All of the results obtained in the present paper show that the liposomal encapsulation of GO containing a slight amount of catalase remarkably improves the efficiency and durability of both enzymes in comparison with the free GO plus catalase system. It is quite meaningful that such a slight amount of catalase as contained in the commercially available GO is enough for the continuous decomposition of H_2O_2 in the liposomal glucose oxidation. The interactions between the lipid bilayer membranes, catalase contained in a slight amount, and H_2O_2 produced should be examined in detail to fully understand the mechanism of the H_2O_2 decomposition observed in the GOL. Nevertheless, the liposomal GO almost completely free of the inhibition would be a useful biocatalyst in the practical bioreactor operated under oxidative conditions.

Magneto/Optical Annexin V, a Multimodal Protein

Eyk A. Schellenberger,[†,‡] David Sosnovik,[†] Ralph Weissleder,[†] and Lee Josephson*[,†]

Center for Molecular Imaging Research, Massachusetts General Hospital, Building 149, 13th Street, Charlestown, Massachusetts 02129, and Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115. Received April 14, 2004; Revised Manuscript Received June 15, 2004

Multimodal proteins, or proteins labeled with both fluorescent and magnetic reporter groups, can be used in a wide range of applications including FACS or fluorescence microscopy, MRI and or near-infrared based optical imaging, or to fractionate cells by magnetic cell sorting. A problem with multimodal proteins, however, is the need to maximize bioactivity, often achieved by minimizing the number of modification points of the protein, while attaching fluorescent and magnetic labels. Here we describe the synthesis of a magneto/optical form of annexin V, achieved by reacting the amino-CLIO nanoparticle with Cy5.5 and SPDP, to produce a fluorescent, sulfhydryl reactive nanoparticle. A single reactive sulfhydryl group was added to annexin V by reaction with SATA that preserved the protein's ability to bind apoptotic Jurkat T cells. Reacting SATAylated annexin V with an SPDP activated nanoparticle yielded Anx-CLIO−Cy5.5, a magneto/optical form of annexin V. The binding of Anx-CLIO−Cy5.5 was specific for apoptotic Jurkat T cells and had an EC_{50} of 3.66 nM. This was comparable to the strength of the interaction of unmodified annexin V with apoptotic cells, measured as the displacement of FITC−annexin by annexin V (2.4 nM). Our conjugation strategy preserves the strength of the interaction between annexin V and apoptotic cells, while yielding a probe, Anx-CLIO−Cy5.5, that is readily detectable by standard MR imaging or NIRF optical methods.

INTRODUCTION

Programmed cell death or apoptosis plays a crucial role during development (embryogenesis), for the maintenance of cellular homeostasis in the adult, and in the pathology of a wide range of diseases. Apoptosis is a central feature in diseases such as AIDS, neurodegenerative disorders (e.g., Alzheimer's disease), in myelodysplastic syndromes such as aplastic anemia and thalassemia, in progressive heart failure, for chronic hepatitis, and for transplant rejection (*1*−*3*). As cells proceed along pathways to apoptosis, phosphatidylserine (PS), a lipid normally facing the cytoplasm, flips and faces the extracellular fluid (*4*, *5*). The human protein annexin V (36 kDa) binds PS strongly and specifically, which is a reflection of a biological role as an anticoagulant (*6*, *7*). The binding of annexin V to PS is an attractive method for determining apoptosis in organs and tissues since PS is expressed early in the commitment to apoptosis (*4*, *8*) and is a feature of apoptotic cells regardless of how apoptosis is induced (*7*).

The ability of annexin V to recognize PS has led to the development of fluorescent or magnetic annexins that are useful in a variety of applications. Annexin V labeled with FITC is a widely used for identifying apoptotic cells by FACS (*9*, *10*), while a Cy5.5 labeled annexin V has been used for the NIRF/optical imaging of chemotherapy-induced apoptosis (*11*, *12*). Magnetic annexin V's are useful reagents for the removal of apopotic cells (*13*, *14*).

Here we describe the development of a magneto/optical annexin V that retains its binding activity for apoptotic cells, while being detectable by both fluorescent and magnetic resonance imaging modalities. Unlike earlier modified annexin V's, which are based on the direct attachment of fluorochromes to annexin V, or the conjugation of annexin V to magnetic particles, the magneto/optical annexin V is based on the attachment of annexin V to a nanoparticle that is both magnetic and fluorescent. The multimodal annexin V can be used with cell-based, fluorescence methods to identify apoptotic cells (FACS or fluorescent microscopy), with small animal optical imaging, or by MRI.

MATERIALS AND METHODS

Synthesis of Magneto/Optical Annexin V. The synthesis of magneto/optical annexin V consisted of three steps. First, the amino-CLIO (cross-linked iron oxide) nanoparticle was labeled with Cy5.5 and activated with SPDP, to yield a compound termed 2PySS−CLIO−Cy5.5. Second, annexin V was reacted with SATA in a manner that preserved its affinity for apoptotic cells Third, SATAylated annexin V was reacted with 2PySS−CLIO−Cy5.5 to yield the multimodal nanoparticle Anx-CLIO−Cy5.5.

Amino-CLIO was prepared as described (*15*, *16*). To 3.5 mL of amino-CLIO (∼10 mg Fe) we added 2.36 mL of 0.1 M sodium bicarbonate, pH 8.5. The buffered nanoparticle was then added to 1.75 mg of the monofunctional *N*-hydroxysuccinimde ester of Cy5.5 (Amersham-Pharmacia, Piscataway, NJ) dissolved in 0.175 mL of DMSO and incubated for 2 h at room temperature. We then added 0.6 mL of 120 mM SPDP (*N*-succinimidyl 3-(2-pyridyldithio) propionate) in DMSO and incubated for an additional 2 h. Unreacted Cy5.5 and SPDP were removed by gel filtration (Sephadex G-25 column equilibrated with 0.02 M Na citrate, 0.02 M Na borate, 0.9 M NaCl, pH 8.5). The number of Cy5.5 per nanoparticle was

determined from the concentrations of iron (*16*) and Cy5.5 dye, the later being determined spectrophotometrically (E_{678} = 250 000), and by assuming 2064 iron atoms per nanoparticle (*17*). The number of 2PySS groups per nanoparticle was determined after the release of 2-pyridine-thione (2-PT) with dithiothreitol (*18*). The resulting nanoparticle, termed 2PySS−CLIO−Cy5.5, was stored at 4 °C until needed.

Annexin V was obtained from Theseus Imaging Corporation (Worcester, MA). To 1 mL of annexin V (3 mg) was added 600 μL of 0.1 M sodium bicarbonate, pH 8.6, and 12 μL of 10.8 mM SATA (*N*-succinimidyl 3-(2-pyridylthio)propionate, S-acetylthioactetate) dissolved in DMSO. After 1 h at room temperature under argon, 220 μL of a solution of 0.01 M hydroxylamine, 0.01 M EDTA (pH 8) was added. The mixture was incubated for 40 min at room temperature under argon, and unreacted SATA separated from annexin V by spin separation (Biogel P6 columns equilibrated with 0.1 M sodium bicarbonate, pH 8).

We then added 200 μL of 2Py-SS−CLIO−Cy5.5 to the SATAylated annexin V and allowed the mixture to stand overnight at room temperature under argon. Unreacted annexin V was removed by gel filtration (Sephadex G-150 equilibrated in 0.02 citrate 0.15 M NaCl, pH 8). Protein content of the resulting nanoparticle was determined by the BCA method (Pierce Chemical, Rockford, IL). Size of the nanoparticle was determined by light scattering using a Zetasizer (Malvern Instruments, Westboro, MA). Relaxivities were measured at 0.47 T and 40 °C using a relaxometer (Bruker Instruments, Braintree, MA).

Interaction of Anx-CLIO−Cy5.5 with Apoptotic Cells. Jurkat T cell cells (Clone E6−1, ATCC #TIB-152) grown in RPMI 1640 medium with 10% fetal bovine serum (Vitacell #30−2021, ATCC, Manassas VA) changed every 2 or 3 days were used in all studies. Apoptosis was induced by the addition of 7 μL of camptothecin (1 mM in DMSO) per milliliter of culture medium for 5−6 h at 37 °C. Induction of apoptosis was verified by staining with propidium iodide and FITC−annexin V using a calcium-containing binding buffer (1.8 mM $CaCl_2$, 10 mM HEPES, 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, pH 7.4). The cells were then analyzed with a FACS−Calibur cytometer (Becton Dickinson, San Jose, CA).

Competition Experiments. The dye-annexin V's we employed (Cy5.5 or FITC) had one mole of dye per mole of annexin V and were prepared as described (*11*, *12*). To assess the bioactivity of annexin V SATAylated to various extents, the ability to block the binding of FITC−annexin V to apoptotic cells was determined by FACS (*11*). Camptothecin-treated Jurkat T cells (10^4−10^5 cells) were incubated with different SATAylated annexin V's (1.0 μg in 200 μL binding buffer) for 5 min at room temperature. FITC−annexin V (0.1 μg) was then added for an additional 10 min at room temperature. Binding of FITC−annexin V to apoptotic cells was determined from the medians of the highest peaks from the FACS analysis as described (*11*). The relative FITC−annexin V fluorescence (Figure 1) was obtained by dividing the median value obtained of SATAylated annexin V's by that median value with no SATAylated annexin, that is by normalization to the binding in the absence of a SATAylated annexin V. IC_{50} values of Anx-CLIO−Cy5.5, annexin V, and Cy5.5−annexin V were determined by the ability to displace FITC−annexin V (4.1 nM or 0.03 μg/500 μL) in the assay above. The direct binding of Anx-CLIO−Cy5.5 to apoptotic cells was assessed by determining the relative cell associated fluorescence in the Cy5.5 channel of the apoptotic cell fraction for camptothecin-treated Jurkat T cells over a range of probe concentrations. The data were fitted to sigmoidal dose−response curves to obtain EC_{50}'s, IC_{50}'s, values of the Hill coefficient (*n*), and the correlation coefficient (R^2), indicating the goodness of fit, using Prism 4 (GraphPad Software, San Diego, CA).

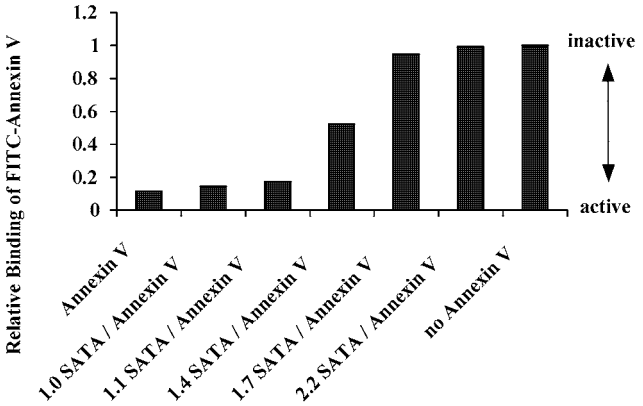

Figure 1. Binding of SATA−annexin V conjugates to camptothecin treated Jurkat T cells. Active SATA-annexin V's displace FITC-annexin V to yield a low Relative Binding by FACS. Inactive SATA-annexin V's, or no annexin V, fail to displace yielding a high Relative Binding. Relative binding is obtained by normalizing to the median fluorescence of the apoptotic cell fraction by FACS.

Optical and Magnetic Imaging With Anx-CLIO−Cy5.5. Jurkat T cells were incubated with Anx-CLIO−Cy5.5 (1 μg Fe/mL) for 10−15 min and washed twice with calcium binding buffer. Cell pellets in 300 μL tubes were prepared by centrifugation and imaged for surface reflectance fluorescence as described (*19*). MR imaging was performed on a 4.7 T Bruker BioSpin scanner. Transverse relation times (T2's) were determined by fitting signal intensity data (TE = 10−200 ms and TR = 2000 ms) to the spin echo signal intensity equation (*20*). A T2 weighted image was also taken at TE = 50/TR = 2000 (Figure 4).

RESULTS

Synthesis of Magneto/Optical Annexin V. The amino-CLIO nanoparticle was reacted with the NIRF dye Cy5.5 and then with the bifunctional reagent SPDP, followed by a single gel filtration step to remove all low molecular weight impurities. The nanoparticle, 2PySS−CLIO had 71 2PySS groups per nanoparticle, assuming 2064 Fe/nanoparticle (*17*). 2PySS−CLIO−Cy5.5 could be stored at 4 °C and is a general reagent for converting sulfhydryl-bearing proteins in to magneto/optical probes. The properties of the dual modality nanoparticle Anx-CLIO−Cy5.5 are summarized in Table 1.

The sensitivity of annexin V to modification of its amino groups by SATA using a FACS displacement assay is shown in Figure 1. The assay indicates that the attachment of one SATA per mole of annexin V does not affect binding to apoptotic cells. On the basis of these results, annexin V with on average one SATA per mole was reacted with the SPDP-activated amino-CLIO. The resulting nanoparticle had 3.5 annexin V's per nanoparticle with R1 and R2's of 19 and 48 $mM^{-1}\,s^{-1}$, respec-

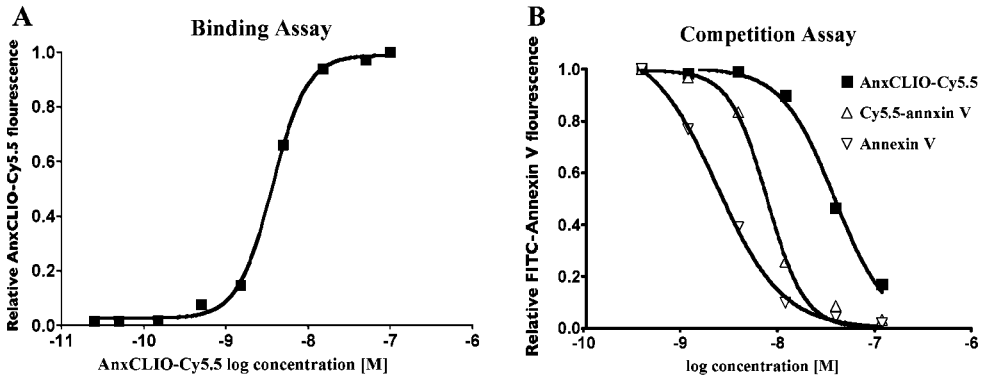
tively, and a diameter of 50 nm by light scattering, which are values similar to CLIO nanoparticles functionalized with other types of biomolecules (*15*, *21*, *22*).



Binding of Magneto/Optical Annexin V, Anx-CLIO−Cy5.5, to Apoptotic Cells. Dual wavelength FACS with FITC−annexin as a reference is an excellent method for examining the specificity of probes such as Anx-CLIO−Cy5.5 for apoptotic cells. Anx-CLIO−Cy5.5 and FITC−annexin V bound in a similar manner to individual cells with populations of normal (Figure 2A) or camptothecin-treated cells (Figure 2B). The binding of probes to cells was in a similar manner at least 95% of the time (Figure 2C). Thus, the conjugation of annexin V to CLIO preserves the specificity of the annexin V interaction with apoptotic cells.

We next examined the strength of the interaction of Anx-CLIO−Cy5.5 with apoptotic cells as shown in Figure 3, using both direct binding and displacement assays. Using the direct binding assay for Anx-CLIO−Cy5.5, we obtained an EC_{50} of 3.66 nM per mole of annexin V, which can be compared to values expressed as dissociation constants as low as 0.1 nM (*23*) or as high as 7 nM (*24*). The conjugation of annexin V to Anx-CLIO−Cy5.5 preserves the strength of the interaction between annexin V and apoptotic cells. However, when the ability of Anx-CLIO−Cy5.5 to displace FITC−annexin was examined, an IC_{50} of 39 nM was obtained which was higher than the IC_{50} for annexin V (2.40 nM) or Cy5.5-annexin (7.8 nM). The multimodal probe Anx-CLIO−Cy5.5 thus interacts with apoptotic cells specifically (Figure 2) and with an affinity similar to native annexin V (3.66 versus 2.40 nM). However, the Anx-CLIO−Cy5.5 nanoparticle, and annexin V protein may interact with the phosphatidylserine in a somewhat different fashion, based on their differing ability to displace FITC−annexin (Anx-CLIO−Cy5.5 IC_{50} = 39 nM; annexin V IC_{50} = 2.4 nM). The presence of 3.5 annexin V's presented on a single 50-nm nanoparticle may bind PS somewhat differently from the 36 kDa annexin V molecule.

Optical and Magnetic Imaging With Anx-CLIO−Cy5.5. We next examined the detection of cells labeled with Anx-CLIO−Cy5.5 by both NIRF and MR imaging modalities. A high signal intensity NIRF signal was observed with apoptotic but not normal cells (Figure 4B) and a corresponding decrease in signal intensity (darkening) of cells was obtained with a T2 weighted MR image (Figure 4C). T2's were 76 ms for the control and 37 ms for the camptothecin-treated cells.

DISCUSSION

Multimodal, or fluorescent and magnetic, nanoparticles have numerous advantages over single modality based probe designs (*25*−*27*). During the research phase of probe development, fluorescence can be used with FACS or fluorescence microscopy to characterize the specificity of interactions with cells or study intracellular processing. Small animal NIRF based imaging for assessing probe targeting is often more convenient and cheaper than MRI. Fluorescence permits the use of multiple, optically distinct fluorochrome probes in conjunction with FACS, microscopy, or animal imaging devices (*19*, *25*). However, despite the rapid advances in small animal optical imaging technology and possible translation of small animal to human imaging (*28*, *29*), the development

and distribution of NIRF based clinical imaging systems lie well in the future while MRI is an established imaging modality.

The strategy we have employed for the design of Anx-CLIO−Cy5.5 yields a multimodal (magnetic and fluorescent) form of annexin V that differs from earlier fluorescent, radioactive, or magnetic annexin V's (*10*, *11*, *30*, *31*). First, we preserved the PS binding activity of annexin V by optimizing the reaction between annexin V and SATA (Figure 1). Annexin V loses its PS binding activity if more than 1 lysine per mole is modified by either SATA or fluorochromes (*32*), and appears to be highly sensitive to modification. We then attached SATAylated annexin V (36 kDa) to the SPDP-activated CLIO, which was about 1000 kDa (or about 30 nm). The nanoparticle had 2064 Fe atoms and 1.8 Cy5.5 dyes per nanoparticle. The resulting Anx-CLIO−Cy5.5 probe was highly active compared to the parent annexin V (Figure 3). Anx-CLIO−Cy5.5 is a PS-binding magneto/optical form of annexin V that is about 1000 kDa rather than 36 kDa, featuring 590 Fe atoms per annexin V (2064/3.5) for MR detection and 0.5 Cy5.5 molecules per annexin V (1.8/3.5) for detection by fluorescence.

The low molecular weight, predominant renal elimination, and short blood half-life of the 36 kDa form of annexin V may limit its ability to bind its target PS. Annexin V shows predominant renal elimination with a blood half-life 24 min in humans (*33*) and less than 10 min in mice (*34*, *35*). Radiolabeled PEGylated annexin V's have been developed in an effort to increase blood half-life and improve PS targeting (*36*), but based on the sensitivity of annexin V to modification, the attachment of PEG and DTPA to a single annexin V poses a considerable risk of inactivating the PS binding activity. Anx-CLIO−Cy5.5 is too large to undergo renal elimination and may have a longer blood half-life than annexin V.

Magneto/optical nanoparticles have been successfully used in several in vivo imaging applications. A fluorescent nanoparticle was used to image the cathepsin B activity of lymph nodes in live mice by simple surface reflectance and to obtain high-resolution MR images of nanoparticle disposition (*27*). We have shown that intra-

venously injected Cy5.5 labeled CLIO is internalized by microglia cells, and can be used as a preoperative MR contrast agent for the visualization of brain tumor in an animal model (*26*). The agent also can be seen by NIRF surface reflectance after removal of the cranium, and provides a method of determining tumor margins intraoperatively. Multimodal probes utilizing dextran rather than nanoparticle carriers have employed gadolinium and (fluorochrome), and have been used to study stem cell migration (*37*, *38*).

The addition of a fluorochrome to the magnetic nanoparticle permits FACS analysis or fluorescent microscopy to determine the disposition of the MR contrast agent. The near-infrared fluorescence of Anx-CLIO−Cy5.5 is distinct from many fluorochromes such as fluorescein or Alexafluor 488, which can be used in colabeling studies to characterize the subpopulation of cells binding the multimodal nanoparticle by FACS analysis, without spillover or compensation. With tissue sections and fluorescent microscopy, there is considerably less background with NIRF probes because mammals do not synthesize near-infrared fluorochromes. Other approaches to visualizing nanoparticles, such as iron staining or histochemical methods, require specific staining reagents and can suffer from higher backgrounds.

The fluorescent and magnetic character of Anx-CLIO−Cy5.5 is not only well suited to the determination of probe behavior in vitro and preclinically, but also offers multiple pathways to the development of a clinical diagnostic agent. First, the fluorochrome can be dropped and an annexin V-polymer coated superparamagnetic iron oxide could be used as an MR contrast agent. Polymer-coated iron oxides are used as MR contrast agents for the liver, lymph nodes, and gastrointestinal tract, and are also used to treat anemia. Although optical imaging is undergoing rapid development (*39*, *40*), MRI currently has the advantages of wide clinical availability and the ability to visualize probe accumulation deep within the human body. Second, the targeting biomolecule, in this case annexin V, and NIRF fluorochromes might be attached to a fluorochrome loaded polymeric molecules such as dextran, to yield a high molecular weight form of annexin V for optical imaging. Annexin V at 36 kDa undergoes renal elimination (*33*, *35*), while higher molecular weight forms may have substantially different and, in some applications, improved pharmacokinetics.

The ability to image apoptotic cells in vivo would likely be of significant value in both the diagnosis and treatment of many diseases and treatments. However, in many organs only a small fraction cells undergo apoptosis at any given moment, and thus probes with an optimized conjugation and labeling chemistry may be needed. Future studies will determine the ability of Anx-CLIO−Cy5.5 to detect apoptosis as the percentage of apoptotic cells by MRI and NIRF imaging methods and compare the 36 kDa Dye-annexin V conjugates and Anx-CLIO−Cy5.5 nanoparticle as optical imaging agents.

Received February 24, 2004; Revised Manuscript Received June 10, 2004

Previously, we showed that labeled bitistatin analogues possessed excellent characteristics for imaging both deep-vein thrombosis and pulmonary embolism. We hypothesized that the N-terminal amino acid sequence of bitistatin, which is different from other disintegrins, likely interacts with the binding site of platelets to confer desirable properties to bitistatin for imaging. In this study, we present the design, synthesis, and initial biological testing of a short-chain analogue of the native 83-amino-acid bitistatin sequence. Our initial molecular modeling of the binding loop of bitistatin showed that the minimal sequence that represented the binding region was a cyclic 10 amino acid sequence *cyclo*[*Cys*−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−*Cys(S)*]. Systematic modeling of a truncated N-terminal sequence of bitistatin fused with the optimized binding region having a thioether sequence through a *Gaba* spacer ultimately yielded the 24-amino acid peptide, *cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH, **1**. The peptide was then coupled to the hydrazino-nicotinic acid bifunctional chelating agent and the purified adduct labeled with ^{99m}Tc using tricine as a coligand. Binding of the unlabeled and labeled peptide to stimulated human platelets was assayed in vitro. The ^{99m}Tc labeling yield was > 90%. The in vitro binding assays showed that the IC_{50} for inhibition of platelet aggregation was 3694 nM, while the Kd of the ^{99m}Tc labeled peptide was 185 nM, indicating moderate affinity for the receptor. The ^{99m}Tc-labeled peptide was able to identify sites of experimental thrombi and emboli in a canine model. The results suggest initial success in attempting to mimic the behavior of bitistatin for imaging thrombi and emboli.

INTRODUCTION

Bitistatin[1] is an 83-amino-acid peptide (Figure 1) isolated from the venom of *Bitis arietans* (*1*). The peptide binds to the αIIbβ3 (Glycoprotein IIb/IIIa) receptor on platelets that is involved in the process of platelet aggregation (*2*). Previously, we showed that radiolabeled analogues of bitistatin gave positive images of deep-vein thrombosis and pulmonary embolism in a single test (*3*, *4*). Deep-vein thrombosis and pulmonary embolism are often different halves of the same thromboembolic disease since a clot in the extremities can dislodge and relocate to the lungs. A test that can provide complete information on thromboembolic disease relatively quickly and noninvasively, as can be provided by radiolabeled bitistatin analogues through scintigraphy, would greatly impact patient management. For this reason, many efforts have been made to develop radiolabeled tracers for imaging thromboembolic disease. Many of these have been reviewed in a recent article (*5*). None of the tracers to date consistently provide high-contrast images of both deep-vein thrombosis and pulmonary embolism in a single test. Because of the great potential of labeled bitistatin, it would be greatly beneficial if short-chain synthetic analogues that mimic the natural peptide were available. In this study, we have designed and synthesized a 24-amino acid analogue, labeled it with technetium-99m, and evaluated its ability to image experimental deep-vein thrombosis and pulmonary emboli.

EXPERIMENTAL SECTION

General Methods and Materials. All chemicals were obtained from either the Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Company (St. Louis, MO). Solvents and chemicals were reagent grade and used as received without further purification. The bifunctional chelating agent, succinimidyl-6-hydrazinopyridine-3-carboxylic acid, was synthesized according to literature procedures (*6*).

Figure 1. Amino acid sequences of selected disintegrins. The sequences are aligned so that RGD domains (shown in bold, KGD for Barbourin) are aligned with bitistatin. Asterisks (***) indicate the position of the RGD or analogue.

Male CD-1 mice were purchased from the Charles River Laboratories (Charles River, MA). Amino acid analyses and MALDI mass-spectral analyses were performed by AnaSpec, Inc. (San Jose, CA). HPLC was performed with a Waters Chromatography Division (Milford, MA) HPLC System equipped with two model 510EF pumps, a model 680 automated gradient controller, a model 490 UV absorbance detector, and a Bioscan NaI scintillation detector connected to a Bioscan Flow-count System. The output from two channels of the UV detector and the output from the Flow-count system were fed into a Gateway 2000 P5−133 computer fitted with an IN/US System, Inc. (Tampa, FL) computer card. HPLC acquisition and analysis were performed with the Winflow software from IN/US. The semipreparative column (C18 Novapak cartridge, 25 mm × 10 cm, 6 μm), the analytical column (C18 Novapak cartridge, 8 mm × 10 cm, 4 μm), and the C18 Light Sep-Pak cartridges were purchased from Waters Chromatography Division. Reversed-phase HPLC solvents consisted of acetontrile containing 0.1% trifluoroacetic acid (solvent A) and water containing 0.1% trifluoroacetic acid (solvent B). The ^{99m}Tc activity of tissues from biodistribution studies was counted on an automated gamma counter (Pharmacia-Wallac model 1282). The ^{99m}Tc activity for synthetic reactions and doses for biodistribution was measured in a Capintec CRC-7 Dose Calibrator.

Molecular Modeling. All molecular modeling was performed on a Silicon Graphics Personal IRIS 4D/25 workstation using Biograf (Accelrys, San Diego, CA), which incorporates the DREIDING II all atom force field. All peptides were constructed using the peptide builder, while all nonpeptide components were similarly constructed using the organic builder; both routines are contained within the main Biograf program. Partial charges for each atom used in calculating the electrostatic energy contribution of the total energy for each structure were derived by the charge equilibration method of Rappe and Goddard (*7*). Energy calculations for each peptide or construct consisted of energy minimization and quenched molecular dynamics calculations for 50 ps., followed by energy minimization of the lowest-energy structure obtained from the molecular dynamics simulation.

The model of bitistatin used has previously been described (*4*). Briefly, the model was developed by homology modeling with kistrin, another disintegrin, whose structure has been determined by NMR and chemical analysis. The amino acid sequence of bitistatin is 63% identical and 75% similar to the sequence of kistrin (Figure 1). The amino acid sequences of bitistatin and kistrin were aligned, and then the NMR-derived coordinates of the backbone atoms of kistrin were used as a starting point. Computer site-directed mutagenesis was used to replace each amino acid side chain of kistrin with the homologous side chain of bitistatin. Residues present in bitistatin, but not present in kistrin, were added to the model. The pairing of cysteine residues in kistrin was assumed to be the same in bitistatin. The two additional cysteines present in bitistatin at positions 5 and 24 were assumed to form a crosslink. Subsequent disulfide mapping studies confirmed these disulfide pairings in bitistatin (*8*). The part of the molecule that is identical to kistrin was kept constant while the domains added as bitistatin were subjected to energy minimization calculations. The entire molecule was then subjected to energy minimization.

The RGD loop of bitistatin ranges from C60 to C79, and contains another Cys residue at position 72 branching to an adjacent disulfide loop (*4*). According to the previous model of bitistatin, a flattened loop structure stretches from A56 to T73 (*4*). For initial modeling, the minimum number of amino acids needed to simulate the native binding site was determined from systematic deletion of amino acids from either end of the binding loop of native bitistatin. A series of disulfide-constrained

peptides was modeled, retaining Cys on each end for cyclization. Starting with the sequence found in native bitistatin, C−R−I−A−R−G−D−W−N−D−D−Y−C, the series of peptides shown in Figure 2 was modeled.

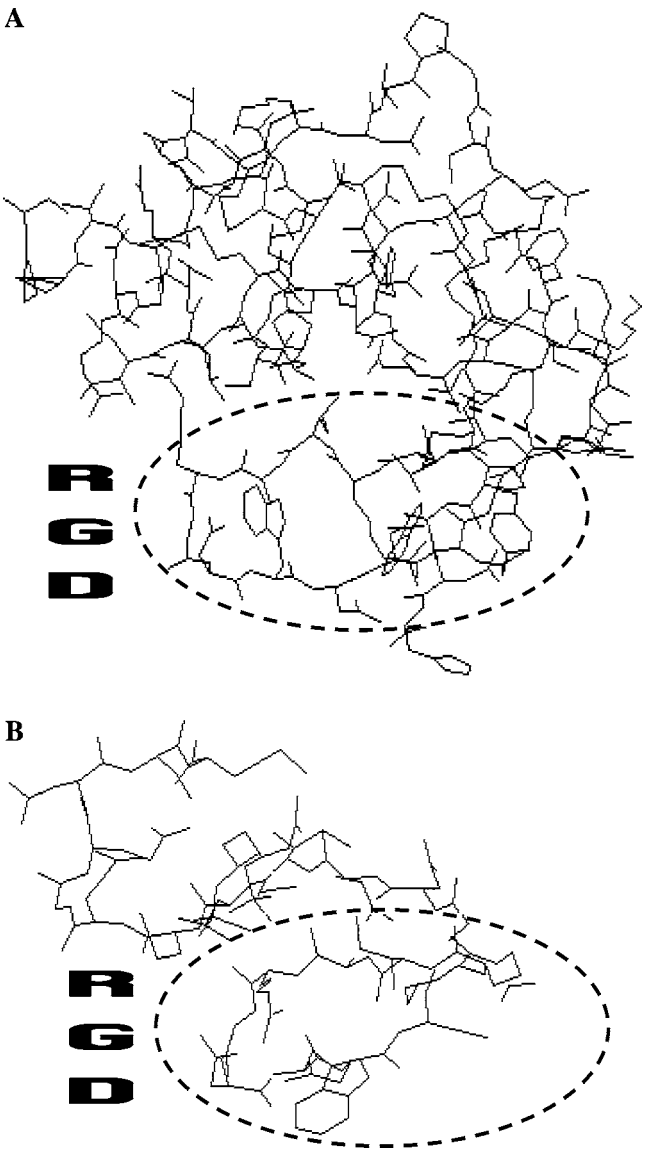
To select peptides or constructs for further study, each modeled structure was overlaid onto the structure of the corresponding amino acids of our model of natural Bitistatin shown in Figure 3A (*4*) while calculating the root-mean-square standard deviation (rms value) between the modeled structures. Structures with the lowest rms value, suggesting the best "goodness of fit", were selected for further study.

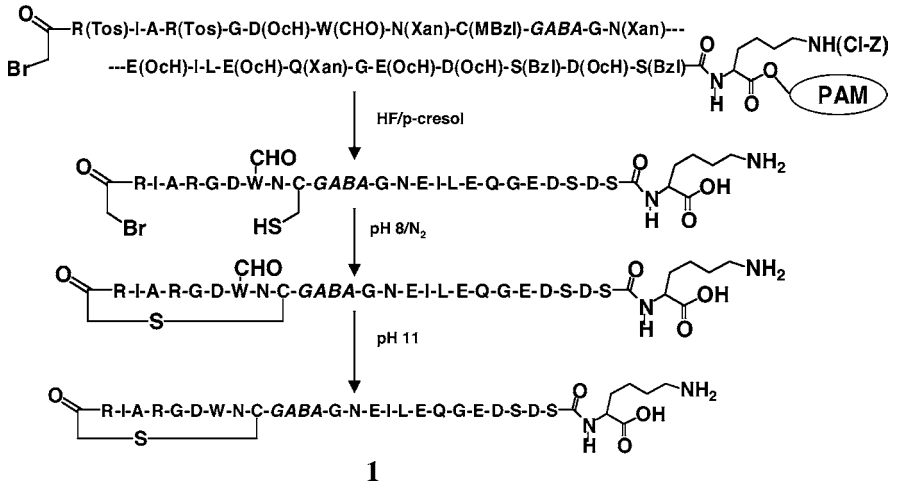
In addition to the RGD-containing loop, bitistatin contains an N-terminal domain of 10−12 amino acids that other related disintegrins lack as depicted in Figure 1. We hypothesized that this N-terminal domain may be responsible for the improved binding properties of bitistatin in vivo. Thus, a second domain was modeled to mimic this section of bitistatin. In native bitistatin, the sequence of the N-terminal domain is S−P−P−V−C-G−N−E−I−L and it is attached to the rest of the molecule by the intervening 47 amino acids and a disulfide bond between C5 and C24. Modeling was used to design a domain that would contain a minimum of amino acids, which could be attached to the single RGD-containing loop peptide modeled above, and which would simulate the tertiary structure of the native N-terminal domain relative to the native RGD-containing domain.

Molecular modeling resulted in the 24 amino acid sequence **1** (Scheme 1), the model of which is depicted in Figure 3B, as a good fit to the structure of bitistatin.

Molecular modeling was also performed on the bifunctional chelator-modified peptide, with and without technetium and tricine, to confirm that these modifications did not adversely affect the orientation of the peptide domains (Figure 4).

Synthesis of the Short Chain Bitistatin Analogue. *cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH, **1**, was synthesized using the BOC technology on an Advanced ChemTech ACT90 automated peptide synthesizer starting with 1.75 g (1.4 mmol, 0.8 mmol/g) Boc−Lys(2Cl−Z)−PAM resin according to Scheme 1. Each Boc-protected amino acid (9 mmol), including Boc−Ser(Bzl)−OH, Boc−Asp(OcHx)−OH, Boc−Glu(OcHx)−OH, Boc−Gly−OH, Boc−Gln(Xan)−OH, Boc−Leu−OH, Boc−Ile−OH, Boc−Asn(Xan)−OH, Boc−*Gaba*−OH, Boc−Cys(Mbzl)−OH, Boc−Trp(CHO)−OH, Boc−Arg(Tos)−OH, and Boc−Ala−OH was reacted with an equimolar mixture of N-hydroxybenzotriazole (HOBt) and 1,3-diisopropylcarbodiimide (DIC) before coupling to the growing sequence. Deprotection of the Boc group was performed in the presence of 35% trifluoroacetic acid, 3% anisole, 0.2% dithiothreitol in dichloromethane (2 times; first time 5 min, second time 25 min). The coupling time per cycle was 30 min. Coupling was repeated if necessary after a ninhydrin test was performed to ascertain completeness of the reaction. The coupling of bromoacetic acid to the sequence followed similar procedures for the amino acids, but used only 1,3-diisopropylcarbodiimide for activation. At the end of chain lengthening, the resin was dried by high vacuum and the peptide was cleaved from the resin with condensed hydrogen fluoride in the presence of *p*-cresol at 0 °C for 1.5 h. The HF was removed under a stream of nitrogen and the residue was washed with ether (3 × 30 mL), then dissolved with 10% acetic acid (100 mL), followed by filtration and lyophilization.





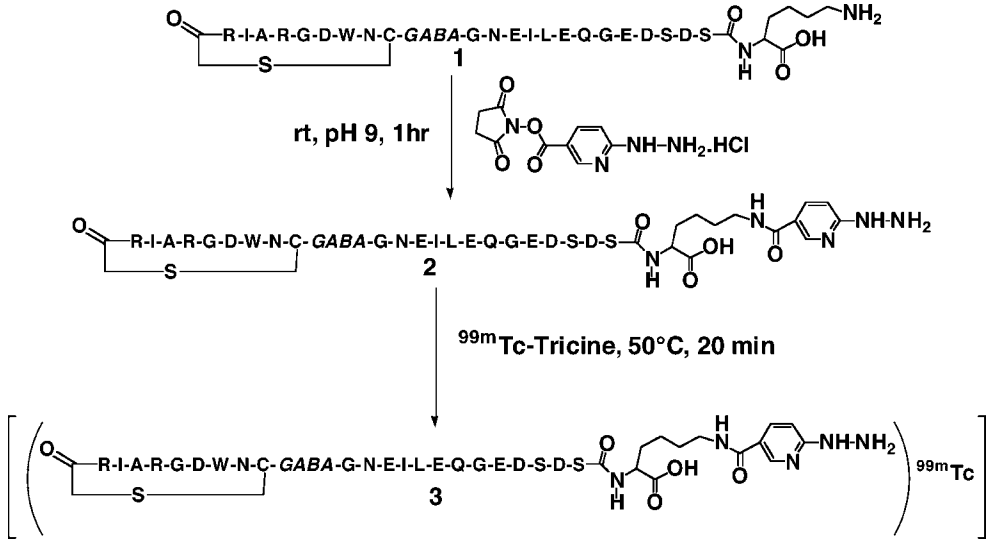


Figure 3. Molecular model of bitistatin (A) compared to the peptide bitistatin analogue (B). The dashed area shows the binding domain.

Cyclization was performed by dissolving 0.5 g of lyophilized powder in 1000 mL water, adjusting the pH to 8.2 with 2 M ammonium hydroxide, and stirring the mixture under nitrogen at room temperature for 24 h. The mixture was then lyophilized again. To remove the formyl (CHO) group on Trp, the mixture was dissolved in water and the pH was adjusted to 11 with 2.5 N sodium hydroxide for 5 min and then readjusted to 7 with 3 N hydrochloric acid. The resulting peptide was purified

(*Ser and Cys were partially destroyed during hydrolysis. **Trp was completely destroyed during hydrolysis).

Coupling of the Peptide to Succinimidyl-6-hydrazinopyridine-3-carboxylic Acid. The bifunctional chelating agent, succinimidyl-6-hydrazinopyridine-3-carboxylic acid (6), was coupled to the peptide according to Scheme 2. A DMF solution of succinimidyl-hydrazinonicotinate·HCl (210 mg/mL, 100 μL) was added to a solution of compound **1** (5 mg, 1.8 μmol) in borate buffer (0.4 mL, 0.1 M, pH 9) and the pH was adjusted to 9 with triethylamine. The mixture was incubated at room temperature for 1 h and then extracted with ether (3 × 2 mL). The aqueous fraction was chromatographed by HPLC with a linear gradient from solvent B (100%) to solvent A (80%)/solvent B (20%) over the course of 60 min at a flow rate of 6 mL/min using the semipreparative column monitored on-line for UV absorption at 220 nm.

^{99m}Tc Labeling of the Peptide. The ^{99m}Tc derivative of ***cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH**, was synthesized according to Scheme 2. To a solution of the coupled peptide in ethanol (10 μg in 0.2 mL) a solution of tricine in water (50 mg, 0.4 mL) was added followed by a solution of freshly prepared stannous chloride

dissolved in HCl(aq) (20 μg in 20 μL 0.1 M HCl). The mixture was vortexed for 1 min. To this mixture was added ^{99m}Tc-pertechnetate in saline solution (10 mCi, 0.4 mL) and the reaction mixture was vortexed for an additional 1 min followed by incubation at 50 °C for 20 min. The product was purified by solid-phase extraction using a C-18 Sep-Pak cartridge. The Sep-Pak cartridge was first washed with ethanol (5 mL) followed by a solution of ammonium acetate (0.05 M, 5 mL). The reaction mixture containing the ^{99m}Tc-labeled ***cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH** was diluted five times with ammonium acetate (0.05 M) and then passed through the Sep-Pak cartridge. The Sep-Pak cartridge was washed with an ammonium acetate solution (0.05 M, 5 mL) followed by elution of the ^{99m}Tc-labeled ***cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH** with ethanol (300 μL). The yield of product was >90%.

Inhibition of Platelet Aggregation. Blood was obtained from anonymous aspirin-free human donors according to an approved Institutional Review Board protocol and anticoagulant (0.1 vol, 3.8% sodium citrate) was added. The blood was centrifuged (160 x g, 12 min) to obtain platelet-rich plasma. The concentration of platelets in human platelet-rich plasma was determined using a hemacytometer, then diluted with the donor's own plasma to obtain a platelet concentration of 300 000/μL. For each measurement, 400 μL of diluted platelet-rich plasma was placed in a cuvette and stirred at 37 °C. Vehicle (saline) or various concentrations of peptide were added in a volume of 10 μL and stirred at 37 °C for 1 min while recording visible light transmission. ADP was then added (final concentration of 10 μM) to induce platelet aggregation. Platelet aggregation was determined by change in light transmission through the platelet-rich plasma, which was recorded for 5 min after ADP addition. The IC_{50} was determined (by least-squares fitting) as the concentration of peptide required to produce 50% inhibition of the response to ADP in the presence of the vehicle. Results were normalized to the results for the tetrapeptide Arg-Gly-Asp-Ser (RGDS).

Equilibrium Platelet Binding Assay. Platelet-rich plasma was obtained as described above. Plasma proteins were then removed by filtering the platelets through Sepharose 2B (80 × 25 mm equilibrated with an elution buffer containing 137 mM NaCl, 2.7 mM KCl, 0.1% glucose, 0.2% bovine serum albumin, 0.4 mM NaH_2PO_4, 12 mM $NaHCO_3$, and 10 mM HEPES, pH 7.45). Fractions containing the highest concentrations were pooled, diluted to a concentration of 10^8 platelets/mL, and used within 1 h of preparation. Aliquots of the platelets were stimulated with 19 μM ADP, combined with a radioligand (^{99m}Tc labeled peptide or ^{125}I labeled rBitistatin) over a range of concentrations, and then incubated for 1 h at 37 °C. Nonspecific binding was determined in the presence of 9 mM EDTA (*3*). Platelet-bound radioligand was separated from free radioligand by centrifuging (13 000 x g, 3 min) the suspension through 30% (W/V) sucrose. Scatchard analysis was used to analyze the data (*9*).

Biodistribution. The ethanolic solution of ^{99m}Tc-labeled peptide from the Sep Pak separation was diluted with physiologic saline to make a final injectate (10 μCi/mL) containing < 0.5% ethanol.

Normal male CD-1 mice weighing 24.8 ± 1.3 g were used for biodistribution studies. The labeled peptide (2 μCi, 200 μL) was injected into mice via the tail vein. At 15, 30, 60, and 180 min postinjection, four mice for each time point were euthanized by cervical dislocation. Major organs were dissected, weighed, and counted in an automated gamma counter with aliquots of the injectate (as standards) counted at the same time. The percent injected dose per organ (% ID/organ) and the percent injected dose per gram (% ID/gram) were calculated. The % ID in blood was estimated with the assumption that the total blood volume is 6.5% of the body weight (*10*).

Imaging Experimental Thrombi. Radiolabeled peptide was evaluated in a standardized canine model of deep-vein thrombosis and pulmonary embolism (*3*, *4*). Briefly, under isoflurane anesthesia, an 8-mm embolization coil was placed in the femoral vein of the dog for deep-vein thrombosis while two 5-mm coils were released in the inferior vena cava for pulmonary embolism. The lesions were allowed to develop and mature for 24 h. The ^{99m}Tc-labeled-peptide (8 mCi) was injected through a foreleg vein. Imaging of ^{99m}Tc was performed for 4 h using a large-field-of-view camera (General Electric Medical Systems, Milwaukee) interfaced to a Macintosh computer (Apple, Cupertino, CA) and a data acquisition and processing board (NucLear Mac, Scientific Imaging, Denver, CO). Regions of interest were drawn around the thrombus in the leg and compared to a region of about the same size around adjacent muscle, and also around the vessel in the opposite leg corresponding to the location of the thrombus. The average counts per pixel in each region were computed for the calculation of the following ratios: thrombus:muscle and thrombus:contralateral site. Similarly, for the chest images, regions for embolus, adjacent lung, heart, and muscle (behind the lungs, near the vertebral column) were drawn to obtain embolus:lung, embolus:heart, and embolus-to-muscle ratios. The presence of clots in the lungs and leg were confirmed at autopsy.

RESULTS AND DISCUSSION

Bitistatin exhibits superior imaging characteristics among radioiodinated disintegrins evaluated for the imaging of experimental thrombosis (*3*). The ^{123}I-labeled analogue showed high thrombus uptake, low soft-tissue uptake, and high thrombus and embolus-to-blood and thrombi and emboli-to-soft-tissue differentiation. The ^{99m}Tc analogue showed the highest thrombus-to-blood and thrombus-to-soft-tissue ratios of any ^{99m}Tc-labeled thrombus and/or embolus imaging agent studied (*4*). Radiolabeled bitistatin analogues, therefore, offer the unique potential to generate radiopharmaceuticals capable of rapid positive imaging of both pulmonary emboli and deep-vein thrombosis in a single test. Because native bitistatin is 83 amino acids long and has multiple internal disulfide crosslinks, chemical synthesis is difficult. Thus, we embarked on an effort to generate a short chain analogue that could more conveniently be synthesized.

Bitistatin contains seven internal disulfide bridges that help to maintain its tertiary structure. Initial molecular modeling of the native bitistatin sequence shown in Figure 3A (*4*) indicated that the required RGD binding motif is presented at the turn of a loop represented by the sequence C−R−I−A−R−G−D−W−N−D−D−Y−C (Figure 2). Systematic sequential deletion of single residues from either end resulted in the cyclic decapeptide sequence *C−R−I−A−R−G−D−W−N−C* as the best match of the native binding sequence.

One major difference between bitistatin and other disintegrins is a highly charged domain of additional

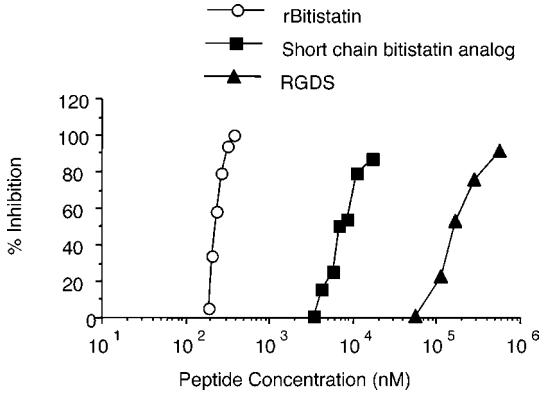

Figure 5. Inhibition of platelet aggregation by the peptides.

amino acids at the N-terminal region. In the model of native bitistatin, this N-terminal sequence appears to be parallel to the binding loop. We hypothesized that this sequence could be interacting with the receptor in some fashion to confer the desirable imaging properties to the molecule. Molecular modeling was performed of components of the N-terminal region fused with the minimal binding site. To confer greater stability to the anticipated peptide and to allow compatibility to a wide variety of bifunctional chelating agents for radiometalation, we replaced the disulfide bridge with the more stable thioether bridge. Furthermore, we attached a Lys residue at the C-terminal to afford the attachment of bifunctional chelating agents to the epsilon amino group. The final molecule having the best fit to the model of bitistatin was the 24-residue peptide *cyclo*-[CH_2CO−Arg−Ile−Ala−Arg−Gly−Asp−Trp−Asn−Cys(S−)]−*Gaba*−Gly−Asn−Glu−Ile−Leu−Glu−Gln−Gly−Glu−Asp−Ser−Asp−Ser−Lys−OH (Scheme 1) whose model is shown in Figure 3B in comparison to the model of bitistatin (Figure 3A). Figure 4 shows that after Tc derivatization, the Tc chelate would be located far from the RGD binding site and thus is not expected to interfere with receptor binding.

Synthesis of the target peptide was performed on an Advanced ChemTech synthesizer ACT90 using the BOC technology as shown in Scheme 1. The final HPLC-purified product was chemically characterized by amino acid analysis and MALDI Mass Spect. Results of in vitro assays of the ability of the new peptide to inhibit platelet aggregation are shown in Figure 5 comparing the activity of the new peptide with a short straight-chain RGD peptide RGDS and recombinant bitistatin (rbitistatin). The IC_{50} of the recombinant bitistatin, the new peptide, and RGDS were 114, 3694, and 100 000 nM, respectively. Thus, while the biological activity of the new peptide was 27-fold better than the RGDS peptide, it was 32-fold less active than recombinant bitistatin.

To label the peptide with ^{99m}Tc, coupling with the hydrazinonicotinamidyl bifunctional chelating agent was performed (Scheme 2). After removal of excess uncoupled reagent by HPLC, the modified peptide was labeled in high yield with ^{99m}Tc using tricine as the coligand. As shown in the Scatchard analysis of in vitro binding studies depicted in Figure 6, the Kd of the peptide was 185 nM with a Bmax of 117 000 sites/cell compared to a Kd of 8 nM and Bmax of 80 000 sites/cell for ^{125}I−rbitistatin. The Kd for ^{99m}Tc-labeled bitistatin from a previous study was 32 nM (*4*). Thus, the ^{99m}Tc-labeled peptide has moderate affinity for the receptor.

Biodistribution studies in normal CD-1 mice showed that the peptide cleared rapidly from the blood and all normal tissues except the kidneys where a substantial amount of the activity accumulates over an extended period of time (Table 1). At 3 h postinjection, there was still significant soft tissue uptake. The highest soft tissue uptake was in the kidneys, which tends to accumulate ^{99m}Tc-labeled small peptides. Varying levels of kidney activity have been associated with ^{99m}Tc−hydrazinonicotinyl−tricine conjugates. The levels of activity exhibited here are higher than usual but similar to those obtained in the kidneys for a ^{99m}Tc-labeled polypeptide, EPI−HNE−2 (*11*), using a similar procedure. The high kidney activity levels may be related to the peptide itself in conjunction with the labeling methodology.

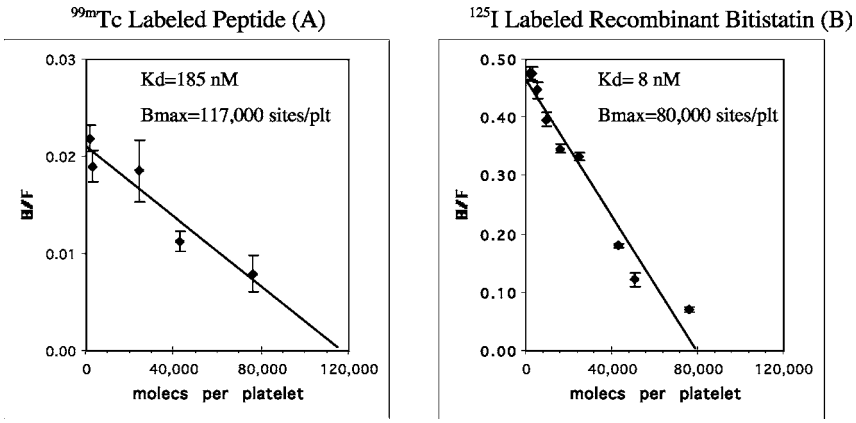

Figure 6. Scatchard plots of the binding of the ^{99m}Tc-Labeled Peptide (A) compared to the ^{125}I-Labeled Recombinant Bitistatin (B). B/F = Bound Ligand/Free Ligand, molecs = molecules.

To investigate the utility of the ^{99m}Tc-labeled peptide for imaging thrombi and emboli, we performed imaging of experimental deep-vein thrombosis and pulmonary emboli in a dog. Figures 7 and 8 show representative images obtained for the deep-vein thrombus and the emboli in lungs of the same dog, respectively. There appeared to be two clots in the lung and one main clot in the leg. The clots in the lung and the leg were discernible within the 4-h imaging period. The clot in the leg could be seen earlier within 45 min postinjection. The target-to-nontarget ratios obtained from the image are presented in Table 2. Comparison of results obtained with bitistatin labeled with ^{99m}Tc in the same fashion (*4*) indicated that the peptide under study was less effective than the native peptide for imaging thrombi and emboli. The lower contrasts obtained with this peptide may be due to the lower affinity of the labeled peptide compared to labeled bitistatin.

Currently, ^{99m}Tc−Apcitide, a small peptide containing a surrogate for RGD constrained in a small loop, is an approved radiopharmaceutical for imaging deep-vein thrombosis. The thrombus uptake of ^{125}I−bitistatin or ^{99m}Tc−bitistatin in the standardized canine model has been consistently much higher than that of ^{99m}Tc−Apcitide. In the same animal model, ^{99m}Tc−Apcitide had image-derived thrombus:contralateral vessel and thrombus:muscle ratios of 2.0 and 1.9 at 4 h postinjection (*12*). The short-chain peptide analogue of bitistatin described here did not exhibit an advantage over ^{99m}Tc−Apcitide with respect to imaging deep-vein thrombosis. However, the bitistatin analogue was able to produce images of pulmonary embolism. No images of pulmonary embolism have previously been reported for ^{99m}Tc−Apcitide.

The RGD-containing loop in bitistatin is very large (more than 13 amino acids). Because of its size, it is inherently flexible and probably depends on the rest of the bitistatin molecule to maintain its orientation. In contrast, the small tetrapeptide loop structure in Apcitide is fairly rigid. Although molecular modeling in this report predicted that a loop structure of 10 amino acids containing RGD would be the best match to the binding loop of bitistatin, it is possible that in the physiologic environment this loop is very flexible and does not have adequately high affinity in all configurations. Previous studies in this animal model with a ^{99m}Tc-labeled linear RGD-containing peptide (*13*) (based upon the binding sequence of an antiplatelet monoclonal antibody) resulted in poorer thrombus binding than the short-chain bitistatin analogue reported here. In this study, we have attempted to simulate the environment created by the N-terminal domain of bitistatin to create the short chain peptide. Other regions of bitistatin may be required to generate a bitistatin analogue that provides the appropriate environment to constrain the orientation of the binding loop. We are currently investigating other structural features of native bitistatin to incorporate in a shorter peptide that would still be amenable to synthesis.

ACKNOWLEDGMENT

The authors would like to thank Dr. Alan Maurer for creating the model of experimental thrombi and emboli. This work was supported in part by NIH grant HL-54578 (L.C.K.).

Poly(ethylene glycol) Prodrugs of the CDK Inhibitor, Alsterpaullone (NSC 705701): Synthesis and Pharmacokinetic Studies

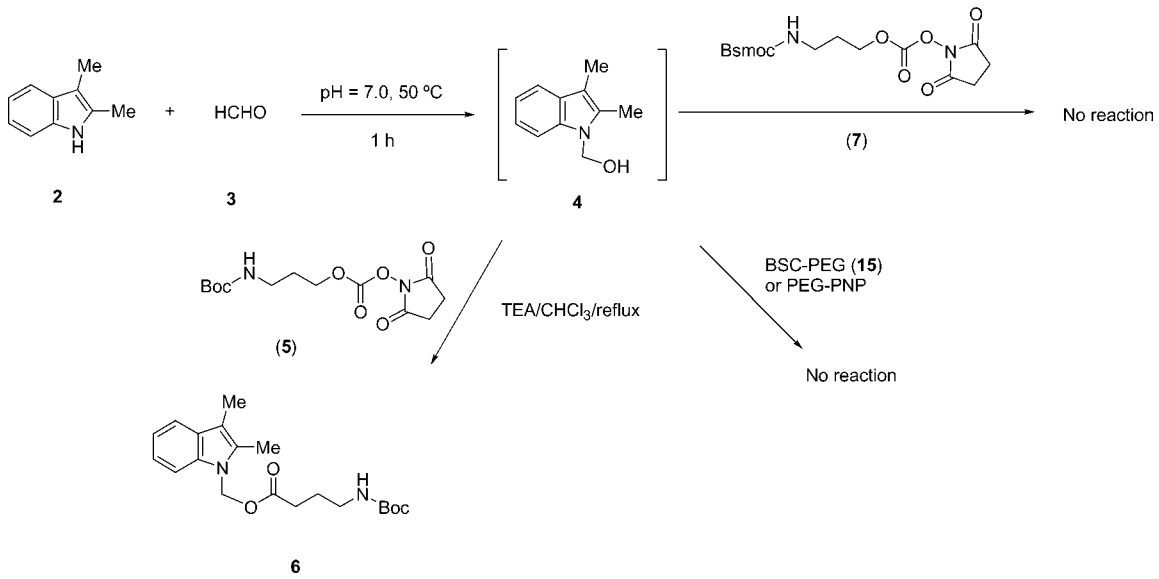
Richard B. Greenwald,* Hong Zhao, Jing Xia, Dechun Wu, Stephen Nervi, Sherman F. Stinson,*,† Eva Majerova,† Chris Bramhall,† and Daniel W. Zaharevitz†

Enzon Pharmaceuticals Inc., Research & Development Division, 20 Kingsbridge Road, Piscataway, New Jersey 08854 and Developmental Therapeutics Program, NCI, Frederick, Maryland 21702.
Received April 14, 2004; Revised Manuscript Received June 22, 2004

Two methods were devised to conjugate PEG to alsterpaullone (NSC 705701) via the N of the indole ring portion of the molecule. In the first approach, activation of the indole was accomplished by reaction with *p*-nitrophenyl chloroformate to produce a reactive carbamate that was then condensed with a mono blocked diamine to form a urea bond followed by deblocking and conjugation to PEG. The second route used the anion of the indole and produced a carbamate bond. Both compounds were highly water soluble, were stable in buffer, and released alsterpaullone in vitro and in vivo. Studies were conducted in mice to investigate the influence of PEGylation on the plasma pharmacokinetics of alsterpaullone. The total plasma clearance rate was decreased up to 32-fold, and the biological halflife lengthened up to 8-fold when alsterpaullone was injected *i.v.* as a PEG-conjugate and compared to injection of the unconjugated compound. The most pronounced effect on the pharmacokinetics of alsterpaullone was produced by a 40-kDa PEG urea-linked conjugate. When the 40- and 20-kDa urea-linked conjugates were administered by *i.p.* injection, high relative bioavailability (46% and 99%, respectively) of alsterpaullone was observed.

INTRODUCTION

The cyclin-dependent kinases (CDKs) are a group of enzymes that are involved in cell cycle progression regulation (*1*). The CDKs activate host proteins through phosphorylation on serine or threonine using adenosine triphosphate as a phosphate donor (*2*). CDKs have attracted much attention as potential therapeutic targets, especially in treating cancer, because they are key players in the control of cell proliferation. Recently, a novel class of small molecule CDK/cyclin B inhibitors, the paullones, containing a four ring fused system were synthesized, and antitumor activity was demonstrated in vitro (*3*). Structure activity studies yielded 9-nitropaullone (alsterpaullone, **1**) as one of the lead compounds in the series; however, due to its poor aqueous solubility (2 μg/mL), **1** could not be easily formulated, and this precluded in vivo testing. Since PEG prodrugs of molecular weight (mw) > 20 000 have been shown to solubilize and release small molecules in a predictable fashion (*4*), we sought to find means by which PEG could be used in a similar manner with **1**, which has only indole and amide N−H functionalities available for attachment to PEG. A successful conjugation would thus solubilize alsterpaullone and permit intravenous (*i.v.*) or interperatoneal (*i.p.*) administration. To this end, we have developed two methods based on indole modification that yielded PEG prodrugs and produced usable levels of **1** in vivo as evidenced by pharmacokinetic (PK) studies.



Chemistry. Synthetic approaches to indole functionalization of alsterpaullone were initiated by attempting reactions with 40 000 mw PEG−isocyanate (*5*) and with SC−PEG (PEG succinimidyl carbonate) (*5*). In no case was any reaction detected. We therefore turned to using a model compound, 2,3-dimethylindole (**2**), hoping to define reaction conditions that would lead to the desired modifications. Reaction was achieved in two different instances. First, condensation of formaldehyde (**3**) with **2** gave the hydroxymethyl derivative **4** in situ, in essentially quantitative yield (monitored by HPLC), which was then coupled to the Boc-protected succinimidyl carbonate, **5**, producing the modified indole **6** (Scheme 1). Unfortunately, deprotection of **6** with TFA caused decomposition to the unmodified indole. Unexpectedly, no reaction with **4** was observed using the base labile Bsmoc (1,1-Dioxobenzo[*b*]thiophene-2-ylmethyloxycarbonyl) (*6*) protected amine **7**, or activated PEG linkers such as N-hydroxyphthalimido PEG (BSC−PEG, **15**). However, when using **1** as the substrate**,** it was found that the formaldehyde reaction would proceed to form **8** in only 50% yield (HPLC). Generally, **8** was not isolated but reacted directly with the bifunctional activated carbonate **5**, to give the indole carbamate, **9**, in about 15% yield (Scheme 2). Again, attempts to remove the Boc protecting group with TFA led to decomposition. Finally, using model compound **2** the activation of the NH bond by carbonyldiimidazole (CDI) and conversion to the activated derivative **11** could be accomplished in almost quantitative yield (Scheme 3). This compound was found to be stable in solution, but was unstable toward silica gel; therefore, it was used in the next step without purification. Reaction of crude CDI derivative **11** with the Boc-protected amine **12** produced urea **13**. TFA deprotection followed by condensation with **15** yielded the PEG derivative of 2,3-dimethylindole, **16**. A similar reaction using **1** gave the desired CDI derivative in only 20% yield. Clearly, the model results were not reflective

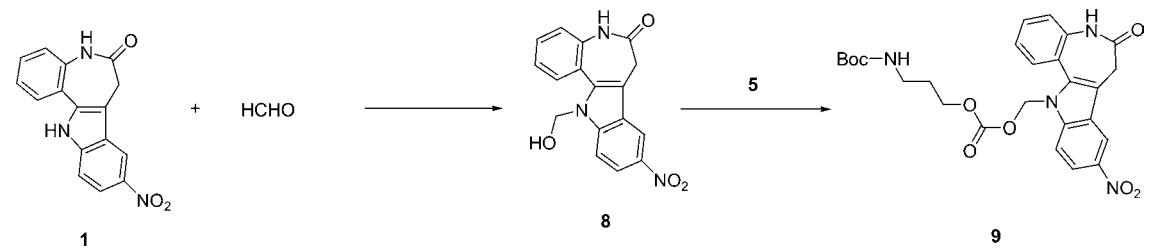
Scheme 1

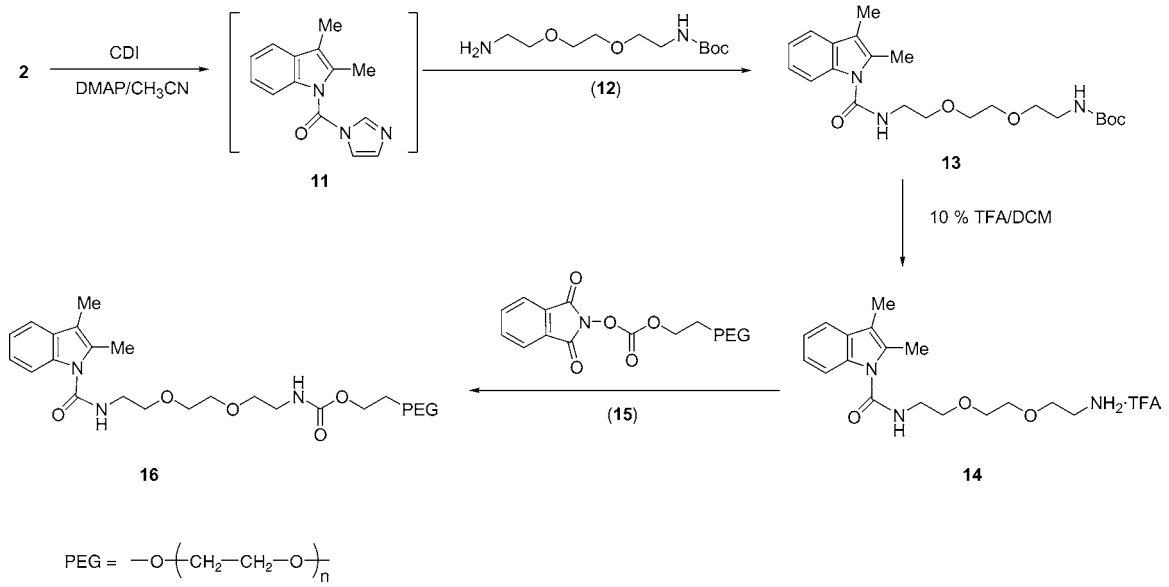
of those obtained for the more highly hindered alsterpaullone, and further use of **2** was abandoned in favor of alternative approaches to modification of **1**.

Using the more reactive reagent, *p*-nitrophenyl chloride (PNP-Cl) condensation with **1** in the presence of DMAP in THF solution yielded the activated carbamate **17** (Scheme 4). This was condensed directly with **12** to give the desired Boc indole urea intermediate **18**. In this case deprotection was successfully accomplished with 33% TFA in DCM to give **19**. PEGylation of **19** proceeded smoothly using **15** to give **20**. Alternatively, **19** was conjugated with PEG acid (**21**) in the presence of EDC to yield **22.** A second strategy that was successfully developed is shown in Scheme 5. Reaction of **1** with KOH in THF/DMF produced the potassium salt (not isolated), which was directly condensed with **23,** yielding the Boc-protected carbamate, **24**. Deprotection under acid conditions proceeded smoothly, to the amine salt (**25**) that was conjugated with **14** and **21** to give the indole carbamate PEG conjugated paullones **26** and **27** respectively.



EXPERIMENTAL SECTION

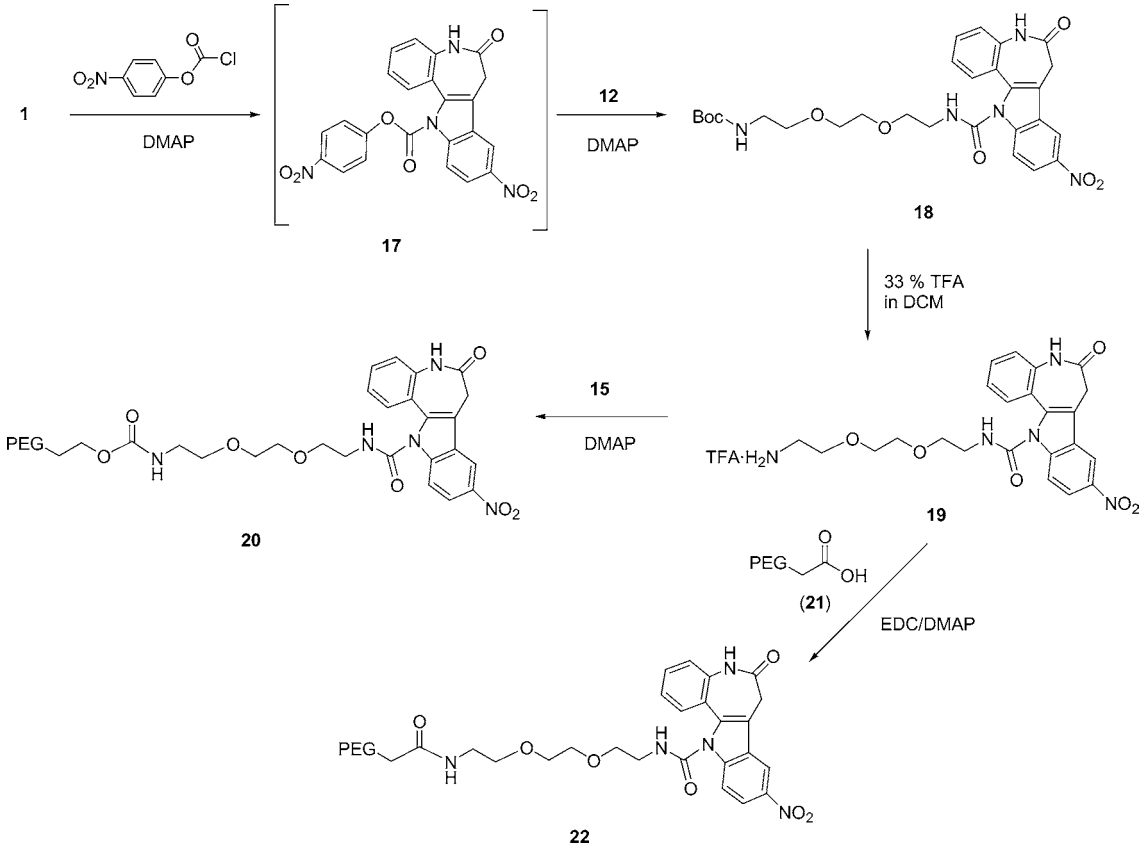
Materials and Methods. *Pharmacokinetics Studies.* Male, young adult (average body weight approximately 27 g) CD2F1 mice (Harlan Sprague−Dawley, Frederick, MD) were used for all studies. The animals were maintained on hardwood chip bedding in temperature-controlled rooms (20 °C) with a 12 h light-dark cycle. Standard diet (Rat and Mouse 18% Protein Diet, PMI Nutrition International, Inc., Brentwood, MO) and water were provided ad libitum. Housing, animal care, and all experimental procedures and manipulations were carried out in strict compliance with the National Institutes of Health guidelines for the care and use of laboratory animals.



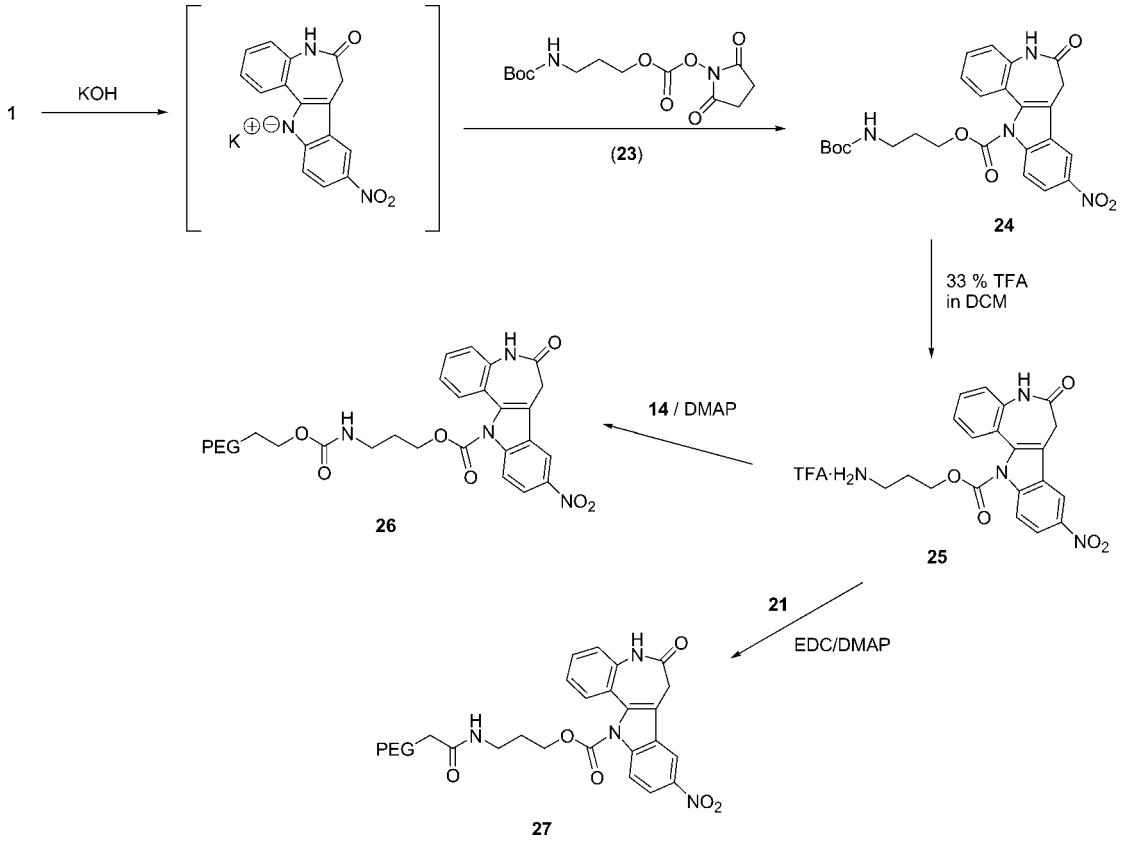
An effort was made to administer all agents at the highest dose possible. Alsterpaullone was given at its maximum tolerated dose (10 mg/kg). Viscosity, rather than toxicity, was the factor limiting the maximum dose of the 40-kDa conjugates; 1000 mg/kg was the greatest concentration resulting in a dosing solution that was workable. The dose of the 20-kDa conjugates (500 mg/kg) was selected so that the alsterpaullone dose would be comparable to that for the 40 kDa studies. The plasma pharmacokinetics of alsterpaullone was investigated following a 0.5 min *i.v.* infusion at a dose of 10 mg/kg, dissolved in a vehicle of DMSO and administered in a dose volume of 1 mL/kg. The conjugates were studied following a short (0.5 min) *i.v.* infusion, or bolus *i.p.* injection (except NSC 723780, compound **26**, and NSC 726143, compound **27**, for which only an *i.v.* study was conducted). The 40-kDa conjugates were given at a dose of 1000 mg/kg dissolved in sterile water (100 mg/mL), in a dose volume of 10 mL/kg. The 20-kDa conjugates were injected at a dose of 500 mg/kg, using the same vehicle and concentration, but in a dose volume of 5 mL/kg. The equivalent dose of alsterpaullone in each case was approximately 14 mg/kg. At selected intervals through 24 h (6 h for the *i.v.* study with alsterpaullone) groups of three mice were lightly anesthetized with methoxyfluorane and were exsanguinated via the retro-orbital sinus. Blood was collected into heparinized microfuge tubes that were then chilled in an ice bath for 1 min, and centrifuged under refrigeration (4 °C) at 13 000 × *g* for 3 min. Plasma was separated and the concentrations of alsterpaullone were immediately assayed by HPLC.

Aliquots (50 μL) of mouse plasma samples were prepared for analysis by precipitation of plasma proteins with 150 μL of chilled (−20 °C) methanol. Samples were vortexed vigorously for 30 s, maintained at −20 °C for

Scheme 2



Scheme 3



50 min, and centrifuged under refrigeration at 13 000 × g for 12 min. Next, 180 μL of the supernatant was combined with an equal volume of 0.05 M formate buffer (pH 3.0), and 330 μL of the mixture was injected on column. The analytical system consisted of a Hewlett-Packard (Palo Alto, CA) model 1050 pump, a refrigerated autosampler (4 °C), and a variable wavelength ultraviolet absorbance detector with associated software for system control and chromatogram and spectrum analysis. The system was equipped with a stainless steel 4.6 × 150 mm column containing 4 μm J'Sphere ODS H-80 packing (YMC, Inc., Wilmington, NC). Chromatography was performed with an isocratic flow rate of 1.0 mL/min using a mobile phase of acetonitrile/0.05 M, pH 3.0 ammonium formate buffer (38:62, v/v). The column eluent was monitored at 300 nm. Under these conditions, conversion of the conjugates to alsterpaullone during sample preparation and assay was negligible (<2%). The retention time for alsterpaullone was 12 min, the absolute recovery was greater than 90%, and the lower limit of quantitation was 10 nM.

Calibration curves were constructed by plotting the chromatographic peak area of the compounds against the known alsterpaullone concentration in plasma standards. Linear least-squares regression analysis was performed to determine the slope and *y*-intercept of the best-fit line.

Scheme 4

Scheme 5

Analyte concentrations in unknown samples were calculated by interpolation from the regression line. Each unknown sample was assayed in triplicate. The average of the closest two determinations was used for pharmacokinetic analysis.

Plasma concentration vs time profiles were constructed using the geometric mean of the plasma concentrations for the individual animals at each time point, as well as the mean of the times of collection. The data were analyzed by noncompartmental methods. The line of best fit was determined by nonlinear regression analysis, and pharmacokinetic parameters were calculated by standard equations as previously described (*7*).

SYNTHESIS

Compound 12. To a solution of di-*tert*-butyl dicarbonate (15 g, 0.086 mol) in 1,4-dioxane (150 mL) cooled to 5 °C in an ice bath was added a solution of 2,2′-(ethylenedioxy)bis(ethylamine) (25.85 g, 174.4 mmol) in 1,4-dioxane (100 mL), dropwise over a period of 1 h. The reaction mixture was allowed to warm to room temperature and was stirred for two more hours. The solvent was removed under reduced pressure and the residue dissolved in methylene chloride (DCM, 150 mL), washed with water (3 × 150 mL), dried ($MgSO_4$), and filtered; the solvent was evaporated under reduced pressure to yield **12** (13.84 g, mmol, 80%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 28.4, 40.1, 70.1, 73.5, 79.0, 115.8.

Compound 14. A solution of **2** (0.10 g, 0.69 mmol), 1,1′-carbonyldiimidazole (CDI, 0.14 g, 0.862 mmol), and a catalytic amount of 4-(dimethylamino)pyridine (DMAP, 2 mg, 0.97 mmol) in anhydrous acetonitrile (10 mL) was refluxed for 16 h. The reaction was cooled to 25 °C, **12** (0.36 g, 1.46 mmol) was added, and the mixture was refluxed for 48 h. The reaction was cooled to 25 °C and the solvent was removed under reduced pressure. The residue was dissolved in methylene chloride (DCM, 10 mL) and washed with 0.25 N HCl (3 × 10 mL);. The organic layer was dried ($MgSO_4$) and filtered; the solvent was removed under reduced pressure to yield crude product **13** (0.26 g, 0.62 mmol, 90%), which was dissolved in 10% trifluoroacetic acid/DCM (6 mL) and stirred at 25 °C for 20 min. The solvents were then removed in vacuo and the residue was dissolved in DCM (5 mL) and then washed with water (3 × 5 mL). The pH of the combined aqueous layers was adjusted to 9.0 by the addition of 1 N NaOH and then extracted by DCM (3 × 15 mL). The combined organic layers were dried ($MgSO_4$) and filtered, and the solvent was removed under reduced pressure to give pure **14** (0.09 g, 0.30 mmol, 48%). ^{13}C NMR (67.8 MHz, $CDCl_3/CD_3OD$) δ 152.8, 134.3, 130.6, 129.1, 121.3, 120.0, 116.9, 110.8, 110.6, 71.2, 69.3, 69.1, 68.4, 39.9, 39.6, 10.1, 8.9.

Compound 16. A solution of **14** (0.08 g, 0.27 mmol), PEG (40,000) linker **15** (2.69 g, 0.066 mmol), and DMAP (0.033 g, 0.27 mmol) in anhydrous DCM (40 mL) was stirred at 25 °C for 16 h. The solution was concentrated under reduced pressure and the PEG conjugate was precipitated by ethyl ether, filtered, and rinsed with additional ether (5 × 100 mL). The solid was crystallized from 2-propanol (IPA, 200 mL) to yield **16** (2.6 g, 0.060 mmol, 91%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 155.8, 152.0, 134.3, 131.6, 129.66, 121.9, 120.8, 117.7, 111.3, 74.0−69.4 (PEG), 63.4, 40.3, 11.8, 8.3.

Compound 18. To a suspension of alsterpaullone (1.50 g, 5.11 mmol) in anhydrous tetrahydrofuran (THF, 600 mL) was added 4-nitrophenyl chloroformate (3.082 g, 15.29 mmol) and DMAP (3.736 g, 30.57 mmol) and the reaction mixture was stirred at room temperature for 2 h. Compound **12** (12.54 g, 50.97 mmol) was added and stirring continued for an additional 12 h. The solvent was removed under reduced pressure, the residue was dis-

solved in DCM (300 mL), filtered, and finally washed with 0.25 N HCl (3 × 300 mL). The organic layer was dried ($MgSO_4$) and filtered, and the solvent was removed under reduced pressure. The residue was further purified by column chromatography to yield **18** (1.18 g, 2.08 mmol, 40.6%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 28.4, 29.7, 31.6, 40.1, 41.0, 68.9, 70.0, 70.3, 79.5, 113.9, 115.1, 116.9, 119.9, 121.7, 123.0, 124.4, 126.4, 129.1, 129.6, 133.9, 135.6, 140.9, 143.4, 150.8, 155.9, 172.9. HRMS: *m/z* calcd for $C_{28}H_{33}N_5O_8$ (M^+ + Na) 590.2227, found 590.2213.

Compound 19. To a mixture of trifluoroacetic acid (TFA, 2 mL) and anhydrous DCM (18 mL) was added compound **18** (1.0 g, 1.76 mmol) and the reaction mixture was stirred for 45 min at room temperature. The solvents were removed under reduced pressure and the crude product was washed with ethyl ether to give **19** (1.02 g, 1.76 mmol, 99%). ^{13}C NMR (75.5 MHz, $CDCl_3$/DMSO-d_6) δ 30.4, 38.8, 40.0, 66.0, 68.3, 69.3, 69.5, 112.1, 114.4, 115.2, 118.4, 121.4, 122.3, 123.6, 125.8, 127.7, 128.6, 134.4, 135.0, 139.9, 142.5, 151.2, 172.4. HRMS: *m/z* calcd for $C_{23}H_{25}N_5O_6$ (free base M^+ + Na) 490.1703, found 490.1708.

Compound 20. To a solution of **19** (0.102 g, 0.176 mmol) in anhydrous dimethylformamide (DMF, 3 mL) and DCM (37 mL) was added 40 kDa PEG linker **15** (2.36 g, 0.059 mmol) and DMAP (0.022 g, 0.176 mmol). The reaction was stirred at room temperature for 12 h, the solution was concentrated under reduced pressure, and the PEG derivative was precipitated with ethyl ether (150 mL). The crude product was crystallized from IPA, (200 mL) to give **20** (2.0 g, 0.05 mmol, 87%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 31.2, 40.2, 40.5, 63.5, 68.6, 69.0, 70.1−74.0 (PEG), 113.3, 114.6, 116.3, 119.2, 121.3, 122.9, 123.7, 126.0, 128.4, 128.9, 135.4, 140.3, 142.8, 150.5, 155.9, 171.6.

Compound 22. To a solution of **19** (0.765 g, 1.64 mmol) in anhydrous DMF (20 mL) and DCM (90 mL) was added 20 kDa PEG diacid **21** (7.5 g, 0.37 mmol), 1-[3-(dimethylamino)-propyl]-3-ethylcarbodiimide hydrochloride (EDC, 0.315 g 1.64 mmol), and DMAP (0.364 g, 2.98 mmol), and the mixture was stirred at room temperature for 12 h. The solvent was removed under reduced pressure and the residue was crystallized from IPA (200 mL) to give **22** (7.2 g, 0.343 mmol, 93%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 31.2, 38.0, 40.5, 68.5−74.0 (PEG), 113.3, 114.6, 116.2, 119.1, 121.2, 122.9, 123.6, 126.0, 128.4, 128.9, 133.8, 135.5, 140.3, 142.8, 150.4, 169.8, 171.6.

Compound 23. To a solution of *tert*-butyl *N*-(3-hydroxypropyl)-carbamate (5.0 g, 28.57 mmol), *N,N′*-disuccinimidyl carbonate (DSC, 9.6 g, 37.5 mmol) in chloroform (125 mL) was added pyridine (3.0 mL, 37.0 mmol) and the reaction mixture was stirred at room temperature for 12 h. The mixture was washed with 0.5 N HCl (60 mL), dried ($MgSO_4$) and filtered, and solvent was removed under reduced pressure to give compound **23** (8.2 g, 25.92 mmol, 90.7%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 25.5, 28.4, 28.9, 36.8, 68.9, 79.4, 151.4, 155.8, 168.5. HRMS: *m/z* calcd for $C_{13}H_{30}N_2O_7$ (M^+ + Na) 339.1168, found 339.1163.

Compound 24. Compound **23** (0.81 g, 2.6 mmol) was added to a reaction mixture of **1** (0.25 g, 0.85 mmol) and finely ground potassium hydroxide (KOH, 0.114 g, 2.03 mmol) in DMF/THF (20 mL/100 mL) previously stirred for 1 h at 0 °C in an ice-salt bath, and the resulting reaction mixture was gradually warmed to room temperature and stirred for 24 h. The solvent was removed under reduced pressure, and the residue was dissolved in DCM (100 mL), filtered, and washed with 0.25 N HCl (2 × 200 mL). The organic layer was dried ($MgSO_4$) and filtered, and the solvent was removed under reduced pressure. The residue was further purified by column chromatography to yield **24** (0.340 g, 0.706 mmol, 83%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 25.7, 28.4, 29.0, 31.4, 37.0, 65.5, 68.0, 76.6, 79.6, 114.8, 115.8, 119.4, 120.7, 122.8, 123.9, 128.0, 128.2, 129.9, 134.7, 141.1, 144.3, 150.8, 155.6, 172.7. HRMS: *m/z* calcd for $C_{25}H_{26}N_4O_7$ (M^+ + Na) 517.1699, found 517.1708.

Compound 25. To a solution of **24** (0.15 g, 0.30 mmol) in DCM (3 mL) cooled to 0 °C using an ice-salt bath was added TFA (3 mL) dropwise over 1 h with stirring. The solvents were removed under reduced pressure to give **25** (0.146 g, 0.295 mmol, ~100%). HRMS: *m/z* calcd for $C_{20}H_{18}N_4O_5$ (free base M^+ + H) 395.1355, found 395.1365.

Compound 26. To a solution of **25** (0.15 g, 0.30 mmol) in anhydrous DMF/DCM (6 mL/9 mL) was added 40 kDa PEG linker **15** (2.98 g, 0.074 mmol) and DMAP (0.072 g, 0.60 mmol). The reaction mixture was stirred at room temperature for 12 h, diluted with DCM, and washed with 0.1 N HCl (2 × 20 mL) and brine (20 mL). Removal of the solvent under reduced pressure gave the crude product, which was crystallized from DMF/ethanol (45 mL/45 mL) to give **26** (2.5 g, 0.061 mmol, 83%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 28.1, 31.4, 38.6, 63.7, 67.1, 69.4, 69.9, 70.1, 70.3−73.5 (PEG), 114.6, 115.4, 119.3, 120.4, 123.1, 123.2, 127.7, 129.0, 129.3, 135.3, 140.9, 144.0, 150.4, 155.6, 171.8.

Compound 27. A solution of **25** (0.46 g, 0.92 mmol) and 20kDa PEG diacid **21** (4.6 g, 0.23 mmol) in anhydrous DMF (30 mL) and DCM (46 mL) was cooled to 0 °C. Next, EDC (0.177 g, 0.922 mmol) and DMAP (0.562 g, 4.6 mmol) were added all at once and the reaction mixture was stirred at room temperature for 12 h. The solution was washed by 0.1 N HCl (2 × 30 mL) and brine (30 mL), dried ($MgSO_4$), and filtered. The solvent was removed under reduced pressure, and the residue was crystallized from IPA (100 mL) to give **27** (4.26 g, 0.205 mmol, 89%). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ 28.1, 31.1, 34.9, 65.2, 68.5−73.5 (PEG), 114.4, 115.4, 118.9, 120.1, 122.7, 123.1, 127.5, 128.7, 129.4, 134.8, 135.3, 140.6, 143.8, 150.3, 169.6, 171.8.

RESULTS

In Vitro Measurements. The solubility of all PEG derivatives was determined by the previously described (*8*) procedure. Rates of hydrolysis in saline and rat plasma of **16**, **23**, **26**, and **27** were carried out as described earlier (*5*). These values are presented in Table 1.

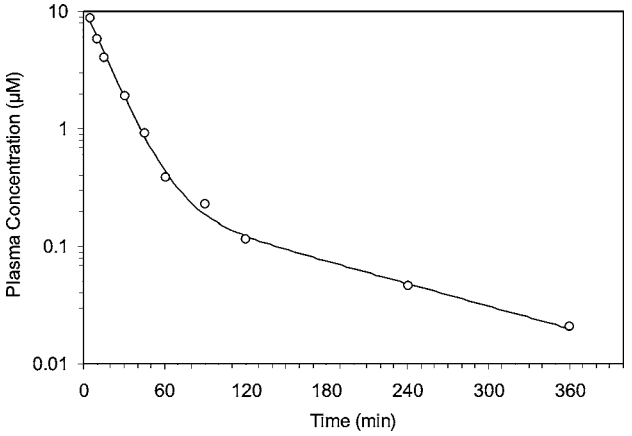

Figure 1. Geometric mean plasma concentrations and lines of best fit observed following *i.v.* administration of **1** to CD2F1 mice at a dose of 10 mg/kg.

Table 2. Selected Pharmacokinetic Parameters Derived from Nonlinear Least Squares Regression Analysis of Alsterpaullone (1) Plasma Concentration vs. Time Data Obtained Following *i.v.* Injection of 10 Mg/kg Body Weight in CD2F1 Mice

parameter	value
$t_{1/2,1}$	11.2 min
$t_{1/2,z}$	1.6 hr
MRT	0.6 hr
CL	9.7 l/hr/kg
V_1	3.1 l/kg
V_z	6.2 l/kg
$AUC_{0-\infty}$	3.5 μM × hr
AUC_1	82%
AUC_z	18%

$t_{1/2,1}$ and $t_{1/2,z}$ = half-lives for the initial and terminal disposition phases, MRT = mean residence time, CL = total plasma clearance rate, V_1 = apparent volume of the central compartment, V_z = apparent volume of distribution, $AUC_{0-\infty}$= area under the plasma concentration−time curve extrapolated to infinity, AUC_1 and AUC_z = percentage of $AUC_{0-\infty}$ represented by the initial and terminal disposition phases.

Pharmacokinetics Studies. Nonlinear regression analysis indicated that plasma concentrations of alsterpaullone declined in a biexponential manner following *i.v.* administration of 10 mg/kg, from nearly 10 μM at 5 min to 20 nM by 6 h (Figure 1). The half-lives for the initial and terminal disposition phases were 11 and 94 min, respectively (Table 2). The total plasma clearance rate (CL) was 9.7 l/hr/kg. The high ratio of the proportion of the area under the plasma concentration−time curve ($AUC_{0-\infty}$) represented by the initial phase relative to that of the terminal phase (82% and 18% respectively) suggests that tissue distribution rather than elimination is a controlling factor in the in vivo disposition of alsterpaullone.

Administration of PEGylated alsterpaullone by the *i.v.* route resulted in a 3 to 32-fold reduction in the CL of unconjugated alsterpaullone (Table 3, Figure 2). The urea linkage was associated with the largest reduction in the CL. The 40- and 20-kDa urea-linked conjugates produced CL values for alsterpaullone (0.3 and 0.7 L/hr/kg, respectively), which were three to four times lower than those found with corresponding carbamate-linked conjugates of equal molecular weight. The biological halflife of alsterpaullone was also three to four times longer with the urea-linked conjugates. The CL of alsterpaullone was one-third to one-half slower, and the biological halflife two to three times longer with the 40-kDa conjugates when compared to corresponding 20-kDa conjugates. The relative bioavailability of alsterpaullone when the urea-linked conjugates were given by the *i.p.* route was 46% for the 40-kDa compounds and 99% for the 20-kDa compounds. Peak plasma concentrations of 4 and 7 μM were achieved 6 h after administration. Levels then declined with halflives of 9 and 3 h for the 40-kDa and 20-kDa conjugates, respectively. Asterpaullone was not detected in the plasma following *i.p.* injection of the 20-kDa carbamate-linked conjugate. An *i.p.* study was not conducted with the corresponding 40-kDa conjugate.

DISCUSSION

PEG has been extensively used due to its ability to increase the solubility, circulating life, safety, and permeable tissue accumulation level for small molecule prodrug platforms (*9*). The use of prodrug design has been applied to numerous therapeutic areas with the goal to improve the pharmacologic properties of drugs. A prodrug is a biologically inactive derivative of a parent drug molecule that usually requires an enzymatic or chemical transformation within the body in order to release the active drug, and has improved delivery properties over the parent molecule (*10*). Essential to drug delivery with a prodrug is the rate of release of the active drug. A rapid breakdown of the prodrug can result in spiking of the parent drug and possible toxicity, while too slow a release rate will compromise the drug's effectiveness. The linkages between the active drug and the carrier molecule can theoretically be chosen so that either pH or enzymatic degradation can mediate prolonged drug release. Therefore, the effectiveness of prodrug delivery is dependent on the stability of the drug conjugate linkage and its potential for controlled degradation. PEG conjugated to

$AUC_{0-\infty}$ = area under the curve extrapolated to infinity, CL = total plasma clearance rate, $t_{1/2,z}$ = terminal disposition phase halflife, F = relative bioavailable fraction, nd = study not done, bld = below the limit of detection.

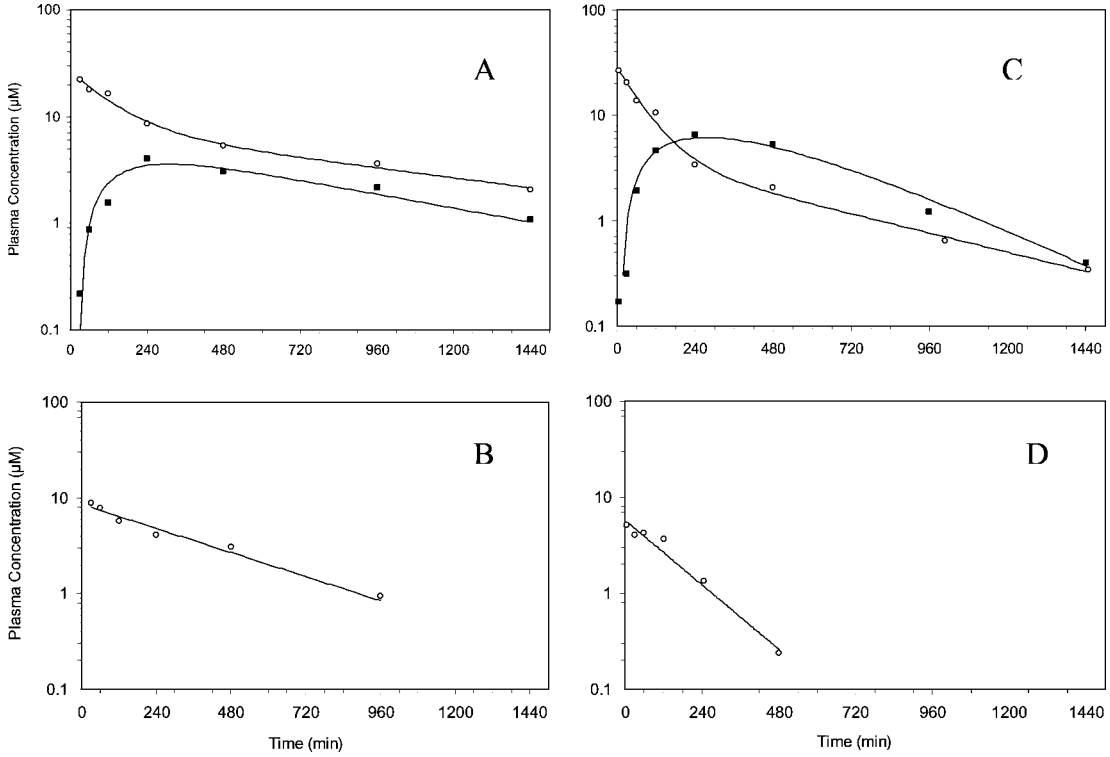

Figure 2. Geometric mean plasma concentrations of **1** and lines of best fit observed following i.v. (○) or i.p. (■) administration of PEG−conjugates to CD2F1 mice at doses equivalent to 14 mg/kg **1** (A, **20**, B, **26**; C, **22**; D, **27**).

amino prodrugs that function via a 1,4- or 1,6-elimination has been demonstrated to be a feasible methodology to deliver anticancer drugs (*5*). Another approach based on PEG technology also has now been proven to be useful for the delivery of insoluble indole-containing systems. PEG linkers were designed to target the indole N−H bond and resulted in a PEG-linked-drug bipartate system that provided alteration of plasma pharmacokinetics, while providing substantial aqueous solubility to the modified alsterpaullone.

The synthetic program conducted for this initial investigation of PEG−alsterpaullone prodrugs provided two distinct types of PEG−alsterpaullone prodrugs: those formed with a carbamate linker and those with a urea connection. These PEG conjugates were highly soluble in saline, (>2.2 mg/mL), and both of these systems demonstrated prolonged stability (>24 h) in saline at 25 °C; thus, physically the conjugates have potential clinical utility as injectable agents.

Alsterpaullone is a potent CDK inhibitor and produces cytotoxicity in sensitive human tumor cell lines exposed to 6 uM concentrations for brief periods (0.75 to 1.5 h) (*11*). An important objective of this investigation was to determine the feasibility of producing effective concentrations of alsterpaullone in vivo. When given to mice at its maximum tolerated dose, plasma concentrations of alsterpaullone were in the effective range for only 10 min. In contrast, when the 20- and 40-kDa urea conjugates were administered, alsterpaullone concentrations exceeded effective levels for 3 or 8 hours, respectively. Furthermore, administration of **1** as a PEG conjugate significantly reduced its plasma clearance rate and lengthened its biological halflife, thereby greatly increasing the in vivo residence time of **1**, and enhancing its potential for producing a therapeutic effect. Thus, this investigation revealed that PEG conjugated to **1** via an indole results in prodrugs that demonstrate significant in vivo release of **1** (Tables 2 and 3).

In vivo investigations of these PEG prodrugs are currently in progress. The results will be reported at a later date.

ACKNOWLEDGMENT

We would like to thank Drs. Laurent Meijer and Conrad Kunick for general discussions of the paullones, and Carol Aitken for her assistance in preparing this manuscript.

First Synthetic Probe for the Detection and Quantification of a Protein with a Potential α,(2→8)Sialyltransferase Activity

Gabriele D'Andrea,* Anna Rita Lizzi, and Arduino Oratore

Department of Biomedical Sciences and Technologies, University of L'Aquila, Coppito 2, Via Vetoio, I-67100 L'Aquila, Italy. Received January 23, 2004; Revised Manuscript Received July 9, 2004

There is considerable interest in monitoring α,(2→8)sialyltransferase (ST8) levels; however, there are few specific and sensitive methods to directly detect and quantitate the protein. This paper reports the development of a synthetic probe composed of oxidized colominic acid coupled to biotinyl-L-lysine hydrazide to detect and quantify ST8 with putative "initiase" activity and its use in three solid-phase applications. The detection limit observed for ST8 purified from K562 cells was ∼2 pg by dot-blot analysis. In Western blots the probe bound and specifically recognized a protein band corresponding to ST8. In ELISA a linear dose response was obtained for pure protein in the range of 50−200 pg. Analysis of 3′-azido-3′deoxythymidine-treated cells by all three methods showed a reduction in ST8 compared to control cells; treated cells had 73% of control levels by ELISA. This probe will be useful for studies on the expression ST8 and its role in glycoconjugate biosynthesis.

INTRODUCTION

A large number of sialyltransferases (STs)[1] are required to terminally add sialic acid on glycoconjugates (*1*, *2*). In the case of humans, the genome encodes probably more than 20 different STs, but up until now about 15 different human ST cDNAs have been encoded and characterized (see the web site given in ref *3*). Among the various ST activities, two of them, namely, ST8Sia II (also known as STX or "initiase") and ST8Sia IV (also known as PST or "elongase"), mediate the so-called polysialylation process, a unique type of modification in which tens of sialic acid residues are joined through an α,(2→8) linkage in a linear array (*4*); usually, polysialic acid (PSA) chains formed by ST8Sia IV are longer than those synthesized by ST8Sia II (*5*−*7*). Due to these interesting and actual observations, remarkable efforts have been directed to develop simple, reliable, inexpensive, and specific assays for different STs in general, but at the moment none is available for the direct detection and quantification of ST8 viewed just as a protein. On the other hand, specific assays in which fluoresceinyl- or radiolabeled CMP−NeuAc is used as donor and asialoglycoproteins or gangliosides are used as acceptors, allow the determination of ST8 enzymatic activity (*8*−*15*). In addition, it has been also possible to set up a protocol for parallel screening of several samples using microtiter filtration plates (*16*). However, due to the heterogeneity of putative acceptor sites, assays that make use of labeled donors hardly discriminate the different ST activities. Nevertheless, the enzyme previously cloned by Livingstone and Paulson (*17*), as well as the subsequent ST8 purified from CHP-134 neuroblastoma cells (*18*), and the affinity-purified ST8 we isolated from K562 cells (*10*, *11*) all recognize solely fetuin as substrate (and not asialofetuin), suggesting that sialyl residues in either the α,(2→3) or α,(2→6) linkage are required for the enzymatic activity: for this reason the enzyme we purified is supposed to possess a potential ST8Sia II activity. Starting from these latter pieces of evidence and taking into strict account our recent studies (*10*, *11*), we report very sensitive and easy assays for the direct detection and quantification of a putative ST8Sia II in cell lysates such as the ones obtained from both control and AZT-treated K562 erythroleukemia human cells.

To this purpose a synthetic probe was prepared comprising oxidized colominic acid coupled to biotinyl-L-lysine hydrazide. In particular, the probe was successfully used in dot-blot, Western blot, and ELISA applications. Thus, many different samples supposed to contain a putative ST8 displaying "initiase"-like activity (ST8Sia II) could be inexpensively screened simultaneously with high sensitivity and specificity in a minimum of time.

EXPERIMENTAL PROCEDURES

Probe Synthesis. Colominic acid (poly[2,8-(*N*-acetylneuraminic acid sodium salt)]; $(C_{11}H_{16}NNaO_8)_n$, Fluka code 27698) was dissolved in 0.1 M sodium *m*-periodate (100 mM sodium acetate, pH 5.5; 2.5 mg/10 mL), and the solution was left at room temperature for 20 min in the dark. Glycerol 86−88% (250 μL) was added to stop the reaction (room temperature for 20 min in the dark). Four dialysis changes against PBS-cations (20 mM potassium phosphate buffer, pH 7.2, containing 0.15 M NaCl, 1 mM each $CaCl_2$ and $MgCl_2$) were then carried out. Subsequently, N_ϵ-(+)biotinyl-L-lysinehydrazide hydrochloride

($C_{16}H_{30}N_6O_3S$·HCl; Fluka code 14415; 2.5 mg/2 mL PBS-cations) was added and the solution incubated at room temperature for 16 h. After the solution had cooled at 0 °C and an equal volume of 30 mM sodium cyanoborohydride (Fluka code 71435) had been added, incubation at 0 °C for 45 min followed. Last, a dialysis step as above was carried out and the solution stored at 4 °C in the presence of 0.02% (w/v) sodium azide.

Cell Cultures. Human erythroleukemia cells (K562), kindly supplied by Dr. L. Di Renzo (Laboratory of Experimental and Pathologic Medicine, University of Rome 'La Sapienza'), were grown as already described (*10*).

Cell Homogenate Preparation and ST8 Purification. K562 cells (6.5×10^8) incubated alone or with 20 μM AZT for 3 h were washed twice with PBS (20 mM potassium phosphate buffer, pH 7.2, containing 150 mM NaCl), resuspended in 1.45 mL of 50 mM MES buffer, pH 6.0, containing 1 mM dithiothreitol (MET buffer), and then homogenized. Sonication for 10 s × 10 and centrifugation at 1120g for 15 min followed. The supernatant solution was centrifuged at 23000*g* for 1 h and the pellet suspended in 500 μL of 0.1% (w/v) Triton CF-54 in MET buffer, pH 6.0, sonicated for 10 s × 10, and centrifuged at 23000*g* for 30 min. This second supernatant solution was used in all types of analyses.

ST8 was purified from K562 as already reported (*10*).

Dot-Blot. Different amounts of protein homogenates from control and AZT-treated samples, or pure ST8, were separately loaded into each well. The PVDF membrane was then washed in TTBS [0.05 M Tris-HCl buffer, pH 7.5, containing 150 mM NaCl and 0.05% (w/v) Tween-20] for 10 min and blocked with 1% (w/v) BSA. After three washes, the membrane was soaked in 25 mM HCl for 20 min, washed again, and then incubated with the probe solution (1.3 μg/mL, 1 h, 25 °C). Further washing steps were carried out, and incubation for 1 h with alkaline phosphatase−Extravidine conjugate (Sigma, Milan, Italy) diluted 1:300 000 followed. Blots were developed by using 10 mL of substrate solution composed of 9.9 mL of TBS, 45 μL of BCIP (13 mg/mL in dimethylformamide), and 55 μL of NBT [20 mg/mL in 70% (v/v) dimethylformamide].

SDS−PAGE and Western Blot. Aliquots of the second supernatant solution (8 μg) and pure ST8 (1 μg) were assayed by SDS−PAGE on a 10% gel according to the method of Laemmli (*19*); bands were visualized by Coomassie brilliant blue staining (Figure 2A). Cell lysates and pure ST8, prepared as above and resolved by SDS−PAGE, were blotted onto PVDF membranes as described elsewhere (*20*), with slight modifications. The membrane was washed, blocked, and treated as reported under Dot-Blot.

ELISA. Cell homogenates (100 μL), or the pure enzyme solutions, diluted in 0.08 M carbonate buffer, pH 9.6, were loaded to the wells of a plastic 96-well microtiter plate and left for 3 h at 37 °C. Wells were then washed four times with PBS-T [20 mM potassium phosphate buffer, pH 7.2, containing 0.15 M NaCl and 0.05% (w/v) Tween-20] followed by incubation with 25 mM HCl for 20 min. After a washing step, 100 μL of probe solution (1.3 μg/mL) was added to each well, and the reaction was allowed to go on for 1 h at 37 °C. The wells were then again washed four times with PBS-T before incubation (1 h at 37 °C) with alkaline phosphatase−Extravidine conjugate (Sigma, Milan, Italy) diluted 1:10 000. After the last washes, 100 μL of 1 mg/mL 4-nitrophenyl phosphate bis(cyclohexylamine) salt in 0.1 M glycine, pH 9.4, was poured into each well, and the absorbance was read at 415 nm after 1 h.

Protein Determination. Total protein concentration was determined according to the Bio-Rad protein assay (*21*).

RESULTS AND DISCUSSION

Polysialic acid (PSA) is a linear homopolymer ($n = \sim 8$ to >100) of α,(2→8)-linked sialic acid joined, most of the time, to an N-linked carbohydrate core (*22*), although a novel member of α,(2→8)sialyltransferase (ST8Sia VI) that sialylates preferentially *O*-glycans has been recently identified (*23*).

However, at the moment it is not clear if the so-called "initiase" activity and the so-called "elongase" activity, both necessary to synthesize PSA, may be subsumed by the two above-mentioned enzymes or are the province of distinct sialyltransferases. It has been reported that cell lines from colon cancer express polysialyltransferases (mainly ST8 IV) without concomitant expression of PSA (*24*). Although different experimental approaches made possible the study on PSA biology (*22*, *25*−*27*), the cellular mechanism by which PSA affects cell interactions has not yet been defined. On the other hand, at present, specific and sensitive assays for ST8 displaying "initiase" activity are scarcely available except the one that makes use of fetuin as glycoprotein substrate acceptor (*10*, *11*, *18*). In the present study we report the first synthetic probe for the direct detection and quantification of a protein displaying a potential, putative ST8Sia II activity. To this purpose some typical methods such as dot-blot, Western blot, and ELISA were set up.

In particular, starting from the evidence that it is possible to purify ST8 basically by colominic acid/polyacrylohydrazido-agarose affinity chromatography (*10*, *11*, *18*), colominic acid was first oxidized and the reaction stopped by incubation with glycerol. Then, after dialysis, the colominic acid solution was recovered and reacted with a biotinylating compound such as biotinyl-L-lysine hydrazide that shows a better solubility in aqueous solution than either biotin hydrazide or biotin LC-hydrazide (*28*). Subsequently, the adduct solution was incubated with sodium cyanoborohydride to further stabilize the bond between the hydrazide and the aldehyde (produced after colominic acid oxidation) (*29*). An additional dialysis step was carried out to remove unbound material and the adduct solution stored a 4 °C. Because our recent studies have been focused on K562 cells expressing an ST8 consistent with an "initiase"-like activity sensitive to AZT (*10*, *11*), this cell system was used to check the ability of our synthetic adduct to recognize ST8Sia II, permitting both the detection and quantitation of the enzymatic protein. To this purpose, three different typical and basic methodological approaches were explored (i.e., dot-blot, Western blot, and ELISA). In all cases, protein extracts obtained after solubilization in Triton CF-54, from both control and AZT-treated K562 cells, were appropriately prepared and analyzed. In dot-blot format the same range of total proteins from both control and AZT-treated cells was exploited (from 0.5 to 20 μg). As shown in Figure 1, the sensitivity limit found for our ST8 purified from K562 cells was ∼2 pg (row ST8). Although by dot-blot analysis it was possible to determine the sensitivity limit of our probe, a different quantitative expression of ST8 between control cells and AZT-treated cells could be only slightly visually appreciated (Figure 1, rows C and T, respectively); furthermore, normal human serum did not give

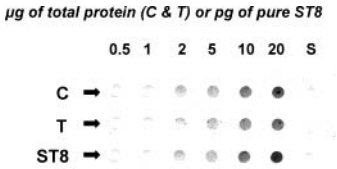

Figure 1. Dot-blot of control (C), AZT-treated (T) K562 cells, and α,(2→8)sialyltransferase (ST8) purified from K562 cells (*10*). S, normal human serum 1:250, 100 μL.

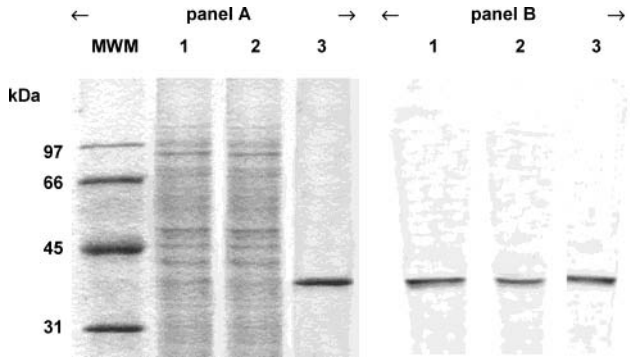

Figure 2. SDS−PAGE (A) and Western blot (B) analyses: (lane 1) control K562 cells; (lane 2) AZT-treated K562 cells; (lane 3) ST8 purified from K562 cells (*10*). MWM, molecular weight markers.

any reaction, indicating the lack of nonspecific binding of our probe at least toward human serum proteins (Figure 1, lane S).

After SDS−PAGE (Figure 2A), samples were blotted onto a PVDF membrane and revelation carried out as reported under Experimental Procedures (Figure 2B). Thus, when the same types of samples were analyzed by Western blot, a specific binding was observed for the protein band that showed a molecular mass of ∼40 kDa and corresponding to ST8, as previously reported (*10*). Interestingly, although the same amount of total proteins was loaded for both types of samples, control sample showed a higher intensity than AZT-treated sample, not only after SDS−PAGE (Figure 2A, lane 1) but also, and much more evidently, after Western blot (Figure 2B, lane 1). Moreover, apart from the net positive reaction observed for ST8, all other protein bands present in cell homogenates did not react with the probe (Figure 2B, lanes 1 and 2). Furthermore, control experiments carried out with different pure commercial sialyltransferases, that is, α,(2→3) (N), α,(2→3) (O), α,(2→6) (N) (Calbiochem), and loaded at the same amount of our pure ST (i.e., 1 μg) did not react versus our probe (data not shown). Eventually, when the pure protein (enzyme) was analyzed by ELISA, a linear dose-dependent response was obtained in the range of 50−200 pg (Figure 3, inset). A similar linear response was observed also for both control and AZT-treated samples, but these latter showed a decrease (73% of control) as calculated from the slope (Figure 3). Remarkably, the value of this decreased amount of protein (73% of control) strictly paralleled the decrease of ST8 activity we previously found in K562 cells treated with 20 μM AZT (75% of control) (*11*). Confirmatory evidence that the probe response in ELISA correlated with ST8 enzymatic activity was achieved through a "reverse" ELISA-like experiment. Briefly, streptavidin-coated microtiter plates (Molecular Probe) were first incubated with our probe and then with K562 cell homogenates from control or AZT-treated cells or with the pure ST8. After intermediate washing steps, elution-in-well by using colominic acid (25 mM) followed. The

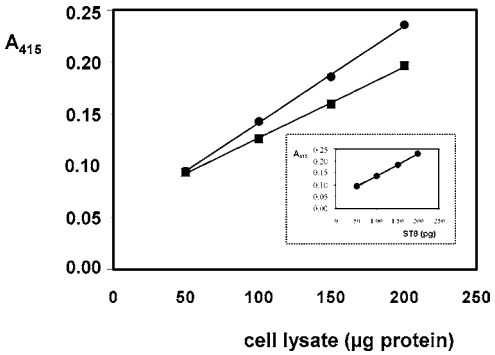

Figure 3. ELISA: absorbance values at 415 nm as a function of cell lysate protein amount in control (●) and AZT-treated (■) K562 cells. (Inset) Standard curve obtained with the pure enzyme ST8 purified from K562 cells (*10*). Data are means of three separate determinations with SD < 3%.

recovered solution was subsequently dialyzed, concentrated, assayed for its enzymatic activity (*10*, *11*), and subjected to dot-blot, Western blot, and ELISA. In all cases, compared to the ST8 enzyme affinity purified, superimposed results were obtained (data not shown). Of course, for an absolute quantitation in other cell systems, the pure protein is required.

It is worth noting that all data here reported, representing the best results achieved, were obtained when incubation with the probe was carried out after incubation with 25 mM HCl (20 min, room temperature). In our opinion this "acidic step" improved all assays probably because the enzymatic protein was freed of some bound anionic compound. This view is partly supported by the evidence that ST8 displaying "initiase"-like activity (ST8Sia II) strongly recognizes and binds to a highly negatively charged molecule such as colominic acid (coupled to polyacrylohydrazido-agarose) and it is eluted from the affinity column by using high colominic acid concentration (*10*, *11*, *18*). However, it should be underscored that although colominic acid binds to ST8Sia II, it does not serve as substrate (*10*, *18*). Last, independently from the analyses we carried out (dot-blot, Western blot, ELISA), the decreased amount of the putative ST8 we found in AZT-treated cells, compared to control cells, was in line with our recent study (*11*).

At the moment further studies are in progress to better characterize the synthetic probe we obtained, mainly from the spectroscopic point of view.

In conclusion, because considerable efforts have been directed to developing simple, reliable, specific, and inexpensive assays for different STs in general, but at present none is available for the direct detection and quantitation of ST8, especially in cell homogenates, we have developed a promising synthetic probe for the direct, rapid, inexpensive, and sensitive detection and quantitation of ST8. Our probe combines the advantage and detection technology of solid-phase reaction, being versatile and capable of simultaneous processing of multiple samples. The probe we synthesized could represent an attractive alternative to the currently used approaches to study ST8, and it is predicted to be a powerful tool for further investigation of ST8.

ACKNOWLEDGMENT

Luminescent lanthanide complexes consisting of a lanthanide-binding chelate and organic-based antenna molecule have unusual emission properties, including millisecond excited state lifetimes and sharply spiked spectra, compared to standard organic fluorophores. We have previously used carbostyril (cs124, 7-amino-4-methyl-2(1*H*)-quinolinone) as an antenna molecule (Li and Selvin, *J. Am. Chem. Soc.*, 1995) attached to a polyaminocarboxylate chelate such as DTPA. Here, we report the chelate syntheses of DTPA conjugated with cs124 derivatives substituted on the 1-, 3-, 4-, 5-, 6-, and 8-position. Among them, the DTPA chelate of cs124-6-SO_3H has similar lifetime and brightness for both Tb^{3+} and Eu^{3+} compared to the corresponding DTPA−cs124 complexes, yet it is significantly more soluble in water. The Tb^{3+} complex of DTPA−cs124-8-CH_3 has significantly longer lifetime compared to DTPA−cs124 (1.74 vs 1.5 ms), indicating higher lanthanide quantum yield resulting from the elimination of back emission energy transfer from Tb^{3+} to the antenna molecule. Thiol-reactive forms of chelates were made for coupling to proteins. These lanthanide complexes are anticipated to be useful in a variety of fluorescence-based bioassays.

INTRODUCTION

Carbostyril (cs124, 7-amino-4-methyl-2(1*H*)-quinolinone) and its derivatives have been used as antenna molecules to absorb light and to transfer excitation energy to lanthanide ions, which significantly increases the fluorescence efficiency of lanthanides (*1*−*4*). To achieve this energy transfer, cs124 or its derivatives are attached to a chelate backbone (such as diethylenetriaminepentaacetic acid, DTPA), which is the site that ligates lanthanide ions. If placed in close range, energy transfer from cs124 (or derivatives) to lanthanide ions is achieved. The chelate backbone site can be further attached to either a thiol-reactive or amine-reactive group for attachment to biomolecules such as DNA and proteins. The advantages of such fluorescence complexes include high solubility in aqueous solution, long fluorescence lifetime (milliseconds), high quantum yields, large Stokes shifts, and sharply spiked emission spectra. These properties make lanthanide complexes attractive probes for fluorescence studies of biomolecules. Such complexes have been used in energy transfer experiments on the muscle protein myosin (*5*−*8*) and on ion channels (*9*).

Most of these lanthanide chelates have used carbostyril as the sensitizer (*10*−*14*). Rarely, a carbostyril derivative was used as a sensitizer (*15*). Because of complex photophysics, the mechanisms of energy transfer from sensitizer to lanthanides have not been fully understood (*16*−*19*). Therefore, it is difficult to rationally design the structures of carbostyril-based lanthanide sensitizers. Given the versatile synthetic possibilities of modifying the cs124 structure (Figure 1), it is interesting to explore how the structural modification can effect the chemical, physical, and photophysical properties of lanthanide chelates. We report the syntheses of new lanthanide chelates with carbostyril derivatives with substitutes on the 1-, 3-, 4-, 5-, 6-, and 8-position as sensitizer, their photophysical properties, and their reactivity to biomolecules.

EXPERIMENTAL METHODS

Chemicals and Materials. The following were purchased from Sigma-Aldrich: diethylenetriaminepentaacetic acid dianhydride (caDTPA), 3′-aminoacetanilide, 2,4-diaminobenzenesulfonic acid, 3,5-diaminobenzyl alcohol dihydrochloride, ethylenediamine (EDA), anhydrous dimethyl sulfoxide (DMSO, in sure seal bottle), and triethylamine (for reaction). DMSO and triethylamine were dried over activated molecular sieves before use. Glacial acetic acid, methanol, and triethylamine (for making triethylammonium acetate (TEAA) buffer) were purchased from Fisher Scientific. *β*-Maleimidopropionic acid hydrazide·TFA (EMPH·TFA) and *N*-hydroxysuccinimidyl bromoacetate were purchased from Molecular Biosciences (Boulder, CO). *N*-(*ϵ*-Maleimidocaproic acid) hydrazide (EMCH) was purchased from Pierce (Rockford, IL). Maltose binding protein (MBP) was a gift from Panvera Inc. (Madison, WI). Distilled and deionized (18 MΩ cm^{-1}) water was used throughout. All glassware was washed

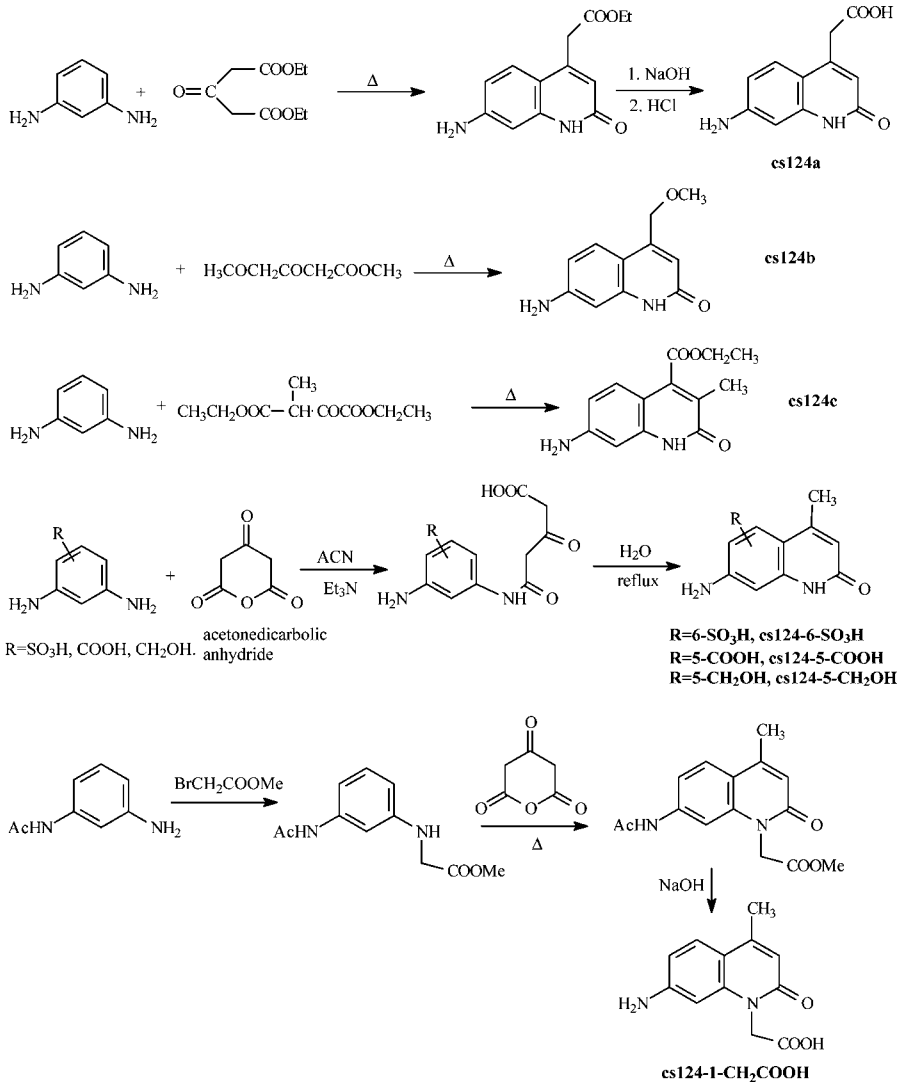

Figure 2. Syntheses and structures of 7-aminoquinolinone derivatives.

with a mixed acid solution and thoroughly rinsed with deionized, distilled water. All plastic labware was purchased from Bio-rad (metal-free). All chemicals were of the purest grade available.

Acetonedicarboxylic anhydride was synthesized according to published method (*20*). 7-Amino-4,8-dimethyl-2-(1*H*)-quinolinone (carbostyril 124-8-methyl, cs124-8-CH_3) was purchased from SPECS & BioSPECS (Rijswijk, The Netherlands). The syntheses of 7-amino-4,6-dimethyl-2-(1*H*)-quinolinone (carbostyril 124-6-methyl, cs124-6-CH_3) and 7-amino-4-methyl-6-sulfonic acid-2-(1*H*)-quinolinone (carbostyril 124-6-SO_3H, cs124-6-SO_3H) had been reported (*21*). In this report, a different synthetic method for cs124-6-SO_3H was used.

Purification. Reverse-phase high-performance liquid chromotography was performed at room temperature on a Waters model 600 system with a Dynamax 60 Å C_{18} column (10 or 25 mm i.d. × 250 mm, Rainin, at 8 mL/min, respectively) using a linear gradient (solvent A = 0.1 M triethylammonium acetate (TEAA), pH 6.5; solvent B = methanol or acetonitrile) over 40 min. The eluted fractions were monitored with a UV detector at a wavelength of 328 nm.

Spectroscopy. NMR spectra were recorded on a Varian Unity 400 spectrometer. Time-resolved and gated luminescence measurements were made on a laboratory-built spectrometer described previously, employing a 5 ns excitation pulse at 337 nm followed by time-resolved detection of lanthanide emission (*22*).

Syntheses of cs124 Derivatives (Figure 2). *Synthesis of 7-Amino-1,2-dihydro-2-oxo-4-quinoline Acetic Acid (cs124a).* 1,3-Diaminobenzene (200 mg, 1.85 mmol) was mixed with diethyl 1,3-acetonedicarboxylate (410 mg, 2.03 mmol). The mixture was heated at ∼160 °C for 24 h under N_2. A brown solid formed at the end. The solid was refluxed with acetone for 1 h. After the mixture was cooled to room temperature, the insoluble material was collected by filtration and washed with acetone. The collected solid was stirred with 5 mL of 10% NaOH for 5 h. Most of the solid dissolved. HCl and acetic acid were used to adjust the pH to ∼9. The solution was filtered through Celite. The filtrate was subjected to HPLC purification with a 20−40% linear gradient of MeOH/TEAA. The peak with the retention time of 12 min was collected. The solvent was removed to afford 7-amino-1,2-dihydro-2-oxo-4-quinoline acetic acid (trace amount, yield <1%). MS, *m/z*: 217 (M^- − 1, ESI). ^{1}H NMR (ppm, DMSO-d_6): 11.13 (s, 1H), 7.42 (d, 1H), 6.39 (d, 1H), 6.34 (s, 1H), 5.87 (s, 1H), 5.65 (s, br, 2H), 3.32 (s, 2H). ^{13}C NMR (ppm, DMSO-d_6): 171.72, 162.27, 151.06, 145.19, 141.00, 125.58, 116.11, 114.56, 110.51, 109.80, 96.74.

7-Amino-4-(methoxymethyl)-2(1H)-quinolinone (cs124b). 1,3-Diaminobenzene (200 mg, 1.85 mmol) was mixed with

methyl 4-methoxyacetoacetate (297 mg, 2.03 mmol). The mixture was heated at ~160 °C for 24 h under N_2, after which a brownish solid formed. The solid was washed with acetone and collected by filtration. The solid was further purified by recrystallization in EtOH to afford a pale-yellow solid, cs124b (232 mg, 69% yield). MS, *m/z*: 205 ($M^+ + 1$, ESI). Anal. Calcd for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92; N, 13.72. Found: C, 63.43; H, 5.93; N, 13.41. ^{1}H NMR (ppm, DMSO-d_6): 11.24 (s, 1H), 7.29 (d, 1H), 6.42 (d, 1H), 6.36 (s, 1H), 6.06 (s, 1H), 5.76 (s, 2H), 4.51 (s, 2H), 3.33 (s, 3H). ^{13}C NMR (ppm, DMSO-d_6): 162.35, 151.05, 147.25, 141.05, 124.96, 112.70, 110.46, 108.06, 96.78, 70.46, 57.99.

7-Amino-1,2-dihydro-2-oxo-3-methyl-4-quinoline Carboxylic Acid Ethyl Ester (cs124c). 1,3-Diaminobenzene (350 mg, 3.24 mmol) was mixed with diethyl oxalpropionate (719 mg, 3.56 mmol). The mixture was heated at ~160 °C for 24 h under N_2. A brownish solid formed and was dissolved in boiling ethyl acetate. The hot solution was cooled in an ice bath, causing yellow crystals to form. The solid was collected by filtration and further purified by passing through a silica gel column with ethyl acetate as the eluent to afford a yellow compound, cs124c (464 mg, 58% yield). MS, *m/z*: 247 ($M^+ + 1$, ESI). Anal. Calcd for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73; N, 11.38. Found: C, 63.15; H, 5.80; N, 11.07. ^{1}H NMR (ppm, acetone-d_6): 10.85 (s, br, 1H), 7.13 (d, 1H), 6.60 (s, 1H), 6.57 (d, 1H), 5.38 (s, br, 2H), 4.47 (q, 2H), 2.03 (s, 3H), 1.40 (t, 3H).

General Procedure for the Syntheses of cs124-6-SO_3H, cs124-5-COOH, and cs124-5-CH_2OH. To a suspension of substituted diaminobenzene dihydrochloride in anhydrous acetonitrile, 1 equiv of Et_3N was added at 0 °C under N_2. The mixture was stirred for 30 min. Acetonedicarboxylic anhydride, 1.2 equiv, was added to the above mixture. The reaction mixture was stirred for 8 h during which the temperature was warmed to room temperature. The organic solvent was removed under reduced pressure. The residue was dissolved in H_2O. $NaHCO_3$ was added until no CO_2 bubbles were released. The aqueous solution was refluxed under N_2 for 36 h. The solution was acidified with HCl and acetic acid to pH ~3−4. Precipitates formed during this process. The solution was allowed to stay overnight to complete the crystallization process. The solid was collected and further purified by recrystallization in ethanol.

cs124-6-SO_3H: yellow solid, 55% yield. MS, *m/z*: 253 ($M^- - 1$, ESI). ^{1}H NMR (ppm, DMSO-d_6): 11.16 (s, 1H), 7.73 (s, 1H), 6.38 (s, 1H), 5.95 (s, 1H), 2.27 (s, 3H).

cs124-5-COOH: white solid, 26% yield. MS, *m/z*: 219 ($M^+ + 1$, FAB). ^{1}H NMR (ppm, DMSO-d_6): 11.29 (s, 1H), 6.39 (s, 2H), 5.96 (s, 1H), 5.90 (s, 2H), 2.28 (s, 3H). ^{13}C NMR (ppm, DMSO-d_6): 172.08, 161.61, 149.79, 147.12, 141.68, 117.00, 109.82, 106.02, 97.56, 20.53.

cs124-5-CH_2OH: white solid, 18% yield. MS, *m/z*: 205 ($M^+ + 1$, FAB). ^{1}H NMR (ppm, DMSO-d_6): 11.15, (s, 1H), 6.58 (s, 1H), 6.30 (s, 1H), 5.88 (s, 1H), 5.73 (s, 2H), 3.34 (s, 2H), 2.54 (s, 3H). ^{13}C NMR (ppm, DMSO-d_6): 161.59, 149.88, 149.36, 142.65, 141.05, 116.60, 112.64, 108.76, 96.65, 63.28, 23.42.

Synthesis of cs124-1-CH_2COOH. 3′-Aminoacetanilide (500 mg, 3.33 mmol) was added to the aqueous solution containing 300 mg (3.57 mmol) of $NaHCO_3$. Methyl bromoacetate (560 mg, 3.66 mmol) was added to the mixture. The reaction mixture was refluxed for 4 h. The solution was cooled to room temperature and stirred overnight. The white solid of *N*-(3′-aminophenyl)glycine methyl ester was formed during the process. The solid was collected by filtration and dried. This solid was used for the next step without further purification.

The synthesized *N*-(3′-aminophenyl)glycine methyl ester (300 mg, 1.35 mmol) was mixed with acetonedicarboxylic anhydride (200 mg, 1.56 mmol) under N_2. The mixture was heated at ~160 °C for 24 h. The resulting deep-red solid was mixed with 3 mL of acetone. The mixture was refluxed for 30 min, then cooled to 0 °C. A precipitate formed during this process and was collected by filtration and washed with cold acetone to yield pale-reddish solid. The solid was further purified by recrystallization in EtOH to afford white 7-acetamide−cs124-1-CH_2COOCH_3 (152 mg, 39% yield). MS, *m/z*: 289 ($M^+ + 1$, FAB).

The obtained 7-acetamide−cs124-1-CH_2COOCH_3 was stirred in 10% NaOH for 8 h under N_2. A clear solution was formed. The solution was acidified with dilute HCl to pH ~3−4. A white precipitate formed during the process. The precipitate was collected and washed with H_2O. The solid was further purified by recrystallization in EtOH to afford 7-amino-*N*-(acetic acid)-2-quinolinone (47 mg, 37% yield). MS, *m/z*: 231 ($M^- - 1$, ESI). ^{1}H NMR (ppm, DMSO-d_6): 7.43 (d, 1H), 6.51 (d, 1H), 6.31 (s, 1H), 6.09 (s, 1H), 5.86 (s, br, 2H), 4.78 (s, 2H), 2.31 (s, 3H). ^{13}C NMR (ppm, DMSO-d_6): 169.85, 161.28, 151.66, 147.50, 141.11, 126.65, 113.51, 110.94, 109.90, 96.54, 43.07, 18.59.

Syntheses of DTPA-Based Lanthanide Chelates (Figure 3). *Gerneral Procedure for the Syntheses of Lanthanide Chelates from cs124 Derivatives.* An amount of 1 equiv of DTPA dianhydride was dissolved in a mixture of DMSO and 5 equiv of Et_3N under N_2. An amount of 0.7 equiv of cs124 derivative dissolved in DMSO was added slowly to the above solution with vigorous stirring. The reaction mixture was stirred at room temperature for 2 h. The solution was saved for the following steps.

If non-thiol-reactive chelates were to be synthesized, the above solution was quenched by addition of acetic acid and 0.1 M TEAA buffer (pH 6.5). The products were purified by reverse-phase HPLC with a linear gradient (typically 20−40% MeOH/TEAA, pH 6.5, over 40 min). The yield varies from ~20% to ~50%, as judged from the HPLC profiles (Table 1).

If the maleimide form of thiol-reactive chelates were to be synthesized, the above solution was transferred rapidly to a DMSO solution containing 1.3 equiv of EMPH·TFA (or EMCH) under N_2. The reaction mixture was stirred at room temperature for 4 h. Acetic acid and 0.1 M TEAA (pH 6.5) were added to quench the reaction. The product was purified by reverse-phase HPLC with a linear gradient (typically 20−40% MeOH/TEAA, pH 6.5, over 40 min). The yield varies from ~15% to 40%, as judged from the HPLC profiles (Table 2).

DTPA−cs124-8-CH_3−EDA-Br was prepared with a procedure similar to that used for DTPA−cs124−EDA-Br (*11*). DTPA dianhydride was reacted with cs124-8-CH_3 and EDA sequentially. The intermediate compound, DTPA−cs124-8-CH_3−EDA, was purified by HPLC. The pH of the concentrated aqueous solution of DTPA−cs124-8-CH_3−EDA was adjusted to ~8.5 by addition of Et_3N. *N*-Hydroxysuccinimidyl bromoacetate (3 equiv) was added to the solution. The reaction mixture was stirred at room temperature for 1 h. The product, DTPA−cs124-8-CH_3−EDA-Br, was purified by HPLC.

Addition of Metals. $TbCl_3$ or $EuCl_3$ was added to the chelate in a 1:2 molar ratio usually at >0.5 mM concentration at pH 6−7, usually in 0.1 M TEAA, pH 6.5 buffer, and allowed to stand for 30 min at room temperature before use.

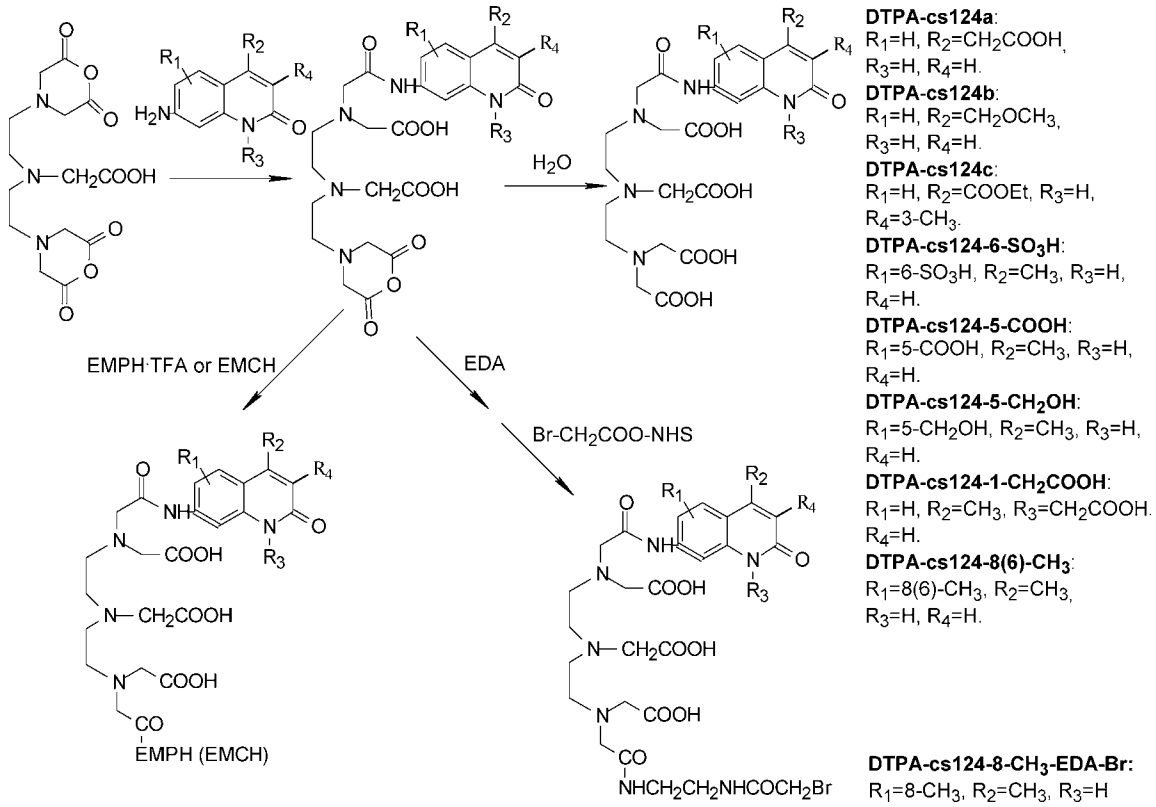

Figure 3. Syntheses of lanthanide chelates from cs124 derivatives.

Table 1. Non-Thiol Reactive Lanthanide Chelates

non-thiol-reactive DTPA chelates	linear gradients	retention time (min)	yield (%)	ESI-MS, $M^- - 1$ (m/z)
DTPA−cs124a	20−40% MeOH/TEAA	13.5	20	592
DTPA−cs124b	20−40% MeOH/TEAA	19	50	578
DTPA−cs124c	30−50% MeOH/TEAA	30.5	36	620
DTPA−cs124-6-SO_3H	30−50% MeOH/TEAA	13.5	20	628
DTPA−cs124-5-COOH	20−40% MeOH/TEAA	15.0	40	592

DTPA−cs124-1-CH_2COOH−EMPH	30−50% MeOH/TEAA	16.5	30	771

Coupling to Biomolecules. The labeling conditions for conjugation to muscle protein (S1 fragment of smooth muscle myosin containing a single cysteine at position 208) have been described previously (*5*, *11*). The procedure for labeling Shaker K^+ ion channels in Xenopus oocytes has also been published (*9*). The maleimide chelates were coupled to muscle protein or to maltose binding protein (MBP, a 65 kDa protein containing a single cysteine) at a typical ratio of 10:1 with a protein concentration of ~15 μM. The coupling reaction was carried out on ice overnight in 20 mM 3-(*N*-morpholino)-propanesulfonic acid, pH 7.0, 5 mM $MgCl_2$. The excess lanthanide chelates were removed by passing the reaction mixture through a Sephadex G-50 size-exclusion column.

RESULTS AND DISCUSSION

Syntheses. The key step in synthesizing carbostyril and its derivatives is the formation of the 2-quinolinone ring. 1,3-Diaminobenzene and its derivatives reacted with β-diketone compounds to form intermediate β-diketone amido compounds, which further underwent ring closure to form the products. The compounds cs124a, cs124b, and cs124c were synthesized by reacting 1,3-diaminobenzene with the corresponding β-diketone esters at high temperature (usually >150 °C). A good yield was obtained for cs124b and cs124c, but a trace amount of cs124a was isolated after hydrolysis. The vast undesired byproducts were not identified.

Compounds cs124-6-SO_3H, cs124-5-COOH, cs124-5-CH_2OH, and cs124-1-CH_2COOH were synthesized with

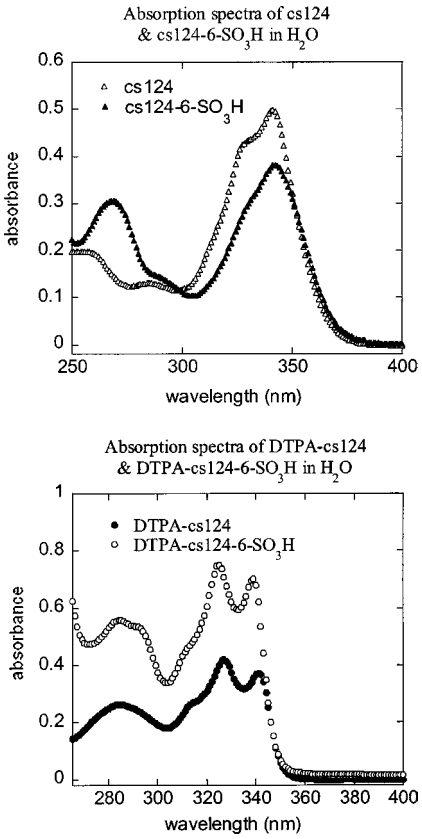

Figure 4. Comparison of the absorption spectra of cs124 and cs124-6-SO_3H and their lanthanide chelates.

a modified method. 1,3-Diaminobenzene derivatives were reacted with 1 equiv of acetonedicarboxylic anhydride at room temperature. The intermediates formed were then refluxed under milder conditions (100 °C) to undergo ring closure. The −COOH group in the intermediates from acetonedicarboxylic anhydride was easily lost to produce the 4-CH_3 group. The advantage of this method is that it does not require as high a temperature as the synthesis using β-diketone esters. This is especially important when the 1,3-diaminobenzene derivatives are not thermally stable. We note that acetonedicarboxylic anhydride had been used to synthesize quinolinone acetic acid compound (*20*). Our efforts in using this method to synthesize cs124a showed that mainly the −COOH depleted product, cs124, was formed.

The luminescent lanthanide chelates were synthesized in a way similar to that in previously reported work (*10*, *11*, *14*). DTPA dianhydride was reacted with cs124 derivatives to form monoanhydride intermediates (Figure 3). These intermediates can be either hydrolyzed or reacted with EMPH (or EMCH) to form thiol-reactive maleimide chelates. The chelates were purified by reverse-phase linear gradient HPLC. The syntheses are straightforward, and the yields are satisfactory.

Absorption Spectra. All of the synthesized cs124 derivatives and their DTPA lanthanide chelates exhibit similar or almost identical absorption spectra to those of cs124 and its DTPA lanthanide chelate. As an example, the UV−vis spectra of cs124-6-SO_3H and DTPA−cs124-6-SO_3H were compared to that of cs124 and DTPA−cs124 (Figure 4).

These absorption spectra were taken in aqueous media. Both of the absorption spectra of free cs124 and cs124-6-SO_3H exhibit the most intense absorption at 342 nm. A shoulder peak appears at ∼326 nm. After the coupling

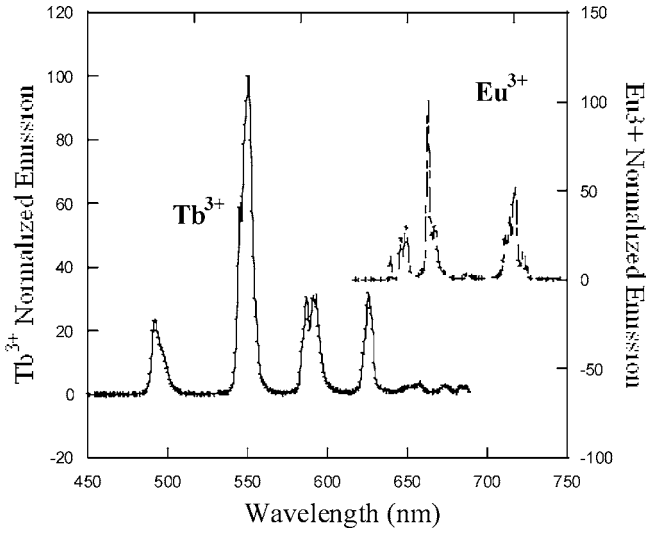

Figure 5. Normalized Tb^{3+} and Eu^{3+} emission spectra in DTPA−cs124-6-SO_3H in 0.1 M TEAA, pH 6.5, at a concentration of 1 μM. Tb^{3+} and Eu^{3+} display their characteristic sharply spiked spectra. Pulsed excitation was at 40 Hz, 3.5 μJ/pulse for Eu^{3+}, 3.0 μJ/pulse for Tb^{3+}. The integration time is 1 s for Tb^{3+} and 10 s for Eu^{3+}.

to DTPA, these two absorption peaks are well resolved, and the absorption at ∼326 nm becomes the most intense peak. These are the characteristic features of carbostyril and its DTPA lanthanide chelates. Such features were also observed for all cs124 derivatives and their lanthanide chelates.

Emission Spectroscopy of Lanthanide Complexes. All the Tb^{3+} and Eu^{3+} complexes exhibit their characteristic sharply spiked emission spectra as demonstrated by their DTPA−cs124-6-SO_3H complexes (Figure 5). Table 3 lists the excited-state lifetimes of Tb^{3+} and Eu^{3+} measured for their complexes with the chelates. Table 4 lists the excited state lifetimes of Tb^{3+} and Eu^{3+} measured for their complexes with the chelates labeled to proteins (smooth muscle myosin, maltose binding protein (MBP), and Xenopus oocytes). Generally, the Tb^{3+} and Eu^{3+} complexes of these chelates have emission brightness comparable to that of the benchmark chelate, DTPA−cs124. By introduction of hydrophilic groups to the sensitizers, the chelates derived from cs124a, cs124-6-SO_3H, cs124-5-COOH, cs124-5-CH_2OH, and cs124-1-CH_2COOH possess increased solubility in water, especially in the case of cs124-6-SO_3H. Although they show emission brightness comparable to that of the reference complex, DTPA−cs124, they often have shorter lifetimes. Contrary to this trend, Tb^{3+}−DTPA−cs124-6-SO_3H shows a slightly longer lifetime, and its brightness is about 62% that of Tb^{3+}−DTPA−cs124. Clearly, the introduction of 6-SO_3H on cs124 has no dramatic effect on the emission properties of its lanthanide complex.

The Tb^{3+} complexes with the chelates of 6- or 8-CH_3 cs124 derivatives, especially the 8-CH_3 derivative, have longer lifetimes than DTPA−cs124 (1.74 vs 1.53 ms). This suggests that a higher lanthanide quantum yield was achieved in these complexes. Increased lanthanide quantum yield could result from either a decrease in solvent quenching or a decrease in energy back transfer to the antenna. We measured the number of solvent molecules coordinated to the lanthanide ion in Tb^{3+}−DTPA−cs124-8-CH_3 using the method of Horrocks and Sudnick (*23*). Lifetimes of Tb^{3+}−DTPA−cs124 and Tb^{3+}−DTPA−cs124-8-CH_3 were measured in both H_2O and D_2O (Table 5). For both molecules, 1.1 H_2O molecules coordinated to

Table 3. Brightness and Lifetimes of Tb^{3+} and Eu^{3+} Complexes of DTPA−cs124 Derivative Chelates

chelate	relative brightness (%)	lifetimes (ms)
	Complexes with Tb^{3+}

Tb^{3+}, demonstrating that there is no difference in solvent quenching. Clearly, the higher quantum yield is achieved from the decrease of energy back transfer from excited Tb^{3+} to cs124-8-CH_3. Such lanthanide to ligands back energy transfer has been observed for other lanthanide complexes (*24*).

Interestingly, the thiol-reactive (maleimide form) chelates with 6- or 8-CH_3 cs124 derivatives exhibit significantly different emission properties. The Tb^{3+} complexes of DTPA−cs124-8-CH_3−EMCH is about 60% as bright as Tb^{3+}−DTPA−cs124 and is biexponential with an ∼80% long lifetime component (2.16 ms) and a ∼20% short lifetime component (0.92 ms). The Eu^{3+} complexes of DTPA−cs124-8-CH_3−EMCH is also biexponential with the brightness about 25% that of Eu^{3+}−DTPA−cs124. In contrast, the Tb^{3+} complex of DTPA−cs124-6-CH_3−EMCH is only 4% as bright as Tb^{3+}−DTPA−cs124 and is biexponential with a reduced population for the long lifetime component (1.85 59%, 0.25 41%). The Eu^{3+} complexes of DTPA−cs124-6-CH_3−EMCH is emission-silent.

The 3-CH_3 substituted chelate, DTPA−cs124c, is fluorescently effective only for Eu^{3+}. With Tb^{3+}, no emission was observed. This is consistent with our previous observation that with a substituent on the 3-position of cs124, its lanthanide chelate was fluorescent only for Eu^{3+} but not for Tb^{3+} (*25*).

In all cases, thiol-reactive chelates with the maleimide functional group are both biexponential and often dimmer compared to the benchmark chelate, DTPA−cs124. In contrast, DTPA−cs124-8-CH_3−EDA-Br is single exponential with both Tb^{3+} and Eu^{3+}. The intensity is about half of that of DTPA−cs124. Its Tb^{3+} complex has a longer lifetime than that of Tb^{3+}−DTPA−cs124 (1.68 vs 1.53 ms). After reaction to glutathione, the lifetimes remain single exponential and did not change.

The maleimide form of chelates have been successfully coupled to proteins and Xenopus oocytes cells. Both Tb^{3+} and Eu^{3+} complexes are biexponential. The Tb^{3+} complexes have a predominant long lifetime (>1 ms) component. Among them, the long lifetime components of Tb^{3+}−DTPA−cs124-8-CH_3−EMCH and Tb^{3+}−DTPA−cs124-6-SO_3H−EMCH have lifetimes significantly longer than the reference, Tb^{3+}−DTPA−cs124.

CONCLUSIONS

New light-harvesting quinolinone chromophors with the modification on the 1-, 3-, 4-, 5-, 6-, and 8-position of cs124 have been synthesized. Generally, their lanthanide chelates have similar brightness and lifetimes to the reference compound, DTPA−c124. The 6- or 8-methyl, especially 8-methyl, derived chelates have even longer lifetimes indicating higher lanthanide quantum yields. The 6-SO_3H derived chelate has similar luminescent properties to the reference compound while possessing dramatically increased water solubility. The thiol-reactive chelates made from these derivatives show promising physical and chemical properties.

Gene-Transferring Efficiencies of Novel Diamino Cationic Lipids with Varied Hydrocarbon Chains

Hong Sung Kim,[†] Jaeho Moon,[†] Keun Sik Kim,[†] Myung Min Choi,[†] Ji Eun Lee,[†] Yeon Heo,[‡] Dae Hyan Cho,[‡] Doo Ok Jang,[‡] and Yong Serk Park*[,†]

Department of Biomedical Laboratory Science and Department of Chemistry, Yonsei University, Wonju 220-710, Korea. Received March 13, 2004

Utilizing three biocompatible components, a series of novel cationic lipids has been chemically synthesized and tested for their gene-transferring capabilities in 293 transformed kidney cells and B16BL6 mouse melanoma cells. The synthesized cationic lipids consisting of a core of lysine and aspartic acid with hydrocarbon chains of varied length were assigned the acronyms DLKD (*O*,*O*′-dilauryl *N*-lysylaspartate), DMKD (*O*,*O*′-dimyristyl *N*-lysylaspartate), DPKD (*O*,*O*′-dipalmityl *N*-lysylaspartate), and DSKD (*O*,*O*′-distearyl *N*-lysylaspartate). The gene-transferring capabilities of these cationic lipids were found to be dependent on the hydrocarbon chain length. Under similar experimental conditions, the order of gene transfection efficiency was DMKD > DLKD > DPKD > DSKD. Addition of cholesterol or dioleoyl phosphatidylethanolamine (DOPE) as a colipid did not change this order. Colipid addition affected the transfection efficiency positively or negatively depending on the length of the cationic lipid acyl chain. On the whole, the length of the hydrophobic carbon chain was a major factor governing the gene-transferring capabilities of this series of cationic lipids. The observed differences in transfection efficiency may be due to differing binding affinities to DNA molecules as well as differences in the surface charge potential of the liposome−DNA complexes (lipoplexes) in the aqueous environment.

INTRODUCTION

Cationic liposomes have become established as one of the leading nonviral gene transfer systems for both clinical and nonclinical purposes. The ease and rapidity of preparation of liposome−DNA complexes (lipoplexes) coupled with their relative safety, demonstrated in a number of preclinical and clinical tests, has expanded their applications despite relatively low transfection efficiency as compared to that of viral vector systems (*1*). The low transfection efficiency is related to the biophysical characteristics of cationic liposomes as well as the biological activity of plasmid DNA inside mammalian cells (*2*). Compared with viral infection, internalization of DNA vectors mediated by cationic lipids is a less specific and less active process. In addition, plasmid DNA transferred into the cytoplasm is incapable of self-replication and is vulnerable to intracellular degradation. However, starting from the initial interactions of lipoplexes with cells and ending with gene expression, the many obstacles encountered along the way suggest that, if they can be resolved, additional possibilities for clinical application of this delivery system may lie in the future.

Potential clinical applications of cationic liposome-mediated gene delivery have been demonstrated in disease models of various cancers (*3*,*4*) and some genetic diseases such as cystic fibrosis (*5*,*6*). However, at present, the low transfection efficiency of cationic lipidic vectors has hindered their application in those areas of gene therapy such as genetic diseases that require persistent gene expression at a therapeutic level. Hence, a great deal of effort, including synthesis of new cationic lipids (*7*) and providing lipoplexes with new characteristics (*8*), has been expended in the search for more effective cationic lipid vectors.

A number of preclinical and clinical studies have claimed that lipoplexes are safe when delivered locally in relatively low doses (*9*). However, it has been reported that, in a mouse model, intravenous administration of high doses of lipolexes induces acute toxicity (*10*). Several groups have been working on establishment of a structure−function relationship to define the requirements for the safe and efficient gene transfection of cationic lipids (*11*).

To begin to address transfection efficiency and safety concerns, we synthesized a series of novel cationic lipids incorporating the biocompatible and biodegradable components, lysine, aspartate, and fatty acyl chains. In this series of cationic lipids based on lysylaspartate (KD), diacyl derivatives with hydrocarbon chains of differing length (C_{12}, C_{14}, C_{16}, and C_{18}) exhibited different DNA-binding affinities which could be correlated with their different in vitro gene-transferring capabilities. The KD derivatives with the short acyl chains (C_{12} and C_{14}) exhibited stronger DNA-binding affinity and more efficient transfection than ones with long acyl chains. Biocompatible cationic liposomes of the type described here may be more suitable for preclinical and clinical applications.

EXPERIMENTAL PROCEDURES

Reagents. Dioleoyl phosphatidylethanolamine (DOPE) and *N*-[1-(2,3-dioleoyloxy)]-*N*,*N*,*N*-trimethylammonium propane methyl sulfate (DOTAP) were purchased from Avanti Polar Lipids (Alabaster, AL). Cholesterol was

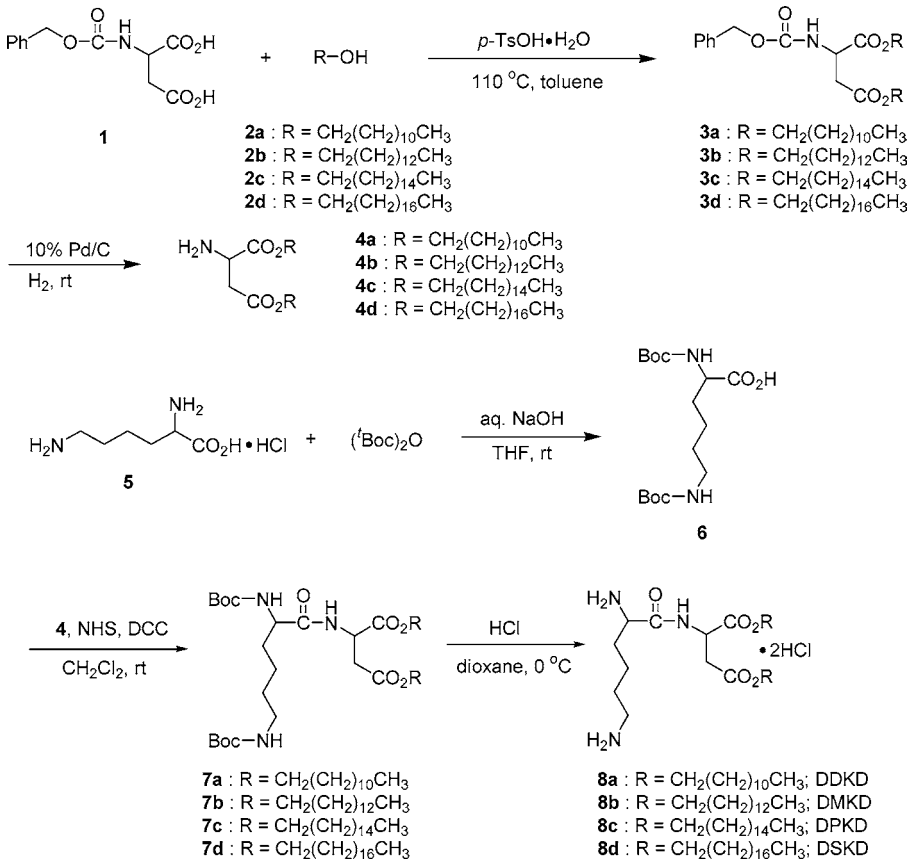

Figure 1. Synthetic outline for the KD series of cationic lipids

purchased from Sigma (St. Louis, MO). All organic reagents employed in the synthesis of cationic lipids were obtained from Aldrich (Milwaukee, WI) and used as received.

Synthesis of Dialkyl *N*-Carbobenzyloxy-L-aspartate (3a−d). Chemical synthesis of the KD series of cationic lipids is outlined in Figure 1. A solution of *N*-carbobenzyloxy-L-aspartic acid (**1**) (500 mg, 1.87 mmol), 1-dodecanol (**2a**) (1.06 mL, 4.68 mmol), and *p*-toluenesulfonic acid monohydrate (71 mg, 0.37 mmol) in toluene (30 mL) was heated at reflux with a Dean−Stark trap. After 16 h, the solution was washed with water and dried over anhydrous $MgSO_4$. After filtration, the solvent was removed in vacuo and the residue purified by column chromatography over silica gel (eluent: hexane−EtOAc = 9.5:0.5) to afford 960 mg of **3a** (85%). ^{1}H NMR ($CDCl_3$) δ 0.90−1.90 (m, 50H), 2.99 (m, 2H), 4.17 (m, 4H), 4.94 (m, 1H), 5.40 (m, 2H), 5.65 (m, 1H), 7.30−7.45 (m, 5H). Compounds **3b**, **3c**, and **3d** were synthesized using the same method as described above for compound **3a** in 66, 62, and 65% yields, respectively. **3b**: ^{1}H NMR ($CDCl_3$) δ 0.93−2.00 (m, 54H), 3.11 (m, 2H), 4.19 (m, 4H), 4.94 (m, 1H), 5.43 (m, 2H), 5.60 (m, 1H), 7.26−7.38 (m, 5H). **3c**: ^{1}H NMR ($CDCl_3$) δ 0.95−1.60 (m, 62H), 2.99 (m, 2H), 4.26 (m, 4H), 4.60 (m, 1H), 5.53 (s, 2H), 5.80 (m, 1H), 7.3−7.5 (m, 5H). **3d**: ^{1}H NMR ($CDCl_3$) δ 0.82−1.84 (m, 70H), 2.99 (m, 2H), 4.18 (m, 4H), 4.60 (m, 1H), 5.21 (s, 2H), 5.80 (m, 1H), 7.3−7.5 (m, 5H).

Synthesis of Dialkyl L-Aspartate (4a−d). A solution of compound **3a** (523 mg, 0.87 mmol) and 10% Pd/C (523 mg, 0.49 mmol) in THF (20 mL) was stirred at room temperature under a hydrogen atmosphere until the reaction was complete. The catalyst was filtered off through a Celite pad and the filtrate concentrated and purified by flash column chromatography on silical gel (eluent: hexane−EtOAc = 8:2) to afford 387 mg of **4a** (95%). ^{1}H NMR ($CDCl_3$) δ 0.78−1.71 (m, 50H), 2.72 (m, 2H), 3.80 (m, 1H), 4.12 (m, 4H). Compounds **4b**, **4c**, and **4d** were synthesized using the same method as described above for compound **4a** in 94, 91, and 92% yields, respectively. **4b**: ^{1}H NMR ($CDCl_3$) δ 0.82−1.72 (m, 54H), 2.74 (m, 2H), 3.81 (m, 1H), 4.12 (m, 4H). **4c**: ^{1}H NMR ($CDCl_3$) δ 0.67−1.63 (m, 62H), 2.39 (m, 2H), 3.39 (m, 1H), 4.11 (m, 4H). **4d**: ^{1}H NMR ($CDCl_3$) δ 0.82−1.62 (m, 70H), 2.74 (m, 2H), 3.80 (m, 1H), 4.12 (m, 4H).

Synthesis of Bis(*N,N′*-*tert*-butoxycarbonyl)aspartic Acid (6). L-Lysine monohydrochloride (200 mg, 1.01 mmol) was dissolved in aqueous NaOH solution (131.5 mg of NaOH in 3 mL of H_2O) followed by addition of a THF (3 mL) solution of di-*tert*-butyl dicarbonate (477.9 mg, 2.19 mmol). The mixture was stirred at room temperature overnight and then was neutralized with 1 M HCl aqueous solution and extracted with CH_2Cl_2. The organic layer was dried over anhydrous $MgSO_4$ and concentrated to give 311 mg of **6** (82%). ^{1}H NMR ($CDCl_3$) δ 1.21−1.91 (m, 24H), 3.12 (m, 2H), 3.76 (m, 1H), 4.28 (br, 1H), 6.03 (br, 1H).

Synthesis of 2-(2,6-Bis-*tert*-butoxycarbonylaminohexanoylamino) Succinic Acid Dialkyl Ester (7a−d). A solution of compound **6** (260 mg, 0.75 mmol), *N*-hydroxysuccinimide (87 mg, 0.75 mmol), and 1,3-dicyclohexylcarbodiimide (388 mg, 1.88 mmol) in THF (30 mL) was stirred for 1 h at room temperature. Compound **4a** (294 mg, 0.63 mmol) was added to the above solution, and the resulting mixture was stirred for an additional 6 h. The reaction mixture was washed with water, dried, and concentrated. The residue was purified by column chromatography on silica gel (eluent: hexane−EtOAc = 8:2) to furnish 377 mg of **7a** (75%). ^{1}H NMR ($CDCl_3$) δ 0.80−1.58 (m, 74H), 2.73−3.12 (m, 4H), 4.15 (m, 4H), 4.64 (br, 1H), 4.82 (m, 2H), 5.15 (br, 1H), 6.91 (br, 1H). Compounds **7b**, **7c**, and **7d** were synthesized using the

same method as described above for compound **7a** in 62, 61, and 62% yields, respectively. **7b**: ^{1}H NMR ($CDCl_3$) δ 0.82−1.58 (m, 78H), 2.76−3.14 (m, 4H), 4.14 (m, 4H), 4.65 (br, 1H), 4.86 (m, 2H), 5.15 (br, 1H), 6.91 (br, 1H). **7c**: ^{1}H NMR ($CDCl_3$) δ 0.96−1.62 (m, 82H), 2.74−3.11 (m, 4H), 4.07 (m, 4H), 4.65 (br, 1H), 4.68 (m, 2H), 5.13 (br, 1H), 6.90 (br, 1H). **7d**: ^{1}H NMR ($CDCl_3$) δ 0.82−1.83 (m, 86H), 2.77−3.16 (m, 4H), 4.17 (m, 4H), 4.69 (br, 1H), 4.91 (m, 2H), 5.14 (br, 1H), 6.91 (br, 1H).

Synthesis of 2-(2,6-Bis-*tert*-butoxycarbonylamino-hexanoylamino) Succinic Acid Dialkyl Ester Dihydrochloride (8a−d). Compound **7a** (494 mg, 0.62 mmol) was dissolved in THF (10 mL) and treated with 4 M HCl in 1,4-dioxane (10 mL) at 0 °C. After 6 h, the reaction mixture was concentrated and the residue was washed with Et_2O, affording 344 mg of **8a** (93%). Similarly, **8b**, **8c**, and **8d** were prepared in 93, 94, and 92% yields, respectively.

Cells and Cell Culture. Transformed kidney cells (293 cells) were purchased from the American Type Culture Collection (ATCC, Manassa, VA). The 293 cells were grown at 37 °C under a 5% CO_2 atmosphere in Dulbecco's Modified Eagle Medium (DMEM) (Gibco, Tulsa, OK), supplemented with 10% fetal bovine serum, 1 mM sodium bicarbonate, 50 μg/mL streptomycin, and 500 U/mL penicillin. Highly metastatic B16BL6 mouse melanoma cells were provided by Dr. Fidler (M. D. Anderson Cancer Center, Houston, TX). The melanoma cells were grown in Minimum Essential Medium Eagle (MEM) supplemented with 5% FBS, 100 μM vitamin solution, 100 μM sodium pyruvate, 10 μM nonessential amino acid, and penicillin/streptomycin antibiotics.

Preparation of Plasmid DNA−Lipid Complexes. The plasmid used in this study was pAAVCMV (prepared by Dr. M. J. During, Jefferson Medical College, Philadelphia, PA) containing a luciferase gene under the control of adeno-associated virus inverted terminal repeats and the cytomegalovirus promoter. The plasmid was prepared with a plasmid maxiprep kit (QIAGEN, Germany).

Appropriate amounts of cationic lipids (DLKD, DSKD, DPKD, DMKD, or DOTAP) alone or with helper lipids (DOPE or cholesterol) were mixed in chloroform. The organic solvent was evaporated under a stream of N_2 gas. Vacuum desiccation for about 2 h ensured removal of the residual organic solvent. The dried lipid films were hydrated in an appropriate amount of saline and then vigorously mixed with a vortex mixer for 5 min. Varied amounts of plasmid DNA in saline were gently mixed with appropriate amounts of the prepared liposomal solution. To provide stable lipoplex formation, the lipid−DNA mixtures were incubated at room temperature for 30 min before they were added to cultured cells.

Gel Retardation Analysis of Lipoplexes. Various amounts of cationic liposomes (0.3−12 nmol in 50 μL of saline) were added to 1 μg of DNA in 50 μL of saline, which were then incubated at room temperature for 30 min. A small aliquot of ethidium bromide (EtBr) solution was added to 20 μL of the lipoplex solution, which was run on 0.7% agarose gel and visualized by UV illumination (Fluor-S MultiImage, Bio-Rad, Herculus, CA).

ζ-Potential Measurement. The ζ-potentials of the lipoplexes were measured using a zetasizer (Zetasizer4, Malvern, U.K.). The lipoplex suspensions in Hepes buffer (pH 7.5) were loaded in the capillary cell mounted on the zetasizer, and their ζ-potentials were measured five times per sample at 25 °C.

In Vitro Gene Transfection. The 293 cells (1×10^5 cells/well) were plated onto 24-well plates and incubated at 37 °C under 5% CO_2 for 24 h. The various lipoplex formulations were added onto the 293 or B16BL6 cells in serum-free media, which were then incubated further for 4 h. After transfection, the cell culture medium containing the lipoplexes was replaced with a fresh serum-containing medium and the transfected cells were incubated for an additional 48 h. After removal of the culture medium by aspiration, the transfected cells in each well were carefully washed twice with 3 mL of PBS. The cells were lysed with 100 μL of lysis buffer (0.1 M Tris-HCl, 2 mM EDTA, and 0.1% Triton X-100, pH 7.8). The luciferase activity in a 10 μL aliquot of the cell lysate was measured with a luminometer (Minilumat LB9506, EG&G, Germany) and a luciferase assay kit (Promega, Madison, WI). The protein concentration of each cell lysate was determined by a standard protein assay (Bio-Rad Protein Assay, Bio-Rad, Hercules, CA). The luciferase activity in each sample was normalized to the relative light unit (RLU) per microgram of protein.

Cytotoxicity of Cationic Liposomes. The cytotoxicity of cationic liposomes was determined by MTT assay (*12*). The B16BL6 cells were plated into 96-well plates (5×10^3 cells per well) and cultured for 24 h. The cells were treated with various concentrations of cationic liposomes and then cultured for 24 h. Fifty microliters of MTT solution (1 mg/mL) was added to the cells, which were further cultured for 4 h. After the media containing MTT were removed, 100 μL of DMSO was added to solubilize the MTT−formazan product. The absorbance at 540 nm was measured with a microplate reader (Molecular Devices, Sunnyvale, CA).

RESULTS

Synthesis of Diacyl Lysylaspartate Cationic Lipids. We have synthesized a series of biocompatible cationic lipids that exhibit potent gene-transferring capability. These KD cationic lipids, composed of three biocompatible molecular moieties, lysine (the cationic headgroup), aspartic acid (the anchor), and two acyl chains (the hydrophobic tails), were synthesized as outlined in Figure 1.

Esterification of *N*-carbobenzyloxy-L-aspartic acid (**1**) with alcohols **2a−d** in the presence of *p*-toluenesulfonic acid monohydrate was carried out to obtain the corresponding diesters **3a−d** in 62−85% yields. Deprotection of the *N*-carbobenzyloxy group of the diesters **3a−d** with 10% Pd/C under hydrogen atmosphere gave the dialkyl aspartates **4a−d**. L-Lysine monohydrochloride (**5**) was transformed into **6** with di-*tert*-butyl dicarbonate, which was coupled with the compounds **4a−d** in the presence of NHS (*N*-hydroxysuccinimide) and DCC at room temperature, affording compounds **7a−d** in 61−75% yields. The desired cationic lipids **8a−d** were prepared by treatment of **7a−d** with 4.0 M HCl in dioxane at 0 °C.

Formation of DLKD-, DSKD-, DPKD-, and DMKD-Based Lipoplexes and Their Surface Charges. (DLKD = *O*,*O*′-dilauryl *N*-lysylaspartate, DMKD = *O*,*O*′-dimyristyl *N*-lysylaspartate, DPKD = *O*,*O*′-dipalmityl *N*-lysylaspartate, and DSKD = *O*,*O*′-distearyl *N*-lysylaspartate.) It has been well documented that electronic interactions between the headgroups of the cationic lipids and DNA molecules cause the formation of liposome−DNA complexes, called "lipoplexes". However, the strength of these interactions is dependent on the biophysical characteristics of the cationic lipids and the polymorphism of the liposomal membranes.

The gel retardation assay is a simple method that can be used to show the relative strength of electric interac-

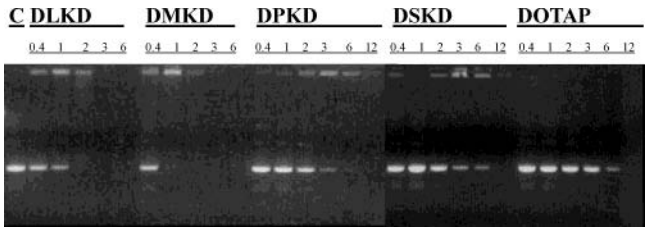

Figure 2. Gel retardation of pDNA complexed to KD liposomes. An aliquot of EtBr solution was added to plasmid DNA complexed to DLKD, DMKD, DPKD, DSKD, and DOTAP liposomes at various charge ratios. The lipoplexes were run on agarose gel and visualized by UV illumination.

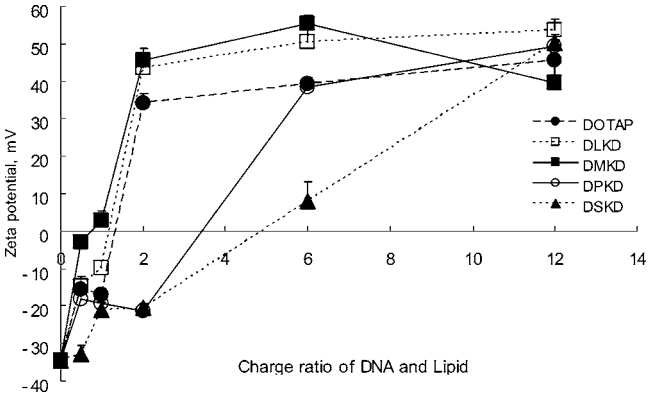

Figure 3. ζ-potentials of KD lipoplexes. The DLKD, DMKD, DPKD, DSKD, and DOTAP lipoplexes were prepared at various charge ratios of lipid to pDNA and loaded into the capillary cell mounted on a zetasizer. The numbers given were calculated from five measurements at 25 °C.

tions between cationic liposomes and DNA molecules. In this assay, a cationic liposome suspension and a DNA solution are mixed in various charge ratios from 0.4:1 to 12:1 (lipid/DNA) and run on an agarose gel. Stable lipoplexes do not penetrate into the agarose gel, but free pDNA, not complexed to cationic liposomes, localizes in the same pattern as the control of pDNA in the absence of cationic liposomes (Figure 2). The DMKD liposomes and DLKD liposomes were able to complete complex formation at approximately 1:1 and 2:1 charge ratios of lipid to DNA, respectively. Meanwhile, the DPKD liposomes and DSKD liposomes completed complex formation at charge ratios higher than 6:1. The DNA-binding affinity of DOTAP liposomes, one of the well-established cationic liposomes, was similar to that of the DPKD liposomes. It is possible that the configuration of cationic charges on the DMKD liposomes and DLDK liposomes confers an advantage in binding pDNA and lipoplex formation over that of the other liposomes.

ζ-potential measurement of cationic liposome−DNA complexes also indicates completion of lipoplex formation, as well as the resulting surface charge, another major parameter governing gene transfection activity. The DMKD lipoplexes exhibited a positively charged surface at a 1:1 (lipid/DNA) charge ratio (Figure 3). The DLKD and DOTAP lipoplexes became positively charged at charge ratios higher than 1:1, and their patterns of surface charge change were similar to each other. However, The DPKD and DSKD lipoplexes exhibited their positive surface charge at a 6:1 charge ratio. These results also indicate that DMKD and DLKD liposomes form stable lipoplexes more effectively than the other liposomes, as was suggested previously (Figure 2).

In Vitro Transfection Activities of KD Cationic Liposomes. To evaluate the transfection efficiencies of KD liposomes, various lipoplex formulations were prepared and tested in 293 transformed human kidney cells and B16BL6 mouse melanoma cells. After a 4 h transfection and an additional 24 h incubation, luciferase expression in the cells was measured by a luciferase activity assay. As is shown in Figure 4, the DMKD liposomes clearly have the most potent transfection efficiency among the series of KD liposomes, and the DLKD liposomes are next. When various amounts of pDNA complexed to the DMKD or DLKD liposomes (1:6, DNA wt/lipid wt) were added to 293 and B16BL6 cells in 24 well plates (Figure 4A and C), luciferase expression was nearly maximal at 0.5 μg of pDNA and saturated at higher DNA concentrations. Transfection with 5 μg of pDNA greatly diminished the luciferase expression in 293 cells. The gene expression pattern by the DPKD and DSKD was different from that by the DMKD and DLKD liposomes. The overall level of gene expression mediated by the DPKD and DSKD liposomes in the two cell lines was significantly lower than that by the DMKD liposomes and was not saturated up to 5 μg of pDNA.

Meanwhile, 293 cells and B16BL6 cells were transfected with 1 μg of pDNA complexed to various amounts of the KD series of cationic lipids to find the optimal ratio for in vitro transfection. In both cell lines, luciferase expression mediated by the DMKD liposomes was maximal at a 1:3−1:6 weight ratio of DNA and lipid and then decreased slightly on addition of more cationic lipids (Figure 4B and D). At all ratios tested, the DMKD liposomes exhibited a transfection efficiency superior to that of the other cationic liposomes including DOTAP liposomes. Under the same transfection conditions, the DLKD liposomes exhibited a similar transfection pattern to that of the DMKD liposomes but a lower transfection activity. In both cell lines, transfection by the DPKD or DSKD liposomes was not saturated up to the ratio 1:9, but their transfection efficiencies were far lower than those of any of the DMKD or DLKD liposomes. Under the best transfection conditions for each liposomal formulation, the order of transfection activities was DMKD > DLKD > DOTAP > DPKD > DSKD. These results implied that the optimal transfection conditions were dependent on the type of cationic liposomes as well as the characteristics of the cell lines.

It has been well documented that helper lipids, such as cholesterol and DOPE, generally enhance the transfection activity of cationic lipids (*13*). We prepared a series of the KD cationic liposomes containing cholesterol or DOPE (50 mol %) and compared their transfection activities in 293 and B16BL6 cells with those of liposomes consisting of only KD lipids. The transfection patterns of the helper lipid-containing liposomes were similar in both cell lines (Figure 5). Addition of cholesterol enhanced the transfection activities of the DSKD and DPKD liposomes 2.6- and 4.0-fold in 293 cells and 10.4- and 6.3-fold in B16BL6 cells, respectively. However, the DMKD and DLKD liposomes containing cholesterol exhibited 5.8- and 2.2-fold lower transfection activity in 293 cells and 4.5- and 2.1-fold lower activity in B16Bl6 cells, respectively. Meanwhile, addition of DOPE further enhanced the transfection activities of the DSKD liposomes (19.8-fold in 293 cells and 33.5-fold in B16BL6 cells) and DPKD liposomes (20.0-fold in 293 cells and 19.1-fold in B16BL6 cells). However, DOPE addition reduced the transfection activities of the DMKD liposomes (28.4-fold in 293 cells and 2.1-fold in B16BL6 cells) and the DLKD liposomes (10.9-fold in 293 cells and 1.3-fold in B16BL6 cells). These results indicated that addition of the helper lipids cholesterol or DOPE could affect the transfection

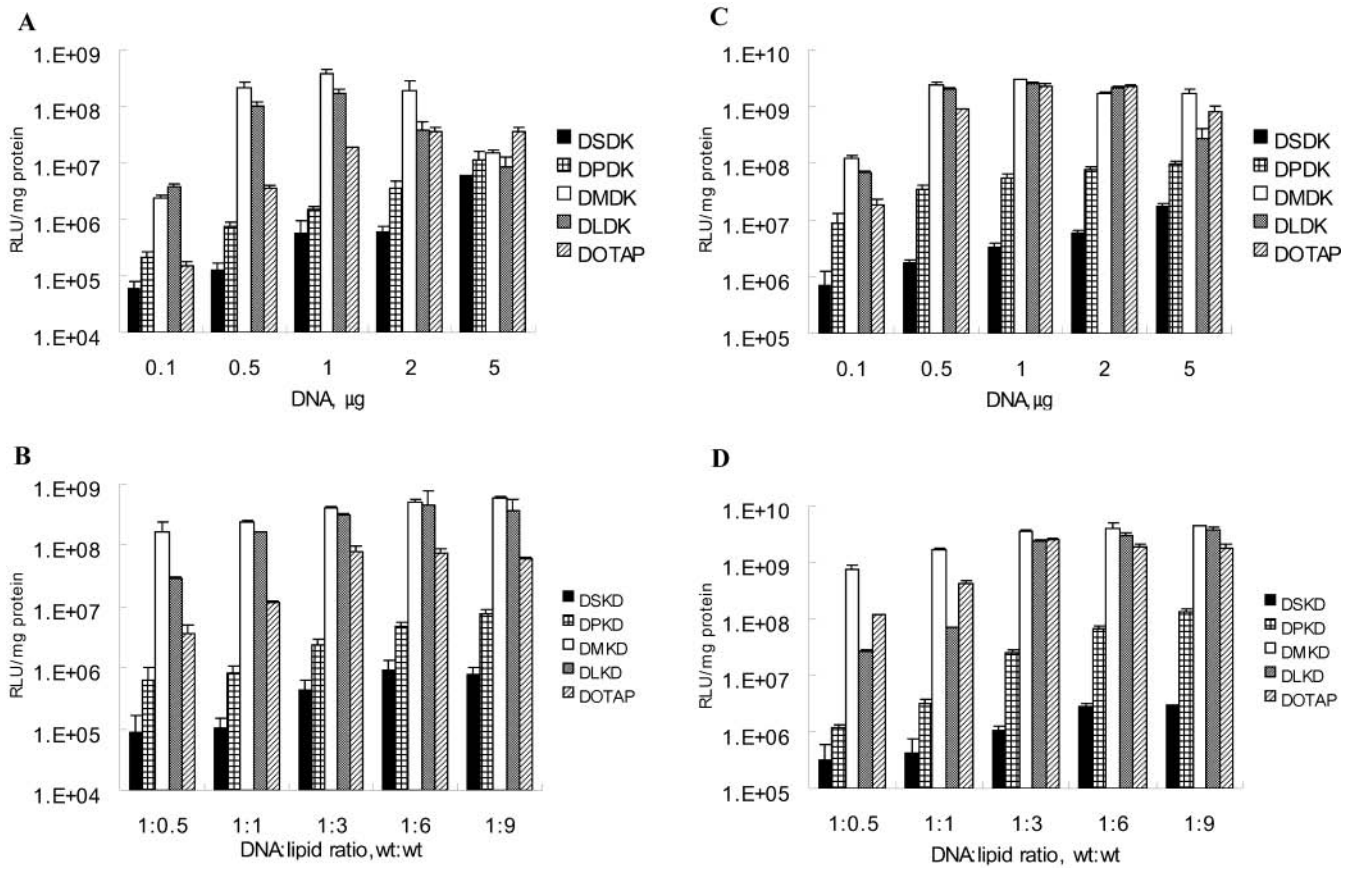

Figure 4. Transfection activities of KD lipoplexes in 293 and B16BL6 cells. Various amounts of pDNA complexed to KD liposomes and DOTAP liposomes (1:6 wt ratio of DNA and lipid) were added to 293 cells (A) and B16BL6 cells (C). Also 1 μg of pDNA complexed to KD liposomes and DOTAP liposomes at various weight ratios was added to 293 cells (B) or B16BL6 cells (D). The cells were transfected for 4 h and incubated for an additional 24 h. The luciferase activity of the cell lysate was measured with a luminometer and a luciferase assay kit. The mean luciferase activity was calculated from three different measurements.

activities of cationic liposomes positively or negatively, depending on the type and characteristics of the cationic lipids.

Cell Toxicity of KD Cationic Liposomes. The B16BL6 cells were incubated in the presence of various concentrations of KD liposomes and DOTAP liposomes to measure their cell toxicities and compare them to each other. In the ranges of lipid concentration for in vitro transfection <10 mg/mL, DMDK, DLKD, DSKD, and DOTAP liposomes did not severely damage the cultured B16BL6 cell, exhibiting over 75% cell viability. However, generally the KD liposomes were more cytotoxic than the DOTAP liposomes at the higher lipid concentrations (see Figure 6).

DISCUSSION

In designing a preclinical or clinical research study in gene therapy, a number of options must be considered in order to ensure effective gene transfer and efficient gene expression. The most important decision affecting transgene expression is whether to employ a viral or a nonviral gene delivery system. Depending on the characteristics of the disease state to be treated and the biological functions of therapeutic genes, a decision can be made as to which system is more desirable. Among the viral systems, one may have certain advantages over others, depending on the specific characteristics of the virus, such as the type of genetic material, life cycle, and so on. When safety and easy application are desired, nonviral gene transfer systems can be a primary choice and, among these, lipofection (gene transfection mediated by cationic liposomes) can be the first consideration.

Since the first report of liposomal gene transfection (*14*), a number of cationic lipids have been synthesized and tested in various cell culture models and animal models (*7*). The knowledge accumulated to date indicates that the transfection activity of a cationic lipid is determined by the chemical structure of the lipid, the charge number and strength, and the physical integrity of the liposomes when complexed to DNA (*2*). To achieve the best results in clinical applications, the transfection efficiency of gene-transferring vehicles must be a primary concern. Among the series of cationic lipids prepared in this study, DLKD and DMKD may satisfy the requirements for an efficient lipidic gene-transferring system.

Even though these synthesized cationic lipids all have a common backbone structure and differ only in the length of the hydrocarbon chains, they exhibited very different DNA-binding capabilities, lipoplex surface charges, and in vitro gene-transferring capability. The cationic lipids with shorter hydrocarbon chains exhibited the stronger DNA binding. The DMKD (C_{14}) liposomes were able to complete lipoplex formation at an approximately 1:1 charge ratio of lipid to DNA, which implied that all of the available cationic lipids are efficiently involved in DNA binding. At a 1:1 charge ratio, all of the pDNA molecules were completely covered by the DMKD cationic liposomal membranes, as indicated by no penetration and binding of EtBr. However, at this charge ratio, the DSKD (C_{18}), DPKD (C_{16}), and DOTAP liposomes were not able to bind all available pDNA molecules and they had to be added in much larger amounts to complete the lipoplex formation. Interest-

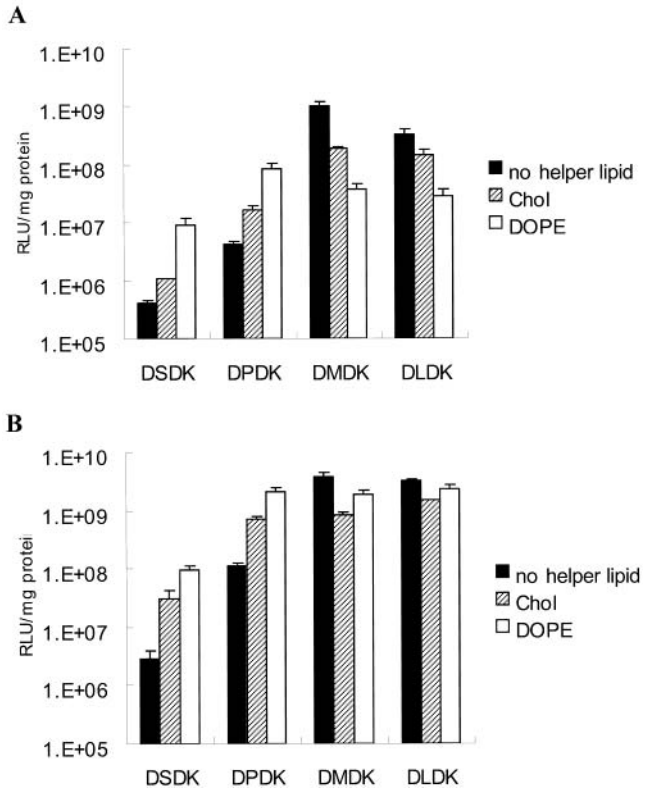

Figure 5. Effects of cholesterol and DOPE on the transfection activity of KD liposomes in 293 and B16BL6 cells. One microgram of pDNA complexed to KD liposomes, KD/cholesterol (50 mol %) liposomes, or KD/DOPE (50 mol %) liposomes at a 1:6 wt ratio of pDNA and lipid was added to each well containing 293 cells (A) or B16BL6 cells (B). The cells were transfected for 4 h and incubated for an additional 24 h. The luciferase activity of the cell lysate was measured with a luminometer and a luciferase assay kit. The mean luciferase activity was calculated from three different measurements.

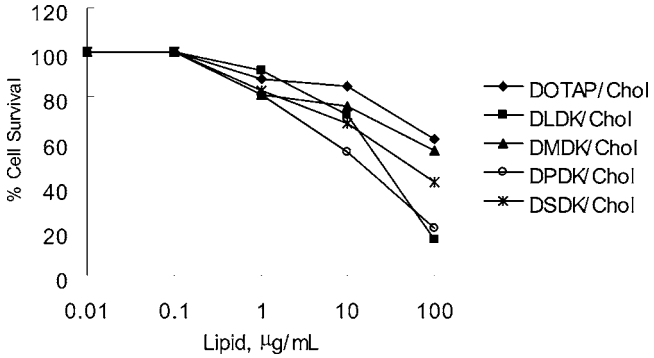

Figure 6. Cell toxicity of KD cationic liposomes. The B16BL6 cells were treated with various concentrations of cationic liposomes and then cultured for 24 h. Cell viability was measured by the MTT assay.

ingly, DLKD (C_{12}) also needs more addition to complete lipoplex formation and has a positive surface charge. These results imply that C_{14} is the optimal length of the hydrocarbon chain of the KD lipid derivatives for effective gene transfection.

Gene transfection activities of the KD cationic liposomes appear to be directly related to their DNA-binding affinities as well as the surface charge of the formed lipoplexes. As stated above, the KD cationic liposomes consisting of longer (C_{16} and C_{18}) or shorter (C_{12}) hydrocarbon chains had to be added more to complete lipoplex formation and to reach a positive ζ-potential. This also implied that the positively charged headgroups of the cationic lipids were not able to participate as effectively in lipoplex formation. Previously, it has been suggested that shorter hydroxyethyl quaternary ammonium lipid derivatives showed better transfection efficiency than longer ones. The order of efficiency was dimyristyl > dipalmytyl > distearyl (*15*). These results and those previously reported strongly indicate that cationic lipid polymorphism and liposomal membrane integrity affect the DNA-binding affinity of cationic liposomes. Even though the mechanism is not fully understood, there is a certain optimal membrane fluidity of liposomal bilayers for more suitable binding and accommodation of pDNA molecules, which may be more effective in interaction with cellular membranes due to proper lipid mixing.

It has been well documented that addition of cholesterol (*16*) or DOPE affects lipid polymorphism in liposomal membranes (*17*,*18*). Liposomal membrane fluidity can be controlled by the amount of cholesterol added (*19*). The addition of DOPE, a typical phospholipid that prefers a non-bilayer hexagonal phase, increases the fusogenic properties of the liposomes (*18*). Generally, incorporation of these two ingredients enhances the transfection activity of cationic liposomes (*20*,*21*). However, their effects on the transfection activities of the KD liposomes were varied depending on the structure of the individual cationic lipids. As is shown in Figure 5, addition of cholesterol or DOPE can interfere with the transfection activity of the DMKD and DLKD liposomes. However, their addition affected the transfection activities of the DSKD and DPKD liposomes both positively. At this moment it is not clear how these two molecules affect the membrane integrity and polymorphism of KD cationic liposomes. However, it can be stated that better gene transfection by cationic liposomes is derived from optimization of the membrane integrity and maximization of their surface charge. Also, the conditions for transfection by cationic liposomes can be changed depending on the characteristics of the target cells.

The KD series of cationic liposomes was expected to exhibit less cytotoxicity than other commercially available cationic liposomes, such as DOTAP-based liposomes, because they consist of lysine, aspartic acid, and two acyl hydrocarbon chains. Unexpectedly, the KD cationic liposomes were relatively more cytotoxic than the DOTAP liposomes. We speculated that the cytotoxicity of the KD liposomes may be due to physical membrane damage induced by detergent-like cationic lipid molecules and not to biochemical damage because their components are all biocompatible and their degradation does not produce any toxic end products in the cell.

In summary, among the KD series of cationic liposomes, the DMKD liposomes were the most effective in gene transfection into 293 and B16BL6 cells, and the DLKD liposomes were next. Since the DMKD liposomes needed much smaller amounts of pDNA and lipid to reach maximal gene transfection than the DOTAP liposomes, it can be stated that the DMKD liposomes are superior to the DOTAP liposomes. The potent transfection activity observed may be attributed to the strong DNA-binding affinity and effective distribution of positive surface charge on the lipoplex surface, which may mediate efficient interactions between cells and the lipoplexes. We have now undertaken in vivo transfection studies using the KD series of cationic lipids. KD liposome transfection systems optimized in vivo will be utilized for preclinical or clinical applications.

Temperature Sensitization of Liposomes by Use of *N*-Isopropylacrylamide Copolymers with Varying Transition Endotherms

Keisuke Yoshino, Atsushi Kadowaki, Toru Takagishi, and Kenji Kono*

Department of Applied Materials Science, Graduate School of Engineering, Osaka Prefecture University, 1-1, Gakuen-cho, Sakai, Osaka 599-8531, Japan. Received November 6, 2003; Revised Manuscript Received May 28, 2004

Three kinds of copolymers of *N*-isopropylacrylamide (NIPAM) with the same conformational transition temperature and varying transition endotherms were synthesized with *N*-acryloylpyrrolidine (APr), *N*,*N*-dimethylacrylamide (DMAM), and *N*-isopropylmethacrylamide (NIPMAM) as the comonomers. Two dodecyl groups were incorporated into the termini of these copolymers as an anchor for the fixation to a liposomal membrane. Egg yolk phosphatidylcholine liposomes having these copolymers were prepared and their temperature-sensitive contents release and association properties were investigated. While these copolymer exhibited a conformational transition at ca. 40 °C, ΔH for the transition increased in the order of poly(APr-*co*-NIPAM) < poly(DMAM-*co*-NIPAM) < poly(NIPMAM-*co*-NIPAM). The liposomes containing poly(NIPMAM-*co*-NIPAM) showed a drastic release enhancement of entrapped calcein above the transition temperature, whereas the liposomes with poly(DMAM-*co*-NIPAM) and those with poly(APr-*co*-NIPAM) exhibited moderate and slight enhancement of calcein release above that temperature, respectively. On the contrary, the liposomes containing poly(APr-*co*-NIPAM) showed significant aggregation above the transition temperature, but the aggregation was hardly observed for the liposomes having poly(NIPMAM-*co*-NIPAM), indicating that poly(APr-*co*-NIPAM) more efficiently made the liposome surface hydrophobic. Thus, we concluded that the copolymer with a large ΔH is suitable for obtaining functional liposomes with a temperature-sensitive contents release property, whereas the copolymer with a small ΔH is appropriate for preparing functional liposomes with a temperature-sensitive surface property.

1. INTRODUCTION

Liposomes have been considered to be a highly attractive material as drug carriers, because of their merits, such as biocompatibility, ability to encapsulate both hydrophilic and hydrophobic drugs, and size controllability (*1*). To increase their usefulness as drug carriers, many efforts have been made to provide liposomes with various functions. pH-Sensitive (*2*−*4*), light-sensitive (*5*−*8*), and temperature-sensitive (*9*−*11*) liposomes have been extensively studied as functional liposomes, which are useful for site-specific and/or cytoplasmic drug delivery.

While several approaches have been employed for the production of functional liposomes, modification of the liposomes with functional polymers is one of the most effective methods (*12*−*14*). For example, Tirrell and coworkers (*3*, *13*) have achieved the sensitization of egg yolk phosphatidylcholine (EYPC) liposomes to pH by the conjugation of a pH-sensitive polymer, poly(2-ethylacrylic acid), which strongly binds to lipid membranes and permeabilizes them. In addition, various synthetic polymers and peptides containing carboxyl groups have been used to render stable liposomes pH-sensitive (*15*−*17*).

Recently, the temperature sensitization of liposomes has been actively attempted by use of thermosensitive polymers, such as poly(*N*-isopropylacrylamide) [poly(NIPAM)] (*14*, *18*−*21*). Poly(NIPAM) is known to exhibit a lower critical solution temperature (LCST) at ca. 32 °C (*22*). This polymer is hydrophilic and soluble in water below the LCST. However, it becomes hydrophobic and forms an insoluble aggregate above this temperature due to hydrophobic interactions and hydrogen bonding. At the molecular level, it undergoes a coil-to-globule transition at the LCST. We have shown that when a homopolymer and copolymers of NIPAM are fixed onto the liposome surface, contents release from the liposome can be triggered by increasing the temperature above their LCST (*18*, *20*, *23*). In addition, it has been demonstrated that surface modification with these thermosensitive polymers provides liposomes with temperature-sensitive surface properties. For example, the hydrophobicity and surface charge density of the thermosensitive polymer-modified liposomes were shown to be controlled by the ambient temperature (*24*, *25*).

The functions of the thermosensitive polymer-modified liposomes are generated through the interaction between the fixed thermosensitive polymer and the liposome membrane. Their performance should be affected by the mechanism and strength of their interaction. The ability of thermosensitive polymers to sensitize liposome membranes should depend on their structures and characteristics. Therefore, for the development of functional liposomes with high temperature sensitivity, it is important to know what characteristics of the thermosensitive polymers will affect their ability to sensitize liposomes.

In this study, three kinds of NIPAM copolymers, which undergo a conformational transition at the same temperature but exhibit different transition endotherms, were synthesized with *N*-acryloylpyrrolidine (APr), *N*,*N*-

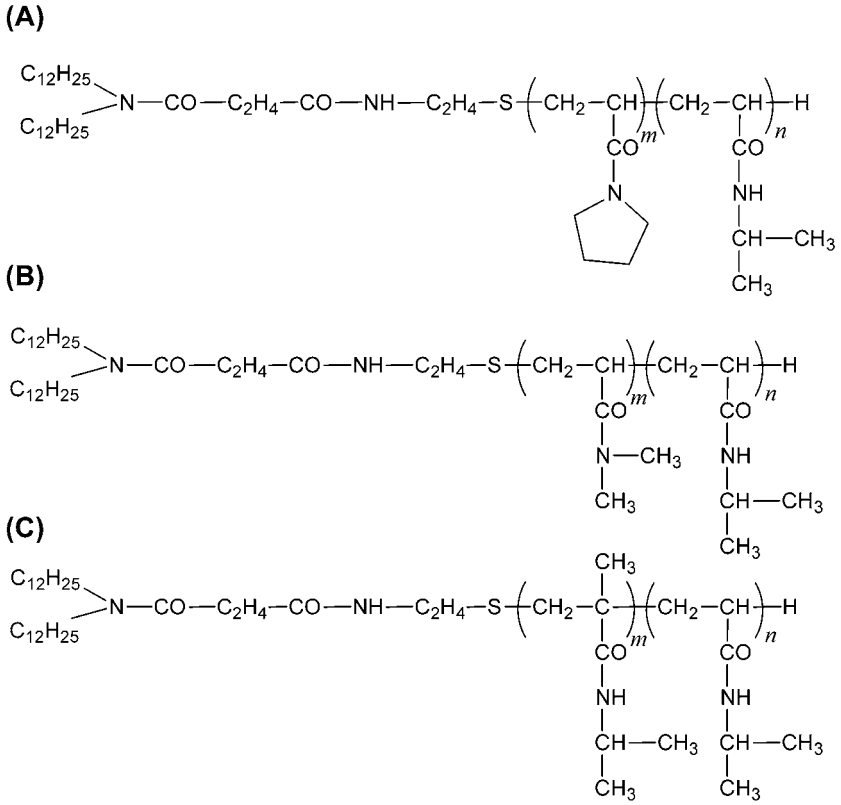

Figure 1. Structures of $2C_{12}$-poly(APr-*co*-NIPAM) (A), $2C_{12}$-poly(DMAM-*co*-NIPAM) (B), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM) (C).

dimethylacrylamide (DMAM), and *N*-isopropylmethacrylamide (NIPMAM) as comonomers. Two dodecyl groups were connected to the chain end of these copolymers as an anchor to a liposomal membrane. These anchor-bearing copolymers are termed $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM) (Figure 1). The close correlation between the transition enthalpies of the copolymers and their ability to sensitize liposomes has been described.

2. EXPERIMENTAL SECTION

2.1. Materials. EYPC was kindly donated by Nippon Oil and Fats Co. (Tokyo, Japan). NIPAM, 2-aminoethanethiol, and Triton X-100 were supplied from Tokyo Kasei (Tokyo, Japan). Calcein, 1,6-diphenyl-1,3,5-hexatriene (DPH), 8-anilino-1-naphthalenesulfonic acid (ANS), and 1-pyrenecarboxaldehyde (PyCHO) were obtained from Sigma−Aldrich Japan (Tokyo, Japan). 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) was obtained from Wako Pure Chemical Industries (Osaka, Japan). Azobis(isobutyronitrile) (AIBN), tris(hydroxymethyl)aminomethane (Tris), *N*,*N*-dimethylformamide (DMF), and ethylenediamineteraacetic acid disodium salt (EDTA) were from Kishida Chemical (Osaka, Japan). NIPAM and AIBN were purified by crystallization from benzene−*n*-hexane and methanol, respectively. APr was prepared as previously reported (*26*). NIPMAM was synthesized according to the method reported by Jordan et al. (*27*). *N*,*N*-Didodecylsuccinamic acid was synthesized according to the method of Okahata and Seki (*28*).

2.2. Synthesis of NIPAM Copolymers with Anchor. Three kinds of NIPAM copolymers having two dodecyl groups at the chain end, $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM) (Figure 1), were prepared according to the method previously reported (*25*, *29*). In brief, for the synthesis of $2C_{12}$-poly(APr-*co*-NIPAM), APr (15.7 mmol), NIPAM (12.8 mmol), 2-aminoethanethiol (0.4 mmol), and AIBN (0.03 mmol) were dissolved in freshly distilled DMF (12 mL) and then the solution was heated at 75 °C for 15 h in N_2 atmosphere. The copolymer was recovered by precipitation with diethyl ether and further purified on a Sephadex LH-20 column eluted with methanol. The obtained poly(APr-*co*-NIPAM) having an amino group (1.5 g) at the terminus was reacted with *N*,*N*-didodecylsuccinamic acid (3.3×10^{-4} mol) in DMF (50 mL) with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (3.3×10^{-4} mol) for 48 h at 4 °C. The copolymer having a didodecyl group, $2C_{12}$-poly(APr-*co*-NIPAM), was purified by an LH-20 column eluting with methanol (yield 1.1 g). The $2C_{12}$-poly(DMAM-*co*-NIPAM) was prepared according to the above method. DMAM (2.4 mmol), NIPAM (9.4 mmol), 2-aminoethanethiol (0.5 mmol), and AIBN (0.13 mmol) were dissolved in DMF (7.5 mL) and then the solution was heated at 75 °C for 15 h in N_2 atmosphere. The obtained poly(DMAM-*co*-NIPAM) having an amino group (0.5 g) at the terminal was reacted with *N*,*N*-didodecylsuccinamic acid (1.5×10^{-4} mol) in DMF (15 mL) with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (1.5×10^{-4} mol) for 48 h at 4 °C. The copolymer having a didodecyl group, $2C_{12}$-poly(DMAM-*co*-NIPAM), was purified as described above (yield 0.25 g). The $2C_{12}$-poly(NIPMAM-*co*-NIPAM) was synthesized by the same method. NIPMAM (15.7 mmol), NIPAM (19 mmol), 2-aminoethanethiol (1.15 mmol), and AIBN (0. 3 mmol) were dissolved in DMF (20 mL) and then the solution was heated at 75 °C for 15 h in N_2 atmosphere. The obtained poly(NIPMAM-*co*-NIPAM) having an amino group (1.5 g) at the terminus was reacted with *N*,*N*-didodecylsuccinamic acid (3.3×10^{-3} mol) in DMF (50 mL) with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (3.3×10^{-3} mol) for 48 h at 4 °C. The copolymer having a didodecyl group, $2C_{12}$-poly(NIPMAM-*co*-NIPAM), was purified as described above (yield 1.1 g).

2.3. Liposome Preparation. The liposomes were prepared as previously reported (*20*, *29*). EYPC in chloroform solution (10 mg/mL, 1 mL) and the copolymer in chloroform solution [10 mg/mL, 1 mL for $2C_{12}$-poly(NIPMAM-*co*-NIPAM) and $2C_{12}$-poly(APr-*co*-NIPAM) or 4 mL for $2C_{12}$-poly(DMAM-*co*-NIPAM)] were mixed in a flask and the solvent was removed by evaporation. The obtained thin lipid/copolymer mixed membrane was further dried under vacuum overnight and dispersed in 1.5 mL of an aqueous calcein solution (63 mM). The obtained liposome suspension was extruded through a polycarbonate membrane with a pore diameter of 100 nm in an ice-cooled water bath. The free calcein and free copolymer were removed by gel-permeation chromatography (GPC) on a Sepharose 4B column at 4 °C in a 10 mM Tris-HCl-buffered solution containing 140 mM NaCl and 1 mM EDTA solution at pH 7.4. The calcein-loaded liposomes were kept at 5 °C until the measurement.

2.4. Calcein Release from Liposome. The release measurements were performed according to the method previously reported (*26*, *29*). An aliquot of dispersion of the calcein-loaded liposomes was added into 2 mL of 10 mM Tris-HCl, 140 mM NaCl, and 1 mM EDTA solution (pH 7.4) in a quartz cell (final concentration of the lipids 10 μM) at a given temperature, and the fluorescence intensity of the solution was monitored on a spectrofluorometer (Shimadzu RF-5000). The excitation and monitoring wavelengths were 490 and 520 nm, respectively. The percent release of calcein from the liposomes was defined as

$$\% \text{ release} = (F^t - F^i)/(F^f - F^i) \times 100$$

where F^i and F^t mean the initial and intermediary fluorescence intensities of the liposome suspension, respectively. F^f is the fluorescent intensity of the liposome suspension after the addition of Triton X-100 (final concentration 0.15%).

2.5. Estimation of the Amount of Copolymer Bound to Liposome. The amount of the copolymer bound to the liposome was estimated by use of high-performance liquid chromatography as previously reported (*24*, *29*). The liposomes bearing the copolymer were dried under vacuum and then dissolved in methanol/water (7:3 v/v). The solution was filtered through a poly(tetrafluoroethylene) membrane with a pore size of 0.25 μm. The filtrate (20 μl) was injected into an SB-803 column (Showa Denko) and the effluent was monitored by the absorbance at 220 nm on a UV detector (Jasco, UV-790). The amount of copolymer was estimated from the absorbance of the separated copolymer. Also, the lipid amount was determined by the method of Bartlett (*30*).

2.6. Fluorescence Measurements. Emission spectra of PyCHO were obtained on a spectrofluorometer with excitation at 365.5 nm. Fluorescence polarization (P) of DPH and ANS was measured as reported previously (*31*). ANS and DPH were excited at 395 and 360 nm, respectively, and the fluorescence intensities of ANS and DPH were monitored at 467 and 428 nm, respectively. The P value was evaluated by use of

$$P = (I_p - I_v)/(I_p + I_v)$$

where I_p and I_v represent the intensities of parallel polarized fluorescence and vertically polarized fluorescence, respectively.

2.7. Other Methods. The size of liposomes was evaluated by dynamic light scattering on a Nicomp 380 ZLS instrument (Particle Sizing Systems). The weight-average molecular weight (M_w) and the number-average molecular weight (M_n) of the polymers were estimated by gel-permeation chromatography on a system equipped with a Shodex KD-803 column (Showa Denko) with differential refractive index detection (Jasco, RI-930) with DMF as an eluent and poly(ethylene glycol) as the standard. Differential scanning calorimetry (DSC) was performed with a DSC 120 microcalorimeter (Seiko Electronics).

3. RESULTS AND DISCUSSION

3.1. Characterization of Copolymer and Copolymer-Modified Liposomes. It is known that the LCST of poly(NIPAM) can be controlled by copolymerization with comonomers having varying degrees of hydrophilicity/hydrophobicity (*32*). In this study, we used three kinds of comonomers, APr, DMAM, and NIPMAM, to obtain NIPAM copolymers that have different structures but exhibit the same LCST. Because the most attractive application of temperature-sensitive liposomes is the drug delivery application, we chose 40 °C as the LCST of the copolymers. Such temperature-sensitive liposomes can deliver drugs by specifically releasing them at the target site, which is mildly heated above that temperature (*2*). APr and DMAM have already been used to obtain NIPAM copolymers with an LCST around the physiological temperature (*26*, *27*).

Copolymerization of NIPAM and these comonomers was performed in the presence of the chain transfer reagent 2-aminoethanethiol to introduce an amino group at one terminus of the copolymer chain (*34*), which can be used for the attachment of a hydrophobic moiety for the fixation of the copolymer chain to the liposome membrane. The compositions of the copolymers were estimated from the integral ratios of signals derived from NIPAM and the comonomer units in the ^{1}H NMR spectra (Figure 2). Also, the number-average molecular weight (M_n), the weight-average molecular weight (M_w), and polydispersity index (M_w/M_n) of the copolymers were evaluated by gel-permeation chromatography with poly(ethylene glycol) as the standard. The results for the copolymers used in this study are listed in Table 1.

The cloud point measurement was performed to determine the LCST of the copolymer before the conjugation of the anchor. Figure 3 shows the transmittance of the aqueous solutions of these copolymers. The solutions were transparent below 38 °C, indicating that these copolymers were soluble in water below 38 °C. However, the solution became turbid around 40 °C, showing that these copolymers became water-insoluble around this temperature. The LCSTs of poly(APr-*co*-NIPAM), poly(DMAM-*co*-NIPAM), and poly(NIPMAM-*co*-NIPAM) were estimated from Figure 3 and are listed in Table 2.

It is known that the LCST of poly(NIPAM) can be determined by DSC (*22*, *35*). Thus, we examined the calorimetric detection of LCST for these copolymer solutions. Figure 4 depicts the typical DSC curves of these copolymer solutions. These curves exhibited an endotherm centered at approximately the same temperature, 40 °C, which agrees well with their LCST determined from the cloud point measurement. However, the amplitude of the endotherm significantly varies among these copolymers. As shown in Table 2, ΔH for the phase separation increases in the order poly(APr-*co*-NIPAM) < poly(DMAM-*co*-NIPAM) < poly(NIPMAM-*co*-NIPAM). Because the endotherm is mainly related to the destruction of water around the hydrophobic groups (*32*), this result suggests that the poly(NIPMAM-*co*-NIPAM) forms

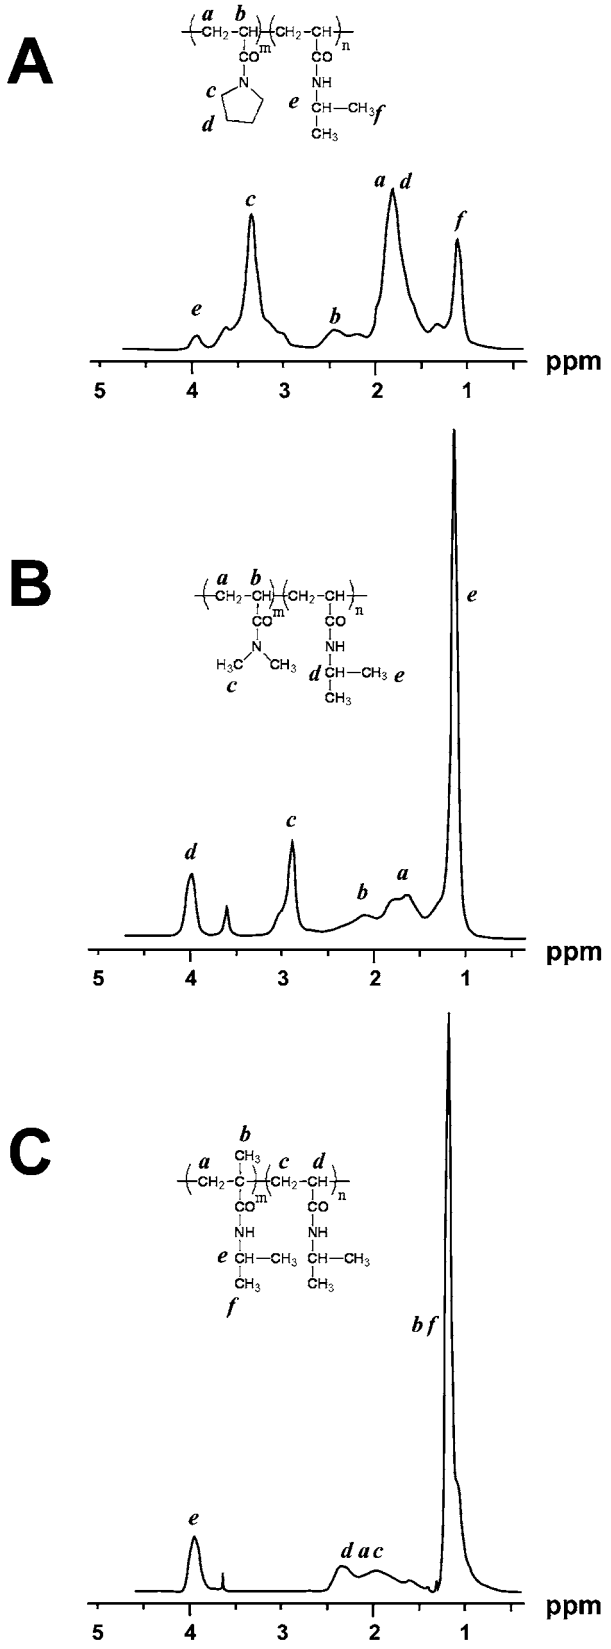

Figure 2. ^{1}H NMR spectra for poly(APr-*co*-NIPAM) (A), poly(DMAM-*co*-NIPAM) (B), and poly(NIPMAM-*co*-NIPAM) (C) in $CDCl_3$.

the most hydrophobic domain above the LCST, whereas poly(APr-*co*-NIPAM) forms the least hydrophobic domain among these copolymers.

Many studies have shown that a variety of hydrophilic polymers with hydrophobic anchor moieties can be fixed

to liposome membranes by a hydrophobic interaction between the hydrophobic moieties and liposome membranes (*12*, *15*, *36*). Since these copolymers have an amino group at one terminus of the chain, two dodecyl groups were introduced to the chain end by reacting didodecylsuccinamic acid with the terminal amino group. We have already shown that the didodecyl group can act as an anchor for the fixation of the NIPAM copolymers to the liposome membranes (*26*, *29*, *31*).

Liposomes modified with the copolymers bearing the anchor, $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM), were prepared by hydration of a mixture of EYPC and the copolymer and subsequent extrusion through a polycarbonate membrane with a pore size of 100 nm. The free

copolymer, which was not bound to the liposome membrane, was removed by GPC. The mean diameters and the standard deviations of the EYPC liposomes modified with $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM) were estimated by dynamic light scattering to be 125.7 ± 1.4, 106.6 ± 11.4, and 95.8 ± 3.8 nm, respectively, at 20 °C. It is apparent that these copolymer-modified liposomes possess diameters close to the pore size of the polycarbonate membrane used to prepare the liposomes. The amounts of the fixed copolymer were found to be 0.66, 0.44, and 0.58 mg/mg of liposomal lipid for liposomes modified with $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM), respectively, indicating that these copolymer-modified liposomes contain similar amounts of the copolymers. As indicated in the Experimental Section, the amounts of $2C_{12}$-poly(APr-*co*-NIPAM), $2C_{12}$-poly(DMAM-*co*-NIPAM), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM) mixed with the lipid (10 mg) were 10, 40, and 10 mg, respectively, for the preparation of the liposomes. Thus, their binding efficiencies are calculated to be 66%, 11%, and 58%, respectively. The contents of the didodecylsuccinamic acid residues in these copolymers were estimated to be 0.6, 0.4, and 1.0 mol %, respectively, from ^{1}H NMR spectra for these anchor-bearing copolymers. Therefore, the low content of the anchor moiety and relatively high polydispersity (Table 1) of $2C_{12}$-poly(DMAM-*co*-NIPAM) may produce the low fixation efficiency.

3.2. Calcein Release from Copolymer-Modified Liposomes. We have already demonstrated that liposomes modified with thermosensitive polymers hardly release their contents below the LCST of the polymer but enhance the contents release above the LCST (*10*, *25*). Figure 5A shows profiles of calcein release from EYPC liposomes modified with these NIPAM copolymers at 25 and 42 °C. As is apparent in Figure 5A, all of the copolymer-modified liposomes did not release calcein at 25 °C. Because these copolymers showed an LCST around 40 °C, this result indicates that well-hydrated chains of these copolymers do not destabilize the liposomal membrane, despite the difference in their molecular structures. In contrast, at 42 °C, an enhancement of the contents release was seen for all of the copolymer-modified liposomes, but the extent of the enhancement was quite different among them. The liposomes modified with $2C_{12}$-poly(APr-*co*-NIPAM) showed only a limited extent of calcein release. However, the liposomes modified with $2C_{12}$-poly(DMAM-*co*-NIPAM) moderately promoted the contents release, and a very rapid and intensive release was observed for the liposomes modified with $2C_{12}$-poly(NIPMAM-*co*-NIPAM).

Figure 5B represents the percent release of calcein from these copolymer-modified liposomes as a function of temperature. For all of the liposomes, the calcein release was enhanced around 40 °C, indicating that the enhancement is triggered by the dehydration of the copolymers above their LCST. For the liposomes modified with $2C_{12}$-poly(APr-*co*-NIPAM), the release gradually increased with increasing temperature above 40 °C. This may be because dehydration of the copolymer chain proceeds with temperature even after its conformational transition. However, even at 50 °C, only 20% of the entrapped calcein molecules were released from the $2C_{12}$-poly(APr-*co*-NIPAM)-modified liposomes. Similarly, for the $2C_{12}$-poly(DMAM-*co*-NIPAM)-modified liposomes, an enhancement in the contents release occurred above 40 °C and the release was promoted by temperature, although the extent of the release was higher than the case

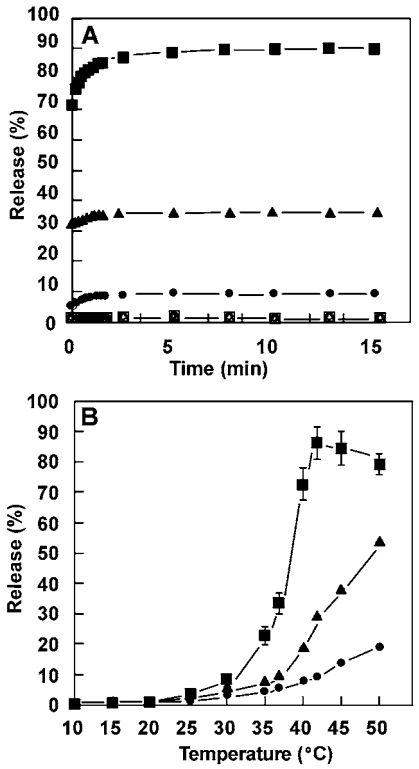

Figure 5. Release of calcein from $2C_{12}$-poly(APr-*co*-NIPAM)-modified (○, ●), $2C_{12}$-poly(DMAM-*co*-NIPAM)-modified (△, ▲), and $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified EYPC liposomes (□, ■) in 10 mM Tris-HCl and 140 mM NaCl solution (pH 7.4). (A) Time course of calcein release at 25 °C (open symbols) and 42 °C (solid symbols). (B) Percent release after 15-min incubation as a function of temperature.

of the $2C_{12}$-poly(APr-*co*-NIPAM)-modified liposomes. For the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified liposomes, an intensive promotion of the release is seen around 40 °C, indicating that this copolymer chain strongly destabilizes the liposome membrane when dehydrated. A certain degree of contents release was also observed at 35 and 37 °C, although these temperatures are below the LCST. As seen in Figure 4, the DSC curve for the poly(NIPMAM-*co*-NIPAM) solution exhibits a large endotherm between 35 and 45 °C. This fact indicates that partial dehydration occurs even below the LCST. Thus, it is likely that the dehydrated segments of the copolymer chain interact with the liposome membrane and induce the contents release to some extent (*29*).

As mentioned above, the extent of partitioning of the copolymers onto the liposome increased in the order of $2C_{12}$-poly(DMAM-*co*-NIPAM) < $2C_{12}$-poly(NIPMAM-*co*-NIPAM) < $2C_{12}$-poly(APr-*co*-NIPAM), although the amounts of the bound copolymer were in the range of 0.44−0.66 mg/mg of lipid and not very different among these copolymer-modified liposomes. Therefore, the observed difference in their degree of contents release behavior cannot be explained from the difference in the extent of the copolymer partitioning. Thus, the ability of the dehydrated copolymer chain to induce the contents release could vary depending on their molecular structures.

3.3. Association of Copolymer-Modified Liposomes. Because the surface of the liposomes is covered by the hydrated copolymer chains below the LCST, these copolymer chains would enhance hydration of the liposome surface. However, above the LCST, dehydration of the copolymer chains would cause binding of the dehydrated copolymer chains onto the liposome surface,

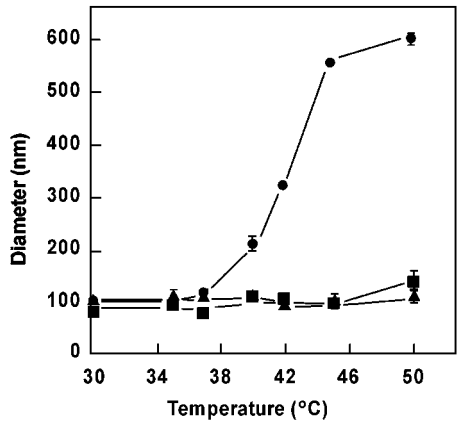

Figure 6. Diameters of $2C_{12}$-poly(APr-*co*-NIPAM)-modified (●), $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified (■), and unmodified (▲) EYPC liposomes in 10 mM Tris-HCl and 140 mM NaCl solution (pH 7.4) as a function of temperature.

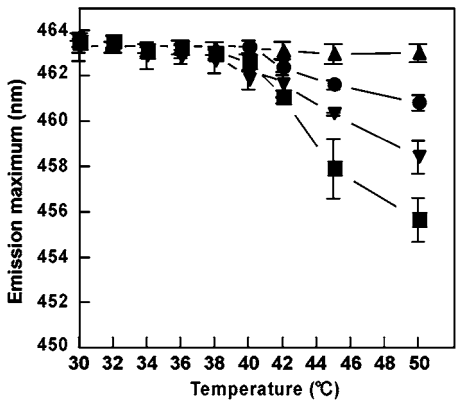

Figure 7. Emission maxima for PyCHO in the absence (▲) or presence of poly(APr-*co*-NIPAM) (●), poly(DMAM-*co*-NIPAM) (▼), and poly(NIPMAM-*co*-NIPAM) (■) in water. The concentrations of PyCHO and the copolymers were 1 μM and 0.4 mg/mL, respectively.

resulting in an increase in hydrophobicity of the liposome surface. Such a temperature-dependent alteration of the characteristic of the copolymer chain on the liposome surface could generate a new type of functional liposome whose surface property is controlled by temperature (*24*). As already shown, from the viewpoint of contents release, $2C_{12}$-poly(NIPMAM-*co*-NIPAM) exhibited the highest ability to sensitize liposomes, whereas $2C_{12}$-poly(APr-*co*-NIPAM) showed the lowest ability among the copolymers prepared in this study. Thus, we examined the temperature-dependent association of the copolymer-modified liposomes for these copolymers.

Figure 6 depicts the apparent diameters of the copolymer-modified and the unmodified EYPC liposomes as a function of temperature. The unmodified liposomes showed essentially the same diameter of ca. 100 nm throughout the experimental temperature range. Both the $2C_{12}$-poly(APr-*co*-NIPAM)-modified and the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified liposomes also exhibited almost the same diameter below the LCST. However, above the LCST, an increase in diameter was observed for both copolymer-modified liposomes, although the extent of the diameter increase is considerably different between them. The $2C_{12}$-poly(APr-*co*-NIPAM)-modified liposomes exhibited a significant increase in the diameter above the LCST, indicating that the dehydrated polymer chains fixed to the liposome made the liposome surface highly hydrophobic and induced aggregation of the liposomes through a hydrophobic interaction. Since the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified liposomes strongly enhanced the contents release above the LCST (Figure 5), we expected that these liposomes would show a more significant association above the LCST. However, the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified liposomes exhibited only a slight increase in the diameter at 50 °C, suggesting that this copolymer does not have the ability to provide a hydrophobic nature to the liposome surface.

3.4. Interaction of Copolymers with Liposome Membrane. Since the NIPAM copolymers exhibited an LCST at ca. 40 °C, these copolymers take on a dehydrated globule above this temperature. However, these copolymers induced the contents release from the liposomes and the association of the liposomes in a very different manner. Because these behaviors of the liposomes might be provided by the hydrophobic nature of the copolymers, the above results imply that the hydrophobicity is different among these copolymers taking on a dehydrated state. Thus, we investigated the hydrophobicity of a domain formed by these copolymers using PyCHO. This molecule is known to change the wavelength of the emission maximum (λ_{max}) of the fluorescence, depending on polarity of the solvent (*37*). By using this property of PyCHO, Schild and Tirrell (*38*) detected collapse of the backbone of the homopolymer and copolymers of NIPAM.

Figure 7 depicts λ_{max} of PyCHO dissolved in an aqueous solution with or without the copolymers. In the absence of the copolymers, λ_{max} did not change in the experimental temperature range. In contrast, in the presence of the copolymers, a marked blue shift above the LCST was observed. However, the extent of the change in λ_{max} was quite different among these copolymers. For poly(APr-*co*-NIPAM), λ_{max} was 463 nm below the LCST but slightly decreased above 40 °C, indicating that the collapsed copolymer chain formed a hydrophobic domain. In the case of poly(DMAM-*co*-NIPAM), however, λ_{max} decreased more significantly above the LCST. The most remarkable blue shift of λ_{max} was observed in the presence of poly(NIPMAM-*co*-NIPAM). Because the λ_{max} of PyCHO linearly increases with dielectric constant of the environment (*37*), this result suggests that poly(NIPMAM-*co*-NIPAM) formed a domain with the highest hydrophobicity, whereas poly(APr-*co*-NIPAM) formed a domain with the lowest hydrophobicity.

To obtain information about their interaction with lipid membranes, we next examined their influence on the membrane fluidity of the liposomes using ANS and DPH (Figure 8). The fluorescence probes ANS and DPH have been frequently used to evaluate membrane fluidity and are known to provide information about the surface and the hydrophobic region of the membrane, respectively (*39*). The inverse polarization of fluorescence probes ($1/P$) was taken as an indication of the membrane fluidity (*39*).

Figure 8A−D depicts the temperature dependence of the membrane fluidities of the EYPC liposomes modified with the copolymers and the unmodified EYPC liposomes as monitored by ANS. For the unmodified liposomes (panel A), the membrane fluidity monotonically increased with the increasing temperature. Similarly, the membrane fluidity of the $2C_{12}$-poly(APr-*co*-NIPAM)-modified liposomes (panel B) increased with temperature and no change in the temperature dependence of the membrane fluidity was observed around the LCST. For the $2C_{12}$-poly(DMAM-*co*-NIPAM)-modified liposomes (panel C), a similar increase in the membrane fluidity was seen between 10 and 40 °C. However, the change in the membrane fluidity was slightly suppressed around the LCST. For the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified

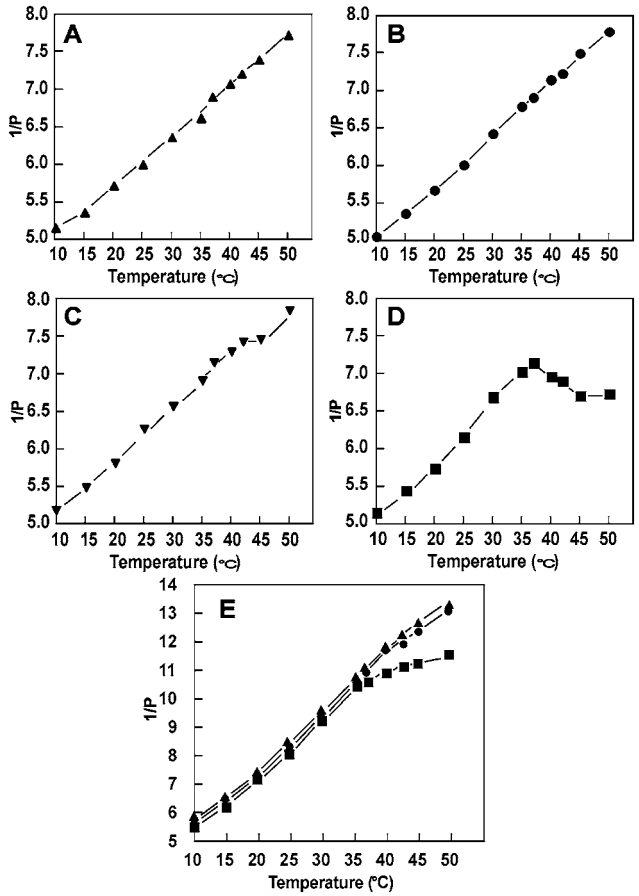

Figure 8. Temperature dependence of membrane fluidity (1/*P*) of $2C_{12}$-poly(APr-*co*-NIPAM)-modified (●), $2C_{12}$-poly(DMAM-*co*-NIPAM)-modified (▼), $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified (■), and unmodified (▲) EYPC liposomes in 10 mM Tris-HCl and 140 mM NaCl solution (pH 7.4) as monitored by ANS (A−D) and DPH (E). The concentrations of EYPC, ANS, and DPH were 0.4 mM, 4.4 μM, and 0.44 μM, respectively.

liposomes (panel D), a marked change in the membrane fluidity took place at the LCST. In this case, the membrane fluidity decreased with temperature above the LCST.

A similar tendency can be seen in the temperature dependence of the membrane fluidity monitored by DPH. As seen in Figure 8E, the membrane fluidity of the $2C_{12}$-poly(APr-*co*-NIPAM)-modified liposomes (●) and that of the unmodified liposomes (▲) increased in almost the same manner. However, for the $2C_{12}$-poly(NIPMAM-*co*-NIPAM)-modified liposomes (■), a remarkable change in the temperature dependence of the membrane fluidity was seen above the LCST. These results indicate that, when hydrated, the chains of these copolymers hardly interact with the lipid membrane. However, when dehydrated, these polymer chains interact with the lipid membrane quite differently. The poly(APr-*co*-NIPAM) chain hardly affected the membrane fluidity even above the LCST, suggesting that their interaction is weak. The poly(DMAM-*co*-NIPAM) chain slightly influenced the membrane fluidity around the LCST, and hence, the copolymer moderately interacts with the membrane. In contrast, poly(NIPMAM-*co*-NIPAM) decreased the membrane fluidity of both the surface and the hydrophobic regions at and above the LCST, indicating that the dehydrated chain of this copolymer strongly interacts with the lipid membrane.

As already described, ΔH for the conformational transition was quite different among these NIPAM copolymers and increased in the order poly(APr-*co*-NIPAM) < poly(DMAM-*co*-NIPAM) < poly(NIPMAM-*co*-NIPAM) (Figure 4). Because this endotherm is related to the destruction of water around the hydrophobic groups (*32*), it is postulated that the copolymer, which exhibits a large ΔH, forms a domain with a higher hydrophobocity after the transition. In fact, the fluorometric measurement with PyCHO clearly demonstrated that the hydrophobicity of a domain formed by the dehydrated copolymer chain increases in the same order (Figure 7). The copolymer with the higher hydrophobicity, indeed, strongly interacts with the lipid membrane. This is consistent with the result of the membrane fluidity measurement, which showed that poly(NIPMAM-*co*-NIPAM) strongly reduced the fluidities of both the surface and the hydrophobic regions of the lipid membrane (Figure 8). Thus, poly(NIPMAM-*co*-NIPAM) could induce a significant contents release, whereas poly(DMAM-*co*-NIPAM) and poly(APr-*co*-NIPAM) provided the liposomes with moderate and weak contents release properties, respectively.

Since poly(NIPMAM-*co*-NIPAM) strongly enhanced the contents release from the liposomes above the LCST (Figure 5), we expected that these liposomes would show more significant associations above the LCST. However, contrary to our expectation, the liposomes having poly(NIPMAM-*co*-NIPAM) chains exhibited only a slight increase in the diameter at 50 °C (Figure 6). Rather, poly(APr-*co*-NIPAM) enhanced the aggregation of the liposomes much more strongly. As is seen in Figure 8D, the dehydrated chain of poly(NIPMAM-*co*-NIPAM) affected the fluidity of the hydrophobic region of the lipid membrane. This fact implies that this copolymer chain deeply penetrates into the lipid membrane and, hence, is buried in the membrane. In contrast, the poly(APr-*co*-NIPAM) chain did not decrease the membrane fluidity even after the conformational transition, suggesting that the dehydrated copolymer chain still exists on the surface of the liposome. Thus, the dehydrated copolymer chains of poly(APr-*co*-NIPAM) could efficiently cover the liposome surface and make its surface hydrophobic.

4. CONCLUSIONS

In this study, we prepared three kinds of NIPAM copolymers with the same conformational transition temperature and varying transition endotherms, and then we investigated their ability to sensitize EYPC liposomes to temperature. We found that their abilities correlated with their ΔH values for the transition. The copolymer with a large ΔH is suitable for obtaining functional liposomes that drastically release contents above the LCST, whereas the copolymer with a small ΔH is appropriate for preparing functional liposomes whose surface becomes hydrophobic above the LCST. These liposomes can release the encapsulated drugs at, or bind to, a target site that is heated above the LCST. Therefore, these liposomes may have potential usefulness for site-specific drug delivery.

Different Immune Response of Mice Immunized with Conjugates Containing Multiple Copies of Either Consensus or Mixotope Versions of the V3 Loop Peptide from Human Immunodeficiency Virus Type 1

Luis J. Cruz,[†] Enrique Iglesias,[‡] Julio C. Aguilar,[‡] Ania Cabrales,[‡] Osvaldo Reyes,[‡] and David Andreu*[,§]

Institut de Recerca Biomèdica de Barcelona, Parc Científic de Barcelona−Universitat de Barcelona, Josep Samitier 1, E-08028 Barcelona, Spain, Centro de Ingeniería Genética y Biotecnología, Apdo 6162, Cubanacán, Habana 10600, Cuba, and Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Doctor Aiguader 80, E-08003, Barcelona, Spain. Received March 5, 2004; Revised Manuscript Received May 28, 2004

The critical role that antibody responses to the V3 loop epitope play in human immunodeficiency virus type 1 (HIV-1) neutralization has caused this peptide to be used in many HIV-1 vaccine candidates. To enhance cross-reactivity toward several V3 sequences, a database of 50 peptides of the V3 region from HIV-1 subtype A was used to design both a consensus peptide and a combinatorial peptide (mixotope) library representative of these sequences. The two immunogens (consensus and mixotope) were incorporated into multiple antigen peptide (MAP) constructions, conjugated to a recombinant surface antigen from hepatitis B virus (HbsAg) carrier protein, and inoculated to mice in combination with a C4 (CD4-binding) peptide MAP construction, also conjugated to HBsAg. The respective responses and cross-reactivity to several V3 loop sequences of both types of immunogens were compared. Mice inoculated with the V3 consensus-MAP−HBsAg + C4-MAP−HBsAg mixture elicited higher antibody responses than those given the V3 mixotope-MAP−HBsAg + C4-MAP−HBsAg mixture. In addition, pooled serum from the first group of immunogens analyzed at dilution 1:100 had higher cross-reactivity against V3 peptides on cellulose membranes than those from mice given the combinatorial immunogen. Fine epitope mapping of both consensus and C4 peptide by the spot synthesis technique showed that sera of the first group strongly recognized both sequences in their entirety, whereas mice immunized with the mixotope library recognized only the N-terminal region of V3. These results seem to suggest that the V3 consensus peptide is superior to the combinatorial strategy in inducing potent and cross-reactive responses to HIV.

INTRODUCTION

The complexity of the HIV[1] life cycle, with high mutation rates and resulting polymorphism, its different mechanisms of evading the immune system, and the absence of suitable animal infection models, have so far combined to forestall the development of successful vaccines. These difficulties notwithstanding, recent advances in the study of HIV entry mechanisms and of structure/function relationships for envelope proteins gp120 and gp41 (*1*) still offer good possibilities for the development of vaccines with preventive and/or therapeutic properties (*2*). Most vaccine prototypes designed so far involve these two targets (*3*). Such prototypes include recombinant proteins (*4*), naked DNA (*5*), and synthetic peptides (*6*).

Several recombinant multiepitope HIV peptide constructions have been described (*7*). For instance, TAB9, which includes six V3 loop peptides (isolates LR150, JY1, RF, MN, IIIB, and BRVA), was used in a phase I clinical study (*8*). The recombinant protein was immunogenic and induced high levels of antibody neutralization, but the immune response was mainly directed at JY1 and LR150 and only weakly at MN, suggesting the need for considerable improvement (*9*). The problem with chimeric polypeptides of this type is that they adopt unpredictable 3D structures that favor the exposure of some epitopes, at the expense of others that in practice remain silent. Alternative strategies, such as synthetic MAP dendrimer constructs, have been proven more effective in achieving more balanced epitope presentations (*10*).

Naked DNA technology has not progressed as far or as fast as expected, largely because no suitable delivery routes have yet been devised. In addition, the long-range collateral effects associated with this approach have not

been adequately clarified. On the other hand, plasmid DNA vaccines, initially regarded as promising, have failed to provide a sufficiently protective response against either HIV or simian immunodeficiency virus (SIV) in primates. Viral mutants escaping plasmid DNA-induced CTL (cytotoxic T lymphocytes) responses have recently been described (*11*).

The synthetic peptide approach makes it possible, in principle, to select only the epitopes of interest and thus largely circumvent problems such as viral variability, unwanted immunosuppression, etc., by focusing on selected segments of envelope proteins such as gp41 and gp120, directly involved in HIV entry and widely regarded as ideal targets for blocking the first step of viral replication. One particular envelope protein, gp120, includes the V3 loop, one of the most widely studied motifs, which defines epitopes for both antibodies and lymphocytes (*12*) and also has a crucial role in viral tropism and pathogenesis (*13*). Consequently, the V3 loop is featured in almost all vaccine candidates currently under evaluation. A recent U.S. clinical trial for a mixture of five V3 peptides showed decreased HIV levels even in patients with strains differing in two or three residues from those used for immunization (*14*). Another relevant gp120 motif, the fourth conserved (C4) domain, is a major player in the binding of HIV to its primary receptor, CD4, leading to virus−cell fusion and replication; a single amino acid change in C4 results in loss of infectivity (*15*).

As is well-known, the V3 region of HIV-1, containing the principal determinant of neutralization, is highly variable. To overcome this difficulty, consensus peptides preserving those amino acid positions more consistently repeated in field or clinical isolates have been explored (*16*). A competing approach, aimed at covering a broad spectrum of V3 sequences, is the generation of combinatorial libraries, named mixotopes (*17*−*19*), representing the more variable positions of the V3 loop. Promising results from this type of strategy have recently been reported (*20*, *21*).

In the present study we have decided to compare both types of strategies. To this end, both consensus and mixotope versions of V3 were synthesized as MAP constructs and conjugated to an HBsAg carrier protein to find out which of the two approaches provides better results in terms of immunogenicity and cross-reactivity. To enhance the immune response, the two kinds of V3 conjugates were coadministered with HBsAg conjugates of a MAP version of the C4 (CD4-binding) sequence. The antibody responses generated by the two types of immunogens were analyzed against several V3 representative peptides, and fine epitope mapping of both groups of sera were performed.

EXPERIMENTAL PROCEDURES

Chemicals and Biologicals. Boc-protected amino acids and other reagents for peptide synthesis were purchased from Bachem (Bubendorf, Switzerland). *p*-Methylbenzhydrylamine (MBHA) resin was from Fluka (Buchs, Switzerland). Solvents for peptide synthesis (DCM, 2-propanol, DMF) were obtained from Merck (Darmstadt, Germany). The recombinant surface antigen from hepatitis B virus (HBsAg) was produced at CIGB (Habana, Cuba). Succinic anhydride was from Sigma (Milwaukee, WI).

MAP Synthesis. All MAPs were prepared by manual stepwise solid-phase synthesis methods (*22*) on *p*-methylbenzhydrylamine (MBHA) resin. The protecting group scheme was based on the Boc group for the α-NH_2 terminus, and the side chains of trifunctional amino acids were protected as benzyl (Asp, Glu, Ser, Thr), 2-chlorobenzyloxycarbonyl (Lys), dichlorobenzyl (Tyr), 2,4-dinitrophenyl (His), formyl (Trp), 4-methoxybenzyl (Cys), and tosyl (Arg) derivatives. The three Lys residues making up the tetravalent dendrimer core were incorporated onto the β-Ala-Cys-MBHA resin as Boc-Lys(Boc) derivatives, by use of TBTU/HOBt/DIEA for the coupling. Cleavage of the Boc group was done with 40% TFA in DCM followed by neutralization with 5% DIEA in DCM. Double couplings with a 10-fold excess of Boc-amino acid and DIPC/HOBt or TBTU/HOBt/DIEA were used for most residues of the V3 epitope. When required by the Kaiser test (*23*), capping steps were performed with 4% acetic anhydride and 1% DIEA in DMF. After low−high HF cleavage and deprotection, the MAPs were extracted into 0.1 M Tris-HCl (pH 8.0) containing 8 M urea, dialyzed against 2 M urea in 0.1 M Tris-HCl (pH 8.0) for 24 h, and then stirred in the same solvent in an open vessel to promote dimerization by disulfide bond formation, until a negative Ellman test (*24*) was obtained. The homodimeric MAPs were then dialyzed against 1 M AcOH, to remove all the urea, and lyophilized.

For the V3 mixotope, a similar synthetic scheme was followed, except that at high-variability positions a representative mixture of the corresponding amino acids (in equimolar proportion) was coupled by means of TBTU/DIEA in DMF under substoichiometric conditions for long reaction times, as previously described (*17*).

Characterization of MAPs. For analytical purposes only, the homodimeric MAP constructs were converted to the monomer form. Lyophilized material was redissolved at 5 mg/mL concentration in 0.3 M Tris-HCl, 6 M guanidinium chloride, and 3 mM EDTA (pH 8.5), a 20-fold molar excess of DTT over Cys residues was added, and the solution was flushed with nitrogen and incubated for 2 h at 37 °C. A 2-fold molar excess of iodoacetic acid over DTT was next added and the solution was kept at room temperature for 1 h in the dark. Modified MAPs were characterized by RP-HPLC on Baker C_8 wide-pore (100 × 4.6 mm) columns in a system consisting of a Pharmacia model 2150 dual pump coupled to a Knauer (FRG) variable-wavelength UV detector. Linear gradients of MeCN (+0.05% TFA) into water (+0.1% TFA) were used for the separation, at 0.8 mL/min flow rate. Optical density was monitored at 226 nm. Data were processed with the BioCrom program (CIGB, Cuba). Electrospray MS analysis was done in a hybrid quadrupole time-of-flight (Q-TOF) instrument (Micromass, Manchester, U.K.) fitted with a Z-spray nano flow ion source (*25*). The mass spectrometer was operated with a source temperature of 80 °C and a drying gas flow rate of 50 L/h. RP-HPLC-purified MAPs were dissolved in a 50% (v/v) water/MeCN solution containing 1% acetic acid, to an approximate concentration of 5 pmol/μL. The MAP solution was infused at 3 μL/ min into the mass spectrometer by use of a syringe pump (Harvard Apparatus, Holliston, MA). The capillary and cone voltage were set to 3 kV and 35 V, respectively. Data acquisition and processing were performed with the Micromass MassLynx package.

For amino acid analysis, samples of S-carboxymethylated MAPs were hydrolyzed with 6 M HCl containing 0.1% phenol and 0.1% 2-mercaptoethanol for 24 h in vacuum-sealed ampules. After evaporation, amino acids in the hydrolysate were determined in a Pharmacia-LKB Alpha Plus 4151 analyzer with a sodium buffer system and *o*-phthalaldehyde derivatization for fluorescence detection. All samples were analyzed in triplicate.

Table 1. Immunization Protocols[a]

group	dose (μg)
A: HBsAg	10
B: C4-MAP−HBsAg	10
C: C4-MAP−HBsAg and consensus MAP−HBsAg	5 + 5
D: C4-MAP−HBsAg and library MAP−HBsAg	5 + 5

[a] All immunogens formulated in CFA (100 μL, day 0) and IFA (days 14, 28, 56). Each group consisted of eight mice.

Conjugation of MAPs to Carrier Protein. Homodimeric, octavalent MAPs were coupled to HBsAg as described by Deen et al. (*26*) (see Figure 1 also). Briefly, 5 mg of HBsAg was dissolved in 5 mL of 0.2 M K_2HPO_4 (pH 8.0), solid succinic anhydride (1 mg) was added, and the solution was stirred until all anhydride was dissolved, with occasional dropwise addition of 3 M NaOH as required to keep the pH at 8−8.5. The activated protein was next exhaustively dialyzed against dilute HCl (pH 4.5), mixed with 7 mg of EDAC, and stirred for 10 min at 25 °C. Then, 5 mg of octavalent MAP dissolved in 1 mL of 3 M guanidine hydrochloride in PBS was added and the mixture was gently stirred for 3 h at 25 °C. The conjugates were purified by gel filtration through Sephadex CL-4B (Pharmacia, Uppsala, Sweden) eluted with PBS. The front-eluting fractions were pooled and quantitated by the Coomassie method (*27*).

Immunizations. Groups of eight female Balb/c mice, 6−8 weeks old (Cenpalab, Cuba), were inoculated subcutaneously on days 0, 14, 28, and 56 with 100 μL of a suspension containing 10 μg of antigens (Table 1) emulsified in either CFA (day 0) or IFA (other days). Animals were bled 10 days after the fourth dose.

Enzyme-Linked Immunosorbent Assay against Synthetic Peptides. ELISA of anti-peptide sera was done as previously described (*28*). Briefly, 96-well (Costar high binding) polystyrene plates (Corning Biosciences, Acton, MA) were coated with 100 μL of 10 μg/mL solutions of consensus or C4 peptides (as BSA conjugates) or of the MAP library and incubated overnight at 4 °C. After three washings with 0.05% Tween 20 in PBS, plates were blocked with 2% milk in PBS (blocking solution) for 1 h at 37 °C. Serum samples were diluted with 0.05% Tween 20−5% sheep serum in blocking solution and incubated for 2 h at 37 °C. After four washings, an anti-mouse IgG peroxidase conjugate (Amersham, Little Chalfont, U.K.) was added and the mixture was incubated for 1 h at 37 °C. The color reaction with *o*-phenylenediamine was allowed to develop for 10 min and then stopped with 3 M H_2SO_4 solution (50 μL), and the absorbance at 492 nm was determined in a SensIdent Scan (Merck). Results were expressed as log titer, determined by interpolation of OD values at fixed serum dilutions into a standard curve of a serum with known titer. Titer was defined as the logarithm of the highest dilution giving twice the absorbance of negative control sera. Titers are given as the geometric mean ± SD of the titers of individual sera.

Epitope Mapping by Use of Cellulose-Bound Peptides. The spot synthesis technique previously described by Frank (*29*) was used. The Whatman 540 paper support (Whatman, Maidstone, U.K.) was functionalized by esterification of Fmoc-β-Ala-OH, activated by DIPC and *N*-methylimidazole in dry DMF, at defined positions to give a spot array suitable to the required number of sequence peptides. All subsequent residues in the different V3 loop sequences were incorporated manually by standard Fmoc/tBu chemistry. All peptides were acetylated at the N-terminus at the end of the synthesis program.

Paper-Based Peptide Enzyme Immunoassay. Washing steps and incubations were performed at 25 °C with Tris-buffered saline (TBS) containing 0.05% Tween-20. Blocking of free binding sites was performed by overnight incubation with 5% skim milk in TBS. Spots were next incubated with sera for 3 h, washed, and incubated for 2 h with alkaline phosphatase-conjugated anti-mouse IgG (Sigma). Detection of bound antibody was achieved with 5-bromo-4-chloro-3-indolyl phosphate (Sigma) in substrate buffer [0.1 M Tris (pH 8.9), 0.1 M NaCl, and 2 mM $MgCl_2$]. Washing with PBS stopped staining. The peptide-bearing cellulose sheets were regenerated and prepared for the next run as described by Frank (*29*).

Statistical Analysis. All ELISA OD values were transformed to the natural logarithm to get a normal distribution in the immunized groups. An *F*-test was performed to assess variance homogeneity between groups and a Student's *t*-test was done ($p < 0.05$ was considered statistically significant).

Table 3. HIV-1 Amino Acid Sequences Used for the Immunogens

Peptide	Sequence synthesized[a]
C4	KQIINMWQEVGKAMYA
Consensus	KSVRIGPGQAFYATGDIIGDIRQA
Combinatorial mixotope[b]	KXXXIGPGQXFYATGXIIGXIRQA SVR A D D GMH T A N LN S E S IG V G AS I S N Q

[a] In the consensus and mixotope sequences, a non-native N-terminal Lys residue was added to facilitate conjugation to the carrier protein. The N-terminal Lys of the C4 sequence is native. [b] In the mixotope top sequence, the Xs denote combinatorial sites, where mixtures of the residues shown below have been incorporated.

RESULTS

Design and Synthesis of V3 Consensus and Combinatorial MAPs. Fifty sequences (Table 2) from the V3 region of HIV-1, subtype A, with (i) reasonable chemical diversity, (ii) adequate geographical representation, and (iii) demonstrated infectivity were manually selected out of ca. 7000 sequences available at the time at the National Center for Biotechnology Information (BLAST program) and used to design a 24-residue consensus sequence, where the most frequent amino acid among the isolates was chosen for each position. The same database was used to build a mixotope combinatorial library (*18*) in which sites with over 90% conservation among the 50 isolates were represented by a single residue, while at more degenerate positions an amino acid mixture representative of the different mutations was incorporated (Table 3).

The design of our immunogens started (Figure 1A) with the incorporation of either the consensus single peptide, or the mixotope library, or of another HIV peptide sequence (C4) known to play a major role in viral binding to the CD4 primary receptor, into tetravalent MAP platforms. The original approach of Tam (*30*) was followed, with two minor modifications: (i) a Lys residue was added at the N-terminus of both consensus and mixotope sequence to facilitate conjugation to carrier protein (the C4 peptide already has a native Lys at the N-terminus), and (ii) a Cys residue was placed at the C-terminus of the entire MAP dendrimer, to allow dimerization by disulfide formation. The resulting octavalent constructions would next be conjugated to HBsAg (see next section and Figure 1B).

All three MAPs were prepared by Boc-based methods of solid-phase synthesis and, after cleavage from the resin with HF, were solubilized under denaturing conditions and dialyzed to remove synthesis and cleavage byproducts while in situ air oxidation was allowed to proceed. The reaction was monitored by HPLC gel filtration and the Ellman test (data not shown). Once shown to be complete by HPLC (see Supporting Information), the dimeric MAPs were dialyzed against 1 M AcOH and lyophilized. MAP dimers were found to be stable at or below pH 7, room temperature, in aqueous solution, with or without chaotropic additives. To further evaluate their quality, an aliquot was reduced, S-carboxymethylated, and characterized by both reverse-phase HPLC and MS (Figure 2). As expected, the HPLC profile corresponding to the combinatorial MAP, containing an estimated mixture of over 5000 different peptide sequences, was a rather broad peak. For the two single-sequence MAPs, the HPLC profiles showed a main fraction that was analyzed by electrospray MS and found to correspond very well with the expected theoretical mass: 11 318.87 Da for the consensus V3-MAP (found *m*/*z* 11 319.63) and 8824.56 Da for C4-MAP (found *m*/*z* 8824.25). In this latter case, the broad elution band overlapping the main peak was attributed to byproducts resulting from Trp degradation during the HF deprotection step. The MAPs were further characterized by amino acid analysis, which in all three cases showed compositions consistent with the expected structure (Table 4).

MAP−HBsAg Conjugates. To further enhance the immunogenicity of the homodimeric MAPs, they were conjugated to recombinant HBsAg, a polymeric protein of about 2000 kDa (*31*, *32*). Our choice of HBsAg was based on its high molecular weight, proven stability, and high immunogenicity and because it is known to act as an effective and safe vaccine in humans. The conjugations were performed with a succinic acid cross-linking between Lys amino groups of the MAP epitopes and the carrier. Thus, HBsAg was first succinylated under mildly alkaline conditions, followed by dialysis to remove excess succinic anhydride and thus avoid unwanted cross-linking. The carboxyl groups on the modified HBsAg were next activated with EDAC (a soluble carbodiimide) and

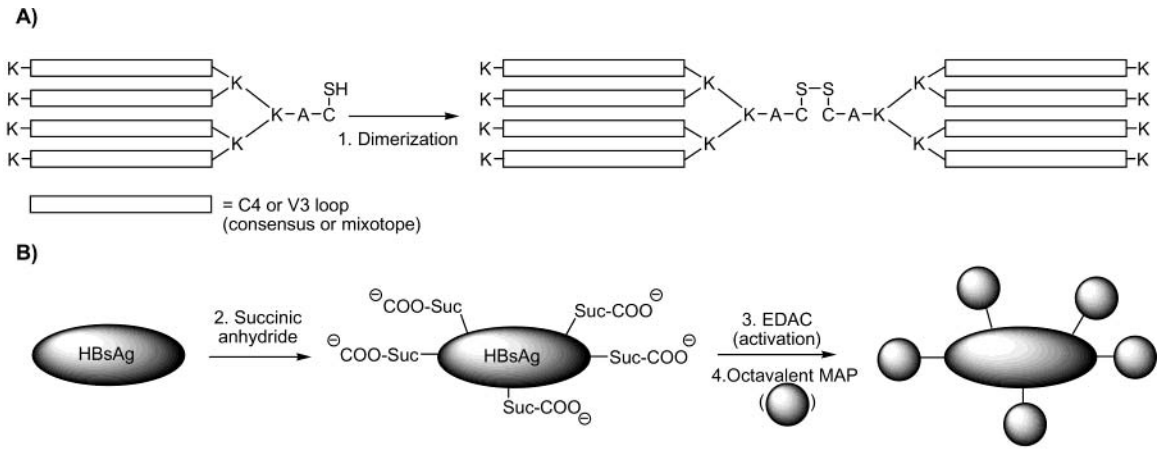

Figure 1. Synthetic strategy for MAP conjugates of C4 and the V3 loop of HIV. (A) Octavalent MAP constructs result from dimerization (1) of synthetic tetravalent MAP through disulfide formation. (B) Amino groups in HBsAg are converted to carboxyls (2) by succinylation and then activated (3) with water-soluble carbodiimide to allow conjugation (4) with the octavalent MAP.

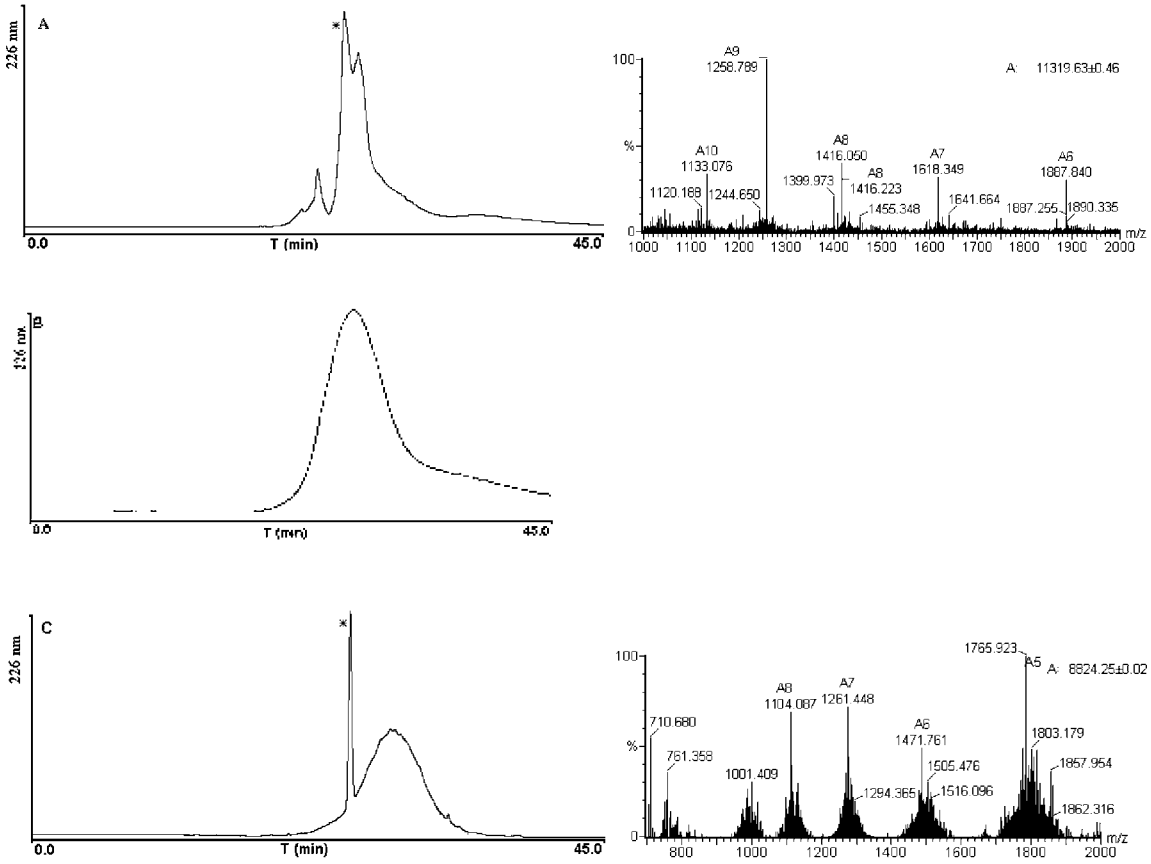

Figure 2. HPLC analysis of tetravalent MAP constructs corresponding to the V3 loop in consensus (A) and mixotope (B) form and (C) to C4. Profiles show the product resulting from reduction and S-carboxymethylation of the synthetic octavalent dimer. In panels A and C, the ESI mass spectrum of the main fraction (marked with an asterisk) is shown at the right of the chromatogram. For the consensus V3 loop MAP, calculated MW 11 318.87 Da; found, *m*/*z* 11 319.63. For the C4 MAP, calculated MW 8824.56 Da; found, *m*/*z* 8824.25.

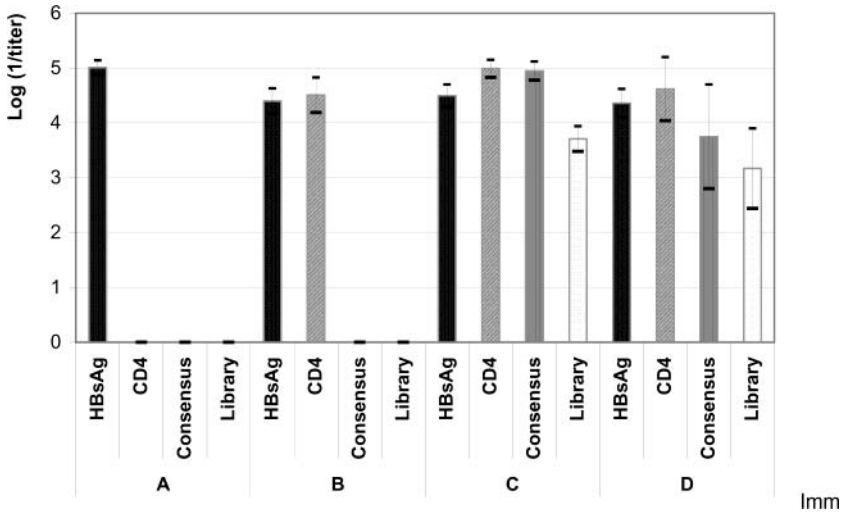

Figure 3. Antibody titers of mice after immunization with four doses of (A) HbsAg, 10 μg; (B) C4-MAP−HBsAg conjugate, 10 μg; (C) mixture of C4-MAP−HBsAg and consensus V3-MAP−HBsAg conjugates, 10 μg; and (D) mixture of C4-MAP−HBsAg and V3 mixotope-MAP−HBsAg, 10 μg. Titers are the geometric mean ± SD of eight mouse antisera.

allowed to react with the free amino grups of each MAP (Figure 1B). The conjugates were purified by gel filtration on Sephadex CL-4B to remove excess carbodiimide and MAP. Since amino acid analysis of HBsAg is notoriously unreliable, no attempt was made to determine MAP-to-HBsAg molar ratios by this method. Instead, a qualitative estimation of the efficiency of epitope incorporation to the conjugates was obtained by ELISA (see Supporting Information).

Analysis of Antibody Response in Mice Immunized with MAP Conjugates. Groups of eight Balb/c mice were inoculated subcutaneously to evaluate the anti-MAP antibody responses against the different immunogens. For coimmunizations, appropriate formulations of each individual conjugate were prepared and mixed before inoculation. All four groups of animals gave anti-HBsAg responses (Figure 3), which were predictably more pronounced in the control group A. Responses to

C4 were also comparable in the three groups immunized with the corresponding MAP−HBsAg conjugate. Co-immunization of C4-MAP−HBsAg with either the V3 consensus MAP−HBsAg or the V3 mixotope-MAP−HBsAg conjugates produced antibody responses against both (V3 and C4) types of B-cell epitopes. Interestingly, animals receiving the consensus V3 immunogen recognized the mixotope somewhat better than those given the mixotope itself. From Figure 3 it is clear that the antibody responses against all three types of immunogen (C4, consensus, and mixotope) were significantly higher for group C mice (inoculated with consensus V3-MAP−HBsAg + C4-MAP−HBsAg) than for group D (V3 mixotope instead of consensus V3 peptide). From these results we conclude that, at least in this particular case, co-administration of two immunogens is advantageous in terms of obtaining a dual antibody response. Such an approach should be valuable for generating bivalent vaccines when the carrier protein is per se a vaccine immunogen such as HBsAg.

Analysis of Cross-reactivity with Peptides Synthesized on Cellulose Membrane. Cross-reactivity of the different antisera was evaluated (Figure 4) against a panel of 50 cellulose-bound peptides corresponding to different isolates of the V3 loop of HIV-1, subtype A. After the third booster, pooled sera from group D (immunized with C4-MAP−HBsAg and V3 mixotope-MAP−HBsAg) at 1:100 dilution recognized 26% (13/50) of the test peptides, 53% (7/13) of them with high reactivity. In contrast, pooled sera from group C (given C4-MAP−HBsAg and consensus V3-MAP−HBsAg) recognized 72% (36/50) of the same peptide panel same peptides panel, 50% (18/36) with high reactivity. Thus, somewhat counterintuitively with the use of a single sequence, the consensus immunogen gives rise not only to higher titers but also to broader cross-reactivities.

Fine Epitope Mapping of Anti-V3 Sera. Given the substantial differences in cross-reactivity observed for antibody responses to either consensus or mixotope strategies, it seemed appropriate to perform a fine epitope mapping of both types of antisera. For this we resorted again to the spot synthesis technique, using 18 and 10 overlapping heptapeptides to cover the sequences of the consensus and the C4 peptides, respectively (Figure 5). ELISA of pooled sera from groups C and D at a 1:100 dilution showed that the former group (immunized with consensus V3-MAP−HBsAg) strongly recognized the N-terminal (KSVRIGP and RIGPGQA), central (FYATGDII), and C-terminal (IGDIRQA) regions of the immunogen. In contrast, mice immunized with the combinatorial mixotope only recognized heptapeptides from the N-terminal region (KSVRIGP and RIGPGQA). Again, a more satisfactory antibody response was found for mice immunized with the V3 consensus MAP.

Figure 4. Cross-reactivity analysis of anti-V3 loop-MAP antibodies against heterologous V3 peptides displayed on cellulose membrane. Pooled sera (after initial inoculation + three boosters) from different immunization groups (A−D as in Figure 3) were analyzed. Boxes are coded as follows: white, no recognition; light gray, weak recognition; dark gray, intermediate recognition; black, strong recognition.

DISCUSSION

Different strategies have been proposed to deal with the challenge that highly variable antigenic sites, such as the V3 loop of HIV-1, pose to synthetic peptide-based vaccination schemes (*33*). Most of these strategies have relied on the use of combinations of several representa-

Figure 5. Epitope mapping of consensus and C4 peptides by the spot synthesis technique. The first 18 overlapping heptapeptides correspond to the consensus V3 loop sequence; the other 10 peptides, to C4. Pooled sera (after initial inoculation + three boosters) from different immunization groups (A−D as in Figure 3) were analyzed. Boxes are coded as follows: white, no recognition; light gray, weak recognition; dark gray, intermediate recognition; black, strong recognition.

tive peptide variants. We had earlier shown that V3 loop-based peptide cocktails, in the form of MAP dendrimers, were a good strategy of epitope presentation (*9*).

In the present study we have compared two alternative approaches to the variability problem, namely, (i) the use of a rationally derived consensus sequence where each position is occupied by the statistically most relevant residue or (ii) the mixotope concept, which not only reproduces a broad spectrum of reported, characteristic mutations, as done before with peptide cocktails (*9*), but additionally merges them in combinatorial fashion. Although our study is confined to basic features of the responses elicited by these two different immunogen types, it provides nonetheless sufficient evidence that the first approach is to be preferred if a strong, cross-reactive, and representative immune response to the V3 loop is wished. Our choice of antigenic presentation, i.e., homodimeric MAPs conjugated to HBsAg, relied on previous data (*32*) demonstrating its enhancing effect on peptide immunogenicity and may have influenced the strength of the immune response (e.g., relative to immunization with free peptides) but would predictably have had parallel effects on both consensus and mixotope formulations and thus little or no effect on the differences we have observed.

In contrast to the report by Resnick et al. (*34*), here we demonstrate that the mixotope strategy did not generate higher levels of cross-reactivity against several V3 peptides than those of the consensus strategy. The fine epitope mapping showed that the anti-peptide antibody response elicited by the consensus MAP was more complete than that generated by the MAP library. The fact that the latter is composed of some 5000 different sequences may account for the substantial reduction in global immune response and may also explain why the antibodies raised against the mixotope library tend to target mainly on the conserved regions of the V3 loop (Figure 5), which are better represented than the variant ones. In conclusion, our data support the hypothesis that, for highly variable antigens, a rationally designed consensus sequence, such as the one derived here for the V3 loop of gp120, may be a valid approach for synthetic vaccine development, providing desirable cross-reactivity and therapeutic advantage.

On-Resin Assembly of a Linkerless Lanthanide(III)-Based Luminescence Label and Its Application to the Total Synthesis of Site-Specifically Labeled Mechanosensitive Channels

Christian F. W. Becker,[†] Daniel Clayton,[‡] George Shapovalov,[‡] Henry A. Lester,[‡] and Gerd G. Kochendoerfer*[,†]

Gryphon Therapeutics, 600 Gateway Boulevard, South San Francisco, California 94080, and Division of Biology, California Institute of Technology, Pasadena, California 91125. Received May 19, 2004; Revised Manuscript Received July 15, 2004

A synthesis strategy for the on-resin assembly of luminescent lanthanide chelates from commercially available compounds was developed. Advantages of the approach include the absence of spacers between the metal ion and the attachment site, and the compatibility with typical chemical protein synthesis protection schemes. Methoxycoumarin-labeled lysine and tris(*tert*-butyl)-DOTA were consecutively coupled with high efficiency to a free amino group in otherwise fully protected peptide segments using standard peptide synthesis methods. Addition of stoichiometric amounts of Tb^{3+} to the modified, cleaved, and purified peptides yielded the desired lanthanide chelate. Incorporation of this label into a chemically synthesized, full-length mechanosensitive channel of large conductance (MscL) of *E. coli* and subsequent reconstitution into vesicles resulted in a functional mechanosensitive channel of comparable conductance to the wild-type channel. However, this channel required increased suction to gate. Excitation of the antenna molecule methoxycoumarin at 336 nm resulted in an emission spectrum typical for Tb^{3+} and a luminescence lifetime of 0.67 ms. The location of the probe close to the backbone of this protein may provide precise information about conformational changes during channel opening from LRET studies.

