the bar (mean).

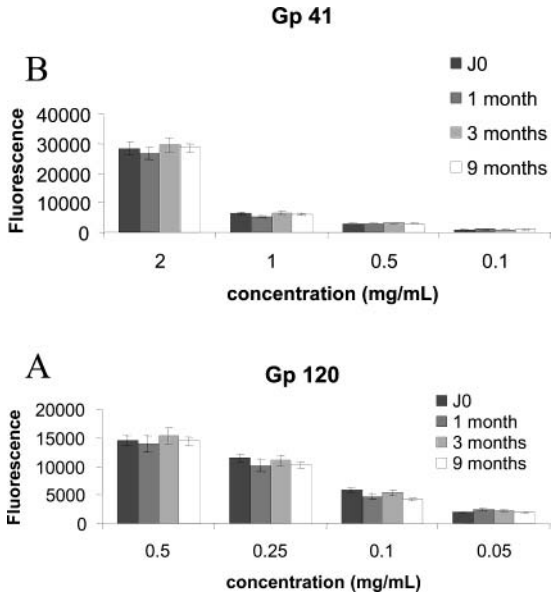

Figure 6. Stability of HIV Gp41 (A) and Gp120 (B) antigens on semicarbazide surfaces. HIV positive referenced serum, $n = 9$, L35, PMT 50. The confidence interval ($p = 0.05$, $t = 2.26$) is indicated at the top of the bar (mean).

(Figure 5A). For the highest concentrations (0.5−2 mg/mL), the signal increased after 1 month and then decreased after 3 months, whereas for the lowest concentration (0.1 mg/mL) the signal always decreased. For Gp120 (Figure 5B), the signal was found to drop for the three highest concentrations. After 3 months, the signal represented only 20% of the initial value at 0.5 mg/mL and 10% at 0.25 mg/mL.

In the meantime, Gp41 and Gp120 antigens were found to be stable on the semicarbazide surface (Figure 6). Thus, the stability study was continued up to 9 months. In the accompanying paper, we show that the highest concentrations used here for Gp41 and Gp120 (2 and 0.5 mg/mL, respectively) permitted the sensitive and

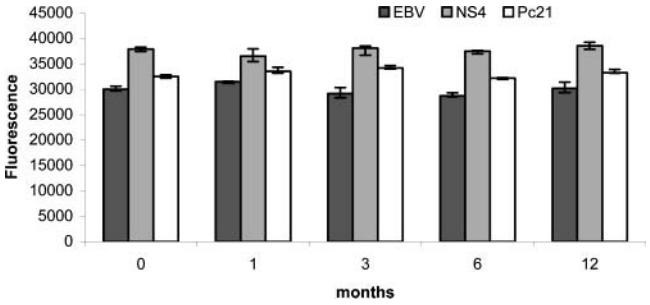

Figure 7. Stability of peptide arrays on semicarbazide slides. HCV P21 and NS4 peptides, EBV VCA p18 peptide, HCV and EBV positive referenced sera. Peptides were printed at 10^{-4} M. $n = 6$, L35, PMT50. The interquartile range is indicated at the top of the bar (median).

specific detection of antibodies against HIV. Interestingly, for these concentrations, the largest variation of the fluorescence intensity relative to the reference data obtained just after printing did not exceed 7%, illustrating the very good stability of both protein antigens on semicarbazide glass slides.

Stability Study of Semicarbazide Microarrays, Peptide Antigens. In the accompanying paper, we have described the utility of semicarbazide glass slides for the fabrication of peptide−protein microarrays. Thus, it is also important to document the stability of the peptide probes during aging.

The covalent attachment of small peptides to the glass surface through the formation of an α-oxo semicarbazone bond is important to avoid the loss of probe during the washing and incubation steps. The stability of the α-oxo semicarbazone linkage toward hydrolysis is expected to have a profound impact upon the results of the aging study. HCV core p21 15−45 (*17*), HCV NS4 1925−1947 (*18*), and EBV VCA p18 153−176 glyoxylyl peptides (*19*) were printed on semicarbazide slides. Figure 7 presents the evolution of the fluorescence intensity for these three peptidic antigens upon a 12-month stability study. For the three peptides, the differences were not found to be significant ($p < 0.05$), thus demonstrating the good stability of peptide α-oxo semicarbazone arrays.

Reproducibility. Another important aspect of microarray technologies is the ability to reach a high level of reproducibility inside a slide and between slides of the same batch or of different batches. We have examined the reproducibility of semicarbazide microarray fabrication and antibodies detection using again Gp120 and 41 HIV antigens.

The variation coefficients for Gp120 (5.0%) and Gp41 (5.5%) inside a slide were determined using 64 spots. These values are close to the variation coefficient obtained for the HCVcore p21 15−45 peptide ($n = 600$).

Next, two batches were tested (five slides per batch). The data presented in Figure 8 show that for a given antigen, the differences between the slides of a batch or between the two batches were not significant at $p < 0.05$, thus showing the good reproducibility of the assay. These results can be attributed to a quality control of the semicarbazide glass slides and to the simplicity of the microarray preparation and use.

Chemical Stability of Semicarbazide Glass Slides. Recently, we have described a method allowing the control of the semicarbazide layer reactivity. This quality control utilized two peptides labeled with (5)-6-carboxytetramethylrhodamine. One peptide Rho-Lys-Arg-NH-$(CH_2)_3$NH-CO-CHO (Rho-COCHO) was modified by a glyoxylyl group and thus was able to react chemoselec-

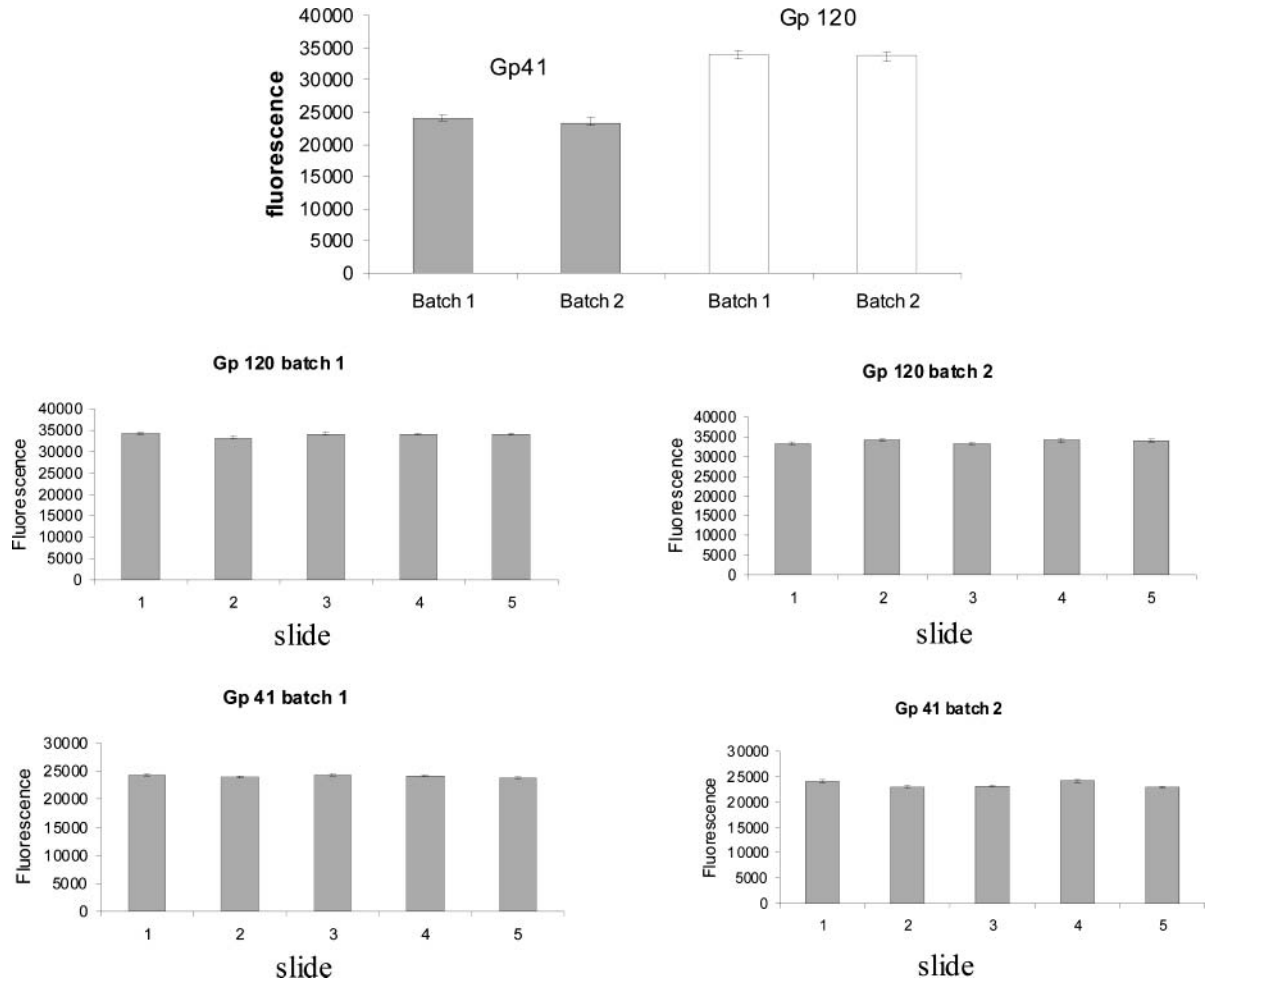

Figure 8. Reproducibility study. The semicarbazide slides were printed with Gp41 (2 mg/mL) and Gp120 (0.5 mg/mL) and used for the detection of anti-HIV antibodies in a diluted human serum ($^1/_{50}$). $n = 6$, L35, PMT50. The interquartile range is indicated at the top of the bar (median).

tively with the accessible semicarbazide groups on the surface, whereas the other peptide Rho-Lys-Arg-NH_2 (Rho-$CONH_2$) was a control lacking the glyoxylyl group for anchorage.

The quality control was performed by immersing one slide 1 h at 37 °C in a 0.1 mM solution of Rho-COCHO and another slide in a solution of the control Rho-$CONH_2$. Both slides were washed to remove the excess of peptide and analyzed using a fluorescence scanner. A large difference in fluorescence intensity between the two slides is indicative of a high level of surface functionalization. The variation coefficient of the fluorescence gives an indication of the homogeneity of the slide.

This method of characterization was used to document the chemical stability of the semicarbazide slides upon aging. The slides of the same batch were analyzed just after preparation or following 3 months of storage at room temperature in a closed chamber. The data presented in Figure 9 show that the fluorescence intensity of the slides did not change over a 3-month period for both labeled peptides ($p < 0.05$). The variation coefficient of the fluorescence intensity was also unaffected in this experiment (4−8% for Rho-COCHO and 4−7% for Rho-$CONH_2$). Thus, the chemical properties of the semicarbazide slides are conserved at least 3 months even if some air pollution could be detected after 30 days of storage by contact angle measurements (see later).

Characterization of the Semicarbazide Surface by Contact Angle Measurements. In the previous section, we have described a chemical method allowing a quality control of the semicarbazide surface reactivity. An interesting aspect of this method is the possibility characterizing the homogeneity of the surface viewed through the reactivity of solvent-accessible semicarbazide groups. A complementary method allowing the rapid, simple, and cheap characterization of surfaces is

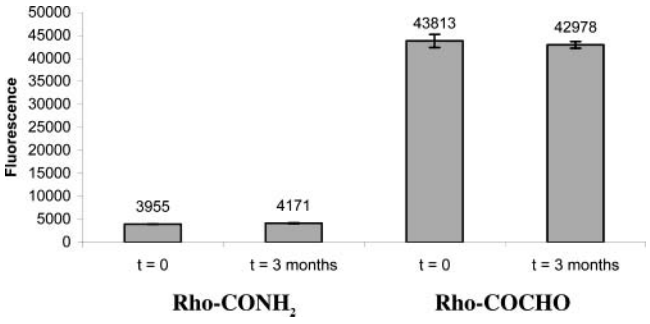

Figure 9. Chemical stability of semicarbazides slides. The slides were analyzed after synthesis or after 3 months of storage in air using glyoxylyl Rho-COCHO or amide Rho-$CONH_2$ peptides labeled with (5)-6-carboxytetramethylrhodamine as described elsewhere. The slides were scanned at L25, PMT40 using an Affymetrix 418 array scanner (MWG, Santa Clara, CA), and the data were analyzed with the Scanalyze software (Stanford University). Thirty measurements were performed per slide. The grid covered about 70% of the glass surface. The bars represent the mean and the confidence interval ($p = 0.05$).

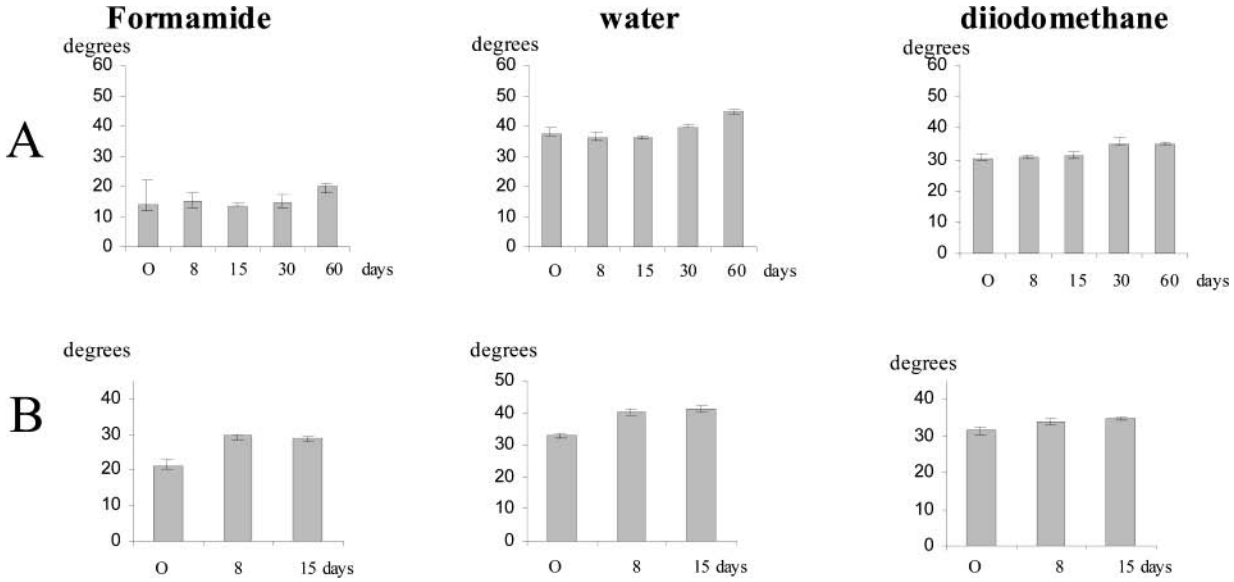

Figure 10. Stability studies on semicarbazide (A) or amine (B) glass slides using contact angle measurements with formamide, water, or diiodomethane, 20 °C. The interquartile range is indicated at the top of the bar (median).

to perform contact angle measurements with liquids whose surface tension is well-known.

α-Bromonaphthalene, dimethyl sulfoxide, and ethylene glycol were found to spread on semicarbazide slides. Diiodomethane, water, and formamide were found to be useful referenced liquids. Contact angle measurements performed just after the preparation of the surfaces can be considered as reference data for a quality control. These contact angles determined for amine and semicarbazide glass slides are collected in Table 1. The use of the Young's equation permitted the determination of the Lifshitz−van der Waals (LW) and Lewis acid and base surface tension parameters according to the van Oss theory (Table 1) (*20*). In addition, we have calculated the interfacial interaction free energy of the surface in water (ΔG_{sws}) and the free energy of binding of water to the surface (ΔG_{sw}), which are a good indication of the hydrophilicity of a surface (*21*, *22*).

The contact angle of diiodomethane was found to be similar on both surfaces ($p < 0.05$, Table 1). The Lifshitz−van der Waals surface tensions of the surfaces were close to 44 mJ/m^2, a typical γ^{LW} value for a large number of substances (*22*). The contact angle of water was found to be slightly greater on the semicarbazide surface ($p < 0.05$, Table 1), but the angle of formamide was found to be similar on both surfaces ($p < 0.05$, Table 1). Thus, the polar surface tension parameters for the two surfaces were also found to be similar. Taken together, it seemed that the amine and semicarbazide surfaces could not be distinguished by this technique. The fact that semicarbazide and amine surfaces have similar surface tension parameters could explain why proteins were found to adsorb similarly on both surfaces, at least if only interfacial interactions are considered.

If we consider now the interfacial interaction free energy between the surfaces in water ΔG_{sws}, both surfaces displayed a positive value (Table 1). In addition, the free energy of binding of water to the surface ΔG_{sw} was found to be inferior to −113 mJ/m^2, a value below which a substance is usually considered as hydrophilic (*22*).

Evolution of Contact Angles on Semicarbazide or Amine Glass Slide upon Aging. Another interesting application of contact angle measurements is to follow the evolution of the surface upon aging. The silane layer covering the glass slide surface can be the subject of changes due to chemical transformation of surface functional groups (for example, air oxidation) or to the deposition of air contaminants. Air pollution of amine surfaces has been well studied (*23*). Contact angle measurements on amine surfaces obtained by silanization with 3-aminopropyltrimethoxysilane demonstrated a rapid pollution of the surface by air impurities. Thus, we have studied the evolution of the contact angles of the three referenced liquids diiodomethane, water, and formamide on both surfaces (Figure 10). The stability study was performed during 15 days for amine and 2 months for semicarbazide glass slides.

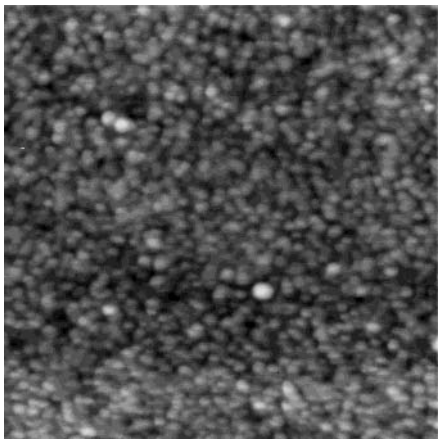

Figure 11. Intermittent contact mode AFM image image (500 × 500 nm^2) of the semicarbazide glass slide surface in air. The gray scale ranges from 0 (black) to 7 nm (white). The mean roughness Ra and the rms roughness were found to be 0.75 and 0.98 nm, respectively.

In agreement with previous studies (*23*), the amine surface was found to be very sensitive to aging, as shown by the data obtained for the three referenced liquids and nonparametric statistical analysis ($p < 0.05$). The major change was observed during the first 8 days of aging.

For semicarbazide glass slides, a significant change in the contact angles was observed after 30 days of aging for diiodomethane and 60 days for water ($p < 0.05$), thus suggesting that the semicarbazide glass slides are more stable toward air pollution than amine glass slides. Interestingly, pollution of the semicarbazide surface by

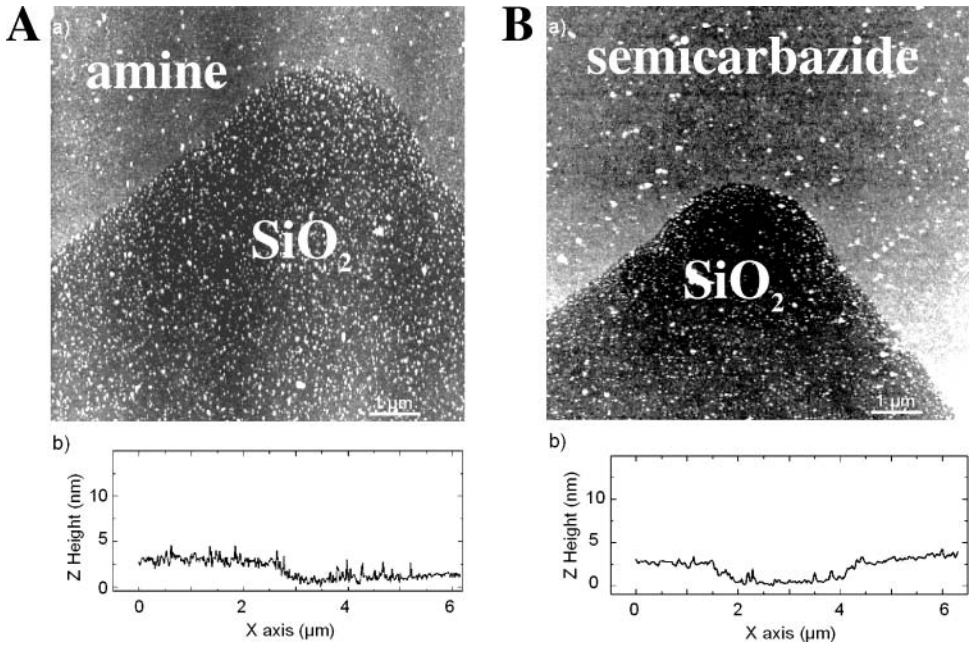

Figure 12. Determination of the amine (A) and semicarbazide (B) layer thickness by reactive ion etching and tapping mode AFM analysis. AFM images showing a dark area, where the silane layer was removed by RIE from the glass surface. The white spots corresponded to contaminants resulting from the cutting procedure of the glass slide. The curves below the AFM images show a representative line cut through the silane and the glass layers. The height of the step separating the two regions was 1.8−2.2 nm for both surfaces.

air contaminants did not alter the reactivity of the layer as shown previously in a 3 months of chemical stability study.

AFM Characterization of Semicarbazide Glass Slides. Glass slides were cleaned using a piranha solution and silanized with 3-(aminopropyl)trimethoxysilane as described elsewhere. Some amine slides were used directly for AFM studies, and the others were treated as usual to install the semicarbazide groups. Thus, AFM measurements were performed on amine or semicarbazide slides coming from the same silanization bath.

Figure 11 gives a typical aspect of a semicarbazide glass slide surface. The mean roughness Ra and the rms roughness were found to be, respectively, 0.75 and 0.98 nm. Similar results were obtained for the amine surface (data not shown).

The thickness of the layer was determined by removing a defined region of the glass surface by reactive ion etching to get the original silicon oxide substrate. The height of the step at the frontier between the silicon oxide and semicarbazide surface was determined by AFM. As shown in Figure 12B, the thickness of the layer was ranging from 1.8 to 2.2 nm, a value superior to the length of one silane unit (about 1 nm in an extended conformation) (*23*). The same results were obtained for the amine surface (Figure 12A).

These AFM studies demonstrate that the amine and semicarbazide layers are very similar in term of rugosity and thickness. We have shown previously that the two surfaces could not be distinguished by contact angle measurements. Nevertheless, the evolution of antigen reactivity on both surfaces was found to be drastically different. Additional studies are necessary to understand these differences.

CONCLUSION

We have demonstrated in this article that semicarbazide functionalized glass slides allow the adsorption of proteins as efficiently as amine slides, with the important advantage of giving stable antibodies detection results. In addition, semicarbazide glass slides were found to be less sensitive to air pollution than amine surfaces and chemically stable. Peptide microarrays prepared by α-oxo semicarbazone site-specific ligation were also found to give stable antibodies detection results, leading to the possibility of preparing high-quality peptide−protein microarrays. Both surfaces could not be distinguished by contact angle measurements or AFM studies. Thus, more experiments are needed to identify the origin of these large differences.

