Binding affinities of the GGA and GGG peptides for the C11U RNA were determined using the same strategy in the case of the boxB RNA (Table 3). Figure 4a shows the relative binding affinities of the peptides for the P22 boxB RNA and the C11U mutant RNA. The GGA peptide bound to the mutant RNA ($K_d = 0.18$ μM) more strongly than to the boxB RNA ($K_d = 0.32$ μM). In contrast, the GGG peptide showed the binding affinity for the C11U RNA as the K_d value of 0.41 μM; this value is inferior to that for the boxB RNA ($K_d = 0.27$ μM). Noticeably, the GGA peptide bound to the C11U mutant RNA more strongly than the GGG peptide did, although the opposite result was obtained in the case of the wild-type RNA. Thus, the GGG and GGA peptides showed a selectivity to the wild-type RNA and the mutant RNA, respectively (Figure 4a). These findings suggested that $A_{NBA}11$ of the GGA peptide could interact more specifically with the U11 base of the RNA than $G_{NBA}11$ of GGG did, and its specific interaction enhanced the binding affinity for the mutant RNA. On the other hand, the binding affinity of the wild-type P22N peptide for the C11U RNA ($K_d = 0.92$ μM) was almost the same as that for the P22 boxB RNA ($K_d = 0.88$ μM). That is, the GGG and GGA peptides could recognize the difference between the cytosine base of the wild-type P22 boxB RNA and the uracil of the C11U mutant more efficiently than the P22 N peptide did. In

Table 4. Dissociation Constants of the Peptides with the 7A15U Mutant RNA

peptide	K_d (μM)	K_d^{P22}/K_d^{7A15U} [a]
GGG	0.36 ± 0.01	0.75
AGG	0.66 ± 0.04	1.41
TGG	0.79 ± 0.05	1.00
CGG	0.94 ± 0.05	0.90
P22N	0.89 ± 0.03	0.99

[a] K_d^{P22}/K_d^{7A15U} represents the ratio of the dissociation constants of each peptide to P22 boxB RNA and the 7A15U mutant RNA.

the NMR structural analyses, Arg11 of P22 N peptide interacts with the phosphate group and the sugar at C11 of the wild-type RNA in an electrostatic manner and as a van der Waals contact, respectively. These interactions, however, are not specific for the C11 base of the wild-type RNA. By use of the de novo designed NBA peptide GGG or GGA, cytosine 11 or uracil 11 of the wild-type or the C11U mutant RNA, respectively, can be recognized more specifically by the nucleobase moiety at position 11 of these peptides than the arginine residue of native P22 N.

The binding affinities of the peptides for the 7A15U mutant RNA were also evaluated (Table 4 and Figure 4b). In this mutant assay, the AGG peptide showed a selectivity for the 7A15U mutant RNA, and the GGG peptide was selective for the wild-type RNA, while TGG, CGG, and P22N did not show the selective binding for the RNA. The AGG peptide showed a higher binding affinity for the 7A15U RNA ($K_d = 0.66$ μM) than for the wild-type boxB RNA ($K_d = 0.93$ μM). In contrast, the binding affinity of the GGG peptide for the 7A15U RNA ($K_d = 0.36$ μM) was slightly lower than that for the wild-type boxB RNA ($K_d = 0.27$ μM). The TGG and CGG peptides showed almost the same affinity as a lower level for both the boxB and the 7A15U RNA. These results indicated that $G_{NBA}3$ could recognize the C7-G15 base pair of the wild-type RNA more effectively than the A7-U15 pair of the 7A15U mutant. In contrast, $A_{NBA}3$ could recognize the A7-U15 pair more effectively than the C7-G15. Incorporation of the NBA units corresponding to the RNA bases into the peptides increases the binding affinities and specificities with the RNA. On the other hand, the dissociation constant of the P22 N peptide for the 7A15U mutant was estimated as $K_d = 0.89$ μM, a value that is similar to that for the wild-type RNA ($K_d = 0.88$ μM). These results of the native P22 were similar to the case of the C11U mutant. That is, the P22 N peptide could not recognize the differences between the C7-G15 and A7-U15 base pairs nor between the C11 and U11 bases. By use of three NBA peptides (GGG, GGA, and AGG), the mutation of the C7-G15 base pair or the C11U of the P22 boxB RNA can be clarified by the difference of their binding affinities.

CONCLUSION

To construct the novel molecules that specifically recognize a hairpin RNA, a series of artificial α-helical peptides with three NBA units were synthesized. These peptides were de novo designed to have simple amino acid sequences. These synthetic peptides showed sufficient potential for forming an α-helical structure. Binding analyses revealed that the NBA units on the peptides could recognize the RNA bases in a specific manner, and some NBA peptides showed selectivity for recognizing the differences between the wild-type and the mutant RNAs. The combined strategy using the NBA units and peptide scaffolds will be developed to design RNA-binding molecules targeting desired sequences and structures of the RNA.

Peptide-Derivatized Shell-Cross-Linked Nanoparticles. 1. Synthesis and Characterization

Matthew L. Becker,[†] Edward E. Remsen,[‡] Dipanjan Pan, and Karen L. Wooley*

Center for Materials Innovation and Department of Chemistry, Washington University, One Brookings Drive, Saint Louis, Missouri 63130. Received March 4, 2004; Revised Manuscript Received April 26, 2004

The conjugation of the protein transduction domain (PTD) from the HIV-1 Tat protein to shell-cross-linked (SCK) nanoparticles is reported as a method to facilitate cell surface binding and transduction of SCK nanoparticles. Attaching increasing numbers of peptide sequences to SCK nanoparticles in a global solution-state functionalization strategy has been devised as a method for increasing the efficiency of the cell-penetrating process. The numbers of peptides per SCK were controlled through stoichiometric balance and measured experimentally by two independent methods, UV−visible spectroscopy and phenylglyoxal analysis. PTD was conjugated in (0.005, 0.01, and 0.02) molar ratios, relative to the acrylic acid residues in the shell, to the SCK nanoparticles resulting in SCK populations possessing nominally 52, 104, and 210 (41, 83, and 202 as measured by phenylglyoxal analysis) PTD peptides per particle, respectively. The methodologies for the block copolymer and nanoparticle syntheses, peptide derivatization, and characterization of peptide-functionalized SCK nanoparticles are reported and the feasibility and efficiency of intracellular internalization of the respective SCKs were quantified.

INTRODUCTION

The interactions of biological species with synthetic constructs are dominated by surface-mediated interactions (*1*). Transduction (*2*) of peptides, proteins, and synthetic constructs, not normally able to access intracellular components, across the cellular plasma membrane is an area of promising research directed toward applications such as disease-state detection and diagnosis, and the delivery of therapeutics. Several proteins (*3*, *4*) and synthetic peptide sequences (*5*−*7*) have been identified as ligands that facilitate transduction, and the sequence and structural effects on the efficiency of uptake are being elucidated (*8*). These sequences are being exploited as facilitators for the cellular membrane transduction of proteins (*9*), antibodies (*10*), block copolymers (*11*, *12*), inorganic nanoparticles (*13*, *14*), and liposomes (*15*), which are, otherwise, ineffective for intracellular and nuclear targeting and delivery strategies.

Advances in the design and preparation of synthetic constructs have enabled rapid progress in their use as transduction media. For example, the self-assembly of block copolymers has emerged as a popular route for the production of complex nanostructured materials (*16*), and recent synthetic advancements in living free radical polymerization (*17*, *18*) have allowed for the preparation of large macromolecular assemblies consisting of well-defined block copolymer precursors. Shell-cross-linked (SCK) nanoparticles (*19*−*21*) are core−shell nanoparticles inspired from biological constructs and are optimized for guest packaging (*22*). SCKs are constructed from polymer micelles assembled in aqueous solution from amphiphilic block copolymer precursors and stabilized through the incorporation of covalent cross-links in the shell layer (*23*). The easily controlled structural and chemical features (*24*) play significant synergistic roles in the resulting binding and sequestration (*25*, *26*) properties of the nanoparticles. Previously, the conjugation of the protein transduction domain (PTD) of the HIV-1 Tat protein to the surface of shell-cross-linked nanocages (*23*) (core-excavated SCKs) using a solid-support resin was demonstrated. The derivatization, which limited (to approximately one) the number of peptides that were presented from the nanocage surface, provided bioactive nanostructures with demonstrated cell surface binding and preliminary evidence of transduction (*27*). Attaching increasing numbers of peptide sequences to the SCK in a global solution-state functionalization strategy was, therefore, devised as a methodology for increasing the efficiency of the cell-penetrating process. SCK assembly, peptide derivatization, and detailed characterization of peptide-functionalized SCK nanoparticles with enhanced transduction capability are reported.

EXPERIMENTAL SECTION

Materials. Unless otherwise listed, all solvents and reagents were purchased from Sigma Aldrich Chemical Co. (St. Louis, MO) and used as received. Monomers were purchased from Sigma Aldrich and distilled over calcium hydride. FMOC-protected amino acids and preloaded solid-phase Wang resins were purchased from NovaBiochem-CalBiochem Corp (San Diego, CA). Spectra/Por dialysis membranes (Spectrum Laboratories, Inc., Rancho Dominguez, CA) were purchased from Fisher Scientific Company (Pittsburgh, PA). Prolong antifade mounting medium was purchased from Molecular Probes Inc. (Eugene, OR).

Measurements. ^{1}H NMR (300 MHz) and ^{13}C NMR (75 MHz) spectra were recorded as solutions on a Varian

Mercury 300 MHz spectrometer with the solvent signal as standard. IR spectra were obtained on a Perkin-Elmer Spectrum BX FT-IR system using diffuse reflectance sampling accessories. Mass spectra were obtained from a Voyager DE-RP MALDI-TOF mass spectrometer (PE Biosystem). HPLC was performed using a Hewlett-Packard Series 1100 with reversed phase C18 column (Dynamax, 300 Å, Rainin) equipped with quaternary pump, solvent degasser, and diode array detector.

Size Exclusion Chromatography (SEC). Size exclusion chromatography was conducted on a Model 150-CV (Waters Chromatography Inc., Medford, MA). The instrument was equipped with a Model 410 differential refractometer, a Model PD2040 dual-angle (15° and 90°) light scattering detector (Precision Detectors Inc., Bellingham, MA), and a three-column set of gel-mixed-bed styrene−divinylbenzene columns (Polymer Laboratories Inc., Amherst, MA). The SEC system was equilibrated at 35 °C in anhydrous THF, which served as the polymer solvent and eluent (flow rate set to 1.00 mL/min then determined gravimetrically). An injection volume of 400 μL was used, and the polymer concentrations ranged from 5 to 10 mg/mL. Data collection was performed with program Precision Acquire (Precision Detectors Inc., Bellingham, MA). Data analysis was performed with program Discovery32 (Precision Detectors Inc., Bellingham, MA). Interdetector delay volume and the light scattering detector calibration constant were determined from a nearly monodisperse polystyrene calibrant (M_p = 90 000 g/mol, M_w/M_n < 1.04; Pressure Chemical Co., Pittsburgh, PA). The differential refractometer was calibrated with standard polystyrene reference material (SRM 706; NIST, Gaithersburg, MD), of known specific refractive index increment, dn/dc (0.184 mL/g). The dn/dc of the analyzed polymers was then determined from the differential refractometer response.

Differential Scanning Calorimetry (DSC). The glass transition temperature (T_g) was measured by differential scanning calorimetry on a Perkin-Elmer DSC-4 differential scanning calorimeter. Heating rates were 10 °C/min and reported values of T_g were measured at the midpoint of the inflection tangent, upon the third heating scan.

Sedimentation Equilibrium (SE). A Beckman Instruments Co. Model Optima XL-I analytical ultracentrifuge operated with a Model An60-Ti, four-hole rotor was used to centrifuge 50 mM NaH_2PO_4, 50 mM NaCl, (PBS) pH 7.1 solutions of the SCK to sedimentation equilibrium. All measurements were made at 20 ± 0.1 °C. Rotor speeds of 2000, 3000, 5000, and 8000 rpm were used. Sedimentation equilibrium data were obtained for three SCK solution concentrations. Resulting sedimentation equilibrium profiles were recorded with the instrument's Rayleigh interferometric (refractive index) detection optics. The ultracentrifuge sample cell was assembled from an Epon charcoal-filled, six-channel centerpiece and matched sapphire windows. The solution volume and the cell's optical path length were 110 μL and 12 mm, respectively. The solution volume and optical path length employed corresponded to a "short" column sedimentation equilibrium experiment with a column height of approximately 2.5 mm. A centrifugation time of 3 to 5 days was used to reach sedimentation equilibrium. Partial specific volume (ν) values for the SCKs were determined via sedimentation equilibrium analysis for protonated and deuterated buffer solutions of SCKs as described previously (*24*). Solutions of the SCK in deuterated buffer were prepared by exhaustive dialysis of protonated buffer stock solutions of SCKs against 50 mM PBS, pD 7.1, in 99.9 atom % D_2O. Calculation of molecular weight employed a built-in data analysis program that employed standard multicomponent least-squares fitting routines. Density at 20.0 ± 0.1 °C for protonated and deuterated buffers was determined with a Mettler-Parr digital density meter. Measurements of ν were reproducible to within ±1% of the mean value given by three determinations. The values of ν obtained by SE were also used for the determination of the weight concentrations of SCK nanoparticle solutions. The digital density meter was employed to measure the solution density at 20.0 ± 0.1 °C for the SCK solutions and their corresponding PBS buffers to an accuracy of ±0.0001 g/mL. These values were used in conjunction with the SE-measured value of ν to determine the weight concentration, C_{SCK}, of the SCK solution in PBS buffer:

$$C_{SCK} = (\rho_{SCK} - \rho_b)/(1 - \nu\rho_b)$$

where ρ_b is the density of the buffer and ρ_{SCK} is the density of the SCK solution.

UV−Visible Spectroscopy. Absorption measurements were made using a Molecular Devices Corp (Sunnyvale, CA) UV−visible spectrophotometer. A Thermomax multiplate reader using SOFTmax PRO software was employed. The concentrations of PTD and SCK in aqueous solutions of functionalized SCK nanoparticles were simultaneously determined using the UV absorbance measured at 230 and 276 nm. Measurements obtained at 230 and 276 nm corresponded to the turbidity of the SCK nanoparticle and the tyrosine (TYR) absorbance of the PTD at these wavelengths. The total absorbance for a functionalized SCK at a given wavelength, A^{λ}, was given by the sum of the absorbances of the nanoparticle's SCK component, $A_{SCK}{}^{\lambda}$, and its PTD component, $A_{TYR}{}^{\lambda}$:

$$A^{230} = A_{SCK}{}^{230} + A_{TYR}{}^{230} \quad (1)$$

$$A^{276} = A_{SCK}{}^{276} + A_{TYR}{}^{276} \quad (2)$$

The individual concentrations of the SCK and PTD (C_{SCK} and C_{TYR}, respectively) components constituting a functionalized nanoparticle were obtained by simultaneously solving eqs 1 and 2 after calibration of the UV spectrum at 230 and 276 nm with PTD and SCK standards of known concentration. The calibration yielded a set of calibration coefficients, K, for the components at 230 and 276 nm:

$$A^{230} = K_{SCK}{}^{230}C_{SCK} + K_{TYR}{}^{230}C_{TYR} \quad (3)$$

$$A^{276} = K_{SCK}{}^{276}C_{SCK} + K_{TYR}{}^{276}C_{TYR} \quad (4)$$

Measured values A^{230} and A^{276} were substituted into eqs 3 and 4 which were expressed in matrix form (eq 5) and then solved by inversion of the matrix of calibration coefficients, **K**:

$$\mathbf{A} = \mathbf{KC} \quad (5)$$

$$\mathbf{K^{-1}A} = \mathbf{K^{-1}KC} \quad (6)$$

$$\mathbf{C} = \mathbf{K^{-1}A} \quad (7)$$

Substitution of computed values of $\mathbf{K^{-1}}$ in eq 7 provided the expressions used to calculate the weight concentrations of SCK and PTD in solution:

$$C_{SCK} = 8.6405A^{230} - 41.5418A^{276} \quad (8)$$

$$C_{TYR} = 9.5652A^{230} - 1.5869A^{276} \quad (9)$$

Experimentally determined weight concentrations were converted to molar concentrations using the known molecular weight of the PTD and the measured molecular weight of the SCK. Molar concentrations of each component provided the requisite information to evaluate the number of peptides (PTD) per SCK nanoparticle (no. peptides per SCK = C_{PTD} (M)/C_{SCK} (M)).

Phenylglyoxal Analysis Measurements. The number of arginine residues (and PTD) was determined experimentally using phenylglyoxal analysis (*28*, *29*). The assay was calibrated by adding aliquots (100 μL) of a PTD solution (100 μL in PBS with 10% methanol, volume fraction) in row 1 of a quartz 96-well plate and diluting serially through column 11. SCK solutions (100 μL) (0.0, 0.5, 1.0, and 2.0%) of known concentrations (1.20, 2.00, 1.20, and 0.60 mg/mL, respectively) were added to each well in the first column and diluted serially as described above. An aliquot (100 μL) of a phenylglyoxal solution (600 μM), in identical buffer, was then added to each well of the plate, and the reaction was allowed to incubate at 4 °C overnight. The 96-well plate was read for absorbance at λ = 310 nm in each well. The control phenylglyoxal absorbance spectrum was subtracted from the PTD absorbance spectra, and by plotting the residual absorbance numbers vs the known concentration of PTD in each well, a calibration curve was generated from which the amount of PTD in unknown solutions could be determined. Measurement of the SCK concentrations by other methods and converting molar ratios provided quantitative information on the number of peptides per particle in each of the four samples.

Dynamic Light Scattering (DLS). Hydrodynamic diameter distribution and distribution averages for the SCKs in PBS solution were determined by dynamic light scattering. A Brookhaven Instruments Co. (Holtsville, NY) DLS system equipped with a Model BI-9000AT digital correlator, a Model EMI-9865 photomultiplier, and a Model 95-2 Ar ion laser (Lexel Corporation, Fremont, CA), operated at 514.5 nm, was used. Measurements were made at 20 ± 0.1 °C. Nanoparticles were dialyzed into 50 mM PBS, pH 7.1, prior to analysis. Buffered nanoparticle solutions were either centrifuged in a model 5414 microfuge (Brinkman Instrument Company, Westbury, NY) for 4 min or filtered through 0.22 μm poly(vinylidene fluoride) and 0.1 μm ceramic filters (Whatman, Maidstone, UK) to remove dust particles. Scattered light was collected at a fixed angle of 90°. The digital correlator was operated with 522 ratio spaced channels, an initial delay of 1.6 μs, a final delay of 10 ms, and a duration time of 15 min. A photomultiplier aperture of 400 μm was used, and the incident laser power was adjusted to obtain a photon counting rate between 200 and 300 Kcps. Only measurements for which the measured and calculated baselines of the intensity autocorrelation function agreed to within ±0.1% were used to calculate nanoparticle hydrodynamic diameter values. All determinations were made in triplicate. The calculations of the nanoparticle diameter distributions and distribution averages were performed with the ISDA software package (Brookhaven Instruments Co.), which employed single-exponential fitting, cumulants analysis, and nonnegatively constrained least-squares particle size distribution analysis routines.

Zeta Potential. Zeta potential (ζ) values for the SCKs were determined with a Brookhaven Instrument Co. (Holtsville, NY) Model ZetaPlus zeta potential analyzer. Measurements were made following dialysis (MWCO 12−14k dialysis tubing, Spectrum Laboratories, Rancho Dominguez, CA) of SCK solutions into 1 mM KH_2PO_4, 1 mM KCl, pH 7.1 buffer. Data were acquired in the phase analysis light scattering (PALS) mode (*30*), following solution equilibration at 25 °C. Calculation of ζ from the measured nanoparticle electrophoretic mobility (μ) employed the Smoluchowski equation:

$$\mu = \epsilon\, \zeta/\eta$$

where ϵ and η are the dielectric constant and the absolute viscosity of the medium, respectively. Measurements of ζ were reproducible to within ±2 mV of the mean value given by 16 determinations of 10 data accumulations.

Transmission Electron Microscopy (TEM). Transmission electron microscopy carbon grids were prepared by oxygen plasma treatment to make the surface hydrophilic. Particle samples were diluted 9:1 in water and further diluted 1:1 with a 1% (mass fraction) phosphotungstinic acid (PTA) stain. Micrographs were collected at 100 000 magnification and calibrated using a 41 nm polyacrylamide bead from NIST. Histograms of particle diameters were generated from the analyses of a minimum of 150 particles from at least three different micrographs.

Atomic Force Microscopy (AFM). Tapping-mode atomic force microscopy measurements were conducted in air with a Nanoscope III Bioscope system (Digital Instruments, Santa Barbara, CA) operated under ambient conditions with standard silicon tips (OTESPA-70; L, 160 μm; normal spring constant, 50 N/m; resonance frequency, 246−282 kHz). The samples were prepared for AFM analysis by depositing a 2-μL drop of the solution onto freshly cleaved mica and allowing it to dry freely in air. Histograms of particle heights were generated from the section analysis of a minimum of 150 particles from at least five different analyses regions.

Cell Lines. Chinese hamster ovary (CHO) cells (ATCC) were obtained as a gift from Professor Jacob Schaefer. (Washington University, Saint Louis, MO). CHO cells were maintained in Roswell Park Memorial Institute (RPMI, Life Technologies, Rockville, MD) 1640 supplemented with 10% (volume fraction) heat-inactivated fetal bovine serum (FBS, Life Technologies, Rockville, MD), in 5% CO_2:95% air (volume fractions) at 37 °C.

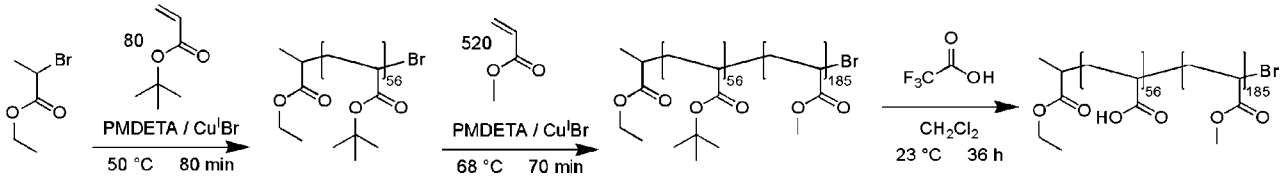
Transduction Experiments. CHO cells were cultured, counted, and resuspended to a final concentration of 100 000 cells/mL. An aliquot of the cell suspension (3.00 mL) was deposited into each well of a tissue culture treated six-well plate (Falcon, 3043), which contained a No. 1.5 glass cover slip (Corning). After 48 h, the cells (50−60% confluence) in each six-well plate were washed with PBS (2 × 5.00 mL). An aliquot of serum free RPMI 1640 media (3.00 mL) was added to each well followed by the respective SCK solutions (1.00 mL each). The plates were then returned to the incubator to incubate at 37 °C. After 1 h, the nanoparticles were removed, and each well was washed with PBS (3 × 5.00 mL). The cells were then fixed using a 4% (mass fraction) paraformaldehyde solution (2.00 mL) in each well and allowing ambient temperature incubation for 1 h. After fixation, the cells were mounted in Prolong antifade mounting medium (Molecular Probes, Eugene, OR) and viewed under bright field and fluorescent conditions using an Olympus IX-70 inverted microscope. The transduction

experiments were repeated using RPMI 1640 media supplemented with 0.1% (mass fraction) sodium azide, and at 4 and 37 °C. For quantification by flow cytometry, the transduction experiments were repeated except that the cells were grown directly on the tissue cultured plates instead of glass cover slips. The cells were trypsinized to remove most of the surface bound particles and release the cells from the plate, centrifuged at 4 °C, and resuspended in PBS and stored on ice briefly. Less than 5 min prior to flow cytometry analysis, propidilium iodide (5.0 μL) was added to each centrifuge tube. Analysis was done on a FACS Calibur (BD Biosciences, Franklin Lakes, NJ) instrument using CellQuest software.

Fluorescence and Confocal Microscopy. Confocal microscopy was accomplished using a Leica TCS SP2 scanning confocal microscopy system equipped with Ar^+, Kr^+, and HeNe laser systems. The excitation wavelength was 488 nm, and the emission was collected over the range of 510−530 nm. Optical slices were taken on 0.5 μm centers with the Leica software compiling the collections of images into the 3-D reconstructions. The incubation and fixation experimental parameters outlined previously were strictly adhered to in the confocal microscopy experiments with the following exceptions. The cover slips from the 37 °C experiments were mounted on slides fitted with a small spacer and PBS was added as the medium. These experiments were repeated with cells being incubated at 4 °C for 1 h and washed and mounted with cold buffer. The cells were viewed for a maximum of 20 min as live whole, unfixed specimens.

FMOC-Solid-Phase Synthesis of PTD on Wang's Resin (1). The protein transduction domain sequence (GGGGYGRKKRRQRRR) was synthesized by standard solid-phase synthesis using Fmoc chemistry. A small amount of beads were removed and washed with NMP, DMF, CH_2Cl_2, and methanol three times each. Peptide cleavage was achieved through treatment of the resin with a 95% TFA:2.5% TIS:2.5% (volume fractions) water solution (10 mL) for a minimum of 4 h. The solution was filtered, and the beads were rinsed with TFA. The solution was concentrated in vacuo, and the concentrate was precipitated into cold ether. The precipitates were centrifuged at 3500 rpm for 10 min. The supernatant was decanted, the pellet was resuspended in cold ether, and the centrifugation process was repeated. The pellet was purified by reversed phase HPLC. MS (MALDI): 1789.5022 $[M + H]^+$ (calcd: 1788.03 MW).

Poly(*tert*-butyl acrylate) (2). A 100 mL Schlenk flask that had been oven-dried overnight, flame-dried under vacuum, and back-filled with argon was charged with copper(I) bromide (891.6 mg, 6.2×10^{-3} mol). *tert*-Butyl acrylate (38.00 mL, 2.6×10^{-1} mol), PMDETA (1.30 mL, 6.2×10^{-3} mol), and ethyl-2-bromopropionate (403 μL, 3.1×10^{-3} mol) were added via argon-washed syringes. The solution was degassed by three cycles of freeze−pump−thaw, and following the final thaw cycle, the mixture was stirred for 10 min before being immersed in an oil bath at 50 °C. After 80 min, the polymerization was quenched by immersion in liquid nitrogen. The reaction mixture was dissolved in THF and passed through an alumina plug to remove the metal/ligand catalyst system. The polymer solution was concentrated and then precipitated into cold methanol. $M_n = 7400$ from SEC, based on multiangle light scattering (MALS). $M_w/M_n = 1.12$. The isolated yield was 28.83 g (85%). $(T_g)_{tBA} = 33$ °C. IR: 3440, 2980, 1750, 1450, 1380, 1265, 1150, 850, 760, 625 cm^{-1}. ^1H NMR ($CDCl_3$) δ 1.05 (d, CH_3CH end group), 1.22 (t, CH_3CH_2O end group), 1.20−1.50 (broad, $(CH_3)_3C$), 1.24−1.70 (broad, meso and racemo CH_2 of the polymer backbone), 1.74−1.94 (broad, meso CH_2 of the polymer backbone), 2.15−2.35 (broad, CH of the polymer backbone), 4.05 (br overlapping m, CH_3CH_2O and $CHBr$ end groups) ppm. ^{13}C NMR ($CDCl_3$) δ 27.9−28, 35.5−37.4, 41.5−41.4, 80.3, 173.6, 173.9 ppm.



Poly(*tert*-butyl acrylate-*b*-methyl acrylate) (3). A Schlenk flask (100 mL) was oven-dried overnight, flame-dried under vacuum, back-filled with argon, and charged with copper(I) bromide (184.1 mg, 1.3×10^{-3} mol) and poly(*tert*-butyl acrylate) **2** (4.7381 g, 6.4×10^{-4} mol). PMDETA (268 μL, 1.3×10^{-3} mol) and methyl acrylate (30.00 mL, 3.3×10^{-1} mol) were added via argon-washed syringes. The solution was degassed by three cycles of freeze−pump−thaw, and following the final thaw cycle, the mixture was stirred for 10 min before being immersed in an oil bath at 68 °C. After 70 min, the polymerization was quenched by immersion in liquid nitrogen. The reaction mixture was dissolved in THF and passed through an alumina plug to remove the metal/ligand catalyst system. The polymer solution was concentrated and then precipitated into a cold methanol/water solution. $M_n = 23\,400$ from SEC, based on MALS. $M_w/M_n = 1.13$. The isolated yield was 9.18 g (16%). $(T_g)_{PtBA} = 32$ °C. $(T_g)_{PMA} = 14$ °C. IR: 3650, 3450, 2970, 1990, 1550, 1450, 1180, 1080, 850 750, 625 cm^{-1}. ^1H NMR ($CDCl_3$) δ 1.20−1.50 (broad, $(CH_3)_3C$), 1.25−1.95 (broad, CH_2 of the polymer backbone), 1.74−1.94 (broad, CH_2 of the polymer backbone), 2.15−2.40 (broad, CH of the polymer backbone), 3.55−3.65 (broad, OCH_3) ppm. ^{13}C NMR ($CDCl_3$) δ 27.9−28, 35.5−37.4, 41.5−41.4, 51.5, 80.3, 173.4, 173.6 ppm.

Poly(acrylic acid-*b*-methyl acrylate) (4). The *tert*-butyl esters along the poly(*tert*-butyl acrylate) block of **3** were cleaved selectively by adding trifluoroacetic acid (30.00 mL) to the diblock, **3** (8.5600 g, 3.66×10^{-4} mol), in dichloromethane (100 mL). After 36 h, the solvent was evaporated in vacuo, and the residue was dissolved in THF and purified by dialysis in presoaked dialysis tubing (MWCO 12−14k) against Nanopure (18.0 mΩ cm^{-1}) water for 3 days. Lyophilization yielded poly(acrylic acid-*b*-methyl acrylate) as a white powder. Yield: 7.25 g (98%); $(T_g)_{PAA} = 145$ °C. $(T_g)_{PMA} = 14$ °C. IR: 3500−2500, 1760, 1660, 1445, 1280, 1180, 1050, 850, 725, 610 cm^{-1}. ^1H NMR ($CDCl_3$) δ 1.25−2.0 (broad, CH_2 of the polymer backbone), 1.74−1.94 (broad, CH_2 of the polymer backbone), 2.20−2.45 (broad, CH of the polymer backbone), 3.55−3.65 (broad, OCH_3) ppm. ^{13}C NMR ($CDCl_3$) δ 34−36.4, 40.5−42.4, 50.5, 173, 178 ppm.

Micelle Formation (5). Polymer micelles of narrow size distribution were obtained by dissolving the block copolymer **4** (1.9968 g, 8.53×10^{-5} mol) in THF (1.000 L, 1.997 mg/mL) followed by gradual addition (20.00 mL/h) of an equal volume of nonsolvent (H_2O) for the hydrophobic poly(methyl acrylate) to induce micellization. The micelles were stirred for 12 h before being transferred to presoaked and rinsed dialysis bags (MWCO 12−14k) and dialyzed against Nanopure (18.0 MΩ cm^{-1}) water for 3 days to remove the organic solvent. The final volume was 2.250 L of aqueous micelle solution for a final concentration of 0.89 mg/mL. DLS: $D_h = 38$ nm, ZETA: $\zeta = -27 \pm 0.7$ mV, TEM: 21.3 ± 3.8 nm.

Shell-Cross-Linked (SCK) Nanoparticle Formation (6). 2,2′-(Ethylenedioxy)-bis(ethylamine) (192 μL, 1.3×10^{-3} mol) was added to 2.125 L of micelle solution (0.90 mg/mL) of poly(acrylic acid-*b*-methyl acrylate). After 30 min, an aqueous solution of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (2.0201 g, 1.05×10^{-2} mol) was added to the reaction vessel. The reaction mixture was stirred for 24 h, and it was then dialyzed

Scheme 1. Sequential ATRP of *tert*-Butyl Acrylate and Methyl Acrylate Afforded Well-Defined Poly(*tert*-butyl acrylate-*b*-methyl acrylate)[a]

[a] The *tert*-butyl esters were cleaved selectively through treatment of the diblock copolymer with TFA in CH_2Cl_2 for 36 h.

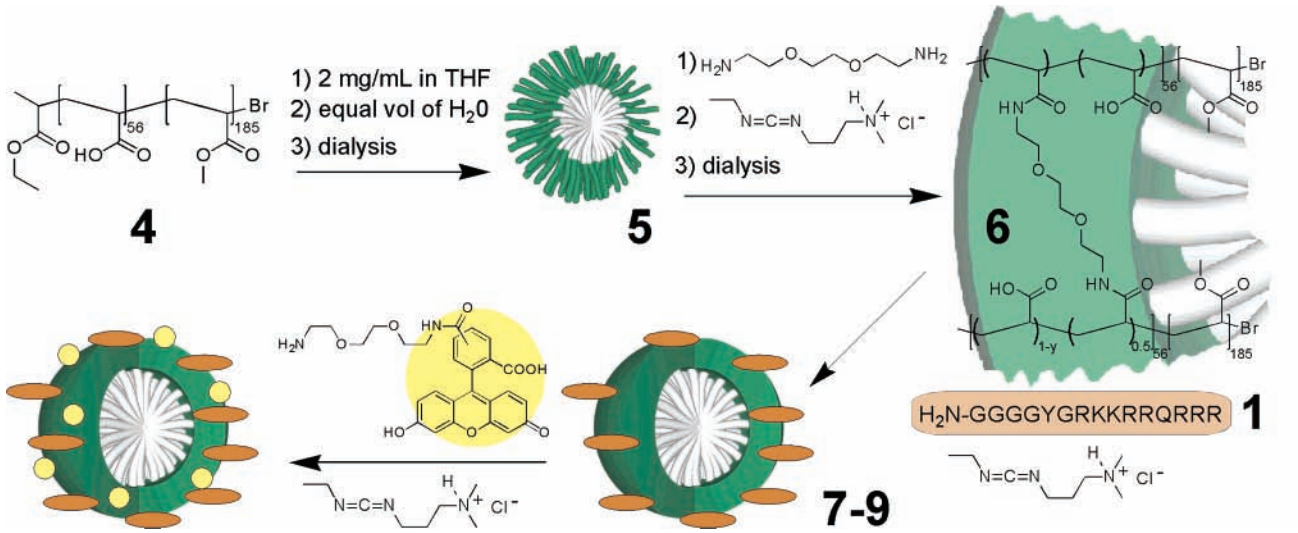
against Nanopure water for 3 days to remove residuals. The SCKs were dialyzed into 50 mM sodium phosphate, 50 mM sodium chloride, pH 7.4 buffer, and the number-average hydrodynamic diameter (D_n) of was determined by dynamic light scattering. DLS: $D_n = 37$ nm. ZETA: $\zeta = -20 \pm 0.5$ mV. TEM: 18.3 ± 3.6 nm. AFM: 3.8 ± 1.8 nm. IR: 3385, 2949, 1738, 1568, 1442, 1163, 829 cm^{-1}. DSC: $T_g = 15$ °C. ^1H NMR (D_2O:THF-d_8, 1:2) δ 1−3.0 (aliphatic protons of polymer backbone), 3.50−3.70 (OCH_3) ppm.

General Procedure for the Functionalization of (SCK) Nanoparticles with Various Molar Ratios of PTD. An SCK solution (50.00 mL, 0.895 mg/mL) was placed into a 100 mL round-bottom flask equipped with a stir bar. Sodium chloride (1.00 g) was placed into each of the flasks to minimize aggregation. A stock solution (50.00 mg/mL) of 1-(3′-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride in sodium phosphate buffer, pH 7.4, was created, and 1.00 mL aliquots (2.5×10^{-4} mol) were added to each flask to activate the acrylic acid residues. A stock solution (18.21 mg/mL) of the PTD peptide, **1**, was made in sodium phosphate buffer, pH 7.4, and aliquots of the solution were added to the respective flasks 20 min after the addition of the carbodiimide.

0.5% PTD Functionalized (7). A PTD stock solution (61 μL, 18.21 mg/mL, 6.25×10^{-7} mol) was added to the activated SCK solution, and the mixture was allowed to react overnight. Following the allocated reaction time, the solution was transferred to presoaked dialysis tubing (MWCO 12−14k) and allowed to dialyze for 3 days against 50 mM sodium phosphate, 50 mM sodium chloride, pH 7.4 buffer, prior to analysis. DLS: $D_n = 35 \pm 3$ nm. ZETA: $\zeta = -28 \pm 0.9$ mV. TEM: 20.2 ± 3.7 nm.

1.0% PTD Functionalized (8). A PTD stock solution (123 μL, 18.21 mg/mL, 1.25×10^{-6} mol) was added to the activated SCK solution, and the mixture was allowed to react overnight. Following the allocated reaction time, the solution was transferred to presoaked dialysis tubing (MWCO 12−14k) and allowed to dialyze for 3 days against 50 mM sodium phosphate, 50 mM sodium chloride, pH 7.4 buffer, prior to analysis. DLS: $D_n = 36 \pm 3$ nm. ZETA: $\zeta = -23 \pm 0.7$ mV. TEM: 21.4 ± 3.6 nm.

2.0% PTD Functionalized (9). A PTD stock solution (245 μL, 18.21 mg/mL, 2.50×10^{-6} mol) was added to the activated SCK solution, and the mixture was allowed to react overnight. Following the allocated reaction time, the solution was transferred to presoaked dialysis tubing (MWCO 12−14k) and allowed to dialyze for 3 days against 50 mM sodium phosphate, 50 mM sodium chloride, pH 7.4 buffer, prior to analysis. DLS: $D_n = 32 \pm 3$ nm. ZETA: $\zeta = -22 \pm 0.5$ mV. TEM: 21.6 ± 3.3 nm.



General Procedure for the Conjugation of a Fluorescent Tag to the PTD-Functionalized Nanoparticles (10−13). The respective PTD-functionalized SCK solutions (10.00 mL, 0.895 mg/mL) (2.24×10^{-9} mol) were placed into 50 mL round-bottom flasks. A 4.0 M KCl solution (1.00 mL) was added to each flask. The vessels were allowed to equilibrate for 30 min before 0.500 mL of a 50 mg/mL carbodiimide stock solution (1.25×10^{-4} mol) was added to each vessel. After 15 min, 200 μL of a 0.400 mg/mL stock solution (1.58×10^{-7} mol) of the fluorescein derivative was added to each round-bottom flask, and the reactions were stirred overnight. The solutions were then transferred to presoaked dialysis bags (MWCO 12−14K) and allowed to dialyze for 3 days against 50 mM phosphate, 50 mM NaCl buffer at pH 7.4. The reaction resulted in approximately 70 fluorophores being coupled to each nanoparticle based on calculations assuming ideal reaction efficiency.

RESULTS AND DISCUSSION

SCK Synthesis and Peptide Derivitization. The amphiphilic block copolymer precursor to the SCKs was prepared by sequential atom transfer radical polymerizations (*17*, *31*) of *tert*-butyl acrylate and methyl acrylate followed by the selective acidolysis of the *tert*-butyl esters. The poly(*tert*-butyl acrylate) macroinitiator was afforded through the polymerization of *tert*-butyl acrylate at 50 °C for 80 min using ethyl 2-bromopropionate as the initiator and the Cu^IBr/PMDETA catalytic system (*32*). The chain was further extended through the addition polymerization of methyl acrylate in bulk in the presence of Cu^IBr/PMDETA at 68 °C for 70 min as shown in Scheme 1. By allowing the reaction to proceed under conditions of high dilution (in monomer), low conversion, and by using a liquid nitrogen quench, a narrow molecular weight distribution for the block copolymer was maintained (*33*). The *tert*-butyl esters were cleaved selectively upon reaction with TFA in CH_2Cl_2, as described previously (*32*, *34*). The solvation of the purified poly(acrylic acid-*b*-methyl acrylate) block copolymer in tetrahydrofuran (1.99 mg/mL) followed by the controlled addition of Nanopure (18 MΩ cm) water (20.00 mL/h), and extensive dialysis against deionized water afforded micelles.

SCKs were formed by intramicellar conversion of approximately 50% of the 1-[3′-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride activated acrylic acid residues in the shell layer to amides using 2,2′-(ethylenedioxy)bis(ethylamine), as shown in Scheme 2. The protein transduction domain sequence of HIV-1 Tat protein extended by four glycine residues (GGGGYGRKKRRQRRR) used in this study was chemically synthesized by Fmoc (9-fluorenylmethoxycarbonyl) solid-phase peptide methodologies. The four additional glycine residues were placed at the N-terminus to function as a spacer between the active peptide sequence and the macromolecular assembly. The peptide was cleaved from the support, purified by reverse phase HPLC, and then coupled in 0.005, 0.01, and 0.02 molar ratios, relative to the acrylic acid residues within the SCK nanoparticles. The peptide coupling to the SCKs involved amidation of the N-terminus to the carboxylic acid residues within the SCK

Scheme 2. SCK 6 Was Prepared through the Micellization of the Block Copolymer 4, Followed by the Cross-Linking of Approximately 50 % of the Acrylic Acid Residues in the Shell Layer with 2,2′-(Ethylenedioxy)-bis(ethylamine)[a]

[a] The SCKs were functionalized with various molar quantities of PTD **1** under high ionic strength conditions to minimize aggregation and interparticle cross-linking. A linker-derivatized 5(6)-carboxyfluorescein dye (approximately 70 fluorophores per particle) was coupled to each of the SCK samples **6**−**9** to facilitate observation under fluorescence conditions.

shell. The molar amounts correspond to approximately 52, 104, and 210 PTD sequences per particle, respectively, assuming complete conversion and using the aggregation number (185 ± 7) of block copolymers within each particle. Following the conjugation, the respective solutions were then purified by dialysis against buffer for 5 days to remove the noncoupled peptide sequences. Noncoupled PTD was identified by UV measurements made at sedimentation equilibrium (SE), as described below.

Molecular Weight and Aggregation Number. The absolute weight-average molecular weight, M_w, of PTD-functionalized SCK nanoparticles was evaluated by sedimentation equilibrium (SE) analysis. Representative SE data (fringe displacement versus radial position, r) are presented in Figure 1A. The partial specific volume, ν, for the SCKs was also determined by SE using a previously described methodology (*24*) that employed sedimentation equilibrium profiles collected for the SCK dispersed in both protonated and deuterated buffer. Linear SE plots were obtained by plotting the log(fringe displacement) versus $r^2/2$ from which the slopes of the plots were determined and ν was computed:

$$\nu = [k - (\sigma_D/\sigma_H)]/[(\rho_D - \rho_H(\sigma_D/\sigma_H)]$$

where ρ_D is the density of the deuterated buffer, ρ_H is the density of the protonated buffer, and k is the ratio of the molar masses for the deuterated SCK to the protonated SCK (*24*).

SE analysis of M_w employed the nonlinear, least-squares fitting of sedimentation equilibrium profiles represented by the data in Figure 1A to a single-component model with ρ_H and ν held constant as measured parameters. The initial concentration of the nanoparticle at the mensicus, c_0, of the sedimentation column, the baseline offset, N_0, and an apparent weight-average molecular weight, $M_{w,app}$, were calculated as adjustable parameters in the fitting procedure. The computed $M_{w,app}$ when expressed as $1/M_{w,app}$ and plotted against the initial loading concentration of SCK nanoparticle, c, showed a dependence on both c and the rotor speed. The observed trends are indicative of molecular weight heterogeneity and nonideal sedimentation due to interparticle interactions or cross-linking. Extrapolation of $1/M_{w,app}$ to zero concentration for the lowest rotor speed employed provided the evaluation of M_w. As summarized in Table 1, the 0% PTD-functionalized SCK nanoparticle produced a ν of 0.556 ± 0.007 mL/g, resulting in a M_w of 4 000 000 ± 151 000 g/mol. Dividing M_w by the copolymer weight-average molecular weight, corrected for the molar mass increase due to 50% cross-linking of each copolymer chain (21 664 g/mol), resulted in a weight-average degree of aggregation, $N_{w,agg}$, of 185 ± 7. The absolute weight-average molecular weights, M_w, of the PTD-functionalized SCK nanoparticles were also evaluated by SE analysis. Interestingly, M_w for the 0.5%, 1%, and 2% PTD-functionalized SCKs were 31%, 37%, and 41% higher, respectively, than M_w for 0% functionalized SCK. Functionalization of the preformed SCK (0% PTD) with the peptide was expected to produce small M_w increases through the incremental addition of molar mass from the PTD. The observed increases in M_w exceed the expected increase by at least 10-fold, suggesting that functionalization with PTD was accompanied by a small percentage of inter-nanoparticle cross-linking reactions or electrostatic aggregation events due to the zwitterionic character of the PTD- functionalized nanoparticles.

Collection of SE profiles using UV−visible detection optics allowed the analysis of the peptide content of the nanoparticles at centrifugation equilibrium. Free peptides were uniformly dispersed throughout the solution volume while the relatively massive particles were depleted from the meniscus along with the peptides bound to them. Therefore, the amount of free vs SCK-bound peptide in solution was determined by the ratio of absorbance at the meniscus to the absorbance of the unfunctionalized micelle and SCK. No absorbance for the tyrosine (λ_{276}) was detected near the meniscus in the 0.5% and 1.0% solutions relative to controls at 5000 rpm, indicating that all of the absorbance from the tyrosine residue of the PTD sequence is associated with the SCK nanoparticle as shown in Figure 1B.

A slight amount of absorbance observed for the 2.0% functionalized SCK solution suggested free peptide in solution however, increasing the rotor speed to 8000 rpm, which depleted the meniscus of nanoparticles indicated

Table 1. Summary of Physical Characterization Data Collected for the Parent SCK Nanoparticle and the PTD-Functionalized SCKs

particle	ν (mL/g)	M_w ($\times 10^6$ Da)	no. of peptides	ζ (mV)	DLS D_n (nm)	TEM D_{av} (nm)
micelle	n.d.	n.d.	0	-27 ± 0.7	38 ± 3	21.3 ± 3.8
SCK	0.556 ± 0.007	4.004 ± 0.151	0	-20 ± 0.5	37 ± 2	18.3 ± 3.6
0.5%	0.587 ± 0.009[a]	5.900 ± 0.241	52 ± 2	-28 ± 0.9	35 ± 3	20.2 ± 3.7
1.0%	0.622 ± 0.009	7.017 ± 0.304	104 ± 4	-23 ± 0.7	36 ± 3	21.4 ± 3.6
2.0%	0.661 ± 0.007	7.818 ± 0.248	210 ± 10	-22 ± 0.5	32 ± 4	21.6 ± 3.3

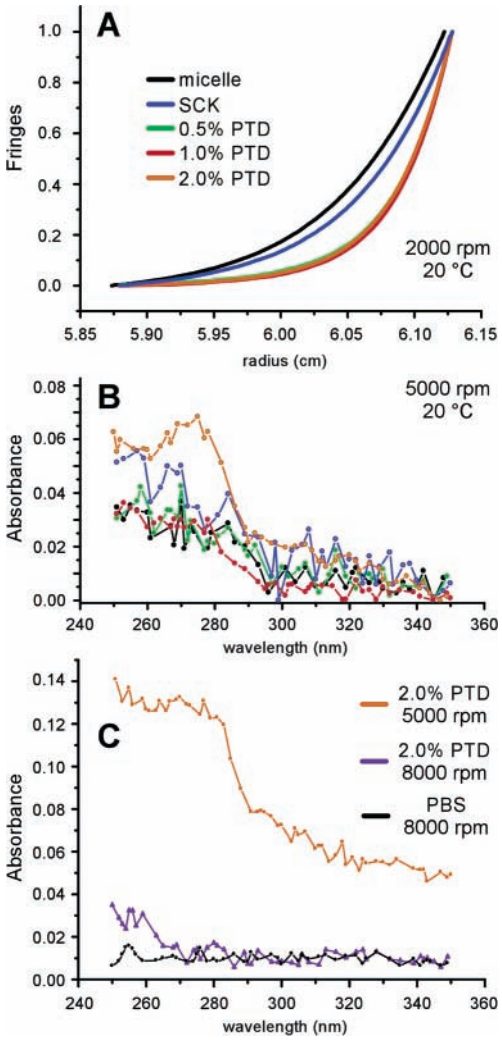


Figure 1. (A) Sedimentation equilibrium profiles collected using an interferometry detector for the micelles, SCKs, and peptide-functionalized nanoparticles. The dramatic increase in weight average molecular weight (M_w) was due to a small percentage of interparticle cross-linking (covalent or electrostatic), which contributed significantly to the molecular weight calculations. (B) UV spectra, recorded near the meniscus of solutions at sedimentation equilibrium, showed negligible absorbance due to free tyrosine residues within the PTD, relative to controls. (C) Repeating the experiment at 8000 rpm indicated that the meniscus was fully depleted of SCK at 8000 rpm, but not at 5000 rpm, and also confirmed that all the PTD was attached to the SCK.

that no free peptide was present in the solution (Figure 1C). This measurement is of particular importance for two reasons: (1) the presence of free peptide can compete with and inhibit the binding of the bioconjugate (*35*), and (2) the PTD sequence has measurable effects on in vitro cell viability and inflammatory response both of which are discussed in detail in the following article of this journal.

Particle Analysis. The SCK nanoparticles were characterized extensively to probe for the differences in size, surface charge, and morphology as a result of post-cross-linking functionalization with the arginine-rich PTD sequence. Dynamic light scattering (DLS) measurements were collected in sodium PBS buffer, pH 7.4. This precaution was used to minimize dilute solution aggregation of the nanoparticles. The polymeric micelle precursor to the SCK was shown to have a number-average diameter, D_n, of 38 ± 3 nm. The corresponding SCK, prepared with 50% cross-linking of its shell, was found to have a D_n of 37 ± 2 nm. A comparison of D_n values calculated using the nonnegatively constrained least squares (NNLS) model for the diameter distributions of the 0.5% (**7**), 1.0% (**8**), and 2.0% (**9**), PTD-functionalized nanoparticles resulted in values of 35 ± 3, 36 ± 3, and 32 ± 4 nm, respectively. When the volume-average diameter, D_v, and the intensity-average diameter, D_z, distributions for the nanoparticles were calculated, the presence of small amounts of aggregated species, representing a maximum of 5 vol %, was apparent in the D_v and D_z diameter distributions. The likely source of these larger diameter fractions is interparticle cross-linking due to the presence of the PTD sequence; however, it is unknown whether the nature of the aggregation arises from covalent cross-linking or electrostatic attraction. These findings are consistent with the large increases noted in M_w for the PTD-functionalized SCKs relative to M_w obtained for preformed SCK, **6**. Since these aggregated species were less than 100 nm in diameter, filtration and/or dialysis were not effective in their removal from the majority population of smaller nanoparticles. However, because these species represent less than 1% of the nanoparticle population by number, the contribution of these aggregates to data sets collected using imaging methods, such as atomic force microscopy (AFM), transmission electron microscopy (TEM), and confocal fluorescence microscopy, was negligible. Analysis of the SCKs by TEM depicted circular shapes that possessed narrow size distributions. The observed TEM nanoparticle diameters were smaller than those measured as D_n in buffer solution, due to drying and the effects of the phosphotunstic acid staining process employed during the TEM sample preparation. Zeta potential measurements also showed a diminishment in the negative surface charge density with increasing functionalization. The zeta potential (ζ) data for the functionalized SCKs are included in Table 1.

Quantification of PTD Functionalization. The number of peptides per particle in each sample was quantified using UV−visible spectroscopy and reaction of phenylglyoxal with the guanidine functionality of arginine as two independent methods of analysis. The number of peptides per particle was measured from UV spectroscopy by solving simultaneously for the peptide and SCK concentration using absorbance measurements recorded at two different wavelengths, λ_{230} and λ_{276}. Analysis of SCK samples **7**, **8**, and **9** resulted in values of 38, 86, and ~500 peptides per particle, respectively. The large number of peptides measured in sample **9** is a result of a slight amount of turbidity arising from aggregation, which dominates the absorbance measure-

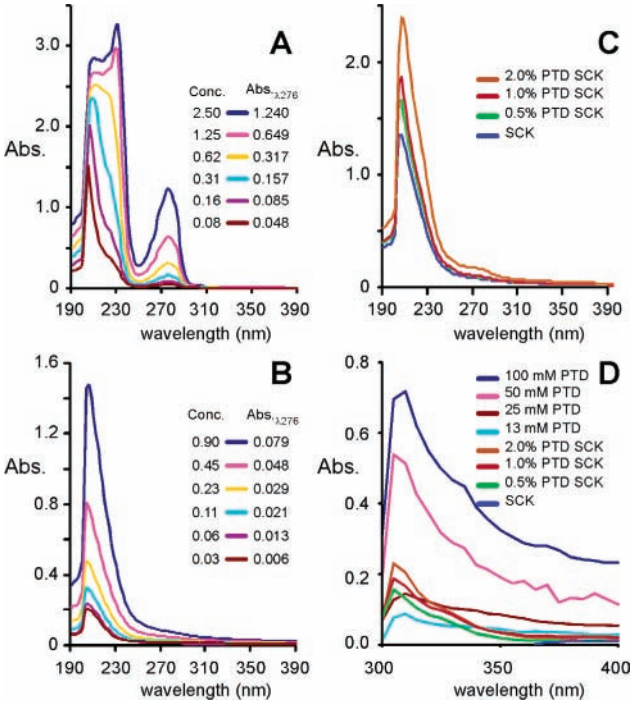

Figure 2. UV−visible spectroscopy afforded the quantitative calculation of the number of peptides per particle by two different methods. The first method involved the simultaneous solving of two unknowns as determined from PTD (A) and SCK (B) concentration calibration plots at λ_{230} and λ_{276}. From the calibration curve generated from A and B, the concentration of PTD in the respective SCK solutions (C) were calculated. The large number of peptides calculated to be in the 2.0% sample is a result of the slight amount of turbidity present in that sample due to aggregation, which is reflected in the absorbance measurement of that sample (orange). The second method involves the measurement of phenylglyoxal derivative formation (D). Phenylglyoxal reacts specifically with the guanidine groups on the side chains of arginine residues yielding a derivative with an absorbance red-shifted (λ_{310}) from that of the parent compound. From a calibration curve generated from known amounts of PTD, the molar concentration of the peptide in unknown solutions was determined. Molar ratios were then applied to quantify the number of peptides per particle.

ment at 230 nm as shown in Figure 2C. The coupling efficiency was approximately 80% and correlated well with the expected peptide numbers.

The second assay performed to quantify the number of peptides per particle employed absorbance measurements at 310 nm, which exhibited a negligible contribution from solution turbidity. Phenylglyoxal reacts specifically with the guanidine group of arginine residues under mild conditions (*29*). The PTD sequence contains six arginine residues which react with one phenylglyoxal moiety each in a mechanism outlined previously (*28*).

Measurements made using this method, again comparing molar ratios, resulted in degrees of functionalization of 41, 83, and 202 peptides for **7**, **8**, and **9**, respectively. These values are in good agreement with the dual wavelength, simultaneous UV spectroscopic determinations for the degree of functionalization in **7** and **8**. The value 202 determined by the phenylglyoxal method for **9** was in better agreement with expected values based on the measured M_w for the SCK (Table 1). The validity of the phenylglyoxal method as a specific assay for the PTD moieties attached to a SCK was also confirmed by performing the same experimental conditions for the nonfunctionalized SCK, as a negative control experiment, which showed no absorbance due to the phenylglyoxal

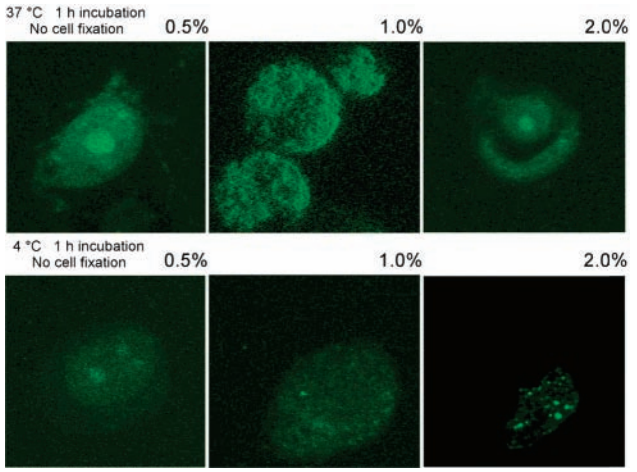

Figure 3. Live cell confocal fluorescence microscopy showing internalization of the 0.5, 1.0, and 2.0% PTD-functionalized nanoparticles at both 37 °C and 4 °C in CHO cells. No uptake or internalization was seen for the unfunctionalized, parent SCK under live cell conditions.

Table 2. the Quantification of PTD Functionalization in Each of the Respective SCK Samples Using Two Different Methods Afforded Similar Numbers of Peptides Per Particle

particle	no. of peptides nominal	no. of peptides UV−vis	no. of peptides phenylglyoxal
SCK	0	0	0
0.5%	52 ± 2	38	41
1.0%	104 ± 4	87	83
2.0%	210 ± 10	∼500	202

derivatization and thus no reaction of phenylygloxal with the unfunctionalized SCK, **6**.

Transduction Experiments. A mixed 5(6)-carboxyfluorescein derivatized with a 2,2′-(ethylenedioxy)bis(ethylamine) linker was conjugated to the PTD-functionalized nanoparticles to visually image binding interactions of the conjugates with mammalian cells using fluorescence microscopy. This type of fluorophore derivatization does not contribute to enhanced cellular uptake (*14*). The conjugation was performed on a molar equivalence basis and resulted in approximately 70 dye molecules per particle, assuming complete conversion. Free dye did not contribute to the analysis, as it was removed via dialysis against sodium PBS buffer. The cell uptake of PTD-functionalized SCKs was investigated by the in vitro transduction of CHO cells. Numerous examples exist describing the sequence specificity (*8*), mechanism (*7*, *35*), cofactor, and cell-type dependence (*36*) on the efficiency of cellular uptake. The mechanism, efficiency, and energy dependence of the particle translocation was investigated in this instance by varying the metabolic conditions of the experiments. Conditions included 1 h incubation times at 37 °C and 4 °C in serum free media, and in the presence of 0.1% sodium azide. Bright field, fluorescence, and confocal microscopies were performed on live cells as well as specimens that were fixed through 1 h incubations at ambient temperature in a 4% paraformaldehyde solution. Confocal microscopy of fixed cells clearly showed an accumulation of the fluorescent PTD functionalized nanoparticles inside the cells in all cases. Although the nonfunctionalized nanoparticles are also internalized, the apparent fluorescence intensities are qualitatively less than those of the PTD functionalized particles. Since fixation of cells involves the inherent perturbation of the cellular membrane, live cells were viewed without fixation to see whether rapid internaliza-

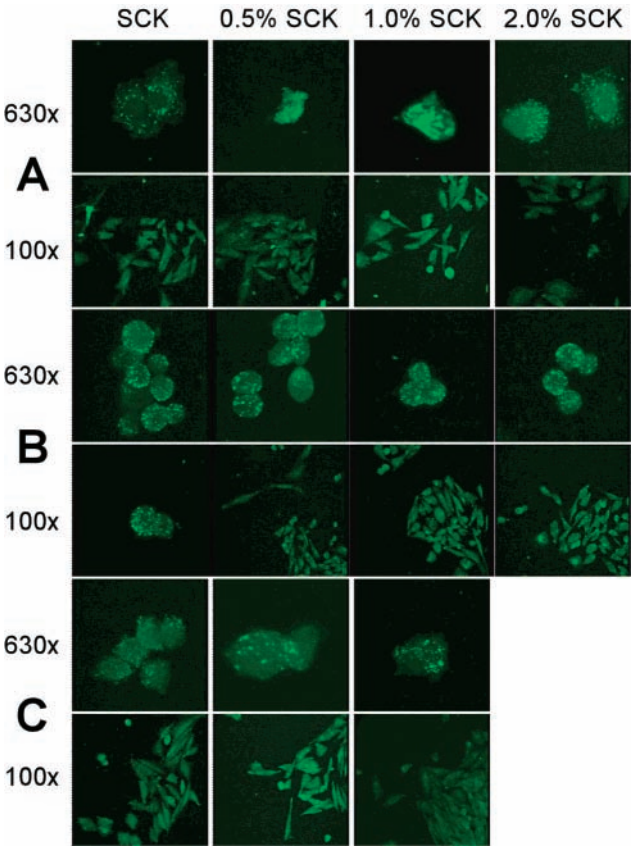

Figure 4. Confocal fluorescence microscopy of PTD-functionalized SCKs using CHO cells fixed with a 4% paraformaldehyde solution commonly used in the literature, shows nonspecific uptake of the nonfunctionalized SCKs, which was not observed in the live cell experiments, in addition to the qualitatively enhanced uptake in each of the PTD functionalized samples. A and B show the confocal reconstructions of the respective SCK samples at 37 °C and 4 °C, respectively, following 1 h incubations and cell fixation. C shows CHO cells that were incubated for 1 h in 0.1% sodium azide with the SCK samples.

tion occurred without the benefit of fixation. In the cases where the cellswere not fixed with the 4% paraformaldehyde solution, the non-PTD-functionalized SCKs were not observed in the intracellular space under fluorescence conditions when incubated at 37 °C or 4 °C, and therefore it was determined that they were either not internalized nonspecifically or not at a level that was readily measurable using optical or fluorescence microscopies. However, the 0.5%, 1.0%, and 2.0% PTD-functionalized SCK nanoparticles were readily internalized at 37 °C, 4 °C, and in the presence of 0.1% sodium azide, regardless of disruptive fixative processes that may or may not contribute to an enhanced nonspecific effect.

Flow Cytometry Analysis. The efficiency of PTD-functionalized SCK cell transduction was quantified by fluorescence activated cell sorting (FACS). Data in Table 2, which indicate the percentage of cells that are fluorescent for the respective samples, depict a trend of increasing cell transduction efficiency with increasing PTD/SCK stoichiometry. The slight decrease in the efficiency of uptake at 4 °C and in the presence of sodium azide, which depletes cellular ATP, relative to measured values at physiological temperatures suggest that endocytotic processes are also contributing to the SCK internalization. However, it is evident that nonendocytotic pathways contribute significantly to cell entry. While FACS analysis of the PTD-functionalized SCKs suggests multiple mechanisms of uptake, the intracellular internalization as visualized by live cell confocal microscopy cannot be disputed. It is important to note however that FACS analysis does not discriminate between internalized and surface bound particles, and efforts to further quantify the efficiency of uptake and exchange of the respective samples by radiolabeling methods are ongoing. The involvement of a single cellular process governing the internalization process has been shown to be increasing unlikely (*37*). While the ionic interactions between the Tat-derivatized species and the cell membrane are generally thought to be the initial step in the internalization process (*38*), the overall negative surface charge density, as measured by zeta potential, of the PTD-functionalized SCK nanoparticles suggest that further evidence is required to bolster that assessment. Recently, Dowdy et al. have shown that Tat-fusion proteins were internalized in a multistep process starting with a receptor-independent association of the fusion protein with the cell surface followed by a lipid raft-dependent macropinocytosis, which was demonstrated to be independent of interleukin-2 receptor/raft-, caveolar- and clathrin-mediated endocytosis (*39*). While these findings shed critical new and thorough insights on the mechanism of internalization, additional research on the nature of the initial construct−cell surface association step is needed.

Table 3. Percentage of Fluorescent CHO Cells Following the Transduction of Fluorescein-Labeled SCKs and PTD-Functionalized SCKs Quantified by Fluorescence-Activated Cell Sorting

particle	37 °C	4 °C	37 °C w/NaN_3	4 °C w/NaN_3
SCK	5.6	7.3	5.2	7.1
0.5%	33.9	10.3	16.3	8.5
1.0%	42.9	32.6	25.7	12.3
2.0%	47.0	36.4	51.8	13.8

CONCLUSIONS

The assembly of well-defined polymeric nanoparticles has been described, and subsequent functionalization of the SCK nanoparticles with PTD has been shown to facilitate their transduction across cellular membranes. The numbers of peptides per SCK were controlled through stoichiometric balance and measured experimentally by two independent methods. The feasibility and efficiency of intracellular internalization were quantified. In the next manuscript of this issue, the biocompatibility of these peptide-deriviatized SCK nanoparticles is measured by enzymatic and apoptosis assays, which measure the effects of SCK exposure on cellular viability, by real-time polymerase chain reaction (RT-PCR) measurements, which quantitatively assess the acute inflammatory response caused by the peptide-functionalized nanoparticles, and by a three-month mouse immunization protocol involving the measurement of IgG levels in the serum in response to nanoparticle immunizations. The biocompatibility evaluation of peptide-functionalized SCK nanoparticles and the identification of potentially detrimental interactions between biological species and SCK nanoparticles is crucial to further efforts to develop in vivo applications.

ACKNOWLEDGMENT

The authors gratefully acknowledge the National Cancer Institute (N01-CO-27103), and a Training Fellowship (M.L.B.) for the Chemistry-Biology Interface Program at Washington University funded by the NIH-NRSA (5-T32-GM08785-02) for supporting this research. Mouse myeloma B and CHO cells were kindly provided

by Professor Jacob Schaefer. TEM and confocal microscopy technical support from senior microscopist G. Michael Veith of the Washington University Department of Biology is gratefully acknowledged. Information related to the use of the phenylglyoxal assay for arginine residue analysis was generously provided by Dr. David C. Wood (Pfizer Inc.).

Peptide-Derivatized Shell-Cross-Linked Nanoparticles. 2. Biocompatibility Evaluation

Matthew L. Becker,*[,†,‡] LeeAnn O. Bailey,[‡] and Karen L. Wooley*[,†]

Center for Materials Innovation and Department of Chemistry, Washington University, One Brookings Drive, St. Louis, Missouri 63130, and National Institute of Standards and Technology, Polymers Division, Biomaterials Group, Gaithersburg, Maryland 20899-8543. Received March 4, 2004; Revised Manuscript Received April 26, 2004

The conjugation of the protein transduction domain (PTD) from the HIV-1 Tat protein to shell cross-linked (SCK) nanoparticles is a method to facilitate cell surface binding and transduction. In the previous report, the preparation, derivatization, and characterization of peptide-functionalized SCK nanoparticles were reported in detail. Following assembly, the constructs were evaluated in vitro and in vivo to obtain a preliminary biocompatibility assessment. The effects of SCK exposure on cell viability were evaluated using a metabolic 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) and a fluorescent apoptosis assay. Furthermore, stages of apoptosis were quantified by flow cytometry. Although higher levels of peptide functionalization resulted in decreased metabolic function as measured by MTT assay, significant apoptosis was not observed below 500 mg/L for all the samples. To evaluate the potential immunogenic response of the peptide-derivatized constructs, a real-time polymerase chain reaction (RT-PCR) system that allows for the in vitro analysis and quantification of the cellular inflammatory responses tumor necrosis factor alpha (TNF-α) and interleukin-1 beta (IL1-*β*) was utilized. The inflammatory response to the peptide-functionalized SCK nanoparticles as measured by RT-PCR show statistically significant increases in the levels of both TNF-α and IL1-*β* relative to tissue culture polystyrene (TCPS). However, the measured cytokine levels did not preclude the further testing of SCKs in an in vivo mouse immunization protocol. In this limited assay, measured increases in immunoglobulin G (IgG) concentration in the sera were minimal with no specific interactions being isolated, and more importantly, none of the mice (>50) subjected to the three 100 *μ*g immunization protocol have died. Additionally, no gross morphological changes were observed in postmortem organ histology examinations.

INTRODUCTION

New synthetic methodologies (*1*−*3*) are enabling remarkable advances in the rational design of polymeric materials that actively control cellular and physiologic responses. These methods produce well-defined materials that are incorporated into scaffolds capable of performing specific functions while being minimally detrimental to normal cellular processes and surrounding tissues for use in therapeutic (*4*−*6*), drug delivery (*7*−*10*), and tissue engineering applications (*11, 12*). One of the critical challenges in clinical medicine currently under intense investigation is the efficient delivery of macromolecules into cells for the purposes of drug, gene, and cancer therapies (*13, 14*). In the previous article of this issue, the preparation, characterization, and biological evaluation of peptide-functionalized shell-cross-linked (SCK) nanoparticles are reported. SCK nanoparticles (*15, 16*) are micellar assemblies of amphiphilic copolymers that have been stabilized through the incorporation of covalent cross-links in the shell layer (*17*). Syntheses of complex block copolymer precursors have afforded control over the physicochemical properties of the respective nanoparticle domains (*6*, *18*, *19*). Surface charge (*20*) and functionality are controlled easily and can be tailored for specific applications (*21*). The protein transduction domain (PTD) of HIV-1 Tat (*22, 23*) has been shown to shuttle much larger molecules into cells independent of classical endocytosis (*24*) which affords intracellular access to living cells for nuclear targeting strategies (*25*), gene (*14, 26*), radiotherapies (*27*−*29*) and other purposes. The attachment of increasing numbers of protein transduction domain (PTD) motifs to SCK nanoparticles is being investigated as a method to increase the efficiency of cell-penetrating transduction. Further extension of the peptide-derivatized conjugates into biological applications requires the elucidation of how increasing peptide functionality affects the biocompatibility of the derivatized nanostructures, including the cellular apoptosis and inflammatory responses. The effects on cell viability are evaluated by metabolic and flow cytometry assays. Measuring the effects of foreign substances on in vitro cell viabilities is typically accomplished by the exposure of a cell population to the conjugate and then monitoring the enzymatic reduction of MTT to formazan in the mitochondria of living cells (*30*). The viability is then expressed as a percentage of

cells that are dead as a function of the nanoparticle concentration. Another method to measure cell viability is an apoptosis assay, which is a technique that monitors cell membrane translocation events and the accessibility of nuclear material in response to extracellular perturbations, and the various stages of apoptosis are then quantified by flow cytometry. The ability to monitor the emission wavelengths of the respective fluorophores affords flow cytometry the ability to discriminate and quantify distinct populations of cells (*31*). It is anticipated that the two techniques will provide a complementary and accurate assessment of the effects of SCK exposure on cell viability.

Measurement of the acute inflammatory reaction in response to peptide-derivatized SCK nanoparticle exposure is another critical component in the assessment of the biocompatibility. Inflammation is characterized by the regulation of cytokines, which are responsible for the initiation, mediation, and propagation of the inflammatory response including lymphocyte activation, proliferation, differentiation, angiogenesis, and apoptosis (*32*). Quantifying the regulatory profile of cytokines at the protein level is difficult due to small sample sizes, which has created a need for alternative measurement methods. The measurement of mRNA levels is used widely to investigate the cytokine profiles at sites of inflammation (*32*). There are several techniques, aside from PCR-based methodologies, used commonly to quantify mRNA expression including Northern blotting, in situ hybridization, RNase protection assays, and cDNA arrays, each of which is limited by low measures of sensitivity (*33, 34*). Real-time polymerase chain reaction (RT-PCR) is a method for enzymatically amplifying defined sequences of mRNA, and it is the most sensitive, accurate, and adaptable of the mRNA quantitative techniques (*33, 35*). Quantitative RT-PCR has the advantage of being extremely sensitive over a large range of quantification, requires no post-PCR sample handling (*36, 37*), and has previously afforded measurement of the genetic regulatory profiles for inflammatory cytokines in response to synthetic materials (*38, 39*). Herein, a preliminary biocompatibility assessment of peptide-derivatized SCK nanoparticles is described in detail including enzymatic and apoptosis assays, which measure the effects of SCK exposure on cellular viability. In addition, RT-PCR measurements were used to quantitatively assess the inflammatory response caused by the peptide-functionalized nanoparticles. Following in vitro testing methodologies, a three-month mouse immunization protocol involving multiple booster immunizations found minimal increases in IgG levels in the serum and furthermore elucidated no specific immunogenic response. The initial biocompatibility evaluation of peptide-functionalized SCK nanoparticles described in this article, while limited in scope, is a critical first step toward the identification of potentially detrimental interactions between biological species and SCK nanoparticles. Furthermore, these in vitro assays and limited in vivo studies provide justification for additional animal studies, including biodistribution and liver function assays, which are crucial to efforts to develop in vivo therapeutic applications.

EXPERIMENTAL PROCEDURES

Materials. FMOC-protected amino acids and preloaded solid-phase Wang resins were purchased from NovaBiochem-CalBiochem Corp (San Diego, CA). Sodium dodecyl sulfate (SDS), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide (98%) (MTT), Tween20, mouse IgG (Fc, Sigma I-8765), and goat anti-mouse IgG alkaline phosphatase conjugate (Fc specific, Sigma A-1418) were purchased from Sigma (St. Louis, MO). Alkaline phosphate substrate solution was purchased from BioRad (Hercules, CA). Spectra/Por dialysis membranes (Spectrum Laboratories, Inc., Rancho Dominguez, CA), 96-well polystyrene plates (Falcon), and ELISA plates (Nunc-Immuno, Maxisorp) were purchased from Fisher Scientific Company (Pittsburgh, PA). QuantiTect SYBR Green RT-PCR Kit and Rneasy Kit were obtained from Qiagen (Valencia, CA). Primer identification, isolation, and probe development were nearly identical to methods described previously (*38, 39*).

Certain commercial materials and equipment are identified in this paper in order to specify adequately the experimental procedure. In no case does such identification imply recommendation by the National Institute of Standards and Technology nor does it imply that the material or equipment identified is necessarily the best available for this purpose.

The Animal Facility at the Washington University Department of Biology handled immunizations, sera collections, and organ histology. Animal studies were conducted under Protocol 20010343 approved by the Animal Studies Committee of Washington University.

Cell Lines. Mouse myeloma B cells (ATCC, Manassas, VA) CRL-1581.1 and CHO cells (ATCC) were obtained as gifts from Professor Jacob Schaefer (Washington University, St. Louis, MO). Mouse myeloma B cells were cultured in RPMI (Life Technologies, Rockville, MD) 1640 media using TCM serum replacement (10%, volume fraction) obtained from Celox Laboratories (St. Paul, MN). RAW 264.7 cells were purchased from ATCC. RAW 264.7 and CHO cells were maintained in RPMI supplemented with 10% (volume fraction) heat-inactivated fetal bovine serum (FBS, Life Technologies, Rockville, MD), in 5% CO_2:95% air (volume fractions) at 37 °C. To harvest, RAW 264.7 cells were washed with calcium- and magnesium-free phosphate-buffered saline and subsequently incubated with HBSS to promote release from the flask.

Determining Cell Viability via MTT Assay. Mouse myeloma B cells were counted and diluted into fresh media at concentrations of 50 000 cells/mL and an aliquot (100 μL) was seeded to each well in a 96-well plate. After deposition of the cell suspension, the plates were placed in an incubator (37 °C, 5% CO_2, volume fraction) and allowed to grow for 24 h. Fresh 96-well plates were loaded with sterile buffer (40 μL), and the first column of each row was loaded with polymer or SCK stock solutions of known concentration. The first columns in each plate were then diluted serially from columns 2 to 11. The last columns were held as controls with no polymer or SCK added. Fresh media (50 μL) was then added to every well in the plates. The original plates were removed from the incubator, and the premixed sample solutions were added to the corresponding wells in each plate. After 24 h incubation, the inoculated plates were removed from the incubator, and an aliquot of MTT (Sigma) (20 μL, 5.00 mg/mL) in PBS (0.05 mol/L phosphate, 0.05 mol/L sodium chloride, pH 7.4) was added to each well. The plates were returned to the incubator and allowed to equilibrate for 2 h. After 2 h, extraction buffer (80 μL, 20% (mass fraction) SDS (Sigma) in 50:50 DMF:H_2O, volume fraction, pH 4.7) was added to each well to extract the aqueous insoluble formazan product. The plates were then returned to the incubator for 18 h to allow for the extraction after which the absorbance of each solution was measured at 560 nm. Concentrations were determined by the weight of lyophilized polymer sample dissolved in PBS and then adjusted for the dilution of

the media. Results are an average of four values, and the standard deviation is reported for each concentration.

Apoptosis Assay. Apoptotic analysis of RAW 264.7 cells was assessed using the Guava Nexin Kit (Guava Technologies, Hayward, CA). RAW 264.7 cells were plated in 12-well plates at 50 000 to 100 000 cells per well and allowed to adhere for 24 h, after which the cells were inoculated with 100 μL aliquots of the respective samples. The initial quantity of SCK was suspended in 0.500 of PBS. The respective samples were subsequently added to RAW 264.7 cultures (100 μL). After 24 h, the media was removed from the cells, and the cultures were washed with PBS. To promote release from the plate, the cells were incubated with 1 mL of HBSS for 30 min. The cells were then gently removed from the plate, and the volume was adjusted to 300 μL. The cell suspension was incubated with 5 μL of Nexin 7-AAD and 5 μL of Annexin V−PE for 5 min in a light-protected environment and subsequently analyzed.

Flow Cytometry. Apoptotic analysis of RAW 264.7 cells incubated on the thin films or in the presence of the nanoparticles was assessed using the Guava Nexin Kit (Guava Technologies, Hayward, CA). RAW 264.7 cells were plated in 24-well plates (50 000 to 100 000) cells per well and allowed to adhere on tyrosine-derived polycarbonate thin films or tissue culture polystyrene for 24 h prior to analysis by flow cytommetry. Full experimental details were described previously (*38, 39*).

mRNA Extraction. Cells were plated in sterile 150 mm × 25 mm nonpyrogenic polystyrene dishes (Daigger, Vernon Hills, IL). SCK nanoparticles were added to plated cells 24 h following seeding. The mRNA extraction was carried out using the materials and protocol provided in the Rneasy Kit from Qiagen (Valencia, CA). The mRNA extraction protocol was followed according to the manufacturer's specification, except a 21-gauge needle was used to homogenize the sample. The RNA was treated with RNA Secure immediately following elution and stored at −20 °C. Standard spectrophotometric measurements were taken, and a 2% (mass fraction) agarose gel stained with 10 μg/mL ethidium bromide (Sigma, St. Louis, MO) was used to image the RNA. Densitometry was performed using the Versa Doc imaging system (Bio-Rad, Hercules, CA).

Standards. The plasmids containing the cDNA inserts for TNF-α, IL-1β, and the18 S ribosomal subunit were purchased from ATCC. The plasmids were grown in *luria-bertani* (LB) medium (ATCC, medium 1065) with 100 μg/mL of ampicillin for selection purposes. Plasmid DNA was isolated using the Plasmid Giga Kit (Qiagen, Valencia, CA) following the manufacturer's protocol. Spectrophotometric measurements were made at 260 nm, and a 1% (mass fraction) agarose gel stained with 10 μg/mL ethidium bromide (Sigma, St. Louis, MO) was used to image the DNA. Densitometry was performed using the Versa Doc imaging system (Bio-Rad, Hercules, CA).

Primer Design. Primers were designed using Primerfinder (Whitehead Institute for Biomedical Research) for the RT-PCR experiments. The primers generated were used in both PCR and RT-PCR experiments. They are as follows:

18S: 5′ agcgaccaaaggaaccataa 3′ and 3′ ctcctcctcctcctctctcg 5′

TNF-α: 5′ tttcctcccaataccccttc 3′ and 3′ agtgcaaaggctccaaagaa 5′

IL-1β: 5' tgtgaaatgccacctttga 3' and 3' gtagctgccacagcttctcc 5'

The amplicons generated from these primers are 204 base pairs, 202 base pairs, and 205 base pairs, respectively. DNA sequencing was performed using the Big Dye Terminator Kit (ABI, Foster City, CA) on a 310 DNA Genetic Analyzer (ABI, Foster City, CA).

RT-PCR. RT-PCR was carried out using the Quanti-Tect SYBR Green RT-PCR Kit and protocol (Qiagen, Valencia, CA). All RT-PCR experiments were performed using the iCycler (Bio-Rad, Hercules, CA). The protocol utilizes the following thermal parameters: Reverse Transcription: 30 min at 50 °C. Activation step: 15 min at 95 °C. Three-step cycling: denaturation for 30 s at 95 °C, annealing for 2 min at 57 °C, extension for 2 min at 72 °C for 45 cycles. A melt curve was subsequently performed to analyze the products generated, which began at 50 °C and increased to 95 °C in 1 °C increments.

Immunization of Mice. For each sample, five mice (female, balb c, 7 weeks old) were inoculated with 100 μL of polymer or SCK solution (1 mg/mL in PBS) at (0, 4, and 8) weeks. The mice were bled for preimmunoserum screening prior to the primary injection. Blood samples were then collected 14 d after (4 and 8)-week booster immunizations, respectively. Serum was obtained after clotting at 4 °C, for 24 h, and centrifugation. Serum samples were stored at −20 °C in small aliquots for later use.

Determining Antibody Titer by ELISA Assay. Samples for ELISA for the five mice were first prepared by dilution in five 96-well plates. PBS buffer (100 μL) was added to each well in the plates. The serum vials were thawed, and each serum sample (5 μL) was diluted 1:100 in PBS and was transferred, in quadruplicate, in aliquots (100 μL) to the first four wells in the top row of each corresponding plate. The serum obtained following the first booster immunization was added to the next four wells, and the serum obtained following the second booster immunization was added to the final four wells, columns 9 to 12. The serum was then serially diluted 2-fold in rows 2−7 in each plate. Following dilution, 100 μL from each well was transferred to a corresponding ELISA (Nunc-Immuno, Maxisorp) plate and incubated overnight at 4 °C. The wells were washed three times with PBS buffer (300 μL) containing 0.05% (mass fraction) Tween 20 (Sigma), and the remaining binding sites on the plates were blocked with sodium caseinate (100 μL, 2.5%, mass fraction, in PBS) followed by overnight incubation at 4 °C. The wells were again washed three times, and a 1:40 000 dilution of goat anti-mouse IgG alkaline phosphatase conjugate (100 μL, Sigma) was added to each well and allowed to incubate for 1 h at room temperature before being washed five times. Alkaline phosphatase substrate solution (100 μL, BioRad) was added to each well. Color development was allowed to take place for 30 min and then was quenched with 4 mol/L H_2SO_4 (50 μL per well). Absorption measurements were made at 405 nm. To determine the absolute antibody concentrations, mouse IgG standards were run in parallel with each ELISA plate. Serial dilutions of mouse IgG (from 5.00 to 0.08 μg/mL) were used to generate the linear calibration plot of absorbance vs concentration. The value corresponding to 0 μg/mL was the background reading and was subtracted from all samples.

RESULTS AND DISCUSSION

The assessment of material biocompatibility is a complicated process, which includes both in vitro and in vivo measurement methods, each of which depend on the physical and chemical nature of the material and the nature of the biological interaction. Surface characteristics such as hydrophobicity, morphology, surface charge, and chemical functionality are all known to play key roles

Table 1. PTD-Derivatized SCK Characterization Data

no.	sample composition	no. of peptides nominal	no. of peptides UV−vis	no. of peptides phenylglyoxal	zeta (mV)	DLS D_n (nm)
5	micelle	0	0	0	−27 ± 0.7	38 ± 3
6	SCK	0	0	0	−20 ± 0.5	37 ± 2
7	0.5% PTD SCK	52 ± 2	38	41	−28 ± 0.9	35 ± 3
8	1.0% PTD SCK	104 ± 4	87	83	−23 ± 0.7	36 ± 3
9	2.0% PTD SCK	210 ± 10	~500	202	−22 ± 0.5	32 ± 4

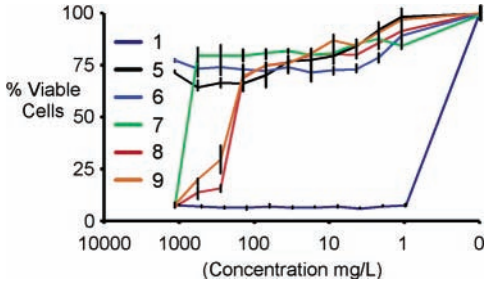

Figure 1. The conjugation of the PTD sequence to the SCKs has dramatic effects on the resulting cell viability. The 2.0% PTD-functionalized SCK **9** is toxic to the cells between 7 mol/L to 13 mol/L in PTD. The 0.5% and 1.0% PTD-functionalized SCKs (**7** and **8**) are toxic between 14 mol/L to 28 and 7 mol/L to 15 mol/L in PTD, respectively. The parent micelles and SCKs (**5** and **6**) did not affect the viability of the cells at any measured concentration. Error bars are representative of one standard deviation from the mean of quadruplicate samples harvested from four separate wells of mouse myeloma B cells and are the estimates of the standard uncertainties.

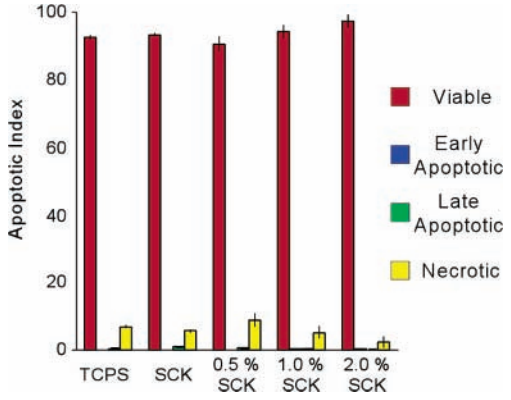

Figure 2. Four distinct populations of cells can be identified with flow cytometry. Viable cells: Annexin V (−) and 7-AAD (−); early apoptotic cells: Annexin V (+) and 7-AAD (−); late stage apoptotic: Annexin V (+) and 7-AAD (+); necrotic: Annexin V (−) and 7-AAD (+). Error bars are representative of one standard deviation from the mean of triplicate samples, each harvested from three separate populations of RAW 264.7 cells, and are the estimates of the standard uncertainties.

in governing cell adhesion and proliferation (*40*). Several physicochemical parameters for the PTD-derivatized SCK nanoparticles whose syntheses and characterization are described in the previous article of this issue are outlined in Table 1. However, a clear framework outlining the critical physiochemical and surface-mediated interactions within which to facilitate the development of materials minimally detrimental to cells does not exist. For applications concerning the delivery of macromolecules into cells, the enhanced efficiency of conjugate transduction must be weighed against any detrimental biological interactions including effects on both cell viability and immune response. The cell viabilities in the presence of the peptide-derivatized polymeric constructs were evaluated by MTT assay (*30*), which monitors enzymatic activity of a cell organelle (in this case mitochondria), and flow cytometry. Previously, the protein transduction sequence has been used at concentrations of up to 100 μmol/L without affecting the viability of certain cell lines (*41*).

As illustrated by the data of Figure 1, the PTD sequence, with four additional glycine residues, was found to decrease the enzymatic reduction of MTT in the mitochondria of mouse myeloma B cells at approximately 110 μmol/L concentrations. In contrast, the viabilities of the cells upon exposure to buffered solutions of micelles or SCKs remain (70 to 90) % at concentrations above 100 mg/L. The small drop in viability is due primarily to the dilution of the media as shown by control experiments in which buffer and no buffer were added to different cell populations. Exposure of the cells to the parent PAA_{56}-*b*-PMA_{185} micelles, **5**, and the corresponding unfunctionalized SCK, **6**, did not affect cell viability up to 1125 mg/L concentrations. However, the derivatization of the nanoparticle with increasing numbers of the PTD sequence has a significant effect on the viability of the cell populations as measured by the enzymatic function. The 2.0% PTD-functionalized SCK **9** is toxic to the cells between (140 and 280) mg/L (7 μmol/L to 13 μmol/L in PTD). The 0.5% and 1.0% PTD-functionalized SCKs (**7** and **8**) are toxic between (560 and 1125) mg/L (14 μmol/L to 28 μmol/L and 7 μmol/L to 15 μmol/L in PTD, respectively). The mechanism of toxicity has not been determined.

In addition to the MTT enzymatic assay, the peptide-derivatized nanoparticles have been evaluated by a fluorescent flow cytometry experiment to determine the effects of incubation with SCKs upon the induction of apoptosis. Apoptosis is characterized by numerous morphological changes, the first of which involves the translocation of phosphatidylserine (PS) from the inner to the outer surface of the cellular plasma membrane. Once exposed to the extracellular environment, PS sites are accessible to Annexin V, a phospholipid binding protein with a high affinity for PS. For measurement purposes, Annexin V is conjugated to FITC and used for the identification of cells in the early stages of apoptosis via flow cytometry. Because PS binding sites are also accessible when the cells are in a necrotic state, Annexin V is not an absolute marker of apoptosis. Therefore, it is often used in conjunction with 7-aminoactinomysin, (7-AAD) which binds to exposed nucleic acids, when the cell membrane integrity is compromised. Cells that are negative (unstained) for both Annexin V and 7-AAD have no indications of apoptosis: PS translocation has not occurred, and the plasma membrane remains intact. Cells that are Annexin V (+) and 7-AAD (−), however, are in early apoptosis, as PS binding sites are exposed, but the plasma membrane is still intact. Cells that are (+) for both Annexin V and 7-AAD are either in the late apoptosis (irreversible) stage or are not viable. The flow cytometry data shown in Figure 2 indicate that the SCKs do not induce apoptosis at the concentrations tested. The total inoculated concentration was 0.5 mg/mL (500 mg/L) for each SCK sample. In addition, a visual assessment of the effects of exposure to PTD-derivatized SCKs at the 5 day time point indicated that the nanoparticles did not affect the continued growth of the cells nor did they

induce significant morphological changes (data not shown). These results are comparable to the MTT assay results. Although the MTT assay depicts a shutdown in mitochondrial function at certain concentrations, exposure of each of the samples to the cells at concentrations of 500 mg/L did not lead to cellular apoptosis.