INTRODUCTION

Lanthanide(III)-based chelates are used increasingly for spectroscopy applications, in particular luminescence resonance energy transfer (LRET),[1] due to the unique luminescence properties of the chelated ions (*1*−*9*). LRET is a type of luminescence assay where a lanthanide donor (Tb^{3+} or Eu^{3+}) transfers excitation energy to an organic fluorescent acceptor in a distance-dependent manner, thus yielding static or dynamic distance information. The unique advantages of lanthanide complexes for this application include luminescence lifetimes in the millisecond range, very sharp emission spectra, high quantum yields, and, in most cases, unpolarized emission (*10*). The advantage of long-lasting fluorescence or luminescence lies in the less costly instrumentation that can be used to detect the emitted signal when compared to measurements of dyes with lifetimes in the nanosecond range. An additional advantage, in particular in the study of highly scattering solutions such as detergent micelle and liposome containing solutions, is the ability to gate the detection in order to reject stray-light. Finally, in the case of oligomeric proteins such as ion channels with multiple distances between nonequivalent positions on identical subunits, the ease of fitting emission decays of long-lived emitters to multiple decay constants allows straightforward deconvolution of these distances (*2*, *7*).

Luminescent lanthanide(III)-based chelates have been principally developed to label folded proteins or DNA. Therefore, they typically utilize flexible linkers with thiol- or amine-reactive groups, and in many cases the sensitizer itself, to distance the chelator moieties from the amino acid side chains of peptides or proteins (*1*, *3*, *11*−*14*). Whereas the presence of a spacer may be desirable for efficient labeling of folded proteins under mild conditions for steric reasons, and in cases where the bulk of the chelate label may interfere with function, such linkers may considerably reduce the accuracy of distance measurements that can be achieved through LRET by introducing additional flexibility to the system.

Our design strategy focused on the fast and facile assembly of a luminescent label that is located close to the backbone of the respective peptide or protein. The label is prepared from commercially available starting materials, DOTA as chelator and methoxycoumarine-labeled lysine as the antenna moiety in protected forms. Commercial availability of these starting materials frees the nonorganic chemist from the solution synthesis steps required for preparation of lanthanide labels described previously in the literature (*1*, *3*, *6*, *11*, *12*, *14*, *15*). The label can be introduced in a straightforward fashion during solid-phase synthesis employing either Boc or Fmoc protecting group strategies. After establishing our approach by preparing a labeled test peptide consisting of 32 amino acids using Boc-chemistry, we extended it to the assembly of multiple luminescent variants of the

mechanosensitive channel of large conductance from *E. coli*. Loading of the DOTA chelator with Tb^{3+} was accomplished following successful synthesis and purification of the test peptide and MscL proteins, respectively, and yielded a lanthanide complex with the desired features for biophysical measurements.

EXPERIMENTAL PROCEDURES

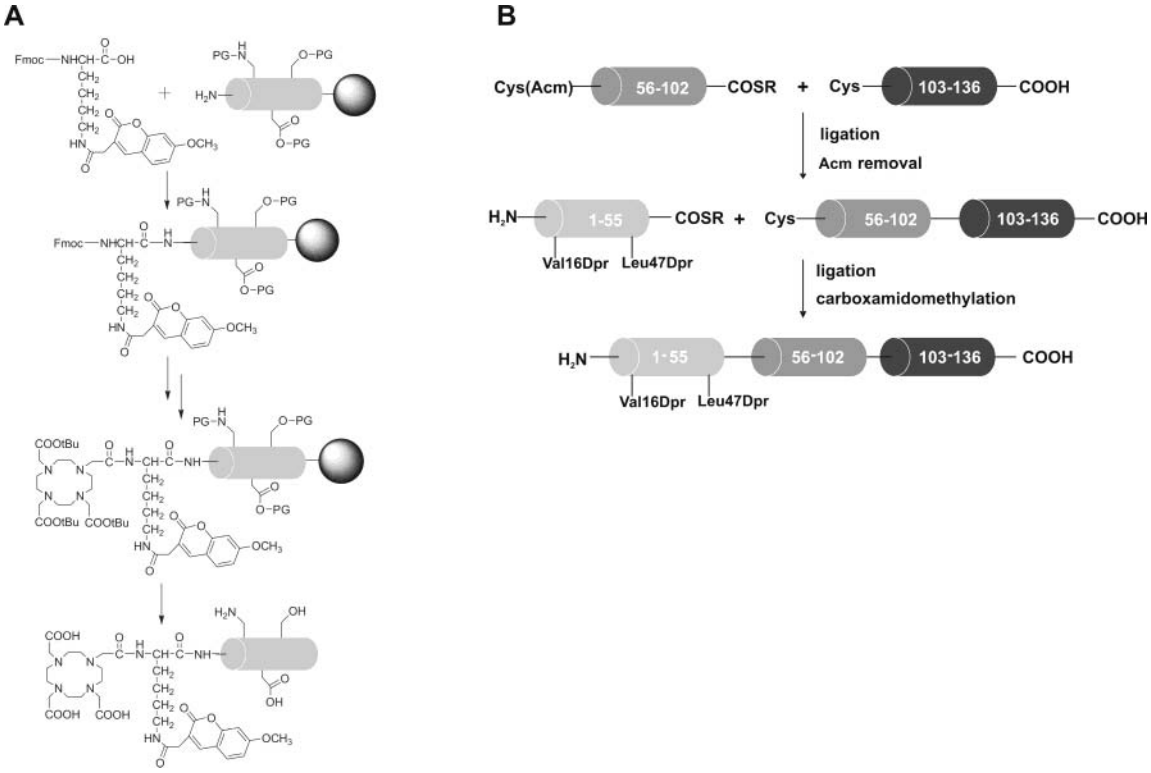
The following reagents were obtained from the indicated sources: Boc-protected amino acids (Midwest Biotech, Fishers, IN); Fmoc-protected amino acids (Novabiochem, San Diego, CA); trifluoroacetic acid (Halocarbon, River Edge, NJ); DIEA (*N*,*N*-diisopropylethylamine) (Applied Biosystems, Foster City, CA); HBTU (2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate) (Spectrum, Gardena, CA); acetonitrile (Burdick & Jackson, Gardena, CA). Other chemicals were obtained from Sigma (St. Louis, MO) or Aldrich (Milwaukee, WI) and were used as received.

Peptide Synthesis and Purification. Peptides were synthesized at a 0.2 mmol scale on a custom-modified Applied Biosystems 433A peptide synthesizer using S-DVB (stryrene−divinylbenzene) resin carrying an $-OCH_2-$PAM linker (Applied Biosystem, Foster City, CA) or a thioester-generating linker, respectively, following an in-situ neutralization protocol for machine-assisted Boc (*tert*-butoxycarbonyl) chemistry (*16*, *17*). Side-chain protecting groups were Arg(Tos), Asn(Xan), Asp(OcHx), Cys(pMeBzl), Glu(OcHx), His(Dnp), Lys(2ClZ), Ser(Bzl), Thr(Bzl), Trp(CHO), and Tyr(2BrZ). The amino acid sequence of the 32mer test peptide used to prototype the DOTA-Mca-label synthesis: H-CAVVFVTRKNRQVSANPEKKAVREYINSLELL-OH(MW: 3676 Da) was derived from the chemokine CCL5 (RANTES). The sequence and assembly of the peptide backbone of the MscL peptide segments (MscL1-55, MscL56-102, and MscL103-136) was as described previously (*18*).

Assembly of the Luminescent DOTA-Mca Label. The label was introduced on-resin into the N-terminus of the test peptide, and into the N-terminus and positions Val16 and Leu47 in the N-terminal peptide segment MscL1-55. For attachment to the N-terminus, the N-terminal Boc group was removed by treatment with 100% TFA for 2 × 1min cycles. For attachment to positions Val16 and Leu47, the side chain Fmoc protecting group of diaminopropionic acid incorporated at the desired position was removed by 3 × 3 min treatments with 3% DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) in DMF. Fmoc-Lys(Mca)-OH (Novabiochem, San Diego, CA) was coupled to the respective free amino group by using a 5-fold excess of the fluorescent amino acid activated with an equimolar amount of HBTU in DMF in the presence of 10% DIEA (*17*). The Fmoc protecting group on the Lys(Mca) label was removed by 3 × 3 min treatments with 3% DBU in DMF, and 1,4,7,10-tetraazacyclododecane-1,4,7-tris(acetic acid-*tert*-butyl ester)-10-acetic acid (DOTA-tris(*tert*-butyl ester) (Macrocyclics, Dallas, TX) was coupled to the resulting free amine using HBTU/DIEA activation as described for Fmoc-Lys(Mca)-OH. The peptides were then deprotected and simultaneously cleaved from the resin support using HF (*16*). MscL peptides were purified as previously described (*18*).

Assembly of Ec-MscL. The total chemical synthesis and refolding of MscL was performed as previously described (*18*). Briefly, MscL protein was produced by consecutive native chemical ligation of three unprotected, purified peptide segments (MscL1-55, MscL56-102, and MscL103-136) to form the full-length protein. Ligations were performed at a reactant concentration of ~0.1 mM in a solution containing 17 mg/mL dodecyphosphocholine (DPC), 8 M urea, and 100 mM NaP_i, pH 7.5, at 40 °C. Peptides were dissolved in this buffer at 40 °C for 5 min and sonicated for 3−5 min. Ligation reactions were initiated by addition of 0.5% thiophenol, and the progress of the reaction was monitored by analytical RP-HPLC and ESI-MS (electrospray ionization mass spectrometry) analysis. Prior to purification, ligation solutions were worked up at 40 °C in a 5-fold excess of a solution of 20% β-mercaptoethanol in 8 M urea containing 17 mg/mL DPC. Following purification of the first ligation intermediate MscL56-136, the Acm (acetamidomethyl) protecting group was removed from the side chain of the N-terminal cysteine residue in preparation for the final ligation step (*19*). After the final ligation, free cysteine residues were modified by adding DPC to a final concentration of >2 mg/mL to the HPLC pool and subsequent reaction with a 30-fold molar excess of bromoacetamide for 30 min at room temperature. The full-length protein containing the label was then purified. Loading of the chelator with Tb^{3+} was achieved by addition of $TbCl_3$ to the protein solution.

Electrophysiological Characterization. DOTA-Mca-labeled Ec-MscL channel protein was reconstituted into artificial liposomes as described (*18*). Single-channel recordings were made at 20−22 °C on the reconstituted labeled as well as recombinant wt protein at a bandwidth of 20 kHz at 50 mV (intracellular medium is negative) in symmetrical 250 mM KCl, 1 mM $MgCl_2$, 5 mM HEPES (pH 7.1) solution. Currents were acquired with an Axopatch 200B amplifier (Axon Instruments, Union City, CA) and digitized with an Axon Digidata 1322A digitizer. Conductance recordings were analyzed using Axon pCLAMP 8 software. The probability of opening (P_{open}) vs suction curves were generated using software developed by one of the authors (G.S.). Boltzmann functions were fitted to the dose−response relations using the Microcal Origin 6.0 software, yielding activation midpoints and gradients.



Fluorescence Spectroscopy. Fluorescence spectroscopy was performed with a FluoroLog-3 system (Jobin Yvon, Edison, NJ) equipped with a Xenon-lamp for continuous excitation and a pulsed Xenon lamp for time-resolved measurements using the phosphorimeter setup. Typical settings were an excitation wavelength of 336 nm for the Mca fluorophore, a delay of the detection window relative to the flash pulse of 50 μs, number of flashes 10 (at 20 Hz), and a scanning range of 370 to 700 nm. Data obtained from lifetime measurements were fitted with a single-exponential equation using Kaleidagraph (Synergy Software).

Mass Spectrometry. All crude, purified, and ligated peptides were identified by ESI-MS using ABI-150 or API−III mass spectrometers (Applied Biosystems, Foster City, CA).

RESULTS AND DISCUSSION

Our objective was to develop a simple and efficient procedure to label synthetic peptides and chemically synthesized proteins site-specifically with luminescent labels during solid-phase peptide synthesis. In our design, the lanthanide ion that ultimately determines the experimental distance in LRET experiments is close to the backbone of the peptide or protein since a lysine branch is employed to scaffold the attachment sites of the chelator and the antenna fluorophore (See Scheme 1). The more distant ϵ-amino group of this lysine carries the coumaryl sensitizer, while the DOTA chelator is attached

to the proximal α-amino group. The lysine scaffold is either attached to the peptide's N-terminus or to a noncoded diaminopropionic acid residue that is incorporated into the sequence of the target peptide or protein in order to minimize the distance to the backbone. As a result, the lanthanide ion is placed at a maximum distance of 10 Å from the backbone as determined by molecular modeling. By contrast, most other luminescent chelates, such as polyaminocarboxylate−coumarin complexes, were mostly designed to employ long alkyl chains as linkers between peptide and lanthanide complex, which results in larger distances between the label and its attachment site (*1, 3, 11*−*14*).

The assembly of the luminescent probe was initiated by coupling Fmoc-Lys(Mca)-OH either to an unprotected α-amino group of the peptide or a side chain amino group of diaminopropionic acid in an otherwise fully protected peptide linked to a solid support (Scheme 1). Deprotection of the α-amino group was achieved by Boc removal with TFA. The side chain amino group of diaminopropionic acid was specifically deprotected by removing an Fmoc group with a sterically hindered base such as DBU. Activation and in situ neutralization using a 5-fold excess of Fmoc-Lys(Mca)-OH gave excellent coupling yields and no further optimization was needed (*17*). Subsequently, the Fmoc group was removed from the Lys(Mca) moiety by treatment with 3% DBU in DMF for 3 × 3 min and a protected DOTA was coupled to the free α-amino group. DOTA has been extensively used as a chelator for radionuclides in imaging and therapy (*20*−*23*). In our case, DOTA was *tert*-butyl protected at three out of its four carboxyl groups to overcome solubility problems that we encountered with unmasked DOTA in all solvents compatible with solid-phase synthesis such as DMF, DMSO, NMP, and DCM. The 4th carboxyl group was used to form a stable amide bond between the chelator DOTA and the peptide. A 3- to 4-fold excess of tris-(*tert*-butyl)-DOTA was sufficient to obtain fully modified peptides using HBTU/DIEA activation.

This synthesis strategy was initially tested on a 32 amino acid peptide by attaching the label to its unblocked N-terminus and later extended toward a C-terminal α-thioester peptide consisting of the 55 N-terminal amino acid residues of Ec-MscL. Subsequently, the purified peptide was used in the total chemical synthesis of Ec-MscL (*18*) to demonstrate compatibility with native chemical ligation strategies (see Scheme 1B). The assembly of the label gave high yields in each case. In all cases, deletion peptides missing either the coumaryl group or the DOTA group were not observed as significant side products, as determined by RP-HPLC and ESI-MS analysis of the crude cleavage products. As a result, coupling yields are estimated to be >95% overall for both coupling steps, and labeled peptides could be obtained in comparable yields to the unlabeled peptides.

Purification of the test peptide from the crude cleavage mixture by RP-HPLC was followed by lyophilization and transfer into an aqueous buffer containing 10% acetonitrile and reconstitution with $TbCl_3$. Successful complexation of the lanthanide ion by the DOTA label was verified by ESI-MS since the affinity between DOTA and Tb^{3+} was strong enough to survive the ionization process (*24*). Figures 1A and 1B show the electrospray mass spectra of the peptide before and after addition of $TbCl_3$ and desalting by RP-HPLC. The mass difference of +158 Da directly demonstrates binding of a single terbium ion to the peptide, presumably to the DOTA chelator (Figure 1B). Since excess $TbCl_3$ was removed by the desalting column, unspecific binding of Tb^{3+} to the peptide is unlikely to be the cause of the mass gain.

After this proof of principle, we proceeded to assemble labeled variants of the mechanosensitive ion channel of *E. coli* (Ec-McL). The recent total chemical synthesis of Ec-MscL allowed the direct, site-specific introduction of

spectroscopic labels at distinct positions of this protein during the peptide assembly stage. Since the open pore of Ec-MscL is predicted to be around 30 Å in diameter (*25*−*29*), LRET studies employing sensitized lanthanide chelates that exhibit large Förster distances and are typically most sensitive for distances between 20 and 100 Å (*8*) are uniquely suited to monitor conformational changes associated with channel opening and are not limited by the small dynamic range of EPR studies (*28*, *30*). Accordingly, a single lanthanide chelate was incorporated into three distinct positions of Ec-MscL, the N-terminus, position Val16 at the cytoplasmic end of the first membrane spanning helix of MscL, and position Leu47 in the loop region between TM1 and TM2 (Scheme 1B). Three positions were chosen in order to get a set of distances in LRET studies after transfer of luminescence to an appropriate acceptor such as TAMRA (tetramethylrhodamine).

After assembly and labeling of the respective N-terminal peptides of Ec-MscL, purification from the crude cleavage mixtures was achieved by RP-HPLC and yielded pure peptides that were used for initial testing of the fluorescent and luminescent properties of the synthetic molecule (data not shown) and as starting materials for the assembly by native chemical ligation. Yields from a synthesis at 0.2 mmol scale on the peptide level were typically 15−20 mg for unlabeled and 10−15 mg for labeled peptide. Assembly of the full-length channel protein largely followed the published procedures (*18*). The assembly process was closely monitored by RP-HPLC

and ESI-MS and was performed in the absence of lanthanide ions. Chemical protein synthesis by native chemical ligation, modification of cysteine ligation sites by bromoacetamide to mask the unnatural cysteine residues, and Acm removal from the ligation intermediates did not modify or alter the label, suggesting that it is fully compatible with the chemical synthesis approach.

Figures 1C and 1D show the HPLC trace and ESI-MS of purified N-terminally DOTA-Mca labeled Ec-MscL (experimental mass: 15 774 Da (±2 Da), theoretical mass: 15 772.9 Da) after assembly (*31*). All other variants could be prepared with comparable purity, and about 1 mg of each variant was prepared in this fashion. The ESI-MS spectra of the intermediate and the final construct also demonstrate that the *tert*-butyl group of the chelator is completely removed prior to protein assembly.

The labeled channel proteins were characterized electrophysiologically in order to ensure correct folding and function. Reconstitution of the synthesized ion channel into artificial liposomes was performed as previously described (*18*) and yielded patches with resistances in the range of 5−20 GΩ. Application of suction produced characteristic single-channel activity that disappeared upon suction release. Figure 2A shows sample activity of the synthesized channel. The single-channel conductance and presence of multiple substates (Figure 2B) correspond to that of the recombinant channel (*18*); however, greater suction was required to open the DOTA-Mca-labeled channel. Figure 2C compares dose−response (P_{open} vs suction) curves for the synthetic (squares) and recombinant (circles) channels. Boltzmann fits to the dose−response curves yielded average activation thresholds of 1.3 ± 0.1 psi (9 ± 1 kPa) for wt and 2.4 ± 0.2 psi (17 ± 1 kPa) for the synthetic channel. It should be noted, however, that the higher activation threshold of DOTA-Mca-labeled channel was similar to the suction at which the liposome membrane in the patches regularly ruptured. Thus, the reported activation midpoint for the DOTA-Mca-labeled channel gives a lower boundary estimate of the value.

Overall, the electrophysiology data confirm that the described synthesis and ligation steps yielded the properly folded and functional protein. However, the introduction of the N-terminal DOTA-Mca label seems to alter channel function either by interfering with the transfer of tension from the bilayer to the channel or by stabilizing the closed-state or destabilizing the open-state. Others have also observed that modifications to the N-terminus can affect the pressure sensitivity of Ec-MscL (*32*). Unfortunately, no reproducible MscL-like conductance could be measured for the MscL variants labeled at positions Val16 and Leu47. In hindsight, this could be rationalized by the location of the label at the membrane−water interface, which might be important for transducing mechanical tension into protein conformational change (*33*). The exploration of alternative labeling sites is ongoing.

To assess the luminescent properties of the resulting protein constructs after reconstitution into a TFE/water mixture (4:1), the methoxycoumarin ring of the label was excited at 336 nm, inducing a strong fluorescence with a maximum intensity at 393 nm due to spontaneous fluorescence of the sensitizer. In the absence of lanthanide ions such as Tb^{3+}, no luminescence signal could be detected. However, after additon of an aqueous solution of $TbCl_3$ to this solution, Tb^{3+} luminescence was detected (Figure 3A). This emission was partially hidden by the stronger Mca background fluorescence. When

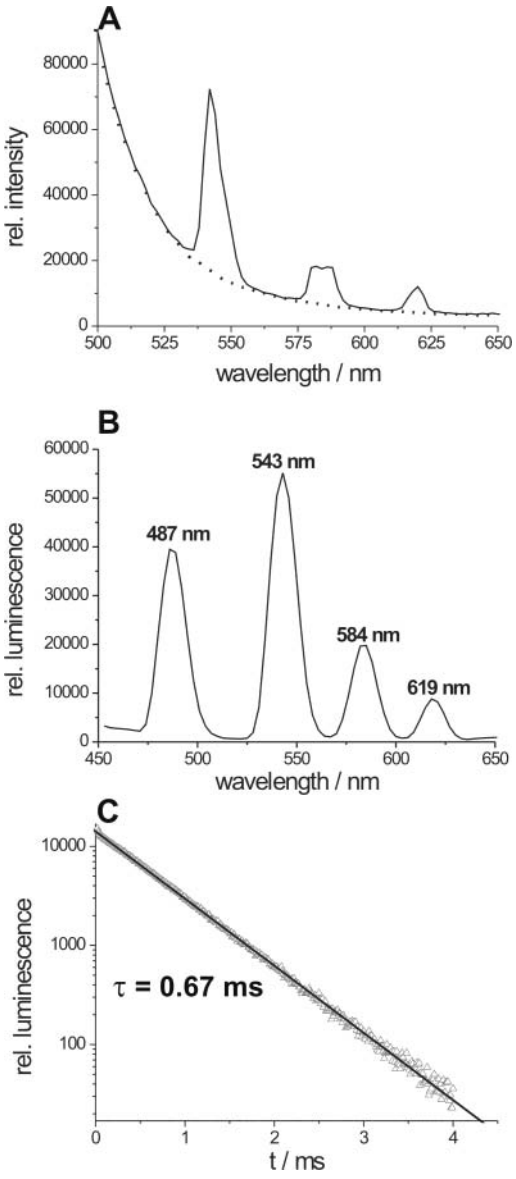

Figure 3. Luminescence of DOTA-Mca-labeled Ec-MscL after excitation at 336 nm. (A) Emission of DOTA-Mca-labeled Ec-MscL with (solid line) and without (dashed line) Tb^{3+} after CW excitation and detection; (B) Tb^{3+} luminescence, after pulsed excitation with a 10 μs pulse and gated detection (50 μs delay); (C) semilogarithmic plot of Tb^{3+}-luminescence decay.

using a phosphorimeter set up that allowed time-gated measurements, a 50 μs delay between excitation of the sample and the starting point for detection of the emission was sufficient to obtain a completely independent Tb^{3+} luminescence signal (Figure 3B). The Tb^{3+} emission showed typical, sharp maxima at 487, 543, 584, and 619 nm, with the strongest emission around 543 nm. The decay was monoexponential, and the luminescence lifetime was determined as 0.67 ms from a semilogarithmic plot of the decreasing luminescence intensity. 0.67 ms is about half of the lifetime found for DOTA-carbostyril-based Tb^{3+} chelates ($\tau \sim 1.5$ ms) in solution (Figure 3C) (*34*). The reduced lifetime may be attributed to less efficient shielding of the Tb^{3+} ion when bound to its DOTA chelator in the context of this chelate. The coordination of water, which might result in nonradiative de-excitation processes, might be facilitated in this chelate. The intrinsic quantum yield for the terbium chelate was estimated by taking the ratio of the luminescence lifetime of Tb^{3+} in the DOTA-Mca chelate and the

intrinsic lifetime of Tb^{3+} (4.75 ms) (*35*, *36*). The resulting estimated luminescence quantum yield of DOTA-chelated terbium in our label is thus 14%. More detailed studies may be needed to investigate the cause of the reduced lifetime and provide a more exact luminescence quantum yield. Nonetheless, the observed luminescence lifetime of the DOTA-Mca chelate is sufficient for LRET experiments.

CONCLUSIONS

We have demonstrated that membrane proteins, site-specifically labeled with a luminescent lanthanide(III)-based chelate, can be prepared by chemical protein synthesis. Preparation of the sensitized chelate from commercial starting materials is a significant improvement to previously reported labels. Introduction of the label close to the protein backbone may allow highly precise measurements of distance changes during the opening of mechanosensitive channels by luminescence resonance energy transfer. Taken together, CPS and LRET provide a powerful combination of techniques for studying the structure−function relationship of membrane proteins such as Ec-MscL.

Received May 7, 2004; Revised Manuscript Received August 2, 2004

A derivative of 1,10-phenanthroline that binds to UO_2^{2+} with nanomolar affinity was found to be a very effective immunogen for the generation of antibodies directed toward chelated complexes of hexavalent uranium. This study describes the synthesis of 5-isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid and its use in the generation and functional characterization of a group of monoclonal antibodies that recognize the most soluble and toxic form of uranium, the hexavalent uranyl ion (UO_2^{2+}). Three different monoclonal antibodies (8A11, 10A3, and 12F6) that recognize the 1:1 complex between UO_2^{2+} and 2,9-dicarboxy-1,10-phenanthroline (DCP) were produced by the injection of BALB/c mice with DCP−UO_2^{2+} covalently coupled to a carrier protein. Equilibrium dissociation constants for the binding of DCP−UO_2^{2+} to antibodies 8A11, 10A3, and 12F6 were 5.5, 2.4, and 0.9 nM, respectively. All three antibodies bound the metal-free DCP with roughly 1000-fold lower affinity. The second-order rate constants for the bimolecular association of each antibody with soluble DCP−UO_2^{2+} were in the range of 1 to 2 × 10^7 M^{-1} s^{-1}. Binding studies conducted with structurally related chelators and 21 metal ions demonstrated that each of these three antibodies was highly specific for the soluble DCP−UO_2^{2+} complex. Detailed equilibrium binding studies conducted with three other derivatives of DCP, either complexed with UO_2^{2+} or metal-free, suggested that the antigen binding sites on the three antibodies have significant functional and structural similarities. Biomolecules that bind specifically to uranium will be at the heart of any new biotechnology developed to monitor and control uranium contamination. The three antibodies described herein possess sufficient affinity and specificity to support the development of immunoassays for hexavalent uranium in environmental and clinical samples.

INTRODUCTION

The mining and processing of uranium ores have contaminated significant quantities of soil and groundwater in the US, Europe, and Russia (*1*−*3*). In the US alone, more than 200 million metric tons of mine tailings and other waste have been identified for cleanup and disposal (*4*). The health effects associated with oral or dermal exposure to natural and depleted uranium appear to be solely chemical in nature and not related to uranium's radiological properties (*5*). The toxicity of natural uranium varies according to its chemical form, and the more soluble, hexavalent form has been shown to be the most potent systemic toxicant (*6*). Uranium is absorbed from the intestine or the lungs. Although most uranium is rapidly excreted in the urine, a small percentage is deposited in the tissues, predominantly kidney, muscle, and bone (*7, 8*). Chronic exposure to uranium in drinking water is weakly associated with altered proximal tubulus function without a clear threshold, which suggests that even low uranium concentrations in drinking water can cause nephrotoxic effects (*9*). Current research suggests that the safe concentration of uranium in drinking water may be close to the value proposed by the US Environmental Protection Agency, 30 μg/L or ∼130 nM (*10*).

As part of an ongoing effort in our laboratories to develop immunoassays for heavy metals in environmental and clinical samples, we have produced and characterized a growing number of monoclonal antibodies directed toward epitopes of metal−chelate complexes (*11*−*17*). Although other laboratories have described the generation and properties of monoclonal and recombinant antibodies directed toward chelated metal ions (*18*−*23*), a detailed characterization of antibodies directed toward an epitope that includes some form of ionic uranium has not been reported. Previous attempts by our laboratories to generate antibodies to chelated hexavalent uranium using bifunctional acyclic polyaminocarboxylate chelators available from similar studies were not successful. These failed attempts led us to hypothesize that bifunctional chelators derived from EDTA and DTPA did not coordi-

nate hexavalent uranium with an affinity high enough to preserve the metal−chelate complex during immune processing in the injected animal.

This paper describes the generation and binding properties of three different monoclonal antibodies directed toward an epitope comprised of the hexavalent UO_2^{2+} and a novel bifunctional derivative of 2,9-dicarboxy-1,10-phenanthroline (DCP)[1]. DCP bound to UO_2^{2+} with an affinity approximately 5 orders of magnitude greater than that determined for EDTA or DTPA. Each of the three monoclonal antibodies produced using this new amine-reactive chelator bound to the soluble DCP−UO_2^{2+} complex with an equilibrium dissociation constant in the low nM range. Equilibrium and kinetic binding studies conducted with different chelators and metal ions indicated that each of these three antibodies possessed sufficient specificity and affinity to create an immunoassay for soluble natural uranium in the concentration range currently proposed by the US Environmental Protection Agency for drinking water (*10*).

EXPERIMENTAL PROCEDURES

Materials. 2,9-Dicarboxy-1,10-phenanthroline (DCP) was synthesized (*24*) or purchased from Alfa Aesar (Wood Hill, MA). 1,10-Phenanthroline, 2,9-dimethyl-1,10-phenanthroline, and 4-(2-pyridylazo)resorcinol (PAR) were products of Aldrich, Inc. (Milwaukee, WI). The 2,9-diphosphonatomethyl-, 2,9-dicarboxymethyl ester-, 2,9-dihydroxymethyl-, and 2,9-ditrichloromethyl-substituted 1,10-phenanthrolines were generously provided by Dow Chemical Co. (Freeport, TX). Uranyl diacetate (ACS-grade) was a product of Mallinckrodt Chemical Works (St. Louis, MO). Other metals (atomic absorption grade) were obtained from Perkin-Elmer (Norwalk, CT). Prepacked Sephadex G-25 columns (PD-10) were products of Pharmacia, Inc. (Piscataway, NJ). Centricon filters were purchased from Amicon (Beverly, MA). Keyhole limpet hemocyanin (KLH) was purchased from CalBiochem (LaJolla, CA). BALB/c inbred mice were obtained from Charles River Laboratories (Wilmington, MA). SP 2/0-Ag14 myeloma cells were from the American Type Culture Collection (Rockville, MD). RIBI and TiterMax adjuvants were purchased from RIBI Immunochemicals (Hamilton, MT) and CyxRx (Norcross, GA). Culture media and other reagents for the preparation of hybridoma cells were obtained from Stem Cell Technologies (Vancouver, BC, Canada). An IsoStrip mouse monoclonal antibody isotyping kit was purchased from Boerhinger-Mannheim (Indianapolis, IN) and used according to the manufacturer's instructions. Fetal bovine serum (low IgG) was the product of Hyclone Laboratories (Logan, UT). 3,3′,5,5′-Tetramethylbenzidine peroxidase substrate (TMB Microwell Substrate) was from Kirkegaard-Perry Laboratories (Gaithersburg, MD). Microwell plates for ELISA (high-binding, flat bottom) and standard tissue culture plasticware were from Corning/Costar (Cambridge, MA). CellLine culture flasks were distributed by Fisher Chemical Co. (Houston, TX). Polystyrene beads (98 micron diameter) for binding studies were purchased from Sapidyne Inc (Boise, ID). HRP- and Cy5-labeled goat anti-mouse IgG were products of Jackson Immunoresearch Laboratories (West Grove, PA). Ethylenediaminetetraacetic acid (EDTA), diethylenetriaminepentaacetic acid (DTPA), pristane, HEPES, RPMI medium, L-glutamine, antibiotics, bovine serum albumin (fraction V, metal-free), and antibodies specific for mouse IgG1, IgG2a IgG2b, IgG3, IgM, and IgA were purchased from Sigma Chemical Co. (St. Louis, MO). The DTPA analogue, *N*-(2-aminoethyl)-*trans*-1,2-diaminocyclohexane-*N*,*N*′,*N*″-pentaacetic acid (CHXDTPA), was available from a previous study (*16*). Elemental analyses were performed by Atlantic Microlab, Inc., Norcross, GA.

Determination of Dissociation Constants for the Interaction of Chelators with UO_2^{2+}. The binding of uranyl ion to colorimetric and noncolorimetric chelators was determined by spectrophotometric titrations performed on an OLIS-14 renovated Cary Spectrophotometer (On-Line Instruments, Inc. Bogart, GA). Visible absorbance spectra of 26 μM PAR in HEPES-buffered saline (HBS, 137 mM NaCl, 3 mM KCl, 10 mM HEPES, pH 7.4) were performed in the absence and presence of varying concentrations of uranyl ions (5−50 μM), and values of Δ absorbance were determined as differences in the spectrum of the metal-free chelator versus the spectrum of the chelator in the presence of uranyl ions. For determination of the dissociation constants of noncolorimetric chelators with uranyl ion, the concentrations of PAR and uranyl ion were fixed at 26 and 30 μM, respectively, and spectra were obtained after adding varying concentrations of the noncolorimetric chelator to the preformed complex. Data were fit to the equations described in Results to obtain equilibrium dissociation constants.

Synthesis of Bifunctional Chelator for UO_2^{2+}. Synthesis of 5-isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid was performed in four steps, as shown in Figure 1.

5-Nitro-2,9-dimethyl-1,10-phenanthroline (**2** in Figure 1). To a mixture of 5 mL of nitric acid and 10 mL of sulfuric acid was added 0.5 g (2.4 mmol) of 2,9-dimethyl-1,10-phenanthroline (**1** in Figure 1), and the solution was heated at 115 °C for 1 h. The solution was poured onto 100 g of ice, and the mixture was adjusted to pH 8 with a concentrated solution of NaOH. The precipitate was filtered and dried at 110 °C to give 248 mg of **2** (0.98 mmol, 41% yield); mp 201−203 °C, 1H NMR δ 2.97 (3H, s), 2.99 (3H, s), 7.66 2H, app t, J = 8.5 Hz), 8.26 (1H, d, J = 8.3 Hz), 8.60 (1H, s) 8.91 (1H, d, J = 8.7 Hz).

5-Nitro-1,10-phenanthroline-2,9-carboxylic Acid (**4** in Figure 1). A mixture of compound **2** (1.0 g, 3.6 mmol) and selenium dioxide (1.0 g, 9.0 mmol) was dissolved in 5 mL of dioxane containing 4% water and heated at reflux for 3 h, then filtered through a pad of Celite while hot. The dialdehyde **3** was isolated from the filtrate as a yellow-red precipitate in 64% yield. Anal. ($C_{14}H_7N_3O_4$) C, H, N.

The dialdehyde was subsequently oxidized to the dicarboxylic acid using 10 mL of 80% nitric acid under reflux for 3 h. The solution was then cooled and poured into ice. The resulting precipitate was collected and recrystallized from aqueous THF to give 580 mg of the bis-acid **4** (1.9 mmol, 46% from **2**); mp 217−220° C; IR 3100 and 1733 cm^{-1}, ^{1}H NMR δ 8.47 (1H, d, J = 8.0 Hz), 8.95 (1H, d, J = 8.0 Hz), 9.04 (1H, d, J = 8.8 hz), 9.17 (1H, s). Anal. ($C_{14}H_7N_3O_6$-1/2 H_2O) C, H, N.

5-Isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic Acid (**5** in Figure 1). Compound **4** (110 mg, 0.3 mmol) was hydrogenated in 5 mL of ethanol at 60 psi in the presence of 15 mg of 10% Pd/C. On exposure to air, the initially yellow solution became bright red. Therefore, the

[1] The following abbreviations are used in the text: BSA, bovine serum albumin; CHXDTPA, *trans*-*N*-(2-aminoethyl)-1,2-diaminocyclohexane-*N*,*N*′,*N*″-pentaacetic acid; DCP, 2,9-dicarboxy-1,10-phenanthroline; DHM, 2,9-dihydroxymethyl-1,10-phenanthroline; DME, 2,9-dicarboxymethyl ester-1,10-phenenthroline; DPP, 2,9-diphosphonatomethyl-1,10-phenanthroline; DTPA, diethylenetriaminepentaacetic acid; EDTA, ethylenediaminetetraacetic acid; PAR, 4-(2-pyridylazo)resorcinol.

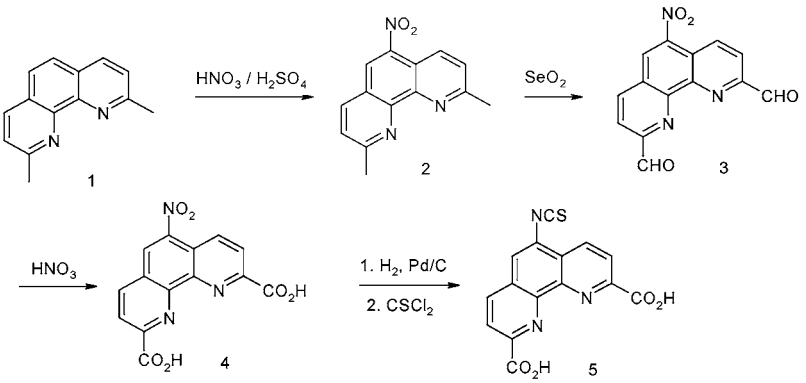

Figure 1. Synthesis of 5-isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid. Scheme for the synthesis of 5-isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid in from 2,9-dimethyl-1,10-phenanthroline.

amine was directly converted to the isothiocyanate. 3 N HCl (10 mL) was added, and the solution was filtered to remove the catalyst. The ethanol was evaporated at reduced pressure, and the solution was cooled to 0 °C. Thiophosgene (5 mL of a 10% solution in chloroform) was then added with rapid stirring, which was continued overnight at room temperature in a chemical hood. Evaporation of the two-phase mixture under reduced pressure gave a solid that was washed with 10 mL of cold water and dried under vacuum to give 98 mg (0.30 mmol, 86% from **4**) of **5**. The isothiocyanate derivative could be used immediately or stored for up to 3 months at −20 °C.

Synthesis of Protein−Chelate Conjugates. 5-Isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid (7.1 mg or 22 μmol, ∼equal molar with respect to total lysine residues in these proteins) was suspended in 1.0 mL of 0.1 M HEPES buffer, pH 9.0, containing 20 mg of BSA or KLH. The pH of the reaction mixture was readjusted to 9.0 if necessary with KOH, and the reactions were stirred overnight at room temperature. The supernatant from this reaction mixture was desalted by filtration through a prepacked Sephadex G-25 column equilibrated with HEPES-buffered saline (HBS, 137 mM NaCl, 3 mM KCl, 10 mM HEPES, pH 7.4). The protein−DCP conjugates eluted in the void volume of the column and could be further concentrated (if necessary) by ultrafiltration in Centricon filters (30 000 mol. wt. cutoff). The concentration of the conjugates was determined using the BCA protein assay kit (Pierce Chemical Co., Rockford, IL) with supplied BSA standards. The degree of lysine substitution in the conjugates was estimated by a modification of a literature method (*25*). The original procedure required additional background measurements because the conjugates had significant absorbance at 345 nm. Protein−chelate conjugates prepared by this method were estimated to have between 20% and 80% lysine substitution (depending upon the preparation) and were light yellow-brown in color when present at a concentration > 2.5 mg/mL.

Mouse Immunization, Hybridoma Production, and Purification of Monoclonal Antibodies. The KLH−DCP conjugate (80% substitution, 0.7 mg in 0.28 mL of HBS) was mixed 0.07 mL of 10× HBS and 0.07 mL of uranyl diacetate (62.5 mM solution in dilute acetic acid, 3.5 μmol), followed by immediate addition of 0.05 mL of KOH (1.8 M aqueous solution) to bring the pH of the mixture to 7.0. The mixture was diluted by the addition of 0.15 mL of water, the pH was adjusted to 7.0, and the final volume of the solution was brought to 0.7 mL. This mixture was emulsified with an equal volume of RIBI or TiterMax adjuvant. The components of this preparation were not fully soluble, but produced homogeneous emulsions with both adjuvants. The final immunogen contained 0.5 mg/mL of the KLH−DCP conjugate and 2.5 mM uranyl diacetate.

Three 6-week old female BALB/c mice were each injected intraperitoneally with 0.1 mL of the prepared immunogen (2 with RIBI and 1 with TiterMax). The injections were repeated after 3 weeks, and the polyclonal antibody responses were measured by indirect ELISA as described below. The mouse with the best polyclonal antibody response to uranium-loaded BSA−DCP was given a final intraperitoneal injection of 50 μg of KLH−DCP with 2.5 mM uranyl diacetate in HBS, and after 72 h the animal was sacrificed and its spleen was removed. Hybridomas were prepared by fusion of splenocytes and SP 2/0-Ag14 myeloma cells using the reagents provided by Stem Cell Technologies and plated into a semisolid growth medium also provided by this manufacturer. After incubation at 37 °C in 95% air/5% CO_2, hybridoma cell colonies began to grow out in 7−10 days. These colonies, visible to the naked eye, were individually transferred to the wells of 96-well plates that contained 0.15 mL of culture medium and incubated for several days. The culture supernatants were assayed for antibody production by indirect and competitive ELISA (described below) and representative cells were cloned twice by limiting dilution before storage in liquid nitrogen.

Ascites fluid was produced in pristane-primed BALB/c mice. For some experiments, large quantities of antibodies were prepared by hybridoma culture in 1-L CellLine culture flasks, used according to the manufacturer's instructions. Monoclonal antibodies were purified by affinity chromatography on protein G as previously described (*11*). The homogeneity of the purified proteins was checked by gel electrophoresis in the presence of sodium dodecyl sulfate and β-mercaptoethanol (*26*). The concentration of the antibodies was determined using the BCA protein assay, and the immunoglobulin subclass was determined and quantified by sandwich ELISA using antibodies specific for IgG1, IgG2a, IgG2b, IgG3, IgM, and IgA. Light chain isotype was identified by using the IsoStrip antibody isotyping kit according to the manufacturer's instructions.

Indirect and Competitive ELISA. Addition of uranyl diacetate to concentrated solutions of the DCP−protein conjugates (>100 μg/mL) caused precipitation. This precipitation could be avoided either by dilution of the conjugate to concentrations less that 10 μg/mL before addition of uranyl ion, or by immobilizing metal-free DCP−protein conjugate onto the ELISA plate and sub-

sequently incubating the plate with a solution of uranyl diacetate. Both procedures gave equivalent results in control experiments (data not shown). ELISA plates were incubated with 2−5 μg/mL of DCP−BSA in HBS amended with 5 μM uranyl diacetate for at least 1 h at 37 °C or overnight at 4 °C. The plates could be stored for several weeks in this coating buffer with no loss of activity. Immediately before use, the plates were washed three times with PBS-Tween (137 mM NaCl, 3 mM KCl, 10 mM phosphate, pH 7.4, and 0.05% Tween-20), blocked for 15 min with 3% BSA in HBS, and washed again three times with PBS-Tween.

For indirect ELISA, diluted serum or hybridoma culture supernatant was incubated for 1 h at room temperature in the coated wells. After three washes in PBS-Tween, the amount of primary antibody bound on the plate was quantified using an HPR-conjugated goat anti-mouse antibody and TMB microwell substrate (see refs 11 and 12 for a more detailed description). For competitive ELISA, diluted hybridoma culture supernatants were incubated in microwell plates coated with BSA−DCP−UO_2^{2+} in the presence of one of the following: 12.5 μM DCP in HBS or 12.5 μM DCP + 5 μM uranyl diacetate in HBS. The binding of the antibodies in HBS alone served as a control in the competitive ELISA's. The amount of primary antibody bound to the plate was quantified as described for indirect ELISA.

Equilibrium Binding Studies and Kinetic Analyses. Equilibrium binding studies and measurements of association rate constants were performed using a KinExA 3000 (Sapidyne Instruments Inc, Boise, ID) flow fluorimeter. The general procedures have been described in detail elsewhere (*11*, *27*, *28*). For these experiments, polystyrene beads coated with UO_2^{2+}−DCP−BSA were used as the capture reagent. Polystyrene beads (98 μm, 200 mg) were incubated with 1 mL of 100 μg/mL DCP−BSA for 1 h at 37 °C. The beads were washed two times with 1 mL of HBS, then any remaining binding sites were blocked by incubation for 1 at 37 °C with BSA (10 mg/mL in HBS containing 0.03% NaN_3.) Beads could be stored in this blocking solution for up to 2 months at 4 °C. Immediately before use, the beads were diluted into 30 mL of HBS amended with 30 μM uranyl diacetate to saturate the immobilized DCP with UO_2^{2+}. The excess uranyl ions were washed away when the coated beads were packed into the capillary observation cell.

RESULTS

Binding of Uranyl Ions to Chelators. Our laboratories have successfully isolated and characterized monoclonal antibodies to chelated forms of ionic cadmium and lead using bifunctional derivatives of EDTA (*11*), CHXDTPA (*16*), and DTPA (*14*) to create metal-binding epitopes on appropriate carrier proteins. In all cases to date, the resulting covalent complexes of chelated metal ions appeared to be weak immunogens, since only a few clones out of hundreds assayed actually produced antibodies that exhibited acceptable specificity for the chelated metal ion in question. In the present case, initial efforts to generate monoclonal antibodies directed against chelated forms of UO_2^{2+} utilized bifunctional acyclic polyaminocarboxylate chelators (DTPA and CHXDTPA). Not a single clone (out of approximately 2000 examined) produced an antibody with acceptable affinity and specificity for chelated ionic uranium (*29*).

One hypothesis to account for these observations is that the affinity of DTPA and CHXDTPA for uranyl ions was insufficient to maintain the intact chelated uranium complex for the period of time necessary to elicit an immune response to the chelated metal. To test this hypothesis, the binding affinity of various chelators for uranyl ions was determined by competitive uranyl binding experiments conducted in the presence of 2-(4-pyridylazo)resorcinol (PAR), a spectrophotometric complexiметric indicator for cationic metal ions (*30*, *31*), including UO_2^{2+}. Figure 2A shows representative absorbance spectra of PAR obtained in the absence and presence of different concentrations of UO_2^{2+}. As the concentration of UO_2^{2+} increased, the absorbance peak of the metal-free PAR at 410 nm decreased concomitantly as a new absorbance peak at 520 nm increased. These UO_2^{2+}-dependent changes in the absorbance spectrum of PAR were exploited to determine the equilibrium dissociation constant for the binding of UO_2^{2+} to the colorimetric chelator. Differences in the spectra were quantified as follows: for the interval from 340 to 453 nm, the area under the spectrum obtained in the presence of UO_2^{2+} was subtracted from the area under the spectrum obtained in the absence of UO_2^{2+}; for the interval from 455 to 640 nm, the area under the spectrum obtained in the absence of UO_2^{2+} was subtracted from that obtained in the presence of UO_2^{2+}; the values of the resulting two quantities were then combined to create the values represented on the ordinate of Figure 2B.

Figure 2B shows the dependence of the spectral changes extracted from the primary data in Figure 2A on the concentration of total uranyl ion. The *dashed lines* represent the theoretical curve anticipated for a 1:1 stoichiometric binding event with infinite affinity. The actual data points clearly conform to a model where PAR binds a single uranyl ion with relatively high affinity. The value of the equilibrium dissociation constant for the binding of UO_2^{2+} to PAR, K_{PAR-U}, was obtained from a nonlinear regression fit of quadratic equation 1 where [P] and [U] are the concentrations of total PAR and UO_2^{2+}, respectively. Equation 1 corresponds to a 1:1 homogeneous binding model where the binding event causes a significant depletion in the concentrations of both of the free, uncomplexed reagents. The value of K_{PAR-U} that provided the best fit of eq 1 to the data in Figure 2B was $4.0 \pm 0.3 \times 10^{-7}$ M.

The next experiment was to study the binding of UO_2^{2+} to a noncolorimetric chelator by quantifying the effects that the colorless chelator had on the interaction of UO_2^{2+} with the colorimetric chelator, PAR. When different concentrations of DTPA (a colorless chelator) were equilibrated with a preformed complex of PAR−UO_2^{2+}, uranyl ions transferred from the PAR to the DTPA, thus regenerating the metal-free form of the colored chelator (primary data not shown). Figure 2C shows the dependence of the spectral changes taken from these 3-component competition experiments on the concentration of total DTPA. The value of the equilibrium dissociation constant for the binding of UO_2^{2+} to DTPA, K_{DTPA-U}, was obtained from a nonlinear regression fit of quadratic equation 2 where [D] is the concentration of total DTPA. Equation 2 differs from eq 1 only in that the concentration of total uranyl ion is divided by the factor $(1 + [D]/K_{DTPA-U})$, which represents the influence of UO_2^{2+} complexation with DTPA on the concentration of

$$\text{fraction of PAR occupied with } UO_2^{2+} = \frac{([P] + [U] + K_{PAR-U}) - \{([P] + [U] + K_{PAR-U})^2 - 4[P][U]\}^{1/2}}{2} \quad (1)$$

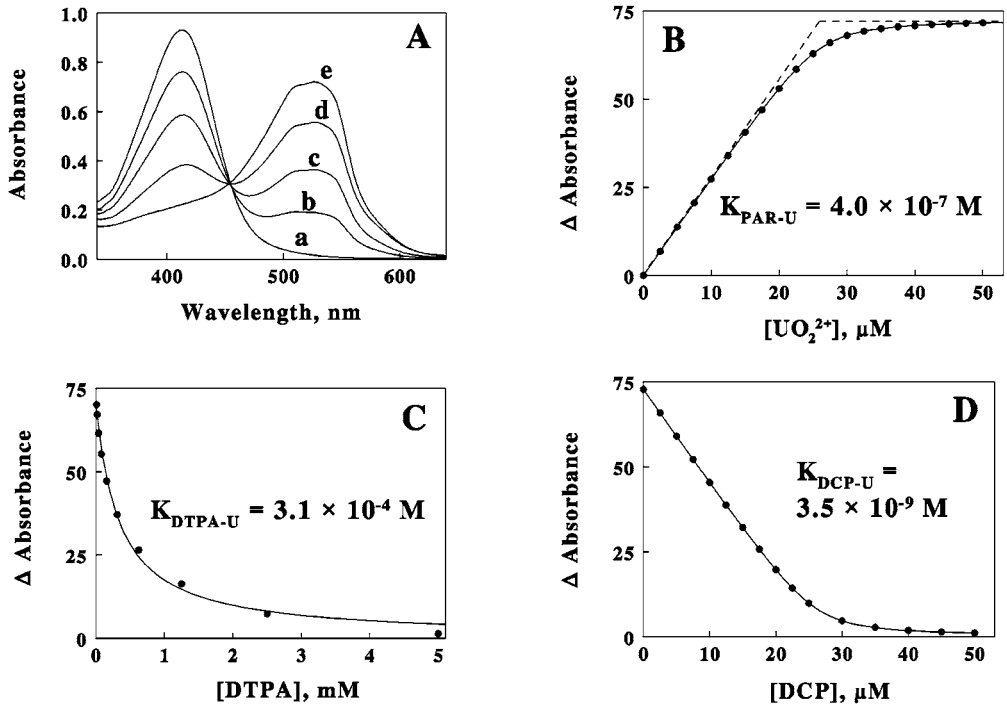

Figure 2. Determination of binding constants for uranyl ion to colorimetric and noncolorimetric chelators. A, visible absorbance spectra of 26 μM 4-(2-pyridazo)resorcinol (PAR) in the absence (a) and presence of 5.0 (b), 12.5 (c), 20 (d), and 50 (e) μM uranyl ion. B, dependence of the changes in the absorbance of 26 μM PAR as a function of the concentration of uranyl ion. The values of Δ absorbance were determined as the differences in the spectrum of the metal-free chelator versus the spectrum of the chelator observed in the presence of uranyl ions. C, dependence of the changes in the absorbance of the PAR−uranyl ion complex as a function of the concentration of DTPA. The concentrations of PAR and uranyl ion were 26 and 30 μM, respectively. The values of Δ absorbance were determined as the differences in the spectrum of the PAR−uranyl complex in the absence of DTPA versus the spectrum of the complex observed in the presence of DTPA. D, dependence of the changes in the absorbance of the PAR-uranyl ion complex as a function of the concentration of DCP. The conditions were the same as those described in C, except that DCP was substituted for DTPA. The parameters for the *curves* drawn through the data points in B, C, and D were determined by nonlinear regression analyses using eqs 1, 2, and 3, respectively, in the text.

Table 1. Equilibrium Dissociation Constants for Uranyl Ion with Selected Complexants

chelator[a]	equilibrium dissociation constant, M
PAR	$4.0 \pm 0.3 \times 10^{-7}$
DTPA	$3.1 \pm 0.2 \times 10^{-4}$
EDTA	$2.4 \pm 0.2 \times 10^{-4}$
CHXDTPA	$3.3 \pm 0.3 \times 10^{-4}$
DCP	$3.5 \pm 0.4 \times 10^{-9}$

[a] Abbreviations are as follows: PAR, 4-(2-pyridylazo)resorcinol; DTPA, diethylenetriaminepentaacetic acid; EDTA, ethylenediaminetetraacetic acid; CHXDTPA, *trans*-*N*-(2-aminoethyl)-1,2-diaminocyclohexane-*N*,*N*′,*N*″-pentaacetic acid; DCP, 2,9-dicarboxy-1,10-phenanthroline.

free UO_2^{2+} that is available to bind to the PAR. The value of K_{DTPA-U} that provided the best fit of eq 2 to the data in Figure 2C was $3.1 \pm 0.2 \times 10^{-4}$ M. Analogous competition experiments were conducted with two other colorless chelators, EDTA and CHXDTPA (primary data not shown). The values of the corresponding equilibrium dissociation constants for the binding of UO_2^{2+} to each of these chelators are summarized in Table 1. These competition experiments provided uranium complexation data consistent with the hypothesis that the low affinity of DTPA and CHXDTPA for UO_2^{2+} was the most probable origin of the failure to identify antibodies directed against the corresponding chelator−uranyl ion complexes.

Figure 2D shows the dependence of spectral changes taken from analogous competition experiments on the concentration of 2,9-dicarboxy-1,10-phenanthroline (DCP), an alternative colorless chelator examined as part of an effort to identify chelators that bound to UO_2^{2+} with higher affinities. Unlike DTPA, where millimolar concentrations of the colorless chelator were required to effectively compete with 26 μM PAR, concentrations of DCP stoichiometric with that of PAR were sufficient to remove UO_2^{2+} from its complex with the colored chelator. The value of the equilibrium dissociation constant for the binding of UO_2^{2+} to DCP, K_{DCP-U}, was obtained from a nonlinear regression fit of quadratic equation 3 where [DCP] is the concentration of total DCP. Equation 3 corresponds to a competition binding model where the

$$\text{fraction of PAR occupied with } UO_2^{2+} = \frac{([P] + [U]/(1+[D]/K_{DTPA-U}) + K_{PAR-U}) - \{([P] + [U]/(1+[D]/K_{DTPA-U}) + K_{PAR-U})^2 - 4[P][U]/(1+[D]/K_{DTPA-U})\}^{1/2}}{2} \quad (2)$$

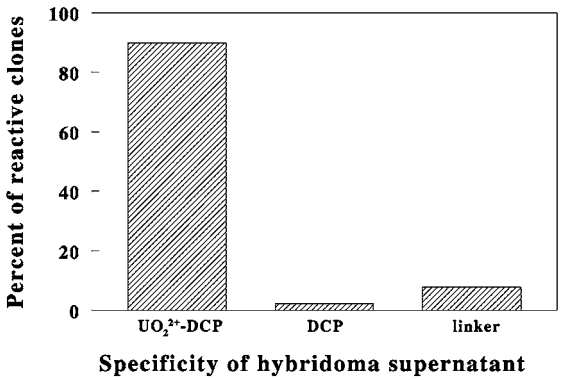
$$\text{fraction of PAR occupied with } UO_2^{2+} = \frac{(2K_{DCP-U}[P] + K_{PAR-U}[DCP] - K_{PAR-U}[P]) - \{(2K_{DCP-U}[P] + K_{PAR-U}[DCP] - K_{PAR-U}[P])^2 - 4(K_{DCP-U} - K_{PAR-U})K_{DCP-U}[P]^2\}^{1/2}}{2 \times (K_{DCP-U} - K_{PAR-U})} \quad (3)$$

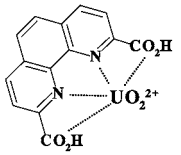
transfer of UO_2^{2+} from PAR to DCP causes significant changes in the concentrations of the metal-free forms of both chelators. Since the concentrations of both chelators were significantly higher than their respective dissociation constants for their binding with UO_2^{2+}, the concentration of free, uncomplexed UO_2^{2+} was assumed to be negligibly small. In addition, all of the PAR initially present in the absence of DCP was assumed to be coordinated with UO_2^{2+}. The value of K_{DCP-U} that provided the best fit of eq 3 to the data in Figure 2D was $3.5 \pm 0.4 \times 10^{-9}$ M. A summary of the equilibrium dissociation constants determined for these complexants at the pH and ionic strength dictated by the immunization protocol is provided in Table 1.

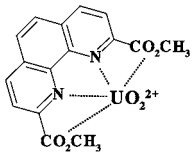
Hybridoma Production and Screening. Clearly, the DCP chelator was superior to EDTA, DTPA, or derivatives thereof in its ability to bind strongly to the UO_2^{2+} ion at the pH and ionic strength required by the immunization protocol. The UO_2^{2+}−DCP complex should therefore be better at eliciting a metal-specific immune response than the forms of chelated UO_2^{2+} previously employed as immunogens. However, this complex was not of sufficient size to generate an immune response, and the chelator needed to be covalently coupled to a carrier protein to be an effective immunogen. Bifunctional derivatives of DCP were not commercially available, and the synthesis of 5-isothiocyanato-1,10-phenanthroline-2,9-dicarboxylic acid from 2,9-dimethyl-1,10-phenanthroline was performed in four steps, as shown in Figure 1. The isothiocyanato derivative of DCP was subsequently coupled to a carrier protein and injected into mice. After a 4-week injection series, all the animals showed high serum titers of antibodies with the ability to bind immobilized UO_2^{2+}−DCP−BSA (data not shown). The animal with the highest titer was given an intraperitoneal boost of antigen, and its spleen was used 72 h later for the preparation of hybridoma cells.

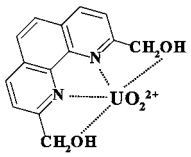
A novel culture procedure that utilized semisolid media (see Experimental Procedures) resulted in the isolation of 1146 individual hybridoma colonies from a single fusion. The culture supernatants from these hybridomas were initially screened for their ability to bind to UO_2^{2+}−DCP−BSA immobilized in 96-well plates, and 486 clones (42.4%) secreted antibodies with reactivity toward uranium-loaded DCP−BSA (defined as an $absorbance_{450\ nm} > 0.3$ in indirect ELISA). When these 486 supernatants were rescreened by competitive ELISA (shown in Figure 3), 89.9% of the reactive supernatants (437/486) or 36.8% (437/1186) of the total hybridomas generated in these experiments were inhibited by soluble UO_2^{2+}−DCP. Of the remaining 49 clones, 2.3% (11/486) were more strongly inhibited by metal-free DCP, and 7.8% (38/486) could not be inhibited by either metal-free DCP or UO_2^{2+}−DCP and were assumed to be directed toward the thioureido group that linked the chelator to the carrier protein.

Three of these clones, 8A11, 10A3, and 12F6, were chosen for further experiments because they had desirable growth characteristics, showed the least reactivity to metal-free DCP, and/or produced supernatants with high specific titers at limiting dilutions (data not shown). These hybridomas were subcloned by limiting dilution to confirm homogeneity. All three hybridomas secreted antibodies of the IgG1 subtype with a κ light chain. Production of antibody for subsequent characterization was performed either by culture as an ascites in pristine-primed BALB/c mice or by in vitro culture in a specialized tissue culture apparatus, followed by purification on protein G. Monoclonal antibodies prepared by these two









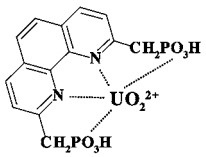


Figure 3. Specificity of antibodies synthesized by hybridomas. The 486 reactive hybridoma ($abs_{450nm} > 0.3$ when tested against immobilized BSA−DCP−UO_2^{2+}) were rescreened by competitive ELISA as described in Methods. Of the 486 supernatants examined in theses experiments, 437 (89.9%) of the hybridomas synthesized antibodies with a primary specificity for DCP−UO_2^{2+}, and 11 (2.2%) showed specificity for metal-free DCP. A small number (38, 7.8%) of the antibodies in hybridoma supernatants bound to immobilized BSA−DCP−UO_2^{2+} but not to immobilized BSA and could not be competitively inhibited by either DCP−UO_2^{2+} or DCP; these antibodies were assumed to be directed toward the linker region between the DCP and the carrier protein.

culture methods showed identical binding properties for metal-free DCP and UO_2^{2+}−DCP (data not shown).

Binding Specificity. The binding specificity of each of the three anti-uranium monoclonal antibodies was investigated by conducting equilibrium binding measurements on a KinExA 3000 immunoassay instrument. The KinExA is a flow fluorimeter designed to achieve the rapid separation and quantification of free, unbound antibody present in reaction mixtures of antibody, antigen, and antibody−antigen complexes; its operation has been described in detail elsewhere (*11*, *27*, *28*). The equilibrium binding data presented in Figure 4 demonstrate that each of the three anti-uranium antibodies bound to the DCP−UO_2^{2+} complex with much higher affinity than it bound to the metal-free DCP. The low affinity binding curves in each panel of Figure 4 were obtained with metal-free DCP, while the corresponding high affinity binding curves were obtained with different concentrations of DCP in the presence of a constant total concentration of UO_2^{2+} of 1.0 μM. Given the affinity of DCP for UO_2^{2+} as determined above, these solution conditions dictated that greater than 99.6% of the DCP was present as the 1:1 complex with UO_2^{2+}; control experiments indicated that 1.0 μM UO_2^{2+} alone did not inhibit the binding of any of the antibodies to the immobilized antigen. In all cases in Figure 4, the value of the equilibrium dissociation constant, K_d, for the binding of the antibody to the soluble ligand was obtained as previously described (*11*, *27*, *28*). Values for the dissociation constants thus obtained are given in Table 2. Antibody 12F6 had the highest affinities for both the metal-free DCP and the DCP−UO_2^{2+} complex; antibody 8A11 had the lowest affinities for the same ligands. Antibody 10A3 showed the highest level of discrimination between the metal-free DCP and the DCP−UO_2^{2+} complex; the difference in Gibbs free energy between the binding of DCP−UO_2^{2+} and metal-free DCP to 10A3 was −4.2 kcal/mol. However, the least discriminatory antibody, 8A11, still exhibited a corresponding difference in Gibbs free energy of −3.9 kcal/mol between its affinity for DCP−UO_2^{2+} versus that for the metal-free chelator.

Each of the three anti-uranium antibodies exhibited appreciable affinity for other chelators that bore a close

Table 2. Equilibrium Dissociation Constants for the Binding of Selected Phenanthroline Derivatives in the Presence and Absence of Uranyl Ion to Monoclonal Antibodies 12F6, 10A3, and 8A11

	Value of K_d, M		
Chelator complex	**12F6**	**10A3**	**8A11**
DCP-UO_2^{2+} 	$9.1 \pm 0.7 \times 10^{-10}$	$2.4 \pm 0.2 \times 10^{-9}$	$5.5 \pm 0.2 \times 10^{-9}$
DME-UO_2^{2+} 	$2.5 \pm 0.1 \times 10^{-9}$	$7.6 \pm 0.2 \times 10^{-9}$	$1.2 \pm 0.1 \times 10^{-8}$
DHM-UO_2^{2+} 	$7.5 \pm 0.4 \times 10^{-9}$	$3.3 \pm 0.1 \times 10^{-7}$	$8.6 \pm 0.3 \times 10^{-8}$
DPP-UO_2^{2+} 	$4.5 \pm 0.3 \times 10^{-6}$	$6.3 \pm 0.2 \times 10^{-6}$	$8.7 \pm 0.6 \times 10^{-6}$
DCP, metal free	$7.5 \pm 0.5 \times 10^{-7}$	$2.8 \pm 0.1 \times 10^{-6}$	$3.7 \pm 0.2 \times 10^{-6}$
DME, metal free	$8.7 \pm 0.6 \times 10^{-7}$	$3.4 \pm 0.3 \times 10^{-6}$	$4.4 \pm 0.2 \times 10^{-6}$
DHM, metal free	$1.9 \pm 0.2 \times 10^{-5}$	$5.1 \pm 0.4 \times 10^{-5}$	$6.7 \pm 0.3 \times 10^{-5}$

structural resemblance to DCP. Table 2 contains values of the equilibrium dissociation constants for the binding of each antibody to the dimethyl ester of DCP in the presence and absence of excess UO_2^{2+}. In general, esterification of the two carboxyl groups on DCP had only a small (<2- to 3-fold) negative influence on the measured affinity of each antibody, regardless of whether UO_2^{2+} was absent or present. Table 2 also contains values of the equilibrium dissociation constants of the binding of each antibody to a derivative of DCP where the two carboxyl groups were replaced with two hydroxymethyl groups. The affinities of 12F6 and 8A11 for the DHM−UO_2^{2+} complex were moderately lower than those for the corresponding DCP−UO_2^{2+} complex (8- and 16-fold, respectively), while the affinity of 10A3 for DHM−UO_2^{2+} was over 120-fold lower than that for DCP−UO_2^{2+}. All three antibodies bound to the metal-free DHM with significantly lower affinities than they did to the metal-free forms of DCP or DME. Finally, Table 2 contains values of the equilibrium dissociation constants for the binding of each antibody to a derivative of DCP where the two carboxyl groups were replaced with two methylphosphonate groups. This substitution lowered the affinity of each antibody for the DPP−UO_2^{2+} complex by roughly 3 orders of magnitude compared with those observed with the corresponding DCP complex. Binding of the metal-free form of DPP to each of the three antibodies was not detected. Similarly, none of the three antibodies showed detectable affinity for unsubstituted 1,10-phenanthroline, the 2,9-dimethyl derivative (neocuproine), or 2,9-ditrichloromethyl-substituted 1,10-phenanthroline, either in the absence or presence of excess UO_2^{2+} (data not shown). In general, all of the antibodies exhibited negligible affinity for other types of metal chelators such as EDTA, DTPA, and CHXEDTA, regardless of whether excess UO_2^{2+} was present or absent. The one exception to this generalization was 12F6, which bound to PAR in the absence and presence of UO_2^{2+} with equilibrium dissociation constants of 1.1×10^{-6} M and 8.7×10^{-7} M, respectively (primary data not shown). Binding of PAR or PAR−UO_2^{2+} to either 10A3 or 8A11 was not detected.

All three antibodies displayed a high degree of specificity for UO_2^{2+} in the DCP−metal ion complex. The data in Table 3 summarize the binding properties of each antibody to DCP−metal complexes that contained metal ions other than UO_2^{2+}. The limiting reagent in each assay was DCP, which was held at a fixed concentration of 2.0 μM; in all cases the concentration of the individual metal ion exceeded 2.0 μM. Thus each response in Table 3 represents a range over which the 2.0 μM DCP−metal complex appeared to inhibit the binding of the soluble

Table 3. Metal Ion Specificity of Monoclonal Antibodies 8A11, 10A3, and 12F6[a]

metal ion	12F6	10A3	8A11
Hg(II)	+	−	−
Ti(III)	−	−	+
Au(III)	−	+	+
Cu(II)	++	++	++
Al(III)	+	−	−
Mo(VI)	+	−	−

[a] Individual KinExA assays were conducted with each antibody amended with 1.0 μg/mL of each metal ion in the presence and absence of 2.0 μM DCP. A '−' response indicates that the assays in the presence and absence of DCP were within ± 5% of each other; a single '+" response indicates that the assays in the presence of DCP were inhibited from 5 to 15% of the assays in the absence of DCP; a double '++' response indicates that the assays in the presence of DCP were inhibited from 15 to 25% of assays in the absence of DCP. For the following metal-DCP complexes, the assays in the presence and absence of metal were within + 5% of each other for all three monoclonal antibodies: Ca(II), Mg(II), Mn(II), Cd(II), Pb(II), Sr(II), Fe(III), Co(II), In(III), Ag(I), Ni(II), Y(III), Pr(III), Er(III), and Zn(II).

antibody to the immobilized DCP−UO_2^{2+} complex in the KinExA instrument. Cupric ion was the only metal ion that weakly inhibited all three antibodies when it was presented in a complex with DCP. The apparent equilibrium dissociation constant for the binding of each antibody to the DCP−Cu(II) complex fell in the range of 6 to 11 μM, greater than 3 orders of magnitude lower affinity than the comparable binding to DCP−UO_2^{2+}. A similar calculation for those responses in Table 3 represented by a single positive sign indicates that those DCP−metal complexes bound to their respective antibodies with a range of calculated K_d values from 11 to 38 μM.

Interference from Bovine Serum Albumin. Preliminary studies to characterize the equilibrium binding properties of the three anti-uranium antibodies provided clear evidence that BSA interfered with the binding interaction between the antibody and the DCP−UO_2^{2+} complex. When different concentrations of BSA were added to antibody−antigen reaction mixtures to minimize the binding of dilute antibodies to surfaces, demonstrably different results were obtained for the binding of DCP or its UO_2^{2+} complex to the antibody. Examples of the effects of BSA on the binding of the DCP−UO_2^{2+} complex to antibodies 12F6 and 8A11 are shown in Figure 5A and B, respectively. Figure 5A shows the decrease in the fraction of occupied binding sites on 12F6 as a function of BSA concentration at a constant concentration of DCP−UO_2^{2+}, while Figure 5B shows the results of the same experiment using antibody 8A11. In both cases the data were consistent with the hypothesis that BSA could bind the DCP−UO_2^{2+} and compete with the antibody for the chelator−metal complex. The values of the apparent equilibrium inhibition constants for the competitive, BSA-dependent loss of DCP−UO_2^{2+} from the antibody−DCP−UO_2^{2+} complex, K_{app}, were obtained from nonlinear regression fits of the following empirical equation to the data in Figures 5A and 5B:

$$\varphi = \left(\frac{[\text{DCP}-\text{U}]}{[\text{DCP}-\text{U}] + K_{\text{DCP}-\text{U}}}\right)\left(1 - \frac{[\text{B}]}{[\text{B}] + K_{\text{app}}}\right) \quad (4)$$

where φ is the fraction of antibody binding sites that are occupied with the soluble antigen DCP−U, [B] and [DCP−U] are the total concentrations of BSA and the DCP−UO_2^{2+} complex, respectively, and $K_{\text{DCP}-\text{U}}$ is the equilibrium dissociation constant for the binding of the

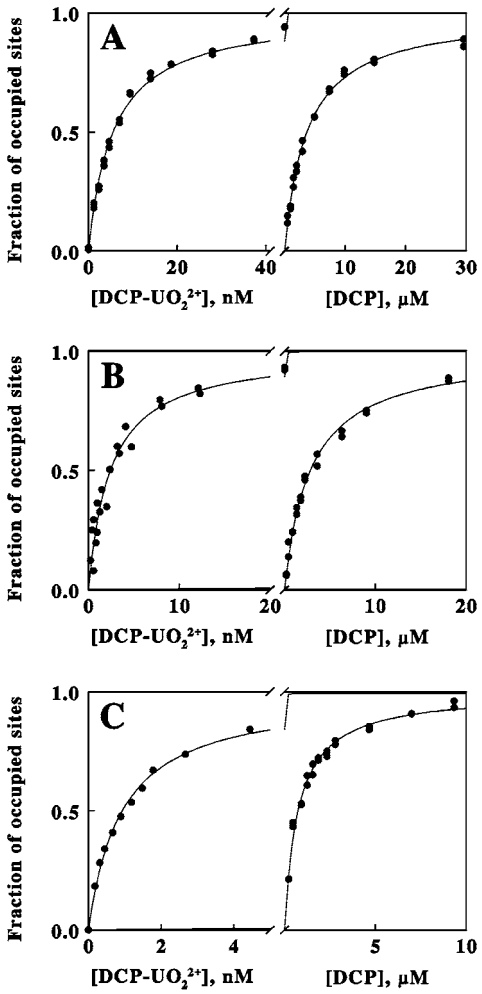

Figure 4. Equilibrium data for the binding of 2,9-dicarboxy-1,10-phenanthroline (DCP) in the presence and absence of uranyl ion to monoclonal antibodies 8A11 (A), 10A3(B), and 12F6 (C). The concentrations of occupied antibody binding sites, determined from kinetic exclusion assays as described in the text, were expressed as a fraction of the concentration of total antibody binding sites and plotted versus the concentration of the total soluble antigen in the mixture. The parameters for the *curves* drawn through the data points were determined by nonlinear regression analyses as described in refs 11, 27, 28.

DCP−UO_2^{2+} complex to the antibody. The values of K_{app} thus obtained are given in the figures.

It was evident that the value of K_{app} was a complex function of the concentration of the total DCP−UO_2^{2+} and the equilibrium dissociation constant of the individual antibody. Using simple one-site homogeneous binding models for the interactions of DCP−UO_2^{2+} with both the antibody and with BSA, the following equation was obtained:

$$[\text{B}]\,\varphi = K_{\text{BSA}-\text{DCP}-\text{U}}\left(1 + \frac{[\text{DCP}-\text{U}]}{K_{\text{DCP}-\text{U}}}\right)(1 - \varphi) - 1 \quad (5)$$

where $K_{\text{BSA}-\text{DCP}-\text{U}}$ is the equilibrium dissociation constant for the binding of the DCP−UO_2^{2+} complex with BSA. The additional assumptions employed in obtaining eq 5 were that (i) the concentration of the antibody−DCP−UO_2^{2+} complex was much less the total concentration of DCP−UO_2^{2+} and (ii) the total concentration of the BSA−DCP−UO_2^{2+} complex was much less than that of the total BSA. Both assumptions were valid under the conditions of the experiments presented in Figures 5A and 5B (see

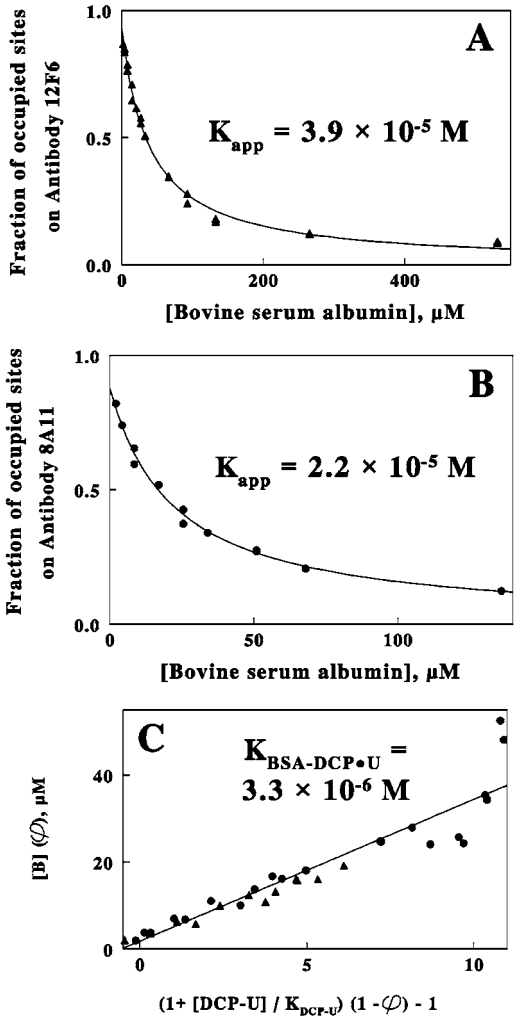

Figure 5. Equilibrium data for the binding of the DCP−uranyl ion complex to BSA. A and B, the fraction of binding sites occupied with the DCP−UO_2^{2+} complex on antibodies 12F6 and 8A11, respectively, as a function of the concentration of BSA. The concentration of DCP−UO_2^{2+} was 11 and 40 nM in A and B, respectively. The parameters for the *curves* drawn through the data points in both panels were determined by nonlinear regression analyses using eq 4 in the text. *C*, a linear plot, according to eq 5 in the text, of the data replotted from *A* and *B*. The *closed circles* and *triangles* represent binding data obtained with antibodies 8A11 and 12F6, respectively. The values of [B], [DCP−U], K_{DCP-U}, and φ were taken from the data in the respective figures. The line drawn through the data points was determined by a linear regression analysis; the value of the slope yielded the value of the equilibrium dissociation constant for the BSA−DCP−UO_2^{2+} complex.

legend to Figure 5). Figure 5C shows a linear plot according to eq 5 of the combined data taken from Figures 5A and 5B. Even though the two sets of data were obtained with different antibodies and a different set concentration of total DCP−UO_2^{2+}, the replotted data in Figure 5*C* appeared to describe a straight line that passed through the origin of the graph. A value of 3.3 × 10^{-6} M was obtained for the equilibrium dissociation constant for the binding of DCP−UO_2^{2+} to BSA from a linear regression fit of eq 6 to the data in Figure 5C. Analogous experiments and analyses were conducted with antibodies 8A11, 12F6, and metal-free DCP (data not shown). The equilibrium dissociation constant for the binding of metal-free DCP to BSA was determined to be 2.9 × 10^{-6} M.

Kinetic Rate Constants. The object of these experiments was to determine values for the kinetic rate

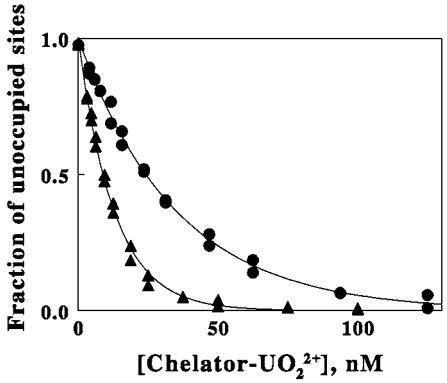

Figure 6. Determination of association rate constants for the bimolecular combination of DCP−UO_2^{2+} (circles) and DME−UO_2^{2+} (triangles) with the 10A3 monoclonal antibody. Antibody (1.5 nM in binding sites) and the chelated uranium complex were incubated for 7 s before separation of the antibody into occupied and unoccupied fractions. The value of the bimolecular association rate constant for each reaction was obtained from a nonlinear regression fit of the data in each curve to the single-exponential function of ligand concentration given by eq 6 in the text. Each determination was performed in duplicate; in some cases the error in the data was less than the diameter of the plotted points.

constants for the binding of those chelator−uranyl ion complexes (DCP−UO_2^{2+} and DME−UO_2^{2+}) that exhibited the greatest affinity for each of the three anti-uranium antibodies. Accordingly, kinetic exclusion assays were conducted to separate and quantify the unoccupied antibody binding sites that remained in reaction mixtures that were far from equilibrium, as has been previously described (*11*, *27*, *28*). Figure 6 shows the dependence of the fraction of unoccupied binding sites that remained on antibody 10A3 at 7 s after mixing on the concentration of either DCP−UO_2^{2+} or DME−UO_2^{2+}. The value of the association rate constant, k_1, for the bimolecular binding of 10A3 with each chelated uranium complex was obtained from a nonlinear regression fit of the kinetic data to the following single-exponential function of ligand concentration:

$$[A] = [A]_0 e^{-k_1[L]t} \quad (6)$$

where [A] is the concentration of unoccupied antibody binding sites at ligand concentration [L], $[A]_0$ is the total concentration of antibody binding sites when no ligand is present, and t is 7 s. Equation 6 represents the time- and ligand concentration-dependent progress of a binding reaction conducted under pseudo first-order conditions where the value of the unimolecular rate constant, k_2, for the dissociation of the antibody−antigen complex is negligible compared with the value of the k_1[L] multiplicand. Values for k_1 of 1.1 × 10^7 M^{-1} s^{-1} and 4.1 × 10^6 M^{-1} s^{-1} were obtained from the data in Figure 6 for the bimolecular association rate constants for the binding of DCP−UO_2^{2+} and DME−UO_2^{2+}, respectively, with antibody 10A3. Analogous kinetic experiments were conducted with antibodies 8A11 and 12F6, and the values of all of the bimolecular association rate constants thus obtained are summarized in Table 4. Table 4 also contains the values of the corresponding unimolecular dissociation rate constants for each reversible binding reaction calculated from the identity $K_d = k_2/k_1$.

A comparison of the kinetic and equilibrium binding data in Tables 2 and 4, respectively, indicated that the differences in equilibrium affinity between the binding of DCP−UO_2^{2+} and DME−UO_2^{2+} to either 8A11 or 10A3

Table 4. Individual Kinetic Rate Constants for the Binding of Chelated Uranyl Ion to Monoclonal Antibodies 8A11, 10A3, and 12F6

antibody	chelator−uranium complex	bimolecular association rate constant, $M^{-1}\ s^{-1}$	unimolecular dissociation rate constant, s^{-1}
8A11	DCP−UO_2^{2+}	$1.9 \pm 0.1 \times 10^7$	$1.0 \pm 0.1 \times 10^{-1}$
8A11	DME−UO_2^{2+}	$6.8 \pm 0.2 \times 10^6$	$8.2 \pm 0.1 \times 10^{-2}$
10A3	DCP−UO_2^{2+}	$1.1 \pm 0.1 \times 10^7$	$2.6 \pm 0.2 \times 10^{-2}$
10A3	DME−UO_2^{2+}	$4.1 \pm 0.1 \times 10^6$	$3.1 \pm 0.2 \times 10^{-2}$
12F6	DCP−UO_2^{2+}	$2.0 \pm 0.1 \times 10^7$	$1.8 \pm 0.2 \times 10^{-2}$
12F6	DME−UO_2^{2+}	$3.0 \pm 0.2 \times 10^7$	$7.5 \pm 0.4 \times 10^{-2}$

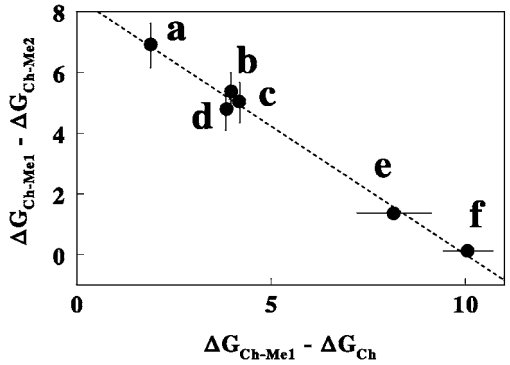

Figure 7. Relationship between metal ion specificity and the relative affinity for metal-free chelator exhibited by six anti-metal monoclonal antibodies. Free energies of binding to antibody: ΔG_{Ch}, chelator in the absence of metal ions; ΔG_{Ch-Me1}, complex of chelator and the metal ion that was used to select the corresponding clone; ΔG_{Ch-Me2}, complex of chelator and the alternative metal ion that elicited the next highest affinity in comparison with the primary metal ion in its interaction with the antibody. Antibody and primary chelator−metal specificity: a, 2C12 and CHXDTPA-Pb(II); b, 12F6 and DCP−U(VI); c, 10A3 and DCP−U(VI); d, 8A11 and DCP−U(VI); e, 15B4 and DTPA-Zn(II); and f, 2A81G5 and EDTA-Cd(II). The *solid lines* represent conservative error estimates; the *dashed line* was generated from a linear regression analysis.

were primarily due to differences in the respective bimolecular association rate constants to form the complex, while the difference observed in the affinity of the two ligands binding to 12F6 was due primarily to a difference in the unimolecular rate constant for the dissociation of the complex. The former observations obtained with 10A3 and 8A11 are inconsistent with the generalization that the value of the equilibrium dissociation constant for an antibody is primarily dependent on the value of the rate constant for the unimolecular dissociation of the antibody−antigen complex; that is, that the bimolecular association of free antibody and antigen to form a complex is close to diffusion controlled and that the corresponding bimolecular rate constant does not vary much from antigen to antigen for the same antibody.

DISCUSSION

With the addition of the three anti-uranium antibodies described herein, our laboratories have now conducted detailed equilibrium binding studies on the affinity and specificity of eight different anti-metal monoclonal antibodies (*11*−*16*). The principal metal ions recognized by these antibodies include Pb(II), U(VI), Zn(II), and Cd(II), while the corresponding chelators are comprised of CHXDTPA, DCP, DTPA, and EDTA, respectively. Despite the diversity in the molecular and ionic properties of these individual chelators and metal ions, the structure−function activity relationship presented in Figure 7 was constructed from the binding data obtained with six of these antibodies. The *abscissa* in Figure 7 represents the difference in free energy between the binding of the antibody to the chelator−metal ion complex that was used to elicit the corresponding clone and the binding of the antibody to the metal-free chelator. A large numerical value on the abscissa signifies that the affinity of the antibody for the metal-free chelator was many orders of magnitude less than that observed for the corresponding complex of chelator and principal metal ion. A small numerical value signifies that the affinity of the antibody for the metal-free chelator was much closer to that observed for the corresponding complex of chelator and principal metal ion. The *ordinate* in Figure 7 represents the difference in free energy between the binding of the antibody to the chelated metal ion that was used to elicit the clone and the binding to the chelated metal ion that exhibited the next highest affinity compared to that of the principal metal ion in its interaction with the antibody. Thus a large numerical value on the ordinate signifies a high degree of metal ion specificity, while a small value signifies a low degree of metal ion specificity. It is evident from the linear relationship in Figure 7 that those antibodies that exhibited the greatest specificities for particular metal ions also exhibited the least differences in their affinities for metal-loaded versus metal-free chelator and vice versa.

For those antibodies that show a relatively high affinity for the metal-free chelator (such as 2C12 binding to CHXEDTA, datum *a* in Figure 7), one hypothesis is that the majority of the amino acid residues that comprise the antigen binding site are devoted to complementing the structure of the chelator itself, regardless of whether a metal ion is coordinated by the chelator. Since the majority of the free energy for binding the chelator−metal complex appears to be dependent on the identity of the chelator and not on the presence of the metal ion, one might reasonably expect such an antibody to show a relatively lower degree of specificity for the metal ion in question. This is certainly not the case with 2C12 and the three anti-uranium antibodies described herein. One means whereby an antibody could provide a high degree of specificity for a particular metal ion could be direct ligation of the metal ion using appropriately positioned amino acid side chains in the antigen binding site. Previous investigations have clearly indicated a role for histidine residues in the binding of aminobenzyl-EDTA−In(III) and EDTA−Cd(II) to their respective monoclonal antibodies (*17*, *19*). In the former case, substitution of a histidine residue at the antigen binding site with leucine dramatically weakened the binding of chelated Cd(II) to the antibody. In the latter case, X-ray crystallographic studies revealed that a histidine residue served as the sixth coordination ligand for chelated In(III), but was prohibited on steric grounds from similarly coordinating with chelated Fe(III). Perhaps there are similar direct ligation reactions that occur at the antigen binding sites of antibodies 8A11, 10A3, and 12F6.

For those antibodies that show a relatively low affinity for the metal-free chelator (such as 2A81G5 binding to

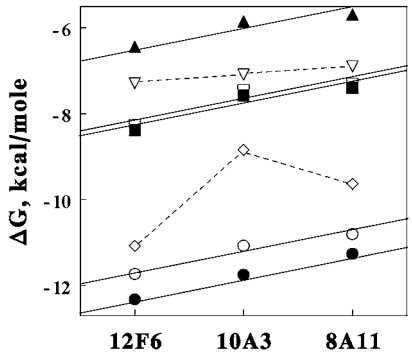

Figure 8. Evidence that the antigen binding sites of antibodies 12F6, 10A3, and 8A11 share common features for the binding of selected ligands. The free energy of dissociation was plotted for all combinations of antibodies and soluble ligands studied herein. Each anti-uranium antibody was assigned an arbitrary position on the abscissa to facilitate a comparison of the curves. Ligands: DCP−UO_2^{2+}, *closed circles*; DME−UO_2^{2+}, *open circles*; DHM-UO_2^{2+}, *open diamonds*; metal-free DCP, *solid squares*; metal-free DME, *open squares*; DPP−UO_2^{2+}, *open triangles*; and metal-free DHM, *open triangles*. The five *solid lines* have identical slopes that represent the average value of the five slopes that were determined individually for each respective ligand. The two *dashed lines* simply connect the data points that were obtained with the other two ligands.

EDTA, datum *f* in Figure 7), one hypothesis is that the majority of the amino acid residues that comprise the antigen binding site are devoted to complementing the complex of the chelator with the metal ion, not the chelator itself. Previous modeling studies have revealed that the only discernible differences among individual EDTA−metal complexes are the subtle ways in which the arms of the chelator encircle the metal ion (*15*). Given that the distance differences between any two analogous atoms in the structures of the antigens are less than 0.6 Å, it is extraordinary that an antibody can actually distinguish among individual complexes of EDTA and different metal ions. It is likely that the metal ion specificity that is achieved by antibodies such as 2A81G5 is due to the sum of many small, additive effects that are achieved by an antigen binding site that must encompass and complement the overall structure of the chelator−metal ion complex.

A second interesting linear free energy relationship was obtained from the equilibrium dissociation data presented in Table 2. The corresponding free energy for dissociation was calculated for each equilibrium dissociation constant in Table 2. These 21 free energy values were then plotted in three vertical columns corresponding to the three anti-uranium antibodies, as illustrated in Figure 8. Each vertical column was placed at an arbitrary position on the abscissa to facilitate the comparison of the data. The relative affinities of the three antibodies for DCP, DCP−UO_2^{2+}, DME, DME−UO_2^{2+}, and DHM−UO_2^{2+} appeared to follow the same pattern of reactivity. That is, antibody 12F6 appeared to bind each of these five antigens with 0.69 ± 0.12 and 0.94 ± 0.11 kcal/mol greater free energies than did antibodies 10A3 and 8A11, respectively. This pattern of behavior is represented in Figure 8 using five parallel solid lines to link the corresponding 15 values of the free energies. It is tempting to hypothesize that each of these five antigens presents approximately the same general conformation in solution, a conformation that is complemented by the antigen binding sites of antibodies 12F6, 10A3, and 8A11 in the same relative manner regardless of the identity of the antigen. In contrast, the values of the free energies for the dissociation of DHM and DPP−UO_2^{2+} from the three antibodies did not follow the same pattern as that observed for each of the other five antigens. Perhaps DHM and DPP−UO_2^{2+} assume general conformations in solution that are different from that hypothesized for the other five antigens, and the antigen binding sites of the three antibodies complement these different antigen conformations in ways that are unique to each antibody. It would be of interest to obtain molecular models of these chelators both in their metal-free forms and chelated with UO_2^{2+} to test these hypotheses regarding the solution conformations of the antigens.

In terms of the eventual application of any of these anti-uranium antibodies to create one or more accurate, sensitive immunoassays for soluble UO_2^{2+}, it is evident that the affinity, metal-ion specificity, and rate of complex formation exhibited by each antibody under the solution conditions of the assay are all crucial parameters in determining the performance characteristics of the assay, regardless of the assay format. Probably the most productive approach for future assay development activities is that each antibody must be analyzed on the assumption that it will exhibit at least some unique feature in its kinetic or equilibrium behavior. Detailed comparisons among the anti-uranium antibodies that appear to express different equilibrium and kinetic behavior may provide the opportunity to deduce the advantages and disadvantages of each for individual assay formats or platforms.

Elemental Analyses. Elemental analyses were performed by Atlantic Microlab, Inc., Norcross, Ga. Elemental analysis for the dialdehyde was as follows: $C_{14}H_7N_3O_4$; C calcd 59.79, found 59.58; H calcd 2.51, found 2.66; N calcd 14.94 found 14.67. Elemental analysis for the diacid (calculated as the hemihydrate) was as follows: $C_{14}H_7N_3O_6 \cdot {}^1/_2H_2O$; C calcd 52.18, found 52.42; H calcd 2.50, found 2.46; N calcd 13.04, found 13.09. Both were within the 0.3% limit.

A Conjugate of a Tumor-Targeting Ligand and a T Cell Costimulatory Antibody To Treat Brain Tumors

Ute Gawlick,[†] David M. Kranz,[‡] Victor D. Schepkin,[§] and Edward J. Roy*[,†]

Neuroscience Program and Department of Biochemistry, University of Illinois, Urbana, Illinois 61801, and Center for Molecular Imaging, University of Michigan, Ann Arbor, Michigan 48109. Received April 9, 2004; Revised Manuscript Received July 22, 2004

T cell immunotherapy is a potential strategy for the treatment of brain tumors because it offers a high degree of specificity, the ability to extravasate into solid tumors, and the potential for eliciting a long-term protective immune response. Various approaches have been developed to overcome T cell immune tolerance to cancer, including the use of cytokines and bispecific antibodies. T cell stimulation with the proinflammatory cytokine IL-12 can elicit antitumor immunity. T cell activation can be increased using bispecific antibodies against activating molecules on the surface of T cells and a tumor antigen. We studied the effects of systemic IL-12 administration in combination with a conjugate of an anti-CD28 antibody and a ligand for the folate receptor. The high affinity folate receptor is expressed on endogenously arising choroid plexus tumors of SV11 mice, which are transgenic for large T antigen under the control of the SV40 promoter. SV11 mice are immunocompetent, yet immunologically tolerant to large T antigen expressed by choroid plexus tumors. MRI analysis showed that the administration of IL-12 and anti-CD28 Fab/folate significantly slowed tumor growth. Proliferating $CD8^+$ T cells were found in choroid plexus tumors of treated animals. Treatment of animals with IL-12 + anti-CD28 Fab/folate prolonged survival compared to IL-12 alone. Cytokine treatment combined with tumor-targeted costimulation may be a useful adjunct treatment.

INTRODUCTION

One goal of immunotherapy against cancer is to induce a response that will lead to cytotoxic T lymphocytes (CTLs) with specificity for the tumor. A major obstacle in the activation of antitumor T cells is the process involving self-tolerance to tumor epitopes, a consequence of several processes, including clonal deletion of higher affinity self-reactive T cells during thymic development and exposure to antigens in a noninflammatory context. T cell activation and proliferation usually requires at least two signals: one in the form of the interaction of the peptide/major histocompatibility complex (pepMHC) on the antigen-presenting cell with the T cell antigen receptor (TCR) on the T cell, the other the engagement of the costimulatory receptor CD28 on the T cell with its ligand B7 (*1*, *2*). Increasing evidence suggests that the dependence of CTL activation on CD28 costimulation is related to surface levels of the pepMHC antigen, affinity of the TCR:pepMHC interaction, and duration of the cell to cell interaction (*3*−*5*). Immunogenic tumors may elicit a T cell response to a viral peptide presented by class I MHC or to an antigen expressed at higher levels that are sufficient to overcome self-tolerance (*6*). In some cases, where there is a higher affinity TCR (e.g. with K_D values below 1 μM), tumors can be eradicated in the apparent absence of ligation of CD28 (*7*). In other cases, nonimmunogenic tumors can stimulate a CTL response when they are transfected with B7, the ligand for CD28 (*8*). Hence, strengthening the CD28 signal would be expected to increase activation of CTLs, particularly those with lower affinity TCRs. The approach described here is to strengthen the activating signals received by T cells by targeting a costimulatory receptor with an antibody conjugated to a tumor-selective ligand.

In addition to CD28 costimulation, IL-12 has emerged as a third signal for CTL activation and a potent cancer therapeutic (*9*). IL-12 is a proinflammatory cytokine that can reverse antigen specific tolerance by affecting signaling through B7 expressed by antigen presenting cells (*10*). Exogenous IL-12 has been demonstrated to be effective in mice for the elimination of P815 tumors in DBA/2 mice (*11*). Furthermore, the coadministration of soluble IL-12 with peptide pulsed dendritic cells induced peptide specific CTLs and protection in mice challenged with P815 tumor cells (*12*). Tumor cell lines that are otherwise nonimmunogenic were rejected when transfected with the IL-12 gene (*13*).

To combine the effects of IL-12 and stimulation through CD28 in the generation of an antitumor CTL response, the costimulatory signals should be linked to the recognition of tumor antigens by the TCR. The high affinity folate receptor (FR) (K_D = 1 nM) has been used as a target because it is expressed at high levels on several types of cancer. Although the low affinity folate binding protein (K_D = 1−100 μM) is widely expressed on normal tissues, the high-affinity folate receptor is more selectively expressed on normal tissues and tumors. FR is expressed on over 90% of ovarian carcinomas, choroid plexus tumors, and ependymomas (*14*, *15*). In the present studies, folate was conjugated to an anti-CD28 antibody in order to link signaling through CD28 to the engagement of tumor cells. In this approach, activaton of the T cell would require recognition by the TCR of pepMHC antigens expressed by the same tumor cell.

FR is expressed on human choroid plexus tumors and ependymomas, and it is expressed in murine tumors of a similar origin. SV11 mice are transgenic for large T antigen (Tag) of simian virus 40 (SV40) on a C57BL/6 background (*16*−*18*). With the large T antigen (Tag) gene under the SV40 promoter, these mice develop endogenous choroid plexus tumors, with some level of Tag expression in the thymus. Tag of SV40 is processed into several specific peptides that are presented by class I MHC and these pepMHC antigens can activate CTLs (*19*). In the mouse, Tag has been shown to contain four peptide epitopes that serve as targets for CTLs that interact with the $H2^b$ MHCs that are found in C57BL/6 mice and SV11 mice (*20*). Epitope V is immunorecessive while epitopes I, II/III, and IV are immunodominant. Tolerance to Tag epitopes in SV11 mice has been demonstrated by the failure of CTL to develop after immunization with Tag transformed cells or Tag expressed by a recombinant vaccinia virus (rVV) (*21*). In SV11 mice receiving adoptively transferred C57BL/6 splenocytes, epitope IV specific CTLs are implicated as the chief mediators of immunity against Tag-expressing choroid plexus tumors (*21*). SV11 mice are tolerant to Tag epitopes, either due to deletion of T cells in the thymus or a mechanism of peripheral tolerance following high levels of expression of Tag in tumors (*22*). Nevertheless, a population of low avidity T cells specific for epitope V of the T antigen does exist in SV11 mice and can be expanded ex vivo by stimulating splenocytes with cells that express large T antigen (*23*).

In an attempt to stimulate a T cell response against endogenous choroid plexus tumors in SV11 mice, we treated mice with a combination therapy of systemic IL-12 and anti-CD28/Folate bispecific conjugate. We found that anti-CD28 Fab/Folate treatment synergizes with systemic IL-12 to increase survival of choroid plexus tumor bearing animals. MRI analysis revealed that the treatment strongly inhibited tumor growth over a 21 day period. Flow cytometry and immunohistochemistry of the tumor revealed activated T cells consistent with a role of CTLs in the therapeutic immune response.

MATERIALS AND METHODS

Mice. SV11 heterozygous mice transgenic for SV40 large T antigen (obtained from Dr. T. A. Van Dyke, University of North Carolina, Chapel Hill, NC) were mated with C57BL/6 females (obtained from Jackson Laboratory, Bar Harbor, ME). Genotyping was done as previously described using PCR for large T antigen gene (*24*). Seven days prior to experiments, animals were placed on folate free chow in order to reduce competition of endogenous folate with the anti-CD28 Fab/Folate. RAG/TCR mice are RAG-1 knockout mice transgenic for 2C T cell (*7*). Animals were housed in animal facilities at the University of Illinois, and all studies were approved by the Institutional Animal Care and Use Committee.

Reagents and Cells. PV-1 hybridoma was obtained from Dr. Jeff Bluestone (University of California, San Francisco). Recombinant murine IL-12 was obtained from Dr. Stan Wolf (Genetics Institute, Cambridge, MA). *N*-α-Pteroyl-*N*-ε-(4′-fluoresceinthiocarbamoyl)-L-lysine (PLF) purchased from T. P. McAlinden (*25*). PV-1 IgG was biotinylated at a concentration of 1 mg/mL using biotinamidocaproate *N*-hydroxysuccinimide ester following standard procedures. Anti-TCR Fab/Folate was made in our laboratory as previously described (*26*). Antibodies and fluorophores used were CY-labeled anti-CD8, CY-labeled anti-CD3, FITC-labeled anti-CD25, PE-labeled anti-hamster IgG (Pharmingen); rat anti-CD8 IgG (Leinco); biotinylated goat anti-rat IgG mouse adsorbed (Vector), anti-BrdU (Becton-Dickinson); SA-594 and SA-488 (Molecular Probes). Flow cytometry was performed at the Flow Cytometry Facility at the University of Illinois. Primary splenocytes were obtained from spleens of euthanized animals and dissociated through wire mesh. Red blood cells were depleted using lysis buffer (0.14 M NH_4-Cl, 0.017 M Tris, pH 7.2) and cells were washed and counted for experiments. Tumor cells lines KB (human) and EL-4 (mouse $H\text{-}2^b$) were maintained in folate free RPMI (Gibco). Culture media contained 10% heat inactivated FCS (Hyclone), 1.3 mM L-glutamine, 50 mM 2-mercaptoethanol, 100 unit/mL penicillin (Gibco), and 100 units/mL streptomycin (Gibco). Cells were grown at 37 °C in 5% CO_2 in a humidified incubator.

Preparation of Anti-CD28 Fab/Folate. Anti-CD28 IgG antibody was purified from ascites fluid generated by the hybridoma PV-1 (*27*). Anti-CD28 IgG was purified by lipid removal, ammonium sulfate precipitation, DEAE column chromatography, and protein A column chromatography. Fab fragments were produced by 24 h incubation with papain conjugated beads (Pierce) at 37 °C on a shaker. Fab fragments were purified over a protein A column, and purity was examined by 10% SDS−PAGE. Anti-CD28 Fab fragments were concentrated to 1 mg/mL and covalently linked to folic acid using the standard EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide) reaction at a molar ratio of 50 folates per one Fab fragment. Labeled fragments were purified over a size exclusion column, dialyzed into phosphate-buffered saline (PBS), and concentrated to 1 mg/mL.

Anti-CD28 Fab/Folate Flow Cytometry Inhibition Assays. To assess binding of anti-CD28 Fab/folate preparations to the FR, a competitive inhibition assay was performed. KB cells were incubated with various concentrations of anti-CD28 Fab/folate at 37 °C for 20 min in 0.01% PBS−BSA. The fluorescent folic acid analogue, *N*-α-pteroyl-*N*-ε-(4′-fluoresceinthiocarbamoyl)-L-lysine, PLF, was added at the indicated concentrations to the cells and incubated at 37 °C for an additional 20 min. To assess binding of anti-CD28 Fab/folate preparations to CD28, a different competitive inhibition assay was performed. Primary C57BL/6 splenocytes were incubated for 20 min at 37 °C with indicated concentrations of anti-CD28 Fab/folate. Biotinylated anti-CD28 IgG was added to the cells and incubated at 37 °C for an additional 20 min. Cells were incubated with SA:PE in 0.01% PBS−BSA for 20 min at 4 °C. Cells were washed 3× in 0.01% PBS−BSA before analysis using a Coulter EPICS XL instrument.

^{3}H-Thymidine Incorporation Assay. KB cells were treated with mitomycin C at 1 mg/mL for 2 h at 37 °C. 10^4 KB cells were incubated with 10^5 TCR/RAG splenocytes in folate-free RPMI and various concentrations of a conjugate of an anti-TCR antibody (KJ16 Fab) with folate (to stimulate the TCR) and various concentrations of anti-CD28 Fab/folate. Cells were cultured in 96-well flat bottom plates for 48 h at 37 °C and 5% CO_2. Cells were pulsed with ^{3}H-thymidine (ICM Pharmaceuticals) for 16 h and harvested using a PHD cell harvester. Thymidine incorporation was assessed using a Beckman LS1801 beta-scintillation counter.

MRI Analysis. Mice were anesthetized using 100 mg/kg ketamine and 15 mg/kg xylazine. MRI data acquisition used a single loop small coil with 14 mm diameter placed around the mouse head and proton MR signals were detected using 4.7 T Varian MR scanner at 200 MHz. Coronal MR images of mouse brain were obtained using SEMS pulse sequence with interleaved slice acquisition. Twenty slices were acquired without gap during each

scan using slice thickness of 0.5 mm. Repetition time TR was 750 ms and echo time TE was 25 ms. Data matrix had 256 × 128 complex points and FOV was 30 × 30 mm. Duration of each MRI experiment was 6.4 min using NEX = 4. Data processing of MR raw data and images was performed using V and TkViewit software packages (BMRL, University of Illinois) and ImageJ (version 1.28). For volume measurements following the sc injection of anti-CD28 Fab/folate, the number of animals (*n*) equaled 9 (IL-12), 12 (IL-12 + anti-CD28 Fab/folate), and 6 (PBS). For volume measurements of intracerebroventricular (ICV) treated animals, *n* = 5 (IL-12), 4 (IL-12 + anti-CD28 Fab/Fol), and 4 (PBS). Data from mice that received IL-12 alone and IL-12 + ICV PBS were combined, as no significant differences were found between these groups. Statistical analysis was done using SAS JMP software.

IL-12 and Anti-CD28 Fab/Folate Treatments and Survival Analysis. $SV11^+$ tumor mice were treated for 10 days starting at day 85 of age with intraperitoneal (ip) injections of either 100 μL of 1% normal mouse serum (NMS) in PBS or 0.1 μg (5 μg/kg) murine IL-12 in 100 μL of 1% NMS in PBS. Anti-CD28 Fab/folate was delivered by one of four routes: iv (2 μg (0.1 mg/kg) on days 4, 7, 9 of IL-12 treatment); sc (2 μg on days 4, 7, 9); ICV as a single injection (5 μg (0.25 mg/kg) on day 6); or ICV as a continuous infusion (a total of 25 μg (1.5 mg/kg) infused from an osmotic minipump on days 6−21). Control mice were injected with PBS for each route of anti-CD28 Fab/folate delivery. Mice were checked daily for health status and weight. If mice were lethargic or weighed less than 75% of their baseline body weight they were euthanized. Survival statistics were analyzed by Kaplan−Meier estimates and log-rank test using SAS JMP software.

Intracerebroventricular (ICV) Injections and Cannula Implantations with Minipumps. For ICV injections and infusions, the tip of the needle or cannula was stereotaxically placed into the lateral ventricle; from bregma: 0.8 mm lateral, 0.5 mm posterior, and 3.1−3.3 mm ventral. Animals were anesthetized using 100 mg/kg ketamine and 15 mg/kg xylazine. The exposed skull was trephined with a 26G needle. For ICV injections, a 27G Hamilton syringe was used to inject 5 μg/5 μL anti-CD28 Fab/folate or PBS. Cannulas (Plastics One) were held in place with Lock-tite and attached with vinyl tubing to an osmotic minipump (Alzet). The pump was implanted subcutaneously at the nape of the neck and filled with 25 μg anti-CD28 Fab/folate in PBS or PBS alone. MRI imaging was used to test whether the osmotic minipump was able to deliver fluid to the indwelling cannula implanted into the lateral ventricle. A Teflon cannula was implanted into the lateral ventricle of a nontumor mouse using the same coordinates as the ICV injections and connected to an osmotic minipump filled with gadolinium. As visualized by MRI, the gadolinium in the pump was delivered to the ventricles and infused the surrounding brain tissue (data not shown).

Immunohistochemistry (IHC). Animals were injected with 50 μg BrdU/g 2 h before sacrifice. Brains were dissected, embedded in Cryomatrix, and frozen at −80 °C. Ten micrometer sections were cut on a cryostat and fixed using 95% ethanol at −20 °C. Slides were rehydrated and washed between incubations in PBS-0.1%Tween20 (PBST). Sections were blocked with Superblock (Pierce) for 1.5 h. Primary anti-CD8 antibody was incubated at room temperature for 30 min. Slides were incubated with secondary biotinylated goat anti-rat antibody at room temperature for 20 min and incubated with SA-488 for 15 min. Sections were coverslipped or incubated in cold 2.7% formaldehyde-0.01% Tween20 at 4 °C for 45 min. Slides washed 2× in PBST, 1× in $NaCl/MgCl_2$ buffer, and incubated 45 min in DNase I, 50 U/150 μL in $NaCl/MgCl_2$ buffer. Slides were blocked in MOM blocker (Vector), 5 min, and incubated in primary anti-BrdU antibody at 4 °C overnight. Secondary biotinylated anti-mouse antibody was incubated for 10 min at room temperature and visualized using SA-594 stained 15 min.

RESULTS

Construction and Characterization of Anti-CD28 Fab/Folate. To eliminate potential complications of tumor-independent, Fc-receptor-mediated activation of T cells, Fab fragments of the anti-CD28 antibody PV-1 were used in these studies. Fab fragments, prepared by digestion with papain coated beads, were run over a protein A column to remove undigested IgG and F_c regions. Fab fragments were labeled with folic acid using the EDC reaction, which links carboxyl groups of folic acid to primary amine groups on the protein. Fab fragments and folate-labeled Fab fragments were examined by SDS−PAGE (Figure 1A). The Fab/folate preparation (lane 3) migrated slightly slower than the Fab fragment (lane 2) suggesting that the protein was successfully coupled to folic acid molecules, given that the molecular weight of folate is 441.

The bispecific conjugate was tested for binding capability to its respective ligands using competition assays and flow cytometry. FR binding of anti-CD28 Fab/folate was tested using *N*-α-pteroyl-*N*-ϵ-(4′-fluoresceinthiocarbamoyl)-L-lysine (PLF), a fluorescein derivative of the lysine analogue of folic acid (*25*). Anti-CD28 Fab/folate was able to inhibit the binding of PLF in a dose dependent manner, retaining its ability to bind FR after EDC coupling (Figure 1B and data not shown). Conjugation of the folate to the larger antibody substantially reduced its affinity, by approximately 2 orders of magnitude on a molar basis. Flow cytometry was used to test CD28 binding of anti-CD28 Fab/folate conjugate. Anti-CD28 Fab/folate conjugate blocked the binding of biotinylated anti-CD28 IgG to C57Bl/6 mouse splenocytes, as detected with PE-labeled streptavidin (Figure 1C). Together, these results indicate that anti-CD28 Fab/folate is functional and can bind both FR and CD28.

Cross-linking of the tumor cell with CD28 on a T cell by the bispecific conjugate is required for CD28-mediated activation and signaling. The ability of the Fab/folate conjugate to costimulate T cells was assessed using ^{3}H-thymidine incorporation into primary splenocytes, upon activation with an anti-TCR Fab/folate conjugate. Primary splenocytes from a Vβ8+ TCR/RAG mouse were cultured with the tumor cell line KB (mitomycin C treated) that expresses the high affinity folate receptor. In the presence of an anti-Vβ8 Fab fragments conjugated to folate (KJ16 Fab/folate) (*26*), T cells proliferated in a dose dependent manner by cross-linking of the TCR to the FR (Figure 2A). Cultures were treated with a concentration of KJ16 Fab/folate (10 ng/mL) below maximal stimulation and various concentrations of anti-CD28 Fab/folate. As predicted from many other studies with anti-CD28 antibodies, anti-CD28 Fab/folate synergized with the KJ16 Fab/folate (Figure 2B). Anti-CD28 Fab/Fol by itself had no effect on proliferation, as expected (data not shown). Taken together, these results indicate that the binding and cross-linking of the anti-CD28 Fab/folate is functional and the conjugate is biologically active.

Systemic Administration Routes of Anti-CD28 Fab/Folate. In previous studies, we found that a 10 day

(B) Flow cytometric analysis demonstrating that anti-CD28 Fab/folate (2×10^{-6} M) inhibits binding of the folic acid analogue PLF (*N*-α-pteroyl-*N*-ϵ-(4′-fluoresceinthiocarbamoyl)-L-lysine, 10^{-8} M). (C) Flow cytometric analysis showing folate conjugated anti-CD28 Fab (2×10^{-6} M) can inhibit binding of divalent anti-CD28 IgG (7×10^{-8} M) to CD28.

course of IL-12 leads to a modest, but significant, increase in survival of SV11 mice (*28*). After IL-12 treatment, T cells were found to migrate into the brain tumor. We reasoned that by providing daily IL-12 intraperitoneal (ip) injections, followed by anti-CD28 Fab/folate treatments beginning on day 4, enhanced costimulatory signals could be delivered to infiltrating lymphocytes in the choroid plexus tumor. SV11 mice were treated with IL-12 and various systemic routes of delivery (intraperitoneal, intravenous, and subcutaneous) of anti-CD28 Fab/folate. SV11 animals received anti-CD28 Fab/folate on days 4, 7, and 10 after onset of IL-12 treatment.

A regimen of three sc injections of anti-CD28 Fab/folate resulted in enhancement of survival and was further

At a given concentration of KJ16 Fab/folate, increasing concentrations of Anti-CD28 Fab/folate stimulated increased splenocyte proliferation.

studied with MRI-based volumetric analysis as the endpoint. Subcutaneous anti-CD28 Fab/folate administration (2 μg × 3 days) in combination with daily IL-12 (0.1 μg ip for 10 days) increased mouse survival from an average of 106 days with PBS alone ($n = 37$), to 115 days with IL-12 alone ($n = 55$, $p < 0.001$ versus PBS), to 121 days with the combination of IL-12 and anti-CD28 Fab/folate ($n = 44$, $p < 0.05$ versus IL-12 alone, Figure 3A).

The 10 day tumor progression from day 85 to day 95 was followed using MRI (Figure 3B and 3C). Volume reconstruction of images was used to assess tumor growth. Tumors of PBS treated animals ($n = 6$) increased by 263% while tumors of IL-12 treated animals ($n = 9$) increased only 81% ($p < 0.05$, Figure 3B). Animals treated with IL-12 in conjunction with anti-CD28 Fab/folate ($n = 9$) decreased tumor growth even further, growing only 8% over 10 days ($p < 0.05$ versus IL-12 alone, Figure 3B).

Intracerebroventricular (ICV) Injection of Anti-CD28 Fab/Folate. It is possible that relatively short circulating lifetime of Fab fragments minimizes their benefits because most of the conjugate does not reach the brain tumor. Thus, the effects of direct administration of anti-CD28 Fab/folate into the brain were investigated. Animals were treated daily for 10 days ip with PBS or IL-12. To allow for T cell infiltrate into choroid plexus tumors mediated by IL-12, ICV anti-CD28 Fab/folate injection was administered on day 6. Figure 4A shows that animals treated with a single administration of 5 μg of anti-CD28 Fab/folate ICV in combination with daily IL-12 ip survived an average of 122 days ($n = 17$), while animals treated with IL-12 alone or IL-12 plus ICV PBS ($n = 14$) survived 114 days ($p < 0.02$). Mice treated with anti-CD28 Fab/folate but without IL-12 pretreatment ($n = 3$) did not survive longer than PBS controls ($n = 7$). The increase in survival in animals treated with the combination of IL-12 and anti-CD28 Fab/folate is com-

(B) MRI analysis showing percent volume increase in choroid plexus tumor size over 10 day treatment. Mice treated with IL-12 + anti-CD28 Fab/folate had smaller increases than mice treated with IL-12 alone ($p < 0.05$). PBS ($n = 6$), IL-12 ($n = 9$), IL-12 + anti-CD28 Fab/folate ($n = 9$). (C) Representative MRI images showing 10 day tumor progression of tumors in mice treated with PBS, IL-12, and IL-12 plus 3 sc injections of Anti-CD28 Fab/folate conjugate. Arrows point to choroid plexus tumors.

parable to experiments described above using three sc injections of 2 μg anti-CD28 Fab/folate (Figure 3A), indicating that a single direct administration of bispecific conjugate to the site of the tumor can produce similar therapeutic effects. The average survival of untreated animals was 106 days, 21 days past start of treatment.

Immunohistochemistry of brain sections from ICV injected animals revealed a proliferating T cell infiltrate. To evaluate the proliferative state of both the tumor and T cells, animals in treatment groups were injected with BrdU 2 h before sacrifice and brain sections stained for BrdU. To examine whether cytotoxic T cells are present in the infiltrate, double staining was also performed with an anti-CD8 antibody. Consistent with the rapid growth observed by MRI, tumor cells were highly proliferative. Within the 2 h window of BrdU exposure, 15−20% of tumor cells were found to be proliferating. In addition, a double positive CD8 and BrdU population was found in anti-CD28 Fab/folate treated animals (Figure 4B), indicative of a tumor-reactive CTL infiltrate into choroid plexus tumors.

Continuous Delivery of Anti-CD28 Fab/Folate. The effect of a 14 day continuous ICV infusion of anti-CD28 Fab/folate through an osmotic minipump was tested in combination with daily IL-12 ip injections. To control for tumor variability inherent in the SV11 model, mice were imaged by MRI for tumors and matched for tumor size among treatment groups at the start of the experiment. Animals received anti-CD28 Fab/folate into the right lateral ventricle, through an indwelling cannula connected to a surgically implanted osmotic minipump. The animals received 0.25 μL/h for 14 days of either PBS or a total dose of 25 μg anti-CD28 Fab/folate. Mice were analyzed by MRI (Figure 5A) on day 1 of treatment and 21 days after treatment (in contrast to MRI analyses after 10 days of treatment described earlier). The PBS treated animals ($n = 4$) had a significant increase in tumor size, 73 mm^3 within the 21 day period (Figure 5B). The IL-12 treated tumors ($n = 5$) grew 30 mm^3, while IL-12 and anti-CD28 Fab/folate treated tumors (= 4) had little growth, 2 mm^3 ($p < 0.05$ versus IL-12, Figure 5B). After anti-CD28 Fab/folate and IL-12 treatments were stopped, tumors rapidly progressed. Both treated groups survived significantly longer than PBS controls ($p < 0.05$, data not shown), but the slower growth of the tumors in mice treated with anti-CD28 Fab/folate did not translate into survival benefit, compared to IL-12 alone. The smaller sample sizes in this experiment (n's = 4 and 5) may have contributed to the lack of effect on survival.

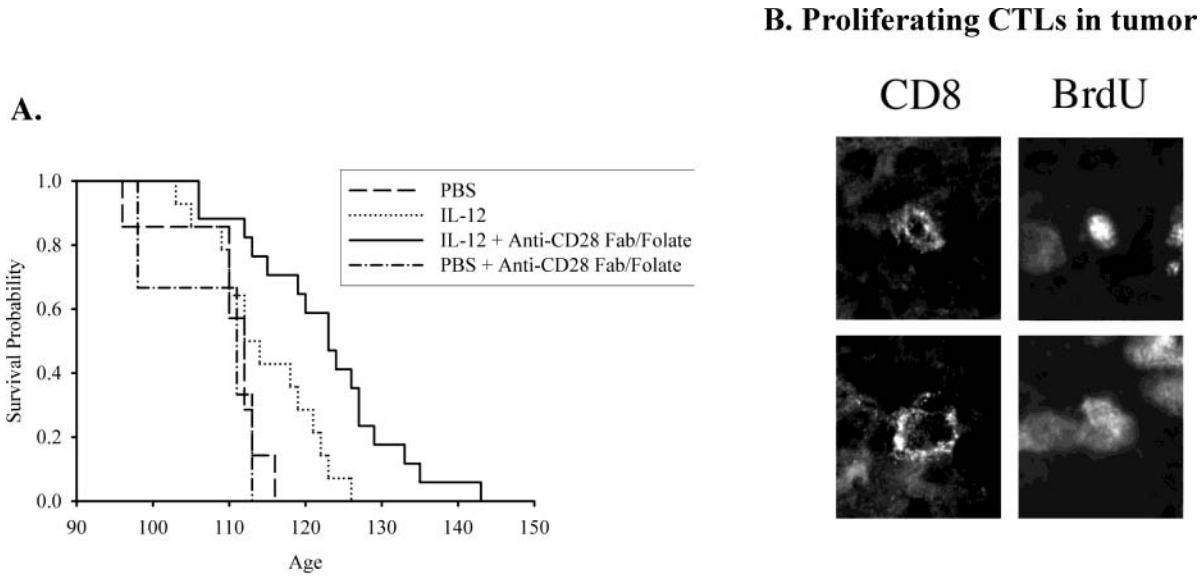

Figure 4. Response to intracerebroventricular (ICV) administration of anti-CD28 Fab/folate. (A) Kaplan−Meier survival curves of four treatment groups showing longest survival for mice treated with IL-12 in combination with anti-CD28 Fab/folate ($p < 0.02$ versus IL-12 alone). (B) Immunohistochemistry of tumor sections from ICV injected animals. $CD8^+$/BrdU double positive cells can be seen within the choroid plexus tumors (60× magnification, IL-12 and anti-CD28 Fab/folate treated animal).

(A) Representative MRI images showing 21 day treatment and progression of tumors after treatment with PBS, IL-12 ip, IL-12 ip + ICV PBS infusion, or IL-12 ip + ICV anti-CD28 Fab/folate infusion. Arrows point to choroid plexus tumors. (B) MRI analysis of tumor volume growth over 21 day treatment. Volumes expressed as mm^3 of tumor growth. PBS ($n = 4$), IL-12 ip ($n = 5$), IL-12 ip + anti-CD28 Fab/folate ICV infusion ($n = 4$).

DISCUSSION

Although immune responses can be readily elicited within transplanted tumor models, attempts at eliciting native host immune responses against endogenously arising tumors have been less successful (*29*, *30*). Among the challenges posed by endogenously arising tumors are that host T cells are tolerant to the tumor. During thymic education, self-reactive T cells undergo apoptosis as the

normal developmental pathway which protects against autoimmunity. However, the process of central tolerance is not complete and allows the escape of low-affinity self-reactive T cells. The T cell repertoire in tumor bearing SV40 transgenic mice is shaped by clonal deletion, as a consequence of the fact that tumor antigens are expressed at low levels in the thymus (*31*). Even though SV40 transgenic mice undergo central tolerance through the expression of Tag during thymic selection, a population of low-avidity autoreactive immune CTLs can escape thymic deletion (*23*, *32*). The polyclonal population of self-reactive T cells which escape deletion during negative selection has been related to T cell avidity (*33*). Highest affinity T cells are deleted in thymus while lower affinity, immunorecessive epitopes persist and offer opportunity for immune-based therapy (*34*).

The effectiveness of a CTL response in the control of SV40 tumors is dependent on the degree of central tolerance and the degree of SV40 antigen expression. Positively selected T cells can also be anergized peripherally as a result of weak stimulating signals received by immature dendritic cells expressing low amounts of pMHC or presentation of pMHC to a low affinity TCR in the absence of costimulatory signals such as B7. T cells with low avidity TCRs are not necessarily deficient in proliferative capacity and can be effectively stimulated by altered peptide ligands with higher affinity for the TCR (*35*). A higher affinity ligand promoted the expansion of these low-avidity self-reactive T cells with increased magnitude of response and maintenance of effector function upon immunization with the peptide. This suggests that the defect in tolerized or anergic CTL responses is not an intrinsic problem but rather a defect in T cell activation (*35*). T cell survival is based upon total strength of stimulation consisting of quantity and affinity for antigen, duration of stimulation, degree of costimulation, and T cell cytokine responsiveness (*36*), and thus additive avenues of activation are most likely needed for a long-term response.

We have previously found that IL-12 stimulates a T cell response against endogenous SV11 tumors (*28*). The present study demonstrates that the antitumor effect of IL-12 is enhanced when combined with the bispecific ligand-antibody conjugate, anti-CD28 Fab/folate. Anti-CD28 Fab/folate targets CD28 on T cells and the FR on tumor cells to enhance a specific an antitumor CTL response. To promote tumor specificity and infiltration, the bispecific antibody conjugate was constructed from an anti-CD28 Fab fragment and directly conjugated to folic acid**.** After chemical conjugation, both CD28 and FR binding were retained and anti-CD28 Fab/folate was able to induce T cell proliferation in vitro in combination with an anti-TCR/folate antibody conjugate.

The dosing schedule and route of administration of anti-CD28 Fab/folate influenced the effectiveness of the treatment in vivo. Although intravenous administration of anti-CD28 Fab/folate in combination with daily intraperitoneal injections of IL-12 did not significantly prolong survival, an increase in infiltrating activated T cells in the tumors suggested that peripheral administration of anti-CD28 Fab/folate was effective in activating T cells focally within the area of the tumor (data not shown). Subcutaneous administration would be expected to provide a more sustained delivery of the agent to the brain, compared to intravenous administration. Consistent with this idea, subcutaneous administration of anti-CD28 Fab/folate in combination with daily intraperitoneal injections of IL-12 over a 10 day period resulted in increased survival and a dramatic decrease in tumor growth as assessed by MRI. Given the fact that choroid plexus epithelium is on the blood side of the blood-CSF barrier and the finding that the tumors enhanced with gadolinium, peripheral injections would be expected to have access to the tumors. However, the relatively short circulating lifetime of Fab fragments, and the possibility that FR+ macrophages are in the periphery, may reduce the effective concentration Fab/folate conjugates that make it to the brain.

The possibility that the bispecific agent acts in the local tumor environment to enhance costimulation of infiltrating T cells was supported by the observations that local administration of anti-CD28 Fab/folate at the site of the choroid plexus tumors was also effective. The survival of mice treated with a single ICV injection of anti-CD28 Fab/folate was comparable to results seen with three subcutaneous injections of the bispecific antibody conjugate. This is significant considering that at the start of treatment, tumors in these animals have rapid tumor growth with high levels of large-T antigen and highly neoplastic pathology (*21*, *37*). The strongest effect on tumor growth assessed by MRI was achieved through the 2 week continuous local ICV administration of anti-CD28 Fab/folate. Choroid plexus tumors in animals treated with anti-CD28 Fab/folate exhibited little or no growth 21 days after initiation of treatment.

Proliferating $CD8^+$ T cells were seen in brain sections of animals treated with IL-12 in combination with ICV injections of anti-CD28 Fab/folate. In efforts to examine whether the specificity of the CD8+ tumor infiltrating cells are specific for the most dominant SV40 Tag epitope (epitope IV bound to K^b), we examined splenocytes with tetramers of epitope IV/K^b. However, we were unable to detect significant binding (data not shown), consistent with findings of Schell that the T antigen specific T cells stimulated in SV11 mice by a T antigen vaccine are specific for epitope V (*23*). Thus, if the T cells stimulated by IL-12 and anti-CD28 Fab/folate are specific for large T antigen, it is possible that they are specific for the immunorecessive epitope V.

Two other SV40 transgenic tumor models have shown recently that strong activating signals are required to overcome T cell tolerance. SV40 under an α-amylase promoter produces endogenously arising osteosarcomas; naïve SV40 epitope I specific T cells adoptively transferred into these SV40 tumor-expressing mice lacked effector function due to peripheral T cell anergy (*38*). However, treatment with an agonist antibody against CD40 in addition to the adoptively transferred CTLs prevented the development of T cell tolerance and promoted the development of CTL effector function, clonal expansion, and memory cell development (*38*). Upon CD40 ligation, dendritic cells upregulate B7 expression as well as secrete IL-12. In contrast, in an SV40 prostate mouse model, CD40 ligation in combination CpG injections failed to reverse SV40 T cell tolerance, but CTLs against the subdominant Tag epitope V could be elicited (*39*).

Overcoming self-tolerance for activation of naïve low-affinity antitumor CTLs requires a considerable synergistic engagement of a variety of receptors on naïve T cells. Increasing evidence points to a three signal model for T cell activation. While the TCR/pMHC interaction confers antigenic specificity, CD28 and IL-12 are needed to amplify the low-affinity activation. While both CD28 and IL-12 can stimulate T cell proliferation and cytokine secretion, growing evidence indicates that CD28 is needed for the development of CTL effector function and IL-12 is needed for T cell memory formation. In the develop-

ment of antitumor immunotherapies, a specific and strong immune response must be elicited to activate tumor-tolerized T cells. The most successful treatment will most likely comprise a combination of therapies that stimulate signaling pathways needed to activate and sustain a specific antitumor T cell response.

Received June 18, 2004

This study presents two-step and multistep reactions for modifying the surface of plasma-functionalized poly(tetrafluoroethylene) (PTFE) surfaces for subsequent conjugation of biologically relevant molecules. First, PTFE films were treated by a radiofrequency glow discharge (RFGD) ammonia plasma to introduce amino groups on the fluoropolymer surface. This plasma treatment is well optimized and allows the incorporation of a relative surface concentration of approximately 2−3.5% of amino groups, as assessed by chemical derivatization followed by X-ray photoelectron spectroscopy (XPS). In a second step, these amino groups were further reacted with various chemical reagents to provide the surface with chemical functionalities such as maleimides, carboxylic acids, acetals, aldehydes, and thiols, that could be used later on to conjugate a wide variety of biologically relevant molecules such as proteins, DNA, drugs, etc. In the present study, glutaric and *cis*-aconitic anhydrides were evaluated for their capability to provide carboxylic functions to the PTFE plasma-treated surface. Bromoacetaldehyde diethylacetal was reacted with the aminated PTFE surface, providing a diethylacetal function, which is a latent form of aldehyde functionality. Reactions with cross-linkers such as sulfo-succinimidyl derivatives (sulfo-SMCC, sulfo-SMPB) were evaluated to provide a highly reactive maleimide function suitable for further chemical reactions with thiolated molecules. Traut reagent (2-iminothiolane) was also conjugated to introduce a thiol group onto the fluoropolymer surface. PTFE-modified surfaces were analyzed by XPS with a particular attention to quantify the extent of the reactions that occurred on the polymer. Finally, surface immobilization of fibronectin performed using either glutaric anhydride or sulfo-SMPB activators demonstrated the importance of selecting the appropriate conjugation strategy to retain the protein biological activity.

INTRODUCTION

Nowadays, biomolecule grafting onto polymer surfaces is often used for biological detection involving viruses, DNA, proteins, etc. (*1*−*5*), as well as for improving biomaterial surface properties such as hemocompatibility and biocompatibility (*6*−*16*). Most of the time, the conjugation procedures involve the chemical modification of the biomolecules to be grafted with appropriate functionalities and subsequent reactions involving reactive groups on the surface (*1*−*4*). However, such biomolecule chemical modifications often lead to denaturation or polymerization phenomena that alter or nullify their biological activity. It seems therefore more suitable to modify the surface onto which the molecule should be conjugated with appropriate chemical functionalities and thereafter proceed to the conjugation of the native and optimally active biomolecule. The first step of the latter strategy involves polymer surface modification with reactive functionalities for further chemical reaction with various reagents that will provide the moieties able to bind biomolecules. In this context, radiofrequency glow discharge (RFGD) plasma treatment was proven in the past to be a technique of choice as it allows the incorporation of reactive moieties onto the polymer surfaces with no modification to the bulk material (*17*, *18*). This approach was successfully used to functionalize the surface of polymers such as polyethylene, polypropylene, polyesters, and poly(tetrafluoroethylene) (PTFE) (*19*−*32*).

Because of some favorable properties such as high electrical resistivity and good thermal and chemical stability, PTFE has been the subject of several investigations to modify its surface through plasma treatments in order to benefit from its bulk characteristics while modulating its surface behavior (*19*, *21*, *22*, *24*, *26*−*35*). In the 1960s, Hansen and Schonhorn were the first to employ plasma treatments to modify the hydrophobic PTFE surface and succeeded in rendering it hydrophilic (*32*). In addition, plasma surface modifications enable the introduction of new chemical functionalities onto the surface depending on the gases employed. For example,

ammonia is used to provide amino groups (*20*, *24*, *28*, *31*, *36*, *37*) as well as other nitrogen-containing moieties on the modified surface. Plasma treatments involving CO_2, H_2O, and CO_2/H_2O, to introduce carboxylic acid groups onto the surface, were also largely utilized as well as treatments with H_2/H_2O, O_2/H_2O and H_2/O_2 leading to alcohols and other oxygen-containing functionalities (*19*, *23*, *38*, *39*). However, performing plasma treatments with different gases requires exhaustive optimization of the reaction parameters such as gas pressure and flow, treatment time, power of the radiofrequency field, to maximize the reactive moieties surface concentration while minimizing surface damages. The optimization of these plasma treatments requires extensive characterization of the modified surfaces, control of the plasma composition, and the plasma−polymer interaction through the use of in-situ plasma spectroscopic quantifications and X-ray photoelectron spectroscopy (XPS) surface analyses.

In this context, our strategy to introduce various chemical functionalities onto the PTFE surface consists of treating the polymer using a fully optimized radiofrequency glow discharge (RFGD) ammonia plasma reactor during the first step of the procedure (*31*). Using appropriate experimental conditions, this protocol allows the maximization of the amino group surface concentration while almost completely eliminating surface damages. In addition, this surface treatment was proven to be noncytotoxic (*36*, *37*), therefore enabling its use in several biological applications where living tissues are involved. The nucleophilic surface amino groups are further used for the covalent binding of various chemical reagents which, in turn, allow the grafting of useful functionalities such as maleimides, carboxylic acids, thiols, acetals and aldehydes. The presence of these reactive surface functionalities on the polymer opens the door to a wide variety of biomolecule conjugation strategies.

In this study, glutaric anhydride was used to introduce carboxylic groups at the surface of the ammonia plasma-treated PTFE films. Likewise, *cis*-aconitic anhydride was reacted with the aim to double the surface concentration of carboxylic groups obtained as compared to glutaric anhydride grafting. Following appropriate activation, acidic moieties are able to react with amino groups to form stable amide bonds. Moreover, reaction with bromoacetaldehyde diethylacetal (BADEA) was also evaluated to provide ethylacetal functionalities on the PTFE ammonia plasma-treated surface. Acetals are commonly used as latent protecting groups for aldehydes (*40*). Once the acetal group is removed, the regenerated aldehyde can react swiftly with aminated entities. Additionally, the reaction of sulfo-succinimidyl-4-(*N*-maleidomethyl)-cyclohexane-1-carboxylate (S-SMCC) and similarly the reaction of sulfo-succinimidyl-4-(*p*-maleimidophenyl)butyrate (S-SMPB) with the surface amino moieties were assessed to provide a maleimide functionality suitable to carry out further chemical conjugations of thiolated molecules such as fibronectin (*41*). Finally, 2-iminothiolane was used to introduce a thiol function onto the fluoropolymer surface that can be used afterward for the coupling of either S-SMCC- or S-SMPB-modified molecules.

Particular attention was paid to quantify the extent of the chemical reactions performed on the polymer surface. Along with calculations originating from surface derivatization strategies, X-ray photoelectron spectroscopy is particularly well suited to perform such measurements. This spectroscopic technique was also very useful for the detection of specific functionalities present through peak fitting of core level spectra, especially that of the carbon 1s orbitals. This spectral region presents a relatively good sensitivity and a wide literature associating the various binding energies to the corresponding carbon binding states (*42*).

EXPERIMENTAL PROCEDURE

Materials. Poly(tetrafluoroethylene) (Teflon) films were purchased from Goodfellow (Huntingdon, England). Phosphate-buffer-saline (PBS, pH 7.4) was purchased from VWR Canlab (Ville Mont-Royal, QC, Canada) while 2-(*N*-morpholino)ethanesulfonic acid buffer (MES, pH 4.75) was obtained from Sigma-Aldrich (Milwaukee, WI). Molecules to be grafted such as glutaric anhydride, *cis*-aconitic anhydride, bromoacetaldehyde diethylacetal, sulfo-SMCC, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC), Lys-Lys dimer, human fibronectin, and reagents such as 5-bromosalicylaldehyde and sodium cyanoborohydride were obtained from Sigma-Aldrich (Milwaukee, WI). Other molecules to be immobilized onto PTFE such as 2-iminothiolane (Traut reagent) and sulfo-SMPB were acquired from Pierce (Brockville, ON, Canada). Buffer solutions were prepared in filtered, deionized water (Nanopure system) at 0.2 M. Fine adjustments of the pH (7.4 or 8.0, depending on the reaction to be performed) were made by adding either 0.1 M of HCl or NaOH to reach the desired value. All chemicals were of commercial grades of highest purity and were used without further purification. The cell culture experiments were performed with the HT1080 human fibrosarcoma cell line (American Type Cell Culture, Manassas, VA) in Dulbecco's modified Eagle's Medium (DMEM) (Sigma-Aldrich, Milwaukee, WI) supplemented with penicillin, streptomycin, and glutamine (Life Technologies, St Paul, MN) using 96-well tissue culture plates (Fisher Scientific, Whitby, ON, Canada).

Methods. *Preparation of PTFE Surfaces.* PTFE surfaces of 3 cm × 3 cm were cleaned ultrasonically for 10 min successively after immersion in high purity methanol, deionized water, and acetone. The films were then air-dried and kept under vacuum until use. The cleaning procedure was validated by XPS showing the presence of only carbon and fluorine in the appropriate stoichiometric ratio.

Plasma Treatment. The ammonia plasma treatment and system apparatus were described elsewhere (*22*, *31*). Briefly, the treatments were performed at a power of 20 W and a pressure of 300 mTorr for 250 s using high purity ammonia gas. The PTFE films were held by a Teflon-made circular sample holder and treated in a cylindrical plasma chamber. Only the internal side of the film was treated using such a plasma configuration and geometry.

Characterization. Immediately following the ammonia plasma treatment, the aminated-PTFE film was cut into nine one-cm^2 samples in a glovebox purged with dry nitrogen in order to minimize the surface oxygen uptake. Three samples, one coming from each row and column, were analyzed by XPS without delay to assess the exact atomic composition of the surface following the plasma treatment. The XPS spectra were recorded using a PHI 5600-ci spectrometer (Physical Electronics, Eden Prairie, MN). A monochromatic aluminum X-ray source (1486.6 eV) at 400 W with neutralizer was used to record the survey spectra while high-resolution spectra were obtained using the monochromatic magnesium X-ray source (1253.6 eV) at 400 W without charge neutralization. The

detection was performed at 45° with respect to the surface normal.

Three other samples were used to quantify the amine surface concentration through vapor-phase chemical derivatization using 5-bromosalicylaldehyde as described previously (*31*). Briefly, the reaction was performed at 85 °C for 2 h in a sealed glass tube in which a 1 cm-thick bed of soda-lime glass beads was used to separate the reagent from the reactive surface. The surfaces were then vacuum-dried overnight at 40 °C and analyzed by XPS. Taking into account the nine newly bonded atoms upon reaction of 5-bromosalicylaldehyde with the surface amino groups, the amine surface concentration can be determined through eq 1.

$$[\%NH_2] = [\%Br]/(100 - 9 \times [\%Br]) \times 100 \quad (1)$$

Yield Calculations. The atomic percentages following plasma treatment and the amine surface concentration are essential to calculate the theoretical atomic percentages expected for any given chemical reaction aiming at providing a new chemical functionality on the ammonia plasma-treated PTFE. Basically, the efficiency of a surface chemical reaction may be calculated from the knowledge of the surface concentration variation for any atom present on the surface before and after the chemical grafting reaction as determined from XPS as described in eq 2.

$$[\%A] = \frac{[A]_0 + y \times [NH_2]_0}{100 + w \times [NH_2]_0} \times 100 \quad (2)$$

In this equation, A is the atom for which the surface concentration is measured by XPS, $[A]_0$ is the surface concentration of the atom A on the plasma-treated film surface measured readily after the plasma treatment, $[NH_2]_0$ is the amine surface concentration determined from the vapor-phase chemical derivatization, *y* and *w* are the number A-type atoms and the total number of atoms in the newly bonded molecule, respectively. The conversion factor, *x*, is equal to 0 in the case where no reaction occurs and 1 in the case of a complete reaction. The denominator in the right term takes into account for the total number of newly added atoms coming from the reagent as well as the atoms lying underneath and probed by the XPS analyses.

The yields of the chemical reactions were obtained from the ratio between the experimental atomic percentage measured by XPS analyses and the calculated theoretical atomic percentage for a particular atom. Indeed, one would expect the atom A experimental relative surface concentration to increase following a chemical reaction with a molecule containing a higher atom A concentration ratio than that measured on the ammonia plasma-treated PTFE surface.

Chemical Reactions. The last three samples to be grafted with the various chemical reagents were placed individually in three 5 mL polypropylene tubes in such a manner to avoid mechanical overlay of the samples that would interfere with the chemical reaction.

For each of the three PTFE-amino modified samples grafted with a molecule, five punctual areas were analyzed by XPS. Moreover, each grafting was made in triplicate to ensure that the values presented therein are statistically significant.

Grafting of Anhydrides. A solution of 55 mg/mL of glutaric anhydride in acetone was prepared in a glovebox under a dry nitrogen atmosphere. The reaction was performed for 60 min at room temperature under mechanical agitation. After 20 and 40 min, the concentration of glutaric anhydride was raised to 65 and 75 mg/mL respectively, to ensure completion of the reaction. Similarly, acetonic solution of *cis*-aconitic anhydride at a concentration of 100 mg/mL was prepared in a glovebox purged with nitrogen. The reaction mixture was mechanically agitated at room temperature for 120 min. After 30 and 60 min, the concentration of *cis*-aconitic anhydride in the solution was increased to 125 and finally 150 mg/mL. One cm^2 films were reacted with 1 mL of the anhydride acetonic solution.

Grafting of BADEA. Plasma-treated films were also reacted with bromoacetaldehyde diethylacetal. The aminated-PTFE samples were immersed individually in 1 mL of pure bromoacetaldehyde diethylacetal and agitated for 2 h at room temperature. To ascertain the success of the reaction, the diethylacetal function was further hydrolyzed afterward in a 10% HCl solution stirred at room temperature for 2 h (*40*). The films were then thoroughly washed with deionized water and the aldehyde functionality was used for the subsequent grafting of the dipeptide Lys-Lys. A solution of 4 mg of Lys-Lys in 1 mL PBS at pH 7.4 was stirred for 5 min at room temperature, and the imine bond formed was immediately reduced to amine by adding 8 mg of $NaBH_3CN$ to the reaction mixture that was stirred for 3 h at room temperature.

Grafting of Maleimide Derivatives. Sulfo-SMCC and sulfo-SMPB were reacted with the ammonia plasma-treated film samples in 1 mL of 3 mg/mL solutions of reagent in PBS at pH 7.4. The reactions were then allowed to proceed for 2 h under a nitrogen atmosphere and under low light intensity to protect the reactants.

Generation of Thiolated Functionalities. Finally, 2-iminothiolane was also reacted with the aminated-PTFE surface immediately after the plasma treatment. The samples were reacted in solutions containing 30 mg/mL of 2-iminothiolane in PBS at pH 8.0. The reaction was allowed to proceed under constant agitation for 2 h under a nitrogen atmosphere. Meanwhile, to ascertain the completion of the reaction, the cross-linking agent S-SMPB was conjugated to Lys-Lys in a solution containing 5 mg of S-SMPB (1.09 mmol) and 7.6 mg of Lys-Lys (2.18 mmol) in 1 mL of PBS at pH 7.4 (41). Lys-Lys was added in excess to ensure that all the terminal succinimidyl groups would react exclusively with the dipeptide's amino groups instead of unreacted amines on the PTFE surface if there were any. This mixture was stirred for 2 h at room temperature. The rinsed thiolated films were then immersed in the solution containing the S-SMPB-derived dipeptide and the reaction allowed to proceed for 2 h under constant mechanical agitation at room temperature.

Grafted films were all washed thoroughly with deionized water. BADEA grafted films were first washed with methanol and then with deionized water. Afterward, the films were vacuum-dried overnight at ambient temperature before analysis by XPS.

Fibronectin Grafting. Prior to the immobilization of human fibronectin, glutaric anhydride-grafted films were activated with a solution containing 3 mg/mL of EDC in MES buffer (0.1 M, pH 4.75). Two subsequent additions of 3 mg of EDC were made to this solution every 10 min during 20 min at room temperature and under stirring (for a total reaction time of 30 min) to minimize the effect of the water-induced hydrolysis of the activator on the grafting efficiency. These films were then extensively washed with the MES buffer. Both the glutaric anhydride-

[a] Determined through vapor-phase chemical derivatization using 5-bromosalicylaldehyde.

grafted films activated with EDC and the S-SMPB grafted films were reacted with a PBS solution containing 10 μg/mL of human fibronectin at pH 7.4 for 3 h under mechanical agitation. They were washed five times with deionized water and cut in 5.9 mm diameter circles with an awl to fit in a 96-well tissue culture plate.

Cell Adhesion Experiments. *Cell Culture.* The HT1080 human fibrosarcoma cell line was used for all the experimentation. The culture medium was Dulbecco's modified Eagle's Medium (DMEM) with 10% fetal bovine serum, 100 U/mL penicillin, 100 μg/mL streptomycin, 0.3 mg/mL glutamine, 100 μM citrate, and 0.1% BSA. The cells were cultured at 37 °C and 98% humidity in air containing 5% CO_2.

Cell Adhesion on Modified PTFE. To check the availability of the cell interaction sites on the PTFE bound fibronectin, adhesion tests were performed with HT1080 cells known for their strong affinity to adhesion sequences of the protein. 5.9 mm diameter circles of clean PTFE, ammonia plasma-treated PTFE, ammonia plasma-treated PTFE conjugated with glutaric anhydride, fibronectin conjugated on ammonia plasma-treated PTFE through glutaric anhydride, ammonia plasma-treated PTFE conjugated with S-SMPB, and fibronectin conjugated on ammonia plasma-treated PTFE through S-SMPB were prepared and put in a 96-well tissue culture plate, with the treated face up. Human fibronectin (10 μg/mL in PBS at pH 7.4) was coated 2 h at 37 °C in five empty wells and washed twice with PBS. All wells were blocked with 1% BSA overnight at 4 °C, to prevent any nonspecific cell adhesion, and washed twice with PBS. The HT1080 cells in culture were harvested with trypsin, counted, and diluted in 10% DMEM serum and 0.1% BSA to reach a final concentration of 250 000 cells/mL. An amount of 50 000 cells was seeded in each well, and the plate was incubated for 10 min at 37 °C. The wells were then washed twice with DMEM without serum, and cells were stained with violet crystal for 20 min. After washing, all wells were photographed and the number of cells per square millimeter was counted. Statistical analysis of the difference between each group was performed using the analysis of variance (ANOVA) followed by Dunnett's test where appropriate. *P* values lower than 0.01 were considered significant and all data were expressed as mean ± standard error (SE).

RESULTS

Surface Composition of the Plasma-Treated Surface. The relative surface concentrations of carbon, fluorine, nitrogen and oxygen atoms as well as the amine concentration were determined for each sample to control the efficiency of each reaction step. The relative atomic percentage of nitrogen detected on the PTFE surface film after plasma treatment was 11.2% on average. Among these nitrogen-containing species, approximately one-fifth were shown to be amino moieties as measured by derivatization with 5-bromosalicylaldehyde (Table 1). These results are in agreement with those already available from the literature (*22, 27, 31*).

Selection of the Atom Used as XPS Probe To Follow the Extent of Surface Reaction. For the purpose of this study, it seemed that in all cases the oxygen content probed at the modified surface by XPS analyses was the best choice for calculating the yield of the reactions. Indeed, the surface concentration of this atom is only slightly affected upon exposure to solvents such as PBS as demonstrated in Figure 1. In addition, the molecules grafted on the PTFE surface are heavily loaded with oxygen atoms. In fact, the newly bonded molecules contained between one and five oxygen atoms. The ratio *O/n* (where n is the total number of newly bonded atoms) were of 3/8 or 38% for glutaric anhydride, 5/11 or 45% for *cis*-aconitic anhydride, 2/8 or 25% for BADEA, 1/6 or 17% for 2-iminothiolane, 3/16 or 19% for SMCC, and finally 3/18 or 17% for SMPB, respectively. The relative oxygen concentration of these molecules is by far higher than that measured on the plasma-treated PTFE surfaces exposed to PBS. In addition, our XPS data (not shown) demonstrated that, once grafted with the various molecules investigated, the surfaces were stable over time. It should be pointed out, on one hand, that both fluorine and carbon surface concentrations, despite leading to less relative variations than those measured for oxygen upon molecule conjugation, provided very similar evaluation of the reaction yields. On the other hand, nitrogen is clearly a less suitable probe, as some of the nitrogen-containing species, other than amino groups, were shown to be readily removed from the surface upon exposure to water, which is the solvent used to perform some of the reactions presented therein. Possible explanations of this phenomenon are related to displacement of polar groups from the surface into the bulk, hydrolysis of surface imine moieties also created during the ammonia plasma treatment, and dissolution in water of low molecular weight fragments known to be formed during the plasma process (*22, 31*). Therefore, this leads to an overestimation (more than 80% in the present case) of the initial nitrogen surface concentration, required to perform an accurate calculation of the reaction

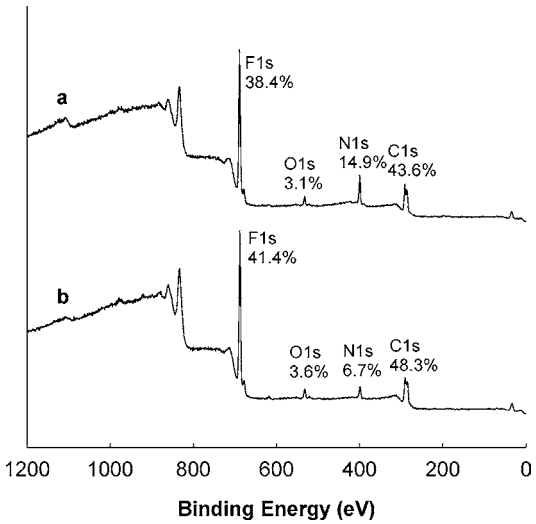

Figure 1. Typical XPS spectra of ammonia plasma-treated PTFE surfaces before (a) and after (b) immersion in PBS, showing that the oxygen surface concentration is only slightly affected upon contact with the aqueous solution.

Table 2. Glutaric Anhydride Grafting. The $[NH_2]_0$ Average for These Plasma Treatments Was 2.4%

	%C	%F	%N	%O
plasma treatment	47.1 ± 1.3	39.7 ± 3.0	11.3 ± 1.1	1.9 ± 0.2
glutaric anhydride	52.5 ± 0.6	35.1 ± 1.8	5.1 ± 0.9	7.3 ± 0.7
theoretical values	49.6	33.3	9.5	7.6
Δ experimental	+5.4	−4.6	−6.2	+5.4
Δ expected	+2.5	−6.4	−1.8	+5.7
% yield	106 ± 3	95 ± 9	54 ± 9	96 ± 6

yields. As XPS probes relative surface concentrations, the loss of nitrogen (8.2% from Figure 1) is mainly reported in the relative concentrations of both carbon and fluorine (Figure 1) and therefore leads to less important relative overestimations, as the surface concentration of these two atoms is inherently higher than that of nitrogen.

Grafted Molecules. These latter observations are further supported through the XPS data recorded in the case of glutaric anhydride conjugation on ammonia plasma-treated PTFE (Table 2). As depicted in Table 2, the oxygen surface concentration increased by 5.4% upon glutaric anhydride grafting. Therefore, based on this atom surface concentration, it can be confirmed that the glutaric anhydride grafting is very successful, the yield of the reaction being near 100%. Both carbon and fluorine XPS signals, with surface variations of +5.4% and −4.6%, respectively, lead to similar conclusions with calculated reaction yields reasonably close to 100% (106 ± 3% and 95% ± 9 using the carbon and fluorine XPS signal, respectively). Performing the calculations with the nitrogen signal leads to a very different trend with an extent of reaction of 54 ± 9%, in agreement with the fact that the initial nitrogen surface concentration is overestimated due to the removal of some of the nitrogen-containing species upon exposure to water.

The successfulness of this reaction is confirmed more visually by the comparison of the XPS spectrum for each steps of the glutaric anhydride grafting process (Figure 2). Nitrogen is obviously not observed on the virgin PTFE surface and presents a surface concentration of 11.3% immediately after the ammonia plasma treatment. The amino group surface concentration on this particular aminated-surface was assessed to be 2.4% through surface derivatization and allowed the grafting of glutaric anhydride thereafter raising the carbon and oxygen peaks from 47.1% and 1.9% to 52.5% and 7.3%, respectively, while diminishing the fluorine and nitrogen peaks from 39.7% and 11.3% to 35.1% and 5.1%, respectively.

The conjugation of glutaric anhydride to aminated-PTFE being successful, further studies were made using *cis*-aconitic anhydride. Reaction of *cis*-aconitic anhydride with the amino groups provides two free carboxylic groups for every grafted molecule (Figure 3a), hence theoretically doubling the density of carboxylic acid group surface concentration as compared to the glutaric anhydride conjugation. In addition, *cis*-aconitic anhydride is recognized to form labile amide bonds with drugs such as daunorubicin that slowly hydrolyze in aqueous solutions to release the drug in its native form (*43*). On the basis of the oxygen surface concentration, the *cis*-aconitic anhydride yielded to a 76% reaction with the amines. The expected 2-fold increase of the carboxylic acid functionalities was therefore not reached. Instead, conjugation with *cis*-aconitic anhydride allows adding approximately 1.5 times more carboxylic acid moieties onto the polymer surface as compared to the aforementioned grafting of glutaric anhydride. As predicted from the molecular structure of *cis*-aconitic anhydride, XPS spectra showed an increase in carbon and oxygen atomic content, from 47.2% and 3.0% to 54.4% and 9.7%, respectively, whereas

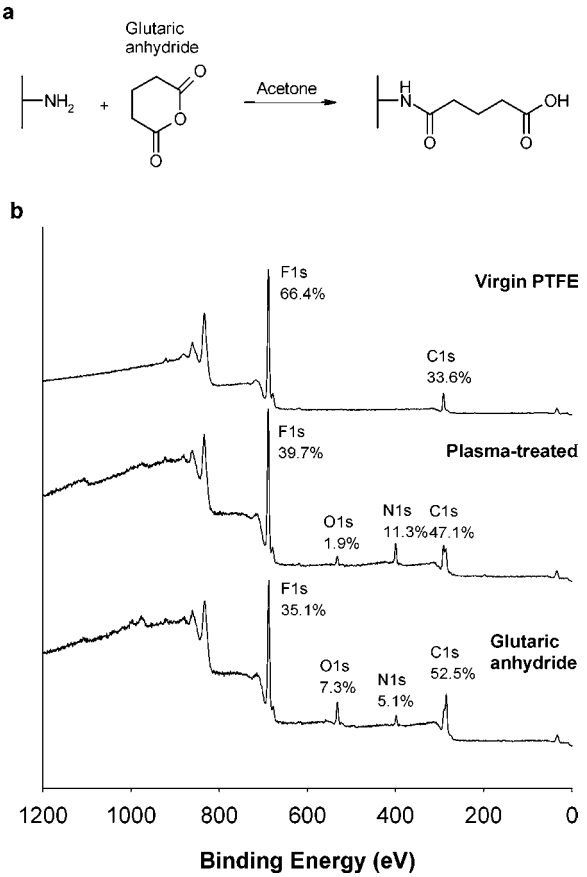

Figure 2. (a) Synthetic scheme of glutaric anhydride grafting onto an ammonia plasma-treated PTFE film. (b) Spectra for plasma-treated PTFE film and glutaric anhydride-grafted PTFE film. $[NH_2]_0$ was 2.4% and the yield of the reaction 96 ± 6% based on the oxygen surface concentration.

the fluorine and nitrogen content decreased along from 35.6% and 13.8% to 30.5% and 5.3%, respectively (Figure 3b).

Grafting of both anhydrides was successful, and thereafter the free carboxylic groups generated could further be activated by several carboxyl-activating agents (*5*, *10*, *41*, *44*) such as *N*-hydroxysuccinimide (NHS), 1-ethyl-3-(3-(dimethylamino)propyl)carbodiimide (EDC), and carbonyldiimidazole (CDI) to conjugate numerous organic or biologic molecules containing amine functionalities, therefore leading to the formation of an amide link between the biomolecule and the polymer surface.

Bromoacetaldehyde diethylacetal (BADEA) also allows the conjugation of amino group-containing biomolecules. However, in this case, the reaction of the imine group generated in the reaction between the PTFE-aldehyde and the amine-bearing biological molecule with the borohydride leads to the formation of a substituted amine, which is stable to hydrolysis. Grafting of BADEA was also successful, with a reaction yield of 57% according to the oxygen surface concentration (Figure 4). Although the atomic percentages obtained from XPS seem to point toward at least a partially grafted surface,

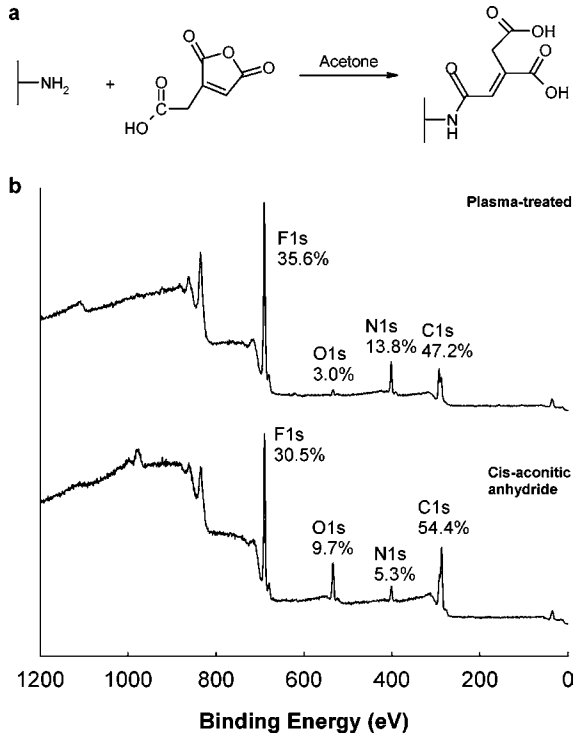

Figure 3. (a) Synthetic scheme of *cis*-aconitic anhydride grafting onto an ammonia plasma-treated PTFE film. (b) Spectra for plasma-treated PTFE film and *cis*-aconitic anhydride-grafted PTFE film. $[NH_2]_0$ was 2.7% and the yield of the reaction 76 ± 15%.

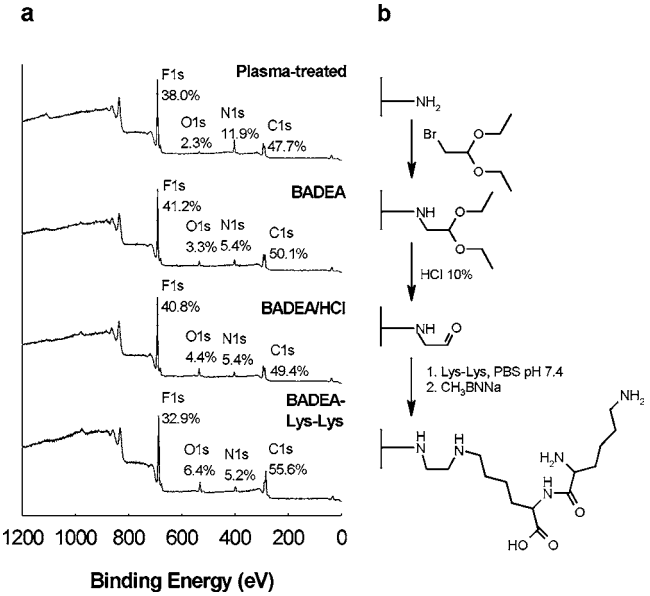

Figure 4. (a) XPS spectra for each step of bromoacetaldehyde diethylacetal grafting and subsequent reaction with dipeptide Lys-Lys. (b) Synthetic scheme of bromoacetaldehyde diethylacetal grafting onto an ammonia plasma-treated PTFE film, subsequent reduction of the diethylacetal into aldehyde functionality, and further conjugation with Lys-Lys. $[NH_2]_0$ was 2.5% and the yield of the reaction of BADEA with the amino groups 57 ± 8%

the reaction was not complete enough to ascertain the grafting. Therefore, to establish whether the BADEA grafting was successful and provided ethylacetal functionality, this functionality was hydrolyzed into the more nucleophilic aldehydic group. The aldehyde moiety provides only three newly bonded atoms to the PTFE surface compared to the plasma-treated analyzed surface. In other words, hydrolysis of the ethylacetal functionality decreases by five the number of atoms as compared to the surface grafted with BADEA before the hydrolysis that is too small to ascertain its presence on the surface. Thus, it was further reacted with the dipeptide Lys-Lys, and immediately the imine group was reduced into a stable amine using sodium cyanoborohydride (Figure 4b). This reaction provides 18 supplementary atoms on the analyzed surface, well enough to confirm its presence and therefore provided indirect solid evidences for the bromoacetaldehyde diethylacetal grafting successfulness. This is confirmed by the atomic percentages obtained at each step of the process and more visually by the XPS spectra of each of these steps (Figure 4a). The oxygen content increases from 3.3% to 4.4% upon hydrolysis of the diethylacetal moieties and finally to 6.4% after conjugation of Lys-Lys to the BADEA-grafted surface. The small increase of the relative atomic oxygen percentage upon hydrolysis of the acetal groups, despite being surprising is normal because the relative oxygen content increases from 25% (two oxygen atoms out of eight atoms total) to 33% (one oxygen atom out of three atoms total).

Grafting of sulfo-succinimidyl-4-(*N*-maleidomethyl)-cyclohexane-1-carboxylate (sulfo-SMCC) on the aminated-PTFE (Figure 5a) was also studied in order to bind the biomolecules through their thiol groups (*41*). It appeared that the reaction between sulfo-SMCC and the amine moieties present at the surface of the PTFE plasma-treated film was very successful, with a quantitative reaction yield, considering the experimental error. The efficacy of the reaction is depicted in Figure 5c: the carbon content increased from 46.1% to 54.5% while the oxygen content increased from 2.2% to 7.9%. Accordingly, the fluorine and nitrogen content decreased from 42.1% and 9.7% to 30.9% and 6.0%, respectively.

The ability of sulfo-succinimidyl-4-(*p*-maleimidophenyl)butyrate (sulfo-SMPB) to react with the amine moieties (Figure 5b) was also tested since, as a cross-linker, it provides the same double bond functionality as S-SMCC with a longer spacer arm, allowing to conjugate a second molecule further apart from the PTFE surface. XPS analyses showed the presence of 0.6% of sulfur (Figure 5d). These sulfur atoms must be originating from the sulfo group of the cross-linker. As aforementioned, sulfur exhibits a low XPS sensibility index and its presence added to an oxygen content superior than expected indicates that a competitive and unexpected reaction takes place. This reaction would allow the SO_3 part of S-SMPB to be grafted or adsorbed on the polymer surface, hence increasing the oxygen and sulfur content. The oxygen atomic percentage reported is therefore widely increased by this unknown reaction that explains the 163% yield calculated according to the oxygen content. Nevertheless the S-SMPB reaction is successful and the double bond function is available for subsequent reactions with for example sulfhydryl containing proteins such as fibronectin, which is known for enhancing cellular adhesion (*45*).

The C1s high-resolution spectra for SMCC and SMPB (Figure 5e) were curve-fitted into four components at 291.1, 288.4, 285.9, and 284.8 eV which were assigned to CF_2 components, $C{=}O$ groups, CN groups, and CH_x, CC, and $C{=}C$ moieties, respectively (*27, 46*). These spectra clearly indicate, either qualitatively and quantitatively, that both SMCC and SMPB are bonded to the PTFE surface. From a qualitative point of view, the relative peak area of the CF_2 components is largely reduced compared to that measured for the plasma-treated surface as the contribution of the other carbon

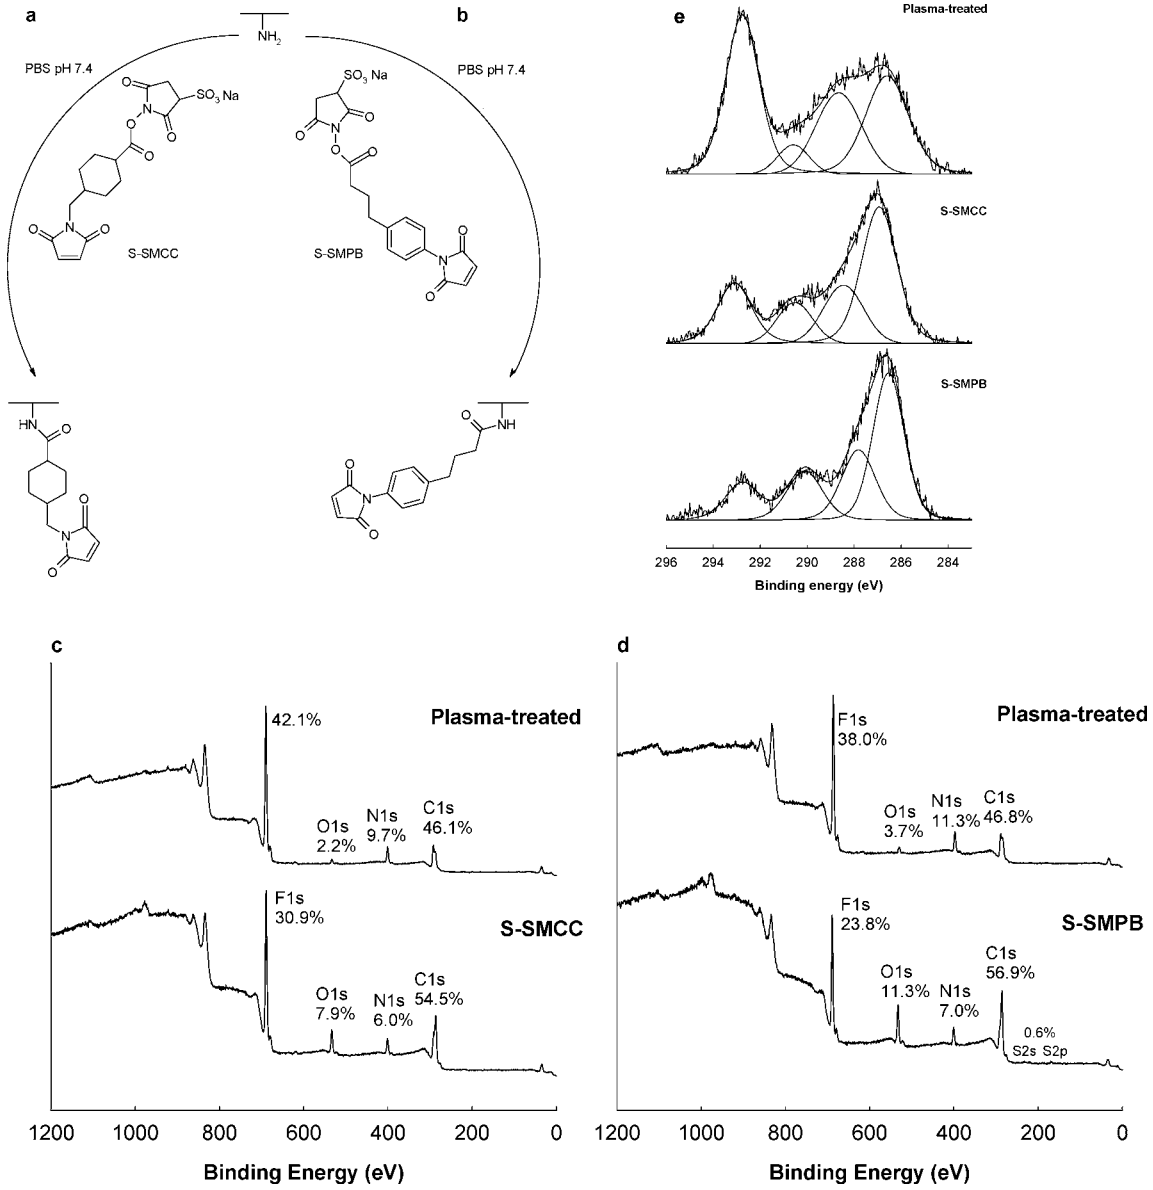

Figure 5. Synthetic schemes for S-SMCC (a) and S-SMPB (b) grafting on an ammonia plasma-treated PTFE film. Spectra for plasma-treated PTFE films and for SMCC- (c) and SMPB- (d) grafted PTFE films. $[NH_2]_0$ was 2.8% for the S-SMCC reaction and 1.9% in the case of S-SMPB grafting reaction. The former reaction presents a yield of 114 ± 25% and the latter reaction 163 ± 20%. C1s high-resolution spectrum (e) for S-SMCC and S-SMPB grafting. Panel e (top to bottom) shows the curve fits of the C1s XPS spectra of the ammonia plasma-treated PTFE surface and S-SMCC and S-SMPB PTFE-grafted surfaces, respectively.

spectral components increases when the cross-linkers are bonded to the surface. Quantitatively, the relative peak area of the curve fittings matches closely with the stoichiometric ratios of the carbon components in the grafted molecules. Moreover, the area of the *C*═O band located at 288.4 eV is useful to calculate the yield of the reactions. In the case of SMCC grafting, the *C*═O component corresponds to 17.0% of the total carbon contribution on the surface. Combining this value with the carbon content of 54.5% measured from the XPS survey spectrum lead to conclude that 9.3% of the atoms on the modified surface are *C*═O groups. As one SMCC-grafted molecule to an amino group provides three carboxylic groups, it means that the initial amino group surface concentration should be one-third of 9.3% that is 3.1%. This simplistic calculation closely matches with the value of 2.8% of amino groups determined through vapor-phase chemical derivatization and leads to a SMCC grafting reaction yield of 111% (3.1/2.8), which is in good agreement with the value of 114 ± 25% presented in Figure 4c. A similar calculation may be performed for the SMPB grafting reaction, as the *C*═O component at 288.4 eV correspond to 18.0% of the 56.9% carbon atom contribution after SMPB grafting. Again, if three *C*═O groups are covalently attached to the surface for every SMPB molecule, there would be 3.4% $[NH_2]_0$ on the plasma-treated PTFE film. For this plasma-treated film, derivatization with 5-bromosalicylaldehyde allowed measurement of an amino group surface concentration of 1.9%, therefore leading to a reaction yield of 179%, in fairly good agreement with the value reported in Figure 5d and therefore confirming the hypothesis of the occurrence of a competitive and unexpected reaction. Nevertheless, as aforementioned, this competitive reaction does not impede further conjugation of other molecules.

Grafting of the 2-iminothiolane was also performed since a successful grafting would provide a thiol functionality on the PTFE-ammonia plasma-treated surface ready to further react with a maleimidyl-containing molecule (*47*) (Figure 6a). Our XPS analysis first revealed

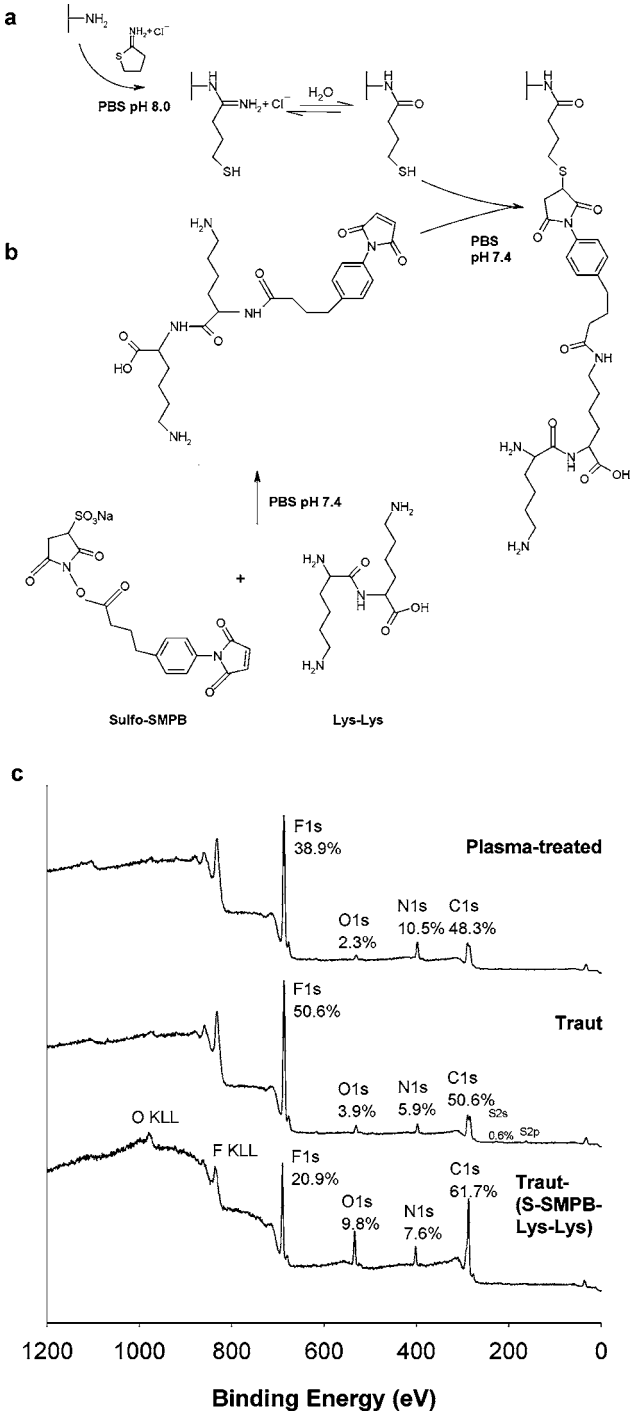

Figure 6. (a) Synthetic scheme of 2-iminothiolane grafting on an ammonia plasma-treated PTFE film and hydrolysis of the $C{=}NH_2^+Cl^-$ into an amide bond. (b) Synthetic scheme of the conjugation of sulfo-SMPB to the dipeptide Lys-Lys and reaction of the succinimidyl moiety of the cross-linker to the thiol function resulting from the reaction of 2-iminothiolane to the aminated-PTFE. (c) Spectra for plasma treated-PTFE film, 2-iminothiolane grafted-PTFE film and 2-iminothiolane-SMPB-Lys-Lys grafted-PTFE film. $[NH_2]_0$ was 2.7%. The yield of the reaction of 2-iminothiolane with the amino groups is 94 ± 12%, and the yield of the conjugation of SMPB-Lys-Lys to the thiol group of 2-iminothiolane is 82 ± 6%

that only 0.6% of sulfur was detected, and since this atom is hardly perceived by XPS spectroscopy, having a very low atomic sensitivity factor of 0.570 (*48*), we proceeded the same way as we did for bromoacetaldehyde diethylacetal to verify the presence of 2-iminothiolane on the plasma-treated PTFE surface. The thiol function was

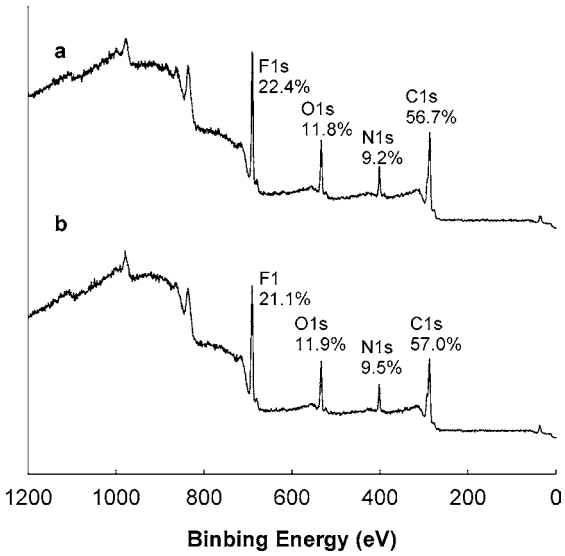

Figure 7. XPS spectra of fibronectin conjugated on ammonia plasma-treated PTFE previously activated with S-SMPB (a) or glutaric anhydride (b).

reacted with the maleimide functionality of sulfo-succinimidyl-4-(*p*-maleimidophenyl)butyrate (sulfo-SMPB) previously conjugated to Lys-Lys (Figure 6b). The increase of the molecular weight of the molecule grafted on the PTFE surface allows ascertaining the successfulness of the Traut reagent conjugation through XPS, as it provides 43 new atoms upon conjugation to the surface. The spectra and the atomic percentages obtained from XPS analyses clearly indicate that the reaction occurred (Figure 6c). 2-Iminothiolane was grafted on the fluoropolymer surface with a yield of reaction estimated to 94% according to the oxygen content, taking into account that the oxygen atom considered in the percentage yield equation comes from hydrolysis of $C{=}NH_2^+Cl^-$ groups into amide moieties. This estimate is also supported by the atomic percentages obtained following the grafting of the 43-atom molecule where again, if this latter reaction is complete, we get a higher than 80% yield for 2-iminothiolane grafting and the subsequent reaction with the dipeptide. The conjugation reaction of 2-iminothiolane to SMPB-lysine-lysine is a two-step reaction, where sulfo-SMPB first reacts with the dipeptide and then reacts with 2-iminothiolane, and both reactions may not be complete. Therefore, it is once more reasonable to assert a 94% yield for the grafting reaction of 2-iminothiolane to the plasma-treated PTFE film.

Grafting Fibronectin on Plasma-Treated PTFE Surfaces: Influence of the Conjugation Strategy on Cell Adhesion. A convincing example of the usefulness of the conjugation strategies and quantification methods presented above is seen through the immobilization of fibronectin on PTFE surfaces. The attachment of this protein on various material surfaces was shown to promote cell attachment and proliferation (*9*). In this context, fibronectin was covalently attached on plasma-treated PTFE samples previously reacted either with glutaric anhydride or S-SMPB. The XPS-spectra (Figure 7) of both surface samples clearly put in evidence that the same amount of protein was grafted with either surface activator, therefore eliminating the possibility of a fibronectin surface concentration effect on the cell adhesion experiments. However, using these surfaces in cell adhesion experiments leads to very different behaviors. As illustrated in Figure 8, a clean PTFE surface does not support cell adhesion. On the other hand, fibronectin

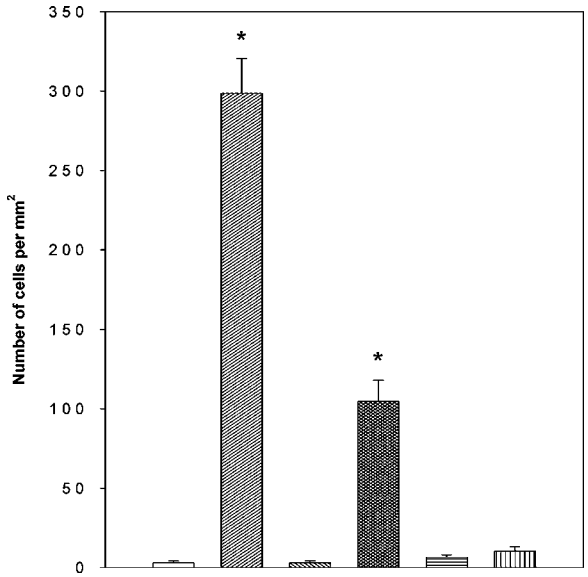

Figure 8. Adhesion of human endothelial vascular cells on a clean PTFE surface (□), in a well coated with fibronectin (right diagonal stripe), on ammonia plasma-treated PTFE conjugated with glutaric anhydride (left diagonal stripe), on fibronectin conjugated on ammonia plasma-treated PTFE through glutaric anhydride (dotted), on ammonia plasma-treated PTFE conjugated with S-SMPB (horizontal stripe), and on fibronectin conjugated on ammonia plasma-treated PTFE through S-SMPB (vertical stripe). (*) indicates a significant difference with respect to the clean PTFE surface with $p < 0.01$ according to Dunnett's test.

conjugated on ammonia plasma-treated PTFE through glutaric anhydride clearly supports cell adhesion, with about one-third of the cells observed for a well coated with fibronectin. In the opposite way, immobilization of fibronectin on ammonia plasma-treated PTFE using S-SMPB as activator gives rise only to slightly more cell adhesion than the clean PTFE surface. This surprising result tends to demonstrate that an inappropriate surface conjugation strategy of fibronectin may lead to conformational changes and/or hiding of biologically relevant protein adhesion sites.

DISCUSSION

Many research groups have focused their efforts for the past decades on modifying polymer surfaces using different types of plasma treatments (*19*, *20*, *28*, *30*, *38*, *49*). However, these treatments require sustained work of characterization over prolonged periods of time in order to determine the most effective plasma treatment conditions for a particular plasma apparatus and a specific polymer. The plasma procedure used in the present study has been the subject of a complete set of characterization while treating PTFE surfaces (*22*, *31*). These previously published data demonstrated that the surface plasma treatments were homogeneous and that it was possible to exert a control over the amine surface concentration through an appropriate selection of experimental parameters such as ammonia gas pressure and flow, treatment time, and radiofrequency power. From these works and considering various parameters intrinsic to the XPS analytical technique (such as the surface elements electron mean free path), it can be concluded that the 2−3.5% amino group relative surface concentration corresponds to about 0.5 to 2 amine every nm^2. This amino surface concentration is by far sufficient to conjugate biological molecules such as proteins, enzymes, or growth factors, considering that the surface plasma modification occurs on the first atomic layers of the polymer surface (*50*). For example, albumin, with a molecular weight of 66 kDa, has an elliptical shape and can cover 12 nm^2 in the best conditions (*51*). It means that one HSA molecule could cover between 6 and 24 amino groups on the PTFE surface, depending on the protein orientation on the surface, therefore showing that the amine surface concentration reached through radiofrequency glow discharge is by far sufficient to allow the grafting of molecules of biological interest.

This study reports a solid proof-of-concept for biotechnological applications of modified polymer-surfaces since only one type of plasma treatment is now required to optimally enable further reaction with chemical reagents and generation of chemical functionalities for biomolecule conjugation. Moreover, it appears that most of the chemical reactions that we have studied are very simple, straightforward, and easily performed using readily available reagents.

Conjugation of molecules onto polymer surfaces is commonly used in various spheres of biotechnology such as biochips and biomaterials fabrication. Most of the time, the developments in these fields are based on the awareness of the biological function and activity of biomolecules and on the assumption that they should preserve their characteristics once conjugated onto surfaces. However, such reasoning does not take into account some important aspects of biomolecule interactions with the surrounding environment. Indeed, the surface concentration of the conjugated biomolecule may play a key role to ensure the proper function of the surface-engineered material. Surface grafting of the vascular endothelial growth factor (VEGF) for improving vascular prostheses self-endothelialization is a good example of this assertion, as one of the characteristics of this molecule regulatory pathway is a cellular down-regulation in response to an excess of the growth factor (*52*, *53*). This issue points toward the fact that the construction of biotechnologically relevant surfaces requires the knowledge and control over the concentration of the linking arms aimed at binding the biomolecules. To our knowledge, the present study is the first to provide quantitative data on the reaction yields and chemical functionality surface concentrations obtained after chemical synthesis on surfaces.

The importance of accurately measuring the surface concentration of chemical moieties on surfaces raises the question of the choice of the surface analytical technique to perform a quantitative characterization. During the course of this study, the potential of other spectroscopic techniques, namely FTIR-ATR and Raman confocal spectroscopies, was also investigated in order to reach our objectives. On one hand, it turned out that FTIR-ATR allowed the measurement of spectral characteristics of the moieties grafted onto the plasma treated PTFE; however, the signal-to-noise ratio was too poor to allow any quantitative analyses. On the other hand, Raman confocal spectroscopy completely failed to provide any data because of the difficulty of precisely focusing the laser beam on the modified layer surface for which the thickness does probably not exceed a few nanometers. In this context, surface derivatization strategies coupled with the surface sensitivity of X-ray photoelectron spectroscopy, that probes about 10 nm in depth, despite being cumbersome, remains one of the best techniques to perform quantitative analyses on surfaces.

The second constraint to overcome upon conjugation of biomolecules onto surfaces is the ability of proteins, enzymes, or nucleic acids to retain their active confor-

mational structure during the surface grafting process. In this context, it is strategically more relevant to perform the first steps of the conjugation protocol on the polymer surface, as these procedures often require the utilization of harsh reaction conditions such as the use of organic solvents, hydrolysis in acidic aqueous solution, or direct contact with chemical reagents. Performing the surface conjugation through the reaction of the biomolecule with the cross-linker as the first step of the reaction may lead (and in fact often lead) to a complete loss of the biomolecule-targeted activity.

In connection with this idea, the various surface conjugation schemes presented in this publication open the way to the possibility of selecting appropriate synthetic pathways for preserving molecules bioactivity. Indeed, the endothelial cell adhesion data presented therein on fibronectin-grafted PTFE surfaces are good examples of the importance of selecting appropriate strategies for grafting biologically active molecules in an attempt to preserve their function. Most of the time, biological molecules are grafted on surfaces without any consideration for the conjugation scheme with the assumption that they will continue to play their biological roles. The Sheardown's group was the first to demonstrate that the surface orientation of cell signaling peptides such as RGD are of prime importance for promoting cell adhesion (*54*). The present publication goes a step further by unambiguously demonstrating that even larger molecules require to be conjugated with appropriate orientation/conformation on surfaces to ensure their biological function.

CONCLUSION

In this study, surface modification strategies for PTFE surfaces were developed to provide various chemical functionalities for further molecule immobilization. In a first step, a radiofrequency glow discharge (RFGD) ammonia plasma treatment was applied to PTFE films to covalently bind amino groups onto their surface. In a second step, various chemical reactions were performed, generating carboxylic acid, thiol, maleimide, ethylacetal, and aldehyde functionalities on the PTFE surfaces. The grafting reactions were carefully controlled at each step by XPS analyses, allowing quantifying the yield of each reaction. Some examples were also provided to confirm the accessibility and the reactivity of these new functional groups used also as a linking arm for relevant proteins, aiming at increasing the compatibility/function of the grafted material.

EDITORIAL: Special Section on Imaging Chemistry

A Symposium on Chemistry and Biological Applications of Imaging Agents and Molecular Beacons, organized by Samuel Achilefu and Darryl Bornhop, was held at the spring 2004 National Meeting of the American Chemical Society. The work presented there inspired a series of reviews and other articles that, along with directly submitted manuscripts, have been collected into a special section on imaging chemistry that appears in this issue of the journal (on pages 1376−1502). A second installment is planned for a later issue.

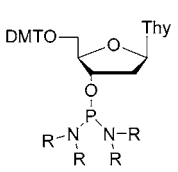
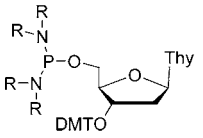
Synthesis of Phosphate-Branched Oligonucleotides

Petri Heinonen* and Harri Lönnberg



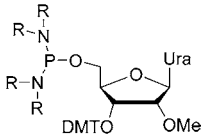
Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received July 1, 2004; Revised Manuscript Received September 16, 2004

A solid-phase synthesis for phosphate-branched oligonucleotides is described. The method is based on coupling of a single nucleoside phosphorodiamidite to terminal hydroxyl functions of two solid-supported oligonucleotides. After oxidation of the phosphite triester obtained to a phosphate triester, the third branch is assembled by conventional phosphoramidite chemistry.



Phosphate-branched nucleic acids have recently received interest for the reason that two small nuclear RNAs (U2 and U6 snRNA) participating in splicing of pre-mRNA have been suggested to form an X-shaped phosphotriester structure by an attack of the 2′-hydroxy group of an adenosine residue of U2 snRNA on an ApG phosphodiester bond of U6 snRNA (*1*). The results obtained by simple ribonucleoside 3′-dialkyl phosphates (*2*−*6*) suggest that such a triester, although susceptible to a facile nucleophilic attack by the neighboring 2′-hydroxy function of the 3′-linked adenosine moiety, may still exist under physiological conditions. For firm conclusions, studies on reactions of oligomeric substrates that more closely mimic the structure of X-shaped RNA are needed. Unfortunately, no methodology for the solid-phase synthesis of phosphate-branched oligonucleotides has been described. The present paper is aimed at partly filling this gap.

Appropriately protected nucleoside phosphorodialkylamidites were introduced in late 1980s as alternative building blocks for the solid-phase synthesis of oligodeoxyribonucleotides (*7*, *8*) and their thioate, (*7*) amidate (*8*), and triester (*7*, *9*) analogues. In addition, they were shown to form 3′,5′-internucleosidic hydrogen-phosphonate (*10*) and phosphorodithioate (*11*) linkages in solution. Since then, phosphorodialkylamidites have rarely found a place in published applications, mainly because of the unfavorable balance between reactivity and hydrolytic stability. These building blocks, however, exhibit one attractive feature. They allow two subsequent couplings and, hence, enable construction of phosphate-branched oligonucleotides. We now report on the use of nucleoside 3′- (**1**) and 5′-phosphorodiamidites (**2**, **3**) as building blocks in solid-phase syntheses of such oligomers.



Phosphorodialkylamidites **1**−**3** may in principle be used in two different ways to obtain phosphate-branched oligonucleotides. Either two solid-supported oligonucleotides are reacted through their terminal hydroxyl functions with a single phosphorodialkylamidite monomer

1a R = Me
1b R = Et
1c R = i-Pr

2 R = Et

3 R = Et

(Reaction A in Scheme 1), or an internucleosidic phosphoramidite linkage of a solid-supported oligonucleotide is converted to a phosphite triester by nucleophilic attack of a monomeric nucleoside hydroxyl function (Reaction B in Scheme 1). The rest of the branches are then assembled, after oxidation of the phosphite triester to a phosphate ester, by conventional phosphoramidite chemistry. As mentioned above, five different nucleoside phoshorodialkylamidite building blocks (**1**−**3**) were prepared, and the coupling reactions indicated in Scheme 1 were studied.

5′-*O*-(4,4′-Dimethoxytrityl)thymidine 3′-*N,N,N′,N′*-tetraethylphosphorodiamidite (**1b**) and its tetraisopropyl analogue (**1c**) were prepared by phosphitylating 5′-*O*-(4,4′-dimethoxytrityl)thymidine with an appropriate bis-(dialkylamino)chlorophosphine, as described previously (*9*, *10*). The corresponding tetramethylphosphorodiamidite (**1a**) was obtained by phosphitylating the same nucleoside with tris(dimethylamino)phosphine, using tetrazole as an activator (*12*, *13*). Formation of **1a** was accompanied by appearance of a ^{31}P NMR resonance at 138.9 ppm**.** The compound was not isolated, but the reaction mixture was used immediately for the solid-phase synthesis. Phosphitylation of 3′-*O*-(4,4′-dimethoxytrityl)thymidine and 3′-*O*-(4,4′-dimethoxytrityl)-2′-*O*-methyluridine with bis(diethylamino)chlorophosphine gave **2** (^{31}P NMR 135.8 ppm) and **3** (^{31}P NMR 133.7 ppm), respectively.

It is essential to note that phosphorodialkylamidites are far more prone to hydrolysis than normal phosphoramidites. The sensitivity to hydrolysis depends on the size of the alkyl group. While chromatographic purification of building block **1a** was impossible, compound **1c** was

[a] According to HPLC. [b] Hypersil ODS column (4 × 15 mm), 50 mmol L^{-1} ammonium acetate to 50% MeCN in 50 mmol L^{-1} ammonium acetate buffer in 30 min. [c] Applied Biosystems Mariner System 5272, ES ionization mode, negative ion polarity.

easy to handle under normal laboratory conditions, and it withstood silica gel column chromatography. In fact, **1a** did not allow reproducible solid-phase synthesis, owing to its extreme hydrolytic instability, although the same compound had successfully been exploited in a related solution-phase synthesis (*12*, *13*). *N*,*N*,*N*′,*N*′-Tetraisopropylphosphorodiamidite (**1c**), in turn, proved to be too unreactive to be used in a solid-phase synthesis of oligonucleotide triesters. Accordingly, main attention was paid to *N*,*N*,*N*′,*N*′-tetraethylphosphordiamidite (**1b**) representing a reasonable compromise between reactivity and hydrolytic stability.

The applicability of ethyl-substituted phosphorodiamidites **1b**, **2**, and **3** was demonstrated by assembling four branched 9-mers (**4**−**7**) on a succinyl linker. Accordingly, T_3 sequences were first assembled in an inverse (5′→3′) direction, and the support was then treated with **1b** or **2** in small portions in excess of tetrazole, which resulted in coupling of a single thymidine phosphorodiamidite to the 3′-hydroxy group of two solid-supported T_3-chains. After oxidation to a phosphate ester, the third branched was assembled by the normal or inverted (5′→3′) phosphoramidite chemistry to obtain **4** and **5**, respectively (Reaction A in Scheme 1). The HPLC chromatograms of the crude reaction mixtures showed that the desired 9-mers had been formed in a 70% (**4**) and 50% (**5**) overall yield (Figure 1, Table 1). A structural analogue of **5** containing dC, dA, and dG in addition to T (**6**) was obtained similarly in a 35% yield. Expectedly, the reaction of a 5′-phosphorodiamidite (**3**) with the 3′-hydroxy function of a solid-supported 2′-*O*-methylribonucleoside was less efficient, but it still allowed preparation of a branched 9-mer (**7**), having an all-ribonucleoside structure at the branching site, in a pure state in more than 20% yield. Both CPG and Tentagel were used as a support. Somewhat surprisingly the support material and a loading on the support had only a marginal effect on the yield of the phosphorotriester product. The phosphotriesters (**4**−**7**) were remarkably stable to the overnight ammonolysis at 55 °C used to cleave the product from the support and to remove the standard benzoyl and isobutyryl protection groups of the base moieties.

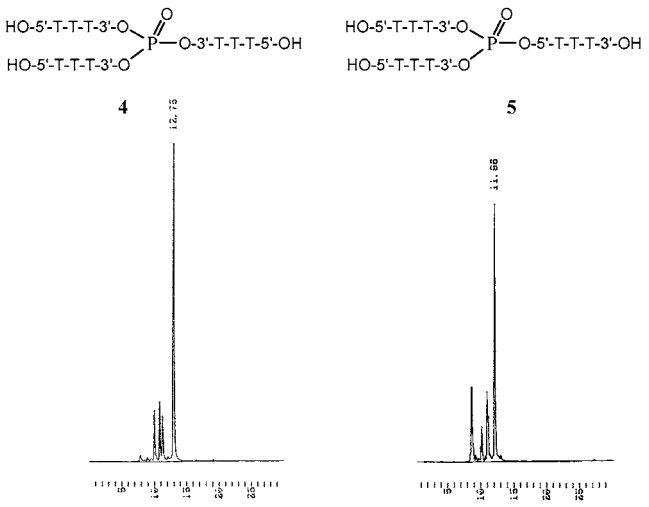

Figure 1. HPLC chromatograms of crude reaction mixtures of phosphate-branched oligonucleotide trimesters obtained by Reaction A in Scheme 1. Hypersil ODS column (4 × 15 mm), 50 mmol L^{-1} ammonium acetate to 50% MeCN in 50 mmol L^{-1} ammonium acetate buffer in 30 min.

Recation B in Scheme 1 represents a more flexible approach to the preparation of phosphate-branched oligonucleotides, since each of the three branches may in principle be elongated independently. Oligonucleotides containing isopropyl triester linkages at selected positions have previously been prepared by displacing the diethylamino ligand of an internucleosidic phosphoramidite linkage with 2-propanol (*9*). Also in our hands the reaction worked; an isopropyl triester was obtained in an 87% yield. Unfortunately, no similar reaction took place on using 3′-*O*-levulinylthymidine as a nucleophile instead of 2-propanol. Accordingly, this approach was not studied in more detail.

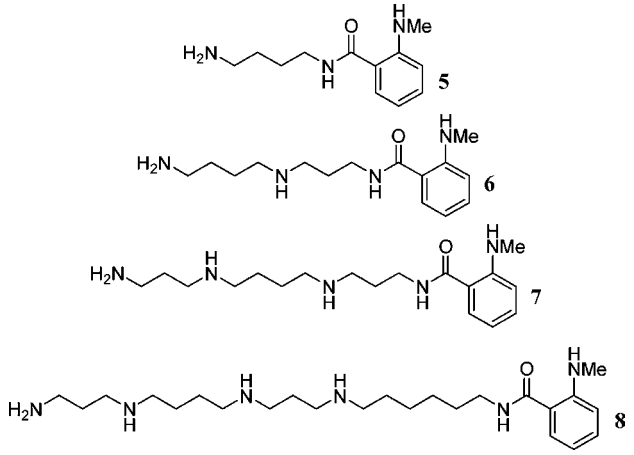
During the asexual cycle of *Plasmodium falciparum* within the host erythrocyte, the parasite induces a stage-dependent elevation in the levels of polyamines by increased metabolism and uptake of extracellular pools. Polyamine amides of *N*-methylanthranilic acid have been synthesized which have embedded within them putrescine, spermidine, or spermine and from a charge perspective mimic natural polyamines. The interaction of these polyamine conjugates with human erythrocytes infected with malaria is described using fluorescent microscopy. The fluorescent spermine mimic was the only probe to show measurable intracellular accumulation. This was observed in late stage development but not in the ring stages or in uninfected erythrocytes.

INTRODUCTION

Putrescine **1**, spermidine **2**, and spermine **3** (Chart 1) are naturally occurring polyamines present in all mammalian cell types and are known to be essential for cell growth (*1*, *2*). Changes in the concentration of intracellular polyamine pools are achieved by regulation of a biosynthetic pathway, a catabolic pathway, and an active transport system (*1*–*4*). Human erythrocytes contain only trace amounts of polyamines and lack the biosynthetic enzymes for their production (*5*, *6*) but are capable of polyamine transport in vitro (*7*). During the asexual cycle of *Plasmodium falciparum*, the parasite induces numerous biochemical, structural, and functional changes in the host erythrocyte. In particular, the parasite induces a stage-dependent elevation in the levels of polyamines by increased metabolism (*5*, 6) and uptake of extracellular pools (*6*, *8*). Polyamine metabolism by *Plasmodium* differs from the metabolism in mammalian cells (*6*). A bifunctional enzyme, ornithine decarboxylase-*S*-adenosylmethionine decarboxylase, has been characterized (*9*), and in the plasmodial resource database, PlasmoDB (http://plasmoDB.org), a putative spermidine synthase (gene PF_0301), has been identified (*10*). The existence of deoxyhypusine synthase and homospermidine synthase has also been established (*11*); these enzymes are involved in spermidine metabolism in *P. falciparum*. The biosynthetic steps for the synthesis of putrescine and spermidine have therefore been identified, but the presence of the enzyme spermine synthase and the ability to synthesize spermine is questionable (*6*), although the parasitized erythrocytes contain appreciable amounts of this polyamine (*5*).

Chart 1. Structures of Putrescine 1, Spermidine 2, Spermine 3, and *N*-Methylanthranilic Acid 4



During the growth of a malarial parasite, the membrane transport characteristics of the host erythrocyte are modified (*6*, *8*, *12*). Increasing evidence suggests that targeting the parasite's polyamine biosynthetic pathway to inhibit growth, while attractive pharmacologically, may be problematic because of an influx of polyamine from extracellular pools (*3*, *5*, *6*, *8*, *12*). This polyamine transport system remains poorly characterized and it is unclear if the parasite is using the endogenous erythrocytic system or a parasite-derived pathway, although a simian putrescine transporter has been reported in *Plasmodium knowlesi*-infected erythrocytes (*8*). The presence of a spermine transport pathway seems likely considering the elevated levels of this polyamine during proliferation (*5*) and the inability of the parasite to synthesize the molecule biosynthetically. The mammalian polyamine transporter appears to tolerate a degree of structural substrate diversity, but it is quite distinct from systems transporting other cellular components, such as amino acids. Generally, the number of charges, the natural polyamine spacing (propylene or butylene), and a nonbranched structure correlate with high affinity for the transporter (*4*, *13*–*16*). Fluorescent polyamine conjugates (*13*, *17*) are promising leads for

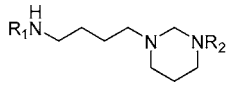
probing and understanding the polyamine transporter for targeted drug delivery.

Herein we report the design and controlled synthesis of fluorescent polyamine amides **6**−**8** (Chart 2) of 2-methylaminobenzoic acid **4** (*N*-methylanthranilic acid or MANT, Chart 1) that mimic both the charge and regiochemical distribution of natural polyamine substrates **1**−**3** (Chart 1). We also report the synthesis of fluorescent conjugate **5** (Chart 2), which contains a single primary amine and can be used along with MANT **4** (Chart 1) as non-polyamine controls. The uptake, via the mammalian polyamine transporter, of conjugates **4**−**8** into a rapidly proliferating leukemic T-cell line is characterized and shown to be consistent with the literature (*13*). Transport of conjugates **4**−**8** into malaria-infected erythrocytes at different stages of maturation is described using fluorescent microscopy.

EXPERIMENTAL PROCEDURES



Materials. Analytical grade reagents were purchased from major suppliers.

Methods. Details of NMR, fluorescent, and mass spectroscopy are supplied as Supporting Information. Chemical analysis data for compounds **4**−**8** are supplied as Supporting Information.

Cell Culture. Jurkat T cells were cultured at a density of 0.2−0.8 million per milliliter in RPMI 1640 media supplemented with 10% fetal bovine serum (FBS) under an atmosphere of 5% CO_2−95% air at a temperature of 37 °C. Intracellular accumulation of MANT conjugates was determined in viable Jurkat cells using a FACS Vantage SE flow cytometer. UV excitation coupled with a 424/44 band-pass detection filter allowed visualization of fluorescence on the FL5 channel. Cells were cultured overnight in the presence of the fluorescent probes (50 μM). Prior to FACS analysis, nonspecific membrane-associated compounds were dissociated by incubation for 2 min in 1 mM free spermine (TFA salt) followed by repeated washing in PBS.

^{3}H-Hypoxanthine Proliferation Assay. The in vitro antimalarial activity of compounds **4**−**8** was evaluated on the growth of ring-stage-synchronized *Plasmodium falciparum* (7G8 strain) malaria cultures[1] by incorporation of ^{3}H-hypoxanthine. Erythrocyte suspensions with ring-stage-synchronized parasites were distributed into 24-well plates at 2% parasitemia and 2% hematocrit and compounds **4**−**8** were added at 1, 10, and 100 μm concentrations in triplicate. The plates were incubated in a candle jar at 37 °C for 24 h. ^{3}H-Hypoxanthine was

Chart 3. Structures of the Intermediates in the Synthesis of Polyamine Amide *N*-Methylanthranilic Acid Conjugates 6

9 R_1 = H R_2 = H
10 R_1 = $COCF_3$ R_2 = H

12 R_1 = H R_2 = MANT

then added to each well at a final activity of 5 μCi/mL. After an additional 24-h incubation period, the cells were harvested onto filters, dried in the oven, transferred to vials with the scintillation fluid, Fluosafe (Fisher Scientific Co., Norcross, GA), and counted on a Beckman LS5000CE scintillation counter.

Fluorescent Microscopy. Fluorescent microscopy was used to visualize the intracellular accumulation of the fluorescent probes **4**−**8** in in vitro *Plasmodium falciparum* (7G8) cultures[1] at 2% hematocrit, 8% parasitemia. Compounds **4**−**8** at 5 μM concentrations were incubated for 17 h and then separated on a Percoll gradient into mature, ring-infected and -uninfected erythrocytes. Cells were fixed with 4% paraformaldehyde and 0.05% glutaraldehyde and air-dried on polylysine-coated slides. The slides were washed in 1 mM unlabeled spermine in PBS (20 min) and PBS (10 min) to remove nonspecifically bound fluorochrome and mounted using Vectashield (Vector Laboratories, Burlingame, CA). Images were then taken using a 100× oil immersion objective with an Olympus IX70 inverted microscope. A 360/40 band-pass excitation filter was used in conjunction with a multipass emission filter which allowed visualization of the 435 nm emission of MANT.

(2-Methylaminobenzoyl)-4-amino-4-aza-butane (5). Putrescine **1** (Chart 1) was selectively N^1-acylated with MANT **4** (Chart 1) (1.0 equiv), mediated by DCC (1.5 equiv) and catalytic 1-hydroxybenzotriazole (HOBt) (0.2 equiv, DCM, 25 °C, 72 h), and purified by RP-HPLC over Supelcosil ABZ+Plus (25 cm × 10 mm, 5 μm) (solvent A: 0.1% TFA in MeCN, solvent B: 0.1% aq TFA, gradient elution, 100% A to 65% A, over 20 min, λ = 340 nm) to afford, after lyophilization, the polytrifluoroacetate salt of polyamine amide **5** (Chart 2, 27%).

(2-Methylaminobenzoyl)-1,8-diamino-4-azaoctane (6). Spermidine **2** (Chart 1) was protected as the hexahydropyrimidine **9** (Chart 3), in quantitative yield, as previously described (*18*). The free primary amino functional group was then orthogonally protected with ethyl trifluoracetate (1.2 equiv, in MeOH, at −78 °C for 1 h and then warmed to room temperature over 1 h) to afford, without purification, the N^1-trifluoroacetamide intermediate **10** (Chart 3). N-Acylation, with MANT **4**

[1] *P. falciparum* strain 7G8 was used in all experiments. Parasites were maintained in cultures of RPMI-1640 medium supplemented with 25 mM HEPES, 23 mM $NaHC0_3$, 10 mM glucose, 10% (v/v) heat-inactivated human plasma (0^+ or A^+), and washed human erythrocytes (A^+) at 2% hematocrit. The growth medium was replaced daily and cultures were gassed with a mixture of 90% N_2, 5% CO_2, and 5% O_2. The morphological characteristics of the parasites and the level of parasitemia were determined by microscopic examination of Giemsa-stained thin blood smears. Alanine lyses erythrocytes infected with the trophozoite stage parasite, leaving intact only erythrocytes with ring-stage parasites. Synchronization to the ring stage was therefore achieved by lysis of cells bearing mature parasites with isoosmotic solution containing 300 mM alanine, 10 mM Tris-HCl, pH 7.4.

(Chart 1) afforded, after purification over silica gel (DCM-MeOH 25:1 to 20:1 v/v), the fully protected acylated spermidine intermediate **11** (Chart 3, 81.6%). The TFA protecting group was then cleaved by stirring in concentrated methanolic ammonia (25 °C, 48 h) to afford, after purification over silica gel (DCM−MeOH−concentrated NH_4OH 50:10:1 to 40:10:1 v/v/v), the hexahydropyrimidine intermediate **12** (Chart 3, 53%). Treatment with malonic acid (3.6 equiv) and pyridine (3.1 equiv, dry MeOH, reflux, 2 h) (*19*), afforded, after purification by RP-HPLC, the polytrifluoroacetate salt of polyamine amide **6** (Chart 2, 60%). This deprotection step resulted in a change of retention time by RP-HPLC from 11.5 (compound **12**) to 7.6 min (compound **6**) (Supelcosil ABZ+Plus, 5 μm, 15 cm × 4.6 mm, solvent A:0.1% TFA in MeCN, solvent B:0.1% aq. TFA, gradient elution 100% A to 65% A over 20 min, 1.5 mL/min, $\lambda = 340$ nm) loss of the required mass by mass spectroscopy and a ^{13}C NMR spectrum consistent with the required unsymmetrical polyamine amide (*20*).

(2-Methylaminobenzoyl)-1,12-diamino-4,9-diazadodecane (7). N^1,N^2,N^3-Tri-*tert*-Boc-spermine was synthesized as previously described (*21*). N-Acylation with MANT **4** afforded, after purification over silica gel (petroleum ether−EtOAc 80:20 to 50:50 v/v), the Boc-protected acylated spermine intermediate (74%). Deprotection with TFA (50:50 TFA-DCM v/v, 25 °C, 2 h) gave, after RP-HPLC purification and lyophilization, the polytrifluoroacetate salt of polyamine amide **7** (Chart 2, 65%).

(2-Methylaminobenzoyl)-1,16-diamino-4,8,13-triazahexadecane (8). Incorporation of an intact spermine moiety was achieved using a previously described spermine desymmetrization protocol (*22*) by reductive alkylation of N^1,N^2,N^3-tri-*tert*-Boc-spermine with 6-benzyloxycarbonylaminohexanal to afford (N^1,N^4,N^9,N^{13}-tetra-*tert*-Boc)-1,19-diamino-4,9,13-triazanonadecane. N-Acylation (88%), poly-Boc deprotection, RP-HPLC purification, and lyophilization afforded the polytrifluoroacetate salt of polyamine amide **8** (Chart 2, 65%). The pK_as of polyamines are a function of the interamine distance as well as their substituents (*18*), so a six-carbon spacer rather than the previously described three-carbon spacer was introduced using aminohexanal.

RESULTS

Polyamine amides **5**−**8** (Chart 2) are homogeneous by RP-HPLC and have been characterized by electrospray MS, ^1H, ^{13}C, and HETCOR NMR, and the polyamine substituents were consistent with previously published spectroscopic data of polyamine amides and carbamates (*21*, *22*). The flow cytometry data are shown in Figure 1 and indicate that compounds **6**−**8** (Chart 2) are all sequestered into viable Jurkat cells. The population shift indicates that approximately 95% of all cells within each population are actively accumulating the fluorescent polyamine analogues. In accord with these data, we have shown that the remaining 5% of the cell population is accounted for by dying cells, as determined by propidium iodide uptake using flow cytometery (data not shown). As approximately 100% of live cells were shown to actively sequester the polyamine analogues, we have used the measure of mean fluorescence intensity (MFI) to give a quantifiable comparison of the degree of uptake of each of the test compounds. These data, Table 1, show that the dicationic putrescine mimic, compound **6**, is the most highly sequestered (MFI 372.26), followed by the spermine mimic, compound **8** (MFI 359.69) and then to a lesser degree the spermidine mimic, compound **7** (MFI 204.65). According to flow cytometery, accumulation of

the monocationic amine **5** and unconjugated MANT **4** is at background levels. These data are consistent with our results obtained with fluorescence microscopy and fluorimetric analysis of cell lysates (see Supporting Information). Fluorimetry was also used to show that uptake of conjugate **6** was energy-, time-, and concentration-dependent and was competitive with the natural substrates (see Supporting Information). The indication of an active transport system, rather than passive diffusion across a lipid membrane (*4*), correlates with literature reports of polyamine−MANT conjugates using the polyamine transport pathway (*13*).

The in vitro antimalarial activity of compounds **4**−**8** was evaluated on the growth of ring-stage-synchronized *Plasmodium falciparum* (7G8 strain) malaria cultures[1] by incorporation of ^3H-hypoxanthine. Figure 2 shows that none of the compounds had antimalarial activity, and microscopic examination of Giemsa-stained, thin blood smears showed normal morphological characteristics of

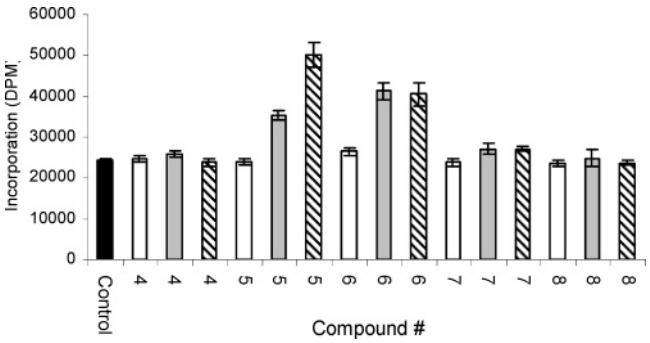

Figure 2. In vitro incorporation of ^3H-hypoxanthine into ring-stage synchronized *Plasmodium falciparum* (7G8 strain) for compounds **4**−**8**: (open) 1 μM, (grey) 10 μM, (hashed) 100 μM as compared to control (black).

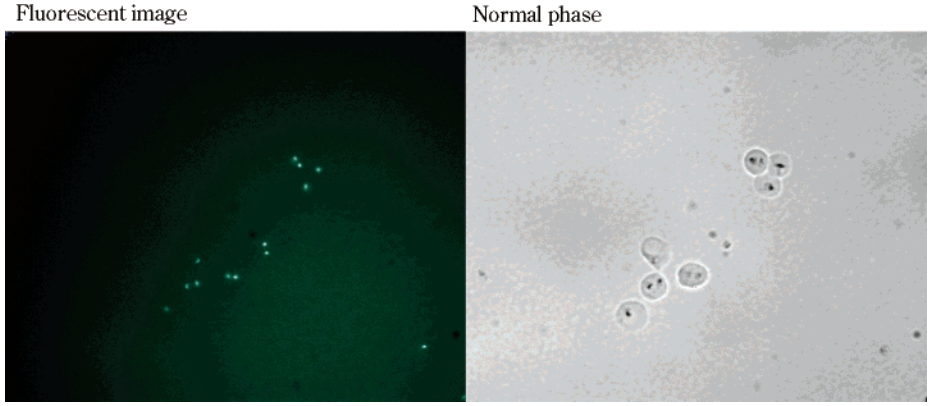

Figure 3. Uptake of polyamine MANT conjugate **8** by intraerythrocytic *P. falciparum* trophozoites as visualized by fluorescent microscopy.

the parasites (data not shown). Thus, these fluorescent polyamine conjugates do not interfere with the normal metabolic function of the malaria parasite within the host erythrocyte and are therefore ideal probes.

Fluorescence microscopy was then used to visualize the intracellular accumulation of the fluorescent probes. Compounds **4**−**7** showed no intracellular accumulation at any of the stages of development of the parasite. However, using fluorescent microscopy, the spermine mimic **8** showed intracellular accumulation in late stage development but not in the ring stages or in uninfected erythrocytes. Figure 3 (right panel) shows the normal phase photograph of trophozoite-infected erythrocytes. The parasites are unstained but the hemozoin within the food vacuole can be seen. The fluorescent image (Figure 3, left panel) shows accumulation of the probe within the cytoplasm of the parasite, which is colocalized with the hemozoin.

DISCUSSION

Previously, the uptake of polyamine-*N*-methylanthranilic acid conjugates into mammalian cells via the polyamine transporter has been characterized (*13*). The MANT fluorophore shows λ_{max} 250 nm (ϵ 5400) and 333 nm (ϵ 2100) and an emission frequency of 436 nm (excitation 341 nm) and is unlikely to perturb the interactions and subsequent distribution of the polyamine analogue (*13*). We have synthesized polyamine amide conjugates that have embedded within them putrescine, spermidine, or spermine, and from a charge perspective mimic the natural polyamines. We have characterized their uptake into a human leukemic T-cell line (rapidly proliferating, metabolically active leukemia of lymphoid origin) and shown them to be consistent with literature reports of uptake via the polyamine transporter for MANT conjugates (*13*). Fluorescence microscopy studies with malaria infected erythrocytes showed only measurable accumulation of the spermine mimic (**8**). Malaria parasites are capable of synthesizing spermidine and putrescine (*5*, *6*, *8*, *9*), but it is questionable whether they are capable of synthesizing spermine (*6*). This fluorescent probe, from a charge perspective, is a mimic of spermine, and we speculate that its accumulation is via the polyamine transporter, although more extensive studies will be required to confirm this. These fluorescent probes will find considerable use in the evaluation of this transport system in malaria for targeted drug therapy.

ACKNOWLEDGMENT

We thank Dr. Simon Carrington (University of Bradford, U.K.) for some useful synthetic discussions. Studies were supported by NIH 1RO1AI051306 (R.B.), RO1AI44857-04 (V.R.G.), UH1-HL03679-05 from National Heart, Lung and Blood Institute, the Office of Research on Minority Health, and by the Howard University General Clinical Research Center Grant M01-RR10284.

Cytosolic Delivery of Macromolecules. 3. Synthesis and Characterization of Acid-Sensitive Bis-Detergents

Aravind Asokan and Moo J. Cho*

Division of Drug Delivery & Disposition, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599. Received May 20, 2004; Revised Manuscript Received August 9, 2004

A serious limitation that precludes utilization of single-tailed, pH-sensitive detergents for the cytosolic delivery of macromolecules is their low limit of incorporation in stable liposomal formulations. To address this issue, we have prepared two Gemini surfactants or 'bis-detergents' by cross-linking the headgroups of single-tailed, tertiary amine detergents through oxyethylene (**BD1**) or acid-labile acetal (**BD2**) moieties. The membrane-bound pK_a of the twin tertiary amine headgroups was determined to be 6.37 ± 0.36 using a fluorescence-based assay. As evidenced by thin-layer chromatography, **BD2** was hydrolyzed under acidic conditions (pH 5.0) with an approximate half-life of 3 h at 37 °C, while **BD1** remained stable. Low pH-induced collapse of liposomes containing acid-labile **BD2** into micelles was more facile than that of **BD1**. With **BD1**, the process appeared to be reversible in that aggregation of micelles was observed at basic pH. The irreversible lamellar-to-micellar transition observed with **BD2**-containing liposomes can possibly be attributed to acid-catalyzed hydrolysis of the acetal cross-linker, which generates two detergent monomers within the bilayer. Liposomes composed of 75 mol % bis-detergent and 25 mol % phosphatidylcholine were readily prepared and could entrap macromolecules such as polyanionic dextran of MW 40 kDa with moderate efficiency. The ability of **BD2**-containing liposomes to promote efficient cytosolic delivery of antisense oligonucleotides was confirmed by (a) their diffuse intracellular distribution seen in fluorescence micrographs, and (b) the up-regulation of luciferase in an antisense functional assay. The low pH-responsive, bis-detergent constructs described herein are suitable for triggered release strategies targeted to acidic intracellular or interstitial environments.

INTRODUCTION

Lipid-based drug carriers often promote membrane fusion or permeabilization by virtue of their inherent bilayer-perturbing conformations. As a result, incorporation of sufficient concentrations of such lipids in stable liposomal formulations poses a formidable challenge. For example, the utility of fusogenic lipids such as dioleoylphosphatidylethanolamine (DOPE) that preferentially adopt the hexagonal phase has been compromised by their low limit of incorporation into liposomal bilayers (*1*−*3*). To address this issue, Guo and Szoka (*4*) have devised an acid-cleavable ortho ester−poly(ethylene glycol) (PEG) conjugate of distearoyl glycerol. The PEGylated lipid not only serves to stabilize DOPE in bilayer vesicles, but also prolongs circulation half-life of the liposomal formulation in vivo. Cleavage of PEG in an acidic environment promotes lamellar-to-hexagonal transition of the liposomal formulation, which in turn results in release of contents and membrane fusion.

A similar problem pertaining to liposomal incorporation of micelle-favoring, pH-sensitive detergents remains unsolved (*5*). Liposomes containing detergent-to-phospholipid ratios greater than 1:3 are inherently unstable (*6*, *7*). Stabilization of such formulations with bilayer-favoring lipids such as cholesterol is counterproductive, in that it compromises their delivery potential (*5*, *8*). As a result, concentrations of pH-sensitive detergents required to promote efficient liposomal collapse and permeabilization of the endosomal membrane remain unattainably high (*9*).

A chemical solution to this problem is to mask the membrane-disrupting ability of such detergents by conjugating a second lipid tail to the detergent headgroup (*10*) or cross-linking two single-tailed detergents with a cleavable moiety (*11*). Unlike conventional detergents, the latter bis-detergents (BD) or Gemini surfactants tend to behave more like phospholipids than surfactants (*12*). Hence, while single-chain detergents tend to adopt micellar structures, bis-detergents due to their cylindrical shape can be incorporated with relative ease in vesicle bilayers (*11*, *13*). More importantly, such constructs allow for in situ generation of single-tailed detergents within stable bilayers upon exposure to specific stimuli, acidic pH in the present case.

On the basis of the above rationale, we have developed a two-step strategy for the cytosolic delivery of macromolecules using cleavable detergent dimers that possess an acid-labile acetal linker between their polar headgroups (Figure 1). Ortho ester, acetal, and vinyl ether groups are stable under neutral conditions but hydrolyze rapidly at acidic pH due to stabilization of the intermedi-

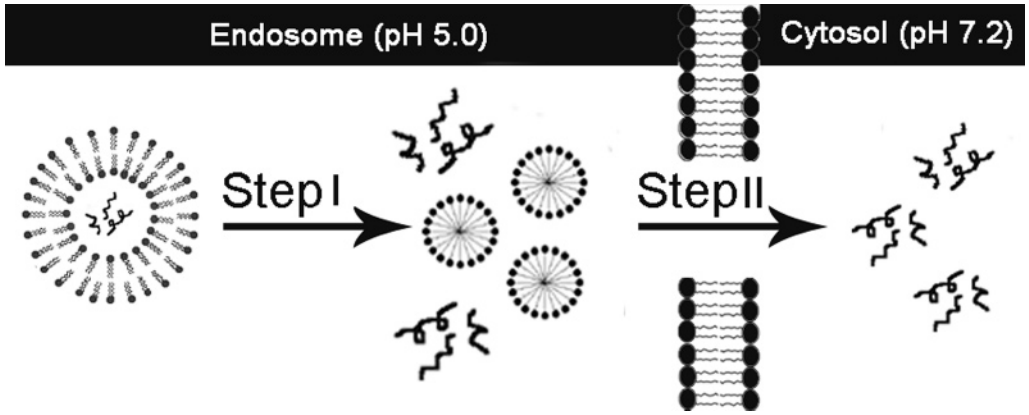

Figure 1. Two-step strategy for cytosolic delivery of macromolecules utilizing liposomes containing acid-labile bis-detergents such as **BD2** in Scheme 1. The proposed two-step mechanism of action is as follows: In Step I, acid-catalyzed hydrolysis of the acetone acetal cross-linker in the bis-detergent within the endosome is expected to generate single-tailed detergents within the liposomal bilayer. Upon reaching a critical concentration, these tertiary amine detergents would promote liposomal collapse into micelles and triggered release of entrapped contents. In Step II, the detergent-containing micelles are expected to form stable or transient pores in the endosomal membrane, which in turn will facilitate cytosolic delivery of initially entrapped contents.

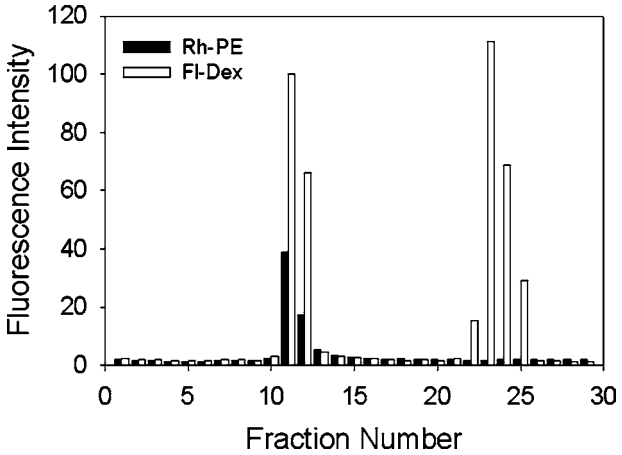

Figure 2. Size exclusion chromatography of **BD1**-containing liposomes encapsulating fluorescein-labeled, polyanionic dextran (MW 40 kDa) using a Sephadex CL-6B column. Rhodamine-labeled liposomes coelute with dextran in fractions no. 11 and 12 confirming entrapment. Later fractions (no. 22−25) contained unentrapped dextran.

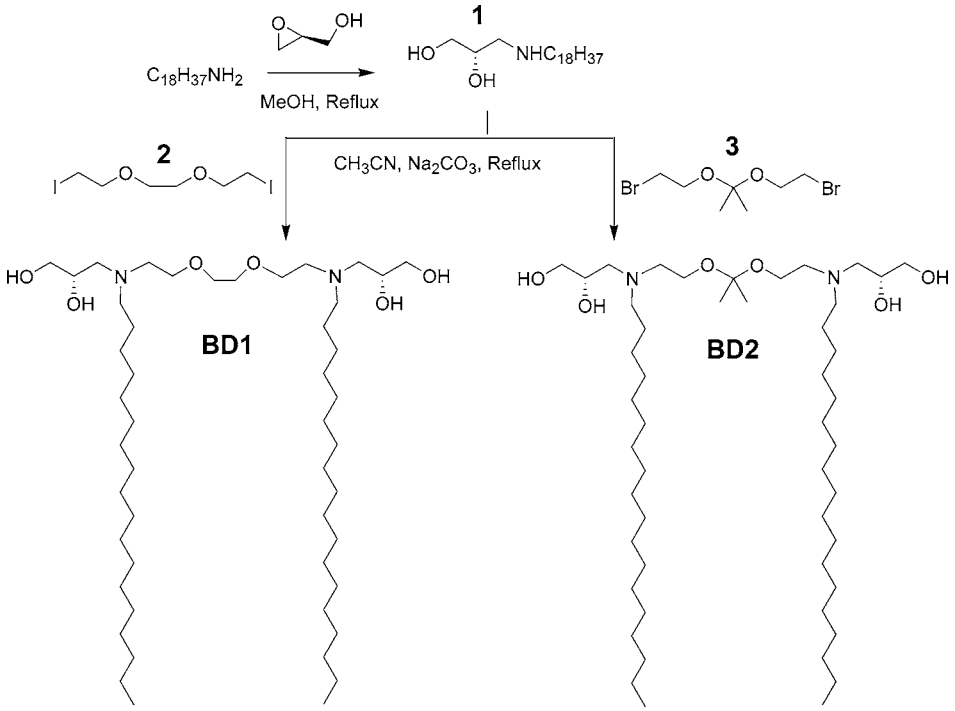
ate carbonium ion by electron-donating groups (*14*, *15*). In the current study, as an example of cleavable and noncleavable bis-detergents, we report the synthesis and characterization of **BD1** and **BD2**, respectively (Figure 2). We demonstrate the ability of such agents to promote vesicle-to-micelle transition under acidic conditions and facilitate the endosome-to-cytosol translocation of macromolecules.

EXPERIMENTAL PROCEDURES



Lipids and Chemicals. All chemicals and solvents were purchased from Aldrich (Milwaukee, WI) and used without further purification. Glass thin-layer chromatography (TLC) plates were also purchased from Aldrich. Egg phosphatidylcholine (PC), cholesterol, and 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (Rh-PE) were obtained from Avanti Polar Lipids (Alabaster, AL). Triton X-100 and *p*-toluidinyl naphthalene sulfonic acid (TNS) was obtained from Sigma (St. Louis, MO). Fluorescein-labeled, polyanionic dextran of MW 40 kDa (Fl-Dex) was purchased from Molecular Probes (Eugene, OR). Antisense 18-mer oligonucleotides (5′-CCU CUU ACC UCA GUU ACA-3′, ON-705) with 2′-*O*-Me phosphorothioate backbones were prepared by The Midland Certified Reagent Company, Inc. (Midland, TX). An unrelated sequence of Texas red-labeled oligonucleotides (TR-ON) was a generous gift from Professor Ryszard Kole (Lineberger Cancer Center, UNC-CH).

Synthesis of Bis-Detergents. The overall synthetic scheme is shown in Scheme 1. Compound **1** was synthesized by reacting (*S*)-glycidol with octadecylamine (*16*). Briefly, 3 g of octadecylamine (12 mmol) was dissolved using a heat gun in anhydrous methanol (5 mL) and transferred to a round-bottomed flask (round-bottom flask, 25 mL) fitted with a reflux condenser. A solution of (*S*)-glycidol (280 mg, 3 mmol) in 5 mL of methanol was then added dropwise to the round-bottom flask with continuous stirring and heat (60 °C). Reaction progress was monitored using TLC, and solvents were removed under vacuum after 1 h. The white residue was dissolved in hexane (50 mL) using a heat gun and allowed to cool, upon which a white precipitate (**1**) was formed. This process was repeated several times, following which the white precipitate was filtered and redissolved in 1 mL of $CHCl_3$:MeOH:aq NH_4OH (80:18:2). The clear solution was loaded onto a silica gel column (115 g) and purified using the same eluent system ($R_f \sim 0.4$). Pure compound **1** was obtained at ~60% yield (600 mg).

Compound **2** was purchased from Aldrich, while compound **3** was prepared by the method of Lorette and Howard (*17*). Briefly, a mixture of 2-bromoethanol (0.6 mol, 75 g), 2,2-dimethoxypropane (0.25 mol, 26 g), benzene (100 mL), and *p*-toluenesulfonic acid (0.2 g) were added into a 500 mL round-bottom flask connected to a fractional distillation apparatus fitted with a vacuum pump. The reaction mixture was distilled until the benzene−methanol azeotrope (~100 mL) boiling between 57 and 60 °C was completely removed. The contents were then cooled below the boiling temperature, and a solution of 0.5 g of sodium methoxide in 20 mL of methanol was added with stirring to achieve nearly instantaneous neutralization of acid. Distillation was resumed under vacuum (7 mmHg) upon which three fractions were collected: 28−30 °C (50 mL, fraction I); 65−75 °C (10 mL, fraction II); and 75−80 °C (2 mL, III). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.39 (s, 6H), 3.45 (t, 4H), and 3.8 (t, 4H) confirmed pure symmetric acetone acetal (**3**) in fraction III.

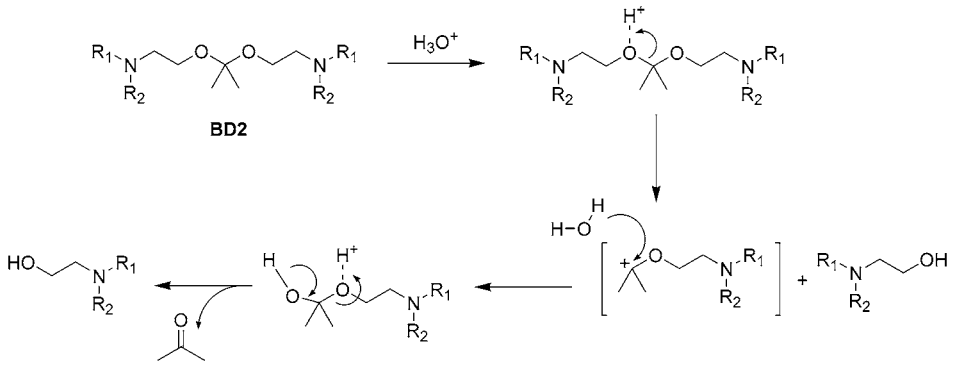
Bis-detergent **BD1** was prepared by subjecting a mixture of compounds **1** (200 mg, 0.6 mmol), **2** (37 mg,

Scheme 1. Synthetic Scheme for Preparation of Bis-Detergents BD1 and BD2

0.1 mmol), and Na_2CO_3 (100 mg) in 20 mL of CH_3CN to reflux overnight. The solvents were then removed under high vacuum, and the residue was resuspended in $CHCl_3$ and filtered using a sintered glass funnel. The concentrated filtrate was then loaded onto a silica gel column (115 g) and eluted using $CHCl_3$:MeOH:aq NH_4OH (80:18:2, $R_f \sim 0.6$). Compound **BD1** was obtained in good yield (65 mg, ~80%). ^1H NMR ($CDCl_3$, 300 MHz, chemical shifts relative to TMS signal): δ 0.88 (t, 6H), 1.25 (br, 60H), 1.48 (br, 4H), 2.6−2.77 (m, 10H), 2.87−2.94 (m, 2H), 3.27 (br, 4H), and 3.49−3.84 (m, 14H), respectively. ESI-MS, calculated 801.76, found $[M + Na]^+$ 824.7 (22%), 750.1 (72%), and 454.5 (6%).

Bis-detergent **BD2** was prepared in a similar fashion by subjecting a mixture of compounds **1** (335 mg, 1 mmol), **3** (70 mg, 0.2 mmol), and Na_2CO_3 (500 mg) in 20 mL of CH_3CN to reflux overnight. A total of 72 mg (~60% yield) of compound **BD2** was obtained after silica gel chromatography using $CHCl_3$:MeOH:aq NH_4-OH (80:18:2, $R_f \sim 0.6$). ^1H NMR ($CDCl_3$, 300 MHz, chemical shifts relative to TMS signal): δ 0.88 (t, 6H), 1.25 (br, 60H), 1.38 (d, 6H), 1.45 (br, 4H), 2.5−2.8 (m, 10H), 2.85−2.95 (m, 2H), 3.45−3.53 (m, 10H), and 3.7−3.76 (m, 4H), respectively. ESI-MS, calculated 814.76, found $[M + Na]^+$ 837.7 (12.5%), 763.7 (1%), 450.4 (37.5%), and 410.3 (49%).

Preparation of Liposomes. Blank liposomes were prepared by generating a thin dry film composed of 7.5 mg of bis-detergent and 2.5 mg of PC in a 10 mL round-bottom flask by removing $CHCl_3$ in vacuo. The film was hydrated using 1 mL of Tris-buffered saline (TBS, pH 8.0) or phosphate-buffered saline (PBS, pH 7.0) and alternatively vortexed and sonicated for 15 min. Vesicles were then extruded 10 times through a 0.22 μm polycarbonate membrane (Millipore) using an extruder (Lipex Biomembranes, Vancouver, CA). The size of vesicles formed was determined using a Nicomp 370 particle sizer (Particle Sizing Systems, CA).



All macromolecules (fluorescently labeled or otherwise) were entrapped within liposomes using the minimum volume entrapment method (*18*). Briefly, a thin dry lipid film containing **BD1** or **BD2** with PC (75:25), generated by removing chloroform under high vacuum, was hydrated with a 100 μL aliquot of TBS or PBS containing a high concentration of oligonucleotides (50 μM) or Fl-Dex (10 μM), respectively, and vortexed at room temperature for 15 min. Vesicles formed were diluted to 1 mL with corresponding buffer and extruded (Lipex Biomembranes) 10 times through a 0.22 μm polycarbonate filter (Millipore) at a pressure of approximately 400 psi.

Finally, unencapsulated solutes were separated from liposomal fractions by elution with TBS/PBS through Sepharose CL-6B (Sigma) or DEAE-Sepharose fast flow anion exchange (Pharmacia) resins packed in a 20 cm × 1 cm glass column. Liposomal fractions were identified by monitoring coelution of Rh-PE as a lipid marker and Fl-Dex (MW 40 kDa) as a fluid-phase marker, respectively. Encapsulation efficiency was determined by dissolving a 10 μL aliquot of liposomes in 100 μL of 2-propanol, diluting to 1 mL with PBS, and measuring the fluorescence intensity/absorbance of the sample. Final concentrations were calculated using the extinction coefficient of oligonucleotides or from a standard curve generated with known concentrations of Fl-Dex.

Membrane-Bound pK_a and Acid-Catalyzed Hydrolysis of Bis-Detergents. Membrane-bound pK_a value of **BD1** (10 mol %) incorporated into PC:cholesterol (70:20) liposomes was determined using TNS (*19*). Acid-catalyzed hydrolysis of the acetone acetal cross-linker in **BD2**, which generates two, single-tailed lysosomotropic detergents and acetone (Scheme 2) was monitored by thin-layer chromatography. Briefly, 2 μL aliquots of **BD2**:PC (75:25) liposomes suspended in low ionic strength buffers of pH 4.0, 5.0, 6.0, and 7.0 were spotted at different time intervals onto silica gel TLC plates and eluted with $CHCl_3$:MeOH:aq NH_4OH (80:18:2). Spots corresponding to **BD2** ($R_f \sim 0.6$) and single-tailed, tertiary amine detergent monomers ($R_f \sim 0.3$) were identified using ninhydrin.

UV Light Scattering. Acid-induced collapse of **BD1**- or **BD2**-containing liposomes into micelles was monitored for approximately 10 min using a Shimadzu Model

Scheme 2. Mechanism of Specific Acid-Catalyzed Hydrolysis of Bis-Detergent BD2 into Tertiary Amine Detergent Monomers and Acetone. The Formation of Stabilized Carbonium Ion Intermediate Is Thought To Be Rate-Determining (*15*)

UV2401-PC UV/Vis spectrophotometer. Briefly, a 30 μL aliquot of blank liposomes containing BD:PC (75:25) was suspended in 3 mL of Tris-buffered saline (pH 8.0) taken in a quartz cuvette and the decrease in absorbance (turbidity) monitored under different conditions at a wavelength of 350 nm. The buffer was acidified or alkalinized by quickly injecting a 10 μL aliquot of acetic acid or 10 μL aliquots of aq NH_4OH into the cuvette. A 100 μL aliquot of 0.1% Triton X-100 injected at the end of the experiment served as positive control.

Cytosolic Delivery of Antisense Oligonucleotides. For fluorescence microscopy experiments, HeLa Luc-705 cells obtained from Professor Ryszard Kole's lab (Lineberger Cancer Center, UNC-CH) were cultured in two-well glass culture slides (2×10^5/well) using Dulbecco's modified eagle's medium (DMEM-H, Gibco), 10% fetal bovine serum, 100 units/mL penicillin, and 100 μg/mL streptomycin under 5% CO_2 humidified atmosphere at 37 °C. The cells were incubated for a period of 6 h with serum-free DMEM-H containing TR-ON (0.1 μM) in (a) free solution, (b) complexed with Lipofectamine (GIBCO, manufacturer specifications), (c) entrapped in **BD1**:PC (75:25) liposomes, or (d) entrapped in **BD2**:PC (75:25) liposomes. The formulations were replaced with serum-containing media and incubated for a further 18 h after which the slides were washed thrice with cold phosphate-buffered saline (PBS) and fixed using 2% paraformaldehyde in PBS. Cells were then examined immediately under a Leica Diaplan fluorescence microscope (25× magnification) equipped with a Texas red filter and a Hamamatsu camera.

For the antisense functional assay (*20*), HeLa Luc-705 cells were seeded in 12-well plates at 10^5 cells per well in DMEM-H containing 10% fetal bovine serum, 100 units/mL penicillin, and 100 μg/mL streptomycin and allowed to adhere overnight in a 5% CO_2 humidified atmosphere at 37 °C. The cells were incubated for a period of 6 h with serum-free DMEM-H containing ON-705 (0.1 μM) in (a) free solution, (b) complexed with Lipofectamine (manufacturer specifications), (c) entrapped in **BD1**:PC (75:25) liposomes, or (d) entrapped in **BD2**:PC (75:25) liposomes. In a separate experiment, Hela Luc-705 cells were incubated with **BD1**:PC or **BD2**:PC liposomes containing ON-705 under similar conditions, but in serum-containing media to reduce apparent toxicity associated with such formulations. All formulations were then replaced with serum-containing media and incubated for a further 18 h after which the wells were washed thrice with Hank's balanced salt solution (HBSS) without calcium/magnesium ions.

An aliquot of 200 μL of cell lysis buffer (BD Pharmingen, San Diego, CA) was then added to each well, and the cells were dislodged using a cell scraper (Costar, Corning, NY), following which the plates were incubated for 15 min at room temperature. The cell lysates were quickly spun down using a microcentrifuge to remove cell debris and a small aliquot used from each for determining protein content using the Bradford assay. Luminescence measurements were performed in a luminometer (Analytical Luminescence Laboratory, Ann Arbor, MI) using a Luciferase assay kit (BD Pharmingen, manufacturer specifications). Luciferase expression was expressed in relative light units (RLU) per μg of cellular protein.

RESULTS

Entrapment of Macromolecules by Bis-Detergent-Containing Liposomes. Liposomes containing **BD1**:PC:Rh-PE (75:24:1) were used to entrap Fl-Dex of MW 40 kDa in PBS (pH 7.0) using the minimum volume entrapment procedure. Following extrusion, liposomes and unentrapped solute were separated by size exclusion chromatography with PBS as eluent. The coelution of rhodamine-labeled liposomes ($\lambda_{ex} = 530$ nm; $\lambda_{em} = 590$ nm) with Fl-Dex ($\lambda_{ex} = 490$ nm; $\lambda_{em} = 515$ nm) in fractions no. 11 and no. 12 seen in Figure 2 indicates successful encapsulation. Un-entrapped Fl-Dex elutes in later fractions (no. 22−25). The average size of purified liposomes was 238 ± 69 nm with ~40% encapsulation efficiency. Liposomes containing **BD1** or **BD2** with PC (75:25) entrapping oligonucleotides were prepared in a similar fashion and separated from unentrapped oligonucleotides by ion exchange chromatography. Encapsulation efficiencies of polyanionic oligonucleotides (~6 kDa) and dextran (40 kDa) in BD-containing liposomes ranged from ~10% in TBS to 40% in PBS.

Membrane-Bound pK_a of BD1 Incorporated into Liposomal Bilayers. The membrane-bound pK_a of **BD1** was determined using the TNS assay. Briefly, increasing membrane potential of **BD1**-containing liposomes with decreasing pH results in increased partitioning and intensity of TNS in liposomal bilayers. No pH-dependent change in membrane potential is seen with liposomes lacking **BD1**. As determined from Figure 3, the twin, tertiary amine headgroups have an average pK_a of 6.37 ± 0.36.

Acid-Catalyzed Hydrolysis of BD2 Embedded in Liposomes. To quickly estimate the sensitivity of the acetone acetal in **BD2** toward acidic conditions relevant to an endosomal/lysosomal setting, a simple TLC assay was used. Briefly, ninhydrin was used to detect products of **BD2** hydrolysis, i.e., detergent monomers upon incubation for different time intervals at 37 °C in buffers of

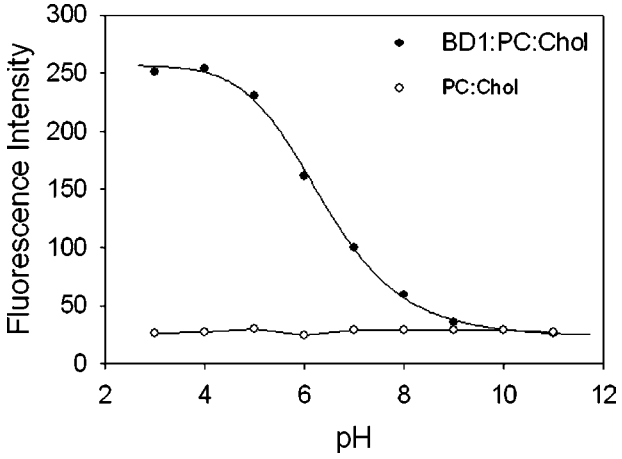


Figure 3. Membrane-bound pK_a of **BD1** determined using the TNS assay described previously. Liposomes containing PC/Chol with 10 mol % **BD1** (●) and without **BD1** (○) served as test and control, respectively. A pK_a of 6.37 ± 0.36 was obtained from triplicate experiments with **BD1**-containing liposomes.

different pH. As shown in Figure 4, **BD2** appears stable at 10 min in all buffers as indicated by the single spot at $R_f \sim 0.6$. However, after an hour, detergent monomers are detectable at pH 4.0 and 5.0 ($R_f \sim 0.3$), but not at pH 6.0 or 7.0. After 3 h, substantial hydrolysis of **BD2** is seen in pH 4.0 buffer and about 50% of starting material is hydrolyzed at pH 5.0. Detergent monomers are also detectable at pH 6.0, but not at pH 7.0. Finally, after 6 h, the detergent dimers are almost completely hydrolyzed at pH 4.0, but still remain intact at pH 7.0. Thus, **BD2** appears to degrade with a $t_{1/2}$ of ~3 h at pH 5.0 at 37 °C.

Low pH-Induced Collapse of BD-Containing Liposomes into Micelles. Liposomal formulations containing 75 mol % of **BD1** or **BD2** were characterized at 37 °C for changes in turbidity by monitoring their UV absorption spectra at 350 nm. This wavelength is the region where changes in particle size will have a large effect on the optical density due to light scattering without any interference from lipid absorbance (*20*). UV spectra were obtained over a time interval of approximately 10 min during which liposomal suspensions in pH 8.0 buffer were (a) acidified to pH 4.2, (b) neutralized to pH 7.1, followed by addition of base increasing pH to 9.0, and (c) finally disrupted completely to micelles with 0.1% Triton X-100.

As seen in Figure 5, addition of acetic acid to a final pH of 4.2 to liposomes containing **BD1** (upper curve) results in ~70% collapse into micelles. When the system was neutralized to pH 7.1, no changes in light scattering were apparent. In contrast, micellar aggregates were formed as suggested by the increase in turbidity observed at pH 9.0. The acidification of **BD2**-containing liposomal suspension (lower curve) resulted in nearly 90% collapse into micelles. Interestingly, neither neutralization nor alkalinization to pH 9.0 had an effect on turbidity. Addition of Triton X-100, which resulted in complete liposomal collapse into micelles served as reference.

Cytosolic Delivery of Antisense Oligonucleotides. The intracellular disposition of Texas red-labeled oligonucleotides (TR-ON) was monitored using fluorescence microscopy (Figure 6). As seen in Panel 6C, liposomes containing acid-stable **BD1** display large punctate spots against a partially diffuse background similar to that seen with Lipofectamine in Panel 6B. Such a distribution pattern suggests a moderate ability of **BD1**-containing liposomes to promote cytosolic delivery of oligonucleotides. In contrast, liposomes containing acid-labile **BD2** show a largely diffuse pattern of fluorescence seen in Panel 6D. This observation is consistent with efficient endosomal permeabilization and cytosolic delivery of oligonucleotides by **BD2**-containing liposomes. Pinocytic uptake of free TR-ON, which is seen as a predominantly punctate pattern, served as control (Panel 6A).

The ability of bis-detergent-containing liposomes to promote the cytosolic delivery of ON-705, an 18-mer oligonucleotide was also confirmed using an antisense functional assay based on luciferase up-regulation in HeLa Luc-705 cells (*20*). Briefly, the assay involves corrective splicing of aberrantly spliced luciferase precursor mRNA (pre-mRNA) to mRNA by ON-705 resulting in up-regulation of luciferase. It is noteworthy to mention that such corrective splicing strategies require backbone-modified antisense oligomers that function via RNase-H independent mechanism. Thus, oligomers with nuclease-resistant backbones, i.e., polyanionic 2′-*O*-methyl phosphorothioate (2′-*O*-Me) were used in this study. As seen in Figure 7, free ON-705 is unable to correct splicing and induce luciferase expression. On the other hand, as evidenced by similar levels of luciferase expression, liposomal formulations containing 75 mol % of **BD1** or **BD2** appear to be as efficient as Lipofectamine in promoting cytosolic delivery of oligonucleotides. In ad-

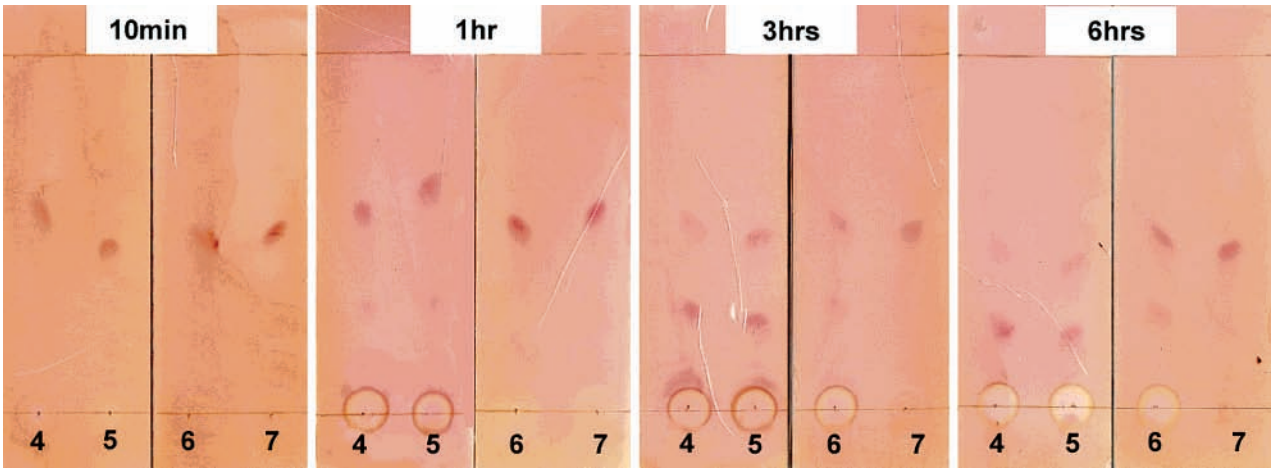

Figure 4. Acid-catalyzed hydrolysis of **BD2**, which generates single-tailed lysosomotropic detergents monitored by thin-layer chromatography. Briefly, 2 μL aliquots of **BD2**:PC (75:25) liposomes suspended in low ionic strength buffers of pH 4.0, 5.0, 6.0, and 7.0 were spotted at different time intervals onto silica gel TLC plates and eluted with $CHCl_3$:MeOH:aq NH_4OH (80:18:2). Spots corresponding to **BD2** ($R_f \sim 0.6$) and single-tailed, tertiary amine detergent monomers ($R_f \sim 0.3$) were identified using ninhydrin.

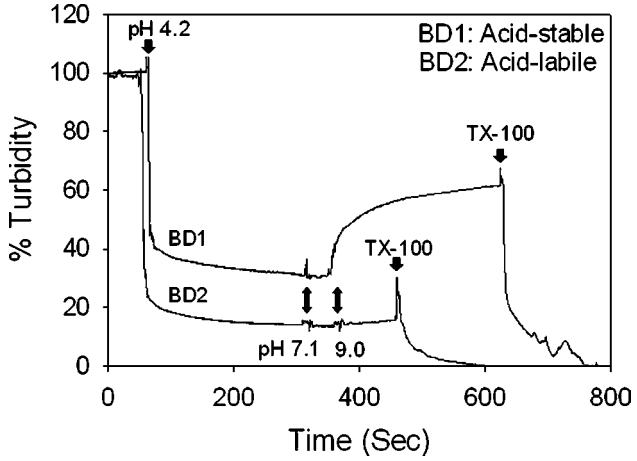

Figure 5. Light scattering by **BD1**:PC (75:25) liposomes (upper curve) and **BD2**:PC (75:25) liposomes (lower curve) at 350 nm. Liposomal formulations were suspended in 3 mL Tris-buffered saline (pH 8.0) in a quartz cuvette and acidified to pH 4.2 with a 10 μL aliquot of acetic acid. Two 10 μL aliquots of aq NH_4OH were added at ~325 s and 375 s increasing the pH to 7.1 and 9.0, respectively. Finally, 100 μL of 0.1% Triton X-100 was used to disrupt vesicles completely (TX-100). All experiments were performed in duplicate.

dition, the ability of **BD2**-containing liposomes to deliver ON-705 to the cytosol and hence up-regulate luciferase expression appears to improve in the presence of serum in comparison with formulations containing the acid-stable **BD1**.

DISCUSSION

The bis-detergents characterized in this study were designed to overcome the issue of low levels of incorporation of single-tailed detergents in stable liposomal drug delivery systems. The strategy involves in situ generation of micelles within the endosome and subsequent cytosolic delivery of initially entrapped contents. Synthesis of the constructs is rather straightforward, although cross-linker **3** is often obtained in low yield. The acetone acetal linker in **BD2** was chosen based on well-established chemistry and examples in the literature (*17*, *22*).

The kinetics of hydrolysis of **BD2** incorporated in liposomes was assessed in a semiquantitative fashion using TLC. The acid-catalyzed hydrolysis of the acetone acetal spacer was rather sluggish ($t_{1/2} \sim 3$ h; pH 5.0) as opposed to that reported in the literature ($t_{1/2} \sim 15$ min; pH 5.0, (*22*)). Such a decrease in rate of hydrolysis can be attributed in part to the lower H_3O^+ activity at the bilayer-water interface in comparison to the bulk aqueous phase. In addition, the acquisition of cationic charge upon protonation of tertiary amine headgroups of **BD2** can further deplete H_3O^+ activity at the liposomal surface due to electrostatic charge repulsion (*15*, *23*, *24*). Indeed, the headgroups of bis-detergents in this study were shown to have an average pK_a of 6.37, thus supporting the near-complete protonation of both tertiary amines at pH 5.0 or so. A detailed, quantitative analysis of the mechanism of acid-catalyzed hydrolysis of **BD2** is currently in progress.

Bis-detergents have been shown to form stable vesicles and more recently, been used to entrap macromolecules such as plasmid DNA (*25*). In the current study, lipid films containing 75 mol % detergent dimers and 25 mol % PC formed vesicles capable of entrapping macromolecules such as dextran. The higher entrapment efficiency in PBS can possibly be attributed to electrostatic interactions between polyanionic dextran and the partially protonated bis-detergent headgroups at neutral pH. This is further supported by the relatively lower encapsulation efficiency of formulations prepared at a higher pH in TBS (pH 8.0) when cationic charge on bis-detergent headgroups is negligible.

We have observed that macromolecular probes such as dextran (MW 10kDa) can be delivered to the cytosol simply upon coincubation with micelles containing single-tailed, pH-sensitive detergents (unpublished data). Such data in conjunction with other published results (*5*, *9*) suggest that acid-induced collapse of liposomes into micelles within the endosome is a prerequisite for endosomal permeabilization and macromolecular escape into the cytosol. Results from the UV light scattering experiment shown in Figure 5, confirm the ability of bis-detergents to promote liposomal collapse into micelles under acidic conditions. Although this set of data does not allow interpretation of the observation at the molecular level, it is likely that the collapse was largely due to repulsion between the protonated twin headgroups of each bis-detergent. Such electrostatic repulsion between twin headgroups of a similar Gemini surfactant has been shown to promote lamellar-to-micellar transition (*25*). However, such low pH-induced vesicle-to-micelle transition appears to be reversible, presumably due to reaggregation of micelles at basic pH (*26*). In contrast, the acid-triggered collapse of liposomes containing acid-labile **BD2** appears irreversible. In summary, it is tempting to speculate that the irreversible, acid-catalyzed hydrolysis of **BD2** into two single-tailed detergents might well be responsible for such efficient liposomal collapse and micelle formation. Pilot studies were therefore conducted to investigate the hypothesis that **BD2** could promote endosomal escape more efficiently than its noncleavable counterpart, **BD1**.

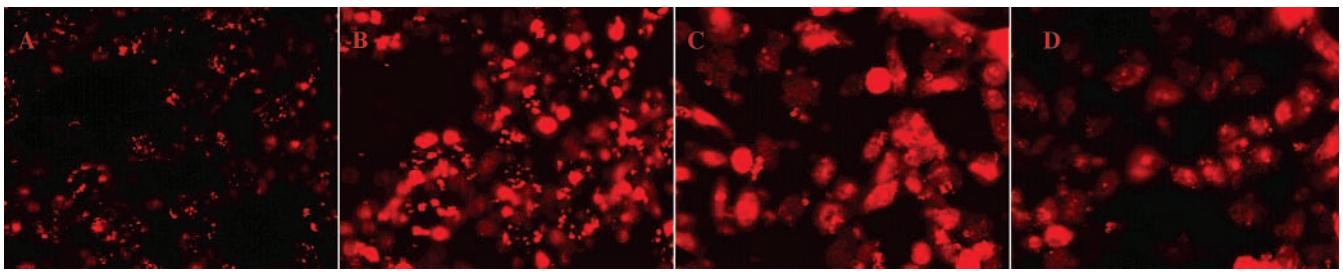

Figure 6. Intracellular distribution of different formulations containing Texas red-labeled oligonucleotides (TR-ON). HeLa Luc-705 cells grown in slide wells were incubated for a period of 6 h with serum-free DMEM-H containing TR-ON (0.1 μM) in (A) solution, (B) complexed with Lipofectamine (GIBCO, manufacturer specifications), (C) entrapped in **BD1**:PC (75:25) liposomes, or (D) entrapped in **BD2**:PC (75:25) liposomes. Formulations were replaced with serum-containing media and cells incubated for 18 h after which slides were washed thrice with cold PBS and fixed using 2% paraformaldehyde in PBS. Slides were immediately examined under a Leica Diaplan fluorescence microscope (25× magnification) equipped with a Hamamatsu camera.

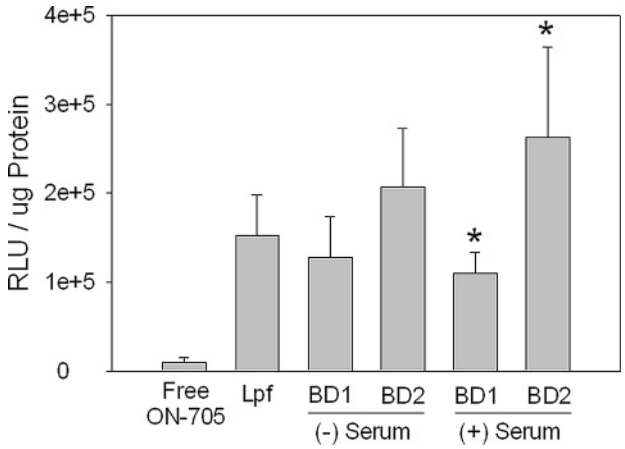

Figure 7. Upregulation of luciferase upon cytosolic delivery of antisense oligonucleotides (ON-705) using different formulations. HeLa Luc-705 cells seeded in 12-well plates were treated for 6 h with serum-free DMEM-H containing ON-705 (0.1 μM) in: solution (n = 6); complexed with Lipofectamine (n = 6, manufacturer specifications); entrapped in **BD1**:PC (75:25) liposomes (n = 3); entrapped in **BD2**:PC (75:25) liposomes (n = 3); or in serum-containing DMEM-H with **BD1**:PC or **BD2**:PC liposomes (n = 3 each). Formulations were replaced with serum-containing media and luciferase expression measured after 24 h in a luminometer using a Luciferase assay kit (manufacturer specifications). Luciferase expression is expressed in relative light units (RLU) per μg of cellular protein (mean ± SD, p < 0.05).

The cytosolic delivery potential of bis-detergent formulations was assessed qualitatively by monitoring the intracellular distribution of initially entrapped TR-ON through fluorescence microscopy. The predominantly diffuse pattern seen in HeLa cells treated with formulations containing acid-labile **BD2** contrasts the partially aggregated fluorescence pattern seen in cells treated with **BD1**-containing liposomes or Lipofectamine. These results are consistent with the notion that acid-labile bis-detergents are likely more efficient in promoting endosome-to-cytosol translocation of macromolecules than noncleavable detergent dimers or cationic lipids.

The delivery efficiency of aforementioned formulations was quantitatively assessed using an antisense functional assay. In the absence of serum, formulations of ON-705 prepared with bis-detergents were as efficient as Lipofectamine in promoting luciferase upregulation. Interestingly, addition of serum, which is known to completely inhibit Lipofectamine-mediated transfection (*27*, *28*) did not attenuate cytosolic delivery potential of **BD1**- or **BD2**-containing liposomes. More importantly, liposomes containing acid-labile **BD2** are presumably more efficient at promoting cytosolic delivery of ON-705 than liposomes containing acid-stable **BD1** in the presence of serum. In summary, acid-labile bis-detergents such as **BD2** appear to offer a dual advantage, i.e., the formulation of stable liposomes at neutral pH as well as in situ generation of membrane-disrupting, single-tailed detergents that promote efficient liposomal collapse into micelles in acidic environments. Such a system can potentially be exploited for cytosolic delivery of macromolecular drugs such as proteins, oligonucleotides, and genes in vitro and in vivo.

CONCLUSION

Two detergent dimer constructs, also referred to as 'bis-detergents' in the present study, with noncleavable (**BD1**) or acid-labile (**BD2**) spacers were synthesized. The bis-detergents were characterized for their ability to form stable liposomes at concentrations as high as 75 mol %, for the pH-dependent protonation of their headgroups and the ability of **BD2**, in particular to hydrolyze under acidic conditions. Liposomes composed of 75% **BD1** or **BD2** and 25% PC collapsed into micelles at mildly acidic pH similar to that found in endosomes/lysosomes. The collapse of **BD2**:PC liposomes was more efficient than that of **BD1**:PC liposomes presumably due to acid-catalyzed hydrolysis of the acetal spacer. Such can be attributed to the accumulation of single-tailed, micelle-favoring detergent species within the liposomal bilayer. Bis-detergent-containing liposomes were utilized to encapsulate antisense oligonucleotides and promote delivery of entrapped contents into the cytosol of HeLa cells. The efficiency of cytosolic delivery was comparable to Lipofectamine and substantially improved in the presence of serum. Further improvements in the cytosolic delivery potential of acid-sensitive bis-detergents can possibly be achieved by incorporation of biodegradable linkers and systematic characterization of formulations thereof. These studies are currently in progress.

ACKNOWLEDGMENT

We would like to thank Professors Rudy Juliano, Hal Kohn, Jeff Krise, Barry Lentz, and Ed LeCluyse for their helpful suggestions on this study. We would also like to acknowledge NIH GM071040 for research support.

Received April 9, 2004; Revised Manuscript Received August 16, 2004

Targeted therapeutics using antibodies are an attractive option over conventional cancer chemotherapeutics due to their potential to deliver a therapeutic specifically to cancer tissue without damaging normal tissue. However, there are known problems with immunoconjugates such as decreased immunoreactivity and poor solubility. Using dendrimers as carriers for these agents has the potential to resolve these issues. We synthesized J591 anti-PSMA (prostate specific membrane antigen) antibody dendrimer conjugates containing fluorophores on the dendrimer. The in vitro studies of these conjugates show that they specifically bind to cells expressing PSMA. Confocal microscopy experiments document the binding and internalization of these conjugates. This research encourages the further study of antibody–dendrimer–drug conjugates for use in targeted therapeutics.

INTRODUCTION

Targeted therapy for cancer offers potential improvements over existing chemotherapy regimens since the drug is preferentially delivered to the cancer tissue. The side effects associated with chemotherapy can be minimized by targeted drug delivery. Moreover, a prodrug attached to a carrier and a targeting agent would further reduce general cytotoxicity as the drug does not become active until it is released in the targeted tissue.

Monoclonal antibodies (mAb) are useful for the targeted delivery of therapeutics (*1*), imaging agents, and radiotherapy to tumors. For targeted therapy, identifying an antigen that is uniquely expressed or overexpressed on tumor cells is of crucial importance since this is essential to target the delivery of drugs to tumors while sparing normal tissue. One such antigen for prostate cancer is the prostate-specific membrane antigen (PSMA) (*2*, *3*). PSMA is a 100-kDa, type II membrane glycoprotein highly expressed by all prostate cancers as well as by nonprostatic tumor neovasculature and the vascular endothelium of virtually all solid sarcoma and carcinoma tumors (*4*). Important to note is that it is not expressed on normal vascular endothelium. Several anti-PSMA mAbs that bind the extracellular PSMA domain might be useful in targeting tumor cells have been developed (*5*). These antibodies define two distinct, noncompeting epitopes on the extracellular domain of PSMA. They induce and increase the rate of internalization of PSMA. The internalized antibodies accumulate in endosomes (*6*). This has led to in vitro and in vivo investigations of these antibodies for immunotherapy (*7*) and radioimmunotherapy (*8*–*11*) for which these antibodies are ideally suited.

Dendrimers (*12*, *13*) are synthetic, nanometer-sized macromolecules that can be modified to suit a specific application. Several types of dendrimers are commercially available, among which PAMAM dendrimers are the most extensively studied for biological applications (*14*, *15*). They have a unique architecture based on β-alanine subunits with primary amine groups on the surface that are available for the attachment of several types of biological material (*16*). Their aqueous solubility and biocompatibility are well suited to carry ligands, fluorochromes, and drugs for targeting, imaging (*17*), and drug delivery (*18*–*21*). Some of the issues associated with immunoconjugates, such as decreased solubility and reduced binding efficiency, can be addressed using dendrimers as carrier molecules attached to antibodies (*22*). Several groups have studied the conjugation of dendrimers to antibodies for targeting applications (*17*, *23*–*25*). Antibody–dendrimer conjugates have been used for radiolabeling (*26*) with minimal loss of immunoreactivity (*23*). The current work shows that the anti-PSMA antibody J591 (*27*), when conjugated to a dendrimer containing a fluorochrome, can be used for targeting prostate cancer and has potential as an efficient delivery system for therapeutics and imaging agents.

EXPERIMENTAL PROCEDURES

Materials. The anti-PSMA antibody, J591, which binds with high affinity to the extracellular domain of PSMA, was used in binding and uptake studies (*28*). Goat anti-mouse IgG-FITC antibody was purchased from Jackson ImmunoResearch Laboratories (West Grove, PA). Generation 5 PAMAM dendrimers were synthesized in our lab by Dr. Douglas Swanson and characterized by ^{1}H and ^{13}C NMR, GPC, and MALDI-TOF mass spectrometry. Fluorescein isothiocyanate (FITC), dithiothreitol (DTT), *N*-ethylmaleimide, acetic anhydride, triethylamine, methanol, and dimethyl sulfoxide were purchased from Aldrich (St. Louis, MO). 6-Carboxytetramethylrhodamine succinimidyl ester (6-TAMRA SE) was pur-

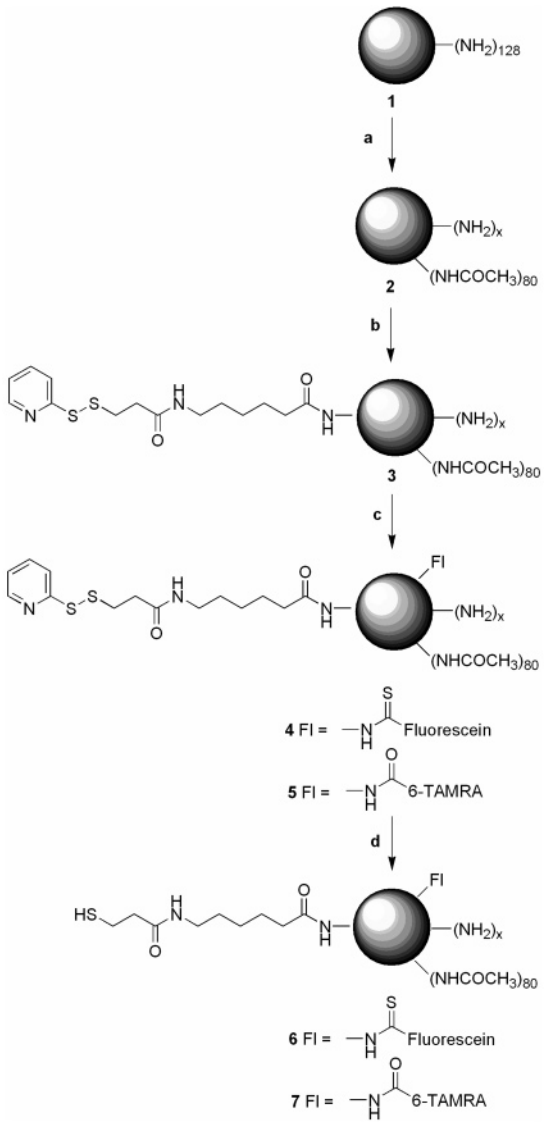
chased from Molecular Probes (Eugene, OR). The water soluble heterobifunctional cross linkers sulfosuccinimidyl 4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC) and sulfosuccinimidyl 6-[3′(2-pyridyldithio)propionamido]hexanoate (Sulfo-LC-SPDP) were purchased from Pierce (Rockford, IL). Prepacked sephadex G-25 PD-10 columns were purchased from Amersham Pharmacia Biotech (Piscataway, NJ) and equilibrated with eluting buffer before sample introduction. Pellicon, microcon, and centricon devices were purchased from Millipore (Bedford, MA). HiPrep Sephacryl S-100, S-200, and S-300 columns were purchased from Amersham Pharmacia Biotech and used in conjunction with the Isco LPLC system with type 11 (254 nm) or type 12 (214 nm) detectors for purification of dendrimer and antibody conjugates. Novex 4−20% trisglycine gels were used for PAGE with trisglycine SDS running buffer. UV measurements were carried out on a Perkin-Elmer Lambda 20 spectrometer. NMR measurements were carried out on a Bruker 500 MHz spectrometer. The PC-3 and LNCaP.FGC cell lines were purchased from American Type Cell Collection (ATCC, Manassas, VA) and grown in RPMI medium supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), 50 mM L-glutamine, and 10% heat-inactivated FBS as the monolayer at 37 °C and 5% CO_2.



Cell Staining Assay. Approximately 80% confluent cells were washed once with PBS, trypsinized, washed again, and resuspended in 0.1% bovine serum albumin in PBS (washing buffer). One million cells in 100 μL of washing buffer were incubated on ice either with the J591 antibody or with the isotype control antibody at a concentration of 1 μg/mL for 30 min and then washed twice in washing buffer and stained with anti-mouse IgG-FITC antibody for 30 min. In some experiments the cells were incubated with conjugates **12**, **13** (see Scheme 3) or respective control nanodevices either on ice or at 37 °C for 30 min. After incubation, the cells were washed, resuspended in washing buffer, and analyzed using flow cytometry.

Flow Cytometry Analysis. Single cell suspensions of cells incubated with fluorescent compounds were washed with washing buffer. Samples were run on a Coulter EPICS-XL MCL Beckman-Coulter flow cytometer, and data were analyzed using Expo32 software (Beckman-Coulter, Miami, FL).