Receptor-associated protein (RAP) is a ligand for all members of low-density lipoprotein (LDL) receptor families. RAP is internalized into cells via receptor-mediated endocytic trafficking, making it an attractive mechanism for efficient gene delivery. In this study, we have developed a gene delivery system using RAP as a targeting ligand. A RAP cDNA lacking a C-terminal heparin-binding domain was amplified by polymerase chain reaction (PCR) from a human liver cDNA library and was reamplified by using a primer containing a cysteine codon at its carboxyl end to facilitate its conjugation to polylysine (polyK). RAP was purified using a bacterial expression system and coupled to poly-D-lysine (PDL) or poly-L-lysine (PLL) of average MW 50 kDa via the heterobifunctional cross-linker SPDP. Using fluorescence-labeled RAP ligand, cellular uptake of the transfection complexes into HepG2 cells was shown to be highly efficient and more specific to PDL-conjugated RAP compared with PLL-conjugated one. Plasmid DNA containing a luciferase reporter gene was condensed with either RAP−PDL or RAP−PLL. In vitro transfection into HepG2 cells with RAP−PDL conjugate resulted in significantly higher luciferase expression levels in comparison to either nonconjugated PDL, or RAP−PLL, or LipofecAMINE/DNA complexes in the presence of 10% fetal bovine serum. Luciferase expression was inhibited by the addition of excess RAP. Treatment of the cells with Lovastatin, which inhibits HMG-Co reductase and increases expression of LDL receptor, stimulates luciferase expression, suggesting that the gene delivery is specifically mediated by LDL receptor. Thus, RAP−PDL conjugates have the potential to be used as a new nonviral gene delivery vector.

INTRODUCTION

Receptor-mediated endocytosis (RME) represents a highly efficient internalization pathway (*1*) and offers an efficient cellular route for the delivery of gene therapy vectors. A number of gene transfer systems have been developed to deliver foreign DNA via RME using specific ligands such as asialoglycoprotein (*2*), transferrin (*3*), or anti-CD3 antibody (*4*). Gene transfer using these ligands has been accomplished by synthetic vectors termed molecular conjugates, which consist of two linked functional domains: a ligand domain and a DNA-binding domain to achieve binding and incorporation of the transgene into the vector complex. For many of these approaches, polylysine (polyK) provides a DNA-condensing carrier function, and chemical linkage methods are used to achieve linkage between the polyK and the ligand domain of the complex (*5*). For some cell types, receptor-mediated transport of DNA is a highly effective and physiological means of introducing DNA into the cells (*3, 4, 6*).

The low density lipoprotein (LDL) receptor gene family is a large family of endocytic receptors that bind and internalize various ligands, which include several apolipoproteins that are involved in cholesterol homeostasis (*7*). This receptor family is ubiquitously expressed in many tissues such as liver and brain (*8*). Moreover, LDL receptor activities are elevated in malignant cells, which have high LDL requirements as do rapidly dividing cells (*9*). The receptor-associated protein (RAP) is a specialized folding chaperone/escort protein that is associated with newly synthesized receptors in the endoplasmic reticulum (*10*) and can bind with high affinity to the members of the LDL receptor family such as the LDL receptor-related protein (LRP), the very low-density lipoprotein (VLDL) receptor, and megalin (gp330) (*8*). Exogenously added RAP binds to receptors on the cell surface in vitro and antagonizes all known ligand interactions with the receptors (*10, 11*). Interestingly, RAP is internalized into cells via receptor-mediated endocytic trafficking (*12, 13*), which is an attractive mechanism for efficient gene delivery.

In this study, we explore the use of RAP as a targeting ligand for receptor-mediated gene transfer into human hepatoma cells (HepG2). The interaction, uptake, and gene expression of the transfection complexes were found to be due to the specific function of RAP ligand. As with other ligand-dependent gene delivery systems, we find that transfected gene expression is decreased by addition of unconjugated RAP ligand in the transfection medium and enhanced by treatment of Lovastatin, which inhibits cholesterol biosynthesis and increases the expression of

LDL receptor (*14, 15*). Because LRP and LDL receptors are abundant on hepatoma cells, RAP-mediated gene delivery systems may be useful for the delivery of therapeutic genes into this cell type.

EXPERIMENTAL PROCEDURES

Materials. Human liver cDNA library and LA Taq with GC buffer kit were purchased from TaKaRa Shuzo Company (Shiga, Japan). Pinpoint Xa protein purification system, pPinPoint Xa-3 vector, factor Xa protease, pRL-CMV, and Dual-Luciferase reporter assay kit were from Promega (Madison, WI). Reagents including LB medium, ampicillin, *N*-[2-hydroxyethyl]piperazine-*N*′-[2-ethanesulfonic acid] (HEPES), 3-(2-pyridyldithio)propionic acid *N*-hydroxysuccinimide ester (SPDP), fetal bovine serum (FBS), streptavidin-fluorescene isothiocyanate (FITC), poly-D-lysine hydrobromide (PDL, molecular weight 30 000−70 000) and poly-L-lysine hydrobromide (PLL, molecular weight 30 000−70 000) were from Sigma Chemical Company (St. Louis, MO). PCR primers, restriction enzymes, isopropyl β-D-thiogalactopyranoside (IPTG), dithiothreitol (DTT), Eagle's minimal essential medium (EMEM), LipofecAMINE reagent, and Opti-MEM medium were purchased from Life Technologies (Rockville, MD). Biotin, Sephacryl S-100 column, and Sepadex G-25 superfine were from Amersham Pharmacia Biotech (UK). Centriplus YM-10 filter device was from Millipore, Co. (Bedford, MA). BCA protein assay kit was from Pierce (Rockford, IL). QIAquick gel extraction kit, EndoFree plasmid Maxi kit, and column were from Qiagen (Germany). Lovastatin was kindly supplied by Choongwae Pharmaceutical Co. (Korea). Deionized−distilled water was produced by using Milli-Q water purification system (Millipore) and FI−STREEM III Bi-Distiller system (Barnstead, Dubuque, IA). All other chemicals and reagents were of tissue culture grade.

Construction and Expression of RAP. The cDNA for partial RAP_{1-260} was amplified in polymerase chain reaction (PCR) from human liver cDNA library with a 5′ primer, GGAGAAGAACCAGCCCAAGC, and a 3′ primer, GCGCAGCCGCTCGCCCCAGGC. The RAP cDNA was reamplified with a 5′ primer containing a *BamH* I restriction site to facilitate its ligation and a 3′ primer containing a *Kpn* I site and an additional cysteine codon preceding a stop codon to facilitate its conjugation to polyK (*6*). The PCR product was cloned into *BamH* I-*Kpn* I-digested pPinPoint Xa-3, a bacterial expression vector with N-terminally biotin-tagged sequence. The plasmid structure was confirmed by DNA sequence analysis with ABI prism 3700 (Applied Biosystems), transformed into *E. coli*/JM109 cells, and expressed according to the manufacturer's instructions.

Purification and Reduction of RAP. RAP expressed with biotin tag was purified using PinPoint Xa protein purification system and digested with factor Xa protease in Xa buffer (20 mM Tris-HCl pH 7.4, 100 mM NaCl). The solution of digested RAP was incubated with avidin resin to remove the biotin tag and passed through Sephacryl S-100 column to remove factor Xa protease. Eluent fractions were concentrated with a centrifugal filter device (Centriplus YM-10). Purified RAP was analyzed using SDS−PAGE and assayed for protein concentration by BCA protein assay kit. A cysteine residue in the C-terminal of recombinant RAP was reduced by dithiothreitol (DTT) to generate free sulfhydryl groups. Briefly, to 1 mg of RAP in 0.8 mL of HEPES-buffered saline (HBS; 150 mM NaCl, 10 mM HEPES pH 7.4) was added 8 μL (4 μmol) of 0.5 M DTT solution. The solution was kept under argon for 1 h, and the pH was adjusted to 5.2 by adding 3 M sodium acetate buffer. After gel filteration (Sepadex G-25 superfine), a solution of reduced RAP for preparing RAP-polyK conjugates was obtained (*3*).

Preparation of RAP−polyK Conjugates. Two kinds of polyK were used to conjugate recombinant RAP; poly-D-lysine (PDL) and poly-L-lysine (PLL), both of which have an average molecular weight of 50 kDa. Purified RAP was conjugated to each polyK, using a heterobifunctional cross-linker, 3-(2-Pyridyldithio)propionic acid *N*-hydroxysuccinimide ester (SPDP) (*3*). Briefly, each polyK, consisting of approximate 400 lysine residues, was mixed with SPDP at a molar ratio of 1:20 in PBS. After incubation for 1 h at room temperature, the reaction mixture was dialyzed against deionized−distilled water for 48 h to remove excess unreacted SPDP. This reaction theoretically yielded a polyK molecule with about 5% SPDP modification of its lysine residues. Each SPDP-polyK was then mixed with RAP and incubated for 24 h at room temperature. These RAP−PDL or RAP−PLL conjugates were used for preparing transfection complexes.

Plasmid Vector. pRL-CMV (4079 bp), a plasmid expression vector containing a cDNA encoding *Renilla reniformis* (sea pansy) luciferase driven by the cytomegalovirus (CMV) promoter, was grown in *E. coli* DH5α cells in LB medium containing ampicillin (100 μg/mL) and was purified using EndoFree plasmid Maxi kit and column.

Gel Retardation Assay. The RAP−PDL/DNA complexes were prepared by adding various amounts of RAP−PDL conjugate, ranging from 0 to 14 μg, in 20 μL of HBS to 1 μg of pRL-CMV DNA in 20 μL of HBS. The RAP−PDL solution was slowly added to the DNA solution and mixed gently. The reaction mixture was incubated for 30 min at room temperature and applied to a 0.8% agarose gel in Tris acetate EDTA buffer, pH 7.6, with 0.5 μg/mL ethidium bromide. Electrophoresis was carried out at 5 V/cm for 50 min.

Cell Line. The human hepatoma cells (HepG2) were obtained from the American Type Culture Collection. HepG2 cells were maintained in T-75 culture flask with vented cap containing EMEM supplemented with heat inactivated 10% fetal bovine serum (FBS), penicillin (100 units/ml), streptomycin (100 μg/mL), 4 mM L-glutamine, and 1.0 mM sodium pyruvate at 37 °C, 5% CO_2.

Preparation of RAP-polyK/DNA Complexes and Transfection. Cells were plated in 24-well culture plates at 5×10^4 cells/well density and incubated for 24 h prior to transfection, by which time the cells were ∼30% confluent. One microgram of plasmid DNA and the various amounts of RAP−PDL were diluted to a final volume of 100 μL with HBS. The RAP−PDL solution was added to the DNA solution, gently mixed, and incubated at room temperature. RAP−PDL/DNA complexes were formed at various weight ratios, which were calculated as molar ratios of the charge of PDL nitrogen to DNA phosphate (N:P); 1 μg of PDL for a N:P ratio of 1.3:1, 3 μg of PDL for 3.8:1, 6 μg of PDL for 7.5:1, 9 μg of PDL for 11.3:1, and 12 μg of PDL for 15:1. Charge ratios were calculated as described (*16*). After 30 min incubation, the solutions of gene transfer complexes (200 μL) were mixed with 1.5 mL of 10% serum-containing medium and added to the cells ($n = 4$). Forty-eight hours after incubation with transfection medium, the medium was removed and luciferase activity was assayed, by which time the cells were ∼90% confluent. RAP−PLL/DNA and PDL/DNA complexes were prepared in an identical manner as with

RAP−PDL/DNA complexes. For the transfection by LipofecAMINE reagent, pRL-CMV DNA (1 μg) in Opti-MEM medium was mixed with an equal volume of LipofectAMINE (14 μg) diluted appropriately in Opti-MEM medium. Complexes were incubated for 30 min at room temperature before addition to cells. Cells were transfected in the presence of 10% FBS.

Assay for Luciferase. Cell lysates were prepared by the addition of 100 μL of lysis buffer (Dual-Luciferase reporter assay kit) and incubation with agitation for 20 min at room temperature. After centrifugation at 12 000 g for 10 min, 10 μL of the supernatant of cell lysates were analyzed for luciferase activity using a Clinilumat LB9502 instrument (Berthold, Germany). These data were normalized for protein content assayed by BCA protein assay kit. Results shown are expressed as integrated light units (ILU)/mg of protein unless otherwise indicated.

Detection of Internalized Gene Transfer Complexes. Complexes containing streptavidin−FITC were formed as follows: RAP containing N-terminal biotin tag was conjugated with PDL or PLL as described above. Ten micrograms of the conjugates was diluted with 100 μL of HBS and incubated with 5 μg of streptavidin−FITC for 10 min with occasional mixing. Plasmid DNA diluted in 100 μL of HBS was added to the mixture and incubated for 30 min at room temperature. Each complex was then diluted in medium containing 10% serum and added to the cells as above. Twenty-four hours after transfection, cellular uptake of FITC-labeled RAP-polylysine/DNA complexes was analyzed with fluorescence microscopy (Olympus IX).

Competitive Inhibition by Free RAP. A competitive inhibition assay using free RAP was performed to confirm the specificity of RAP ligand-dependent gene delivery. Briefly, 10^5 HepG2 cells (24-well plate) were incubated with free recombinant RAP (0.2, 0.5, and 1 mg/mL in 1.5 mL of the medium) for 10 min in CO_2 incubator, followed by the addition of gene transfer complexes in the presence of free RAP, which consisted of 1 μg of pRL-CMV and 9 μg of RAP−PDL with 200 μL of HBS. Transfection medium was removed after 24 h incubation, and luciferase activity of cell lysates was measured as described above.

Treatment with Lovastatin. To further confirm receptor-mediated gene delivery, transfection efficiency of RAP−PDL conjugate was measured after treatment with Lovastatin, which inhibits a rate-limiting enzyme for cholesterol biosynthesis, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase (K_i = 0.6 nM). The transfection and luciferase assay were performed as described in the above competition experiment except that Lovastatin was added to the medium with the transfection complexes simultaneously.

RESULTS

Cloning and Expression of Recombinant RAP. We amplified a partial cDNA of the RAP gene (amino acids 1−260) lacking its C-terminal heparin-binding domain by PCR from human liver cDNA library. The PCR product was reamplified with primers that contain restriction sites for cloning and a C-terminal cysteine residue for conjugation (*6*) and then cloned into a bacterial expression vector. DNA sequencing analysis revealed that the cloned RAP gene showed 99.6% homology with the previously reported RAP gene (accession number: NM_002337, GI: 4505020) (*17*), and the predicted protein sequence was identical (data not shown).

Purification and Reduction of Recombinant RAP. Recombinant RAP was produced in the form of a 47 kDa fusion protein that is biotinylated in the N-terminal tag (Figure 1, lane 4), of which approximated 10 mg was recovered using 30 mL of avidin resin. This purified fusion protein was digested with factor Xa protease for 10 h at 37 °C. Coomassie staining revealed a 30 kDa band corresponding to RAP; however, biotin tag (17 kDa) and factor Xa protease (44 kDa) contaminants were present (Figure 1, lane 5). To improve the purity, the solution of digested fusion protein was incubated with avidin resin (Figure 1, lane 6). After further purification by Sephacryl S-100 column chromatography, pooled fractions containing recombinant RAP displayed a single band at 30 kDa (Figure 1, lane 7), and the solution was concentrated. Approximately 500 μg of RAP was obtained from one liter of bacterial culture. The single cysteine residue at the C-terminal end of the purified RAP was reduced by DTT treatment and used in the following experiments.

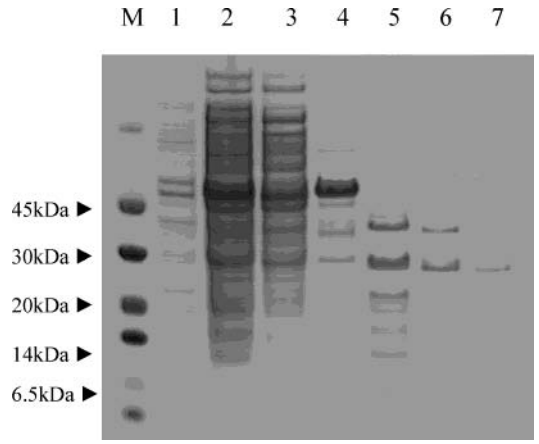

Figure 1. Expression and purification of RAP. The cell lysates of RAP fusion protein expressing *E. coli* and purified RAP were analyzed by 4−20% gradient SDS-polyacrylamide gel and Coomassie staining. Lanes: 1, *E. coli* cell lysate before induction of the fusion protein; 2, lysate after induction; 3, lysate after binding with avidin resin; 4, eluant RAP with biotin tag (47 kDa); 5, RAP and biotin tag fragment incubated with factor Xa for 10 h; 6, RAP and factor Xa after incubaion with avidin resin; 7, purified RAP after column chromatography (30 kDa).

Synthesis of RAP−polyK Conjugates. A heterobifunctional cross-linker, SPDP, was used to introduce a dithiopyridine linker into polyK, where the NHS ester group of SPDP reacted with ϵ-amino groups of polyK to form an amide linkage (*18*). Ziady et al. reported that reaction with 20× molar excess of SPDP modifies 3.5% of the lysine residues in a polyK molecule with dithiopyridine linkers (*19*). These linkers will readily react with sulfhydryl groups of RAP, yielding disulfide linkages between RAP and polyK (*6*). Purified RAP−PDL or RAP−PLL displayed reduced electrophoresis in SDS gradient polyacrylamide gel because of the basic amino acids in each polyK. We did not detect a significant amount of unconjugated free RAP in the reaction product (data not shown).

Gel Retardation Assay. To determine the optimal RAP−PDL/DNA ratio by measuring the effect of complex formation and charge neutralization, agarose gel electrophoresis was performed (*2*). As shown in Figure 2, electrophoretic mobility of the RAP−PDL/DNA complex decreased gradually with increasing amounts of RAP−PDL conjugates. DNA band retardation occurs due to the neutralization of DNA negative charges by the positive charges of RAP−PDL conjugates. At a weight ratio of 1 μg DNA:8 μg PDL coupled to RAP, plasmid DNA showed complete retardation, indicating that the DNA negative

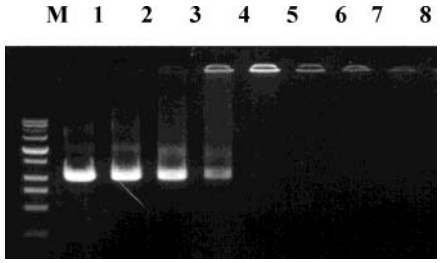

Figure 2. Gel retardation assay of DNA complexed with RAP−PDL. Lanes: M, size marker (1 kbp ladder); 1, plasmid DNA alone (1 μg); 2−8, DNA mixed with 2, 4, 6, 8, 10, 12, or 14 μg of PDL conjugated with RAP, respectively.

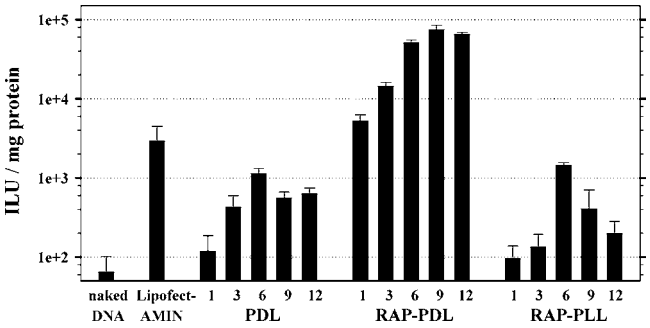

Figure 3. Transfection efficiency of RAP−polylysine/DNA complexes with human HepG2 hepatoma cells. The increasing amounts (μg) of polylysines shown on the ordinate (1, 3, 6, 9, 12) were used to complex 1 μg of DNA (pRL-CMV; 4079 bp). Each DNA complex (in 0.2 mL HBS) was mixed with 1.5 mL of culture medium (EMEM containing 10% FBS) and added to 5 $\times$ 10^4 cells per well in 24-well plates. After 48 h, the transfection medium was removed and cells were harvested. Luciferase activity is shown as means ± SD (n = 4). Transfection efficiency of naked DNA (1 μg), LipofectAMINE-DNA (14 μg) and unconjugated PDL is shown for comparison.

charge was neutralized or slightly positively charged with RAP−PDL conjugate at this weight ratio (Figure 2, lane 5).

Formulation Optimization of RAP−polyK/DNA Complexes. The RAP ligand-dependent transfection efficiencies of the complexes in five different weight ratios of polyK to DNA are shown in Figure 3. To detect gene expression, cells were transfected with particles containing the plasmid pRL-CMV, a vector with a luciferase reporter gene insert driven by the cytomegalovirus (CMV) promoter/enhancer. Plasmid DNA (1 μg) was either complexed with PDL alone, with RAP conjugated to PDL (RAP−PDL), or with RAP conjugated to PLL (RAP−PLL). Plasmids complexed with RAP−PDL showed the highest transfection efficiencies (Figure 3, RAP−PDL). In addition to ligand specificity, transfection efficiencies were dependent on the cation:anion ratio. A weight ratio of 1 μg DNA:9 μg RAP−PDL yielded the highest luciferase expression level (up to 65-fold higher than those obtained with unmodified PDL and up to 25-fold higher than with LipofectAMINE, a commercial cationic lipid formulation). At the highest weight ratio (1 μg:12 μg), the viability of the cells was not significantly affected (viability ≥95%, data not shown) and the transfection efficiency decreased slightly (less than 14%). This decrease was observed in a previous study using polyK coupled to anti-CD3 antibody (*4*) and could be due to excess polyK relative to the amount of DNA used (1 μg). Interestingly, compared to their effectiveness at high cation:anion ratios, RAP−PDL/DNA complexes were more effective at lower cation:anion ratios than were ligand-free PDL/DNA complexes. Transfection efficiencies

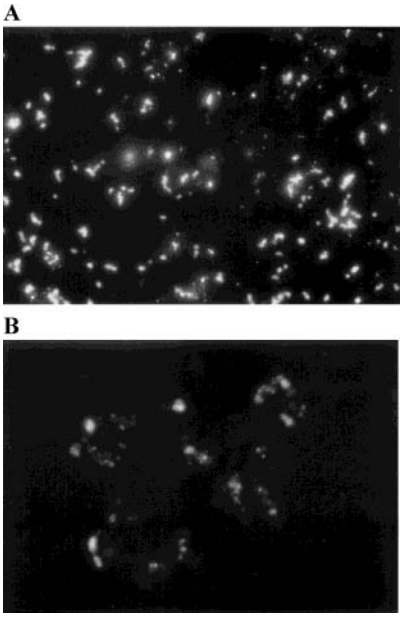

Figure 4. Cellular uptake of fluorescence-labeled RAP−polyK/DNA complexes into HepG2 cells. RAP fusion protein expressed with biotin tag was coupled to PDL or PLL, as described in Materials and Methods, and incubated with equal amounts of streptavidin−FITC. Twenty-four hours after addition of each fluorescence-labeled conjugate/DNA complex (9 μg:1 μg), endocytosed particles were visualized with fluorescence microscopy. The internalized gene transfer complexes of RAP−PDL (A) and RAP−PLL (B).

of RAP−PLL/DNA complexes were similar to those of ligand-free PDL/DNA complexes over all cation:anion ratios.

Cellular Uptake of Fluorescence-Labeled RAP−polyK/DNA Complexes. The uptake of RAP−PDL gene transfer complexes into HepG2 cells was assessed by using fluorescence microscopy (Figure 4). RAP components of the complexes were labeled with streptavidin−FITC. Following transfection with FITC-labeled RAP−PDL/DNA, almost 100% of HepG2 cells contained endocytosed gene transfer particles. In each transfected cell, several FITC-labeled RAP−PDL/DNA complexes were observed (Figure 4A). In contrast, following transfection with FITC-labeled RAP−PLL/DNA complexes, only about 30% of the cells contained observable internalized gene transfer particles distributed in intracellular vesicles (Figure 4B). The number of fluorescent particles per cell was also lower in transfection with RAP−PLL/DNA complexes, and the morphology of intracellular particles appeared to be more diffused than that of RAP−PDL/DNA complexes. Endocytosed particles were only detected using RAP−PDL/DNA or RAP−PLL/DNA complexes; in cells incubated with the complexes containing unconjugated PDL, distinct internalized gene transfer particles were not detectable.