Immunogenicity Results. The extent of PTD functionality is of significant importance as it may affect the immune response. The nature of the response has significant clinical implications, as severe inflammatory responses may prevent in vivo applications. Recent literature has reported that the addition of HIV Tat PTD enhances minigene epitope presentation in tissue culture, but the attachment of PTD to full-length proteins does not enhance the immune response of the construct (*42*). The reported data were for a 1:1 stoichiometry of PTD: protein, and it is unclear whether the presentation of multiple copies of the sequence on the surface of an SCK would have a synergistic or negligible effect on the cellular immune response. The initiation and propagation of an immune response is ultimately regulated by cytokines. Cytokines are the primary mediators of a host immune response and are able to both induce apoptosis and modulate survival through the activation of genes in response to bacterial toxins, inflammatory products, and other invasive stimuli (*43*). Two of the most important cytokines in the acute inflammatory response are tumor necrosis factor alpha (TNF-α) and interleukin-1 beta (IL1-*β*) (*44*). TNF-α is synthesized and secreted by macrophages. TNF-α is part of a complex network of cytokines and is capable of initiating cascades, which control the synthesis and expression of signaling molecules, hormones, and their receptors (*45*−*47*). Knowledge of the cellular cytokine profile is key to identifying the processes involved in the immune response (*48*) and crucial to the further elucidation on the physicochemical properties of the bioconjugate that are inducing the response. Another prominent cytokine involved in the inflammatory responses is interleukin-1 (IL-1). Although IL-1 protects the organism by enhancing the response to pathogens and initiating healing process, its overproduction can induce numerous pathological consequences including septic shock and leukemia (*21*). The measurement of mRNA levels has been used widely to measure cytokine proliferation, which is responsible for the initiation, mediation, and propagation of cellular inflammatory responses (*32*). The genetic expression profiles of IL-1*β* and TNF-α have been measured by real-time polymerase chain reaction (RT-PCR) (*49*). In this study, the mRNA profiles of TNF-α and IL-1*β* in response to PTD, SCKs, and SCKs derivatized with increasing amounts of PTD sequences were investigated using RT-PCR. In the previous manuscript of this issue, PTD was conjugated in (0.005, 0.01, and 0.02) molar ratios, relative to the acrylic acid residues in the shell, to the SCK nanoparticles resulting in SCK populations nominally possessing 52, 104, and 210 (41, 83, and 202 as measured by phenylglyoxal) PTD peptides per particle, respectively. RAW 264.7 cells were used because they retain the characteristics of primary cultured macrophages in vitro, including the ability to release cytokines (*50*−*53*). Cells were exposed to the respective SCK nanoparticle samples by adding the conjugates to the murine macrophages 24 h following seeding. After a 24 h incubation period, the mRNA was extracted from the cell populations. Using a reverse transcriptase enzyme, mRNA is converted to the cDNA template necessary for amplification. Once cDNA is generated, gene specific primers, a DNA polymerase, and a fluorescent moiety are utilized to amplify and label

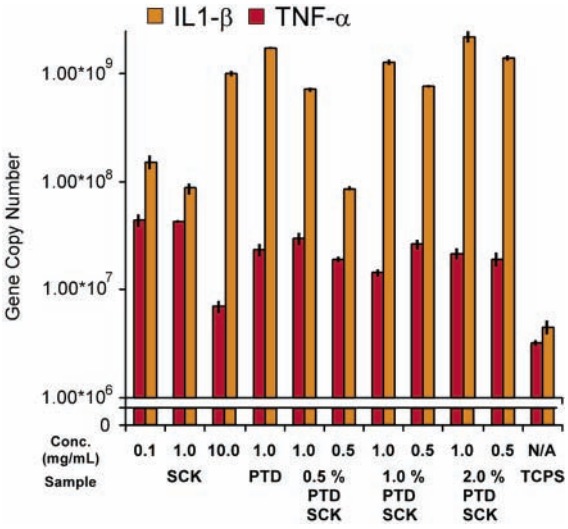

Figure 3. Genetic cellular inflammatory responses exhibited 24 h after incubation with different concentrations of peptide-functionalized SCK nanoparticles were quantified by RT-PCR. The data depict minimal increases in the production of TNF− and an elevation in the levels of IL-1 relative to tissue culture polystyrene. Error bars are representative of one standard deviation from the mean of triplicate samples, each harvested from three separate populations of RAW 264.7 cells, and are the estimates of the standard uncertainties.

the amplicon generated. The gene product accumulation was then measured during the exponential phase of the amplification reaction (*36*). The copy number from each of the samples was obtained by extrapolating to a standard gene curve of known concentration and copy number to yield quantitative data. The assay also includes the analysis of mRNA that does not change in relative abundance (18S) during the course of treatment to serve as an internal control (*54*). The genetic profiles of the inflammatory response to SCKs (**1**−**3**), PTD (**4**), PTD-functionalized SCK nanoparticles (**5**−**10**), and tissue culture polystyrene (TCPS, **11**) are shown in Figure 3.

TNF-α mRNA synthesis was up-regulated 2-fold to 14-fold (depending on concentration) in response to exposure of the parent SCK nanoparticle, **6**, over TCPS. It is interesting to note that the highest concentration, 10.0 mg/L, of the parent SCK **6** actually caused less of an increase, 2.2-fold, than lower concentrations, 0.1 and 1.0 mg/L, of SCK **6**, 13.5-fold and 13.2-fold, respectively. When looking at the effects of parent SCK concentration on TNF-α production, the difference between (0.1 and 1.0) mg/mL are statistically insignificant, while the 10.0 mg/mL sample measures 6.1-fold less than at the 1.0 mg/mL level. Interestingly, the down-regulation of TNF-α has been demonstrated previously in liposome vectors formulated with cationic lipids (*55*). The measured TNF-α levels for the PTD-functionalized SCKs are less than the levels of the parent SCK in all cases (1.5-fold to 3.0-fold) and show no concentration or functionality dependence. The levels of TNF-α measured in response to the peptide-functionalized nanoparticles, regardless of the extent of derivatization and concentration tested, are statistically insignificant when compared to the levels induced by the PTD domain itself. The copy numbers, fold increases, and the p values ($p < 0.05$ significant at 95% confidence, derived from the students t-test) indicating statistical significance are listed in Table 2.

The measured increases of IL1-*β* production in response to PTD-, SCK-, and PTD-functionalized SCKs are much more pronounced than the copy number levels of TNF-α as compared to TCPS. The measured levels range

from 18.8-fold to 483.5-fold increases over TCPS and 1-fold to 25.4-fold increase over SCKs of similar concentration and show statistical dependence with regard to both concentration and PTD functionalization. The differences in TNF-α and IL1-β expression measured in this series reflect different pathways of signal transduction (*56*) with regard to both the time frame and the severity of the response (*31, 38, 57, 58*) to the respective inflammatory stimuli.

Following the in vitro measurements on cell viability and inflammatory response, the SCKs and PTD-derivatized SCKs were then tested in vivo to gauge their immunogenic response in balb c mice. Enzyme-linked immunosorbent assays (ELISA) were used to quantify the increases in IgG production in response to immunization with the test compounds. Efforts to isolate specific responses by plating the SCKs on the ELISA plate prior to serum incubation were not successful due to an insignificant specific antibody response. This result can be attributed to two possible factors: (1) the nanoparticles could induce a nonspecific immune response, and (2) the sera used for the ELISA measurements were collected 14 d following the respective immunization, a sufficiently long time that any acute inflammatory response may have passed. We therefore decided to look at the increases in IgG concentration on an individual mouse basis to look for relatively large increases. Figure 4 shows the three antibody titers determined for each mouse in the study. The PTD peptide by itself is not immunogenic after two booster immunizations, and the parent SCKs possessing poly(acrylic acid-*co*-acrylamide) shells display negligible values of titer increases over the control PBS injections. Those SCKs possessing various amounts of PTD functionality, 0.5%, 1.0%, and 2.0% (**7**, **8**, and **9**), qualitatively showed a general trend of increasing antibody titer in the serum with increasing degrees of nanoparticle functionalization. The relative increases in antibody titer relative to the initial value are listed in Table 2. Qualitatively, the only significant immunogenic response depicted arose from the 2.0% functionalized SCK, **9**. The 0.5%, 1.0%, and 2.0% SCKs (**7**, **8**, and **9**) exhibited increases of 100% or more in 20% (1 of 5), 60% (3 of 5), and 100% (5 of 5) of the mice, respectively, following two booster injections.

While limited in scope, the immunogenicity results for the SCKs functionalized to a lesser degree are consistent

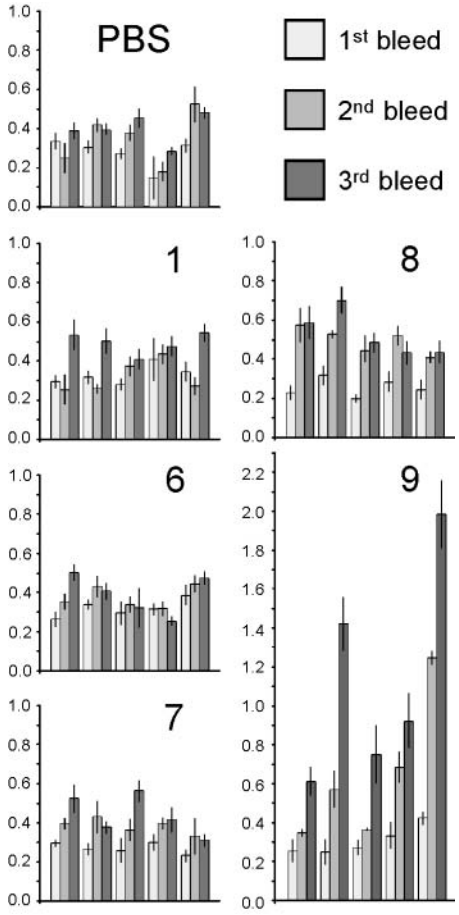

Figure 4. Each group of three bars within a data set corresponds to a titer measurement from an individual mouse. The red bars correspond to the prebleed, the orange bars represent the bleed two weeks after the 1st booster immunization, and the yellow bars represent the bleed two weeks following the 2nd booster immunization. Detrimental immunogenic effects, relative to controls, are negligible in all samples except for the 2.0% (**9**) sample, which suggests that the quantity of PTD and the manner in which it is presented on the surface have a synergistic effect that is able to produce an immune response significantly greater that the response elicited by the peptide itself. Error bars are representative of one standard deviation from the mean of triplicate samples harvested from two separate serum vials and are the estimates of the standard uncertainties.

with the literature (*42*), but when large numbers of PTD are presented, the particles do elicit an increase in IgG concentration within the serum. While no specific responses could be detected for the any of the SCK nanoparticles, it is perhaps more important that no deaths resulted from the mice (>50) being subjected to the immunization protocol (three × 100 μg) and no gross morphological changes were observed in postmortem organ histology examinations.

CONCLUSIONS

SCK nanoparticles derivatized with various stoichiometric derivatizations with PTD have been evaluated in vitro and in vivo for biocompatibility. Although these data are somewhat limited in scope, the initial evaluation and early identification of detrimental interactions between biological species and SCK nanoparticles are crucial to further efforts to develop in vivo applications. Apoptosis assays measured by flow cytometry have complemented enzymatic (MTT) toxicity results demonstrating a lack of detrimental effects on cell viability below 500 mg/L for all the samples. Although higher levels of peptide functionalization resulted in decreased metabolic function, loss of cell viability was observed at a sufficiently high concentration, suggesting the use of even 2% PTD-functionalized SCKs would not be prohibited in vivo. In addition, RT-PCR data have provided quantitative information regarding the lack of immunogenicity elicited by SCKs and peptide-derivatized SCK nanoparticles. The inflammatory response to the peptide-functionalized SCK nanoparticles as measured by RT-PCR show increases in the levels of both TNF-α and IL1-β relative to TCPS. Although these levels are statistically significant and show large increases of IL1-β with increasing peptide functionalization, the levels did not preclude the preliminary testing of SCKs in vivo. An in vivo mouse immunization model found measured increases in IgG concentration were minimal with no specific interactions being identified, and more importantly, none of the mice (>50) subjected to the three 100 μg immunization protocol died. Additionally, no gross morphological changes were observed in postmortem organ histology examinations. While these in vitro assessments and preliminary in vivo tests show promising results, additional in vivo animal studies, which are currently in progress including biodistribution and nanoparticle clearance, are needed to compliment these initial findings and to extend the potential therapeutic applications of functionalized SCKs. However, up-regulation of IL1-β and larger than expected IgG increases for the 2.0% PTD-functionalized SCKs suggest that nanoparticles functionalized in polyvalent strategies may be interesting scaffolds for the attachment of known antigens for use in vaccination applications.

ACKNOWLEDGMENT

The authors gratefully acknowledge the National Cancer Institute (N01-CO-27103), and a Postdoctoral Fellowship (M.L.B.) from the National Research Council for supporting this research. Immunization, sera collections, and suggestions from Dan Piatchek and Jack Diani of the Washington University Department of Biology are gratefully acknowledged.

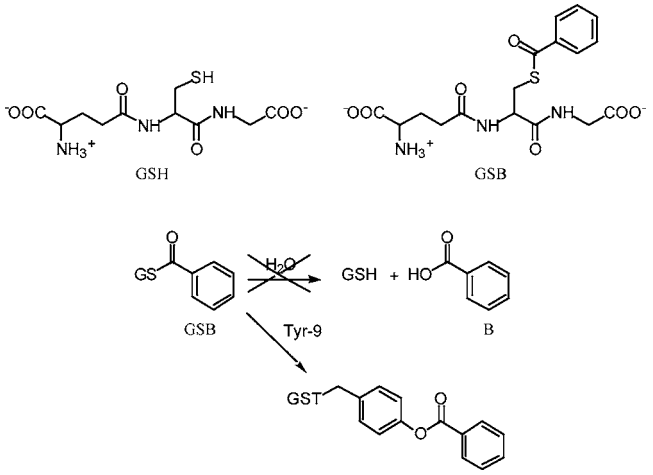
Combinatorial Chemical Reengineering of the Alpha Class Glutathione Transferases



Johan Viljanen, Lotta Tegler, and Kerstin S. Broo*

IFM, Department of Organic Chemistry, Linköping University,
S-581 83 Linköping, Sweden. Received October 21, 2003; Revised Manuscript Received March 16, 2004

Previously, we discovered that human glutathione transferases (hGSTs) from the alpha class can be rapidly and quantitatively modified on a single tyrosine residue (Y9) using thioesters of glutathione (GS-thioesters) as acylating reagents. The current work was aimed at exploring the potential of this site-directed acylation using a combinatorial approach, and for this purpose a panel of 17 GS-thioesters were synthesized in parallel and used in screening experiments with the isoforms hGSTs A1-1, A2-2, A3-3, and A4-4. Through analytical HPLC and MALDI-MS experiments, we found that between 70 and 80% of the reagents are accepted and this is thus a very versatile reaction. The range of ligands that can be used to covalently reprogram these proteins is now expanded to include functionalities such as fluorescent groups, a photochemical probe, and an aldehyde as a handle for further chemical derivatization. This site-specific modification reaction thus allows us to create novel functional proteins with a great variety of artificial chemical groups in order to, for example, specifically tag GSTs in biological samples or create novel enzymatic function using appropriate GS-thioesters.

Creating new function in an existing protein scaffold is a challenging task, even though progress has been made lately through rational design (*1*−*3*) and combinatorial approaches (*4*, *5*). A less explored route to novel functional proteins is that of chemical modification of a protein scaffold to introduce an artificial group (*6*−*9*). Picking a versatile scaffold is of course crucial in any protein reengineering project, and we have focused on the glutathione transferases (GSTs, EC 2.5.1.18),[1,2] a large family of phase II detoxication enzymes that catalyze the nucleophilic addition of glutathione (GSH, Scheme 1) to a broad range of hydrophobic electrophilic molcules (*10*−*13*). The proteins exist as homo- or heterodimers (*12*, *14*), and the mode of binding of GSH in the N-terminal domain is essentially conserved throughout the classes (*10*, *15*). The differences between the isoenzymes are generally located in the promiscuous hydrophobic electrophile binding sites (H-sites) to provide a broad substrate specificity (*16*). The catalytic function is highly dependent on a conserved tyrosine, serine or cysteine residue in the glutathione-binding site (G-site) that aids in the ionization of GSH to form the more reactive thiolate ion (*10*). The modular features of these proteins with a stringent G-site and an adjacent, promiscuous H-site, in combination with their stability and ease of purification (*17*) and the vast knowledge of structure−activity relationships (*18*), are all factors that point to the GSTs as ideal candidates in protein engineering experiments (*19*−*26*) with the goal of obtaining novel function.

Scheme 1

Previously, we found that a thioester of glutathione (GS-thioester) termed GSB (Scheme 1) was able to rapidly modify Y9 (Figure 1) of the human GSTs from the alpha class (*27*). The reaction is highly specific and, for example, targets one out of 51 nucleophiles in hGST A1-1. Out of the three GS-thioesters we investigated, two were able to acylate the alpha class GSTs (*27*). The covalent modification reaction presents us with the

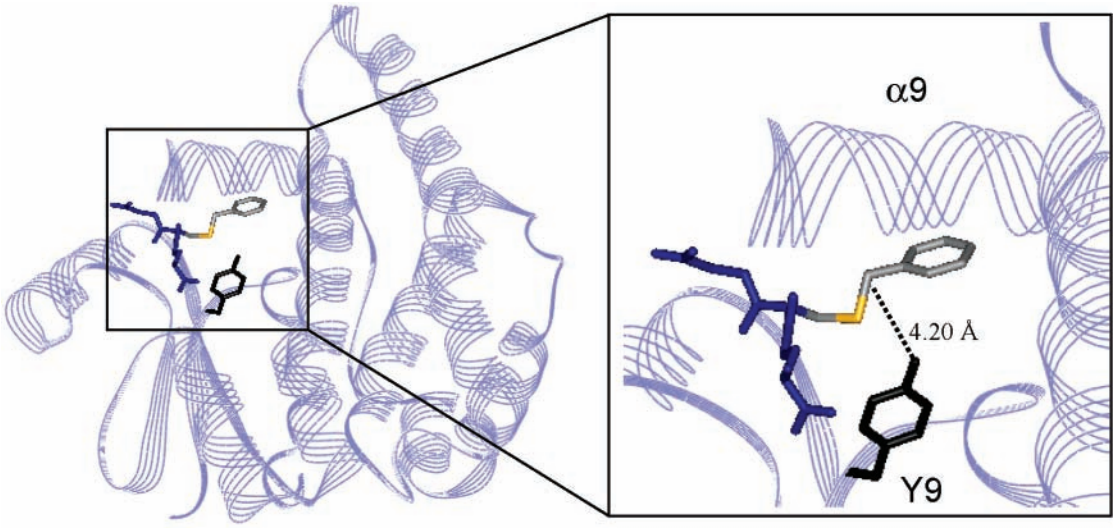

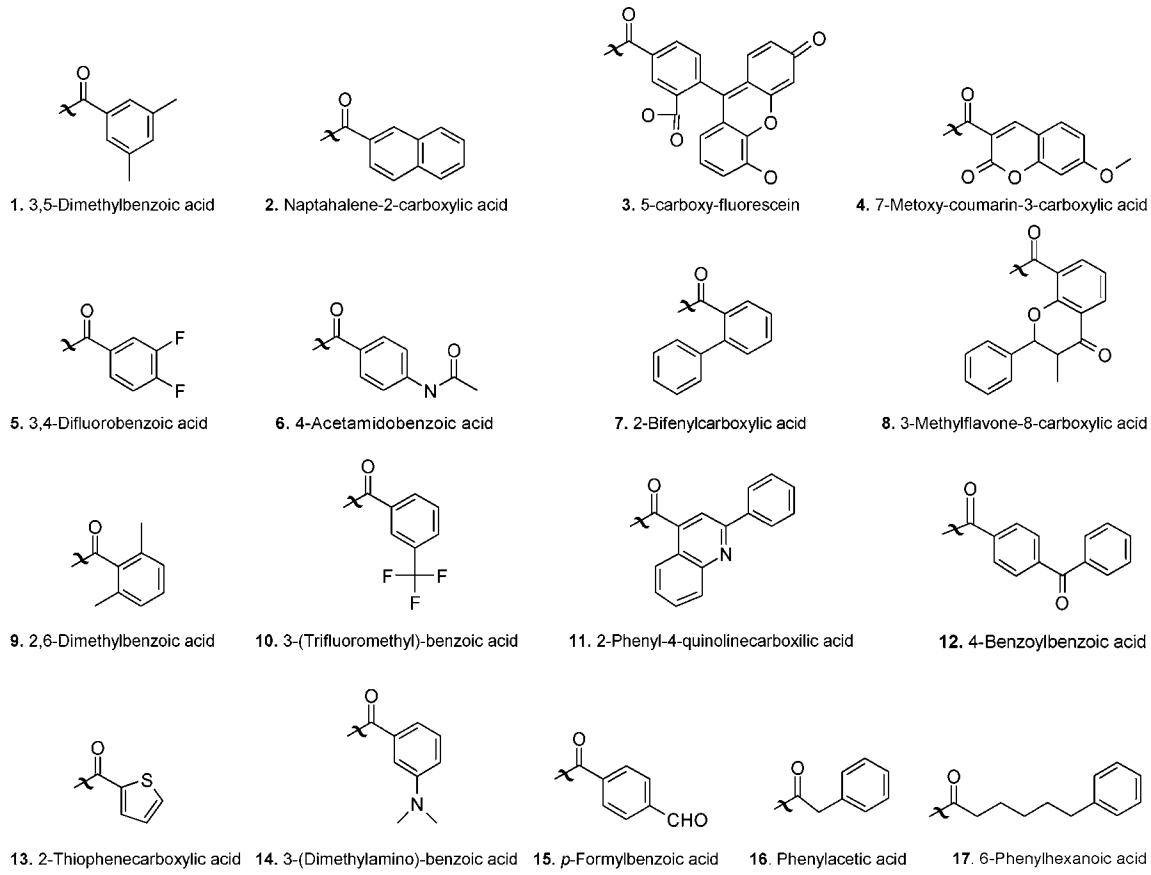

Figure 1. A close-up of the crystal structure (1GUH) of hGST A1-1 in a complex with *S*-benzyl-glutathione (*15*). The distance between the hydroxyl oxygen of Y9 and the ligand benzyl CH_2 is 4.2 Å. The distinguishing feature of the alpha class GSTs helix 9 (α9) is also indicated in the figure. The protein is dimeric but shown here as a monomer for reasons of clarity of presentation.

Chart 1

opportunity to create novel functional proteins through the design and synthesis of GS-thioesters with appropriate chemical groups. Thioesters could be synthesized to introduce, for example, a fluorescent group that could bind in the nearby H-site to form the basis for a biosensor system, or an artificial catalytic group that could result in a new type of enzymatic activity (*28*, *29*). It is thus important to understand the potential and limitations of the reaction. To do so, we synthesized 17 different GS-thioesters (Chart 1) in parallel and screened this collection against hGSTs A1-1, A2-2, A3-3, and A4-4. The combined screening of both reagents and proteins was done in order to investigate if any of the alpha class isoenzymes is better suited as a scaffold for protein reengineering experiments and also to try to obtain general information about reagent requirements. The GS-thioesters therefore span a wide range of reactivities, hydrophobicities, shapes, and sizes. Some of the reagents have functionalities that can be used in downstream experiments, for example fluorescent groups (GS-3, GS-4) and a handle for further chemical derivatization (GS-15).

MATERIALS AND METHODS

Protected amino acids and acids (DiversiChem kit) were purchased from Novabiochem (Läufelfingen, Switzerland). Preactivated acids (5-carboxyfluorescein succinimidyl ester, *p*-formylbenzoic acid succinimidyl ester, 4-benzoylbenzoic acid succinimidyl ester) were purchased from Molcular Probes. All chemicals and reagents used were of the highest purity available. The glutathione transferases were kind gifts from the group of Professor Bengt Mannervik at the Department of Biochemistry, Uppsala University, Sweden. All solid-phase syntheses were carried out in a VacMaster (International Sorbent Technology). The HPLC experiments were carried out using a Kromasil C_8-column (4.6 mm × 250 mm, Supelco inc.) attached to a Varian system with a ProStar 230 Delivery System, a ProStar 330 Photodiode Array Detector, controlled by the Varian LC Software. All mass spectra were recorded with a MALDI/TOF-MS (Voyager System 4212, Applied Biosystems) with detection in the positive mode. The UV measurements were performed using a Varian Cay 100 Scan UV−visible spectrophotometer and analyzed with the CaryWin UV software.

Synthesis of Fully Protected, Polymer-Bound, γ-Glu-Cys-Gly. The tripeptide γ-Glu-Cys-Gly (0.71 mmol scale) was synthesized using standard Fmoc protocols starting from Fmoc-Gly-Wang resin. The thiol was orthogonally protected with the Mmt group to enable selective deprotection with 1% TFA in DCM. Each deprotection and coupling step was monitored by a Kaiser test (*30*), to estimate the amount of free amino groups. After completed synthesis, the polymer was washed thoroughly with DMF and DCM and dried under vacuum.

Synthesis of Thioester Reagents. The GS-thioesters were synthesized in parallel using 0.03 mmol polymer for each ligand. In each case, the Mmt-group was removed with DCM:TFA:TIS (97:1:2). After deprotection of the thiol the polymer was washed with DMF, and the subsequent coupling of the acid was performed in DMF using acid: HOBt:DIPCDI:DIPEA (2:3:3:6) with addition of a catalytic amount of 4-pyrrolidinopyridine. The couplings were allowed to proceed overnight following an additional boosting of the same amount of coupling-cocktail after 1 h. Preactivated acids (5-carboxyfluorescein succinimidyl ester, *p*-formylbenzoic acid succinimidyl ester, 4-benzoylbenzoic acid succinimidyl ester) were coupled using a mixture of ester:DIPEA (2:6) in DMF during the first hour, after which DIPCIDI:HOBt:DIPEA (2:3:3:6) was added and the coupling was allowed to proceed overnight. Global deprotection and simultaneous cleavage from the solid support was achieved with TFA: H_2O (97.5:2.5). Following precipitation with ice-cold diethyl ether and lyophilization, each GS-thioester was dissolved in 5 mL of Milli-Q water as a stock solution used for all further experiments. The concentrations of the stock solutions were calculated from the weights of the products assuming 100% purity. The yields of the syntheses, according to weighing, range from 11% to 48%, with most of them around 30%. The peptides were analyzed with reversed-phase HPLC using a C8 column and a shallow H_2O:ACN (both 0.1% TFA) gradient. The identities of the products were confirmed with MALDI-TOF MS using an α-cyano-4-hydroxycinnamic acid matrix with detection in the positive mode. The measured masses of the GS-thioesters were in good agreement with the calculated masses.

Amount of GSH in the GS-Thioester Stock Solutions. The Ellmans test (*31*) was carried out to analyze the amount of unreacted GSH in the GS-thioester solutions. The samples were prepared by adding 10 μL of GS-thioester stock solution to 90 μL of 10 mM DTNB in 0.1 M NaPi, pH 8. Thiol groups react with DTNB and produces equivalent amounts of TNB. The amount of produced TNB (ϵ_{412} = 13 600 M^{-1} cm^{-1}) was measured using a Fluostar Galaxy plate-reader (BMG Lab technologies) equipped with a 420 nm filter. The amount of free GSH varied from 0.5 to 3%. These calculations did not take into account the GS-thioesters intrinsic absorbances at this wavelength and correspond therefore to an upper limit.

Glutathione Transferases. The activities of the GSTs were checked with a standard assay (*32*) containing 1 mM each of 1-chloro-2,4-dinitrobenzene and GSH (pH 6.5 in 0.1 M NaP_i at 30 °C). Protein concentrations were estimated using previously published extinction coefficients for hGSTs A1-1 (*33*), A2-2 (*34*), A3-3 (*35*), A4-4 (*23*). The proteins were stored in NaP_i-buffered solutions containing NaCl and 10% glycerol at −80 °C or −20 °C until used in the experiments.

Modification Reactions. A typical modification reaction was performed with 100 μM GS-thioester and 50 μM GST in buffer (0.1 M NaP_i, pH 7). The reaction was allowed to proceed at 25 °C for 5 h. To control the temperature, the incubation was performed in an Eppendorf Master cycler gradient.

Proteolytic Digestion of Modified GSTs. The digestions were performed in the following way: 5 μL of modification mixture was diluted with 13 μL of buffer (50 mM NH_4OAc, pH 4), 2 μL of *Staphylococcus areus* V-8 Protease from Pierce Biotechnology, Inc., Rockford, IL, (stock solution 1 μg/μL) was added, and the sample was incubated at 25 °C for up to 2 h. The sample was then acidified with 20 μL of 0.1% TFA and desalted with C_{18} ZipTips (Millipore Corporation, Bedford, MA). In the case of tryptic digestion, 10 μL of modification mixture was diluted with 10 μL of buffer (0.2 M $NaHCO_3$, pH 8), and the reaction was initiated by adding 1 μL of trypsin (stock solution 0.2 μg/μL in 0.1 mM HCl) and allowed to proceed at 25 °C for up to 2 h. The sample was then analyzed directly or acidified and desalted (C_{18} ZipTips) prior to MALDI-MS analysis.

HPLC Analysis of the Modification Reactions of hGST A1-1. Each GS-thioester (100 μM) was incubated with hGST A1-1 (50 μM) at 25 °C (in 100 mM NaP_i, pH 7) in a total volume of 36 μL. After 5 h, the reaction was quenched by adding 4 μL of a mixture of TFA (final concentration 0.4% v:v) and internal standard, 2-chloro-4-nitrophenol (final concentration 200 μM). As a reference, each GS-thioester was also incubated in buffer without protein and quenched after 5 h. All samples were then analyzed with reversed-phase HPLC using a C8 column and a shallow H_2O:ACN (both 0.1% TFA) gradient. The injection volumes were 25 μL. The quenched samples from the HPLC experiments were also digested with trypsin as described before except that 2 μL of each sample mixture was diluted with 18 μL of buffer before adding the enzyme. After 2 h of incubation, the samples were analyzed with MALDI-MS. To each sample was added 0.1 M citrate to the matrix on the MALDI plate to enable analysis without desalting. In some cases, the peak of the modified protein fragment coincided with other peptides, and we then used *S. areus* V-8 protease to digest the protein mixture.

Acyl Group Exchange Experiment. hGST A1-1 (5 μM) was reacted overnight at 25 °C with 100 μM GSB. The reaction mixture was desalted with YM-30 filters (Millipore) and washed with 0.1 mM NaP_i pH 7. The sample was then diluted back to the original volume and

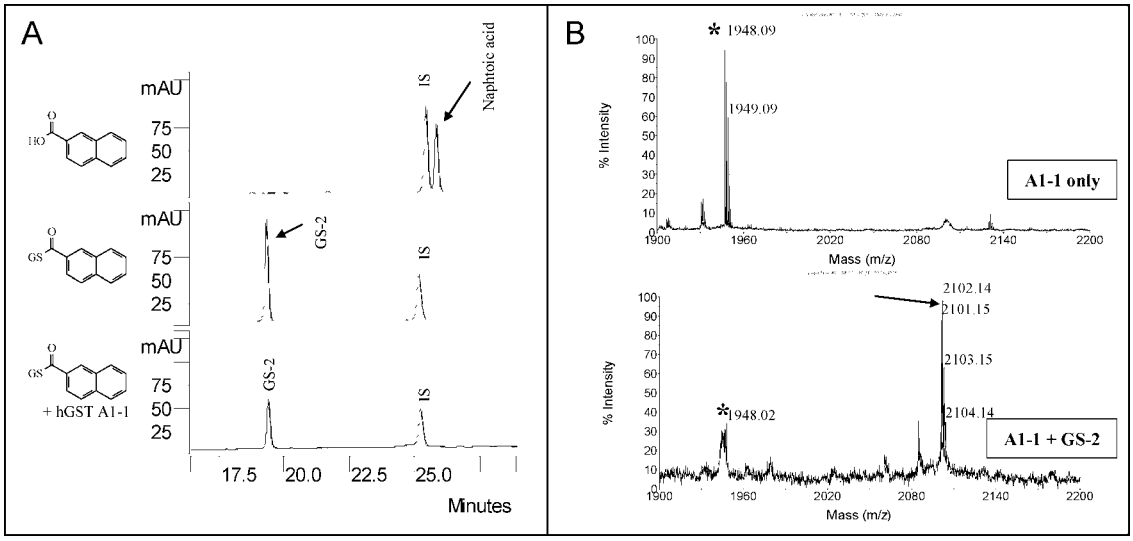

Figure 2. The reaction between GS-2 (100 μM) and hGST A1-1 (50 μM) at pH 7 monitored by (A) HPLC and (B) MALDI-MS. The chromatograms are shown at 250 nm for naphthoic acid, a reference sample of GS-2 incubated without protein, and the GS-2 sample incubated with protein for 5 h at 25 °C. The internal standard (2-chloro-4-nitrophenol) is abbreviated IS. The MALDI-MS are recorded after proteolytic (*S. aureus* V8) digestion, and both the unmodified and the modified fragment (AEKPKLHY*FNARGRME) containing Y9 are indicated in the sample incubated with GS-2.

subjected to 100 or 10 μM GS-2. Samples were withdrawn at 15 min, 1 h, 5 h, and after overnight incubation at 25 °C. The time-points were digested with trypsin and analyzed by MALDI-MS.

RESULTS

Quality and Yield of GS-thioesters. The GS-thioesters were synthesized from one batch of fully protected, polymer-bound GSH with yields ranging from 11% to 48% according to weighing. All GS-thioesters were identified with MALDI-MS. According to the Ellmans test (*31*), the amount of free thiol, i.e., free GSH, was between 0,5% and 3%. In addition to the Ellmans tests, the qualities of the products were evaluated from HPLC (for an example, see Figure 2, GS-2) and deemed satisfactory for use in the screening experiments without further purification.

Addition of the GS-thioester Panel to hGST A1-1. The outcome of adding the GS-thioesters to hGST A1-1 was investigated by analytical HPLC. Each reagent (100 μM, except GS-17, see Discussion) was incubated with protein (50 μM) at 25 °C, and the reaction was quenched after 5 h by adding a solution of TFA (0.4% final concentration) and an internal standard (2-chloro-4-nitrophenol). The thoroughly investigated GSB (*27*) was also incorporated as one of the reagents in order to include a positive control. As a reference, each GS-thioester was also incubated without protein for 5 h in buffer at 25 °C. The samples were then analyzed with reversed-phase HPLC (Figure 2). The peak area of each reagent incubated with protein was compared with the peak area of the reagent in the reference sample and also to a sample of the corresponding acid injected on the same gradient. These data were used to assess whether there was any decrease in thioester concentration and/or increase in free acid concentration (Table 1).

The quenched samples from the HPLC experiments were also analyzed by MALDI-MS following proteolytic digestion in order to ensure that decreases in peak areas corresponded to modifications of Y9 (Figure 2). If Y9 becomes covalently modified, the mass of the fragment containing Y9 increases with the mass of the corresponding acid minus the weight of water (Scheme 1). Out of the 18 GS-thioesters we investigated (GSB included), 14, or 78%, were able to covalently modify hGST-A1 as judged by both HPLC and MALDI-MS (Table 1).

Table 1. GS-thioesters after Five Hours Incubation, pH 7 and 25 °C

	HPLC[a]

[a] + corresponds to decrease of GSX peak (cutoff 20% decrease) and − corresponds to appearance of acid peak (cutoff 5% increase). [b] + and − corresponds to modified or not modified Y9 fragment, respectively.

MALDI-MS Screening of the GS-thioester Panel against hGSTs A2-2, A3-3, and A4-4. The acyl group preferences of hGSTs A2-2, A3-3, and A4-4 were investigated using the panel of GS-thioesters with GSB included as a positive control. For each reagent, the reaction was monitored with a GS-thioester concentration of 100 μM (except GS-17, see Discussion), and protein concentrations ranging from 5 μM to 50 μM, with an incubation time of 5 h at 25 °C. After incubation, the samples were digested with trypsin or *S. aureus* protease V-8 depending on possible overlaps from other fragments. Through MALDI-MS experiments, we then identified modified Y9-fragments for 83% of the GS-thioesters for both hGSTs A2-2 and A3-3, and for 72% of the reagents for hGST A4-4 (Table 2, Figure 3). A positive identifica-

tion corresponds to more than 10% modified Y9-fragment relative to the parent fragment (unmodified Y9). This relatively low threshold was set because MALDI-MS is not a quantitative technique and also because of the relatively large error in estimating GS-thioester concentrations (Discussion).

Exchange of Acyl Groups in Already Modified hGST A1-1. The ability to exchange acyl groups in already modified hGST A1-1 was investigated by subjecting benzoic acid-modified hGST A1-1 (5 μM) to GS-2 at two different concentrations (10 and 100 μM) (Figure 4). Time points were withdrawn, and the reaction mixtures were digested and analyzed with MALD-MS to obtain semiquantitative data regarding the amount of modification for each acyl group.

DISCUSSION

The speed and selectivity of the previously described site-directed covalent modification reaction between hGSTs from the alpha class and GS-thioesters (*27*) encouraged us to investigate the potential of this reaction both with respect to protein promiscuity and also to the linked question of reagent requirements. The natural substrates of GSTs differ widely in size and hydrophobicity (*16*), and we therefore found it likely that this would be a quite general modification reaction. The previous report was based on a set of three different GS-thioesters (Scheme 1 and Chart 2); GSB, GS-ANT, and *S*-lactoylglutathione. Out of these, the only one that did not react with Y9 was the only one that was not an aromatic GS-thioester (*S*-lactoylglutathione). This, in combination with the report that rat GST A1-1, highly homologous to hGST A1-1, hydrolyses a nonaromatic GS-thioester (*36*), raised the question that this perhaps was a unique reaction only involving aromatic GS-thioesters. With the intention to study this, we therefore included GS-16 and GS-17 (Scheme 1) in the panel of GS-thioesters. The individual GS-thioesters within the set of 17 new reagents thus vary widely in size, shape, hydrophobicity, and also reactivity (pK_a of acid) in order to screen as many parameters as possible.

GS-ANT S-lactoylglutathione

HPLC and MALDI-MS Analysis of the Reactions between the GS-thioester Panel and hGST A1-1. The outcome of adding the panel of reagents to hGST A1-1 was analyzed using both HPLC and MALDI-MS with the objective to get detailed information about the fate of the acyl group. Previously, we did a thorough investigation and could conclude that GSB reacts with hGST A1-1 in a stoichiometric fashion to produce 1 equiv of GSH and one 1 equiv of benzoic acid-modified protein (*27*). The reagent GSB is not hydrolyzed upon incubation at pH 7, even after 9 days, but instead the acyl group migrates to the α-amino group of GSH. However, we could not assume that this was valid for all GS-thioesters. To track the acyl group, we therefore incubated the reagents with

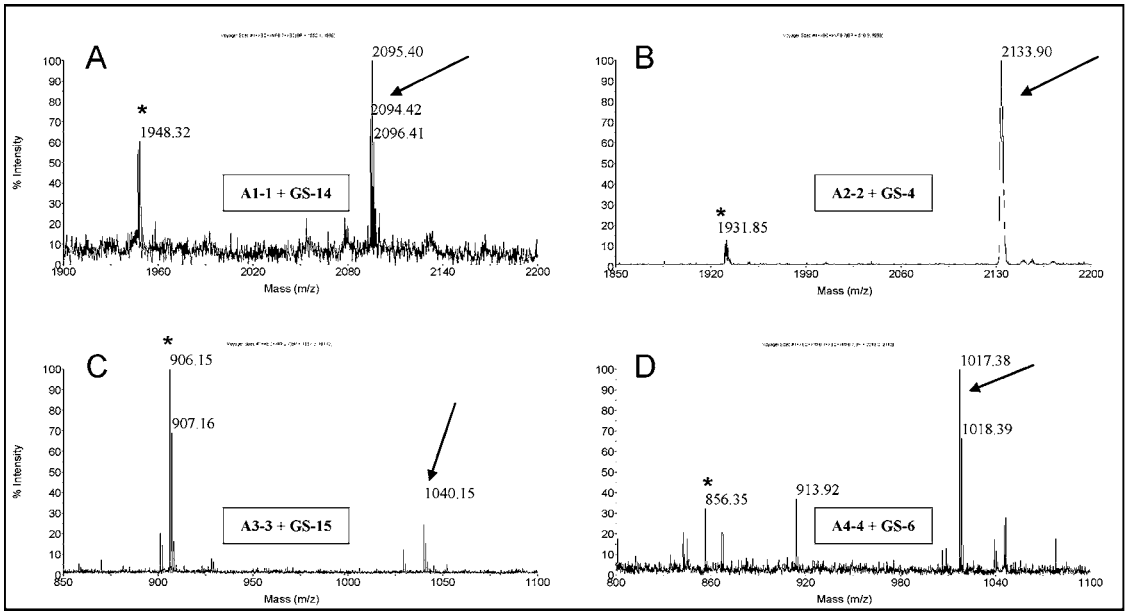

Figure 3. MALDI-MS spectra of proteolytic peptide fragments from hGSTs (A) A1-1, (B) A2-2, (C) A3-3, and (D) A4-4 following 5 h incubations with different GS-thioesters (100 μM) specified in the figure. The interval containing the Y9 fragments are shown in the figure. Parent fragments are indicated with asterisks, and modified fragments are highlighted with arrows.

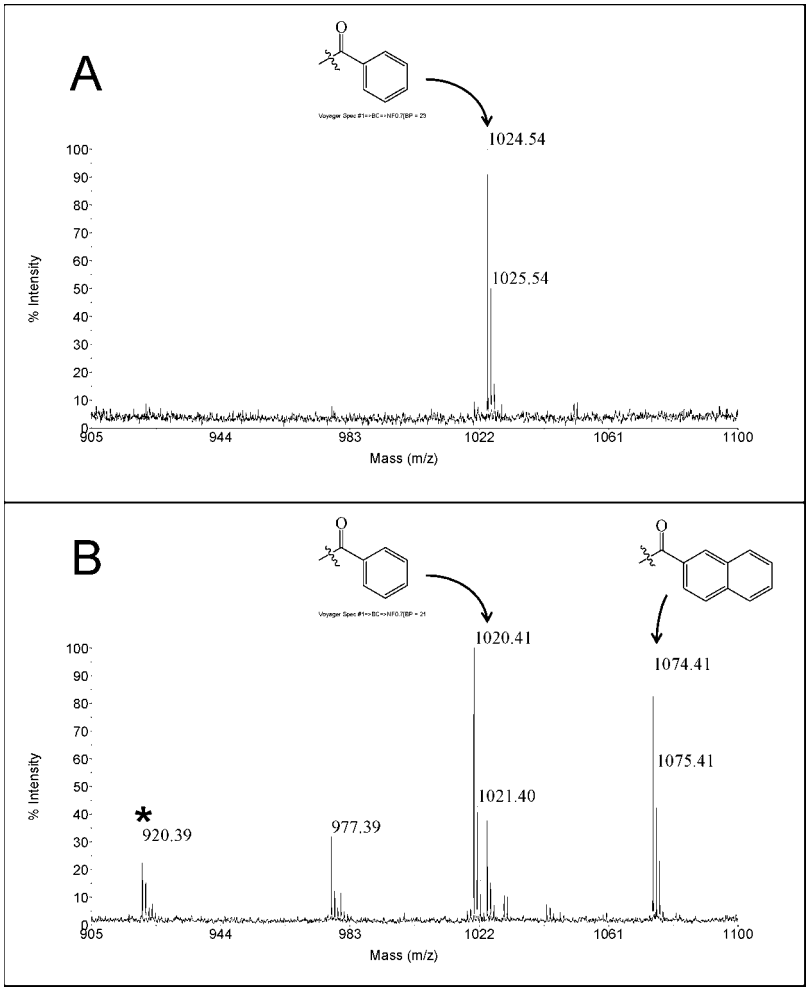

Figure 4. Benzoic acid-modified hGST A1-1 (5 μM) was subjected to GS-2, time points were withdrawn, and the reaction mixtures were digested with trypsin and analyzed with MALDI-MS. The figure shows (A) the spectrum before GS-2 was added and (B) the spectrum after 5 h incubation with 100 μM GS-2. The interval containing the Y9 fragments are shown in the figure. The parent fragment is indicated with an asterisk.

and without hGST A1-1 for 5 h, and we also injected the acids using the same gradient. A decrease in the peak area of the GS-thioester reagent that is due to hydrolysis can then be identified in the chromatogram. If a rearrangement reaction takes place, the result is not so easily interpreted since a migration event, in combination with oxidation of the produced thiol, would result in a total of up to five or even seven peaks, should hydrolysis also occur. The areas of the peaks thereby become very low and would be hard to detect at the concentration of GS-thioesters used during the experiments. Because of the relative concentration of reagent to protein (2:1), the maximum decrease of any GS-thioester peak should be 50% when hGST A1-1 is added if the event corresponds to modification of hGST A1-1. However, since the concentrations of the GS-thioester solutions are derived from weighing, the decreases could be greater than 50% even if the only event that takes place is modification of the protein in the sample. This is due to several reasons: this is a screening approach and we have not purified each substrate but used them after only ether precipitation (see above), the mixtures contain a small amount of free GSH (less than 3%), and peptides are also inherently hygroscopic. Weighing does therefore overestimate the amount of thioester reagent in the reaction mixture. The HPLC data is therefore presented in Table 1 as decrease or no decrease of thioester reagent. The exact figures can be found in the Supporting Information. The conditions we have used to analyze these reactions are not suitable for direct detection of the modified protein since it elutes as a very broad peak preceding the internal standard (Figure 2). Through these experiments we found that the great majority of the reagents are stable under the reaction conditions (5 h incubation at 25 °C). The migration event could be observed for GS-17 to some extent, and this, in combination with the poor extinction coefficient, motivated us to use a higher initial concentration of this reagent (250 μM) in the derivatization experiments. Only in one case (GS-11) was an acid peak observed in the absence of protein.

The quenched samples from the HPLC experiments were also digested and analyzed directly with MALDI-MS, and the results from the HPLC experiments could be verified (Table 1) in that we detected fragments that corresponded to modified Y9. In the presence of hGST A1-1, some of the GS-thioesters were hydrolyzed to some extent, most notably GS-11 and GS-16; however, none of these did show up as modified Y9 fragments in the MALDI-MS experiments and were thus classified accordingly.

In one case (GS-12) we could observe a small peak of the expected mass in the beginning of the ionization process, but the peak disappeared as the laser beam continued, and it did not reappear. It is perhaps likely that this is due to the acyl group itself, since it is photolabile and it might thus be destroyed in the MALDI-MS. Overall, the correlation between the HPLC and the MALDI-MS results is very good. The combined results

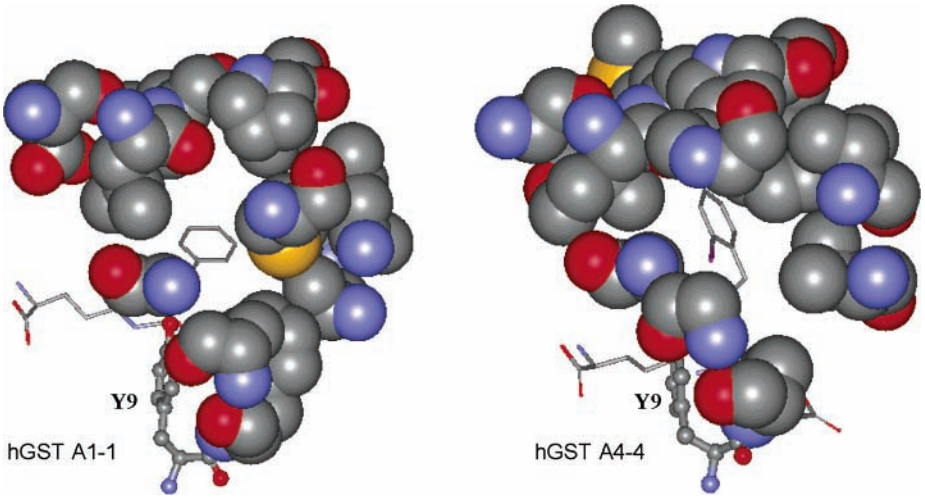

Figure 5. Close-ups of the crystal structures of hGST A1-1 (1GUH) (*15*) and hGST A4-4 (1GUL) (*41*) crystallized with glutathione conjugates showing the potential "back-door" leading out from the hydrophobic binding site. The H-site residues are shown in CPK, the G-site residues Y9 in ball-and-stick, and the glutathione-derived ligands in line representation. Both proteins are dimeric, but here are shown as monomers for reasons of clarity of presentation.

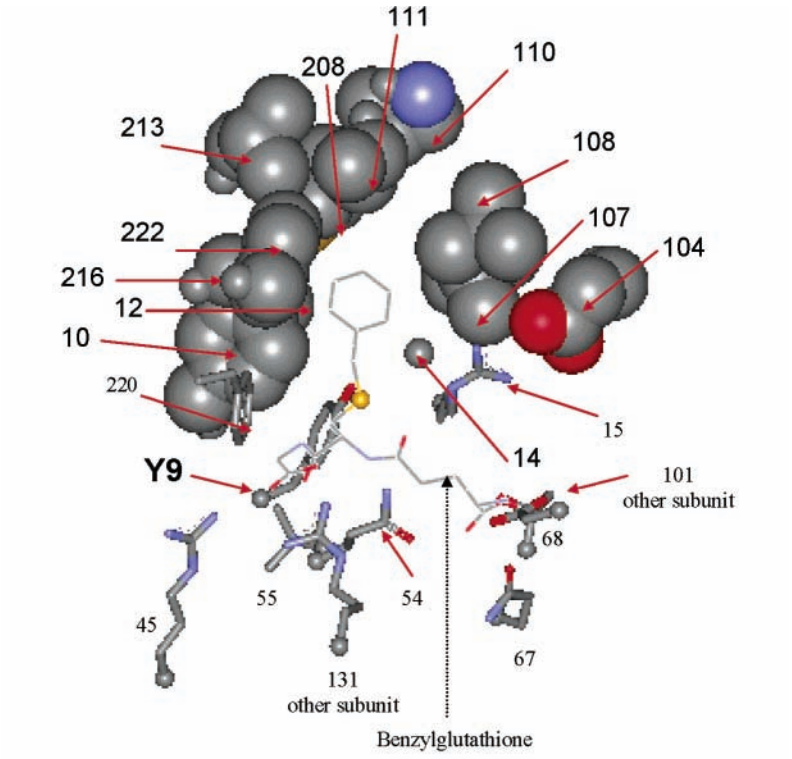
from MALDI-MS and HPLC thus showed that 14 of the GS-thioesters, or 78%, were able to modify hGST A1-1 (Table 1).

Modification of the Alpha Class hGSTs A2-2, A3-3, and A4-4. To explore the versatility of each of the alpha class proteins, we also screened hGSTs A2-2, A3-3, and A4-4 against all GS-thioesters (Table 2) using proteolytic digestion and MALDI-MS. Since the HPLC experiments had demonstrated that the GS-thioesters were stable in the absence of hGST A1-1, we chose to focus on the MALDI-MS experiments that more directly show the presence of modified protein. We found that all of the alpha class GSTs are highly promiscuous, and the percentage of accepted modification reagents range from 72 to 83%. This is perhaps not so surprising since the isoenzymes catalyze reactions where the hydrophobic substrates vary hugely in size and hydrophobicity (*16*, *21*, *34*, *37*−*40*). The relaxed hydrophobic substrate specificity of the GSTs that originates from their biological function as detoxication enzymes make them ideally suited as protein scaffolds in reprogramming experiments, and there is also room left, both in the G-site and in the H-site, even after Y9 has been modified with a new functional group. In all, the alpha class GSTs seems to be equally well suited as protein scaffolds in chemical reengineering experiments since they can all be reprogrammed with a large variety of functional groups.



The extent of modification varies, which is not surprising, since we used standardized conditions with respect to incubation time, temperature, and reagent concentration for all reactions. In our previous paper (*27*), we could observe that the extent of modification using GSB and hGST A1-1 was a function of time and concentration of reagent. We tried to maximize the extent of modification in one case, hGST A3-3 and GS-15 (Figure 3C), but we were not able to achieve more than a slight increase of modified protein even after raising the concentration of modifying reagent and allowing 24 h of modification. It is probably due to hydrolysis of the reagent as can be seen in Table 1 already after 5 h and also perhaps due to the slow deterioration of the protein at room temperature. The rate of modification, hydrolysis, and deterioration are in this case probably incompatible.

There are crystal structures of hGSTs A1-1 (*15*) and A4-4 (*41*) (Figure 5), and the distinguishing feature of the alpha class is helix 9 (α9) that forms a lid over the active site (Figure 1). The H-sites of the alpha class proteins differ from hGSTs A1-1 in three (A2-2), four (A3-3), and nine amino acids (A4-4), respectively (Figure 6). The differences within the alpha class lead to subtle differences in substrate specificity and also in the dynamic features of the proteins. For instance, α9 can be observed in the crystal structure of hGST A4-4 without ligand (*41*), but for hGST, A1-1 α9 is only ordered in the presence of a substrate (*15*, *42*). It is thus an advantage that all of the alpha class hGSTs are amenable to this type of chemical reengineering experiment because different qualities may become useful in different types of applications. In addition, one can also potentially refine the properties of the proteins through combinatorial approaches such as gene shuffling experiments (*43*) due to the high homology between the isoenzymes, without losing the ability of chemical reengineering of the resulting protein scaffolds.

No Apparent GS-thioester Requirements. There does not seem to be a systematic reason (size, reactivity, hydrophobicity, substitution pattern, etc.) predicting the ability of a GS-thioester to modify an alpha class GST. The reaction seems to be pretty general, and we found only one unreactive GS-thioester (GS-9). This acyl group (2,6 dimethylbenzoic acid) is di-ortho-substituted, and the likely explanation is that GS-9 is too sterically hindered to function, especially since the di-meta-substituted analogue GS-1 (3,5-dimethylbenzoic acid) is an excellent derivatization reagent for all four proteins.

The size of the acyl group does not seem to be of importance since these vary from 2-thiophenecarboxylic acid (GS-13) to 5-carboxyfluorescein (GS-3). Again, this is not surprising since the natural substrates of GSTs range widely in size and shape (*16*). This tolerance could perhaps in part be explained by observing the crystal structures of hGST A1-1 and A4-4, where there seems to be something like a "back door" leading out from the H-site (Figure 5).

The relative reactivities of the GS-thioesters correlate with the leaving group, which is GSH in all cases, and also with the pK_a value of the acyl group. The reported (*44*) or calculated (*45*) pK_a values of the acyl groups in the series (Supporting Information) span a range from 3.35 (2,6-dimethylbenzoic acid) to 4.80 (6-phenylhexanoic acid), but these differences are not reflected in the ability of a GS-thioester to function as an acylating reagent. The

Figure 6. The hydrophobic binding sites of hGSTs A2-2, A3-3, and A4-4 differ from that of hGST A1-1 (*15*) in up to nine positions, as indicated in the table. In this figure, the H-site residues are shown as CPK models with the α-carbons as balls. G-site residues are shown in stick model, again with the α-carbons as balls. The sulfur atom of the ligand *S*-benzylglutathione is also shown as a ball. Amino acids 101 and 131 originate from the other subunit in the dimeric protein and protrude into the G-site.

hydrophobicities of the acyl groups also differ quite substantially with log *P* values (the partitition coefficient between water and *n*-octanol) from 1.3 (4-acetamidobenzoic acid) to 3.8 (2-phenyl-4-quinolinecarboxylic acid) (Supporting Information). This trend is again not reflected in the success of modification.

In our previous work we commented on the fact that there might be a need for an aromatic GS-thioester for this reaction to work (*27*). This was based on the observation that in our small set of three reagents, the two aromatic ones were able to acylate Y9 whereas the naturally occurring, alkyl thioester *S*-lactoylglutathione was not (Scheme 1 and Chart 2). In addition, rat GST A1-1 has been shown to function as a thioester hydrolase for the alkyl thioester GS-ethacrynic acid (*36*). To illuminate this, we included two acyl groups: phenylacetic acid (GS-16) and 6-phenylhexanoic acid (GS-17) that are closely related to benzoic acid (GSB). Even though the hydrophobicity would increase, we chose to use 6-phenylhexanoic acid instead of merely hexanoic acid since the phenyl ring is valuable as a UV marker in HPLC experiments. The reactivities of these GS-thioesters are very similar since the pK_a values are 4.2, 4.3, and 4.8 for benzoic acid, phenyl acetic acid, and 6-phenylhexanoic acid, respectively (Supporting Information). This range is included within the span of aromatic GS-thioesters that work as acylating reagents. The hydrophobicities are also within the span of the other reagents (Supporting Information) since the log *P* values are 1.9, 1.4, and 3.3 for benzoic acid, phenylacetic acid, and 6-phenylhexanoic acid, respectively. It does appear as if adding hGST A1-1 to GS-16 increases the rate of hydrolysis of the reagent (Table 1). However, the results suggest that even though the phenylacetic acid-derived GS-16 did not acylate hGSTs A1-1 and A4-4, the reagent with the longer spacer, GS-17, did function as an acylating reagent for all of the GSTs (Tables 1 and 2). On the basis of theses screening experiments, we can now conclude that there does not appear to be an absolute need for an aromatic GS-thioester for the acylation reaction to work, something that significantly expands the versatility of the chemical reengineering approach.

Besides the possible bias against di-ortho-substituted acyl groups, we cannot state any specific reagent requirements, in part because of the high success rate (>70%) in this set of GS-thioesters. Not all reagents work for all alpha class GSTs, and the reasons behind a successful modification probably depends on the combination of

protein and reagent that in turn leads to an optimal positioning of the reactive Y9 residue for the reaction to occur.

Benzoic Acid-Modified hGST A1-1 Can Be Morphed into Naphthoic Acid-Modified A1-1. We found through exchange experiments that benzoic acid-modified hGST A1-1 can be altered by adding another thioester reagent (GS-2) to instead form the naphthoic acid-modified protein (Figure 4). Intriguingly, part of the premodified protein becomes deacylated during the incubation, which is odd since the benzoic acid-modified protein is completely stable during identical reaction conditions without GS-2 (*27*). Also, in the reaction between GS-2 and hGST A1-1, we observe naphthoic acid-modified protein but no free naphthoic acid (Table 1) as would be expected should the deacylation reaction proceed through a naphthoic acid intermediate. This finding is thus quite interesting and needs to be further studied.

CONCLUSIONS

Through a combinatorial screening approach we have substantially expanded the range of GS-thioesters that are able to covalently modify the alpha class hGSTs. The set now includes fluorescent probes and a handle for chemical derivatization. The covalent modification reaction is very versatile in that a large number of GS-thioesters are accepted by the alpha class GSTs, and the reaction is fast and site-directed toward one residue in the protein with minimal side reactions. This precision allows for chemical reengineering of protein scaffolds with the goal of obtaining new function through the design and synthesis of appropriate GS-thioesters.

Pyridine-Containing 6-Hydrazinonicotinamide Derivatives as Potential Bifunctional Chelators for ^{99m}Tc-Labeling of Small Biomolecules

Ajay Purohit, Shuang Liu,* Charlie E. Ellars, Dave Casebier, Stephen B. Haber, and D. Scott Edwards

Discovery Chemistry, Bristol-Myers Squibb Medical Imaging, 331 Treble Cove Road, North Billerica, Massachusetts 01862. Received August 14, 2003; Revised Manuscript Received April 30, 2004

As a continuation of our interest in novel ^{99m}Tc chelating systems, several pyridine-containing HYNIC (6-hydrazinonicotinamide) derivatives (L1−L5) have been synthesized and characterized by NMR (^{1}H and ^{13}C) and LC−MS. ^{99m}Tc complexes of L1−L5 were prepared by the reaction of the HYNIC derivative with $^{99m}TcO_4^-$ in the presence of excess tricine and stannous chloride. Results from this study show that the attachment site of the linker is critical for the formation of macrocyclic ^{99m}Tc complexes. For example, the pyridine-N in L3 is not able to bond to the Tc, because the lysine linker is attached to the 4-position. When the linker is at the 2-position, L1 forms the macrocyclic complex [^{99m}Tc(L1)-(tricine)], but the radiochemical purity is relatively low. If the linker is attached to the 3-position of the pyridine ring, the HYNIC derivatives form macrocyclic complexes [^{99m}Tc(L)(tricine)] (L2, L4, and L5) in high yield (>95%). The HPLC data suggest that the macrocyclic complex [^{99m}Tc(L2)(tricine)] exists in solution as four isomers: two diastereomers and two conformational isomers. Diastereomers are due to a combination of the chirality of the lysine linker and of the Tc chelate. Replacing lysine with a pentamethylenediamine linker results in the macrocyclic complex [^{99m}Tc(L4)(tricine)] with two conformational isomers, which interconvert rapidly at room temperature. Changing the linker from pentamethylenediamine to hexamethylenediamine did not eliminate the minor isomer; but the percentage of the minor isomer was reduced from ∼10% for [^{99m}Tc(L4)(tricine)] to only 6% for [^{99m}Tc-(L5)(tricine)]. The linker length is an important parameter to minimize the minor isomer. LC−MS data of complexes [^{99m}Tc(L)(tricine)] (L2, L4, and L5) are completely consistent with their proposed compositions. On the basis of these data, it is concluded that pyridine-containing HYNIC derivatives have the potential as bifunctional chelators for ^{99m}Tc-labeling of small biomolecules if the linker is attached to the 3-position of the pyridine ring.

INTRODUCTION

For the last several years, we have been successful in using a ternary ligand system (HYNIC, tricine, and TPPTS) (HYNIC = 6-hydrazinonicotinamide, TPPTS = trisodium triphenylphosphine-3,3′,3″-trisulfonate) for ^{99m}Tc-labeling of small biomolecules (BM), including chemotactic peptides (*1*) and LTB_4 receptor antagonists (*2, 3*) for imaging infection and inflammation, integrin $\alpha_v\beta_3$ receptor antagonists for tumor imaging (*4*), and a GPIIb/IIIa receptor antagonist for imaging thrombus (*5*−*10*). The combination of HYNIC−BM, tricine, and TPPTS results in a unique and versatile ternary ligand system that forms ^{99m}Tc complexes [^{99m}Tc(HYNIC−BM)(tricine)-(TPPTS)] (BM = peptide or nonpeptide receptor ligands) with extremely high specific activity. These ternary ligand−^{99m}Tc complexes are stable in solution for at least 6 h and are formed as equal mixtures of two diastereomers, if the biomolecule has a chiral center. The composition of ternary ligand−^{99m}Tc complexes has been determined to be 1:1:1:1 for Tc:HYNIC−BM:tricine:TPPTS, through a series of mixed ligand experiments, and confirmed by LC−MS at both the tracer (^{99m}Tc) and macroscopic (^{99}Tc) levels (*11, 12*). The use of HYNIC for ^{99m}Tc-labeling of small biomolecules has recently been reviewed (*13*−*16*).

Previously, we reported two prototype phosphine-containing HYNIC chelators (Figure 1), HYNIC−Kp-DPPB and HYNIC−Ko-DPPB (K = lysine, DPPB = diphenylphosphinobenzoic acid), and their macrocyclic ^{99m}Tc complexes (*17*). We found that both HYNIC−Kp-DPPB and HYNIC−Ko-DPPB form highly stable ^{99m}Tc complexes, [^{99m}Tc(HYNIC−Ko-DPPB)(tricine)] and [^{99m}Tc-(HYNIC−Kp-DPPB)(tricine)]. We also found that [^{99m}Tc-(HYNIC−Kp-DPPB)(tricine)] exists as only one *detectable* isomer in solution while [^{99m}Tc(HYNIC−Ko-DPPB)(tricine)] has three isomers, which interconvert at elevated temperatures. Unfortunately, HYNIC−Kp-DPPB is very prone to oxidation during radiolabeling. This presents a significant challenge, since the oxidized phosphine-containing HYNIC chelator (HYNIC−Kp-ODPPB) will form a binary ligand complex, [^{99m}Tc(HYNIC−Kp-ODP-PB)$(tricine)_2$], as a radioimpurity.

Like phosphines, pyridine analogues have also been used as coligands for ^{99m}Tc-labeling of small biomolecules (*10*). Compared to phosphines, pyridine analogues are air-stable and are more amendable for further derivatization. Therefore, as a continuation of our interest in new ^{99m}Tc chelating systems, we now present the synthesis of several pyridine-containing HYNIC derivatives (Figure

1, L1−L5). [1] The main objective of this study is to explore the potential of L1−L5 as bifunctional chelators (BFCs) for ^{99m}Tc-labeling of small biomolecules.

EXPERIMENTAL SECTION

N-ϵ-(*tert*-Butoxycarbonyl)lysine methyl ester hydrochloride was purchased from Calbiochem Inc. 1,6-Diaminohexane, 1,5-diaminopentane, 1-hydroxyazabenzotriazole, 4 M HCl in dioxane, isonicotinic acid, nicotinic acid, picolinic acid, 1-*O*-(*N*,*N*′,*N*″,*N*‴-tetramethyluronium)-azabenzotriazoloxy hexafluorophosphate, and tricine were purchased from Sigma-Aldrich (St. Louis, MO). $Na^{99m}TcO_4$ was obtained from a Technelite $^{99}Mo/^{99m}Tc$ generator at Bristol-Myers Squibb Medical Imaging Inc., N. Billerica, MA. Sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)-hydrazono)nicotinate (HYNIC−NHS) was prepared according to a literature procedure (*18*). Synthesis of *N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)-lysine methyl ester was described in our previous communication (*17*).

[1] [1]Abbreviations: L1 = *N*-ϵ-(isonicotinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester; L2 = *N*-ϵ-(nicotinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)-nicotinyl)lysine methyl ester; L3 = *N*-ϵ-(picolinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester; L4 = 1-(*N*-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl))-6-(nicotinoyl)pentanediamine; and L5 = 1-(*N*-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl))-6-(nicotinoyl)hexanediamine.

Instruments. NMR spectral data (^{1}H and ^{13}C) were recorded on a 600 MHz Bruker DRX FT NMR spectrometer and are reported as δ (ppm) relative to TMS. Electrospray MS analyses were performed using an IonSpec Ultima FT mass spectrometer in the positive ion mode. LC−MS spectral data were collected using a HP1100 LC/MSD system with an API-electrospray interface. The LC−MS method used a Zorbax C_{18} column (4.6 mm × 150 mm, 3.5 μm particle size). The flow rate was 1 mL/min with a gradient mobile phase starting at 80% solvent A (25 mM ammonium acetate buffer, pH 6.8) and 20% solvent B (acetonitrile) and going to 75% A and 25% solvent B at 20 min.

The preparative HPLC method used a Varian Prep Star system equipped with an UV/visible detector (λ = 220 nm) and a Jupiter C_{18} prep column (15 μm, 300Å, 21.2 × 250 mm). The flow rate was 80 mL/min with the mobile phase starting with 100% solvent A (0.1%TFA in water) and going to 80% solvent B (0.1%TFA in 90% acetonitrile) and 20% solvent A at 40 min. The radio-HPLC methods used a HP-1100 system with an IN-US radio-detector and a Zorbax C_{18} column (4.6 mm × 250 mm, 300 Å). The flow rate was 1 mL/min with a gradient mobile phase starting at 80% solvent A (25 mM ammonium acetate buffer, pH 6.8) and 20% solvent B (acetonitrile) and going to 75% A and 25% solvent B at 20 min. The ITLC method used GelmanSciences silica gel paper strips and a 1:1 mixture of acetone and saline as eluant. By this method, ^{99m}Tc complexes migrate to

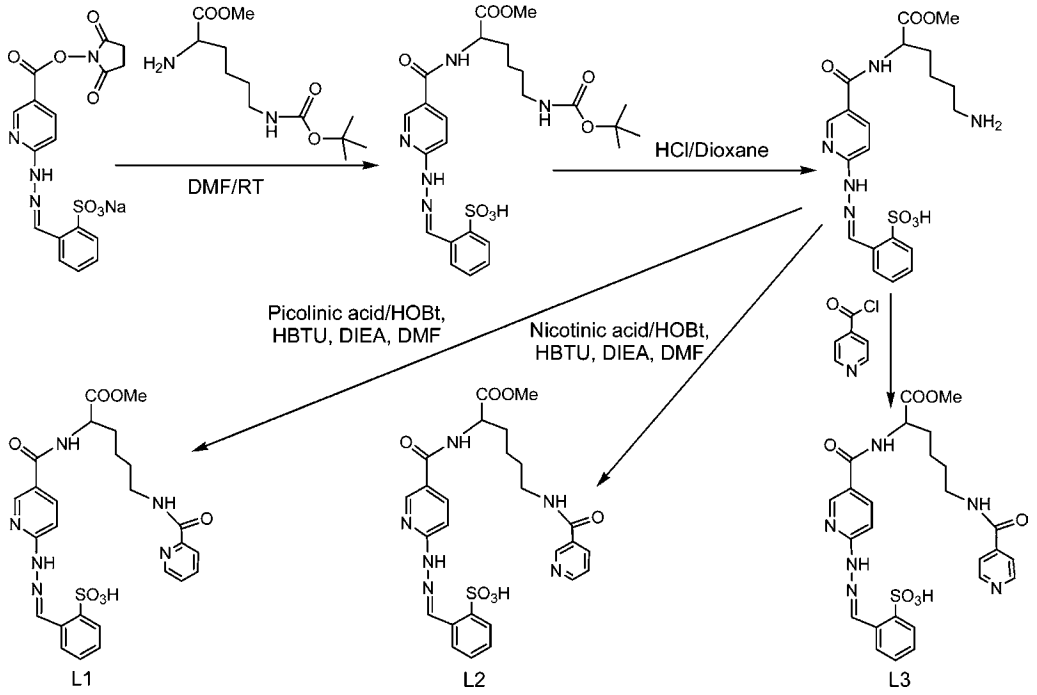
the solvent front while $^{99m}TcO_4^-$ and [^{99m}Tc]colloid remain at the origin.

Synthesis of *N*-ε-(Isonicotinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine Methyl Ester (L1). To a 25 mL round-bottom flask was added isonicotinoyl chloride hydrochloride (16.0 mg, 0.90 mmol) and 3 mL of DMF. To the solution above was added *N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)-nicotinyl)lysine methyl ester hydrochloride (50 mg, 0.10 mmol), followed by addition of DIEA (0.0695 mL, 51.62 mg) in DMF (1 mL). The reaction mixture was stirred for 20 min. DMF was removed in vacuo and the crude oil subjected to HPLC purification. The collected fractions were combined and lyophilized to give a white powder. The yield was 35.5 mg (~70%). MS (ESI, +ve): m/z = 463.15 for $C_{20}H_{25}N_5O_6S$ ([M + H]$^+$). ^{1}H NMR (DMSO-d_6 + D_2O): 9.38 (s, 1H), 9.06 (d, 2H, J = 6.6 Hz), 8.632 (s, 1H), 8.49−8.36 (m, 4H), 7.81 (dd, 1H, J = 8.4, 7 Hz), 7.4 (m, 2H), 7.22 (br, 1H), 4.4 (m, 1H), 3.65 (s, 3H), 3.3 (m, 2H), 1.86 (m, 2H), 1.59−1.43 (m, 4H).

Synthesis of *N*-ε-(Nicotinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine Methyl Ester (L2). To a 25 mL round-bottom flask was added nicotinic acid hydrochloride (14.32 mg, 0.09 mmol), followed by 5 mL of DMF and 1-*O*-(*N*,*N*′,*N*″,*N*‴-tetramethyluronium)azabenzotriazoloxy hexafluorophosphate (41 mg, 0.1 mmol), 1-hydroxyazabenzotriazole (14.6 mg, 0.1 mmol) and DIEA (0.104 mL, 0.774 g). After stirring for 5 min, *N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester hydrochloride (50 mg, 0.10 mmol) was added. The resulting solution was stirred for 30 min. DMF was removed under vacuum and the crude oil subjected to HPLC purification. The collected fractions were combined and lyophilized to give a fluffy white solid. The yield was 42 mg (82%). MS (ESI, +ve): m/z = 569.1815 for $C_{26}H_{28}N_6O_7S$ ([M + H]$^+$). ^{1}H NMR (DMSO-d_6 + DCl): 9.3 (d, 2H, J = 16.2 Hz), 9.0 (d, 1H, J = 4.8 Hz), 8.9 (d, 1H, J = 8.4 Hz), 8.6 (s, 1H), 8.49 (d of d, 1H, J = 2.4, 7.2 Hz), 8.43 (d, 1H), 8.1 (m, 1H), 7.8 (dd, 1H, J = 2.4, 1.2 Hz), 7.4(m, 2H). 7.28(d, 1H), 4.4 (m, 1H), 3.65 (s, 3H), 3.29 (m, 2H), 1.8 (m, 2H), 1.59−1.44 (m, 4H).

Synthesis of *N*-ε-(Picolinyl)-*N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)-nicotinyl)lysine Methyl Ester (L3). To a round-bottom flask were added picolinic acid (10 mg, 0.08 mmol), 5 mL of DMF, 1-*O*-(*N*,*N*′,*N*″,*N*‴-tetramethyluronium)azabenzotriazoloxy hexafluorophosphate (38 mg, 0.1 mmol), 1-hydroxyazabenzotriazole (14.6 mg, 0.1 mmol), and DIEA (0.104 mL, 0.077 gm). After the solution was stirred for 7 min, *N*-α-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl)lysine methyl ester hydrochloride (50 mg, 0.10 mmol) was added. The reaction mixture was stirred for another 30 min. DMF was removed under vacuum and the crude oil subjected to HPLC purification. The collected fractions were combined and lyophilized to give a fluffy white solid. The yield was 34 mg (73%). MS (ESI, +ve): m/z = 569.1815 for $C_{26}H_{28}N_6O_7S$ ([M + H]$^+$). ^{1}H NMR (DMSO-d_6 + DCl): 9.32 (br s, 1H), 8.62 (m, 1H), 8.52 (s, 1H), 8.3 and 8.24 (bs, 2H), 8.0−7.9 (m, 2H), 7.8 (dd, 1H, J = 1.2 Hz, J = 6 Hz), 7.5 (m, 1H), 7.4 (m, 2H), 7.19 (d, 1H, 9.6 Hz), 4.4 (m, 1H), 3.64 (s, 3H), 3.3 (m, 2H), 1.9−1.8 (m, 2H), 1.6−1.54 (m, 2H), 1.45−1.25 (m, 2H).

Synthesis of 1-(*N*-(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl))-6-(nicotinoyl)pentanediamine (L4). To a 15 mL round-bottom flask was added sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinate (50 mg, 0.113 mmol) followed by DMF (3 mL) and by pentamethylenediamine (13.8 mg, 0.135 mmol). The mixture was stirred for 30 min. A precipitate begins to form a few minutes into the reaction. The precipitate was filtered and was confirmed as the intermediate product according to LC−MS. The intermediate was used directly without any further purification for the next step.



1-(*N*-(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl))pentanediamine (23 mg, 0.056 mmol) was added to a flask containing nicotinic acid (7.5 mg, 0.061 mmol), 1-*O*-(*N*,*N*′,*N*″,*N*‴-tetramethyluronium)azabenzotriazoloxy hexafluorophosphate (24 mg, 0.063 mmol), and diisopropylethylamine (58 mg, 0.45 mmol) in DMF (3 mL). The reaction mixture stirred at room temperature for 4 h. DMF was removed in vacuo and the crude product was purified by HPLC. The collected fractions were combined and lyophilized to give a fluffy white solid. The yield was 15 mg (52%). MS (ESI, +ve; m/z = 511.1754 for $C_{24}H_{26}N_6O_5S$ ([M + H]$^+$). ^{1}H NMR (600 MHz, DMSO-d_6 + DCl): 9.35 (s, 1H), 9.33 (s, 1H), 9.0 (m, 2H), 8.58 (s, 1H), 8.4 (d of d, 1H, J = 2.0, 7.2 Hz), 8.1 (m, 1 H), 7.8 (m, 1H), 7.4 (m, 2H), 7.23 (br, 1H), 3.3 (t, 2H), 3.2 (t, 2H), 1.5 (m, 4H), 1.3 (m, 2H).

Synthesis of 1-(*N*-(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl))hexanediamine. To a 15 mL round-bottom flask was added sodium succinimidyl 6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinate (100 mg, 0.226 mmol) followed by DMF (3 mL) followed by hexamethylenediamine (26.3 mg, 0.226 mmol). The mixture was stirred for 10 min. DMF was removed in vacuo and the crude mixture subjected to purification by HPLC. The collected fractions were combined and lyophilized to give a white solid. The yield was 46 mg (~49%). MS (ESI, +ve): m/z = 406.15 for $C_{18}H_{24}N_5O_4S$ ([M + H]$^+$). ^{1}H NMR (DMSO-d_6 + DCl): 9.34 (s, 1H), 8.59 (s, 1H), 8.50 (dd, 2H, J = 2.0, 7.2 Hz), 8.09 (t, 1 H), 7.8 (m, 1H), 7.4 (m, 2H), 7.23 (br, 1H), 3.25 (t, 2H), 2.73 (m, 2H), 1.5 (m, 4H), 1.31 (m, 4H).

Synthesis of 1-(*N*-(6-(2-(2-Sulfonatobenzaldehyde)hydrazono)nicotinyl))-6-(nicotinoyl)hexanediamine (L5). To a 15 mL round-bottom flask was added nicotinic acid (5.34 mg, 0.043 mmol) and 1-*O*-(*N*,*N*′,*N*″,*N*‴-tetramethyluronium)azabenzotriazoloxy hexafluorophosphate(18.14 mg, 0.047 mmol). To the above mixture were added DMF (3 mL) and diisopropylethylamine (16.78 mg, 0.130 mmol, 0.022 mL). The solution was stirred for 5 min, after which 1-(*N*-(6-(2-(2-sulfonatobenzaldehyde)hydrazono)nicotinyl))hexanediamine (20 mg, 0.047 mmol) was added in one lot. The reaction mixture was stirred for another 30 min at room temperature. After removal of DMF, the crude oil was subjected to HPLC purification. The collected fractions were combined and lyophilized to give a white solid. The yield was 18 mg (80%). MS (ESI, +ve): m/z = 525.1915 for $C_{25}H_{28}N_6O_5S$ ([M + H]$^+$). ^{1}H NMR (600 MHz, DMSO-d_6 +DCl): 9.3 (d, 2H, J = 7.2 Hz), 9.04 (d, 1H, J = 5.4 Hz), 9.02 (d, 1H, J = 8.4 Hz), 8.58 (s, 1H), 8.48 (dd, 2H, J = 1.8, 7.8 Hz), 8.17 (m, 1H), 7.79 (m, 1H), 7.4 (m, 2H), 7.23 (br, 1H), 3.3 (t, 2H, J = 7.2 Hz), 3.2 (t, 2H, J = 7.2 Hz), 1.54 (m, 4H), 1.35 (m, 4H).

General Procedure for Preparation of ^{99m}Tc Complexes. To a 5.0 mL vial were added the HYNIC chelator (1.0−40 μg), 0.4 mL of 0.25 M succinate buffer (pH = 5.0), and 0.4 mL of tricine solution (25−100 mg/mL in 0.25 M succinate buffer, pH = 5.0). After addition of 0.5 mL of $^{99m}TcO_4^-$ solution (40−80 mCi/mL in saline) and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl), the mixture was heated in a water bath at 95−100 °C for 10−15 min. After cooling to room temperature, a sample

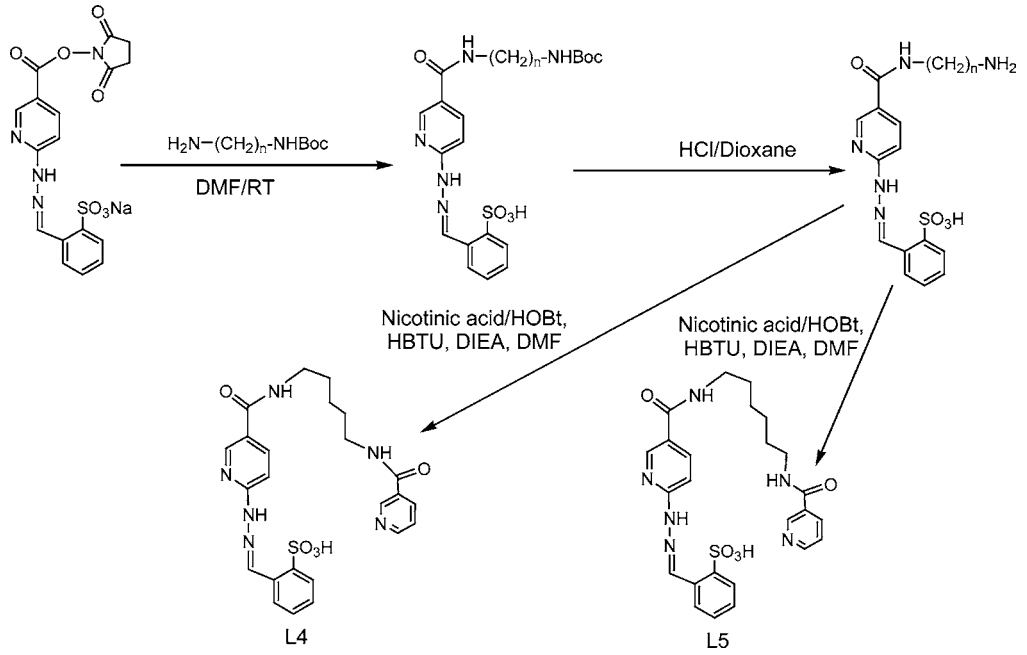
Scheme 1. Synthesis of L1−L3

of the resulting solution was analyzed by radio-HPLC and ITLC. In all cases, formation of [^{99m}Tc]colloid was minimal.

Solution Stability Studies. For solution stability in the kit matrix, the macrocyclic complex [^{99m}Tc(L2)-(tricine)] was prepared, and samples of the resulting reaction were analyzed by radio-HPLC at t = 0, 1, 2, 3, and 4 h postlabeling. For solution stability of HPLC-purified [^{99m}Tc(L2)(tricine)], peaks A and C were collected into a 25 mL round-bottom flask. Solvents were removed using a rotary evaporator. The residue was dissolved in saline, and samples of the resulting solution were analyzed by radio-HPLC over 4 h postpurification. For TPPTS and cysteine challenge experiments, the complex [^{99m}Tc(L2)(tricine)] was prepared first and diluted with an equal volume of saline containing TPPTS (1 mg/mL) or cysteine (1 mg/mL). Samples of the resulting solution were analyzed by radio-HPLC over 6 h.

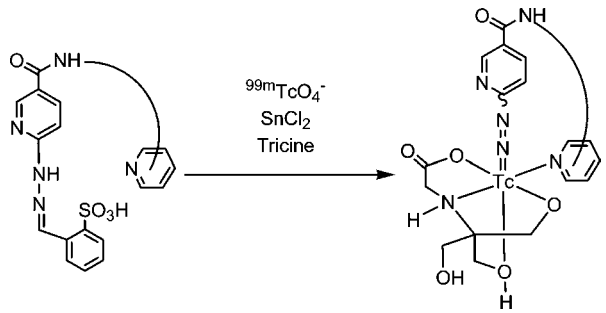
Radiolabeling Efficiency Experiment. To a 5.0 mL vial were added 0.05−0.5 mL of the L2 solution (20 μg/mL) in 0.25 M succinate buffer (pH = 5.0) and 0.2 mL of tricine solution (100 mg/mL in 0.25 M succinate buffer, pH = 5.0). The total volume in each vial was adjusted to ∼1.2 mL using 0.25 M succinate buffer, pH = 5.0). After addition of 0.3 mL of $^{99m}TcO_4^-$ solution (∼30 mCi) and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (1.0 mg/mL in 0.1 N HCl), the mixture was heated at 100 °C for 10 min. After cooling to room temperature, the resulting solution was analyzed by radio-HPLC. Each condition was carried out in duplicate and the radiolabeling yield was calculated as the average of the two vials.

General Procedure for Preparation of Macrocyclic ^{99}Tc Complexes. To a 5.0 mL vial were added the pyridine-containing HYNIC chelator (500−1000 μg), 0.5 mL of 0.25 M succinate buffer (pH = 5.0), and 0.5 mL of tricine solution (100 mg/ mL in 0.25 M succinate buffer, pH = 5.0). After addition of 0.5 mL of $^{99}TcO_4^-$ solution (1 mg/mL in water) and 25 μL of $SnCl_2 \cdot 2H_2O$ solution (10 mg/mL in 0.1 N HCl), the mixture was heated at 100 °C for ∼15 min. After cooling to room temperature, a sample of the resulting solution was analyzed by LC−MS.



RESULTS AND DISCUSSION

Synthesis of Pyridine-Containing HYNIC Derivatives. L1−L5 were prepared according to Schemes 1 and 2. For L1−L3, HYNIC−NHS was allowed to react with ω-Boc-lysine methyl ester at room temperature in DMF to give the intermediate HYNIC−(ω-Boc)K as its methyl ester. The Boc-protecting group was readily removed in a 4 M HCl dioxane solution to afford HYNIC−K(OMe) as the hydrochloride salt. Conjugation of HYNIC−K(OMe) with picolinic acid, nicotinic acid, and isonicotinyl chloride produced L1−L3, respectively, as their methyl esters. For L4 and L5, the synthetic procedure was similar to that for the synthesis of L1−L3, except that pentamethylenediamine and hexamethylenediamine were used as the linker instead of lysine methyl ester. L1−L5 were purified by HPLC with the purity being >98% before radiolabeling. NMR (^{1}H and ^{13}C) and mass spectral data are completely consistent with the proposed structures.



Synthesis of ^{99m}Tc Complexes. ^{99m}Tc complexes of L1−L5 were prepared (Scheme 3) using conditions similar to those described in our previous communication (*17*). The HYNIC derivative was allowed to react directly with $^{99m}TcO_4^-$ in the presence of stannous chloride and excess tricine. Radiolabeling was achieved by heating the reaction mixture at 100 °C for 10−15 min. Since the pyridine-containing HYNIC derivatives are air-stable, there was no need for exclusion of air before addition of $^{99m}TcO_4^-$. After radiolabeling, a sample of the resulting solution was analyzed by radio-HPLC and TLC. The ^{99m}Tc-labeling efficiency is extremely high for L2, L4, and L5. The minimum amount of L2 to achieve high-yield ^{99m}Tc-labeling (>95%) was about 1 μg for 30 mCi of $^{99m}TcO_4^-$, corresponding to a molar ratio of ∼8:1 for L2:Tc.

We also tried to use other polydentate aminocarboxylates, such as nitrilotriacetic acid (NTA), *N*-(2-hydroxyethyl)iminodiacetic acid (HIDA), *N*-(2-hydroxyethyl)-glycine (monocine), ethylenediamine-*N*,*N*′-diacetic acid (EDDA), and *N*-(hydroxyethyl)ethylenediamine triacetic acid (HEDTA), as coligands to replace tricine. The yields for these ^{99m}Tc complexes were always low (<30%).

Scheme 2. Synthesis of L4 and L5

Scheme 3. Synthesis of ^{99m}Tc Complexes: [^{99m}Tc(L)(tricine)] (L = L1−L5)

Among various polydentate aminocarboxylates, tricine remains the best coligand with respect to the radiolabeling yield, radiochemical purity, and the number of isomers formed. The concentration of the tricine coligand ranges from 10 to 100 mg/mL. If the tricine concentration is <10 mg/mL, the formation of [^{99m}Tc]colloid may become significant. If the tricine concentration is >100 mg/mL, the radiolabeling yields for the ^{99m}Tc complexes decreases.

Attachment Site and Macrocyclic Chelate Formation. L1−L3 were specifically designed to study the impact of the attachment site on the formation of macrocyclic Tc chelates. To determine if pyridine-N atoms in L1−L3 are able to bond to the Tc, we also used HYNIC−(ω-Boc)K to prepare the binary ligand ^{99m}Tc complex [^{99m}Tc(HYNIC−(ω-Boc)K)(tricine)$_2$]. A reverse-phase HPLC method (20−25% acetonitrile over 20 min) was used to analyze the synthesized ^{99m}Tc complexes. Figure 3 shows radio-HPLC chromatograms of ^{99m}Tc complexes [^{99m}Tc(L1)(tricine)] (top) and [^{99m}Tc(L2)(tricine)] (bottom). Figure 4 shows radio-HPLC chromatograms of [^{99m}Tc(L3)(tricine)$_2$] (top) and [^{99m}Tc(HYNIC−(ω-Boc)K)-(tricine)$_2$] (bottom). In the absence of the pyridine-N donor, the radio-HPLC chromatogram of the binary ligand ^{99m}Tc complex [^{99m}Tc(HYNIC−(ω-Boc)K)(tricine)$_2$] always shows multiple peaks between 3 and 25 min. The radio-HPLC chromatogram of [^{99m}Tc(L3)(tricine)$_2$] is very similar to that of [^{99m}Tc(HYNIC−(ω-Boc)K)(tricine)$_2$] (Figure 4). It is quite clear that the 4-substituted analogue is not able to bond to the Tc. Thus, L3 is not a suitable BFC for the ^{99m}Tc-labeling of small biomolecules, at least when lysine is used as the linker.

The complex [^{99m}Tc(L1)(tricine)] shows two major radiometric peaks at ~3.7 and 10 min. Obviously, the pyridine-N in L1 is able to bond to the Tc. Many attempts have been made to minimize the peak at 3.7 min by changing component levels in the formulation matrix, but these were not successful. Thus, the peak at 3.7 min is treated as a radioimpurity, instead of part of [^{99m}Tc(L1)-(tricine)]. Since the radiolabeling yield for [^{99m}Tc(L1)-(tricine)] is low (65−70%), L1 is not an ideal BFC for the ^{99m}Tc-labeling of small biomolecules either.

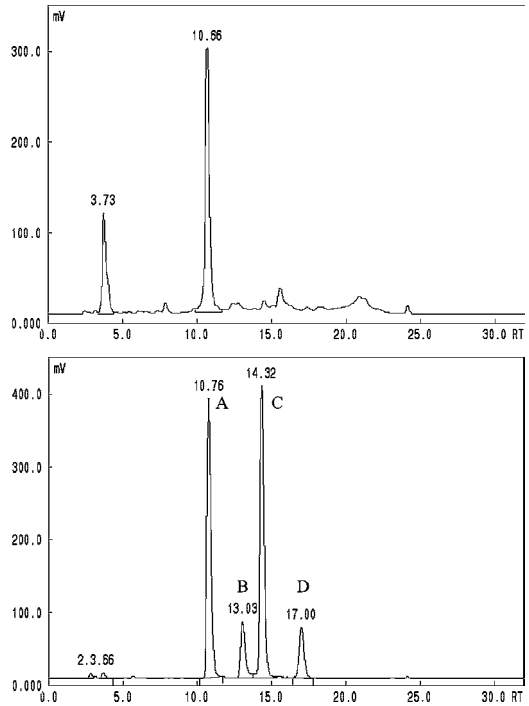


Figure 2. Typical radio-HPLC chromatograms of macrocyclic complexes [^{99m}Tc(L1)(tricine)] (top) and [^{99m}Tc(L2)(tricine)] (bottom).

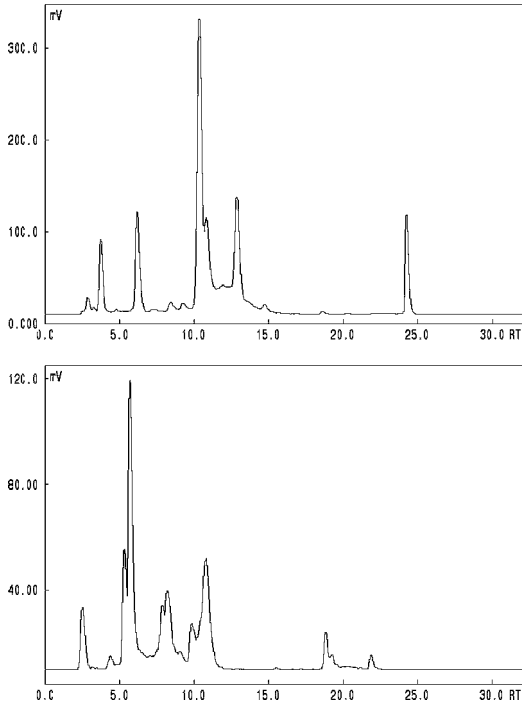

Figure 3. Radio-HPLC chromatograms of ^{99m}Tc complexes [^{99m}Tc(L3)(tricine)$_2$] (top) and [^{99m}Tc(HYNIC−(ω-Boc)K)-(tricine)$_2$] (bottom).