Microscopy Analysis. To determine the bleaching rate of FITC and 6-TAMRA dendrimer conjugates, 1 μL of 1 M solutions of each of the dendrimer conjugates was placed on a slide coated with gelatin and dried. Appropriate filter and lasers were used for imaging. For the FITC conjugate, a 488 nm 60% neutral density filter with a 505−530 band-pass emission filter was used, and for the 6-TAMRA conjugate, a 543 nm 0% neutral density filter with a 650−615 nm band-pass emission filter was used. The gain was set to within 10% of each other (686−700), and the laser intensity was adjusted with the neutral density filter to saturate the detector. Two line scans from the center to the edge of the sample drop were imaged and averaged. This was repeated 999 times.

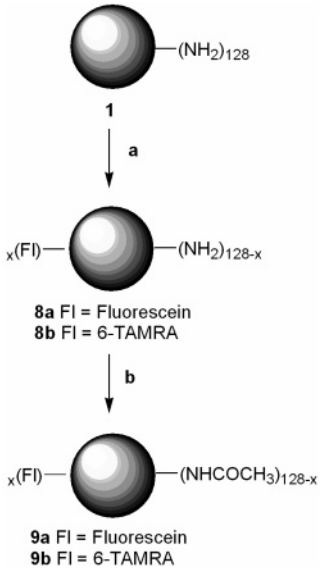
Three-dimensional imaging was done with a Zeiss 510 Meta LSCM. A Zeiss 40× Plan apo 1.2 NA was used at 4× digital zoom. Both fluorescence and differential interference contrast images were acquired simultaneously using a 543 nm HeNe laser. An image stack was acquired using confocal fluorescence with a 1 airy unit pinhole with appropriate laser and filters for 6-TAMRA (543 nm laser, 560 nm long pass filter). The image stack size, resolution, and sampling rate settings assured that an individual cell could be rendered in 3D with enough detail to discern internalization of the nanodevice. There were 31 optical sections in a 512 × 512 pixel image stack. Each optical section was 1.5 μm thick. The image stacks were imported into Volocity (Improvision, Inc.) for deconvolution and 3D reconstruction. The deconvolution used an iterative maximum entropy algorithm and a theoretical confocal point spread function run to achieve 85% confidence level. Three-dimensional rendering enabled us to select, measure, and identify individual endocytosed vesicles.

Scheme 1. Synthesis of Dendrimer Conjugates by Terminal Group Modifications on Generation 5 PAMAM Dendrimer[a]

[a] Reagents and conditions: (a) Acetic anhydride, Et_3N, methanol, rt, 16 h; (b) Sulfo-LC-SPDP, PBS, rt, 3 h; (c) FITC or 6-TAMRA SE, DMSO; (d) DTT, PBS−EDTA.

Synthesis of Dendrimer Conjugates. To a methanolic solution of generation 5 PAMAM dendrimer **1** (1.85 g; 72 μmol) (Scheme 1) under nitrogen, triethylamine (0.56 g; 5.5 mmol), and acetic anhydride (0.552 g; 5.4 mmol) were added dropwise while stirring (*20*). Stirring continued at an ambient temperature for 16 h. Methanol was removed in vacuo, and the residue was ultrafiltered using a Pellicon Device (10K MWCO), washing initially with a pH 8.0 PBS buffer and then for several recirculations with deionized water. The partially acetylated

dendrimer conjugate **2** was lyophilized; 1.5 g was recovered. To a solution of conjugate **2** (0.2 g; 7 μmol) in PBS (20 mL), sulfo-LC-SPDP (21 mg; 40 μmol) was added. The unreacted reagents and byproduct were separated after 3 h. by ultrafiltration using a 10K MWCO Pelicon device, washing initially with PBS and then with DI water. The conjugate was lyophilized to give 115 mg of disulfide conjugate **3** as an off-white powder.



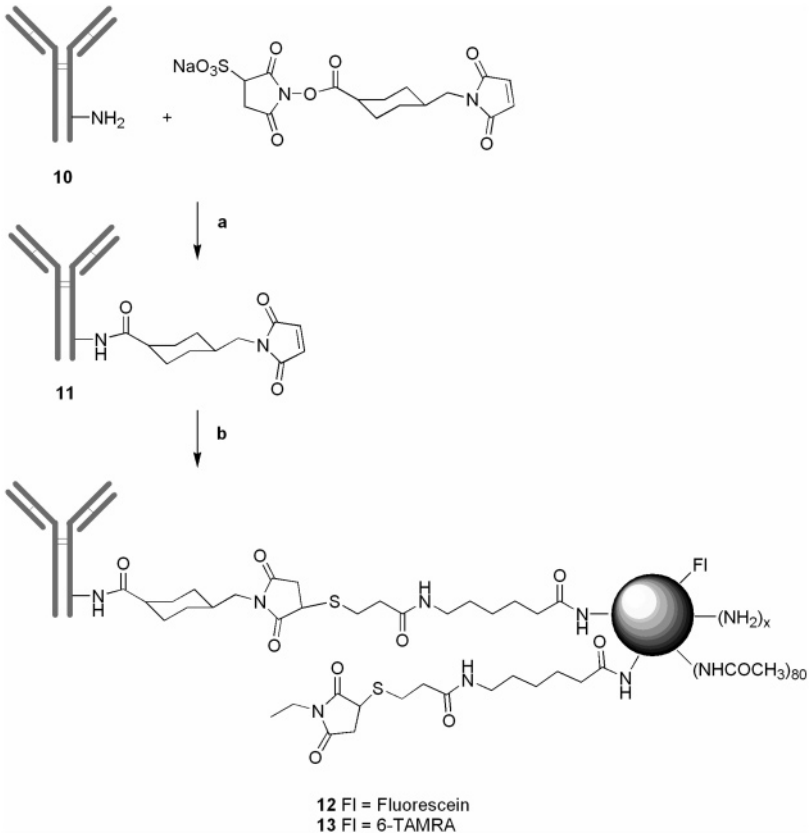
To the dendrimer disulfide conjugate **3** (45 mg; 1.5 μmol) in DMSO (5 mL), a solution of FITC (3.4 mg; 8.7 μmol) in DMSO (0.5 mL) was slowly added while stirring over a period of 30 min in darkness under nitrogen at ambient temperature. Stirring continued for 16 h. The reaction mixture was cooled on an ice bath, water was added, and the solution was dialyzed in a 15K MWCO regenerated cellulose bag in the dark. The initial buffer exchanges were with PBS and later with deionized water. The resultant purified dendrimer−FITC−disulfide conjugate was lyophilized to yield 35 mg of conjugate **4**. Similarly, 6-TAMRA succinamidyl ester (5 mg; 9.4 μmol) in DMSO (0.5 mL) was slowly added to dendrimer conjugate **3** (41 mg; 1.4 μmol) in DMSO (5 mL) at room temperature and stirred in the dark under nitrogen for 16 h. The reaction mixture was then dialyzed in a 15 K MWCO regenerated cellulose membrane. The initial red permeate fractions releasing free 6-TAMRA faded, and the dialysis continued until the permeate fractions were colorless. After dialyzing further in deionized water, the retentate was lyophilized to give 25 mg of dendrimer−6-TAMRA−disulfide conjugate **5** as an amorphous red powder.

The disulfide bonds on dendrimer conjugates **4** and **5** (2 mg each; 64 nmol) were reduced by using 10 mM DTT in degassed PBS-EDTA buffer (0.5 mL) at RT under argon to provide the corresponding dendrimer−thiol conjugates **6** and **7**. These conjugates were purified by gel filtration, eluting with PBS-EDTA buffer under nitrogen on a PD-10 column to remove excess reagents and byproducts, and were immediately used for subsequent antibody conjugation.

Dendrimer conjugates without antibody, for in vitro control experiments, were prepared by treating G5 PAMAM dendrimer **1** (100 mg; 4 μmol) with a 6-fold molar excess of FITC (9 mg; 24 μmol) or 6-TAMRA (12.6 mg; 24 μmol) dropwise in DMSO (10 mL) under an inert atmosphere of nitrogen in the dark (Scheme 2). The conjugates were purified by dialysis using a 10K MWCO regenerated cellulose membrane. The resultant conjugates **8a** and **8b** (25 mg each; 0.94 μmol) were then acetylated in a 1:1 mixture of PBS:DMSO (5 mL) at pH 8.0 using an excess of acetic anhydride (15.3 mg; 150 μmol) with equimolar triethylamine (15.1 mg; 150 μmol). The pH was readjusted to 8 after 3 h, and another 1 equiv of acetic anhydride was added. The resultant conjugates were purified by dialysis after 12 h as before and lyophilized to give completely acetylated dendrimer conjugates **9a** (G5−FITC) and **9b** (G5−6-TAMRA).

Antibody Conjugation. Modification of J591 anti-PSMA mAb (Scheme 3). The J591 antibody (**10**) was provided in 5 mg/mL concentration in PBS buffer and used without dilution. A thiol reactive maleimide group was introduced on the antibody by reacting the J591 mAb with sulfo-SMCC in PBS at ambient temperature for 2 h to give conjugate **11** using standard protocols (*29*). The excess reagent was removed by gel filtration on a Sephadex G-25 column. This maleimide-linked antibody conjugate **11** was then concentrated on a microcon YM50 and immediately reacted with dendrimer thiolates **6** or **7** in degassed PBS-EDTA buffer at an ambient temperature for 2 h under an inert atmosphere. Excess thiol groups on the dendrimer were then quenched using *N*-ethylmaleimide to minimize dimer formation. The products were then concentrated by centrifugal ultrafiltration using YM100 microcon devices to remove excess dendrimer and other reagents. They were further purified on a S-200 Sephacryl column to give conjugates **12** and **13**.

Scheme 2. Dendrimer Labeled with FITC or 6-TAMRA for Control Experiments



[a] Reagents and conditions: (a) DMSO, FITC or 6-TAMRA SE; (b) acetic anhydride, Et_3N, PBS−DMSO, rt, 12 h.

RESULTS AND DISCUSSION

Dendrimer Conjugate Characterization. The dendrimer terminal group modification is shown in Scheme 1. Amine-terminated PAMAM dendrimers can nonspecifically bind to cells due to the positive surface charge. To improve targeting efficacy and decrease nonspecific interactions, the generation 5 PAMAM dendrimer **1** was partially acetylated. The use of 80 times molar excess of acetic anhydride leaves some amines unreacted on the dendrimer for further conjugation. Acetylation also decreases the intermolecular interactions, minimizing aggregate formation and solubility problems. Initially using pH 7.4 PBS, for ultrafiltration, removes loosely bound side products that would otherwise be retained if ultrafiltered only against water. The purity of the conjugate **2** and the extent of acetylation can be measured (*30*) and monitored by ^{1}H NMR, which shows a distinct signal for the terminal NHCOCH_3 protons of the dendrimer at δ 1.85. If acetic acid contamination is detected upfield at δ 1.80, it can be removed by repeated dialysis in PBS and water.

To introduce a disulfide group, the water-soluble heterobifunctional cross-linking agent sulfo-SPDP was conjugated to the partially acetylated dendrimer **2** to provide a protected thiol in the form of a disulfide, which is later cleaved with DTT. The extent of disulfide modification can be monitored by UV spectroscopy, using the pyridine-2-thione assay (Figure 1) by adding DTT to a measured quantity of dendrimer and recording the absorbance of the released 2-thiopyridine at 343 nm. On the basis of this measurement, it was calculated that there are an average of two disulfide groups per dendrimer in conjugate **3** in agreement with values obtained by ^{1}H NMR by comparing the integration values of the

Scheme 3. Antibody–Dendrimer Conjugation[a]

[a] Reagents and conditions: (a) PBS, pH 7.4, rt, 2 h; (b) conjugate **6** or **7**, PBS-EDTA, pH 7.4, rt, 2 h, *N*-ethylmaleimide.

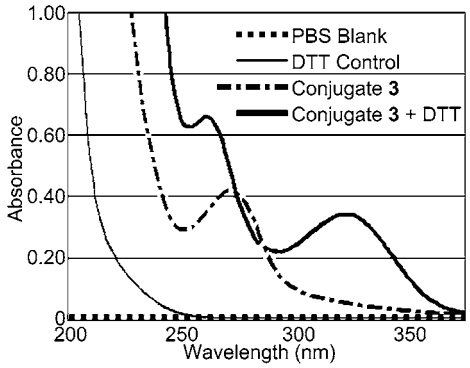


Figure 1. Pyridine-2-thione assay. The increase in absorbance at 343 nm for the conjugate is due to the release of 2-thiopyridine.

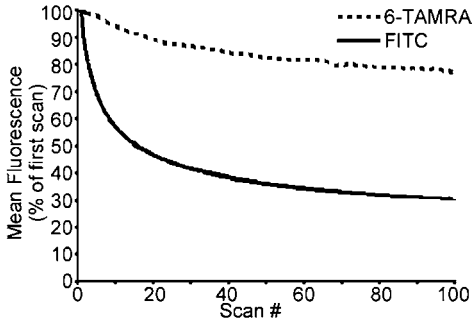

Figure 2. Comparison of photobleaching of FITC and 6-TAMRA labeled dendrimer conjugates (**9a** and **9b**) in the confocal microscope. A rapid decrease of 50% fluorescence in dendrimer conjugated to FITC was observed after 25 scans. The fluorescence decreased by only 10% for dendrimer–6-TAMRA conjugate after 25 scans.

heteroaromatic signals of the pyridine and the aliphatic signals of the dendrimer.

Imaging of cells by flow cytometry or confocal microscopy requires a detectable fluorescent probe. We have investigated the use of different fluorescent probes on the dendrimer for this purpose. Remarkably, up to 20 times molar excess of these probes, which have aromatic groups, can be conjugated to the dendrimer while still having the conjugate remain soluble in aqueous buffers. To retain complete solubility but still provide an imaging source for these studies, the amount of FITC labeling was decreased to six per dendrimer. The UV spectrum of conjugate **4** shows absorption for the fluorescein at λ_{max} 498 nm. The ^{1}H NMR of the conjugate shows overlapping signals in the aromatic region for both the fluorescein and the pyridine ring from the disulfide linker apart from the expected aliphatic signals for the dendrimer. The fluorescein label is ideally suited for flowcytometry experiments for in vitro studies; it, however, photobleaches under confocal microscopy conditions. For the confocal microscopy experiments, we tested 6-TAMRA, a dye with a higher quantum yield and with minimal photobleaching compared to FITC.

We tested the rate of photobleaching in dendrimer conjugates with FITC and 6-TAMRA (Figure 2). A rapid decrease of 50% fluorescence in the FITC-labeled dendrimer conjugate was observed as compared to a 10% decrease in fluorescence on the 6-TAMRA dendrimer conjugate using the confocal microscope. Hence, the antibody–dendrimer conjugate with 6-TAMRA was used for confocal microscopy experiments to detect binding and internalization. Therefore we synthesized the corresponding dendrimer conjugate **5** with 6-TAMRA. Even though the conjugation efficiency of the 6-TAMRA succinamidyl ester is less than that of the FITC, using a

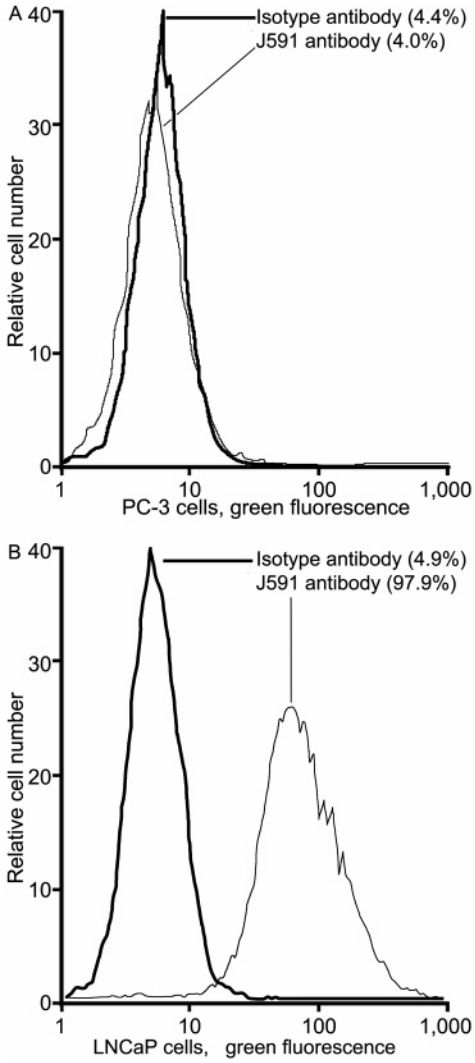

Figure 3. PC-3 (a) and LNCaP.FGC (b) cells were incubated either with isotype control or J591 antibodies (1 μg/mL), for 30 min. on ice, and then stained with anti-mouse IgG-FITC antibody, and green florescence was analyzed on FCM.

slight excess resulted in a stable conjugate that is water soluble. The reduction of disulfide bonds on dendrimer conjugates **4** and **5** was carried out by using DTT. The resultant dendrimer thiols **6** and **7** can undergo oxidation and hence the reactions were carried out and purified carefully under an inert atmosphere in degassed PBS−EDTA buffer.

For in vitro control experiments, G5 PAMAM dendrimer was labeled with FITC and 6-TAMRA. The ^{1}H NMR of the purified conjugates **8a** and **8b** showed additional signals in the aromatic region between δ 6−8 ppm. The UV−vis spectrum of **8a** had absorption at λ_{max} 498 nm for the conjugate. The conjugates **8a** and **8b** were then completely acetylated with excess acetic anhydride in the presence of triethylamine at pH 8 to give conjugates **9a** and **9b**. An additional peak at δ 1.8 for the CH_3 of the terminal acetyl group and the merging of methylene proton signals α to the NH_2 in the starting material confirms the complete acetylation of the terminal amines.

A thiol reactive maleimide group was introduced on the antibody with water soluble sulfo-SMCC using standard protocols and the resultant conjugate was purified by gel filtration. To minimize the free antibody, 5-fold molar excess of dendrimer conjugates was used in the antibody−dendrimer conjugation; the unreacted thiols

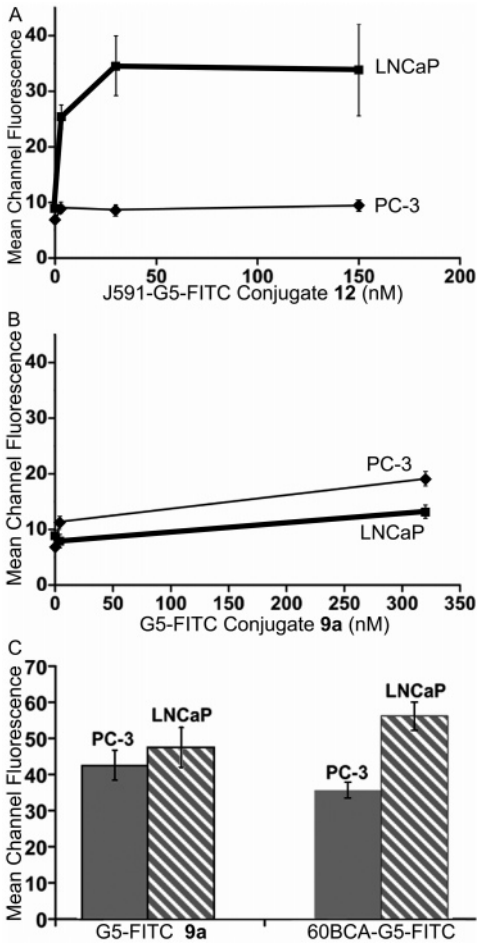

Figure 4. PC-3 and LNCaP.FGC cells were stained with increasing concentrations of J591-G5-FITC conjugate (**12**) (a, top panel), G5-FITC (**9a**) (b, middle panel) or 150 nM of irrelevant 60BCA-G5-FITC antibody−dendrimer conjugate (c, bottom panel) and analyzed on FCM.

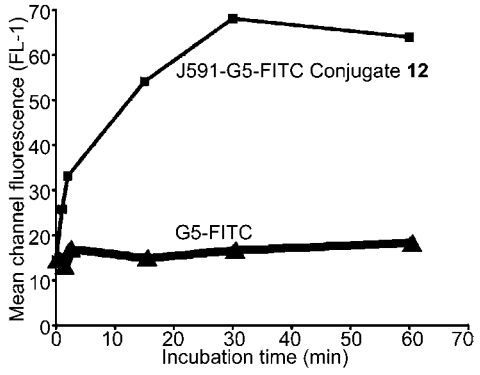

Figure 5. Kinetics of binding J591-G5-FITC dendrimer to LNCaP.FGC cells. The cells were incubated with a 50 nM concentration of **12** or control G5-FITC dendrimer (**9a**) for the indicated periods of time at rt. After incubation, cells were washed and the mean channel fluorescence of stained cells was determined by FCM.

were quenched with *N*-ethylmaleimide to minimize dimer formation due to cross-linking of dendrimer to antibodies. Free unreacted dendrimer was removed initially by filtration with a 100K MWCO microcon. Further purification on a S-200 Sephacryl column removed any residual free dendrimer. The resultant conjugates **12** and **13** were analyzed using PAGE, which shows a band above the antibody band that confirms the conjugation and an absence of a band for the free dendrimer. The fluores-

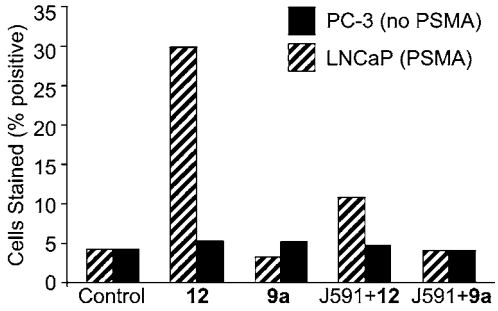

Figure 6. The specific binding of J591–G5–FITC conjugate to LNCaP.FGC cells. The PSMA positive and negative cells were preincubated in the absence or presence of free J591 antibody and further incubated with either **12** or **9a**. The 'control' represents cells that have not undergone any treatment. After washing, the stained cells were analyzed on FCM.

cence of the conjugates gives an indirect proof of conjugation since the fluorescent probe was conjugated to the dendrimer.

Targeting PSMA-Positive Prostate Cancer Cells with Monoclonal Antibody. To confirm the specificity of the J591 antibody toward the extracellular domain of PSMA, live PSMA-positive LNCaP.FGC cells and PSMA-negative PC-3 cells were incubated with J591 antibody and stained with anti IgG-FITC. The J591 antibody shows a great specificity against PSMA antigen. More than 97% of LNCaP.FGC cells were positively stained with J591 mAb (Figure 3b) compared to a nonspecific stain with the isotype antibody. The PC-3 cells showed (Figure 3a) only background-level staining with both antibodies (J591 and isotype) and no specificity. This confirms that the J591 antibody specifically binds to the LNCaP.FGC cells, and the binding is highly specific (*27*).

Targeting PSMA-Positive Prostate Cancer Cells Using Monoclonal Antibody–Dendrimer Conjugates. Dendrimer conjugation to the antibody can alter the binding characteristics of the antibody since it has the potential to block the binding sites. To ascertain whether the targeting efficacy and specificity of the antibody–dendrimer conjugate toward PSMA is maintained, three types of conjugates were tested, conjugates **9**, **12**, and another antibody dendrimer conjugate, 60BCA-G5-FITC, as a control (a dendrimer conjugated to an irrelevant antibody). At a 3 nM concentration of **12** (J591-G5-FITC), the LNCaP.FGC reached approximately 25 units of mean channel fluorescence (MCF) (Figure 4a). At 10 times higher concentration, the fluorescence reached an upper plateau at 35 MCF. Staining with a similar concentration (4 nm) of the G5-FITC control dendrimer conjugate **9a** (without the antibody) yielded less than 15 MCF (Figure 4b). The MCF never exceeded 20 units even at a 300 nm concentration of conjugate **9a**. Both conjugates (**9a** and **12**) have nonspecific staining of PC-3 cells equal to the background (Figure 4) fluorescence. The irrelevant antibody (same class) conjugate (60BCA-G5-FITC) did not bind significantly to either cell line (Figure 4c).

We have also examined the kinetics of the binding of conjugate **12** and control dendrimer **9a** to LNCaP.FGC cells. The binding of **12** to LNCaP.FGC cells reached a plateau after 30 min. of incubation. The mean fluorescence of cells stained with **12** increased from 14.5 to 68.1 MCF, while the mean fluorescence increase of cells stained with **9a** was insignificant (Figure 5). To further prove the specific binding of the dendrimer–antibody conjugate, LNCaP.FGC and PC-3 cells were preincubated with free J591 antibody at 750 ng/mL concentration for 15 min. on ice to block the receptor sites. Dendrimer conjugates **12** and **9a** (48 nM) were added, and the cells were incubated for an additional 30 min and then washed and subjected to FCM analysis. Free J591 antibody

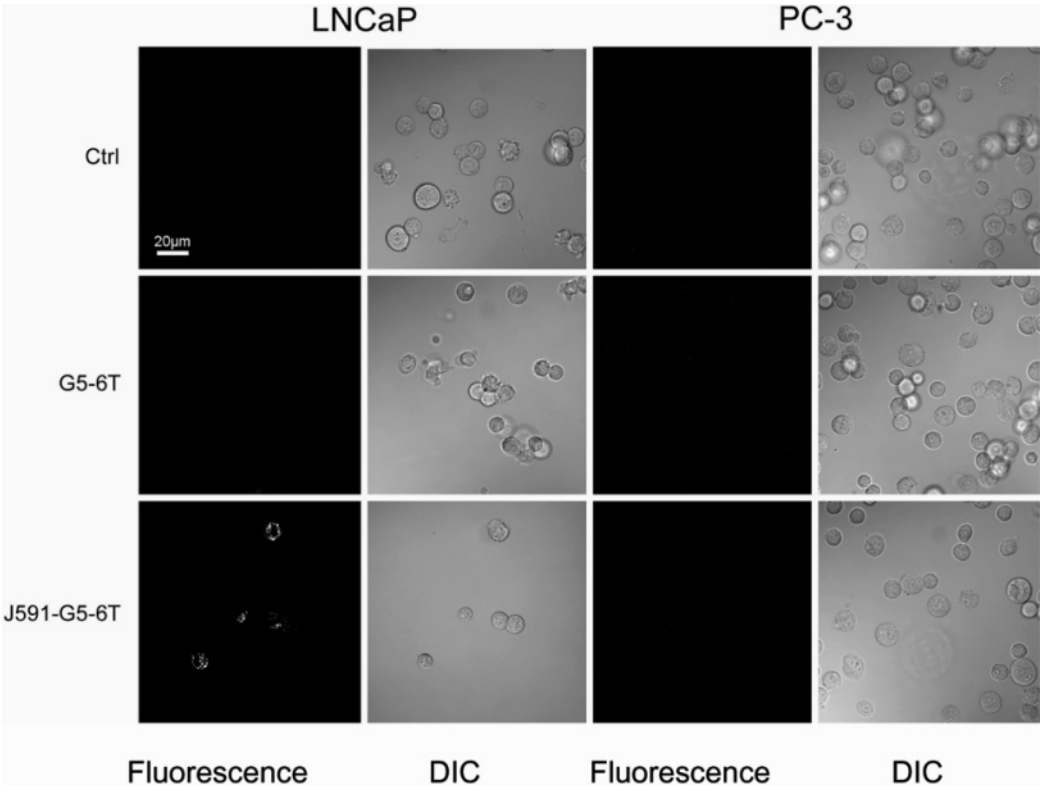

Figure 7. LNCaP.FGC and PC-3 cells were incubated with either J591–G5–6T (conjugate **13**; bottom row) or G5–6T (conjugate **5**; middle row) or with the vehicle (PBS; top row) for 60 min. at 37 °C, washed, and analyzed under the confocal microscope. The antibody–dendrimer conjugate **13** shows intracellular localization in the LNCaP.FGC cells, but not in the PC-3 cells. The control dendrimer (G5–6T) failed to associate with both cell lines.

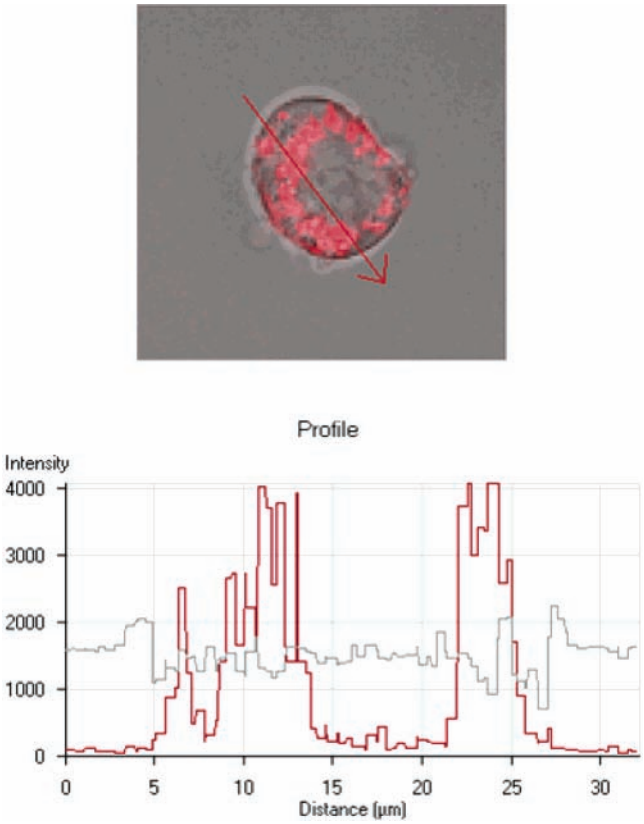

Figure 8. Confocal microscopy demonstration of internalization of J591 antibody dendrimer conjugate **13**. An optical section (top) from an image stack showing a medial 0.7 μm slice of a single cell. The fluorescence intensity profile (bottom) taken along the line shown by the arrow.

inhibited the binding of the conjugate to LNCaP.FGC cells by more than 71%, while nonspecific binding to PSMA-negative cells remained unchanged (Figure 6). This blocking experiment proves that the antibody−dendrimer conjugate retains specific binding to PSMA.

Internalization of the Dendrimer Conjugates by PSMA-Positive Cells. Free J591 antibody is readily internalized by LNCaP.FGC cells (*6*). We examined whether the antibody−dendrimer retains this ready internalization. Initial confocal microscopy studies with the dendrimer conjugate **12** and live cells provided inconclusive results due to the photobleaching of the FITC and background autofluorescence. Changing the fluorescent probe on the dendrimer to 6-TAMRA gave a better signal-to-noise ratio which allowed conclusive measurements. The PC-3 and LNCaP.FGC cells were trypsinized, washed, and incubated with conjugate **13** for 1 h. at 37 °C and then washed and analyzed.

LNCaP.FGC cells yielded the highest fluorescence when stained with conjugate **13** (Figure 7). We observed minimal fluorescence in PC-3 cells stained with conjugate **13**. To analyze the fluorescence intensity in both cell types quantitatively, we selected 3D-rendered images of representative LNCaP.FGC and PC-3 cells and determined the number of fluorescent voxels per cell. The LNCaP.FGC yielded 12 520 voxels, while PC-3 yielded only 1156. Since both LNCaP and PC-3 are human prostate cell lines grown under identical conditions and they are very similar in size, the order of magnitude difference in the number of fluorescent voxels can be attributed to differences in dendrimer uptake. The confocal images were further analyzed by taking optical sections to determine internalization of the conjugate. Medial optical scans (Figure 8) clearly show internalization of the antibody−dendrimer conjugate **13** into the PSMA-positive LNCaP.FGC cells. The fluorescence profile shows increased intensity in the cytoplasm but not inside the nucleus.

CONCLUSION

Dendrimers are useful as carrier macromolecules for targeting, imaging, and drug delivery agents. Terminal group functionalization of water-soluble PAMAM dendrimers with different aromatic and hydrophobic molecules allows delivery of many types of drugs but may significantly reduce the aqueous solubility of the conjugates. Altering the surface amine functionality to a more neutral acetylated surface reduces the formation of aggregates and retains the water solubility of the conjugates. The acetylated terminal groups also decreased the nonspecific binding to the cells (*20*). The conjugation of the targeting J591 antibody to surface-modified G5 dendrimers has been achieved. Flow cytometry experiments showed that the antibody−dendrimer conjugate is specifically bound by the PSMA-positive LNCaP.FGC cell line but does not bind to the PC-3 cell line which does not express PSMA. Dendrimers not conjugated to an antibody did not show any significant binding. Confocal microscopy studies also confirmed the binding and internalization of the antibody−dendrimer conjugate, while the dendrimer alone did not show significant binding or uptake into the cells. Studies are under way to synthesize a multifunctional dendrimer conjugate with drug, fluorochrome, and antibody for targeted drug delivery and imaging.

In most cases, unmodified oligonucleotides designed as antigene molecules are incapable of binding to DNA with sufficient stability to prevent gene expression. To stabilize binding to a polypurine tract in the HER-2/neu promoter, a triplex forming oligonucleotide (TFO) was conjugated to a pyrrolo[1,4]-benzodiazepine (PBD), desmethyltomaymycin, and site-specific DNA binding was evaluated. An activated ester of the PBD moiety was conjugated by an acylation reaction to a free primary amine on a 50-atom aliphatic linker at the 5′ end of the TFO. This long aliphatic linker was designed to provide a bridge from the major groove binding site of the TFO to the minor groove binding site of the PBD. Triplex formation by the resulting TFO–PBD conjugate occurred more slowly and with a nearly 30-fold lower affinity compared to an unconjugated TFO. PBD binding to the triplex target was demonstrated by protection from restriction enzyme digestion, and covalent binding to the exocyclic amino group of guanine was inferred by substituting specific guanines with inosines. Although the binding of the TFO was less efficient, this report demonstrates that in principle, TFOs can be used to direct the binding of a PBD to specific location. Further optimization of TFO–PBD conjugate design, likely involving optimization of the linker and perhaps placing a PBD at both ends of the TFO, will be needed to make gene modification robust.

INTRODUCTION

The sequence-specificity of triplex forming oligonucleotides (TFOs[1]) gives these molecules tremendous potential as tools to alter gene expression (*1*). TFOs can potentially regulate gene expression by several different mechanisms including recombination, mutagenesis, and inhibition of RNA transcription (*2*, *3*). Interstrand DNA triplex formation occurs through the binding of a TFO in the major groove of a polypurine:polypyrimidine tract of DNA (*4*, *5*) by forming base specific Hoogsteen hydrogen bonds (*6*, *7*). While TFOs have been successfully used to regulate gene expression in several model systems, a number of cellular barriers still limit the ability of TFO to inhibit target gene expression in living cells. One of these barriers is removal of the TFO by the DNA repair machinery or by DNA helicases (*8*–*11*). To improve the stability of triplex formation within cells, DNA-reactive agents can be conjugated to the ends of TFOs to covalently bind the third strand to the target sequence (*12*). For example, psoralen, reactive minor groove binders (MGBs), bromoacetyl, nitrogen mustard, and aziridinyl quinone residues have been conjugated with TFOs and shown to react with target sites (*13*–*17*).

The HER-2/neu oncogene is a good target for triplex formation because it has two polypurine tracks capable of triplex formation with a third strand (*18*, *19*) and because HER-2/neu directed therapies have established the principle that preventing the expression or function of the HER-2/neu gene product can induce the regression of metastatic tumors that overexpress HER-2/neu (*20*, *21*). The HER-2/neu promoter has served as a good model for evaluating triplex formation by TFO–alkylator conjugates in previous studies (*11*, *22*) as well as in the present report. The triplex target site is located from −218 to −245 upstream of the first codon (+1) in a region of HER-2/neu promoter that is necessary for the efficient initiation of HER-2/neu transcription (Figure 1). Previous studies demonstrated that a preformed triple helix with an unmodified DNA oligonucleotide as the third strand was undetectable 24 h after transfection of a reporter plasmid bearing the target sequence, demonstrating the limited stability of the triple helix in cells. Conjugation to nitrogen mustards greatly improved the stability of third strand binding, and a TFO conjugated to phenylacetic acid mustard (PAM) at both ends efficiently suppressed HER-2/neu expression from a reporter plasmid. The ability of DNA unwinding by polymerases and

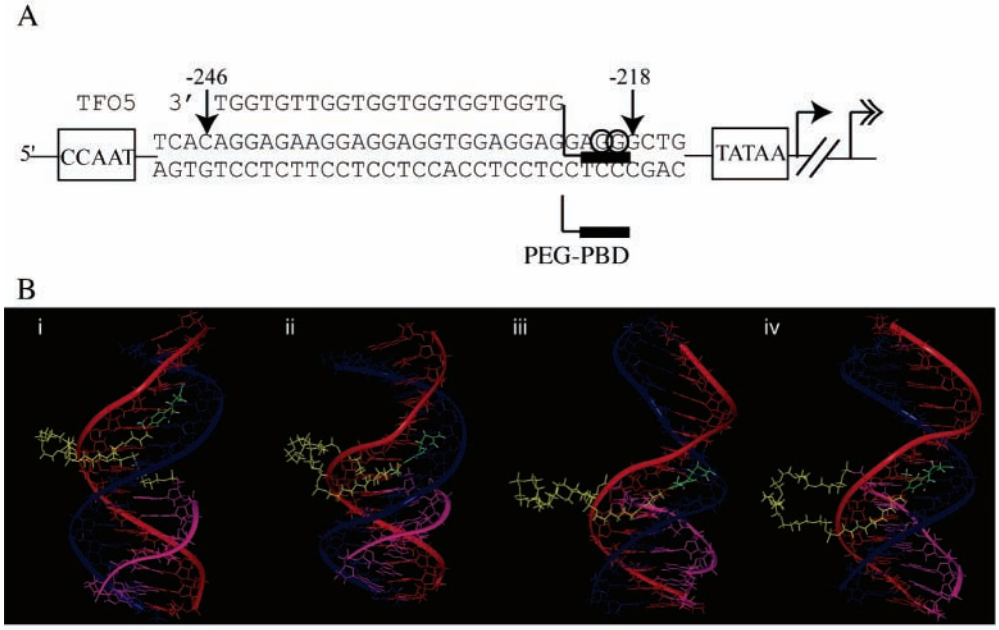

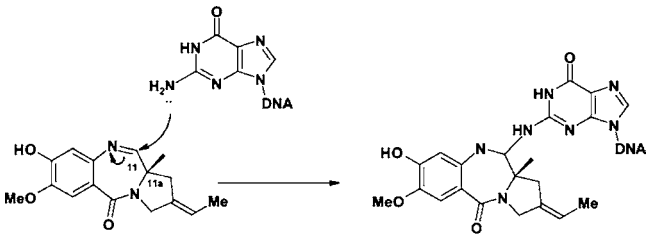

Figure 1. Triplex formation in the HER-2/neu promoter with TFO5. (A) Schematic representation of the HER-2/neu promoter with the triplex target sequence located from −245 to −218 relative to the first codon. TFO5 is an antiparallel GT motif TFO conjugated to desmethyltomamycin (PBD) with a PEG wraparound linker that allows the PBD to bind in the minor groove at an adjacent 5′Pu-G-Pu site. TFO5 is designed to direct PBD binding to the AGG (−219 to −221) or the GGG (−218 to −220) sequences that are just downstream of the triple helix, which ends at −223. A covalent adduct is formed with the central guanine in the PBD binding site (circled). Additional PBD binding sites at the GGA (−221 to −223) or the AGG (−222 to −224) at the duplex−triplex junction are also predicted by molecular modeling studies. (B) Molecular models of triplex formation and PBD binding to the HER-2/neu promoter. The models consists of 15 bp of the HER-2/neu promoter from −215 to −229 (purine strand, red; pyrimidine strand, blue) with seven base triplets from the 5′ end of the TFO (−223 to −229, magenta), the PEG wraparound linker (yellow), and the PBD (atom colors) binding in the minor groove and forming adducts with guanines at positions (i) −219, (ii) −220, (iii) −222, or (iv) −223.

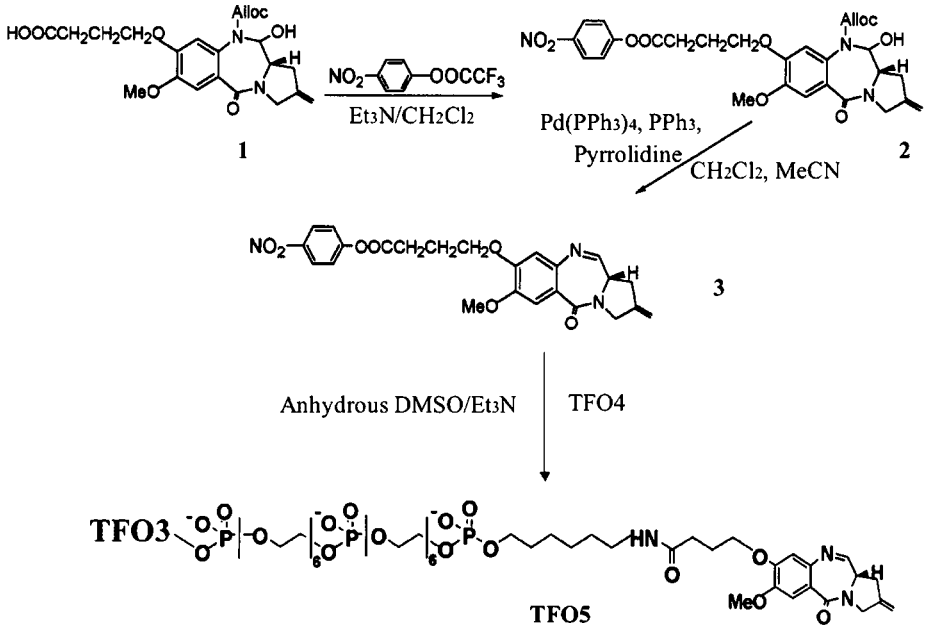
helicases to displace a TFO has been reported and can be prevented by triplex formation coupled with covalent modification of the DNA (*8*, *9*, *11*, *19*, *23*−*30*).

Nitrogen mustards have a mechanism of DNA alkylation involving the spontaneous formation of a highly reactive aziridinium cation intermediate in aqueous solution followed by the electrophilic attack of the relatively nucleophilic N7 of guanine (*31*). Short TFOs conjugated to a nitrogen mustard can drive DNA alkylation to near completion, as shown by the site-specific alkylation of an isolated genomic DNA target using 12-mer TFOs (*32*). The electrophilic aziridinium cation can also react with other nucleophiles or with water to give degradation products that are incapable of guanine alkylation, and in permeabilized cells or isolated nuclei, triplex directed alkylation by a nitrogen mustard is much less efficient (*32*, *33*). The short half-life of the aziridinium cation in aqueous solution presents a potential barrier to the effectiveness of a TFO conjugated to nitrogen mustard in gene targeting in living cells (*34*).



In the present report, we wished to develop TFO−alkylator conjugates with an alkylating agent that does not become inactive in aqueous solution. We selected the pyrrolo[1,4]benozdiazepines (PBDs) as a class of DNA alkylating agents that would not be as unstable in water as the nitrogen mustards. Anthramaycin, tomaymycin, sibiromycin, and the neothramycins are members of a potent group of antitumor antibiotics, the PBDs, initially isolated from various *Streptomyces* species (*35*). The DNA binding reaction of the PBDs initially proceeds through reversible, noncovalent binding in the minor groove of DNA that positions the reactive C11 of the B ring of the PBD facing into the minor groove for covalent binding to the exocyclic amino group of a guanine (Scheme 1). The aminal bond that forms is labile and potentially reversible to regenerate an active PBD (*36*). The formation of a PBD−DNA adduct at purine-guanine-purine (5′Pu-G-Pu) sequences has been shown to block RNA polymerase, and anthramycin and tomaymycin are the most potent blockers of transcription (*37*). The formation of a DNA−PBD adduct can interfere with the linear translocation of DNA-processing enzymes or inhibit their recognition of specific DNA sequences (*38*). The cytotoxicity and antitumor activity of the PBDs is related to their ability to inhibit DNA and RNA synthesis; however, the binding of PBDs at the large number of 5′Pu-G-Pu sites throughout the genome may explain the high level of toxicity observed with this class of compounds. For this reason, several groups have investigated ways to improve the site-specificity of PBD binding by using PBD dimers, PBDs conjugated to other MGBs, or PBDs conjugated to polyamides (*39*−*42*). In the current report, we have taken advantage of potential PBD binding sites in the polypurine tract of the HER-2/neu promoter to use a TFO to direct the binding of a PBD to a specific location adjacent to the triple helix (Figure 1). TFOs conjugated to PBDs could have some advantages over TFOs conjugated to spontaneously reactive nitrogen mustards and improve the specificity of the PBD.

Scheme 1. Covalent Adduct Formation by a PBD with the 2-Amino Group of Guanine

Tomaymycin

Scheme 2. Synthesis of Desmethyltomaymycin−TFO Conjugate, TFO5

A challenge for the design and synthesis of TFO−PBD conjugates is the fact that the TFO binds in the major groove while the PBD binds in the minor groove. In other studies of TFOs conjugated to MGBs such as cyclopropapyrroloindoles (CPI), this challenge was addressed with a long, poly(ethylene glycol) "wrap-around" linker (PEG) to form a bridge from the major groove to the minor groove (*43*, *44*). The long flexible linker will allow the MGB to wrap around the DNA duplex to find a binding site within 4−8 bp of the TFO terminus. In this report we describe the design and synthesis of a novel bioconjugate of desmethyltomaymycin to a DNA TFO and demonstrate the site-specific interaction of the PBD with the intended target site in the HER-2/neu promoter.

EXPERIMENTAL PROCEDURES

Materials. Solvents and chemicals obtained from commercial sources were analytical grade or better and were used without further purification. Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μM) prior to use.

Spectral Analysis. ^{1}H NMR spectra were obtained on a Bruker AVANCE (300 MHz) instrument. Matrix-assisted laser desorption/ionization (MALDI) mass spectra of oligonucleotides were measured on a Bruker-Reflex-III MALDI-time-of-flight (MALDI-TOF) mass spectrometer. 3-Hydroxypicolinic acid (0.1 M) with 0.1% ammonium tartrate was used as the matrix, and a conventional N_2 laser (337 nm) was used to generate ions. Fast atom bombardment (FAB) mass spectra of desmethyltomaymacin were determined on a JEOL HX110A instrument using a matrix of 50% glycerol, 25% thioglycerol, and 25% *m*-nitrobenzyl alcohol containing 0.1% of trifluoroacetic acid (TFA). Preparative HPLC purification was performed on a Varian ProStar system equipped with a photodiode array (PDA) detector.

Molecular Modeling. Modeling of triplex formation and PBD binding was performed using methods that have been previously described (*45*, *46*). Briefly, molecular mechanics and dynamics were performed using Macromodel 7.0 (*47*) with an implicit solvent algorithm (GB/SA water solvation) using the AMBER* force field. The models were initially minimized (1000 steps steepest decents followed by 1000 steps Polak-Ribier conjugate gradient) followed by molecular dynamics simulations (100 ps equilibrium phase and 500 ps production phase, 1.5 fs time step, 300 K, followed by averaging 25 samples of the last 50 ps, with subsequent minimization as above). Models of the HER-2/neu promoter triple helix and PBD binding site included 15 bp of the target duplex, d(G-GAGGAGGAGGGCTG)-d(CAGCCCTCCTCCTCC) and seven bases of the TFO from the 5′ end, d(GGTGGTG). Multiple simulations were completed using the chiral *S* configuration of the PBD based on a reported structure (*48*). Covalent adducts of the PBD with G-223, G-222, G-220, and G-219 are illustrated in Figure 1B.

Synthesis of Desmethyltomaymycin *p*-Nitrophenyl Ester. The C8 substituted tomaymycin analogue **1** (Scheme 2) was synthesized starting from vanillic acid and using the thioacetal method described by Thurston and co-workers (*49*). The intermediate compound **1** was then converted to the active *p*-nitrophenyl ester **2**, deprotected with $Pd(PPh_3)_4$, PPh_3, and pyrrolidine to afford compound **3** in 60% yield as a yellow oil, and crystallized from Et_2O to afford **3** as a yellow solid. ^{1}H HMR (d_6-acetone) δ2.32 (m, 2H, $(CH_2)_3$), 2.87 (t, 2H, $(CH_2)_3$, J = 6.7), 2.94 (d, 1H, H1a, J = 16.1), 3.12 (dd, 1H, H1b, J = 15.8, J = 8.3), 3.87−3.89 (m, 1H, H11a), 3.93 (s, 3H, OCH_3), 4.18 and 4.22 (2m, 2H, H3), 4.29 (s, 2H, $(CH_2)_3$), 5.17 and 5.20 (2x br s, 2H, C=CH_2), 6.84 (s, 1H, H9), 7.30 (d, 2H, Ph, J = 8), 7.52 (s, 1H, H6), 7.70 (d, 1H, H11), 8.27 (d, 2H, Ph, J = 8); *m/z* (FAB) 466 (M + 1).

Synthesis and Purification of Oligonucleotides. DNA oligonucleotides (ODNs) used for conjugation to the PBD (TFO3, TFO4, and TFO5) were prepared by our group (TFO sequences are given in Table 1). ODNs were synthesized on an Expedite System Model 8909 synthesizer using 1 μmol phosphoramidite protocols supplied by the manufacturer and phosphoramidite reagents from Glen Research. TFO5 also contained a 3′ hexanol modification, introduced into TFO4 and TFO5 during automated DNA synthesis using a hexanol-modified CPG support from Glen Research. The linker was composed of hexa(ethylene glycol) phosphate groups and a C6-amino group (Scheme 2), synthesized by adding two

[a] PAM, phenylacetic acid mustard; PEG, poly(ethylene glycol) wraparound linker; PBD, pyrrolo[1,4]benzodiazepine; *G*, pyrazolopyrimidine analogue of guanine (underlined).

Spacer Phosphoramidite 18 groups and an N-MMT-hexanolamine phosphoramidite to the 5′ end of the oligonucleotide during automated synthesis (linker phosphoramidites were from Glen Research). ODNs were cleaved and deprotected in ammonium hydroxide, purified by HPLC, detritylated, precipitated, and suspended in deionized water. The concentrations of all ODNs were determined from UV absorbance at 260 nm in water. MALDI-TOF MS analysis of starting TFO4 for $C_{260}H_{351}N_{89}O_{166}P_{25}$ $[M + H]^+$: calculated 8154.5, found 8154.4. All ODNs were analyzed by reverse phase HPLC (C_{18} HPLC) using a 250 × 4.6 mm C_{18} column equipped with a guard column (Alltech Adsorbosil, 5 μm particle size). A gradient of 2 to 60% solvent B over 20 min was used. Solvent B was acetonitrile (flow rate 1 mL/min), and solvent A was 0.1 M triethylammonium acetate in water (pH 7.5). The triethylammonium (TEA) salt of the ODN was eluted from the column. Detection was carried out by UV absorbance at 260 nm. All ODNs were greater than 95% pure by C_{18} HPLC. TFO2 was synthesized with the pyrazolopyrimidine analogue of guanine (PPG, 8-aza-7-deazaguanine) in place of guanines and was conjugated at both ends to phenylacetic acid mustard (PAM) as previously described (*11*). Unmodified ODNs (TFO1 and synthetic target sequences) were purchased from commercial sources and gel-purified before use. The sequences of the synthetic duplex DNA target sequences are HNP36 d(TCACAGGAGAAGGAGGAGGTGGAGGAGGAGGGCTGC)-d(GCAGCCCTCCTCCTCCTCCACCTCCTCCTTCTCCTGTGA); HNP40-ApaI d(TCACAGGAGAAGGAGGAGGTGGAGGAGGAGGGCCCCTTGA)-d(TCAAGGGGCCCTCCTCCTCCTCCACCTCCTCCTTCTCCTGTGA); HNP40-inosine d(TCACAGGAGAAGGAGGAGGTGGAGGAGGAIIICTGCTTGA)-d(TCAAGCAGCCCTCCTCCTCCTCCACCTCCTCCTTCTCCTGTGA).

Synthesis of the ODN−PBD Conjugate. TFO4 (37 nmol, 0.3 mg), bearing the PEG wraparound linker ending in a C6-amino group, was redried, and the residue was dissolved in 0.1 mL of dimethyl sulfoxide (DMSO) with 15 μL of triethylamine. A 2 mg/100 μL solution of **3** in DMSO was prepared, and 17 μL (0.34 mg, 7.4 μmol) was added to the ODN. The mixture was incubated for 21 h at 37 °C with occasional shaking. The product was precipitated with $NaClO_4$/acetone, the pellet was sonicated with 2 mL of acetone, recentrifuged, and dried in a vacuum, and the crude product was stored at −20 °C. The product then was analyzed by C_{18} HPLC using the gradient described above. The product peak was collected and precipitated with ethanol, and the pellet was sonicated with 2 mL of ethanol, recentrifuged, and dried in a vacuum. The purified ODN−PBD conjugate, TFO5, was dissolved in water. MALDI-TOF MS analysis of TFO5 for $C_{278}H_{369}N_{91}O_{170}P_{25}$ $[M + H]^+$: calculated 8483.1, found 8483.8. The yield of TFO5 was 41% (0.12 mg).

Electrophoretic Mobility Shift Assay (EMSA) Analysis of Triplex DNA Formation. TFOs were incubated with the 36-base pair HER-2/neu duplex target sequence end-labeled on the pyrimidine strand. Reaction mixtures included increasing concentrations of the TFO with 0.01 μM target duplex in 1× TBM buffer (90 mM Tris pH 7.4, 90 mM borate, 10 mM $MgCl_2$) for 24, 48, and 72 h at 37 °C before nondenaturing gel electrophoresis with 1× TBM in both the gel and running buffer. Dissociation constants (K_d) were calculated to compare binding affinities of the TFOs by plotting the fractional yield (y) of triplex [triplex/(triplex + duplex)] as a function of the oligonucleotide concentration (*45*). It should be mentioned that the K_d is not a true dissociation constant for a reversible reaction at steady state, since the PBD may form a covalent bond with guanine, but remains a useful numerical representation of these data. Roughly, K_d is a TFO concentration under which 50% formation of triplex occurred; that is why we decided not to use the term K_d but use C_{50} instead.

Restriction Enzyme Protection Reactions. Triplex formation was performed as described above, but with a 40-base pair HER-2/neu duplex that was mutated to contain an ApaI site (5′GGGCTG3′→ 5′GGGCCC3′) adjacent to the polypurine tract and PBD binding site. Triplex mixtures (5 μL) were digested with ApaI for 2 h at 37 °C by adding 30 units of ApaI, restriction enzyme buffer (final concentration 10 mM Tris, pH 7.5, 10 mM $MgCl_2$), and water to bring reaction volumes up to 50 μL. Reactions were terminated with 30 μL of formamide loading buffer, denaturated for 2′ at 95 °C, and separated on a 12% denaturing gel.

Chemical and Enzymatic Footprinting. A 250 bp PstI/XmaI fragment of the pGL3/HNP410 plasmid containing a 410 bp HER-2/neu promoter within the PGL3 basic luciferase promoter plasmid (Promega) was used to create an end-labeled template by Klenow filling. To compare native versus inosine-substituted PBD binding sites, synthetic oligonucleotides were 5′-labeled on the purine-rich strand, annealed, and gel-purified prior to use. Triplex formation was performed in 1× TBM at 37 °C for 24 h. For dimethyl sulfate (DMS) footprinting, samples (10 μL) were mixed with 4 μg of sonicated salmon sperm DNA and treated with 0.5 μL of 10% ethanol solution of dimethyl sulfate (DMS) for 5 min. The reaction was stopped by the addition of 5 μL of DMS stop solution mixture. The DNA samples were ethanol-precipitated and lyophilized. Piperidine cleavage was performed by heating the DNA pellet with 50 μL of 10% piperidine for 20 min at 90 °C followed by ethanol-precipitation. Samples were suspended in water and an equal volume of formamide gel loading buffer and denatured at 95 °C for 2 min before electrophoresis. For DNaseI footprinting, samples (10 μL) were mixed with 2 μL poly(dI-dC)(1 mg/mL), 4 μL DNaseI binding buffer (Roche), and 15 μL of a mixture of 10 mM $CaCl_2$ and 10 mM $MgCl_2$. The samples were digested with 1 μL of Dnase I (0.1 U/μL) for 30 s, and the reactions were stopped by adding 25 μL formamide gel loading buffer and heating to 95 °C for 2 min. Footprinting reactions were separated on 10% denaturing gels.

Transient Transfections. HeLa cells were obtained from the American Type Culture Collection and cultured according to supplier guidelines. The pGL3/HNP410 plasmid (2 μg) containing the HER-2/neu promoter was incubated in 1× TBM at 37 °C with 10 μM TFO1, TFO3, or TFO5 for 48 h or with 1 μM of TFO2 for 4 h. Unbound

TFO was removed using 1× TBM equilibrated Chromaspin-100 columns (Clontech). Transfection was accomplished with Lipofectamine 2000 (Invitrogen) and included 20 ng of an internal control plasmid (pRL/SV40, Promega). Cell lysates were obtained at 24 h, and dual luciferase assays (Promega) were performed. Data from at least three assays were averaged, were normalized for transfection efficiency, and are presented as a percentage of luciferase activity from plasmid without TFO treatment.

RESULTS

Design of the TFO−PBD Conjugate. The ODN selected for conjugation to a PBD is a 23-mer GT antiparallel motif TFO, TFO3, that will form a triple helix with the polypurine tract in the HER-2/neu promoter, but will leave the last 5 bp of the tract available adjacent to the end of the triple helix for PBD binding (Figure 1). TFO sequences are given in Table 1. A 28-mer GA motif TFO (TFO1, Table 1) was shown to bind with high affinity to that region and prevent transcription in vitro (Ebbinghaus 1993), but required modification at both ends with a nitrogen mustard (TFO2, Table 1) to suppress the expression of HER-2/neu from a reporter plasmid in tumor cells (*11*). Substitution of guanines with the pyrazolopyrimidine analogue of guanine (PPG) in TFO2 prevents self-association of guanine rich oligonucleotides and improves triplex formation in physiological buffers (*32*). Studies comparing GA and GT motif TFOs for this target sequence showed similar binding affinities slightly favoring the GT motif (*45*). Tomaymycin is one of the most potent representatives of the PBD antitumor antibiotic family, and like all PBDs, it has a sequence preference for 5′Pu-G-Pu and forms a covalent bond with the exocyclic amino group of the central guanine of its binding sequence (Scheme 1). There are multiple potential PBD binding sites in the polypurine tract, and we selected a site at the downstream end of the polypurine tract for PBD binding. The synthetic PBD compound used in this study is structurally similar to the naturally occurring tomaymycin, but lacking a methyl group at the unsaturated C2-exo position. The unsaturation at the C2-exo position causes a flattening of the C ring and leads to a better fit in the minor groove. At the same time, an alkyl substituent at the C8-position of the A ring might reduce both DNA-binding affinity and cytotoxicity by a small degree (*50*), but this modification provides the bridge for conjugation with the ODN. Two hexa(ethylene glycol) chain linkers with one internal phosphodiester bond in each plus a 6-aminohexyl tail were introduced at the 5′end of TFO3 (resulting in TFO4, Table 1) to make a linker that is 50 atoms in length to allow for effective interaction of the PBD with the minor groove adjacent to the triple helix (Figure 1). The molecular models in Figure 1B show the triple helix, wraparound linker, and PBD bound to 5′Pu-G-Pu sites in the duplex region adjacent to the triple helix (Figure 1B, i and ii), or the duplex−triplex junction (Figure 1B, iii and iv) forming a covalent adduct with G-219 (i), G-220 (ii), G-222 (iii), or G-223 (iv). These models predict that triplex formation by the TFO−PBD conjugate (TFO5, Table 1) with the relatively long flexible linker will allow the PBD to reach the minor groove by wrapping around one DNA strand to bind at nearby 5′Pu-G-Pu binding sites.

Conjugation of the PBD to an Oligonucleotide. A mild method to introduce a nucleophilic alkylamine group on the end of the ODN for conjugation with an electrophilic derivative of the drug was employed, using DMSO as the solvent (*51*). The TEA salt of the ODN is soluble in DMSO and allows the lipophilic PBD moiety to be successfully conjugated in an organic solvent. The amine-containing linker was added to the growing ODN sequence during automated synthesis, resulting in TFO4. The TEA salt of the HPLC purified ODN was modified with the PBD as shown in Scheme 2. The *p*-nitrophenyl ester of desmethyltomaymycin was chosen as the activated moiety of the PBD for conjugation. *p*-Nitrophenyl esters are traditionally used in acylation reaction with amine-containing molecules to give amide bonds. *p*-Nitrophenyl esters can be purified by column chromatography and have slow rates of hydrolysis compared to some other activated esters. The activated ester of desmethyltomaymycin **3** was prepared as shown in Scheme 2. Anhydrous DMSO is a polar aprotic solvent that is useful for ODN conjugation chemistry. Generally the conjugation process requires an aqueous base to dissolve the ODN and to increase the nucleophilicity of the alkylamine linker. At the same time an organic cosolvent is needed in the system to increase the solubility of the liphophilic electrophiles. Although the PBD is stable in aqueous conditions, deactivation of the ester moiety might result in a lower yield of conjugation reaction and require a large excess of the PBD. In addition, desmethytomaymycin is lipophilic and has poor solubility in aqueous solutions. For these reasons, anhydrous conditions were used for synthesis of the ODN−PBD conjugate.

The progress of the conjugation reaction was monitored by HPLC and UV absorbance as shown in Figure 2. A PDA detector simplifies analysis because the PBD is a unique chromophore. The absorption spectra of the *p*-nitrophenyl ester of desmethyltomaymycin has a broad absorbance maximum at 225−240 nm.The HPLC chromatogram (Figure 2A) shows that 25 min after beginning, the reaction mixture contains an excess of starting unconjugated PBD (retention time 21 min), TFO4 (unconjugated ODN-linker), and a small peak of conjugated product, TFO5, close to TFO4 (retention time 13.3 and 12.9 min, respectively). After 21 h of incubation, the amount of unconjugated PBD is considerably decreased while the conjugated product, TFO5, represents the major peak in the chromatogram. UV absorbance monitoring (Figure 2B) demonstrates a very unique absorbance curve for the conjugated product, and the intensity of the absorbance of TFO5 is increased dramatically after 6 h of incubation. After 21 h of incubation, TFO5 was precipitated from the DMSO by adding sodium perchlorate in acetone. The resulting crude mixture was purified by reverse phase HPLC, and the identity of the conjugate was confirmed by mass spectral analysis.

Detection of Triplex Formation and Calculation of Binding Affinities by EMSA. The binding of TFO5 to the triplex target site in the HER-2/neu promoter was evaluated by EMSA (Figure 3A). Triplex mixtures were incubated in 1× TBM buffer for 24−72 h. After 24 h, triplex formation with TFO5 proceeds with a $C_{50} = 3.2$ μM that is very poor compared to TFO3 ($C_{50} = 0.015$ μM). Longer incubation with TFO5 improves the binding so that after 48 h the formation of triplex proceeds with $C_{50} = 2.1$ μM, and after 72 h with $C_{50} = 0.9$ μM. This experiment demonstrates that the presence of the PBD on the end of the TFO slows the process of triplex formation, but also shows that the PBD remains active for at least 72 h. The TFO itself may have potential PBD binding sites, and intramolecular interaction of the PBD with the TFO or self-association of the guanine rich oligonucleotides might account for the poor binding to the

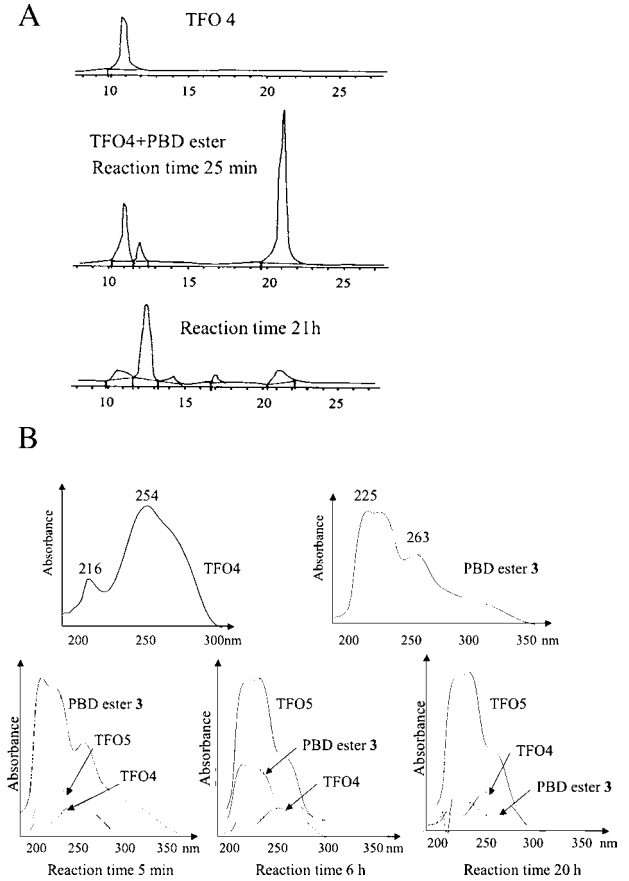

Figure 2. HPLC and UV monitoring of the TFO–PBD conjugation reaction. (A) HPLC analysis monitoring the conjugation between TFO4 and PBD ester **3**. The top chromatogram shows unconjugated TFO4 at time zero, t_R = 12.9 min. The middle chromatogram shows the reaction mixture after 25 min with a large peak for the unconjugated PBD ester **3**, t_R = 21 min, and a small peak for TFO5, t_R = 13.3 min. The bottom chromatogram shows the reaction mixture after 21 h, with a large peak for TFO5 at 13.3 min. (B) UV monitoring of the conjugation reaction between TFO4 and the PBD ester **3**. Top panels, UV spectra of TFO4 (left) and the PBD *p*-nitrophenyl ester **3** (right). Bottom panels, UV spectra of the conjugation reaction at monitoring of progress in conjugation reaction at 5 min, 6 h, and 20 h.

target sequence. EMSAs were performed with increasing concentrations of TFO5 alone for up to 72 h, and no self-association of TFO5 was observed by methylene blue staining (not shown). Because the triplex target sequence contains many potential PBD binding sites, we speculate that the process of PBD docking in the minor groove in the triplex target sequence is interfering with the formation of the triple helix within major groove. The structure and length of the TFO and linker might cause sterical obstacles for positioning the drug in the desired location adjacent to the TFO binding site and may be amenable to further optimization (*44*).

Enzymatic and Chemical Footprinting. To precisely determine the binding site for TFO5, we used DNase I footprinting. DNase I has been used extensively to footprint TFOs and some MGBs such as distamycin, netropsin, Hoechst 33258, and berenil. These MGBs cause clear changes in the DNase I digestion patterns, but no simple footprints (*52*). In contrast, the PBD analogue DC-81 does not alter DNase I cleavage patterns, and among the PBDs, tomaymycin binding produces the least distortion of the duplex (*39*, *53*). Our DNaseI footprinting experiment with TFO3, TFO4 (not shown), and TFO5 demonstrated that all three TFOs protect the

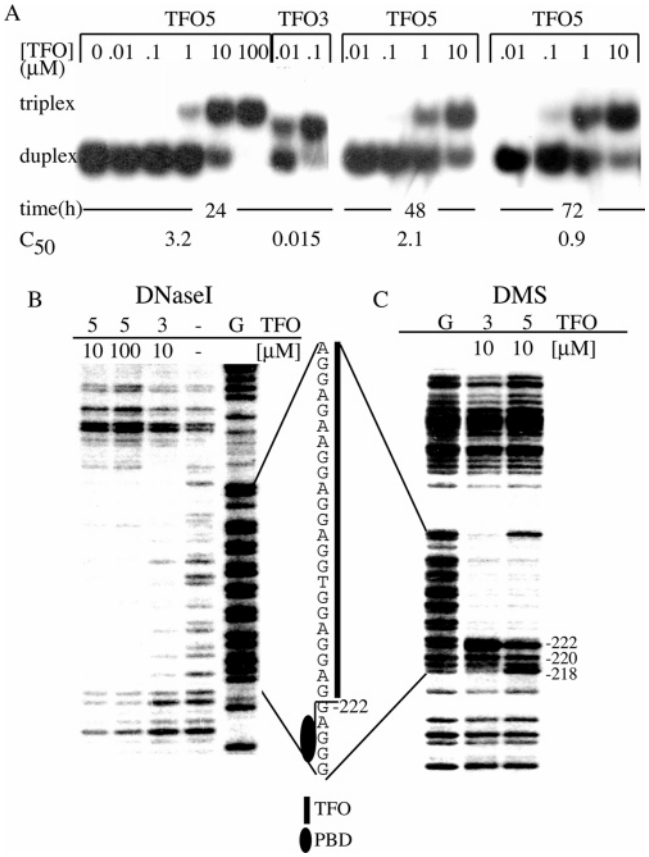

Figure 3. Triplex formation by TFOs with and without PBD. (A) EMSAs showing triplex formation at 24, 48, and 72 h. Apparent dissociation constants (K_d) for TFO3 and TFO5 calculated from these EMSAs are shown below each time point. (B) DNaseI footprints showing the binding of TFO3 and TFO5 to the HER-2/neu promoter. A stronger footprint is observed for TFO5. (C) DMS footprints showing the binding of TFO3 and TFO5 to the triplex target sequence. Note the hypersensitivity of G(−222) at the duplex–triplex junction in the absence of PBD binding with TFO3, and the hypersensitivity of G(−218) in the presence of PBD binding with TFO5. Also note partial protection of G(−219) and G(−220) in the presence of PBD binding with TFO5.

duplex from cleavage by DNase I, with identical binding sites for the TFO with and without the PBD conjugate (Figure 3B). We do not observe an altered cleavage pattern due to the PEG linker or PBD interaction with the DNA template, in accord with previous observations of the absence of altered DNase I cleavage patterns produced by tomaymycin. At the same time, these footprints demonstrate that TFO5 provides greater protection of the duplex than TFO3, suggesting that PBD binding stabilizes triplex formation between duplex and TFO5 conjugate.

Triplex formation was also evaluated with DMS footprinting (Figure 3C). DMS can be used to determine the accessibility of the N7 position of guanines, and protection from DMS alkylation occurs due to the Hoogsteen bonds formed by the TFO. DMS cleavage patterns can also reflect changes in the nucleophilicity of the N7 of guanine, which can be influenced by flanking bases and drug binding to DNA in the vicinity of the guanine (*54*). Thus, although the PBD binds in the minor groove and reacts with the exocyclic amino group of guanine, changes in the DMS cleavage pattern adjacent to the triple helix would be indicative of PBD binding. The DMS footprints in Figure 3C show that both TFO3 and TFO5 protect the guanines in the triple helix. TFO3 binding produces a hypersensitive guanine immediately adjacent to the triple

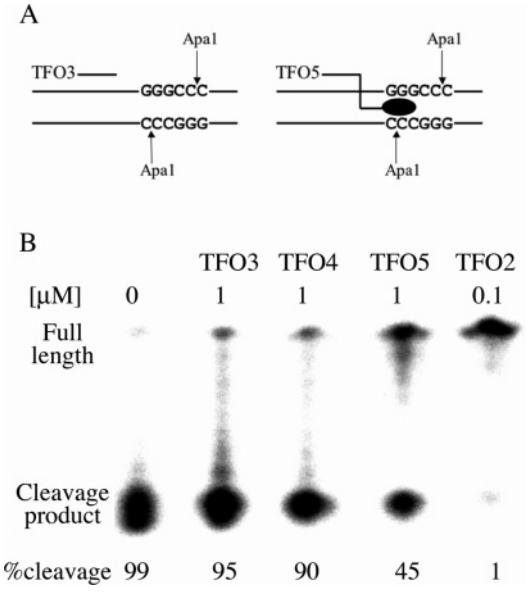

Figure 4. PBD binding adjacent to the triple helix protects the target sequence from restriction enzyme digestion with ApaI. (A) Schematic representation of the location of the engineered ApaI site in the HER-2/neu promoter relative to the triple helix formed by TFO3, TFO4, and TFO5. (B) The cleavage products of ApaI digestion before and after triplex formation by TFO2−TFO5 were resolved on a denaturing gel and quantified by densitometry.

helix at G(−222) that is not observed with the binding of TFO5, indicating that either the wraparound linker blocks the accessibility of the N7 of this guanine to DMS or that PBD binding alters its reactivity to DMS. TFO5 binding also decreases the reactivity of G(−220) and G(−219) while inducing a hypersensitive guanine at G(−218). Interestingly, a guanine at the opposite end of the triple helix from the expected PBD binding site, G(−244), is also more reactive with TFO5 compared to TFO3, perhaps due to a 3′ hexanol modification in TFO5. Agents that bind to the minor groove have been shown to alter DMS cleavage patterns over a fairly long range so that assignment of explicit drug binding sites is difficult (*54*). Nonetheless, these footprints suggest that the PBD moiety of TFO5 binds to either the AGG (−221 to −219) or the GGG (−220 to −218) 5′Pu-G-Pu PBD binding sites adjacent to the triple helix.

Restriction Endonuclease Protection Analysis. To provide further evidence for PBD binding adjacent to the triple helix formed by TFO5, we evaluated the ability of PBD binding to prevent restriction endonuclease cleavage adjacent to the triple helix (Figure 4). For this assay, we modified two bp of the HER-2/neu promoter downstream of the polypurine tract to form an ApaI (native sequence: 5′GGGCTG3′→ ApaI mutant sequence: 5′GGGCCC3′) so that PBD binding would protect this sequence from ApaI cleavage (Figure 4A). TFO3, TFO4, and TFO5 were added to the ApaI mutant sequence at a final concentration of 1 μM and incubated for 48 h, while TFO2 was incubated with the duplex for 4 h at a concentration of 0.1 μM. Figure 4B shows the cleavage products of ApaI digestion after triplex formation with TFOs with and without a PBD conjugate. Of these, only TFO5 containing the PBD conjugate inhibited ApaI digestion. The triple helix itself does not prevent ApaI cleavage, since nearly complete digestion is seen with TFO3 (unmodified TFO). Similarly, the 50-atom linker does not appear to sterically inhibit ApaI recognition or cleavage, since nearly complete digestion is seen with TFO4 (TFO with the linker). TFO2, a slightly longer TFO conjugated to PAM, completely prevented ApaI digestion, while restriction endonuclease protection by TFO5 was incomplete, suggesting that PBD binding at the ApaI site is either less efficient or less stable than PAM binding; however, it is important to note that the triple helix formed by TFO2 overlaps the ApaI site, whereas the triple helix formed by TFO5 does not, and ODN binding in the major groove may more effectively block the restriction site than PBD binding in the minor groove. PBD binding to DNA has been previously demonstrated by methidiumpropyl EDTA-Fe(II) (MPE-Fe) cleavage (*37*, *53*), but our attempts to obtain a differential cleavage pattern between TFOs with and without the PBD (TFO3 and TFO5) using MPE-Fe were not successful, perhaps because tomaymycin produces the least distortion of the double helix of any member of the PBD family. Nonetheless, the combination of DMS footprinting and endonuclease protection studies clearly demonstrates that TFO5 directs the binding of the PBD moiety to a PBD binding site adjacent to the triple helix.

DMS Footprints with an Inosine-Substituted PBD Binding Site. The 2-amino (exocyclic amino) group of guanine is a critical element in the sequence-specific recognition of DNA through the minor groove, where most small molecules bind (*55*, *56*). For this reason, footprinting studies performed on DNA fragments containing inosine in place of guanine are useful for demonstrating minor groove binding by proteins and small molecules. Inosine (I) is a guanine analogue that lacks the exocyclic amino group (Figure 5A) and is therefore not able to donate a hydrogen bond nor form a covalent bond with a PBD. Inosine-substituted oligonucleotides were used in studies that showed the aminal bond formed between the C11 of tomamycin and the exocyclic amino group of guanine (*57*). We compared the DMS footprints produced by TFO3, TFO4, and TFO5 in a duplex target with three inosine substitutions I(−218), I(−219), and I(−220) in the PBD binding site. EMSA analysis demonstrates that inosine substitution at these positions does not significantly alter the ability of the TFOs to form a triple helix with the target sequence (Figure 5B). The DMS cleavage pattern adjacent to the triple helix again demonstrates that PBD binding in the native sequence greatly reduces the reactivity of a hypersensitive guanine, G-222, at the duplex−triplex junction (Figure 5C, left panel). In contrast, in the inosine-substituted sequence, the DMS reactivity of G-222 is essentially identical for TFO3, TFO4, and TFO5 (Figure 5C, right panel). In addition, the DMS reactivity of the guanine at −218 is again reduced by PBD binding to the native sequence, while the DMS reactivity of all three inosine bases is essentially identical for TFO3, TFO4, and TFO5. These data clearly demonstrate the interaction between the PBD molecule and the guanines adjacent to the triple helix and, taken together with prior studies (*57*), provide inferential evidence for a covalent PBD interaction with a guanine in the PBD binding site.

Transient Transfection Assays. To determine whether PBD binding sufficiently stabilized triplex formation to prevent HER-2/neu transcription initiation, we performed transient transfection assays with a HER-2/neu promoter-luciferase reporter plasmid. Triple helix formation by TFOs with and without 5′ and 3′ PAM groups (TFO1 and TFO2) was compared to triplex formation by TFOs with and without a 5′PBD (TFO3 and TFO5). For these experiments, the plasmid was treated with the TFO under ideal binding conditions, purified from unbound, excess TFO by column chromatography, and transfected into HeLa cells. Figure 6 shows HER-2/

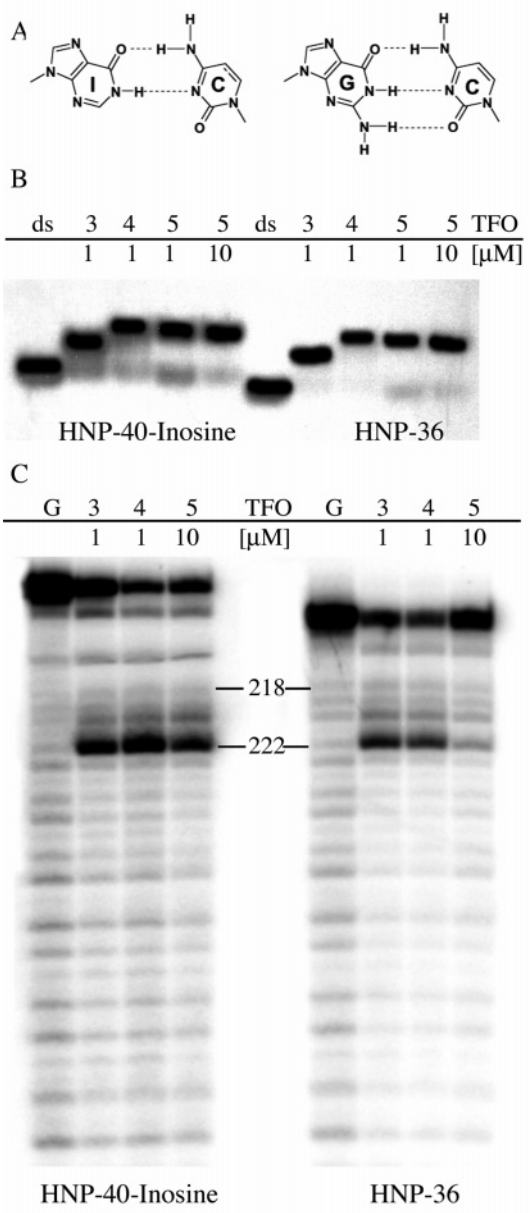

Figure 5. The PBD binding site adjacent to the triple helix was demonstrated with DMS footprints on an inosine-substituted, synthetic HER-2/neu promoter fragment. (A) Structure of hydrogen-bonded guanine-cytosine and guanine-inosine base pairs. (B) EMSA demonstrating that the amount of triplex formation by TFO3−TFO5 is equivalent between the inosine-substituted (HNP-40-inosine) and native (HNP-36) synthetic HER-2/neu promoter fragments. Inosines were substituted for guanines at the putative PBD binding site (−218 to −220). (C) DMS footprints demonstrating identical cleavage patterns for TFOs with (TFO5) and without (TFO3, TFO4) a PBD in the inosine-substituted HER-2/neu promoter fragment. Note the hypersensitivity of G(−222) at the duplex−triplex junction in the absence of PBD binding seen with all TFOs in the inosine-substituted sequence, but only for TFO3 and TFO4 in the native sequence.

neu driven luciferase activity at 24 h after treatment with TFOs, presented as relative expression compared to untreated plasmid and normalized for transfection efficiency by a cotransfected reporter plasmid. These data demonstrate that triplex formation by itself (TFO1 and TFO3) is incapable of preventing HER-2/neu transcription, while triplex formation and covalent adduct formation at both ends of the triple helix with a nitrogen mustard (TFO2) is capable of suppressing transcription from the HER-2/neu promoter by approximately 60% and

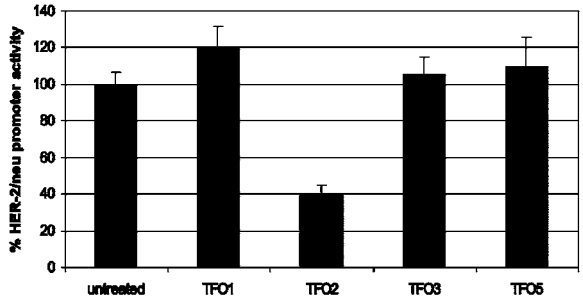

Figure 6. Transient transfection analysis of the effects of triplex formation by unmodified TFOs (TFO1 and TFO3) and TFO conjugates (TFO2 and TFO5) on HER-2/neu expression. HeLa cells were transfected with a firefly luciferase plasmid controlled by a 410 bp HER-2/neu promoter and treated with TFOs prior to transfection, and luciferase activity was measured at 24 h.

reproduce our earlier findings (*11*). Triplex formation and PBD binding (TFO5) failed to suppress HER-2/neu transcription in these studies, even though the binding conditions for TFO5 in this experiment were shown to yield complete binding to the target sequence by the TFO and at least reasonably efficient binding by the PBD in other assays. We have previously shown that guanine adduct formation at only one end of the triple helix by a nitrogen mustard was inefficient at preventing HER-2/neu transcription in this assay system, and the present results are in accord with our findings that covalent binding at both ends of the HER-2/neu triplex target sequence is probably needed to prevent HER-2/neu transcription by a TFO in cells.

DISCUSSION

We report the synthesis of a novel oligonucleotide−pyrrolo[1,4]benzodiazepine conjugate by a versatile method. This TFO−PBD conjugate is capable of forming a triple helix with the HER-2/neu promoter and directing the site-specific binding of the PBD adjacent to the triple helix. Conceptually, this strategy could improve the binding of the TFO and direct the biological activity of the PBD to a single gene of interest. However, our results demonstrate some of the challenges to this strategy that may be amenable to further optimization.

First, the presence of the PBD moiety on the TFO slows the process of triplex formation, since the TFO alone completely binds to the target sequence after 4 h at 37 °C. PBDs are known to initially bind slowly and reversibly to DNA, and binding may be incomplete even after 48 h at 37 °C (*58*−*60*). Alternately, the linker between the major groove binding TFO and the minor groove binding PBD may be critical to the activity of the conjugate. The long, flexible linker used in this study may allow the PBD to bind to any available PBD binding site before the TFO binds, until an optimal TFO−PBD binding site is finally encountered. The HER-2/neu promoter is rich in potential PBD binding sites, and we speculate that reversible PBD binding at unintended PBD binding sites prevents binding by the TFO and initially slows binding by the TFO−PBD conjugate. Once the TFO binds, the high local concentration of the PBD adjacent to the triple helix may actually improve covalent bond formation by the PBD and improve overall binding by the conjugate.

Conjugation of the PBD to a minor groove binding polyamide carrier improves PBD binding to DNA and antiproliferative activity in tissue culture, suggesting that the presence of the alkylating moiety and the carrier

in the same minor groove of DNA can create a more stable drug−DNA interaction (*39*, *61*). The CPIs are another class of MGBs that have been tethered to TFOs. CPIs appear to bind more rapidly, and in the context of a TFO−CPI conjugate, triplex formation is the rate-limiting step in the binding of the conjugate (*43*). Studies of TFO−CPI conjugates also demonstrate the importance of the linker between the major groove and the MGB and suggest that an aromatic molecule capable of intercalating into the DNA and threading the duplex may be a more robust means of using a TFO to direct the site of the MGBs (*44*).

Second, the interaction of the TFO−PBD conjugate with the HER-2/neu promoter is not sufficient to prevent HER-2/neu expression from a reporter plasmid. It is likely that the triple helix formed by the TFO−PBD conjugate is not sufficiently stable in cells, even though the TFO−PBD conjugate produces a stronger DNaseI and DMS footprint, indicative of an improvement in binding, compared to the unconjugated TFO. Our previous studies with TFOs conjugated to PAM at one or both ends demonstrated that a mono-conjugate was practically inactive at suppressing transcription within cells, while a bis-conjugate significantly suppressed HER-2/neu expression in this assay system and was the least susceptible to displacement by a recombinant DNA helicase (*11*). Similarly, TFO−psoralen conjugates that create a single locus of DNA damage are efficiently repaired in cells while triplex-directed cross-links at both ends of the triple helix are not (*62*).

Helicase activity is present in many of the enzymes that process DNA, including replication, transcription, and repair. DNA interactive small molecules differ in their ability to inhibit DNA helicase translocation and unwinding, and nogalamycin is one of the most potent helicase inhibitors, because it intercalates and binds in both the major and minor grooves into both grooves of DNA (*63*). MGBs including distamycin and netropsin can also block DNA helicase (*64*). PBD−DNA adducts, however, are stable only as long as the double helix structure of DNA is maintained (*65*) and thus may be unable to remain bound to DNA in the face of an advancing helicase. C8 linked PBD dimers, which form interstrand cross-links, are able to resist the repair process in cells for more than 48 h (*66*). A single tomaymycin molecule on the end of the TFO may be unable to resist displacement by helicases, and conjugation to a PBD dimer capable of forming cross-links or to a PBD molecule at both ends of the TFO would likely be more active in this regard.

In conclusion, we report the first example of an ODN−PBD conjugate and demonstrate that triplex formation by the ODN directs the PBD to a specific location adjacent to the triple helix. Although our studies did not directly demonstrate covalent PBD binding to the target sequence, the lack of PBD binding to an inosine-substituted target sequence demonstrates the need for the exocyclic amino group of guanine in accord with previous data that demonstrate covalent PBD binding to guanine. This study demonstrates the conceptual feasibility of site-specific PBD targeting by a TFO, but shows that further optimization of the design of this bioconjugate will be needed to address the obstacles of slow binding to DNA and instability of the interaction within cells.

ACKNOWLEDGMENT

This work was supported by grants from the NIH (CA85306) and the Flinn Foundation (1580). The authors gratefully acknowledge the Lajos Szabo for assistance with HPLC analysis and David Milesi for assistance with the conjugation reactions.

NOTE ADDED AFTER ASAP POSTING

In the version of the manuscript posted October 30, 2004, “Pyrrolobenzodiazepine” replaces “Tomaymycin” in the manuscript title. In line 19 of the first paragraph of the Results section, “Desmethyltomaymycin” is replaced by “Tomaymycin”. In line 29 of the same paragraph, the phrase “but lacking a methyl group at the unsaturated C2-exo position” is inserted. Finally, a corrected Scheme 1 has been inserted into the second page. The corrected version of the manuscript was posted November 9, 2004.

Influence of Pendant Arms Bearing Ligating Groups on the Structure of Bismuth Porphyrins: Implications for Labeling Immunoglobulins Used in Medical Applications

Zakaria Halime,[†,‡] Lydie Michaudet,[†] Mohammed Lachkar,[‡] Pierre Brossier,[§] and Bernard Boitrel*[,†]

Institut de Chimie, Université de Rennes1, UMR CNRS 6509, 35042 Rennes Cedex, France, Faculté des Sciences Dhar El Mehraz, Laboratoire d'Analyses, d'Essais et d'Environnement (L.A.E.E), Université Sidi Mohammed Ben Abdellah, B.P. 1796 (Atlas), 30000 Fès, Morocco, and Laboratoire de microbiologie médicale et moléculaire, Facultés de médecine et pharmacie, Université de Bourgogne, 7 Bd Jeanne d'Arc, 21000 Dijon, France. Received July 2, 2004; Revised Manuscript Received September 3, 2004

The synthesis of two picket bismuth(III) porphyrins is reported, and their crystal structures are compared. The influence of the nature of the pickets, as well as their number, is discussed in terms of stability, kinetics of metalation, structure, and distortion of the porphyrin. Unexpectedly, the results indicate that the coordination sphere of bismuth is not affected by different types of distortion nor is the stability of the complex. For both types of complexes, the X-ray crystallography revealed that a single arm is actually in direct interaction with the bismuth cation, thereby allowing further functionalization on the porphyrin core as the linkage with immunoglobulins or anti-rabbit antibodies (both noted IgG), which have been used in diagnostic or therapeutic applications.

INTRODUCTION

Bismuth coordination has long been represented by bismuth citrate because of its activity in the treatment of gastric ulcers (*1*, *2*). Very recently, the structure of colloidal bismuth subcitrate has also been investigated in dilute acidic medium (*3*). Additionally, compounds containing radioactive isotopes of bismuth such as ^{213}Bi are now under investigation due to the potential of α-emitting nuclides in radioimmunotherapy (*4*, *5*). However, a major issue remains the stable in vivo binding of the metal to the ligand without any leakage because it has been shown, for instance, that the binding constant of bismuth to human serum albumin is 10^{11} and that its binding to transferrin is even stronger (*6*). Different types of cyclic structures have also been investigated as potential chelates of bismuth. Among them, one can cite crown-ethers, tetraazamacrocyles and porphyrins (*7*−*11*). Until the early 1980s, few reports dealing with the complexation of bismuth into porphyrins had been published, presumably because of their instability (*12*). On the other hand, during the past decade, various studies led to a better understanding of the coordination of bismuth in porphyrins, whether in organic or aqueous medium (*13*−*17*). Our group has also investigated the potential of picket porphyrins as bismuth chelates, targeting on one hand a better knowledge of the coordination of bismuth and on the other hand the preparation of bifunctional linkers ready to be linked on biological proteins such as immunoglobulins (IgG). We have published the solid-state structures of two related porphyrins (*18*, *19*), as well as an evaluation of the length of the picket bearing an ethyl ester group (*20*).

In this study, we report the detailed preparation of these two bismuth porphyrins, a precise comparison of the corresponding X-ray structures, its implications for the transformation of the initial chelates in several analogous bifunctional linkers, and their reactivity toward IgG by means of different spacers.

EXPERIMENTAL PROCEDURES

General. Unless otherwise stated, the analytical facilities were provided by the Université de Bourgogne (C.S.M.) in Dijon. ^{1}H (500.13 or 300.14 MHz) and ^{13}C (125.05 or 75.47 MHz) NMR spectra were recorded on Bruker Avance DRX 500 or Avance 300 spectrometers and referenced with respect to the residual protonated solvents. Mass spectra were performed on a MS/MS ZABSpec TOF spectrometer at the University of Rennes I (C.R.M.P.O.). UV/vis spectra were recorded on a Varian Cary 1E spectrometer, λ/nm (10^{-3} ϵ, M^{-1} cm^{-1}). IR spectra were recorded on a Bruker IFS 66 spectrometer in cm^{-1}. All solvents (ACS for analysis) were purchased from Carlo Erba. THF was distilled over potassium metal. CH_2Cl_2 was used as received. Triethylamine was distilled over CaH_2. The starting materials were generally used as received (Acros, Aldrich) without any further purification. All reactions were performed under an argon atmosphere and monitored by TLC (silica, CH_2Cl_2/CH_3-OH). Column flash chromatography was performed on silica gel (Merck TLC-Kieselgel 60H, 15 μm). Immunoglobulins and anti-rabbit antibodies were purchased from Sigma.

Syntheses. α-*5,10,15,20-Tetrakis{2-[3-(ethoxycarbonyl)propionylamido] phenyl} Porphyrin,* ***1****.* αααα-Tetra-*ortho*-aminophenyl Porphyrin (TAPP) (0.2 g, 0.3 mmol) was dissolved in 20 mL of freshly distilled THF under argon. Ten equivalents of anhydrous Et_3N was added, and the mixture was cooled to 0 °C. Ethyl succinyl chloride (5 equiv) was then added, and the solution was stirred overnight. Solvent was evaporated to dryness, and the residue was dissolved in a minimum amount of CH_2-

Cl_2 to be poured on a silica gel chromatography column. Product was eluted with a 0.1% CH_3OH/CH_2Cl_2 mixture and obtained in 93% yield (330 mg, 0.28 mmol). Microanalysis, $C_{68}H_{66}N_8O_{12}\cdot CH_3OH$, found (calcd): C, 68.25 (67.97); H, 4.44 (4.79); N, 9.33 (9.19)%. FAB-MS: *m/z* = 1187.8 $[M + H]^+$. FTIR (KBr, cm^{-1}): 1731 $(CO)_{ester}$, 1694 $(CO)_{amide}$. UV−vis (CH_2Cl_2, λ nm, 10^{-3} ϵ, M^{-1} cm^{-1}): 419 (337), 514 (20.9), 546 (5.8), 588 (6.7), 643 (3.7). ^1H NMR ($CDCl_3$, 323 K, 500 MHz): δ_H 8.86 (8H, s, β-pyr), 8.59 (4H, d, J = 7.1 Hz, aro), 8.00 (4H, d, J = 7.5 Hz, aro), 7.86 (4H, t, J = 7.6 Hz, aro), 7.55 (4H, t, J = 7.2 Hz, aro), 7.19 (4H, s, −NHCO), 3.44 (8H, br s, $-CH_2CH_3$), 2.18 (8H, t, J = 6.7 Hz, $-CH_2CH_2$), 1.70 (8H, br s, $-CH_2CH_2$), 0.79 (12H, br s, $-CH_2CH_3$), −2.59 (2H, s, −NH pyr). ^{13}C NMR ($CDCl_3$, 300 K, 125 MHz): δ_C 172.6, 170.1, 138.7, 135.4, 132.1, 130.3, 123.9, 122.9, 115.5, 60.7, 31.5, 29.0, 14.1.

α-*5,10,15,20-Tetrakis{2-[3-(ethoxycarbonyl)propionylamido] phenyl} Porphyrin Bismuth(III) Nitrate,* ***1BiNO$_3$***. In a 50 mL flask, **1** (26 mg, 0.02 mmol) was dissolved in 7 mL of pyridine. This solution was warmed to 55 °C before $Bi(NO_3)_3\cdot 5H_2O$ (100 mg, 0.2 mmol) was added. After the solution was heated for 2 h, the solvent was evaporated, and the residue was dissolved in a minimum amount of CH_2Cl_2 to be poured on a silica gel chromatography column. The product was eluted with a 1.2% CH_3OH/CH_2Cl_2 mixture and obtained in 85% yield (25 mg, 0.017 mmol). Microanalysis, $C_{68}H_{64}BiN_9O_{15}\cdot 2H_2O$, found (calcd): C, 55.16 (54.73); H, 4.47 (4.59); N, 8.27 (8.45)%. FAB-MS: *m/z* = 1393.8 $[M - NO_3]^+$. UV−vis (CH_2Cl_2, λ nm, 10^{-3} ϵ, M^{-1} cm^{-1}): 354 (42.4), 472 (176.9), 598 (9.8), 644 (8.3). FTIR (KBr, cm^{-1}): 1732 $(CO)_{ester}$, 1695 $(CO)_{amide}$, 1384 (NO_3), 991 (Bi−Np). ^1H NMR ($CDCl_3$, 300 K, 500 MHz): δ 9.24 (8H, s, β-pyr), 8.68 (4H, br s, aro), 8.22 (3H, br s, −NHCO), 8.13 (1H, br s, −NHCO), 7.89 (4H, m, aro), 7.90 (4H, t, aro), 7.56 (4H, br s, aro), 3.46 (2H, br s, $-\mathbf{CH_2}CH_3$), 3.32 (6H, br s, $-\mathbf{CH_2}CH_3$), 2.04 (8H, br s, $-CH_2CH_2$), 1.92 (8H, br s, $-CH_2CH_2$), 0.96 (3H, br s, $-CH_2\mathbf{CH_3}$), 0.87 (9H, s, $-CH_2\mathbf{CH_3}$). ^{13}C NMR ($CDCl_3$, 300 K, 125 MHz): δ_C 173.5, 170.8, 149.3, 140.4, 134.9, 133.5, 131.3, 130.6, 123.6, 123.1, 122.7, 119.3, 60.8, 31.5, 29.5, 14.1.

α-*5,10,15-Tris(2-(acetylamido)phenyl)-*α*-20-{2-[3-(ethoxycarbonyl)propionylamido] phenyl} Porphyrin,* ***3***. Compound **2** (0.37 g, 0.4 mmol), prepared as previously described, was dissolved in 30 mL of freshly distilled THF under argon. Ten equivalents of anhydrous Et_3N (0.3 mL, 4 mmol) was added, and the mixture was cooled to 0 °C. Ethyl succinyl chloride (21.60 μL, 0.15 mmol) was then added, and this mixture was stirred overnight. The solvent was evaporated to dryness, and the residue was dissolved in a minimum amount of CH_2Cl_2. The compound was purified by chromatography on a silica gel column. The product was eluted with a 0.8% CH_3OH/CH_2Cl_2 mixture and obtained in 92% yield (407 mg, 0.37 mmol). Microanalysis, $C_{56}H_{48}N_8O_6\cdot CH_3OH\cdot H_2O$, found (calcd): C, 70.02 (69.92); H, 5.14 (5.56); N, 10.83 (11.44)%. FAB−HRMS: calcd *m/z* = 929.3775 $[M + H]^+$, found 929.3763. FTIR (KBr, cm^{-1}): 1741 $(CO)_{ester}$, 1679 $(CO)_{amide}$. Cross-Linking Reactions with the IgG. The employed IgG was provided from an antiserum (whole molecule) developed in goat using rabbit IgG as the immunogen (Sigma product no. R-1131). The antiserum has been treated to remove lipoproteins. Only the protein concentration was determined (the antiserum contains 17.2 mg of specific IgG per milliliter). The F(ab)′ fragment was obtained after reduction of the disulfide bridges of F(ab)′2 fragment (Sigma product no. R-9130) resulting from pepsin-digested antiserum (Sigma product no. R-1131).

Different solutions were prepared to be employed in the linking experimental procedures.

Buffered Solution A. The solution contains 0.1 M sodium phosphate dihydrate ($NaH_2PO_4 \cdot 2H_2O$) and 5 mM ethylenediamine tetraacetic acid dihydrate ($H_4EDTA \cdot 2H_2O$) in distilled water. The pH of the solution was tuned to 6 by addition of sodium hydroxide.

Buffered Solution B. The solution contains 0.1 M sodium phosphate dihydrate ($NaH_2PO_4 \cdot 2H_2O$), 1 mM ethylenediamine tetraacetic acid dihydrate ($H_4EDTA \cdot 2H_2O$), and 1 mM sodium chloride in distilled water. The pH of the solution was tuned to 7.5 by addition of hydrochloric acid.

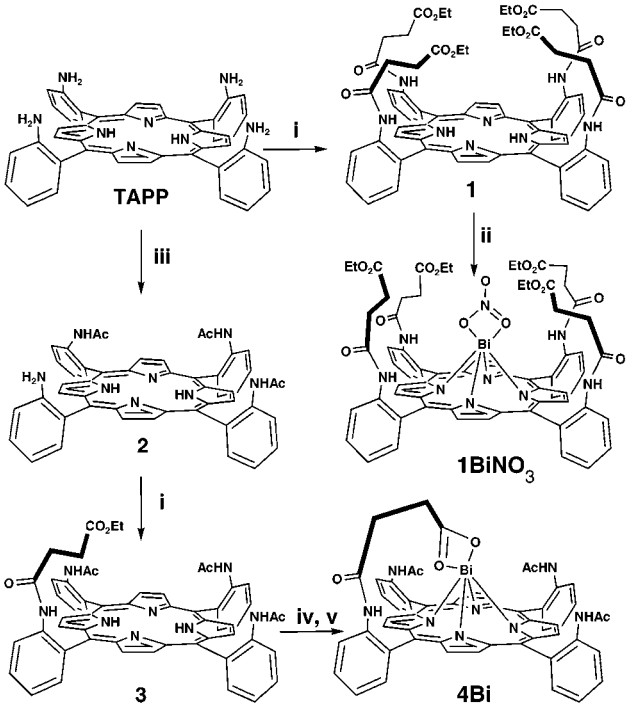
Buffered Solution C. The solution contains 50 mM sodium tetraborate decadihydrate ($Na_2B_4O_7 \cdot 10H_2O$) and 5 mM ethylenediamine tetraacetic acid dihydrate ($H_4EDTA \cdot 2H_2O$) in distilled water. The pH of the solution was tuned to 8.3 by addition of diluted chlorohydric acid.

N-Succinimidyl(4-iodoacetyl)aminobenzoic Acid (SIAB) Solution. SIAB (1.4 mg, 0.003 mmol) was dissolved in 1 mL of DMSO.

Solution of Porphyrin ***5***. Porphyrin **5** (1.2 mg) was dissolved in 0.12 mL of DMSO to obtain a concentration of 9.44 mM.

Solution of Porphyrin ***6***. Porphyrin **6** (3.7 mg, 50 equiv relative to the antibody) was dissolved in 0.38 mL of DMSO to obtain a concentration of 8.5 mM.

Coupling Reaction of Porphyrin 5 with Fab′ Fragments Activated with SIAB, Fab′−SIAB−5. SIAB solution (10 μL, 5 equiv/protein) was added to the solution of reduced IgG. The mixture was then incubated in the dark at room temperature during 1 h. This solution of the activated Fab′ was purified by gel filtration chromatography over a Sephadex G25 column and eluted with buffered solution C. To the solution of purified Fab′−SIAB, 38 μL of the solution of **5** (50 equiv/protein) was added. The mixture was incubated for 1 h in the dark at room temperature to allow complete coupling of the Fab′. The solution of the final conjugate was purified again by gel filtration chromatography over a Sephadex G25 column and eluted with buffered solution C. A second chromatography did not change the ratio porphyrin/antibody.



Coupling Reaction of Porphyrin 6 with a Reduced IgG Fragment, Fab′−6. As a test reaction, the same porphyrin has been coupled with thiophenol, and the resulting porphyrin led to consistent analytical data. In a hemolysis tube, 2.5 mg of IgG was dissolved in 1 mL of buffered solution A. 2-Mercaptoethanolamine (MEA, 6.6 mg) was added, leading to a MEA concentration of 50 mM. The mixture was then stirred at 37 °C for 1 h, 30 min. Buffered solution B (2.5 mL) was added, and the Fab′ fragments were purified by gel filtration chromatography over a Sephadex G25 column (NAP-10 Pharmacia, Sweden). The reduced IgG were dissolved in 2.5 mL of buffered solution B, and 100 μL of solution of porphyrin **6** was added; then the mixture was stirred at room temperature. The conjugate was purified by gel filtration chromatography over a Sephadex G25 column and eluted with buffered solution B.

Coupling Reaction of Porphyrin 7 with Anti-Rabbit Antibodies, Ab−7. Porphyrin **7** was dissolved in THF together with *N*-hydroxysuccinimide and dicyclohexylcarbodiimide (DCC) under an argon atmosphere. After 24 h of stirring, the reaction mixture was filtered to remove the precipitate due to formation of DCU, evaporated and used without any further purification. The activated porphyrin was dissolved in DMSO, and 50 equiv/protein was employed. The same experimental procedure as above was applied.

RESULTS AND DISCUSSION

Obviously, the porphyrinic macrocycle is attractive owing to its coordination properties but also because it

Scheme 1: Synthetic Pathway for the Preparation of Succinylamido Picket Porphyrins[a]

[a] Reagents and conditions: (i) $ClCO(CH_2)_2CO_2Et$ (5 equiv for **1** or 1.1 equiv for **3**), NEt_3, THF; (ii) $Bi(NO_3)_3{\cdot}5H_2O$ (10 equiv), 55 °C, pyridine, 2 h; (iii) CH_3COCl (3 equiv), NEt_3, THF; (iv) KOH, EtOH, 55°C → **4**; (v) $Bi(NO_3)_3{\cdot}5H_2O$ (1.2 equiv), rt, pyridine, 10 min.

represents a relatively rigid and disk-shaped structure suitable as a framework to build up new types of artificial chelators. Furthermore, meso-ortho-substituted phenyl porphyrins, owing to their possible atropisomerization, provide another interesting property that allows preorganization on a specific side of the macrocycle. We have taken advantage of this particularity by performing very simple reactions on αααα-tetra-*ortho*-aminophenyl porphyrin (TAPP). The initial idea consisted in supplementing the porphyrin by four ester pickets, assuming that one or several pickets would bend over the porphyrin ring to complete and satisfy the coordination sphere of the metal, making it inaccessible to dissociation (*21*). Besides, in compound **1BiNO$_3$**, the picket fence could protect the metal from any intermolecular interaction. In a second step, we have prepared the single carboxylic acid picket porphyrin **4**, keeping in mind that, bismuth being trivalent, the carboxylate function would lead to a neutral complex. The synthesis of these two ligands is detailed in Scheme 1.

Where porphyrin **1** bearing four ethyl succinyl pickets (4ES) is obtained by a straigthfoward acylation of the αααα atropisomer of TAPP with ethyl succinyl chloride, the preparation of **4** requires several extra steps to reach the single succinic acid compound (1SA). Indeed, the first step of the synthesis requires the protection of three amino groups of TAPP with acetyl chloride in dry THF. The optimization of the yield (55%) toward the three-protected porphyrin **2** requires the use of 3 equiv of the acylation reagent, and the separation of undesired compounds such as the tetra- and diacylated porphyrins was performed on a silica gel chromatography (*20*). The remaining amino group was functionalized with 1.1 equiv of ethyl succinyl chloride to obtain **3** (89%) the ester group of which was hydrolyzed with KOH, leading to **4**. So far, we performed the metal insertion by heating at 50 °C

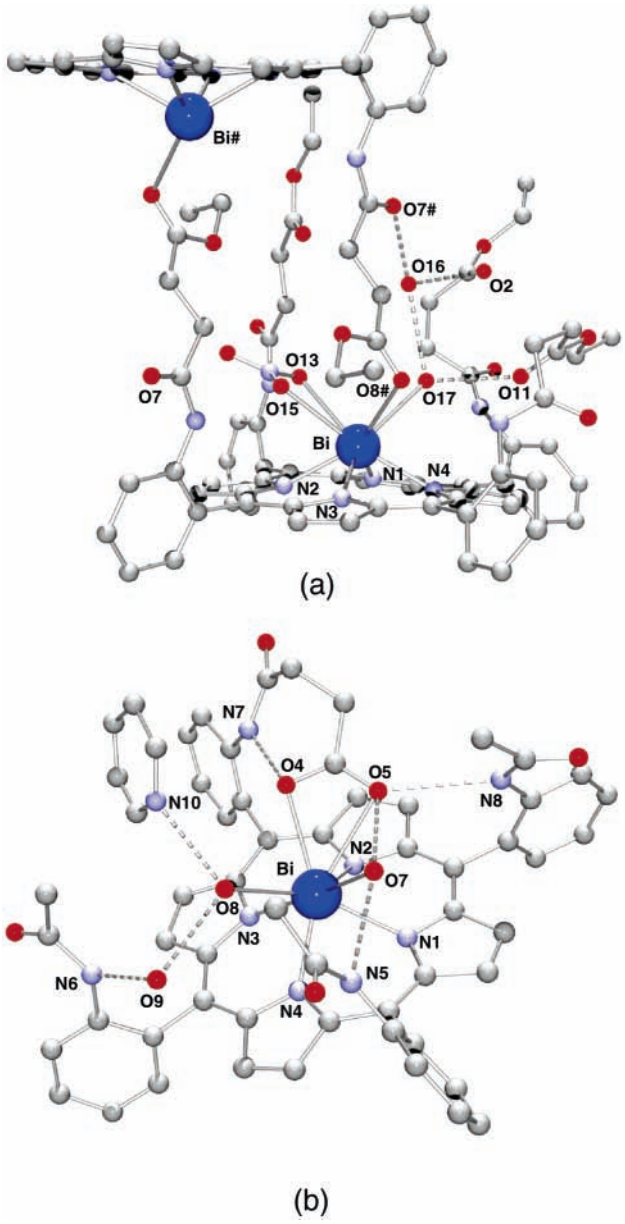


Figure 1. Ball and stick representation of the crystal structure of (a) **1BiNO$_3$** and (b) **4Bi**.

the free-base porphyrin with bismuth nitrate in pyridine. Actually, we found out that this complexation is achieved after stirring for 10 min at room temperature. Both complexes led to an X-ray structure, and the detailed comparison of these structures (Figure 1) is instructive both in terms of differences and similarities.

In both complexes, the Bi(III) is eight coordinate with an approximate square antiprismatic geometry. One square is formed by the four nitrogen atoms from the porphyrin, the other one being composed of four oxygen atoms. Two of them come from the bidentate counteranion, whether nitrate in **1BiNO$_3$** or carboxylate for **4Bi**. The third bound oxygen atom comes from a water molecule included in a hydrogen bonding net: O17 in **1BiNO$_3$**; O7 in **4Bi**. In **1BiNO$_3$**, the fourth bound oxygen comes from a carbonyl oxygen atom O8# of the terminal ester group belonging to an arm attached to a symmetrically related macrocycle, forming in this way, a centrosymmetric dimer. For **4Bi**, which exhibits a mononuclear structure—the first major difference between the two structures, a second water molecule represents the fourth oxygen atom O8. For both compounds, only one

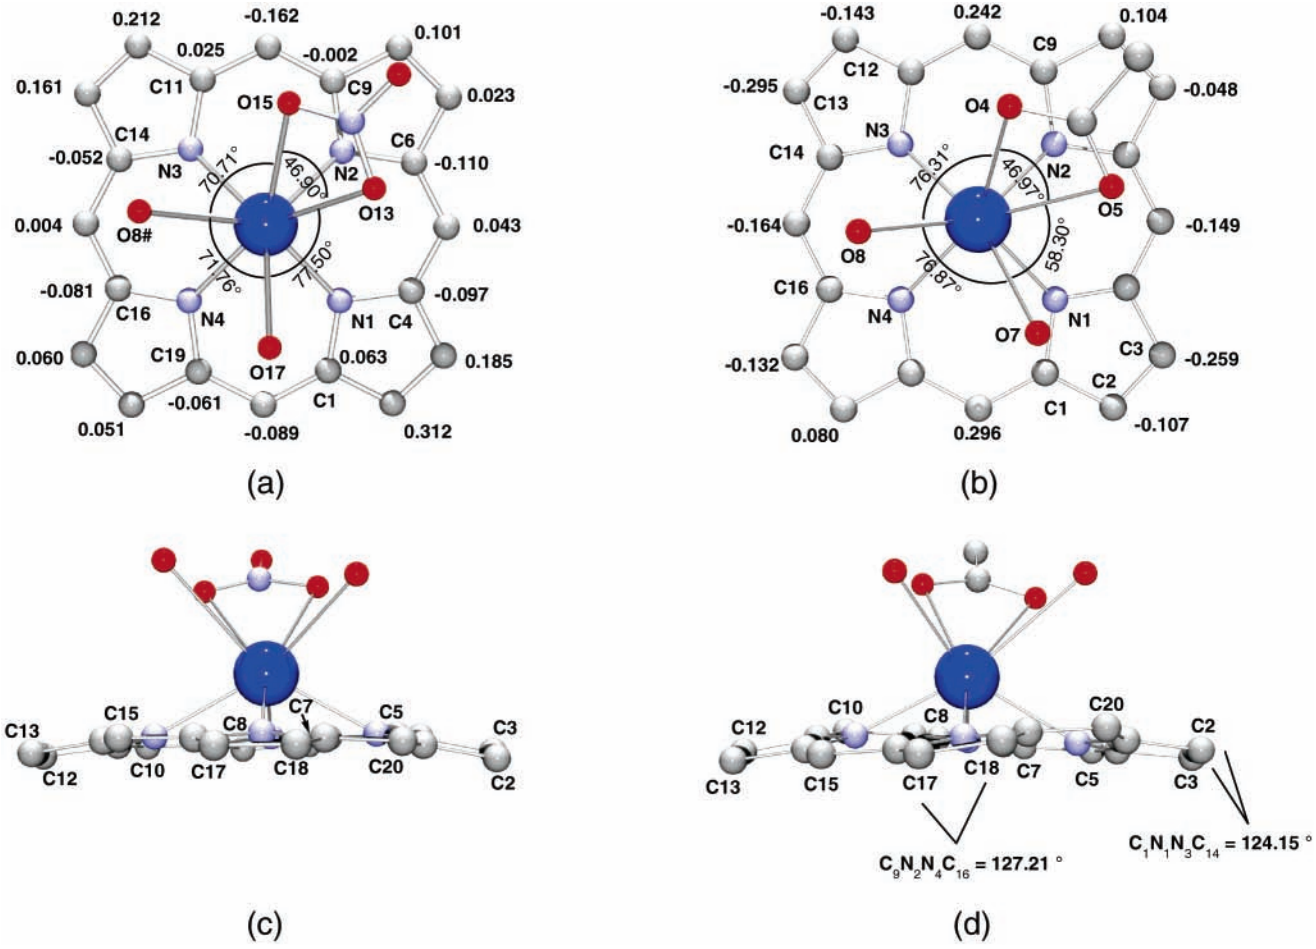

Figure 2. Ball and stick polyhedron coordination top views of (a) **1BiNO$_3$** and (b) **4Bi** and side views of (c) **1BiNO$_3$** and (d) **4Bi**. All the deviations refer to the mean porphyrin plane.

arm is in direct interaction with the metal, either in an intermolecular fashion in **1BiNO$_3$** or in an intramolecular scorpionate-like coordination in **4Bi**. Indeed, for the dimer, two other ester pickets are taking part to the hydrogen bonding net including the water molecule O17. But the fourth picket seems to have no function in the stability of the complex: this detail is worth underlining and will be discussed later in terms of further functionalization of the ligand. In the monomer, the amide function from the three acetyl pickets belongs to the hydrogen bonding net, which also includes the two bismuth-bound water molecules O7 and O8. However, the major driving force of this structure is undoubtely the carboxylate group, which binds in a bidentate fashion the metal, occupying two coordination sites and leading to a neutral complex. In organic solvents, this tailed carboxylate group allows porphyrin **4** to complex bismuth almost instantaneously. This represents a significant improvement in the kinetics of metalation relative to its ester picket analogue for which heating the ligand at 50 °C was necessary to obtain a complete metalation (*20*).

In both structures, the bismuth cation is largely displaced out of the N_4 plane of the porphyrin, 1.125 and 1.145 Å in **1BiNO$_3$** and **4Bi**, respectively. In the binuclear structure of **1BiNO$_3$**, the intermetallic distance is 10.61 Å. Our preliminary study was in favor of a monomeric structure in solution (*20*). However, this conclusion was reached for the compound dissolved in an organic solvent. In terms of therapeutic applications, and so in aqueous medium, if this binuclear edifice was maintained, it would be possible to deliver not one but two radioactive nuclei per complex. This would represent a simple and efficient method to directly increase the amount of α particles around the targeted cells.

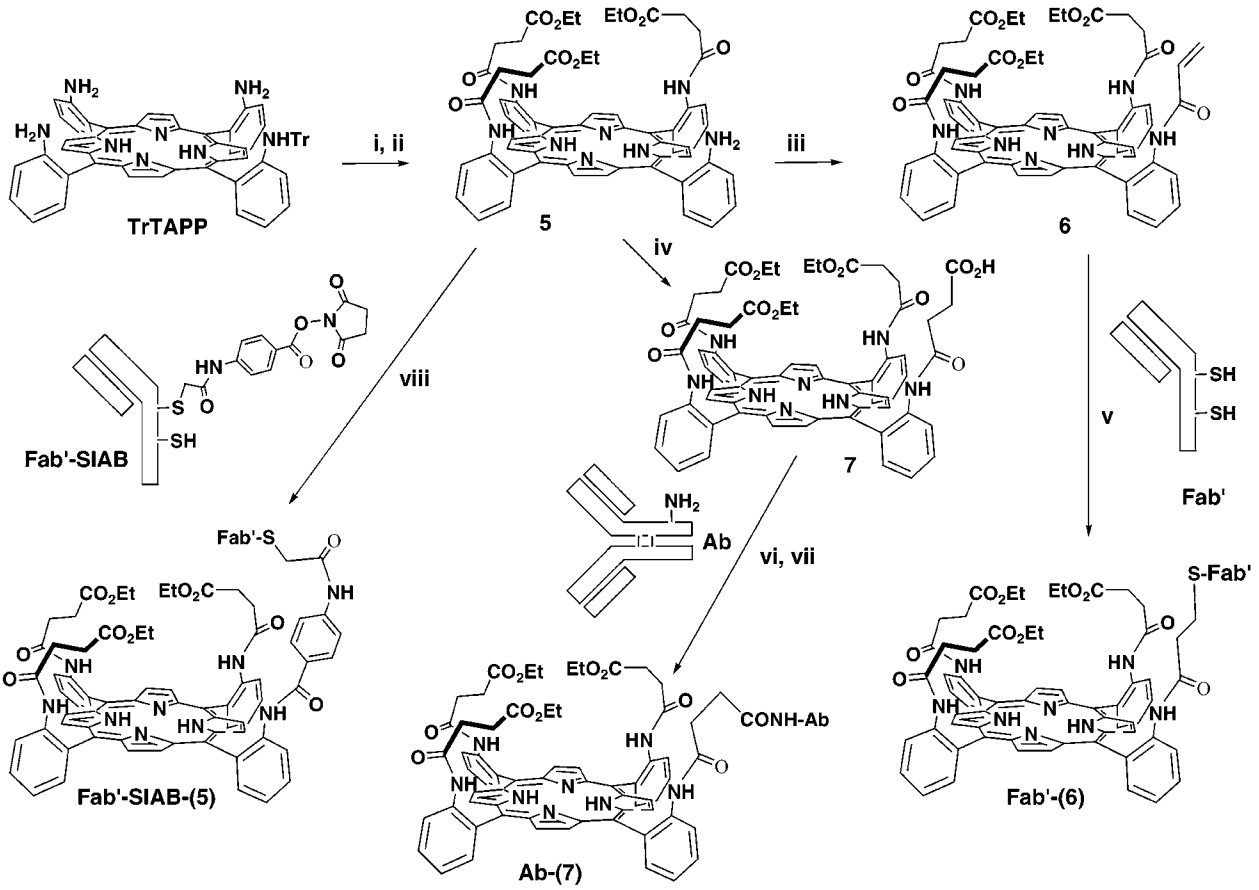
Two other significant differences between these two complexes are exhibited in Figure 2, which outlines the coordination sphere of bismuth (panels a and b), as well as a side view of the porphyrin plane (panels c and d). The first one concerns the antiprismatic coordination sphere, which is almost regular in **1BiNO$_3$** but severly distorted in **4Bi**. For example, the angle in the dimer between O13−Bi and Bi−O17 is 77.5°, but the angle is only 58.3° in the monomer between O5−Bi and Bi−O7. A possible explanation for this distortion in which a labile water molecule takes part could be that O7, to be stabilized, requires being equidistant between O5 and N5, but the length of the hydrogen bonds O5−O7 (2.821 Å) and O7−N5 (3.053 Å) are not very consistent with this explanation. In fact, the angle between the oxygen atom−Bi bonds of the bidentate ligand is the only one to be identical in the two complexes.

The second main distortion to be observed concerns the porphyrin core itself. Indeed, porphyrins are known to adopt various conformations according to the bound metal and the steric hindrance or the electronic properties of its substituents. Chiefly, to identify this distortion, the displacement of the four meso carbon atoms, as well as the eigth β-pyrrolic carbon atoms, in respect to the 24 atom mean porphyrin plane is calculated. The mean porphyrin plane refers to the least-squares mean plane calculated for the 24 atom macrocycle and not that for the four coordinating nitrogen atoms, the metal being not included in the calculations. The Cα−N−N−Cα torsion angle is also taken into account to quantify the degree

of ruffling. According to these displacements, it appears that the porphyrin in the dimer is domed (*22*, *23*), whereas it is both ruffled (*24*, *25*) and saddled (*26*, *27*) in the monomer. The former distortion is quite usual in most of the previously reported X-ray structures of bismuth porphyrins (*15*, *17*) and could be attributed to the out-of-plane coordination of the metal itself. Typically, the domed conformation is only observed when the porphyrin is coordinated to a large central metal ion, usually with one or more axial ligands. Indeed, in Figure 2a, it is clear that all the β carbons are on one side (below with a positive displacement) of the porphyrin mean plane where the meso carbons are in or near the plane. All the α carbons but two, C1 and C11, and the nitrogens are located above the mean porphyrin plane with negative displacements, on the same side as the metal (*28*).

On the other hand, the unusual mixed conformation of the monomer is presumably due to the nonsymmetrical substitution pattern of the porphyrin. Indeed, the carbon atoms in the opposite meso positions (5,15 and 10,20) are not located in the 24-atom least-squares plane but above or below. More precisely, the deviations (Cm) from the mean porphyrin plane of these atoms are 0.296, −0.149, 0.242, and −0.164 Å, leading to an average absolute value of 0.213 Å. This is expected for a ruffle conformation and not for a saddled macrocycle. But in the former conformation, the β carbons of the same pyrrolic subunit should be on opposite sides of the porphyrin mean plane. This distribution is not regularly observed for **4Bi** because C2 and C3 as well as C12 and C13 are located on the same side of the macrocyle. However, the torsion angles C9N2N4C16 and C1N1N3C14 are found to be equal to 127.21° and 124.15°, respectively, representing the signature of a ruffled macrocycle. Moreover, the tilts of the pyrrole planes against each other are 8° and 17°, confirming clearly this significant ruffling. This conformation has been found in porphyrins with small metal ions such as Ni(II) owing to the Ni−N bond shortening (*29*, *30*) but to the best of our knowledge was unkown for a large cation with a crystalline radius of 1.31 Å (for a coordination of 8) (*31*). These two major distortions seem also to be the result of a too short length of the coordinating arm because the latter has to pull the meso carbon on which it is tethered to be able to coordinate the metal. Nevertheless, it is worth noting that **4Bi**, bearing a single coordinating picket and exhibiting significative distortions, is as stable as **1BiNO$_3$** in organic solvents. Of course, this situation may be altered in aqueous medium because our final objective remains to link these chelates on a protein. A direct consequence of this observation is that by replacing the succinyl motif by a longer coordinating arm it should be possible to obtain an even more stable complex with a planar, or at least a less distorted, porphyrin core.

In light of both X-ray structures, we have verified that this type of porphyrin could be further functionalized without interfering with the key features of the coordination sphere. This is the reason, as a test reaction, we have chosen to transform ligand **1** in a bifunctional linker (*32*) ready to react with immunoglobulins (IgG). Indeed, for future applications with the radioactive isotope, the free carrier, and not the metalled complex, will be attached to the IgG.



As earlier mentioned, in **1BiNO$_3$**, only one picket does not seem to be decisive in the stability of the complex. We reasoned that this ethylsuccinyl picket could be replaced by a linker properly designed without perturbing considerably the coordination properties of the ligand. The synthesis consists of sparing one amino function of TAPP by employing the single trityl TAPP (TrTAPP), prepared as previously described (*33*). The further steps then introduce a reactive function for either primary amines of the lysine residues or thiol groups from the cysteine and particularly those obtained after reduction of the disulfide bridges of immunoglobulins, which leads to the Fab′ fragments (Scheme 2) (*34*). The reaction targeting coupling with thiol groups of the Fab′ was performed from the reduced fragment of the IgG obtained according to the usual methodology with 2-mercaptoethanolamine. Thus, porphyrin **5**, easily synthesized from TrTAPP and bearing only three succinyl pickets, was transformed in porphyrin **6** and porphyrin **7** by reaction with acryloyl chloride and succinic anhydride, respectively. In the first case, the sulfhydryl groups of the reduced IgG are known to react with the acrylamide function according to a 1,4 addition creating a stable thioether bond (*34*). In the second case, the resulting porphyrin **7** bearing a four-carbon spacer was activated by the *N*-hydroxysuccinimide (NHS) method and then coupled with the complete IgG via formation of amide bonds. Because of the lack of precise methods such as γ emission counting, only a rough evaluation of the porphyrin/IgG ratios was possible. Indeed, because the porphyrin absorbs around 420 nm with an average ϵ of 350 000 M^{-1} cm^{-1} and the protein (IgG) absorbs at 280 nm with an ϵ = 195 000 M^{-1} cm^{-1}, this evaluation was performed by UV−visible spectroscopy. This methodology has already been successfully employed with a sulfonated aluminum phthalocyanine bearing a 6-aminohexanoic acid spacer and a murine anti-CEA monoclonal antibody (*35*). Additionally, in our case, it is also expected to be convenient for future in vivo studies with the bismuth complex, which absorbs at 470 nm.

A typical UV−visible spectrum is illustrated by the coupling of porphyrin **7** to an antibody (Figure 3). The molar protein concentration, C_{ab}, and molar porphyrin concentration, C_p, are given by the following equations: $A_{280\ nm}/(l\epsilon_{ab}) = C_{ab}$ and $A_{428\ nm}/(l\epsilon_p) = C_p$. This calculation allows one to obtain an approximate number of dye molecules per antibody molecule.

We first investigated the coupling of porphryin **6** to Fab′ fragments. With an excess of 50 equiv of this porphyrin and ϵ_p = 350 800 M^{-1} cm^{-1}, only 40% of the Fab′ were found to be conjugated to the porphyrin. When the excess of porphyrin was decreased to 25 equiv, only 15% of the Fab′ were labeled. The same type of measurement was performed to evaluate the coupling between IgG and porphyrin **7** according to the activated ester method, but the result was as disapointing as that for the previous one. Indeed, only 20% of the protein was linked to the porphyrin. In fact, although the two reactions cannot be compared, these two results are consistent with one another and could be explained by a too short length of the spacers (3−4 atom-length). Indeed, it has been reported that the approach of the reactive functions from the antibodies can be sensitive to the steric hindrance of the chelate (*36*).

This prompted us to reinvestigate this conjugation by using a commercially available spacer. We have chosen the *N*-succinimidyl(4-iodoacetyl)aminobenzoic acid (SIAB) for two reasons. First, the length of this spacer is greater than the two previous ones with a value of 10.6 Å. Second, the activated ester function of the spacer allows the direct coupling of the Fab′ on porphyrin **5** without any other reaction or purification step on it. The iodoactetyl function of this heterobifunctional cross-linker will react with the thiol groups of the reduced IgG (Fab′). According to the same method, the ratio C_p/C_{ab} is found to equal 1.5.

Scheme 2: Synthesis of Different Bifunctional Ligands Related to 1 and Their Coupling with an Antibody (Ab) or Reduced Antibody (Fab′)[a]

[a] Reagents and conditions: (i) $ClCO(CH_2)_2CO_2Et$ (4 equiv), NEt_3, THF; (ii) TFA, CH_2Cl_2; (iii) $ClCOCH{=}CH_2$ (1.5 equiv), NEt_3, THF; (iv) succinic anhydride (2 equiv), EtOH, 50 °C, 48 h; (v) reduced antibody (Fab′); (vi) NHS/DCC; (vii) antibody; (viii) SIAB-activated reduced antibody.

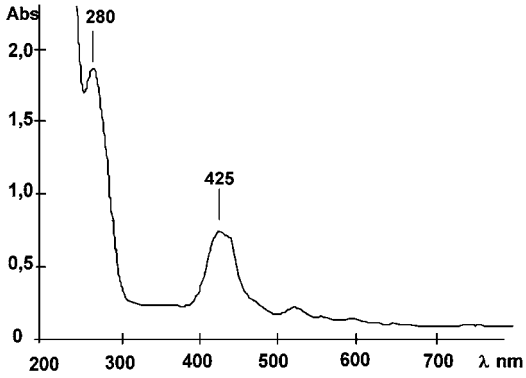


Figure 3. UV−vis spectrum of the immunoconjugate **Ab**−**7**.

If one considers that the Fab′ is completely labeled, 50% is attached to one porphyrin whereas the other 50% is doubly marked. This third coupling test reaction clearly indicates that with a chelate such as picket porphyrins, the length of the linker becomes critical in comparison with other ligands such as nonaromatic tetraazamacrocycles.

CONCLUSIONS

In summary, we have shown that both bismuth complexes for which the solid-state structures are known are valid molecules for further investigations in radioimmunotherapy applications. For the dimeric complex, three pickets among the four available are included in the structure of the complex. Interestingly, if the dimeric structure is maintained in aqueous medium with the hot radioisotope, this type of edifice could carry two radioactive nuclei instead of one, thereby delivering a higher dose of high linear energy emission. For the monomer, the scorpionate built-in tail guarantees the neutrality of the complex without any exogenous counteranion and a faster complexation of the bismuth. Various bifunctional chelates have been synthesized by introducing usual reactive groups for linking these ligands with immunoglobulins (IgG) or reduced IgG (Fab′). Our results indicate that the length of the spacer between the chelate and the IgG or reduced IgG is a crucial parameter. Work is in progress to investigate the immunological properties of these conjugates toward the rabbit IgG immunogen before and after the complexation of the radioactive isotope of bismuth.

The localized, sustained delivery of growth factors for wound healing therapy is actively being explored by gene transfer to the wound site. Biocompatible matrices such as bovine collagen have demonstrated usefulness in sustaining gene therapy vectors that express growth factors in local sites for tissue repair. Here, new synthetic biocompatible materials are prepared and shown to deliver a protein to cultured cells via the use of an adenoviral delivery vector. The synthetic construct consists of a linear, β-cyclodextrin-containing polymer and an adamantane-based cross-linking polymer. When the two polymers are combined, they create an extended network by the formation of inclusion complexes between the cyclodextrins and adamantanes. The properties of the network are altered by controlling the polymer molecular weights and the number of adamantanes on the cross-linking polymer, and these modifications and others such as replacement of the β-cyclodextrin (host) and adamantane (guest) with other cyclodextrins (hosts such as α, γ, and substituted members) and inclusion complex forming molecules (guests) provide the ability to rationally design network characteristics. Fibroblasts exposed to these synthetic constructs show proliferation rates and migration patterns similar to those obtained with collagen. Gene delivery (green fluorescent protein) to fibroblasts via the inclusion of adenoviral vectors in the synthetic construct is equivalent to levels observed with collagen. These in vitro results suggest that the synthetic constructs are suitable for in vivo tissue repair applications.

INTRODUCTION

The enhancement of dermal and epidermal regeneration is a significant goal for the treatment of chronic wounds. Studies aimed at understanding the complex cascade of wound healing have shown that the use of growth factors may be a useful therapeutic strategy, and several growth factors in the form of proteins have been evaluated as therapeutics agents (*1*, *2*). A significant limitation for direct use of proteins is their fast degradation when exposed to an in vivo environment. This loss in activity makes it difficult to maintain therapeutic protein levels within treatment sites (*3*, *4*). One approach to potentially bypass this issue is to use localized gene therapy to promote the continuous production of the desired growth factor at a specific tissue site.

A major challenge in localized gene delivery is to determine the best means to introduce the therapeutic gene into a site such that cells can be transduced and express it. Gene transfer with naked DNA was one of the earliest methods investigated. It has been shown that naked DNA can be successfully transferred to the skin by direct injection (*5*, *6*). Recently, in an effort to increase transgene expression in skin wounds, a new technique called microseeding was developed (*7*, *8*). This method delivers naked DNA by microneedles that are inserted directly into the healing wound. The depth of penetration can be determined by the needle design, and by variation of the DNA concentration and the amount loaded into the needles, the magnitude of gene expression can be affected. Cationic liposome-mediated gene transfer to wounds has also been accomplished (*9*, *10*). Sun et al. administered a plasmid coding for an acidic fibroblast growth factor (FGF-1) to the skin of diabetic mice with incisional wounds by either topical or subcutaneous injection (*9*). It was found that FGF-1 improved wound treatment when compared to controls. A drawback to liposomal vectors is their low in vivo transfection efficiencies. Low transfection efficiencies can be overcome with the use of viral vectors. Adenoviral vectors are known to be very effective for both in vitro and in vivo gene transfer. Adenoviral gene transfer of platelet-derived growth factor-B (PDGF-B) to ischemic rabbit excisional wounds enhanced granulation tissue volume and re-epithelialization of the wound (*11*). Transgene expression was observed for up to 2 weeks in that study.

Although gene therapy appears promising for wound healing, the need for effective ways to deliver genes at the desired site with high level of gene transfer and cellular expression remains. A number of delivery systems have been designed to increase transfection efficiency. A particle-mediated device for gene transfer, the gene gun technology, was one of the earliest delivery techniques used to transfer naked DNA into the skin (*12*−*14*). The technique uses physical force to penetrate the cellular membranes and to deliver DNA that is adhered to microscopic particles. This approach has been used to deliver genes encoding PDGF-B (*15*) and keratinocyte growth factor-1 (*16*) for wound repair. Low

transfection rates and cellular damage due to the consequences of the method of introducing the particles were the major limitations of this technique.

Various biomaterials have been developed to achieve localized, sustained delivery of the genes. Collagen was initially investigated and is a readily available component that allows cell infiltration and proliferation (*17*). Fang et al. were the first to explore and successfully demonstrate the possibility of using collagen sponges as implantable carriers for naked plasmid DNA (pDNA) (*18*). Collagen was used to generate a so-called gene-activated matrix (GAM), since the collagen matrix physically entraps pDNA. GAM has been used in a variety of tissues including skin (*19*), bone (*20*), nervous system (*21*), and blood vessels (*22*). Collagen has also been employed as a carrier of nonviral DNA vectors (*23*−*25*). Adenoviruses delivered in collagen matrices have also been evaluated in dermal wound healing studies (*26*, *27*). The adenoviral delivery of the gene encoding PDGF-B induced a wound healing cascade that culminated in complete regeneration of skin. Further enhancements of the wound repair response have been achieved by combining matrix-enabled gene transfer with molecular targeting where the adenovirus was conjugated to a basic fibroblast growth factor ligand (FGF-2) (*28*, *29*). Adenoviruses delivered in collagen matrices have also demonstrated promising results for repair of bone defects (*30*).

These studies have shown that through the application of matrix-mediated delivery to gene therapy, the DNA vector as well as the transgene product is retained within the defect site, and this leads to an increase in efficacy. However, collagen is an animal-derived protein and its use may raise discussions about safety. The GAM concept can be extended to materials other than collagen. Synthetic materials represent another promising approach for the delivery of pDNA.

Matrices of poly(lactide-*co*-glycolide) (PLGA) loaded with plasmids that encode rhPDGF-B showed a significant increase in the thickness of granulation tissue and neovascularization in rats after transfection (*31*). Recently, triblock copolymers, poly[ethylene glycol-*b*-(D,L-lactic acid-*co*-glycol acid)-*b*-ethylene glycol] (PEG−PLGA−PEG) have been used to effectively deliver genes into skin cells (*32*). The PEG−PLGA−PEG polymers form thermosensitive biodegradable hydrogels that are able to deliver pDNA in a sustained fashion. These encouraging results indicate the potential use of synthetic materials for therapies of skin disorders and wound healing.

Wide and diverse ranges of polymer compositions have been used to prepare hydrogels and other types of matrices (*33*), and many cross-linking methods to create these materials (including chemical or physical cross-linking methods) have been investigated (*34*). In recent years, there has been increasing interest in physically cross-linked gels obtained via noncovalent interactions, ionic interactions, hydrophobic interactions, crystallization, etc. Recently, a new strategy based on inclusion complex formation has been described in which supramolecular structures have been prepared by noncovalent host−guest interactions. Cyclodextrins have been extensively studied as host molecules since they can form inclusion complexes with a wide variety of guest molecules ranging from small hydrophobic compounds to polymers (*35*−*37*). Huh et al. have reported the formation of supramolecular hydrogel based on inclusion complexation between α-cyclodextrin and poly(ethylene glycol)-grafted dextran (*38*) or poly(ethylene glycol)-modified chitosan (*39*). Li et al. have also developed polymer inclusion complex-based supramolecular hydrogels between pluronics (commercial triblock copolymers of poly(ethylene oxide)−poly(propylene oxide)−poly(ethylene oxide) (PEO−PPO−PEO) and α-cyclodextrin (*40*). This strategy for preparing polymer inclusion complex hydrogels is promising but is available for a limited combination of polymers and cyclodextrins. Amiel and co-workers have reported another associating system that involves inclusion complex interactions between hydrophobically modified poly(ethylene oxide) (PEO) and β-cyclodextrin polymers formed by randomly linking the cyclodextrins with epichlorohydrine (*41*, *42*). PEO was end-capped with adamantyl and naphthyl hydrophobic moieties since they are known to form stable inclusion complexes with β-cyclodextrins. These polymers induced interesting associative properties; however, this type of network formation may be difficult to control because the β-cyclodextrin polymer preparation is also difficult to control and can lead to gel formation by itself (*43*). β-cyclodextrin polymers formed by polycondensation of β-cyclodextrin with epichlorohydrin give a highly random conformation because epichlorohydrin can react with any of the 21-hydroxyl groups of the cyclodextrin cup (Figure 1).

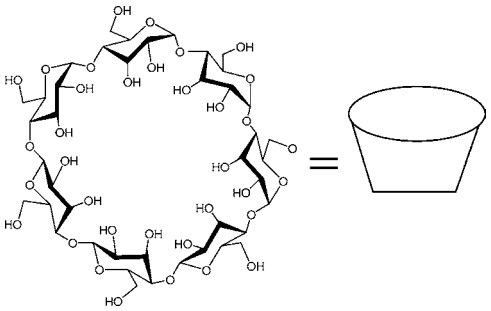

Figure 1. Schematic illustration of β-cyclodextrin.

Over the past few years, our group has demonstrated the use of cyclodextrins as building blocks for the preparation of a suite of linear, cyclodextrin-based polymers for systemic gene delivery (*44*−*46*). In this study, we develop cyclodextrin-based constructs that consist of a linear, cyclodextrin-containing polymer and a cross-linking agent that contains adamantane groups. The constructs are prepared by inclusion complex formation when the two components are combined. If the synthetic components are mixed together in the presence of adenovirus, the construct can serve as a gene carrier for local controlled gene delivery. Here, the preparation and characterization of linear cyclodextrin-based poly(ethylene glycol) polymers and their inclusion complex formation with adamantane end-capped poly(ethylene glycol) polymers is described. We report the influence of polymer structure and size on the construct properties and evaluate the feasibility of using these biodegradable inclusion complex cyclodextrin-based constructs to formulate adenovirus vectors that carry genes encoding growth factors.

EXPERIMENTAL PROCEDURES

Material Preparation and Characterization. *Linear Cyclodextrin-based Poly(ethylene glycol) Polymers (CD*−*PEG).* CD−PEG polymers (Figure 2) were prepared by the polymerization of a difunctionalized β-cyclodextrin (CD) monomer (A) with a difunctionalized poly(ethylene glycol) comonomer (B) to give an ABAB product. 6A,6D-Dideoxy-6A,6D-di(2-aminoethanethio)-β-cyclodextrin (denoted dicysteamine-β-cyclodextrin) (**1**) was synthesized according to previously described procedures (*44*, *47*). Disuccinimidyl propionate poly(ethylene glycol) (PEG−

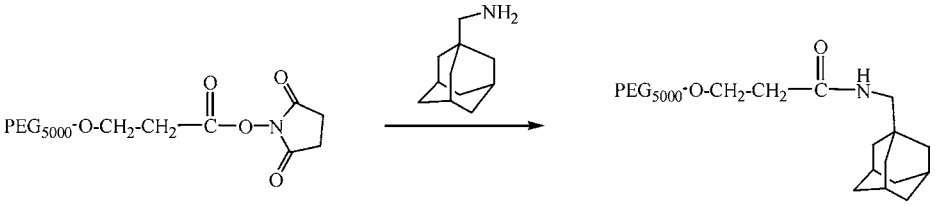

Figure 3. Synthesis of adamantane−poly(ethylene glycol) conjugate (ADA−PEG).

diSPA, MW 3400) (**2**) was purchased from Nektar (Huntsville, AL). In a typical experiment, (**1**) (0.4 g, 0.32 mmol) was acidified with HCl, precipitated with acetone, and then dried under vacuum for 14 h. PEG−diSPA (1.08 g, 0.32 mmol) and anhydrous DMSO (8 mL) were added under argon. After 10 min of stirring, anhydrous diisopropylethylamine (DIEA) (254 μL, 1.46 mmol) was added under argon. The resulting mixture was then allowed to stir at room temperature under argon. The reaction was followed over time (2, 15, 30, 60, 180, and 300 min), addition of DIEA being at time zero. At the end of the reaction, the solution was transferred to a 10 000 MWCO membrane (Spectra/Por 7, Spectrum Laboratories Inc., Rancho Dominguez, CA) and dialyzed against deionized water for 48 h. The solution was then lyophilized to dryness. The polymer samples were analyzed on a Hitachi D6000 HPLC system equipped with a ERC-7512 RI detector, a Precision Detectors PD2020/DLS static light scattering detector, and a PL aquagel-OH 30 (Polymer Laboratories, Amherst, MA) column using phosphate-buffered saline (PBS, 150 mM) as eluant at a 0.7 mL/min flow rate. The specific refractive index increment, dn/dc, was measured in PBS (Cellgro, Mediatech, Inc, Herndon, VA) using a Bausch & Lomb ABBE-3L refractive index detector.

Adamantane−Poly(ethylene glycol) (ADA−PEG). ADA−PEG (Figure 3) was synthesized according to published procedures (*45*). In brief, succinimidyl propionate poly(ethylene glycol) (Nektar) (PEG−SPA, MW 5000, 2 g, 0.4 mmol) was reacted with 1-adamantane-methylamine (Aldrich, Milwaukee, WI; 142 μL, 0.8 mmol) dissolved in dichloromethane. The resulting solution was stirred at room temperature for 4 h. The solvent was removed under vacuum, and water was added to the remaining solution. The solution was centrifuged at 15 000 rcf for 15 min to remove unreacted 1-adamantane-methylamine. The aqueous portion was collected and dialyzed (Slide-A-Lyzer MWCO 3500, Pierce, Rockford, IL) for 24 h against water. The dialyzed solution was then lyophilized to dryness to give ADA−PEG in 97% yield. The product was analyzed on a Beckman Coulter Gold HPLC system equipped with a Richards Scientific Sedere evaporative light scattering detector and a C18 reversed phase column (Hichrom HIRPB-4438, Richards Scientific) using a gradient of water and acetonitrile at 1 mL/min. The product was found to be pure (retention time of PEG−SPA, 10.7 min; retention time of ADA−PEG, 12.1 min). The product was also confirmed by mass spectroscopy matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) analysis (Voyager DE-PRO, Applied Biosystems, Foster City, CA).

Adamantane−Poly(ethylene glycol)−Adamantane (2-ADA−PEG). Disuccinimidyl propionate poly(ethylene glycol) (Nektar) (PEG-diSPA, MW 3400) (2 g, 0.59 mmol) was reacted with 1-adamantane-methylamine (Aldrich) (219 μL, 1.24 mmol) dissolved in dichloromethane (Figure 4). The resulting solution was stirred at room temperature for 4 h. The solvent was removed under vacuum, and water was added to the remaining solution. The solution was centrifuged at 15 000 rcf for 15 min to remove unreacted 1-adamantane-methylamine. The aqueous portion was collected and dialyzed (Slide-A-Lyzer MWCO 1000, Pierce) for 24 h against water. The dialyzed solution was then lyophilized to give 2-ADA−PEG in 95% yield. The product was analyzed using the same HPLC technique as that for ADA−PEG. The product was found to be pure (retention time of PEG−diSPA, 10.4 min; retention time of 2-ADA−PEG, 13.4 min). The product was also confirmed by mass spectroscopy MALDI-TOF analysis (Voyager DE-PRO, Applied Biosystems).

Tetraadamantane−Poly(ethylene glycol) (4-ADA−PEG). 1-Adamantane-methylamine (0.069 g, 0.44 mmol, Aldrich) was added to 1 g of four-arm poly(ethylene glycol) succinimidyl succinate (PEG-(ss)$_4$, MW 10 000) (SunBio, Inc., Anyang City, S. Korea) (0.1 mmol) previously dissolved in 10 mL of dichloromethane (Figure 5). The resulting solution was stirred at room temperature overnight. The solvent was evaporated under vacuum,

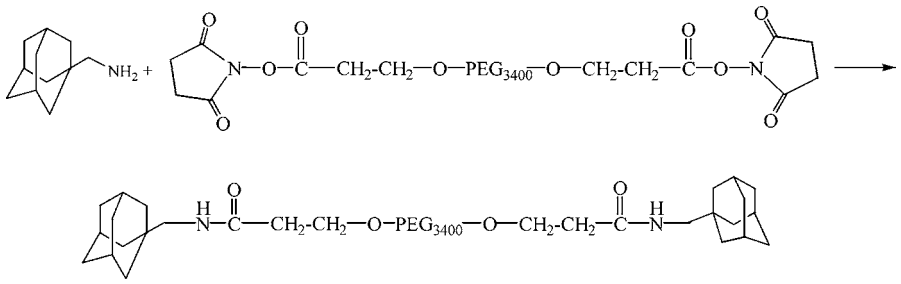

Figure 4. Synthesis of diadamantane−poly(ethylene glycol) cross-linker (2-ADA−PEG).

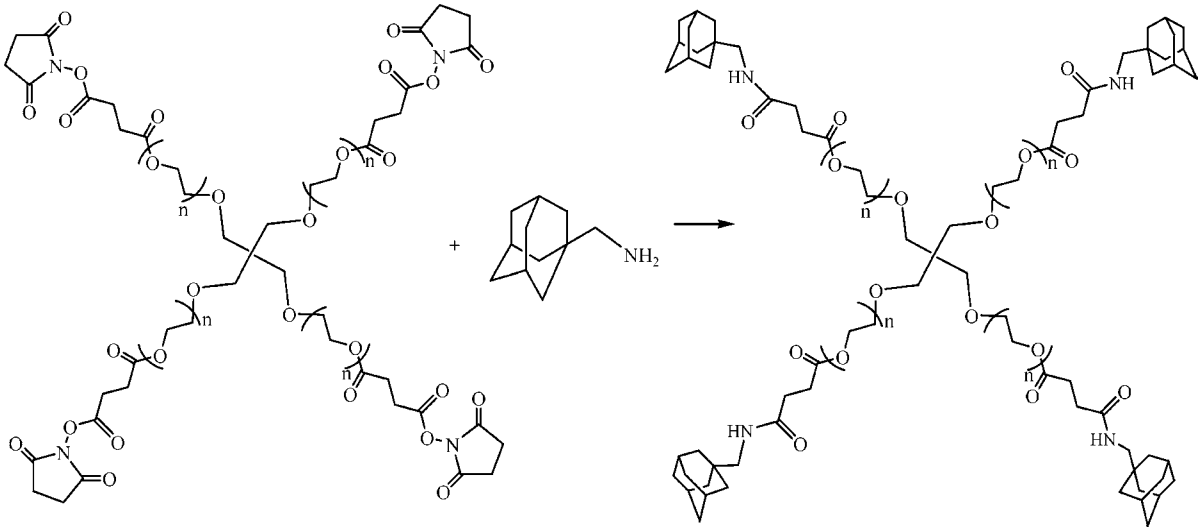

Figure 5. Synthesis of tetraadamantane−poly(ethylene glycol) cross-linker (4-ADA−PEG).

and the resulting polymer was precipitated with ether. The resulting solid was dried and analyzed using the same HPLC technique as that for ADA−PEG. The product was found to be pure (retention time of PEG-$(ss)_4$, 11.4 min; retention time of 4-ADA−PEG, 15.1 min). The product was also confirmed by mass spectroscopy MALDI-TOF analysis (Voyager DE-PRO, Applied Biosystems).

Synthetic Construct Preparation and Characterization. *Preparation of Polymeric Inclusion Complex-Based Construct between Cyclodextrin-Based Poly(ethylene glycol) Polymer (CD-PEG) and Adamantane-Containing Poly(ethylene glycol) Cross-Linker (CD-ADA Matrix).* Cyclodextrin-based poly(ethylene glycol) polymer was dissolved at 250 mg/mL in water. PBS (10×) and adamantane-containing poly(ethylene glycol) cross-linker (2-ADA−PEG) dissolved in water were then added such that the resulting complex had a CD−PEG concentration of 100 mg/mL and a 1/1 adamantane/cyclodextrin ratio (39.5 mg/mL) in 1x PBS, pH 7.2 (Figure 6). The resulting mixture was mixed vigorously to form a homogeneous solution. An increase in the viscosity was observed in about 1 min. For comparison, the mono- and the tetraadamantane poly(ethylene glycol) derivatives (ADA−PEG and 4-ADA−PEG, respectively) were tested at the same concentration as 2-ADA−PEG (39.5 mg/mL). For cell culture studies, 5% dextrose in water (D5W) was used instead of 1× PBS.

Rheology Study. Oscillatory rheological measurements were performed on an RFS 3 (TA Instruments, New Castle, DE) with a parallel plate geometry equipped with a Peltier temperature element. A sequence of three tests was performed for each sample. First, a time sweep at a frequency of 10 rad/s and 0.5% strain was performed for

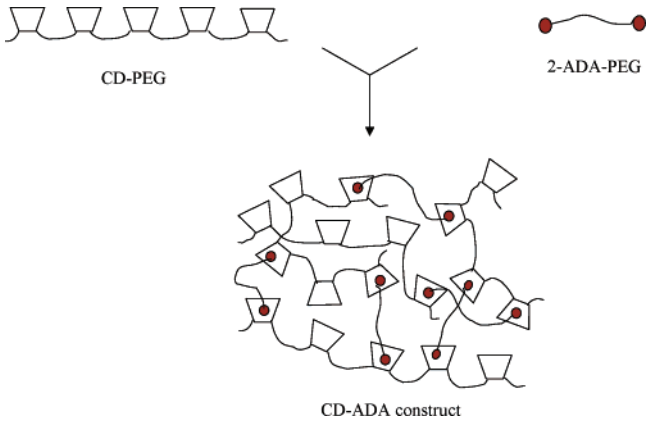

Figure 6. Schematic illustration of the structure of the polymer inclusion complex-based contruct between cyclodextrin−poly(ethylene glycol) polymer (CD−PEG) and adamantane−poly(ethylene glycol) polymer (2-ADA−PEG or 4-ADA−PEG).

1800 s. Second, a frequency sweep from 1 to 100 rad/s was performed at 0.5% strain. Third, a strain sweep from 0.02% strain to 100% strain was performed at a frequency of 10 rad/s. The reported loss factor, tan δ, and complex viscosity, η^*, were determined as the respective means of the constant portion in the strain sweep at 10 rad/s.

Recombinant Adenovirus (rAd) Construction and Purification. rAd-GFP is an E1-, E3-, and pIX-deleted adenoviral vector containing the eGFP (Clontech, Palo Alto, CA) expression cassette driven by a human CMV promoter. Homologous recombination in 293 cells (Microbix Biosystems, ON, Canada) was used to generate infectious virus (*49*). Virus was grown in 293 cells, purified by column chromatography (*50*), and quantitated by anion-exchange HPLC (*51*).

Cell Culture and Cellular Studies. *Cell Viability.* Human skin fibroblasts, CCD-1074sk (1×10^4 cells, ATCC, Manassas, VA) in DMEM media (Cambrex Bio Science, Walkersville, MD) containing 10% fetal bovine serum (JRH Biosciences, Lenexa, KS) and 1% penicillin−streptomycin solution (Invitrogen Life Technologies, Carlsbad, CA) were placed on top of 400 μL of either 2.4 mg/mL Cell Prime liquid bovine collagen (Cohesion, Palo Alto, CA) or 100 mg/mL CD−ADA matrix in a 24-well tissue culture plate (Becton Dickinson, Franklin Lakes, NJ) and incubated at 37 °C. Forty-eight hours later, the cells were examined under phase contrast using an inverted microscope (Nikon, Melville, NY).

Cell Mobility through Matrix. Two hundred microliters of 100 mg/mL CD−ADA matrix containing 10 ng/mL hPDGF-BB protein (Chemicon, Temecula, CA) was placed in an 8.0 μm pore FluoroBlokTM insert (Becton Dickinson, Franklin Lakes, NJ) for a 24-well plate. CCD-1074sk cells (1×10^4 cells) were stained for 30 min with 5 μM Calcein-AM, a fluorescent dye that labels viable cells (Molecular Probes, Eugene, OR), washed, and resuspended in DMEM media containing 10% FBS and 1% penicillin−streptomycin solution and then seeded on top of the CD−ADA matrix containing hPDGF-BB. Media containing 50 ng/mL hPDGF-BB protein was placed in the lower chamber to provide a chemoattractant gradient to stimulate cell migration through the FluoroBlokTM pores. Seventy-two hours later, the FluoroBlokTM inserts were photographed at 100× magnification under GFP fluorescence using an inverted microscope (Nikon) to look for cell migration through the insert pores.

In Vitro Transduction Studies. A total of 1×10^9 particle numbers (PN) per well of rAd-GFP was mixed with either 100 μL of DMEM media containing 10% FBS alone (no matrix), 100 μL of CD−ADA matrix at a concentration of 100 mg/mL, or 100 μL of collagen at a concentration of 2.4 mg/mL and plated onto a 24-well flat bottom tissue culture plate, in duplicate, then incubated at 37 °C for 30 min. CCD-1074sk cells (1×10^4 cells) in 0.4 mL media were layered over the above matrix/virus or media/virus mixture and incubated for 48 h at 37 °C and 5% CO_2, then photographed at 100× magnification under identical GFP fluorescence settings for all samples.

Fluorometric Analyses. A total of 1×10^9 PN/well of rAd-GFP was mixed with either 50 μL of DMEM media containing 10% FBS alone (no matrix), 50 μL of CD−ADA construct at a concentration of 100 mg/mL, or 50 μL of collagen at a concentration of 2.4 mg/mL and plated onto a 96-well flat bottom tissue culture plate, in triplicate, then incubated at 37 °C for 30 min. CCD-1074sk cells (5×10^3 cells) in 150 μL of media were layered over the matrix/virus or media/virus mixture and incubated for 48 h at 37 °C and 5% CO_2, then read on a fluorometer (PerSeptive Biosystems, Foster City, CA) to measure expression of rAd-GFP transduction (excitation = 485 nm; emission = 530 nm). Results are reported in fluorescence intensity (FI) units.

Cell Proliferation Assay. CCD-1074sk cells (5×10^3 cells) were plated in media alone, CD−ADA construct, or collagen as described above (fluorometric analysis) but without any virus added. After 48 h at 37 °C and 5% CO_2, 40 μL of a MTS-based dye [MTS = (3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium] (Cell Titer 96 Aqueous One, Promega, Madison, WI) was added to each well, incubated for an additional 3 h, and read on a spectrophotometer (Molecular Devices, Sunnyvale, CA) to determine cell proliferation (λ_1 = 490 nm minus λ_2 = 630 nm). Results are reported in optical density (OD).

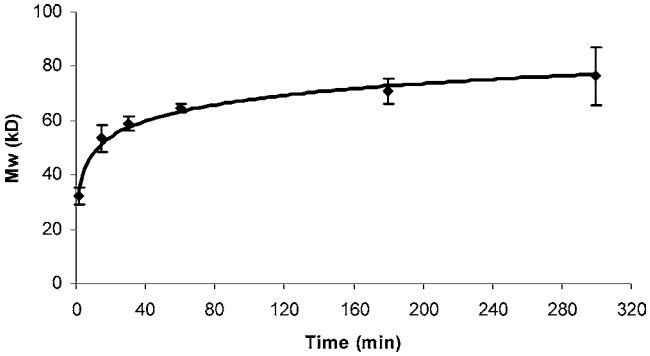

Figure 7. Molecular weight of CD−PEG as a function of polymerization time. The results shown are mean ± SD for three experiments.

RESULTS

CD-PEG Synthesis and Characterization. CD−PEG polymers were synthesized by reacting dicysteamine-β-cyclodextrin−2HCl comonomer with PEG−diSPA in anhydrous DMSO solution under argon. The viscosity of the polymerization solutions increased dramatically after the addition of a nonnucleophilic organic base such as DIEA. DIEA deprotonated the amino groups of **1** to render them more nucleophilic for coupling with PEG−diSPA. Polymerization of **1** with PEG−diSPA typically produced polymers in yields greater than 90%. The polymer MW, determined by light scattering, increased to around 80 kD over a 5 h time course (Figure 7) with a polydispersity index of 1.5. This polymerization is thus a fast but reproducible reaction. Polymers with MW ranging from 30 to 80 kD can be easily obtained by controlling the polymerization time. These polymers are highly soluble in aqueous solution. They can be easily dissolved in water or PBS at concentrations of at least 100 mg/mL. The polymers with high MW go into solution more slowly.

CD-ADA Construct Preparation and Characterization. Hydrophobically modified poly(ethylene glycol) polymers were obtained by reaction between the succinimidyl propionate or succinimidyl succinate termini of the PEG molecules with 1-adamantane-methylamine. The structural formulas of the polymers obtained are schematically illustrated in Figures 3−5. CD−PEG polymers with a molecular weight of 30, 65, or 85 kD were dissolved in PBS at 100 mg/mL and were mixed with these adamantane-containing poly(ethylene glycol) derivatives (39.5 mg/mL).

The macroscopic properties of the constructs are probed via rheological measurements, and the direct consequences of the formation of cross-linking inclusion complexes observed in the data (Table 1). Oscillatory rheology measurements were performed on an RFS 3 (TA Instruments) using a parallel plate geometry. Figure 8 shows measured values of the storage modulus (G') and the loss modulus (G'') vs frequency for a mixture of CD−PEG (85 kD MW) polymer and 2-ADA−PEG (A). In the frequency range from 1 to 100 rad/s, G' is found to be much smaller than G''. The same behavior is observed at various polymer lengths and temperatures and using different cross-linkers with increasing functionality (2-ADA−PEG, 4-ADA−PEG). In fact, using a monovalent ADA−PEG control, the behavior is similar. A summary of the observed ratios of G'' to G', that is, the loss factor, tan δ, is shown in Table 1. A high value of tan δ indicates that the polymer sample behaves more like a viscous fluid rather than a typical gel that would show a tan δ smaller

Table 1: Rheological Characterization of CD−PEG Polymer (30, 65, and 85 kD) at 100 mg/mL Mixed with ADA−PEG, 2-ADA−PEG, or 4-ADA−PEG (39.5 mg/mL) Compared to a Bovine Collagen Matrix[a]

[a] The loss factor, tan δ, is the ratio of loss modulus G'' to storage modulus G' (>1 for mostly viscous behavior and <1 for mostly elastic behavior). Slope of G' (2 for ideally elastic and 0 for ideally viscous fluids), complex viscosity, η^*, and increase in viscosity after cross-linking are also shown. In certain cases no slope of G' could be determined because the frequency sweep resulted in measurements below sensitivity range of the instrument. [b] Not applicable.

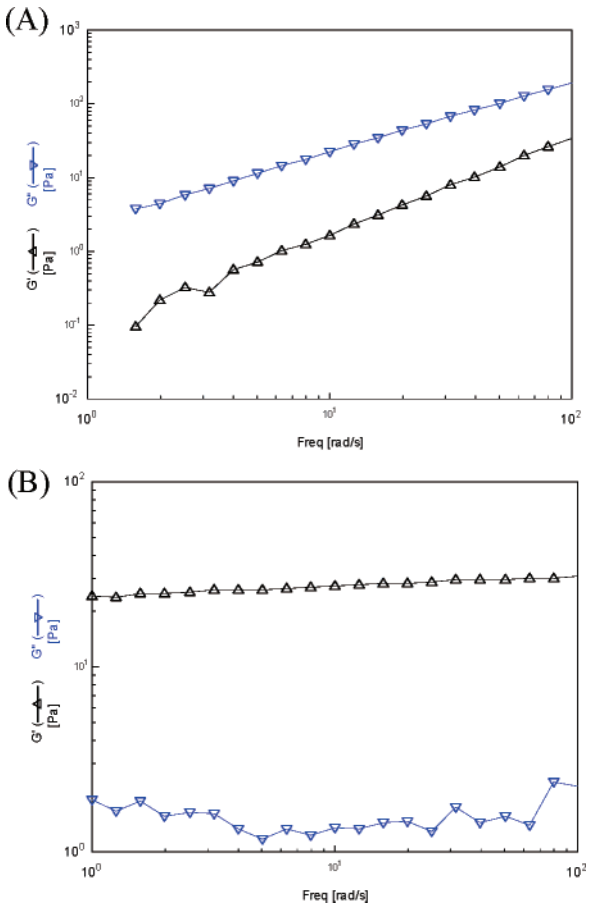

Figure 8. G' and G'' vs frequency for CD−ADA construct (A) and bovine collagen (B) at 35 °C.

than one. For comparative purposes, Figure 8B gives a frequency scan of G' and G'' for bovine collagen, a matrix previously used for gene delivery to wounds (*27*). At 35 °C, G' is significantly larger than G'' over the frequency range observed, resulting in a tan δ value $\ll 1$. In the frequency range studied, G' and G'' do not cross each other.

Another measure that characterizes the viscoelastic behavior of the sample is the slope of G' vs frequency, which is close to 2 for ideally viscous and zero for ideally elastic materials. While the slopes of G' are between 0.9 and 1.7 for CD−PEG polymer samples (Table 1), indicating mostly viscous behavior, the slope of G' is 0.052 for the bovine collagen matrix, indicating strong elastic behavior.

Figure 9 shows the complex viscosity of the CD−ADA as a function of CD−PEG polymer molecular weight at both 20 (A) and 35 °C (B) using 2- and 4-ADA−PEG as cross-linkers. Monovalent ADA−PEG is used as control. The viscosity increases with the MW of the polymer and with the functionality of the cross-linker. The viscosity is noticeable lower at 35 than at 20 °C.

In Vitro Biocompatibility Study. Biocompatibility of the CD−ADA construct was assessed by visually monitoring cell viability (Figure 10). CCD-1074sk cells were placed on top of either collagen (Figure 10A) or the CD−ADA construct (Figure 10B) and examined 48 h later under phase contrast. Figure 10 shows that CCD-1074sk cells are not affected by the presence of CD−ADA construct (cells are viable and have the appropriate morphology); thus, the CD−ADA construct is biocompatible with cells.

To test whether CCD-1074sk cells can migrate through the CD−ADA material, cell-migration assays, using the FluoroBlokTM insert system, were carried out (Figure 11). CCD-1074sk cells, labeled with the fluorescent dye Calcein-AM, were placed on the CD−ADA construct containing a low concentration of hPDGF-BB protein in the top chamber of the insert. hPDGF-BB protein was also placed in the lower chamber at a higher concentration to provide a chemoattractant gradient and stimulate cell migration through the FluoroBlokTM pores (Figure 11A). Figure 11B shows fluorescence from cells migrating through the pores 72 h after plating, demonstrating that the CD−ADA construct supports migration of CCD-1074sk cells.

In Vitro Transgene Expression Study. rAd-GFP was mixed with media alone (no matrix), the CD−ADA construct, or collagen and placed onto a 24-well flat bottom tissue culture plate. After 30 min at 37 °C, CCD-

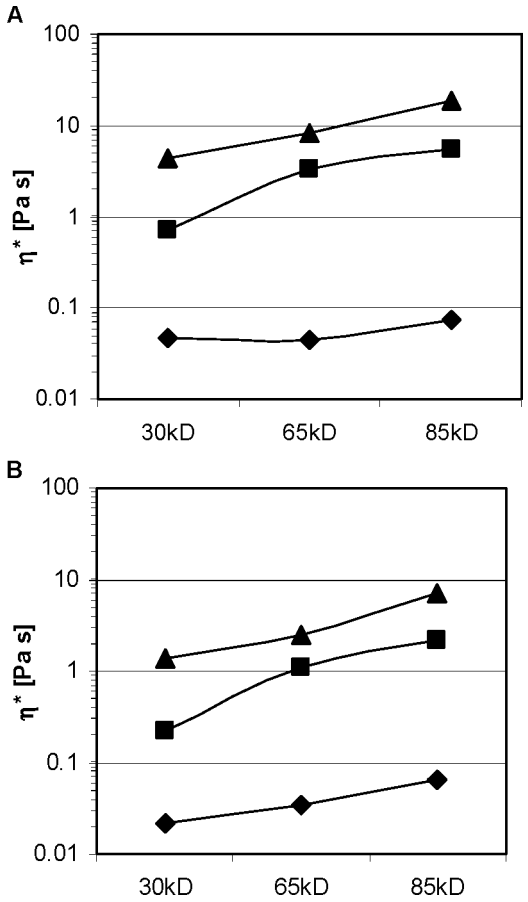

Figure 9. Complex viscosity of CD−ADA construct as a function of CD−PEG polymer molecular weight at 20 (A) and 35 °C (B) using various cross-linker functionalities (2-ADA−PEG (■) and 4-ADA−PEG (▲)). Monofunctionalized ADA−PEG (◆) is included to establish a baseline for a non-cross-linked polymer solution.

1074sk cells were layered over the virus/matrix or virus/media mixtures and incubated for 48 h. The cells from the various treatment groups were examined and photographed at 100× magnification under an inverted microscope using identical settings for all samples (Figure 12). All cells, regardless of the type of matrix or media, appeared to be healthy by visual inspection (phase contrast view). Wells treated with virus had cells that were positive to rAd-GFP transduction when viewed under a fluorescent light source, while cells that were not treated with virus showed no GFP signal (data not shown). Cells in the CD−ADA construct appeared to be more numerous in cell count than cells in collagen.

The visual GFP expression results were corroborated when the plates were quantitatively analyzed with a fluorometer (Figure 13A). At 48 h, cells in the CD−ADA construct have the highest average fluorescent intensity, followed by cells in media alone (no matrix) then cells in the collagen matrix (5455, 5280, and 4659 avg FI units, respectively). However, observed differences in fluorescence were not statistically significant ($p > 0.1$, unpaired two-tailed t-test). The CD−ADA complex therefore allows for adenoviral transduction of dermal fibroblast cells in vitro at levels comparable to collagen or media alone.

The MTS-based cell proliferation assay shows that plating in media alone resulted in the highest number of viable cells after 48 h (0.85 OD), followed by cells in collagen (0.37 OD) and cells in CD−ADA construct (0.27 OD) (Figure 13B). However, statistical analysis (unpaired two-tailed t-test) shows that the observed differences between the CD−ADA construct and collagen were not significant ($p > 0.1$).

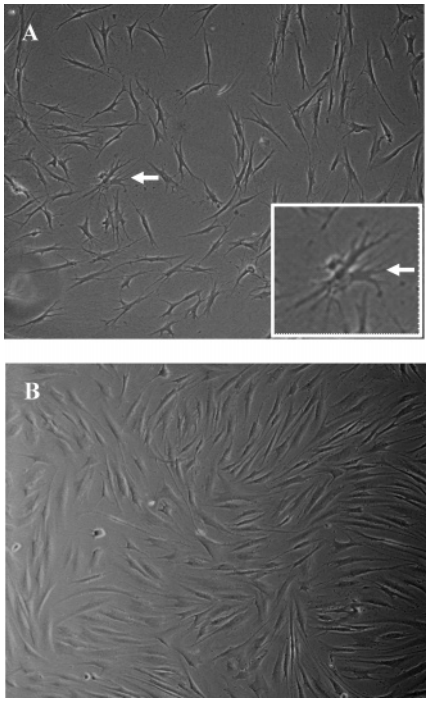

Figure 10. Biocompatibility of CCD-1074sk cells with collagen (A) or CD−ADA construct (B). The picture was taken at 100× magnification. The inset in panel A is a 200× magnification of a skin fibroblast cell marked by an arrow. Filopodia, a morphological feature associated with cell migration, are indicated by an arrow in the inset.

DISCUSSION

The objective of this study is to synthesize and evaluate a new type of construct for use in gene transfer in cutaneous wound repair. The complete construct consists of three components, a linear, cyclodextrin-containing polymer, an adamantane-containing polymer that is used as a cross-linking agent, and a recombinant adenovirus. The assembly of the construct involves the mixing of two polymers: a hydrophobically end-capped poly(ethylene glycol) and a β-cyclodextrin-based polymer that create an associating network via inclusion complex formation between the cyclodextrins and adamantanes. The inter-

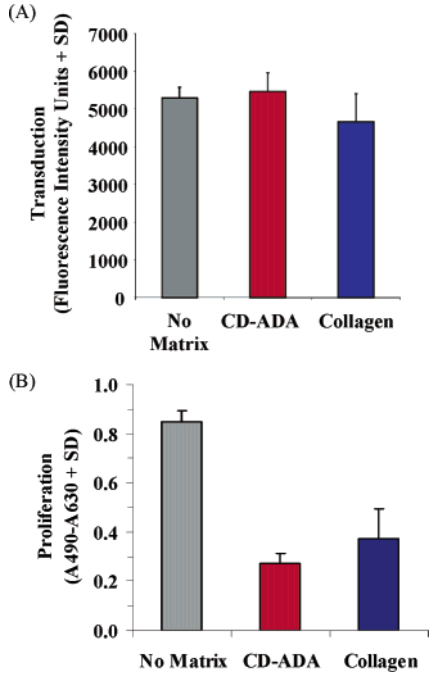

Figure 13. Fluorometric (A) and MTS (B) analyses of CCD-1074sk cells after transduction with rAd-GFP in three formulations: no matrix, CD−ADA construct, and collagen. The graphs represent values after the background (wells containing only media alone, CD−ADA, or collagen, respectively) is subtracted.

actions between these two types of polymers have been previously described (*42*), but the β-cyclodextrin polymer used in that study was prepared by polycondensation with epichlorohydrin. One of the drawbacks in the use of epichlorohydrin is the highly random conformation of the resulting β-cyclodextrin polymer since the reaction can occur on any of the 21 exterior hydroxyl groups of the cyclodextrin cavity (7 primary hydroxyl at one rim and 14 secondary hydroxyl at the other rim) (Figure 1) (*43*). Here, only two of the 21 hydroxyls are converted to diamino cyclodextrin derivatives (dicysteamine-β-cyclodextrin (**1**)), and well-defined and controlled syntheses of linear, cyclodextrin-based polymers are achieved. The rational control over polymer properties is necessary to have control over the characteristics of the final construct formed.

Linear cyclodextrin-based poly(ethylene glycol) polymers were synthesized by reacting **1** with an activated difunctionalized derivative. Due to the bulky size of the CD, disuccinimide groups separated by a relatively long distance were used to minimize the steric hindrance between cyclodextrin cups in the construction of polymers chains. PEG−diSPA was thus used as comonomer for the polymerization. Linear, CD-based polymers with MWs greater than 50 kD can be easily synthesized in a reproducible manner using this method (Figure 7). Since β-CD does not form complexes with PEG (*36*), no cross-linking was observed in these polymers.

Hydrophobically modified PEGs were obtained by reacting succinimide-functionalized PEG with 1-adamantane-methylamine (Figures 3−5). Adamantane is a hydrophobic moiety known for its ability to form stable inclusion complexes with β-CD. The hydrophobic molar ratio was varied by using a four-arm branched PEG (Figure 5). Monofunctionalized ADA−PEG was included as a control since it cannot cross-link.

The general strategy for the design of the cyclodextrin-containing constructs is illustrated in Figure 6. The association between the adamantane and cyclodextrin components was investigated by rheology measurements (for a comprehensive presentation on rheology see ref *48*). In the frequency range from 1 to 100 rad/s, G' was found to be much smaller than G'' for the CD−PEG samples. However, with collagen, G' was significantly larger than G'' over the frequency range observed (tan δ value $\ll 1$). This result indicates that the CD−ADA complex behaves more like a viscous liquid than an elastic gel such as collagen. A possible explanation for the behavior of the CD−PEG samples is the reversible nature of the inclusion complex formation between adamantane and β-cyclodextrin as proposed by Amiel and Sebille (*41*). Another possible explanation could be that aggregates of limiting size are formed instead of an extended network. In the frequency range studied, G' and G'' did not cross one another. In the "Maxwell model", the crossover frequency is the inverse of the average relaxation time that is characteristic for the transient network (*48*). By using the model of Tanaka and Edwards, the relaxation time can be related to the dissociation kinetics between the chemical groups forming the network (*48*). For the CD−PEG samples, the crossover frequency (if it exists) was found to be higher than 100 rad/s. It is of interest that in the case of a highly elastic network such as bovine collagen, no G'/G'' crossover was observed in the same frequency range (Figure 8B).

The CD−PEG polymer length and cross-linker functionality influences the viscosity of the resulting polymer solutions. The complex viscosity increases as a function of both molecular weight of the CD−PEG polymer and cross-linker functionality (Figure 9). Significant increases in viscosity over the baseline established with monovalent ADA−PEG were observed after addition of cross-linker (Table 1). As expected, the viscosities are higher at 20 vs 35 °C, but the same type of behavior is observed at both temperatures.

In vitro biocompatibility studies show that human skin fibroblasts are viable in both the collagen and CD−ADA matrices, as indicated by the presence of elongated and translucent cells (morphologies typically observed with healthy fibroblasts). Cells in collagen appear to be in a migratory phenotype at 48 h because lamellipodia and filopodia fingerlike structures that extend from the appendages of the cells are observed (Figure 10, inset) (*52*). It is known that dermal fibroblasts plated on collagen are stimulated to migrate (*53*, *54*). Cells in CD−ADA did not appear to be in a migratory phenotype. However, we have shown that CCD-1074sk cells will also migrate through the CD−ADA matrix when stimulated to do so by a chemo-attractant gradient such as rhPDGF−BB (Figure 11). Evaluation of these migratory cells at higher magnification also shows the presence of lamellipodia and filopodia at the appendages (data not shown).

In vitro transgene expression studies show that a recombinant adenovirus encoding GFP formulated in the CD−ADA construct can efficiently transduce CCD-1074sk cells. While fluorescent pictures suggest that the CD−ADA construct enables higher levels of expression than collagen or media alone, fluorometric data indicate that the observed differences are not statistically significant.

Cell proliferation is significantly higher ($p < 0.05$) in the media alone group compared to collagen and the CD−ADA matrix. It has been reported that floating collagen matrices have an inhibitory effect on proliferation of fibroblasts (*55*). Cells in floating collagen matrices also exhibit distinct morphological characteristics generally described as an extended dendritic network (*56*). In our

observations, fibroblasts plated on collagen show a proliferation pattern and morphology similar to what is observed in floating collagen matrices. Fibroblasts in the CD−ADA construct proliferate at a rate comparable to cells in the collagen matrix but have a slightly different morphological appearance than cells plated in either media alone or collagen. This is not unexpected, since a mainly PEG-based polymer will not provide the same signaling to cells as collagen, nor will it provide the rigid attachment points for cells found on a plastic surface.

Taken together, these results indicate that the CD−ADA construct can serve as a highly tunable and biocompatible matrix for recombinant adenovirus-mediated gene delivery to local wound sites. The properties of the network can be altered by controlling the polymer molecular weights and the number of adamantanes on the cross-linking polymer, and these modifications and others such as replacement of the β-cyclodextrin (host) and adamantane (guest) with other cyclodextrins (hosts such as α, γ, and substituted members) and inclusion complex forming molecules (guests) provide the ability to rationally design network characteristics. The CD−ADA constructs are highly biocompatible and will thus be useful for in vivo applications. We have successfully employed these constructs in wound healing animal models and will report our results elsewhere.

Poly(3-guanidinopropyl methacrylate): A Novel Cationic Polymer for Gene Delivery

Arjen M. Funhoff, Cornelus F. van Nostrum, Martin C. Lok, Marjan M. Fretz, Daan J. A. Crommelin, and Wim E. Hennink*

Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Sciences (UIPS), Utrecht University, P.O. Box 80082, 3508 TB, Utrecht, The Netherlands. Received June 11, 2004; Revised Manuscript Received September 15, 2004

A cationic polymethacrylate with a guanidinium side group was designed in order to create a polymer with cell membrane-penetrating properties such as Tat or other arginine-rich peptides. The polymer, poly(3-guanidinopropyl methacrylate), abbreviated as pGuaMA, was synthesized by free radical polymerization. The DNA-condensing properties of pGuaMA (Mw 180 kDa) were investigated via dynamic light scattering and zeta potential measurements, and small, positively charged particles (110 nm, +37 mV) were found. It was shown that polyplexes based on pGuaMA were able to transfect COS-7 cells efficiently in the absence of serum, while under the same conditions poly(arginine) (pArg) polyplexes did not show detectable transfection levels. Addition of a membrane-disrupting peptide, INF 7, derived from the influenza virus, to preformed pGuaMA polyplexes did result in ~2 times increased transfection levels. DLS, zeta potential measurements, gel electrophoresis, and ethidium bromide displacement measurements indicated that serum induced aggregation of the polyplexes at high polymer/plasmid ratios, while at low polymer/plasmid ratios the polarity of the polyplexes reversed likely due to adsorption of negatively charged proteins on their surface. Likely, the unfavorable interactions of pGuaMA polyplexes with serum proteins is the reason for the absent transfection activity of these polyplexes in the presence of serum. Confocal laser scanning microscopy indicated cellular internalization via endocytosis of both polyplexes and free polymer. Thus, pGuaMA polyplexes enter cells, as reported for other polyplexes, by endocytosis and not, as hypothesized, via direct membrane passage.

INTRODUCTION

The use of genetic material as medicines to cure life-threatening diseases is currently under investigation. Several potential vehicles for gene delivery (called vectors) into target cells are investigated, each with its own advantages and disadvantages. There exist however a number of physical and biological barriers (*1*–*5*) which limit the potential transfection activity of the presently investigated nonviral (= synthetic) gene delivery systems. It is widely accepted that complexes of the carrier system and DNA (called polyplexes in the case of polymers or polypeptides (such as pEI, pDMAEMA, or pLL), and lipoplexes in the case of lipids (such as DOTAP)) (*6*–*9*), are taken up by cells via endocytosis (*2*) and end up in endosomes/lysosomes. The content of the endosomes/lysosomes is eventually degraded by the enzymes present in these organelles. Therefore, poly-/lipoplexes have to escape from the endosomes/lysosomes before this degradation occurs. The overall efficiency of this process is usually low, resulting in low gene-expression levels, but it has been demonstrated that the transfection efficiency of polyplexes can be increased using endosomal escape agents (*10*). However, completely circumventing endocytosis as the pathway of uptake and making use of an alternative route to enter the cell cytoplasm is an attractive strategy to improve the overall efficiency of nonviral gene delivery systems.

In the past few years, it was reported that some peptides are taken up by cells by a route other than endocytosis. Uptake of these peptides is seemingly receptor- or protein-independent and already occurs at 4 °C, although the actual mechanism is not clarified. These peptides are called cell-penetrating peptides or protein transduction domains, as they easily pass cellular membranes. Two examples of such peptides are the basic domain from the HIV-1 Tat protein (*11*) and a sequence from the *Drosophila melanogaster* antennapedia protein (Ant) (*12*). A common feature of these two peptides is that they consist of a large number of positively charged amino acids, mainly arginine and lysine. It was shown that other arginine-rich peptides (*13*) as well as oligoarginines (*14*) show the same cellular uptake as the Tat peptide. These peptides were coupled to macromolecular therapeutics to facilitate the cellular uptake of these compounds. The group of Kopeçek showed that when the Tat peptide was coupled to a *N*-(2-hydroxypropyl)-methacrylamide copolymer, cellular uptake and nuclear localization of the copolymer was substantially improved (*15*). Coupling of the Tat or the Ant peptide to antisense oligonucleotides also increased the cellular uptake (*16*). It was even shown that if the backbone of peptide nucleic acids (PNAs) was modified with guanidinium groups, cellular uptake of the PNAs was much higher and directed toward the nucleus (*17*).

Since the guanidinium group is highly basic (pK_a = 12.5), it is fully protonated at physiological pH. Therefore, synthetic polymers (e.g., poly(meth)acrylates) bearing guanidinium side chains should be able to complex and

condense DNA into small particles. On the basis of the above-mentioned literature, we initially expected that such polymers and/or polyplexes based thereon will be taken up by cells via another pathway than endocytosis and localize in the nucleus. This may result in increased transfection levels. For poly(arginine), the ability to condense DNA into small particles has been shown by Pouton et al. (*18*). However, the transfection efficiency of poly(arginine)-based polyplexes was the lowest of the tested cationic polypeptides. When compared to polymethacrylates, polypeptides have a much lower transfection efficiency (*19*), thus changing the backbone of poly(arginine) to a methacrylate may be advantageous.

In more recent publications the spontaneous passage of arginine-rich peptides over the plasma membrane has been questioned. Richard et al. (*20*) suggested that the observed 'spontaneous' membrane passage by these peptides might be an artifact created by the fixation of the cells with formaldehyde, as diffuse fluorescence in the cytosol was only found when cells were fixated, whereas a punctuate distribution was found in living cells. Krämer et al. reported that the Tat peptide is not able to penetrate the lipid bilayer of liposomes or the cell membrane of living cells (*21*). Both Richard et al. and Krämer et al. concluded therefore that endocytosis is the main pathway of internalization of these cationic peptides. Although the cell-penetrating properties of these peptides are questionable, they may still be useful for drug delivery purposes. Console et al. showed that the Ant or Tat peptide promotes cellular uptake of macromolecules and liposomes through endocytosis (*22*). The amount of internalized FITC-labeled avidin or streptavidin was higher when it was bound to biotinylated Ant or Tat peptide. Thus, although our initial approach to synthesize a polymer with cell membrane-translocating properties is probably not feasible, an increase in cellular uptake can also promote the transfection efficiency and may therefore be of interest.

This paper reports on the synthesis of the monomer 2-methacrylic acid 3-guanidinopropyl ester and the corresponding polymer. The transfection activity and mechanism of cellular uptake of polyplexes based on this polymer are studied as well.

EXPERIMENTAL PROCEDURES

Materials. The following materials were used as received: 3-amino-1-propanol (Janssen Chimica), 2-ethyl-2-thiopseudourea hydrobromide (Aldrich), *N*-(aminopropyl)methacrylamide hydrochloride (Polysciences), rhodamine B isothiocyanate (Aldrich), poly(L-aspartic acid) sodium salt (pAspA) (Sigma), poly(L-arginine hydrochloride) (pArg) (Sigma, $M_w = 42.4$ kDa). Methacryloyl chloride purum ≥ 97% (Fluka) was distilled before use. The plasmid pCMVLacZ, containing a bacterial LacZ gene preceded by a nuclear localization signal under control of a CMV promoter, was purchased from Sanvertech (Heerhugowaard, The Netherlands). INF-7, a 24 amino acid containing peptide with fusogenic activity derived from the influenza virus, was synthesized via standard Fmoc solid-phase synthesis (*23*). The reference polymers: poly((dimethylamino)ethyl methacrylate) (pDMAEMA, $M_n = 92$ kg/mol) was synthesized via radical polymerization (*24*), and PEI (branched 25 kDa) was purchased from Sigma.

Synthesis of 2-Methacrylic Acid 3-Guanidinopropyl Ester (GuaMA). 2-Guanidinopropanol was synthesized according to Fishbein and Gallaghan (*25*). In detail, 3-aminopropanol (0.641 g, 8.54 mmol) was added dropwise to 2-ethyl-2-thiopseudourea hydrobromide (1.58 g, 8.54 mmol) in a 10 mL flask. After 5 min of stirring, 1 mL water was added. The resulting solution was stirred overnight at room temperature. Next, water was removed under reduced pressure to obtain a white solid, which was further dried (yield 1.67 g, 8.43 mmol, 99.8%). NMR spectra were recorded on a Varian G-300 300 MHz spectrometer (Varian, Palo Alto, CA). ^{1}H NMR (DMSO): $\delta = 7.6-6.6$ (multiple bs, 4H, NH's), 4.7 (bs, 1H, OH), 3.44 (t, 2H, HOCH_2CH$_2$CH$_2$N), 3.14 (t, 2H, HOCH$_2$-CH$_2$CH_2N), 1.60 (dt, 2H, HOCH$_2$CH_2CH$_2$N). ^{13}C NMR (DMSO): $\delta = 157.1$ (CH$_2$NH*C*(NH)NH$_2$), 58.0 (HO*C*H$_2$-CH$_2$CH$_2$), 38.2 (CH$_2$*C*H$_2$NHC), 31.6 (CH$_2$*C*H$_2$CH$_2$NH).

2-Methacrylic acid 3-guanidinopropyl ester was synthesized as follows. Methacryloyl chloride (0.892 g, 8.50 mmol) was added to guanidinopropanol (1.67 g, 8.43 mmol) dissolved in acetonitrile (10 mL) and stirred at room temperature for 2 days. Acetonitrile was removed under reduced pressure, resulting in a white solid. The crude product was purified by column chromatography over silica (eluent EtOAc/EtOH 1/1, $R_f = 0.68$), and the solvent from the pooled fractions with the desired product was removed under reduced pressure, resulting in a white solid, the HCl salt of the monomer. This was recrystalized in EtOAc, yielding 1.04 g (46%). ^{1}H NMR (DMSO): $\delta = 7.6$ and 7.2 (bs, 4H, NH's), 6.04 (s, 1H, H_2C=C), 5.68 (s, 1H, H_2C=C), 4.12 (t, 2H, OCH_2CH$_2$), 3.19 (m, 2H, CH$_2$CH_2NHC), 1.87 (s, 3H, C=C(CH_3)), 1,82 (m, 2H, CH$_2$CH_2CH$_2$). ^{13}C NMR (DMSO): $\delta = 157.4$ (CH$_2$NH*C*(NH)NH$_2$), 136.4 (H$_2$C=*C*), 126.6 (H$_2$*C*=C), 62.3 (O*C*H$_2$CH$_2$), 38.3 (CH$_2$*C*H$_2$NC), 28.3 (CH$_2$*C*H$_2$CH$_2$NH), 18.6 (C=C(*C*H$_3$)).

Polymerization. pGuaMA was synthesized via radical polymerization as described before for pDMAEMA (*24*). In brief, 0.500 g of monomer was dissolved in 2 mL of 1 M hydrochloric acid, and the pH was adjusted to 5. Polymerization was carried out under a nitrogen atmosphere at 60 °C overnight with ammonium peroxodisulfate as initiator at a M/I ratio of 100. After cooling to room temperature, the solution was poured into a dialysis tube (MWCO 3.5 kDa) and extensively dialyzed against water. The polymer was collected as a white fluffy solid after freeze-drying (yield 0.366 g, 73%). Molecular weights were determined via gel permeation chromatography (GPC) relative to dextran standards (Fluka) (*24*). GPC measurements were performed with two thermostated (30 °C) columns in series (Shodex OHpak K80P and KB-80M, Showa, Denko, Japan) on a system consisting of a pump Model 600, an autoinjector Model 486, and a refractive index detector Model 410 (all Waters Associates, Milford, MA). The eluent was an aqueous solution of 0.7 M $NaNO_3$, 0.1 M Tris (pH 7.2), and the flow rate was 1 mL/min.

A fluorescently labeled polymer was synthesized by copolymerization of GuaMA with 5 mol % *N*-(aminopropyl)methacrylamide using the same synthetic procedure as described above. Rhodamine isothiocyanate (1 mg, 1.87 μmol) was coupled to the free amines of the polymer (50.0 mg, 17.3 μmol free NH_2) in 2.50 mL of 20 mM HEPES buffer, pH 7.4, overnight at 4 °C. Unreacted rhodamine was removed by gel permeation chromatography over a Sephadex G25 column (Pharmacia) using water as an eluent. The fractions with the polymer were collected, and the fluorescently labeled polymer was obtained via lyophilization of the combined fractions (yield 39.7 mg, 78%).

Physical Characterization of Polyplexes. Polyplexes with different polymer-to-plasmid ratios (expressed as *N*/*P* ratios, where *N* is the amount of protonated nitrogens in the polymer (for pGuaMA/pArg: one

per side chain) in moles and *P* is the amount of plasmid phosphate in moles) were made by adding a pGuaMA or pArg solution (700 μL, various concentrations) in buffer (HEPES (20 mM) buffered saline (HBS) for particle size measurements, 20 mM HEPES buffer pH 7.4 for ζ-potential measurements) to a plasmid DNA solution (175 μL, 75 μg/mL). After incubation of the polyplex dispersions for 30 min at room temperature, *Z*-average diameters were measured with dynamic light scattering at 25 °C with a Malvern 4700 system using an argon-ion laser (488 nm) operating at 10.4 mW (Uniphase) and PCS (photon correlation spectrometry) software for Windows version 1.34 (Malvern, UK). Viscosity and refractive index of pure water at 25 °C were used. The system was calibrated with an aqueous dispersion of polystyrene particles with a 100 nm diameter. The ζ-potential of the polyplexes was determined at 25 °C in a DTS5001 cell with a Zetasizer 2000 unit (Malvern). The instrument was calibrated with a polystyrene dispersion with known ζ-potential.

In Vitro Transfection and Cell Viability Studies. Transfection and cell viability studies were performed in COS-7 cells as described before (*26*). The plasmid pCMVLacZ was used as reporter gene. Plates (96-well) were seeded with 3×10^4 cells/cm^2 24 h before transfection. At the day of transfection, 250 μL pGuaMA/pArg polyplex dispersions in HBS were made essentially as described above with the exception that the DNA concentration used was 50 μg/mL (instead of 75 μg/mL). INF-7 coated pGuaMA polyplexes were made by mixing 150 μL of polymer solution and 50 μL of DNA solution in HBS. After 30 min of incubation, 50 μL of INF-7 solution (150 μg/mL in HBS) was added, and the polyplexes were incubated for an additional 15 min. Previous studies showed that positively charged polyplexes were coated with the negatively charged INF-7 peptide (*27*). After washing of the cells with HBS, 100 μL of polyplex dispersion and 100 μL of culture medium (with or without fetal bovine serum) were applied to the cells for 1 h, after which the cells were washed and fresh culture medium was applied. All studies were performed in two identical series in two different 96-well plates. After 48 h of incubation, one plate was evaluated for reporter gene (β-galactosidase) expression with *o*-nitrophenyl-β-D-galactopyranoside, the other plate was used to determine cell viability using a XTT colorimetric assay (*28*). As a reference, pDMAEMA and PEI polyplexes prepared at the same DNA concentration and an *N*/*P* ratio of 6 were used. The transfection activity of the pDMAEMA polyplex formulation was set at one.

Influence of Serum on the Biophysical Properties of Polyplexes. To determine the effect of serum on the biophysical properties of the polyplexes, their size in the presence or absence of serum was measured. In detail, 500 μL polyplex dispersions in HBS were made as described above. After 30 min incubation, the polyplex dispersions were split into two equal volumes and 1 to 1 diluted with either buffer solution or buffer solution containing 10% serum. These dispersions were incubated for another hour before *Z*-average diameters were measured using DLS. For zeta potential measurements, a 2.5 mL polyplex dispersion (30 μg/mL DNA) in 20 mM HEPES buffer, pH 7.4, was diluted with 2.5 mL of 20 mM HEPES buffer containing 10% serum.

To study whether serum proteins induced polyplex dissociation, two different tests were performed. In the first test, DNA condensation (by pGuaMA/pArg) and poly(aspartic acid) (pAspA)-mediated dissociation of the formed complexes in the absence or presence of 5% serum was monitored using agarose gel electrophoresis. Polyplexes were made by mixing 10 μL plasmid solution (80 μg/mL in HBS) with 10 μL of polymer solution (various concentrations in HBS), and the dispersions were incubated for 30 min at room temperature. Next, 5 μL of buffer or buffer containing 30% serum was added, and the dispersions were incubated for 15 min. Subsequently, 5 μL of pAspA (10 mg/mL) (or 5 μL buffer as a control) was added, and the dispersions were incubated for another 30 min. After addition of 3 μL of sample buffer (containing bromophenol blue 0.4% (w/v), 10 mM EDTA, and 50% (v/v) glycerol in water), 30 μL of this mixture was applied onto a 0.7% agarose gel containing 0.5 μg/mL ethidium bromide. After development of the gel, DNA was visualized with a UV lamp using a GelDoc system (BioRad) (*26*).

In the second test, free DNA was detected via fluorescence with ethidium bromide that was added to a DNA solution (25 μg/mL in HBS) in a 1:10 molar ratio to the DNA phosphates. A solution of pGuaMA (400 μL, various concentrations in HBS) was added to 100 μL of DNA, vortexed for 5 s, and incubated for 30 min. This was done in two identical series. To one series, 500 μL buffer was added, and to the other series 500 μL of buffer containing 10% serum. The dispersions were incubated at room temperature for 1 h after which the fluorescence was measured using a Spex Fluorlog III spectrofluorimeter (Spex, Edison, NJ). The excitation and emission wavelength were 520 and 600 nm, respectively, and the slits were 1.26 and 4.52 nm, respectively. The relative fluorescence (F_r) values were determined as follows:

$$F_r = (F_{obs} - F_e)/(F_0 - F_e)$$

where F_{obs} is the fluorescence of the polyplex dispersion, F_e is the fluorescence of ethidium bromide in the absence of DNA, and F_0 is the initial fluorescence of DNA/ethidium bromide in the absence of pGuaMA.

Cellular Uptake of Polyplexes and Free Polymer. The cellular uptake of polyplexes and free polymer was investigated via confocal laser scanning microscopy (CLSM) in living cells in the absence or presence (only polyplexes) of an endocytosis inhibitor (1 mM iodoacetamide) or at 4 °C. DNA was labeled with AlexaFluor 647 C_2 maleimide (Molecular Probes) using the Fasttag FL labeling kit from Vector Laboratories. Polyplexes were made with the rhodamine-labeled polymer, and for experiments in the presence of inhibitor nonlabeled DNA was used. In a 16-well glass plate, cells were seeded (3×10^4 cells/cm^2) and culture medium was added. The cells were grown at 37 °C in a humidified 5% CO_2-containing atmosphere. Twenty-four or 47 h after seeding, 100 μL of serum-free culture medium and 100 μL of either polyplexes with an N/P ratio of 2.7 (10 μg/mL DNA, polymer 15 μg/mL) or free pGuaMA (15 μg/mL) were applied for 1 h to the cells. As control, pDMAEMA based polyplexes (N/P = 6) were applied to the cells 24 h after seeding. Thereafter, the polyplex dispersion and the free polymer were removed and culture medium was applied. The cells were cultured for 48 h in total after seeding, after which the cells were rinsed with PBS, and covered with a glass slide. Directly afterward, fluorescent and transmitted light microscope images were taken simultaneously on a Leica TCS−SP microscope equipped with an argon 488 nm, a krypton 568 nm and a HeNe 647 nm laser and were analyzed with Leica TCS−SP Power Scan software (Leica Microsystems, Rijswijk, The Netherlands).

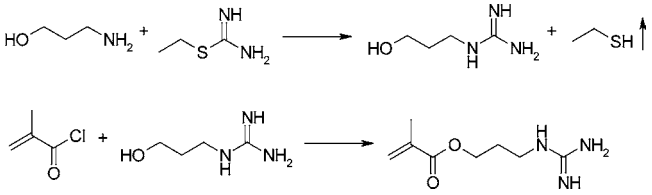

Figure 1. Synthetic route toward 2-methylacrylic acid 3-guanidinopropyl ester.

RESULTS AND DISCUSSION

Monomer and Polymer Synthesis. The synthesis of 2-methacrylic acid 3-guanidino-propyl ester (GuaMA) was performed in two steps (Figure 1). In the first step, 3-aminopropanol was converted into guanidinopropanol using 2-ethyl-2-thiopseudourea hydrobromide with the release of ethanethiol (*25*). This reaction yielded the desired product in quantitative yield and good purity (>97% by NMR). In the second step, guanidinopropanol was esterified with methacryloyl chloride and purified via column chromatography and recrystallization from ethyl acetate. This resulted in the desired monomer in reasonable yield (46%) and good purity (>97% by NMR, melting point 65 °C). Free radical polymerization of this monomer in an aqueous HCl solution and subsequent dialysis and lyophilization gave poly(3-guanidinopropyl methacrylate) (yield 73%) with a weight average molecular weigh (M_w) of 180 kDa and a number average molecular weight (M_n) of 25 kDa as determined with GPC relative to dextran standards. A pGuaMa M_w 180 kDa was synthesized since high molecular weight cationic polymers have, generally speaking (as demonstrated, for example, for pDMAEMA (*24*)), the best DNA-condensing properties.

Biophysical Characterization of Polyplexes. The biophysical properties of pArg- or pGuaMA-based polyplexes were investigated by DLS and zeta potential measurements. Figure 2 shows the average size and zeta potential of these polyplexes as a function of the polymer-to-DNA ratio (in the absence of serum proteins). As can be seen in Figure 2A, pArg was able to condense DNA in small particles of approximately 80 nm at all tested *N*/*P* ratios. Zeta potential measurements showed negatively charged polyplexes at low *N*/*P* ratios. With increasing *N*/*P* ratios the zeta potential of the polyplexes raised to approximately + 20 mV. As shown in Figure 2B, pGuaMA condensed DNA into small particles of approximately 100 nm when an excess of the polymer was used. The particles have a zeta potential of approximately +37 mV at these ratios, which is rather high when compared to the pArg polyplexes and other polyplexes (*29*−*31*). This might suggest that under the conditions where small and stable particles are formed (*N*/*P* > 5) DNA binds more pGuaMA than pArg in a polyplex. pGuaMA polyplexes prepared at an *N*/*P* ratio of 2 were neutral, and consequently, due to the absence of electrostatic repulsion, large aggregates were formed in the polyplex formulation. At lower ratios negatively charged polyplexes were formed. Similar DNA condensation behavior has been found for other cationic polymers (*29*−*31*).

In Vitro Transfection and Cell Viability Studies. Transfection studies were performed in COS-7 cells (Figure 3). The transfection activity and cytotoxicity of the pGuaMA/pArg polyplexes was compared with those of pDMAEMA and PEI systems. When serum was present during the incubation of the polyplexes and the cells, no transfection was found for both pGuaMA- and pArg-based polyplexes. Compared to pDMAEMA-based

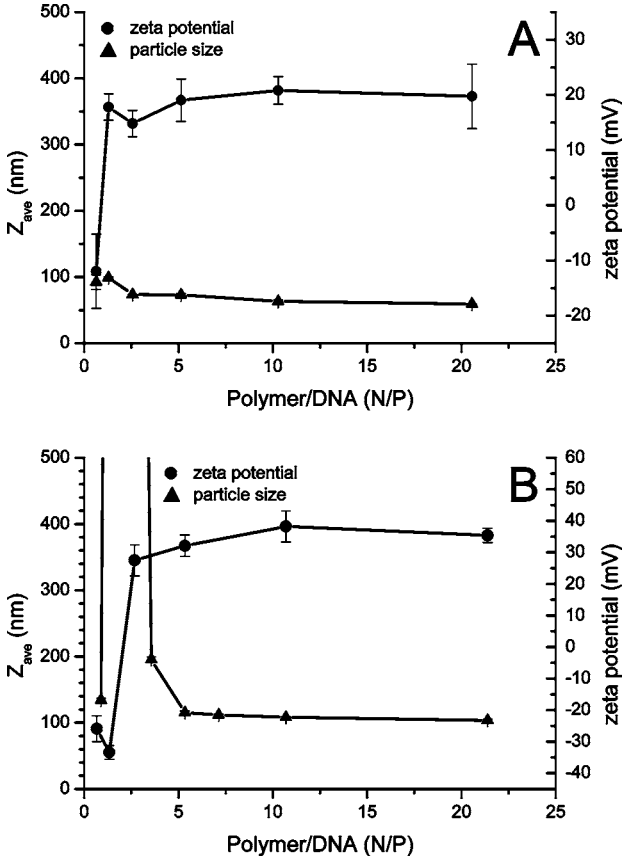

Figure 2. Physical characteristics of pArg (A)- and pGuaMA (B)-based polyplexes: particle size (▲) and zeta potential (●) as a function of the *N*/*P* ratio. All experiments were done in triplicate.

polyplexes, the pGuaMA and pArg polyplexes had a low toxicity since the concentration of polymer resulting in 50% cell death was 100 μg/mL for pArg and 150 μg/mL for pGuaMA (Table 1), respectively, whereas it was 30 μg/mL for pDMAEMA. For the pGuaMA polyplexes prepared at *N*/*P* ratios above 22, it was observed by visual inspection that a precipitate was deposited onto the cells. These precipitates likely are aggregates of the free pGuaMA present in the polyplex formulation and serum proteins (see section 'Influence of Serum on pGuaMA Based Polyplexes'). Therefore, transfection experiments were also done in the absence of serum. As can be seen in Figure 3 and Table 1, this had a major effect on both the transfection activity and the cytotoxicity of the pGuaMA polyplexes. Transfection efficiencies of 0.20 relative to the reference polymers (pDMAEMA and PEI) were found at an *N*/*P* ratio of 5.4. As has been found for other polymer (*24*, *30*), small, positively charged polyplexes were formed at ratios where transfection occurred. Above an *N*/*P* ratio of 5.4, the transfection levels decreased most likely due to the increasing toxicity of the polyplexes as can be seen in Figure 3B. Thus serum proteins mask the toxicity of the polyplexes, as has been observed previously for other polyplex systems (*31*, *32*). In contrast, omitting serum proteins did not result in detectable transfection levels or polyplexes based on pArg, while the cytotoxicity of the polyplexes was comparable to pGuaMA-based polyplexes (Figure 3). Pouton et al. compared different cationic polypeptides, among which pArg and poly(L-lysine) (pLL), as vectors for gene delivery in B16 cells and they showed that pArg had the lowest transfection efficiency (*18*). It is known that different polymers, albeit having related structures, may

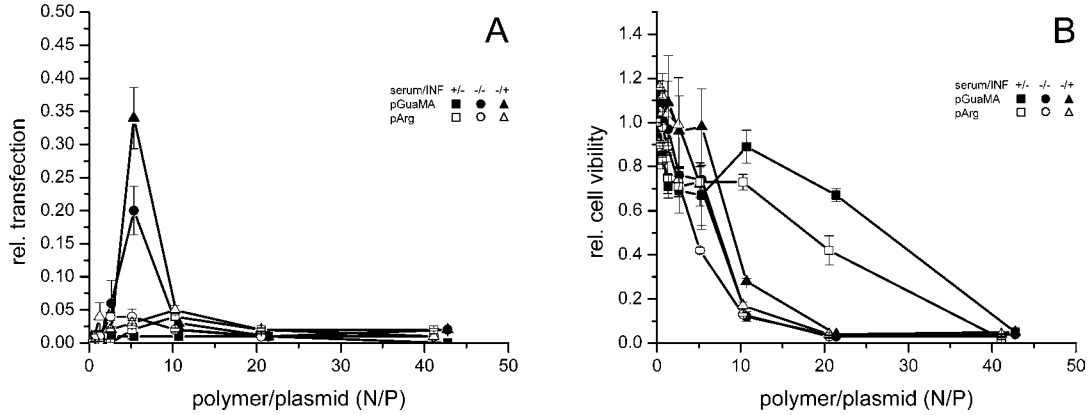

Figure 3. Transfection efficiency (A) and cell viability (B) of pGuaMA (closed symbols)- and pArg (open symbols)-based polyplexes in the presence (square) or absence (circle) of serum and of pGuaMA-based polyplexes in the absence of serum and presence of INF-7 (triangle) in COS-7 cells. All experiments were done in triplicate. Both reference polyplex formulations (pDMAEMA or PEI/DNA 6/1 (*N/P*) had comparable transfection activity, respectively 1.0 (pDMAEMA) and 1.05 (PEI), in the absence of serum.

Table 1. IC_{50} Values of pGuaMA and pArg Polyplexes under Different Transfection Conditions[a]

	transfection conditions		
polymer	+ serum − INF	− serum − INF	− serum + INF
pGuaMA	152 ± 5	42 ± 8	51 ± 4
pArg	105 ± 5	26 ± 2	42 ± 4

[a] The IC_{50} value is defined as the concentration polymer (in μg/mL) resulting in 50% cell death.

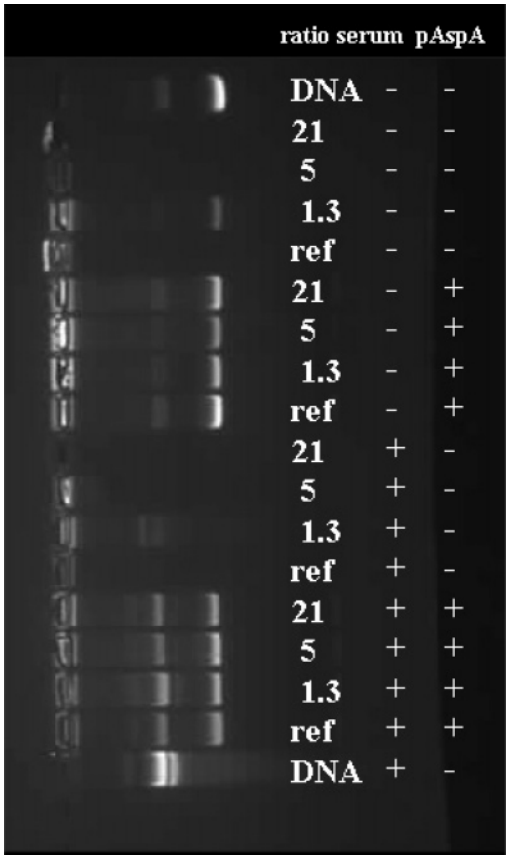

Figure 4. Gel electrophoresis of pGuaMA-based polyplexes in the absence (−) or presence (+) of serum or poly(aspartic acid) at various *N/P* ratios. Ref = pDMAEMA-based polyplexes at *N/P* = 6.

show substantial differences in transfection activity (*33*). Probably, changes in the polymeric backbone, such as from amino acid (pArg) to methacrylate (pGuaMA) can also affect the transfection activity.

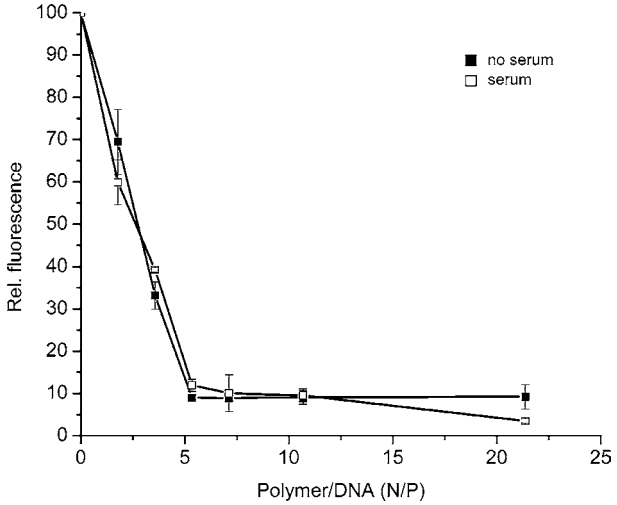

Figure 5. Ethidium bromide fluorescence (relative intensity) of pGuaMA-based polyplexes in the absence (■) or presence (□) of 5% serum. All experiments were done in triplicate.

Figure 3 shows that when the membrane-disrupting peptide INF-7 was added to pGuaMA-based polyplexes, an increase in transfection was observed by a factor of approximately 2. In contrast, addition of the peptide to pArg-based polyplexes did not result in increased transfection levels (data not shown). Probably, one of the following processes (e.g., polyplex destabilization, nuclear uptake) in gene delivery is rate limiting. As observed for other polyplexes (*30*, *33*, *34*), the cell viability was not influenced by the addition of the peptide. To investigate whether an endocytosis inhibitor had effect on the transfection, experiments in the presence of 1 mM iodoacetamide were performed. However, no detectable expression of the transgene was found at all pGuMA/DNA ratios tested. Both experiments indicated that the polyplexes are taken up via endocytosis rather than direct membrane passage.

Influence of Serum on pGuaMA-Based Polyplexes. Free polymer present in the polyplex dispersions prepared at high *N/P* ratios probably binds to negatively charged serum proteins, causing large aggregates, as has been demonstrated for pDMAEMA polyplexes (*35*). Incubating free polymer with serum in the same concentrations indeed resulted in large aggregates (data not shown). Because the pGuaMA polyplexes did not show

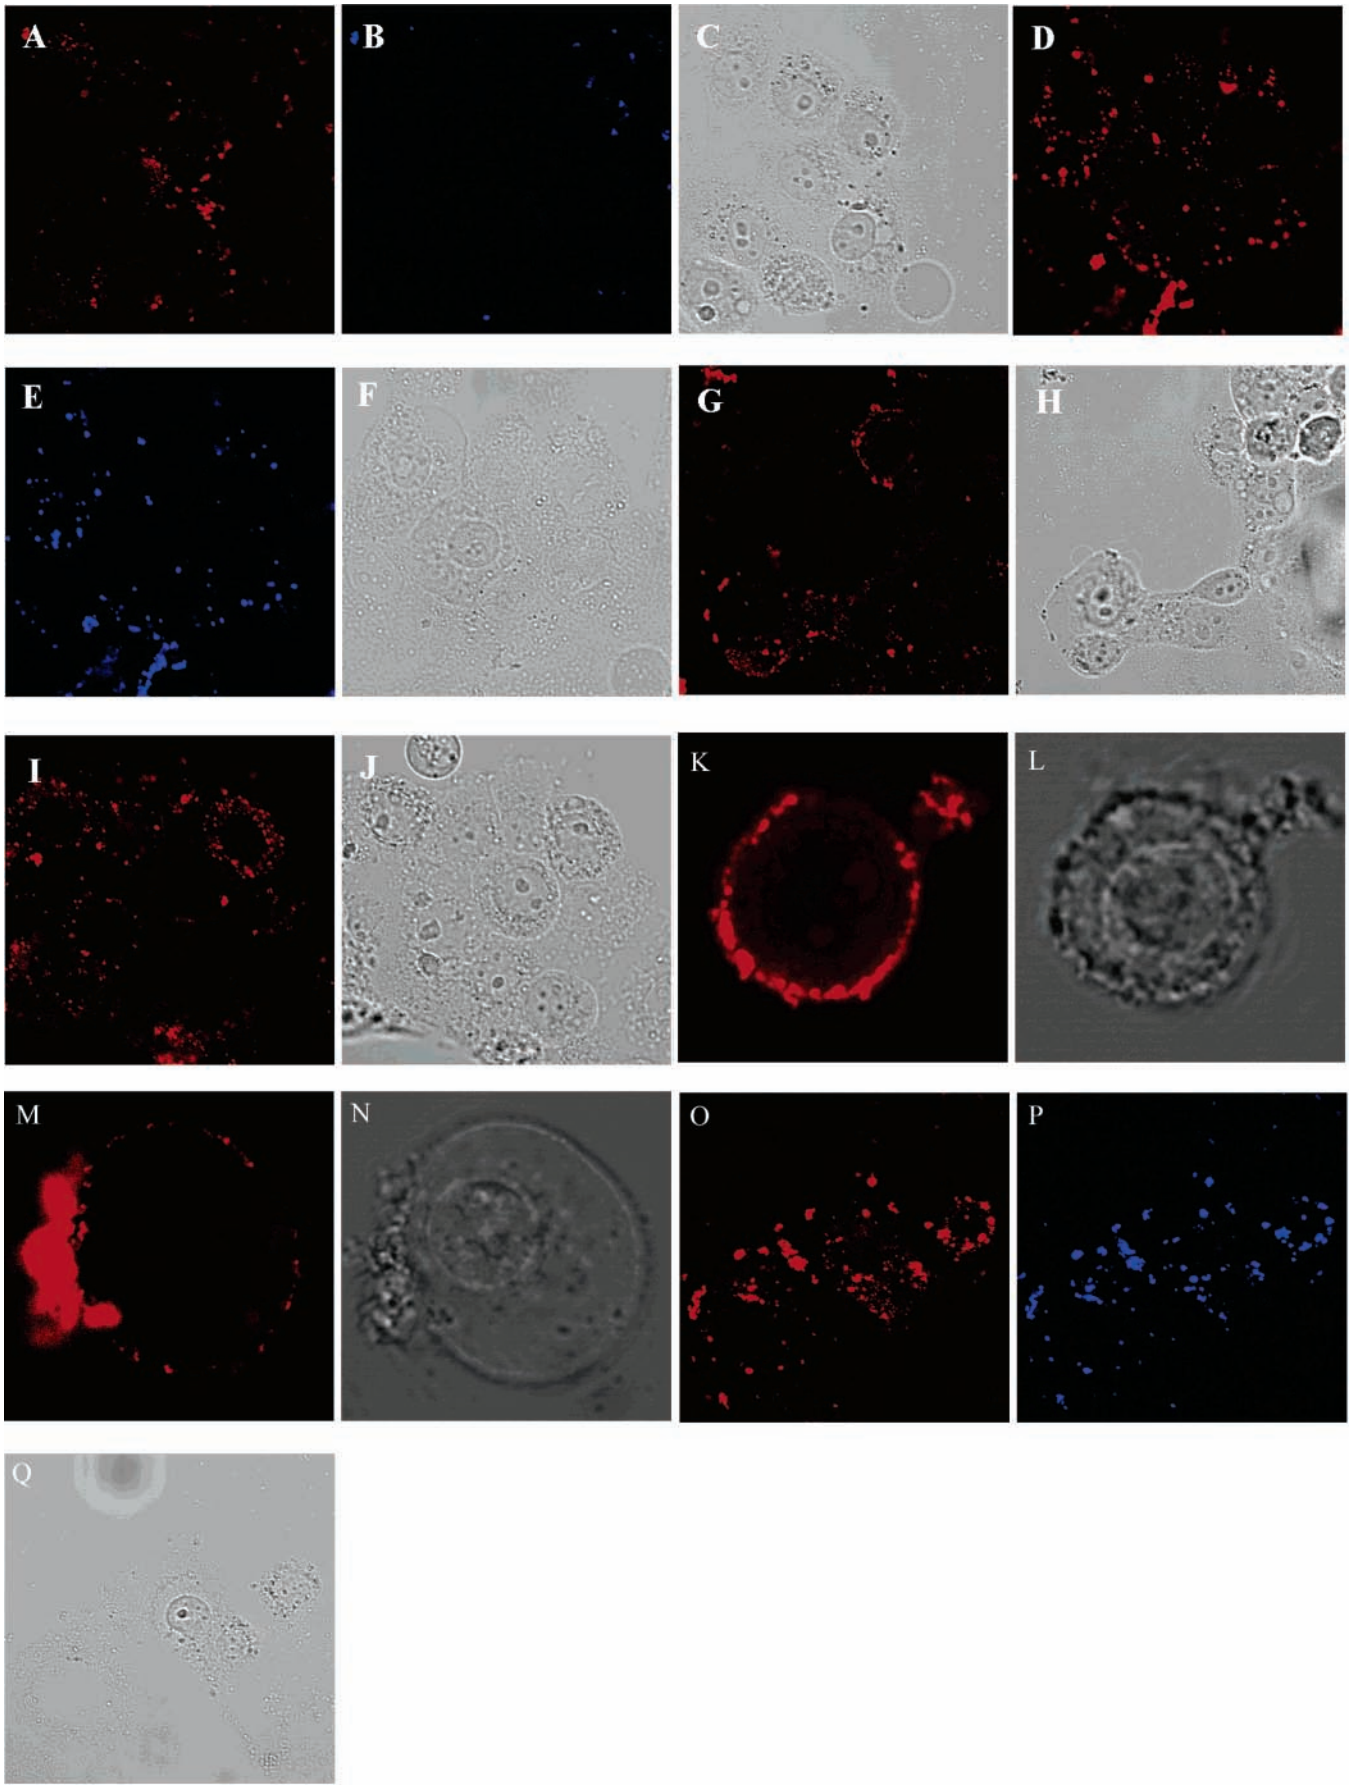

Figure 6. CLSM pictures of pGuaMA-based polyplexes (*N*/*P* ratio of 2.7) (A−C 1 h, D−F 24 h) and free polymer (15 μg/mL) (G−H 1 h, I−J 24 h) in the absence and polyplexes in the presence (K, L) of endocytosis inhibitor or at 4 °C (M, N). pDMAEMA-based polyplexes (*N*/*P* ratio of 6) (O−Q, 24 h) were used as control.

detectable transfection in COS cells and simultaneously large aggregates were visible, possible adverse interactions of serum with these polyplexes were investigated. It is known that serum proteins can cause aggregation of polyplexes or cause polyplex destabilization (*36*, *37*).

DLS measurements showed that polyplexes prepared at *N*/*P* ratios <10 did not show an increase in size when incubated with serum (data not shown). Zeta potential measurements, however, revealed that independent of the *N*/*P* ratio, pGuaMA polyplexes had a negative surface charge (zeta potential −14 mV) when serum was present. A substantial increase in particles size from 70 nm to >1 μm was observed when pGuaMA polyplexes (*N*/*P* > 10) were incubated with serum. At this ratio free polymer is probably present. When serum was added to a pGuaMA solution with the same concentration as used for the preparation of the *N*/*P* = 10 polyplexes, large aggregates were formed. Thus serum proteins adsorb on the positively charged polyplexes by which their zeta potential becomes negative. It has been shown before that polyplexes with a negative zeta potential had low aspecific cellular binding and consequently low transfection activity (*33*). Moreover, it has been reported that serum proteins can also induce polyplex destabilization (*36*, *37*). Figure 4 shows the gel electrophoretic patterns of pGuaMA polyplexes prepared at three different *N*/*P* ratios in the presence or absence of serum and poly(aspartic acid) (pAspA), a known and strong polyplex destabilization agent (*26*, *38*) pDMAEMA-based polyplexes (*N*/*P* = 6) were used as a reference. In the absence of pAspA, all DNA was found in the starting slots at *N*/*P* ratios 5 and 21, demonstrating that the DNA was bound to the polymer. A small amount of free DNA could be detected at an *N*/*P* ratio of 1.3. This is in agreement with DLS data (Figure 2), which showed small, positively charged particles at *N*/*P* ratios of 5 and 21, but aggregates at *N*/*P* ratio of 1.3. The electrophoretic patterns in the presence of serum gave the same results, suggesting that serum was not able to dissociate the polyplexes. When pAspA was present, free DNA could be detected at all ratios, indicating that the polyplexes were dissociated. Also here, no influence of serum was found.

Figure 5 shows the change in ethidium bromide fluorescence when pGuaMA is added to DNA in the absence or presence of serum. This figure shows that serum does not affect the complex formation between DNA and pGuaMA. Considering all the data, it can be concluded that not polyplex destabilization but interaction of serum proteins with the polyplexes is probably the main reason for the low transfection activity of the pGuaMA polyplexes in the presence of serum. These adverse interactions of polyplexes with serum proteins may be prevented by pegylation of the polyplexes. Moreover, pegylation of polyplexes has the additional advantage that the circulation times in vivo are increased, thereby increasing the accumulation of the polyplexes at the desired site (*39*−*41*).

Cellular Uptake of Polyplexes. Polyplexes based on previously described polymers (e.g., pDMAEMA, pEI) are taken up by cells via endocytosis (*2*). As pointed out in the Introduction, for Tat and other arginine-rich peptides another pathway than endocytosis that leads to the direct introduction of the peptide in the cytoplasm, has been suggested. However, this has been questioned in latter publications and uptake by endocytosis was suggested for these peptides. To investigate the pathway by which pGuaMA polyplexes are taken up by cells, confocal laser scanning microscopy (CLSM) studies were done in living cells, to avoid fixation artifacts (*20*, *21*). Cells in serum-free medium were incubated with polyplexes made with a red fluorescent labeled polymer and (blue labeled) DNA, or with free labeled polymer. CLSM and transmission pictures are shown in Figure 6. From these photographs it can be seen that the polyplexes and free polymer were associated with the cellular membrane 1 h after polyplex addition, whereas hardly any fluorescence was observed intracellularly, in agreement with previous observations (*33*). Twenty-four hours after administration, the polyplexes and free polymer were intracellularly located in small, punctuated spots lying around the nucleus of the cells. These spots most likely represent endosomes or lysosomes, as has also been found for other cationic polymers (*30*, *33*). When iodoacetamide, an endocytosis inhibitor, was added during incubation of the polyplexes with cells, or when the cells were incubated at 4 °C, only membrane binding of the polyplexes was found. The diffuse fluorescent pattern in the cytoplasm, due to cell membrane passage found for Tat peptide (conjugates) in the studies mentioned in the Introduction, was not observed in our experiments. This indicates that the route of uptake of pGuaMA polyplexes is, as for other polyplexes, mainly endocytosis.

As pGuaMA-based polyplexes do transfect cells to some extent, escape from the endosomes has to occur. For some cationic polymeric gene delivery systems, the 'proton sponge mechanism' has been proposed as an explanation for their endosomal escape (*42*, *32*). However, this mechanism is suggested for polymers having a buffering capacity around physiological and lysosomal pH. As pGuaMA is already fully protonated at physiological pH (pK_a = 12.5) and consequently does not have buffering capacity, the proton sponge mechanism cannot be the reason for endosomal escape for polyplexes based on this polymer. However, indications that the proton sponge mechanism is not generally valid were reported recently because polymers having buffering capacities around physiological pH were not able to transfect cells after endosomal uptake (*30*, *43*). Still, pGuaMA-based polyplexes, because they give transfection, obviously can escape from the endosomes and thus must have some membrane destabilizing activity.

CONCLUSION

A new polymethacrylate with a guanidinium side group, abbreviated as pGuaMA, was synthesized. The polymer was able to transfect cells, but only when serum was absent during transfection, as absorption of serum proteins changed the polarity of the polyplexes. When compared to the polypeptide analogue pArg, a substantial better transfection was observed. Polyplexes based on pGuaMA were internalized in small, punctuate spots as visualized via CLSM. No evidence was found with CLSM that polyplexes were taken up via an endocytosis-independent way, as has been suggested for arginine-rich peptides and other guanidine-containing structures, but disputed in recent publications.

Hydrotropic Dendrimers of Generations 4 and 5: Synthesis, Characterization, and Hydrotropic Solubilization of Paclitaxel

Tooru Ooya,[†] Jaehwi Lee,[‡] and Kinam Park*,[‡]

School of Materials Science, Japan Advanced Institute of Science and Technology, 1-1 Asahidai, Tatsunokuchi, Ishikawa 923-1292, Japan, and Departments of Pharmaceutics and Biomedical Engineering, Purdue University, West Lafayette, Indiana 47907. Received August 1, 2004; Revised Manuscript Received October 1, 2004

Polyglycerol dendrimers (PGDs) with 4−5 generations were synthesized and used to investigate the effect of dendritic architecture and its generation on aqueous solubilization of paclitaxel (PTX), a poorly water-soluble drug. Chemical and physical properties of the PGDs were characterized by NMR, MALDI-TOF mass, GPC, viscosity, and dynamic light scattering measurements. The PTX solubility in all the solutions of PGDs, even below 10 wt %, was much higher than that in PEG400 that is commonly used as a cosolvent or a hydrotropic agent. Increase in the PTX solubility by PGDs was dependent on the dendrimer generation. The dendritic structure was the reason for the enhanced solubility of PTX even at low concentrations. ^{1}H NMR spectra of PTX before and after mixing with PGDs in D_2O suggested that the aromatic rings and some methyne groups of PTX were surrounded by PGDs. PGDs, which do not require hydrophobic segment as in polymeric micelles, provide an alternative method of hydrotropic solubilization of poorly soluble drugs.

INTRODUCTION

Formulation of poorly water-soluble drugs has been one of the most important problems in drug delivery. Previous formulations have utilized surfactant and polymeric micelles, micro- or nanoparticles, solid dispersion, complexation with cyclodextrin, and cosolvents (*1*). Cosolvent methods have been widely used because of easy processing for fabricating oral as well as injectable formulations (*2*, *3*). The U.S. Food and Drug Administration has approved six water-miscible cosolvents: glycerin, poly(propylene glycol), poly(ethylene glycol) (PEG), *N*,*N*-dimethylformamide, Cremophor, and ethanol (*1*). Use of such organic solvents is limited because of their toxicities. In commercially available formulations, paclitaxel is formulated in a 50:50 mixture of Cremophor EL (castor oil modified with PEG-35) and ethanol, which is diluted in normal saline or dextrose solution (to make 5 wt % paclitaxel concentration) before administration (*4*). This formulation can cause fatal hypersensitivity reactions mainly due to cytototoxity of the amphiphilic compound and the organic solvent (*5*). For this reason, safer vehicles for delivery of paclitaxel have been explored.

PEGs have been frequently used for increasing the water-solubility of poorly soluble drugs. PEG with molecular weight of 400 g/mol (PEG400) has been used as a cosolvent for various poorly water-soluble drugs (*6*, *7*). PEG400 increases the solubility of β-estradiol 4−5 orders of magnitude when its concentration is 80 wt % and higher (*6*). The majority of PEG400 are capable of self-association through hydrogen bonding at higher concentration regions (over 80 wt %). Such associations may alter water structure to influence the water-solubility of poorly soluble drugs (*8*). A high density of PEG400 or ethylene glycol units is the key factor in increasing the solubility of poorly water-soluble drugs.

In our previous studies, graft and star-shaped graft copolymers of PEG400 were examined as solubilizers of paclitaxel (*9*). These molecular architectures enhanced the aqueous solubility of paclitaxel. In addition to graft and star-shaped graft copolymers of PEG400, polyglycerol dendrimers (PGDs) were examined for their ability to increase the water-solubility of paclitaxel. Well-defined hyperbranched polyglycerols were synthesized by ring-opening multibranching polymerization (*10*) and used as biocompatible materials (*11*, *12*). PGD with generation 3 was synthesized by step-by-step allylation and dihydroxylation (*13*). The density of ethylene glycol units in PGDs is expected to be higher than that of linear PEGs. PGDs have a good potential as biomaterials because of their high water solubility, chemical reactivity, and structural similarity to PEG with high density of the ethylene glycol unit. PGDs increased solubilization of paclitaxel more than the graft and star-shaped graft copolymers did. Although the PGDs have a good potential as a drug solubilizer, PGDs with 4 and 5 generations were not characterized, and the mechanism of the solubility enhancement of paclitaxel was not examined. In this study, PGDs with 4 and 5 generations were synthesized and characterized in terms of chemical structure, solution properties, and solubility mechanism of paclitaxel.

MATERIALS AND METHODS

Materials. Tetrabutylammonium bromide (TBAB), 50 wt % of sodium hydroxide solution, allyl chloride, magnesium sulfate ($MgSO_4$), silica gel, *N*-methylmorpholine *N*-oxide (NMO), and aqueous (4 wt %) OsO_4 solution were purchased from Aldrich (Milwaukee, WI) and used without further purification. *t*-Butanol (*t*-BuOH) and

Scheme 1. Synthesis of Polygrycerol Dendrimers (PGDs)[a]

[a] TBAB: tetrabutylammonium bromide, NMO: *N*-methylmorpholine *N*-oxide, OsO_4: osmium oxide 4 wt % aqueous solution.

N,*N*-dimethylformamide (DMF, HPLC grade) were purchased from Fisher. Benzylated cellulose membrane (MWCO 1000) was purchased from Sigma (St. Louis, MO). Paclitaxel was obtained from Samyang Genex Corp. (Taejeon, South Korea). Acetone, petroleum ether, ethyl acetate, toluene, and methanol were of a reagent grade.

Synthesis of Polyglycerol Dendrimers (PGDs) Started from Generation 3 (Scheme 1). PGDs (generations 4 and 5) were synthesized according to the report of Haag et al. (*13*). Each generation of the dendrimer was synthesized by a two-step process based on allylation of alcohols and catalytic dihydroxylation. A part of the purification process was modified.

PGD with Generation 3 (PGD G-3). PGD G-3 was synthesized in the same method of Haag et al. (*13*). ^{1}H NMR (300 MHz, CD_3OD): 4.85 (s, O*H*), 3.90−3.31 (m, 105H), 3.31 (s, 6H, C(C*H*$_2$)$_3$), 1.42 (q, 2H, C*H*$_2$CH$_3$), 0.89 (t, J = 7.20 Hz, 3H, C*H*$_3$); ESI-MS (4.52 kV, positive) calcd for $C_{69}H_{140}O_{45}$ 1688.9, found 1689.5, 1711.9 (+ Na).

Allylated PGD with Generation 3 (PGD G-3.5). In a three-neck flask, PGD G-3 (10.1 g, 5.98 mmol, OH groups: 143.5 mmol) was dissolved in 50 wt % of sodium hydroxide (57 mL) with heating. To the solution, TBAB (4.6 g, 14.3 mmol) was added and dispersed under vigorous stirring using a mechanical stirrer. Then, allyl chloride (75.7 mL, 930 mmol) was added over 20 h at 45 °C under vigorous stirring using the mechanical stirrer. After the addition of 143 mL of toluene to the mixture, the organic phase was separated from the other phase, dried over $MgSO_4$, filtered, and concentrated using a rotary evaporator. The crude was further purified by column chromatography (silica gel, petroleum ether/ethyl acetate 10:1 to 1:1) to obtain colorless oil. Oxygen was removed by flowing N_2 gas during the whole process. Yield: 11.1 g, ^{1}H NMR (300 MHz, $CDCl_3$): 5.88 (m, 24H, C*H*=CH$_2$), 5.18 (m, 48H, CH=C*H*$_2$), 4.14 (d, J = 5.40 Hz, 24H, CHOC*H*$_2$CH=CH$_2$), 3.99 (d, J = 5.40 Hz, 24H, CH$_2$-OC*H*$_2$CH=CH$_2$), 3.67−3.39 (m, 105H, C*H*$_2$C*H*(OR)C*H*$_2$O), 3.26 (s, 6H, C(C*H*$_2$)$_3$), 1.38 (q, 2H, CH$_3$C*H*$_2$), 0.84 (t, J = 7.21 Hz, 3H, C*H*$_3$); ^{13}C NMR (75 MHz, $CDCl_3$): 135.7 (CHOCH$_2$*C*H=CH$_2$), 135.2 (CH$_2$OCH$_2$*C*H=CH$_2$), 117.1 (CH$_2$OCH$_2$CH=*C*H$_2$), 116.9 (CHOCH$_2$CH=*C*H$_2$), 78.0

($CH_2CH(OR)CH_2$), 77.6 ($CH_2CH(OCH_2CH{=}CH_2)CH_2$), 72.6 ($CH_2CH(OR)CH_2$), 72.5 ($CH_2OCH_2CH{=}CH_2$), 71.6 ($CH_2OCH_2CH{=}CH_2$), 70.7 ($CHOCH_2CH{=}CH_2$), 43.6 ($C(CH_2)_4$), 23.6 ($CH_2CH_3$), 8.3 ($CH_2CH_3$); ESI-MS (4.52 kV, positive) calcd for $C_{141}H_{236}O_{45}$ 2649.6 found 2649.4.

PGD with Generation 4 (PGD G-4). In a one-neck flask, PGD G-3.5 (10.9 g, 5.42 mmol, 130 mmol allyl equivalents) and *N*-methylmorpholine *N*-oxide (NMO) (16.8 g, 143 mmol) were added to a mixture of acetone (65 mL), distilled water (65 mL), and *t*-BuOH (13 mL). Aqueous (4 wt %) OsO_4 solution (2.6 mL) was added and stirred for 20 h at room temperature. Then, all volatile compounds were removed in vacuo. The crude products were further purified by dialysis in methanol using benzylated cellulose membrane (MWCO 1000). The solution was concentrated in vacuo, and water was added to the obtained pale yellow oils. Water-insoluble impurity was removed by passing through a microfilter (pore size: 0.45 μm). Finally, the solute was lyophilized to obtain pure PGD G-4 as pale yellow oils. Yield: 11.7 g, ^{1}H NMR (300 MHz, CD_3OD): 4.85 (s, O*H*), 3.89−3.42 (m, 231H), 3.35 (s, 6H, $C(CH_2)_3$), 1.44 (q, 2H, CH_2CH_3), 0.92 (t, J = 6.92 Hz, 3H, CH_3); ^{13}C NMR (75 MHz, CD_3OD): 80.3 ($(CH_2)_2CH_2C$(H)OR), 74.5 ($CH_2OCH_2CH(OH)CH_2OH$), 73.4 ($C(CH_2)_3$), 72.9 ($ROCH_2C$(H)(OR)CH_2OR), 72.6 ($CHOCH_2CH(OH)CH_2OH$), 71.7 ($CHOCH_2CH(OR)CH_2OR$), 64.9 (CH_2OH), 45.1 ($C(CH_2)_4$), 25.2 (CH_2CH_3), 9.0 (CH_2CH_3); MALDI-TOF MS calcd for $C_{144}H_{290}O_{93}$ 3507.8 found 3507.4 +H, 3491.7 $-H_2O$.

Allylated PGD with Generation 4 (PGD G-4.5). In a three-neck flask, PGD G-4 (8.3 g, 2.63 mmol, OH groups: 126.2 mmol) was dissolved in 50 wt % of sodium hydroxide (45 mL) with heating (viscous gum was sometimes observed). To the solution, TBAB (3.65 g, 11.3 mmol) was added and dispersed under vigorous stirring using a mechanical stirrer. Then, allyl chloride (64.4 mL, 791 mmol) was added over 20 h at 45 °C under vigorous stirring using the mechanical stirrer. After the addition of 126 mL of toluene to the mixture, the organic phase was separated from the other phase, dried over $MgSO_4$, filtered, and concentrated using a rotary evaporator. The crude was further purified by column chromatography (silica gel, petroleum ether/ethyl acetate 10:1 to 1:1) to obtain colorless oil. Oxygen should be removed via flowing N_2 gas during the whole process. Yield: 5.84 g, ^{1}H NMR (300 MHz, $CDCl_3$): 5.90 (m, 48H, $CH{=}CH_2$), 5.24 (m, 96H, $CH{=}CH_2$), 4.15 (d, J = 5.10 Hz, 48H, $CHOCH_2CH{=}CH_2$), 4.00 (d, J = 5.10 Hz, 24H, $CH_2OCH_2CH{=}CH_2$), 3.67−3.30 (m, 231H, $CH_2CH(OR)CH_2O$), 3.33 (brs, 6H, $C(CH_2)_3$), 1.44 (brq, 2H, CH_3CH_2), 0.86 (brt, 3H, CH_3); ^{13}C NMR (75 MHz, $CDCl_3$): 135.7 ($CHOCH_2CH{=}CH_2$), 135.3 ($CH_2OCH_2CH{=}CH_2$), 117.2 ($CH_2OCH_2CH{=}CH_2$), 117.1 ($CHOCH_2CH{=}CH_2$), 77.9 ($CH_2CH(OR)CH_2$), 77.5 ($CH_2CH(OCH_2CH{=}CH_2)CH_2$), 72.7 ($CH_2CH(OR)CH_2$), 72.7 ($CH_2OCH_2CH{=}CH_2$), 71.7 ($CH_2OCH_2CH{=}CH_2$), 70.7 ($CHOCH_2CH{=}CH_2$), 43.4 ($C(CH_2)_4$), 23.5 ($CH_2CH_3$), 8.2 ($CH_2CH_3$).

PGD with Generation 5 (PGD G-5). In a one-neck flask, PGD G-4.5 (5.84 g, 1.1 mmol, 52.8 mmol allyl equivalents) and *N*-methylmorpholine *N*-oxide (NMO) (6.72 g, 57.2 mmol) were added to a mixture of acetone (26 mL), distilled water (26 mL), and *t*-BuOH (5.2 mL). Aqueous (4 wt %) OsO_4 solution (1.1 mL) was added and stirred for 20 h at room temperature. Then, all volatile compounds were removed in vacuo. The crude products were further purified by dialysis in methanol using benzylated cellulose membrane (MWCO 1000). The solution was concentrated in vacuo, and water was added to the obtained pale yellow oils. Water-insoluble impurity was removed by passing through a microfilter (pore size: 0.45 μm). Finally, the solute was lyophilized to obtain pure PGD G-5 as pale yellow oils. Yield: 6.1 g, ^{1}H NMR (300 MHz, CD_3OD): 4.85 (s, O*H*), 3.79−3.42 (m, 477H), 3.35 (s, 6H, $C(CH_2)_3$), 1.45 (brq, 2H, CH_2CH_3), 0.94 (brt, 3H, CH_3); ^{13}C NMR (75 MHz, CD_3OD): 80.3 ($(CH_2)_2CH_2C$(H)OR), 74.4 ($CH_2OCH_2CH(OH)CH_2OH$), 73.4 ($C(CH_2)_3$), 72.9 ($ROCH_2C$(H)(OR)CH_2OR), 72.6 ($CHOCH_2CH(OH)CH_2OH$), 71.7 ($CHOCH_2CH(OR)CH_2OR$), 64.9 (CH_2OH), 45.1 ($C(CH_2)_4$), 25.2 (CH_2CH_3), 9.0 (CH_2CH_3); MALDI-TOF MS calcd for $C_{291}H_{584}O_{189}$ 7103.6 found 6769.2 +H, 6959.2 −H.

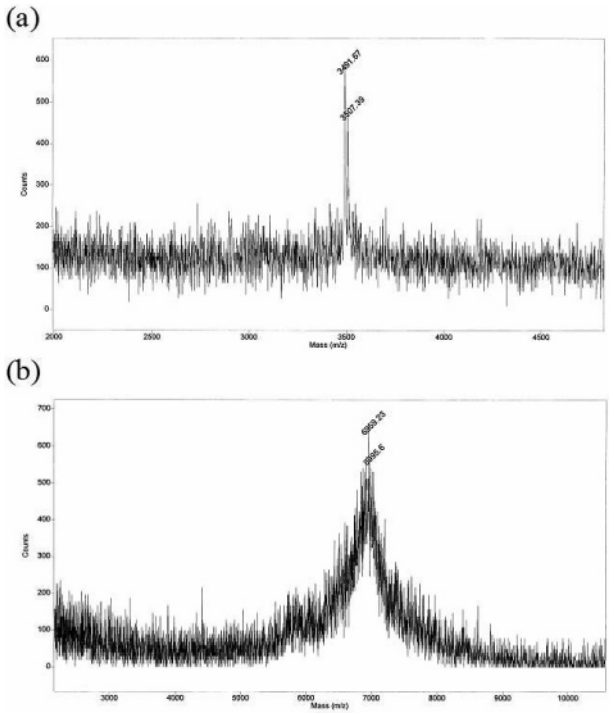

Figure 1. MALDI-TOF mass spectra of (a) PGD G-4 and (b) PGD G-5.

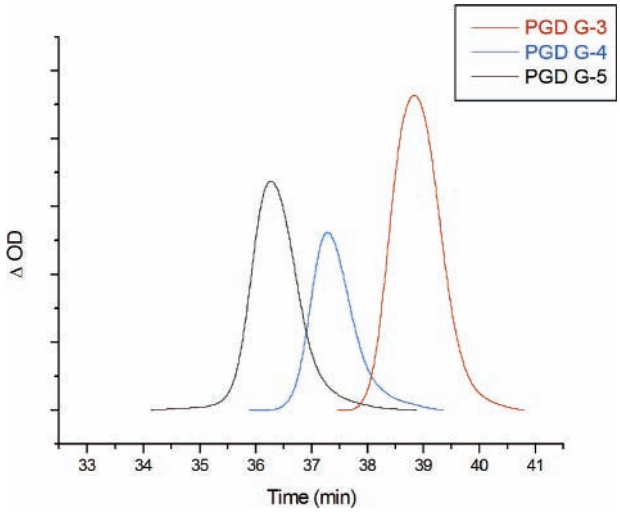

Figure 2. GPC charts of PGDs (G-3, G-4, and G-5). Eluent: DMF; flow rate: 0.6 mL/min; detectot: reflactive index.

Characterization of PGDs. *NMR Spectroscopy*. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker ARX300 spectrometer at 300 and 75 MHz, respectively. For the analysis of the interaction between PGDs and paclitaxel in a solubilized state in D_2O, a 750 MHz NMR apparatus (Varian, Unity plus, CA) was used.

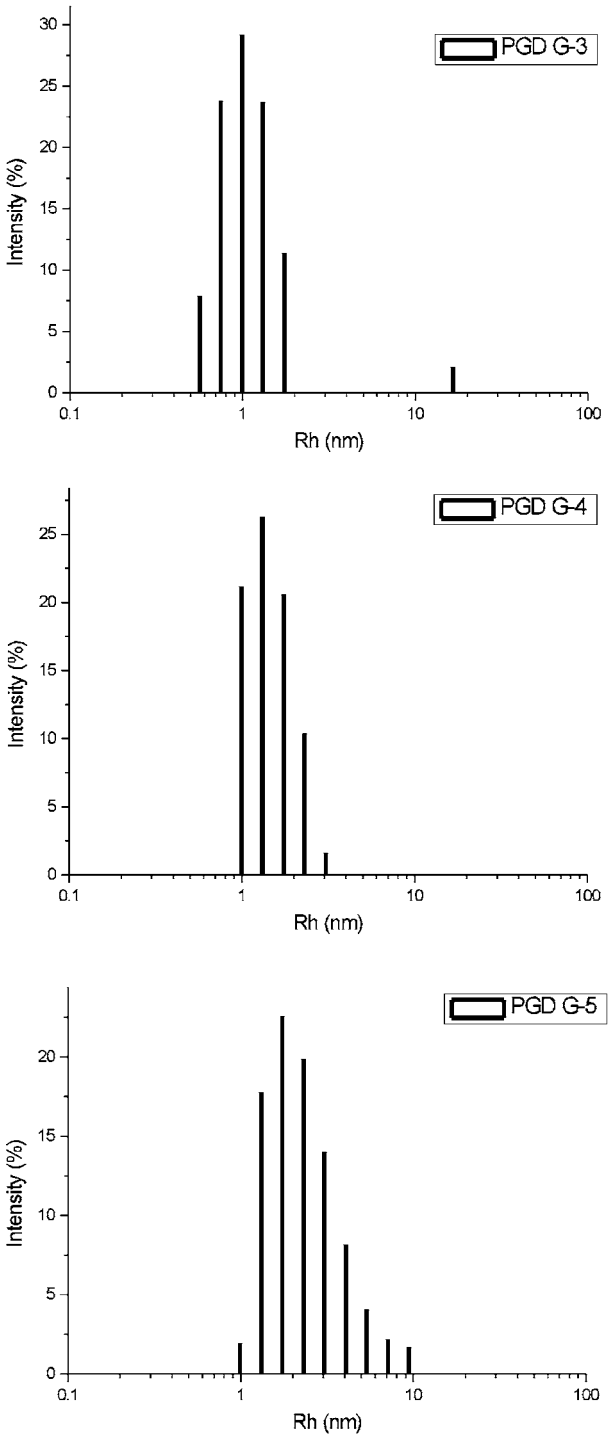

Figure 3. Regularization histgrams of PGDs on DLS. (a) G-3, (b) G-4, and (c) G-5.

Mass Spectroscopy. Electrospray ionization mass spectrometry (ESI-MS) assay was carried out on a Finnigan-MAT LCQ (ThermoFinnigan Corp, San Jose, CA). The electrospray needle voltage was set at 4.5 kV, the heated capillary voltage was set to 10 V, and the capillary temperature was set to 225 °C. Typical background source pressure was 1.2×10^{-5} Torr as read by an ion gauge. The sample flow rate was approximately 10 μL/min. The drying gas was nitrogen. The LCQ was scanned to 2000 amu for these experiments. Matrix-assisted laser desorption ionization (MALDI) mass spectroscopy was carried out using a PerSeptive Biosystems Voyager mass spectrometer (Framingham, MA) in linear mode. Samples were prepared by casting the matrix compound (2,5-dihydroxyacetophenone) with PGDs (~0.2 mg/mL in methanol) onto the slide, and the solvent was evaporated. Ionization was accelerated with 20 kV in the positive ion mode.

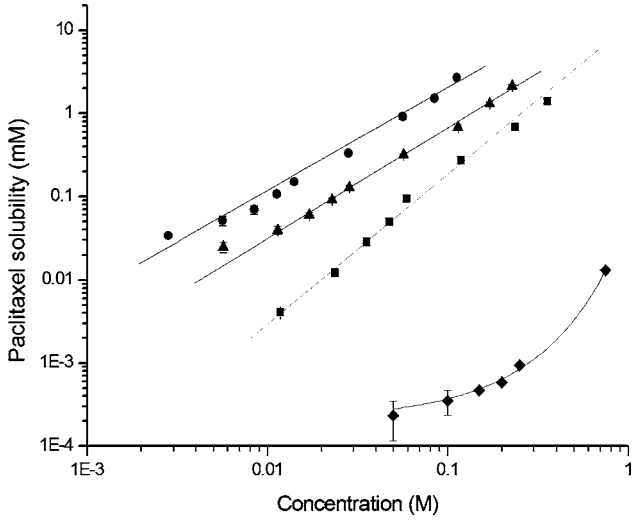

Figure 4. Aqueous paclitaxel solubility as a function of the PGD concentration (mean ± SD, $n = 3$). (circle) G-5, (triangle) G-4, (square) G-3, and (diamond) PEG400.

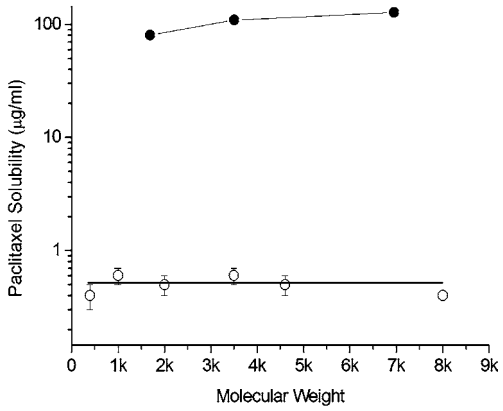

Figure 5. Dependence of molecular weight of PGDs (closed circle) and PEG (open circle) on the aqueous paclitaxel solubility. The concentration of PDGs and PEG was 10 wt%.

Gel permeation Chromatography (GPC). The molecular weight and molecular weight distribution were analyzed by GPC equipped with an Agilent 1100 series RI detector, quaternary pump, and PL aquagel-OH columns with pore sizes of 30, 40, and 50 Å (Agilent Technologies, Wilmington, DE). The eluent was DMF, and flow rate was 0.6 mL/min. The molecular weights are calibrated with poly(ethylene oxide) standards.

Dynamic Light Scattering (DLS) Measurements. Hydrodynamic radius (R_h) of the PGDs was measured by DLS using a DynaPro 99 (Protein Solutions, Inc.) at a fixed angle (90°). The wavelength of the laser source was 826 nm. The membrane filter with Watman Anotop 10 attachment and the pore diameter 20 nm was used, and 0.15 mL of PGD-dissolved 0.2 M NaCl aqueous solution was injected into a cell. Solution concentration was 1 wt %.

Viscosity Measurements. The viscosity of PGDs in water was measured at 25 °C using a Cannon-Manning Semi-Micro Viscometer (Size: 50 C286, Cannon Instrument Co., PA). Specific viscosity (η_{sp}) of PGDs was calculated by the following equation:

$$\eta_{sp} = (\eta - \eta_0)/\eta_0 = (t - t_0)/t_0$$

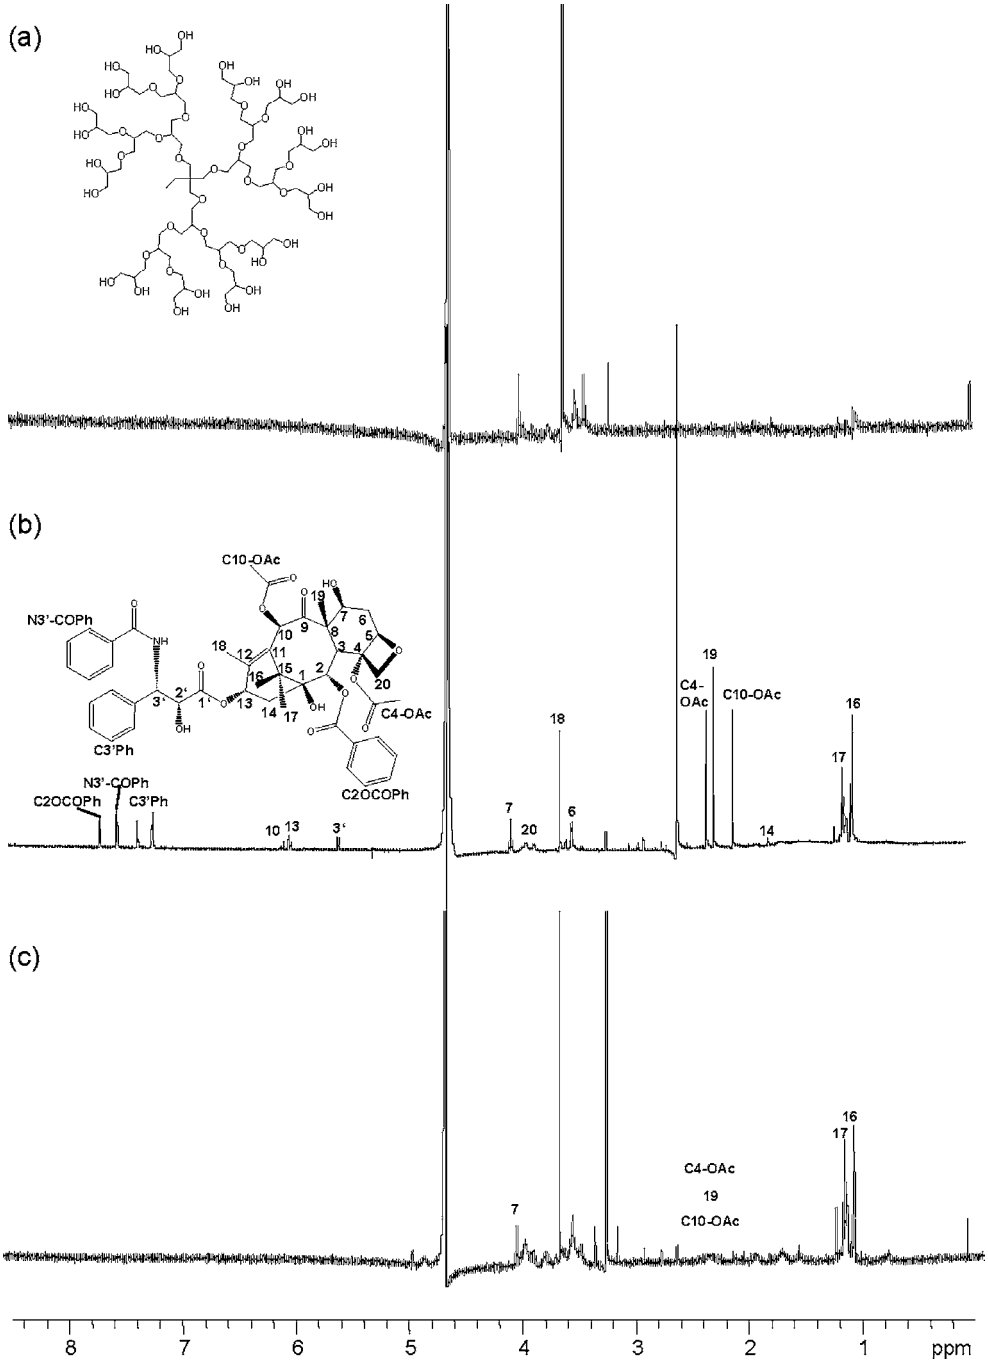

Figure 6. ^{1}H NMR spectra measured using a 750 MHz NMR apparatus in D_2O. (a) PGD G-3 (0.35 μM), (b) paclitaxel (0.35 μM), and (c) mixture of PGD G-3 and paclitaxel.

where η is the solution viscosity, η_0 the viscosity of water, t the measuring time of the solution, and t_0 the measuring time of water. From Huggins plot, [η] of PGDs was determined.

Solubility Test of Paclitaxel. Excess paclitaxel (~10 mg/mL) was added to screw-capped vials containing fixed volume of PGD solutions. This mixture in the vials was stirred using a magnetic stirring bar at 37 °C. The samples were taken after 24 h, filtered through a 0.2 μm nylon membrane, and analyzed for paclitaxel using HPLC. The concentration of paclitaxel was determined by an isocratic reverse-phase HPLC (Agilent 1100 series, Agilent Technologies, Wilmington, DE) using a Symmetry column (Water Corp., Milford, MA) at 25 °C. The mobile phase consisted of acetonitrile−water (45:55 v/v) with a flow rate of 1.0 mL/min. A diode array detector was set at 227 nm and linked to ChemStation software for data analysis. The paclitaxel concentrations in the samples were obtained from a calibration curve.

RESULTS AND DISCUSSION

Synthesis and Structural Characterization of PGD G-4 and G-5. The obtained PGDs were characterized by NMR, mass, GPC, DLS, and viscosity measurements (Table 1). The ^{1}H and ^{13}C NMR spectra of PGD G-3.5 and G-4.5 were attributed to allyl group [e.g., 5.88 (CH=CH_2), 5.18 (CH=CH_2) on the ^{1}H NMR spectra, and 135.2 (CH_2OCH_2CH=CH_2), 116.9 ($CHOCH_2CH$=CH_2) on the ^{13}C NMR sperctra]. The ^{1}H and ^{13}C NMR spectra of PGD G-4 and G-5 were also attributed to the monomer units. The M_w of the G-4 and G-5 dendrimers were determined by MALDI TOF-MS. As shown in Figure 1a, two peaks were observed at m/z 3507.4 +H, 3491.7 $-H_2O$, indicating that successful synthesis of PGD G-4. As for

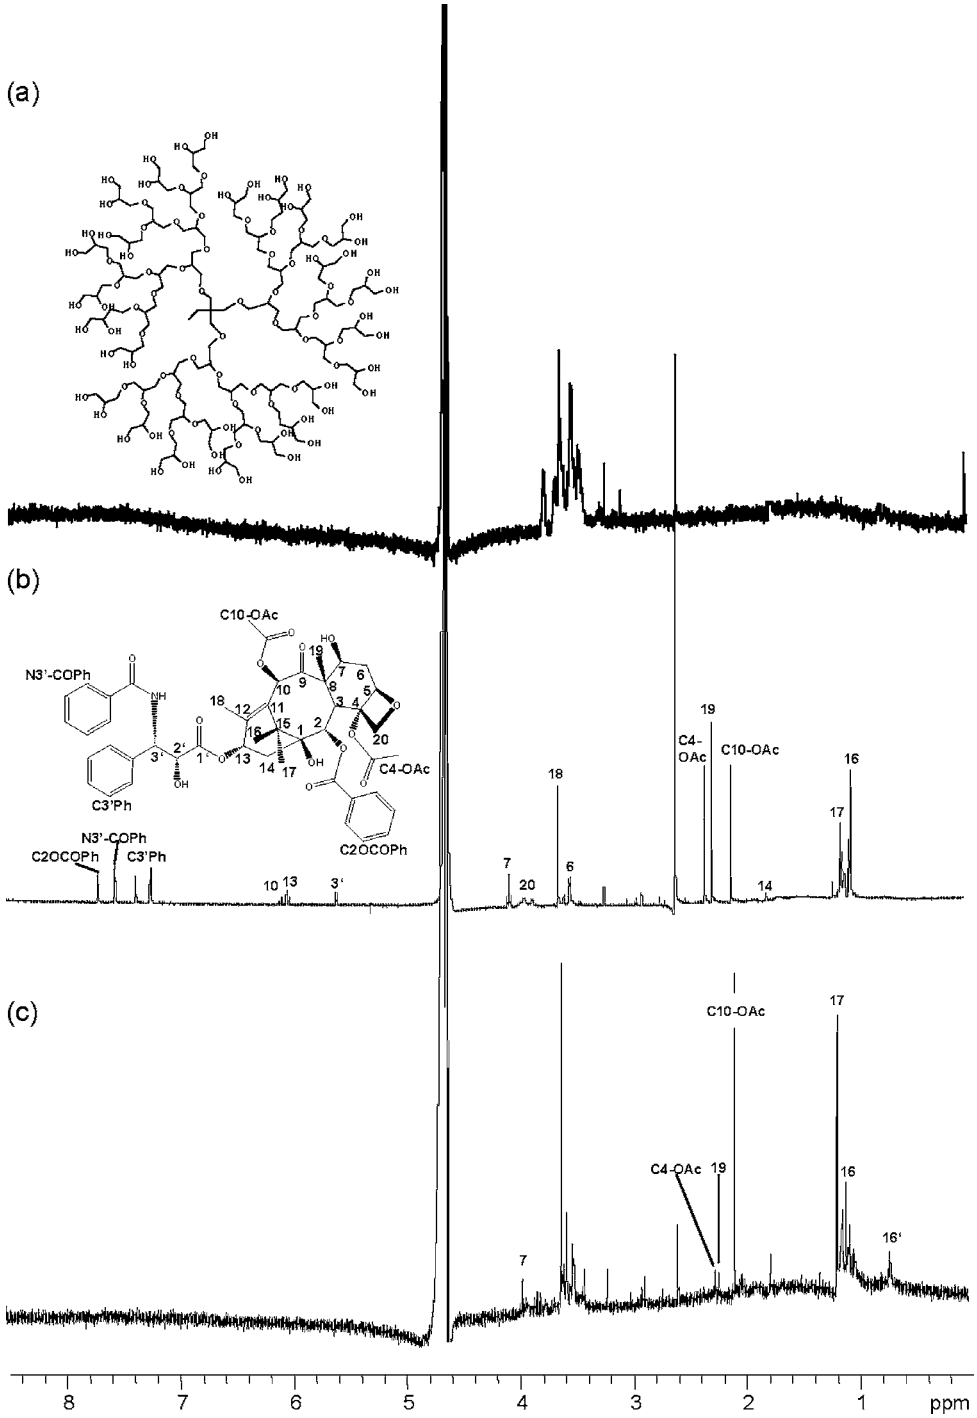

Figure 7. ^{1}H NMR spectra measured using a 750 MHz NMR apparatus in D_2O. (a) PGD G-4 (0.35 μM), (b) paclitaxel (0.35 μM), and (c) mixture of PGD G-4 and paclitaxel.

Table 1. Results of MALDI-MS, GPC, DLS, and Viscosity of PGDs

sample code	MALDI		GPC			DLS	[η]
	M_{theo}[a]	M_w[b]	M_w[c]	M_n[c]	M_w/M_n	R_h (nm)	(mL·g^{-1})
PGD G-3	1689	1690	2309	2356	1.02	1.1	1.89
PGD G-4	3508	3507	3764	3841	1.02	1.9	3.90
PGD G-5	7104	6959	5312	5450	1.03	2.4	3.06

[a] Theoretical molecular weight. [b] Determined by MALDI-TOFF mass measurements. [c] Determined by GPC using DMF as an eluent with calibration curve of poly(ethylene oxide) standards.

the PGD G-5, two peaks were observed at 6769.2 +H, 6959.2 −H (Figure 1b). These values were smaller than the calculated value (7103.6), so that there was structural defect. Steric hindrance of crowded hydroxyl groups of PGD G-4 is thought to be the reason for decreased conversion of allylation and/or dihydroxylation. The molecular weight and molecular weight distribution (M_w/M_n) were also analyzed by GPC. As shown in Figure 2, retention time of the PGDs on the GPC charts became shorter with increasing the generation. This order was consistent with the results of mass spectroscopy. As expected, M_w/M_n was close to 1.00, indicating that the molecular weight distribution of these PGDs was very narrow. The observed molecular weights of G-3, G-4, and G-5 were found to be larger, a little bit larger, and smaller, respectively, than the calculated values. These results, along with MALDI mass, indicate that the PGDs

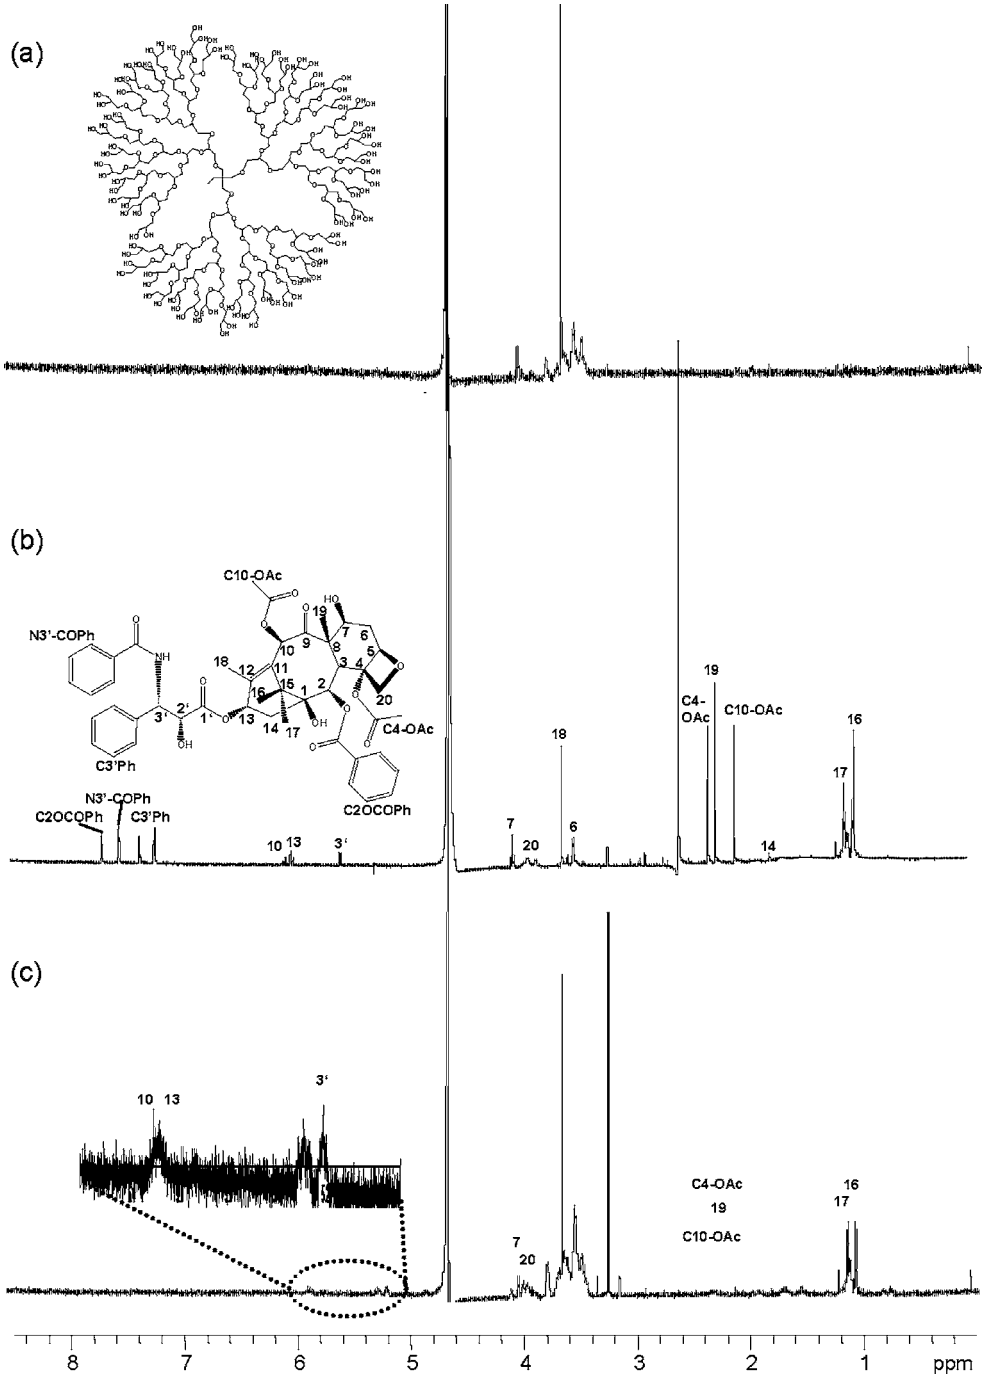

Figure 8. ^{1}H NMR spectra measured using a 750 MHz NMR apparatus in D_2O. (a) PGD G-5 (0.35 μM), (b) paclitaxel (0.35 μM), and (c) mixture of PGD G-5 and paclitaxel.

became compact with increasing the generation. This compacted state of dendrimers was consistent with starburst dendrimers (*14*). Hydrodynamic radius (R_h) of the PGDs was measured by DLS. As shown in Figure 3, the regularization histograms indicate very narrow distribution of those R_h values. The mean R_h values of PGD G-3, G-4 and G-5, calculated by cumulant analysis, were ca. 1.1, 1.9 and 2.4 nm, respectively. [η] values of PGD G-3, G-4 and G-5 were 1.89, 3.90 and 3.06 mL/g, respectively. Since [η] value of PEG 400 was 4.36 (data not shown), the PGDs seemed to behave as low-molecular-weight compounds in single molecule state in water. These results were also consistent with the GPC results that suggest the compact state of PGDs.

The Effect of PGD G-4 and G-5 on Paclitaxel Solubility. The effect of PGD G-4 and G-5 on paclitaxel solubilization in water was examined by measuring the concentration of solubilized paclitaxel using HPLC. Paclitaxel solubilities in all the solutions of PGDs (including G-3) were much higher than those of PEG400 (Figure 4). Since the molecular weights of PGDs were much higher than PEG400, the molecular weight should be considered as one of the important factors. To estimate the effect of molecular weight and the dendritic structure, paclitaxel solubilities in various PEGs with different molecular weights were measured and compared with those in PGD solutions (Figure 5). The paclitaxel solubilities in 10 wt % of PEG (M_n: 400 $\sim$ 8000) aqueous solutions were found to be 0.4−0.6 μg/mL, which was similar to the paclitaxel solubility in water (0.3 μg/mL) (*15*). On the other hand, the paclitaxel solubilities in 10 wt % of PGDs (M_n: 1690−6960) were 80−128 μg/mL,

which were 3 orders of magnitude higher than that in pure water. These results suggest that the increased solubility is due to the dendritic architecture. Since the concentration of PGDs required for solubilization of paclitaxel was 30−5000 times higher than the concentration of paclitaxel (Figure 4), it is likely that paclitaxel might not be incorporated into the dendrimer core and PGDs provide hydrotropic effect by providing local high concentrations of ethylene glycol units (*16*). The ability to enhance the paclitaxel solubility was in the order of G-5 > G-4 > G-3, which is understandable from the hydrotropic effect of dendrimers.