Competitive Inhibition with Free RAPs. To confirm the specific interaction of RAP−PDL conjugates with hepatoma cells, competitive inhibition experiments were performed with excess free RAP, which was added to the cell culture medium during transfection (Figure 5). The addition of soluble RAP ligand at three concentrations decreased transfection efficiencies of RAP−PLD/DNA complexes by 10−30%. RAP concentrations of 0.2, 0.5, and 1 mg/mL were approximately 2, 5, and 10 molar equiv in excess of conjugated RAP. In transfections with unconjugated PDL/DNA complexes, coincubation with excess free RAP did not affect reporter gene expression in cells. These results indicate that the cell interaction,

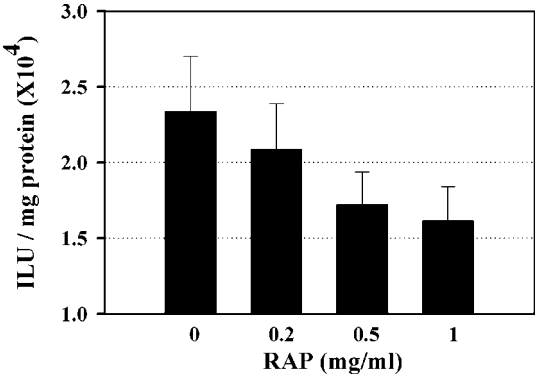

Figure 5. Free RAP competition experiment. Nine micrograms of RAP−PDL were used to complex 1 μg of DNA. DNA complexes in 200 μL of HBS were added to HepG2 cells (10^5 cells per well in 24-well plates) in 1.5 mL of EMEM containing 10% FBS in the absence or presence of the free RAP at three concentrations as indicated. The cells were harvested 24 h after transfection. Luciferase activity was measured as described in Materials and Methods and shown as means ± SD (n = 4).

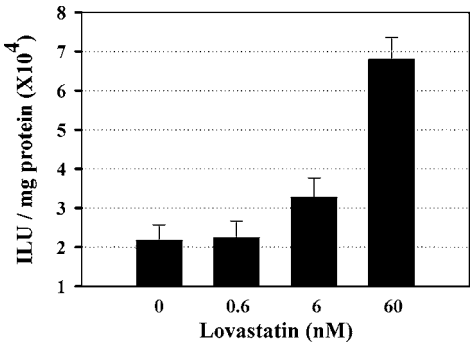

Figure 6. Enhanced transfection efficiencies of RAP−PDL conjugates by the treatment of Lovastatin, an inhibitor of HMG CoA reductase. The experiment was performed as described in the legend of Figure 5, except that transfections were carried out in the absence or presence of three concentrations of Lovastatin as indicated.

uptake, and gene expression of the RAP−PDL/DNA complexes in HepG2 cells is due to the specific interaction of the RAP−PDL conjugate with its receptor(s).

The Effect of Lovastatin on RAP-Mediated Gene Transfer. Lovastatin (Mevinolin) is a potent competitive inhibitor of a rate-limiting enzyme of cholesterol biosynthesis, HMG-CoA reductase (K_i = 0.6 nM) (*20*). Lovastatin activates LDL receptor gene expression in HepG2 cells (*15*). The presence of Lovastatin in RAP−PDL/DNA (1 μg:9 μg) transfections augmented reporter gene expression in a dose-dependent manner (Figure 6). The addition of 60 nM Lovastatin together with gene transfer complexes increased the transfection efficiency of RAP-mediated gene delivery by a factor of 100 relative to that of Lovastatin nontreated cells.

Duration of Transgene Expression. The time-course of luciferase expression in HepG2 cells is shown in Figure 7. Cells were transfected when they were 20−30% confluent and continued to grow for 2 days post-transfection, at which time the transfected cells approached confluence. The maximum level of luciferase activity was detected 2 days posttransfection. Luciferase activity decreased to ∼10% by the fifth day posttransfection. The degree of luciferase expression steeply declined 3 days after transfection and persisted for at least 5 days.

A potential concern of gene transfer using RAP−PDL conjugates is the influence of cell proliferation. To assess

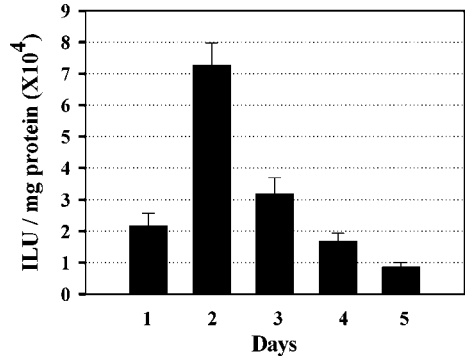

Figure 7. Duration of transgene expression. The experiment was performed as described in the legend of Figure 5, except that luciferase activity was measured 1, 2, 3, 4, and 5 days after transfection. Data represented are a mean of four independent experiments.

Table 1. Effects of Serum on the Transfection Efficiency of RAP−PDL/DNA Complexes[a]

transfection conditions	luciferase activity: (ILU × 10^{-4}/mg cell protein)
without serum	0.1 ± 0.3
5% serum	1.8 ± 0.5
10% serum	2.3 ± 0.7
25% serum	2.5 ± 0.4
50% serum	2.6 ± 0.7

[a] Note: HepG2 cells were transfected with RAP−PDL/DNA complexes (9 μg:1 μg). The experiment was performed as described in the legend of Figure 5, except that the complexes were diluted in medium with different amounts of fetal bovine serum, as indicated. Data are expressed as ILU × 10^{-4}/mg cell protein. Results shown are mean values ± SD (n = 4).

this potential influence, cells were retransfected at day 3 with the same complexes. This second transfection yielded marginal increases (∼5%) in gene expression levels at days 4 and 5 posttransfection. This result suggests that RAP-mediated gene delivery and expression may depend on cell proliferation.

Effects of Serum on Transfection. Effects of serum on the transfection of RAP−PDL complexes was also investigated by comparing the expression level of reporter gene following transfection in the presence (final concentration 50%) or absence of serum (Table 1). Addition of fetal bovine serum (FBS) to the transfection medium slightly increased reporter gene expression. In the absence of FBS, the transfection efficiency was ∼25-fold lower than that in 10%, 25%, or 50% FBS.

DISCUSSION

The development of a safe and efficient method for the delivery of transgenes to target cells and tissues still represents a major challenge. It has been reported that polycation conjugated with ligand for asialoglycoprotein receptor (*2*), transferrin receptor (*3*), c-kit receptor (*21*), or EGFR receptor (*22, 23*) resulted in specific gene delivery to cells expressing these receptors. The LDL receptor gene family is well-characterized. LDL-receptor−ligand interactions lead to endocytosis, providing an attractive mechanism for gene transfer. The LDL receptor is abundant in liver tissue, which is the principle organ of several genetic, acquired, and viral diseases amenable to gene therapy (*24*). Furthermore, all actively dividing cells require cholesterol which is taken up by the cells as a ligand−lipoprotein complex through receptor-mediated endocytosis (RME) (*8*). The expression of LDL receptors is particularly high on proliferating malignant cells as compared with the corresponding normal

tissues (*25, 26, 27*), making the LDL receptor an attractive target for cancer therapy.

For this reason, there are many studies on the selective delivery of cytotoxic compounds to cancer cells using LDL as a vehicle through the RME pathway (*9*). However, very few studies on gene transfer through LDL receptor-mediated endocytosis have been reported. Sipehia et al. developed a new method for DNA transfection of cultured endothelial cells using apolipoprotein E (Apo E) adsorbed lipofection reagent−DNA complexes (*28*). The transfection efficiencies with this method was found to be more efficient than conventional methods including calcium phosphate precipitation and lipofection. Furthermore, Kim et al. demonstrated another gene delivery vehicle (Terplex DNA) that is generated through electrostatic and hydrophobic interactions between LDL, stearyl-PLL, and DNA (*29*). However, receptor-mediated gene delivery of ligand−polycation conjugates via LDL receptor gene family members has not been reported previously.

To exploit this ubiquitous and efficient transport mechanism for introducing transgene into cells, human RAP was purified at high yields using a bacterial expression system and was conjugated with a DNA-binding polycation, polyK. The affinity of RAP for LDL receptor gene family is equivalent to that of apolipoprotein E, a high affinity ligand for the receptors (*7*). The intact 39-kDa RAP (323 amino acids) contains several structural and functional domains (*7*). In this study, we used a truncated version of RAP (N-terminal 260 amino acids), which contains at least two high affinity binding domains for LDL receptor gene families (*30, 31*) but does not contain RAP's C-terminal heparin binding domain. Because this truncated RAP lacks a cysteine residue, we engineered our recombinant RAP to contain a C-terminal cysteine residue. RAP-containing complexes were prepared by coupling SPDP-polyK to the cysteine residue of recombinant RAP. Recently, Gupta et al. (*6*) developed a similar recombinant ligand for receptor-mediated gene delivery: a single chain Fv of a monoclonal antibody (directed against human polymeric immunoglobulin receptor [plgR]), containing a C-terminal cysteine residue conjugated to polyK.

We chose two DNA-binding polycations for conjugating to RAP that had previously been used in the RME-based gene transfer system: PLL (*2*−*4, 32*) and PDL (*33*). The results of in vitro experiments clearly showed that the conjugation of the targeting ligand RAP to PDL results in a 65-fold increase in the transfection efficiency in HepG2 cells (Figure 3). For the RAP−PDL/DNA complexes, the best transfection efficiency was found at a ratio of 1 μg DNA:9 μg RAP−PDL. Corresponding results indicated complete retardation of the complexes at a ratio of 1 μg DNA:8 μg in a gel retardation assay (Figure 2). The increase of transfection efficiency was blocked by addition of free RAP (Figure 5), indicating that RAP ligand dependent uptake of the transfection complex is responsible for the higher transfection efficiency. This result is consistent with previous reports of receptor-mediated gene delivery (*4, 6*). Uptake of gene transfer particles into HepG2 cells via RAP−PDL is highly efficient: almost all cells contained several endocytosed particles following transfer of the FITC-avidin labeled complexes (Figure 4).

In contrast to the RAP−PDL system, transfection efficiencies of RAP−PLL/DNA complexes were similar to that of ligand-free PDL/DNA complexes (Figure 3). These data (both Figures 3 and 4) indicate that the PDL complex is more stable than the PLL complex in a lysosomal environment as well as in transfection media. Furthermore, the transfection of fluorescence-labeled RAP−PLL/DNA complexes showed that the internalized fluorescence particles, which had a diffused morphology (Figure 4), could be observed in about 30% of the cells. In a study of the endocytic trafficking of RAP/gp330, a member of the LDL receptor gene family, RAP dissociated from the receptor complex in late endosomes and was then rapidly delivered to lysosomes and degraded (*13*). The data from our study show that a portion of the endocytosed RAP−PLL/DNA complexes might remain unstable and be degraded in lysosomal compartments, whereas RAP−PDL is resistant to such degradation and released into the cytoplasm, entering the nucleus. Thus, media instability and lysosomal degradation of PLL and DNA may explain why, as observed in the PLL-based system, inclusion of membrane-active agents such as adenovirus capsid or membrane-active compounds into the gene transfer complexes greatly enhances transfection efficiency (*22, 34, 35*).

DNA encoding the luciferase gene complexed to RAP−PDL conjugate was specifically and efficiently transfected into HepG2 cells bearing LDL receptor and LRP. Gene transfer by this method is ligand dependent and receptor mediated. DNA complexes containing RAP were shown to be effectively internalized into HepG2 cells by ligand−receptor interaction. HepG2 cells, which are abundant in LRP and LDL receptor, were efficiently transfected with the RAP−PDL/DNA complexes in a ligand-dependent manner. Nontargeted complexes that lacked the RAP ligand did not efficiently transfect HepG2 cells. Transfection of a luciferase reporter gene by the RAP−PDL conjugate could be inhibited by addition of an excess of free RAP. Although we did not test competition by the other ligands for the receptors such as Apo E or Apo B, they are likely to compete for the following reason: The transfection efficiency of the conjugates into HepG2 cells was greatly enhanced in the presence of Lovastatin (a cholesterol biosynthesis inhibitor), which results in the overexpression of the LDL receptors in HepG2 cells. The transfection efficiencies of RAP−PDL conjugates in Lovastatin treated cells increased up to 100-fold relative to that in nontreated cells.

In addition to enhancing transfection efficiency, the incorporation of ligands offers the opportunity for specific targeting of gene delivery. Since rapidly dividing cells express the LDL receptor at a high level, RAP is a promising ligand in cancer gene therapy when proliferating cells such as malignant cells are to be targeted. However, specificity of target tissue and/or organ may be difficult to achieve using RAP due to the broad expression of the RAP binding receptor, the LDL receptor gene family, in the human body. This difficulty may be overcome by incorporating a tissue specific enhancer and/or promoter sequence in the expression vector.

In conclusion, we have developed a novel gene delivery system via the RME pathway using RAP conjugated with PDL as a gene delivery vector. Gene delivery using PDL itself or RAP−PLL was not efficient. Our data demonstrate that synthetic RAP−PDL is an effective reagent facilitating formation of DNA-ligand complexes for subsequent receptor-mediated gene transfer. RAP−PDL is thus a promising tool for enabling targeted transfer of genes in vivo.

Immobilization of a Novel Antibacterial Agent on Solid Phase and Subsequent Isolation of EF-Tu

Martin R. Deibel, Jr.,* Alice L. Bodnar, Anthony W. Yem, Cindy L. Wolfe, Charlotte L. Heckaman, Michael J. Bohanon, W. Rodney Mathews, Michael T. Sweeney, Gary E. Zurenko, Keith R. Marotti, Timothy P. Boyle, and Atli Thorarensen*

Pharmacia, Kalamazoo, Michigan 49001-0199. Received April 21, 2003;
Revised Manuscript Received December 11, 2003

Screening of our compound collection identified PNU-92560, a 2-[1,3,4]thiadiazolo[3,2-*a*]pyrimidine-6-carboxamide, as a novel antibacterial agent. Extensive analogue development identified that the 2-position of the thiadiazole could be functionalized with a linker that would allow the compound to be attached to a solid support. The extreme insolubility of the analogues prevented the mechanism of action for these compounds to be determined utilizing traditional methodology. The solid-supported compounds were utilized as affinity columns to identify elongation factor Tu (EF-Tu) as a putative target for this class of compounds. The activity of the compounds in a metabolic labeling experiments and in translation assay supports the identity of the target for these compounds to be EF-Tu.

INTRODUCTION

Bacterial resistance is a significant problem in the treatment of bacterial infections (*1*−*3*). This emerging resistance has fueled a continuous search for new antibiotics, resulting in numerous commercially available products. A key limitation of existing antibiotics is that they constitute a narrow range of structural diversity, and bacterial resistance has been shown in some cases to encompass entire structural classes, thus rendering all agents from that class ineffective. Moreover, the microorganisms have the ability to acquire resistance against new members of an antibiotic class relatively quickly. This ability of the organism to rapidly adapt fuels the search for novel antibiotics.

Recent advances in biology and automation have resulted in an impressive rate of discovery of new bacterial targets (*4*). These approaches may employ both genomics and whole cell-based high throughput screening (*5*). Current efforts at Pharmacia have utilized a combination of genomics for the identification of novel mechanistic targets essential for bacterial survival with whole cell screening of the compounds against the microorganism *Staphylococcus aureus*. Such assays have been used for screening of the Research Compound Collection (RCC). In addition, several mechanistic screens have been performed which identified potential templates for evaluation. We have previously reported our effort in the identification of a novel peptidyl deformylase (PDF) inhibitor as well as the identification of antibacterial potentiators (*6*).

An alternative approach to antibiotic drug discovery is to search for potent antibacterial agents without prior knowledge of their mechanism. This approach is complementary to the mechanism-based approach and has the attractive feature that the identified bacterial agents already have whole-cell activity. Given that the lack of whole-cell activity can be the major hurdle in working with mechanism-based leads, the cellular activity of screening leads can be a key advantage. Historically this approach has been utilized in the search for new antibiotics, and the literature has a plethora of examples where new natural products have been identified due to their antibacterial activity. The identification of vancomycin, its commercialization, and subsequent elucidation of its mechanism of action serves as an illustrative example of the success of this approach (*7*, *8*). The inherent disadvantage of the latter approach is that the mechanism is unknown and the reason for the cellular activity of the compounds may simply be nonspecific toxicity. Therefore it is imperative to couple the chemical optimization of such leads with intensive biological efforts, devoted to the identification of their mechanism of action.

One such method for identifying molecular targets of small molecular agents has been immobilization followed by affinity chromatography. Immobilization has been successfully applied in the past in combination with molecular biology to unravel several fascinating aspects of how small molecules interact with large biomolecules. This strategy was successfully explored by Schreiber for the identification of the FK506 binding protein FKBP12 using an immobilized rapamycin (*9*), as well as by Yem for the identification of the FK506 binding proteins immunophilin hsp56 (FKBP52), and a chicken homologue of the human protein (*10*). Further, this approach was recently applied to a membrane protein target, resulting in the identification of a 36-kDa microfibril-associated glycoprotein protein as the potential target of tranilast (*11*). An important advantage of this affinity method is that the drug concentration can be set at levels significantly above the binding constants for target receptors, particularly if such receptors exist as a family with variable binding constants. A disadvantage of the bound ligand approach relates to the requirement for using cell homogenates, under which increased nonspecific interactions are possible (i.e. higher background noise). Ad-

ditionally, in such an environment, the probability of finding low abundance receptor proteins is diminished. A related affinity approach relies on the use of biotin as part of the linker connected to the pharmacophore. In this technique, streptavidin Sepharose can be utilized to affinity bind to the biotinylated drug and any accompanying biochemical targets. This approach has benefits in that the drug can be delivered to a target bacterial cell, thereby decreasing the chances for nonspecific interactions. A major disadvantage of this approach is that the drug of interest must have good solubility. There are several additional approaches available to elucidate the mechanism of action of compounds, such as photoaffinity labeling. There are drawbacks to each method, such as handling of radiolabeled material, solubility of reagents, etc. (*12*).

We have previously disclosed our initial evaluation of potent enols as antibacterial agents with an unknown mechanism of action (*13*). In this paper we disclose the discovery of a novel pyrimidine carboxamide antibacterial agent with potent broad-spectrum antibacterial activity. In addition, the subsequent immobilization of potent analogues in an attempt to identify the mechanism of action of this promising antibacterial template will be described. Figure 1 highlights our two strategies for identifying the molecular target of PNU-92560, a potent antibacterial agent.

MATERIAL AND METHODS

All reactions were performed under an atmosphere of nitrogen with the exception of the reactions performed in water or otherwise explicitly stated. Brine refers to a saturated solution of sodium chloride. Solvents utilized for reactions or chromatography were HPLC grade and were used as is with the exception of when the following solvents were utilized for reactions: tetrahydrofuran (THF) (distilled Na/benzophenone), toluene (Na), and CH_2Cl_2 (distilled P_2O_5). Reactions were monitored by thin-layer chromatography on Analtech 10 × 20 cm (250 μm) silica gel GF glass plates. Visualization was achieved with ultraviolet light, phosphomolybdic acid, or anisaldehyde solution. Silica gel chromatography was performed on Biotage Flash 15−40 utilizing cartridges with KP-SIL (32−63 μm) silica gel. Melting points were performed in open capillary tubes on a Thomas-Hoover melting point apparatus and are uncorrected. NMR spectra were recorded on Brucker Model AM-300 spectrometer and chemical shifts (δ) are reported in parts per million relative to tetramethylsilane. Spectra were referenced relative to tetramethylsilane as an internal standard or the chemical shift of the appropriate NMR solvent. Other physical data, such as IR, MS, and elemental analysis were performed by the Structural, Analytical and Medicinal Chemistry Unit.

Dimethyl 2-[(4-Bromoanilino)carbonyl]malonate, 1. In a 1 L round-bottom flask were placed THF (500 mL), dimethyl malonate (14.86 mL, 126.3 mmol, 1.00 equiv), and potassium *tert*-butoxide (14.15 g, 126.3 mmol, 1.00 equiv). This was stirred vigorously for 10 min upon which time 4-bromophenyl isocyanate (25.00 g, 126.3 mmol, 1.00 equiv) was added and stirred vigorously for 2 h. The THF was removed in vacuo and diluted with water. Acidification with concentrated HCl caused precipitation of the product, which was collected by filtration, rinsed well with water, and dried on high vacuum to provide 37.13 g (89%) of crude material. Recrystallization from EtOAc/heptane yielded 19.299 g (46%) of **1**. ^{1}H NMR (DMSO-d_6) δ 10.52 (s, 1 H), 7.52 (s, 4 H), 4.79 (s, 1 H), 3.73 (s, 6 H). ^{13}C NMR (DMSO-d_6) δ 165.1, 161.2, 137.6, 131.8, 121.0, 115.6, 59.7, 52.9.

***N*-(4-Bromophenyl)-7-hydroxy-5-oxo-2-sulfanyl-5*H*-[1,3,4]thiadiazolo[3,2-*a*]pyrimidine-6-carboxamide Dimethylamine Salt, 3.** In a 250 mL round-bottom flask were placed 2-amino-5-thio-1,3,4-thiadiazole (2.00 g, 15.04 mmol, 1.00 equiv), diester amide 1 (5.38 g, 15.04 mmol, 1.00 equiv), *o*-xylene (150 mL), and DMF (0.8 mL). The mixture was refluxed for 16 h. After cooling to room temperature, a precipitate formed which was collected by filtration and rinsed with acetone to provide 4.042 g (67%) of the desired product as the dimethylamine salt. The brown product was decolorized to a tan by further rinsing with acetone to finally provide 2.863 g of **3** (48%). Mp 235−237 °C ^{1}H NMR (TFA) δ 7.95 (d, J = 8.7 Hz, 2 H), 7.76 (d, J = 8.7 Hz, 2 H), 3.32 (t, J = 5.7 Hz, 6H). ^{13}C NMR (DMSO-d_6) δ 173.5, 170.2, 168.3, 166.3, 156.4, 136.3, 131.9, 122.6, 116.5, 88.5, 34.4. IR (drift) 3061 (b), 2753, 2499 (w), 2378 (w), 2097 (w), 1675, 1608, 1542 (s), 1507 (s), 1487 (s), 1465, 1429, 1403 (s), cm^{-1} MS (FAB) m/z (rel intensity) 399 (MH^+, 2), 202 (5), 200 (28), 129 (4), 127 (6), 118 (10), 74 (4), 47 (5), 46 (99), 44 (5), 39 (14). HRMS (FAB) calcd for $C_{12}H_7BRN_4O_3S_2$+H_1 398.9221, found 474.9211. HRMS (FAB) calcd for $C_{12}H_7BRN_4O_3S_2$+C_2H_8N 443.9800, found 443.9796.