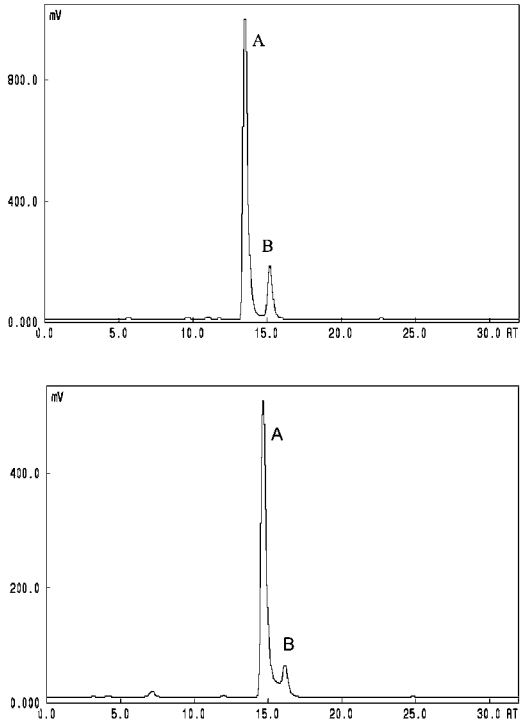

Figure 4. Typical radio-HPLC chromatograms for macrocyclic complexes [^{99m}Tc(L4)(tricine)] (top) and [^{99m}Tc(L5)(tricine)] (bottom).

The radio-HPLC chromatogram of [^{99m}Tc(L2)(tricine)] (Figure 2) shows two pairs of radiometric peaks. The peak ratio of (A + D) over (B + C) is always close to 50%:50%. The relative peak ratios remain constant over 6 h postlabeling. Apparently, the pyridine-N in L2 is bonded to the Tc and forms a macrocyclic Tc chelate ring, and the position for attachment of the linker is critical for both the formation of macrocyclic Tc chelate and the number of isomeric forms of the resulting ^{99m}Tc complex

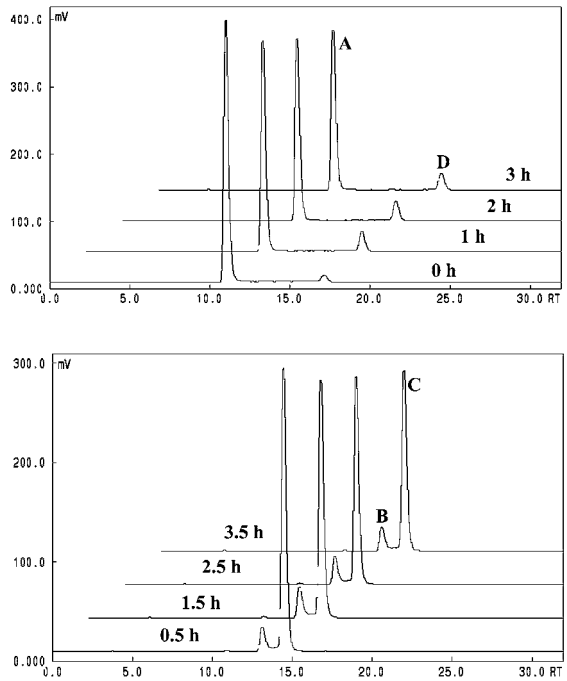

Figure 5. Conversion from A to D (top) and C to B (bottom) for the macrocyclic complex [^{99m}Tc(L2)(tricine)] at room temperature.

in solution. The 3-position seems to be the best for attachment of the lysine linker.

Isomerism in Macrocyclic ^{99m}Tc Complexes. In ternary ligand ^{99m}Tc complexes [^{99m}Tc(HYNIC−BM)-(tricine)(L)] (BM = biomolecules; L = phosphines and pyridine analogues), there are always two diastereomers due to the asymmetric bonding of the tricine coligand, if the targeting biomolecule contains one or more chiral centers. That often leads to the observation of two radiometric peaks in their radio-HPLC chromatograms (*5*−*10*). There are two pairs of radiometric peaks in the HPLC chromatogram of [^{99m}Tc(L2)(tricine)]. Apparently, the chiral center in the lysine linker plays a significant role for the presence of these two pairs of isomers.

To prove this assumption, we prepared L4 and L5, which contain no chiral centers on the linker. Macrocyclic complexes [^{99m}Tc(L4)(tricine)] and [^{99m}Tc(L5)(tricine)] were prepared in the same fashion as [^{99m}Tc(L2)(tricine)]. Figure 5 shows radio-HPLC chromatograms of [^{99m}Tc(L4)-(tricine)] and [^{99m}Tc(L5)(tricine)]. Only two isomers are detectable if the linker contains no chiral centers. This experiment clearly demonstrates that [^{99m}Tc(L2)(tricine)] exists in solution as a pair of diastereomers (A and C or B and D) and a pair of conformational isomers (A and D or B and C).

How do we know that A and D or B and C are conformational isomers in the complex [^{99m}Tc(L2)(tricine)]? To answer that question, we isolated A and C and studied their relationship with the other two peaks. Peaks A and C were separated by HPLC into two separate flasks. After removal of volatiles, the residue in each flask was redissolved in saline to give a concentration of 2 mCi/mL. The resulting solutions were analyzed by HPLC every 30 min over 4 h. Figure 5 shows "staggered" HPLC chromatograms for A and C. At room temperature, part of A was rapidly converted to D while part of C was converted to B. There is no conversion from A to C or C to A. The conversion from A to D or B to C suggests that A and D or C and B are most likely conformational isomers due to restricted rotations of the macrocycle.

Table 1. LC−MS Data for Macrocyclic ^{99m}Tc Complexes

[^{99}Tc(L5)(tricine)], B	$C_{24}H_{33}N_7O_7Tc$	630.47	630.2

The fast rate of conversion from A to D and from C to B is significant. In our previous communication (*17*), we found that the major isomer of [^{99m}Tc(HYNIC−Ko-TPPB)-(tricine)] remained relatively unchanged at room temperature and was converted to the other two isomers only at elevated temperatures (>50 °C). Compared to the triphenylphosphine moiety, the pyridine group is much smaller. The energy barrier between different conformational isomers is much lower than that in [^{99m}Tc(HYNIC−Ko-TPPB)(tricine)]. It is not surprising that A is able to convert to D (or C to B) and to reach equilibrium within 3 h even at room temperature.

To further support these hypothesis, we used LC−MS to determine the composition of each isomer of complexes [^{99m}Tc(L)(tricine)] (L = L2, L4, and L5) at the tracer level. The LC−MS data are listed in Table 1. Due to the extremely low concentration, determination of the composition for the smaller peaks {B and D of [^{99m}Tc(L2)-(tricine)] and B of [^{99m}Tc(L4)(tricine)] and [^{99m}Tc(L5)-(tricine)]} was not possible at the tracer level. Therefore, we prepared ^{99}Tc complexes [^{99}Tc(L)(tricine)] (L = L2, L4, and L5) at the milligram level. The composition of all the isomers in the macrocyclic complexes [^{99}Tc(L)(tricine)] (L2, L4, and L5) has been determined. The LC−MS data for macrocyclic ^{99}Tc complexes are listed in Table 2 and are completely consistent with the proposed composition for macrocyclic ^{99m}Tc complexes [^{99m}Tc(L)(tricine)]. All four isomers of [^{99}Tc(L2)(tricine)] have the same molecular weight at $m/z = 674$ for $[M + H]^+$. Both isomers of [^{99}Tc(L)(tricine)] (L = L4 and L5) also have the same molecular weight at $m/z = 616$ for [^{99}Tc(L4)(tricine)] and $m/z = 630$ for [^{99}Tc(L5)(tricine)]. These results clearly show that the presence of four peaks in the radio-HPLC chromatogram of [^{99m}Tc(L2)(tricine)] is indeed due to resolution of four different isomers. The formation of these four isomers is in part due to the presence of chirality in the lysine linker and in part due to the restricted rotation of the macrocyclic Tc chelate ring.

Linker Length and Isomerism in Macrocyclic ^{99m}Tc Complexes. In ternary ligand ^{99m}Tc complexes, [^{99m}Tc(HYNIC−BM)(tricine)(L)] (L = pyridine analogues), HYNIC is most likely monodentate due to the presence of the tricine and monodentate pyridine coligands (*10*). However, the HYNIC group in [Tc(L)(tricine)] (L = L2, L4, and L5) may be forced to become bidentate (Figure 6) due to the bonding of pyridine-N. The tridentate tricine may result in formation of many different coordination isomers due to its asymmetric nature in bonding to the Tc. If that were true, the coordinated tricine would have been much more fluxional and there would have been a rapid exchange among all four isomers (A, B, C, and D). The fact that there is no conversion from A to C or C to A is not consistent with this explanation. Therefore, HYNIC is most likely to be monodentate in [Tc(L)-(tricine)] (L = L2, L4, and L5).

There are several ways to minimize the number of conformational isomers. These include (1) increasing the linker length so that the macrocycle can rotate freely and (2) reducing the linker length in such a way that only one conformational isomer is possible. We prepared HYNIC−en-NIC to see if the use of the 1,2-ethylenediamine linker would result in the reduction of isomerism. Unfortunately, the ethylenediamine linker is too short for the pyridine-N of the nicotinyl group to bond to the Tc (unpublished data). The minimum linker length seems to be C4−C5 or an equivalent. In this study, we prepared L5 using a hexamethylenediamine linker. In doing so, we were able to reduce the percentage of the minor isomer B from ~10% for [^{99m}Tc(L4)(tricine)] to only ~6% for [Tc(L5)(tricine)]. However, we were not able to totally eliminate the minor conformational isomer at ~16 min (Figure 4).

Solution Stability of Macrocyclic ^{99m}Tc Complexes. We examined the solution stability of the macrocyclic complex [^{99m}Tc(L2)(tricine)] in the kit matrix. The stability was assessed by radio-HPLC by performing six injections over 6 h. Figure 7 shows the plot of RCP versus time for [^{99m}Tc(L2)(tricine)]. There is no significant RCP change over 6 h, suggesting that [^{99m}Tc(L2)(tricine)] is stable in the kit matrix for at least 6 h. We also examined the solution stability of the HPLC-purified [^{99m}Tc(L2)-(tricine)]. Peaks A and C were collected into separate flasks. After removal of volatiles under vacuum, the residue was dissolved in saline. The solution was then monitored by radio-HPLC. It was found that [^{99m}Tc(L2)-(tricine)] remains stable for at least 4 h at room temperature after HPLC purification (Figure 5). There is no indication of any significant decomposition during this period of time, suggesting that [^{99m}Tc(L2)(tricine)] is

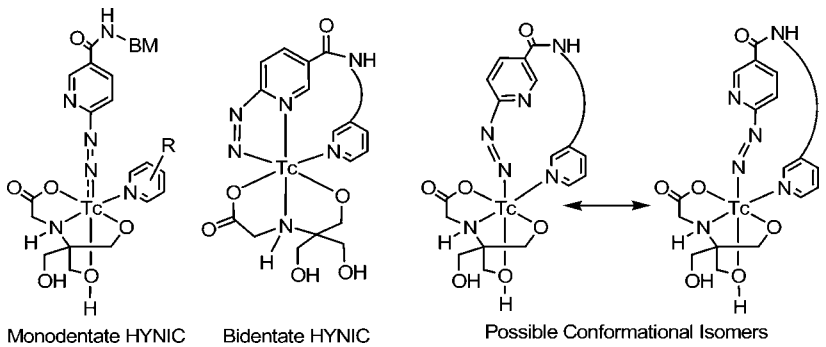

Figure 6. Possible structures for macrocyclic complexes [^{99m}Tc(L)(tricine)] (L = L2, L4 and L5).

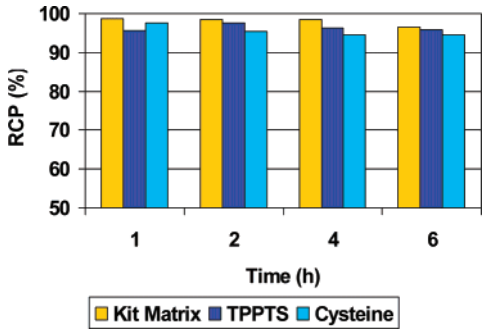

Figure 7. Solution stability of the complex [^{99m}Tc(L2)(tricine)] in the matrix and in the presence of TPPTS (1 mg/mL) or cysteine (1 mg/mL).

Table 3. Radiolabeling Yield for the Macrocyclic Complex [^{99m}Tc(L2)(tricine)]

L2 level (μg)	amount of $^{99m}TcO_4^-$ (mCi)	average % yield
1	30	94.8
2	30	95.6
4	30	96.8
5	30	98.8
10	30	98.8

highly stable, since the decomposition of the ^{99m}Tc complex often leads to formation of $^{99m}TcO_4^-$.

For the TPPTS and cysteine challenge experiments, we added TPPTS and cysteine (1 mg/mL: $2-5 \times 10^{-3}$ M) into solutions containing [^{99m}Tc(L2)(tricine)]. It was found that the addition of TPPTS or cysteine caused minimal changes in the radiochemical purity over 6 h at room temperature (Figure 7). The fact that [^{99m}Tc(L2)-(tricine)] remains intact in the presence of a large excess (10^7-fold) of TPPTS is significant, because TPPTS is a much stronger ligand than pyridine analogues (*10*). This suggests that the ligand exchange reaction is not dependent on the concentration of the entering ligand, and dissociation of pyridine-N is most likely the rate-limiting step. Therefore, the high solution stability of [^{99m}Tc(L2)-(tricine)] is probably due to its kinetic inertness. Similar results were also obtained for ternary ligand ^{99m}Tc complexes [^{99m}Tc(HYNIC−BM)(tricine)(L)] (L = pyridine analogues) (*10*) and the macrocyclic ^{99m}Tc complex [^{99m}Tc-(HYNIC−Ko-DPPB)(tricine)] (*17*).

Radiolabeling Efficiency. We examined the radiolabeling efficiency of L2 by varying the L2 concentration in the formulation matrix from 1 to 10 μg/mL for 30 mCi of $^{99m}TcO_4^-$. The tricine concentration remained the same in all cases. Each condition was carried out in duplicate and the yield was reported as the average of two vials. The radiolabeling yield was calculated as the total percentage of all four peaks (A, B, C, and D), and is summarized in Table 3. It is clear that [^{99m}Tc(L2)(tricine)] could be prepared in high yield (>95%) using 1 μg of L2 for 30 mCi of $^{99m}TcO_4^-$, corresponding to the molar ratio of 8:1 for L2:^{99m}Tc.

The fact that the pyridine-N atoms in L2, L4, and L5 are able to bond to the Tc and form the macrocyclic Tc chelate is truly amazing. Traditionally, it is often believed that for the chelator to form a stable metal chelate, the number of atoms in each chelate ring is ether five or six. Chelate rings containing more than six atoms often result in less stability. The number of atoms between the β-N of HYNIC and pyridine-N of the nicotinyl group is more than 18 in macrocyclic complexes [^{99m}Tc(L)(tricine)] (L = L2, L4, and L5), but these macrocyclic complexes are formed with high stability and extremely high radiolabeling efficiency.

There are several factors contributing to the high solution stability of macrocyclic complexes [^{99m}Tc(L)-(tricine)] (L = L2, L4, and L5). The pyridine-containing HYNIC chelators (L2, L4, and L5) are designed in such a way that when HYNIC binds to the Tc center, the "effective concentration" of the attached pyridine-N donor in the vicinity of Tc will be increased dramatically. This makes it much easier for the pyridine-N donor to bond to the Tc and form a macrocyclic ^{99m}Tc chelate. Of course, the linker length and the attachment site on the pyridine ring have to be appropriate for metal binding, as demonstrated in this study. Once the pyridine-N donor binds to the Tc and completes the octahedral coordination sphere, it is hard for the pyridine-N to become dissociated, since six-coordinated Tc(III) complexes are often kinetically inert (*11*). This is supported by the fact that [^{99m}Tc(L2)(tricine)] remains intact in the presence of a large excess (10^7-fold) of TPPTS while the corresponding ^{99}Tc analogue, [^{99}Tc(L2)(tricine)], remains stable in aqueous solution for 2−3 weeks without any significant decomposition.

Since Abrams and co-workers first reported the use of organic hydrazines as BFCs for the ^{99m}Tc-labeling of polyclonal IgG (*19*, *20*), HYNIC has been used for ^{99m}Tc-labeling of a variety of biomolecules for the development of target-specific radiopharmaceuticals. These include antibodies (*19*−*22*), chemotactic peptides (*23*−*26*), somatostatin analogues (*27*−*32*), liposomes (*33*), antisense oligonucleotides (*34*, *35*), and a folate receptor ligand (*36*). It is well-documented that the ^{99m}Tc-labeled HYNIC−protein conjugates have very high solution stability (*19*−*22*), while the ^{99m}Tc-labeled small biomolecule−HYNIC conjugates are not stable and exist in solution as a mixture of multiple species if tricine or glucoheptonate is used as coligand (*1*, *5*, *14*, *27*, *31*). We are also puzzled by the high level of blood activity for ^{99m}Tc-labeled HYNIC conjugates of small biomolecules, including somatostatin analogues (*27*, *31*) and oligonucleotides (*34*, *35*). Results from this study provide a reasonable explanation of these observations.

Proteins, including antibodies and antibody fragments, contain histidine residues. When the HYNIC group bonds to the Tc, the imidazole-N from a nearby histidine residue may be able to coordinate to the Tc and form an "intramolecular" macrocycle, which is kinetically inert toward further ligand exchange with other chelators. As a result, the ^{99m}Tc-labeled HYNIC−protein conjugates often show high in vitro and in vivo stability. On the other hand, small biomolecules often contain no histidine residues and are not able to form the "intramolecular" macrocycle. When tricine is used as the coligand, the HYNIC−BM conjugates will form binary ligand complexes [^{99m}Tc(HYNIC−BM)(tricine)$_2$], which are not stable and exist as multiple species in solution. Once the binary ligand complex [^{99m}Tc(HYNIC−BM)(tricine)$_2$] is injected into the biological system, it may react with the imidazole group of the histidine residue from circulating blood proteins such as albumin. The serum protein binding capability is most likely responsible for the high blood activity levels of ^{99m}Tc-labeled HYNIC−BM conjugates.

CONCLUSIONS

In this study, we report the synthesis of several pyridine-containing derivatives (L1−L5) and their ^{99m}Tc complexes. Preliminary results have demonstrated that the attachment site of the linker on the pyridine ring is critical for the formation of macrocyclic ^{99m}Tc complexes. For example, the pyridine-N in L3 is not able to bond to

the Tc because the lysine linker is at the 4-position. If the lysine linker is at the 2-position, L1 is able to form the macrocyclic complex [^{99m}Tc(L1)(tricine)], but the radiochemical purity is low. When the lysine linker is attached to the 3-position of the pyridine-N, L2 is able to form the macrocyclic complex [^{99m}Tc(L2)(tricine)] in high yield (>95%). The radio-HPLC data suggest that [^{99m}Tc(L2)(tricine)] exists in solution as four isomers: two diastereomers and two conformational isomers. Diastereomers are formed due to the chirality of the lysine linker and the Tc chelate. Replacing lysine with a pentamethylenediamine linker results in the macrocyclic complex [^{99m}Tc(L4)(tricine)] with only two conformational isomers, which interconvert rapidly at room temperature. Changing the linker from pentamethylenediamine to hexamethylenediamine did not completely eliminate the minor isomer, but the percentage of the minor isomer was reduced from ~10% for [^{99m}Tc(L4)(tricine)] to only 6% for [^{99m}Tc(L5)(tricine)]. The LC−MS data for complexes [^{99m}Tc(L)(tricine)] (L2, L4, and L5) are completely consistent with the proposed composition.

On the basis of these results, it is concluded that pyridine-containing HYNIC chelators have the potential as bifunctional chelators for ^{99m}Tc-labeling of small biomolecules, if the linker is attached to the 3-position of the pyridine ring. Although L2 is able to form the macrocyclic ^{99m}Tc complex in high yield (>95%) and high radiolabeling efficiency, it is not ideal as a BFC for the ^{99m}Tc-labeling of small biomolecules, mainly due to the presence of two diastereomers and two conformational isomers. Our ultimate goal is to develop a chelating system that forms the macrocyclic ^{99m}Tc complex with only diastereomers or more preferably without isomerism.

Amphiphilic Corroles Bind Tightly to Human Serum Albumin

Atif Mahammed,[†] Harry B. Gray,*[,‡] Jeremy J. Weaver,[‡] Karn Sorasaenee,[‡] and Zeev Gross*[,†]

Department of Chemistry and Institute of Catalysis Science and Technology, Technion - Israel Institute of Technology, Haifa 32,000, Israel, and Department of Chemistry and Beckman Institute, California Institute of Technology, Pasadena, California 91125. Received September 30, 2003; Revised Manuscript Received May 3, 2004

Amphiphilic 2,17-bis-sulfonato-5,10,15(trispentafluorophenyl)corrole (**2**) and its Ga and Mn complexes (**2-Ga** and **2-Mn**) form tightly bound noncovalent conjugates with human serum albumin (HSA). Protein-induced changes in the electronic absorption, emission, and circular dichroism spectra of these corroles, as well as results obtained from HPLC profiles of the conjugates and selective fluorescence quenching of the single HSA tryptophan, are interpreted in terms of multiple corrole:HSA binding sites. High-affinity binding sites, close to the unique tryptophan, are fully occupied at very low concentrations. At biologically relevant HSA concentrations (2−3 orders of magnitude larger than those employed in our studies), all corroles (**2**, **2-Ga**, and **2-Mn**) may be considered as fully conjugated.

INTRODUCTION

The bioinorganic chemistry of porphyrins is a broad field, ranging from natural to completely synthetic systems. The field also includes work on a large variety of porphyrin-like molecules (porphyrinoids), such as the chlorophyll-related chlorins and bactereochlorins as well as completely synthetic phthalocyanines and expanded porphyrins (*1, 2*). A great deal of research has been devoted to the interactions of porphyrinoids with biomolecules, owing to their tendency to accumulate in cancer cells and to intercalate DNA (*3, 4*). Surprisingly, although corroles have been known for almost four decades (*5, 6*), there has been very little work on their interactions with biological molecules. This situation does not reflect a lack of interest in these tetrapyrrolic macrocycles (they are related to the cobalt-chelating corrin in vitamin B_{12} by virtue of an identical carbon skeleton and to porphyrins by being fully conjugated), but only because their syntheses heretofore have been long and tedious. This situation has recently changed in dramatic fashion: facile synthetic methodologies have been introduced during the last 5 years, allowing for the preparation of more than 100 new corroles (*7*−*17*); transition metal complexes (Cr, Mn, Fe, Rh) of the most extensively investigated derivative (tris(pentafluorophenyl)corrole, **1**) function as versatile catalysts for a variety of organic reactions (*18*−*22*); and the Ga^{III} and Al^{III} complexes of corrole **1** are highly fluorescent, with quantum yields (0.37 up to 0.76) that exceed those of all other porphyrinoids (*23, 24*). In addition, it has been discovered recently that electrophilic substitution of **1** offers a facile and highly selective synthetic method for the preparation of corroles with polar headgroups located in only one-half of the macrocycle (amphiphilic corroles) (*25, 26*). This finding is key for the utilization of corroles in biological systems, since amphiphilic porphyrinoids have been shown to be the molecules of choice for many applications (*27*−*29*).

As the most abundant protein in blood plasma, human serum albumin (HSA) plays a role in many biological processes (*30*−*32*). Available are high-resolution X-ray structures of HSA as well as information about its binding affinities to many natural and synthetic molecules (*33*). However, with the exception of one preliminary report, there are no X-ray structures of HSA conjugates with any porphyrinoid or related macrocyclic molecule (*34*). Accordingly, information about noncovalent binding of porphyrinoids to HSA comes from data acquired by spectroscopic methods (*35*). Selected results from such investigations are set out in Table 1 (*36*−*45*).

In many cases, the conclusions about the number of binding sites and the association constants are based on a limited number of spectroscopic measurements, a likely reason for the significant scattering in published results that is evident from inspection of rows 6−9. Nevertheless, it is clear that only negatively charged porphyrinoids associate with HSA, and, in most cases, the protein has one well-defined high-affinity site and several other lower-affinity sites (*42*). Another important finding is the inverse relationship between the association constants and the number of charged groups. The strongest association to HSA occurs with porphyrinoids that contain only two carboxylato or sulfonato groups located on the pyrrole, benzopyrrole, or phenyl rings. Intriguingly, these dipolar and amphiphilic molecules are also the most active derivatives in photodynamic therapy. A major drawback, however, is that porphyrins or phthalocyanines with a limited (less than four) number of polar headgroups are not readily accessible, as illustrated by the bis-sulfonated phthalocyanines that are obtained and used as a mixture of at least eight nonseparable isomers, even after separation of derivatives with a different degree of sulfonation (*46*). In sharp contrast to all other synthetic porphyrinoids, the amphiphilic 2,17-bis-sulfonato-5,10,15(trispentafluorophenyl)corrole (**2**) with its two precisely located sulfonate groups can be obtained in very simple synthetic steps from readily available starting materials (Scheme 1) (*25, 26*). Accordingly, we decided to investigate the association of **2** and its gallium(III) and manganese(III) complexes (**2-Ga**, and **2-Mn**, respectively) to HSA as a first step toward utilization of corroles in bioinorganic applications. Employing several complementary physical methods, we have found that all three corroles form noncovalent conjugates with HSA. The binding affinities of these conjugates decrease ac-

Scheme 1

cording to **2** ≤ **2-Ga** < **2-Mn**. It is apparent that corrole **2** and its metal complexes will be fully bound to HSA under physiological conditions; accordingly, any biological activity observed for these molecules likely will be attributable to their protein conjugates.

EXPERIMENTAL PROCEDURES

Chemicals. Preparations of corrole **2** and its metal complexes are described in previous publications (*25*, *26*). HSA was purchased from Sigma (essentially fatty acid free, catalog no. A 1887) and used as received. Throughout these studies, 0.1 M phosphate buffer solutions of pH 7.0 were used. The extinction coefficients of the corroles under these conditions are as follows: **2**: ϵ (414 nm) = 71000 M^{-1} cm^{-1}; **2-Ga**: ϵ (424 nm) = 75000 M^{-1} cm^{-1}; **2-Mn**: ϵ (422 nm) = 21000 M^{-1} cm^{-1}; and for HSA, ϵ (280 nm) = 37400 M^{-1} cm^{-1}. Importantly, perfectly linear plots of OD vs corrole concentration were obtained in the range of 10^{-6} to 10^{-4} M, ruling out self-aggregation phenomena at the concentrations that were used in these studies. Further support for this conclusion comes from the practically identical extinction coefficients measured in aqueous and polar organic solvents (CH_3CN, MeOH).

Electronic Spectroscopy. UV/Vis absorption measurements were performed on a HP8452A diode array spectrophotometer, using 3 mL of corrole solutions at $2-10 \times 10^{-5}$ M and adding either microliter portions of HSA solution or milligram amounts of solid HSA.

Emission Spectroscopy. The fluorescence of HSA or the corroles was measured on an AB2 Luminescence Spectrometer. For titration of HSA's fluorescence, microliter portions of concentrated corrole solutions were added to 3 mL solutions of HSA wherein the absorbance at the excitation wavelength of 280 nm was less than 0.15. For titration of **2** or **2-Ga**, either microliter portions of a concentrated HSA solution or milligram amounts of solid HSA were added to 3 mL solutions of the corroles until no further changes in the emission intensity occurred.

Circular Dichroism Spectroscopy. CD spectra were recorded in the visible range on an Aviv model 62A DS Circular Dichroism Spectrometer using 3 mL of corrole solutions at $2-10 \times 10^{-5}$ M and adding either microliter portions of concentrated HSA solution or milligram amounts of solid HSA. UV−CD spectra were recorded using an HSA concentration of 1.8×10^{-6} M (in a 4-mm cuvette) and 3.7×10^{-6} M (in a 10-mm cuvette) with varying ratios of **2-Ga**.

Reversed Phase HPLC. HPLC analyses were performed on Merck Hitachi HPLC linear gradient using LiChrospher 100, a RP-18 column (5 μm, 4 × 125 mm), and a flow rate of 1 mL/min. The mobile phase was 100% water at time zero, turning to 100% acetonitrile within 15 min, continued for 5 min with acetonitrile only, turning back to 100% water within another 15 min, and continued for 10 min with water only. Eluted components were monitored spectrophotometrically at 436, 426, and 486 nm for **2**, **2-Ga**, and **2-Mn**, respectively, wavelengths at which the absorbances of free and conjugated corroles are identical. An initial concentration of [HSA] = 2.5×10^{-4} M was used for experiments at [HSA]:[corrole] ratio of 5:1 and [corrole] = 5×10^{-5} M for the [HSA]:[corrole] ratio of 1:5 experiments. The cells were made of quartz with a 10 mm path length.

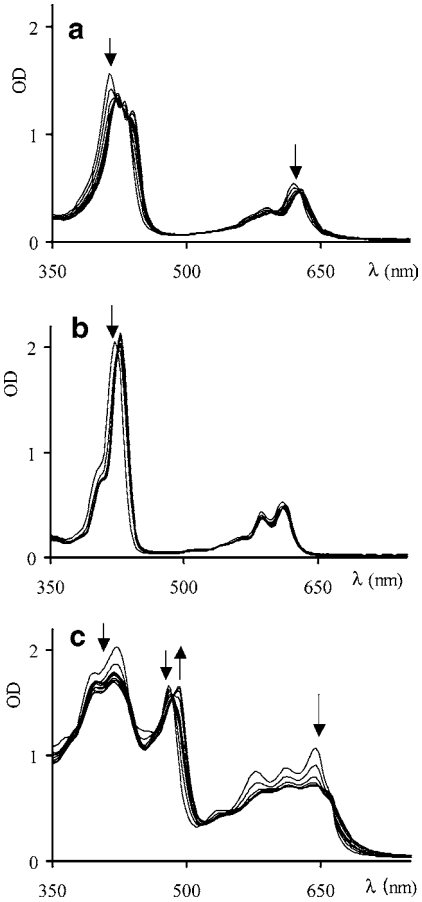

Figure 1. Changes in the UV−vis spectra of corrole **2** (a) and its metal complexes **2-Ga** (b), and **2-Mn** (c), upon titration with increasing amounts of HSA. [**2**] = 2.2 × 10^{-5} M, [**2-Ga**] = 2.7 × 10^{-5} M, [**2-Mn**] = 10^{-4} M; [HSA] = 0−10^{-4} M.

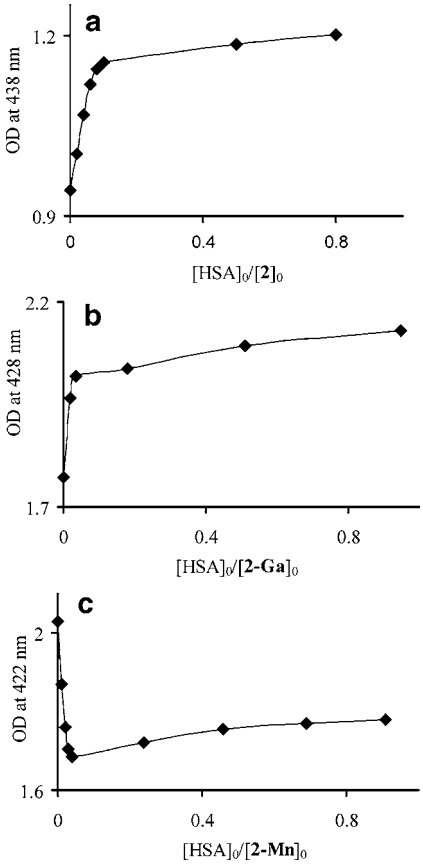

Figure 2. UV-vis spectral changes at selected wavelengths as a function of the [HSA]:[corrole] ratio for (a) **2**, (b) **2-Ga**, and (c) **2-Mn**.

RESULTS AND DISCUSSION

Binding of Corroles to HSA. Electronic spectra of corroles when treated with increasing amounts of HSA are shown in Figure 1. For **2** and **2-Ga**, respective shifts of the Soret bands from 416 to 424 nm and from 424 to 430 nm are observed. For metal-free **2**, this effect could indicate changes in the protonation state of the inner N_4 core from triply to doubly protonated. The pK_a for this process has been determined to be 5.2 in water (*47*), and it might be quite different in a more hydrophobic environment. We do not believe this explanation is correct: the changes in the Q-bands upon titration with HSA are very different from those observed upon NH-deprotonation of **2** in aqueous solutions (*47*), so the results are likely attributable to a "solvent effect" that would manifest itself in the interior of the protein. The same interpretation also accounts for the Soret shift of **2-Ga**. Spectral changes for **2-Mn** were most pronounced: most bands just decreased in intensity, but the 480 nm band was clearly replaced by a 492 nm band. It is known that this particular band (No. V in manganese(III) porphyrins) is very sensitive to axial ligation. Adding imidazole to an aqueous solution of **2-Mn** gave almost the same spectrum as addition of HSA, suggesting the participation of histidine residues in the binding of this metal complex. In all three cases, there were no more spectral changes after the addition of about 1 equiv of HSA, suggesting very strong association. More detailed information was obtained by following the intensity changes at selected wavelengths (Figure 2). The majority of the intensity increase at 438 and 428 nm for **2** and **2-Ga**, respectively, is complete much before a 1:1 ratio is achieved, suggesting that there are multiple HSA binding sites for these corroles. This phenomenon is even more pronounced for **2-Mn**: the intensity at 422 nm decreases sharply up to a [HSA]:[**2-Mn**] ratio of 0.04 and increases slightly when a 1:1 ratio is approached. Taken together, the results clearly indicate that several corrole molecules associate with one protein and that redistribution takes place at higher [HSA]:[corrole] ratios in favor of the 1:1 conjugate. As the number of binding sites in protein−chromophore conjugates and the corresponding binding constants are frequently determined from Scatchard plots (*48*), we also attempted to do so. However, this method and the underlying equations require the presence of unbound chromophore, while our later indications show that there is no free corrole at the lowest concentrations that can be measured by UV−vis (10^{-6} M). Accordingly, none of the binding constants can be determined by UV−vis titrations.

Effect of HSA on Corrole Fluorescence. Binding of corroles to HSA can be quantified by monitoring the highly intense fluorescence of **2** and **2-Ga**, allowing experiments to be performed at significantly lower corrole concentrations. Another major advantage of fluorescence monitoring is that free and bound corroles might have different emission maxima and/or intensities. The differences in emission wavelengths of both **2** and **2-Ga** in the presence and absence of HSA are only a few nm, but the fluorescence intensities are very sensitive to the [HSA]:[corrole] ratio (Figure 3). These effects are further demonstrated for selected wavelengths in Figure 4: the initial fluorescence of **2** is reduced to less than 40% at a [HSA]:[**2**] ratio of 0.1:1 and it is 60% of the initial intensity at a 1:1 ratio. The results for **2-Ga** were

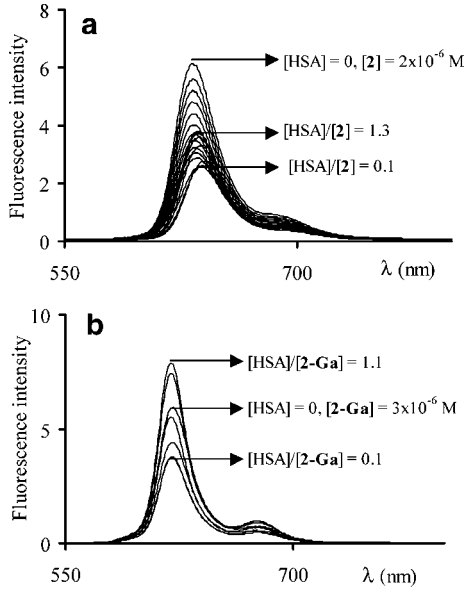

Figure 3. Emission spectra of corrole **2** (a, $\lambda_{exc} = 436$ nm) and **2-Ga** (b, $\lambda_{exc} = 426$ nm) as a function of added HSA.

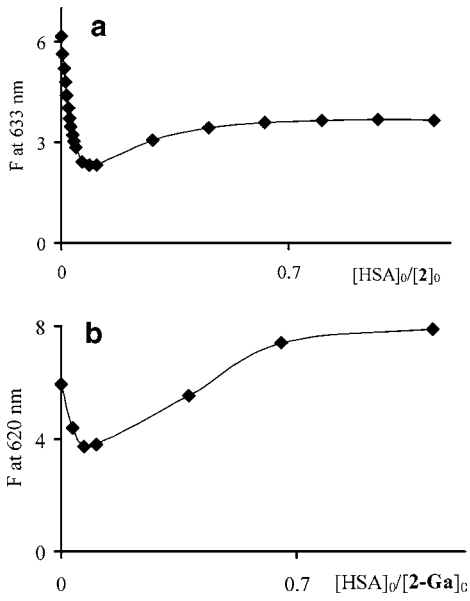

Figure 4. Fluorescence intensity at selected wavelengths of **2** (a) and **2-Ga** (b) as a function of the HSA:corrole ratio.

even more pronounced: about 40% reduction at a [HSA]:[**2-Ga**] ratio of 0.1:1 and 130% of the initial intensity at a 1.1:1 ratio. The latter phenomenon suggests that the extent of nonradiative decay of the excited state is lowered upon binding of the fluorophore to the protein (less degrees of freedom), reflected in increased fluorescence. Nevertheless, the intensity becomes lower when many corrole molecules are bound to the same protein because of self-quenching.

For quantitative elucidation of the dissociation constants (K_d) assigned to the high-affinity binding sites, the fluorescence intensities of equimolar conjugates were measured as a function of concentration, with the expectation of a nonlinear correlation if there is significant dissociation. However, a linear correlation was obtained in the range [**2-Ga**] = [HSA] = 2×10^{-6} to 4×10^{-8} M, thereby confirming that no significant dissociation takes place, even at very low (40 nM) conjugate concentrations.

Circular Dichroism (CD). CD spectra of corrole solutions as a function of HSA concentration are shown in Figure 5. Since HSA does not absorb visible light, the CD spectrum at long wavelengths ($\lambda > 360$ nm) can only be attributed to corrole interactions with the chiral environment of the folded protein. Intriguingly, the **2-Mn** CD signal (Figure 5c) is centered at around 490 nm, which is the region of the spectrum that is most sensitive to axial ligands. Moreover, the response to HSA addition is irregular, as can be seen from the shifts of λ_{max} and the inversion from negative to positive ellipticity at 482 nm. This phenomenon is amplified at 440 and 425 nm, respectively, in the spectra of **2** and **2-Ga** (Figure 5a,b). These data accord with the earlier conclusions about weak and strong binding sites, which in the present case is observed by redistribution of weakly bound corroles (under the conditions of [corrole] ≫ [HSA]) as the [corrole]:[HSA] ratio approaches 1:1. The results show that there are multiple chiral binding sites, albeit with significant differences in wavelengths and ellipticities.

CD spectra of HSA in the region 200−250 nm as a function of added **2-Ga** also were obtained to monitor possible changes of protein secondary structure in response to corrole binding (*49*). As can be seen in Figure 6, HSA gives rise to a strong CD signal at 222 nm, attributable to α-helical structures. The intensity of the signal drops as a function of the [**2-Ga**]:[HSA] ratio (0.4%, 1.1%, 1.5%, 2% at 1:1, 2:1, 3:1, and 4:1, respectively), and, at a ratio of 10:1, roughly 8% of helical structure is lost. Although there is some degree of conformational change, these corrole-induced perturbations of protein secondary structure are smaller than those observed for BSA−porphyrin conjugates (*48*).

HPLC of HSA:Corrole Conjugates. There are many precedents in which serum albumins are used to affect the retention time of ligands with which they interact strongly, including even the immobilization of BSA or HSA on HPLC stationary phases (*50*). However, we are not aware of any report about noncovalent conjugates of HSA remaining intact during HPLC separation. Apparently, under the high dilution conditions intrinsic to the experiment, most conjugates dissociate. Nevertheless, because of the aforementioned indications of extremely low dissociation constants of the noncovalent HSA/corrole conjugates, we decided to examine them by HPLC. Separate injections revealed that HSA is eluted much faster (1 min, indicative of negligible interaction with the solid phase) than any of the corroles (9−10 min) on the reversed-phase column. Next, HPLC chromatograms of premixed mixtures of HSA and the corroles were examined, setting the detector wavelength at $\lambda > 400$ nm (436, and 426, and 486 nm for **2**, **2-Ga**, and **2-Mn**, respectively) as to determine if the eluted HSA fractions contain bound corrole. The results shown in Figure 7 clearly demonstrate the following phenomena: the fastest eluting peak (at 1−2 min) corresponds to HSA-bound corrole, while the two later peaks (at ∼8 min and ∼9 min) to corrole that dissociated from HSA during chromatography (*50*). For an initial ratio of [HSA]:[corrole] of 5:1, the percentage of corrole that remained bound to HSA was 80, 70, and 40% for **2**, **2-Ga**, and **2-Mn**, respectively. (With 0.1 M phosphate buffer solutions of pH 7.0 instead of unbuffered water, the percentage of corrole that remained bound to HSA was 74, 66, and 46% for **2**, **2-Ga**, and **2-Mn**, respectively). This indicates that the relative dissociation constants (K_d) of the conjugates are in the order **2** ≤ **2-Ga** < **2-Mn**. Since an excess of HSA was used, we may safely assume that this trend reflects the K_d of particularly strong binding sites. This assumption was checked by the following experiments: injection of mixtures that contain an initial 1:5 ratio of

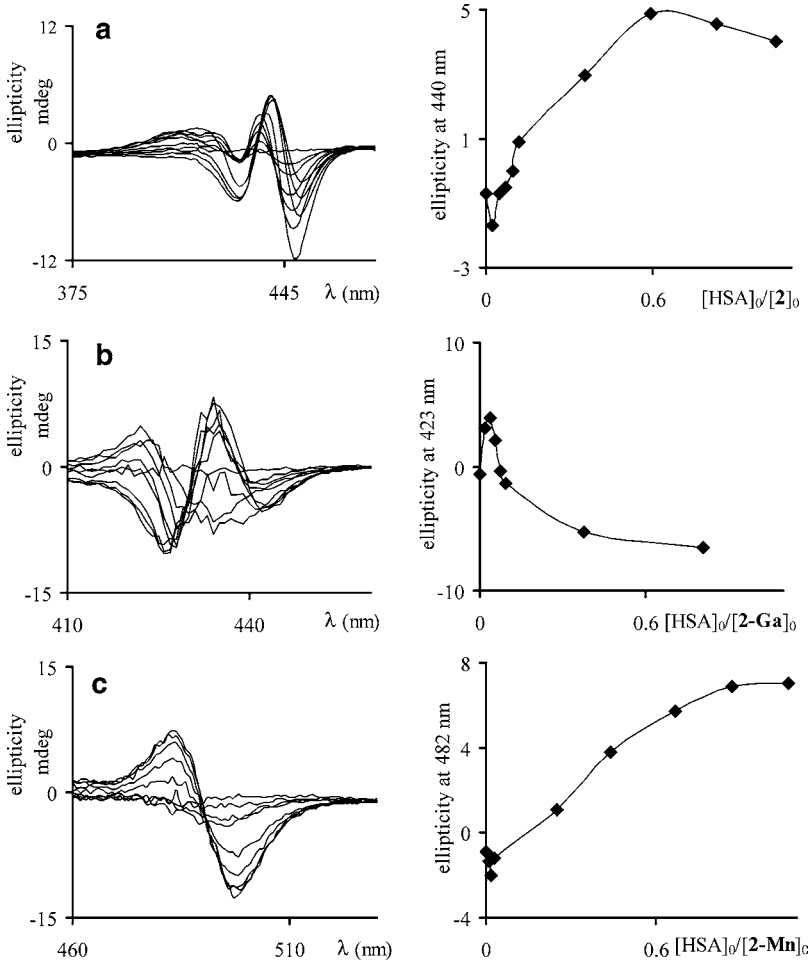

Figure 5. HSA titrations of (a) **2**, (b) **2-Ga**, and (c) **2-Mn**, followed by CD spectroscopy. [**2**] = 2.11 × 10^{-5} M, [**2-Mn**] = 10^{-4} M, [**2-Ga**] = 2.7 × 10^{-5} M; [HSA] = 0−10^{-4} M.

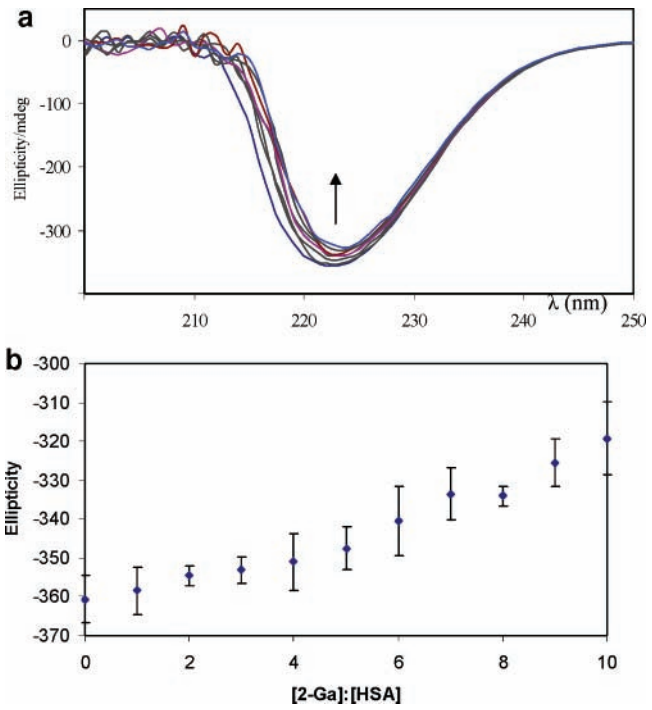

Figure 6. (a, b) CD spectra of HSA as a function of [**2-Ga**]:[HSA] (0, 1, 2...10) at constant [HSA] (3.7 × 10^{-6} M).

[HSA]:[corrole], isolation of the HSA containing fraction, and examination of the [HSA]:[corrole] therein by recording the full electronic spectrum and relying on the corresponding ϵ values. The results show that [HSA]:[corrole] ratios in the HPLC-eluted conjugates were 1:0.5, 1:0.4, and 1:0.2 for **2**, **2-Ga**, and **2-Mn**, respectively. Apparently, the final [HSA]:[corrole] ratio did not exceed 1:1 even with corrole in excess; thus, the K_d trend **2** ≤ **2-Ga** < **2-Mn** reflects only the high-affinity binding sites. Since hemin also has been reported to form a tight conjugate with HSA (K_d = 10^{-8} M), it also was analyzed by HPLC. At a [HSA]:[hemin] ratio of 5:1, 92% of hemin remained HSA-bound, and when the initial ratio of [HSA]:[hemin] was 1:5, the [HSA]:[hemin] ratio in the HPLC-eluted conjugates was 1: 0.5. All these results show that HPLC experiments provide a good tool for estimating noncovalent binding of porphyrinoids to proteins. Nevertheless, the acquired information must be considered as qualitative rather than quantitative, since other factors such as the water solubility of different porphyrinoids (hemin vs corrole in the current case) may affect the results significantly.

Quenching of Trp^{214} Emission. One of the earliest and simplest methods that was used for investigating hemin binding is fluorescence quenching of the single tryptophan residue (Trp^{214}) in HSA (*40*). The advantage of this approach is that it reports selectively on binding sites that are not too distant from the fluorophore. Results obtained by exciting HSA's Trp^{214} at 280 nm and recording its emission (λ_{max} = 340 nm) as a function of the concentration of **2-Ga** are shown in Figure 8a. Notably, full and selective quenching was achieved, as can be seen from the residual emission (λ_{max} = 310 nm) due to the many tyrosine residues that are present in

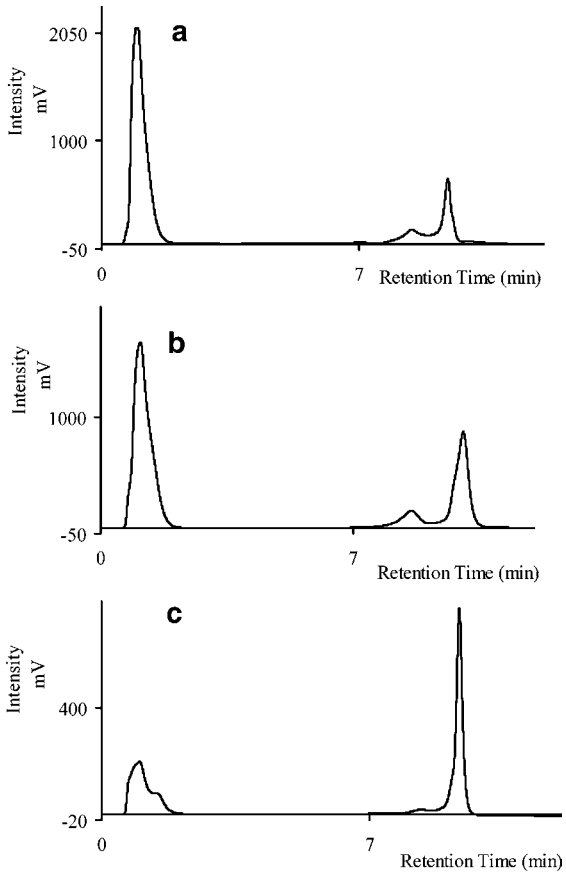

Figure 7. HPLC chromatograms of HSA conjugates (a) **2**, (b) **2-Ga**, and (c) **2-Mn**, ([HSA]$_0$ = 2.5 × 10^{-4} M, [corrole]$_0$ = 5 × 10^{-5} M) with the detector set at the wavelength where the absorbance of free and conjugated corroles are identical (436, 426, 486 nm for a, b, c).

HSA. More quantitative information was obtained from plots of fluorescence intensity as a function of the [HSA]:[corrole] ratio (Figure 8b). The responses (slopes) of **2** and **2-Ga** are practically identical, and that of **2-Mn** somewhat smaller. The up to 50% quenching at equimolar concentrations of HSA and corrole obtained in the first two cases implies that **2** and **2-Ga** occupy close to Trp^{214} binding sites with very high-affinity. If **2-Mn** also associates to similar binding sites, Figure 8b may be analyzed as reflecting an opposite relationship between the steepness of the slopes and the K_d of the HSA:corrole conjugates. This would lead to relative K_d from high-affinity sites in the order of **2** ∼ **2-Ga** < **2-Mn**, in line with the previously mentioned indications. The roughly 50% quenching at a 1:1 ratio between HSA and **2** or **2-Ga** may be interpreted either one of two limiting ways: 100% quenching efficiency by sites that are only 50% occupied (= large K_d) or 50% quenching efficiency by sites that are 100% occupied (= small K_d). Two sets of experiments were performed to distinguish between these possibilities. The first consisted of dilution experiments on 1:1 mixtures of HSA and the corroles. For all three corroles (data for **2-Ga** are shown in the inset of Figure 9) there was no deviation from linearity in the concentration vs fluorescence-intensity plots in the range 4 × 10^{-6} to 7 × 10^{-7} M (K_d < 10^{-8} M for the conjugates). Figure 9 shows the other set of experiments: measuring fluorescence intensity of HSA as a function of the relative amount of **2-Ga**, at four different absolute concentrations. The normalized plots are identical as long as the corrole is not in excess of HSA, clearly confirming the absence of any dissociation. The plots become different only after

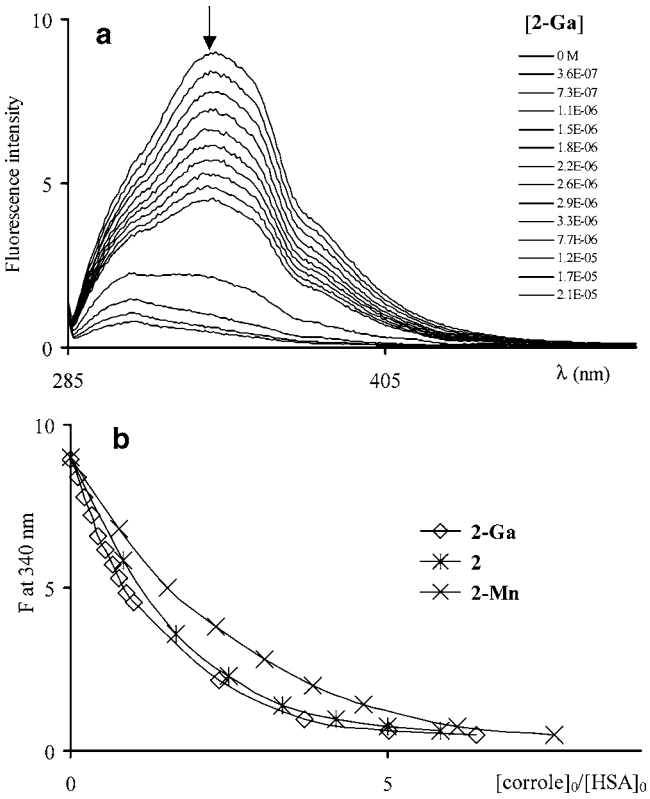

Figure 8. Quenching of the emission of HSA by (a) increasing amounts of **2-Ga** and (b) the dependence of the emission on the [corrole]/[HSA] ratio. λ_{exc} = 280 nm, [HSA] = 3.3 × 10^{-6} M.

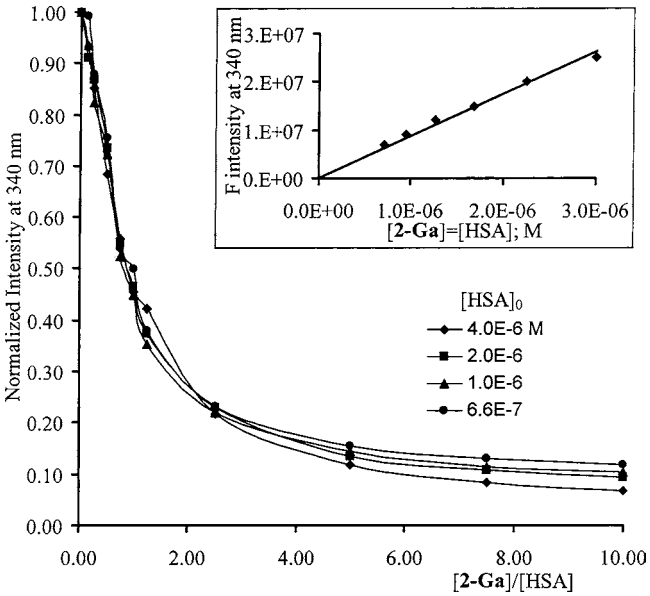

Figure 9. Normalized fluorescence intensity of HSA as a function of the [**2-Ga**]:[HSA] ratio at different initial concentrations of HSA. Inset: Fluorescence intensity at 340 nm of equimolar concentrations of **2-Ga** and HSA at different absolute concentrations.

the [**2-Ga**]:[HSA] is above 1, indicating the presence of slightly weaker secondary binding sites. Importantly, although a reliable measurement of K_d is problematic because of the large number of corrole molecules that can be accommodated by HSA, the trends of Figure 9 show that dissociation from weaker binding sites is very small as well. Therefore, the approximately 50% quenching seen at a 1:1 ratio between HSA and corrole is consistent with incomplete quenching of Trp^{214} fluorescence by corroles that occupy high affinity sites.

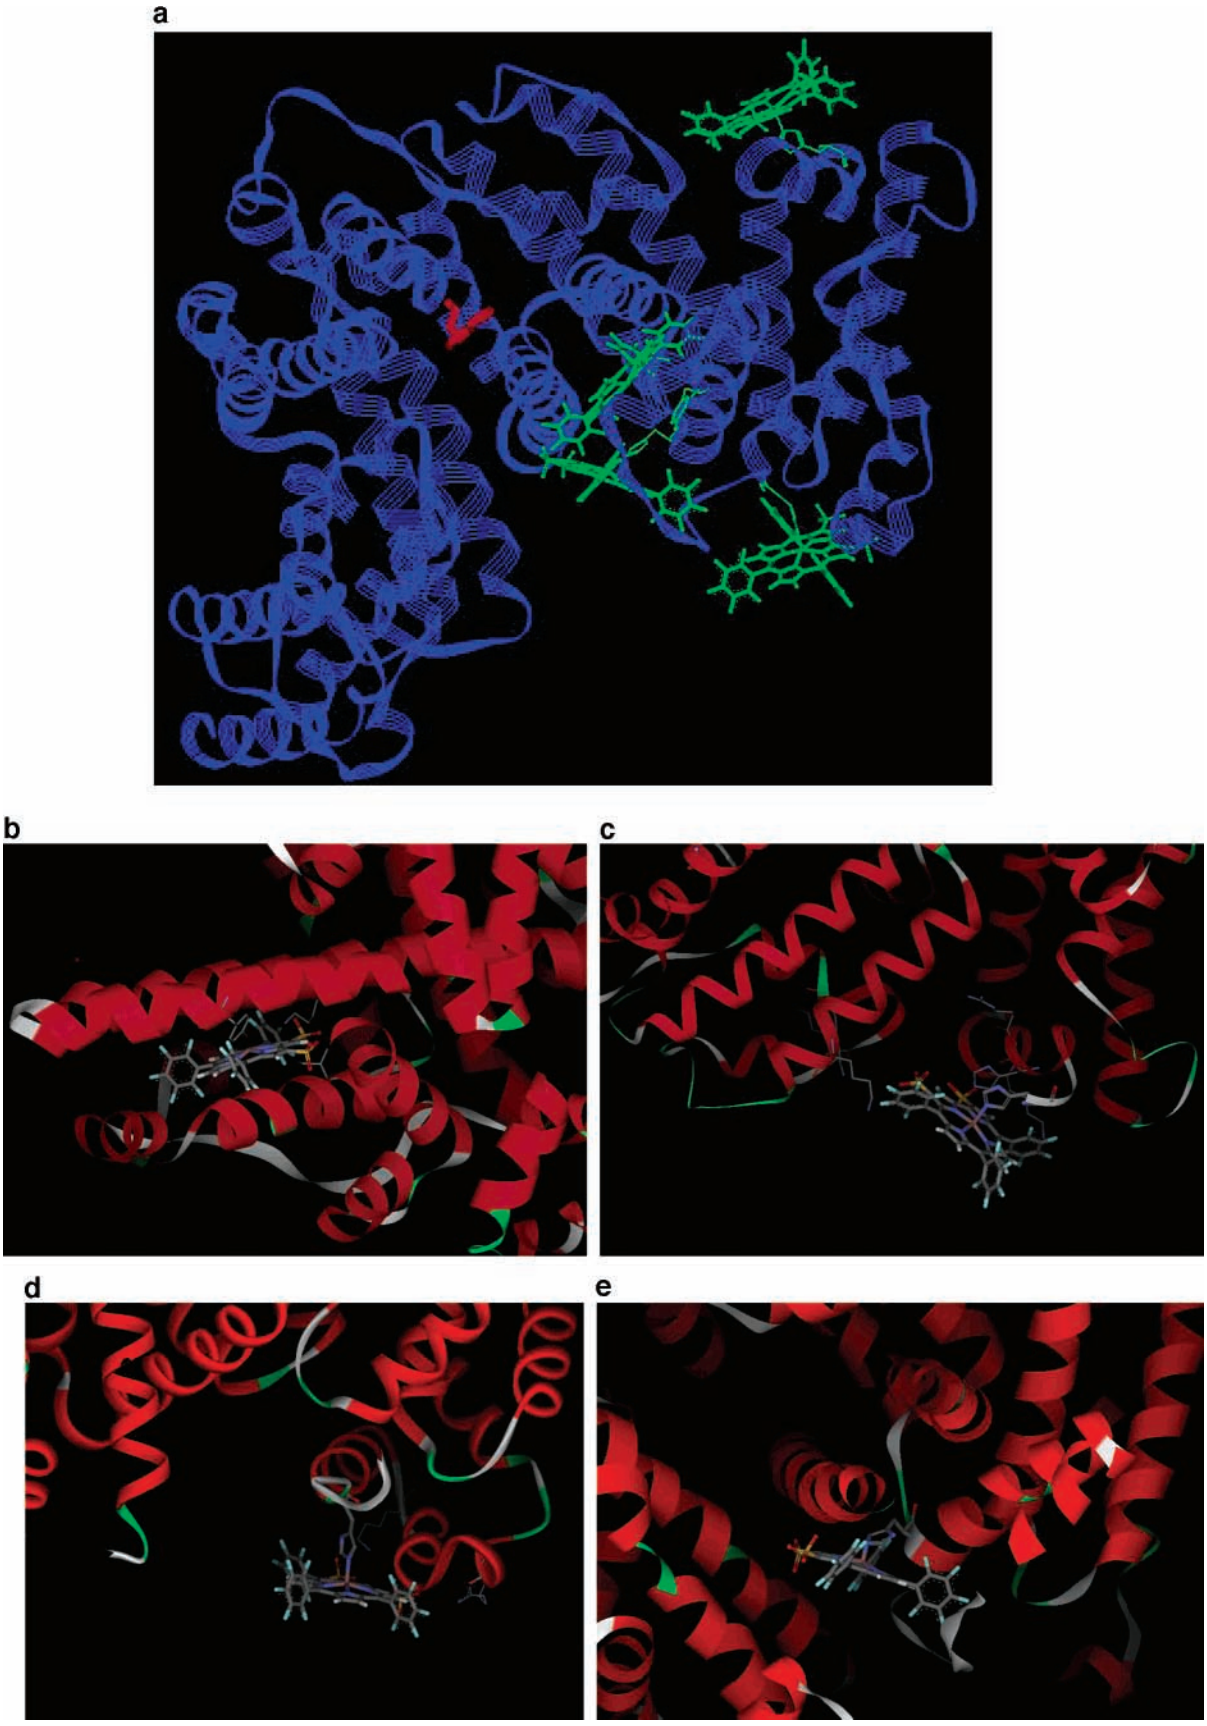

Figure 10. (a) Structural models depicting four potential binding sites for **2-Ga** to HSA. (b) **2-Ga** in place of the heme of methemalbumin. (c) **2-Ga** coordinated to His^{3}. (d) **2-Ga** coordinated to His^{105}. (e) **2-Ga** coordinated to His^{146}. The proposed locations were chosen as follows: one is the heme binding site; others are histidine binding sites whose positions are consistent with the Trp^{214} quenching experiments, except for e.

Binding Sites for 2-Ga. Since the three-dimensional structure of HSA is known, we have attempted to estimate the distance between Trp^{214} and a corrole binding site via standard Förster energy transfer equa-

tions, using the roughly 50% fluorescence quenching by **2-Ga**.

$$R_o^6 = 8.8 \times 10^{-5}(\kappa^2 n^{-4} \phi_o J) \quad (1)$$

$$J = \frac{\int_0^\infty F_o(\lambda) E_A(\lambda)\, \lambda^4 \mathrm{d}\lambda}{\int_0^\infty F_o(\lambda) \mathrm{d}\lambda} \quad (2)$$

Equations 1 and 2 were used for evaluation of the Förster distance (*51*, *52*), where J is the overlap between the luminescence spectrum of the donor and the absorption spectrum of the acceptor (weighted by λ^4), ϕ_o is the luminescence quantum yield in the absence of energy transfer, n is the refractive index, and κ is an orientation factor dependent on the alignment of the donor and acceptor dipoles ($\kappa^2 = 2/3$ for random alignment). According to the above expressions, our experimental data yielded a value for the overlap integral J between the fluorescence spectrum of the protein HSA and the absorption spectrum of the quencher **2-Ga** of 6.26×10^{14}. Based on the J value and eq 1, the Förster distance (R_o) between **2-Ga** and Trp^{214} (HSA) was calculated to be 30 Å. Moreover, models of the **2-Ga**−HSA conjugate based on crystallographic data for [Ga(tpfc)(py)] (tpfc = 5,10,15-tris(pentafluorophenyl)corrolate; py = pyridine) and HSA were constructed (*53*). In the HSA crystal structure, a heme (Fe^{III}-protoporphyrin IX) is located in a hydrophobic pocket in subdomain IB, and there are additional interactions involving Tyr^{161}, Ile^{142}, Tyr^{138}, His^{146}, and Lys^{190} with the heme. In one of our proposed structures, where noncovalent interactions are dominant (Figure 10a), **2-Ga** replaces the heme in the hydrophobic cavity; at this site, the distances between **2-Ga** and Trp^{214} are 20−24 Å (from the edge of the corrole−from the metal), in fair agreement with the estimated distance based on fluorescence quenching. Figures 10b and 10c show two **2-Ga**-HSA interactions that involve metal-coordination to His. As examples, we propose that **2-Ga** could bind to surface-exposed His^3 and His^{105} with distances between His-bound **2-Ga** and Trp^{214} of 24−30 and 30−34 Å, respectively. We also note that coordination of **2-Ga** to His^{146} located in the heme binding pocket (Figure 10d) is unlikely due to a considerable difference between the Förster distances measured in the model and that estimated from quenching experiments (16−19 Å vs 30 Å).

CONCLUDING REMARKS

We report results from an investigation of interactions between corroles and biomolecules. Corrole **2** is especially promising for biomedical research because of its structural similarity to the most active porphyrin-based drugs and because amphiphilicity is easily achieved. Our work has focused on interactions with HSA because any medical application must take into account associations with the most abundant protein in serum. Two metal complexes of **2** were investigated, with the goal of elucidating any effects due to ligation to relevant residues of the protein.

The changes in the electronic absorption spectra of **2**, **2-Ga**, and **2-Mn** as well as in the emission spectra of **2** and **2-Ga** as a function of increasing amounts of HSA revealed many protein binding sites. With corrole in excess, both absorption and emission intensities decreased, which is behavior that is frequently encountered when porphyrins form aggregates, usually because of limited solubility in water. However, the corroles of the current investigation do not aggregate in aqueous solutions, and, accordingly, we propose that the above phenomena are due to self-quenching of many corrole molecules that are aggregated/associated in binding pockets within the protein. Examination of published crystal structures of HSA reveals the presence of a large calixarene-like amphiphilic pocket that seems appropriate for accommodation of the corroles. When the [corrole]:[HSA] ratio approaches 1:1, the absorption and emission intensities increase, thereby indicating redistribution of corroles from the weaker binding pocket to high-affinity sites.

We have used many different methods to investigate the interactions of corroles with HSA. The results clearly show that all derivatives form tightly bound conjugates with the protein, with dissociation constants in the nanomolar range in the order **2** ≤ **2-Ga** < **2-Mn**. Under biologically relevant conditions (HSA concentrations 2 to 3 orders of magnitude larger than those examined here), all the derivatives will be fully bound to proteins. This information is of prime importance for any potential utilization of the corroles in bioinorganic systems such as for therapeutic applications and biomimetic catalysis, approaches that are currently under investigation in our laboratories.

Reversible Meso-Scale Smart Polymer−Protein Particles of Controlled Sizes

Samarth Kulkarni,[†] Christine Schilli,[‡] Axel H. E. Müller,*[,‡] Allan S. Hoffman,*[,†] and Patrick S. Stayton*[,†]

Department of Bioengineering, University of Washington, Seattle, Washington 98195 and Makromolekulare Chemie II, Universität Bayreuth, D-95440 Bayreuth, Germany. Received November 20, 2003; Revised Manuscript Received May 4, 2004

Functionalized beads and particles in the size range of tens to hundreds of nanometers (nano- to meso-scale) are finding increased applications in the bioanalytical field. We show here that conjugates of streptavidin and the temperature-responsive polymer poly(*N*-isopropylacrylamide) (PNIPAAm), synthesized with low polydispersities by reversible addition−fragmentation chain transfer (RAFT) polymerization, rapidly formed mesoscale polymer−protein particles above the lower critical solution temperature (LCST). The average hydrodynamic diameters of these particles could be controlled between 250 nm to 900 nm by the choice of conjugate concentration and polymer molecular weight, and/or through control of the rate of temperature change. Once formed, the biohybrid particles were found to be stable for >16 h at the controlled size, unlike the free PNIPAAm which continued to aggregate and grow over time into very large and polydisperse aggregates. The reversibility between the smart polymer−protein particles and the free polymer−protein conjugates opens potential uses in traditional diagnostic formats and in microfluidic formats where the differential diffusive and physical properties might be exploited for separations, analyte concentration, and signal generation.

INTRODUCTION

There is a continuing need for better upstream processing of sample fluids, control over molecular recognition events, and better sensitivity in the bioanalytical field. Important developments in the synthesis of micro- and nanoparticles with controlled physical and chemical properties are providing new opportunities for this field (*1*−*3*). Controlled structures such as micelles, cylindrical rods, and vesicles self-assemble in aqueous phases from amphiphilic block copolymers or synthetic peptides and can be subsequently derivatized with functional biomolecules (*4, 5*). There has also been considerable progress recently in the synthesis of metal-based and inorganic nanoparticles that exhibit interesting optical properties and which can be functionalized with a variety of synthetic and biomolecular coatings (*6, 7*).

"Smart" beads are another interesting class that exhibit a reversible change in their properties in response to signals such as temperature or pH. A variety of synthetic techniques have been described to construct such beads, typically based on incorporating a stimuli-responsive polymer into a cross-linked bead or particle, or by grafting a stimuli-responsive polymer onto the cross-linked bead or particle (*8, 9*). Our own group has been developing biohybrid materials that utilize the stimuli-responsiveness of the smart polymer chain to control the molecular recognition activity of proteins or to reversibly control smart bead aggregation in microfluidic channels (*10, 11*). The polymer component serves as an antenna and a switch to reversibly control the activity and aggregation state of smart polymer−protein conjugates or smart polymer−bead conjugates. It was recently shown that one mechanism by which protein switching activity can be designed involves reversible particle formation and dissolution that is driven by the polymer phase transition (*12*). The free polymer−protein conjugates in solution were in an on-state, and the switching activity (i.e. off-state) was found to be dependent on the orientation of the protein active site relative to the polymer in the aggregated particle state. These initial findings motivated the current study of the physical properties of the smart polymer−protein particles. Better control of the size and formation kinetics of these smart meso-scale particles that form and dissolve upon exposure to specific stimuli should provide design opportunities for bioanalytical and diagnostic technologies.

EXPERIMENTAL PROCEDURES

Materials. *N*-Isopropylacrylamide (Aldrich, 97%) was recrystallized twice from benzene/hexane 3:2 (v:v) and dried under vacuum prior to use. 1,4-Dioxane (Merck) was refluxed over potassium for 3 days and then distilled. Azobis(isobutyronitrile) (AIBN, Fluka) was recrystallized from methanol and dried under vacuum prior to use. 1-Biotinamido-4-[4′-(maleimidomethyl)cyclohexanecarboxamido]butane (BMCC) was obtained from Pierce, IL. Recombinant streptavidin was expressed in *Escherichia coli* and purified as previously described (*13*).

Synthesis of PNIPAAm with Functional SH End Group. PNIPAAm with narrow molecular weight distribution was synthesized using the reversible addition−

fragmentation chain transfer (RAFT) polymerization technique as described previously (*14*). The chain transfer agent (CTA), benzyl 1-pyrrolecarbodithioate, was synthesized as described (*15*). RAFT polymerization was performed at 60 °C using the benzyl CTA, AIBN as initiator, and the monomer under a nitrogen atmosphere in 1,4-dioxane as a solvent. For the polymerization series conducted at different benzyl CTA concentrations, stock solutions were prepared with a monomer concentration of 1.8 mol/L, an initiator concentration of 6.90 mmol/L, and CTA concentrations of 3.92×10^{-2}, 1.96×10^{-2}, and 4.90×10^{-3} mol/L. CTA (0.915−0.114 g; 3.92−0.49 mmol) was dissolved in 1,4-dioxane (98 mL), and the solution was degassed by three freeze−thaw evacuation cycles. AIBN (0.115 g, 0.70 mmol) was dissolved separately in 1,4-dioxane (2 mL) and degassed by three freeze−thaw evacuation cycles. The monomer (20.37 g, 0.18 mol) was added via a Schlenk tube under nitrogen to the solution of the chain transfer agent in dioxane. After the monomer was completely dissolved and the mixture heated to 60 °C (temperature of oil bath), the initiator solution was injected with a syringe. All polymerization reactions were carried out under nitrogen atmosphere and aliquots were withdrawn at different time intervals. The aliquots were immediately immersed in liquid nitrogen and subsequently freeze-dried. Residual monomer was removed by sublimation. The dried samples were dissolved in THF containing 0.25% tetrabutylammonium bromide for GPC analysis. The dithiocarbamate end groups of the synthesized polymers were hydrolyzed under basic conditions to yield the corresponding thiol-terminated polymers. The polymer was dissolved in a mixture of MeOH/aq 28% NaOH (7:3) for 4 h. Ethylenediaminetetra(acetic acid) (EDTA) was added to the solution to prevent oxidation of the resultant thiol groups. The reaction mixture was acidified with 88% formic acid, MeOH was evaporated, and the residue was freeze-dried.

Lower Critical Solution Temperature (LCST) Measurement of PNIPAAm. The LCST was determined as the temperature at 10% of the maximum absorbance at 600 nm. PNIPAAm at a concentration of 0.25 wt. % in deionized H_2O was used. The data were collected using a UV−vis spectrophotometer with a jacketed cuvette holder to control the temperature of the sample. A heating rate of 0.5 °C/min was used, and absorbance values were measured every 30 s.

Biotinylation of PNIPAAm and Complexation with Streptavidin. The PNIPAAm-SH was biotinylated using a functionalized biotin, 1-biotinamido-4-[4′-(maleimidomethyl)cyclohexanecarboxamido]butane (BMCC). Briefly, BMCC was dissolved in DMSO at a concentration of 2.4 mg/mL. Four milligrams of PNIPAAm was dissolved in 875 μL of phosphate buffer (PB), 50 mM, pH 7.0, just prior to the reaction. BMCC solution (75 μL) was added to the PNIPAAm solution and the reaction proceeded overnight at RT. The excess BMCC was removed by desalting on a PD-10 column (Pierce) using PB, 50mM, pH 7.0, as an eluent. The efficiency of biotinylation of the PNIPAAm was determined using the neutravidin−HABA assay as described by Lackey et al (*16*). The biotinylated PNIPAAm (b-PNIPAAm) was physically mixed with streptavidin in PB, 50 mM, pH 7.4, and incubated overnight for conjugation. The b-PNIPAAm and tetrameric streptavidin were mixed stoichiometrically at a 4:1 ratio.

Dynamic Light Scattering. Sizing measurements were performed using a Brookhaven BI90Plus instrument equipped with a 535-channel correlator. A 656 nm laser source was used as the incident beam, and measurements were performed at a 90° angle. Samples were filtered through 0.2 μm cutoff mixed cellulose ester filters (Whatman), and 75 μL sample volumes were used for measurement. PB, 50 mM, pH 7.4, was used as a diluent to achieve various concentrations of the conjugate. A heater within the cuvette holder of the instrument was used to heat or cool the sample to various temperatures. The temperature of the sample was measured using a thin wire thermocouple (Cole Palmer). Measurements were performed at several temperatures below and above the LCST of the PNIPAAm. For each conjugate concentration, fresh samples were prepared on different days and measurements were performed in triplicate.

The intensity autocorrelation function (ACF), $G^{(2)}(\tau)$, was measured in the self-beating mode and can be expressed by the Siegert relationship:

$$G^{(2)}(\tau) = B(1 + f^2|g^{(1)}(\tau)|^2)$$

where τ is the decay time, B is a measured baseline, f is the coherence factor, and $g^{(1)}(\tau)$ is the normalized first-order electric field time autocorrelation function $E(\tau)$. $g^{(1)}(\tau)$ is related to the line-width distribution $G(\Gamma)$ by:

$$|g^{(1)}(\tau)| = \int_0^\infty G(\Gamma)\exp(-\Gamma\tau)d\Gamma$$

Using the cumulant analysis (*17*),

$$|g^{(1)}(\tau)| = \exp(-\Gamma\tau)[1 + (\mu_2/2!)\tau^2 - (\mu_3/3!)\tau^3 + ...]$$

the average line width $\langle\Gamma\rangle$ is obtained. This yields the apparent diffusion coefficient, $D_{app} = \langle\Gamma\rangle/q^2$, which can be extrapolated to zero scattering vector, q, to obtain the translational diffusion coefficient, D. The hydrodynamic radius, R_h, is then determined using the Stokes−Einstein relation:

$$R_h = k_B T/(6\pi\eta_o D)$$

where k_B, T, and η_o are the Boltzmann constant, the absolute temperature, and solvent viscosity, respectively. For relatively narrow decay-rate distributions, the second moment, μ_2, designated as the polydispersity index, can be used to estimate the relative distribution width. Assuming a log-normal size distribution for the particles, the full-width at half-maximum (fwhm) was calculated from R_h and μ_2 using:

$$\text{fwhm} = 2R_h\text{sqrt}(\mu_2)$$

The reliability of size measurements by the cumulant analysis was verified by applying other established models to the obtained correlation function. The models chosen were the nonnegatively constrained least squares (NNLS) (*18*, *19*) and CONTIN (*20*, *21*). Root-mean-square deviations for each of the model fits were calculated and used for preliminary comparison of model fits.

Stability of the Nanoparticles. To determine the stability of the particles, a 100 μL sample of PNIPAAm−streptavidin conjugate was heated to 42.5 °C in the cuvette as described above. An airtight lid on the cuvette was used to minimize evaporation. Size measurements were taken at different time points up to 1000 min. As a control, a b-PNIPAAm sample, without the streptavidin was used. This PNIPAAm sample had the same molar concentration as that of the polymer (both bound and unbound) in the conjugate solution.

Particle Formation and Dissolution Kinetics. Since sizing measurements cannot be performed within

small time intervals, the scattering intensity, *I*, in counts per second (CPS), was used as an index of nanoparticle formation. As the PNIPAAm−streptavidin conjugates transform from free soluble conjugates to particulate form above the LCST, the scattering intensity increases. This scattering intensity is measured to analyze the kinetics of formation of the particles. The cuvette containing the conjugate sample was cooled to 23 °C and then placed in the heated cuvette holder of the DLS instrument maintained at 42.5 °C. The intensities were measured at a sampling interval of 5 μs as the temperature increased and finally equilibrated at 42.5 °C. For particle dissolution studies, the conjugate sample incubated at 42.5 °C in a cuvette was subsequently placed in the jacketed cuvette holder maintained at 25 °C. Intensities were measured at a sampling interval of 5 μs as the sample cooled. The temperature profile for the sample was recorded using a thermocouple with a sampling interval of 15 s.

Dependence of Nanoparticle Size on Concentration and Molecular Weight of PNIPAAm. Nanoparticle hydrodynamic diameters were measured for the bioconjugates of streptavidin with PNIPAAm of molecular weights (number-averaged molecular weight, M_n) 2.9 kDa, 4.8 kDa, 14.9 kDa, and 25.9 kDa, respectively, to determine the dependence of size on molecular weight of the polymer. The concentration dependence was determined by using concentrations of 9 μM, 3 μM, 1 μM, 500 nM, and 100 nM for each bioconjugate. The Tukey−Kramer multiple comparisons statistical test was used to analyze the data.

Effect of Heating Rate. Size measurements were made at three different heating rates for the 14.9 kDa PNIPAAm−streptavidin conjugate at a 1 μM concentration. The cuvette containing the conjugate was cooled to 23 °C and then placed in the heated cuvette holder of the DLS instrument maintained at 33, 38.5, and 42.5 °C to get different heating rates. The temperature of the conjugate solution in the cuvette was measured using a thermocouple with a sampling time of 15 s. The heating rates were measured by calculating the derivative of the temperature−time curve at the respective LCST values. Heating rates of 0.04 °C/s, 0.12 °C/s, and 0.16 °C/s were obtained for the 32.5, 38.5, and 42.5 °C block temperatures, respectively.

RESULTS

Synthesis of PNIPAAm with Narrow Molecular Weight Distributions. Using the RAFT technique, PNIPAAm of different molecular weights with narrow molecular weight distributions were synthesized. A range of four molecular weights (M_n) were chosen for conjugation to streptavidin: 25.9 kDa (polydispersity = 1.08), 14.8 kDa (polydispersity = 1.09), 4.8 kDa (polydispersity = 1.16), and 2.9 kDa (polydispersity = 1.16). The dithiocarbamate end group on the polymer from the chain transfer agent was cleaved to generate a functional thiol end group that was used for end-specific biotin conjugation. The LCST values, as defined by 10% change in absorbance at 0.2 mg/mL polymer concentration, for the 25.9 kDa (31 °C) and 14.9 kDa (31.4 °C) polymers were similar, but those for the 2.9 kDa (26.8 °C) and 4.8 kDa polymers (29.0 °C) were slightly lower. A linear dependence of LCST values versus reciprocal molecular weight values was previously described for the dithiocarbamate-terminated polymers (*22*).

Biotinylation of PNIPAAm and Complexation with Streptavidin. Biotinylation efficiencies calculated by the HABA assay yielded average values of 57% for the 25.9 and 14.9 kDa polymers, 62% for the 4.8 kDa polymer, and 60% for the 2.9 kDa polymer. The biotinylation efficiency was used to calculate the amount of polymer to be added to streptavidin for complexation. We have shown previously that a maximum of two biotinylated polymers are bound per tetrameric streptavidin due to steric hindrance (*23*). In these studies, a ratio of 2.4 biotinylated PNIPAAm polymer chains to streptavidin tetramer was used.

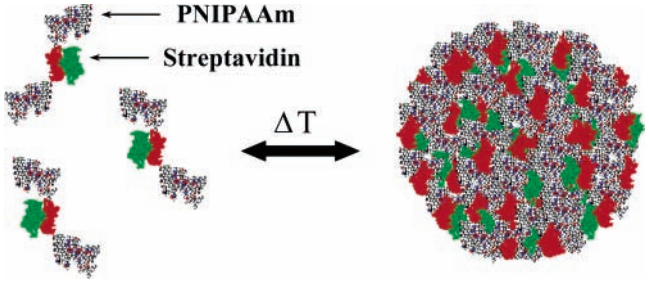

Figure 1. Schematic representation of the formation of PNIPAAm−streptavidin smart nanoparticles. Below the LCST, the PNIPAAm is hydrophilic and the bioconjugate remains in solution. Above the LCST, the hydrophobicity of the PNIPAAm directs the aggregation of the bioconjugates into nanoparticles of defined sizes. The hydrophilic streptavidin stabilizes the nanoparticles and prevents further aggregation.

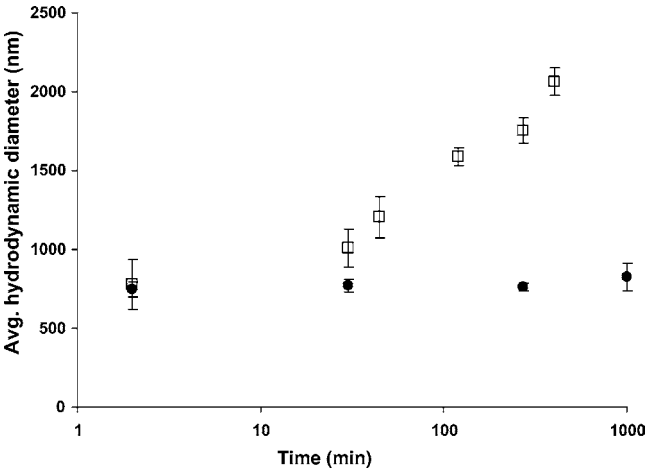

Figure 2. Stability of the nanoparticles formed from the 14.9 kDa PNIPAAm−streptavidin conjugate at 42.5 °C and a concentration of 3 μM is shown. The particles fomed by the bioconjugate (●) are stable in size for over 16 h. In contrast, aggregates of b-PNIPAAm (□) at the same concentration do not have a hydrophilic moiety to stabilize the size and aggregate over time into larger particles. Error bars represent ± 1 standard deviation over the three measurements.

Stability and Kinetic Properties of Streptavidin−PNIPAAm Particle Formation. The polymer−streptavidin conjugates are soluble at temperatures below the LCST of PNIPAAm, and no sizing measurements could be made due to the low level of scattering intensities. As the conjugate was heated to temperatures above the LCST of PNIPAAm, the polymer becomes hydrophobic and drives the aggregation of the conjugates into uniform and stable particles (Figure 1). The stability of the nanoparticle size for the 14.9 kDa conjugate at a fixed concentration of 3 μM is shown in Figure 2. Once formed, the particles did not aggregate further and had the same average size after 16 h (Tukey−Kramer test, $p < 0.05$). In contrast, PNIPAAm−biotin alone continued to aggregate into larger particles over this time period (>1 μm diameter after 1 h). Sizing measurements could not

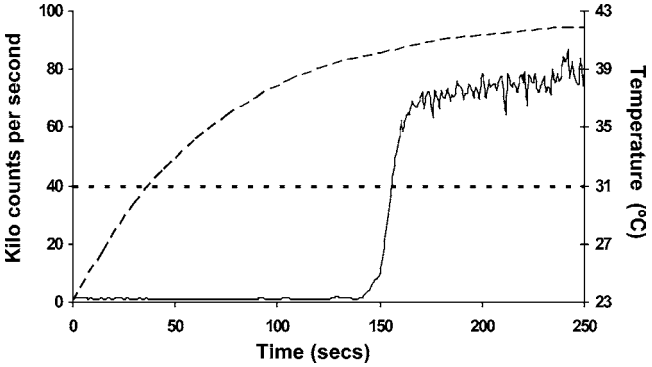

Figure 3. The kinetics of formation of particles by the 14.9 kDa PNIPAAm−streptavidin conjugate at a concentration of 1 μM as measured by light scattering intensity is shown. The scattering intensity (—) is measured as the temperature of the conjugate is ramped from 23 °C to 42.5 °C. As the particles are formed, the scattering intensity, measured in kilocounts per second (kCPS), increases in a highly cooperative manner. The increase in sample temperature (– – –) with time is overlaid onto the kinetic trace. The LCST of the PNIPAAm (- - -) is shown on the temperature axis.

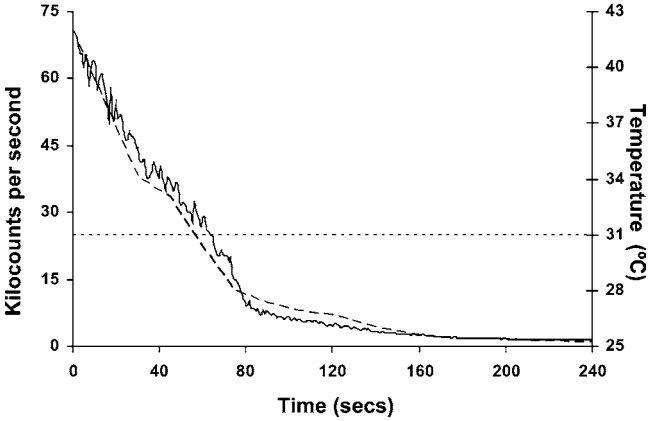

Figure 4. Dissolution kinetics for the 14.9 kDa PNIPAAm−streptavidin conjugate at a concentration of 1 μM is shown. The scattering intensity is measured as the sample is cooled from 42.5 °C to 25 °C. As the particles dissolve, the scattering intensity (—), measured in kilocounts per second (kCPS), decreases. The decrease in sample temperature (– –) with time is overlaid onto the kinetic trace. The LCST of the PNIPAAm (···) is shown on the temperature axis.

be made beyond 400 min for the PNIPAAm−biotin as the size exceeded the range of the instrument.

The particle formation kinetics, measured by the increase in scattering intensity as the conjugate was heated from 20 °C to 42.5 °C, are shown in Figure 3. The transition from soluble conjugates to particles was found to be rapid (within 20 s) and occurs in a narrow temperature range at the critical point. The time lapse of ca. 100 s observed after the temperature of the solution surpasses the LCST suggests that there is an induction period with early nucleation events that fall below the resolution of this observation technique. After reversal of the temperature stimulus, the scattering intensity decreased by more than 90% within 2 min, consistent with the dissolution of the particles in this time period (Figure 4). In Figure 4, it is seen that the dissolution of the particles commences as soon as the sample is removed from the 42.5 °C heat block and exposed to the atmosphere. This anomaly could be due to dissolution of particles exposed to the surface, where cooling is faster than in the bulk (where temperature was measured).

Particle Size Controlled by Concentration and Molecular Weight. At temperatures above the LCST, the bioconjugates assemble into stable particles whose size is dependent on the concentration and the molecular weight of the PNIPAAm (Table 1). The dependence of particle hydrodynamic diameter on conjugate concentration for the 14.9 kDa conjugate at 42.5 °C is shown in Figure 5. The particle size increases with the concentration of the bioconjugate for all the molecular weights of PNIPAAm tested (a complete concentration curve could not be obtained for the 2.9 kDa polymer due to insufficient scattering intensity at low concentrations). Furthermore, the particles were stable once formed (>16 h) and further dilution at the elevated temperatures did not significantly affect the size of the particles (data not shown).

The hydrodynamic particle sizes also depend on the molecular weight of the PNIPAAm used for conjugation. Figure 6 shows the dependence of particle diameter on PNIPAAm molecular weight for a fixed concentration of the conjugate. Particle sizes were comparable for the 25.9, 14.9, and 4.8 kDa conjugates, with no significant change in size with change in molecular weight ($p < 0.05$). The 2.9 kDa conjugate had a much smaller size, indicating that below a threshold molecular weight, the nucleation and growth mechanism changes. Table 1 shows particle sizes and full widths at half-maximum (fwhm) for the

Table 1. Particle Sizes of Streptavidin−PNIPAAm Bioconjugates[a]

M_n of PNIPAAm conjugate to streptavidin		concentration 9 μM	3 μM	1 μM	0.5 μM	0.1 μM
PNIPAAm−25.9 kDa-Stav	D_h (nm)	719	670	426	336	236
	fwhm (nm)	51	92	131	123	81

	fwhm (nm)	124	149			

[a] Size data for the particles formed from PNIPAAm−streptavidin conjugates of different molecular weights and different concentrations is shown. The particles were formed by heating the sample to 42.5 °C. D_h represents the average hydrodymamic diameter, and fwhm represents the relative width of the size distribution. Sizing data for the 2.9 kDa PNIPAAm conjugate could not be obtained at lower concentrations due to insufficient scattering from the particles. Values represent the average of three measurements for each molecular weight and concentration.