Proposed Mechanism of the Hydrotropic Solubilization. The hydrotropic solubilization of paclitaxel by the PGDs was examined in more detail. Since ^{1}H NMR data provide valuable information on direct interactions between dendrimer and hydrophobic compounds (*17*), the chemical shifts of paclitaxel in D_2O before and after mixing with PGD G-3, G-4, and G-5 were examined (Figures 6−8). The 750 MHz NMR apparatus made us to obtain the spectra of paclitaxel even in the lower concentration in D_2O (0.35 μM). The measurements at much higher concentration of paclitaxel in the presence of PGD G-4 (Figure 4) were tried, but several hundred times higher concentration of PGD G-4 hindered observing the spectra of paclitaxel. Therefore, the concentration of paclitaxel was fixed to be maximum concentration (0.35 μM), and the same molar amounts of PGDs G-3, G-4, and G-5 were dissolved in the solution to observe the chemical shifts. Before mixing paclitaxel with PGDs, the peaks of all the aromatic rings (C2OCOPh, N3′-COPh, and C3′-Ph) and methyne groups of C10, C13, and C3′ were observed at 7.69, 7.53, 7.35−7.21, 6.05, 6.01, and 5.94, respectively (Figures 6−8b). When mixing with the same concentration of PGDG-3, those peaks of all the aromatic rings, methyne groups were suppressed (Figure 6c). In addition, the peaks of C4−OAc (2.25 ppm), methyl of C19 (2.21 ppm) and C10−OAc (2.06 ppm) in Figure 6b were broadened (Figure 6c). Similar tendency of the peak suppression has been reported in the case of hydrophilic−hydrophobic block copolymers (*18*) and dendrimers (*19*): the peaks of hydrophobic parts were suppressed in D_2O when the polymers form micelles with core−shell structure. Thus, the results suggest that the aromatic rings, methyne groups, and acetyl groups of paclitaxel are surrounded by the PGD G-3. The methyl peaks of C17 and 16 (1.11−1.0 ppm) were clearly observed after the mixing, suggesting that the whole paclitaxel molecules could not be incorporated in the PGD core. Similar tendency in the case of PGD G-4 was observed, but the peaks of C7 methyne (3.99 ppm), C4−OAc (2.25 ppm), methyl of C19 (2.21 ppm), C10−OAc (2.06 ppm), and the methyl peaks of C17 and 16 were observed after the mixing, as shown in Figure 7c. Interestingly, when mixing with PGD G-5, the methyne peaks of C10, C13, and C3′ were observed with some chemical shift change to higher magnetic fields (Figure 8c). These results suggest that the way of intermolecular interactions for the hydrotropic solubilization is changeable with increasing the generation of PGDs. Presumably, the increased number of hydroxyl groups participates hydrogen bonds with amide, ester, and/or hydroxyl group of paclitaxel. Since PGDs did not have any hydrophobic core like the dendritic unimolecular micelles composed of many aromatic rings (*19*), the solubilization ability without using the hydrophobic region (such as aromatic rings) suggests a new mechanism of solubilization. Our ongoing study shows that the solubilized paclitaxel is amorphous, but the chemical structure was stable in the solubilized states over several months.

CONCLUSION

Polyglycerol dendrimers (PGDs) with 4−5 generations were synthesized and characterized by NMR, MALDI-TOF mass, GPC, viscosity, and dynamic light scattering measurements. Polydispersity of the obtained PGDs was very narrow, and the PGDs in water exist in compacted states. The paclitaxel solubility was increased with the higher generation of PGD, and the effect was due to the dendritic architecture. PGDs increased the paclitaxel solubility by surrounding aromatic rings and some methyne groups of paclitaxel. The hydrotropic solubilization by PGDs does not require a hydrophobic segment as in polymeric micelles, and it provides an alternative approach of increasing the solubility of poorly soluble drugs.

ACKNOWLEDGMENT

This study was supported in part by National Institute of Health through grant GM 65284, Samyang Corp., and Japanese Government through Monbukagakusho grant for visiting research scholar. The authors would like to thank Mr. Koichi Higashimine (JAIST) for 750 MHz ^{1}H NMR measurements.

Tuning of Intercalation and Electron-Transfer Processes between DNA and Acridinium Derivatives through Steric Effects

Joshy Joseph,[†] Elizabeth Kuruvilla,[†] Asha T. Achuthan,[†] Danaboyina Ramaiah,*[,†] and Gary B. Schuster[‡]

Photosciences and Photonics Division, Regional Research Laboratory (CSIR), Trivandrum 695019, India, and School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400. Received July 23, 2004; Revised Manuscript Received September 27, 2004

A series of acridinium derivatives **1**−**6**, wherein steric factors have been varied systematically through substitution at the 9 position of the acridine ring, have been synthesized and their DNA interactions have been investigated by various biophysical techniques. The unsubstituted and methylacridinium derivatives **1** and **2** and the *o*-tolylacridinium derivative **6** exhibited high fluorescence quantum yields ($\Phi_f \cong 1$) and lifetimes (τ = 35, 34, and 25 ns, respectively), when compared with the arylacridinium derivatives **3**−**5**. The acridinium derivatives **1** and **2** showed high DNA binding affinity ($K = 7.3-7.7 \times 10^5\ M^{-1}$), when compared to the arylacridinium derivatives **3**-**5** ($K = 6.9-10 \times 10^4\ M^{-1}$). DNA melting and viscosity studies establish that in the case of the aryl-substituted systems, the efficiency of DNA binding is in the order, phenyl > *p*-tolyl > *m*-tolyl ⋙ *o*-tolyl derivative. The increase in steric crowding around the acridine ring hinders the DNA binding interactions and thereby leads to negligible binding as observed in the case of **6** (*o*-tolyl derivative). These results indicate that a subtle variation in the substitution pattern has a profound influence on the photophysical and DNA interactions. Further, they demonstrate that π-stacking interactions of the ligands with DNA are essential for efficient electron transfer between the DNA bases and the ligands. These water soluble and highly fluorescent molecules which differ in their DNA binding mode can act as models to study various DNA−ligand interactions.

INTRODUCTION

The study of interactions of various ligands with DNA has been the subject of considerable interest because of its importance in the design of drugs targeted to DNA as well as in understanding the electron and energy transfer properties of DNA (*1*−*10*). Of the various types of interactions, the intercalative interactions of ligands with DNA is particularly important because of the fact that many anticancer drugs and antibiotics exert their biological activity through DNA intercalation (*11*−*14*). A better understanding of the factors that govern the binding mode of ligands with DNA is not only essential for the design of efficient drugs targeted to DNA and development of probes for various DNA structures but also for the use of DNA in electronic materials applications (*15*).

To investigate how steric and conformational factors influence the mode and extent of binding of small molecules with DNA, we have chosen systems based on the acridine chromophore for study. Acridines are a special class of compounds not only because of their interesting chemical and physical properties but also due to their immense utility in the pharmaceutical and dye industries (*16*, *17*). Acridines were the first chromophore that was extensively studied for its noncovalent DNA interactions. These studies led to the concept of intercalation. The study of the steric and conformational effects on the DNA binding properties of acridine chromophores has received less attention (*11*, *12*, *18*, *19*). In this context, we have designed a series of acridinium derivatives **1**−**6**, wherein we have systematically varied the steric factors through substitution at the 9 position of the acridinium ring (Figure 1) to assess the energetics and nature of their DNA binding interactions. The results of these investigations indicate that subtle variation in the substitution pattern on the acridinium chromophore has a profound influence on their photophysical and DNA binding interactions. These results demonstrate that these water soluble and highly fluorescent molecules can act as models to study various DNA interactions.

EXPERIMENTAL PROCEDURES

The equipment and procedure for spectral recordings are described elsewhere (*19*). The fluorescence lifetimes were measured on an IBH picosecond single photon counting system using a 401 nm IBH NanoLED source and a Hamamatsu C4878−02 MCP detector. The fluorescence decay profiles were deconvoluted using IBH Data Station software V2.1, fitted with a mono-, bi-, or triexponential decay and minimizing the χ^2 values of the fit to 1 ± 0.1. The oligonucleotides (**DNA1**: 5′-CGT GGA CAT TGC ACG GTA C-3′; **DNA2**: 5′-GTA CCG TGC AAT GTC CAC G-3′) were synthesized on an Applied Biosystems DNA Synthesizer as described earlier (*20*). Solution of calf thymus DNA (CT DNA, Pharmacia Biotech, USA) in phosphate buffer was sonicated for 1 h and filtered through a 0.45 μM Millipore filter. The concentrations of the CT DNA solutions were determined by using the average extinction coefficient value of 6600 $M^{-1}\ cm^{-1}$ for a single nucleotide at 260 nm (*21*). Polynucleotides (Amersham Pharmacia Biotech Inc.) were dissolved in phosphate buffer, and the concentrations were deter-

mined by using the average extinction coefficient value of 7400 M^{-1} cm^{-1} at 253 nm for poly(dG).poly(dC) and 6000 M^{-1} cm^{-1} at 260 nm for poly(dA).poly(dT) (*21*). The absorption and fluorescence titrations of the acridinium derivatives with DNA were carried out by adding small aliquots of DNA solution containing the same concentration of the compound as that in the test solution. The binding affinities were calculated using fluorescence quantum yields, according to the method of McGhee and von Hippel by using the data points of the Scatchard plot (*22*−*24*).

Preparation of the Acridinium Derivatives 1−6. The acridine derivatives **8b**−**f** were synthesized by a modified Bernthsen procedure as shown in Scheme 1 (*25*). The condensation reaction of diphenylamine with the corresponding carboxylic acid in the presence of anhydrous $ZnCl_2$ yielded the acridine derivatives **8b**−**f** in 50−60% yields. The quarternization of these acridine derivatives with methyl iodide gave the corresponding acridinium derivatives **1**−**6** in quantitative yields, which were recrystallized from a mixture (4:1) of acetonitrile and methanol (*26*).

10-Methylacridinium iodide (1): 79%; mp 230−232 °C; ^{1}H NMR (300 MHz, DMSO-d_6) δ 4.87 (3H, s), 8.05 (2H, t, J = 7.5 Hz), 8.48 (2H, t, J = 8 Hz), 8.63 (2H, d, J = 8.4 Hz), 8.79 (2H, d, J = 9.2 Hz), 10.21 (1H, s); ^{13}C NMR (75 MHz, DMSO-d_6) δ 150.96, 141.69, 139.43, 131.98, 128.15, 126.60, 119.36, 39.44. RESULTS AND DISCUSSION

The photophysical properties of the acridinium derivatives were investigated under different conditions, and these results are summarized in Table 1. The acridinium derivatives **1**, **2** and the *o*-tolylacridinium derivative **6** exhibited quantitative fluorescence quantum yields ($\Phi_f \cong 1$) with an emission maximum around 500 nm. In contrast, the fluorescence quantum yields of the arylacridinium derivatives **3**−**5** (Φ_f = 0.09, 0.05, and 0.11, respectively) were found to be significantly quenched. The acridinium derivative **1** exhibits a single-exponential decay with a lifetime of 35 ns, whereas the *o*-tolylacridinium derivative **6** shows a reduced lifetime of 25 ns (Table 1). When compared to **1**, **2**, and **6**, unusually low lifetimes were observed for the arylacridinium derivatives **3**−**5** (τ = 1.3, 0.6, and 1.7 ns, respectively). The lower values of the fluorescence quantum yields and lifetimes observed for the arylacridinium derivatives **3**−**5** can be attributed to enhanced nonradiative decay pathways due to the rotation between the acridinium and the phenyl ring and the favorable quenching of the singlet excited state by the aryl group through an electron-transfer mechanism (*26*, *30*, *31*). Interestingly, the excited-state properties of the *o*-tolylacridinium derivative **6**, is very similar to that of the simple acridinium derivatives **1** and **2**, probably because of the steric constraints offered by the *o*-methyl substituent.

The acridinium derivatives **1**−**6** can in principle interact with DNA through intercalation and/or electrostatic modes. Figure 2 shows the change in the absorption spectra of the acridinium derivative **2** with increasing DNA concentrations. The addition of CT DNA to a solution of **2** results in a strong decrease in the absorption of the acridinium chromophore, along with a red shift of around 3 nm. Furthermore, with the increase in DNA concentration, a strong quenching of the acridinium fluorescence emission is observed as shown in Figure 3. Similar changes in absorption and fluorescence emission

Inset shows the change in absorption spectra of **6** (42.5 μM) in phosphate buffer (10 mM; pH 7.4) with increasing concentration of CT DNA. [DNA] (a) 0, (b) 0.17, (c) 0.34, and (d) 0.42 mM.

spectra were observed for the acridinium derivatives **1** and **3**−**5** (Supporting Information; Figures S1−S4). Among all the acridinium derivatives, the *o*-tolylacridinium derivative **6** showed an interesting variation. Insets of Figures 2 and 3 show the changes in the absorption and fluorescence emission spectra of **6**, respectively, with increasing concentration of DNA. Both the absorption

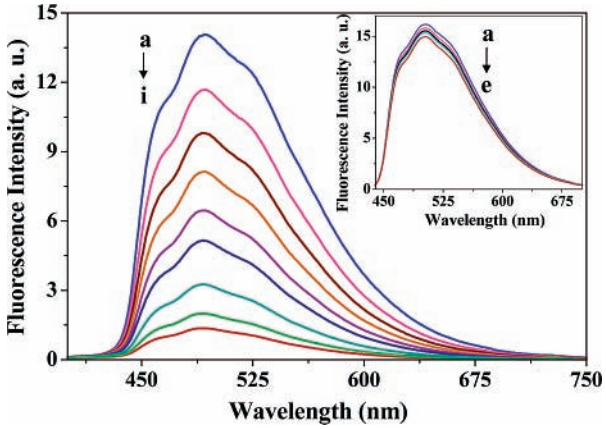

Figure 3. Change in fluorescence spectra of **2** (32 μM) in phosphate buffer (10 mM; pH 7.4) with increasing concentration of CT DNA. [DNA] (a) 0, (b) 0.05, (c) 0.09, (d) 0.12, (e) 0.16, (f) 0.19, (g) 0.26, (h) 0.34, and (i) 0.42 mM. Inset shows the change in fluorescence spectra of **6** in phosphate buffer (10 mM; pH 7.4) with increasing concentration of CT DNA. [DNA] (a) 0, (b) 0.17, (c) 0.34, (d) 0.42, and (e) 1 mM. Excitation wavelength, 363 nm.

and fluorescence studies indicate that the ortho-derivative **6** exhibits negligible interactions with DNA.

With a view to understanding the effect of various DNA sequences, we have investigated the interaction of the acridinium derivatives with polynucleotides such as poly(dG)·poly(dC) and poly(dA)·poly(dT). The addition of poly(dG)·poly(dC) to a solution of **2** resulted in a strong decrease in the absorption of the acridinium chromophore, along with a red shift of around 5 nm with an isosbestic point at 450 nm. Similar observations were made with poly(dA)·poly(dT) and with other acridinium derivatives (Supporting Information; Figure S5). Furthermore, with the increase in poly(dG)·poly(dC) concentration, a strong quenching of the acridinium fluorescence emission is observed as shown in Figure 4. The poly(dG).poly(dC) exhibits an efficient fluorescence quenching of the acridinium derivative **2** when compared to CT DNA and poly(dA)·poly(dT) (inset of Figure 4), indicating thereby the preferential interactions of these molecules with DNA rich in guanosine sequences.

The DNA association constants (K) of the complexes formed between the acridinium derivatives **1**−**5** and DNA were determined based on fluorescence titration experiments, according to the method of McGhee and von Hippel by using the data points of the Scatchard plot (*9*) and are reported in Table 1. For example, 10-methylacridinium (**1**) shows a binding constant of 7.7×10^5 M^{-1},

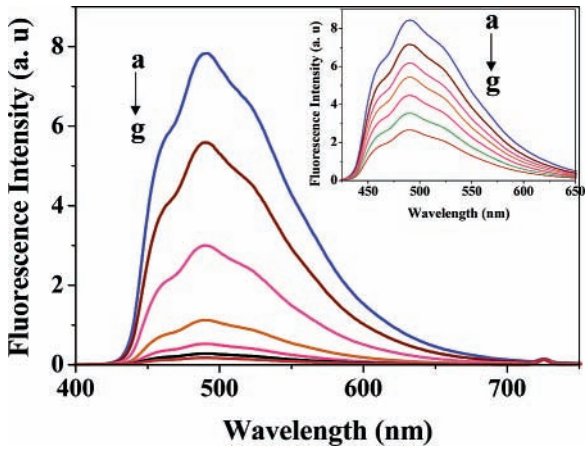

Figure 4. Change in fluorescence spectra of **2** (32 μm) in phosphate buffer (10 mM; pH 7.4) with increasing concentration of poly(dG).poly (dC). [poly(dG).poly(dC)] (a) 0, (b) 0.08, (c) 0.16, (d) 0.24, (e) 0.30, (f) 0.38, (g) 0.5 mM. Inset shows the change in fluorescence spectra of **2** in phosphate buffer (10 mM, pH 7.4) with increasing concentration of poly(dA).poly(dT). [poly(dA).poly-(dT)] (a) 0, (b) 0.08, (c) 0.17, (d) 0.25, (e) 0.33, (f) 0.48, (g) 0.63 mM. Excitation wavelength, 363 nm.

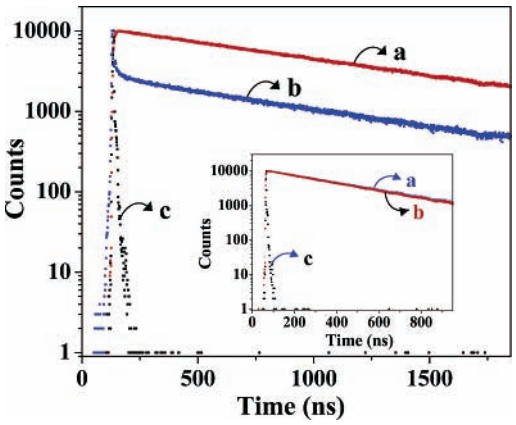

Figure 5. Fluorescence decay profiles of **2** (32 μM) in the presence and absence of DNA in phosphate buffer (10 mM; pH 7.4). [DNA] (a) 0 and (b) 0.34 mM. Inset shows the fluorescence decay profiles of **6** in the presence and absence of DNA under similar conditions. [DNA] (a) 0 and (b) 0.34 mM. Excitation wavelength, 401 nm.

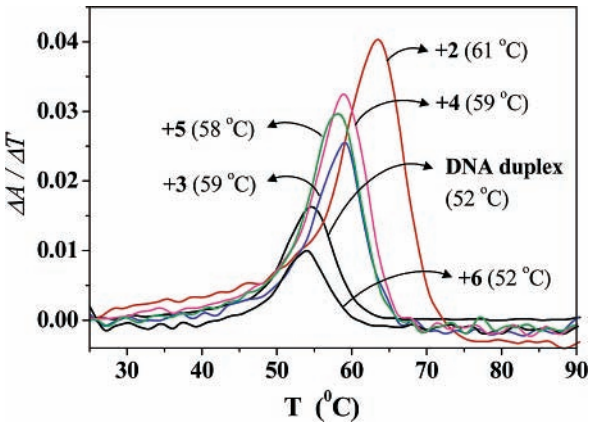

Figure 6. First derivative plots for the thermal denaturation curves of the DNA duplex, **DNA1.DNA2** in the presence and absence of the acridinium derivatives **1**−**6** (20 μM) in 10 mM phosphate buffer (pH 7.4). **DNA1:** 5′-CGT GGA CAT TGC ACG GTA C-3′; **DNA2:** 5′-GTA CCG TGC AAT GTC CAC G-3′.

whereas the arylacridinium derivatives **3**−**5** show relatively lower values of DNA association constants. These association constants were also found to be sensitive to the DNA sequences. For example, the association constant of the acridinium derivative **2** with poly(dG)·poly-(dC) was found to be around 1.2 and 2 times greater than that of CT DNA and poly(dA)·poly(dT).

Interestingly, the binding site size (n) was found to be greater for the arylacridinium derivatives **3**−**5** ($n = 6-7$) than the acridinium derivatives **1** and **2** ($n = 2.5$). Thus, a comparison of the DNA binding constants indicate that the acridinium derivatives **1** and **2** bind to DNA by nearly one order greater efficiently when compared with the arylacridinium derivatives **3**−**5**. In the case of the aryl-substituted derivatives, the efficiency was found to be in the order, phenyl > *p*-tolyl > *m*-tolyl ⋙ *o*-tolyl, wherein the increase in steric factors around the acridine ring hinders the DNA binding interactions and finally leads to a negligible binding as observed in the case of the *o*-tolylacridinium derivative **6**.

Picosecond time-resolved fluorescence studies in the presence and absence of DNA indicate that the acridinium derivative **2** exhibits a single-exponential decay in buffer with a fluorescence lifetime of 34 ns (Figure 5), while in the presence of DNA it shows a triexponential decay with lifetimes of 35 ps, 0.8 ns and 33 ns. The short lifetimes observed (35 ps and 0.8 ns) may be attributed to the intercalative binding of the acridinium chromophore at two different base sequence environments, whereas the third lifetime could be due to the unbound molecules. On the other hand, the ortho-derivative **6**, having a fluorescence lifetime of 25 ns in buffer, exhibited negligible changes in the presence of DNA (inset of Figure 5). These observations confirm that the acridinium chromophore in the case of **6** undergoes neither intercalative nor groove binding interactions with DNA.

Figure 6 shows the first derivative plots for the thermal denaturation curves obtained for the duplex **DNA1** and **DNA2** in the presence and absence of the acridinium derivatives **2**−**6**. The oligonucleotide duplex melts at 52 °C in the absence of ligands, whereas the presence of 20 μM of acridinium derivative **2** stabilizes the duplex by 9 °C. As expected, the arylacridinum derivatives **3**−**5**, under similar conditions, stabilize the duplex less (6−7 °C), whereas, the ortho-derivative **6** provides negligible stabilization to the DNA duplex. The absorbance changes observed at 260 nm, corresponding to DNA during the thermal denaturation of DNA in the presence and absence of the acridinium derivatives, clearly reflect the extent and nature of binding interactions of these derivatives with DNA. Similar absorption changes were observed when monitored at 355 nm corresponding to the acridinium chromophore, which further supports the binding trends observed in the case of the substituted acridinium derivatives.

Figure 7 shows the results of the viscometry studies of representative examples which indicate that the viscosity of DNA increases proportionally with the binding affinity of the acridinium derivatives **2** and **4**, whereas negligible viscosity changes are observed for the ortho-derivative **6**. The change in viscosity could be attributed to the π-stacking of the acridinium derivatives between DNA base pairs, which results in the increase in the viscosity of DNA as in the case of typical intercalators (*32*, *33*). On the other hand, the ortho-derivative **6** shows negligible binding with DNA by intercalation as reflected from the physical and spectroscopic studies. The intercalative interactions of several acridinium conjugates with DNA have been well characterized in the literature by various biophysical and NMR techniques (*34*−*37*).

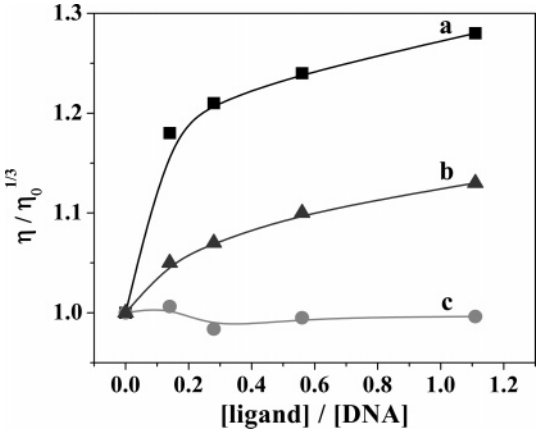

Figure 7. Effect of increasing concentrations of the acridinium derivatives **2** (a), **4** (b), and **6** (c) on the relative viscosity of CT DNA (0.7 mM) at 26 ± 0.2 °C in phosphate buffer (10 mM, pH 7.4).

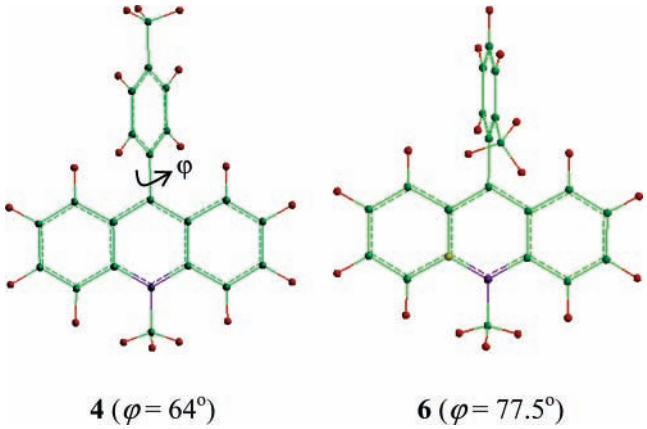

Figure 8. Minimum energy conformations of *p*- and *o*-tolylacridinium derivatives **4** and **6**, obtained by AM1 calculations.

The differences observed in DNA binding affinity of these acridinium derivatives could be rationalized in terms of the steric effects offered by the substituents. The structural analysis of the arylacridinium derivatives reveals that the acridinium as well as the aryl substituent are out of plane to each other and the dihedral angle (φ) according to the minimum energy conformations for **3**−**6** are 64.8°, 64°, 64.7°, and 77.5° (Figure 8) (*38*). To achieve effective intercalation of the acridinium chromophore, the aryl group has to undergo a rotation during the process of intercalation. The feasibility of this rotation is the deciding factor in effective binding of these molecules to DNA. In the case of the ortho-derivative **6**, the rotation of the tolyl group is sterically hindered and hence no significant binding with DNA was observed.

The π-stacking of the acridinium chromophore between the DNA bases as in the case of the simple acridinium derivatives **1** and **2** and arylacridinium derivatives **3**−**5** causes a strong quenching of the fluorescence of the molecule due to the possible electron-transfer processes from DNA bases (*39*). Whereas, in the case of the ortho-derivative **6**, which does not intercalate, the electron transfer is not an efficient process and hence the fluorescence emission properties remain unchanged in the presence of DNA. On the basis of the limiting fluorescence intensity (under conditions where >99% of the substrate is bound to DNA), the rate constant for the static quenching of the singlet excited state of the acridinium chromophore by DNA (k_{DNA}) could be evaluated using eq 1,

$$I_o/I = 1 + k_{DNA}/k_{SI} \quad (1)$$

where I_o and I are the fluorescence intensities in the absence and presence of DNA and k_{SI} is the sum of rate constants ($k_r + k_{nr}$) of the singlet excited-state deactivation (*28*, *29*). As shown in Table 1, for the acridinium derivatives **1**−**5**, which bind with DNA through intercalation, the rate constant for static quenching was found to be in the order of 10^{10} s^{-1}. This observation confirms that the intercalative mode of binding is crucial to observe an efficient quenching of fluorescence of ligands through the electron transfer process from the DNA bases. Moreover, the electron transfer rate constant in the case of the polynucleotide enriched with GC content, poly(dG)·poly(dC), was found to be around 3.5 and 16 times greater than that of CT DNA and poly (dA)·poly(dT), respectively (Table 1). This can be explained in terms of lower oxidation potential of guanosine (*39*) and hence greater feasibility of electron transfer from guanosine to the singlet excited state of the acridinium moiety.

In conclusion, we have demonstrated that by introducing subtle steric factors one may alter the DNA binding properties of acridinium derivatives. It was observed that the unsubstituted and methylacridinium derivatives **1** and **2** bind with DNA by nearly one order more efficiently when compared to the bulky arylacridinium derivatives **3**−**5**. In the case of the aryl-substituted derivatives, the efficiency of binding was found to be in the order, phenyl > *p*-tolyl > *m*-tolyl ⋙ *o*-tolyl, wherein the increase in steric factors around the acridine ring hinders the DNA binding interactions and finally leads to a negligible binding as observed in the case of the *o*-tolylacridinium derivative **6**. Furthermore, these results support the fact that intercalative π-stacking interactions of the ligands with DNA are essential for observing efficient electron transfer reactions between the DNA bases and the ligands. Studies related to the use of these highly fluorescent molecules for the recognition of various DNA structures and duplexes containing mismatches and base bulges are in progress in our laboratory.

Binding Behavior of Aliphatic Oligopeptides by Bridged and Metallobridged Bis(*β*-cyclodextrin)s Bearing an Oxamido Bis(2-benzoic) Carboxyl Linker

Yu Liu,* Yan-Li Zhao, Yong Chen, Fei Ding, and Guo-Song Chen

Department of Chemistry, State Key Laboratory of Elemento-Organic Chemistry, Nankai University, Tianjin 300071, P. R. China. Received June 3, 2004; Revised Manuscript Received August 31, 2004

β-Cyclodextrin dimers bearing an oxamido bis(2-benzoic) carboxyl linker (**1**) or its metal complexes (**2** and **3**) were newly synthesized, and their inclusion complexation behavior with a series of representative aliphatic oligopeptides, i.e., Leu-Gly, Gly-Leu, Gly-Pro, Glu-Glu, Gly-Gly, Gly-Gly-Gly, and Glu(Cys-Gly), was elucidated by means of UV/vis, circular dichroism, fluorescence, and 2D NMR spectroscopy in Tris-HCl buffer solution (pH 7.4) at 25 °C. The results obtained indicated that metallobridged bis(*β*-cyclodextrin)s **2** or **3** could significantly enhance the original molecular binding abilities of parent bis(*β*-cyclodextrin) **1** toward model substrates through the cooperative binding of two cyclodextrin moieties and the additional chelation effect supplied by the coordinated metal centers. It is interesting that hosts **2** and **3** displayed an entirely different fluorescence behavior upon complexation with guest oligopeptides. Among the guest peptides examined, **3** showed the highest complex formation constant of 68 200 M^{-1} for Glu-Glu, up to 510-fold as compared with **1** (135 M^{-1}), while **1** gave excellent molecular selectivity for Glu(Cys-Gly)/Glu-Glu pair, up to 51-fold. The molecular binding ability and selectivity were discussed from the viewpoints of the induced-fit and multiple recognition mechanism between host and guest.

INTRODUCTION

Over the past three decades, numerous efforts have been devoted to molecular recognition studies of binding of biological molecules to various synthetic receptors, and among them, peptide recognition has become an exciting topic (*1*−*10*). These investigations potentially promote our insights into the selective binding between a designed molecular receptor (host) and a recognition target (guest). As one of the most successful receptors for peptide recognition and separation, cyclodextrins (CDs), a class of cyclic oligosaccharides with 6−8 glucopyranose units, and their derivatives have been widely applied due to their hydrophobic cavities capable of binding guest molecules through simultaneous contributions of several noncovalent interactions (*11*−*20*). Breslow et al. (*11*) studied the binding behavior of *β*-CD derivatives with some peptides using combinatorial chemistry, microcalorimetric titration, and a capillary electrophoresis approach, which showed that modified *β*-CDs could be used as sequence-selective peptide-cleaving reagents. Moroder et al. (*12*) linked the heptapeptide amide to mono(6-succinylamino-6-deoxy)-*β*-CD to analyze the effect of the bulky cyclic carbohydrate moiety on both the recognition of peptides by the G-protein-coupled CCK-B/gastrin receptor and their signal transduction potencies. Recently, Inoue et al. (*14*) reported chiral recognition thermodynamics of dipeptides with native *γ*-CD as studied by microcalorimetry, discussing the effects of length, bulkiness, and flexibility of the tether connecting the two aromatic moieties in a guest. These studies were not only directed toward an understanding of the thermodynamic aspects of binding and chiral/molecular discrimination of CDs, but also provided valuable information on the effects of changes in functionality and chirality, which attempt to elucidate the nature of molecular recognition between CDs and peptide guests.

It is interesting to note that a CD dimer (bis-CDs) connected with a linker of different length and structure, which possesses dual hydrophobic cavities in close proximity, can bind diverse molecules to form supramolecular sandwich complexes and thus give much higher binding abilities and molecular selectivities than those exhibited by parent CD. Furthermore, their metal complexes can extend the binding affinity of bis-CDs through the electrostatic interaction and/or cooperative chelation between ligated metal and accommodated guest molecule. Accordingly, a number of bis-CDs linked by functional tethers have recently been designed and synthesized to gain insights into the factors and mechanism controlling the inclusion complexation phenomena (*21*−*25*). However, the molecular recognition of metal-coordinated bridged bis-CDs to small peptides, especially aliphatic peptides, have not been well investigated so far (*11a*), although these studies are very important to elucidate the molecular recognition mechanism and control the binding behavior of biological receptors. In the present paper, we wish to report our investigation results on the binding behavior of bridged oxamide bis(2-benzoic) carboxyl linked bis(*β*-CD) (**1**) and its metal copper(II) (**2**) or nickel(II) (**3**) complexes (Scheme 1) with some representative oligopeptides (Chart 1) in Tris-HCl buffer solution (pH 7.4). The results obtained indicated that hosts **2** and **3** significantly enhanced the original binding abilities of parent bis(*β*-CD) (**1**) toward oligopeptides. Interestingly, **2** and **3** were found to induce different fluorescence behaviors upon addition of guest oligopeptides; that is, the fluorescence intensity of **2** or **3** gradually decreased upon addition of Glu(Cys-Gly) or Glu-Glu, but increased

with addition of other guests, which enabled these metallobridged bis(β-CD)s to be efficient fluorescence probes for the recognition of peptides. On the basis of the investigation of circular dichroism and 2D NMR spectroscopy, the molecular binding mode and complex formation constants (K_S) of substrates with bridged bis(β-CD)s **1**−**3** were discussed from the viewpoints of cooperative chelation and molecular multiple recognition between the host and guest. It is our special interest to examine the molecular recognition mechanism of oligopeptides by β-CD oligomers with ligated metal centers, which will serve our further understanding of this recently developing, but less investigated, area of metallobridged bis(β-CD)s.

EXPERIMENTAL PROCEDURES

Materials. β-CD of reagent grade was recrystallized twice from water and dried in vacuo at 95 °C for 24 h prior to use. *N*,*N*-Dimethylformamide (DMF) was dried over calcium hydride for 2 days and then distilled under reduced pressure prior to use. The oligopeptides Leu-Gly, Gly-Leu, Gly-Pro, Glu-Glu, Gly-Gly, Gly-Gly-Gly, and Glu(Cys-Gly) were commercially available and used without further purification. Oxamido bis(2-benzoic) acid (**4**) and its Cu(II) complex (**5**) were prepared according to the procedure reported by Kahn et al. (*26*). Mono[6-*O*-(*p*-toluenesulfonyl)]-β-cyclodextrin (6-OTs-β-CD) was prepared by the reaction of *p*-toluenesulfonyl chloride with β-CD in alkaline aqueous solution (*27*). Then, 6-OTs-β-CD was converted to mono(6-aminoethylamino-6-deoxy)-β-CD in 70% yield upon heating in excess ethylenediamine at 70 °C for 7 h (*28*, *29*).

Instruments. Circular dichroism and UV/vis spectra were recorded in a conventional quartz cell (light path 10 mm) on a JASCO J-715S spectropolarimeter or a Shimadzu UV-2401PC spectrophotometer equipped with a PTC-348WI temperature controller to keep the temperature at 25 °C. Fluorescence spectra were recorded in a conventional quartz cell (10 × 10 × 45 mm) at 25° C on a JASCO FP-750 fluorescence spectrometer with excitation and emission slits of 10 nm width. Elemental analysis was performed on a Perkin-Elmer 2400C instrument. NMR spectra were recorded on a Varian Mercury VX300 spectrometer.

[Oxamido bis(2-benzoic)acylamide]ethyleneamino-6,6′-deoxy-bis(β-CD)s 1. Mono(6-aminoethylamino-6-deoxy)-β-CD (1 mmol) was dissolved in DMF (30 mL) in the presence of a small amount of 4 Å molecular sieves, and then DCC (1 mmol) and **4** (0.5 mmol) were added.

The mixture was stirred for 2 days in an ice bath and another 2 days at room temperature and then allowed to stand for 5 h until no more precipitate deposited. The precipitate was removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in a minimum amount of hot water and then poured into 150 mL of acetone, and the precipitate formed was collected by filtration. This procedure was repeated several times. The crude product obtained was purified on a column of Sephadex G-25 with water as eluent. After the residue was dried in vacuo, a pure sample **1** was obtained in 27% yield. UV/vis λ_{max} (H_2O)/nm (log ϵ): 305.8 (3.62). ^{1}H NMR (D_2O, TMS, ppm): δ 2.54∼2.95 (m, 8H); 3.34∼3.79 (m, 84H); 4.85∼4.87 (m, 14H); 7.15∼7.20 (m, 2H); 7.43∼7.48 (m, 2H); 7.88∼8.04 (m, 2H); 8.39∼8.42 (m, 2H). IR (KBr, cm^{-1}): ν 3336.0, 2927.8, 2362.7, 2061.9, 1672.5, 1584.4, 1503.7, 1434.0, 1365.5, 1202.8, 1155.2, 1078.6, 1029.7, 944.9, 846.7, 756.7, 705.6, 578.2. Anal. Calcd for $C_{104}H_{160}O_{72}N_6 \cdot 8H_2O$: C, 44.76; H, 6.36; N, 3.01. Found: C, 44.65; H, 6.47; N, 2.87.

Bis(β-CD)−Copper(II) Complex 2. Bis(β-CD) **1** was added dropwise to a dilute aqueous solution of slightly excess copper(II) perchlorate in an ice/water bath. Several drops of chloroform were further added, and the resultant solution was kept at 5 °C for 2 days. Then, the solution was evaporated under reduced pressure, and the precipitate formed was collected by filtration, washed successively with a small amount of ethanol and diethyl ether, and then dried in vacuo to give complex **2** as a blue solid in 63% yield. UV/vis λ_{max} (H_2O)/nm (log ϵ): 306.8 (3.55). IR (KBr, cm^{-1}): ν 3351.4, 2930.4, 2051.0, 1637.0, 1581.1, 1449.5, 1426.1, 1364.2, 1333.6, 1152.1, 1118.4, 1080.2, 1029.0, 944.5, 846.0, 757.2, 706.3, 627.5, 577.8, 529.6, 415.3. Anal. Calcd for $C_{104}H_{160}O_{72}N_6 \cdot 2Cu(ClO_4)_2 \cdot 11H_2O$: C, 37.07; H, 5.44; N, 2.49. Found: C, 37.31; H, 5.23; N, 2.61.

Bis(β-CD)−Nickel(II) Complex 3. Bis(β-CD)−nickel(II) complex **3** was prepared, according to procedures similar to those in the synthesis of **2**, as a green solid (yield 58%). UV/vis λ_{max} (H_2O)/nm (log ϵ): 307.4 (3.55). ^{1}H NMR (D_2O, TMS, ppm): δ 2.96∼3.20 (m, 8H); 3.35∼3.86 (m, 84H); 4.94 (s, 14H); 7.21∼7.24 (m, 2H); 7.48∼7.52 (m, 2H); 8.01∼8.05 (m, 2H); 8.40∼8.43 (m, 2H). IR (KBr, cm^{-1}): ν 3336.0, 2931.0, 2044.0, 1665.9, 1587.6, 1506.9, 1439.9, 1334.1, 1299.5, 1240.9, 1152.7, 1079.6, 1029.8, 946.7, 843.6, 756.7, 706.6, 626.8, 578.2, 411.0. Anal. Calcd for $C_{104}H_{160}O_{72}N_6 \cdot 2Ni(ClO_4)_2 \cdot 13H_2O$: C, 36.78; H, 5.52; N, 2.47. Found: C, 36.96; H, 5.38; N, 2.56.

RESULTS AND DISCUSSION

Metal Coordination and Stoichiometry. As shown in Scheme 1, the metallobridged bis(β-CD)s **2** and **3** were prepared from bis(β-CD)s **1** by the coordination reaction with copper(II) and nickel(II) in aqueous solution, respectively. In addition to the elemental analysis data, the ^{1}H NMR, IR, and UV/vis spectra provided additional evidence about the formation of the **2** and **3**. Since the paramagnetic disturbance caused by the ligated copper(II) complex makes the ^{1}H NMR spectrum of **2** unavailable to measure, we compared the ^{1}H NMR spectra of **1** and its nickel(II) complex **3**. Some changes in the chemical shift of the aromatic protons of **3** were observed relative to those in **1**: the H1, H2, H3, and H4 protons shifted downfield ca. 0.07, 0.05, 0.05, 0.01 ppm, respectively, which indicated that a complex had formed between the **1** and nickel(II). The IR spectra of **1**−**3** showed that the stretching vibration of carbonyl groups

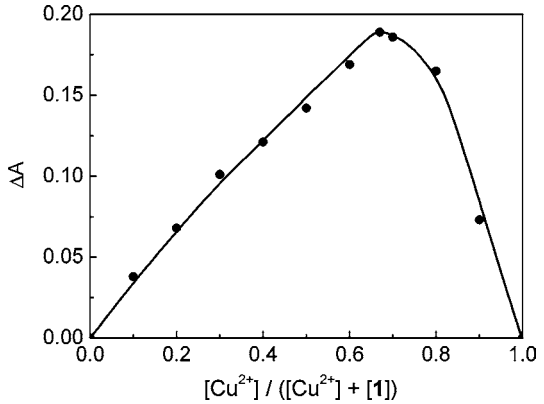

Figure 2. Job's plot of **1**/Cu(II) system at 350.0 nm. ([**1**] + [Cu(II)] = 2.0 × 10^{-4} mol dm^{-3}).

shifted from 1672.5 cm^{-1} for **1** to 1637.0 cm^{-1} for **2** and 1650.9 cm^{-1} for **3**, which could also be ascribed to the coordination of metal ions. Additionally, a weak absorption at 627.5 cm^{-1} for **2** (626.8 cm^{-1} for **3**), which may be assigned to a weakly coordinated perchlorate, was also observed, and indicated that the copper(II) or nickel(II) ion was coordinated to the bridged bis(β-CD) to form metallobridged bis(β-CD)s.

To compare the coordination behavior of bis(β-CD)s **1** with metal ions, spectrophotometric titrations of **1** with copper(II) or nickel(II) ions have been performed at 25 °C in aqueous solution. A typical titration curve of **1** with copper(II) ion was illustrated in Figure 1a. As can be seen in Figure 1a, the absorption intensity of **1** at 259 and 350 nm gradually increased with the addition of varying amounts of copper(II) perchlorate, accompanying an obvious bathochromic shift of absorption peaks. In the control experiments, UV/vis spectra of copper(II) ion within measurement concentration range displayed no appreciable change at 200−400 nm under comparable experimental conditions. Figure 1b showed the absorbance changes of **1** at 350 nm with the addition of copper(II) perchlorate. Furthermore, Job's experiments were also performed to explore the coordination stoichiometry of the bis(β-CD)−metal(II) complex in aqueous solution. The results obtained indicated that the complex stoichiometry was 1:2 for both **2** and **3**. A representative Job's plot for the coordination of **1** with copper(II) perchlorate was shown in Figure 2. The plot for the **1**/Cu(II) system showed a maximum at 0.67 which corresponded to the 1:2 **1**/Cu(II) stoichiometry. This result indicated that one

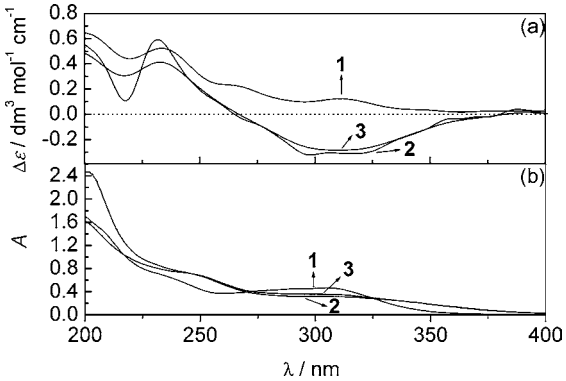

Figure 3. Circular dichroism (a) and absorption (b) spectra of **1** (1.1×10^{-4} mol dm^{-3}), **2** (8.9×10^{-5} mol dm^{-3}), and **3** (1.0×10^{-4} mol dm^{-3}) in aqueous solution at 25 °C.

bis(β-CD) **1** could bind two copper(II) ions, as illustrated in Scheme 1. According to the spectrophotometric titration and the Job's experiments, we can deduce that the coordination of **1** with Cu(II) should be a two-step process. The spectra from *a* to line *f* (Figure 1), which gave two isosbestic points at 273.8 and 322.2 nm, might refer to the coordination process of **1** with the first metal ion, while the spectra from line *g* to line *l* (Figure 1) might point to the coordination process of the second metal ion. Therefore, as an overall illustration of this two-step process, the spectra of absorption titration of **1** with Cu(II) did not give clear isosbestic points.

Conformations of Hosts 1−3. Achiral organic compounds can show an induced circular dichroism (ICD) signal around their corresponding transition bands in cases where there is a chiral microenvironment. Therefore, to deduce the conformation of interaction between the achiral chromophoric compound and the β-CD chiral cavity, ICD spectra of **1**−**3** were measured at 25 °C in aqueous solution. As can be seen from Figure 3, the circular dichroism spectrum of **1** showed two positive Cotton effects around 233.0 nm ($\Delta\epsilon = 0.52$ dm^{-3} mol^{-1} cm^{-1}) and 311.0 nm ($\Delta\epsilon = 0.12$ dm^{-3} mol^{-1} cm^{-1}), respectively. Interestingly, host **2** gave a positive Cotton effect around 232.0 nm ($\Delta\epsilon = 0.59$ dm^{-3} mol^{-1} cm^{-1}) and a negative Cotton effect around 298.0 nm ($\Delta\epsilon = -0.32$ dm^{-3} mol^{-1} cm^{-1}), while **3** gave a positive Cotton effect around 233.0 nm ($\Delta\epsilon = 0.41$ dm^{-3} mol^{-1} cm^{-1}) and a negative Cotton effect around 310.0 nm ($\Delta\epsilon = -0.28$ dm^{-3} mol^{-1} cm^{-1}). According to the pioneering studies (*24*, *30*, *31*) on the ICD phenomena of cyclodextrin complexes, we can deduce that the oxamide bis(2-benzoic) carboxyl group of **1** was shallowly included in the β-CD cavity with an acclivous orientation to form the self-included complexes. After the metal coordination, the linker group was located outside the β-CD cavity, leading to an opposite ICD signal around 300 nm for **2** or **3**. In addition to the ICD experiments, the 2D NMR experiments gave the primary evidence of inside−outside movement of the linker group, which is described below.

2D NMR spectroscopy has recently become an important method for the investigation of not only the interaction between host CDs and guest molecules, but also the self-included mode between the CD cavity and its substituent groups, since the NOE cross-peaks between the protons that are closer than 0.4 nm in space will be observed in the NOESY or ROESY spectrum and the relative intensities of these cross-peaks depend on the spaces between the corresponding protons. The height and the diameter of the β-CD cavity are about 0.79 ± 0.01 nm and 0.60−0.65 nm, respectively. Therefore, while

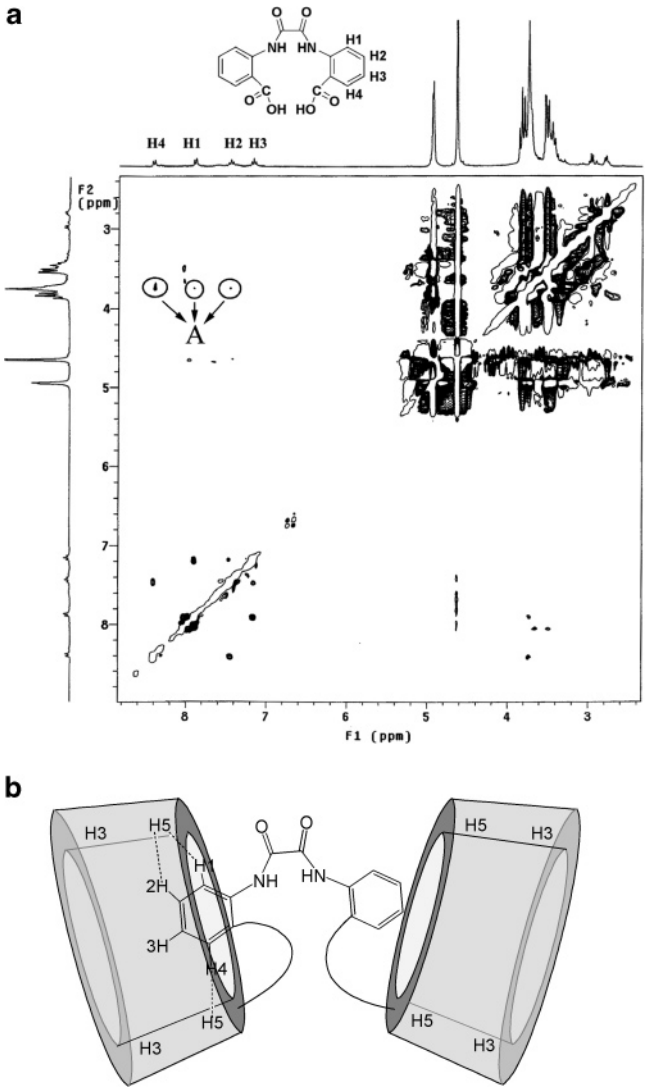

Figure 4. (a) ^{1}H ROESY spectrum of **1** (3.8×10^{-3} mol dm^{-3}) in D_2O at 25 °C with a mixing time of 400 ms, (b) possible conformation of **1**.

the substituent group is included into the β-CD cavity, the NOE correlations between the protons of the substituent group and the inner protons of the β-CD cavity (H-3 and H-5) will be measured. On the other hand, according to the relative intensity of these cross-peaks (*32*), it is possible to estimate the orientation of the substituent group within the β-CD cavity. To obtain further evidence about the original conformation of **1**−**3**, 2D NMR spectroscopy experiments were performed in D_2O solution. As shown in Figure 4a, the ROESY spectrum of **1** displayed clear NOE cross-peaks between the H5 of β-CD and the H1, H2, and H4 protons of oxamide bis(2-benzoic) carboxyl group (peaks A), which indicated distinctly that the linker group of **1** was shallowly self-included into the hydrophobic cavity from the primary side of β-CD. According to these results, a possible conformation of **1** was shown in Figure 4b. At the same time, the NOE cross-peaks between the β-CD's H5 and/or H3 and the protons of the linker group were not found in the ROESY spectrum of **3** (Figure 5), which indicated that the linker group of **3** should be located outside the β-CD cavity. Therefore, the results of the ROESY experiments not only further supported the ICD investigation results on the conformations of bridged bis(β-CD)s **1**−**3**, but also may serve to establish correlation

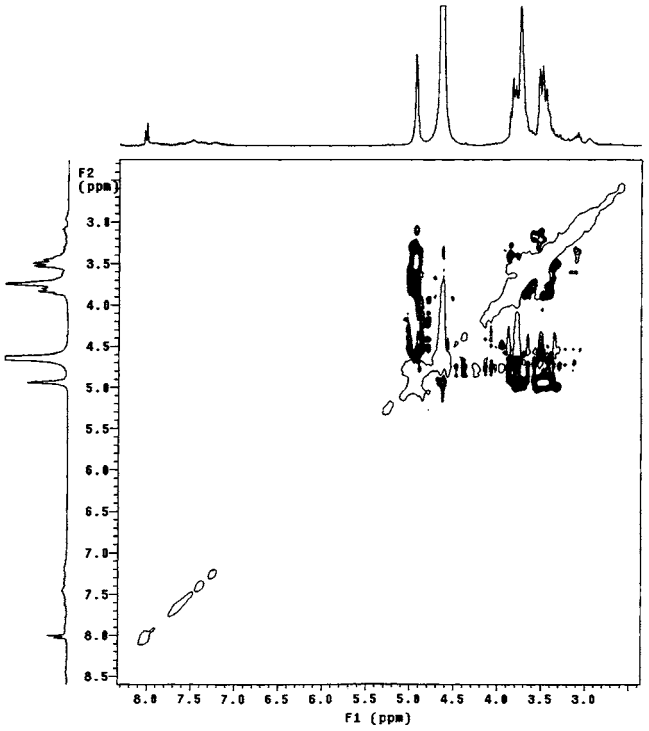

Figure 5. ^{1}H ROESY spectrum of **3** (3.5×10^{-3} mol dm^{-3}) in D_2O at 25 °C with a mixing time of 400 ms.

between the original conformation of modified β-CDs and their molecular recognition ability.

Spectral Titration. As elucidated above, the oxamide bis(2-benzoic) carboxyl group was either shallowly included in the β-CD cavity to form the self-included complexes (the case of **1**) or located on the edges of the β-CD cavity (the case of **2** and **3**). Therefore, the linker group might suffer substantial conformational change upon guest inclusion and thus result in the relevant spectral changes, which allows the bis(β-CD) to function as a spectral probe to obtain binding constants in differential fluorescence spectrometry. Herein, we chose some representative aliphatic oligopeptides, i.e., Leu-Gly, Gly-Leu, Gly-Pro, Glu-Glu, Gly-Gly, Gly-Gly-Gly, and Glu(Cys-Gly), to determine their binding behavior with hosts **1**−**3** by spectral titration experiments. Figure 6 illustrated a representative Job's plot for **2**/Glu-Glu system in Tris-HCl buffer solution (pH 7.4) at 25 °C. In the used concentration range, the plot for metallobridged bis(β-CD) showed a maximum at a molar fraction of 0.5, indicating the 1:1 inclusion complexation between the host and guest. The same results were obtained in the

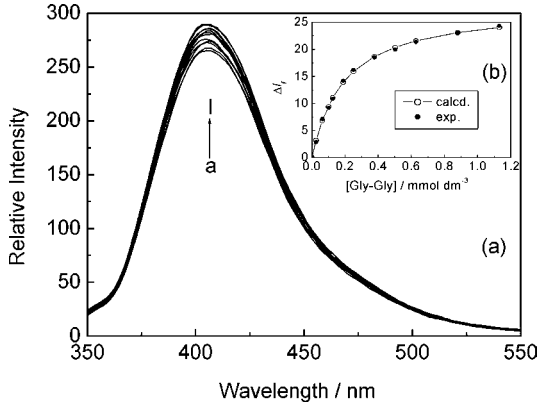

Figure 7. (a) Fluorescence spectral changes of host **3** (1.0×10^{-5} mol dm^{-3}) upon addition of Gly-Gly (0 to 1.13×10^{-3} mol dm^{-3} from *a* to *l*) in Tris-HCl buffer solution (pH 7.4) at 25 °C. (b) the nonlinear least-squares analysis of the differential intensity (ΔI_f) to calculate the complex formation constant (K_S). ($\lambda_{ex} = 314.0$ nm, $\lambda_{em} = 406.0$ nm).

cases of the inclusion complexation of other bis(β-CD)s with selected oligopeptide guests.

Using 1:1 host/guest stoichiometry, where the two β-CD moieties in **1**−**3** were treated as one unit, the complexation of the oligopeptide guest (OP) with the bis(β-CD) host (CD) can be expressed by eq 1.

$$\mathrm{CD} + \mathrm{OP} \overset{K_S}{\rightleftharpoons} \mathrm{CD{\cdot}OP} \qquad (1)$$

The relative fluorescence intensity change of host unit (ΔI_f) upon addition of guest molecule, where $\Delta I_f = I_f$ (with guest molecule) − I_f (without guest molecule), was assumed to be proportional to the concentration of inclusion complex formed by bis(β-CD) unit with model substrate, i.e., $\Delta I_f = \alpha[\mathrm{CD{\cdot}OP}]$. The proportionality coefficient α was taken as a sensitivity factor for the fluorescence change upon inclusion complexation. Then, the effective complex formation constant (K_S) (*33*, *34*) can be expressed by eq 2:

$$K_S = \frac{[\mathrm{CD{\cdot}OP}]}{[\mathrm{CD}][\mathrm{OP}]} = \frac{[\mathrm{CD{\cdot}OP}]}{([\mathrm{CD}]_0 - [\mathrm{CD{\cdot}OP}])([\mathrm{OP}]_0 - [\mathrm{CD{\cdot}OP}])} = \frac{\Delta I_f/a}{([\mathrm{CD}]_0 - \Delta I_f/a)([\mathrm{OP}]_0 - \Delta I_f/a)} \qquad (2)$$

where $[\mathrm{CD}]_0$ and $[\mathrm{OP}]_0$ denoted the initial concentrations of bis(β-CD) host and oligopeptide guests, respectively. Subsequently, eq 2 can be solved for ΔI_f to give eq 3:

$$\Delta I_f = \{\alpha([\mathrm{CD}]_0 + [\mathrm{OP}]_0 + 1/K_S) - \sqrt{\alpha^2([\mathrm{CD}]_0 + [\mathrm{OP}]_0 + 1/K_S)^2 - 4\alpha^2[\mathrm{OP}]_0[\mathrm{CD}]_0}\}/2 \qquad (3)$$

Using the nonlinear least squares curve-fitting method according to eq 3 (*35*), we obtained the complex formation constant for each host−guest combination from the analysis of the sequential changes of fluorescence intensity (ΔI_f) at various guest concentrations. Figure 7b illustrated a typical curve-fitting plot for the titration of Gly-Gly with **3**, which showed excellent fits between the experimental and calculated data obtained. A good correlation between the experimental and calculated result indicated the reliability of the obtained complex formation constants. The complex formation constants (K_S) and

Gibbs free energy changes ($-\Delta G°$) obtained for the complexation of bis(β-CD)s **1**−**3** with oligopeptide guests were compiled in Table 1. When repeated measurements were made, the K_S values were reproducible within an error of ±5%.

Binding Mode. It is well-known that the competitive inclusion, cooperative binding, and induced-fit generally occur in the molecular binding process of modified β-CDs, and therefore it is very important to investigate the inclusion modes between host β-CDs and guest molecules for elucidating the mechanism of molecular recognition. In our previous research by means of ^{1}H NMR, circular dichroism, and fluorescence spectroscopy as well as CPK model examination (*24*), we found that a multiple sandwich binding mode was operative in the association of the guest molecule with bridged bis(β-CD); that is, upon inclusion complexation with bis(β-CD), two side groups of the guest molecule were embedded into the hydrophobic β-CD cavities from the primary side of β-CD to form a sandwich host−guest inclusion complex. In the present paper, we wish to establish the possible binding mode of bridged and metallobridged bis(β-CD)s **1**−**3** with oligopeptides according to the results of circular dichroism, ^{1}H NMR, and fluorescence spectral experiments.

For the self-included CD hosts, there should exist a competition between the substituent group of host and guest upon inclusion complexation with the CD cavity, and this competitive inclusion may be verified by the circular dichroism spectral studies. Typically, a series of ICD signals of **2** in the presence of different amounts of Gly-Gly were shown in Figure 8. As can be seen from Figure 8, the ICD intensity of host **2** around 310 nm increased gradually upon the addition of increasing amounts of Gly-Gly. However, the corresponding absorption intensity around 340 nm decreased gradually, accompanied by the appearance of an isobestic point at 309 nm. Since Gly-Gly displayed no ICD signal in the range of 210−400 nm, one possible explanation for these spectral phenomena was that, during the inclusion complexation, the guest molecule was cooperatively bound by two β-CD cavities from the primary side, which forced the linker group of bis(β-CD) away from the β-CD cavity and thus gave the weak ICD signals.

Interestingly, the **2** and **3** were found to show different fluorescence behaviors upon complexation of guest peptides. The gradual addition of Glu-Glu or Glu(Cys-Gly) to a dilute solution of **2** or **3** significantly decreased the fluorescence intensity (Figure 9). However, fluorescence intensity for **2** or **3** gradually enhanced with the stepwise addition of other peptides under comparable conditions. In a control experiment, neither disodium oxamidobis-(2-benzoxylate) nor its Cu(II) complex **5** exhibited appreciable fluorescence change upon the addition of oligopeptides. In additional control experiments, the formation constant (K_S) of disodium oxamido bis(2-benzoxylate) with Cu(II) ion was also determined by means of UV−vis spectral titration, and the obtained K_S value was 27930 ± 1390 M^{-1}, which indicated a strong association of oxamido bis(2-benzoxylate) with Cu(II). Moreover, we also compared the NMR spectra of disodium oxamido bis-(2-benzoxylate) ([**4**−Na] = 4.6 × 10^{-4} mol dm^{-3}), a 1:1 complex of **4**−Na with Ni(II) ([**4**−Na/Ni] = 3.8 × 10^{-4} mol dm^{-3}), and a 1:1 mixture of **4**−Na/Ni with Glu-Glu ([**4**−Na/Ni] = [Glu-Glu] = 3.9 × 10^{-4} mol dm^{-3}). The reason for choosing Ni(II) as metal ion was to avoid the paramagnetic disturbance caused by Cu(II). As can be seen in Figure 10, several changes of the δ values of the aromatic protons in the **4**−Na/Ni system were observed as compared with those in **4**−Na; that is, the δ values of H1, H2, H3, and H4 protons shifted downfield ca. 0.11, 0.08, 0.07, and 0.04 ppm, respectively, indicating that the Ni(II) ion was coordinated to the oxamido bis(2-benzoxy-

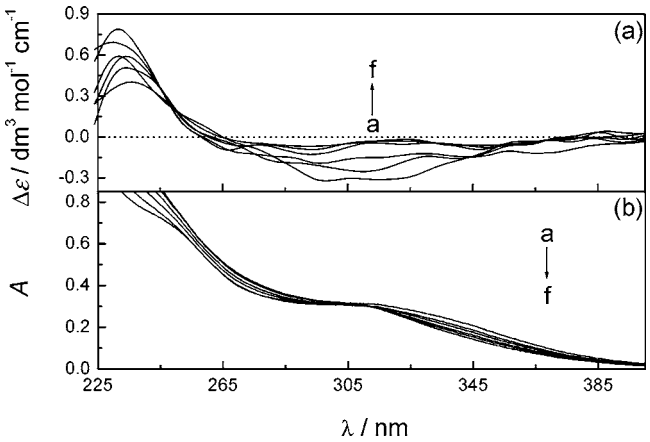

Figure 8. Circular dichroism (a) and absorption (b) spectra of **2** (8.9 × 10^{-5} mol dm^{-3}) upon addition of Gly-Gly (0 ∼ 9.13 × 10^{-3} mol dm^{-3} from *a* to *f*) in Tris-HCl buffer solution (pH 7.4) at 25 °C.

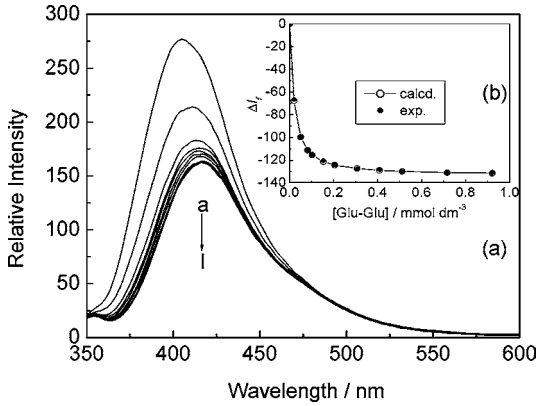

Figure 9. (a) Fluorescence spectral changes of host **3** (1.1 × 10^{-5} mol dm^{-3}) upon addition of Glu-Glu (0∼0.92 × 10^{-3} mol dm^{-3} from *a* to *l*) in Tris-HCl buffer solution (pH 7.4) at 25 °C and (b) the nonlinear least-squares analysis of the differential intensity (ΔI_f) to calculate the complex formation constant (K_S). (λ_{ex} = 314.0 nm, λ_{em} = 405.0 nm).

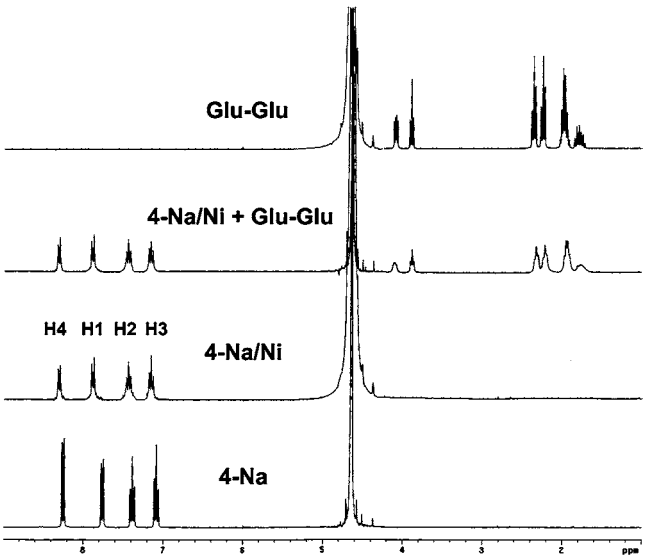

Figure 10. The ^{1}H NMR spectra of **4**−Na (4.6×10^{-4} mol dm^{-3}), a 1:1 complex of **4**−Na with Ni(II) ([**4**−Na/Ni] = 3.8×10^{-4} mol dm^{-3}), a 1:1 mixture of **4**−Na/Ni with Glu-Glu ([**4**−Na/Ni] = [Glu-Glu] = 3.9×10^{-4} mol dm^{-3}), and Glu-Glu (4.2×10^{-4} mol dm^{-3}) in D_2O at 25 °C.

late) ligand. However, the δ values of the aromatic protons in **4**−Na/Ni did not show any appreciable changes after adding Glu-Glu. These unchanged δ values before and after adding guest oligopeptides may indicate that the metal ion was still bound to the oxamido bis(2-benzoxylate) ligand in the presence of guest oligopeptides, because the demetalation of **4**−Na/Ni by the guest would make the δ values of the aromatic protons in **4**−Na/Ni shift upfield to the original position. The results of these control experiments jointly indicated that the increased or decreased fluorescence of hosts **1**−**3** upon the addition of guests was mainly attributed to the inclusion complexation, not just to the simple enhancing/quenching effect of the linker group or the demetalation of metallobridged bis(β-CD) by the guest. That is to say, such contrasting fluorescence behavior indicated that the different binding modes were operative in the inclusion complexations of Glu-Glu with **1** and **3**. The increased fluorescence intensity could be rationalized by the increased microenvironmental hydrophobicity and/or steric shielding around the fluorophore arising from the cooperative interactions between the host and guest (*36*). Therefore, the fluorescent group of the host could be efficiently shielded from the deactivating water attack by the formation of a sandwich inclusion complex, which consequently contributed to the fluorescence enhancement of the host (Figure 11b). On the other hand, for guests Glu-Glu or Glu(Cys-Gly), their branch groups (amino and carboxyl groups for Glu-Glu, amino and sulfydryl for Glu(Cys-Gly)) could interact strongly with the coordinated metal center of host **2** or **3** through the cooperative chelation effect (Figure 12b) (*6*, *37*), which led to the degressive fluorescence intensity of **2** or **3** upon inclusion complexation.

To obtain direct evidence to further elucidate the origin of these opposite fluorescence behaviors, ^{1}H ROESY experiments of **1** and **3** with the representative guest Glu-Glu were performed in D_2O at 25 °C. As illustrated in Figure 11a, the ^{1}H ROESY spectrum of a mixture of host **1** with guest Glu-Glu in D_2O displayed sophisticated NOE cross-peaks, which came from not only the intermolecular interactions between β-CD and Glu-Glu, but also the intramolecular interactions of **1** or Glu-Glu. Among these

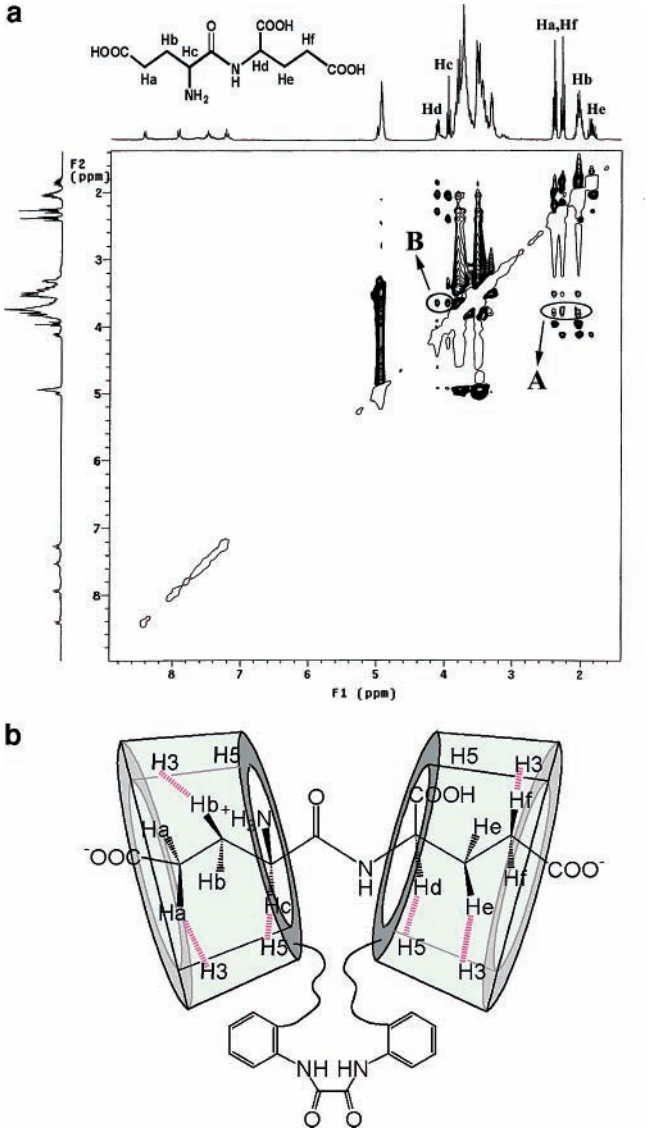

Figure 11. (a) ^{1}H ROESY spectrum of a mixture of **1** (2.5×10^{-3} mol dm^{-3}) with Glu-Glu (2.9×10^{-3} mol dm^{-3}) in D_2O at 25 °C with a mixing time of 400 ms; (b) possible complex structure of **1** with Glu-Glu.

signals, the NOE cross-peaks between the protons in the linker group of **1** and the H5/H3 protons of β-CD as well as the protons of Glu-Glu were not found, but the correlations between Ha, Hb, Hf protons of Glu-Glu and H3 protons of β-CD (peaks A), and the correlations between Hc, Hd protons of Glu-Glu and H5 protons of β-CD (peaks B), were clearly observed. These phenomena indicated that the Glu-Glu molecule was located in the β-CD cavity, while the linker group of **1** outside. According to the 2D NMR experimental results, a possible conformation of host **1** with Glu-Glu was shown in Figure 11b.

Figure 12a showed the ^{1}H ROESY spectrum of a mixture of **3** with Glu-Glu. Although the NOE correlation peaks between the H3/H5 of β-CD and the protons of Glu-Glu (peaks A) were not clear enough to estimate their relative intensity, we could deduce unambiguously that there did exist the corresponding NOE correlations. Simultaneously, the correlation peaks between the H3/H5 of β-CD and the protons of the linker group in **3** were not observed, which indicated that Glu-Glu was located in the β-CD cavities but the linker group outside the cavities (Figure 12b).

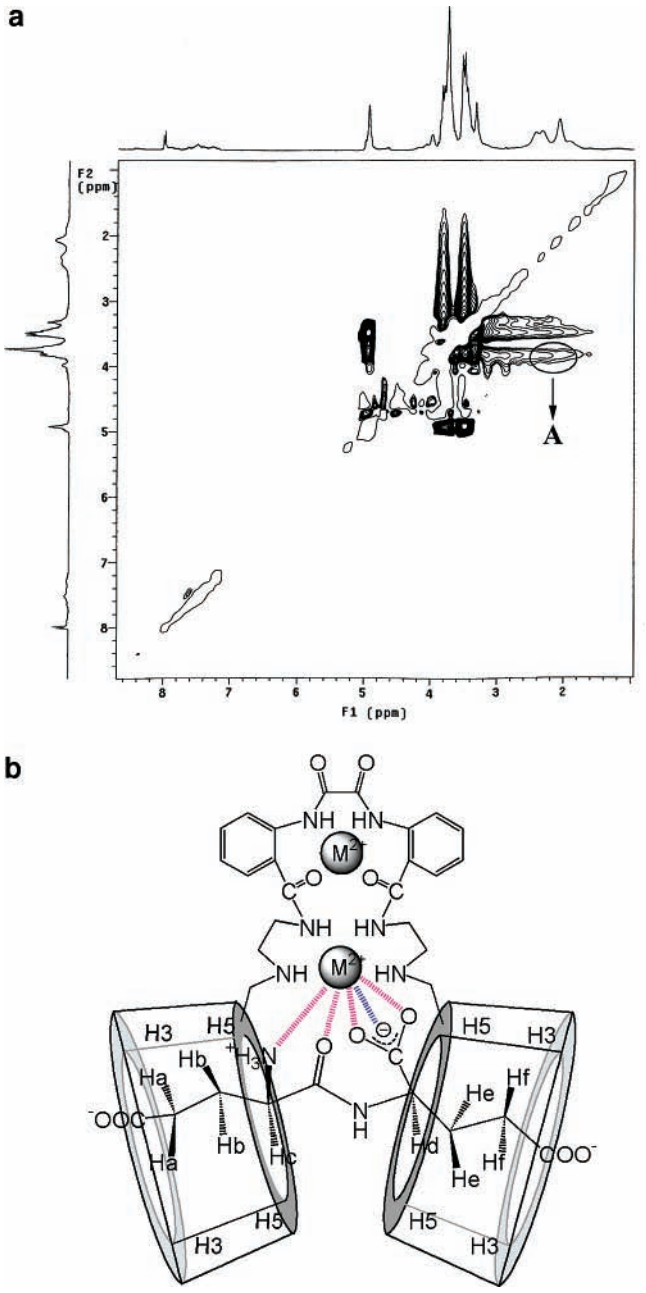

Figure 12. (a) ^{1}H ROESY spectrum of a mixture of **3** (2.7×10^{-3} mol dm^{-3}) with Glu-Glu (3.1×10^{-3} mol dm^{-3}) in D_2O at 25 °C with a mixing time of 400 ms; (b) possible complex structure of **3** with Glu-Glu.

Binding Ability and Molecular Selectivity. Native and simply modified CDs afford only very small binding constants to model substrates, probably due to the weak hydrophobic interactions between the host and guest. Bridged bis(β-CD), however, can enhance the original binding ability through cooperative binding of two adjacent cavities and potential multiple recognition ability. It is significantly noted that the introduction of the metal ions alters not only the original conformation of the linker group but also the distance and orientation of two β-CD cavities in bridged bis(β-CD). As compared with monomeric and dimeric CDs, metallobridged bis(β-CD)s can afford much more stable inclusion complexes with model substrates, owing to a fixed conformation by metal ligation, and additional cooperative chelation, electrostatic interaction, and/or electron transfer between ligated metal and accommodated guest. Furthermore, investigations on the inclusion complexation conformation of bridged and metallobridged bis(β-CD)s with guests also indicate that the cooperative binding and metal coordination can dominate the stability of complex formed between bis(β-CD)s and model substrate, leading to stronger van der Waals and hydrophobic interactions, since these interactions are closely related to the distance and contacting surface area between the host and guest. As can be seen from Table 1, the complex formation constants (K_S) for **1** with oligopeptides were variable according to the guest structures. Among the guest peptides examined, host **1** afforded the highest complex formation constant of 6850 M^{-1} for the inclusion complexation with Glu(Cys-Gly) and the largest molecular selectivity for Glu(Cys-Gly)/Glu-Glu pair ($K_S^{Glu(Cys-Gly)}/K_S^{Glu-Glu} = 51$). This may be attributed to the strict size/shape fitting relationship between the longest guest Glu(Cys-Gly) and the long-tethered bis(β-CD) **1**, which fully enjoyed the cooperative binding of two β-CD cavities with one guest molecule. However, possessing three carboxyl groups, Glu-Glu was more hydrophilic than other guests, which reduced the hydrophobic interactions as well as the extent of desolvation upon inclusion complexation and thus resulted in poor association with bis(β-CD).

Furthermore, metallobridged bis(β-CD)s **2** and **3** showed significantly enhanced binding abilities and molecular selectivities upon inclusion complexation with oligopeptides as compared with those of parent bis(β-CD) **1**. It can be seen from Table 1 that the coordination of the linker group to the metal ions further enhanced the binding abilities of **1** for guest peptides by a factor of 1.4−510. This further enhancement may point to a mechanism concerning a multiple recognition behavior of metallobridged bis(β-CD)s toward model substrates. Upon complexation with guest molecules, the metallobridged bis(β-CD)s not only afforded two hydrophobic binding sites (two β-CD cavities) cooperatively associating with a guest but also provided additional binding interactions between the heteroatoms of peptides and the coordinated metal center. Thus, as a cumulative result of these factors, metallobridged bis(β-CD)s displayed significantly enhanced binding abilities toward guest peptides as compared with parent bis(β-CD).

It is also interesting to compare the molecular selectivity sequence of hosts **1**−**3**. The complex formation constants (K_S) for the inclusion complexation of hosts **1**−**3** with oligopeptides decreased in the following order:

For **1**: Glu(Cys-Gly) > Leu-Gly > Gly-Gly-Gly > Gly-Gly > Gly-Leu > Gly-Pro > Glu-Glu

For **2**: Glu-Glu > Glu(Cys-Gly) > Leu-Gly > Gly-Pro > Gly-Gly-Gly > Gly-Leu > Gly-Gly

For **3**: Glu-Glu > Glu(Cys-Gly) > Leu-Gly > Gly-Pro > Gly-Gly-Gly > Gly-Gly > Gly-Leu

It can be seen that, different from parent bis(β-CD), metallobridged bis(β-CD)s showed the highest binding ability for Glu-Glu. This is because, besides the cooperative binding of two adjacent β-CD cavities and the heteroatom−metal chelation effects, the electrostatic interactions between the cationic metal center and the anionic carboxyl group located in the middle of Glu-Glu (blue line in Figure 12b) also contributed to the strong inclusion complexation of Glu-Glu with metallobridged bis(β-CD)s, since the carboxyl groups in peptides should exist as anions in this medium (pH = 7.4).

Another intriguing finding is the relatively high sequence selectivity of hosts **1**−**3** upon complexation of guest peptides. As can be seen in Table 1, hosts **1**−**3** could differentiate the sequence of dipeptide, with the selectivity as high as 2.0−4.2 for the Leu-Gly/Gly-Leu pair and

1.4−3.0 for the Gly-Gly-Gly/Gly-Gly pair. This sequence recognition ability of bis(β-CD)s could be accounted for in terms of the size/shape fit between host and guest. Possessing a quasi-linear structure, Leu-Gly was more favorable to the cooperative binding of two β-CD cavities than Gly-Leu that possessed a large isobutyl branch. On the other hand, the longer guest Gly-Gly-Gly was a better fit to the intercavity distance of bis(β-CD)s than Gly-Gly, which in turn led to stronger host−guest inclusion complexation.

As a whole, we can see that the host selectivity sequence of bis(β-CD)s **1**−**3** for each oligopeptide guests was **3** > **2** > **1**. This indicated that nickel(II)-coordinated bis(β-CD) **3** could give stronger binding abilities to oligopeptides than parent bis(β-CD) and its copper(II) complex, which may be helpful to select the appropriate metal ion as the coordination center in the design of the functional β-CD dimers and their metal complexes.

CONCLUSIONS

In summary, novel bridged bis(β-CD)s **1** can recognize the size and hydrophobicity of guest peptides through the cooperative binding of two CD cavities, having higher binding abilities toward relatively long peptides. Especially, its metal complexes effectively enhanced the original binding ability and sequence selectivity of parent **1** through a simultaneous contribution of the multiple chelation effects and/or the electrostatic interactions between the coordinated metal center and the guest peptide. On the other hand, the metal coordination can switch the fluorescence behavior of the parent bis(β-CD) for special substrates, which potentially enabled these novel bis(β-CD)s to function as fluorescence sensors for the molecular recognition of biological guests.

Received March 12, 2004; Revised Manuscript Received August 19, 2004

Application of cell-penetrating peptides for delivering various hydrophilic macromolecules with biological function into cells has gained much attention in recent years. We compared the protein transduction efficiency of four cell-penetrating peptides: penetratin, Tat peptide, transportan, and pVEC and studied the effects of various medium parameters on the uptake. Depletion of cellular energy and lowering of temperature strongly impaired the internalization of protein complexed with cell-penetrating peptides, confirming the endocytotic mechanism of peptide-mediated protein cellular transduction. Peptide-induced protein association with HeLa cells decreased 3−6-fold in energy-depleted cells. Inhibition of clathrin-dependent endocytosis by the hyperosmolar medium decreased the uptake of peptide-avidin complexes 1.5−3-fold and the removal of cholesterol from the plasma membrane 1.2−2-fold, suggesting that both clathrin-dependent and independent endocytosis were involved in peptide-induced cellular delivery of avidin. However, even under conditions of cellular energy depletion, ceasing of cellular traffic, and partial depolarization of plasma membrane, peptide−protein complexes associated with HeLa cells, as observed by FACS analysis and spectrofluorimetry. Among the studied peptides, pTat and transportan revealed higher protein transduction efficiency than penetratin or pVEC.

INTRODUCTION

Discovery and design of various cell-penetrating peptides (CPP) (for reviews see ref 1) have opened a possibility of introducing different hydrophilic macromolecules into cells (*2*, *3*). These peptides show a capability to enter cells in culture even at low temperature and in the presence of endocytosis inhibitors. Although the primary structure of CPPs is highly variable, some general features, envisaged to be essential for efficient cell entry, can be outlined. An abundance of positive charges, especially from arginines (*4*−*6*) and the presence of amino acids with a bulky hydrophobic side-chain (*7*) in the peptide sequence have been suggested to be crucial for efficient cellular uptake. The ability of a peptide to form an amphipathic helix is in correlation with cellular uptake efficacy for some peptides (*8*), whereas for most CPPs, folding into an α-helical structure is not required.

Recently we compared the carrier properties of the four most widely used CPPs, loading them with a small model peptide as a cargo (*9*). The obtained results enabled the division of the peptides into two major classes, based on cargo delivery efficiency and membrane disturbance. Tat peptide (pTat) and penetratin had no adverse effect on plasma membrane permeability in high concentration, but possessed lower cargo delivery efficiency. The model amphipathic peptide (MAP) and transportan, on the contrary, showed higher delivery yield but induced stronger plasma membrane leakage (*9*).

It was recently suggested that some arginine-rich peptides share a common mechanism of cell entry (*10*). On the other hand, different cellular uptake mechanisms for the arginine-rich pTat and its protein conjugates were demonstrated (*11*). However, translocation of fluoresceinyl-penetratin and -pTat into living cells was questioned lately (*12*, *13*). The uptake detected at higher concentrations was ascribed to membrane perturbation and the toxic effects of labeled peptides. Still, the conjugates of the respective CPPs with PNA oligomers internalized efficiently (*12*). The uptake of fluorescein-labeled pTat and Arg_9 was suggested to proceed mainly by the endocytic pathway (*13*). In addition, internalization of lipid-interacting peptides SynB5 and penetratin was also shown to proceed by absorptive endocytosis rather than by temperature-independent translocation (*14*, *15*). The characteristic diffuse localization of CPPs in the cytoplasm reported in numerous studies earlier was suggested to stem from the fixation and permeabilization of cells (*13*, *16*). On the other hand, the uptake of pTat and Arg_7 by living cells under endocytosis-blocking conditions was demonstrated recently (*17*), and the authors suggested the presence of an additional nonendocytic pathway. Later the observed diffuse localization of CPPs in the cytoplasm associated with the nonendocytic internalization was suggested to be caused by the escape of peptides from endosomal structures, since the inhibition of acidification of endosomes blocked the translocation of CPPs into cytoplasm (*18*, *19*). Cellular uptake of heterologous fusion proteins comprising Tat or its protein transduction domain and EGFP is shown to proceed by a cholesterol- and cellular-energy-dependent caveolae-mediated pathway (*20*, *21*). The cellular uptake of Cre-

recombinase fusion protein with the pTat, however, was very recently demonstrated to occur by caveolin-independent macropinocytosis of lipid rafts (*22*).

The present study characterizes the ability of CPPs (see Table 1 for structures) to target a protein cargo into HeLa cells. We studied the impact of low temperature, endocytosis inhibitors, modulation of the plasma membrane composition and culture medium on the protein cellular transduction efficiency. Inhibition of relevant cellular processes affects the cargo delivery efficiency of different CPPs in a divergent manner. We assume that the observed changes in protein delivery may help elucidate the mechanism by which the four studied peptides facilitated the cellular uptake of proteins.

MATERIALS AND METHODS

Peptide Synthesis. The peptides (Table 1) were synthesized as described earlier (*23*, *24*) on a peptide synthesizer (Applied Biosystems model 431A, USA) in a stepwise manner in a 0.1-mmol scale using the *t*-Boc strategy of solid-phase peptide synthesis. *tert*-Butyloxycarbonyl amino acids were coupled as hydroxybenzotriazole (HOBt) esters to a *p*-methylbenzylhydrylamine (MBHA) resin (Neosystem, Strasbourg, France) to obtain C-terminally amidated peptides.

Biotin was coupled manually to the N-terminus (or to $N^{\epsilon 13}$-Lys in transportan) of the peptide by adding a 3-fold excess of HOBt and *o*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium tetrafluorborate (TBTU) activated biotin (Chemicon, Hampshire, UK) in DMF to the peptidyl-resin. Deprotection of the dinitrophenyl group was carried out by treatment with 20% thiophenol in DMF for 1 h at room temperature. Deformylation was carried out by treatment with 20% piperidine in DMF for 40 min at room temperature. The peptides were finally cleaved from the resin with liquid HF at 0 °C for 1 h in the presence of *p*-cresol. Purification of peptides with reverse-phase HPLC was carried out with a Supelcosil LC-18 preparative column (25 cm × 21.2 mm, 5 μm) (Sigma Aldrich Chemie, Steinheim, Germany) using water–acetonitrile, both containing 0.1% CF_3COOH, gradient from 20 to 100%. The purity of peptides was >98% as demonstrated by HPLC on an analytical Nucleosil 120-3 C-18 RP-HPLC column (0.4 × 10 cm). Correct molecular masses were obtained by using a MALDI-TOF mass spectrometer (Voyager-DE STR, Applied Biosystems, Foster City, CA) (Table 1).

Cell Culture. HeLa cells (ATCC CCL-2) were cultivated in Iscove's Modified Dulbecco's Medium (IMDM) supplemented with 100 IU/mL penicillin, 100 μg/mL streptomycin, and 10% fetal calf serum (FCS) at 37 °C in humidified atmosphere containing 5% CO_2. Effects of CPPs on plasma membrane integrity were assayed by measuring the LDH release using the CytoTox-ONE Assay (Promega Corp. Madison, WI). In parallel, the MTT-assay was also performed.

Uptake Experiments. The cells were incubated with fluorescein-labeled avidin complexed with biotinyl-CPPs in IMDM containing 10% FCS if not stated otherwise. The CPP–avidin complexes were preformed by associating fluorescein-labeled avidin with biotinyl-CPP at room temperature in a minimal volume for 5 min and applied to the cells after dilution with the culture medium to the concentration of 0.15 μM and 0.5 μM, respectively. Incubation was carried out at 37 °C or on ice, and the incubation time was varied from 15 min to 24 h, depending on the experiment. For experiments at low temperature, the cells were preincubated on ice for 15 min. Depletion of cellular energy was achieved by inhibiting oxidative phosphorylation and glycolysis with 0.5 or 1% sodium azide and 25 or 50 mM 2-deoxyglucose (DOG), respectively, either alone or in combination (*25*) prior to the application of complexes. The hyperosmolar medium was prepared by dissolving sucrose at a concentration of 0.4 M in IMDM, and solutions containing deoxyglucose were prepared in Dulbecco's PBS. The cells were treated with a solution containing the respective agent for 30 min, and then avidin or CPP–avidin complexes in the same solution were applied and the uptake was measured after 30 min incubation. Organization of plasma membrane lipids was modified by incubating the cells in serum-free IMDM with 10 mM methyl β-cyclodextrin, which extracts cholesterol from the cells' plasma membrane (*26*), leads to the disappearance of rafts and caveolae and inhibits their re-formation (*27*).

FACS Analysis. The cells were seeded in six-well plates to a density of 250 000 cells per well in 2.5 mL medium and used for experiments 1 day after seeding at 70–90% confluence. After incubation with peptide–protein complexes, the cells were rinsed twice with PBS and detached from the plastic by incubating with trypsin solution (0.5 mg/mL in PBS containing 0.2 mg/mL EDTA) at 37 °C for 3, 15, or 30 min, respectively. Trypsinized cells were suspended, collected by centrifugation at 250*g* for 5 min at 4 °C, and resuspended in PBS. The intactness of the cells was estimated by resuspending the cells' pellet in PBS containing 1 μg/mL of propidium iodide. In the flow cytometry analysis 30 000 cells per sample were counted by the FACS Calibur, using Cell Quest software (BD Biosciences, Heidelberg, Germany). Each value represents a mean of three separate determinations.

Spectrofluorimetric Quantification of Internalized Avidin. The cells were treated with the complexes as described in uptake experiments and trypsinized for 15 min, and the washed cell pellet was dissolved in 1 mL 0.1 M NaOH. The fluorescence signal in the obtained solution was measured in a 10 × 10 mm cuvette at 520 nm using excitation at 490 nm by a F-4500 fluorescence spectrophotometer (Hitachi, Japan). Quantitative data analysis was performed by MS Excel.

Confocal Scanning Microscopy. HeLa cells in eight-well chambered coverglasses (Nalge Nunc International, Rochester, NY) were incubated with 0.15 μM Alexa Fluor 488 labeled avidin (Molecular Probes, Leiden, Netherlands) and 0.5 μM biotinyl-CPP in 10% of FCS containing

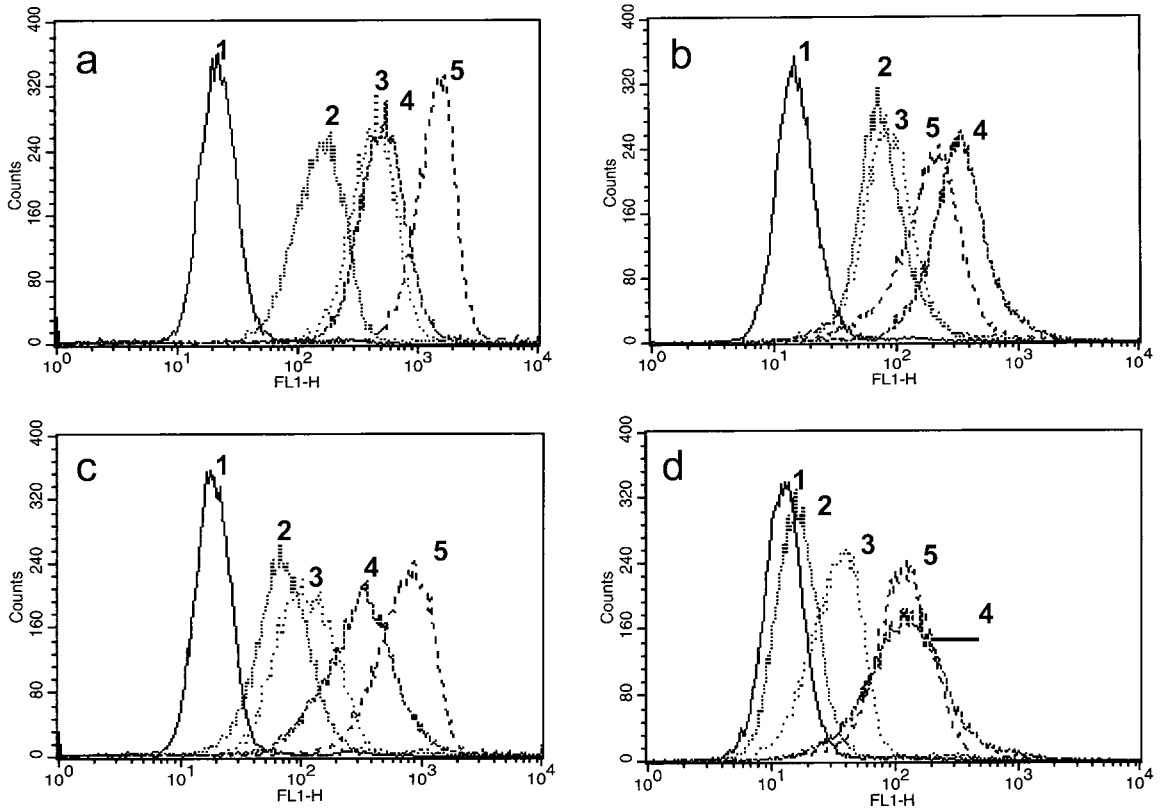

Figure 1. Cellular uptake of FITC-labeled avidin complexes with different biotinyl-CPPs. HeLa cells were incubated with complexes of 0.15 μM FITC-labeled avidin and 0.5 μM biotinyl-CPP for 30 min at 37 °C (a, c) or 4 °C (b, d) and thereafter treated with trypsin for 3 min (a, b) or 15 min (c, d). The cells were incubated with FITC-labeled avidin (1) or complexed with biotin-tagged penetratin (2), pVEC (3), pTat (4), or transportan (5). The number of cells (*y*-axis) is plotted against the fluorescence signal of cells (*x*-axis).

IMDM for 45 min at 37 °C. The medium with the complexes was removed, the cells were rinsed twice with PBS, covered with PBS (containing 1 mM of $CaCl_2$ and 0.5 mM $MgCl_2$), and the serial images were recorded using the laser confocal scanning microscope MRC-1024 (Bio-Rad Laboratories, Hercules, CA). After recording the images, an equal volume of 8% (w/v) paraformaldehyde in PBS was added. The images from the cells were obtained in the course of fixation with 4% PFA every 10 min using the identical settings of the microscope.

RESULTS

Peptides. All peptides were synthesized and biotinylated by using conventional peptide synthesis protocols. Orthogonal protection group strategy was used for the labeling of transportan at the 13th position with biotin (*23*, *28*). The studied peptides (Table 1) at the used concentrations were not toxic in the applied conditions and did not impair the viability of cells, judged by the standard methods for measuring cell viability, using a MTT-based assay and plasma membrane integrity by the LDH leakage assay (data not shown).

Protein Transduction Ability of CPPs Differs. Addition of fluorescein-labeled avidin into the culture medium and incubation for 30 min led to negligible, if any, detectable increase in the fluorescence of HeLa cells (Figure 1a). Coapplication of FITC-labeled avidin with 0.5 μM biotinyl-CPP led to a marked increase in the cells' fluorescence that ranged from about a 10-fold gain with biotinyl-penetratin to a more than a 100-fold rise with biotinyl-transportan (Figure 1a). The effect of biotinyl-derivatives of pTat and pVEC peptides lay between these limits (Figure 1a). Although the total gain of fluorescence intensity widely varied for avidin−FITC complexes with different biotinyl-CPPs, the uptake of each complex is rather uniform, i.e., all cells were labeled and only one cell population was present.

Lowering the incubation temperature from 37 to 4 °C led to a remarkable drop in fluorescence intensity, showing a decreased association/uptake of biotinyl-CPP−avidin complexes with/into cells (Figure 1b). Still, all the cells were stained and the order of potency among the four CPPs was the same as at the physiological temperature. Protein delivery with the Tat peptide was less affected upon lowering the incubation temperature as compared to complexes with the other studied CPPs.

The avidin−biotinyl-CPP complexes loosely bound at the plasma membrane may interfere with the FACS analysis (*13*). After a prolonged trypsin treatment for 15 min, cells incubated with biotinyl-CPP−avidin complexes revealed markedly lower fluorescence intensity, showing that a significant fraction of complexes is still accessible to extracellularly applied trypsin (Figure 1c). The amount of cell-associated protein complexes with biotinyl-penetratin and biotinyl-pVEC was more and complexes with biotinyl-pTat and biotinyl-transportan less affected upon a prolonged trypsin treatment, revealing lower accessibility of the latter to the enzyme. However, the changes induced by prolonged trypsin treatment did not change the principal order of delivery efficiency of the studied CPPs (Figure 1c). Analogous results were obtained with complexes of FITC-labeled streptavidin and the respective CPPs. When the biotin moiety was coupled to the CPP via an aminohexanoic acid spacer, the uptake of avidin complex was identical with the spacer-free biotinyl-CPPs (data not shown).

The avidin−CPP complexes, associated with cells at low temperature, were highly accessible and a substan-

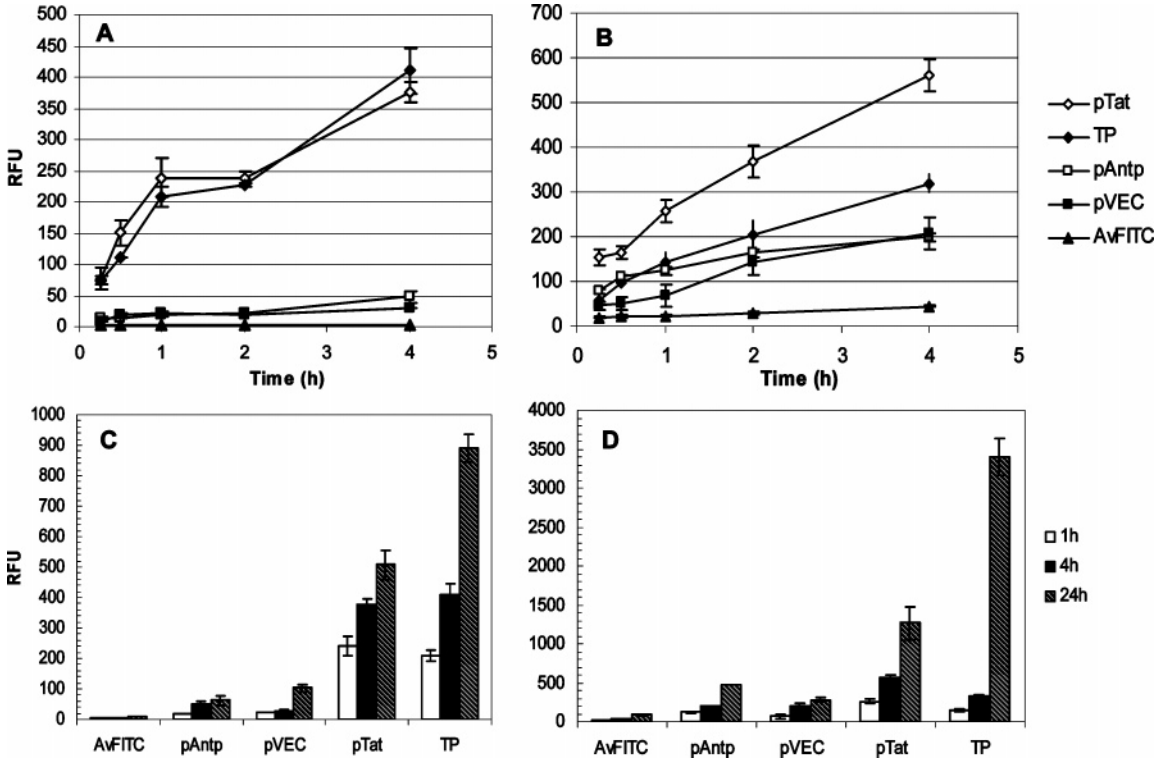

Figure 2. Cell association kinetics of CPP−avidin complexes. HeLa cells were incubated with 0.15 μM FITC-labeled avidin or its complexes with the respective 0.5 μM biotinyl-CPP and fluorescence was measured by FACS (a, c) in live cells or by spectrofluorimetry (b, d) in cell lysates. Association kinetics of complexes during the first 4 h (a, b) and from 1 to 24 h (c, d). Each value is the mean ± SD of three separate determinations. The fluorescence intensity in the cells is expressed as a ratio to the fluorescence of untreated control cells.

tial fraction of complexes was removed by trypsin. The association of avidin complexes with penetratin was more and complexes with pTat less affected in comparison with other peptides. Probably the penetratin−avidin complexes remained loosely bound to the cell surface at low temperatures. Stable association of penetratin−avidin complexes with HeLa cells seems to be more temperature-dependent than that of other studied CPPs.

Lowering of the incubation temperature or the prolongation of trypsin treatment did not cause any detectable increase in the number of cells taking up propidium iodide as compared to untreated control cells (data not shown). Therefore, we believe that the barrier function of the cells plasma membrane was not compromised and the integrity of the cells was not impaired by these treatments.

Uptake Kinetics of CPP−Avidin Complexes. Marked reduction in the fluorescence signal under an extended trypsin treatment implies that after 30 min a substantial fraction of biotinyl-CPP complexes with FITC-labeled avidin are still located on the cell surface. The uptake of complexes was measured in a serum-containing culture medium in order to maintain favorable conditions for cells. Prolongation of incubation time with CPP−avidin complexes from 15 min to 4 h led to a gradual increase in cell-associated fluorescence (Figure 2a).

Analogous time-dependency of internalization was observed for all the biotinyl-CPP complexes studied. However, in the serum-supplemented culture medium the uptake of complexes with transportan was reduced and slightly less efficient than that of Tat complexes.

Although the protein transduction efficiency of the studied CPPs is different, the initial stable association is very fast and already in 15 min a substantial amount of complexes is stably associated with the cells. Cellular fluorescence increases linearly during the first hour. After 2-h incubation a deceleration in the uptake was observed, followed by a new fast increase (Figure 2a), and the internalization of CPP−avidin complexes continued for at least 24 h at this peptide concentration (Figure 2c). Uptake of fluorescein-labeled avidin shows a rather similar time-dependence, though at a markedly lower level. Spectrofluorimetry did not reveal any deceleration in the uptake of fluorescent CPP−avidin complexes after 1 h, but a continuous increase during the first 4 h. While the FACS analysis shows an approximately 10-fold difference in transduction efficiency between the Tat and penetratin peptides, comparison by spectrofluorimetry reveals less than a 3-fold difference after 4 h incubation (Figure 2b). Prolonged incubation of cells with complexes from 4 to 24 h approximately doubles the intracellular concentration of the labeled complex (Figure 2c). Surprisingly, the cellular uptake of transportan−avidin complexes did not slow after 4 h incubation but continued increasing at high speed. Growing accumulation of transportan−avidin complexes in HeLa cells from 4 to 24 h was detected by both, FACS and spectrofluorimetry (Figure 2c, d). Perforation of the plasma membrane and free entrance into cells is not the reason for the observed accumulation since the integrity of cells is not compromised as confirmed by the exclusion of propidium iodide.

Constituents of Serum and Tissue Culture Medium Slightly Modulate the Uptake of CPP−Avidin Complexes. It is usually considered that the cellular uptake of CPPs and their cargoes is reduced in the presence of serum. However, the uptake of CPP−avidin complexes by HeLa cells was more efficient in a serum containing medium and less efficient in PBS (Figure 3). Transportan was an exception, inducing the internalization of a higher amount of avidin in a serum-free than serum containing medium (Figure 3). On the other hand, a less efficient uptake of transportan−avidin complexes

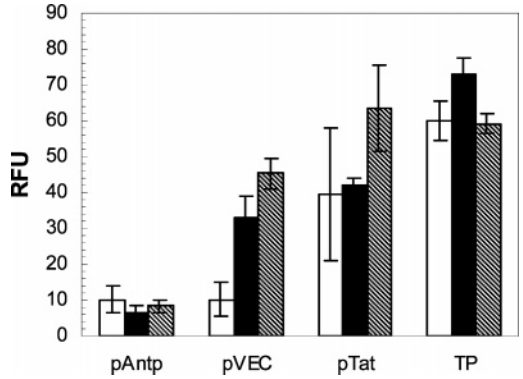

Figure 3. Effect of culture medium on protein cellular uptake. HeLa cells were incubated with complexes of 0.15 μM FITC-labeled avidin with the respective 0.5 μM biotinyl-CPP in PBS (empty bars), serum-free IMDM (black bars), or serum-containing IMDM (striped bars) for 30 min at 37 °C. Fluorescence intensity in the cells is expressed as a ratio to the fluorescence of control cells that were incubated with FITC-labeled avidin.

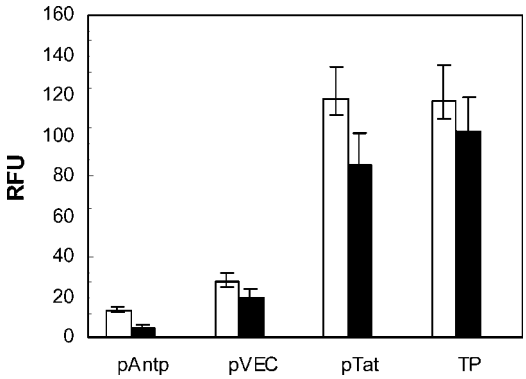

Figure 4. Inhibition of the cellular uptake of CPP−avidin complexes in hyperosmolar cell culture medium. HeLa cells were incubated with 0.15 μM FITC-labeled avidin with the respective 0.5 μM biotinyl-CPPs in isotonic IMDM (empty bars) or hyperosmolar culture medium containing 0.45 M sucrose (black bars).

in the presence of serum was observed only with short incubation times of 15 to 30 min. In less than 1 h the uptake of complexes with transportan was equal both in serum-containing and serum-free media (data not shown). After longer incubations, the internalization of transportan−avidin complexes followed the rule: a higher uptake took place in the presence of serum.

Role of Clathrin-Mediated Endocytosis in the Uptake of CPP−Avidin Complexes. The cellular uptake of FITC-labeled avidin complexed with biotinylated CPPs decreased under hyperosmolar conditions, which inhibits clathrin-dependent endocytosis as compared to a normal isotonic medium. The uptake of avidin complexes formed with penetratin decreased about 3-fold under hyperosmolar conditions, but the uptake could not be completely blocked by inhibiting clathrin-dependent endocytosis (Figure 4). The uptake of pTat-avidin, transportan−avidin, and pVEC−avidin complexes by HeLa cells decreased in the hyperosmolar medium only slightly, about 1.5-fold, pointing at a possible different mode of interaction at the plasma membrane and the internalization pathway for penetratin.

Depletion of Cellular Energy Minimizes the Association of Peptide−Protein Complexes with HeLa Cells. Deprivation of cellular energy strongly impaired the uptake of avidin complexed with any of the four CPPs (Figure 5). Sodium azide inhibited the uptake of CPP−avidin complexes more, reducing the fluorescence signal about 2−5-fold, while the change from glucose to DOG

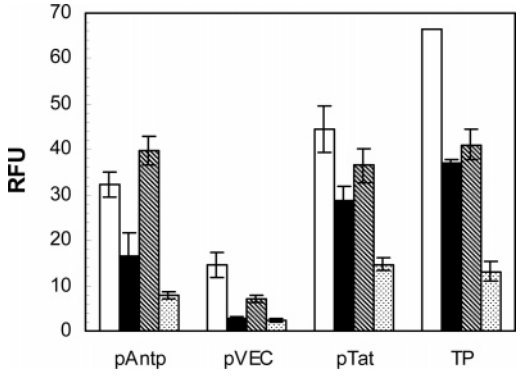

Figure 5. Inhibition of uptake of avidin−CPP complexes by depletion of cellular energy. Uptake in the presence of 0.5% NaN_3 in IMDM (black bars), 25 mM 2-deoxyglucose in PBS (striped bars), or both inhibitors in PBS (dotted bars). Control cells were incubated in IMDM (empty bars). HeLa cells were treated with the respective inhibitors for 30 min at 37 °C, and then the complexes of 0.15 μM FITC-labeled avidin with the respective 0.5 μM biotinyl-CPPs in the same solution were applied and incubated for additional 30 min at 37 °C.

had almost no effect as with penetratin−avidin complexes, or a small inhibitory effect of 1.2−2-fold. Coapplication of inhibitors had an additive effect, and the fluorescence signal associated with the cells was reduced about 3−6-fold, depending on the CPP examined. Identical reduction in the uptake was obtained with 1% sodium azide (i.e., by doubling the concentration) alone. Increase in the DOG concentration from 25 to 50 mM slightly (about 1.5-fold) enhanced its inhibitory effect (not shown). Still, a clearly detectable fraction of CPP−avidin complexes stably associated with cells in the presence of both inhibitors with all the tested peptides. This residual fluorescence could not be eliminated by extensive treatment with trypsin or pronase (not shown).

In the absence of cellular energy, about 2- to 5-fold more FITC-labeled avidin associated with cells when complexed to a biotinyl-CPP than without a carrier peptide. This is in the line with the results obtained at low temperature, suggesting that by energy depletion the stable association of CPPs with the cells was not completely blocked.

Organization of Membrane Lipids is Essential for CPP-Mediated Protein Delivery. Extraction of cholesterol from cells leads to the disappearance of caveolae, flattening of the plasma membrane, and the loss of rafts and abolishes staining with filipin as observed in electron microscopy (*27*). Treatment of HeLa cells with methyl-β-cyclodextrin removed more than 2/3 of cholesterol from the plasma membrane as indicated the staining of cells with filipin. Cholesterol-depleted HeLa cells took CPP−avidin complexes up less avidly than the untreated cells. However, a drop in the uptake of complexes was not uniform for all the four CPPs examined (Figure 6). Uptake of avidin, complexed with penetratin or pVEC decreased about 2-fold, while that of transportan and pTat complexes by only about 20%.

Intracellular Localization of CPP−Avidin Complexes. Incubation of cells with complexes of any used biotinyl-CPP and fluorescently labeled avidin for more than 15 min led to an intense labeling of all cells in the culture as revealed by fluorescence microscopy. The complexes appeared first as punctuate structures on the plasma membrane and of spherical or tubular shape in cortical cytoplasm. Later the complexes shifted more centrally and were detectable also in the perinuclear region of HeLa cells (Figure 7). The punctuate pattern

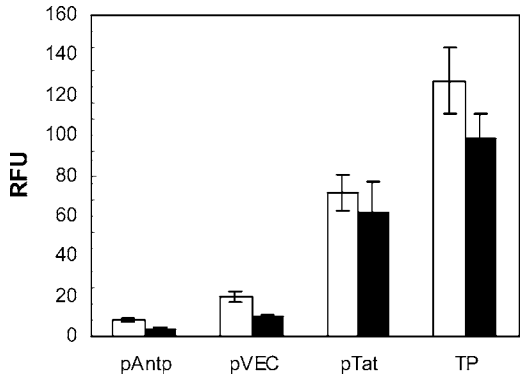

Figure 6. Effect of cholesterol removal from the plasma membrane on the uptake of avidin−CPP complexes. Cholesterol was extracted from the HeLa plasma membranes by incubating cells for 30 min in the medium with 10 mM methyl-β-cyclodextrin. The complexes of 0.15 μM FITC-labeled avidin with the respective 0.5 μM biotinyl-CPPs were applied in the same solution and incubated for additional 30 min at 37 °C. Uptake by cholesterol-depleted HeLa cells (black bars) and control cells (empty bars).

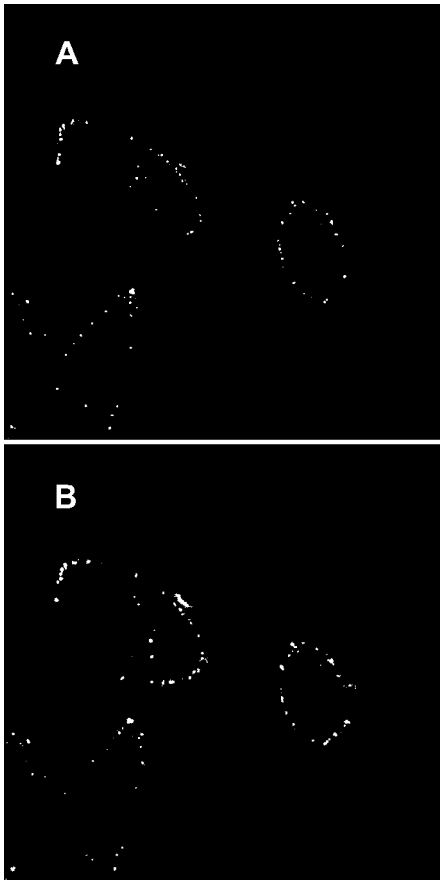

Figure 7. Localization of avidin−FITC complexes with biotinylated transportan in living and fixed HeLa cells. Confocal fluorescence microscopy images of HeLa cells (equatorial view) incubated with 0.5 μM biotinyl-transportan and 0.15 μM avidin−Alexa Fluor 488 for 45 min before (A) and after fixation (B) in 4% paraformaldehyde for 15 min.

of staining of HeLa cells prevailed also after 4 h incubation, suggesting the localization of avidin−CPP complexes mainly in vesicular structures. However, some uniform diffuse staining of cytoplasm was also detectable after at least 30 min incubation.

Distribution of fluorescein-labeled CPPs from the plasma membrane into intracellular structures upon fixation leading to an artifactual staining pattern was demonstrated recently (*12*, *13*, *16*). To study the redistribution, we assessed the localization of fluorescent CPP−avidin complexes in the course of fixation with 4% paraformaldehyde by confocal scanning microscopy during 40 min. No marked redistribution of avidin−CPP complexes upon fixation was observed within this time period (Figure 7a,b).

DISCUSSION

We estimated the ability of different CPPs to target/deliver proteins into cells by following the cellular uptake of fluorescein-labeled avidin complexed with biotinylated peptides by fluorescence microscopy, flow cytometry and spectrofluorimetry. Transduction of fluorescently labeled avidin and/or streptavidin into cells after complexing with biotinylated transportan (*29*), pVEC (*24*), pTat, penetratin (*15*), and proline-rich peptides (*30*) was demonstrated recently. Therefore, instead of synthesizing a multitude of CPP−protein covalent conjugates, we used the complexes of a respective biotinyl-CPP with fluorescein-labeled avidin. Tagging of a peptide with biotin could introduce conformational constraints and interfere with association with avidin or influence the translocation activity. We assumed that biotinylation restrains peptides analogously and all the studied CPPs complexed with fluorescein-labeled avidin and induced its cellular uptake under physiological conditions. The biotin moiety associating a peptide with avidin, on the other hand, may be considered as a spacer reducing constraints posed by a cargo to CPP activity.

Penetratin, pTat, transportan, and pVEC were chosen as representatives of the respective CPP families. The motifs that are considered to be essential for cell penetration are, in general, arginines for pTat (*5*, *31*), positively charged amino acids (*32*) and tryptophan for penetratin (*33*), hydrophobic N-terminal region for pVEC (A. Elmquist personal communication), and the amphipathic carboxyterminal part for transportan (*34*). A multitude of molecular determinants necessary for the cellular uptake of particular peptides suggests that different CPPs may vary in cellular penetration ability (*35*).

The four CPPs studied here were capable of targeting the complexed FITC-labeled avidin to the HeLa cell plasma membrane and inducing cellular uptake. Transportan and pTat were more efficient in the transduction of complexed avidin than penetratin and pVEC. A substantial fraction of CPP−avidin complexes was not internalized but tightly bound extracellularly and removed only by extending trypsin treatment to 15 min. Extensive trypsin treatment affected the amount of cell-bound penetratin−avidin complexes more, implying a slower passage across the plasma membrane into cytoplasm or better accessibility to the enzyme in the plasma membrane. Lower avidin/streptavidin delivery efficiency with biotinyl-penetratin compared to biotinylated Tat peptide has been observed also earlier (*15*). Avidin cargo may introduce conformational constraints on a penetratin and pVEC molecule, leading to a reduced uptake as suggested for a human calcitonin-derived peptide (*36*). On the other hand, the interaction of penetratin and pVEC with the plasma membrane of cells might be more dependent on the concentration of peptide, temperature, and cellular energy. Tryptophan in the sixth position of pAntp has been shown to serve as a membrane anchor and induce cellular transduction (*37*); therefore, higher stiffness of plasma membrane at lower temperatures might impede stable association of penetratin with HeLa cells and subsequent translocation.

The amount of internalized CPP−avidin complexes increased rapidly in physiological conditions during the first 4 h. Spectrofluorimetry showed an about 2−3-fold difference in the transduction potential between pTat and penetratin, whereas the FACS analysis suggested an almost 10-fold difference. Discrepancy between the obtained results could be explained by the sensitivity of fluorescein emission to the microenvironment and partial quenching in the endosomal structures of living cells used for the FACS analysis (*19*). Transportan or pTat might disrupt the acidic vesicular structures and escape into cytoplasm more efficiently than penetratin or pVEC. By analogy, a relative deceleration in the cellular uptake of complexes observed by FACS may also be caused by the translocation of complexes into acidic vesicular structures. The uptake of complexes did not cease after 4 h and continued slowly for three studied peptides for 24 h. Transportan−avidin complexes continued to concentrate intracellularly after 4 h incubation at high speed, suggesting that transportan could stimulate the uptake by modulating intracellular processes without compromising the intactness of cells (*38*).

The lowering of temperature decreases plasma membrane permeability and partially depolarizes the cells leading to a dramatically reduced internalization of CPPs (*14*). CPP-mediated protein cellular delivery decreased even more, suggesting that the uptake process was energy-dependent and the stiffening of the plasma membrane minimized the uptake. About 80−90% of FITC-labeled avidin associated with HeLa cells by biotinyl-CPPs was removed by an extensive trypsin treatment, demonstrating that at low temperature the majority of complexes remained in the plasma membrane and were not internalized. Cellular energy deficiency reduced the uptake of CPP−avidin complexes even more strongly. Still, a small fraction of CPP−protein complexes associated with energy-deficient cells and association took place also at low temperature, suggesting a stable association or uptake. This might imply that the initial interaction of CPPs with the plasma membrane was not dependent on cellular metabolic energy and activity.

All endocytic processes, clathrin-dependent and -independent endocytosis, micro- and macropinocytosis, are blocked at low temperature and in energy-deficient cells (*39*). Hyperosmolar medium, which inhibits clathrin-mediated endocytosis, led to a minor inhibition of the internalization of avidin−CPP complexes, showing a small role of this mechanism in the uptake and a prevalence of other, clathrin-independent endocytic processes. Detergent resistant membrane fractions (DRM) that are rich in cholesterol and sfingolipids form "rafts" and caveolae in the plasma membrane are necessary for clathrin-independent endocytosis to occur (*40*). Caveolae are suggested to mediate Tat-phage internalization into COS-1 cells (*41*) and EGFP fusion proteins with the Tat protein or peptide into HeLa cells (*20*, *21*). On the other hand, it has been recently shown that caveolae are highly immobile plasma membrane microdomains that are not involved in constitutive endocytosis (*42*), and the raft regions might mediate the uptake. Uptake of avidin complexed with the tested CPPs by HeLa cells was strongly impaired after removing cholesterol from the plasma membrane by methyl-β-cyclodextrin. Cell transducible fusion proteins with Tat are suggested to enter HeLa cells by caveolar endocytosis (*20*, *21*) and mouse lymphocytes by macropinocytosis (*22*). Both these processes are cholesterol-dependent and start from lipid rafts. Our data do not enable us to distinguish between these two pathways of cellular uptake. However, in our earlier studies with fixed cells we detected transportan−protein conjugates and complexes at the plasma membrane in structures of various size and volume but not in highly uniform and morphologically defined caveolae.

The potential application of CPP-mediated transport in vivo necessitates knowledge about the influence of serum and other medium constituents on the cellular uptake of particular CPPs. Serum is usually considered to reduce the cellular uptake of CPPs and their cargoes but the protein delivery efficiency of the studied CPPs was slightly enhanced in the presence of serum. Potentiation of cargo delivery by the presence of serum could give CPP-mediated cell transduction an advantage over lipofection, for example, for in vivo use.

In conclusion, all four studied peptides are capable of promoting the cellular delivery of avidin. Although these peptides are classified as cell-penetrating, their protein delivery potential differs substantially. Changes in experimental conditions such as temperature, medium composition and osmolarity, cellular energy, and plasma membrane composition affect protein transduction by these peptides in a rather similar manner. This suggests that the four studied transport peptides could share a common mechanism to promote the cellular uptake by endocytosis. The peptide-mediated cellular transduction of proteins comprises several subsequent steps of binding to the cellular surface, interaction at the plasma membrane, and translocation into and traffic inside the cell. Probably, various interaction modes at the plasma membrane cause most of the observed differences in the internalization efficiency of CPP−protein complexes (*43*, *44*).

ACKNOWLEDGMENT

We are grateful to Dr. U. Soomets for peptide synthesis and discussions. This work was supported by grants from the European Community (QLK3-CT-2002-01989), the Estonian Science Foundation (ESF 4007 and 5588), the Swedish Institute Visby Program, Swedish Royal Academy of Sciences, and Swedish Research Councils TFR and NFR.

Acetals as pH-Sensitive Linkages for Drug Delivery

Elizabeth R. Gillies, Andrew P. Goodwin, and Jean M. J. Fréchet*

Center for New Directions in Organic Synthesis, Department of Chemistry, University of California, Berkeley, California 94720-1460. Received June 24, 2004; Revised Manuscript Received August 11, 2004

pH-Sensitive linkages designed to undergo hydrolysis at mildly acidic pH can trigger the release of therapeutics selectively at targets such as tumor and inflammatory tissues and in the endosomes and lysosomes of cells. Acetals have the potential to be used as linkages for a range of alcohol functionalities, and, by altering their chemical structure, it is possible to tune their hydrolysis rate. The syntheses of four conjugates of model drug molecules with PEO using acetals of varying chemical structure are described herein. Primary and secondary alcohols, as well as syn-1,2-diols, were incorporated in the conjugates. The hydrolysis kinetics were investigated by HPLC, and the conjugates had half-lives ranging from less than 1 min to several days at pH 5.0, with slower hydrolysis at pH 7.4 in all cases. These acetal linkages are therefore promising for use in a variety of drug delivery applications ranging from polymer−drug conjugates to pH-sensitive micelles and nanoparticulate systems.

INTRODUCTION

Research has revealed that numerous pH gradients exist in both normal and pathophysiological conditions. For example, tumor (*1*, *2*) and inflammatory tissue (*3*) have a pH slightly more acidic than the blood and normal tissue. In addition, although the endocytic pathway of cells begins near the physiological pH of 7.4, it drops to a lower pH of 5.5−6.0 in endosomes and approaches pH 4.5−5.0 in lysosomes (*4*). Therefore, pH-responsive systems can potentially be exploited in a broad range of drug delivery applications. It has been shown for example that attachment of anticancer drugs to high molecular weight polymers can significantly improve their solubility, circulation half-lives, and tumor targeting (*5*). However, as the drug is often not active in its conjugated form, it is necessary to design methods to release the drug selectively in tumor tissue or upon uptake of the polymer therapeutic by endocytosis. Furthermore, for the delivery of biomacromolecules such as proteins and DNA that are sensitive to enzymatic degradation in lysosomes, researchers have been working to develop systems that are capable of rapidly releasing biomolecules from mildly acidic endosomes prior to reaching lysosomes (*6*−*8*).

To successfully engineer systems that release therapeutic molecules under the mildly acidic conditions accessible physiologically, it is necessary to have a set of linkages available that can be used with a variety of functional groups and that are responsive to subtle changes in pH. Several acid-sensitive linkages have been tested in recent years for the development of polymer−drug or antibody−drug conjugates. For example, Greenfield and co-workers (*9*, *10*) have investigated various hydrazone linkages for the conjugation of the ketone group of doxorubicin to hydrazides. These hydrazones have also been exploited by several other groups (*11*−*14*). They typically have half-lives of several hours at pH 4.5, depending on the specific structure. *cis*-Aconityl linkages have been used for conjugation of the amino group of doxorubicin onto polymers and antibodies (*15*−*17*). The reported half-life of this linkage is 3 h at pH 4 (*15*). Trityl groups have also been used for the conjugation of amine-containing moieties onto carriers with variable half-lives ranging from 2 to 26 h at pH 5.4 depending on the substitution on the aromatic groups of the trityl linkage (*18*, *19*). Ortho esters have been used for the preparation of acid-sensitive polymers (*20*) and lipids (*21*), and as protein cross-linking agents (*22*).

Acetals are promising candidates for the development of acid-sensitive linkages for hydroxyl groups because their hydrolysis is generally first order relative to the hydronium ion, making the expected rate of hydrolysis 10 times faster with each unit of pH decrease (*23*). In addition, acetals can be formed using a variety of types of hydroxyl groups including primary, secondary, tertiary, and syn-1,2- and -1,3-diols, and the rate of hydrolysis can be tuned by varying the structure of the acetal. Despite this, there are only a few reports of acetals applied as protein cross-linking agents (*22*, *24*) and as pH-sensitive protecting groups masking anticancer drug activity (*25*−*27*). Therefore, the goal of this work is to broadly explore the usefulness of acetals as pH-sensitive linkages for drug delivery. In particular, we are interested in developing methods for the conjugation of drug hydroxyl groups to polymers. Here we report the design, synthesis, and hydrolysis studies of four different acetal-based conjugates using model drugs and polymers. These conjugates are composed of various acetal structures, different types of alcohol groups and display a broad range of hydrolysis rates at mildly acidic pH.

MATERIALS AND METHODS

General Procedures and Materials. Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. THF was distilled from Na/benzophenone, and CH_2Cl_2 and pyridine were distilled from CaH_2 prior to use. NMR chemical shifts are reported in ppm and calibrated against residual solvent signals of $CDCl_3$ (δ 7.26, 77.2). All coupling constants are reported in Hz. For NMR spectra of compounds containing acid-sensitive groups, the $CDCl_3$

was dried and neutralized by filtering over activated basic alumina immediately prior to use. FT-IR spectroscopic analyses were performed using a thin film from CH_2Cl_2 on a reflective mirror surface and are reported in cm^{-1}. FAB mass spectrometry was performed at the UC Berkeley Mass Spectrometry Facilities. MALDI-TOF MS was performed on a Voyager-DE from PerSeptive Biosystems using *trans*-3-indoleacrylic acid as a matrix. Elemental analyses were performed at the UC Berkeley Micro-Mass Facilities.

5-Hydroxymethyldihydrofuran-2-one (2). Pentenoic acid (4.0 g, 1.0 equiv, 40 mmol) was added to a stirring biphasic mixture of 30% hydrogen peroxide (6.3 mL, 1.4 equiv, 56 mmol) in water, 125 mL of chloroform, and methyltrioxorhenium (VII) (0.30 g, 0.03 equiv, 1.2 mmol). The reaction was stirred at room temperature for 40 h, during which time the yellow solution became colorless. A saturated solution of sodium carbonate in water (50 mL) was added, and the aqueous layer was extracted with chloroform/2-propanol (1:1). The organic layers were dried with $MgSO_4$, filtered, and evaporated yielding 4.1 g (89%) of **2** as a colorless oil. Spectral data agreed with those previously reported in the literature (*28*).

Benzoic Acid 5-Oxotetrahydrofuran-2-ylmethyl Ester (3). Benzoyl chloride (0.79 g, 1.2 equiv, 5.6 mmol) was added to a solution of **2** (0.54 g, 1.0 equiv, 4.7 mmol) in dry pyridine (8 mL) at 0 °C. The mixture was stirred at room temperature for 30 min and then heated at reflux for 90 min. The solution was then diluted with CH_2Cl_2 and washed twice with 1 M $NaHSO_4$, twice with a 10% Na_2CO_3, and then saturated brine. The organic layers were dried with $MgSO_4$, filtered, and evaporated. The resulting product was diluted with dichloromethane and filtered through a silica gel plug. Evaporation of the solvent provided 0.92 g (89%) of **3** as a colorless oil. Spectral data agreed with those previously reported in the literature (*29*).

Benzoic Acid 5-Methoxytetrahydrofuran-2-ylmethyl Ester (4). A solution of **3** (0.52 g, 2.4 mmol) in 6 mL of dry THF was cooled to −78 °C, and then 4.25 mL of 1 M diisobutylaluminum hydride in hexane was added dropwise over 1 h with the temperature not exceeding −70 °C. The reaction mixture was stirred for 30 min, and then water was added slowly to the mixture until bubbling ceased followed by 2 mL of 6 M HCl to dissolve solids. The product was warmed to room temperature and extracted twice with diethyl ether. The ether solution was dried over $MgSO_4$, filtered, and evaporated. Immediately, the colorless liquid was dissolved in a 0.2% solution of HCl in methanol and stirred for 30 min. The solution was neutralized by addition of a 5% solution of KOH in methanol and then concentrated in vacuo. The product was taken up in benzene, filtered, and concentrated again. The residue was then purified via silica gel chromatography using hexane/ethyl acetate (19:1) as an eluent to yield 0.78 g (68%) of **4** as a mixture of cis and trans diastereomers (approximately 1:1) as a colorless oil. Spectral data agreed with those previously reported in the literature (*30*).

4-Nitrophenyl Carbonate-Activated PEO (7). Poly(ethylene glycol) monomethyl ether (**6**) (2.0 g, 1.0 equiv, 1.0 mmol) with a peak MW of 2100 according to MALDI-TOF MS was dissolved in 20 mL of dry CH_2Cl_2. Dry pyridine (0.64 mL, 8.0 equiv, 8.0 mmol) was added, followed by 4-nitrophenyl chloroformate (0.80 g, 4.0 equiv, 4.0 mmol). The reaction mixture was stirred at room temperature overnight and then precipitated into 200 mL of diethyl ether two times. The product was dissolved in benzene, pyridinium salts were filtered off, and the resulting solution was precipitated again into diethyl ether to provide 1.5 g (75%) of **7** as a white powder. IR: 3115, 3075, 1767, 1510. ^1H NMR (500 MHz, $CDCl_3$): δ 3.29 (s, 3H), 3.56 (br s, 190H), 4.35−4.37 (m, 2H), 7.30−7.37 (m, 2H), 8.19−8.22 (m, 2H). MS calcd for $[M]^+$ based on the peak MW of the starting material: 2266. Found: (MALDI-TOF MS): 2266.

Tetrahydrofuranylmethyl Acetal-Activated PEO (8). Acetal **4** (0.15 g, 0.64 mmol) was added to a 1.0 wt % solution of KOH in methanol and the solution stirred at room temperature for 1 h. The methanol was removed gently under vacuum, and the resulting oil was partitioned between dichloromethane and water. The aqueous layer was extracted with CH_2Cl_2, and the combined organic layers were dried over $MgSO_4$, filtered, and evaporated. Without further purification, the oil (**5**) (75 mg, 1.5 equiv, 0.57 mmol) was dissolved in 3 mL of dry CH_2Cl_2. To this solution were added carbonate **7** (0.82 g, 1.0 equiv, 0.38 mmol) and *N*,*N*-dimethyl-4-aminopyridine (0.66 g, 1.4 equiv, 0.54 mmol). The solution was stirred at room temperature for 72 h, and then the product was precipitated into cold diethyl ether providing 0.68 g (83%) of **8** as a mixture of cis and trans diastereomers (approximately 1:1) as a white powder. IR: 1746. ^1H NMR (500 MHz, $CDCl_3$): δ 1.55−2.08 (m, 4), 3.24 (s, 2H), 3.26 (s, 1H), 3.30 (s, 3H), 3.41−3.74 (m, 190H), 4.01−4.13 (m, 2H), 4.20−4.27 (m, 4H), 4.91 (br d, 0.4H, J = 4.5), 4.97 (br d, 0.6H, J = 4.5). MS calcd for $[M + Na]^+$ based on the peak MW of the starting material: 2282. Found: (MALDI-TOF MS): 2284.

Podophyllotoxin−PEO Acetal Conjugate (10). Podophyllotoxin (**9**) (30 mg, 72 μmol) and **8** (0.12 g, 56 μmol) were dissolved in 1 mL of dry toluene. The solution was heated to 110 °C, and then *p*-toluenesulfonic acid (0.50 mg, 0.05 equiv, 3.0 μmol) was added. The mixture was stirred for 3 h at 110 °C with a distillation head for azeotropic removal of methanol, and then the reaction was quenched by addition of 100 μL of NEt_3. The solvent was removed in vacuo, and the resulting solid was purified by silica gel chromatography using ethyl acetate/methanol (80:20) with 2% NEt_3 as an eluent to yield 0.11 g (80%) of **10** as a mixture of stereoisomers as a white powder. IR: 3510, 1775, 1747. ^1H NMR (400 MHz, $CDCl_3$): δ 1.58−2.28 (m, 4), 2.68−2.82 (m, 1), 2.97−3.09 (m, 1), 3.30−3.78 (m, 400), 3.98−4.25 (m, 8), 4.40−4.59 (m, 2), 4.80−5.44 (m, 1), 5.88−5.95 (m, 2), 6.32 (d, 2, J = 4), 6.44 (d, 1, J = 4), 6.82−7.27 (m, 1). MS calcd for $[M + Na]^+$ based on the peak MW of the starting material: 2664. Found: (MALDI-TOF MS): 2665.

2-(7-Methoxyoct-6-enyl)-isoindole-1,3-dione (14). A suspension of the phosphonium salt **12**, prepared as previously reported (*31*) (0.45 g, 1.5 equiv, 1.3 mmol) in 5 mL of dry THF, was cooled to −43 °C under nitrogen in a dry ice/acetonitrile bath. 0.52 mL (1.0 equiv, 0.84 mmol) of a 1.6 M solution of ^{n}BuLi in hexanes was added dropwise resulting in a deep red color. The reaction mixture was stirred at −43 °C for 1 h, and then a solution of 6-bromohexanal (**11**) (*32*) (0.15 g, 1.0 equiv, 0.84 mmol) in 2.5 mL of dry THF was added. The reaction mixture was stirred for 10 min before allowing it to come to room temperature. It was then diluted with diethyl ether and extracted with water, and the aqueous layer was extracted two times with diethyl ether. The ether layers were combined and dried with $MgSO_4$, filtered, and evaporated. The crude product was partially purified by silica gel chromatography using hexanes with 2% triethylamine as an eluent to provide 136 mg of the enol ether **13** containing a triphenylphosphine impurity. The

product was taken to the next step without further purification.

The enol ether was dissolved in 1 mL of DMF, and potassium phthalimide (0.34 g, 3.0 equiv, 1.8 mmol) was added. The reaction mixture was stirred at room temperature overnight and then was diluted with CH_2Cl_2 and washed with water to remove DMF. The organic phase was dried with $MgSO_4$ and then evaporated. The resulting material was purified by silica gel chromatography using hexanes/ethyl acetate (95:5) with 2% triethylamine as an eluent to provide 155 mg (27% yield over two steps) of **14** as a mixture of *E* and *Z* stereoisomers (approximately 1:1) as a colorless oil. IR: 1772, 1710, 1615. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.33−1.38 (m, 4H), 1.62−1.67 (m, 2H), 1.73 (s, 1.6H), 1.77 (s, 1.4H), 1.92−2.06 (m, 2H), 3.44 (s, 1.6H), 3.50 (s, 1.4H), 3.63−3.68 (m, 2H), 4.31 (t, 0.6H, J = 7.3 Hz), 4.36 (td, 0.4H, J = 1.0, 7.2), 7.67−7.72 (m, 2H), 7.79−7.84 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 16.2, 17.5, 24.5, 26.4, 26.6, 26.8, 28.6, 29.6, 30.5, 38.1, 38.2, 54.0, 55.7, 96.4, 108.4, 123.2, 123.3, 132.29, 132.31, 133.9, 134.0, 151.1, 153.4, 168.5. MS calcd $[M]^+$ ($C_{17}H_{21}NO_3$): 287. Found: (FABLR) 287. Anal. Calcd for $C_{17}H_{21}NO_3$: C, 71.06; H, 7.37; N, 4.87. Found: C, 70.85; H, 7.24; N, 4.86.

5-Flouro-2′-deoxyuridine Acetal Conjugate (16). 5-Fluoro-2′-deoxyuridine **15** (10 mg, 1.0 equiv, 40 μmol) and the enol ether **14** were dissolved in dry THF and 100 μL of a 3.5 mg/mL solution of *p*-toluenesulfonic acid were added. The reaction was stirred at room temperature for 15 min and then quenched with 100 μL of NEt_3. The solvent was evaporated and the product was purified by silica gel chromatography using CH_2Cl_2 with 2% MeOH and 2% NEt_3 as an eluent and then again using EtOAc with 2% MeOH and 2% NEt_3 to provide 11 mg (50%) of the acetal **16** as a mixture of diastereomers (approximately 1:1) along with a small amount of triethylamine salt. IR: 3444, 3200, 3064, 1770, 1711. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.32−1.36 (m, 9H), 1.62−1.73 (m, 4H), 2.19−2.25 (m, 1H), 2.43−2.48 (m, 1H), 3.21 (s, 3H), 3.61−3.74 (m, 4H), 4.14−4.17 (m, 1H), 4.51−4.59 (m, 1H), 6.36 (t, 1H, J = 6.2), 7.71−7.74 (m, 2H), 7.84−7.86 (m, 2H), 8.24 (d, 1H, J = 6.4). ^{13}C NMR (100 MHz, $CDCl_3$): δ 14.4, 15.0, 21.3, 21.5, 23.9, 24.2, 26.7, 26.8, 28.3, 28.5, 29.1, 29.4, 36.8, 36.9, 38.0, 38.1, 41.5, 45.9, 48.7, 59.9, 60.1, 71.5, 71.8, 85.7, 86.4, 102.7, 123.4, 123.5, 124.8 (d, J = 34), 132.2, 132.3, 134.1, 134.2, 140.8 (d, J = 238 Hz), 149.1, 149.2, 157.2 (d, J = 27), 168.7, 168.9. MS calcd $[M + H]^+$ ($C_{26}H_{32}FN_3O_8$): 534. Found: (FABLR) 534.

5-Flouro-2′-deoxyuridine−PEO Acetal Conjugate (18). The phthalimide **16** (22 mg, 41 μmol) was dissolved in 5 mL of 0.2 M hydrazine in MeOH containing 0.1 mL of NEt_3. The reaction was stirred at room temperature overnight, and then the volatile compounds were removed under vacuum. Without further purification, the resulting amine **17** (1.5 equiv) was combined with **7** (60 mg, 1.0 equiv, 28μmol), *N*,*N*-(dimethylamino)pyridine (1.0 mg, 0.30 equiv, 8.3 μmol) and NEt_3 (4.5 mg, 1.6 equiv, 44 μmol) in 2 mL of 1:1 Benzene/DMF and the reaction was stirred at room temperature overnight. The solvents were then removed under vacuum and the product was purified by silica gel chromatography using CH_2Cl_2 containing 2% MeOH and 2% NEt_3 as an eluent to provide 30 mg (45%) of **18** as a glassy solid. IR: 3335, 1707, 1522, 1466. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.26−1.33 (m, 11H), 1.56−1.68 (m, 2H), 2.11−2.17 (m, 1H), 2.37−2.44 (m, 1H), 3.18 (s, 3H), 3.35 (s, 3H), 3.51−3.53 (m, 2H), 3.62 (br s, 190H), 4.09−4.12 (m, 2H), 4.13−4.18 (m, 2H), 4.46−4.49 (m, 1H), 4.93−5.01 (m, 0.5H), 5.08−5.14 (m, 0.5H), 5.53 (s, 1H), 6.216.31 (m, 1H), 8.18−8.27 (m, 1H). MS calcd for $[M]^+$ based on the peak MW of the starting material: 2530. Found: (MALDI TOF MS): 2529.

2-(7-Methoxyhept-6-enyl)isoindole-1,3-dione (21). This enol ether was prepared using the same procedure as for the preparation of **14**, except that (methoxymethyl)-triphenylphosphonium chloride (**19**) was used in place of **12** to provide **21** (33% over 2 steps) as a mixture of *E* and *Z* stereoisomers (approximately 1:1) as a colorless oil. IR: 3468, 3033, 1773, 1710, 1653, 1617. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.28−1.39 (m, 4H), 1.60−1.70 (m, 2H), 1.89−1.92 (m, 1H), 2.00−2.06 (m, 1H), 3.48 (s, 1.5 H), 3.56 (s, 1.5 H), 3.67 (t, 2H, J = 7.5), 4.31 (dd, 0.5 H, J = 7.3, 13.8), 4.66−4.72 (m, 0.5H), 5.85 (d, 0.5H, J = 6.0), 6.26 (d, 0.5 H, J = 13.0), 7.69−7.71 (m, 2H), 7.82−7.84 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 23.6, 26.1, 26.4, 27.4, 28.35, 28.40, 29.2, 30.2, 37.9, 38.1, 55.8, 59.4, 102.7, 106.5, 123.08, 123.10, 132.11, 132.13, 133.77, 133.80, 146.2, 147.1, 168.4. MS calcd $[M + H]^+$ ($C_{16}H_{20}NO_3$): 274. Found: (FABLR) 274. Anal. Calcd for $C_{16}H_{19}NO_3$: C, 70.31; H, 7.01; N, 5.13. Found: C, 70.13; H, 7.19; N, 5.00%.

Tri(ethylene glycol)-Derivatized Estradiol (24). Estradiol (**22**) (0.30 g, 1.1 mmol, 1.0 equiv) was dissolved in 5 mL of DMF, and the chloride **23** (*33*) (0.30 g, 1.7 mmol, 1.5 equiv) was added followed by K_2CO_3 (0.30 g, 2.2 mmol, 2.0 equiv) and a catalytic amount of KI. The reaction mixture was heated at 110 °C overnight, cooled, diluted with CH_2Cl_2, and washed three times with 0.1 M NaOH. The organic phase was dried with $MgSO_4$, filtered, and evaporated. The product was purified by silica gel chromatography using a gradient from 70:30 to 50:50 hexanes/ethyl acetate to provide 0.26 g (57%) of **24** as a colorless oil. IR: 3460, 1725, 1607, 1500. ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.76 (s, 3H), 1.13−1.20 (m, 1H), 1.24−1.51 (m, 7H), 1.64−1.72 (m, 1H), 1.79 (s, 1H), 1.84−1.88 (m, 1H), 1.91−1.95 (m, 1H), 2.05−2.12 (m, 1H), 2.13−2.18 (m, 1H), 2.27−2.31 (m, 1H), 2.78−2.88 (m, 2H), 3.37 (s, 3H), 3.53−3.55 (m, 2H), 3.64−3.74 (m, 7H), 3.83 (t, 2H, J = 4.8), 4.09 (t, 2H, J = 5.0), 6.63 (d, 1H, J = 2.5), 6.70 (dd, 1H, J = 2.5, 8.5), 7.17 (d, 1H, J = 8.5). ^{13}C NMR (125 MHz, $CDCl_3$): δ 11.2, 23.2, 26.4, 27.4, 29.9, 30.6, 36.8, 38.9, 43.3, 44.0, 50.1, 59.1, 67.4, 69.9, 70.7, 70.8, 70.9, 72.0, 81.9, 112.2, 114.7, 126.4, 132.9, 138.0, 156.7. MS calcd $[M + H]^+$ ($C_{25}H_{39}O_5$): 419. Found: (FABLR) 419. Anal. Calcd for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.40; H, 9.39%.

Estradiol Acetal Conjugate (25). Estradiol derivative **24** (115 mg, 0.28 mmol, 1.0 equiv) and enol ether **21** (150 mg, 0.55 mmol, 2.0 equiv) were dissolved in dry THF, and *p*-toluenesulfonic acid (5.0 mg, 0.030 mmol, 0.1 equiv) was added. The reaction mixture was stirred at room temperature overnight under nitrogen and then quenched by addition of 100 μL of NEt_3. The solvent was evaporated, and then the product was purified by silica gel chromatography using gradient from 90:8:2 to 70:28:2 hexanes/ethyl acetate/triethylamine to provide 80 mg (42%) of **25** as a mixture of diastereomers (approximately 1:1) as a colorless oil. IR: 3030, 1770, 1712, 1614. ^{1}H NMR (500 MHz, $CDCl_3$): δ 0.78 (s, 3H), 1.13−1.19 (m, 1H), 1.24−1.69 (m, 18H), 1.83−1.86 (m, 1H), 1.89−1.94 (m, 1H), 1.97−2.03 (m, 2H), 2.13−2.17 (m, 1H), 2.23−2.27 (m, 1H), 2.78−2.88 (m, 2H), 3.27 (s, 1.5 H), 3.29 (s, 1.5 H), 3.37 (s, 3H), 3.53−3.55 (m, 2H), 3.57−3.67 (m, 7H), 3.71−3.73 (m, 2H), 3.82 (t, 2H, J = 5.0), 4.09 (t, 2H, J = 5.0), 4.43 (t, 0.5H, J = 5.5), 4.46 (t, 0.5H, J = 5.5), 6.62 (d, 1H, J = 2.5), 6.69 (d, 1H, J = 8.8), 7.16 (dd, 1H, J = 2.5, 8.8), 7.68−7.70 (m, 2H), 7.81−7.84 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 23.2, 23.3, 24.7, 24.9, 26.4, 26.9, 27.3, 27.4, 28.2, 28.7, 28.9, 29.19, 29.25, 29.9, 33.6,

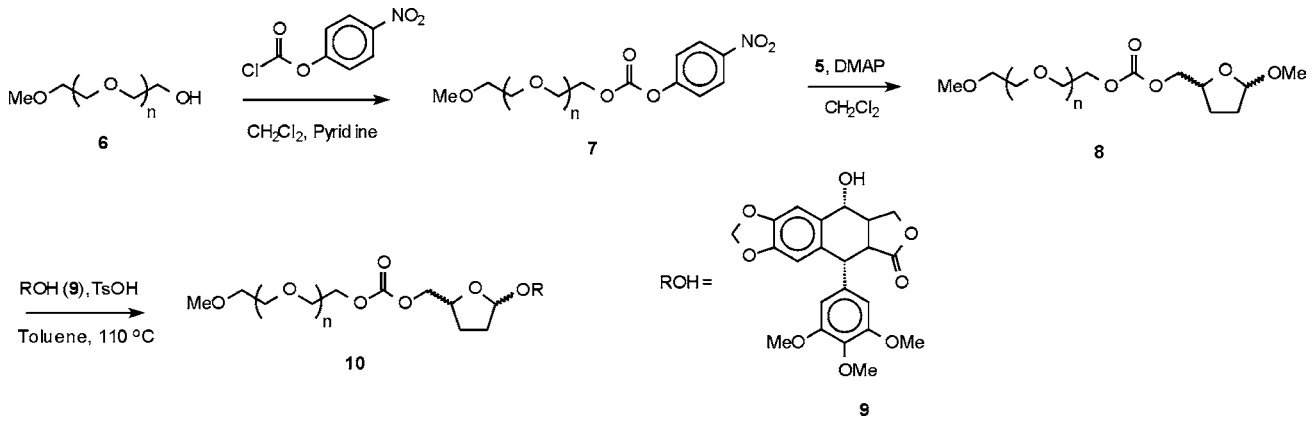
5-Fluorouridine Acetal Conjugate (31). The aldehyde **29** (91 mg, 1.0 equiv, 0.19 mmol) was dissolved in 5 mL of dry THF, and 5-fluorouridine (**30**) (100 mg, 2.0 equiv, 0.38 mmol) was added, followed by 1.5 g of 5 Å molecular sieves and *p*-toluenesulfonic acid (10 mg, 0.30 equiv, 57 μmol). The reaction was stirred at room temperature overnight and then quenched with 100 μL of NEt_3. The reaction mixture was filtered, and the filtrate was evaporated. The resulting product was purified by silica gel chromatography using a gradient from EtOAc with 2% NEt_3 to EtOAc/MeOH (95:5) with 2% NEt_3 to provide 76 mg (58%) of **31** as a mixture of diastereomers (approximately 1:1) along with a small amount of triethylamine salt. IR: 3490, 3233, 3065, 1770, 1720, 1608, 1592. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.28−1.37 (m, 6H), 1.37−1.45 (m, 2H), 1.61 (m, 2H), 1.68 (m, 2H), 3.65 (t, 2H, J = 7.5), 3.76 (s, 3H), 3.78−3.86 (m, 4H), 3.87−3.98 (m, 3H), 4.26−4.29 (m, 0.5H), 4.50−4.53 (m, 0.5H), 4.83−4.88 (m, 1H), 4.96 (dd, 0.5 H, J = 6.0, 2.5), 5.10 (t, 0.5H, J = 5.3), 6.06 (s, 1H), 5.76 (d, 0.5 H, J = 2.5), 6.06 (s, 1H), 6.08 (s, 1H), 6.14 (d, 0.5 H, J = 2.0 Hz), 6.52 (s, 0.5H), 6.75 (s, 0.5H), 7.67−7.69 (m, 2.5H), 7.80−7.84 (m, 2.5H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 26.0, 26.9, 28.7, 29.2, 29.3, 29.2, 38.1, 55.9, 56.1, 62.5, 63.0, 64.6, 68.1, 70.6, 80.2, 81.7, 83.9, 84.3, 84.8, 86.1, 91.5, 91.6, 93.6, 100.3, 102.7, 102.9, 104.5, 123.3, 126.5 (d, J = 34), 126.7 (d, J = 34), 132.22, 134.1, 140.6 (d, J = 235), 149.5, 149.7, 157.7 (d, J = 26), 157.6 (d, J = 26), 160.6, 160.9, 162.2, 162.5, 168.7. MS calcd $[M + H]^+$ ($C_{34}H_{38}N_3O_{11}F$): 684. Found: (FABLR) 684.

5-Fluorouridine−PEO Acetal Conjugate (32). The same procedure was used as for the preparation of **18** to provide **32** (68%) as a glassy solid. IR: 3515, 3068, 1711, 1671, 1592. ^{1}H NMR (500 MHz, $CDCl_3$): δ 1.25−1.48 (m, 10H), 1.71−1.77 (m, 2H), 3.06−3.14 (m, 2H), 3.35 (s, 3H), 3.51−3.54 (m, 2H), 3.62 (br s, 200H), 3.73−3.85 (m, 8H), 3.88−3.98 (m, 2H), 4.16−4.19 (m, 2H), 4.27−4.30 (m, 0.5H), 4.52−4.54 (m, 0.5H), 4.84−4.91 (m, 1H), 4.94 (dd, 0.5H, J = 6.0, 3.0), 5.07−5.09 (m,0.5H), 5.81 (d, 0.5H, J = 1.0), 6.06 (s, 1H), 6.09 (s, 1H), 6.18 (s, 0.5H), 6.53 (s, 0.5H), 6.77 (s, 0.5H), 7.77 (d, 0.5H, J = 6.0), 7.91 (d, 0.5H, J = 6.0). MS calcd for $[M + Na]^+$ based on the peak MW of the starting material: 2704. Found: (MALDI TOF MS): 2705.



Determination of the Hydrolysis Rate for Conjugate 18. For determination of the hydrolysis rate at pH 7.4, a solution of conjugate **18** (25 μg/mL drug equiv) was incubated in 10 mM pH 7.4 phosphate buffer at 37 °C. Aliquots were removed at time points ranging from 10 min to 8 h, and the extent of hydrolysis was determined by HPLC. For determination of the hydrolysis rate at pH 5.0, a solution of conjugate **18** (250 μg/mL) was incubated in 10 mM pH 5.0 acetate buffer at 37 °C. At time points ranging from 30 s to 1 h, aliquots were removed and the hydrolysis was slowed by 10-fold dilution with 10 mM pH 7.4 buffer, followed by freezing at −4 °C. Following completion of the hydrolysis, the samples were thawed one at a time and the extent of hydrolysis was determined by HPLC. HPLC was performed at 25 °C on an Agilent 1100 series HPLC system (Agilent Technologies, Palo Alto, CA) equipped with a diode array detector and an Eclipse XDB−C8 column (4.6 × 150 mm, Agilent Technologies). The injection volume was 50 μL, the flow rate was 1 mL/min, and a gradient from 10 mM pH 7.4 phosphate buffer in H_2O to buffer/acetonitrile (35:65) over 5 min. was used as the eluent. Detection was by absorbance at 270 nm, and the % hydrolysis was determined using peak area. Errors on peak area measurements were about ±4%.

Determination of the Hydrolysis Rate for Conjugate 26. **26** was dissolved in 10 mM pH 7.4 (phosphate) or pH 5.0 (acetate) buffer at a concentration of 0.5 mg/mL drug equiv and one Eppendorf tube containing 100 μL of solution was prepared for each time point. At the desired time point, 100 μL of CH_3CN was added to the solution to dissolve any released estradiol derivative that had precipitated. The extent of hydrolysis was deter-

Scheme 1

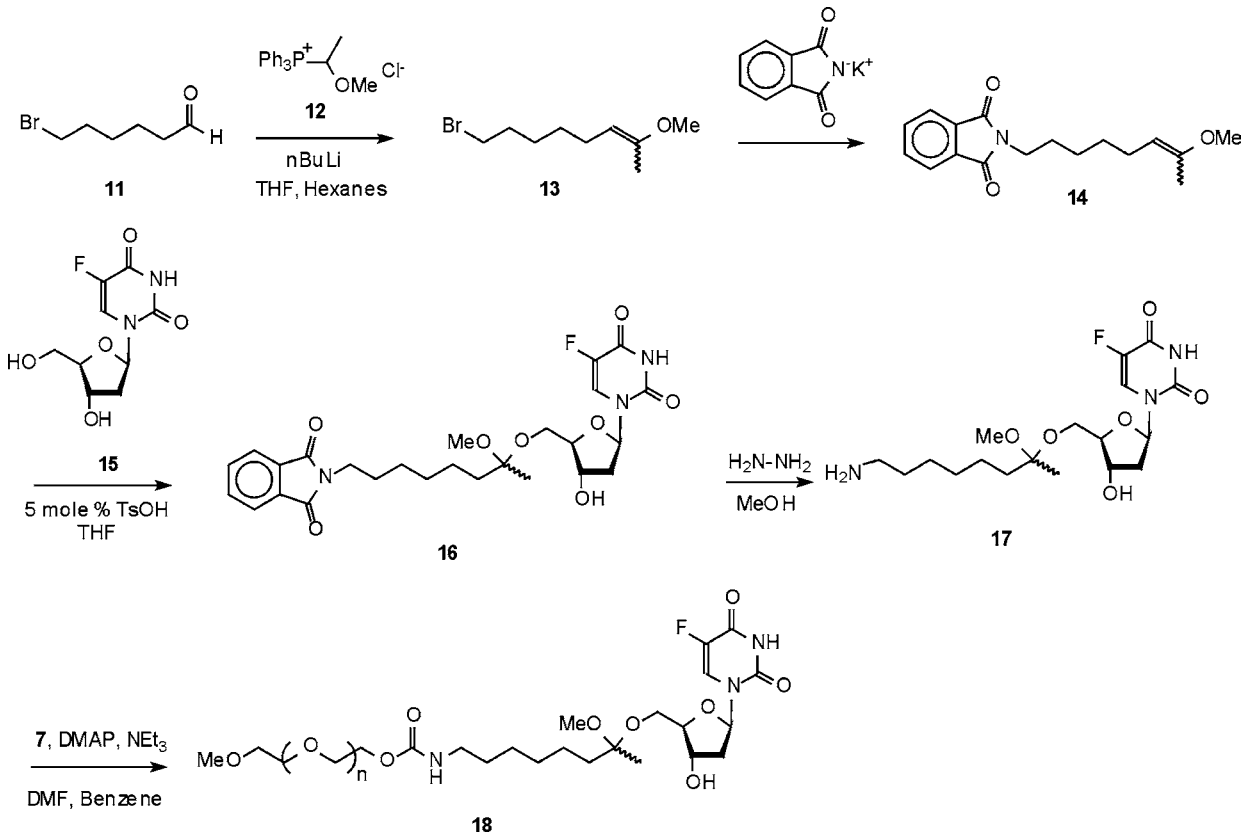
Scheme 2

mined by HPLC as described above but using a gradient from MeOH/water (80:20) to 100% MeOH over 4 min, and detection was at 280 nm.

Determination of the Hydrolysis Rate for Conjugate 32. The hydrolysis rate for the 5-fluorouridine conjugate **32** was determined at pH 7.4 and pH 5.0 by HPLC using the same method used for **18** at pH 7.4.

RESULTS AND DISCUSSION

Design and Synthesis. The design of acetal linkages sensitive to mildly acidic conditions is facilitated by the fact that acetals are commonly used protecting groups for alcohols in organic synthesis, and their hydrolysis rates have generally been well studied and reported in the literature (*35*). However, whereas protecting groups are simply capping agents, a pH-sensitive linkage used to conjugate a polymer with a drug must be bifunctional. Thus one goal of this work was to select promising acetal candidates and to develop synthetic methods that accommodate the required bifunctional character of the linkage in order to achieve orthogonal coupling to drug on one side and polymer on the other.



Our initial investigation of tetrahydrofuranyl (THF) acetals as drug linkages was motivated by reports in the literature of a half-life of 75 min for a THF-protected secondary alcohol at pH 5.0 and 20 °C (*36*). We proposed that acetals of this structure could be adapted for polymer conjugation by introduction of a functional handle on the 5 position of the furan ring. Thus, the synthesis of this linkage was initiated by the cyclization of 4-pentenoic acid **1** to the lactone **2** via rhenium(VII)-catalyzed oxidation as shown in Scheme 1. The free alcohol was then protected by esterification to form the benzoate **3** (Scheme 1). The lactone was reduced to the hemiacetal, which, following removal of solvent, was treated immediately with acidic methanol to provide methyl acetal **4** in an approximately 1:1 cis:trans ratio according to ^{1}H NMR spectroscopy. The benzoate could then be saponified under basic conditions to give the alcohol **5**, which was used directly in the polymer coupling step due to its relatively high volatility.

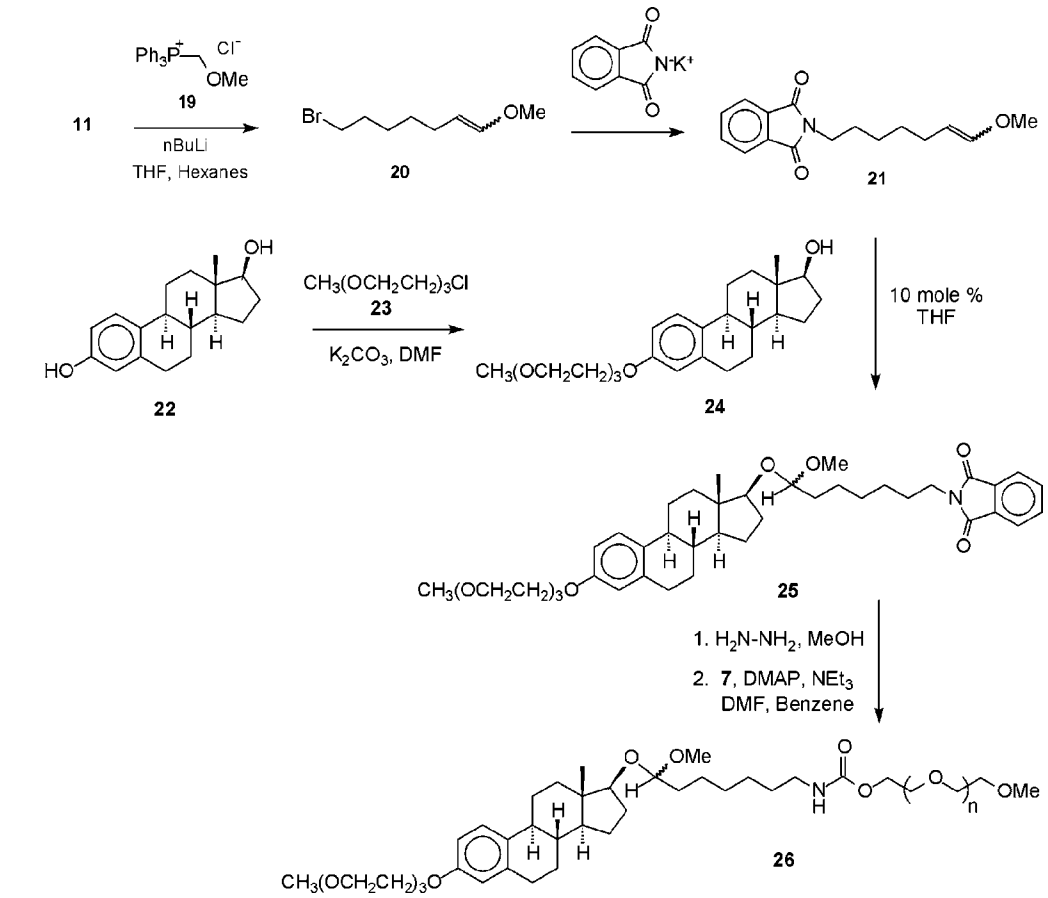
Poly(ethylene oxide) (PEO) was chosen as a model polymer because of its high water solubility and its extensive use in drug delivery applications (*37*). Poly(ethylene glycol) monomethyl ether (MW 2000 g/mol) (**6**) was first functionalized by addition of 4-nitrophenyl chloroformate to form the activated carbonate **7** as shown in Scheme 2. This carbonate could then be reacted with **5** in the presence of 4-(dimethylamino)pyridine (DMAP) to give **8**. Podophyllotoxin (**9**), an anticancer drug precursor having a secondary alcohol, was chosen as a model drug for attachment to the linker. Acid-catalyzed transacetalization conditions were employed with azeotropic removal of methanol from the reaction mixture to afford **10** as a mixture of diastereomers. The identity of **10** was confirmed by NMR spectroscopy, using comparisons with both starting materials, and by MALDI-TOF MS. Although multiple peaks exist in the mass spectrum of **10** due to the initial polydispersity of the starting PEO, end group analysis of various peaks by mass difference from the starting material, as well as a shift in the peak MW from the starting material, verifies the presence of the linkage and drug on the polymer.

The next target linkage was pursued based on literature reports of the rapid hydrolysis rates of acetals of aliphatic ketones such as acetone (*38*). Therefore, an acetal derived from acetone and a primary alcohol is expected to hydrolyze very rapidly with a half-life of about 90 s at pH 5.0 and 6 h at pH 7.4 at 25 °C. Such a fast hydrolyzing acetal would be most applicable to systems where targeting to tissues such as the tumors is quite rapid, and it should be possible to release the drug even at the very mildly acidic extracellular tumor pH.

The synthesis of this highly acid-sensitive linkage began with conversion of 6-bromohexanal **11** (*32*) to the enol ether **13** by a Wittig reaction using the phosphonium salt **12** (*31*) as shown in Scheme 3. The bromide was subsequently converted to a phthalimide by reaction with potassium phthalimide to provide **14**, containing a masked amine group for coupling to the polymer. The anticancer compound 5-fluoro-2′-deoxyuridine (**15**) was then conjugated to **14** by acid-catalyzed electrophilic addition to the enol ether to form the acetal **16** with selective reaction of the primary alcohol over the secondary alcohol of the drug. Two diastereomers of the acetal were produced in

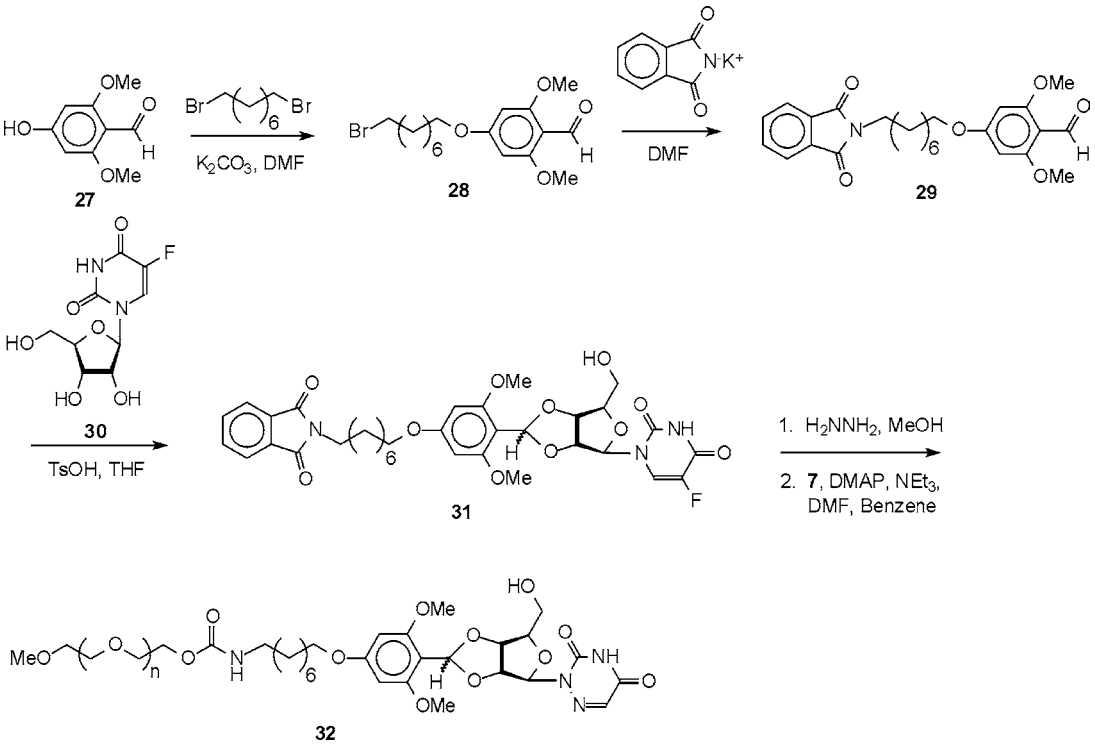
Scheme 3

approximately a 1:1 ratio according to ^{1}H NMR spectroscopy. The phthalimide protecting group was then removed by treatment with hydrazine in MeOH containing 2% NEt_3 to give an amine **17** which was reacted with the activated polymer **7** to provide the desired conjugate **18**. The identity of the compound was verified by NMR spectroscopy and MALDI-TOF MS as for conjugate **11**. The fact that the drug was stable to the phthalimide deprotection and polymer conjugation conditions was verified by liberation of the free drug from an acidic D_2O solution and comparison of the ^{1}H NMR spectrum with that of an authentic sample of 5-fluoro-2′-dexoyuridine.



Because of the absence of the second electron-donating methyl group to stabilize the carbocation intermediate during hydrolysis, acetals of aldehydes generally hydrolyze much more slowly than those of ketones. For example, based on previous work, an acetal obtained from acetaldehyde and primary alcohols is expected to have a hydrolysis half-life of about 100 h at pH 5.0 and about 3 years at pH 7.4. (*38*). Therefore, such acetals could be useful for applications where stability over prolonged period at pH 7.4 is required. In addition, as acetals with structure **18** are too unstable to be used for the conjugation of secondary alcohols, it was hypothesized that the use of this more stable acetal might be useful for secondary alcohols and may show increased hydrolysis rates relative to those reported for primary alcohols.

To prepare this class of acetals, the enol ether **21** was prepared by a synthetic route (Scheme 4) analogous to that used for the preparation of **14**. To prepare a model drug having a secondary alcohol, the phenol of estradiol **22** was reacted with chloride **23** (*33*) to provide **24**. A tri(ethylene glycol) monomethyl ether moiety was introduced both to protect the phenol from interfering in the coupling of the secondary alcohol and also to provide enhanced water solubility to the product, a feature that would be beneficial in the subsequent kinetic study. The secondary alcohol of **24** was then smoothly conjugated to enol ether **21** in the presence of acid to provide the acetal **25** as a mixture of two diastereomers (approximately 1:1). The phthalmide protecting group was then removed, and the resulting amine was conjugated to **7** to provide the target acetal **26**.



To demonstrate the versatility of acetals in the development of pH-sensitive linkages, we were also interested in preparing sensitive cyclic acetals from syn-1,2- and -1,3-diols. However, cyclic acetals based on five- and six-membered rings are known to hydrolyze very slowly relative to their acyclic counterparts (*23*). In previous work we have prepared cyclic benzylidene acetals from 1,3-diols and have found that introduction of electron-donating methoxy groups in the 2, 4, and 6 positions of the aromatic rings accelerates the rate of hydrolysis to provide a half-life of 1 h at pH 5.0 and several days at pH 7.4 (*39*). Therefore, we were interested in exploring the use of this type of cyclic acetal to prepare polymer−drug conjugates.

The synthesis of a cyclic acetal conjugate was initiated by reaction of 2,6-dimethoxy-4-hydroxybenzaldehyde (**27**) with excess 1,8-dibromooctane to provide **28**, and then the bromide was converted to a phthalimide group by reaction with potassium phthalimide, giving **29** as shown in Scheme 5. The anticancer compound 5-fluorouridine (**30**) was selected as a model drug containing a syn-1,2 diol and was converted to the cyclic acetal **31** by reaction with the aldehyde **29** in dry THF containing catalytic *p*-toluenesulfonic acid and 5 Å molecular sieves. Both cis- and trans-diastereomers were produced in approximately a 1:1 ratio. After removal of the phthalimide protecting group, the amine was coupled to the activated polymer **7** to provide the target **32**. As for all previous conjugates, the identity of this conjugate was verified by NMR and MALDI-TOF MS.

Scheme 5

Determination of Acetal Hydrolysis Rates. The hydrolysis of the podophyllotoxin−PEO conjugate **10** was initially investigated by ^{1}H NMR at pH 5.0 using an acetate buffer in D_2O. Surprisingly, after 24 h at 37 °C, the NMR spectrum still showed unchanged conjugate, and no peaks corresponding to the free drug were observed. In addition, no free drug was observed by TLC after the same time period. After 11 h, a very small amount of hydrolysis was observed by TLC at pH 4.0 and somewhat more at pH 3.0, but the acetal was clearly too stable to undergo hydrolysis under the mildly acidic conditions accessible physiologically. The discrepancy

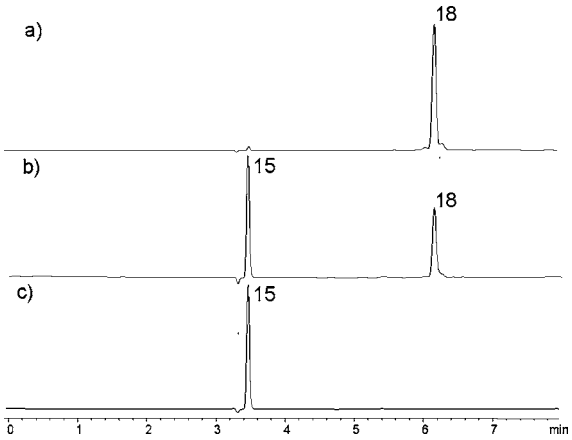

Figure 1. HPLC chromatograms of (a) conjugate **18** prior to hydrolysis; (b) conjugate **18** after 1 min. at pH 5.0; (c) 5-fluoro-2′-deoxyuridine (**15**).

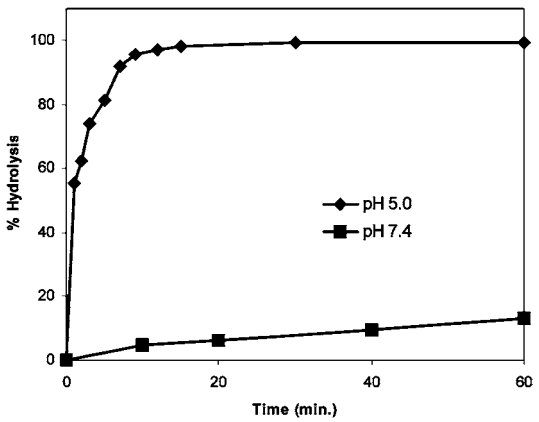

Figure 2. Hydrolysis rates for conjugate **18** at pH 5.0 and pH 7.4.

between these results and those previously reported in the literature may be due to the fact that the previous kinetic studies were performed in 1:1 THF/H_2O with HCl added to adjust to pH 5.0 (*36*). It is possible that these conditions do not extrapolate appropriately to a fully aqueous buffer system.

After initial verification by NMR spectroscopy that conjugate **18** underwent substantial hydrolysis at pH 5.0 after 10 min to afford free 5-fluoro-2′-deoxyuridine (**15**), a more detailed HPLC study of the hydrolysis rate was undertaken. Samples of **18** were dissolved in aqueous buffers of pH 7.4 and pH 5.0 and were incubated at 37 °C. Aliquots of the sample at pH 7.4 were withdrawn and directly injected into the HPLC instrument. Due to the very rapid rate of hydrolysis at pH 5.0 relative to the time required for the HPLC separation, aliquots at pH 5.0 were first neutralized by dilution with pH 7.4 buffer and then frozen until HPLC injection to prevent undesired hydrolysis prior to chromatographic analysis. An HPLC chromatogram of conjugate **18** and its hydrolysis products after 1 min at pH 5.0 is compared to a chromatogram of free drug **15** in Figure 1. Chromatographic analysis confirms that intact drug is indeed released upon hydrolysis, and that the hydrolysis rate is rapid at pH 5.0 with a half-life of less than 1 min. A comparison of the hydrolysis rates at pH 7.4 and pH 5.0 is shown in Figure 2. The results indicate that hydrolysis is nearly complete at pH 5.0 after 20 min, whereas at pH 7.4 less than 15% hydrolysis had occurred after 1 h. The observed hydrolysis rate is therefore consistent with that previously reported for acetals of similar structure (*38*).

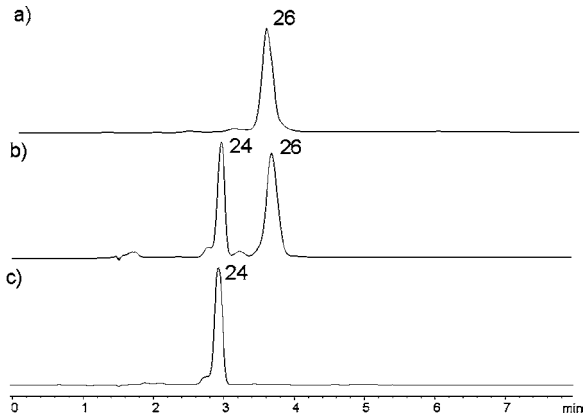

Figure 3. HPLC chromatograms of (a) conjugate **26** prior to hydrolysis; (b) conjugate **26** after 70 h at pH 5.0; (c) estradiol derivative **24**.

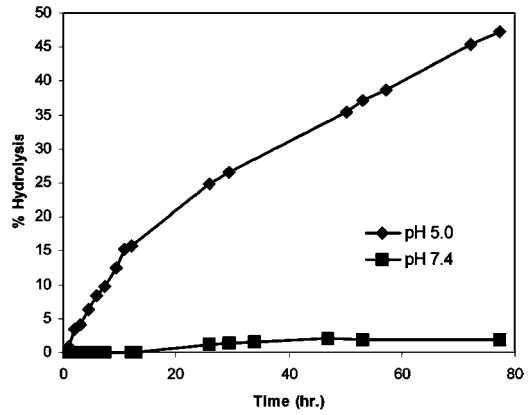

Figure 4. Hydrolysis rates for conjugate **26** at pH 5.0 and pH 7.4.

The hydrolysis of acetal **26** at pH 5.0 and 7.4 at 37 °C was also investigated by HPLC. In Figure 3, HPLC chromatograms of conjugate **26** prior to hydrolysis and after 70 h at pH 5.0 are compared to that of the estradiol derivative **24**, illustrating the gradual release of the model drug. A comparison of the hydrolysis rates at pH 7.4 and pH 5.0, as shown in Figure 4 illustrates that only a negligible amount of hydrolysis occurs at pH 7.4 over 80 h, while at pH 5.0 the half-life was found to be 88 ± 3 h. These results are also close to those reported in the literature for acetals of acetaldehyde with primary alcohols (*38*), and this work therefore shows that the rate of hydrolysis of these acetals is not significantly accelerated by conjugation of secondary rather than primary alcohols. This may be explained by the lack of steric hindrance, a factor that may contribute to accelerating the hydrolysis of other secondary alcohol derivatives.

HPLC chromatograms of the cyclic acetal conjugate **32** prior to hydrolysis, **32** after 7 h at pH 5.0 and 37 °C, and of a pure sample of 5-fluorouridine (**30**) are shown in Figure 5, and a comparison of the hydrolysis rates at pH 7.4 and pH 5.0 is shown in Figure 6. At pH 5.0, more than 70% of the drug is released after 30 h., while at pH 7.4, less than 2% of the drug is released over the same time period. A half-life of 17.6 ± 0.4 h at pH 5.0 and on the order of weeks at pH 7.4 was determined using the kinetic data. Interestingly, the hydrolysis rate of this five-membered ring cyclic acetal is significantly slower than that of the six-membered ring analogues formed from 1,3-diols such as serinol and 1,1,1-tris(hydroxymethyl)ethane that we have previously investigated (*39*). Presumably, this is due to entropic reasons associated with the five-

membered ring and also because, for this system, free rotation about the carbon−carbon bond between alcohol groups is not permitted, in contrast to the situation that prevailed with previously investigated systems.

CONCLUSIONS

Acetals of varying chemical structure were investigated for their potential as pH-sensitive linkages in drug delivery applications. Several conjugates of model drug molecules with PEO were successfully prepared, illustrating that acetals can be applied for the conjugation of primary and secondary alcohols as well as diols. The hydrolysis rates were investigated by HPLC and half-lives ranging from less than 1 minute to several days at pH 5.0 were determined for the conjugates. In each case the conjugates showed significantly higher stability at pH 7.4. These acetals can therefore be applied as polymer−drug linkages in a variety of drug delivery applications, ranging from situations where rapid hydrolysis is desired in mildly acidic endosomes or tumor tissue to those where high stability at neutral pH accompanied by gradual drug release at acidic pH is necessary. In addition, these acetals can potentially be applied to the development of other pH-sensitive systems including micelles and nanoparticles designed to undergo pH dependent release of low MW drugs as well as proteins and DNA.

Tumor-directed drug delivery is a promising strategy in cancer treatment, and in this field, monoclonal antibodies constitute an important class of targeting vehicles. A critical issue in the design of targeting conjugates is the timing of the release of the cytotoxic payload, with the ideal situation being the release at the maximum tumor uptake of the targeting molecule. A site-specific radiolabeling technique was used to elucidate the biodistribution and in vivo drug release pattern of an antibody conjugate of paclitaxel (PTX, **1**, Figure 1) in which the drug and the antibody moieties were connected by a succinate (SX) linker. In this new method, a metabolite of PTX, 3′-(4-hydroxyphenyl)paclitaxel (3′-OH-PTX, **2**, Figure 1) was used as a tyrosine mimic for the synthesis of the drug site-labeled conjugate (DSL, [^{125}I]-3′-OH-PTXSXC225). This was achieved by iodogen ^{125}I-labeling of 3′-OH-PTXSX and subsequent conjugation to C225. The antibody site-labeled conjugate (ASL, PTXSX-[^{125}I]-C225) was prepared by direct radioiodination of PTXSXC225. Biodistribution of these compounds was studied in *Balb/c* nude mice bearing DU-145 human prostate carcinoma xenografts. While the 4 and 24 h tumor uptake (in percent injected dose per gram of tissue, %ID/g) for [^{125}I]-3′-OH-PTXSXC225 were 3.3 ± 1.5 and 1.7 ± 0.6%ID/g, the PTXSX–[^{125}I]-C225 showed tumor uptake values of 3.8 ± 4.2 and 14.8 ± 4.2%ID/g at these time points. This difference in the tumor uptake over time indicates an early cleavage of the drug with respect to the antibody tumor localization. This was further confirmed by an in vitro drug release kinetics study leading to a half-life of about 2 h for PTXSXC225 under physiological conditions. To increase the stability of the PTX–MAb bond, a new conjugate (PTXGLC225) with glutaric acid (GL) as the linker was synthesized. Under the same conditions, the PTXGLC225 showed a 16-fold increase in the half-life ($t_{1/2}$) of the drug release. The effect of the increased $t_{1/2}$ of this compound on the antitumor activity of the conjugate was tested in a DU-145 human prostate tumor-implanted mouse model. In comparison to a previous similar experiment with PTXSXC225, better antitumor activity was observed for the PTXGLC225 conjugate as compared to controls. These results demonstrated the first time use of radioiodinated 3′-OH-PTX for in vivo tracing of a paclitaxel conjugate and application of the resulting information to the design of a therapeutically more useful PTX–MAb linker.

INTRODUCTION

Monoclonal antibodies (MAbs)[2] are being utilized in tumor-targeted cancer treatment due to the potential of this strategy for efficient and specific delivery of tumoricidal agents (*1*–*5*). MAb-mediated targeted drug delivery usually involves covalent conjugation of the antitumor agent to the MAb with the latter to guide the construct for tumor localization (*6*–*8*). The benefits of this targeted strategy are expected to be 2-fold: Enhancing the antitumor efficacy of the drug due to its targeted, tumor-specific delivery, and ameliorating the systemic toxicity and side-effects due to the possibilities of reduced dosing.

These seemingly straightforward expectations could not, however, be taken for granted, as important hurdles may be encountered in practice. Two important issues to be considered in the design of drug-delivering conjugates are the in vivo rate of the release of the drug from the conjugate, and the tissue distribution pattern prior to that release. An early and premature release of the drug will result in lowered or totally compromised drug efficacy. This may be particularly true of conjugates with large molecular weights such as antibodies. The observed maximum tumor uptake time for an IgG monoclonal antibody has been reported to be over 24 h (*9*−*12*). The drug segment of a conjugate intended for tumor targeting, and released within a narrower time window, therefore, will have a smaller chance of being delivered tumor-specifically. Lowered drug efficacies may be also experienced if the drug has too slow a cleavage mechanism, that is, release of the drug after the peak tumor uptake period and after the catabolism and clearance of the antibody. The latter scenario would be particularly harmful to the performance of *prodrug* conjugates, compounds in which the native drug will resume full antitumor efficacy only after cleavage from the tumor-targeting vehicle (*13*−*16*). Information on the in vivo behavior of a drug−MAb conjugate in terms of the rate of the release of the drug and the extent of tissue uptake of the targeting molecule may be, therefore, of critical importance in the design of conjugates with intended therapeutic applications. We have previously reported the synthesis and biological evaluation of conjugates of PTX to a bombesin receptor-recognizing peptide, and to the anti-EGFR MAb C225 (*17*−*19*), in which succinic acid was used as the drug−MAb linker. Improved cytotoxicities were observed for PTX in these conjugates as compared to its free, "untargeted" form in both types of conjugates. However, while compared to untreated control both C225 and PTXSXC225 showed higher antitumor activity, there was no significant advantage between C225 and the conjugate. We hypothesized that one reason could be an untimely in vivo release of the drug as a result of the low stability of the succinate linker (*19*). The aim of the present study was to design more in-depth in vitro and in vivo experiments to test this hypothesis and to compile information for the development of PTX−MAb conjugates suitable for therapeutic applications. Accordingly, comparative drug release and biodistribution studies were conducted with succinate- and glutarate-linked PTXC225 conjugates leading to the selection of the latter linker for further antitumor activity experiments. In this report, we describe the results of this investigation.

EXPERIMENTAL PROCEDURES

General. The paclitaxel-2′-*mono*-succinate (PTXSX) and -glutarate (PTXGL) were prepared according to the procedure of Deutsch et al. (22) with slight modifications as described in Results and Discussion. 3′-(4-Hydroxyphenyl)paclitaxel and C225 (Erbitux) were donated as gifts by Tapestry Pharmaceuticals, Inc. (Boulder, CO) and ImClone Systems (New York, NY), respectively. Amino poly(ethyleneglycol) carboxylate was purchased from Nektar (Huntsville, AL). [^{14}C]-2′-Benzoylpaclitaxel (50 μCi) and sodium [^{125}I]-iodide were obtained from Moravek Biochemicals (Brea, CA) and NEN Life Sciences (Boston, MA), respectively. Gel filtration chromatography was performed in PD-10 Sephadex G-25 M columns (Amersham Pharmacia AB, Uppsala, Sweden) equilibrated and eluted with phosphate-buffered saline (PBS, 10 mM, pH 6.5). Taxol was supplied by Bristol-Myers Squibb (Princeton, NJ). Radioactivity monitoring was carried out in Packard (Shelton, CT) Minaxi-Gamma (5000 Series) gamma and Packard (Meriden, CT) TRI-CARB 1900 TR scintillation counters. HPLC analyses were performed with a Beckman System Gold instrument consisting of a SG 125 solvent module and a SG 166 UV/vis detector, operated by Beckman 32 Karat Version 5.0 software. Analytical UV/radiodetected HPLC experiments used a Bio-Rad (Hercules, CA) Model 2800 solvent delivery system operated by Bio-Rad ValueChrome software and a UV-1806 UV/vis detector connected in series to a Beckman Model 170 radioisotope detector. Reversed-phase (RP) HPLC used either a 4.6 × 250 mm C18 column (Vydac, Hesperia, CA) for analytical separations or a Vydac 10 × 250 mm C18 column for semipreparative separations. Columns were eluted with 0.1% TFA/water (solvent A) and a 10% to 90% gradient of 0.1:60:40, TFA: CH_3CN:H_2O (v/v) (solvent B). Retention times (t_R) in minutes are reported for each compound, with the corresponding percent purities in parentheses. For analytical SE-HPLC, a 7.5 mm × 25 cm G3000SW column (TosoHaas, Montgomeryville, PA) was used. A 10 mM PBS containing 10 mM Na_2SO_4 at pH 6.7 was used as solvent. Sep-Pak C18 cartridges were obtained from Waters (Milford, MA). Mass spectra in ES mode were recorded either on an API VI triple quadruple mass spectrometer (PE-Sciex, Toronto, Ontario) or Micromass Platform LCZ mass spectrometer (Beverly, MA). MALDI MS were analyzed in the positive mode on a Voyager Elite mass spectrometer with delayed extraction technology (PerSeptive Biosystems, Framingham, MA). Sinapinic acid was used as matrix, and samples were prepared in a 50:50 (v/v) mixture of 0.1% TFA/acetonitrile. A 1 pmol/L solution of bovine serum albumin was added as an internal standard. NMR spectra were acquired on a Varian Inova 600, operating at 599.7 MHz for ^{1}H and at 150.8 MHz for ^{13}C, or a Bruker DRX-500, operating at 500.13 MHz for ^{1}H and at 125.78 MHz for ^{13}C. Female *Balb/c* nude mice were obtained from the National Cancer Institute Frederick Research laboratory (Frederick, MD). Procedures to minimize discomfort, pain, and distress were in accord with the Animal Resource Program at the University of Alabama at Birmingham, accredited by the American Association for Accreditation of Laboratory Animal Care.

3′-(4-Hydroxyphenyl)paclitaxel-2′-succinate (3′-OH-PTXSX). 3′-(4-Hydroxyphenyl)paclitaxel (76.3 mg, 87.7 μmol) and succinic anhydride (52.6 mg, 526.2 μmol) were dissolved in dry pyridine (1.5 mL), and the solution was kept at room temperature and under argon for 10 h. TLC of the reaction mixture (10:90, methanol:chloroform, v/v) showed complete disappearance of the starting material and formation of a new compound. The solvent was distilled off in high vacuum, and the residue was purified in a silica gel column using chloroform and a

0% to 3% methanol gradient to afford the pure 3′-OH-PTXSX as a white crystalline solid (72 mg, 84.6%). RP-HPLC t_R: 23.3 min (98%); ^{1}H NMR ($CDCl_3$, 599.7 MHz): 1.13 (s, 3H), 1.22 (s, 3H), 1.68 (s, 3H), 1.88 (m, 1H), 1.91 (s, 3H), 2.22 (s, 3H), 2.25 (m, 1H), 2.38 (m, 1H), 2.39 (s, 3H), 2.55 (m, 1H), 2.72−2.62 (m, 2H), 2.74 (br, 2H), 3.79 (d, J = 7.0 Hz, 1H), 4.20 (AB, J = 7.0 Hz, 1H), 4.31 (AB, J = 7.0 Hz, 1H), 4.42 (dd, J = 6.7, 10.8 Hz, 1H), 4.99 (dd, J = 1.8, 9.5 Hz, 1H), 5.58 (d, J = 3.0 Hz, 1H), 5.69 (d, J = 7.0 Hz, 1H), 5.90 (dd, J = 3.0, 9.1 Hz, 1H), 6.24 (br t, J = 8.7 Hz, 1H), 6.29 (s, 1H), 6.75 (d, J = 8.5 Hz, 2H), 7.03 (d, J = 9.1 Hz, 1H), 7.16 (d, J = 8.5 Hz, 2H), 7.41 (t, J = 7.7 Hz, 2H), 7.50 (t, J = 7.7 Hz, 1H), 7.50 (t, J = 7.7 Hz, 2H), 7.60 (t, J = 7.7 Hz, 1H), 7.75 (d, J = 9.0 Hz, 2H), 8.13 (d, J = 7.3 Hz, 2H). ^{13}C NMR (150.8 MHz): 9.66, 14.89, 20.84, 22.05, 22.61, 26.87, 28.72, 28.96, 35.54, 35.57, 43.14, 45.67, 52.25, 58.54, 71.93, 72.19, 74.19, 75.05, 75.64, 76.46, 79.11, 81.24, 84.37, 115.90 (2C), 127.17 (2C), 127.93 (2C), 128.31, 128.76 (2C), 128.78 (2C), 129.14, 130.22 (2C), 132.12, 132.88, 133.44, 133.73, 142.68, 156.16, 167.03, 167.44, 168.13, 170.31, 171.32, 171.37, 174.6, 203.72. ESMS: *m/z* 971 $(M + H)^+$.

[^{125}I]-3′-OH-PTXSX. The iodogen method (*20, 21*) was used with slight modification. Briefly, 3′-OH-PTXSX was dissolved in DMF and the solution was mixed with 200 mM PBS at pH 7.6. Poly(styrene) beads coated with iodogen (1,3,4,6-tetrachloro-3a,6a-diphenylglyguril, IODOGEN, Pierce, Rockford, IL), and Na [^{125}I]-I (500 μCi) were added, and the mixture was shaken at room temperature for 10 min after which time it was diluted with 400 μL of 200 mM ammonium acetate buffer (pH 4.2). The mixture was loaded in a C18 Sep-Pak cartridge, prewashed sequentially with 3 mL each $H_2O/CH_3CN/H_2O$. The cartridge was washed with the acetate buffer (2 mL) and water (2 mL) and was eluted with 6 × 500 μL fractions of CH_3CN. Radioactivity of the eluted fractions was measured in a gamma counter. Fractions 1 and 2 showed 98.5% of the loaded activity. These were pooled and used for conjugation to C225 as described in the general procedure above.

PTXSX-[^{125}I]-C225. The indogen bead procedure was used. A solution of the conjugate (100 μL, 500 mg/mL) was mixed with 400 μL PBS (200 mM, pH 7.6) and iodogen beads (4/mg of the conjugate) were added. A solution of Na [^{125}I]-I (1.5 mCi) in 0.1 M sodium hydroxide (5 μL) was added, and the mixture was gently shaken for 5 min. The labeled conjugate was purified by gel filtration chromatography using a PD-10 column, eluted with 10 mM PBS, pH 6.5. This procedure afforded the PTX−[^{125}I]-C225 conjugate with a specific activity of 2 mCi/mg.

Iodo-3′-OH-PTXSX. Iodogen (0.22 mg, 0.51 μmol) was dissolved in methylene chloride (500 μL) in a poly(propylene) centrifuge tube, and the solvent was evaporated under argon and was replaced with 400 μL of phosphate buffer (50 mM, pH 7.3). With stirring, a solution of 3′-OH-PTXSX (3.8 mg, 3.9 μmol) in DMF (20 μL) was added followed by the addition of 8 × 3.5 μL of a solution of sodium iodide (2.0 mg, 13.3 μmol) in water, which developed a light yellow color. The addition of NaI was done over a period of 8 h in approximately 1 h intervals. The heterogeneous mixture was stirred vigorously at room temperature, and the reaction progress was monitored by analytical RP-HPLC. Formation of two new compounds was observed with gradual fading of the yellow color. The new products, as well as the unreacted starting material 3′-OH-PTXSX, were separated and purified by RP-HPLC using solvents A and B. This procedure afforded 1.2 mg and 0.37 mg of *mono*-iodo-3′-OH-PTXSX (28%) and *di*-iodo-3′-OH-PTXSX (7.7%), respectively.

3′-(4-Hydroxy-3-iodophenyl)paclitaxel-2′-succinate. RP-HPLC t_R: 25.1 min (96%); ^{1}H NMR ($CDCl_3$, 599.7 MHz): 1.13 (s, 3H), 1.23 (s, 3H), 1.68 (s, 3H), 1.89 (m, 1H), 1.92 (s, 3H), 2.19 (m, 1H), 2.23 (s, 3H), 2.34 (dd, J = 9.3, 15.3 Hz, 1H), 2.43 (s, 3H), 2.56 (m, 1H), 2.82−2.68 (m, 4H), 3.80 (d, J = 7.0 Hz, 1H), 4.19 (AB, J = 7.0 Hz, 1H), 4.32 (AB, J = 7.0 Hz, 1H), 4.42 (dd, J = 6.7, 10.8 Hz, 1H), 4.98 (dd, J = 1.8, 9.5 Hz, 1H), 5.47 (d, J = 3.0 Hz, 1H), 5.68 (d, J = 7.0 Hz, 1H), 5.85 (dd, J = 3.0, 9.1 Hz, 1H), 6.23 (br t, J = 8.7 Hz, 1H), 6.29 (s, 1H), 6.94 (d, J = 8.5 Hz, 1H), 7.02 (d, J = 9.1 Hz, 1H), 7.24 (dd, J = 2.0, 8.5 Hz, 2H), 7.42 (t, J = 7.7 Hz, 2H), 7.53 (t, J = 7.7 Hz, 1H), 7.53 (t, J = 7.7 Hz, 2H), 7.61 (t, J = 7.7 Hz, 1H), 7.67 (d, J = 2.0 Hz, 1H), 7.77 (d, J = 9.0 Hz, 2H), 8.13 (d, J = 7.3 Hz, 2H). ^{13}C NMR (150.8 MHz): 9.83, 15.05, 21.06, 22.27, 22.88, 27.07, 28.67, 29.11, 35.73, 35.78, 43.42, 45.84, 52.01, 58.73, 72.27, 72.41, 74.40, 75.24, 75.79, 76.68, 79.35, 81.41, 84.63, 86.04, 115.71, 127.44 (2C), 128.67, 128.99 (2C), 129.01 (2C), 129.31, 130.45 (2C), 131.11, 132.47, 133.13, 133.45, 133.98, 136.98, 142.76, 155.47, 167.30, 167.53, 167.98, 170.22, 171.33, 171.52, 174.74, 203.92. ESMS: *m/z* 1097 $(M + H)^+$.

3′-(4-Hydroxy-3,5-diiodophenyl)paclitaxel-2′-succinate. RP-HPLC t_R: 26.6 min (95%); ^{1}H NMR ($CDCl_3$, 599.7 MHz): 1.13 (s, 3H), 1.22 (s, 3H), 1.67 (s, 3H), 1.88 (m, 1H), 1.91 (s, 3H), 2.16 (m, 1H), 2.23 (s, 3H), 2.32 (dd, J = 9.3, 15.3 Hz, 1H), 2.45 (s, 3H), 2.56 (m, 1H), 2.82−2.68 (m, 4H), 3.79 (d, J = 7.0 Hz, 1H), 4.20 (AB, J = 7.0 Hz, 1H), 4.33 (AB, J = 7.0 Hz, 1H), 4.43 (dd, J = 6.7, 10.8 Hz, 1H), 4.98 (dd, J = 1.8, 9.5 Hz, 1H), 5.39 (d, J = 3.0 Hz, 1H), 5.68 (d, J = 7.0 Hz, 1H), 5.78 (dd, J = 3.0, 9.1 Hz, 1H), 5.84 (br, 1H), 6.23 (br t, J = 8.7 Hz, 1H), 6.29 (s, 1H), 7.02 (d, J = 9.1 Hz, 1H), 7.43 (t, J = 7.7 Hz, 2H), 7.52 (t, J = 7.7 Hz, 1H), 7.54 (t, J = 7.7 Hz, 2H), 7.62 (t, J = 7.7 Hz, 1H), 7.69 (s, 2H), 7.76 (d, J = 9.0 Hz, 2H), 8.13 (d, J = 7.3 Hz, 2H).^{13}C NMR (125.7 MHz): 9.58, 14.80, 20.83, 22.06, 22.63, 26.85, 28.42, 28.98, 35.50, 35.54, 43.18, 45.59, 51.30, 58.52, 72.13, 72.15, 74.18, 74.97, 76.42, 76.80, 79.13, 81.19, 82.65, 84.39, 127.25 (2C), 128.78 (2C), 128.82 (2C), 129.03, 130.20 (2C), 132.30, 132.97, 133.02, 133.78, 137.58 (2C), 137.65, 139.38, 142.41, 153.92, 167.05, 167.10, 167.49, 169.86, 170.93, 171.27, 173.73, 203.69. ESMS: *m/z* 1222 (M + H). RP-HPLC analyses on samples of the purified [^{125}I]-3′-OH-PTXSX and 3′-(4-hydroxy-3-iodophenyl)-PTXSX were performed in an analytical C18 column, both individually and as a mixture, all showing a t_R of 19.9 ± 0.14 min.

[^{14}C]-PTXSXC225. Paclitaxel (19.6 mg, 23 μmol) was spiked with [^{14}C]-2′-benzoylpaclitaxel (50 μCi), and the mixture was used for the synthesis of the [^{14}C]-PTXSXC225 conjugate according to the general procedure described below. Radiochemical analyses determined a [^{14}C]-PTXSX:C225 molar ratio of 1.3:1.

General Procedure for the Synthesis of PTXSXC225 and PTXGLC225 Conjugates. The previously reported protocol was employed (*19*). Briefly, the taxane (TAX), i.e., paclitaxel or its 3′-hydroxy derivative, was converted to the corresponding succinate (TAXSX) or glutarate (TAXGL) according to the procedure described above for 3′-OH-PTXSX. The PTXSX and PTXGL were identified by ESMS and by comparison to the reported analytical data (*22*). The 3′-OH-PTXSX was identified by ESMS and by ^{1}H and ^{13}C NMR as shown above.

The carboxylated taxanes ($TAXCO_2H$) thus prepared were used for the preparation of the antibody conjugates as follows: A solution of $TAXCO_2H$ (1 equiv) in DMF was treated with NHS (2 equiv) and EEDQ (1.25 equiv) for 30 min, and the resulting solution was added to that of C225 in PBS (pH 8.1) at a 10:1, TAX:C225, molar ratio. The solution was gently stirred at 0 °C for 1 h, and the conjugate was purified by SE-HPLC.

Drug Release Kinetics of [^{14}C]-PTXSXC225. Equal volumes of the [^{14}C]-PTXSXC225 and freshly prepared human serum were mixed, and a 20-μL aliquot was withdrawn and quenched by shock freezing in a dry ice–methanol bath and stored in a −20 °C freezer. The remaining mixture was incubated at 37 °C in an incubator. Two-hundred-microliter aliquots were withdrawn at 0.5, 1, 1.5, 2, 3, 4, and 6.5 h, at which time the beginning of the plateau portion of the decay curve was indicated. The reaction solution was then kept incubated to yield an equilibrium concentration of the cleaved [^{14}C]-PTX at 22.5 h postincubation. Samples were extracted with ethyl acetate (0.5 mL per aliquot) by vortexing the immiscible layers. The organic layers were separated and stored at −20 °C. The ethyl acetate extracts were individually mixed with 10 mL of scintillation cocktail and were counted in a scintillation counter. The end-point of the run was the equilibrium at which no further increase in the concentration of the cleaving [^{14}C]-PTX was observed. The increasing radioactivity counts were then plotted against sampling times.

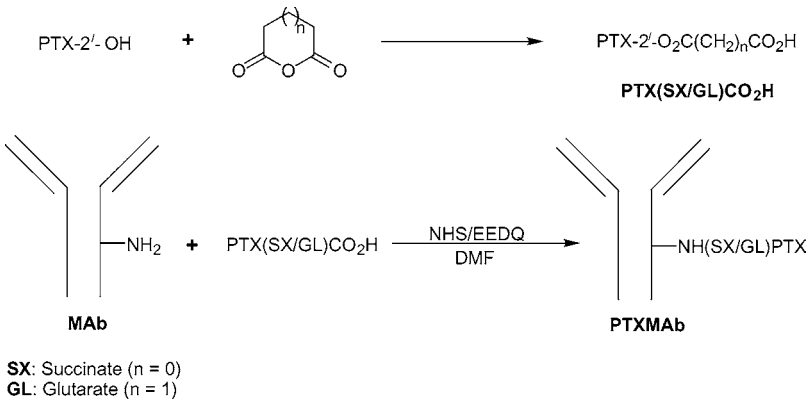
PTXSXPEGCO$_2$H. To a solution of the PTXSX (1.5 equiv) in dry DMF (250 μL/mg) were added NHS (2.5 equiv), EEDQ (1.5 equiv), and DIEA (2 equiv), and the mixture was stirred at room temperature for 30 min under argon. A solution of H_2N-PEG-CO_2H·HCl (1 equiv) and DIEA (2 equiv) was then added, and the clear solution was stirred for another 6 h. The DMF was removed in a vacuum, and the residue was mixed with 500 μL of ice-cold ammonium acetate buffer (0.2 M, pH 4.2). The suspension was transferred into a dialysis membrane with a 1000 MW cutoff and was dialyzed against 3 × 2 L of purified (18.2 MΩ) water at 4 °C and for 24 h. Lyophylization afforded a white solid product. Yield: 78%. MALDI: 4750. HPLC t_R: 23.30 min (98%).

PTXGLPEGCO$_2$H. The same procedure as for PTXSXPEGCO$_2$H was used, with PTXGL as the starting material, to afford a white solid product after lyophylization. Yield: 84%. MALDI: 4700. HPLC t_R: 24.0 min (96%).

Drug Release Kinetics of PTXPEG Conjugates. The PEG conjugate (PTXSXPEGCO$_2$H or PTXGLPEGCO$_2$H, 5 mg) was dissolved in DPBS (250 μL), and the solution was mixed with an equivalent volume of freshly prepared normal human serum at 0 °C. A 50-μL aliquot was immediately withdrawn and quenched by shock freezing at −72 °C to serve as the time-zero HPLC reference. The conjugate solution was incubated at 37 °C with occasional stirring. At certain time intervals, 50-μL aliquots were withdrawn and analyzed in an RP-HPLC system. At equilibrium (no further growth in the PTX peak, predetermined with an authentic PTX sample), the percent area under the peak (%AUC) for the decomposing conjugate and the forming PTX in each aliquot were plotted against time.

This experiment was repeated with the PTXGLPEGCO$_2$H conjugate in 100 mM acetate buffer at pH 5.0 containing an equal volume of human serum and also in 100 mM acetate buffer at pH 4.0, both at 37 °C.

Biodistribution Studies. Four groups (one group/conjugate/time point) of female *Balb/c* nude mice (6/group) were inoculated *subcutaneously* with the androgen-independent DU-145 human prostate carcinoma cells (1×10^7 cells/animal). With tumor sizes around 7 mm in diameter, the mice were injected *intraveneously* with 2 μCi each of purified [^{125}I]-3′-OH-PTXSXC225 or PTXSX-[^{125}I]-C225. The mice were sacrificed at 4 and 24 h postinjection, weighed samples of the tumors and normal organs were resected, washed with saline, and blotted dry, and the radioactivity associated with each sample was counted in a gamma counter. Tissue uptake of the radioactivity in %ID/g were then calculated from the raw activity counts for blood (BL), heart (HT), lung (LU), liver (LI), stomach (ST), small intestine (SI), spleen (SP), kidney (KD), bone (BN), muscle (MU), lining of abdominal cavity (AB), uterus (UT), pancreas (PA), and tumor (TU).



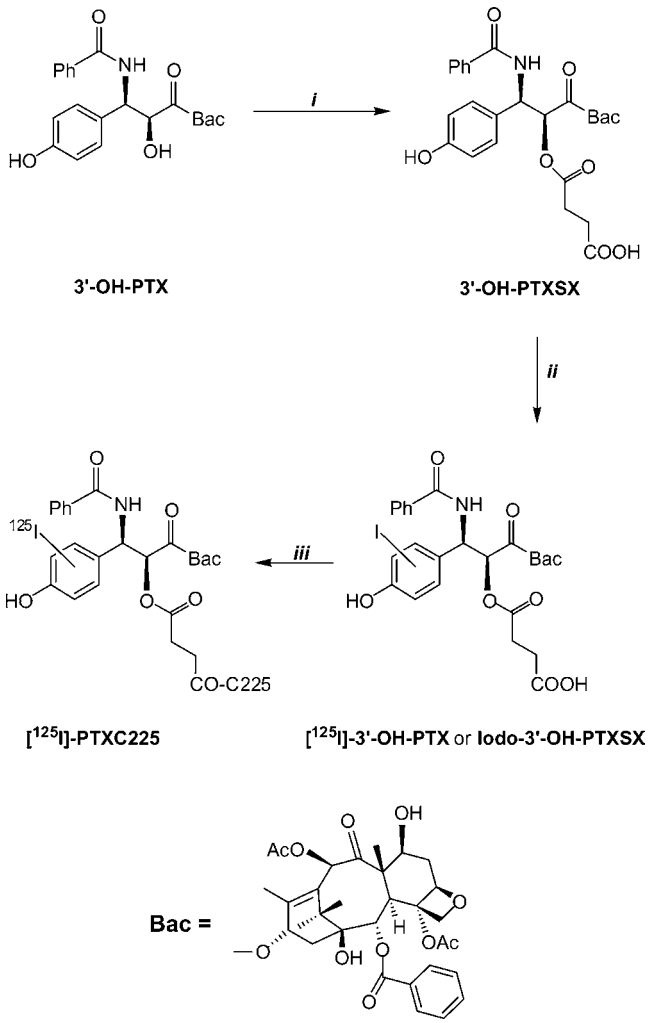
Antitumor Activity Studies. *Balb/c* mice were inoculated sc with DU-145 cells (2×10^7 cells per mouse) and were randomized into three groups of eight when the tumor sizes reached around 7 mm in diameter. The mice were treated by 6 i.v. injections every 72 h as follows (administered doses are shown in parentheses in mg/kg body weight/injection/mouse): Group 1, saline; Group 2, Taxol + C225 (0.22 + 12.5); Group 3, PTXGLC225 conjugate (0.22/12.5). The PTXGLC225 conjugate had a drug:MAb ratio of 3.1 by MALDI. The mice were observed daily for survival and tumors were measured three times a week by vernier calipers.

Statistical Analyses. The three treatment groups, saline (7 animals), Taxol + C225 (8 animals), and conjugate (8 animals), were compared with respect to in vivo antitumor efficacy over time using two statistical methods. In the first method, the tumor sizes were modeled over time through a mixed linear model growth curve analysis, using the MIXED procedure in the Statistical Analysis System (SAS). The second approach defined inhibition of tumor growth as extension of tumor tripling times. In this method, the number of days at which the tumors tripled in surface area (product of two diameters, mm^2) relative to baseline on day 10 after tumor cell injection was used in the tripling time analysis. Only one tumor from the conjugate group had not tripled by the last day of experiment. The tripling time for this tumor was treated as censored in the analysis, and the last day in the experiment (105 days) was substituted as the tumor's day of tripling. One animal from the saline group died before its tumor size tripled. In this case, the day of death was substituted as the tumor's day of tripling and that value was treated as censored in the analysis. The tumor tripling time data were analyzed using one-way analysis of variance (ANOVA), the nonparametric Kruskal–Wallis test, and log-rank test on the survival curves. The Kaplan–Meier survival curves were also plotted. All statistical analyses were conducted in SAS using the MIXED, GLM, NPAR1WAY, and LIFETEST procedures.

RESULTS AND DISCUSSION

Synthesis. Paclitaxel and its 3′-(4-hydroxyphenyl) derivative were conjugated to the anti-EGFR receptor antibody C225 according to Scheme 1. A two-step procedure was used starting with 2′-hemisuccinylation (Scheme 1, $n = 0$) or 2′-hemiglutarylation (Scheme 1, $n = 1$) of these taxanes through a previously reported reaction (*22*). Slight modifications in this procedure (lower succinic anhydride:PTX molar ratio and silica gel chromatography instead of the acetone/water recrystalization reported in ref 22) significantly improved the yield and purity of

Scheme 1



PTXSX in our hands. This procedure produced in good yield the 2′-hemisuccinate of the 3′-(4-hydroxyphenyl) derivative without protection of the phenolic oxygen, which in turn, was due to scarcity of this starting material. Evidence for this observation was provided by unambiguous ESMS of the purified product and information from the NMR integration data. Should the phenolic hydroxy group have the same, or higher, activity toward hemisuccinylation as the 2′-hydroxyl group, an exposure of the phenolic derivative to excess succinic anhydride would have been expected to form a *di-succinylated* derivative with readily detected analytical characteristics. This was not observed to any detectable scale in this synthesis.

To further support these findings, we carried out a model succinylation reaction, using as the substrate, Fmoc-tyrosine,[3] which shares the same 4-hydroxyphenyl function with the 3′-(4-hydroxyphenyl)-PTX.[3] Chromatographic (TLC, HPLC) and MS analyses determined formation of no *O*-succinylated products and the starting tyrosine was still present intact.

Conjugation of the PTX to the MAb was carried out by the NHS/EEDQ method (Scheme 1) as described previously (*19*). This protocol produced batches of conjugate with a PTX:C225 molar ratio of 3 ± 0.2 as determined by MALDI-TOF mass spectrometry. Not exceeding this drug-to-MAb ratio is critical as precipitation of the higher conjugates were observed due to low aqueous solubility of the PTX nucleus (*19*).

To demonstrate the drug site-specific radioiodination of the 3'-OH-PTXSX conjugate, a nonradioactive iodination reaction of the drug was carried out to allow for the chromatographic comparison of the products and establishing an analytical correlation between these and the product formed by the radioiodination procedures. Iodination of the succinylated PTX-3'-OH and conjugation of the product to C225 are shown in Scheme 2. In the nonradioactive procedure, a 25 mol % excess of iodogen and 300 mol % excess of sodium iodide resulted in complete conversion of the 3′-OH-PTXSX to the *di*-iodo product within 30 min. On the other hand, an excess (300 mol %) of NaI with respect to the substrate, and only 13 mol % of iodogen, resulted in the formation of the *mono*-iodo compound as the major (28%) and the *di*-iodo derivative as the minor (7.7%) products. The products were identified by the observation of the right molecular

Scheme 2[a]

[a] (i) Succinic anhydride/dry pyridine; (ii) Na [^{125}I]-I or NaI/iodogen; (iii) (a) [^{125}I]-3′-OH-PTXSX/NHS/EEDQ/DMF, (b) C225/PBS/pH 8.1.

weights in ESMS as well as by ^{1}H and ^{13}C NMR spectroscopy. We did not pursue optimization of the reaction conditions to achieve a higher *mono*:*di* product ratio, since in this work the compounds were needed only as controls and in small quantities, and also due to significant limitations in the supply of the 3′-OH-PTX starting material. The HPLC purities of these compounds (95−98%), however, were suitable for the comparative radiolabeling and conjugation studies reported here. The *mono*-iodo-3′-OH-PTXSX thus prepared was used for comparative RP-HPLC analyses with [^{125}I]-3′-OH-PTX.

[3] Fmoc-Tyrosine was incubated with a 6 molar excess of succinic anhydride in dry pyridine, and at room temperature for 10 h. The solution was then analyzed by TLC (in two solvent systems) and RP-HPLC (C18 column). No detectable reaction was observed.

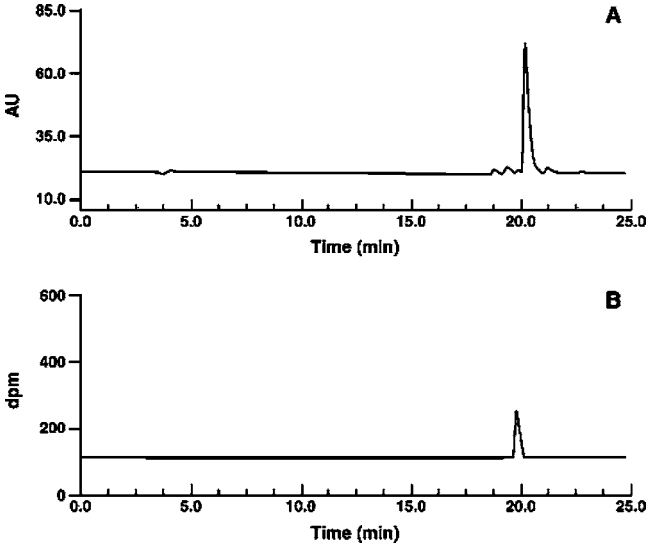


Figure 2. RP−HPLC UV (A) and radioactivity (B) traces of *mono*-iodo-3′-OH-PTXSX (A) and [^{125}I]-3′-OH-PTXSX (B). These and a *mixed* trace (not shown) measured a t_R of 19.9 ± 0.14 min showing the same chemical identity for the two isotopically different compounds. The slight difference in retention times is due to the in-series connection of the two detectors.

The RP-HPLC traces on the two compounds, both individually and as a mixture, showed identical retention times in dually (radioactivity and UV) detected analyses (Figure 2). These experiments demonstrated that the radioiodinated species detected in the [^{125}I]-radiolabeling of 3′-OH-PTXSX was indeed the expected 3′-(4-hydroxy-3-[^{125}I]-iodo)-phenyl paclitaxel hemisuccinate. In this iodination reaction, the PTX metabolite functions similar to a tyrosine side-chain in direct radioiodination reactions (*23*) of proteins. This procedure may be, therefore, useful in tracing studies of paclitaxel derivatives, particularly the nonprotein polymeric constructs (see following section) (*24*−*26*).

Antibody Radiolabeling and Biodistribution Studies. Originally, biodistribution of the drug site- and antibody site-labeled conjugate was attempted with [^{125}I]-labeled [^{14}C]-PTXSXC225. This would have had the advantage of simultaneous ^{14}C/^{125}I-traced biodistribution studies. To this end, the [^{14}C]-PTXSX-[^{125}I]-C225 conjugate was synthesized, through Scheme 1 by the use of commercially supplied [^{14}C]-PTX, and subsequent antibody iodination of the intermediate [^{14}C]-PTXSXC225 product. However, in biodistribution analysis, we found that the ^{14}C activities in all tissues, after resection and workup, were too low to be detected, particularly in the presence of the ^{125}I with some spillover effect. The latter problem jeopardized an unbiased independent tracing of the two radioisotopes and led to the use of only radioiodinated conjugates described here.

3′-(4-Hydroxyphenyl)paclitaxel (3′-OH-PTX), was isolated as a metabolite of paclitaxel from treated patients (27) and was later synthesized by Reddy et al. (*28*). We reasoned that the presence of the 4-hydroxyphenyl ring would render the molecule a tyrosine mimic, and thereby, would allow for direct radiolabeling of the conjugate through standard oxidative radioiodination protocols. To test this, 3′-OH-PTXSX was treated with nonradioactive NaI in the presence of iodogen, a condition similar to that of a standard radioiodination protocol (*20, 21*). Mass spectral and HPLC analyses of the products confirmed the presence of a *mono*-iodinated 3′-OH-PTXSX, and the compound was selected for the two-step synthesis of the DSL conjugate (Scheme 2). This approach, in which the drug segment was radioiodinated before conjugation to the antibody, ensured the placement of ^{125}I on the PTX nucleus and thus allowed for an exclusively PTX-traced biodistribution analysis. Indeed, preconjugation radioiodination of 3′-OH-PTXSX proceeded in good (75%) yield (see the preceding section). The resulting [^{125}I]-3′-OH-PTXSX product was purified by reversed-phase filtration and was conjugated to C225 by the EEDQ/NHS procedure (*19*). In a separate experiment, the ASL conjugate (PTXSX-[^{125}I]-C225) was prepared in a standard iodogen reaction for the antibody-traced in vivo distribution experiments.

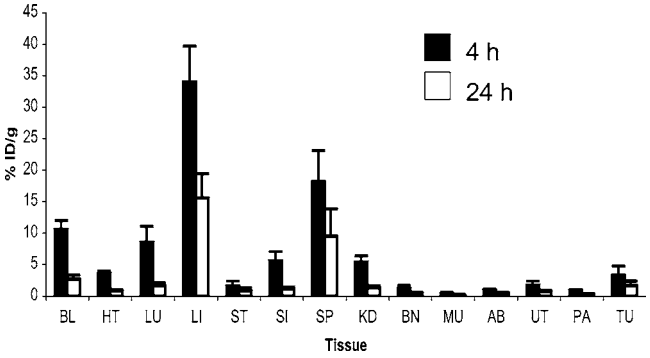

Figure 3. Biodistribution of the DSL conjugate [^{125}I]-3′-OH-PTXSXC225 in Balb/c nude mice bearing sc DU-145 human prostate carcinoma xenografts at 4-h and 24-h time points.

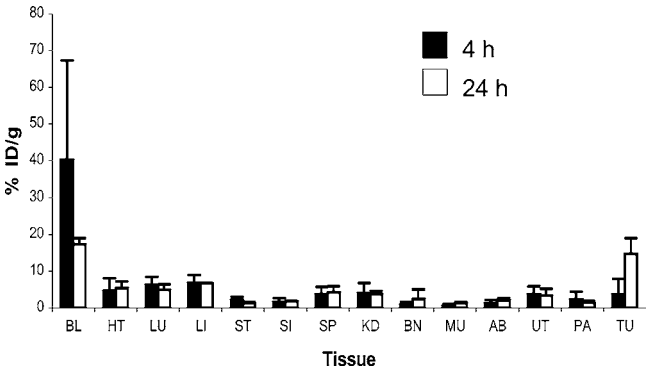

Figure 4. Biodistribution of the ASL conjugate PTXSX-[^{125}I]-C225 in Balb/c nude mice bearing sc DU-145 human prostate carcinoma xenografts at 4-h and 24-h time points.

The labeled conjugates were used for biodistribution studies in *Balb/c* nude mice implanted sc with DU-145 human prostate carcinoma cells. Each mouse received an *iv* injection of the labeled compound and the biodistribution analyses were performed at 4-h and 24-h time points. The results of these experiments are shown in Figures 3 and 4 for [^{125}I]-3′-OH-PTXSXC225 and PTXSX-[^{125}I]-C225, respectively.

The 24-h serum clearance rate of the DSL ([^{125}I]-PTXSX-C225) was about twice as fast as that for the ASL (PTXSX-[^{125}I]-C225). On the other hand, while the ASL conjugate had an increase (from 3.8 ± 4.2%ID/g to 14.8 ± 4.2%ID/g) in tumor uptake from 4 to 24 h postinjection, the DSL conjugate showed a decrease (from 3.3 ± 1.5%ID/g to 1.7 ± 0.6%ID/g) within this time interval. This pattern of biodistribution of DSL may point to the behavior of a molecule with a smaller overall size than a typical IgG conjugate such as the PTXC225. This is further supported by the liver activity of DSL, which decreased by around 50% from 4 to 24 h (34.0 ± 5.7%ID/g to 15.6 ± 3.8%ID/g), while that of ASL was almost constant within this time (6.7 ± 2.1%ID/g to 6.6 ± 1.2%ID/g), indicating a more rapid metabolism/clearance

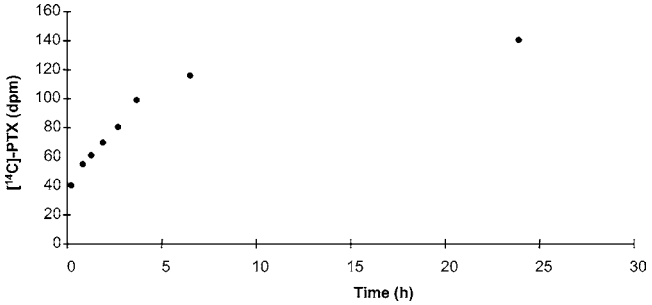

Figure 5. Drug release profile for [^{14}C]-PTXSXC225 at 37 °C and pH 7.4 PBS and in the presence of human serum. Each data point is the average of values from two independent runs.

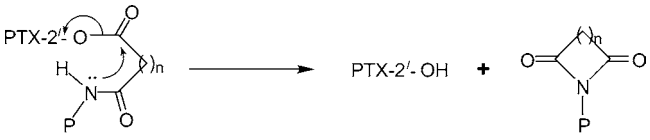
Table 1. Half-Lives ($t_{1/2}$) of Hydrolysis for Different PTX-2′-Succinate Conjugates at 37 °C and at pH 7.4

conjugate[a]	condition	$t_{1/2}$ (min)	ref
2′-PTX		54	29
2′-PTX−*di*-PEG^{5K,8K,9K}	hSe[b]	60	30
2′-PTX−PEG$^{3.4K}$−BBN[7−13]	hSe[b]	113	18
[^{14}C]-PTXSXC225	hSe[b]	165	



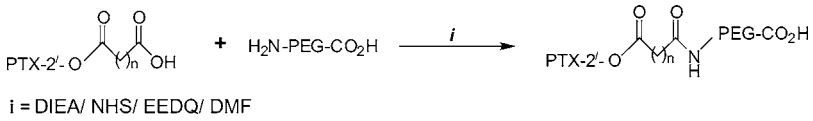
[a] Superscripted numbers indicate PEG molecular weights. [b] Reaction medium included human serum.

process for DSL than for ASL. Also, the kidney activities were 5.5 ± 1.0%ID/g (4 h) to 1.3 ± 0.2%ID/g (24 h) and 4.0 ± 2.9%ID/g (4 h) to 3.8 ± 0.7%ID/g (24 h) for DSL and ASL, respectively, which parallel the serum clearance for these conjugates. Collectively, and considering that both conjugates were of the same molecular size, the biodistribution results clearly demonstrate an early release of the drug from the PTXSXC225 conjugate with respect to the peak tumor uptake of the antibody.

Furthermore, the loss of label due to lysosomal dehalogenation of the conjugates (29, 30) was not taken into account in this experiment. It is not known, therefore, whether the observed tumor uptake could be higher, had it not been for such a postinternalization catabolism. On the other hand, since only a comparison of biodistribution of the conjugates with respect to each drug and antibody segments was of interest, exclusion of the dehalogenation mechanisms might still be a safe practice.

Drug Release Kinetics. To further validate the findings of biodistribution experiments, a direct (in vitro) determination of the timing of PTX cleavage from C225 was carried out. Since the choice of either ^{14}C- or ^{125}I-labeled conjugate carried no advantage over each other for an in vitro experiment, and due to the availability of [^{14}C]-PTXSXC225, this conjugate was selected for this release study. Thus [^{14}C]-PTXSXC225 was incubated at 37 °C in PBS containing freshly prepared human serum. The increase in the cleaved PTX was monitored at certain time intervals by a quench/extract/count procedure using ethyl acetate as the PTX-extracting solvent. The radioactivity of the extracted aliquots was then measured in a scintillation counter. Plotting the counts against time afforded the PTX release profile for this conjugate (Figure 5). Using this profile, a drug release half-life ($t_{1/2}$) of 2.7 h was estimated for this conjugate. For comparison, the $t_{1/2}$ values of PTX release from this and various other conjugates are shown in Table 1 (*31, 32*). Although in some studies, including this work, $t_{1/2}$ evaluations are performed under *physiological* conditions and in the presence of human serum, it should be emphasized that these half-lives are still in vitro measurements and the actual in vivo times may be somewhat different. The in vitro release times are, nevertheless, useful guides for formulation considerations and design of the therapy protocols.

Scheme 3



Although the corresponding half-lives of Table 1 seem to be highly structure- and condition-related, they demonstrate relatively short cleavage time windows for *2′*-succinylated PTX conjugates and are in agreement with our present findings on the PTXSXC225. While for low-MW tumor-targeting conjugates, such as those derived from small-molecule peptides (*18*), shorter cleavage times may be an advantage, it could be a significant disadvantage for antibody-conjugated drugs. For a drug−MAb conjugate with a drug release $t_{1/2}$ of 2 h, for example, more than 96% of the originally conjugated drug could be released and cleared from the circulatory system at the peak tumor antibody uptake time of 24 h. Accordingly, PTX−MAb linkers with higher physiological stabilities than that of the succinate may be required for an effective targeted delivery of this drug.

Since our work with the tumor-targeting PTX conjugates had used succinic acid as the *lead* linker, we naturally were interested in examining different derivatives of this molecule in our search for high-stability linkers. We anticipated that the cleavage of PTX from conjugates was a one-step ring-closing reaction with the formation of an imide resulting from the PTX displacement by the N-terminal nitrogen of the peptide or protein residue as shown in Scheme 3. It has been shown that in such processes, the change in the entropy of the reaction transition state ($\Delta S^{\ddagger}$) is a rate-determining factor, with the five-membered ring structures (Scheme 3, $n = 2$) presenting a rate constant 2 and 3 orders of magnitude faster than the four- ($n = 1$) and six-membered ($n = 3$) ring closures, respectively (*33*). Accordingly, we reasoned that a PTX−MAb conjugate with glutaric acid as a linker might have the desired longer $t_{1/2}$ of drug release. Prior to the synthesis of glutarate-linked antibody conjugates, however, we set out to test this by an in vitro release kinetics study on the direct comparison of the two linkers under the same conditions. Thus, conjugates of PTX to an amino-PEG, using the succinate ($n = 2$) and glutarate ($n = 3$) linkers, were synthesized as shown in Scheme 4. The rationale for the incorporation of the amino PEG was 2-fold: The water-solubilizing effect of this polymer on the otherwise insoluble drug, and the pseudo-anchimeric assistance, which might be expected from the amino PEG nitrogen atom in cleaving the PTX nucleus as shown in Scheme 3. The latter situation was expected to be similar to that of an actual PTX−MAb conjugate where the PTX-linker is attached to the ϵ-amino groups of the MAb lysine residues. Although the free carboxylic acid functions of both PTXSX and PTXGL might have generated solubility by conversion to their corresponding salts, we elected to avoid this route of solubilization, as a pH too basic for the PTX-linker bond might have resulted. This high pH could cleave the drug from the linkers before a timed study could be performed.

As shown in Figures 6 and 7, the glutarate conjugate has a considerably longer cleavage $t_{1/2}$ than the succi-

Scheme 4

nate, that is, ~2.6 h and ~44 h, for PTXSXPEG and PTXGLPEG, respectively, indicating the better compatibility of the former linker with MAb-mediated PTX delivery. Furthermore, Figure 6 also shows excellent agreement between the release $t_{1/2}$ of the PEG conjugate with that of the PTXSXC225 shown in Figure 5.

On the basis of a previous report on the limited stability of the PTX–glutarate bond in a low-pH acetate buffer (100 mM, pH 4) (*34*), we investigated the stability of the PTXGLPEG conjugate in the same buffer as well as in a pH 5 acetate buffer with human serum. No detectable amount of released PTX was noticed under either condition and after at least 24 h (pH 5) and several days (pH 4) of incubation at 37 °C.

These findings justified the use of glutaric acid instead of succinic acid as the PTX–MAb linker for a drug release timing which matches with that of the peak tumor uptake of the conjugate. The PTXGLC225 was prepared by the same method as for the succinate congener (Scheme 2) and was used for a preliminary antitumor activity study described below.

Antitumor Activity Studies. The first clue on the finding that the SX might not have been a suitable linker for in vivo MAb-targeted PTX delivery came from the observation that the conjugate showed only very modest antitumor activity in several experiments (data not shown). This was also despite high (in vitro) cytotoxic activity of the PTXSXC225 conjugate as compared to the free PTX in several human carcinoma cell lines. With the development of the cleavage kinetics data, it was anticipated that the antitumor activity of the conjugate might improve by the use of a linker with a higher release $t_{1/2}$. To this end, a therapy experiment using the PTXGLC225 conjugate and in a mouse model with DU-145 human prostate carcinoma implants was initiated. Injections were given iv and every 72 h. The 72-h timing of injections was selected based on the tumor %ID/g values in the biodistribution experiments (i.e., unlikelihood of tumor saturation), the expected 24-h tumor uptake peak, the 24-h blood half-life, and the slow release $t_{1/2}$ of the glutarate linker. Increase in the surface area (product of two diameters) was used as a measure of tumor growth.

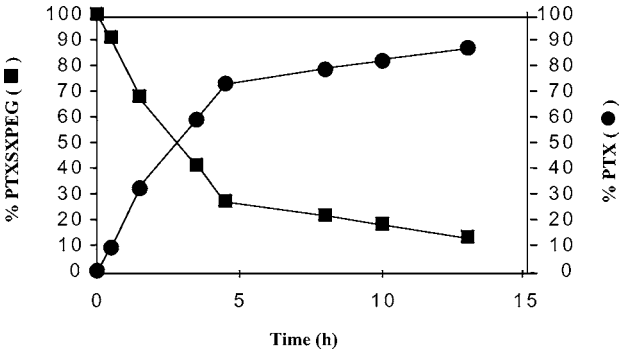


Figure 6. Drug release profile for PTXSXPEG at 37 °C in pH 7.4 PBS containing normal human serum. Each point is the average of values from two independent runs.

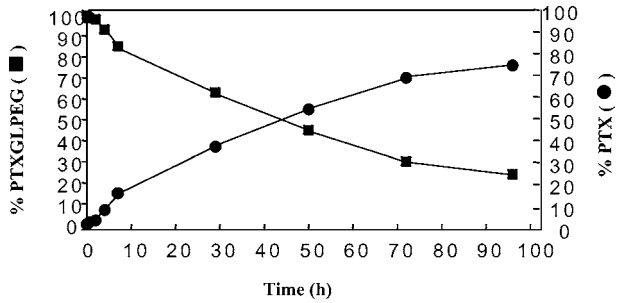

Figure 7. Drug release profile for PTXGLPEG at 37 °C in pH 7.4 PBS containing normal human serum. Each point is the average of values from two independent runs.

In this experiment, and based on the two statistical analyses described in Experimental Procedures, the conjugate group showed significantly better antitumor efficacy over time as compared to the saline and Taxol + C225 mixture. The mixed linear model on the raw (tumor size over time) growth curves, using the MIXED procedure in SAS, showed (Figure 8) a significantly slower rate of growth over time (on average a smaller slope in the growth curves) for the conjugate group as compared to the Taxol + C225 and saline groups ($p < 0.001$). In the tumor tripling time analysis, we recorded the time during which tumors had tripled in surface area. All but two of the 23 tumors had tripled by the end of study. Three separate statistical analyses, including one that takes into account censoring (Kaplan–Meier and associated log-rank test), resulted in the same statistical conclusions. The tumors were fast growing tumors which doubled on average quite quickly, with over half of the Taxol + C225 and conjugate groups having doubled within 48 and 52 days (6/7 of the saline group tumors doubled by 25 days and 7/7 of them doubled by 43 days). On the basis of this, we concluded that tripling time analysis was more appropriate in this situation. In addition to the tripling time analysis, the tumor sizes were modeled over time through a mixed linear model growth curve analysis, which resulted in the same conclusions as the tripling time analysis. Therefore, although doubling time is traditionally used in these types of analyses, the tripling time analysis seemed to be appropriate and accurately reflected the differences in tumor growth inhibition. Table 2 contains the statistics summarizing the tumor tripling times per group. Based on Analysis of Variance (ANOVA), there were overall significant mean differences in tripling times between groups ($p = 0.001$). Subsequent multiple comparisons indicated that the conjugate group had significantly longer mean tumor-tripling times than the Taxol + C225 and saline groups and that the Taxol + C225 group had significantly longer tumor tripling times over the saline group. The nonparametric Kruskal–Wallis test confirmed this result. The Kaplan–Meier curves for the time-to-tumor-tripling, shown in Figure 9, clearly demonstrate superior tumor growth inhibition in the treated groups over the saline control group, and the associated log-rank test confirms that the time-to-tumor-tripling for the PTXGLC225 was significantly extended as compared to the Taxol + C225 groups ($p = 0.018$) and the saline control group ($p = 0.008$).

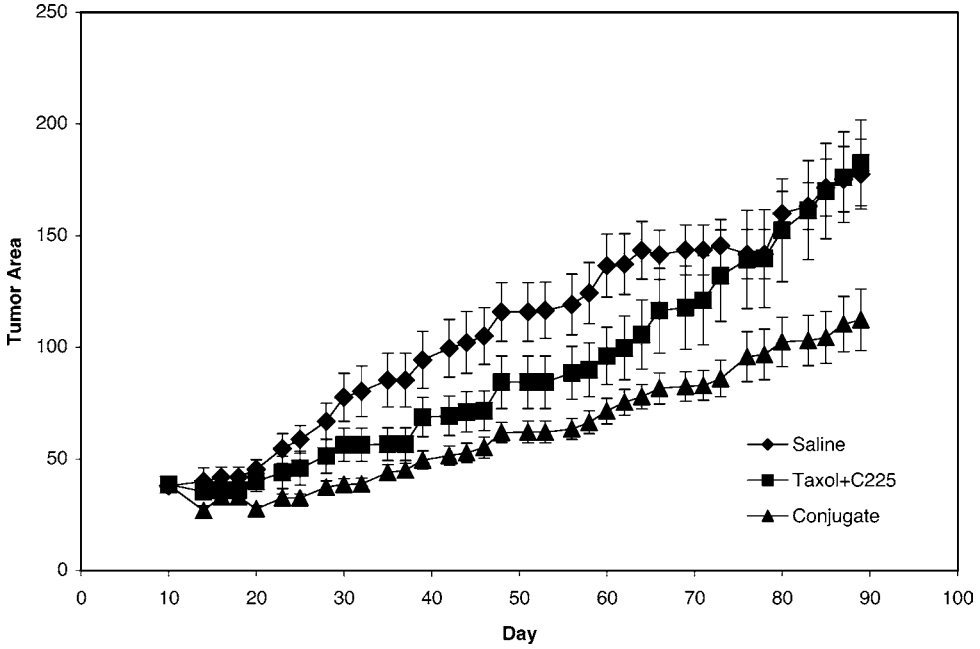

Figure 8. Tumor growth inhibition induced by the PTXGLC225 conjugate in *Balb/c* nude mice bearing sc DU-145 human prostate carcinoma tumors. Saline and a physical mixture of Taxol and C225 were used as controls.

Table 2. Summary Statistics on the Times-to-Tumor Tripling[a]

group	*N*	number of nontripled tumors	mean (days)	median (days)	standard error (days)
saline	7	1	38.4	39.0	7.3
Taxol + C225	8	0	60.6	59.5	5.0
conjugate	8	1	77.6	79.0	4.6

[a] Based on ANOVA, the conjugate group had significantly longer mean tumor-tripling times than the Taxol + C225 and saline groups, and the Taxol + C225 group had significantly longer tumor-tripling times over the saline group.

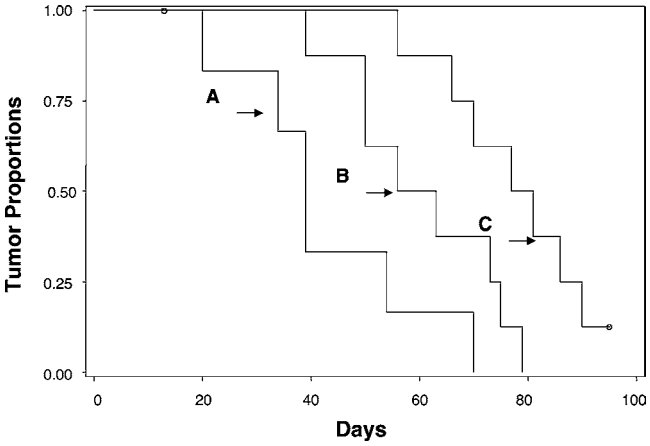

Figure 9. Kaplan-Meier tumor tripling time curves in *Balb/c* nude mice bearing sc DU-145 human prostate carcinoma tumors and treated with either Taxol + C225 mixture (B) or the PTXGLC225 conjugate (C) as compared to the untreated controls (A). The ordinate represents the estimated proportion of tumors that tripled over time (shown in days on the abscissa). The circles indicated censored values.

CONCLUSIONS

While an early cleavage of the drug molecule from the conjugate will reduce the possibility of its tumor-targeted delivery, too slow a release may result in an unsuccessful therapy outcome as well. The latter would be particularly harmful to the performance of prodrug conjugates, which may require a timely drug cleavage/activation mechanism. Information on the kinetics of the release would be, therefore, critical in designing drug−antibody conjugates with useful therapeutic features. In the work described here, drug-site and antibody-site radioiodinated PTXSXC225 conjugates were synthesized and were used to study the in vivo fate of both the drug and the antibody segments. These experiments were performed in DU-145 tumor-implanted *Balb/c* nude mice and demonstrated that the time of cleavage of the PTX from the succinic acid-linked conjugate (PTXSXC225) was shorter than the time required for C225 tumor localization. This finding was further supported by an in vitro drug release rate estimation experiment, which indicated half-times of 2.75 and 2.6 h for the cleavage of PTX from [^{14}C]-PTXSXC225 and PTXSXPEG conjugates, respectively. According to the biodistribution results, however, less than 4%ID/g of the PTXSXC225 localized in the tumor at 4 h postinjection. On the other hand, a glutaric acid-linked conjugate showed a significantly longer drug release mechanism and was selected for a therapy study in DU-145-bearing mice. As compared to the previously performed therapy experiments with the PTXSXC225 conjugate, better antitumor activity was observed with the PTXGLC225 in this controlled experiment. In addition to the introduction of a new method for the synthesis of drug-site radiodinated PTX−MAb conjugates, the results presented in this article demonstrate the effect of the PTX−antibody linkers on the overall antitumor activity of the conjugate. These results are being utilized in an ongoing work toward the design and synthesis of PTX−MAb conjugates with optimal therapeutic features.

ACKNOWLEDGMENT

The generous donations of 3′-OH-PTX and C225 by Tapestry Pharmaceuticals (Boulder, CO) and ImClone Systems (New York, NY), respectively, are greatly acknowledged. The authors would like to thank the UAB Comprehensive Cancer Center Mass Spectrometry Shared Facility for MW determinations, and Sheila Bright and Cherlene Hardy for assisting in the biodistribution experiments. Soneshia McMillan and Dr. Abhijit Roy-

cowdhury are thanked for preparing the manuscript and the synthetic schemes, respectively. Supported by Department of the Army Award Numbers DAMD17-02-1-0004 and DAMD17-02-1-2068.

Sequence-Selective Cleavage of Oligoribonucleotides by 3d Transition Metal Complexes of 1,5,9-Triazacyclododecane-Functionalized 2′-*O*-Methyl Oligoribonucleotides

Teija Niittymäki and Harri Lönnberg*

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received July 14, 2004; Revised Manuscript Received September 10, 2004

2′-*O*-Methyl oligoribonucleotides bearing a 3′-[2,6-dioxo-3,7-diaza-10-(1,5,9-triazacyclododec-3-yl)decyl phospate conjugate group have been shown to cleave in slight excess of Zn^{2+} ions complementary oligoribonucleotides at the 5′-side of the last base-paired nucleotide. The cleavage obeys first-order kinetics and exhibits turnover. The acceleration compared to the monomeric Zn^{2+} 1,5,9-triazacyclododecane chelate is more than 100-fold. In addition, 2′-*O*-methyl oligoribonucleotides having the 1,5,9-triazacyclododec-3-yl group tethered to the anomeric carbon of an intrachain 2-deoxy-β-D-*erythro*-pentofuranosyl group via a 2-oxo-3-azahexyl, 2,6-dioxo-3,7-diazadecyl, or 2,9-dioxo-3,10-diazatridecyl linker have been studied as cleaving agents. These cleave as zinc chelates a tri- and pentaadenyl bulge opposite to the conjugate group approximately 50 times as fast as the monomeric chelate and show turnover. The cleavage rate is rather insensitive to the length of linker. Interestingly, a triuridyl bulge remains virtually intact in striking contrast to a triadenyl bulge. Evidently binding of the zinc chelate to a uracil base prevents its catalytic action. Replacement of Zn^{2+} with Cu^{2+} or Ni^{2+} retards the cleaving activity of all the cleaving agents tested.

INTRODUCTION

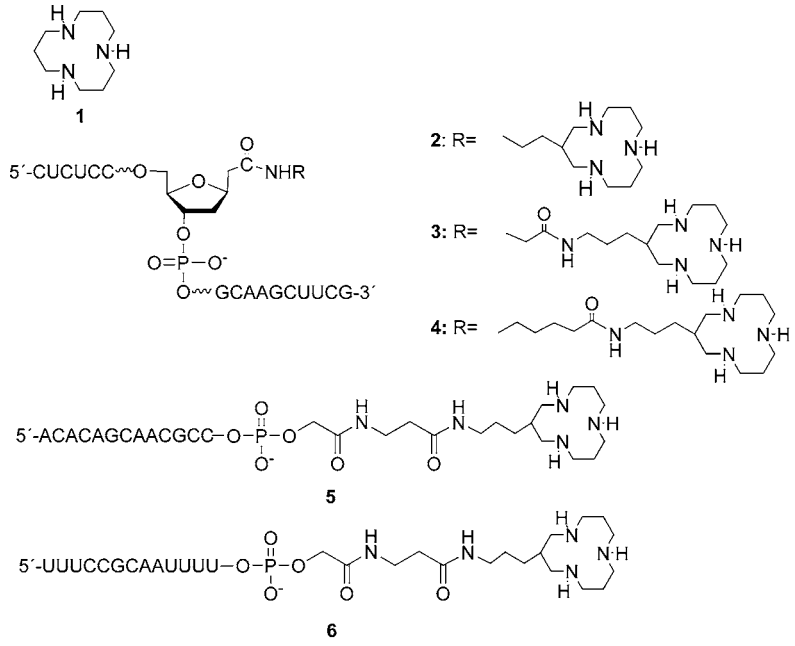
Oligonucleotide conjugates that sequence-selectively cleave complementary RNA targets have attracted considerable attention during the past decade (*1*–*5*). Such cleaving agents may enable chemical tailoring of RNA and, hence, serve as artificial restriction enzymes for RNA in vitro. In addition, they may possibly find applications in chemotherapy as chemically reactive antisense oligonucleotides that are able to destroy their target mRNA and exhibit RNase H independent turnover. The feasibility of such of an approach has been demonstrated by in vitro studies on cell lines (*6*, *7*), although not in vivo.

Most of the artificial ribonucleases described are conjugates of metal ion chelates having a lanthanide ion (*8*–*15*), Cu^{2+} (*16*–*19*), or Zn^{2+} (*20*–*22*) as the central ion. In addition, conjugates of peptidelike oligomers have been reported to catalyze sequence-selective phosphodiester hydrolysis, but their catalytic activity is still low compared to that of the metal ion-dependent cleavers (*23*–*31*). Since certain macrocyclic polyamines, the so-called azacrowns, bind 3d transition metal ions very tightly (*32*–*33*), in fact more tightly than many of the previously described metal-ion-dependent cleaving agents, and since some of these chelates, above all 1,5,9-tirazacyclododecane ([12]aneN_3, **1**), have been shown to promote the hydrolysis of RNA fragments rather efficiently (*34*–*37*), azacrown-functionalized oligonucleotides may be regarded as viable candidates of artificial RNases. For this purpose, we have recently prepared 2′-*O*-methyl oligoribonucleotides bearing a 1,5,9-triazacyclododec-3-yl group tethered either to the 3′-terminus of the oligonucleotide or to an intrachain abasic sugar unit (*38*). We now report on evaluation of the applicability of their Zn^{2+} complexes as artificial RNases. A detailed kinetic analysis of the cleavage reaction has been carried out by using synthetic oligoribonucleotides as targets. The influences of the concentration of the target and cleaving agent, the structure of the linker connecting the azacrown to the oligonucleotide, and the size and base content of the bulge created on the target upon hybridization have been studied. In addition, some comparative measurements with Cu^{2+} and Ni^{2+} complexes have been carried out.

EXPERIMENTAL PROCEDURES

Materials. Preparation of the azacrown-functionalized 2′-*O*-methyl oligoribonucleotides **2**–**4** and **6** has been described previously (*38*). Conjugate **5** was obtained as reported for **6**, and its authenticity was verified by ESI-MS. MS(ESI) for **5**: *m/z* 587.6 (8%) $[M - 8H]^{8-}$, 671.9 (30%) $[M - 7H]^{7-}$, 783.8 (76%) $[M - 6H]^{6-}$, 940.7 (100%) $[M - 5H]^{5-}$, 1175.9 (94%) $[M - 4H]^{4-}$, 1568.0 (44%) $[M - 3H]^{3-}$. M_{obs} 4708.5, M_{calcd} 4707.4.

The chimeric 2′-*O*-methylribo/ribo oligonucleotides (**7**–**17**) used as targets were assembled from commercially available 2′-*O*-methyl and 2′-*O*-triisopropylsilyloxymethyl (2′-*O*-TOM) protected 2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite building blocks (Glen Research) by conventional phosphoramidite strategy using a 1.0 μmol scale and following the standard RNA-coupling protocol of Applied Biosystems 392 DNA/RNA Synthesizer.



The buffer reagents and salts employed were of reagent grade. All buffer solutions were prepared in sterilized water, and sterilized equipments were used for their handling.

Kinetic Measurements. The reactions were carried out in Eppendorf tubes immersed in a water bath, the

temperature of which was maintained at 35.0 ± 0.1 °C. The volume of the reaction mixture was 200 μL. The pH was adjusted to 7.3 with a HEPES buffer (0.1 mol L^{-1}). The Zn^{2+}, Cu^{2+} and Ni^{2+} ions were added as nitrates to give a total metal ion concentration of 50 μmol L^{-1}, and the ionic strength was adjusted to 0.1 mol L^{-1} with sodium nitrate. The concentration of the azacrown-functionalized oligonucleotides and their targets was varied from 9 to 36 μmol L^{-1} and 18 to 36 μmol L^{-1}, respectively. *p*-Nitrobenzenesulfonate ion was used as an internal standard.

Aliquots of 20 μL were withdrawn at suitable intervals and immediately cooled to 0 °C. The reaction was quenched by adding aqueous hydrogen chloride (1.0 μL of 1.0 mol L^{-1} solution). The samples were analyzed immediately.

Analysis of Samples. The samples were analyzed by capillary zone electrophoresis (CZE; Beckman Coulter P/ACE MDQ CE System) using a fused silica capillary (50 μm inner diameter, 60.2 cm total length, 50 cm effective length). The inverted polarity and citrate buffer (0.2 mol L^{-1}, pH 3.1) were used. The voltage applied was −30 kV. The temperature of the capillary was kept at 25 °C. The samples were injected using hydrodynamic injection with 2 psi for 8 s. The capillary was flushed with water, 10 mmol L^{-1} aqueous hydrogen chloride, and the background electrolyte buffer (for 3 min each) between every analytical run. UV-detection at 254 nm was applied to quantify the oligonucleotides and the internal standard.

Calculation of Rate Constants. First-order rate constants for the cleavage of the target oligonucleotides were calculated by applying the integrated first-order rate law to the disappearance of the starting material. The peak area was first normalized by dividing the area by the migration time and then by the similarly normalized area of the internal standard.

Determination of the Cleavage Site. The cleavage site within target **10** was determined by spiking with standards **12**−**17**. Each of the standards was added one after another to an aliquot of the reaction mixture, which contained the cleaved target **10**, and the mixtures were analyzed by CZE as described above. Standards **13**, **14**, and **17** did not comigrate with the cleavage products. Standard **16** comigrated with the minor product of the cleavage reaction. Standards **12** and **15** both comigrated with the major product. For this reason, those mixtures were additionally analyzed by an otherwise similar CZE method but using a different background electrolyte, viz. iminodiacetic acid (50 mmol L^{-1}, pH 2.3). Measurements in this more acidic buffer revealed standard **15** to be identical with the major cleavage product.

RESULTS AND DISCUSSION

Structure of the Cleaving Agents and Their Target Oligonucleotides. Chart 1 shows the cleaving agents studied (**2**−**6**), their target oligonucleotides (**7**−**11**), and the oligonucleotide standards used for the determination of the cleavage site (**12**−**17**). The cleaving agents are fully 2′-*O*-methylated oligoribonucleotides bearing the catalytically active [12]aneN_3 chelate tethered either to an abasic sugar unit within the chain (**2**−**4**) or to the 3′-terminal hydroxy function (**5**, **6**). The

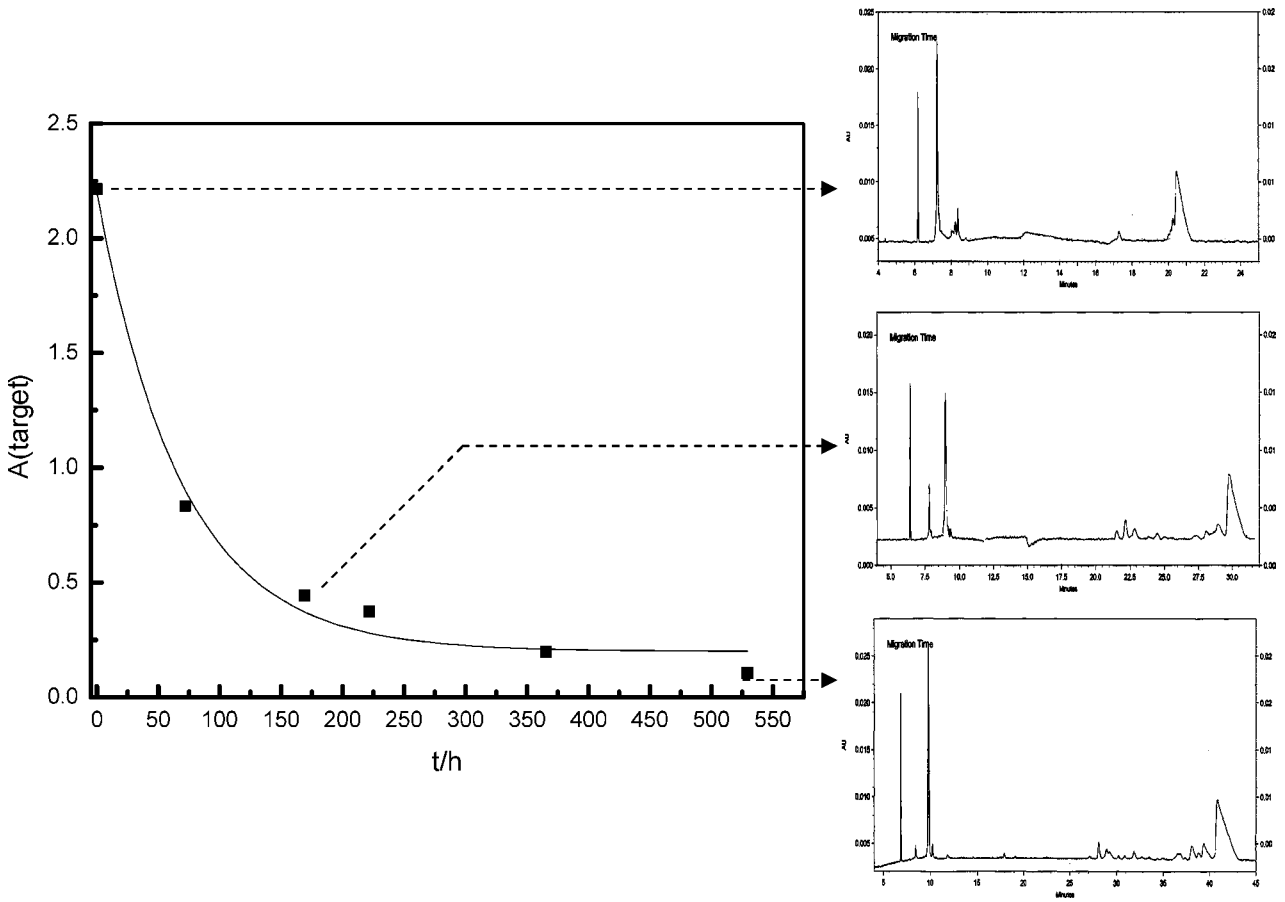

Figure 1. Cleavage of chimeric 2′-*O*-methylribo/ribo oligonucleotide **10** by sequence-selective cleaving agent **5** in 0.1 mol L^{-1} HEPES buffer at pH 7.3 and 35 °C (I = 0.1 mol L^{-1} with $NaNO_3$), and the electropherograms obtained at time 0, 165, and 530 h. The initial concentration of both the target oligonucleotide and the cleaving agent is 36 μmol L^{-1}.

targets are chimeric 2′-*O*-methylribo/ribo oligonucleotides containing several unsubstituted ribo units in the vicinity of the expected cleavage site, i.e. either 6 or 8 ribonucleosides in the middle of an 2′-*O*-methylribonucleotide chain (**7**−**9**) or 11 ribonucleosides at the 5′-end of a 2′-*O*-methylribonucleotide chain (**10**, **11**). The base sequences are selected so that upon hybridization of the cleaving agent with target, either a tri- or pentanucleotide bulge is formed on the target sequence (binding of **2**−**4** to **7**−**9**) or the sequence of the cleaving agent is fully complementary with the 3′-terminal sequence of the target (binding of **5** to **10** or **6** to **11**). Creation of a bulge to achieve intrachain cleavage is essential, since it has been shown that [12]aneN_3 cleaves oligoribonucleotide within a bulged region, even at a single nucleotide bulge, but it is unable to cleave phosphodiester bonds within a double helical region (*36*, *37*). Insertion of 2′-*O*-methylribonucleosides in the target sequence facilitates the synthesis and ensures high affinity of the target to the cleaving agent, preserving the A-type duplex structure (*39*).

Cleavage by the 3′-Tethered Conjugates. Figure 1 shows as an illustrative example the cleavage of target **10** by conjugate **5** in 0.1 mol L^{-1} HEPES buffer at pH 7.3 and 35.0 ± 0.1 °C. The concentration of both oligomers (**5**,**10**) was 36 μmol L^{-1} and that of Zn^{2+} somewhat higher, about 50 μmol L^{-1}, to ensure complete complexing [the stability constant for Zn^{2+}[12]aneN_3 is $10^{8.6}$ L mol^{-1} (*33*)]. Increasing of the Zn^{2+} concentration to 150 μmol L^{-1} did not, however, have any influence on the cleavage rate. The ionic strength was adjusted to 0.1 mol L^{-1} with $NaNO_3$. The progress of the reaction was followed by determining the composition of the aliquots withdrawn at suitable intervals by capillary electrophoresis. To facilitate the quantification, *p*-nitrobenzenesulfonate was used as an internal standard. As seen from the electropherograms in Figure 1, the target **10** entirely disappeared and a product oligonucleotide appeared at a longer retention time. First-order kinetics were reasonably well obeyed.

The cleavage site within target **10** was determined by spiking the product mixture with the potential cleavage products, i.e. with separately synthesized chimeric 2′-*O*-methylribo/ribo oligonucleotide standards **12**−**17**. Each of the standards was mixed separately with an aliquot of the reaction mixture containing the cleaved target **10**. The major product of the cleavage reaction, representing about 80% of the total cleavage, was observed to be **15**, the minor product being **16**. Accordingly, target **10** is predominantly cleaved at the 5′-side of the last base-paired nucleotide and to a minor extent at the phosphodiester bond one nucleotide toward the 5′-end.

The cleavage reaction also shows turnover. As seen from Figure 2, the target oligonucleotide is entirely cleaved obeying first-order kinetics, even when the target is present in a 4-fold excess compared to the cleaving agent. Cleaving agent **6** that contains only three cytosine bases and one guanine base and, hence, binds to its target (**11**) less firmly than **5** that forms eight CG base-pairs with **10**, exhibits under these turnover conditions 5-fold cleaving activity compared to **5**. Most likely the enhanced cleavage does not, however, result from the reduced affinity to the target, but from the fact that an 5′-UpA-3′ bond is cleaved instead of an 5′-ApG-3′. It is known that

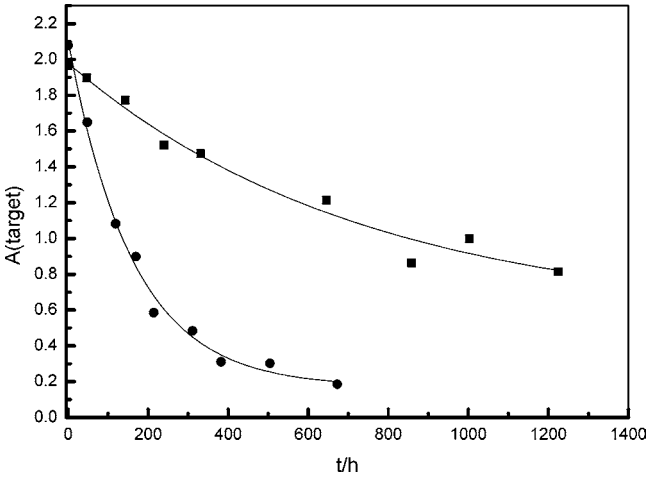

Figure 2. Cleavage of chimeric 2′-*O*-methylribo/ribo oligonucleotide **10** by cleaving agent **5** (squares) and **11** by **6** (circles). The concentration of the target oligonucleotides (**10**,**11**) is 36 μmol L^{-1} and that of the cleaving agents (**5**,**6**) 9 μmol L^{-1}. For the conditions, see the legend of Figure 1.

Table 1. First-order Rate Constants for the Cleavage of Targets 10 and 11 by Metal Ion Chelates of Conjugates 5 and 6, Respectively, in 0.10 Mol L^{-1} HEPES Buffer at pH 7.3 and 35 °C (I = 0.1 Mol L^{-1} with NaNO$_3$)[a]

6	**11**	Zn^{2+}	18	36	0.77 ± 0.06
			9	36	1.0 ± 0.1
6	**11**	Cu^{2+}	9	36	0.62 ± 0.08
6	**11**	Ni^{2+}	9	36	0.71 ± 0.03

[a] The total concentration of M^{2+} was 50 μmol L^{-1}. Even at [M^{2+}] = 150 μmol L^{-1} the cleavage rate, however, remained unchanged.

within many sequences, the inherent hydrolytic stability of the 5′-UpA-3′ bond is lower than that of the other phosphodiester bonds (*40*).

Table 1 records the first-order rate constants obtained for the cleavage of targets **10** and **11** with conjugates **5** and **6**, respectively. With the more stable pair of the cleaving agent and target, **5/10**, the reaction rate is increased with the increasing concentration of **5**. Although the reaction at each concentration of **5** shows turnover, the rate is not strictly proportional to the concentration of **5**, but the rate constants obtained in excess of the target **10** are only half of the values expected on the basis of first-order dependence of the rate on the concentration of **5**. The reaction possibly is subject to moderate product inhibition, suggesting that the cleaving agent hybridizes slightly more efficiently with the product oligonucleotides **15**, **16** than with the target **10**. This inhibition is not, however, sufficiently strong to markedly deviate the cleavage from first-order kinetics. At 1:1 concentration ratio of the cleaving agent **5** and target **10**, the cleavage rate is independent of the concentration, as shown by the fact that the rate constants obtained at 36 and 18 μmol L^{-1} are equal within the limits of experimental error. Evidently in this concentration range the duplex formation is virtually quantitative. Surprisingly, the less efficiently hybridizing cleaving agent/target pair **6/11** behaved quite differently. Increasing the concentration of the cleaving agent from 9 to 18 μmol L^{-1} did not accelerate the cleavage of **11** on keeping the concentration of the latter constant (36 μmol L^{-1}). A possible, but still fully tentative, explanation is that **6**, containing two sequences of contiguous uracil bases, tends at higher concentrations to undergo intermolecular association by mutual interaction between the zinc chelate in one conjugate and a uracil sequence in another. For comparison, simultaneous binding of two Zn^{2+} chelates of 1,4,7,10-tetraazacyclododecane to two thymine bases has been shown to exhibit stability constants in micromolar range (*41*).

Table 2. First-Order Rate Constants for the Cleavage of Targets 7−9 by Zn^{2+} Chelates of Conjugates 2−4 in 0.10 Mol L^{-1} HEPES Buffer at pH 7.3 and 35 °C (I = 0.1 Mol L^{-1} with NaNO$_3$)[a]

[a] The total concentration of Zn^{2+} was 50 μmol L^{-1}. Even at [Zn^{2+}] = 150 μmol L^{-1} the cleavage rate, however, remained unchanged.

Table 3. First-Order Rate Constants for the Cleavage of Targets 7 and 8 by Metal Ion Chelates of Conjugates 3 and 4 in 0.10 Mol L^{-1} HEPES Buffer at pH 7.3 and 35 °C (I = 0.1 Mol L^{-1} with NaNO$_3$)[a]

cleaving agent	target	M^{2+}	c (cleaving agent), μmol L^{-1}	c (target), μmol L^{-1}	k, 10^{-6} s^{-1}
3	**7**	Zn^{2+}	18	36	0.96 ± 0.05
		Cu^{2+}	18	36	0.25 ± 0.01
		Ni^{2+}	18	36	0.17 ± 0.02
3	**8**	Zn^{2+}	18	36	0.88 ± 0.04
		Cu^{2+}	18	36	0.55 ± 0.08
		Ni^{2+}	18	36	0.26 ± 0.02
4	**7**	Zn^{2+}	18	36	0.60 ± 0.04
		Cu^{2+}	18	36	0.20 ± 0.02
		Ni^{2+}	18	36	0.12 ± 0.01
4	**8**	Zn^{2+}	18	36	0.96 ± 0.05
		Cu^{2+}	18	36	0.44 ± 0.06
		Ni^{2+}	18	36	0.14 ± 0.01

[a] The total concentration of M^{2+} was 50 μmol L^{-1}.

In addition to Zn^{2+}, some comparative measurements were carried out with Cu^{2+} and Ni^{2+}. As seen from Table 1, both of these accelerated the cleavage of **10** by **5** and **11** by **6** less efficiently than Zn^{2+}.

Cleavage by the Intrachain Conjugates. Three targets, **7**−**9**, differing with respect to the size and base content of the bulge formed upon hybridization with the cleaving agent, were subjected to cleavage by metal ion chelates of three oligonucleotide conjugates, **2**−**4**, bearing the 1,5,9-triazacyclododecan-3-yl group in an intrachain position. The cleaving agents employed differed only with respect to the length of the tether by which the 1,5,9-triazacyclododecan-3-yl group was attached to the *C*1-β-carboxymethyl group of the abasic sugar unit. Tables 2 and 3 record the rate constants obtained.

Cleavage by the intrachain conjugates **2**−**4** shows turnover without any indication of product inhibition. In other words, the disappearance of the target is complete and obeyes first-order kinetics throughout a kinetic run, even when used in 4-fold excess compared to the cleaving agent. The cleavage rate is proportional to the concentration of the cleaving agent, as long as the target is present in excess and its concentration remains constant (36 μmol L^{-1}).

Somewhat unexpectedly, the length of the tether appears to play only a minor role. The cleavage of target **7**, forming a trinucleotide A_3-bulge upon hybridization, is retarded by 30% on going from the shortest (**2**) to the longest tether (**4**), when the target and cleaving agent are used in 1:1 concentration ratio (18 μmol L^{-1}). With target **8** forming a pentanucleotide A_5-bulge, the differences in the cleavage rate are even smaller (Table 2).

The more flexible pentanucleotide A_5-bulge is cleaved 1.6 to 1.8 times as fast as the trinucleotide A_3-bulge. Similar differences in the hydrolytic stability of pentanucleotide and trinucleotide bulges have previously been observed on using monomeric Zn^{2+}[12]aneN_3 as a cleaving agent (*37*). Interestingly, a trinucleotide U_3-bulge is considerably more stable than its A_3-counterpart. One may tentatively assume that the well-established tendency of Zn^{2+} azacrown chelates to bind uracil bases (*41*) prevents the interaction with internucleosidic phosphodiester bonds and, hence, the catalytic action is impeded.

Table 3 lists the first-order rate constants for the cleavage reactions on using Cu^{2+} or Ni^{2+} as a catalytic species instead of Zn^{2+}. As with the 3′-terminal conjugates, the Cu^{2+} and Ni^{2+} chelates of the oligonucleotide conjugates are less efficient cleaving agents than the Zn^{2+} chelates. However, the Cu^{2+} chelate is now more efficient than the Ni^{2+} chelate, while the situation with the 3′-terminal chelates is the opposite. It has been shown (*42*) that monomeric Zn^{2+}[12]aneN_3 cleaves polyuridylic acid 20 times more readily than the corresponding Ni^{2+} chelate. With the sequence-selective cleaving agents of the present study, the difference in the catalytic activity is less marked.

Cleaving Activity Compared to Other Zn^{2+}-Based Cleaving Agents. We have previously studied the cleavage of phosphodiester bonds within chimeric 2′-*O*-methylribo/ribo oligonucleotides using monomeric Zn^{2+}[12]aneN_3 as a catalyst (*37*). For example, the first-order rate constant for the cleavage of a 5′-UpA-3′ bond within a linear single strand in 5 mmol L^{-1} Zn^{2+} chelate solution at pH 7.4 and 35 °C is 4.2×10^{-6} s^{-1}. As seen from Table 1, the first-order rate constant for the cleavage of a 5′-UpA-3′ bond by cleaving agent **6** at 9 μmol L^{-1} concentration is 1.0×10^{-6} s^{-1} at pH 7.3. Accordingly, the acceleration compared to a monomeric chelate is 130-fold. Comparison of the rate constants observed for the cleavage of a A_3-bulge by cleaving agent **2** at 18 μmol L^{-1} concentration (0.74×10^{-6} s^{-1}) and by the monomeric Zn^{2+} chelate at 5 mmol L^{-1} concentration (4.5×10^{-6} s^{-1}) gives, in turn, a 46-fold acceleration. A comparable rate-enhancement compared to a monomeric cleaving agent has been previously obtained by tethering 2,9-dimethylphenanthroline to *C*5 of an intrachain uracil base (*18*, *22*). These dimethylphenanthroline conjugates cleave their complementary targets about 1 order of magnitude faster than the azacrown conjugates described in the present paper, because the Zn^{2+} complex of 2,9-dimethylphenanthroline is a more efficient cleaving agent than Zn^{2+}[12]aneN_3. The azacrown functionalized oligonucleotides have, however, one major advantage over the dimethylphenanthroline conjugates. The stability constant for the Zn^{2+} complex of 1,5,9-triazacyclododecane is $10^{8.6}$ L mol^{-1} (*33*), whereas the Zn^{2+} complex of 2,9-dimethylphenanthroline is more than 4 orders of magnitude less stable. Accordingly, while the dimethylphenanthroline conjugates are more efficient cleaving agents in excess of Zn^{2+}, the situation in all likelihood is the opposite at low metal ion concentrations and, hence, under intracellular conditions.

Received February 22, 2004; Revised Manuscript Received September 12, 2004

Acid-degradable protein-loaded polymer particles show promise for antigen-based vaccines due to their ability to activate cytotoxic T lymphocytes (CTLs) in vitro. Protein loadings and cytotoxic T lymphocyte activation efficiencies have now been enhanced through novel delivery vehicle designs. In particular, the use of a more hydrophilic acid-degradable cross-linker leads to increased water dispersibility and increased protein loading efficiency for the particles. A 2.5-fold increase in protein encapsulation allows the delivery of more protein antigen to antigen presenting cells (APCs) leading to a 20-fold rise in antigen presentation levels. The mechanism by which APCs internalize these particles was explored using the phagocytosis inhibitor, cytochalasin B. In addition, preliminary in vivo experiments were conducted to investigate the ability of the protein-loaded particles to provide immunity against tumors in mice, and an enhanced survival rate over the use of protein alone was observed, indicating that this vaccine delivery strategy has great practical potential.

INTRODUCTION

Traditional vaccine strategies have been ineffective at generating vaccines against diseases such as AIDS and hepatitis C, largely due to the high toxicity of the associated live attenuated viruses (*1*). Therefore, new vaccine strategies based on protein antigens are being investigated and have considerable promise due to their low toxicity and widespread applicability (*2*). Protein antigens have been identified for a number of different diseases, such as prostatic acid phosphatase for prostate cancer and gp120 and Tat for HIV, but the effectiveness of each of these would require the development of a more effectual vaccination strategy (*3*, *4*). Efficient protein-based vaccines must be able to activate CTLs, which play a central role in combating viral infections and tumors and generating immunity (*5*, *6*).