2-{[4-(Acetylamino)benzyl]sulfanyl}-*N*-(4-bromophenyl)-7-hydroxy-5-oxo-5*H*-[1,3,4]thiadiazolo-[3,2-*a*]-pyrimidine-6-carboxamide, 4a. In a 10 mL two-neck round-bottom flask were placed DMSO (anhyd, 6 mL) and NaH (60% with mineral oil, 0.055 g, 1.38 mmol, 1.10 equiv) and stirred for 10 min. **3** (0.500 g, 1.25 mmol, 1.00 equiv) was then added in one portion and stirred until the solution was clear, about 20 min. 4-Acetamidobenzyl chloride (0.211 g, 1.25 mmol, 1.00 equiv) was then added and stirred for 1 h. The reaction mixture was then diluted with EtOAc and a small amount of acetone/heptane. The resulting precipitate was collected by filtration to provide

the product **4a** as a brown solid (0.442 g, 65%). Mp 204−206 °C. ^{1}H NMR (DMSO-d_6) δ 11.10 (s, 1 H), 7.62 (d, J = 8.9 Hz, 2 H), 7.56 (d, J = 8.5 Hz, 2 H), 7.41 (d, J = 6.0 Hz, 2 H), 7.40 (d, J = 6.0 Hz, 2 H), 4.45 (s, 2 H), 2.03 (s, 3 H). ^{13}C NMR (TFA) δ 176.2, 168.4, 165.0, 164.2, 135.3, 134.0, 133.2, 130.7, 124.8, 124.1, 122.4, 37.5, 21.3. IR (drift) 2350 (w), 1675 (s), 1626, 1602, 1586, 1550 (s), 1532 (s), 1516 (s), 1488, cm^{-1}. MS (FAB) *m*/*z* (rel intensity) 546 (MH$^+$, 25), 570 (57), 568 (59), 397 (48), 148 (99), 106 (59), 69 (71), 67 (50), 57 (60), 55 (73), 43 (48). HRMS (FAB) calcd for $C_{21}H_{16}BrN_5O_4S_2$+Na 567.9725, found 567.9733.

Methyl 4-[({6-[(4-Bromoanilino)carbonyl]-7-hydroxy-5-oxo-5*H*-[1,3,4]thiadiazolo[3,2-*a*]pyrimidin-2-yl}sulfanyl)methyl]benzoate, 4b. In a 10 mL two-neck round-bottom flask were placed DMSO (anhyd, 6 mL) and NaH (60% with mineral oil, 0.055 g, 1.38 mmol, 1.10 equiv) and stirred for 10 min. **3** (0.500 g, 1.25 mmol, 1.00 equiv) was then added in one portion and stirred until the solution was clear, about 20 min. Methyl 4-(bromomethyl)benzoate (0.286 g, 1.25 mmol, 1.00 equiv) was then added and stirred for 1 h. The reaction mixture was then diluted with EtOAc and a small amount of acetone/heptane. The resulting precipitate was collected by filtration to provide 0.381 g (56%) of the product **4b** as a brown solid. Mp > 250 °C. ^{1}H NMR (DMSO-d_6) δ 7.94 (d, J = 8.3 Hz, 2 H), 7.64 (d, J = 8.3 Hz, 2 H), 7.61 (d, J = 8.9 Hz, 2 H), 7.41 (d, J = 8.8 Hz, 2 H), 4.58 (s, 2 H), 3.84 (s, 3 H). ^{13}C NMR (DMSO-d_6) δ 170.7, 166.2, 165.8, 157.1, 141.7, 139.2, 131.2, 129.6, 129.3, 128.8, 121.0, 90.1, 52.1, 35.9. IR (drift) 2350 (w), 1931 (w), 1720, 1676, 1626, 1610, 1551 (s), 1531 (s), 1517 (s), cm^{-1}. MS (FAB) *m*/*z* (rel intensity) 533 (MH$^+$, 86), 535 (99), 534 (61), 533 (86), 532 (21), 362 (32), 170 (11), 147 (10), 135 (44), 118 (57), 59 (10). HRMS (FAB) calcd for $C_{20}H_{13}BRN_4O_5S_2$+H 532.9589, found 532.9586. % Water (KF): 0.11. Anal. Calcd for $C_{20}H_{13}BrN_4O_5S_2$: C, 45.04; H, 2.46; N, 10.50; Br, 14.98; S, 12.02. Found: C, 44.54; H, 2.55; N, 10.69.

4-[({6-[(4-Bromoanilino)carbonyl]-7-hydroxy-5-oxo-5*H*-[1,3,4]thiadiazolo[3,2-*a*]pyrimidin-2-yl}sulfanyl)methyl]benzoic Acid, 6. In a 100 mL two-neck round-bottom flask were placed **3** (1.625 g, 3.65 mmol, 1.00 equiv) and DMSO (anh., 36 mL) and stirred until dissolved. NaH (60% with mineral oil, 0.146 g, 3.65 mmol, 1.00 equiv) was added with vigorous bubbling noted. This was stirred until the solution was clear, and then 4-(chloromethyl)benzoic acid (0.624 g, 3.65 mmol, 1.00 equiv) was added and stirred at room temperature for 16 h. The reaction was diluted with EtOAc until no more precipitation was noted (about 1 L) and the solid collected by filtration to provide 0.681 g (35%) of crude material highly complexed to sodium, as evidenced by elemental analysis. The crude material was dissolved in DMSO (10 mL), and 1.0 N HCl/Et$_2$O (3.8 mL, 3 equiv) was added and stirred, capped, for 2 h. A precipitate slowly came of solution. Collection by filtration provided a white solid (0.142 g, 7%) as the pure product **6** as a very hygroscopic material. ^{1}H NMR (DMSO-d_6) δ 11.53 (s, 1 H), 7.90 (d, J = 8.3 Hz, 2 H), 7.65−7.56 (m, 6 H), 4.65 (s, 2 H). MS (FAB) *m*/*z* (rel intensity) 533 (MH$^+$, 21), 1463 (19), 557 (26), 555 (23), 535 (23), 533 (21), 362 (19), 200 (33), 135 (19), 118 (27), 46 (99). HRMS (FAB) calcd for $C_{20}H_{13}BrN_4O_5S_2$+H 532.9589, found 532.9582.

6-Affigel 102 Column. 6 (300 mg, 0.561 mmol) was dissolved in DMSO (67 mL) followed by the addition of NaH (60%, 45 mg, 1.12 mmol, 2.0 equiv). The resulting mixture was stirred at room temperature for 1 h. A volume of 50 mL (packed) of Affigel 102 (Bio-Rad) were washed on a glass filter with water and then with 50% DMSO (v/v). The resin suspension along with the compound in solution were mixed in a 500 mL flask. Since a slight turbidity was noted, an additional 130 mL of DMSO were added to improve solubility. The pH was checked at this time and found to be 8.3. EDAC [1-ethyl-3-(3-dimethylaminopropyl)carbodiimide] was added in small increments, creating some turbidity over time. An additional volume of DMSO was then added (85 mL) resulting in clearance. The suspension of resin and compound/EDAC solution was stirred for 16 h at room temperature. The product (**6**-Affigel 102) was obtained by removal of the noncoupled compound and carbodiimide byproducts by scintered glass filtering. The resin was washed with 250 mL of DMSO, followed by 500 mL of ethanol and 500 mL of water. The resin was collected and mixed with 50% glycerol for storage at −20 °C, or was dried down by Savant vacuum centrifugation and stored as a powder. The yield of immobilized **6** was determined by elemental analysis (bromine content). The final concentration of the compound was 2.6 mM (where

mM is measured as mmoles of compound per liter of resin). Observed elemental bromine analysis wt % Br (**6**-affigel resin) 0.05−0.35; (Affigel control) 0.0

Preparation of *S. aureus* S30 Lysates. The procedure for making *S. aureus* S30 extracts was followed according to Mahmood, R. et al. with some modifications (*14*). Six liters of BHI media were inoculated with 250 mL of a *S. aureus* overnight culture and grown at 37 °C for 4−5 h to an OD600 of 2−4. Cells were washed successively with 500 mL of cold S30−Buffer A (10 mM Tris-acetate, pH 8.0, 14 mM Mg-acetate, 1 mM DTT) containing 1 M KCl and then 250 mL of Buffer A containing 50 mM KCl. Cell pellets (∼50 gm wet weight) were stored at −70 °C. Frozen cell pellets were thawed on ice for 30−60 min. The slurry was resuspended up to a final volume of 99 mL of Buffer B (10 mM Tris-acetate, pH 8.0, 20 mM Mg-acetate, 50 mM KCl, 1 mM DTT). 1.5 mL of 0.8 mg/mL lysostaphin in Buffer B was added to the bottom of three precooled, 35 mL polyallomer SS-34 centrifuge tubes. 33 mL of cell slurry each was transferred to the three tubes containing lysostaphin solution (35 ug/mL final), capped, and gently but extensively mixed by inversion. Incubation was at 37 °C for 45−60 min. The tubes were inverted periodically. After incubation, 150 μL of 0.5 M DTT is added to each tube and mixed gently by inversion. The lysed cells were spun at 4 °C in an SS-34 rotor (16000 rpm; 30000*g*) for 30 min. The supernatant was removed, and the cell pellet was spun under the same conditions. For prolonged storage of the S30 lysate, it is mixed with an equal volume of glycerol and stored at −20 °C.

Bioaffinity Chromatography of S30 Lysates Using Immobilized 6-Affigel. *S. aureus* S30 lysate was diluted 100× with buffer (50 mM Tris HCl, pH 8.0) and mixed with 1 mL of **6**-Affigel 102 matrix that had been equilibrated with buffer. The mixture was incubated for 30−40 min on a mechanical rocker at 8 °C. The resin was then washed with 25 mL of low ionic buffer (50 mM Tris HCl, pH 8.0). This was followed by a high ionic buffer wash (2 M NaCl, 50 mM Tris HCl, pH 8.0) and a deionized water wash. These stringent washing steps were installed to limit nonspecific binding of proteins onto the affinity column. The deionized water wash elutes protein that may be binding to the affinity column or to proteins through hydrophobic interactions alone. This step facilitates the final TFA (trifluoroacetic acid) (1%) elution of the remaining bound protein on the column. This type of elution has been described previously (*10*). To concentrate the eluted protein(s), the elute was freeze-dried on a Speed-vac (Savant) system and was analyzed by SDS polyacrylamide gel electrophoresis (SDS PAGE). Affinity elution or competitive displacement of bound proteins with **6** was impossible due to the insoluble nature of the compound. A freeze-dried sample was also provided for mass spectral analysis (proteomics). The affinity matrix tends to lose its capacity to bind and retain protein after several uses for an unknown reason. This demanded that new column resin had to be used for each experiment. Possible explanations for the loss of function include compound tautomerization, metal binding, or actual chemical changes. To address this issue, a Br analysis was completed on new vs one time used resin. The latter resin had lost the capacity to bind to the protein target(s). The Br analysis showed that the same level of Br was present, indicating that the compound itself was still on the matrix, but somehow changes physically after a single experiment.

SDS Polyacrylamide Gel Electrophoresis (1D). Protein samples were analyzed by 15% polyacrylamide gel electrophoresis. Precision Protein Standard (BioRad) marker proteins were used for size referencing. Samples were treated with sample denaturing buffer (2% SDS, 5% 2-mercaptoethanol) at 100 °C for 2−3 min. For record keeping, each gel was transferred onto a PVDF matrix using a semidry electroblot system (Polyblot) run according to the manufacturer's instructions. Proteins transferred to the blot were visualized by Coomassie Blue R250 staining followed by destaining with 30% ethanol to remove background staining. Storage of the blots was possible after air-drying.

C4 Reverse Phase Chromatography of Proteins Bound to 6-Affigel 102. Eluted protein collected from the immobilized **6**-affinity column (in 0.1% trifluoroacetic acid (TFA)) was injected onto a C4 column (SMART System, Pharmacia). The column was developed with a linear gradient of 0−55% acetonitrile in 1% TFA over 60 min. A large protein peak was detected after the gradient with an 80% acetonitrile/0.1% TFA elution. The peak was collected for tryptic digestion, and the peptide fragments were analysis by mass spectroscopy. The protein was positively identified as elongation factor-Tu (EF-Tu).

Trypsin Digest. HPLC fractions were taken to dryness in a vacuum centrifuge and reconstituted in digestion buffer, 50 mM ammonium bicarbonate pH 8.5. Following the addition of trypsin the solution was incubated overnight at 37° C. Aliquots of the protein digest solution were analyzed by MALDI-Tof and nanoLC/MS/MS as described below.

MALDI-Tof Mass Spectrometry. Matrix-assisted laser desorption ionization time-of-flight (MALDI-Tof) analysis was performed on a Applied Biosystems Voyager STR mass spectrometer operated in the reflector mode with delayed extraction. Typical instrument operating conditions were: total accelerating voltage 20 kV; grid voltage, 73%; guide wire, 0−0.02%; and delay time, 225 ns. An aliquot of the trypsin digest was mixed with MALDI matrix (α-cyano-4-hydrozycinnamic acid), spotted to the MALDI target, and analyzed. Typically 256 laser shots were acquired and averaged for each spectra. The resulting spectra were internally calibrated using the autocatalyzed trypsin peaks at *m/z* 842.51, 1045.56, and 2211.10. A local copy of the database search program MS-Fit (prospector.ucsf.edu) was used to search against the Human Genome Sciences (HGS) database for protein identification.

Liquid Chromatography Tandem Mass Spectrometry (LC-MS/MS). Samples were analyzed by LC-MS/MS on a Finnigan LCQ (San Jose, CA) with a New Objectives PicoView (Cambridge, MA) nanospray adapter and a New Objectives tip coated PicoTip needle (360 mm OD × 20 mm ID × 10 mm tip diameter). LC was performed with a LC Packings Ultimate (San Francisco, CA) pump and a LC Packings Famos autoinjector. The Ultimate was operated at a flow rate of 300 nL/min. A sample volume of 2 to 5 μL was injected and concentrated onto an LC Packings PepMap precolumn (300 mm ID × 5 mm) by flow of 0.1% formic acid at 40 μL/min produced by auxiliary Gilson 305 pump (Gilson Medical Electronics, Middleton, WI). After 3 min of washing, samples were directed to a Fusica II column (75 mm ID × 150 mm) with 5 mm Vydac C18 stationary phase (LC Packings). The mobile phases used to elute the peptides were (A) 0.1% formic acid and (B) 90% acetonitrile, 0.1% formic acid. The peptides were eluted with a gradient of 5−75% B in 10 min. The following are instrumental parameters for the LCQ: heated capillary temperature, 230 °C; needle voltage, 1.60 kV. The LCQ MS spectra were acquired in data dependent mode. The MS/MS spectra

were selected and submitted to a local copy of Sequest (Thermoquest, San Jose, CA) for protein identification using the HGS database.

Metabolic Labeling Experiments. Drugs are tested at a series of 2-fold dilutions surrounding the reported MIC value: 4×, 2×, 1×, 0.5×, 0.25× MIC. In some instances, using the reported MIC value did not yield a profile that exhibited the expected dose−response type of curve, especially in the case of some of the standards. In such cases, the MIC value used was adjusted such that a dose−response type of curve was obtained. Typically, a 10 mM stock solution of drug is made in 100% DMSO, and the appropriate dilution is performed to obtain 200 mL of a 4× stock. Subsequently, 2-fold serial dilutions are made to obtain the other stock solutions. If the 4× MIC stock is greater than 10 mM, then the original stock solution must be adjusted accordingly. An aliquot of 5 mL of the appropriate concentration is added to each well, into a final volume of 150 mL; the 4× stock must take this aliquot size into account to obtain the correct final concentration. A Microsoft Excel file has been designed that performs all the necessary calculations for resuspending and diluting the compound to obtain the correct concentrations. Once all the stock solutions of drug are made, aliquots are transferred into a sterile round-bottom microtiter dish (Falcon 3918). Drug concentrations are run in quadruplicates; thus, a total of 24 wells are needed per macromolecular synthesis assayed. Radiolabeled substrates are ^{14}C-leucine, ^{14}C-uridine, ^{14}C-thymidine (50 mCi/ml, Amersham), and ^{14}C-D-alanine (100 mCi/ml, American Radiolabeled Chemicals) to assay for protein synthesis, RNA synthesis, DNA synthesis, or cell wall synthesis, respectively. ^{14}C-leucine is used neat; the other three substrates are used diluted 1:4. Typically, a repeating pipettor is used for dispensing, so an excess of substrate needs to be made. An aliquot of 5 mL is added to each well containing drug or vehicle. *Staphylococcus aureus* strain 31552 is used (UC9218). For the assay, 2 mL of an overnight culture of sa31552 are added to 18 mL of LB in a 50 mL conical tube and incubated at 37 °C for 45 min, 250 rpm. Using a multichannel pipet, 140 mL of this culture is added to each well previously aliquotted with drug/vehicle and ^{14}C-labeled substrate. A lid is placed on the microtiter plate and it is incubated at 37 °C at 1000 rpm for 1.5 h in an Eppendorf Thermomixer. Near the end of the incubation, a Millipore filterplate, type MAHV, is prepared. Each well receives a 50 mL aliquot of cold 25% TCA. After about 10 min, the TCA is filtered using the manifold apparatus designed for the filterplate. Each well of the filterplate then receives 100 mL of 50% ice cold TCA; the filterplate is kept on ice to keep the TCA cold. After 1.5 h of incubation, 100 mL of the incubation culture are removed from each well using a multichannel pipet and put into the corresponding wells containing 50% TCA. The filterplate is shaken on the Thermomixer for 1 min at 800 rpm and then placed at 0−4 °C for 1 h. After 1 h, the filterplate is placed into the vacuum manifold, and a low vacuum is applied to the unit. The filterplate is washed four times with 245 mL of 10% ice-cold TCA per well each time. The filterplate is then separated from its underdrain backing and blotted onto a paper towel. Finally, the filterplate is suspended in the hood such that airflow underneath the bottom thoroughly dries the filters, about 15−25 min. A Multiscreen Liner (EG&G Wallac) is fitted onto the underside of the filterplate. An aliquot of 25 mL of SuperMix scintillation fluid is added to each well, and a sealing tape is placed over the top of the wells. The filterplate assembly is then placed into a Wallac 1450−106 cassette. The plate is allowed to rest on the bench for at least 1 h before being counted in a Wallac Tri-Lux counter. Sample counts of 5 min per well are performed, and results are normalized against a ^{14}C control. Results are reported in CPM.

Immobilization of 3 onto UltraLink Iodoacetate. Ultralink iodoacetyl (5 mL, Pierce Chemical Co.) was washed with 25 mL of coupling buffer (50 mM Tris HCl, 5 mM EDTA (Na), pH 8.5). The resin was transferred to a flask after the immediate supernatant was removed. Compound **3** (30 mg) dissolved in DMSO was added to the moist resin. An additional amount of DMSO was then added (15 mL). The suspension was stirred slowly at room temperature for 1 h. The solution phase was then removed by gravity filtration. At this stage, the solution did not exhibit a positive reaction with Ellman's reagent, indicating that the reaction was likely quantitative. The resin was washed with 25 mL of DMSO, followed by washing with buffer alone. At this point, 25 mL of buffer containing 5 mg of cysteine was added (pH adjusted) to block remaining active substituents. This suspension was incubated for an additional 30 min at room temperature. After several washing steps, the resin was ready to use. Some of the conjugated resin was dried in vacuo and was submitted for bromine analysis. Observed elemental bromine analysis wt % Br (**3**−Ultralink resin) 0.88−1.07; (Ultralink control) 0.0.

Bioaffinity Chromatography of S30 Lysates Using Immobilized 3-Ultralink. *S. aureus* S30 lysate was diluted 100× with buffer (50 mM Tris HCl, pH 8.0) and mixed with 1 mL of **3** matrix that had been equilibrated with buffer. The mixture was incubated for 30−40 min on a mechanical rocker at 8 °C. The resin was then washed with 25 mL of low ionic buffer (50 mM Tris HCl, pH 8.0). This was followed by a high ionic buffer wash (2 M NaCl, 50 mM Tris HCl, pH 8.0) and a deionized water wash. These stringent washing steps were incorporated to limit nonspecific binding of proteins onto the affinity column. The deionized water wash elutes proteins that may be binding either to the affinity column or to other bound proteins through hydrophobic interactions alone. This step facilitates the final TFA (trifluoroacetic acid) (1%) elution of the remaining bound protein on the column. Alternatively, the bound specific protein was eluted with **3**. To concentrate the eluted protein(s), the elute was freeze-dried on a Speed-vac (Savant) system and was analyzed by SDS polyacrylamide gel electrophoresis (SDS PAGE). A new column resin was used for each experiment.

SDS Polyacrylamide Gel Electrophoresis (1D). Protein samples were analyzed by 15% polyacrylamide gel electrophoresis. Precision Protein Standard (BioRad) marker proteins were used for size referencing. Samples were treated with sample denaturing buffer (2% SDS, 5% 2-mercaptoethanol) at 100 °C for 2−3 min. For record keeping, each gel was transferred onto a PVDF matrix using a semidry electroblot system (Polyblot) run according to the manufacturer's instructions. Proteins transferred to the blot were visualized by Coomassie Blue R250 staining followed by destaining with 30% ethanol to remove background staining. Storage of the blots was possible after air-drying.

Cloning and Expression of *S. aureus* EF-Tu in *E. coli*. Using polymerase chain reaction (PCR), we amplified the region of *S. aureus* EF-Tu beginning with the start codon at nucleotide 51 and ending at 1232 just before the natural stop codon. *S. aureus* genomic DNA (RN4220) was used as a template. BamHI sites were introduced on either end of the EF-Tu in this PCR

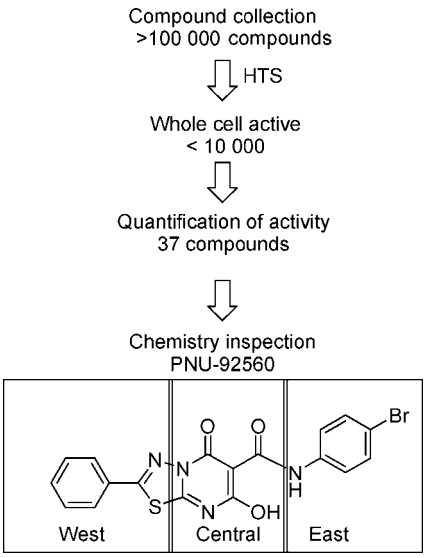
reaction using oligonucleotide primers EF-1: 5′-GCG ATC GGA TCC ATG GCA AAA GAA AAA TTC G-3′ and EF-2: 5′-GCG CTC GGA TCC TTT AAT GAT TTC AGT AAT-3′. We chose to ligate the EF-Tu into the *E. coli* expression vector pQE60 which would code for the EF-Tu with a C-terminal hexa-histidine (His6) tag. PQE60 was first linearized with BamHI, dephosphorylated with calf intestinal alkaline phosphatase (CIAP), and gel purified. After digestion of the ends of the EF-Tu PCR product with BamHI and gel purification of the DNA, we ligated it into the BamHI sites of pQE60 using Pharmacia Biotech's T4 DNA ligase Ready-to-go kit. Resulting plasmids were transformed into Promega competent JM109 *E. coli*. Restriction mapping revealed that although we had obtained clones of the EF-Tu insert in pQE60, all were in the reverse orientation. EF-Tu insert purified from one such reverse clone was ligated back into pQE60 and produced clones, which contained the EF-Tu insert in the correct orientation. DNA sequence analysis confirmed that although one nucleotide change was detected, this change did not affect our desired amino acid sequence for the EF-Tu followed by a C-terminal His6 tag.