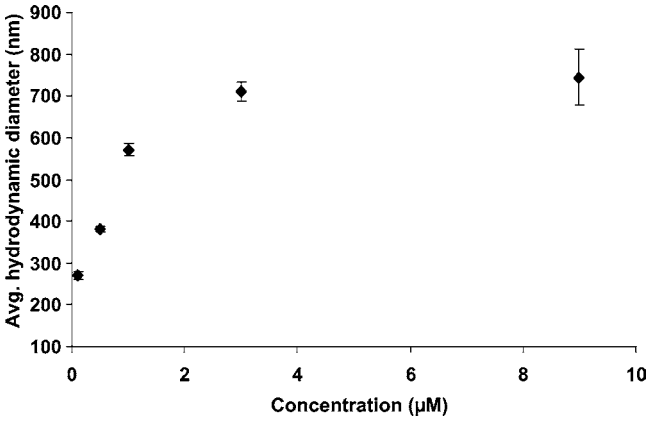

Figure 5. Dependence of the average hydrodynamic particle diameter on conjugate concentration is shown for the 14.9 kDa PNIPAAm−streptavidin conjugate at 42.5 °C. Size measurements were performed 20 min after particle formation. Error bars represent ± 1 standard deviation over three measurements with freshly prepared samples. The average hydrodynamic diameters increase with concentration.

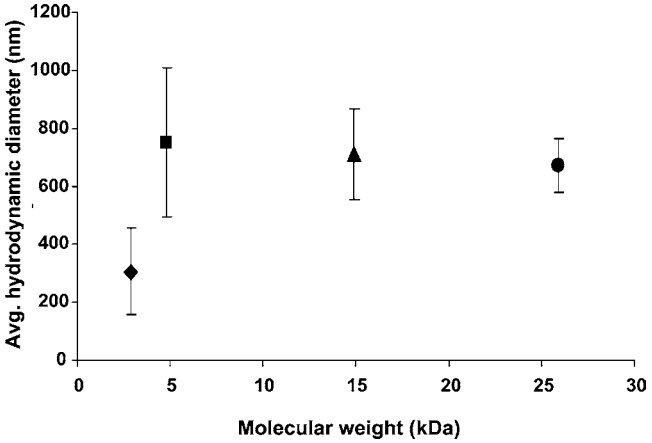

Figure 6. Dependence of the average hydrodynamic particle diameter on molecular weight (number averaged molecular weight) of the PNIPAAm used for conjugation to streptavidin is shown for the 25.9 kDa (●), 14.8 kDa (▲), 4.8 kDa (■), and 2.9 kDa (◆) conjugates at a concentration of 3 μM at 42.5 °C. Average particle hydrodynamic diameters are comparable for the 25.9 kDa, 14.8 kDa, and 4.8 kDa conjugates but significantly lower for the 2.9 kDa conjugate. Error bars represent ± 1 standard deviation from triplicate sizing measurements made for each conjugate.

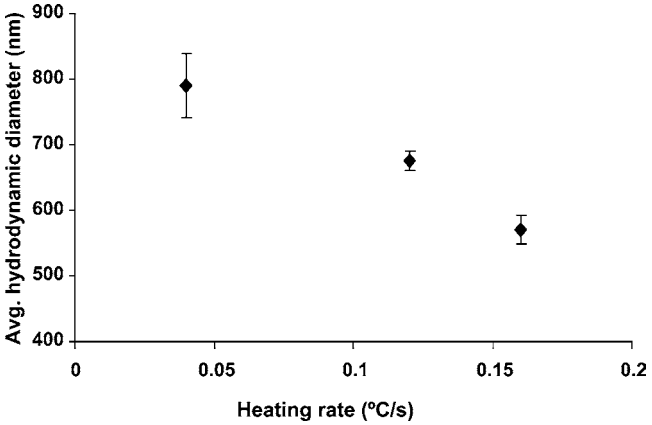

Figure 7. Effect of heating rate on the hydrodynamic particle diameter for the 14.9 kDa PNIPAAm−streptavidin conjugate at a concentration of 1 μM is shown. Different heating rates were achieved by heating the sample incubated at 23 °C to final temperatures of 33, 38, and 42.5 °C corresponding to heating rates of 0.04, 0.12, and 0.16 °C/s, respectively. The size measurements were made 5 min after reaching the final temperature. The average hydrodynamic diameter of the particles decreases with heating rate. Error bars represent ± 1 standard deviation from three measurements.

different polymer molecular weights and concentrations. The fwhm values have been calculated from the second moment μ_2 (polydispersity index) and reflect the relative distribution width of the particles. The average values of the polydispersity index ranged from 0.02 to 0.18, indicating narrow distributions of particle size. From the fwhm values, it was observed that the higher molecular weight polymers yielded particles with narrower relative (to size) distribution widths. This indicates that conjugates of higher molecular weight polymers form more uniform particles. Taken together, these data demonstrate that discrete particle sizes between the range of ca. 250 and 900 nm can be designed through appropriate choice of polymer molecular weight and concentration.

Effect of Heating Rate on Particle Size. Particle size was observed to be dependent on the heating rate of the conjugate solution (Figure 7). Smaller particles were formed at higher heating rates and nanoparticles of fixed sizes could be formed by varying the heating rate. For example, the size of the 14.9 kDa PNIPAAm−streptavidin conjugate could be tightly controlled to 675 nm (± 20 nm) at a concentration of 1 μM by choosing a heating rate of 0.12 °C/s. Additionally, it was observed that the particles had a wider distribution when formed at lower heating rates. The different heating rates were achieved by incubating the sample at 23 °C and then inserting into heating blocks maintained at different temperatures, resulting in different final temperatures for each sample. Our experimental set up did not allow the sample to be ramped to the same final temperatures at different heating rates. To address the question of relative importance of the final temperature (equilibrium effect) versus the heating rate (kinetic effect) on particle size, the temperatures were changed after formation of the particles. Particles of size 790 nm (± 50 nm) were formed on ramping the temperature to 33 °C at a heating rate of 0.04 °C/s. There was no significant change in the size of these particles by subsequently raising the temperature of this sample to 42.5 °C (data not shown). Similarly, no change in size was observed when particles that were formed by heating to 42.5 °C were cooled to 38 °C (data not shown). This demonstrates that the particle size is largely governed by the kinetics of aggregation at defined concentrations and polymer molecular weights.

DISCUSSION

The particle properties of a temperature-responsive polymer−streptavidin conjugate have been investigated in this study. The size of the particles formed above the PNIPAAm LCST could be controlled across an interesting and application relevant mesoscale of ca. 250−900 nanometers by manipulating the polymer molecular weight, the conjugate concentration, and/or the heating rate. Once formed, the particles were remarkably stable with narrow size distributions and yet could be formed or dissolved rapidly. This behavior was not seen with PNIPAAm alone, even at dilute concentrations, as the polymer aggregated into continually larger aggregates over time.

The aggregation of PNIPAAm polymers at dilute concentrations into mesoscopic globules above its LCST has also been reported by Gorelov et al. (*24*). The authors reported that the mesoglobules formed by high molecular weight PNIPAAm (M_n = 2−9 MDa), at dilute concentrations of 1−5 nM, are stable and do not aggregate further. In our experiments, however, we have observed that at concentrations typical of bioanalytical reactions, aggregates formed from lower M_n PNIPAAm alone are unstable and aggregate continuously (Figure 2). Particles formed from the biohybrid conjugates, however, are stabilized by the charged and hydrophilic streptavidin and remain stable in size even at higher concentrations. The protein thus serves as a hydrophilic capping agent to limit the bioconjugate particle size, similar to surfactants that prevent the superaggregation of similar temperature-responsive polymers (*25*). Similar observations have been made with colloidal particles of DNA−PNIPAAm conjugates where the DNA acts as the hydrophilic shell (*26*).

These experiments also indicate that the formation of the particles is largely a kinetic phenomenon dependent on the concentration and heating rate of the sample. The predominant effect of heating rate over the final equilibrium temperature on particle size demonstrates that once formed, the particles are kinetically stable and changes in equilibrium conditions over the temperature range studied do not alter the particle size. This is also

substantiated by the fact that dilution after formation of the particles does not significantly change the particle size distribution.

The properties of this meso-particle system provide interesting opportunities for the bioanalytical field. The reversibility of the bioconjugate particle formation allows molecular recognition steps to be performed with the free conjugates, while then enabling separation and concentration steps based on particle properties or vice versa. For example, the streptavidin conjugates can be used to capture biotinylated antibodies and their targets in homogeneous solution but can then be filtered as the mesoscale beads after temperature-triggered particle formation. After isolation, the bioconjugates can be released back as free molecular species with simple temperature reversal. Alternatively, the different diffusive properties of the particles might be exploited in microfluidic devices to separate particle-bound targets from freely diffusing contaminants, with the benefit again of being able to regenerate the bioconjugate species at controlled places in the channel device for capture or release (*27*, *28*).

In addition to these microfluidic device applications, many lab assays (e.g., PCR) depend on sequential processing steps that could benefit from all reagents being placed in a single complex mixture. The timing of each processing step could subsequently be controlled by sequential signals directing flocculation/aggregation and redispersal of specific biomolecular species. In this application it would be desirable to have the aggregated species turned off, which we have shown can be accomplished by controlling the orientation of the protein active site relative to the polymer (*12*). Similarly, for bioprocessing applications relying on sequential enzyme reactions, it should be possible to control sequential enzyme activities by bringing them together at specific times to amplify the sequential nature of the reactions.

Received January 22, 2004; Revised Manuscript Received April 27, 2004

Nonviral gene vectors remain inefficient in vivo largely because of their rapid clearance from the circulation and also their nonspecific association with the extracellular matrix. To overcome such drawbacks, cationic lipoplexes are now frequently coated with hydrophilic polymers such as PEGs to reduce nonspecific interactions, and ligands are also linked to their surface to obtain cell-specific gene transfer. In view of the development of vectors for systemic gene delivery, we have designed and studied lipoplexes that carry a triantennary galactosyl ligand attached to the distal end of a $(PEG)_{45}$-conjugated lipid. We incorporated this targeted PEGylated lipid into lipoplexes using two strategies of formulation, i.e., using either preformed micelles or liposomes. We demonstrated that the incorporation of PEG chains stabilized lipoplexes and masked, but only partially, the positive charges exposed on the surface of the particles. We have also shown that incorporation into lipoplexes of a lipidated PEG chain, bearing a ligand at its distal end, yielded particles that exhibited an accessible ligand throughout the whole range of cationic lipid to DNA ratios. We obtained a targeted transfection in HepG2 cells with one of the formulations. Our results strengthen the validity of using a ligand carried by a long PEG spacer arm for targeted gene transfer.

INTRODUCTION

Clinical applications of gene therapy require the development of vectors allowing systemic administration and target tissue restricted gene delivery (*1*). Viral vectors are generally effective gene transfer agents; however, their use remains hampered by safety concerns. For that reason, vectors such as cationic polymers and cationic lipids, although less efficient, represent attractive alternatives that have been extensively explored during the past decade (*2*). However, gene transfer efficiency of polyplexes and lipoplexes (cationic polymer/DNA and cationic lipid/ DNA complexes, respectively) remains quite low in vivo, in part due to their rapid clearance from the circulation by the cells of the reticuloendothelial system (RES) and also to nonspecific association with the extracellular matrix (*3*, *4*). This situation has imposed severe limitations on the use of these nonviral vectors for therapeutic gene delivery (*5*). To overcome such drawbacks, lipoplexes or polyplexes can be coated with polymers such as poly(ethylene glycol) (PEG), which introduce a steric barrier at their surface (Figure 1). These PEGylated lipoplexes or polyplexes exhibit a reduction of interaction with opsonins and/or nonspecific interactions with RES cells (*6*). However, the PEG coating may also reduce the cationic particle−cell membrane interactions that are needed for cell uptake, the consequence of which would lead to a decrease in gene transfer. Another approach to enhance the gene transfer efficiency of nonviral vectors is to incorporate targeting elements that bind efficiently to cell-surface receptors (*7*, *8*). However, when targeted lipoplexes are used, PEG coating may interfere with the recognition between the ligand and its specific receptor on the target cell surface. Therefore, it was found preferable to conjugate the ligand at the distal end of a PEG spacer arm linked to polylysine (*9*−*11*), to PEI (*12*−*15*), or to a lipid (*16*−*21*). These targeted PEG−lipids were mostly incorporated in liposomes (*16*, *17*, *20*, *21*) or vesicles (*19*) but only rarely in lipoplexes (*18*).

In view of the development of vectors for systemic gene delivery, we have designed and studied lipoplexes that carry a triantennary galactosyl ligand attached to the distal end of a $(PEG)_{45}$-conjugated lipid (Figure 2). This ligand was used previously to target lipoplexes in vitro to human hepatoma cells (*22*). Because of the length of the spacer (PEG_{45}), we expected the ligand to protrude from lipoplexes and interact without hindrance with the Gal/GalNAc receptor expressed at the surface of the target cells. In the present work, we have explored the feasibility of forming PEG-modified lipoplexes and assessed (i) the effect of PEG on their physicochemical characteristics and (ii) their capacity to mediate targeted cell transfection.

EXPERIMENTAL PROCEDURES

General. Reagent-grade solvents were used without further purification. *N*,*N*′-Dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), *N*-ethyldiisopropylamine (DIPEA), and *O*,*O*′-bis(2-aminoethyl)poly(ethylene glycol)

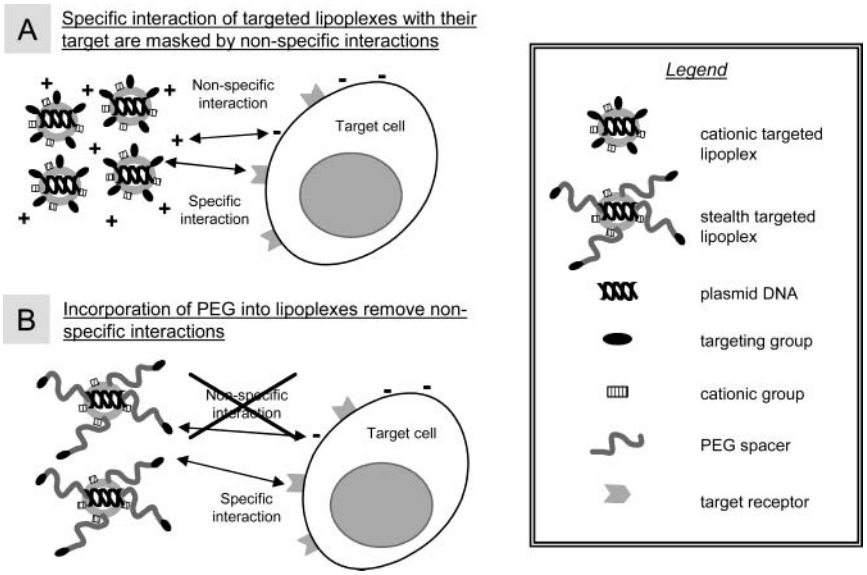

Figure 1. Schematic representation of the interaction of targeted lipoplexes with their target cells.

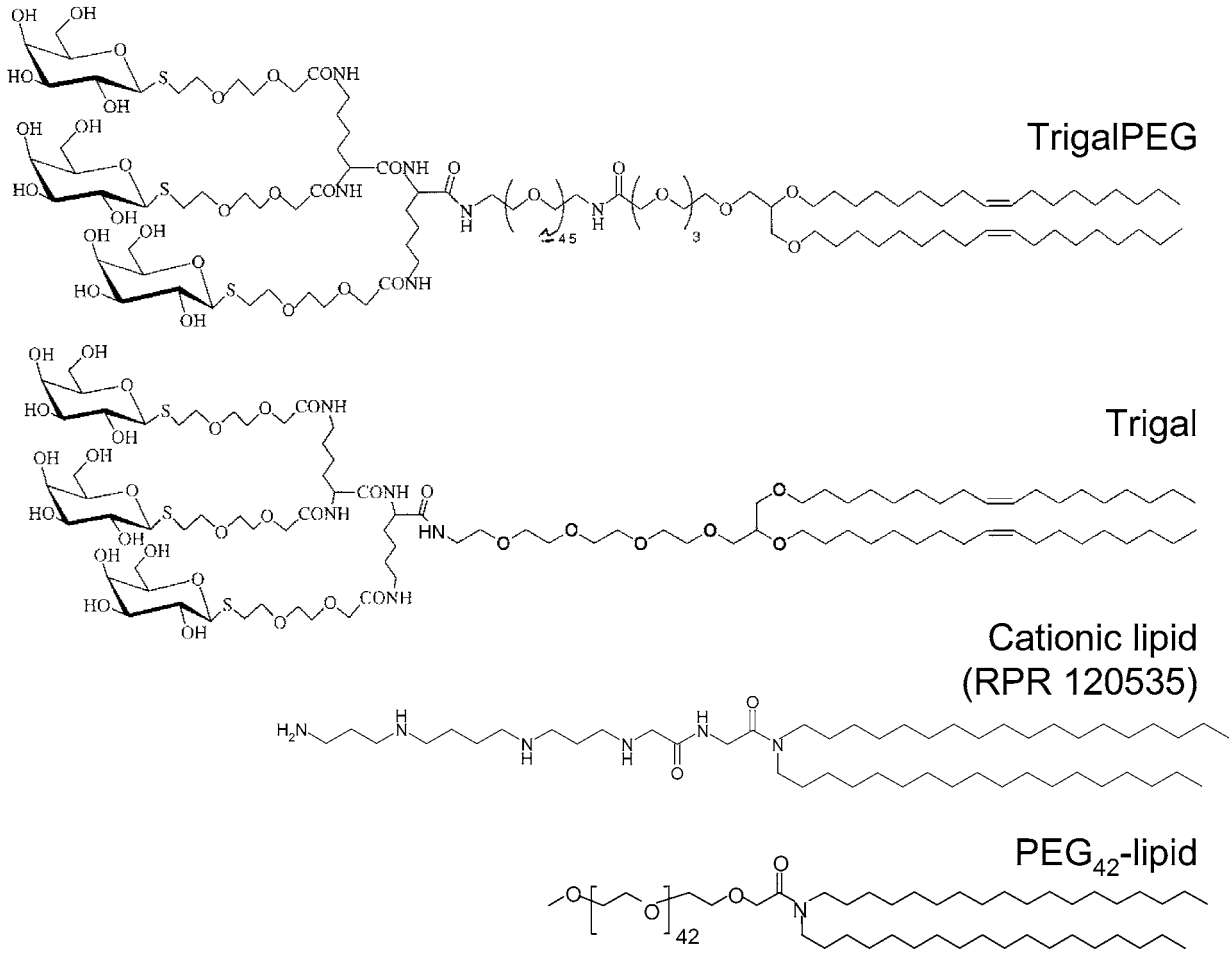

Figure 2. Molecular structure of the cationic, neogalactosylated, and PEGylated lipids used in this study. Targeted lipids consisted of a triantennary galactosyl headgroup linked to a double C18:1 lipid anchor via a $(PEG)_{45}$ spacer (TrigalPEG) or via a $(PEG)_3$ spacer (Trigal). RPR 120535 contained a spermine as cationic headgroup linked to a double C18:0 anchor via a short spacer. PEG-modified lipid contained a $(PEG)_{42}$ linked to a double C18:0 lipid chain.

(MW 2000) ($NH_2PEG_{45}NH_2$) were from Fluka (L'Isle D'Abeau Chesnes, France). Silica gel 60 F 254 plates for thin-layer chromatography were purchased from Merck (Darmstadt, Germany). ^1H NMR spectra were recorded on Bruker DPX 200 (200 MHz) and DPX 300 (300 MHz) spectrometers.

Lipids (Figure 2). DOPE (1,2-dioleoyl-*sn*-glycerol-3-phosphoethanolamine) was purchased from Avanti Polar. Cationic lipid RPR 120535 was prepared as described (*23*).

Preparation of PEG_{42}−Lipid (MeO−$(PEG)_{42}$−DODA). PEG_{42}−lipid (MeO−$(PEG)_{42}$−DODA) was pre-

pared by condensation of dioctadecylamine on previously oxidized MeO−$(PEG)_{42}$ (*24*). The one-step synthesis was carried out using Castro's reagent in alkaline medium (*25*) and the expected product was purified by preparative HPLC [C4 phase, water (+0.1% TFA)/acetonitrile (+0.08% TFA) gradient, UV detection 220 nm]. MeO−$(PEG)_{42}$−DODA was isolated as a white lyophilisate; ^{1}H NMR, MS (electrospray), and IR assessed structure and purity.

Synthesis of (2-{2-[2-(2,3-Bis(octadec-9-enyloxy)-propoxy)ethoxy]ethoxy}ethoxy)acetic Acid ($DOGP_3$-COOH). $DOGP_3OH$ (*26*) was dissolved in 40 mL of acetone. Under stirring, 1.7 mL of 2.67 M Jones reagent (26.72 g of chromium(IV) oxide in 23 mL of concentrated sulfuric acid brought to a final volume of 100 mL of water) was added dropwise over 15 min. After 2 h a few drops of 2-propanol were added followed by 50 mL of water to dissolve the precipitated chromium salts. The organic solvent was then removed under reduced pressure and the aqueous phase extracted three times with 100 mL of CH_2Cl_2. The combined organic extracts were dried on $MgSO_4$ and concentrated, and the residue was chromatographed on a silica gel column eluted with CH_2Cl_2:CH_3OH (20:1 to 20:2). The product was obtained as a colorless oil (1 g, 60% yield): R_f 0.46 (CH_2Cl_2:CH_3OH, 9:1); ^{1}H NMR ($CDCl_3$:CD_3OD, 1:1, 200 MHz) δ 5.35 (m, 4H, *CH*=*CH*), 4.00 (s, 2H, COCH_2O), 3.75−3.44 (m, 21H, OCH_2, *CHCH*$_2$O, CH_2CH_2O), 2.01 (m, 8H, CH_2CH=CHCH_2), 1.55 (m, 4H, $OCH_2CH_2CH_2$), 1.33−1.30 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.91 (t, J = 6.6 Hz, 6H, CH_3).

Synthesis of $DOGP_{45}NH_2$. $DOGP_3COOH$ (1 g, 1.28 mmol) was added to a solution of 20 mL of anhydrous CH_2Cl_2 containing $NH_2PEG_{45}NH_2$ (5.2 g, 2.56 mmol), DCC (400 mg, 1.92 mmol), and *N*-hydroxysuccinimide (147 mg, 1.28 mmol). The coupling reaction was carried out overnight, under argon, at room temperature. After elimination of dicyclohexylurea by filtration, the solvents were removed under reduced pressure. The title compound was purified by chromatography on a 400 mL silica gel column eluted with CH_2Cl_2:CH_3OH (95:5 to 85:15). The organic phase was concentrated under reduced pressure. The product was obtained as a white solid (1.2 g, 34% yield): R_f 0.6 (CH_2Cl_2:CH_3OH, 85:15); ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.35 (m, 4H, *CH*=*CH*), 4.00 (s, 2H, COCH_2O), 3.75−3.38 (m, 200H, OCH_2, *CHCH*$_2$O, CH_2CH_2O, NH_2CH_2, CH_2NH), 2.01 (m, 8H, CH_2CH=CHCH_2), 1.55 (m, 4H, $OCH_2CH_2CH_2$), 1.29−1.26 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.91 (t, J = 6.6 Hz, 6H, CH_3).

Synthesis of $DOGP_{45}TG(Ac)$. $DOGP_{45}NH_2$ (1 g, 0.36 mmol) and DIPEA (61 μL, 0.36 mmol) were dissolved in 10 mL of anhydrous CH_2Cl_2. The mixture was added to a solution of 15 mL of anhydrous CH_2Cl_2 containing TG(Ac) (*27*) (711 mg, 0.4 mmol), DCC (82 mg, 0.4 mmol), and *N*-hydroxysuccinimide (46 mg, 0.4 mmol). The coupling reaction was carried out overnight, under argon, at room temperature. After elimination of *N*,*N*′-dicyclohexylurea by filtration, the solvents were removed under reduced pressure. The title compound was purified by chromatography on a 400 mL silica gel column eluted with CH_2Cl_2:CH_3OH (95:5 to 80:20). The organic phase was concentrated under reduced pressure. The product was obtained as a colorless oil (1 g, 60% yield): ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.41 (d, 3H, H_4-sugar, J = 3.39 Hz), 5.35 (m, 4H, *CH*=*CH*), 5.23−5.14 (m, 3H, H_2-sugar), 5.05 (m, 3H, H_3-sugar), 4.61−4.51 (m, 3H, H_1-sugar), 4.49−4.24 (m, 2H, *CH*CONH), 4.23−3.90 (m, 17H, OCH_2CO, H_6-sugar, H_5-sugar), 3.79−3.38 (m, 220H, OCH_2, *CHCH*$_2$O, CH_2CH_2O, NHCH_2, CH_2NH), 3.32−3.22 (m, 4 H, CONHCH_2), 2.99−2.75 (m, 6H, SCH_2), 2.13; 2.05; 2.03; 1.96 (4s, 12H, CH_3COO), 2.01 (m, 8H, CH_2CH=CHCH_2), 1.95−1.47 (m, 16H, CH$CH_2CH_2CH_2$, $OCH_2CH_2CH_2$), 1.29−1.26 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.91 (t, J = 6.6 Hz, 6H, CH_3).

Synthesis of TrigalPEG ($DOGP_{45}TG$). $DOGP_{45}TG$-(Ac) (1 g, 0.22 mmol) and K_2CO_3 (110 mg, 0.8 mmol) were dissolved in 10 mL of methanol. The deacetylation reaction was carried out for 3 h, under argon, at room temperature; the solvents were then removed under reduced pressure. The title compound was purified by chromatography on a 200 mL silica gel column eluted with CH_2Cl_2:CH_3OH:H_2O (60:40:0 to 60:40:5). The solvents were eliminated under reduced pressure. The product was obtained as a colorless oil (540 mg, 64% yield): ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.35 (m, 4H, *CH*=*CH*), 4.53 (d, 3H, H_1-sugar, J = 9.04 Hz), 4.42−4.33 (m, 2H, *CH*CONH), 4.23−3.90 (m, 11H, OCH_2CO, H_4-sugar), 3.84−3.38 (m, 240H, OCH_2, *CHCH*$_2$O, CH_2CH_2O, NHCH_2, CH_2NH, H_6-sugar, H_5-sugar, H_3-sugar, H_2-sugar), 3.32−3.22 (m, 4 H, CONHCH_2), 3.02−2.83 (m, 6H, SCH_2), 2.01 (m, 8H, CH_2CH=CHCH_2), 1.95−1.47 (m, 16H, CH$CH_2CH_2CH_2$, $OCH_2CH_2CH_2$), 1.29−1.26 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.91 (t, J = 6.6 Hz, 6H, CH_3).

Synthesis of $DOGP_3TG(Ac)$. $DOGP_3NH_2$ (*28*) (100 mg, 0.13 mmol) was dissolved in 1 mL of anhydrous CH_2Cl_2. The mixture was added to a solution of 5 mL of anhydrous CH_2Cl_2 containing TG(Ac) (230 mg, 0.13 mmol), DCC (30 mg, 0.145 mmol), and *N*-hydroxysuccinimide (15 mg, 0.13 mmol). The coupling reaction was carried out for 2 days, under argon, at room temperature. After elimination of *N*,*N*′-dicyclohexylurea by filtration, the solvents were removed under reduced pressure. The title compound was purified by chromatography on a 120 mL silica gel column eluted with CH_2Cl_2:CH_3OH (100:0 to 95:5). The organic phase was concentrated under reduced pressure. The product was obtained as a colorless oil (130 mg, 42% yield): ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.44 (d, 3H, H_4-sugar, J = 3.2 Hz), 5.35 (m, 4H, *CH*=*CH*), 5.23−5.14 (m, 3H, H_2-sugar), 5.05 (m, 3H, H_3-sugar), 4.61−4.51 (m, 3H, H_1-sugar), 4.49−4.24 (m, 2H, *CH*-CONH), 4.23−3.90 (m, 15H, OCH_2CO, H_6-sugar, H_5-sugar), 3.80−3.20 (m, 43H, OCH_2, *CHCH*$_2$O, CH_2CH_2O, NHCH_2), 3.00−2.80 (m, 6H, SCH_2), 2.15; 2.06; 2.03; 1.98 (4s, 12H, CH_3COO), 2.20−1.98 (m, 8H, CH_2CH=CHCH_2), 1.95−1.47 (m, 16H, CH$CH_2CH_2CH_2$, $OCH_2CH_2CH_2$), 1.29−1.26 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.88 (t, J = 6.58 Hz, 6H, CH_3).

Synthesis of Trigal ($DOGP_3TG$). $DOGP_3TG(Ac)$ (130 mg, 0.13 mmol) was dissolved in 10 mL of methanol:water:DIPEA (5:4:1, v:v:v). The deacetylation reaction was carried out for 72 h, under argon, at room temperature. The solvents were removed under reduced pressure. The title compound was purified by chromatography on a 120 mL silica gel column eluted with CH_2Cl_2:CH_3OH:H_2O (90:10:0 to 65:25:4). The organic phase was concentrated under reduced pressure. The product was obtained as a colorless oil (50 mg, 50% yield): ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.39 (m, 4H, *CH*=*CH*), 4.42 (d, 3H, H_1-sugar, J = 9.16 Hz), 4.35−4.22 (m, 2H, *CH*CONH), 4.22−3.90 (m, 9H, OCH_2CO, H_4-sugar), 3.84−3.38 (m, 54H, OCH_2, *CHCH*$_2$O, CH_2CH_2O, NHCH_2, H_6-sugar, H_5-sugar, H_3-sugar, H_2-sugar), 3.32−3.22 (m, 4 H, CONHCH_2), 3.02−2.83 (m, 6H, SCH_2), 2.01 (m, 8H, CH_2CH=CHCH_2), 1.95−1.47 (m, 16H, CH$CH_2CH_2CH_2$, $OCH_2CH_2CH_2$), 1.29−1.26 (m, 44H, $CH_3(CH_2)_6$, $OCH_2CH_2(CH_2)_5$, 0.91 (t, J = 6.6 Hz, 6H, CH_3).

Cationic Liposomes and Micelles Preparation. *Cationic Liposome Preparation*. The lipids were dissolved in chloroform in 10 mL round-bottom flasks, and a film

was obtained after evaporation of the solvent, under vacuum at 20 °C overnight, using a Heidolph rotating-desiccator. The dried film was then hydrated for 24 h with sterile MilliQ water at 4 °C to produce large multilamellar vesicles. The suspension was finally sonicated at 4 °C for 2 min (115 V, 80 W, 50−60 Hz) with a G112SP1G model sonicator (Laboratory Supplies Co. Hicksville, NY) to obtain small unilamellar liposomes. The opalescent liposome preparation was stored up to 1 month at 4 °C. Four different liposome types were prepared (see Table 1).

Micelle Preparation. MilliQ water was added to the appropriate amount of lipids. The resulting suspensions were then heated at 60 °C and sonicated as described above until the suspension became clear. Three types of micelle were prepared (see Table 1).

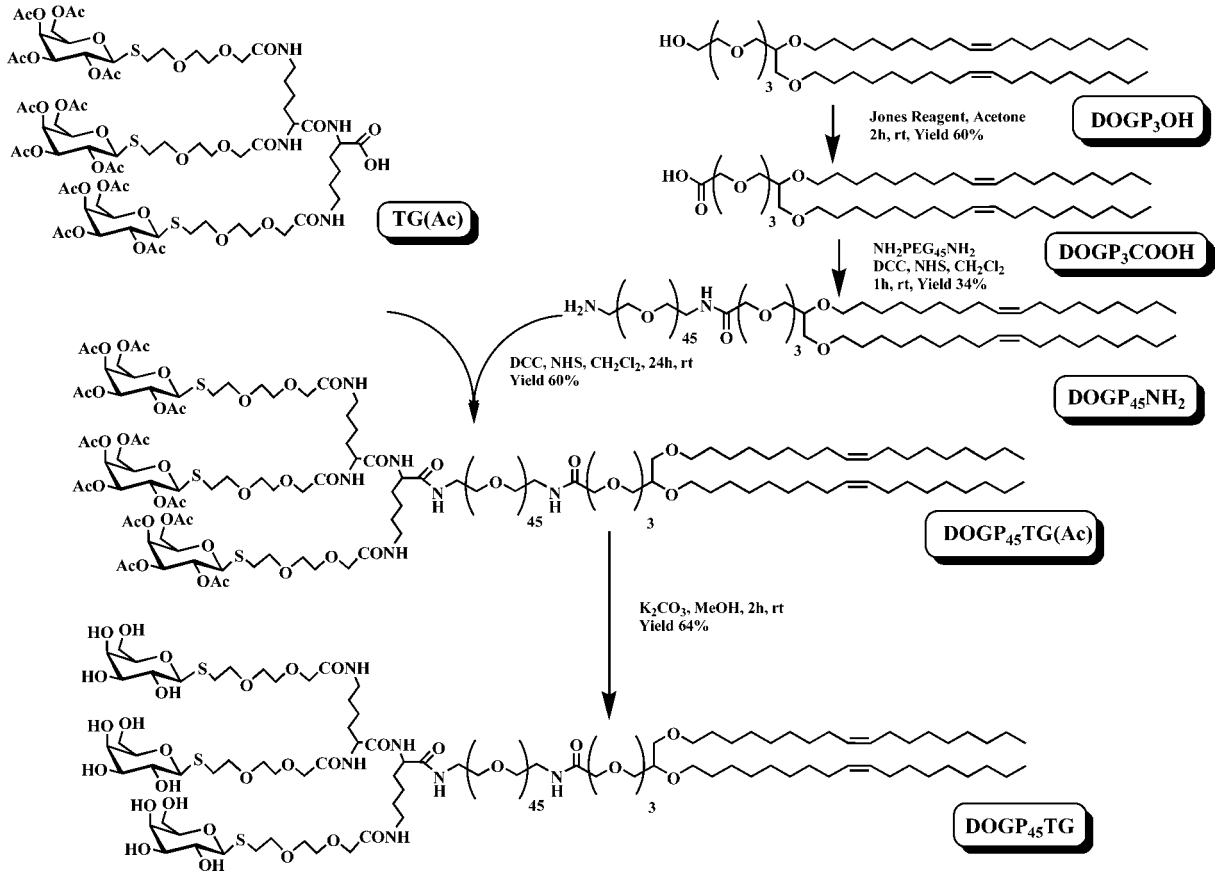
Preparation of Lipoplexes. Plasmid pXL3031 (pCMV−Luc+), obtained as described elsewhere (*29*) and suspended in 300 mM NaCl, was mixed with an equivalent volume of aqueous suspensions of liposomes or micelles prepared at the appropriate concentrations. Since the cationic lipid RPR120535 has three positive groups, a ratio of 6 nmol of cationic lipid/μg DNA corresponds to a charge ratio of 6. The lipoplexes were formed at room temperature for at least 30 min. For transfection assays and ζ-potential measurements, the final concentrations of plasmid DNA were 5 and 10 μg/mL, respectively.

Size Measurement by Photon Correlation Spectroscopy. Dynamic light scattering analyses of liposomes and lipoplexes were performed on a Coulter N4-Plus nanosizer. The liposome preparation was diluted to the hundredth in a final volume of 800 μL of water for injection (wfi) before the measurement. Lipoplexes were not diluted for the assay. After 3 min equilibration, sizes were measured at 90° for 10 min.

Determination of ζ-Potential. Suspensions of liposomes (100 μL in 2 mL of 20 mM NaCl) or lipoplexes (800 μL prepared as described above in 4 mL wfi) were injected into a Malvern Zetasizer 3000 HS. From three to five determinations were made at 25 °C with 10 s between each measure.

Agglutination Assays with *Ricinus communis* Agglutinin (RCA_{120}). The agglutination assay was adapted from ref 30 and performed in standard 96-microwell plates. The liposome suspensions were diluted in 200 μL of 150 mM NaCl and the aggregation of the vesicles was assessed by following the changes, at room temperature, of the turbidity at 450 nm after addition of 10 μg of RCA_{120} (*R. communis* agglutinin, Sigma). With this lectin concentration, the carbohydrate binding sites were almost equimolar to the galactose ligands present on the targeted liposomes, micelles, and lipoplexes. The absorbance at 450 nm was measured 10 times over the time course of 20 min in a Wallac Victor^2 microplate reader. The absorbance of the control (diluted liposomal preparation without addition of the RCA_{120} solution) was subtracted from the absorbance of the aggregated liposomal suspension. The reversibility of the agglutination was verified by addition of 20 μL of 1 M galactose to the aggregated suspensions. For agglutination assay of the lipoplexes, the particles were prepared as described above and RCA_{120} was directly added to the lipoplex dispersion.

Cell Culture. SK-Hep-1 (human adenocarcinoma from liver; ATCC HTB-52) and HepG2 (human hepatocellular carcinoma; ECACC 85011430) cells were grown in minimum essential medium (MEM, Gibco, Invitrogen Corp.) supplemented with 2 mM glutamine, penicillin/streptomycin (100 U/mL and 100 μg/mL, respectively), 1 mM sodium pyruvate, nonessential amino acids, and 10% (v/v) foetal bovine serum. Cultures were maintained at 37 °C in a 5% CO_2/air incubator. Both cell lines were tested for the expression of the Gal/GalNAc receptor by western blot (see Supporting Information) using a mouse monoclonal antibody anti-human Gal/GalNAc receptor (no. 183120, Calbiochem) (*31*). HepG2 cells expressed the protein, whereas, as expected (*32*), SK-Hep-1 cells did not. We verified the localization of the protein on the cell surface by immunomicroscopy with the same antibody (see Supporting Information).



Transfection. Cells were seeded on 24-well culture plates the day before the transfection experiments (120 000 and 80 000 cells/well for HepG2 and SK Hep-1 cells, respectively). Lipoplexes prepared as described above were diluted in incomplete (without serum) cell culture medium containing 100 μM chloroquine. This transfection medium was added to the cells that were further incubated for 36 h at 37 °C in the presence of 5% CO_2. The transfected cells were then washed twice with PBS and lysed with 200 μL cell culture lysis reagent (Promega). Light emission due to luciferase was measured in white 96-microwell plates (OptiPlate TM, Packard) using a Wallac Victor^2 microplate reader equipped for luminescence. The results are expressed in cps (count per second) normalized to the protein concentration of each sample, as determined using the Pierce BCA assay (Interchim).

Cellular Uptake of Fluorescently Labeled Lipoplexes. For lipoplexes prepared from liposomes, fluorescent lipoplexes were obtained by incorporating rhodamine-labeled DOPE in liposomes (5 mol % of total lipid). For lipoplexes prepared from micelles, a fluorescent plasmid was used to form the labeled lipoplexes. Fluorescent plasmid was prepared as described previously (*33*) and contained 30 fluorophores by plasmid DNA. Fluorescent lipoplexes were made and incubated with the cells as described above, except that cells were grown on glass coverslips. At the end of the incubation time, the cells were rinsed with PBS, fixed with 3% paraformaldehyde, stained with DAPI (0.1 μg/μL in PBS), and mounted on slides in Mowiol for examination with a Zeiss Axiophot fluorescence microscope, with a 100× objective lens, coupled to a CCD camera (Hamamatsu) using a Samba imaging software (Unilog, France).

RESULTS

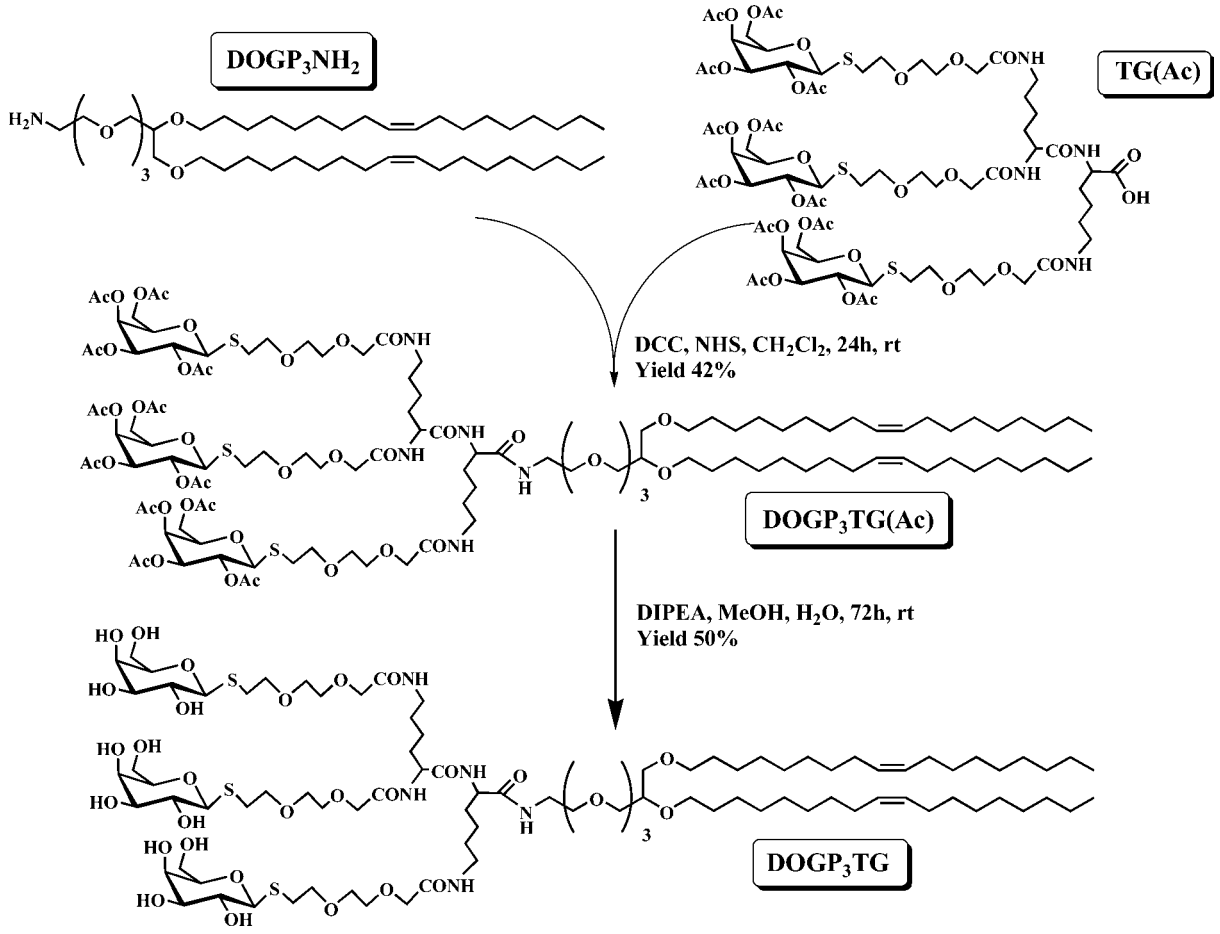
Synthesis of Galactosylated Targeted PEGylated Lipid. The synthesis of TrigalPEG ($DOGP_{45}TG$) (Scheme 1) first required the production of the lipid $DOGP_3OH$ which was synthesized in eight steps starting from glycerol, tetraethylene glycol, and oleyl alcohol according to a procedure described previously (*26*). The primary alcohol of $DOGP_3OH$ was then first oxidized with Jones reagent to give $DOGP_3COOH$ with a good yield. $DOGP_{45}$-NH_2 was readily obtained by reacting the carboxylic function of $DOGP_3COOH$ with an excess of commercial

Scheme 1. Synthesis of the Conjugate TrigalPEG[a]

[a] $DOGP_{45}TG$ is three galactose residues attached to a di-L-lysine scaffold that is conjugated to a dioleyl glycerol anchor via a long polyethylene glycol spacer arm.

$NH_2PEG_{45}NH_2$ in the presence of DCC and NHS. The carboxylic acid function of TG(Ac) (*27*) was activated with DCC and NHS at room temperature in the presence of diisopropylethylamine and reacted with the free amine of $DOGP_{45}NH_2$ to give $DOGP_{45}TG(Ac)$.

The final product TrigalPEG ($DOGP_{45}TG$) was obtained after deprotection of the acetyl groups of the galactose residues with potassium carbonate in methanol. Trigal ($DOGP_3TG$) (Scheme 2) was synthesized according to the same series of reactions starting this time with $DOGP_3NH_2$ (*28*). PEG_{42}−lipid was synthesized to provide a PEGylated lipid equivalent to TrigalPEG but lacking the galactosylated ligand.



Preparation and Characterization of Targeted Stealth Lipoplexes. Two main strategies exist to prepare targeted lipoplexes; they involve the complexation/condensation of plasmid DNA with either positively charged liposomes or positively charged micelles. Targeted liposomes are formed by mixing neutral (e.g. DOPE) and cationic lipids with a lipid carrying a ligand. Targeted micelles are prepared from cationic lipids and the targeted lipid. If the targeted lipid contains a PEG spacer between the ligand and the lipid group, stealth liposomes or stealth micelles are obtained. Targeted lipoplexes are then prepared by adding plasmid DNA to targeted cationic liposomes or micelles.

We have prepared stealth targeted cationic liposomes and micelles by classical methods (see experimental procedures) with the lipids described in Figure 2. PEGylated liposomes and micelles contained 5 and 10 mol % of lipid−PEG, respectively (see Table 1 for the composition). 5 mol % was the maximal amount of TrigalPEG that could be incorporated in the lipidic film to obtain liposomes. When we tried to incorpore more than 5 mol % of TrigalPEG, we failed to obtain liposomes, probably due to the fact that TrigalPEG can adopt a micellar structure in aqueous environment and therefore it is no longer available to be incorporated into liposomes. Targeted PEGylated micelles containing up to 10 mol % TrigalPEG were more easily prepared than targeted PEGylated liposomes. Nontargeted control stealth liposomes or micelles (PEG) were prepared using PEG_{42}−lipid. Standard control liposomes or micelles (C), without PEG−lipids, were also prepared. Lipoplexes were formed by addition of the appropriate amount of liposomes or micelles to plasmid DNA (see the Experimental Procedures).

Lipoplexes prepared with the control liposomes and micelles lacking PEG exhibited an aggregation zone around 2 nmol of cationic lipid/μg of DNA (data not shown), which corresponds to globally neutral particles as previously described (*34*). PEG-containing lipoplexes had a constant size, around 150 nm, in the whole range of charge ratios examined, independent of the presence of the ligand (data not shown). In conclusion, due to the incorporation of PEG in lipoplexes, the aggregation zone of the lipoplexes disappeared. Moreover, the presence of the ligand at the distal end of the PEGylated ligand did not modify the stability of the PEGylated lipoplexes.

Is the Incorporation of PEG in Lipoplexes Efficient To Mask Completely the Surface Charge of the Lipoplexes? Incorporation of 5 mol % PEG−lipid resulted in the decrease of the positive ζ-potential of cationic liposomes from 100 to 130 mV (for liposome C) to 20−25 mV (for both PEG and TriGalPEG liposomes) (data not shown).

Scheme 2. Synthesis of the Conjugate Trigal[a]

[a] $DOGP_3TG$ is three galactose residues attached to a di-l-lysine scaffold that is conjugated to a dioleyl glycerol anchor via a short polyethylene glycol spacer arm.

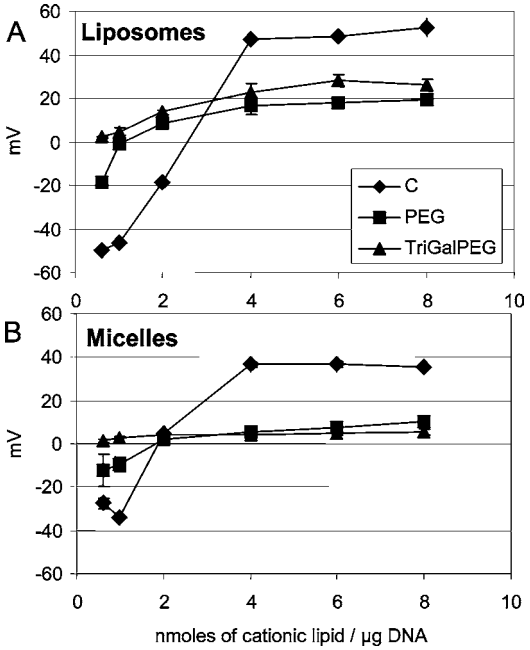
In the presence of increasing amounts of cationic lipid for a given amount of plasmid DNA, lipoplexes were formed that were characterized by a gradually increase of the ζ-potential, which eventually reached a plateau (Figure 3). When PEG−lipid was incorporated into liposomes to form lipoplexes, ζ-potentials reached a plateau at about 20 mV for PEG lipoplexes and 25 mV for TrigalPEG lipoplexes, whereas the plateau was at 50 mV for lipoplexes without PEG. When micelles were used to form lipoplexes, ζ-potentials reached a plateau at about 10 mV for PEG lipoplexes and 5 mV for TrigalPEG lipoplexes, whereas the plateau was at 40 mV for lipoplexes without PEG. The decreased values of ζ-potential obtained at the plateau for lipoplexes prepared with micelles compared to lipoplexes prepared with liposomes probably reflected the decrease in the amount of lipid−PEG incorporated in liposomes (5 mol %) compared to micelles (10 mol %)

In conclusion, incorporation of PEG into lipoplexes substantially masked the positive surface charge of lipoplexes. However, even with 10 mol % of lipid−PEG, the masking of the charge was not complete.

Are the Ligands Properly Exposed on the Surface of Such Lipoplexes? Accessibility of the galactosyl ligands at the particle surface was assayed using the ricin agglutination test. Ricin agglutinin (RCA) is able to aggregate particles (liposomes, micelles, or lipoplexes) that exhibit galactose residues on their surface. This agglutination is inhibited in the presence of an excess of free galactose. All the assays were performed with the same amount of lectin and the same final concentration of galactosylated lipid, namely, 15 μM. We first tested the agglutination of liposomes or micelles without DNA. As indicated in Figure 4A, micelles or liposomes that contained TrigalPEG were agglutinated by ricin, whereas control preparations, lacking galactosyl ligands, were not affected. This agglutination was specific, since it could be reversed by addition of galactose (100 mM).

Lipoplexes formed with micelles or liposomes were then assayed at different cationic lipid to DNA ratios (Figure 4B). An increase of agglutination was observed when the cationic lipid to DNA ratio was increased, despite the fact that the concentration of the galactosylated lipid remained unchanged. For lipoplexes, at cationic lipid to DNA ratio of 6, the agglutination level was nearly the same as the one observed with particles without DNA added. This result was observed for lipoplexes formed from liposomes as well as from micelles. In conclusion, the galactose ligand is accessible to external proteins in all the particles it was inserted in, i.e., lipoplexes, liposomes, or micelles. In the case of lipoplexes, this accessibility is greatest in particles formed with an excess of cationic lipid.

Does the Incorporation of PEG in Lipoplexes Increase the Accessibility of Ligand? To address this question, we have prepared liposomes with Trigal (Figure 2), a lipid containing the same trigalactosyl ligand as TrigalPEG but lacking the $(PEG)_{45}$ spacer. In analogy to the results described above, Trigal-containing liposomes were reversibly agglutinated by ricin (Figure 4A). We also prepared lipoplexes with different cationic lipid to DNA ratios and tested them for agglutination (Figure 4B).



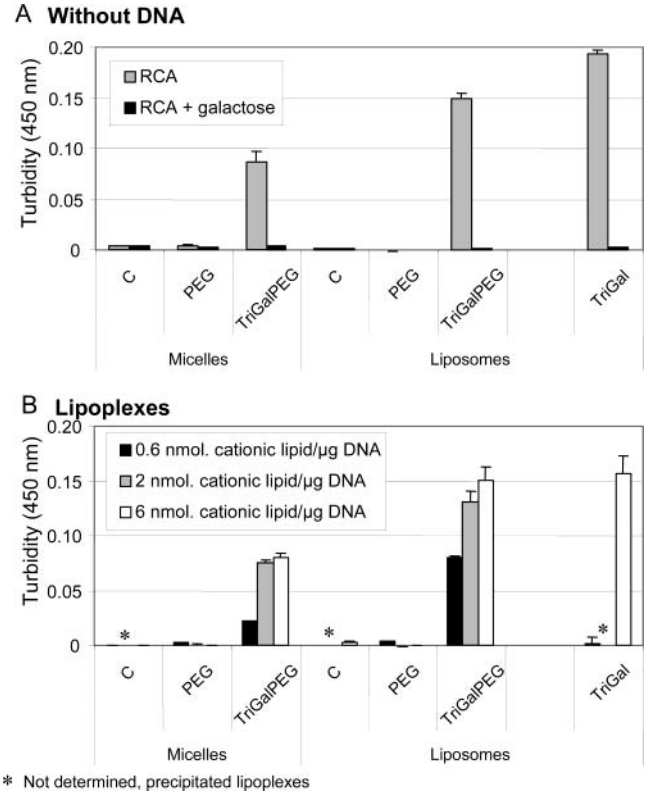


Figure 3. ζ-Potentials of PEG-modified lipoplexes at various cationic lipid to DNA ratios. ζ-Potential of lipoplexes formed with liposomes (A) or micelles (B) at various charge ratios (expressed in nanomoles of cationic lipid per micrograms of DNA) were measured in 150 mM NaCl. C: control lipoplexes with (A) RPR 120535/DOPE (1/1) or (B) RPR 120535. PEG: lipoplexes with (A) RPR 120535/DOPE/$(PEG)_{42}$−lipid (1/1/0.1) or (B) RPR 120535/$(PEG)_{42}$−lipid (1/0.1). TriGalPEG: lipoplexes with (A) RPR 120535 /DOPE/TrigalPEG (1/1/0.1) or (B) RPR 120535/TrigalPEG (1/0.1).

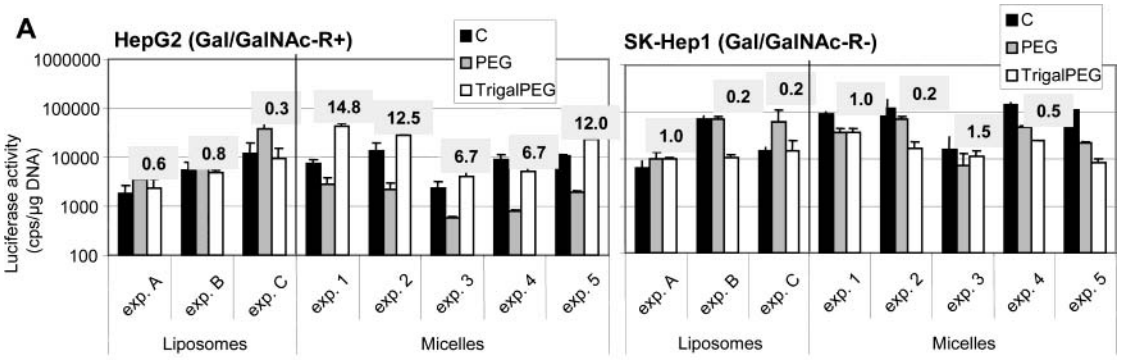

* Not determined, precipitated lipoplexes

Figure 4. Agglutination of liposomes, micelles and lipoplexes by ricin. Liposomes, micelles or lipoplexes were mixed with *R. communis* agglutinin (RCA) (50 µg/mL) at a final concentration of galactosylated lipid of 15 µM. Nontargeted particles were assayed at an equivalent concentration of cationic lipid. Agglutination was followed by measuring the increase of turbidity (at 450 nm). For all samples assayed, increased turbidity was inhibited by an excess of free galactose (100 mM). (A) Agglutination of micelles and liposomes without DNA. Micelles: C, RPR 120535; PEG, RPR 120535/$(PEG)_{42}$−lipid (1/0.1); TriGalPEG, RPR 120535/TrigalPEG (1/0.1). Liposomes: C, RPR 120535/DOPE (1/1); PEG, RPR 120535/DOPE/$(PEG)_{42}$−lipid (1/1/0.1); TriGalPEG, RPR 120535/DOPE/TrigalPEG (1/1/ 0.1); Trigal, RPR 120535/DOPE/Trigal (1/1/0.1). (B) Agglutination of lipoplexes prepared at three lipid to DNA ratios (0.6, 2, and 6 nmol of cationic lipid/µg of DNA). * indicates that the agglutination test was not performed since at this charge ratio lipoplexes lacking PEG aggregated spontaneously.

When compared to lipoplexes containing TrigalPEG, we found that for a cationic lipid to DNA ratio of 6 nmol cationic lipid/µg of DNA, the presence of PEG had no effect on the extent of agglutination. For a ratio of 2 nmol cationic lipid/µg DNA, the lipoplexes lacking PEG aggregated spontaneously and the lectin-triggered agglutination test became unapplicable; in contrast, at the same ratio, the TrigalPEG lipoplexes were stable and, in the presence of ricin, exhibited nearly the same agglutination as liposomes or lipoplexes at a ratio of 6. For the ratio of 0.6 nmol cationic lipid/µg DNA, no agglutination could be observed for lipoplexes lacking PEG, whereas PEG-containing lipoplexes exhibited an agglutination that represented half of the maximal agglutination value. In conclusion, incorporation into lipoplexes of a lipidated PEG chain, bearing a ligand at its distal end, led to particles that exhibited an accessible ligand throughout the whole range of cationic lipid to DNA ratios.

Does Incorporation of PEG Lead to Targeted Gene Transfer? Lipoplexes, prepared with liposomes or micelles, were used to transfect two cell lines, HepG2 and SK-Hep-1. Both derive from human hepatocyte carcinoma, but only HepG2 cells express the Gal/GalNAc receptor at their surface (see Supporting Information). Transfection was performed with a pCMVLuc plasmid during 36 h at 37 °C in the presence of 100 µM chloroquine and in the absence of serum. This treatment resulted in the reduction of the cell growth, as indicated by the determination of the amount of proteins (Figure 5B), but the cells kept a normal morphology upon examination by phase contrast. In addition, there was no noticeable difference of cytotoxicity between the various formulations or type of lipoplexes. Thus, despite the toxicity of the treatment, we considered that we could compare the efficiency of gene transfer of formulations tested under the same culture conditions. In the absence of chloroquine, only lipoplexes lacking PEG led to an efficient transfection (data not shown). As shown in Figure 5A, for lipoplexes prepared from liposomes, no appreciable difference in transfection yield was observed, for both cell lines, between either TrigalPEG lipoplexes or PEG lipoplexes. In addition, the transfection efficiency obtained with PEG-containing lipoplexes was rather surprising, since incorporation of PEG should have been inhibitory. For lipoplexes prepared with micelles, the presence of TriGalPEG resulted in a targeted transfection, since we observed an increased transfection efficiency with HepG2 cells (10.5-fold ± 3.3, $n = 5$) compared to PEG-containing lipoplexes or control lipoplexes; no such targeting effect was found with SK-Hep-1 cells (0.7-fold ± 0.5, $n = 5$). No targeted transfection was observed in the presence of serum (data not shown).

We next wondered whether this targeted transfection could be related to an enhanced uptake of the targeted lipoplexes in HepG2 compared to SK-Hep-1 and to nontargeted lipoplexes. We then incubated fluorescent lipoplexes under culture conditions needed to obtain a

B

	Culture condition			
	10% serum	without serum	10% serum 0.1 mM chloroquine	without serum 0.1 mM chloroquine
HepG2	100	60 ± 30	37 ± 15	20 ± 10
SK-Hep1	100	80 ± 25	40 ± 15	25 ± 10

Figure 5. Transfection efficiency of targeted lipoplexes on human hepatocyte cell lines. (A) HepG2 (Gal/GalNAc−R^+) and SK-Hep-1 (Gal/GalNAc−R^-) cells were transfected in the absence of serum, in the presence of 100 μM chloroquine with lipoplexes prepared at 6 nmol cationic lipid/μg pCMV−Luc+ plasmid (ratio = 6 nmol cationic lipid/μg of DNA) for 36 h at 37 °C (0.5 μg of DNA/well, each condition in triplicate) in 24-well culture plates. Three (for liposomes) and five (for micelles) independent experiments are shown. Composition of the lipoplexes is as indicated in the legend of Figure 4. The numbers indicated at the top of the bars are the enhancement factor between transfection with the targeted TriGalPEG lipoplexes and untargeted PEG lipoplexes. (B) Toxicity study. For each culture condition, the amount of proteins was determined at the end of the transfection. Results are given as percentage of the value obtained with 10% serum in the culture medium. For a given culture condition, there was no significant difference in the amount of proteins recovered for cells transfected with any of the different lipoplexes.

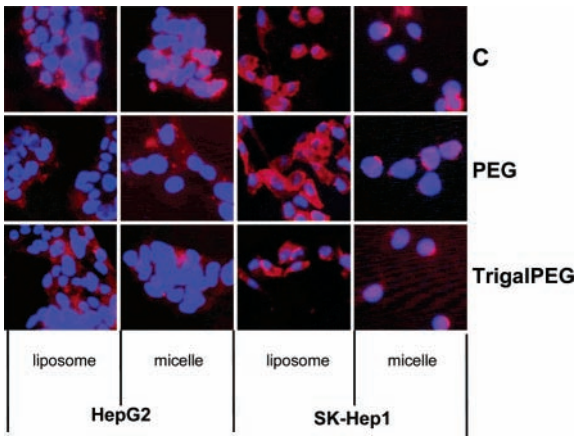

Figure 6. Uptake of fluorescent lipoplexes by human hepatocyte cell lines. HepG2 (Gal/GalNAc−R^+) and SK-Hep-1 (Gal/GalNAc−R^-) cells were incubated with fluorescent lipoplexes as described in the legend of Figure 5. After 36 h of incubation, cells were fixed and mounted for observation.

targeted transfection and examined the cells using a fluorescent microscope. As shown in Figure 6, all lipoplexes, including the PEGylated lipoplexes, were efficiently internalized by both cell lines. Although, compared to control lipoplexes, the uptake of PEGylated lipoplexes appeared less efficient, we observed no clear-cut correlation between a targeted uptake and a targeted transfection.

DISCUSSION

Shortly after the initial utilization of liposomes as drug delivery systems, it became apparent that these lipid vesicles are rapidly removed from the circulation by the cells/organs comprising the reticuloendothelial system (see review in ref 35). Early studies demonstrated that several physical and chemical properties of conventional liposomes, such as size, lipid composition, and surface charge, are able to influence their pharmacokinetic parameters (*36*). Subsequently, the ability of incorporated amphipathic PEG conjugates to prolong the circulation time of these so-called "stealth" liposomes has been demonstrated (*36*). It has also been suggested that PEG chains may provide a steric hydrophilic barrier, which results in a reduced interaction with opsonins and with the RES cells (*37*). Cationic lipoplexes and polyplexes are also cleared extremely rapidly from the circulation in mice (*3*, *4*) because of binding to serum components and nonspecific ionic interactions with cells. Due to these shortcomings, which severely limit their use in vivo, at least after systemic administration, lipoplexes and polyplexes, in analogy to stealth liposomes, have also been coated with hydrophilic polymers, such as PEG (*6*, *17*, *38*, *39*). Such a strategy should result in lipoplexes or polyplexes with a decreased ability to nonspecifically interact with the cells. However, the incorporation of a ligand is required to trigger a specific binding and internalization of the complexes into the target cells (*10*, *17*, *18*). Whereas several groups have described the synthesis of conjugated PEG−lipids bearing a ligand at the distal end of the PEG (*16*−*21*), these targeted PEG−lipids were mostly incorporated in liposomes (*16*, *17*, *20*, *21*) or vesicles (*19*) but only rarely in lipoplexes (*18*). We have chosen a ligand that has been previously used to successfully target hepatocytes (*22*) and linked it at the distal end of a PEGylated lipid. This targeted PEGylated lipid has then been inserted into lipoplexes formulated with a cationic lipid that has been extensively studied (*23*, *40*). We have first characterized the size and the charge of these targeted lipoplexes.

We have demonstrated that the incorporation of PEG into lipoplexes results in a stabilization of the complexes

and in a decrease of their charge surface. However, ζ-potential measurements indicated that the positive charges on the lipoplexes (ratio of 6 nmol cationic lipid/μg DNA) were not completely shielded through use of about 5 or 10 mol % PEG-modified lipids. Consequently, one should expect that nonspecific interactions of PEGylated positively charged lipoplexes with the negatively charged cell surfaces cannot be totally avoided. This observation could explain why PEG-containing lipoplexes lacking a ligand still exhibited a good transfection activity in the presence of chloroquine, a compound known to breach endosomal compartments. If PEG-containing lipoplexes are internalized by cells due to their residual surface charge, chloroquine can promote their escape from endosomes and lead to an efficient gene transfer. Our fluorescence microscopy data suggest an efficient uptake of PEG-containing lipoplexes (Figure 6), which tends to prove that our PEGylated complexes are indeed internalized by cells. In the absence of chloroquine, PEG-containing lipoplexes had no transfection efficiency. In that case, we suspected that lipoplexes were internalized but were unable to escape from endosomes and probably ended up in the lysosomal degradative processes. Of note, an incomplete masking of the charges in PEGylated complexes, resulting in an uptake of the complexes, has already been described (*41*−*43*).

Some authors have recently suggested that PEG-induced inhibition of cell transfection by PEGylated lipoplexes could be explained by a reduction of the insertion of perturbing lipids, such as DOPE, into the endosome/lysosome membranes rather than by inhibiting the interaction of the complexes with the cell surface (*41*, *43*−*45*). It has been shown that lipoplexes are highly ordered structures and that inverted hexagonal phases in the complexes, e.g. provided by DOPE, strongly promote transfection efficiency (*44*, *46*, *47*). In contrast, the presence of lamellar phases in the complex is correlated with stable particles that display substantially lower transfection potency (*44*, *46*). Incorporation of PEG into lipoplexes (with or without DOPE) could stabilize the lamellar phases in the complexes by preventing their transition to hexagonal phases and decrease the transfection potency of these particles. In our case, the addition of chloroquine could be sufficient to destabilize endosomes and lead to an efficient gene transfer.

We also studied the accessibility of the ligand at the surface of the complexes. In analogy to conventional liposomes (*16*, *48*) and cationic lipids (*18*), we attached the trigalactosyl ligand at the distal end of a PEG chain. According to this strategy, the ligand can extend from the lipoplex at the end of a long and flexible spacer arm. We have demonstrated that the trigalactosyl ligand was easily accessible when assayed in an agglutination test with ricin agglutinin. In addition, this accessibility was largely enhanced by incorporation of a PEG spacer. For instance, for lipoplexes lacking PEG, no aggregation with RCA could be obtained at cationic lipid to DNA ratio of 0.6. This probably resulted from the presence of noncompacted DNA that extends around the lipoplexes and prevents the association of galactosylated ligands with RCA. When the charge ratio increases, with increasing amounts of cationic lipid for a given amount of DNA, DNA becomes completely compacted and is no longer able to prevent the binding between the lectin and its ligand. For lipoplexes containing PEG, at the same ratio, a significant aggregation could be obtained. This enhanced accessibility of the ligand due to the presence of PEG was encouraging in the perspective of in vivo targeting lipoplexes.

We were nonetheless unable to obtain a targeted gene transfer with TrigalPEG-lipoplexes prepared from cationic liposomes. We suspect that these lipoplexes are still able to bind nonspecifically to cells, despite the presence of PEG, and that these nonspecific interactions, which lead to an efficient transfection, largely mask the specific, targeted transfection. We succeeded, however, in obtaining a targeted transfection with lipoplexes that were formed with micelles, i.e., particles that lack DOPE. With such lipoplexes, we obtained a 1 order of magnitude enhancement of transfection with TrigalPEG lipoplexes compared to control lipoplexes using HepG2 cells that contain the specific receptor. This was not the case with SK-Hep-1 cells that do not express the Gal/GalNAc receptor. We have also tried to perform a competition study by addition of an excess of free galactose in the transfection medium. However, we obtained poorly reproducible results. We hypothesized that a single galactose molecule was not an efficient enough competitor for a triantennary ligand, due to the binding cooperativity resulting from the presence of three galactose residues in an adequate spatial arrangement (clustering effect). It was, however, surprising that this targeted transfection was only observed with lipoplexes formulated from micelles and not with lipoplexes formulated with liposomes. In addition, in the presence of serum, we failed to observe a targeted transfection, but our lipoplexes induced an efficient transfection. In line with other reports (*12*, *49*−*51*), targeted transfection is not easy to observe and seems to appear only in a rather limited window in which specific interactions between the ligand and its receptor are prominent over nonspecific interactions. This window is determined by various factors, namely charge ratio, relative amount of ligand, size of the complexes, presence or absence of serum, and maybe in our case formulation of lipids in micelles rather than in liposomes.

In conclusion, we have proved for lipoplexes the validity of using a targeted ligand carried by a long PEG spacer arm. Indeed, the presence of PEG stabilized lipoplexes and enhanced the accessibility of the ligand throughout the lipid to DNA ratios range used. However, the presence of residual surface charges and the fact that an efficient targeted transfection was only obtain in the presence of chloroquine, in the absence of serum and with micelle formulations, suggest that other strategies than simple PEGylation should be explored in order to develop an in vivo application of targeted lipoplexes. These strategies could use the design of (i) PEGylated lipids that contain acid-sensitive linkages between PEG and lipids that would be susceptible to "depegylate" in acidic endosomes (*14*, *52*) or (ii) other polymers than PEG that would mask more completely the surface charge of the complexes and would not stabilize lipoplexes in lamellar phases. We are currently working on these options.

Supporting Information Available: Western blot of total cell lysate obtained from HepG2 and SK-Hep-1 cell lines and localization of the Gal/GalNAc receptor on the surface of HepG2 by immunofluorescence microscopy. This material is available free of charge via the Internet at http://pubs.acs.org.

Secondary mAb−vcMMAE Conjugates Are Highly Sensitive Reporters of Antibody Internalization via the Lysosome Pathway

Kerry Klussman, Bruce J. Mixan, Charles G. Cerveny, Damon L. Meyer, Peter D. Senter, and Alan F. Wahl*

Departments of Biochemistry and Chemistry, Seattle Genetics, Inc., 21823 - 30th Drive Southeast, Bothell, Washington 98021. Received January 26, 2004; Revised Manuscript Received April 30, 2004

Monoclonal antibodies (mAb) selectively recognizing tumor surface antigens are an important and evolving approach to targeted cancer therapy. One application of therapeutic mAbs is drug targeting via mAb−drug conjugate (ADC) technology. Identification of mAbs capable of internalizing following antigen binding has been accomplished by tracking decline of surface-bound mAb or by internalization of a secondary mAb linked to a toxin. These methods may not be sufficiently sensitive for screening nor wholly predictive of the mAbs' capacity for a specific drug delivery. We have developed a highly selective and sensitive method to detect mAbs for cell internalization and drug delivery. This system uses secondary anti-human or anti-murine mAbs conjugated to the high-potency drug monomethyl auristatin E (MMAE) via a highly stable, enzymatically cleavable linker. Prior studies of this drug linker technology demonstrated internalization of a primary ADC leads to trafficking to lysosomes, drug release by lysosomal cathepsin B, and ensuing cell death. A secondary antibody−drug conjugate (2°ADC) capable of binding primary mAbs bound to the surface of antigen-positive cells has comparable drug delivery capability. The system is sufficiently sensitive to detect internalizing mAbs in nonclonal hybridoma supernatants and is predictive of the activity of subsequently produced primary ADC. Because of their high extracellular stability, the noninternalized 2°ADC are 100−1000-fold less toxic to cells over extended periods of time, permitting an assay in which components can be added without need for separate wash steps. This homogeneous screening system is amenable to medium-throughput screening applications and enables the early identification of mAbs capable of intracellular trafficking for drug delivery and release.

INTRODUCTION

Monoclonal antibodies (mAbs) that are selective for tumor cells but not efficacious in antitumor treatment are being increasingly applied as vectors for the therapeutic delivery of toxins or cytotoxic agents to the interior of tumor cells (*1*). Success in this latter application requires that the antibody−drug conjugate (ADC) remain stable in circulation, display tumor selectivity, and be internalized upon binding of surface antigen into an appropriate intracellular pathway facilitating drug release and delivery. The utility of mAbs conjugated to small, highly potent cytotoxics has increased with the advance of more potent agents and development of conditionally labile linkage systems. These linkers exhibit a high degree of stability in plasma and selective drug release within the tumor cell (*2*). Current methods to identify mAbs for drug delivery applications depend on a primary screen for selective binding to the tumor cell, and then on secondary assessment for internalization, prior to construction and evaluation of direct mAb−drug conjugates. Approaches to assessing candidate mAbs for internalization include direct labeling with indicators such as colloidal gold or fluorophores for microscopy (*3*, *4*), direct labeling of mAbs with toxins such as Pseudomonas exotoxin A (*5*), or by use of a secondary mAb, reactive with the first and linked to a toxin such as ricin A chain (*6*). The latter approach, while advancing the field of antibody−drug conjugate discovery, may be skewed by the behavior of the protein toxin compared to the trafficking and release of a high potency small molecule. Additionally, the composition of these toxin conjugates may be heterogeneous and the linkage used in such reporters is not sufficiently stable (*7*) to permit continuous cell exposure without significant background toxicity. Taken together, existing tools may demonstrate characteristics and selectivity that may not be optimal for homogeneous screening of hybridoma arrays for mAb with drug delivery capability.

To speed the discovery of tumor-selective internalizing mAbs from hybridoma screening efforts, we have constructed homogeneous assays employing secondary antibody−drug conjugates (2°ADC), composed of secondary antibodies stably linked to the potent cytotoxic agent MMAE via a valine-citrulline peptide linker (*2*). This linker was originally identified based on its high stability outside of cells and ability to be efficiently and selectively cleaved by lysosomal cathepsin B (*8*). Antigen-dependent internalization and lysosomal release was initially shown for doxorubicin (*8*, *9*), but subsequent studies with taxanes and camptothecin (*10*, *11*) and most recently auristatins (*2*) have extended the capability of this linker to other drugs. Two secondary mAbs were examined with specificities toward IgGs of either human or mouse origin and exhibited cytotoxicity dependent upon the binding, internalization, and lysosomal transit characteristics of the primary antibody. We have previously shown the drug remains stably appended to the mAb in serum or plasma and is highly attenuated when incubated with

antigen-negative cells (*2*, *12*). Upon ADC binding and internalization in antigen-positive cells, the drug linkage is fragmented by lysosomal proteases (*8*) releasing the cytotoxic agent MMAE into the cytosol. Internalization results in a 100−1000× increase in selectivity over noninternalizing mAb−2°ADC pairs. Thus the system is sufficiently sensitive to identify small amounts of internalizing mAbs in heterogeneous mixtures such as nonclonal hybridoma cultures.

MATERIALS AND METHODS

Cells and Reagents. Hybridomas for mAb HB43, a murine IgG1 reactive with human IgG1 gamma heavy chain (*13*), mAb 187.1, a rat IgG1 reactive with mouse kappa light chain (*14*), and OKT9, a murine IgG1 specific for human transferrin receptor (*15*), were obtained from the American Type Culture Collection (ATCC, Manassas, VA). mBR96 is a murine IgG3 reactive with an extended form of the Lewis Y (Le^y) antigen found on numerous human carcinoma cells (*16*). cBR96 is a chimeric form of mBR96 composed of a human IgG1 H and L framework (*17*). mAC10 is a murine IgG2b reactive with human CD30 (18). cAC10 is a chimeric form of mAC10 composed of a human IgG1 H and L framework (*19*). mAb hup97 is a human IgG1 directed against melanotransferrin. cL6 is a chimeric form of mL6, a monoclonal antibody recognizing a tumor-associated antigen, known as L6 antigen, present on carcinomas of the lung, breast, colon and ovary, composed of a human IgG1 H and L framework (20). H460, H358, H226, and A549 lung carcinoma and MDA-MB-453 breast carcinoma lines were obtained from ATCC. H3677 and H3396 breast carcinoma were gifts from Dr. I. Hellstrom (Pacific Northwest Research Foundation, Seattle, WA). LX-1 lung carcinoma was a gift from Dr. E. Neuwelt (Oregon Health Sciences University, Portland, OR) and was originally isolated at the Mason Research Institute, Worcester, MA. The anaplastic large cell lymphoma (ALCL) line, Karpas 299, was obtained from the DSMZ (Braunschweig, Germany). All cell lines and hybridomas were grown in RPMI-1640 media (Life Technologies Inc., Gaithersburg, MD) supplemented with 10% fetal bovine serum (Life Technologies Inc.) and were verified to be mycoplasma-free by PCR (ATCC Mycoplasma detection kit, American Type Culture Collection, Manassas, VA). Antibody was purified from culture supernatants by Gamma Bind (Amersham Pharmacia Biotech, Piscataway, NJ) chromatography. Goat anti-mouse-FITC and goat anti-human-FITC were from Jackson Immunoresearch, (West Grove, PA).

Linker Synthesis. The synthesis of the activated valcit linkage system to append drug was modified from the previously described procedure (*9*).

Drug Synthesis. The synthesis of auristatin E has been previously described (*21*). The monomethyl derivative of auristatin E (MMAE) was prepared by replacing a protected form of monomethylvaline for *N*,*N*-dimethylvaline in the synthesis of auristatin E. MMAE was then further modified with an activated derivative of maleimidocaproyl-valine-citrulline that contained a *p*-aminobenzylcarbamate spacer between the MMAE and the linker as previously described (*2*).

Conjugate Preparation. *Antibody Reduction.* To 5 mL of each mAb (10 mg/mL) was added 600 μL of 500 mM sodium borate/500 mM NaCl, pH 8.0, followed by 600 μL of 100 mM DTT in water. After incubation at 37 °C for 30 min, the buffer was exchanged by elution over G25 resin equilibrated and eluted with PBS containing 1 mM DTPA (Aldrich, Milwaukee, WI). The thiol/Ab value was checked by determining the reduced antibody concentration from the absorbance at 280 nm of the solution, and the thiol concentration by reaction with DTNB (Aldrich) and determination of the absorbance at 412 nm.

Conjugation of the Reduced Antibody. The reduced mAb was chilled on ice. The drug-linker (vcMMAE) was used as a frozen DMSO solution of known concentration, and the quantity of drug-linker added to the reaction mixture was calculated as follows:

L stock solution = $V \times$ [Ab] × fold excess/[drug-linker], where V and [Ab] are the volume and molar concentration of the reduced antibody solution, respectively. Cold PBS/DTPA (2.3 mL) was added to each of the two reduced antibody solutions. For the vcMMAE conjugate, 133.6 μL of 7.5 mM maleimidocaproyl-vcMMAE stock solution was diluted into 1.47 mL of acetonitrile. The acetonitrile drug-linker solution was chilled on ice then added to the reduced antibody solutions. The reactions were terminated after 1 h by the addition of a 20-fold molar excess of cysteine over maleimide. The reaction mixtures were concentrated by centrifugal ultrafiltration and purified by elution through desalting G25 in PBS. ADCs were then filtered through 0.2 μm filters under sterile conditions and immediately frozen at −80 °C. ADCs were analyzed for concentration, by UV absorbance; aggregation, by size exclusion chromatography; drug/Ab, by measuring unreacted thiols with DTNB; and residual free drug, by reverse phase HPLC. The procedure reproducibly yielded ADC of <3% aggregate, 8 drugs/mAb and <1% free drug.

Flow Cytometric Analysis of mAb Binding. To evaluate binding of the primary mAbs to cells, 4×10^5 cells were combined with mAb at 10 μg/mL in ice-cold staining media (PBS/2% FBS/0.02% sodium azide) for 30 min on ice and washed twice with ice cold PBS. Cells were then incubated with either goat anti-mouse-IgG FITC or goat anti-human-IgG-FITC, depending on the primary mAb at 10 μg/mL in ice-cold staining media on ice for 30 min and washed as described above. Labeled cells were resuspended in 0.3 mL of PBS and then analyzed on a FACScan (Becton Dickinson Immunocytometry Systems, Mansfield, MA) using the CellQuest software package. Data are shown in histogram format with fluorescence intensity displayed in log intervals on the *x*-axis and number of events (linear scale) on the *y*-axis.

Cytotoxicity Assays. Cell lines were plated at previously determined densities (based on proliferation rates and Alamar Blue labeling efficiency) in 100 μL of complete media and cultured overnight to adhere to the well. Primary mAb and 2°ADC were combined at a ratio of 1:2 in complete media and allowed to complex at room temperature for 15 min prior to serial dilution in complete media. Fifty microliters of these dilutions was added to the cell plate, and the plates were incubated at 37 °C for 96 h. At 92 h cells were labeled with Alamar Blue (Biosource International, Camarillo, CA), at a final concentration of 10% culture volume, and cytotoxicity was measured according to manufacturers directions on a Fusion HT fluorescent plate reader (Packard Instruments, Meriden, CT). (*22*). Raw data was analyzed in an Excel spreadsheet and cytotoxicity expressed by dose−response curves plotted for percent cell viability compared to untreated control wells (*y*-axis), versus concentration of mAb/ADC treatments (*x*-axis).

For comparison of the activity of the 2°ADC with two commercially available secondary immunotoxins (2° IT), Mab-ZAP (*23*) and Hum-ZAP (Advanced Targeting Systems, San Diego, CA), MDA-MB-453 breast carcinoma

cells (Le^{y+}) were plated at 1×10^5 cells/mL (0.1 mL/well) in RPMI 1640 + 10% FBS and allowed to incubate overnight at 37 °C. The following day the 2°ADC or 2°IT was added to cultures at 2 μg/mL (100 ng/well) in complete medium. Immunotoxins consisted of goat-anti-mouse IgG-saporin (Mab-ZAP) or a goat-anti-human-saporin (Hum-ZAP). Serial dilutions of mAb were then added to the cultures and incubated for 96 h. Cytotoxicity was measured by reduction of Alamar Blue. Secondary reagents were tested in the absence of targeting mAb in this system and had no effect on cell growth.

Evaluation of Hybridoma Supernatants and Purified mAb for Internalization by 2°ADC. Three NSCLC cell lines, H460, H358, and H226, were combined and plated at 1×10^3 cells of each line/well in complete media and allowed to adhere overnight. As released drug is distributive to bystander cells, combining multiple cell lines allows identification of internalization if only one cell line is antigen positive. Fifty microliters of neat hybridoma-conditioned culture supernantant from a NSCLC immunization/fusion was combined with 2°ADC, allowed to complex for 15 min at RT, then added to cells for a 6-day incubation at 37 °C. Master wells were frozen for subsequent reculture. Alamar Blue label was added for the last 4 h of culture and fluorescence measured to assess cell viability compared to cells in untreated control wells. Frozen master wells were recultured, and those with supernatant showing >60% cytotoxicity were recloned and the conditioned media evaluated as above. This evaluation was continued through subsequent rounds to purified antibody from isolated clonal cells.

RESULTS

Characterization of mAbs and Cell Lines. As models for evaluation, we selected mAbs and antigen expressing cell lines previously shown to have varying levels of internalization following mAb binding. Cell lines used were also demonstrated to show similar sensitivity to MMAE, with IC_{50} values of the following: 0.88 nM, A549; 0.07 nM, Karpas 299; 0.4 nM, H3396; 1.2 nM, LX-1; and 0.52 nM, H3677. mAb BR96 targets an extended form of the Le^y antigen present on numerous carcinomas and undergoes rapid internalization following antigen ligation (*16*). mAb OKT9 recognizes the transferrin receptor (CD71) expressed on most dividing cells and has also been shown to undergo efficient internalization upon antigen binding (*24*). We have recently shown that cAC10, a chimeric antibody against the CD30 antigen present on numerous hematalogic malignancies, is a highly effective internalizing mAb for intracellular drug delivery (*12*). Murine AC10 and cAC10, a chimeric version of AC10, were evaluated both as an unmodified mAb in combination with 2°ADC, and cAC10 as a direct antibody−drug conjugate. mAb L6 is reactive with L6 antigen expressed on lung, breast, and colon carcinomas (*25*). mAb L6 has been shown to mediate both complement activation (CDC) and antibody-dependent cellular cytotoxicity (ADCC) leading to the destruction of human tumor cells in vitro (*26*), yet was shown to be poorly internalizing when examined as a conjugate with ricin A chain toxin (*27*). Cytotoxicity, and presumably internalization of mAb L6-toxin conjugates, could be increased in combination with the lysosomal disrupting agent listeriolysin, suggesting that internalization of L6-toxin was not followed by release of the active toxin from the lysosome (*27*) and further suggesting that mAb L6 could not effectively deliver a drug via the lysosomal pathway. mAbs hup97 and L49 bind the human melanoma-associated antigen, melanotransferrin (p97). P97 is stably expressed on the cell surface and not detectably internalized upon mAb binding (*28*, *29*). The p97 mAb/Ag complex served as a noninternalizing control in these studies. The antigen expressing lines, reactive antibodies, and respective 2°ADC are summarized in Table 1.

Table 1. Primary and Secondary Reagents

antigen	primary mAb	secondary ADC
CD71	OKT9	187.1-vcMMAE (RAM-MMAE)
Le^Y	cBR96	HB43-vcMMAE (MAH-MMAE)
Le^Y	mBR96	187.1-vcMMAE (RAM-MMAE)
L6 Ag	cL6	HB43-vcMMAE (MAH-MMAE)
p97	huAnti-p97	HB43-vcMMAE (MAH-MMAE)
CD30	cAC10	HB43-vcMMAE (MAH-MMAE)
CD30	mAC10	187.1-vcMMAE (RAM-MMAE)

Comparison of p97- and L6-Targeted Internalization. To evaluate the 2°ADC reporter, H3677 melanoma cells and A549 and LX-1 lung carcinoma cell lines were evaluated for cytotoxicity in response to internalization and drug release by mAb/2°ADC complexes. Figure 1A shows FACS analysis of the relative levels of binding of the previously reportedly noninternalizing mAbs L6 and L49 to their respective antigens on A549, LX-1, and H3677 cells as compared to binding of the secondary FITC reporter reagent alone. FACS evaluations were done at 4 °C in the presence of NaN_3 to stabilize surface binding and to block modulation. All three cell lines were positive for both antigens, with the L6 antigen showing ~1-log greater expression as judged by mAb binding compared to p97.

The cytotoxicity of L6-positive, p97-positive cells was examined in response to mAbs, 2°ADCs, or mAb/2°ADC complexes. Figure 1B shows the sensitivity of LX-1 cells to mAb L6/2°ADC or mAb p97/2°ADC complexes or the 2°ADCs alone. mAb L6/2°ADC was significantly more potent (IC_{50} = 1 μg/mL) than either mAb p97/2°ADC complexes or the 2°ADC alone (IC_{50} indeterminate). Figures 1C and 1D show parallel studies preformed on A549 (lung) and H3677 (melanoma) lines, respectively. As with LX-1 cells, only the combination of anti-L6 and 2°ADC resulted in significant cytotoxicity (IC_{50} on A549 and H3677 = 9 ng/mL and 10 ng/mL, respectively) while nominal cytotoxicity was observed from treatment with the noninternalizing anti-p97/2°ADC complexes or the 2°ADC alone (IC_{50} > 5 μg/mL). Together these data indicate the primary mAb L6 was efficiently internalized to deliver the associated 2°ADC with cytotoxic effect and, contrary to early reports examining L6-toxin conjugates (27), suggest mAb L6 provided efficient delivery of a small, high potent drug.

Le^y-, CD30-, and CD71-Targeted Internalization. To evaluate internalization of mAbs directed to antigens Le^y, CD30 and CD71, the breast carcinoma line H3396 and the anaplastic large cell lymphoma line Karpas 299 were first analyzed for the presence of these antigens by flow cytometry. Figure 2A (upper panels) shows that H3396 cells stained strongly with cBR96 (against the Le^y antigen) moderately with OKT9 (CD71 antigen) and not with cAC10 (CD30 antigen). Karpas 299 cells displayed moderate to high levels of staining with both cAC10 and OKT9, reflecting high expression of the CD30 and CD71 antigens respectively, and nominal staining for Le^y (Figure 2A, lower panel). Together, H3396 and Karpas 299 cells provided reciprocal, nonbinding controls for these studies. As both cell lines expressed CD71, mAb OKT9 was used as a common positive control for internalization.

Using the CD30+ cell line, Karpas 299, both AC10 and cAC10 forms of the CD30 antibody were evaluated for

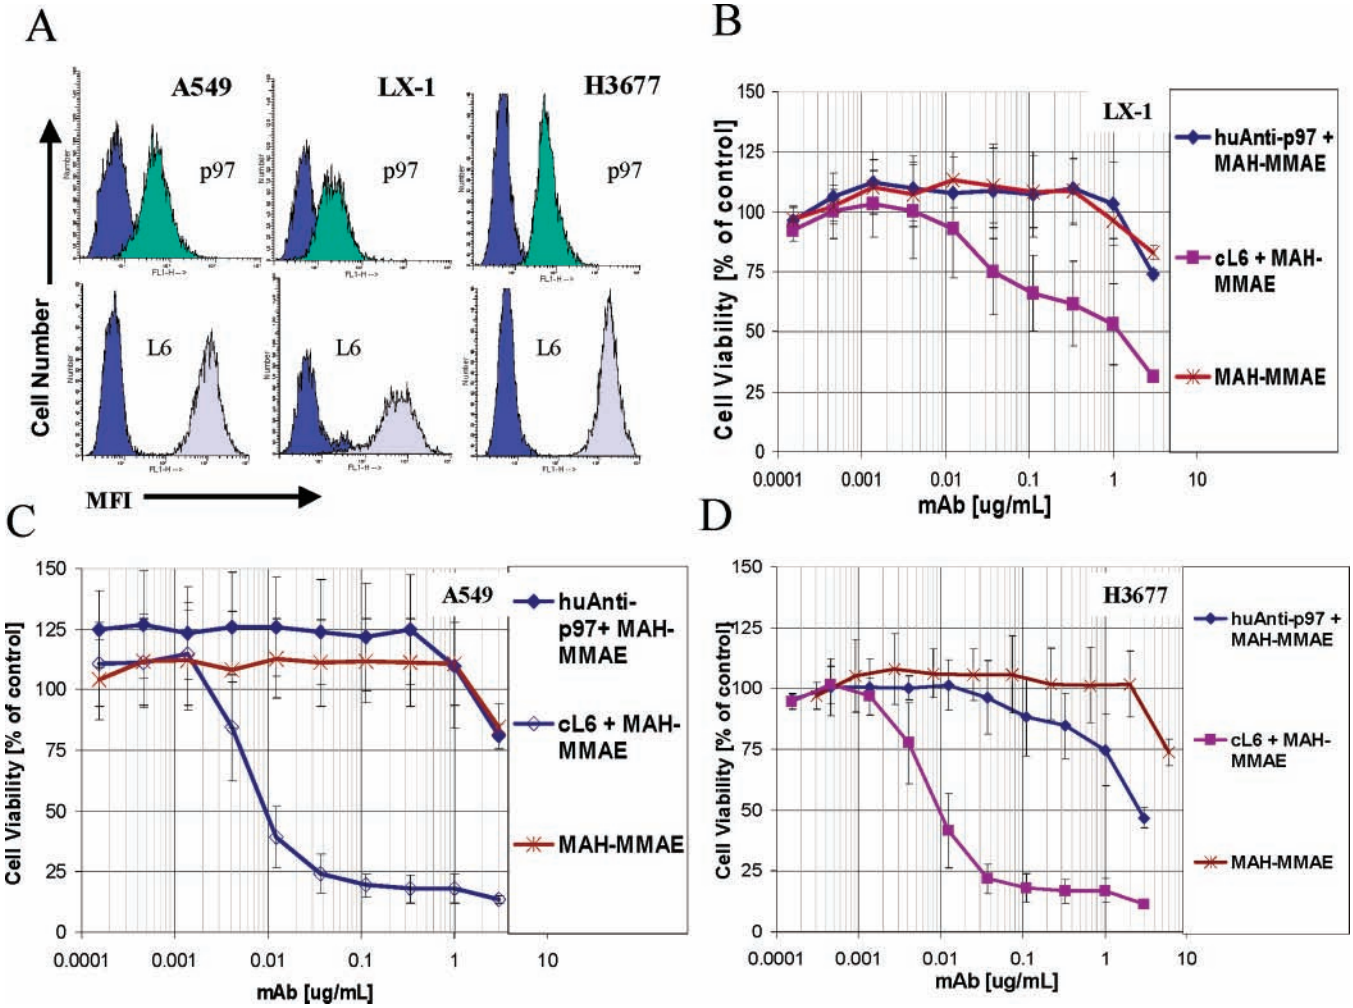

Figure 1. (A) Evaluation of p97 and L6 mAbs on tumor cells. A549, LX-1, and H3677 tumor cells (4 × 10^5 of each) were stained for 30 min on ice with 10 μg/mL of the designated primary mAbs, washed as described in Materials and Methods followed by incubation with 10 μg/mL FITC-labeled secondary Ab for 30 min on ice. After final washes, cells were resuspended in PBS and the resultant fluorescent intensity analyzed by flow cytometry. Blue histograms indicate staining with secondary anti-human FITC only. Shaded histograms, top panel huAnti-p97/secondary anti-human FITC, bottom panel cL6/secondary anti-human FITC. (B) Sensitivity of LX-1 cells to a secondary 2°ADC complexed with mAb-p97 or mAb-L6. (C) Sensitivity of A549 cells to a secondary 2°ADC complexed with mAb-p97 or mAb-L6. (D) Sensitivity of H3677 cells to a secondary ADC complexed with anti-p97 or anti-L6. Cells (2 × 10^3) were plated in microtiter wells in complete media and allowed to adhere overnight, and titrations of primary mAbs complexed with a 2°ADC were added. Mab/2°ADC complexes were preformed at RT for 15 min, and titrations were made in complete media and added to plates containing cells. Cultures were incubated for a total of 96 h at 37 °C, and Alamar Blue label was added for the last 4 h of incubation. A 96-well fluorescence plate reader measuring emission from metabolized dye was used to assess cell viability compared to control wells containing cells as described in Materials and Methods. Shown are the dose−response curves resulting from primary mAb−2°ADC complexes and 2°ADC alone. Data points are the mean of quadruplicate determinations.