A key step in activating CTLs is the delivery of antigens into the cytoplasm of professional APCs, which process these cytoplasmic proteins by degrading them into peptides that are then assembled with major histocompatibility complex (MHC) class I molecules. These MHC class I peptide complexes are transported to the cell surface where they are recognized by antigen specific CTLs, which then become activated and primed to recognize and kill cells that have been infected with that particular antigen.

Therefore, a major challenge in generating this CTL response is to create a vaccine system that can efficiently deliver proteins into the cytoplasm of APCs in order to induce protective immunity against a specific disease. A delivery system is needed because exogenous antigens, proteins not synthesized in the cytoplasm, cannot efficiently reach the cytoplasm of APCs when administered alone as a vaccine because they are taken up through endocytosis and are sequestered and degraded in endosomes or lysosomes of the cell (*7*).

One class of protein delivery systems that is able to introduce exogenous proteins into the cytoplasm of APCs and has shown potential in vaccine research is polymer particles. One advantage of using particles as delivery vehicles is that they can be easily targeted to professional APCs by adjusting their size since it is known that APCs phagocytose particles that are 0.5−3 μm in diameter and cross-linked polymer beads of this size range have been shown to successfully encapsulate proteins (8-11). In theory, these particles could deliver a variety of protein antigens making this technology applicable to many diseases. In addition, encapsulation of proteins inside of the particles protects them from inactivation and unfavorable immune reactions that may occur during delivery.

Antigens associated with particles, such as proteins adsorbed onto polycaprolactone or polystyrene beads, as well as proteins covalently linked to the surface of iron oxide beads, have been shown to present peptides via the MHC class I pathway (*12*, *13*). Also, proteins encapsulated inside poly(lactide-*co*-glycolide) particles have been used to activate CTLs (*14*). These particle-based systems have demonstrated the validity of this method of protein delivery as a useful vaccination strategy. They were thought to weakly disrupt endosomes of APCs after internalization, which allowed a fraction of the protein to be delivered to the cytoplasm. However, while these particles were capable of being taken up by APCs, there

was no well-defined mechanism for the transfer of protein from endosomal compartments to the cytoplasm.

To improve upon the cytoplasmic delivery using polymer-based systems, we have reported previously a particle system that was designed to be strongly endosomal disruptive (*15*, *16*). These particles release encapsulated protein in a pH-dependent manner. They are stable at the physiological pH of 7.4 but degrade quickly in the pH 5.0 environment of endosomes, freeing the protein. The rationale for this design, known as the colloid osmotic mechanism (*7*, *17*), is to generate a quick degradation of the particles into many molecules, thus increasing the osmotic pressure within the endosome, leading to a rapid influx of water across the membrane resulting in its disruption. Rupture of the endosomal compartment affords the viral antigen an outlet to the cytoplasm of the cell while also circumventing the possible degradation of the protein by hydrolytic enzymes present in the mildly acidic endosome.

The acid-sensitive protein-loaded particles were synthesized by copolymerizing an acid-degradable cross-linker, **1** (Figure 1) and acrylamide in the presence of a protein using an inverse emulsion polymerization technique. Preliminary experiments have demonstrated that these particles were nontoxic and were capable of MHC class I presentation and CTL activation in vitro, which was determined by the LacZ assay (*16*). Although this system showed promise for applications in vaccine development, this new strategy had not been optimized or evaluated using in vivo experiments.

In this report the protein-loading capacity and enhanced water dispersibility of the particle system are investigated. In addition, we present in vitro studies evaluating the CTL activation levels of the optimized particles and discuss the mechanism by which the particles are internalized by APCs. Finally, preliminary in vivo experiments testing the ability of the protein delivery vehicle to provide a protective immunity against tumors using an ovalbumin model are presented.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. Tetrahydrofuran was distilled under a nitrogen atmosphere from Na/benzophenone immediately prior to use. *p*-Toluenesulfonic acid was dehydrated and then recrystallized from toluene. *N*-(2-Hydroxyethyl)-2,2,2-trifluoroacetamide and acryloyl chloride were freshly distilled before each use. Combined organic layers after extractions were dried over anhydrous $MgSO_4$. Solvents were removed under reduced pressure using a rotary evaporator. Merck Kieselgel plates coated with silica gel 60 F_{254} were used for thin-layer chromatography, and compounds were visualized by UV activity. Flash column chromatography was done with Merck Kieselgel 60 silica gel (230−400 Mesh). Mice were purchased from Jackson Laboratory, and cells were purchased from the ATCC. The SIINFEKL peptide was purchased from the Synpep Corporation. The antibody 25.D1-16 was produced from the hybridoma cells generously provided by Dr. Ronald Germain of NIAID, and the goat anti-mouse antibody labeled with R-phycoethrin (PE) was purchased from Pharmingen.

Characterization. ^{1}H NMR spectra were recorded at 300 or 400 MHz, and ^{13}C spectra were recorded at 100 MHz. NMR chemical shifts are reported in ppm relative to tetramethylsilane (TMS) and are calibrated against residual solvent peaks: $CDCl_3$ (δ 7.26, δ 77.23) or DMSO-d_6 (δ 2.49, δ 39.51). All coupling constants are reported in Hz. High-resolution fast atom bombardment mass spectrometry (FAB-HRMS) experiments were performed at the UC−Berkeley mass spectrometry facility. FT-IR spectroscopic analyses were performed using a thin film cast from $CHCl_3$ on a reflective mirror surface. Elemental analyses were performed by M-H-W Laboratories or at the UC−Berkeley Analytical Laboratory.

***N,N′*-Diacryloyl-bis(2-aminoethoxy)-[4-(1,4,7,10-tetraoxaundecyl)phenyl]methane (1).** This compound was prepared according to literature procedure (*16*).

1-Chloro-3,6,9,12-tetraoxatridecane (3). This compound was prepared according to the reaction conditions reported by Schafheute et. al. used to prepare 1-chloro-3,6,9,12,15-pentaoxahexadecane (*18*). This procedure was modified by using dichloroethyl ether as the dichloride compound. The product was isolated by short path distillation (106 °C/2 mmHg). ***p*-(1,4,7,10,13-Pentaoxatetradecyl)benzaldehyde (4).** Chloride **3** (13.3 g, 58.6 mmol, 1.5 equiv) and *p*-hydroxybenzaldehyde (4.78 g, 39.1 mmol, 1 equiv) were dissolved in dry THF (15 mL). K_2CO_3 (5.4 g, 39.1 mmol, 1 equiv) was added followed by 18-crown-6 (103 mg, 0.39 mmol, 0.01 equiv) and KI (64.9 mg, 0.39 mmol, 0.01 equiv). The reaction mixture was stirred at reflux for 48 h. The resulting mixture was cooled to room temperature, and water (150 mL) was added. The product was extracted with three 150 mL portions of ethyl acetate, and the combined organic layers were dried and concentrated. The oil was loaded onto a silica gel column and eluted with a 1:1 mixture of ethyl acetate/hexane to afford 11.8 g (97%) of **4** as a clear oil. IR (cm^{-1}): 1693 (s), 1132 (s). ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.33 (s, 3), 3.50 (t, 2, J = 4.5), 3.72−3.58 (m, 10), 3.86 (t, 2, J = 4.8), 4.18 (t, 2, J = 4.8), 6.99 (d, 2, J = 8.7), 7.79 (d, 2, J = 8.6), 9.80 (s, 1). ^{13}C NMR ($CDCl_3$): δ 58.82, 67.59, 69.26, 70.32, 70.41, 70.43, 70.69, 71.73, 114.70, 129.84, 131.74, 163.68, 190.59. Calcd: $[M + H]^+$ ($C_{16}H_{25}O_6$) m/z = 313.1651. Found FAB-HRMS: $[M + H]^+$ m/z = 313.1643.

***N,N′*-Bis(trifluoroacetyl)-bis(2-aminoethoxy)-[4-(1,4,7,10,13-pentaoxatetradecyl)phenyl]methane (5).** Aldehyde **4** (6.65 g, 21.3 mmol, 1 equiv) and *N*-(2-hydroxyethyl)-2,2,2-trifluoroacetamide (25.4 g, 161.8 mmol, 7.6 equiv) were dissolved in dry THF (40 mL). *p*-Toluenesulfonic acid (586 mg, 3.4 mmol, 0.16 equiv) and 5 Å molecular sieves (52 g) were added. The reaction mixture was stirred overnight and then quenched with triethylamine (3.8 mL, 27.7 mmol, 1.3 equiv). The reaction mixture was filtered, and water (150 mL) was added to the filtrate. The product was extracted with five 150 mL portions of ethyl acetate, and the solvent was evaporated. To remove the excess alcohol, benzoyl chloride (16.3 mL, 140.4 mmol, 1 equiv), triethylamine (40.0 mL, 280.8 mmol, 2 equiv), and dry THF (100 mL) were

added. The reaction mixture was stirred at room temperature for 1 h. Water (250 mL) was added and the product was extracted with five 250 mL portions of ethyl acetate, and the solvent was evaporated. The remaining oil was loaded onto a silica gel column and eluted with a 3:7 mixture of ethyl acetate/hexane, followed by a 4:1 mixture of ethyl acetate/hexane to afford 10.4 g (82%) of **5** as a white solid. MP: 74.6−75.0 °C. IR (cm^{-1}): 3292 (br), 1701 (s), 1560 (m), 1209 (s), 1178 (s). ^1H NMR (400 MHz, DMSO-d_6): δ 3.21 (s, 3), 3.34−3.41 (m, 6), 3.46−3.58 (m, 14), 3.72 (t, 2, $J = 4.6$), 4.07 (t, 2, $J = 4.6$), 5.52 (s, 1), 6.91 (d, 2, $J = 8.4$), 7.29 (d, 2, $J = 8.4$), 9.53 (t, 2, $J = 5.6$). ^{13}C NMR (DMSO-d_6): δ 39.22, 58.01, 62.56, 67.12, 68.89, 69.56, 69.76, 69.81, 69.91, 71.26, 100.54, 113.92, 115.19 (q, $J = 288$), 127.72, 130.25, 156.38 (q, $J = 36$), 158.51. Calcd: $[M]^+$ ($C_{24}H_{34}F_6N_2O_9$) $m/z = 608.2168$. Found FAB-HRMS: $[M]^+$ $m/z = 608.2153$. Anal. Calcd. for $C_{24}H_{34}F_6N_2O_9$: C, 47.37; H, 5.63; N, 4.60. Found: C, 47.20; H, 5.84; N, 4.54.

***N,N′*-Diacryloyl-bis(2-aminoethoxy)-[4-(1,4,7,10,-13-pentaoxatetradecyl)phenyl]methane (2).** Compound **5** (0.40 g, 0.66 mmol, 1 equiv) and 6 M NaOH (2.8 mL) were added to dioxane (1.8 mL), and the reaction mixture was stirred at room temperature for 3.5 h. Upon complete removal of the acetamide groups, as determined by TLC using ninhydrin staining, the reaction mixture was cooled to 0 °C and triethylamine (0.6 mL) was added. Acryloyl chloride (1.1 mL, 14 mmol, 21 equiv) and triethylamine (5.6 mL, 40.0 mmol, 61 equiv) were added in small alternating portions while periodically monitoring the pH to maintain it above 7. A 10% K_2CO_3 in water solution (40 mL) was added, and the reaction was stirred for 10 min before extracting the product with six 40 mL portions of ethyl acetate. The organic layers were dried and concentrated to afford a yellow oil. The crude product was purified by column chromatography and eluted with a 2:1 mixture of ethyl acetate/hexane, followed by ethyl acetate, and a 1:9 mixture of methanol/ethyl acetate to afford 0.20 g (58%) of **2** as a white solid. MP: 62.0−63.0 °C. Inverse Emulsion Polymerization. To generate protein-loaded particles, an inverse emulsion polymerization technique was used. The organic phase consisted of hexane (5 mL) and 150 mg of surfactants. A 3:1 weight ratio of Span 80 (sorbitan monooleate) and Tween 80 (poly(ethylene glycol)−sorbitan monooleate) was used. The oxygen dissolved in the organic phase was removed by sparging with nitrogen for 10 min. The aqueous phase consisted of acrylamide and cross-linker (250 mg combined in a range of ratios) dissolved in 300 mM sodium phosphate-buffered water (pH 8, 500 μL). The oxygen dissolved in the aqueous phase was removed by purging with nitrogen for 1 min. Free radical initiator, potassium peroxodisulfate (12 mg), and ovalbumin (labeled with cascade blue dye or unlabeled) were added to the aqueous phase and then emulsified with the organic phase by sonicating for 30 s. Polymerization was initiated by the addition of *N,N,N′,N′*-tetramethylethylenediamine (TMEDA) and stirred for 10 min at room temperature. The mixture was centrifuged at 2800 rpm for 10 min, and the supernatant was decanted. The particles were washed with two 20 mL portions of hexane, followed by four 20 mL portions of acetone, and finally centrifuged. The solvent was decanted, and the purified particles were dried in vacuo overnight.

Nondegradable particles were prepared using the method described above using *N,N′*-methylene-bis-acrylamide as the cross-linker. The mole percent of cross-linker and total weight of monomer and cross-linker combined were the same as above.

Scanning Electron Microscopy. The particles were dried in vacuo to remove residual water, sputter-coated with a 20 nm gold layer, and viewed in a scanning electron microscope (WDX ISI-ds130C, Microspec Corporation, Inc.). Photographs were taken at 15 kV.

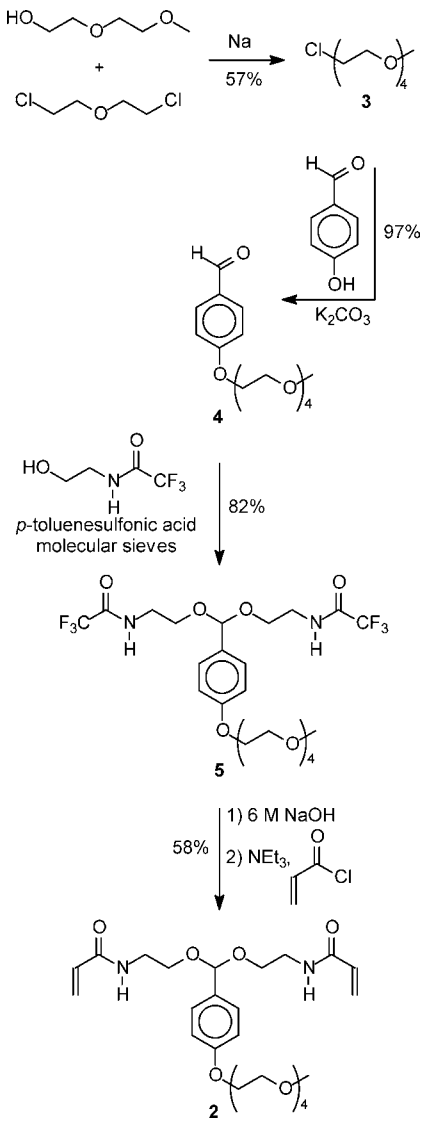
Protein Encapsulation Measurements. A small amount of each particle sample (2 mg) containing ovalbumin labeled with cascade blue was dispersed in 300 mM sodium phosphate-buffered water (pH 8, 500 μL). The samples were then centrifuged for 5 min, and the supernatant was removed. The pellet was then redispersed into 300 mM sodium acetate buffered water (pH 1.6, 500 μL). Once completely hydrolyzed, the fluorescence emission of the aqueous solution was measured at 405 nm with an excitation at 355 nm. The unknown protein concentration of each particle sample was calculated by fitting the emission to a calibration curve made from known concentrations of ovalbumin labeled with cascade blue. The background emission of the buffer was measured and subtracted from all of the readings. Each sample was done in triplicate.

The protein determination of the nondegradable particles was performed differently since they do not degrade in acidic conditions. The samples were weighed and washed in a pH 8 buffer. The solid was then redispersed into 6 M NaOH to hydrolyze the protein−cascade blue into smaller pieces that could diffuse out of the particles. After 1 day, the solid was removed by centrifugation and the fluorescence emission of the aqueous solution was measured at 405 nm with an excitation at 355 nm. The unknown protein concentration of each microparticle sample was calculated by fitting the emission to a calibration curve made from known concentrations of ovalbumin−cascade blue that had been dissolved in 6 M NaOH for the same period of time. Each sample was done in triplicate, and degradable particles were also analyzed at the same time in this fashion for direct comparison. Although the amount of protein measured for the degradable samples using this method was higher than found for the method above, a relative comparison between the samples was performed.

Class I Antigen Presentation Assay. The class I antigen presentation assay (LacZ assay) was performed using the OVA-derived SIINFEKL peptide/K^b-specific B3Z T cell hybridoma and RAW 309.1 CR antigen presenting cells. RAW cells were plated at 5×10^4 cells per well in a 96-well plate and allowed to grow overnight. Ovalbumin loaded particles were dispersed in DMEM medium (5 mg/mL) and sonicated for 5 min. An appropriate amount of the particle stock solution was added to the cells, in a 100 μL volume. The RAW cells were incubated with the particles for 6 h at 37 °C and then washed several times with DMEM medium. B3Z cells (1×10^5) were added to the RAW cells, and the two cell lines were incubated together for 16 h in RPMI media at 37 °C. LacZ activity was measured as the absorbance at 595 nm of the cleavage product of chlorophenol red-β-D-

galactopyranoside. All samples were performed in triplicate.

For each antigen presentation assay performed, a standard peptide curve was prepared by incubating the RAW cells with a series of SIINFEKL concentrations alongside the particle samples. The absorbance at 595 nm was plotted against the log of the peptide concentration. The resulting curve was sigmoidal, but only the optimal concentrations were used for the linear standard so high and low concentrations were deleted. The trendline equation was then used to quantify the amount of peptide presented using the absorbance values.



Cytochalasin B Assay. To inhibit phagocytosis, RAW cells were incubated in a 17 μM solution of cytochalasin B in DMEM 2 h before the particle samples were added. Identical particle samples were added to both the inhibited and uninhibited groups of cells in triplicate. The remainder of the experiment was the same as described above for the class I antigen presentation assay.

In Vivo Tumor Protection Experiment. Experiments were performed with female C57BL/6 mice and all immunizations were administered by subcutaneous injections using 26 gauge needles. There were three groups (15 mice per group): control mice injected with saline (200 μL); mice injected with free ovalbumin in saline (50 μg in 200 μL); and mice injected with ovalbumin encapsulated in particles (Sample D) dispersed in saline (1.13 mg particles, corresponds to 50 μg ovalbumin, in 200 μL). A second identical immunization was delivered 2 weeks after the first. Then 10 days after the second immunization, tumors were established by administering an injection of 1×10^6 EG7-OVA tumor cells in 100 μL saline into the shaved left flank of each mouse. One week prior to injection, the EG7 cells were stained with the anti-SIINFEKL/K^b monoclonal antibody 25.D1-16 and the secondary goat anti-mouse antibody labeled with R-phycoethrin (PE). Then highly ovalbumin-expressing cells were collected using flourescence-activated cell sorting (FACS) and proliferated. After injection, the tumor growth was monitored by measuring two perpendicular axes using digital calipers. Tumor volume was then calculated using the equation, volume = 0.5 $\times$ length $\times$ width^2, with the length being the longest diameter and the width being the shortest diameter of the two perpendicular measurements. Once the tumor reached 1.5 cm in average diameter, the mouse was removed from the experiment and euthanized according to guidelines set by the UC−Berkeley Animal Care and Use Committee. Mice were also removed if they showed other signs of pain or distress such as a lack of cleaning, eating, or mobility. A log rank test was used to determine *p*-values. A *p*-value of 0.05 or less was considered to be statistically significant.

RESULTS AND DISCUSSION

Controlling the Hydrophilicity of the Cross-Linker. The dispersibility of particles made with cross-linker **1**, while sufficient for proof-of-concept experiments, required further improvement, as the particles it afforded as a white powder could be suspended in an aqueous solution, but they readily aggregated and formed a precipitate. For practical application as a vaccine, the material should be uniformly dispersed in solution, enabling it to be used by injection. Covering the particle surface with a long hydrophilic oligoethylene glycol layer would be expected to enhance the colloidal properties of the particles in water due to greater hydration and steric stabilization afforded by the layer (*19*−*21*). However, the use of high molecular weight poly(ethylene glycol) chains was not pursued since it has been shown that a 5 kDa poly(ethylene glycol) surface on poly(lactic-*co*-glycolic acid) particles diminished the recognition of particles by phagocytic cells, and this would clearly be detrimental in our target application (*20*). To balance the need for enhanced hydrophilicity and the requirements of inverse microemulsion polymerization (*16*), we prepared cross-linker **2** in which the solubilizing group is extended by one ethylene oxide unit over that of our earlier cross-linker **1**.

Scheme 1. Synthesis of Cross-Linker

This target molecule **2** was prepared in four steps as shown in Scheme 1. 1-Chloro-3,6,9,12-tetraoxatridecane, **3**, was prepared and coupled to *p*-hydroxybenzaldehyde and K_2CO_3 to afford **4** in 97% yield. Intermediate **5** was synthesized in 82% yield by reaction of **4** with *N*-(2-hydroxyethyl)-2,2,2-trifluoroacetamide in the presence of a catalytic amount of *p*-toluenesulfonic acid and a drying agent to shift the equilibrium toward the acetal product. To install the polymerizable handles, the primary amine groups of **5** were deprotected with 6 M NaOH and coupled to acryloyl chloride in dioxane using biphasic conditions, affording **2** in 58% yield. Triethylamine was added in the final step to quench any HCl byproduct in order to avoid any possible and untimely degradation of the acid labile acetal.

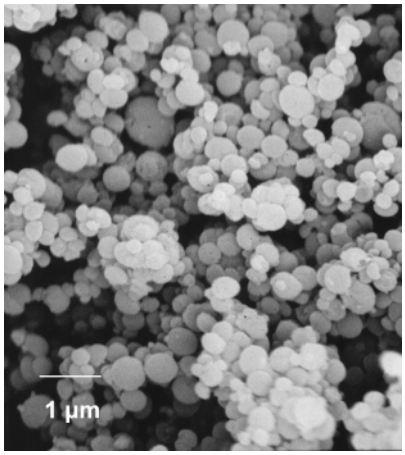


Figure 2. SEM image of particles prepared with cross-linker 2.

Inverse Emulsion Polymerization with Cross-Linker 2. Cross-linked protein-loaded particles were synthesized using **2** and acrylamide as the monomers in an inverse microemulsion polymerization process (*16*, *22*). First, **2** and acrylamide were dissolved in buffered water, and ovalbumin and the polymerization initiator, potassium peroxodisulfate, were then added. The aqueous phase was dispersed into an organic phase, which consisted of a 3:1 blend of Span 80 and Tween 80 surfactants in hexane. Span 80 and Tween 80 were chosen because they are nonionic and nontoxic. The emulsion was created by sonication and polymerization was initiated upon addition of TMEDA. After polymerization, the particles were isolated by centrifugation, washed, and dried to remove residual hexane and surfactants. The particle size ranged from 250 to 500 nm in diameter, as determined by Figure 2, and we observed that the particles were readily dispersible in water unlike particles synthesized with the less hydrophilic cross-linker **1**.

Protein Loading Studies. Increasing the amount of protein encapsulated in the particles was an important step in developing an effective and better controlled delivery system. Ideally, the amount of protein delivered to an APC per particle would be large enough to produce efficient MHC class I presentation. This is especially important for in vivo experiments where a smaller number of particles per cell would be taken up as compared to tissue culture. In initial studies with cross-linker **1** (*16*), it was noted that the protein loading did not change with the degree of cross-linking. Therefore, protein loading studies were carried out using a fixed amount of cross-linker **1** (12.8%) and acrylamide in the polymerization mixture, varying only the concentration of ovalbumin labeled with cascade blue. Following inverse microemulsion polymerization, the amount of protein encapsulated was determined for each sample by hydrolyzing the particles in acidic conditions until the solution became completely clear and then measuring the fluorescence of the released ovalbumin in solution.

Protein loading increased with initial ovalbumin concentration in the polymerization mixture as shown in Table 1. For example, when the initial amount of protein in the polymerization was tripled from 5.4 mg to 16.8 mg, the amount of ovalbumin encapsulated doubled from 9.5 μg/mg to 22.0 μg/mg as illustrated by samples A (*16*) and B in Table 1. Also, when the initial amount was 33.2 mg, the final ovalbumin loading increased 6-fold from 9.5 to 62.6 μg/mg as shown in sample C. The appearance and stability of the particles remained the same even though more protein had been encapsulated. The maximum ovalbumin encapsulation achieved with this system using cross-linker **1** was 62.6 μg/mg particles for sample C. The use of higher initial protein concentrations in reaction mixtures involving this set of monomers and polymerization conditions resulted in a large amount of aggregation and precipitation during the polymerization.

Table 1. Particle Samples with Increased Protein Loading

sample	cross-linker	initial amount of cascade blue-labeled ovalbumin (mg)	encapsulated ovalbumin/particles (μg/mg)
A	1	5.4	9.5
B	1	16.8	22.0
C	1	33.2	62.6
D	2	5.2	44.3
E	2	33.0	135.6
F	2	45.6	154.8

The same experiments were performed using the new, more hydrophilic, cross-linker **2** with the same mole percent of cross-linker (12.8%), keeping the total amount of monomers (acrylamide and **2**) constant. The concentration of ovalbumin labeled with cascade blue in the initial polymerization mixture was varied as shown in Table 1. Unexpectedly, higher protein encapsulation efficiencies were achieved using the more hydrophilic **2**. This increase in efficiency may be due to increased stabilization of the particles and protein in the emulsion or aqueous solution causing less protein aggregation and precipitation. The protein encapsulation efficiency of particles made with **2** was over twice that of particles made with **1**. For example, when 33 mg of ovalbumin was added to the initial mixture, the loading of particles made with **1** was 62.6 μg ovalbumin/mg particles (sample C), whereas the loading of particles made with **2** was 135.6 μg protein/mg particles (sample E). The maximum protein encapsulation obtained with cross-linker **2** was 154.8 μg ovalbumin/mg particles in sample F. Therefore, our goals of increasing the hydrophilicity of the particles while achieving better control over their protein content were met with the development and application of cross-linker **2**.

Antigen Presentation Experiments with Highly Loaded Particles. LacZ antigen presentation assays, developed by Karttunen et al., were performed to determine if the increased encapsulation of protein in the acid-degradable particles resulted in enhanced cytoplasmic delivery of protein to APCs, leading to higher MHC class I presentation levels and CTL activation (*23*). To demonstrate CTL activation, the particles were first incubated at various concentrations with the antigen presentation cell line, RAW 309.1 CR, for 6 h. After removal of extracellular particles, the APCs were incubated with ovalbumin specific B3Z cells. These B3Z cells are CTLs engineered to secrete β-galactosidase after binding to the ovalbumin-derived SIINFEKL peptide in a MHC class I (K^b)-restricted manner. This allows T cell activation to be quantified by β-galactosidase activity. Higher β-galactosidase activity, quantified by absorbance measurements at 595 nm due to release of a dye, infers greater antigen presentation and CTL activation levels. The measured absorbance values at 595 nm can then be converted into the corresponding concentration of SIINFEKL peptide presented using a standard peptide curve.

An antigen presentation assay was run testing samples A, B, C, and E since they displayed a range of protein loadings. Figure 3 illustrates that higher ovalbumin loadings lead to greater antigen presentation levels as

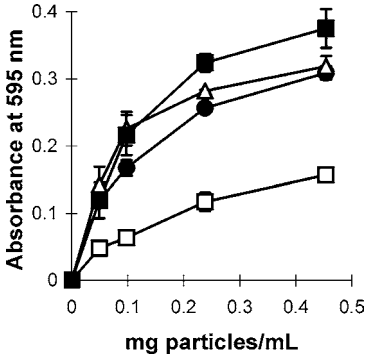

Figure 3. Antigen presentation assay testing particles with varied protein loadings. Sample A (□); sample B (●); sample C (△); sample E (■).

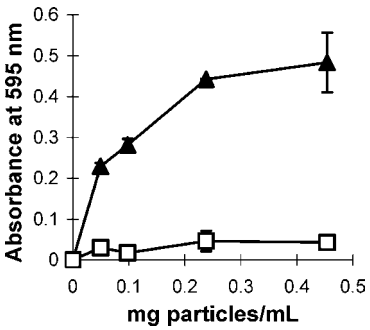

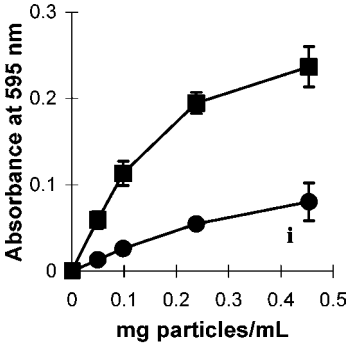

Figure 4. Effect of degradability on antigen presentation. Degradable (▲); nondegradable (□).

indicated by higher β-galactosidase activity. Also, increasing sample concentration leads to greater antigen presentation levels. These trends are likely due to the rise in the amount of ovalbumin delivered to the cytoplasm of the APCs, leading to more SIINFEKL peptide presentation. For example, at a sample concentration of 0.45 mg particles/mL, after conversion of absorbance values to presented peptide concentration, sample E shows a 20-fold enhancement over sample A which we reported previously in our proof-of-concept system (*16*).

To determine if the acid-degradable characteristic of the particles enhanced MHC class I presentation, a nondegradable ovalbumin-loaded particle sample was synthesized using *N*,*N*′-methylene-bis-acrylamide as the stable cross-linker. An antigen presentation study was then performed comparing nondegradable and degradable particles with similar protein content. Figure 4 clearly demonstrates that the degradable particles enhance MHC class I presentation, suggesting that the hydrolysis of the cross-linker and release of small molecules in the lysosome may help to destabilize the membrane resulting in the transport of protein into the cytoplasm for processing.

Phagocytosis-Mediated Antigen Delivery into MHC Class I Presentation. To help determine if the particles enter APCs through the process of phagocytosis, antigen presentation assays were performed in the presence of a phagocytosis inhibitor, cytochalasin B (*13*). Cytochalasin B inhibits phagocytosis by preventing actin polymerization and the interaction of actin filaments. Figure 5i shows that the antigen presentation levels for the cells incubated with the inhibitor are greatly reduced as compared to the cells that were not. For example, at the highest particle concentration, the calculated concentration of presented peptide for cells incubated with the inhibitor is only 30% of the peptide presented as calculated for the cells incubated without cytochalasin B. This finding is consistent with a process in which the particles undergo phagocytosis. Another key point is that the peptide presentation levels of the cells incubated without cytochalasin B are very close to the concentration of presented peptide at saturation (Figure 5ii). The saturation concentration is determined from the standard peptide curve, which is prepared by adding free SIINFEKL peptide to the RAW cells in various concentrations. This free peptide is not delivered to the cytoplasm of the RAW cells, but instead directly binds to MHC class I molecules that are on the surface of the cells. These SIINFEKL complexes can also activate the B3Z cells. The concentration of free SIINFEKL at which the absorbance at 595 nm levels off is considered to represent the saturation concentration of presented peptide, which was 2 nM in this experiment (Figure 5ii). For the particle sample, at 0.45 mg particles/mL the concentration of peptide presented without the phagocytosis inhibitor is 1.7 nM of peptide (Figure 5i), which is near the saturation level. This study suggests that this acid-sensitive particle system is very efficient for in vitro delivery of the protein antigen into the MHC class I presentation pathway.

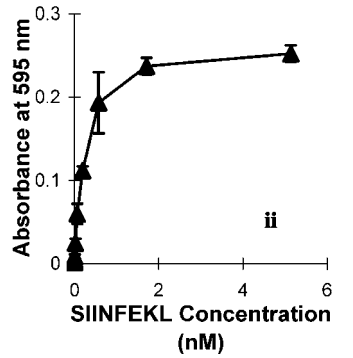

Figure 5. (i) Antigen presentation assay with phagocytosis inhibitor. Sample D (■); sample D with cytochalasin B (●). (ii) Antigen presentation assay of SIINFEKL peptide.

In Vivo Tumor Protection. To assess the ability of the acid-degradable protein-loaded particles to deliver protein to the cytoplasm of APCs and activate CTLs and provide a protective immunity in vivo, a preliminary tumor protection experiment was performed using the EG7 tumor model (*24*, *25*). EG7 is a derivative of the thymoma EL4, which was transfected with the ovalbumin gene, making it a target cell for CTLs activated against ovalbumin. Sample D was chosen for this experiment because it had the best dispersibility of all of the samples in Table 1, an important consideration for the study since the particles had to be suspended in saline and injected into animals. Samples E and F, although also prepared with cross-linker **2**, were somewhat more difficult to suspend than Sample D, most likely due to a degree of particle aggregation as a result of higher ovalbumin content.

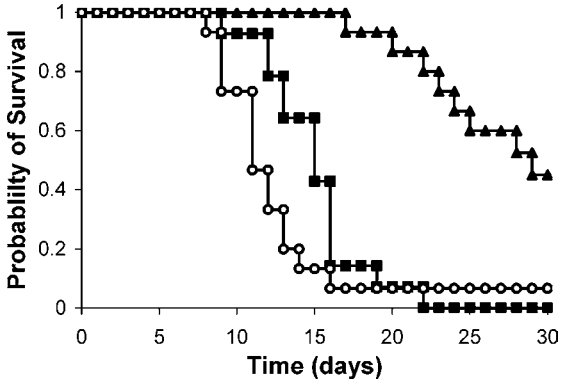

Figure 6. Kaplan−Meier survival plot. Saline (○); free ovalbumin (■); ovalbumin in particles (▲).

The experiment involved three groups of animals as follows: mice immunized with free ovalbumin, mice immunized with an equal amount of ovalbumin encapsulated in the particles (Sample D), and a control group receiving only saline. Each mouse received two subcutaneous immunizations that were 2 weeks apart. Ten days after the final immunization, EG7 tumor cells that had been previously sorted into a set of highly ovalbumin expressing cells were injected subcutaneously into each mouse, and tumor growth was then monitored, with Day 1 being the first day of tumor establishment. Tumors were visible on almost all of the mice in the saline and free ovalbumin groups 7 days after the EG7 injection, whereas 13 out of 15 mice in the particle group did not show any visible tumors until Day 16. In general, tumor growth in the saline control group occurred early in the experiment and was very rapid, resulting in the removal of all but 1 mouse by Day 16. The free ovalbumin group also demonstrated tumor growth early in the experiment but at a slower rate resulting in the removal of all mice from the study by Day 21. For the mice receiving particles, EG7 tumors were not observed until midway through the experiment, and the growth was slower in comparison to the other groups. At the completion of the study, Day 30, five mice in the particle group had yet to be removed from the experiment, although they did have tumors. The trends seen in tumor growth also correlated with the survival rates. This can be seen in the Kaplan−Meier survival plot (Figure 6). The slope of the saline and free ovalbumin series is much steeper than the particle series. The mice that received the particles had a survival rate of 100% after 17 days versus approximately 14% and 7% for the free ovalbumin and saline groups, respectively. The probability of survival eventually dropped to 0% for the free ovalbumin mice by Day 22 while the saline group remained at 7% while the particle group only fell to 45% by the end of the experiment. There was a statistically significant difference between the particle group and the other two groups (compared to saline $p < 0.0001$; compared to ovalbumin alone $p < 0.00001$), but there was no difference between the ovalbumin and saline groups ($p > 0.1$). These encouraging preliminary results suggest that the particles can stimulate an immune response against EG7 tumor cells that is more effective than ovalbumin alone, indicating that the particles can provide a protective immune response against tumor cells in vivo. Future experiments will seek to improve these results by taking advantage of the synthetic flexibility of the system through incorporation of APC targeting and immunostimulatory groups such as mannose and CpG DNA into the particles (*6*, *26*−*28*). Additional studies will also test samples with varied doses and protein loadings to determine if these variables have the same effect in vivo as they do in vitro.

CONCLUSION

This study confirms that tuning the hydrophilicity of acid-degradable cross-linkers such as **2** can be used to enhance the potential of antigen-loaded particles for the delivery of vaccines. Particles prepared with this cross-linker have higher protein loading efficiencies and better dispersibility in aqueous solution than our earlier proof-of-concept system. The MHC class I presentation levels achieved with these particles are vastly enhanced as a result of their ability to deliver more protein into the cytoplasm of APCs. Experiments involving the addition of cytochalasin B, which significantly reduces MHC class I antigen presentation levels provide support for our assumption of a phagocytosis mechanism for the internalization of these particles. Initial animal studies showed promising results with the demonstration that these acid-sensitive particles can stimulate the immune system against an injected protein resulting in the enhanced rejection of EG7 tumor cells in vivo. This new protein delivery system should find applications in vaccines targeted against viruses and tumors, where the activation of CTLs is required for the generation of immunity.

ACKNOWLEDGMENT

We thank Ann Fischer (UC Berkeley Cell Culture Facility) for help with the cell culture studies and Lindsey Jennings (UC Berkeley Animal Facility) for help with the animal studies. We thank the U.S. Department of Energy (Grant DE-ACO3-76SF00098) for funding the development of biocompatible acid-degradable particles and the National Institute of Health (Grant RO1EB002047) for funding the biological studies. Received July 9, 2004; Revised Manuscript Received September 10, 2004

The cDNA encoding human cystatin C (HCC) was subjected to site-specific substitution of alanine for serine at the position 37, to obtain the Asn_{35}-Lys_{36}-Ser_{37} sequence that is a signal for asparagine-linked (*N*-linked) glycosylation of protein in eukaryotes, and was transformed into *Pichia pastoris* X33. As a result, 1.2 mg/L oligomannosyl HCC with a carbohydrate chain of $Man_{10}GlcNAc_2$ was produced by the *Pichia* transformant. The oligomannosyl HCC was more stable at the low ionic strength condition of 50 mM potassium phosphate buffer, pH 7.0, than the wild-type. In addition, the oligomannosylation substantially improved the molecular stability of cystatin against an aspartic proteinase, cathepsin D, in which the susceptibility decreased to less than 50% of nonglycosylated one. The anti-rotavirus activity of HCC was substantially enhanced by the site-directed glycosylation using the yeast expression system. A MA-104 cell line was used as a host cell for human rotavirus type-2 *Wa* strain in this study, to which both the wild-type and oligomannosyl HCCs did not show cytotoxicity at a concentration of 100 μg/mL. More than 80% viability of the host cell infected with 1.0×10^5 PFU/mL of rotavirus was conserved under the condition coexisting with 75 μg/mL of the oligomannosyl HCC, which was 15.2% higher than that of wild-type HCC. Thus, the in vitro anti-rotavirus assay indicated that the supplement of a proper amount of the oligomannosyl HCC could be used as an anti-rotavirus agent.

INTRODUCTION

Human cystatin C, a monomeric cysteine protease inhibitor consisting of 120 amino acid residues with two disulfide bonds, belonging to family II of the cystatin superfamily (*1*), is known to be ubiquitous in tissues and body fluids and has a well-defined molecular structure (*2*−*4*). This proteinaceous inhibitor has been investigated for potential application as antivirus medication for inhibiting replication of picornaviruses (*5*), coronaviruses (*6*, *7*), and herpes simplex type 1 virus (*8*, *9*). It has also been reported that brewer yeast polysaccharides had protective effects against bacterial infections (*10*, *11*). Therefore, if carbohydrate chains are attached to the protein molecule, functionality of human cystatin C will be improved for potential application for food or pharmaceutical aid. Our previous study has reported that mouse cystatin C, with a possible site for N-linked glycosylation, was successfully glycosylated and expressed in both *Saccharomyces cerevisiae* and *Pichia pastoris* (*12*); hereby, we intended to employ human cystatin C instead of mouse cystatin C as a template for biosynthesis using the yeast expression system. While most of the family II cystatins including human cystatin C have no recognition site for asparagine-linked (N-linked) glycosylation on their DNA sequences (*13*), we introduced an Asn-X-Thr/Ser sequence, using a site-specific glycosylation technique, and were able to produce glycosylated human cystatin C in the *Pichia* transformant expression system (*14*).

We have already identified the most possible introduction sites for glycosylation of cystatins belonging to family II for improving stability without any severe loss in their bioactivities (*15*) based on the information from rodent cystatin C and kininogens (*2*, *16*−*18*). The prospective sites for glycosylation in human cystatin C include amino acid residues at the positions 35, 36, and 79 (*15*). Since there were some reports in that the efficiency of the glycosylation decreases with the distance of the glycosylation signal from the N-terminus (*14*, *19*−*21*), we chose the glycosylation site at the position 35 in the molecule. Thus, a mutant human cystatin C, A37S, in which the alanine residue was replaced by serine residue at the position 37 in order to obtain Asn_{35}-Lys_{36}-Ser_{37} sequence, was constructed.

The main objective here was to determine physicochemical properties and anti-rotavirus activity of the mutant human cystatin C with an oligomannnosyl chain on its molecular surface. This study also investigates molecular stability of the oligomannosyl human cystatin C.

MATERIALS AND METHODS

Materials. *Escherichia coli* DH5α and *Epicurian coli* XL1-Blue were used as routine plasmid amplification and host cell for site-directed mutagenesis, respectively. *Pichia pastoris* X33 was employed as a protein expression host (Invitrogen, Carlsbad, CA). Human rotavirus type-2 *Wa* strain was by courtesy of Dr. O. Nishio, National

Institute of Public Health (Tokyo, Japan). A cell line derived from embryonic rhesus monkey kidney, MA-104, was obtained from Shimane Prefectural Institute of Public Health and Environmental Science (Matsue, Japan). All tissue culture media and materials were from Nissui Pharmaceutical Co. Ltd. (Tokyo, Japan). EDTA-trypsin and Cell-Banker (BLC-1) were from CosmoBio Co. Ltd. (Tokyo, Japan) and Jujifield Inc. (Tokyo, Japan), respectively. Egg-white cystatin, *N*α-benzoyl-DL-Arg-*p*-nitroanilide (BAPNA)[1] and MTT (3-[4,5-dimethylthiozol-2-yl]-2,5-diphenyltetrazolium bromide) were from Sigma-Aldrich Japan (Tokyo). Other chemicals used were of all analytical grade and from Wako Pure Chemical Industries, Ltd. (Osaka, Japan) and Sigma-Aldrich Japan (Tokyo, Japan).

Synthesis, Mutation and Expression of Human Cystatin C Gene. A synthetic gene encoding the primary amino acids sequence of human cystatin C was prepared as previously described (*15*). The resulting synthetic gene was cut with *Xho* I and *Xba* I and ligated into a *Pichia pastoris* expression vector, pPICZα-A (Invitrogen, Carlsbad, CA). The inserted gene was sequenced on both strands by the dideoxynucleotide protocol in order to confirm that the DNA sequence encoded for the amino acid sequence of human cystatin C. Site-directed mutagenesis for the introduction of Asn_{35}-Lys_{36}-Ser_{37} sequence, A37S mutation, was performed according to QuikChange Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA). Oligonucleotide primers used for the mutation were 5′-GGTGAGTACAACAAGTCCTC-TAACGACATG-3′, and its antisense pPICZα-A carrying the A37S gene was linearlized with *Dra* I and transformed *P. pastoris* ×33 according to *Pichia* EasyComp Transformation Kit (Invitrogen). Integration of the mutant gene into the yeast genome was confirmed by genomic PCR using 5'AOX1 primer (5′-GACTGGTTC-CAATTGACAAGC-3′) paired with 3'AOX1 primer (5′-GCAAATGGCATTCTGACATCC-3′). A single colony of transformants was inoculated into 2 mL of YPD medium and incubated at 30 °C with shaking at 250 rpm. Cells were grown in 60 mL of YPD. Following collection of cells by centrifugation at 1500*g*, the resultant cell pellet yeast was suspended with 24 mL of BMMY (1% yeast extract, 2% peptone, 100 mM potassium phosphate buffer at pH 7.0, 1.34% yeast nitrogen base, 4×10^{-5} % biotin, and 0.5% methanol as the sole carbon source). Methanol was added to a final concentration of 0.5% every 24 h to maintain induction. After 2-day induction with methanol, the culture was centrifuged at 10 000*g* for 10 min, and then recombinant proteins were purified by hydrophobic interaction chromatography using Hiprep 16/10 Phenyl low-sub column (Amersham Pharmacia Biotech., Japan, Tokyo) followed by size-exclusion chromatography using Superdex 200 HR 10/30 column (Amersham Pharmacia Biotech). Glycosylated protein was prepared by affinity chromatography using concanavalin A-Sepharose (Amersham Pharmacia Biotech). The con-A column was prewashed with 10 bed volumes of 100 mM potassium phosphate (pH 7.0) containing 0.5 M NaCl and washed with the same buffer after loading sample until the washing solution was free from proteins. The absorbed glycoprotein was subsequently eluted with 100 mM α-methylmannoside in the 20 mM Tris-HCl buffer containing 0.5 M NaCl. The glycoprotein solution was dialyzed against 0.1 M NaCl−100 mM potassium phosphate buffer (pH 7.0) and used for further examination,

Endo-H Treatment and SDS−Polyacrylamide Gel Electrophoresis. Endo-β-*N*-acetylglucosaminidase (endo-H) was used to digest the carbohydrate-chain according to the method of Tarentino and Maley (*22*) with slight modifications. Recombinant proteins (0.1 mg/mL) were boiled in 50 mM sodium citrate buffer (pH 5.5) containing 1% SDS and 200 μg/mL of phenylmethylsulfonyl fluoride for 5 min. After cooling, samples were supplemented with an equal volume of either 0.02 unit of endo-H in 50 mM sodium citrate buffer (pH 5.5) or the same buffer without the enzyme and were subsequently incubated at 37 °C for 20 h. After incubation, the samples were analyzed by SDS-polyacrylamide gel electrophoresis (PAGE). SDS−PAGE was conducted according to the method of Laemmli (*23*) using 15% acrylamide separating gel and 5% stacking gel containing 1% SDS. Samples were heated at 100 °C for 5 min in 0.01 M Tris-glycine buffer (pH 8.8) containing 1% SDS and 1% β-mercaptoethanol. Electrophoresis was carried out at a constant current of 10 mA for 5 h using an electrophoretic buffer of Tris-glycine containing 0.1% SDS. After electrophoresis, the gel sheet was stained with 0.025% Coomassie Brilliant Blue R-250.

Analysis of Carbohydrate Moiety. The total sugar content of the glycosylated mutant A37S was estimated using the phenol−sulfuric acid reaction employing mannose as a standard. HPLC analysis serves as a method of identification of the hexose liberated from glycosylated A37S cystatin by hydrolysis with 2 N HCl at 100 °C for 3 h in a sealed glass ample. The hydrolysates were dried, dissolved in water, and chromatographed on an Asahipak NH2P-50 column (Asahi Chemical, Tokyo) in 75% acetonitrile using the Hitachi HPLC system equipped with an RI detector. For the analysis of hexosamine, the hydrolysates with 3 N HCl at 100 °C for 4 h were dried and then analyzed using an amino acid analyzer (Tosoh, HLC 805).

Papain-Inhibitory Activity. Papain-inhibitory activity of recombinant proteins was determined using a synthetic substrate of papain, N^{α}-benzoyl-DL-Arg-*p*-nitroanilide (*24*). The inhibitory activity was expressed as the amount of active inhibitor (AI) present in the aliquot taken for assay: AI (μmol) = {% inhibition/100} × {PA (μg)/23 400 (μg/μmol)} where PA is the amount of papain present in the assay solution. The protein concentration of the solution was determined by Bio-Rad protein assay kit (Bio-Rad Lab., Tokyo) using egg-white cystatin as the protein standard.

Circular Dichroism (CD) Analysis. The far-ultraviolet (190−260 nm) CD spectra of wild-type and mutant proteins were recorded at a protein concentration of 300 μg/mL protein in 50 mM potassium phosphate buffer (pH 7.0) using a spectropolarimeter (JASCO J-720, Tokyo) using a 1.0-cm cuvette. The temperature of the cuvette was maintained at 25 °C with a circulating water bath. The accuracy of the data was improved by averaging 10 scans integrated using the data processor, JASCO Series 700. Accumulation of the CD spectra was initiated within 5 min of recording the absorbance spectra of the samples. The resulting averaged spectra were normalized to molar ellipticities (molar ellipticity [θ] in deg cm^2/dmol).

Molecular Stability. The melting curve of recombinant protein was determined using CD spectroscopy. A 300 μg/mL protein solution prepared as described for the above CD measurement was put into a 1.0-cm cuvette, and the average ellipticity signal in the CD spectra was measured at 222 nm at different temperature. The

[1] Abbreviations: BAPNA, *N*α-benzoyl-DL-Arg-*p*-nitroanilide; CD, circular dichroism; FBS, fetal bovine serum; MEM, Eagle's minimum essential medium; MTT, 3-[4,5-dimethylthiozol-2-yl]-2,5-diphenyltetrazolium bromide; PAGE, polyacrylamide gel electrophoresis; PCR, polymerase chain reaction; SDS, sodium dodecyl sulfate.

temperature of the sample was gradually increased from 40 °C to 90 °C at a rate of 1 °C/min.

The protein solution (300 μg/mL protein) was mixed with potassium phosphate buffer (pH 7.0) containing guanidine hydrochloride (up to 6 M) and incubated at 25 °C for 5 h, and then changes of CD spectra were measured. Unfolding fraction was expressed as the relative ratio at 222 nm. Also we determined changes of the CD spectra and papain-inhibitory activity after 30-day incubation at 4 °C in 50 mM phosphate buffer (pH 7.0) with and without NaCl (up to 0.5 M). Susceptibility of recombinant cystatins to cathepsin D was measured to determine the conformational stability of oligomannosyl cystatin. Five hundred microliters of a 0.1 mg/mL protein solution of cystatin was incubated with an equal volume of 0.5 μM cathepsin D at 37 °C. After a preset time up to 40 min, 100 μL samples were removed and mixed with 1 μM pepstatin A to terminate the enzymatic activity of the cathepsin D. Residual papain-inhibitory activity determined using BAPNA was expressed as percentage of the initial activity.

Cytotoxicity Assay against MA-104 Cells. To assess cytotoxicity of recombinant cystatins, 1.0×10^5 cells/mL MA-104 cells were seeded in Eagle's minimum essential medium (MEM) containing 10% fetal bovine serum (FBS) on a 96-well tissue culture microplate (IWAKI Co, Tokyo) and incubated at 37 °C for 24 h in a CO_2 incubator. Then, 100 μg/mL protein (as a final concentration) sample was added with MEM containing 10% FBS and incubated for 3 days under the 5% CO_2 environment. The number of vial cells was determined using MTT method as described earlier (*25*).

Anti-Rotavirus Assay in Vitro. The inhibitory effects of recombinant cystatins on the replication of rotaviruses were determined by inhibition rate (%) of virus-induced cytotoxicity in MA-104 cells. The cells were grown to confluence in a 96-well plate in the presence of MEM and 10% FBS at 37 °C under 5% CO_2 environment. The cells were washed with serum-free media before use. Aliquots of recombinant cystatins were diluted with MEM and mixed with an equivalent volume of rotavirus *Wa* strain. Thus, the confluent monolayer culture of MA-104 was infected with the final concentration of 1.0×10^5 PFU/mL rotavirus coexistent with various concentrations of recombinant cystatins and then continuously incubated for 3 days in 5% CO_2. After incubation, cell viability was determined by the MTT assay (*25*).

RESULTS

Production of Recombinant Cystatins. The wild-type and A37S human cystatin C's were successfully expressed in *P. pastoris* and purified by hydrophobic interaction chromatography and size-exclusion chromatography. SDS−PAGE results showed that mutant A37S was expressed in two different forms: a major form with apparent molecular mass of 15 kDa and a minor form with 20 kDa. As shown in Figure 1, the 20 kDa band completely disappeared, and the 15 kDa band remained by the deglycosylation with endo-β-*N*-acetylglucosaminidase, suggesting that the 20 kDa cystatin was glycosylated with N-linked carbohydrates and the 15 kDa protein was nonglycosylated. Glycosylated human cystatin C secreted from yeast was separated from nonglycosyl cystatin C by con-A affinity chromatography and determined for the composition of the carbohydrate moiety. Chemical analysis revealed that the oligosaccharide chain consisted of 10 mol of mannose and 2 mol of *N*-acetylglucosamine, indicating that the glycosylated

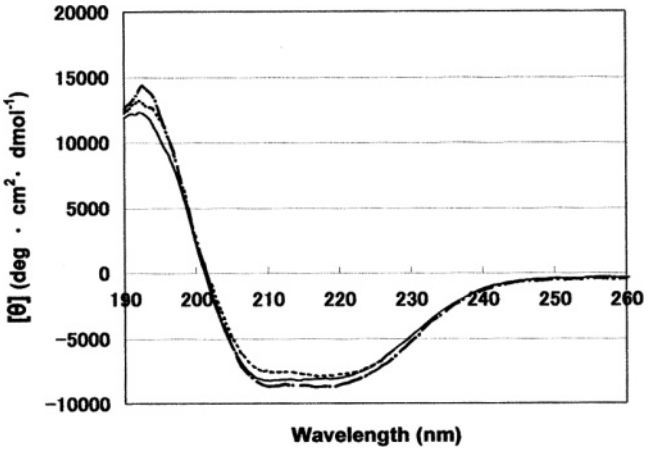

Figure 2. CD spectra of wild-type and mutant cystatins. The CD spectra were recorded at a protein concentration of 300 μg/mL in a 50 mM potassium phosphate buffer (pH 7.0) in a cuvette (1.0 cm) at 25 °C. The spectra are from a representative experiment repeated three times with similar results. —, wild-type cystatin; — · -, oligomannosyl cystatin; - - - -, nonglycosylated cystatin.

cystatin carried $Man_{10}GlcNAc_2$-linked oligomannosyl form. The average secretion amount was 1.2 mg/L culture for oligomannosyl cystatin C, while that of nonglycosyl type was 53 mg/L culture.

Molecular Stability of Oligomannosyl Cystatin C. The effect of the glycosylation on the conformation of human cystatin C was analyzed by CD measurement. As shown in Figure 2, no substantial changes in CD spectra were observed among wild-type, nonglycosylate, and glycosylated human cystatin C, suggesting that no conformational changes occurred with the site-directed mutagenesis as well as the attachment of an oligomannosyl chain.

Heat stability was determined by monitoring changes changes in ellipticity of cystatin C at 222 nm of CD spectra at temperature increments. The structures of all three recombinant cystatins were stable up to 58 °C with T_m value of 68 °C. While wild-type and nonglycosylated cystatins were completely denatured at 74 °C, oligom-

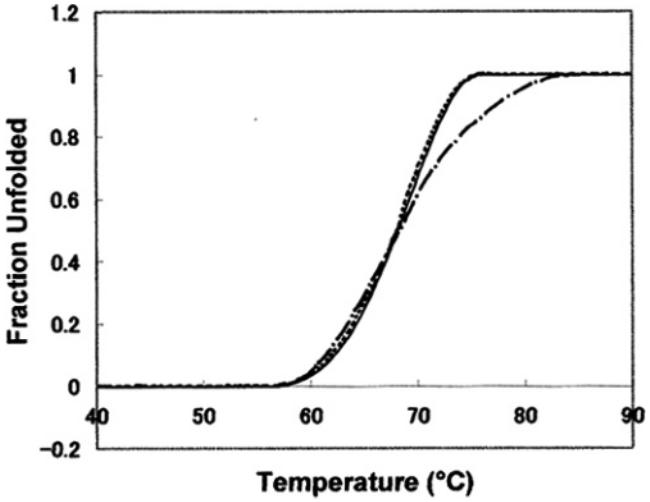

Figure 3. Heat stabilities of recombinant cystatins. A 300 μg/mL protein in a 50 mM potassium phosphate buffer (pH 7.0) was put into a 1.0 cm cuvette, and the average ellipticity signal in the CD spectra was measured at 222 nm at the temperature range of 40−90 °C. Unfolding fraction was expressed as the relative ratio at the wavelength. Data are from a representative experiment repeated three times with similar results. —, wild-type cystatin; — · —, oligomannosyl cystatin; - - - -, nonglycosylated cystatin.

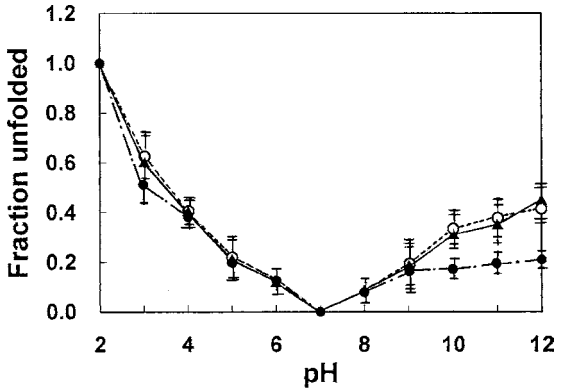

Figure 4. Molecular stability of recombinant cystatins under various pH conditions. A 300 μg/mL protein in a various buffer (pH 2−8, Citrate-Na_2HPO_4 buffer; pH 9 and 10, Tris-HCl buffer; pH 11 and 12, Na_2HPO_4−NaOH buffer) was incubated at 25 °C for 1h, and the average ellipticity signal in the CD spectra was measured at 222 nm. Unfolding fraction was expressed as the relative ratio at the wavelength. All data are expressed as mean ± SD (n = 3). ▲—▲, wild-type cystatin; ●—·—●, oligomannosyl cystatin; ○- - - -○, nonglycosylated cystatin.

annosyl cystatin was completely denatured at 83 °C (Figure 3). Furthermore, the molecular stabilities of recombinant cystatins were assessed under various pH conditions. No substantial changes appeared at pH 1−12 for wild-type and nonglycosylated cystatins; however, structure stability was greatly increased for oligomannosyl cystatin at pH 10−12, as shown in Figure 4.

Measurement of tolerance to guanidine hydrochloride was based on concentration-dependent denaturation. A complete denaturation was observed in wild-type and nonglycosylated cystatins in the salt density of 3 M, whereas that of oligomannosyl cystatin was 4 M, as shown in Figure 5. Interestingly, oligomannosyl cystatin showed a biphase structure transition, in contrast to a monophase transition of wild-type cystatin and nonglycosylated A37S. Effects of the salt existence on molecular stability of recombinant cystatins were also investigated after 1 month storage at 4 °C. According to the CD spectra around 222 nm (220−240 nm), their structures

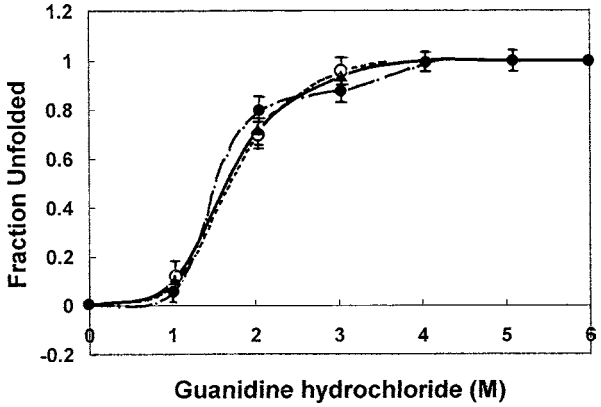

Figure 5. Molecular stability of recombinant cystatins to guanidine hydrochloride. A 300 μg/mL protein in a 50 mM potassium phosphate buffer (pH 7.0) containing guanidine hydrochloride (0−6 M) was incubated at 25 °C for 5 h, and the average ellipticity signal in the CD spectra was measured at 222 nm. Unfolding fraction was expressed as the relative ratio at the wavelength. All data are presented as mean ± SD (n = 3). ▲—▲, wild-type cystatin; ●—·—●, oligomannosyl cystatin; ○- - - -○, nonglycosylated cystatin.

were most stable in 0.5 M NaCl for both wild type and variation types (Figure 6). The phenomena were consistent with the papain-inhibitory activity of the tested cystatins, in that the strongest activities were observed under the 0.5 M NaCl condition. At the lower ionic strength condition of 50 mM potassium phosphate buffer, pH 7.0, without any additional NaCl, activities of wild-type and nonglycosylated cystatin decreased to 61.4 % and 59.8% of original stocks, respectively, while oligomannosyl cystatin maintained 95.7 % activity (Figure 7). Besides, stability of cystatin C to cathepsin D proteolysis was also investigated. Cathepsin D, a typical lysosomal aspartyl proteinase, is widely distributed in all mammalian tissues. Pepstatin A, an inhibitor of aspartyl proteinases, was used to avoid further digestion of recombinant cystatins by cathepsin D after a certain incubation time. As shown in Figure 8, the papain-inhibitory activity was better maintained in the oligomannosyl cystatin than in the wild-type and nonglycosyl ones. The papain-inhibitory activity of the oligomannosyl cystatin retained about 20 % of the initial activity after incubation with cathepsin D for 40 min, while both unglycosylated cystatins were rapidly inactivated with increasing incubation time. It is concluded that the site-directed glycosylation confers cystatin's better conformational stability in various undesirable environmental conditions.

Antivirus Effect of Oligomannosyl Cystatin C. Recombinant cystatins was used at a concentration of 100 μg/mL protein, at which no cytotoxic effect was observed on MA-104 cells. Confluent MA-104 cells were continuously incubated for 3 days at 37 °C in 5% CO_2 under new MEM with and without 1.0×10^5 PFU/mL rotavirus (Figures 9A and 9B). As a result, cells were destroyed, were detached from the well base, and floated in the culture in the rotavirus infection system (Figure 9B). As an extension, preventing effects of recombinant cystatins on rotavirus infection were investigated. On the other hand, many adhered cells were observed in the well base in the coexisting system with 10 μg/mL protein recombinant cystatins, as shown in Figure 9C and 9D. The dose−response relationship showed a greater effect with increasing concentration of cystatins (Figure 10). Furthermore, it revealed that the effect of oligomannosyl cystatin C was more effective than the wild-type coun-

terpart. One hundred μg/mL protein of the glycoprotein retained more than 80% viability of the host cells after a 3-day incubation with a rotavirus.

DISCUSSION

Rotaviruses, nonenveloped and double-stranded RNA viruses belonging to the Reoviridae family, were discovered in 1963 in mice as etiologic agents of acute gastroenteritis (*26*), and human rotaviruses were first identified in 1973 as a cause of infectious gastroenteritis in infants (*27*). Rotavirus infections have been associated with a high rate of infant mortality with more than one million incidents in developing countries (*28*, *29*), and now they are the leading causes of dehydrating diarrhea throughout the world (*30*−*32*). Each year in the United States, rotavirus infections account for an estimated 3.5 million cases of diarrhea and vomiting among children aged less than 5-years old (*33*). Current surveillance reveals that all age groups are regarded as being susceptible to rotavirus infection (*34*−*39*), and a large amount of foodborne diseases are associated with viruses, especially rotaviruses (*40*−*43*). Vaccines have been developed for the prevention of the gastrointestinal virus infections; however, a rotavirus vaccine, rhesus-human reassortant rotavirus tetravalent vaccine licensed by the FDA, has already been withdrawn due to rare but severe complications of intussusception (*44*). There is a growing awareness of the need for the development of new and safe anti-rotavirus medicines.

Thus, a protease inhibitor, human cystatin C, was employed for the template for the prevention and/or

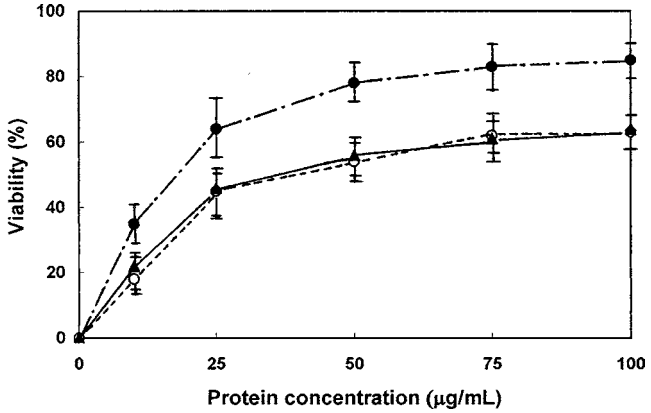

Figure 10. Concentration dependency of anti-virus effects. All data are presented as mean±SD (n = 3). ▲—▲, wild-type cystatin; ●—·—●, oligomannosyl cystatin; ○- - - -○, nonglycosylated cystatin.

treatment agent of rotavirus infections in this study. The result revealed that recombinant cystatins exhibited potential antivirus effects to human rotavirus type-2 *Wa* strain. The anti-rotavirus effect of glycosylated cystatin was stronger than that of wild-type or nonglycosylated cystatin. The improved conformational stability of cystatin due to its oligomannosylation could be attributed to high antiviral activity. As shown in Figures 3−6, the oligomannosyl cystatin was found to be appreciably more stable than unglycosylated controls under various harsh conditions. Although cystatin has a tightly packed conformation (*45*), further enhancement of the molecular stability was observed in the oligomannosyl cystatin. According to our previous work, the reversibility of the denatured glycosyl lysozyme was observed in the DSC, obtained by reheating after heat denaturation (*46*). The oligomannosyl cystatin seems to easily refold due to the excellent reversibility of denaturation. Cathepsin D, a typical lysosomal aspartyl proteinase, is widely distributed in all mammalian tissues, and it is assumed that the protease is responsible for the regulation of sulfhydryl proteinase activity by inactivating cystatin C and kininogen (*47*). As shown in Figure 7, the papain-inhibitory activity was better maintained in the oligomannosyl cystatin than in the unglucosylated controls. The carbohydrate chain probably blocked physical accessibility of cathepsin D to the proteolytic cleavage sites in the oligomannosyl cystatin, and resulting conformational stability of oligomannosyl cystatin might play a key role in the enhancement of antirotavirous effect, compared to nonglucosylated cystatin.

Oligomannosyl cystatin might also prevent rotavirus binding to MA-104 cells and inhibit virus replication in the target cell. As shown in Figure 8, oligomannosyl cystatin was able to keep most host cells intact under the rotavirus coexisting system. Antivirus properties of glycoproteins and protease inhibitors have attracted attention from many researchers (*48*−*55*). In the early 1990s, bovine submaxillary mucin, a glycoprotein, was found to inhibit the replication of rotaviruses. It was suggested that the mucin served as an analogue of the rotaviral receptor and prevented the cell attachment by binding to the virus (*48*). Later, more glycoproteins with various carbohydrate chains, such as ovoalbumin, ovomucoid, and lactoferrin, were found to inhibit rotavirus replication, and the antiviral effect was attributed to prevent virus entry in the host cell, either by blocking cellular receptors or by direct binding to the virus particles (*56*−*59*). Although it well-known that the sialic acid moiety of the oligosaccharides plays an important role in the inhibition of rotaviral infection, there also are some papers that describe carbohydrate chains without sialic acid that could be receptors for rotaviruses (*60*−*62*). It has been reported that polysaccharides from brewer yeast showed antivirus effects against 13 kinds

of DNA and RNA viruses, by protecting host cells from being infected with the tested viruses (*63*). It has been found that rotaviruses had a preference in binding glycoproteins on the cell membrane (*64*), which was possibly associated with its outer capsid glycoprotein components of VP4 and VP7 (*65*). VP7 contains a high-mannose oligosaccharide (*66*). The enhanced antivirus activity of oligomannosylated human cystatin C could be due to the synergetic effect of its improved structure stability and carbohydrate moiety, which might compete with rotavirus caspid glycoproteins for cell receptors and also bind with the rotavirus.

The present study successfully prepared oligomannosylated human cystatin C in the *Pichia* expression system and demonstrated that it had higher anti-rotavirus inhibition effect than nonglycosylated cystatin. It opened the opportunity to prevent rotavirus infection by applying human cystatin C. The highly efficient mechanism of the anti-rotavirus effect of oligomannosyl cystatin could be related to binding of the oligomannosyl chain to the rotavirus. Our finding reveals a new potential avenue for antiviral therapeutics and prophylaxis, targeting specific oligosaccharide-comprised sites in rotaviruses, and certain enveloped viruses, including influenza virus and HIV. Further studies will be performed to investigate mechanisms of enhanced antirotavirus effect of glycosylated cystatin.

Reversible Photocontrol of Peptide Helix Content: Adjusting Thermal Stability of the Cis State

Nina Pozhidaeva, Marie-Eve Cormier, Anita Chaudhari, and G. Andrew Woolley*

Department of Chemistry, University of Toronto, 80 Saint George Street, Toronto M5S 3H6, Canada. Received June 21, 2004; Revised Manuscript Received September 7, 2004

Cross-linking reagents based on an azobenzene core can be used to reversibly photoregulate secondary structure when introduced as intramolecular bridges in peptides and proteins. Photoisomerization of the azobenzene core in the trans to cis direction is triggered by photon absorption but isomerization from cis to trans occurs thermally as well as photochemically. The rate of the thermal process effectively determines the half-life of the cis form as well as the extent to which the trans form can be recovered. We designed and characterized a series of methanethiosulfonate (MTS)-bearing thiol-reactive azobenzene-based cross-linkers. These cross-linkers are shown to permit photoregulation of helix content in a test peptide with half-lives for the cis conformation ranging from 11 s to 43 h at 25 °C. The cross-linkers described here thus broaden the range of reagents available for reversible photocontrol of peptide and protein conformation.

INTRODUCTION

Upon irradiation at appropriate wavelengths, azobenzene chromophores undergo reversible cis−trans isomerization (*1*). Kumita et al. introduced thiol-reactive azobenzene cross-linkers as tools for the control of peptide conformation (*2*−*4*). They designed a symmetrical reagent 4,4′-bis(iodoacetamide)azobenzene (Figure 1) in which two Cys-reactive iodoacetamide moieties are linked to the azobenzene chromophore. When the reagent was used to intramolecularly cross-link peptides with Cys residues spaced at either i, i+4, i, i+7 or i, i+11 positions, photoisomerization led to predictable changes in peptide secondary structure.

Azobenzene isomerization in the cis-to-trans direction, in addition to being promoted by irradiation with light at >400 nm, occurs thermally. The half-life of the cis isomer of the bis(iodoacetamide)azobenzene cross-linker shown in Figure 1 is approximately 12 min at 25 °C (*3*). Half-lives for thermal isomerization are important for determining the practical usefulness of such photochemical switches. For instance, if structural studies are intended with the cis form, a much longer half-life than 12 min may be desired. Alternatively, if a pulsed conformational change is desired as part of a biochemical switch, then rapid return to the trans state would be preferable. Additionally, a rapid thermal relaxation to the trans form ensures virtually complete conversion to the trans isomer, important where a complete "off" state is desired for a biochemical switch. Because of the overlap in absorption spectra of cis and trans azobenzenes, irradiation never produces only one isomer. We note that natural photoswitches (e.g. photoactive yellow protein, phytochromes) also employ thermal relaxation to reset the switch (*5*).

Several groups have shown that the rate of thermal isomerization of azobenzenes can be varied substantially by altering the nature of substituents on the aromatic rings (e.g. (*6*−*9*)). For instance, thermal stability can be

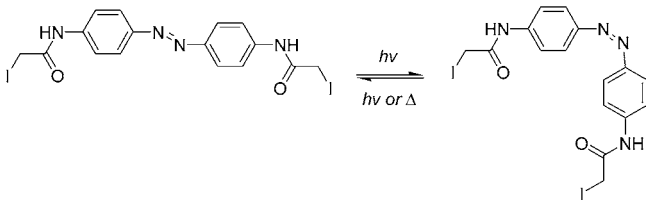

Figure 1. Cis−trans isomerization of 4,4′-bis(iodoacetamide)-azobenzene.

Figure 2. Two resonance forms of a substituted diamino-azobenzene.

adjusted by varying substituents that control the relative contribution of an N−N single bond resonance structure (Figure 2)(*8*, *10*). Precisely how this operates to lower transition state energies is not clear, however, since the mechanism of isomerization (rotation or inversion) remains controversial (*11*).

We wished to create a series of azobenzene cross-linkers analogous to the Kumita compound but showing a range of thermal stabilities. To enhance stability, we designed a derivative with sp^3 carbon atoms in the para positions in the expectation that it would show stability similar to *p*-methyl azobenzene ($\tau^1/_2$ 2−3 days)(*6*). To increase the rate of thermal reversion we designed derivatives in which enhanced delocalization of the *p*-amino group lone pair electrons would be possible. High reactivity and selectivity toward Cys residues was achieved by introducing methanethiosulfonyl groups. These groups enable reversible attachment of the cross-linker to peptides and proteins via disulfide linkages (*12*). The effects of the cross-linkers on the conformation of a test peptide (FK-11)(*3*) were evaluated.

EXPERIMENTAL PROCEDURES

The following includes general experimental procedures, specific details for representative reactions, and

isolation and spectroscopic information for the new compounds prepared. All ^1H and ^{13}C NMR spectra were recorded using a Varian Unity 400 or a Varian Gemini 300 spectrometer. All chemicals were purchased from Aldrich Chemical Co. except if specified otherwise. High-resolution mass spectra were obtained either by electron impact (EI) or electrospray (ESI) ionization. Peptide mass spectra were obtained either by electrospray (ESI) or MALDI ionization.

Synthesis of 4,4′-Dimethylazobenzene (6). *p*-Toluidine (2.0 g, 18.7 mmol) was dissolved in dichloromethane (160 mL). Potassium permanganate (8.86 g, 56.1 mmol) and cupric sulfate pentahydrate (9.32 g, 37.3 mmol) were added, and the suspension was stirred at room temperature for 48 h. The suspension was filtered through a mixture of Celite and silica and eluted with dichloromethane. The solid obtained after evaporation of the filtrate was redissolved and purified on a silica column with dichloromethane as solvent to give **6** as an orange solid (780 mg, 40%). ^1H NMR (300 MHz, $CDCl_3$) δ 2.43 (s, 6H, CH_3), 7.31 (d, 4H, J = 8.1 Hz, Ar), 7.80 (d, 4H, J = 8.1 Hz, Ar); ^{13}C NMR (100 MHz, $CDCl_3$) δ 21.5, 122.7, 129.7, 141.2, 150.8. HRMS-EI for $C_9H_8O_4S$, calcd 210.1166, found 210.1157.

Synthesis of 4,4′-Dibromomethylazobenzene (7). 4,4′-Dimethylazobenzene (**6**)(202 mg, 0.97 mmol), *N*-bromosuccinimide (343 mg, 1.9 mmol), and benzoyl peroxide (7.0 mg, 0.03 mmol) were suspended in carbon tetrachloride (4 mL) and refluxed for 2 h. Another aliquot of benzoyl peroxide (7.0 mg, 0.03 mmol) was added to the mixture and reflux continued for another 2 h. The mixture was then stirred at room-temperature overnight. The solution was filtered, and the orange solid obtained was redissolved in dichloromethane. The organic layer was then washed with water, dried over $MgSO_4$, and concentrated under vacuum. The product was purified by flash chromatography using hexanes/EtO_2 (1:1) as eluant to give **7** as an orange solid (175 mg, 49%). ^1H NMR (300 MHz, $CDCl_3$) δ 4.58 (s, 4H, CH_2), 7.55 (d, 4H, J = 8.4 Hz, Ar), 7.90 (d, 4H, J = 8.4 Hz, Ar); ^{13}C NMR (100 MHz, $CDCl_3$) δ 32.7, 123.4, 129.9, 140.8, 152.3 HRMS-EI for $C_9H_8O_4S$, calcd 365.9371, found 365.9367.

Synthesis of 4,4′-Diiodomethylazobenzene (8). Sodium iodide (5.83 g, 39 mmol) was dissolved in dry acetone (50 mL) and stirred under nitrogen for 10 min. 4,4′-Dibromomethylazobenzene (**7**)(143 mg, 0.39 mmol) was added to the mixture in dry tetrahydrofuran (14 mL). The mixture was refluxed for 6 h and then stirred at room-temperature overnight. The solvent was evaporated and the solid resuspended in dichloromethane. The excess of sodium iodide and sodium bromide was filtered out, and the solution was evaporated under vacuum to give **8** as an orange solid (173 mg, 96%). ^1H NMR (300 MHz, $CDCl_3$) δ 4.53 (s, 4H, CH_2), 7.52 (d, 4H, J = 8.8 Hz, Ar), 7.84 (d, 4H, J = 8.8 Hz, Ar); ^{13}C NMR (100 MHz, $CDCl_3$) not soluble enough in $CDCl_3$ and DMSO for routine ^{13}C; HRMS-EI for $C_9H_8O_4S$, calcd 461.9090, found 461.9099.

Synthesis of 4,4′-Methanethiosulfonatemethyl-azobenzene (1) (MTS-alkyl-azobenzene). 4,4′-Diiodomethylazobenzene (**8**) (28 mg, 0.062 mmol) and sodium methanethiosulfonate (Toronto Research Chemicals) (42 mg, 0.31 mmol) were dissolved in a mixture of ethanol (2 mL) and dichloromethane (2 mL) and refluxed overnight. Dichloromethane and water were added to the mixture. The organic layer was dried over $MgSO_4$ and evaporated. The product was dissolved in dichloromethane and precipitated with a few drops of pentane to give **1** as an orange solid (12 mg, 45%). ^1H NMR (300 MHz, $CDCl_3$) δ trans isomer 2.99 (s, 6H, CH_3), 4.45 (s, 4H, CH_2), 7.57 (d, 4H, J = 8.4 Hz, Ar), 7.93 (d, 4H, J = 8.4 Hz, Ar); ^{13}C NMR (100 MHz, $CDCl_3$) δ 40.7, 51.6, 123.7, 130.2, 138.6, 152.2; HRMS-ESI for $C_9H_8O_4S$, calcd 431.0222, found 431.0231.

Synthesis of 4,4′-Dichloroacetamide Azobenzene (10). 4,4′-Diaminoazobenzene (**9**) (255 mg, 1.2 mmol) (Lancaster, Pelham NH) was dissolved in anhydrous tetrahydrofuran (20 mL) and stirred under nitrogen for 15 min protected from light. Three equivalents of triethylamine (500 μL, 3.61 mmol) was added, followed by the dropwise addition of 3 equiv of chloroacetyl chloride (287 μL, 3.61 mmol). The reaction mixture was left stirring under nitrogen for 30 min at room temperature. The reaction mixture was filtered via vacuum filtration to remove the precipitate that formed, and the tetrahydrofuran was removed by rotary evaporation. The crude product was redissolved in a solution of tetrahydrofuran and dichloromethane (1:1) and extracted with water acidified with a few drops of 1% HCl. The filtrate was dried over anhydrous $MgSO_4$ and vacuum filtered, and solvents were removed by rotary evaporation producing a yellow-brown solid (**10**) (395 mg, 91%). ^1H NMR (DMSO-d_6, 300 MHz): δ 4.31 ppm (s, 4H), δ 7.79 ppm (d, J = 9.0 Hz, 4H), δ 7.87 ppm, (d, J = 9.0 Hz, 4H), δ 10.65 ppm (s, 2H). ^{13}C NMR (DMSO-d_6, 75 MHz): δ 43.6, 119.6, 123.5, 141.2, 148.0, 165.0; EI−HRMS: ($C_{16}H_{14}Cl_2N_4O_2$), calcd 364.0494, found 364.0498.

Synthesis of 4,4′-Diiodoacetamide Azobenzene (11). Anhydrous acetone (20 mL) and anhydrous tetrahydrofuran (15 mL) were combined and the solvent mixture degassed. Sodium iodide (1 g, 7.1 mmol) was dissolved in the degassed solvent and added to 150 mg (0.71 mmol) of dichloroacetamide azobenzene (**10**). The reaction mixture was stirred for 12 h under nitrogen and protected from light. After filtration to remove NaCl, the solvent was removed by rotary evaporation to produce a yellow-brown solid. The solid was redissolved in a solution of tetrahydrofuran and dichloromethane (1:1), and excess of NaI was removed by vacuum filtration. The filtrate was extracted with water, dried over anhydrous $MgSO_4$, vacuum filtered, and solvents were removed by rotary evaporation to produce a yellow-brown solid (**11**) (330 mg, 85%). ^1H NMR (DMSO-d_6, 300 MHz): δ 3.87 ppm (s, 4H), δ 7.76 ppm (d, J = 9.0 Hz, 4H), δ 7.86 ppm, (d, J = 9.0 Hz, 4H), δ 10.67 ppm (s, 2H); ^{13}C NMR (DMSO-d_6, 100 MHz), δ 1.4, 119.3, 123.5, 141.5, 147.8, 167.0; EI−HRMS: ($C_{16}H_{14}I_2N_4O_2$), calcd 547.9209, found 547.9199.

Synthesis of 4,4′-Methanethiosulfonylacetamide Azobenzene (2). 4,4′-Diiodoacetamide azobenzene (**11**) (90 mg, 0.164 mmol) and sodium methanethiosulfonate (48.4 mg, 0.361 mmol) (Toronto Research Chemicals) were dissolved in a degassed mixture of anhydrous ethanol (15 mL) and anhydrous tetrahydrofuran (15 mL) and refluxed for 12 h. The solvents were removed by rotary evaporation to produce a yellow-brown solid (**2**) that was washed with water to remove excess sodium methanethiosulfonate and dried (77 mg, 85%). ^1H NMR (DMSO-d_6, 300 MHz): δ 3.61 ppm (s, 6H), δ 4.24 ppm (s, 4H), δ 7.78 ppm (d, J = 9.0 Hz, 4H), δ 7.87 ppm, (d, J = 9.0 Hz, 4H), δ 10.72 ppm (s, 2H); ^{13}C NMR (75 MHz, DMSO-d_6), δ 38.4, 50.6, 119.6, 123.5, 141.2, 148.0, 165.6; ESI−HRMS: ($C_{18}H_{21}N_4O_6S_4$)(MH^+), calcd 517.0343, found 517.0338.

Synthesis of 4,4′-*p*-Nitrophenoxyacetamide Azobenzene (12). 4,4′-Diaminoazobenzene (**9**)(80 mg, 0.377 mmol) (Lancaster, Pelham NH) was dissolved in anhydrous dichloromethane (20 mL) and stirred under nitrogen for 15 min protected from light. Four equivalents of *p*-nitrophenyl chloroformate (304 mg, 1.509 mmol) (Flu-

ka) were dissolved in anhydrous dichloromethane (10 mL) and added to the diaminoazobenzene solution, followed by the dropwise addition of 4 equiv of pyridine (121.4 μL, 1.509 mmol). The reaction mixture was stirred under nitrogen at room temperature for 2 h. The volume of the solvent was reduced by half, and the solid precipitate was collected. The precipitate was purified by washing with water, 5% HCl, 5% NaOH, and water again to give **12** as a yellow-brown solid (165 mg, 81%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 7.58 ppm (d, J = 9.0 Hz, 4H), δ 7.72 ppm, (d, J = 9.0 Hz, 4H), δ 7.89 ppm (d, J = 9.0 Hz, 4H), δ 8.32 ppm (d, J = 9.0 Hz, 4H), δ 10.87 ppm (s, 2H); ^{13}C NMR (100 MHz, DMSO-d_6), δ 118.9, 123.0, 123.6, 125.3, 141.0, 144.7, 147.8, 150.5, 155.3; Molecular ion was not observed with EI-MS.

Synthesis of 4,4′-(Methanethiosulfonate-ethyloxy)-acetamide Azobenzene (3). 4,4′-*p*-Nitrophenoxyacetamide azobenzene (**12**) (15.8 mg, 0.029 mmol) and 2-hydroxyethyl methanethiosulfonate (10 mg, 0.064 mmol) (Toronto Research Chemicals) were combined together and suspended in DMSO (3 mL). Diisopropylethylamine (2.2 equiv, 11.2 μL, 0.064 mmol) was added, and the reaction mixture was stirred at room temperature under nitrogen for 6 h. The solvent was removed under high vacuum. The crude product was washed with water, 5% sodium bicarbonate, and water and dried (10 mg, 60%). ^{1}H NMR (acetone-d_6, 300 MHz): δ 3.470 ppm (s, 6H), δ 3.85 ppm (q, J = 5.7 Hz, 4H), δ 4.31 ppm (t, J = 5.7 Hz, 4H), δ 7.83 ppm (d, J = 8.7 Hz, 4H), δ 7.96 ppm, (d, J = 8.7 Hz, 4H), δ 9.80 ppm (s, 2H). ^{13}C NMR (100 MHz, acetone-d_6), δ 33.7, 38.9, 54.7, 120.7, 122.9, 140.4, 148.1, 154.0. ESI−HRMS: ($C_{20}H_{25}N_4O_8S_4$)(MH^+), calcd 577.0555, found 577.0549.

Synthesis of 4,4′-(Methanethiosulfonate-ethyl-amino)acetamide Azobenzene (4). One equivalent of 4,4′-*p*-nitrophenoxyacetamide azobenzene (**12**) (63 mg, 0.116 mmol) and 2.5 equiv of 2-aminoethyl methanethiosulfonate hydrobromide (68.4 mg, 0.290 mmol) (Toronto Research Chemicals) were combined together and suspended in DMSO (4 mL). Diisopropylethylamine (2.5 equiv, 50 μL, 0.290 mmol) was added, the reaction mixture was stirred at room temperature under nitrogen for 6 h, and then the solvent was removed under high vacuum. The crude product was washed with water, 5% sodium bicarbonate, and water and then dried (53 mg, 80%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 3.35 ppm (t, J = 6.4 Hz, 4H), δ 3.48 ppm (dt, J_1 = 6.4, J_2=5.6 Hz, 4H), δ 3.57 ppm (s, 6H), δ 6.58 ppm (t, J = 5.6 Hz, 2H), δ 7.58 ppm (d, J = 7.8 Hz, 4H), δ 7.75 ppm, (d, J = 7.8 Hz, 4H), δ 9.04 ppm (s, 2H); ^{13}C NMR (100 MHz, DMSO-d_6), δ 36.0, 38.7, 50.2, 117.7, 123.4, 142.9, 146.5, 154.8; ESI−HRMS: ($C_{20}H_{27}N_6O_6S_4$)(MH^+), calcd 575.0874, found 575.0869.

Cross-Linking of MTS-alkyl-azobenzene to FK-11. A 10 mM solution of the cross-linker **1** in DMSO and a 0.49 mM solution of FK-11 in water were prepared. The peptide solution (1.23 mL, 0.6 μmol), a first aliquot of the cross-linker solution (30 μL, 0.3 μmol), and 410 μL of DMSO were stirred at room temperature, in the dark, for 15 min. Another aliquot of cross-linker was added (30 μL, 0.3 μmol), and the solution was stirred for anther 15 min. The last aliquot of cross-linker (30 μL, 0.3 μmol) was added to the solution, and stirring was continued for another 40 min. The solvent was evaporated under high vacuum. The product was purified by HPLC on a preparative C18-column (Apex, ODS Prepsil, 25 cm 8 μm) with an ACN (0.1% TFA) and H_2O (0.1% TFA) gradient (step 1: 15% to 90% ACN in 45 min; step 2: 90% ACN for 3.0 min; step 3: 90% to 15% ACN in 3.0 min), with detection at 360 nm. The retention time was 24 min (flow rate 10 mL/min). MS/ESI: calcd 2018, found 672.9 (3+), 1009.4 (2+).

Cross-Linking of MTS-amide-azobenzene to FK-11. An 11.6 mM solution of the cross-linker **2** in DMSO and 0.549 mM solution of FK-11 in water were prepared. The peptide solution (1.09 mL, 0.6 μmol) and the first out of three aliquots of the cross-linker solution (55 μL, 0.6 μmol) were combined together followed by addition of extra 400 μL of pure DMSO. The reaction mixture was stirred at room temperature, in the dark, for 15 min. Another aliquot of cross-linker was added (55 μL, 0.6 μmol), and the solution was stirred for another 15 min. The last aliquot of cross-linker (55 μL, 0.6 μmol) was added, and stirring was continued for another 1.5 h. After completion the solvent was removed under high vacuum. The product was purified by HPLC on a semi-preparative SB-C18 column (Zorbax, 9.4 mm ID × 25 cm) with an ACN (0.1% TFA) and H_2O (0.1% TFA) gradient (step 1: from 15% to 90% ACN in 45 min; step 2: 90% ACN for 8 min; step 3: from 90% to 15% ACN in 8 min). Absorbance at 360 nm was monitored, and the pure product was eluted at 50% ACN with a retention time 14 min (flow rate 2.1 mL/min). MALDI-MS [MH^+]: ($C_{81}{}^{13}C_2H_{128}N_{31}O_{26}S_4$) calcd 2106 0.38, found 2106.96, 1053.96 (2+).

Cross-Linking of MTS-carbamate-azobenzene to FK-11. A 4.5 mM solution of the cross-linker **3** in DMSO and a 0.55 mM solution of FK-11 in water were prepared. The peptide solution (1.09 mL, 0.6 μmol) and the first out of three aliquots of the cross-linker solution (132 μL, 0.6 μmol) were combined together followed by addition of extra 200 μL of pure DMSO. The reaction mixture was stirred at room temperature, in the dark, for 15 min. Another aliquot of cross-linker was added (132 μL, 0.6 μmol), and the solution was stirred for another 15 min. The last aliquot of cross-linker (132 μL, 0.6 μmol) was added, and stirring was continued for another 1.5 h. After completion the solvent was removed by high vacuum pumping. The product was purified by HPLC on a semipreparative SB-C18 column (Zorbax, 9.4 mm ID × 25 cm) with an ACN (0.1% TFA) and H_2O (0.1% TFA) gradient (step 1: from 10% to 90% ACN in 45 min; step 2: 90% ACN for 5 min; step 3: from 90% to 10% ACN in 5 min), with monitoring at 360 nm. The pure product was eluted at 44% ACN with the retention time 25 min (flow rate 2.1 mL/min). MALDI-MS [MH^+]: ($C_{83}{}^{13}C_2H_{134}N_{31}O_{28}S_4$) calcd 2166.45, found 2165.97.

Cross-Linking of MTS-urea-azobenzene to FK-11. A 5.92 mM solution of the cross-linker **4** in DMSO and a 0.549 mM solution of FK-11 in water were prepared. The peptide solution (1.09 mL, 0.6 μmol) and the first out of three aliquots of the cross-linker solution (100 μL, 0.6 μmol) were combined together followed by addition of extra 400 μL of pure DMSO. The reaction mixture was stirred at room temperature, in the dark, for 15 min. Another aliquot of cross-linker was added (100 μL, 0.6 μmol), and the solution was stirred for another 15 min. The last aliquot of cross-linker (100 μL, 0.6 μmol) was added, and stirring was continued for another 1.5 h. After completion, the solvent was removed under high vacuum. The product was purified by HPLC on a semipreparative SB-C18 column (Zorbax, 9.4 mm ID × 25 cm) with an ACN (0.1% TFA) and H_2O (0.1% TFA) gradient (step 1: from 35% to 80% ACN in 45 min; step 2: 80% ACN for 5 min; step 3: from 80% to 35% ACN in 5 min) with monitoring at 360 nm. The pure product was eluted at 41% ACN with the retention time 6 min (flow rate 2.1

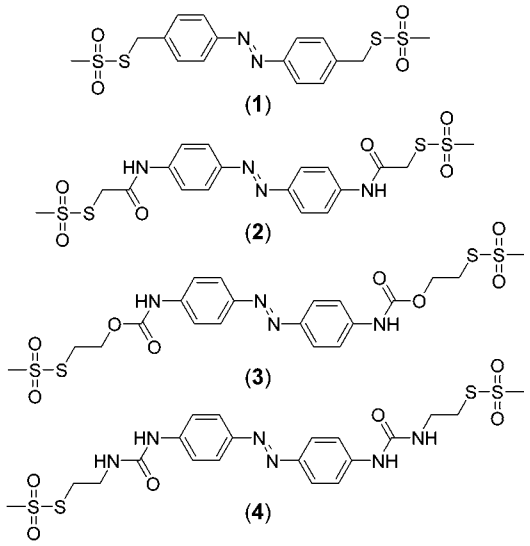

Figure 3. Structures of MTS-azobenzenes synthesized: MTS-alkyl-azobenzene (**1**), MTS-amide-azobenzene (**2**), MTS-carbamate-azobenzene (**3**), MTS-urea-azobenzene (**4**).

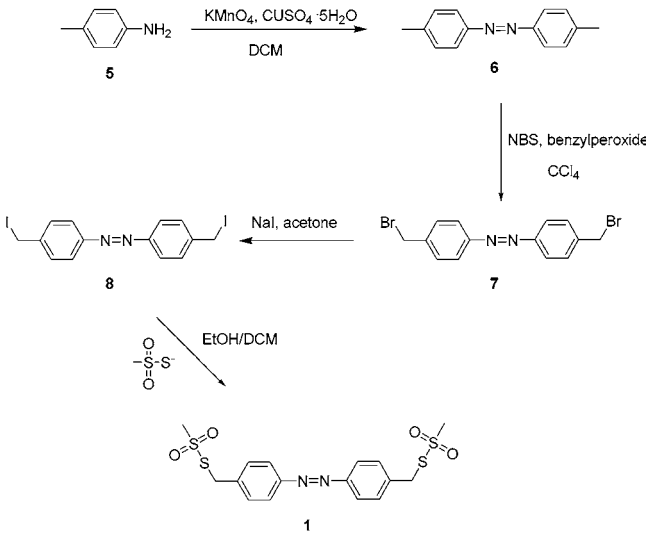
mL/min). MALDI-MS [MH^+]: ($C_{83}{}^{13}C_2H_{136}N_{33}O_{26}S_4$) calcd 2164.48, found 2165.07.

Synthesis of Glutathione Derivatives. One equivalent of each cross-linker was dissolved in 500 μL of DMSO. Ten equivalents of γ-glutathione were dissolved in 500 μL of TrisCl buffer (100 mM, pH 8) and added dropwise to each solution of cross-linker in DMSO. The reaction mixture was stirred at room temperature for 2 h in the dark. After completion, the solvent was removed under high vacuum. The products were purified by HPLC on a semipreparative SB-C18 column (Zorbax, 9.4 mm ID $\times$ 25 cm) as described above. Structures were confirmed by MALDI-MS.



Photoisomerization. A 70 W Metal Halide Tri-Lite Lamp (World Precision Instruments Inc., FL) coupled with either a 340 $\pm$ 10 nm, 370 $\pm$ 10 nm, or 380 $\pm$ 10 nm band-pass filter (Harvard Apparatus Canada, PQ) was used to photoisomerize peptide solutions to the cis isomers. For photoisomerization to the trans isomer, a 455 nm cutoff filter (Harvard Apparatus Canada, PQ) was used coupled to the same lamp. Photoisomerization in both directions was completed within 10 min.

UV/Vis and CD Spectroscopy and Relaxation Curves. Peptide samples were dissolved in a 5 mM phosphate buffer (pH 7). For the relaxation curves experiments, the spectra were taken using a BDS 100 Fiber Deuterium/Tungsten light source, a Quantum Northwest temperature control and an Oceanoptics UBS 2000 diode-array. Quartz cuvettes (0.1 cm path length) were used for the measurements. Relaxation curves were fit to single exponentials and time constants and activation energies evaluated in the standard way.

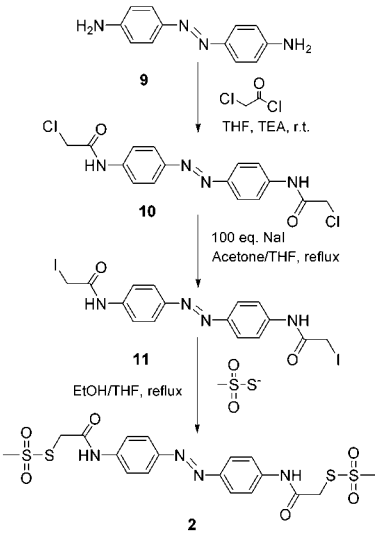
All the circular dichroism (CD) experiments were performed on a Jasco Model J-710 spectropolarimeter using thermostated quartz cuvettes (0.1 or 1.0 cm path length). The samples were dissolved in a 5 mM phosphate buffer (pH = 7). A 10 nm/min, 1.0 nm bandwidth and a 4 s response time were used. Corrected CD spectra for 100% cis isomers were obtained using the following equation: θ (100% cis) = [θ (observed after irradiation) $-$ (fraction trans $\times$ θ (dark-adapted))]/fraction cis.

Calculations of Absorbance Spectra. Models of each chromophore were built in Spartan 04 for Windows (Wave function Inc.) with structures as shown in Figure 3 except that the $CH_3S(O)_2SCH_2$ unit was replaced by a methyl group. Geometry was optimized using the ab intio HF 6-31G* method in Spartan. Only trans geometries of the azo unit were studied. Wavelengths for absorbance maxima together with oscillator strengths were calculated using the DFT EDF1 6-31G method in Spartan. ZINDO/S calculations were performed on the HF 6-31G* minimized structures using Hyperchem v.6 (Hypercube Inc.).

Scheme 1. Synthesis of MTS-alkyl-azobenzene

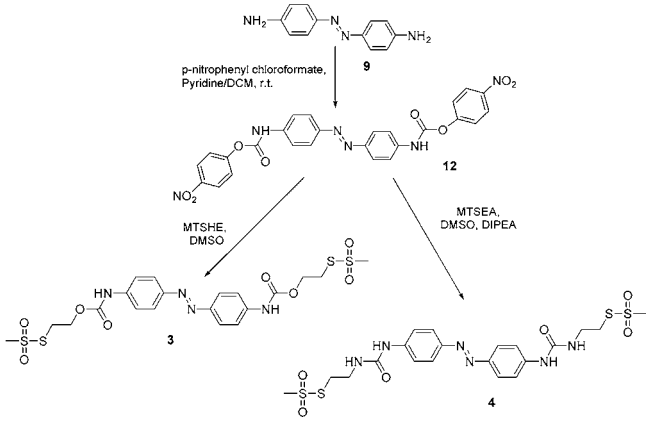
RESULTS AND DISCUSSION

Synthesis of MTS-azobenzene Cross-Linkers. A series of azobenzene-based thiol-reactive cross-linkers was synthesized with structures as shown in Figure 3. For convenience we will refer to these compounds according to the type of linkage between the azobenzene group and the thiol-reactive MTS moiety (e.g. MTS-carbamate-azobenzene). It is this linkage that primarily affects the thermal stability of the compounds.



The MTS-alkyl-azobenzene cross-linker (**1**) was obtained in a four-step synthesis (Scheme 1). First, *p*-toluidine **5** was oxidized using a mixture of potassium permanganate and cupric sulfate to give **6**. Bromination of the benzylic methyl groups was achieved through a radical reaction using *N*-bromosuccinimide in carbon tetrachloride with benzoyl peroxide as an initiator. In our first trials, we attempted to install MTS on **7** by displacement of the bromide but the yield of this reaction was low. We therefore carried out a bromo/iodo exchange reaction on **7**. Refluxing **8** in a mixture of dichloromethane and ethanol with the sodium methanethiosulfonate was sufficient to obtain the desired product **1**.

The MTS-amide-azobenzene cross-linker (**2**) was obtained by a simple displacement reaction between Na-MTS and the Kumita cross-linker synthesized as described previously (Scheme 2).



The MTS-carbamate-azobenzene cross-linker (**3**) and MTS-urea-azobenzene cross-linker (**4**) were obtained as outlined in Scheme 3. Reaction of diaminoazobenzene with *p*-nitrophenyl chloroformate produced the carbamate **12**. This reacted rapidly with 2-aminoethyl methanethiosulfonate and more sluggishly with 2-hydroxyethyl methanethiosulfonate with DMSO as solvent to form cross-linkers **3** and **4**, respectively.

Peptide Cross-Linking with MTS-azobenzenes. On the basis of previous studies, we chose the peptide FK-11 (Acetyl-Glu-Ala-Cys-Ala-Arg-Glu-Ala-Ala-Ala-Arg-Glu-Ala-Ala-Cys-Arg-Gln-amide) as a target for photo-

Scheme 2. Synthesis of MTS-amide-azobenzene

Scheme 3. Synthesis of MTS-carbamate-azobenzene and MTS-urea-azobenzene

control (*3*, *13*). FK-11 has cysteine residues spaced 11 residues apart and is known to form stable α-helices in water (*3*, *14*). Molecular models of cross-linked FK-11 indicated that when the peptide is in a helical conformation, the distance between the two Cys residues can accommodate the trans isomer of the cross-linkers with relatively little distortion of the helix. The end-to-end distance of the cis conformation of the cross-linker is less compatible with this Cys residue spacing. Trans-to-cis isomerization is thus is expected to lead to decreased peptide helical content in aqueous solution.

Cross-linking of the peptides was achieved rapidly and efficiently by dissolving the peptide in water and slowly adding a solution of the cross-linker in DMSO. The modified peptides were purified by HPLC. To test for effects of peptide structure on the thermal stability of the cross-linker, the MTS-azobenzene cross-linkers were also reacted with glutathione to furnish a chemically similar adduct without secondary structure.

Spectral Properties and Thermal Stability. Spectra were obtained for each of the MTS-azobenzene peptide conjugates after dark adaptation to produce pure trans isomers (Figure 4). Absorption maxima are collected in Table 1.

The absorption maximum of the trans isomer of the MTS-alkyl-azobenzene is close to that observed for unmodified azobenzene (340 nm) and at a significantly shorter wavelength than that for the amide-, carbamate-, and urea-substituted compounds. The trend in absorption

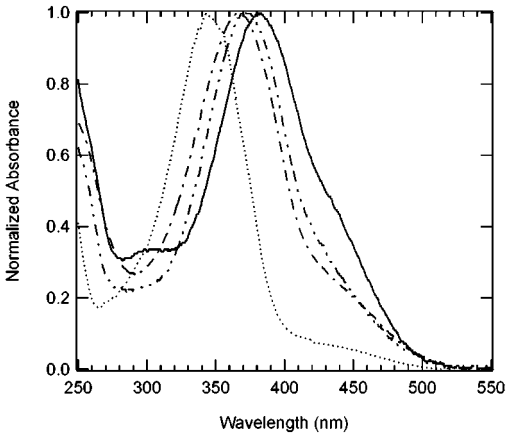


Figure 4. Spectra of dark-adapted (trans isomers) of cross-linked peptides: (···) MTS-alkyl-azobenzene FK-11, (– · –) MTS-amide-azobenzene FK-11, (– ·· –) MTS-carbamate-azobenzene MTS, (—) MTS-urea-azobenzene FK-11.

Table 1. Experimental and Calculated Absorption Maxima of Chromophores

structure	λ_{max}, nm (obsd) (trans)	λ_{max}, nm (ZINDO) (trans)	λ_{max}, nm, DFT EDF1 6-31G* (trans)
alkyl	342	335 (1.018)	330 (0.817)
amide	366	349 (1.190)	379 (1.519)
carbamate	372	349 (1.198)	376 (1.555)
urea	382	350 (1.212)	387 (1.567)

maxima is predicted by the ZINDO semiempirical method (*9*, *15*, *16*) although predicted λ_{max} values are too small, as has been observed in related studies (*16*). The DFT EDF1 method gives a better match to experiment (Table 1). The trend in absorption maxima can be understood in terms of a greater degree of delocalization of electrons associated with the benzylic atom from alkyl through urea structures in the series. Spectra of pure cis forms for the alkyl and amide derivatives were similar to those reported previously for unmodified azobenzene (*17*) and the Kumita compound (*3*). Spectra for the pure cis isomers of the carbamate and urea compounds were not obtained in the present study due to complications arising from the rapid thermal reversion to the trans isomer (vide infra). In contrast to observations with some other some delocalized azobenzene derivatives ((*16*)), however, significant degrees of conversion to the cis isomer were obtained as can be seen from the spectra shown in Figure 5.

Thermal stabilities of the cis isomers of cross-linked FK-11 peptides together with the corresponding glutathione adduct were measured. After irradiation, recovery of the trans form in the dark was monitored by following absorption at 370 nm for series of different temperatures (Figure 6). These data are collected in Table 2 together with calculated activation energies for the thermal isomerization process. As observed previously, half-lives depend on the nature of the attached peptide,i.e. whether it is unstructured glutathione or the highly structured FK-11 peptide (*3*). Nevertheless, a clear correlation is observed between the absorption wavelength maximum of the cross-linker and the thermal stability of the cis form. With more delocalization, absorption maxima increase and half-lives decrease.

Effects of Photoisomerization on Peptide Conformation. Circular dichroism spectroscopy (CD) was employed to determine the effect of cross-linker isomerization on the FK-11 peptide structure. The CD spectrum of dark-adapted MTS-alkyl-azobenzene cross-linked

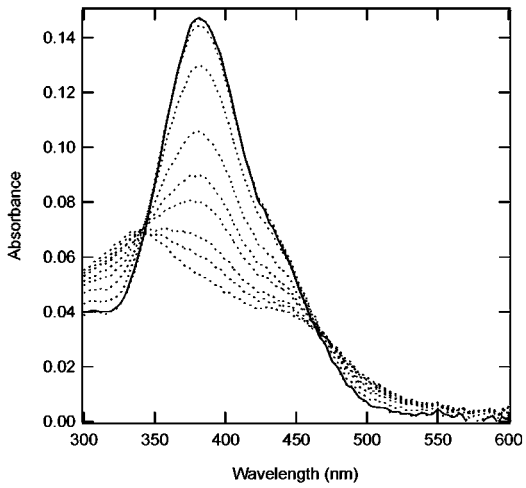

Figure 5. Spectra showing thermal relaxation at 4 °C of MTS-urea-azobenzene FK-11 after irradiation at 370 nm. Spectra were recorded at 0.65, 1.3, 2.0, 3.3, 6.5, 12.3, and 61.3 min (solid line) after irradiation.

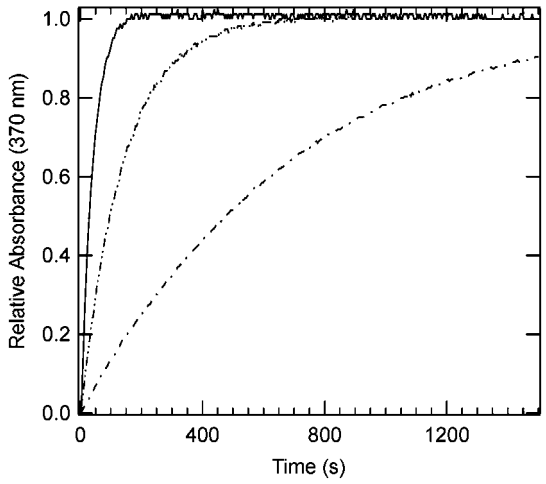

Figure 6. Time courses for thermal relaxation (25 °C) of FK-11 peptides cross-linked with linkers: (– · –) MTS-amide-azobenzene FK-11, (– ·· –) MTS-carbamate-azobenzene MTS, (—) MTS-urea-azobenzene FK-11. The absorbance of the MTS-alkyl-azobenzene cross-linked peptide shows no change over this time period.

Table 2. Half-lives and Activation Energies for Cross-Linked FK-11 Peptides

structure	$\tau_{1/2}$@25 °C	$\tau_{1/2}$@37 °C	E_a (kJ/mol)
alkyl-FK11	43 h	12 h	82
amide-FK11	8 min	3 min	72
carbamate-FK11	96 s	33 s	69
urea-FK11	26 s	10 s	62
alkyl-glutathione	43 h	12 h	82
amide-glutathione	12 min	4 min	76
carbamate-glutathione	80 s	30 s	67
urea-glutathione	11 s	5 s	60

FK-11 peptide at 10 °C shows bands at 208 and 222 nm, characteristic of a helical peptide (Figure 7A). Upon irradiation at 340 nm, the intensity of the two bands decreases, the largest difference being for the band at 222 nm, consistent with a decrease in peptide helical content. The normalized spectrum for the pure cis form (calculated by subtracting the contribution of the remaining trans isomer) is shown in Figure 7A. Upon irradiation at >450 nm, the helical content returns to the level observed for the dark-adapted state. For each of the cross-linked peptides, photoisomerization of the cross-linker from trans to cis causes a decrease in peptide helicity as expected (Figure 7B–D). Thermal relaxation recovered the dark-adapted (trans) spectra.

The size of the effect can be evaluated by measuring the percent change in ellipticity at 222 nm. However, as noted above, rapid thermal relaxation of the MTS-carbamate and MTS-urea derivatives prevents isolation of the cis isomers for determination of their spectra. Nevertheless, the effect of irradiation on the absorption spectra of each of the derivatives is qualitatively similar (Figure 5) so that ~75±5% conversion to the cis isomer is likely occurring in each case. Using this assumption, the change in percent helix content observed upon irradiation for each peptide was calculated (Table 3)

The magnitude of the effect of trans-to-cis isomerization on peptide helix content follows the order MTS-alkyl-azobenzene > MTS-amide-azobenzene > MTS-carbamate-azobenzene ≈ MTS-urea-azobenzene. This pattern can be qualitatively understood by examining distance ranges between atoms corresponding to Cys-γ-S atoms in models of the free linkers (Table 3). The ideal S–S distance range between Cys-γ-S atoms in positions i, i +11 of an α-helix is 14.1 to 19.2 Å. Whereas each linker is able to accommodate this distance range in the trans conformation,

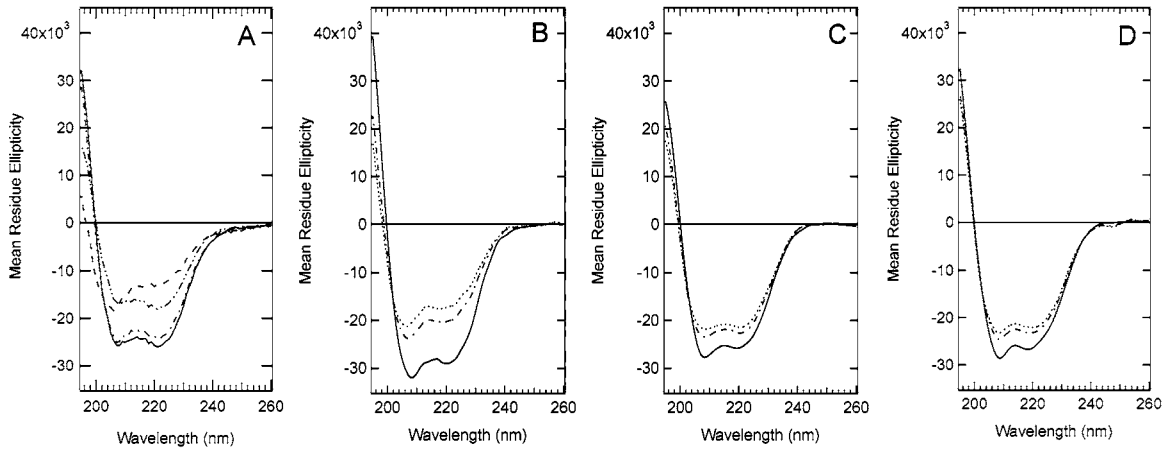

Figure 7. CD spectra of MTS-alkyl-azobenzene cross-linked FK-11 (A), MTS-amide-azobenzene cross-linked FK-11 (B), MTS-carbamate-azobenzene cross-linked FK-11 (C), MTS-urea-azobenzene cross-linked FK-11 (D). For A: Dark-adapted (—); 100% cis (- - -) (after irradiation at 340 nm and corrected for % conversion as described in the methods section); irradiated with a 450 long pass filter (– · –); after treatment with TCEP (– ·· –). For (B–D): Dark-adapted (—); after irradiation at 370 nm (– · –), corrected for 100% cis (- - -). After thermal relaxation the dark-adapted spectra were recovered in each case.

Table 3

structure	% helix change obsd[a]	S−S range, Å (trans)[b]	S−S range, Å (cis)[b]
MTS-alkyl-azo-FK11	45	9.8−17.7	3.3−13.0
MTS-amide-azo-FK11	39	14.3−22.4	3.2−16.5
MTS-carbamate-azo-FK11	14	14.9−26.3	4.0−18.0
MTS-urea-azo-FK11	16	15.1−26.5	3.2−18.9

[a] Calculated as % helix (dark) − % helix (cis), where 100% helix is −30 000 deg·cm^2·dmol^{-1}. [b] S−S range is the distance between Cys-γ-S atoms. In an ideal α-helix this distance range is 14.1−19.2 Å for Cys residues spaced at i, i+11.

the alkyl linker is least compatible with this distance range when in the cis conformation. The MTS-urea-azobenzene and MTS-carbamate-azobenzene cross-linkers, in particular, are long and flexible enough to accommodate a significant part of the optimal distance range between Cys-γ-S atoms even when in the cis conformation. The length of these linkers may make them more suitable (in the trans conformation) for cross-linking between Cys residues spaced more than 11 residues apart in an α-helix. Alternatively, the cis conformations of the linkers may be used to link closely spaced Cys residues (e.g., i, i+4) in peptide sequence. In that case, photoisomerization in the trans-to-cis direction should stabilize an α-helical structure.

Cleavage of the Cross-Linked Peptides. Under standard photoisomerization conditions the peptides appear chemically stable. Mass spectra of the samples after irradiation showed that the cross-linked peptides remained intact during at least 10−20 photocycles. Extensive irradiation at higher temperatures (50 °C) was found to cause some cleavage of the cross-linkers from the peptide.

A possible advantage of the MTS-activated cross-linkers over the Kumita iodoacetamide linker is that they can be removed from the peptide upon addition of thiols or mild reducing agents. Addition of the water-soluble reducing agent triscarboxyethylphosphine (TCEP) to a solution of cross-linked peptide caused rapid and complete removal of the linker. Figure 7A shows the CD spectra obtained for FK-11 after treatment with TCEP. After cleavage, the only peak observed in the electrospray mass spectrum is the molecular ion for the un-cross-linked peptide.

SUMMARY AND CONCLUSIONS

The new azobenzene-based cross-linkers described here can be covalently attached to peptides or proteins through cysteine residues and removed again by reduction using TCEP. When used to cross-link the test peptide FK-11 the linkers enabled photocontrol of peptide helical content in a manner similar to the iodoacetamide based cross-linker introduced by Kumita et al. (*2*, *3*, *18*) but with a large range of thermal stabilities observed for the cis forms from 11 s to 43 h at 25 °C. The cross-linkers described here thus broaden the range of reagents available for reversible photocontrol of peptide and protein conformation.

Size exclusion chromatography (SEC) was used to determine the viscosity radii of equivalent spheres for proteins covalently grafted with poly(ethylene glycol) (PEG). The viscosity radius of such PEGylated proteins was found to depend on the molecular weight of the native protein and the total weight of grafted PEG but not on PEG molecular weight, or PEG-to-protein molar grafting ratio. Results suggest grafted PEG's form a dynamic layer over the surface of proteins. The geometry of this layer results in a surface area-to-volume ratio approximately equal to that of a randomly coiled PEG molecule of equivalent total molecular weight. Two simple methods are given to predict the viscosity radius of PEGylated proteins. Both methods accurately predicted (3% absolute error) the viscosity radii of various PEG-proteins produced using three native proteins, α-lactalbumin (14.2 kDa MW), β-lactoglobulin dimer (37.4 kDa MW), and bovine serum albumin (66.7 kDa MW), three PEG reagents (2400, 5600, and 22500 MW), and molar grafting ratios of 0 to 8. Accurate viscosity radius prediction allows calculation of the distribution coefficient, K_{av}, for PEG-proteins in SEC. The suitability of a given SEC step for the analytical or preparative fractionation of different PEGylated protein mixtures may therefore be assessed mathematically. The methods and results offer insight to several factors related to the production, purification, and uses of PEGylated proteins.

INTRODUCTION

Covalent modification of proteins with poly(ethylene glycol) (PEG) molecules often dramatically improves their clinical efficacy. Terminal end-functionalized PEG molecules are typically used to modify proteins by reacting with protein amine or other (e.g. sulfhydryl) reactive groups (*1*, *2*). PEGylation may (a) mask and reduce immune-recognition and clearance from the body, (b) protect from enzymatic or chemical alteration, and clearance (*3*−*5*), (c) enhance hydrodynamic size and reduce glomerular filtration (*2*). The effectiveness of small therapeutic proteins (<20 kDa) is particularly prone to enhancement through PEGylation (*6*−*8*). Many PEGylated therapeutic proteins are FDA approved, and more are under development as PEGylation increases efficacy, reduces dosage frequency, allows for novel dosage mechanisms, and may prolong shelf life (*4*, *5*, *9*).

The major drawback of PEGylation is that PEGylated proteins are prepared from pure proteins, which are converted to product mixtures of PEG, native protein, and PEG-proteins having varied PEGylation extent (also known as degree of modification or grafting ratio, *N*) and variation in the site(s) of modification. Such PEGylated proteins may vary substantially in both physicochemical and biomedical properties. Low molecular weight byproducts formed during PEGylation and/or hydrolysis of functionalized PEG's also add to product complexity.

The extent of PEGylation must routinely be determined in research, development and production laboratories. The current method of choice for analysis is mass spectrometry, particularly matrix-assisted laser desorption ionization−time-of-flight mass spectrometry (MALDI-TOF MS). Other methods include capillary electrophoresis (*10*) or light scattering (*11*). All such methods are relatively complex, require specialized equipment, and have little direct relationship to the chromatographic, filtration, and other methods used to purify PEGylation reaction product mixtures.

Size exclusion chromatography (SEC) and related methods are attractive for fractionation of native and PEGylated proteins due to the significant increases in protein viscosity radii which result from PEG grafting. In addition, PEGylation may variously alter protein properties and behavior in regard to solubility, electrophoresis, ion exchange, affinity, or other interactions typically used to facilitate their purification.

SEC is also a simple, low-cost technique that has been used for many decades to estimate the molecular weight (MW) of proteins and polymers through the use of calibration curves between molecular weight and the distribution coefficient,

$$K_{av} = \frac{(V_R - V_o)}{(V_c - V_o)} \quad (1)$$

where V_R, V_o, and V_c represent solute elution volume, void volume, and the total bed volume of fluid and SEC media combined, respectively.

Given the above, SEC is attractive for both the purification and characterization of PEG-proteins, and there is a significant need to be able to predict SEC results based only on native protein MW, PEG MW, and *N*. However, proteins and PEG molecules of similar MW differ greatly with respect to their distribution coefficients

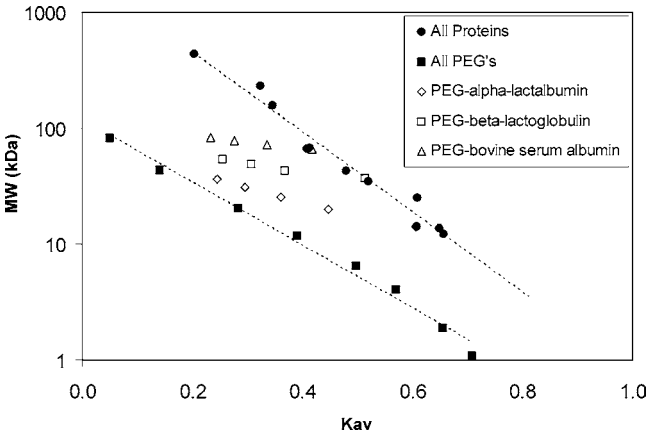

Figure 1. Distribution coefficient, K_{av}, as a function of $\ln(M_r)$ for protein and PEG molecular weight standards in a Superdex 200 HR 10/30 gel filtration column. Also shown are α-lactalbumin, β-lactoglobulin, and BSA, PEGylated to various extents with mPEG-SPA 5000.

in SEC media (*12*). This is illustrated by Figure 1 which shows calibration curves for protein and PEG molecular weight standards in a Superdex 200 HR10/30 SEC column (Amersham Biosciences, Uppsala, Sweden).[1]

PEG-proteins are hybrid molecules, and their SEC column distributions should not necessarily mimic that of either proteins or PEG molecules (*13*). One solution would be to calibrate SEC columns for PEG-proteins using protein MW standards modified with defined types of PEG's at defined degrees of modification. Clearly such calibrations are tedious, expensive, and may not pertain to PEG-proteins produced using novel PEG's or proteins. As such there is a significant need to develop simple methods to predict the SEC behavior of PEG-proteins.

Such a need is supported by previous literature. McGoff et al. (*14*) fractionated samples of PEGylated superoxide dismutase by SEC and concluded that determination of PEG-protein molecular weights based on protein standards was unreliable. Fortier and Laliberté (*15*) used protein MW standards and SEC to estimate the MW's of PEGylated horseradish peroxidase samples. They noted significant deviations from molecular weights estimated by other means, and that use of the SEC results to estimate N gave noninteger values, e.g., ranging from 3.1 to 6.0 against an expected value of 4 (lysines per protein). Christakopoulos et al. (*16*) cautioned about use of SEC to estimate PEG-protein MW's but nevertheless used SEC to relate an average increase of 30 to 40 kDa in the apparent MW of endogluconase to estimate N as 6 to 8 PEG molecules added per protein molecule. Veronese (*17*) noted that elution times of PEGylated proteins in SEC are not directly related to the increase in molecular weight due to the linked PEG, the implication being that SEC is not a useful analysis method for determining the degree of PEGylation. Fee (*13*) recently showed the apparent MW's of α-lactalbumin and β-lactoglobulin PEGylated with 5000 MW PEG increased nonlinearly between 50 and 100 kDa per grafted PEG molecule, when estimated by SEC calibrated with protein MW standards. However, the SEC MW estimates increased linearly by 7 kDa when the column was calibrated with PEG MW standards.

The present work addresses the need for a simple method to predictively model the SEC behavior of PEGylated proteins. The viscosity radii of PEG-proteins were determined using several SEC columns and two models for predicting the viscosity radii (and therefore the distribution coefficients) of PEG-proteins were derived. The first approach is based on a proposed linear relationship between total grafted PEG MW and PEGylated protein size, leading to a simple predictive equation dependent on two experimentally determined constants, a and b. The second approach assumes that PEG-protein size is determined primarily by the conformation of the grafted PEG layer. The resultant model depends only on the viscosity radii of the native protein and PEG's and contains no experimentally determined parameters.

The models were tested experimentally using PEG-protein samples prepared using three different proteins of MW 14 to 67 kDa, three different PEG reagents of MW 2 to 20 kDa, and N values of 1 to 8. Both models provide an accurate prediction of the viscosity radii of PEG-proteins. Both enable the prediction of SEC to separate different PEG-proteins, and the identification of N by SEC using a single calibration curve, based on protein or PEG or a combination of protein and PEG molecular weight standards. In addition to their practical significance, the predictive accuracy of the models suggests they provide insight to the possible behavior of PEG's when grafted to globular protein surfaces.

EXPERIMENTAL METHODS

Apparatus and Materials. Chromatographic experiments were carried out on an AKTAFPLC liquid chromatography system with protein species detected by UV absorbance at 280 nm (Amersham Biosciences, Uppsala, Sweden). PEG and PEG-containing species were detected with a Waters Model 410 Refractive Index detector (Waters Corporation, Milford, MA). The chromatography system was operated using Unicorn software, version 4.1 (Amersham Biosciences, Uppsala, Sweden).

Superdex 200 HR 10/30 and Superdex 75 HR 10/30 prepacked columns (30 cm length × 1.0 cm i.d., nominal $d_p = 13\ \mu m$, $V_c = 23.562$ mL) were obtained from Amersham Biosciences (Uppsala, Sweden).

Phosphate buffered saline (PBS), Tris-HCl, Blue Dextran ($M_r = 2000000$), α-lactalbumin from bovine milk (85% pure by polyacrylamide gel electrophoresis (PAGE)), β-lactoglobulin from bovine milk (90% pure by PAGE), and bovine serum albumin (BSA) from bovine plasma (98% pure by PAGE) were purchased from Sigma (St. Louis, MO). The nominal molecular weights of α-lactalbumin, β-lactoglobulin dimer, and BSA were, respectively, 14.2, 36.0, and 66.0 kDa and were estimated by MALDI-TOF mass spectrometry to be 14.2, 37.4, and 66.7 kDa, respectively. Mono-methoxy-poly(ethylene glycol)-succinimidyl propionate (mPEG-SPA) reagents of nominal molecular weights 2000, 5000, and 20000 Da were purchased from Nektar Therapeutics (Huntsville, AL). The actual molecular weights were estimated by MALDI-TOF mass spectrometry to be 2.4, 5.6, and 22.5 kDa, respectively.

Low Molecular Weight and High Molecular Weight gel filtration calibration kits containing ribonuclease A (M_r 13.7 kDa), chymotrypsinogen A (M_r 25 kDa), ovalbumin (M_r 43 kDa), albumin (M_r 67 kDa), aldolase (M_r 158 kDa), catalase (M_r 232 kDa), and ferritin (M_r 440 kDa) were obtained from Amersham Biosciences (Uppsala, Sweden). Polyethylene glycol 106−20000 MW, and Poly(ethylene oxide) 20000−1000000 MW Size Exclusion Calibration kits, containing molecular weights of 1100, 1900, 4000, 6500, 11800, 20400, 43500, and 82300, were purchased from Polymer Laboratories Ltd (Shropshire, UK).

[1] For ease of comparison, protein and polymer molecular weights determined by various methods are herein referred to in Daltons (Da) or kDa.

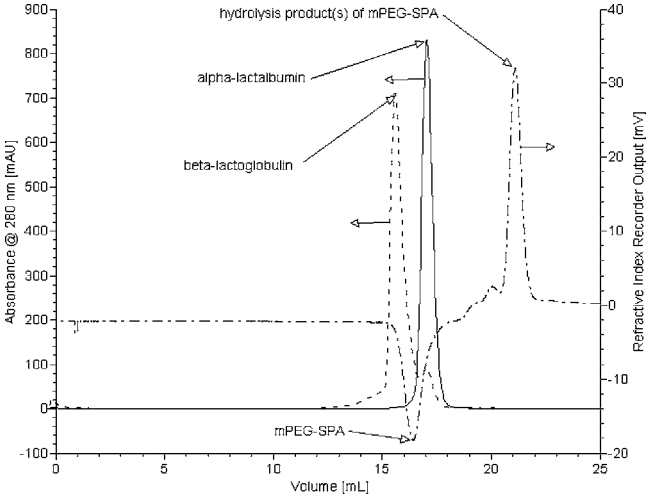

Figure 2. Chromatograms of native protein and mPEG-SPA 5000 reagent species in a Superdex 200 HR 10/30 SEC column.

Methods. Size-exclusion columns were calibrated against protein and PEG molecular weight standards. Individual solutions of each standard were prepared according to the manufacturer's instructions. 50 μL samples were injected onto each size exclusion column, using PBS running buffer at 0.5 mL/min. UV absorbance at 280 nm (protein standards) and refractive index (PEG standards) were used to determine the elution volumes of each standard. V_o was measured by the elution volume of Blue Dextran ($M_r = 2000000$) marker. V_o values were found to be 7.97 and 7.83 mL for the Superdex 200 and the Superdex 75 columns, respectively. K_{av} values were calculated for each column using eq 1 and plotted against molecular weight. Figure 1 shows the calibration curves for the Superdex 200 HR 10/30 column. Similar curves were obtained for the Superdex 75 column (data not shown).

SEC curves for individual samples of α-lactalbumin, β-lactoglobulin (dimer), and BSA proteins, and mPEG-SPA 5000 PEGylation reagent, are plotted in Figure 2. All had retention volumes consistent with their native molecular weights according to corresponding MW calibration curves. Corresponding curves for mPEG-SPA 2000 and mPEG-SPA 20 000 were omitted for clarity, but they exhibited peak maxima at retention volumes consistent with their molecular weights. The UV active peak eluting at about 20 mL is believed to represent *N*-hydroxysuccinimide acid byproduct of the hydrolysis of mPEG-SPA.

Batch PEG grafting was carried out for each protein individually. All solutions were made up in PBS at pH 7.4. Typically 5 mL of 20 mg/mL mPEG-SPA solution was added to 5 mL of 20 mg/mL native protein and stirred in an open 10 mL beaker at room temperature. One sample (approximately 1 mL) was withdrawn immediately after mixing the reactants and further samples were taken at 2, 5, 10, 20, 30, 40, 50, and 60 min. Samples were immediately acidified with three drops of 0.1 M HCl to stop the reaction. 50 μL of each sample was then analyzed separately by SEC under the same conditions as used during column calibration. 100 μL samples were used when collecting fractions for MALDI-TOF analysis. In such cases fractions containing protein were collected in 1 mL samples and exchanged into 20 mM ammonium bicarbonate buffer using a HiTrap desalting column (5 mL) (Amersham Biosciences, Uppsala, Sweden) prior to MALDI-TOF analysis.

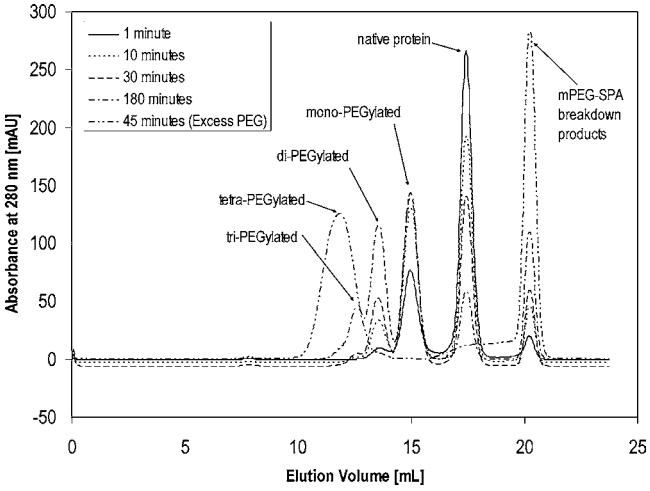

Figure 3. SEC chromatograms for samples withdrawn at intervals from batch PEGylation of α-lactalbumin with mPEG-SPA 5000, showing change in extent of PEGylation with time.

An Ettan II MALDI-TOF mass spectrometer (Amersham Biosciences, Uppsala, Sweden), operated in linear mode at 20 kV, was used to determine the molecular weights of native and PEGylated proteins. The matrix was prepared by saturating a solvent (consisting of 500 μL each of acetonitrile and MilliQ water and 9 μL of trifluoroacetic acid) with sinapic acid. Equal volumes of sample and matrix solution were mixed, and 0.3 μL of the mixture was applied to the sample plates.

RESULTS AND DISCUSSION

Figure 3 shows a representative size exclusion chromatograph obtained in the Superdex 200 column for the products of batch PEGylation of α-lactalbumin by mPEG-SPA 5000. As expected, several products with distinctly different molecular sizes result from the modification of the protein, and there is a shift in the areas of the product peaks with time as the degree of PEGylation increases. Similar results were observed for batch PEGylation of β-lactoglobulin and BSA (data not shown for brevity). Such behavior has been extensively reported in the literature (*5*). The reaction products were tentatively identified as mono-, di-, tri-, and tetra-PEGylated protein by inference from progression of the reaction and the chromatograph in Figure 3. Fractions were then collected in a repeat SEC run with a larger sample, and the molecular weights were confirmed by MALDI-TOF. As noted in the previous section, the peak at 20 mL may represent a low MW byproduct of the grafting reaction.

Similar chromatograms were obtained (data not shown) using a Superdex 200 column for analyzing proteins PEGylated with mPEG-SPA 2000 and 20 000. Peak maxima corresponding to the individual PEG-protein products were not resolved for mPEG-SPA 2000 except for α-lactalbumin. Similar chromatograms were also obtained (data not shown) using a Superdex 75 column for modification of α-lactalbumin with mPEG-SPA 2000 and 5000 and for modification of β-lactoglobulin with mPEG-SPA 2000.

Where peak maxima were clearly resolved, the K_{av} values of each PEG-protein reaction product identified were calculated using eq 1. In Figure 1, values for mPEG-SPA 5000-grafted proteins separated on the Superdex 200 column are plotted against their corresponding molecular weights (calculated from the native protein plus mPEG-SPA molecular weights and confirmed by MALDI-TOF). Comparison of experimental data points

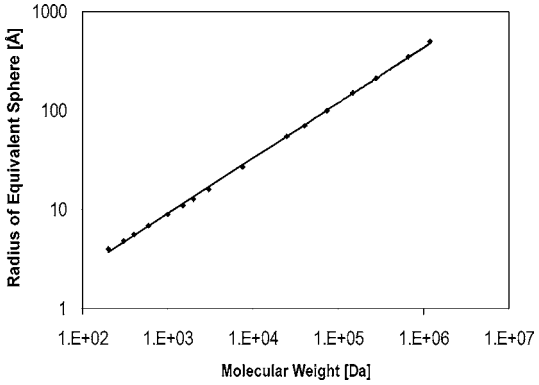

Figure 4. Viscosity radius of PEG molecules versus molecular weight (after Kuga et al. (*21*)).

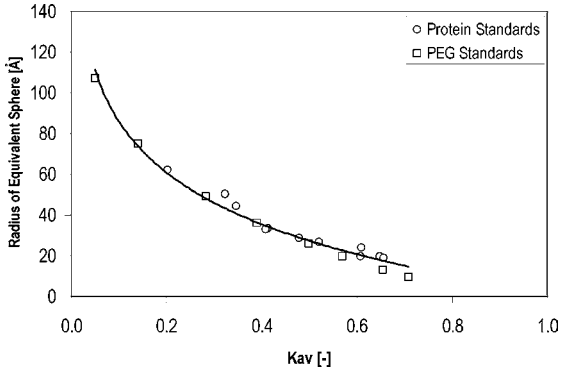

Figure 5. Universal calibration curve, viscosity radius versus K_{av} for PEG and protein molecular weight standards.

with the protein and PEG calibration curves in Figure 1 confirms that PEGylated proteins behave neither as proteins nor as PEG molecules (of similar MW) in size exclusion media. Rather, as more PEG is grafted to a protein, the related K_{av} shifts from the native protein's position on the protein standard curve toward the PEG standard curve (see also Fee (*13*)).

Clearly the distribution coefficients of the PEG-proteins in Figure 1 depend on the molecular weights of both PEG reagents and native proteins, as well as the PEGylation extent. However, the effects of increasing$N$ (and the total mass of PEG grafted) appears to correlate for samples related to each type of native protein. This suggests existence of a general method to relate such distribution coefficients to values for native protein MW, PEG reagent MW, and N.

It is common practice to calibrate SEC columns using molecular weight (M_r) standards and to produce a calibration chart in terms of the K_{av} versus ln(M_r). Normally such a curve is approximately linear over a range of molecular weights for a given SEC media. However, the distribution coefficient in SEC is not governed by molecular weight but, more generally, by the hydrodynamic volume or viscosity radius, R_h, of the molecule (*18*). A universal calibration method, though not in common use for proteins, can be produced for a given SEC media for globular proteins and flexible polymers such as PEG in terms of K_{av} versus viscosity radius (*19*).

For globular proteins, the viscosity radius (in Ångströms) of the molecule (assuming a spherical shape) is related to its molecular weight in Da, by eq 2 (*20*).

$$R_{h,prot} \approx (0.82 \pm 0.02)M_r^{1/3} \quad (2)$$

Kuga (*21*) collated data from 14 authors on the limiting viscosity numbers and diffusion coefficients of a variety of polymers in water, including PEG, and used these to calculate the R_h of the equivalent sphere for each compound. The radii calculated from viscosity and diffusion data agreed well with each other when correlated to MW across 6 orders of magnitude. A subset of Kuga's data for PEG's of MW 0.2 to 1200 kDa yields the following power-law relationship (correlation coefficient $R^2 = 0.9995$) between viscosity radius (Å) and molecular weight (Da) (Figure 4):

$$R_{h,PEG} = 0.1912M_r^{0.559} \quad (3)$$

The viscosity radii of all proteins and PEG's studied were calculated using eqs 2 and 3, respectively, and a universal calibration curve was produced for each SEC column studied. Figure 5 shows the "universal" calibration curve for Superdex 200 HR 10/30. A similar curve was obtained for the Superdex 75 column (data not shown).

Figure 5 shows that, in keeping with Kunitani et al. (*19*), the PEG in water standard data noted above falls on the same universal curve as for protein standards in PBS. Although the relative size of PEG polymer random coils is expected to be affected by aqueous solution temperature, salt concentration, and salt type, one might not expect much difference in hydration radius and SEC behavior between PEG's in PBS and distilled water at room temperature, since both conditions lie far from lower critical solution conditions. Under similar conditions, when characterizing ion exchange media, Hunter and Carta (*22*) showed that ionic strength had no effect on the retention volume of neutral flexible polymers. We therefore conclude that the sizes of PEG's in phosphate-buffered saline are approximately the same as they are in water. Since the viscosity radii of both proteins and PEG molecules lie on the same universal calibration curve for a given SEC media, it is reasonable to expect that PEGylated proteins will also conform to the same curve. It should therefore be possible to experimentally estimate the viscosity radii of PEG-proteins from their elution volumes in an SEC column calibrated in this way.

Tables 1−3 show viscosity radii data for all of the PEG's, proteins, and PEG-proteins studied in this work, as determined from the above universal calibration curves using K_{av} values calculated from experimentally determined elution volumes.

Two methods and related models for predicting the viscosity radii of PEG-proteins will now be described. We must be cautious in interpreting the viscosity radius too literally in terms of an actual physical radius. Chromatography is a stochastic process, so the hydrodynamic radius that is calculated from chromatography data represents an average of many molecular level interactions. The viscosity radius throughout this paper refers to the radius of an equivalent sphere in aqueous solution, whatever the true shape of the molecule. However, as a starting point for analysis we consider the radius, $R_{h,PEGprot}$, of a molecule formed by the conjugation of a protein of radius $R_{h,protein}$ and a PEG molecule of radius $R_{h,PEG}$.

Model 1. We assume that the generally benign effect of PEG grafting on protein activity (and the fact that PEG is a common food additive and is one of the compounds listed by the US Food and Drug Administration as "generally regarded as safe") indicates that the general shape (viscosity radius) of a protein is maintained in the PEG-protein conjugate. Now observe that in the aqueous environments related to this study the experimentally

Table 1. Properties of Proteins PEGylated with mPEG-SPA 2000

determined viscosity radius (R_h = 53.0 Å) of α-lactalbumin modified with four mPEG-SPA 5000 molecules (Table 2) is similar to that of α-lactalbumin modified with one mPEG-SPA 20 000 (R_h = 52.3 Å, Table 3). This implies that the final molecular size for each PEG-protein species is determined by native globular protein size and the total amount of PEG grafted, rather than by PEG reagent molecular weight or degree of grafting. We have observed the same behavior for cytochrome C modified with mPEG-NHS reagents of 10 000, 20 000, and 40 000 kDa, wherein PEGylated species with the same total amount of PEG grafted per protein molecule elute during SEC at the same volume, regardless of *N* (data not shown).

It follows from the previous paragraph that the excess (or difference in) viscosity radii between a native protein and PEGylated forms of that protein can be expressed as a function of the total PEG molecular weight, $M_{r,totPEG}$. The simplest function is a linear one such that

$$R_{h,PEGprot} - R_{h,protein} = a + bM_{r,totPEG} \quad (4)$$

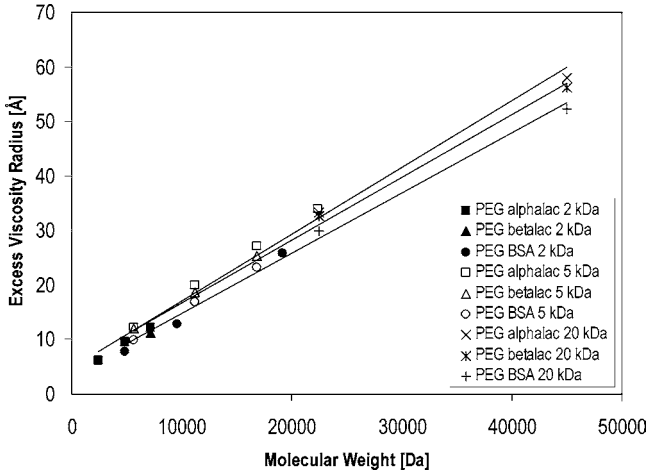

Figure 6. Excess radii of PEGylated proteins versus the total molecular weight of conjugated PEG.

where a and b are constants. Figure 6 shows that a plot of $(R_{h,PEGprot} - R_{h,protein})$ vs $M_{r,totPEG}$ yields the expected linear relationship for each protein, with a regression coefficient $R^2 > 0.99$ in each case. Therefore the viscosity radius (Å) of a PEGylated protein is given by

$$R_{h,PEGprot} = 0.82(M_{r,prot})^{0.33} + a + bM_{r,PEGtot} \quad (5)$$

where a = 4.88, 5.21, and 3.73 Å for α-lactalbumin, β-lactoglobulin, and BSA, respectively, and b = 0.0012 Å/Da for α-lactalbumin and β-lactoglobulin and b = 0.0011 Å/Da for BSA.

Intuitively, we expect the value of a to be 0, i.e., as the molecular weight of total grafted PEG approaches zero, so should the excess radius. It may be that the relationship between excess radius and total PEG molecular weight is actually weakly nonlinear. The above values of a correspond to a discrepancy of approximately 100 to 300 Da. If the relationship is indeed linear, this nonzero intercept might be due to several factors including (a) the length of the amide linkage (MW 43) formed between the PEG and the protein, (b) covalent grafting altering the contribution (via freedom of movement and hydration) of a few ethylene oxide units (CH_2CH_2O, MW 44) to the overall structure, (c) the grafting reaction and localization of PEG at the protein surface slightly altering the protein conformation and thus its contribution to the viscosity radius of the PEG-protein, (d) weak interactions between a few polymer units of the PEG and the protein surface.

Tables 1−3 show that the experimentally determined viscosity radii and those predicted by eq 5 are in excellent agreement (<3% absolute average error) in relation to both the Superdex 75 and 200 SEC column measurements.

In Tables 1−3, experimental values are given only for those cases where individual peak maxima were resolved. In the case of grafting with mPEG-SPA 2000, neither of the two SEC columns was able to resolve individual peaks for PEGylated β-lactoglobulin and BSA that differed by less than $N = 2$. This is not unexpected, as the K_{av} values for species differing by only a 2 kDa PEG are not large enough to obtain peak resolution in these media. However, MALDI-TOF analysis of fractions collected during elution confirmed that the elution volumes of the PEG-protein species corresponded to those expected of molecules with viscosity radii calculated from eq 5 (Table 1).

In all cases, except mPEG-SPA 20 000-grafted β-lactoglobulin, SEC elution volumes corresponded to those expected from molecular species having viscosity radii calculated from eq 5. This occurred even when chromatographed samples contained native protein, several PEG-protein species, unreacted mPEG-SPA reagent, and reaction byproducts. This suggests little interaction between the species when on the column.

In the case of mPEG 20 000-β-lactoglobulin (Table 3) the initial elution volume of the mono-PEGylated protein ($N = 1$) corresponded to a viscosity radius of 66.6 Å, versus 58.6 Å predicted from eq 5. The elution volume for $N = 2$ corresponded to a viscosity radius of 82.4 Å, versus 85.6 Å predicted. Both peaks showed significant tailing. Such results were very reproducible and, when grafting reactions were repeated, the products yielded the same result. MALDI-TOF analysis confirmed the identities of the products in these peaks to be mono- and di-PEGylated β-lactoglobulin dimers (Table 3).

β-Lactoglobulin consists of two 18.7 kDa monomeric chains held together by Ca^{2+}-mediated linkages. It does not appear that PEGylation resulted in multiply PEGylated protein monomers, as SEC determined viscosity radii did not correspond to any possible combinations of PEGylated monomeric β-lactoglobulin proteins.

A new hypothesis suggested that different PEGylated β-lactoglobulin proteins associated weakly with one another in the early regions of the SEC, chromatographing initially as a larger aggregate and then separately during their migration down the column. Fresh PEG-protein samples were run again and the peaks collected separately before being subjected to individual SEC runs. The viscosity radius of the $N = 1$ species (58.8 Å) calculated from the elution volumes agreed well with the 58.6 Å prediction from eq 5. The viscosity radius of the $N = 2$ species (77.4 Å from SEC) was smaller than the eq 5 related value of 85.6 Å. Such discrepancies were only seen with one reagent and one dimeric protein. They are noted here to illustrate that the relations described here may not apply to certain proteins under some circumstances.

Model 2. Although eq 5 appears to accurately predict viscosity radii, and the values of the constants a and b are closely similar between protein species, optimal accuracy demands that unique values of a and b should be determined experimentally for each protein. In developing model 2 we sought a predictive method that does not depend on experimentally determined parameters. We again picture a scenario in which the protein molecule remains unchanged in size and the final size of the conjugate is determined by alterations to the conformation of the PEG molecule alone. Calculating the volume of the equivalent sphere from the viscosity radius and subtracting the volume of the equivalent sphere for the native protein gives the volume that can be attributed to the PEG portion of the conjugated molecule.

The volumes of the equivalent spheres for mPEG-SPA 2000, 5000, and 20 000 in PBS are 13 667 Å^3, 57 263 Å^3, and 582 896 Å^3, respectively. Tables 1−3 show that the volume added to the protein molecule by the first PEG is much larger than the volume of the original PEG molecule in free solution. Also, each successive PEG group added to the conjugate molecule contributes an increasingly larger volume to the conjugate. However, if we examine the outer surface area of the conjugate and the volume contributed by the PEG, we find that the ratio of the surface area of the PEG exposed to the ionic environment to the PEG layer volume remains virtually constant for a given total PEG molecular weight (Tables

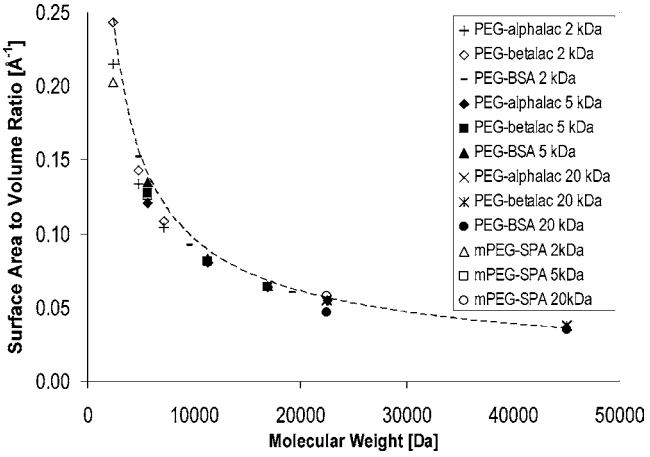

Figure 7. Surface area-to-volume ratio for the PEG molecules and for the PEG layer surrounding PEGylated proteins (line from eq 6).

1−3). Figure 7 shows the surface area-to-volume ratio for a given total molecular weight of PEG is approximately constant both for the individual PEG reagents in free solution and for the PEG layers surrounding all three protein species PEGylated to any extent, although the ratio increases slightly with increasing molecular weight of the native protein.

These observations, together with the fact that the final radius is determined by the total molecular weight of conjugated PEG and not by the number of PEG molecules conjugated, strongly suggests that the PEG forms a continuous layer surrounding the protein and that it adjusts its thickness such that the surface area-to-volume ratio of the layer is approximately the same as that of a PEG molecule with the equivalent molecular weight in free solution. Rather than a rigid coating, we envisage a very dynamic and flexible PEG molecule with enough surface interaction to result in what is in effect a protein with significant surface masking by PEG rather than a PEG spheroid grafted to a protein spheroid. Such a conformation would allow protein surface diffusion and the approach of other molecules, though such movement would be subject to some steric hindrance. The PEG layer mobility would presumably be most constrained near the site of conjugation. The protein would therefore maintain its biological function but with its in vitro activity reduced by an amount dependent on the position(s) of conjugation relative to the active site(s) of the protein. This view is consistent with the widely reported effects of the PEGylation location on protein activity. This is discussed further below.

We can now use the fact that under the low conductivity, room temperature conditions studied, the surface area-to-volume ratio is approximately constant for any given total molecular weight of PEG, to calculate the thickness of the PEG layer surrounding a PEGylated protein and thus its final viscosity radius. The ratio, AV_{PEG}, of surface area to volume of the equivalent sphere for a PEG molecule in free solution is

$$AV_{PEG} = \frac{3}{R_{h,PEG}} \tag{6}$$

and the surface area, $A_{PEGprot}$, of the PEGylated protein exposed to the phosphate buffered saline environment is

$$A_{PEGprot} = 4\pi(R_{h,PEGprot})^2 \tag{7}$$

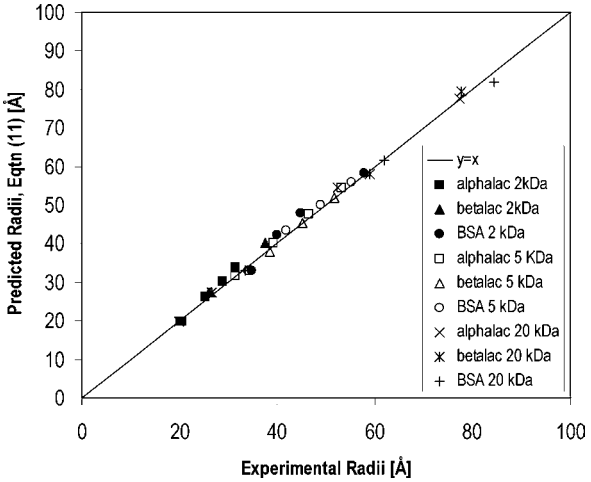

Figure 8. Comparison between experimentally determined viscosity radii of PEGylated proteins and those predicted by eq 11.

where $R_{h,PEGprot}$ is the viscosity radius of the PEGylated protein. The volume of the PEG fraction of the PEGylated protein, assuming that the protein volume is unchanged by PEGylation, is

$$V_{PEGlayer} = \frac{4\pi}{3}({R_{h,PEGprot}}^3 - {R_{h,prot}}^3) \tag{8}$$

The surface area-to-volume ratio of the PEG layer in the PEGylated protein, $AV_{PEGprot}$, is obtained by combining eqs 6−8, noting that $R_{h,PEG}$ is the viscosity radius of the equivalent sphere for a PEG molecule having a molecular weight equal to the total molecular weight of PEG conjugated to the protein, yielding

$$AV_{PEGlayer} = \frac{{R_{h,PEGprot}}^2}{({R_{h,PEGprot}}^3 - {R_{h,prot}}^3)} = \frac{1}{R_{h,PEG}} \tag{9}$$

Equation 9 can be rearranged to give a cubic equation in $R_{h,PEGprot}$

$${R_{h,PEGprot}}^3 - R_{h,PEG}{R_{h,PEGprot}}^2 - {R_{h,prot}}^3 = 0 \tag{10}$$

Equation 10 has only one real root, given by eq 11.

$$R_{h,PEGprot} = \frac{1}{6}[108{R_{h,prot}}^3 + 8{R_{h,PEG}}^3 + 12(81{R_{h,prot}}^6 + 12{R_{h,prot}}^3{R_{h,PEG}}^3)^{1/2}]^{1/3} + \frac{2}{3}\frac{{R_{h,PEG}}^2}{[108{R_{h,prot}}^3 + 8{R_{h,PEG}}^3 + 12(81{R_{h,prot}}^6 + 12{R_{h,prot}}^3{R_{h,PEG}}^3)^{1/2}]^{1/3}} + \frac{1}{3}R_{h,PEG} \tag{11}$$

Equation 11 shows that the viscosity radius of the PEGylated protein is a function only of the viscosity radius of the native protein and that of an equivalent sphere for a PEG molecule having a molecular weight equal to the total PEG molecular weight conjugated to the protein. Using eqs 2 and 3 to substitute for $R_{h,prot}$ and $R_{h,PEG}$ in terms of molecular weight allows eq 11 to be solved for any total amount of PEG added to a given protein. Figure 8 shows the correlation between predictions using eq 11 and experimental measurements for each of the PEGylated species studied. The fit is very good (marginally better than when using eq 5, with average absolute errors of less than 3%). So too, the

values predicted by eq 11 agree well with the experimentally determined values for both mono- and di-PEGylated β-lactoglobulin (with mPEG-SPA 20 000) when these species were analyzed separately (Table 3).

Either eq 5 or eq 11 can be used to calculate $R_{h,PEGprot}$. Equation 5 is simpler to calculate but requires experimental determination of the constants a and b. It is beyond the scope of this paper to determine the dependence of a and b on the protein species but we surmise, based upon our experience with the three proteins used in this study, that these constants are not strongly affected by protein type. Equation 11 possibly represents a more robust model of the physical situation and requires no experimentally determined parameters.

Finally, the K_{av} (and therefore the elution volume) of any PEGylated species may be predicted from either eq 5 or eq 11 together with the universal calibration curve for a given SEC column.

The general shape and size of PEG random coils appear to be dictated by polymer hydration and excluded volume (HEV) effects (*23*, *24*) and to a somewhat lesser degree by interaction with solution ions (*25*). Thus, above a few thousand MW, PEG's take on random coil spherical shapes that, due to weak segment-segment interactions, are more flexible and relatively larger than for proteins of similar MW. It is now well appreciated that PEG segments are capable of assuming conformations with considerable variation in relative hydrophilicity and hydrophobicity (*23*, *26*, *27*). When PEG molecules are attached to a surface, they lose conformational freedom, and in the case of a well-hydrating environment and a surface which does not exhibit strong interactions with the polymer, this is expected to lead to entropic repulsion, such that the PEG chains extend normal to the surface (*23*, *28*). Such surface structures are influenced by polymer MW and surface grafting density (*28*, *29*). Terminally grafted PEG conformations may vary from essentially spherical to extended "brush" conformations depending on grafting density. In the case of PEG's of 5000 to 6000 MW this may involve polymer layer thicknesses of 40 to 100 Å (*29*). Naturally there are conditions (raised salt concentration, temperature, and pressure) where the polymer can be induced to interact more favorably with the surface and affect its surface conformation as well as protein adsorption.

Under the physiological salt, room temperature, and atmospheric pressure conditions of the present study, PEG interactions with proteins might be expected to be dominated by HEV effects and therefore to be repulsive (*23*, *29*−*33*). Such behavior is believed to be responsible for the ability of PEG-coated surfaces to reduce protein adsorption, and for PEGylated proteins to show enhanced biocompatibility, serum circulation lifetime, and resistance to enzymatic degradation. Thus, one might expect low-density single-point conjugation of PEG to a protein to yield a complex product composed of two linked but distinct molecular spheroids.

In contrast, the present study strongly suggests that the protein and conjugated PEG favorably interact to create a single spheroid PEG-protein complex, with the PEG portion forming a layer surrounding the protein. This is supported in particular by the excellent predictions of viscosity radius obtained by eq 11. Also, the viscosity radius of a protein conjugated with distinct PEG spheroids would tend to be increasingly independent of N above a value of 2 or 3, since each additional PEG group added would likely be contained within the swept volume of a rotating protein molecule with a PEG spheroid grafted on opposite sides. Tables 1−3 and Figure 6 clearly show that this is not the case but that the excess radii of PEGylated proteins are linearly related to N for all proteins studied, including up to the case of $N = 8$ for BSA PEGylated with mPEG 2000. The shape and other properties of PEG in the outer layer appear to be influenced by the same HEV factors experienced by free PEG in solution, as the surface area-to-volume ratio of the PEG remains approximately constant between the free solution and conjugated forms. However, the volume of the layer is much larger than that for the free PEG in solution, indicating increased overall hydration (though not necessarily uniform throughout the layer).

Partition of proteins such as BSA and lactalbumin into aqueous phases rich in PEG is well documented (*31*, *34*, *35*) particularly in the presence other polymers such as dextran. We considered the possibility that the Superdex media, being dextran based, might provide a unique partitioning environment that caused the PEG layer to preferentially associate with the protein rather than the matrix. However, we obtained identical results (not shown) when using a Superose 12 SEC media, which is agarose based. While this does not preclude the possibility of such partitioning, it adds confidence to the general relevance of the results obtained in the Superdex media.

It may be wrong to relate the interactions of PEG and protein molecules when each is free in solution to their interactions when conjugated, as the latter case involves a closest point of contact within their mutual hydration shells and double layers. Instead, it is possible to speculate on a variety of favorable PEG to protein interactions such as hydrogen bonding, divalent cation chelation, hydrophobic interactions, and so on (*29*, *31*, *33*).

It is beyond the scope of this paper to model such behavior, but it would be of great interest to know if such a model were theoretically possible and, if so, what would be its implications for the biomedical properties of PEGylated proteins. The concept of PEGylated proteins consisting of conjugated but distinct spheroids is not in keeping with biomedical results (*32*, *36*, *37*) which suggest that PEGylation even with relatively small MW PEG's can dramatically alter a protein's average surface properties. Such results are more in keeping with the single spheroid concept assumed in the present study in deriving eq 11.

CONCLUSIONS

When molecular weight is used to calibrate a SEC column, PEGylated proteins apparently behave differently from both pure proteins and pure PEG molecules in size exclusion media. However, the distribution coefficients of protein and PEG macromolecules in size exclusion chromatography columns are related to their hydrodynamic volumes or viscosity radii such that a single universal calibration curve can be created for each column. The relationship between the distribution coefficient and viscosity radius apparently extends also to PEGylated proteins, and thus the viscosity radii of these proteins can be determined experimentally from a column calibrated with PEG and/or protein standards alone.

The viscosity radius of PEGylated proteins in phosphate-buffered saline is dependent on the native protein size and the total amount of PEG conjugated but is independent of the PEGylation extent, N. There is a linear relationship between the effective radius added to a protein and the total molecular weight of grafted PEG.

On the basis of the assumption that the native protein conformation is unaffected by PEGylation, it is proposed

that the conjugated PEG acts to form a dynamic, hydrated polymer-rich layer at the protein surface whose thickness is such that it maintains an external surface area-to-volume ratio (i.e., the surface area exposed to the external ionic environment divided by the volume of the PEG layer) approximately equal to that of a PEG molecule of equivalent molecular weight in free solution.

Two equations for predicting the viscosity radii of PEGylated proteins in PBS, an ionic environment that closely matches physiological conditions, have been presented. Equation 5, based on the simple assumption that PEG-protein radius is linearly related to the total conjugated PEG molecular weight predicts viscosity radii to within 3% of experimental values. Equation 11 is based on the assumption of a constant protein molecular conformation, together with a constant PEG layer surface area-to-volume ratio. The latter method is more representative of the physical situation and predicts the viscosity radii well, without the need for experimentally determined parameters.

The K_{av} (and therefore the elution volume) of any PEG-protein species may be predicted from either eq 5 or eq 11 together with the universal calibration curve for a given SEC column.

Peptide Nucleic Acid (PNA) Amphiphiles: Synthesis, Self-Assembly, and Duplex Stability

James P. Vernille, Lara C. Kovell, and James W. Schneider*

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890. Received July 14, 2004

Peptide amphiphiles comprising a class of conjugates of peptide nucleic acid (PNA), natural amino acids, and *n*-alkanes were synthesized and studied. These PNA amphiphiles (PNAA) self-assemble at concentrations between 10 and 50 μM and exhibit water solubilities above 500 μM. The highly specific, stable DNA binding properties of PNAs are preserved by these modifications, with no significant differences between the thermodynamics of DNA binding of the PNA peptide and the PNA amphiphile. Proper solubilization of the PNAA required the attachment of $(Lys)_2$ and $(Glu)_4$ peptides to PNAs, which affected the PNAA–DNA duplex stability by electrostatic interactions between these charged amino acids and the negatively charged DNA backbone. These electrostatic effects did not affect the specificity of DNA binding, however. Electrostatic effects are screened with added salt, in a manner consistent with previous studies of PNA–DNA duplex stability and predictions from a charged-cylinder model for the duplex.

INTRODUCTION

Peptide nucleic acid (PNA) is a structural mimic of DNA that replaces the negatively charged sugar–phosphate backbone of DNA with an uncharged *N*-(2-aminoethyl)glycine backbone with attached nucleobases (*1*, *2*). PNA oligomers bind DNA oligomers in an antiparallel orientation, following Watson–Crick base pairing rules (*3*), but PNA–DNA duplexes are significantly more stable than the corresponding DNA–DNA duplex. The added stability of PNA–DNA duplexes has a largely electrostatic origin and is highest at low ionic strength conditions that destabilize DNA–DNA duplexes (*4*). PNA–DNA duplex stabilities are highly sensitive to sequence mismatches at the single-base level (*5*, *6*). PNA can also bind specific dsDNA targets by triplex formation, even in biological buffers that suppress triplex formation between ssDNA and dsDNA (*7*, *8*). Leveraging these unique DNA-binding properties, PNAs have been implemented in platforms for DNA sensing (*9*–*17*) and separation (*18*–*21*), primarily by linking PNAs to solid surfaces or fluorophores.

The attachment of peptides to lipophilic materials to form "peptide amphiphiles" is a convenient means to functionalize surfaces for cell attachment and proliferation (*22*, *23*) and for the measurement of molecular-level interactions between biomolecules using the atomic force microscope (AFM) (*24*) or surface force apparatus (SFA) (*25*–*27*). Surface functionalization generally requires water-insoluble peptide amphiphiles to enable Langmuir–Blodgett deposition or vesicle formation. Depending on the exact design, water-soluble peptide amphiphiles may self-assemble in solution to form disklike micelles (*28*), rodlike micelles (*29*), or helical ribbons (*30*) above their critical micelle concentration (cmc). Stupp and co-workers have shown that peptide amphiphiles can micellize with pH-dependent reversibility and that the micelles can be formed irreversibly by cross-linking of the peptide headgroups (*31*). We are working on the responsive, controlled self-assembly of peptide amphiphiles for implementation in DNA sensing and separation modalities such as liquid chromatography and capillary zone electrophoresis. With that goal in mind, we have attached *n*-alkanes and natural amino acids to form water-soluble PNA amphiphiles (PNAA). Recently, we have demonstrated that PNAA–DNA duplexes are easily separated from unbound DNA oligomers in hydrophobic interaction chromatography (*32*). The PNAA acts as a nonpolar sequence tag that helps separate target DNA from mixtures of DNA oligomers of up to 60 bases in length. Separation of longer DNA oligomers and dsDNA might be achieved with a better understanding of the binding and micellization properties of PNAA.

Because PNA is uncharged, it is sparingly soluble in water without the attachment of charged groups (*1*, *2*). For biophysical studies, either PNA oligomers are used at low concentration or a single lysine group is attached to confer greater water solubility. We expect that the attachment of *n*-alkane chains will exacerbate the poor water solubility of PNAA. For the design of PNAA, we wish to provide a moderate water solubility while maintaining sequence-specific DNA binding properties. One might expect that both the *n*-alkane and the requisite charged groups would also affect the PNAA–DNA duplex stability. For example, attachment of *n*-alkanes to collagen peptides has resulted in the stabilization of their triplexes (*33*), and the attachment of *n*-alkanes to antimicrobial peptides has been shown to promote their antimicrobial activity (*34*).

In this work, we have synthesized a series of PNAAs and measured their micellization properties and the stability of their duplexes with DNA oligomers. It should be noted that others have synthesized PNAs linked to lipophilic materials, including attachment of rhodamine and fluoroscein for thermodynamic studies (*35*) and the nonpolar group adamantane for improved cellular uptake of PNA (*36*). The distinction here is that our water-soluble PNA peptide amphiphiles have been designed for

a controlled, tunable self-assembly applicable to next-generation bioanalytical devices.

MATERIALS AND METHODS

PNAA Synthesis. All solvents (sequencing grade) were purchased from Fisher Scientific (Pittsburgh, PA), and buffers and salts were purchased from Sigma-Aldrich (St. Louis, MO). PNAAs were synthesized by solid-phase peptide synthesis using Fmoc/Bhoc-protected PNA monomers (Applied Biosystems) (*37*) and Fmoc-protected PAL-PEG-PS resin (Peptides International, Louisville, KY) with a 0.25 mmol/g loading capacity. One hundred milligrams of resin was shaken gently in dichloromethane (DCM) for several hours to expose reactive sites on the resin prior to peptide coupling. The resin was then deprotected three times with 20% piperidine in *N*,*N*-dimethylformamide (DMF) for 5 min to remove the Fmoc protecting group. A 5-fold excess of PNA monomer (based on manufacturer's reported loading capacity) in base solution (Applied Biosystems) and activator solution (Applied Biosystems) was then prepared (*38*), The base solution consists of a mixture of 2,6-lutidine and *N*,*N*-diisopropylethylamine in DMF. The activator is a solution of *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) in DMF. Following a 2-min activation step, the solution was added to the resin. The initial monomer coupling to resin was allowed to proceed for at least 1 h to ensure complete coupling on the optimal number of resin sites. We found that the longer coupling time was required for high yields. The resin was washed with DCM and DMF following the coupling step and a small fraction collected for a ninhydrin test. Unreacted sites were then capped by a 10-min incubation of the resin with the acetic anhydride. The resin was washed with DCM and DMF, and the process was repeated with 20-min coupling steps until the desired PNA peptide was synthesized. Lauric acid (Sigma-Aldrich) was then coupled to the N terminus of the PNA peptide, also in a 5-fold excess.

The resin was soaked in a mixture of 4:1 trifluoroacetic acid (TFA)/*m*-cresol (total volume = 2 mL) for 2 h to cleave the PNAA from the resin and remove Bhoc side protecting groups. Once cleaved from the support, the PNAA was precipitated by the addition of dry ether (~10-fold excess over PNAA). The precipitated PNAA was cooled for 5 min in a −80 °C freezer to ensure complete precipitation. The solid was separated from the ether by centrifugation (1000*g*) for 5 min. The top phase was decanted off and the pellet resuspended with another addition of dry ether. The cooling and centrifugation process was done in triplicate. Upon completion, the PNAA pellet was dried within a stream of nitrogen and dissolved in deionized water. In many cases, yields of PNAA were improved substantially by foregoing the ether precipitation step and injecting the cleavage cocktail directly into the HPLC for purification.

Semipreparative-scale PNAA purification was performed on a Waters Delta 600 HPLC using a Symmetry300 C_4 column with a particle size of 5 μm. Elution of the PNAA product was achieved using a 30-min linear gradient (0.1% TFA in acetonitrile to 0.1% TFA in water) and a 20 mL/min flow rate. The product eluted as a single peak and following collection was lyophilized to a powder. The yield of the reaction was ~30% (based on the manufacturer's reported resin loading), or 0.0075 mmol of PNAA product. The following $[M + H]^+$ values for PNA peptides and PNAA amphiphiles were obtained: C_{12}-tttccg-$(Lys)_2$, 2050 Da (theoretical: 2049.96); NH_2-tttccg-$(Lys)_2$, 1865.91 Da (theoretical: 1866.71); C_{12}-agtgatctac-$(Glu)_4$, 3425.8 Da (theoretical: 3425.52); NH_2-agtgatctac-$(Glu)_4$, 3242.52 Da (theoretical: 3241.59).

The naming convention we use lists the PNA peptide sequence in the N to C direction from left to right (Figure 1). PNA sequences listed in the N to C direction follow the same Watson−Crick base pairing rules as the corresponding DNA sequence listed in the 5′ to 3′ direction. Note that the resin used here leaves a terminal amine group at the C terminus. PNA nucleobases are in lower case to distinguish them from DNA nucleobases (upper case). The three-letter abbreviation is used for the natural amino acids, and the length of *n*-alkane is the subscript under "C."

Solubility Measurements. PNAA solubilities were measured by centrifugation of saturated PNAA solutions in buffer. A large (>1 mM) amount of PNAA was dissolved in 20 mM sodium phosphate buffer (pH 7.0) and cooled to 4 °C. Samples were then warmed to room temperature and centrifuged (Eppendorf 5415C microcentrifuge) to sediment aggregated or precipitated material. The PNAA concentration in the supernatant was measured spectrophotometrically on a Varian Cary 3 spectrophotometer at 260 nm. PNAA concentrations were calculated from the measured absorbance by Beer's law. Extinction coefficients for the PNAA were calculated by

summing the extinction coefficients for each monomer on the PNA peptide (ϵ_{260} = 13700, 11700, 8600, and 6600 L/mol-cm for A, G, T, and C, respectively.) Absorbance measurements were made at 80 °C to ensure that the nucleobases were completely destacked and that hypochromicity could be neglected.

cmc Measurements. Critical micelle concentrations for the PNAA were obtained by light scattering using a Malvern Zetasizer 3000 system (Malvern Instruments). Solutions of PNAA in 20 mM sodium phosphate buffer (pH 7.0) were prepared and filtered to remove dust or large PNAA aggregates using 0.2-μm syringe filters (Fisher). UV absorbance measurements were made on the filtrate to account for any losses of PNAA during filtration. The filtered solutions were then placed in a 1-mL cuvette and installed in the Zetasizer instrument. The intensity of laser light (532 nm) scattered 90° from incidence was measured using an internal photomultiplier and recorded by the Zetasizer software. Disposable cuvettes were used to obviate any carry-over of PNAA from sample to sample. The cmc was taken to be the PNAA concentration at which the intensity versus [PNAA] plot had a pronounced slope discontinuity.

UV Melting Curves and Circular Dichroism (CD). DNA oligomers were purchased from Integrated DNA Technologies (Coralville, IA) and used as received. DNA purity was assessed using anion-exchange chromatography (Waters Spherisorb S5 SAX column, 80-Å pore size and 5-μm particle size), with a 30-min linear gradient from 20 mM Tris-HCl (pH 8.0) to 20 mM Tris-HCl in 1 M NaCl (pH 8.0). Samples with purity of <95% were rejected. Stock solutions of DNA oligomers were prepared in 20 mM phosphate buffer (pH 7.0) for UV melting analysis.

CD spectra were run on a Jasco J-715 spectropolarimeter equipped with a thermoelectrically controlled single-cell holder. CD spectra for PNAA−DNA mixtures were obtained in 5 mM sodium phosphate buffer (pH 7.0) with 100 mM NaCl and 1 mM EDTA.

UV melting curves were obtained at 260 nm for PNAA−DNA solutions in 20 mM sodium phosphate buffer (pH 7.0) using a Varian Cary 3 spectrophotometer equipped with a thermoelectrically controlled multicell holder using 1-cm quartz cuvettes (Starna, Atascadero, CA). PNAA−DNA mixtures were initially heated to 90 °C and held there for 2 min to equilibrate. The temperature was then lowered at 1.0 °C/min to a lower target value (5−20 °C) and cycled between the upper and lower temperature limits several times.

Melting temperatures and thermodynamic data for all melting curves were determined by a van't Hoff analysis under a two-state model for hybridization

$$S_{PNA} + S_{DNA} \leftrightarrow D_{PNA/DNA} \quad (1)$$

where S denotes single strands and D duplex. The two-state model is considered to be valid for short sequences (4−20 base pairs) (*39*). The absorbance versus temperature plot is converted to a plot of duplex fraction (α) versus temperature. The total absorbance (A) is assumed to be the sum of the absorbance of the single strands (A_S) and the double strands (A_D):

$$A = \alpha A_D + (1 - \alpha)A_S \quad (2)$$

The melting transition temperature (T_m) is taken to be the temperature at which $\alpha = 0.5$. The absorbance values of the single- and double-stranded forms of the DNA and PNA are assumed to vary linearly with temperature and take the form

$$A_S = m_S T + b_S$$
$$A_D = m_D T + b_D \quad (3)$$

As nucleotide length increases, the nucleobase stacking dynamics become more pronounced and the slopes m_S and m_D will deviate from zero.

The equilibrium constant for the hybridization process is

$$K = \frac{[D_{PNA/DNA}]}{[S_A][S_B]} = \frac{2\alpha}{(1 - \alpha)^2 C_T} \quad (4)$$

where C_T is the total concentration of strands, on a single-strand basis. The equilibrium constant, K, versus temperature data can be analyzed using the van't Hoff equation to obtain the enthalpy of hybridization ΔH

$$\frac{d \ln K}{d(1/T)} = \frac{-\Delta H^\circ}{R} \quad (5)$$

where R is the gas constant.

RESULTS AND DISCUSSION

PNAA Synthesis. Most PNA syntheses have been accomplished by solid-phase synthesis using Boc/Z-protected monomers following the protocol of Christensen et al. (*40*). In our case, we were interested in attaching dialkyl chains with ester linkages that are hydrolyzed under the cleavage conditions required for Boc/Z. The milder cleavage conditions required by Fmoc/Bhoc protection have been shown to maintain the ester linkage (*41*), and therefore we used the Fmoc/Bhoc approach. The Fmoc/Bhoc PNA synthesis protocol provided by Egholm and Casale (*42*) was developed for automated PNA synthesis, and it was refined for manual synthesis in our laboratory. The most significant changes were increasing the coupling, capping, and deprotection times and the use of a 5-fold excess of monomer for each coupling. To obtain high yields, we found it necessary to increase the time of the initial resin−monomer coupling to 1 h, but subsequent couplings could be performed for 20 min. Because the alkane-modified PNAs are more nonpolar than the PNA peptides, it was often necessary to inject the cleavage cocktail directly into the HPLC for high-yield purification. The PNAA structures we are mainly concerned with in this paper are listed in Figure 1.

Solubility and cmc Measurements. Unmodified PNAs are sparingly soluble in water and have a tendency to self-aggregate even when the PNAs are apparently solubilized (*2*). A typical approach to improve water solubility is attachment of a C-terminal lysine residue to the sequence, which for the PNA peptide NH_2-t_{10}-Lys confers a water solubility of >1.5 mM in 10 mM sodium phosphate buffer (pH 7.0) (*37*). For PNAA, additional charges need to be added to bring the solubility of PNAA above their cmc, enabling self-assembly. To find an appropriate combination of alkane substitution and charging, we synthesized about 12 variants with different PNA sequences and substitutions. The PNAAs C_{18}-tttccg-Lys, C_{16}-tttccg-Lys, and C_{14}-tttccg-Lys gave a cloudy solution at 1−10 μM concentrations in water or 10 mM sodium phosphate buffer (pH 7.0). C_{12}-tttccg-$(Lys)_2$ had twice the solubility of C_{12}-Lys-tttccg-Lys and was studied in more detail (Figure 1A). For longer PNA sequences, such as C_{12}-t_{10}-$(Lys)_4$ in 20 mM phosphate buffer (pH 7.0),

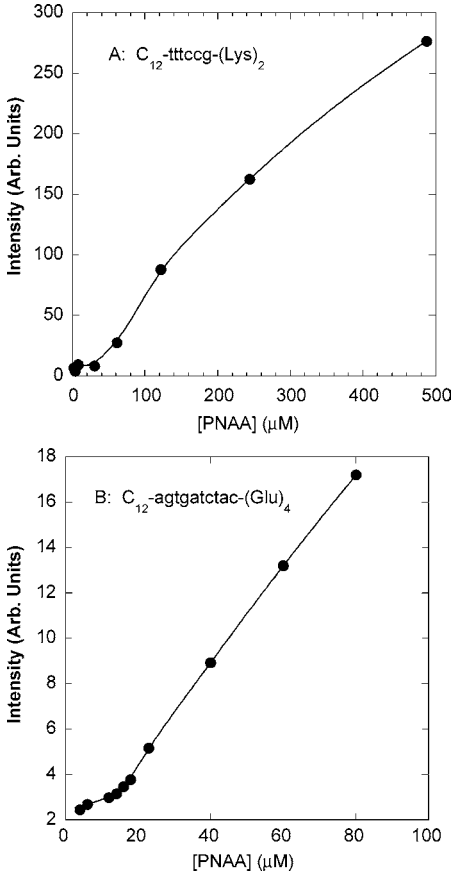

Figure 2. Scattered intensity versus [PNAA] for (A) C_{12}-tttccg-$(Lys)_2$ and (B) C_{12}-agtgatctac-$(Glu)_4$ in 20 mM sodium phosphate buffer (pH 7.0). The cmc is marked by an abrupt increase in scattered intensity (*43*).

Table 1. Solubilities and Critical Micelle Concentrations for PNA Amphiphiles in 20 mM Phosphate Buffer (pH 7.0)

	solubility, 25 °C (μM)	cmc, 25 °C (μM)
C_{12}-tttccg-$(Lys)_2$	1000	40
C_{12}-agtgatctac-$(Glu)_4$	650	15

addition of either complementary or noncomplementary DNA to 20 mM phosphate buffer clouded the solution. The clouding was mitigated by the use of glutamic acid groups to charge the PNAA, the use of a Tris-HCl (pH 7−8) buffer rather than phosphate buffer, or adjusting the pH to pH ∼2−3. The PNAA C_{12}-agtgatctac-$(Glu)_4$ (Figure 1B) has a solubility of 1000 μM in 20 mM sodium phosphate buffer and >1400 μM in 10 mM Tris-HCl (pH 7.0).

Although the effect of tail length, charge amount and type, and length of PNA sequence have not been exhaustively studied, some rules of thumb have emerged. Generally, 6-mer sequences require two charged groups and 10-mer sequences require four charged groups for solubilities on the order of 500−1000 μM. Charged groups placed at the N terminus of the PNA peptide were more effective than those placed between the alkane and the PNA peptide.

cmc measurements were made by a light-scattering method using a laser Doppler velocimetry system in static mode. The cmc is marked by a large increase in scattered intensity as shown in Figure 2 (*43*). The shorter PNAA sequence of C_{12}-tttccg-$(Lys)_2$ gave a slightly higher cmc than C_{12}-agtgatctac-$(Glu)_4$ (Table 1). cmc values for C_{14}-tttccg-$(Lys)_2$ and C_{18}-tttccg-$(Lys)_2$ were similar to that of C_{12}-tttccg-$(Lys)_2$, indicating that the primary driving force

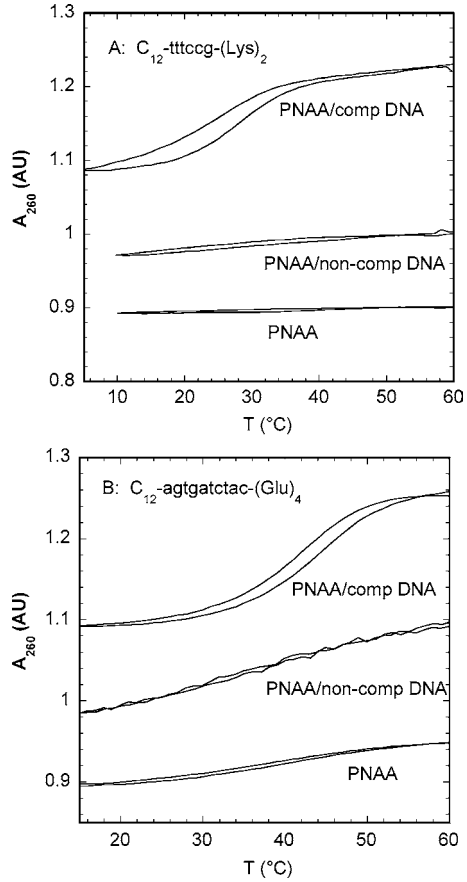

Figure 3. UV melting curves for PNAA with and without DNA: (A) C_{12}-tttccg-$(Lys)_2$ alone, with noncomplementary DNA (5′-ATAGCC-3′), and with complementary DNA (5′-CGGAAA-3′); (B) C_{12}-agtgatctac-$(Glu)_4$ alone, with noncomplementary DNA (5′-TGTACGACTC-3′), and with complementary DNA (5′-GTAGATCACT-3′). For (A) and (B), a ramp rate of 1.0 °C/min and a total strand concentration of 20 μM in 20 mM sodium phosphate at pH 7.0 were used. In each case, the self-melt was shifted up by 0.4 AU and the PNAA/noncompDNA was shifted down by 0.1 AU for clarity.

for micellization is attractive interactions between the PNA peptides. Accordingly, longer sequences tend to lower the cmc. To avoid complications, the measurements presented below were made at concentrations below the cmc for both PNAA.

Hybridization of PNA Amphiphiles with DNA. The substitutions made on the PNA peptide to form PNAA include the *n*-alkane tail and the charged amino acids, and both could potentially affect the specificity of binding to DNA oligomers and the stability of the resulting PNAA−DNA duplex. Figure 3A shows UV melting curves for the PNAA C_{12}-tttccg-$(Lys)_2$ with an equimolar amount of its 6-mer DNA complement (5′-CGGAAA-3′), a noncomplementary 6-mer (5′-ATAGCC-3′), and the PNAA on its own. Significant hypochromicity was observed only for the PNAA/complementary DNA mixture (T_m = 27.6 °C), indicating sequence specificity is preserved. Figure 3B shows UV melting curves for the PNAA C_{12}-agtgatctac-$(Glu)_4$ with an equimolar amount of its 10-mer DNA complement (5′-GTAGATCACT-3′), a noncomplementary 10-mer (5′-TGTACGACTC-3′), and the PNAA on its own. In this case, each of the three curves shows hypochromicity. A van't Hoff analysis of the PNAA/complementary DNA curve gave T_m = 42.0 °C. Other hypochromicities are likely due to self-melt characteristics for the longer DNA and PNAAs of Figure 3B. Self-melts are generally larger for PNAs compared to

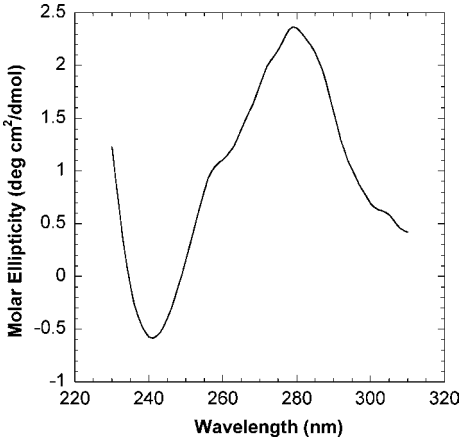

Figure 4. CD spectrum for C_{12}-agtgatctac-$(Glu)_4$ with 5′-GTAGATCACT-3′ at a total strand concentration of 5 μM (averaged over 10 scans) 20 mM sodium phosphate at pH 7.0 (T = 25 °C).

Table 2. Melting Temperatures for PNAA with Complementary DNA Targets (5′-CGGAAA-3′ and 5′-GTAGATCACT-3′) in 20 mM Phosphate Buffer (pH 7.0), along with T_m Predictions from a Nearest-Neighbor Model (*45*)

	T_m (°C),[a] exptl	T_m (°C), theor
NH_2-tttccg-$(Lys)_2$	27.4	24.3
C_{12}-tttccg-$(Lys)_2$	27.6	24.3
NH_2-agtgatctac-$(Glu)_4$	38.9	53.7
C_{12}-agtgatctac-$(Glu)_4$	42.0	53.7

[a] T_m had an associated error of 0.5 °C.

DNAs as the more flexible PNA backbone allows the nucleobases to stack to a greater degree. Because the hypochromicity is comparable for the PNAA and the PNAA with noncomplementary DNA, we conclude that the mixture does not form a duplex or other intermolecular association. This self-structured nature of the C_{12}-agtgatctac-$(Glu)_4$ can be considered a small potential source of error when the melting curve for thermodynamic parameters is analyzed. Note that the self-melt is not evident in the case of the shorter PNAA and DNA 6-mers (Figure 3A). A small hysteresis between the melting and cooling curves was observed in each case. For the C_{12}-agtgatctac-$(Glu)_4$ PNAA−DNA melting curve, the hysteresis decreased from 1.54 to 0.41 °C when the scan rate was slowed from 1 to 0.5 °C/min.

To verify duplex formation, the secondary structure of the PNAA−DNA duplex was confirmed using CD (Figure 4). Hybridization of C_{12}-agtgatctac-$(Glu)_4$ with complementary DNA 5′-GTAGATCACT-3′ shows the formation of a right-handed helix with maxima at 260 and 280 nm and a minimum at 240 nm. These features compare well with those measured by Ratilainen (*35*) for a PNA peptide with a single lysine group attached. CD spectra were not obtained for the duplex of C_{12}-tttccg-$(Lys)_2$ and its 6-mer DNA complement, since the duplex is marginally stable in phosphate buffer at room temperature.

UV melting curves were also obtained for the corresponding PNA peptides without alkylation and are summarized in Table 2. For both PNAAs studied here, the corresponding peptide shows about the same T_m. Similar observations have been made by Griffin and Smith (*44*) for PNAs with attached 8-amino-3,6-dioxaoctadecanoic acid groups and by Ørum et al. (*18*) for PNAs with attached $(His)_6$ peptides. Although alkylation appears to have little effect on the binding, the substantial amount of charged amino acids required for solubilization does.

Table 3. Thermodynamic Parameters for Hybridization of PNAA C_{12}-agtgatctac-$(Glu)_4$ with Complementary DNA (5′-GTAGATCACT-3′) in 10 mM Tris Buffer (pH 7.0, unless Otherwise Indicated) with Increasing Concentrations of NaCl[a]

[NaCl] (mM)	T_m (°C)	ΔH (kJ/mol)	ΔG_{298} (kJ/mol)
0 (pH 4.0)	41.7	−256	−45.7
0	39.7	−274	−45.0
20	42.7	−254	−46.2
40	43.8	−265	−47.8
60	44.5	−277	−49.2
80	45.0	−270	−49.1
100	45.3	−286	−50.3
1000	47.2	−300	−52.9

[a] T_m had an associated error of 0.5 °C, ΔH had an error of 10 kJ/mol, and ΔG had an error of 0.5 kJ/mol.

Giesen et al. (*45*) provided an extension to the nearest-neighbor model of SantaLucia (*46*) for PNA−DNA duplexes. The model claims to be valid over a wide range of ionic strengths and does not include the effects of amino acids or lipids and, hence, serves as a useful reference. Table 2 includes a comparison of the model predictions and the observed T_m and shows that T_m is underpredicted in the case of C_{12}-tttccg-$(Lys)_2$ and overpredicted in the case of C_{12}-agtgatctac-$(Glu)_4$, pointing to an electrostatic contribution to the duplex stability.

To verify the electrostatic nature of the stabilization in the case of C_{12}-tttccg-$(Lys)_2$ and destabilization in the case of C_{12}-agtgatctac-$(Glu)_4$, the effect of added salt on PNAA−DNA duplex stability was determined for C_{12}-agtgatctac-$(Glu)_4$ (Table 3). As the ionic strength was increased (pH 7.0), T_m increased and ΔG decreased as expected. Additionally, the duplex was stabilized by decreasing the pH to 4.0 (no added salt), likely due to the lowering state of charging for the Glu residues, the side-chain carboxylic acid of which has a pK_a of 4.07. Below pH 4.0, UV spectra were excessively noisy due to light scattering from insoluble aggregates of PNAA.

The effect of ionic screening on PNAA−DNA duplex stability can be predicted by a Poisson−Boltzmann-type model (*47*, *48*) that considers the oligomers to behave as charged cylinders with a higher charge density in duplex form than as a single-stranded coil. An increase in bulk cation concentration acts to stabilize the high charge density state, resulting in a higher thermal stability. The change in melting temperature with changing salt concentration can be related to the thermodynamic differential counterion association parameter per phosphate group ($\Delta\psi$) by (*4*, *49*)

$$\frac{dT_m}{d \log [Na^+]} = 0.9\left\{\frac{2.03RT_m^2}{\Delta H}\right\}(N_u\Delta\psi) \qquad (6)$$

where ΔH is the helix-to-coil transition enthalpy, R is the gas constant with units of cal/(mol K), and N_u is the number of charged groups (phosphate, in the case of DNA) per cooperative melting unit. The data of Table 3 have $dT_m/d \log [Na^+]$ for C_{12}-agtgatctac-$(Glu)_4$ of 3.8 K, indicating that counterion association takes place upon PNA−DNA helix formation. From ΔH and T_m values taken from the van't Hoff analysis of the melting curves, the thermodynamic differential counterion association parameter ($\Delta\psi$) was calculated to be 0.059.

Table 4 summarizes these results and compares them to literature values. Because the PNAA C_{12}-tttccg-$(Lys)_2$ has a low T_m, it was difficult to obtain the full sigmoidal curve required for accurate thermodynamic data in the presence of added salt. Instead, we measured melting

Table 4. Salt Concentration Dependence on Duplex Stability for PNAA with Complementary DNA (5′-CGGAAA-3′ and 5′-GTAGATCACT-3′) in 10 mM Tris Buffer (pH 7.0)

duplex	$d(T_m)/d(\log[Na^+])$ (K)	$RT_m^2/\Delta H$ (K)	$\Delta\psi$ (mol/mol of duplex)
C_{12}-tttccg-$(Lys)_2$−DNA	−4.2	1.95	−0.17
C_{12}-agtgatctac-$(Glu)_4$−DNA	3.8	3.10	0.059
PNA−DNA[a]	−3.4	3.52	−0.05
DNA−DNA[a]	15.9	2.74	0.15

[a] Literature values for PNA and DNA decamers and their DNA−decamer complements (*4*).

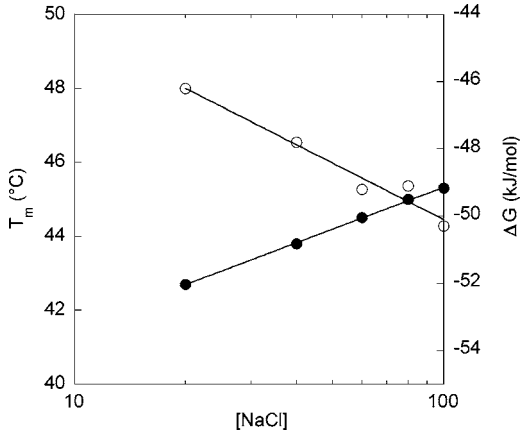

Figure 5. Dependence of T_m (filled circles) and ΔG (open circles) on the concentration of NaCl added to 10 mM Tris buffer for hybridization of PNAA C_{12}-agtgatctac-$(Glu)_4$ with complementary DNA (5′-GTAGATCACT-3′). The T_m data are fit to the equation $T_m = 37.8 + 3.77\log([Na^+])$, and the ΔG data are fit to the equation $\Delta G = -38.9 - 5.58\log([Na^+])$. Regression coefficients are >98% in both cases.

curves in pure water (deemed to have an effective $[Na^+] = 10^{-5}$ M) and compared them to the buffer case (effective $[Na^+] = 2 \times 10^{-2}$ M). In this case, $\Delta\psi = -0.17$, indicating that counterions are released on duplex formation owing to the complexation of positively charged lysine and negatively charged phosphates. Tomac et al. (*4*) made similar measurements and obtained a value of $\Delta\psi = -0.05$ for an unmodified PNA 10-mer with fully complementary DNA and $\Delta\psi = 0.15$ for the corresponding DNA−DNA duplex. This indicates that the addition of 4 Glu residues has the same destabilizing effect as about 2.5 phosphate groups. Although each group carries a negative charge, in principle, this result is reasonable considering the separation between the distal Glu groups and DNA phosphate groups and the possibility of incomplete dissociation of the side-group carboxylic acids at pH 7.0. Figure 5 is a plot of T_m and ΔG with added salt, showing a semilog dependence. Griffin and Smith obtained a value of $d\Delta G/d\log[Na^+] = -1.82$ kJ/mol for fully complementary PNA (unmodified) and DNA 9-mers. The PNA−DNA duplex is stabilized by added salt, because

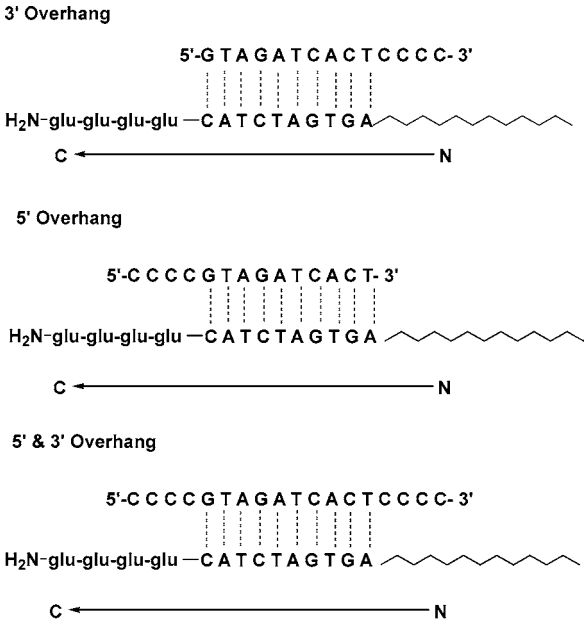

Figure 6. Orientation of the PNAA/DNA duplex with overhanging DNA bases on the 3′, 5′, and 3′ and 5′ ends.

the helix carries a greater charge density than the coil, as described above. We obtained a value of $d\Delta G/d\log[Na^+] = -5.58$ kJ/mol, indicating a much greater free energy penalty for the introduction of $(Glu)_4$ to the duplex than the closer proximity of phosphate charges required for helix formation.

Datta and Armitage have reported a stabilizing effect of overhanging, unbound DNA bases on PNA−DNA duplexes with length asymmetries (*50*). The overhang effect was ascribed to an enthalpic gain provided by stacking of the overhanging DNA bases with those in the PNA−DNA duplex. The effect is more evident in PNA−DNA duplexes than in DNA−DNA duplexes, presumably due to the wider pitch of the PNA−DNA helix that leaves bases more exposed to solvent. To determine if the alkane tail would have any impact on overhang-induced stabilization, we also collected UV-melting data using longer DNA strands, those with overhanging C bases surrounding a 10-mer binding site (Table 5; Figure 6). The first conclusion we draw is that, for overhangs on both sides of the PNAA binding sequence of the DNA, there appears to be no difference for the PNA peptide compared to the PNA amphiphile. Additionally, DNA overhangs on the 3′ end of the binding sequence (closest to the PNAA alkane, Figure 6) stabilize the duplex while those on the 5′ end (closest to the $(Glu)_4$ group, Figure 6) destabilize the PNAA−DNA duplex. Because the thermodynamic data for PNAA−DNA duplexes mirror those for PNA−DNA duplexes, we must presume that the stabilization afforded by the 3′ overhangs is due to the same effect reported by Datta and Armitage, whereas the destabilization by the 5′ overhangs has an electrostatic origin that

either exists along with an overhang stabilization (but outweighing it) or prevents the molecular arrangements required for overhang stabilization from occurring. Finally, we note that the overhang-induced stabilization appears to saturate with six cytosine bases on each end of the binding sequence, because the stability is not improved with eight bases on each end. This appears to agree with results from Datta and Armitage, who found a significant added stabilization of PNA−DNA duplexes with eight overhanging bases rather than four.

CONCLUSIONS

We have provided details concerning the synthesis and characterization of PNA amphiphiles (PNAA), self-assembling compounds that bind DNA with high selectivity. We have found that the addition of the alkane tail makes self-assembly possible, but does not affect the binding selectivity or the stability of the resulting PNAA−DNA duplex. The incorporation of about four charged amino acids per 10-mer (or two per 6-mer) was required for adequate water solubility. Addition of a $(Glu)_4$ peptide destabilized the duplex, whereas addition of a $(Lys)_2$ peptide stabilized it. Both effects were attenuated with increased ionic strength, indicating an electrostatic mechanism. This electrostatic control over the stability could be useful for the tuning of the duplex melting temperature for future applications of these materials in bioanalytical devices. Stabilization of the PNAA−DNA duplex was also observed when using DNAs with overhanging bases, but this overhang stabilization was not affected by the PNAA alkane.

ACKNOWLEDGMENT

We acknowledge the National Science Foundation (BES-0093538), the Arnold and Mabel Beckman Foundation, and a joint grant from the Air Force Office of Scientific Research and the DARPA SIMBIOSYS program for financial support of this work. We also thank Bruce Armitage and Stu Kushon for helpful discussions.

Various poly(ethylene glycol)(PEG)-based prodrug conjugates of the HIV-1 protease inhibitor (PI) saquinavir (SQV) were prepared using several types of chemical groups potentially capable of modifying its pharmacokinetic properties. These prodrug conjugates included SQV−cysteine-PEG3400, SQV−cysteine-PEG3400-biotin, SQV−cysteine(R.I.CK-Tat9) [a cationic retro-inverso-cysteine-lysine-Tat nonapeptide]-PEG3400, and SQV−cysteine(R.I.CK(stearate)-Tat9)-PEG3400. SQV was linked to cysteine to form a releasable SQV−cysteine ester bond in all of the conjugates. The amino group of the cysteine moiety provided an attachment site for a slower-degrading amide bond with *N*-hydroxysuccinimide-activated forms of PEG- and PEG-biotin. Disulfide bonds were used to attach the cationic peptides, R.I.CK-Tat9 and R.I.CK(stearate)-Tat9 to the cysteine moiety in order to provide cell-specific release. An assay was established and validated for measuring the activity of SQV and other protease inhibitors in biological samples. In this assay, cleavage of an internally quenched fluorescent substrate, Arg-Glu(EDANS)-Ser-Gln-Asn-Tyr-Pro-Ile-Val-Gly-Lys(DABCYL)-Arg by HIV-1 protease was inhibited by SQV in a dose-dependent manner at concentrations of 0.05−0.5 μM. All prodrug conjugates were shown to be inactive in this assay until the ester bond was cleaved and active SQV was released. The prodrug reconversion half-lives in 0.1 N HCl, phosphate-buffered saline (PBS) at pH 7.4 and in spiked plasma at 37 °C were 9, 14, and 0.9 h, respectively. The anti-HIV-1 activity (ED_{50}) of the PEG-based SQV prodrug conjugates was evaluated in MT-2 cells using an MTT assay. The activity of conjugated SQV was reduced (ED_{50} = 900 nM) for the PEG only conjugate, but restored with the addition of biotin (ED_{50} = 125 nM), R.I.CK-Tat9 (ED_{50} = 15 nM), and R.I.CK-(stearate)-Tat9 (ED_{50} = 62 nM) as compared to maximum achievable anti-HIV-1 activity (unconjugated SQV, control, ED_{50} = 15 nM), suggesting enhanced cellular uptake of conjugates. Cytotoxicity (LD_{50}) was assessed for all prodrug conjugates using non-HIV-1 infected cells and was found to be in the micromolar range. The difference between the LD_{50} and ED_{50} suggests a favorable therapeutic index for the prodrug conjugates. In conclusion, these promising initial results demonstrate that the reconversion of the conjugate prodrugs was complete and that active SQV was released. Since the major delivery advantages of PEG prodrug conjugates can only be observed in vivo, issues of reconversion and elimination half-lives in plasma will have to be further studied in an in vivo model. The current results also demonstrate that the protease inhibition assay is a simple yet effective bioanalytical tool that can be used to assess the release and anti-HIV-1 activity of HIV-1 PIs from their prodrug forms.

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) is a degenerative disease of the immune and central nervous systems caused by the human immunodeficiency virus (HIV). HIV-1 protease is the target of the protease inhibitors, a class of drugs commonly used for AIDS therapy. SQV[1] is the first HIV-1-protease inhibitor (PI) to be approved by the U.S. Food and Drug Administration. However, therapeutic use of SQV suffers from problems of low absorptive and high secretory permeability, bioconversion to inactive metabolites, and poor solubility (*1, 2*). The oral bioavailability of SQV in clinical formulations is low and/or variable with limited penetration into the lymphatic and central nervous systems (CNS) (*3*−*6*). While its low and variable bioavailability is primarily attributed to metabolism by cytochrome P-450 3A, recent results published by our group (*7, 8*) and others (*9*) suggest that multiple membrane transporters may also contribute significantly to the observed behavior. The consequence of variable SQV bioavailability can be the development of viral resistance, ultimately resulting in therapeutic failure. Clearly, better drug

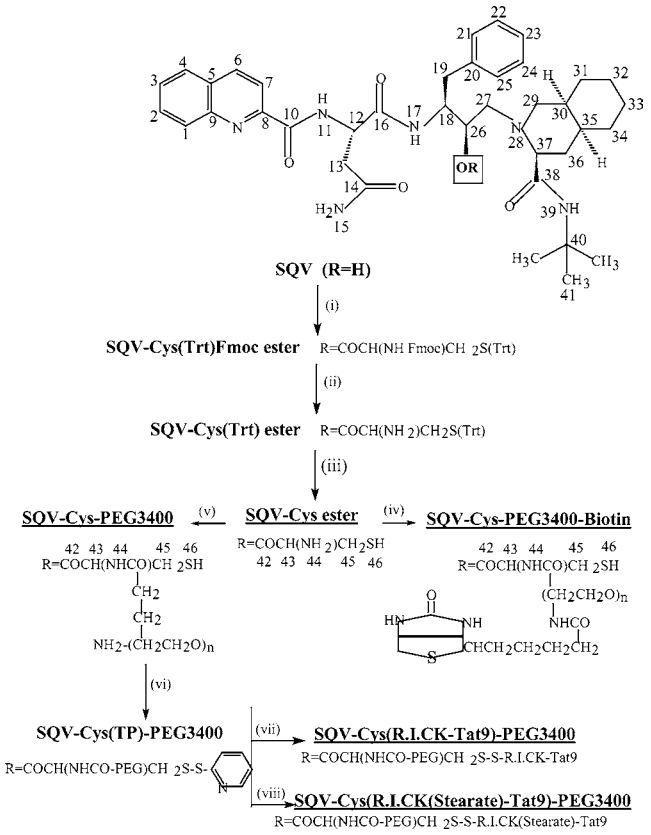
delivery methods are required to enhance the bioavailability of SQV and to reduce the associated variability observed in the clinic.

One common drug delivery approach to enhancing bioavailability is to utilize prodrugs. A 'prodrug' approach has the potential advantage of achieving greater drug bioavailability by altering the physicochemical properties of the drug, minimizing processes that would otherwise cause elimination or breakdown of the parent drug, or by increasing cellular uptake. Various ester PI prodrugs derived from SQV, indinavir, or nelfinavir connected to fatty acids, L-valine, L-tyrosine, PEG, or D-glucose (*10, 11*) have been reported. The most encouraging results were obtained with the L-valine PI prodrugs (*12*) which prompted the extension of this series to include L-leucine and L-phenylalanine along with new ester PI prodrugs derived from L-tyrosine or that are linked to diglycerides (*13*). Among the strategies explored up to now, the most successful has been the "hydrophilic" prodrug approach which has led to the discovery of fosamprenavir, a water-soluble phosphate ester prodrug of the sparingly water-soluble amprenavir that was approved in 2003. The absorption enhancement of amprenavir that is observed by using the fosamprenavir prodrug occurs because the water solubility of this poorly soluble drug is dramatically increased and net systemic absorption is greatly enhanced. Unfortunately, prodrugs are rapidly converted back to the parent drug in vivo either in the intestinal environment or on the first pass through the intestine and liver. Therefore, once a prodrug is "absorbed", only the drug appears in the blood and the potential benefits of the prodrug are lost. Since nearly all PIs are faced with poor cellular uptake/retention, metabolism, and protein binding, the maximal therapeutic potential of these agents is not likely to be achieved using a classical prodrug approach since concentrations in target cells such as T4 helper lymphocytes or macrophages will be difficult to control.

In the current report, macromolecular prodrug conjugates were designed to overcome several biopharmaceutical challenges associated with HIV-1 PIs and prodrugs in general including poor solubility, cellular uptake/retention, metabolism/stability, and variable cellular drug concentrations. The conjugate scaffold used in the current study was based on PEG. PEGylation has been shown to significantly enhance the biopharmaceutical properties (i.e., circulation half-life, aqueous solubility, etc.) of drugs resulting in more effective in vivo delivery (*14*−*18*). Enhancing cell association and/or uptake was also an important design element. This was addressed by using biotin (*17,18*), R.I.CK-Tat9 (*19, 20*), or R.I.CK-(stearate)-Tat9 (*21*) to enhance cell uptake. In addition to being an effective cell-penetrating peptide (CPP), R.I.CK-Tat9 is also an anti-HIV-1 agent that acts on nonprotease targets (*22*−*25*) and may be useful in combination therapy. In this report, the design, synthesis, and initial characterization of prototype prodrug conjugates of SQV with PEG-based substituents are described. These substituents were linked to the drug using releasable (ester and disulfide) and nonreleasable (amide) bonds. For these prodrug conjugates, the anti-HIV-1 activity was assessed in HIV-infected MT-2 cells using an MTT assay and compared to the maximal possible in vitro therapeutic potential of unconjugated SQV. Also, a novel HIV-1 protease inhibition assay was used to monitor the release of active drug from the prodrug conjugates.



EXPERIMENTAL PROCEDURES

Materials. Fluorenylmethoxycarbonyl (Fmoc)-amino acid derivatives, MBHA Rink amide resin, BOP (benzotriazol-1-yl-oxytris(dimethylamino)phosphonium hexafluorophosphate) and HOBt (*N*-hydroxybenzotriazole) were purchased from Calbiochem-Novabiochem Corp. (La Jalla, CA). Fmoc-PEG-NHS (MW 3400) and biotin-PEG-NHS (MW 3400) were obtained from Nektar Therapeutics AL, Corp. (formerly Shearwater Corp.) (Huntsville, AL). Stearic acid, DIEA (diisopropylethylamine), aldrithiol, piperidine, and hydrazine were obtained from Sigma Chemicals (St. Louis, MO). Acetic anhydride and diethyl ether were purchased from Fischer Chemicals (Pittsburgh, PA). Dde (1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl), EDT (ethanedithiol), TIS (triisopropyl silane), DMAP (4-(dimethylamino)pyridine), DIPC (1,3-diisopropylcarbodiimide), anhydrous dimethylformamide (DMF), and anhydrous dimethyl sulfoxide (DMSO) were obtained from Aldrich Chemicals (Milwaukee, WI). Dichloromethane (DCM) obtained from Sigma was dried over calcium hydride and freshly distilled prior to use. Trifluoroacetic acid (TFA) obtained from Aldrich was distilled with H_2SO_4 before use. SQV from commercially purchased capsules (Inverase, Roche) was extracted with methanol. Chemical reactions were carried out under a nitrogen atmosphere. The purity of all new compounds was checked by mass spectrometry, TLC, and/or NMR.

Spectral Analyses. UV spectra were recorded on a Shimadzu UV-1201 spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker ARX 300. Chemical shifts (δ) were expressed as parts per million (ppm) using tetramethylsilane (TMS) as the internal standard (δ = 0.0 ppm). Coupling constants (J values) are expressed in Hz, and multiplicities are referred to as s (singlet), d (dublet), t (triplet), m (multiplet), bs (broad singlet), and td (triplet dublet). Electrospray ionization mass spectra (ESI-MS) were recorded on a Finnigan MAT TSQ 7000 equipped with an atmospheric pressure ionization source. This method used in positive mode detects either the $(M + H)^+$ and/or $(M + Na)^+$ signal. Mass spectrometry using matrix-assisted-laser-desorption-ionization time-of-flight (MALDI-TOF) was performed on a PE Biosystems Voyager System 6080. $^1H/^{13}C$ NMR and mass spectrometry (ESI-MS and/or MALDI-TOF) data fully confirm the signal assignments and structure of the materials. For atom numbering, see Scheme 1.

Scheme 1. Synthetic Pathway to SQV Prodrug Conjugates[a]

[a] (i) 3 equiv of Fmoc-Cys(S-Trt)-COOH in CH_2Cl_2 with DIPC/DMAP; (ii) 20% piperidine in CH_2Cl_2; (iii) TFA/CH_2Cl_2 (1:1); (iv) 2 equiv of biotin-PEG-NHS in CH_2Cl_2 with DIEA; (v) 2 equiv of Fmoc-PEG-NHS in CH_2Cl_2 with DIEA; (vi) 2 equiv of 2,2′-dithiodipyridine in DMSO; (vii) 2 equiv of R.I.CK-Tat9 in DMSO; (viii) 2 equiv of R.I.CK(stearate)-Tat9 in DMSO.

Chromatography. All reactions were monitored by TLC analysis on precoated silica gel F_{254} plates (Merck) with detection by UV absorption and by charring with 50% methanol−sulfuric acid solution, $KMnO_4$, or ninhydrin. Column chromatographic separations were carried out as flash chromatography using silica gel 60 (Merck, 70−230 mesh). Gel permeation chromatography was done on a Sephadex LH-20 column using dimethylformamide as solvent. The UV absorbance of each fraction obtained from gel permeation chromatography was detected at 239 nm, the absorption maximum for SQV (*26*). Peptide purification was done by HPLC on Vydac protein and peptide preparative column RP-C_{18} (10 μm)-packed column (2.2 × 25 cm) with detection at 220 nm, the maximum absorbance for peptides. The fractions obtained after HPLC purification were dried using a lyophilizer. Amino acid analysis was performed by cation exchange chromatography. Amino acid elution was accomplished by using a two buffer system initially eluting with 0.2 N sodium citrate, pH 3.28, followed by 1.0 N sodium citrate, pH 7.4. The amino acids were detected by on-line postcolumn reaction with ninhydrin. Derivatized amino acids were quantitated by their absorption at 570 nm wavelength. This procedure was performed on an automated Beckman system Gold HPLC amino acid analyzer.

SQV−Cys Ester. Fmoc-Cys(S-Trt)-COOH (0.220 g, 0.375 mmol) was dissolved in 100 mL of anhydrous CH_2Cl_2 at room temperature, and to this solution was added DMAP (0.32 g, 0.265 mmol), DIPC (58.7 μL, 0.375 mmol), and SQV (0.074 g, 0.11 mmol) at 0 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. The product was washed with 0.1 N HCl, dried over $MgSO_4$, and evaporated under reduced pressure to yield the solid product. The crude residue was chromatographed [silica gel chromatography (eluent: AcOEt)] yielding, 63 mg (85% recovery) of SQV−Cys(Trt)-Fmoc ester as a white powder. TLC (AcOEt/MeOH: 90/10, v/v, UV detection): $R_f = 0.75$. ESI-MS (*m/z*): 1238.5 $(M + H)^+$; 1260.5 $(M + Na)^+$. The Fmoc-protecting group was removed by dissolving the SQV−Cys(Trt)Fmoc ester (50 mg) in a mixture of CH_2Cl_2 and piperidine (80:20) and stirring at room temperature for 2 h. Solvent was evaporated under reduced pressure and the product subjected to silica gel chromatography (eluent: AcOEt) to yield 45 mg (90% recovery) of SQV−Cys(Trt) ester as a white solid. TLC (AcOEt/MeOH: 90/10, v/v, UV detection): $R_f = 0.80$. ESI-MS (*m/z*): 1016.5 $(M + H)^+$; 1038.5 $(M + Na)^+$. The protecting group (Trt) was removed by incubating SQV−Cys(Trt) ester (49 mg) for 3 h in a mixture of CH_2Cl_2 and TFA (trifluoroacetic acid) (50:50). The product was recrystallized from cold ether (Et_2O) and dried under vacuum overnight to give 40 mg (82% recovery) of SQV−Cys ester as a white powder. TLC (AcOEt/MeOH: 90/10, v/v, UV detection): $R_f = 0.85$. ESI-MS (*m/z*): 774.5 $(M + H)^+$; 796.5 $(M + Na)^+$. ^{1}H NMR ($CDCl_3$): δ 9.19 (d, *J* 7.2 Hz, H11); 8.24 (d, *J* 8.8 Hz, H7); 8.14 (d, *J* 8.5 Hz, H6); 8.12 (d, *J* 8.0 Hz, H1); 7.82 (d, *J* 8.1 Hz, H4); 7.74 (td, *J* 1.5 Hz, 8.1 Hz, H2); 7.59 (td, *J* 1.5 Hz, 8.1 Hz, H3); 7.51 (d, *J* 8.8 Hz, H17); 6.89−7.13 (m, H21−25); 6.50 (s, H15); 5.76 (bs, H39); 5.33 (m, H26); 4.81 (m, H12); 4.37 (m, H18); 4.12 (m, H43); 2.61−2.98 (m, H13/19/27/29/30/35/36/37); 2.44 (d, *J* 8.6 Hz, H44); 2.30 (t, *J* 7.6 Hz, H45); 1.92 (t, *J* 7.5 Hz, H46); 1.34−1.81 (m, H31−34); 1.22 (s, H41). ^{13}C NMR ($CDCl_3$): δ 173.7, 173.4 (C14/16); 170.4 (C38); 164.8 (C10); 155.6 (C42); 149.1 (C8); 146.8 (C9); 137.5 (C5); 137.1 (C6); 129.8−130.1 (C1/4); 129.4 (C20); 129.2 (C22/24); 128.5 (C21/25); 128.2 (C2); 127.7 (C3); 126.5 (C23); 118.7 (C7); 73.4 (C26); 70.8 (C37); 59.9 (C29); 57.1 (C27); 51.8 (C12); 51.3 (C43); 51.0 (C40); 49.8 (C18); 37.4 (C13); 36.1 (C45); 35.8 (C30); 35.5 (C19); 33.2 (C35); 30.8 (C36); 28.8 (C41); 30.7, 26.2, 25.8, 20.7 (C31−34).

SQV−Cys-PEG3400. SQV−Cys ester (12.5 mg, 0.016 mmol) and Fmoc-PEG-NHS (3400 molecular mass of PEG) [105.0 mg, 0.031 mmol] were added to CH_2Cl_2 (1.25 mL), and DIEA (12.5 μL) was added to adjust the pH to basic. The reaction was stirred for 3 h at room temperature. The product was recrystallized from cold ether and dried under vacuum overnight. The product obtained as a white powder and after Fmoc removal was subjected to gel permeation chromatography using a Sephadex LH-20 column in DMF, and absorbance was monitored at 239 nm. Two separate peaks were obtained as shown in Figure 1. The first peak corresponded to the purified SQV−Cys-PEG3400 and the second peak to the unreacted SQV−Cys ester. The fractions of first peak were combined and the solvent removed under reduced pressure to obtain SQV−Cys-PEG3400 with 75−80% recovery. Mass spectrometry of the conjugate showed a polydisperse peak at the expected molecular weight [*m/z*(%) 4044.9 Da] using MALDI-TOF (Figure 2). ^{1}H NMR ($CDCl_3$): δ 9.18 (d, *J* 7.6 Hz, H11); 8.27 (d, *J* 8.3 Hz, H7); 8.16 (d, *J* 8.2 Hz, H6); 8.11 (d, *J* 8.0 Hz, H1); 7.86 (d, *J* 8.2 Hz, H4); 7.73 (td, *J* 1.6 Hz, 8.3 Hz, H2); 7.64 (td, *J* 1.6 Hz, 8.3 Hz, H3); 7.51 (d, *J* 8.6 Hz, H17); 7.34 (d, *J* 8.1 Hz, H44); 6.85−7.15 (m, H21−25); 6.52 (s, H15); 5.70 (bs, H39); 5.30 (m, H26); 4.82 (m, H12); 4.32 (m, H18); 4.20 (m, CH_2CH_2); 4.11 (m, H43); 3.57 [bs, $CH_2(OCH_2CH_2)_n$]; 2.63−3.05 (m, H13/19/27/29/30/35/36/37);

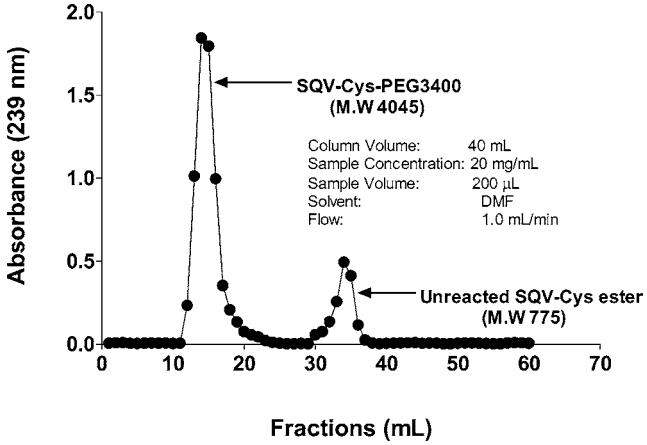

Figure 1. Gel permeation chromatogram showing separation of SQV−Cys-PEG3400 from unreacted SQV−Cys ester using Sephadex LH-20 column in DMF. The absorbance of each fraction was detected at a wavelength of 239 nm, the absorption maximum for SQV.

2.41 [s, NH_2]; 2.33 (t, J 7.4 Hz, H45); 1.92 (t, J 7.6 Hz, H46); 1.36−1.81 (m, H31−34); 1.22 (s, H41). ^{13}C NMR ($CDCl_3$): δ 173.5, 173.1 (C14/16); 172.5 (CH_2CONH); 170.6 (C38); 165.1 (C10); 155.6 (C42); 149.3 (C8); 146.5 (C9); 137.8 (C5); 137.2 (C6); 129.8−130.1 (C1/4); 129.6 (C20); 129.2 (C22/24); 128.6 (C21/25); 128.1 (C2); 127.8 (C3); 126.5 (C23); 118.4 (C7); 73.1 (C26); 72.5 ($OCH_2CH_2)_n$; 70.5 (C37); 59.2 (C29); 57.9 (C27); 55.5 (CH_2CH_2CO); 52.5 (CH_2CH_2CO); 51.9 (C12); 51.3 (C43); 51.3 (C40); 49.5 (C18); 37.9 (C13); 36.1 (C45); 35.7 (C30); 35.3 (C19); 33.0 (C35); 30.5 (C36); 28.5 (C41); 30.3, 26.2, 25.0, 20.8 (C31−34).

SQV−Cys-PEG3400-Biotin. The above process, when applied to NHS-PEG-biotin (3400 molecular mass of PEG) and SQV−Cys ester, followed by gel permeation chromatography in DMF, yielded SQV−Cys-PEG3400-biotin as a white powder with 70% recovery. Mass spectrometry of this conjugate using MALDI-TOF showed a polydisperse peak at 4059.6 Da (m/z) identical to the expected molecular weight. ^{1}H NMR ($CDCl_3$): δ 9.13 (d, J 7.3 Hz, H11); 8.26 (d, J 8.3 Hz, H7); 8.15 (d, J 8.3 Hz, H6); 8.11 (d, J 8.0 Hz, H1); 7.85 (d, J 8.1 Hz, H4); 7.76 (td, J 1.6 Hz, 8.3 Hz, H2); 7.66 (td, J 1.6 Hz, 8.3 Hz, H3); 7.48 (d, J 8.4 Hz, H17); 7.34 (d, J 8.1 Hz, H44); 7.24 (s, NH-CO−NH); 7.20 [s, N$H(CH_2CH_2O)_n$]; 6.84−7.13 (m, H21−25); 6.52 (s, H15); 5.70 (bs, H39); 5.34 (m, H26); 4.84 (m, H12); 4.35 (m, H18); 4.13 (m, biotin aliphatic chain); 4.11 (m, H43); 3.56 [bs, $(OCH_2CH_2)_n$]; 2.61−3.08 (m, H13/19/27/29/30/35/36/37); 2.33 (t, J 7.4 Hz, H45); 1.92 (t, J 7.6 Hz, H46); 1.35−1.84 (m, H31−34); 1.26 (s, H41). ^{13}C NMR ($CDCl_3$): δ 175.8 (NHCONH); 173.6, 173.1 (C14/16); 172.5, 172.9 [CONH $(CH_2CH_2O)_nC$ONH]; 170.6 (C38); 164.9 (C10); 155.7 (C42); 149.6 (C8); 146.3 (C9); 137.9 (C5); 137.2 (C6); 129.8−130.1 (C1/4); 129.5 (C20); 129.2 (C22/24); 128.6 (C21/25); 128.3 (C2); 127.9 (C3); 126.8 (C23); 118.5 (C7); 73.1 (C26); 72.5 ($OCH_2CH_2)_n$; 70.4 (C37); 59.7 (C29); 57.9 (C27); 55.5 (biotin); 52.5 (CH_2CH_2CO); 51.9 (C12); 51.5 (C43); 51.0 (C40); 49.5 (C18); 37.5 (C13); 36.1 (C45); 35.8 (C30); 35.5 (C19); 33.1 (C35); 30.9 (C36); 28.8 (C41); 30.7, 26.3, 25.8, 20.6 (C31−34).

SQV−Cys(R.I.CK-Tat9)-PEG3400. Aldrithiol (2,2′-dithiodipyridine, 1.6 mg, 0.007 mmol) was dissolved in 2.0 mL of DMSO, and to this solution was added 12 mg (0.004 mmol) of SQV−Cys-PEG3400 having a free thiol group on cysteine. The reaction was stirred at room temperature. The completion of the reaction was monitored by measuring the absorbance of 2-thiopyridine (TP) release at 343 nm (*27*) until the absorbance value remained constant. Solvent was evaporated under reduced pressure to yield 9.5 mg (79% recovery) of SQV−Cys(TP)-PEG3400 as a white powder. The retro-inverso-cysteine-lysine-Tat nonapeptide (R.I.CK-Tat9), N-acetyl-CKRRRQRRKKR-NH_2 was synthesized manually on a MBHA Rink Amide resin by Fmoc chemistry in the presence of coupling activating reagents, BOP and HOBt. The two additional residues at the N-terminus, Cys and Lys, were reserved for further conjugations. For acetylation, the assembled peptide on the solid support was allowed to react with acetic anhydride in the presence of BOP, HOBt, and 1% DIEA for 6 h. The peptide was cleaved from the support and deprotected by treatment

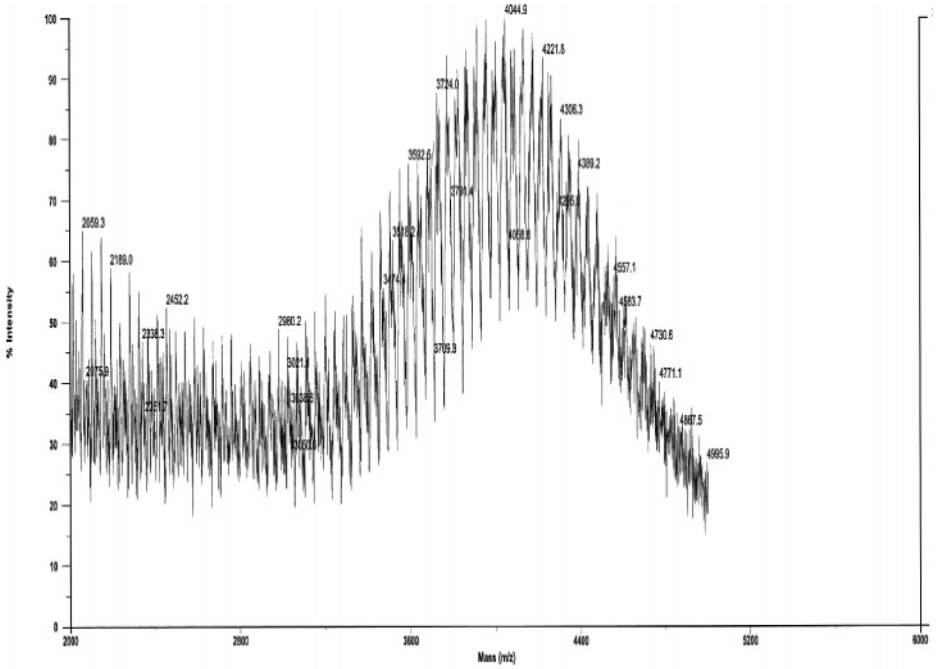

Figure 2. MALDI-TOF (m/z) spectrum of SQV−Cys-PEG3400 showing a polydisperse peak at 4044.9 Da.

with a mixture of 94% TFA, 2.5% water, 2.5% EDT, and 1% TIS for 3 h at room temperature. The crude product was obtained after ether precipitation. The R.I.CK-Tat9 peptide was purified (>95%) by preparative C_{18} reverse-phase high-performance liquid chromatography (RP-HPLC). The fractions obtained after HPLC purification were lyophilized to obtain the dry purified peptide. HPLC: 0.05% TFA (v/v) in water (mobile phase A) and 0.05% TFA (v/v) in a mixture of 10% water, 20% 2-propanol, and 70% acetonitrile (mobile phase B), linear gradient (t = 0 min, 20% B, 80% A; t = 5 min, 20% B, 80% A; t = 35 min, 50% B, 50% A; t = 36 min, 100% B, 0% A, t = 40 min stop), flow rate = 3 mL/min, UV detection = 220 nm, t_R (retention time) = 25 min. ESI-MS: 1613 $(M + H)^+$, 807.4 $[(M + 2H)/2]^+$, 538.5 $[(M + 3H)/3]^+$. R.I.CK-Tat9 peptide concentration was determined by amino acid analysis. R.I.CK-Tat9 (10.0 mg, 0.006 mmol) was dissolved in 2.0 mL of DMSO, and to this solution was added 10.2 mg (0.003 mmol) of SQV−Cys(TP)-PEG3400. The reaction was stirred to completion at room temperature and monitored at 343 nm to measure TP release. Solvent was evaporated under reduced pressure to yield a white microcrystalline powder. This product was subjected to gel permeation chromatography using a Sephadex LH-20 column in DMF, yielding a single sharp peak (absorbance monitored at 239 nm). The fractions of this peak were combined, and the solvent was removed under reduced pressure to obtain SQV−Cys(R.I.CK-Tat9)-PEG3400 with 65% recovery. Mass spectrometry of the conjugate demonstrated a polydisperse peak at the expected molecular weight [m/z(%) 5447.6 Da] using MALDI-TOF.

SQV−Cys(R. I.CK(Stearate)-Tat9)-PEG3400. The synthesis of R.I.CK(stearate)-Tat9 [*N*-acetyl-CK(ϵ-stearate)RRRQRRKKR] entailed the same procedure as R.I.CK-Tat9 except for attachment of fatty acid, stearic acid was coupled to the side chain of the N-terminal lysine residue. To allow this reaction, this N-terminal lysine residue had the ϵ-Dde protecting group, which was selectively removed from the resin-bound peptide using 2% hydrazine in DMF. Thereafter, 3 equiv of stearic acid were dissolved in DMF with coupling agents HOBt and BOP and reacted with peptide on the solid support for 3 h at room temperature. After cleavage from the MBHA Rink amide resin, the peptide was precipitated in precooled ether. The crude peptide was then subjected to HPLC purification, lyophilized, and determined by amino acid analysis and mass spectrometry. HPLC: 0.05% TFA (v/v) in water (mobile phase A) and 0.05% TFA (v/v) in a mixture of 10% water, 20% 2-propanol, and 70% acetonitrile (mobile phase B), linear gradient (t = 0 min, 50% B, 50% A; t = 5 min, 50% B, 50% A; t = 35 min, 100% B, 0% A; t = 40 min, 100% B, 0% A, t = 41 min stop), flow rate = 3 mL/min, UV detection = 220 nm, t_R (retention time) = 32 min. ESI-MS: 1880 $(M + H)^+$, 940.1 $[(M + 2H)/2]^+$, 627.2 $[(M + 3H)/3]^+$. The above process when applied to R.I.CK(stearate)-Tat9 and SQV−Cys(TP)-PEG3400, followed by gel permeation chromatography using Sephadex LH-20 in DMF, yielded SQV−Cys(R.I.CK(stearate)-Tat9)-PEG3400 as a white microcrystalline powder with 68% recovery. Mass spectrometry of this conjugate using MALDI-TOF showed a polydisperse peak at 5716.6 Da (m/z) identical to the expected molecular weight.

Protease Inhibition Assay. An assay developed by Matayoshi and co-workers that is based on intramolecular fluorescence resonance energy transfer (FRET) was adapted and modified (*28*). The assay uses quenched fluorogenic substrates having a peptide sequence derived from a natural processing site for HIV-1 protease (PR). The quenched fluorogenic substrate 1 (obtained from Sigma) was Arg-Glu(EDANS)-Ser-Gln-Asn-Tyr-Pro-Ile-Val-Gly-Lys(DABCYL)-Arg, where EDANS is the fluor and DABCYL the quencher. Recombinant HIV-1 PR was obtained from the NIH AIDS Research and Reference Reagent Program, Division of AIDS, National Institute of Allergy and Infectious Diseases. Incubation of recombinant HIV-1 PR with the fluorogenic substrate at 37 °C results in specific cleavage of a tyrosine-proline bond, causing an increase in fluorescence due to elimination of intramolecular quenching. In the presence of an inhibitor such as SQV, the fluorescence signal is expected to decrease with increasing concentration of inhibitor. Cleavage by the HIV-1 PR occurs at the pseudo-phenylalanine-proline bond in SQV and at the tyrosine-proline bond in substrate 1. Thus, inhibition of HIV-1 PR by SQV in the presence of substrate 1 is observed as a decrease in fluorescence intensity. Therefore, the release of SQV is measured resulting from the hydrolysis of the prodrug SQV−Cys ester. Steady-state fluorescence data were obtained on a Cytofluor Spectrofluorometer (excitation at 340 nm, emission at 490 nm). All data were corrected with blanks. Solutions of HIV-1 PR and substrate 1 were prepared in the HIV-1 protease assay buffer at pH 4.7 using published procedures (*28*). In all of the experiments, the protease was added last to keep the incubation times consistent.

Determination of Hydrolysis Kinetics of SQV−Cys Ester. The fluorogenic protease inhibition assay was used to measure the hydrolysis kinetics of the prodrug, SQV−Cys ester. The chemical stability of the ester was determined in 0.1 N HCl at 37 °C, and the biological stability was determined in PBS at pH 7.4 and in plasma both measured at 37 °C. Initially, different SQV concentrations (0.05−0.5 μM) were taken separately in 0.1 N HCl, in PBS at pH 7.4, and in plasma. Plasma samples (90 μL) were spiked with 10 μL of various concentrations of SQV dissolved in DMSO. For the determination of SQV, plasma samples were deproteinated with 200 μL of ice cold MeOH. The samples were vortexed followed by centrifugation to precipitate the plasma proteins. The clear supernatant was then dried down and reconstituted in protease assay buffer. SQV samples taken in 0.1 N HCl were neutralized with sodium bicarbonate before fluorescence measurements. A fixed amount of substrate 1 (110 μM) and HIV-1 PR (35 nM) were added, and the reaction was carried out for 60 min in the HIV protease assay buffer at pH 4.7 (Figure 3). From the measurement of fluorescence versus SQV concentration, calibration curves were obtained in 0.1 N HCl, in PBS at pH 7.4, and in spiked plasma (Figure 4). Thereafter, the prodrug, SQV−Cys ester (0.15 μM) was incubated separately in 0.1 N HCl, in PBS at pH 7.4, and in spiked plasma at 37 °C, respectively. Aliquots were taken at different time points and measuring the protease inhibitory activity using the fluorogenic assay assessed the release of SQV, resulting from ester bond hydrolysis. Each measurement was done in triplicate. All fluorescence signals were converted to moles of SQV using the calibration curves derived in each medium (Figure 4) to obtain a plot of percentage of released SQV versus incubation time (Figure 5). The rate constant (k) was obtained from the linear plot of $\ln[(SQV)_t - (SQV)_\infty]$ versus incubation time, t (h), where $[SQV]_t$ = concentration of SQV at different incubation times, t, and $[SQV]_\infty$ = concentration of SQV at the last time point, when hydrolysis is complete (Figure 6). The half-life ($t_{1/2}$) for ester hydrolysis was estimated from the relation $t_{1/2} = 0.693/k$ where k is the slope of the linear plot.

Antiviral Assay. The in vitro antiviral activity of poly(ethylene glycol)(PEG)-based SQV prodrug conjugates was determined using a MTT-based HIV-1 susceptibility assay that was performed using MT-2 cells infected with the HIV-1 strain LAV/LAI (*29*). In this assay, the maximal potential antiviral efficacy was assessed by using unconjugated SQV. SQV remained in the test media for the entire duration of the in vitro test unlike the in vivo situation where SQV is rapidly cleared from cells and the body. Therefore, the in vitro antiviral activity of all conjugates was compared to the maximum achievable effect. The cytotoxicity of the prodrug conjugates was evaluated in parallel to their antiviral activity and was based on the viability of noninfected cells as monitored by the MTT method. The MT-2 cell line is an HTLV-1-transformed human T-cell leukemia cell line isolated from cord blood lymphocytes and cocultured with cells of patients with adult T-cell leukemia. The MT-2 cells were grown in RPMI 1640 DM (Dutch modification) medium, supplemented with 20% FBS, 1% w/v pen−strep, and 1% w/v L-glutamine. The cells were maintained at 37 °C in a humidified atmosphere of 5% CO_2 in air. Every 2−3 days, the growth medium was changed, and

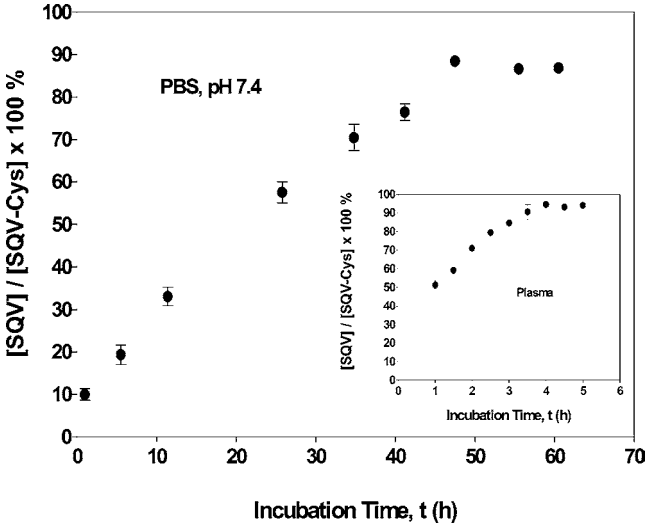

Figure 5. Release of SQV by hydrolysis of the prodrug, SQV−Cys ester (0.15 μM) in PBS, pH 7.4, at 37 °C, using protease assay. Inhibition of protease by released SQV was determined at 37 °C. The ester was hydrolyzed to release SQV as monitored by steady-state fluorescence. The fluorescence measured due to the released SQV was converted to moles of SQV using the calibration curves from Figure 4. All measurements were done in triplicate. Inset. Release of SQV by hydrolysis of SQV−Cys ester (0.15 μM) in plasma at 37 °C.

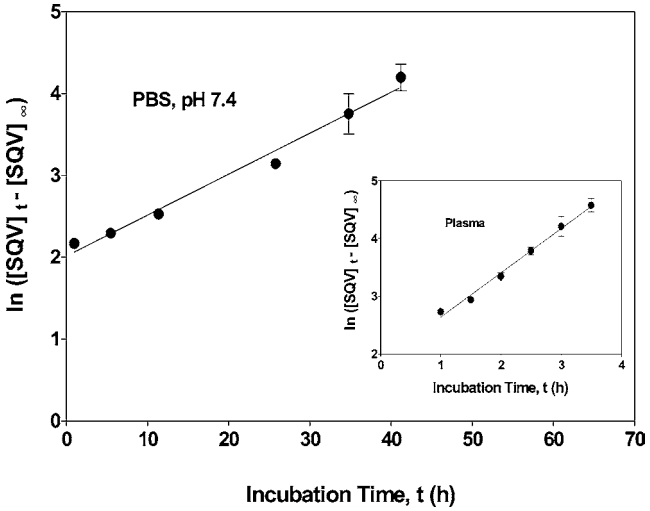

Figure 6. Plot of $\ln[(SQV)_t-(SQV)_\infty]$ (derived from Figure 5) versus incubation time (t) of SQV−Cys ester in PBS, pH 7.4 at 37 °C. The rate constant (k) is the slope of this linear plot. The half-life ($t_{1/2}$) for the ester hydrolysis was calculated using the relation $t_{1/2} = 0.693/k$. Inset**.** Plot of $\ln[(SQV)_t - (SQV)_\infty]$ versus incubation time (t) of SQV−Cys ester in plasma at 37 °C.

the cells were diluted to 2×10^5 cells/mL and recultured. The cultured MT-2 cells were infected using a multiplicity of infection (MOI) of 0.01 (1 viral particle per 100 cells) causing the death of 90% of the cells 5 days later. The tested prodrug conjugates were diluted with RPMI 1640 medium and were added to the cultured MT-2 cells after viral infection. Dosage of each prodrug conjugate was given in terms of SQV concentration, and this was determined by absorbance of prodrug conjugate at 239 nm (λ_{max} of SQV) with a calibration standard of SQV. Each prodrug conjugate was tested in triplicate for its antiviral activity. Cell viability was measured by the colorimetric MTT test, which is based on the capacity of living cells to reduce the yellow colored MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] to blue formazan by mitochondrial dehydrogenases. The

quantity of formazan produced (absorbance at 540 nm) is directly proportional to the number of living cells. The percentage protection achieved by different concentrations of the tested prodrug conjugate in HIV-1-infected cells after 5 days of incubation at 37 °C was calculated using the formula:

$$[(A_{TC})_{HIV} - (A_{UC})_{HIV}]/[(A_{UC})_{NHIV} - (A_{UC})_{HIV}] \times 100$$

where $(A_{TC})_{HIV}$ is the absorbance measured for treated HIV-1-infected cells, $(A_{UC})_{HIV}$ is the absorbance measured for untreated HIV-1-infected cells, and $(A_{UC})_{NHIV}$ is the absorbance for untreated noninfected cells. The dose achieving 50% protection according to the above formula is defined as the 50% effective dose (ED_{50}). The prodrug conjugate ED_{50} values were determined from the curves of percentage protection versus prodrug conjugate concentration.

For cytotoxicity, the effect of the prodrug conjugates on cell viability was measured in noninfected cells using the colorimetric MTT test after 5 days of incubation at 37 °C with various concentrations of the tested compounds. The percentage cytotoxicity of the tested prodrug conjugates was calculated using the formula:

$$[(A_{TC})_{NHIV}]/[(A_{UC})_{NHIV}] \times 100$$

where $(A_{TC})_{NHIV}$ is the absorbance measured for treated noninfected cells. The dose achieving 50% toxicity is defined as the 50% lethal dose (LD_{50}). The prodrug conjugate LD_{50} values were determined from the curves of the percentage of living cells against prodrug conjugate concentration.

RESULTS

Synthesis of Prodrug Conjugates. A series of SQV prodrug conjugates, SQV−Cys-PEG3400, SQV−Cys-PEG3400-biotin, SQV−Cys(R.I.CK-Tat9)-PEG3400, and SQV−Cys(R.I.CK(stearate)-Tat9)-PEG3400 was prepared and characterized. In all of these prodrug conjugates, the SQV hydroxyl group was covalently linked to a Cys carboxylic acid group by a releasable ester bond. The two other functional groups on Cys were then used for further derivatization. The thiol group of Cys was used to attach R.I.CK-Tat9 and R.I.CK(stearate)-Tat9 via a releasable disulfide bond. The amino group of Cys was used to attach PEG3400 and PEG3400-biotin via a more stable amide bond.

In the synthesis of the SQV prodrug conjugates (Scheme 1), the active hydroxyl function of SQV was esterified with Fmoc-Cys(S-Trt)-COOH using DIPC/DMAP as coupling reagent. SQV−Cys ester was obtained with 82% yield after Fmoc removal with piperidine, followed by TFA-deprotection of the Trt group. The esterification of the hydroxyl of SQV after silica gel purification was unambiguously confirmed by ESI-MS and ^1H and ^{13}C NMR. Different types of prodrug conjugates were synthesized keeping the SQV−Cys ester as the common prodrug element. PEGylation (using Fmoc-PEG3400-NHS and biotin-PEG3400- NHS) of the SQV−Cys ester was carried out using DIEA/DCM with the formation of relatively more stable amide linkages. The PEGylated products (SQV−Cys-PEG3400 and SQV−Cys-PEG3400-biotin) were purified using gel permeation chromatography (Sephadex LH-20 column in DMF, UV 239 nm) (Figure 2) resulting in 70−80% yield. The formation of these products was confirmed by MALDI-TOF (Figure 3) and ^1H and ^{13}C NMR. In the synthesis of SQV−Cys-(R.I.CK-Tat9)-PEG3400 and SQV−Cys(R.I.CK(stearate)-Tat9)-PEG3400, the thiol group of the Cys in SQV−Cys-PEG3400 was first activated with 2,2′-dithiodipyridine in DMSO to give SQV−Cys(TP)-PEG3400. With the addition of R.I.CK-Tat9 or R.I.CK(stearate)-Tat9 to the activated PEGylated form of SQV, TP release (343 nm) was monitored to confirm reaction completion. The formation of the respective SQV−Cys(R.I.CK-Tat9)-PEG3400 and SQV−Cys(R.I.CK(stearate)-Tat9)-PEG3400 having reversible disulfide bonds in 65−68% yield range was confirmed by MALDI-TOF. Finally, significant increases in water solubility of these PEG-based SQV prodrug conjugates were observed relative to unconjugated SQV.

Chemical and Biological Stability of the Prodrug, SQV−Cys, and Release of SQV. The HIV-1 PR inhibition assay was used for measuring the release of active (i.e., free) SQV resulting from the hydrolysis of the prodrug, SQV−Cys ester. This study was important since the level of HIV-1 inhibition by the prodrug conjugates depends on the apparent hydrolysis kinetics of SQV release. Since the SQV−Cys ester was the common intermediate for all of the synthesized prodrug conjugates, the in vitro stability of the prodrug was the initial focus of the investigation. The chemical stability of SQV−Cys in 0.1 N HCl and the biological stability in PBS at pH 7.4 and in spiked plasma were evaluated at 37 °C.

In the absence of SQV, the incubation of fluorogenic substrate 1 with HIV-1 PR produced a 40-fold increase in fluorescence signal in a reaction that was approximately linear for 30 min (Figure 3). However, SQV inhibited this response in a dose-dependent manner at concentrations of 0.05−0.5 μM as shown in Figure 3. The calibration curves of fluorescence versus concentration of SQV in 0.1 N HCl, PBS at pH 7.4, and plasma were linear with a correlation coefficient (R^2) of 0.9834 for 0.1 N HCl, 0.9779 for PBS at pH 7.4, and 0.9787 for plasma (Figure 4). SQV−Cys ester (0.15 μM) itself did not inhibit fluorescence, suggesting that the SQV prodrug was inactive. The inhibition of fluorescence signal increased with time of hydrolysis of SQV−Cys ester. Therefore, prodrug reconversion is necessary in order for SQV to exert protease inhibition. At the latest time point (31 h in the case of 0.1 N HCl, 47.5 h for PBS at pH 7.4, and 4 h in plasma) there was about a 90% inhibition of enzyme activity by free SQV (Figure 5). Since this level of inhibition is about the same as that produced by 0.15 μM parent drug (Figure 3), the reconversion to active drug was deemed essentially complete. Plots of $\ln[(SQV)_t - SQV)_\infty]$ versus incubation time, t(h), were linear within the concentration range studied with correlation coefficients (R^2) of 0.9939 (for 0.1 N HCl), 0.9834 (for PBS at pH 7.4), and 0.9916 (for plasma), indicating that the hydrolysis is a first-order process with respect to the prodrug (Figure 6). The half-lives of hydrolysis ($t_{1/2}$) obtained from each of the media were calculated from these linear plots. The prodrug reconversion half-lives in 0.1 N HCl, in phosphate-buffered saline (PBS) at pH 7.4, and in spiked plasma at 37 °C were 9, 14, and 0.9 h, respectively. These studies demonstrate that SQV prodrug conjugates with their in-built SQV−Cys ester are inactive until the bond between SQV and cysteine is cleaved.

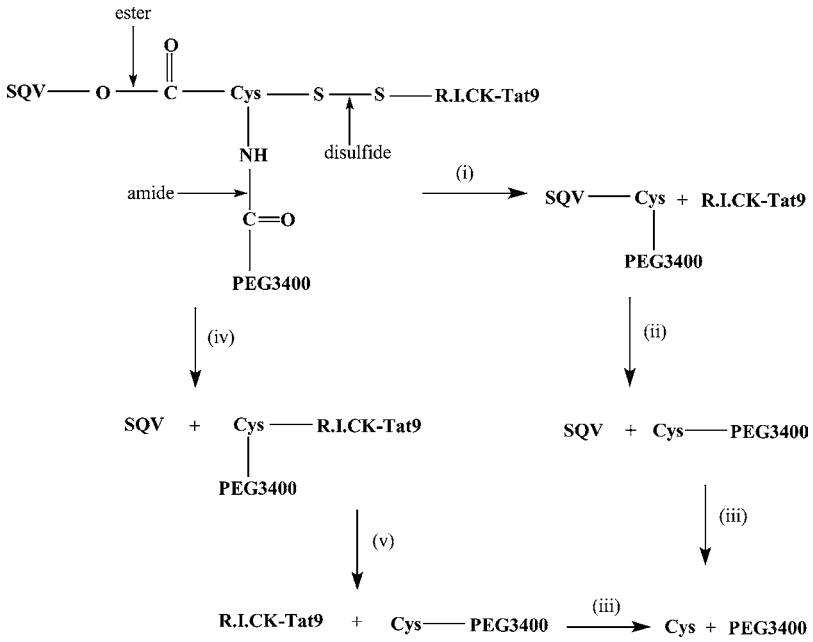
Biological Activity of Prodrug Conjugates. The HIV-1 inhibition levels and cytotoxicities of PEG-based SQV prodrug conjugates were evaluated against HIV-1 in vitro in MT-2 cells according to an established antiviral assay (*29*). Since the active hydroxyl group of SQV is responsible for its protease inhibitory potency, it is essential that this functional group is free and accessible

Table 1. Anti-HIV-1 Activity (ED_{50}) and Cytotoxicity (LD_{50}) Data for SQV and Its Prodrugs[a] in MT-2 Cells Infected with HIV-1 Strain LAV/LAI (MOI of 0.01)[b]

compound	ED_{50} (μM)	R[c]	LD_{50} (μM)	therapeutic index LD_{50}/ED_{50}
SQV ($MeSO_3H$)	0.015	–	25	1667
SQV−Cys-PEG3400	0.90	60	45	50
SQV−Cys-PEG3400-biotin	0.125	8.3	15	120
SQV−Cys(R.I.CK−Tat9)-PEG3400	0.015	1	12.5	833
SQV−Cys(R.I.CK(stearate)-Tat9)-PEG3400	0.062	4.1	6.3	102

[a] These data reflect the amount of parent drug that was released during the 5 day incubation at 37 °C. [b] Several assays of each compound were done with variations in the virus stock, dosage, and days of incubation. [c] R is the ED_{50} ratio of the prodrug to that of its parent drug, as previously described (*10*).

for antiviral activity. Thus, the level of HIV-1 inhibition of the prodrug conjugates would depend on their hydrolysis kinetics, which in turn reflects the release rate of the active parent drug, SQV. The antiviral activity of the SQV prodrug conjugates was determined by incubating HIV-1-infected MT-2 cells in the presence of different concentrations of prodrug conjugates for 5 days at 37 °C (Table 1). On the basis of the hydrolysis half-lives of the prodrug, SQV−Cys ester, and the antiviral activity results of the prodrug conjugates, it appears that most of the SQV was released during the 5-day incubation period. The appended putative cell uptake promoting groups (PEG3400, PEG3400-biotin, R.I.CK-Tat9, and R.I.CK(stearate)-Tat9) might have influenced the hydrolysis half-lives and/or cell uptake of the prodrug conjugates as measured by differences in antiviral activity (Table 1). The activity of SQV in prodrug conjugates compared to the maximal achievable antiviral efficacy (control, ED_{50} = 15 nM) was reduced (ED_{50} = 900 nM) for PEG alone, but restored with the addition of biotin (ED_{50} = 125 nM), R.I.CK-Tat9 (ED_{50} = 15 nM), or R.I.CK-(stearate)-Tat9 (ED_{50} = 62 nM). Similar results were obtained during repeated assays of each compound with variations in the virus stock, dosage, and days of incubation. The cytotoxicities of the SQV prodrug conjugates were measured by incubating noninfected MT-2 cells in the presence of different concentrations of prodrug conjugates for 5 days at 37 °C. The cytotoxicity (LD_{50}) of all the tested conjugates was in the low micromolar range (6.3−45 μM). Results also show that all the SQV-based prodrug conjugates were less toxic than free SQV. The ratio of LD_{50}/ED_{50} was used as an indicator of the in vitro therapeutic index and is shown in Table 1.



DISCUSSION

HIV-1 protease inhibitors are "peptoids" or "peptidomimetics" that bind and block the active site of the viral proteinase enzyme, thereby inhibiting maturation of the virus. HAART (highly active anti-retroviral therapy) regimens that utilize inhibitors of HIV-1-encoded protease combined with reverse transcriptase inhibitors result in a profound and sustained suppression of viral replication, reduce morbidity, and prolong life in patients with HIV-1 infection (*30*−*32*). Current guidelines recommend that initial treatment of all HIV-1-infected patients include the administration of an HIV-1-protease inhibitor (*33*). However, despite attaining nondetectable viral blood levels, the development of resistance and the inability to ultimately cure HIV-1 infection has raised considerable debate about evaluating treatment efficacy (*34*) and which drugs should be used in optimal combination therapy. The control of HIV-1 infection and the ultimate cure of AIDS will require the development of not only new and more potent therapeutic agents but also of novel pharmacodelivery strategies. The current report represents an initial effort in developing smarter drug delivery strategies to overcome the many biopharmaceutical challenges associated with anti-HIV-1 therapeutic regimens.

In the current study, macromolecular prodrug conjugates have been designed and evaluated. Classical prodrugs are typically designed to overcome problems with solubility, stability, or limited absorption. Some prodrugs of anti-HIV-1 agents have been reported in the literature (*10, 11, 13, 35*). However, these previous efforts have focused on improving absorption by improving the physicochemical properties of these drugs. The current work focuses on a prodrug conjugate approach that attempts to control the kinetics of release and cellular concentrations of SQV at the target sites and protects the "cargo" (i.e., SQV) until it reaches the site of action where it can be released. As a first step toward improving the cellular bioavailability and efficacy of SQV, various prototype prodrug conjuates were designed, based on their known pharmacological properties. PEG-based prodrug conjugates composed of the putative cell uptake enhancing agents, biotin, R.I.CK-Tat9, and R.I.CK(stearate)-Tat9 were synthesized (Scheme 1), characterized. and studied in order to test the hypothesis that improved delivery would result in an enhancement in the pharmacological properties of SQV.

The various components of the conjugates were carefully selected. The rationale for this selection and the results obtained for each conjugate component will be discussed separately. (1) PEG was chosen as a scaffold based on its ability to promote an extended half-life in blood or extracellular fluid and to increase the solubility of SQV (*14, 15*). PEG conjugates are less toxic than free drug (*16*) and have also been found to prevent in vivo binding to plasma proteins, as well as inactivation and rapid elimination from the blood (*36*). The conjugation of PEG to SQV yielded a less active prodrug conjugate, SQV−Cys-PEG3400 (Table 1). In this conjugate, PEG is stably bound to Cys by an amide bond, while the carboxylic acid group of Cys has a reversible ester bond with SQV. The 60-fold lower activity of the conjugate compared to the parent drug could be due to the slow cleavage of the ester bond and/or cell uptake of the conjugate. (2) Biotin was incorporated into the conjugate to enhance the uptake of the conjugates into cells (*17, 18*) since the hydrophobicity of biotin is known to promote cell membrane adhesion and enhanced cellular penetration (*37, 38*). Indeed, about 8-fold greater antiviral activity was observed when biotin was appended to the distal end of the long PEG chain (Table 1). This phenomenon has been observed in other systems as well. For example, the biotinylated form of Tat protein shows better cell uptake and transactivating activity presumably due to increased hydrophobic interactions with the plasma membrane (*39*). We also observed this with a prodrug conjugate of the anticancer drug, camptothecin (CPT), in which an ester bond with the carboxylic acid group of glycine (Gly) has to be cleaved to generate the

Scheme 2. Possible Metabolic Pathways Shown for SQV−Cys(R.I.CK-Tat9)-PEG3400[a]

[a] If the disulfide bond is cleaved first (i), then the product is still an inactive prodrug, which can be further cleaved at the ester bond (ii) to form the active drug, SQV. The remainder of the conjugate might be degraded (iii). Alternatively, if the ester bond is cleaved first, active drug SQV is released (iv). The remainder of the conjugate might be degraded (v). Released Tat might also contribute to antiviral activity (see Discussion).

parent drug (*17*). In that study, the Gly-PEG conjugate of CPT was about 12-fold more potent than CPT alone. However, an additional biotin group appended to the distal end of PEG, CPT-Gly-PEG3400-biotin, gave a further increase in potency of 5-fold, similar to the effect of biotin in the present study (Table 1). (3) R.I.CK-Tat9 was chosen for two reasons. First, it possesses anti-HIV-1 activity and may be useful in combination therapy. Tat analogues have been shown to exert an inhibitory effect by interacting with HIV-1 RNA (*22, 23*) or by binding to the $CXCR_4$ receptor on $CD4^+$ cells (*24, 25*). Second, polycationic peptides such as Tat9 have been reported to facilitate membrane penetration (*19, 20*). The R.I.CK (retro-inverso-cysteine-lysine)-Tat9 consisted of D-amino acids assembled in the reverse order of the natural L-amino acid Tat9 peptide, *N*-acetyl-L-Arg-L-Lys-L-Lys-L-Arg-L-Arg-L-Gln-L-Arg-L-Arg-L-Arg-NH_2. Thus, R.I.CK-Tat9 represents the sequence of all D-amino acids: *N*-acetyl-D-Cys-D-Lys-D-Arg-D-Arg-D-Arg-D-Gln-D-Arg-D-Arg-D-Lys-D-Lys-D-Arg-NH_2. R.I. peptides have similar shapes and charge distributions to the natural L-amino acid peptides but are more stable to proteases and retain pharmacological activity (*40*). The attachment of the Tat peptide by a reversible disulfide linkage to the Cys residue returns the prodrug conjugate to the full antiviral activity of the parent drug, SQV (Table 1). The prodrug conjugate containing Tat peptide could have an even greater interaction with the plasma membrane due to the eight basic amino acids, including five arginines, which could interact with the phosphate headgroups of the lipid bilayer. Thus, immobilization of the conjugate to the plasma membrane might then increase cell uptake, although other factors such as the effect of Tat peptide on hydrolysis rate may be involved in the antiviral activity. Furthermore, the Tat peptide and similar cationic peptides (*23, 25*) also participate in a relatively strong interaction with the chemokine receptor, CXCR4 on T-cells, which is inhibitory to HIV-1 infection (*24, 25*). As a result, SQV−Cys(R.I.CK-Tat9)-PEG3400 might possess two different antiviral activities that are additive in function (Table 1). Further studies will have to be performed to determine the exact mechanism of enhancement. (4) Tat-like peptides appended to fatty acids such as stearic acid have been reported to possess a greater penetrating ability for DNA delivery into cells (*21*). In the present work, the stearate group was initially appended to the Tat peptide in order to combine the hydrophobic and cationic properties and thereby achieve even greater membrane affinity. Instead, the stearate adduct had less activity (Table 1). This could be due to an inhibitory effect on the binding of Tat peptide to the chemokine receptor. Improvements in the ability of cationic peptides to augment drug uptake continue to be published (*41*). (5) The various conjugate components are linked to the scaffold by bonds that control the site and rate of release of the components and SQV from the conjugate. This is an important consideration for improving the delivery properties of SQV since it was previously demonstrated that SQV conjugates with a stable carbamate bond between the hydroxyl group of SQV and an amino group of an amino acid linker did not possess anti-HIV-1 activity (*13*). In contrast, a less stable ester bond with cysteine was used for the conjugates prepared for the current study resulting in releasable SQV conjugates. One mechanism of control utilized in the current studies was a labile ester bond present in the SQV−Cys ester that can be hydrolyzed by cellular esterases to regenerate the parent antiviral drug. Similar ester prodrugs of SQV have been reported (*10, 11, 13, 42*). The in vivo stability of ester bonds in conjugates with other drugs was previously reported by Greenwald and co-workers (*14, 43−45*). Using the fluorescence-based HIV-1 PR inhibition assay, the in vitro release of SQV was assessed (Figures 5, 6). The labile disulfide linkage used for conjugating R.I.CK-Tat9 compounds to SQV−Cys-PEG3400 can be cleaved by glutathione, a physiologically relevant reducing agent. This linkage might be especially useful for drug delivery into cells, due to the stronger reducing environment within cells than in extracellular fluids (*46*). Thus, a disulfide-linked conjugate is expected to be

relatively stable in extracellular fluids or plasma but should be cleaved once inside cells. Previously, disulfide linkages have been successfully used by our group to link PEG-based polymers to a cysteine-containing peptide (*46*). However, cleavage of the disulfide bond is not sufficient to regenerate free SQV. Instead, an inactive prodrug, SQV−Cys-PEG3400, as well as free R.I.CK-Tat9 (or R.I.CK(stearate)-Tat9) are released (Scheme 2). For this particular situation, two consecutive release steps (i.e., cleavage of the disulfide bond followed later by ester bond cleavage) would be valuable since esterases are ubiquitous, and SQV release would occur readily in the blood stream. Hence, these prodrug conjugates would be no more effective than traditional prodrugs. However, the relative stability of the disulfide bond must be designed to protect the ester bond by stearic hindrance or by electron-donating effect and thereby ensure that SQV release would occur preferentially inside cells. A rapid release of SQV inside cells might result in cellular concentrations that are higher than the secretory K_m for transporters such as P-gp and MRP2, resulting in prolonged and more effective cellular drug concentrations.

The HIV-1 MTT assay was used to determine the maximal achievable antiviral activity of free SQV and to determine if all SQV was released from the conjugates in vitro. While the MTT assay format is good for assessing if the conjugates release active SQV, the assay does not yield other mechanistic information that might further suggest differences in the in vivo performance between the various conjugate forms or in comparison to free SQV. The reasons for the limitations relate to the closed nature of the test system and the 5-day time frame of the study. Released SQV is available for the entire 5 days of the assay. For the case of the control, free SQV is present during the entire study, and this therefore represents the maximal achievable antiviral activity. This limitation is not uncommon and was recently demonstrated for PEGylated α-interferon. PEGylated α-interferon is an example of a clinically useful drug conjugate for which an improvement in therapeutic value was not revealed by an in vitro assay (*47*). In that study, the receptor affinity and the specific activity of the PEGylated interferon were substantially lower (about 7%), but the half-life was increased almost 10-fold in vivo after subcutaneous injection. This would lead to a substantial increase in the "area under the curve" (i.e., blood level amounts), and, instead of injecting the patient 3 times each week, the PEGylated protein may be administered weekly, giving nearly constant drug levels (*48*). Furthermore, comparison of the two forms of interferon in a clinical trial of chronic hepatitis C (*49*) demonstrated greater efficacy with PEGylated interferon α-2a. While these examples further point out limitations in the in vitro assay, the assay is a reliable indicator of SQV activity and release. However in vivo studies are needed in order to evaluate delivery system performance and possible in vivo effectiveness.

SUMMARY AND CONCLUSIONS

The current results suggest that SQV bioconjugates can be synthesized and active SQV can be released. This is critical since conjugated SQV is inactive. The in vitro anti-HIV-1 activity of all conjugates was evaluated against an unconjugated SQV control where the drug was 100% available during the entire anti-HIV-1 test. This rigorous test is unlike an in vivo situation where SQV is quickly cleared from target cells and the body; however, it gave an indication of the expected maximum therapeutic potential of SQV in this in vitro system. Appending various putative cell uptake enhancing moieties to the SQV conjugates produced variable effects on anti-HIV-1 activity, and in vitro activity was fully restored compared to nonconjugated SQV with one conjugate. Since conjugated SQV is inactive, the current results suggest that the appended moieties may be significantly modifying the release of SQV from the conjugate. Also, further work is required to ascertain the specific mechanism of enhancement for the Tat-based conjugate since Tat also possesses anti-HIV-1 activity. In conclusion, SQV conjugates were successfully synthesized and chemically characterized. They also show promise since anti-HIV-1 activity is not lost in vitro. However, the major benefits of conjugation are expected to be observed in vivo, and this is the focus of the next set of studies.

ACKNOWLEDGMENT

This work was supported by NIH Grants AI 33789 and 51214. The following reagent was obtained through the NIH AIDS Research and Reference Reagent Program, Division of AIDS, NIAID, NIH: HIV-1HXB2 KIIA Protease, cat. no. 4375 from Drs. David Davis, Stephen Stahl, Paul Wingfield, and Joshua Kaufmann. We acknowledge Dr. Hsin-Ching Lin for assistance in establishment of the HIV assays.

Novel NMR Platform for Detecting Gene Transfection: Synthesis and Evaluation of Fluorinated Phenyl β-D-Galactosides with Potential Application for Assessing LacZ Gene Expression†

Jianxin Yu, Pieter Otten, Zhenyi Ma, Weina Cui, Li Liu, and Ralph P. Mason*

Department Radiology, The University of Texas Southwestern Medical Center at Dallas, Dallas, Texas 75390-9058. Received March 12, 2004; Revised Manuscript Received October 1, 2004

Gene therapy holds great promise for the treatment of diverse diseases, but widespread implementation is hindered by difficulties in assessing the success of transfection. The development of noninvasive reporter techniques based on appropriate molecules and imaging modalities may help to assay gene expression. Fluorophenyl-β-D-galactopyranosides provide a novel class of NMR active molecules, which are highly responsive to the action of β-galactosidase (β-gal), the product of the lacZ gene. The reporter molecules are stable in solution and with respect to wild-type cells, but the enzyme causes liberation of the aglycon, a fluorophenol, accompanied by distinct color formation and a ^{19}F NMR chemical shift of 5−10 ppm, depending on pH. Synthetic strategy, experimental methods, and molecular and ^{19}F NMR characteristics are reported for a series of molecules in solution, blood, and tumor cells. This class of molecules presents a new strategy for assaying gene expression with a highly versatile molecular structural platform.

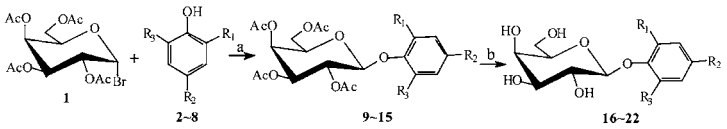
INTRODUCTION

Gene therapy holds great promise for the treatment of diseases including cancer, cystic fibrosis, and immunodeficiency. However, a major hurdle to widespread successful implementation is the need to verify successful transfection, in particular, the spatial distribution of gene expression in the target tissue, together with assays of the longevity of expression. An image-based assay could greatly facilitate optimal gene therapy vector dosing, in a precise temporal and spatial manner.

Two approaches are gaining popularity for reporter genes. One method favors the use of genes producing reporter molecules such as green fluorescent protein, which are directly detectable by physical methods such as fluorescence. The second approach uses genes to produce enzymes, which act upon substrates administered to specifically interrogate gene expression. A critical criterion is that the reporter gene not be normally present or expressed in the cells of interest. The most popular reporter genes today are associated with optical imaging, because this is a cheap modality and is highly sensitive and the results are rapidly available (*1*, *2*). Thus, fluorescent imaging of green fluorescent protein [GFP[1] and longer wavelength variants (*3*)] and bioluminescent imaging (BLI) of luciferase activity on administered D-luciferin (*4*) are popular. These techniques are useful only in superficial tissues and have extensive applications in mice, but application to larger bodies is limited by shallow light penetration.

Several nuclear medicine approaches have been demonstrated by exploiting the action of thymidine kinase on a variety of substrates including iodo- and fluoronucleosides, such as FIAU and gancyclovir, and various radionuclide labels including ^{123}I, ^{124}I, ^{125}I, and ^{18}F (*5*, *6*). For cancer, thymidine kinase has the advantage that not only does the gene serve as a reporter, but the gene products can themselves have therapeutic value. An alternative approach uses the sodium iodine symporter (hNIS), which works well with both iodide and pertechnetate substrates (*7*).

NMR has been applied to cells transfected to express melanin or transferrin resulting in iron accumulation, which produces proton MRI contrast (*8*, *9*). ^{19}F NMR has been used to detect conversion of 5-fluorocytosine to 5-fluorouracil following introduction of cytosine deaminase (*10*).



Historically, the bacterial *lac*Z gene, encoding the enzyme β-galactosidase (β-gal, EC 3.2.1.23), has been the most popular reporter gene. The lac operon was the first gene expression system to be well characterized, some 40 years ago by Jacob and Monod (*11*), and it is a recognized tool for the study of problems in cell and molecular biology and the recently emerging fields of genomics and proteomics (*12*). Its induction has become a standard means of assaying clonal insertion and transcriptional activation (*13*). The long-established tests for β-gal based on colorimetric assay of *o*- and *p*-nitrophenyl-β-galactopyranoside hydrolysis to release yellow *o*- or *p*-nitrophenols remain popular (*14*). However, because of the broad substrate specificity of the enzyme, alternate reporter substrates have been proposed (*15*−*19*), and many are commercially available. Fluorogenic galactosides based on fluorescein and resorufin, such as *p*-naphtholbenzein, 1,2-dihydroxyanthraquinone, 4-methylumbeliferone, 5-bromo-4-chloro-3-indoxyl-β-galactopyranoside (X-Gal), and 3,4-cyclohexenoesculetin-β-galactopyranoside (S-Gal) are well established (*16*, *20*−

23). The staining methodologies described above are effective for histological specimens and in vitro, but in vivo capabilities would promise new applications to study, and clinically evaluate, gene transfection.

Recently, Louie et al. (*24*) demonstrated an elegant MRI assessment of β-gal activity based on 1-[2-(β-D-galactopyranosyloxy)propyl]-4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecane)gadolinium(III) (EgadMe). Access of water to the first coordination sphere of the paramagnetic Gd^{3+} is blocked by a galactopyranose bridge, but β-gal cleaves the bridge, yielding a 20% increase in relaxivity. Whereas EgadMe is a poor substrate for the enzyme (several orders of magnitude less efficient than the colorimetric biochemical agent ONPG) and does not penetrate cells, it facilitated effective investigation of cell lineage following direct intracellular microinjections (*24*). These studies prompted us to consider other NMR active analogues, and it appeared that introduction of a fluorine atom into the popular colorimetric biochemical indicator ONPG could produce a strong candidate molecule. Diverse fluorinated reporter molecules have been successfully applied previously to metabolic and physiological studies (*25*, *26*). ^{19}F-labeled molecules exploit the high NMR visibility of fluorine, the great NMR sensitivity of ^{19}F to the environmental milieu, and the lack of background signal. We recently reported the successful synthesis of a prototype reporter molecule, *p*-fluoro-*o*-nitrophenyl β-D-galactopyranoside (PFONPG; **16**), and demonstrated initial NMR applications (*27*). We have now synthesized and evaluated a series of analogues and provide structural characterization, together with evaluation of their activity in solution and in cell culture, and compare the relative merits of the substrates.

EXPERIMENTAL SECTION

General Methods. NMR spectra were recorded on Varian Inova spectrometers (400 or 600 MHz for ^1H, 100 or 150 MHz for ^{13}C) with $CDCl_3$ (for **9**−**15**) or DMSO-d_6 (for **16**−**22**) as solvents, and ^1H and ^{13}C chemical shifts were referenced to TMS, as internal standard. Compounds were characterized by acquisition of ^1H, ^{13}C, DEPT, ^1H−^1H COSY, or NOESY experiments at 25 °C. ^{19}F NMR (376 MHz) measurements were performed at 25−37 °C in aqueous solution with ^{19}F signals referenced to dilute sodium trifluoroacetate (NaTFA) in a capillary, as an external standard. High-resolution mass spectra were obtained on an ABI Voyager STR MALDI-TOF mass spectrometer in reflector mode (service provided by Dr. Tichy, Department of Chemistry, Texas A&M University).

Reactions requiring anhydrous conditions were performed under nitrogen or argon. Solutions in organic solvents were dried with anhydrous sodium sulfate and concentrated in vacuo below 45 °C. Column chromatography was performed on silica gel (200−300 mesh) with cyclohexane−EtOAc. Analytical TLC (silica gel GF_{254}; Aldrich Chemical Co.) used detection by UV or staining with 5% ethanolic H_2SO_4 at 110 °C for 10 min.