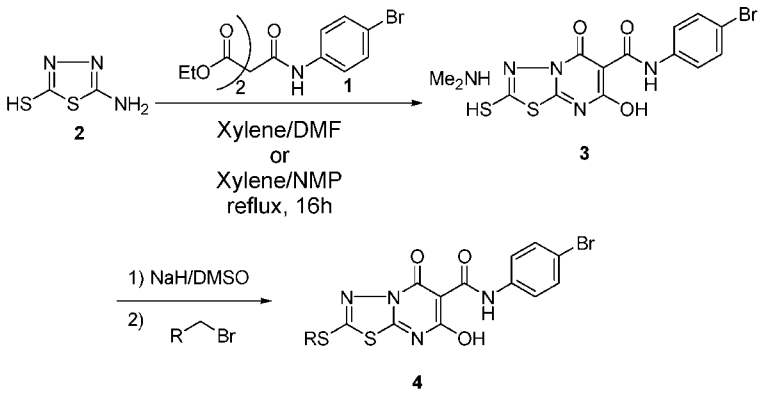
Purification of His-Tagged Recombinant *S. aureus* EF-Tu Expressed in *E. coli*. Four liters of *E. coli* expressing *S. aureus* EF-Tu were grown in M9 media and harvested after 2 h of ITPG induction. The cell pellet was resuspended in ∼160 mL of 50 mM Tris HCl, pH 8.0 buffer. One milliliter of an inhibitor cocktail (Boehringer Mannheim) was prepared according to the manufacturer's recommendation and added to the cell mixture. This suspension was placed in an ice bath and sonicated at maximum gain (Branson) for 15 s/min over a period of 6 min. The mixture was clarified by centrifugation (SS-34 rotor, Sorvall 205000 rpm for 40 min at 6 °C) and the supernatant collected was mixed with 15 mL of Ni−NTA (Qiagen) affinity matrix that had been pre-equilibrated with Tris buffer as described. The affinity-attached rEF-Tu was competed off from the column with 200 mM imidazole. The protein was further purified and desalted by Superose-12 (Pharmacia) gel filtration column chromatography. The final protein purified was roughly 90% pure and was stored at −20 °C in 50% glycerol after YM-10 ultrafiltration concentration.

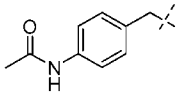
In Vitro Susceptibility Test. Minimum inhibitory concentration (MIC) values were determined by standard broth microdilution methods (*15*).

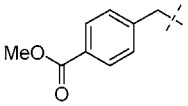
RESULTS

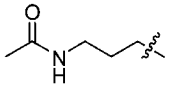
Identification of Lead Structure. Our compound collection was screened for compounds with whole cell antibacterial activity, and the compounds that exhibited good potency were further evaluated. The potency of the compounds in this initial set was confirmed, leading to the identification of a handful of compounds with good potency. Rigorous evaluation of these initial leads based on their chemical tractability resulted in the emergence of PNU-92560, Figure 2. Related compounds have been previously described in the literature as antihelmintic agents (*16*). PNU-92560 had broad-spectrum antibacterial activity against a panel of important pathogenic Gram-positive and Gram-negative bacteria. One of our initial evaluations of this template relied on inspection of its historical activity in our HTS screens. Gratifyingly, while this compound had been screened in a variety of assays, nonspecific broad ranging activity was not noted (*17*). Furthermore, testing of this compound against a range of cell lines indicated that this compound was surprisingly nontoxic. For example, screening against a broad panel of fungi revealed that this compound was inactive with all MIC values >32 μg/mL. Subsequently, when we evaluated the pharmacokinetic properties of PNU-92560, it demonstrated 44% bioavailability, and it appeared to have no adverse effects on the animals. Extensive searches of the literature indicated that pyrimidines having a substructure of PNU-92560 had been reported as inhibitors of tumor growth (*18*). Testing of this compound in a metabolic assay was hampered by its poor solubility, thus providing no useful information regarding potential mechanism of action. While hampered by poor solubility, given the importance of identifying this compound's mechanism of action, we decided to employ an affinity-based technique in an effort to identify its bacterial target.











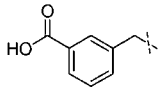


Figure 2. This schematic representation illustrates the stepwise process that resulted in the identification of PNU-92560 as a viable lead for chemistry optimization and detailed biology evaluation. MIC (μg/mL) values for PNU-92560 were *S. aureus* 0.125; *E. faecalis* 0.25; *S. epidermidis* 0.5; *S. pneumoniae* 2; *H. influenzae* 4; *E. coli* >128; *K. pneumoniae* >128; *P aeruginosa* >128.

Identification of Linker Attachment to PNU-92560. To implement our strategy to use bioaffinity isolation of potential targets, there were several chemistry requirements necessary for the approaches described above to be successful. These included (1) identification of an appropriate linker site, (2) identification of a suitable linker, (3) preparation of compounds for immobilization followed by actual immobilization, and (4) the selection of appropriate controls. To address these issues, we sought to identify a fully functionalized molecule with a protected form of the linker that exhibited comparable antibacterial activity to PNU-92560. After the identification of the linker, the compound would be attached to the affinity matrix. An extensive chemistry effort was initiated to evaluate the structure−activity relationships on PNU-92560, and it identified that only the western portion (Figure 2) of the molecules tolerated attachment of linkers (*19*). We therefore turned our attention toward identifying a suitable linker attached to PNU-92560 analogues. These molecules were easily prepared by the condensation of tricarbonyl compound **1** with the appropriate thiadiazole derivative **2** at elevated temperature in DMF or NMP/xylene mixtures. The thiol salt **3** was easily obtained in large quantities and could be easily functionalized with alkyl halides. The initial set of analogues provided some interesting observations,

including that *S*-alkyl-substituted analogues were equipotent to the corresponding alkyl-substituted analogues (**4a**/**4b** vs PNU-92560). In addition, alkyl substituent **4c** could replace the aryl ring found in PNU-92560 with some loss of potency. Our attempt to identify a suitable linker as in **4d** with the attaching unit unprotected was unsuccessful since the compound had very poor activity. Gratifyingly, we identified **4a** and **4b** with significant activity containing an embedded linker.

First Generation Affinity Matrix. The advantage of using a soluble affinity matrix is that the conjugate might retain solubility for use on living bacterial cells. In this approach, the biotinylated compound could be delivered to *S. aureus* cells in culture using serum free media, thereby allowing targeting to the intracellular space where contact with a receptor could occur. A biotin analogue was prepared through a multistep synthesis, but immediate concerns related to compound solubility emerged. The compound was only partially soluble in DMSO stock solution, so that when dilutions were made into the cell lysate solution, precipitation occurred readily. Nevertheless, after incubation in S30 lysate solution, the solution was passed over a streptavidin Sepharose column. Unfortunately, no protein signals were detected using this approach.

In an effort to circumvent this solubility problem, attention was turned next to a solid-phase affinity matrix approach. The corresponding fully functionalized compound ready for immobilization was easily prepared on large scale by an S-alkylation. The acid was then coupled to Affi-gel 102 resin. This coupling was found to be difficult to achieve, since only low amounts of the compound actually reacted with the amino group on the resin in the presence of the carbodiimide, EDAC. This difficulty hampered a reproducible coupling onto the resin. After extensive experimentation, it was found that deprotonation of **6** with 2 equiv of NaH in DMSO was optimal to achieve a consistent loading on the column. It is thought that solubility of the compound was enhanced using the latter method, enabling the coupling reaction to occur (Scheme 1). The actual yield of coupling was determined by elemental analysis of the bromine content of the resin. The amount of bromine (i.e., representing **6**) was on average in the millimolar range (mmoles of compound per liter volume of resin) when the NaH method was utilized, but appreciably lower when other coupling methods were employed. The resulting affinity matrix was washed sufficiently with neat DMSO in order to remove noncoupled compound which may resist washes in aqueous solution due to its insolubility.

Scheme 1

Affinity Isolation. The use of the immobilized **6**-Affigel 102 as an affinity matrix was examined under conditions which would clearly represent compound concentrations well above the binding constant for any possible receptor (i.e., 1−5 mM). With this approach, the binding interactions with proteins and nucleic acids in the solution phase would be favored, compared to the extremely low concentrations of biotinylated compound used in experiments described above. *S. aureus* S30 lysates were incubated with the resin as described in Materials and Methods. After a short period of time, the nonbound fraction was collected. The resin was then washed with incubation buffer to remove nonspecifically bound protein, followed by a wash with 2 M NaCl to displace those proteins bound to the resin through weakly ionic interactions. After a water wash step to remove proteins bound through hydrophobic interactions, the protein(s) bound to the column was eluted with trifluoroacetic acid (TFA) and evaporated to dryness. Importantly, in this process the development of binding and washing conditions for specific receptors to immobilized compounds is a time-consuming venture. Careful analysis must follow since nonspecific interactions may occur at higher levels than specific interactions. Generally, our approach was to use a control matrix lacking the coupled compound, but exposed to the same conditions needed to generate the experimental resin. Any proteins found from the latter column are considered to be nonspecific proteins.

In the **6**-Affigel 102 experiment, the protein(s) eluted from the column were next analyzed by 1D electrophoresis (see Figure 3). As shown in Figure 3, a principle band was observed at about 53 kD, along with other minor bands. Of particular interest was the observation that this band was almost completely removed from the starting lysate (as shown in the nonbound fraction). This result provides a point of reference for the analysis using proteomics technology. This latter approach involves separation and identification of proteins selectively retained by the affinity column. The proteins of interest, which may be a subset of the total proteins separated and quantified, are identified by mass spectrometry. For these experiments, the most abundant protein was

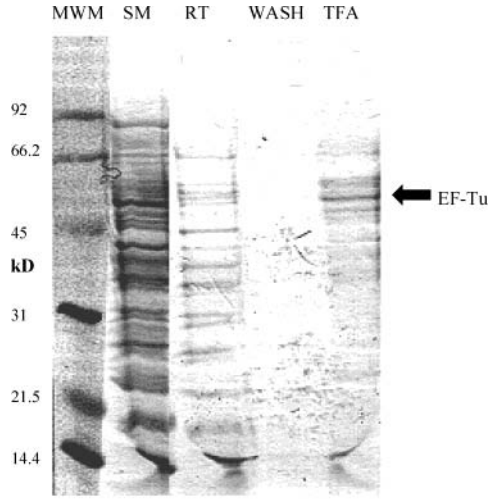

Figure 3. 1D polyacrylamide gel electrophoresis analysis of the eluant from a **6**-Affigel 102 column treated with *S. aureus* S30 lysate. The experimental procedures are described in Materials and Methods. Lanes from left to right are MWM, molecular weight marker proteins (with kD indications on the left *Y*-axis); SM, starting material (S30 lysate) used for the bioaffinity experiment; RT, the pool of material which was not bound to the column; WASH, a series of steps to include both high and low salt; and TFA, the protein eluted by dilute trifluoroacetic acid. The arrow indicates the position of what was determined to be an EF-Tu band.

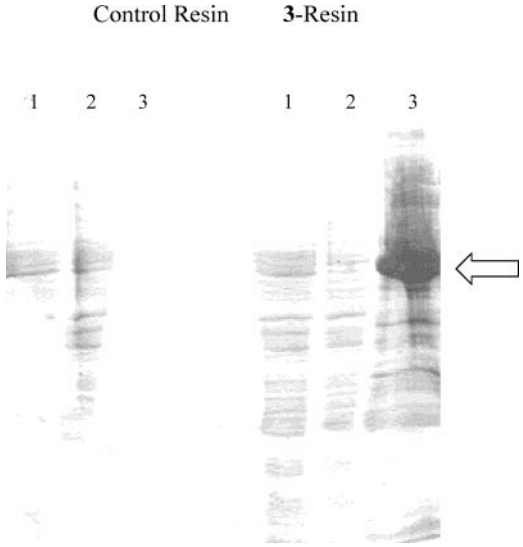

Figure 4. The binding of *S. aureus* S30 lysate protein to a control (no drug)-UltraLink resin column versus a **3**−UltraLink column resin. Lane 1, column starting material (S30 lysate from *S. aureus*); Lane 2, nonbound protein; Lane 3, elution by 5 mM **3** in 50 mM Tris-HCl, pH 8.0. The gel was run with an equal volume of the starting material and run through, and for the eluted fractions, i.e., 5 mM **3** or 0.1% TFA, with an aliquot of sample concentrated by freeze-drying.

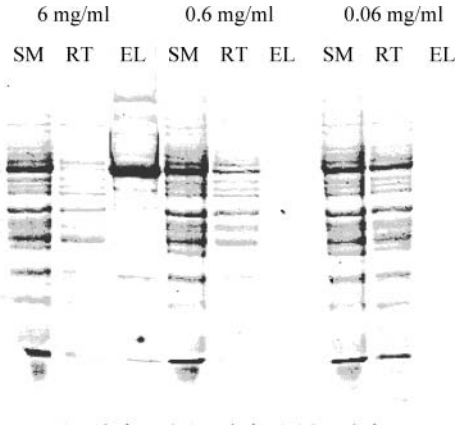

Figure 5. Effect of the concentration of immobilized **3** on binding of protein. Different amounts of **3** were immobilized on UltraLink iodoacetic acid (Pierce) in three concentrations: 6, 0.6, and 0.06 mg/mL. Only at 6 mg/mL or higher was the observed protein interaction displayed. At 0.6 and 0.06 mg/mL drug, no binding was observed.

selected for identification. The proteins retained by the affinity column were eluted by 0.1% TFA and resolved on a C4 reverse phase column. The major peak was digested with trypsin and analyzed by MALDI-Tof mass spectrometry. The experimentally determined masses of the tryptic peptides (referred to as the peptide mass fingerprint of the protein) were used to search the HGS sequence database using the software program MS-fit. The results of the database search resulted in the sequence of EF-Tu being identified as the major component being retained by the column.

Second Generation Affinity Matrix. The Affigel columns employed in the above experiments did not allow a careful control of compound density on the matrixes. We were able to circumvent this problem by preparing an alternative affinity matrix by reacting **3** in a DMSO solution with Ultralink iodoacetyl resin. Using this second generation approach, we were able to control the loading as judged by elemental bromine analysis. This resin appeared to have very similar affinity to EF-Tu as the affigel resin as depicted in Figure 4. The protein targets captured by bioaffinity chromatography were identified using proteomics techniques as described above. To define the nature of the affinity of the proteins to **3**, the effect of variation of compound concentration was examined with **3** immobilized at three different concentrations, all differing by one log. The resulting affinity eluted materials were analyzed by SDS PAGE (Figure 5). Only the highest concentration (roughly 6 mg/mL) was shown to bind protein (i.e., EF-Tu) (Figure 5, top)

Relevance of EF-Tu as a Molecular Target. Using the immobilization method, we have identified EF-Tu as a putative molecular target in *S. aureus* for these compounds. Results from metabolic labeling experiments indicate that **4b** acts via inhibition of bacterial protein synthesis, which is consistent with EF-Tu as the mechanistic target (Figure 6). Metabolic labeling experiments allow for a determination of the effect drugs have on the four major pathways in bacteria: DNA synthesis, RNA synthesis, protein synthesis, and cell wall synthesis. Compounds are analyzed by serial dilutions around the reported MIC value (4×, 2×, 1×, 0.5×, 0.25× MIC). Radiolabeled substrates ^{14}C-leucine, ^{14}C-uridine, ^{14}C-thymidine, and ^{14}C-D-alanine are used to monitor protein synthesis, RNA synthesis, DNA synthesis, or cell wall synthesis, respectively. Control antibiotics do demonstrate a complete inhibition of protein synthesis at 32× the MIC. However, the compounds reported in this study have very limited solubility and actually readily precipitate out in the growth medium so that even though the amount of compound added to the bacterial culture is 32× the MIC, in reality, only a small portion of that is in solution. In these and other experiments in which several PNU-92560 analogues were analyzed, the data clearly support the conclusion that PNU-92560 compounds primarily affect protein synthesis, but not DNA synthesis. We have evaluated a range of these compounds in a transcription/translational assay (*20*). In this assay several of the compounds display significant inhibition (at 100 μM, **3** had inhibition of 72% and **4b** had inhibition of 21%) despite the difficulties encountered due to insolubility of the compounds (*21*, *22*).

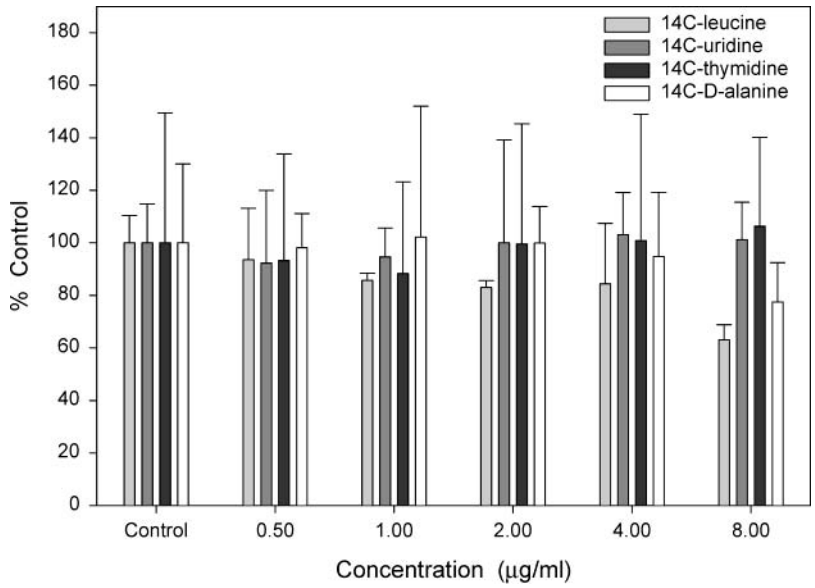

Figure 6. Metabolic labeling experiments of *S. aureus* with **4b**. Results from metabolic labeling experiments indicate that PNU-92560 acts via the inhibition of bacterial protein synthesis, which is consistent with EF-Tu as the mechanistic target. Metabolic labeling experiments allow for a determination of the effect drugs have on the four major pathways in bacteria: DNA synthesis, RNA synthesis, protein synthesis, and cell wall synthesis.

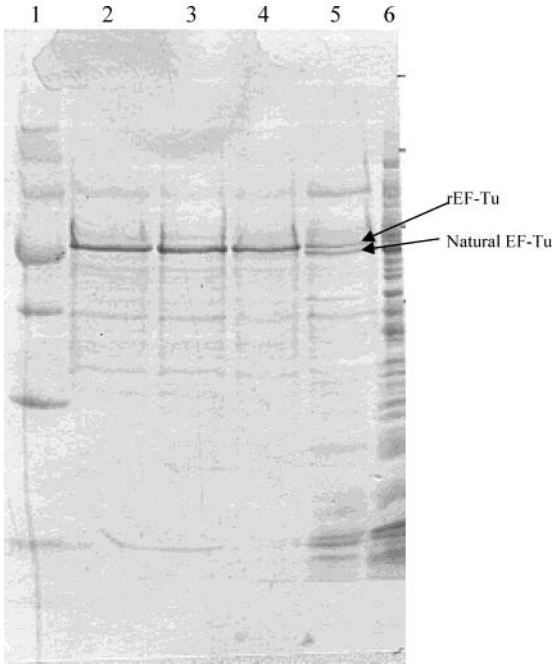

Figure 7. A demonstration that **6**-Affigel 102 binds to native and recombinant EF-Tu. Lane 1: Molecular size markers; Lane 2, rEF-Tu loaded onto a **6**-Affigel 102 column; Lane 3, Flow through containing rEF-Tu, indicating that the binding sites on the column were saturated with rEF-Tu; Lane 4, protein bound to the column (tested as a control); Lane 5, the effect of competition by an S30 lysate, allowing natural EF-Tu to compete with the rEF-Tu from the column; Lane 6 is the S30 lysate.

To validate whether EF-Tu is a target of these compounds, a recombinant form of *S. aureus* EF-Tu was cloned, expressed, and purified in an *E. coli* expression system as described in Materials and Methods. The EF-Tu protein system has been well characterized, particularly in *E. coli* (*23*). The recombinant protein has been crystallized and its structure solved in the presence and absence of several antibiotics (*24*). In our attempts to express the *S. aureus* rEF-Tu in *E. coli*, we were successful in obtaining the purified protein. We examined the interaction of the protein with **3** as shown in Figure 7. The affinity matrix could be shown to bind to the recombinant EF-Tu and also to directly compete with natural EF-Tu from S30 lysates of *S. aureus* (Figure 7, lane 5).

DISCUSSION

In this report, it has been shown that bioaffinity chromatography combined with proteomics can be used to identify an unknown receptor of a compound having a biologically measurable activity. Two important lessons can be learned in this set of experiments: (1) the choice of a compound and how it is covalently attached to a solid support is critical to the success of the project; and (2) the biochemical methods, including the ability to utilize intact living cells versus the necessity of using cellular lysates, can be crucial in the success of identifying a target. For the latter, two biochemical methods are described which have widely different impacts. The first approach involves the use of a ligand attached to the compound, which provides an enhanced method for bioaffinity purification. Most commonly, the ligand used is biotin, since it can be readily removed, along with bound targets, by streptavidin Sepharose. For this method it is possible to use intact living cells to allow the biotinylated compound to internalize and bind to appropriate targets. Unfortunately this approach failed due to the significant insolubility of the compounds in both organic (including DMSO) and aqueous solutions. The second approach involves the use of immobilization of a compound onto a solid support such that concentrations exceeding all binding constants for likely receptors are achieved. Importantly, in most cases, the compound concentration presented on a Sepharose resin far exceeds the possible solution-phase solubility of the compound. This improves the likelihood of a truly insoluble compound of being able to select out protein targets. The negative side of such experiments is the need to use cell extracts or lysates, rather than intact whole cells, and the necessity for the use of detergent-solubilized cell extracts if one expects a membrane protein. Unfortunately, if such action causes the loss of function of a protein target, binding to an immobilized compound may not occur. We have determined that **3** binds to EF-Tu by affinity chromatography. In addition, **3** has been successfully used to displace bound EF-Tu from **3**−UltraLink in an apparently competitive manner. Finally, the interaction of the compounds with EF-Tu was studied using purified recombinant EF-Tu. In this case, the recombinant protein was able to bind to the immobilized compound columns as well as compete for binding effectively with the natural EF-Tu present in the *S. aureus* lysate. It is therefore logical to conclude that the interaction of this class of compounds with EF-Tu does occur, although the precise mechanism governing this interaction is not known at present. The next challenges will be to determine where the drug binds to EF-Tu and a relative binding affinity. Competition with known EF-Tu inhibitors might offer an approach to this problem. Additional experiments are underway to better define the role of EF-Tu as a putative target of this novel class of antibacterials. The plan is to raise resistance mutants to the compounds, map the gene, and sequence the mutant gene to definitively identify the mechanism of action. In addition, we will overexpress the EF-Tu gene to demonstrate that overexpression will result in an increase in the MIC in the presence of our compounds. Nevertheless, results, including those from the metabolic labeling experiments, which show that protein synthesis is inhibited, are consistent with the concept of EF-Tu as the mechanistic target.

CONCLUSION

In this paper we have reported the discovery of a novel antibacterial agent PNU-92560. Subsequently a site on this compound was identified where a linker could be attached for affinity isolation of putative targets. The affinity chromatography identified EF-Tu as the major component obtained from the columns. Additional work such as metabolic labeling, activity in a transcription/translation assay, and affinity for recombinant EF-Tu supports the relevance of this protein as a target for this class of compounds. Additional work will be necessary to unravel the details of the affinity of these compounds for EF-Tu, as well as to discover the binding site on the protein and the general mechanism of inhibition of protein translation afforded by these compounds.

ACKNOWLEDGMENT

We are grateful to Ping Gao for formulation of PNU-92560 and Wei-Zhu Zhong for the pharmacokinetic evaluation of PNU-92560. We acknowledge the people in the Structural, Analytical and Medicinal chemistry unit for their fine analytical services. We are particularly

appreciative for the help of Jack Kreling and Jack DeZwaan for determination of the bromine content of the immobilized compound resins. We also acknowledge the help of Robert Murray who provided us with *S. aureus* S30 lysate, and Jerry Slightom and colleagues for DNA sequence support (recombinant EF-Tu). Finally, we thank Jeffrey A. Pfefferkorn and Dr. Jeffrey for critical reading of this manuscript.