CD30-targeted internalization using corresponding anti-mouse or anti-human 2°ADCs (Figure 2B). The nonbinding and binding primary mAbs mBR96 and OKT9 were included as negative and positive controls, respectively, as were the two 2°ADCs alone. Treatment with either AC10 or cAC10 in combination with their respective 2°ADCs resulted in similar IC_{50}s of 3−4 ng/mL. OKT9/2°ADC complexes gave intermediate toxicity (IC_{50} = 50 ng/mL), perhaps attributable to the lower CD71 levels compared to CD30 on the cells (Figure 2A). In contrast, neither the nonbinding control complex, BR96/2°ADC, nor the 2°ADCs alone resulted in cytotoxicity at concentrations below 3 μg/mL (Figure 2B). These results suggest that the 2°ADCs were capable of internalization and delivering drug to the cytosol only when complexed with the internalizing anti-CD30 mAbs or anti-CD71 mAbs. The ~1000-fold potency difference between relevant and irrelevant mAbs also suggest the 2°ADCs remain intact and do not release free drug outside the cell during the course of the 96 h assay.

In a reciprocal experiment, Le^y-positive/CD30-negative H3396 cells were treated with mBR96 or cBR96 (binding Le^y) and their appropriate anti-mouse or anti-human 2°ADCs. mAb OKT9, binding CD71 on these cells, and the nonbinding mAb mAC10 were also evaluated in the presence of 2°ADCs, as were the two 2°ADCs alone. Figure 2C shows moderate H3396 sensitivity to OKT9/2°ADC and high sensitivity to the two BR96 mAbs in the presence of their respective 2°ADCs. IC_{50}s were 80 ng/mL for OKT9/2°ADC and 20−25 ng/mL for the cBR96/2°ADC and mBR96/2°ADC, respectively. The difference in sensitivity may be attributable, in part, to the ~2-logs greater expression of Le^y compared to CD71 on H3396 cells. IC_{50}s for the 2°ADCs alone were indeterminate, and no toxicity was observed with the primary mAbs alone tested at up to 3 μg/mL (data not shown).

Comparison of mAb/2°ADC Complex versus Primary ADC. The results of mAb/2°ADC studies shown above suggested that a direct drug conjugate constructed from mAbs cAC10 or cL6 would efficiently kill respective

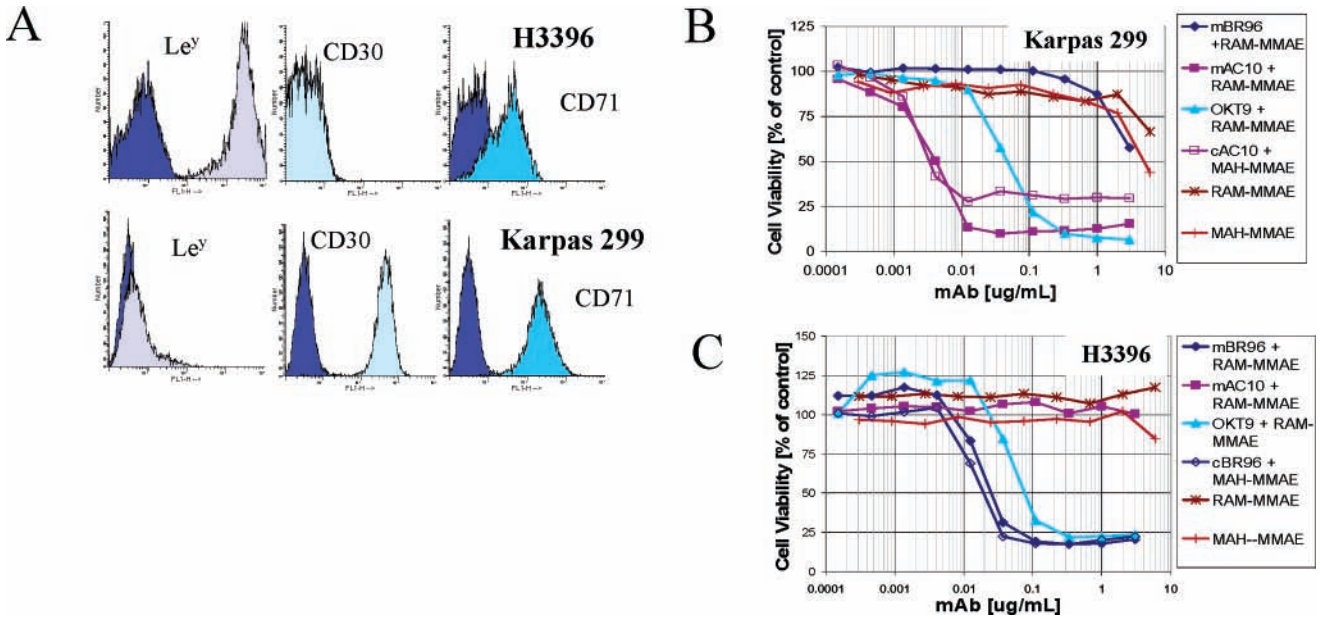

Figure 2. (A) Binding levels of mAb to Le^y, CD30, and CD71 on H3396 and Karpas 299 cells. Tumor cells (4×10^5) were pelleted and resuspended in 10 μg/mL primary mAb in ice-cold staining media and incubated on ice for 30 min, washed as described in Materails and Methods, and resuspended in 10 μg/mL FITC-labeled secondary Ab in ice-cold staining media. Following a 30-min incubation on ice, cells were washed, resuspended, and analyzed by flow cytometry as described in Materials and Methods. Blue histograms indicate FITC-labeled secondary antibody staining only, anti-human FITC (left and center panels), and anti-mouse FITC (right panel). Shaded histograms indicate staining in conjunction with primary mAbs, cBR96 (left panel), cAC10 (center panel) and OKT9 (right panel). (B). Cytotoxic effect of chimeric and murine anti-CD30 mAbs combined with respective 2°ADCs on CD30-positive Karpas 299 cells. Karpas cells were plated at 1×10^4/well in 100 μL of complete media. Precomplexed primary mAbs + 2°ADCs were titrated and added to wells containing cells. Cultures were incubated 96 h at 37 °C with addition of Alamar Blue label for the last 4 h of culture. Fluorescence from the metabolized dye was measured to assess cell viability compared to control wells containing untreated cells as described in Materials and Methods. Response curves show the effects of primary mAbs cAC10 (chimeric) and mAC10 (murine), complexed with their appropriate 2°ADC. IC_{50} values in μg/mL = 0.0034 and 0.004, respectively. Response curves for irrelevant control mAb mBR96/2°ADC complex, IC_{50} = >3 μg/mL, positive internalization control mAb OKT9/2°ADC complex, IC_{50} = 0.047 μg/mL, and the secondary ADCs alone, with IC_{50} values ≥ 5 μg/mL are also shown. C. Cytotoxic effect of chimeric and murine anti-Le^y mAb BR96 combined with anti-human or anti-mouse 2°ADCs on Le^y-positive H3396 carcinoma cells. Cells were plated at 4×10^3/well in microtiter wells in 100 μL/well complete media. Following overnight adherence, titrations of primary mAb + 2°ADC that had been allowed to precomplex for 15 min at RT were added in 50 μL/well, and the assay evaluation was carried out as in B above. Response curves indicate effects of primary mAbs mBR96 (murine) and cBR96 (chimeric), complexed with their appropriate 2°ADC. IC_{50} values in μg/mL = 0.024 and 0.02, respectively. Also shown are response curves for positive internalization control mAb OKT9/2°ADC complex, IC_{50} = 0.075 μg/mL, irrelevant control mAb mAC10/2°ADC complex, and the secondary ADCs alone, IC_{50}s indeterminate. Data points are the mean of quadruplicate determinations.

antigen-positive cells. We have previously shown that conjugation of mAbs via this method does not change binding characteristics as compared to the parent mAb (*2*, *12*). Primary ADCs were prepared from the two mAbs, and their potency and selectivity were compared with that of the primary mAb/2°ADC complex.

The L6-positive cell line A549 was used to evaluate mAb cL6 in the form of a primary ADC (cL6−vcMMAE) or L6 mAb/2°ADC complex, and the resultant dose−responses are shown in Figure 3A. The primary ADC and the primary mAb/2°ADC complexes showed comparable cytotoxicity (IC_{50} = 0.02−0.03 μg/mL for either treatment) whereas the 2°ADC alone had no significant effect.

In a parallel study, the cytotoxicity of a direct conjugate of mAb cAC10 (cAC10−vcMMAE) was compared with that of a cAC10 mAb/2°ADC complex (cAC10 + MAH−vcMMAE). Figure 3B shows CD30-positive Karpas 299 cells treated with either cAC10 + MAH−vcMMAE or cAC10−vcMMAE resulted in IC_{50}s = 8 and 4 ng/mL, respectively. These data suggest that cytotoxicity resulting from the screening with primary mAb/2°ADC complexes would be predictive of the potency of a subsequently produced primary ADC. In the absence of a target-specific primary mAb, the 2°ADC alone demonstrated limited or no cytotoxicity with an IC_{50} not reached for the 2°ADC alone on cells treated up to 6 μg/mL.

Comparison of 2°ADC with 2°IT. The Le^y-positive/CD30-negative cell line MDA-MB-453 was used to compare the potency of a secondary vcMMAE ADC with that of a commercially available 2° IT. Using either mBR96 or cBR96 in combination with their respective 2°ADC gave IC_{50}s of 0.12 and 0.3 μg/mL (Figure 4). In contrast, the IC_{50} was indeterminate using a secondary anti-human immunotoxin (Figure 4A). The potency of an anti-mouse immunotoxin to detect internalization of the mBR96 was diminished 100-fold over that detected with a secondary anti-mouse ADC (Figure 4B). No cytotoxicity was detected with either secondary reagent alone or these secondary reagents in the presence of an irrelevant (anti-CD30) primary mAb at exposures up to 2 μg/mL (data not shown). These data suggest that the route of internalization and degradation of BR96 mAbs is more amenable to delivering the vcMMAE ADC than a protein toxin, as only the 2°ADC reagents retained their antigen selectivity and drug delivery capability in the presence of primary mAb over the concentration range examined.

Screening of Hybridoma for Internalizing mAb. The characteristics of the secondary anti-mouse ADC, high stability and attenuated toxicity outside of cells and highly potent cytotoxicity upon internalization, suggested it could be used to identify internalizing mAbs at low concentration early in the hybridoma screening process. To examine this utility, a primary hybridoma fusion,

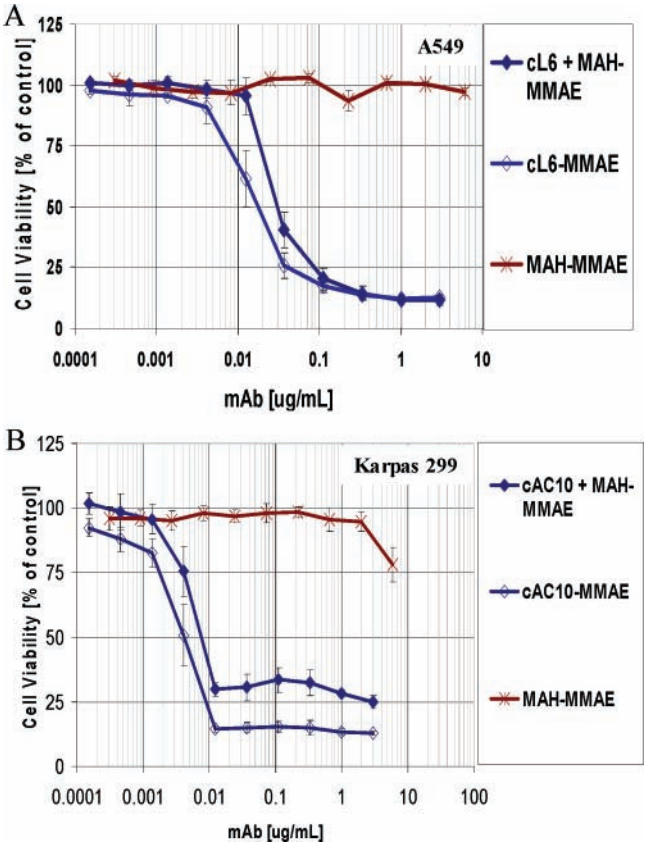

Figure 3. Comparative cytoxicity of primary ADC versus primary mAb/2°ADC complex. (A) mAb cL6 on L6 antigen-positive cells. A549 carcinoma cells were plated at 1×10^3/microtiter well in 100 μL/well complete media. Following overnight adherence, cells were exposed to a titration of either a primary antibody−drug conjugate or a primary antibody complexed with a 2°ADC. Mab/2°ADC complexes were preformed at RT for 15 min, and titrations were made in complete media and added to plates containing cells. Cultures were incubated for a total of 96 h at 37 °C, and Alamar Blue label was added for the last 4 h of incubation. A 96-well fluorescence plate reader measuring emission from metabolized dye was used to assess cell viability compared to control wells containing cells as described in Materials and Methods. Dose−responses shown are for primary mAb/2°ADC complexes, primary ADC, and 2°ADC alone. All data points are an average of quadruplicate determinations. (B) anti-CD30 on CD30-positive cells. CD30 positive Karpas 299 cells were plated at 1×10^4/well in 100 μL of complete media. Titrations of either a primary ADC or primary mAb/2°ADC complex were added to cells plated in microtiter wells and assays carried out as in A above. Data points are the mean of quadruplicate determinations (±SE).

producing mAb against an immunization of multiple NSCLC membrane antigens was arrayed in 15 96-well plates at ∼4−10 different clones/well. The hybridoma were cultured for 5 days followed by three daily media changes. Following this, hybridoma were allowed to condition the media for an additional 72 h, and an aliquot of culture supernantant was removed for screening. Hybridoma plates were frozen for subsequent reculture, and an aliquot of supernatant (50 μL) was combined with a final concentration of 2 μg/mL of secondary anti-mouse ADC and added to wells containing normal lung epithelium or the NSCLC line mixture H460, H358, and H226. Free MMAE is distributive, and ADC internalization and drug release by one antigen-positive cell will result in cytotoxicity of neighboring antigen-negative cells (data not shown). Cultures were incubated for 6 days to allow maximum opportunity of internalization and resultant toxicity evaluated as described above. This method identified multiple wells in which viability was reduced by >60% compared to untreated control (Figure 5A). Plates were thawed, positive wells were expanded, and the screening was repeated with serial dilution. Figure 5B shows the titrated cytotoxicity of supernatant from clone 5D7 and other positive cultures following secondary expansion of masterwells in combination with 2°ADC. Following reexpansion and final cloning of well 5D7, the mAb was purified and evaluated for cytotoxicity in combination with 2°ADC in parallel with known internalizing and noninternalizing controls (Figure 5C). Of note, mAb 5D7 was identified as an IgM, and its stability as a purified mAb has been problematic. This could account for the diminished activity observed with the purified antibody (Figure 5C) but points up the ability of this system to identify both IgG and IgM isotypes.

These data suggest the 2°ADC is sufficiently sensitive to identify low levels of an internalizing mAb in a small volume of nonclonal hybridoma supernatant.

DISCUSSION

The successful use of antibody−drug conjugates for targeted-tumor drug delivery requires that the ADCs be directed to the site via tumor-selective antigens, undergo internalization through antigen modulation, and release drug by intracellular processes. We have combined the elements of a highly potent cytotoxic agent, MMAE, with a highly stable valine-citrulline linker system that is selectively cleavable by lysosomal proteases (*2*, *9*). This lysosomally cleavable linker has been shown to be broadly applicable to intracellular delivery of a variety of cytotoxic agents including doxorubicin, paclitaxel, and camptothecin (*8*−*11*). The resultant ADCs are potent drug delivery systems to antigen-positive cells yet are significantly less toxic to cells lacking the antigen even under conditions of sustained exposure (*2*, *12*). These qualities also suggested this ADC system could be applied early in the screening process for the identification of mAbs that would optimally internalize and deliver drug.

In the course of discovery of internalizing mAbs it would not be practical to prepare primary drug conjugates from the thousands of mAb candidates emanating from a single hybridoma fusion. A screening strategy for internalizing antibodies using a secondary antibody coupled to a protein toxin was initially described by Till et al. (*6*). We have applied this strategy using a novel drug linker and describe here an approach to the discovery of internalizing mAbs using highly sensitive secondary anti-mouse or anti-human antibody−drug conjugate (2°ADC) reporters. These permit the screening of heterogeneous mixtures at low concentrations typically found in early, nonclonal hybridoma supernatants. In the presence of the 2°ADC, internalizing primary mAbs can be clearly identified by resultant cytotoxicity of cultured tumor cell lines using a homogeneous format. The system provides several appealing features: the high potency of the released drug, MMAE, produces significant cytotoxicity only in the presence of an internalizing primary mAb, whereas the attenuation and high stability of the 2°ADC outside the cell allows them to be combined with test cells in the absence of a internalizing mAb for extended periods of time (observed up to 6 days) without appreciable increase in cytotoxicity. This characteristic also allows for addition of the primary mAb and 2°ADC, and eventually cell viability reagent, without the need for intermediate wash steps. The necessity to wash cells at progressive steps adds significantly to the work and assay variability when assessing thousands of hybridoma

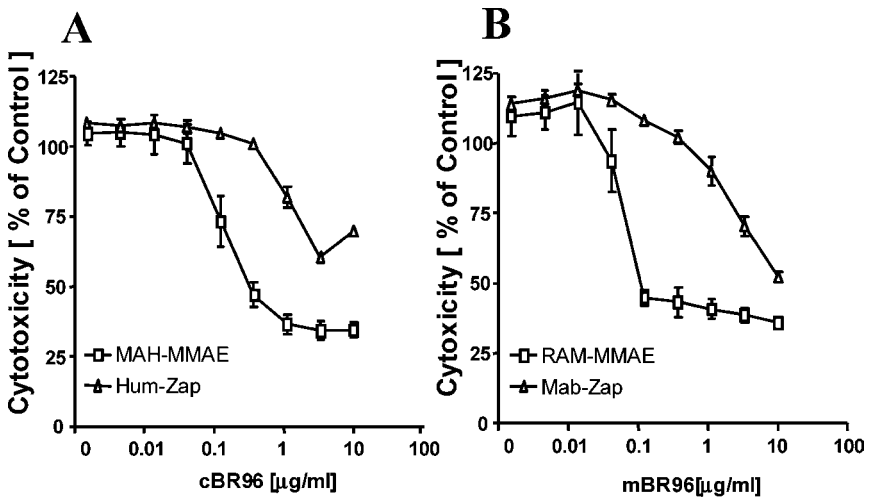

Figure 4. Comparison of 2°ADC and 2°IT reporters. The cell line MDA-MB-453 (Le^y-positive/CD30-negative) was used to compare the potency of a secondary vcMMAE ADC with that of a 2°IT. Cells were exposed to (A) human chimeric mAb BR96 combined with either MAH-MMAE or with Hum-ZAP, or (B) murine mAb BR96 combined with either RAM-MMAE or with Mab-ZAP. Viability was assessed by Alamar Blue metabolism following 96 h incubation. Data points are the mean of quadruplicate determinations (± SE).

supernatants. Additionally, the continuous cell exposure for the duration of a 6 day assay of such supernatants produces >1000-fold difference between internalizing and noninternalizing primary mAb, allowing the identification of even very weakly internalizing mAbs or those present at low (ng/mL) concentrations.

Importantly, comparison of mAb conjugated to drug and immunotoxin (Figure 4) suggests that evaluation of a mAb via a 2° IT reporter may not be predictive of the potential of this mAb to deliver a small drug from conjugate. Previous studies with immunotoxin reporters used primary mAb at 10 μg/mL in order to detect internalization (*16*). In the present study cytotoxicity is clearly detectable at 1/100 this level of primary mAb. It is unclear whether these differences are a function of drug potency or alternate routes of trafficking and release, but worth noting that under the conditions described, the 2° IT would likely not have identified mAb BR96 as internalizing. At the highest concentration of cBR96 tested, cytotoxicity appeared to decrease with the Hum-ZAP (Figure 4A), suggesting that optimal sensitivity is dependent on an optimal ratio of primary mAb and secondary indicator. This was not seen with the 2°ADC reporter suggesting it is less sensitive to the ratio of primary and secondary mAb.

We have examined the effect of 2°ADC reagents on cytotoxicity when used in combination with mAbs and antigens previously reported to rapidly internalize and recycle (*24*), internalize upon mAb ligation (*16*, *12*), or not to undergo antigenic modulation after mAb binding (*28*, *29*). In general our results with the 2°ADC confirm the previously reported behavior of the primary mAbs. Treatment of the cell lines H3396 and Karpas 299 with anti-transferrin receptor mAb, OKT9/2°ADC, resulted in comparable cytotoxicity on the antigen-positive lines. The internalizing mAb BR96, in both murine and chimeric forms, was cytotoxic on Le^y+ H3396 and diminished by >1000-fold on antigen-negative Karpas 299 cells (Figure 2A,B). Conversely, mAb AC10, tested in either its murine or chimeric form, complexed with 2°ADC, showed potent cytotoxicity on the CD30+ line Karpas 299 and diminished by >1000-fold on antigen-negative H3396. Comparison of the direct conjugate cAC10−vcMMAE and the cAC10/2°ADC complex gave similar cytotoxicity on CD30-positive cells, suggesting that results with the mAb/2°ADC complex can predict the activity of a direct ADC made from the primary mAb. Additionally, the comparable cytotoxicity resulting from murine and chimeric forms of a mAb in combination with anti-mouse or anti-human 2°ADC may be a useful indicator of how well antigen recognition and trafficking is preserved in the chimerization or huminazation process.

Studies with the noninternalizing antigen p97, when evaluated with anti-human p97 mAb/2°ADC on three antigen-positive lines, showed significant cytoxicity only at 2−3 logs higher concentration than other mAbs. These results are in agreement with the previous observation that p97 does not undergo mAb-mediated modulation.

mAb L6 has been shown to mediate both CDC and ADCC activity (26), yet L6 conjugated to ricin A chain internalized poorly upon Ag binding (27). Interestingly, treatment of all three L6 antigen-positive lines with mAb cL6/2°ADC resulted in significant cytotoxicity (Figure 1B−D), an effect paralleled by the potency of the direct cL6−vcMMAE conjugate. These data again suggest that the efficacy of mAb−toxin conjugates or secondary mAb−toxin reporters may not be predictive of the activity of the same mAb delivering a drug such as MMAE, and that the 2°ADC system is predictive of the activity of an ADC subsequently produced with the primary mAb.

The system described herein enables the identification of internalizing mAbs against tumor cell antigens based on their optimal delivery of this drug linker system. Because of the significant (3−4 log) increase in cytotoxicity upon binding and internalization, the system is amenable to the identification of internalizing mAbs in dilute and heterogeneous media from hybridoma culture. The high stability and low toxicity of the 2°ADC linker system outside the cell allow for a simple, homogeneous screening tool with significant signal-to-noise ratio when performed over 96 h of continuous exposure. To this end we have successfully used this method to screen a series of hybridoma-conditioned supernatants to identify tumor reactive, internalizing mAbs. The released MMAE is distributive, and ADC internalization and drug release by one antigen-positive cell will result in cytotoxicity of neighboring antigen-negative cells. Thus multiple carcinoma lines can be combined in screening for internalizing antibodies against unknown tumor markers. One mAb identified in this manner and conjugated to vcMMAE was shown to be a potent and selective antitumor agent (A. F. Wahl, manuscript in preparation), validating the

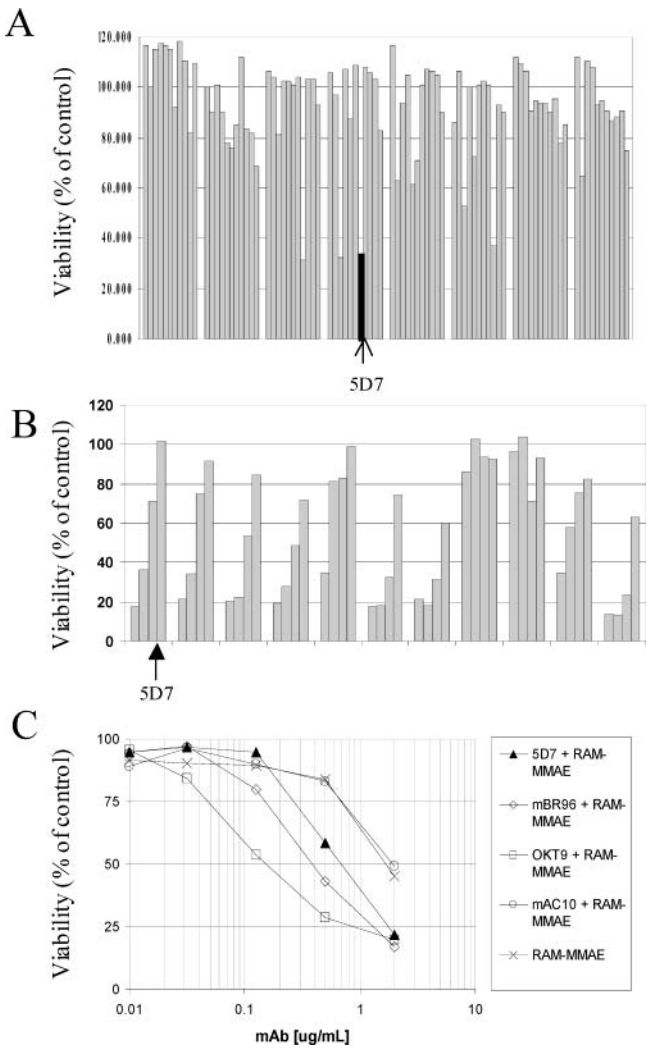

Figure 5. Evaluation of hybridoma supernatants and purified mAb for internalization by 2°ADC. (A). Three NSCLC cell lines, H460, H358, and H226, were combined and plated at 1×10^3 cells of each line/well and allowed to adhere overnight. Fifty microliters of neat hybridoma-conditioned culture supernatant from a NSCLC immunization/fusion were combined with 2°ADC, allowed to complex for 15 min at RT, and then added to cells for a 6-day incubation at 37 °C. Alamar Blue label was added for the last 4 h of culture and fluorescence measured to assess cell viability compared to cells in untreated control wells as described in Materials and Methods. Signal from cells treated with representative positive well 5D7 shown in black bar. (B) Cytotoxicity evaluation of well 5D7 supernatant and other internalization-positive cultures in serial dilution (left to right) following secondary expansion of masterwells. (C) Cytotoxicity evaluation of purified antibody from subsequently isolated clone 5D7 in combination with 2°ADC. Also shown are the 2°ADC alone, and 2°ADC in combination with internalizing mAbs OKT9 and BR96 and nonbinding control mAb AC10.

2°ADC system for discovery. Together with the results presented here this 2°ADC system is a highly useful screening tool to identify optimal antitumor mAbs for drug delivery.

We have investigated poly(amidoamine) (PAMAM) dendrimer interactions with supported 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) lipid bilayers and KB and Rat2 cell membranes using atomic force microscopy (AFM), enzyme assays, flow cell cytometry, and fluorescence microscopy. Amine-terminated generation 7 (G7) PAMAM dendrimers (10−100 nM) were observed to form holes of 15−40 nm in diameter in aqueous, supported lipid bilayers. G5 amine-terminated dendrimers did not initiate hole formation but expanded holes at existing defects. Acetamide-terminated G5 PAMAM dendrimers did not cause hole formation in this concentration range. The interactions between PAMAM dendrimers and cell membranes were studied in vitro using KB and Rat 2 cell lines. Neither G5 amine- nor acetamide-terminated PAMAM dendrimers were cytotoxic up to a 500 nM concentration. However, the dose dependent release of the cytoplasmic proteins lactate dehydrogenase (LDH) and luciferase (Luc) indicated that the presence of the amine-terminated G5 PAMAM dendrimer decreased the integrity of the cell membrane. In contrast, the presence of acetamide-terminated G5 PAMAM dendrimer had little effect on membrane integrity up to a 500 nM concentration. The induction of permeability caused by the amine-terminated dendrimers was not permanent, and leaking of cytosolic enzymes returned to normal levels upon removal of the dendrimers. The mechanism of how PAMAM dendrimers altered cells was investigated using fluorescence microscopy, LDH and Luc assays, and flow cytometry. This study revealed that (1) a hole formation mechanism is consistent with the observations of dendrimer internalization, (2) cytosolic proteins can diffuse out of the cell via these holes, and (3) dye molecules can be detected diffusing into the cell or out of the cell through the same membrane holes. Diffusion of dendrimers through holes is sufficient to explain the uptake of G5 amine-terminated PAMAM dendrimers into cells and is consistent with the lack of uptake of G5 acetamide-terminated PAMAM dendrimers.

INTRODUCTION

Poly(amidoamine) (PAMAM) dendrimers have demonstrated great promise for a variety of biomedical applications. This class of polymers has a number of favorable properties including well-defined chemical structure, globular shape, low polydispersity index (close to 1.0), biocompatibility, and controlled terminal functional groups. Amine-terminated PAMAM dendrimers have proven to be effective as a nonviral cell transfection agent (*1*, *2*). Modification of the PAMAM dendrimer surface functional groups with targeting compounds, fluorescent groups, and drugs have produced promising imaging and therapeutic agents (*3*−*7*).

The success of PAMAM dendrimers in biomedical applications such as those mentioned above raises the question regarding how PAMAM dendrimers interact with cell membranes at the molecular level. The complex structure of cell membranes has prompted several research groups to employ phosphatidylethanolamine-containing vesicles as model systems. Efficient cross-membrane transport and membrane disruption were observed with a strong dependence on dendrimer size (generation), chemical structure of the dendrimer, and composition of the model membranes (*8*−*10*). Based upon these studies, the internalization mechanism of dendrimers into cells has been explained as a dendrimer-mediated endocytosis. Endocytosis is a complex multistep process and can be generally described in terms of cell transfection efficiency. A cationic polymer (e.g. poly(lysine) or PAMAM dendrimer) is proposed to bind with the outer cell membrane and be internalized into the cell through endocytosis. The polymer then exits from the endosome, which is a step that controls the transfection efficiency (*11*). The electrostatic interaction between the polymer and the lipid bilayer membrane and concomitant osmotic imbalance have been understood as important driving forces for polycation-mediated endocytosis (*10*, *12*). Other oligomers that may follow similar pathways include the cell-penetrating peptides (CPPs) such as Tat and oligoarginine (*13*, *14*).

The model systems studied to date show good evidence for membrane disruption by PAMAM dendrimers (*8*, *10*).

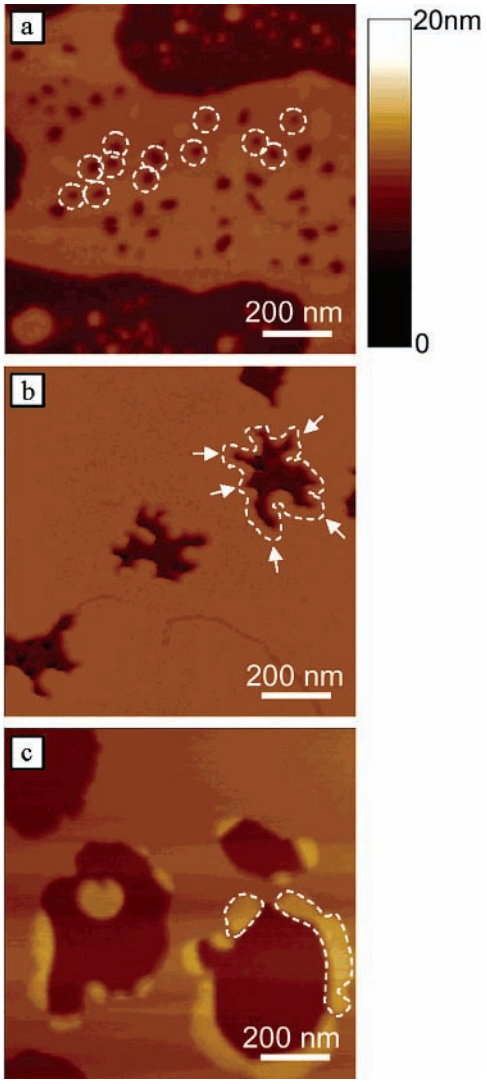

Figure 1. AFM height images of DMPC bilayer after interaction with dendrimers. White lines highlight some of the areas where dendrimers have affected the bilayer (the dendrimer themselves cannot be seen on these images). (a) G7-NH_2 cause the formation of small holes, 15−40 nm in diameter, in the previously intact parts of the bilayer (see dark spots). (b) G5-NH_2 remove lipid molecules primarily from edges of existing bilayer defects, i.e., dark areas grow in size, see arrows. (c) G5-Ac do not remove lipid molecules from the surface. Instead they adsorb to edges of existing bilayer defects.

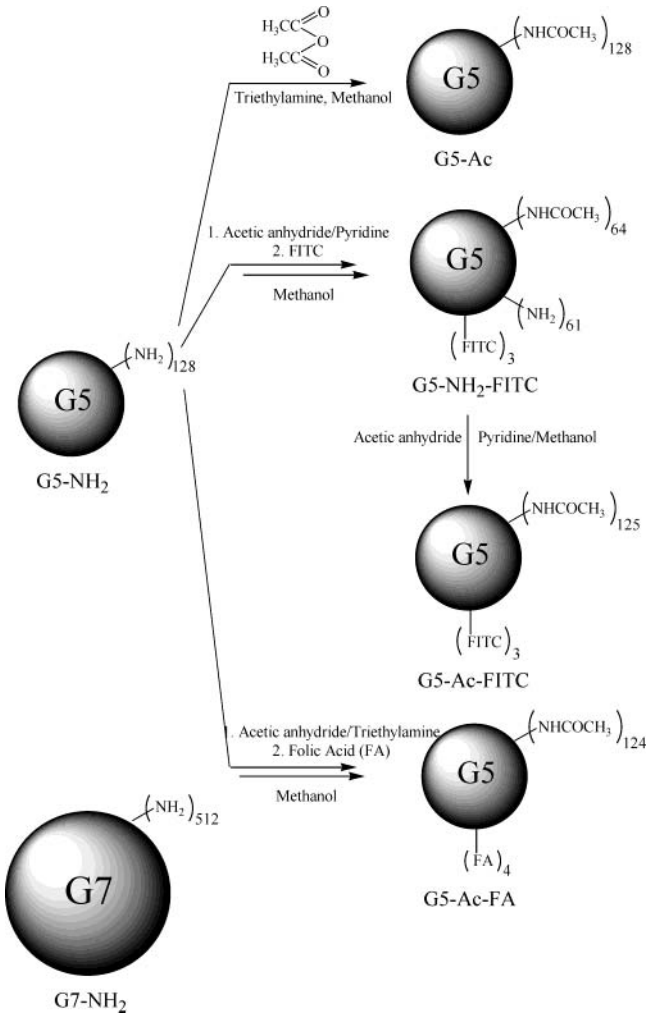
However, they do not provide direct evidence for the nature of the membrane/dendrimer interaction or the endocytosis process. To study this interaction in greater detail, we have used atomic force microscopy (AFM) to directly image supported DMPC lipid bilayers upon exposure to PAMAM dendrimers. The results of this study are summarized in Figure 1 (*15*, *16*). G7 with amine-terminated surfaces (G7-NH_2) generated 15−40 nm-size holes in the bilayer (Figure 1a). In the case of G5-NH_2, however, few new holes were observed (Figure 1b). Instead, the dendrimer removed lipid molecules from edges of existing bilayer defects expanding the size. Amine-terminated dendrimers are protonated in neutral water (*9*, *17*) and therefore can be anticipated to have a substantial electrostatic interaction with the DMPC lipid. The G7-NH_2 has a larger number of primary amine groups (512) than the G5-NH_2 (128) at the same molar concentrations, resulting in a greater charge density. G7-NH_2 also has a larger radius of curvature. These two physical differences likely contribute to the higher level of membrane disruption for the G7 dendrimer. Varying the chemical functionality of the surface significantly changed the outcome of the interaction. Acetamide-terminated G5 PAMAM dendrimer (G5-Ac) did not result in hole formation or the expansion of existing defects. Instead, G5-Ac intercalated at edges of preexisting bilayer defects (Figure 1c). These results illustrate that holes are formed and/or expanded in DMPC-supported bilayers by the addition of G7-NH_2 or G5-NH_2 (both positively charged in neutral water). The addition of neutral G5-Ac dendrimer does not cause hole formation at 10−100 nM concentrations. This set of results is particularly striking because PAMAM dendrimers must have charge-neutralized surfaces for selective drug delivery applications (*3*, *18*). These results confirm that amine-terminated materials show undesirable nonselective uptake into tested cell types. In contrast, the amine-terminated dendrimers are highly efficient nonspecific transfection agents while the acetamide-terminated polymers do not transfect cells.



The AFM experiments on supported lipid bilayers suggest the following hypotheses: (1) amine-terminated PAMAM dendrimers can induce the formation of holes in cell membranes, (2) the holes generated in the cell membranes allow the diffusion of molecules into and out of the cell, (3) acetamide-terminated dendrimers do not enter cells because they do not interact with membrane phospholipids and generate holes.

In this paper, we test the three hypotheses by investigating the interaction of G7-NH_2, G5-NH_2, and G5-Ac PAMAM dendrimers with KB and Rat2 cell membranes. We have evaluated the release of two cytosolic enzymes, lactate dehydrogenase (LDH) and luciferase (Luc), from the cells upon exposure to dendrimers in terms of generation and the identity of surface functional group (amine or acetamide). The temperature dependence of the binding and internalization has also been studied. It was found that G7-NH_2 and G5-NH_2 PAMAM dendrimers induce significant leakage of LDH and Luc whereas G5-Ac does not. Similarly, the presence of G5-NH_2 was shown to make the cell membrane permeable to the small molecules such as propidium iodide (indicating diffusion into cells) and fluorescein (indicating diffusion out of cells) even though the cell was still viable. These results, in addition to others discussed in this paper and the AFM data illustrated in Figure 1, provide direct experimental support for hypotheses 1, 2, and 3.

EXPERIMENTAL PROCEDURES

Preparation of Materials. Generation 5 and 7 PAMAM dendrimers were synthesized at the Center for Biologic Nanotechnology, University of Michigan. All other chemicals were acquired from Aldrich and used without further purification. Water used in this work was purified by Milli-Q Plus 185 system and had a resistivity higher than 18 MΩ/cm. The PAMAM dendrimers were purified using ultrafiltration and dialysis (*2*). Purified PAMAM dendrimers were then acetamide capped using triethylamine (20% mol excess to acetic anhydride) as a proton acceptor as described in the literature (*18*). Folic acid (FA) was conjugated to G5 PAMAM dendrimers after partial acetylation, followed by full acetylation (*3*). Numbers of primary amine end groups were measured by potentiometric titration (*18*) and numbers of modified end groups were calculated based upon the titration result of the starting G5-NH_2.

Scheme 1. End Group Modification of PAMAM Dendrimers Investigated in This Study: Amine End Groups (−NH_2, Generations 5 and 7) and Acetamide End Groups (−$NHCOCH_3$, Generation 5)[a]

[a] Note that the numbers of end groups and functional groups are given as the theoretical values in this scheme.

Dendrimer−fluorescein conjugates were obtained as follows. G5-NH_2 (54.4 mg) in 5 mL of methanol was acetylated by adding 11.7 mg of acetic anhydride in an equal volume of methanol and vigorously stirring the mixture for 24 h, resulting in acetylation of half the primary amine groups (Scheme 1). Fluorescein isothiocyanate (FITC) (2.62 mg) in 10 mL of methanol was then added, and the mixture was stirred for 24 h. 10 mL of the reaction mixture was then dialyzed against 0.5 M NaCl solution followed by dialysis against water (six times, 4 L) for 3 days to remove methanol solvent and unreacted small molecules. The water was removed using a rotary evaporator, and the resulting solids were redissolved into 3−5 mL of water. Lyophilization for 3 days produced solid G5-NH_2−FITC conjugate. The remaining 10 mL of the reaction mixture including unpurified G5-NH_2−FITC conjugate and unreacted small molecules was fully acetylated and purified, resulting in G5-Ac−FITC.

Identification of Dendrimer Conjugates. The dendrimer-based conjugates (G5-Ac−FA, G5-NH_2−FITC, and G5-Ac−FITC) were analyzed by UV/vis spectroscopy. The maximum absorbance (λ_{max}) of FA was shifted from 280 to 289 nm after conjugation, indicating that FA was conjugated to the PAMAM. Absorbance peaks of free FITC appeared at wavelengths of 270 and 490 nm. After the conjugation reaction, the FITC peaks were shifted to 280 and 500 nm, respectively. Further purification of synthesized dendrimers was performed by repeated ultrafiltration, dialysis with water and methanol, and lyophilization (*3*, *19*). The dendrimer−FITC conjugates were also evaluated by gel eletrophoresis after purification using agarose gel with 2% ethidium bromide to confirm that the polymers have the desired charged groups and no impurities are present such as free FITC.

MALDI-TOF measurements were carried out using a Waters Tofspec-2E (Milford, MA) using the linear delayed extraction mode. The instrument was calibrated with a mixture of known proteins in a sinapinic acid matrix before use. Five microliters of each sample solution in ultrapure water/methanol (50/50 by vol %) was mixed with 5 μL of matrix solution, and 1 μL spots were placed on the target. The matrix solution was 2,5-dihydroxybenzoic acid (Aldrich, Milwaukee, WI), dissolved in 50/50 acetonitrile/water with 0.1% TFA, at a concentration of 10 mg/mL. Five laser shots were added per spectrum, and multiple spectra were added together. The mean smoothing algorithm was applied to the data, and the baseline was subtracted. A comparison between theoretical and experimental molar masses is provided in Table 1.

Preparation and AFM Measurement of Supported DMPC Lipid Bilayers. DMPC lipid bilayers were chosen since these phospholipids are an important part of mammalian cell membranes, and the lipid bilayers are easily accessible to high-resolution imaging by AFM under physiological conditions. DMPC was purchased from Avanti Lipids, Alabaster, AL. A 0.5−0.7 mg/mL suspension of small, unilamellar vesicles (SUVs) was prepared using literature procedures (*15*). Supported lipid bilayers were formed by depositing 80 μL of liposome suspension on a piece of freshly cleaved mica. After an incubation time of about 20 min, the sample was gently rinsed with water to remove excess lipids and placed in the AFM for imaging as described elsewhere (*15*). All AFM measurements were performed in tapping mode on a Nanoscope IIIa Multimode scanning probe microscope from Digital Instruments (DI, Veeco Metrology Group, Santa Barbara, CA). The AFM was equipped with a liquid cell (DI) and a silicone nitride cantilever (DI model NPS, spring constant 0.32 N/m, length 100 μm) operating at a drive frequency of about 6−9 kHz. After taking an initial image of the bilayer, 20−30 μL of dilute dendrimer solution was injected into the liquid cell. The resulting dendrimer concentrations were in the range of 10−100 nM. After adding the dendrimers, imaging continued to observe their effect on the bilayer.

Cell Lines. The KB and Rat2 cell lines were purchased from the American Type Tissue Collection (ATCC; Manassas, VA) and grown continuously as a monolayer at 37 °C, and 5% CO_2 in RPMI 1640 medium (Mediatech, Herndon, VA) and Dulbecco's modified Eagle's medium (DMEM, Gibco, Eggenstein, Germany), respectively. Both cell lines were transfected to permanently express the Luc gene using PAMAM dendrimer-mediated gene transfection as previously reported (*1*, *20*). The Luc expressing KB and Rat2 Cells are noted as KBpLuc and Rat2pLuc, respectively. The RPMI 1640 and DMEM media were supplemented with penicillin (100 units/mL), streptomycin (100 μg/mL), and 10% heat-inactivated fetal bovine calf serum (FBS) before use. Folic acid receptor expressing KB cell line (FAR-KB) was also used for specific binding with G5-Ac−FA. The KB cell line for specific binding was cultured in the RPMI 1640 medium without

Table 1. Molar Mass and Chemical Composition of the Dendrimers Employed in This Study

dendrimers	no. of amine terminal groups	no. of acetamide terminal groups	no. of FITC	no. of FA	theoretical molar mass[d]	experimental molar mass[e]
G5-NH_2	110[a]	-	-	-	28826	28260

G5-Ac−FA	13[c]	93[c]	-	4[c]	33394	32519

[a] Measured by potentiometric titration. [b] Calculated from titration result of G5-NH_2. [c] Determined by stoichiometry of the conjugation reaction based on the titration data of starting G5-NH_2. [d] Theoretical molar mass values for G5-Ac, G5-NH_2−FITC, G5-Ac−FITC, and G5-Ac−FA are calculated based upon the experimental molar mass of the G5-NH_2 starting material employed. Note that G5-Ac and G5-Ac−FA were prepared from G5-NH_2 containing 110 primary amine groups and having a molar mass of 28,260 as measured by MALDI-TOF. The G5-NH_2−FITC and G5-Ac−FITC were prepared from starting G5-NH_2 with 109 primary amine groups and molar mass of 26,462 as measured by MALDI-TOF. [e] Measured by MALDI-TOF spectroscopy.

folic acid (Mediatech, Herndon, VA) for at least 4 days, resulting in the FAR-KB cell line.

Luc and LDH Assays. To assess the release of cytosolic enzymes caused by general toxicity, the cytotoxicity of the G5 dendrimers was preassayed using a BCA protein assay (*21*). The assay results show that the both G5-NH_2 and G5-Ac are not cytotoxic up to a 500 nM concentration (>90% cell viability). Based on this information, the assays performed to investigate the cytosolic enzyme release were carried out in a dendrimer concentration range of 10−500 nM. Within this range, dendrimers are non-cytotoxic so the observed enzyme release can be ascribed to an increase in cell membrane permeability as opposed to general lysis due to cell death.

A concentration of 5×10^4 cells/well of both KBpLuc and Rat2pLuc cells were seeded on 24-well plates to prepare cell monolayers. After 24 h, cell culture media were removed and replaced by 300 μL/well of dendrimer/PBS (Ca^{2+}, Mg^{2+}) solutions at various dendrimer concentrations. Cells were incubated either at 6 or 37 °C at 5% CO_2. The supernatants were then collected at specific time points ranging from 1 h to 3 h. Cell debris were removed by centrifugation of the supernatant (at 400 × g for 2 min).

The LDH activity in the cell supernatant was analyzed using an LDH assay kit (Promega Co., Madison, WI). The supernatant (20 μL) was mixed with 50 μL of reagent solution, incubated at room temperature for 30 min, followed by adding 50 μL of stop solution (acetic acid). The change in absorbance (proportional to LDH activity) was measured at 490 nm at room temperature using Spectra Max 340 ELISA Reader (Molecular Devices, Sunnyvale, CA) spectrophotometer. Luc activity was quantified using a chemiluminescence assay. Light emission from collected supernatants (10 μL) incubated with 2.35×10^{-2} μmol of luciferin substrate (Promega Co., Madison, WI) was measured in the chemiluminometer (LB96P; EG & G/Berthold, Gaithersburg, MD). The measured LDH and Luc activities were either adjusted for the protein concentration of the sample or recalculated by percentage to the activities of cell lysates of intact cells.

Fluorescence Microscopy Observation. Rat2 cells (4×10^4) were seeded on six MatTek glass-bottom Petri dishes (35 mm) and incubated at 37 °C under 5% CO_2 for 24 h. The media was removed, and 2 mL of dendrimer−FITC conjugate/PBS (Ca^{2+}, Mg^{2+}) solution was added. Three dishes were incubated with added dendrimer solutions at 37 °C under 5% CO_2 for 1 h. The other three dishes were precooled at 6 °C for 30 min before adding the dendrimer solutions and incubated with the dendrimer solution at 6 °C for 1 h. Dendrimer solutions were removed, and the resulting cell monolayer was washed with PBS. Cells were fixed with 2% formaldehyde

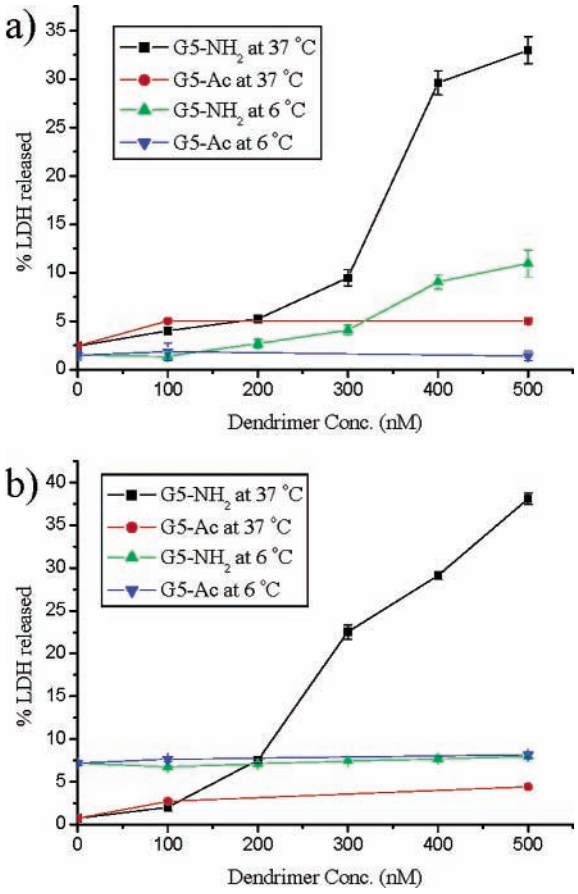

Figure 2. Dose-dependent LDH release from (a) KBpLuc and (b) Rat2pLuc cell lines at 37 °C and 6 °C by G5-NH_2 and G5-Ac PAMAM dendrimers.

in the PBS (Ca^{2+}, Mg^{2+}) at room temperature for 10 min, followed by washing with PBS twice. DNA in the cell nucleus was then stained by DAPI. The samples were imaged with a Nikon diaphot 200 inverted microscope, using appropriated filters and dichroic to image FITC (465−495 nm excitation, 505 nm dichroic, 515−555 nm emission). A mercury vapor lamp was the light source for the epiflourescense imaging. Nikon 20× plan Apo 0.9 na was used as an objective. Images were captured with an Orca-ER16 bit gray scale CCD. The light path filters were controlled with Sutter Instrument Company's Lambda N2 TTL controller, and the camera was driven with Compix software.

Assessment of Reversibility of Dendrimer-Induced Membrane Permeability. Four wells with 5×10^4 Rat2 cells were prepared for each particular dendrimer concentration resulting in 16 wells in total. The supernatants were removed from two wells out of four

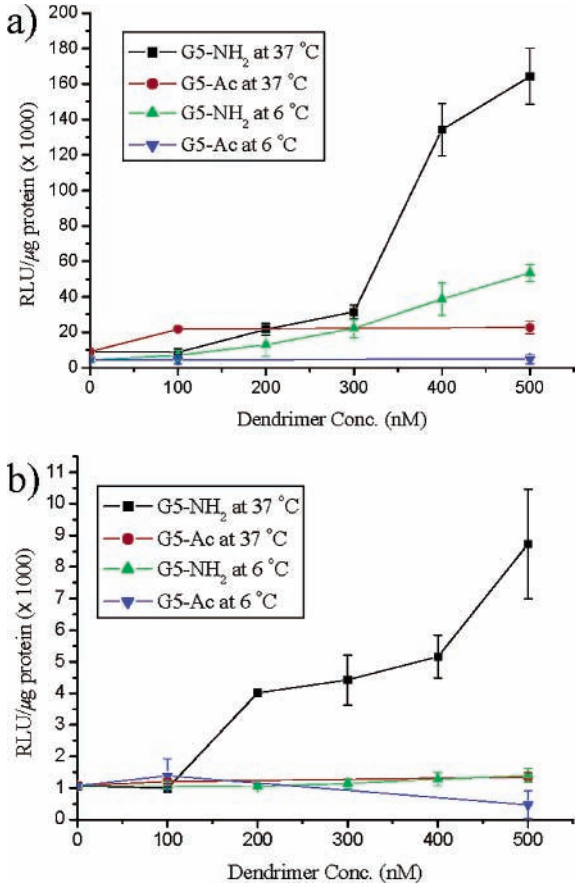

Figure 3. Dose-dependent Luc release from (a) KBpLuc and (b) Rat2pLuc cell lines at 37 °C and 6 °C by G5-NH_2 and G5-Ac PAMAM dendrimers.

wells after 1 h incubation and assayed using the techniques described above for LDH. These wells were then replaced with PBS and assayed again after an additional2 h. The other two wells were incubated with G5-NH_2 dendrimer solutions for 3 h and also assayed.

PI and FDA Staining and Flow Cytometry. The cells were stained with propidium iodide (PI; Molecular Probes, Eugene, OR) and fluorescein diacetate (FDA; Molecular Probes, Eugene, OR) by modification of a protocol described previously (*22*). One milliliter of 2.5 $\times$ 10^5 KB and Rat2 cells was seeded in 12-well plates and incubated at 37 °C under 5% CO_2 for 24 h. FDA staining was performed as follows. The media was removed, and 50 μL of 10 mg/mL FDA/H_2O solution was added. Dendrimer/PBS solution (300 μL) was then added after 30 min and incubated for another 30 min. For PI staining, 300 μL of dendrimer/PBS solution was added after removal of cell culture media followed by addition of 50 μL of 10 mg/mL PI/H_2O solution. For both PI and FDA staining, total incubation time was 1 h. After the incubation, cells were trypsinized with trypsin−EDTA and centrifuged at 1200 rpm for 5 min. Resulting cell pellets were then resuspended in PBS with 0.1% bovine serum albumin (BSA).

The fluorescence signal of individual cells was assessed with a Coulter EPICS/XL MCL Beckman-Coulter flow cytometer and data were analyzed using Expo32 software (Beckman-Coulter, Miami, FL) (*23*, *24*).

RESULTS

Dendrimer-Induced Enzyme Leakage from Cells. The effects of G7-NH_2, G5-NH_2, and G5-Ac dendrimers on the membrane permeability of KB and Rat2 cells were investigated using LDH and Luc assays. Concentration dependent dendrimer-induced LDH release at 37 and 6 °C is shown in Figure 2. As the concentration of G5-NH_2 increases, the LDH release from both KBpLuc and Rat2pLuc increases. In contrast, neither cell line releases a significant amount of LDH as a result of exposure to G5-Ac. KBpLuc and Rat2pLuc cells incubated with both G5-NH_2 and G5-Ac at 6 °C exhibited no LDH release. Luc release followed the same general trend observed for LDH release (Figure 3).

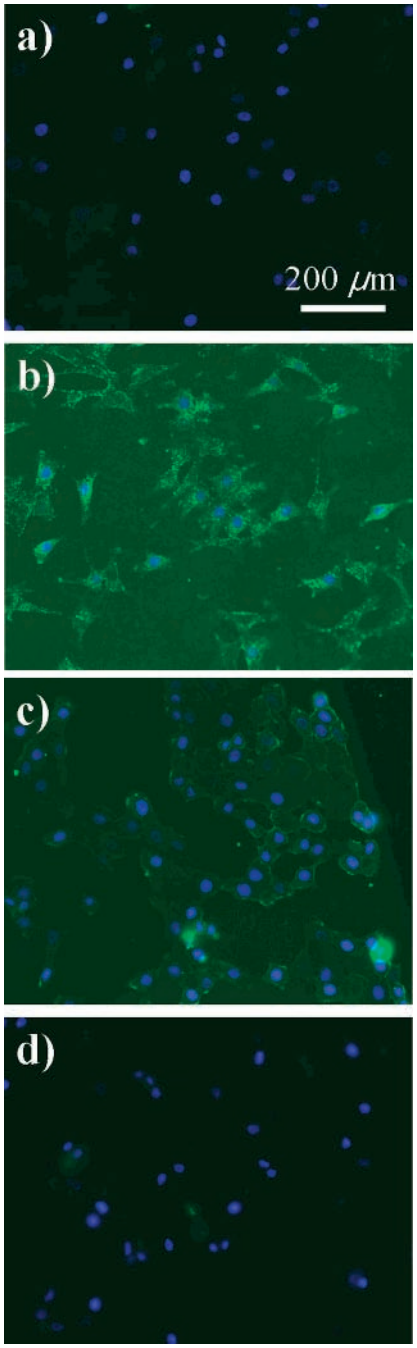

Figure 4. Fluorescence microscopy of (a) untreated Rat2 cells (control), (b) Rat2 cells incubated with 200 nM G5-NH_2−FITC at 37 °C for 1 h, (c) Rat2 cells incubated with 200 nM G5-NH_2−FITC at 6 °C for 1 h, and (d) Rat2 cells incubated with 200 nM G5-Ac−FITC at 37 °C for 1 h. Blue spots represent the cell nucleus stained by DAPI and green spots are dendrimer−FITC conjugates.

Binding and Internalizaton of Dendrimers. To investigate the binding and internalization of den-

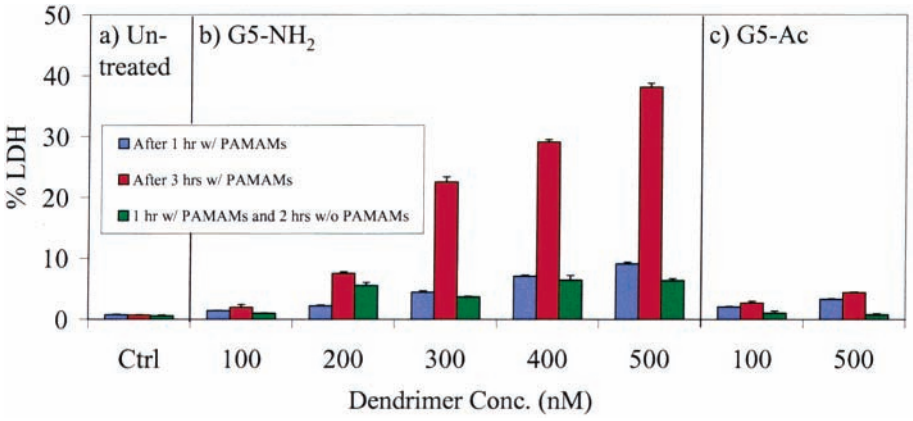

Figure 5. Enzyme release of Rat2 incubated with (a) G5-NH_2 and (b) G5-Ac. Light blue and red bars represent the release after 1 h and 3 h incubation with dendrimer solutions, respectively. Green bars represent enzyme release after 1 h incubation with dendrimers followed by washing and 2 h incubation in pure PBS buffer to allow recovery of membrane integrity.

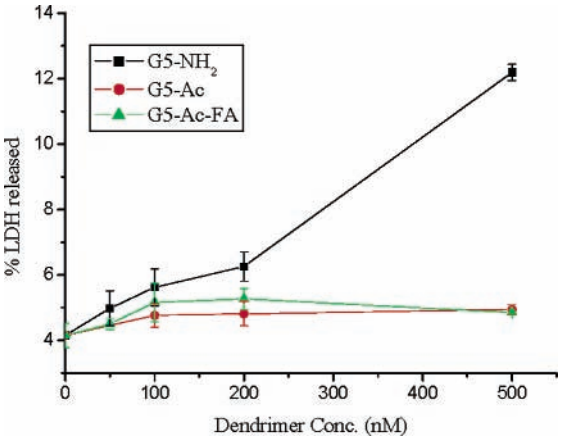

Figure 6. Comparison of interaction of G5-NH_2, G5-Ac, and G5-Ac−FA with FAR-KB cell line. Note that G5-Ac−FA is internalized by receptor-mediated endocytosis.

drimers, fluorescence images of Rat2 cells were taken after incubation with dendrimer−FITC conjugates at different temperatures. Rat2, a fibroblast cell line, was chosen in this experiment due to its stable surface adherence. DNA in the cell nucleus was stained by DAPI. The stained nuclei can be seen as blue spots in Figure 4a−d while dendrimer−FITC conjugates emit green fluorescence. Figure 4b shows a fluorescence image of Rat2 cells incubated with 200 nM of G5-NH_2−FITC at 37 °C for 1 h. Dendrimers are apparent both inside the cells as well as associated with the membrane. This indicates that the G5-NH_2−FITC dendrimers interact with the cell membrane and enter the cell at physiological temperature (37 °C). At 6 °C, however, although the dendrimers associate with the cell membrane, no significant internalization was observed (Figure 4c). Identical experiments employing G5-Ac−FITC at 200 nM concentration indicate no association with the cell membrane nor internalization into the cell (Figure 4d).

Reversibility of Dendrimer-Induced Membrane Permeability. Testing the reversibility of the dendrimer-induced membrane permeability was performed by replacing a solution of G5-NH_2 dendrimer with a dendrimer-free PBS and monitoring the LDH release. The dendrimer-induced membrane permeability of cell lines in the presence of G5-NH_2 was not permanent and cells recovered their membrane integrity upon removal of dendrimer/PBS solutions (Figure 5), as indicated by LDH release. This "resealing" behavior is consistent with the observation that G5-NH_2 dendrimers are not cytotoxic up to 500 nM as after removal of the dendrimer solution. The cell can return the membrane permeability back to the normal level.

The Role of Dendrimer Surface Functionalization: Amine vs Acetamide. To test possible mechanisms of internalization and their implications for cytosolic enzyme release (Figure 6), comparisons between G5-NH_2, G5-Ac, and G5-Ac−FA were carried out using the LDH assay. It has been demonstrated that internalization of G5-Ac−FA occurs through receptor-mediated endocytosis, initiated by binding of folic acid (FA) to folic acid receptors (FAR) on KB cells (*3*). Under the same conditions, no uptake of G5-Ac is observed. The LDH

assay results show no significant LDH release from KB cells following a 3-h incubation with G5-Ac−FA or G5-Ac. However, incubation with G5-NH_2 induced significant LDH release, consistent with previous experiments.

Effect of Dendrimer Generation on Cell Membrane Permeability. It is well-known that high generation PAMAM dendrimers are unusually effective at disrupting cell membranes (*10, 25*). We also observed a distinct difference in the ability to form holes in supported DMPC bilayers (Figure 1). To test this effect upon LDH release, G5-NH_2 and G7-NH_2 dendrimers were analyzed at 37 and 6 °C. The results of an LDH assay comparing enzymatic leakage for both KB and Rat2 cell lines after exposure to varying concentration of G5-NH_2 and G7-NH_2 are shown in Figure 7. At 37 °C, G7-NH_2 causes a greater release of LDH than G5- NH_2 at all concentrations. In addition, whereas LDH release was not observed for G5-NH_2 at 6 °C, the G7-NH_2 was still capable of causing LDH release (Figure 7b).

Are Holes Present in the Cellular Membrane? Tests for Diffusion of Dyes. To study passive diffusion in and out of the cell, small molecular probes (PI and FDA) were used according to a modification of a previous literature method (*22*). PI is readily internalized into cells with disrupted membranes but is excluded from cells with intact membranes. On the other hand, FDA, a nonfluorescent compound, readily enters intact cells and then undergoes hydrolysis by endogenous esterase, resulting in release of fluorescein into the cytosol. The cytosolic fluorescein is not able to transverse a normal cell membrane without holes. Thus, the FDA is used as a marker for diffusion-out. Consequently, it is presumed that fluorescence intensity of PI should be increased and that of fluorescein should be decreased if the presence of G5-NH_2 makes the membrane permeable to these dyes.

Figure 8 shows flow cytometer data of Rat2 cells incubated with G5 PAMAM dendrimers and then stained with PI. As illustrated in Figure 8a−c and 8e, PI is internalized into the cells in a G5-NH_2 concentration dependent manner. In the case of G5-Ac, however, no significant difference in PI incorporation was observed as compared to the control cells (Figure 8d,e).

Fluorescence intensity of fluorescein in cells as a function of G5-NH_2 dendrimer concentration is illustrated in Figure 9. Consistent with previous results (*22*), FDA was internalized through intact cell membranes, resulting in a substantial signal for free fluorescein in Rat2 cells. As the G5-NH_2 concentration increased, however, the signal intensity of the fluorescein significantly decreased, indicating that the membrane had become permeable (Figure 9e). Rat2 cells incubated with G5-Ac did not show any noticeable difference from the control experiment (Figure 9d).

Controls (first three columns): cells in pure PBS buffer, cells in the buffer with PI, and dead cells incubated with 30% ethanol solution for 30 min.

DISCUSSION

Summary of Evidence for PAMAM-Induced Hole Formation in the Cell Lipid Bilayer. AFM observation (Figure 1) of holes formed in DMPC lipid bilayers triggered our in vitro experiments to investigate the interactions between dendrimers and viable cell membranes. The release of cytosolic enzymes, LDH and Luc, demonstrates an increase in membrane permeability (Figures 2 and 3). The increased permeability is consistent with the hypothesis of PAMAM-induced hole formation in the cell lipid bilayer. The larger enzyme of the two, LDH, is a 135−140 kDa complex protein with a hydrodynamic radius of ∼4.3 nm (*26*). Thus, it is small enough to fit through the 15−40 nm holes suggested by the AFM experiment. The smaller 62 kDa enzyme, Luc composed of α- and β-subunits, should be able to diffuse through the hole. The overall dimensions of this heterodimer are reported as 7.5 nm × 4.5 nm × 4.0 nm (∼2.7 nm in radius) (*27*). Membrane permeability returns to normal following removal of the dendrimer-containing solution. In contrast to the supported lipid bilayer, where holes remain for a relatively long time, the cell has additional lipid available and the membrane can regenerate its membrane within 2 h (as assayed by permeability in Figure 5).

Although permeability to cytosolic enzymes is consistent with hole formation, the possibility that cytosolic enzymes leak out during an endocytosis process must be addressed. This is a particularly important issue since amine-terminated PAMAM dendrimers, protonated in aqueous solution, have been proposed to enter cells via an endocytosis mechanism (*11*). However, experiments

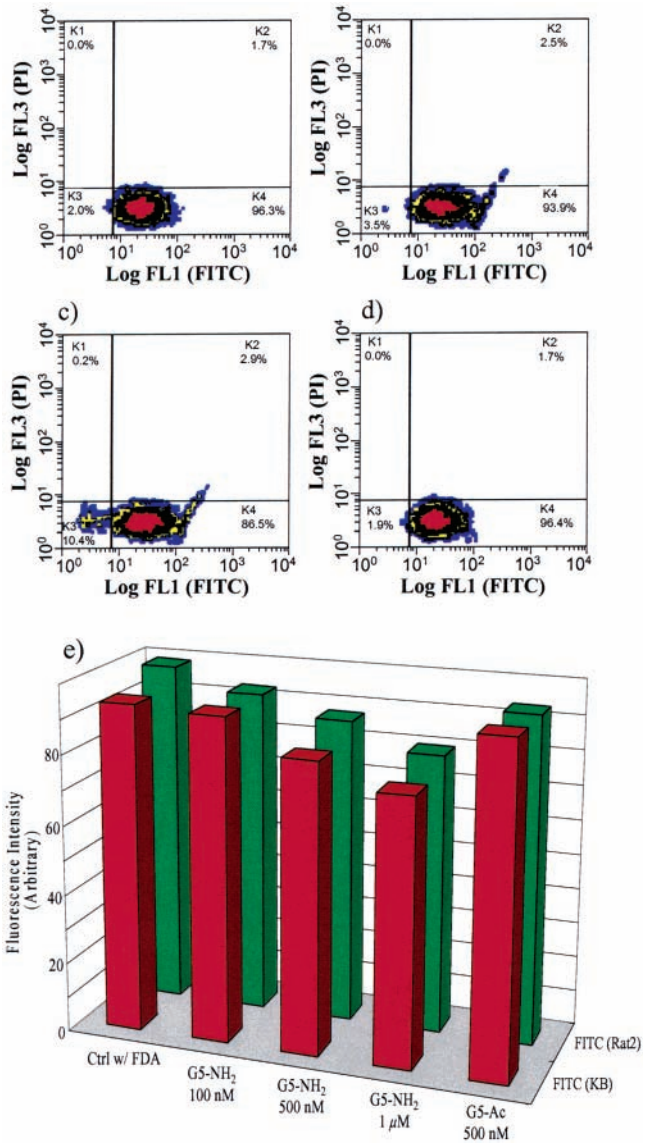

Figure 9. Flow cytometer diagrams of Rat2 cells at several representative conditions. (a) untreated, (b) incubated with FDA and 500 nM G5-NH_2, (c) incubated with FDA and 1 μM G5-NH_2, and (d) incubated with FDA and 500 nM G5-Ac at 37 °C for 1 h. using G5-Ac−FA, a material known to undergo endocytosis via the folic acid receptor, did not cause leakage of LDH or Luc (Figure 6). This demonstrates that noncharged PAMAM dendrimers can enter the cell via receptor-mediated endocytosis without causing cytosolic enzyme leakage (*13*, *14*). However, we still cannot rule out the possibility that the G5-NH_2 dendrimer undergoes an endocytosis process sufficiently different in mechanism to cause leakage. To test this possibility, we examined the behavior of two common dyes in the presence of G5-NH_2 and G5-Ac dendrimers.

PI and FDA were used respectively as tests for the mechanistic process of diffusion in and out of the cells. If dendrimer-induced holes are present, the dyes would be expected to diffuse in and out of the cell, respectively. However, the positively charged PI would be repelled from the polycationic G5-NH_2 dendrimer in aqueous solution and would not be anticipated to accompany the dendrimer during endocytosis. The experimental data shows that as G5-NH_2 concentration increases, PI signal intensity is increased while FITC intensity is decreased (Figures 8 and 9). The diffusion behavior of these small molecular probes is consistent with the formation of small holes in the membrane. The PI data is inconsistent with the molecules accompanying a polycation-mediated endocytosis.

To further test the possibility of an endocytosis mechanism, we examined the temperature dependence of cytosolic enzyme leakage (Figures 2, 3, 4, and 7). At 6 °C, no enzyme leakage is observed for G5-NH_2 dendrimers at concentrations showing substantial leakage at 37 °C. This is consistent with either endocytosis or hole formation mechanisms as both would be expected to be temperature dependent. When G7-NH_2 dendrimer is employed at 6 °C, however, cytosolic enzyme leakage can again be observed. Note that endocytosis processes will be just as disfavored as for the G5-NH_2 case. However, as indicated in Figure 1, G7-NH_2 has a greater propensity to form holes. Thus, it is not surprising that G7-NH_2 can continue to cause hole formation in the cell plasma membrane.

Taken as a whole, the leakage of the cytosolic enzymes, the free diffusion of PI and FITC dye, and the direct observations made by fluorescence microscopy as shown in Figures 2, 3, 4, 7, 8, and 9 provide experimental support for hypotheses 1 and 2: (1) amine-terminated PAMAM dendrimers can induce the formation of holes in cell membranes, and (2) the holes generated in the cell membranes allow the diffusion of polymers, enzymes, and molecules into and out of the cell. In addition, these data support hypothesis 3 that acetamide terminated dendrimers do not cause holes (Figure 1) or induce enzyme release (Figures 2 and 3). These data are consistent with previous observations that acetylated PAMAM dendrimers prevent nonselective interaction between dendrimers and cell membrane (*3*, *18*).

Cell transfection (internalization) is a complicated process. It has previously been reported that dendrimer-mediated transfection occurs mainly through active uptake (e.g. in the case of dendrimer/DNA complexes or noncharged dendrimers with a cell surface targeting moiety) (*11*). Evidence of membrane disruption caused by positively charged dendrimers has been demonstrated using model membranes such as anionic vesicles (*8*) as well as synthetic membranes with a preference for nonlamellar phases (*10*). The experimental data in this paper suggests an alternative mechanism involving the formation of 15−40 nm holes in the membrane. This proposal is consistent with the previous experiments showing dendrimer-mediated transfection and dendrimer-induced membrane disruption as well as the cytosolic enzyme leakage assays, dye diffusion, fluorescence microscopy, and AFM experiments discussed in this paper. Additional experiments are planned to fully address this question and will be the subject of future reports.

Conclusions: Relationship of These Experiments to Targeted Drug Delivery. Intracellular drug delivery has advantages over simple diffusion of drug into cells. A number of candidates for drug delivery vehicles have been evaluated mostly based on charged polymeric materials (*5*, *28*). Higher drug efficiency can be achieved with therapeutic transport agents targeted to specific cells. From our results, the positively charged polymeric material causes the formation of holes or the dendroporation of the cell membrane leading to nonselective internalization into cells. Moreover, the polycation eventually causes cell death if the concentration is high enough (>500 nM in this study). Charge neutral dendrimers, however, do not cause hole formation or den-

droporation and show no nonspecific binding or internalization. They can be internalized into the cell only if the dendrimer is linked to a targeting compound such as FA as previously described (*3*).

ACKNOWLEDGMENT

This project has been funded with federal funds from the National Cancer Institute, National Institutes of Health, under Contract # NOI-CO-97111. S.H. appreciates the Dwight F. Benton Fellowship from the Program in Macromolecular Science and Engineering, College of Engineering, University of Michigan.

Synthetic Bivalent CD4-Mimetic Miniproteins Show Enhanced Anti-HIV Activity over the Monovalent Miniprotein

Hengguang Li, Haijing Song, Alonso Heredia, Nhut Le, Robert Redfield, George K. Lewis, and Lai-Xi Wang*

Institute of Human Virology, University of Maryland Biotechnology Institute, University of Maryland, Baltimore, Maryland 21201. Received February 18, 2004; Revised Manuscript Received May 2, 2004

HIV-1 envelope glycoprotein gp120 is displayed as a trimeric complex on the surface of virion and infected T-cells, making it a typical multivalent target. This paper describes the design and synthesis of bivalent CD4-mimetic miniproteins to target the conserved CD4-binding pockets in the trimeric gp120. Using miniprotein CD4M9 as the model inhibitor, we created bivalent inhibitors in which two CD4M9 moieties were tethered by a spacer of varied length and evaluated their anti-HIV activity using a cell culture assay. The synthetic bivalent miniproteins showed 5−21-fold enhancement in anti-HIV activity over the monovalent miniprotein. The activity enhancement is dependent on the length of the spacer. The study suggests that targeting the oligomeric gp120 complex by novel multivalent ligands offers a valuable strategy for developing highly specific and effective HIV entry inhibitors.

INTRODUCTION

In the absence of an effective vaccine, anti-HIV drugs will continue to play a key role in combating the worldwide epidemic of HIV/AIDS. Most FDA-approved anti-HIV drugs target two viral proteins: the HIV protease and reverse transcriptase (*1*). The highly active antiretroviral therapy (HAART) that combines two or more reverse transcriptase/protease inhibitors has prolonged the survival of AIDS patients and significantly reduced plasma viral loads in HIV infected patients. However, the toxicity and emergency of drug-resistant viruses associated with current drug regimen prompt development of new drugs that act with different mode of action and with improved anti-HIV potency (*2*). The initial step of HIV entry is characterized by the interaction of HIV-1 envelope glycoprotein gp120 with host receptor CD4 (*3*). The CD4 binding site on gp120 is centered on a conserved, hydrophobic pocket denoted the "Phe43 cavity" (*4*, *5*). The conserved CD4-binding site of gp120, therefore, provides an attractive target for HIV entry inhibitor design. It was demonstrated that molecules targeting the conserved CD4-binding pocket, such as soluble CD4 and HIV-neutralizing antibody b12, are potent inhibitors against HIV infection (*6*−*10*). Through rational engineering, Vita et al. generated a series of scorpion toxin-based miniproteins that reproduce the nativelike conformation and gp120-binding domain of CD4 (*11*). A 28-mer CD4-mimetic miniprotein, CD4M9, was shown to bind to the Phe43 cavity of gp120 and inhibit HIV-1 infection at μM concentration (*12*). Further engineering of CD4M9 with nonnatural amino acid substitutions led to another miniprotein CD4M33 that can inhibit the binding of CD4 to gp120 at nM concentration (*13*).

Compelling data from recent structural and biochemical studies have demonstrated that the HIV-1 envelope glycoprotein gp120 is displayed as a gp41-associated trimer and forms envelope spikes on the surface of HIV virions (*14*−*18*). Recent electron tomography further confirmed the notion (*19*). Thus, the trimeric gp120 complex of the envelope spike constitutes a typical multivalent target, which presents three Phe43 cavities. On the other hand, enormous examples have demonstrated that multivalent interactions generated by a multivalent ligand for a multivalent target can be collectively much stronger than corresponding monovalent interactions (*20*−*25*). On the basis of these observations, we hypothesize that multivalent inhibitors capable of simultaneously occupying two or more of the CD4-binding cavities in the trimeric gp120 complex will bind to the envelope spikes much more tightly and thus will be more effective in blocking HIV-1 infection. As the first step to test the hypothesis, we describe in this paper the design, synthesis, and anti-HIV activity of CD4M9-based bivalent miniproteins. Our experimental data have shown that synthetic bivalent CD4M9 miniproteins, in which two CD4M9 moieties were spaced with a linker of varied length, demonstrate significantly enhanced anti-HIV activity over the monovalent miniprotein CD4M9.

EXPERIMENTAL PROCEDURES

General. All Fmoc-protected amino acids used for peptide synthesis were purchased from Novabiochem. HATU, DIPEA, and Fmoc-PAL-PEG-PS were purchased form Applied Biosystems. HPLC-grade acetonitrile was purchased from Fisher Scientific. DMF was purchased from B & J Biosynthesis. 1,11-Bis-maleimidotetraethyleneglycol (bi-maleimide-SS) was purchased from Pierce. All other chemicals were purchased from Pierce or Aldrich/Sigma and used as received. ^{1}H and ^{13}C NMR spectra were recorded on Inova 500 NMR machine. The ESI-MS spectra were measured on a Waters ZMD mass spectrometer. TLC was performed on glass plates coated with silica gel 60 F254 (E. Merck). Flash column chro-

matography was performed on silica gel 60 (EM Science, 230−400 mesh). Analytical HPLC was carried out with a Waters 626 HPLC instrument on a Waters Nova-Pak C18 column (3.9 × 150 mm) at 40 °C. The column was eluted with a linear gradient of 0−70% MeCN containing 0.1% TFA at a flow rate of 1 mL/min over 20 min. Compounds were detected at 214 nm. Preparative HPLC was performed with a Waters 600 HPLC instrument of a Waters C18 column (Symmetry 300, 19 × 300 mm). The column was eluted with a suitable gradient of MeCN containing 0.1% TFA at 12 mL/min.

1,8-Bis-(6-maleimidocaproylamido)triethyleneglycol (bi-Maleimide-MS). To a solution of 2,2′-(Ethylenedioxy)bis-(ethylamine) (10 mg, 67 μmol) in THF (2 mL) containing a few drops of $NaHCO_3$ (0.1 M) was added N-(6-maleimidocaproyloxy)succinimide ester (EMCS) (42 mg, 135 μmol). After stirring for 3 h, the reaction mixture was condensed by a rotary evaporator under diminished pressure. The residue was subject to flash column chromatography using methanol/ethyl acetate (1:9, v/v) as the eluent to give bi-Maleimide-MS as a light white solid (29 mg, 81%): mp 112−114 ° C; ^{1}H NMR (500 MHz, $CDCl_3$/TMS): δ 6.69 (s, 4H, 2 CH═CH), 5.99 (br. s, 2H, 2 NH), 3.62 (s, 4H, OCH_2CH_2O), 3.56 (t, 4H, J = 5.2 Hz, 2 NCH_2CH_2O), 3.51 (t, 4H, J = 7.2 Hz, 2 $N-CH_2$), 3.46 (q, 4H, J = 5.3 Hz, 2 NCH_2CH_2O), 2.17 (t, 4H, J = 7.4 Hz, 2 CH_2CON), 1.66 (q, 4H, J = 7.5, 7.6 Hz, 2 $CH_2C\ H_2$-CON), 1.60 (q, 4H, J = 7.5, 7.4 Hz, 2 $N-CH_2CH_2$), 1.32 (q, 4H, J = 7.5, 7.9 Hz, 2 $N-CH_2CH_2\ CH_2H_2CH_2CON$); ^{13}C NMR (500 MHz, $CDCl_3$/TMS) 134.05, 70.21, 69.92, 39.12, 37.62, 28.23, 26.32, 25.04; ESI-MS calcd for $C_{26}H_{38}N_4O_8$ (M) 534.27; found 535.46 $(M + H)^+$.

1,8-Bis-[6-(4-N-maleimidomethylcyclohexane-1-carboxyl)amido]caproxyltriethyleneglycol (bi-Maleimide-LS). A mixture of 2,2′-(ethylenedioxy)bis(ethylamine) (4.1 mg, 28 μmol) and succinimidyl-4-(N-maleimidomethyl)-cyclohexane-1-carboxy-(6-amidocaproate) (LC-SMCC) (25 mg, 56 μmol) in THF (2 mL) containing $NaHCO_3$ was reacted as described for the preparation of bi-maleimide-SS. Column chromatography of the residue gave bi-maleimide-LS as a light white solid (9 mg, 76%): mp 178−180 ° C; ^{1}H NMR (500 MHz, $CDCl_3$/TMS), δ 6.69 (s, 4H, 2 CH═CH), 6.22 (br. s, 2H, 2 NH), 5.78 (br. s, 2H, 2 NH), 3.62 (s, 4H, OCH_2CH_2O), 3.57 (t, 4H, J = 5.3 Hz, 2 NCH_2CH_2O), 3.44 (m, 4H, 2 NCH_2CH_2O), 3.36 (d, 4H, 6.8 Hz, 2 $N-CH_2$), 3.21 (m, 4H, 2 $CONHCH_2$), 2.18 (t, 4H, J = 7.4 Hz, 2 $CH_2CONHCH_2CH_2O$), 1.87 (m, 4H, 2 $CH_2CONHCH_2CH_2O$), 1.73 (m, 4H, 2 $CH_2CONHCH_2$-CH_2), 1.62 (s, 8H, cyclohexane), 1.49 (t, 4H, J = 6.8 Hz, $CHCONHCH_2CH_2CH_2CH_2CH_2CONH$), 1.44 (m, 2H, 2 cyclohexane-$CHCH_2N$), 1.42 (m, 2H, 2 cyclohexane-$CHCONH$), 1.33 (m, 4H, cyclohexane), 0.99 (m, 4H, cyclohexane); ^{13}C NMR (500 MHz, $CDCl_3$/TMS) 133.96, 70.22, 69.88, 45.91, 43.64, 39.55, 38.98, 36.32, 36.30, 29.82, 29.20, 28.90, 26.31, 24.96; ESI-MS calcd for $C_{42}H_{64}N_6O_{10}$ (M) 812.47; found 813.65 $(M + H)^+$

Peptide Synthesis. Peptides were synthesized on a Pioneer automatic peptide synthesizer (Applied Biosystems) using fluorenylmethyloxycarbonyl (Fmoc)-protected amino acids as building blocks, 2-(1-H-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) as the coupling reagent and poly(ethylene glycol)-polystyrene resin with a peptide amide linker (PAL-PEG-PS resin) as the solid support. Reduced peptide red-CD4M9-Cys was synthesized on a 0.2 mmol scale and cleaved from resin and deprotected as described previously (*26*). The crude peptide was precipitated in ethyl ether and purified through PR−HPLC to give red-CD4M9-Cys (320 mg, 52%). t_R =13.20 min (under the analytical HPLC condition described in the general method); ESI-MS calcd M = 3089.83; found 1030.88 $(M + 3H)^{3+}$, 773.43 $(M + 4H)^{4+}$, and 619.12 $(M + 5H)^{5+}$.

Folding of Red-CD4M9-Cys. The reduced peptide red-CD4M9-Cys (37 mg, 12 μmol) was dissolved in degassed guanidine hydrochloride (1 M, 75 mL). Reduced glutathione (9.5 mg, 31 μmol) was added into the mixture followed by addition of oxidized glutathione (19 mg, 31 μmol). To the mixture was added a $NaHCO_3$ solution (0.1 M) to adjust pH to 8.5. The mixture was shaken under N_2 overnight when HPLC indicated the formation of a major single peak that moved faster then the reduced peptide. Lyophilization of the reaction mixture and subsequent HPLC purification gave the folding product CD4M9-Cys-Glutathione (30.5 mg, 75%). t_R =11.06 min (Under the analytical HPLC condition described in the general method); ESI-MS calcd M = 3389.08; found 1695.41 $(M + 2H)^{2+}$, 1130.50 $(M + 3H)^{3+}$, 848.29 $(M + 4H)^{4+}$, 678.96 $(M + 5H)^{5+}$, and 565.79 $(M + 6H)^{6+}$.

Selective Cleavage of the Intermolecular Disulfide Bond to Give CD4M9-Cys. The folded product CD4M9-Cys-Glutathione (15 mg, 4.4 μmol) was dissolved in degassed guanidine hydrochloride (30 mL, 1 M). To the solution was added tris[2-carboxyethyl]phosphine hydrochloride (TCEP) (7.57 mg, 26.4 μmol). The mixture was gently shaken for 10 h and then lyophilized. HPLC purification gave the desired product CD4M9-Cys with a free cysteine at the C-terminus (10.6 mg, 78%). t_R =11.67 min (under the analytical HPLC condition described in the general method); ESI-MS calcd M = 3083.16; found 1542.69 $(M + 2H)^{2+}$, 1028.69 $(M + 3H)^{3+}$, 771.91 $(M + 4H)^{4+}$, and 617.75 $(M + 5H)^{5+}$.

Tagging of the Free Cysteine in CD4M9-Cys with Iodoacetamide. A solution of CD4M9-Cys (2 mg) in a phosphate buffer (1 mL, pH 8.0) was treated with iodoacetamide (50 mM) for 2 h at room temperature. RP-HPLC purification gave the acetamide-tagged miniprotein (2 mg, quantitative). t_R =11.62 min (Under the analytical HPLC condition described in the general method); ESI-MS calcd M = 3141.12; found 1047.98 $(M + 3H)^{3+}$, 786.26 $(M + 4H)^{4+}$, and 629.20 $(M + 5H)^{5+}$.

Proteolytic Digestion and Edman Degradation. The above-described acetamide-tagged miniprotein (1.5 mg, 1 mg/mL) was treated with trypsin and chymotrypsin (20 μL, 0.5 mg/mL each) at room temperature in 50 mM Tris buffer (pH 8.3) containing 0.005% Triton X-100 and 20 mM $CaCl_2$. The reaction was monitored by analytical RP-HPLC (monitored at 214 nm), and the peptide fragments were isolated and subject to ESI-MS analysis. A major fragment with a mass of 1486.2 Da (fragment c) was subject to one-step manual Edman degradation. Briefly, the peptide was suspended in pyridine/water (1:1, 300 μL), to which 20 μL phenylisothiocyanate (PITC) was added. The mixture was incubated at 50°C for 30 min, and the solvent was removed under vacuum. TFA (200 μL) was added, and the mixture was reacted at 50°C for 15 min to cleave the N-terminal residues. TFA was removed under vacuum and the residue was suspended in water (200 μL). After extraction with pentane/ethyl acetate (4:1, 200 μL), the aqueous solution was subject to HPLC, and the fragments were isolated and analyzed by ESI-MS. Again, a major fragment with a mass of 874.1 Da (fragment g) was isolated and was subject to two steps of Edman degradation following the procedures described above. The degradation products were analyzed by HPLC and ESI-MS.

General Procedures for Chemoselective Ligation of CD4M9-Cys with Bis-maleimide Scaffold. CD4M9-Cys (1.2 mol. equiv. per maleimide functionality) was

dissolved in degassed phosphate buffer (50 mM, pH 6.6) containing 50% acetonitrile. Then a solution of bis-maleimide scaffold (bi-maleimide-SS, bi-maleimide-MS, or bi-maleimide-LS) in acetonitrile was added. The mixture was gently shaken under N_2 at room temperature. The processing of ligation was monitored with analytic HPLC and the reaction was complete within 1−2 h. The ligation product was purified and characterized by ESI-MS.

Bi-CD4M9-SS (With a Shorter Spacer). 90% yield; t_R 12.20 min (under the analytical HPLC condition described in the general method); ESI-MS calcd M = 6520.50; found 1305.08 $(M + 5H)^{5+}$, 1087.74 $(M + 6H)^{6+}$, 932.54 $(M + 7H)^{7+}$, 816.12 $(M + 8H)^{8+}$, 725.54 $(M + 9H)^{9+}$.