Although many nitrophenol glycosides have been described (*28*, *29*) including nitrophenyl fluorogalactoside (*30*), to our knowledge there have been no published syntheses of the β-D-galactosides **16**−**22**. For the construction of *O*-glycosidic linkages, many strategies are available using anhydrous zinc chloride (for the α anomer) or *p*-toluenesulfonic acid (for the β anomer), but the *p*-nitrophenyl glycosides were usually obtained in low yield (*31*−*33*).

We initially tested the method of Yoon et al. (*30*), which involves the reaction of a potassium salt of an acidic phenol with an α-D-galactopyranosyl bromide. Aryl β-D-galactopyranosides **16** and **17** were prepared by a nucleophilic substitution reaction of a phenolate ion on acetobromo-α-D-galactose **1** followed by saponification of the acetyl groups. We applied two different procedures for generating the phenolate ion, depending on the acidity of the phenol. The brightly colored solid potassium salts of fluoronitrophenols **2** and **3** could be isolated by lyophilizing an aqueous solution of phenol with a slight excess of aqueous KOH. The salts were subsequently used directly in excess for the synthesis of the corresponding fluoronitrophenyl tetra-*O*-acetyl β-D galactopyranosides **9** and **10**. Compounds **9** and **10** were isolated pure in moderate yields (58−77%) after basic extractive workup and flash chromatography. A different strategy had to be applied for the less acidic 2-fluorophenol **5**. The phenolate was generated in situ with K_2CO_3 in refluxing acetone in the presence of a catalytic amount of 18-crown-6 (*34*).

However, given the reported high yields, mild reaction conditions, and high stereospecificity, we ultimately explored phase-transfer catalysis for the synthesis of our desired glycosides (Figure 1) (*30*, *34*).

Fluorophenyl β-D-Galactopyranoside Tetraacetates 9−15. *General Procedure (Figure 1).* A solution of **1** (1 mmol; 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide, Sigma) in CH_2Cl_2 (5 mL) was added dropwise

to a vigorously stirred solution of fluorophenol **2**−**8** (1.2 mmol) and tetrabutylammonium bromide (0.48 g, 1.5 mmol) in H_2O (5 mL; pH 8−9) at 50 °C in a three-neck round-bottom flask equipped with a condenser and thermometer. After TLC showed complete reaction (∼1 h), the organic layer was separated, washed, dried, evaporated under reduced pressure, and recrystallized (EtOH−H_2O) or purified by column chromatography on silica gel to give fluorinated aryl β-D-galactopyranoside tetraacetates **9**−**15**, as white crystals.

Kinetic Experiments. Relative substrate efficacies of **16**−**22** were compared using ^{19}F NMR. Enzyme reactions were conducted at 37 °C in PBS (0.1 M, pH 7.4) using β-gal (E801A, Promega, Madison, WI). Fluorophenyl β-D-galactopyranosides **16**−**22** (15 mmol) were dissolved in PBS (600 μL, pH 7.4) and β-gal (20 μL, 1 unit/

μL E801A in PBS) was added, followed by immediate ^{19}F NMR data acquisition at 37 °C with subsequent spectra every 101 s providing a kinetic curve over 51 min.

Substrate efficacy relative to traditional indicators was assessed by spectrophotometry. PFONPG **16** and ONPG (2.5 μmol/mL), respectively, were dissolved in buffer (pH 4.5, 10 mM sodium hydrogen phosphate, 5 mM citric acid). A solution of β-gal [G5160 from *Aspergillus oryzae* (Aldrich), 95 μg in 10 μL of buffer] was added and the absorption ($\lambda = 420$ nm) measured every 30 s for 10 min at room temperature.

Cell Culture and Cell Proliferation Assay. Dunning R3327-MAT-Lu rat prostate cancer cells (isolated for growth in culture by us from solid tumor tissues originally provided by Dr. Peter Peschke of the DKFZ, Heidelberg, Germany) and MTLn3 rat breast cancer cells (ATCC, Manassas, VA) were maintained in RPMI-1640 medium supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% fetal bovine serum (FBS) at 37 °C, with 5% CO_2 and 95% humidified air. Using TransFast transfection reagent (Promega), MAT-Lu and MTLn3 cells were cotransfected with pCMVβ (Clontech, Palo Alto, CA) comprising the *Escherichia coli lacZ* gene located under the human cytomegalovirus (CMV) immediate-early enhancer/promoter region and pCI-neo (Promega) carrying the neomycin phosphotransferase gene and were selected in growth medium containing 400 μg/mL G418 (Cellgro, Merndon, VA). Cells were harvested, trypsinized and resuspended in PBS, pH 7.4. **17** (1.9 mg, 100 μL) was added to cell suspension in PBS (10^8 cells in 600 μL), and ^{19}F NMR spectra were acquired immediately at 37 °C and again at various times up to 72 h. The β-gal activity of MAT-Lu-LacZ cells was 196 milliunits/10^7 cells and that for MTLn3-LacZ cells, 67 milliunits/10^7 cells.

The toxicity of aglycons and conjugates was assessed in both wild-type and LacZ-transfected MAT-Lu cells using a colorimetric CellTiter 96 Aqueous Nonradioactive MTS Cell Proliferation Assay (Promega). Assays were performed in triplicate using 24-well plates seeded with 10^3 cells per well in 500 μL of RPMI-1640 without phenol red and supplemented with 10% FCS and 2 mM glutamine. After 24 h of incubation, the medium was replaced with fresh medium. To determine IC_{50}, cells were incubated (72 h) with molecules **2**−**8** (0−1.6 mM) and **16**−**22** (0−4.5 mM), followed by the MTS assay. In each case successive dilutions were 2-fold. In some cases maximum tested doses were lower because some molecules showed poor solubility.

RESULTS

The methodology presented by Yoon et al. (*30*) to synthesize phenyl fluorogalactoside tetraacetates using potassium salts of the phenol produced mediocre yields for the fluorophenyl analogues **9** and **10**. By contrast, the phase-transfer approach using TBAB produced fluorophenyl β-D-galactopyranoside tetraacetates **9**−**15** in nearly quantitative yields. The anomeric β-D-configuration of compounds **9**−**15** in the $^4C_1$ chair conformation was unambiguously established on the basis of the observed ^{1}H NMR chemical shifts (δ_H 5.00−5.25) of the anomeric protons and the $J_{1,2}$ ($J \sim 8$ Hz) and $J_{2,3}$ ($J \sim 10$ Hz) coupling constants (*34*). The signals of the ^{13}C NMR spectra of **9**−**15** were assigned by comparison with the chemical shifts of *p*-nitrophenyl β-D-galactopyranoside (*30*). As expected, the anomeric carbon resonances appeared at ~100 ppm in accord with the β-D-configuration.

Deacetylation of **9**−**15** gave the free galactopyranosides **16**−**22** in nearly quantitative yields. ^{1}H NMR spectra of

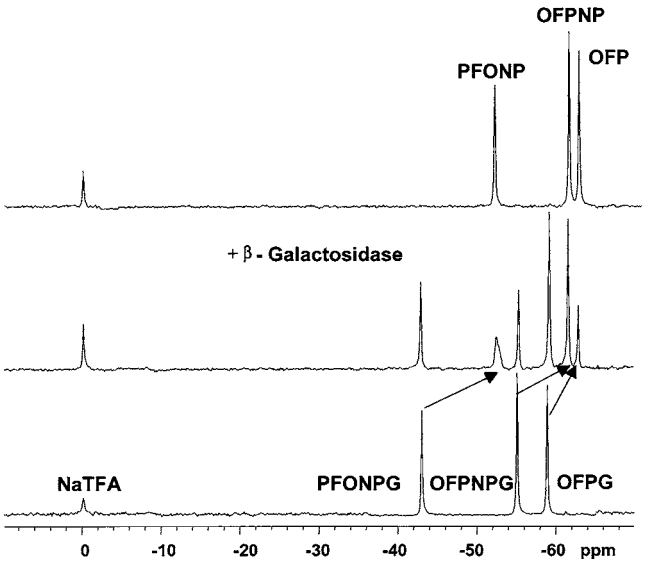

Figure 2. ^{19}F NMR spectra of β-D-galactopyranosides **16** (PFONPG), **17** (OFPNPG), and **19** (OFPG) in PBS at 37 °C (a) and following addition of β-gal [2 min) (b) and 34 min (c)].

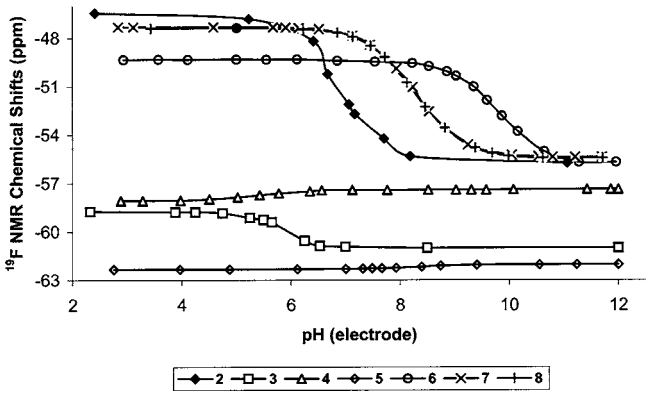

Figure 3. ^{19}F NMR chemical shift pH titration curves of **2**−**8** in saline at 25 °C.

16−**22** were assigned by ^{1}H−^{1}H COSY spectra and D_2O exchange. The ^{1}H NMR chemical shifts (δ_H 4.91−5.85) of the anomeric protons and the coupling constants ($J_{1,2} \sim 8$ Hz; $J_{2,3} \sim 10$ Hz) showed that the free galactopyranosides **16**−**22** (except **18**) retained the anomeric β-D-configuration with the $^4C_1$ chair conformation. The synthesis of **18** was more complex with the isolation of two distinct and separable isomers **18A** and **18B** in a 1:1 ratio, which also gave distinct ^{19}F NMR spectra. The downfield shifts of **18B** δ_{H1} at 5.85 with $J_{1,2} = 3.2$ Hz and δ_C at 104.14 compared to those of **18A** at 5.00 ppm with $J_{1,2} = 7.6$ Hz and δ_C at 106.06 suggest α and β isomers, respectively (*35*−*38*). Further evidence supporting the structural assignment of **18B** is that the α anomer resists activity of β-gal (Figure 4). Epimerization likely occurs during removal of the acetyl groups, possibly via a carbocation pathway due to the excellent leaving group ability of the 2-fluoro-6-nitrophenol anion group.

All except **18A** were stable in saline (0.9%), PBS (0.1 M), and fresh whole rabbit blood, at 25 and 37 °C, for extended periods showing no breakdown by ^{19}F NMR even after 1 week. **18A** hydrolyzed completely within 2 h in 0.1 M PBS buffer solution (pH 7.4) at 25 °C. By contrast, **18B** was stable even at 60 or 100 °C. As expected, the more polar substituted phenyl β-D-galactopyranosides **16**−**18** were most soluble and **19**−**21** quite

soluble in water, buffer, and whole blood, but 2-bromo-4-fluorophenyl β-D-galactopyranoside **22** was poorly soluble.

^{19}F NMR. Compounds **16**−**22** each gave a single, narrow ^{19}F NMR signal essentially invariant ($\Delta\delta \leq 0.03$) in rabbit whole blood, 0.9% saline, and PBS in the pH range 3−12 and at various temperatures ranging from 25 to 37 °C. The liberated aglycons display a chemical shift range of ∼16 ppm (Table 1; Figure 2). Addition of β-galactosidase (E801A) in PBS (0.1 M, pH 7.4) at 37 °C caused each substrate to hydrolyze, releasing the pH sensitive aglycons **2**−**8** appearing also as a single narrow ^{19}F NMR signal (Figure 2; Table 1), consistent with the titration curves of **2**−**8** (Figure 3; Table 2). The minimum ^{19}F NMR chemical shift response observed was 3.56 ppm for **19** and maximum was 9.84 ppm for **16** at pH 7.4 (Table 1).

The various substrates **16**−**22** exhibited differential sensitivity to β-galactosidase in PBS (pH 7.4), and kinetics were monitored by changes in the integration of the ^{19}F NMR signals (Figures 2 and 4). The shapes of the kinetic curves suggest straightforward first-order kinetics for all substrates. The best substrate was **18A**, with an initial rate of 0.74 mM/min/unit, although this molecule hydrolyzed spontaneously within 2 h. **16**, **17**, and **19** also showed rapid cleavage, whereas **20**−**22** were somewhat slower and **18B** resisted enzyme action (as expected for an α anomer). By colorimetric assay **16** was essentially equivalent to ONPG as a substrate (Figure 5).

Several of the aglycons (**2**, **3**, **6**−**8**) exhibit a large ^{19}F NMR chemical shift in response to pH with $\Delta\delta$ reaching 9.3. However, **4** and **5** showed little response (Figure 3). The observed pK_a values were found to be in the range of 5.4−9.8 (Table 2). There was a strong linear correlation between initial rate of enzymatic hydrolysis of the substrates and pK_a of the aglycon (Figure 6).

When **17** was incubated with wild-type MAT-Lu rat prostate cancer cells (4 h, PBS, 37 °C under air−5% CO_2 with 95% humidity), ^{19}F NMR spectra showed no changes. When **17** was incubated with MAT-Lu-LacZ cells (92 ×

[a] Greater than 90% survival at the highest dose tested.

10^6, 1803 milliunits of β-gal) in PBS, cleavage proceeded in a smooth monotonic manner with hydrolysis complete after 19 h (Figure 7). MTLn3-*LacZ* breast cancer cells (9.8×10^6, 67 milliunits of β-gal) hydrolyzed ~50% of **17** in 19 h.

Toxicity was evaluated for both aglycons and conjugates using both wild-type and lacZ expressing MAT-Lu cells (Table 3). **5** and **7** were severely cytotoxic, **2** was somewhat toxic (IC_{50} < 0.4 mM), and the other aglycons, **3**, **4**, **6**, and **8**, were less toxic (IC_{50} > 1 mM), making them more suitable for in vivo NMR investigations. Most conjugates were much less toxic; in particular, the toxicity of the aglycons was masked in **19** and **21**.

DISCUSSION

We have presented a method to efficiently and stereoselectively synthesize a series of fluorophenyl β-D-galactopyranosides **16**−**22** as potential ^{19}F NMR-based gene reporter molecules. We previously demonstrated that **16** could be used to assess β-gal activity in transiently transfected human prostate cancer cells (*27*). We have now assessed the relative substrate efficacy of a series of analogues and demonstrated the utility of **17** to assess β-gal activity in stably transfected rat breast and prostate tumor cells.

^{19}F NMR provides a large chemical shift response to small changes in molecular structure or microenvironment (*25*, *26*). Here, hydrolysis provided a minimum $\Delta\delta$ 3.56 between the substrate and the aglycon at pH 7.4, although depending on the pH, it could range from 1.6 to 12.9 ppm. Significantly, because of the chemical shift range of the ^{19}F signals of the aglycons **2**−**8** (up to 9.3 ppm), several substrates and aglycons can be detected simultaneously, allowing direct comparison of substrate efficacy (Figure 2). Preliminary data suggest that the approach used here could also be applied to glucosidases and glucoronides. Indeed, Schmidt and Monneret (*39*) presented ^{19}F NMR analysis of a fluorine-tagged nitrogen mustard pro-drug activated by glucuronidase. ^{19}F NMR spectroscopy lacks the spatial resolution of ^{1}H MRI, but the chemical shift accompanying substrate cleavage by β-gal unequivocally reveals enzyme activity. Comparing the substrates shows a 10-fold range in rate of substrate reaction at pH 7.4, the optimal pH for activity of β-gal derived from *Escherichia coli*. The observed initial rates were found to have a strong linear correlation with the pK_a of the aglycon (Figure 6), consistent with previous work by Richard et al. (*40*), who examined a series of alkyl β-galactosides. At pH 4.5—the optimal pH for β-gal derived from *Aspergillus oryzae*—**16** showed very similar activity in comparison with the traditional colorimetric indicator ONPG.

Substrates **16** and **17** share many attributes with similar sensitivity to β-gal at pH 7.4 (Figure 4), a large chemical shift range, and effective response to cells expressing β-gal (Figure 7) (*27*). All of the aglycons are electronically similar to the classic biochemical uncoupler dinitrophenol, raising potential concerns of toxicity. We have found extensive cell lysis upon direct exposure to the product aglycon **2** (IC_{50} < 0.4 mM), but **16** has allowed us to assess β-gal expression in culture (*27*). Other aglycons, **3**, **4**, **6**, and **8**, are less toxic, making them more suitable for in vivo NMR investigations, although **5** and **7** are severely cytotoxic. The conjugates are generally much less toxic, and indeed **19** and **21** showed essentially no toxicity up to the highest concentrations tested in wild-type or lacZ-expressing cells. Intriguingly, the conjugate **17** was more toxic that its aglycon. Similar toxicity was observed for all materials in wild-type or LacZ cells. Release of the less toxic, pH-sensitive aglycons suggests a novel approach to measuring pH at the site of enzyme activity. Moreover, noting the broad specificity of β-gal, we have synthesized an alternative galactoside with the ^{19}F NMR pH indicator fluoropyridoxol (*25*), as the aglycon and preliminary data show that it is also sensitive to enzyme activity (*41*).

We believe that noninvasive detection of gene reporter molecules will become increasingly important in biomedicine. It will be important to have diverse agents, genes, and modalities for specific applications. Fluorophenyl β-D-galactosides offer a novel approach for addressing β-gal activity. Moreover, we believe the concept of using ^{19}F NMR to monitor gene transfection, together with the molecular approach presented here, can serve as a platform technology with widespread application to many diverse genes and enzymes.

ACKNOWLEDGMENT

Supported in part by DOD Breast Cancer Initiative IDEA Award BC022001 DAMD17-03-1-0343-01, a DOD Prostate Cancer Initiative Postdoctoral Award W81XWH-04-10331 (L.L.), and the Cancer Imaging Program, NCI Pre-ICMIC P20 CA086354. NMR experiments were conducted at the Mary Nell and Ralph B. Rogers NMR Center, an NIH BTRP facility (P41-RR02584).

DNA Complexing Lipopolythiourea

Isabelle Tranchant, Nathalie Mignet, Estelle Crozat, Jeanne Leblond, Christian Girard, Daniel Scherman, and Jean Herscovici*

Laboratoire de Pharmacologie Chimique et Génétique CNRS-UMR 8115, INSERM-U640, ENSCP 11 rue Pierre et Marie Curie 75231 Paris Cedex 05, France, and Faculté des Sciences Pharmaceutiques Biologiques 4, avenue de l'Observatoire 75270 Paris Cedex 06, France. Received March 31, 2004; Revised Manuscript Received October 1, 2004

We present a neutral lipopolythiourea (DTTU) as a potential DNA-binding agent. Light scattering experiments showed that mixing a lipopolythiourea with dipalmitoylphosphatidylcholine (DPPC/DTTU) led to small particles with sizes ranging from 100 to 150 nm at optimum conditions. Setting a fixed DNA amount, an increasing amount of DTTU/DPPC or DPPC lipids was added. Particle size increased only with DTTU/DPPC, indicating that interaction occurred between the DTTU/DPPC particles and DNA. In the same way, only DTTU/DPPC limited the ethidium bromide accessibility to plasmid DNA. These data suggest that DTTU/DPPC liposomes associate to DNA, which was confirmed by agarose gel experiments. To prove the active part of the DTTU lipid itself in DNA compaction, pegoylated-lipid was used. Cholesterol-PEG_{2000} alone was not able to condense DNA. In contrast, DTTU/PEG-cholesterol was able to retain plasmid DNA on an agarose gel. In vivo injection of DTTU/DPPC/ complexes was studied. Circulation time increase for noncationic particles as compared to cationic. More obvious was the lack of nonspecific accumulation in the lung, where a gain of 3 to 40 fold was measured.

INTRODUCTION

Among the many constructs that have been used to facilitate oligonucleotides, RNA, and plasmids intracellular delivery, cationic lipids and cationic polymers have received the greatest attention (*1*). Over the course of the past several years, it has become clear that the use of cationic lipids for nucleic acid in vivo delivery is compromised by substantial problems such as interaction with negatively charged extracellular components, complement activation, platelet aggregation, and related toxicity (*2*, *3*)

To overcome these hurdles, PEG-lipid was added to cationic lipoplexes aiming at reducing their blood clearance (*4*, *5*) as was previously shown for conventional liposomes (*6*). Unexpectedly, the coating providing a steric barrier against opsonising proteins did not necessarily extend blood circulation time (*7*, *8*).

The necessity of new nonviral delivery methods prompted us and others to investigate nucleic acid complexation by noncationic systems. Efficient encapsulation of DNA plasmids inside small, neutral liposomes was achieved by the addition of optimized amounts of ethanol and calcium chloride to an aqueous mixture of small unilamellar vesicles (SUVs) and plasmid (*9*). High plasmid confinement into neutral lamellar phase was shown to be possible, without electrostatic interactions, at high lipid/DNA weight ratios (*10*).

In the present approach, we present a neutral lipopolythiourea as a potential nucleic acid binding agent. The relatively acidic thiourea NH protons (*11*), with a strong hydrogen-bond donor capability, can establish multipoint hydrogen-bonded patterns with complementary acceptor groups in a specific and predictable manner. Moreover, bis-thiourea moieties selectively bind to dihydrogenphosphate via multitopic hydrogen bonding, giving stronger complexes with $H_2PO_4^-$ than any synthetic neutral receptor known so far (*12*). Finally, thioureas show a lower tendency to self-associate than the corresponding urea analogues (*11*).

All these data prompted us to prepare and study the physicochemical properties of lipopolythiourea/DNA complexes. To compare these complexes to cationic lipoplexes, we based the design on lipopolyamine the previously reported RPR 122766 (*13*). We chose the same hydrophobic anchor connected to a trithiourea by a succinic linker to obtain a comparable size for the two lipids (Figure 1).

MATERIALS AND METHODS

All solvents were purchased from SDS (Peypin France). Dichloromethane was distilled from P_2O_5. DMF was dried over 3 Å molecular sieves and pyridine over KOH. All chemicals were purchased from Sigma-Aldrich-Fluka or Lancaster. Other solvents and products were used without further purification. Reactions were monitored by thin-layer chromatography using Merck precoated 60 F_{254} silica gel plates. Column chromatography was performed over SDS (Peypin France) 35−70 μm silicagel according to the method of Still, Khan, and Mitra (*14*). ^1H and ^{13}C NMR spectra were recorded on a BRUKER Avance DRX-300 spectrometer at 300.13 MHz for the proton and 75.47 MHz for the carbon. NMR spectra were processed using xwinnmr (Bruker) or SwaN-MR (*15*). MS and elemental analysis were carried out at the Analysis Department of Aventis, Vitry sur Seine France. Dipalmytoylphosphatidylcholine (DPPC), egg phosphatidylcholine (EPC), and phosphatidylethanolamine-lissamine rhodamine were purchased from Aventi Polar Lipids (Alabaster Alabama). All in-vivo experiments were performed with distilled water for injection. Size measurements were performed

by dynamic light scattering (HPPS, Malvern Intruments). Ethidium Bromide assays were performed in a fluorospectrophotometer (Fluoromax2, Jobin Yvon).

Synthetic Procedures. *[2-(3-Ditetradecylcarbamoyl-propionylamino)-ethyl]-carbamic Acid tert-Butyl Ester (**4**).* PyBop (4.6 g, 8.84 mmol), (2-amino-ethyl)-carbamic acid *tert*-butyl ester (**3**) (1.56 g, 9.72 mmol), and diisopropylethylamine (4.24 mL, 24.31 mmol) were added successively to a stirred solution of *N,N*-ditetradecyl-succinamic acid (**2**) in dichloromethane (88 mL) at room temperature. After 4 h the solution was filtrated and evaporated to dryness. The resulting oil was purified by chromatography (heptane/ethyl acetate 1:1 then 2:8) to yield 3.79 g of **4** (66%).

^{1}H NMR ($CDCl_3$): δ (ppm) 0.87 (t, 6H, J = 6.6 Hz, H-14′), 1.25 (m, 44H, H-4′-H-11′), 1.43 (s, 9H, $(CH_3)_3$), 1.48 (m, 4H, H-2′), 2.56 (t, 2H, J = 6.7 Hz, H-2), 2.69 (t, 2H, J = 6.2 Hz, H-3), 3.28 (m, 4H, H-1′), 3.3 (m, 4H, H-5 and H-6).

^{13}C NMR ($CDCl_3$): δ (ppm) 14.07 (C-14′), 22.56 (C-13′), 26.99 ($(CH_3)_3$), 27.73 (C-3′), 28.29 (C-2), 28.59 (C-2′), 29.27 (C-4′-C-11′), 29.55 (C-3), 31.41 (C-12′), 39.85 (C-5), 40.39 (C-6), 46.21 et 47.98 (C-1′), 78.77 (C-8), 156.33 (C-7), 171.46 (C-1), 173.14 (C-4).MS (IS) calcd. for $C_{39}H_{77}N_3O_4$ 652,05, found 653.05 (MH^+), Anal. Calcd. C = 71.84; H = 11.90; N = 6.44, found C = 70.42; H = 12.45; N = 6.49.

*2-(3-Ditetradecylcarbamoyl-propionylamino)-ethylammonium Trifluoroacetate (**5**).* The carbamate **4** (1.59 g, 2.44 mmol) was dissolved in trifluoroacetic acid then the solution was stirred for 4 h. The acid was removed by evaporation then the residue was coevaporated twice with cyclohexane at room temperature. The resulting oil was dried overnight over NaOH pellets under vacuum to afford **5** (100%)

^{1}H NMR ($CDCl_3$): δ (ppm) 0.91 (t, 6H, J = 6.6 Hz, H-14′), 1.29 (m, 44 H, H-4′-H-11′), 1.51 (m, 4H, H-2′), 2.59 (t, 2H, J = 6.7 Hz, H-2), 2.71 (t, 2H, J = 6.2 Hz, H-3), 3.29 (m, 4H, H-1′), 3.31 (m, 4H, H-5 and H-6).

^{13}C NMR ($CDCl_3$): δ (ppm) 14.00 (C-14′), 22.67 (C′-13′), 27.35 (C-3′), 27.95 (C-2), 28.53 (C-2′), 29.65 (C-4′-C-11′), 30.70 (C-3), 31.94 (C-12′), 37.83 (C-5), 40.08 (C-6), 47.85 et 49.42 (C-1′), 171.72 (C-1), 173.26 (C-4).

*(2-{3-[2-(3-Ditetradecylcarbamoyl-propionylamino)-ethyl]-thioureido}-ethyl)-carbamic Acid tert-Butyl Ester (**7**).* The amine **5** (1.62 g, 2.44 mmol) was treated by triethylamine (1.36 mL, 9.76 mmol) for 15 min then the mixture was dissolved in dichloromethane (24.4 mL) and **6** was added (0.59 g, 2.92 mmol). The reaction mixture was stirred at room temperature for 12 h then the solvent was removed. The resulting oil was purified by chromatography (ethyl acetate/heptane 6:4 then pure ethyl acetate) to give 1.34 g of the thiourea **7** (yield 73%).

^{1}H NMR ($CDCl_3$): δ (ppm) 0.67 (t, 6H, J = 6.4 Hz, H-14′), 1.05 (m, 44 H, H-4′-H-11′), 1.26 (s, 9H, $CH_3)_3$), 1.35 (m, 4H, H-2′), 2.31 (m, 2H, H-2), 2.49 (m, 2H, H-3), 3.06 (m, 4H, H-1′), 3.11 (m, 4H, H-5 and H-9), 3.47 (m, 4H, H-6 and H-8), 7.14 (2H, H thiourea).

Preparation of the Liposomes DTTU/DPPC by the Film/Hydration Method. Compound **11** (2 mg, 2.4 μmol) and DPPC (3.5 mg, 4.8 μmol) were dissolved in 500 μL of $CHCl_3$. After solvent removal under vacuum, the film obtained was hydrated with 240 μL of H_2O at 4 °C to give a 30 mM multilamellar liposome. Liposomes were successively heated at 45 °C and sonicated (Branson) during 10 min to form a polydisperse population of liposomes with a mean diameter of 142 ± 41 nm.

Preparation of the Liposomes DTTU/DPPC by the Ethanolic Injection Method. Compound **11** (2 mg, 2.4 μmol) and DPPC (3.5 mg, 4.8 μmol) were dissolved in 500 μL of a 1/1 mixture of acetone/ethanol. This mixture was dropped on stirred water (5 mL). Most of the solvents were removed under vacuum to obtain a fairly concentrated suspension (580 μL of H_2O, 12.4 mM) of liposomes exhibiting a mean diameter of 101 ± 34 nm.

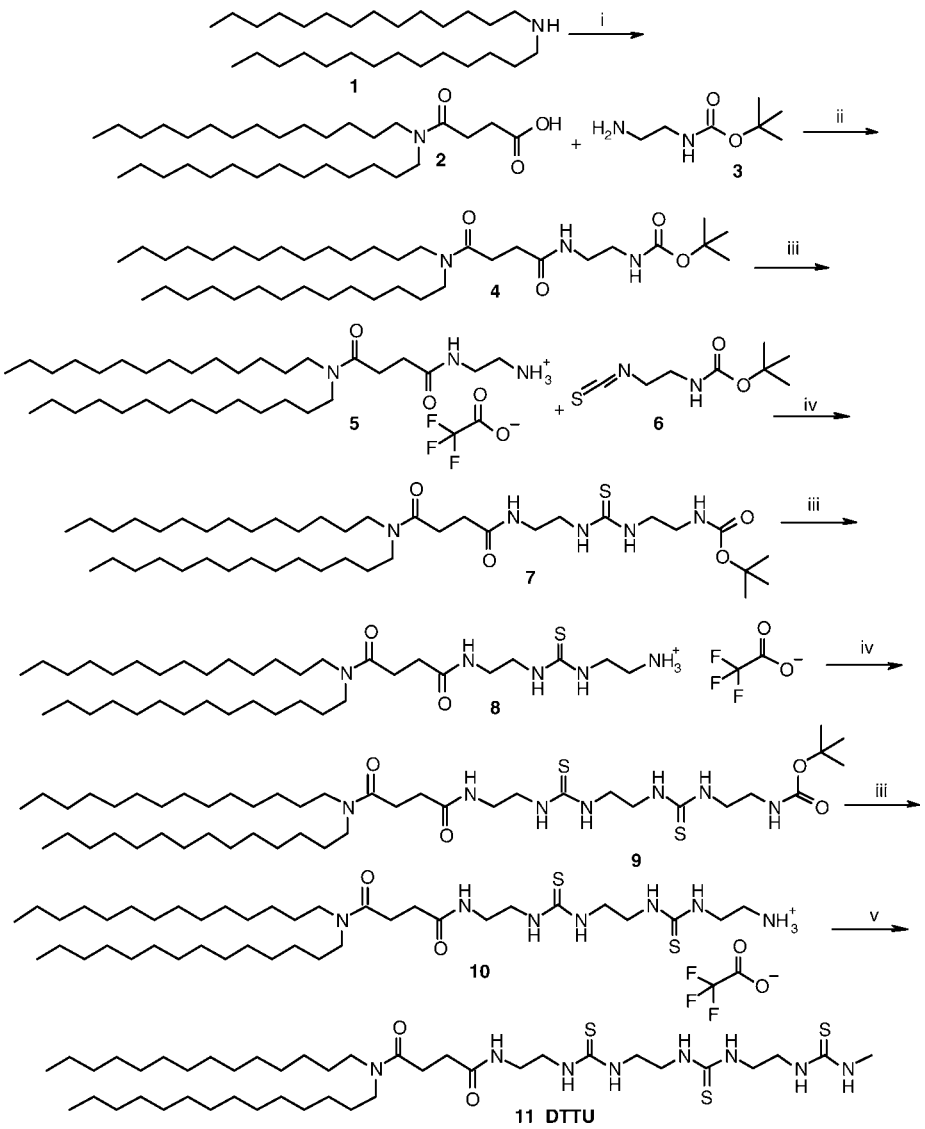
Preparation of the Liposomes DTTU/PEG-Cholesterol. Compound **11** (2 mg, 2.4 μmol) and cholesterol-PEG_{2000} (0.12 μmol) were dissolved in 500 μL of $CHCl_3$. After solvent removal under vacuum, the film obtained was hydrated with 250 μL of H_2O at 4 °C to give a 10 mM multilamellar liposome. Liposomes were successively warmed and sonicated (Branson) during 10 min to form a polydisperse population of liposomes with a mean diameter of 200 ± 45 nm.

Preparation of the Complexes DPPC/DTTU/DNA. Plasmid DNA (pXL3031, from Gencell S.A) (400 μL, 0.02 g/L in Hepes 40 mM, pH 7.4; NaCl 300 mM) was added to various amounts of DPPC/DTTU liposomes (400 μL, 5 mM total lipids, H_2O) at RT, and the mixture was vortexed during 10 s and left at RT for 2 h before size measurements, which were performed on a HPPS (Malvern Intruments), using water viscosity and refractive index.

Ethidium Bromide Displacement Assays. A Jobin-Yvon Spex Fluoromax-2 spectrofluorometer (Longjumeau, France) was used to measure ethidium bromide fluorescence (Excitation 260 nm, emission 590 nm) at 25 °C. EtBr (3 μL, 1 mg/mL) was added to the complex suspension (800 μL, 10 μg/mL DNA). Values are expressed as a fluorescence percentage of ethidium bromide with free plasmid DNA, taken as a 100%.

Agarose Gel Electrophoresis. Samples were prepared as described above (20 μL) and 5 μL of 30% glucose was added. The mixtures were loaded into 0.8% (w/v) agarose gel at 70 V/cm in TBE buffer (1 M Tris, 0.9 M boric acid, 0.01 M EDTA). DNA was revealed with EtBr and visualized under UV light.

Zeta Potential Analysis. The zeta potential was determined using a ZetaSizer 3000HS (Malvern Instruments, Southborough, MA). The system was calibrated using a −50 ± 5 mV standard (DTS 50/50 Standard; Malvern Instruments). Complex samples prepared as described above in 20 mM NaCl subjected to 3 × 30 s (1000 Hz, no field correction) measurement.



DNA Stability in Mouse Serum. A solution of complexes was prepared in 5% glucose, [DNA] = 0.25 g/L, with a total lipid/DNA charge ratio = 40 or 60 nmol/μg. For each complex tested, 50 μL of lipoplexes was incubated for 30 min at 37 °C/5% CO_2 in 1 mL serum diluted or not in 150 mM NaCl. Phenol/chloroform (1/1, v/v, 200 μL) and a solution of TRIS-EDTA (100 μL; 100 mM−10 mM, pH 8) were added to the lipoplex mixture in serum (200 μL). The mixture was vortexed and then centrifuged (Jouan MR 18 22, 12 000 rpm, 5 min, 4 °C) in microtubes. The aqueous phase was isolated and washed with a same volume of $CHCl_3$, and then centrifuged (Jouan MR 18 22, 12 000 rpm, 5 min, 4 °C). A solution of AcONa (10 μL, 3M) and EtOH (300 μL) was added in aqueous phase and stored at −20 °C. After 30 min, the mixture was centrifuged (Jouan MR 18 22, 12 000 rpm, 20 min, 4 °C), and the solvent was delicately removed. DNA was resuspended in H_2O and 1 μg was loaded on 1% agarose gel in 1% TBE buffer and electrophorized for 2 h at 70 V/cm in TBE buffer. DNA was revealed with ethidium bromide and visualized under UV light.

In Vivo Distribution in Tumor-Bearing Mice. Lewis Lung carcinoma tumors were implanted subcutaneously in the right flank of 6-week-old female C57Bl/6 mice (Charles River), and 10−14 days after biodistribution studies were undertaken as previously described.

Six-week-old female C57Bl/6 mice (Charles River) were anesthetized by intraperitoneal injection of a mix of ketamine (85.8 mg/kg; Merial) and xylazine (3.1 mg/kg; Bayer) diluted in 150 mM NaCl. Two hundred microliters of rhodamine-labeled complexes (10 μg of DNA, 400 nmol lipids in 5% glucose) were injected into the mouse tail vein. Blood was collected by cardiac puncture at appropriate intervals (30 min, 1, 2, 4, and 6 h after injection) and mice were euthanized at the end of the experiment. In the distribution study, mice were sacrificed at 30 min and 8 h after injection and the liver, spleen, lungs, and tumors were removed, weighed, and homogenized in pH 7.4 PBS (5 mL/g tissue). Experiments were conducted following the NIH recommendation for animal experimentation and Aventis local ethic committee on animal care and experimentation.

Rhodamine-labeled lipids were extracted from 100 μL of blood or tissue homogenates with 3 mL of $CHCl_3$/MeOH (1/1, v/v) by vigorously mixing during 30 min for blood and 40 min for tissue homogenates, followed by centrifugation (3000 rpm, 10 min). The fluorescence intensity was assayed on the supernatant with a fluorospectrophotometer (Fluoromax 2, Jobin Yvon). The amount of lipoplexes in the blood or tissue homogenates

Scheme 1. Preparation of the Lipopolythiourea[a]

[a] Reagents and conditions: (i) succinic anhydride, DMAP, pyridine, CH_2Cl_2, 98%; (ii) PyBop, diisopropylethylamine, RT, 66%; (iii) trifluoroacetic acid, RT, 100%; (iv) triethylamine, 67−72%; (v) triethylamine, methyl isothiocyanate, 51%.

was evaluated with a calibration curve and expressed as the remaining percentage of injected dose.

RESULTS

The lipopolythiourea was prepared as shown in Scheme 1. First, ditetradecylamine was reacted with succinic anhydride in the presence of DMAP and pyridine to give the succinate **2** in 98% yield. Reaction of **2** with the monoprotected diethylamine **3** in the presence of PyBop afforded **4** in 66% yield. After removal of the *tert*-butoxy carbamate, using trifluoroacetic acid, the resulting amine **5** was treated with the isothiocyanate **6** (*16*) to yield the thiourea **7** (73%).

Deprotection of **7**, then condensation with **6**, led to the amino thiourea **9**. Repetition of the same sequence on **9** afforded the di-thiourea **10**. Finally, removal of the protecting group then treatment with methyl isothiocyanate gave the ditetradecyl amino trithiourea **11** (DTTU) in 51% yield.

Formulation Study. The ability of lipopolythiourea (DTTU) **11** to form micellar or liposomal particles was then evaluated. The DTTU hydrophobicity prevents its solubilization in H_2O and particle formation. We added phosphatidylcholine (PC) as an amphiphilic co-lipid because of its high hydration potency and its zwitterionic nature. We evaluated the association to DTTU of EPC and of DPPC. Both EPC and DPPC formed mixed vesicles with DTTU. A ratio DTTU/DPPC of 1/2 is optimal to obtain a stable lipidic suspension. Energy gained by sonication to reduce particle size resulted in particles exhibiting a 142 ± 41 nm size distribution, as found by dynamic light scattering experiments. The potential primary amine containing lipid due to DTTU degradation was checked before and after sonication using the fluorescamine test (*17*) and zeta potential measurements ($\zeta = +7.1 \pm 2.8$ mV before sonication, $\zeta = +8.8 \pm 3.4$ mV after sonication).

The formation of liposomes by ethanol injection, which does not require any energy gain by sonication, was also performed with the same ratio DTTU/DPPC and spontaneously gave smaller particles (diameter 101 ± 34 nm; $\zeta = +5.4 \pm 4.3$ mV).

Interaction of DTTU/DPPC with DNA. The capacity of the DTTU/DPPC particles to associate to plasmid DNA was then studied and compared to DPPC/DNA association. Setting a fixed DNA amount, we added an increasing amount of DTTU/DPPC or DPPC lipids and measured the size of the particles obtained by dynamic

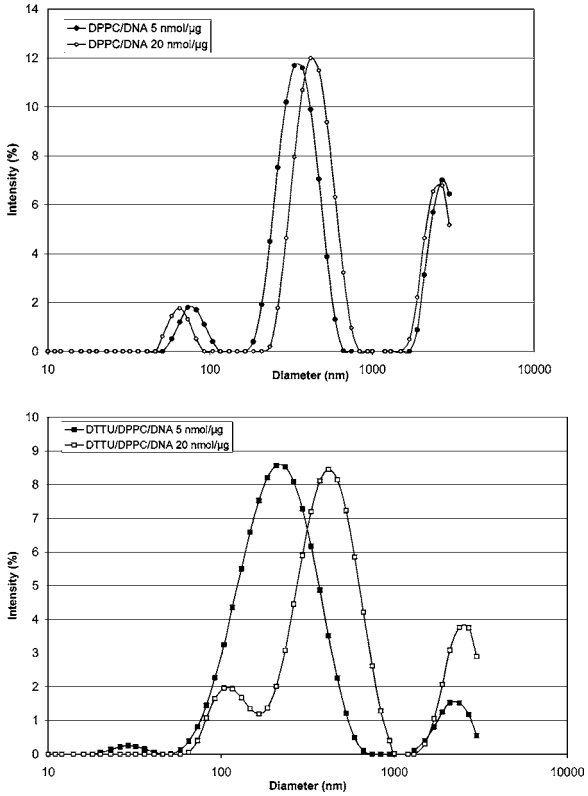


Figure 2. Diameter of the (a) DPPC/DNA particles and (b) DTTU/DPPC/DNA particles measured by dynamic light scattering. Plasmid DNA (8 μg) was added to various amounts of total lipid.

light scattering. Increasing the amount of DPPC from 5 to 20 nmol/μg DNA did not lead to any particle size modification (Figure 2). In contrast, above a ratio of 5 nmol of DTTU/DPPC lipids/μg of DNA, particle size increase was observed, leading to micrometer-range particles (Figure 2). This diameter change clearly indicated that in the conditions used an interaction occurred between the DTTU/DPPC particles and DNA and not between DPPC and DNA.

Interestingly, by increasing the amount of total lipid (over 20 nmol of lipid/μg of DNA), we observed stabilized particles with a size distribution of 170 $\pm$ 45 nm. We had previously observed such an interaction profile with a cationic lipid, by increasing the ratio lipid over DNA ratio (*18*), aggregation then stabilization.

We observed that addition of DPPC to DNA did not alter significantly ethidium bromide intercalation into DNA. In contrast, DTTU/DPPC presence limited the ethidium bromide accessibility to plasmid DNA, reducing the ethidium bromide fluorescence by a factor of 4 when the ratio lipid/DNA was increased from 0 to 20 nmol/μg. The observed decrease of ethidium bromide fluorescence reveals a lower DNA intercalation. It suggests that DTTU/DPPC liposomes associate to DNA, leading to a DNA compacted state preventing ethidium bromide access to DNA.

Agarose gel electrophoresis of the liposome/DNA complexes confirmed that plasmid DNA associates to DTTU/DPPC liposomes, with a decreasing amount of DNA migrating in the gel. In contrast, mixing the same lipid amount of DPPC alone with DNA did not retain DNA in the wells (Figure 4). The signal UV active in the wells might indicate that part of the nonmigrating DNA, which is associated to DTTU/DPPC liposomes, is accessible to ethidium bromide intercalation. Addition of cations such as Ca^{2+} instead of Na^{+} did not modify DNA retention on an agarose gel under the same conditions (not shown).

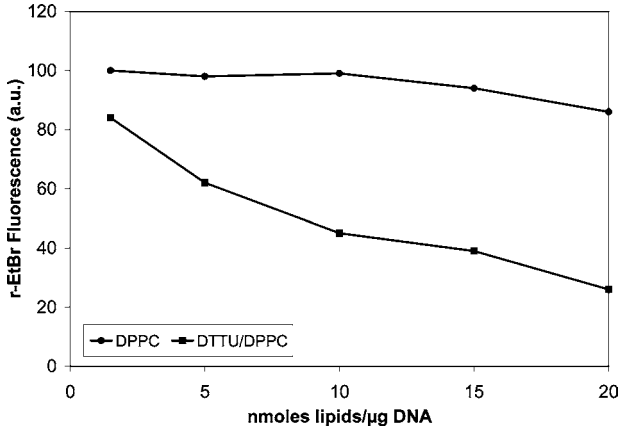

Figure 3. DNA was mixed with various amounts of DTTU/DPPC (1/2) liposomes. Ethidium bromide was then added and fluorescence was monitored at 590 nm.

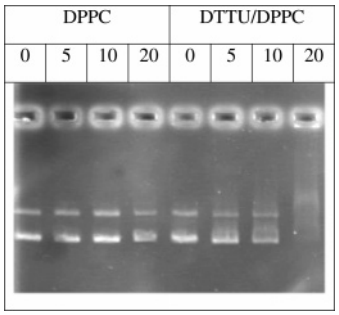

Figure 4. Migration of the DPPC/DNA and DTTU/DPPC/DNA complexes on a 0.8% agarose gel in TBE (1×). Complexes were revealed with ethidium bromide staining. From left to right, the lanes correspond to 0, 5, 10, 20 nmol of lipid/μg of DNA.

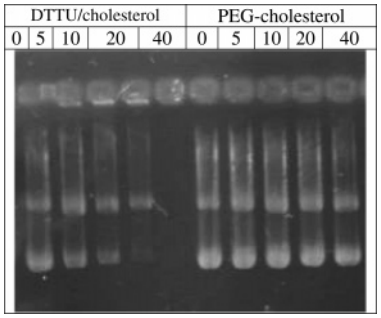

Figure 5. Complexes DTTU/cholesterol-PEG_{2000}/DNA and cholesterol-PEG_{2000}/DNA were loaded on a 0.8% agarose gel in TBE (1×) and revealed with EtBr staining. Total amount of lipids used is indicated (nmol of lipid/μg of DNA).

To prove the active part of the DTTU lipid itself in DNA compaction, we used a pegoylated-lipid (*7*) (cholesterol-PEG_{2000}) neutral as a co-lipid for DTTU lipid. We then checked by agarose gel electrophoresis the ability of this lipid mixture to associate with plasmid DNA. As observed in Figure 5, within the amount of lipid used, cholesterol-PEG_{2000} alone was not able to condense DNA and allowed DNA electrophoresis in the gel. In contrast, the mixture DTTU/PEG-cholesterol was able to retain plasmid DNA in deposit wells at 10, 20, and particularly 40 nmol of lipid/μg of DNA. This experiment confirms the active role played by the DTTU lipid in DNA association.

Zeta potential of the mixture DTTU/DPPC $\pm$ DNA was compared to the one obtained for lipopolyamine/DPPC $\pm$ DNA. Addition of DNA to DTTU/DPPC induced a

Table 1. Zeta Potential (mV) of DTTU/DPPC ± DNA, DTTU/Cholesterol-PEG$_{2000}$ ± DNA Complexes and RPR209120/DPPC/DNA Complexes Measured in 20 mM NaCl on a Malvern Instruments 3000HS[a]

	method	20 mM NaCl	+DNA/ 20 mM NaCl
lipopolyamine (L/D 5)	ethanolic injection	+60.1 ± 2.4	+30 ± 3.5
DTTU/DPPC 1/2 (L/D 20)	film + hydration	+8.8 ± 3.4	−20.3 ± 3.5
DTTU/DPPC 1/2 (L/D 20)	ethanolic injection	+5.4 ± 4.3	−16.6 ± 2.5
DTTU/CholPEG (L/D 20)	film + hydration	+1.8 ± 4.2	−0.2 ± 3.2

[a] L/D = ratio lipid/DNA in nmol of lipid/μg of DNA.

negatively charged zeta potential of −20.3 ± 3.5 mV for the DTTU/DPPC particles prepared by the film hydration method and −16.6 ± 2.5 mV for the particles prepared by the ethanolic injection method (Table 1).

Zeta potentials obtained by the two methods are quite comparable (with or without DNA) and far below the one obtained for the lipopolyamine control and other previously described cationic lipids (*19*). As expected, addition of 10% cholesterol-PEG$_{2000}$ to the DTTU lipid gave a zeta potential close to neutrality in the presence and absence of DNA. To explain the slightly positive value of potential zeta obtained for the DTTU/DPPC formulation in 20 mM NaCl, we searched for a potential amine contamination in each formulation using the fluorescamine test. Reaction of fluorescamine with alanine was taken as the calibration curve for amine quantification. We found 0.2% mol of amine in the DTTU/DPPC liposome prepared by the film method after sonication. This amount of amine could be responsible for the slightly positive zeta potential obtained, although this amount of amine could undeniably not be responsible for the DNA retention on an agarose gel or lipoplex size increase. Indeed, the amount of DTTU/DPPC used for DNA association: 20 nmol/μg lipid would represent 0.013 nmol of amine content/nmol of DNA phosphate, which is clearly not enough to account for the association effect observed.

DNA Protection toward Serum Enzymatic Degradation. DNA protection toward serum degradation was investigated in 20 and 100% serum in the absence and presence of DTTU/DPPC. After 30 min incubation at 37 °C, DNA was extracted by a phenol/chloroform process and loaded onto an agarose gel (Figure 6). In these two conditions, free DNA is fully degraded (lanes 4 and 7), while DNA integrity is conserved in 20% serum and partially maintained in 100% serum when associated to DTTU/DPPC (40 and 60 nmol/μg).

In Vivo Injection of DTTU/DPPC/DNA Complexes. Our interest in DTTU as complexing agent lies in the passive accumulation into tumor that could arise from longer circulation time, as previously reported with PEG-coated liposome (*20*). Indeed, reducing the charge of the lipid/DNA complexes should result in less protein interaction. Complexes including 5% PEG-cholesterol for stability and 1% DOPE-rhodamine for detection were injected into mice subcutaneously implanted with a Lewis lung carcinoma model. The lipids were extracted from the organs and treated for rhodamine recovery as described (Figure 7) (*12*).

Circulation time increase for noncationic particles as compared to cationic particles was noticeable after 30 min; 34 versus 17% was recovered in the blood. More obvious was the lack of nonspecific accumulation in the lung, where a gain of 3−40 was measured for noncationic

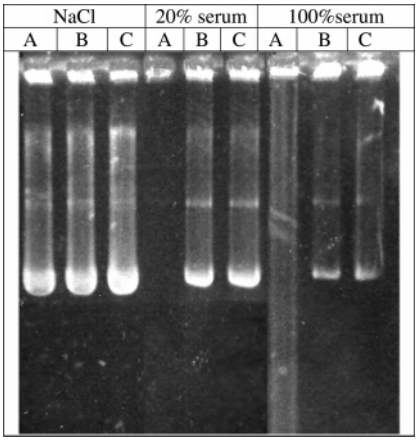

Figure 6. Integrity of plasmid DNA after complex exposure to mouse serum. DNA (A), DTTU/DPPC/DNA, 40 nmol/μg (B), and 60 nmol/μg (C) were incubated at 37 °C for 30 min in 150 mM NaCl, 20% serum or 100% serum. Plasmid was then extracted with phenol/$CHCl_3$ and its integrity was analyzed on a 0.8% agarose gel.

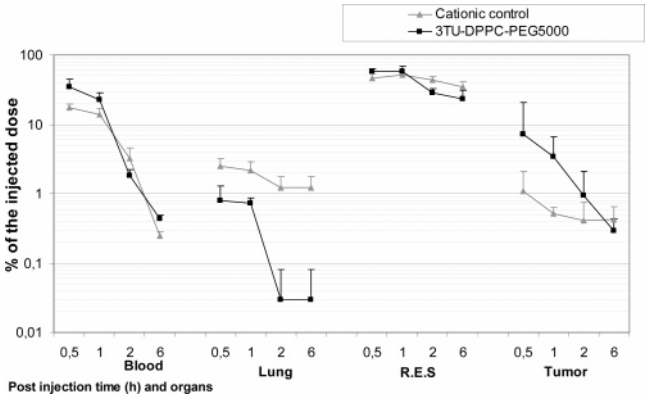

Figure 7. Biodistribution of fluorescently labeled particles. Cationic particles RPR209120/DPPC/cholesterol-PEG$_{2000}$/PE-rhodamine (triangles) used for the control were prepared via the ethanolic injection method as DTTU/DPPC/cholesterol-PEG$_{2000}$/PE-rhodamine particles (squares). Each point is an average of 5 mice + SD.

particles with regard to the cationic controls. Noncationic particles were also recovered in the reticuloendothelial system (liver + spleen) even at the early times. Passive accumulation seems to have occurred since a factor of 6.5 increase was found in the tumor at 30 min postinjection and was maintained after 1 h for noncationic particles versus cationic controls. No increase in transgene expression was found associated to the lipid accumulation, despite the co-injection of lipids/DNA where the plasmid-DNA expressed chloramphenicol acetyl transferase. It has to be noted that a low amount of DNA was injected (10 μg) per mouse.

DISCUSSION

The above data show that the lipopolythiourea DTTU can associate with plasmid DNA and protect it from degradation in serum. To date, this is the first report of a noncationic lipid able to associate to polyanionic DNA at low lipid concentration (*10*) and without addition of divalent cationic ions (*21*). DNA was shown to bind to DPPC zwitterionic lipid bilayers strongly enough to perform AFM studies (*9*, *22*). However, in our conditions, the DPPC binding is not sufficient to retain DNA on agarose wells, compete with ethidium bromide intercalation between DNA base pairs, nor induce a DPPC particle

size increase. The active part played by the lipopolythiourea in the interaction between DNA and DTTU/DPPC was evidenced by formulating DTTU with a cholesterol-PEG instead of DPPC.

Several processes could explain how DNA interaction occurs with DTTU/DPPC particles. The slightly positive zeta potential observed with DTTU/DPPC particles might be explained by the strong polarization of the NH linkage in the thiourea functions, which might be involved in the hydrogen bonds with DNA phosphates. As hypothesized, hydrogen bonds between the DNA phosphate groups and the thiourea headgroups might occur (*23*).

An alternative hypothesis to explain DNA association to neutral lipopolythiourea is to consider the polarization of the lipopolythiourea moiety. One can assume that the negatively polarized sulfur interacts with cationic monovalent or divalent cations from the solution. Such an interaction might account for the positive zeta potential of the DTTU/DPPC liposomes. It might also account for the DNA complexation effect. The involvement of cations has been demonstrated in the case of cochleates which are delivery particles composed of anionic lipids (*20*).

In conclusion, we describe here a new "noncationic" DNA interacting self-assembling system. Because of their very low zeta potential precluding nonspecific binding to plasmatic membrane and adsorption mediated endocytosis, we did not expect DTTU/DPPC/DNA particles to display high transfection efficiency. Indeed, preliminary experiments led to very weak transfection. Targeting DTTU/DPPC/DNA particles to membrane receptor and receptor-mediated transfection might represent the most suitable way to use these new DNA complexing particles for gene transfer. This lipid family might prove to be better tolerated in vivo than cationic DNA delivery vectors. Its ultimate capacity to efficiently deliver plasmid DNA in vitro and in vivo through the use of targeting moieties as well as the study of new polythiourea structures (*24*) is under investigation.

Received July 15, 2004; Revised Manuscript Received September 27, 2004

Four platinum (II) complexes (**13**−**16**) were synthesized by reacting either [Pt *trans*-DACH]$(NO_3)_2$ with a 6-maleimidocaproic acid, a 15-maleimido-4,7,10,13-tetroxapentadecanoic acid, and a 6-maleimido-4-oxacaproic ester derivative of cyclobutane-1,1-dicarboxylic acid (CDBA) or [Pt$(NH_3)_2$]$(NO_3)_2$ with a 6-maleimido-4-oxacaproic ester derivative of CBDA. Both complexes containing the 6-maleimido-4-oxacaproic ester (**15**, **16**) showed good water solubility (≥8 mg/mL) and CE experiments revealed rapid binding to human serum albumin and the formation of biadducts with dGMP and dAMP. In the MaTu xenograft model in nude mice, both complexes showed an improved antitumor effect at their maximum tolerated dose (2 × 50 mg/kg carboplatin equivalents) compared to therapy with carboplatin at equimolar dose or at its optimal dose (2 × 75 mg/kg).

INTRODUCTION

Carboplatin is a potent antineoplastic metal complex in the treatment of ovarian, cervix, and lung carcinoma as well as tumors of the head and neck (*1*). However, therapy with carboplatin causes several side effects such as myelotoxicity, nephrotoxicity, ototoxicity, stomatis, nausea, and vomiting (*1*).

Due to our interest in the role that human plasma proteins play in the in vivo distribution of anticancer metal complexes (*2*, *3*), we set out to develop albumin-binding carboplatin analogues considering that carboplatin shows a low degree of plasma protein-binding and fast renal clearance (*2*). Endogenous albumin is a potential drug carrier because it accumulates in solid tumors due to the pathophysiology of tumor tissue, characterized by angiogenesis, hypervasculature, a defective vascular architecture, and an impaired lymphatic drainage (*4*, *5*).

Recently, we have shown that maleimide derivatives of the anticancer drugs doxorubicin and camptothecin bind rapidly to the cysteine-34 position of circulating albumin after intravenous administration (*6*−*8*). Such designed prodrugs have shown enhanced antitumor efficacy in vivo compared to the respective free drug. An acid-sensitive (6-maleimidocaproyl)hydrazone derivative of doxorubicin, which demonstrated superior antitumor efficacy in several animal models and a significantly improved toxicity profile compared to the clinical standard doxorubicin (*7*), is currently being investigated in a phase I clinical trial.

In this work we synthesized strict analogues of carboplatin containing the bidendate ligand cyclobutane-1,1-dicarboxylic acid (CBDA)[1] that—once bound to human serum albumin (HSA)—would retain or improve the antitumor efficacy of the parent complex. The general structure of such compounds is depicted in Figure 1. The maleimide group was selected as the thiol-binding group owing to its specific and selective reaction with the cysteine-34 position of endogenous albumin. In contrast to our previous design of albumin-binding prodrugs, we did not specifically introduce an acid-sensitive or enzymatically degradable bond in the linker (*7*, *9*), considering that the platinum diammino moiety is released through hydrolysis from the CBDA ligand as the active agent in the tumor cell (*10*, *11*). To date, maleimide derivatives and polymer conjugates containing a diamino-dichloroplatinum(II) moiety (*12*−*14*) or a malonato-diammineplatinum(II) moiety (*15*−*17*) have been developed, but no reports of platinum polymer conjugates with a CBDA ligand have yet appeared in the literature.

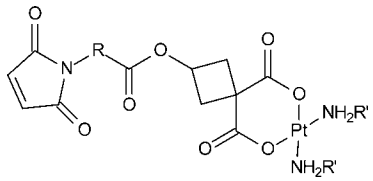

Figure 1. General structure of an albumin-binding carboplatin analogue. R is the backbone of the linker (alkyl or alkoxyalkyl chain). R′ is H or 1,2-cyclohexyl.

In this paper, we report on the synthesis, characterization, and in vitro as well as in vivo efficacy of albumin-binding platinum complexes incorporating cyclobutane-1,1-dicarboxylate and either 1,2-diaminocyclohexane (DACH) or diammine as the amine ligand.

EXPERIMENTAL PROCEDURES

General. Chemicals and solvents were purchased from Sigma-Aldrich, Fluka, and Merck and were used without further purification except for methylene chloride, which was dried over calcium hydride and freshly distilled prior to use. Potassium tetrachloroplatinate was a gift from Degussa (Frankfurt, FRG). Bis(4-methoxybenzyl) malonate was prepared according to the literature (*18*). All organic reactions were carried out under a nitrogen atmosphere. Elemental analysis was performed on a Perkin-Elmer Elemental analyzer 240. HSA (20% solution) was purchased from Dessau Pharma, FRG that contained approximately 35% free thiol groups as assessed with the Ellmann's test. The buffers used were vacuum-filtered through a 0.2 μm membrane (Sartorius, FRG) and thoroughly degassed with argon or nitrogen prior to use. Human blood plasma was obtained from healthy volunteers. Cell culture media, supplements (L-glutamine, antibiotics, trypsin versene/EDTA) and fetal calf serum (FCS) were purchased from Bio Whittaker (Serva, Heidelberg, FRG). All culture flasks were obtained from Greiner Labortechnik (Frickenhausen, FRG).

Spectral Analyses. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker ARX 300. Chemical shifts are expressed as parts per million using tetramethylsilane as the internal standard ($\delta = 0.0$ ppm) or acetone in case of the spectra measured with D_2O. The ^{195}Pt NMR spectrum was recorded on a Varian and refers to K_2PtCl_4 as a standard. Mass spectra were obtained on a Finnigan MAT 312 with associated MAT SS 200 data system using electron spray ionization at 4.0 kV. The infrared spectrum was recorded on a Bruker Vector-22-FTIR.

Chromatography. All organic reactions were monitored by TLC. Column chromatographic separations were carried out as flash chromatography using silica gel 60 from Merck with a particle size of 0.040−0.063 mm. HPLC for the determination of purity of the compounds was performed on a Nucleosil C18 column (100-5, 250 × 4 mm) from Macherey-Nagel using a HPLC pump 590 from Waters (flow: 1 mL/min) and a LKB Bromma UV Detector ($\lambda = 220$ nm). The same HPLC system was also used for the purification of **14**. For incubation studies with albumin or blood plasma, HPLC was performed with a Waters System (pump: Waters 616, detector: Waters 996 Photodiode Array detector and a Merck F-1050 Fluorescence spectrophotometer; controller: Waters 600S, auto sampler: Waters 717; software: Millenium Vers. 2.10; column: Waters, 300 Å, symmetry C18 [4.6 × 250 mm] with precolumn; chromatographic conditions: flow: 1.2 mL/min, mobile phase: 15% CH_3CN, 85% 20 mM potassium phosphate (pH 7.0), mobile phase B: CH_3CN, gradient: 0−25 min 100% mobile phase; 25−40 min increase to 70% CH_3CN, 30% 20 mM potassium phosphate; 40−50 min 70% CH_3CN, 30% 20 mM potassium phosphate; 50−60 min decrease to initial mobile phase; injection volume: 50 μL.

Capillary Electrophoresis. CE for the investigation of albumin binding was performed using a P/ACE 5510 instrument controlled by the P/ACE Station software version 1.21 (Beckman Coulter, USA). An uncoated capillary (37 μm ID, effective separation length 30 cm) was assembled in the P/ACE cartridge. Detection was performed on-line by UV absorption at 214 nm. The following conditions were used: running buffer: 20 mM sodium phosphate, pH 7.4; capillary temperature: 25 °C; separation voltage: 7 kV; injection: pressure 5 psi, 5 s; rinse prior to each analysis: separation buffer 2 min; rinse after each analysis: 0.1 M NaOH 2 min, water 1 min.

The same CE system was also used to study the reaction toward nucleotides. An uncoated capillary (57 μm ID, effective separation length 50 cm) was assembled in the P/ACE cartridge. Detection was performed on-line by UV absorption at 254 nm. The following conditions were used: running buffer: 400 mM borate, pH 9.1; capillary temperature: 18 °C; separation voltage: 25 kV; injection: pressure 5 psi, 5 s; rinse prior to each analysis: separation buffer 1 min; rinse after each analysis: 0.1 M NaOH 1 min, water 1 min.

1,3-Dibromo-2-(*tert*-butyldimethylsiloxy)propane (1). A solution of 1,3-dibromo-2-propanol (50.6 g, 221 mmol) in 25 mL of anhydrous DMF was added dropwise within 10 min to a solution of *tert*-butyldimethylchlorosilane (41.1 g, 265 mmol) and imidazole (33.0 g, 485 mmol) in 200 mL of anhydrous DMF. After stirring of the sample for 16 h at ambient temperature, the mixture was taken up in 800 mL of water and extracted with DCM. The combined organic layers were washed with 3 × 400 mL of water and dried over $MgSO_4$ and the volatiles were removed in vacuo. Purification of the crude product by silica column chromatography (isohexane) yielded 73.4 g (100%) of **1** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 0.13 (s, 6H, Si(CH_3)$_2$), 0.91 (s, 9H, C(CH_3)$_3$), 3.46 (dd, J_1 = 10.6 Hz, J_2 = 4.9 Hz, 2H, CH_2Br), 3.49 (dd, J_1 = 10.6 Hz, J_2 = 5.3 Hz, 2H, CH_2Br), 4.00 ('p', J = 5.1 Hz, 1H, CHOTBS). ^{13}C NMR ($CDCl_3$): δ −4.63 (Si(CH_3)$_2$), 18.06 (C(CH$_3$)$_3$), 25.68 (C(CH_3)$_3$), 35.45 (CH_2Br), 71.25 (CHOTBS). Anal. ($C_9H_{20}Br_2OSi$) C, H, Br.

Bis(4-methoxybenzyl) 3-(*tert*-Butyldimethylsiloxy)-cyclobutane-1,1-dicarboxylate (2). Bis(4-methoxybenzyl) malonate (6.00 g, 17.4 mmol) was added dropwise within 30 min to a suspension of potassium hydride (35% in mineral oil) (2.10 g, 18.3 mmol) in 20 mL of anhydrous dioxane and stirring was continued for 15 min at ambient temperature. Then **1** (6.08 g, 18.29 mmol) was added and the mixture was heated under reflux for 16 h. After cooling of the sample to room temperature, potassium hydride (35% in mineral oil) (2.10 g, 18.3 mmol) suspended in 10 mL of dioxane was added within 1 h and the reaction mixture was heated under reflux for a further 3 days. The hot mixture was filtered over Celite and the solvent was removed in vacuo. Purification of the crude product by silica column chromatography (EtOAc/isohexane 1:10) yielded 2.78 g (31%) of **2** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 0.01 (s, 6H, Si(CH_3)$_2$), 0.85 (s, 9H, C(CH_3)$_3$), 2.41−2.51 (m, 2H, CH_2CHOTBS), 2.74−2.84 (m, 2H, CH_2CHOTBS), 3.79 (s, 6H, ArOCH_3), 4.32 ('p', J = 7.3 Hz, 1H, CHOTBS), 5.04/5.06 (s, 4H, CH_2-Ar), 6.82/6.83 (d, J = 8.7 Hz, 4H, Ar-H), 7.17 (d, J = 8.7 Hz, 4H, Ar-H). ^{13}C NMR ($CDCl_3$): δ −4.86 (Si(CH_3)$_2$), 17.92 (C(CH_3)$_3$), 25.75 (C(CH_3)$_3$), 40.84 (CH_2CHOTBS), 45.90 (C(COOPMB)$_2$), 55.23 (ArOCH_3), 62.02 (CHOTBS), 66.95/67.09 (CH_2Ar), 113.85/113.88, 127.57/127.65, 129.81/129.92, 159.61/159.64 (Ar), 170.80/171.74 (C=O). Anal. ($C_{28}H_{38}O_7Si$) C, H.

Bis(4-methoxybenzyl) 3-Hydroxycyclobutane-1,1-dicarboxylate (3). To a solution of **2** (2.69 g, 5.23 mmol) in 25 mL of anhydrous THF was added TBAF (2.47 g, 7.85 mmol). After stirring of the sample for 15 min at ambient temperature, the volatiles were removed in vacuo. Purification of the crude product by silica column chromatography (EtOAc/isohexane 1:1) yielded 1.85 g (88%) of **3** as a colorless oil which slowly crystallizes. ^{1}H NMR ($CDCl_3$): δ 2.28−2.51 (m, 3H, CH_2CHOH), 2.80−2.91 (m, 2H, CH_2CHOH), 3.78 (s, 6H, ArOCH_3), 4.33 ('p', J = 7.4 Hz, 1H, CHOH), 5.05 (s, 4H, CH_2Ar), 6.82 (d, J = 8.5 Hz, 4H, Ar-H), 7.16/7.17 (d, J = 8.5 Hz, 4H, Ar-H). ^{13}C NMR ($CDCl_3$): δ 40.27 (CH_2CHOH), 46.02 (C-

(COOPMB)$_2$), 55.24 (ArOCH$_3$), 62.22 (CHOH), 67.18 (CH$_2$Ar), 113.92, 127.50, 129.91/129.95, 159.67 (Ar), 171.18/171.42 (C=O). Anal. ($C_{22}H_{24}O_7$) C, H.

***tert*-Butyl 6-Hydroxy-4-oxacaproate (4).** Sodium (65 mg, 2.9 mmol) was added to a solution of ethylene glycol (40.0 mL, 715 mmol) in 100 mL of anhydrous THF, and the mixture was stirred until the sodium dissolved completely. Subsequently, *tert*-butyl acrylate (21.0 mL, 143 mmol) was added dropwise within 2 min to the reaction mixture. After stirring of the sample for 4 days at ambient temperature, the reaction mixture was neutralized with 1 M HCl and the volatiles were removed in vacuo. The oily residue was taken up in 100 mL of water and extracted with 3 × 60 mL of Et_2O. The combined organic layers were dried over $MgSO_4$ and the solvent was removed in vacuo. Purification of the crude product by silica column chromatography (EtOAc/isohexane 1:1) yielded 16.1 g (59%) of **4** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 1.46 (s, 9H, C(CH$_3$)$_3$), 2.51 (t, J = 6.2 Hz, 2H, CH$_2$C(O)O^{t}Bu), 2.81 (bs, 1H, OH), 3.59 (t, J = 4.7 Hz, 2H, OCH$_2$), 3.71 (t, J = 4.7 Hz, 2H, OCH$_2$), 3.73 (t, J = 6.2 Hz, 2H, OCH$_2$). ^{13}C NMR ($CDCl_3$): δ 28.09 (C(CH$_3$)$_3$), 36.15 (CH$_2$C(O)O^{t}Bu), 61.56 (HOCH$_2$), 66.44, 70.28 (OCH$_2$), 80.60 (C(CH$_3$)$_3$), 171.26 (CH$_2$C(O)O^{t}Bu). Anal. ($C_9H_{18}O_4$) C, H.

***tert*-Butyl 6-Maleimido-4-oxacaproate (5).** A stirred solution of **4** (12.3 g, 64.5 mmol) and triphenyl phosphine (12.4 g, 47.3 mmol) in 250 mL of anhydrous THF was cooled to 0 °C. Finely ground maleimide (4.3 g, 43.0 mmol) followed by DIAD (9.7 g, 47.3 mmol) were added and the mixture was kept for 5 min at 0 °C. The cooling bath was removed and stirring was continued for 3 h at room temperature. The volatiles were removed in vacuo and the oily residue was purified by silica column chromatography (EtOAc/isohexane 1:3) yielding 8.0 g (69%) of **5** as a colorless oil which slowly crystallizes. ^{1}H NMR ($CDCl_3$): δ 1.43 (s, 9H, C(CH$_3$)$_3$), 2.43 (t, J = 6.6 Hz, 2H, CH$_2$C(O)O^{t}Bu), 3.51−3.79 (m, 6H, NCH$_2$, OCH$_2$), 6.69 (s, 2H, CH=CH). ^{13}C NMR ($CDCl_3$): δ 28.09 (C(CH$_3$)$_3$), 36.16 (CH$_2$C(O)O^{t}Bu), 37.24 (NCH$_2$), 66.43, 67.55 (OCH$_2$), 80.56 (C(CH$_3$)$_3$), 134.13 (CH=CH), 170.62 (C(O)CH=CHCO), 170.70 (CH$_2$C(O)O^{t}Bu). Anal. ($C_{13}H_{19}NO_5$) C, H, N.

6-Maleimido-4-oxacaproic Acid (6). A solution of **5** (7.09 g, 26.3 mmol) in 20 mL of anhydrous DCM was treated with 20 mL of trifluoroacetic acid and the reaction mixture was stirred for 1 h at ambient temperature. The volatiles were removed in vacuo and the residue was recrystallized from EtOAc/PE 60/80 1:2 yielding 4.90 g (87%) of **6** as a colorless solid. ^{1}H NMR ($CDCl_3$): δ 2.57 (t, J = 6.0 Hz, 2H, CH$_2$COOH), 3.60−3.75 (m, 6H, NCH$_2$, OCH$_2$), 6.72 (s, 2H, CH=CH), 10.56 (bs, 1H, COOH). ^{13}C NMR ($CDCl_3$): δ 34.81 (CH$_2$COOH), 37.11 (NCH$_2$), 65.76, 67.67 (OCH$_2$), 134.18 (CH=CH), 170.74 (C(O)CH=CHCO), 177.16 (COOH). Anal. ($C_9H_{11}NO_5$) C, H, N.

General Procedure for the Esterification of Maleimidocarboxylic Acids with 3. To a solution of **3** (1.97 g, 4.91 mmol), the maleimidocarboxylic acid (7.37 mmol), and triethylamine (2.04 mL, 8.64 mmol) in 30 mL of anhydrous DCM was added 2-chloro-1-methylpyridinium iodide (1.88 g, 7.37 mmol) as a finely ground solid. Stirring was continued for 2 h at room temperature during which the initially cloudy mixture turned into a yellow solution. The mixture was diluted with 140 mL of DCM and washed with 2 × 80 mL of 1 M HCl, 2 × 80 mL of water, and 80 mL of brine. The organic layer was dried over $MgSO_4$, the solvent was removed in vacuo and the residue was purified as described below.

Bis(4-methoxybenzyl) 3-(6-Maleimidohexanoyl)-cyclobutane-1,1-dicarboxylate (7) (from the reaction with EMC). Purification of the crude product by silica column chromatography (chloroform) afforded 2.16 g (74%) of **7** as a colorless oil which slowly crystallizes. ^{1}H NMR ($CDCl_3$): δ 1.22−1.36 (m, 2H, CH$_2$), 1.52−1.74 (m, 4H, CH$_2$), 2.24 (t, J = 7.2 Hz, CH$_2$COO), 2.53−2.64 (m, 2H, CH$_2$CHOR), 2.88−2.99 (m, 2H, CH$_2$CHOR), 3.50 (t, J = 7.4 Hz, 2H, NCH$_2$), 3.80 (s, 6H, ArOCH$_3$), 4.97−5.10 (m, 5H, CHOR, CH$_2$Ar), 6.67 (s, 2H, C(O)CH=CHCO), 6.83 (d, J = 8.3 Hz, 4H, Ar-H), 7.18 (d, J = 8.3 Hz, 4H, Ar-H). ^{13}C NMR ($CDCl_3$): δ 24.24 (CH$_2$), 26.22 (CH$_2$), 28.18 (CH$_2$), 33.84 (CH$_2$COO), 37.17 (CH$_2$CHOR), 37.60 (NCH$_2$), 47.12 (C(COOPMB)$_2$), 55.26 (ArOCH$_3$), 63.77 (CHOR), 67.22/67.35 (CH$_2$Ar), 113.91/113.95, 127.37/127.47, 129.97/130.06 (Ar), 134.07 (C(O)CH=CHCO), 159.70/159.73 (Ar), 170.44, 170.82, 170.89, 172.62 (C(O)-CH=CHCO, C(COOPMB)$_2$, CH$_2$COO). Anal. ($C_{32}H_{35}NO_{10}$) C, H, N.

Bis(4-methoxybenzyl) 3-(15-Maleimido-4,7,10,13-tetroxapentadecanoyl)cyclobutane-1,1-dicarboxylate (8) (from the reaction with 15-maleimido-4,7,10,13-tetroxapentadecanoic acid). Purification of the crude product by silica column chromatography (EtOAc) afforded 3.29 g (92%) of **8** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 2.55 (t, J = 6.4 Hz, 2H, CH$_2$COO), 2.56−2.66 (m, 2H, CH$_2$CHOR), 2.89−2.99 (m, 2H, CH$_2$CHOR), 3.57−3.77 (m, 18H, NCH$_2$, OCH$_2$), 3.80 (s, 6H, ArOCH$_3$), 5.00−5.13 (m, 1H, CHOR), 5.06/5.07 (s, 4H, CH$_2$Ar), 6.69 (s, 2H, C(O)CH=CHCO), 6.83 (d, J = 8.7 Hz, 4H, Ar-H), 7.18 (d, J = 8.7 Hz, 4H, Ar-H). ^{13}C NMR ($CDCl_3$): δ 34.87 (CH$_2$COO), 37.11 (NCH$_2$, CH$_2$CHOR), 47.04 (C(COOPMB)$_2$), 55.24 (ArOCH$_3$), 63.92 (CHOR), 66.57 (OCH$_2$), 67.20/67.34 (CH$_2$Ar), 67.80, 70.04, 70.42, 70.46, 70.53, 70.57, 70.61 (OCH$_2$), 113.89/113.92, 127.33/127.42, 129.97 (Ar), 134.14 (C(O)CH=CHCO), 159.68/159.70 (Ar), 170.38, 170.65, 170.75, 170.86 (C(O)CH=CHCO, C(COOPMB)$_2$, CH$_2$COO).

Bis(4-methoxybenzyl) 3-(6-Maleimido-4-oxacaproyl)cyclobutane-1,1-dicarboxylate (9) (from the reaction with **6**). Purification of the crude product by silica column chromatography (chloroform/MeOH 200:1) afforded 2.89 g (99%) of **9** as a colorless oil. ^{1}H NMR ($CDCl_3$): δ 2.47 (t, J = 6.4 Hz, 2H, CH$_2$COO), 2.54−2.65 (m, 2H, CH$_2$CHOR), 2.88−2.98 (m, 2H, CH$_2$CHOR), 3.55−3.75 (m, 6H, NCH$_2$, OCH$_2$), 3.80 (s, 6H, ArOCH$_3$), 4.97−5.13 (m, 1H, CHOR), 5.06/5.07 (s, 4H, CH$_2$Ar), 6.67 (s, 2H, C(O)CH=CHCO), 6.83 (d, J = 8.7 Hz, 4H, Ar-H), 7.26 (d, J = 8.7 Hz, 4H, Ar-H). ^{13}C NMR ($CDCl_3$): δ 34.84 (CH$_2$COO), 37.13 (NCH$_2$, CH$_2$CHOR), 47.06 (C(COOPMB)$_2$), 55.26 (ArOCH$_3$), 63.97 (CHOR), 65.94 (OCH$_2$), 67.22/67.36 (CH$_2$Ar), 67.68 (OCH$_2$), 113.90/113.94, 127.35/127.45, 129.98/130.00 (Ar), 134.13 (C(O)CH=CHCO), 159.69/159.72 (Ar), 170.39, 170.58, 170.61, 170.91 (C(O)-CH=CHCO, C(COOPMB)$_2$, CH$_2$COO). Anal. ($C_{31}H_{33}NO_{11}$) C, H, N.

General Procedure for the Cleavage of the PMB Protective Groups. A solution of the PMB protected dicarboxylic acid (4.63 mmol) and anisole (7.57 mL, 69.5 mmol) in 50 mL of anhydrous DCM was treated with 10 mL of trifluoroacetic acid at 0 °C. After stirring of the sample for 2 h at 0 °C, the volatiles were removed in vacuo and the residue was purified as described below.

3-(6-Maleimidohexanoyl)cyclobutane-1,1-dicarboxylic Acid (10) (from the reaction with **7**). Purification of the crude product by silica column chromatography (chloroform/MeOH 10:1) afforded 577 mg (35%) of **10** as a colorless sirup. ^{1}H NMR (DMSO-d_6): δ 1.13−1.27 (m, 2H, CH$_2$), 1.41−1.58 (m, 4H, CH$_2$), 2.26 (t, J = 6.8 Hz, CH$_2$COO), 2.35−2.47 (m, 2H, CH$_2$CHOR), 2.70−2.83 (m, 2H, CH$_2$CHOR), 3.38 (t, J = 7.4 Hz, 2H, NCH$_2$), 4.90 ('p',

J = 7.4 Hz, 1H, CHOR), 7.00 (s, 2H, C(O)CH=CHCO), 12.97 (bs, 2H, COOH). ^{13}C NMR (DMSO-d_6): δ 23.67 (CH_2), 25.37 (CH_2), 27.48 (CH_2), 32.99 (CH_2COO), 36.52 (CH_2CHOR), 36.77 (NCH_2), 46.29 (C(COOH)$_2$), 63.18 (CHOR), 134.34 (C(O)CH=CHCO), 170.96, 171.80, 172.08, 172.42 (C(O)CH=CHCO, C(COOH)$_2$, CH_2COO).

3-(15-Maleimido-4,7,10,13-tetroxapentadecanoyl)-cyclobutane-1,1-dicarboxylic Acid (11) (from the reaction with **8**). Purification of the crude product by silica column chromatography (chloroform/MeOH 10:1) afforded 2.00 g (89%) of **11** as a colorless sirup. ^{1}H NMR (DMSO-d_6): δ 2.35−2.56 (m, 4H, CH_2CHOR, CH_2COO), 2.68−2.83 (m, 2H, CH_2CHOR), 3.32−3.66 (m, 18H, NCH_2, OCH_2), 4.92 ('p', J = 7.3 Hz, 1H, CHOR), 7.02 (s, 2H, C(O)CH=CHCO). ^{13}C NMR (DMSO-d_6): δ 34.40 (CH_2COO), 36.49 (CH_2CHOR), 36.73 (NCH_2,), 46.32 (C(COOH)$_2$), 63.33 (CHOR), 65.80, 66.86, 69.33, 69.58, 69.68, 69.71 (OCH_2), 134.46 (C(O)CH=CHCO), 170.45, 170.82, 171.79, 172.42 (C(O)CH=CHCO, C(COOH)$_2$, CH_2COO). ESI-MS (4.0 kV, MeOH): m/z (%) 510.2 ([M+Na]$^+$, 100).

3-(6-Maleimido-4-oxacaproyl)cyclobutane-1,1-dicarboxylic Acid (12) (from the reaction with **9**). Purification of the crude product by silica column chromatography (chloroform/MeOH 20:1) afforded 1.28 g (78%) of **12** as a colorless sirup. ^{1}H NMR ($CDCl_3$): δ 2.53 (t, J = 6.2 Hz, 2H, CH_2COO), 2.64−2.79 (m, 2H, CH_2CHOR), 2.95−3.10 (m, 2H, CH_2CHOR), 3.57−3.77 (m, 6H, NCH_2, OCH_2), 5.05−5.19 (m, 1H, CHOR), 6.74 (s, 2H, C(O)-CH=CHCO), 10.01 (bs, 2H, COOH). ^{13}C NMR ($CDCl_3$): δ 34.83 (CH_2COO), 37.19, 37.30 (NCH_2, CH_2CHOR), 46.78 (C(COOH)$_2$), 64.08 (CHOR), 66.00 (OCH_2), 67.71 (OCH_2), 134.25 (C(O)CH=CHCO), 170.97, 171.09 (C(O)-CH=CHCO, CH_2COO), 174.81, 175.51 (COOH). Anal. ($C_{15}H_{17}NO_9$) C, H, N.

***trans-(R,R/S,S)*-Cyclohexane-1,2-diaminoplatinum(II)-[3-(6-maleimidohexanoyl)cyclobutane-1,1-dicarboxylate] (13).** [Pt *trans*-DACH]$(NO_3)_2$ (263 mg, 607 μmol) was dissolved at 50 °C in 30 mL of water. The solution was cooled to room temperature and **10** (236 mg, 668 μmol) dissolved in 5 mL of 0.01 M KOH was added. The pH was adjusted to pH 5.5 using 0.1 M KOH and the reaction mixture was stirred in the dark for 3 h. After cooling of the sample to 0 °C, the white precipitate was centrifuged, washed two times with 5 mL of water and dried in vacuo yielding 269 mg (67%) of **13** as a colorless powder. ^{1}H NMR (CD_3OD): δ 1.11−1.41 (m, 6H, CH_2, cyclohexyl-H), 1.50−1.70 (m, 6H, CH_2, cyclohexyl-H), 1.93−2.06 (m, 2H, cyclohexyl-H), 2.19−2.40 (m, 4H, CH_2-COO, cyclohexyl-H), 2.70−2.81 (m, 2H, CH_2CHOR), 3.36−3.46 (m, 2H, CH_2CHOR), 3.50 (t, J = 7.4 Hz, 2H, NCH_2), 6.81 (s, 2H, C(O)CH=CHCO). ^{13}C NMR (CD_3-OD): δ 25.44, 25.55, 27.17, 29.18 (CH_2, cyclohexyl), 33.25 (cyclohexyl), 34.78 (CH_2COO), 38.34, 39.94, 40.07 (CH_2-CHOR, NCH_2, cyclohexyl), 51.27 (C(COOH)$_2$), 63.86 (CHOR), 135.38 (C(O)CH=CHCO), 172.64, 174.83 (C(O)-CH=CHCO, CH_2COO), 180.50, 180.78 (C(COOH)$_2$). ESI-MS (4.0 kV, MeOH):

m/z (%) 1343.5 ([2*M+Na]$^+$, 100), 1321.6 ([2*M]$^+$, 22), 683.3 ([M+Na]$^+$, 35), 661.3 ([M]$^+$, 30). Anal. ($C_{22}H_{31}N_3O_8$-Pt) calculated: C: 40.00%, H: 4.73%, N: 6.36%, found: C: 39.45%, H: 4.56%, N: 5.91%. Purity determined by HPLC (water/MeCN 70:30 + 0.05% TFA) >93%.

***trans-(R,R/S,S)*-Cyclohexane-1,2-diaminoplatinum (II)-[3-(15-maleimido-4,7,10,13-tetroxapentadecanoyl-)cyclobutane-1,1-dicarboxylate] (14).** [Pt *trans*-DACH]-$(NO_3)_2$ (175 mg, 405 μmol) was dissolved at 50 °C in 30 mL of water. The solution was cooled to room temperature and **11** (217 mg, 445 μmol) dissolved in 5 mL of water was added. The pH was adjusted to pH 5.5 using 0.1 M KOH and the reaction mixture was stirred in the dark for 3 h. After the solution was concentrated in vacuo to a volume of 5 mL, the yellowish precipitate was removed by centrifugation and the supernatant was purified by preparative HPLC [*Nucleosil* 100−7-C18 column (250 × 15 mm), water/MeCN 80:20 + 0.05% TFA, flow: 20 mL/min, retention time: approximately 20 min]. The eluent was removed in vacuo and the oily product was crystallized by adding 1 mL of 2-propanol yielding 60 mg (19%) of **14** as a colorless solid. ^{1}H NMR (D_2O): δ 0.98−1.35 (m, 4H, cyclohexyl-H), 1.44−1.62 (m, 2H, cyclohexyl-H), 1.94−2.06 (m, 2H, cyclohexyl-H), 2.28−2.48 (m, 2H, cyclohexyl-H), 2.66 (t, J = 6.0 Hz, CH_2COO), 2.80−2.93 (m, 2H, CH_2CHOR), 3.34−3.50 (m, 2H, CH_2-CHOR), 3.54−3.84 (m, 18H, NCH_2, OCH_2), 4.93 ('p', J = 7.1 Hz, 1H, CHOR), 6.85 (s, 2H, C(O)CH=CHCO). ^{13}C NMR (D_2O): δ 24.30 (cyclohexyl), 32.22 (cyclohexyl), 34.91 (CH_2COO), 37.37, 38.54, 38.72 (CH_2CHOR, NCH_2, cyclohexyl), 50.71 (C(COOH)$_2$), 63.05 (CHOR), 65.37, 66.52, 68.02, 69.73, 69.97, 70.01 (OCH_2), 134.86 (C(O)-CH=CHCO), 173.39, 174.11 (C(O)CH=CHCO, CH_2COO), 180.30, 180.47 (C(COOH)$_2$). ^{195}Pt−NMR (D_2O): δ −311. IR (KBr): ν = 3448 (ss, b), 2934 (w, b), 1709 (ss), 1627 (s), 1353 (m), 1094 (ss, b), 696 (w) cm^{-1}. ESI-MS (4.0 kV, MeOH): m/z (%) 816.9 ([M+Na]$^+$, 100). Anal. ($C_{27}H_{41}N_3O_{12}$-Pt*H_2O) C, H, N. Purity determined by HPLC (water/MeCN 80:20 + 0.05% TFA) >94%.

***trans-(R,R/S,S)*-Cyclohexane-1,2-diaminoplatinum(II)-[3-(6-maleimido-4-oxacaproyl)cyclobutane-1,1-dicarboxylate] (15)** [Pt *trans*-DACH]$(NO_3)_2$ (300 mg, 692 μmol) was dissolved at 50 °C in 60 mL of water. The solution was cooled to room temperature and **12** (271 mg, 762 μmol) dissolved in 5 mL of water was added. The pH was adjusted to pH 5.5 using 0.1 M KOH and the reaction mixture was stirred in the dark for 3 h. After the solvent was removed in vacuo, the crude product was purified by silica column chromatography (ethanol) yielding 291 mg (61%) of **15** as a colorless powder. ^{1}H NMR (CD_3OD): δ 0.97−1.29 (m, 4H, cyclohexyl-H), 1.38−1.56 (m, 2H, cyclohexyl-H), 1.81−1.96 (m, 2H, cyclohexyl-H), 2.19−2.36 (m, 2H, cyclohexyl-H), 2.42 (t, J = 5.9 Hz, CH_2-COO), 2.60−2.79 (m, 2H, CH_2CHOR), 3.27−3.41 (m, 2H, CH_2CHOR), 3.46−3.66 (m, 6H, NCH_2, OCH_2), 4.67−4.86 (m, 1H, CHOR), 6.76 (s, 2H, C(O)CH=CHCO). ^{13}C NMR (CD_3OD): δ 25.51, 33.30 (cyclohexyl), 35.92 (CH_2COO), 38.17 (NCH_2), 39.80/40.09 (CH_2CHOR), 51.35 (C(COOH)$_2$), 63.81/63.86 (cyclohexyl-NH_2), 65.66 (CHOR), 67.22, 68.65 (OCH_2), 135.50 (C(O)CH=CHCO), 172.52, 172.80 (C(O)-CH=CHCO, CH_2COO), 180.41, 180.61 (C(*C*OOH)$_2$). ESI-MS (4.0 kV, MeOH): m/z (%) 663.0 ([M+1]$^+$, 100). Anal. ($C_{21}H_{29}N3O_9Pt$) C, H, N. Purity determined by HPLC (water/MeCN 70:30 + 0.05% TFA) >97%.

Diammineplatin(II)-[3-(6-maleimido-4-oxacaproyl)-cyclobutane-1,1-dicarboxylate] (16) *cis*-$[Pt(NH_3)_2]$-$(NO_3)_2$ (485 mg, 1.37 mmol) was dissolved at 50 °C in 60 mL of water. The solution was cooled to room temperature and **12** (538 mg, 1.51 mmol) dissolved in 5 mL of water was added. The pH was adjusted to pH 5.5 using 0.1 M KOH and the reaction mixture was stirred in the dark for 3 h. After the solvent was removed in vacuo, the crude product was purified by silica column chromatography (ethanol) yielding 263 mg (33%) of **16** as a colorless powder. ^{1}H NMR (CD_3OD): δ 2.55 (t, J = 5.9 Hz, CH_2COO), 2.77−2.88 (m, 2H, CH_2CHOR), 3.32−3.44 (m, 2H, CH_2CHOR), 3.63−3.77 (m, 6H, NCH_2, OCH_2), 4.79−4.91 (m, 1H, CHOR), 6.87 (s, 2H, C(O)CH=CHCO). ^{13}C NMR (CD_3OD): δ 35.02 (CH_2COO), 37.52 (NCH_2), 38.70 (CH_2CHOR), 50.67 (C(COOH)$_2$), 65.33 (CHOR),

Table 1. IC_{50} Values [μM][a] for Carboplatin, 15+HSA, and 16+HSA in LXFL 529 Lung Tumor Cells and MaTu Breast Tumor Cells as Determined with the MTT Assay

	IC_{50} [μM][a]	
compound	LXFL 529	MaTu
carboplatin	3.9 ± 0.7	6.4 ± 0.9
15+HSA	21.0 ± 1.6	49.0 ± 2.0
16+HSA	38.0 ± 1.6	41.0 ± 1.8

[a] IC_{50} values (50% inhibitory concentration) represent the mean ± standard deviation (n = 4); similar results were obtained in a further independent experiment.

66.32, 67.90 (OCH_2), 134.81 (C(O)CH=*C*HCO), 173.32, 174.00 (C(O)CH=CHCO, $CH_2CO\overline{O}$). ESI-MS (4.0 kV, MeOH): *m/z* (%) 581.8 ([M]$^+$, 100). Anal. ($C_{15}H_{21}N_3O_9$-Pt) C, H, N. Purity determined by HPLC (water/MeCN 70:30 + 0.05% TFA) >95%.

Albumin-Binding Experiments. 15 and **16** (150 μM) were each incubated with HSA (600 μM) at 37 °C (incubation buffer 4 mM sodium phosphate, pH 7.4). The samples were directly analyzed using capillary electrophoresis after an incubation time of 1, 5, 10, 15, and 20 min. The free compounds and albumin were detected at 214 nm. The linearity of the free compounds was shown between 3 and 300 μM. Blocking of sulfhydryl groups was achieved by preincubating HSA with an excess of EMC for 10 min at 37 °C.

Reactivity of 15 and 16 toward dAMP and dGMP. 15 or **16** (150 μM) was incubated with the nucleotides dAMP and dGMP (150 μM) at 37 °C (incubation buffer 4 mM sodium phosphate, 4 mM sodium chloride pH 7.4). dAMP and dGMP were quantified and the adduct formation was monitored up to 72 h with capillary electrophoresis. Separately incubated oxaliplatin and cisplatin solutions were co-injected to identify the formed adducts.

Cell Culture. The MTT assay was performed in analogy to a literature protocol (*19*). Briefly, approximately 5000 cells were plated in each well of a 96-well tissue culture plate. Medium supplemented with 10% FCS was added and cells were allowed to adhere for 24 h. Subsequently, cells were preincubated with various drug concentrations (0.1−300 μM) for 72 h and then labeled by adding sterile-filtered MTT (5 mg/mL PBS). Cultures were incubated at 37 °C for 2 h. Subsequently, the supernatant was removed and 100 μL of DMSO added to each well. After an incubation time of 10 min, the extinction of the samples was quantified with an ELISA reader (Dynatech Laboratories Inc., Sullyfield, UK) at a wavelength of 570 nm. IC_{50} values (50% inhibitory concentration) were calculated using GraphPad Prism and represent the mean ± standard deviation (n = 4); similar results were obtained in a further independent experiment. For cell culture experiments, a 3 mM stock solution of carboplatin in 10 mM sodium phosphate, 5% D-(+)-glucose, pH 6.4 was prepared. Albumin conjugates with **15** and **16** were prepared by preincubating **15** and **16** (750 μM) with HSA (3000 μM) for 30 min at 37 °C.

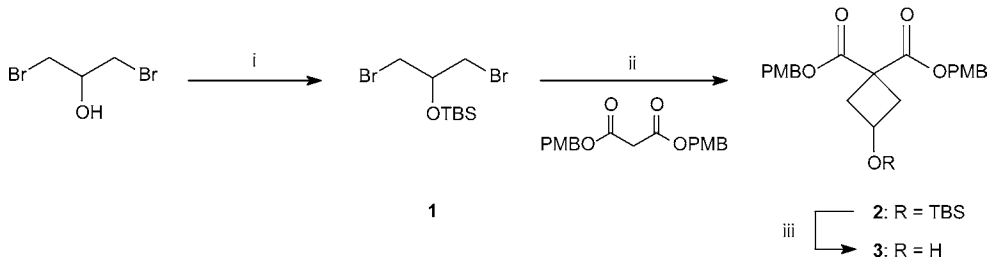
In Vivo Efficacy of 15 and 16. For the in vivo testing of **15** and **16** in comparison with carboplatin female NMRI: nu/nu mice (M&B A/S, Ry, Denmark) were used. The mice were held in laminar flow shelves under sterile and standardized environmental conditions (25 ± 2 °C room temperature, 50 ± 10% relative humidity, 12 h light-dark-rhythm). They received autoclaved food and bedding (ssniff, Soest, Germany) and acidified (pH 4.0) drinking water ad libitum. All animal experiments were performed under the auspices of the German Animal Protection Law.

10^7 cells of MaTu cells from in vitro culture were transplanted subcutaneously (s.c.) into the left flank region of anaesthetized (40 mg/kg i.p. Radenarkon, Asta Medica, Frankfurt, Germany) mice on day zero. Mice were randomly distributed to the experimental groups (8 mice per group). When the tumors were grown to a palpable size, treatment was initiated (see Figure 7 and Table 2). Mice were treated intravenously at day 7 and 14 or 7, 14, and 21, respectively, with either glucose phosphate buffer (10 mM sodium phosphate, 5% D-(+)-glucose, pH 6.4), carboplatin, **15** or **16** dissolved in glucose phosphate buffer; for doses see Table 2 and Figure 7. The injection volume was 0.2 mL/20 g body weight.

Tumor size was measured twice weekly with a calliper-like instrument in two dimensions. Individual tumor volumes *(V)* were calculated by the formula V = (length + [width]^2)/2 and related to the values on the first day of treatment (relative tumor volume, RTV). Statistical analysis was performed with the U-test (Mann and Whitney) with $p < 0.05$. The body weight of mice was determined every 3 to 4 days and the change in body weight (BWC) after initiation of treatment is presented in Figure 8.

RESULTS AND DISCUSSION

Chemistry. For developing water-soluble platinum complexes with CBDA ligands and an albumin-binding maleimide group, the following aspects were considered: (1) The maleimide group is sensitive to base and should therefore be introduced at a late stage of synthesis. (2) The base-sensitivity of the maleimide requires the use of acid-cleavable protection for the carboxylic groups of the CBDA ligand. (3) The synthetic approach should be flexible enough to incorporate different types of spacers (varying in length and number of solubilizing ether groups) between the protein-binding and platinum-binding unit to fine-tune the water solubility of the platinum complexes.



Considering the benefit of a functionalized CBDA ligand that can serve as a universally applicable platinum-binding precursor (e.g., for the development of other macromolecular platin prodrugs), our synthetic route began with the preparation of a hydroxy functionalized

Table 2. Treatment Schedule, Antitumor Activity, and Toxicity Data for Carboplatin, 15, and 16 in Nude Mice Bearing Human Breast Xenografts (MaTu)

CBDA ligand as depicted in Scheme 1. 1,3-Dibromo-2-propanol was TBS protected in a first step and subsequently reacted with bis(4-methoxybenzyl) [bis(PMB)] protected malonic acid forming the four-membered ring under the conditions of a malonic ester synthesis. In the past, acid-cleavable PMB protective groups have proved useful for the synthesis of a carboplatin−cephalosporin conjugate (*18*). Deprotection of the hydroxy group yielded the bis(PMB) protected CBDA derivative **3**, which was further reacted with different maleimidocarboxylic acids as shown in Scheme 3. Our first attempt of preparing albumin-binding carboplatin analogues was to esterify **3** with the commercially available 6-maleimidocaproic acid (EMC). The ligand **10** was obtained after deprotection of the carboxylic acid groups and then further reacted to a first albumin-binding platinum prodrug (**13**) as depicted in Scheme 4. Due to the base-sensitive properties of the maleimide group, we chose a method for complex formation that is carried out in weak acid solution (pH 5.5) employing nitrato complexes of platinum. The precursors with *trans*-DACH and diammine ligands were prepared according to the literature (*20*). **13** with a *trans*-DACH ligand turned out to be poorly water soluble (<1 mg/mL) and precipitation occurred spontaneously during complex formation. To increase water solubility of the complexes that is suitable for intravenous administration, 15-maleimido-4,7,10,13-tetroxapentadecanoic acid with a highly hydrophilic oligo(ethylene glycol) backbone was selected as a linker. In our previous work, the introduction of 3−4 oligo(ethylene glycol) units in the maleimide linker had significantly enhanced water solubility for maleimide derivatives of doxorubicin (*9*), but not for albumin-binding prodrugs of camptothecin (*8*). Using this linker, we prepared a *trans*-DACH complex (**14**) in analogy to **13** (see Schemes 3 and 4). Substituting the hydrophobic EMC for the tetraethylene glycol derivative **9** resulted in a dramatic increase in water solubility (>100 mg/mL). Due to its hydrophilic properties, complex **14** had to be purified by preparative HPLC, which is not practical for large-scale synthesis. Furthermore, molecular modeling of the covalent interaction of maleimide spacers with the cysteine-34 position of HSA suggested that the optimal length of an aliphatic maleimide spacer consists of five to seven carbon atoms

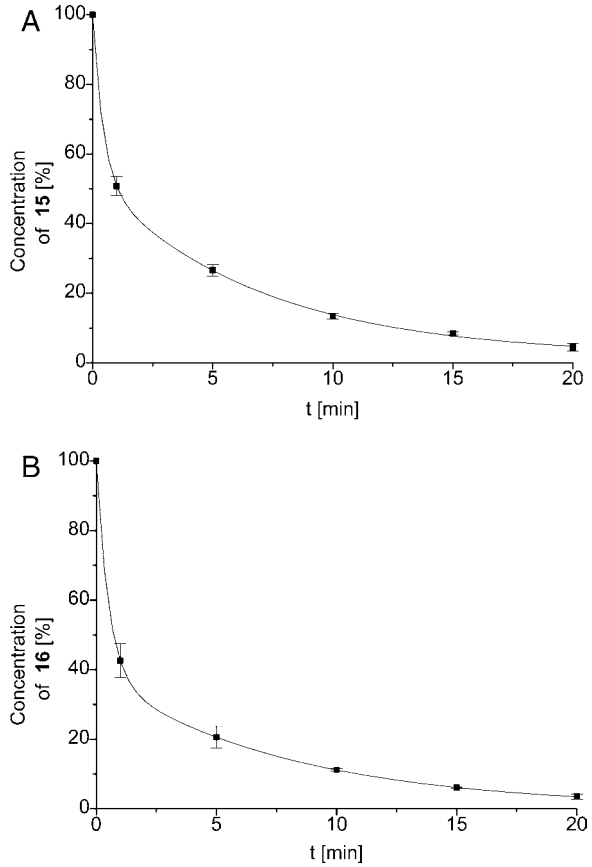

Figure 2. Decrease of free (a) **15** and (b) **16** after incubation with human serum albumin at 37 °C and pH 7.4 ($n = 3$).

(*7*). Therefore, we prepared a maleimide-functionalized linker with a shorter ethylene glycol chain that contained only one ether group (see Scheme 2). Starting with a monoalkylation of ethylene glycol using *tert*-butyl acrylate, the maleimide group was introduced under Mitsunobu conditions. Cleavage of the *tert*-butyl protective group afforded the linker **6**, which was further reacted with compound **3** (see Scheme 3). After removal of the PMB protective groups, ligand **12** was used for complex formation with [Pt *trans*-DACH]$(NO_3)_2$ and *cis*-[Pt$(NH_3)_2$]-

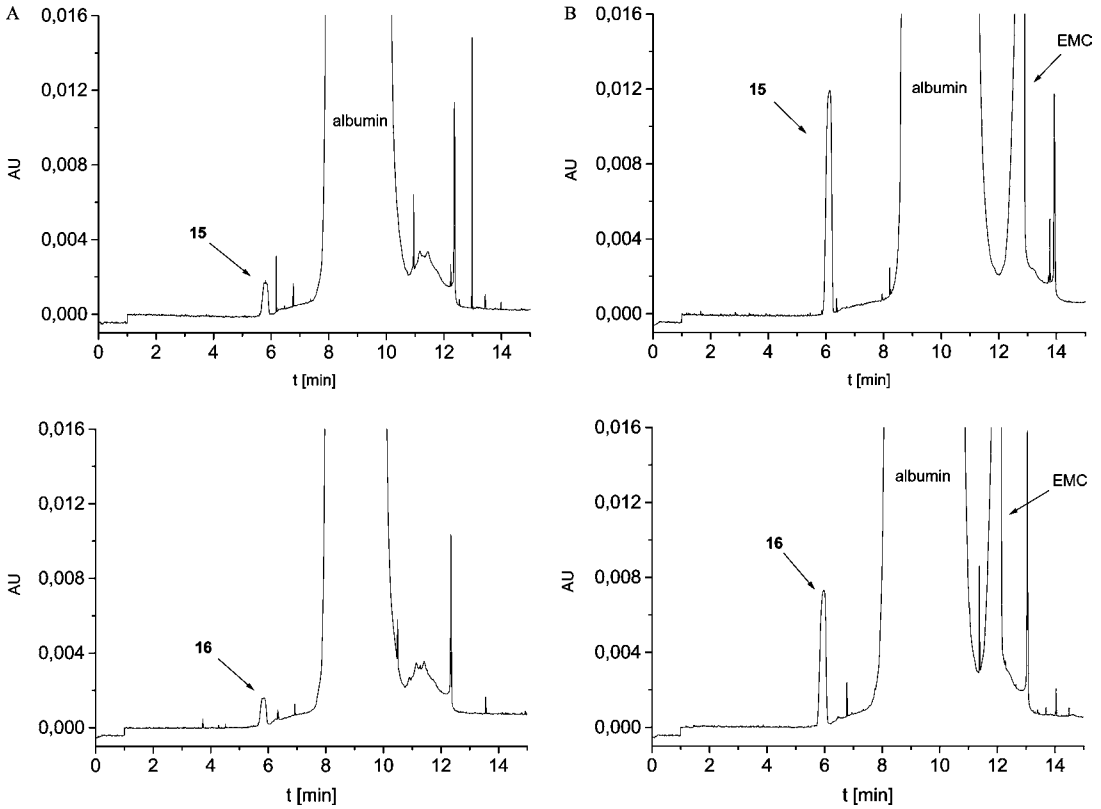

Figure 3. Electropherograms after a 10 min incubation of **15** and **16** (150 μM) with human serum albumin (600 μM) (A) and after a 10-min incubation with EMC-blocked human serum albumin (B).

$(NO_3)_2$ affording **15** and **16**, respectively, in moderate yields (see Scheme 4). **15** and **16** were obtained as colorless solids which were characterized by NMR spectroscopy, mass spectrometry, elemental analysis, and HPLC (see Experimental Section). It is a noteworthy finding that both complexes could be purified by column chromatography on silica gel with ethanol as an eluent, which represents a convenient and previously unknown method for the workup of platinum complexes. Although the water solubility of **15** and **16** was reduced when compared to complex **14**, both were adequately water soluble for assessing their biological activity in animal models (solubility in water was determined to be ~50 mg/mL for **15** and ~8 mg/mL for **16**). It is remarkable that compounds **13** and **15**, which merely differ in one oxygen atom in the chain of the linker, exhibit such dissimilar water solubilities. Substituting a methylene group for an oxygen atom increases the solubility by a factor of approximately 50, in contrast to our recently published work on albumin-binding prodrugs of camptothecin (*8*).

Albumin-Binding Properties of 15 and 16. In our previous work, we could show by mass spectrometry that the maleimide group of doxorubicin derivatives reacts specifically and selectively with the cysteine-34 group of exo- and endogenous HSA (*21*).

To investigate binding of **15** and **16** to albumin, the complexes (150 μM) were incubated at 37 °C with HSA (600 μM), which is a mixture of mercaptalbumin (~35%) and nonmercaptalbumin (~65%) in which the cysteine-34 position is oxidized by sulfhydryl compounds such as cysteine, homocysteine, glutathione, or nitric oxide (*22*–*24*). The samples were directly analyzed by capillary electrophoresis after an incubation time of 1, 5, 10, 15, and 20 min. The decrease in concentration of the platinum complexes **15** and **16** is depicted in Figure 2. Electropherograms recorded 10 min after incubation with HSA are shown in Figure 3.

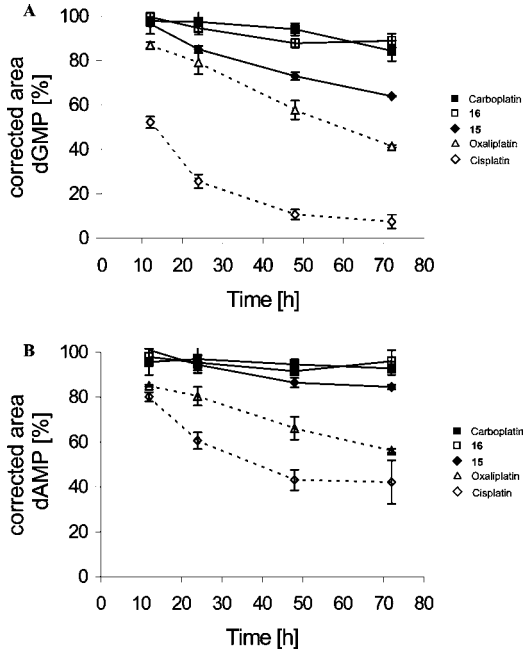

Figure 4. Decrease of dGMP (150 μM, A) and dAMP (150 μM, B) after incubation with **15**, **16**, carboplatin, oxaliplatin, and cisplatin (150 μM).

Approximately 50% of **15** or **16** are bound to albumin within the first minute and after 15 min less than 10% of the free complexes remained. To show that the maleimide group binds to the cysteine-34 position of HSA, experiments were carried out in which the thiol group was blocked by preincubating HSA with an excess of EMC prior to incubation with **15** or **16**. In these experiments, essentially no reaction of **15** or **16** could be

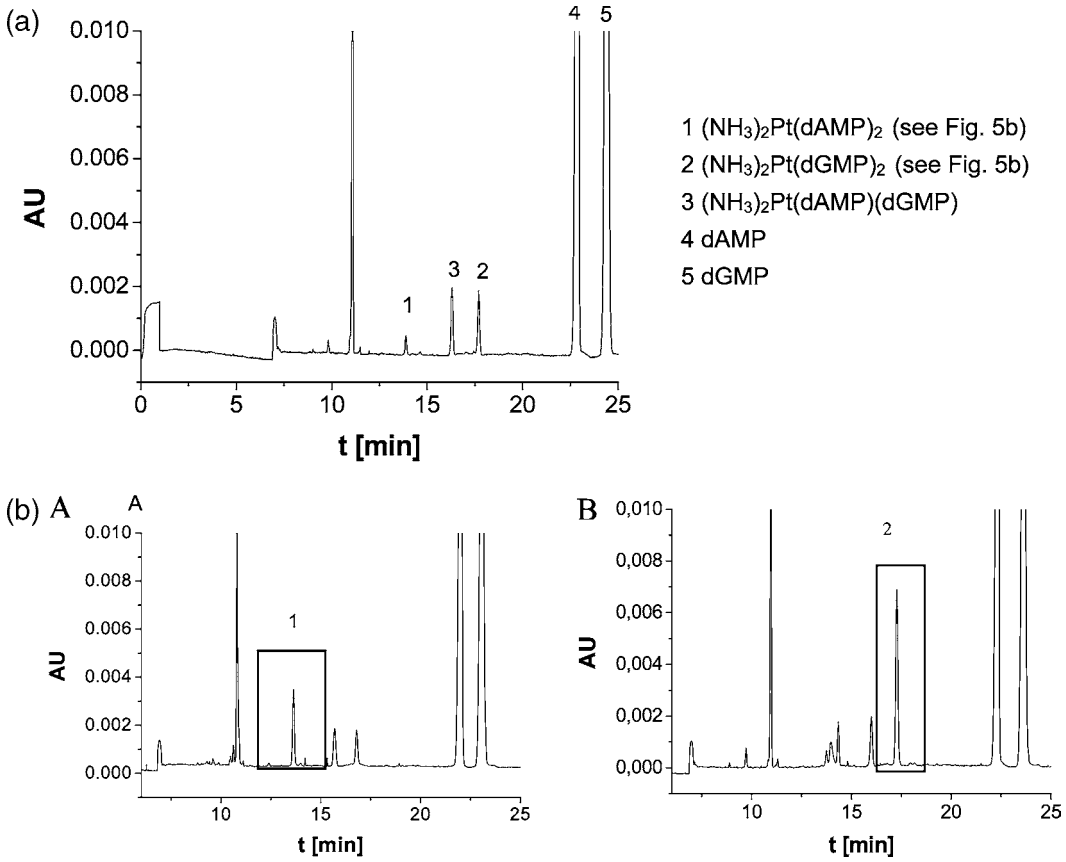

Figure 5. (a) Electropherogram obtained 48 h after incubation of dAMP and dGMP (150 μM each) with **16** (150 μM). (b) Electropherogram obtained 48 h after incubation of dAMP and dGMP (150 μM each) with **16** (150 μM) and co-injection of separately incubated cisplatin with dAMP (A) and dGMP (B).

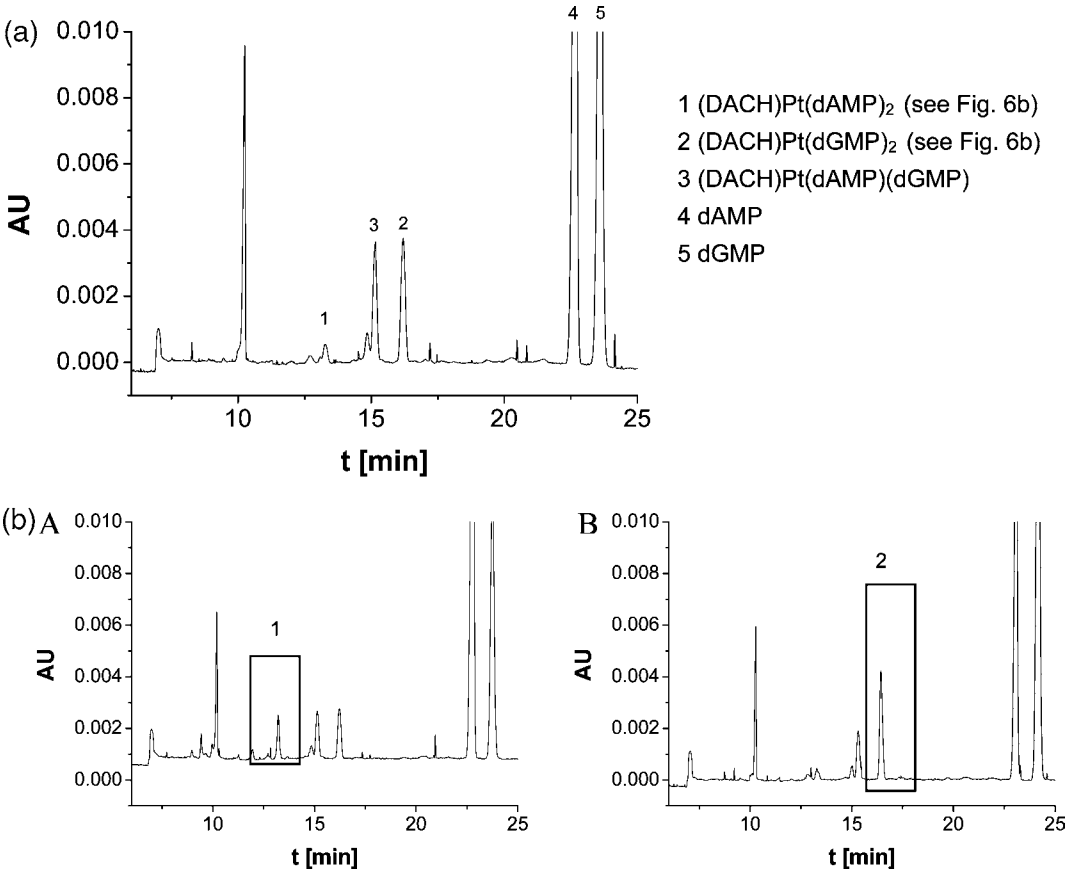

Figure 6. (a) Electropherogram obtained 48 h after incubation of dAMP and dGMP (150 μM each) with **15** (150 μM). (b) Electropherogram obtained 48 h after incubation of dAMP and dGMP (150 μM each) with **15** (150 μM) and co-injection of separately incubated oxaliplatin with dAMP (A) and dGMP (B).

observed after incubating the complexes for 10 min with the blocked albumin (see Figure 3B).

In Vitro Reactivity toward the Nucleotides dAMP and dGMP. To characterize the reactivity of **15** and **16** with DNA nucleotides, the two compounds (150 μM) were incubated each with dAMP and dGMP (150 μM) for 72 h. dAMP and dGMP were quantified up to 72 h using capillary electrophoresis. A higher reactivity of **15** compared to **16** and carboplatin was observed (Figure 4). The formed adducts were identified by co-injection of separately incubated solutions of oxaliplatin (for **15**) or cisplatin (for **16**) since these complexes should form identical adducts. Only biadducts were detected over the period of 72 h (Figures 5a,b and 6a,b).

Antiproliferative Activity against Two Tumor Cell Lines. The antiproliferative activity of the albumin conjugates of the platinum complexes **15** and **16** and of free carboplatin was assessed in the following two tumor cell lines using the MTT assay: LXFL 529 human lung carcinoma and MaTu human mamma carcinoma. The IC_{50} values that were obtained after a 72 h cell exposure are summarized in Table 1. Carboplatin is cytotoxic in both cell lines with IC_{50} values of 3.9 and 6.4 μM, respectively. The albumin conjugates of **15** and **16** are less active in both cell lines (IC_{50} values are 5−8-fold higher), but still showed cytotoxicity compared to controls. These results are in accordance with our experience with albumin conjugates of doxorubicin that were found to be approximately 10-fold less active than the parent compound (*7*).

In Vivo Efficacy against Human MaTu Breast Carcinoma. The two platinum complexes **15** and **16** were evaluated in xenografted nude mice (human MaTu breast carcinoma) in comparison to carboplatin. Both prodrugs were assessed at a dose of 2 × 50 mg/kg and 3 × 25 mg/kg (i.v.) carboplatin equivalents. These doses were selected based on preliminary toxicity studies at a dose of 1 × 50 mg/kg and 1 × 100 mg/kg carboplatin equivalents. Carboplatin was tested at the same doses and additionally at a dose of 2 × 75 mg/kg (i.v.), which is the MTD for carboplatin in nude mice models. Figure 7 shows the results of this experiment (dose schedules are summarized in Table 2, Figure 8 depicts body weight change). Treatment with carboplatin produced low antitumor effects at 3 × 25 mg/kg and 2 × 50 mg/kg with only a marginal reduction in tumor size compared to untreated animals after 35 days. A moderate activity was only observed at the high dose (2 × 75 mg/kg) with a 4-fold increase in tumor size at the end of the experiment compared to controls (optimum T/C value of 50%). Prodrug **16** at the low dose (3 × 25 mg/kg, 75 mg/kg total dose) showed a similar antitumor response compared to therapy with carboplatin at its optimal dose (i.e., twice the dose 2 × 75 mg/kg, 150 mg/kg total dose). (Complex **15** was also evaluated at 3 × 25 mg/kg (i.v.) carboplatin equivalents. However, this dose proved to be above the MTD producing two toxic deaths.) At the higher dose (2 × 50 mg/kg) treatment with **15** and **16** achieved the best efficacy, which resulted in a 2.5−3-fold increase in tumor size at the end of the experiment (optimum T/C values of 45 and 50%, respectively). This antitumor effect was significant to untreated animals ($p < 0.05$), whereas the effects achieved with carboplatin were not found to be significant at any dose. The carboplatin derivative (**16**) shows a change in body weight that is similar to the parent compound (BWC between −6 to −8% at all doses). In contrast, platinum complex **15** with the DACH ligand exhibited a higher toxicity (BWC: −15%).

CONCLUSIONS

This work focused on the development of novel albumin-binding derivatives of carboplatin analogues consisting of a thiol-binding maleimide group attached through a spacer molecule to a derivatized CBDA ligand as the platinum-complexing unit. We established a convenient synthesis for the ligand based on the esterification of a maleimidocarboxylic acid with a hydroxy functionalized bis(PMB) protected CBDA derivative (**3**) that could be readily prepared in a three-step procedure starting with 1,3-dibromo-2-propanol and including a malonate synthesis to form the four-membered ring. The number of

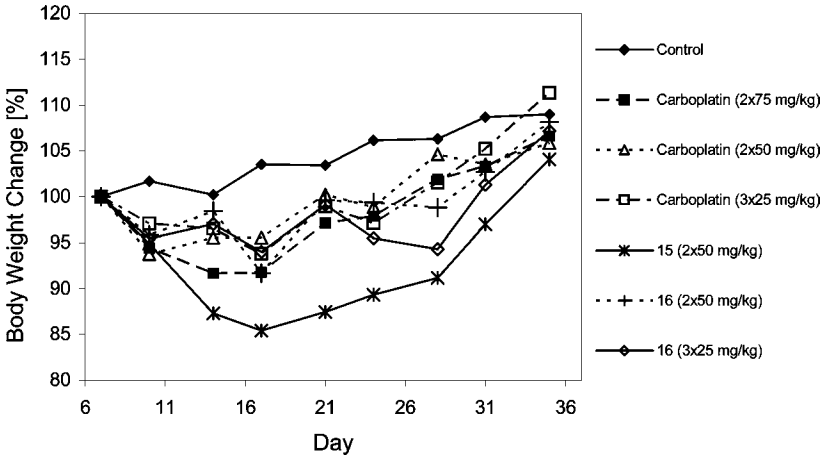

Figure 8. Curves depicting body weight change (BWC) of mice bearing subcutaneous MaTu xenografts under therapy with carboplatin, **15**, and **16**.

ethylene glycol units present in the spacer had a pronounced influence on water solubility of the developed platinum complexes, and one ether bond rendered good water solubility that was sufficient for preclinical assessment.

Both **15** and **16** were as or more effective than carboplatin in reducing the tumor size of nude mice bearing MaTu human breast tumors. **16**, the strict analogue of carboplatin, proved to be less toxic than **15** containing the DACH ligand and has been selected for further studies with respect to its mode of action on the cellular level and its antitumor efficacy in other preclinical models.

Design of Metalloporphyrin−Carbohydrate Conjugates for a New Superoxide Dismutase Mimic with Cellular Recognition

Shoichiro Asayama,* Kaori Mizushima, Shoji Nagaoka, and Hiroyoshi Kawakami

Department of Applied Chemistry, Tokyo Metropolitan University, 1-1 Minami-Osawa, Hachioji, Tokyo 192-0397, Japan. Received June 11, 2004; Revised Manuscript Received August 18, 2004

Metalloporphyrin−carbohydrate conjugates have been synthesized as superoxide dismutase (SOD) mimics with cellular recognition. To synthesize the conjugates, aliphatic primary amino groups for conjugation were introduced, with the cationic pyridyl groups for the SOD activity of porphyrin preserved. The reductive amination between introduced amino groups and the reducing end of lactose was then carried out. The resulting conjugates consisting of manganese (Mn)-porphyrin surrounded by several lactose molecules possessed significant SOD activity and low cytotoxicity. Compared with metalloporphyrins having no lactose molecule, the recognition of the resulting conjugates by human hepatoma HepG2 cells increased. The cellular recognition was inhibited by competitors of β-galactose. These results suggest that the Mn-porphyrin−lactose conjugates recognized the hepatic lectin on the cell surface.

INTRODUCTION

Reactive oxygen species (ROS[1]) are considered to be implicated in the pathogenesis of a number of diseases, such as atherosclerosis, cancer, and Alzheimer's disease (*1*−*3*). Their toxic effects are amplified by pathological events including neutrophil activation, hyperoxia, metabolism of redox-active drugs, radiation exposure, and ischemia/reperfusion. Subsequently, the overproduced ROS, such as superoxide radical anion ($O_2^{\bullet-}$), cause the membrane damage resulting from lipid peroxidation, as well as the attack on proteins and nucleic acids. Therefore, antioxidant enzymes are useful for the therapy of ROS-mediated injuries and diseases.

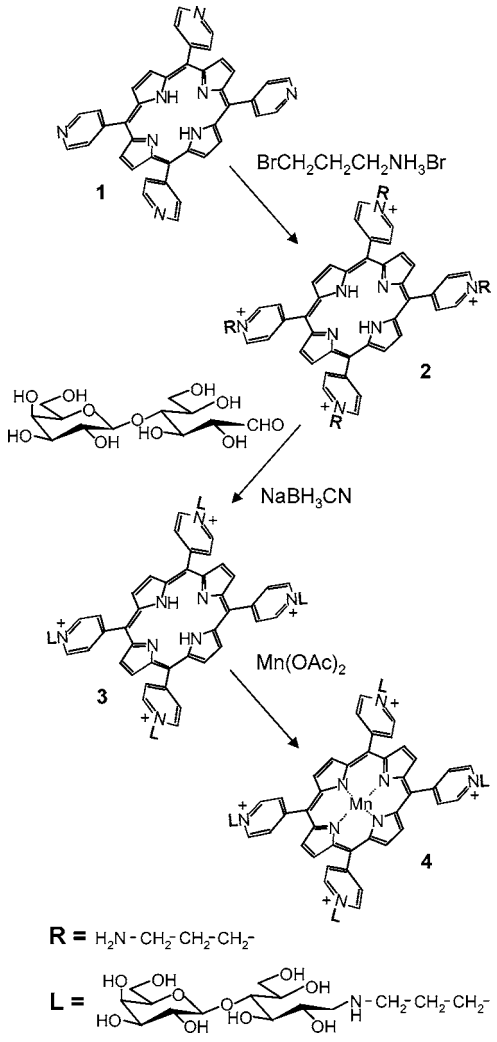
Superoxide dismutase (SOD) catalyzing the reduction from $O_2^{\bullet-}$ to H_2O_2 is the key enzyme for the protection from oxidative stress. As a defense mechanism against microorganisms and various exogenous compounds (*4*), on the other hand, phagocytic cells, i.e., neutrophils, monocytes, and macrophages, generate ROS during the respiratory burst by membrane-bound NADPH oxidase (*5*). These merits and demerits of ROS have led us to create a drug delivery system using SOD to reduce oxidative stress.

Fridovich and co-workers have reported that manganese porphyrins (Mn-porphyrins) are promising compounds as SOD mimics with chemical versatility (*6*). Subsequently, we have synthesized a macromolecular Mn-porphyrin for enhancing half-life in the blood circulation (*7*). However, these Mn-porphyrins lack the ability to target cells that overproduce $O_2^{\bullet-}$, although the selective delivery of SOD mimics into every particular cell is promising for a radical approach (*8*) to various therapies.

In this study, we have synthesized a new SOD mimic with the carbohydrate to facilitate receptor binding and hence active targeting. Carbohydrates are known as various ligands of cell surface lectins (*9*, *10*). In particular, the triantennary carbohydrate containing three terminal β-galactose residues is a high affinity ligand for a hepatic lectin, asialoglycoprotein receptor (ASGP-R) (*11*). Therefore, the Mn-porphyrin with several β-galactose residues is expected to be recognized by the ASGP-R expressed on hepatocytes or hepatoma cells, so we have designed new SOD mimic Mn-porphyrin−lactose (4-*O*-β-D-galactopyranosyl-D-glucose) conjugates with cellular recognition.

EXPERIMENTAL PROCEDURES

Materials. Pyridine-4-aldehyde and pyrrole were purchased from Tokyo Kasei Kogyo Co. Propionic acid, acetic anhydride, 3-bromopropylamine hydrobromide, lactose monohydrate, sodium cyanoborohydride ($NaBH_3CN$), and $Mn(OAc)_2{\cdot}4H_2O$ were from Kanto Chemical Co. 4-(2-Hydroxyethyl)-1-piperazinylethanesulfonic acid (HEPES) and dimethyl sulfoxide (DMSO) were purchased from Nacalai Tesque Inc. Potassium superoxide (KO_2) was purchased from Aldrich Chemical Co., and asialofetuin was from Sigma Chemical Co.



Synthesis of Mn-Porphyrin−Lactose Conjugates. The synthetic route of the conjugates is shown in Scheme 1. 5,10,15,20-Tetrakis(4-pyridyl)porphine (**1**) was synthesized, as reported in the literature (*12*). The typical procedure for the synthesis of Mn-porphyrin−lactose conjugates is as follows: the hydrophobic **1** (0.3 g, 0.5 mmol) was reacted with 3-bromopropylamine hydrobromide (3 g, 14 mmol) in DMF for 3 days under refluxing conditions. After the reaction, the mixture was dried on a rotary evaporator, followed by the extraction with water in methylene chloride. The PF_6^- salt of the porphyrin **2** was precipitated by the addition of a concentrated aqueous solution of NH_4PF_6. The compound was then dissolved in acetone, and a concentrated acetone solution of tetraethylammonium chloride was added, until the majority of the porphyrin **2** had precipitated in the form of its chloride salt. The precipitate was washed thoroughly with acetone, dissolved in methanol, and dried in vacuo. **2**: ^{1}H NMR (DMSO-d_6, 270 MHz) δ −3.0 (s,

2H, inner H), 3.5 (CH_2N), 5.0 (8H, N^+CH_2), 9.0 (8H, pyridinium), 9.3 (s, 8H, β-pyrrole), 9.7 (8H, pyridinium); λ_{max} (H_2O) 422, 519, 586, 643 nm.

The resulting water-soluble porphyrin **2** (0.04 g, 0.04 mmol) and lactose monohydrate (0.4 g, 1.1 mmol) were preincubated at 40 °C for 3 days in 4 mL of sodium borate buffer (0.1 M, pH 8.5). Then, a reducing agent, $NaBH_3CN$, was added to the mixture of **2** and lactose at a final concentration of 0.3 M. The reaction mixture was incubated at 40 °C for 4 days, followed by dialysis against distilled water using a Spectra/Por CE (cellulose ester) membrane (molecular weight cutoff = 500) to remove unreacted lactose. The resulting conjugate **3** was obtained by freeze-drying. **3**: ^{1}H NMR (DMSO-d_6, 270 MHz) δ −3.1 (s, 2H, inner H), 3.2–5.1 (CH protons of lactose), 9.0–9.6 (CH protons of porphyrin); λ_{max} (H_2O) 422, 519, 582, 640 nm.

The resulting porphyrin **3** and an equivalent amount of $Mn(OAc)_2{\cdot}4H_2O$ were incubated in H_2O at 40 °C for 24 h. The reaction was monitored by UV–visible spectroscopy and was stopped when the Soret band shift was completed (from 422 to 464 nm). The reaction mixture was dialyzed again against distilled water (molecular weight cutoff = 500). The resulting metalloporphyrin **4** was obtained by freeze-drying. **4**: λ_{max} (H_2O) 378, 400, 464, 561, 678 nm.

Stopped-Flow Kinetic Analysis. The rate constant (k_c) of the $O_2^{\bullet-}$ dismutation was measured with an SX.18MV stopped-flow spectrometer purchased from Applied Photophysics Ltd., UK, according to the literature (*13*). A DMSO solution of KO_2 was rapidly mixed with a HEPES buffer solution at pH 8.1 and 36 °C to give $O_2^{\bullet-}$ (*14*). The decay of $O_2^{\bullet-}$ was spectrophotometrically monitored at 245 nm (*15*). In the experimental runs, the points of 1000 data were acquired using a time basis of 1 s for monitoring the reaction. The absorbance data were processed to obtain an observed rate constant (k_{obs}) which was calculated from the slop of the plot of ln(absorbance at 245 nm) versus time. The k_c was determined from the slop of a plot of k_{obs} versus the concentration of the metalloporphyrins. The rate constants were determined from the mean of at least 20 experiments.

Cell Viability Assay. HepG2 cells (a gift from the Japan Health Sciences Foundation), human hepatoma cell line, were cultured in tissue culture flasks containing EMEM supplemented with 10% heat-inactivated fetal bovine serum. The cells were seeded at 5×10^3 cells/well in a 96-well plate and incubated overnight at 37 °C in a 5% CO_2 incubator. The cells were treated with each metalloporphyrin (0–100 μM) and incubated for 18 h at 37 °C. By further incubation for 5 h (approximately total 24 h), the cell viability was measured using the Alamar Blue assay (*16*) in quadruplicate.

Recognition of Mn-Porphyrin–Lactose Conjugates by HepG2 Cells. HepG2 cells were incubated in 75-cm^2 tissue culture flasks containing EMEM supplemented with 10% heat-inactivated fetal bovine serum. After confluent growth, each metalloporphyrin (100 μM) was added to the adherent cells, followed by the incubation for 24 h at 37 °C. For the competition assay, the Mn-porphyrin–lactose conjugates were incubated for 24 h at 37 °C in the presence of 4 mM lactose or 1 mg/mL of asialofetuin. The resulting cells were detached, counted, and washed with PBS (−) to remove free metalloporphyrins. Then, the cell lysis was obtained by adding 4 mL of 0.5 N HNO_3. The manganese in the lysis was determined by atomic absorption spectrometry at 403 nm using a Varian SpectraAA-640 (Varian Australia Pty., Ltd., Australia).

RESULTS AND DISCUSSION

Synthesis of Mn-Porphyrin–Lactose Conjugates. To deliver SOD mimics into hepatoma cells, we have designed a Mn-porphyrin–lactose conjugate, as shown in Scheme 1. For SOD activity, cationic pyridyl groups are necessary. Furthermore, for the conjugation of biomolecules, aliphatic primary amino groups are selected, due to the ease of chemical modification (*17*), e.g., ϵ-amino groups of lysine residues of a protein. To introduce cationic pyridyl groups and primary amino groups at once, we have reacted the hydrophobic porphyrin **1** with 3-bromopropylamine. The resulting water-soluble porphyrin **2** was subjected to reductive amination (*18*) between the introduced amino groups and the reducing end of lactose using $NaBH_3CN$ as a reducing agent. As shown in Figure 1, the spectrum of the freebase porphyrin **3** shifted completely after Mn introduction; namely, the Soret band was completely shifted from 422 to 464 nm. The resulting spectrum of the metalloporphyrin **4** exhibited no turbidity, which suggested that the Mn-porphyrin–lactose conjugate **4** was water-soluble. On average, the lactose content of the purified conjugate was estimated to be about 2.5 molecules per metalloporphyrin backbone by the phenol–sulfuric acid method (*19*), with lactose as the standard.

SOD Activity of Mn-Porphyrin–Lactose Conjugates. The resulting Mn-porphyrin–lactose conjugate

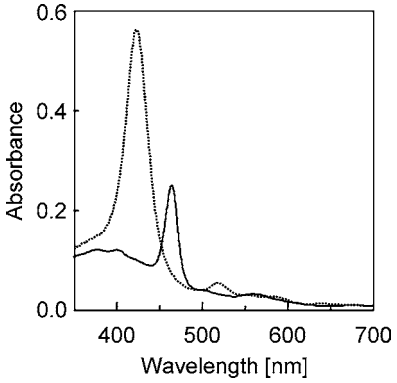

Figure 1. Optical spectra of the porphyrin−lactose conjugate before (dotted line) and after (solid line) Mn introduction. Both spectra were obtained at 5 μM porphyrin concentration in H_2O.

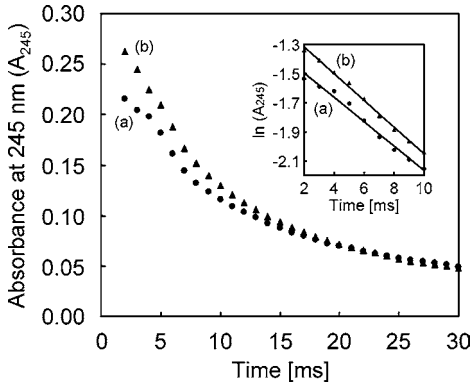

Figure 2. Stopped-flow traces of the conjugate-catalyzed decay of superoxide. The decay of superoxide was monitored spectrophotometrically at 245 nm and 37 °C. Inset: the first-order decay of superoxide. The concentration of the Mn-porphyrin−lactose conjugate was (a) 0 μM and (b) 0.5 μM.

Table 1. SOD Activity of Mn-Porphyrins

porphyrin	k_c, 10^6 M^{-1} s^{-1}
Mn-MPyP[a]	14(±1.6)
Mn-LacAPPyP[b]	5.6(±1.6)

[a] L = CH_3 in Scheme 1. [b] **4** in Scheme 1.

consists of a SOD mimic surrounded by several targeting ligands. To examine the SOD activity of the conjugate, we used the stopped-flow kinetic analysis technique developed for detecting and quantifying the dismutation of $O_2^{\bullet-}$. The decay of $O_2^{\bullet-}$ was spectrophotometrically monitored at 245 nm, the absorbance maximum for superoxide, with a stopped-flow spectrometer. Figure 2 shows the conjugate-induced decay of $O_2^{\bullet-}$. An observed rate constant (k_{obs}) was obtained from the slope of a plot of ln(absorbance at 245 nm) versus time (Figure 2, inset). Finally, the catalytic rate constant (k_c) was determined from the slope of a plot of k_{obs} versus conjugate concentration (0−4 μM). As shown in Table 1, the k_c value for the conjugate was 5.6(±1.6) × 10^6 M^{-1} s^{-1}, while that for Mn-porphyrin (L = CH_3 in Scheme 1) was 14(±1.6) × 10^6 M^{-1} s^{-1} under these conditions. It can be said that the Mn-porphyrin−lactose conjugate showed significant SOD activity despite the chemical modification of the metalloporphyrin. The native SOD enzymes react with $O_2^{\bullet-}$ at rate in the range 10^8 M^{-1} s^{-1} for mitochondrial Mn-SOD (*20*) and at the near-diffusion-limited rate of 2 × 10^9 M^{-1} s^{-1} for Cu,Zn-SOD (*21*). These metalloenzymes are, however, found at micromolar intracellular concentrations (*22*). If the new SOD mimics are concentrated at an intracellular site, the apparent activity of the enzyme is expected to increase.

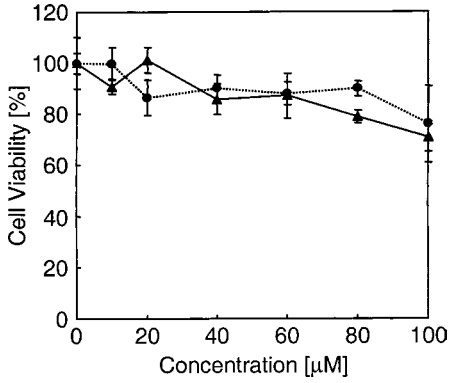

Figure 3. Effect of Mn-porphyrin derivatives on the viability of HepG2 cells after 1 day incubation: (●) Mn-porphyrin (L = CH_3 in Scheme 1); (▲) Mn-porphyrin−lactose conjugate. Symbols and error bars represent the mean and standard deviation of the measurements made in quadruplicate wells.

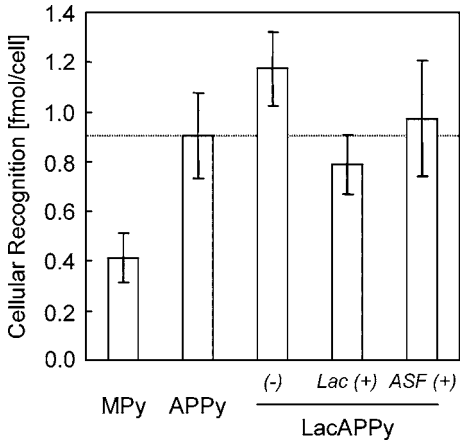

Figure 4. Cellular recognition of Mn-porphyrin derivatives by HepG2 cells. HepG2 cells were incubated with 100 μM normal Mn-porphyrin (L = CH_3 in Scheme 1; MPy), Mn-porphyrin precursor without lactose (L = R in Scheme 1; APPy), or Mn-porphyrin−lactose conjugate (LacAPPy). For competition, the Mn-porphyrin−lactose conjugates were incubated in the presence of 4 mM lactose (*Lac*(+)) or 1 mg/mL of asialofetuin (*ASF*(+)). Error bars represent the mean and standard deviation of the measurements made in at least triplicate.

Cellular Recognition of Mn-Porphyrin−Lactose Conjugates. To confirm the required property as antioxidant, we first carried out a cytotoxicity assay. Figure 3 shows the effect of the Mn-porphyrin−lactose conjugates on the viability of HepG2 cells after 1 day incubation. The cell viability did not significantly decrease when the conjugates were added up to the concentration of 100 μM. The control metalloporphyrin exhibited the almost same tendency as the conjugate. These results suggest that the Mn-porphyrin−lactose conjugates with no apparent cytotoxicity promised effective antioxidative activity.

As a result of no apparent cytotoxicity, we finally examined whether the Mn-porphyrin−lactose conjugates were specifically recognized by HepG2 cells. HepG2 cells are a human hepatoma cell line, so that ASGP-Rs are expressed on the cell surface (*23*). Figure 4 shows the recognition of Mn-porphyrin derivatives by HepG2 cells. The amount of Mn-porphyrin−lactose conjugates recognized by the cells was 1.2 ± 0.15 fmol/cell, which was approximately thrice greater than that of normal Mn-porphyrin (L = CH_3 in Scheme 1; 0.4 ± 0.10 fmol/cell). In the presence of approximately 10 equiv of free lactose molecules (4 mM), however, the recognition of Mn-porphyrin−lactose conjugates significantly (P < 0.01)

decreased up to 0.8 ± 0.16 fmol/cell, which was the almost same level of the Mn-porphyrin precursor without lactose (L = R in Scheme 1; 0.9 ± 0.17 fmol/cell). Furthermore, an asialoglycoprotein, asialofetuin (1 mg/mL), also inhibited the recognition between the Mn-porphyrin−lactose conjugate and HepG2 cells. These results suggest that the cellular recognition of the conjugates was inhibited by the competition of lactose molecules with β-galactose. The inhibition up to nonspecific interaction level (see Figure 4, dotted line) led us to consider that the conjugate recognized the HepG2 cells via asialoglycoprotein receptors on cell surface.

CONCLUSION

We have synthesized a new SOD mimic Mn-porphyrin−lactose conjugate. The resulting conjugate showed significant SOD activity, negligible cytotoxicity, and cellular recognition. From a practical point of view, the protective effects of the targeted conjugate against oxidative stress are important, so the protective experiments are now in progress. We expected that the new SOD mimic synthesized in this study would be the first step in targeting the various cells that overproduce $O_2^{\bullet-}$, through the interaction with carbohydrate-binding receptors.

In Vitro Cytotoxicity and in Vivo Distribution after Direct Delivery of PEG–Camptothecin Conjugates to the Rat Brain

Alison B. Fleming,[†] Kraig Haverstick,[†] and W. Mark Saltzman*,[†,‡]

School of Chemical and Biomolecular Engineering, Cornell University, 120 Olin Hall, Ithaca, New York 14853, and Department of Biomedical Engineering, Yale University, 227 Becton Center, New Haven, Connecticut 06511. Received September 30, 2003; Revised Manuscript Received September 2, 2004

Low water solubility and rapid elimination from the brain inhibits local delivery via implants and other delivery systems of most therapeutic drugs to the brain. We have conjugated the chemotherapy drug, camptothecin (CPT), to poly(ethylene glycol) (PEG) of molecular weight 3400 using previously established protocols. These new conjugates are very water-soluble and hydrolyze at a pH-dependent rate to release the active parent drug. We have studied the uptake of these conjugates by cells in vitro and quantified their cytotoxicity toward gliosarcoma cells. These conjugates were loaded into biodegradable polymeric controlled-release implants, and their release characteristics were studied in vitro. We implanted similar polymeric disks into rat brains and used a novel sectioning scheme to determine the concentration profile of CPT in comparison to conjugated CPT in the brain after 1, 7, 14, and 28 days. We have found that PEGylation greatly increases the maximum achievable drug concentration and greatly enhances the distribution properties of CPT, compared to corelease of CPT with PEG. Although only one percent of CPT in the conjugate system was found in the hydrolyzed, active form, drug concentrations were still significantly above cytotoxic levels over a greater distance for the conjugate system. On the basis of these results, we believe that PEGylation shows great promise toward increasing drug distribution after direct, local delivery in the brain for enhanced efficacy in drug treatment.

INTRODUCTION

Camptothecin, first isolated from the Chinese tree *Camptotheca acuminata* in the 1960s (*1*), is a potent anticancer agent that targets the DNA-unwinding enzyme topoisomerase I in the cell nucleus. Due to camptothecin's extremely low aqueous solubility, there has been much interest in the synthesis of more water-soluble derivatives. This effort has resulted in FDA approval of two small molecule analogues, topotecan and irinotecan, and also in the creation of CPT[1]–polymer conjugates. Camptothecin has been conjugated to several polymers including poly(ethylene glycol) (*2*), dextran (*3*), poly(L-glutamic acid) (*4*), and *N*-(2-hydroxypropyl)methacrylamide (*5*).

Camptothecin is a planar molecule composed of five rings (see Figure 1A). Of these rings, the α-hydroxy-δ-lactone moiety (ring E) is thought to be critical for cytotoxic activity. This lactone ring is subject to reversible hydrolysis to an open carboxylate form in aqueous solution with the dominant form at equilibrium depending on the pH of the solution. More specifically, it has been shown that the majority of camptothecin will be in the lactone form at pH <5, whereas the carboxylate form

predominates at pH >8 (*6*). This has important implications for the efficacy of delivered camptothecin, since the open-ring carboxylate (i.e. the inactive form) will be favored at physiological pH.

Most attempts to increase the solubility of CPT have focused on stable substitutions at rings A and B (*7*). Although such substitutions may solve the problem of solubility, they have no effect on the rate of lactone hydrolysis (*8*). An alternative strategy is to modify the lactone moiety reversibly in order to create a water-soluble "prodrug" capable of releasing active-lactone CPT via hydrolysis or enzyme-mediated processes. The success of such PEG conjugates has been recently reviewed (*9*). This approach has been utilized in the creation of PEG−CPT conjugates for systemic administration (*1*, *7*, *10*, *11*). In these studies, attachment to PEG of molecular weight 40 000 (PEG40000) achieved water solubility, an increased residence time in the circulation, and stabilization of the essential lactone ring. CPT was linked to PEG40000 via a water-labile ester bond, and it was found that employing different spacer groups could alter the hydrolysis rate of the resulting conjugate (*12*).

In previous work, we showed that local controlled delivery of anticancer compounds could provide cytotoxic levels of agents in the brain tissue for prolonged periods of time (*13*, *14*); however, the volume of treatment is limited by the ability of drug molecules to penetrate into the local tissue before they are eliminated (*13*). We hypothesized that optimal local delivery requires agents that are both water-soluble, to prevent rapid clearance through capillary permeation, and stable in the brain extracellular space (*15*); conjugates of active drugs with inert polymers may provide these features (*16*). Therefore, we sought to synthesize PEG−CPT conjugates appropriate for local delivery to the brain using modifications of a previously published chemical approach (*12*).

PEG−camptothecin conjugates theoretically meet basic requirements for a successful polymeric carrier system for localized, direct drug delivery to the brain. Previously reported promising PEGylated drug conjugates relied on high molecular weight PEG to increase the circulation time of the conjugate during systemic delivery (*9*). In the present case of local delivery to the brain by diffusion from a polymeric implant, the molecular weight of the PEG must be optimized. Although increasing the molecular weight of the PEG increases the solubility of the drug, it decreases the rate of diffusion of the conjugate, which is the primary means of distribution of the conjugate in the brain. We expected conjugation to PEG3400 to solubilize CPT and increase the effective molecular weight beyond the theoretical threshold for blood−brain barrier penetration (*17*); these PEG3400 conjugates should also diffuse readily through the extracellular space (*18*). In addition, these conjugates should be capable of releasing free, active CPT upon ester hydrolysis. Three different PEG3400−CPT conjugates were synthesized. All conjugates were linked via an ester bond, either directly or through a single amino acid (Figure 1B−D). The variation in the nature of the linkage chemistry resulted in conjugates with different stabilities in aqueous solutions.

The primary objectives of this study were to measure solubility and stability of CPT conjugates in biological fluids, to determine if CPT released from our synthesized conjugates was capable of inducing cell death in culture, and to determine the drug distribution in vivo from a controlled release device implanted in the rat brain. Since it is known that large water-soluble polymers do not generally diffuse across cell membranes (*19*), these conjugates are likely taken up actively by endocytosis. It was thus of interest to determine if PEG−CPT conjugates release drug via hydrolysis outside of cells or if it is possible for the conjugate to enter the cell and release drug closer to its nuclear target.

EXPERIMENTAL PROCEDURES

Materials. (*S*)-(+)-Camptothecin (CPT) and poly(ethylene glycol), average M_n 3400 (PEG3400) were purchased from Aldrich Chemical Co. (Milwaukee, WI). Stock solutions of CPT were created by dissolving drug in dimethyl sulfoxide (DMSO; Sigma Chemical Company, St. Louis, MO), and the solutions were stored at 4 °C. Carboxymethyl-PEG3400 was purchased from Shearwater Polymers (now Nektar Therapeutics, Huntsville, AL). The MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium, inner salt] assay reagent kit was purchased from Promega (CellTiter 96 Aqueous Non-Radioactive Cell Proliferation kit; Madison, WI). The LysoTracker Red probe for acidic organelles was purchased from Molecular Probes (Eugene, OR). Poly-L-lysine, type VI-S acetylcholinesterase from electric eel, crude esterase from porcine liver (liver esterase), type I protease from porcine pancreas, and *p*-nitrophenyl acetate were purchased from Sigma Chemical Company (St. Louis, MO). Poly(1,3-bis(*p*-carboxyphenoxy)propane: sebacic acid) 20:80 (p(CPP:SA)) was donated by Guilford Pharmaceuticals. The Coomassie Protein Reagent was purchased from Pierce Biotechnology (Rockford, IL).

Methods. Analysis of Conjugates. MALD/I TOF mass spectrometry was done at the Biotechnology Resource Center at Cornell University on a Bruker Daltonics Biflex III with α-cyano-4-hydroxycinnamic acid (ACCA) as the matrix. The raw MALD/I data and the list of major MALD/I peaks are shown in the Supporting Information. ^{1}H and ^{13}C nuclear magnetic resonance spectroscopy was done on an INOVA 500 MHz spectrometer at the NMR Facility at Cornell University. $CDCl_3$ was the solved used, and CPT peaks were correlated to published results for CPT in DMSO (*20*).

Synthesis of Camptothecin−Poly(ethylene glycol) Conjugates. These procedures were modified for PEG3400 from previously published protocols (*12*). The structures of the three conjugates appear in Figure 1. NMR peaks are labeled using the atom numbering shown for CPT in Figure 1B.

CM-PEG−CPT. Carboxymethyl-PEG3400 (244 mg, 0.068 mmol) was dried by azeotroping in 75 mL of toluene for 2 h. Remaining toluene was removed under vacuum, and the PEG and CPT (50 mg, 0.144 mmol) were dissolved in 100 mL of methylene chloride under stirring. The solution was cooled to 0−5 °C in an ice bath. 2-Chloro-1-methylpyridinium iodide (65 mg, 0.253 mmol) and 4-(dimethylamino)pyridine (67 mg, 0.547 mmol) were added. The solution was allowed to warm to room temperature, and the reaction was continued for 48 h. The organic solution was then washed with 0.5 M HCl (2 × 25 mL) and dried over $MgSO_4$. Solvent was removed under vacuum. The product was redissolved in 1−2 mL of methylene chloride and precipitated upon addition of 200 mL of 2-propanol. The precipitate was collected by filtration and dried under vacuum. The product was redissolved in 1−2 mL of methylene chloride and precipitated upon addition of 200 mL of ether. The precipitate was collected by filtration and dried under vacuum. The product was tested for purity by TLC with 5% dimethylformamide in chloroform. Yield = 90% CM-PEG−CPT. ^{1}H NMR ($CDCl_3$): δ(ppm) = 0.97 (t, 6, C(18)-

H_3), 2.17, 2.28 (mm, 4, C(19)H_2), 3.63 (m, >300, PEG), 4.34 (q, 4, OCH_2CO), 5.29 (t, 4, C(5)H_2), 5.41, 5.68 (dd, 4, C(17)H_2), 7.21 (s, 2, =C(14)*H*), 7.67 (t, 2, =C(10)*H*), 7.83 (t, 2, =C(11)*H*), 7.94 (d, 2, =C(9)*H*), 8.20 (d, 2, =C(12)-*H*), 8.40 (s, 2, =C(7)*H*). ^{13}C NMR ($CDCl_3$): δ(ppm) = 7.83 (C18), 32.02 (C19), 50.23 (C5), 67.45 (C17), 68.36−71.27 (PEG), 76.60 (C20), 96.19 (C14), 120.59 (C16), 128.35 (C10), 128.45 (C8), 128.50 (C9), 128.68 (C12), 129.86 (C6), 130.99 (C11), 131.53 (C7), 145.64 (C3), 146.64 (C13), 149.10 (C15), 152.49 (C2), 157.57 (C16a), 167.50 (*C*OO-CPT), 169.95 (C21). MALD/I TOF: [CM-PEG3400−CPT + 2ACCA +H]$^+$ predicted *m/z*: [CM-PEG3400 + 2ACCA +H]$^+$ + 660.69, observed: + 662.94.

CM-PEG-Gly-CPT. H-Gly−CPT·TFA was synthesized using a previously established protocol (*12*). Carboxymethyl-PEG3400 (200 mg, 0.056 mmol) was dried by azeotroping in 100 mL of toluene for 2 h. The volume of toluene was reduced to 20 mL, and the solution was cooled to room temperature. H-Gly−CPT·TFA (140 mg, 0.27 mmol), 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (62 mg, 0.25 mmol), and DMAP (110 mg, 0.90 mmol) were added. The solution was stirred at 55−60 °C for 16 h. Solvent was removed under vacuum, and the product was isolated by recrystallizing in 100 mL of 2-propanol, filtering, washing with ice-cold ether, and drying under vacuum. A second recrystallization was done when necessary to improve purity. Yield = 85% CM-PEG-Gly−CPT. ^{1}H NMR ($CDCl_3$): δ(ppm) = 0.96 (t, 6, C(18)H_3), 2.14, 2.25 (mm, 4, C(19)H_2), 3.61 (m, >300, PEG), (q, 4, OCH_2CO), 3.97 (m, 4, NHCH_2CO), 4.15, 4.46 (dd, 4, COCH_2O), 5.25 (t, 4, C(5)H_2), 5.37, 5.65 (dd, 4, C(17)H_2), 7.31 (s, 2, =C(14)*H*), 7.63 (d, 2, =C(10)*H*), 7.66 (q, 2, CON*H*), 7.80 (t, 2, =C(11)*H*), 7.90 (d, 2, =C(9)*H*), 8.22 (d, 2, =C(12)*H*), 8.38 (s, 2, =C(7)*H*). ^{13}C NMR ($CDCl_3$): δ(ppm) = 7.82 (C18), 32.02 (C19), 40.66 (CO*C*H_2NH), 50.22 (C5), 67.32 (C17), 70.27−71.32 (PEG), 76.96 (C20), 96.52 (C14), 120.25 (C16), 128.32 (C10), 128.38 (C8), 128.40 (C9), 128.67 (C12), 129.92 (C6), 130.95 (C11), 131.52 (C7), 145.78 (C3), 146.62 (C13), 149.00 (C15), 152.44 (C2), 157.55 (C16a), 167.37 (*C*OO-CPT), 169.16 (NH*C*O), 171.09 (C21). MALD/I TOF: [CM-PEG3400-Gly−CPT + 2ACCA +H]$^+$ predicted *m/z*: [CM-PEG3400 + 2ACCA +H]$^+$ + 774.79, observed: + 774.15.

CM-PEG-Sar-CPT. H-Sar−CPT·TFA was synthesized using a previously established protocol (*12*). Carboxymethyl-PEG3400 (239 mg, 0.067 mmol) was dried by azeotroping in 100 mL of toluene for 2 h. Remaining toluene was removed under vacuum, and the PEG was dissolved in 20 mL of methylene chloride under stirring. The solution was cooled to 0−5 °C in an ice bath. H-Sar−CPT·TFA (150 mg, 0.28 mmol), diisopropylcarbodiimide (42 μL, 0.27 mmol), and DMAP (33 mg, 0.27 mmol) were added. The solution was allowed to warm to room temperature, and the reaction was continued for 16 h. Solvent was removed under vacuum, and the product was isolated by recrystallizing in 100 mL of 2-propanol, filtering, washing with 2-propanol, and drying under vacuum. A second recrystallization was done when necessary to improve purity. Yield = 70% CM-PEG-Sar−CPT. ^{1}H NMR ($CDCl_3$): δ(ppm) = 0.97 (t, 6, C(18)H_3), 2.13, 2.24 (mm, 4, C(19)H_2), 3.04 (s, 6, N(CH_3)), 3.61 (m, >300, PEG), 4.03, 4.64 (dd, 4, COCH_2N(CH$_3$)), 4.20 (q, 4, OCH_2CO), 5.24 (t, 4, C(5)H_2), 5.37, 5.66 (dd, 4, C(17)-H_2), 7.31 (s, 2, =C(14)*H*), 7.64 (t, 2, =C(10)*H*), 7.80 (t, 2, =C(11)*H*), 7.90 (d, 2, =C(9)*H*), 8.23 (d, 2, =C(12)*H*), 8.37 (s, 2, =C(7)*H*). ^{13}C NMR ($CDCl_3$): δ(ppm) = 7.84 (C18), 31.96 (C19), 35.64 (N(**C**H$_3$)), 49.27 (CO*C*H$_2$N(CH$_3$)), 50.22 (C5), 67.36 (C17), 70.07−70.78 (PEG), 77.06 (C20), 96.57 (C14), 120.06 (C16), 128.30 (C10), 128.38 (C8), 128.38 (C9), 128.66 (C12), 129.98 (C6), 130.90 (C11), 131.47 (C7), 145.80 (C3), 146.65 (C13), 149.01 (C15), 152.45 (C2), 157.54 (C16a), 167.60 (*C*OO−CPT), 168.58 (N(CH$_3$)-*C*OCH$_2$), 170.31 (C21). MALD/I TOF: [CM-PEG3400-Sar−CPT + 2ACCA +H]$^+$ predicted *m/z*: [CM-PEG3400 + 2ACCA +H]$^+$ + 802.84, observed: + 804.96.

Stability of Conjugates in Neutral and Acidic Conditions. The hydrolysis rate of conjugates was determined in phosphate-buffered saline (PBS) at pH 7.4 and in citrate-phosphate buffer solutions at pH 5.5 and pH 6.0. Conjugates were dissolved at a concentration of 10 μg/mL and incubated at 37 °C. For HPLC analysis (Waters 2690 HPLC with photodiode array detector, Milford, MA), at each time point 10−40 μL of sample was injected and eluted on a 40-min, 80:0:20 to 0:80:20 (water: acetonitrile:water/0.5%TFA) gradient. Free CPT eluted at 12.9 min on a Zorbax 300SB−CN column (Phenomenex, Torrance, CA). Areas of absorbance peaks at 254, 354, and 369 nm were compared to CPT standards to determine concentrations. For extraction analysis, at specified time points, 250 μL was removed from each of the conjugate solutions and subjected to a modified extraction procedure (*21*). Since ethyl acetate preferentially extracts free CPT out of solutions containing free and conjugated drug, this procedure provided a rapid method to isolate free CPT. Briefly, each 250-μL sample was acidified to pH 3.0 with 1 M HCl. Water-saturated ethyl acetate (500 μL) was added to extract out CPT, and the sample was vortexed for 10 s. The sample was then centrifuged at 8160*g* for 5 min. Half of the ethyl acetate layer (250 μL) was transferred to a clean tube, while the remaining ethyl acetate was transferred to waste. An additional 500 μL of ethyl acetate was added to the aqueous sample, and the extraction procedure was repeated, with 250 μL of the organic phase retained. The combined ethyl acetate extracts (500 μL) were evaporated to dryness under a gentle stream of nitrogen, reconstituted in 95% ethanol (1 mL) and the fluorescence intensity of CPT was determined at an emission wavelength of 434 nm after excitation at 370 nm.

Stability of Conjugates in Simulated Biological Fluids. Conjugate stability studies were carried out at 37 °C and pH 7.4 in simulated biological fluids. Conjugates were present at a concentration of approximately 10 μg/mL in all cases. At specified time points, 250-μL samples were removed from the conjugate solutions and free CPT was quantified after preferentially extracting out the drug. The extraction procedure was the same as used for neutral and acidic stability experiments (see above), with the following changes. Ice cold citrate-phosphate buffer was used to reduce the pH to 3, and centrifugation was for 10 rather than 5 min.

Six in vitro solutions were tested: PBS, acetylcholinesterase in PBS, liver esterase in PBS, pancreatic protease in PBS, 9L lysates in PBS, and brain homogenate in PBS. To create the test solutions, acetylcholinesterase, esterase, and protease proteins were dissolved in PBS at 15 U/mL of enzymatic activity, based on activity reported by the vendor. Cell lysate solutions were created from 9L gliosarcoma cells in culture. Six 75-cm^2 flasks of cells were trypsinized at confluence, washed twice in PBS, and resuspended in 20 mL of PBS. Cells were lysed with sonication (TEKMAR Soni Disruptor, TM300) on ice at 40% power for 2 min. The lysate was centrifuged at 1070*g* for 10 min. The supernatant was diluted with approximately 30 mL of PBS to create a total volume of 50 mL, and the resulting lysate was diluted 1:1 with PBS to create the final solution used in the release study. Brain homogenate solutions were created by homogeniz-

ing (PowerGen Homogenizer, Fisher Scientific, Pittsburgh, PA) the brain of an adult female rat (Harlan Sprauge-Dawley) at a concentration of 50 mg/mL in PBS.

Total protein content in the cell lysate solution and brain homogenate was determined using the Coomassie Protein Reagent Kit. For the total protein assay, 100 μL of serially diluted samples and standards prepared from liver esterase were placed into the wells of a 96-well plate, followed by 100 μL of the Coomassie Protein Reagent. Absorbance was measured at 595 nm on a microplate reader (Molecular Devices, Sunnyvale, CA). Total protein content was based on comparison to a BSA standard provided with the assay kit. The esterase activity of brain homogenate and cell lysate solutions was measured using *p*-nitrophenyl acetate (PNPA) as a model substrate. PNPA was dissolved in DMSO to create a 100 mg/mL stock solution which was stored at −20 °C. From this stock, an assay solution of 0.1 mg/mL PNPA in PBS was made. Serially diluted 100-μL brain homogenate samples and standards prepared from liver esterase were placed into the wells of a 96-well plate, followed by 100 μL of the PNPA assay solution. Absorbance was measured at 405 nm using a microplate reader after 10 min of incubation at room temperature. Esterase activity was based on comparison to the liver esterase standards in PBS.

Cell Line. The 9L gliosarcoma cell line (9L) was kindly provided by Dr. Henry Brem of Johns Hopkins University (Baltimore, MD). The cell line was maintained in DMEM media (with L-glutamine) supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin at 37 °C and 5% CO_2 in a humidified environment. All tissue culture reagents were purchased from Gibco, BRL (Grand Island, NY). Cells were subcultured every 3−4 days at a relative cell density of 1:8.

In Vitro Cytotoxicity. The cytotoxicity of CPT conjugates and free CPT was measured against 9L cells in monolayer culture. Cells were plated in 96-well plates (200 cells/well) and allowed to attach. Drug was serially diluted in cell culture media; CPT conjugates were dissolved directly into media whereas CPT was added from a stock solution in DMSO (1 mg/mL). Plated cells were incubated in media containing free or conjugated drug for 24, 72, or 120 h. In the case of the 24 and 72-h time points, the free drug- or conjugate-containing media was removed and replaced with fresh media, and the cells were returned to the incubator. After 120 h, cell viability was determined in all wells using an MTS assay and a microplate reader. The fraction of cells surviving was calculated by dividing mean optical density produced by treated cells by the mean optical density from untreated control cells.

Cellular Uptake in Monolayer Culture. Glass slides were placed in six-well tissue culture plates and coated with a solution of poly-L-lysine in PBS (25 μg/mL) for 1 h at 37 °C. After the slides were rinsed with PBS, 9L cells were seeded at a density of 1.5×10^4 cells/cm^2 and allowed to attach overnight. The cells were then incubated in medium containing conjugated drug or free drug (100 μg/mL) for 5 h. In some cases a fluorescent marker for acidic organelles (LysoTracker Red) was added during the final 30 min of incubation at a concentration of 50 nM. After incubation, cells were rinsed three times with cold PBS and fixed with 4% paraformaldehyde for 15 min at room temperature. The resulting cell preparations were studied by fluorescence microscopy using an Olympus BX-50 fluorescence/DIC microscope with a mercury lamp excitation source. Camptothecin and LysoTracker fluorescence were visualized using UV and red filters, respectively.

Fabrication of Controlled-Release p(CPP:SA) Implants. Controlled-release devices containing CPT conjugates at 20 wt % were prepared by first codissolving 50 mg of each conjugate and 200 mg of p(CPP:SA) in methylene chloride (2 mL). Each solution was thoroughly vortexed and, after complete dissolution, placed under vacuum at room temperature for 24 h. The resulting material was crushed into a homogeneous powder consisting of relatively uniform particles. To produce implantable disks approximately 1 mm in thickness, 10 mg of the powder was placed in a stainless steel die (3 mm diameter) and 0.25 tons of pressure was applied with a Carver press for 20 s. Disks to release unmodified CPT were prepared containing CPT plus unconjugated PEG3400 (20 wt % total loading). CPT and free PEG were combined in methylene chloride at a CPT:PEG ratio of 1:6.14 to match the drug content of conjugated material. Unlike the CPT conjugates, CPT did not completely dissolve in methylene chloride.

Measurement of Drug Release into Phosphate-Buffered Saline. The in vitro release characteristics of matrixes made into disks were determined in continuously stirred phosphate-buffered saline (pH 7.4) at 37 °C. Three identical disks from each group were incubated in individual aliquots of 1.5 mL of PBS in test tubes. At various time points the entire volume of each tube was removed and replaced with fresh buffer. The amount of CPT released was quantified in the resulting samples by measurement of the intrinsic fluorescence of the drug. Individual samples were diluted with PBS to a total volume of 700 μL and acidified with 7 μL of 1 M hydrochloric acid to convert any free CPT in the carboxylate form back to the lactone. A 10% SDS solution was then added (100 μL) to break up any aggregation of CPT conjugates, the mixture was thoroughly vortexed, and bubbles were allowed to dissipate. The fluorescence of the samples was measured at 428 nm (excitation at 370 nm). In some cases the samples were briefly centrifuged at 8160*g* for 1 min to remove undegraded p(CPP:SA) wafer remnants prior to analysis. No significant change in the fluorescence of CPT conjugate solutions with time was detected, and it was assumed that CPT conjugates and the CPT released from the conjugates had the same fluorescence yield.

Implantation of p(CPP:SA) Matrixes into the Normal Rat Brain. Male Fischer 344 rats (200 g, Harlan, Indianapolis, IN) were anesthetized by intraperitoneal injection of 0.6 mL of a solution containing 25 mL of ketamine hydrochloride (100 mg/mL, Abbott Laboratories, N. Chicago, IL), 2.5 mL of xylazine (100 mg/mL, Bayer Corporation, Shawnee Mission, KS), 14.2 mL of ethanol (95%), and 58 mL of physiological saline (The Butler Company, Columbus, OH). A 3-cm incision was made above the skull, and the bregma was exposed. An oval-shaped burr hole was drilled 1 mm anterior to the bregma and perpendicular to the midline. A slit 4 to 5 mm deep was made in the dura and brain parenchyma with the tip of a number-11 scalpel blade, and the polymer matrix was gently inserted into the tissue, until it was no longer visible. Once the bleeding had ceased, the skin was closed with surgical staples. All procedures were approved by the Institutional Animal Care and Use Committee at Cornell University.

Brain Tissue Analysis. Rats were sacrificed 1, 7, 14, or 28 days following implantation. At the time of sacrifice, the brains were frozen in hexanes over dry ice. On the day of analysis, brains were cut into three bulk sections,

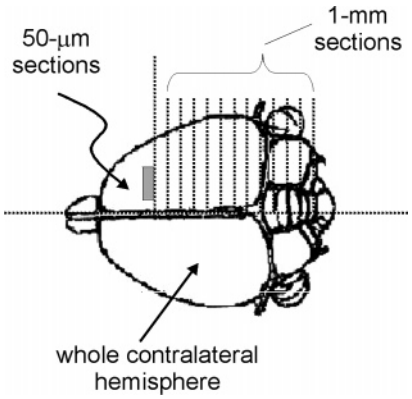

Figure 2. Implantation and sectioning scheme. The implant (grey rectangle) was placed 0.5−1 mm anterior to bregma. The frozen brain was first cut down the midline and then directly behind the polymer implant. The tissue posterior to the implant was sectioned into 1 mm slices. The tissue anterior to the implant was sectioned into 50 μm slices with a cryo-microtome.

first down the midline, and then directly behind the p(CPP:SA) implant (see Figure 2).

Posterior Sectioning. The portion of the brain behind the implant was sectioned in the coronal plane. Brains were placed in a chamber maintained at −20 °C, and razor blades, fastened at 1-mm intervals with screws and washers, were forced through the tissue under gentle pressure. The tissue was allowed to refreeze, and the 1-mm (thick) sections were weighed in tared vials. These tissue slices and the entire contralateral hemisphere were homogenized in citrate-phosphate buffer containing 1% SDS (pH 3.0) at a concentration of 20 mg tissue per mL buffer. One milliliter of each tissue sample was centrifuged at 16 000*g* for 5 min, and the supernatant (700 μL) was analyzed for the presence of CPT and conjugated CPT by spectrofluorimetry.

Anterior Sectioning. The frontal section of brain containing the polymer implant was placed on a cryostat chuck, embedded in OCT embedding medium, and cut into 50-μm (thin) sections using a cryomicrotome (Microm, Heidelberg, Germany) at −20 °C. Alternating sections were collected into separate tubes: one 50-μm section for total drug analysis, the next two 50-μm sections together for extraction of liberated CPT, one for total drug analysis, and so on. Thus total CPT levels (conjugated plus unconjugated) were measured in 50-μm sections of brain, whereas the fraction of drug in the free, liberated form was quantified in 100-μm sections (2, 50-μm sections).

Total Drug Levels in Thin Brain Slices. The total amount of CPT (in either conjugated or free form) was quantified in 50-μm sections of brain tissue. The sections were homogenized in citrate-phosphate buffer containing 1% SDS (pH 3.0) by sonication (Tekmar Soni Disrupter, microtip #4) on ice at 30% power for 10 s. The samples were centrifuged at 16 000*g* for 5 min, and the resulting supernatant (200 μL) was analyzed for the presence of CPT and conjugated CPT by spectrofluorimetry.

Amount of Liberated, Free CPT in Thin Brain Slices. Free drug in 100-μm sections of brain was quantified by an extraction method similar to that described for the simulated biological fluids with two alterations. After the solution was acidified to pH 3, the sample was homogenized by sonication at 30% power for 20 s on ice, and as the final step, 200 mL of ethanol was used to reconstitute the CPT residue. We expected that in brains implanted with p(CPP:SA) matrixes releasing unmodified CPT, procedures to measure the amount of total drug (conjugated plus free) and the amount of free drug would yield equivalent values since all drug was released from p(CPP:SA) in the free form. Since this was, in fact, the case for the first several animals studied, subsequent brains were grouped into 100-μm slices and subjected only to the extraction procedure.

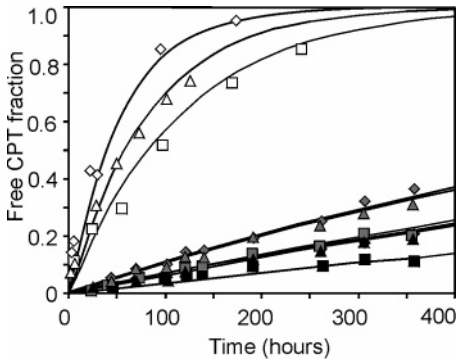

Figure 3. Stability of PEG-camptothecin conjugates in water at 37 °C. Experiments were done at pH 7.4 (white), at pH 6.0 (grey), and at pH 5.5 (black) for CM-PEG−CPT (◇), CM-PEG-Gly−CPT (△), and CM-PEG-Sar−CPT (□). The presence of free CPT was monitored as a function of time. Data at pH 7.4 was acquired by HPLC analysis and corroborated by extraction technique. Data at pH 6.0 and 5.5 were obtained by extraction.

Table 1. Conjugate Hydrolysis Half-Lives per Hour at Different pHs

	pH 7.4	pH 6.0	pH 5.5
CM-PEG−CPT	38.5	603	1000
CM-PEG-Gly−CPT	57.8	630	1050
CM-PEG-Sar−CPT	81.5	924	1820

RESULTS

In Vitro Experiments. Conjugates were first placed in aqueous solutions that simulated biological fluids, and the rates of hydrolysis were measured either by HPLC analysis or an extraction procedure with fluorescence detection. The stability of the CPT conjugates was determined in buffered solutions at pH 7.4, pH 6, and pH 5.5 to simulate the cytoplasmic/extracellular space, the endosome, and the lysosome, respectively (*22*). The resulting hydrolysis data appear in Figure 3. Independent measurements by HPLC and extraction at pH 7.4 gave identical results. The curves in Figure 3 represent best first-order fits to the data, and the half-lives for these curves are given in Table 1. All conjugates were much more stable at pH 6.0 and 5.5 than at pH 7.4, with the trend in hydrolysis rates for the three conjugates remaining the same (CM-PEG-Sar−CPT<CM-PEG-Gly−CPT<CM-PEG−CPT). The hydrolysis half-lives of the conjugates were increased 10-fold at pH 6.0 and 20-fold at pH 5.5 over pH 7.4 values.

Once a method of measuring free CPT was established for drug released from the newly synthesized CPT conjugates, it was necessary to confirm that the liberated drug maintained its cytotoxic activity. The response of 9L gliosarcoma cells was tested in vitro by seeding the cells and exposing them to various concentrations of conjugated or free CPT. Cells were exposed to drug for 24, 72, or 120 h and assayed for metabolic activity after a total of 120 h in all cases. Representative data for CPT and conjugate appear in Figure 4. The assay confirmed the cytotoxic nature of the conjugates, and it demonstrated that much more CPT-conjugate was required to achieve a level of cell death equivalent to that achieved by the parent compound, CPT. An effect of duration of

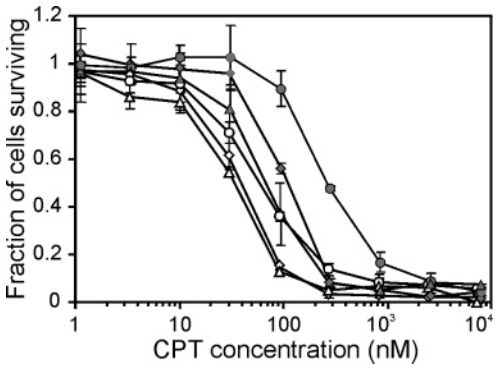

Figure 4. In vitro cytotoxicity of free CPT (white) and CM-PEG-Gly−CPT (grey) as a function of time of exposure. Cells were exposed to drug for 24 (○), 72 (◇), or 120 (△) hours and assayed for proliferation with a metabolic MTS assay after 120 h.

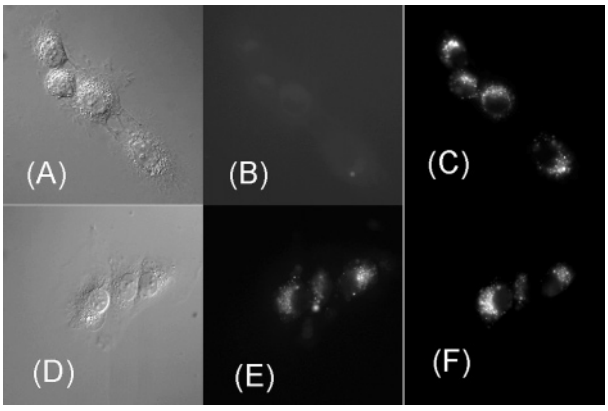

Figure 5. Uptake by 9L gliosarcoma cells counterstained with LysoTracker Red. Equivalent CPT concentration was 100 μg/mL for CM-PEG-Sar−CPT. Images shown at 38× magnification. Free CPT: (A) DIC image of cells, (B) CPT fluorescence with UV filter, (C) LysoTracker fluorescence with red filter. CM-PEG-Sar−CPT: (D) DIC image of cells, (E) CPT fluorescence with UV filter, (F) LysoTracker fluorescence with red filter.

exposure to drug or conjugate was also assessed. Increasing time of exposure to free drug or conjugate shifted the cytotoxicity curves toward a lower concentration, as anticipated for this cell cycle-specific drug. The shift was more dramatic for conjugate (as seen by the curves of dark-colored points in Figure 4) than for free drug, presumably because the amount of active drug in the medium being generated by conjugate hydrolysis was continually increasing with time during incubation.

Since CPT conjugates are relatively stable at physiological pH, it was of interest to determine if these compounds can enter cells and by what mechanism. CPT exhibits intrinsic fluorescence, and the uptake by 9L gliosarcoma cells was investigated qualitatively by fluorescence microscopy following incubation with conjugate or free drug. For all three conjugates, a punctate intracellular distribution pattern could be seen after a 5-h incubation period (see Figure 5E). This pattern of uptake is consistent with the sequestering of conjugate in intracellular compartments (endosomes and lysosomes) after the active uptake of the compound (*23*). The fluorescence exhibited by cells incubated with free drug was not any brighter than background (Figure 5B), and free drug distribution was clearly not limited to any intracellular compartments. To obtain further evidence that conjugate is taken up by endocytosis, CM-PEG-Sar−CPT was coincubated with LysoTracker Red, a fluorescent probe that labels lysosomes, endosomes, and other acidic cellular compartments. Colocalization of the CPT fluorescence pattern (blue excitation) with the pattern associated with LysoTracker Red (red excitation) suggests that CM-PEG-Sar−CPT was located within the acidic endosomal and lysosomal compartments (compare Figure 5E and 5F).

CPT conjugates and free CPT were next incorporated into biodegradable disks of p(CPP:SA) matrixes in order to create implantable devices capable of releasing these compounds in a sustained manner. Matrixes containing each of the three CPT conjugates were loaded at 20 wt %. Since conjugated material was comprised of approximately 14% CPT and 86% PEG by weight, free-CPT-releasing matrixes were created by combining CPT and PEG3400 in this ratio to obtain a final (free CPT + free PEG) loading of 20%. The in vitro release of CPT from the resulting devices was monitored for 25 days in continuously stirred PBS at 37 °C (Figure 6). Under these conditions all three types of CPT conjugates exhibited similar release kinetics. CPT conjugates were released from the devices over a period of 12−14 days. The conjugate release curve is characterized by a burst of 50% of the total dose in the first 3 h followed by a linear release over the next 11 days (Figure 6A). The total amount of CPT conjugates (Figure 6B) released from the devices differed due to the fact that the three conjugate forms had different loadings of CPT. The release of free CPT was very different from conjugated drug, presumably because free CPT is so much less water-soluble. Free CPT was slowly released in a linear fashion over the entire 25-day study, and even at that point only 60% of the drug had been released. On the basis of this result, it is clear that coreleasing CPT and PEG3400 is not sufficient to enhance the solubility of CPT and, further-

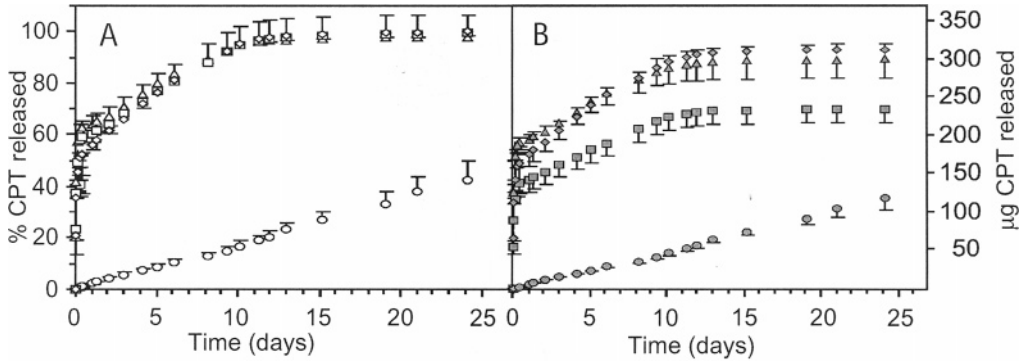

Figure 6. Controlled release of free CPT (○), CM-PEG-Sar−CPT (□), CM-PEG-Gly−CPT (△) and CM-PEG−CPT (◇) from 20%-loaded p(CPP:SA) matrixes in vitro. (A) Release as "percent of loading". (B) Release as "weight of CPT released" are indicated from the same experiments. Three identical 10-mg matrixes were incubated in continuously stirred PBS at 37 °C. Error bars represent the standard deviation in measurement for three matrixes.

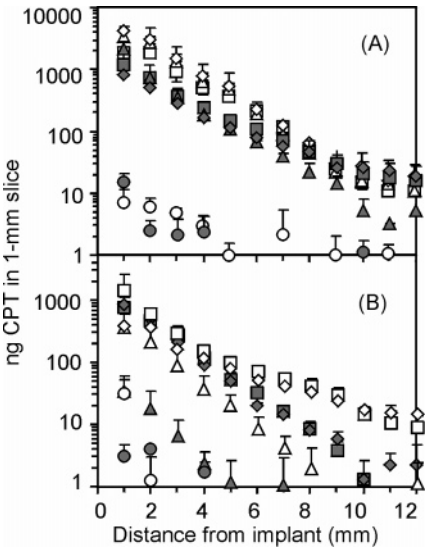

Figure 7. Total CPT found in 1-mm slices posterior (see Figure 2) to implants releasing free CPT (○), CM-PEG-Sar−CPT (□), CM-PEG-Gly−CPT (△), or CM-PEG−CPT (◇) at various time points. Animals were sacrificed for analysis at (A) 1 day (white), 7 days (grey), (B) 14 days (white), and 28 days (grey) following implantation. Error bars represent standard deviation of measurements made in three animals.

more, that a covalent attachment dramatically alters the controlled release kinetics of the drug.

Distribution of Drug in the Rat Brain. Similar p(CPP:SA) disks loaded with drug or conjugate were implanted in the brains of male Fischer rats (see Figure 2). To compare the extent of distribution of CPT conjugates to free CPT, we quantified the total amount of CPT (conjugated and unconjugated) in 1-mm slices posterior to the implant site at various time points (Figure 7). Conjugates were clearly distributed throughout the implant hemisphere at 1, 7, and 14 days following implantation. CPT delivered as free drug, on the other hand, was present in much lower levels and was only found in slices within 4 mm of the implant. The tissue levels of the three conjugate forms are similar up to one week following implantation, but at later time points (Figure 7B) the CM-PEG-Gly−CPT conjugate levels are significantly lower than CM-PEG-Sar−CPT and CM-PEG−CPT. In fact, almost all of the CM-PEG-Gly−CPT conjugate was eliminated from the brain by 28 days.

The analysis of 1-mm tissue (Figure 7) slices revealed the enhanced distribution of CPT conjugates as compared to free CPT. However, the gross resolution of this approach does not give detailed information about the distribution close to the polymer (0−2 mm). Thus, to gain more resolution, the brain anterior to the implant was cut into fine (50-μm) sections. Total levels of CPT (conjugated plus unconjugated) were determined in these 50-μm slices for the three conjugate forms, CM-PEG-Sar−CPT (Figure 8A), CM-PEG-Gly−CPT (Figure 8B), and CM-PEG−CPT (Figure 8C). Representative concentration profiles for the conjugates in the 50-μm slices are shown in Figure 8 at various time points after implantation of 20%-loaded p(CPP:SA) matrixes. The results of the more detailed thin slice analysis are in qualitative agreement with the data from thick (1-mm) slice sections. The three conjugate types exhibit similar distributions at early times (as shown in Figure 8), whereas at later times CM-PEG-Gly−CPT seems to be present at lower concentrations than both CM-PEG-Sar−CPT and CM-PEG−CPT. It is also of interest to note that while the penetration distance appears to be reduced in the thin slice data compared to the 1-mm slice data, this is most likely due to the relatively short distance from the polymer edge to the front tip of the brain (4 mm, see Figure 2).

It was also possible to determine concentration profiles close to the polymer disk in brain tissue following implantation of 20%-loaded free CPT matrixes (Figure 9). The interfacial concentration achieved by free CPT (25 ng/mg) was much lower than that achieved by conjugated drug (500 ng/mg, see Figure 8). The profiles for CPT were fairly constant throughout the treatment period (Figure 9) and, at all times, dropped off to background levels at 1−1.5 mm from the tissue/matrix interface. In contrast, measurable concentrations of CPT were found at 4 mm from the implant for all three CPT conjugates as early as 24 h after implantation (Figure 8).

Regarding the distributions in Figure 8, some experimental assumptions must be noted. For all of the conjugate forms, the p(CPP:SA) matrix had degraded substantially after one week, making it difficult to identify visually the polymer edge, which was used as a reference in measuring distribution distances. The distribution samples gathered for delivery of free CPT from the p(CPP:SA) disk, however, did not have this ambiguity, because the matrix remained fairly intact for the entire 28-day study. Also, because the concentrations in Figure 8 were calculated assuming semi-one-dimensional diffusion from the p(CPP:SA) matrix, the amount of drug

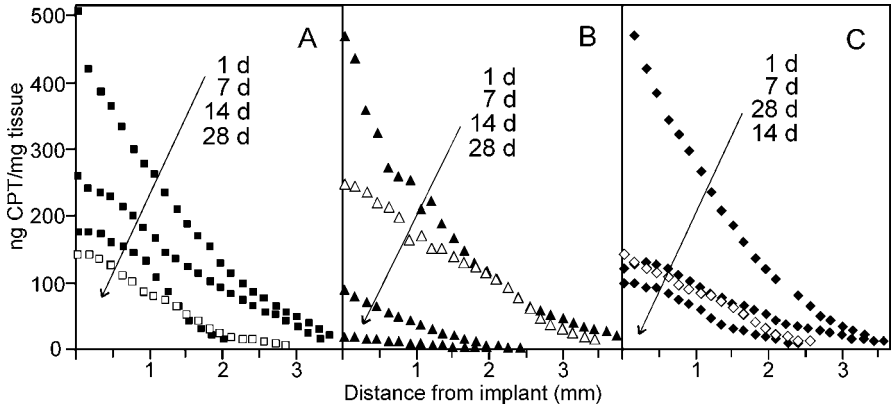

Figure 8. Anterior (see Figure 2) concentration profiles of Total CPT at 1, 7, 14, and 28 days following implantation of20%-loaded p(CPP:SA) matrixes containing (A) CM-PEG-Sar−CPT (□) [day 28 in gray for clarity], (B) CM-PEG-Gly−CPT (△) [day 7 in gray], and (C) CM-PEG−CPT (◇) [day 28 in gray]. Tissue anterior to the implant was sliced into 50-μm sections and total CPT was quantified by fluorescence. The C_0 values decreased with time for all cases except CM-PEG−CPT, where C_0 increased from day 14 to day 28.

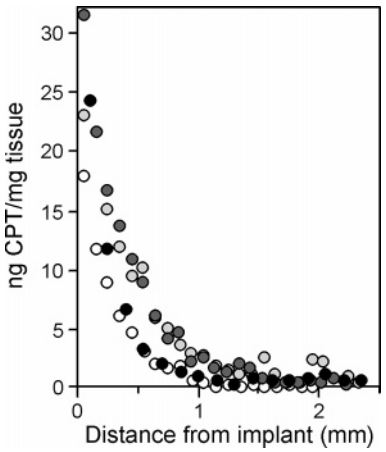

Figure 9. Anterior concentration profiles of Free CPT following release from 20%−CPT-loaded p(CPP:SA) matrixes on day 1 (white), 7 (light gray), 14 (grey), or 28 (black) following implantation. Errors were generally less than 10% of the mean value for plotted data points. Tissue anterior to the implant was sliced into 50 μm, and two slices were combined to make a 100 μm section. CPT was quantified by fluorescence following an extraction procedure of the combined slices.

in the 50-μm slices was normalized with a fixed volume of tissue based on the diameter of the implant source and the thickness of the slice. In reality, however, some drug diffused radially, resulting in this method overestimating concentrations close to the source.

An acceleration of hydrolytic release of drug in blood plasma has been reported for PEG40000−CPT compounds with the same linkage chemistry as ours. It was suggested in that study that an esterase for ester-bonded conjugates or protease for amino acid-linked conjugates mediates an acceleration of conjugate hydrolysis (*2*). As a test of our CM-PEG−CPT conjugates in the presence of such enzymes, several buffer solutions with different biological constituents were prepared and the release of CPT from conjugates in these environments was monitored over time by preferential extraction of free CPT. No increase in the hydrolysis rate was observed for CM-PEG−CPT, CM-PEG-Gly−CPT, or CM-PEG-Sar−CPT in any of the esterase, protease, lysate, or homogenate solutions tested.

Our distribution data (Figures 7 and 8) obtained in both gross and fine sections of brain tissue suggest that there may be a stability difference in vivo between the different conjugate forms. Furthermore, the observation that CM-PEG−CPT and CM-PEG-Sar−CPT remain in the brain up to two weeks after the p(CPP:SA) source would be exhausted indicates that these compounds are more stable in the brain than one would anticipate on the basis of their in vitro half-lives. Some of the reduction in CPT recovery, seen when enzymatic proteins are present in solution, may be due to the binding of proteins to unconjugated CPT. It is also possible that protein can bind and stabilize the conjugated compounds to slow the hydrolysis. The amount of CPT recovery was inversely dependent on the amount of protein present in the solution. No significant difference in the fraction of CPT recovered for each of the three types of conjugate compounds was detected for any of the solutions tested. Thus, there was no notable difference in the level of protein binding were it to occur between the three conjugate forms.

Having demonstrated that PEGylated forms of CPT produce an enhanced distribution in the rat brain, we wanted to determine the concentration of free, active CPT in the rat brain for the PEGylated system. We expected that hydrolysis of the ester between PEG and CPT must occur in order for the CPT to exert a toxic effect on cancer cells. Such an assumption is supported by previously reported results with PEGylated small molecule conjugates. When paclitaxel, methotrexate, and doxorubicin were permanently modified with PEG, the toxicity of the conjugates was found to be lower than the toxicity of the free drugs by a factor of 50 to 1000 (*24*). It was therefore of interest to determine what fraction of the measured total CPT was in the unconjugated, active form. Thin (50-μm) sections proved useful in answering this question, since alternating sections could be analyzed with different assays. More specifically, brains containing CPT conjugates were analyzed by measuring total drug in 50-μm sections and also by performing an extraction on alternating 100-μm sections to remove and quantify unconjugated CPT. By this extraction technique, the amount of free CPT in tissue was found to be low and often close to the detection limit of 1 ng/mg of the assay for all three conjugate forms. On samples from days 1 and 7, fluorescence levels above background could be detected only within 1 mm of the p(CPP:SA) source in all animals. After 7 days, levels consistently above background were not found. When compared to total drug levels measured in alternating slices, it was noted that roughly 1% or less of the dose in each section corresponded to liberated drug, and that a significant difference in the free drug fraction between the three types of conjugates was not measured.

DISCUSSION

The characteristic distribution profiles created by controlled release delivery from polymeric devices in brain tissue have been demonstrated both experimentally (*13*−*15, 25*) and theoretically (*26*). For most compounds, including several chemotherapy drugs, the concentration drops off exponentially with distance from the surface of the device and significant concentrations do not normally penetrate more than 3 mm into the tissue. A high-resolution method is necessary to capture the fine details of this type of distribution. Quantitative autoradiography, a technique in which autoradiographic films are exposed to thin sections (10−20 μm) of tissue containing radiolabeled drug and subsequently digitized for quantification, has been employed several times for this purpose (*13*−*15*). Autoradiography achieves very high spatial resolution and has therefore been useful to characterize steep concentration profiles. This type of analysis was used to validate a mathematical model for local delivery (*26*). The drawbacks of this technique, however, are a difficulty in confirming that the radiolabel corresponds to actual drug and an inability to quantify total levels of drug within tissue.

A more macroscopic approach is to quantify the total amount of drug in the implant and contralateral hemispheres with an analytical method such as spectrofluorimetry (*27*). This technique allows for accurate quantification of total drug levels with time, but there is a complete loss of spatial information. A reasonable compromise in resolution between analysis of 20-μm slices and the whole brain was met in a method demonstrated in this lab to study the delivery of nerve growth factor (NGF) to the brain (*28*). In these studies, brains were sliced into 1-mm thick sections and subsequently analyzed by a sensitive ELISA assay, thus obtaining gross spatial information rapidly.

Since it was anticipated that CPT conjugates could be present throughout the brain, a method capable of

Table 2. Cytotoxicity and Distribution Properties of CPT and PEGylated CPT (a = data from anterior brain sections; b = data from posterior brain section)

		k/D

elucidating the full extent of distribution was desired to analyze conjugate-containing brains. The method of quantification of the intrinsic fluorescence of drug in 1-mm sections seemed appropriate to meet this goal. On the other hand, since higher resolution information is of interest, especially in the measurement of free CPT, a new brain-sectioning scheme was used. In this scheme, the drug-releasing source was implanted near the front portion of the brain and the implanted hemisphere was sectioned into 1-mm slices posterior to the implant and 50-μm slices anterior to the implant (see Figure 2). The intrinsic fluorescence of CPT was used to quantify drug in both gross and fine sections, providing information about the overall distribution of conjugate as well as more detailed concentration profiles from the same brain sample.

In the synthesized CPT conjugates, the polymer is linked to the drug on its active pharmacore, the lactone ring. Thus, we expected hydrolytic cleavage of the ester bond to occur before the drug can exert a significant cytotoxic effect (*24*). Hydrolysis studies (see Figure 3) demonstrated that free CPT is released from CPT conjugates in PBS, with the hydrolysis rate strongly dependent on pH. Figure 4 illustrates that CPT conjugates are capable of releasing drug in order to kill tumor cells in culture. To compare the potency of the compounds, the concentration of drug it takes to kill 50% of the cells (LC_{50}) was estimated from survival curves, including the curves in Figure 4, obtained from replicate experiments. The concentration of conjugated CPT required to kill half of the cells in culture (LC_{50}) was greater for all CPT conjugate forms than for free drug (Table 2, column 1). Time of exposure was more important for conjugates. For example, as exposure time increased from 24 to 72 to 120 h, LC_{50} dropped from 325 to 124 to 80 nM for CM-PEG-Gly−CPT compared to 62 to 43 to 36 for CPT. Also, the LC_{50} of the conjugates correlated with the hydrolytic stabilities of the compounds in PBS, suggesting that more conjugate was needed to kill an equivalent fraction of cells, because the conjugates released CPT over time whereas incubation with free drug resulted in a bolus dose.

If the predominant mechanism of cytotoxicity of the CPT conjugates is the hydrolysis of CPT conjugate in the medium followed by diffusion of free CPT into the cell, taking the release kinetics into account, one would expect the potency of the conjugate to be equivalent to free drug. To test this notion, the area under the concentration−time curve (AUC) was calculated based on the experimentally determined hydrolysis half-life for each conjugate in PBS at 37 °C. The calculation of AUC allows the release of free drug to be taken into account, and thus the AUC represents a time-weighted free CPT concentration in the media. Cytotoxicity data, such as from Figure 4, was then plotted versus AUC rather than total CPT concentration to produce Figure 10. This analysis is

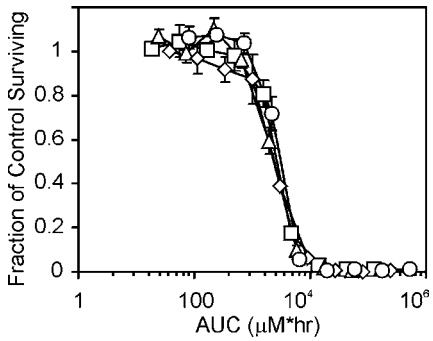

Figure 10. Fraction of cells surviving in vitro after 72 h of exposure as a function of AUC for CM-PEG-Sar−CPT (□), CM-PEG-Gly−CPT (△), CM-PEG−CPT (◇), and free CPT (○). In the calculation of AUC, the release rate of CPT from PEG−CPT conjugates was assumed to be the same as in PBS, at pH 7.4. When the cell survival is plotted in a way that takes into account the release kinetics of the conjugates, the potency of all compounds tested is equivalent.

oversimplified in that it does not account for the conversion of the lactone form of CPT to the carboxylate, but it does give an estimate of the quantitative effect of controlled CPT delivery as compared to a bolus dose. Once the cytotoxicity data was reanalyzed in this manner, little difference could be discerned in the potency of free drug and conjugates (Figure 10), further supporting the premise that drug liberation from the PEG precedes drug activity. A further discussion of calculation of AUC is given in the Supporting Information.

Polymer−drug conjugates are generally thought to enter cells by endocytosis rather than passive diffusion due to their large size (*19*). Since the CPT conjugates do not contain a targeting moiety, internalization will probably occur by a specific type of endocytosis known as pinocytosis, which involves nonspecific fluid phase uptake by the cell (*29*). Following internalization, conjugates will be transported to intracellular compartments, first to endosomes where the pH drops to 6 and then to lysosomes, which have an internal pH of 5.5 (*22*). Fluorescence microscopy of conjugate uptake was consistent with this mechanism of entry into the cell (Figure 5). Some form of endocytosis was assumed based on the punctate distribution pattern of CPT conjugate within the cell (Figure 5E) as well as the colocalization of intrinsic CPT fluorescence with a marker for endosomes and lysosomes (Figure 5F).

Since internalization by cells can potentially localize drug in perinuclear lysosomes, endocytosis could be an important mechanism in facilitating delivery of the lactone form of CPT to its site of action in the nucleus. Unfortunately, however, the stability of CPT conjugates was greatly enhanced in pH conditions that simulated the endosomal and lysosomal compartments (Figure 3). It is therefore likely that the release of free CPT from conjugates within the endosomes and lysosomes occurs very slowly. Extracellular release of free drug from the conjugate followed by free diffusion of CPT into the cell may thus be the dominant mechanism of cytotoxicity in culture, rather than free drug liberation within the acidic intracellular compartments. More detailed future studies of drug and conjugate concentration in the endosome versus free drug concentration in the cytoplasm are needed to answer this question completely.

Unlike conjugated CPT, free drug should be capable of diffusing across the cell membrane to the nucleus. Microscopy of cells following exposure to free CPT showed only a level of intracellular fluorescence close to back-

ground forcing us to conclude that in our experiment we could not detect free CPT in the cells (Figure 5B). The lack of signal above background level across the cells does indicate, however, that the CPT is not sequestered in any intracellular organelles. This is not entirely surprising given previous reports regarding CPT accumulation in cells. It has been demonstrated that uptake occurs rapidly within 10 min of incubation, followed by a gradual loss of drug over the next hour, and washing of cells with PBS following incubation was shown to remove a large fraction of the CPT from the cells (*30*).

The distribution of PEGylated and free CPT in the rat brain was characterized in thin sections of tissue at various time points following the implantation of 20%-drug-loaded p(CPP:SA) matrixes. The distribution data clearly demonstrate the superiority of the conjugates in penetrating tissue in high concentrations, but since there was such a disparity in the release kinetics between free CPT and conjugated CPT at 20% loading, the distribution difference could simply be the result of enhanced release of conjugate. A more complete analysis of the distribution data, however, does suggest that the difference results from a large change in transport properties in vivo in addition to a difference in release kinetics from p(CPP:SA). The 1-day data in Figures 8 and 9 was found to fit a previously established pharmacokinetic model for drug distribution in the brain (*26*). This model at steady-state reduces to the following equation in rectangular coordinates:

$$C(x) = C_0 e^{-x(k/D)^{1/2}} \quad (1)$$

where C is drug concentration at a distance x from the brain/implant interface, C_0 is drug concentration at the brain/implant interface, k is the first-order rate of elimination in the brain, and D is the effective diffusion coefficient in the brain. Equation 1 is appropriate for the case of a semi-infinite slab releasing into an infinite, homogeneous space.

The natural logarithm of the concentration data was found to vary linearly with distance, as predicted by this model, and a linear fit was used to extrapolate to $x = 0$ to estimate the interfacial concentration. The concentration at a distance from the implant was divided by the interfacial concentration to get the data points in Figure 11. The curves in Figure 11 represent best fits of the model to the experimental data. For our conjugate data derived from slices anterior to the implant, the logarithm of concentration deviates from linearity as the brain boundary at 4 mm is approached, and the data points past 2.5 mm were ignored in determining C_0 and k/D. The k/D values obtained by fitting Equation 1 to the Figure 11 data appear in column 2 of Table 2 and represent upper limit values of k/D. The k/D value is reduced more than 20-fold as a result of higher values of k/D resulting from PEGylation of CPT. A further explanation of determining k/D is given in the Supporting Information.

It is important to note that, although the distributions for the conjugates in the direction anterior to the matrix were significantly enhanced over free CPT (Figure 11), the penetration distances shown in Figure 8 are likely an underestimate of what could be achieved. In this experiment the polymer implant was located approximately 4 mm from the front tip of the brain, and on day-one after implantation, conjugate could be detected at a concentration of 10−30 ng/mg in slices close to the edge of the brain. Thus transfer of conjugate from the brain into the cerebrospinal fluid (CSF) likely occurred at the

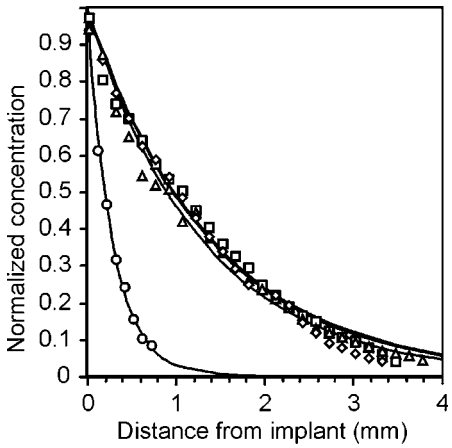

Figure 11. Normalized concentration profiles at distances anterior to the implants of CM-PEG-Sar−CPT (□), CM-PEG-Gly−CPT (△), CM-PEG−CPT (◇), and free CPT (○), fit to an established pharmacokinetic model (eq 1) 1 day following implantation of 20%-loaded p(CPP:SA) matrixes. Profiles were normalized with the concentration at the matrix/tissue interface that was estimated by extrapolating the experimental concentration data to the origin. Normalized data suggest that, in addition to the solubility and release kinetics, the transport properties of CPT in the brain have been changed by conjugation.

brain/CSF interface, effectively accelerating the apparent elimination of the compounds from the brain. Without the physical boundary at 4 mm, we would expect the drop-off to be slower, giving lower k/D values. Data from 1-mm slices posterior to the brain (Figure 7) showed the presence of high concentrations of conjugate more than 4 mm from the polymer, supporting the notion that greater penetration can be achieved by the conjugates in the absence of anatomical boundaries.

To determine the effect of the brain boundary, we have taken the rough 1-mm posterior distribution data, normalized it in the same way as for the thin-slice data, and fit it to the same steady-state distribution equation. No deviation from linearity was seen with these data, and data out to 10 mm was used for curve-fitting. Figure 12 shows the resulting data and curve fits for conjugates for both the 1-day and 7-day time points. A comparison of the k/D values in columns 3 and 4 to column 2 of Table 2 shows that the k/D value is similar for CM-PEG−CPT and CM-PEG-Sar−CPT in all three cases. The k/D is lower for the posterior data, indicating greater distribution is achieved once the anatomical boundary is removed. CM-PEG-Gly−CPT is an anomaly, in that the k/D value is always higher than for the other two conjugates and does not decrease between 1 and 7 days in the posterior sections. The k/D values for CM-PEG-Gly−CPT are consistent with our observation that total CPT concentrations are significantly lower for CM-PEG-Gly−CPT at later time points compared to the other two conjugate systems. Either the direct ester and sarcosine conjugates are stabilized by a mechanism not available to the glycine conjugate, or an additional route eliminates the glycine conjugate, yet to be identified, that is not available for the other two conjugates.

The distributions of CM-PEG-Sar−CPT, CM-PEG-Gly−CPT, and CM-PEG−CPT were characterized in 1-mm sections of tissue at various time points following the implantation of 20%-drug-loaded p(CPP:SA) matrixes (Figure 7). From data at 28 days after implantation, CM-PEG-Gly−CPT is present in lower concentrations than CM-PEG−CPT and CM-PEG-Sar−CPT despite their relatively similar rates of hydrolysis in vitro (see Figure

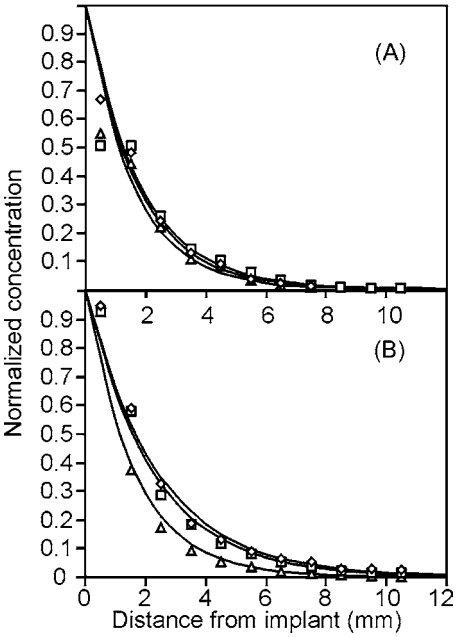

Figure 12. Normalized concentration profiles posterior to implant of CM-PEG-Sar−CPT (□), CM-PEG-Gly−CPT (△), and CM-PEG−CPT (◇): (A) 1 day following implantation and (B) 7 days following implantation of 20%-loaded p(CPP:SA) matrixes. Profiles are normalized with the concentration at the matrix/tissue interface. The interfacial concentration was estimated by extrapolating concentration data to the origin.

1). Furthermore, since we anticipate that the conjugate-releasing source is exhausted by two weeks following implantation, we would expect to see a large decrease in the concentration of conjugates in vivo between 14 and 28 days. Figure 7 shows that although this anticipated decrease was observed for CM-PEG-Gly−CPT, the concentrations of CM-PEG−CPT and CM-PEG-Sar−CPT stayed relatively high. On the basis of this reasoning, it seems that CM-PEG-Sar−CPT and CM-PEG−CPT may be stabilized in vivo by a mechanism that does not affect CM-PEG-Gly−CPT. For example, CM-PEG-Sar−CPT and CM-PEG−CPT may be specifically bound in a way that reduces or stops their hydrolysis to a greater extent than CM-PEG-Gly−CPT. Others have previously shown that when incubated in human plasma, only 25% of CPT was recovered from CM-PEG40000−CPT as compared to a 65% recovery of free drug for CM-PEG40000-Gly−CPT (*12*). This finding supports the idea that interactions with biological molecules can stabilize these conjugates in a manner dependent on their linkage chemistries. However, despite the fact that CM-PEG-Gly−CPT seems to be eliminated from the rat brain more rapidly than CM-PEG−CPT or CM-PEG-Sar−CPT, the levels of liberated drug measured for the three conjugate forms were similar. Since it is not known if the reduced retention of CM-PEG-Gly−CPT correlates with an increase in the amount of CPT liberated in vivo, it is not possible to conclude whether CM-PEG-Gly−CPT performs better or worse than the other conjugate forms based solely on the retention data.

If drug is eliminated at brain boundaries into the CSF as we expect, it is possible for compounds to enter back into brain tissue in distant locations. This mechanism may contribute to the noted presence of drug in the cerebellum following the delivery of CPT conjugates. The cerebellum was located approximately 10 mm from the implant site. Figure 7 shows levels of CPT above background in sections corresponding to this brain region for all conjugate forms up to one week after delivery. This was unexpected, since, although the cerebrum and the cerebellum are in contact, they are discrete regions of tissue and, intuitively, it would seem that the anatomical boundary between them would be a barrier for diffusion. Thus, this observation may indicate that convection in the CSF, which bathes the entire brain, may play a role in disseminating conjugate to distant regions of the brain.

In addition to measuring total CPT levels in thin sections of brain, alternating tissue slices were used to measure the fraction of total CPT in the unconjugated form. For all conjugates, only low levels of unconjugated drug, less than 1% of total CPT, could be detected. If we look at accumulation of CPT in our system:

$$\frac{dC_{CPT}}{dt} = k_h C_{conj} - k_e C_{CPT} \quad (2)$$

where k_h is the conjugate hydrolysis rate and k_e is the CPT elimination rate, the maximum ratio of CPT-to-conjugate would be found at steady-state, where $0 = k_h C_{conj} - k_e C_{CPT}$, or

$$\frac{C_{CPT}}{C_{conj}} = \frac{k_h}{k_e} \quad (3)$$

We have shown a k_h value of 0.012 h^{-1} for the sarcosine conjugate, and a k_e value of 1.2 h^{-1} for CPT are good estimates which would give a steady-state ratio of about 1-to-100. Our experimental finding of 1% or less free CPT is therefore not surprising. However, in comparing the detection limit of our assay (1 ng/mg) with the concentration of free drug required to kill cells in culture (LC_{50} = 0.015 ng/mg for a 3-day exposure), we see that it is not possible to predict the potential efficacy of the conjugates based on these free drug measurements, since even though concentrations are below the detection limit, they may be sufficient to kill tumor cells.

In summary, the synthesized CPT conjugates have pH-dependent hydrolysis rates similar to those reported for conjugates of PEG40000 (*2*). The conjugates were shown to be cytotoxic in cell culture. Fluorescence microscopy studies demonstrated that conjugate can be endocytosed by cells, but the conjugates were shown to be highly stable in acidic conditions, suggesting that this mechanism for toxicity may not make a large contribution to the overall cell kill. On the basis of LC_{50} data, the potency of the conjugates appears to be lower than for free drug, but in considering the dynamics of drug release from the conjugates, the shift in LC_{50} can be accounted for by release of drug over time rather than an irreversible loss of potency of the camptothecin molecule upon conjugation. Comparison of the distributions of CPT conjugates and unmodified CPT in rat brains demonstrated the capacity of conjugation to alter the transport properties of small molecules in brain tissue. When CPT was delivered in the conjugated form, the ratio of elimination to diffusion decreased, much higher concentrations of drug could be achieved within tissue, and drug could be detected at a greater distance from the source. These findings suggest that drug conjugation would be a useful adjunct to localized drug delivery in the brain.

REVIEWS

Multimodality in Vivo Molecular-Genetic Imaging

Michael Doubrovin, Inna Serganova, Philipp Mayer-Kuckuk, Vladimir Ponomarev, and Ronald G. Blasberg*

Departments of Neurology and Radiology, Memorial Sloan-Kettering Cancer Center, New York, New York 10021. Received June 18, 2004

Multimodality imaging is increasingly being used in molecular-genetic studies in small animals. The coupling of nuclear and optical reporter genes represents the beginning of a far wider application of this technology. Optical imaging and optical reporter systems are cost-effective and time-efficient, they require less resources and space than PET or MRI, and they are particularly well suited for small animal imaging and for in vitro assays to validate different reporter systems. However, optical imaging techniques are limited by depth of light penetration and scatter and do not yet provide optimal quantitative or tomographic information. These issues are not limiting for PET- or MRI-based reporter systems, and PET- and MRI-based animal studies are more easily generalized to human applications. Many of the shortcomings of each modality alone can be overcome by the use of dual- or triple-modality reporter constructs that incorporate the opportunity for PET, fluorescence and bioluminescence imaging. We optimistically expect that some form of tomographic, small animal optical imaging capability will be developed soon, and that this will provide the opportunity for the colocalization of optical signals to anatomical structures provided by tomographic CT and MR imaging.

INTRODUCTION

As this was the first presentation at the Symposium on Chemistry and Biological Applications of Imaging Agents and Molecular Beacons, and is the initial article in this series of reviews, it might be advantageous to provide some background on the origins and development of "molecular imaging". The past several decades have witnessed an astonishing increase in our knowledge and understanding of the genetics and molecular biology of human disease. Significant progress has been made in our understanding of the molecular-genetic mechanisms of many diseases, and this has been achieved with the advent of the modern molecular-biological assays. In parallel with the developments in genetics and molecular biology, the imaging sciences have also made remarkable advances in technology for visualizing tissue structure and function. This progress includes the development of new instruments (e.g., microPET, microCT, high-field strength magnets, and novel optical and ultrasound technology) for imaging small animals with improved image resolution and sensitivity (*1*–*5*). There have been corresponding improvements in clinical imaging instrumentation as well. The molecular/cellular and imaging disciplines rarely interacted until the 1990s. In the mid 1990s, several investigators and the NCI began to promote "cellular and molecular imaging", and this convergence of the "molecular" and "imaging" sciences was nurtured by Richard Klausner, then director of the NCI. Molecular imaging–cancer imaging was designated as one of six "Extraordinary Scientific Opportunities for Investment" in 1997, and this initiative was strongly supported by two imaging-based NCI programs (the Small Animal Imaging Resource Program, SAIRP, and the In Vivo, Cellular and Molecular Imaging Centers, ICMIC). More recently, other NIH institutes and the Department of Energy (DOE) have also developed "molecular imaging" program support.

The convergence of molecular biology and noninvasive imaging was timely and addresses several experimental objectives. For example, ex vivo molecular assays in animal models of disease and in transgenic animals require invasive sampling procedures. Tissue sampling may not always adequately represent the biochemical or pathological process under investigation due to tissue heterogeneity, which is especially characteristic of cancer. Furthermore, time-course studies require large numbers of animals that are sacrificed at specific time points in order to achieve a statistically significant temporal profile. The development of versatile and sensitive assays to monitor molecular-genetic and cellular processes in vivo would be of considerable value in human subjects, as well as in experimental animal models of different diseases. Noninvasive imaging of molecular-genetic and cellular processes would compliment existing ex vivo molecular-biological assays and can provide a spatial as well as a temporal dimension to our understanding of various diseases.

At this point it may be helpful to provide the readership of this series on "molecular imaging" with a definition of this newly emerging and rapidly evolving field. We developed the following definition several years ago: "the visualization of cellular processes in space and time at a molecular or genetic level of function". Other

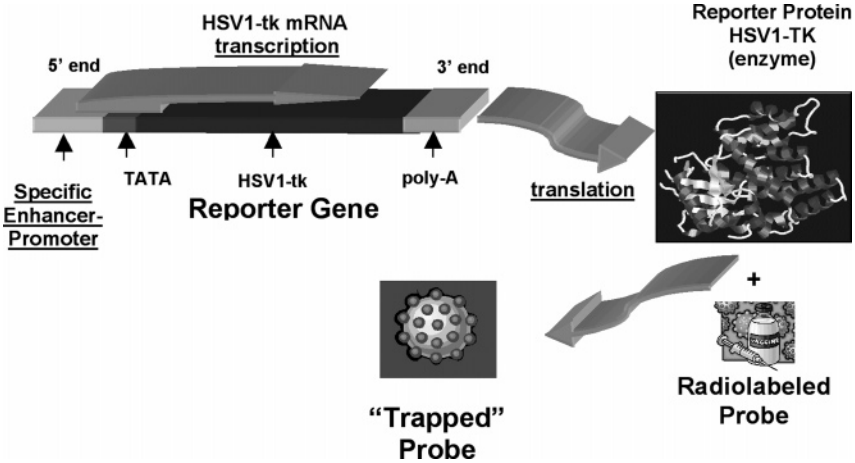

Figure 1. HSV1-*tk* reporter construct and the indirect reporter imaging paradigm. The basic structure of a reporter gene complex is shown, in this case herpes simplex virus type 1 thymidine kinase (HSV1-*tk*). The control and regulation of gene expression is performed through promoter and enhancer regions that are located at the 5′ end ("upstream") of the reporter gene. These promoter/enhancer elements can be "constitutive" and result in continuous gene expression ("always on"), or they can be "inducible" and sensitive to activation by endogenous transcription factors and promoters. Following the initiation of transcription and translation, the gene product, a protein, accumulates. In this case the reporter gene product is an enzyme (HSV1-TK). HSV1-TK will phosphorylate selected thymidine analogues (e.g., FIAU or FHBG), whereas these probes are not phosphorylated by endogenous mammalian TK1. The phosphorylated probe does not cross the cell membrane readily; it is "trapped" and accumulates within transduced cells. Thus, the magnitude of probe accumulation in the cell (level of radioactivity) reflects the level of HSV1-TK enzyme activity and level of HSV1-tk gene expression.

definitions of "molecular imaging" abound and include variations on the theme and some emphasize different aspects to explain the advent, development, and evolution of this new discipline.

The readers of this chapter are urged to consult other reviews of imaging transgene expression and molecular-biological reporter gene imaging that have been written (*6*−*13*), and other perspectives on molecular imaging (*14*−*20*). In addition, there are two new journals that are specifically serving the molecular imaging community: Molecular Imaging (MIT Press; the official journal of the Society of Molecular Imaging, www.molecularimaging-.com) and Molecular Imaging and Biology (Elsevier, the official journal of the Academy of Molecular Imaging, (http://149.142.143.206/index.html).

Molecular Imaging Strategies. Three imaging strategies have been described: "direct", "indirect", and "biomarker". Direct imaging strategies are based on imaging the target directly, usually with a target-specific probe. This strategy has been established using nuclear, optical, and MR imaging technology. The resultant image of probe localization and concentration (signal intensity) is directly related to its interaction with the target. Imaging cell surface specific antigens with radiolabeled antibodies and genetically engineered antibody fragments (e.g., minibodies) are examples of direct molecular imaging that has evolved over the past 30 years. In vivo imaging of receptor density/occupancy using small radiolabeled ligands has also been widely used, particularly in neuroscience research, over the past two decades. These examples represent some of the first "molecular imaging" applications used in clinical nuclear medicine research. More recent research has focused on chemistry and the synthesis of small radiolabeled or fluorescent probes (and paramagnetic nanoparticles) that target specific receptors (e.g, the estrogen or androgen receptors) and florescent probes that are activated by endogenous proteases (*21*). For example, the alpha(v)beta3 integrin is highly expressed on tumor vasculature and plays an important role in metastasis and tumor-induced angiogenesis; initial studies targeting and imaging of the alpha(v)beta3 integrin with radiolabeled glycosylated RGD-containing peptides are very encouraging (*22*). The development of other novel direct-imaging probes and ligands will be discussed by other contributors to this series, including C. Meares, R. Pandrey, D. Bornhop, J. Katzenellenbogen, W. Eckelman, D. Hnatowich, W. Welsh, and others.

Indirect molecular imaging strategies are a little more complex. One example of indirect imaging that is now being widely used is "reporter gene imaging". It requires "pretargeting" (delivery) of the reporter gene to the target tissue (by transfection/transduction), and it usually includes transcriptional control components that function as "molecular-genetic sensors" and initiate reporter gene expression. Reporter gene imaging may also require a specific probe that must interact with the reporter gene product in order to produce an image. In this case, the "target" molecule (or the activity of a specific intracellular signal transduction pathway) is not imaged directly. A simplified description and cartoon of a reporter gene is shown in Figure 1, and a representation of different reporter genes for imaging transduced cells is shown in Figure 2. The resultant image reflects multiple processes that include the transfer of the reporter gene into the target cells, followed by the initiation of reporter gene transcription and subsequent translation of the reporter protein (the reporter gene product). These issues and others related to the intracellular or membrane localization and the degradation or ubiquination of the reporter protein, the biodistribution and clearance of reporter probes, and the optimal conditions for fluorescence and bioluminescence imaging are more fully addressed below.

Biomarker or surrogate marker imaging can be used to assess downstream effects of one or more endogenous molecular-genetic processes. This approach is particularly attractive for potential translation into clinical studies in the near-term, because existing radiopharmaceuticals and imaging paradigms may be useful for monitoring downstream effects of changes in specific molecular-genetic pathways in diseases such as cancer. A recent example of clinically useful biomarker imaging for "early" assessment of treatment response is FDG PET imaging of gastrointestinal stromal tumors (GIST) pre- and post-

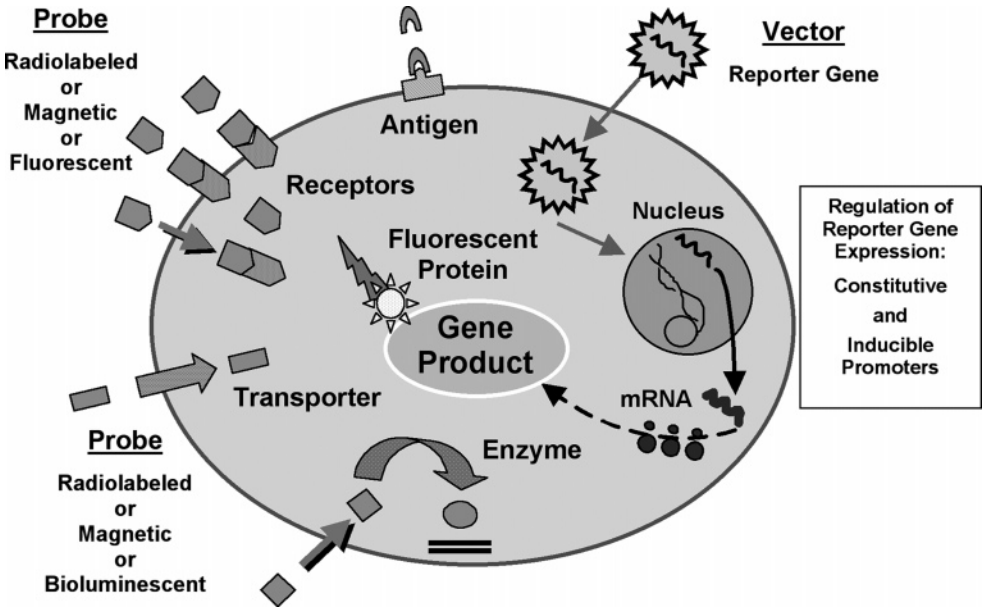

Figure 2. Different reporter systems. The reporter gene complex is transfected into target cells by a vector (e.g., a virus). Inside the transfected cell, the reporter gene may or may not be integrated into the host-cell genome; transcription of the reporter gene to mRNA is initiated by "constitutive" or "inducible" promoters, and translation of the mRNA to a protein, occurs on the ribosomes. The reporter gene product can be a cytoplasmic or nuclear enzyme, a transporter in the cell membrane, a receptor at the cell surface or part of cytoplasmic or nuclear complex, an artificial cell surface antigen, or a fluorescent protein. Often, a complimentary reporter probe (e.g, a radiolabeled, magnetic, or bioluminescent molecule) is given, and the probe concentrates (or emits light) at the site of reporter gene expression. The level of probe concentration (or intensity of light) is usually proportional to the level of reporter gene expression and can reflect several processes, including the level of transcription, the modulation and regulation of translation, protein−protein interactions, and posttranslational regulation of protein conformation and degradation.

Table 1. The Most Widely Used Imaging Modalities

- optical (fluorescence, bioluminescence, spectroscopy, optical coherence tomography)
- magnetic resonance (contrast, diffusion-weighted imaging, spectroscopy)
- radionuclide (PET, SPECT, gamma camera, autoradiography)

STI571 (Gleevec) treatment (*23*, *24*). Although glucose uptake and glycolytic enzyme activity is homeostatically regulated, glucose metabolism has been shown to be regulated by extracellular signals mediated by cell surface receptors. Receptor-mediated regulation of glucose uptake is thought to involve activation of PI 3-kinase, Akt, mTOR, and S6 kinase. A likely explanation for the dramatic effect of STI571 (Gleevec) on glucose uptake in GIST is that Kit receptor signaling regulates glucose uptake as well as glucose metabolism.

Imaging Modalities. The most widely used imaging modalities are listed in Table 1, although other modalities, such as ultrasound and CT, are seeing increasing application and could be included. The convergence of these different modalities to support current molecular imaging efforts is largely based on the development of multimodality reporter systems for both optical and radionuclide imaging (see below). A number of different strategies are also being developed for magnetic resonance reporter gene imaging, and they are being combined with other reporter systems to broaden the range of biological applications (*25*−*28*). MR spectroscopy can detect and measure the concentration of specific molecules such as 5FU. MR spectroscopy was used in combination with 5FC and yeast cytosine deaminase (yCD) in suicide gene therapy protocol and was shown to be effective (*29*). The interaction of several disciplines, including molecular-cell biology and chemistry with different imaging modalities, is illustrated by the Ven diagram (Figure 3) and illustrates the theme of this presentation. Namely, a mutimodality, mutidisciplinary approach to molecular imaging provides distinct advantages. Several of the imaging modalities (fluorescence, bioluminescence, and nuclear) will be illustrated in the following paragraph, and their combined advantage will be highlighted.

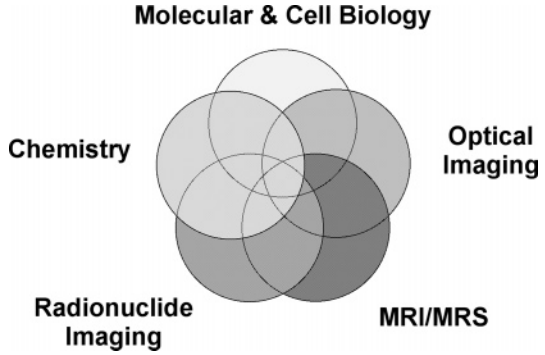

Figure 3. Mutidisciplinary approach to molecular imaging. Molecular and cell biology, along with chemistry, provide the foundation and resources for developing novel in vivo molecular constructs and imaging paradigms. Three imaging modalities currently dominate the field, but this will soon expand to include other modalities. The Ven diagram emphasizes the interaction between disciplines and different imaging modalities; it is this interaction that provides a broad new approach to the field.

Reporter Gene Imaging. This report will focus on noninvasive multimodality nuclear and optical reporter imaging in small animals. It will highlight the application and advantages of a multimodality imaging approach, as well as discuss the potential limits of reporter-gene imaging and its translation into clinical studies. It is important to note at the outset of this discussion that imaging transgene expression requires transfection/transduction of a reporter gene construct into target cells.

This is usually accomplished with a vector that is capable of transfecting/transducing the target tissue (cells), and several currently available vector types can be used (e.g., plasmid, retrovirus, adenovirus, adeno-associated virus, lentivirus). The reporter transgene can encode for an enzyme, (e.g., *HSV1-tk* (*30*) or *luciferase* (*31*)), a receptor (e.g., *hD2R* (*32*)) or *hSSTR2* (*33*)), or a transporter (e.g., *hNIS*) (*34*)), or it can encode for a fluorescent protein (e.g., *eGFP* (*35*)) (Figure 2).

The paradigm for quantitative imaging of transgene expression involves several key steps, including the transfer of the reporter construct into target tissue or cells, the initiation of transcription (that can be controlled by specific promoter/enhancer elements), the process of DNA transcription, and subsequent translation of mRNA into the gene product. As outlined below, recent studies have demonstrated that all these key events can be specifically visualized in vivo by utilizing reporter gene imaging. A general paradigm for gene imaging using radiolabeled probes was initially described in 1995 (*30*) and our first in vivo (autoradiographic) imaging study using herpes simplex virus type 1 thymidine kinase (HSV1-*tk*) as a reporter gene and 5-iodo-2′-fluoro-2′deoxy-1-β-D-arabino-furanosyl-uracil (FIAU) as a reporter probe is shown in Figure 4B. Subsequent imaging was performed with [^{131}I]FIAU (*36*) and a gamma camera (Figure 4C) and then with [^{124}I]FIAU (*37*) and PET (Figure 4D).

A common feature of all reporter constructs is the cDNA expression cassette containing the reporter gene(s) of interest (e.g., HSV1-*tk*) which can be placed under the control of specific promoter-enhancer elements. The versatility of reporter gene imaging results in part from the flexibility to tailor the expression cassette to an individual need. In most cases, standard molecular biology techniques are sufficient to design a suitable expression cassette. Using specific expression cassettes, reporter genes can be "always turned on" by constitutive promoters (such as LTR, RSV, CMV, PGK, EF1, etc.) and used to monitor cell trafficking by identifying the location, migration, targeting, and proliferation of stably transduced cells. Alternatively, the promoter/enhancer elements can be constructed to be "inducible" and "sensitive" to activation in selected cell types and regulation by specific endogenous pathways. Promoter activation can be tissue specific, where promoter/enhancer elements are activated by transcription factors that are overexpressed in specific tissue, e.g. the PSMA promoter shows significant activity in prostate cancer cells (*38*), the albumin promoter is expressed in liver (*39*), and the CEA promoter is highly expressed in colorectal cancer (*40*). Inducible reporter genes can also be constructed to be sensitive to specific endogenous molecular processes, including the regulation of endogenous gene expression (*41*), the activity of specific signal transduction pathways (*42*), and specific protein−protein interactions (*43*, *44*), and post-transcriptional regulation of protein expression (*45*).

Another example of the versatility of reporter systems is the ability to create multimodality reporter constructs. For example, a fusion gene containing cDNA from two or three different reporter genes can be constructed, where the gene product yields a single fusion protein that retains functionality of each of the composite gene products (*46*) (Figure 5). A second strategy links two reporter genes by a type II internal ribosomal entry site (IRES) sequence, where the IRES element enables translation initiation within the bicistronic mRNA, thus permitting gene coexpression by cap-dependent translation of the first cistron and cap-independent, IRES-mediated translation of the second cistron (*47*, *48*). A third strategy uses one vector containing two different promoters and two different reporter genes. A fourth strategy uses multiple vectors, where one or more vectors carry a therapeutic gene and other vectors carry the reporter genes (*49*). All four strategies are based on demonstrating a proportional and constant relationship in the coexpression of two or more transgenes over a wide range of expression levels.

Radionuclide-Reporter Gene Imaging. Wild-type *HSV1-tk* (*37*) and a mutant *HSV1-tk* gene, *HSV1-sr39tk* (*50*), are the reporter genes most commonly used in current molecular imaging studies using radiolabeled probes and PET imaging. The *HSV1-tk* and *HSV1-sr39tk* gene products are enzymes that have less substrate specificity than mammalian thymidine kinase 1 (TK1) and can phosphorylate a wider range of compounds. The viral kinases can phosphorylated acycloguanosines (e.g., acyclovir, ACV; ganciclovir, GCV; 9-[4-fluoro-3-(hydoxymethyl)butyl]guanine, FHBG) and 2′-fluoro-nucleoside analogues of thymidine (e.g., 5-iodo-2′-fluoro-2′deoxy-1-β-D-arabino-furanosyl-uracil, FIAU), whereas mammalian TK1 has limited or no ability to phosphorylate these compounds (*51*). This difference between mammalian and viral TK enzymes permits the development and use of radiolabeled probes that are selectively phosphorylated by HSV1-TK or HSV1-sr39TK. The advantages and disadvantages of different radiolabeled probes for imaging viral TK expression have been compared and extensively discussed in the literature (*52*, *53*). It is most likely that [^{124}I]FIAU (*54*) and [^{18}F]FHBG (*55*) will be the radiolabeled probes that will be first introduced into the clinic for imaging HSV1-tk gene expression. As noted above, other radionuclide-based reporter systems have been developed. Several of these reporter systems have distinct benefits with respect to initiating molecular/reporter imaging in human subjects, since the reporters are derived from human genes.

Optical-Reporter Gene Imaging. Optical-based (bioluminescence and fluorescence) reporter systems are receiving increased attention because of their efficiency for sequential imaging, operational simplicity, and substantial cost benefits. Bioluminescence reporter genes are being widely used for whole body imaging in small animals (Figures 5 and 6). The most commonly used bioluminescence reporter systems include the *Firefly* (FLuc) or *Renilla* (RLuc) luciferase genes (*56*). As with nuclear and magnetic resonance reporter systems, bioluminescence imaging depends on the delivery of a specific substrate to the reporter gene expressing cells. Further, the light emitting bioluminescence reaction catalyzed by luciferases depends on the presence of oxygen (*57*) and for example in the case of FLuc additionally on the cofactor ATP. The *Firefly* and *Renilla luciferase* reporter systems, in combination with their corresponding luminescent substrates (luciferin and coelenterazine), have several advantages for imaging small living animals. Autobioluminescence in most cases is essentially nonexistent and results in very low background light emission; this contributes to the very high sensitivity and specificity of this optical imaging technique (*58*, *59*). Semiquantitative accuracy and reproducibility requires that the luciferin, ATP, and oxygen levels are *not* rate determining, but rather are in excess. Under these conditions, the photon emission flux (light intensity) is directly related to reporter gene expression and the level of reporter gene product, namely, luciferase. Another potential concern is the fact that the substrate for *Renilla luciferase*, coelenterazine, is a substrate for the MDR1 transporter.

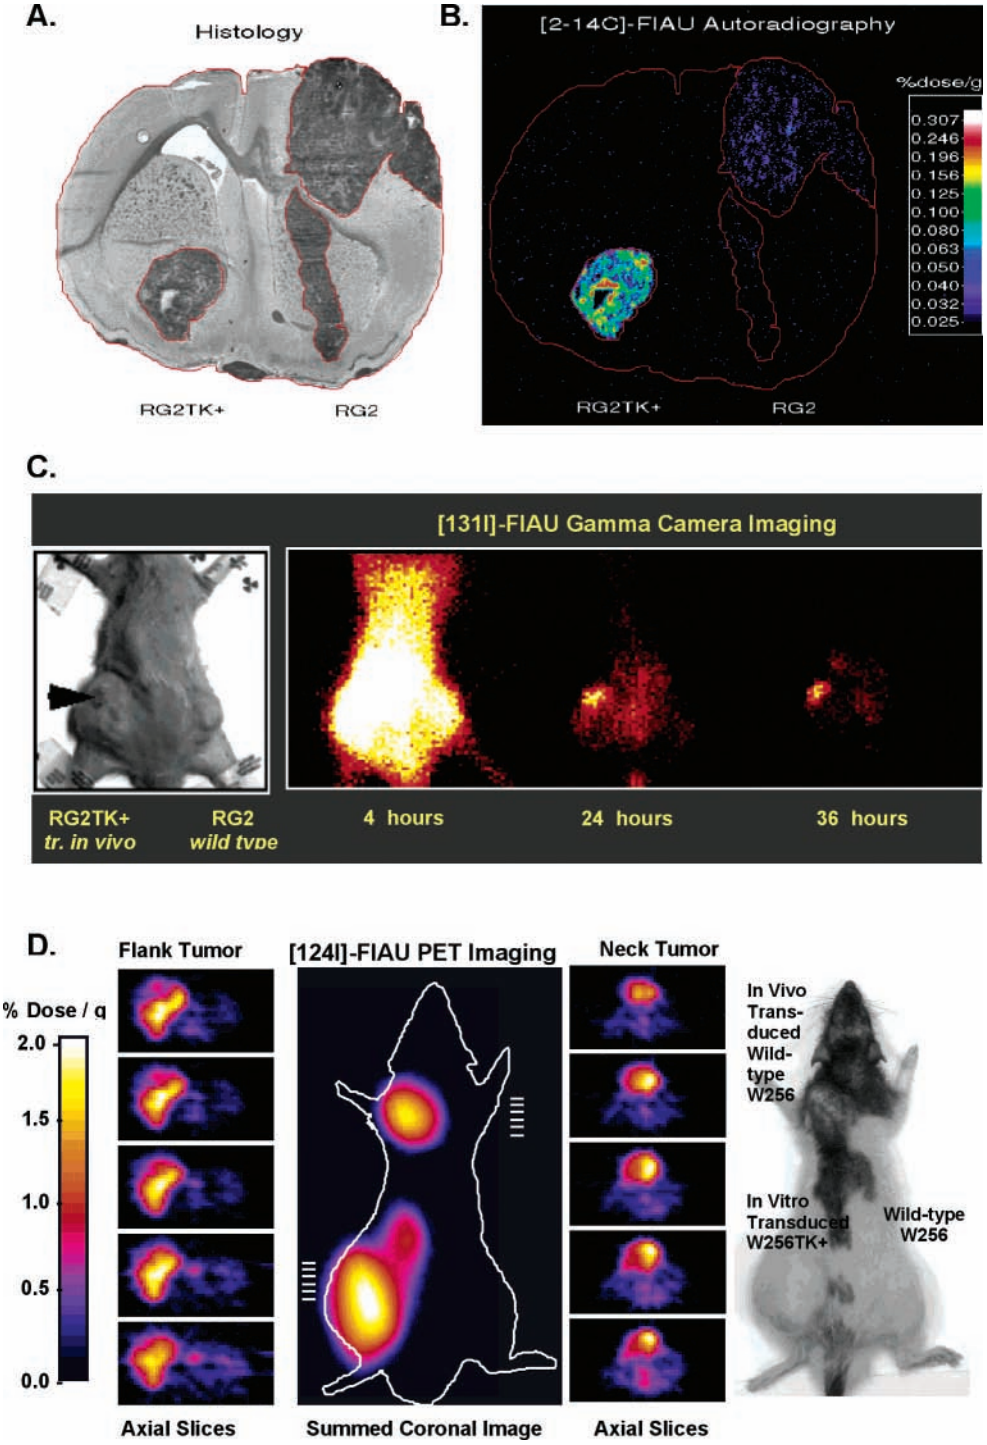

Figure 4. *Autoradiographic imaging HSV1-tk expression*. An animal with a stably transduced RG2TK+ xenograft in the left hemisphere and a wild-type (nontransduced) RG2 xenograft in the right hemisphere was studied. The histology and autoradiographic images were generated from the same tissue section (panels A and B). Both xenografts in the brain of this rat are clearly seen in the toluidine blue stained histological section (panel A). Twenty four hours after iv administration of [^{14}C]FIAU, the RG2TK+ tumor is clearly visualized in the autoradiographic image (panel B), whereas the RG2 tumor is barely detectable; the surrounding brain is at background levels. Figure adapted from ref 30. *Gamma camera imaging HSV1-tk expression* (panel C). Gamma camera imaging was performed at 4, 24, and 36 h after [^{131}I]FIAU injection in an animals bearing bilateral RG2 flank xenografts; the images have been normalized to a reference standard (not shown in the field of view). The site of inoculation of HSV1-*tk* retroviral vector producer cells (gp-STK-A2) into the left flank xenograft is indicated by the arrow. The sequential images demonstrate washout of radioactivity from the body, with specific retention of activity in the area of gp-STK-A2 cell inoculation and transduction of RG2 tumor cells with the HSV1-*tk* reporter (see the 24 and 36 h images). The nontransduced contralateral xenograft (right flank) and other tissues did not show any retention of radioactivity. Figure adapted from ref 36. *PET imaging HSV1-tk expression* (panel D). Three xenografts were produced in rnu Sprague Dawley R-Nu rats. A W256TK+ (positive control) xenograft was produced from stably transduced W256TK+ cells and is located in the left flank, and a wild-type W256 (negative control) xenograft was produced in the dorsum of the neck and in the right flank. The neck tumor (wild-type) was inoculated with 10^6 gp-STK-A2 vector-producer cells (retroviral titer: 10^6-10^7 cfu/mL) to induce HSV1-*tk* transduction of the tumor in vivo. Fourteen days after gp-STK-A2 cell inoculation, no-carrier-added [^{124}I]FIAU (25 μCi) was injected iv and PET imaging (GE Advance) was performed 30 h later. Localization of radioactivity is clearly seen in left flank tumor (positive control) and in the in vivo transduced neck tumor (test), but only low background levels of radioactivity were observed in the right flank tumor (negative control). Figure adapted from ref 37.

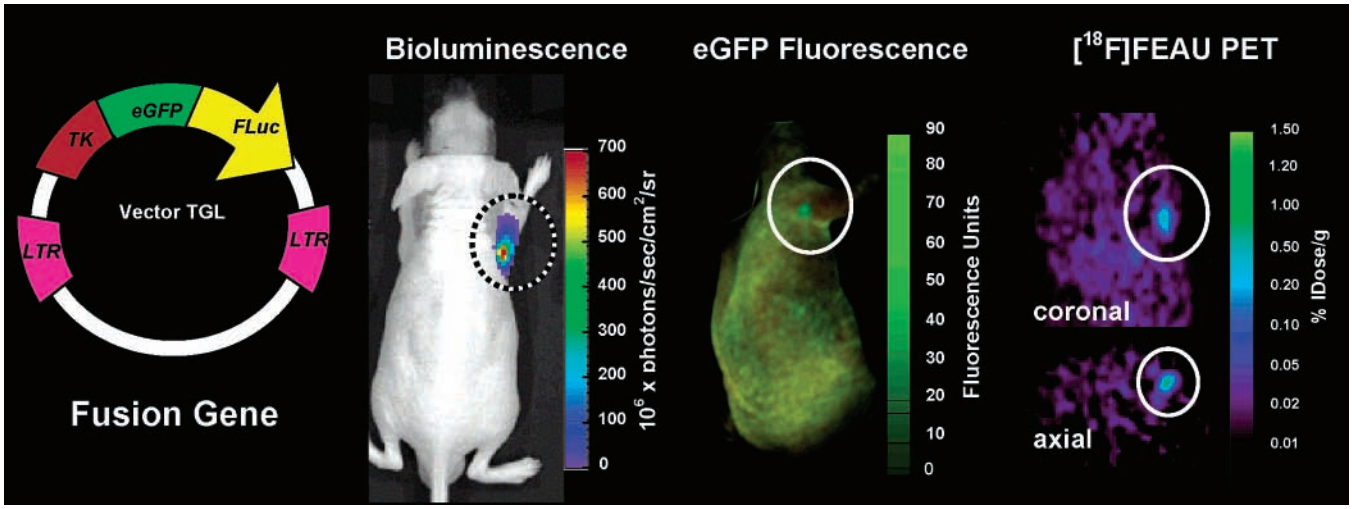

Figure 5. Multimodality triple-reporter system. Schematic structure of a retroviral vector (TGL) for mammalian expression of a triple-fusion reporter gene (HSV1-thymidine kinase, *TK*; enhanced green fluorescent protein, *eGFP*; firefly luciferase, *FLuc*) driven by an LTR promoter (left panel). Noninvasive, multimodality imaging of mice bearing subcutaneous xenografts produced from HSV1-tk/eGFP-cmvFluc transduced U87 cells (right shoulder) and wild-type (nontransduced) U87 cells (left shoulder). The xenografts were 4−5 mm in diameter. Whole-body fluorescence imaging (A), whole-body bioluminescence imaging (B), and axial and coronal microPET images of [^{18}F]FEAU accumulation are shown for the same mouse. Figure adapted from ref 77.

It has recently been shown that coelenterazine is rapidly exported from cell lines that express MDR1, and this could impact on the photon emission flux from the coelenterazine−*Renilla luciferase* reporter system in these cells (*60*). In vivo bioluminescence imaging has been successfully applied to many novel reporter systems and is rapidly expanding in the molecular and cell biology communities.

Fluorescent protein-based reporter gene systems started with different spectral shifted variants of *Aequorea victoria* green fluorescent protein (*GFP*), including an enhanced GFP (*eGFP*) (*61*−*67*). A number of red fluorescent proteins including *Discosoma species* (ds*Red1* and *dsRed2*) (*68*, *69*) and *Heteractis crispa* (HcRed) (*70*) have also been described. Fluorescence imaging has been shown to be very useful for in vitro applications such as (1) tracking the translocation of proteins within cells, (2) identifying and selecting transduced cells using FACS, and (3) cost-effective in vitro assays to validate the function and sensitivity of specific-inducible reporter systems. The development of whole body transcutaneous fluorescent imaging technology provides for (1) imaging reporter gene expression in small living animals (Figures 5 and 6), and (2) localizing transduced cells and/or the expression of inducible reporter systems (e.g., expression of p53, Figure 7) in tissue sections at the microscopic level by in situ fluorescence imaging (*16*, *71*). Limitations of fluorescence reporter imaging include the requirement of an external source of light and the exponentially decreasing intensity of light with increasing depth of the target. However, a new class of red fluorescent proteins and near-infrared dyes are providing better deep tissue imaging characteristics (*68*−*70*) and are a focus of current research development.

Endogenous autofluorescence of tissues frequently results in substantial background emissions that limit the sensitivity and specificity of this imaging technique, and this contributes to an important advantage of bioluminescence over fluorescence reporters. However, the use of selective filters or the application of spectral analysis can significantly reduce the contribution of autofluorescence to the acquired images. Nevertheless, in vivo bioluminescence reporter imaging remains more sensitive than in vivo fluorescence reporter imaging.

Luciferase may be well suited to monitor transcription due to its relatively fast induction (*72*) and to the considerable short biological half-life of luciferin and luciferase (*73*). This is an advantage compared to the longer-lived *eGFP*. However, short-lived (rapidly degradable) variants of *eGFP* have been recently developed, and *eGFP* can be used for higher resolution imaging in cells in vitro. Combining these reporter genes into a single gene could provide additional tools for the analysis of cancer cells in vivo and ex vivo. Such a dual-function reporter gene was created and the single encoded protein was shown to be fluorescent and bioluminescent (*74*).

Multimodality Nuclear and Optical Reporter Imaging. The coupling of a nuclear reporter gene (e.g. *HSV1-tk*) with an optical reporter gene (e.g., *eGFP*) has been reported (*75*). More recently a series of *TKeGFP* mutants were developed with altered nuclear localization and better cellular enzymatic activity to optimize the sensitivity for imaging HSV1-tk/eGFP reporter gene expression (*46*). The *TKeGFP* reporter gene has been introduced into several different reporter systems to assess different molecular-biological pathways (*41*, *42*). A mutant thymidine kinase (HSV1-sr39tk)−Renilla luciferase (RL) fusion reporter construct ($tk_{20}rl$) was recently developed for both nuclear and optical imaging (*76*). This study demonstrated the specificity and sensitivity of bioluminescence imaging and showed a good correlation between the nuclear (microPET) and optical (CCD camera) readouts of the dual reporter system.

More recently, a triple-fusion reporter construct, TKeGFPLuc (TGL), has been developed (*77*, *78*), and representative images are shown in Figure 5 and 6. A single reporter construct (vector) with a gene product that can be assayed by three different imaging technologies (fluorescence, bioluminescence, and nuclear or magnetic resonance) provides the benefits of each modality. It will facilitate the development, validation, and testing of new reporter systems in small animals, as well as provide preliminary data that will facilitate the translation of such studies into humans.

Although optical imaging does not yet provide optimal quantitative or tomographic information, these issues are not limiting for PET-based reporter systems, and PET

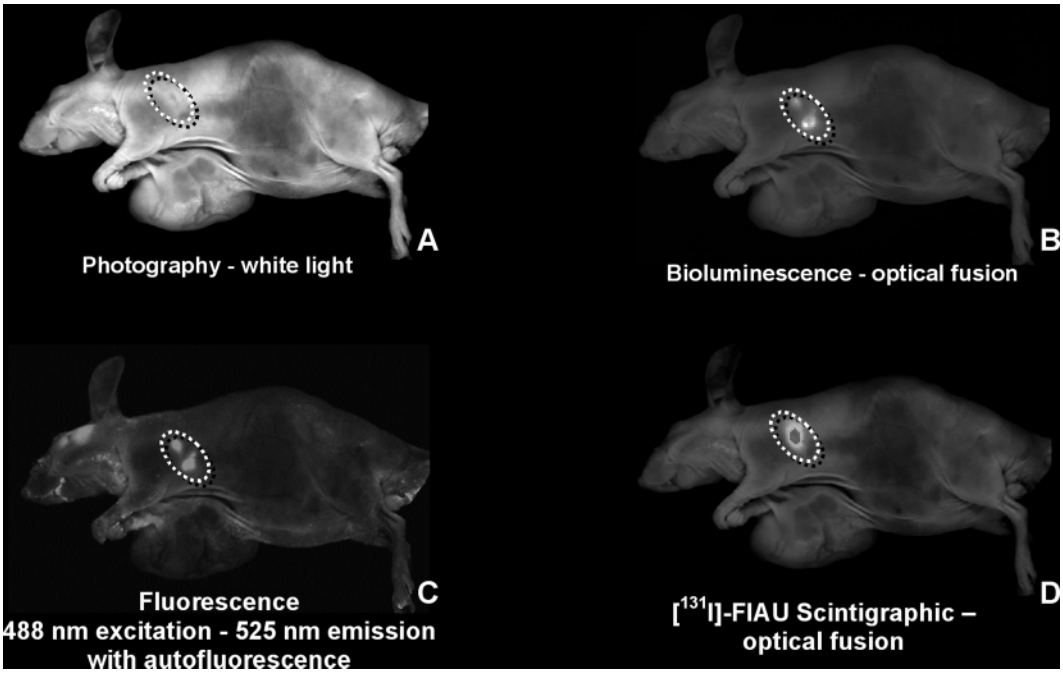

Figure 6. Multimodality imaging system. Multimodality imaging of a mouse bearing two xenografts: a small left shoulder xenograft (dashed oval outline) produced from 2×10^6 U87 cells transduced with the TK-eGFP−FLuc triple-modality reporter, and a large nontransduced U87MG xenograft located in the right shoulder and extending beneath the animal. A white light photograph is initially obtained (A), followed by whole-body fluorescence imaging − without correction for autofluorescence (B), followed by whole-body bioluminescence imaging (C), followed by whole-body scintigraphic imaging of [^{131}I]radioactivity, 24 h after iv [^{131}I]FIAU administration (D). All images were obtained from the same mouse at the same imaging session, and the mouse remained stationary between each imaging session. Note that panels C and D include optical fusion with the white-light photograph shown in panel A. Images were obtained on a Kodak R2000MM multimodal imaging system.

animal studies are more easily generalized to human applications. Using dual or triple modality reporter constructs (PET, fluorescence, and bioluminescence) overcomes many of the shortcomings of each modality alone. Multimodality reporters have been shown to facilitate the development, validation, and testing of new reporter systems in small animals (*41*, *42*), as well as provide preliminary data that will facilitate the translation of such studies into humans.

Imaging Biological Processes. Reporter-gene imaging is being used to address biological issues at the cellular and molecular level, even though our imaging resolution is at macroscopic levels. Within the past 5 years, proof-of-principle experiments in small animals have shown that it is possible to noninvasively image tissue-specific gene expression and the activity of several signal transduction pathways, and many of these studies involved multimodality imaging techniques. In addition, feasibility studies have shown that it is possible to image the endogenous regulation of transcription (*41*, *42*), posttranscriptional modulation of translation (*45*), specific protein−protein interactions (*43*, *44*, *79*), protein degradation and the activity of the proteosomal pathway (*80*), apoptosis (*81*), etc. Also, noninvasive imaging of viral (*82*, *83*), bacterial (*84*), and cell trafficking (*85*) studies have been published. Reporter gene labeling provides the opportunity for repetitive imaging and sequential monitoring of the tumor growth rate and response to treatment (*86*), as well as imaging metastases (*71*).

Imaging Transcriptional Regulation of Endogenous Genes. Noninvasive imaging of transcriptional regulation in living animals (and potentially in human subjects) will provide a clearer understanding of normal and cancer-related biological processes. A recent paper from our group (*42*) was the first to show that p53-dependent gene expression can be imaged in vivo with PET and by in situ fluorescence using a retroviral vector containing a *Cis*-p53/*TKeGFP* dual-reporter gene under control of a p53-specific response element (Figure 7). DNA damage-induced upregulation of p53 transcriptional activity was demonstrated and correlated with the expression of p53-dependent downstream genes (including p21). These findings were observed in U87 (p53 +/+) cells and xenografts, but not in SaOS (p53 −/−) cells. This was the first demonstration that a *Cis*-activated dual reporter system (*Cis*-p53/TKGFP) was sufficiently sensitive to image endogenous gene expression using noninvasive nuclear (PET) imaging. The PET images corresponded with up-regulation of genes in the p53 signal transduction pathway in response to DNA damage induced by BCNU chemotherapy. PET imaging of p53 transcriptional activity in tumors using the *Cis*-p53TKGFP reporter system could be used to assess the effects of new drugs or other novel therapeutic paradigms that are mediated through p53-dependent pathways. For example, specific p53 gene therapy strategies that are based on p53 overexpression could be monitored by noninvasive imaging.

The dual reporter construct (*TKeGFP*−fusion gene) provides the opportunity for multimodality (both nuclear and optical imaging) imaging of endogenous p53-dependent gene expression, in vivo. The *TKeGFP* reporter gene could be introduced into other reporter assay systems to assess other molecular-biological pathways. It should also be possible to use the *TKeGFP* reporter gene in transgenic animals; this will facilitate the monitoring and assessment of newly cloned genes or novel signal transduction pathways. Another advantage of the dual reporter system is the ability to compare the images of reporter gene expression obtained with PET, gamma camera, or autoradiography with corresponding in situ GFP fluorescence images. The comparison between GFP

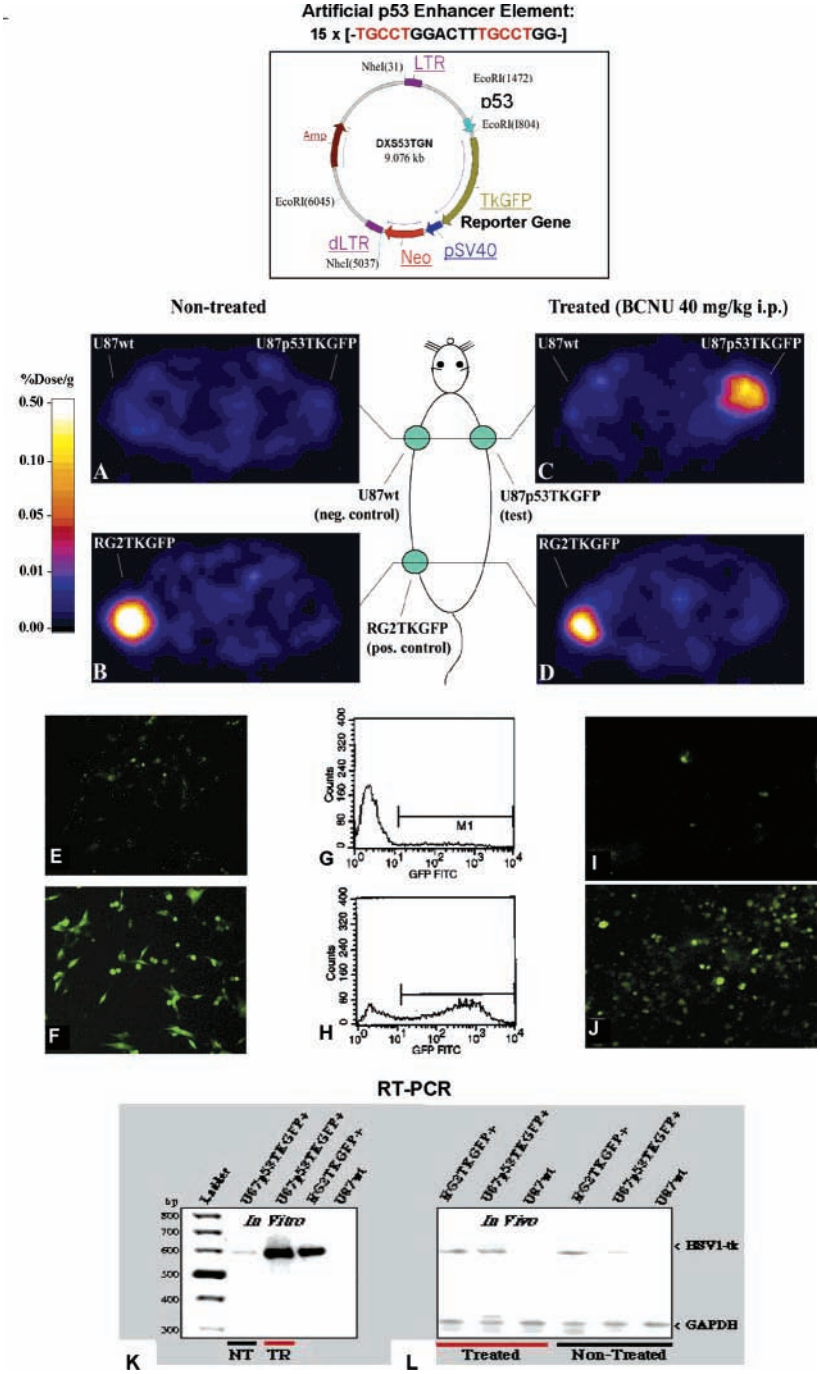

Figure 7. The p53-sensitive, dual-modality reporter vector (top panel) contains an artificial p53 specific enhancer element that activates expression of the *TKeGFP* reporter gene. A constitutively expressed neomycin selection gene is also included in the retroviral vector construct. Transaxial PET images (GE Advance tomograph) through the shoulder (A, C) and pelvis (B, D) of two rats are shown (second panel); the images are color-coded to the same radioactivity scale (%dose/g). An untreated animal is shown on the left (A, B), and a BCNU-treated animal, which is known to activate the p53 pathway, is shown on the right (C, D). Both animals have three sc xenografts: a U87p53TKGFP (test) in the right shoulder, a U87 wild-type (negative control) in the left shoulder, and a RG2TKGFP (positive control) in the left thigh. The nontreated animal on the left shows localization of radioactivity only in the positive control tumor (RG2TKGFP); the test (U87p53TKGFP) and negative control (U87wt) xenografts are at background levels. The BCNU-treated animal on the right shows significant radioactivity localization in the test tumor (right shoulder) and in the positive control (left thigh), but no radioactivity above background in the negative control (left shoulder). Fluorescence microscopy and FACS analysis (third panel) of a transduced U87p53/TKGFP cell population in the noninduced (control) state (E, G), and 24 h after a 2 h treatment with BCNU 40 mg/mL (F, H) are shown. Fluorescence microscopic images of post-motem U87p53/TKGFP sc tumor samples obtained from nontreated rats (I) and rats treated with 40 mg/kg BCNU ip (J) are also shown. These results (F−J) demonstrate a corresponding activation of the reporter system (increased fluorescence) due to p53 induction by BCNU treatment. RT-PCR blots from in vitro (K) and in vivo (L) experiments (lower panel) show very low HSV1-*tk* expression in nontreated U87p53TKGFP transduced cells and xenografts-bearing animals, respectively, and no HSV1-*tk* expression in wild-type U87 cells and tumor tissue, respectively. When U87p53TKGFP transduced cells and xenografts-bearing animals are treated with BCNU, there is a marked increase in HSV1-*tk* expression comparable to that in constitutively HSV1-*tk* expressing RG2TK+ cells and xenografts. Figure adapted from ref 42.

fluorescence and autoradiographic images, coupled with histology of corresponding tissue sections provides for spatial and quantitative assessments of reporter gene expression at the microscopic as well as macroscopic level.

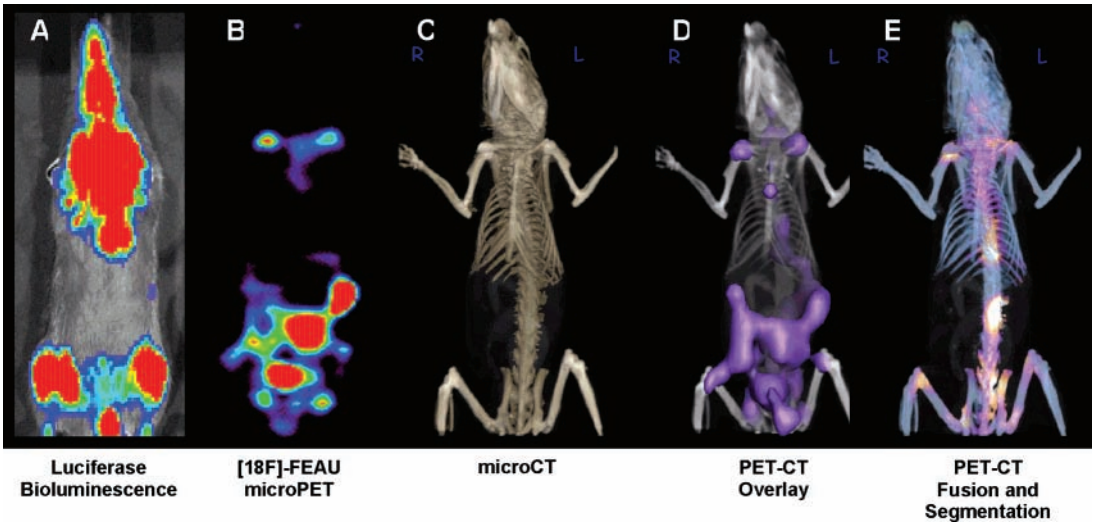

Figure 8. Multimodality imaging of autologous bone marrow-derived cells targeting bone. Multimodality imaging: bioluminescence (A); microPET (B); microCT (C); microPET-CT overlay (D); microPET-CT registration, segmentation, and fusion (E). Bone marrow-derived cells were transduced with a constitutively expressing triple-modality reporter (Figure 5) The images show targeting of bone 6 days after iv administration. Note that the tomographic display (E) confirms the targeting of transduced cells to bone; a future objective is to perform microPET-MR acquisitions and a similar tomographic microPET-MR registration and fusion to identify soft tissue structures that are targeted or are involved in trafficking of transduced reporter cells. It is also expected that some time in the near-future that tomographic bioluminescence and fluorescence images can be obtained, and that these images will be registered with currently available CT, MR, and PET tomographic images. The image fusion and segmentation was performed by Dr. Luc Bidault, MSKCC.

Imaging the Trafficking of T-Lymphocytes. T cells are an important component of the immune response and participate in the elimination of abnormal cells and infectious agents. Imaging the trafficking of T-lymphocytes has been performed using optical, MR, and PET-based imaging studies. Passive (ex vivo) labeling of T-cells with radioactive isotopes can be unstable and does not account for proliferation of activated T-cells in the body. An objective of ongoing studies in our laboratory is to image the in vivo targeting and the accumulation of EBV-lymphoma specific cytotoxic T-cells in allogeneic HLA-matched EBV B-lymphomas using PET and optical imaging modalities. Cytotoxic T-cells (CTL) specific for autologous EBV-transformed B-lymphocytes were obtained and stably transduced with a constitutively expressing dual reporter gene (*HSV1tk/egfp* fusion gene). Specific accumulation and localization of radioactivity was observed only in the autologous EBV(+) lymphoma, in the allogeneic HLA-matched EBV(+) lymphoma, and in the spleen; no localization was seen in the allogeneic HLA-matched non-EBV lymphoma and the HLA-mismatched EBV(+) lymphoma (*85*). Sequential imaging over 72 h in another set of animals showed trafficking as well as targeting of the transduced and radiolabeled CTLs. These preliminary studies indicate that it may be feasible to isolate and transduce CTLs (and other immune-specific cells) with reporter constructs and then monitor their targeting and proliferation in the donor or HLA-matched recipient using noninvasive reporter gene PET imaging.

Imaging the Trafficking of Bone Marrow-Derived Cells. Multimodality optical-, MR- and PET-based imaging studies can be performed. The use of PET for monitoring bone marrow and progenitor (stem) cell transplantation has lagged behind optical and MR techniques (*87*, *88*). In most cases, PET imaging has been applied to monitoring bone marrow transplantation (BMT), to assess for residual disease (*89*), or BMT conditioning regime-related toxicities (*90*). Monitoring the fate of bone marrow stem cells with PET following direct labeling with [^{18}F]fluorobenzoate and transplantation was first reported by Olasz et al. (*91*). Direct labeling of bone marrow-derived cells is limited by the half-life and quantity of isotope used in the labeling. Reporter gene technology precludes this limitation and allows for extended monitoring of stem cell engraftment. Recently, Cao et al. reported luciferase bioluminescence imaging of hematopoietic stem cells following transplantation into irradiated recipient mice (*92*). Donor stem cells were derived either from a luciferase or luciferase/GFP transgenic mouse and purified through cell sorting. After systemic administration, repeated optical imaging was used to detect the sites and kinetics of hematopoietic stem cell engraftment. The data suggests that the stem cells initially home to the bone marrow or spleen, while little specificity for a particular bone marrow compartment exists. Interestingly, different subsets of progenitor cells, such as short or long term repopulating cells, showed comparable homing profiles but differences in their proliferative potential. The potential of bioluminescence imaging to monitor engraftment of hematopoietic progenitor cells was previously shown in a mouse model of xenotransplantation of human hematopoietic stem cell populations (*93*). We have applied reporter gene technology to image the trafficking and distribution of bone marrow cells using a multiple-modality reporter gene approach (*94*). Coregistration of microPET and microCT images facilitated interpretation of the PET signal and allowed localization radioactive foci to specific anatomical structures (Figure 8). Others have studied effects of the bone marrow transplanted cells on the reconstruction of the ischemic myocardium (*95*, *96*).

COMMENTS

Multimodality imaging is increasingly being used in molecular-genetic studies in small animals. Fluorescence and bioluminescence imaging provides an efficient, rapid and low cost imaging alternative to more expensive and time-consuming microPET and MR imaging modalities. Optical reporter genes, including luciferase and eGFP, have unique properties that make each useful for particular experimental applications as described above.

Combining these reporter genes into a single fusion or bicistronic gene provides additional advantages. Nevertheless, optical imaging techniques are limited by depth of light penetration and scatter of emitted light photons, and optical imaging does not yet provide optimal quantitative or tomographic information. These issues are not limiting for PET- or MR-based reporter systems. In addition, PET and MR animal studies are more easily generalized to human applications. The use of dual-modality reporters has proven very successful in our laboratory, and this utility has been expanded by the development of a triple reporter system. Advantages of each separate imaging modality include the following: (1) fluorescence reporters provide for shorter development and validation times of new reporter systems by rapid and cost-effective real-time readout of cell-based in vitro assays and by in situ imaging of transduced cells in tissue samples; (2) bioluminescence reporters also provide for rapid, cost-effective real-time reporter imaging in small animals that is particularly useful for generating sequential time-dependent image profiles; (3) nuclear (and magnetic resonance) reporters provide the opportunity to obtain tomographic as well as quantitative measures of reporter gene expression. Since PET and MR are now well developed for imaging in human subjects as well as small animals, they provide a translational link from animal to human studies.

Thus, a single reporter construct (vector) with a gene product that can be assayed by three different imaging technologies (fluorescence, bioluminescence, and nuclear or magnetic resonance) would provide the benefits of each modality. It will facilitate the development, validation, and testing of new reporter systems in small animals, as well as provide preliminary data that will facilitate the translation of such studies into humans. In this respect, the triple modality reporter will be substantially greater than the sum of its individual parts.

ACKNOWLEDGMENT

A special acknowledgment is given to our friend and colleague, Juri Gelovani-Tjuvajev, who joined our group in 1991. He has recently accepted a well-deserved appointment as Chairman, Department of Experimental Diagnostic Imaging at M.D. Anderson Cancer Center in Houston. He was a leading investigator in our group and initiated many of the projects in our laboratory, including the development of noninvasive multimodality reporter transgene imaging.

Converting Weak Binders into Infinite Binders

Todd M. Corneillie, Paul A. Whetstone, Kelvin C. Lee, Jeremy P. Wong, and Claude F. Meares*

Department of Chemistry, University of California, Davis, California 95616. Received July 22, 2004

Monoclonal antibody 2D12.5 binds DOTA chelates of all the rare earths with $K_d \approx 10^{-8}$ M, making it useful for the capture of probe molecules with a variety of properties. To make 2D12.5 even more useful for biological applications, we have engineered a single cysteine residue at position 54 of the heavy chain, a site proximal to the protein's binding site, so that weakly electrophilic metal complexes of (*S*)-2-(4-acrylamidobenzyl)-DOTA (AABD) may bind and form permanent linkages. At 37 °C, pH 7.5, all of the rare earth−AABD complexes bind permanently to the 2D12.5 G54C mutant within 5 min, in yields that correlate with their relative binding affinities. Surprisingly, indium−AABD also binds permanently in >50% yield within 5 min, despite the fact that changing the metal to indium reduces the affinity ≈100×; even copper−AABD, which has ≈10 000× lower binding affinity than the rare earths, binds permanently in >70% yield within 2 h. However, acrylamido compounds with no measurable affinity do not bind permanently. The important practical implication is that the G54C mutant of 2D12.5 may be used for applications that include not only the rare earths, but also an unexpected range of other elements as well. This infinite binding system can exhibit selective and permanent attachment with a remarkable range of structurally related ligands, albeit at slower rates as affinities decrease.