Preparation of Bionanoreactor Based on Core−Shell Structured Polyion Complex Micelles Entrapping Trypsin in the Core Cross-Linked with Glutaraldehyde

Montree Jaturanpinyo, Atsushi Harada,† Xiaofei Yuan, and Kazunori Kataoka*

Department of Materials Engineering, Graduate School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan. Received August 26, 2003; Revised Manuscript Received January 20, 2004

Recently, the polyion complex (PIC) micelle has been suggested as a promising carrier system for peptide and proteins. However, its utilities are limited by its sensitivity to the environment such as dilution and ionic strength of the solution. In this study, to overcome these obstructions, PIC micelles prepared from an anionic block copolymer, poly(ethylene glycol)−poly(α,β-aspartic acid), and a cationic protein, trypsin, were cross-linked with glutaraldehyde through the Schiff base formation. On the basis of a light scattering technique, the results revealed an efficient resistance of the cross-linked PIC micelle to a high salt concentration, which was a key parameter controlling the structure of the PIC micelles. Moreover, the stability of trypsin after cross-linking was remarkably improved. Evidently, as a bionanoreactor and/or bionanoreservoir, the PIC micelles entrapping protein molecules in the cross-linked core reveal an improved stability, allowing their wide application in the fields of biotechnology and pharmaceutical sciences.

INTRODUCTION

Peptides and proteins are now available in sufficient quantities to provide new utilities in the fields of biotechnology and pharmaceutical sciences. However, their use is still limited by their own sensitive characteristics and various environmental factors (*1*−*3*). Recently, a novel bioconjugating system, polyion complex (PIC) micelles, which are formed through the driving force of the electrostatic interaction between a pair of oppositely charged block copolymers, has emerged (*4*−*7*). On the basis of the charged properties of the protein, egg white lysozyme having an isolectric point of 11 was first examined for incorporation into the core of the PIC micelles using an anionic block copolymer, poly(ethylene glycol)−poly(α,β-aspartic acid) block copolymer [PEG-P(Asp)] (*8*, *9*). Not only the achievement of a stable PIC micelle formation was easily obtained but also the apparent enzymatic activity of the lysozyme entrapped in the cores of the PIC micelles was increased (*10*, *11*). Additionally, this system revealed valuable advantages including a narrow size distribution on a mesoscopic scale, total water solubility, and biocompatibility due to the core−shell architecture having a water-insoluble protein−polyelectrolyte complex core completely protected from an undesirable environment by the PEG shell. With such properties, PIC micelles entrapping protein in the core may be one of fulfilling systems for improving the stability and activity of proteins.

As is widely known, the stability and characteristics of micelles, including PIC micelles, are influenced by various factors involving their chemical compositions and their vicinity. In particular, for PIC micelles, the ionic strength of solution is a key parameter for the stability because of the shielding effect of ionic species on the Coulombic interactions. Consequently, the feasibility of controlling the activity and enhancing the stability of proteins through the core−shell structure of PIC micelle seems to be obstructed. To date, some approaches have been reported, which include the stabilization of micelles by cross-linking the shell (*12*−*14*) and the core (*15*, *16*). The structures of the micelles are locked and efficiently prevent any dissociation from the fluctuating environment. Therefore, for application in both biotechnology and pharmaceutical sciences, one solution to overcome this obstruction of salt stability may be to cross-link the core of the PIC micelle.

Glutaraldehyde has been introduced as a powerful fixative reagent for electron microscopy for many decades (*17*). Recently, the interest in glutaraldehyde used as a protein cross-linking reagent has significantly increased, making it often used to immobilize and stabilize proteins for many purposes (*18*, *19*). Because of its fairly small size, glutaraldehyde rapidly penetrates into tissues to thoroughly cross-link proteins. The nature of the cross-linkage is the formation of imines (Schiff base) between the aldehyde groups of glutaraldehyde and the primary amino groups of the protein.

The aim of this study is to introduce a novel approach for maintaining the activity of proteins through the stabilization of the PIC micelle, which is composed of an anionic segment, P(Asp), and trypsin having a pI of 10.5 (*20*), by cross-linking in the core (Figure 1). The stability of cross-linked PIC micelle entrapping protein in the core under high ionic strength is examined by light scattering measurements. Furthermore, the enzymatic activity of trypsin entrapped in the cores after cross-linking is evidenced by using L-lysine *p*-nitroaniline as a substrate. This new prototype might have a practical utility acting as a bionanoreactor and/or bionanoreservoir in the fields of biotechnology and pharmaceutical sciences.

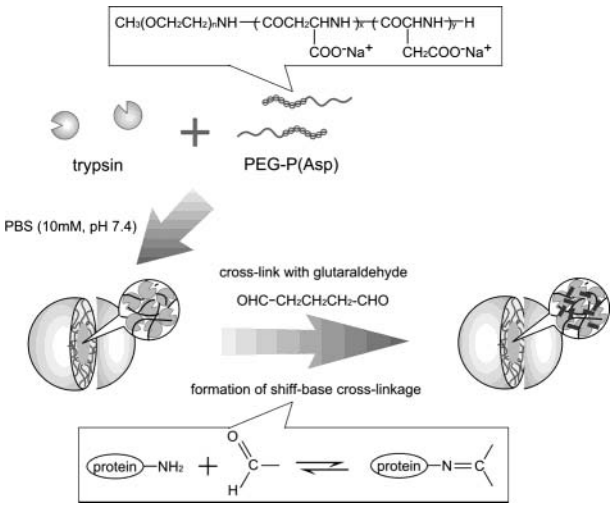

Figure 1. Schematic concept and preparation of PIC micelles entrapping trypsin in the core cross-linked with glutaraldehyde.

EXPERIMENTAL SECTION

Materials. The poly(ethylene glycol)−poly(α,β-aspartic acid) block copolymer [PEG-P(Asp), 12 000 g/mol of PEG M_w, 63 polymerization degree of P(Asp)] was synthesized as already described (*8*). Bovine pancreas trypsin (M_w = 23 800) and L-lysine *p*-nitroaniline were purchased from Sigma (St. Louis, MO) and used without further purification. $Na_2HPO_4 \cdot 12H_2O$, $NaH_2PO_4 \cdot 2H_2O$, and 70% glutaraldehyde were reagent grade and were purchased from Wako Pure Chemical Industries (Osaka, Japan).

Preparation of Polyion Complex Micelles Entrapping Trypsin in the Core. Given amounts of trypsin and PEG-P(Asp) were separately dissolved in phosphate buffer solution (PBS, 10 mM, pH 7.4) at ambient temperature. The solutions were mixed at the optimum mixing ratio of PIC micelle formation from trypsin and PEG-P(Asp), in which the ratio of the number of Asp residues in PEG-P(Asp) to the total number of Lys and Arg residues in trypsin is 0.75. The solution was stored at 4 °C overnight before further use or evaluation.

Preparation of Cross-Linked PIC Micelles Entrapping Trypsin in the Core with Glutaraldehyde. To introduce cross-linking to the core of the PIC micelles, the PIC micelles entrapping trypsin in the core were treated with various amounts of 70% glutaraldehyde solutions, which were calculated on the basis of the glutaraldehyde cross-linking ratios (GR) defined as the total number of aldehyde groups in the glutaraldehyde solution versus the total number of Lys residues in trypsin of 10, 50, 100, 500, and 1000. The cross-linked PIC micelle solutions were then kept at 4 °C for 24 h to ensure the completion of the cross-linking process.

Characterization of PIC Micelles Entrapped Trypsin in the Core. The characteristics of the cross-linked PIC micelles were investigated by light scattering measurements at a wavelength of 488 nm from an Ar ion laser at 25 °C using a DLS-7000 spectrometer (Otsuka Electronics Co., Ltd., Japan).

Synthesis of ω-Acetyl-PEG-P(Asp). Poly(ethylene glycol)−poly(β-benzyl-L-aspartate) block copolymer [PEG−PBLA, 12 000 g/mol of PEG M_w, 60 polymerization degree of PBLA], which is a precursor of PEG-P(Asp) and prepared by the ring-opening polymerization of β-benzyl-L-aspartate *N*-carboxyanhydride initiated from the terminal amino group of α-methoxy-ω-aminopoly(ethylene glycol) (*8*), was dissolved in distilled DMF at 50 mg/mL. To this solution was added 10 equiv of acetic anhydride to the ω-amino group of PEG−PBLA. After the reaction at 40 °C for 2 h under an Ar atmosphere, the polymer was precipitated into a mixture of ethyl acetate and hexane (40/60 v/v). The acetylation of the ω-amino group of PEG−PBLA was confirmed by ^{1}H NMR in DMSO-d_6. The degree of acetylation of the end group of the block copolymer was determined to be 91% from the peak intensity ratio of methyl protons of the acetyl group (CH_3CO-, 1.8 ppm) and ethylene protons of PEG (CH_2CH_2O, 3.7 ppm). The benzyl group of the obtained ω-acetyl-PEG−PBLA was removed in 0.5 N NaOH to obtain ω-acetyl-PEG-P(Asp) [PEG-P(Asp)-$NHCOCH_3$]. No change in the acetylation degree of the end group of ω-acetyl-PEG-P(Asp) as well as the polymerization degree of the P(Asp) segment through the deprotection procedure was confirmed by ^{1}H NMR measurement in D_2O.

Transmittance Measurement. The time course of transmittance at 800 nm for the cross-linked PIC micelles at GR100 after the addition of NaCl solutions at various concentrations were monitored using a V550 spectrophotometer (Jasco, Japan) at 25 °C.

Enzymatic Activity. The cross-linked PIC micelles prepared at GR 100 were dialyzed against PBS in order to remove excess glutaraldehyde. Complete removal of the excess glutaraldehyde was confirmed using 3-methyl-2-benzothazolinone hydrazone (*21*). The enzymatic activity of trypsin was evaluated using L-lysine *p*-nitroaniline as the substrate (*22*). The reaction rate was determined by monitoring the change in absorbance at 410 nm; at this wavelength, the extinction coefficient of *p*-nitroaniline is 8800 cm^{-1} M^{-1}.

RESULTS AND DISCUSSION

Cross-Linked PIC Micelles Entrapping Trypsin in the Core with Glutaraldehyde. In 10 mM PBS (pH 7.4), trypsin and PEG-P(Asp) spontaneously associated to form PIC micelles through the driving force of electrostatic interaction. On the basis of a DLS measurement, the PIC micelles incubated at 25 °C for 30 min had an average diameter of ca. 70 nm and a polydispersity index of less than 0.1, suggesting that there was a well-defined structure and no secondary aggregation. The obtained PIC micelles had a trypsin/P(Asp) complex core surrounded by a PEG shell layer. However, this system was quite unstable even in the medium with low ionic strength such as 10 mM PBS.

As seen in Figure 2, the relative light intensity as well as cumulant diameter of the un-cross-linked PIC micelles in 10 mM PBS (closed circle) rapidly decreased as a function of time. The complete dissociation was observed after incubating the sample at 25 °C for 2.5 h. As is widely known, trypsin is a proteolytic enzyme, which cleaves a peptide bond next to the basic amino acids, Lys and Arg, in the peptide chain. Thus, it also digests itself, which is called self-digestion or autolysis. Time-dependent decrease in the stability of the un-cross-linked PIC micelles is most likely to be correlated with this autolysis of trypsin. Indeed, there was no change in the relative scattering intensity of un-cross-linked micelles with time in the presence of 8.0 M urea (closed square in Figure 2a), a condition that enzymatic activity of trypsin is completely inhibited (*23*). Note that the enzymatic activity of trypsin, examined by using L-lysine *p*-nitroaniline as a model substrate, suggests that the rate of autolysis is even accelerated in the micelle system compared with free trypsin, which might be due to the condensation of trypsin molecules in the core, and eventually, this accelerated autolysis results in an abrupt disintegration of the un-cross-linked PIC micelles.

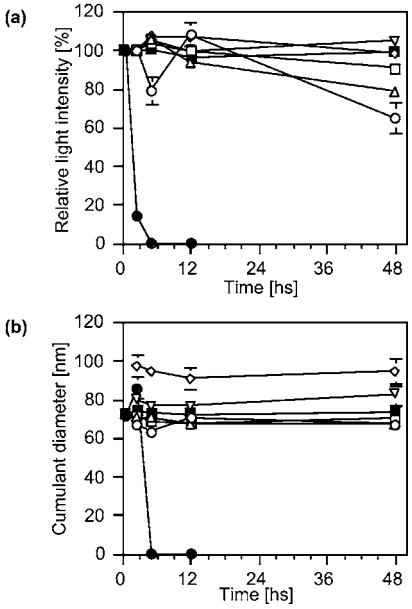

Figure 2. Time-dependent change in relative light scattering intensities (a) and cumulant diameters (b) of PIC micelles entrapping trypsin in the core cross-linked with glutaraldehyde at various ratios (GR = 0 (●), 10 (○), 50 (△), 100 (□), 500 (▽), and 1000 (◇) in the absence of urea and GR = 0 (■) in the presence of 8.0M urea) measured by SLS and DLS at a detection angle of 90° and temperature of 25 °C. The plots are presented as the average of three experiments ± SEM. Error bars for some data points were smaller than the size of symbols and are not visible in the figures.

Cross-linked cores entrapping trypsin are simply established by just adding glutaraldehyde to the previously prepared PIC micelle solution. The cross-linking reaction was carried out at 4 °C in order to suppress the autolysis of trypsin. After treatment with glutaraldehyde, no precipitation was observed in the micelle solution at all the glutaraldehyde ratios, compared with free trypsin, which gradually aggregated and thus precipitated from the entire solution. This result indicates that the core of the PIC micelle serves as a nanoscopic domain for the cross-linking reaction. Note the high reproducibility of the cross-linked PIC micelle preparation from the error bar being very small for all the plots. Furthermore, the cross-linked proteins are completely protected from aggregation by the steric stabilization effect of the PEG shell layer. DLS measurements reveal no difference in the initial cumulant diameter ($t = 0$) between the cross-linked micelles and un-cross-linked PIC micelles (Figure 2b). Consequently, the cross-linking process has no significant influence on the structure of the micelles. In addition, the unimodality of the representative histogram of the PIC micelles cross-linked with glutaraldehyde at GR 100 as shown in Figure 3 and the polydispersity index, less than 0.1, confirm that there is no aggregation and alteration of the structure of the micelles by the cross-link reaction. The slight changes in the diameters of cross-linked PIC micelles at GR 500 and 1000 might be explained by the influence of excess glutaraldehyde on the viscosity of the solvent involving the Stokes−Einstein equation used to calculate the hydrodynamic diameter in the DLS measurements. Furthermore, the association number of trypsin and PEG-P(Asp) was calculated from the micellar mass prepared at GR = 0 and 100, which was determined by Debye plots of SLS. The micellar mass of GR = 0, i.e., un-cross-linked micelle, was determined to be 2 100 000, and the association numbers of trypsin and PEG-P(Asp) were then calculated

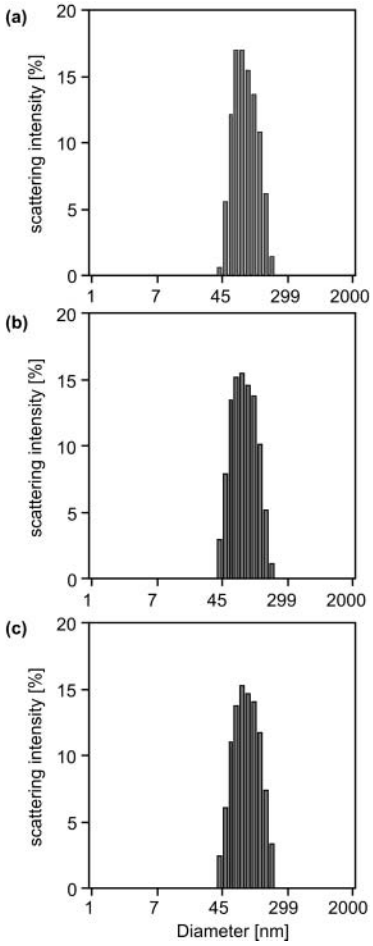

Figure 3. Size distributions of PIC micelles entrapping trypsin in the core without cross-linking (a), PIC micelles entrapping trypsin in the core cross-linked with glutaraldehyde at GR 100 before adding NaCl (b), and that after adding NaCl (0.15M) (c) determined by DLS (histogram method) at a detection angle of 90° and temperature of 25 °C.

to be 77 and 15. The cross-linked micelle at GR = 100 had similar micellar mass (2 300 000) compared with un-cross-linked micelle. The association numbers of trypsin and PEG-P(Asp) were calculated by disregarding the amount of glutaraldehyde and were found to be 84 and 16, respectively. The small difference in the micellar mass as well as the association number between un-cross-linked and cross-linked micelles indicates that the cross-linking could be constructed with the core−shell structure maintained.

The time-dependent relative light intensities and diameters of the cross-linked PIC micelles at varying GRs in Figure 2 obviously indicate that the cross-linked PIC micelles are much more stable than the un-cross-linked PIC micelles. This might be due to the immobilization of the entrapped trypsin by cross-linkages, thus retarding the autolysis through the interaction of trypsin molecules in the core. At GRs 10 and 50, the relative light scattering intensities of the cross-linked micelles are slightly decreased with time despite no change in their diameters. This suggests that even for the condition with a relatively low GR the micelle structure can be maintained by fixation of the cross-linked core although the un-cross-linked fraction of the trypsins may be partially self-digested.

Stability of Cross-Linked PIC Micelles against NaCl. Basically, the electrostatic interaction in the core of the PIC micelle is shielded by increasing the NaCl

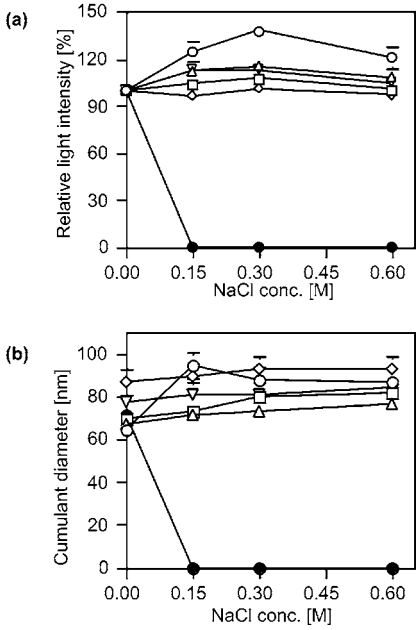

Figure 4. Changes in relative light scattering intensities (a) and cumulant diameters (b) with NaCl concentrations of PIC micelles entrapping trypsin in the core cross-linked with glutaraldehyde at various ratios (GR = 0 (●), 10 (○), 50 (△), 100 (□), 500 (▽), 1000 (◇)) obtained from SLS and DLS at a detection angle of 90° and temperature of 25 °C. The plots are presented as the average of three experiments ± SEM. Error bars for some data points were smaller than the size of symbols and are not visible in the figures.

concentration, thus leading to dissociation. Preliminary results of the cross-linked PIC micelles at GR 0.00−4.00 demonstrated that they were unable to resist NaCl concentrations greater than the physiological conditions (0.15 M). From GR 0.00 to 1.00, the PIC micelles rapidly dissociated, whereas at GR 2.00 and 4.00, they gradually precipitated from the solution. The precipitation may be caused by an incomplete cross-linking between trypsin and the primary amino group of the ω-end group of PEG-P(Asp), resulting in the secondary aggregation of the cross-linked trypsin molecules after the PEG-P(Asp) chains are removed from the core−shell structure by an increased shielding effect. The effect of the end group of the block copolymer on the stabilization of the micelle structure will be discussed later.

Figure 4 illustrates the relative light scattering intensities and cumulant diameters of the cross-linked PIC micelles against NaCl at various concentrations. Obviously, the cross-linked PIC micelles at all GRs greater than 10 have an improved stability against a high salt concentration despite the observation that the diameters of the cross-linked PIC micelles tend to increase at all GRs, especially at GR 10 ($p < 0.05$ for 0−0.15 M NaCl; $p < 0.05$ for 0−0.30 M NaCl; $p < 0.05$ for 0−0.60 M NaCl), as a result of shielding of the electrostatic interaction in the core. Additionally, the representative histogram in Figure 3c at GR 100 after increasing the NaCl concentration to 0.15 M is still unimodal, confirming the high resistance of the cross-linked PIC micelle structure to the change in the ionic strength of the solution.

One aspect that should be mentioned here is that the structure of the micelle can still exist in a medium with an appreciably high ionic strength without any electrostatic interaction between PEG-P(Asp) and trypsin. It might be explained by two possibilities that include the physical entrapment of polymer chains being entangled in the cross-linked cores and the formation of a cross-

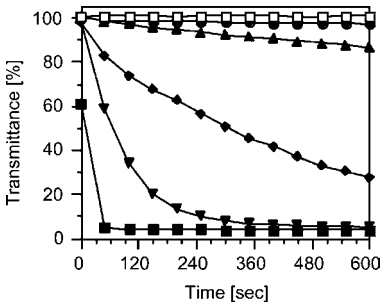

Figure 5. Time course of change in transmittance for GR100-NH2 at 0.1 M NaCl (□) and GR100-NHCOCH3 at various NaCl concentrations (0.01 M (●), 0.02 M (▲), 0.03 M (◆), 0.04 M (▼), 0.1 M (■)): trypsin concentration = 3.2 mg/mL, ratio of glutaraldehyde GR = 100, monitor weavelength = 800 nm, temperature = 25 °C.

linkage between the primary amino groups at the ω-end of the P(Asp) segments and aldehyde groups in glutaraldehyde. To evaluate the importance of the cross-linking between trypsin and PEG-P(Asp), another type of trypsin-entrapped PIC micelle at GR 100 (GR100-$NHCOCH_3$) was prepared using the PEG-P(Asp)-$NHCOCH_3$. The change in the transmittance after NaCl addition was monitored to compare the stabilities of these two kinds of PIC micelles against the change in ionic strength in the solutions, and the obtained result is shown in Figure 5. With an increase in the NaCl concentration, the transmittance of the GR100-$NHCOCH_3$ micelles immediately decreased because of the precipitation of the solutes, especially at NaCl concentrations over 0.04 M. It might be reasonably considered that the precipitates were mainly composed of the secondary aggregation of the cross-linked trypsins after partial or entire PEG-P(Asp)-$NHCOCH_3$ chains are removed from the core−shell structure by the shielding effect of NaCl. The transmittance of the GR100-NH_2 micelle at 0.1 M NaCl showed no change in the monitored time period as shown in Figure 5, and the GR100-NH_2 micelles also showed no change in relative scattering intensity and cumulant diameter even at 0.6 M NaCl as shown in Figure 4. Such a difference in the stability against the change in ionic strength between the GR100-$NHCOCH_3$ and GR100-NH_2 micelles was induced by the presence of the end reactive group, the primary amino group, in the block copolymer. Consequently, it was concluded that the cross-linkages of not only protein−protein but also protein−polymer were required for the preparation of stable cross-linked micelles.

Enzymatic Activity of Cross-Linked Trypsin Entrapped in the Core of PIC Micelles. The enzymatic activity of trypsin entrapped in the core of the PIC micelles was examined using L-lysine *p*-nitroaniline. It was selected as a substrate because of the low molecular weight, which was small enough to penetrate into the core to react with the entrapped trypsin. Before measurement of the enzymatic activity of the cross-linked trypsin, the sample was dialyzed against PBS in order to remove excess glutaraldehyde, which interferes with enzymatic reaction by a possible reactivity toward the primary amino group of the substrate.