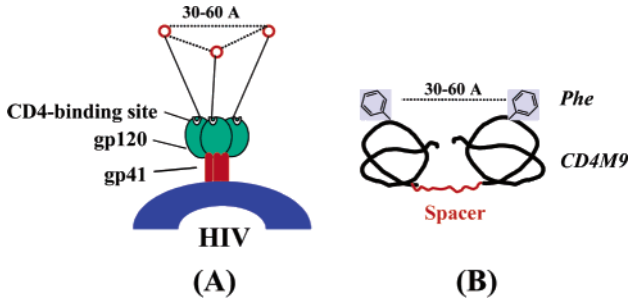
Bi−CD4M9-MS (With a Medium Spacer). 80% yield; t_R 12.37 min (Under the analytical HPLC condition described in the general method); ESI-MS calcd M = 6703.50; found 1118.18 $(M + 6H)^{6+}$, 958.56 $(M + 7H)^{7+}$, 838.97 $(M + 8H)^{8+}$, 745.83 $(M + 9H)^{9+}$, 671.37 $(M + 10H)^{10+}$.

Bi-CD4M9-LS (With a Longer Spacer). 56% yield; t_R 12.66 min (Under the analytical HPLC condition described in the general method); ESI-MS calcd M = 6980.97; Found 1164.50 $(M + 6H)^{6+}$, 998.34 $(M + 7H)^{7+}$, 873.71 $(M + 8H)^{8+}$, 776.77 $(M + 9H)^{9+}$, 699.20 $(M + 10H)^{10+}$, 635.76 $(M + 11H)^{11+}$.

Antiviral Assays. Peripheral blood mononuclear cells (PBMCs) were separated from whole blood of HIV-seronegative donors by density centrifugation over Ficoll-Hypaque (Sigma). The culture medium consisted of RPMI supplemented with 10% fetal bovine serum (FBS), 2 mM glutamine, and penicillin/streptomycin (Gibco, Grand Island, NY). For infection studies, PBMCs were stimulated with 2.5 μg/mL phytohemagglutinin (PHA; Boehringer Mannheim, Indianapolis, IN) for 3 days. Stimulated PBMCs were infected by incubation with HIV-1_{IIIB} at a multiplicity of infection of 1000 $TCID_{50}/10^6$ PBMC for 2 h. PBMCs were then washed three times with PBS and cultured at 37 °C in RPMI/10% FBS supplemented with 100 units/ml rIL-2 (Boehringer Mannheim) and the bivalent inhibitors at varied concentrations. PBMCs were seeded in 96-well flat-bottom plates at a density of 2×10^5 PBMCs/200 μl. Following 3 days of culture, half of the medium was replaced with fresh medium containing IL-2 and the antiviral agents. After 7 days of culture, virus production in the culture supernatant was assayed by measuring HIV-1 reverse transcriptase (RT) activity as described (*27*). Cell viability in culture in the presence or absence of antiviral agents was measured by commercial MTT assay, as per the manufacturer's instructions (Boehringer, Mannheim, Germany).

RESULTS AND DISCUSSION

1. Design. Although the crystal structure of the truncated gp120 core has been solved (*4*), the atomic structure of the proposed gp120 trimer is not known. Nevertheless, Kwong et al. have modeled the orientation of gp120 in the trimer by using quantifiable criteria of carbohydrate exposure, occlusion of conserved residues, and steric considerations with regard to the binding of the neutralizing antibody 17b (*17*). It was assumed that the trimeric model of gp120 was constrained to be 3-fold symmetric (*17*). To measure the distance across the three Phe43 cavities of the CD4-binding sites in the trimeric gp120, we performed similar modeling of the trimeric gp120 using the same structural constraints (data not shown). We found that the trimeric complex of gp120 is



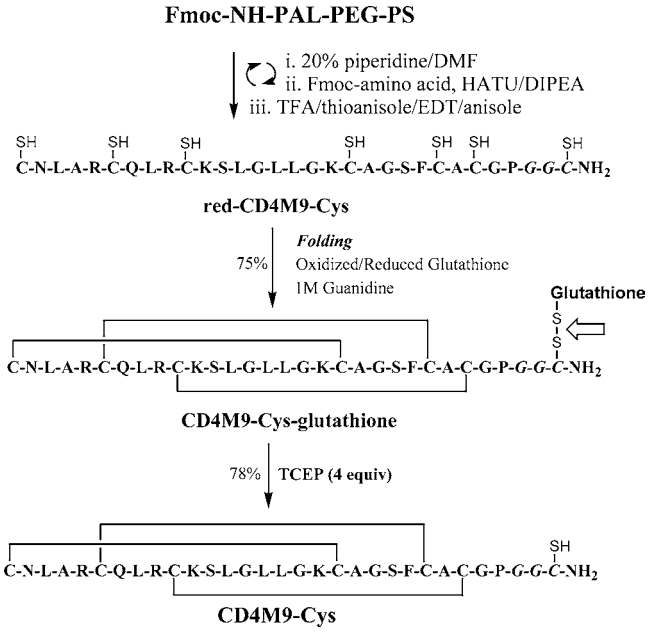


Figure 1. Schematic depiction of the trimeric gp120 complex (A) and the designed bivalent miniproteins (B). (Illustration is not to scale.)

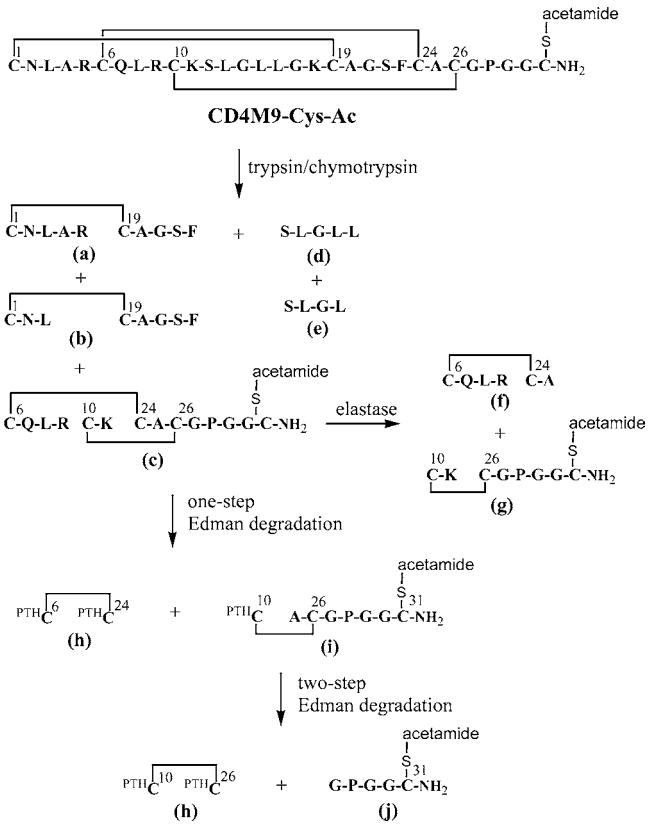
a dynamic structure and the distance between any two of the Phe43 cavities was estimated to be in the range of 30−60 Å (Figure 1a). To match the distance between any two of the CD4-binding cavities, we designed bivalent miniproteins by tethering two CD4M9 moieties through a linker of varied length. A general structure of the designed bivalent inhibitors was shown in Figure 1b. For constructing such a covalently linked bivalent miniprotein, we decided to introduce an extra cysteine residue at the C-terminus of CD4M9 as a tag for late-stage chemoselective ligation, because the model of the interaction between CD4M9 and gp120 suggested that the C-terminus of CD4M9 did not have any contact with residues of gp120 and was pointed away from the binding sites (*12*). The length and flexibility of the linker are critical to place the two CD4M9 moieties in an appropriate spatial position to match the two binding sites in the trimeric gp120. We envision that this could be probed by varying the length of the linker.

2. Synthesis of a Modified Miniprotein CD4M9-Cys. For chemoselective conjugation, a tripeptide sequence GGC was added to the C-terminus of the CD4M9 sequence to give a 31-amino acid peptide. The reduced, 31-mer precursor was synthesized by solid-phase peptide synthesis using Fmoc-chemistry. After HPLC purification, the reduced peptide was then folded in the presence of reduced/oxidized glutathione in a 1M guanidine−HCl solution. HPLC monitoring indicated that the folding proceeded smoothly to give a major product. The expected mass of the folded miniprotein would be 3083.16 Da, whereas ESI-MS analysis of the folding product gave a molecular mass of 3389.1 Da, indicating the introduction of a glutathione moiety to the folded molecule. The glutathione moiety was most likely linked to the molecule through an intermolecular disulfide bond formation with the extra cysteine residue in the molecule. This notion was confirmed by the selective cleavage of the intermolecular disulfide linkage. Thus, treatment of the glutathione-tagged protein with tris[2-carboxyethyl]phosphine hydrochloride (TCEP) selectively removed the glutathione moiety to give the miniprotein CD4M9-Cys (Scheme 1). It should be pointed out that using other reducing agents such as DTT and β-mercaptoethanol resulted in a complicated mixture (as revealed by HPLC monitoring), probably due to simultaneous cleavage of intramolecular disulfide bonds and subsequent misfolding of the protein (thiol−disulfide shuffling). The product CD4M9-Cys was purified by HPLC and analyzed by ESI-MS spectrometry. As described in the Experimental Section, the molecular mass of the reduced miniprotein red-CD4M9-Cys was found to be 3089.6 Da, while the molecular mass of the final, folded miniprotein CD4M9-Cys was found to be 3083.38 Da. A 6 Da difference in molecular mass of the reduced and folded

Scheme 1. Synthesis of Cysteine-Tagged Miniprotein CD4M9-Cys

forms clearly indicated the formation of three pairs of disulfide bonds in the folded miniprotein CD4M9-Cys with an extra free cysteine residue.



3. Validation of Correct Folding of the Modified Miniprotein. CD4M9-Cys was modified from the known miniprotein CD4M9 by introducing a three peptide sequence GGC at the C-terminus. The disulfide connectivity of CD4M9 was previously assigned as $C^{1-}C^{19}$, $C^{6-}C^{24}$, and $C^{10-}C^{26}$ (*12*). The NMR structure of CD4M9 and the molecular modeling of the complex of CD4M9 with gp120 indicated that the C-terminus was pointing away from the folding core and did not seem to be involved in direct interaction with gp120 (*12*, *13*). Therefore, we assume that introduction of a sequence GGC at the C-terminus would not interrupt the folding of the protein. However, it is still possible that the introduction of an extra cysteine in the molecule may lead to misfolding through a thiol−disulfide shuffling. To validate the disulfide connectivity in the folded CD4M9-Cys, we performed proteolytic digestion of the miniprotein and subsequent Edman degradation of key peptide fragments, following a recently published procedure (*28*). First, the free cysteine in CD4M9-Cys was tagged with an acetamide group for final identification. The tagged protein was then digested with trypsin and chymotrypsin. Trypsin is specific for amides with positively charged side-chains, e.g., Lys and Arg, while chymotrypsin is specific for amides with aromatic or other large hydrophobic side-chains such as Phe and Leu. Treatment of the acetamide-tagged CD4M9-Cys with trypsin and chymotrypsin yielded several major fragments which were separated by reverse phase HPLC. ESI-MS analysis of the peptide fragments gave the information on their molecular masses: 1057.5, 829.4, 1486.2, 501.4, and 388.3 Da, corresponding to the fragments a−e, respectively (Table 1 and Scheme 2). The isolation of fragments a and b clearly indicated a disulfide pairing between C^1 and C^{19}. To determine the next disulfide connectivity, fragment c was subject to enzymatic hydrolysis with elastase, which is specific for Ala residue. Elastase treatment resulted in formation of fragment f (708.5 Da) and fragment g (795.7 Da). The formation of fragment f indicated that C^6 was paired with C^{24} in the folded protein, because the connection of C^6

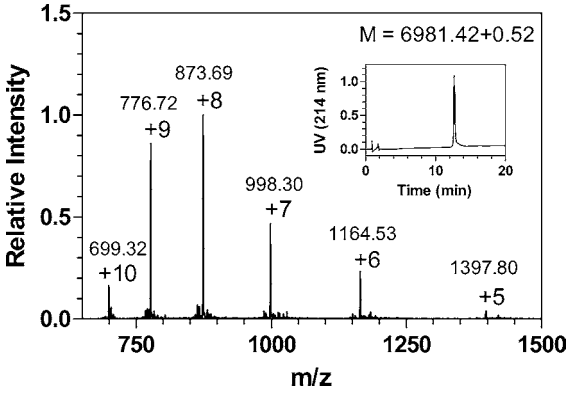
	MW (Da)		
fragments (#)	calcd	found	HPLC*a* (t_R, min)
a	1057.5	1057.5	7.95(1)
b	829.9	829.4	8.56(1)
c	1486.3	1486.2	6.12(1)
d	501.6	501.4	10.11(1)
e	388.2	388.3	8.80(1)
f	708.4	708.5	7.93(1)
g	795.2	795.7	8.05(1)
h	510.3	510.9	9.62(2)
i	874.8	874.1	11.27(2)
j	447.1	447.4	12.34(2)

[a] Analytical HPLC was performed on a Waters Nova-Pak C18 column (3.9 × 150 mm) at 40 °C. The column was eluted with a linear gradient of MeCN containing 0.1% TFA at a flow rate of 1 mL/min, and fragments were detected at 214 nm: (1) the column was eluted with 0−90% MeCN in 30 min; (2) the column was eluted with 0−90% MeCN in 15 min. The peptide fragments derived from the proteolytic digestion and Edman degradation were isolated by HPLC and subject to ESI-MS analysis.

Scheme 2. Validation of the Miniprotein's Folding Pattern by Proteolytic Digestion and Edman Degradation

with any other cysteine residues would not give fragment f after elastase treatment. This was further verified by one-step Edman degradation of fragment c. Edman degradation would tag all the three N-terminal amino acid residues with a phenylthiohydantoin (PTH) derivative and simultaneously cleave the first amide bonds from the three N-termini. The identification of fragment h (510.9 Da) and fragment i (874.1 Da) confirmed the assignment of C^6-C^{24} connection. Finally, to determine whether C^{10} was connected to C^{26} or C^{31}, the fragment i was subject to two-step Edman degradation to give two fragments, h and j (447.4 Da). The identification of these two fragments unambiguously confirmed the disulfide



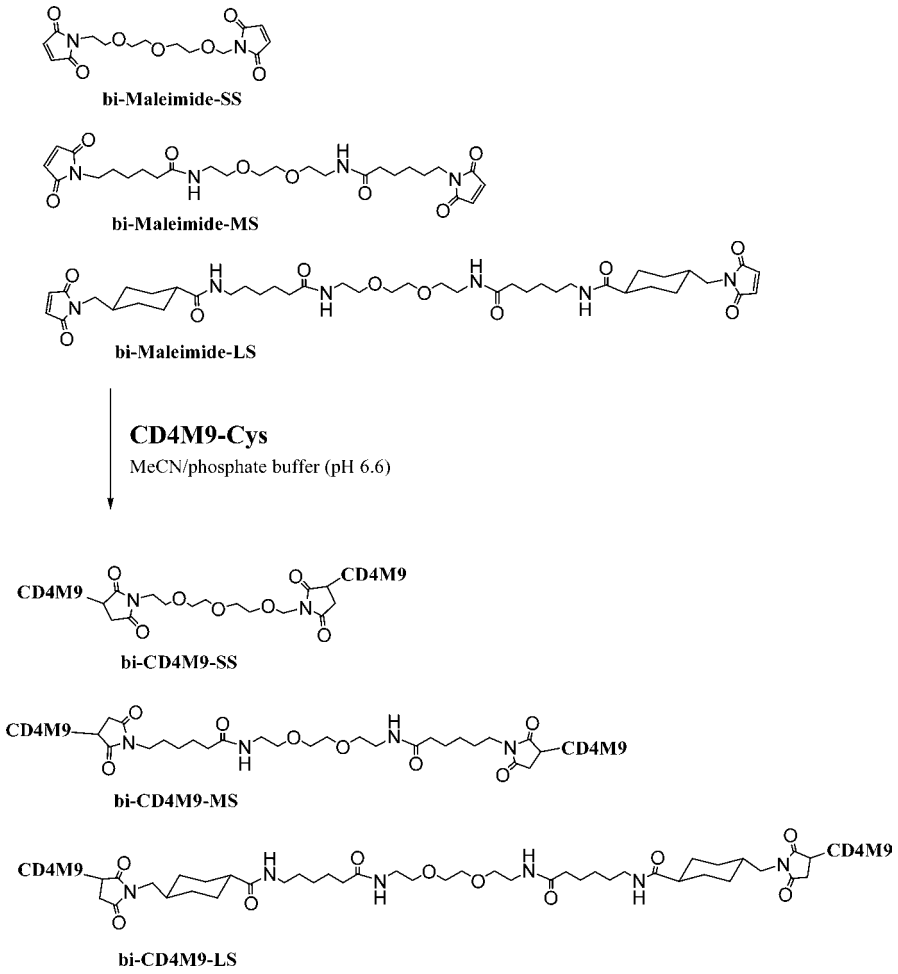


Figure 2. The ESI-MS and HPLC profiles of the bivalent minprotein bi-CD4M9-LS. Analytical HPLC was performed on a Waters Nova-Pak C18 column (3.9x150 m) at 40 °C. The column was eluted with a linear gradient of 0-70% MeCN containing 0.1% TFA at a flow rate of 1 mL/min over 20 min (detection: 214 nm).

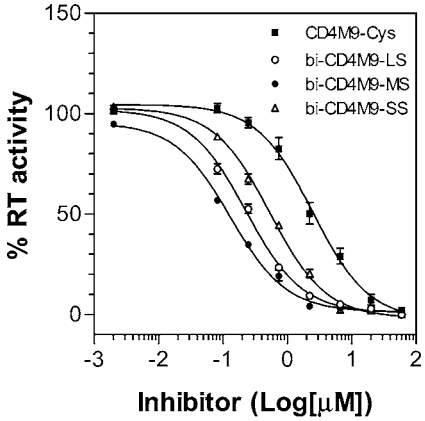

connection between C^{10} and C^{26}. The results were summarized in Table 1 and Scheme 2. It should be pointed out that the fragment j somehow appeared very hydrophobic compared to other fragments under the reverse-phase HPLC conditions (Table 1). Taken together, the enzymatic digestion coupled with Edman degradation unambiguously verified the assumed folding pattern of CD4M9-Cys, which would have a free cysteine at the C-terminus and bear the following disulfide connectivity: $C^{1-}C^{19}$, $C^{6-}C^{24}$, and $C^{10-}C^{26}$.

To confirm that the synthetic miniprotein maintains the same activity as the parent compound CD4M9, we performed anti-HIV assays of the synthetic CD4M9-Cys and compared its activity with standard CD4M9. Both miniproteins showed no difference in anti-HIV activities in our assays with peripheral blood mononuclear cells (PBMCs) as the host cells with infection by HIV-1_{IIIB}. The IC50 (concentration for 50% inhibition of HIV infection) for both CD4M9-Cys and CD4M9 was found to be 1−5 μM, depending on the donors of PBMCs. The results further suggested that the protein was properly folded and the introduction of a C-terminal tag GGC did not seem to interfere with its anti-HIV activity.

4. Synthesis of Bivalent Miniproteins. To construct bivalent CD4M9, three bivalent maleimides were chosen as the scaffolds, in which the two maleimide moieties were spaced at a maximum of 18, 32, and 44 Å in distance, respectively. The ligation of the scaffold and CD4M9-Cys was performed in a phosphate buffer (pH 7.2) containing acetonitrile to give the corresponding bivalent miniproteins bi-CD4M9-SS, bi-CD4M9-MS, and bi-CD4M9-LS with a short, medium, and a long spacer, respectively (Scheme 2). The products were purified by HPLC and characterized by ESI-MS. A typical HPLC and ESI-MS profiles for the purified bivalent minprotein bi-CD4M9-LS was shown in Figure 2, which indicates the purity and identity of the ligation product. Based on the folded structure of CD4M9 (*12*), the distance between the C-terminal Cys in CD4M9-Cys and the Phe residue, which binds to the "Phe43 cavity" of gp120, was estimated to be ca. 10 Å. Therefore, it can be deduced that

Scheme 3. Synthesis of Bivalent CD4M9 Miniproteins

Compound	IC50 (μM)	Relative activity
CD4M9-Cys	2.5	1
bi-CD4M9-LS	0.23	11
bi-CD4M9-MS	0.12	21
bi-CD4M9-SS	0.54	4.6

Figure 3. Inhibition of HIV-1 infection by bivalent CD4M9 miniproteins. PBMCs were infected by HIV-1_{IIIB} in the presence or absence of the synthetic miniproteins at various concentrations. Virus production was assessed by measuring viral reverse transcriptase (RT) activity. The IC50 was defined as the concentration that reaches 50% inhibition of viral production.

the maximal distance between the two Phe groups in the synthetic bivalent miniproteins would be 38, 52, and 64 Å for bi-CD4M9-SS, bi-CD4M9-MS, and bi-CD4M9-LS, respectively. The maximal distance of the two Phe ligands in the synthetic bivalent ligands falls into the estimate range of 30−60 Å between any two of the three "Phe43 cavities" in the modeled trimeric gp120 complex (*17*).

5. Evaluation of Anti-HIV Activity of the Synthetic Bivalent Miniproteins. The antiviral activity of the synthetic bivalent inhibitors was examined on donor peripheral blood mononuclear cells (PBMCs) infected with HIV-1_{IIIB}. All the bivalent miniproteins showed enhanced anti-HIV activity over the monovalent miniprotein CD4M9-Cys (Figure 3). In comparison, the best bivalent miniprotein bi-CD4M9-MS, in which the two Phe residues could be spaced in a maximal distance of 52 Å, showed a 21-fold increase of anti-HIV activity over the monovalent inhibitor. The bivalent inhibitors bi-CD4M9-SS (with a shorter spacer) and bi-CD4M9-LS (with a longer spacer) showed a 4.6 and 11-fold increase over the monvalent inhibitor, respectively. Although we have not yet performed direct binding studies of the synthetic bivalent inhibitors with reconstituted oligomeric gp120 (*14*, *15*), we assume that this activity enhancement could be resulted directly from the enhanced binding of the bivalent inhibitors to the multivalent CD4-binding sites of the trimeric gp120 complex. The difference in activities among the bivalent inhibitors with a linker of varied length suggests that the two binding ligands in the bivalent miniproteins should be spaced adequately to match the binding sites on the trimeric gp120, so that a simultaneous multivalent interaction can occur to achieve a high affinity binding.

In conclusion, our experiments demonstrated that creation of simple bivalent inhibitors could lead to a significant enhancement of anti-HIV activity over the corresponding monvalent inhibitor. This preliminary study provides proof-of-concept data, suggesting that attacking the multivalent target, the oligomeric gp120, by creating a multivalent ligand constitutes a valuable approach toward effective HIV inhibition. Thus, it is conceivable to think that trivalent or multivalent ligands that can occupy the three CD4-binding sites in the trimeric gp120 complex simultaneously might be super active in inhibiting HIV infection. Research along this direction is currently in progress and will be reported in due course.

ACKNOWLEDGMENT

We thank Drs. Wuyuan Lu and Zhibin Wu for valuable discussions. The work was supported in part by the Institute of Human Virology, University of Maryland Biotechnology Institute, and National Institutes of Health (NIH Grants AI51235 and AI54354 to L.X.W.).

Design and Synthesis of AX7574: A Microcystin-Derived, Fluorescent Probe for Serine/Threonine Phosphatases

Kevin R. Shreder,* Yongsheng Liu, Tyzoon Nomanhboy, Stacy R. Fuller, Melissa S. Wong, Wen Zhi Gai, Jiangyue Wu, Phillip S. Leventhal, Jennie R. Lill, and Sergio Corral

ActivX Biosciences, Inc., 11025 N. Torrey Pines Road; La Jolla, California 92037. Received February 20, 2004; Revised Manuscript Received May 1, 2004

The design and synthesis of AX7574, a microcystin-derived probe for serine/threonine phosphatases, is described. A key step in the synthesis was the conjugation under basic conditions of a tetramethylrhodamine 1,3-diketone derivative to the arginine side chain present in microcystin-LR. The resulting conjugate specifically labeled the active site of protein phosphatases 1 (PP-1) with a 1:1 stoichiometry and IC_{50} of 4.0 nM. AX7574 was used to isolate and identify PP-1, PP-2A, PP-4, and PP-6 in Jurkat cells. Finally, AX7574 was able to record changes in the phosphatase activity levels of calyculin A treated Jurkat cells versus untreated control cells.

INTRODUCTION

A major challenge that faces proteomic research is to develop methods to characterize and functionally annotate the more than 30000 protein products encoded by the human genome (*1, 2*). While two-dimensional gel electrophoresis (2DE) and mass spectrometry (MS) have been developed to determine the relative abundance of proteins in complex proteomic mixtures, these conventional methods provide only a global analysis of protein expression levels and lack the ability to detect variation in the functional state of individual proteins and protein families (*3*). To address these shortcomings, a chemical proteomic method referred to as activity-based protein profiling (ABPP) has recently been developed that utilizes active site-directed probes to directly monitor the functional state of enzyme families in complex proteomes. For example, activity-based probes (ABPs) have been successfully generated for cysteine and serine hydrolases (*4*).

The latter set, serine hydrolase probes, are based on the fluorophosphonate (FP) affinity label for this enzyme family and are perhaps the most studied example of an ABP. Such tagged chemical probes are composed of three structural elements: an enzyme reactive headgroup, a linker, and a tag that can be used for quantitation and/or capture of the covalently modified enzyme (*5*). Pioneered by Cravatt et al. (*6*), FP probes have been used, for example, to identify up- and down-regulated serine hydrolases in invasive cancer cell lines (*7*) and in the proteomic screening of enzyme inhibitors (*8*). In their tetramethylrhodamine (TAMRA) tagged form (*9*), they have been shown to have superior sensitivity and quantitative ability versus their biotinylated congeners (*10*).

Like the serine hydrolases, the phosphatase enzyme family is an attractive target for the design of ABPs. Over 100 phosphatases are known and phosphatases, many yet to be discovered, have been estimated to constitute greater than 1% of all proteins in the human genome (*11*). In addition, because of the important regulatory role that phosphatases play in a variety of disease states, the pharmaceutical industry is becoming increasingly interested in the design of phosphatase inhibitors as therapeutic agents (*12, 13*). Thus, reagents that can detect and quantify phosphatase activity will play an important role in deconvoluting phosphatase biology and could lead to the discovery of novel enzymatic targets for drug discovery.

One pharmaceutically relevant subclass of phosphatases, the phosphoprotein phosphatases (i.e. enzymes that use phosphoproteins or phosphopeptides as substrates), can be broken down into three categories: protein tyrosine phosphatases (PTPases), serine/threonine phosphatases, and dual specificity (serine/tyrosine) phosphatases. An ABP for the PTPase category has been described by Lo et al. (*14, 15*). The authors synthesized both biotin- and fluorophore-tagged versions of 4-(fluoromethyl)phenyl phosphate, a mechanism-based phosphatase inhibitor that upon dephosphorylation generates a protein-alkylating quinone methide (*16*). A dansylated version was reported to label PTB-1B but not trypsin or β-galactosidase. The biotin-tagged probe was reported to label PTB-1B selectively in the presence of five other bystander proteins. Despite the interest in understanding the role that serine/threonine phosphatases, such as PP-1 and PP-2, play in cell signaling pathways (*17*) and tumorigenesis (*18*), there are no prior reports of probes to study this important class of phosphatases.

In the present work, we present the design and synthesis of AX7574, a fluorescent probe that takes advantage of the ability of microcystin, a natural product toxin, to irreversibly bind serine/threonine phosphatases. A key step in the synthesis was the conjugation of TAMRA to the arginine side chain present in microcystin-LR. The resulting phosphatase probe specifically labeled the active site of PP-1 with a 1:1 stoichiometry and IC_{50} of 4.0 nM. Furthermore, AX7574 was used to isolate, identify, and record changes in the activity levels of serine/threonine phosphatases in Jurkat cells.

EXPERIMENTAL PROCEDURES

Materials. All solvents and reagents were obtained from the Sigma-Aldrich Co. (St. Louis, MO, and Milwaukee, WI) unless otherwise indicated. The mixed succinimidyl esters of 5-(and-6)-carboxytetramethylrhodamine

(TAMRA-OSu) was obtained from Molecular Probes (Eugene, OR). Microcystin-LR, calyculin A, rabbit protein phosphatase inhibitor 2, and fostriecin were purchased from Calbiochem (San Diego, CA). PP-1 (rabbit) was purchased from New England BioLabs, Inc. (Beverly, MA).

Synthesis Methods. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker 400 MHz NMR spectrometer using the residual solvent peak as the internal standard. LC/MS analysis was performed on an Agilent 1100 Series LC/MSD (electrospray ionization) using ChemStation software. High-resolution mass spectrometry (MALDI−FTMS) was determined by The Scripps Center for Mass Spectrometry (The Scripps Research Institute; La Jolla, CA) using 2,5-dihydroxybenzoic acid (DHB) as the matrix. Preparative HPLC was carried out on a C_{18} reverse phase column (Polaris, 5 μm column, 150 mm × 21 mm; Varian; Torrance, CA) using a binary system of water and acetonitrile with 0.1% trifluoroacetic acid as a modifier. Analytical LC/MS was carried out on a C_{18} reverse phase column (Polaris, 5 μm column, 50 × 4.6 mm; Varian; Torrance, CA) using a binary system of water and acetonitrile with 0.1% trifluoroacetic acid as a modifier. The purity of HPLC fractions was determined by analyzing the LC/MS trace at both 220 and 550 nm.

***N*-Piperidin-4-ylmethylamino-TAMRA·TFA (1).** To a solution of 4-(aminomethyl)-1-*N*-Boc-piperidine (24 mg, 0.10 mmol) in DMSO (1.0 mL) was added *N*-methylmorpholine (20 μL) followed by TAMRA-OSu (25 mg, 0.05 mmol). The reaction was stirred at ambient temperature for 6 h and then lyophilized to remove the DMSO. To the residue was added 1:1 TFA/CH_2Cl_2 (3.0 mL) and the reaction was allowed to stand for 1.5 h. The solvent was removed using rotary evaporation and the resulting solid was dissolved in a minimal amount of DMSO and purified by C_{18} reverse phase chromatography. The fractions containing the product in >95% HPLC purity were collected, and the solvent was removed using lyophilization, affording compound **2** as a dark purple solid (24 mg, 75% yield). ^{1}H NMR δ (D_2O): 8.39 (d, 0.6H), 8.10 (d, 0.4H), 8.00 (m, 1H), 7.67 (bs, 0.4H), 7.45 (d, 0.6H), 7.01 (m, 2H), 6.69 (m, 2H), 6.24 (m, 2H), 3.37 (m, 4H), 3.20 (d, 1H), 2.96 (s, 12H), 2.87 (m, 1H), 1.93 (m, 3H), 1.40 (m, 2H). ESMS: 527.0 $[M + H]^+$. MALDI−FTMS (DHB): *m*/*z* 527.2635 ($C_{31}H_{33}N_4O_4$ + H requires 527.2653).

***N*-[1-(4,6-Dioxoheptanoyl)piperidin-4-ylmethylamino]-TAMRA (2).** A solution of 4,6-dioxoheptanoic acid (36 mg, 0.23 mmol) and 1,1′-carbonyl-diimidazole (30 mg, 0.19 mmol) in anhydrous THF (0.7 mL) was stirred at ambient temperature for 1.5 h. To the stirred solution was added dropwise a solution of compound **1** (37 mg, 0.07 mmol) and TEA (49 μL, 0.36 mmol) in anhydrous DMSO (0.7 mL). The reaction was stirred for 2.5 h and then quenched with 4 drops of H_2O. This crude mixture was purified by reverse phase chromatography. The fractions containing the product in >95% purity by HPLC were collected and lyophilized overnight, affording compound **3** as a dark purple solid (31 mg, 66% yield). ^{1}H NMR δ (CD_3CN): 8.67 (d, 0.6H), 8.33 (d, 0.4H), 8.21 (dd, 0.6H), 8.09 (dd, 0.4H), 7.74 (d, 0.4H), 7.57 (t, 0.6H), 7.42 (m, 1H), 7.11 (d, 2H), 6.94 (dd, 2H), 6.84 (d, 2H), 5.65 + 5.63 (enol H's, 2 x S, 0.49H), 4.45 (m, 1H), 3.91 (m, 1H), 3.65 + 3.63 (dione CH_2's, 2 × S, 1.38H), 3.42 (m, 2H), 3.25 (s, 12H), 3.00 (m, 4H), 2.59 (m, 2H), 2.15 + 2.14 (dione-CH_3's, 2 × S, 1.77H), 2.00 + 1.99 (enol-CH_3's, 2 × S, 1.23H), 1.79 (m, 3H), 1.18 (m, 2H). ESMS: 667.0 $[M + H]^+$. MALDI−FTMS (DHB): *m*/*z* 667.3102 ($C_{38}H_{41}N_4O_7$ + H requires 667.3126).

AX7574. Microcystin-LR (578 μg, 0.58 μmol) and compound **2** (4 mg, 6.0 μmol) in 1 M $NaHCO_3$ (pH 9.0, 40 μL) and dioxane (10 μL) were heated for 2 days at 65 °C. LC/MS analysis indicated the consumption of microcystin-LR and the presence of a new TAMRA-containing peak (as evidenced by its absorption at 550 nm) with the desired product mass. This material was purified via preparative C_{18} HPLC using a flow rate of 30 mL/min and a 90 min gradient of 0.08% TFA/acetonitrile:0.1% TFA/water (2−98%) to yield the title compound as a purple solid. The quantity of the probe was determined spectroscopically in MeOH using an extinction coefficient of 95 000 M^{-1} cm^{-1} (34 μg, 4%) (*19*). MALDI−FTMS (DHB): *m*/*z* 1625.8402 ($C_{87}H_{112}N_{14}O_{17}$ + H requires 1625.8464). ES-MS: 813.4 $[M + 2H]^{2+}$. ES-MS/MS (*m*/*z* 813.4): (1099.5 ± 0.5, 55%), (527.4 ± 0.5, 100%). ES-MS/MS/MS (*m*/*z* 527.4): (430, 30%), (369, 22%), (341, 70%), (297, 35%). ES-MS/MS/MS (*m*/*z* 1099.5): (1071, 25%), (695, 100%), (842, 45%), (814, 35%), (674, 84%), (657, 51%), (592, 52%), (574, 35%), (408, 55%), and (390, 25%).

Structural Characterization Using Mass Spectrometry. The structure of AX7574 was characterized using tandem mass spectrometry (MS^n). Analyses were performed in an LCQ Deca ion trap mass spectrometer (Thermo Finnigan, San Jose, CA). AX7574 was dissolved in 1:1 methanol/deionized water and injected into the electrospray ionization source of the mass spectrometer with a syringe pump at a flow rate of 4 μL/min. The analysis was performed in the positive ion mode using the following parameters: spray voltage, 4 kV; sheath gas flow, 30 units; capillary temperature, 200 °C; capillary voltage, 46 V; relative collision energy, 40%. Two major fragment ions (*m*/*z* 1099.5 ± 0.5, 55% and *m*/*z* 527.4 ± 0.5, 100%) from AX7574 (*m*/*z* 813.4 ± 0.5, MH_2^{2+}) were further isolated individually and MS/MS/MS fragmentation was performed to obtain additional structural information. Four major fragment ions (*m*/*z* 430, 30%; *m*/*z* 369, 22%; *m*/*z* 341, 70%; and *m*/*z* 297, 35%) along with other minor fragments (relative abundance < 20%) were observed from the MS^3 on ion *m*/*z* 527. Ten major fragment ions (*m*/*z* 1071, 25%; *m*/*z* 965, 100%; *m*/*z* 842, 45%; *m*/*z* 814, 35%; *m*/*z* 674, 84%; *m*/*z* 657, 51%; *m*/*z* 592, 52%; *m*/*z* 574, 35%; *m*/*z* 408, 55%; and *m*/*z* 390, 25%) along with other minor fragments (relative abundance < 20%) were observed in the MS^3 experiment on ion *m*/*z* 1099.

Labeling of PP-1 with AX7574. To analyze the kinetics of PP-1 labeling, PP-1 (25 nM) was incubated with AX7574 (0.5 μM) in 50 mM HEPES, 5% DMSO, 0.01% Triton x-100, pH 7.4, at room temperature. At 1, 3, 6, 11, 21, 25, and 28 h, 20 μL sample aliquots were quenched with an equal volume of 2X gel sample buffer (120 mM Tris pH 6.8, 20% glycerol, 4% SDS, and 5% β mercaptoethanol), after which the samples were completely denatured by heating at 65 °C for 10 min. The denaturing protein conditions used in this analysis were presumed to break any noncovalent interaction between AX7574 and PP-1. To examine the inhibition of AX7574 labeling of PP-1 by phosphatase inhibitors, PP-1 (25 nM) was first preincubated with either calyculin A, protein phosphatase inhibitor 2, or fostriecen (100 nM each) for 10 min at room temperature. As a positive control, a reaction sample was included without any added phosphatase inhibitor. In addition, as a negative control, a reaction sample containing PP1 that was denatured by heating at 65 °C for 10 min was also included. AX7574 (0.5 μM) was then added and the labeling reaction quenched after 3 h and denatured as described above.

Determination of PP-1 IC_{50} Values for Microcystin and AX7574. PP-1 IC_{50} values for microcystin and AX7574 were determined by examining the inhibition of *p*-nitrophenyl phosphate (pNPP) hydrolysis by PP-1. PP-1 was diluted in 50 mM Tris, pH 7.0, 0.1 mM NaEDTA, 5 mM DTT, and 0.025% Tween 20. Inhibitors and substrate were diluted in 50 mM Tris, pH 8.1, 20 mM $MgCl_2$, 0.2 mM $MnCl_2$, and 0.5 mg/mL BSA. The reaction was initiated by first incubating PP-1 (10 μL) with each compound (10 μL) at various concentrations for 10 min, followed by addition of pNPP substrate (30 μL). The final concentrations of PP-1 and substrate were 5 nM and 20 mM, respectively, while the inhibitors were used at a range of concentrations between 0 and 30 nM. A control was included for background subtraction without any phosphatase or inhibitor. Samples were incubated at 37 °C for 90 min and the A_{450} of the samples was determined using a VERSAmax microplate reader (Molecular Devices, Sunnyvale, CA). SOFTmax Pro Version 3.1.2 software (Molecular Devices, Sunnyvale, CA) was used to analyze the data. For each inhibitor, A_{450} was plotted versus the inhibitor concentration, and the points were fit to the following equation to estimate the IC_{50} of the inhibitors:

$$A = A_{\min} + \frac{(A_{\max} - A_{\min})}{\left\{\left[1 + \left(\frac{IC_{50}}{[Inh]}\right)^{s}\right]\right\}}$$

where A is A_{450}, $A_{\min}$ is the A_{450} in the absence of enzyme, $A_{\max}$ is the A_{450} in the absence of inhibitor, and s is a parameter determining the slope of the curve. Curve-fitting was carried out using the Igor Wave Metrics software (Wave Metrics, Lake Oswego, OR).

Gel Electrophoreses Protocol and Data Analysis. Samples were loaded onto 8 × 10 cm, 12.5% Laemli gels and electrophoresed for 55 min at 200 V. The gels were then scanned on a flatbed scanner (FMBio II, Hitachi Genetic Systems; Alameda, CA) with excitation provided by the 532-nm line of a 50 mW neodymium-doped yttrium−aluminum-garnet laser. A 605 nm band-pass filter was used to detect TAMRA fluorescence. The scanned images were analyzed using Image Analysis 3.0 software (Hitachi Genetic Systems; Alameda, CA) and the integrated band intensities (normalized for volume) were calculated for the activity levels of the labeled proteins. The integrated fluorescence of TAMRA was correlated to probe-labeled protein concentration by use of a calibration curve generated from treatment of known quantities of fatty acid amide hydrolase with a TAMRA-FP serine hydrolase probe (*20*).

Identification of AX7574-Labeled Proteins. Isolation of AX7574-labeled proteins was achieved using anti-TAMRA antibody beads as previously described for serine hydrolase fluorophosphonate probes (*21*) After elution of the immunocaptured samples, enriched microcystin-probe-labeled proteins were separated by SDS−PAGE. 1D gels were poured using Bind Silane solution (Amersham Biosciences, Piscataway, NJ) to adhere the gel to the bottom plate. Use of this agent enabled the removal of the short plate such that a gel band could be picked directly off of the bottom plate without disturbing the integrity of the entire gel. The fluorescent gel bands of interest were excised using an Ettan spot picker (Amersham Biosciences; Piscataway, NJ). Gel plugs were picked into a 96 well polystyrene microtiter plate (Costar) in methanol (100 μL). The plate was then placed on an Ettan digestion station (Amersham Biosciences; Piscataway, NJ) for a wash series. After washing with water (3 × 50 μL), 70:30 20 mM ammonium bicarbonate/acetonitrile (3 × 50 μL), and again with water (3 × 50 μL), the gel pieces were evaporated to dryness using a steady stream of nitrogen gas at 60 °C (TurboVap 96; Fisher; Tustin, CA), after which an overnight, in-gel tryptic digestion (porcine modified trypsin, 80 ng per spot, Promega, Madison, WI) was performed in the presence of 20 mM ammonium bicarbonate, pH 8.0. This buffered solution was removed and the gel pieces washed with 0.1:40:60 TFA/water/acetonitrile (20 μL) with vortexing. The ammonium bicarbonate and the TFA/water/acetonitrile solutions were pooled, the volume was reduced to 5 μL, and 5% acetic acid (20 μL) was added to the concentrate. The resultant peptides were separated using nanocapillary reverse-phase chromatography by loading the concentrate solution at a flow rate of 10 μL/min onto a reverse phase micro-precolumn (Agilent; Palo Alto, CA) and then washing the column for 10 min at the same rate in solvent A [water + 0.1% formic acid (Sigma; St, Louis, MO)] to remove inorganic salts. The column was then back-flushed onto a nanocapillary analytical column (pulled fused silica, 100 μm inner diameter × 10 cm) packed with C_{18} reverse phase media (Zorbax C_{18}; Agilent; Palo Alto, CA) at a flow rate of 400 nL/min with a 50 min gradient from 10 to 90% 0.08% formic acid/acetonitrile in 0.08% formic acid/water. Peptides were analyzed in data-dependent mode with an ion trap mass spectrometer (LCQ Deca XP; Thermo Electron; San Jose, CA). The heated capillary was set at 180 °C with a spray voltage of 1.8 kV. Peptides were scanned between 400 and 1500 Da with three microscans collected per scan. Peptides were sequenced and the corresponding proteins identified using the Mascot search algorithm (Matrix Science; London, UK) (*22*).

Cell Culture and Cell Lysate Preparation. Jurkat cells were grown in RPMI medium 1640 containing 10% fetal calf serum (Gibco/Invitrogen Corp., San Diego, CA). Cells were harvested by centrifugation and washed twice with cold phosphate-buffered saline, pH 7.4. Cell pellets were briefly sonicated and Dounce homogenized in 50 mM HEPES, pH 7.4. Cell extracts were centrifuged at 100 000*g* to provide soluble cellular proteome fractions.

Labeling of Cell Lysates with AX7574. Soluble fractions were adjusted to a final protein concentration of 1.5 mg/mL in 50 mM HEPES (pH 7.4) and treated with AX7574 (0.5 μM) for 60 min at room temperature. Control reactions consisting of soluble fractions were preincubated with microcystin (1 μM) and calyculin A (1 μM) for 10 min prior to the addition of AX7574. Reactions were quenched with one volume of standard 2× SDS/PAGE loading buffer (reducing), separated from unreacted probe by SDS/PAGE, and visualized in-gel with a Hitachi FMBio IIe flatbed fluorescence scanner (Mirai-Bio; Alameda, CA)

Western Blot Analysis. Quenched AX7574 reactions were separated using SDS−PAGE (20 μg/lane). Proteins were then transferred by electroblotting onto nitrocellulose membranes (Protran). Western blot analysis using an anti-PP1 mouse monoclonal antibody and anti-PP2A rabbit polyclonal antibody (Santa Cruz Biotechnology; Santa Cruz, CA) were conducted as described previously (*20*).

RESULTS AND DISCUSSION

Microcystins are a class of toxic cyclic peptides produced by the cyanobacterial genera, *Microcystis*, *Oscillatora*, *Anabaena*, and *Nostoc*. Many variants have been

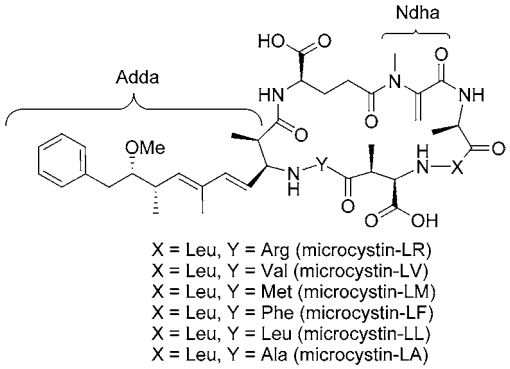

Figure 1. Structure of microcystin variants. Ndha = *N*-methyldehydroalanine; Adda = 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4(*E*),6(*E*)-dienoic acid.

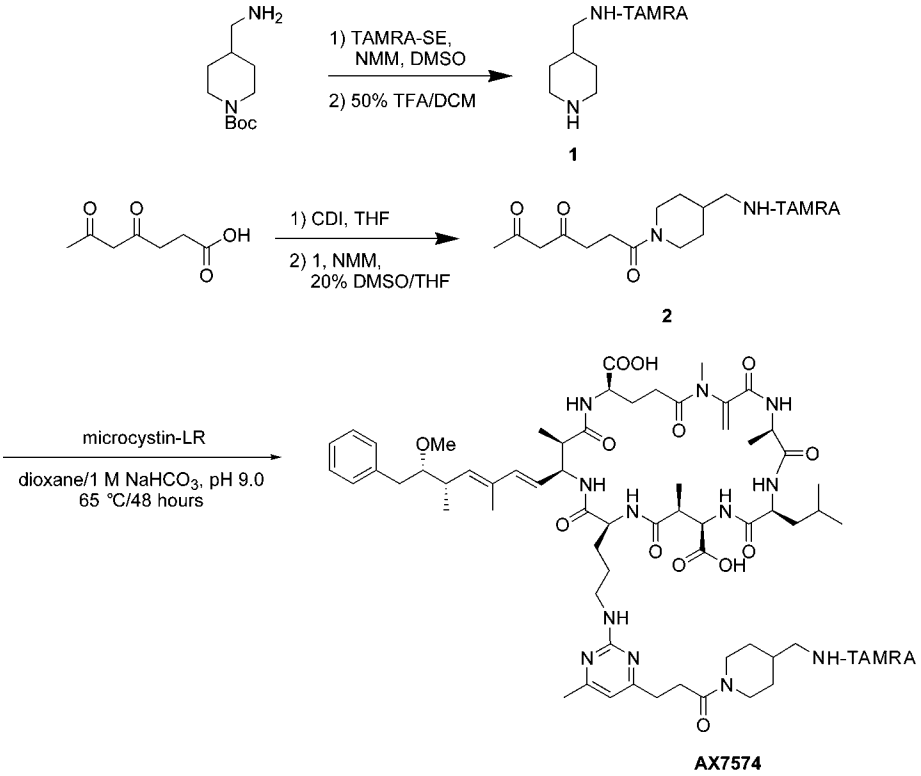
identified and are differentiated by their amino acid residue composition (*23*). Accordingly, nomenclature is defined using the single amino acid letter codes of these interchangeable residues (Figure 1). In countries where freshwater is susceptible to contamination by cyanobacterial blooms, microcystins have been responsible for a variety of adverse effects on human health. For example, in China the incidence of colorectal and liver cancer has been shown to be considerably higher than average among populations drinking water contaminated with microcystins (*24*, *25*). Since their identification as the causative agent in such outbreaks, microcystins have been determined to be potent hepatotoxins (*26*) and tumor promoters (*27*).

As part of the investigation into the molecular nature of this toxicity, serine/threonine phosphatases, such as PP-1 and PP-2A, were identified as the enzymatic target of microcystins. A mechanistic study by Holmes et al. reported that these phosphatases are irreversibly inhibited by microcystin such as LR, LA, and LL via a two-step mechanism (*28*). The first step includes the rapid binding and reversible inhibition of these phosphatases. The second step involves the covalent attachment of the bound microcystin to the phosphatase, as evidenced by protein adducts observable via HPLC. While the kinetics of the first step is fast, on the order of minutes, the second step takes place on the order of hours. More specifically, after incubation of PP-1 with microcystin-LR for 16 h, 65% of the covalent adduct was formed.

The potency of microcystin-LR for PP-1 is relatively insensitive to substitution of the arginine residue. Microcystin-LR is considered a potent inhibitor of PP-1, with IC_{50} values ranging from 0.15 to 6 nM, depending on the assay used to measure inhibition (*29*). Seven other variants of the LR type, in which the arginine residue was replaced with a more hydrophobic side chain, were isolated from *Microcystis aeruginosa* and associated strains present in Canadian lakes. When the PP-1 IC_{50}s for these varieties, which included the microcystins LV, LM, LF, and LL, were determined, the values were found to range between 0.06 and 0.4 nM. By comparison, the IC_{50} value of microcystin-LR was determined in the same study to be 0.15 nM (*30*). Thus, the arginine residue of microcystin-LR can be modified without a significant impact on the potency of the microcystin scaffold.



When the crystal structure of the microcysin-LR/PP-1 complex was solved, both the nature of the irreversible binding and the interchangeability of arginine were made clear (*31*). The joining between inhibitor and enzyme is the result of a Michael-type addition of the active site Sγ atom of Cys273 to the terminal carbon atom of the microcystin *N*-methyldehydroalanine (Ndha, Figure 1) side chain. Furthermore, the crystal structure explained the tolerance of the arginine residue for substitution: when the inhibitor is complexed, the arginine side chain is solvent-exposed. Consequently, changing this residue does not interrupt any critical inhibitor−protein interactions. Interestingly, a comparison of the solid state complexed microcystin-LR to the solution structure of microcystin-LR shows both to have similar conformations, a fact that likely contributes entropically to the high affinity of microcystin-LR for PP-1 (*32*).

To synthesize a functional probe for serine/threonine phosphatases based on microcystin, we wished to maintain both the high affinity associated with microcystins as well as the ability of microcystins to covalently modify their enzymatic targets. While two synthetic methodologies to create microcystin conjugates are known from the literature, neither was suitable to achieve these goals. In the first approach, a thioether bond is formed by the addition of thiol nucleophiles to the microcystin Ndha residue via a Michael-like addition. This chemistry was utilized to derivatize microcystins with redox sensitive (ferrocene) (*33*) and chemiluminescent responsive (dansyl) (*34*) tags for quantitative HPLC analysis. This same synthetic approach has also been used to create a microcystin-LR-biotin conjugate suitable for phosphatase affinity chromatography. Modification of the Ndha residue with a dithiol linker followed by treatment with iodoacetyl−LC−biotin yielded a biotinylated derivative that could be used in conjunction with an avidin column (*35*). Interestingly, detoxification of microcystin in the liver proceeds in an analogous Michael-like fashion, albeit enzymatically, with glutathione (*36*). Unfortunately for our purposes, in all of these cases the resulting thioether conjugates are rendered impotent with respect to their ability to irreversibly modify phosphatases. Because a microcystin derived probe would need to covalently tag its enzymatic target, Michael addition chemistry could not be used.

In the second known synthetic approach, Diels−Alder chemistry has been used to create a linker between microcystin and the fluorescent tag DMEQ-TAD, a reagent designed to react with diene-containing natural products (*37*). When DMEQ-TAD was reacted with microcystin-LR, modification of the diene-containing Adda residue (Figure 1) resulted in two sterochemically distinct adducts (*38*). Again, this chemistry was designed for derivatization and subsequent quantitative HPLC analysis; no information on the potency or binding properties of these conjugates for phosphatases was given. Because the Adda residue makes several hydrophobic contacts critical to the formation of the microcystin-LR/PP-1 complex, we forewent this approach as well.

To avoid any modifications to the microcystin scaffold that would adversely impact its binding properties, we chose to target the arginine side chain of microcystin-LR for linker incorporation. Because this side chain did not make any significant contacts with PP-1, a fluorophore conjugated through this residue was expected to have minimal impact on the activity of any so-derivatized microcystin probe. To effect the modification, the 1,3-diketone functionality was chosen, a group long known as an arginine-specific modifying agent (*39*, *40*). Upon condensation and subsequent dehydration, 1,3-diketones will convert an arginine residue to a hydrolytically stable N^{δ}-(2-pyrimidyl)ornithyl residue. A recent application of this condensation by Budzikiewicz and Kinzel has been used to conjugate the cyclic peptide pyoverdin to cephalexin through a 4,6-dioxoheptanoic acid linker (*41*). The authors showed pyoverdin could be modified directly with

Scheme 1. Synthesis of the Microcystin−TAMRA Probe AX7574

4,6-dioxoheptanoic acid to form a carboxylic acid bearing derivative. However, this acid was not further elaborated upon. In the end, they chose a synthetic route in which 4,6-dioxoheptanoic acid was carbodiimide coupled to cephalexin and the resulting dione conjugated to pyoverdin in 20% yield. Because microcystin modification with 4,6-dioxoheptanoic acid would yield a tricarboxylic acid, any resulting amidation with an amine bearing fluorophore derivative would be difficult to accomplish selectively. Consequently, we started our approach, analogous to the case of cephalexin, with the synthesis of a fluorophore-dione derivatization reagent. In particular, we chose to use tetramethylrhodamine (TAMRA) as the fluorophore, because of its previous success as a sensitive and quantitative tag for ABPs.

The requisite dione was prepared from the mixed succinimidyl esters of 5-(and 6)-carboxytetramethylrhodamine (TAMRA-OSu). Reaction of TAMRA-OSu with (Boc-4-aminomethyl)piperidine followed by treatment of the resulting product with 1:1 TFA/DCM produced the secondary amine **1** (Scheme 1). When this amine was treated with an excess of *N*,*N*′-carbonyldiimidazole-activated 4,6-dioxoheptanoic acid, compound **1** was quantitatively converted into the desired dione **2**. After purification via C_{18} reverse phase HPLC, the TAMRA-dione **2** was isolated in 66% yield. As expected, ^{1}H NMR analysis showed the presence of resonances for both the enol and dione form of compound **2**. Furthermore, doubling of the enol, dione, and aromatic resonances was observed from the use of the mixed TAMRA isomer starting material.

The probe AX7574 was produced from the condensation of compound **2** with microcystin-LR under basic conditions. Microcystin-LR (580 μg) was heated with a 10-fold excess of dione in a mixture of 20% dioxane/1 M $NaHCO_3$ (pH 9.0) for 2 days at 65 °C. LC/MS analysis indicated the consumption of microcystin-LR and the presence of a new TAMRA-containing peak (as evidenced by an absorption at 550 nm) with the desired product mass (MALDI−FTMS (DHB): *m*/*z* 1625.8402 − $C_{87}H_{112}N_{14}O_{17}$ + H requires 1625.8464). AX7574 was isolated from other impurities using C_{18} reverse phase chromatography in 4% yield.

AX7574 was characterized structurally using tandem mass spectrometry. Fragmentation of the parent ion (MS/MS) resulted in two major ions, 1099.5 and 527.4. These ions were assigned to the fragments that result from the N−CO cleavage of the tertiary amide bond found in the linker. Further isolation and fragmentation of these ions (MS/MS/MS) were consistent with the expected structure of AX7574 (see Figure 2). For the former ion, fragmentations corresponding to cleavage of the cyclic peptide backbone, decarbonylation, and loss of the pyrimidine moiety were seen. For the latter ion, fragments corresponding to cleavage about the amide bond of the linker−TAMRA moiety were observed.

Once the structure of AX7574 was secured, attention was turned to demonstrating its ability to label PP-1. PP-1 (25 nM) was incubated with AX7574 (0.5 μM) in 50 mM HEPES, 5% DMSO, 0.01% Triton x-100, pH 7.4, at ambient temperature. At various timepoints, sample aliquots were removed, quenched with DTT-containing sample buffer, and then heat-denatured. The resulting samples were subjected to denaturing SDS−PAGE, and labeled enzyme was visualized using a flatbed laser-induced fluorescence scanner. Importantly, the TAMRA tag provided a sensitive fluorescent handle by which the degree of labeling could be quantified (see Experimental Procedures). Consistent with the results of Holmes et al. (vide supra), the kinetics of PP-1 labeling was on the order of hours (see Figure 3) with 65% of the labeling occurring at ∼16 h. When the time course data were fit to a single exponential, maximal labeling was determined to approach a ratio of 1:1 PP-1 to AX7574.

Several additional experiments were run to determine if the observed labeling was specific for the active site of

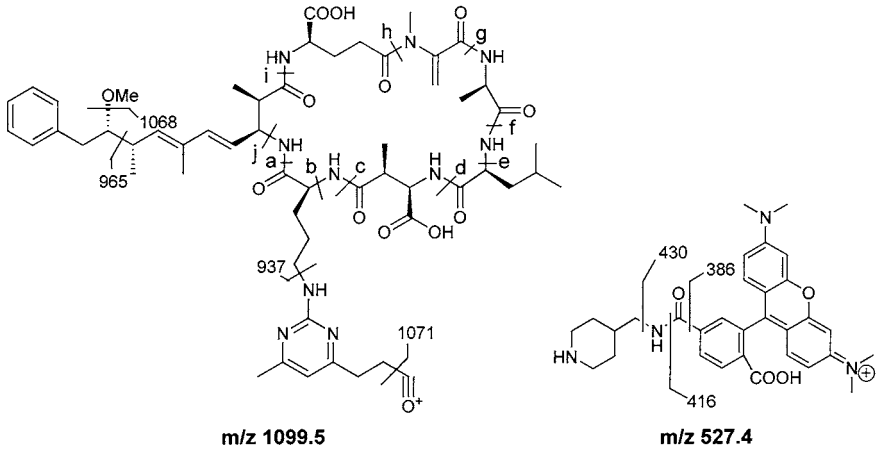


Figure 2. Mass spectrometric (MS) structural identification of AX7574. Shown are some of the observed fragmentation patterns from the two major parent ions observed during the MS/MS analysis of the doubly charged parent ion peak. Dual letter fragment masses (vide infra) are derived from a counterclockwise trace along the cyclic peptide backbone of AX7574 from the designated point of fragmentation to the next indicated point of fragmentation: ea − H_2O = 592, ga + NH_2−H_2O = 521, fb = 842, fb − CO = 814, dc = ih = 971, gc = ai = 786, hc = 703, ic = ag = 574, ad = 390, af = 503, ah = 657, jh = 674, hj − H_2O = 408.

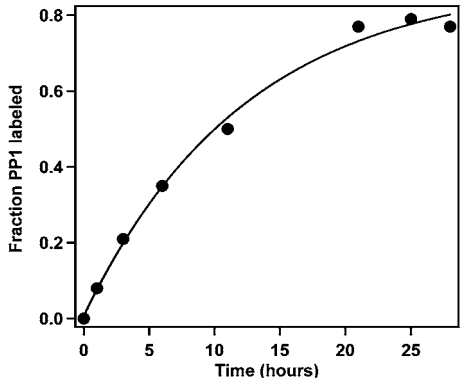

Figure 3. Kinetics of AX7574 labeling of PP-1. PP-1 (25 nM) was labeled with AX7574 (0.5 μM). At the indicated timepoints, sample aliquots were quenched. The quenched samples were electrophoresed, the gel was scanned, and the fraction of PP-1 labeled was determined as described in the Experimental Procedures. The curve drawn is the best fit of the data to a single exponential.

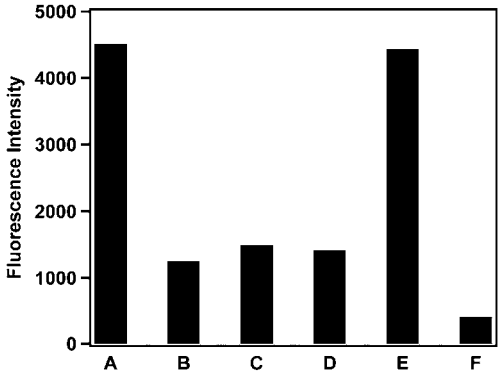

Figure 4. Inhibition of AX7574 labeling of PP-1 with phosphatase inhibitors. PP-1 (25 nM) was labeled with AX7574 (0.5 μM) (A) in the absence of phosphatase inhibitors or in the presence of (B) microcystin-LR, (C) calyculin A, (D) protein phosphatase inhibitor 2, and (E) fostriecen at 100 nM each. An additional AX7574 (0.5 μM) labeling experiment using denatured PP-1 (25 nM, F) is also shown. Labeling reactions were quenched after 3 h. The samples were electrophoresed, the gel was scanned, and the scanned image was quantified as described in the Experimental Procedures.

PP-1 (see Figure 4). In the first set of experiments, inhibition of AX7574 labeling with known inhibitors of

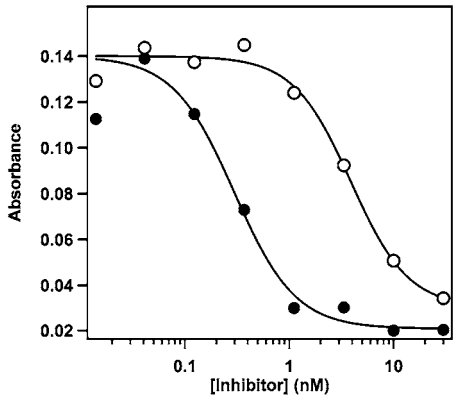

Figure 5. PP-1 IC_{50} determination for microcystin (●, IC_{50} = 0.3 nM) and AX7574 (○, IC_{50} = 4.0 nM). The curves drawn are the best fit of the data to a variation of the Hill equation (see Experimental Procedures section).

PP-1 was tested. The inhibitors selected included microcystin, calyculin A (PP-1 IC_{50} = 1.2 nM) (*29*), and protein phosphatase inhibitor 2 (PP-1 IC_{50} = 1 nM) (*42*). These particular inhibitors were selected because they interact with phosphatases through diverse mechanisms. For example, microcystin is an irreversible inhibitor, and both calyculin A and protein phosphatase inhibitor 2 are reversible ones. Furthermore, while microcystin and calyculin A are small molecules, protein phosphatase inhibitor 2 is a protein macromolecule (MW = 31 kDa). In addition, fostriecin, a weak inhibitor of PP-1 (PP-1 IC_{50} = 131 μM, PP-2A IC_{50} = 3.2 nM), was included as a negative control. PP-1 (25 nM) was preincubated for 10 min with microcystin (100 nM), calyculin A (100 nM), protein phosphatase inhibitor 2 (100 nM), or fostriecin (100 nM) or allowed to stand for 10 min in the absence of added phosphatase inhibitors. Afterward, AX7574 (0.5 μM) was added to each sample and the labeling reaction stopped after 3 h using DTT-containing sample buffer. When compared to the same labeling reaction done in the absence of phosphatase inhibitors, significantly less labeling with AX7574 was observed in the presence of microcystin, calyculin A, or protein phosphatase inhibitor 2. In the case of microcystin and calyculin A, the results indicate that AX7574 competes for the active site where these inhibitors are known to bind. As expected, the PP-2A specific inhibitor, fostriecin, did not cause a significant decrease in labeling of PP-1 by AX7574.

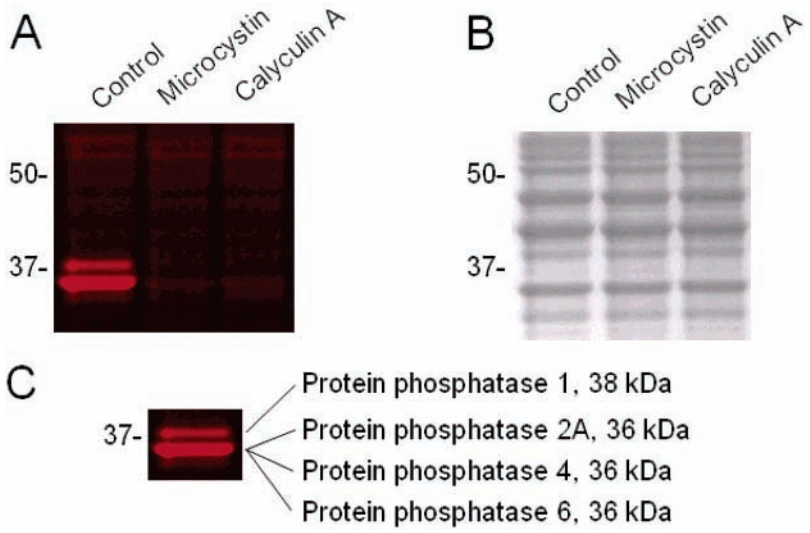

Figure 6. AX7574 can detect serine/threonine phosphatases in a proteome. (A) Soluble proteome derived from Jurkat cells preincubated with or without microcystin (1 μM) or calyculin a (1 μM) for 10 min and then treated with AX7574 (0.5 μM) for 60 min. Reactions were quenched with standard 2× SDS/PAGE loading buffer (reducing), separated from unreacted AX7574 using SDS−PAGE, and visualized in-gel using a flatbed laser-induced fluorescence scanner. (B) Coomassie blue stained gel from Figure 6A confirming that all three lanes contained approximately equal amounts of protein. (C) AX7574-labeled proteins identified using MS protein identification.

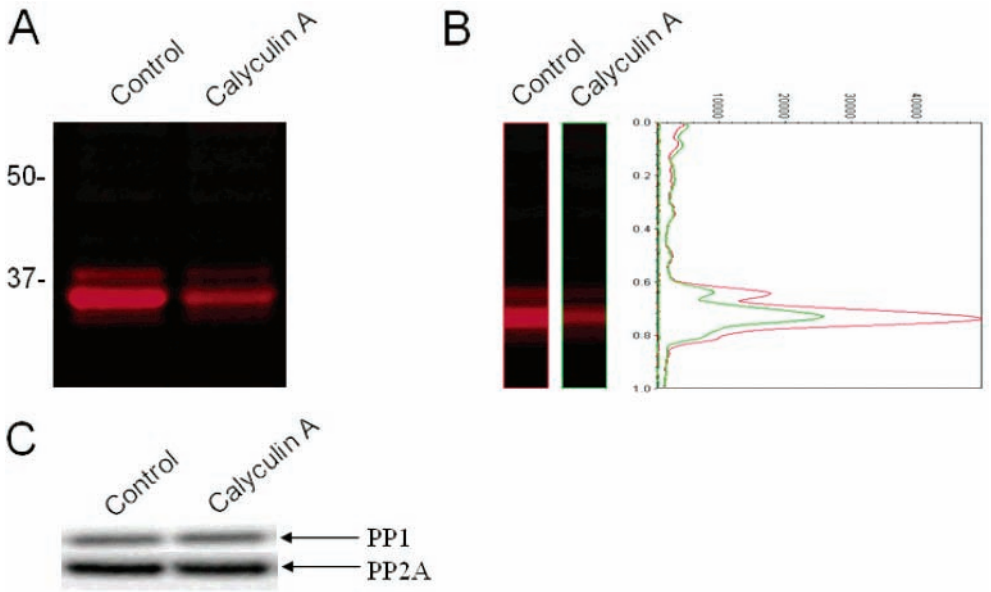

Figure 7. AX7574 can detect the decrease of serine/threonine protein phosphatase activities in calyculin A-treated Jurkat T cells. (A) Jurkat cells treated with calyculin A (25 nM) for 60 min or control DMSO, and soluble proteome derived from these cells were treated with AX7574 (0.5 μM) for 60 min. Reactions were quenched with standard 2× SDS/PAGE loading buffer (reducing), separated by SDS/PAGE, and visualized in-gel using a flatbed laser-induced fluorescence scanner. (B) Side-trace analysis of the gel data from Figure 7A. (C) The scanned gel from A was transferred to nitrocellulose and immunoblotted with anti-PP1 and anti-PP2A.

A second kind of experiment was carried out to examine whether the labeling of PP-1 by AX7574 required PP-1 to retain its native tertiary structure (see Figure 4). To address this question, PP-1 (25 nM) was first denatured by heating the protein at 65 °C for 10 min. The subsequent addition of AX7574 (0.5 μM) resulted in no significant labeling of PP-1. This result indicates that the recognition and subsequent attachment of AX7574 to PP-1 does in fact require the native structure of PP-1.

To investigate the impact of TAMRA conjugation on the affinity of the microcystin scaffold for PP-1, the IC_{50} values of both microcystin-LR and AX7574 for PP-1 were determined and compared (see Figure 5). Both compounds at various concentrations (0−30 nM) were incubated with PP-1 (5 nM) for 10 min. Postincubation, *p*-nitrophenyl phosphate (pNPP, 20 mM) was added and the degree of substrate hydrolysis measured spectroscopically at 450 nm. For each inhibitor, A_{450} was plotted versus inhibitor concentration, and the points were fit to a variation of the Hill equation (*43*) to determine IC_{50} values. Such an analysis yielded IC_{50} values of 0.3 and 4.0 nM for microcystin and AX7574, respectively. By comparison, a similar pNPP-based determination yielded a PP-1 IC_{50} value of 0.25 nM for microcystin-LR (*44*). As evidenced by these values, TAMRA conjugation had only a modest impact on binding and the resulting probe AX7574 remained a potent PP-1 inhibitor.

To test whether AX7574 would react with serine/threonine protein phosphatases in a complex proteome, we incubated soluble fractions of Jurkat cells with this probe (0.5 μM) for 60 min. Protein separation of the

sample was achieved using SDS−PAGE and visualized in-gel using a flatbed laser-induced fluorescence scanner. As seen in Figure 6A, AX7574 strongly labeled only two sets of proteins (36 and 38 kDa) and the labeling of these proteins by AX7574 was strongly inhibited by both microcystin and calyculin A. Protein staining revealed that all lanes contained approximately equal amounts of protein (Figure 6B), an indication that the labeling was specific for the proteins in those bands and not merely the result of labeling highly abundant proteins nonspecifically.

To confirm that the proteins labeled by AX7574 in Jurkat soluble fractions were serine/threonine protein phosphatases, mass spectrometric (MS) protein identification was performed (see Experimental Procedures): The two fluorescent gel bands were excised (Figure 6A), labeled proteins isolated using anti-TAMRA antibody beads, and the captured proteins digested using trypsin. Subsequent MS sequence analysis of the resulting peptides was used to identify the protein composition of each band. The 38-kDa protein band was shown to be PP-1 and the 36-kDa protein band was found to contain PP-2A, PP-4, and PP-6 (Figure 6C). Both PP-2A and PP-4, a phosphatase closely related to PP-2A (*45*), have previously been shown to be inhibited by microcystin-LR with IC_{50} values of 0.15 nM for both enzymes (*46*, *47*). In addition, PP-2A, PP-4, and PP-6 have been captured *noncovalently* using a microcystin−sepharose column as part of an effort to purify these proteins from soluble bovine testes extracts. Our data, which relies on the covalent labeling of these phosphatases, is the first account, to the best of our knowledge, of the irreversible binding of PP-4 and PP-6 by a microcystin derivative. Ultimately, and perhaps most importantly, the MS identification results demonstrate that AX7574 is able to react with and detect numerous serine/threonine phosphatases in a crude cell sample.

To test whether AX7574 could record changes in serine/threonine protein phosphatase activity levels, we treated Jurkat cells with calyculin A dissolved in a minimal amount of DMSO (2% v/v) such that the final concentration of inhibitor was 25 nM. Calyculin A was chosen not only for its cell permeability but also its potent activity against both PP1 (IC_{50} = 1.2 nM) and PP2A (IC_{50} = 7.3 nM) (*29*). As a control, Jurkat cells were treated with an equivalent volume of DMSO alone. After labeling with AX7574 (0.5 μM) for 60 min, AX7574-reactive serine/threonine protein phosphatases showed significantly lower labeling intensities in the calyculin A-treated Jurkat cells versus the control Jurkat cells (see Figure 7A and 7B). These results indicated that serine/threonine protein phosphatase activities were strongly inhibited by calyculin A. Critically, western blot analysis using anti-PP1 and anti-PP2A antibodies identified the same quantity of PP1 and PP2A in both control and calyculin A-treated Jurkat cells (see Figure 7C). These results further confirm that AX7574 labels serine/threonine protein phosphatases in an activity-dependent manner, recording variations in protein phosphatase activity rather than protein level. Without the AX7574 probe, western blot analysis and/or standard proteomics studies would have difficulties in distinguishing active from inactive protein phosphatases in these samples.

In conclusion, we describe herein the synthesis of AX7574, a microcystin derived fluorescent probe for serine/threonine phosphatases. The conjugation of a 1,3-diketone-containing fluorophore to the arginine-containing scaffold of microcystin was critical in maintaining the specific, high affinity, and irreversible-bond forming nature of the microcystin-phosphatase interaction. The ability to form a covalent bond within the phosphatase active site allowed this tagged chemical probe to capture and visualize the activity of this important class of enzymes in a complex proteome. Importantly, AX7574 expands the range of activity-based probes and provides a means to investigate the role that serine/threonine phosphatases play in physiological and/or pathological events.

Pegylated paramagnetic and fluorescent immunoliposomes were designed to enable the parallel detection of the induced expression of molecular markers on endothelial cells with magnetic resonance imaging (MRI) and fluorescence microscopy. MRI is capable of three-dimensional noninvasive imaging of opaque tissues at near cellular resolution, while fluorescence microscopy can be used to investigate processes at the subcellular level. As a model for the expression of a molecular marker, human umbilical vein endothelial cells (HUVEC) were treated with the pro-inflammatory cytokine tumor necrosis factor α (TNFα) to upregulate the expression of the adhesion molecule E-selectin/CD62E. E-selectin-expressing HUVEC were incubated with pegylated paramagnetic fluorescently labeled liposomes carrying anti-E-selectin monoclonal antibody as a targeting ligand. Both MRI and fluorescence microscopy revealed the specific association of the liposomal MR contrast agent with stimulated HUVEC. This study suggests that this newly developed system may serve as a useful diagnostic tool to investigate pathological processes in vivo with MRI.

INTRODUCTION

A challenge in diagnostics is noninvasive detection of molecular markers of disease in order to identify and visualize pathology in an early stage and to be able to follow the effect of therapy (*1*). Traditional immunohistochemical techniques can only be applied after invasive procedures, which excludes their use for in vivo detection and thus makes longitudinal studies of disease progression impossible.

In recent years, magnetic resonance imaging (MRI) has emerged as one of the leading noninvasive imaging modalities (*2*). With MRI it is possible to measure the morphology and function of healthy and diseased soft tissues in vivo by exploiting a remarkable range of physical and chemical properties of water protons, including the T_1 relaxation time. MRI, however, suffers from limited resolution and specificity, compared to optical and traditional staining techniques. In contrast to nuclear tracer methods such as PET or SPECT, MRI has a relatively low inherent sensitivity (*3*). A number of approaches can be taken to overcome these limitations. First, specific information on molecular markers can be obtained with the use of targeted contrast agents, which are directed to a molecular entity of interest, e.g. an endothelial cell surface receptor that is overexpressed as a consequence of a disease process. Second, the low inherent sensitivity of MRI requires that the targeted contrast agent is very effective in producing a local MRI signal change. This can be achieved by the use of colloidal particles that can accommodate large amounts of Gd-chelates (*4*−*6*), which are widely used for contrast-enhanced T_1-weighted MRI. Additional information can be obtained by labeling such particles with markers for other imaging modalities, such as fluorescence imaging (*7*), for multimodality characterization of (patho)physiological processes.

In this paper, we report on the development and application of targeted liposomes that carry a high payload of MRI contrast agent. Liposomes have been studied extensively during the last two decades as drug carrier vehicles (*8*−*11*). For that purpose, liposomes have previously been optimized in terms of their stability, circulation time in vivo, and membrane composition (*11*). Liposomes are biocompatible, they are composed of either natural or synthetic amphiphilic lipids, they can be sized to a defined diameter in the range of 50 to 500 nm, and they can be coated with polymers to increase stability and to prolong circulation half-life in vivo (*12*). A wide range of amphiphilic and hydrophobic molecules can be incorporated in the bilayer of the liposomes. The aqueous interior can be loaded with water soluble drugs, proteins, or DNA for therapeutic applications (*13*). Another potential application is the use of liposomes as a (targetable) contrast agent for MRI (*4*, *5*, *14*−*16*).

The goal of this study was to develop paramagnetic pegylated liposomes with a targeting ligand coupled to

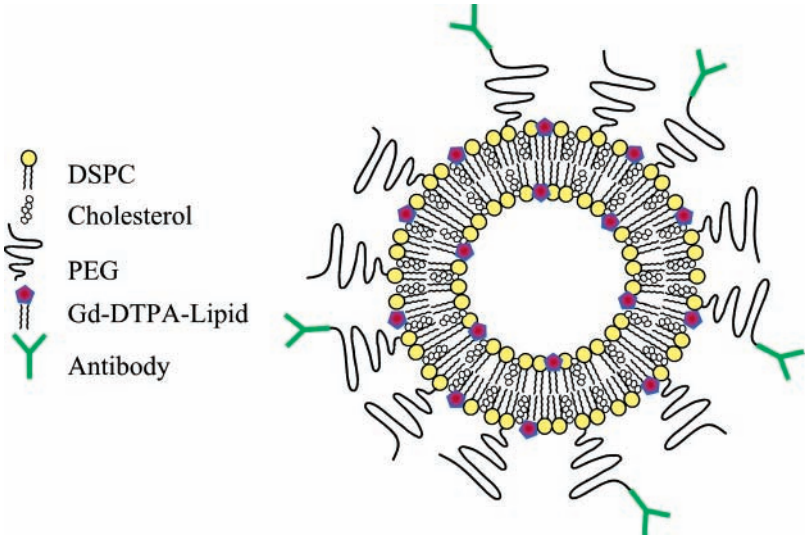

Figure 1. Schematic representation of a pegylated paramagnetic liposome that is composed of Gd-DTPA-bis(stearylamide) (Gd-BSA), 1,2-distearoyl-*sn*-glycero-3-phosphocholine (DSPC), cholesterol (Chol), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG2000-DSPE) and has antibodies coupled to the distal end of the PEG-chains.

the distal end of the PEG-chains for contrast-enhanced MR imaging of molecular markers (Figure 1). Gd-DTPA-bis(sterylamide) (Gd-BSA) was incorporated in the bilayer of the liposomes as a paramagnetic MRI contrast agent. We have used the antibody-conjugated liposomal system to detect E-selectin expression on HUVEC in vitro. This is an attractive model for receptor expression on endothelial cells, since E-selectin levels can be up-regulated approximately 10-fold by TNFα (*17*−*19*). E-selectin can be considered a model system for a variety of endothelial cell surface receptors that are of pathophysiological and therapeutic importance, including αvβ3-integrins (*20*, *21*) and vascular endothelial growth factor receptor (*22*, *23*). We show that the association to TNFα stimulated HUVEC was specific for liposomes carrying E-selectin antibodies. The antibody-dependent liposomal association was accompanied by a pronounced shortening of the T_1 relaxation time of HUVEC suspensions as evidenced by MRI.

MATERIALS AND METHODS

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphocholine (DSPC), cholesterol (Chol), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG_{2000}-DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide(poly(ethylene glycol))2000] (Mal-PEG_{2000}-DSPE), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (rhodamine-PE) were obtained from Avanti Polar Lipids (Albaster, AL). Gd-DTPA-bis(stearylamide) (Gd-BSA) was purchased from Gateway Chemical Technology (St. Louis, MO). *N*-Succinimidyl *S*-acetylthioacetate (SATA) and calcein were obtained from Sigma Chemical Co. (St. Louis, MO), and HEPES was obtained from Merck (Darmstadt, Germany). All other chemicals were of analytic grade or the best grade available. Polycarbonate filters for liposome extrusion were from Costar (Cambridge, MA).

H18/7 monoclonal antibody against human E-selectin, kindly donated by Dr. M. A. Gimbrone (Boston, MA), was isolated from hybridoma culture supernatant using protein A affinity chromatography according to standard procedures.

Preparation of Paramagnetic PEG Liposomes. Liposomes were prepared by lipid film hydration. A mixture of the appropriate amounts of lipids (typically: 120 μmol of total lipid) was dissolved in chloroform/methanol 1:1 (v/v) and evaporated to dryness by rotary evaporation at 40 °C. For the paramagnetic PEG-liposomes, Gd-BSA, DSPC, cholesterol, and PEG_{2000}-DSPE were used at a molar ratio of 0.75/1.10/1/0.15. For PEG-liposomes that were used to attach antibodies to the distal end of the PEG-chains, Gd-BSA, DSPC, cholesterol, PEG_{2000}-DSPE, and Mal-PEG_{2000}-DSPE were mixed at a molar ratio of 0.75/1.10/1/0.075/0.075. For fluorescence microscopy, 0.1 mol % of rhodamine-PE was added to these preparations. The lipid film was subsequently hydrated in 3 mL of HEPES-buffered saline (HBS), containing 20 mM HEPES, 135 mM NaCl (pH 6.5). The resulting lipid dispersion was extruded sequentially six times through polycarbonate membrane filters with a pore diameter of 400 nm and subsequently 10 times through filters with a pore diameter of 100 nm using a Lipofast Extruder (Avestin, Canada). The temperature during extrusion was 60 °C.

Coupling of the Antibodies to Liposomes. The monoclonal antibody H18/7 against human E-selectin (AbEsel) was coupled to liposomes containing Mal-PEG_{2000}-DSPE by a sulfhydryl-maleimide coupling method as described previously (*18*, *24*). In short, H18/7 monoclonal antibody (1 mg/mL) was modified with *N*-succinimidyl *S*-acetylthioacetate (8:1 SATA:antibody mole:mole ratio) and incubated for 45 min at a roller-bench at room temperature. Free SATA was separated from the antibody/SATA solution by centrifugation on Vivaspin concentrator with a 50 kD MW cut-off filter followed by thorough washing four times with HBS. The SATA-derivatized antibody was deacetylated by incubation with a hydroxylamine solution for 1 h at room temperature. The activated antibody was added to the Mal-PEG_{2000}-DSPE-containing liposomes in a 50 μg/μmol protein/lipid ratio. This preparation was stored at 4 °C under N_2 overnight. Uncoupled antibody was separated from immunoliposomes by centrifugating two times at 65 000 rpm for 45 min. The supernatant was removed and an appropriate amount of buffer, typically 1.5 mL, was added to the pellet to obtain a lipid suspension with a lipid concentration of approximately 20 mM. The final liposomal suspension was stored at 4 °C under N_2 and used within 7 days.

Liposome Characterization. *Size, Lipid/Protein Ratio.* The size and size distribution of the bare liposomes and the antibody-coupled liposomes were determined by dynamic light scattering (DLS) at 25 °C with a Malvern 4700 system using an argon-ion laser (488 nm) operating at 10.4 mW (Uniphase) and PCS (photon correlation spectrometry) software for Windows version 1.34 (Malvern, U.K.). For data analysis, the viscosity and refractive index of water was used. The system was calibrated with a polystyrene dispersion containing particles of 100 nm. The phospholipid content of the liposome preparations was determined by phosphate analysis according to Rouser (*25*) after destruction with perchloric acid, and the protein content was determined according to Petterson (*26*).

Efficiency of Gd-BSA Incorporation. The efficiency of Gd-BSA incorporation in the liposomal bilayer was determined as a function of the Gd-BSA fraction in the lipid mixture. Lipid films of Gd-BSA/DSPC/Chol/Mal-PEG_{2000}-DSPE with 10, 20, 30, and 50 mol % Gd-BSA were prepared by dissolving the lipids in chloroform/methanol (1:1), followed by evaporation to dryness. The combined Gd-BSA and DSPC content was kept constant at 62 mol %, while the molar ratios of cholesterol and Mal-PEG_{2000}-DSPE were fixed at 33 and 5 mol %, respectively. The lipid film was subsequently hydrated in 3 mL of HBS and the phosphate and gadolinium content were determined. The resulting lipid dispersion was extruded as described above, after which the phosphate and gadolinium content were again determined. The extruded liposomes were centrifuged at 65 000 rpm for 45 min, and the phosphate and gadolinium content of the pellet and the supernatant were once more determined. Phosphate determinations were done according to Rouser (*25*) and gadolinium content was determined by inductively coupled plasma-atomic emission spectroscopy (ICP-AES).

Membrane Stability of the Liposomes. Calcein has been used as a fluorescent marker to investigate membrane permeability (*27*) and its release profile from the liposomal lumen reflects membrane stability. Calcein containing DSPC/Chol/Mal-PEG_{2000}-DSPE liposomes and calcein containing Gd-BSA/DSPC/Chol/Mal-PEG_{2000}-DSPE (25 mol % Gd-BSA) liposomes were prepared as described above by hydration with 50 mM calcein/150 mM sucrose/10 mM Hepes buffer (pH 7.4). The prepared liposomes were dialyzed at 4 °C for 4 days with phosphate-buffered saline (PBS, pH 7.4) to remove the untrapped calcein. The size and the lipid/calcein ratio were determined. Following dialysis both formulations were tested for the release of calcein upon incubation in 10% calf serum at 37 °C for 24 h. Calcein leakage from the aqueous interior of the liposomes was determined fluorometrically at excitation and emission wavelengths of 485 and 512 nm, respectively, using a fluorescence spectrophotometer. After incubation liposome size was determined again.

T_1 Relaxation Time Measurements. An important quality criterion for MRI contrast agents is their molar relaxivity r_1 (in units of $mM^{-1}\ s^{-1}$). A higher r_1 will lower the detection threshold of local contrast agent deposition with T_1-weighted MRI. MR spectroscopic measurements of the T_1 relaxation times of 0.5 mL of buffered liposome suspensions (leading to final concentrations of 7.1, 3.6, 1.8, and 0.9 mM gadolinium) and Gd-DTPA solutions (5.0, 2.5, 1.3, and 0.6 mM gadolinium) were performed using a 7 T MR spectrometer (Varian, Palo Alto, CA). T_1 relaxation times were obtained by the inversion recovery method, using 13 different inversion times, ranging from 10 to 3100 ms in an exponential fashion, and a repetition time of 10 s. To determine the temperature dependence of T_1, the temperature was varied between 25 and 80 °C, using steps of 5 °C and an equilibration time of 10 min. For comparison the T_1 relaxation times of 2 mL of buffered liposome suspensions (7.1, 3.6, and 0.9 mM gadolinium) were also determined at 1.5 T, a field strength frequently used in clinical MRI, using a Philips S15/ACS whole-body MR scanner. The molar relaxivity r_1 was obtained from the slope of the linear fit of the inverse of the measured T_1-values as a function of the gadolinium concentration (*28*).

In Vitro Targeting Experiments. Human umbilical vein-derived endothelial cells (HUVEC) were cultured on gelatin (0.2% in PBS)-coated tissue culture flasks (Costar, Cambridge, MA) in culture medium, RPMI-1640 (Life Technologies, Breda, The Netherlands), 20% human serum (HS; University Hospital Maastricht, The Netherlands), 2 mM glutamine (Life Technologies), and 100 U/mL penicillin and 0.1 mg/mL streptomycin (ICN Biomedicals, Aurora, OH). For all incubations, 10^6 cells of passage 2−3 were used for experiments.

Association of paramagnetic AbEsel-immunoliposomes (25 mol % Gd-BSA) to endothelial cells was assessed using fluorescence microscopy and magnetic resonance imaging. For this, HUVEC were grown to 70−80% of confluence in tissue culture flasks and stimulated for 3 h with 4 ng/mL human recombinant TNFα (rhTNFα; Boehringer, Germany). The effect of the stimulation was verified by FACS analysis of E-selectin expression (*17, 29*) and by visual verification of the change in cell shape. Control cells were left untreated. Subsequently, paramagnetic AbEsel-immunoliposomes and bare paramagnetic liposomes were added to control and TNFα-treated cells (1000 nmol lipid/mL medium). After 3.5 h of incubation with liposomes, the cultures were washed two times with PBS, and cells were harvested by incubation in EDTA and a mild trypsinization procedure. Cells and medium were collected in tubes and were washed twice in PBS. A small amount of cells (10^4) was taken to assess the association of liposomes using fluorescence microscopy. The obtained pellets, $10^6 \pm 10^5$ cells, were put in small eppendorf-cups, and 40 μL of 4% paraformaldehyde solution was added to a final volume of approximately 50 μL. Next, the samples were used for MR imaging.

Magnetic Resonance Imaging of Cell Pellets. MRI was performed on pellets of HUVEC, using a 6.3 T horizontal 9.5 cm bore magnet. A 3 cm send and receive birdcage coil was used. In all imaging experiments the samples described above were placed in a custom-made sample holder, capable of carrying four eppendorf-cups. A T_1-weighted spin−echo sequence (TR 1200 ms, TE 9 ms) was used for imaging. For absolute quantification of T_1, an inversion recovery spin−echo sequence was used with 13 different inversion times, ranging from 10 to 3100 ms in an exponential fashion. For quantification of T_2 a spin−echo sequence was used with different echo times, ranging from 9 to 64 ms. In all experiments the FOV was 3×3 cm^2, matrix size was 256×128, and the slice thickness was 1 mm. From the images, a T_1-map or a T_2-map was calculated using Mathematica (Wolfram Research, Inc.). T_1 and T_2 of the different cell pellets were determined in regions-of-interest and averaged for three independent experiments.

Statistical Analysis. Values for T_1, obtained from the pellets of HUVEC as described above were analyzed using multiple *t*-tests ($p < 0.05$) with correction for multiple comparisons (*30*).

RESULTS

Characterization of the Paramagnetic Liposomes. The mean size of a typical batch of liposomes before coupling of the AbEsel-antibody was 120 nm with a polydispersity index of 0.05. After the antibody was coupled, the mean size of the liposomes increased to 150 nm and the polydispersity index increased to 0.2. The initial coupling started with 50 μg protein/μmol lipid. The final protein-to-lipid ratio was 25 μg protein/μmol lipid, corresponding to a 50% efficiency. This corresponds to an estimated number of 30 antibody molecules per liposome.

First, we established the maximal amount of Gd-BSA that could be incorporated in the liposomal bilayer. From a standard DSPC/Chol/PEG-DSPE 1.85/1/0.15 formulation an increasing amount of DSPC was replaced by Gd-BSA. When DSPC was replaced by 10, 20, or 30 mol % Gd-BSA (percentage of the total amount of lipid), all Gd-BSA did incorporate into the bilayer, and the phosphate/Gd ratio before and after extrusion of the liposomal dispersion was identical. Higher percentages of Gd-BSA resulted in a decrease of the incorporation efficiency: at 50 mol % Gd-BSA, the Gd-to-total lipid ratio in the liposomal suspension after extrusion was decreased from an expected value of 50 mol % to a value of 40 mol %.