A ligand−receptor system that permanently forms a specific complex may have a number of applications in the delivery or sequestration of the ligand. The purposeful development of such systems is a new endeavor, and a number of basic questions remain to be answered. So far, the most promising results in combining specificity with permanent attachment have involved engineering a reactive cysteine side chain at a position proximal to the ligand-binding site of a protein, accompanied by synthesis of a ligand bearing an appropriate complementary reactive group such as acryl (*1*−*3*). The reactivity of the protein side chain is modulated by its surface accessibility and location, while the reactivity of the ligand may be tuned with the tools of synthetic chemistry; attachment can occur within minutes, so that complexes form permanently in good yield when ligand and receptor first associate (*1*). Two acryl compounds that irreversibly target specific cysteines on human epidermal growth factor receptors are now in clinical trials (*4*). Recently Chen et al. explored ligands that bind permanently to a specific histidine (*5*), and Pollack et al. previously exploited reversible binding to attach a nucleophile that introduced catalytic activity near an antibody binding site (*6*); both attachments occurred at slower rates.

Monoclonal antibody 2D12.5 binds DOTA chelates of all the rare earths with $K_d \approx 10^{-8}$ M, making it useful for the capture of probe molecules for imaging and therapy (*7*−*9*). To make 2D12.5 even more useful for biological applications, we have engineered single cysteine residues near the protein's binding site so that acryl-DOTA chelates may bind and form permanent linkages (*10*). Three consecutive glycine residues that do not contact the ligand are located in a loop of the heavy chain, near the ligand p-substituent (Figure 1). We anticipated that mutating a single glycine to cysteine would not alter the loop conformation drastically: the other glycines could flexibly adjust their conformation to maintain the geometry required for binding. We prepared the three mutants and selected G54C for more extensive study because it had the best expression level and activity. The G54C mutant binds reversible ligands such as Y−NBD[1] with affinities comparable to the native protein (Supporting Information).

Formation of a permanent link between the engineered ligand and receptor requires specific binding, which increases the effective local concentration, accelerating an otherwise slow bond-forming reaction. We chose a weak Michael acceptor for the ligand so that permanent attachment is specific even in mixtures containing a variety of competing nucleophiles (*1*−*3*). We synthesized Y−AABD (Figure 2) as a candidate irreversible ligand and found that this yttrium complex bound reversibly to native 2D12.5 with $K_d \approx 4 \times 10^{-9}$ M, comparable to the reversible ligand Y−NBD.

We prepared ^{90}Y−AABD and tested it for permanent binding to the G54C mutant. The results in Figure 2B show that at 37 °C, pH 7.5, ^{90}Y−AABD permanently and specifically attaches to the G54C mutant. Under these conditions, the half-time for attachment is ≈13 min.

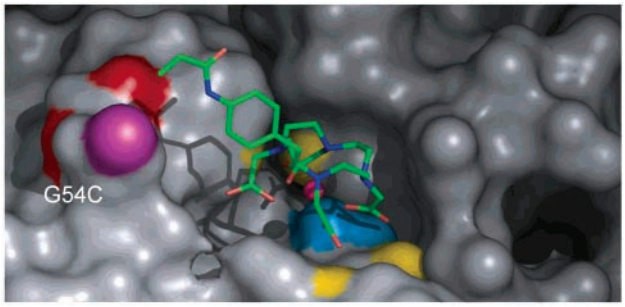

Figure 1. Site-directed cysteine mutations were designed (*10*) using the crystal structure of 2D12.5 Fab bound to the Y-DOTA derivative, Y−HETD[1], which was modified in silico to the electrophilic acryl derivative, Y−AABD (the p-substituent does not contact the protein). The native glycine residues 54, 55, and 56 in complementarity determining region 2 of the heavy chain appeared to be best suited for replacement with cysteine. The G54C mutant (cysteine sulfur colored purple) is shown (Cα's for G55 and G56 are colored red).

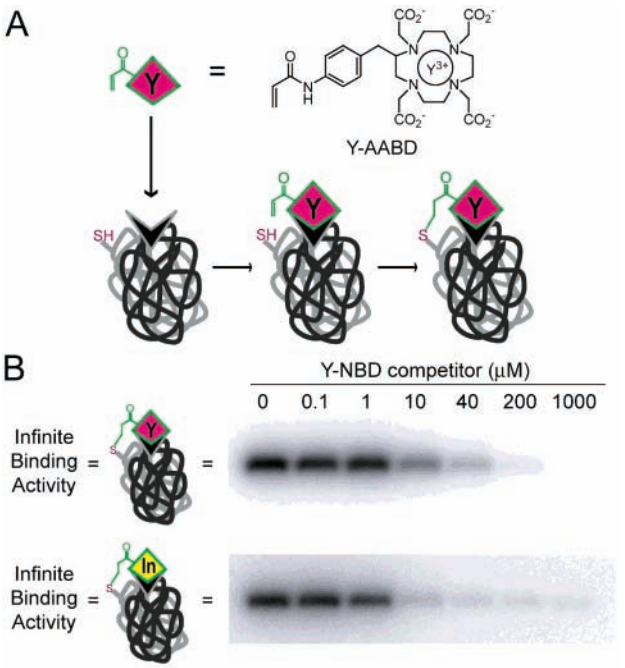

Figure 2. (A) Scheme describing the permanent binding pair. (B) Permanent binding is observed not only for ^{90}Y−AABD but also for ^{111}In−AABD, assayed by SDS−PAGE under denaturing conditions where only permanently bound complexes remain attached to the antibody. Increasing the concentration of unlabeled Y−NBD, a reversibly binding competitor, increasingly inhibits permanent attachment by preventing ^{90}Y−AABD or ^{111}In−AABD from accessing the binding site.

In addition, we discovered a new aspect of infinite binding: the reversible In−NBD chelate binds only weakly, but the acryl ligand ^{111}In−AABD binds permanently to the G54C mutant. Figure 2B shows that ^{111}In−AABD binds specifically to G54C, with a yield similar to the stronger ligand ^{90}Y−AABD. An important practical implication is that the G54C mutant of 2D12.5 may be used for applications that include not only radiotherapy with ^{90}Y, but also imaging with ^{111}In. The range of metals with useful probe properties thus extends beyond the rare earths ($K_d \approx 10^{-8}$ M for reversible binders) to scandium and indium, whose complexes do not have useful affinities as reversible binders ($K_d \approx 10^{-6}$ M), and perhaps beyond.

We were curious to see if an even weaker binder such as a copper chelate ($K_d \approx 10^{-4}$ M for Cu−NBD) would

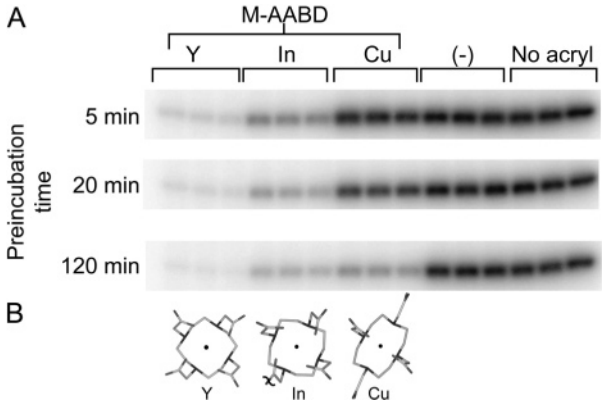

Figure 3. The G54C mutant was preincubated in triplicate with 10 μM AABD complexes of Y^{3+}, In^{3+}, or Cu^{2+}, a negative control *N*-(1-carbamoyl-2-(4-nitrophenyl)ethyl)acrylamide or *N*-(4-carboxymethylphenyl)acrylamide, or just buffer, for 5, 20, or 120 min at 37 °C, pH 7.5. At the stated times, ^{90}Y−AABD (1 μM) was added to each solution to compete for free G54C. Permanent binding was assayed by measuring band intensities after SDS−PAGE. (A) Phosphorimage of gel. The fainter the bands, the greater the permanent binding by the unlabeled ligand. (B) Crystal structures of Y−DOTA, In−DOTA-mono(*p*-aminoanilide) (some atoms removed for clarity) and Cu−DOTA.

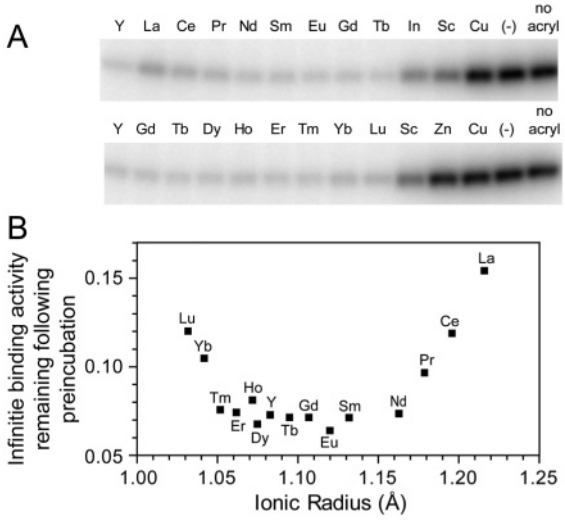

Figure 4. (A) Metal−AABD (10 μM) complexes were preincubated separately with aliquots of G54C for 5 min, followed by addition of 1 μM ^{90}Y−AABD, which competes for free G54C, and SDS−PAGE analysis. (B) From quantitative phosphorimaging, the highest-affinity AABD complexes form permanent bonds with G54C with higher yields than more weakly binding rare earth−AABD complexes whose ionic radii are slightly smaller (Lu^{3+}, Yb^{3+}) or larger (Ce^{3+}, La^{3+}) than ideal.

bind irreversibly under ordinary conditions. We tested this by comparing the permanent binding of Y^{3+}−, In^{3+}−, and Cu^{2+}−AABD, using competitive ^{90}Y−AABD attachment as an indicator (Figure 3). The positive control Y−AABD does not allow a significant amount of ^{90}Y−AABD to attach to the G54C: as expected, ^{90}Y−AABD is blocked from >90% of the sites after preincubation with Y−AABD. Weaker binding In−AABD blocks >50% of the sites after 5 min preincubation and even more at later times. Very weakly binding Cu−AABD initially occupies only about 10% of the G54C sites under these conditions, but it has permanently attached to G54C in good yield after 2 h, blocking >70% of the sites. In accord with their K_d values, evidence from crystal structures shows significant differences in preferred coordination geometry between the DOTA complexes of Y, In, and Cu (Figure 3B) (*11*−*15*). Control experiments with two acrylamido

compounds having no measurable affinity for 2D12.5 show no permanent attachment to G54C, indicating that ligand binding is required for the covalent bond-forming reaction to occur.

DOTA complexes of all the trivalent rare earth ions bind to 2D12.5 with similar affinities (*7*). Upon careful examination, the free energies of binding the rare earth−DOTA complexes to the antibody show a parabolic dependence on the ionic radius of the metal, with Gd at the bottom and La and Lu at the extremes. Figure 4 shows that the rare earth−AABD complexes bind permanently to G54C in yields that correlate with their relative affinities.

These results demonstrate that an infinite binding system can exhibit selective and permanent attachment with a surprising range of structurally related ligands, albeit at slower rates as affinities decrease. Separately engineering the reactivities of both ligand and receptor provides a direct route to the capture of a set of similar molecules, with unsurpassed affinity.

Irreversible Engineering of the Multielement-Binding Antibody 2D12.5 and Its Complementary Ligands

Todd M. Corneillie, Kelvin C. Lee, Paul A. Whetstone, Jeremy P. Wong, and Claude F. Meares*

Department of Chemistry, University of California, Davis, California 95616. Received July 22, 2004

Engineering the permanent formation of a receptor−ligand complex has a number of potential applications in chemistry and biology, including targeted medical imaging and therapy. Starting from the crystal structure of the rare-earth-DOTA binding antibody 2D12.5 (Corneillie, T. M., Fisher, A. J., and Meares, C. F. (2003) *J. Am. Chem. Soc. 125*, 15039−15048), we used the site-directed incorporation of cysteine nucleophiles at the periphery of the antibody's binding site, paired with the chemical design of a weakly electrophilic ligand, to produce a receptor−ligand pair that associates efficiently and permanently. Protein residues proximal to the ligand's side chain were identified for engineering cysteine mutants. Fab fragments incorporating a cysteine at position 54, 55, or 56 of the heavy chain (complementarity determining region 2) were designed from the structure and then cloned, expressed in *Drosophila* S2 cells, and tested for reactivity with mildly electrophilic DOTA−yttrium ligands. All showed permanent binding activity, indicating that there is some tolerance for the location of the reactive mutant on the protein surface near the binding site. The G54C Fab mutant displayed the highest expression levels and permanent binding activity in initial experiments and was produced in high yield for further study. Upon examining the behavior of the G54C mutant with a small set of electrophilic ligands, differences in reactivity were observed which indicated that the substituents near the electrophilic atom can be important determinants of permanent binding. The G54C mutant permanently attaches to Y^{3+} complexes of (*S*)-2-(4-acrylamidobenzyl)-DOTA with a half-time of ≈13 min at 37 °C, making it potentially useful for in vivo pretargeting applications.

INTRODUCTION

For pretargeted imaging and therapy applications, achieving efficient capture of a small-molecule ligand by a protein-based receptor, as well as a long lifetime on the target, is essential. This is particularly true for radioactive ligands, which require a long residence time at a cancer cell to maximize treatment efficacy. Often a radionuclide suitable for in vivo use has a half-life that ranges from several hours to several days; if the nuclide is bound at the tumor for only a fraction of that period, the majority of radiation events will occur off target.

Antibodies are among the most heavily manipulated protein scaffolds and can be developed to bind a variety of natural and unnatural ligands (*1*). For applications where cell-surface antigens are targeted with bivalent antibodies, the bound lifetime can be extended due to the avidity of the antibody (*2*). However, because the binding interaction between antibodies and soluble small-molecule ligands is monovalent and gains no avidity advantage, the bound lifetime of the pair becomes a limiting factor in antibody-based probe capture schemes.

The half-life for ligand dissociation from a typical antibody with nanomolar affinity is likely to be on the order of 1 h at most (*3*−*6*). To improve the bound lifetime for ligands, either the valency or affinity of the system can be manipulated. Karacay et al. enhanced the bound lifetime of an antibody against an In−DTPA[1] derivative by using bivalent ligands to cross-link antibodies at cell surfaces (*7*). Others have used advances in combinatorial selection or directed evolution to produce affinities much stronger than nanomolar, into the picomolar or even femtomolar range, with half-lives for dissociation up to several days (*8*−*12*).

A different approach to improving the stability of the complex between a receptor and its ligand is to engineer infinite affinity (*13, 14*). This unconventional strategy for developing high affinity ligand−receptor pairs exploits chemical complementarity and reactivity novel to biology. Complementary reactive groups are designed and placed in the ligand and receptor such that their individual reactivities are negligible in a biological environment; however, upon complex formation, their mutual reactivity is remarkably enhanced by proximity, efficiently making association permanent.

Several groups have recently described the permanent coupling of a weakly electrophilic ligand to a nucleophilic amino acid—often cysteine, but also histidine or tyrosine—that is located near the ligand binding site of a protein (*13*−*17*). In the case of cysteine, which incorporates the most reactive nucleophile, there seems to be some practical tolerance in its location relative to the electrophilic ligand. Electrophilic species that have the requisite weak electrophilicity and stability in complex biological environments include acryl-based Michael acceptors, epoxides, and thioesters.

Recently we discovered a surprising aspect of infinite affinity: even ligands with modest affinity for reversible binding to a parent antibody can be converted to bind permanently (*18*). Acryl-DOTA−metal complexes that bind reversibly to antibody 2D12.5 with an affinity as low as 10^{-4} M can attach irreversibly to a 2D12.5 mutant in reasonable yield. Thus a family of probe molecules with structures that are similar can bind to a single receptor with infinite affinity. The basis of this effect appears to be that as long as a weak electrophile can be closely juxtaposed to a complementary nucleophile for a sufficient time, a permanent bond can be formed. We expect that as long as the bound lifetime of a weak ligand is at least comparable to the time required for reaction, the bond will be formed with good efficiency. This contrasts with the basis of combinatorial selection, which seeks complementary surfaces in ligand and receptor, enhancing affinity for a single structure without regard to others.

Here we describe the engineering and characterization of a new infinite binding antibody-based capture system, based on antibody 2D12.5 and metal−DOTA complexes (*19, 20*). A collection of chimeric Fab antibody fragments incorporating site mutations were designed in silico (Figure 1) and then cloned, expressed, and tested for attachment to complementary electrophilic yttrium-DOTA derivatives that were chosen to have low reactivities suited for use in vivo (Figure 2).

[1] Abbreviations: AABD, (*S*)-2-(4-acrylamidobenzyl)-DOTA; AABD-tBu, (*S*)-2-(4-acrylamidobenzyl)-DOTA tetra-*tert*-butyl ester; ABD, (S)-2-(4-aminobenzyl)-DOTA; ABD-tBu, (*S*)-2-(4-aminobenzyl)-DOTA tetra-*tert*-butyl ester; AMU, atomic mass units; BAD, (*S*)-2-(4-bromoacetamidobenzyl)-DOTA; CDR, complementarity determining region; C_{H1} and C_L, regions of the heavy chain and light chain comprising the constant domains of the Fab; CPM, 7-(diethylamino)-3-(4′-maleimidylphenyl)-4-methylcoumarin; DIEA, diisopropylethylamine; DMF, *N*,*N*-dimethylformamide; DMSO, dimethyl sulfoxide; DOTA, 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid; DTPA, diethylenetriamine-*N*,*N*,*N*′,*N*″,*N*″-pentaacetic acid; DTT, dithiothreitol; FCS, fetal calf serum; ELISA, enzyme-linked immunosorbent assay; ESI-MS, electrospray ionization mass spectrometry; Fab, antigen-binding fragment of an antibody; FABD, (*S*)-2-(4-(*trans*-3-carboxyacrylamido)benzyl)-DOTA; HC, heavy chain; HCIC, hydrophobic charge-induction chromatography; HETD, (*S*)-2-(4-(2-(2-hydroxyethylthio)acetamido)benzyl)-DOTA; HRP, horseradish peroxidase; HSA−2IT−Y−BAD, human serum albumin conjugated to Y−BAD through a 2-iminothiolane linker; IMAC, immobilized metal affinity chromatography; IDA, iminodiacetic acid; $IMAC_{10}$ buffer, 20 mM sodium phosphate, 500 mM NaCl, 10 mM imidazole, pH 7.4; $IMAC_{20}$ buffer, 20 mM sodium phosphate, 500 mM NaCl, 20 mM imidazole, pH 7.4; $IMAC_{300}$ buffer, 20 mM sodium phosphate, 500 mM NaCl, 300 mM imidazole, pH 7.4; LC, light chain; mAb, monoclonal antibody; MABD, (*S*)-2-(4-(*cis*-3-carboxyacrylamido)benzyl)-DOTA; MEA, 2-mercaptoethylamine-HCl; MEP, 4-mercaptoethylpyridine; MOPS, EDTA buffer, 25 mM MOPS, 100 mM NaCl, 10 mM EDTA, pH 7.5; MWCO, molecular weight cutoff; NBD, (*S*)-2-(4-nitrobenzyl)-DOTA); PMSF, phenylmethanesulfonyl fluoride; SAB, nonreducing SDS−PAGE sample application buffer: 2% lithium dodecyl sulfate, 10% glycerol, 62.5 mM Tris, 5 mM EDTA, pH 6.8 (reducing SAB contains 1% 2-mercaptoethanol in addition to these components); SDS−PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis (lithium dodecyl sulfate was used here); TBST, TBS (24.8 mM Tris, 137 mM NaCl, 0.269 mM KCl, pH 7.4) supplemented with 0.05% Tween-20 (v/v); TEA, triethylamine; TFF, tangential flow ultrafiltration; TLC, thin-layer chromatography; TMB, 3,3′,5,5′−tetramethylbenzidine; V_H and V_L, variable domains of an antibody heavy chain and light chain, respectively; Y−NBD, yttrium−NBD.

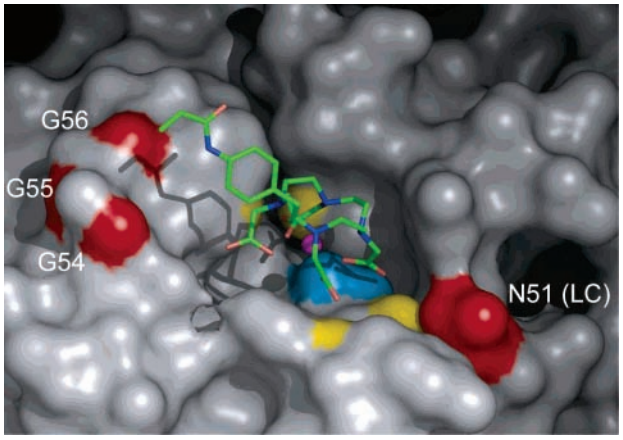

Figure 1. Native glycine residues 54, 55, and 56 (Kabat numbering) in CDR2 of the heavy chain (C_α atoms colored red) were selected as candidates for site-directed single-cysteine mutations. A fourth site, N51 (light chain, side chain colored red), was selected as a negative control (see text). The original Y−HETD ligand in the 2D12.5 Fab crystal structure was remodeled to Y−AABD to aid in the identification of preferable sites for mutagenesis. The theoretical G54C mutant positions the nucleophilic sulfur approximately 4.3 Å from the electrophilic acryl carbon. Protein atoms making noncovalent binding contacts with the HETD ligand carboxylates are colored yellow, and an arginine side chain that forms a stabilizing salt-bridge with a HETD carboxylate is colored blue.

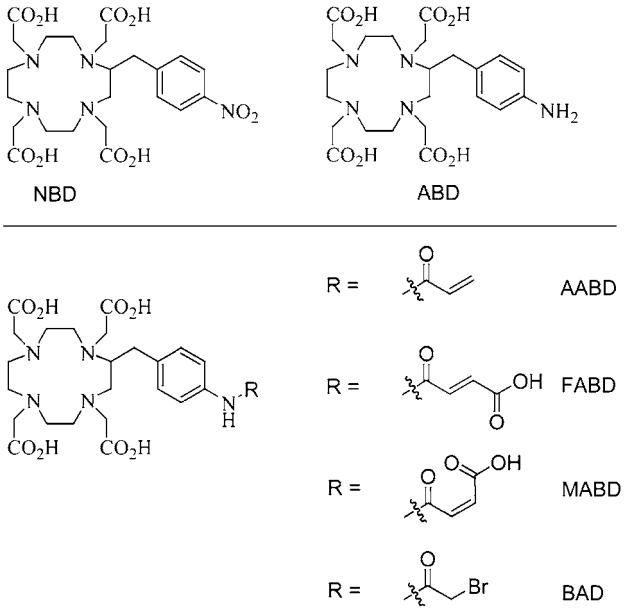

Figure 2. DOTA derivatives used to explore the permanent binding behavior of engineered 2D12.5 Fab mutants. The reversibly binding ligands, NBD and ABD, were used as negative controls and as competitors to characterize the permanent bond-forming capability of the Michael acceptor ligands AABD, FABD and MABD. The bromoacetamide DOTA derivative, BAD, was used as a positive control.

MATERIALS AND METHODS

Materials. Vent DNA polymerase, restriction enzymes, and T4 ligase were purchased from New England BioLabs, Beverly, MA. Taq DNA polymerase was purchased from Promega, Madison, WI. S2 cells, the inducible cloning vector pMTBiP/V5-His A, hygromycin-B, and anti-V5-AP and HRP conjugates were purchased from Invitrogen, Carlsbad, CA. Goat anti-human κ-AP conjugate was purchased from Southern Biotechnology Associates, Inc., Birmingham, AL. Schneider insect media

was supplied by Cambrex, Baltimore, MD. FCS (heat-inactivated, gamma-irradiated) and EX-CELL 420 serum-free media were purchased from JRH Biosciences, Lenexa, KS. MEP Hypercel resin was supplied by Ciphergen, Freemont, CA, and Chelating Sepharose Fast Flow resin and a Tricorn 10/300 column were purchased from Amersham Biosciences, Piscataway, NJ. Empty Econo-Pac columns were purchased from Bio-Rad, Hercules, CA. Sephadex G50 was purchased from Sigma, St. Louis, MO. 2-Mercaptoethylamine-HCl was purchased from Pierce Biotechnology, Rockford, IL. A Fluostar fluorescence microplate reader (BMG LabTechnologies, Durham, NC) and the CPM reagent (Molecular probes, Eugene, OR) were used for free thiol quantitation. Ultrafree centrifugal protein concentrators (10 000 MWCO) were obtained from Millipore, Bedford, MA. Analytical and preparative reversed phase HPLC was performed on an Altima 5 μm, 4.6 $\times$ 250 mm C_{18} column and an Altima 5 μm, 22 $\times$ 250 mm C_{18} column (Alltech Associates, Inc., Deerfield, IL), respectively. Hexahydrate chloride salts of yttrium and gadolinium were purchased from Sigma Aldrich (St. Louis, MO) and were obtained in their highest available purity. An Atlantis 3 μm, 2.1 $\times$ 100 mm dC_{18} column (Waters, Milford, MA) was used for LC/MS separation of peptide samples on a Thermo Finnigan LCQ Deca electrospray ion trap mass spectrometer. $^{90}YCl_3$ and $^{111}InCl_3$ solutions in 0.05 M HCl were purchased from PerkinElmer Life Sciences, Boston, MA. Pure water (18 MΩ cm) was used throughout.

Construction of Chimeric 2D12.5 Fab Heavy and Light Chain Genes for Expression in S2 Cells. Variable domain sequences of 2D12.5 heavy and light chains were obtained from total mRNA that was isolated from 2D12.5 hybridoma cells using Novagen's Ig Prime kit. Chimeric constructs of the murine 2D12.5 variable domains and human anti-tetanus toxoid antibody C_L and C_{H1} domains were assembled by two-step overlap extension (*21*). Bgl II and Xba I restriction sites were introduced into the 5′ and 3′ ends, respectively, of both the heavy and light chain genes during overlap extension, and were used to introduce each gene construct into the pMTBiP/V5-His A plasmid cassette for propagation in *E.coli* and expression in *Drosophila* S2 cells, which have been demonstrated to efficiently express whole antibodies, antibody Fab fragments, and single-chain antibodies (*13, 22*−*24*). The heavy and light chain genes were inserted into separate plasmids. Because light chains are generally overexpressed relative to heavy chains (*25, 26*), the heavy chain was placed in frame to include V5 and His tags at the C-terminus, while the light chain was cloned to prevent inclusion of the tags in the final expressed light chain product. Fab molecules incorporating a light chain paired with a heavy chain could then be selectively separated (using the His tag on the heavy chain) from improperly paired light chains lacking a His tag. Four cysteine mutants were constructed. Each site-directed mutation was prepared using four primers and two stages of PCR. Vent and Taq polymerases were used in stages one and two, respectively (*27*).

Transfection and Expression of Chimeric 2D12.5 Fab Genes in Drosophila S2 Cells. S2 cells were split to a density of 1 $\times$ 10^6 cells/mL in six-well microplates and cultured overnight in Schneider media containing 10% FCS at 27 °C in a humidified incubator. Transient expression of heavy and light chain plasmids was accomplished by cotransfecting *Drosophila* S2 cells the following day using precipitating calcium phosphate. Cells were induced after 3 days using 500 μM $CuSO_4$, and samples were taken to assay for gene expression by noncompetitive ELISA. Cotransfection of a plasmid containing the hygromycin B phosphotransferase gene with the heavy and light chain plasmids produced stable cell lines. Stable cell line selection proceeded for 3−4 weeks posttransfection with 300 μg/mL hygromycin B. Once cell populations reached approximately 0.8−1 $\times$ 10^7 cells/mL, cells were transferred to T25 flasks. Stable cell lines were induced with $CuSO_4$ for 3−4 days, and the presence of functional Fab was determined by noncompetitive ELISA of media that had been separated from cells.

Large-Scale Expression. S2 cells in T75 flasks were cultured to a density of approximately 1 $\times$ 10^7 cells/mL in Schneider media supplemented with 10% FCS before adapting to growth in Erlenmeyer and Fernbach shake flasks containing modified serum-free EX-CELL 420 medium. EX-CELL 420 was supplemented with 18 mM L-glutamine (90 mL of 200 mM L-glutamine added to 1 L EX-CELL 420). To transfer cells from serum-containing medium, cells were centrifuged at 1000*g* for 5 min and washed once with a small volume of EX-CELL 420 and centrifuged a second time before resuspending in fresh EX-CELL 420. 200 mL cultures were grown in 500 mL Erlenmeyer flasks at 130 rpm, 27 °C for 3−4 days (density increased from approximately 1 $\times$ 10^6 to 1 $\times$ 10^7 cells/mL). Cultures were pelleted by centrifugation, resuspended in 800 mL modified EX-CELL 420, and grown for 1 day at 27 °C (density $\approx$ 4 $\times$ 10^7 cells/mL). Media was exchanged again after pelleting cells and resuspending in fresh media. 500 μM $CuSO_4$ was added immediately, and cell density was monitored over several days. After 2.5 days, D-(+)-glucose was added to a final concentration of 0.2% (*28*). At days 2 and 4 of induction, the cell density was stable at approximately 4−6 $\times$ 10^7 cells/mL. Gene expression was monitored by ELISA; the highest expression levels were observed 3−4.5 days postinduction. Generally, the media was harvested when protein expression reached levels >5 mg/L.

Assaying 2D12.5 Chimeric Fab Expression and Activity. S2 cells transfected with chimeric 2D12.5 genes, adapted to growth in EX-CELL 420 media, were induced with 500 μM $CuSO_4$ for several days. Media containing Fab, separated from cells by centrifugation and filtration, was serially diluted in microtiter plates containing immobilized HSA−2IT−Y−BAD (*20, 29*). Following incubation for 1 h at 37 °C, wells were washed with TBST. Anti-V5-HRP antibody, which binds a C-terminal V5 tag expressed on the heavy chain, and a TMB substrate were used to quantify binding.

First Stage Purification of Chimeric 2D12.5 Fab Expressed in S2 Cells by MEP Hypercel HCIC. A two-step purification method was developed for the isolation of purified chimeric 2D12.5 Fab from S2 cell expression media. MEP Hypercel, which is reported to have high affinity for antibody Fc domains and somewhat weaker affinity for Fab domains (*30, 31*), was evaluated for chimeric 2D12.5 Fab purification. Previously reported methods provided initial guidance for method development (*26, 32*). Approximately 24 mL of MEP Hypercel gel resin was packed into a Tricorn 10/300 column and equilibrated at a flow rate of 2 mL/min (50 mM sodium phosphate, pH 7.2). Media containing Fab was separated from S2 cells by centrifugation and adjusted to pH 7.2 with Na_2CO_3. EDTA was added to a final concentration of 5 mM, and the solution was then sterile filtered and stored at 4 °C until further use. Before MEP resin purification, the media containing Fab was immediately filtered (0.2 μm) and allowed to warm to room temperature. Approximately 700−800 mL of media was then

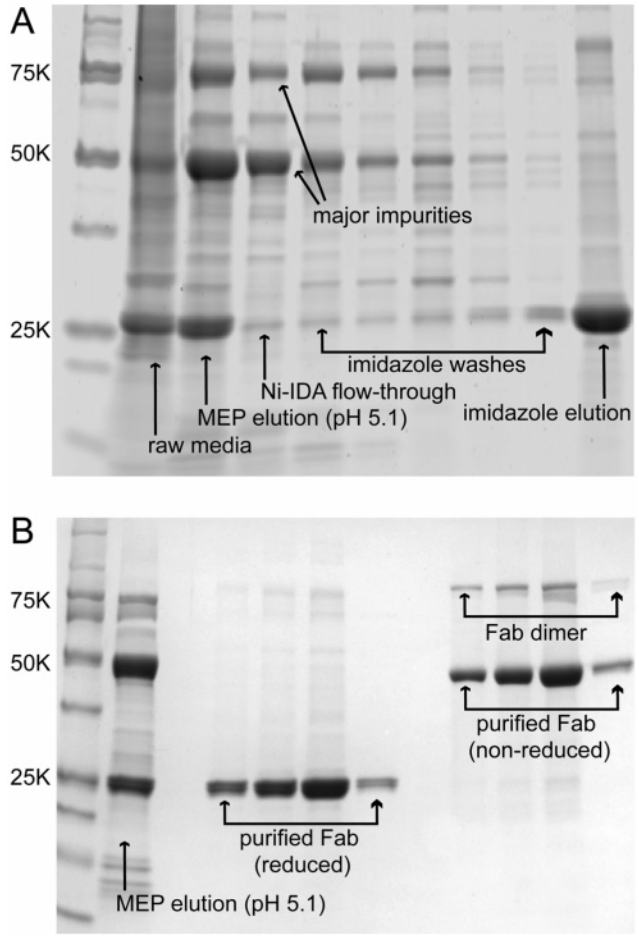

Figure 3. Purification of 2D12.5 G54C Fab from *Drosophila* S2 cell culture in serum-free expression media. (A) First stage MEP Hypercel purification yielded a partially purified Fab (SDS−PAGE, Sypro Ruby, lane 3). Second stage IMAC purification using Ni−IDA removed most of the remaining impurities including unpaired light chains that were cloned without a His tag (rightmost lane). (B) Purified Fab samples of different concentrations were analyzed for purity by SDS−PAGE (Coomassie Blue). Samples were either reduced to identify the separated light chain and heavy chains (lanes 4−7) or not reduced (lanes 9−12) to determine that the majority of the Fab was indeed monomeric. A small percentage of the purified Fab was isolated as a disulfide-linked dimer, indicating that the engineered cysteines of two Fab molecules had likely paired with each other.

loaded onto the MEP column at a flow rate of 2 mL/min. The column was washed with approximately five column volumes of phosphate buffer, and the Fab-containing fraction was isolated using a single step elution (50 mM sodium acetate, pH 5.1). The isolated fraction was then mixed 1:1 with 100 mM sodium phosphate, 1 M NaCl, 20 mM imidazole, pH 7.4, and stored overnight at 4 °C. All samples were analyzed by SDS−PAGE.

Second Stage IMAC Purification of Chimeric 2D12.5 Fab Expressed in S2 Cells. Chelating Sepharose Fast Flow (IDA) was loaded with Ni^{2+} ions by incubating washed gel with an excess of $NiSO_4$ according to the manufacturer's instructions. Ni^{2+}-charged resin was stored at 4 °C until use. An approximate working capacity of 2 mg Fab per mL IMAC gel was determined experimentally. MEP purified Fab solutions were warmed to room temperature and diluted 1:1 with 2× $IMAC_{10}$ load buffer. One milliliter of IMAC gel equilibrated in $IMAC_{10}$ buffer per 2 mg Fab was added to the Fab-containing solution, and the mixture was incubated with end-over-end rocking for 30 min. The mixture was then poured into an empty, capped Econo-Pac column equipped with a glass frit filter, and the gel was allowed to settle by gravity. A top frit was placed on the column, and the solution was allowed to flow through the column. The gel was washed with 10 column volumes of $IMAC_{10}$ buffer followed by an additional 10 column volumes of $IMAC_{20}$ buffer. Next, two column volumes of $IMAC_{300}$ were applied to the column, and the solution was allowed to flow into the gel and to incubate for 5 min. An additional three column volumes of $IMAC_{300}$ were added to the column, and allowed to flow through the column. All five column volumes of $IMAC_{300}$ were collected; the $IMAC_{300}$ solution eluted 90% of the bound Fab with high purity. A second $IMAC_{300}$ elution released the remaining 10% of bound Fab molecules. Samples were analyzed for purity by SDS−PAGE (Figure 3) and dialyzed into MOPS, EDTA buffer before storing at 4 °C. Purified yields of the 2D12.5 G54C Fab mutant approached 8−10 mg/L.

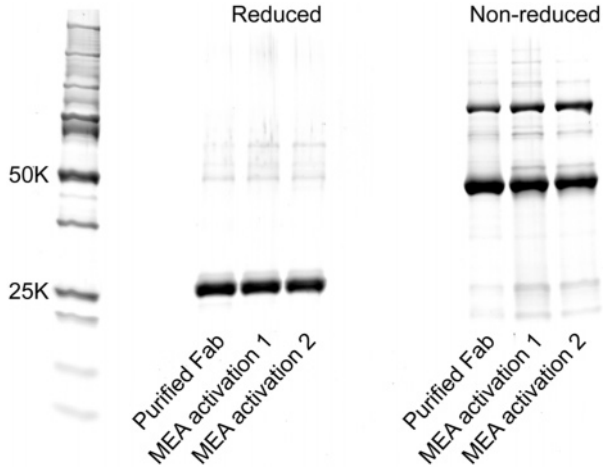

Figure 4. Purified G54C Fab was treated with MEA to remove blocking groups on the engineered cysteine. Samples were analyzed by reducing and nonreducing SDS−PAGE and stained with Sypro Ruby protein stain to confirm that no significant Fab reduction or change in dimerization occurred during the incubation with MEA.

Activation of Blocked Engineered Cysteine Residues with MEA. Fab isolated and purified from S2 cell expression was concentrated to 20−35 μM by centrifugal ultrafiltration. A 100 mM stock solution of MEA was dissolved into MOPS, EDTA buffer and added to the Fab solution to a final concentration of 10 mM. The solution was incubated overnight at room temperature and buffer exchanged using two consecutive Penefsky gel filtration columns to remove the MEA (*33*). The protein solution was assayed for free thiol activity using the fluorescent maleimide-containing compound CPM and stored at 4 °C (*34*). A standard curve was constructed using 2-mercaptoethanol. Free thiol activity for the G54C mutant ranged from a low of 5% to a high of 65% before and after activation of the site-directed cysteine mutant, respectively. Nonreducing SDS−PAGE analysis confirmed that the interchain disulfide between the light and heavy chains of the Fab remained intact following treatment with MEA (Figure 4).

Chelate Synthesis. *(S)-2-(4-Aminobenzyl)-1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid tetra-tert-butyl ester* (ABD-tBu, see Figure 2) was prepared according to previously published methods (*35*−*38*). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.0−5.0 (m, 63H), 6.39 (d, J = 8.7 Hz, 2H), 6.73 (d, J = 8.7 Hz, 2H).

(S)-2-(4-Acrylamidobenzyl)-1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid tetra-tert-butyl ester

(AABD-tBu) was prepared as follows: ABD-tBu (0.27 mmol) was dissolved in CH_2Cl_2 (2 mL) under Ar. Acryloyl chloride (1.5 equiv) and DIEA (2 equiv), each separately dissolved in CH_2Cl_2 (2 mL), were added dropwise through addition funnels over 15 min, and the resulting solution was allowed to stir for 10 min at room temperature. The solution was washed with 1% TEA in H_2O until the aqueous fractions remained basic. The CH_2Cl_2 layer was then dried over Na_2SO_4 and filtered, and solvent was removed under reduced pressure to yield AABD-tBu as a crude yellow solid. (ESI-MS *m/z* calcd (MNa^+): 810.51. Found: 810.53.

(S)-2-(4-Acrylamidobenzyl)-1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic Acid (AABD). The crude AABD-tBu product was dissolved in neat CF_3COOH at 4 °C under an Ar atmosphere, stirred overnight, and allowed to warm to room temperature. The CF_3COOH was removed under reduced pressure, and a portion of the resulting solid was purified by preparative reverse phase chromatography to yield a white solid after lyophilization. HPLC gradient: solvent A, water with 0.1% CF_3COOH; solvent B, CH_3CN with 0.075% CF_3COOH, 0−5 min, 5% B, 5−15 min, 5−30%, 15−45 min, 30−50% linear solvent B, 6 mL/min. (ESI-MS *m/z* calcd (MH^+): 564.26. Found: 564.28. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.0−5.0 (m, 25H), 5.74 (d, J = 10.2 Hz, 1H), 6.24 (d, J = 16.8 Hz, 1H), 6.43 (d,d, J = 16.8 Hz, 10.2 Hz, 1H), 7.18 (d, J = 7.8 Hz, 2H), 7.60 (d, J = 7.8 Hz, 2H), 10.12 (s, 1H).

(S)-2-(4-(cis-3-Carboxyacrylamido)benzyl)-1,4,7,10-tetrazacyclododecane-N,N′,N″,N‴-tetraacetic Acid (MABD). ABD-$(HCl)_4$ (0.030 mmol) was dissolved in 100 μL of water. To this solution, maleic anhydride (0.122 mmol, 4 equiv) dissolved in 100 μL of DMF was added and stirred at room temperature for 1 h. Solvent was removed under reduced pressure, and the resulting solid was redissolved in water and purified by reverse-phase HPLC to yield a yellow solid. HPLC gradient: solvent A, water; solvent B, methanol, 0−5 min, 5% 5−35 min, 5−55%, 4 mL/min. (ESI-MS *m/z* calcd (MH^+): 608.26. Found: 608.26. NMR (300 MHz, D_2O) δ 1.0−5.0 (m, 25H), 6.20 (d, J = 12.3 Hz, 1H), 6.43 (d, J = 12.3 Hz, 1H), 7.29 (d, J = 8.4 Hz, 2H), 7.47 (d, J = 8.4 Hz, 2H).

(S)-2-(4-(trans-3-Carboxyacrylamido)benzyl)-1,4,7,10-tetrazacyclododecane-N,N′,N″,N‴-tetraacetic Acid (FABD). ABD-$(HCl)_4$ (0.030 mmol) and DIEA (0.122 mmol, 20 μL) were dissolved in 100 μL of water and 100 μL of CH_3CN and added dropwise over 5 min to a 10 mL round-bottom flask containing fumaryl chloride (0.122 mmol) dissolved in 100 μL of acetonitrile. The solvent was removed under vacuum, and the resulting solid was redissolved in water and purified by reverse-phase HPLC. The HPLC purification method was identical to that used for MABD. ESI-MS *m/z* calcd (MH^+): 608.26. Found: 608.26. NMR (300 MHz, DMSO-d_6) δ 1.0−5.0 (m, 25H), 6.64 (d, J = 15.3 Hz, 1H), 7.13 (d, J = 15.3 Hz, 1H), 7.21 (d, J = 8.4 Hz, 2H), 7.61 (d, J = 8.4 Hz, 2H), 10.49 (s, 1H).

Metalation of Chelates. ^{90}Y and ^{111}In were received as solutions in 0.05 M HCl. Approximately 50 μCi of ^{90}Y or ^{111}In was incubated with a 0.5 mM solution of the indicated DOTA derivative in a total volume of 25 μL 0.1 M triethylammonium acetate buffer for 45−60 min at 70 °C. TLC confirmed completion of the complexation reaction. Solutions were stored at −20 °C prior to use. Metalation of chelates with nonradioactive metal ions was accomplished as described previously (*19, 29*).

Initial Evaluation of 2D12.5 Fab Proteins for the Ability to Bind Irreversibly to ^{90}Y−AABD. The heavy-chain CDR2 single-cysteine mutants (G54C, G55C, and G56C) were studied as unpurified protein samples, concentrated from the serum-free expression media used to support S2 cells, and dialyzed into buffer. Briefly, cells were grown in suspension (spinner flask) to an approximate density of 1×10^7 cells/mL and induced with 500 μM $CuSO_4$ for 3 days. Media (600−800 mL) was concentrated by TFF to approximately 50 mL and dialyzed into 10 mM MOPS, 100 mM NaCl, 1 mM EDTA, pH 7.2. The protein solutions were stored at 4 °C and used without further purification. These protein solutions demonstrated affinity for reversibly binding Y−NBD complexes by noncompetitive ELISA.

2D12.5 Fab solutions were estimated to be approximately 100 nM; carrier-free ^{90}Y complexes were <1 nM. The radioactive metal complex solutions and protein solutions were mixed in 100 mM MOPS, 100 mM NaCl, pH 7.4, and incubated at 37 °C for 3 h. Samples were denatured, and disulfides were reduced with reducing SAB containing 1% 2-mercaptoethanol. Samples were boiled for 5 min, flash frozen in liquid N_2, and stored at −20 °C prior to analysis by SDS−PAGE (~50 nCi per lane). Gels were fixed, rinsed, and exposed to a phosphor plate sensitive to radioactive decay for 20−90 min.

Characterizing 2D12.5 G54C Fab Reactivity with Various ^{90}Y Chelates. Solutions containing 2D12.5 G54C Fab (1 μM) and carrier-free ^{90}Y complexes (final DOTA concentration 1 μM) were mixed in 100 mM MOPS, 100 mM NaCl, 10 mM EDTA, pH 7.5, and allowed to incubate for 37 °C for 2 h. Aliquots were withdrawn after 2 h and immediately denatured with nonreducing or reducing SAB and analyzed by SDS−PAGE.

Labeling, LC/MS, and MS^2 Analysis of G54C Fab Labeled with Tb−AABD and Tm−AABD. Equivalent aliquots of MEA-activated G54C Fab (1.3 nmol dissolved in 60 μL MOPS, EDTA buffer) were incubated separately with either Tb−AABD or Tm−AABD (100 μM) at 37 °C for 2.5 h. The two aliquots were combined, and buffer was exchanged according to the method of Penefsky (*33*) prior to digestion with chymotrypsin. Tris, urea, and DTT were added to final concentrations of 125 mM, 5 M and 28.1 mM, respectively, and the resulting solution was incubated at 55 °C for 45 min. Iodoacetamide (dissolved to 500 mM in water) was added to a final concentration of 56 mM and incubated at room temperature for 20 min in the dark. Chymotrypsin (6 μg, 2.4 μL, 1/20 w/w, dissolved in 1 mM HCl) was added; the digestion mixture was allowed to incubate at room temperature for 14 h, whereupon PMSF was added to a final concentration of 1 mM. The resulting solution was diluted 1:1 in 25 mM triethylammonium acetate, pH 7, and purified by 2D12.5 affinity chromatography (*39*). A fraction (1/5) of the elution (0.4% CF_3COOH, 1:1 CH_3CN:H_2O) was concentrated under reduced pressure and injected onto a Thermo Finnigan LCQ Deca electrospray ion trap mass spectrometer equipped with an Atlantis dC_{18} column. HPLC gradient: solvent A, H_2O with 0.2% HCOOH; solvent B, CH_3CN with 0.175% HCOOH, 0−5 min, 5% B, 5−50 min, 5−25% B, 50−65 min, 25−55% B, 65−70 min 55−100% linear solvent B, 250 μL/min. ESI-MS *m/z* calcd (SC(Tb−AABD)GGTAY, MH^+): 1377.41. Found: 1377.39; *m/z* calcd (SC(Tm−AABD)GGTAY, MH^+): 1387.42. Found: 1387.41.

Kinetics of Permanent Bond Formation between 2D12.5 G54C Fab and Y−AABD. Two separate solutions were prepared as follows: ^{90}Y−AABD (^{90}Y, 0.24 nM) was mixed with 10 μM nonradioactive Y−AABD in MOPS, EDTA buffer preincubated at 37 °C. MEA-activated 2D12.5 G54C Fab (1 μM) was added to each tube, and the resulting solution incubated at 37 °C. Nonradioactive

Table 1. Cloned and Expressed Chimeric 2D12.5 Fabs

name	heavy chain	light chain
native	native	native
N85D	N85D	native
G54C	G54C, N85D	native
G55C	G55C, N85D	native
G56C	G56C, N85D	native
N51C (LC)	N85D	N51C

Y−NBD competitor (1 mM) was added to one of the tubes after 6 min. Aliquots were removed from each stock solution at indicated time points, denatured, and reduced by addition to a 5× SAB solution containing 5% 2-mercaptoethanol (1% 2-mercaptoethanol following sample addition), boiled for 5 min, flash frozen in liquid N_2, and stored at −20 °C for SDS−PAGE analysis.

RESULTS AND DISCUSSION

The crystal structures of antibody 2D12.5 bound to DOTA complexes of Y^{3+} and Gd^{3+} were solved to identify preferred residues on the protein for engineering single-cysteine mutants capable of forming a permanent bond with a captured rare earth-DOTA ligand (*20*). Two binding modes for the ligand (differing by a 90° rotation of the DOTA) are observed, as a consequence of the DOTA ligand's symmetry and the orientation in the binding pocket.

An ideal single-cysteine mutant would place the reactive cysteine at a site on the protein surface close enough to the binding site to react with a weakly electrophilic metal−DOTA complex such as AABD, yet at a position that does not interfere with binding of the ligand to the protein. Analysis of the crystal structure indicated that the CDR2 loop of the heavy chain best met these requirements: three glycine residues positioned at the top of the loop did not interact in any way with the ligand. We expect that these three consecutive glycines add flexibility to this segment of the polypeptide chain and hypothesized that a Gly to-Cys mutation at any one of these positions would not meaningfully alter the loop's shape. The remaining two glycines might adjust their conformations if necessary to maintain the binding ability of the native protein.

The 2D12.5 Fab crystal structures indicated that the heavy-chain CDR2 loop mutants were best positioned to interact with a derivatized ligand bound in one of the two possible binding modes (see Figure 1, which shows the binding mode for Y−HETD (*20*)). The other binding mode orients the para-substituent of the ligand over CDR3 of the heavy chain, a domain that plays a crucial role in ligand binding (see the binding mode displayed for Gd-NBD (*20*)); this second binding mode also orients the electrophilic domain of the para-substituted ligand away from the general surface of the protein. In case this turned out to be the preferred mode in solution, a fourth site for a single-cysteine mutation (light-chain CDR2 residue N51, see Figure 1) was identified as a possible reactive site for the second ligand binding mode. For para-substituted ligands such as AABD, it was expected that light chain mutant N51C would behave as a negative control; new ligands with the electrophile in different positions would be required to attach to N51C.

In all, six different chimeric Fab molecules were constructed, expressed, and assayed (Table 1). The first contained the native heavy chain, composed of the 2D12.5 mAb's variable domain fused with the C_{H1} of a human anti-tetanus toxoid antibody (*40*). The native variable domain of the heavy chain contained a N-linked glycosylation site at position 85 in framework 3. This glycosylation site was removed by incorporating a N85D mutation, because glycosylated recombinant proteins often exhibit heterogeneity due to differences in glycosylation. Also, different eukaryotes glycosylate proteins differently and may elicit an undesirable immune response when used in vivo *(41, 42)*. The N85D mutant was used as a heavy chain template to construct three heavy chain single-cysteine mutants (G54C, G55C, and G56C); therefore, the heavy chain cysteine mutants incorporated both the N85D mutation and the desired cysteine mutation. The native chimeric light chain and a single light chain cysteine mutant (N51C) were also constructed (Table 1). Each of the heavy chains was cotransfected with the native light chain in *Drosophila* S2 cells. The N85D heavy chain was cotransfected with the N51C light chain mutant.

Stably transfected *Drosophila* S2 cells were induced, and the media was assayed for protein expression by means of nonreducing SDS−PAGE separation followed by western blot analysis. Noncompetitive ELISA was used to assay binding activity of each of the chimeric Fabs (data not shown). In general, the native and N85D Fabs exhibited the highest expression levels, followed by the G54C and G56C heavy chain mutants. The G55C (HC) and N51C (LC) mutants yielded the lowest expression levels.

To assess the ability of the recombinant 2D12.5 Fab mutants to bind permanently to weakly electrophilic ligands, unpurified cell culture media containing each single-cysteine mutant in low concentration was concentrated and dialyzed into MOPS, EDTA buffer, and incubated with 10 μM ABD (negative control), 10 μM AABD, or 10 μM BAD (positive control) complexes containing ^{90}Y at 37 °C, pH 7.5 (Figure 5). After 2.5 h incubation, we investigated whether a permanent bond had formed between each engineered 2D12.5 single-cysteine Fab mutant and ^{90}Y−AABD. AABD incorporates a weakly electrophilic acryl functionality that has been shown to be unreactive with nucleophilic species naturally present in vivo *(13, 14)*. Following the incubation, protein samples were denatured and reduced, which destroys the binding site and breaks any reversible binding interactions between the protein and ligand. Permanent bonds are not broken by the sample treatment and analysis. Therefore, protein bands permanently tagged by the radioactive ligand are visible by autoradiography or phosphor plate. ABD, AABD, or BAD complexes of ^{90}Y that are not permanently bound migrate with the dye-front at the bottom of the gel.

All of the mutants incorporating the cysteine on CDR2 of the heavy chain showed permanent binding activity with ^{90}Y−AABD, and the Fab was the only protein labeled in cell culture media mixture (indicating high specificity). The G54C sample exhibited the highest concentration of protein with permanent binding activity. The N51C (LC) mutant showed no permanent attachment to ^{90}Y−AABD (data not shown). All of the cysteine mutants (including the N51C (LC) mutant) also formed permanent bonds with ^{90}Y−BAD, which incorporates a much more reactive electrophile. The higher background signal in the ^{90}Y−BAD containing lanes indicates that the ^{90}Y−BAD is less specific for its target and reacts with other proteins in the mixture. The N85D HC mutant showed no permanent bond-forming activity, as expected since a nucleophilic amino acid has not been engineered near the binding pocket. Negative controls incubated with the nonelectrophilic ^{90}Y−ABD also showed no attachment, as expected.

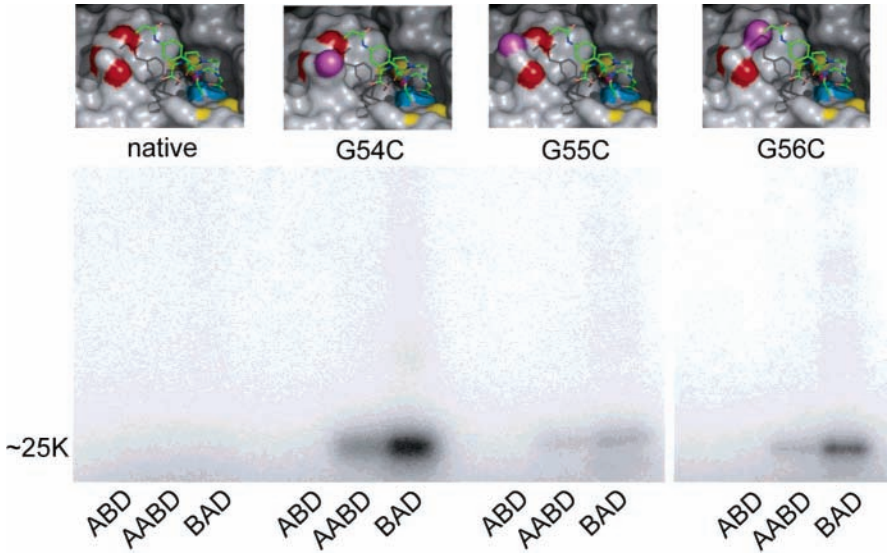

Figure 5. The single-cysteine mutants in CDR2 of the heavy chain were incubated with three DOTA ligands (ABD, AABD, and BAD) to evaluate their ability to form a permanent covalent bind with ^{90}Y−AABD. Raw media containing expressed protein was concentrated and dialyzed into a buffer for evaluation. Samples were adjusted to the same total protein concentration, so they contained different concentrations of Fab. All of the CDR2 (HC) mutants successfully formed a permanent covalent bind with ^{90}Y−AABD, but the G54C, N85D (HC) mutant appeared to be the most abundant and was selected for further study. All of the single-cysteine mutants reacted with ^{90}Y−BAD as expected. The ^{90}Y−AABD is highly selective for the Fab in dialyzed media containing significant amounts of other proteins, while the ^{90}Y−BAD reacts with other proteins in the mixture as well (background signal in BAD gel lanes).

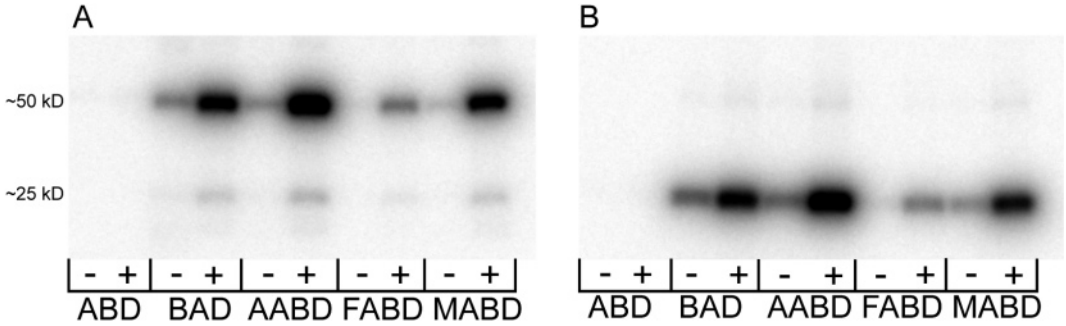

Figure 6. Several different carrier-free ^{90}Y−DOTA derivatives were evaluated for their ability to form a permanent covalent complex with purified G54C Fab. It is known that engineered cysteines often are blocked reversibly through heterogeneous disulfides formed with glutathione or cysteine. The G54C Fab was treated with MEA to activate the reversibly blocked cysteine; the Fab was evaluated for its capability to form a permanent covalent bond with indicated ^{90}Y−DOTA derivatives pre (−) and post (+) activation with MEA. The permanent bond-forming capacity of the G54C Fab improves dramatically with all tested electrophilic ^{90}Y−DOTA complexes following activation with MEA. MABD and FABD display markedly differing reactivities, with the cis-orientation of MABD considerably more favorable for permanent bond formation, while ^{90}Y−AABD, which lacks the carboxyl at the other end of the Michael acceptor, is more reactive than the ^{90}Y complex of either MABD and FABD. Samples were boiled and prepared for SDS−PAGE analysis without a reducing agent (A) and in the presence of 1% 2-mercaptoethanol (B). The nonreduced gel demonstrates that the interchain disulfide of the Fab is intact in almost all of the Fab molecules following treatment with MEA.

It is not clear from this experiment whether the higher infinite binding activity observed for the G54C mutant is due simply to its higher expression level or to the Cys location on the protein. Although analysis of the crystal structure indicates that the G54C mutant may be best positioned to form a permanent link with Y−AABD, experimental challenges make it difficult to assess the relative reactivity of each mutant. For example, engineered cysteines may be reversibly blocked with glutathione or cysteine when recombinant proteins are isolated from eukaryotic expression systems (*43, 44*). The percentage of cysteines that are blocked may vary with their surface accessibility.

Having developed a method for isolating purified chimeric Fab in high yield, we investigated whether the G54C mutant's engineered cysteine was reversibly blocked. Commonly, a mild reducing agent such as MEA may be used to preferentially reduce solvent-exposed disulfides while sparing buried ones (*43, 45*). Others have reported using stronger reducing agents such as DTT (*46*). Treatment of purified G54C Fab with 10 mM MEA overnight at room temperature, pH 7.5, significantly enhanced the permanent bond-forming capacity of the engineered Fab (Figure 6). MEA treatment of the Fab increased the free thiol activity by approximately an order of magnitude and was confirmed using a CPM thiol assay (*34*). Purified Fab samples always consisted of both monomer and a minor amount of Fab dimer (Figure 3). No significant change in the amount of Fab dimer was observed immediately following MEA activation of the cysteine mutant. Also, no significant reduction of the Fab's interchain disulfide was observed (Figure 4 and Figure 6A (nonreduced gel)). The disulfide linking the Fab dimer is apparently protected from solvent, similar to the interchain disulfide that covalently links the light and heavy chains, protecting the dimer from reduction by MEA. The Fab dimers present in solution showed no permanent bond-forming activity, as expected.

We compared the permanent binding activity of untreated and MEA-activated G54C Fab using ^{90}Y−AABD

and yttrium complexes of two other Michael acceptors, MABD and FABD (Figure 6). The experiment clearly shows that permanent binding capacity is significantly enhanced following MEA activation for each of the electrophiles. The smaller AABD shows higher reactivity than MABD or FABD, and apparently the cis-conformation of MABD is preferable to the trans-conformation of FABD. MABD may be interesting for further study because it is nearly as active as AABD, but may exhibit improved in vivo pharmacokinetic properties such as improved blood clearance because of its additional negative charge and overall higher hydrophilicity.

To be certain that we were labeling the G54C mutant specifically at the engineered cysteine site, we sought to further characterize the permanent bond formation between the G54C mutant and rare earth complexes of AABD. To simplify identification of the labeled site, ECAT methodology was used (*39*). Briefly, we incubated equal aliquots of MEA-activated G54C Fab with either Tb− or Tm−AABD, removed unlabeled AABD complexes by gel filtration and mixed the two protein samples. The combined sample was then digested with chymotrypsin, as the trypsin fragment would have been too large to identify conveniently with our MS instrumentation. Any peptides incorporating a metal−AABD tag were separated from untagged peptides using an immobilized 2D12.5 affinity column. The masses of any peptides tagged with Tb−AABD or Tm−AABD differ by 10 amu, a mass differential not commonly found in proteins. A search of the LC data identified only a single peptide that showed a pair of *m/z* peaks with a mass differential of 10 amu. MS^2 confirmed that the sequence of the peptide was SCGGTAY, and the cysteine was labeled with either Tb−AABD or Tm−AABD (Figure 7). This peptide incorporates the G54C mutation.

The LC/MS labeling experiments demonstrate that the covalent link between the G54C Fab mutant and metal−AABD complexes is specific to residue G54C. Further evidence for the specificity of permanent bond formation was collected through kinetics experiments, one of which incorporated the reversibly binding competitor Y−NBD (Figure 8). In the first experiment ^{90}Y-labeled 10 μM Y−AABD was added to purified G54C Fab (1 μM) at 37 °C, pH 7.5. Samples were withdrawn at various time points and were immediately boiled and reduced under denaturing conditions to effectively destroy the binding site and halt any further permanent bond formation. Samples were then analyzed by SDS−PAGE, and the extent of permanent bond formation was determined by measuring the relative radioactivity of bands using a phosphor screen sensitive to radioactive decay. The $t_{1/2}$ for permanent bond formation was ≈13 min.

In a second experiment performed in parallel, conditions were identical to the first except that after 6 min the unlabeled reversible competitor Y−NBD was added in great excess (1 mM) relative to [^{90}Y]Y−AABD (10 μM), effectively preventing rebinding of any [^{90}Y]Y−AABD that dissociated from the G54C Fab. Recall that there are two possible binding modes for Y−AABD to antibody 2D12.5 (*20*). If neither binding mode is favored over the other, the Y−AABD ligand should distribute evenly between them. Since only one of these modes is positioned to react with the G54C mutant, we expect to gain some insight into events in the binding site by adding the Y−NBD competitor at a time when all the sites are expected to be filled but few of the Y−AABD molecules are expected to have dissociated. Because it is in large excess, the Y−NBD should block any Y−AABD that may have initially been bound in the unreactive orientation from rebinding after dissociation. However, the Y−NBD should not affect rearrangements of Y−AABD within the binding site that do not involve dissociation.

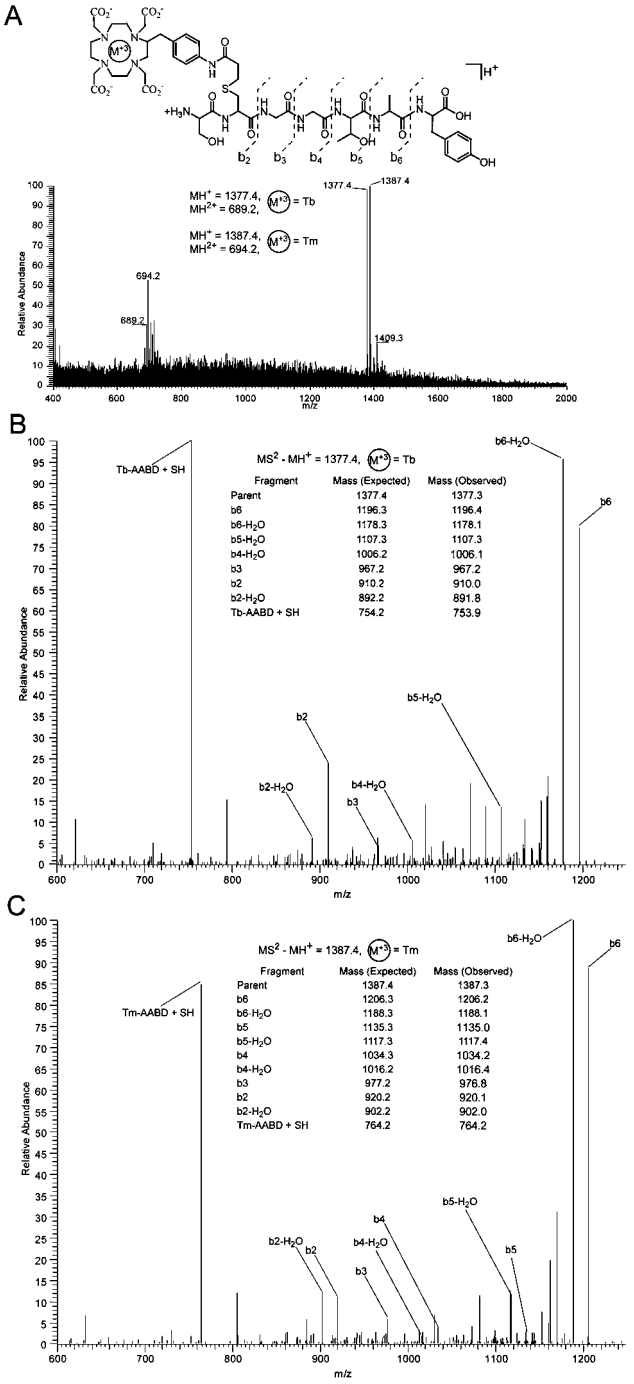

Figure 7. (A) LC/MS and LC/MS^2 analysis of (B) Tb−AABD and (C) Tm−AABD labeled G54C Fab subjected to enzymatic digestion with chymotrypsin. Equivalent aliquots of MEA-activated G54C Fab were incubated separately with either Tb−AABD or Tm−AABD and combined prior to digestion with chymotrypsin. Only the peptide containing the G54C engineered cysteine was labeled, and the ratio of Tb− and Tm−AABD labeled peptide was approximately equal as expected. MS^2 analysis confirmed the sequence of the peptide and presence of either the Tb−AABD or Tm−AABD label. The labeled peptide was affinity purified with an immobilized 2D12.5 column prior to LC/MS analysis as described previously (*39*). The Tb^{3+} and Tm^{3+} labels act as useful mass tags; the unnatural difference of 10 mass units between the Tb− and Tm−AABD labeled peptides simplifies peptide identification.

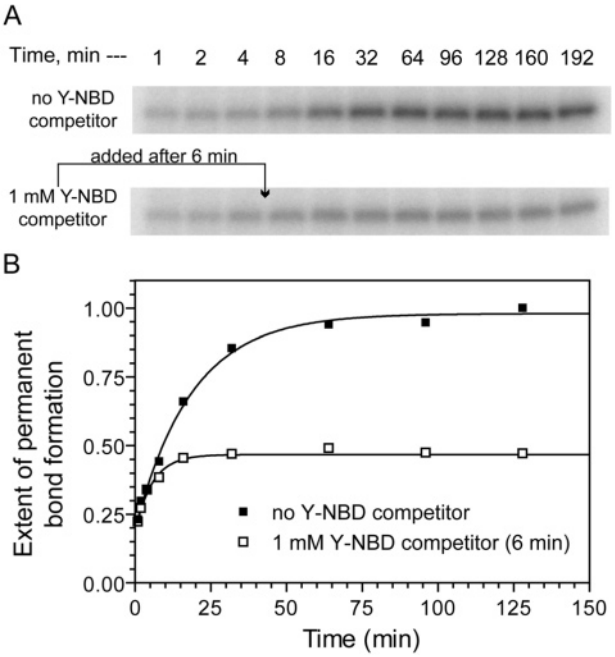

Figure 8. Kinetics of permanent bond formation between G54C Fab (1 μM) and ^{90}Y−AABD (including 10 μM Y−AABD carrier). The addition of a high concentration of Y−NBD, a reversibly binding competitor, after 6 min blocks the rebinding of Y−AABD after dissociation. The experiment containing no competitor, on the other hand, allows any Y−AABD molecules initially bound in an unreactive mode to dissociate and rebind in an orientation favorable for permanent covalent bond formation until a maximum is reached.

The experiment containing no competitor allows Y−AABD molecules to sample both binding orientations; those initially bound in the mode disfavored for permanent bond formation may dissociate and redistribute between the two orientations until all reactive sites are filled and permanent binding reaches a maximum. The overall $t_{1/2}$ of 13 min observed in the absence of competitor includes the time required for dissociation of unproductive complexes and rebinding of the Y−AABD ligand in the binding pocket. A much shorter $t_{1/2}$ for permanent binding (≈4 min) was observed in the presence of competitor, along with a yield ≈45%. A simple interpretation of these results is that the 4-min half-life measured in the latter experiment approximates the half-life for permanent bond formation for Y−AABD ligands bound in only the favored orientation, and that binding in the favored orientation occurs with at least 45% probability. While the kinetic scheme will not be fully understood without extensive study, it seems clear that a significant fraction of the G54C mutant attaches to the Y−AABD ligand in a short time under physiological conditions.

CONCLUSIONS

We have developed an artificial receptor system that binds irreversibly to its engineered ligands, using the general strategy first reported by Chmura et al. (*13*). In contrast to the earlier work, this system is notable for permanently binding a collection of structurally similar electrophilic ligands (*18*). Because the G54C mutant of 2D12.5 reacts quickly and with high specificity with both rare earth-AABD ligands and AABD complexes of other metals, it should be well suited for future applications that may place the receptor at cell surfaces for pretargeting applications.

The observed differences in reactivity between Y^{3+} complexes of MABD and FABD and the 2D12.5 G54C Fab mutant indicate that the steric bulk and conformation of atoms near the electrophilic site of the ligand can be important determinants of permanent binding. Initial experiments with the G55C and G56C mutants of 2D12.5 indicate that cysteines placed at these sites also exhibit permanent binding activity. Similar to the conclusions drawn by Levitsky et al. *(15)*, there seems to be some tolerance for the location of the reactive nucleophile on the protein surface near the binding site. Further work including the other 2D12.5 mutants introduced here should help delineate the importance of general surface location and ligand substitution and how these variables correlate with reactivity.

The tolerance for location coupled with the extension of permanent binding to ligands with weak affinity significantly enhances the general applicability of the infinite affinity concept and should lead to other examples. Recently, proximity accelerated coupling of ligand to protein and ligand to ligand has been applied to the identification of weakly binding ligand scaffolds for new combinatorial leads (*47, 48*). Proteins and/or ligands incorporating complementary reactive functional groups that are suitable for use in vivo may expand pharmaceutical design by offering alternative approaches to combating drug resistance or to target a family of similar molecules. In addition, the purposeful development of artificial receptor systems to produce binding pairs that exceed the affinity of even the avidin−biotin pairing should create a wealth of new possibilities for systems where high affinity has been difficult to attain.

Developing a Peptide-Based Near-Infrared Molecular Probe for Protease Sensing

Wellington Pham, Yongdoo Choi, Ralph Weissleder, and Ching-Hsuan Tung*

Center for Molecular Imaging Research, Massachusetts General Hospital, Harvard Medical School, Charlestown, Massachusetts 02129. Received March 25, 2004; Revised Manuscript Received May 3, 2004

Recently near-infrared (NIR) molecular probes have become important reporter molecules for a number of types of in vivo biomedical imaging. A peptide-based NIR fluorescence probe consisting of a NIR fluorescence emitter (Cy5.5), a NIR fluorescence absorber (NIRQ820), and a protease selective peptide sequence was designed to sense protease activity. Using a MMP-7 model, we showed that NIRQ820 efficiently absorbs the emission energy of Cy5.5 resulting in a low initial signal. Upon reacting with its target, MMP-7, the fluorescence signal of the designed probe was increased by 7-fold with a K_{cat}/K_m of 100 000 M^{-1} s^{-1}. The described synthetic strategy should have wide application for other NIR probe preparations.

INTRODUCTION

To identify promising drug candidates, reliable assays, which could truly report drug efficacy, are critical to initial screening and further evaluation. Many proteolytic assays have been reported and applied in vitro, but direct imaging of the therapeutic effect of drugs in vivo was not available until recently (*1*). A matrix metalloproteinase (MMP)-activatable near-infrared (NIR) fluorescence probe was developed to report inhibitor effect on proteolytic activity in animals (*1*). On each probe molecule, multiple NIR fluorochromes were anchored, via an MMP-selective peptide spacer. This probe is optically silent in its native (quenched) state and becomes highly fluorescent after the proteolysis of MMP substrate peptide linkers by the enzyme. Although this approach works well, it is reasonable to think of a simpler and more defined probe for in vivo assay.

For detecting enzymatic activity in vivo and for the imaging of deeper tissues in vivo, the use of near-infrared (NIR) light is required because hemoglobin and water, which are the major absorbers of visible and infrared light, respectively, have their lowest absorption coefficient in the NIR region around 650−900 nm (*2*). Although many fluorescence enzyme substrates have been reported and widely used, for example, coumarin, *p*-nitrophenol, and other analogues, most of these fluorochromes are in the visible range. The challenge of moving from visible into NIR window is to find a good matching pair of fluorescence donor and acceptor. The underlying principle of designing a NIR probe relies on fluorescence resonance energy transfer (FRET) between a fluorescent donor and a fluorescent or a nonfluorescent acceptor molecule linked via a protease substrate peptide linker. We reported this type of design previously for caspase-3 enzyme detection, using a synthesized nonfluorescence azulene quencher (abs = 750 nm) pairing with a commercial available fluorochrome (em = 700) (*3*). More than 4-fold increase in fluorescence signal was observed when treated with its target enzyme. Lately, we found that a previously synthesized NIR fluorochrome, NIRQ820 (*4*), served as a better acceptor for the fluorochromes with emission around 700 nm.

MMPs are known to be important in normal tissue remodeling, but also known to play critical roles in many diseases, such as lung diseases, atherosclerosis, and cancer (*5*−*7*). Elevated level of MMPs have been found in tumors and shown to correlate well with their invasive and metastatic profiles in both experimental cancer models and in human malignancies (*8*, *9*). The presence of extracellular and membrane-bound MMPs in tumors not only aids the degradation of extracellular matrix by neoplastic cells, but also facilitates their motility and directs cell invasion (*10*). Thus, MMPs have long been of interest as pharmaceutical targets (*11*−*13*). Among those MMPs, MMP-7 has been an important target, because it was overexpressed in pancreatic, colon, and breast cancers *(14, 15)*, In this report, we describe the design of a new type of well-defined low molecular weight peptide-based NIR fluorescence probe, designed primarily for sensing of tumor-associated MMP-7 activity.

EXPERIMENTAL PROCEDURES

Unless otherwise stated, reagents and solvents were obtained from commercial sources without further purification. All moisture or air-sensitive reactions were carried out under a static argon atmosphere. Standard Fmoc-amino acids, *N*-hydroxybenzotriazole (HOBt), and 2-(1*H*-benzotriazole 1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (Applied Biosystem, Foster City, CA), Rink amide resin (100−200 mesh) (Novabiochem, San Dieago, CA), Cy5.5 mono maleimide (Amersham, Piscataway, NJ), and active human recombinant MMP-9 and MMP-7 enzymes (Calbiochem, San Diego, CA) were used.

Reverse phase HPLC purification was performed on a Hitachi Model D-7000 incorporated with Diode Array Detector L-7455 using Vydac 218TP1010 C_{18} column (Hesperia, CA) at a flow rate of 4.0 mL/min. The elution gradient was set from 0 to 50% of buffer B (10% of A in acetonitrile) in 45 min where buffer A was 0.1% TFA in

deionized water. Detection was monitored from 200 to 800 nm range and MALDI-TOF mass spectra were determined (Tufts Core Mass Spectrometry Facility, Boston, MA). Absorption and emission spectra were determined using Hitachi U-3000 Spectrophotometer and F-4500 Fluorescence Spectrophotometer, respectively.

Probe Synthesis. MMP-7 substrate, GVPLSLTMGC−NH_2, with glycine and cysteine at both ends for conjugation was synthesized on an automatic synthesizer (433A Peptide Synthesizer, Applied Biosystem) by Fmoc chemistry (0.1 mmol) using Rink amide resin (0.43 mmol/g) and HBTU/HOBt as the activating reagents. After the completion of the peptide synthesis, the fluorescence quencher, NIRQ820, was coupled to the N-terminus (*4*). NIRQ820 (0.4 mmol, 326.16 mg) was first activated with HBTU (0.2 mmol, 75.86 mg) and HOBt (0.2 mmol, 27.02 mg) in DMF in the presence of argon for 3 h and then reacted overnight. The NIRQ820-labeled peptide **3**, NIRQ820-GVPLSLTMGC−NH_2, was cleaved by a cocktail of TFA/thioanisole/ethandithiol/anisole (90/5/3/2), and purified by C18 reversed-phase HPLC to afford green-colored product. MALDI-TOF MS calcd (M + H)$^+$ 1774.57, found 1774.83.

The fluorescence donor, Cy5.5 mono maleimide (1 mg, 0.87 μmol), was reacted with the previously purified compound **3** (1.5 μmol) in 400 μL buffer (1:1 acetonitrile/50 mM sodium acetate, pH = 7.4) at room temperature in the dark with random shaking for 2 h. The final produce **4**, NIRQ820-GVPLSLTMGC(Cy5.5)-NH_2, was purified by reversed- phase HPLC. MALDI-TOF MS (M + H)$^+$ calcd. 2814.76, found 2814.99.

A control probe **5**, NIRQ820-GSMLPVTLGC(Cy5.5)-NH_2, was synthesized using the same approach.

Stern−Volmer Plot (*16*). A Stern−Volmer plot was obtained at room temperature where a fixed concentration of Cy5.5 (13 μM) was treated with an increasing amount of NIRQ820 (6.0−24 μM) in deionized water. The emission intensity was measured at 690 nm and the relative emission efficiencies of Cy5.5 in the absence and in the presence of NIRQ820 provided a straight line in the concentration range. The following equation was used to derive the Stern−Volmer quenching constant:

$$F_0/F = 1 + K_{sv}[\text{NIRQ820}]$$

where F_0 is the unquenched fluorescence intensity of Cy5.5, F is the fluorescence intensity at [NIRQ820], and K_{sv} is the Stern−Volmer quenching constant.

In vitro probe activation. Peptide-based probes were dissolved in deionized water and the concentration was determined by Beer's law: [C] = A/ϵ where A is the absorbance at 674 nm and ϵ is the molar extinction coefficient (250 000 M^{-1} cm^{-1}) of Cy5.5. The activation of the probes (10μM) was commenced with the addition of MMP-7 or MMP-9 enzymes (30 nM) in a buffer consisting of a 50 mM Tris (pH = 7.6), 200 m NaCl, 5 mM $CaCl_2$, and 1 μM $ZnCl_2$. The fluorescence signal was monitored using 667 nm excitation and 690 nm emission at room temperature for 3 h by SPECTRAmax Gemini (Molecular Devices, Sunnyvale, CA). The plate was set to stir 5 s prior to measurement.

Tumor Extraction. Human fibrosarcoma cell line (HT1080, ATCC, Manassas, VA) was grown in Dulbecco's medium (DMEM, Cellgro, Mediatech, Washington, DC) containing 10% (v/v) fetal bovine serum (FBS, Cellgro) and 1% penicillin/streptomycin at 37 °C in a humidified 5% CO_2 atmosphere. To induce solid tumors, 2×10^6 cells in DMEM media were injected subcutaneously into the mammary fat pad of athymic nude mice (6−7 weeks old)

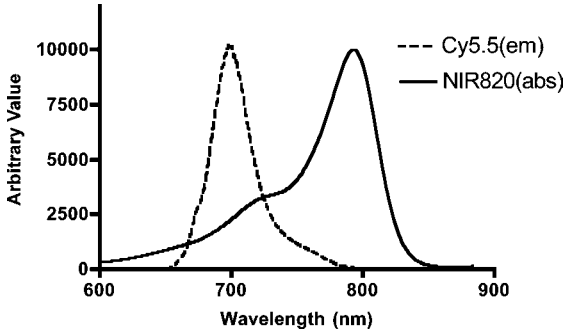

Figure 1. Normalized spectral overlap between the absorption of NIRQ820 (—) and emission of Cy5.5 (- - -). The spectra were obtained in water at room temperature.

(Charles River, Wilmington, MA). When the tumors were grown to 6−9 mm in diameter, the mice were anesthetized by means of intraperitoneal injection of ketamine (90 mg/kg body weight) and xylazine (10 mg/kg body weight). The tumor tissues were carefully dissected and reserved in a buffer solution (pH = 7.4, 50 mM Tris-HCl, 0.15 M NaCl, and 10 mM $CaCl_2$) followed by homogenization and centrifugation at 4 °C. The supernatant was collected and stored at −80 °C for future analysis. All procedures using the animals were conducted in compliance with state and federal guidelines and approved by institutional Animal Care.

Casein Zymography. To confirm the presence of active MMP-7 in tumor tissue, zymography using casein-loaded SDS-polyacrylamide gel was performed as described previously (*17*). Briefly, a 12% SDS-polyacrylamide gel was copolymerized with bovine β-casein (final concentration: 0.5 mg/mL), and then the prepared gel was pre-run at room temperature. Tumor tissue extract (20 μL) and the control MMP-7 enzyme (6 ng) were treated with mercaptoethanol-free Laemmli buffer followed by electrophoresis at 4 °C. SDS was removed from the gel by washing twice with 50 mM Tris-HCl (pH 7.5), 2.5% Triton X-100 for 30 min, and twice more for 10 min with 50 mM Tris-HCl (pH 7.5). The degradation of β-casein in the gel was started by incubating the gel overnight at 37 °C with 50 mM Tris-HCl (pH 7.5), 0.15 M NaCl, 10 mM $CaCl_2$, 0.1% Triton X-100, and 0.02% NaN_3. The staining was performed for 1 h at room temperature with 0.5% Coomassie brilliant blue R-250 in 10% acetic acid and destaining with 10% acetic acid. Caseinolytic activity was visualized as clear bands at 19 kDa of lysis against the dark background.

Probe Activation in Tumor Extract. For the fluorescence assay using tumor extract, 50 μL of tumor extracts were added into 96-well plate and mixed with 150 μL of the buffer solutions (pH = 7.6, 50 mM Tris, 200 m NaCl, 5 mM $CaCl_2$, and 1 μM $ZnCl_2$) containing probe **4** or **5** (10 μM). The solutions containing only probe **4** or probe **5** were also tested as controls. The fluorescence signal was monitored simultaneously for 3 h as described above.

RESULTS AND DISCUSSION

NIRQ820, a cyclohepta polymethine fluorochrome, ex/em = 790/820 nm, is a water soluble NIR fluorochrome with great chemical stability, and a good NIR fluorochrome for protein labeling (*4*). By studying NIRQ820 with a shorter wavelength commercial available fluorochrome, Cy5.5 (ex/em = 675/694 nm, Figure 1), it was found that NIRQ820 acted as an efficient quencher for Cy5.5. To assess the quenching efficiency of this FRET pair, a Stern−Volmer plot was obtained where the

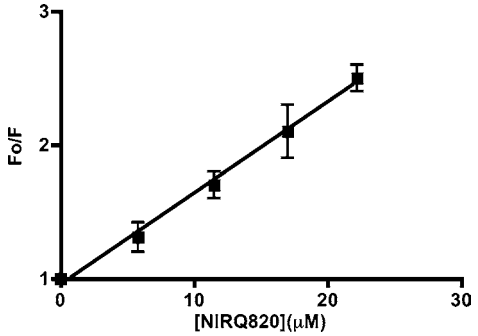

Figure 2. Stern−Volmer plot for determining quenching efficiency of NIRQ820 toward Cy5.5 in water. F_0 and F are fluorescence intensity of Cy5.5 (13 μM) in the absence and in the presence of NIRQ820, respectively. Values are means from two assays.

fluorescence intensity of the donor, Cy5.5, was measured with or without the acceptor, NIRQ820 (Figure 2). There was a decrease in the fluorescence intensity of Cy5.5 (1.32×10^{-5} M) with the increasing concentration of NIRQ820 (0.59×10^{-5} to 2.22×10^{-5} M). A nearly perfect linear line with a steep slope intercepting at 1 implied an effective dynamic diffusion control quenching effect (*18*, *19*).

Previously we have demonstrated that NIRQ820 can be conveniently synthesized in large quantity and is compatible with Fmoc solid-phase peptide synthesis (SPPS) (*4*). We thus chose to couple NIRQ820 quencher onto a MMP-7 selective peptide on solid support and label the peptide with the fluorescence donor, Cy5.5, later in solution (Figure 3).

The core specific peptide substrate, VPLSLTMG, for MMP-7 was selected from a combinatory peptide library (*20*). It has been shown that it is at least 10 to 100 times more selective for MMP-7 than for MMP-1, -2, -3, -9, and MT1-MMP. To the core MMP-7 substrate sequence, glycine and cysteine residues were incorporated at N- and C-termini, respectively, as handles for fluorochromes labeling. The peptide (GVPLSLTMGC) was synthesized on a Rink amide resin by Fmoc chemistry using SPPS. Upon complete synthesis of the peptide sequence, the N-terminal Fmoc group was removed and the sole active amino group was confirmed by ninhydrin test (*21*). NIRQ820 was preactivated by HOBt/HBTU in anhydrous DMF under the presence of argon for 2 h. The intermediate was then coupled to the peptide catalyzed by pyridine for 4 h. The green solid supports were washed with DMF, followed by methanol, before being subjected to standard cleavage conditions.

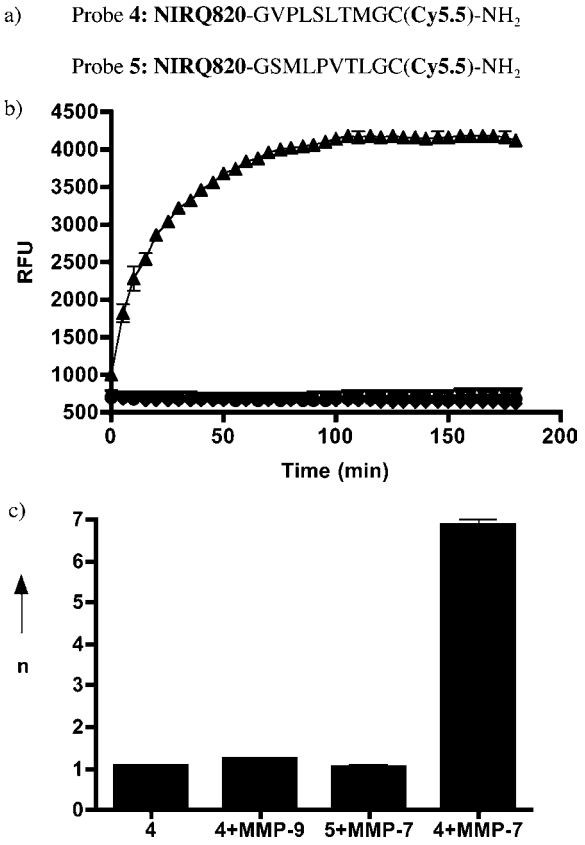

Figure 5. Activation of peptide-based NIR probes with MMPs. (a) Sequence of MMP-7 probe **4** and control scramble probe **5**. (b) Fluorescence signals change upon incubation with **4** alone (◆), **4** + MMP-9 (▼), **5** + MMP-7 (●), and **4** + MMP-7 (▲) in a 50 mM Tris (pH = 7.6), 200 M NaCl, 5 mM $CaCl_2$, and 1 μM $ZnCl_2$ buffer. (c) Fold increase of fluorescence signal at 100 min. Values are means of two assays.

After precipitation and washing with *tert*-butyl methyl ether at 4 °C, the labeled green peptide **3** was purified by HPLC and the product was stored at −78 °C for several months without trace of decomposition. Excess unreacted NIRQ820 was recovered by recrystallization in methanol/water. The thio-reactive maleimide moiety of Cy5.5 was further incorporated into the peptide sequence via the C-terminal cysteine residue in sodium acetate for 2 h following by HPLC purification to provide the MMP-7 probe **4** quantitatively (Figure 4).

The enzyme selectivity of the probes was studied with different controls in an optimal buffer condition using 50 mM Tris (pH = 7.6), 200 mM NaCl, 5 mM $CaCl_2$, and 1 μM $ZnCl_2$ (Figure 5). To follow the proteolytic reaction,

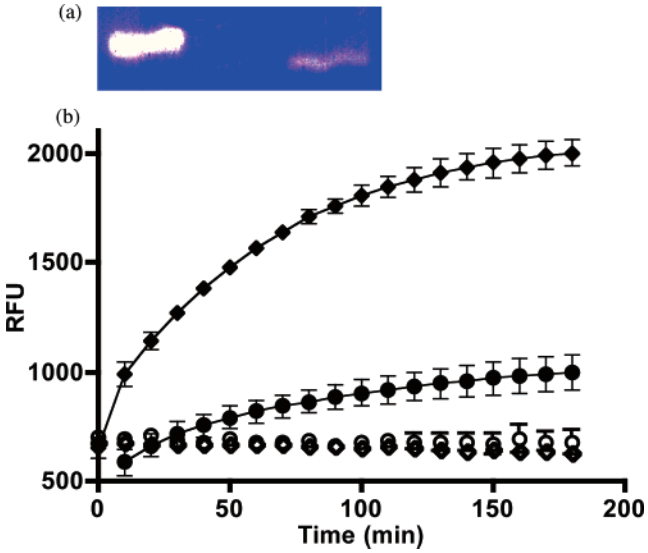

Figure 6. Activation of MMP-7 probe using tumor extract. (a) Casein zymography of HT1080 tumor extract. The 19 kDa bands indicate the active MMP-7 from standard (left) and from tumor extract (right). (b) Activation of NIR probes (10 μM) with tumor extract in a 50 mM Tris, 200 M NaCl, 5 mM $CaCl_2$, and 1 μM $ZnCl_2$ buffer or buffer only. Probe **4** plus tumor extract (solid diamond), scrambled probe **5** plus tumor extract (solid circle), probe **4** in buffer only (open diamond), scrambled probe **5** in buffer only (open circle).

fluorescence changes of Cy5.5 at 690 nm (excitation at 667 nm) were accessed by a fluorescence plate reader. Within 100 min, the Cy5.5 fluorescence signal of probe **4** increased 7-fold with MMP-7 as compared to the control enzyme, MMP-9, or when the probe **4** was incubated without MMP-7 (Figure 5). To further prove the specificity of this probe, a scrambled control probe **5**, SMLPVTLG, was synthesized (Figure 5a). There was no increase in the fluorescence intensity when MMP-7 was incubated with scrambled probe. The enzyme kinetics of probe **4** with MMP-7 was determined using the Michaelis−Menten equation. To obtain accurate initial rate of substrate cleavage, the inner filter effect was corrected according to a previously reported method (*22*). The determined k_{cat}/K_m was 100 000 M^{-1} s^{-1}. This result is consistent with the kinetics of the originally reported peptide sequence, k_{cat}/K_m = 120 000 M^{-1} s^{-1} (*20*). It suggests that chemical attachment of the fluorescence donor and acceptor did not significantly alter enzymatic reactivity and selectivity.

To evaluate the usage of probe **4** in detecting MMP-7 activity in biological systems, a HT1080 human fibrosarcoma tumor model was selected. It has been demonstrated previously that HT1080 has the overexpression of MMP-7 enzyme (*23*). The tumors were dissected when they were about 6−9 mm in size, and the tumor-associated enzymes were extracted by gradient centrifugation. The presence of active 19 kDa MMP-7 in the tumor extract was first confirmed using casein zymography (Figure 6). The fluorescence signal of probe **4** increased by 4-fold after incubating with the tumor extract in 3 h; however, the control probe **5** also gave a 2-fold increase in signal. In the previous experiment, it has been demonstrated that the control probe **5** could not be activated by recombinant MMP-7 (Figure 5C), thus the signal increase has to be caused by other proteases which were extracted from the whole tumor. This result suggests that nonspecific activation of the probe could be expected in the future in vivo imaging of MMP-7 activity.

In summary, we described a rational design of a peptide-based NIR probe. Efficient quenching effect between NIR fluorochrome at 700 nm and NIRQ820 was demonstrated. In the MMP-7 model, the probe is able to release fluorescence signal by 7-fold after enzymatic degradation. This probe design could be applied to assay enzyme activity in vitro, for example high-throughput screening of various inhibitors, and potentially can be used for in vivo imaging of tumor-associated enzyme activity.

Synthesis and Characterization of Poly(L-glutamic acid) Gadolinium Chelate: A New Biodegradable MRI Contrast Agent

Xiaoxia Wen,[†] Edward F. Jackson,[‡] Roger E. Price,[‡] E. Edmund Kim,[†] Qingping Wu,[†] Sidney Wallace,[†] Chusilp Charnsangavej,[†] Juri G. Gelovani,[†] and Chun Li*,[†]

Department of Experimental Diagnostic Imaging and the Department of Imaging Physics, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030. Received April 12, 2004; Revised Manuscript Received August 10, 2004

Most currently evaluated macromolecular contrast agents for magnetic resonance imaging (MRI) are not biodegradable. The goal of this study is to synthesize and characterize poly(L-glutamic acid) (PG) gadolinium chelates as biodegradable blood-pool MRI contrast agents. Two PG chelates of gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA) were synthesized through the use of difunctional and monofunctional DTPA precursors. The conjugates were characterized with regard to molecular weight and molecular weight distribution, gadolinium content, relaxivity, and degradability. Distributions of the polymeric MRI contrast agents in various organs were determined by intravenous injection of ^{111}In-labeled polymers into mice bearing murine breast tumors. MRI scans were performed at 1.5 T in mice after bolus injection of the polymeric chelates. PG-Hex-DTPA-Gd, obtained from aminohexyl-substituted PG and DTPA-dianhydride, was partially cross-linked and was undegradable in the presence of cathepsin B. On the other hand, PG-Bz-DTPA-Gd synthesized directly from PG and monofunctional *p*-aminobenzyl-DTPA(acetic acid-*tert*-butyl ester) was a linear polymer and was degradable. The relaxivities of the polymers at 1.5 T were 3−8 times as great as that of Gd-DTPA. Both polymers had high blood concentrations and were primarily accumulated in the kidney. However, PG-Bz-DTPA-Gd was gradually cleared from the body and had significantly less retention in the blood, the spleen, and the kidney. MRI with PG-Bz-DTPA-Gd in mice showed enhanced vascular contrast at up to 2 h after the contrast agent injection. The ability of PG-Bz-DTPA-Gd to be degraded and cleared from the body makes it a favorable macromolecular MRI contrast agent.

INTRODUCTION

Noninvasive imaging of the intravascular compartment is of critical importance in clinical medicine. Many diseases, e.g., infection, ulcer, cardiovascular diseases, solid tumors, involve gross hemorrhage, abnormal vascular growth, or vascular occlusion (*1, 2*). With the help of blood-pool contrast agents, imaging using computed tomography (CT), ultrasonography, gamma scintigraphy, and magnetic resonance imaging (MRI)[1] can provide minimally invasive angiography, assess angiogenesis, quantify the number and spacing of blood vessels, and measure blood volume and blood flow. MRI blood-pool agents are often paramagnetic gadolinium chelates of high-molecular-weight polymers that are largely retained within the intravascular space during the time frame of an MRI examination (*3*). For example, blood-pool agents for contrast-enhanced magnetic resonance angiography allow prolonged imaging times for higher contrast and resolution. Imaging may be performed during the steady state when the contrast agent is distributed through the complete vascular system (*4*). Recent studies have shown that tumor vascular permeability measurements, derived from polymeric contrast agents enhanced dynamic MRI, correlate with tumor microvessel density counts, suggesting that MRI may be used to characterize tumor angiogenic activity (*5, 6*). Furthermore, polymeric MRI contrast agents may permit more accurate grading of tumor invasiveness than do small-molecular-weight contrast agents, e.g., Gd-DTPA (*7, 8*).

One approach toward clinically acceptable blood-pool MRI agents takes advantage of a small-molecular-weight Gd^{3+}-based agent (i.e., MS-325) that binds strongly but reversibly to human serum albumin (*9, 10*). MS-325 is designed in such a way that an equilibrium between free and protein-bound compound exists, ensuring efficient renal excretion. An alternative approach is to develop macromolecular MRI contrast agents. Various polymeric MRI contrast agents, including human serum albumin (*11*), polylysine (*12, 13*), dendrimers (*16*−*19*), polyamide (*15, 20*), and grafted copolymers (*21*), have been synthesized and evaluated as blood-pool imaging agents. Although most of these agents fulfill the criteria of long blood circulation time and high relaxivity, the safety of these agents has yet to be established. The clinical applications of many current macromolecular contrast agents are limited by slow excretion from the body and potential toxicity of free Gd^{3+} ions released by the metabolism of the contrast agents (*12*−*14, 22, 23*). For an albumin-based product, the possibility of immunogenic response makes the use of serum proteins less attractive. Dendrimer-based blood-pool MRI agents have the ad-

vantage of extremely narrow molecular weight distribution. However, these agents are not biodegradable.

Ideally, a polymeric MRI contrast agent will reside in the blood long enough to allow for thorough MRI examinations and then be degraded and cleared from the body after completion of the imaging procedures. Poly(L-glutamic acid) (PG) is a synthetic polyamino acid that can be readily degraded by lysosomal enzymes to its basic component, L-glutamic acid, a nontoxic natural compound (*24*). The polymer contains a large number of carboxyl functional groups for drug attachment. Conjugation of paclitaxel to PG has resulted in a water-soluble paclitaxel conjugate with reduced systemic toxicity and enhanced antitumor efficacy (*25*). In various studies in rodents, PG used alone as a control agent at doses from 200 to 800 mg/kg did not cause apparent toxic effects. Phase III clinical trials of PG−paclitaxel (Xyotax) as a chemotherapeutic agent are now in progress, underscoring the safety of this polymeric carrier. Recently, Lu et al. (*26*) reported a PG-based MRI agent using cystamine as the cleavable spacer. Gd^{3+} chelates were cleaved from the polymer backbone through a disulfide−thiol exchange reaction. However, potential interaction of the polymer with endogenous thiol-containing biomolecules raises concerns over the safety of this type of agents. Also, it appears that the release and clearance of DTPA−Gd from the polymer backbone through in vivo disulfide−thiol exchange reaction is a rapid process, which may limit its application in steady-state MRI applications.

In this study, we describe the synthesis, characterization, and preliminary evaluation of Gd^{3+}-chelated PG polymers for blood-pool imaging applications. We demonstrate that the resulting polymeric conjugate is cleared from the body as a result of polymer backbone degradation.

EXPERIMENTAL PROCEDURES

Materials. PG sodium salt, *N-tert*-butoxycarbonyl-1,6-diaminohexane hydrochloride (*t*-Boc-Hex-NH_2), 1,3-diisopropylcarbodiimide, pyridine, 4-(dimethylamino)pyridine, trifluoroacetic acid (TFA), diethylenetriaminepentaacetic acid (DTPA) dianhydride, gadolinium(III) chloride hexahydrate, 2,4,6-trinitrobenzenesulfonate (TNBS), 4-(2-pyridylazo)resorcinol, PBS (0.01 M phosphate-buffered saline containing 138 mM NaCl and 2.7 mM KCl, pH 7.4), cathepsin B, and all the other reagents and solvents were purchased from Sigma-Aldrich (St. Louis, MO). *p*-Aminobenzyldiethylenetriaminepenta(acetic acid *tert*-butyl ester) was obtained from Macrocyclics (Dallas, TX). $^{111}InCl_3$ was obtained from Perkin-Elmer Life Sciences (Boston, MA). Spectra/Pro 7 dialysis tubing with molecular weight cutoff (MWCO) of 10 000 and Centricon Plus-20 centrifugal filters were purchased from Fisher Scientific (Pittsburgh, PA). PD-10 columns came from Amersham-Pharmacia Biotech (Piscataway, NJ).

Analytical Methods. Gel permeation chromatography (GPC) was performed on a Waters (Milford, MA) high-performance liquid chromatography (HPLC) system consisting of a 600 controller, a 717 plus auto sampler, and a Viscotek E-Z^{pro} triple detector (Viscotek, Houston, TX) that records refractive index, viscosity, and light-scattering signals. The samples were separated using an TSK-G4000PW 4.6 mm × 30 cm column (TosoHaas, Montgomeryville, PA) eluted with PBS containing 0.1% LiBr at a flow rate of 1.0 mL/min. Number-average molecular weights of the polymer conjugates were calculated using Viscotek TriSEC GPC software. Radio-GPC was performed with a HPLC unit equipped with a LDC pump (Laboratory Data Control, Rivera Beach, FL) and a LUDLUM radiometric detector (Measurement Inc., Sweetwater, TX). The samples were separated using a Phenomenex Biosep SEC-S3000 7.8 mm × 30 cm column eluted with PBS containing 0.1% LiBr at a flow rate of 1.0 mL/min. ^1H NMR was recorded at 300 MHz on a Bruker Avance 300 spectrometer (Billerica, MA) using D_2O as a solvent. Elemental analysis was performed by Galbraith Laboratories, Inc. (Knoxville, TN). Free amino groups in the polymer conjugates were quantified using a TNBS assay following a reported protocol (*27*).

Synthesis of 6-Aminohexyl Poly(L-glutamine) [PG-NH(CH_2)$_6$$NH_2$]. The aqueous solution of sodium salt of poly-L-glutamic acid (number-average molecular weight M_n, 17 500; degree of polymerization, 116) was converted to its acid form by acidifying with 1 N HCl to pH 3−4. The polymer precipitate was collected by centrifugation, washed with deionized water, and lyophilized. Into a solution of PG (0.66 g, 5 mmol [COOH]) in 15 mL of anhydrous dimethylformamide were added *t*-Boc-Hex-NH_2 hydrochloride (1.28 g, 5 mmol), 1,3-diisopropylcarbodiimide (0.76 g, 6 mmol), 0.5 mL of pyridine, and a trace amount of 4-(dimethylamino)pyridine. The reaction mixture was stirred at room-temperature overnight. The precipitate was filtered off, and the solvent was removed under vacuum. The residue was dissolved in 10 mL of trifluoroacetic acid in an ice bath and stirred at 4 °C overnight. Excess of trifluoroacetic acid was removed under vacuum. After dissolving of the residual solid in ice−water followed by neutralization with 1 N NaOH, the solution was dialyzed against PBS followed by deionized water (MWCO 10 000). The dialysate was lyophilized to yield 0.65 g (66%) of a spongelike solid. About 75% (87 of 116) of the glutamic acid residues in PG were converted to 6-aminohexyl glutamine based on the ratio of the integrals of 6-CH_2 protons adjacent to the amine in the 6-aminohexyl group (δ = 2.88 ppm, t) to the α-CH proton in the PG backbone (δ = 4.17 ppm, s).

Synthesis of PG-NH(CH_2)$_6$NH-DTPA-Gd (PG-Hex-DTPA-Gd). DTPA-dianhydride (1.43 g, 4 mmol) was added in portions over a period of 30 min into a solution of PG-NH(CH_2)$_6$$NH_2$ (500 mg, ∼1.1 mmol [NH_2]) in 15 mL of 0.1 M $NaHCO_3$. The pH of the reaction solution was adjusted to 8 by adding aliquots of 0.1 N NaOH solution. After being stirred at room temperature for 2 h, the reaction mixture was dialyzed against PBS and deionized water (MWCO 10 000). The resulting solution was concentrated to 5 mL on a centrifugal filter (MWCO 10 000) and stored at 4 °C for future use. The amount of DTPA attached to PG-NH(CH_2)$_6$$NH_2$ was determined by quantifying unreacted amino groups with the TNBS assay. Approximately 60% (52 of 87) of the amino groups in PG-NH(CH_2)$_6$$NH_2$ were conjugated to DTPA.

To chelate with Gd^{3+}, a solution of $GdCl_3$·$6H_2O$ in water (100 mg/mL) was added dropwise to the aqueous solution of PG-NH(CH_2)$_6$NH-DTPA (PG-Hex-DTPA). The presence of trace amounts of unchelated Gd^{3+} ion in the mixture was monitored with a Gd^{3+} indicator 4-(2-pyridylazo)resorcinol. The reaction solution was dialyzed against water (MWCO 10 000) until no free gadolinium was detected in the receiving medium. The product was further purified by gel filtration on a PD-10 column. Fractions that showed only a single polymer peak on GPC were pooled and lyophilized to give 1.0 g of product (91% yield based on PG-Hex-NH_2). The compound contained 11.9% (w/w) of gadolinium as determined by elemental analysis.

Synthesis of PG-Benzyl-DTPA (PG-Bz-DTPA). PG (M_n, 42 000; 130 mg, 1.0 mmol of carboxylic unit) and *p*-aminobenzyldiethylenetriaminepenta(acetic acid *tert*-butyl ester) (281 mg, 0.36 mmol) were dissolved in 5 mL of anhydrous DMF, followed by the addition of 1,3-diisopropylcarbodiimide (52 mg, 0.4 mmol), 0.16 mL of pyridine, and a trace amount of 4-(dimethylamino)-pyridine. The reaction mixture was stirred at 4 °C overnight. To remove the protecting groups, the reaction mixture was treated with TFA at 4 °C overnight. After removal of TFA under vacuum, 10 mL of ice-cold 1 M $NaHCO_3$ was added into the residual solid. The pH of the solution was brought up to 7.5 with 1 M NaOH, and the solution was dialyzed against PBS and water sequentially (MWCO 10 000). The resulting solution was filtered through 0.2 μm membrane filters and lyophilized to yield 230 mg of spongelike powder (yield 88%). About 55 of 278 glutamic acid residues were coupled to benzyl-DTPA, determined by measurement of UV/Vis absorbance of Bz-DTPA at 250 nm.

Synthesis of PG-Bz-DTPA-Gd. Into a PG-Bz-DTPA (110 mg) solution in 10 mL of sodium acetate-buffered aqueous solution (0.1 M, pH 5.5) was added 0.37 mL of $GdCl_3 \cdot 6H_2O$ (100 mg/mL, 0.1 mmol) in 0.1 M sodium acetate solution in small fractions. The solution was dialyzed against water (MWCO 10 000) until no free Gd^{3+} was detectable in the receiving vessel. The solution was lyophilized to yield 100 mg of white powder (yield of polymer 81%). The number-average molecular weight of Gd^{3+}-chelated polymeric conjugate was about 101 200 as measured by GPC. The compound contained 12.3% (w/w) of gadolinium. Approximately 24% of Glu repeating units contained Gd.

Determination of Relaxivity. Solutions of PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd were prepared in water at gadolinium concentrations of 0.005, 0.01, 0.02, 0.04, 0.08, and 0.16 mM. Spin lattice (T_1) and spin−spin (T_2) relaxivities were measured at 1.5 T on a GE Signa LX scanner (Milwaukee, WI) using inversion recovery and mutiecho pulse sequences, respectively. Relaxivities (R_1 or R_2 in $mM^{-1}\ s^{-1}$) were obtained from linear least-squares determination of the slopes of $1/T_1$ vs [Gd] or $1/T_2$ vs [Gd] plots.

Biodegradation of Gd-Chelated PG Polymers. Gadolinium chelated PG polymers were dissolved in PBS buffer (pH 5) at a concentration of 5.3 mg/mL. Cathepsin B was added to the solutions to a final concentration of 10 units/mL. The solutions were incubated at 37 °C. At predetermined time intervals, aliquots of the polymer solution were removed for GPC analysis.

^{111}In-Labeling of Gd-Chelated PG Polymers. An aqueous solution of either PG-Hex-DTPA-Gd or PG-Bz-DTPA-Gd (10−15 mg) in 1 M sodium acetate buffer (pH 5.5) was incubated with 300 μCi of $^{111}InCl_3$ at room temperature for 15 min. Free ^{111}In was removed by gel filtration on a PD-10 column eluted with PBS. The purity of the radiolabeled compounds was analyzed by radio-GPC.

Biodistribution Studies. Female C3Hf/Kam mice (20−25 g) were bred and maintained in a specific pathogen-free mouse colony in the Department of Experimental Radiation Oncology at the University of Texas M. D. Anderson Cancer Center. All experiments involving animals were performed in accordance with the guidelines of the Institutional Animal Care and Use Committee. Solid murine MCa-4 tumors were generated in the muscles of the right thigh of mice by inoculating 5×10^5 viable tumor cells in suspension in PBS. When tumors had grown to 8 mm in average diameter, mice were randomly allocated into groups, with each group consisting of 3−4 mice. Mice in each group were injected intravenously with either ^{111}In-labeled PG-Hex-DTPA-Gd (0.5 mg, 2 μCi per mouse) or ^{111}In-labeled PG-Bz-DTPA-Gd (0.4 mg, 15 μCi per mouse). Animals were killed at 5 min, 2 h, 24 h and 48 h after injection. Blood, liver, spleen, kidney, muscle, and tumor tissues were removed, weighed, and counted for radioactivity with a gamma counter (Packard, Downers Grove, IL). Uptakes of contrast agent in various tissues were calculated as the percentage of the injected dose per gram of tissue. Student's *t* test was used to compare differences in tissue uptakes between the two agents, with *p* values less than 0.05 considered significant.

Magnetic Resonance Imaging. For MRI studies, mice were anesthetized with 1−2% isoflurane in a 1 L/min O_2 flow and placed prone within a custom sled. A custom catheter made from 2 Fr silicon tubing and a 27 gauge needle was inserted in the tail vein of the mice. Gd-DTPA (0.1 mmol Gd/kg), PG-Hex-DTPA-Gd (0.008 mmol Gd/ml, 0.04 mmol Gd/kg), or PG-Bz-DTPA-Gd (0.008 mmol Gd/ml, 0.04 mmol Gd/kg) was injected through the catheter and the catheter flushed with normal saline. Two-dimensional coronal section spin−echo images were obtained before and at 10 min, 2 h, and 24 h after contrast agent injection using a 2.5 cm quadrature birdcage coil on a 1.5 T Signa LX MR scanner (GE Medical Systems, Milwaukee, WI). Six 1.5 mm contiguous sections were obtained using a 6 cm field-of-view, a 256 × 192 acquisition matrix, and four averages.

A dynamic T1-weighted image set was acquired using a custom multiphase fast spin−echo sequence with an echo train length of 4, echo time of 15 ms, and repetition time of 400 ms with a temporal resolution of 13.6 s/imaging set. After baseline images were acquired, polymeric contrast agent (0.04 mmol/kg) was rapidly injected through a tail vein catheter and followed by a saline flush. The total scan time for the dynamic sequence was 600 s.

RESULTS

Synthesis and Characterization of Gd-Chelated PG Polymers. Two methods were used to synthesize Gd-chelated PG polymers. The synthetic schemes for both synthetic routes were shown in Figure 1. In the first method, DTPA was conjugated to PG through 6-aminohexyl linkers previously introduced to the side chains of PG. Thus, *t*-Boc-Hex-NH_2 was coupled to the side chains of PG using carbodiimide-mediated coupling reaction, followed by removal of *t*-Boc protecting groups and subsequent reaction of the resulting PG-$NH(CH_2)_6NH_2$ with DTPA-dianhydride to give PG-Hex-DTPA (Figure 1). About 87 of the 116 carboxyl groups in PG were converted to 6-aminohexyl glutamine based on ^{1}H NMR analysis. Sixty percent of these 87 aminohexyl groups were further coupled to DTPA when reacted with DTPA-dianhydride on the basis of consumption of NH_2. Thus, the degree of DTPA substitution on the PG polymer was about 0.45 mol DTPA/mol of COOH (Table 1). On the basis of elemental analysis, the Gd content in PG-Hex-DTPA-Gd was 11.9%, indicating that about 0.28 mol COOH in PG was substituted with Gd-DTPA for each mole of COOH units (Table 1).

In the second method, monofunctional, *tert*-butyl ester-protected *p*-aminobenzyldiethylenetriaminepenta(acetic acid) was directly reacted with carboxylic groups of PG, followed by a deprotection step to yield PG-Bz-DTPA (Figure 1). Fifty-five out of 278 glutamic acid units, or

[a] Calculated on the basis of degree of substitution and the molecular weight of parent PG. For PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd, the number-average molecular weights (M_n) of parent PG were 17 500 Da and 42 000 Da, respectively. [b] Measured by gel permeation chromatography with a Viscotek E-Z^{pro} triple detector system as described in Materials and Methods section. Polydispersity = M_w/M_n. [c] Measured by ^1H nuclear magnetic resonance. [d] Determined by quantifying [NH_2]. [e] Determined by UV/Vis measurement of Bz-DTPA attached to PG. [f] Measured by elemental analysis. [g] All data were obtained at 1.5T in phosphate-buffered saline. Data for Gd-DTPA were taken from ref 20.

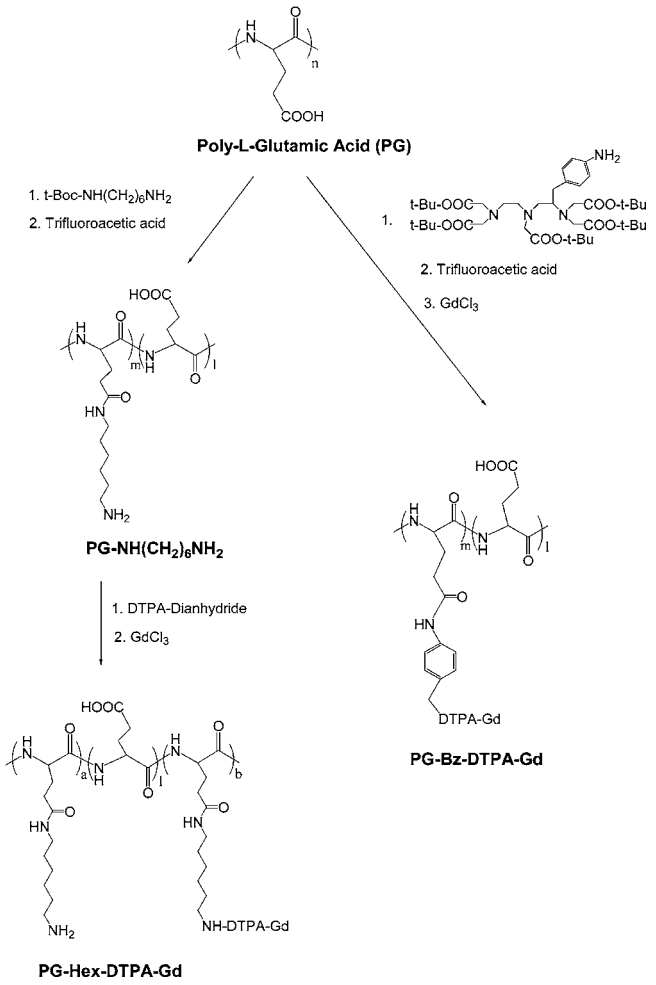

Figure 1. Reaction scheme for the synthesis of PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd.

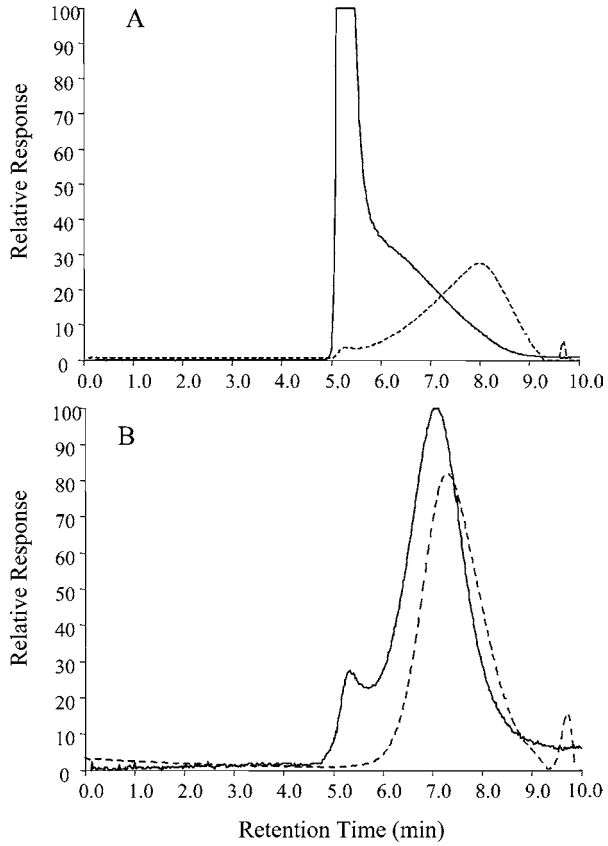

Figure 2. GPC profiles of PG-Hex-DTPA-Gd (A) and PG-Bz-DTPA-Gd (B) revealed by refractive index (- - -) and light scattering (—). The viscosity profile is not shown for reasons of clarity. The chromatography was run on an TSK-G4000PW column eluted with PBS containing 0.1% LiBr at a flow rate of 1.0 mL/min.

0.20 mol/mol of COOH, were attached to benzyl-DTPA as measured by UV absorbance of benzyl-DTPA at 248 nm. The degree of Gd-DTPA substitution based on Gd content in PG-Bz-DTPA-Gd (12.3%) was calculated to be 0.22 mol/mol COOH (Table 1).

Other physicochemical properties of the Gd^{3+}-chelated PG polymers are also summarized in Table 1. The reported number average molecular weights were estimated from GPC analyses. For comparison, the theoretical number-average molecular weights calculated on the basis of starting molecular weight of PG and the degree of substitution are also listed. The polydispersity of PG-Hex-DTPA-Gd (M_w/M_n = 3.34) was much greater than that of the starting PG polymer (M_w/M_n = 1.2) and PG-Bz-DTPA-Gd (Mw/Mn = 1.23) (Table 1). Both Gd^{3+}-chelated PG polymers had greater relaxivities than that of small molecular weight DTPA-Gd.

GPC chromatograms of PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd are presented in Figure 2. A strong peak from the light-scattering profile was observed in the GPC chromatogram of PG-Hex-DTPA-Gd (Figure 2A).

Biodegradation. The degradation of Gd-chelated PG polymers in the presence of cathepsin B was studied by analyzing changes in polymer molecular weights at various time intervals. PG-Bz-DTPA-Gd degraded rap-

[a] All data (other than time) are presented as percentage of injected dose per gram of tissue. Each value represents mean ± standard derivation ($n = 3$ or 4).

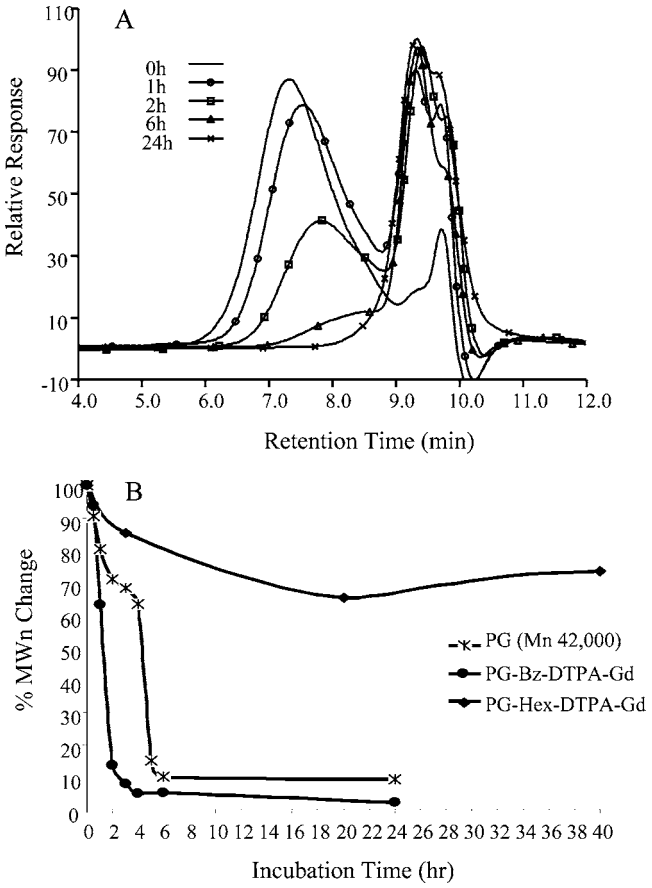

Figure 3. Degradation of Gd^{3+}-chelated PG polymers in the presence of cathepsin B. The polymers were incubated with a PBS solution (pH 5) of cathepsin B (10 units/ml) at 37 °C. GPC chromatograms of PG-Bz-DTPA-Gd at various time intervals revealed rapid degradation of the polymer (A). A comparison of changes in the number-average molecular weights for PG, PG-Bz-DTPA-Gd, and PG-Hex-DTPA-Gd is presented in B.

idly, with the main polymeric peak disappeared completely within 24 h (Figure 3A). On the other hand, the molecular weight of PG-Hex-DTPA-Gd only decreased 30% over a 48-h period (Figure 3B).

Biodistribution. Both Gd^{3+}-chelated polymers were successfully labeled with ^{111}In as demonstrated by the absence of small-molecular-weight ^{111}In-DTPA (retention time, 9.34 min) in the GPC chromatograms of the radiolabeled polymers (data not shown). Biodistribution data for ^{111}In-labeled Gd^{3+}-chelated polymers are summarized in Table 2. Both contrast agents had high blood activity (~28% injected dose per gram of blood, IND/g) at 5 min after contrast injection. By 2 h after contrast injection, substantial activities were still found in the blood, being 16.4% IND/g and 7.7% IND/g for mice injected with ^{111}In-labeled PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd, respectively. The highest uptakes at 2−48 h period for both ^{111}In-labeled PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd were found in the kidney. However, the activity of ^{111}In-labeled PG-Bz-DTPA-Gd in the kidney had decreased to 10.07%IND/g by 48 h postinjecition, while that of ^{111}In-labeled PG-Hex-DTPA-Gd remained at 44.6% IND/g. Interestingly, markedly increased uptake in tumors between 5 min and 2 h was observed with both polymers (PG-Hex-DTPA-Gd, 2.8-fold increase; PG-Bz-DTPA-Gd, 3.3-fold increase). At 48 postinjection, significantly lower activities were found in the blood ($p < 0.001$), the spleen ($p < 0.05$), the kidney ($p < 0.001$), and the tumor in mice injected with ^{111}In-labeled PG-Bz-DTPA-Gd than in mice injected with ^{111}In-labeled PG-Hex-DTPA-Gd (Table 2). No difference was found between their uptakes in the liver ($p = 0.1$). While the uptakes of ^{111}In-labeled PG-Hex-DTPA-Gd in the liver, the spleen, the kidney, and the muscle did not have significant change over the period of 24−48 h, the uptakes of ^{111}In-labeled PG-Bz-DTPA-Gd in these organs had decreased 15.7%, 22.4%, 42.6%, and 29.1%, respectively, over the same time period.

MRI Findings. Representative normalized MR signal intensity in the major blood vessel (e.g., IVC) and the muscle over time obtained immediately after the injection of PG-Bz-DTPA-Gd is shown in Figure 4. Figure 5 presents MR images obtained at 10 min, 2h, and 24 h after injection of PG-Bz-DTPA-Gd. Blood vessels such as the vena cava as well as myocardial, hepatic, lung, and renal perfusion were clearly visualized at 2 h after contrast injection at an injected dose of 0.04 mmol Gd/kg (Figure 5). By 24 h after contrast injection, the blood-pool activity had largely returned to the precontrast level. Interesting, the contrast in certain regions of the tumors was clearly enhanced at 24 h after contrast injection, reflecting enhanced permeability and retention of macromolecules in solid tumors. Similar findings were also observed in mice injected with PG-Hex-DTPA-Gd (data not shown).

DISCUSSION

The purpose of this study was aimed at development of biodegradable polymeric MRI contrast agents as blood-pool imaging agents. PG was chosen as the polymeric carrier for Gd^{3+}-chelates owing to its degradability and biocompatibility. Two methods were used to conjugate DTPA to the side chains of PG, resulting in two distinctly different Gd^{3+}-chelated PG polymers: PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd (Figure 1).

The two polymers differ in the way in which the metal chelator DTPA is introduced to PG. In PG-Hex-DTPA, DTPA was conjugated to PG through hexylamine spacers previously introduced to the side chains of PG. During

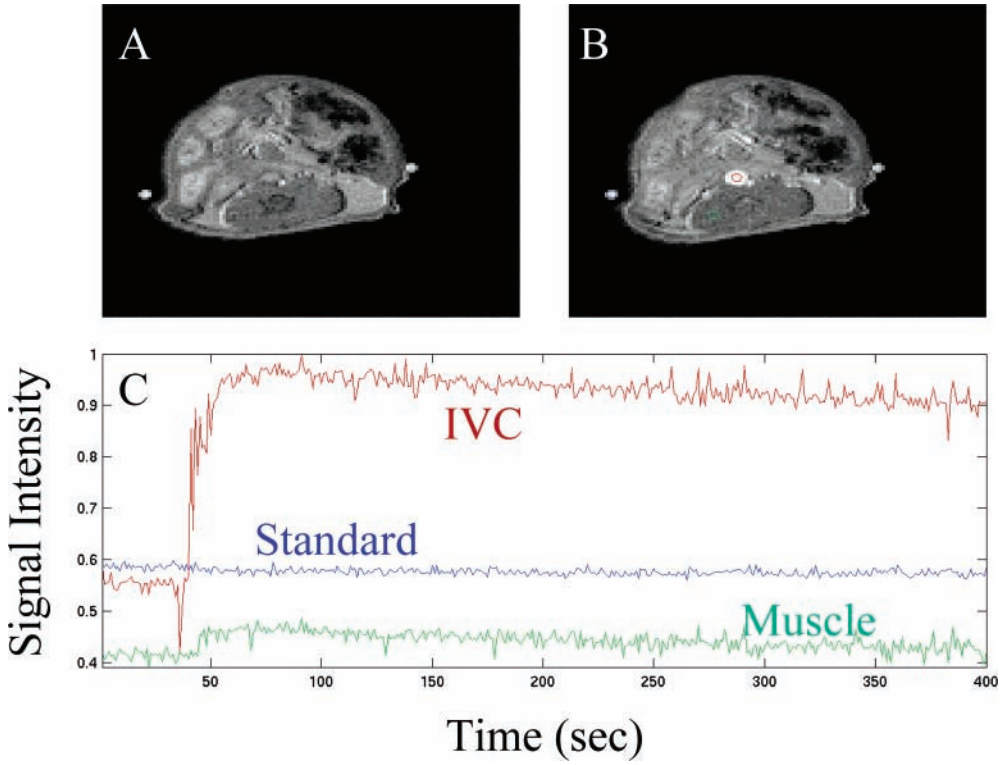

Figure 4. Precontrast (A) and postcontrast (B) of T_1-weighted images from the dynamic MRI series acquired after bolus injection of PG-Bz-DTPA-Gd. Time course of normalized MR signal intensity from regions indicated in B represents signals obtained from inferior vena cava (IVC) (red), muscle (green), and a standard (blue) (C).

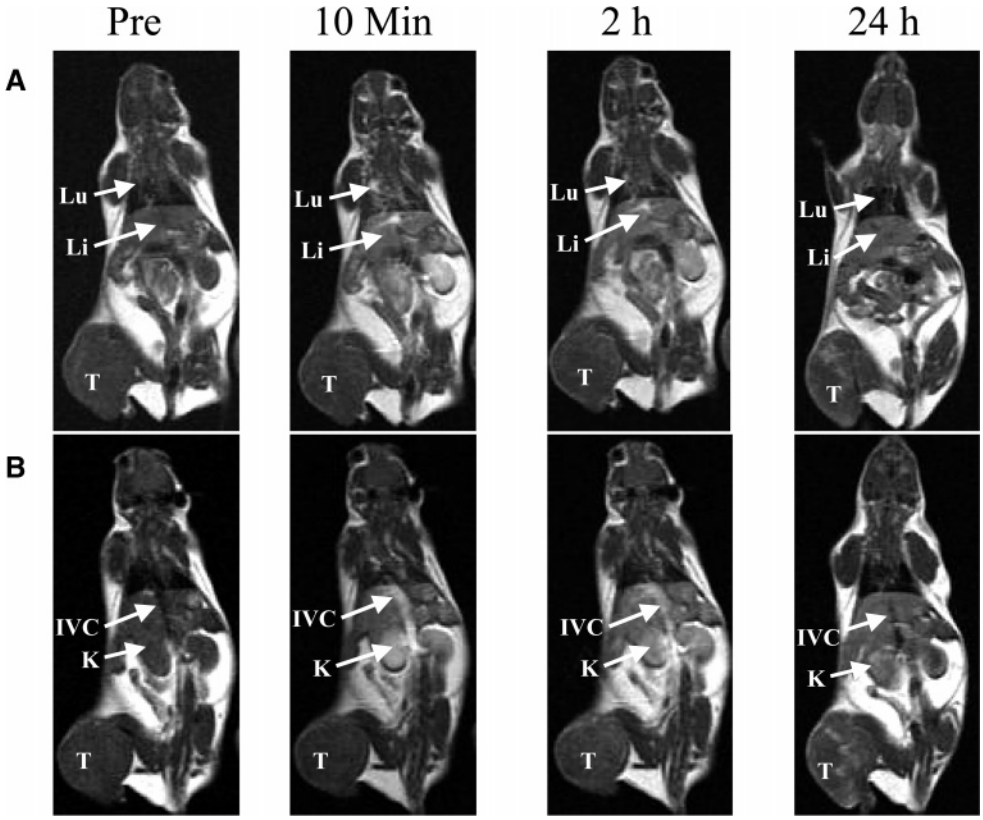

Figure 5. Whole body images of mice before and at 10 min, 2 h, and 24 h after intravenous injection of PG-Bz-DTPA-Gd at a dose of 0.04 mmol Gd/kg. (A) Selected anterior coronal image after injection of contrast agent demonstrates pulmonary and hepatic perfusion. (B) Selected posterior coronal image after injection of contrast agent demonstrates renal perfusion as well as persistent enhancement of the vena cava. Note enhancement of tumor at 24 h postinjection. Lu: lung; Li: liver; IVC, inferior vena cava; K, kidney; T: tumor.

conjugation of DTPA-dianhydride with PG-Hex-NH_2, some cross-linking reactions took place. This is supported by the following observations: (1) The measured molecular weight of PG-Hex-DTPA-Gd was much higher than its corresponding to theoretical molecular weights calculated on the basis of degree of substitution. (2) PG-

Hex-DTPA-Gd had much wider molecular weight distribution than the parent PG polymer. (3) The GPC profile of PG-Hex-DTPA-Gd showed a large peak at the dead volume of the column when light scattering signal was monitored, although this peak only represented a small fraction of polymer mass as shown by the GPC chromatogram of refractive index (Figure 2A). Cross-linking reactions occurred because bifunctional DTPA-dianhydride was used to introduce DTPA to PG-Hex-NH_2. To minimize cross-linking reaction, DTPA-dianhydride was added into a dilute solution of PG-Hex-NH_2 in multiple fractions over a prolonged period. The resulting PG-Hex-DTPA-Gd conjugate remained water-soluble and could be given safely to mice at a dose of up to 0.32 mmol Gd/kg. Doses higher than 0.32 mmol Gd/kg could not be given because of the limitation on injection volume.

In PG-Bz-DTPA-Gd, a monofunctional DTPA precursor *p*-aminobenzyldiethylenetriaminepenta(acetic acid *tert*-butyl ester) was directly conjugated to the carboxyl groups on the side chains of PG (Figure 1). This resulted in a linear polymer, as evidenced by its relatively narrow molecular weight distribution, by the close agreement between calculated molecular weight and GPC-measured molecular weight (Table 1), and by the lack of a fraction of cross-linked molecules (Figure 2B). Compared to PG-Hex-DTPA-Gd, PG-Bz-DTPA-Gd had much higher relaxivity. The reason for this phenomenon is not clear at this time. It is plausible that linear PG-Bz-DTPA-Gd may be more readily accessible to water molecules than cross-linked PG-Hex-DTPA-Gd polymer.

Several studies used isolated tissue lysosomal enzymes to investigate the degradability of PG and its derivatives (*28, 29*). PG was found to be more susceptible to lysosomal degradation than poly(L-aspartic acid) and poly(D-glutamic acid) (*29*). Recent results by Singer and his colleagues prove that monomeric L-glutamic acid is formed in the lysosomal degradation of PG (*30*). Evidence obtained from these studies suggests that cystein proteases, particularly cathepsins B, play key roles in the lysosomal degradation of PG (*28, 30*). Our results show that the difference in the linker groups (hexyl vs benzyl) and perhaps more importantly the presence/absence of polymer cross-link had profound effect on the biodegradability and distribution of Gd-chelated PG polymers. While PG-Hex-DTPA-Gd was essentially not degradable in the presence of cathepsin B, PG-Bz-DTPA-Gd degraded rapidly within 24 h (Figure 3). In vivo, PG-Bz-DTPA-Gd was cleared from the blood, spleen, and kidney faster than PG-Hex-DTPA-Gd. Significantly less uptakes in these tissues were found in mice injected with PG-Bz-DTPA-Gd than in mice injected with PG-Hex-DTPA-Gd at 48 h postinjection. (Table 2). It is noted that although the cross-linked polymer PG-Hex-DTPA-Gd had a high level of uptake in the kidney, the kidney uptake of the linear polymer PG-Bz-DTPA-Gd, on the other hand, was only about one-fourth of that of PG-Hex-DTPA-Gd at 48 h after contrast injection. Unlike PG-Hex-DTPA-Gd, the uptake of PG-Bz-DTPA-Gd in the kidney decreased steadily over a period of 48 h. Therefore, PG-Bz-DTPA-Gd, but not PG-Hex-DTPA-Gd, warrants further development for potential clinical applications.

Dynamic MR images obtained with PG-Bz-DTPA-Gd confirm that the agent markedly enhanced vascular contrast without causing significant loss of signal because of its limited diffusion into intravascular fluid space (Figure 4). MR imaging of mice bearing MCa-4 mammary tumors before and at various time points after the injection of PG-Bz-DTPA-Gd revealed significant contrast enhancement of blood vessels at up to 2 h after their intravenous injection. Indeed, vena cava and pulmonary, myocardial, hepatic, and renal perfusion of mice were clearly visualized (Figure 5). The signal intensities in the blood vessels gradually decreased over the time. By 24 h postinjection, the signal intensities in the blood pool had returned to the preinjection level, suggesting degradation and gradual clearance of the contrast agent from the body. Interestingly, the signal intensity in the tumor had increased during the same time period. These results indicate that PG-Bz-DTPA-Gd was retained in the MCa-4 tumors, possibly a result of the increased permeability and retention effect of macromolecules.

In summary, we have demonstrated that the degradability and biodistribution pattern of Gd^{3+}-chelated PG polymers are strongly affected by the way Gd^{3+} chelators are coupled to PG carrier. PG-Bz-DTPA-Gd and its ability to be cleared from the body make it a favorable macromolecular MRI contrast agent. The dose of PG that would need to be introduced into the body to obtain an equivalent Gd dose of 0.04 mmol/kg is estimated to be less than 52 mg PG/kg. These doses are 10- to 20-fold less than the dose of PG given to rodents without causing apparent toxic effect (*25*). Detailed studies are necessary to fully assess the toxicity of PG-Bz-DTPA-Gd before it is introduced into clinical applications. Further evaluation of both PG-Hex-DTPA-Gd and PG-Bz-DTPA-Gd is ongoing.

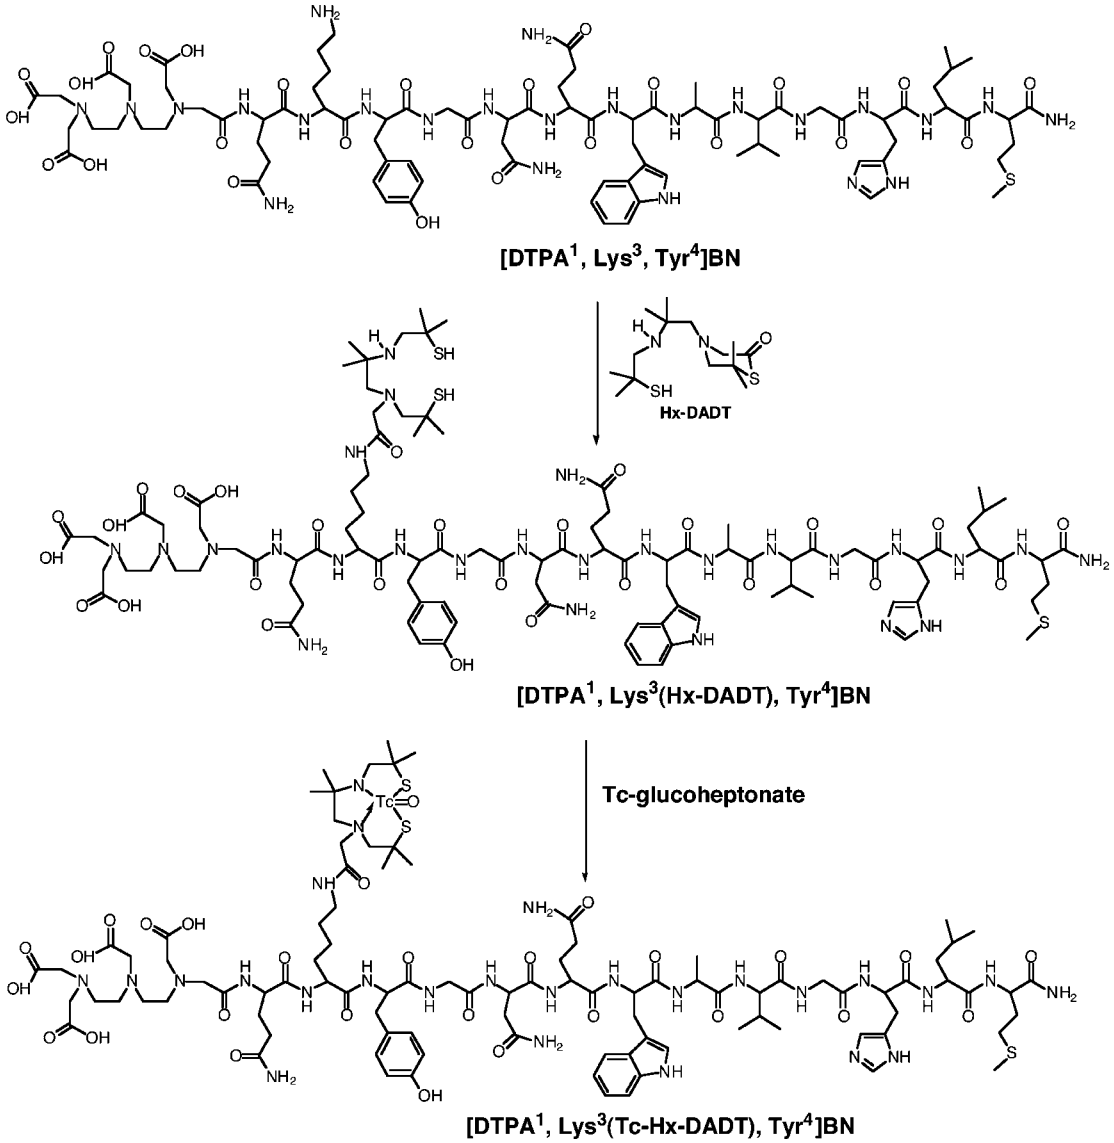
Received July 20, 2004; Revised Manuscript Received August 27, 2004

The bombesin (BN)/gastrin-releasing peptide (GRP) receptor is expressed in high density on the cell surface of a variety of tumors. This makes the receptors accessible as a molecular target for the detection of lesions in which they are expressed. In this study, we describe a high affinity hydrophilic ^{99m}Tc-labeled BN analogue, [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN, having diethylenetriaminepentaacetic acid (DTPA), as a build-in pharmacokinetic modifier, to direct its excretion through the urinary system in order to lower abdominal background activity. In vitro binding studies using [^{125}I-Tyr^4]BN (K_d, 0.1 nM) and human prostate cancer PC-3 cell membranes showed that the inhibition constant (K_i) of [DTPA^1, Lys^3(^{99}Tc-Hx-DADT), Tyr^4]BN was 19.9 ± 8.0 nM. Biodistribution studies in normal mice showed fast blood clearance (0.15 ± 0.01% ID/g, 4 h postinjection), low intestinal accumulation (9.16 ± 2.35% ID/g, 4 h postinjection), and significant uptake in BN/GRP receptor rich tissues such as the pancreas (21.83 ± 2.88% ID/g, 15 min postinjection). The pancreas/blood, pancreas/muscle, and pancreas/liver ratios were highest at 2 h postinjection at 23, 74, and 8.4, respectively. The uptake in the pancreas could be blocked by BN (11.96 ± 1.17 vs 0.65 ± 0.16% ID/g), partially blocked by neuromedin B (11.96 ± 1.17 vs 6.66 ± 0.51% ID/g), but not affected by somatostatin (11.96 ± 1.17 vs 12.91 ± 2.53% ID/g), indicating that the binding of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN to the receptors was specific. Scintigraphic imaging of human PC-3 prostate cancer xenografts in SCID mice gave a high target to nontarget ratio on the image. Thus, [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN has the potential for imaging BN/GRP receptor-positive lesions.

INTRODUCTION

Bombesin (BN), an amphibian tetradecapeptide originally isolated from frog skin (*1*), and its mammalian analogue, gastrin-releasing peptide (GRP), share the same C-terminal heptapeptide, Trp-Ala-Val-Gly-His-Leu-Met-NH_2, and bind with high affinity to the BN/GRP receptor. BN-like peptides have a wide range of physiological activities including stimulation of the release of numerous gastrointestinal hormones (*2*), stimulation of pancreatic enzyme secretion (*3*, *4*), effects on the central nervous system such as thermoregulation (*5*), and inhibition of thyroid-stimulating hormone (*6*).



The BN/GRP receptor has also been shown to be overexpressed on many cancer cells including small cell lung cancer, glioblastoma, gastric, pancreatic, prostate, breast, and colon cancer (*7*−*14*) as well as premalignant cells in the case of prostate, gastric, and lung cancers (*13*−*15*). BN/GRP receptor expression could be used as a potential marker for early diagnosis as well as the staging of BN/GRP receptor-positive cancers and their metastasis if suitable tracers could be developed for in vivo scintigraphy of the receptors. Radionuclides, such as ^{111}In, ^{125}I, and ^{105}Rh (*16*−*18*), have been used to label BN/GRP analogues for in vivo scintigraphy of BN/GRP receptor-bearing tumors. However, due to the advantages of ^{99m}Tc, such as ready availability, low cost, excellent imaging properties (141 keV photon energy and 89% photon flux), favorable dosimetry, and high specific activity, the development of ^{99m}Tc-labeled BN/GRP analogues for cancer imaging would be even more promising. For his reason several investigators have investigated ^{99m}Tc-labeled analogues of bombesin for imaging cancer (*19*−*25*).

To label biomolecules with ^{99m}Tc, it is necessary to provide a site on the substrate for the chelation of the radiometal. The diaminodithiol (DADT) chelating system forms one of the most stable complexes with Tc. Tc complexes of this system, however, tend to be highly lipophilic. Therefore, upon the use of the ligand system to label substrates with ^{99m}Tc, the resultant tracers tend to be excreted primarily through the hepatobiliary system. For example, in a previous study (*19*), we reported a ^{99m}Tc-labeled BN analogue, Lys^3(^{99m}Tc-Hx-DADT)BN in which the diaminedithiol bifunctional chelating agent, Hx-DADT (Scheme 1) was used to chelate the Tc. This technetium analogue showed high affinity for the BN/GRP receptor. However, due to its lipophilicity, the radioactivity was excreted mainly through the hepatobiliary pathway as indicated by the high percent injected dose (% ID) in the liver and intestines (96% ID) at 1 h

postinjection. This high accumulation of radioactivity in the liver and intestines would jeopardize the imaging of BN/GRP receptor-positive cancers and their metastases in the abdominal area. Since radiotracers with higher hydrophilicity tend to be excreted through the urinary system (*26*−*28*), different strategies, such as the use of a water-soluble bifunctional chelating agent (*29*), more hydrophilic coligands (*30*), or cleavable linkers (*31*), have been investigated as ways to increase the hydrophilicity of ^{99m}Tc-labeled peptides. In this study, we report the design, synthesis, and initial evaluation of a high affinity, hydrophilic ^{99m}Tc-labeled BN/GRP analogue, [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN (Scheme 1), modified with a build-in pharmacokinetic modifier, diethylenetriaminepentaacetic acid (DTPA), at the N-terminus to direct its clearance through the urinary system.

EXPERIMENTAL PROCEDURES

Materials and General Methods. BN, neuromedin B, somatostatin, 1,3-diisopropylcarbodiimide (DIC), hydroxybenzotriazole (HOBt), Boc-L-methionine-*p*-methylbenzhydrylamine resin, and Boc-protected amino acids were purchased from Advanced ChemTech (Louisville, KY). [^{99}Tc]NH_4TcO_4 and [^{125}I-Tyr^4]BN were purchased from PerkinElmer Life Science (Boston, MA). [^{99m}Tc]-$NaTcO_4$ was purchased as a solution in physiologic saline from Syncor (Timonium, MD). The Glucoscan kit was purchased from the Du Pont Radiopharmaceutical Division (Billerica, MA). All other chemicals were obtained from either the Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Company (St. Louis, MO). Solvents and chemicals were reagent grade and used as received without further purification. The DADT bifunctional chelating agent, Hx-DADT (Scheme 1), was synthesized according to our previously published procedures (*31*).

Male CD-1 mice were purchased from the Charles River Laboratories (Charles River, MA). All in vivo studies on mice were approved by the Institutional Animal Care and Use Committee. The PC-3 cell line was obtained from the American Type Culture Collection (Rockville, MD) and grown in the Cell Culture Laboratory, School of Medicine, The Johns Hopkins University (Baltimore, MD). Amino acid analyses and MALDI mass spectroscopy were performed by AnaSpec, Inc. (San Jose, CA). FAB mass spectroscopy was performed by the Mass Spectrometry Service Laboratory of the University of Minnesota (Minneapolis, MN).

HPLC was performed with a Waters Chromatography Division (Milford, MA) HPLC System equipped with two

model 510EF pumps, a model 680 automated gradient controller, a model 490 UV absorbance detector, and a Bioscan NaI scintillation detector connected to a Bioscan Flow-count System (Bioscan, Inc., Washington, DC). The output from two channels of the UV detector and the output from the Flow-count system were fed into a Gateway 2000 P5−133 computer fitted with an IN/US System, Inc. (Tampa, FL) computer card. HPLC acquisition and analysis were performed with the Winflow software from IN/US. The semipreparative column (C18 Novapak cartridge, 25 mm × 10 cm, 6 μm), the analytical column (C18 Novapak cartridge, 8 mm × 10 cm, 4 μm), and the C18 Light Sep-Pak cartridges were purchased from Waters Chromatography Division. The G3000SW size exclusion column (7.5 mm × 30 cm, particle size 10 μm, pore size 25 nm) was purchased from TosoHaas (Montogomeryville, PA). Reversed phase HPLC solvents consisted of acetonitrile containing 0.1% trifluoroacetic acid (solvent A) and water containing 0.1% trifluoroacetic acid (solvent B). Liquid scintillation counting for quantification of ^{99}Tc activity was performed on an LKB Wallac instrument model 1219 Rackbeta using Ecolume (ICN Pharmaceuticals, Inc., Costa Mesa, CA) as cocktail. Filtration of in vitro assay mixtures was performed on a BRANDEL, 48M Harvester (Biomedical Research and Development Laboratories Inc., Gaithersburg, MD). ^{125}I activity on filters from in vitro assays and ^{99m}Tc activity of tissues from biodistribution and blocking studies were counted on an automated gamma counter (Pharmacia-Wallac model 1282). Analyses of in vitro binding assay results were performed using the EBDA/LIGAND programs from Biosoft (Milltown, NJ). ^{99m}Tc activity for synthetic reactions and doses for biodistribution were measured in a Capintec (Pittsburgh, PA) CRC-7 Dose Calibrator.

Synthesis of [DTPA^1, Lys^3, Tyr^4]BN. [DTPA^1, Lys^3, Tyr^4]BN was synthesized in an Advanced ChemTech 90 Tabletop Peptide Synthesizer using the *tert*-butyloxycarbonyl (Boc) protocol starting with Boc-L-methionine-*p*-methylbenzhydrylamine resin (3 g, 1 mmol/g). Each coupling step was performed with DIC (9 mmol), HOBt (9 mmol), and the appropriate Boc-protected amino acid (9 mmol) including N^{im}-tosyl His, N^{in}-formyl Trp, *N*-γ-xanthyl Gln, *N*-β-xanthyl Asn, *O*-2,6-dichlorobenzyl Tyr, and N^{ϵ}-2-chlorobenzyloxycarbonyl Lys in methylene chloride/dimethylformamide (1:1). The coupling reaction was usually complete in 30 min and was repeated if the nynhydrin test was positive. Trifluoroacetic acid (25%) in methylene chloride was used for Boc group deprotection during each cycle. DTPA was conjugated as the last step using the method of Mokotoff et al. (*32*). After assembly, peptide cleavage and side chain deprotection were performed using anhydrous hydrogen fluoride (14 g) at 0 °C for 1.5 h in the presence of anisole (19.7 mmol). After drying, the peptide was extracted into 5% aqueous acetic acid (50 mL) and purified by HPLC with a linear gradient from solvent A (15%)/solvent B (85%) to solvent A (40%)/solvent B (60%) over the course of 50 min at a flow rate of 6 mL/min using the semipreparative column monitored on-line for UV absorption at 220 nm. Eluates containing the product with a retention time of 26.0 min were collected, pooled, and lyophilized. The purity of [DTPA^1, Lys^3, Tyr^4]BN was >95% as assessed by analytical HPLC. The yield of [DTPA^1, Lys^3, Tyr^4]BN was 968 mg (17%). Amino acid analysis gave the expected amino acid ratio; calcd/found Asn (1/0.98), His (1/1.01), Val (1/1.00), Leu (1/1.00), Lys (1/1.02), Gln(2/1.96), Gly (2/2.03), Ala (1/1.02), Tyr (1/0.96), Met (1/1.00). MALDI MS: calcd MW for [DTPA^1, Lys^3, Tyr^4]BN 1904.9, found $[M + H]^+$ 1905.8.

Coupling of Hx-DADT to [DTPA^1, Lys^3, Tyr^4]BN. Hx-DADT was coupled to [DTPA^1, Lys^3, Tyr^4]BN according to Scheme 1. Hx-DADT·2HCl (3.6 mg, 9.1 μmol) and [DTPA^1, Lys^3, Tyr^4]BN (3.3 mg, 1.73 μmol) were dissolved in a mixture of borate buffer (0.4 mL, 0.1 M, pH 9) and acetonitrile (0.4 mL), and the pH was adjusted to 9 with triethylamine. The mixture was incubated at room temperature for 2 h and then extracted with ether (3 × 2 mL). The aqueous fraction was chromatographed by HPLC with a linear gradient from solvent B (100%) to solvent A (80%)/solvent B (20%) over the course of 60 min at a flow rate of 6 mL/min using the semipreparative column monitored on-line for UV absorption at 220 nm. The product with a retention time of 33.0 min was collected and then lyophilized. The yield of [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN was 1.7 mg (44%). Amino acid analysis gave the expected amino acid ratios; calcd/found Asn (1/0.88), His (1/1.02), Val (1/1.04), Leu (1/1.04), Lys (1/0.99), Gln(2/1.87), Gly (2/2.18), Ala (1/1.01), Tyr (1/1.00), Met (1/0.87). MALDI MS: calc MW for [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN 2209.1, found $[M + H]^+$ 2211.3.

^{99m}Tc Labeling of the [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN. ^{99m}Tc labeling of [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN was performed as depicted in Scheme 1. A glucoheptonate kit (Glucoscan) was reconstituted with water (1.0 mL). From this solution, [^{99m}Tc]glucoheptonate was prepared by addition of an aliquot (200 μL) to a [^{99m}Tc]pertechnetate solution (500 μL, 10−20 mCi). The mixture was vortexed for 1 min and allowed to stand at room temperature for 15 min. An aliquot of the [^{99m}Tc]-glucoheptonate solution (300 μL) was added to a solution of the [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN (0.5 μmol) in water (500 μL), and the mixture was vortexed for 1 min and incubated at room temperature for 10 min. The labeling reaction was followed by reversed phase HPLC using a linear gradient from solvent A (25%)/solvent B (75%) to solvent A (55%)/solvent B (45%) over the course of 60 min at a flow rate of 2 mL/min on the analytical column. HPLC was monitored on-line for UV absorption at 220 nm and scintillation for radioactivity. A single product designated as [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN with a retention time of 37.0 min was obtained. The yield of the product was >90%.

Preparation of the ^{99}Tc Analogue of [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN. To a solution of [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN (2.6 mg, 1.18 μmol) in a methanol/water mixture (1:1, 800 μL) was added a solution of [^{99}Tc]glucoheptonate in water (60 μL, 20 mM). The mixture was stirred at room temperature for 1 h. A similar product was obtained as described above for the ^{99m}Tc analogue. The product was isolated by HPLC using the same conditions above for the purification of the ^{99m}Tc analogue. The yield of the product was 43%. MALDI MS: calcd MW for [DTPA^1, Lys^3(^{99}Tc-Hx-DADT), Tyr^4]BN 2321.0, found $[M + H]^+$ 2321.0.

Stability Test of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN in Human Serum. The purified ethanolic solution (300 μL) of [DTPA^1, Lys^3(^{99m}Tc-HX-DADT), Tyr^4]BN was diluted with saline (3 mL), and then 100 μL of this diluted solution was mixed with 900 μL of human serum. The mixture was incubated in a 37 °C water bath. After 2, 4, and 6 h, an aliquot (100 μL) was removed and analyzed by isocratic size exclusion HPLC.

The HPLC eluent flow rate was 1 mL/min using the size exclusion column monitored on-line for UV absorption at 220 and 280 nm and scintillation for radioactivity.

The eluent consisted of 10% acetonitrile in 0.2 M phosphate buffer (pH 7.15) containing 0.05% sodium azide. The serum proteins eluted at retention time ranging from 5 to 10 min, and [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN eluted at the retention time of 15.8 min.

Competition of Hydrolyzed Hx-DADT with DTPA for ^{99m}Tc. Hx-DADT·2HCl (2 mg, 5.3 μmol) was dissolved in water (400 μL) and then hydrolyzed by the addition of 2.5 N NaOH (100 μL). After 10 min incubation, the pH was adjusted to 7 with 1 N HCl. DTPA (104 mg, 264 μmol) was added to the mixture, and the pH was readjusted to 7 with 2.5 N NaOH.

^{99m}Tc-glucoheptonate (300 μL, ~10 mCi) was added to the mixture, vortexed for 1 min, and then incubated at room temperature for 20 min. For comparison another reaction was set up with all the reagents except DTPA. The reactions were followed by reversed phase HPLC. The HPLC conditions used were the same as described above for the purification of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN. Both reaction mixtures showed similar HPLC spectra with two products, at retention time of 12.2 min (minor) and 24.8 min (major). The total labeling yield was >95% and the ratio of major/minor product was ~5.

^{99}Tc complexes of hydrolyzed Hx-DADT were similarly prepared using [^{99}Tc]glucoheptonate (1.05 μmol). Two products were obtained as described above for the ^{99m}Tc analogues. The total labeling yield was 56% and the ratio of major/minor product was ~1.5. FAB MS: calcd MW for ^{99}Tc-Hx-DADT 416.1, found $[M + H]^+$ 417.2 for both major and minor products.

In Vitro Binding Assay of BN Analogues. The binding studies were performed using a modified method of Reile et al. (*33*). Briefly, 10 μg membrane protein was incubated at 25 °C for 35 min with 100 pM [^{125}I-Tyr^4]BN in the presence or absence of various concentrations of BN, somatostatin, [DTPA^1, Lys^3, Tyr^4]BN, [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN or [DTPA^1, Lys^3(^{99}Tc-Hx-DADT), Tyr^4]BN ranging from 10 pM to 1 μM in the assay buffer (50 mM Tris-HCl buffer, pH 7.4, containing 1 mg/mL bovine serum albumin (BSA) and 2 μg/mL bacitracin, 125 μL total volume). Nonspecific binding was determined in the presence of 1 μM bombesin. The reaction was terminated by rapid filtration through Whatman GF/B glass fibers presoaked for 30 min in the wash buffer (50 mM Tris-HCl buffer, pH 7.4, containing 1 mg/mL BSA). The filter was washed 3 × 5 mL with ice-cold wash buffer. Radioactivity on the filters was counted in the automated gamma counter. The results of the assay were analyzed by the EBDA/LIGAND computer programs (*34*). The assays were performed in duplicate and the whole experiment was repeated 3 times.

Biodistribution of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN in Normal Mice. The HPLC-purified [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN was isolated from the HPLC eluate by solid-phase extraction using the C18 Light Sep-Pak cartridge. The Sep-Pak cartridge was first washed with ethanol (5 mL) followed by a solution of ammonium acetate (0.05 M, 5 mL). The HPLC eluate containing [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN was diluted five times with ammonium acetate (0.05 M) and then passed through the Sep-Pak cartridge. The Sep-Pak cartridge was washed with an ammonium acetate solution (0.05 M, 5 mL) followed by elution of the [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN with ethanol (300 μL). The ethanolic solution was diluted with physiologic saline to make a final injectate (10 μCi/mL) containing <0.5% ethanol.

Normal male CD-1 mice weighing 23.6 ± 1.1 g were used for biodistribution studies. [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN (2 μCi, 200 μL) was injected into mice via the tail vein. At 15 min, 1, 2, and 4 h postinjection, four mice for each time point were sacrificed by cervical dislocation. Major organs were dissected, weighed, and counted in an automated gamma counter with aliquots of the injectate (as standards) counted at the same time. The percent injected dose per organ (% ID/organ), and the percent injected dose per gram (% ID/g) was calculated. The % ID in blood was estimated with the assumption that the total blood volume is 6.5% of the body weight.

In blocking studies, each mouse received a subcutaneous injection of a suspension containing 700 μg of BN, neuromedin B, or somatostatin in saline (100 μL) 35 min before the injection of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN. Control (unblocked) mice received an injection of saline (100 μL) 35 min prior to the injection of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN. One hour after the injection of the tracer, the mice were euthanized and major organs were dissected, weighed, and counted as described above.

Imaging of Human Prostate Cancer PC-3 Tumor in Mice. Male SCID mice (24.0−32.6 g) were injected subcutaneously with 10^6 PC-3 human prostate cancer cells in matrigel (0.3 mL) in one flank. The mice having palpable tumors (0.5−1.2 g) after 8 weeks were used for imaging studies. HPLC purified [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN (200 μCi) was injected through the tail vein. At 6 h postinjection, the mice were anesthetized with urethane and placed directly on the face of one crystal head of a Phillips IRIX VT camera fitted with a low energy high resolution parallel hole collimator and planar static images acquired for 15 min using a 512 × 512 matrix. Image analysis was performed using the Odyssey FX 8.9C software. Image contrast was adjusted in order to see the outlines of the mouse and the target to nontarget ratio on the image was calculated from regions of interest drawn over the tumor area (target) and the contralateral region (nontarget) of the image.

RESULTS AND DISCUSSION

It is becoming increasingly evident that the BN/GRP receptor becomes expressed early in the process of carcinogenesis in a number of cancers that have been investigated. For example, pulmonary BN/GRP receptor levels in adult lung are extremely low or nonexistent under normal conditions (*35*, *36*). However, prolonged tobacco exposure, transformed cells, and lung cancer result in marked increases in pulmonary BN/GRP levels and the expression of their receptors (*7*, *15*, *37*−*39*). In prostate tissue, a massive BN/GRP receptor overexpression has been demonstrated in prostatic intraepithelial proliferative lesions, a premalignant condition and in prostate carcinoma but not in normal tissues or other prostate hyperplasias (*13*). Similar results have also been reported for gastric cancer where a high density of receptors is present in gastric cancer and Menetrier's disease, a mucosal disorder known to be premalignant, but absent in the surrounding normal tissues (*14*). Such data are not only of biological significance but also provide a molecular basis for potential applications such as BN/GRP-receptor scintigraphy for early tumor detection if suitable radiotracers were available.

To label peptides with ^{99m}Tc, we have been investigating DADT ligands derivatized as bifunctional chelating agents. DADT ligands have been shown to be one of the

most promising chelators for Tc labeling. Having the advantages of stable Tc complexation, well characterized Tc-complex structures, and mild conditions for Tc labeling, DADT ligands have been used to label both proteins and peptides with ^{99m}Tc for applications such as cancer and inflammation imaging (*19*, *40*−*42*). In previous studies (*19*), we reported a ^{99m}Tc-labeled BN analogue, Lys^3(^{99m}Tc-Hx-DADT)-BN, using Hx-DADT as the bifunctional chelating agent and Lys^3-BN as the bombesin analogue. The Tc-chelate core of Hx-DADT is neutral and highly lipophilic. Therefore, while Lys^3(^{99m}Tc-Hx-DADT)-BN showed high affinity ($K_i = 5.2 \pm 1.5$ nM) for the BN/GRP receptor, the high lipophilicity conferred by the Tc-DADT chelate core resulted in most of the radioactivity being excreted through the hepatobiliary pathway (>96% ID). As a result, Lys^3(^{99m}Tc-Hx-DADT)BN would not be suitable for imaging BN/GRP receptor-positive tumors and their metastases in the abdominal area. To increase the hydrophilicity of ^{99m}Tc-labeled BN analogues, we have synthesized this new BN/GRP analogue, [DTPA^1, Lys^3, Tyr4]BN with a built-in pharmacokinetic modifier, DTPA, at the N-terminus so as to direct tracer clearance through the urinary system. To test the utility of this approach, we chose the highly lipophilic ^{99m}Tc-Hx-DADT chelate for labeling.

In the design of [DTPA^1, Lys^3, Tyr^4]BN we sought minimal modification of the structure of BN in order to preserve high affinity binding to the BN/GRP receptor. All modifications were restricted to the N-terminal region in order not to interfere with the C-terminal octapeptide binding site of the peptide. Pyr at the N-terminus was replaced by DTPA, which serves as the pharmacokinetic modifier. The assumption for using DTPA was that, as constructed, the four carboxylic groups introduced to the peptide after coupling DTPA to the peptide would be negatively charged at physiologic pH. Therefore, the peptide would be highly charged, aiding urinary excretion preferentially over hepatobiliary excretion. Arg at the third position of BN was replaced by Lys to provide an ϵ-amino group for coupling to the Tc-coordinating moieties such as Hx-DADT. Leu, the fourth residue, was also replaced by Tyr to allow the potential direct iodination of the resulting analogue. The binding site of BN was retained unaltered in the new analogue. The product, [DTPA^1, Lys^3, Tyr^4]BN, was purified by semipreparative reversed phase HPLC to a single species and characterized by both mass spectrometry and amino acid analysis. It is noteworthy that as constructed, the peptide can potentially be labeled with radionuclides other than ^{99m}Tc such as ^{111}In, $^{123/125/131}$I, ^{18}F and $^{186/188}$Re.

Coupling of the bifunctional chelating agent, Hx-DADT, to [DTPA^1, Lys^3, Tyr^4]BN was performed at pH 9 using a Hx-DADT:[DTPA^1, Lys^3, Tyr^4]BN ratio of 5:1 (Scheme 1). No side chain protection was necessary since the indole and imidazole groups of Trp and His, respectively, are weak nucleophiles under the coupling conditions. The purified adduct was also characterized by both mass spectrometry and amino acid analysis.

We have prepared both no-carrier-added (^{99m}Tc) and milligram quantities (^{99}Tc) of the Tc-labeled BN analogue, [DTPA^1, Lys^3(Tc-Hx-DADT), Tyr^4]BN (Scheme 1). Only one product was obtained in both cases. The yield of ^{99m}Tc product was >90% after a 10 min incubation at room temperature as determined by HPLC. The ^{99}Tc product with 43% isolated yield was characterized by mass spectrometry.

DTPA is capable of coordinating Tc. Therefore, a pertinent issue in the design of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN was whether the Tc was chelated by DTPA, DADT or both. The result from mass spectrometry of [DTPA^1, Lys^3(^{99}Tc-Hx-DADT), Tyr^4]BN indicated that only one technetium-oxo (TcO) group was chelated to [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN. Proteins labeled with Tc using DTPA as the bifunctional chelate usually show poor stability both in vitro and in vivo (*43*) whereas the use of DADT based chelates result in stable products. Results of the stability test of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN in human serum showed that less than 6% of radioactivity was transferred to serum proteins after 6 h incubation at 37 °C. This indicates strong binding of Tc in this product and suggests DADT chelation. In the competition study, identical products (^{99m}Tc-Hx-DADT) were obtained in the presence or absence of excess DTPA confirming that DTPA is unable to compete with DADT for Tc. The products had the same mass expected for Tc-Hx-DADT, indicating isomeric forms of this product as expected for Tc-DADT complexes. The combination of these facts strongly suggests that Tc is chelated to [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN via the DADT core rather than DTPA.

Table 1. Results of in Vitro Binding Studies of Bombesin Analogues to PC-3 Cell Membranes

compound	K_i [a] (nM)
BN	1.7 ± 0.6
[DTPA^1, Lys^3, Tyr^4]BN	3.1 ± 1.3
[DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN	11.2 ± 5.4
[DTPA^1, Lys^3(^{99}Tc−Hx-DADT, Tyr^4]BN	19.9 ± 8.0
somatostatin	>10000

[a] Values represent the mean ± SD ($n = 4$). [b] The blood volume was estimated to be 6.5% of the body weight.

As a first step in the evaluation of the biological activity of [DTPA^1, Lys^3(Tc-Hx-DADT), Tyr^4]BN, we investigated the ability of [DTPA^1, Lys^3(Tc-Hx-DADT), Tyr^4]BN to bind to the BN/GRP receptor on human prostate cancer PC-3 cell membranes. These studies involved competitive binding experiments using the authentic BN receptor ligand [^{125}I-Tyr^4]BN. Results of analysis of the binding data with the EBDA/LIGAND computer programs are shown in Table 1. The apparent affinity, K_i, of [DTPA^1, Lys^3, Tyr^4]BN for the BN receptor was comparable to that of BN itself (3.1 ± 1.3 vs 1.7 ± 0.6 nM). Coupling of Hx-DADT to [DTPA^1, Lys^3, Tyr^4]BN and the subsequent labeling of Tc resulted in products, [DTPA^1, Lys^3(Hx-DADT), Tyr^4]BN and [DTPA^1, Lys^3(^{99}Tc-Hx-DADT), Tyr^4]BN, with slightly lower affinity ($K_i = 11.2 \pm 5.4$ and 19.9 ± 8.0 nM, respectively).

Results of the biodistribution studies of [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN in normal mice are summarized in Tables 2 and 3. [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN showed fast clearance from the blood (0.23 ± 0.01 ID, 0.15 ± 0.01%ID/g, 4 h postinjection) and nontarget tissues. The radioactivity excreted through the hepatobiliary system (liver plus intestines, ∼21% ID,

[a] Values represent the mean ± SD ($n = 4$).

4 h postinjection) was much lower compared to the results of Lys[3](99mTc-Hx-DADT)BN (>96% ID, 3 h postinjection) in our previous studies (*19*), indicating the success of the pharmacokinetic modifier, DTPA, in reducing the radioactivity in the gut even with the use of the highly lipophilic 99mTc-Hx-DADT chelate for labeling. Only small amounts of activity remained in the kidneys, stomach and liver at 4 h postinjection (2.66 ± 0.70, 1.16 ± 0.05 and 0.83 ± 0.23% ID/g, respectively). The pancreas, which expresses BN receptors (*39*), has been used as a target by other investigators (*25*, *45*) for the biological evaluation of newly developed radiolabeled BN analogues. In this study, a significant uptake (21.83 ± 2.88% ID/g, 15 min postinjection) of the radioactivity was found in the pancreas. This demonstrates the ability of [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN to target BN/GRP receptor expressing cells in vivo. The pancreas/blood and pancreas/muscle ratios were highest at 2 h postinjection at 23 and 74, respectively. These ratios are similar to the ratios (22 and 80, 4 h postinjection) obtained by Karra et al. (*25*) using 99mTc-P_2S_2−$BN^{(7-14)}$, a BN analogue labeled with 99mTc by the use of a hydrophilic dithiadiphospine-based bifunctional chelating agent. However, compared to 99mTc-P_2S_2−$BN^{(7-14)}$, [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN showed less radioactivity excreted through the hepatobiliary pathway (liver plus intestines, 21 vs 35% ID, 4 h postinjection) and therefore higher pancreas/liver ratio (8.4, 2 h postinjection vs 2.1, 4 h postinjection). Since the hydrophilic dithiadiphospine-based bifunctional chelating agent also reduced the accumulation of radioactivity in the gut compared to [Lys[3](99mTc-Hx-DADT)]BN from our previous study (*19*), it will be interesting to combine both the built-in pharmacokinetic modifier with a hydrophilic bifunctional chelating agent in the same peptide to investigate the effect on hepatobiliary excretion.

Results of the receptor blocking studies with BN, neuromedin B, and somatostatin (Table 4) confirmed the specificity of [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN toward the BN/GRP receptors. The difference in the uptake of [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN with and without subcutaneous injection of 700 μg of BN are significant in the pancreas (0.65 ± 0.16 vs 11.96 ± 1.17% ID/g), intestines (4.23 ± 0.46 vs 6.90 ± 0.68% ID/g) and stomach (0.64 ± 0.24 vs 1.40 ± 0.47% ID/g). Acini cells of the pancreas, submucosal layer of the small intestine, circular muscle, and submucosal layer of the colon as well as the circular muscle of the gastric fundus and antrum all have been shown to express BN/GRP receptors (*44*, *46*). Neuromedin B (*47*), another mammalian analogue of BN, which shows moderate affinity (K_i, 150−350 nM against [125I-Tyr[4]]BN toward BN/GRP receptors in acini cells of rat pancreas) partially blocked the uptake of

[a] Values represent the mean ± SD ($n = 4$). The animals were sacrificed 1 h after the injection of [DTPA[1], Lys[3](99mTc−Hx-DADT), Tyr[4]]BN. [b] 700 μg (in 100 μL saline) BN, neuromedin B or somatostatin was injected subcutaneously 30 min before the injection of [DTPA[1], Lys[3](99mTc−Hx-DADT), Tyr[4]]BN.

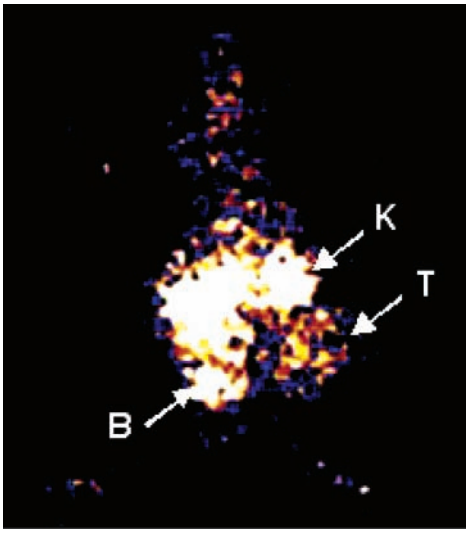

Figure 1. Image of a mouse carrying a human prostate PC-3 xenograft 6 h postinjection with [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN. Tumor, T; kidney, K; bladder, B.

radioactivity in pancreas (6.66 ± 0.51 vs. 11.96 ± 1.17% ID/g). In contrast, somatostatin with very low affinity for BN/GRP receptor showed no effect on the biodistribution of [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN. These results suggest that the uptake of [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN in receptor rich areas in vivo is specific.

In a preliminary study, we investigated the capability of using [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN for imaging prostate cancer using the PC-3 xenograft model in SCID mice. A representative image is shown in Figure 1. The site of the tumor could be differentiated in the 6 h image. The target to nontarget ratio on the image was 8:1, suggesting that the labeled peptide has potential for imaging prostate cancer and its metastases.

In summary, we have described a new hydrophilic peptide, [DTPA[1], Lys[3], Tyr[4]]BN, whose 99mTc-chelate-labeled product [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN showed greatly reduced accumulation of radioactivity in the liver and intestines compared with an analogue lacking the pharmacokinetic modifier. It may be possible to use [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN for imaging BN/GRP receptor-positive tumors. Since DADT ligands are also capable of forming highly stable complexes with Re, the congener of Tc, the 186Re and 188Re analogues of [DTPA[1], Lys[3](Hx-DADT), Tyr[4]]BN could be directly applicable for the radiotherapy of many cancers on account of the energetic beta emissions from these radionuclides.

The study demonstrates successful modification of in vivo pharmacokinetics using DTPA even when the highly lipophilic ^{99m}Tc chelate core, ^{99m}Tc-Hx-DADT, was used for labeling.

PEG-*g*-poly(GdDTPA-*co*-L-cystine): A Biodegradable Macromolecular Blood Pool Contrast Agent for MR Imaging

Aaron M. Mohs,[†] Xinghe Wang,[†] K. Craig Goodrich,[‡] Yuda Zong,[†] Dennis L. Parker,[§] and Zheng-Rong Lu*,[†]

Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112, Department of Radiology, LDS Hospital, Salt Lake City, Utah 84112, and Department of Radiology, University of Utah, Salt Lake City, Utah 84112. Received July 16, 2004

Biodegradable PEGylated Gd-DTPA L-cystine copolymers, PEG-*g*-poly(GdDTPA-*co*-L-cystine), were prepared and tested as a blood pool contrast agent in mice. The biodegradable macromolecular agent was designed to be broken down into smaller Gd complexes by endogenous thiols via the disulfide−thiol exchange reaction to facilitate the clearance of Gd complexes after the contrast-enhanced MRI examination. Gd-DTPA L-cystine copolymers were synthesized by condensation polymerization of L-cystine and DTPA-dianhydride in water followed by chelating with $Gd(OAc)_3$. MPEG-NH_2 (MW = 2000) was then conjugated to the polymeric backbone in different ratios. The macromolecular contrast agent was readily degraded with the incubation of L-cysteine. It also demonstrated superior contrast enhancement in the heart and blood vessels as compared to a low molecular weight control agent, Gd-(DTPA-BMA). At 1 h postcontrast, the PEGylated macromolecular agent still showed prominent enhancement, while little contrast enhancement was detectable in the blood pool by the control agent. PEG-*g*-poly(GdDTPA-*co*-L-cystine) shows promise as an MR blood pool imaging agent.

INTRODUCTION

Gadolinium complexes, Gd-DTPA, GD-DOTA, or their derivatives, are routinely used as extracellular MRI contrast agents in the detection and diagnosis of various cardiovascular pathological conditions by enhancing the morphology and functionality of the condition. Albeit these low molecular weight agents have low toxicity, their inherent pharmacokinetic properties, including transient blood pool retention time, do not render them ideal for cardiovascular imaging. These agents can rapidly extravasate out of blood vessels into the extracellular matrix, introducing difficulties for a quantitative diagnosis that force the application of complex mathematical models (*1*). In addition, the relaxation time of these molecules is relatively slow, necessitating a higher dose of extravascular contrast agent to achieve signal enhancement comparable to that of a macromolecular agent (*2*).

In order for macromolecular Gd complexes to be safe and effective it must be large enough to remain in the blood stream, yet small enough to be excreted after the exam. Previous attempts in the design of macromolecular blood pool agents have been hampered by the potential toxicity of the agents due to the slow clearance of the Gd complexes. Current blood pool agents based on macromolecular Gd(III) complexes from polymers, dendrimers, polypeptides, and polysaccharides have a less complete elimination than their low molecular weight counterparts, resulting in the possible accumulation of toxic metabolic byproducts (*3*−*6*).

The size limitation to macromolecular Gd(III) complexes presents a significant barrier for their application. In response, polymeric Gd(III) chelate conjugates with a cleavable disulfide spacer or polydisulfide-based biodegradable macromolecular Gd complexes were introduced to circumvent the problem of long-term toxic Gd^{3+} accumulation (*7*, *8*). The disulfide bond is cleaved by endogenous or exogenous thiols via the disulfide−thiol exchange reaction to release Gd(III) chelates from the conjugates or break down the macromolecular complexes into smaller complexes to facilitate the clearance of Gd(III) complexes. The plasma concentration of free thiols in humans is approximately 15 μM, allowing for gradual, yet sufficient breakdown of the macromolecules into smaller Gd complexes for complete elimination of the agent after the MRI examination (*9*, *10*).

Previously, we reported the first polydisulfide-based macromolecular Gd(III) complexes, Gd-DTPA cystamine copolymers. This agent resulted in more significant and prolonged blood pool contrast enhancement than a low molecular weight control, Gd-(DTPA-BMA). The agent was then rapidly degraded and extravasated from the blood pool (*8*). Further structural modification of the agent is needed to optimize its physicochemical and pharmacokinetic properties. Here we report a modified biodegradable polydisulfide-based macromolecular Gd(III) complex, poly(GdDTPA-*co*-L-cystine) grafted with monomethoxy-poly(ethylene glycol)amine (MPEG-NH_2), PEG-*g*-poly(GdDTPA-*co*-L-cystine). Poly(ethylene glycol) is a nontoxic, nonantigenic and biocompatible polymer that has a large hydrodynamic radius rendering itself ideal for biomedical applications. With respect to MRI, PEG has been used to stabilize paramagnetic vesicles (*11*), used in formulation with an oral contrast agent to enhance the distal ileum (*12*), incorporated into the

backbone of copolymeric contrast agents (*13*−*15*), and grafted onto polymeric contrast agents (*16*, *17*). Preliminary results show significant contrast enhancement in the blood pool of mice for a longer period of time with the PEGylated polydisulfide agent compared to the clinically used low molecular weight agent, Gd-(DTPA-BMA), while still showing acceptable clearance.

EXPERIMENTAL PROCEDURES

DTPA was purchased from J. T. Baker (Phillipsburg, NJ). L-Cystine was purchased from Sigma (St. Louis, MO). $Gd(OAc)_3$ was purchased from Alfa Aesar (Ward Hill, MA). Monomethoxy-poly(ethylene glycol)-amine ($MPEG\text{-}NH_2$, MW = 2000) was synthesized according to the literature (*18*) as was DTPA dianhydride (*19*).

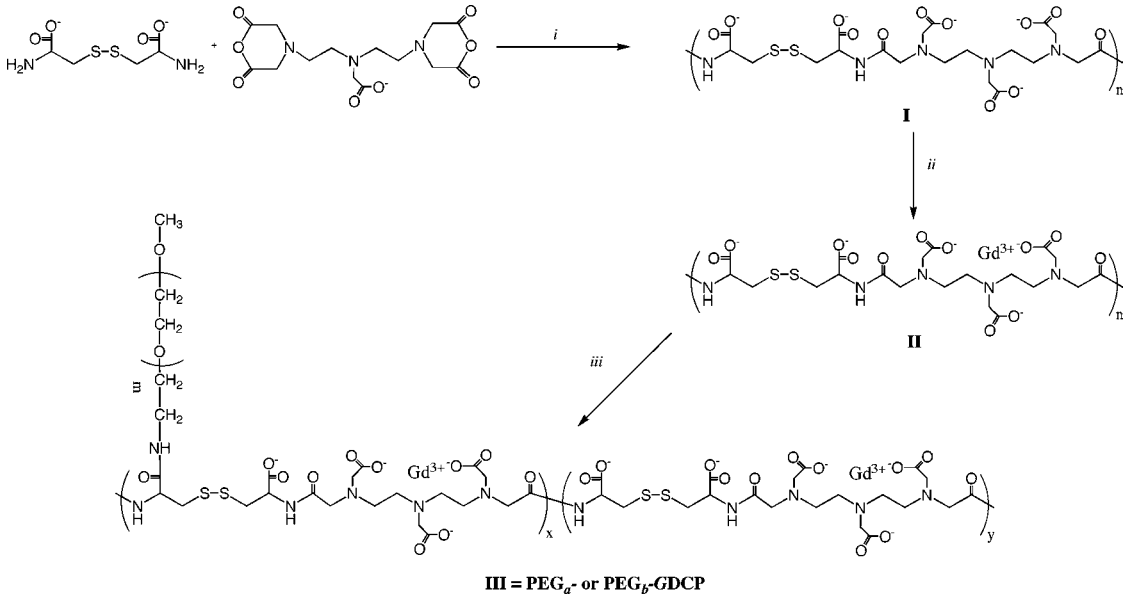
Synthesis of Poly(GdDTPA-*co*-L-cystine). Poly-(DTPA-*co*-L-cystine) (**I**) was first synthesized with the following procedure. L-Cystine (2.40 g, 10 mmol), deionized water (10 mL), and Na_2CO_3 (4.2 g) were stirred for 15 min. DTPA-dianhydride (3.93 g, 11 mmol) was then added in portions to the mixture with stirring, and the mixture was stirred overnight at room temperature. The copolymers were dialyzed against deionized water for 24 h using a regenerated cellulose membrane (MWCO = 6000−8000 Da) and were then concentrated in vacuo to dryness. The molecular weights of the copolymers were determined by size exclusion chromatography (SEC) on an AKTA FPLC system with a Superose 12 (10/300 GL) column and UV and refractive index detectors. The molecular weights were calibrated with poly[*N*-(2-hydroxypropyl)methacrylamide] standards. The number average (M_n) and weight average (M_w) molecular weights of the copolymers were 10.2 and 11.4 kDa, respectively. Proton NMR (ppm, D_2O): 2.94 (m, 8H, N*CH*$_2$*CH*$_2$N), 3.18 (s, 4H, N*CH*$_2$CONH), 3.25 (d, 2H, NHCH*CH*$_2$S), 3.32 (s, 4H, N*CH*$_2$COOH), 3.48 (s, 2H, N*CH*$_2$COOH), 4.42 (m, 1H, NH*CH*CH_2S).

Complexation was achieved by reacting poly(DTPA-*co*-L-cystine) with $Gd(OAc)_3$ in 8 mL of deionized water. Xylenol orange indicator was added and 1 N HCl was added dropwise until pH 5−5.5 was reached. Gd(III) acetate was added to the mixture until the color became pink, indicating an excess of free Gd^{3+} ions. Excess $Gd(OAc)_3$ was removed by eluting the solution through a Sephadex G-25 desalting column (Pharmacia). The purified poly(GdDTPA-*co*-L-cystine) (**II**, GDCP) was concentrated to dryness in vacuo and the molecular weights of the copolymers were determined by SEC, M_n = 10.0 kDa, M_w = 10.1 kDa. Gd content was 862 μmol Gd/g polymer as determined by ICP-OES (Perkin-Elmer, Norwalk, CT, Optima 3100XL).

Synthesis of PEG-*g*-poly(GdDTPA-*co*-L-cystine) (A). Poly(GdDTPA-*co*-L-cystine) (200 mg, 0.26 mmol cystine) was dissolved in 4 mL deionized water, and *N*-hydroxysuccinimide (270 mg, 2.4 mmol) was then added with stirring. An excess of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (700 mg, 3.65 mmol) was slowly added, and the resulting yellow solution was stirred for 15 min. $MPEG\text{-}NH_2$ (MW = 2000 Da, 262 mg) was added in portions, and the reaction mixture was stirred overnight. White precipitate was removed by filtration. Unreacted PEG and salts were removed by ultrafiltration using a Centricon-10 concentrator (membrane MWCO = 10 000 Da). The resulting PEGylated poly(GdDTPA-*co*-L-cystine) (PEG_a-GDCP) was characterized by SEC and ICP-OES as described above. PEG_a-GDCP: M_n = 21.0 kDa, M_w = 24.5 kDa; 720 μmol Gd/g polymer.

Synthesis of PEG-*g*-poly(GdDTPA-*co*-L-cystine) (B). PEG-*g*-poly(GdDTPA-*co*-L-cystine) (PEG_b-GDCP) with high PEG content was prepared similarly with a high PEG to poly(GdDTPA-*co*-L-cystine) ratio. Briefly, poly-(GdDTPA-*co*-L-cystine) (200 mg, 0.26 mmol cystine) was dissolved in 4 mL deionized water, and *N*-hydroxysuccinimide (270 mg, 2.4 mmol) and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (700 mg, 3.65 mmol) were then added with stirring. $MPEG\text{-}NH_2$ (524 mg) was added to the reaction and the mixture was stirred overnight. Unreacted PEG and salts were removed by ultrafiltration using a Centricon-10 concentrator (membrane MWCO = 10 000 Da). PEG_b-GDCP: M_n = 19.9 kDa kDa, M_w = 22.9 kDa; 449 μmol Gd/g polymer.

Relaxivity of PEG-*g*-poly(GdDTPA-*co*-L-cystine). The T_1 of different PEGylated complexes was determined on a Siemens Trio 3T scanner. T_1 relaxation times for three concentrations of the polymeric contrast agents were determined, along with reference values for water and Gd-(DTPA-BMA) by sequential application of a standard inversion−recovery (IR) pulse sequence with TR = 5000 ms, TE = 17 ms for inversion times TI = 22, 25, 30, 35, 40, 50, 100, 200, 300, 400, 500, 600, 700, and 800 ms. Net magnetization amplitude data for each sample were determined from the appropriate ROI and fit using the Marquardt−Levenberg algorithm for multiparametric nonlinear regression analysis to simultaneously determine T_1 and M_0. Regressions were individually inspected for convergence. Parameters and standard errors were determined using ANOVA as provided in the Mathematica Statistics Toolbox. Slope of the plot of $1/T_1$ vs [Gd(III)] then gave the relaxivity R_1.



Degradation of PEG-*g*-poly(GdDTPA-*co*-L-cystine). PEGylated polymers PEG_a-GDCP and PEG_b-GDCP and un-PEGylated GDCP were separately incubated in an aqueous cysteine solution (100 μM) at 37°C. SEC was performed on the samples at 0, 3, and 24 h after incubation to demonstrate the time dependent degradation of the disulfide bonds by looking at the molecular weight change of the copolymers. MALDI-TOF mass spectrometry was then performed on the reaction mixture to observe the degradation products of PEG_a-GDCP, PEG_b-GDCP, and GDCP.

In Vivo MR Imaging. In vivo contrast enhanced MR imaging with the macromolecular agents was investigated in CD-1 mice (Charles River Laboratories). The animals were cared for under an approved protocol and the guidelines of the University of Utah Institutional Animal Care and Use Committee. The mice were anesthetized by the intramuscular administration of a mixture of ketamine (80 mg/kg) and xylazine (12 mg/kg). Contrast-enhanced images of mice were obtained on a Siemens Trio 3T MR scanner with a wrist coil pre- and postcontrast using the following imaging parameters: TE = 1.74 ms, TR = 4.3 ms, 25° RF tip angle, 3D acquisition with 128 slices/slab, 120 mm FOV, and 1.6 mm coronal slice thickness. Either Gd-(DTPA-BMA) (0.1 mmol Gd/kg) or a polymeric agent GDCP, PEG_a-GDCP, or PEG_b-GDCP (0.03 mmol Gd/kg for all polymeric agents) was injected via a tail vein into anesthetized mice and images were acquired at 1, 5, 15, 30, and 60 min postinjection of contrast agent. Each agent was investigated in a group of four mice.

RESULTS

Synthesis of PEG-*g*-poly(GdDTPA-*co*-L-cystine). The synthetic procedure of PEG-*g*-poly(GdDTPA-*co*-L-cystine) is described in Scheme 1. Poly(DTPA-*co*-L-

Scheme 1. Synthesis of PEG-*g*-poly(GdDTPA-*co*-L-cystine)[a]

[a] (i) Na_2CO_3, H_2O, rt, overnight; (ii) $Gd(OAc)_3$, pH 5.0−5.5, rt, 2 h; (iii) NHS, EDC, MPEG-NH_2, H_2O, pH 7−8, rt, overnight

cystine) was first synthesized by the copolymerization of DTPA dianhydride with L-cystine. L-Cystine is sparingly soluble in organic solvents and the copolymerization was performed in Na_2CO_3 aqueous conditions. The weak base Na_2CO_3 was used to maintain a relatively basic pH and to minimize the hydrolysis of the dianhydride. The molecular weight of poly(DTPA-*co*-L-cystine) was relatively low due to partial hydrolysis of the dianhydride, limiting chain growth of the copolymers.

The monomethoxy-PEG amine with an average molecular weight of approximately 2000 Da was used in the modification of GDCP. The content of PEG in PEG-*g*-poly(GdDTPA-*co*-L-cystine) was controlled by the molar ratio of MPEG-NH_2 and GDCP. PEG-*g*-poly(GdDTPA-*co*-L-cystine) with two different degrees of PEG modification were prepared. The molar ratio of PEG to the Gd-DTPA monomer was 0.33 and 0.76 for conjugates PEG$_a$-GDCP and PEG$_b$-GDCP, respectively, calculated from the Gd content per gram of polymer sample before and after PEGylation as determined by ICP-OES. The ratio of PEG grafted to cystine residues in the GDCP backbone is lower than the stoichiometric ratios used in the reaction, possibly due to the spatial restriction caused by the large hydrodynamic radius of PEG blocking the conjugation of more PEG molecules to the adjacent cystine residues. PEGylation increased the hydrodynamic volume of the copolymers. However, the increasing PEG content did not result in further increase of the hydrodynamic volume of the copolymers when comparing PEG$_a$-GDCP (M_w = 24.5 kDa) with PEG$_b$-GDCP (M_w = 22.9 kDa).

In Vitro Degradation. The in vitro degradation study was performed by incubating the macromolecular agent with L-cysteine to verify the degradability of the agents via the disulfide−thiol exchange reaction. The results showed the expected decrease for the high molecular weight fraction and an increase in PEGylated degradation products of the agents in the incubation mixture. SEC analysis of the incubation mixtures showed that there was a significant shift of molecular weight distribution to lower molecular weight, representing a breakdown in the most prominent polymer species. The time-dependent molecular weight distribution of PEG$_a$-GDCP in the incubation is shown as an example in Figure 1. The initial polymer peak at 27.4 min completely disappeared after 24 h of incubation. Consequently, there is a rise in signal intensity at 31.4 and 34.8 min over the same time period representing an increase in the PEGylated and unPEGylated degradation units, respectively. The low molecular weight degradation complexes **IV**, **V**, and **VI** in Scheme 2 were identified in the MALDI-TOF mass spectrum acquired on the reaction mixture at the end of the incubation period.

Relaxivity. Both PEGylated polymers, PEG$_a$-GDCP and PEG$_b$-GDCP, had a higher relaxivity than GDCP (5.5 mM^{-1} s^{-1}), while PEG$_a$-GDCP had a higher relaxivity than PEG$_b$-GDCP, 16.3 and 12.7 mM^{-1} s^{-1}, respectively. It is likely that PEG offers some steric limitation to the movement of the polymer, which increases the rotational correlation coefficient of the copolymers and in turn the relaxivity (*20*). However, PEG$_b$-GDCP with high PEG content possessed lower relaxivity than PEG$_a$-GDCP with low PEG content.

In Vivo MR Imaging. Figure 2 shows the coronal MR images of the heart of mice contrast enhanced with PEG$_a$-GDCP, PEG$_b$-GDCP, GDCP, and Gd-(DTPA-BMA) at various time points. Strong contrast enhancement was observed in the heart with the macromolecular agents at a dose of 0.03 mmol-Gd/kg 1 min postcontrast and the signal intensity gradually decreased over the period of observation. Significant contrast enhancement was still visible in the heart at 60 min for the polymeric agents. The low molecular weight control agent, Gd-(DTPA-BMA), produced visible contrast enhancement at a dose of 0.1 mmol/kg 1 min postinjection and little to no enhancement afterward.

The macromolecular agents also resulted in significant contrast enhancement in mouse blood vessels with the same trend. Figure 3 shows the coronal images of the descending aorta and common iliac arteries at various time points. The macromolecular agents clearly revealed the blood vessels 1 min post-contrast while little contrast enhancement was observed with the control agent. The blood vessels with PEGylated agents were more visible 5 min postinjection than those with the un-PEGylated polymeric agent. This demonstrates that PEGylation contributes to increased vascular retention, possibly by increasing the size of the agent.

DISCUSSION

Polydisulfide-based macromolecular Gd complexes have been designed to facilitate the clearance of Gd complexes after the MRI examination. Previously, we have demonstrated the feasibility of contrast-enhanced MRI with the first polydisulfide-based contrast agent, (Gd-DTPA)-cystamine copolymers (*8*). The copolymers resulted in significant blood pool contrast enhancement in rats in the early period postcontrast, approximately 2 min at a high dose (0.1 mmol-Gd/kg). However, less significant blood pool contrast enhancement was observed with the agent at a low dose (0.03 mmol-Gd/kg). PEGylated GDCP was designed and prepared to modify the physicochemical properties and in vivo contrast enhancement of biodegradable macromolecular agents.

PEGylation increased the molecular weight and hydrodynamic size of the macromolecular agent. It is interesting to note that the amount of MPEG-NH_2 grafted on the GDCP did not significantly affect on the hydrodynamic volume of the grafted agent. The increase of

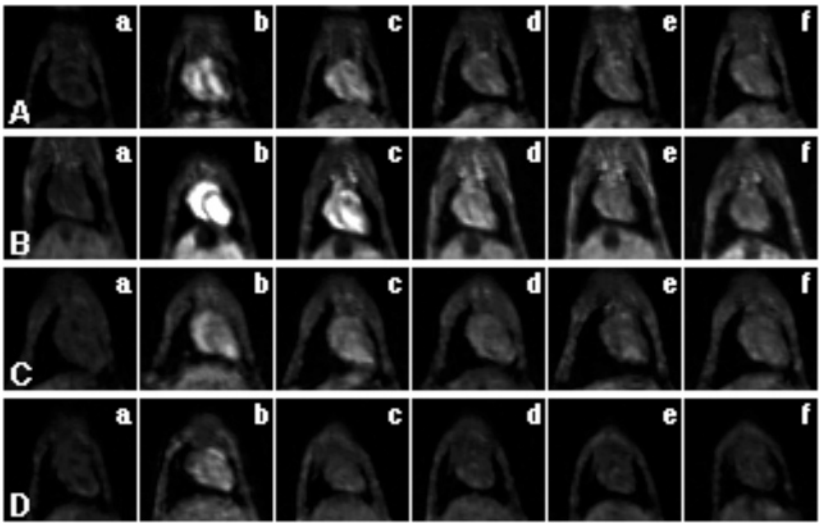

Figure 2. Coronal MR images of mouse heart preinjection (a) and 1 (b), 5 (c), 15 (d), 30 (e), and 60 min (f) postintravenous injection of PEG_a-GDCP (A), PEG_b-GDCP (B), GDCP (C), and Gd(DTPA-BMA) (D). Polymeric agents were given at a dose of 0.03 mmol-Gd/kg, and Gd(DTPA-BMA) was given at the standard clinical dose of 0.1 mmol/kg.

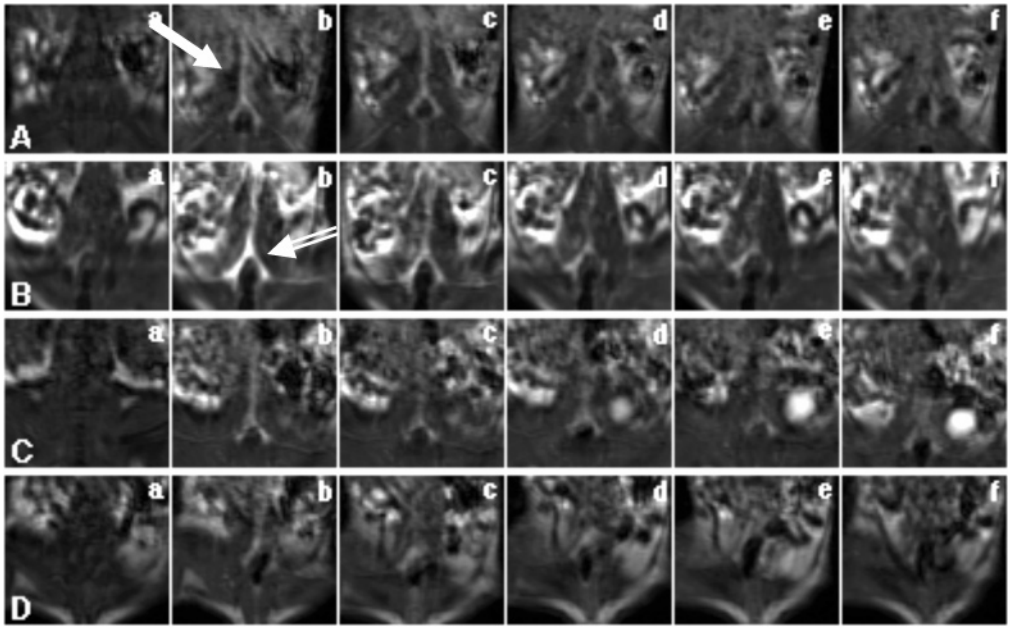

Figure 3. Coronal MR images of descending aorta (solid arrow) and common iliac arteries (hollow arrow) of the mouse preinjection (a) and 1 (b), 5 (c), 15 (d), 30 (e), and 60 min (f) postintravenous injection of PEG_a-GDCP (A), PEG_b-GDCP (B), GDCP (C), and Gd(DTPA-BMA) (D). Polymeric agents were given at a dose of 0.03 mmol-Gd/kg, and Gd(DTPA-BMA) was given at the standard clinical dose of 0.1 mmol/kg.

hydrodynamic volume of PEG_b-GDCP with a high PEG to Gd ratio (approximately 0.76:1) was less appreciable than that of PEG_a-GDCP with a low ratio (approximately 0.33:1). Although this seems counterintuitive because of PEG's large hydrodynamic radius, it is plausible that when more PEG is added, the density of PEG molecules on the polymer chain with a fixed length increases and it does not extend the length of the copolymers. The higher PEG density along the polymer chain may increase intermolecular interaction between the PEG chains and, probably, diminish their contribution to the hydrodynamic volume of the macromolecules.

The graft of PEG also increased the relaxivity of GDCP, most likely due to steric limitation on the rotational movement of the polymer increasing the rotational correlation coefficient and in turn the relaxivity (*20*). However, a further increase of PEG in PEG_b-GDCP resulted in decreased relaxivity. These results are consistent with the literature. Raymond et al. suggested that this is due to the possible association of water to PEG (*21*). As more PEG is added, more water is associated to PEG via hydrogen bonding, effectively reducing the local concentration of water proximal to the Gd^{3+} ions. This causes a probable decrease in the water−ion exchange rate, which increases the residence time of the coordinated water, τ_M, resulting in a decreased relaxivity, as shown in the following equation:

$$R_{1p}^{is} = \frac{c \times q}{55.6} \times \frac{1}{T_{1M}^{H} + \tau_M}$$

where R_{1p}^{is} is the inner coordination sphere relaxation of bulk water surrounding the paramagnetic ion, c is the concentration of the ion, q is the number of coordinated water molecules to the metal ion, and T_{1M}^{H} is the longitudinal relaxation time of the coordinated water (*22*).

In addition to increased relaxivity, the other advantage of PEGylation is the reduced tissue uptake of the macromolecular agents by the reticuloendothelial system (RES) and nonspecific binding. PEG is commonly used in the modification of biological and physiochemical properties of biological systems to minimize bioadhesion and immunological response (*23*). The incorporation of PEG in drug delivery systems significantly reduces the liver uptake of the systems and prolongs their circulation half-life. Kobayashi and co-workers have also reported that when the PEG content is increased on dendrimeric contrast agents, less contrast agent accumulates in the liver, spleen and kidneys leaving a larger percent in the blood pool, accounting for the increased signal intensity (*17*).

The PEGylation of polydisulfide-based biodegradable macromolecular Gd complexes, GDCP, resulted in high relaxivity and relatively large size of the modified agent and improved blood pool contrast enhancement in mice at a relatively low dose. The size of GDCP was relatively small due to the limitation of the current synthetic method. The blood pool contrast enhancement with the PEGylated agent may be further improved if GDCP with a larger size is used. Detailed investigations on the novel biodegradable macromolecular agents with different sizes are ongoing. The studies are focusing on the size impact of the PEGylated biodegradable macromolecular agent with respect to its physicochemical properties and in vivo contrast enhancement, pharmacokinetics, clearance, and long-term tissue Gd(III) accumulation.

CONCLUSION

Biodegradable PEGylated macromolecular Gd(III) complexes, PEG-*g*-poly(GdDTPA-*co*-L-cystine), were prepared and tested as a blood pool contrast agent in mice. The PEGylated macromolecular contrast agent demonstrated superior contrast enhancement in the heart and blood vessels as compared to the low molecular weight agent, Gd-(DTPA-BMA). An in vitro study demonstrated the time-dependent and complete degradation of PEG-*g*-poly(GdDTPA-*co*-L-cystine). MALDI-TOF mass spectrometry confirmed the degradation products. PEG-*g*-poly(GdDTPA-*co*-L-cystine) shows promise as a blood pool MRI contrast agent because of its increased signal intensity and retention time as well as its controllable degradation characteristics.

ACKNOWLEDGMENT

This research is supported in part by NIH grant EB00489. We thank Dr. Matthias Schabel for technical assistant in T_1 measurement and MR image acquisition. Mass spectral data were acquired at the University of Utah Mass Spectrometry Facility.

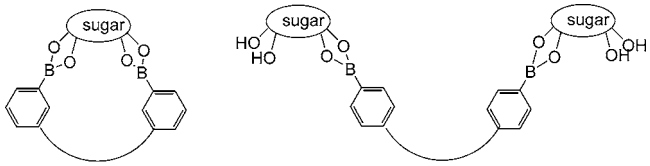
Cyclen-Based Phenylboronate Ligands and Their Eu^{3+} Complexes for Sensing Glucose by MRI

Robert Trokowski,[†] Shanrong Zhang,[§] and A. Dean Sherry[†,§,*]



Department of Chemistry, The University of Texas at Dallas, P.O. Box 830688, Richardson, Texas 75083-0688, and The Rogers Magnetic Resonance Center, Department of Radiology, University of Texas Southwestern Medical Center, 5323 Harry Hines Boulevard, Dallas, Texas 75390-9085. Received April 25, 2004; Revised Manuscript Received August 4, 2004

Novel cyclen-based phenylboronate ligands and their corresponding Eu^{3+} complexes have been examined as glucose sensors using chemical exchange saturation transfer (CEST) MR imaging for detection. Two isomeric bis-phenylboronate complexes, Eu(**4**) and Eu(**10**), and a mono-phenylboronate complex, Eu(**12**), had been prepared and characterized by UV and circular dichroism spectroscopy, mass spectrometry, and CEST imaging. Both the free ligands and their Eu^{3+} complexes bind to simple sugars, but their selectivity and binding affinities vary with sugar structure. Interestingly, the free ligands, **4** and **10**, are selective for fructose over glucose, but this selectivity order switches in the respective Eu^{3+} complexes. Of the complexes examined, Eu(**4**) shows the highest selectivity and binding affinity for glucose ($2275 \pm 266\ M^{-1}$ at pH 10.2 and $339 \pm 29\ M^{-1}$ at pH 7). Glucose acts as a "capping" moiety in the Eu(**4**)·glucose binary complex and modulates water exchange between a single Eu^{3+}-bound water molecule and bulk water, an effect that can be detected by CEST imaging. Thus, Eu(**4**) represents a new class of metabolite-specific imaging agents that may allow mapping of metabolites by MRI of the bulk water signal.

INTRODUCTION

Sugars play important roles in energy production and storage in living organisms so methods to access their concentration and distribution in vivo are becoming increasingly important. A variety of techniques have been reported for quantification of glucose, the most abundant sugar in mammalian cells, but few provide information about its distribution in tissues (*1*). Among the detection methods, the most common are based on the enzymatic detection by glucose oxidase (*2*) or chemical sensors based on complexation of *cis*-hydroxy groups of sugars by phenylboronic acids. Such binding interactions have been detected by using a variety of spectroscopic techniques, including UV, fluorescence, or circular dichroism (CD) or electrochemical methods (*3*−*7*). Unfortunately, most of these methods cannot be applied to detect sugars in vivo (*8*). Magnetic resonance imaging (MRI) or spectroscopy (MRS) techniques have been used to obtain maps of common metabolites such as lactate, creatine, and *N*-acetylaspartate by ^{1}H detection and high energy metabolites by ^{31}P detection (*9*). Free glucose has been measured in brain by ^{1}H NMR (*10*, *11*) and by ^{13}C NMR (*12*) although ^{1}H detection is complicated by the numerous overlapping resonances in the 2−4 ppm range from other endogenous molecules. Recently, a ^{13}C-edited ^{1}H T-SEDOR technique had been used to image glucose in brain of living mice (*13*) but this requires double resonance techniques not commonly available on clinical MR scanners and the infusion of a high cost tracer (^{13}C-enriched glucose). Thus, a simple method for mapping this common metabolite in vivo, especially from tissues deep within the body, remains an important goal.

Scheme 1

a **b**

It is known that simple phenylboronic acids form reversible, cyclic ester bonds with *cis*-diols in a variety of sugars (*14*) and that the binding constants for these 1:1 complexes is highly dependent upon the orientation of the *cis*-diol groups in the sugar, typically decreasing in the order of D-fructose ≫ D-galactose > D-mannose > D-glucose (*15*, *16*). Sensors having two phenylboronic acid functionalities in juxtaposition form intramolecular 1:1 complexes with both "ends" of a sugar molecule (Scheme 1a) and often show a different stability order related to the specific spatial position of two boronic acid groups. In such complexes, a sugar can be selectively captured by appropriate positioning two phenylboronic acids in the same sensor molecule. The goal of this work was to create a sensor for glucose that might be used to image this important metabolite in tissues by magnetic resonance imaging (MRI). On the basis of prior experience with paramagnetic chemical exchange saturation transfer (PARACEST) agents (*17*), we anticipated that lanthanide complexes derived from tetraaza-tetraamide ligands with two appended phenylboronic acid groups might capture a glucose by forming a "bridge" above a single Ln^{3+}-bound water molecule and, in doing so, the encapsulated glucose might slow the rate at which the Ln^{3+}-bound water molecule exchanges with bulk water. In prototype experiments reported elsewhere (*18*), we demonstrated that upon binding of glucose to Eu(**4**) (see structure of ligand

4 in Scheme 2), water exchange is indeed about 2-fold slower and this was sufficient to image glucose in vitro by MRI. Here, we describe details of the synthesis and characterization of two isomeric bis-phenylboronate sensors, Eu(**4**) and Eu(**10**), and a mono-phenylboronate sensor, Eu(**12**). The binding constants between various sugars and these sensors were determined by UV and CD spectroscopy, and their potential as PARACEST imaging agents were compared.

EXPERIMENTAL PROCEDURES

Instrumental Methods. Column chromatography was performed using Mallinckrodt Silicar silica gel-150 (60−200 mesh). Hydrogenations were performed on a Parr hydrogenation apparatus. ECI and MALDI TOF mass spectral analyses were obtained from HT Laboratories in San Diego. FAB mass spectral analyses were obtained from University of Kansas Mass Spectrometry Lab. CD spectra were recorded on AVIV Circular Dichroism Spectrometer Model 202. NMR spectra were recorded on JEOL Eclipse 270 MHz. UV−vis spectra were recorded on Hewlett-Packard 8453 UV−vis spectrophotometer. MRI images were recorded on a 4.7T Varian imager. A 2.5 cm surface coil was used to excite and to receive the magnetic resonance signal. A spin−echo pulse sequence was modified by adding a frequency-selective a presaturation pulse before the imaging pulses. Typically, a presaturation period of 1 s was used. The saturation power was set to 36 db (corresponding to B_1 field of 1020 Hz). The saturation frequency was set to 50 ppm (on the Eu^{3+}-bound water resonance), 30 ppm (between the Eu^{3+}-bound water and the bulk water), and −50 ppm (opposite to the Eu^{3+}-bound water), respectively. The CEST images were obtained by pixel by pixel subtraction the image at 50 ppm from that at 30 ppm, respectively. All other imaging parameters were presented in the corresponding figure captions.

Data Analysis. Data fitting was performed by using the commercial software, PSI-PLOT version 7.5, Poly Software International, Inc.. Binding constants were obtained by nonlinear fitting the experimental data to a 1:1 binding model (*28*).

$$A_{exp} = \frac{A_0 + A_{lim}K_a[\text{sugar}]}{1 + K_a[\text{sugar}]} \quad (1)$$

where K_a is the binding constant, A_0, A_{lim}, and A_{exp} are the initial, equilibrium, and experimental values, either the relative UV, CD signal intensities, or MRI CEST ratios.

Reagents. 1,4,7,10-Tetraazacyclododecane was purchased from Strem Chemicals, Inc. (Newburyport, MA); phenylboronic acid and 10% Pd/C were purchased from Aldrich Chemical Co. (Milwaukee, WI). All other reagents used were of analytical grade.

Syntheses. 3-Nitrophenylboronic acid and 3-aminophenylboronic acid was prepared as described by Seaman and Johnson (*26*) and Groziak et al. (*49*), respectively. 2-Bromo-*N*-methylacetamide was prepared by the method of Valtancoli et al. (*50*) and 1,7-bis(benzyloxycarbonyl)-1,4,7,10-tetraazacyclododecane was prepared by methods described by Kovacs and Sherry (*21*, *22*).

3-Bromoacetylaminophenylboronic Acid. To a mixture of 3-aminophenylboronic acid (1.77 g; 12.19 mmol) and sodium carbonate (2.74 g; 24.38 mmol) in THF (85 mL) cooled in an ice bath was added bromoacetyl bromide (3.4 mL; 36.57 mmol). The mixture was stirred at 0 °C for 30 min and at 25 °C for 1 h. The solution was filtered and the filtrate was evaporated under vacuum. Water (10 mL) was added to the residue, and the solid was filtered, washed with water (10 mL), and dried to yield 2.63 g (79%) of white solid. ^{1}H NMR (CD_3OD); δ (ppm): 3.95 (s; 1H); 7,29 (t; 1H; J = 7.9); 7,47 (b.s; 1H); 7.62 (d; 1H; J = 7.9); 7,80 (s; 1H); ^{13}C NMR (CD_3OD); δ (ppm): 28.46; 121.95; 125.39; 127.85; 129.89; 137.29; 166.36; ECI mass spectrum: 719 ($M - H^+$; anhydrous trimer).

1,7-Bis(benzyloxycarbonyl)-4,10-bis(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (2). To a solution of 1,7-bis(benzyloxycarbonyl)-1,4,7,10-tetraazacyclododecane (2,0 g; 4,54 mmol) and 2-bromo-*N*-methylacetamide (1,8 g; 11,48 mmol) in acetonitrile (70 mL) was added sodium carbonate (0.96; 9.05 mmol). The mixture was refluxed for 18 h. The remaining solids were removed by filtration, and filtrate was rotary evaporated in a vacuum. The residue was loaded on silica gel column (250 g), and the product was eluted with chloroform: methanol (5:0,2). The fractions containing the product were combined, and the solvent was removed in a vacuum to give 2.24 g (84%) of colorless oil. ^{1}H NMR ($CDCl_3$); δ (ppm): 2.58−2.85 (m; 14H); 3.12 (br.s; 4H); 3.39 (br.s; 8H); 5.07 (s; 4H); 7.29−7.31 (m; 10H); ^{13}C NMR ($CDCl_3$); δ (ppm): 25.58; 48.9; 55.4; 67.56; 128.32; 128.46; 128.73; 136.48; 157.05; 171.5.

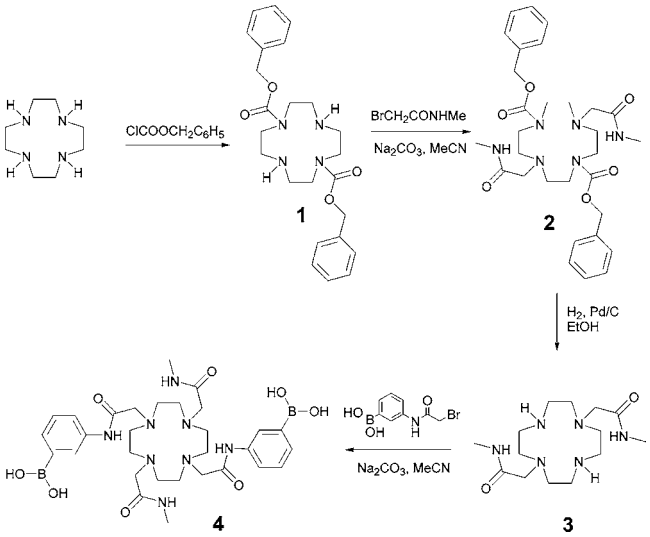
1,7-Bis(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (3). A mixture of 1,7-bis(benzyloxycarbonyl)-4,10-bis(methyl(carbamoylmethyl))-1,4,7,-10-tetraazacyclododecane (2.24 g; 3.85 mmol) and 10% Pd/C (0.51 g) in absolute ethanol (60 mL) was shaken under 45 psi of H_2 for 3 days. The catalyst was removed by filtration, and the filtrate was rotary evaporated to dryness in a vacuum to give 1.18 g (98%) of white solid. ^{1}H NMR (CD_3OD); δ (ppm): 2.79 (s; 6H); 2.84−2.89 (m; 8H); 2.97−3.03 (m; 8H); 3.35 (s; 4H); ^{13}C NMR (CD_3OD); δ (ppm): 25.19; 44.10; 51.10; 57.35; 172.74.

1,7-Bis((*m*-dihydroxyborylphenyl)carbamoylmethyl)-4,10-bis(methyl(carbamoylmethyl))-1,4,7,-10-tetraazacyclododecane (4). To a solution of 1,4-bis-(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (1.18 g; 3.77 mmol) and 3-bromoacetylaminophenylboronic acid (2.04 g; 7.99 mmol) in methanol:acetonitrile (25:25 mL) was added sodium carbonate (0.80 g; 7.54 mmol). The mixture was refluxed overnight. The solvent was removed by rotary evaporation in a vacuum, and the remaining residue was dissolved in 0.5 M HCl (60 mL) and subsequently extracted with ethyl acetate (3 × 50 mL). The aqueous layer was neutralized with 2 M NaOH to pH 7, and the solid that precipitated at this point was filtered and dried to yield 2.01 g (80%) of a white solid. ^{1}H NMR (CD_3OD); δ (ppm): 2.25−2.45 (m; 14H); 2.66 (br.s; 8H); 3.05 (br.s; 4H); 3.27 (br.s; 4H); 7.22 (t; 1H; J = 8.1 Hz); 7.42 (br.s; 1H); 7.69 (d; 1H; J = 8.1 Hz); 7.79 (br.s; 1H); ^{13}C NMR (CD_3OD); δ (ppm): 25.10; 50.68; 56.55; 57.59; 125.35; 127.77; 129.49; 137.79; 170.98; 173.05; Fab mass spectrum: 781.4 ($M + H^+$; glycerol complex).

11,12-dioxo-1,4,7,10-tetraazabicyclo[8.2.2]-tetradecane (5); **4,7-bisbenzyl-1,4,7,10-tetraaza bicycle[8.2.2]-tetradecane-11,12-dione (6)** and **1,4-dibenzyl-1,4,7,10-tetraazacyclododecane (7)** were prepared according to the method of Handel at al. (*23*).

1,4-Bisbenzyl-7,10-bis(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (8). To a solution of 1,4-dibenzyl-1,4,7,10-tetraazacyclododecane (3.5 g; 9.94 mmol) and 2-bromo-*N*-methylacetamide (3.5 g; 23.02 mmol) in acetonitrile (300 mL) was added sodium carbonate (2.1 g; 19.81 mmol). The mixture was refluxed overnight. The remaining solid was filtered and the

solvent removed by rotary evaporation in a vacuum. The residue was dissolved into chloroform, loaded onto silica gel column (270 g), and eluted with chloroform:methanol (5:0.4). The fractions containing the product were combined, and the solvent was removed in a vacuum to give 4.06 g (83%) of a colorless oil. ^{1}H NMR ($CDCl_3$); δ (ppm): 2.54 (br.s; 8H); 2.71−2.79 (m; 14H); 3.1 (s; 4H); 3.55 (s; 4H); 7.12−7.33 (m; 10H); ^{13}C NMR ($CDCl_3$); δ (ppm): 26.09; 51.73; 53.41; 53.55; 54.53; 58.98; 59.90; 127.32; 128.35; 129.27; 137.7; 172.11.



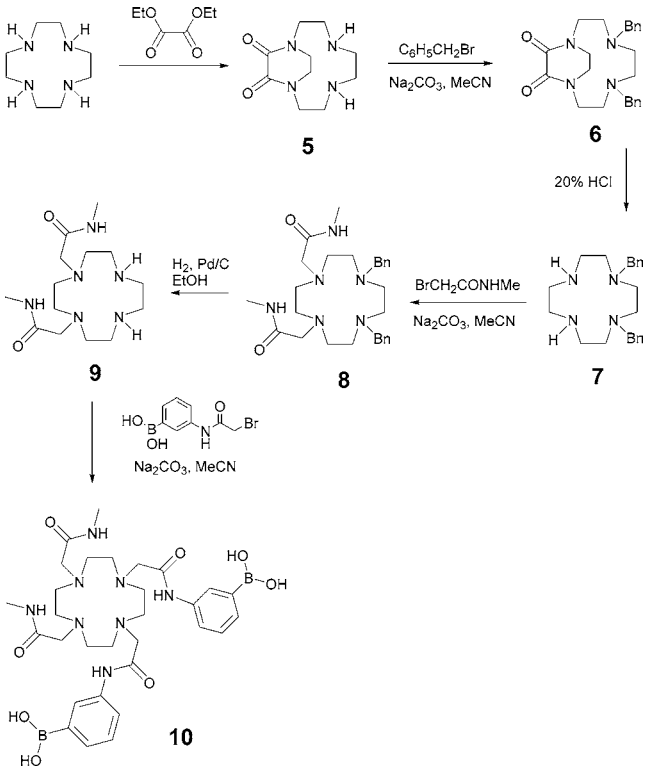
1,4-Bis(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (9). A mixture of 1,4-bis-benzyl-7,10-bis(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (2.55 g; 5.16 mmol) and 10% Pd/C (0.7 g) in absolute ethanol (60 mL) was shaken under 45 psi of H_2 for 3 days. The catalyst was removed by filtration and the solvent removed by rotary evaporation in a vacuum to give 1.5 g (92.5%) of a yellow oil. ^{1}H NMR ($CDCl_3$); δ (ppm): 2.51−2.57 (m; 8H); 2.63−2.72 (m; 10H); 2.81 (s; 4H); 3.06 (s; 4H); ^{13}C NMR ($CDCl_3$); δ (ppm): 18.25; 25.84; 44.91; 46.32; 52.33; 53.92; 58.06; 58.51; 171.88.

1,4-Bis((*m*-dihydroxyborylphenyl)carbamoylmethyl)-7,10-bis(methylcarbamoylmethyl)-1,4, 7,10-tetraazacyclododecane (10). To a solution of 1,4-bis-(methyl(carbamoylmethyl))-1,4,7,10-tetraazacyclododecane (0.95 g; 3.02 mmol) and (*m*-dihydroxyborylphenyl) bromo acetylamide (1.7 g; 6.6 mmol) in methanol:acetonitrile (25:25 mL) was added sodium carbonate (0.64 g; 6.04 mmol). The mixture was refluxed overnight. The solvent was removed by rotary evaporation in a vacuum, and the residue was dissolved in 0.5 M HCl (50 mL) and extracted with ethyl acetate (3 × 50 mL). The aqueous layer was neutralized with 2 M NaOH to pH 7, and the precipitate that formed was filtered and dried to yield 1.27 g (64%) of a white solid. ^{1}H NMR (CD_3OD); δ (ppm): 2.20−2.65 (m; 14H); 2.70−2.85 (m; 8H); 3.1 (br.s; 4H); 3.25 (br.s; 4H); 7.08 (d; 1H; J = 8 Hz); 7.27 (br.s; 1H); 7.56 (t; 2H; J = 8 Hz); ^{13}C NMR (CD_3OD); δ (ppm): 24.96; 50.47; 56.57; 57.22; 124.93; 127.56; 129.14; 137.64; 170.58; 172.75. Fab mass spectrum: 781.3 ($M + H^+$; glycerol complex).

1-(*m*-Dihydroxyborylphenyl)carbamoylmethyl)-1,4,7,10-tetraazacyclododecane (11). 3-Bromoacetylaminophenylboronic acid (1.0 g; 3.87 mmol) in methanol (150 mL) was added dropwise to a solution of 1,4,7,10-tetraazacyclododecane (4.8 g; 27.86 mmol) in acetonitrile (350 mL) over 2 days at room temperature. The reaction mixture was stirred for an additional day at room temperature. The solvent was removed by rotary evaporation in a vacuum. Acetonitrile as added to the remaining residue and the precipitate that formed was filtered, washed twice with acetonitrile, and dried to yield 1.0 g (60%) of a hydrobromide salt. ^{1}H NMR (CD_3OD); δ (ppm): 2.76−2.99 (m; 16H); 3.43 (s; 2H); 7.15 (t; ^{1}H; J = 7.4 Hz); 7.31 (d; ^{1}H; J = 7.4 Hz); 7.41 (s; ^{1}H); 7.61 (d; ^{1}H; J = 7.4 Hz). ^{13}C NMR (CD_3OD); δ (ppm): 44.15; 44.36; 45.29; 51.85; 57.88; 118.19; 124.82; 126.75; 129.38; 136.48; 170.87.

1-((*m*-Dihydroxyborylphenyl)carbamoylmethyl)-4,7,10-tris(methylcarbamoylmethyl)-1,4,7,10-tetraazacyclododecane (12). To a solution of 1-(*m*-dihydroxyborylphenyl)carbamoyl methyl)-1,4,7,10-tetraazacyclododecane (1.0 g; 2.32 mmol) and 2-bromo-*N*-methylacetamide (2.12 g; 13.95 mmol) in methanol:acetonitrile (25:25 mL) was added sodium carbonate (1.48 g; 13.95 mmol). The mixture was refluxed 2 days. The remaining solids were removed by filtration, and solvent was removed by rotary evaporation in a vacuum. The resulting residue was extracted first with chloroform:methanol

Scheme 2



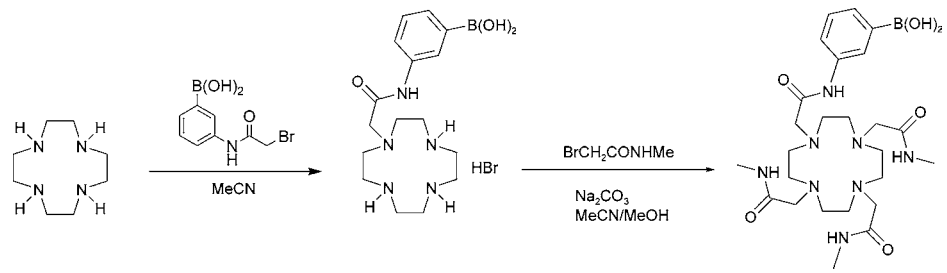
(50:0.5) and then by acetonitrile and finally removed by filtration, washed with cold water, washed twice with acetonitile, and dried to yield 0.9 g (69%) of a white solid. ^{1}H NMR (CD_3OD); δ (ppm): 2.31−2.49 (m; 4H); 2.68−2.81 (m; 15H); 3.05−3.14 (m; 6H); 3.35 (s; 8H); 7.11 (t; 1H; 7.7 Hz); 7.22−7.36 (m; 2H); 7.69 (d; 1H; 7.7 Hz). ^{13}C NMR (CD_3OD); δ (ppm): 25.04; 50.54; 56.66; 56.89; 57.53; 117.78; 124.52; 126.42; 129.33; 136.57; 170.29; 172.66; 172.74. Fab mass spectrum: 619.3 ($M + H^+$; glycerol complex).

Eu(4), Eu(10), and Eu(12) Preparation. Typically, ligand (10% excess) was added to an aqueous solution of $EuCl_3$ (0.2 M), and the resulting solution was stirred at room-temperature overnight to ensure full complexation. If necessary, a small amount of concentrated NaOH was added to maintain the pH near 7 until free Eu^{3+} could no longer be detected using xylenol orange as colorimetric indicator (in 1 M NaAc/HAc buffer solution at pH 5.3). Excess free ligand was filtrated, and the residue was freeze-dried.

RESULTS

Synthesis and Characterization of Phenylboronic Acid-Appended Macrocycles. Lanthanide cyclen complexes with amide pendant arms exhibit high kinetic inertness even in very acidic condition (*19*) and consequently have been found to have very important application as MRI contrast agents via a novel route based on chemical exchange saturation transfer (CEST) mechanism (*20*). We therefore focused on preparing new ligands based on tetramide derivatives of cyclen with phenylboronic acids groups as pendant arms. For bis-substitutions, two possibilities exist: one where the phenylboronic acids are trans to one another across the cyclen ring (ligand **4**) and another where they are cis to one another (ligand **10**). 1,7-Substituted cyclen was achieved by following a procedure reported by Kovacs and Sherry (*21*, *22*) through protection of *trans*-amines in cyclen by using benzyl chloroformate (Scheme 2). Treatment of **1** with 2-bromo-*N*-methylacetamide and sodium carbonate in MeCN followed by hydrogenolysis afforded **3** with methyl amide arms selectively substituted at positions 1 and 7. In the final step, reaction of **3** with 3-bromoacetylaminophenylboronic acid in MeCN:MeOH/sodium carbonate afforded the target ligand **4**. As these phenylboronate products have low solubility in water at pH 7 in water, they were easily purified by precipitation. Solid **4** was isolated in 80% yield.

Scheme 3



Selective protection of adjacent nitrogens of the cyclen ring was achieved following the procedure reported by Handel and co-workers (*23*) through formation of the oxamide by condensation with diethyl oxalate. This was followed by alkylation with benzyl bromide and deprotection by selective hydrolysis of the bicyclic diamide to afford **7** (Scheme 3). Reaction of **7** with 2-bromo-*N*-methylacetamide in MeCN/sodium carbonate yielded **8** and hydrogenolysis afforded the 1,4 methyl diamide derivative **9** in 92% yield. The reaction of **9** with 3-bromoacetylaminophenylboronic acid in MeCN:MeOH/sodium carbonate followed by precipitation from water at pH 7 yielded the cis-ligand **10** in 64% yield.

Finally, selective monoalkylation of cyclen can be run using two main strategies, either direct alkylation of excess of cyclen with the appropriate alkyl halide (*24*) or selective N-functionalization followed by alkylation−deprotection steps (*25*). We found that the best experimental conditions to perform the monoalkylation of cyclen required the use of 7 equiv of cyclen in MeCN in room temperature. In this way, we could isolate compound **11** in satisfactory yield (60%) without using chromatography (Scheme 4). Once the monoalkylated product **11** was isolated, conversion to the corresponding *N*-monophenylboronate compound **12** was accomplished by reaction of **11** with 2-bromo-*N*-methylacetamide in MeCN:MeOH/sodium carbonate. **12** was isolated as a white solid from water at pH 7 in 69% yield. All compounds were characterized by ^{1}H and ^{13}C NMR and mass spectroscopy. Elemental analyses of these boron-containing products were unsuccessful due to formation of incombustible residues (*26*) and the possibility of existences of mixture of acids and anhydrides that are common moieties of boronic acids. Europium complexes were formed by reaction with $EuCl_3$ at pH 7 and room temperature. The complexes were conveniently purified by filtering off the excess ligand from water at pH 7.

pH Titrations. The UV absorption spectra of phenylboronic acids undergo characteristic changes along with the sample pH that reflect conversion of neutral $B(OH)_2$ to anionic $B(OH)_3^-$ species. Typical absorption spectra of Eu(**4**) at various pH values are shown in Figure 1. Even though Eu(**4**) has two boronic acids, the single isobestic point near 253 nm indicates that the two groups titrate independently and have identical pK_a values. For this reason, plots of A_{271} versus pH for Eu(**4**), Eu(**10**), and Eu(**12**) were fit to a single protonation step to give the pK_a values shown in Table 1. Upon addition of excess sugar (D-fructose in this case), there is a shift in apparent pK_a of these systems to lower values that reflects a decreased boron−oxygen bond angle in the $-B(OR)_2$-$(OH)^-$ species and an increase in acidity of the boron center. D-Fructose was chosen as the reference sugar in this experiment because it has been reported that this sugar provides the largest pK_a shift upon binding to boronic acids (*14*, *27*). The UV spectra of Eu(**4**), Eu(**10**), and Eu(**12**) collected as a function of pH in the presence of excess D-fructose shows that all three phenylboronate derivatives form complexes with sugar and experience a similar pK_a shift upon binding to D-fructose.

Sugar Titrations. Changes also occur in the UV spectrum of phenylboronic acid upon addition of sugars (at constant pH) and these may be monitored to determine a conditional binding constant characteristic of that pH value (*28*). Initial binding experiments for Eu(**4**), Eu(**10**), and Eu(**12**) were performed at pH 10.2 (well above the pK_a of the boronic acids in these systems) with the three most abundant monosaccharides in human plasma, D-glucose (∼5 mM), D-fructose (∼0.05 mM), and D-galactose (∼0.05 mM) (*29*). Although D-fructose is known to display the highest affinity among these monosaccharides for mono-phenylboronic acid derivatives, some bis-phenylboronic acid derivatives bind selectively with D-glucose, providing that the phenylboronic acid functionalities are appropriately positioned (*30*−*33*). Typical changes in absorbance of Eu(**4**) upon addition of D-fructose and D-glucose are shown in Figure 2. In most experiments with monosaccharides, a general increase in absorbance such as that shown here for D-fructose is observed but an opposite behavior was observed upon

Scheme 4

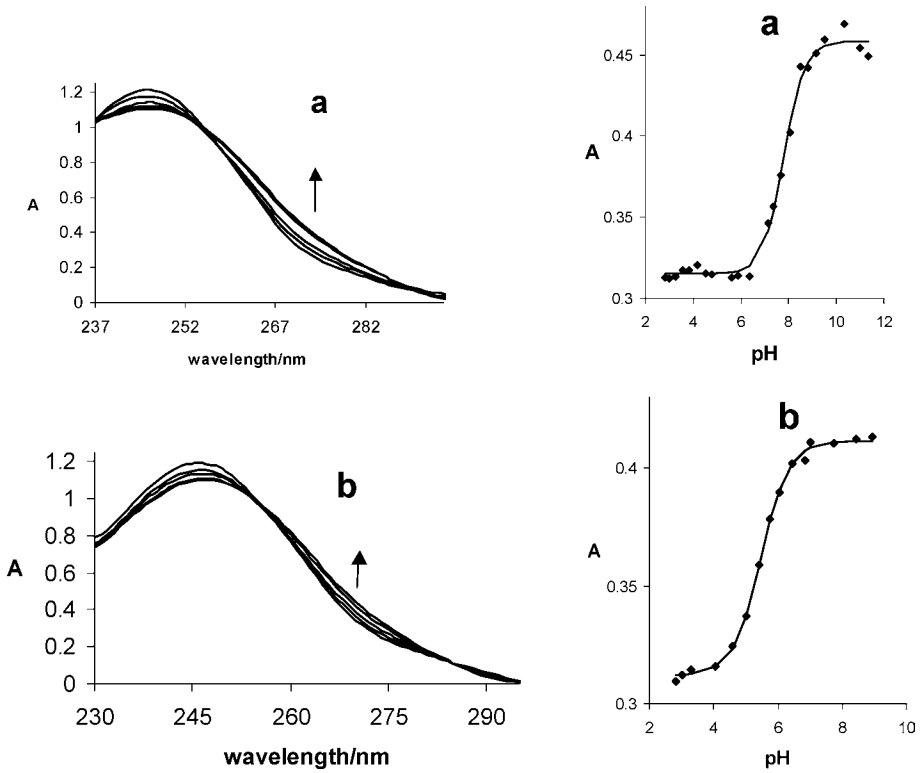


Figure 1. Absorption spectra of Eu(**4**) (5.64×10^{-5} M) as a function of pH. The changes in A_{271} are shown plotted as a function of pH in the absence (a) and presence (b) of 50 mM D-fructose.

Table 1. pK_a Values of Eu(4), Eu(10), and Eu(12) in the Absence and Presence of Excess D-Fructose As Measured by UV Spectroscopy

complex	pK_a (without D-fructose)	pK_a (with D-fructose)	ΔpK_a
Eu(**4**)	7.81	5.47	2.34
Eu(**10**)	8.03	5.71	2.32
Eu(**12**)	8.03	5.50	2.53

binding of D-glucose to Eu(**4**). Plots of these absorbance changes as a function of added sugar are shown in Figure 2. The solid lines represent the best fit of these data to 1:1 binding model for all systems. Fitting of the Eu(**4**) and Eu(**10**) data to a 1:2 binding model yielded rather poor agreement with the experimental values. Hence, a 1:1 binding model was assumed to hold for all combinations of Eu^{3+} complexes and sugars (more evidence is provided below for formation of 1:1 complexes). The resulting values are summarized in Table 2.

These data reveal a marked difference in stability between the three Eu^{3+} complexes and these sugars. The data for Eu(**12**) is typical of mono-phenylboronic acid−sugar interactions with the stability order of D-frucose > D-galactose > D-glucose (*15*, *16*). Eu(**10**) also displays the highest affinity for D-fructose but has an approximate 2-fold greater affinity for D-glucose than D-galactose. Eu(**4**), however, shows a completely different binding trend with these same sugars. This complex, the 1,7-*trans*-bis-phenylboronate, displays the highest affinity for D-glucose followed by D-fructose, D-galactose, and the other sugars. This indicates that the distance and positioning of the two phenylboronates in Eu(**4**) is most favorable for a bridging a single glucose molecule between the two complexing centers.

Binding of Eu^{3+} in the macrocyclic cavity of ligands such as these likely alters the geometry of the ligand side-chains and this in turn could have a profound effect upon the phenylboronate−sugar binding. To test this hypothesis, binding studies were also carried out between the free ligands and these same sugars (Table 3). It should be noted that free ligand **4** binds to D-fructose with such high affinity that it became difficult to arrive at a true equilibrium situation at the concentrations required for the spectroscopic measurement, i.e., essentially all of the fructose is bound at even the lowest ratio of D-fructose to ligand **4**. Hence, the K_a listed in Table 3 for this system (8325 ± 2192 M^{-1}) has a rather large error. Nonetheless, the experiment does prove that free ligand **4** does have the highest binding affinity for D-fructose among the sugars examined. Interestingly, in the absence of Eu^{3+}, **10** shows greater selectivity toward glucose than does **4**, a result just opposite from that seen with the corresponding Eu^{3+} complexes. The stability of the complex formed between **4** and glucose is ~8-fold lower than the stability of the complex formed between Eu(**4**) and glucose. This indicates that the selectivity of bis-phenylboronic acid derivatives for sugars is quite dependent on the distance separating the two phenylboronic acid moieties, consistent with other bis-phenylboronates (*29*, *34*, *35*). This also suggests that it may be possible to modulate the affinity of such cyclen-based systems for glucose by other factors that may influence the distance between the phenylboronates such as bulkiness of the other two amide side-chains or perhaps even the size of the lanthanide cation.

CD Spectroscopy. Sugar binding can also be conveniently monitored by changes in the chirality as detected by CD spectroscopy. Molecules containing bis-phenylboronic acid receptors typically become CD active when sugars form cyclic 1:1 complexes such as those illustrated by Scheme 1a while 1:2 complexes are less rigid (Scheme 1b) and are typically CD-silent (*36*−*39*). This makes CD spectroscopy a very convenient tool for differentiating between these two possible structural patterns. The CD spectra of Eu(**4**) and Eu(**10**) are silent in the absence of sugars but become active in the presence of all sugars examined here except D-fructose. The ketose, D-fructose, appears to be unique in this regard for reasons that are

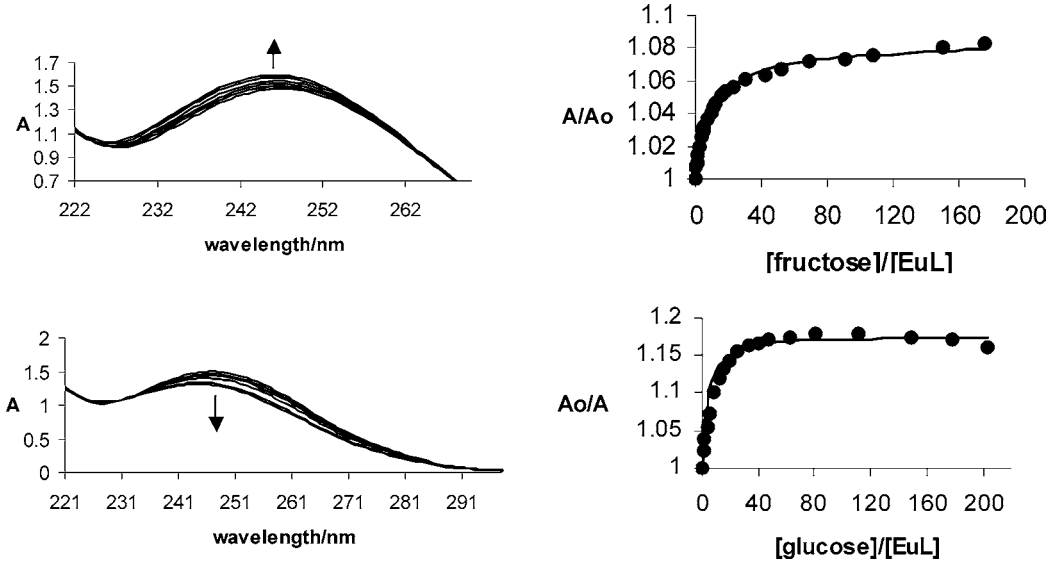

Figure 2. Absorption spectra of Eu(**4**) (7.52×10^{-5} M) as a function of added D-fructose (top row) or D-glucose (bottom row) at a constant pH = 10.2 (48 mM carbonate buffer). [D-fructose] was varied from 0; 1.8; 4.4; 11.3; 41.9; 108.3 mM while [D-glucose] was varied from 0; 0.9; 1.8; 5.6; 15.4; 24.9; 80.7 mM.

Table 2. Binding Constants (K_a, M^{-1}) for Formation of 1:1 Complexes between Eu(4), Eu(10), and Eu(12) and Various Saccharides at pH 10.2

saccharides	Eu(**4**)	Eu(**10**)	Eu(**12**)
glucose	2275 ± 266	319 ± 48	73 ± 13
galactose	198 ± 20	124 ± 15	118 ± 14
fructose	1259 ± 106	1503 ± 130	820 ± 124
lactose	110 ± 24	63 ± 9	159 ± 27

Table 3. Binding Constants (K_a, M^{-1}) between Free Ligands, 4 and 10, and Various Sugars at pH 10.2

saccharides	**4**	**10**
glucose	243 ± 32	1165 ± 106
galactose	671 ± 54	274 ± 54
fructose	8325 ± 2192	831 ± 208
lactose	137 ± 47	25 ± 54

not entirely clear. This same behavior has been observed for many other bis-phenylboronate systems that have been studied using CD spectroscopy (*3*, *16*, *40*, *41*). The CD spectra of Eu(**4**) and Eu(**10**) in the presence of excess D-glucose are shown in Figure 3. Clearly, both the *cis*-phenylboronate complex (Eu(**10**)) and the *trans*-phenylboronate complex (Eu(**4**)) form bridging 1:1 complexes with glucose but with opposite chirality. As a check, spectra of Eu(**4**) and Eu(**10**) with also run in the presence of excess L-glucose (data not shown) and the CD spectra of these were the mirror images of those shown in Figure 3. This lends support to the opposite chirality of Eu(**4**)·D-glucose and Eu(**10**)·D-glucose.

Binding constants between Eu(**4**) were also measured by CD spectroscopy at pH 10.2 (to compare with the UV results) and again at pH 7 (Figure 4). A fitting of the CD binding data at pH 10.2 gave a binding constant, K_a = 2280 M^{-1}, identical to the value determined in the UV titration. The titration performed at pH 7 gave a binding constant, K_a = 339 M^{-1}, again identical to the value determined previously in a CEST titration (383 M^{-1}) (*18*). This binding constant is in a reasonable range for using Eu(**4**) to detect physiological levels of glucose (~5 mM) by MRI.

Verification of Eu(4)·sugar stoichiometry by MALDI TOF Mass Spectrometry. To verify that glucose indeed binds to Eu(**4**) in a bridging manner as suggested by CD spectroscopy, mass spectroscopy was also performed on aqueous samples containing 10 mM Eu(**4**) plus either D-fructose or D-glucose at 1:1 and 1:2 ratios. For both glucose and fructose at pH 7, a mass peak at 1065 Da corresponding to a 1:1 complex was observed. For a sample recorded at pH 10 where the binding affinity is much higher, again a mass peak at 1066 Da dominated the spectrum. Only very small amounts of the 1:2, Eu(**4**)·$(sugar)_2$, complexes were detected at either pH value. This result verified the fits of the binding data and the CD active spectrum observed for Eu(**4**)·sugars described above.

MR Images of Phantoms Containing Eu(4) or Eu(12) Plus Simple Monosaccharides or Glycated HSA. To test whether these new sensors might be used to detect sugars by MRI based upon a CEST mechanism (*20*), phantoms consisting of four tubes (I.D. 4 mm) each containing 10 mM Eu(**4**) or Eu(**12**) and different amounts of monosaccharides were prepared in 100 mM PIPES

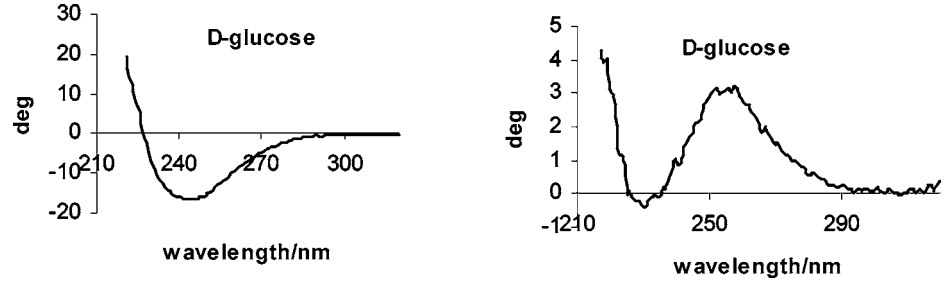

Figure 3. CD spectral changes of Eu(**4**) (left) and Eu(**10**) (right) in the presence of 50-fold excess D-glucose (24 mM carbonate buffer, pH 10.2; the concentrations of Eu(**10**) and Eu(**4**) were 7.52×10^{-5} M).

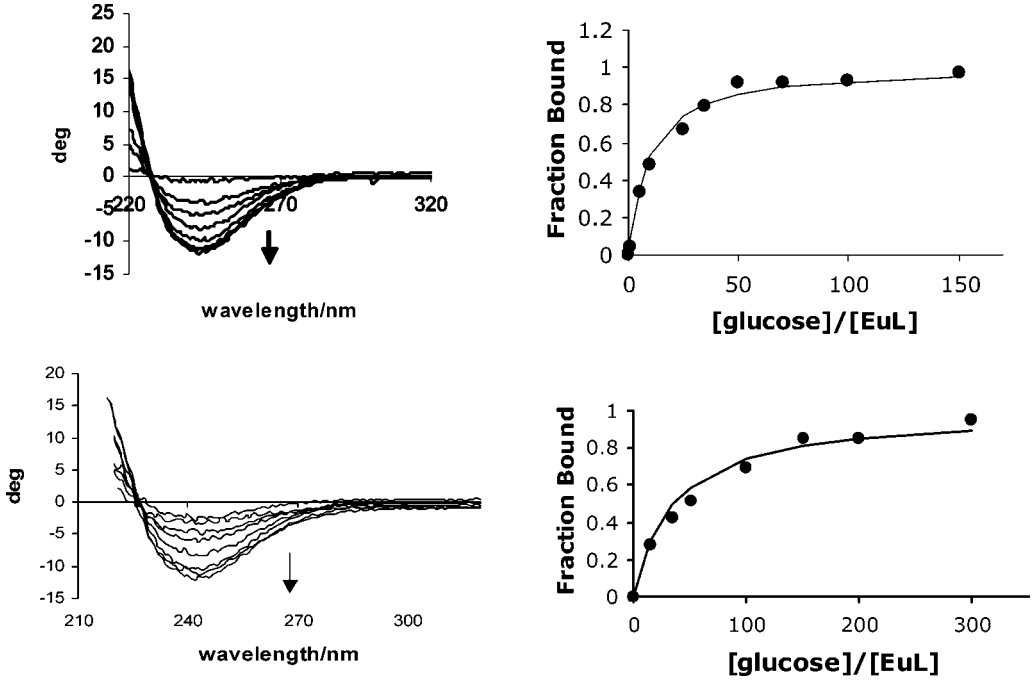

Figure 4. CD intensity changes of Eu(**4**) (5.26×10^{-5} M) in the presence of increasing concentrations of D-glucose. The top row is data collected at pH 10.2 (24 mM carbonate buffer) while the bottom row is data collected at pH 7.2 (24 mM phosphate buffer).

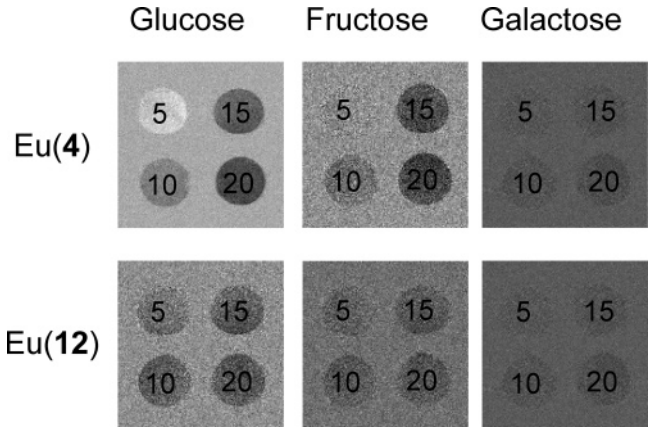

Figure 5. CEST images of phantoms containing 10 mM Eu(**4**) or Eu(**12**) and 0, 5, 10, and 20 mM sugar, respectively. PIPES (100 mM) was used to buffer the pH at 7.0. The image parameters were as follows: TR/TE = 3000/18 ms, FOV = 40 × 40 mm, coronal thickness 2 mm, data matrix 256 × 256, saturation duration time of 2 s at a power of 1020 Hz at a frequency offset of 50 and 30 ppm. The CEST images were obtained by pixel by pixel subtraction of the image at 50 ppm from that at 30 ppm, respectively.

buffer at pH 7.0. Eu(**4**) was selected because it has the highest binding ability to glucose, while Eu(**12**) was imaged simply for comparison. Images were acquired after alternatively applying identical presaturation pulses at 50 ppm (bound water) versus 30 ppm (between the bound and bulk water peaks) (*18*). Although the intensities of these individual images were visually similar, the difference images (referred to as a CEST image) show clear intensity gradations that parallel the sugar concentrations. Typical CEST images for Eu(**4**) or Eu(**12**) in the presence of different amounts of glucose, fructose, and galactose were shown in Figure 5. For example, using a gray scale of 0−255 (from the darkest to the brightest), the image intensities were 208, 148, 112, and 96 for samples containing 10 mM Eu(**4**) and either 0, 5, 10 and 20 mM glucose, respectively, while they were 134, 114, 110, and 106 for Eu(**12**) phantom. This demonstrates that Eu(**4**) may be used to quantitatively image glucose near physiological concentrations (∼5 mM). A comparison of the CEST images of Eu(**4**) in the presence of glucose or fructose suggests that fructose would likely interfere with detection of glucose if both sugars were presented at similar concentrations. This is consistent with the ∼2-fold lower binding constant for Eu(**4**) and fructose versus glucose (Table 2). However, the concentration of fructose in tissues is typically about 100-fold lower than glucose so one would anticipate that fructose would not interfere with quantitative imaging of glucose. Galactose binding is weak for both Eu^{3+} complexes, and the corresponding CEST images are little affected by this sugar.

CEST imaging experiments were also performed on samples containing glycated human serum albumin (HSA) to determine whether Eu(**4**) could be used as a sensor of sugars bound to proteins. Figure 6 shows images of phantoms containing 10 mM Eu(**4**) plus increasing amounts of glycated HSA (with an average of five hexose units per albumin). Assuming that Eu(**4**) binds to each of the five fructosamine moieties with equal binding affinity, a binding constant of 791 ± 301 M^{-1} was estimated from the limited CEST image intensity data of Figure 6. Although this binding constant has a rather large error, the value found is the same order of magnitude as the constants found for Eu(**4**) binding to simple sugars at this same pH. This indicates that amidation of fructose does not destroy recognition by Eu(**4**). However, the amounts of glycated proteins, such as albumin and hemoglobin, are proportional to the level of blood glucose with albumin glycated to an extent of about 10% at normal plasma levels (*42*). Thus, at a plasma concentration of 10% × 0.6 or ∼0.06 mM, the amount of glycated HSA present in plasma of a normal individual should not interfere with using Eu(**4**) as a sensor for glucose in tissue. On the other hand, this binding property could be useful as a rapid throughput analysis of the extent of glycation of HSA in vitro after separation of excess simple sugars. Glycation of proteins has been implicated in the development of diabetic complications and the aging process (*43*).

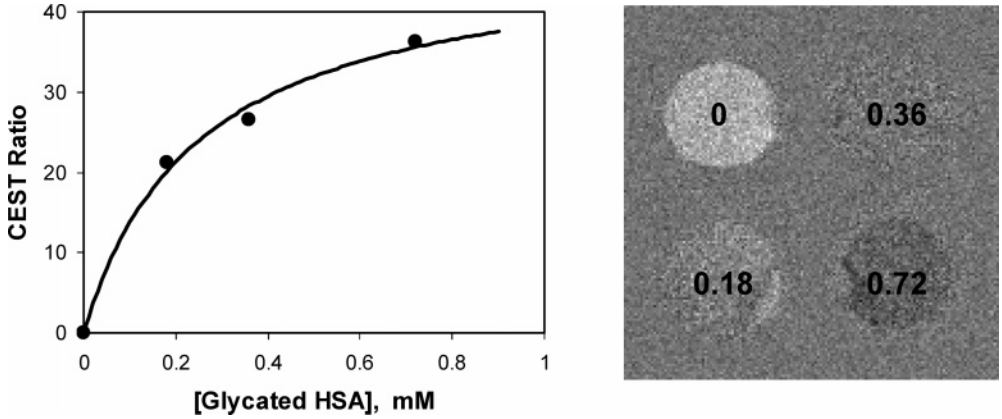

Figure 6. CEST images of phantoms containing 10 mM Eu(**4**) and 0, 0.18, 0.36, and 0.72 mM glycated HSA, respectively. PIPES (100 mM) was used to buffer the pH at 7.0. The image parameters are identical to those shown in Figure 5.

DISCUSSION

Three new cyclen-based tetraamide ligands containing either mono- and bis-phenylboronate extended arms were synthesized and their Eu^{3+} (europium) complexes characterized by UV, circular dichroism, mass spectrometry, and CEST imaging. The Eu^{3+} complexes of **4**, **10**, and **12** display quite different binding behavior with glucose, fructose, and galactose. The initial binding experiments were carried out at pH 10.2 (well above the physiological pH range) because it is well-known that phenylboronates have a much higher affinity for sugars at pH values above the pK_a of the boronic acid. Given that the affinity of many phenylboronates for sugars is too low to detect at pH values near 7, most binding studies are carried out first at pH values near 10 to ensure adequate binding. The design of bis-phenylboronic acid molecules as sensors specific for glucose assumes that bis-phenylboronic acids will be positioned at the proper distance and orientation to bind glucose with high affinity and selectivity. Although this has been demonstrated previously for several fluorescent molecules containing two phenylboronate groups (*29*, *44*−*46*), the degree of selectivity and binding affinity remains rather empirical. The goal of this project at the onset was to create a glucose sensor using MRI as the readout device. It has been shown recently that water exchange in cyclen-based Eu^{3+}-tetraamide complexes is quite sensitive to the identity of the appended amine side-chains (*17*, *47*) so it was reasonable to assume that one might be able to modulate water exchange in such systems by using glucose as a "capping" moiety over a Eu^{3+}-bound water molecule. Hence, the *trans*-1,7-bis-phenylboronate ligand (**4**) became the target ligand of choice while the *cis*-1,4-bis-phenylboronate ligand (**10**) was designed as a control. While simple mono-phenylboronic acids typically display a much higher affinity for fructose over glucose (for example, phenylboronic acid has a K_a of 162 M^{-1} for fructose and 5 M^{-1} for glucose (*48*)), bis-phenylboronic acids systems tend to become more selective for glucose. As anticipated, the mono-phenylboronic acid system, Eu(**12**) displayed an ∼11-fold selectivity for fructose over glucose and even had a greater affinity for galactose than glucose. Surprisingly, free ligand **4** also had an ∼34-fold binding selectivity for fructose over glucose and an unusually high affinity for fructose, comparable to some of the more favorable bis-phenylboronate systems that have been reported (*34*), while free ligand **10** slightly favored glucose in preference to fructose (more typical of over bis-phenylboronate systems). This indicates that the exact positioning of the two phenylboronate moieties not only determines sugar selectivity but also substantially impacts binding affinity. It is quite interesting and again surprising that formation of Eu^{3+} complexes with these same ligands has a much more dramatic impact in the case of Eu(**4**) than Eu(**10**). Now, Eu(**4**) favors glucose over fructose by ∼2-fold, a nearly 40-fold switch in binding selectivity upon going from free ligand **4** to Eu(**4**). This rather dramatic effect must be ascribed to a repositioning of the two phenylboronate side-chains upon entry of Eu^{3+} into the cyclen cavity and suggests that the ionic radius of the central metal ion might be used as an adjustable parameter for fine-tuning glucose selectivity and affinity. Conversely, a comparison of free ligand **10** with Eu(**10**) shows an opposite effect with free ligand **10** favoring glucose and Eu(**10**) favoring fructose. Here, the switch in binding affinity is less dramatic but nonetheless ∼7-fold. As predicted a priori, water exchange between the Eu^{3+}-bound water molecule in Eu(**4**) is indeed slower when glucose is bound, and this feature can be detected by CEST imaging (*18*). The images shown in Figure 5 indicate that water exchange is also slowed upon binding of fructose to Eu(**4**), but the effect is smaller in this system due to a combination of lower binding affinity and perhaps lower modulation of water exchange (the exchange rate has not been measured in this system). Addition of galactose to Eu(**4**) or addition of any monosaccharides to Eu(**10**) does not initiate a CEST effect. The later observation is not surprising since binding of sugars to the later *cis*-1,4-bis-phenylboronate complex would like not disturb the Eu^{3+}-bound water site.

Compared to other organic-based bis-phenylboronate glucose sensors, Eu(**4**) has a reasonably high binding affinity for glucose (2275 ± 266 M^{-1} at pH 10.2 and 339 ± 29 M^{-1} at pH 7) but only a modest selectivity for glucose over fructose. Sensor Eu(**4**) represents an improvement of about 455-fold in affinity and about 60-fold improvement in selectivity for glucose over fructose compared with simple phenylboronic acid. Although fructose and glycated HSA have similar binding affinities as glucose with Eu(**4**), it is unlikely that these sugars will interfere with imaging of glucose in tissues because the plasma concentrations of fructose and glycated HSA are much lower than that of glucose. Thus, Eu(**4**) is an important advance toward an optimal agent for imaging the tissue distribution of glucose by MRI.

Labeling biomolecules with $^{99m}Tc(CO)_3^+$ (^{99m}Tc tricarbonyl) is attracting increasing attention. Although histidine is often considered an ideal bifunctional chelator for ^{99m}Tc (or ^{188}Re) tricarbonyl, the family of dipicolylamine carboxylate chelators may be a useful alternative because of the expected ease of synthesis and because the structure provides a pendent carboxylate for potential conjugation to biomolecules. The dipicolylamine chelator *N*,*N*-bis(2-pyridylmethyl)-4-aminobutyric acid (BPABA) was synthesized using 4-aminobutyric acid in place of glycine or aminopropionic acid in the literature, to avoid possible involvement of the carboxylate in the complex formation process by forming five- or six-membered chelation rings. Using a commercial tricarbonyl kit (Mallinckrodt), the complex formation properties of both BPABA and commercial histidine with ^{99m}Tc tricarbonyl were investigated, and the in vitro complex stabilities in saline and in serum were compared. Stability in vivo was also examined following i.v. administration to normal mice. BPABA was synthesized simply and quantitatively by reacting picolyl chloride with aminobutyric acid in one step. On RP HPLC, the product eluted essentially in one peak and the structure was confirmed by ESI-MS. After labeling, both BPABA and histidine were shown by RP HPLC to form tricarbonyl complexes. In both cases, after incubation at 100 °C for 20 min, only one predominant peak of $^{99m}Tc(CO)_3^+$−histidine or $^{99m}Tc(CO)_3^+$−BPABA was apparent, and both complexes were stable at room temperature in saline for at least 24 h. After incubation for 24 h in 37 °C serum, by SE HPLC, 20% of the $^{99m}Tc(CO)_3^+$−histidine was bound to serum protein compared to less than 10% for $^{99m}Tc(CO)_3^+$−BPABA. A 5000 molar excess of histidine at 100 °C for 6 h was unable to dissociate $^{99m}Tc(CO)_3^+$−BPABA. By contrast, BPABA easily dissociated $^{99m}Tc(CO)_3^+$−histidine under the same conditions. Both complexes were stable in vivo in mice, and $^{99m}Tc(CO)_3^+$−BPABA showed rapid and specific hepatobiliary clearance while $^{99m}Tc(CO)_3^+$−histidine was cleared through the kidneys. In conclusion, BPABA was easily synthesized and was shown to possess properties comparable to histidine for labeling of biomolecules with ^{99m}Tc tricarbonyl. However, it was found that the chelator concentration required for quantitative ^{99m}Tc tricarbonyl labeling with both BPABA and histidine were 2 orders higher than that required with more conventional labeling using MAG_3. Finally, the complex $^{99m}Tc(CO)_3^+$−BPABA itself was found to clear exclusively via the hepatobiliary pathway and may have value as a potential hepatobiliary imaging agent.

INTRODUCTION

We have been investigating tumor imaging by pretargeting with antibodies conjugated with phosphodiamidate morpholino oligomers (MORFs) along with ^{99m}Tc-radiolabeled complementary MORFs as effector using MAG_3 as chelator (*1*−*4*). Our overall objective is to perform ^{188}Re radiotherapy using this MORF pretargeting approach. While MAG_3 performs well as a chelator for ^{99m}Tc, it falls short of ideal for the chelation of ^{188}Re. Preliminary studies showed that, when using MAG_3 as a chelator for ^{188}Re in the labeling of MORF, oxidization to $^{188}ReO_4^-$ during preparation was excessive (*5*). Since more suitable chelators for ^{188}Re are therefore still needed, the ^{188}Re-tricarbonyl core was investigated as an alternative labeling strategy because of the predicted kinetic inertness of these complexes (*6*−*8*). Initially, the ^{188}Re tricarbonyl labeling was achieved with Hynic-MORF (*9*). Evaluation showed improved stability of the label to oxidation but with kidney levels high enough to be problematic with ^{188}Re (or ^{99m}Tc). We suspected that the tricarbonyl complexes (*10, 11*) was binding to robust groups such as imidazole in kidney tissue proteins possibly through interaction of the open position of the tricarbonyl complex of the bidentate Hynic chelator.

Numerous ligands have now been recommended as chelators for labeling biomolecules with technetium or rhenium tricarbonyl cores, and it now seems clear that bidentate chelators are not ideal because of the remaining open position (*10, 11*). Of the tridentates considered, those containing the basic formula of [aromatic N-heterocycle]−[amine]−[carboxylate] have received the most attention (*8, 10*−*14*), although the tridentates [aromatic N-heterocycle]−[amine]−[thiol] (*15*) and [thioether]−[thioether]−[carboxylate] (*16*) have also been tested. Examples of rhenium tridentate tricarbonyl complexes are shown in Figure 1. Recently, when *N*,*N*-dipicolylglycine or *N*,*N*-di(imidazolylmethyl)glycine was allowed to react with $Re(CO)_3^+$, the complex with the two

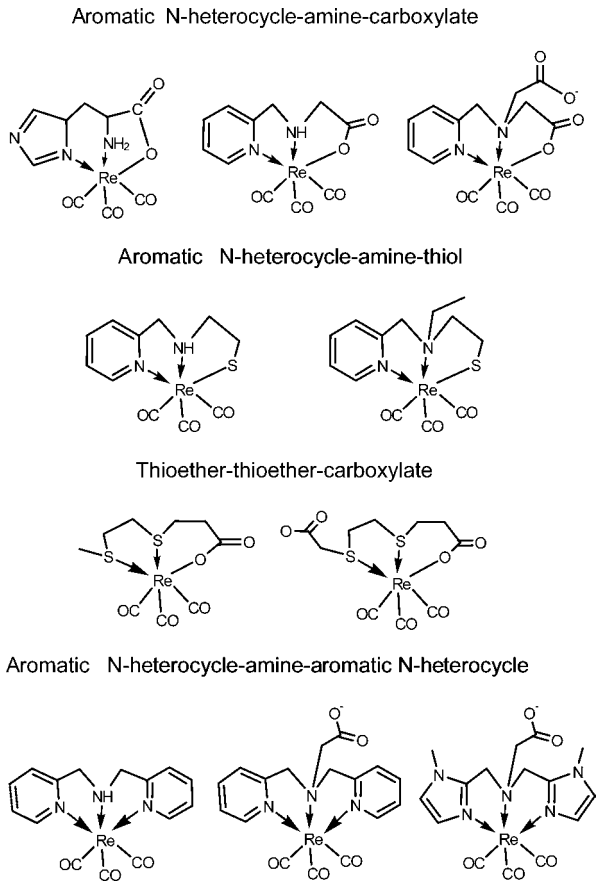

Figure 1. Examples of chemical structures between Re tricarbonyl and tridentates of different classes.

aromatic N-hetercyclic nitrogens and the amine in coordination was obtained leaving the carboxylate free (*17*). This suggested that tridentates with the formula of [aromatic N-heterocycle]−[amine]−[aromatic N-heterocycle] might be preferable for technetium or rhenium tricarbonyl labeling over [aromatic N-heterocycle]−[amine]−[carboxylate].

Lately we have become particularly interested in tridentates of *N*,*N*-dipicolyl-ω-amino acids. Besides providing the [aromatic N-heterocycle]−[amine]−[aromatic N-heterocycle] chelation site, these molecules have a pendent carboxylate group suitable for conjugation to the amines on biomolecules. They can be synthesized in one step simply by reacting picolyl chloride with the corresponding ω-amino acid (*17*).

We report herein on the labeling with $^{99m}Tc(CO)_3^+$ of a new dipicolylamino acid and the properties of the complex. While our ultimate goal is to develop a chelation strategy for $^{188}Re(CO)_3^+$, in this investigation $^{99m}Tc(CO)_3^+$ was used instead because of the ready availability of ^{99m}Tc and its tricarbonyl kit with a recognition of the structural similarities between rhenium and technetium.

MATERIALS AND METHODS

Bis(2-pyridylmethyl)-4-aminobutyric acid (BPABA), also called dipicolylaminobutyric acid, was synthesized in house while histidine was purchased from Aldrich (St. Louis, MO). The MS analysis was performed by the UMMS Proteomics and Mass Spectometry Facility. The Isolink kits for synthesizing $^{99m}Tc(CO)_3^+$ were gifts from Mallinckrodt Medical (St Louis, MO). Each lyophilized kit contained 8.5 mg of sodium tartrate, 2.85 mg of $Na_2B_4O_7{\cdot}10H_2O$, 7.15 mg of sodium carbonate, and 4.5 mg of sodium boranocarbonate. The $^{99m}TcO_4^-$ was eluted from a ^{99}Mo-^{99m}Tc generator (Bristol-Myers Squibb MedicalImaging, Inc., North Billerica, MA). All other chemicals were reagent grade and were used without purification.

Synthesis of Bis(2-pyridylmethyl)-4-aminobutyric Acid (BPABA). The reaction was achieved essentially according to a reported procedure (*17*) with a modification in separation method. The 2-chloromethylpyridine hydrochloride (33.7 g, 196 mmol) and 4-aminobutyric acid (8.3 g, 80 mmol) were dissolved in 100 mL of water, and the pH was adjusted to 10 and maintained in the range of 8−10 for 4 d by adding 5 M NaOH at intervals (total ~18 g, 450 mmol). The black reaction mixture was washed with $CHCl_3$ (70 mL × 4), followed by pH adjustment to 8 and concentration of the aqueous phase via evaporation. Toward the end of the evaporation, concentrated HCl was added to facilitate removal of as much NaCl as possible. The product was characterized by ESI-MS and HPLC.

HPLC Analysis. Reverse phase HPLC (RP HPLC) with an YMC-Pack C-18 column (system 1) was used for separation and analysis during synthesis of BPABA, while a Vydac C-18 column (system 2) was used for analysis during the ^{99m}Tc tricarbonyl labeling. Size exclusion HPLC (SE HPLC) was also used for in vitro and in vivo stability investigations of the ^{99m}Tc tricarbonyl complexes (system 3).

System 1: Semipreparative YMC-Pack C-18 column (250 × 10 mm, 5 μm, 323 Å); 10 mM HCl as solvent A and acetonitrile as solvent B; flow 2.0 mL/min. Gradient table: 0-15 min, 90% A; 15−20 min, 90−70% A; 20−23 min, 70−90% A, and 23−35 min, 90% A.

System 2: The Vydac C-18 column (5 μm, 250 × 4.6 mm); 0.05 M TEAP (triethylamine phosphate, pH 2.0) as solvent A and methanol as solvent B; 1.0 mL/min. Gradient table: 1-3 min, 100% A; 3−6 min, 100%-75% A; 6−9 min, 75% −66% A; 9−20 min, 66%-0% A; 20−27 min, 0% A; 27−40 min, 0%-100% A; 40−50 min, 100% A.

System 3: The Superose-12 size-exclusion column; 0.10 M pH 7.2 phosphate buffer; isocratic flow 0.6 mL/min.

Formation of $^{99m}Tc(CO)_3^+$ Complexes. The $^{99m}Tc(CO)_3^+$ core was prepared fresh daily by introducing 1 mL of $^{99m}TcO_4^-$ saline solution into a kit and heating in boiling water. An incubation time of 20 min was routinely used. After neutralization with 120 μL of 1 N HCl, an equal volume of aliquot was added to a vial containing either 1 mM BPABA or 1 mM histidine of pH 7.0 and heated in a boiling water bath normally for 20 min. Both the labeled compounds of $^{99m}Tc(CO)_3^+$−BPABA or $^{99m}Tc(CO)_3^+$−histidine were characterized by RP HPLC (system 2) and SE HPLC.

In Vitro Stability of $^{99m}Tc(CO)_3^+$-Labeled BPABA and Histidine. The stabilities of both complexes were tested by diluting the labeled solution 100 fold in saline or human serum, incubating at 37 °C, and analyzing at intervals using SE HPLC.