In Figure 6, free trypsin and un-cross-linked trypsin entrapped in the PIC micelle dramatically lose their activities within a week by self-digestion. In contrast, after 1 week, the cross-linked trypsin entrapped in the core of the PIC micelles (GR = 100) significantly reveals a remaining catalysis rate of 4.76×10^{-7} M/s, which is approximately twice as great as that of the freshly prepared free trypsin. Worth noticing is that the activity

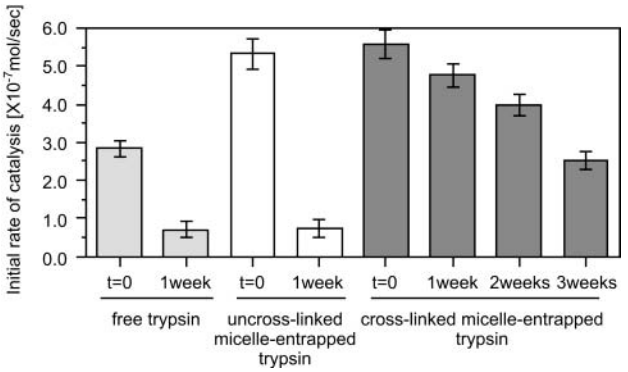

Figure 6. Catalytic activity of free trypsin and trypsin entrapped in un-cross-linked and cross-linked PIC micelles incubated at 25 °C for 1−3 weeks compared to that of freshly prepared free trypsin. The data are presented as the average of three experiments ± SEM.

of the entrapped trypsin cross-linked by glutaraldehyde still remained at the same level as the freshly prepared free trypsin even after 3 weeks, although it slowly decreased. The change in the apparent enzymatic activity of trypsin entrapped in cross-linked PIC micelles was explained by the substrate condensation, and the details of this effect will be reported elsewhere (*24*). These results clearly indicate that the stability of trypsin was improved in a controllable manner by its entrapment in the cross-linked core of the PIC micelles.

CONCLUSION

The stability of the PIC micelles entrapping proteins in the core was significantly improved by introducing cross-linking in the core with glutaraldehyde through a Schiff base formation of the protein−protein and protein−block copolymer. Not only stable cross-linked PIC micelles were obtained with a well-defined structure and narrowly distributed size on a mesoscopic scale but also trypsin entrapped in the cores still retained appreciable activity for small substrate molecules and was much more stable than the native one. These results provide a novel concept in the design of a bionanoreactor and/or bionanoreservoir potentially useful as protein delivery systems, including enzyme prodrug therapy, and as bioengineered production systems.

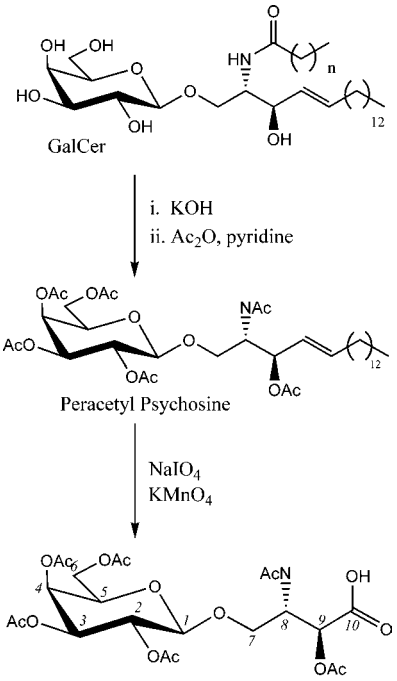
Synthesis of Novel, Multivalent Glycodendrimers as Ligands for HIV-1 gp120

Richard D. Kensinger,[†] Brian C. Yowler,[†] Alan J. Benesi,[‡] and Cara-Lynne Schengrund*[,†]

Department of Chemistry, The Pennsylvania State University, 152 Davey Laboratory, University Park, Pennsylvania 16802, and Department of Biochemistry and Molecular Biology H171, The Pennsylvania State University College of Medicine, 500 University Drive, Hershey, Pennsylvania 17033. Received September 3, 2003; Revised Manuscript Received December 18, 2003

Multivalent neoglycoconjugates are valuable tools for studying carbohydrate−protein interactions. To study the interaction of HIV-1 gp120 with its reported alternate glycolipid receptors, galactosyl ceramide (GalCer) and sulfatide, galactose- and sulfated galactose-derivatized dendrimers were synthesized, analyzed as ligands for rgp120 by surface plasmon resonance, and tested for their ability to inhibit HIV-1 infection of CXCR4- and CCR5-expressing indicator cells. Four different series of glycodendrimers were made by amine coupling spacer-arm derivatized galactose residues, either sulfated or nonsulfated, to poly(propylenimine) dendrimers, generations 1−5. One series of glycodendrimers was prepared from the ceramide saccharide derivative of purified natural GalCer, and another was from chemically synthesized 3-(*β*-D-galactopyranosylthio)propionic acid. Synthesis of 3-sulfogalactopyranosyl-derivatized dendrimers was accomplished using the novel compound, 3-(*β*-D-3-sulfogalactopyranosylthio)propionic acid. The fourth series was made by random sulfation of the 3-(*β*-D-galactopyranosylthio)propionic acid functionalized dendrimers. Structures of the carbohydrate moieties were confirmed by NMR, and the average molecular weights and polydispersities of the different glycodendrimers were determined using MALDI-TOF MS. Surface plasmon resonance studies found that rgp120 IIIB bound to the derivatized dendrimers tested with nanomolar affinity, and to dextran sulfate with picomolar affinity. In vitro studies of the effectiveness of these compounds at inhibiting infection of U373-MAGI−CCR5 cells by HIV-1 Ba-L indicated that the sulfated glycodendrimers were better inhibitors than the nonsulfated glycodendrimers, but not as effective as dextran sulfate.

INTRODUCTION



The primary protein receptors for HIV-1 are the cell surface CD4 molecules (*1*). Interaction of viral envelope glycoprotein, gp120, with CD4 results in a conformational change within gp120 that allows it to interact with a chemokine coreceptor (*1*, *2*). This results in formation of a 'fusion pore' which leads to fusion of viral and cellular membranes (*2*−*4*). In the absence of CD4, however, it is believed that the cell surface glycosphingolipids (GSLs), GalCer and its 3′-sulfated derivative, sulfatide (SGalCer), act as alternate receptors for HIV-1 gp120 (*5*−*10*). It has been shown that gp120 has distinct binding sites for GalCer and CD4 (*5*, *11*, *12*), and that the GalCer binding site has a nanomolar affinity for GalCer (*8*, *13*, *14*)—which is on the order of that reported for the affinity of gp120 for CD4 (*15*−*17*). The fact that the GalCer binding site is distinct and of relatively high affinity has made it a target for the development of GalCer and SGalCer mimetics as potential inhibitors of the interaction of HIV-1 with its target cells. Support for this idea is provided by a number of studies of the effectivieness of GalCer analogues as ligands for gp120 or as inhibitors of HIV infectivity (*18*−*25*).

Cell surface GSLs are involved in membrane trafficking, cell adhesion, cell morphogenesis, and signal transduction (*26*−*29*). In addition to these functions, GSLs in lipid rafts are used by a variety of pathogens for cellular entry (*30*, *31*). GSLs consist of a ceramide (*N*-acylated sphingosine) backbone and a carbohydrate moiety *β*-linked to the terminal hydroxyl group of the sphingosine. The ceramide portion intercalates into the phospholipid bilayer of the cell membrane, and the carbohydrate moiety extends outward from the membrane surface. Although the role of the ceramide portion in bacterial and viral adhesion is debatable (*13*, *23*, *24*), the consensus is that it is necessary for the positioning of the saccharide moiety such that it is available as a ligand for the pathogen (*13*, *32*). It is interesting that the carbohydrate moieties of GSLs function as receptors for various pathogens, since individual carbohydrate−protein interactions are often of low affinity (*33*−*35*). This is counterintuitive for biological processes that require high specificity and avidity. Nature has overcome this problem of innately weak monosaccharide interactions by clustering carbohydrate ligands together on the cell surface to yield a 'cluster' or 'multivalency' effect, that results in much stronger interactions (*35*−*38*). In some cases, the cluster effect has been observed to result in affinities that are greater than would be expected based on the sum of the total individual carbohydrate−protein interactions themselves—a cooperative affinity greater than that of valency (*36*, *38*). The clustering of GSLs in cell surface lipid rafts or 'detergent insoluble membranes' is a good example of the natural clustering of carbohydrate residues (*29*, *39*). Lipid rafts have been shown to serve as docking sites for

various bacterial toxins and viruses (*31*). Therefore, it is reasonable to hypothesize that a successful inhibitor of the binding of trimers of gp120 found on the surface of HIV-1 to GalCer/SGalCer would need to mimic the natural clustering of the carbohydrate moieties found in lipid rafts.

Multivalent neoglycoconjugates have been found to be useful mimetics of the natural clustering of carbohydrate residues (*40*, *41*). Glycodendrimers (*42*−*44*) are particularly effective due to their propensity to form spherical nano-cellular decoys (*33*, *36*). Effective ligands for influenza virus (*33*), cholera toxin (*45*), and various lectins (*37*, *46*) have been successfully prepared by conjugating cell surface carbohydrate ligands to spherical hyperbranched dendrimers. To study the interaction of HIV-1 gp120 with GalCer and SGalCer, and to develop potential carbohydrate-based inhibitors of this interaction, we synthesized several series of novel glycodendrimers of increasing size as multivalent mimetics of GalCer and SGalCer. This was accomplished by chemically isolating the saccharide portions of GalCer (compound **1**, see Scheme 1) and SGalCer and then using amine coupling to conjugate the "ceramide saccharide" (*47*) to polypropylenimine (DAB-Am) dendrimers. DAB-AM dendrimers were also functionalized with 3-(*β*-D-galactopyranosylthio)-propionic acid (compound **2**, Scheme 2) and 3-(*β*-D-3-sulfogalactopyranosylthio)propionic acid (compound **3**, Scheme 2). Failure to obtain efficient linkage of the 3-sulfated, spacer-arm derivatized galactose molecule to the DAB-Am dendrimer cores led us to randomly sulfate dendrimers derivatized with compound **2**. NMR was used to confirm synthesis of the various saccharides, and the average molecular weights and polydispersities of the glycodendrimers were determined by MALDI-TOF MS. Surface plasmon resonance (SPR) was used for kinetic analysis of the interaction of HIV-1 rgp120 IIIB with the different glycodendrimers, and dextran sulfate (DxS)—a known potent binding inhibitor of HIV-1. Last, the effectiveness of the glycodendrimers at blocking HIV-1 infection of cultured indicator cells was ascertained.

EXPERIMENTAL PROCEDURES

Abreviations. Bu_2SnO, dibutyltin oxide; BF_3Et_2O, borontriflouride dietherate; COSY, correlated spectroscopy; DCM, dichloromethane; DCE, dichloroethane; DIPEA, diisopropylethylamine; DxS, dextran sulfate; DAB-Am, poly(propylene imine) dendrimers; DMF, dimethylformamide; Et_3N, triethylamine; GalCer, galactosyl ceramide; HATU, *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(7-azabenzotriazol-1-yl)uronium hexafluorophosphate; HMBC, heteronuclear multiple bond correlation; HMQC, heteronuclear multiple quantum correlation; HPTLC, high performance thin-layer chromatography; IAA, *trans*-3-indoleacrylic acid; $KMnO_4$, potassium permangenate; k_a, association rate constant; k_d, dissociation rate constant; K_D, equilibrium dissociation constant; kDa, kilodaltons; M_n, number-average molecular weight; M_w, weight-average molecular weight; MALDI-TOF MS, matrix-assisted laser desorption ionization time-of-flight mass spectrometry; MTS, 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium, inner salt; NaOMe, sodium methoxide; PD, polydispersity; PMS, phenazine methosulfate; SO_3NMe_3, sulfur trioxide trimethylamine complex; SGalCer, sulfatide; SPR, surface plasmon resonance; R_{max}, maximum binding capacity in RUs; RU, resonance unit (change in surface concentration of ∼1 pg of protein/mm^2); THAP, trihydroxyacetophenone.

Materials. GalCer, SGalCer, lyso-sulfatide, and psychosine standards were purchased from Matreya, Inc (Pleasant Gap, PA). GalCer and SGalCer for ceramide saccharide syntheses were purified from bovine brain white matter as previously described (*48*). Recombinant HIV-1 IIIB gp120 was obtained from Immunodiagnostics, Inc (Woburn, MA), DAB-Am dendrimers were from Aldrich (Milwaukee, WI), and silica gel 60 HPTLC plates were from Merck (Germany). Unless designated otherwise, all other materials were commercially available, and used without further purification.

Preparation of Peracetylated GalCer Ceramide Saccharide (1). GalCer was deacylated to form psychosine using reaction conditions described by Radin and by Dubois et al. for the removal of the fatty acid side-chain

from GSLs (*49*, *50*). The ceramide saccharide derivative of GalCer was made from pyschosine according to procedures published by Mylvaganum and Lingwood (*51*). MALDI-TOF MS *m/z* 548 $[M - H]^-$: $C_{22}H_{31}NO_{15}$ (549).

3-(β-D-Galactopyranosylthio)propionic Acid (2). 3-Mercaptopropionic acid (10.5 mL, 120 mmol) was added with stirring to a solution of galactose-β-pentaacetate, 11.7 g (30 mmol), in 60 mL of anhydrous DCM. This was followed by the addition of 5.7 mL (45 mmol) of $BF_3 \cdot Et_2O$ (*52*, *53*). The reaction was stirred at room temp and followed by TLC ($BuOH:CH_3OH:H_2O$; 2:1:1, v/v/v). Upon completion (~5 h), the reaction mixture was poured into ice water in a separatory funnel. The lower organic phase was removed, and the aqueous phase was rinsed 3× with DCM. The combined organic phases were washed with water, treated with anhydrous sodium sulfite, filtered over Celite, and dried by rotary evaporation. Peracetylated galactothiopropionic acid was isolated from the resulting viscous oil on a silica gel column and eluted with a step gradient of $DCM:CH_3OH$ of increasing polarity. It was recovered as a colorless oil in 80% yield. For NMR analysis and regioselective sulfation, a portion of the peracetylated galactothiopropionic acid was deacetylated using NaOMe in anhydrous CH_3OH. After stirring overnight at room temp, it was neutralized using DOWEX 50W $[H^+]$. ^1H NMR (400 MHz, D_2O, 25 °C): $\delta = 2.50$ (t, $J_{7A,8} \approx 7$ Hz, $J_{7B,8} \approx 7$ Hz, 2H, H-8), 2.90 (m, $J_{7A,8} \approx 7$ Hz, $J_{7B,8} \approx 7$ Hz, 2H, H-7), 3.52 (t, $J_{1,2} = 9.72$ Hz, $J_{2,3} = 9.6$ Hz,1H, H-2), 3.61 (dd, $J_{2,3} = 9.6$ Hz, $J_{3,4} = 3.4$ Hz, 1H, H-3), 3.66 (m, 1H, H-6B), 3.67 (m, $J_{4,5} = 0.2$ Hz, 1H, H-5), 3.72 (m, 1H, H-6A), 3.93 (d, $J_{3,4} = 3.36$ Hz, $J_{4,5} = 0.2$ Hz, 1H, H-4), 4.46 (d, $J_{1,2} = 9.72$ Hz, 1H, H-1). ^{13}C NMR (D_2O, 25 °C): $\delta = 27.3$ (C-7), 38.6 (C-8), 61.7 (C-6), 69.5 (C-4), 70.3 (C-2), 74.55 (C-3), 79.6 (C-5), 86.65 (C-1), 181.4 (C-9). MALDI-TOF MS *m/z* 291 $[M + Na]^+$: $C_9H_{16}O_7S$ (268).

3-(3-Sulfo-β-D-galactopyranosylthio)propionic Acid (3). Compound **3** was prepared because the carbohydrate moiety of sulfatide (SGalCer) is galactose-3-sulfate, and the hypothesis was that it would probably be the best mimetic for sulfatide. Galactothiopropionic acid, 5.86 g (21.87 mmol), and Bu_2SnO, 5.99 g (1.1 equiv, 24.05 mmol), were refluxed in 200 mL of anhydrous CH_3OH for 4 h at 90 °C (*54*, *55*). The resulting translucent yellow solution was dried by rotary evaporation, taken up in 150 mL of DMF, and 3.42 g SO_3NMe_3 (1.2 equiv, 24.6 mmol) was added. The mixture was sonicated (~1 min) and stirred at room temp for 30 h (*54*, *55*). The reaction was quenched with CH_3OH, dried by rotary evaporation using an oil vacuum pump, and purified on a silica gel column eluted with a $CHCl_3:CH_3OH$ step gradient. ^1H NMR (400 MHz, D_2O, 25 °C): $\delta = 2.68$ (t, $J_{7A,8} \approx 7$ Hz, $J_{7B,8} \approx 7$ Hz, 2H, H-8), 2.97 (m, $J_{7A,8} \approx 7$ Hz, $J_{7B,8} \approx 7$ Hz, 2H, H-7), 3.70 (dd, $J_{1,2} = 9.90$ Hz,1H, H-2), 3.72 (m, 1H, H-6B), 3.75 (m, 1H, H-5), 3.75 (m, 1H, H-6A), 4.32 (s, 1H, H-4), 4.33 (dd, 1H, H-3), 4.60 (d, $J_{1,2} = 9.90$ Hz, 1H, H-1). ^{13}C NMR (D_2O, 25 °C): $\delta = 26.4$ (C-7), 36.9 (C-8), 61.6 (C-6), 67.9 (C-4), 68.3 (C-2), 79.25 (C-5), 82.1 (C-3), 86.3 (C-1), 179.0 (C-9). MALDI-TOF MS *m/z* 347 $[M]^-$: $C_9H_{15}O_{10}S_2^-$ (347).

Conjugation of Functionalized Saccharides to Polypropylenimine Dendrimers. The peracetylated derivative of compound **1**, **2**, or **3**, 50 to 100 mg (1.5 equiv per dendrimer terminal primary amine), was taken up in CH_3CN (10 mg/mL). One equivalent of HATU (Aldrich, Milwaukee, WI) in CH_3CN (10 mg/mL) and 1 equiv of DIPEA were added to each sample to activate the terminal carboxyl group (*56*). After 5−10 min, the appropriate amount of DAB-AM dendrimer at a concentration of 10 mg/mL in DCM was added dropwise to the stirring mixture. Reactions were adjusted to 1:1, DCM:CH_3CN, and allowed to incubate at room temperature with stirring overnight. Product formation was monitored by TLC ($BuOH:CH_3OH:H_2O$; 2:1:1, v/v/v). Free amino groups were visualized using ninhydrin spray and sugar residues using 5% sulfuric acid in ethanol. Upon completion, the mixture was dried under vacuo and the product deacetylated with $Et_3N:CH_3OH:H_2O$ (2:6:10; v/v/v) at a final concentration of 0.5 mg/mL. After being stirred at 37 °C for 4 h, the reaction was dried, washed with 10 m*M* HCl in 90% EtOH (*51*), dried again, and purified on a BioGel P2 column. Fractions were spotted on TLC plates, and carbohydrate-containing conjugates were visualized with 5% H_2SO_4 in EtOH. Fractions containing the purified glycodendrimers were pooled, dried, and lyophilized. Once dried, the average molecular weights of the glycodendrimers were determined by MALDI-TOF MS. Glycodendrimers that were built by conjugating **1** to DAB-Am dendrimers, generations 1−5, are referred to as glycodendrimers, **1a**−**e**, where **1a** is the 4-mer glycodendrimer and **1e** is the 64-mer. Likewise, glycodendrimers made from compounds **2** and **3** are referred to as glycodendrimers **2a**−**e** and **3c**−**e**.

Direct Sulfation of Dendrimers Derivatized with 3-(β-D-Galactopyranosylthio)propionic Acid (2c, 2d, and 2e). Random sulfation of **2c**, **2d**, and **2e** was done in order to make sulfated 3-(β-D-galactopyranosylthio)-propionic acid-derivatized dendrimers. 30 mgs of **2c**, **2d**, or **2e** were taken up in 30 mL of DMF, prior to the addition of SO_3NMe_3 (2 equiv per hydroxyl group). The reaction mixture was refluxed with stirring at 60 °C for 30 h and then dried by rotary evaporation under reduced pressure supplied by an oil vacuum pump. Dried films were taken up in 2 mL of 1 M NaCl, and **4c**, **4d**, and **4e** were purified by size-exclusion chromatography on a BioGel P2 column, using water as the eluate.

Matrix-Assisted Laser Desorption Ionization Time-of-Flight (MALDI-TOF) Mass Spectrometry. MALDI-TOF MS was done on a Perseptive Biosystems Voyager DE-PRO spectrometer. Spectra (100) of negatively charged sugars were generated in linear, negative ion mode using THAP matrix, or in linear, positive ion mode using IAA. Glycodendrimer spectra (200) were generated in linear, positive ion mode using an IAA matrix (20 mg/mL in DMF, diluted 11:1 with a 1 mM aqueous solution of glycodendrimer to yield a matrix-to-analyte ratio of ~1000:1) (*57*). In some instances, negative ion mode was used to detect the sulfated glycodendrimers. Average molecular weights and polydispersities of the glycodendrimers were calculated using Data Explorer version 4.0 (Applied Biosystems). Macros within this software allow for the calculation of M_n (the number-average molecular weight), M_w (the weight-average molecular weight), and the polydispersity (PD) from the ratio of M_w to M_n according to the following equations:

$$M_n = \sum(N_i M_i)/\sum N_i$$

$$M_w = \sum(N_i M_i^2)/\sum N_i M_i$$

where N_i and M_i represent signal intensity and mass at point *i*, respectively (*58*, *59*).

Nuclear Magnetic Resonance (NMR) Analyses. All spectra were obtained on a Bruker DRX-400 NMR spectrometer operating in the quadrature mode at 25.0 °C using a triple-axis-gradient broadband inverse probe. ^1H chemical shifts were referenced indirectly to TMS (0

ppm) via DSS (sodium-2,2-dimethyl-2-silapentane-5-sulfonate), a secondary reference. ^{13}C chemical shifts were referenced indirectly to TMS (0 ppm) via acetone (30.89 and 215.9 ppm), a secondary reference. All samples were dissolved in D_2O. One bond $^1H-^{13}C$ correlation 2D spectra were obtained using the gradient-selected version of the phase-sensitive HMQC experiment. Long range (2 and 3 bond) $^1H-^{13}C$ correlation 2D spectra were obtained using the gradient-selected version of the magnitude-mode HMBC experiment. When necessary for assignment purposes, gradient-selected Double-Quantum-Filtered COSY experiments were used to verify $^1H-^1H$ couplings.

Surface Plasmon Resonance. SPR experiments were done at 25 °C using a Biacore 3000 system and CM5 sensor chips (Biacore, Uppsala, Sweden). Glycodendrimers **1c**−**e** and **2c**−**e** were amine-coupled to the sensor chip according to the manufacturer's protocol, using the free amines that were not functionalized on the glycodendrimers. To obtain a low-density surface suitable for affinity analysis, 350−500 RUs of each glycodendrimer were immobilized. Varying concentrations of rgp120 (62.5−0.98 nM) were injected simultaneously over a blank control surface and the immobilized glycodendrimers at a flow rate of 30 μL/min for 3 min in HBS-EP buffer (10 mM HEPES, 150 mM NaCl, 3 mM EDTA, 0.005% P-20 surfactant, pH 7.4). Following the injection, the dissociation of the rgp120-glycodendrimer complex was measured for 10 min. Any remaining bound rgp120 was removed by a 1 min injection of 4 M KCl. This regeneration step prepared the surface for the next injection of rgp120. Each concentration of rgp120 was injected in duplicate over the immobilized glycodendrimer, with a representative sensorgram chosen for analysis.

The sulfated glycodendrimers, **4c**−**e**, did not couple to the CM5 chip, presumably due to repulsion of the negatively charged sulfate groups by the negatively charged carboxyl groups on the carboxymethylated dextran matrix. Therefore, approximately 3000 RUs of rgp120 was amine-coupled to the CM5 sensor chip and the potential ligand used as analyte. DxS (50 kDa, 12.5−0.39 nM), **4c**, **4d**, or **4e** (89−0.36 nM) were injected simultaneously over a blank control surface and the immobilized rgp120 at a flow rate of 30 μL/min, for 3 min. Dissociation of the complex was measured for 10 min, followed by a 1 min injection of 4 M KCl to regenerate the rgp120 surface. Nonspecific binding was accounted for by subtraction of the blank control surface from each of the test surfaces. Subtracted sensorgrams were then analyzed by fitting the data to a 1:1 (Langmuir) binding model and kinetic constants determined using the BiaEvaluation 3.2 software.