Incorporation of a large amount of Gd-DTPA-bis(stearylamide) (Gd-BSA) might affect the stability of the liposomes. Therefore, the stability of liposomes with a Gd-BSA/DSPC/Chol/PEG (25 mol % Gd-BSA) formulation was compared with a DSPC/Chol/PEG formulation by enclosing calcein in the aqueous lumen and monitoring the release of calcein upon incubation in serum. Both formulations did not show a measurable release of calcein upon incubation at 4 °C in buffer for 24 h. Upon incubation of the liposomes in 10% calf serum buffer at 37 °C for 24 h, both formulations showed a calcein release of 4−6%. The size of both liposome preparations remained the same after the 24 h incubation in serum, as determined from dynamic light scattering data. Based on the above data, it was decided to use a molar percentage of 25% Gd-BSA in the E-selectin targeting studies on HUVEC cells.

Since the Gd-BSA-containing liposomes are to be used in contrast-enhanced T_1-weighted MRI, it is critical to determine the efficiency with which the paramagnetic particles shorten the T_1 relaxation time of water. This efficiency is conveniently expressed as the molar relaxivity, r_1, in units $mM^{-1}\ s^{-1}$, which is determined from the dependence of the measured T_1 relaxation rate on the contrast agent concentration. The longitudinal relaxivity r_1 of a buffered liposome suspension was determined at 7 T as a function of temperature and was compared with the r_1 of free Gd-DTPA that is in clinical use (Figure 2). At 37 °C, the r_1 of Gd-BSA contained in the liposomal membrane was 1.5 times that of the solution with free Gd-DTPA. The r_1 of Gd-DTPA decreased with increasing temperature. For the liposomal Gd-BSA suspension, r_1 increased up to 55 °C, while decreasing above 55 °C. The r_1 of the liposome suspension as measured at 1.5 T was 5.5 $mM^{-1}\ s^{-1}$ at room temperature, which is similar to the r_1 at 7 T at room temperature (5.2 $mM^{-1}\ s^{-1}$).

In Vitro Targeting Experiments. Treatment of endothelial cells with TNFα leads to activation and overexpression of adhesion molecules involved in leukocyte interactions. When HUVEC were treated with 4 ng/mL TNFα, next to a morphological change, E-selectin protein expression increased 10-fold as deduced from FACS analysis (data not shown). Fluorescence microscopy showed a pronounced association of the AbEsel-immunoliposomes to TNFα-treated HUVEC (Figure 3B). The association of the AbEsel-immunoliposomes by the HUVEC was partly due to internalization of the liposomes into the cytosol (insert Figure 3B). Nontargeted liposomes did not associate with either resting (data not shown) or TNFα-activated HUVEC (Figure 3C).

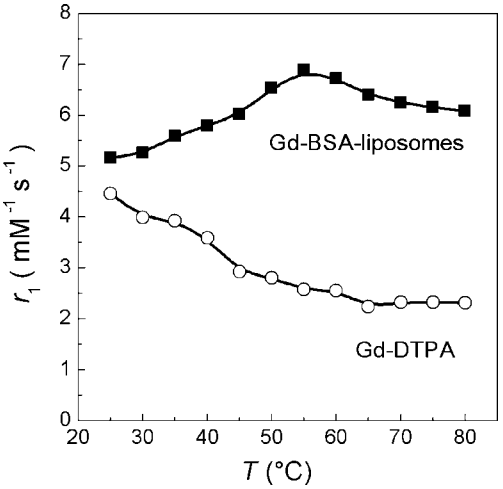

Figure 2. The molar relaxivities r_1 of free Gd-DTPA (○) and Gd-BSA containing liposomes (■) were determined as function of the temperature at a field strength of 7 T. The Gd-DTPA concentration was varied between 0.6 and 5.0 mM. The Gd-BSA content of the liposomes was fixed at 25 mol %, while the effective Gd-BSA concentration in the medium was varied from 0.9 to 7.1 mM Gd-BSA to determine r_1. The lines connecting the data points are aimed to guide the eye.

For MR imaging, HUVEC treated with TNFα and incubated with AbEsel-immunoliposomes were compared with three controls. Figure 4 shows a schematic representation of these experiments. A T_1-weighted image, a T_1-map, and a T_2-map of a typical experiment are depicted in Figure 5. The average T_1 and T_2 of different systems are listed in Table 1. In the T_1-weighted image (Figure 5A) the region corresponding with the test incubation, TNFα-treated HUVEC incubated with AbEsel-immunoliposomes, was much brighter than the three control incubations, indicating that there is a distinct difference in T_1 of the test incubation compared to the controls. This difference was quantified by generating a T_1-map of the setup (Figure 5B) with an inversion recovery experiment and averaging the T_1s found in three independent experiments (Table 1). The T_1 of the pellet of stimulated HUVEC incubated with AbEsel-immunoliposomes was 457 ± 62 ms, which is almost a factor 5 lower than the T_1 of the nonstimulated cells incubated with AbEsel-immunoliposomes (T_1 of 2156 ± 130 ms). The stimulated cells that were incubated with nontargeted liposomes had a T_1, which was comparable with the T_1 of nonstimulated cells incubated with AbEsel-immunoliposomes: both T_1s were approximately 2150 ms. The pellet of control HUVEC had a T_1 of 2412 ± 122 ms, which was significantly longer than all other three systems. The same trend was observed for the T_2 values (Figure 5D, Table 1). The association of AbEsel-immunoliposomes with TNFα-activated HUVEC led to a decrease in the T_2 relaxation time from 103 ± 12 to 16 ± 1 ms (Table 1). The other incubations of paramagnetic liposomes with HUVEC did not cause significant alterations in the T_2 of water.

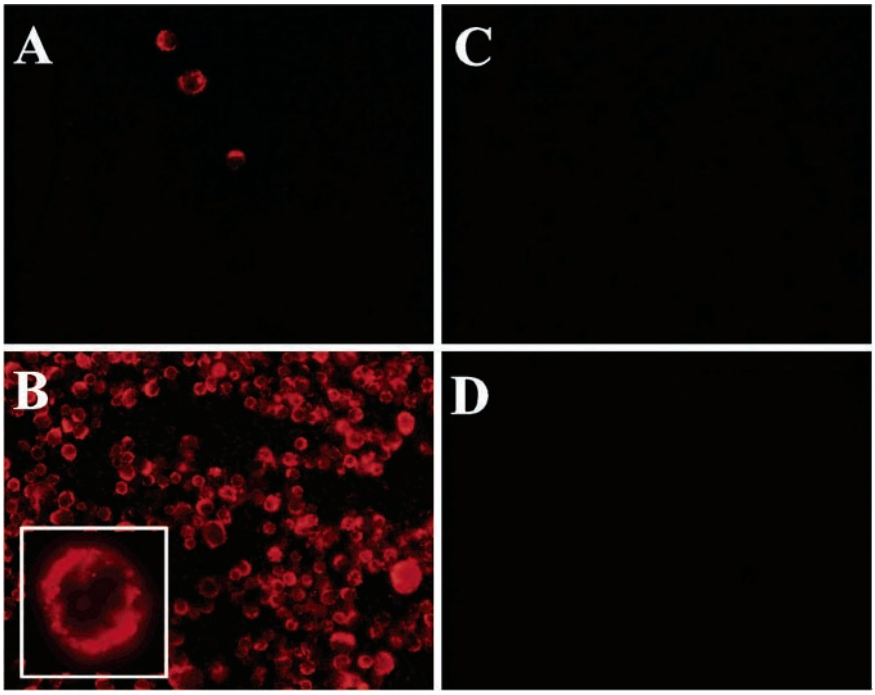

Figure 3. Fluorescence microscopy of liposomal targeting to HUVEC. (A) Fluorescence microscopy image of nonstimulated HUVEC that were incubated for 3.5 h with paramagnetic AbEsel-immunoliposomes showed very little fluorescence. (B) TNFα-treated HUVEC showed massive association of paramagnetic AbEsel-immunoliposomes. Insert in B demonstrates that the fluorescence partly originates from the cell interior (magnification 630 ×). (C) TNFα-treated HUVEC incubated with nontargeted liposomes. (D) Control HUVEC that were not incubated with liposomes.

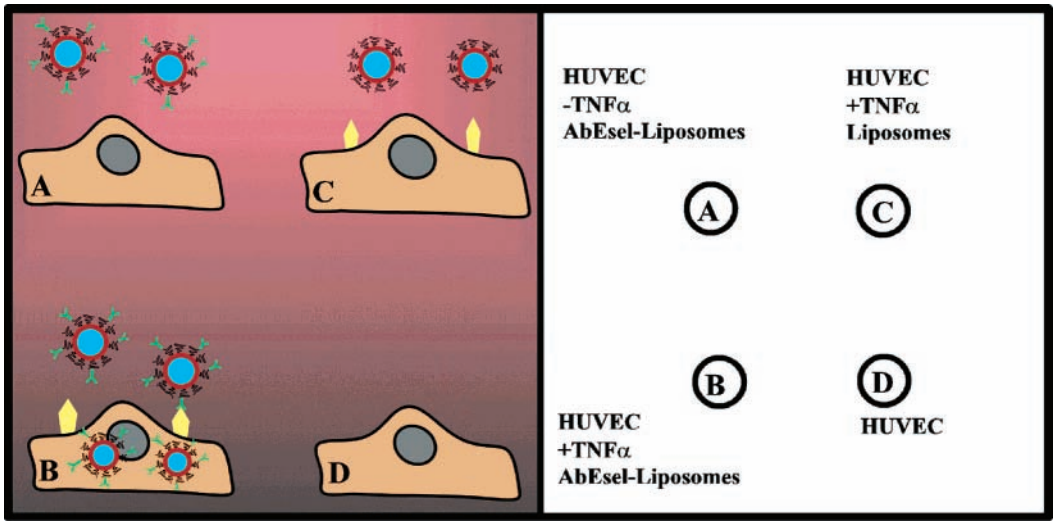

Figure 4. Schematic representation of the setup used for MRI analysis of liposomal targeting to HUVEC. The left side of the figure schematically depicts the setup of the experiment, in which B is the test incubation (TNFα-treated HUVEC incubated with AbEsel-immunoliposomes). A (non-TNFα-treated HUVEC incubated with AbEsel-immunoliposomes), C (TNFα-treated HUVEC incubated with bare liposomes), and D (HUVEC) are controls. The right side of the figure gives the setup of the pellets of HUVEC used for MR imaging.

DISCUSSION

The in vivo upregulation of receptors expressed on vascular endothelial cells at diseased sites represents an attractive target for early detection of a range of important disease processes (*31*). In inflamed or angiogenic tissues, such as tumors, atherosclerotic plaques, or rheumatic joints, blood vessels express high and upregulated levels of activation-related receptors. E-selectin, a molecule involved in leukocyte vessel wall interactions, is profoundly upregulated in tissues exposed to inflammatory cytokines (*32*). Detection of such receptors can be of prime importance in diagnosis of these diseases at an early stage. An established in vitro system for endothelial cells, which allows the induction of the typical inflammation related adhesion molecule E-selectin has been described previously (*18*, *19*, *33*, *34*). In these studies endothelial cells (HUVEC) were stimulated by cytokines such as IL-1β or TNFα, which resulted in a strong upregulation of E-selectin. Particles carrying antibodies against E-selectin are capable of specific binding to HUVEC-expressing E-selectin and can be internalized by these cells. Previous studies have shown an efficient association of AbEsel-immunoliposomes targeted to E-selectin, using the H18/7 antibody as a targeting ligand, by activated endothelial cells in vitro *(18*, *19*). The use of an H18/7 Fab-coupled iron oxide particle to target

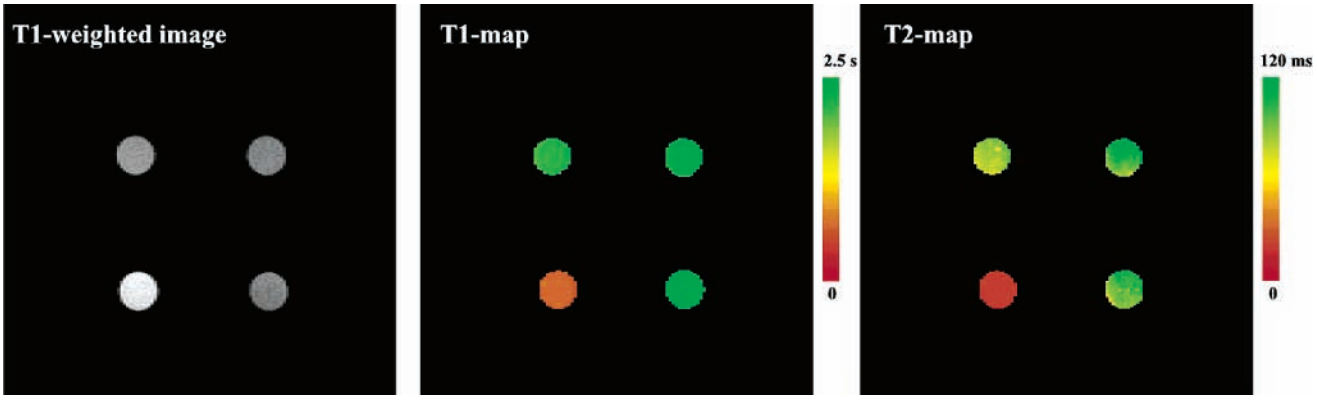

Figure 5. MR image of a typical experiment shows a slice through four pellets of HUVEC of the setup schematically depicted in Figure 4. The test incubation (B) showed enhanced signal intensity in the T_1-weighted image (TR 1200 ms, TE 9 ms). The T_1-map and T_2-map, generated as described in Materials and Methods, revealed a dramatic shortening of both T_1 and T_2 of the stimulated cells incubated with paramagnetic AbEsel-immunoliposomes, while the T_1 and T_2 of nonstimulated cells and the stimulated cells that were incubated with liposomes, that did not contain an antibody, only slightly differed from the control HUVEC.

Table 1. Quantification of T_1 and T_2 of HUVEC[a]

batch ($n = 3$)	T_1 (ms)	T_2 (ms)
A HUVEC, − TNFα, AbEsel-L	2156 ± 130	90 ± 11
B HUVEC, + TNFα, AbEsel-L	457 ± 62	16 ± 1
C HUVEC, + TNFα, Bare-L	2135 ± 84	106 ± 12
D HUVEC	2412 ± 122	103 ± 12

[a] MRI-based quantification of the water T_1 and T_2 (mean ± SD) in pellets of $10^6 \pm 10^5$ HUVEC of the different incubations ($n = 3$). A−D refer to the systems described in Figure 4. The T_1s of the different incubations have been analyzed using multiple *t*-tests ($p < 0.05$) with correction for multiple comparisons. The T_1 of incubation B is significantly different from incubations A, C, and D. The difference between the T_1 of A and C is not significant, whereas the T_1 of D is significantly higher than that of other incubations.

E-selectin on endothelial cells in vitro showed the capability of detecting E-selectin expression with MRI (*33*). The contrast generated by iron oxide particles can be ascribed to their superparamagnetic properties. This results in a dramatic shortening of T_2 and causes dark spots in T_2- and T_2*-weighted images, which is termed negative contrast (*35*, *35*, *36*).

In this study we tested the possibility to MR image the uptake of Gd-DTPA-based paramagnetic AbEsel-immunoliposomes, which is accompanied by signal enhancement (i.e., positive contrast) in T_1-weighted imaging, by activated endothelial cells. AbEsel (H18/7) antibodies were covalently coupled to the distal end of the PEG-chains of the paramagnetic liposomes, which resulted in an efficient conjugation of 25 μg protein/umol lipid without compromising the liposomal size distribution. The average diameter of the AbEsel-immunoliposomes was 150 nm diameter, with a polydispersity index of 0.2. Sipkins et al. (*4*) and Lanza et al. (*6*) have described paramagnetic particles of approximately 250 nm in size, without a PEG-coating, to which antibody was coupled via a noncovalent biotin−avidin interaction. When comparing these two paramagnetic particles, the immunoliposomal system described in this study has several advantages: it has a high flexibility in size (ranging from ca. 80 to 500 nm), it may be expected to have long circulation times because of the PEG-coating (*11*), and it has the antibody covalently coupled. The applied covalent coupling of targeting ligands is advantageous as it is more efficient (*37*) and does not involve a large protein complex like in the biotin−avidin−biotin method, which is known to be strongly immunogenic (*38*). The coupling of the antibody at the terminal end of the PEG chain is known to result in liposomes that retain their favorable pharmacokinetic behavior (*39*, *40*) and likely have prolonged circulation times compared to the existing paramagnetic systems. These properties may result in a more efficient targeting of our liposomal contrast agent in vivo. Liposomes composed of DSPC/Chol/PEG were stable upon incubation in serum containing buffer. The incorporation of 20−30 mol % of Gd-BSA did not significantly alter the stability properties of the liposomes. The stability data suggest that the Gd-BSA-containing liposomes may also be used as a drug carrier vehicle, carrying a payload of water soluble drugs in the aqueous interior or carrying hydrophobic drugs in the liposomal bilayer. The system could thus be a tool for combining molecular marker imaging with local therapy.

The relaxivity properties of the paramagnetic liposomes differed from the relaxivity properties of free Gd-DTPA. At room temperature the r_1 of the paramagnetic liposomes and Gd-DTPA were approximately the same. The longer rotational correlation time of the liposomes was expected to result in a larger relaxivity. With increasing temperature the r_1 of Gd-DTPA decreased, whereas the r_1 of the liposomes increased up to a temperature of 55 °C (Figure 2). From 55 °C the r_1 of the liposomes decreased again but remained higher than the r_1 of Gd-DTPA. The peak of the liposomal r_1 at 55 °C might be explained by the increasing water exchange across the liposome membrane at higher temperatures allowing Gd-chelates present on the inner side of the bilayer to contribute more to the overall relaxivity. The transition temperature of this liposomal formulation is ca. 55 °C (*41*), implying that the liposomal bilayer is in the gel phase below 55 °C and in the fluid phase above 55 °C. A bilayer in the fluid phase is more permeable to water (*41*). These results suggest that at room temperature only part of the gadolinium contributes to the overall relaxivity. Therefore, a liposomal formulation with a transition temperature below the physiological temperature may be more suitable as an in vivo contrast agent in terms of relaxation properties. On the other hand, the altered composition might result in impaired stability and/or decreased Gd-BSA loading capacity.

Strongly enhanced interaction of AbEsel-immunoliposomes with TNFα-treated cells was observed by fluorescence microscopy compared to control incubations. The fluorescence pattern represents a combination of cell membrane binding of fluorescent liposomes as well as intracellularly present fluorescence representing internalized liposomes, which is in agreement with previous studies (*18*, *19*). Internalization of the liposomes might

be important for in vivo detection since the low inherent sensitivity of MRI requires large amounts of Gd-DTPA to be present at the targeted site. Binding of the liposomes to the receptors expressed at the endothelium alone might not generate sufficient contrast in MR imaging to localize the liposomes with this technique.

MRI experiments on pellets of 10^6 HUVEC were in excellent agreement with fluorescence microscopy. The T_1-weighted image of the pellet containing TNFα-treated HUVEC incubated with AbEsel-immunoliposomes (Figure 5A) had a much higher signal intensity than that of the three control systems. This can be explained by the large shortening of the T_1 in the former system (Figure 5B). The much less pronounced shortening of T_1 for the nonactivated HUVEC, incubated with AbEsel-immunoliposomes, as well as the mild shortening of T_1 for the HUVEC that were stimulated and incubated with liposomes that did not contain the anti-E-Selectin antibody can be explained by a low affinity, nonspecific cellular uptake of liposomes.

In vivo, this anti-E-selectin MR contrast agent can be useful for the detection of atherosclerosis, angiogenesis, and inflammation. The described technique is also applicable for detection of other internalizing cell surface receptors as markers of the activated and/or angiogenic endothelial phenotype.

CONCLUSIONS

We described the preparation, characterization, and successful in vitro targeting of paramagnetic liposomes for use in combination with MRI. The liposomes have a PEG-coat, and they do not leak upon incubation in serum. An anti-E-selectin antibody was coupled to the distal end of the PEG-chains of the liposomes. Other targeting ligands, like peptides (*42*) can also be coupled. The system both carries a MR-marker and a fluorescent marker, and we have demonstrated the E-selectin-dependent association of the liposomes to stimulated HUVEC by MRI and fluorescence microscopy. These results imply that this novel MR contrast agent may potentially serve as a useful diagnostic tool to investigate disease processes in vivo and to follow therapeutic efficacy.

ACKNOWLEDGMENT

The authors would like to thank Prof. Dr. Ben de Kruijff, Dr. Eefjan Breukink, and Dr. Marcel van Genderen for useful discussions and Larry de Graaf for technical assistance.

Received March 13, 2004; Revised Manuscript Received May 18, 2004

Genetic economy leads to symmetric distributions of chemically identical subunits in icosaherdal and helical viruses. Modification of the subunit genes of a variety of viruses has permitted the display of polypeptides on both the infectious virions and virus particles made in expression systems. Icosahedral chimeric particles of this type often display novel properties resulting in high local concentrations of the insert. Here we report an extension of this concept in which entire proteins were chemically cross-linked to lysine and cysteine residues genetically engineered on the coat protein of icosahedral Cowpea mosaic virus particles. Three exogenous proteins, the LRR domain of internalin B, the T4 lysozyme, and the Intron 8 gene product of the of the HER2 tyrosine kinase receptor were derivatized with appropriate bifunctional cross-linkers and conjugated to the virus capsid. Characterization of these particles demonstrated that (1) virtually 100% occupancy of the 60 sites was achieved; (2) biological activity (either enzyme or binding specificity) of the attached protein was preserved; (3) in one case (LRR-internalin B) the attached protein conformed with the icosahedral symmetry to the extent that a reconstruction of the derivatized particles displayed added density with a shape consistent with the X-ray structure of the attached protein. Strategies demonstrated here allow virus particle targeting to specific cell types and the use of an icosahedral virus as a platform for structure determination of small proteins at moderate resolution.

INTRODUCTION

Several rod shaped and icosahedral viruses have been used for expression and display of foreign peptides (*1*−*10*). Cowpea mosaic virus (CPMV) offers novel advantages for presentation of foreign epitopes on its surface (*1*−*6*). The virus capsid is highly permissive to genetic alterations, accumulates to high levels in plants, and the virus is stable over a wide range of pH and temperature conditions, making it amenable for chemical modification. The structure of the virus has been resolved to 2.8 Å resolution, allowing rational designing of peptide presentation on the virus surface (*11*−*15*). The inherent nature of the viral symmetry coupled with the polyvalent display of exogenous protein opens up additional venues for structure determination of the foreign epitope being displayed (*16*−*18*).

Surface presentation of foreign polypeptides that are introduced genetically into the capsid, however, is restricted to approximately 30 amino acids (*4*, *18*−*19*). A useful extension of this technology will be to display full-length proteins and protein domains on the virus capsid. We explored the option of chemically coupling exogenous proteins to the virus capsid using a variety of readily available homo-and heterobifunctional cross-linkers and investigated the suitability of CPMV to serve as a scaffold for structure determination of the conjugated proteins by directly imaging the altered virus particle with methods that make use of the icosahedral redundancy.

The CPMV genome consists of two separately encapsidated RNA molecules of 6.0 kb (RNA 1) and 3.5 kb (RNA2) (*20*, *21*). The viral capsids contain 60 copies each of the large and small coat protein subunits arranged with icosahedral symmetry (*22*). Any attachment on the viral capsid therefore translates into the heterologous protein being presented on the virus surface 60 times, assuming 100% occupancy. To illustrate the versatility of CPMV as a polyvalent display platform, we used proteins with different biological functions as well as size range for cross-linking (8−22 kDa) to the virus surface. Some of these proteins were chosen to provide the necessary proof of principle that the structural information derived from the virus-protein-conjugated complexes is authentic while others were selected to determine the effect of enhanced local concentration from the multivalent presentation of the protein on the virus capsid.

The attachment sites for chemical derivatization of the viral capsid were engineered by site-specific mutagenesis of four of the five surface lysine residues to arginine thereby retaining only one reactive lysine on the virus (*23*). Further, wild-type CPMV does not have any surface

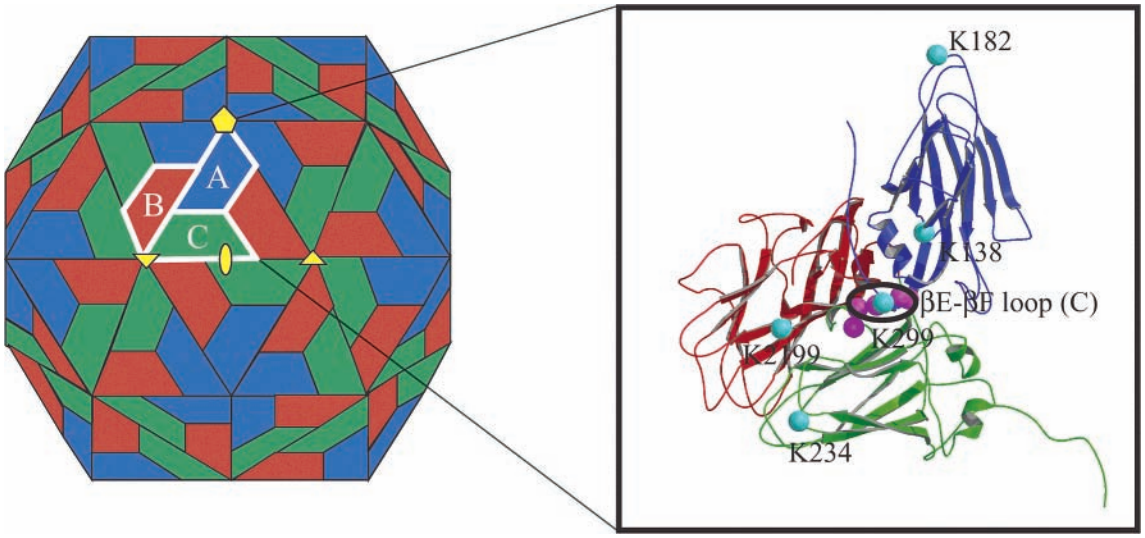

Figure 1. Left. Schematic diagram of CPMV capsid. The reference asymmetric unit is framed and the symmetry elements are labeled. Small (S) subunits labeled A are in blue, and the large (L) subunits formed by two domains are in red (B domains) and in green (C domains). The oval represents a 2-fold axis; the triangle is a 3-fold axis and the pentagon a 5-fold axis. Right. Ribbon diagram of the asymmetric unit comprised by three jellyroll β sandwiches with surface Lys residues represented as spheres in cyan. Residue numbers are preceded by a 1, if they are in the small subunit and a 2, if they are in the large subunit. K138 and K182 are in the A domain, K299 and K234 are in the C domain, while K2199 is in the B domain. Two mutants were used for the conjugation. Mutant vK299 contains the unique K299 (encircled) and mutant vEFB contains a unique cysteine engineered in the βE-βF loop of the C domain (magenta). The figure is drawn with MOLSCRIPT.

exposed cysteines on the virus capsid; hence, it was straightforward to engineer a cysteine residues at a unique location on the virus surface (*24, 25*). These CPMV mutants were used for directed modification of the virus with foreign proteins (Figure 1).

EXPERIMENTAL PROCEDURES

Propagation of the Virus in Plants. The primary leaves of cowpea seedlings were mechanically inoculated with 10 μg each of cDNA plasmids encoding RNA1 (pCP1) and RNA2 (pCP2) (*26*). The initial virus inoculum was extracted from infected cowpea leaves with 0.1 M potassium phosphate, pH 7.0 (phosphate buffer) 7 days post infection. Typically 50 plants were infected with the plant extract, and the symptomatic leaves were harvested after three weeks. For the lysine and cysteine mutants of CPMV, the respective mutant cDNA clones of RNA 2 in conjunction with pCP1 were used to initiate the infection.

Purification of LRR-internalin B, T4 Lysozyme, and Intron 8. The LRR domain of internalin B (LRR-InlB, *27)* and the Intron 8 proteins (Int 8, *28*) were cloned as plasmids in *E coli* expression vectors (pet 28 and pet 30, respectively, Novagen) and overexpressed in bacterial cells BL21 under the control of T7 promoter. Both proteins have the 6xHIS tag and therefore can be purified readily on Ni-NTA beads using the well-developed metal affinity chromatography (*29*). The cys mutant of T4 lysozyme was purified by ion exchange chromatography on a Mono S column (Amersham Pharmacia Biotech). The proteins were further purified on Superdex 200 (Amersham Pharmacia Biotech) columns by size exclusion chromatography and confirmed by immunoblots using anti HIS antibody (Clontech).

Chemical Conjugation of Heterologous Proteins on the Virus Capsid. Both LRR−InlB and the T4 lysozyme have cys residues that were used as the reactive groups to attach a homo- or a heterobifunctional cross-linker with its reactive maleimide or NHS ester group cross-linked to the unique cysteine or lysine residues on the virus, respectively. There are no unique cysteines present on the Int 8; therefore, thiolation reagent SATA was used to modify the N-terminal amine of the protein to introduce a protected thiol group (*30*). The protected thiol group is treated with hydroxylamine hydrochloride just before addition of the cross-linked virus to deprotect the introduced thiol and used for conjugation.

Briefly, the conjugation reaction was completed in two steps. In the first step, the heterobifunctional cross-linker, 50 μL of 5 mg/mL solution of sulfo SMCC (Pierce) dissolved in DMSO (Pierce), was added to the virus sample (4−5 mg) and stirred gently at room temperature for 1 h. The samples were later purified on a Sephadex G-25 column to get rid of the excess cross-linker and added to the protein samples in 50× excess molar ratios of protein to the virus. The samples were incubated at room temperature for 2 h or overnight at 4 °C. The conjugated samples were finally purified on superose6 column and the virus specific peak was collected and analyzed for the conjugated reaction products by western blots.

Biochemical Analysis of the Conjugated Samples. Typically, the retention time of wt CPMV on Superose6 column (Pharmacia) is 12 min (at flow rate 0.4 mL/min), but the conjugated samples eluted at approximately 8.7 min, indicating that the virus size was larger than the wild type. The virus conjugate peak was collected and analyzed on 4−12% Bis Tris gels (NuPAGE, Invitrogen) and probed with both CPMV and anti HIS antibodies using standard procedures for immunoblotting (*31*).

Bioassays for T4 Lysozyme and Int 8. *T4 Lysozyme.* The rate of lysis of *Micrococcus lysodeikticus* is determined as suggested by Shugar et al. (*32*). The cells were prepared by suspending 9 mg of dried *M. lysodeikticus* (Sigma) cells in 25 mL of 0.1 M potassium phosphate buffer, pH 7.0. A 100 μL aliquot of the virus-T4-conjugated sample (4 mg/mL) was mixed with 1 mL of *M. lysodeikticus* cell suspension. The samples were then analyzed on a UV−vis spectrophotometer to record the decrease in the absorbance of the samples at 450 nm as a function of time.

Intron 8. Monolayer cultures of $\approx 5 \times 10^6$ NIH-3T3 cells stably transfected with HER-2 (17−3−1) or parental

NIH-3T3 cells were plated in 10-cm tissue culture plates and incubated with the virus-Int 8 conjugate or wild-type CMPV in serum-free DMEM for 30 min at 37 °C. The cells were washed two times with phosphate buffered saline (PBS) and extracted in MTG (50 mM Tris·HCl (pH 7.0), 1.0% NP-40, 0.1% deoxycholic acid, 30 mM Na_3VO_4, 1 mM PMSF). Lysates were cleared by centrifugation and quantified using the Bradford Assay (BioRad). Equal amounts (20 μg total protein per lane) were resolved by SDS−PAGE in a 4−12% gradient polyacrylamide gel and transferred onto nitrocellulose. Ponceau stain was used to assess protein transfer and protein amounts in loaded samples. Membranes were blocked in 5% milk and then probed with α-CPMV or α Int 8 antibody, to assess virus-Int 8 binding, or with α-phosphotyrosine (Sigma) to assess receptor activation.

Electron Microscopy and Image Reconstruction of the Conjugates. Bioconjugated samples at a concentration of 1 mg/mL in 100 mM potassium phosphate, pH 7.0 (phosphate buffer), were placed on glow-discharged carbon film and stained for 1 min with 2% uranyl acetate. The grids were observed under a Philips CM120 microscope operated at 100 kV at a magnification of 45 000×. The micrographs were recorded under minimal dose conditions (<20 e/Å^2) on Kodak S0−163 film using a nominal defocus of ∼1.0 μm and scanned to a final resolution of 21 μm on a Zeiss SCAI scanner. The particles were selected manually using the program Boxer, and an initial map at 25 Å resolution of WT-CPMV was used as starting model for the classification procedure. Initial origin and orientation values were determined for 200 particles for LRR−InlB.

Multiple cycles of refinement, computed with the program SPIDER (*33*), yielded final three-dimensional maps at ∼26−28 Å resolution. The atomic models determined by X-ray crystallography were fitted into the electron density maps determined by electron microscopy with the aid of program O (*34*). The programs WEB (*33*) and Bobscript (*35*) were used for final rendering of the images.

RESULTS AND DISCUSSION

Conjugation of Heterologous Proteins on the Virus Capsid. Different conjugation schemes were investigated to cross-link foreign proteins on the virus capsid depending upon the features of the foreign protein being cross-linked.

Bioconjugation of LRR−InlB to CPMV. LRR−InlB, is a 22 kDa, leucine rich repeat (LRR) domain of internalin B protein isolated from the bacterial pathogen *Listeria monocytogenes* (*36*). The rationale for choosing LRR−InlB for attachment to the virus capsid was based upon its ability to induce specific internalization into different mammalian nonphagocytic cell types (*37*−*39*). A CPMV-LRR−InlB conjugate therefore could have potential applications as a drug delivery vehicle if LRR−InlB can confer the cell invasion property to the virus after conjugation. In addition, the crystal structure of LRR−InlB is known (*27*, *38*, *40*) and serves as a control for the structural information derived from the CPMV-LRR−InlB conjugates.

The LRR−InlB domain has a unique cysteine at its C-terminus, and this was conjugated to the Cys mutant of CPMV with the homobifunctional, bismaleimide thiol-reactive cross-linker ($BMPEO_4$). This cross-linker was selected because it has an eight-atom polyether spacer arm (17.8 Å) that separates the two reactive maleimide groups and may therefore have a reduced chance of conjugate precipitation during cross-linking. Also, the reactive cysteine on the virus surface is not fully exposed but resides in a cavity near the 5-fold axis of the virus. A long cross-linker will have a greater probability to reach the somewhat hidden cysteine on the virus capsid and form the thioether linkages.

The conjugation reaction was completed in two steps. First, LRR−InlB was mixed with the cross-linker and the excess cross-linkers and the byproducts were removed on Sephadex G-50 columns. Second, the activated protein was incubated with the virus to effect the final conjugation reaction. The conjugate was subsequently passed through a Superose6 size exclusion column to isolate the decorated virus.

The CPMV-LRR−InlB conjugate was verified in SDS PAGE gels by an increase in the molecular weight of the modified viral subunit. The purified LRR−InlB protein has a 6× His tag at its N-terminus. The large subunit of the viral capsid is 38 kDa but after cross-linking with the LRR−InlB protein (22 kDa), the size of the large subunit increased to 60 kDa (Figure 2A, lane 1) as probed by anti HIS antibodies in a western blot. The same 60 kDa band was also detected in western blots probed with anti CPMV antibody confirming that the increase in the size of the large subunit was due to the conjugation reaction with LRR−InlB (Figure 2A, lane 2). The fact that no protein band corresponding to 38 kDa was detected in blots probed with anti CPMV antibodies indicated that the modification of the large subunit was probably complete (Figure 2A).

The images obtained after 3D reconstruction revealed extra electron density around the capsid that was associated with the attached LRR−InlB molecules (Figure 2B). The docking of atomic structure into the EM map obtained was performed manually using the program O. (*34*). The Inl B protein was located on the virus surface in a manner that its unique cysteine and the viral surface cysteine were facing each other at a distance of ∼20 Å, corresponding with the size of the cross-linker used. In this position the conjugated InlB protein lays flat on the virus surface fitting the density and keeping the correct distance with the virus capsid and symmetry related neighbor proteins (Figure 2C).

The structural information for LRR−InlB derived from the image reconstruction of the conjugate demonstrated that CPMV could be used as a scaffold for structural studies of small proteins by electron microscopy.

Bioconjugation of T4 Lysozyme to CPMV. We chose the bacteriophage T4 lysozyme for attachment to CPMV surface to investigate the effects of chemical coupling on the activity of the conjugated enzyme because it can be readily assayed using UV−vis spectrophotometry. T4 lysozyme (cys mutant) was conjugated to wt CPMV with a heterobifunctional cross-linker, sulfo SMCC. This is a water-soluble cross-linker (11.6 Å in length) with a cyclohexane bridge to provide extra stability to the maleimide reactive group in aqueous solutions. The NHS ester end of the cross-linker was reacted with the primary amines on the wild-type CPMV to form stable amide bonds. There are five surface exposed lysine residues present per asymmetric unit of the virus capsid and in situations that require maximum number of molecules being conjugated for greatest efficacy rather than their icosahedral distribution, the wild-type virus capsid becomes a preferred platform as opposed to the unique lysine mutants of CPMV. Therefore, for T4 lysozyme conjugation, wt CPMV was chosen to permit maximum loading of the lysozyme molecules.

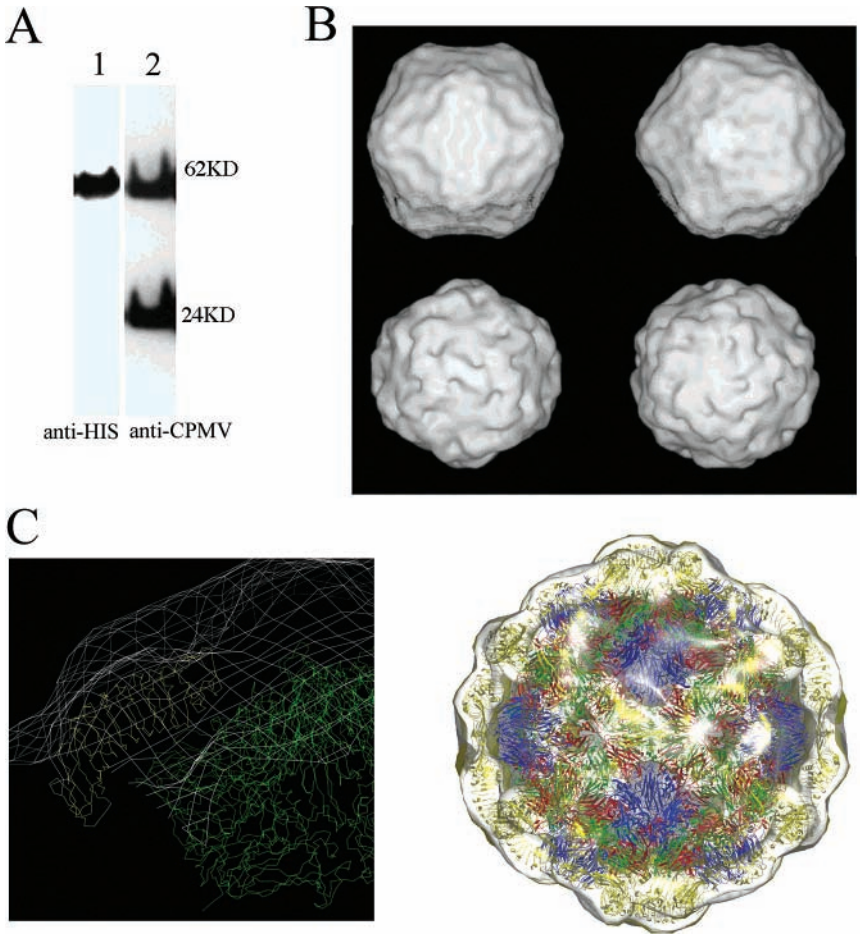

Figure 2. (A) Detection of CPMV-LRR−InlB conjugate by immunoblotting. The CPMV-LRR−InlB conjugate was made using a bis-maleimide reactive homobifunctional cross-linker and purified on a size exclusion column. The virus specific peak eluted from the Superose6 column was probed with anti HIS antibody (Lane 1) as well as anti CPMV antibody (Lane 2). The relative position of the modified large subunit of the virus is indicated by the molecular weight marker. (B) Surface morphology of the wild type, unmodified CPMV (top) and the CPMV-LRR−InlB conjugated particles (bottom) as visualized by electron microscopy and image reconstruction. The particles were stained with 2% uranyl acetate. A total of 200 particles were selected and 3D reconstruction was performed applying icosahedral symmetry using EMAN and SPIDER program packages. (C) Left. The docking of atomic structure of LRR−InlB (gold) and CPMV into the electron density map. The electron density is in chicken wire. The LRR−InlB model is drawn in yellow tracing and the C domain is in green. LRR−InlB lays on the virus surface fitting the density and keeping the correct distance with the virus capsid atoms and symmetry related neighbor proteins. Right. The ribbon diagram of CPMV/LRR−InlB conjugate and the electron density generated from electron microscopy. The electron density is transparent and depicted in pale white; LRR−InlB is shown in yellow. The capsid A domain is represented in blue, B domain is drawn in red, and the C domain is illustrated in green.

The water-soluble cross-linker was dissolved in 100 mM phosphate buffer. Since the NHS ester end of the cross-linker is more easily hydrolyzed in solution, the lysine modification of the virus was done first followed by the maleimide reaction on the lysozyme. The virus specific peak identified with size exclusion chromatography was analyzed by immunoblotting using anti CPMV antibody (Figure 3A). It is evident from the chromatogram that the conjugated virus elutes faster than the native, unconjugated virus, indicating an increase in the molecular weight of the modified virus. Immunoblotting of the conjugated virus specific peak revealed an increase in the molecular weight of capsid subunits, suggesting that both the large and the small subunits of the virus capsid were modified since the surface lysine residues are present on both subunit types (Figure 3B, lane 1, *32*). The products of cross-linking reaction prior to purification on the size exclusion column (Figure 3A) are shown in the adjacent lane (Figure 3B, lane 2). The functionality of the conjugated T4 enzyme was determined with turbidity assays. The reduction in the turbidity of the cell suspension was used as a measure of the enzymatic activity. About 6×10^6 cells of *M. lysodeikticus* were incubated with the 100 μg of T4-virus conjugate and the decrease in the absorbance at 450 nm was measured over a period of time. As depicted in the Figure 3C, the T4-CPMV conjugate efficiently lysed the bacterial cells over a period of 4 min whereas the wild-type unconjugated CPMV did not affect the turbidity of the cell suspension at all. On the basis of the coupling efficiency, the slope of the curve, and the concentration of the virus in solution (*32*) it was calculated that 0.8 mg of lysozyme was conjugated per 100 μg of virus. The activity of the conjugated lysozyme was estimated to be 22 000 units/mg that is comparable to 27 000 units/mg of the unattached enzyme. These results demonstrated that the chemical cross-linking procedure did not affect the biological activity of the conjugated enzyme adversely.

Bioconjugation of Int8 to CPMV. The above examples of protein conjugation rely on the availability of reactive functional groups (either a lysine or a cysteine) being present on the attached proteins. However, even in the absence of either of the two most nucleophilic groups on the heterologous protein, the viral scaffold can still be used for presentation of the foreign proteins by modifying the cross-linking schemes for conjugation. We accom-

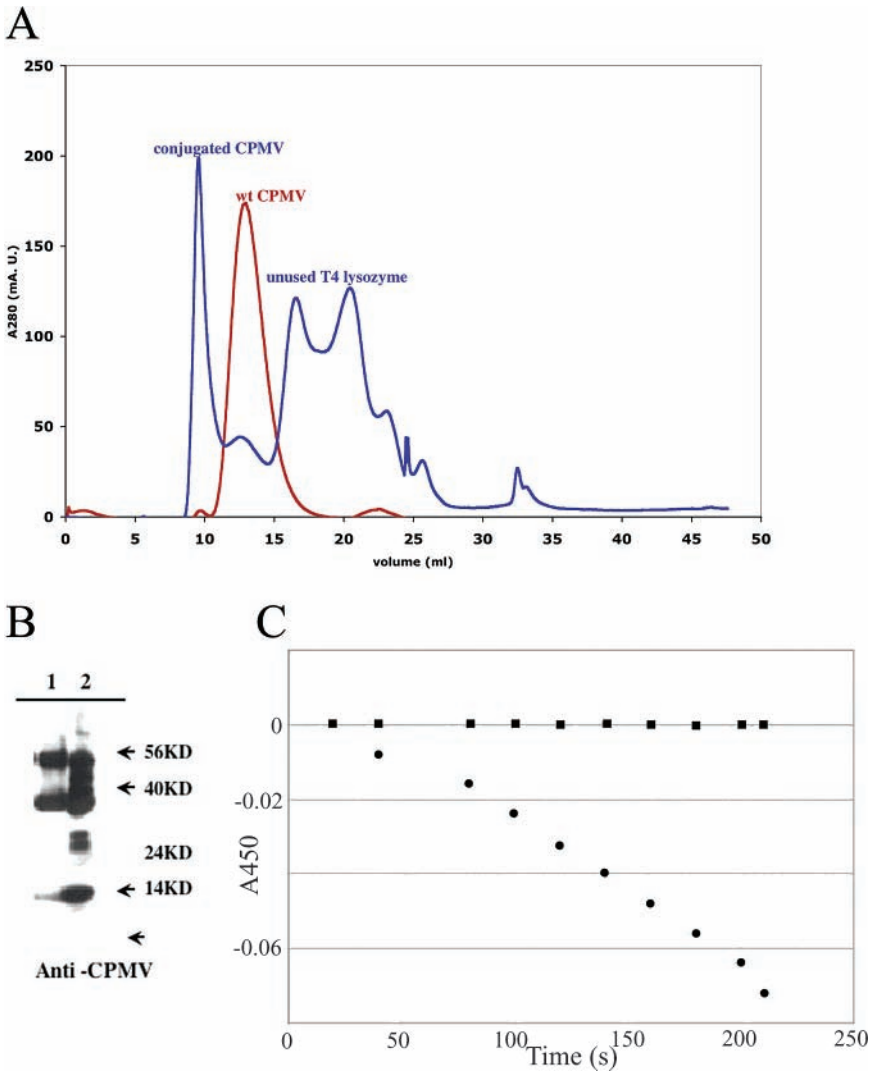

Figure 3. (A) Size exclusion chromatography profile of conjugation reaction products as resolved on a superose 6 column (blue trace). Besides the main virus peak that elutes at 8.7 mL, there are other smaller protein species that might represent either the dimerized T4 or the excess, unconjugated T4 lysozyme. The red trace indicates the retention time of the native, unconjugated virus on the same column. (B) Western blot analysis of CPMV-T4 lysozyme conjugate as probed with anti CPMV antibody. The T4 lysozyme was conjugated on wild-type CPMV using a heterobifunctional cross-linker, SMCC. The success of the conjugation reaction is supported by an increase in the molecular weight of both the small (~40 kDa) and the large (~56 kDa) subunits of the virus coat protein (Lane1). Lane 2 shows the cross-linked reaction products prior to virus conjugate purification on the Superose6 column. (C) Biological activity of conjugated T4 lysozyme−CPMV complex. The enzyme activity was assessed by the ability of the conjugated CPMV sample (circular dots) to hydrolyze a suspension of *M. lysodeikticus* cells. Unconjugated wt CPMV (shown in squares) was used as a control. The change in turbidity of cell suspension was recorded by a decrease in the absorbance at 450 nm over time. At the beginning of the experiment, the samples were blanked to 0 against the cell suspension at 450 nm.

plished this by coupling the intron 8-encoded domain (Int 8) of Herstatin on the virus surface using thiolation reagents.

Herstatin, an auto inhibitor of the ErbB family of receptor tyrosine kinases, is a product of an alternate splicing event from the Her2/neu gene. Her-2 intron 8 is retained and a translational read through results in a truncated protein consisting of subdomains I and II of the HER 2 receptor followed by a 79 amino acid C-terminal extension encoded by intron 8 (Int 8, *41*). Herstatin blocks receptor activation and modulates intracellular signaling through these receptors (*41*−*43*). The Int 8 is a receptor-binding module that binds with nanomolar affinity to epidermal growth factor receptor (EGFR) and HER-2 receptors (*41* and Shamieh et al., manuscript in preparation). The Int 8 was considered a candidate with therapeutic potential for conjugation to CPMV capsid, because of its role in binding to carcinoma cells that overexpress and are driven by HER-2 or the EGFR.

The attachment of functional Int 8 to CPMV was not straightforward because it does not have any lysine or cysteine residues in its sequence. In addition, the protein is soluble and stable only above pH 8 and forms oligomers at moderate concentrations. A strategy was developed to modify the protein with a thiolation reagent before conjugation with a heterobifunctional cross-linker. The active NHS ester end of SATA (N-succinimidyl S-acetylthioacetate) was reacted with the N-terminal amine in Int 8 at pH 8.0 to form a stable amide linkage (Figure 4A, top, i). The modified Int 8 now contained a protected thiol that could be stored without degradation and precluded oligomerization of the heterologous protein. The sulfhydral-modified Int 8 was coupled with maleimide-activated CPMV (unique lysine mutant, vK299) after deacetylation with an excess of hydroxylamine HCl (Figure 4A, top,

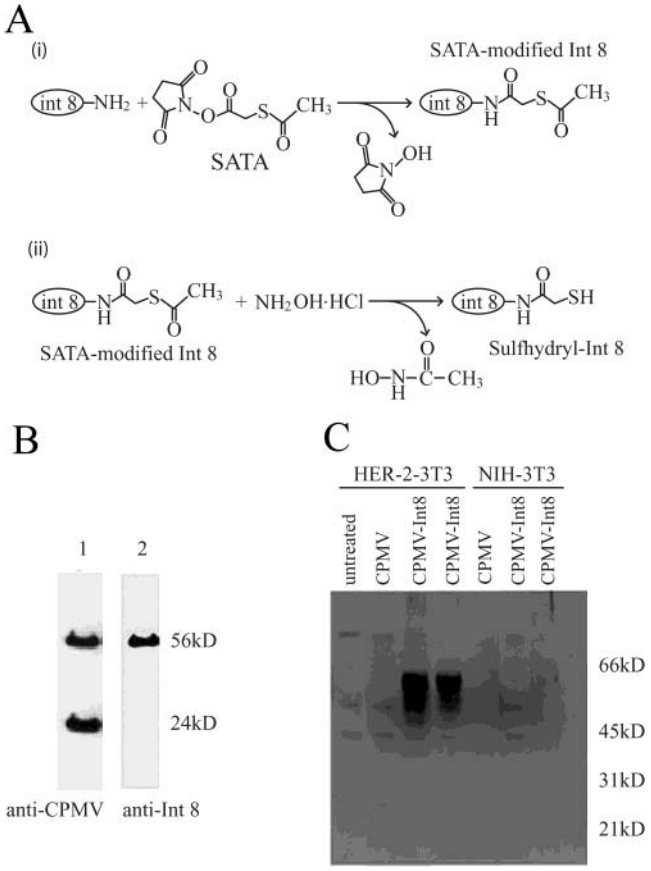

Figure 4. (A) Top: Reaction scheme for generating a thiol group on the Int 8 using the thiolation reagent SATA. (i) The active NHS ester end of SATA reacts with the N-terminal amine of Int 8 to form a protected sulfhydryl derivative and (ii) deprotection with hydroxylamine of the acetylated thiol of SATA modified Int8 yields a free sulfhydryl group that can be used for conjugation to CPMV using SMCC. (B) Detection of Int 8-CPMV conjugate by Western blotting. The Int 8 peptide was cross-linked to the virus capsid via unique lysine residue present on the large subunit using a heterobifunctional cross-linker. Virus specific peak was eluted from the Superose6 column and verified with anti CPMV (Lane 1) and anti Int 8 (Lane 2) antibodies. The retarded band at 56 kDa indicates the increase in the molecular weight of the viral large subunit as a result of conjugation. The specificity of the reaction was judged by the absence of any modification of the small subunit with Int 8. (C) Specific binding of the CPMV−Int8 conjugate to NIH-3T3 cells stably transfected with HER 2. A slow migrating band at approximately 56 kDa was observed with anti CPMV antibodies only in conjugated samples (Lanes 3 and 4). The wild-type CPMV (Lanes 2 and 5) did not show any binding to HER-2 transfected or parental 3T3 cells indicating that the intron 8-encoded domain is needed to direct binding to the HER-2 receptor. The untreated cells were used as a negative control (Lane 1). The specificity of binding was also confirmed by assessing the ability of the conjugate to bind to parental NIH 3T3 (Lanes 5−7).

ii). The reaction was mixed gently and left at 4 °C to allow a slow but specific reaction. Western blots analysis of Int 8-modified CPMV samples revealed that the viral large subunit was modified with the heterologous protein, and the increase in size of the large subunit was consistent with the corresponding size of Int 8 attached to the virus capsid (Figure 4B).

The CPMV−Int 8 conjugate was tested in vitro for specific binding to NIH-3T3 cells expressing the HER2 gene. As shown in the blots (Figure 4C), the CPMV−Int 8 conjugate was found to specifically associate with NIH-3T3 cells stably transfected with HER-2 but not with parental cells. Also, the wild type CPMV did not show binding to either of the two cell types tested, indicating that the bound Int 8 was biologically active and responsible for specific binding to the receptor overexpressing cells. The fact that the heterologous proteins displayed on the virus capsid retain their biological properties and function after conjugation suggests that cross-linking to the virus capsid may be a potential strategy to target and deliver drug molecules into the cell.

CONCLUSIONS

We have extended the chimera technology for surface display of full length, biologically active heterologous proteins by chemical cross-linking methods using CPMV as a platform. In addition, it is demonstrated that the icosahedral presentation of the foreign proteins allows CPMV to be used as a scaffold for imaging and structure determination of proteins that are too small to be analyzed by electron microscopy. It is reasonable to expect that there might be a limitation with respect to the size of the heterologous protein being conjugated to the capsid. Thus far, the largest protein that has been coupled to the virus surface with complete occupancy is the 22 kDa LRR domain of LRR−InlB. However, with larger proteins such as the 45 kDa CD48 molecule we only observed 60% modification of the virus capsid (data not shown), suggesting that additional coupling schemes or alternate cross-linkers may have to be explored to present larger proteins on the virus surface. The recently reported grafting techniques using synthetic scaffolds (*44*, *45*) also suffer from size constraints (<19 amino acid), and in this respect CPMV has surpassed the size barrier to tolerate modification of the viral capsid with much larger heterologous proteins. Finally, since the cross-linking approach reported here preserves the biological activity of the heterologous protein as well as its structure, it opens up prospects to simultaneously present ligands involved in cellular uptake, trafficking or delivery on the virus surface for generating nano delivery capsules with biomedical applications.

ACKNOWLEDGMENT

A.C. thanks Erica Strable for helpful discussions. The authors wish to acknowledge the support from NIH (R01EBB00432 02 to J.E.J., the Office of Naval Research grants # N00014-00-1-0671 to J.E.J., and N00173-01-C2012 to T.L.) G.C. would like to acknowledge funding from NIH (NIHCA83503).

Carboplatin is a low-molecular-weight anticancer drug that acts by binding to the nuclear DNA of cells. Thus, efficient delivery of the platinum drugs to the nucleus of the cancer cells may enhance the cytotoxicity of the drug. Efficient drug delivery to the nucleus of cancer cells requires three levels of localization: targeting to the cancerous tissue, accumulation in the cancer cells, and intracellular localization in the nucleus. Nuclear localization signals (NLS) are short positively charged basic peptides that actively transport large proteins across the nuclear membrane. We have prepared conjugates in which the NLS is tethered to poly(ethyleneglycol)carboplatin conjugate (NLS−PEG−Pt) and compared their pharmacological properties to those of their untargeted analogues that do not possess the NLS (PEG−Pt). NLS−PEG−Pt conjugates are rapidly internalized into cancer cells and accumulate in the nucleus. Despite their rapid nuclear localization, they form less Pt−DNA adducts than the untargeted analogues, PEG−Pt, and are also less cytotoxic. These results support the hypothesis that carboplatin (unlike cisplatin) may require cytosolic activation prior to its binding to nuclear DNA.

INTRODUCTION

Cisplatin, carboplatin, and oxaliplatin (See Figure 1) are three FDA approved anticancer agents that are believed to owe their anticancer activity to their ability to covalently modify cellular DNA (*1*, *2*). Cisplatin and carboplatin form the identical major adducts with DNA where the *cis*-$[Pt(NH_3)_2]^{2+}$ moiety is covalently coordinated to the N7 atoms of two adjacent guanines on the same strand forming the 1,2-d(G*pG*) intrastrand cross-link (*3*). The 1,2 intrastrand cross-links bend the DNA toward the major groove, resulting in a local distortion of the double helix, and it is this distortion that is believed to trigger a series of cellular events that results in the eventual death of the cancer cell (*4*). The most common dose limiting effects for platinum based drugs are nephrotoxicity, ototoxicity, neurotoxicity, and myelosuppression. In addition, cancer cells are either inherently refractory to the platinum drugs or can acquire resistance to the drugs. There are several known resistance mechanisms to cisplatin: reduced cellular accumulation, increased production of intracellular platinophiles such as glutathione and metalothionein, enhanced DNA repair and increased tolerance to DNA platination, and decreased cellular apoptotic response (*5*−*7*). The first two mechanisms of resistance attempt to prevent the drug from reaching the nuclear DNA, its critical binding site. Higher levels of Pt−DNA adducts are expected to result in improved cytotoxicity. Thus, rapid and efficient delivery of the platinum drugs to the nucleus of the cancer cells may overcome some of the resistance pathways and could enhance the cytotoxicity of the drugs.

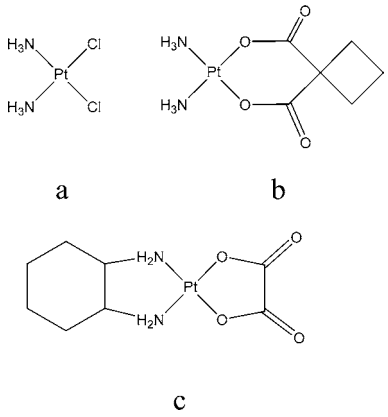

Figure 1. Platinum-based anticancer drugs: (a) cisplatin, (b) carboplatin, and (c) oxaliplatin.

Efficient drug delivery to the nucleus of cancer cells requires three levels of localization: targeting to the cancerous tissue, accumulation in the cancer cells, and intracellular localization in the nucleus (*8*, *9*). We recently described the preparation and pharmacological properties of a conjugate comprised of a poly(ethylene glycol) (PEG)[1] carrier to which folic acid (FA) was attached on one end (to exploit the folic acid receptor mediated endocytotic

pathway) and a carboplatin analogue to the other end (FA−PEG−Pt) (*10*). PEG was chosen as the carrier because attaching a low molecular-weight drug to a hydrophilic polymer such as PEG results in high aqueous solubility, slower clearance, reduced systemic toxicity, and efficient accumulation in tumors through enhanced permeability and retention (EPR) (*11*). PEG is a water soluble amphiphilic polymer showing excellent biocompatibility and is frequently used in biomedical applications. Several drugs such as doxorubicin, camptothecin and paclitaxel, have been conjugated to PEG carriers and these conjugates are in various stages of clinical trials (*12*). Folic acid has been used extensively to internalize covalently tethered cargos into cancer cells, via the FRME, since many cancer cell lines overexpress folic acid receptors (*13*, *14*).

When the cell uptake, cellular DNA binding and cytotoxicity of FA−PEG−Pt were compared to those of the PEG−Pt conjugate (without the FA), it was found that FA−PEG−Pt conjugates were taken into the cytosols of the cancer cells significantly more rapidly than the PEG−Pt conjugates. Yet incubation with the PEG−Pt conjugates afforded twice as many platinum cellular DNA adducts as did FA−PEG−Pt. This is not necessarily surprising since it has been reported that most endocytosed compounds end up in the lysosome or in some compartment that is separated from the cytosol by a membrane, preventing them from reaching their critical biological targets (*15*). Thus, there is a need to explore a nonendocytotic pathway for the efficient delivery of platinum complexes to the nuclei of cancer cells.

The research following discovery that the HIV-1 Tat protein can cross cellular membranes, established that positively charged peptides such as Tat(49−57) and Antp-(43−58) have membrane translocating properties that can be exploited for the delivery of oligonucleotides, proteins, imaging agents liposomes, etc. (*16*, *17*). While the exact mechanism by which the basic peptides enter the cells remains to be elucidated, it seems that they do not enter the cells by endocytosis and it is the amphipathicity of the peptides that is responsible for the cellular translocation. Nuclear localization signals (NLS) are short positively charged basic peptides that actively transport large proteins across the nuclear membrane. They have been used to localize cargo molecules (to which they have been conjugated) from the cytosol to the cell nucleus (*18*).

The cellular delivery and particularly intracellular localization of therapeutics are two of the foremost challenges facing the medicinal chemists. In this manuscript we report the design, synthesis, and preliminary pharmacological properties of novel PEG−NLS conjugates as carriers for carboplatin analogues.

EXPERIMENTAL PROCEDURES

Materials. All reagents were purchased from Sigma-Aldrich Israel, Ltd., at least reagent-grade and were used without purification. Solvents for synthesis and for HPLC were synthesis and HPLC-grade accordingly.

Compound Preparation. *NH_2-GABA-Cys-Gly-Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Gly-Gly-CO−Resin (**1**).* GABA−FMOC. A 1 g (9.7 mmol) sample of γ-aminobutyric acid (GABA) was dissolved in 10% $NaHCO_3$. A 1.5 g (5.8 mmol) sample of FMOC−Cl was dissolved in 30 mL of acetonitrile and was added dropwise over 2 h to the GABA solution. The reaction mixture was allowed to stand for 1 additional hour, and then the acetonitrile was evaporated and the solution was acidified to pH 1 with HCl. The white precipitate was filtered, washed with two portions of water and one portion of ethyl acetate, and desiccated over P_2O_5 (yield 80%).

NH_2-Cys-Gly-Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Gly-Gly-CO−Resin. The peptide NH_2-Cys-Gly-Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Gly-Gly-COOH was synthesized by the solid-phase FMOC method on a Rink amide resin with the carboxy terminus still attached to the resin and the amino acid side chains protected as follows: Lys (ϵ-N-BOC), Arg(Pmc), and Cys(S-Trt).

NH_2-GABA-Cys-Gly-Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Gly-Gly-CO−Resin. A 50 mg (0.017 mmol) sample of the peptide on the resin was put in a Merrifield vessel, and 14 mg (0.043 mmol) of GABA−FMOC, 2 mL of NMP, 19 mg (0.043 mmol) of BOP-reagent and 50 μL of DIEA were added. The reaction was agitated overnight at room temperature, after which the reaction mixture was filtered and a sample from the resin was used for a Kaiser test (for primary amines). If the test was positive, the reaction was repeated until the test came negative, indicating complete coupling. The resin was washed with 2 mL portions of DMF, and then 2 mL of a 20% piperidine in DMF was added and the deprotection was allowed to proceed for 2 h at room temperature with constant shaking and subsequently the resin was washed with four 2 mL portions of DMF.

*FITC-NH-GABA-Cys-Gly-Gly-Pro-Lys-Lys-Lys-Arg-Lys-Val-Gly-Gly-CO−Resin (**2**).* A 10 mg (0.043 mmol) sample of FITC, 2 mL of DMF, and 50 μL of TEA were shaken overnight with the resin at room temperature, the resin was filtered, and a small portion of the resin was tested for free amines using the Kaiser test. After a negative Kaiser test was obtained the resin was washed with four 2 mL portions of DMF.

*HO-NLS−Cys−GABA−FITC (**3**).* A 150 mg sample of phenol, 0.05 mL of thioanisole, 0.05 mL of water, and 0.025 mL of dithioethane in 2 mL of TFA were added to the resin, and the reaction was left for 3 h at room temperature with constant shaking. The reaction mixture was filtered, 20 mL of diethyl ether was added, and the orange precipitate that was formed was isolated by centrifugation. The precipitate was washed with three 20 mL portions of diethyl ether and then dissolved in 2 mL of water and lyophilized to yield an orange powder (yield 60%). RP18 HPLC: Rt = 10.2 min. Mass spectra (ESIMS): four peaks corresponding to four charge states of the compound were observed at *m*/*z* values of 423.4, 564.1, 845.3 and 1688.4, indicating a molecular mass of 1687.4 (calcd 1687.2)

*H_2N-PEG-NH_2 (**4**).* The compound was prepared as described by us recently (*10*).

*Cbz−PEG-NH_2 (**5**).* A 500 mg sample of Na_2CO_3 and 3 g of H_2N-PEG-NH_2 (1 mmol) were dissolved in 150 mL of water, and 50 mL of acetonitrile was then added. A 170 mg (1 mmol) sample of benzyl chloroformate was dissolved in 50 mL of acetonitrile and was added very slowly at room temperature over approximately 3 h to the reaction mixture. After the addition of the benzyl

[1] Abbreviations: CBDCA, cyclobutane-1,1-dicarboxylate; PEG,-poly-(ethylene glycol); FA, folic acid; FRME, folate receptor-mediated endocytosis; FMOC, fluorenylmethyl chloroformate; Cbz-Cl, benzyl chloroformate; FITC, fluorescein isothiocyanate; DCC, dicyclohexylcarbodiimide; DCU, dicyclohexylurea; ECI, 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride; DIEA diisopropylethyl-amine; AA, atomic absorption; CPG, carboxypepidase G; MALDI-TOFMS, matrix-assisted laser desorption ionization time-of-flight mass spectrometry; HiFr, high folate receptor; Icp-Ms, inductively coupled plasma mass spectrometry; FACS, fluorescence-assisted cell sorting; MB, methylene blue; PEG3000,-$(CH_2CH_2O)_{68}$-; NHS, N-hydroxysuccinimide.

chloroformate was completed, the acetonitrile was removed under reduced pressure, and the remaining aqueous solution was extracted with two 100 mL portions of dichloromethane. The organic fractions were combined, dried over $MgSO_4$, and crystallized from 100 mL of diethyl ether. The crude product contained some starting material (H_2N-PEG-NH_2), the desired product (Cbz−PEG-NH_2), and some Cbz−PEG−Cbz. The desired monocationic momoprotected PEG was purified by cation exchange chromatography on a Sephadex CM-50 resin with UV detection at 254 nm. The reaction mixture was dissolved in a minimal amount of water (5 mL) and loaded on the column, and the neutral Cbz−PEG−Cbz was removed from the column with deionized water. The desired product was eluted with 25 mM NaCl and showed a UV absorption at 254 nm and also gave a positive test for a primary amine with fluorescamine. The product was lyophilized and dissolved in 100 mL of dichloromethane, the NaCl was filtered off, the solvent was removed, and the product was crytalized from 50 mL of diethyl ether. The yield was 30%. RP18-HPLC: one peak Rt = 16.2 min. ^{1}H NMR (DMSO-d_6) δ(ppm):

7.32(m, 5H, −CH−(ph)), 7.23(t, 1H, Cbz-*NH*−), (bs, ∼280H, −PEG_{3000}−), 3.14(q, 2H, Cbz-NH-CH_2−, 2.95(t, 2H, −CH_2-NH_2).

*FA−PEG-NH_2 (**6**).* The synthesis of FA−PEG−FMOC was described in ref *10*. FA−PEG−FMOC was used as the starting material for the preparation of FA-PEG-NH_2. The FMOC protecting group was removed from FA-PEG-FMOC by piperidine treatment. FA−PEG−FMOC (400 mg) was dissolved in 50 mL of 25% aqueous piperidine. The white precipitate was removed by filtration, the solvents were evaporated to remove all traces of piperidine, and the product was dissolved in water and evaporated again. The process was repeated twice. RP18-HPLC: Rt = 14.34 min. ^{1}H NMR (D_2O) δ(ppm): 8.62(s, 1H, *folate-C(8)H*), 7.65(d, 2H, *folate*(*PABA*)H_2), 6.81(d, 2H, *folate*(*PABA*)H_2), 4.51(s, 2H, *folate*(NH-CH_2)), 3.6(bs, ∼280H, −PEG_{3000}−), 3.14(m, 2H, folate-NH−CH_2), 2.95-(t, 2H, -CH_2−NH_2), 2.21−1.95(bm, 4H, *folate*(*Glu*)β,γ-CH_2) 4.22(m, 1H, *folate*(*Glu*)α-*CH*).

*FA−PEG−Maleimide (**7**).* 300 mg (0.095 mmol) of FA−PEG-NH_2 was dissolved in a 5 mL of a saturated solution of $NaHCO_3$, and the solution was cooled in an ice bath. An 80 mg (0.52 mmol) sample of N-methoxycarbonylmaleimide was added with stirring, and the reaction mixture was left in the ice bath for 15 min and was stirred for an additional 30 min at room temperature. The product was isolated on a Sephadex 25 column and immediately lyophilized to yield a white powder. Yield, 90%. RP18-HPLC: Rt = 16.51min. ^{1}H NMR (D_2O) δ(ppm): 8.62(s, 1H, *folate-C(8)H*), 7.65(d, 2H, *folate*-(*PABA*)H_2), 7.01(2H, −*CH*=*CH*−), 6.81(d, 2H, *folate*-(*PABA*)H_2), 4.51(s, 2H, *folate*(NH-CH_2)), 4.22(m, 1H, *folate*(*Glu*)α-*CH*) 3.6(bs, ∼280H, −PEG_{3000}−), 3.14(m, 4H, maleimide-NH-CH_2-/folate-NH-CH_2), 2.21−1.95(bm, 4H, *folate*(*Glu*)β,γ-CH_2).

*NLS−FITC−PEG−FA (**8**).* A 100 mg sample of FA−PEG−maleimide (**7**) was dissolved in a 50 mM phosphate buffer (pH 5.8), and to the reaction mixture was added 70 mg of HO-NLS−Cys−GABA−FITC (**3**) (0.041 mmol) and the reaction mixture was stirred at room temperature for 45 min. The product was isolated by semipreparative RP-HPLC and was lyophylized. The yield was 50%. A 10 mg sample of (8) was dissolved in 10 mL of PBS buffer, and the concentrations of the fluorescein (ϵ_{490} = 67 000) and folate (ϵ_{363} = 6197) were determined. The ratio between the fluorescein and the folate was 1.0: 0.95, attesting to the purity of the product. RP18 HPLC: Rt = 14.17 min. MALDI-TOF-MS showed a bell distribution with the center around 5412 amu).

*Cbz−PEG−Maleimide (**9**).* A 300 mg (0.095 mmol) sample of Cbz−PEG-NH_2 was dissolved in a 5 mL saturated solution of $NaHCO_3$, and the solution was cooled in an ice bath. An 80 mg (0.52 mmol) sample of *N*-methoxycarbonylmaleimide was added with stirring, and the reaction mixture was left in the ice bath for 15 min and was stirred for an additional 30 min at room temperature. The product was isolated on a Sephadex 25 column and immediately lyophilized to yield a white powder. Yield, 90%. RP18 Rt = 17.15 min.

*NLS−PEG−FITC (**10**).* A 100 mg (0.031 mmol) sample of Cbz−PEG−maleimide was dissolved in a 50 mM phosphate buffer (pH 5.8), 70 mg (0.041 mmol) of NLS−Cys−GABA−FITC was added, and the reaction mixture was stirred for 45 min. The product was purified and isolated by semipreparative RP-HPLC and lyophilized to yield an orange powder. Yield, 60%. RP18 HPLC Rt = 15.11 min. MALDI-TOF-MS a bell distribution centered around 5200 amu (Calc. 5203 amu).

*Di-tert-butyl 2-(3-succininylaminopropyl)malonate (**11**).* The synthesis and characterization of compound **11** were detailed in ref *10*.

^{1}H NMR (DMSO-d_6) δ(ppm): 7.84(bt, 1H, C(O)-*NH*−), 3.16(t, 1H, α-*CH*−), 2.99(q, 2H, NH-CH_2−), 2.38(t, 2H, *succ.*-CH_2−), 2.29(t, 2H, *succ.*-CH_2−), 1.61(m, 2H, −CH_2-CH−), 1.41(bs, 20H, −CH_2-CH_2-CH_2-/*t-Bu*).

*Cbz−PEG−Mal−(tBu) (**12**).* The synthesis and characterization of compound **12** were detailed in ref 10.

*Maleimide−PEG−Malonic Acid, Disodium Salt (**13**).* Initially the Cbz protective group of compound **12** was removed by hydrogenation, and then the primary amine was converted to the maleimide in the same way as was done for the preparation of compound **7**. The hydrolysis of the *tert*-butyl protecting groups was performed by dissolving 500 mg of maleimide−PEG−Mal-tBu in 30 mL of 25% TFA in CH_2Cl_2; after 2 h of stirring the solvent was removed, and the product was taken up in 3 mL of 50 mM Na_2CO_3. The product was purified on a Sephadex 25 column and lyophilized yielding a white solid (yield 90%).

^{1}H NMR (D_2O) δ(ppm): 6.88(s, 2H, −*CH*=*CH*-), 3.6-(bs, ∼280H, −PEG_{3000}−), 3.36(t, 4H, PEG-CH_2-N), 3.14-(t, 2H, −NH-CH_2−), 2.92(t, 2H, α-*CH*−), 2.48(m, 4H, *succ.*-CH_2−), 1.60(m, 2H, −CH_2-CH−), 1.37(m, 2H, −CH_2-CH_2-CH_2−).

cis-Diamminediaquaplatinum(II) (**14**). The *cis*-[Pt-$(NH_3)_2(D_2O)]^{2+}$ was obtained by reacting *cis*-Pt$(NH_3)_2Cl_2$ with 1.95 equiv of $AgNO_3$ in D_2O as previously described (*10*). ^{195}Pt NMR (D_2O) δ(ppm): −1580 maleimide−PEG-Pt (**15**).

The platination, purification, and characterization of the Pt conjugate were performed by reacting a slight excess of compound 13 with compound 15, as previously described (*10*). RP18 HPLC: Rt = 16.3 min

^{1}H NMR (D_2O) δ(ppm): 6.88(s, 2H, −*CH*=*CH*−), 3.6-(bs, ∼280H, −PEG_{3000}−), 3.36(t, 4H, PEG-CH_2-NH−), 3.14(t, 2H, −NH-CH_2−), 3.08(t, 2H, α-*CH*−), 2.48(m, 4H, *succ.*-CH_2−), 2.21(m, 2H, −CH_2-CH−), 1.49 (m, 2H, −CH_2-CH_2-CH_2−). ^{195}Pt NMR (D_2O) δ(ppm): −1703.

*NLS−PEG−Pt (**16**).* Compound **15** was coupled to the commercially prepared NLS peptide (including the terminal Cys) using the procedure described for the preparation of compound **8**. The reaction was monitored by RP-HPLC Rt(product) = 14.8 min and Rt(reactant) = 16.3 min. The reaction was over in 45 min, and the product was purified by semipreparative HPLC with a yield of 50%.

RP18 HPLC: Rt = 14.8 min.

^{195}Pt NMR (D_2O) δ(ppm): −1701.

FITC−PEG−Pt(17/18). Compounds **18** and **19** were prepared using the methodologies described above.

^{195}Pt NMR (D_2O) δ(ppm): −1689(31), −1692(32).

*FITC−Pt (**19**).* Di-*tert*-butyl 2-(3-Aminopropyl)malonate was prepared as described (*10*). A 100 mg (0.37 mmol) sample of this compound was dissolved in 30 mL of pyridine and 100 mg (0.26 mmol) of FITC, and 50 μL of TEA was added with stirring. The reaction was left overnight, and subsequently the solvent was removed under reduced pressure. The residue was taken up by 50 mL of CH_2Cl_2, and the excess amine was removed by washing with two portions of 50 mL solutions of 10% acetic acid. After evaporation an orange solid is obtained. Yield 80%. Mass Spectrum, (LC ESIMS): single peak at 553.2 (calculated 552.7). The deprotection of the malonate and platination was performed as described above, and the product precipitated as an orange solid and was filtered and washed with ethanol and ether. Yield 90%. ^{195}Pt NMR (D_2O) δ(ppm): −1708 ppm.

NMR Spectroscopy. NMR data were collected on a Varian Unity Inova 500 MHz spectrometer equipped with a 5 mm switchable probe for ^{1}H, ^{13}C, ^{195}Pt NMR, and 500 MHz ^{1}H{^{13}C/X} 5 mm PFG tunable triple inverse detection probe for 2D-[^{1}H,^{15}N] HSQC.

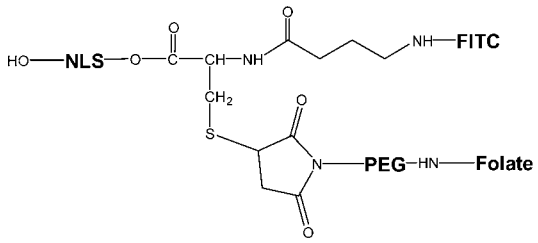
^{195}Pt NMR. The platinum chemical shifts were measured relative to the external reference signal of K_2PtCl_4, set at −1624 ppm. A line-broadening (lb) of 300 Hz was normally applied, and data were processed using the VNMR software.

Inductively Coupled Plasma Mass Spectrometry (Icp-Ms). Icp-Ms measurements were performed on a Elan-DRC II, Perkin-Elmer Sciex spectrometer. The platinum concentration was calculated according to a known concentration of a K_2PtCl_4 standard solution (10 ng/mL Pt).

Cell Culture and Biological Studies. Medium. Cells were cultured in FA-free RPMI medium (RPMI-1640, Biological Industries, Beyt Haemek, Israel), with 10% fetal bovine serum (GIBCO, Grand Island, NY), 2 mM glutamine, 50 units/mL penicillin, and 50 μg/mL streptomycin. The concentration of FA in serum-containing FA-free medium is only 3 nM, as opposed to 2.26 μM (1 mg/L) under normal culture conditions. Cells were routinely passaged by treatment with a trypsin (0.05%)/EDTA (0.02%) solution in calcium- and magnesium-free phosphate-buffered saline (PBS).

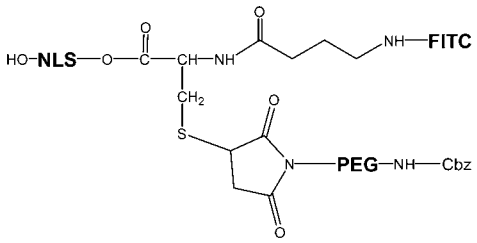
Cell Lines. M109 is a murine lung carcinoma line of BALB/c mice (*19*). By culturing these cells in FA-free medium for several passages, we obtained a subline expressing a high amount of FA receptors, named M109 HiFR or M109FR, to emphasize the overexpression of folic acid receptors (*20*).

Fluorescent Microscopy Studies. Cells were grown on eight-well glass slides (Nunk). Forty-eight hours prior to the experiment, 0.2×10^5 cells were seeded per each well of the slide. The cells were washed with FA, serum-free RPMI medium and incubated for 4 h at 37 °C with 0.2 mL of a 0.5 μM solution of fluorescein-labeled PEG's in FA, serum-free RPMI medium. Free folate competition experiments were conducted under the same conditions, except that incubation solutions contained, in addition to fluorescein-labeled PEG, free folic acid at a concentration of 1 mM. After incubation, cells were washed three times with 0.5 mL of RPMI medium and fixed with 3% formaldehyde in PBS. The fluorescent images were obtained with an LSM410 invert Laser Scan Confocal Microscope, at the wavelength $\ddot{I}$) 488 nm.



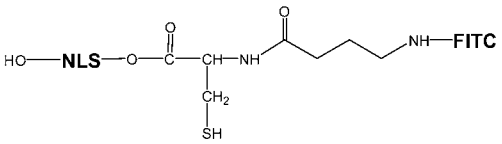
Cell Growth Inhibition Studies. The cytotoxic effect of free carboplatin and two PEG−Pt conjugates (FA−PEG−Pt and PEG−Pt) was assayed colorimetrically by the MB staining method described previously (*10*). In our assays, M109HiFR cells in 200 μL aliquots were plated onto 96-well flat-bottom microtiter plates. Following 20 h in culture, 20 μL of the tested drug was added to each well. For each 10-fold increase in drug concentration, five drug concentration points were tested. Each test was performed in triplicate wells and in two parallel plates. The cells were treated continuously for 72 h. The drug concentration which caused a 50% inhibition of the control growth rate (IC_{50}) was calculated by interpolation of the two closest values of the growth inhibition curve.

Cell Lines and Culture Conditions for the Cytotoxicity Measurement with the Human Ovarian Cancer Cell Lines. Cultures of pairs of cisplatin sensitive and resistant ovarian cancer cell lines (A2780/A2780cisR, 41M/41McisR, and CH1/CH1cisR) have been described elsewhere (*21*). These pairs of cell lines were selected on the basis of encompassing all of the known major mechanisms of resistance to cisplatin: 41McisR being resistant primarily through reduced drug transport (*22*), CH1cisR through enhanced DNA repair/tolerance (*23*), and A2780cisR through a combination of decreased uptake, enhanced DNA repair/tolerance, and elevated GSH levels (*24*).

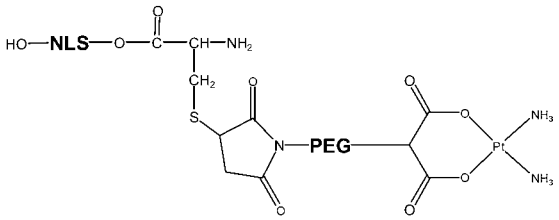


Cell survival in compound-treated cultures was evaluated by the MTT method as previously reported (*25*). Platinum compounds were added to 96 microwell plates containing the cell cultures at final concentrations between 0 and 200 μM. After 24 h, cell survival was evaluated by measuring the absorbance at 520 nm, using a Whittaker microplate reader 2001. IC_{50} values (compound concentration that produces 50% of cell killing) were calculated from curves constructed by plotting cell survival (%) versus compound concentration (μM). Experiments were carried out in quadruplicate.

Pt Accumulation Studies with Continuous Incubation. The cellular accumulation of the Pt compounds was assayed through measurement of the level of cell-associated Pt. Forty-eight hours prior to an assay, 2×10^6 cells were seeded per 60 mm dish, to obtain 5×10^6 cells/plate. At the day of the assay, plates were washed twice with RPMI medium and incubated for 4 h at 37 °C with 2 mL of FA-free RPMI medium, containing three different concentrations (100, 200, and 500 μM) of the platinum compound. Then the incubation solution was removed, and cells were washed with 2 mL of RPMI medium, released from plates with trypsin/EDTA treatment, washed three times with PBS, counted, and dried under reduced pressure. Cell-associated platinum was extracted with 0.1 mL of concentrated nitric acid for 15 min at 90 °C. Subsequently, solutions were diluted with water, and the Pt concentration was established using Icp-Ms.



Pt Binding to Cellular DNA. Cells were centrifuged, and the DNA was extracted by the salting out procedure (*26*). Cells were re-suspended in 10 mL of Nuclear Lysis buffer (10 mM Tris at pH 8.2, 400 mM NaCl, 2 mM EDTA). The cell lysates were digested for 4 h at 37 °C with 0.5 mL of 10% SDS and 0.1 mL of protease K solution (Sigma, 20 μg/mL water solution). Then, 5.5 mL of a saturated NaCl solution was added to the lysates, and the mixture was shaken vigorously followed by centrifugation at 10 000 rpm for 15 min. The supernatant containing the DNA was transferred to another tube,



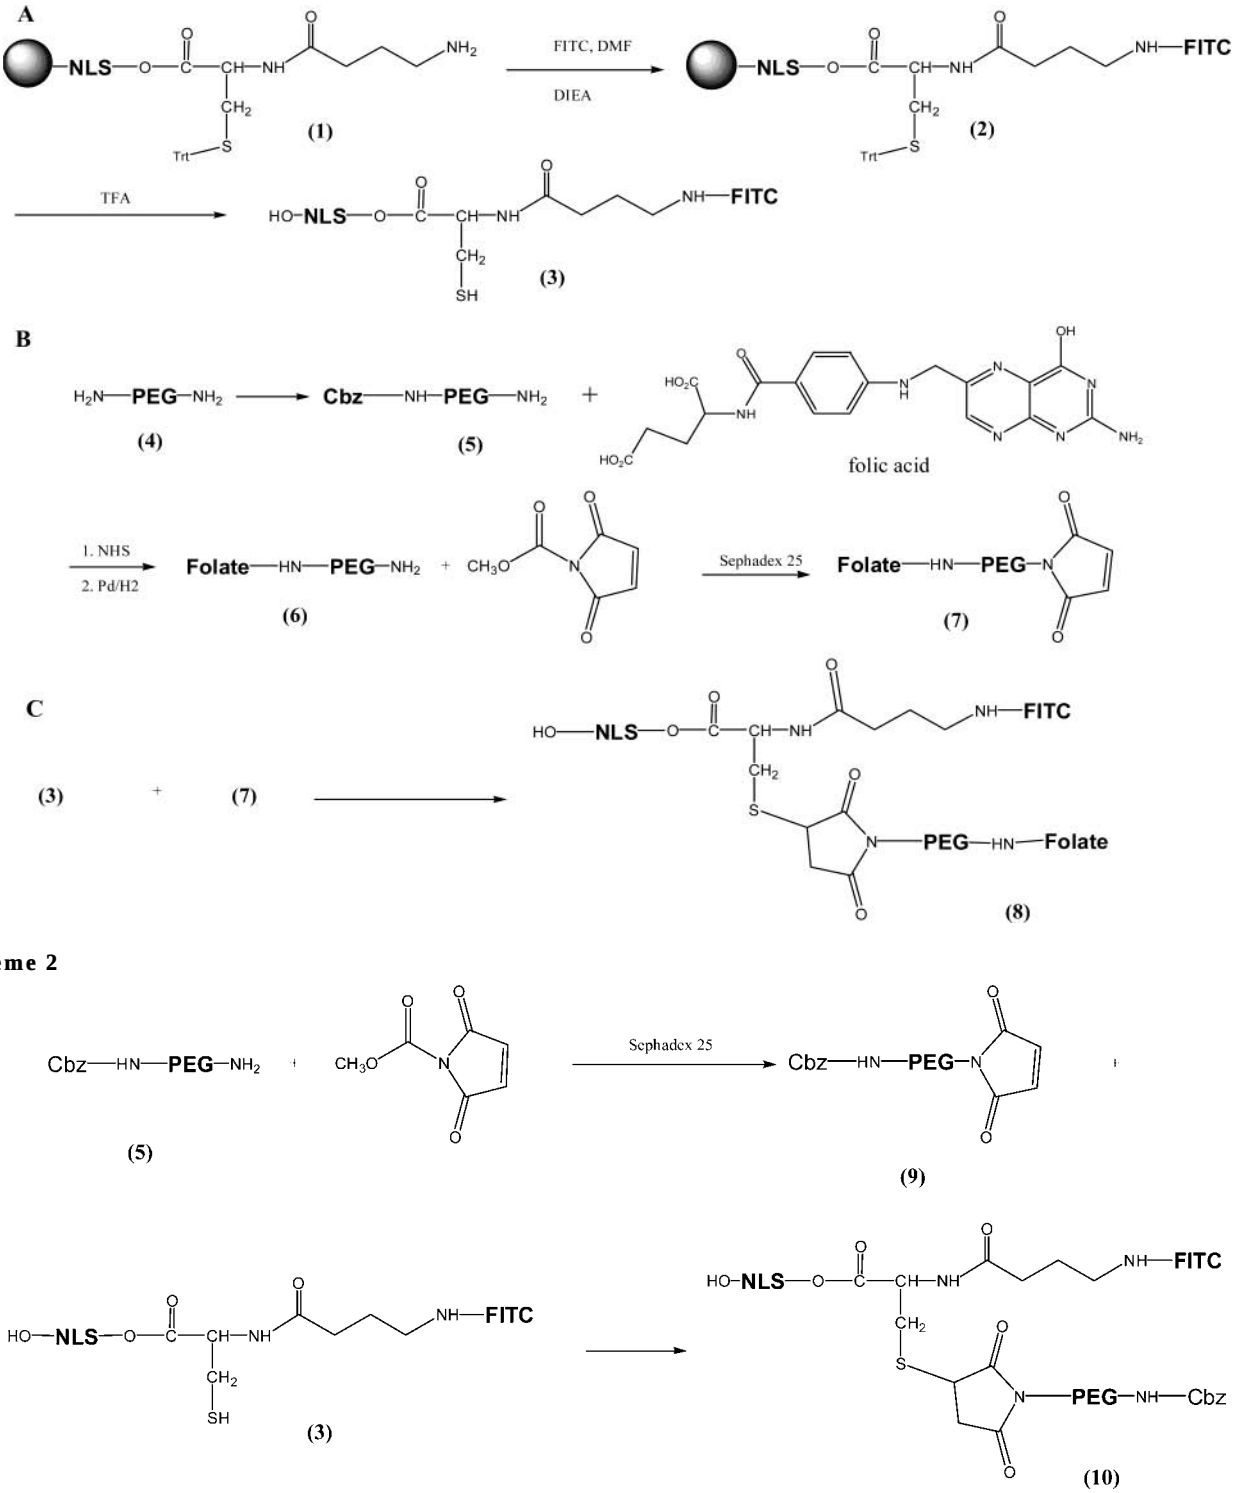
NLS-FITC-PEG-FA

NLS-FITC-PEG

NLS-FITC

NLS-PEG-Pt

Figure 2. The NLS conjugates that were prepared for this study.