The affinity of $^{99m}Tc(CO)_3^+$ for BPABA relative to histidine was also measured by mixing $^{99m}Tc(CO)_3^+$−BPABA in 100 mM histidine at a molar ratio of BPABA to histidine of 1:5000 and incubating either at 37 °C for 24 h or in a boiling water bath 6 h. The identical procedure was also performed starting with $^{99m}Tc(CO)_3^+$−histidine in 100 mM BPABA.

In Vivo Stability and Biodistribution of ^{99m}Tc Tricarbonyl-Labeled BPABA. A group of four normal CD-1 mice (35−45 g) were each injected with 70 μCi of $^{99m}Tc(CO)_3^+$−BPABA or $^{99m}Tc(CO)_3^+$−histidine via a tail vein. After 35 min, the mice were sacrificed under

halothane anesthesia. Selected organs were harvested and rinsed, and their radioactivity was measured in a Cobra II auto-gamma counter (Packard, Downers Grove, IL). To provide an estimate of in vivo stability, plasma, urine, and an extract from small intestine contents were analyzed by SE HPLC. Plasma was obtained by adding 0.5 mL of blood from each mouse into a tube containing 0.068 mL of 7.5% K_3EDTA followed by centrifugation at 650−700 *g* for 10 min. The small intestine extract was obtained by washing with 4 mL of water and centrifuging the wash at 2500*g* for 20 min.

RESULTS

Characterization of BPABA. Analysis by RP HPLC (System 1) reveals one major peak at 7.8 min with over 90% of peak area and a small peak at 8.7 min, presumably due to $(PyCH_2)_2N(CH_2)_3COOH$ and $(PyCH_2)_3N^+(CH_2)_3$-COOH. The broad peak at 29 min is due to the solvent.

The ESI-MS analysis of BPABA shows a product peak attributed to $[(PyCH_2)_2NH^+(CH_2)_3COOH$ [MH^+: 286.2 *m/z*, abundance 100%; corresponding isotope peak at 287.2 *m/z*, abundance 17%] and a byproduct peak due to the quaternary ammonium salt $(PyCH_2)_3N^+(CH_2)_3COOH$ [M^+: 377.2 *m/z*, abundance 43%; corresponding isotope peak at 378.2 *m/z*, abundance 11%]. All other peaks are lower than 10% (data not presented). Confirmation of structure is apparent in that fragmentation of the molecular ion peak 286.2 *m/z* provide a series of fragment peaks: $(PyCH_2)_2NH^+(CH_2)_3COOH$, *m/z* 286.2, abundance 15.5%; $(PyCH_2)_2N(CH_2)_3CO^+$, *m/z* 268.2, abundance 25%; $(PyCH_2)_2NH_2^+$, *m/z* 200.2, abundance 13%; Py-CH=$NH^+(CH_2)_3COOH$ *m/z* 193.1, 25.0%; Py-CH=$N(CH_2)_3CO^+$ *m/z* 175.1, 16%.

Formation Kinetics of ^{99m}Tc(CO)$_3^+$−BPABA vs ^{99m}Tc(CO)$_3^+$−Histidine. On RP HPLC (System 2) the $^{99m}Tc(CO)_3^+$ core elutes at 4 min (Figure 2A) as described by the manufacturer and forms complexes with both BPABA and histidine (Figures 2B and 2C), resulting in single peaks and indicating a radiochemical purity of over 90%. Reaction times over 5−40 min in boiling water makes no difference in complex formation as shown by HPLC profiles identical to that of Figure 2B or 2C (data not presented). However, heating more than 60 min considerably increases the impurity peaks with both $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine (data not presented). It was therefore judged safe in this study to employ a routine heating time of 20 min for complex formation.

In Vitro Stability of ^{99m}Tc(CO)$_3^+$−BPABA vs ^{99m}Tc(CO)$_3^+$−Histidine. Both $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine are unaffected by 24 h incubation in 37 °C saline, but both show serum protein binding after 24 h incubation in 37 °C human serum (data not presented). The percentage of serum binding with $^{99m}Tc(CO)_3^+$−histidine is higher than that with $^{99m}Tc(CO)_3^+$−BPABA (20 vs 9.5% at 24 h), indicating that $^{99m}Tc(CO)_3^+$−histidine may be less stable against transchelation to proteins than $^{99m}Tc(CO)_3^+$−BPABA under these conditions.

Ligand exchange between BPABA and histidine was also investigated by SE HPLC (system 3). In this system, the $^{99m}Tc(CO)_3^+$ core itself does not elute probably due to interaction of the core with the cross-linked agarose matrix. The HPLC chromatograms of $^{99m}Tc(CO)_3^+$−histidine and $^{99m}Tc(CO)_3^+$−BPABA are shown in Figure 3 A and 3D, respectively. Incubation of $^{99m}Tc(CO)_3^+$−histidine with a 5000 molar excess of BPABA pH 7 at 37 °C over 1 d shows minimal replacement of histidine by BPABA (Figure 3 B); however, heating of the same mixture in a boiling water bath for 6 h induces almost total replacement of histidine by BPABA (Figure 3C). In contrast, incubation of $^{99m}Tc(CO)_3^+$−BPABA with a 5000 molar excess of histidine shows no replacement of BPABA (Figure 3 E) even at 100 °C for 6 h (Figure 3F). The capability of BPABA to replace histidine in its $^{99m}Tc(CO)_3^+$ complex, but not vice versa, reflect a higher affinity of BPABA for ^{99m}Tc tricarbonyl.

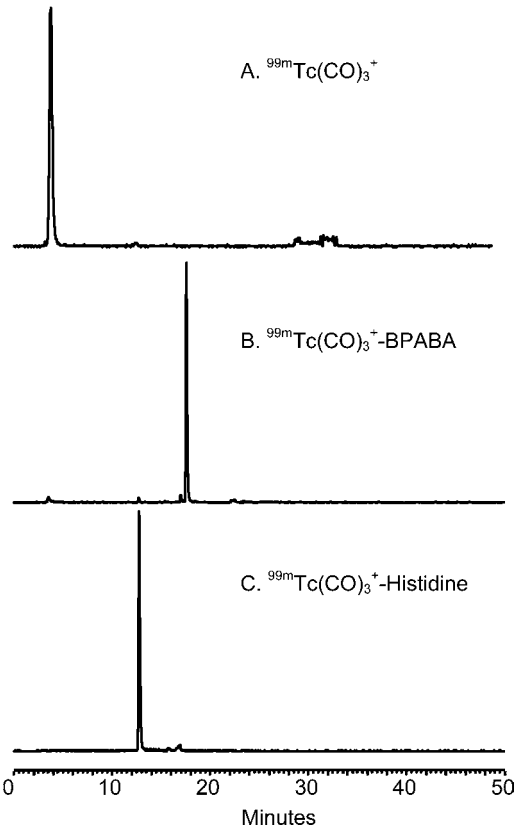

Figure 2. Radiochromatograms by RP HPLC (System 2) of $^{99m}Tc(CO)_3^+$ core (panel A) and $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine following incubation at 37 °C for 40 min or less (panels B and C, respectively).

Biodistribution and In Vivo Stability of ^{99m}Tc(CO)$_3^+$−BPABA vs ^{99m}Tc(CO)$_3^+$−Histidine. Table 1 presents the biodistribution in normal mice at 35 min postadministration of $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine. The biodistribution of $^{99m}Tc(CO)_3^+$−BPABA shows rapid hepatobiliary excretion with 57% in the small intestine, 5% in the large intestine, and 15% in liver including gall bladder at 35 min. Less than 8% was excreted into urine at this time. By SE HPLC analysis, only 30% (2.4%ID) of the radioactivity in urine was present as $^{99m}Tc(CO)_3^+$−BPABA. The remaining urine radioactivity was due to the approximately 5% radiochemical impurities in the $^{99m}Tc(CO)_3^+$−BPABA injectate. While clearance of these impurities via the kidneys was rapid and quantitative, the excretion of $^{99m}Tc(CO)_3^+$−BPABA via the kidney was largely negligible. By contrast, $^{99m}Tc(CO)_3^+$−histidine is predominantly excreted through kidney as reported previously (*10*, *11*) with 50% of $^{99m}Tc(CO)_3^+$−histidine in urine in 35 min. Though rapid, the kidney excretion is not as rapid as typical kidney imaging agents such as ^{99m}Tc−BPHA (*18*), ^{99m}Tc−DTPA (*19*), and ^{99m}Tc−MAG_3 (*20*).

The in vivo stabilities of $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine were evaluated by comparing the SE HPLC radiochromatograms of the injectates with that

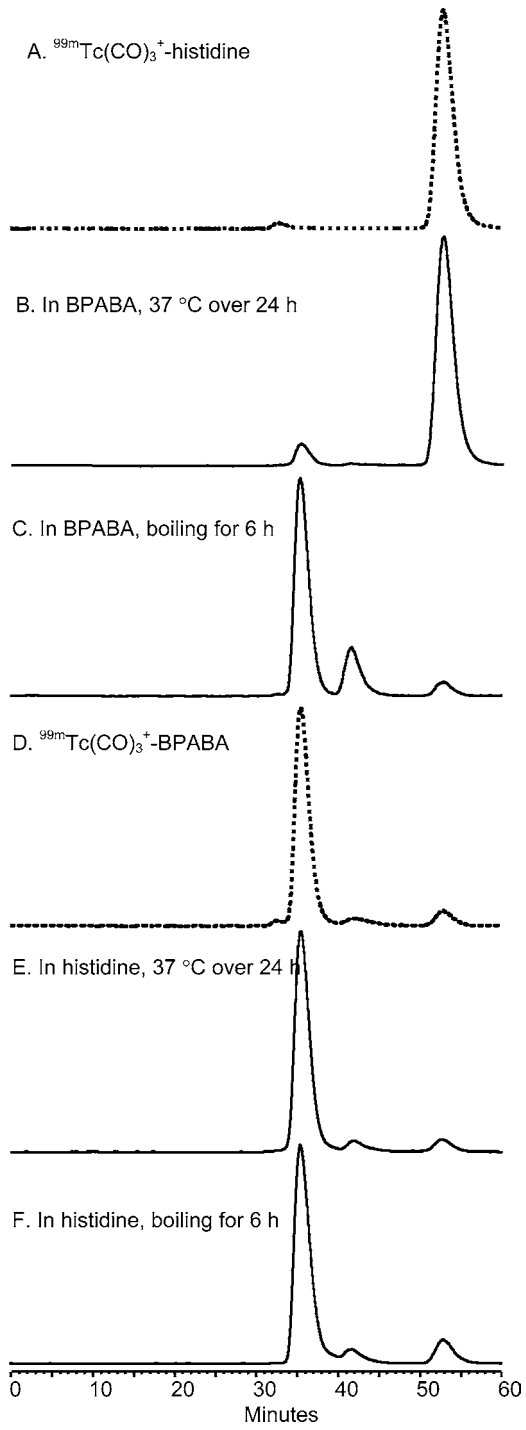

Figure 3. Radiochromatograms by SE HPLC (System 3) of $^{99m}Tc(CO)_3^+$−histidine alone (panels A) and after incubation with a 5000-fold molar excess of BPABA for 24 h at 37 °C (panel B) and 6 h at 100 °C (Panel C). Also presented are radiochromatograms of $^{99m}Tc(CO)_3^+$−BPABA alone (panels D) and after incubation with a 5000-fold molar excess of histidine for 24 h at 37 °C (panel E) and 6 h at 100 °C (Panel F).

of urine, plasma, and extracts of small intestine obtained from animals administered the complexes 35 min earlier. As shown in Figure 4, $^{99m}Tc(CO)_3^+$−BPABA is still intact in plasma as well as in the wash from the small intestines. Because of the negligible urinary excretion of $^{99m}Tc(CO)_3^+$−BPABA (less than 8% ID) the HPLC profile of urine is not presented. Like $^{99m}Tc(CO)_3^+$−BPABA, $^{99m}Tc(CO)_3^+$−histidine is also intact in plasma and in urine. Because of the negligible hepatobilliary excretion of $^{99m}Tc(CO)_3^+$−histidine, an HPLC profile of small intestine wash was not obtained in this case. These results show that both $^{99m}Tc(CO)_3^+$−BPABA and $^{99m}Tc(CO)_3^+$−histidine are "stable" in vivo.

DISCUSSION

In this investigation, BPABA has been chosen as a model compound because of its ease of synthesis and the presence of a pendent carboxylate group for conjugation to biomolecules. In addition, the molecule was selected to avoid five- or six-membered chelation rings with the ^{99m}Tc tricarbonyl core. Thus free BPABA should exhibit similar labeling properties to conjugated BPABA and therefore should serve as a reliable model for the behavior of BPABA-conjugated biomolecules. The result of this investigation show that the properties of complex formation and stability of BPABA are comparable, if not superior to, that of histidine, often considered a model compound for ^{99m}Tc tricarbonyl labeling (*10, 11, 14*).

Our interest in tricarbonyl labeling is in connection with phosphodiamidate morpholino (MORF) pretargeting in which it will eventually be necessary to radiolabel MORF with ^{188}Re and in a manner that avoids unacceptably large reoxidation to $^{188}ReO_4^-$. Because of the recognized kinetic inertness of these complexes (*6*−*8*), tricarbony labeling of biomolecules via BPABA is expected to avoid the oxidation problem at least to a greater degree than experienced in this laboratory with a more conventional labeling method for ^{188}Re using MAG_3 as a chelator (*5*). However, a drawback to the use of the tricarbonyl strategy resulting from kinetic inertness is "high" chelator concentration required for quantitative labeling (*10, 11*), a phenomenon verified in this research. A chelator concentration of 10^{-4} or 10^{-5} M was required for a labeling efficiency of 90%, even with histidine. By contrast, the concentration of MAG_3 can be reduced to below 10^{-6} M when labeling MAG_3-conjugated MORF or phosphorothioate DNA while still achieving a labeling efficiency of over 90% (*21*).

Parenthetically, it may be worth mentioning that the results presented here on the properties of $^{99m}Tc(CO)_3$−BPABA suggest that this complex may have utility for imaging the hepatobiliary system. The ^{99m}Tc-labeled hepatobiliary imaging agents include ^{99m}Tc−IDAs (*22,*

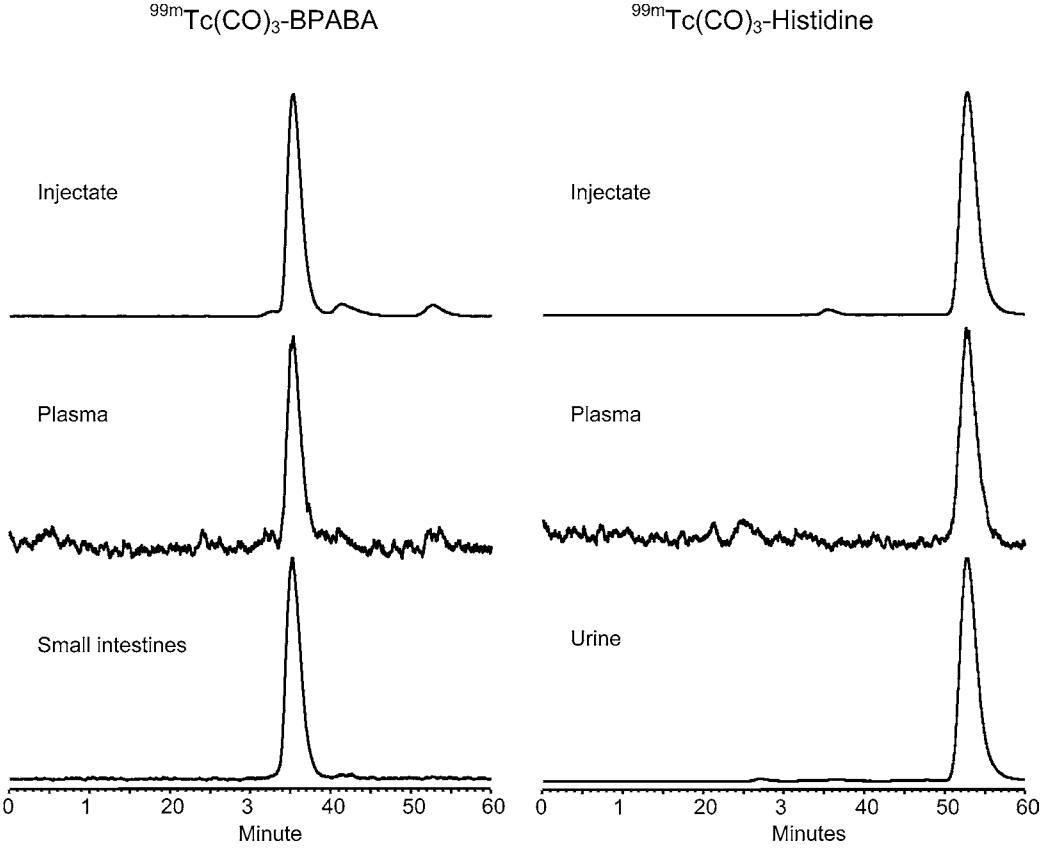

Figure 4. Radiochromatograms by SE HPLC (System 3) of ^{99m}Tc(CO)$_3^+$−BPABA injectate (top left panel) and ^{99m}Tc(CO)$_3^+$−histidine injectate (top right panel) and analysis of plasma (middle row), extract from the small intestines (in the case of ^{99m}Tc(CO)$_3^+$−BPABA) (left bottom panel), and urine (in the case of ^{99m}Tc(CO)$_3^+$-hisidine) (right bottom panel) from an animal injected 35 min earlier.

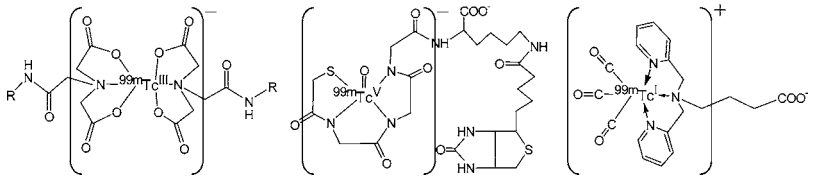

Figure 5. Structures of reported hepatobiliary specific imaging agents. (A) ^{99m}Tc−IDAs, (B) ^{99m}Tc−MAG$_3$−biocytin, and (C) ^{99m}Tc(CO)$_3^+$−BPABA.

23), ^{99m}Tc−pyridoxylidine glutamate (*24*), ^{99m}Tc−penicillamine (*25*), and ^{99m}Tc−MAG$_3$−biocytin (*26, 27*), with ^{99m}Tc−IDAs being the most extensively investigated. Both ^{99m}Tc−IDAs and ^{99m}Tc−MAG$_3$−biocytin are excreted exclusively via the hepatobiliary pathway in contrast to both ^{99m}Tc−pyriddoxylidine glutamate and ^{99m}Tc−penicillamine. Similar to the ^{99m}Tc−IDAs (<97% ID) and ^{99m}Tc−MAG$_3$−biocytin (>90%ID), ^{99m}Tc(CO)$_3$−BPABA is also cleared exclusively via the hepatobiliary pathway (97%ID).

The mechanism of hepatobiliary processing is reported to be different among these agents. As shown in Figure 5, the structures of the ^{99m}Tc−IDAs, ^{99m}Tc−MAG$_3$-biocytin and ^{99m}Tc(CO)$_3$−BPABA are fundamentally different and, as a result, each is expected to clear by a different mechanisms of hepatobiliary excretion. For example, ^{99m}Tc−IDAs and ^{99m}Tc−MAG$_3$-biocytin must clear by different mechanisms since only the former can be blocked by endogenous bilirubin (*26*) with the result that hepatobiliary function in patients with high serum bilirubin levels can be evaluated only with ^{99m}Tc−MAG$_3$-biocytin. Since ^{99m}Tc(CO)$_3$−BPABA possesses a different structure to those of ^{99m}Tc−IDAs and ^{99m}Tc−MAG$_3$-biocytin, the mechanism by which ^{99m}Tc(CO)$_3$−BPABA clears through the liver may be different as well. Therefore, should ^{99m}Tc(CO)$_3$−BPABA be investigated as a potential imaging agent for the hepatobiliary system, it may be shown to be cleared via a unique transporter, the function of which could then be evaluated.

CONCLUSION

The tridentate chelator *N*,*N*-bis(2-pyridylmethyl)-4-aminobutyric acid (BPABA) is easily synthesized and forms a "stable" complex with ^{99m}Tc(CO)$_3^+$. The property of stability might apply to radiorhenium as well for use in radiotherapy studies. Further development efforts are needed to improve the labeling recipes for high specific activity. Finally, the ^{99m}Tc(CO)$_3$−BPABA complex itself is hepatobiliary specific and might be useful in imaging malfunction of specific transporter in liver.

ACKNOWLEDGMENT

The authors are grateful to Mary Dyszlewski (Mallinckrodt Medical, St. Louis, MO) for providing the technetium tricarbonyl kits. Financial support for this investigation was provided in part by the National Institutes of Health (CA94994, CA107360, and CA79507).

^{18}F-Fluorothiols: A New Approach To Label Peptides Chemoselectively as Potential Tracers for Positron Emission Tomography†

Matthias Glaser,*,‡ Hege Karlsen,§ Magne Solbakken,§ Joseph Arukwe,§ Frank Brady,‡ Sajinder K. Luthra,‡ and Alan Cuthbertson§

Hammersmith Hospital, Hammersmith Imanet Ltd., Du Cane Road, London W12 0NN, U.K., and Medicinal Chemistry, Medical Diagnostics, GE Healthcare Bio-Sciences, P.O. Box 4220, Nydalen, N-0401 Oslo, Norway. Received May 26, 2004; Revised Manuscript Received August 31, 2004

[^{18}F]Fluorothiols are a new generation of peptide labeling reagents. This article describes the preparation of suitable methanesulfonyl precursors and their use in no-carrier-added radiosyntheses of ^{18}F-fluorothiols. The preparations of (3-[^{18}F]fluoropropylsulfanyl)triphenylmethane, (2-{2-[2-(2-[^{18}F]-fluoroethoxy)ethoxy]ethoxy}ethylsulfanyl)triphenylmethane, and 4-[^{18}F]fluoromethyl-*N*-[2-triphenylmethanesulfanyl)ethyl]benzamide starting from the corresponding methanesulfonyl precursors were investigated. Following the removal of the triphenylmethane protecting group, the ^{18}F-fluorothiols were reacted with the N-terminal chloroacetylated model peptide $ClCH_2C(O)$-LysGlyPheGlyLys. The corresponding radiochemical yields of ^{18}F-labeled isolated model peptide, decay-corrected to ^{18}F fluoride, were 10%, 32%, and 1%, respectively. These results indicate a considerable potential of ^{18}F-fluorothiols for the chemoselective labeling of peptides as tracers for positron emission tomography (PET).

INTRODUCTION

Radiolabeled peptides are important imgaging agents for nuclear medicine in general and for positron emission tomography (PET) in particular. This is reflected by the number of review articles (*1*−*5*). The positron emitter fluorine-18 ($T_{1/2}$ = 110 min) as a widespread positron emitter has been widely used to radiolabel peptides and proteins of medical interest. Although there are reports on direct incorporation of ^{18}F into peptides (*6*, *7*), the most promising approach still relies on the use of prelabeled ^{18}F reagents.

The majority of known ^{18}F reagents for peptide and protein labeling are targeting primary amino groups such as the N-terminus or lysine side chains. This is achieved through active esters (*8*−*10*), aldehydes (*11*), imidate (*12*), or azido functionalities (*2*). Fluorine-18-labeled amine was also coupled to a peptide with a prelabeled *N*-succinimidyl moiety (*13*). However, these peptide-coupling reactions are often low yielding, which is usually due to hydrolysis side reactions of the activated ^{18}F reagent. In addition, the synthesis of the ^{18}F prosthetic groups usually requires the time-consuming preparation and purification of multiple radioactive intermediates, reducing the available amount of ^{18}F at the end of synthesis. For instance, the production of the established *N*-succinimidyl *p*-[^{18}F]fluorobenzoate comprises three steps dealing with synthesis and purification of radioactive intermediates (*8*, *14*). More recently, efficient radiohalogenation was achieved by condensation of *p*-[^{18}F]fluorobenzaldehyde with aminooxy-modified peptide (*15*).

Alkylation reactions have only rarely been used for peptide labeling with fluorine-18-containing prosthetic groups. For example, one report mentions *p*-[^{18}F]fluorophenacyl bromide to label several proteins (*12*). However, there was no control on the binding site of the labeling reagent.

Alternatively, it is possible to take advantage of the high nucleophilicity of thiolates to couple an ^{18}F containing molecule with activated peptides. Here, we wish to describe the preparation of ^{18}F-prelabeled thiols and their chemoselective alkylation reaction with a chloroacetyl-modified model peptide.

RESULTS AND DISCUSSION

Precursors and [^{19}F]Fluoro Standard Compounds. Methanesulfonic acid 3-tritylsulfanyl-propyl ester **1** was prepared from 3-mercapto-1-propanol by reacting with trityl chloride and mesyl chloride (Scheme 1). The *S*-trityl-protected fluoro product **2** was obtained by fluoro demesylation of **1** using the KF−Kryptofix complex.

The PEG derivative **3** was designed in order to have a prosthetic group with potentially better pharmacologic properties available. Tetra(ethylene glycol) was thiolated by reacting its monotosylate with thiourea followed by hydrolysis of the resulting uronium salt. Reaction with trityl chloride and mesyl chloride gave mesylate precursor **3**. Reaction of **3** with tetrabutylammonium fluoride (TBAF) formed **4**.

The benzamide precursor **5** was devised as a reagent with improved UV−visiblity during chromatography. In the synthesis of **5**, cysteamine was S-tritylated using triphenylmethanol in trifluoroacetic acid (TFA). After coupling with 4-hydroxymethylbenzoic acid pentafluorophenyl ester, the hydroxymethyl function was mesy-

lated. The fluoro standard **6** was prepared by reaction of **5** with KF−Kryptofix.

[^{18}F]Fluorothiols. The mesylate **1** gave only moderate yields of ^{18}F-**2** (24%) after a 5 min reaction with [^{18}F]KF−Kryptofix carbonate in acetonitrile at 80 °C as analyzed by HPLC. A plateau of 60% was reached after 30 min. DMF as solvent under identical conditions showed an improvement (72% after 30 min). However, DMSO proved to be the optimal solvent resulting in 79 ± 10% (n = 6) after already 5 min reaction time (Figures 1 and 2a).

The PEG-type mesylate **3** did react in DMSO somewhat slower using the above conditions. The maximum incorporation was observed after 15 min (77% of ^{18}F-**4**, Figure 2b). The yields in acetonitrile and DMF after 30 min were relatively low with 30% and 41%, respectively. The slower kinetics might be explained by the larger size of mesylate **3** compared with the small propyl compound **1**.

The benzamide mesylate **5** was tested using the experimental settings described. Here, the best yields of ^{18}F-**6** were obtained after reacting in acetonitrile for 5 min (25%, Figure 2c). The use of DMF and DMSO resulted only in yields of 7% and 17%, respectively (after 5 min), suggesting that the choice of solvent may have little impact on labeling efficiency. The benzyl mesylate

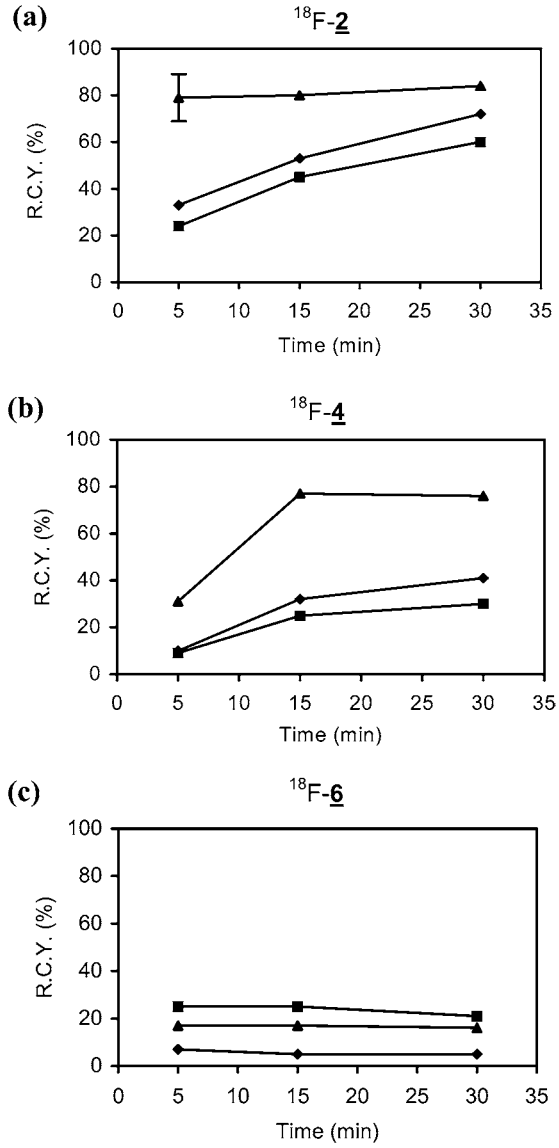

Figure 2. Radiolabeling yields of (a) ^{18}F-**2**, (b) ^{18}F-**4**, and (c) ^{18}F-**6** in DMSO (▲), DMF (◆), or MeCN (■) as obtained from HPLC analysis.

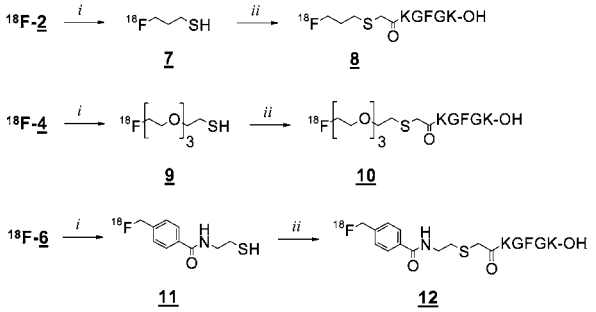
group is highly activated toward nucleophilic displacements as it was already observed during the ^{19}F labeling work. In those studies the mesylate **5** HPLC signal quickly degraded as a new peak appeared instead. This compound was identified as 4-hydroxymethyl-*N*-[2-(tritylsulfanyl)ethyl]benzamide. A similar behavior could be seen in the synthesis of ^{18}F-**6**. At the present this effect is not fully understood as the reaction was carried out in a strictly anhydrous environment. The ^{18}F-fluorodemesylation of **5** was also investigated at lower temperatures. The reaction occurred already at room temperature forming 22% of ^{18}F-**6** after 7 min. After that time, HPLC analysis revealed complete consumption of **5**. Cooling to −17 °C followed by warming up to room temperature gave no ^{18}F-**6** but only the hydrolysis product mentioned above. In an experiment without potassium carbonate neither hydroxy product or ^{18}F-**6** were detected after 5 min at room temperature and heating for 15 min at 80 °C. Obviously, the yields of ^{18}F-**6** might be still improved either by testing some alternative bases with the ^{18}F−Kryptofix complex or by using higher substrate concentrations of **5**.



Further, our experiments indicated some degradation of already formed ^{18}F-**6** in all three solvent systems after

Scheme 2. Preparation [^{18}F]Fluorothiols 7, 9, and 11 as Labeling Reagents for the Corresponding [^{18}F]Fluoropeptides 8, 10, and 12[a]

[a] Reagents and conditions: (*i*) 1. ^{t}C18-SepPak-plus; 2. TFA/TIS/H_2O; (*ii*) $ClCH_2C(O)$-KGFGK-OH, pH 9−10, 70−80 °C, 30 min.

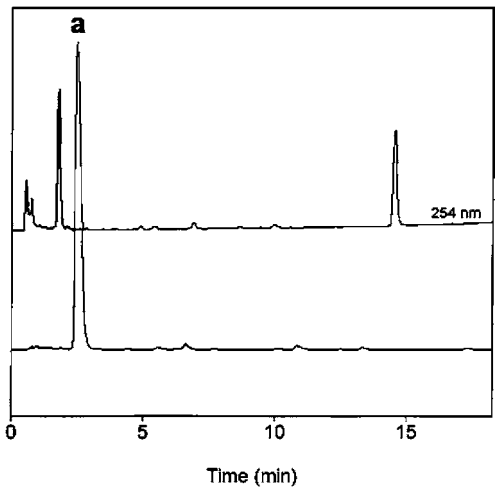

Figure 3. HPLC analysis of the reaction mixtures of the deprotection product ^{18}F-**7** (a).

5−15 min heating. In fact, the stability of ^{18}F-fluorobenzyl derivatives has been recently studied by others (*16*).

Peptide Labeling with [^{18}F]Fluorothiols. After its preparation, the *S*-trityl compound ^{18}F-**2** could be quantitatively transferred from DMSO into acetonitrile using a C18 SepPak cartridge. The radiochemical purity of ^{18}F-**2** was >99%. The trityl protecting group was removed with TFA in the presence of triisopropylsilane (TIS) to form **7** in good yield (Scheme 2, Figure 3, Table 1). The *N*-chloroacetylated model peptide $ClCH_2C(O)$-KGFGK-OH could be labeled in excellent yield. An analytical HPLC trace of the labeling mixture is shown in Figure 4.

Following identical protocols, the [^{18}F]fluorothiol compounds ^{18}F-**4** and ^{18}F-**6** were deprotected to react with the chloroacetyl peptide to form **9** and **11**, respectively. The efficiencies of the single steps are summarized in Table 1.

An investigation to test the stability of deprotected thiol **7** was carried out. This experiment suggested poor stability of the ^{18}F-thiol at pH 9−10 at room temperature.

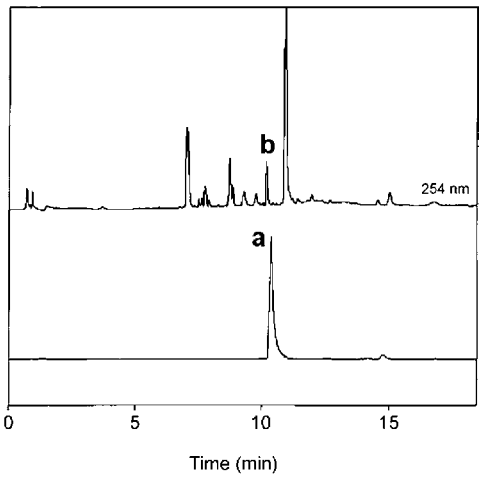

Figure 4. HPLC analysis of the reaction mixture of the labeled peptide ^{18}F-**8** (a) with spiked standard **8** (b).

After 1 h the HPLC signal of **7** was completely degraded. The use tris(2-carboxyethyl)phosphine (TCEP) as stabilizer was considered. TCEP as a selective reductant for disulfides has been described to be superior to dithiothreitol (*17*, *18*). Thiol **7** showed high stability in the presence of TCEP. Therefore, an additive of this stabilizer was used in the subsequent peptide labeling work.

The isolated radiochemical yields of [^{18}F]fluoropeptides **8**, **10**, and **12** are listed in Table 1. Both the reduced thermal stability of the ^{18}F-fluorobenzyl group and loss of radiolabeled peptide during the final HPLC purification possibly led to a decreased radiochemical yield of peptide **12**.

Only low levels of radioactivity of ^{18}F have been used for this study, and therefore, specific radioactivities have not been measured.The total synthesis time was 2−3 h.

CONCLUSIONS

[^{18}F]Fluorothiols have been introduced as a new group of no-carrier-added ^{18}F-reagents to label peptides as tracers for PET. The chloroacetyl function was used to chemoselectively enable the binding of the prosthetic ^{18}F-group to a model peptide. The protocol simplifies peptide labeling because the reagent is prepared in only two steps that involved handling of ^{18}F. In addition, there was also no need to purify the ^{18}F-compound. The radiochemistry should be easily amenable to automation.

MATERIALS AND METHODS

Preparation of Precursors and Standards. Chemicals. Fmoc amino acids, the Fmoc-Lys(Boc)-Sasrin resin, and peptide coupling reagents were purchased from Novabiochem, Bachem, and Applied Biosystems, respectively. 4-Hydroxymethylbenzoic acid pentafluorophenyl ester was obtained from MilliGen. All other reagents and solvents were purchased from Acros, Aldrich, or Fluka.

Mass spectra were recorded on a Finnigan LCQ system using electrospray ionization (ESI). MALDI-TOF mass spectra were measured on a Finnigan Lasermat 2000

instrument. Accurate mass spectra (HRMS) were measured on a Micromass Q-Tof Ultima machine coupled with a nano-LC system using Mass Lynx 3.5 software. NMR spectra were obtained from a Varian Unity Inova 500 instrument at 25 °C using a 5 mm $^1H\{^{15}N-^{31}P\}$ indirect detection pfg probe. Analytical and semipreparative reversed-phase HPLC using different gradients [solvent A: water (0.1% TFA), solvent B: acetonitrile (0.1% TFA)], and UV detection at 214 and 254 nm were performed on Shimadzu, Beckman, or Waters chromatography systems.

Cl-Ac-Lys-Gly-Phe-Gly-Lys-OH. Assembly of the amino acid sequence Lys-Gly-Phe-Gly-Lys-OH was done using fully automated synthesis (ABI 433A synthesis machine) with Fmoc-Lys(Boc)-Sasrin resin (0.25 mmol) using the Fastmoc Single Couple procedure with HBTU activation. Chloroacetic acid was coupled manually using chloroacetic anhydride (1.25 mmol). Simultaneous removal of the peptide from the resin and deprotection of side-chain protecting groups were carried out in trifluoroacetic acid containing triisopropylsilane and water (95: 2.5:2.5 v/v/v). After filtration, the solution was concentrated under reduced pressure and the residue was washed with diethyl ether. The crude product was purified by reversed-phase preparative chromatography (Phenomenex Luna C18(2) column, 250 × 50 mm, 10 μm; gradient 0−30% solvent B over 60 min; flow rate 50 mL/minute), affording 128 mg (83%) of pure compound. The product was analyzed by HPLC [Phenomenex Luna C18-(2), 50 × 4.6 mm, 5 μm; gradient 0−30% solvent B over 10 min; flow rate 2 mL/min; t_R = 5.1 min] and MS, *m/z* = 612.8 $(M + H)^+$; HRMS: found *m/z* = 612.2936 $(M + H)^+$ for $C_{27}H_{42}N_7O_7Cl$ calcd *m/z* = 612.2907.

Methanesulfonic Acid 3-Tritylsulfanylpropyl Ester 1. A solution of triphenylmethanol (391 mg, 1.50 mmol) in trifluoroacetic acid (10 mL) was added dropwise to a stirred solution of 3-mercaptopropyl alcohol (127 μL, 1.50 mmol) in trifluoroacetic acid (10 mL). The trifluoroacetic acid was evaporated under reduced pressure immediately after mixing of the reagents. The crude product was purified by reversed-phase preparative chromatography (Phenomenex Luna C18(2) column, 250 × 50 mm, 10 μm; gradient 70−80% solvent B over 60 min; flow rate 50 mL/min), affording 372 mg (74%) of pure compound (mp 122−125 °C). ^1H NMR (chloroform-*d*, 500 MHz): 7.40−7.44 (m, 6H, trityl *o*-H); 7.26−7.31 (m, 6H, trityl *m*-H); 7.19−7.24 (m, 3H, trityl *p*-H); 3.56 (t, 2H, $^3J_{HH}$ = 6.2 Hz, CH_2O); 2.28 (t, 2H, $^3J_{HH}$ = 7.2 Hz, CH_2S); 1.62 (t of t, 2H, $^3J_{HH}$ = 6.2 Hz, $^3J_{HH}$ = 7.2 Hz, $OCH_2CH_2CH_2S$).

To a solution of 3-tritylsulfanylpropan-1-ol (372 mg, 1.11 mmol) in tetrahydrofuran (10 mL) were added triethylamine (209 μL, 1.50 mmol) and methanesulfonyl chloride (117 μL, 1.50 mmol). The precipitate was filtered off after stirring at room temperature for 1 h. Tetrahydrofuran was evaporated under reduced pressure, and the crude product was purified by reversed-phase preparative chromatography (Phenomenex Luna C18(2) column, 250 × 50 mm, 10 μm; gradient 80−100% solvent B over 60 min; flow rate 50 mL/min), affording 318 mg (69%) of pure compound (mp 122−125 °C). ^1H NMR (chloroform-*d*, 500 MHz): 7.39−7.44 (m, 6H, trityl *o*-H); 7.26−7.32 (m, 6H, trityl *m*-H); 7.19−7.24 (m, 3H, trityl *p*-H); 4.13 (t, 2H, $^3J_{HH}$ = 6.4 Hz, CH_2O); 2.92 (s, 3H, CH_3S); 2.29 (t, 2H, $^3J_{HH}$ = 7.1 Hz, CH_2S); 1.71 (t of t, 2H, $^3J_{HH}$ = 6.4 Hz, $^3J_{HH}$ = 7.1 Hz, $OCH_2CH_2CH_2S$).

(3-Fluoropropylsulfanyl)triphenylmethane 2. Potassium fluoride (1.4 mg, 0.024 mmol) and Kryptofix (9 mg, 0.024 mmol) were dissolved in acetonitrile (0.2 mL) with heating. A solution of mesylate **1** (5 mg, 0.012 mmol) in acetonitrile (0.2 mL) was added. The mixture was heated at 80 °C for 90 min. The crude product was purified by HPLC (Vydac 218TP column, C18, 250 × 22 mm, 10 μm; gradient 40−90% B in 40 min; flow rate 10 mL/min; λ = 254 nm). The yield of **2** was 2 mg (50%). The product was analyzed by HPLC [Phenomenex Luna C18(2) column, 50 × 4.6 mm, 3 μm; gradient 40−80% solvent B in 10 min; flow rate 1 mL/min; t_R = 7.12 min, λ = 254 and 214 nm] and ^1H NMR (chloroform-*d*, 500 MHz): 7.39−7.44 (m, 6H, trityl *o*-H); 7.26−7.31 (m, 6H, trityl *m*-H); 7.19−7.24 (m, 3H, trityl *p*-H); 4.36 (d of t, 2H, $^2J_{HF}$ = 47.2 Hz, $^3J_{HH}$ = 5.9 Hz, CH_2F); 2.28 (t, 2H, $^3J_{HH}$ = 7.3 Hz, CH_2S); 1.72 (d of t of t, 2H, $^3J_{HF}$ = 25.4 Hz, $^3J_{HH}$ = 5.9 Hz, $^3J_{HH}$ = 7.3 Hz, $FCH_2CH_2CH_2S$).

Methanesulfonic Acid 2-{2-[2-(2-Tritylsulfanylethoxy)ethoxy]ethoxy}ethyl Ester 3. Triethylamine (13 mL, 93 mmol) was added to a stirred solution of *p*-toluenesulfonyl chloride (9.82 g, 51.5 mmol) in tetra(ethylene glycol) (20.0 g, 103 mmol) at 0 °C. The suspension was stirred at 0 °C for 1 h and at room temperature for 16 h. After adding of dichloromethane (350 mL), the solution was extracted with hydrochloric acid (1 M, 2 × 100 mL) and water (200 mL). The organic phase was dried ($MgSO_4$). After concentration, the product was purified by flash chromatography (ethyl acetate, first fraction: tetra(ethylene glycol) ditosylate) to give *p*-toluenesulfonic acid 2-{2-[2-(2-hydroxyethoxy)ethoxy]-ethoxy}ethyl ester as a colorless oil (8.9 g, 49%). ^1H NMR (chloroform-*d*, 500 MHz): 7.78−7.83 (m, 2H, $CH_3C_6H_4S$); 7.32−7.37 (m, 2H, $CH_3C_6H_4S$); 4.15−4.19 (m, 2H, $SOCH_2CH_2$); 3.58−3.74 (m, 14H, OCH_2CH_2); 2.45 (s, 3H, $CH_3C_6H_4S$).

A solution of thiourea (0.94 g, 12 mmol) and *p*-toluenesulfonic acid 2-{2-[2-(2-hydroxyethoxy)ethoxy]ethoxy}-ethyl ester (4.09 g, 11.8 mmol) in absolute ethanol (32 mL) was heated at reflux for 24 h under argon. The reaction mixture was cooled and a solution of sodium hydroxide (1.23 g, 30.8 mmol) in ethanol/water (9:1 v/v, 15 mL) was added. The mixture was refluxed under argon for 2.5 h, cooled to room temperature and acidified to pH 2 (concentrated HCl). After concentration the residue was purified by flash chromatography (ethyl acetate/ethanol, 10:1 v/v) to give 2-{2-[2-(2-mercaptoethoxy)ethoxy]ethoxy}-ethanol as a colorless oil (1.6 g, 66%).

^1H NMR (chloroform-*d*, 500 MHz): 3.72−3.76 (m, 2H, OCH_2CH_2O); 3.60−3.71 (m, 12H, OCH_2CH_2); 2.71 (d of t, 2H, $^3J_{HH}$ = 8.1 Hz, $^3J_{HH}$ = 6.6 Hz, $HSCH_2CH_2O$); 2.41 (broad s, 1H, $HOCH_2CH_2O$); 1.63 (t, 1H, $^3J_{HH}$ = 8.1 Hz, $HSCH_2CH_2O$).

To 2-{2-[2-(2-mercaptoethoxy)ethoxy]ethoxy}ethanol (310 mg, 1.47 mmol) and trityl chloride (452 mg, 1.62 mmol) under argon was added simultaneously triethylamine (2.1 mL, 14.7 mmol) and tetrahydrofuran (25 mL). After stirring for 7 h, methanol (6 mL) was added and stirring was continued for 5 min. The product was isolated by flash chromatography (ethyl acetate) to give 2-{2-[2-(2-tritylsulfanylethoxy)ethoxy]ethoxy}ethanol as a colorless oil (550 mg, 83%). ^1H NMR (chloroform-*d*, 500 MHz): 7.39−7.43 (m, 6H, trityl *o*-H); 7.25−7.30 (m, 6H, trityl *m*-H); 7.18−7.23 (m, 3H, trityl *p*-H); 3.68−3.72 (broad m, 2H, CH_2OH); 3.61−3.67 (m, 4H, OCH_2CH_2O); 3.57−3.60 (m, 2H, OCH_2CH_2OH); 3.56−3.59 (m, 2H, OCH_2CH_2O); 3.43−3.47 (m, 2H, OCH_2CH_2O); 3.30 (t, 2H, $^3J_{HH}$ = 6.9 Hz, OCH_2CH_2S); 2.44 (t, 2H, $^3J_{HH}$ = 6.9 Hz, OCH_2CH_2S); 2.40 (broad t, 1H, $^3J_{HH}$ = 5.8 Hz, OCH_2CH_2OH).

Methanesulfonyl chloride (47 μL, 0.60 mmol) was added to a stirred solution of tetrahydrofuran (12 mL),

2-{2-[2-(2-tritylsulfanylethoxy)ethoxy]ethoxy}ethanol (227 mg, 0.500 mmol), and triethylamine (139 μL, 1.00 mmol). After stirring for 2 h, the mixture was filtered and concentrated. The residue was purified by flash chromatography (ethyl acetate) affording **3** as a colorless oil (238 mg, 90%). ^{1}H NMR (chloroform-*d*, 300 MHz): 7.38−7.45 (m, 6H, trityl *o*-H); 7.17−7.32 (m, 9H, trityl *m*-H and *p*-H); 4.33−4.37 (m, 2H, S(O)$_2$O*CH*$_2$CH$_2$O); 3.71−3.77 (m, 2H, S(O)$_2$OCH$_2$*CH*$_2$O); 3.58−3.68 (m, 4H, O*CH*$_2$*CH*$_2$O); 3.41−3.58 (m, 4H, O*CH*$_2$*CH*$_2$O); 3.3 (t, 2H, O*CH*$_2$CH$_2$S, $^3J_{HH}$ = 6.9 Hz); 2.99 (s, 3H, CH$_3$S); 2.42 (t, 2H, OCH$_2$*CH*$_2$S, $^3J_{HH}$ = 6.9 Hz).

(2-{2-[2-(2-Fluoroethoxy)ethoxy]ethoxy}ethyl)trityl Sulfide 4. A stirring solution of **3** (71.7 mg, 0.14 mmol) and tetrabutylammonium fluoride (1.1 M in tetrahydrofuran, 127 μL, 0.14 mmol) was heated at 90 °C for 30 min. The solvent was evaporated, and the residue was purified by flash chromatography (ethyl acetate/hexane, 1/1) to give **4** as a colorless oil (45 mg, 70%). ^{1}H NMR (chloroform-*d*, 500 MHz): 7.40−7.45 (m, 6H, trityl *o*-H); 7.25−7.31 (m, 6H, trityl *m*-H); 7.25−7.31 (m, 3H, trityl *p*-H); 4.47−4.60 (d of m, 2H, $^2J_{HF}$ = 47.8 Hz, F*CH*$_2$CH$_2$O); 3.68−3.78 (d of m, 2H, $^3J_{HF}$ = 29.6 Hz, FCH$_2$*CH*$_2$O); 3.62−3.68 (m, 4H, O*CH*$_2$*CH*$_2$O); 3.44−3.60 (m, 4H, O*CH*$_2$*CH*$_2$O); 3.31 (t, 2H, $^3J_{HH}$ = 6.9 Hz, O*CH*$_2$-CH$_2$S); 2.44 (t, 2H, $^3J_{HH}$ = 6.9 Hz, OCH$_2$*CH*$_2$S); HRMS: found *m/z* = 472.2333 (M + NH$_4$)$^+$ for C$_{27}$H$_{31}$O$_3$SF calcd *m/z* = 472.2316.

Methanesulfonic Acid 4-[2-(Tritylsulfanyl)ethylcarbamoyl]benzyl Ester 5. To a stirred solution of cysteamine (3.85 g, 50.0 mmol) in trifluoroacetic acid (50 mL) was added triphenylmethanol (13.0 g, 50.0 mmol). The mixture was stirred at room temperature for 30 min and concentrated. After addition of diethyl ether (250 mL), the precipitate was filtered off and washed with diethyl ether (2 × 50 mL). The trifluoroacetic acid salt was partitioned between aqueous KOH solution (1 M, 150 mL) and diethyl ether (150 mL). The organic phase was dried (MgSO$_4$) and *S*-tritylcysteamine was crystallized from diethyl ether/*n*-hexane to give a white solid (9.2 g, 58%). ESI-MS: *m/z* = 243 (M − Ph)$^{\bullet+}$; ^{1}H NMR (chloroform-*d*, 500 MHz): 7.41−7.44 (m, 6H, trityl *o*-H); 7.25−7.30 (m, 6H, trityl *m*-H); 7.19−7.23 (m, 3H, trityl *p*-H); 2.60 (t, 2H, $^3J_{HH}$ = 6.6 Hz, CH$_2$N); 2.32 (t, 2H, $^3J_{HH}$ = 6.6 Hz, CH$_2$S); 1.07 (broad s, 2H, NH$_2$).

To a solution of *S*-trityl cysteamine (1.6 g, 5.0 mmol) and 4-hydroxymethylbenzoic acid pentafluorophenyl ester (1.5 g., 5.0 mmol) in dichloromethane (40 mL) was added *N*-methylmorpholine (0.55 mL, 5.0 mmol). After stirring at room temperature for 36 h, the precipitate was filtered off, washed with dichloromethane (3 × 5 mL), and dried to give 4-hydroxymethyl-*N*-[2-(tritylsulfanyl)-ethyl]benzamide as a white solid (1.3 g, 57%). ESI-MS: *m/z* = 476 (M + Na$^+$); ^{1}H NMR (DMSO-d_6, 500 MHz): 8.53 (t, 1H, $^3J_{HH}$ = 5.7 Hz, NH); 7.75−7.79 (m, 2H, OCH$_2$*C*$_6$*H*$_4$CO); 7.36−7.40 (m, 2H, OCH$_2$*C*$_6$*H*$_4$CO); 7.29−7.35 (m, 12H, trityl *o*-H and *p*-H); 7.22−7.28 (m, 3H, trityl *p*-H); 5.29 (t, 1H, $^3J_{HH}$ = 5.6 Hz, OH); 5.54 (d, 2H, $^3J_{HH}$ = 5.6 Hz, CH$_2$O); 3.23 (d of t, 2H, $^3J_{HH}$ = 5.7 Hz, $^3J_{HH}$ = 7.1 Hz, CH$_2$N); 2.33 (t, 2H, $^3J_{HH}$ = 7.1 Hz, CH$_2$S).

To a solution of 4-hydroxymethyl-*N*-[2-(tritylsulfanyl)-ethyl]benzamide (226 mg, 0.50 mmol) in anhydrous tetrahydrofuran (8 mL) were added *N*-methyl-2-pyrrolidinone (61 μL, 0.55 mmol) and methanesulfonyl chloride (85 μL, 1.1 mmol). The reaction mixture was stirred for 48 h at room temperature and filtered through silica. Purification by column chromatography (silica, 1% methanol in chloroform) gave **5** as an oil that solidified slowly on storage (213 mg, 80%). ^{1}H NMR (chloroform-*d*, 500 MHz): 7.72−7.76 (m, 2H, OCH$_2$*C*$_6$*H*$_4$CO); 7.46−7.50 (m, 2H, OCH$_2$*C*$_6$*H*$_4$CO); 7.40−7.44 (m, 6H, trityl *o*-H); 7.24−7.30 (m, 6H, trityl *m*-H); 7.19−7.24 (m, 3H, trityl *p*-H); 6.23 (broad t, 1H, $^3J_{HH}$ = 5.7 Hz, NH); 5.28 (s, 2H, CH$_2$O); 3.30 (d of t, 2H, $^3J_{HH}$ = 5.7 Hz, $^3J_{HH}$ = 6.2 Hz, CH$_2$N); 2.55 (t, 2H, $^3J_{HH}$ = 6.2 Hz, CH$_2$S); 2.97 (s, 3H, CH$_3$S).

4-Fluoromethyl-*N*-[2-(tritylsulfanyl)ethyl]benzamide 6. A solution of Kryptofix (15 mg, 40 μmol) in anhydrous acetonitrile (0.2 mL) was added to solid potassium fluoride (2.3 mg, 80 μmol). The mixture was shaken for 5 min and added to **5** (21 mg, 40 μmol) in acetonitrile (0.4 mL) followed by heating at 65 °C for 10 min. Product **6** was isolated by preparative HPLC [Phenomenex Luna C18 (2) column, 250 × 21.2 mm, 5 μm; gradient 40−80% solvent B over 10 min; flow rate 10 mL/min] as a white solid (4.5 mg, 25%). ^{1}H NMR (chloroform-*d*, 500 MHz): 7.71−7.75 (m, 2H, FCH$_2$*C*$_6$*H*$_4$CO); 7.42−7.44 (m, 2H, FCH$_2$*C*$_6$*H*$_4$CO); 7.40−7.44 (m, 6H, trityl *o*-H); 7.24−7.29 (m, 6H, trityl *m*-H); 7.19−7.23 (m, 3H, trityl *p*-H); 6.23 (broad t, 1H, $^3J_{HH}$ = 5.8 Hz, NH); 5.44 (d, 2H, $^2J_{HF}$ = 47.4 Hz, CH$_2$F); 3.65 (d of t, 2H, $^3J_{HH}$ = 5.8 Hz, $^3J_{HH}$ = 6.5 Hz, CH$_2$N); 2.55 (t, 2H, $^3J_{HH}$ = 6.5 Hz, CH$_2$S); HRMS: found *m/z* = 478.1624 (M + Na)$^+$ for C$_{29}$H$_{26}$OSF calcd *m/z* = 478.1611.

6-Amino-2-{2-[2-(2-{6-amino-2-[2-(3-fluoropropylsulfanyl)acetylamino]hexanoylamino}acetylamino)-3-phenylpropionylamino]acetylamino}hexanoic Acid (^{19}F-8). The trityl compound **2** (1 mg, 3 μmol) was deprotected with a mixture of trifluoroacetic acid (25μL), triisopropylsilane (5 μL), and water (5μL) at room temperature for 5 min. The mixture was cooled to 0 °C, a solution of ClAc-KGFGK-OH (3.6 mg, 6 μmol) in water (1 mL) added, followed by adjusting the pH to 9 (25% ammonia), and heating for 30 min at 60 °C. Product ^{19}F-**8** was isolated by preparative HPLC [Phenomenex C18(2) column, 250 × 10 mm, 10 μm; gradient 0−30% solvent B in 30 min; flow rate 5 mL/min; λ = 254 nm] with 0.5 mg (20%) yield. The labeled peptide was characterized by LC-MS [Phenomenex Luna C18(2) column, 50 × 4.6 mm, 3 μm, gradient 0−30% solvent B in 30 min; flow rate 1 mL/min; λ = 214 and 254 nm, R_f = 6.88 min, *m/z* = 670.35 (M + H)$^+$]; HRMS: found *m/z* = 670.3410 (M + H)$^+$ for C$_{30}$H$_{48}$N$_7$O$_7$FS calcd *m/z* = 670.3393.

6-Amino-2-{2-[2-(2-{6-amino-2-[2-(2-{2-[2-(2-fluoroethoxy)ethoxy]ethoxy}ethylsulfanyl)acetylamino]-hexanoylamino}acetylamino)-3-phenylpropionylamino]acetylamino}hexanoic Acid (^{19}F-10). To a vial containing trityl compound ^{19}F-**4** (1.2 μmol) was added a trifluoroacetic acid/triisopropylsilane/water mixture (95:2.5:2.5 v/v/v, 130 μL). After gentle agitating for 5 min, the mixture was concentrated in vacuo and sodium carbonate/bicarbonate buffer (0.1 M, pH 9.1, 0.1 mL) was added followed by a solution of ClAc-KGFGK-OH (3.6 mg, 6.0 μmol) in sodium carbonate/bicarbonate buffer (0.1 M, pH 9.1, 0.15 mL). The coupling product ^{19}F-**10** was purified by preparative HPLC [Phenomenex Luna C18(2) column, 250 × 10 mm, 10 μm; gradient 40−80% solvent B over 30 min; flow rate 5 mL/min] giving a yield of 4.0 mg (42%). The labeled peptide ^{19}F-**10** was characterized by MALDI-MS, *m/z* = 788 (M + H)$^+$; HRMS: found *m/z* = 788.4061 (M + H)$^+$ for C$_{35}$H$_{58}$N$_7$O$_{10}$FS calcd *m/z* = 788.4023.

6-Amino-2-(2-{2-[2-(6-amino-2-{2-[2-(4-fluoromethylbenzoylamino)ethylsulfanyl]acetylamino}hexanoylamino)acetylamino]-3-phenylpropionylamino}-acetylamino)hexanoic Acid (^{19}F-12). The labeled peptide ^{19}F-**12** was synthesized using the protocol for the preparation of ^{19}F-**10**.

The coupling product ^{19}F-**12** was purified by preparative HPLC [Phenomenex Luna C18(2) column, 250 × 21.2

mm, 5 μm; gradient 5−60% acetonitrile over 60 min; flow rate 10 mL/min] yielding 2 mg (42%) of a white solid. The labeled peptide was characterized by LC-MS [Phenomenex Luna C18(2) column, 50 × 4.6 mm, 3 μm; gradient 5−60% acetonitrile over 10 min; flow rate 0.3 mL/min, t_R = 4.3 min, m/z = 789.4 ($M + H^+$)]; HRMS: found m/z = 789.3743 $(M + H)^+$ for $C_{37}H_{53}N_8O_8SF$ calcd m/z = 789.3764.

Radiochemistry. Chemicals. Chemicals including anhydrous solvents were purchased from Sigma-Aldrich (Gillingham, UK). HPLC solvents were received from Fisher Scientific (Loughborough, UK).

Production of ^{18}F. Fluorine-18 was produced by a Scanditronix MC 40 cyclotron using the $^{18}O(p,n)^{18}F$ reaction. Enriched [^{18}O]H_2O (10−30% ^{18}O) was irradiated by protons (19 MeV) with an integrated beam current of 5−10 μAh.

HPLC. The HPLC system was a Beckman System Gold instrument equipped with a gamma detector (Bioscan Flow-count). A Phenomenex Luna C18(2) column (50 × 4.6 mm, 3 μm; flow rate 1 mL/min) was used for analytical HPLC. A semipreparative column [Phenomenex Luna C18(2), 250 × 10 mm, 5 μm; flow rate 4 mL/min] was used for the final purification of labeled peptides. The following mobile phase/gradient systems were used: solvent A: water (0.1%) TFA, solvent B: acetonitrile (0.1% TFA).

gradient 1: 1 min 40% B, 40−80% B in 15 min

gradient 2: 1 min 30% B, 30−80% B in 10 min

gradient 3: 1 min 30% B, 5−30% B in 20 min, 30−80% B in 5 min

gradient 4: 1 min 0% B, 0−30% B in 10 min

3-[^{18}F]Fluoro-1-mercaptotritylpropane (^{18}F-2). Fluorine-18 containing water (370 MBq, 1 mL) was added to a Wheaton vial (2 mL), charged with Kryptofix 222 (10 mg, 27 μmol), potassium carbonate (1 mg, 7 μmol, dissolved in 50 μL water), and acetonitrile (0.8 mL). The solvent was removed by heating at 110 °C for 1 h under a stream of nitrogen. Anhydrous acetonitrile (0.5 mL) was added and again evaporated as before. This step was repeated twice. The vial was cooled to room temperature followed by injecting a solution of **1** (1 mg, 2.4 μmol) in anhydrous DMSO (0.2 mL). The reaction mixture was stirred at 80 °C for 5 min and analyzed by HPLC (gradient 1, t_R = 16.2 min).

The reaction mixture was diluted with DMSO/water (1:1 v/v, 0.15 mL) and loaded onto a SepPak-Plus cartridge (^{t}C18, Waters) that had been conditioned (10 mL acetonitrile, 20 mL water). The cartridge was washed with water (10 mL) and the ^{18}F-**2** eluted using acetonitrile.

2-{2-[2-(2-[^{18}F]Fluoroethoxy)ethoxy]ethoxy}mercaptotritylethane (^{18}F-4). This preparation was carried out from **3** as described for ^{18}F-**2**. The reaction mixture was analyzed by HPLC (gradient 2, t_R = 12.6 min).

3-[^{18}F]Fluoromethyl-*N*-(2-mercaptotritylethyl)-benzamide (^{18}F-6). Again, ^{18}F-**6** was prepared as described for ^{18}F-**2**. The mesylate precursor **5** was stirred at room temperature for 15 min to give ^{18}F-**6** as analyzed by HPLC (gradient 1, t_R = 13.6 min).

6-Amino-2-{2-[2-(2-{6-amino-2-[2-(3-[^{18}F]fluoropropylsulfanyl)acetylamino]hexanoylamino}acetylamino)-3-phenylpropionylamino]acetylamino}hexanoic Acid (^{18}F-8). A solution of ^{18}F-**2** in acetonitrile (72 MBq, 0.5 mL) was evaporated to dryness using a stream of nitrogen and heating at 100 °C. A mixture of trifluoroacetic acid (0.05 mL), triisopropylsilane (0.01 mL), and water (0.01 mL) was added followed by heating for 10 min at 80 °C. The resulting thiol ^{18}F-**7** was not isolated (analytical HPLC: gradient 1, t_R = 2.5 min,). After the vial was cooled to 0 °C, ammonia (28% in water, 0.1 mL, Aldrich), TCEPxHCl (38 mg, 1.3 μmol, Aldrich) and peptide precursor ClAc−KFGFK−OH (2 mg, 3.2 μmol) in water (0.05 mL) were added. The mixture was stirred for 30 min at 80 °C. After diluting with 0.2 mL of water/MeCN/TFA (95:5:0.1 v/v/v), the mixture was purified on a semipreparative HPLC (gradient 3, t_R = 19.2 min) and analyzed by analytical HPLC (gradient 4, t_R = 10.3 min).

6-Amino-2-{2-[2-(2-{6-amino-2-[2-(2-{2-[2-(2-[^{18}F]-fluoroethoxy)ethoxy]ethoxy}ethylsulfanyl)acetylamino]hexanoylamino}acetylamino)-3-phenylpropionylamino]acetylamino}hexanoic Acid (^{18}F-10). The preparation of ^{18}F-**10** was carried out from ^{18}F-**4** following the method described for ^{18}F-**8**. The labeled peptide ^{18}F-**10** was isolated by semipreparative HPLC (gradient 3, t_R = 19.8 min).

6-Amino-2-(2-{2-[2-(6-amino-2-{2-[2-(4-[^{18}F]fluoromethylbenzoylamino)ethylsulfanyl]acetylamino}-hexanoylamino)acetylamino]-3-phenylpropionylamino}acetylamino)hexanoic Acid (^{18}F-12). The labeled peptide ^{18}F-**12** was synthesized from ^{18}F-**6** using the protocol for the preparation of ^{18}F-**8**. The product ^{18}F-**12** was obtained from semipreparative HPLC (gradient 3, t_R = 22.8 min).

Stability Test of ^{18}F-7. ^{18}F-**2** was deprotected as described above and dispensed in two conical vials A and B (1 MBq in 20 μL each). A yield of 70% deprotection product ^{18}F-**7** was established by HPLC analysis. A solution of TCEP × HCl (10 μL, 2.7 μmol) was added to vial A, followed by ammonia (50 μL, 28%). Ammonia (50 μL, 28%) was also added to vial B. After 1 h at room temperature, aliquots (10 μL) of both vials were analyzed by HPLC. Vial A showed 43% of thiol ^{18}F-**7** preserved with an increased peak at the solvent front. Numerous radioactive products but no signal for ^{18}F-**7** were found in vial B.

ACKNOWLEDGMENT

We would like to thank Colin Steel and the cyclotron operators of Hammersmith Imanet Ltd. for providing us with fluorine-18.

Streptavidin in Antibody Pretargeting. 4. Site-Directed Mutation Provides Evidence That Both Arginine and Lysine Residues Are Involved in Kidney Localization

D. Scott Wilbur,*,† Donald K. Hamlin,† James Sanderson,† and Yukang Lin§

Department of Radiation Oncology, University of Washington, Seattle, Washington 98195, and Fred Hutchinson Cancer Research Center, Seattle Washington 98109. Received June 5, 2004;
Revised Manuscript Received October 4, 2004

The in vivo application of the protein streptavidin is limited by its propensity to localize to kidney, particularly when it is used as a carrier of radionuclides in Targeted Radionuclide Therapy. Our previous studies demonstrated that modification of recombinant "core" streptavidin (rSAv) by reaction of lysine residues with succinic anhydride and arginine residues with 1,2-cyclohexanedione dramatically decreases the kidney concentrations over that obtained with wild-type rSAv. In this investigation, we explored the role of lysine and arginine residues in kidney localization further by evaluating site-directed mutants of rSAv. In the five mutants studied, the four lysine residues found in each subunit of rSAv were replaced (independently) with an alanine (K80A, K121A, K132A, K134A), and a specific arginine was replaced with a histidine (R59H). The rSAv mutants were prepared from a "core" rSAv construct produced by expression in *E. coli* that had 124 amino acids (residues 13−136). Another rSAv construct that had 127 amino acids (residues 13−139), used in most of our previous studies, was also included for comparison. As an additional comparison, succinylated rSAv was prepared and evaluated. The rSAv proteins were radioiodinated and injected into athymic mice that were on a biotin-free diet for 5−7 days prior, and biodistribution data were obtained (for most proteins) at 1, 4, 24, and 48 h postinjection. The data obtained show large differences in kidney localizations of the wild-type rSAv and some rSAv mutants. The largest difference in the kidney concentration was noted for the rSAv-K134A mutant (1.90 ± 0.22%ID/g; 24 h pi) as compared to the wild-type rSAv (31.83 ± 5.26%ID/g) at the same time point. The concentration of rSAv-K134A mutant in kidney was slightly lower than that obtained with succinylated rSAv. At the 24 h time point, the kidney concentrations of the rSAv-R59H mutant (8.95 ± 2.94%ID/g) and the rSAv-K121A mutant (11.86 ± 1.61%ID/g) were lower than wild-type rSAv, but the rSAv mutants rSAv-K80A (27.95 ± 1.82%ID/g) and rSAv-K132A (32.50 ± 10.09%ID/g) were essentially the same. The data suggests that specific lysine and arginine residues are involved in kidney localization. Possible mechanisms for the observed kidney localization are discussed.

INTRODUCTION

The very high binding affinity (10^{13}−10^{15} M^{-1}) of the egg white protein avidin (Av)[1] (*2*) and the bacterial protein streptavidin (SAv) (*3*) with biotin make them valuable chemical tools for a wide variety of applications. While most of the applications developed thus far are in vitro assays (*4*−*10*), in vivo applications are also being developed. For in vivo applications, protease resistant "core" recombinant SAv (rSAv) is being used (*11*). An inherent problem for use of the proteins Av and rSAv in vivo is their propensity to localize to kidney and liver. Importantly, there is a marked difference in the in vivo characteristics of the two proteins. Av clears rapidly from blood and is localized in both kidney and liver, whereas rSAv clears from blood more slowly and localizes primarily in kidney (*12*, *13*). The difference in pharmacokinetics and tissue localization of these similar proteins comes from Av being glycosylated and having a much higher pI than SAv (i.e. pI ∼10 vs 6−7). Deglycosylation of Av makes it more homogeneous (*3*) and results in blood clearance that is similar to rSAv, but the high pI can cause nonspecific interaction with tissues. Therefore, SAv is often considered more attractive for in vivo applications.

The natural propensity for SAv to localize to kidney is problematic for its use in vivo, except perhaps in some unique applications (*14*). We are investigating the use of SAv in an approach to cancer therapy termed "pretargeting" (*15*−*18*). In those studies, SAv is radiolabeled and injected into mice bearing human prostate tumor xenografts, which have been pretargeted with a biotinylated antibody or antibody fragment (*19*). While we demonstrated that an equal molar quantity of radiolabeled rSAv can bind with the biotinylated antibody on the tumor, a majority of the radiolabeled rSAv localizes to kidney. In this situation, the high concentration of

radioactivity in the kidney precludes administration of an adequate quantity of a radionuclide to kill the tumor due a dose-limiting toxicity in the kidney. For this reason, we are investigating methods for alleviating the kidney localization of rSAv. In prior studies, we demonstrated that chemical modification of lysine amines by reaction with succinic anhydride (*20*) and modification of arginine guanidine groups by reaction with 1,2-cyclohexanedione (*21*) on rSAv resulted in decreased kidney concentrations with minimal affect on biotin binding.

An alternative method for modifying lysine and arginine residues in rSAv is to conduct site-directed mutations in which lysine and arginine residues are replaced with other amino acids. Indeed a large number of site-directed mutations of rSAv have been conducted with truncated or "core" SAv (*11*, *22*) to probe interactions in the biotin-binding pocket (*23*−*28*) and produce mutants with desirable properties for specific applications (*29*−*36*). As rSAv is made up of four identical subunits (*3*), site-directed mutation of one amino acid results in changing four amino acids in the tetrameric intact molecule. Importantly, decreased kidney concentrations were observed in previous studies involving high specific activity (i.e. very low concentration) acylation of lysine residues with the reagent, *p*-[^{125}I]iodobenzoate *N*-hydroxysuccinimide ester, suggesting that modification of only one lysine residue per subunit might be required to decrease the kidney localization (*13*). It was reasoned that site-directed mutations which replace only one of the four lysines at a time could provide information as to whether this observation was correct, and if it were, identify which residue was responsible for kidney localization. Additionally, it had been postulated that kidney localization may be due to the ^{59}RYD^{61} sequence in SAv (*37*). As previously mentioned, modification of arginine residues with 1,2-cyclohexanedione demonstrated that kidney localization was dramatically decreased (*21*). Thus, site-directed mutation of that specific arginine[2] (R59) might also provide confirmation that arginine was involved in kidney localization of rSAv. On the basis of these considerations, we have conducted an investigation in which the four lysine residues in each streptavidin subunit (K80, K121, K132, K134) were replaced with alanine residues, and the arginine residue of interest (R59) was replaced with a histidine residue. Following production of the rSAv mutants, they were radioiodinated and injected into athymic mice, and their concentrations in tissues (including kidney) were assessed at selected times (e.g. 1, 4, 24, and 48 h) postinjection (pi). The experimental methods used, and results obtained, in that investigation are described herein.

EXPERIMENTAL PROCEDURES

General. All chemicals purchased from commercial sources were analytical grade or better and were used without further purification. Chloramine-T (ChT) and phosphate-buffered saline (PBS) were obtained from Sigma (St. Louis, MO). Recombinant streptavidin was obtained from Boehringer Mannheim (Indianapolis, IN). Iminobiotin affinity matrix was obtained from Pierce Chemical (Rockford, IL). Solvents for HPLC analyses were obtained as HPLC grade and were filtered (0.2 μm) prior to use. The biotin derivative containing the cyanocobalamin chromophore (biotin-CNCbl) was obtained[3] as previously described (*38*). Rhodamine-derivatized biotin (biotin-Rhd) was prepared as previously described (*39*). Biotin deficient diet chow with 10% egg white solids (TD 96343) was obtained from Harlan Teklad (Madison, WI, www.harlan.com). Centricon-10 and -30 centrifugation concentrators were obtained from Amicon (Beverly, MA). PD-10 and NAP-10 (Sephadex G-25) size-exclusion columns were obtained from Amersham Pharmacia Biotech AB (Uppsala, Sweden).

Na[^{125}I]I and Na[^{131}I]I were purchased from Perkin-Elmer Life and Analytical Sciences (formerly NEN/Dupont, Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I and ^{131}I was accomplished on the Capintec CRC-15R. Tissue samples were counted in a Wallac 1480 Wizard gamma counter with the following window settings: 15−85 keV for I-125 and 260 to 430 keV when ^{125}I and ^{131}I are counted together. The ^{125}I counts are compensated for spillover counts from the ^{131}I in the calculations.

Chromatography. FPLC purifications of the rSAv's were performed on a Pharmacia 2000 FPLC system fitted with a 280 nm detector. Expression level and purification recovery were determined using biotin-Rhd binding (*39*) in conjunction with size exclusion separation on a Zorbax GF-250 column (Dupont) run at 1.0 mL/min using a mobile phase of 20 mM sodium phosphate, pH 7, containing 15% DMSO, 1 mM sodium azide, and 500 mM sodium chloride. The effluent was monitored at 547 nm using a Varian Dynamax PDA-2 detector, and the peak area corresponding to the rSAv elution was determined using a Varian Dynamax HPLC Data System (Walnut Creek, CA).

HPLC separations of the modified rSAv were conducted on a Hewlett-Packard isocratic system consisting of a Model 1050 pumping system and a Model 1050 Multiple Wavelength Detector (280 nm). Proteins were evaluated on a Protein Pak 300 SW glass size-exclusion column (10 μm, 8 mm × 30 cm, Waters Corporation, Milford, MA) run at 1.0 mL/min eluting with 50 mM sodium phosphate buffer (pH 6.8) which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Analyses of the HPLC data were conducted on Hewlett-Packard HPLC ChemStation software.

Radiolabeled Proteins. Size-exclusion chromatography was also used to evaluate radioiodinated rSAv. HPLC separations of radioiodinated proteins were conducted on a system that consisting of a Model 1050 pumping system, a Waters Lambda-Max 481 UV detector, and a Beckman model 170 radioisotope detector. The detectors were connected to a computer through a Hewlett-Packard Model 35900 interface, and data from the chromatograms was obtained on a computer running Hewlett-Packard ChemStation Software. The same size-exclusion column and elution conditions were used for the radiolabeled proteins as unlabeled proteins.

Mass Spectral Analyses. Electrospray mass spectra were obtained by atmospheric pressure chemical ionization on a Micromass Quattro II Tandem Quadrupole Mass Spectrometer (Micromass Ltd., Manchester, U.K.). The sample was introduced by direct injection. The mass spectral data was obtained on a PC running Windows NT based Micromass MaxEnt software. Prior to the mass spectral analyses, rSAv proteins were desalted. In the desalting procedure, 100 μL of a SAv in PBS solution was placed on a NAP-10 column that was equilibrated with deionized water. The column was eluted with deionized water, and the protein fractions were combined. The combined fractions were placed in a Centricon-30 ultrafiltration apparatus, concentrated, and washed three times with 1 mL of deionized water. The filtered solution was then concentrated to yield approximately 1 mg/mL of protein.

Preparation of Streptavidin Mutants. Preparation of wild-type rSAv, rSAv mutants[2] R59H, K80A, K121A, K132A, and K134C was accomplished in four steps: (1) construction of the rSAv mutant gene, (2) expression of rSAv mutant in *E. coli*, (3) refolding of rSAv proteins, and (4) purification. The procedures used in each step follow.

(1) The site-directed mutagenesis was performed using the QuickChange kit (Stratagen, La Jolla, CA). Plasmid A140−9, which contains the wild-type of core SAv gene in a pET3a vector (Novagen, Madison, WI) was the starting construct. The reactions were carried out in 50 μL of supplied reaction mixture containing 400 nM of each oligonucleotide primer and 100 ng of plasmid DNA. Reactions were performed on a PTC-100 thermal cycler (MJ Reaction, Waltham, MA) with 1 cycle of 95 °C for 30 s and 17 cycles of the following profile: 95 °C for 30 s; 55 °C for 1 s; 68 °C for 12 min. The reaction mixture (3 μL) was used to transform *E. coli* XL-1 Blue competent cells (60 μL, Statagene). Plasmid DNA were prepared from cultures of the transformants using a QIAprep Spin Miniprep kit (Qiagen, Valencia, CA). The sequences were confirmed using a Big Dye terminator cycle sequencing kit (Applied Biosystems, Foster City, CA).

(2) Cultures of the plasmid-containing *E. coli* BL21 (DE3) pLysS (Novagen) were grown in shake flasks overnight at 37 °C in Terrific broth (40 mL; Invitrogen, Carlsbad, CA) containing 50 μg/mL of carbenicillin (Sigma Chemical, St. Louis, MO). The cultures were diluted ~100-fold into fresh media (8 × 500 mL) contained in 2 L shake flasks and were grown until the cultures reached an optical density of 0.3−0.6 at 600 nm. At that point, isopropyl β-D-thiogalactopyranoside (Amersham Pharmacia Biotech Inc., Piscataway, NJ) was added to a final concentration of 0.5 mM. Incubation was continued for an additional 16 h. Cells were harvested by centrifugation at 4000*g* for 10 min at 10 °C and then washed twice with PBS (7 mM Na_2HPO_4, 150 mM NaCl, pH 7.0) before processing.

(3) Cell pellets were resuspended in ice-cold TE (30 mM Tris, 1 mM EDTA at pH 8.0) at 25% w/v. The cells were disrupted through two cycles of microfluidization (M-110S, Microfluidics International, Newton, MA). The inclusion bodies were recovered by centrifuging the suspension at 15 000*g* for 90 min at 10 °C, and then the supernatant was discarded. Recovery of the mutants from the pelleted inclusion bodies was performed as described in the literature (*35*). Briefly, a microfluidized pellet was resuspended in 8 mL of ice-cold 8 M guanidine-HCl at pH 1.5 per liter of cell culture. The resuspension was dialyzed at 5−10 °C against 6 M guanidine-HCl at pH 1.5 to remove endogenous biotin. The dialysate was centrifuged at 10 000*g* for 20 min, and then the supernatant was added dropwise to vigorously stirred, ice-cold refolding buffer (4 mM KH_2PO_4, 16 mM Na_2HPO_4, 115 mM NaCl at pH 7.0) using a volume of at least 31× that of the supernatant volume. The suspension was incubated at 4 °C overnight without stirring, and spun at 7000*g* for 5 min at 10 °C. The pellet was discarded.

(4) Prior to loading on the iminobiotin affinity column, the supernatant (from above) was adjusted to 50 mM glycine, 500 mM NaCl at pH 9.6, using concentrated stock. Conductivity was adjusted to 46−48 mSiemens/cm with deionized water, and the solution was filtered through a 2 μm membrane overlaid with a thin film of Cell Pure P-100 diatomaceous earth. The iminobiotin matrix was packed in a column and was equilibrated in 50 mM glycine, 500 mM NaCl at pH 9.6. The capacity for rSAv was >2 mg/mL bed volume under a flow of 3 mL/cm^2/min. The refolded rSAv mutant was loaded at room temperature onto a column which contained 150 mL of matrix bed volume per 75 g of cells. After washing with 20-bed volumes of 50 mM glycine, 500 mM NaCl at pH 9.6, the rSAv was eluted using 0.2 M sodium acetate, 0.1 M NaCl at pH 4.0. The eluate was neutralized to pH 7 with 300 mM Tris buffer (pH 8.0) and then exhaustively dialyzed in PBS at 4 °C. It was subsequently sterile filtered for refrigerated storage at 4 °C. Samples from the refolding and purification steps were run on 4−20% SDS−PAGE gels (Invitrogen, Carlsbad, CA) to qualitatively assess the rSAv expression levels and recovery of the tetrameric rSAv mutants. Quantitative assessment was performed using biotin-Rhd by size-exclusion chromatography. The final concentration of rSAv was calculated by comparison with a rSAv standard analyzed under the same conditions.

Succinylation of Streptavidin. The succinylation reactions were conducted in a manner similar to that previously described (*20*). Briefly, a 200 μL aliquot of a 5 mg/mL solution of rSAv (1 mg, 1.9×10^{-2} μmol) was added to 370 μL of 50 mM $NaHCO_3$ buffer (pH 8.5). To this solution was added either 50 equiv (94 μg; 0.94 μmol) or 100 equiv (188 μg; 1.88 μmol) of succinic anhydride in 20 μL DMSO. After 30 min at room temperature, the contents were transferred to a Centricon-10 and concentrated to approximately 50 μL. PBS (500 μL) was added and the solution was again concentrated to 50 μL. This wash step was repeated five times. The final concentrations of protein (e.g. 3.2 mg/mL) and recovery yields (80−85%) were determined for each succinylation reaction.

Isoelectric Focusing. IEF were obtained on a Novex PowerEase 500 instrument with the XCell II chamber using Invitrogen (Novex) precast gels, pH 3−10 or pH 3−7 (1.0 mm × 12 well) running under the standard IEF Program. The protein was stained with GelCode Blue Stain (Pierce). IEF standards were from Serva Electrophoresis GmbH: pI = 10.7 − cytochrome C; 9.5 − ribonuclease A; 8.3, 8.0, 7.8 − lectin; 7.4, 6.9 − myoglobin; 6.0 − carbonic anhydrase; 5.3, 5.2 − β-lactoglobulin; 4.5 − trypsin inhibitor; 4.2 − glucose oxidase; 3.5 − amyloglucosidase.

Biotin-Binding Studies. Biotin binding studies were conducted using biotin-CNCbl[3] as previously described (*38*). Briefly, to 300 μL of a 1 mg/mL solution (300 μg; 5.65 nmol) of wild-type rSAv or a rSAv mutant in a plastic microcentrifuge vial was added a freshly prepared solution containing approximately 4 equiv (22.6 nmol) of biotin-CNCbl dissolved in 30 μL of 10% aqueous DMSO. The rSAv/biotin derivative mixture was incubated for 1 h at room temperature and 100 μL of the solution was assayed on the HPLC. To the remaining rSAv/biotin derivative solution was added 40 μL of a 1 mg/mL

[2] Single letter designations for amino acids are used for simplification. Some single letter designations used in this paper include the following: R, arginine; K, lysine; A, alanine; H, histidine; G, glycine; D, aspartic acid; Y, tyrosine. Single letter designations for amino acids can be found in biochemistry text books (*1*). Site-directed mutations are designated by the one letter code for the amino acid that was originally present, followed by the residue number of that amino acid and then the single letter designation for the replacement amino acid. For example the abbreviation R59H designates that the arginine residue at amino acid 59 was replaced with a histidine residue.

[3] The biotin-CNCbl reagent is commercially available from Quanta BioDesign (Powell, OH, www.quantabiodesign.com) as biotin-dPEG$_4$-cyanocobalamin.

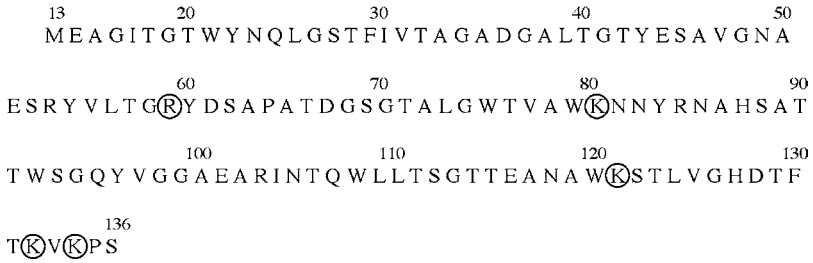

Figure 1. Amino acid sequence of the "core" streptavidin used. Wild-type rSAv (residues 13−136) has the sequence shown, with the exception that residue number 13, which is an alanine in native SAv, was replaced with a methionine to initiate translation. The amino acid residues where site-directed mutations were performed (R59H, K80A, K121A, K132A, K134A) are circled in the sequence.

solution (40 μg; 164 nmol) of biotin in 10% aqueous DMSO. That solution was incubated for 4 h and 100 μL was removed for analysis by HPLC. Areas under the peaks for bound and unbound biotin derivative were evaluated to determine if a change in the percent bound had occurred. Due to difficulties in assessing the quantity of rSAv mutant present, in some examples there was a slight excess (<10%) of the biotin-CNCbl that was not bound. The percent dissociation was adjusted for that material. Biotin binding capacity was additionally determined by incubation of the proteins with a 9-fold molar excess of [^{3}H]biotin [New England Nuclear/Sigma]. After the removal of unbound biotin using a PD-10 column, the amount of radioactivity associated with the protein was determined by liquid scintillation using a Hewlett-Packard beta counter.

Radioiodination of Proteins. Radioiodination reactions were conducted using chloramine-T as previously described (*13*). Radioiodination yields of ^{131}I-labeled rSAv (13−136) and of ^{131}I-labeled succinylated SAv ranged from 45 to 81%. Radioiodination yields for the rSAv mutants ranged from 28 to 72%.

Biodistributions. *General.* Animal use and procedures were approved by the University of Washington's Institutional Animal Care and Use Committee (IACUC). Animal care and use was conducted in accordance with the NIH guidelines.[4] Male athymic mice (BALB/c nu/nu), 4−5 weeks of age were obtained from Charles River Laboratories (Hollister, CA). All injections of reagents were administered to mice in a total volume of approximately 100 μL (injectate weighed) via the lateral tail vein. Injections and sacrifice of the animals were done at predetermined times. Tissues excised included muscle, lung, kidney, spleen, liver, intestine, neck (including thyroid), and stomach. A blood sample was obtained by cardiac puncture immediately before sacrifice. A urine sample was obtained by syringe bladder tap at the time the tissues were excised. Excised tissues were blotted free of blood, weighed, and counted. Calculation of the percent injected dose (%ID) and percent injected dose per gram (% ID/g) in the tissues was based on internal standards containing 1 μL of the injected dose. Total blood volume was estimated to be 8% of body weight for the calculations (*40*).

In the experiments, mice were placed on biotin-free diets for 5−7 days prior to beginning the study. Each mouse was injected with a mixture containing 15 μg of succinylated [^{131}I]rSAv and 15 μg of wild-type SAv or [^{125}I]-rSAv mutant, to result in a total of 30 μg protein per injection. The times for sacrifice, quantity of radioactivity injected for the mice, and experiment that the data was obtained from are described in the legend of Tables S1−S8 in the Supporting Information.

[4] NIH guidelines are described in NIH Publication 86-23: "Guide for the Care and Use of Laboratory Animals".

Molecular Modeling. The locations of, and distances between, the amino acid residues R59, K80, K121, K132, and K134 in core rSAv were modeled using ChemDraw 3D (version 8.0; CambridgeSoft, Cambridge, MA), and Swiss-PdbViewer/Deepview for OSX v3.71b1 (GlaxoSmithKline R&D and Swiss Institute of Bioinformatics, Geneva, Switzerland; http://www.expasy.org/spdbv/). The rSAv crystal structure used in the modeling came from the file 1SWE.pdb, which was obtained from the Research Collaboratory for Structural Bioinformatics (http://www.rcsb.org/pdb/). As the terminal amino acids were not observed in the crystal structure, the last three amino acids of both the N- and C-termini were added for illustration purposes. The ribbon/molecular structures provided as Figures S17 and S18 in the Supporting Information were prepared using the program iMol (v.0.30 www.pirx.com/iMol).

RESULTS

Modification of rSAv. Most previous studies in this laboratory employed rSAv purchased from Boehringer Mannheim (Indianapolis, IN). That "core" rSAv has 127 amino acids, which represent the amino acids that are found in residues 13−139 of the native SAv molecule. In this study, the rSAv (13−139) was used for comparison, but a slightly shorter rSAv construct of 124 amino acids was used to prepare the rSAv mutants. In the construct, the amino acid sequence is the same as found in residues 13−136 of the wild-type SAv molecule, except the amino terminal alanine was replaced with a translation-initiating methionine residue (A13M) as previously described (*35*). The shorter rSAv (13−136) was used in the site-directed mutagenesis to form the targeted rSAv mutants. The amino acid sequence of the rSAv (13−136) construct is shown in Figure 1.

Site-directed mutations of rSAv (13−136) were conducted by expression in *E. coli* using the standard techniques. All *E. coli* cultures produced between 66 and 90 g of cells per 4 L of media when grown overnight under the described shake flask conditions. Upon solubilization of inclusion bodies and subsequent refolding, wild-type rSAv expressed at 3 mg/g of cells (assessed by biotin-Rhd assay) were comparable to the levels reported in an earlier site-directed mutagenesis to reduce immunogenicity (*35*). Both rSAv-R59H and rSAv-K134A expressed at this same level while the rSAv mutants K80A, K121A, and K132A expressed at 39%, 59%, and 33% of wild-type, respectively. All mutant rSAv's bound and subsequently eluted from the iminobiotin affinity matrix in similar fashion, with comparable recoveries of 60−70%. Using the biotin-Rhd assay, no rSAv was detected in either the flow-thru or the wash. All of the purified rSAv preparations displayed a single band of molecular weight appropriate for tetrameric rSAv on SDS−PAGE. Upon boiling, all migrated as monomer.

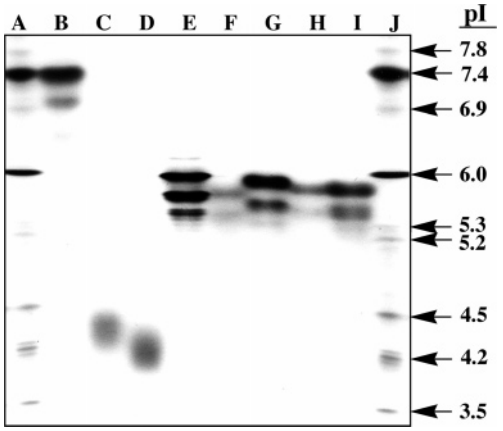

Figure 2. Digitized image of IEF gel comparing pI of unmodified rSAv, succinylated rSAv, and rSAv mutants. Lanes A and J: IEF standards (Serva IEF markers 3−7); Lane B: unmodified rSAv (control); Lane C: succinylated rSAv (50 equiv); Lane D: succinylated rSAv (100 equiv); Lane E: SAv mutant R59H; Lane F: SAv mutant K80A; Lane G: SAv mutant K121A; Lane H: SAv mutant K132A; Lane I: SAv mutant K134A.

Succinylated rSAv was prepared for comparison with the rSAv mutants. Previous studies demonstrated that succinylation of rSAv obtained from Boehringer Mannheim, when reacted with 50 equiv of succinic anhydride for 30 min at room temperature, had dramatically lower concentrations in kidney than the unmodified rSAv (*20*). In this investigation, an initial preparation of succinylated rSAv as previously described resulted in kidney concentrations considerably higher than expected. Evaluation of IEF and mass spectral data from that succinylated rSAv indicated that less modification of the lysines had occurred in the preparations than was obtained in previous studies (data not shown). Further investigation led to the finding that use of succinic anhydride which had been on the shelf for a long time (unknown period) did not give adequate reaction under the conditions employed to fully modify the lysine amines (unreported IEF data). Conducting the conjugation reaction of rSAv with newly obtained succinic anhydride under the standard reaction conditions provided a much higher percentage of lysine modification. Due to a concern about having the variances in the succinylated rSAv prepared, another preparation was made in which 100 equiv of succinic anhydride were reacted. Comparison of the pI values (Figure 2, lanes C and D) and mass spectra (Figures S15 and S16) of the rSAv modified with either 50 or 100 equiv of succinic anhydride clearly indicated that a higher percentage of lysines were modified using the larger quantity of succinic anhydride.

Characterization of Modified rSAv. Once isolated and purified, the rSAv, rSAv mutants, and succinylated rSAv were characterized by size-exclusion HPLC, mass spectral analyses, and isoelectric focusing (IEF) analyses. Size-exclusion HPLC chromatograms of rSAv(13−136) and the rSAv mutants R59H, K80A, K121A, K132A, and K134A all displayed single peaks that eluted with the same retention time (t_R = 10.3−10.4 min; Figures S1−S6 in Supporting Information). These data indicated that the tetrameric protein was formed and was likely to be the desired material. As previously noted (*21*), rSAv succinylated with 50 equiv of succinic anhydride eluted as a single peak with an earlier retention time (t_R = 9.84 min; Figure S7) than unmodified rSAv or its mutants, and rSAv succinylated with 100 equiv of succinic anhydride eluted at an even earlier retention time (t_R = 9.77 min; Figure S8).

Electrospray mass spectral analyses provided masses for monomeric subunits of rSAv (25% of molecular mass). The mass spectral data for the wild-type rSAv and rSAv mutants indicated that the correct compounds had been obtained (see Figures S9−S14 in Supporting Information). Mass spectral data obtained for rSAv succinylated using 50 equiv of succinic anhydride (Figure S15; Supporting Information) indicated that most subunits had three lysines modified, but that there were more protein subunits with only two lysines modified than there were with all four lysines modified. In contrast, when 100 equiv of fresh succinic anhydride was reacted with rSAv, the majority of rSAv subunits had three lysines modified, but a large number had four lysines modified and only a few subunits had just two lysines modified (Figure S16; Supporting Information).

IEF analyses were conducted on rSAv, succinylated rSAv, and rSAv mutants. A digitized scan of an IEF gel (pH 3−7) is shown in Figure 2. The wild-type rSAv (lane B) has a pI range 7.0−7.4. Succinic anhydride reacts with the ϵ-amines of lysine residues, resulting in a change from a positive ammonium ion to an anionic carboxylate ion. Since there are four lysine amines in each of the four subunits, complete succinylation can change rSAv by 32 charge units. As previously observed, the pI of succinylated rSAv varied with the quantity of succinic anhydride reacted. When 50 equiv of succinic anhydride were reacted, the pI range is 4.3−4.5 (lane C) and decreased to a pI range of 4.1−4.4 (lane D) when 100 equiv were reacted. This result is consistent with the mass spectral data that indicates more of the lysine amines react when 100 equiv of succinic anhydride is used. Replacement of an arginine residue with a histidine residue or a lysine residue with an alanine changes the charge on each subunit by one (positive) unit. Therefore, a smaller change in charge on the rSAv is expected (4 positive units) when a mutation is made. In fact, a smaller change in pI is noted, as all of the rSAv mutants, rSAv-R59H (lane E), rSAv-K80A (lane F), rSAv-K121A (lane G), rSAv-K132A (lane H) and rSAv-K134A (lane I) have pI in the range of 5.5−5.9.

Assessment of biotin binding capacity of the rSAv mutants using saturating levels of ^{3}H-biotin indicated that all mutants bound the full complement of four biotins per tetrameric moiety. To compare biotin-binding affinity among the mutants, the degree of dissociation of a biotin-CNCbl, when challenged with a large excess of biotin, was determined. While only providing a qualitative assessment, this assay has been previously used to determine if modifications of biotin derivatives alters their binding with rSAv (*38*, *41*). No (or insignificant) differences were observed at 4 h post addition of the large excess of biotin (data not shown), indicating that all of the rSAv mutants retained high binding affinities.

Comparative Tissue Distribution Studies. Five biodistribution studies (A−E) were conducted in athymic mice to compare the tissue distributions of the site-directed rSAv mutants with the two "core" rSAv (13−136 and 13−139) and succinylated rSAv. An initial biodistribution study was conducted in which the unmodified wild-type [^{131}I]rSAv (13−136), succinylated [^{125}I]-rSAv (13−136), and the rSAv mutants ([^{125}I]rSAv-R59H; [^{125}I]rSAv-K80A; [^{125}I]rSAv-K121A; [^{125}I]rSAv-K132A; [^{125}I]-rSAv-K134A) were evaluated in athymic mice at 4 h pi. The purpose of the experiment (study A) was to determine if any of the rSAv mutants could be eliminated from further study by comparing the concentration of radioiodinated rSAv in kidney at the 4 h sacrifice time. While the data (Figure 3, 4 h) did not indicate that any of the

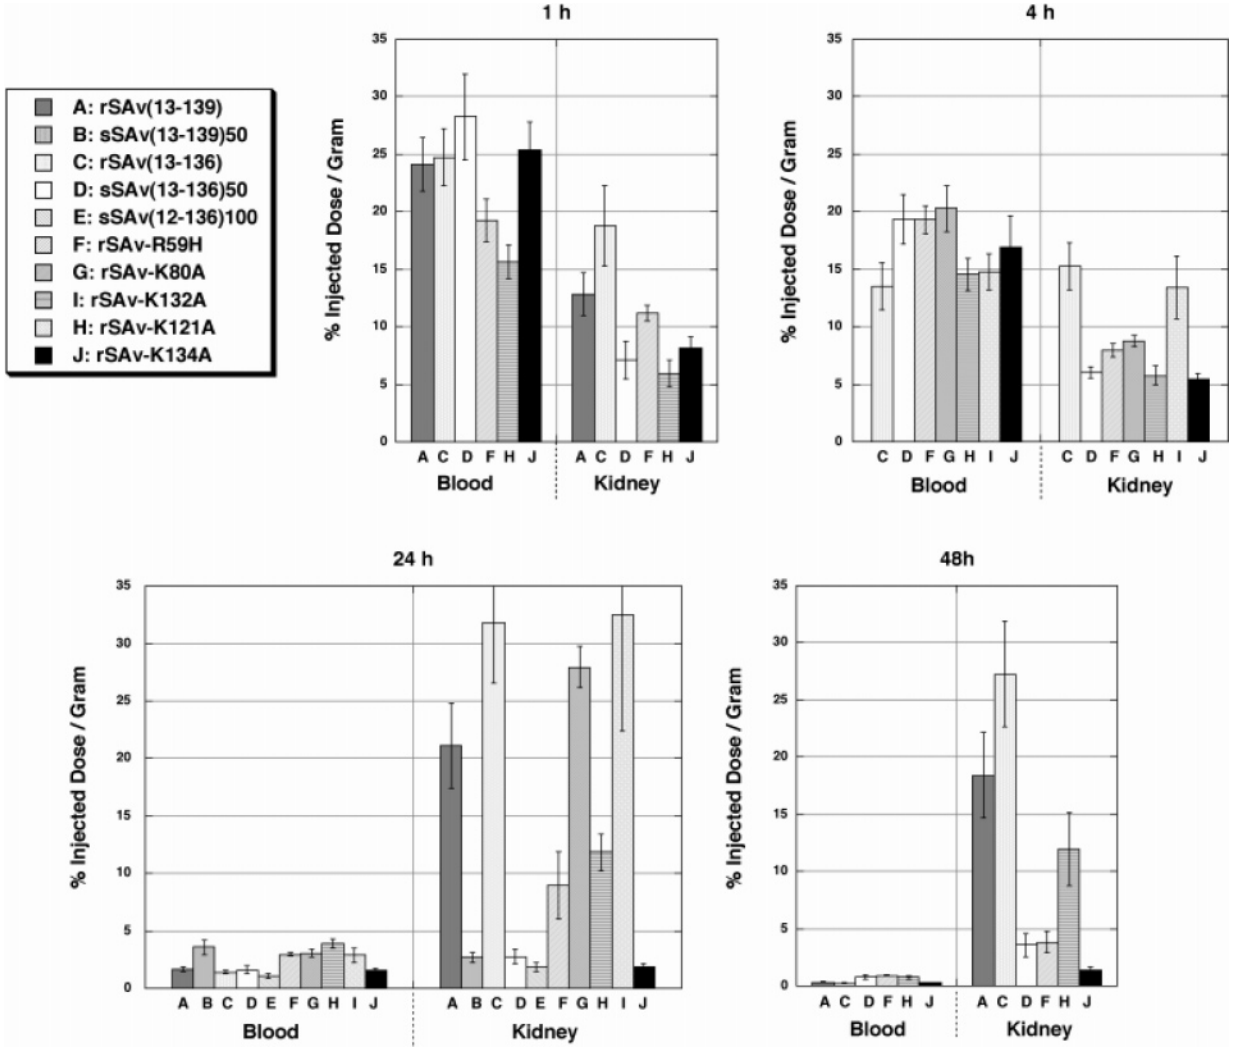

Figure 3. Bar graphs representing data obtained in biodistribution studies at 1, 4, 24, and 48 h after administration of reagents to athymic mice. Reagents studied are depicted as capital letters under the individual bars. The data plotted are for: (A), rSAv (13−139 from Boehringer Mannheim); (B), rSAv (13−139) succinylated with 50 equiv; (C), rSAv (13−136, expressed from *E. coli*); (D), rSAv(13−136) succinylated with 50 equiv; (E), rSAv(13−136) succinylated with 100 equiv; (F), rSAv-R59H; (G), rSAv-K80A; (H), rSAv-K121A; (I), rSAv-K132A; (J), rSAv-K134A. Data for some reagents (i.e. B, E, G, I) were obtained at only one or two time points, therefore the graphs do not have complete sets of reagents. All data were obtained from groups of five mice, except data obtained for G at 24 h and J at 48 h pi had four mice per group. Percent injected dose/gram data for all tissues excised are provided in Tables S1−S8 in Supporting Information.

rSAv mutants could be eliminated, we chose to evaluate [^{125}I]rSAv-K121A and [^{125}I]rSAv-K134A versus succinylated [^{131}I]rSAv next, as these rSAv mutants appeared to have the lowest concentrations in kidney at the 4 h pi time point. In that experiment (study B), the proteins were evaluated at 1, 24, and 48 h pi (4 h data was available from experiment A). In a subsequent experiment (study C) the mutant [^{125}I]rSAv-R59H was compared with succinylated [^{131}I]rSAv at the 1, 24, and 48 h time points. Due to obtaining higher than expected values for the succinylated rSAv in some experiments, an additional study comparing succinylated rSAv was conducted. In that experiment (study D), the biodistribution of succinylated [^{131}I]rSAv (13−139, from Boehringer Mannheim) was compared at 24 h pi with succinylated [^{125}I]rSAv (13−136; 50 and 100 equiv) along with the rSAv mutants [^{125}I]rSAv-K80A and [^{125}I]rSAv-K132A. In a further experiment (study E), the biodistribution of [^{131}I]rSAv (13−136) and [^{125}I]rSAv (13−139) were compared at 1, 24, and 48 h pi time points.

The data obtained from the biodistribution studies is provided in Tables S1−S8 in the Supporting Information, and the blood and kidney concentrations (%ID/g) at the four time points have been plotted in Figure 3. The bar graphs in Figure 3 (1, 4, 24, and 48 h panels) show clear differences in blood clearance and kidney localization between some of the rSAv proteins studied. Because the kidney concentration data obtained for rSAv-K80A and rSAv-K132 at 24 h pi (study D) was not different from unmodified rSAv, their biodistributions were not determined at 1 and 48 h pi. While blood concentrations of all the rSAv proteins studied decreased with time, kidney localization of unmodified rSAv (bars A and C) and rSAv mutants rSAv-K80A (bar G), rSAv-K121A (bar H), and rSAv-K132A (bar I) increased with time. However, it should be noted that the rSAv-K121A mutant reached only about half of the kidney concentration of the unmodified rSAv. In contrast, the kidney concentration of succinylated rSAv (bars B, D, E) and mutants rSAv-R59H (F) and rSAv-K134A (J) decreased with time.

It is readily apparent from the 24 and 48 h panels in Figure 3 that succinylated rSAv (bars D, E) and rSAv mutant K134A (bar J) provide the lowest concentrations in kidney over the time frame studied. Succinylated rSAv was included in this investigation as a coinjected dual-labeled control (^{131}I) since this modification had previ-

ously shown to dramatically decrease the kidney localization of rSAv. However, unexpectedly high concentrations observed in kidney in some biodistribution studies resulted in succinylation of rSAv becoming part of the study. To investigate this further, an animal study was conducted to compare the in vivo distributions of rSAv from Boehringer Mannheim (13−139) modified by reaction with 50 equiv of fresh succinic anhydride with the shorter rSAv (13−136) that had been modified by reaction with 50 or 100 equiv of succinic anhydride. The data obtained at 24 h pi indicate that there is no significant difference in kidney localization between the two rSAv proteins when both are modified with 50 equiv of succinic anhydride, but that use of 100 equiv decreases the concentration in kidney slightly (Table S4, Supporting Information). Interestingly, the shorter succinylated rSAv (13−136) appears to have a significantly lower blood concentration at the 24 h time point. On the basis of these data, we now use 100 equiv of succinic anhydride in modifications of rSAv to ensure that conjugation is sufficient to alleviate most of the kidney localization.

DISCUSSION

The propensity for rSAv to localize in kidney is a serious problem if it is to be used in vivo as a carrier for radionuclides in Targeted Radionuclide Therapy. While chemical linker methods have been developed for releasing the radioactivity postkidney localization (*42*), the fact that core rSAv is very resistant to protease degradation (*11*, *43*) makes this approach questionable as the linkers are often cleaved postdegradation of the protein. Lack of in vivo degradation is observed for the radioiodinated rSAv, which contrary to most radioiodinated proteins has an extended residence time (i.e. residualization) of the radioactivity in the kidney. Due to our interest in using rSAv as a carrier molecule for α-emitting radionuclides in pretargeting approaches to cancer therapy (*19*), we have investigated methods for reducing the high kidney concentrations of radiolabeled rSAv. We based previous investigations on literature reports that (1) infusion of basic amino acids diminished renal clearance of proteins (*44*−*50*), (2) lysine modification in proteins, including avidin and SAv, can decrease kidney localization (*12*, *51*−*54*), and (3) a report that a specific arginine (R59) may be involved in kidney localization as the RYD sequence in rSAv might bind with the RGD receptor on renal cells (*37*). The results obtained in our prior studies demonstrated that kidney localization can be diminished by using any of these three approaches. However, the results did not provide information on whether the specific arginine residue (R59) in the RYD sequence, or whether a specific lysine residue of the four present in each subunit of rSAv, was responsible for kidney localization. Preparation and evaluation of the site-directed rSAv mutants (R59H, K80A, K121A, K132A, K134A) allowed us to probe that question.

The question of whether a specific arginine or lysine is responsible for the high kidney concentrations of rSAv is not readily answered by inspection of the bar graphs in Figure 3. The fact that three of the rSAv mutants studied (R59H, K121A, K134A) appear to affect kidney localization, albeit to varying degrees, seems to indicate that no single amino acid residue is responsible for kidney localization. Since it is likely that kidney localization of rSAv occurs via the same mechanism(s) as other proteins, it is important to consider the possible mechanisms involved to interpret the results obtained. It is known that there are several mechanisms that cause protein localization in kidney (*55*). One mechanism is simple filtration through the glomerular wall. It has been shown that molecular size, shape, and charge influence filtration of macromolecules across the glomerular capillary wall (*56*). In those studies, it was shown that neutral macromolecules (e.g. dextrans) that have molecular radii smaller than 20 Å have no restriction to glomerular filtration, and that the fraction of a macromolecule filtered through the glomerular wall progressively decreases as its molecular radii increases from 20 Å to about 44 Å. In a more recent review, it is indicated that the glomerular filtration membrane has pores of about 75 Å size, allowing proteins of up to 60 kDa to pass (size not discussed). From molecular modeling using crystal structures of recombinant core streptavidin the shape and size of the molecule can be fit into a cube with dimensions of 55 Å × 55 Å × 55 Å. On the basis of the literature report that any molecule over 44 Å is excluded from glomerular filtrations (*56*), this size might be expected to be restricted from filtration. However, if the pore size is 75 Å, perhaps some molecules larger than 44 Å will filter. We previously hypothesized that the high anionic character of the succinylated rSAv would not allow it to pass through the glomerular pores due to the repulsion by the anionic membrane. This may be the correct explanation, but there are other plausible explanations as well.

In these studies we evaluated the size-exclusion chromatograms obtained when rSAv was succinylated with 50 and 100 equiv of succinic anhydride and found that higher degree of succinylation resulted in a faster column transit time. While the size of a protein cannot be accurately measured from the elution times on a size exclusion HPLC column, differences in elution times of modified rSAv can provide information on what might be considered their "effective size". Indeed, the highly acidic rSAv produced with 100 equiv of succinic anhydride has an elution time by size-exclusion HPLC (t_R = 9.8 min) that is between an antibody Fab′ (t_R = 9.0 min) and a F(ab′)$_2$ (t_R = 10.3 min) on the same column. Considering that Fab′ is about the same size (e.g. ∼50 kDa) as rSAv and F(ab′)$_2$ is twice that size (∼100 kDa), the effective size would be somewhere between these values. Thus, an alternative explanation for the lack of filtration of succinylated rSAv is that its effective size is too large for passing through the pores. However, other mechanisms for renal localization are required for the rSAv mutants, as their (effective) size is the same as unmodified rSAv.

A hypothesis that has been forwarded in the literature is that the ^{59}RYD^{61} (Arg-Tyr-Asp) sequence in rSAv (Figure 1) is "RGD-like" resulting in binding to the cell surface adhesion receptors by a "RGD mimicry" (*37*, *57*). Our previous studies involving chemical modification of arginine residues provided results that were consistent with that hypothesis (*21*). However, the results obtained when rSAv was succinylated (*20*) were not consistent with the hypothesis, unless another mechanism such as the size or charge effect noted above is operative. The fact that the results obtained in this investigation indicate that mutation of the lysine residue 134 has more of an effect on kidney localization than mutation of the arginine residue 59 in the RYD sequence seems contrary to the RGD-mimicking receptor hypothesis. While the RYD binding hypothesis was a plausible explanation due to the fact that fibronectin was found to efficiently displace rSAv from chinese hamster ovary cells (*37*), at present it does not appear that there is any conclusive evidence that a RYD sequence will bind specifically with the RGD receptors. Indeed, binding of the RGD sequence

with integrins is very specific, even involving a specific conformation and stereochemistry of the sequence (*58*, *59*). It seems unlikely that this high specificity would accommodate the large steric difference between having a glycine and a tyrosine, particularly in that it has been previously shown that small changes in the sequence, such as substitutions of lysine for the arginine, alanine for the glycine, or aspartic acid for the glutamic acid, eliminated the RGD binding (*60*). More recently, investigators have conducted site-directed mutagenesis altering the RYDS sequence to RYES and found that this very small change resulted in greatly diminished binding with (Lewis) kidney (NRK) cells in vitro (*61*). Unfortunately, no in vivo evaluations were conducted with the rSAv mutant. In contrast, other investigators have engineered the RGD sequence into rSAv and found a dose-dependent specific binding with rat aortic endothelial cells and human melanoma cells, whereas wild-type rSAv had no specific binding with these cells (*62*). While not disproved by the results obtained in this or our prior studies, the data seem to indicate that it is unlikely the RYD sequence plays a major role in the in vivo localization of rSAv to kidney.

The data obtained in this investigation indicate that both lysine and arginine residues participate in the kidney localization of rSAv. Both of these residues have positive charges in aqueous media. It has been previously demonstrated that alteration of the charge on proteins is very important in kidney localization. Although it is apparent that the charge on rSAv can contribute to the rate of filtration, it cannot be a major factor for the rSAv mutants, as they all have the same charge but are sequestered by the kidney to varying degrees. Rather than simply changing the charge, it may be that modification of rSAv alters specific arginine and lysine residues involved in binding with renal cells. Uptake of proteins by renal cells is accomplished by an endocytic process after adsorption on the luminal membrane (*63*). The uptake process is thought to be dependent on interaction of the protein with anionic sites on the surface of renal cells, resulting in anionic molecules being filtered more slowly and cationic molecules being filtered more rapidly than neutral molecules (*51*, *64*). Studies involving the cationic protein lysozyme demonstrated that absorption was a saturable process, which had a high capacity and low affinity (*64*). The fact that it is saturable may help explain why infusions of the basic amino acids lysine and arginine can decrease the kidney localization of proteins, but quickly come back to normal after stopping the administration of amino acids. The results suggest that the endocytic process (*65*) may be dependent on specific interactions with arginine and lysine residues in rSAv. rSAv-K134A (Figure 3, bar J) has the largest decrease in kidney localization relative to the corresponding wild-type rSAv (bar C) or any of the rSAv mutants studied. This amino acid residue is near the carboxyl terminus and has more freedom for interaction with renal cells, as it can move some distance from the bulky rSAv structure.

Computer-aided molecular modeling was conducted to determine if anything unusual could be noted about the locations of the mutated amino acids that might account for the differences in kidney localization. An interesting observation was made from the molecular modeling. The observation that lysine and arginine residues which have an effect on the kidney concentration of rSAv (R59, K121, K134) are paired, or can be paired,[5] in close proximity of each other. When paired in close proximity there are less than 16 Å between the lysine amines or arginine guanidine groups. In contrast, the lysine residues that do not have an effect on the kidney localization are distant from one another (e.g. >30 Å). The pairing effect of arginine and lysine residues is due to the symmetrical nature of the tetrameric rSAv molecule. Graphical depictions of the proximity of lysines 121, 134, and arginine 59 to one another are provided as Figures S17 and S18 in the Supporting Information. Molecular modeling using space filling views also show the positive charges of these residues to be surface exposed. While it is apparent from the results of these studies that arginine 59 and lysine 121 have an influence on the kidney localization of rSAv, we have not provided evidence that the nature of their location, and/or distance between residues of two positive charges, is important in the renal cell endocytosis process. Further studies will be required to answer such questions.

Summary. It is apparent from this investigation that some lysine residues affect the kidney localization of rSAv more than others. In particular, the most accessible lysine (K134) near the carboxyl terminus of each subunit has the largest effect on kidney localization when it is replaced with alanine. This may indicate that it is essential in the initial recognition/binding in kidney. Another lysine residue (K121) has an effect on kidney localization, but it is much less. This may indicate that it is also involved in the binding/internalization process, but it only occurs if the terminal lysine (K134) binds first. The arginine residue studied (R59) also has an effect on the kidney localization that appears to be secondary to the binding of the terminal lysine (K134), although the overall effect of its replacement with a histidine is comparable to that observed with succinylated rSAv. No data was obtained for other arginine residues, but these may also contribute to the kidney localization. These data do not provide a proof of the mechanism of kidney localization, but the location of the arginine and lysine residues within the rSAv structure appears to have a significance effect regarding kidney localization. Most importantly, we have found that mutation of only one lysine residue (per subunit) can provide a rSAv molecule that has a very low sequestration in the kidney.

ACKNOWLEDGMENT

We thank Janna Quinn and Dr. Robert Vessella for their contributions to the biodistribution studies. We thank NeoRx Corporation for their contribution to these studies. The rSAv mutants were prepared at NeoRx Corporation when two authors (J.S., Y.L.) were employed in the company. We are grateful for the financial support provided by the Department of Energy, Medical Applications and Biophysical Research Division, Office of Health and Environmental Research under grant number DE-FG03-98ER62572.

Supporting Information Available: Complete biodistribution data for wild-type rSAv, succinylated rSAv, and rSAv mutants (Tables S1−S8); size-exclusion HPLC and mass spectra for rSAv, rSAv mutants and succinylated rSAv (Figures S1−S16); and graphical representations of the proximity of paired lysines 121/134 and arginine

[5] The lysine amines in K134 have free movement so a close proximity can be attained; however, the groups are not held in that configuration. The location of the amines shown in Figure 17 (Supporting Information) are not established, as those amino acids were added to the crystal structure data for molecular modeling purposes.

Radiopharmaceuticals for Assessment of Multidrug Resistance P-Glycoprotein-Mediated Drug Transport Activity

Vijay Sharma*

Molecular Imaging Center, Mallinckrodt Institute of Radiology, Washington University Medical School, St. Louis, Missouri 63110. Received June 30, 2004; Revised Manuscript Received October 5, 2004

Multidrug resistance (MDR) mediated by overexpression of *MDR1* P-glycoprotein (Pgp) is one of the best characterized transporter-mediated barriers to successful chemotherapy in cancer patients. Thus, noninvasive interrogation of Pgp-mediated transport activity in vivo would be beneficial in guiding therapeutic choices. Both small organic medicinals as well as metal complexes characterized as transport substrates for Pgp are amenable to incorporation of PET or SPECT radionuclides and may enable noninvasive imaging of Pgp in cancer patients. Toward this objective, clinically approved agents, exemplified by ^{99m}Tc-Sestamibi and ^{99m}Tetrofosmin, have already shown promise for the functional evaluation of Pgp-mediated transport activity in human tumors in vivo. In addition, selected agents from an upcoming class of substituted Schiff-base gallium(III) complexes containing an N_4O_2 donor core in their organic scaffold and capable of generating both SPECT and PET radiopharmaceuticals have also been shown to be promising for noninvasive assessment of Pgp activity in vitro and in vivo.

INTRODUCTION

Resistance to chemotherapy represents a major obstacle in the treatment of cancer. Many tumors are intrinsically resistant to chemotherapy, whereas others initially respond to treatment, but acquire resistance to selected cytotoxic drugs during chemotherapy. Multidrug resistance (MDR) can be broadly defined as a phenomenon by which cultured cells in vitro and tumor cells in vivo show resistance simultaneously to a variety of structurally and functionally dissimilar cytotoxic and xenobiotic compounds *(1−6)*. While several different genes have been shown to be associated with a multidrug resistance phenotype *(7−9)*, MDR mediated by overexpression of the *MDR1* gene product, P-glycoprotein (Pgp), represents one of the best characterized barriers to chemotherapeutic treatment in cancer *(6, 10)*. Pgp, a 170 kD plasma membrane protein, is predicted by sequence analysis to comprise two symmetrical halves that share both homology with a family of ATP-binding cassette (ABC) membrane transport proteins and a common ancestral origin with bacterial transport systems *(5, 11)*. Characterized by 12 transmembrane domains and two nucleotide-binding folds *(3, 5)*, the protein is thought to hydrolyze ATP to affect outward transport of substrates across or off the cell surface membrane *(5, 12)*. Although the specific protein domains and amino acids involved in substrate recognition continue to be characterized, genetic and biochemical evidence has conventionally been interpreted to show putative membrane-associated domains interacting directly with selected cytotoxic agents to affect transport *(10, 13−15)*. Regardless of mode of interaction, the net effect is that Pgp reduces the intracellular concentration of substrates in Pgp-expressing multidrug resistant cells compared with non-Pgp-expressing cells.

PROBABLE MECHANISM(S) FOR *MDR1* PGP-MEDIATED DRUG TRANSPORT

Commonly, *MDR1* Pgp has been postulated to act as an ATP-dependent efflux transporter of xenobiotics and chemotherapeutic drugs (*6*). In addition, several studies provide evidence supporting alternative mechanisms for the diminished Pgp-mediated drug accumulation in MDR cells. For example, a flippase model has been proposed for Pgp *(16)*. This model suggests that Pgp flips hydrophobic cytotoxic compounds from the inner to outer leaflet of the lipid bilayer wherein the agents can diffuse away. Alternatively, Pgp acts as a phospholipid flippase altering membrane permeability, thereby accounting for diminished intracellular concentration of drug and accounting for the broad specificity of Pgp toward its recognized substrates. In addition, cells expressing *MDR1* may have intracellular compartments that are more acidic than non-Pgp expressing cells *(17, 18)*, altered intracellular distribution of drug *(19)*, or altered membrane permeability resulting in decreased drug influx *(20)*. For example, Piwnica-Worms and co-workers have shown sustained expression of Pgp without use of chemotherapeutic drugs in a line of stable transfectants, MCF-7/*MDR1,* using a bicistronic vector for selection of cells *(21)*. Electrical current and drug transport experiments demonstrated insignificant variations in membrane potential or membrane conductance between parental MCF-7 and MCF-7/*MDR1* cells, but reduced unidirectional influx and steady-state cellular content of Pgp substrates. There was no change in unidirectional efflux of substrates from cells. These authors concluded that the dominant effect of *MDR1* Pgp in this system was reduction of drug influx, possibly through an increase in intramembranous dipole potential *(21)*. Finally, *MDR1* Pgp may interfere with or

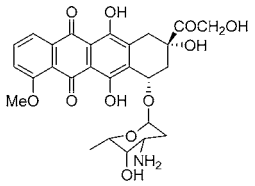
Published on Web 11/02/2004

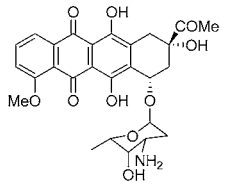
alter pathways of apoptosis (programmed cell death) *(22, 23)*, therefore offering protection from cytotoxic compounds.

Thus, although the exact mechanism remains to be biochemically elucidated, the observed combined net effect is a decreased intracellular concentration of cytotoxic drugs that results from overexpression of *MDR1* Pgp, thereby rendering chemotherapeutic treatment ineffective in cancer.



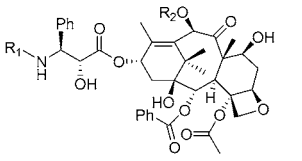
ROLE OF *MDR1* PGP IN PHARMACOKINETICS

In addition to its overexpression in tumors, *MDR1* Pgp is normally located in several tissues involved in excretory functions, including the brush border of proximal tubule cells in the kidney, the biliary surface of hepatocytes, and the apical surface of mucosal cells in the small intestine and colon *(24, 25)*. *MDR1* Pgp also is located on the luminal surface of endothelial cells lining capillaries in the brain and in the testis *(26−28)* as well as on the apical surface of choroid plexus epithelial cells *(27)*. However, despite its widely disseminated expression, the function of *MDR1* Pgp in normal physiology has not been clearly defined, although Pgp may have a role in protection from xenobiotics *(29)*. Piwnica-Worms and co-workers have also suggested a role for *MDR1* Pgp in intracellular cholesterol trafficking *(30)*. Furthermore, inhibition of Pgp with an MDR modulator could provide an effective means for increasing oral absorption of drugs and reducing drug excretion, resulting in decreased dosing requirements for treatment of cancer and infectious diseases. For example, Pgp modulation is currently under evaluation as a means to improve oral absorption of chemotherapeutics and HIV-1 protease inhibitors such as indinavir, nelfinavir, saquinavir, and rotonavir *(31, 32)*. Similarly, use of *MDR1* Pgp inhibitors (commonly known as MDR modulators or reversal agents) could allow drug penetration into Pgp protected sites in the body, such as the brain and selected hematopoietic cells, as has been shown for penetration of protease inhibitors into the central nervous system *(32)*. In addition, transgenic expression of the *MDR1* gene has been explored for hematopoietic cell protection in the context of cancer chemotherapy *(33−35)*, wherein Pgp could protect hematopoietic progenitor cells from chemotherapy-induced myelotoxicity. Hematopoietic cells transduced via retroviral-mediated transfer of the *MDR1* gene have shown preferential survival in vivo after treatment with MDR drugs *(35)* and data from pilot clinical studies support this approach *(36)*.



Thus, a noninvasive method of determining Pgp-mediated drug transport activity could be important in the use of new modulators, applications of gene therapy to chemotherapeutic protocols, and predicting oral absorption, pharmacokinetics, and penetrance of MDR drugs into target tissues and brain.

MDR1 PGP-MEDIATED DRUG TRANSPORT IN CHEMOTHERAPY



Compounds recognized by Pgp are typically characterized as modestly hydrophobic (octanol/water partitioning coefficient, log $P > 1$), often contain titratable protons with a net cationic charge under physiological conditions, and are predominately "natural products" with an aromatic moiety *(37, 38)*. In addition, incorporation of methoxy functionalities has been shown to enhance *MDR1* Pgp recognition. Among an extensive list of conventional cytotoxic compounds, anthracyclines (doxorubicin **1**, daunorubicin **2**), taxanes (paclitaxel **3**, docetaxel **4**), *Vinca* alkaloids (vincristine **5**, vinblastine **6**, vindesine **7**), and etoposides **8** (VP-16) are examples of

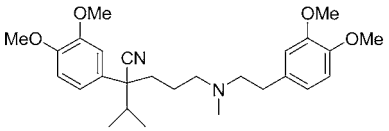
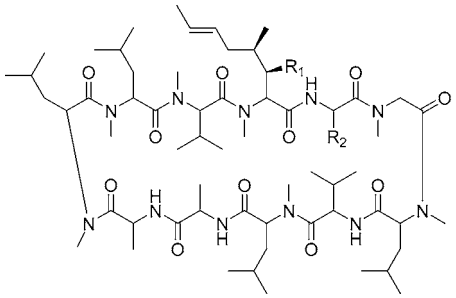
7

8



clinically important chemotherapeutic drugs recognized by *MDR1* Pgp (*6, 7, 37, 39*). The broad diversity in the scaffolds of these agents emphasizes the key characteristic feature of multidrug resistance, i.e., the apparent capacity of Pgp to recognize a large group of cytotoxic compounds sharing little or no structural or functional similarities. Furthermore, even targeted drugs have encountered MDR in clinics *(40)*. For example, Gleevec, **9**, a 2-phenylaminopyrimidine derivative *(41, 42)*, while



9

a highly potent inhibitor of receptor tyrosine kinases, such as BCR-Abl and PDGF−R, is also recognized and transported by *MDR1* Pgp *(6, 43)*. Thus, it would appear that even novel targeted therapeutics will remain susceptible to broad-specificity transporter-mediated resistance mechanisms.

Because clinical studies have documented the poor outcomes associated with *MDR1* Pgp expression in tumors *(39, 44)*, reversal of multidrug resistance by nontoxic agents that block the transport activity of *MDR1* Pgp has been an important target for pharmaceutical development. When coadministered with a cytotoxic agent, these nontoxic compounds (MDR reversal agents) enhance net accumulation of relevant cytotoxic drugs within the tumor cells. Many compounds known to have other pharmacological sites of action initially were used to reverse MDR in cancer cells grown in culture and several underwent pilot clinical trials *(37)*. These compounds included verapamil **10**, cyclosporin A **11**, quinidine **12**, trifluoperazine **13**, and their derivatives *(37)*.

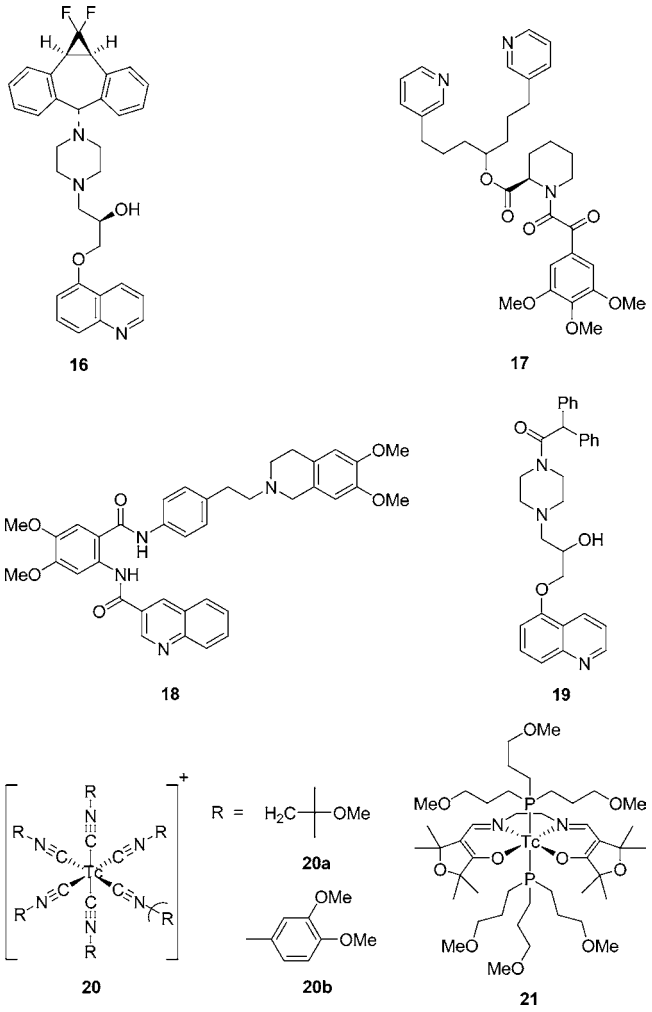
13

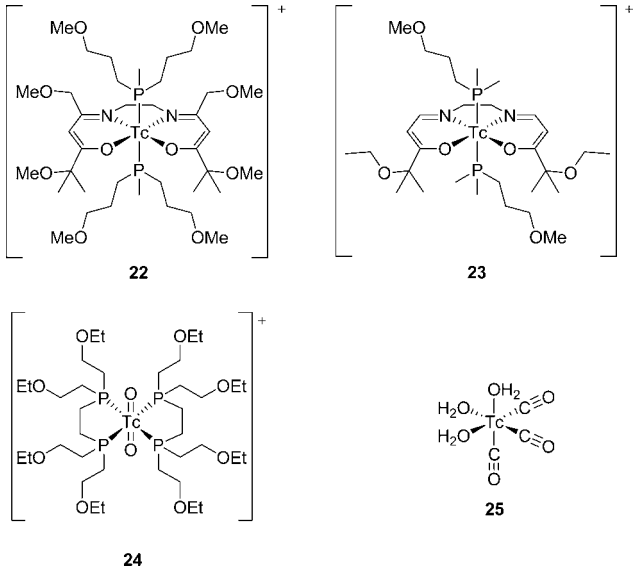
However, these agents had limited clinical utility because of unacceptable toxicities at serum levels of drug needed to modulate *MDR1* Pgp *(39)*. Second generation modulators, such as dexverapamil, an optically pure verapamil *(45)*, and PSC 833 (Valspodar) **14**, a cyclic undecapeptide analogue of cyclosporin A (*46*) were soon developed with improved efficacy. These were followed by third generation modulators, such as GF120918, **15**, a substituted isoquinolinyl acridonecarboxamide *(47)*, LY335979, **16**, a difluorocyclopropyl dibenzosuberane *(48)*, VX710 (biricodar) **17**, an amido-keto-pipecolinate *(49)*, XR9576 (tariquidar) **18**, an analogue of anthranilamide pharmacophore *(50−52),* and MS209, **19**, a quinoline-derivatized

15



analogue *(53, 54)*, that have been developed more recently. Thus, the MDR phenotype may be modulated more effectively with these more selective reversal agents to improve the efficacy of chemotherapeutic agents by delivering an appropriate dose at the targeted site.

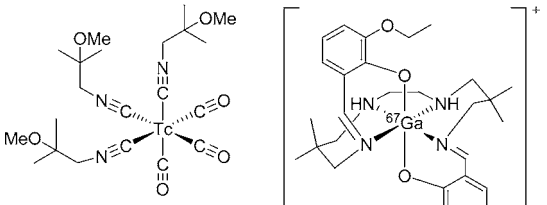
SPECT RADIOPHARMACEUTICALS FOR EVALUATION OF P-GLYCOPROTEIN-MEDIATED TRANSPORT ACTIVITY



Increasingly, the choice of systemic therapy for cancer is based on a priori analysis of tumor markers to assess the presence or absence of a molecular pathway or target (such as a key receptor or enzyme activity) for a given therapeutic agent. Identification of tumor markers with diagnostic agents assists in the proper selection of patients most likely to benefit from targeted therapy. Measurement of MDR is one potentially important marker in planning systemic therapy. However, expression of *MDR1* Pgp, as detected at the level of messenger RNA or protein, does not always correlate with the functional assessment of Pgp-mediated transport activity. Because Pgp transport activity is affected by specific mutations as well as the phosphorylation state of the protein (*5, 55, 56*), altered or less active forms of Pgp may be detected by polymerase chain reaction (PCR) or immunohistochemistry which do not accurately reflect the status of tumor cell resistance. Thus, methods for functionally interrogating Pgp transport activity have been sought *(57)*. Imaging with a radiopharmaceutical that is transported by *MDR1* Pgp may identify noninvasively those tumors in which the transporter is not only expressed, but functional. Thus, significant effort has been directed toward the noninvasive detection of transporter-mediated resistance using planar scintigraphy or single-photon emission computed tomography (SPECT) employing radiolabeled metal complexes characterized as transport substrates for *MDR1* Pgp.

Hexakis(2-methoxyisobutylisonitrile)technetium-99m (commonly known as [^{99m}Tc]Sestamibi) **20a**, although originally developed as a radiopharmaceutical for myocardial perfusion imaging *(58, 59)*, subsequently was the first metal complex shown to be a Pgp transport substrate *(60)*. Characterized by octahedral geometry around the central technetium(I) core *(58, 61)*, the radiopharmaceutical possesses a cationic charge and modest hydrophobicity similar to many chemotherapeutic agents in the MDR phenotype. In the absence of Pgp expression, this ^{99m}Tc-isonitrile complex accumulates within the interior of cells in response to the physiologically negative mitochondrial and plasma membrane potentials maintained within cells *(62, 63)*. However, in Pgp-expressing multidrug resistant tumor cells, net cellular accumulation levels of [^{99m}Tc]Sestamibi are inversely proportional to the level of *MDR1* Pgp expression *(60, 64−67)*. Furthermore, complete reversal of the Pgp-mediated exclusion of [^{99m}Tc]Sestamibi has been affected by treatment with conventional *MDR1* Pgp inhibitors such as verapamil **10**, cyclosporin A **11**, and quinidine **12** or newer more potent reversal agents such as PSC 833 **14**, GF120918 **15**, LY335979 **16**, or VX710 **17** (*30, 38, 60, 64, 65, 68−73*), and more recently, XR-9576 **18** *(6, 50)*. Furthermore, to optimize the transport and Pgp-targeting characteristics of [^{99m}Tc]isonitrile complexes, several studies investigating structure−activity relationship (SAR) have been performed. In one study, the alkyl chains in [^{99m}Tc]-Sestamibi were replaced with longer chain ether functionalities. The hexakis(2-ethoxy-isobutylisonitrile)[^{99m}Tc] complex ([^{99m}Tc]EIBI) was shown to be a transport substrate recognized by Pgp, but with slightly greater nonspecific cell binding than [^{99m}Tc]Sestamibi *(74)* that would result in inferior target/background ratios compared with [^{99m}Tc]Sestamibi. Piwnica-Worms and coworkers have also explored substituted aromatic isonitriles *(75)*. A series of substituted arylisonitrile analogues were obtained from their corresponding amines through a reaction with dichlorocarbene under phase transfer-catalyzed conditions, and non-carrier-added hexakis-(arylisonitrile)-Tc-99m complexes were produced by reaction with pertechnetate in the presence of sodium dithionite. SAR studies resulted in a lead compound, **20b**, which demonstrated an overall encouraging transport profile in Pgp expressing cells, but significant nonspecific adsorption to hydrophobic compartments was identified. Nevertheless, results suggested that methoxy substituents, compared with other functionalities, preferentially contributed to enhanced Pgp recognition for this class of

compounds. However, none of these radiolabeled complexes exceeded [^{99m}Tc]Sestamibi in their Pgp-targeting properties.



In addition, several entirely different classes of technetium-complexes have been identified as Pgp transport substrates. Using a planar Schiff-base moiety and hydrophobic phosphines, nonreducible Tc(III) monocationic compounds known as "Q-complexes" were developed for applications in myocardial perfusion imaging *(76, 77)*. The lead complex for clinical development was *trans*-[(1,2-bis(dihydro-2,2,5,5-tetramethyl-3(2*H*)furanone-4-methyleneimino)ethane)bis(tris(3-methoxy-1-propyl)phosphine)]Tc(III), known as [^{99m}Tc]Furifosmin **21** *(78)*. Because the hydrophobicity and Pgp-targeting properties of these complexes could be readily adjusted by varying functionalities on the Schiff base or phosphine moieties independently, a variety of novel ^{99m}Tc-Q-complexes with subtle structural variations were synthesized *(68, 79)*. This approach allowed the coordination environment of the Tc(III) metal core to be maintained while altering the overall electronic environment, thereby enabling evaluation of structural features conferring Pgp-mediated transport properties. Ether functionalities can be incorporated into the equatorial Schiff base ligand by condensation of ethylenediamines with ether-containing β-dicarbonyl compounds *(80)*. The presence of *gem*-dimethyl groups sterically hinders the attack of diamine at the adjacent carbonyl and the strategy results in regioselective condensation at the less hindered carbonyl. Preparation of the tertiary phosphines was accomplished in a two-step, one-pot reaction involving treatment of 1-chloro-3-methoxypropane with magnesium in tetrahydrofuran and subsequent reaction of the reagent with dimethylchlorophosphines or dichloromethylphosphines to provide the necessary substituted phosphines with overall yield of 50−70% *(79)*. The desired ^{99m}Tc-Q-complexes were then obtained by a two-step synthetic approach using the phosphines as both reductants and ligands *(81)*. From MDR transport assays in vitro, the *trans*-[2,2′-(1,2-ethanediyldiimino)bis(1,5-methoxy-5-methyl-4-oxohexenyl)]-bis[methyl-bis(3-methoxy-1-propyl)phosphine]Tc(III) complex **22** and the *trans*-[5,5′-(1,2-ethanediyldiimino)bis(2-ethoxy-2-methyl-3-oxo-4-pentenyl)]-bis[dimethyl(3-methoxy-1-propyl)phosphine]Tc(III) complex **23** were discovered. These complexes mimic [^{99m}Tc]Sestamibi for their Pgp recognition properties in vitro *(68, 79)*. In addition, a Tc(V) complex known as [^{99m}Tc]Tetrofosmin *(82)*, bis-[1,2-bis{bis(2-ethoxyethyl)phosphino}ethane]Tc(V) **24**, has been identified as another ^{99m}Tc-complex with highly favorable *MDR1* Pgp-mediated transport properties *(79, 83)*. While these metal complexes do not share any

obvious structural homology, they do share the common features of a delocalized cationic charge and modest hydrophobicity. Overall, which of these selected ^{99m}Tc-complexes would be most clinically useful in evaluation of the Pgp status of tumors by single photon emission computed tomography (SPECT) imaging continues to be rigorously investigated.

Another class of technetium based-radiopharmaceuticals has emerged on the basis of pioneering work done on the development of an air- and water-stable organometallic aqua complex [^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ **25** obtained from reaction of pertechnetate in saline under 1 atm of CO *(84)*. Because it was shown that the coordinated water molecules were labile, thus exchangeable with other ligands, complexes with heterogeneous ligands could be generated. Upon the basis of these observations, these water molecules were substituted with methoxyisobutylisonitrile ligands to obtain another novel class of Pgp-targeted radiopharmaceuticals, tris(carbonyl)tris(2-methoxyisobutylisonitrile)technetium(I); [^{99m}Tc(CO)$_3$(MIBI)$_3$]$^+$ **26** *(85)*. Cellular accumulation of **26** in human epidermal carcinoma KB 3-1 (−Pgp) and KB 8-5 (+Pgp) cells demonstrated uptake profiles inversely proportional to Pgp expression indicating it to be recognized as a transport substrate *(86)*.

26 27

Organic scaffolds capable of coordinating other metals have also been explored. Multidentate ligands with an N_4O_2 donor core have the ability to form stable monomeric, monocationic, hydrophobic complexes with a variety of main group *(87, 88)* and transition metals *(89−91)*. Schiff-base Ga(III) complexes were previously reported as potential PET (positron emission tomography) radiopharmaceuticals with utility as myocardial perfusion imaging agents *(92, 93)*. These complexes, exemplified by the lead compound **27**, demonstrated pharmacological profiles consistent with their potential utility as PET probes of *MDR1* Pgp activity in tumors *(94−96)*. Substituted salicylaldehydes were obtained by ortho-formylation of phenols, and substituted linear tetramine was obtained through a reaction of dibromoethane and 2,2-dimethylpropane-1,3-diamine at room temperature. The triaryl precursors containing a central imidazolidine ring were synthesized by condensation of an appropriate substituted linear tetramine with substituted salicylaldehydes. The desired metal(III) complexes were obtained by cleavage of the imidazolidine ring via transmetalation reactions using appropriate metal(III) acetylacetonates. For evaluation of *MDR1* Pgp-targeting properties, these compounds were screened for their cytotoxicity in Pgp expressing tumor cells and their appropriate control (−Pgp) cells (Figure 1). Selected metal(III) complexes were able to differentiate between human epidermal carcinoma KB-3-1 (−Pgp) and KB-8-5 (+Pgp) cells through

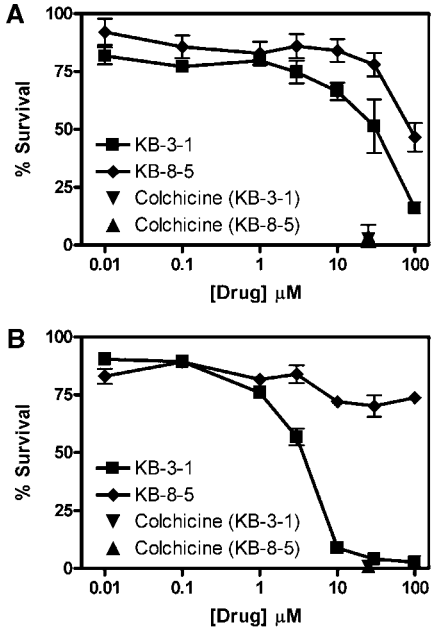


Figure 1. Cell survival studies in parental KB-3-1 (−Pgp) and multidrug resistant KB-8-5 (+Pgp) cells at increasing concentrations of R-ENBPI gallium(III) [R= 3-methoxy (A); 4,6-dimethoxy (B)] complexes, colchicine (25 μM, positive control). Each point represents the mean of triplicate determinations; bars represent ± SEM when larger than symbol; solid lines are a spline presentation of the data.

differential cytotoxicity profiles indicating *MDR1* Pgp-mediated transport *(95)*. The active metal complexes containing 4,6-dimethoxy-substituted aromatic rings (Figure 1B) were more potent than their corresponding 3-methoxy analogues (Figure 1A). SAR studies led to discovery of a lead compound, [{bis(3-ethoxy-2-hydroxybenzylidene)-*N*,*N*′-bis(2,2-dimethyl-3-aminopropyl)ethylenediamine}gallium(III)], [Ga-ENBDMPI]$^+$ **27**. The crystal structure provided direct evidence that gallium is coordinated symmetrically and simultaneously to the N_4O_2 donor core of the ligand. The structure revealed that the central gallium is hexacoordinated, involving two phenoxy oxygens (O1 and O2), two secondary amine nitrogens (N2 and N3), and two imine nitrogens (N1 and N4) with overall trans-pseudooctahedral geometry (Figure 2). For biochemical studies, the ligand was labeled with gallium-67/68 through a simple transmetalation reaction of $^{67/68}$Ga(acetylacetonate)$_3$ and ligand dissolved in ethanol. The radiolabeled compound was purified through a C-18 sep-pack. For analysis of metabolites, the lead SPECT radiotracer, ^{67}Ga-ENBDMPI, was incubated in buffer and calf serum at 37 °C for 2 h. In addition, the radiopharmaceutical was extracted from mouse tissues (liver and kidney) 15 min after tail-vein injection. Radio-TLC analysis of the radiotracer in buffer,

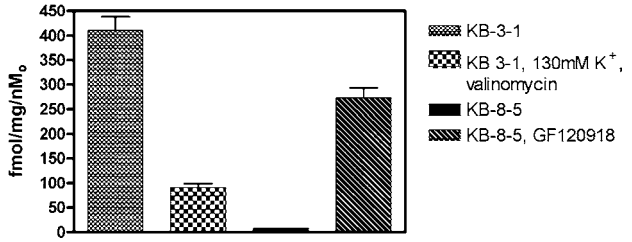

Figure 4. Accumulation of ^{67}Ga-ENBDMPI (**27**) in KB-3-1 cells (−Pgp) and MDR KB-8-5 cells (+Pgp) as indicated. Shown is net uptake [fmol/mg protein/nM$_o$] at 30 min. Each bar represents the mean of 4 determinations; line above the bar denotes +SEM.

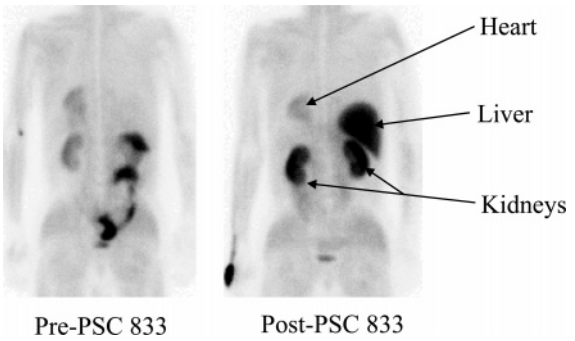

Figure 5. Effect of the *MDR1* Pgp inhibitor, PSC 833 on pharmacokinetics of ^{99m}Tc-Sestamibi in vivo: Whole body posterior planar image obtained at 2h postinjection of radiopharmaceutical. Left Panel: The pharmacokinetics demonstrated decreased retention of the radiotracer in the liver and kidney, 2h postinjection of the radiotracer in the absence of PSC 833. Right Panel: Following 24h treatment with PSC 833, image was obtained 2h postinjection of radiotracer. Because PSC 833 blocks Pgp, considerable amount of radioactivity was retained in the liver and kidney (right panel). Note that heart, being a Pgp (−ve) organ, retains the same amount of activity in both cases (Pre-PSC 833 and Post-PSC 833; left and right panels).

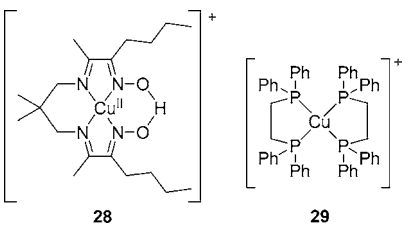
calf-serum, and tissue extracts indicated primarily a nonmetabolized agent (Figure 3). Because, net cell contents of hydrophobic and cationic radiopharmaceuticals transported by Pgp are a function of both passive potential-dependent influx and transporter-mediated efflux. Therefore, favorable cationic ^{67}Ga complexes would likely penetrate KB-3-1 cells as result of the inwardly directed electrochemical driving forces. Furthermore, membrane potential-dependent influx in KB-3-1 cells in 120 mM K^+/20 mM Cl^- buffer containing the potassium ionophore valinomycin (1 μg/mL) was shown to collapse mitochondrial and plasma membrane potentials toward zero and reduce net tracer uptake of membrane potential-responsive hydrophobic cations *(94, 96)*. Resultantly, net accumulation of the ^{67}Ga-complexes would be reduced in high K^+/valinomycin buffer, and furthermore, tracer levels greater than that expected from equilibrium distribution into the water spaces under these conditions would provide one measure of nonspecific adsorption to intracellular hydrophobic compartments. Conversely, *MDR1* Pgp-mediated outward transport of ^{67}Ga complexes would be expected to decrease net cellular accumulation in KB-8-5 cells compared with KB-3-1 cells. Following these criteria, ^{67}Ga-ENBDMPI accumulated in cells showing profiles inversely proportion to Pgp expression (Figure 4). While residual uptake in control KB-3-1 cells in the presence of high K^+/valinomycin buffer indicated modest nonspecific interaction, the inhibitor GF120918 induced uptake in MDR KB-8-5 cells (Figure 4) demonstrated target specificity *(94, 97)*. These results suggested that radiolabeled analogues of these Ga(III) complexes also could provide templates for ^{68}Ga-PET radiopharmaceuticals to probe Pgp transport activity in tumors *(96)*.



While gallium(III) radiopharmaceuticals are undergoing preclinical evaluation, technetium-99m based radiotracers have been clinically evaluated for assessment of the Pgp-mediated transport activity. Toward this objective, validation of successful inhibition of the transport function is necessary to evaluate the effects of Pgp inhibitors on patient outcomes. Initial clinical data indicates that [^{99m}Tc]Sestamibi can be used to detect inhibition of Pgp-meditated transport function in patients (Figure 5). Overall, pharmacokinetic studies demonstrated retention of activity in the liver and kidney (Pgp positive tissues) of patients treated with PSC 833, 2 h postinjection of the radiopharmaceutical (Figure 5) *(70, 71)*. In addition, the heart a Pgp negative tissue, acting as an internal control tissue, displayed no difference in retention of activity in either pre-PSC 833 (left panel, Figure 5) or post-PSC 833 (right panel, Figure 5). Overall, results indicated the potential of [^{99m}Tc]Sestamibi to serve as an efficient diagnostic probe of Pgp-mediated transport activity in vivo.

PET AGENTS FOR ASSESSMENT OF P-GLYCOPROTEIN-MEDIATED TRANSPORT ACTIVITY

Positron emission tomography (PET) radiopharmaceuticals offer enhanced spatial resolution and quantification capabilities compared to SPECT agents. To probe Pgp transport activity, PET-based radiopharmaceuticals have been actively investigated on three fronts: (a) employing SPECT organic ligands capable of accommodating PET radionuclides, (b) bioinorganic radiolabeled complexes, and, (c) conventional PET organic medicinals.

Among organic scaffolds that coordinate both SPECT and PET radionuclides, two validated examples make use of the PET radionuclides ^{94m}Tc and ^{68}Ga. Thus, the radiosynthesis and biochemical validation of ^{94m}Tc-Sestamibi and ^{68}Ga-ENBPI complexes have been reported *(94, 98)*. As expected chemically, the highly favorable Pgp-targeting properties of these metal complexes were retained upon transformation from SPECT agents to PET imaging agents.

On another front, organic scaffolds capable of accommodating PET radionuclides that generate novel metallopharmaceuticals through short synthetic routes have been reported. Thus, based upon rigorous prior contributions (*99*, *100*), a stable, monocationic radiolabeled complex of copper(II) **28** was obtained as a potential ^{64}Cu PET radiopharmaceutical for targeting Pgp *(101)*. The desired diiminedioxime ligand was synthesized from 2,3-dimethyl-propane-1,2-diamine and heptane-2,3-dione-3-oxime. Cellular accumulation in MES-SA (−Pgp) and MES-SA (+Pgp) cells demonstrated uptake profiles inversely proportional to Pgp expression. Furthermore, an inhibitor-induced accumulation was observed in Pgp (+) cells.

28 **29**

Bidentate tertiary phosphine ligands have the ability to generate stable copper(I) complexes through a one step synthesis in quantative yields (*102, 103*) and represent another class of potential ^{64}Cu PET radiopharmaceuticals

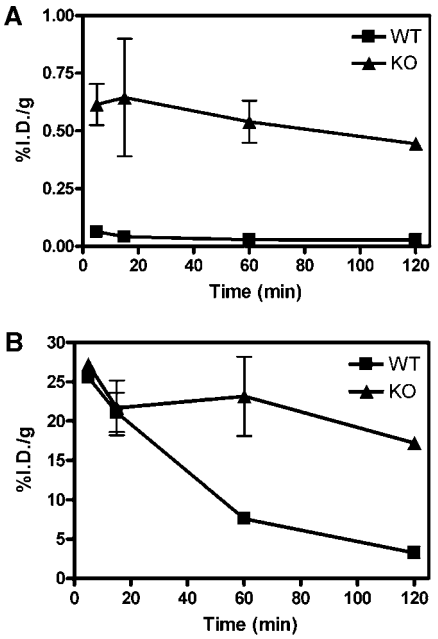


Figure 6. Pharmacokinetics of ^{67}Ga-ENBDMPI (**27**) in brain (A) and liver (B) of FVB mice. Wild-type [WT] and *mdr1a/1b* (-/-) [KO] *(123)* mice were administered **27** by bolus injection into a lateral tail vein and organs harvested at the indicated times for analysis. Data are expressed as percent of injected dose of radioactivity per gm tissue at each respective time point. Data points represent the mean of 2−4 determinations each; bars represent ± SEM when larger than the symbol.

targeting Pgp. These complexes previously demonstrated potent antitumor properties compared with their free ligands alone (*104, 105*). As with ^{99m}Tc-Q-complexes, herein phosphines were exploited as both ligands and reducing agents to generate cationic, hydrophobic, and tetrahedral copper(I) complexes **29** with 1,2-bis(diphenylphosphino)ethane. These potential PET radiopharmaceuticals show evidence of Pgp-targeting properties (*106, 107*). Although several leads exist for a ^{64}Cu-based radiopharmaceutical for interrogation of Pgp by PET, these radiopharmaceuticals show only modest Pgp-targeting properties compared with ^{94m}Tc-Sestamibi or ^{68}Ga-ENBDMPI.

To demonstrate the potential use of radiolabeled probes as imaging markers of Pgp-mediated transport in vivo, quantitative pharmacokinetic analysis in mice was performed following intravenous injection of tracers. Mice have two isoforms of Pgp (*mdr1a* and *mdr1b*) which confer multidrug resistance *(108)*. Drug-transporting *mdr1a* Pgp isoform is expressed in capillary endothelial cells of the brain wherein the protein is a major component of the blood−brain barrier *(109)*. Here, Pgp limits entry of a variety of amphipathic compounds into the central nervous system *(108)*. Drug-transporting Pgp isoforms are also expressed along the biliary cannalicular surface of hepatocytes wherein the transporters function to secrete substrates into the bile *(108)*. In this regard, *mdr1a/1b* (-/-) gene disrupted (KO) mice, which have no drug-transporting Pgp, are a robust model for evaluation of candidate MDR agents by interrogating net tracer accumulation into brain and liver tissues *(68)*. Therefore, analysis of initial tissue uptake and retention of ^{67}Ga-ENBDMPI **27** in *mdr1a/1b* (-/-) mice in comparison to wild-type (WT) FVB mice was performed (Figure 6). Relative to WT, the KO mice showed 10-fold more radiotracer **27** in brain parenchyma 5 min after injection of the complex (Figure 6A). Furthermore, the AUC_{5-120} of **27** in *mdr1a/1b* (-/-) brain was 62.5 ± 16.1 μCi (injected μCi)$^{-1}$ (g tissue)$^{-1}$ × 100 × minute (n = 8), a value 17-fold greater than wild-type mice ($p < 0.005$). While comparing to FDA approved radiopharmaceuticals for noninvasive imaging, ^{67}Ga-ENBDMPI showed 3- to 5-fold greater differences in brain AUC_{5-120} between WT and KO mice than ^{99m}Tc-Sestamibi *(110)* and ^{99m}Tc-Tetrofosmin *(111)*, further documenting its potential superiority for imaging Pgp activity in vivo. In addition, the liver showed twice the retained activity of ^{67}Ga-ENBDMPI **27** in KO mice compared with WT mice (Figure 6B). Thus, the data further validated **27** as a substrate for Pgp in vivo and showed its potential as a molecular imaging probe of transporter function and inhibition in the living organism.

A third focus has been directed toward incorporation of conventional PET radionuclides ^{11}C or ^{18}F into small organic medicinals characterized as substrates or inhibitors known to interact with Pgp (*112−114*). Employing this strategy, various labeled PET agents, including ^{11}C-colchicine, ^{11}C-verapamil, ^{11}C-daunomycin, and ^{11}C/^{18}F-paclitaxel, have been reported (*114−122*). While promising, some of these PET agents suffer from modest radiochemical yields and others from complex pharmacokinetics in vivo mediated, at least in part, by rapid metabolism of the radiolabeled compounds. In addition, these ^{11}C/^{18}F-radiopharmaceuticals are obtained in custom-designed, dedicated facilities located near cyclotrons that produce these isotopes, thereby imposing potential restrictions in their widespread distribution.

CONCLUSION

In summary, *MDR1* Pgp recognizes and outwardly transports a wide variety of bioinorganic complexes with a broad diversity of scaffolds in their chelation cores as well as conventional anticancer drugs. Both small organic medicinals as well as coordination compounds are amenable to incorporation of PET or SPECT radionuclides that may enable diagnostic imaging for functional interrogation of the MDR phenotype in cancer patients. In particular, clinically approved ^{99m}Tc-complexes have already shown to be beneficial in the evaluation of functional *MDR1* Pgp transport activity in human tumors in vivo. Therefore, contributions of bioinorganic radiochemistry and conventional organic radiochemistry are rapidly growing to enhance the existing armamentarium of targeted agents that would be capable of functionally analyzing the presence of Pgp in vivo.

ACKNOWLEDGMENT

The author is grateful to Prof. David Piwnica-Worms for inspiring and helpful discussions and co-workers (both past and present) for their contributions that led to successful execution of this review. This educational project was funded by DOE FG02 94ER61885 and NIH P50 CA94056.

TECHNICAL NOTES

Evidence of Antisense Tumor Targeting in Mice

K. Nakamura,[†] C. Fan,[‡,§] G. Liu,[‡] S. Gupta,[‡] J. He,[‡] S. Dou,[‡] A. Kubo,[†] M. Rusckowski,[‡] and D. J. Hnatowich*[,‡]

Received April 13, 2004; Revised Manuscript Received May 27, 2004

Even though increased accumulations of radiolabeled antisense DNAs compared to control DNAs are becoming a routine observation in cultured tumor cells, trustworthy evidence of tumor targeting in vivo by an antisense mechanism remains elusive. The goal of this study was to obtain convincing evidence of antisense tumor targeting in nude mice by using two different tumors and both intratumoral (i.t.) and intravenous (i.v.) administration of radiolabeled antisense and control sense DNAs. Both the MDR++ cell line KB-G2 and its parent MDR+ cell line KB-31 were used in this study. The antisense (AS) DNA was directed against the AUG start codon of the MDR1 mRNA and, along with the sense (S) control DNA, was a uniform phosphorothioate administered naked. In previous cell culture studies from our laboratories, the accumulation of this AS DNA was strikingly high in KB-G2 cells and only average in KB-31 cells, a fact we attribute to the 1000-fold higher expression by RT-PCR of MDR1 mRNA in the former cell line. In this study, both DNAs were radiolabeled with ^{99m}Tc via MAG3 and administered i.t. or i.v. at 1 μg (100 μCi) per animal 24 h prior to sacrifice and dissection in mice bearing thigh tumors of about 1 g. Following i.t. administration, no statistically significant differences (Student's t test, $p < 0.05$, $N = 4$) between the AS and S DNA biodistributions in normal tissues were observed except in the KB-G2 mice in which muscle levels were lower for the S control. In contrast, tumor levels in the KB-G2 animals were significantly higher for the AS DNA vs S DNA (14.7 vs 8.5% ID/g) while this difference (8.6 vs 4.3% ID/g) was insignificant in the KB-31 animals. The whole body images obtained just prior to sacrifice clearly show improved targeting of AS DNA vs S DNA in the KB-G2 but not the KB-31 animals. Calculations based on these results show that about 60 000 AS DNAs accumulated specifically (i.e. AS DNA − S DNA) per KB-G2 tumor cell following i.t. administration. When administered i.v. rather than i.t., higher tumor levels in KB-G2 animals compared to KB-31 were not observed, most likely because of the lower dosage reaching the tumors. When the KB-G2 and KB-31 results are combined, no statistically significant differences between the AS and S DNA biodistributions in normal tissues were observed except in blood in which S DNA levels were higher and in spleen in which they were lower. In contrast, tumor levels were significantly higher for the AS DNA vs S DNA (0.100 vs 0.063% ID/g). Calculations based on these results show that about 400 AS DNAs accumulated specifically per tumor cell following i.v. administration. Therefore evidence for tumor targeting in vivo by an antisense mechanism has been obtained in that statistically higher tumor accumulations of the ^{99m}Tc-AS DNA were observed compared to the control ^{99m}Tc-S DNA both following i.t. and i.v. administrations. The successful localization of AS DNA in tumor demonstrates that in vivo AS targeting of tumor is feasible although improvements in tumor delivery and normal tissue clearance are needed for practical antisense imaging.

INTRODUCTION

Before radiolabeled antisense (AS) oligomers merit serious consideration as targeting modalities for tumor and other tissues, it must first be demonstrated to the greatest possible extent that localization follows an antisense mechanism. To prove an antisense mechanism may be extremely difficult especially in the case of phosphorothioate DNAs that show high binding affinities for proteins. One obvious concern is the possibility of binding by an aptameric mechanism in which the AS oligomer, but not its control oligomer, assumes a particular configuration that encourages binding to cellular proteins by a sequence-specific but non-antisense mechanism (*1*). If increased accumulations compared to control DNAs are observed for a variety of DNAs, radiolabeled by different methods, with antisense base sequence against different messenger RNA (mRNA) targets and

in different cell types with irrelevant base sequences (e.g. sense, random, scrambled), then an aptameric mechanism for the increased accumulations may be largely excluded. Since oligomers with different base sequences will show differences in behavior, a large number of such studies with positive accumulations compared to controls will be necessary to exclude aptameric effects as a plausible mechanism.

In general, to help establish an antisense mechanism by a different means, at a minimum, four criteria should be met: (1) higher accumulations must be demonstrated for the AS oligomer in comparison to a control oligomer designed to be as identical as possible to that of the study DNA but with restricted or nonexistent hybridization affinities for the mRNA target; (2) higher accumulations compared to controls should be demonstrated for the AS oligomer in a variety of cell types, hopefully with accumulations in proportion to the estimated mRNA target concentrations of each cell type; (3) the higher accumulations should be demonstrated for different AS oligomers directed against different mRNA targets as evidence against aptameric effects; and (4) the higher accumulations of the AS oligomer should be shown to decrease with increasing AS DNA concentrations as evidence of specific binding.

While a direct demonstration of an antisense mechanism remains elusive even in cell culture, indirect evidence of this mechanism is now common. We have observed statistically significant increased accumulation of radioactivity in LS174T colon cancer cells and ACHN kidney cancer cells with endogenously labeled ^{35}S as well as ^{99m}Tc-radiolabeled uniform phosphorothioate MAG3-DNA against the regulatory subunit I alpha (RIα) mRNA of protein kinase A (PKA) compared to sense and random DNA controls but not in HC2 cells with irrelevant murine RIα mRNA (*2*). An increased accumulation of radioactivity in MDA-MB-231 breast cancer cells with ^{99m}Tc-labeled Hynic-DNA antisense to the c-myc oncogene compared to the S DNA control has also been observed (*3*). Recently a statistically significant increased accumulation was also observed in targeting of multidrug resistance mRNA in epidermal carcinoma cells KB-G2 and KB-31 with ^{99m}Tc-labeled AS MAG3-DNA compared to the S DNA control (*4*). Should an AS oligomer assume a particular configuration that encourages increased cellular accumulation by an aptameric effect, this would be extremely unlikely to be the case for each of the large variety of base sequences, labeling methods, mRNA targets and cell types described in the above studies.

Another test of specific mechanism of localization is to demonstrate that accumulation decreases with increasing dosage as binding becomes saturated. When ACHN cells were incubated with ^{99m}Tc-labeled AS DNA with increasing concentrations of unlabeled AS DNA in the range 7 to 100 nM and compared to the accumulations of ^{99m}Tc-labeled S DNA with increasing concentrations of unlabeled S DNA in the same range, the difference in AS compared to S DNA accumulations decreased and became statistically insignificant as the concentration increased (*2*). More definitive results have recently been observed for ^{99m}Tc-labeled AS and control S DNAs in the KB-G2 and KB-31 cells as well as TCO-1 cells, another multidrug resistance positive cell type (*4*).

These studies in cell culture therefore generally satisfy the above four conditions necessary to claim evidence of an antisense mechanism. The more important remaining challenge is therefore to demonstrate evidence of an antisense mechanism in vivo. Herein we report on the first results from these laboratories of in vivo antisense targeting of tumor in mice. The MDR++ cell line KB-G2 and its parent MDR+ cell line KB-31 were again used along with the same AS and control S DNAs used previously with these cell types. The expression of MDR1 has been reported to be 1000-fold higher by RT-PCR for KB-G2 cells compared to KB-31 cells (*4*). In that investigation, the increased expression of MDR in the KB-G2 cells compared to KB-31 cells and the specificity of the AS DNA for its target were both confirmed in cell culture using ^{99m}Tc-sestamibi, a substrate of MDR. Because delivery is an important issue in antisense targeting, especially when oligomers are to be administered naked as in this case, intratumor (i.t.) as well as intravenous (i.v.) administrations were performed.

MATERIALS AND METHODS

Uniform phosphorothioate DNAs were obtained for this investigation with a primary amine on the 5′-end via a six-carbon alkyl linker (Qiagen, Alameda, CA). All DNAs were 20-mer and all were HPLC purified by the supplier. The base sequence of the AS DNA was 5′-CCA-TCC−CGA-CCT-CGC-GCT-CC while that of the S control was 5 '-GGA-GCG-CGA-GGT-CGG-GAT-GG (*5*). S-Acetyl NHS-MAG3 was synthesized in house (*6*) and its structure confirmed by elemental analysis, proton nuclear magnetic resonance, and mass spectroscopy. The P4 medium for separation was purchased (Bio-Rad Laboratories Inc., Hercules, CA). The ^{99m}Tc-pertechnetate was eluted from a $^{99}Mo-^{99m}Tc$ generator (Bristol-Myers Squibb Medical Imaging, Inc., North Billerica, MA, or Daiichi Radioisotopes, Tokyo, Japan). The two cell lines were a generous gift from Dr. I. Sugawara, Research Institute of Tuberculosis, Tokyo, Japan. Other chemicals were obtained from various suppliers and used without purification.

DNA Conjugation and Radiolabeling. Both DNAs were conjugated with *S*-acetyl NHS-MAG3 via the 5′-derivatized amine as previously described (*7*). A solution of 1 mg (about 0.15 μmol) of DNA in 200 μL of 0.2 M pH 8.0 HEPES buffer was added to a vial containing 1.7−2.0 mg (about 4.5 μmol) *S*-acetyl NHS-MAG3. The vial was vortexed immediately and incubated for 1 h at room temperature. The DNA was then purified on a 0.7 × 20 cm P4 column with either 0.25 M pH 5.2 NH_4OAc buffer or 0.05 M PBS pH 7.2 buffer as eluant. The peak fractions were pooled and the DNA concentration quantitated by UV absorbance at 265 nm.

Radiolabeling of the DNAs was achieved by introducing about 1 mCi (20−40 μL) of ^{99m}Tc-pertechnetate generator eluate into a combined solution consisting of 50 μL (about 10 μg) MAG3-conjugated DNA in either buffer, 25 μL of 50 μg/μL Na_2tartrate·$2H_2O$ in a pH 9.2 buffer, and 5 μL of fresh 4 μg/μL $SnCl_2$·$2H_2O$ in 10 mM HCl. The final pH was about 7.8. After vortexing and then heating for 20 min in boiling water, the labeling was confirmed by C18 SepPak (Waters, Milford, MA) in which the first elution with PBS removes radiolabeled pertechnetate and tartrate, the second elution with 40% acetonitrile removes radiolabeled DNA and the SepPak retained radiolabeled colloids. In most cases, the radiochemical purity exceeded 90% without purification, and the specific radioactivity was about 100 μCi/μg.

Biodistribution Studies. All animal studies at UMMS were performed with the approval of the UMMS Institutional Animal Care and Use Committee while all animal studies at Keio University School of Medicine were performed with the approval of The Laboratory Animal Care and use Committee.

For the i.t. studies, the cells were grown in D-MEM supplemented with 10% fetal bovine serum (FBS), 100

units/mL penicillin, and 100 μg/mL streptomycin (Gibco-Invitrogen, Carlsbad, CA). Cells were maintained as monolayers in a humidified 5% carbon dioxide atmosphere, normally in T75 flasks (Falcon, Becton Dickinson, Lincoln Park, NJ). The cells were trypsinated in the T75 flasks at 80−90% confluence using 0.05% trypsin/0.02% EDTA and were then suspended in MEM with 10% FBS.

For the i.v. studies, the cells were grown in RPMI medium (RPMI 1640, Gibco BRL Products, Gaithersburg, MD) with 2.0 mg/L sodium bicarbonate, supplemented with 10% FBS. The cells were trypsinated in the T75 flasks at 80−90% confluence using 0.5% trypsin and were then suspended in PBS.

Nude mice (i.t. studies: NIH Swiss, Taconic Farms, Germantown, NY, 30−40 g; i.v. studies: BALB/c AnNCrj-nu male, Oriental, Tokyo, 25−30 g) were each injected subcutaneously in the left thigh with a 0.1 mL suspension containing 10^7 KB-G2 or KB-31 tumor cells with greater than 95% viability. Animals were used 10 days (KB-31) or14 days (KB-G2) later when the tumors were about 1.0 cm in any dimension. Each tumored nude mouse was injected with 1.0 μg of DNA (100 μCi) in 100 μL i.v. via a tail vein or with 50 μL i.t. Animals were sacrificed under halothane anesthesia at 24 h, blood and other organs were removed, weighed, and counted in a NaI(Tl) well counter along with a standard of the injectate. Statistical significance between tissue radioactivity levels in animals receiving AS vs S DNA was established by the Student's t test two-tailed distribution and paired.

In the case of animals receiving radiolabeled DNA by i.t. administration, prior to sacrifice, the animals were imaged simultaneously in groups of four while resting on the collimator of an Elscint APEX 409 M large view gamma camera (Hackensack, NJ).

RESULTS

The biodistribution results obtained 24 h post i.t. administration of radiolabeled AS and S DNAs to nude mice bearing KB-G2 and KB-31 tumors are presented in Tables 1 and 2, respectively. The only normal tissues showing statistically significant differences in radioactivity accumulation of AS DNA compared to S DNA are in the KB-G2 animals in which muscle levels were lower for the S DNA. Possibly because of differences in pharmacokinetic properties of the DNAs resulting from the different base sequence, tissue levels tend to be higher in general following administration of the S DNA when administered i.t. That this difference was not seen following i.v. administration may be due to pharmacokinetic differences following delivery into the vasculature compared to the lymphatics.

While the tumor accumulations were higher in both animal models following administration of the AS DNA compared to S DNA, this difference was significant only in the KB-G2 case. The absence of significance in the KB-31 case may be related to the large standard deviations of the tumor values resulting from the i.t. administrations. That the accumulations of AS DNA in KB-G2 tumor compared to KB-31 were significantly higher ($P = 0.047$) may be related to the higher expression levels of the target MDR1 mRNA in the former tumor type. The higher accumulation of S DNAs in KB-G2 tumors compared to KB-31 tumors failed to reach significance ($P = 0.13$).

These biodistribution results are faithfully reflected in the whole body radioactivity images obtained at 22 h postadministration as shown in Figures 1 and 2. Each figure is a composite in which scintigraphic whole body images have been superimposed on a photographic image taken during imaging to provide accurate registration. In each image, two animals receiving the AS DNA have been imaged simultaneously with two animals receiving the S DNA, as indicated in the figures. The higher radioactivity levels in tumor (left thighs) in animals receiving the AS DNA compared to animals receiving the S DNA is readily apparent in Figure 1 for KB-G2 tumored mice. The higher levels are less evident in Figure 2 for KB-31 animals.

From the specific radioactivity of the labeled DNAs, the dosage administered, the percent accumulating in each gram of tumor and under the assumption of 10^8 tumored cells per gram, a simple calculation will show that about 66 000 AS DNAs accumulated specifically (i.e. AS DNA accumulation − S DNA accumulation) per KB-G2 cell while for KB-31, this value was 53 000 per cell.

Table 3 presents biodistribution results obtained in the identical fashion to that of Tables 1 and 2 except that administration was intravenous rather than intratumoral. This study was performed separately for both KB-G2 and KB-31 animals. However, unlike the i.t. study, no differences were apparent between the biodistributions obtained in KB-G2 and KB-31 animals following

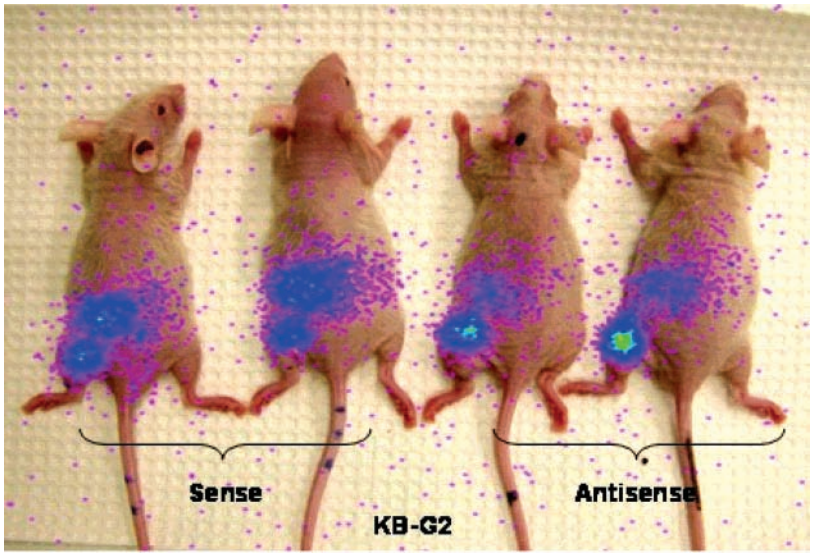

Figure 1. A composite obtained at 22 h postadministration in KB-G2 tumored mice. The scintigraphic whole body image has been superimposed on a photographic image taken during imaging to provide accurate registration. Two animals receiving the AS DNA are on the right while two identical animals receiving the control S DNA are on the left. In all cases, the tumor is in the left thigh.

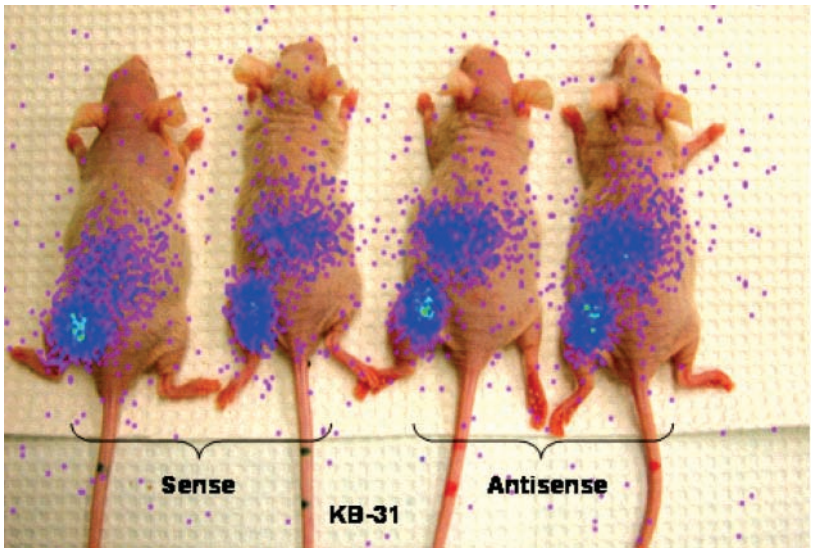

Figure 2. A composite obtained at 22 h postadministration in KB-31 tumored mice. The scintigraphic whole body image has been superimposed on a photographic image taken during imaging to provide accurate registration. Two animals receiving the AS DNA are on the right while two identical animals receiving the control S DNA are on the left. In all cases, the tumor is in the left thigh.

i.v. administration (data not presented). Whereas tumor levels for both DNAs were higher in KB-G2 compared to KB-31 animals following i.t. administration, tumor levels were identical following i.v. administration. This may be due to the much smaller dosage of DNA reaching the tumor following i.v. administration compared to i.t. such that the difference in the number of mRNA targets between the two tumors may be immaterial under the i.v. conditions. The KB-G2 and KB-31 results have therefore been combined in Table 3 to improve the estimate of statistical significance.

Among the normal tissues considered, only blood and spleen showed statistically significant accumulations between AS and S DNAs with the former showing lower levels and the latter higher levels for the S DNA. The accumulation of AS DNA was higher in most normal organs as shown in Table 3 although these differences are not significant. Since the mouse MDR1 gene is reported to be expressed in most mouse organs such as liver, kidney, lung, and heart and since there is reported to be homology in the mouse and human gene (*8*), some of the observed increased accumulations of AS DNA in normal tissues may be specific.

Possibly because the variability in tumor accumulations was much smaller following i.v. vs i.t. administration, the higher accumulation of the AS DNA in tumor compared to S DNA following i.v. administration is considerably more statistically significant compared to that of the KB-G2 tumors following i.t. administration. The identical calculation applied to animals administered i.v. as that described above for animals receiving i.t. injections show that about 400 AS DNAs accumulated specifically in each tumor cell.

DISCUSSION

An evaluation of studies in cell culture with AS oligomers permits the conclusion that, thus far, results have been very positive (*2*). Accumulations have been observed by what appears to be an antisense mechanism, and the magnitude of these accumulations have been much greater than that predicted on the basis of estimated steady-state mRNA levels (*9*). The more difficult

challenge that remains is now to demonstrate that AS oligomers will accumulate in target tissues in vivo by an antisense mechanism. Among the factors that will make this challenge difficult is insufficient delivery of AS DNA into tumor cells when administered i.v. While in culture, cellular accumulations are at levels that would certainly provide adequate nuclear medicine images; the barriers to in vivo cellular accumulations will reduce these levels considerably. Another factor contributing to the difficulties ahead may be nonspecific accumulations of radiolabeled DNAs in nontarget tissues leading to high background radioactivity levels.

An impression that antisense imaging may not be achievable has been reinforced by the general absence of positive results thus far in the limited number of published studies of in vivo antisense targeting (*10*, *11*). Recently positive images were reported in mouse xenografts in which the target mRNA could be upregulated by epidermal growth factor (*12*). Superior images were obtained following ^{111} In-labeled DNA administration in mice bearing the tumor following upregulation. However, since no significant differences were observed between the AS DNA and its random control DNA, the improvement in imaging with upregulation may not be due to an antisense mechanism. The possibility that the intratumor administration of epidermal growth factor has altered tumor phenotype to explain the increased accumulations cannot be excluded. Recently, several other in vitro and/or in vivo studies have been reported using control tumors (*13*−*15*). While useful in other ways, the results of these investigations shed little light on whether accumulations were by an antisense mechanism since control oligomers were not used. Convincing evidence of an antisense mechanism in the in vivo targeting of firefly luc gene in the brain of transgenic mice was obtained using a ^{125}I-labeled peptide nucleic acid (PNA) and quantitative autoradiography. Higher accumulations of the antisense oligomer was reported compared to control oligomer (*16*). Autoradiography had also earlier been used to show higher in vivo accumulations of a ^{11}C-labeled AS DNA against a target mRNA expressed in rat tumor compared to a mismatched control DNA (*17*). A more recent report presents whole body images of tumored rats obtained with ^{68}Ga-AS DNA directed against the K-ras mRNA (*18*). While a control tumor not expressing the target mRNA was used and accumulation of labeled AS DNA compared to the study tumor, a control DNA was apparently not used in the imaging studies. In another study, a careful investigation of antisense targeting of c-myc mRNA in mice using ^{99m}Tc-labeled PNAs showed a significantly higher accumulation in tumor of the AS compared to mismatched control oligomer at 4 h but not 24 h post i.v. administration (*19*). Despite the encouraging results of this study, a positive biodistribution in a tumored animal that may be attributed to antisense targeting has not yet been reported. In a pioneer study, Dewanjee et al. reported surprisingly positive results in a mouse tumor model using an AS DNA of unspecified sequence complementary to the initiation codon site of the c-myc oncogene mRNA (*20*). However, these favorable results have yet to be reproduced elsewhere.

The results obtained in this in vivo investigation are encouraging. In the absence of additional studies, it is not possible to claim that the mechanism of tumor accumulation observed herein involved in vivo antisense targeting. However, the significantly higher levels of AS DNA compared to control S DNA accumulated in tumor both following i.t. and i.v. administrations in a well characterized AS DNA/tumor cell system *(4)* provides what may be convincing, albeit not yet definitive, evidence for antisense tumor targeting. These results would appear to satisfy two of the four criteria described above that may be necessary and sufficient to claim evidence of an antisense mechanism. First, tumor accumulation of AS DNA reached higher levels compared to control DNA. Second, tumor accumulation appeared to increase with increasing target mRNA levels in that the accumulations in Pgp++ KB-G2 tumors exceeded that of Pgp+ KB-31 tumor following i.t. administration. That no difference between tumor types was observed following i.v. administration may be attributed to the low dosage of DNAs delivered via this route that may have been so far below saturation levels that differences in mRNA target concentrations became irrelevant.

In conclusion, evidence for tumor targeting in vivo by an antisense mechanism has been obtained. The successful localization of AS DNA in tumor demonstrates that in vivo antisense targeting of tumor is feasible although improvements in tumor delivery and clearance from normal tissues are needed for practical antisense imaging.

Synthesis and Properties of Fluorescent NF-κB-Recognizing Hairpin Oligodeoxyribonucleotide Decoys

Valeri Metelev,† Ralph Weissleder, and Alexei Bogdanov, Jr.*

Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, Massachusetts 02129, and Department of Radiology, Harvard Medical School, Boston, Massachusetts 02129. Received April 6, 2004; Revised Manuscript Received May 27, 2004

Intramolecular fluorescence quenching of cyanine dyes was investigated using a model hairpin oligonucleotide decoy encoding a NF-κB p50 subunit binding site. Two types of hairpin oligonucleotides were synthesized: (1) 5′-(6-aminohexyl)- and 3′-(3-aminopropyl)-linked (**I**); (2) 5′-(6-aminohexyl)- and 3′-[3-(3-hydroxypropyldithio)propyl]-linked (**II**). Oligonucleotide **I** was covalently modified using monofunctional either Cy3- or Cy5.5-*N*-hydroxysuccinimide esters. Using reverse-phase HPLC, mono- and dicyanineamide derivatives of **I** were isolated. Mono-Cy3-modified derivatives of **I**, but not the mono-Cy5.5-modified derivatives, showed a 2-fold higher Cy3 fluorescence intensity compared to the free dye. There was no detectable difference in fluorescence between the di-Cy3 derivative of **I** and the free dye at the same concentration. However, there was a 4-fold quenching of fluorescence in the case of the di-Cy5.5 derivative of the same hairpin oligonucleotide. The quenching of Cy5.5 fluorescence could not be explained by the interaction of Cy5.5 with nucleotide bases as demonstrated by incubating free Cy5.5 dye with oligonuclotides. The quenching effect was further investigated using an oligonucleotide bearing a cleavable 3′-amino-terminated linker bearing an S−S bond (**III**). After modification of the 5′- and 3′-end of oligonucleotide **III** with a Cy5.5 monofunctional hydroxysuccinimide ester, a 70−75% quenching of fluorescence was observed. Fluorescence was 100% dequenched after the reduction of S−S bond. The obtained result unequivocally demonstrates that the formation of intramolecular Cy5.5 dimers is the dominant mechanism of fluorescence quenching in symmetric dye−dye hairpin decoy beacons.

INTRODUCTION

The ability to attenuate the level of target gene expression in living cells allows individual biochemical pathways to be dissected (*1*) as well as alteration of the phenotype and, potentially, enables the attenuation of gene expression in vivo (*2*−*6*). The "knockdown" of gene expression could be achieved at transcription and post-transcription. In the first case, oligonucleotide hairpin decoys could be used (reviewed in ref 7). In the second case, siRNA (small interfering) (*8*, *9*) and antisense oligonucleotides have been proven to be effective. The inhibitive effect of both DNA-based and RNA-based constructs depends to a large extent on their ability to penetrate into the cellular interior and on the rate of intracellular catabolism of short oligo deoxy- or ribonucleotides. Both endo- and exonuclease degradation severely limits the half-life of oligodeoxyribo- or oligoribonucleotides in vitro and in vivo. Nevertheless, the stability of oligonucleotides can be modified by applying a variety of synthetic strategies (*10*, *11*), reviewed in refs 12−14). While recent research has proved that antisense oligoribonucleotides (especially siRNAs) are undoubtedly efficacious in vitro, they are susceptible to rapid degradation prior to interaction with target mRNA in vivo (*15*). Small interfering RNAs are also known to activate interferon-mediated pathways resulting in a broad interferon-mediated gene upregulation (*16*, *17*).

Hairpin oligonucleotide decoys are designed to block the transcription of a target gene by competing with genomic DNA for relevant transcription factors. For example, decoys bearing a NF-κB recognition sequence, which binds the p50 subunit of a transcription factor, were amenable to modifications with reactive nucleotide analogues that enabled trapping of NF-κB on the decoy and resulted in apoptosis (*18*−*20*). To assess the efficacy of intracellular penetration and to track their intracellualr fate, oligonucleotides can be labeled with molecular probes to make them detectable by imaging techniques, either microscopic, or macroscopic for in vivo work (*21*−*24*). The goal of this work was to synthesize and characterize far-red fluorochrome-labeled decoys. Indocyanine far red fluorescent dyes have excellent photostability, are pH insensitive, and potentially could be detected in vivo. We anticipate that such labeled oligonucleotides will prove useful in elucidating mechanisms of hairpin decoy penetration into cells and imaging interactions between the decoy and target transcription activators.

MATERIALS AND METHODS

Materials. Oligodeoxyribonucleotides with 3′,5′-diaminoalkyl linkers were synthesized at MGH Department of Molecular Biology, DNA Oligonucleotide Synthesis Core (Dr. Jay Klaren) and supplied in ammonia solution.

Triethylammonium acetate solution (2 M, TEAA), pH 7.0, was purchased from Glen Research (Sterling VA), 2-aminoethyl-2′-aminoethanethiosulfonate from Pierce-

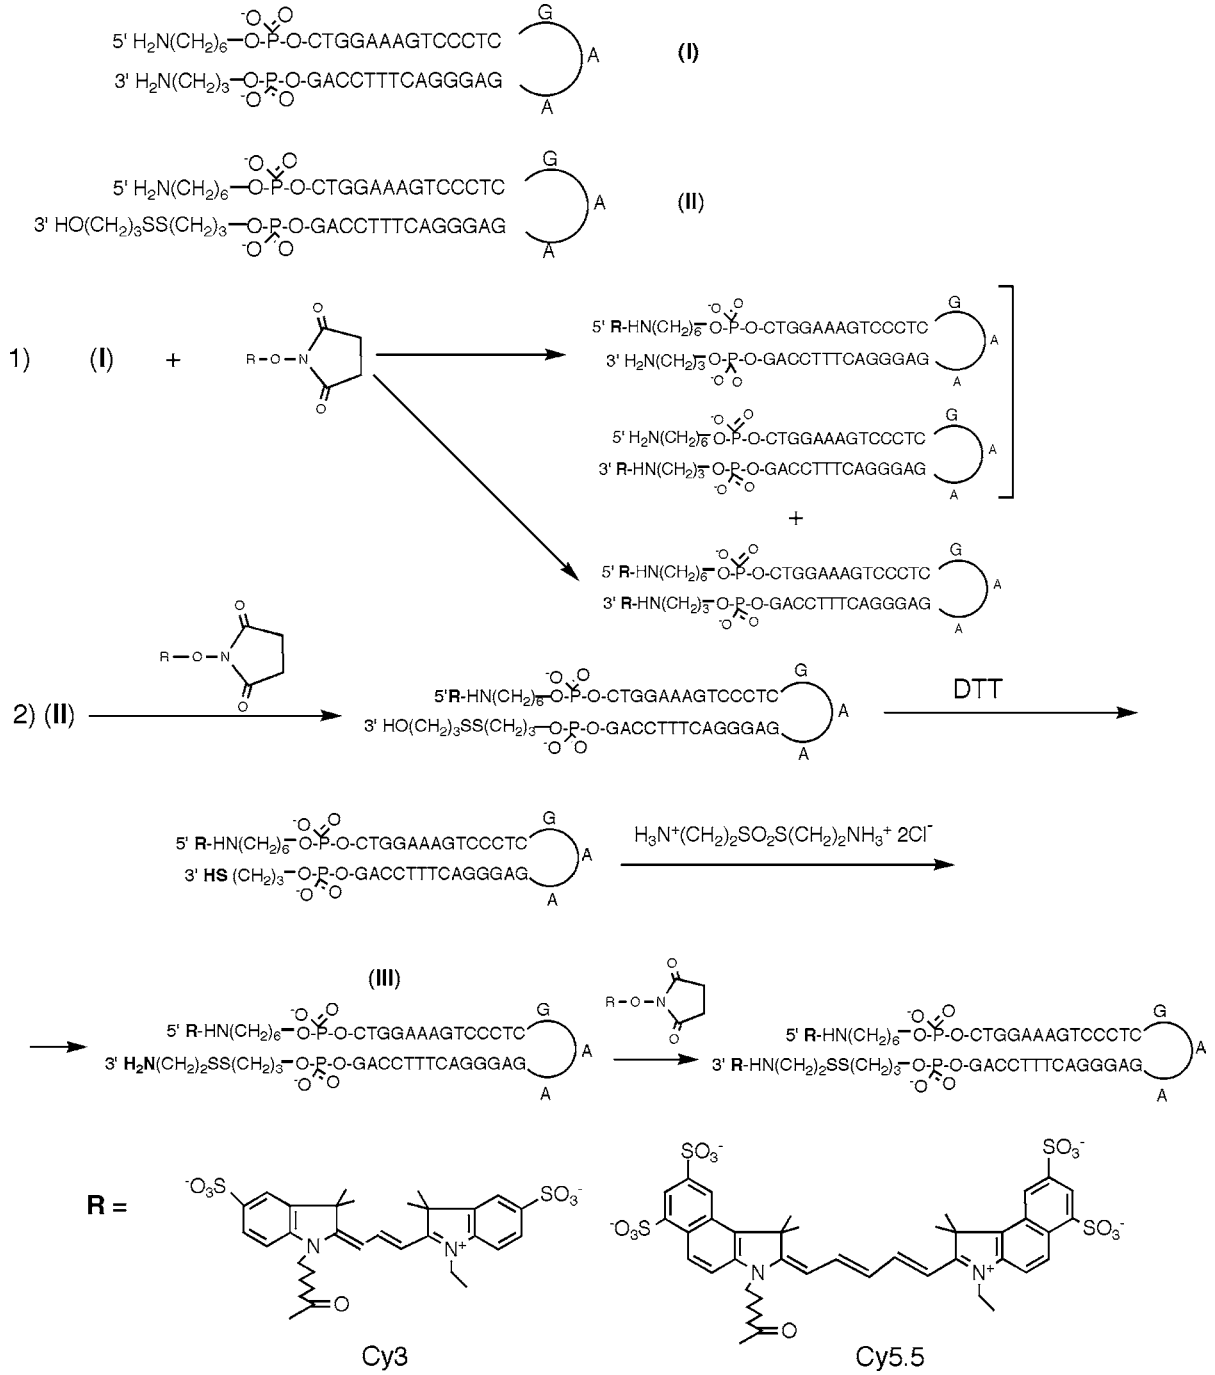

Figure 1. Scheme of fluorescently labeled hairpin oligonucleotide decoy synthesis. **I**, precursor (noncleavable, diamino terminated) oligonucleotide; **II**, oligonucleotide with a 3′-dithio linker; **III**, monomodified oligonucleotide with an amino-terminated dithio linker.

Endogen (Rockford, IL), Cy5.5 mono-*N*-hydroxysuccinimide ester (NHS) and Cy3 NHS from Amersham Biosciences (Piscataway, NJ). Micro Bio-Spin 6 columns (SSC buffer, pH 7.0) were obtained from Bio-Rad (Hercules CA). All other chemicals were from Sigma-Aldrich (St. Louis, MO).

Initial Purification of Oligonucleotides. The ion-pair reversed-phase HPLC method was used for the isolation and purification of modified oligodeoxyribonucleotides on a C18 column (Zorbax ODS 4.6 × 25 mm, DuPont). For HPLC linear gradient the following buffers were used: A, 2% acetonitrile in 0.1 M TEAA, pH 7; B, 50% acetonitrile in 0.1 M TEAA, pH 7. The column was eluted at 1 mL/min at room temperature. Purified oligonucleotides were concentrated in a centrifugal vacuum concentrator (SpeedVac, Savant).

Modification of Oligodeoxyribonucleotides Bearing 3′- and 5′-Aminoalkyl Linkers (Figure 1, Reaction 1). Ten nanomoles of the oligonucleotide d(pCTG-GAAAGTCCCTCGAAGAGGGACTTTCCAGp) bearing 3′- and 5′-aminoalkyl linkers was dissolved in 15 μL of 0.1 M $NaHCO_3$. To this was added 7 μL of 62 mM Cy3-NHS (or 49 mM Cy5.5-NHS in DMSO), and the mixture was incubated at room temperature for 6−16 h in the dark. Then 40 μL of water was added, and the modified oligonucleotide was separated from excess dye by two consecutive separations on Micro Bio-Spin 6 columns according to the manufacturer's recommendations. After the second spin-chromatography, oligonucleotides were precipitated by standard ethanol−sodium acetate treatment and purified by HPLC as described above. The chromatography showed complete absense of free dyes

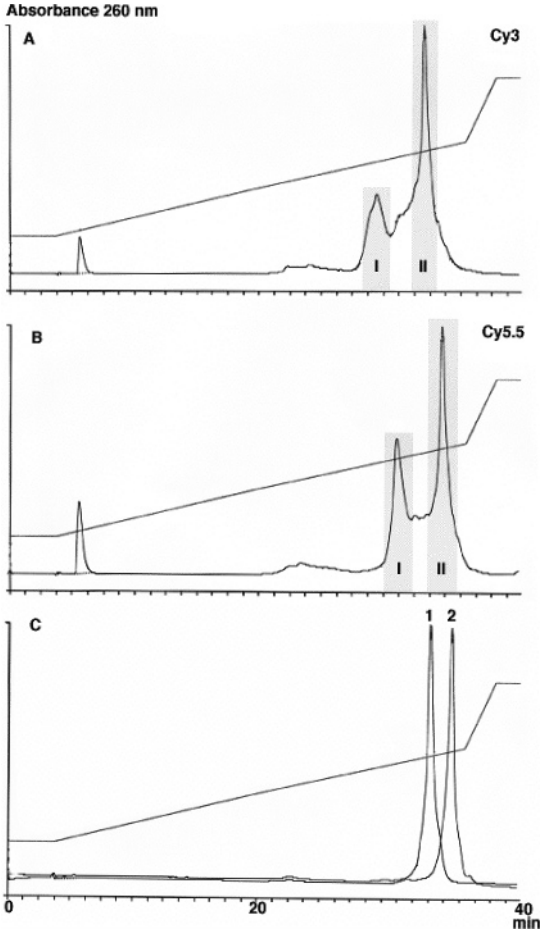

Figure 2. Preparative HPLC of Cy3 (A) and Cy5.5 (B) modified oligonucleotide **I**. Shaded peaks corresponding to mono (I) and di- (II)- modified oligonucleotides were collected for further analysis; (C) superimposed elution profiles of purified dicyanine-modified oligonucleotides: 1, Cy3-modified; 2, Cy5.5-modified oligonucleotide **I**.

and a disappearance of the peak corresponding to the nonlabeled oligonucleotide. Fractions corresponding to mono- and dimodified oligonucleotides were collected (Figure 2) and concentrated by evaporation using a centrifugal vacuum concentrator (final volume about 50−100 μL). Oligonucleotides were precipitated in ethanol−sodium acetate by adding a 0.1 volume of 3 M sodium acetate, pH 5.5, followed by 5 volumes of cold ethanol. Labeled oligonucleotides were characterized using MALDI-mass spectrometry (Integrated DNA Technologies, Coralville, IA) and yielded for di-Cy3-labeled (**I**) ($M + H^+$) 11195.8 (calculated, 11207.0) and for di-Cy5.5 labeled (**I**) ($M+H^+$) 11775.1 (calculated, 11796.5). In calculations we assumed that acetate anion served as a counterion of the quarternized nitrogen in Cy dye residues.

Synthesis of Fluorescent Oligonucleotide Decoy Probes Bearing a Dithio Bond (Figure 1, Reaction 2). The initial compound used for the synthesis of dual-labeled probes was 5′-N-MeOTr-**II**, i.e. oligonucleotide d(pCTGGAAAGTCCCTCGAAGAGGGACTTTCCAGp) bearing asymmetric 5′-(6-MeOTr-aminohexyl)- and 3′-[3-(3-hydroxypropyldithio)propyl] linkers (Figure 1). 5′-N-MeOTr-**II** was purified by HPLC on an octadecyl silica column (Zorbax ODS 5 μm, DuPont) using a linear gradient of buffers A and B (10−100% B, 30 min) and was detritylated using 80% acetic acid for 1 h. Further synthesis included the following steps: (1) reacting the purified oligonucleotide with NHS esters of Cy5.5 or Cy3 dyes as described above; (2) isolating the monolabeled oligonucleotide on the HPLC column and reducing the 3′-disulfide bond with dithiotreitol, resulting in the formation of an oligonucleotide bearing a 3′-(3-mercaptopropyl) linker. Briefly, 10 μL of 1 M DTT was added to the monolabeled oligonucleotide dissolved in 100 μL of 0.02 M $NaHCO_3$. After a 1 h incubation at room temperature, the reduced oligonucleotide was precipitated by using ethanol−sodium acetate treatment; (3) reacting the above oligonucleotide with 2-aminoethyl-2′-aminoethane thiosulfonate. The reaction yielded oligonucleotide **III**, containing a 3′-[3-(2-aminoethyldithio)propyl] linker (Figure 1). Briefly, the oligonucleotide was dissolved in 50 μL of 0.2 M $NaHCO_3$, the solution was cooled to 4 °C, mixed with 15 μL of 0.15 M 2-aminoethyl-2′-aminoethanethiosulfonate and incubated for 1 h at 4° C followed by separation on a Micro Bio-Spin 6 column; (4) modifying oligonucleotide **III** with an *N*-hydroxysuccinimide ester of the reporter dye (Cy5.5 or Cy3); (5) isolating dual-labeled oligonucleotide by HPLC. Oligonucleotides were precipitated by adding 2% lithium perchlorate in acetone and redissolved in water. By MALDI-mass spectrometry the ($M+H^+$) was 11905.6 (calculated − 11893.8).

Interaction of Hydrolyzed Cyanine NHS-esters with Oligonucleotide Containing 3′,5′-Diaminoalkyl Linkers. Three nanomoles of the oligonucleotide was dissolved in 25 μL of solution containing hydrolyzed Cy5.5-NHS, and the resulting mixture was incubated at the same conditions as the standard Cy5.5-NHS oligonucleotide reaction mixture. To obtain hydrolyzed Cy5.5-NHS ester, 7 μL of 49 mM Cy5.5-NHS in DMSO was dissolved in 18 μL of 0.2 M $NaHCO_3$, and the mixture was incubated for 36 h in the dark at room temperature.

Interaction of Hydrolyzed Cy5.5 NHS with DTT or Glutathione. To 35 μL of hydrolyzed Cy5.5 were added 10 μL of 1 M DTT (or 0.5 M reduced glutathione) and 10 μL, 0.2 M $NaHCO_3$, and the solution was incubated in the dark overnight.

The Reduction of Disulfide Bond in Dual-Labeled Oligonucleotides. To reduce the dithio bond in the oligonucleotide and to achieve dequenching of fluorescence, dual-labeled probes were diluted in 1−1.5 mL of PBS buffer (pH 7.5) and subjected to fluorimetry, followed by mixing with 15 μL of 1 M DTT or with 30 μL of 0.5 M reduced glutathione. The solutions were incubated overnight at room temperature followed by fluorimetry as described above.

DNAse Digestion of Labeled Probes. Solutions of the oligonucleotides were prepared in magnesium-containing Dulbecco's PBS, pH 7, at the concentration of 20−100 μM. Each solution was divided into aliquots. For each oligonucleotide, a half of the samples was treated with DNAse I (10 U/mL, Stratagene, La Jolla CA) for 6 h at 37 °C. Control samples were not treated with DNAse. Absorbance and fluorescence at appropriate wavelengths were measured in DNAse-treated samples and compared to the control samples.

Spectral measurements were performed at room temperature using a U-3000 and F-4500 Hitachi spectrophotometer and spectrofluorometer, respectively. The cyanine dyes and labeled oligonucleotides were diluted in 2 mL of PBS, pH 7.5, and absorbance and fluorescence spectra were recorded sequentially in quartz cuvettes.

RESULTS AND DISCUSSION

Tagging oligonucleotides with imaging probes provides a means of tracking these molecules in living cells and ultimately in vivo. For example, labeling of oligonucle-

otides with radioactive isotopes has been used for noninvasive tracking of oligonucleotide biodistribution. This approach potentially enables localizing sites of target gene expression (reviewed in (*25*, *26*)). Conjugation of oligonucleotides with cyanine dyes could result in highly useful "beacons" based on the effect of fluorescence quenching between the labeled proximal 3′- and 5′-termini. The quenching effect is abrogated by the dequenching of fluorescence upon the interaction with in vitro targets in structurally constrained stem-loop beacons as well as stemless beacons (reviewed in 27, 28). Moreover, it has been demonstrated that enzyme-specific dequenching of cyanine-labeled macromolecules can be imaged in vivo (*29*). In this report we investigated quenching and dequenching effect in hairpin oligonucleotide decoys using two commercially available cyanine dyes.

Purification of Initial Oligonucleotides. To obtain a first generation of quenched oligonucleotide decoy probes, we used d(pCTGGAAAGTCCCTCGAAGAGGGACTTTCCAGp) as a precursor for synthesis of dye-labeled probes. This oligonucleotide was prepared to enable asymmetric modifications at the 3′- and 5′-termini using a protected 5′-(6-MeOTr-aminohexyl)-linker as well as a free amino group-containing 3′-(3-aminopropyl) linker (Figure 1). We assumed that above linkers would provide a means of conjugating the first dye (reporter or quencher) specifically to the 3′-amino group. The synthesis would be followed by (1) the isolation of the 3′ mono Cy-dye labeled 5′-N-MeOTr-**I** fraction by HPLC; (2) detritylation of **I** by 80% acetic acid. Deprotected compound would then be used to attach the second dye (quencher or reporter) to the free 5′-amino group followed by HPLC purification. Contrary to our expectations, we found that the 5′-MeOTr-NH bond is unstable and hydrolyzes rapidly during the purification of **I** by HPLC in 0.1 M TEAA, pH 7.0, or by using the Poly-Pack cartridge method. Since partial (10−30%) detritylation of the 5′-amino group took place, oligonucleotide **I** could not be used for synthesis of probes dually labeled by two different dyes. Therefore, after HPLC isolation from the reaction mixture, oligonucleotide **I** was detritylated by 80% acetic acid, and the obtained oligonucleotide (HPLC elution time, 18.5 min) was used to synthesize probes dually labeled by Cy3 or Cy5.5 cyanine dyes.

Purification of dye-modified oligonucleotides from nonreacted dyes was attempted using three approaches: (a) by repeated ethanol−sodium acetate precipitation of oligonucleotide; (b) by gel filtration on NAP-10 cartridges; (c) by separating on Micro Bio-Spin 6 columns. We found that the particular dyes and oligonucleotides used in this work could not be efficiently separated using size-exclusion chromatography on a Sephadex G-25 column (NAP-10). A procedure involving separations on Micro Bio-Spin 6 columns followed by ethanol−sodium acetate precipitation of the oligonucleotides was clearly superior over other purification strategies. The mono- and dimodified derivatives could then be easily separated using a C18 HPLC column Figure 2 (A,B, peaks I and II). The isolated fluorescent dimodified oligonucleotides showed a very high purity (Figure 2, C) suitable for further spectral analysis and mass-spectrometry. Elution times on HPLC column were 27.0 min for the di-Cy3-modified oligonucleotide and 28.3 min for the di-Cy5.5-modified one.

Spectral Properties of Modified Oligonucleotide I. To investigate spectral properties of cyanine dye-modified oligonucleotides, we initially performed a modification of hairpin oligonucleotide **I** with Cy3-NHS and Cy5.5-NHS followed by the isolation of mono- and dicyanine derivatives of **I** using HPLC. The above dyes were chosen because of the advantageous photostability of Cy3 and the near-infrared "in vivo imaging" fluorescence range of Cy5.5 (*29*, *30*). The initial experiments showed that the attachment of dyes to hairpin oligodeoxyribonucleotides with 3′-(3-aminopropyl), 5′-(6-aminohexyl)-linkers resulted in significant changes in the visible range of cyanine dye absorption when spectras of nonconjugated dyes were compared to the cyanine-modified oligonucleotides. First, we observed an increase of absorbance in the range of 500−525 nm in the case of Cy3 (Figure 3A) and in the range of 600−650 nm in the case of Cy5.5 after the conjugation (Figure 3B). Such spectral changes were previously attributed to a formation of dimers in Cy-modified proteins (*31*). In our case, such spectral changes were detectable only in the case of dimodified oligonucleotides as opposed to its mono-Cy derivative. There was no evidence of the formation of J-aggregates that absorb light at longer wavelengths. The increase of absorption at shorter wavelengths was especially prominent in the case of Cy5.5 and was less prominent for Cy3 derivatives (Figure 3). In addition, there was a small but detectable 3−5 nm-"red" shift of the fluorescence emission maximum. We also observed that covalent linking of a single Cy3 group to **I** causes a 100% increase of the fluorescence intensity. In the case of Cy5.5 fluorescence in the mono-derivatized oligonucleotide did not change appreciably whereas dimodified **I** showed a substantial quenching of Cy5.5 fluorescence which could be reliably measured using extensive enzymatic degradation of the oligonucleotide. As a result of DNAse-mediated cleavage, fluorescence increased approximately 13 times. Additional control experiments that included incubating hydrolyzed cyanine dye esters with the oligonucleotide showed that the above fluorescence effects were specific for conjugated dyes and could not be explained by simple interaction of cyanine moiety with nucleotides (e.g. partial intercalation of cyanine group between the nucleotide pairs).

Experiments with Derivatives of Oligonucleotide II Containing a Cleavable Bond. To prove that the observed self-quenching effects were caused by the interaction of two cyanine dye residues positioned in close proximity to each other (i.e. that hairpin conformation induces the dimerization of Cy5.5 dye), we designed a hairpin oligonucleotide **II** (HPLC elution time, 19.1 min) with a nucleotide sequence identical to that of **I** but containing a dithio bond at the 3′-terminus of the molecule (Figure 1). We hypothesized that the bond could be reduced and that the formed 3′-sulfhydryl could then react with 2-aminoethyl-2′-aminoethanethiosulfonate to form a 3′-amino linker bearing a dithio bond. The amino group could be then used for further modification of **II** with a second fluorophore or other probe to yield oligonucleotide **III** (Figure 2, HPLC elution time, 28.0 min). In oligonucleotide **III** that bears two Cy5.5 modifications, the 3′-dithio bond could be reduced using a 10−15 mM dithiotreitol (or glutathione). First, we excluded potential quenching of Cy dyes as a result of chemical interaction with DTT or glutathione. Second, we tested whether the reduction that cleaves the S−S bond results in the dissociation of the dimer and resultant dequenching of fluorescence. As expected, after DTT or glutathione treatment, we observed a change in absorbance in the range of 600−650 nm (Figure 4 A) and a dequenching of the Cy5.5 fluorescence (Figure 4B and 4C). The ratio of fluorescence intensities measured after and before the treatment with DTT was in the range of 3.5 to 4. The latter quenching factor was close to that measured using

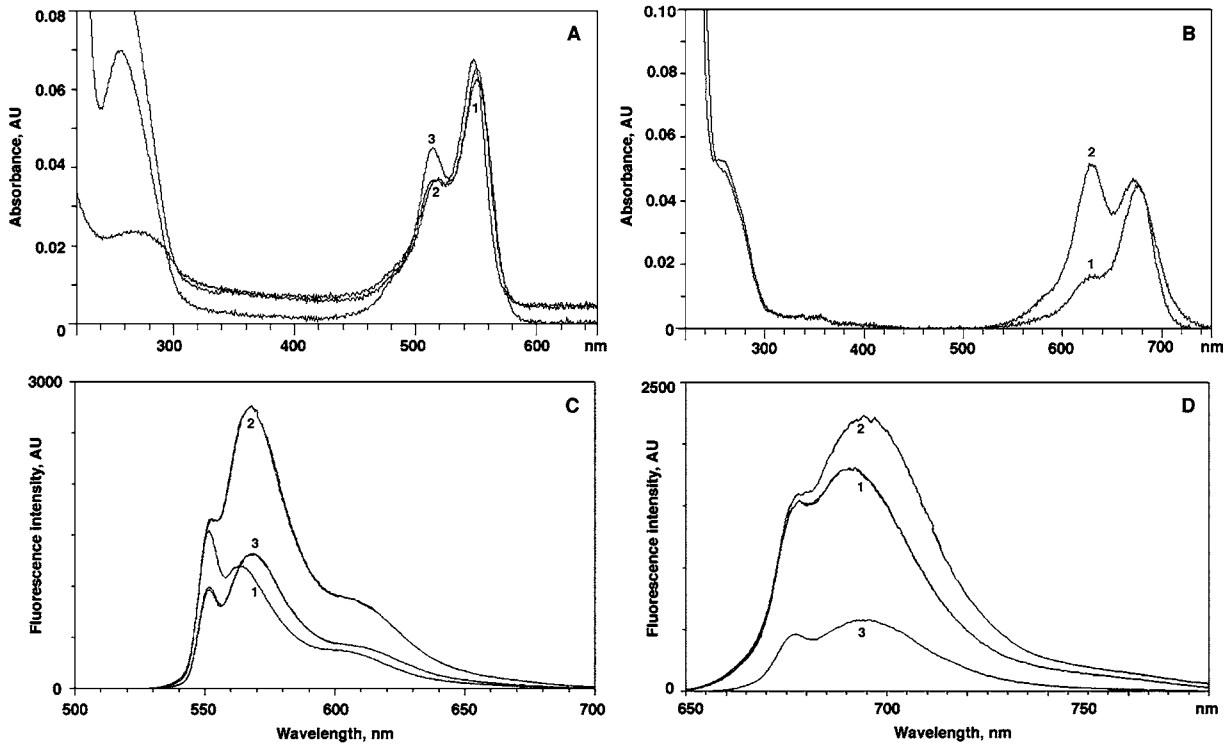

Figure 3. (A) Absorption and (C) emission spectra of 1, Cy3 dye; 2, mono-Cy3 derivative; and 3, di-Cy3 derivative of oligonucleotide **I**. (B) Absorption spectras of 1, mono-Cy5.5; 2, di-Cy5.5 derivative of oligonucleotide **I**, (D) Emission spectra of 1, Cy5.5; 2, mono-Cy5.5 derivative; and 3, di-Cy5.5 derivative of oligonucleotide **I**. The spectrum of di-Cy5.5 oligonucleotide **I** shows strong absorption at 629 nm due to the dye dimerization and no absorption due to J-aggregates.

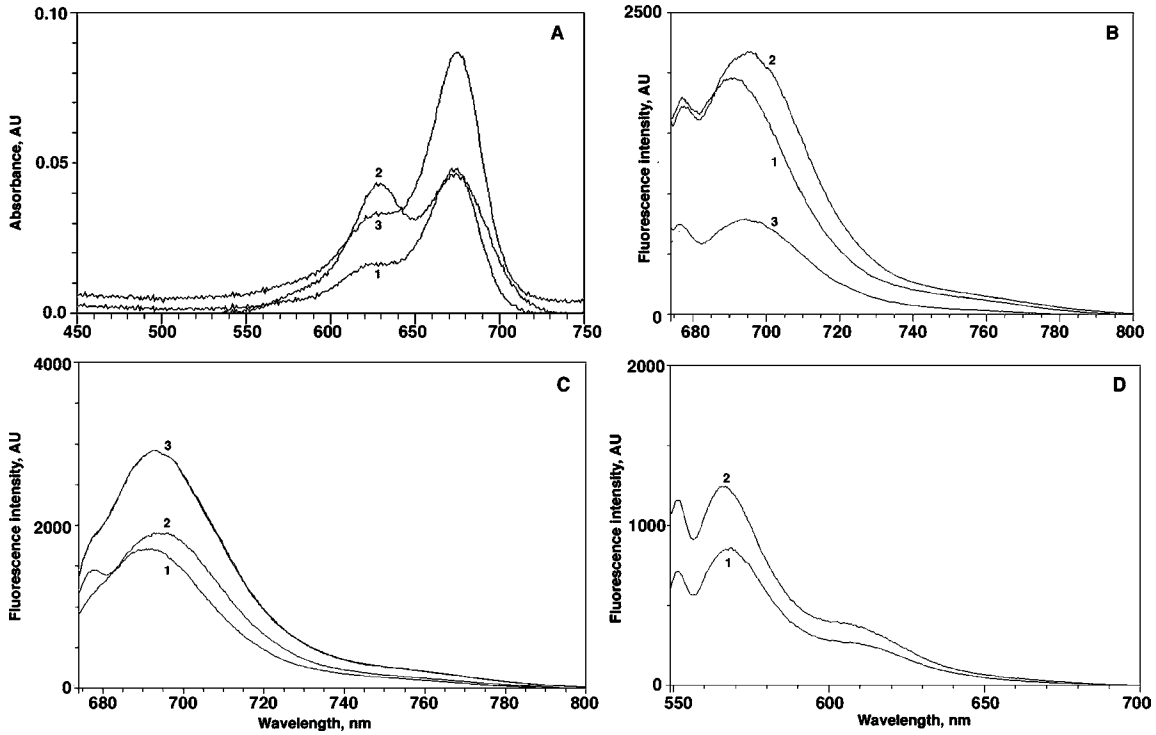

Figure 4. (A) Absorption spectra: 1, Cy5.5 in PBS; 2, dimodified oligonucleotide **III** before disulfide bond reduction with DTT; 3, after DTT treatment. (B) Emission spectra before DTT treatment: 1, Cy5.5; 2, mono-Cy5.5-modified oligonucleotide **III**; 3, di-Cy5.5-modified oligonucleotide **III**. (C) Emission spectra after disulfide bond reduction with DTT: 1, Cy5.5; 2, mono-Cy5.5-modified oligonucleotide **III**; 3, di-Cy5.5-modified oligonucleotide **III**. (D) Emission spectra of di-Cy3-modified oligonucleotide **III** : 1, before; and 2, after DTT treatment.

extensive DNAse I-mediated degradation (5.4 times, Table 1). The absorbance spectrum reverted to the typical Cy5.5 shape following the reduction with a concomitant 1.8- fold increase at the maximum of absorbance because of the transition of 50% of the dimerized, blue-shifted Cy5.5 molecules into the noninteracting pool of molecules. Interestingly, dye quenching in non-DTT-cleavable di-Cy5.5 decoy was more efficient than that of in a cleavable one (Table 1). The observed difference in quenching factors (12.9 for 3′-Cy5.5-**I**-5′-Cy5.5 vs 5.6 for 3′-Cy5.5-

Table 1. Some Fluorescent Properties of Cyanine Dyes and Labeled Oligonucleotide Hairpin Probes

fluorophore/labeled oligonucleotide	excitation, nm	emission max., nm	quenching factor[a]
Cy3	548	563	1.0
Cy5.5	674	692	1.0
Cy3-**I**	548	568	—[b]
Cy3-**I**-Cy3	548	568	5.4
Cy5.5-**I**	674	695	1.1
Cy5.5-**I**-Cy5.5	674	695	12.9
Cy3-**II**	548	568	ND[c]
Cy3-**III**-Cy3	548	567	ND
Cy5.5-**II**	674	695	1.2
Cy5.5-**III**-Cy5.5	674	695	5.6

[a] Quenching factor was calculated as a ratio of fluorescence intensities measured in a sample containing 20−100 μM of labeled hairpin oligonucleotide decoy without DNAse I to that of containing DNAse I. [b] Fluorescence of oligonucleotide-conjugated Cy3 was higher than that of the free Cy3 by a factor of 2. [c] ND, not done.

III-5′-Cy5.5, Table 1) could be a result of differences in both linker length and structure in above constructs. Alternatively, thiol−disulfide exchange catalyzed by minute amounts of free thiols in oligonucleotide **III** dimodified preparation could result in partial dequenching of Cy5.5 dye.

The DTT treatment of di-Cy3-modified oligonucleotide lead only to a modest increase of fluorescence (1.4 times, Figure 4D). However, as noted before, in the case of Cy3 it is problematic to estimate the degree of true quenching of Cy3 conjugated to a hairpin nucleotide since the monomodified Cy3-oligonucleotide had higher fluorescence than free Cy3 dye at the same molar concentration (see Figure 4C). In the case of a monomodified oligonucleotide (i.e. Cy3-NH-oligonucleotide-S−S−CH_2CH_2-CH_2OH) disulfide reduction did not result in any appreciable changes of probe fluorescence (not shown).

In conclusion, we synthesized and tested fluorescent hairpin oligonucleotides bearing one or two fluorophores at their termini. Our results demonstrate that (1) there is a dimerization of cyanine dyes both in the case of dimodified Cy5.5 and dimodified Cy3-labeled oligonucleotides, (2) dimerization of the Cy5.5 fluorophore results in strong self-quenching, and (3) fluorescence quenching in dimodified Cy5.5 oligonucleotides could be reversed by dissociating one of the linkers between the oligonucleotide and one of the dyes. The observed effects and developed synthetic approaches are instrumental in further design of hairpin oligonucleotide beacons that would have reversible, quenched near-infrared fluorescence. We are currently refining the developed synthetic strategy for achieving highly termini-specific labeling with fluorescent probes and fluorescence quenchers.

Molecular imaging is a powerful tool that has the ability to elucidate biochemical mechanisms and signal the early onset of disease. Overexpression of the peripheral benzodiazepine receptor (PBR) has been observed in a variety disease states, including glioblastoma, breast cancer, and Alzheimer's disease. Thus, the PBR could be an attractive target for molecular imaging. In this paper, the authors report cellular uptake and multimodal (MRI and fluorescence) imaging of PBR-overexpressing C6 glioblastoma (brain cancer) cells using a cocktail administration approach and a new PBR targeted lanthanide chelate molecular imaging agent.

INTRODUCTION

Recent discoveries in molecular imaging (MI) are certain to play a vital role in the early detection, diagnosis, and treatment of disease, as well as aid in the study of biological and biochemical mechanisms, immunology, and neuroscience (*1*−*7*). The ubiquitous clinical agent, Magnevist, is a perfusion agent that can give vascularity and fluid transport information, but has the limitation of lacking the ability to target specific tissues. Generally, targeted MI agents consist of a targeting functionality such as an antibody, peptide (*8*), sugar (*9*), or a ligand such as a peripheral benzodiazepine receptor (PBR) ligand (*10*) combined with a signaling moiety (a fluorophore, radioisotope, or Gd^{3+} ion, etc.). In some cases, the signal can be activated by a species found in the target environment such as an enzyme or high Ca^{2+} concentration (*11*−*13*). Targeted fluorescent MI agents show great promise for following gene therapy/delivery (*14*), for elucidating signaling pathways (*1*), and for performing disease diagnosis at the molecular level (*6*). Magnetic resonance MI agents have also been developed that provide unique insights on system physiology (*11*) and allow effective tumor imaging (*5, 12*).

While existing MI agents have been functional, another limitation of most existing MI agents is that they provide a single signature. Multimodal agents have the potential to enhance visualization of diseased tissue by generating more than one signature from a single biological matrix. Two-signature integrated molecules for bimodal imaging have been used by Meade and coworkers to follow cell lineage in *Xenopus laevis* (*15*) and even stem cell migration (*16*). Figure 1 shows the result obtained when a *X. laevis* embryo was injected with Gd−(DTPA)-tetramethylrhodamine-hydroxypropylpoly-(D-lysine) ($GRIP_c$, Figure 1A) into a marginal blastomere (*15*) and subsequently imaged with confocal microscopy (Figure 1B) and MRI (Figure 1C). Both MR and fluorescence signatures seem to colocalize in similar regions of the embryo.

More recently, Josephson, Weissleder, and co-workers have reported an activatable polymeric agent that combines NIR fluorescence and MR properties (*17*). The agent, shown in Figure 2, utilizes a protease cleavable carrier that can be labeled with Cy5.5 and cross-linked iron oxide particles (CLIO). Two dye-arginyl peptide nanoparticle conjugates were reported, Cy5.5-R4-SS-CLIO and Cy5.5-R4-SC-CLIO, where "SS" denotes a disulfide linkage between the peptide and the iron oxide while "SC" denotes a thioether linkage, while R4 stands for four L-arginyl peptides. As reported, the primary amine of a dextran-coated CLIO was reacted with one of two activating agents, either *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) or succinimdyl iodoacetate (SIA), to produce two reactive forms of the CLIO as shown in Figure 2. The L-arginyl peptide is attached to the activated CLIO through a C-terminal cysteine residue while the *N*-hydroxysuccinimide ester of Cy5.5 is attached via the terminal amine, yielding the bifunctional species. Upon in vivo administration of Cy5.5-R4-SC-CLIO, MR and fluorescence signals were observed to be colocalized in lymph nodes (Figure 2A−D). While both of these imaging strategies show promise, the aforementioned contrast agents are of a nontargeted (perfusion) nature. Bimodal *targeted* imaging using a PBR ligand would be particularly attractive due to the importance of this receptor in cell physiology (*18*).

Thus, an alternate approach to bimodal imaging using "cocktails" of the PBR targeted fluorescent Eu-PK11195 and the MR active Gd-PK11195 complex is demonstrated for the first time. Multiple signature moieties could facilitate development of practical methodologies for correlating intraoperative in vivo fluorescence detection with MRI, thereby enhancing tumor resection and subsequently improving patient outcome.

Numerous targets exist for molecular imaging, including the sigma 2 (*19*), EGFr (*20*), and peripheral benzodiazepine receptor (PBR) (*18, 21, 22*). The 18 kDa protein, PBR, located in the mitochondria, has been demonstrated to be associated with numerous biological functions including regulation of cellular proliferation, immunomodulation, porphyrin transport, heme biosynthesis, anion transport, regulation of steroidogenesis, and even apoptosis (*18, 23, 24*). PBR density changes have important implications when acute and chronic human neurodegenerative pathologies are present. For example, temporal cortex obtained from Alzheimer's patients showed an increase in PBR (*25*). Additionally, correlations with Huntington's disease (*26*), multiple sclerosis (*27, 28*), and gliosis (*29, 30*) have been observed. Combined with evidence that PBRs play a major role in proliferation of aggressive tumor cells (*31*), overexpression of PBR in these cells creates an excellent target for study of diseased human tissues and represents a potential tool for improving detection, diagnosis, prevention, and, very likely, treatment of certain cancers.

Because PBR overexpression in diseased tissue has been suggested as an effective target for glioma and CNS disease (*32*), a number of ligands have been developed for targeting this receptor (*10, 22, 33*). Even though PBRs are expressed throughout the body (*18*), their density in the CNS is primarily limited to the ependymal cells and glia (*25*). Thus, compounds based on the well-character-

Scheme 1. Synthesis of Conjugable PBR Ligand (2) and PBR-Targeted Ligand (10)

ized, high affinity PBR ligand (*33*) PK11195 have been tested as PET agents for visualizing rat and human glia (*22*) and as a targeted therapeutic agent when conjugated to the drug gemcitabine (*34*). Furthermore, the ^{11}C PET version is currently being tested in the clinic to study acute brain injury and neuroinflammation (*35*).

Here we describe the first PBR-targeted MI agent that could facilitate MR imaging and, when delivered as a cocktail (Eu^{3+} and Gd^{3+}) of a Ln-PK11195 complex, produces cellular-scale bimodal (MR and fluorescence) imaging. The MI agent described is a PK11195 (nanomolar binding PBR ligand) analogue conjugated to a trifunctional lanthanide chelate (Ln-QM-CTMC) (*36*−*38*). When prepared as the Eu^{3+}complex, Eu-QM-CTMC-PK11195 (Eu-PK11195), exhibited visibly bright fluorescence (*38*). By substitution with Gd^{3+}, Gd-PK11195 then acts as a MRI agent with molar relaxivity comparable to Magnevist. This new MI agent could be useful for numerous applications in molecular imaging including disease mapping, surgical resection guidance through in vivo imaging, and the further elucidation of PBR function in cell biology.

EXPERIMENTAL PROCEDURES

Uptake Experiments. C6 glioblastoma cells were cultured in Dulbecco's Modified Eagle Medium (DMEM)-F12 medium (Gibco/Invitrogen) supplemented with 15% horse serum (ATCC), 2.5% FBS (Gibco/Invitrogen), and 0.1% 50 mg/mL gentamicin sulfate (Biowhittaker). Standard medium pH was between 7.2 and 7.4. Cells were maintained in a Forma Scientific incubator at 37 °C in a sterile air environment containing 5% CO_2 and were plated for imaging on glass coverslips just prior to confluency. Next, cells were dosed with 1 mL of the contrast agent in 0.9% saline (25 μM Eu-PK11195) and allowed to incubate at either 37 °C (or 4 °C, cold study) for various times, including 35 min, 45 min, 60 min, and beyond. At the end of the incubation time, the cells were thoroughly rinsed with saline and imaged in white light and fluorescence directly using a standard epi-illumination fluorescence microscope (Carl Zeiss, Axioskop). The microscope was configured to facilitate the imaging of our complex. The optical train consisted of a UG11 filter inserted into the excitation path. The subsequent light was reflected onto a dosed sample using a 400 nm cutoff dichroic mirror. Finally, fluorescence was collected through a 40× objective (NA = 0.5), passed through a 612 × 25 nm emission filter, and directed onto a Sinsys CCD camera. Images were collected and stored on a pc.

Displacement Experiments. C6 glioblastoma cells were plated out on glass coverslips and incubated at 37 °C until just prior to confluency. Next, cells were dosed with 1 mL of contrast agent in 0.9% saline (25 μM Eu-PK11195) and allowed to incubate at 37 °C for 60 min. At the end of the incubation time, the cells were thoroughly rinsed with saline and imaged in white light and fluorescence directly using a standard epi-illumination fluorescence microscope (Carl Zeiss, Axioskop). Next, a 6-fold molar excess of PK11195 was allowed to incubate with the fluorescing cells at 37 °C for 1 h. At the appropriate time, the cells were again rinsed with saline and imaged directly under the fluorescence microscope. To calculate the change in fluorescence intensity between the dosed and displaced experiments, the total gray scale

Scheme 2. Complexation of Ln-PK11195 Facilitating the Preparation of a PBR-Targeted MR Agent

intensity was integrated over both pictures (same integration times) using Adobe Photoshop. Values were recorded, and the displaced intensity was compared to the dosed intensity to give the percent fluorescence change [100 − (displaced/dosed) × 100].

MR Imaging. Sample solutions (Magnevist and Gd-PK11195) were prepared in water and imaged via a T_1-weighted Spin−Echo pulse sequence in a standard 4.7 T instrument where TE was kept constant and TR was varied 100−3000 ms.

Cocktail Imaging. Approximately 10^6 C6 glial cells were inoculated with a 40−60 cocktail (1 mM total Ln-PK11195 concentration) of the Eu-PK11195 and the Gd-PK11195 complexes. Directly after 60-min incubation time, fluorescence microscopy was performed on a small number of cell cultures that were flash frozen for subsequent MR imaging. Images of thawed cells (in μL centrifuge tubes) were acquired using a 4.7 T instrument (Figure 8, TE/TR = 11/1000 ms, FOV = 4 cm, slice thickness = 1 mm). The data matrix was 256 × 128, extrapolated to 256 × 256 for the final images.

RESULTS AND DISCUSSION

Initially, we prepared the PBR targeted ligand by coupling our conjugable form of PK11195 to a trifunctional lanthanide chelate (*38*) (Scheme 1). The conjugable PBR ligand was realized by first synthesizing 1-(2-chlorophenyl)isoquinoline-3-carboxylic acid using established procedures (*39*). We completed the conjugable molecule by appending the carboxylic acid residue with a diamine linker (*38*). Previously, we have reported the synthetic methodology leading to the trifunctional lanthanide chelator {Griffin, 2001 #48; Manning, 2004 #46}. Briefly, cyclen is first selectively di-protected with benzyloxycarbonyl groups at low pH (*40*). Next, the 1, 7-diprotected macrocycle can then be mono-alkylated with an antenna to later be used for lanthanide sensitization. The macrocycle is then fitted with a pendant carboxylic ester residue for conjugation (*36*). The protecting groups are removed under mild hydrogenation conditions using cyclohexene and Pd/C, and complexation arms are then added. Initially, we chose to alkylate the remaining cyclen nitrogen atoms with phosphonate acid-ester pendant arms, which, upon hydrolysis have very good chelation ability (*41*). After hydrolysis, the completed trifunctional lanthanide chelator was coupled to the conjugable form of PK11195 in mixed aqueous organic solvent (*38*). Complexation of the ligand with europium resulted in a fluorescent derivative that gave the expected lanthanide luminescence (*38*).

The Gd^{3+} derivative was prepared as shown in Scheme 2. While the substitution may seem trivial, simply exchanging the metal ion in the complex results in another agent with an entirely different signature. In this way, one scaffold offers multiple facets of imaging opportunity. For example, aside from fluorescence (M = Tb or Eu) and MRI (Gd), additional metal substitution (M = Ga, Cu, Ho, etc.) can facilitate applications for PET imaging and ultimately, targeted therapeutic dose delivery.

Next, we evaluated the magnetic resonance signature of this new PBR-targeted compound (Gd-PK11195) by correlation to the clinical MRI agent Magnevist. A series of dilutions of each contrast agent at similar concentrations was used to measure the molecular relaxivity at 4.7 T. From the linear calibration plot ($r^2 = 0.999$, data not shown), $r1_{Gd\text{-}PK_{11195}} = 5.94\ s^{-1}\ mM^{-1}$ and $r1_{Magnevist} = 6.45\ s^{-1}\ mM^{-1}$. These data show that the new PBR targeted MI has a T_1 relaxivity value comparable to a commonly used perfusion agent.

To evaluate functional contrast, the same solutions were imaged as phantoms in a standard MR imaging system, again at 4.7 T. Figure 3 shows the result of this experiment, the T_1 weighted phantom images of Gd-PK11195 and Magnevist solutions over a range of concentrations. As the images demonstrate, Gd-PK11195 gives similar MR contrast to Magnevist. Therefore, Gd-PK11195 delivered to the specific target, PBR, results in contrast comparable with an accepted agent. Such specificity for PBR-overexpressing cells or tissues could

prove useful in elucidating the critical functions of PBR, dealing with reactive oxygen species (*31*), and even improved detection of mitochondrial misfunction diseases (*21*).

To evaluate Ln-PK11195-targeted delivery, we performed uptake and displacement studies. PBR-overexpressing C6 glioma cells (*10, 22*) were dosed with Eu-PK11195 at concentrations of 10 μM to 1.0 mM for times ranging from 20 to 60 min. Quinoline-sensitized fluorescence from the Eu^{3+} complex (*38*) was readily detectable in the cells at all incubation times and concentrations using a modified epi-illumination fluorescence microscope affixed with a CCD camera. For 10−500 μM concentrations of the agent, the optimum dosage time was found to be between 45 min and 1 h. As illustrated in Figure 4A, there is substantial uptake of Eu-PK11195 by C6 glioma cells, with fluorescence being associated with distinct internal structures, suggesting specific organelle location of the protein. PBRs are in fact known to be expressed in the outer mitochondrial membrane (*18, 42*). Preliminary coregistration studies indicate that Ln-PK11195 is localized in the same region of the cell as the mitochondrial dye JC-1 (*43*). Figure 4B presents the control, an undosed population of C6 cells of comparable

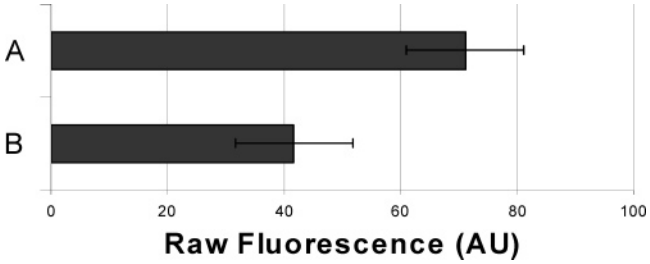

Figure 7. Average raw fluorescence of agent-dosed C6 glioblastoma cells. Bar A is the raw fluorescence after dosing with Eu-PK11195. Bar B is the raw fluorescence after PK11195 displacement of contrast agent from PBR. Error bars represent the standard deviation of triplicate experiments.

density, which is relatively devoid of fluorescence. To demonstrate that the Eu-PK11195 molecule was being transported into the cells as opposed to simply adhering to the surface, we performed a standard biological cold-uptake mechanism study where C6 glioma cells were incubated with the same concentration of Eu-PK11195 at both 37 °C and 4 °C. As seen in Figure 5A, the cells incubated with the contrast agent at 37 °C show appreciable fluorescence, while those incubated at 4 °C (Figure 5B) show very little. These data suggests that the molecule is labeling the cell internally, consistent with endocytosis, although the exact transport mechanism remains unknown (*44*). Next, a preliminary displacement study to obtain an estimate for the binding affinity of Ln-PK11195 for PBR relative to the high affinity ligand PK11195 was undertaken. Utilizing procedures similar to Pramanik (*45*), we labeled cells with our agent and quantified the binding via fluorescence intensity. We then treated the same cells with a 6-fold excess of the native, nonlabeled PBR ligand, PK11195. The reduction in fluorescence intensity was used to give an estimate of ligand displacement (*45*). One result of these experiments is displayed in Figure 6. The false colorized image in Figure 6A is of cells dosed with Eu-PK11195, while Figure 6B shows the cells after 60-min competition with excess PK11195. Cell repositioning, due to rinsing procedures, accounts for the differences in appearance of the images. The average reduction in fluorescence intensity (triplicate determinations) after displacement of Eu-PK11195 with PK11195 was 37% (Figure 7), indicating that Eu-PK11195 functions as a PBR ligand. Yet, there is still appreciable fluorescence remaining in the cells after the displacement dosage of a 6-fold excess of the native PK11195, suggesting that our complex is binding to the PBR with substantial affinity as desired (*10*). Additional studies are currently underway to quantify binding affinity, with nanomolar K_d values expected.

Next, cocktail mixtures were prepared in varying ratios (20:80, 30:70, 40:60, and 50:50, Eu^{3+}:Gd^{3+}) and used for examination of C6 glioma cell colonies in order to demonstrate the "cocktail" approach. All ratios gave both signatures, with Figure 8 illustrating that the 40% Eu^{3+}: 60% Gd^{3+} cocktail has readily quantifiable fluorescence and MR contrast from the *same* population of C6 cells. A cursory evaluation of these preliminary data indicates contrast enhancement (signal-to-background ratio) by the MI agent to be 9:1 for fluorescence and 1.7:1 for MR. Of particular intrigue is the observation of significant MR contrast using Gd-PK11195 given the controversy surrounding quantitative receptor imaging using Gd^{3+} complexes. To be sure, MR imaging of receptors is only possible if the receptor of interest is expressed at a sufficiently high rate, and if the agent of interest can be delivered and retained in sufficient concentration. Tweedle and co-workers have estimated that at least 10^6 receptor-bound Gd^{3+} agents are required per cell to achieve approximately 2:1 S/N in a conventional 2T MR imager (*46*). Thus, assuming a 1:1 receptor−contrast agent pair, there would have to be on the order of 10^6 PBR in a cell to observe MR contrast. In fact, Papadopoulos has indeed reported PBR concentrations in cancer cells on the order of 10^6 receptors/cell, assuming 10^{10} cells/g (*42, 47*). Therefore, given the expression profile reported for PBR, in conjunction with our experiments being performed at high field (4.7 T), it would appear that PBR can be imaged in cells with Gd-PK11195.

In conclusion, we have demonstrated targeted delivery of Ln-PK11195 to PBR-overexpressing C-6 glioma cells. Bright, localized fluorescence of the Eu-PK11195 was observed with standard microscopy and displacement studies indicated PBR ligand functionality. Furthermore, it was shown that the Gd^{3+} complex of Ln-PK11195 has a relaxivity and an MR signature comparable in brightness to the clinical agent Magnevist but with the benefit of specificity. Through internalization and association with the PBR within the mitochondria, we can now use MRI to study expression, identify up-regulating cells, and further elucidate PBR functions, including its association with apoptosis (*48*). Finally, bimodal cellular-scale contrast−enhancement was afforded using a cocktail of Eu-PK11195 and Gd-PK11195.

These investigations demonstrate that both fluorescence and MRI signatures are possible and were observed in C6 glioma cells using a PBR ligand-based MI agent. To expand on these findings, experiments are underway to determine if PBR expression can be imaged in real-time using Ln-PK11195. Other investigations with this new MI agent include both relaxivity determination (contrast enhancement) in PBR-overexpressing tissues and quantification of K_d for PBR. Other variations of the metal-PK11195 complex could potentially facilitate targeted imaging with PET (M = Ga, Cu, etc.) and eventu-

ally site-directed therapy delivery of a radioactive isotope (M = ^{166}Ho, ^{177}Lu). We envision that Eu-PK11195 can be useful as a histopathological stain, and that this unique strategy of integrating optical imaging with the specificity of a targeted delivery could ultimately facilitate intraoperative multimodal imaging, impacting diagnosis and treatment of malignant brain cancer and other neurological dysfunctions.

Estimating the Number of Bound Waters in Gd(III) Complexes Revisited. Improved Methods for the Prediction of *q*-Values

Benjamin P. Hay,*,† Eric J. Werner,§ and Kenneth N. Raymond§

Chemical Sciences Division, Pacific Northwest National Laboratory, P.O. Box 999, Richland, Washington 99352, and Department of Chemistry, University of California, Berkeley, California 94720-1460. Received July 9, 2004; Revised Manuscript Received September 27, 2004

Two literature computational methods for the prediction of the number of inner-sphere aqua ligands, *q*, have been applied to a test set of seven Gd(aminocarboxylate) complexes. The first method is based on the hypothesis that *q* should be proportional to the solvent-accessible surface area of the ligand-complexed Gd ion (Castonguay, L. A., Treasurywala, A. M., Caulfield, T. J., Jaeger, E. P., and Kellar, K. E. (1999) Prediction of *q*-Values and Conformations of Gadolinium Chelates for Magnetic Resonance Imaging. *Bioconjugate Chem. 10*, 958). The second method is based on the hypothesis that *q*-values can be deduced by examining series of steric energy versus ionic radii plots as a function of coordination number (Reichert, D. E., Hancock, R. D., and Welch, M. J. (1996) Molecular Mechanics Investigation of Gadolinium(III) Complexes. *Inorg. Chem. 35*, 7013). This study identifies deficiencies in these methods and, with respect to the first method, describes some apparent errors. Although neither method was reliable at predicting *q*, two alternate approaches based on either molecular mechanics strain thresholds or exposed Gd surface area thresholds are shown to predict observed *q*-values for all Gd aminocarboxylate complexes in the test set.

INTRODUCTION

Magnetic resonance imaging (MRI) has become an important tool in modern medicine, providing high-quality three-dimensional images without the use of harmful ionizing radiation (*1*). Signal intensity in MRI stems mainly from the relaxation rate of in vivo water protons and is enhanced by the administration of a contrast agent prior to the scan. Such agents include a paramagnetic metal ion that decreases the relaxation times of nearby water protons. Contrast media often employ gadolinium(III) due to its high magnetic moment and slow electronic relaxation rate. As free Gd(III) is toxic (*2*), the design of ligands that form stable Gd(III) complexes for MRI application remains a significant area of research (*2*−*4*).

The efficacy of Gd-based contrast agents is determined by the extent to which the relaxation rate of water protons is increased, in other words, relaxivity. Agent design focuses mainly on attaining higher inner-sphere, longitudinal relaxivity, r_1, from protons of water molecules directly coordinated to the metal. Theory reveals the need to maximize *q*, the number of inner-sphere water molecules, to obtain optimal relaxivity (*2*, *3*). Simply decreasing the number of binding sites in the ligand will lead to higher *q*-values, but may weaken the Gd-ligand binding and possibly release free Gd(III) in vivo. Therefore, one design goal for MRI contrast agents is to increase the *q*-value without significantly decreasing the binding affinity of the ligand (*2*−*4*).

The ability to predict *q* prior to synthesis and testing would facilitate the design of improved contrast agents. Molecular dynamics simulations of Gd−ligand complexes in aqueous solution have been shown to predict correctly the number of bound waters in several cases (*5*). However, such simulations require a significant amount of computational resources and are not suitable for the evaluation of large numbers of candidate structures. This situation has prompted the development of simpler methods for estimating *q* from static structures that have been optimized with molecular mechanics models. One approach is based on the hypothesis that *q* should be proportional to the solvent-accessible surface area of the ligand-complexed Gd ion (*6*). Another approach is based on the hypothesis that *q*-values can be deduced by examining a series of steric energy versus ionic radii plots as a function of coordination number (*7*).

Our interest in these methods originated from a desire to apply them to a new family of potential MRI agents that are based on catecholate and hydroxypyridinonate donor groups (*8*). As the first step toward this goal, we chose to test the predictive capability of these methods on known compounds. Since the reported methods were tested primarily on aminocarboxylates, we selected a set of aminocarboxylate ligands for this verification. The test set, shown in Figure 1, was chosen for two reasons. First, *q*-values in aqueous solution, which span a range of 0 to 3, have been determined for these structures either via experimental measurement with the similar sized Eu(III) ion (*2*) and/or by MD simulation with the Gd(III) ion (*5*). Second, with the exception of NOTA, crystal structure data are available for Gd complexes with these ligands in which bound water is the only other inner-sphere ligand (*9*, *10*). It is interesting to note that, in all cases where comparison is possible, the *q*-values in aqueous solution are in agreement with the number of bound waters observed in the crystal structures.

After extending the MM3 model to treat Gd(III) complexes with aminocarboxylate and aqua ligands, we evaluated the ability of the "Connolly surface area" method (*6*) and the "coordination scan" method (*7*) to

predict q-values for the ligand test set (Figure 1). Neither approach was entirely successful. The "Connolly surface area" method, which we find to be misnamed, fails to predict q-values for two out of the seven cases. The "coordination scan" method systematically underestimates q-values for all cases. Although the reported methods fail, the evaluation of optimized geometries for Gd(ligand)$(O)_n$ complexes, where $n = 0$ to $q + 1$, yields alternative approaches that allow q-value predictions to be made for all seven cases using either Gd surface areas or strain energies.

COMPUTATIONAL DETAILS

Force Field Model. Molecular mechanics calculations were carried out using the MM3 program (*11*), which has been modified to support POS metal atom types (*12*). In the POS approach (*13*), all "bound" ligand atoms are formally connected to the metal ion requiring the definition of M−L stretch, M−L−X bend, and M−L−X−X torsion potentials (M = metal, L = donor atom, X = any other atom). All L−M−L angles are omitted, and van der Waals interactions between the L groups attached to the metal are added. In a recent study of steric interactions in U(IV) complexes, we have shown that the aqua ligand can be modeled as a neutrally charged oxygen atom (*14*), and the same approximation was used in this study. Prior parameter sets for Gd(III) complexes with aminocarboxylate and aqua ligands have been developed for POS force fields and shown to reproduce the geometries of these complexes with a fair degree of accuracy (*7*, *15*, *16*). Using these prior parametrizations as a starting point, we optimized geometries for Gd(EDTA)$(O)_3$, Gd(DO3A)$(O)_2$, Gd(DOTA)(O), Gd(DTPA)(O), Gd(THPA), and Gd(TTHA) complexes starting from their X-ray structure coordinates (*10*). The parameter set was then adjusted to minimize the sum of the rmsd values for superposition of calculated and experimental structures. The final parameter set and input files for all complexes are available as Supporting Information.

Surface Area Calculations. Connolly surface areas and exposed van der Waals (VDW) surface areas for Gd were calculated with GEPOL (*17*). Tripose VDW radii used for the organic atoms were as follows: H, 1.500 Å; C, 1.700 Å; N, 1.555 Å; O, 1.520 Å (*18*). VDW radii for Gd were assigned based on the 53 Å^2 surface area reported for the bare Gd ion (*6*). For the Connolly surface area calculations with a default probe radius of 1.40 Å, this surface area is achieved with a Gd radius of 0.65 Å. For exposed VDW surface area calculations this surface area is achieved with a Gd radius of 2.05 Å.

Calibration curves to establish the relationship between Gd surface area and q-value were prepared using the $Gd(OH_2)_9$ X-ray structure (*19*) with strict adherence to the published method (*6*). Gd surface areas were calculated for the structures obtained after removal of 0 to 9 water molecules from this crystal structure *without any optimization*. When there was more than one way to remove the water, all ways were examined subject to the following restriction. For $n = 2$ to 8, only sets of contiguous waters were removed. A plot of surface area versus q-value was generated from the results. A second calibration curve was prepared for $n = 0$ to 9 by plotting the Gd surface areas obtained from the model complex $Gd(O)_n$ where the complex was optimized with the MM3 model after the addition of each oxygen atom.

Exposed VDW surface areas for the metal ion in Gd(ligand) complexes were obtained from MM3 optimized geometries. Initial geometries for these optimizations were taken from X-ray coordinates (*10*). For each complex investigated, the number of added oxygen atoms was varied from 0 to $q+1$. In cases where there was more than one possible placement for the oxygen atoms, all placements were tried and the lowest energy geometry was retained.

Coordination Scan Calculations. Initial geometries for Gd(ligand)$(O)_n$ complexes were prepared as described above for $n = 0$ to q. The size of the metal was varied by systematically altering the M−N and M−O equilibrium bond length parameters in the following manner: M−N bond length = ionic radius + 1.7 Å; M−O bond length = ionic radius + 1.4 Å. Scans were performed by varying the ionic radius from 0.5 to 1.5 Å in 0.1 Å intervals with the stretching force constant kept at a constant value of 0.695 mdyn/Å (equivalent to the 100 kcal/mol·Å^2 force constants used in the prior study) (*7*). Plots of steric energy versus metal radius were then generated for each coordination number and superimposed on the same graph. The results were interpreted with the following ionic radii for Gd(III): 0.94 Å for six-coordinate, 1.00 Å for seven-coordinate, 1.05 Å for eight-coordinate, and 1.11 Å for nine-coordinate environments (*20*).

Strain Threshold Calculations. Initial geometries for each Gd(ligand)$(O)_n$ complex were prepared as described above for $n = 0$ to $q+1$. After geometry optimization, the strain energy associated with adding the ith oxygen atom to the inner-sphere was taken as the difference $U_i - U_{i-1}$, where U_i is the steric energy of the complex with the ith oxygen atom present and U_{i-1} is the steric energy of the complex before the ith oxygen atom was added.

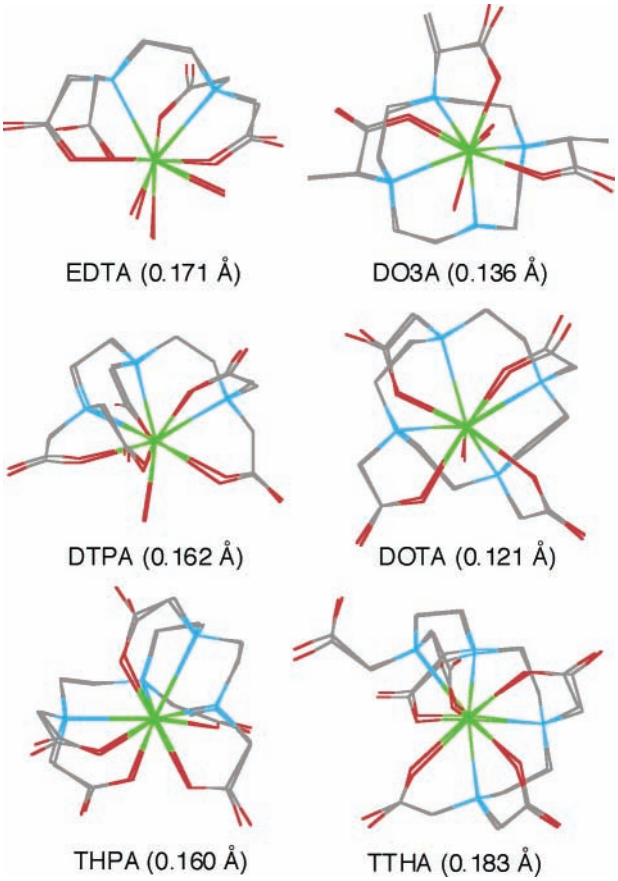

Figure 2. Superposition of calculated and X-ray geometries. The rmsd value for each structure is given in parentheses.

RESULTS AND DISCUSSION

Force Field Model Validation. Application of q prediction methods requires a molecular model to compute geometries for the Gd(ligand) complexes. The MM3 force field was extended to treat Gd(III) complexes with aminocarboxylate and aqua ligands. A model capable of reproducing the metal complex geometries observed in the solid state was obtained after adjusting parameters taken from prior POS force field models (*7*, *15*, *16*) to yield the best overall fit to crystal structure data (*10*). The root-mean-squared deviation (rmsd) between the calculated and experimental atom positions for all non-hydrogen atoms provides a measure of the accuracy of the model. In this instance the superposition of calculated and experimental structures, shown in Figure 2, yields an average rmsd of 0.156 Å. This level of accuracy is as least as good or better than that of the models used in prior q predictions (*6*, *7*).

"Connolly Surface Area" Method. A Connolly surface, also known as a solvent-accessible surface, is the surface traced out by the center of a test probe as it is rolled over a molecule (*21*). The Connolly surface for a single atom in a molecule can be computed as the surface traced out by the test probe center while the probe remains in direct contact with the atom. It was reported that the Connolly surface area for the Gd(III) ion in a Gd(ligand) complex can be used to predict the q-value for that complex (*6*). The stated method involves (1) optimization of a geometry for the Gd(ligand) complex, (2) calculation of the Connolly surface area for the Gd(III) ion, and (3) comparison of this surface area with a calibration curve relating surface area to the number of bound water molecules. The calibration curve was purportedly generated by rolling a test probe of radius 1.4 Å over $Gd(OH_2)_n$ structures, where $n = 0$ to 9, to yield a linear correlation running from ~53 Å^2 for the bare Gd(III) ion to 0 Å^2 for the nonaaqua ion. The reported relationship is depicted in Figure 3. Error bars on the points reflect the degree of variation resulting from removal of different sets of contiguous water molecules.

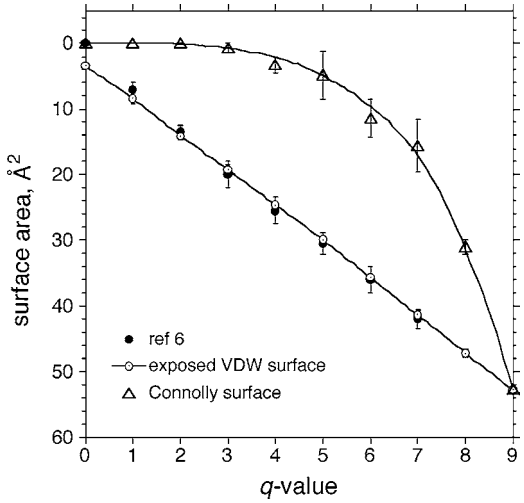

Figure 3. Relationship between various Gd surface areas and q, where $q = 9 -$ number of bound aqua ligands. Literature values were taken from Figure 1 in ref 6.

We attempted to reproduce the calibration curve using atomic coordinates from the same $Gd(OH_2)_9$ X-ray structure used in the prior study. Default Sybyl force field VDW radii were used for the oxygen and hydrogen atoms. To calculate a Connolly surface area of ~53 Å^2 for the bare Gd(III) using a test probe radius of 1.40 Å, it is a mathematical requirement that the Gd(III) radius be set to a value near 0.65 Å. A plot of the Connolly surface area for Gd(III) versus the number of bound water molecules is also shown in Figure 3. Comparison of the Connolly surface areas to the surface areas reported in the prior study reveals a large difference in behavior, establishing that the reported values were not obtained by the Connolly method.

Further calculations showed that computing a different geometric property, the exposed VDW surface area for the Gd(III) ion could largely reproduce the reported surface areas. This surface corresponds to the surface of the metal ion that would be visible in a space-filling model of the complex. Our calibration curve was not linear, however, showing a slight curvature at the higher coordination numbers (see Figure 3). Even with nine bound water molecules, 3.5 Å^2 or 6.6% of the metal ion surface remains exposed. Another difference was a significantly smaller extent of area fluctuation as a function of the choice of contiguous water molecules removed. Where the literature calibration curve suggests fluctuations as large as ±1.5 Å^2 about the mean, our range of area values was less than ±1.0 Å^2 at any given coordination number.

A second calibration curve was generated by computing the exposed VDW surface area for Gd(III) in a series of MM3 optimized model complexes, $Gd(O)_n$, where $n = 0$ to 9. Comparison with the average surface areas obtained by removing sets of contiguous water molecules from the $Gd(OH_2)_n$ X-ray structure revealed that the Gd(III) surface areas differed by less than 1.0 Å^2 at all coordination numbers. Thus, an exposed VDW surface area versus q plot essentially identical to that shown in Figure 3 is obtained by using (1) oxygen atoms to model aqua ligands

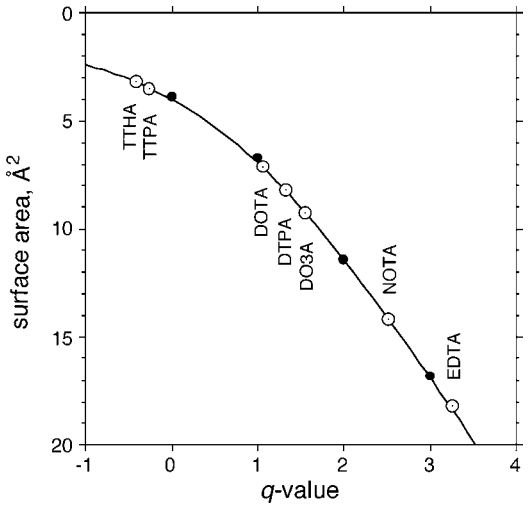

Figure 4. Interpolation of q-values for Gd(ligand) complexes from a plot of exposed VDW surface versus q generated from $Gd(O)_n$ complexes.

Table 1. Exposed Gd VDW Surface Areas in Gd(ligand) Complexes and Predicted *q*-Values Interpolated from the Calibration Curve (Figure 4)

ligand	surface area, Å^2	q-value (calcd)	q-value (obsd)
EDTA	18.2	3.26	3
NOTA	14.2	2.52	3
DO3A	9.3	1.56	2
DTPA	8.2	1.33	1
DOTA	7.1	1.06	1
TTPA	3.5	-0.26	0
TTHA	3.2	-0.41	0

and (2) a single optimized geometry to calculate the surface area at each coordination number.

This second calibration curve was used to predict q-values based on the exposed Gd VDW surface areas in MM3 optimized Gd(ligand) complexes (see Figure 4). The surface areas and predicted q-values are given in Table 1. The method successfully predicts q-values for five of the test cases, but leads to ambiguous predictions for DO3A, which lies midway between $q = 1$ and 2, and NOTA, which lies midway between $q = 2$ and 3. Thus, while there exists a definite trend between the exposed surface area of the metal ion in a nonhydrated Gd(ligand) complex and the number of water molecules that will bind, the method fails as an accurate predictor of q-value in two out of seven cases.

There is an issue with using the exposed VDW surface areas obtained from Gd(ligand) structures that have been optimized in the absence of any bound water. Metal−ligand distances generally increase with increasing coordination number. Thus, the inner sphere will swell in size as more oxygen atoms are added. As the bound atoms move outward, more metal ion surface will be exposed. Therefore, the surface areas calculated for Gd(ligand) complexes will at best represent a lower limit to the actual area that is allowed by the ligand under consideration. This effect is observed by comparing the Gd surface area in the optimized Gd(ligand) geometry to that in an nonoptimized Gd(ligand) geometry created by removing the water molecules from the X-ray structure. For example, Gd(EDTA) exhibits18.2 Å^2 in the optimized geometry versus 20.5 Å^2 in the X-ray geometry and Gd(DTPA) exhibits 8.2 Å^2 in the optimized geometry versus 10.1 Å^2 in the X-ray geometry.

"Coordination Scan" Method. This method involves calculation of the steric energy of the metal complex as a function of both metal ion size and coordination number (*7*, *22*). These plots are superimposed to yield a family of curves. The curves exhibit intersection points that define zones of preferred coordination number as a function of metal ion size. By comparing the ionic radii of a metal ion in different coordination states to this family of curves it is possible to determine which coordination number is sterically favored for that metal ion.

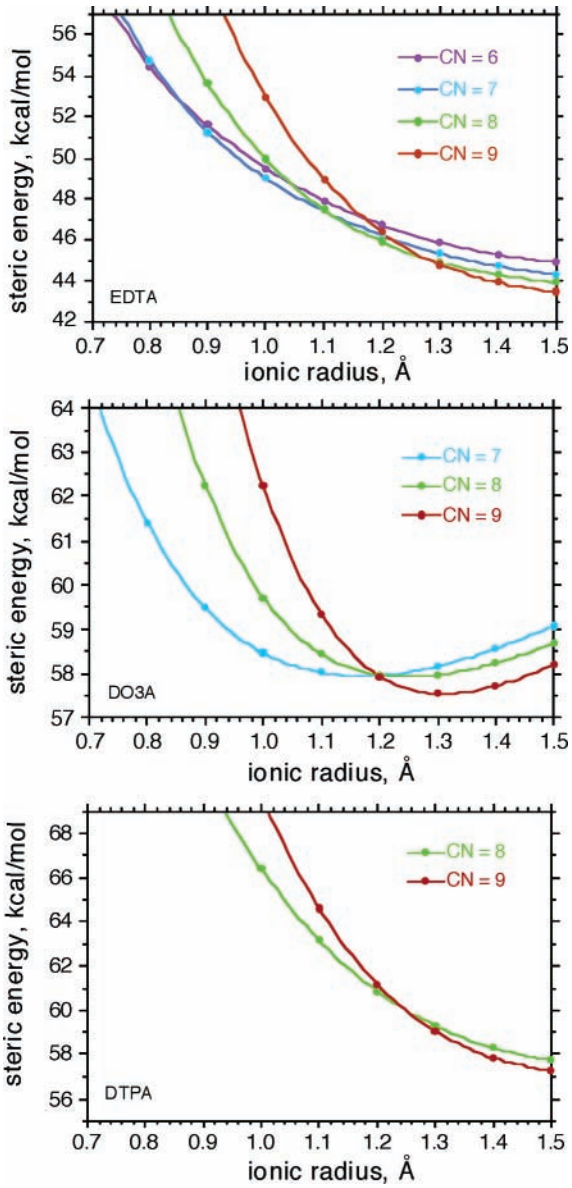

Figure 5. Coordination scan plots for EDTA (top), DO3A (middle), and DTPA (bottom).

Using the extended MM3 model, coordination scans were performed on EDTA, NOTA, DO3A, DTPA, and DOTA. As illustrated by the examples shown in Figure 5, a series of intersecting curves are obtained on superposition of the scans. The EDTA plot shows that a six-coordinate environment is preferred for metals with ionic radii below 0.85 Å, a seven-coordinate environment is preferred for ionic radii between 0.85 and 1.11 Å, an eight-coordinate environment is preferred for ionic radii between 1.11 and 1.28 Å, and a nine-coordinate environment is preferred for radii above 1.28 Å. Comparison with the ionic radii for Gd in different coordination states (0.94 Å, CN = 6; 1.00 Å, CN = 7; 1.05 Å, CN = 8; 1.11 Å CN = 9) predicts that Gd(EDTA) complex has a steric preference for a seven coordinate environment, thereby

predicting $q = 1$. Performing this analysis for the other ligands also predicts q-values that are too low: NOTA, $q = 1$; D03A, $q = 0$; DOTA, $q = 0$; DTPA, $q = 0$.

These results are in disagreement with the prior application of this method (*7*) in which the correct q-values were obtained for these same ligands using a modified Tripose force field model, TAFF (*18*). We suspect the discrepancy between the results arises from differences in the TAFF and MM3 force fields. With the POS metal ion treatment used in both studies, the shape of the steric energy versus metal ionic radius curves will depend strongly on the VDW radii assigned to atoms attached directly to the metal ion. The VDW radii used in the TAFF model (nitrogen 1.555 Å, oxygen 1.520 Å) are significantly smaller than those used in MM3 model (nitrogen radius 1.93 Å, oxygen radius 1.82 Å). In addition, different functional forms are used for VDW interactions in these two models, TAFF (Leonard−Jones 12-6) and MM3 (Buckingham exp-6).

It is clear that the coordination scan method underestimates q-values in the current application. Although the method may work with other force field models, we note that there is a fundamental flaw with the approach. The method relies on the use of a model in which the inner-sphere atoms are formally connected to the metal. In such models, each metal−ligand bond stretch interaction is treated with a potential function that has an interaction energy of zero when the bond is at its equilibrium length. These models are useful for predicting structures and examining conformational potential surfaces, but they do not address completely the energetics of bond formation. Thus, while the "coordination scan" method may indicate which coordination number is *sterically* favored as a function of metal ion radius, it ignores any compensating stabilization that might result from $Gd-OH_2$ bonding interactions.

"Strain Threshold" and "Surface Area Threshold" Methods. To overcome the inherent deficiency in the "coordination scan" approach, we chose an alternate way of interpreting the steric energies for a series of $Gd(ligand)(O)_n$ complexes. The method is based on the concept that adding a water molecule to the coordination sphere in the absence of any steric hindrance will result in a bonding interaction with a stabilizing energy. If the destabilizing strain energy for adding the next water molecule exceeds an intrinsic stabilization energy threshold, then the water will not be bound. An analogous threshold concept can be applied to the interpretation of Gd surface area data. In other words, there is a minimal space requirement for adding another oxygen atom to the inner sphere. If there is insufficient space, then the water will not be bound.

To test these concepts, we optimized a series of $Gd(ligand)(O)_n$ complexes, where $n = 1$ to $q+1$, for each ligand in the test set. Incremental strain energies for the sequential addition of oxygen atoms and exposed Gd surface areas are summarized in Table 2. It can be seen that the strain for adding an oxygen atom to the inner sphere gradually increases as the coordination number increases (*23*). The strain energies for forming the $n = q$ species range from 5.3 to 7.8 kcal/mol. The strain energies for forming the $n = q+1$ species are significantly higher, 11.3 to 23.5 kcal/mol. Thus, there is a threshold energy that lies somewhere between 8 and 11 kcal/mol. Setting a threshold in the middle of this range yields the following criterion that correctly predicts q for all structures in the test set: if the strain energy for adding the next oxygen atom exceeds 9.5 ± 1.5 kcal/mol, then the next oxygen atom will not bind.

Table 2. Strain Energies for the Addition of O Atoms and Exposed Gd VDW Surface Areas Used To Predict q-Values via Threshold Methods

complex	strain energy, kcal/mol	Gd surface area, Å	predicted q-value	observed q-value
Gd(EDTA)(O)	0.4	12.4		
$Gd(EDTA)(O)_2$	2.2	7.7		
$Gd(EDTA)(O)_3$	5.3	4.5	3	3
$Gd(EDTA)(O)_4$	11.3	2.9		
Gd(NOTA)		14.2		
Gd(NOTA)(O)	1.2	9.6		
$Gd(NOTA)(O)_2$	7.1	6.5		
$Gd(NOTA)(O)_3$	6.1	4.5	3	3
$Gd(NOTA)(O)_4$	20.4	3.4		
Gd(DO3A)		9.3		
Gd(DO3A)(O)	4.0	6.3		
$Gd(DO3A)(O)_2$	6.4	3.9	2	2
$Gd(DO3A)(O)_3$	17.1	2.9		
Gd(DTPA)		8.2		
Gd(DTPA)(O)	7.8	5.8	1	1
$Gd(DTPA)(O)_2$	13.3	4.1		
Gd(DOTA)		7.1		
Gd(DOTA)(O)	5.8	4.2	1	1
$Gd(DOTA)(O)_2$	21.9	4.8		
Gd(TTHA)		3.5	0	0
Gd(TTHA)(O)	23.4	3.6		
Gd(TTPA)		3.2	0	0
Gd(TTPA)(O)	23.5	3.1		

Similarly, as the number of atoms in the inner sphere increases the surface area decreases. At $n = q - 1$, where there should be sufficient space to allow another bound oxygen atom, Gd surface areas range from 6.3 to 8.2 Å^2. At $n = q$, where there should not be sufficient space to allow another bound oxygen atom, the Gd surface areas range from 3.2 to 5.8 Å. Thus, there is a threshold surface area that lies near 6.0 Å^2. Interestingly, this is exactly the surface area consumed when a single oxygen atom is bound to a bare Gd(III) ion. These observations lead to a second criterion that also correctly predicts q for all structures in the test set: if the exposed Gd surface area is less than 6.0 Å^2, then the next oxygen atom will not bind.

SUMMARY AND CONCLUSIONS

The reported "Connolly surface area" method (*6*) is based on the exposed VDW, rather than the Connolly, surface of the Gd ion. We find that while there exists a definite trend between the exposed surface area of the metal ion in a nonhydrated Gd(ligand) complex and the number of water molecules that will bind, the method fails as an accurate predictor of q-value in two out of seven test cases. We have presented a modified approach, the "surface area threshold" method, which predicts all q values in the test set using exposed Gd VDW surface areas from geometry optimized $Gd(ligand)(O)_n$ complexes.

The "coordination scan" method is force field dependent and systematically underestimates q with our extended MM3 model. Efforts to compensate for an inherent deficiency in the "coordination scan" approach led us to develop an alternate method to apply POS force fields to q prediction. In the "strain threshold" method, q is predicted by evaluating the increase in strain that accompanies successive addition of oxygen atoms to the inner sphere. A water molecule will not be bound when this increase exceeds a threshold energy. Calibration of this method on the test set yields a threshold value that correctly predicts q in all cases. With the MM3 model used here, this value is 9.5 ± 1.5 kcal/mol. Although this threshold will depend on the parameter set, the "strain threshold" method should be applicable with other force

fields. Calibration with a set of known compounds must be performed to establish the appropriate threshold for the force field used.

Finally, this study demonstrates that simple approaches based on steric hindrance can be used to predict observed q values for Gd aminocarboxylate complexes. The predictions are based on thresholds for surface area and strain. These thresholds, which reflect a competition between steric and electronic effects, may vary as a function of the binding sites that are present in the ligand. Binding sites that are more electron donating than amine nitrogen atoms and carboxylate oxygen atoms might make it more difficult to add an inner sphere aqua ligand. This situation would be expected to increase the surface area threshold and decrease the strain energy threshold. It remains to be seen whether the thresholds derived from this set of aminocarboxylate ligands are transferable to complexes bearing other classes of ligands.

ACKNOWLEDGMENT

This research was performed at the Pacific Northwest National Laboratory, operated by Battelle for the U.S. Department of Energy (DOE) under contract DE-AC06-76RLO 1830 and supported (PNNL) by Grant No. 73759 of the Environmental Management Science Program of the Office of Science, DOE, and (UCB) NIH Grant HL69832. The authors would like to thank Profs. R. D. Hancock and D. E. Reichert for their helpful comments and suggestions.

Supporting Information Available: The extended MM3 parameter set and input files for the Gd−aminocarboxylate complexes. This material is available free of charge via the Internet at http://pubs.acs.org/BC.