Cell Culture. U373-MAGI-CCR5 cells were obtained from the AIDS Reagent Program #3597. Cells were propagated in 'Selection Media' consisting of DMEM supplemented with 10% FCS, 0.4 mg/mL L-glutamine, penicillin and streptomycin (0.08 mg/mL each), 0.05% sodium bicarbonate, 0.2 mg/mL G418, 0.1 mg/mL hyrgromycin B, and 1.0 ug/mL puromycin. 'Culture Media' for virus inhibition assays consisted of DMEM with 10% FCS and 0.05% sodium bicarbonate. Cells were grown at 37 °C in an atmosphere of 95% air/5% CO_2.

Viral Inhibition Assays. Cells, in Selection Media, were plated in 96-well tissue culture plates at a density of 1.0×10^4 cells per well. One day later, commercially available (Advanced Biotechnologies, Columbia, MD), concentrated cell-free viral preparations of HIV-1 Ba-L (R5) were diluted 1:400 in 'Culture Media'. Glycodendrimer and DxS stock solutions were made up in culture media and serially diluted with culture media in separate sterile V-bottom 96-well microtiter plates, to a final volume of 30 μL per well. This was followed by the addition of 30 μL of the diluted virus and incubation at 37 °C for ∼ 20 min. Selection Media was then removed from the plated cells, and 50 μL of virus or virus plus potential inhibitor was added to the plated cells. The virus- or virus plus inhibitor-exposed cells were then incubated at 37 °C in an atmosphere of 95% air/5% CO_2 for 2 h. After the absorption period, 200 μL of Culture Media was added to the wells, and the cells were allowed to grow for an additional 40−48 h. Cells treated with culture media served as negative controls, and cells treated with virus only were positive controls. All measurements were done in quadruplicate.

After the 48 h incubation, culture media was removed from the wells, the cells were washed with 200 μL of PBS, and β-galactosidase activity was measured using the Galacto-Star β-Galactosidase Reporter Gene Assay System from Applied Biosystems (Foster City, CA), according to the manufacturer's instructions. Briefly, after the cells were washed with PBS, 10 μL of lysis solution was added to each well and the plate incubated for 10 min at 37 °C. The Galacto-Star substrate was diluted 1:50 and 100 μL added to each well containing cell lysate. Well contents were mixed and 90 μL were removed and added to a 96-well opaque luminometer plate. One hour after the Galacto-Star substrate was added, luminescence was determined using a luminometer. Percent inhibition was determined as $[(L_{\text{no inhibitor}} - L_{\text{inhibitor}})/L_{\text{no inhibitor}}] \times 100$. The effective concentration that inhibited 50% of viral infectivity (EC_{50}) was determined by plotting the percent inhibition versus the log of the concentration of the potential inhibitor.

Cytotoxicity. The effect of the glycodendrimers and control compounds on cell viability was determined using the CellTiter 96 AQ_{ueous} Cell Proliferation Assay (Promega, Madison, WI). In this viability assay, mitochondrial dehydrogenases in metabolically active cells catalyze the conversion of MTS into a formazan product. The absorbance of formazan is read at 490 nm and is directly proportional to the number of viable cells. Assays were performed according to the manufacturer's instructions.

Replicate 96-well plates of each of the HIV infection inhibition assay plates were set up and treated identically, with the exception that no virus was added to the cells. After the 48 h incubation, the cell culture media was removed, cells were washed with PBS, and 100 μL of culture media was added to each well. The MTS reagent was mixed with the electron coupling reagent PMS according to the instructions, and 100 μL of the mixture was added to the cells. The 96-well replicate plates were incubated for 3 h at 37 °C, in an atmosphere of 95% air/5% CO_2, and absorbance was read on an ELISA plate reader at 490 nm. Cell viability indices were calculated by dividing the average absorbance of nontreated cells (negative control wells) into the average absorbance obtained for each concentration of each compound tested. Therefore, nontreated cells would have a viability index of 1.0 while that for cells exposed to cytotoxic compounds would be less than 1.0. The index obtained for each concentration of a compound was then used to correct for inhibition due to cell death induced by a potential inhibitor.

RESULTS

Synthesis of Spacer-Arm Derivatized Saccharides. To build multivalent GalCer and SGalCer derivatized dendrimers, the saccharide moiety of GalCer and

SGalCer (galactose and galactose-3-sulfate, respectively), containing a portion of the sphingosine moiety, were isolated from the natural GSLs (Scheme 1). Techniques described by Mylvaganum and Lingwood, for the preparation of glycolipid ceramide saccharides for neoglycoconjugation (*51*), were used for the synthesis of the peracetylated ceramide saccharides directly from GalCer (**1**) and SGalCer. This was achieved by deacylation of the GSL followed by its acetylation to block vicinal hydroxyls prior to oxidative cleavage of the double bond of the sphingosine to obtain the acetylated "ceramide saccharide" (Scheme 1). The carboxyl group of the *N*-acetylated butyric acid provided the reactive group needed to link the sugar to a primary amine on the dendrimer core. The yield of ceramide saccharide derivative of SGalCer obtained was very low (<20%), and the resulting product did not conjugate to the DAB-Am dendrimers efficiently. Also, according to MALDI-TOF MS, deacetylation of the peracetyl SGalCer ceramide saccharide resulted in the loss of approximately 40% of the sulfate residues (data not shown). Therefore, this approach was not pursued.

These results led to a search for a more efficient method of making galactopyranosyl and 3-sulfogalactopyranosyl derivatized dendrimers. The method described by Ashton et al. for the synthesis of 3-(*β*-D-galactopyranosylthio)propionic acid (**2**) was used to derivatize the sugars with a spacer arm that could be used to link them to the DAB-Am dendrimers (*60*). This method was efficient, with the yield of derivatized galactose molecules greater than 80%. While **2** was not made directly from natural GSLs, its structure is similar to **1**, and it may actually be better suited for synthesis of neoglycoconjugates because the thioglycosidic linkage is more resistant to cleavage by endogenous glycosidases than the corresponding *O*-glycosides (*61*).

To make a spacer-arm derivatized galactose-3-sulfate molecule, the novel 3′-sulfated derivative of **2** was made according to methods described by Lubineau and Lemoine, and Guilbert et al. for the regioselective sulfation of dibutylstannylene acetals (*54*, *62*). In this technique, dibutyltin oxide was used to form stannylene acetal complexes between cis diols, C-3 and C-4 on compound **2** (63) (Scheme 2). The C-3 was then preferentially sulfated by reacting the complex with SO_3NMe_3 in DMF for 30 h at 60 °C. After purification, novel **3** was obtained in ∼70% yield. NMR data shown in Table 1 confirmed that sulfation occurred at position C-3. The chemical shifts obtained agree with those published by Ikami et al. (1997) for compounds they synthesized as sulfatide mimetics (*64*). HPTLC (Figure 1) indicated that the precursors used and the compounds synthesized (**1**, **2**, and **3)** contained no visible contaminants. It can be seen that the less polar GalCer (Figure 1, lane a), peracetylated psychosine (lane c), and galactose-*β*-D-pentaacetate (lane e) migrated closest to the solvent front while the more polar compounds **2** (lane g) and **3** (lane h) had the slowest mobilities.

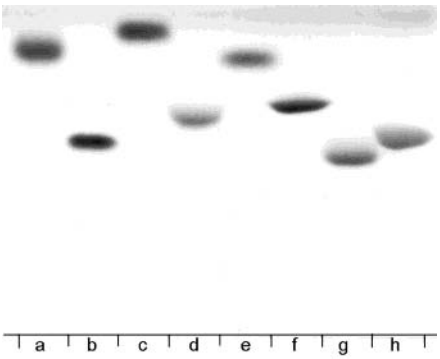

Figure 1. HPTLC showing the relative mobilities of functionalized carbohydrates and their precursors. (a) GalCer; (b) psychosine; (c) peracetylated psychosine; (d) GalCer ceramide saccharide (**1**); (e) galactose-*β*-D-pentaacetate; (f) peracetylated 3-(*β*-D-galactopyranosylthio)propionic acid; (g) 3-(*β*-D-galactopyranosyl-thio)propionic acid (**2**); (h) 3-(3-sulfo-*β*-D-galactopyranosylthio)propionic acid (**3**). The plate was chromatographed in 2:1:1 BuOH:CH_3OH:H_2O (v/v/v), and compounds visualized by charring with 5% H_2SO_4 in EtOH.

Conjugation of Derivatized Saccharides to DAB-Am Dendrimers. Compounds **1**, **2**, and **3** were conjugated to DAB-Am dendrimers, generations 1−5, by amine-coupling the terminal carboxyl groups on the derivatized saccharides to the terminal primary amines on the DAB-Am dendrimers. The carboxyl activator, HATU, commonly used in peptide synthesis, was used to activate the peracetylated derivatized saccharides. In this manner glycodendrimers **1a**−**e, 2a**−**e,** and **3c**−**e** were built; where the designations **a**−**e** correspond to DAB-Am generations 1−5, respectively (Figure 2). MALDI-TOF MS was used to determine the average number of saccharide residues incorporated onto the DAB-Am dendrimers. To calculate the average number of residues incorporated, the theoretical molecular weight of the starting DAB-Am dendrimer was subtracted from the M_w of the functionalized dendrimer and the difference divided by the weight of one derivatized saccharide, minus 18 Da to account for the loss of a H_2O molecule during formation of the amide bond. Table 2 shows the average molecular weights (M_w), polydispersities (PD), and average number of incorporated sugars for glycodendrimers **1a**−**e**, **2a**−**e**, and **3c**−**e**.

MALDI-TOF MS analysis revealed that less than 50% of the dendrimer arms were derivatized with **3**. Failure to fully link **3** to the DAB-Am dendrimers may have been due to the lack of solubility of the sulfated products formed during the reaction, or due to steric hindrance enhanced by electrostatic repulsion between sulfate groups. Regardless, attempts to build a fully functionalized gal-3-sulfate derivatized dendrimer by directly coupling **3** to a DAB-Am dendrimer core were unsuccessful. Therefore, regioselective sulfation of the C-3 position on the galactose moieties of galactose-derivatized dendrimers **2a**−**e**, via the stannylene acetal intermediate was tried. However, this approach was also unsuccessful, presumably due to the solubility differences between the dibutyltin oxide reagent and the glycoden-

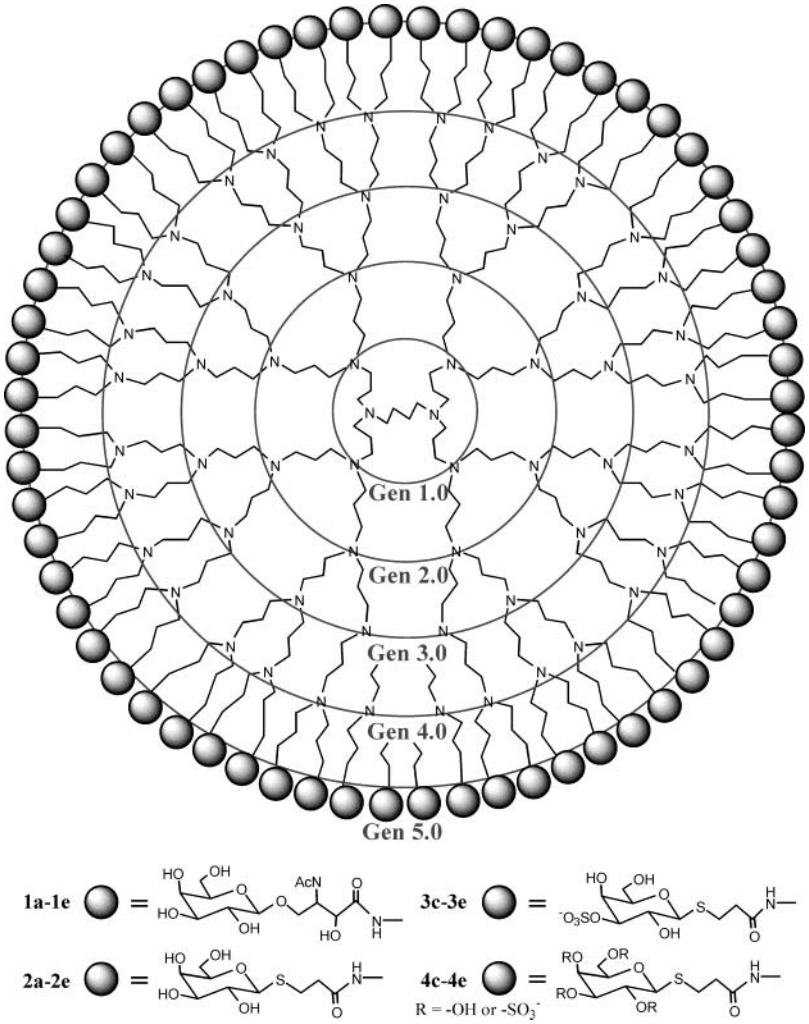

Figure 2. Schematic representation of the glycodendrimers synthesized. The generation circles indicate where one generation ends, and the next begins. Glycodendrimers are labeled according to their functionalized compounds **1**, **2**, **3**, or **4** followed by the generation of dendrimer, where generations 1−5 correspond to a−e, respectively.

drimers **2a**−**e**. Therefore, glycodendrimers **2c**, **2d**, and **2e** were randomly sulfated using a 2-fold excess of SO_3NMe_3 per hydroxyl group. This gave the sulfated galactose-derivatized dendrimers **4c**, **4d**, and **4e** (Figure 2). Subtraction of the starting molecular weights of **2c**, **2d**, and **2e** from the respective sulfated products **4c**, **4d**, and **4e**, followed by division of the molecular weight of one sulfate−pyridine salt minus 1 H^+ (158), gave the average number of sulfate groups incorporated (Table 2). MALDI-TOF MS analysis indicated that on average 12, 23, and 34 sulfate groups were added to the glycodendrimers **4c**, **4d**, and **4e**, respectively (Table 2). Proton NMR analysis of the randomly sulfated **4d** glycodendrimer showed broad, overlapping peaks for the H-2 through H-6 protons, suggesting that different hydroxyls were sulfated (data not shown). While the relative amount of sulfation of each hydroxyl was not determined, reports in the literature indicate that sulfation most likely occurred at C-6 followed by C-4 and C-3 (*62*, *65*).

Kinetic Analysis of the Interaction between rgp120 IIIB and the Synthesized Glycodendrimers. SPR was used to study the binding kinetics of rgp120 to the different derivatized dendrimers. Sensorgrams were analyzed by fitting the data to a 1:1 (Langmuir) binding model and kinetic constants determined using the BiaEvaluation 3.2 software. Rate constants and affinity constants for the interaction of rgp120 with each of the glycodendrimers and DxS are shown in Table 3. Overall, the affinities of rgp120 for the various glycodendrimers were in the nanomolar range, with the SGal-derivatized denrimers (**4c**−**e**) displaying somewhat stronger affinities than their Gal-derivatized dendrimer counterparts (**2c**−**e**). Gp120 had the greatest affinity for DxS, with an equilibrium dissociation constant (K_D) of 2.29×10^{-11}.

Inhibition of HIV-1 Ba-L Infection of Cultured Glioblastoma Indicator Cells. Glycodendrimers **1c**−**e**, **2c**−**e,** and **4c**−**e**, and DxS 50 kDa, were tested for their ability to inhibit HIV-1 BaL (R5-tropic) infection of U373-MAGI−CCR5 cells and their affect on cell viability. The 4- and 8-mer derivatized dendrimers were not tested due to preliminary results that indicated that the larger molecules were better inhibitors. The observed EC_{50s} for the sulfated glycodendrimers **4c**, **4d**, and **4e** were 90μM, 70μM, and 20μM, respectively (Figure 3). While the increase in inhibition seen with increasing size of the sulfated glycodendrimers was small, it was reproducible. DxS was a potent inhibitor of infection by HIV-1 BaL with an EC_{50} lower than that of the lowest concentration tested, 1.6 μM. The galactose functionalized glycodendrimers (**1c**−**e** and **2c**−**e**) showed little or no inhibitory effect. The 50% inhibition level was not reached at concentrations of galactose-derivatized dendrimer as high as 2.5 mg/ml (see Figure 3 for data for **2d**). Neither **4c**−**e**, **2d**, nor DxS were cytotoxic to the cultured indicator cells at the highest concentrations tested (2.5 mg/ml).

DISSCUSSION

SPR is a powerful technique for examining the association of two biological molecules; however, to correctly interpret the data, certain experimental conditions must be met. For the SPR studies reported here, two control experiments were done to determine the validity of the binding data and the 1:1 model used. The first was a mass transfer control experiment. This was done to determine whether the association rate was limited by the transport of analyte from the bulk solution to the immobilized ligand on the sensor chip surface. For each of the nonsulfated glycodendrimers, a single concentration of analyte (gp120) was injected over the ligand at three different flow rates (5, 15, and 75 μL/min). The association phases were then overlaid to determine whether binding was increased by the increased flow rate. In each case, this was not observed, indicating that binding was not limited by mass transport. The second control experiment was to determine whether the association and dissociation steps occurred in a single phase. Again, for each glycodendrimer tested, a single concentration of analyte was injected over the ligand at a constant flow rate, but for different lengths of time (1, 3, and 20 min). The dissociation phases were then overlaid to determine whether there were any differences. Typically, if binding is biphasic, a more stable complex will form over time. This complex will then dissociate more slowly than the less stable complex. For example, if the binding was biphasic, a 20 min injection would most likely allow for the formation of a more stable complex and give a slower dissociation rate than a 1 min injection. For each sample studied, no differences in the dissociation phases were observed, which indicated that the binding in each case was monophasic.

Another variable that must be accounted for is the goodness of fit of the binding model applied to the data. An indication of the goodness of fit of a model to the data is the residual plot (shown in Supporting Information). The residuals are simply the difference between the data and the fitted model. Residuals should be less than 5% of the experimental R_{max} (maximum binding response). For each of the fits reported here, the residuals were generally less than 5% of the experimental R_{max}. Another indication of the goodness of fit of the model to the data is the χ^2 value. The χ^2 is a numerical representation of the goodness of fit, the sum of the squared residuals (see Supporting Information). The χ^2 value should be less than 5% of the experimental R_{max}. Each of the χ^2 values reported here was less than 5% of the R_{max}.

Although the glycodendrimers are multivalent ligands, the results from the SPR data indicated that the 1:1 (Langmuir) binding model accurately described the interaction of rgp120 with both DxS and each of the glycodendrimers tested. This model assumes that each analyte binds independently, in one step, to a single site on the immobilized ligand. Control experiments were

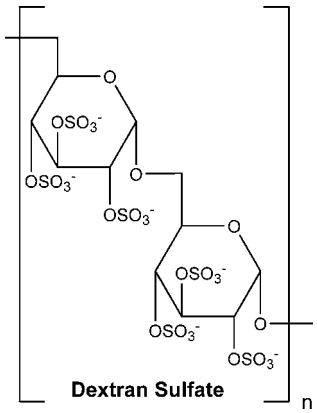

Figure 4. Structure of DxS. All hydroxyls are shown as sulfated.

performed to determine the presence of mass transfer limitations or multiphasic binding. No clear deviations from a 1:1 interaction were observed for the glycodendrimers or DxS. Additionally, the chi square (χ^2), an indication of the goodness of fit of the data to the model, was less than 5% of R_{max} for each of the fits reported. Therefore, the fits meet the requirements for acceptable SPR kinetic data.

The observation that rgp120 contains a single high affinity binding site for the GalCer mimetic glycondendrimers agrees with the affinities reported for gp120 binding to GalCer (8,13). It was interesting to note, however, that despite the observed nanomolar affinity of gp120 for the GalCer mimetic glycodendrimers (**1c**−**e** and **2c**−**e**), no inhibition of HIV-1 Ba-L infection was seen (Figure 3). In contrast, the SGal glycodendrimers (**4c**−**e**), which were also bound by rgp120 with nanomolar affinity, were able to inhibit HIV-1 Ba-L infection of the cultured indicator cells with micromolar EC_{50s} (corresponding to ∼0.5 mg/mL). Interestingly, the affinity of rgp120 IIIB for DxS was much greater than that for the derivatized dendrimers. However, DxS is a known potent binding antagonist of HIV infection in vitro, and the EC_{50} of DxS observed in Figure 3A was lower than the lowest concentration tested (1.6 μM or 80 μg/mL), which may reflect the picomolar affinity of gp120 for DxS. Therefore, for the sulfated glycodendrimers and DxS, it appears as though the SPR data is a good indication of inhibition of HIV infectivity. We hypothesize that the lack of inhibition by the nonsulfated glycodendrimers reflects their inability to block the interaction of the positively charged V3-loop of gp120 with the negatively charged, sulfated-tyrosine residues of the N-terminus of the chemokine coreceptors (*66*). The fact that DxS was reported to bind gp120 at the V3-loop, thus preventing interaction with the chemokine co-receptors (*67*), and the fact that GalCer was also reported to bind at or near the V3-loop (*7*, *9*, *68*), supports this hypothesis. Despite its binding to the V3-loop, GalCer apparently does not inhibit the interaction of the V3-loop with the sulfated-amino terminus of the chemokine coreceptors (CXCR4 and CCR5); and therefore, does not prevent the formation of the fusion pore complex.

The affinity and infectivity differences observed for the glycodendrimers and DxS are likely due to structural differences. DxS consists of repeating, branched glucose units linked (β1−6). It is made up of approximately 17% sulfur, which corresponds to approximately 2.3 sulfate groups per repeating glucosyl residue (Figure 4). Therefore, the degree of sulfation for DxS is more than twice that of the sulfated glycodendrimers **4c**−**e**, which had on average less than 1 sulfate group per galactose residue. Division of the average molecular weight of DxS (50 kDa) by the MW of one glucosyl residue with 2.3 sulfates, and multiplication of that value by 2.3 results in an estimation of 387 sulfate groups per molecule of DxS. In contrast, glycodendrimer **4e** had only 34 sulfate groups per molecule. The observation that rgp120 bound to glycodendrimer **4e** with a K_D of 1.9×10^{-9} and to DxS with a K_D of 2.34×10^{-11} allows the hypothesis that the incorporation of another one or two sulfate groups per galactose residue of compounds **4c**−**e** might result in their being bound with greater affinity by rgp120. The fact that sulfate groups on DxS are found on C-2, C-3, and C-4 of its repeating glucosyl residues, combined with the likelihood that the sulfates on glycodendrimers **4c**−**e** are on C-6, and then C-4 and C-3, permits the hypothesis that addition of a sulfate to the C-3 position of the galactosyl residues on **4c**−**e** might increase their ability to function as ligands for gp120 IIIB. In conclusion, the randomly sulfated galactose-derivatized dendrimers described are good ligands for rgp120 IIIB and may serve as the basis for the development of a novel class of HIV-1 binding antagonists.

ACKNOWLEDGMENT

We thank Dr. Mary Cloninger for her helpful conversations and for the MADLI-TOF glycodendrimer protocol, Dr. Bruce Stanley for his teaching and instruction regarding the use of the MALDI-TOF mass spectrometer, and Dr. Samir Qamar for his help with purifying and deacylating GalCer. We also thank our collaborators, Dr. Brian Wigdahl, Dr. Fred Krebs, and Dr. Bradley Cantalone, for their input into the HIV inhibition and cytotoxicity experiments. This work was supported in part by Public Health Service grants RO1 NS40231 to C-L.S. and F31 NS11184-01 to R.D.K. from the National Institute of Neurological Disorders and Stroke.

Supporting Information Available: NMR spectra for compounds **1**, **2**, and **3**, representative SPR data fit for compound **2d**, and MALDI-TOF MS traces. This material is available free of charge via the Internet at http://pubs.acs.org.