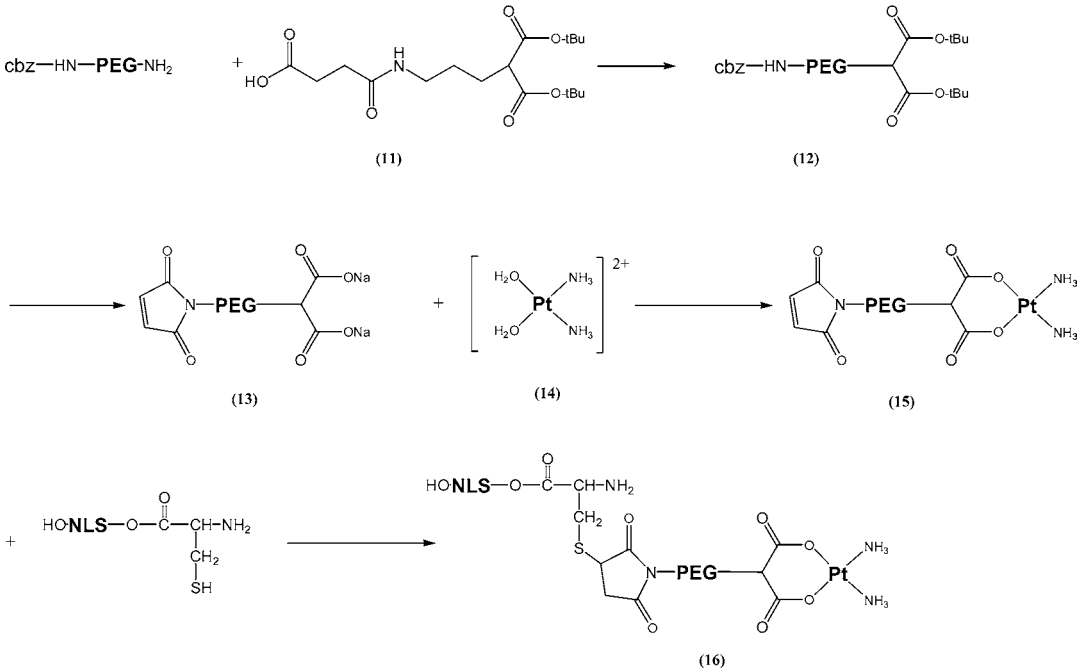
containing 20 mL of absolute ethanol and mixed gently. DNA strands were removed, washed three times in water/ethanol mixture (1:1), and dissolved in 2 mL of distilled water. DNA concentration was established according to absorbance at 260 nm, and the samples were diluted with TE buffer (10 mM Tris pH 8, 1 mM EDTA) buffer. DNA purity was determined by calculating the ratio of absorbance at 260 nm to absorbance at 280 nm. All samples showed the *A*260/*A*280 ratio of 1.7−1.9, which indicates that we obtained DNA with a high degree of purity. The platinum content in the DNA solutions was determined by Icp-Ms measurements.

RESULTS

Synthesis. The conjugates that were prepared for this study, NLS−FITC−PEG−FA, NLS−FITC−PEG, NLS−FITC, and NLS−PEG−Pt, are depicted in Figure 2. Since the NLS is the terminal moiety of all of these conjugates and since the NLS is prepared on a solid phase support, it seems like the synthesis of a NLS−PEG conjugates would best be performed by conjugating the PEG moiety to the peptide while the latter is still bound to the solid phase column. This would result in a single product that could be easily purified by size exclusion chromatography. All attempts to couple the PEG moiety to the peptide while still bound to the solid-phase resin were unsuccessful. Therefore another strategy for the synthesis of NLS−FITC−PEG−FA conjugate was devised and is shown in Scheme 1. The approach taken was to initially prepare the fluorophorated peptide (**3**), then the functionalized PEG (**7**), and in the final step to conjugate them to each other in solution to obtain the desired product (**8**). Often, conjugation of peptides is accomplished by coupling the primary amine of the peptide to a carboxylate group of the cargo thereby forming a stable amide linkage. There are two main reasons for not using the primary amine groups of the NLS peptide for coupling the peptide to the PEG: (a) since there are several primary amines on the peptide (four lysines and one terminal amine), from a chemical point of view, it will be impossible to obtain selectivity in coupling the peptide to a PEG-carboxylate and obtain only one product; (b) from a biological point of view, the lysines and arginines of the NLS are essential for attaining nuclear localization and should not be tampered with. Thus, a unique functional group that can be used for coupling to the PEG must be appended to the peptide. Thiols are known to react rapidly and selectively with maleimide groups, even in the presence of primary amine, and so we decided to add a thiol to the peptide and a maleimide to the PEG conjugate to allow selective and efficient coupling. The details of the synthetic approach are depicted in Scheme 1A. A cysteine was appended to the NLS sequence to provide a specific coupling moiety (**1**). A spacer of γ-aminobutyric acid (GABA) was added to the cysteine, and the fluorophore (FITC) was selectively coupled to the primary amine of the GABA on the solid-phase resin (while all the other amines were still protected). After deprotection and purification by RP-HPLC the peptide (**3**) was obtained and was characterized by electrospray ionization mass spectrometry and NMR spectroscopy. Thiols can be air oxidized to disulfides that are unreactive toward maleimide. High-performance liquid chromatography was used to check for the formation of intermolecular disulfide bond. Very little oxidation was observed but to be on the safe side, DTT was added to the peptide prior to coupling of the thiol to the maleimide.

The second component of the final conjugate (see Scheme 1B) was a PEG_{3000} to which a maleimide group was appended on one end. The synthetic approach was to initially prepare the monoprotected Cbz−HN-PEG-NH_2 (**5**) as the universal starting material for all subsequent syntheses of the PEG conjugates. The unprotected free primary amine was coupled to the desired carboxylate, and subsequently, the Cbz protecting group was removed by hydrogenation and the primary amine at the other side of the PEG could be coupled to another carboxylate group, yielding a nonsymmetric bifunctionally modified PEG. In this specific case, the folic acid was activated by NHS as previously described (*10*), followed by the removal of the protecting group to yield H_2N−PEG−FA (**6**). Since the hydrodynamic properties of the PEG dominate the chromatographic behavior of the conjugates, it is difficult, if not impossible, to separate

Scheme 1



Scheme 2

the PEG conjugates from the unmodified PEGs. Therefore, a large excess of the low molecular weight moieties was used in all the conjugation reactions, to try and force the reaction to completion and to simplify the purifications.

The preparation of a PEG having a terminal maleimide is depicted in Scheme 1B. The amino terminus of the FA−PEG-NH_2 was converted to the maleimide using the *N*-methoxycarbonylmaleimide reagent, followed by purification by gel-permeation chromatography (GPC), and was characterized by ^{1}H NMR spectroscopy. The double bond of the maleimide reacts specifically and rapidly with thiols yielding stable thioether bonds (Scheme 1C). The reaction between the PEG−maleimide and the NLS−Cys−GABA−FITC was monitored by RP-HPLC and after 45 min the reaction was complete. The product, FA−FITC−PEG−FA (**8**), was purified by HPLC and characterized by mass spectrometry.

The synthesis of NLS−PEG−FITC (**10**) is depicted in Scheme 2. Initially the Cbz−PEG-NH_2 (**5**) was synthesized, and subsequently the NH_2 was converted to the maleimide with N-methoxycarbonylmaleimide (**9**). An excess of the flourophorated peptide (**3**) was reacted with the FA-PEG-maleimide, and the conjugate was purified by HPLC.

Scheme 3

The synthesis of the NLS−PEG−Pt is depicted in Scheme 3. Di-*tert*-butyl 2-(3-succininylaminopropyl)malonate (**11**) and **1**−Cbz,*ω*-aminopolyoxyethylene3000, Cbz−PEG-NH_2 (**5**), were prepared as previously described (*10*). and then were coupled using EDCI to yield compound (**12**). The Cbz was removed by hydrogenation, and the resulting primary amine was converted to a maleimide group as described to yield compound (**13**). The NLS with the appended cysteine (without the GABA and FITC) was prepared and purified as described. There are two synthetic pathways that could be taken at this point: to first couple the peptide to the PEG-di-tBu-malonate (**13a**), remove the *tert*-butyl protecting group with acid, and neutralize the resulting diacid (**13b**), converting the maloante into the disodium salt (**13c**); and finally to platinate the ligand (conjugate). The second option is to first deprotect the malonate and convert it to the disodium salt (**13c**), then platinate and purify the platinum complex and finally to conjugate the NLS−PEG to the Pt−malonate. More often than not, the approach taken by the bioinorganic chemists and by the inorganic medicinal chemists is to initially complete the ligand synthesis and leave the platination for the last step. In this instance we chose the opposit approach, as depicted in Scheme 3. The rationale behind this choice stems from the fact that the reactive *cis*-$[Pt(NH_3)_2(H_2O)]^{2+}$ (**14**) could react with the thioether that connects the PEG-maleimide with the NLS−Cys and even possibly with the lysines and arginines of the peptide.

On the other hand, the diamminemalonate coordination sphere of the platinum(II) renders the Pt(II) quite inert, and the reaction of the cysteine thiol with the maleimide is expected to be faster and more selective than its reaction with the inert Pt moiety. There are reports in the literature showing that carboplatin can react with the thioether of methionine (*27*), raising question as to the potential stability of the conjugate. We have checked the stability of the conjugate by HPLC and by preparing the ^{15}N labeled Pt complex and measuring the two-dimensional NMR [^1H,^{15}N] HSQC spectrum. The cross-peak of the diamminemalonate at −78.8/4.15 was stable for weeks in solution, and no cross-peak was observed in the ^{15}N chemical shift range around −40 ppm, which is typical for the thioether binding. The observed stability is probably due to the polymeric moiety (PEG) that separates the Pt from the sterically hindered thioether and prevents facile intramolecular reactions. At pharmacological concentrations there is probably no need to worry about intermolecular interactions between two conjugates.

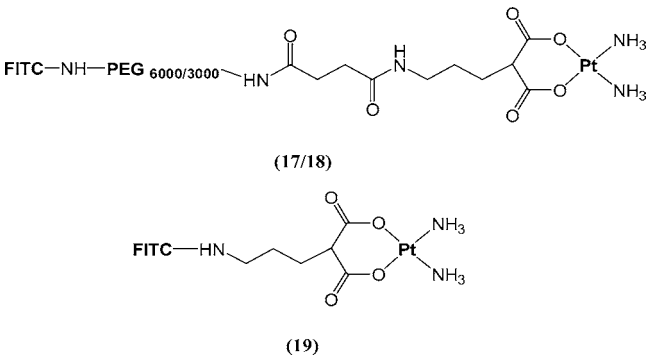


Figure 3. Pt−PEG conjugates that were prepared for this study.

To test how the Pt moiety and the properties of the PEG affect cellular uptake, three more fluorophorated platinum complexes (FITC−PEG_{6000}−Pt, FITC−PEG_{3000}−Pt, and FTIC−Pt) (**17**, **18** and **19**, respectively) were prepared as controls for the cell uptake and cytotoxicity studies of the conjugates. The molecules are depicted in Figure 3, and their synthesis was accomplished using the chemistry described above.

Cell Accumulation and Intracellular Distribution. We initially designed and prepared the FITC−PEG-NLS−FA conjugate in order to obtain: selectivity toward cancer cells, in which the FA receptors are overexpressed, uptake by FRME, and accumulation in the nucleus with the aid of the NLS. A 25 μM solution of compound (**8**) was incubated with M109FR cells for 2 h, and the results of the confocal microscopy are depicted in Figure 4A, clearly demonstrating that the conjugates have accumulated in the cell nucleus. Since this conjugate has two moieties (the NLS and the FA) capable of transferring the conjugate across the cell membrane, further

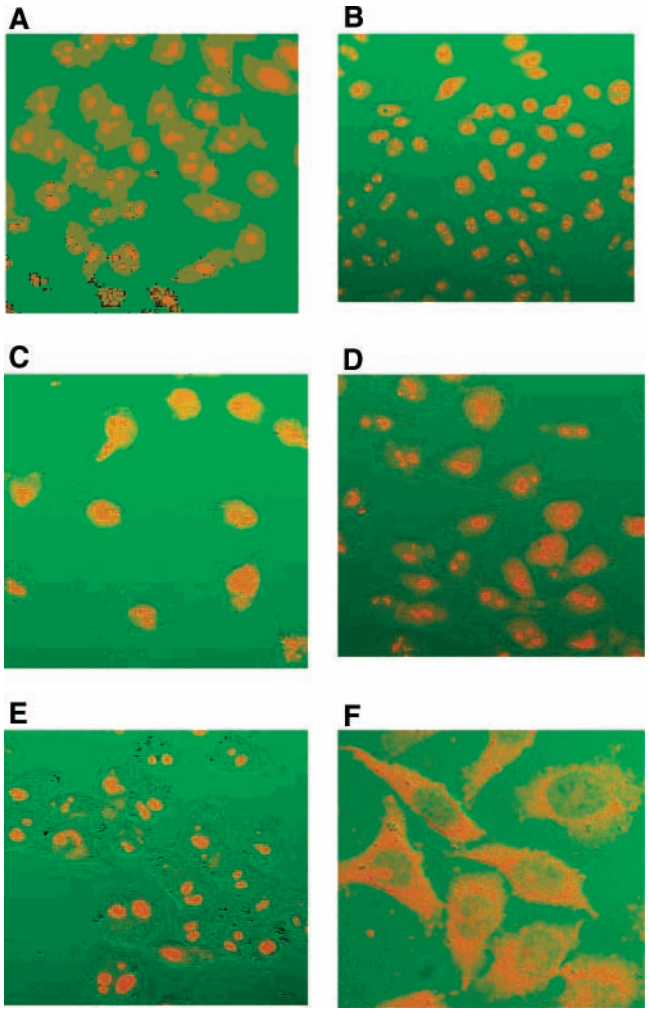

Figure 4. Confocal microscopy pictures showing the cellular localization of (a) NLS−FITC−PEG−FA with M109FR cells, (b) NLS−FITC−PEG with M109FR cells, (c) NLS−FITC with M109FR cells,(d) NLS−FITC−PEG−FA with M109FR cells in the presence of an excess of FA, (e) NLS−FITC−PEG−FA with wild-type M109 cells, and (f) FITC−PEG−FA with M109FR cells.

experiments were performed to establish the mechanism of cellular internalization. The FITC−PEG−NLS conjugate (**10**) was prepared and incubated with the M109FR cells, and again, nuclear localization was observed (Figure 4B), demonstrating that the peptide itself can translocate the conjugate across the cell membrane. Just to verify that it is indeed the NLS, and not the PEG, which is responsible for the cell internalization, the NLS was conjugated directly to the FITC (without the PEG), and again, nuclear localization was obtained (Figure 4C). To establish whether the NLS or the FA are the dominant factors in the cell internalization of compound (**8**) that contains both moieties, we studied the cell accumulation of this compound in the M109FR cell line when in competition with free FA. In the competition experiment with a large excess of free FA, the cellular accumulation was not affected (Figure 4D), indicating that the conjugate does not enter the cell via the FRME. In addition, we also studied the cellular accumulation in the native M109 cell line that is not enriched with FA receptors in order to factor out the contribution of the folic acid. The accumulation profile in M109 cells (Figure 4E) is practically identical to that observed in M109FR cells, reinforcing the results of the previous experiments. Incubation of the conjugate without the NLS (FITC−PEG−FA) with

Table 1. Pharmacological Data on the NLS−PEG−Pt Conjugate[a]

	IC_{50} μM	uptake ng Pt/10^6 cells	DNA-adducts ng Pt/mg DNA
carboplatin	33.15 ± 0.5	6.7 ± 1.2	10.75 ± 2.5
NLS−PEG−Pt	83.5 ± 2.1	19 ± 1.7	5.9 ± 1.8

[a] Based on experiments with M109 cell line.

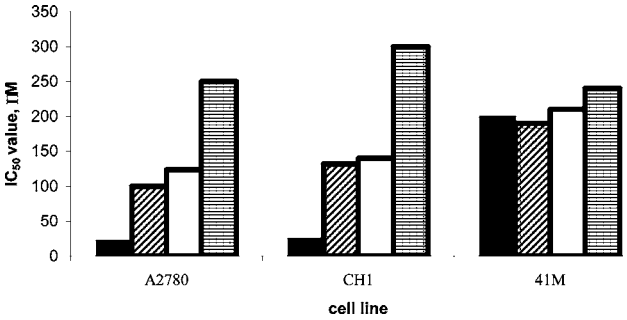

Figure 5. Cytotoxicity data for the interactions of carboplatin and compounds 17−19 (left to right) with human ovarian cancer cell lines. Each result is an average of three measurements with an average standard deviation of ±3.

the M109FR cells results in cytosolic accumulation of the conjugate (Figure 4f). Thus, both the experiments show clearly that the conjugate does not enter the cells via the FRME suggesting that it is the NLS that is responsible for both cellular accumulation and nuclear localization. Therefore, in the presence of NLS, the FA moiety does not contribute to selectivity via FR and pathway of uptake via FRME of the conjugates. NLS appears to be the prevailing moiety responsible for cell uptake of the conjugate.

We also studied the cellular accumulation of Pt−PEG complexes with an FITC reporter group. Toward this end the molecules (**17**−**19**) in Figure 3 were prepared and purified, and their cellular accumulation was studied by confocal microscopy, FACS and ICPMS. The results indicate that the PEGless Pt−FITC conjugate (**19**) is accumulated within the M109 cells approximately twice as much as the Pt−$PEG_{6000/3000}$−FITC conjugates (the FACS intensities were 71, 71, and 126 for compounds **17**, **18**, and **19**, respectively). This indicates that PEGylation of the conjugate retards cell uptake. However, PEGylation may also retard efflux of the conjugate from the cell and enable more effective activation of carboplatin in the cytosol, as shown previously (*10*).

Cytotoxicity and Intracellular DNA Adduct Levels. The pharmacological data for the studies performed in wild-type M109 cancer cells are listed in Table 1. Contrary to our expectation, the NLS−PEG−Pt conjugate was less cytotoxic than the Pt−PEG conjugate and produced less DNA−Pt adducts, despite the higher cellular accumulation and nuclear localization of the NLS conjugates observed by confocal microscopy. This indicates that NLS delivers carboplatin to the nucleus in a nonbioavailable form.

The cytotoxicity of FITC−PEG_{3000}−Pt, FITC−PEG_{6000}−Pt, and FTIC−Pt was measured in three human ovarian cell lines (A2780, CH1, and 41M), and the results are depicted in Figure 5. It is interesting to note that although FITC−Pt is accumulated within the cells twice as efficiently as the FITC−PEG−Pt conjugates, it is significantly less cytotoxic than the FITC−PEG−Pt conjugates. Also, it seems that the length of the PEG (3000 vs 6000) does not affect the cellular accumulation nor does it have an effect on the cytotoxicity.

DISCUSSION

A commonly accepted notion is that rapid nuclear localization should result in a higher level of formation of platinum−DNA adducts and hence superior cytotoxicity. Thus, over the years many attempts have been made to conjugate platinum complexes to DNA binding moieties such as intercalators (*28*−*32*) in order to increase the DNA binding affinity and specificity. The tethering of DNA binding agents to platinum complexes via stable covalent bonds yields in fact novel complexes that are bound to have properties that are quite different from those of the active moieties and thus they cannot be considered true delivery systems or prodrugs for the established drugs. One of the major concerns during the design of these systems is to ensure that the cytotoxic moiety, *cis*-$[Pt(NH_3)_2]^{2+}$ in this case, separates from the carrier at the right time and location. This rationale dictated for our choice of a carboplatin analogue since the release of the *cis*-$[Pt(NH_3)_2]^{2+}$ is expected to occur in a fashion similar to what happens with carboplatin itself. Yet, not only was the cytotoxicity of the NLS−PEG−Pt conjugate inferior to that of PEG−Pt but also the latter attained higher platination levels with cellular DNA despite its inferior cellular accumulation and intracellular localization. Clearly, the cytotoxic *cis*-$[Pt(NH_3)_2]^{2+}$ moiety is not efficiently released from the carrier in the nuclear environment.

The activation of carboplatin has been subject to a certain amount of debate since direct reaction of carboplatin with double stranded DNA results in very low levels of DNA platination (*33*). Fichtinger-Schepman observed that exposure of carboplatin to Chinese hamster ovary cells and subsequent reaction with Salmon sperm DNA resulted in much higher DNA platination levels when compared with platination levels of cell-free Salmon sperm DNA by carboplatin. In fact the platination was 10 times more efficient (*34*). This may indicate that carboplatin requires some intracellular activation by yet unknown mechanisms is order to be able to more efficiently platinate DNA. Sadler has shown that carboplatin can be chemically activated by thiols that react with the platinum complex, forcing the ring opening of the chelating malonate and rendering the Pt moiety more reactive (*35*). Sadler's work was performed in vitro and describes one possible mechanism for the activation of carboplatin though other intracellular activation processes may be involved.

When the platinum medicinal chemists design novel platinum anticancer agents, they normally tend to think of the cytosol of the cancer cell, with its wealth of platinophiles, as an obstacle that the platinum drug has to be overcome en route to the nuclear DNA. Yet it may be worthwhile to make a distinction between the more reactive diaminedichloroplatinum(II) complexes such as cisplatin, *trans*-platinum complexes with iminoether, aliphatic amines, planar amines, and nonplanar cyclic amine ligand and the inert compounds such as carboplatin, oxaliplatin, and nedaplatin, for which intracellular activation may be necessary for their activity. The results of this study suggest that the activation process, whatever it may be, probably takes place in the cytosol rather than in the nucleus. Thus, NLS based delivery is probably not suitable for carboplatin, oxaliplatin, and nedaplatin or any other platinum complex that requires cytosolic activation. We are in the process of testing the NLS−PEG conjugates as delivery systems for other anticancer drugs that bind to nuclear DNA.

The PEG itself, at the lengths tested, impedes the cellular uptake of the platinum complexes yet it enhances the cytotoxicity of the conjugates relative to those without the PEG. This may be due to the fact that while carboplatin or FITC−Pt are taken into the cell efficiently they might also be effluxed more easily than the PEGylated analogues (*10*), and since carboplatin analogues probably require relative long cytosolic residence times for activation, the PEG conjugates may just provide this necessary time frame for activation. It is noteworthy that the FITC−Pt conjugate is significantly less cytotoxic than carboplatin, indicating that the intracellular interactions of the two compounds are not identical. Since attempts to study the intracellular distribution of platinum compounds often entail functionalizing them with fluorophores that significantly alter the properties of the drug, the results reported here indicate that great care must be taken in the interpretation of such experiments.

ACKNOWLEDGMENT

This work was supported partially by the European Cooperation in the Field of Scientic and Technical Research Network (COSTD20/003/00 Action: "Biochemistry, Structural and Cellular Biology of Non-Classical Antitumor Platinum Compouds" (J.M.P. and D.G.). The work done at Dr. Gabizon's laboratory was supported in part by a grant from the Israel Cancer Association. A specific and institutional grant from Fundación Ramón Areces is also acknowledged (J.M.P.). Received March 25, 2004; Revised Manuscript Received April 22, 2004

To develop a novel nonviral gene carrier, three types of polyamine−dialky phosphates conjugates were synthesized via an unprecedented synthetic intermediate, dimerized dicetyl phosphate (DCP) anhydride, and the transfection efficiency and the complexation properties of the conjugate−DNA were evaluated. Condensation of DCP by 1,3,5-triisopropylbenzenesulfonyl chloride, TPSCl, gives the dimerized anhydride, which is stable enough to isolate by column chromatography in ∼90% yield. The anhydride is reactive with various amines, i.e., spermidine, spermine, and polyethylenimine (PEI-(1800)), providing corresponding polyamine−DCP conjugates via phosphoramidate linkage. The polyamine−DCP conjugates exhibited moderate transfection efficacy evaluated by β-galactosidase assay. The conjugate−DNA complex was observed by using an atomic force microscope (AFM), revealing that the PEI(1800)−DCP conjugate, which showed the most efficient transfection, enables the formation of the more compact complex with DNA.

INTRODUCTION

Development of more efficient and safer gene-transfer systems is one of the most challenging aspects of gene therapy (*1*). The two major approaches at present for gene transfer are viral and nonviral systems. The latter is safer and easier for mass production despite the higher efficiency of the former. Therefore, nonviral systems, such as cationic liposomes and polycations (*2*−*8*) as well as nonionic carriers (*9*), continue to be developed to improve their efficiency.

The mechanism of gene delivery by such cationic carriers probably involves an endosomal pathway (*10*); however, the details remain to be clarified. In this regard, the polymorphism including lamellar, multilamellar, and hexagonal structures of polycation−DNA complexes have been studied (*11*−*16*). A nucleosome-like structure in which DNA wraps around an aggregate of dioctadeyl-amidoglycylspermine (DOGS)[1] molecules has been reported by Yoshikawa et al. by using fluorescence and electron microscopy (*11*). The nucleosome-like assemblies further associate with each other to form a network, which may play a role in effective transfection. However, the relationship between polycation−DNA assembly and the efficiency of gene transfection is far from well-understood.

We have recently reported that polycation liposomes (PCL) composed of cetylated polyethylenimine (cetyl-PEI) possess high gene transfer activity (*17*−*20*). In the most recent report, we proposed a possible mechanism of PCL-mediated gene transfer wherein PCL−DNA complexes are taken up by endosomal pathway; this was based on tracking of fluorescence-labeled components, PCL lipid, cetyl-PEI, and DNA, as cetyl PEI−DNA complex is released and transferred into the nucleus via the cytosol (*20*). The key step of gene transfer mediated by cationic liposomes is thought to be entry into the nucleus (*21*). Thus, compaction of DNA should be crucial; both electrostatic and hydrophobic interactions in the cetyl PEI−DNA complex are likely to be responsible for its effective compaction.

PEI is used as a gene transfer vector by itself; however, it has inherent disadvantages, i.e., cytotoxicity and polydispersity. In this report, we synthesize a series of polyamine−dicetyl phosphate (DCP) conjugates via reaction of a novel synthetic intermediate, dimerized DCP anhydride, with various polyamines, spermidine, spermine, and PEI (Scheme 1). Since spermidine and spermine are naturally occurring polyamines, we expected low cytotoxicity. These conjugates exhibited moderate gene transfer activity. We also observed the morphology of the conjugate−DNA complex by using atomic force microscopy (AFM). We briefly discuss the relationship between the assembling structure of the conjugate−DNA and their transfection efficiency.

Scheme 1. Synthetic Strategy for Polyamine−DCP Conjugates via Synthetic Intermediate, 1, DCP Anhydride

without further purification. DCP was purchased from Sigma. PEI(1800) with an average molecular weight of 1800 was kindly provided by Nippon Shokubai Co., Ltd (Osaka, Japan). The PEI(1800) was purified by ultrafiltration with an ultrafilter membrane (YM-1, Amicon Corp., Danvers, MA). NMR spectra were recorded on either a Varian Gemini-2000 (300 MHz) or a Bruker AVANCE600 (600 MHz) instrument. Secondary ion mass spectra were obtained by using HITACHI M-2000S. Infrared spectroscopy was carried out on a PerkinElmer Spectrum 2000 FT-IR spectrometer. Suspensions of polyamine conjugates were prepared in Tris-HCl buffer (15 mM, pH 8.4) by ultrasonication for 3 min. To the suspension was added 5 μg of ColE1 plasmid DNA (6646 bp, Nippon Gene), followed by equilibration for 15 min at room temperature. Displacement of ethidium bromide, EtBr, intercalated into DNA was measured with a fluorescence spectrophotometer FP-777 (JASCO) at EtBr/nucleotide = 50/1 (mol/mol) with varying polyamine contents. EtBr fluorescence at 590 nm (excitation wavelength: 260 nm) was recorded to obtain the relative fluorescence intensity, I/I_0, where I and I_0 are fluorescence intensities in the presence and the absence of polyamine derivatives, respectively. Measurement of dynamic light scattering was carried out on a Nicomp Model 370 particle size analyzer. AFM images of the conjugate−DNA complexes were acquired with a JEOL JSPM-4210 equipped with a cantilever (MikroMasch, type A: 110 μm, 7.5 N/m), using the discrete contact mode (AC mode). A sample was deposited on a dry mica surface by spin coating, followed by drying at ambient pressure. For observation of a negatively charged specimen, e.g., ColE1 plasmid DNA, a mica surface was premodified with polylysine. For DLS and AFM measurements, suspensions of the polyamine conjugates were prepared in distilled and deionized water.

Synthesis of Dimerized Dicetyl Phosphate Anhydride (1). Dicetyl phosphate, DCP (50 mg, 90 μmol), was dissolved in 1 mL of anhydrous pyridine. To this solution was added 1,3,5-triisopropylbenzenesulfonyl chloride (TPSCl, 277 mg, 0.91 mmol) as a powder. After the reaction mixture was stirred for a few hours at room temperature under a nitrogen atmosphere, DCP was converted into DCP anhydride, whose molybdenum blue-active spot appeared at R_f 0.97 (SiO_2, $CHCl_3$/MeOH/H_2O, 13/6/1). The solvent was evaporated, and the crude product was purified by column chromatography (Aldrich silica gel, eluted by $CHCl_3$). After being dried in vacuo, the isolated pure product, **1**, was obtained as a white powder (44.3 mg, 41 μmol, 90% yield). ^{1}H NMR (600 MHz, $CDCl_3$) δ: 0.88 (t, 12H), 1.25 (br s, 96H), 1.37 (m, 8H), 1.70 (m, 8H), 4.0−4.2 (m, 8H); ^{31}P NMR (243 MHz, $CDCl_3$, 10% H_3PO_4 in D_2O as an external standard) δ: −12.27, −0.13; ^{13}C NMR (150 MHz, $CDCl_3$) 14.01, 22.68, 25.36, 25.45, 29.16, 29.36, 29.54, 29.60, 29.66, 29.71, 30.31, 31.92, 67.67, 69.12; FT-IR (KBr) ν (cm^{-1}): 2849, 1471, 1294, 1108, 1021, 952; SIMS for $(C_{64}H_{133}O_7P_2)^+$ calcd 1075.9, found 1075.4.

Synthesis of Dicetyl Phosphate−Spermidine Conjugate (2). To a solution of spermidine (6.74 mg, 46 μmol) in 0.5 mL of dry pyridine was added **1** (10 mg, 9.3 μmol) in 0.1 mL of anhydrous pyridine. The reaction mixture was stirred under nitrogen atmosphere for 5 h at room temperature. Removal of solvent under reduced pressure, followed by column chromatography [1 g of silica gel, eluting with $CHCl_3$/MeOH/Et_3N (10/1/0.1, v/v/v) and then $CHCl_3$/MeOH/Et_3N (1/1/0.02, v/v/v), gave 4.9 mg (78%) of **2** as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.88 (t, 6H), 1.26 (s, 52H), 1.56 (m, 4H), 1.70 (m, 6H), 2.61−3.12 (bm, 12H), 3.98 (bm, 4H); FT-IR (KBr) ν (cm^{-1}): 3235, 2917, 2850, 1636, 1467, 1210, 959; SIMS for $(C_{39}H_{85}N_3O_3P)^+$ calcd 674.6, found 674.8.

Synthesis of Spermine−Dicetyl Phosphate Conjugate (3). To a solution of spermine (10 mg, 49 μmol) in 0.5 mL of dry pyridine was added **1** (10 mg, 9.3 μmol) in 0.1 mL of anhydrous pyridine. The reaction mixture was stirred under a nitrogen atmosphere for 5 h at room temperature. Removal of solvent under reduced pressure was followed by column chromatography [1 g of silica gel, eluting with $CHCl_3$/MeOH/Et_3N (10/1/0.1, v/v/v)] to re-

move free DCP component. The product absorbed on the silica gel was eluted by washing with $CHCl_3$/MeOH/Et_3N (1/1/0.02, v/v/v), giving 4.5 mg (66%) of **3** as a white powder. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.88 (t, 6H), 1.26 (s, 52H), 1.42 (bm, 8H), 1.55 (bm, 4H), 2.15 (br, 5H), 3.17 (bm, 8H), 3.63 (bm, 4H), 3.97 (m, 4H). ^{31}P NMR (243 MHz, $CDCl_3$, 10% H_3PO_4 in D_2O as external standard) δ: 9.76. FT-IR (KBr) ν (cm^{-1}): 3426, 3235, 2917, 2850, 1637, 1466, 1212, 1012; SIMS for $(C_{42}H_{92}N_4O_3P)^+$ calcd 731.7, found 731.5.

Synthesis of PEI(1800)−Dicetyl Phosphate Conjugate (4). To a solution of PEI(1800) (16.7 mg, 9.3 μmol) in 0.5 mL of dry pyridine was added **1** (10 mg, 9.3 μmol) in 0.1 mL of anhydrous pyridine. The reaction mixture was stirred under a nitrogen atmosphere for 5 h at room temperature. Removal of solvent under reduced pressure was followed by column chromatography [1 g of silica gel, eluting with $CHCl_3$/MeOH/Et_3N (10/1/0.1, v/v/v)] to remove free DCP component. The product absorbed on the silica gel was extracted by washing out with $CHCl_3$/MeOH/Et_3N (1/1/0.02, v/v/v), giving 3.5 mg (20.7%) of **4**. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.88 (t, 6H), 1.1−1.6 (br, 83H), 1.65 (bm, 4H), 2.5−3.1 (bm, 125H), 4.1 (m, 4H); FT-IR (KBr) ν (cm^{-1}): 3253, 2915, 2846, 1637, 1466, 1214, 1033.

Cell Culture. Primary vascular smooth muscle cells were obtained by removal of the thoracoabdominal aortas of Wistar rats, which were then stripped of endothelium and adventitia (*22*). Medial VSMCs were maintained in Dulbecco's Modified Eagle's Medium (DMEM), 20% fetal bovine serum (FBS), 200 units/mL penicillin, 200 μg/mL streptomycin (all Gibco, Gaithersburg, MD) at 37 °C with 5% CO_2. At confluence, the cells were passaged using 0.25 mg/mL trypsin/EDTA (Clonetics, Walkersville, MD).

Transfection Procedure. The cells were seeded in 96-well plates at 24 h before transfection at densities to give about 80% confluence at the time of transfection. β-Galactosidase plasmid DNA (purchased from Clontech Labtories Inc. (Palo Alto, CA) and propagated and purified by Bayou Biolabs (Harahan, LA)) was diluted in serum-free cell culture medium to 20 μg/mL. The transfection reagents were suspended in D-PBS at 1 mg/mL, diluted in the same volume of serum-free cell culture medium as that of DNA (the dilution factor was varied as appropriate to give the desired ratio of the transfection reagent to DNA), and then pipetted into plasmid DNA. The resultant complexes were incubated at room temperature for 15 min and then added to the cells that were either in medium lacking serum or medium containing 20% fetal bovine serum (FBS). At 3 h after addition of complexes, the cells were washed with PBS and fresh medium containing 20% FBS was added.

Cells were assayed for β-galactosidase activity 24 h after transfection with a microplate fluorometric assay (*23*), modified by inclusion of a heating step (50 °C, 45 min) to inactivate endogenous enzyme activity. Following aspiration of the medium from each well, the cells were washed once with PBS and then lysed by addition of 100 μL of lysis buffer (0.03% Triton X-100 in 100 mM HEPES, pH 7.8, containing 1 mM $MgSO_4$, 10 mM KCl). The plates were placed at 50 °C for 45 min and then allowed to cool to room temperature. Into each well was added 10 μL of fluorescein di-β-D-galactopyranoside, FDG (100 μM). Fluorescence was measured with a microplate fluorimeter (Model 7620, Cambridge Technology Inc.) after incubation at 37 °C overnight. Under these assay conditions, 0.1 milliunit of β-galactosidase corresponded to 16 000 fluorescence units.

RESULTS AND DISCUSSION

Synthetic Strategy for Polyamine−Dialkyl Phosphate Conjugates via a Synthetic Intermediate. Our preliminary idea for the syntheses of polyamine−DCP conjugates was to use the bromoethylated compound, **5**, as a synthetic intermediate via condensation of DCP and 2-bromoethanol (Scheme 1) by using TPSCl (*24*, *25*). Instead of the expected adduct, **5**, however, we obtained another product having a high R_f value, 0.97 (R_f = 0.56 for DCP by eluting $CHCl_3$/MeOH/H_2O = 13/6/1, v/v/v). The resulting product is stable enough to be isolated by column chromatography. SIMS indicates almost double molecular mass, 1075.4 (546.9 for DCP). The observed IR absorption band at 952 cm^{-1} is assignable to the P−O−P stretching mode. The ^{31}P NMR spectrum of the product, whose signals appear at δ = −12.27 and −0.13 ppm, is clearly distinguishable from that of DCP having a signal at δ = 2.15 ppm. This evidence, taken together, leaves no doubt that the product is dimerized DCP in anhydrous form, **1** $[(C_{64}H_{133}O_7P_2)^+$ calcd 1075.9], connected via P−O−P bonding. Hydrolytic decomposition of **1** is negligible for a few days in chloroform or anhydrous pyridine at room temperature. In wet chloroform, however, the decomposition is accelerated, and under acidic and basic conditions, e.g., chloroform containing small amount of diluted HCl, sodium carbonate, ammonia, or triethylamine, the decomposition is further accelerated. There are some prior examples in the synthesis of pyrophosphate derivatives bearing small alkyl moieties, methyl, ethyl, propyl, and butyl (*26*); however, the dimerized anhydride, **1**, bearing phospholipid-like long alkyl chains is an unprecedented compound. This compound is a convenient synthetic intermediate for formimg phosphoramidate bonds, as described below.

The anhydride **1** readily react with amines, e.g., spermidine, spermine, and even polymer, PEI(1800), to form the phosphoramidate, P−N bond, providing the corresponding adducts, **2**, **3**, and **4**, respectively. The reactivity toward these nucleophiles indicates that the anhydrous compound **1** is potentially a good synthetic intermediate for making polyamine−dialkyl phosphate conjugates via the P−N bond. When reacted with spermine, for example, the adduct **3** readily forms, concomitantly with the loss of DCP. The ^{31}P NMR signal of compound **3** is shifted downfield, to 9.76 ppm compared with that of DCP at 2.15 ppm, indicating the formation of the P−N bond in the compound. The downfield-shifted signal is attributed to the lower electronegativity of the nitrogen atom in spermine relative to the oxygen atom in DCP. Although structural ambiguity of the resulting adducts, **2**, **3**, and **4**,[2] cannot be completely eliminated, anhydride **1** is a useful synthetic intermediate because it is (1) stable yet reactive with amino groups, (2) very simple and easy to prepare, and (3) produced in high yield (∼90%). In addition, it should be noted that a potential advantage of the conjugation via P−N bond is that it may cleave in endosomes, because the linkage is very unstable under acidic conditions. Such a cleavable bond would have advantages in terms of disruption of endosomes: the cleaved DCP portion could facilitate release of the polyamine−DNA complex from the endosome. In addition, it should confer biodegradability on the compound.

[2] The asymmetric molecule, spermidine, has two distinguishable primary amines. Product **2**, bearing a spermidine moiety, has two isomers, which, to date, have not been identified spectroscopically. Along the similar lines, content of primary amine of PEI(1800) in the product **4** is 25% in total amino moieties; thus, the structural uncertainty cannot be avoided.

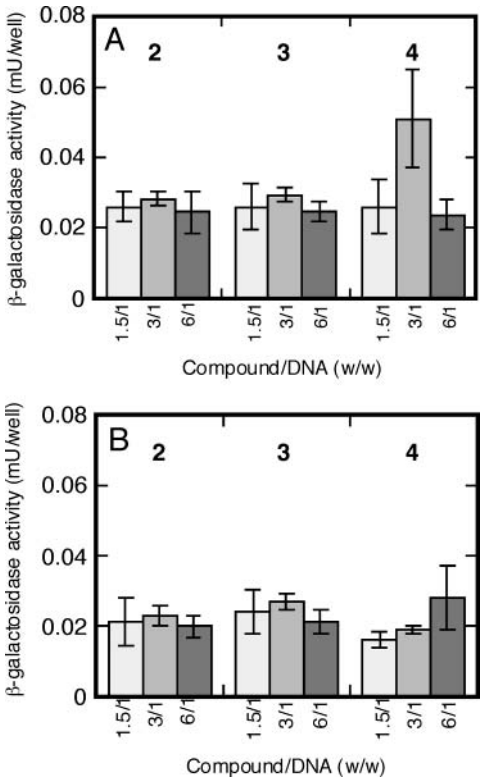

Figure 1. Transfection efficacy of polyamine−DCP conjugates **2**−**4** on VSMC, in the absence (A) and the presence of 20% of FBS (B). The ratios of compound−β-galactosidase plasmid DNA (w/w) were 1.5/1, 3/1, and 6/1, respectively.

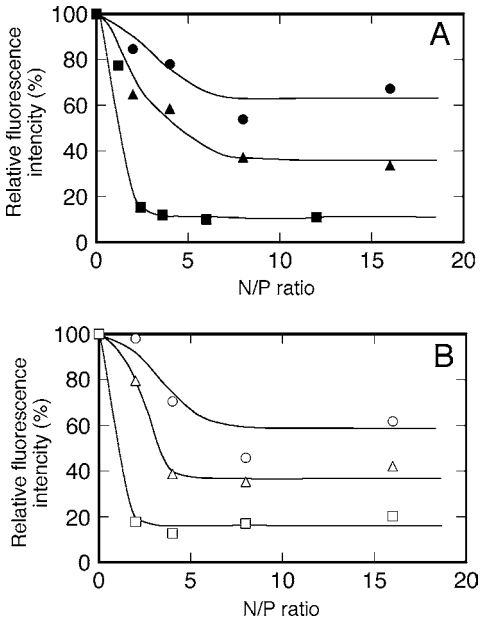

Figure 2. Changes in fluorescence intensity of ethidium bromide intercalated into Col E1 plasmid DNA−polyamine compounds: (A), spermidine (●), spermine (▲), and PEI(1800) (■); (B), spermidine−DCP (○), spermine−DCP (△), and PEI-(1800)−DCP (□).

These compounds could hence provide new category of polycationic lipids.

Transfection Efficacy. The polyamine−DCP conjugates **2**−**4** were subjected to transfection assay using the β-galactosidase expression system. Figure 1A shows the transfection efficiency of **2**, **3**, and **4** evaluated according to β-galactosidase activity (milliunit/well), in the absence of FBS. Compared with the commercially available transfection reagent, *O*-ethyl DOPC (E-DOPC) (*5*), which produced 0.1 milliunit/well transgene expression, compounds **2**−**4** exhibit moderate efficiency, ∼30 to 50% of the efficiency of E-DOPC. The transfection efficiencies of the components themselves, i.e., DCP, spermidine, spermine, and PEI(1800), were almost negligible (data not shown). Thus, the transfection activity results from the conjugation of two moieties: a hydrophilic polyamine and a hydrophobic DCP. Compound **4** shows the highest efficiency at 3/1 (w/w) of **4**−DNA, whereas the efficiency of the other compounds are comparable and insensitive to the compound−DNA ratio within the range of error. In Figure 1B is shown the transfection efficiency in the presence of 20% FBS. The efficiency of these compounds was not influenced by the presence of 20% FBS, retaining 80−100% of the activity (except compound **4** at 3/1 (w/w)). Such serum-resistant activity was also observed for the PCL gene transfection system previously reported (*19*). It is well-known that serum often inhibits transfection; such inhibition is due to binding of negatively charged serum proteins to the cationic transfection reagents resulting in forming aggregates ineffective to the transfection. Although it is not clear why the polyamine−DCP conjugates are not influenced by the presence of the serum, the polyamine part may be assumed to efficiently interact with DNA via electrostatic interactions.

Compound **4** exhibits maximum efficacy at a 3/1 of **4**−DNA ratio in this series (Figure 1A). We examine complexation of the polyamine−DCP conjugates with DNA by intercalation of EtBr, DLS, and AFM as described below.

Complexation with ColE1 Plasmid DNA. It was found that DNA (ColE1 plasmid DNA) complexes with various polyamines (A) and polyamine−DCP conjugates (B) by monitoring the decrease of fluorescence from EtBr initially intercalated into DNA (Figure 2A and 2B). With an increase in the cation (*N*)/anion (*P*) ratio, defined as *N*/*P*, the relative fluorescence intensity decreased as a result of complexation of DNA and polyamine. As shown in Figure 2A, the polymeric molecule, PEI(1800) ($N \sim 42$ per molecule) most efficiently forms a complex with DNA; the complexation was almost complete at $N/P = 3$. Spermidine ($N = 3$ per molecule) and spermine ($N = 4$ per molecule) are less effective than PEI(1800), however, with complexation being complete at around $N/P \sim 7$. For polyamine−DCP conjugates (Figure 2B), the tendency for the fluorescence intensity to decrease is due to the complexation with DNA in the same way as that of the free amines, although influence of the hydrophobic alkyl chain in the complexation is not at all pronounced.

The mean particle diameters of various polyamine−DCP conjugates in an aqueous suspension, as given by dynamic light scattering, is summarized in Table 1: 155 ± 54 nm for **2**, 173 ± 46 nm for **3**, and 128 ± 38 nm for **4**. AFM images for the suspension of these compounds exhibited spherical or ellipsoidal particles, whose sizes, defined according to diameter for the spheres and major × minor axes for the ellipsoid, were 132 nm for **2**, 156 nm for **3**, and 209 × 145 nm for **4** (Figure 3A, B, and C, respectively). The particle sizes for these compounds as observed by AFM show good agreement with those obtained by DLS. The molecular shapes of these compounds are regarded to be the "cone" type, due to the attachment of the large polyamine moiety. We have endeavored to make liposome from these compounds; however, entrapment of a fluorescence probe, calcein, was

Table 1. Estimated Size and Shape of 2−4 and Complexes with ColE1 DNA Suspended in Aqueous Solution[a]

	DLS (nm)		AFM/shape (size (nm)) and height (nm)[b]			
compound	conjugate alone	complex with DNA	conjugate alone		complex with DNA	
2	155 ± 54	409 ± 115	sphere (132)	21	aggregate (∼1000 × 437)	16
3	173 ± 46	237 ± 127	sphere (156)	24	aggregate (569 × 317)	20
4	128 ± 38	115 ± 40	ellipsoid (209 × 145)	12	sphere (120)	20

[a] The ratio of polyamine conjugate−DNA was 3/1 (w/w). Complexation of polyamine conjugate with DNA was carried out in water. [b] Sample solution was spreaded on a mica surface and dried. AFM images were obtained under dry condition. Width and height of the complexes were estimated from the AFM images in Figures 3 and 4.

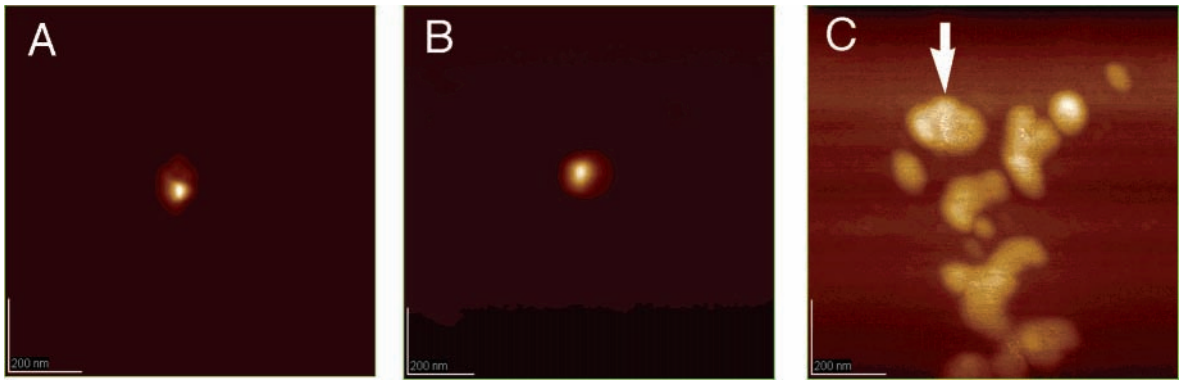

Figure 3. AFM images of arrays of compounds **2** (A), **3** (B), and **4** (C). The compound was suspended in distilled water and then dropped onto a mica surface by spin coating. All scale bars represent 200 nm. The object indicated by the arrow is discussed in the text.

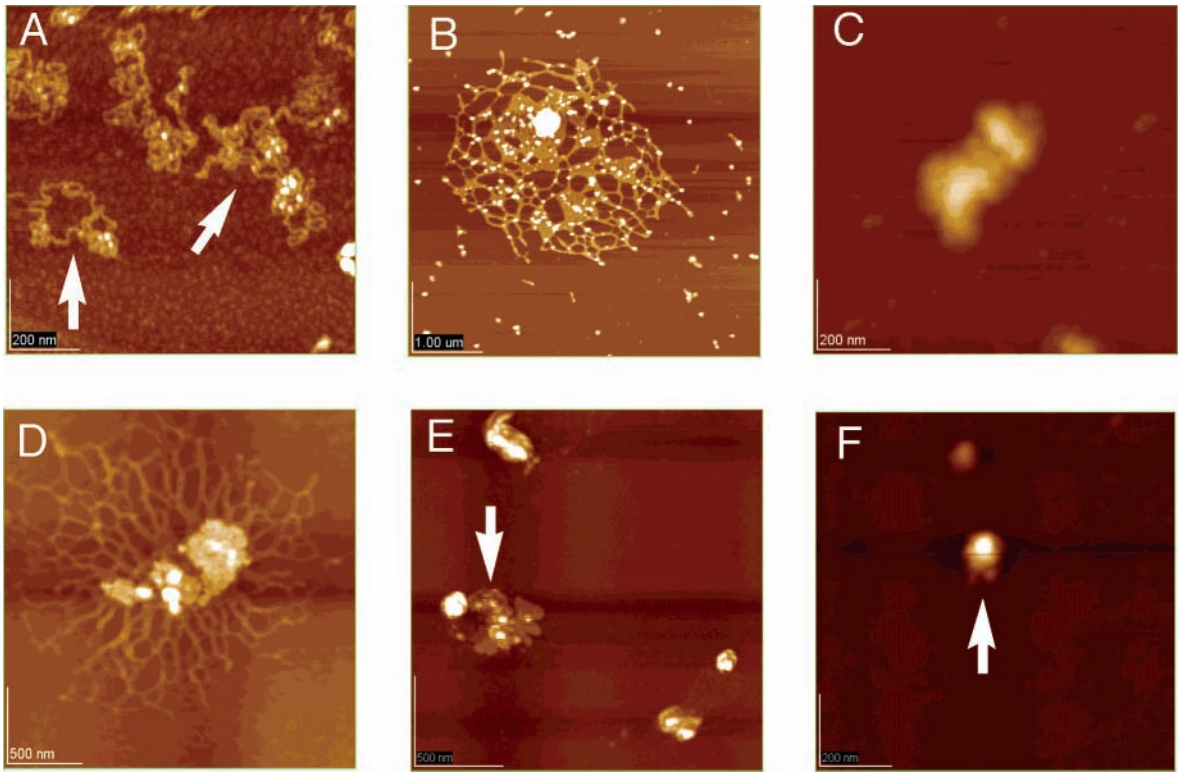

Figure 4. AFM images of polyamine-ColE1 plasmid DNA complexes: (A), ColE1 plasmid DNA alone on polylysine-treated mica; (B), spermine−DNA; (C), PEI(1800)−DNA; (D), spermidine−DCP−DNA; (E), spermine−DCP−DNA; (F), PEI(1800)−DCP−DNA. The polyamine−DNA ratio was 3/1 (w/w). Scale bars inserted in these images represent (A) 200, (B) 1000, (C) 200, (D) 500, (E) 500, and (F) 200 nm, respectively. The objects indicated by arrow(s) are discussed in the text.

impossible. Therefore, we assume that the particle consisting of polyamine−DCP conjugates is a micellelike aggregate.

Particle sizes of the conjugate−DNA (3/1: w/w) complex evaluated by DLS is 409 ± 115 nm for **2**, 237 ± 127 nm for **3**, and 115 ± 40 nm for **4**, respectively (Table 1). With increase in the size of polyamine portion, the particle size significantly decreases. AFM images support this conclusion. Figure 4 shows an AFM image of DNA (A) and of the complexes it forms with various polyamines (B−F). Figure 4A reveals a clear image of partially coiled ColE1 plasmid DNA (6646 bp), whose size is estimated to be 300−400 nm. The height is ∼2 nm, corresponding to the diameter of B-form DNA, ca. 2.4 nm. When DNA was complexed with compound **2**, a "spider nest"-like structure was observed (Figure 4D). The size of the

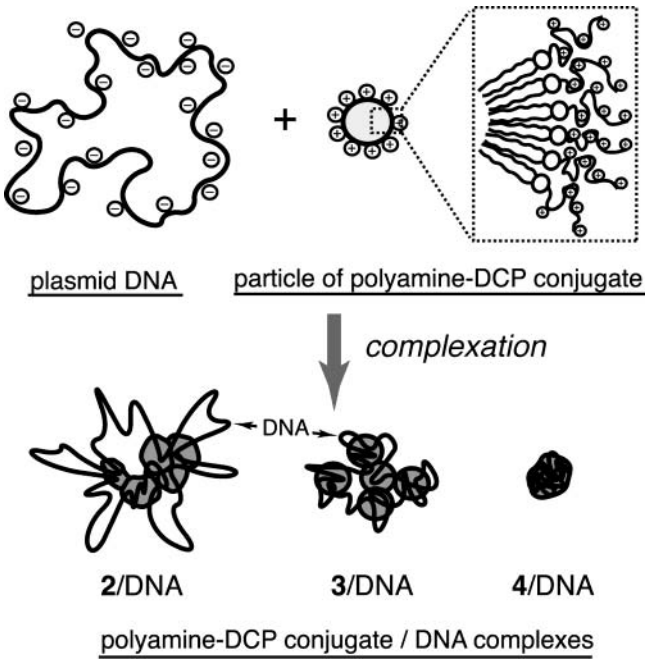

Figure 5. Hypothetical complexation of polyamine−DCP conjugates **2**−**4**, with ColE1 plasmid DNA based on the AFM images as shown in Figures 3 and 4. The bright-gray sphere represents micelle of polyamine−DCP conjugate **2**, **3**, or **4**. When the plasmid DNA complexes with the conjugate micelles via electrostatic interaction, different types of conjugate−DNA, **2**−DNA, **3**−DNA, and **4**−DNA, form depending on the conjugates. The solid lines and the dark-gray spheres depicted in the complexes represent the plasmid DNA and aggregates consisting of the conjugate and DNA, respectively.

"quasi-ellipsoidal core region" is ∼1000 × 437 nm and the height is ∼16 nm. The height of the radiating peripheral "nest" region is ∼2 nm, suggesting the nest region consists of free DNA. The height of the core region (∼16 nm) is clearly larger than that of the DNA part; therefore, the core region of the structure must consist of the **2**−DNA complex. Thus, complexation of compound **2** and DNA gives rise to a segregated array, having complex and free DNA portions. Compound **3** forms a similar but distinguishably different complex structure with DNA (Figure 4E), which resembles a "pearl necklace-like" aggregate (*11*), 569 × 317 nm in the plane of the substrate and 4−20 nm in height. The size of the pearl parts is 120−170 nm in diameter and 11−20 nm in height. These parts are connected by a region that is 4−5 nm in height. It appears from the image that the assembly consists of a tightly packed **3**−DNA complex and regions of partially compacted DNA parts. Pronounced compaction of the complex was observed for the **4**−DNA, which formed a spherical cluster (120 nm in width and ∼20 nm in height) (Figure 4F). The order of increasing compaction of DNA, **2** < **3** < **4**, is consistent with the extent of intercalation of EtBr (Figure 2B); that is, the more tightly packed was the DNA complex, the lower was the extent of intercalation of EtBr. On the basis of the AFM images of the polyamine conjugate−DNA complexes, the hypothetical shapes of the complexes are as depicted in Figure 5.

Upon comparison of the observed DNA complex with free polyamines, spermine (Figure 4B) and PEI (1800) (Figure 4C), the complex size and shape are obviously distinguishable from the corresponding conjugate forms; much larger complexes form with these free polyamines. The dimension of the spermine−DNA complex (Figure 4B) is ∼3 μm; the compaction of DNA is obviously incomplete, judging from the presence of the "nest" portion of DNA that is similar to peripheral part of the **2**−DNA complex (Figure 4D). The PEI(1800)−DNA complex is smaller (416 × 218 nm by 22 nm high) than the former complex, suggesting that the greater cationic charge makes the complex smaller. When one considers the effect of the hydrophobic portion in the polyamine compound on the size of the complex, it is clear that hydrophobic alkyl parts in the conjugates play an important role in the compaction of DNA, which is most prominently observed in conjugate **4** (Figure 4C vs 4F). From these results, the prominent transfection efficiency of **4** likely results from the more efficient compaction of DNA in the complex **4**−DNA, whereas the lower activity of **2** and **3** is likely due to their much weaker compaction.

Because high compaction is needed for transfection, **2** and **3** exhibited only moderate transfection activity. The efficiency of **2** and **3** does not depend on the dose in the range of 1.5/1 to 6/1 (w/w), whereas the efficacy of conjugate **4** decreases at 6/1 (w/w). This may be a consequence of the cytotoxicity of PEI portion. One may wonder why the morphologies of the complexes of **2** and **3** with DNA are so different despite the small structural difference in the cationic portion. It might come from the difference in delicate balance of hydrophilic/hydrophobic factor and/or molecular shapes which reflect a packing parameter. A wide variety of similar polyamine−dialkyl phosphate derivatives bearing different type of hydrophobic alkyl chain, e.g., shorter or unsaturated, is synthetically available. It should be intriguing to see the effect of hydrophilic/hydrophobic balance on not only the morphology of the complex with DNA but also transfection efficacy.

Although the precise mechanism remains to be clarified, the compaction by these polyamine compounds probably plays an important role because entry into the nucleus is thought to be a key step and a smaller complex is likely to be associated with more efficient transfection. The conjugates in this study possibly decompose into separate polyamine and DCP portions in the endosome. We assume that two critically important factors are involved in the present transfection system: compaction of DNA by the polyamine part and with the hydrophobic dialkyl portion and decomposition of the conjugate in the endosome so as to liberate the DNA−polyamine complex to be transported into nucleous. As previously reported, DNA accompanied by cetyl-PEI enters into the nucleus.

In conclusion, we described herein novel types of polyamine−dialkyl phosphate conjugates that have moderate gene transfection activity for the β-galactosidase assay. These conjugates are easy to prepare via a novel synthetic intermediate, dimerized DCP anhydride, **1**. The synthetic approaches described herein are flexible and possess potential for the rationale design of highly efficient gene carriers with single or narrow ranges of molecular weight. It is one of critical aspects for practical usage.

Linear and branched poly(ethylenimines), lPEI and bPEI, respectively, grafted with β-cyclodextrin are prepared to give CD−lPEI and CD−bPEI, respectively, and are investigated as in vitro and in vivo nonviral gene delivery agents. The in vitro toxicity and transfection efficiency are sensitive to the level of cyclodextrin grafting. The cyclodextrin-containing polycations, when combined with adamantane−poly(ethylene glycol) (AD−PEG) conjugates, form particles that are stable at physiological salt concentrations. PEGylated CD−lPEI-based particles give in vitro gene expression equal to or greater than lPEI as measured by the percentage of EGFP expressing cells. Tail vein injections into mice of 120 μg of plasmid DNA formulated with CD−lPEI and AD−PEG do not reveal observable toxicities, and both nucleic acid accumulation and expression are observed in liver.

INTRODUCTION

Cationic polymers have received much attention for their potential use as nonviral gene delivery agents. Under certain conditions, these polymers self-assemble with poly(nucleic acids) via electrostatic interactions and condense them into submicron size particles that can be endocytosed by cells. Polymeric gene delivery vehicles have several advantages over their viral counterparts including nonimmunogenicity, adaptability, and ease of manufacture that make their development of interest for gene therapy applications. However, many polymers used for gene delivery are not suitable for systemic administration due to their toxicity and tendency to aggregate under physiological conditions (*1*).

We have previously demonstrated the use of cyclodextrins (cyclic oligomers of glucose) as building blocks for the preparation of a suite of linear, cyclodextrin-based polycations (CDPs) that have been used for gene delivery (*2*−*9*). Like other polycations, these polymers assemble with plasmid DNA via electrostatic interactions to form small spherical particles with diameters ∼100 nm. The particles are able to transfect cultured mammalian cells and show low toxicity both in vitro and in vivo (*2*−*9*). The importance of the cyclodextrin in mediating low toxicity was demonstrated by the high in vitro toxicity of poly(amidine) polymers lacking cyclodextrins. Although these polymers still transfected cells with high efficiency, their IC_{50}'s were 2−3 orders of magnitude lower than cyclodextrin-based poly(amidine) polymers (*3*, *5*, *9*).

While other polycations show reduced toxicities with sugar and/or other functional group incorporation (*10*−*12*), cyclodextrins are unique entities because they also serve as potential sites for modification via inclusion compound formation. Cyclodextrins are water-soluble, cup-shaped molecules that form inclusion complexes with small, hydrophobic compounds such as adamantane. The ability of cyclodextrins to form inclusion complexes can be utilized to modify the surface of the cyclodextrin-based, DNA-containing particles without interfering with polycation/DNA interactions and particle morphology (*4*, *8*, *9*). For example, adamantane−poly(ethylene glycol) (AD−PEG) conjugates provide salt stability to β-cyclodextrin-based particles (*4*, *9*). The adamantane in the AD−PEG conjugates form inclusion complexes with the β-cyclodextrins that are on the particle surfaces and thus anchor the PEG polymers to the surface to provide a PEG brush layer for particle stabilization. We have demonstrated the use of this inclusion formation technology to provide particle stability, tune particle surface charge, and modify particles with targeting ligands (*9*) such as galactose (*4*) and transferrin (*8*). This modification method utilizes self-assembly for the formulation, allows for great diversity in the types of surface modification, and is easily scalable.

Poly(ethylenimine) (PEI) is a cationic polymer often used in nonviral gene transfer. PEI can provide for efficient, in vitro gene transfer, and this efficiency is speculated to be at least partially due to enhanced endosomal escape via pH-buffering (*13*, *14*). PEI is one of the few polymers where transfection efficiency is not significantly increased by the presence of chloroquine, and this may be because of its mechanism of endosomal release (*15*). Nevertheless, the use of PEI as in vitro and in vivo transfection reagent is severely limited by its toxicity and difficulties in formulation. The LD_{50} of linear PEI (lPEI) is reported to be 4 mg/kg in Balb/C mice (*16*), 50-fold less than the LD_{50} of linear, cyclodextrin-based polymers (at least 200 mg/kg in Balb/C mice (*3*)). Particles formed from the condensation of PEI with poly(nucleic acids) ("PEI-based polyplexes"), like most polyplexes, also

aggregate rapidly in physiological salt conditions. Approaches for improving the stability of PEI-based polyplexes include grafting of PEI with PEG and grafting of preformed PEI-based polyplexes with amine-reactive PEG (*17*, *18*). However, PEI−PEG may not condense DNA into small spherical particles; rodlike and wormlike structures are often instead observed by transmission electron microscopy (*1*). Also, grafting of polyplexes with reactive PEG is difficult to control and scale-up.

The objective of our study is to merge the beneficial qualities of the cyclodextrin-based polymers (low toxicity and the ability to modify the polyplex via inclusion complex formation) with the desirable features of the PEI polymers (efficient transfection). In this work, we describe the synthesis of β-cyclodextrin-grafted PEI (CD−PEI) polymers and their use as in vitro and in vivo nonviral gene delivery media. It is shown here that the transfection and toxicity profiles of the β-CD−PEI polymers are sensitive to the level of cyclodextrin grafting. The resulting polyplexes can be modified and stabilized by adamantane−poly(ethylene glycol) conjugates via inclusion complex formation. This modification creates particles that are formulated at high concentrations without flocculation, are stable in physiological salt concentrations, and are applicable for in vivo, systemic administration. Systemic delivery of plasmids containing the p53 gene with cyclodextrin-containing PEI delivery vehicles show significantly reduced toxicity when compared to PEI-based delivery vehicles in mice. Additionally, p53 gene expression is observed in liver when using cyclodextrin-containing PEI's (unmodified PEI's typically reveal expression in lung).

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Cyclodextrin−PEI Polymers. *Preparation of Cyclodextrin-Grafted Branched PEI (CD−bPEI) (Figure 1a).* Branched $PEI_{25\,000}$ (282 mg, 11.3 μmol, Aldrich, Milwaukee, WI) and 6-monotosyl-β-cyclodextrin (2.18 g, 1.69 mmol, Cyclodextrin Technologies Development, Inc.) were dissolved in 100 mL of various H_2O/DMSO solvent mixtures (Table 1). The resulting solution was stirred at 70 °C for 72 h and then transferred to a Spectra/Por MWCO 10 000 membrane and dialyzed against water for 6 days. The dialyzed solutions were lyophilized to afford a slightly colored solid. Cyclodextrin/PEI ratio was calculated based on the proton integration of ^{1}H NMR and shown in Table 1 (Varian 300 MHz, D_2O) δ 5.08 ppm (s br., C_1H of CD), 3.3−4.1 ppm (m br. C_2HC_6H of CD), 2.5−3.2 ppm (m br. CH_2 of PEI).

Preparation of Cyclodextrin-Grafted Linear PEI (CD−lPEI) (Figure 1b). Linear $PEI_{25\,000}$ (500 mg, 20 μmol, Polysciences, Inc., Warrington, PA) and 6-monotosyl-β-cyclodextrin (3.9 g, 3 mmol, Cyclodextrin Technologies

Development, Inc.) were dissolved in 36 mL of DMSO. The resulting mixture was stirred at 70 °C for 6 days. The solution turned slightly yellow. The solution was then transferred to a Spectra/Por MWCO 10 000 membrane and dialyzed against water for 6 days. Water was then removed by lyophilization to afford a slightly colored solid. Cyclodextrin/PEI ratio was calculated based on the proton integration of ^{1}H NMR (Varian 300 MHz, D_2O) δ 5.08 ppm (s br., C_1H of CD), 3.3−4.1 ppm (m br. C_2H-C_6H of CD), 2.5−3.2 ppm (m br. CH_2 of PEI) and found to be 1 CD: 8.4 amines.

pH-Titration. Each polymer was dissolved to a concentration of 11.7 mM of amines in 150 mM NaCl and titrated with 0.1 N HCl or 0.1 N NaOH (*19*). pH measurements were carried out at 25 °C with a Beckman Coulter pH meter Φ340.

Adamantane−Poly(ethylene glycol) (AD−PEG) Synthesis. AD−PEG was synthesized as described previously (*4*). In brief, PEG_{5000}−SPA (Nektar AL, Huntsville, AL) was reacted with 5 equiv of 1-adamantanemethylamine (Aldrich) in dichloromethane. The solvent was removed in vacuo and water added to the remaining solution. The solution was centrifuged at 15 K rcf for 15 min to precipitate unreacted 1-adamantanemethylamine. The aqueous portion was then dialyzed (Slide-A-Lyzer MWCO 3500 Pierce, Rockford, IL) for 24 h against water and lyophilized to yield a white, fluffy powder in 97% yield.

Cell Culture and Plasmids. PC3 (human prostatic carcinoma) cells were purchased from the ATCC and cultured in DMEM/F12 media containing 10% (v/v) fetal bovine serum containing 100 units/mL penicillin in a 5% CO_2 humidified atmosphere at 37 °C. The pGL3-CV (containing the luciferase gene under the control of the SV40 promoter) and pEGFPLuc (containing the gene coding for an EGFP/luciferase fusion protein under the control of the CMV promoter) plasmids were purchased from Promega (Madison, WI) and Clontech (Palo Alto, CA), respectively, and amplified by Elim Biopharmaceuticals (Hayward, CA).

Formulation and Characterization of CD−PEI/DNA Complexes. *Formulation.* CD−PEI/DNA polyplexes were prepared by adding an equal volume of CD−PEI solution (CD−PEI dissolved in dH_2O) to a plasmid DNA solution (0.1 mg DNA/mL in dH_2O) at the appropriate N/P ratio. PEGylated CD−PEI/DNA polyplexes were prepared by mixing equal volumes (25% of final volume) of CD−PEI and AD−PEG solutions (both dissolved in dH_2O). The CD−PEI/AD−PEG solution was then added to an equal volume of plasmid DNA solution (0.1 mg DNA/mL in dH_2O).

Transmission Electron Microscopy. Polyplexes containing the pGL3-CV plasmid were prepared as described above. Five microliters of sample was then applied to glow-discharged, 400-mesh carbon-coated copper grids for 45 s, after which excess liquid was removed by blotting. The samples were then negatively stained with 2% uranyl acetate for 45 s before observation. Images were recorded using a Philips 201 electron microscope operated at 80 kV.

Salt Stability Study. Two micrograms of pGL3-CV plasmid was formulated with CD−PEI, CD−PEI/AD−PEG, PEI, or PEI/AD−PEG as described above. One sample was diluted by the addition of 1.2 mL of water to determine initial particle size. A second duplicate sample was then diluted by the addition of PBS (pH 7.2) to determine salt stability. Particle size was recorded every minute for 10 min using a ZetaPALS dynamic light scattering detector (DLS, Brookhaven Instruments Corporation, Holtsville, NY).

In Vitro Transfection and Toxicity Assays. *Luciferase Expression.* PC3 cells (human prostate epithelial adenocarcinoma cells from ATCC) were plated at 50 000 cells/well in 24-well plates 24 h before transfection. Immediately prior to transfection, cells in each well were rinsed once with PBS before the addition of 200 μL of Opti-MEM (Invitrogen, Carlsbad, CA) containing polyplexes (1 μg of DNA complexed with polycation at 10 N/P). After 4 h, transfection media was aspirated and replaced with 1 mL of complete media. Forty-eight hours after transfection cells were washed with PBS and lysed by the addition of 100 μL of Cell Culture Lysis Buffer (Promega, Madison, WI). Cell lysates were analyzed for luciferase activity with Promega's luciferase assay reagent. Light units were integrated over 10 s with a luminometer (Monolight 3010C, Becton Dickinson).

Toxicity. The IC_{50}'s of the various polymers to PC3 cells were determined by MTT assay as described previously (*3*). All experiments were conducted in triplicate and averaged. Average absorbance was plotted versus polymer concentration and IC_{50} values were determined by interpolation.

Plasmid Delivery. PC3 cells were plated at 1 000 000 cells/well in six-well plates. After 24 h, the cells were exposed to 5 μg of fluorescently labeled plasmid (pEGFPLuc plasmid labeled with YOYO-1 (Molecular Probes, Eugene, OR) at a density of 1 dye molecule per 100 bp DNA) complexed with polymer at 10 N/P in 1 mL of OptiMEM (Gibco, Carlsbad, CA). Fifteen minutes after initial exposure, the polyplex-containing, culture media was aspirated. Cells were washed with PBS, Cell Scrub buffer (Gene Therapy Systems, San Diego, CA), trypsinized, and analyzed by flow cytometry for the uptake of the polyplexes.

EGFP Expression. PC3 cells were plated at 250 000 cells/well in six-well plates. After 48 h, the cells were transfected with 5 μg of pEGFPLuc plasmid assembled with polymer at 10 N/P in 1 mL of OptiMEM (for some samples, OptiMEM containing 100 μM chloroquine was added). Four hours after transfection, the culture media was removed and replaced with 5 mL of complete media. Cells were washed with PBS, trypsinized, and analyzed by flow cytometry for EGFP expression 48 h after transfection.

In Vivo Experiments. Tolerability was evaluated in immune competent female Balb/c mice. Animals were injected with the various formulations into the tail vein using a 0.4 mL volume and an injection speed of approximately 0.2 mL/15 s. Animals were sacrificed at 24 h after treatment by carbon dioxide euthanasia. Blood was collected by heart-puncture into sodium citrate containing tubes (platelets and white blood cell (WBC) counts) and serum tubes (transaminases, creatinine). Platelets and WBC counts were evaluated at Biomedical Testing Services Inc., and transaminases (ALT/AST) and creatinine using a Cobas Mira (Roche) autoanalyzer. Livers and lungs were collected, formalin fixed, sections H & E (hematoxilin (stains nucleus) and eosin (stains cytoplasm)) stained, and pathologically examined.

Tolerability and transgene expression were evaluated in immune-compromised female nude mice bearing subcutaneous PC3 tumors. Tumors were established by injecting 1×10^7 PC3 cells in a volume of 0.2 mL subcutaneously in the left flank of animals. Tumors were grown to an average size of 100 mm^3 before treatment. Animals were injected with complexes intravenously into the tail vein using a 0.4 mL volume and an injection

speed of approximately 0.2 mL/15 s. Animals were sacrificed at 24 h after treatment and blood and serum collected as described above. Organs were collected into identically sized aluminum foil, weighed, and snap-frozen in liquid nitrogen for PCR/RT-PCR analysis.

Quantitative PCR and RT-PCR (QPCR, QRT-PCR) were used to quantify p53 DNA and transgene expression as previously described (*20*). Briefly, DNA and RNA were coextracted from approximately 100 mg of tissue using Tri-reagent (Molecular Research Center, Inc., Cincinnati, OH). Purified RNA was DNased and complete removal of DNA was confirmed by PCR. QPCR/QRT-PCR was performed using the ABI 7900 sequence detector (Applied Biosystems, Inc., Foster City, CA). Rodent GAPDH DNA and RNA were used as internal controls to assess the quality of purified RNA and DNA and to ensure equal amounts of sample input. Primer and probe sequence used for QPCR and QRT-PCR were as follows: p53; forward primer 5′-AACGGTACTCCGCCACC-3′, reverse primer 5′-CGTGTCACCGTCGTGGA-3′ and probe FAM-CAGCTGCTCGAGAGGTTTTCCGATCC-TAMRA. GAPDH; forward primer, 5′-ACGTGCCGCCTGGAGAA-3′, reverse primer, 5′-CATGAGGTCCACCACCCTGTT-3′ and probe FAM-ATGACATCAAGAAGGTGGTGAAGCAGGC-TAMRA.

Tissue matched p53 standards were used to quantify p53 DNA levels in tissues as described previously (*21*). To generate the standardards, briefly, liver, kidney, lung and tumor were collected from naïve animals. Tissues were minced thoroughly and aliquoted into several 100 mg samples. Six to eight 10-fold serially diluted samples of p53 plasmid, ranging from 1.0×10^3 to 1×10^9 particles, were spiked into each aliquot. p53-spiked tissue aliquots were extracted and processed for QPCR in a manner identical to the test samples, generating standard curves for each type of tissue. Standard curves were used to estimate the number of p53 DNA in test samples, which were expressed as genome equivalent fg per mg of tissue. p53 mRNA was quantified using rAd-p53 cRNA as reported previously (*20*) and was expressed as copies/mg of tissue.

RESULTS

Synthesis and Characterization of CD−bPEI and CD−lPEI Conjugates. β-Cyclodextrin-grafted poly(ethylenimines) (CD−PEI's) were synthesized by reaction of mono-tosylated cyclodextrins with the primary and secondary amines of poly(ethylenimine) using a protocol similar to that described by Suh et al. (Figure 1) (*22*). This synthesis approach resulted in cyclodextrin conjugation to both branched and linear PEI (denoted here as CD−bPEI and CD−lPEI, respectively). The degree of CD substitution was determined by integration of the appropriate ^{1}H NMR spectra and was found to depend on the amount of water in the reaction solvent. This effect was expected since the tosyl activating group is readily hydrolyzed by water. A series of CD−bPEI polymers with varying degrees of CD substitution (ranging from 5% to 16% amine substitution) were synthesized by changing the water to DMSO solvent ratio (Table 1). The transfection efficiency and toxicity of these various polymers were measured as described below to determine the synthesis conditions necessary for the best in vitro gene delivery behavior. CD−lPEI was also prepared following a similar protocol.

Effect of CD-Grafting on Transfection and Toxicity of bPEI. The CD−bPEI polymers were formulated with pGL3-CV at charge ratios ranging from 2 N/P (amine to phosphate) to 20 N/P and exposed to PC-3 cells plated in 24-well plates. The cells were lysed and analyzed for gene expression 48 h after transfection. Luciferase expression was detected at 4 N/P for all polymers and increased with charge ratio until toxicity was observed (generally around 15 N/P; results not shown). A comparison of transfection efficiency at 10 N/P as a function of CD grafting is shown in Figure 2. Luciferase activity is not normalized by total cell protein levels (RLU/mg) because this practice gives artificially high values for samples with low protein levels resulting from polymer toxicity. Instead, total luciferase activity per sample (RLU/well) is reported with polymer toxicity analyzed separately.

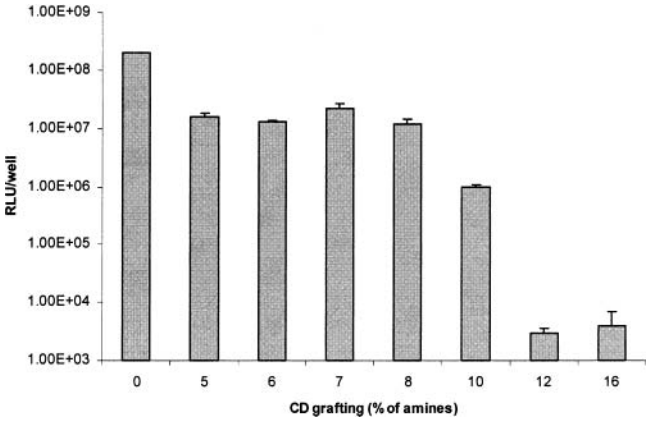

Figure 2. Effect of cyclodextrin grafting on CD−bPEI transfection efficiency to PC3 cells. CD−bPEI polymers were complexed with pGL3-CV plasmid at 10 N/P to form polyplexes for transfection. Luciferase activity was measured 48 h after transfection and reported as mean RLU/well ± SD for three replicates. Error bar on 0% CD grafting is too small to be observed.

Grafting of CD to bPEI reduces transfection efficiency. Modification of only 5% of the bPEI amines decreases luciferase activity by 1 order of magnitude (2×10^8 RLU/well for bPEI vs $(1-2) \times 10^7$ RLU/well for CD−bPEI with 5% to 8% amine grafting). CD grafting level is correlated with lower transfection; 10% amine modification results in a 2 orders of magnitude decrease in transfection to 1×10^6 RLU/well, and 16% amine modification reduces luciferase activity by over 4 orders of magnitude to 5×10^3 RLU/well.

The toxicities of bPEI and the CD−bPEI polymers were determined by comparing the IC_{50} values of the polymers with PC3 cells as measured by the MTT assay (Figure 3). PC3 cells were plated in 96-well plates and exposed to serially diluted concentrations of the polymers. The cells were then assayed for cell viability 24 h after initial polymer addition and IC_{50} values calculated by interpolation. All IC_{50} values are reported as ethylenimine monomer concentrations. The IC_{50} values of CD−bPEI polymers are proportional to the extent of cyclodextrin grafting. At lower grafting percentages, polymer IC_{50}'s are 2- to 5-fold higher (CD−bPEI IC_{50} of 0.64 mM and 1.45 mM for 5% and 8%, respectively, compared with bPEI's IC_{50} of 0.28 mM). High levels of cyclodextrin grafting increases IC_{50} values by over 20-fold (4.8 mM for 12% grafting and 6.7 mM for 16% grafting).

On the basis of the transfection and toxicity data, the CD−bPEI with 8% amine modification was chosen as the polymer with the best in vitro transfection and tolerability characteristics. This CD−bPEI polymer was used in the experiments described below. A similar synthesis procedure was used to prepare CD−lPEI (with 12% CD

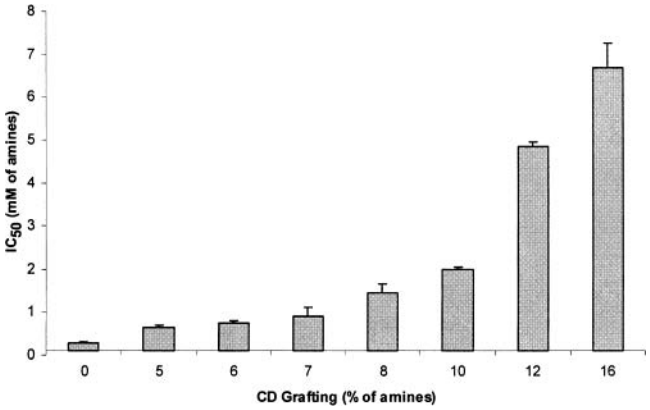

Figure 3. Effect of cyclodextrin grafting on CD−bPEI toxicity to PC3 cells. Polymers were exposed to PC3 cells in serial dilutions for 24 h. Cells were then assayed for viability by MTT assay. The IC_{50}'s, reported as ethylenimine monomer concentrations, were determined by interpolation on a best-fit line and reported mean values ± SD for three replicates.

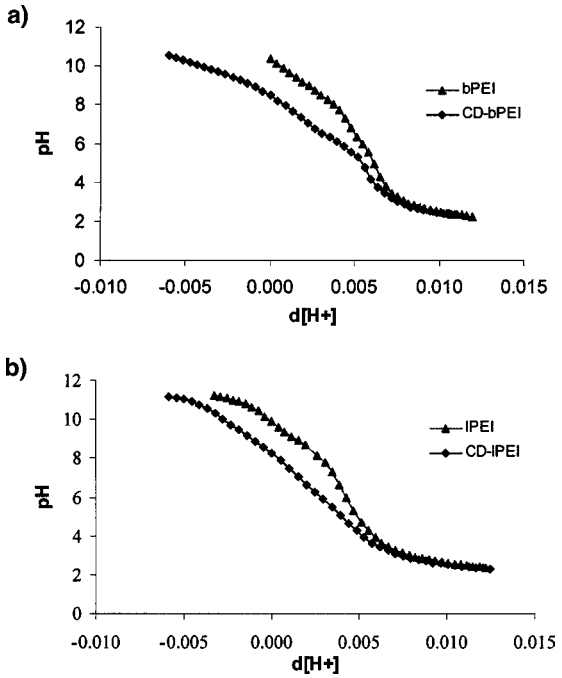

Figure 4. Acid/base titration curves for bPEI, lPEI, CD−bPEI, and CD−lPEI polymers. The value reported on the *x*-axis is the change in concentration of hydrogen ion required to achieve the pH indicated on the *y*-axis. (a) bPEI and CD−bPEI; (b) lPEI and CD−lPEI.

modification). Cyclodextrin modification of lPEI reduced polymer toxicity. The IC_{50} for lPEI was increased by severalfold by cyclodextrin grafting (0.38 mM for lPEI compared with 0.92 mM for CD−lPEI; all IC_{50}'s determined in triplicate and averaged). This CD−lPEI was also used in subsequent experiments. The titration curves of the CD−bPEI (8% amine modification), CD−lPEI (12% amine modification), and the unmodified bPEI and lPEI polymers are shown in Figure 4.

Salt Stabilization of CD-PEI Polymers by AD−PEG. CD−bPEI and CD−lPEI polymers self-assemble with and condense plasmid DNA to small spherical particles with average diameters ranging from 100 to 160 nm (not shown), as measured by dynamic light scattering (DLS). The particles can be PEGylated by the addition of AD−PEG_{5000} (poly(ethylene glycol) conjugated to adamantane). The adamantanes form inclusion complexes with the cyclodextrins on the surface of the particles, resulting in particle PEGylation (Figures 5a and 5b). PEGylation does not significantly affect particle size or particle morphology (Figures 5c and 5d). The PEGylated particles, like the unmodified particles, are predominately spherical in structure.

Table 2. Blood Chemistry Data

	nude mice		Balb/c mice	
blood parameter	D5W[a]	CD−lPEI + AD−PEG[b]	untreated	CD−lPEI + AD−PEG[b]
ALT (U/L)[c]	38	32	25	29
AST (U/L)[d]	60	53	45	75
Balb/c mice platelets (/mL)[e]	1175	1458	1335	624
WBC (/mL)[f]	12.5	9.6	7.4	6.4
CRE (mg/dL) [g]	n/a	n/a	0.8	0.9

[a] D5W: 5 wt % dextrose solution used as control. [b] Particles formulated with CD−lPEI + AD−PEG and plasmid DNA (120 μg). Average particle diameter was 117 nm. [c] Alanine aminotransferase (ALT). [d] Aspartate aminotransferase (AST). [e] Platelet count per milliliter. [f] White blood cell count per milliliter. [g] Creatinine.

Salt stability of the unmodified and PEGylated CD−PEI particles was tested by formulating the particles in a small volume of water (40 μL), adding 1.2 mL of PBS (150 mM salt concentration), and immediately monitoring average particle size by DLS with recorded measurements every minute for 10 min. All samples were run in triplicate and averaged for each time point. Figure 6 shows particle diameter versus time in salt solution for each type of formulation. All unmodified polyplexes aggregate in salt solutions. The addition of AD−PEG at 1 AD to 1 CD ratio reduces aggregation rate by forming a protective hydrophilic PEG brush layer on the particle surface. Complete particle stabilization is obtained by formulation with AD−PEG at 2 AD:1 CD (not shown). AD−PEG addition to bPEI and lPEI polyplexes does not stabilize the particles.

Plasmid Uptake with CD−PEI Polymers. CD−bPEI, CD−lPEI, bPEI, and lPEI were complexed with fluorescently labeled plasmids at 10 N/P and exposed to PC-3 (human prostatic carcinoma) cells for 15 min. The cells were then washed with PBS and Cell Scrub Buffer (to remove surface-associated polyplexes), trypsinized, and analyzed for polyplex uptake by flow cytometry. Uncomplexed plasmids were not readily taken up by cells (<1% cells YOYO-1 positive). lPEI and bPEI mediated plasmid uptake to PC3 cells (Figure 7). CD−lPEI and CD−bPEI both demonstrated higher plasmid uptake than the unmodified PEI polymers (Figure 7). The addition of AD−PEG to either CD-containing polymers did not impede plasmid uptake (Figure 7).

Comparison of Plasmid Delivery Efficiencies. The in vitro transfection efficiencies of the CD−PEI polymers were determined by delivery of the EGFP plasmid to PC3 cells with analysis by flow cytometry. Cyclodextrin grafting to the PEI's did not reduce transfection efficiencies from the parent PEI's (Figure 8). Addition of AD−PEG did not practically lower transfection with CD−lPEI but significantly lowered the number of expressing cells with CD−bPEI (Figure 8).

Chloroquine is an endosomal buffering agent often used to enhance nonviral transfection efficiency. When transfections were conducted in the presence of 100 μM chloroquine, CD−PEI-mediated transfection increased in the presence and absence of AD−PEG (Figure 8). In contrast, bPEI and lPEI did not benefit from chloroquine addition as has been reported in the literature.

In Vivo Experiments. Table 2 lists the results obtained from blood analyses. Balb/c mice tolerated the

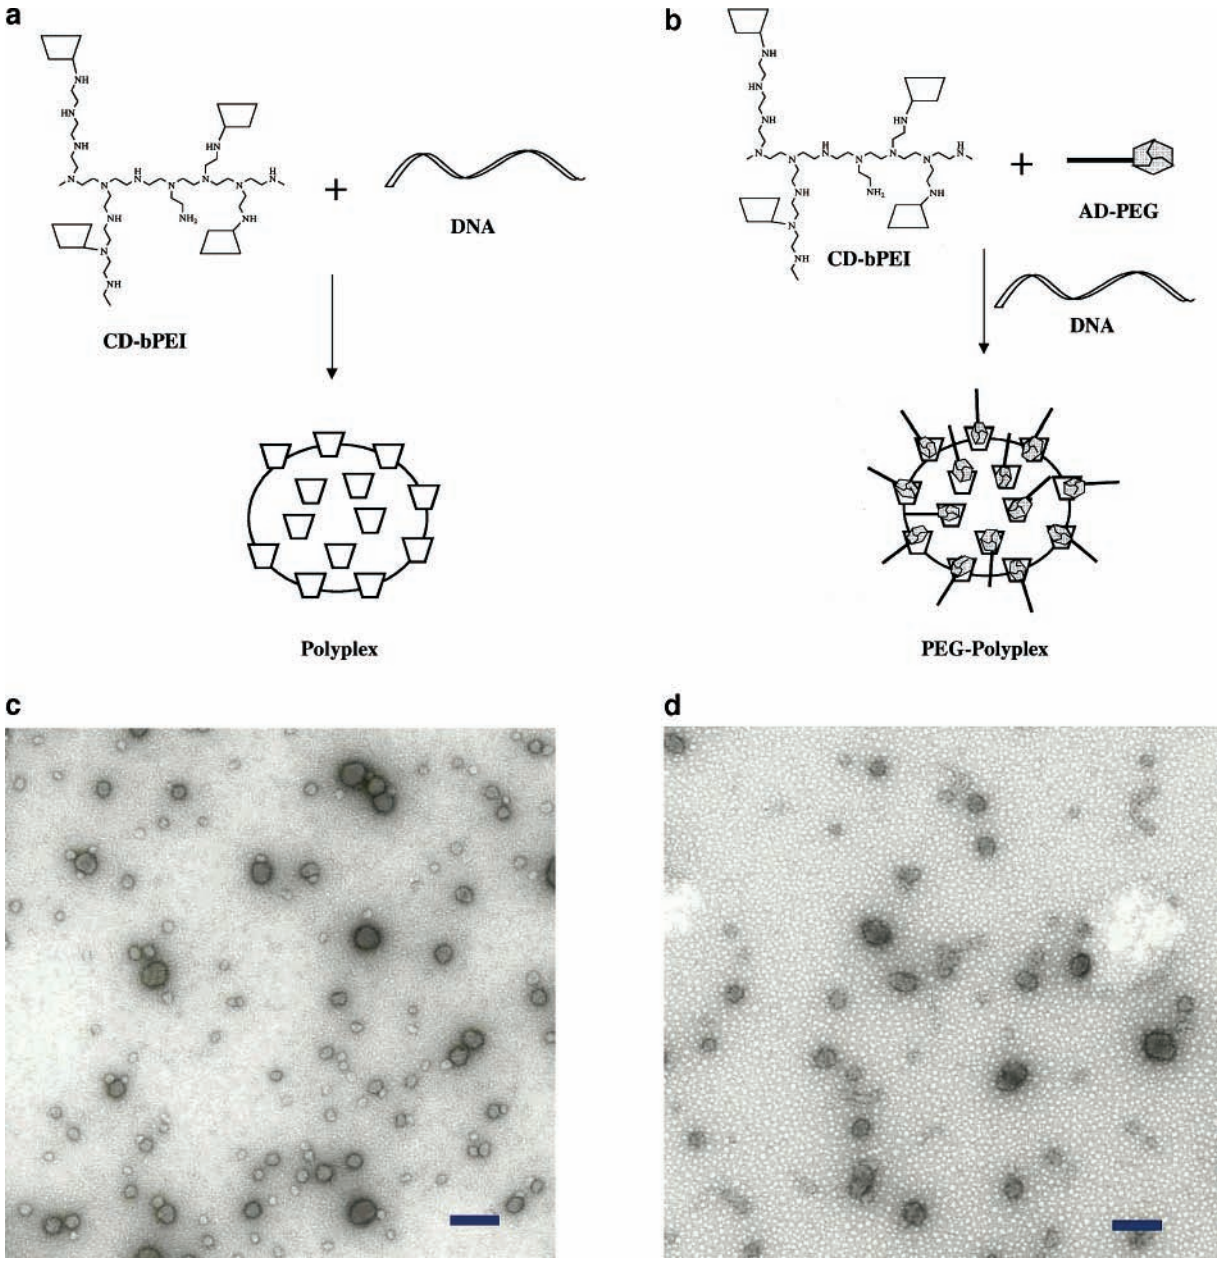

Figure 5. Schematics and electron micrographs of CD−bPEI (a and c) and PEGylated CD−bPEI polyplexes (b and d). Polyplexes were negatively stained with uranyl acetate and images recorded using a Philips 201 electron microscope. Bar represents 200 nm.

treatment well, and, with the exception of platelets, no significant difference in any blood parameter was seen between treated and untreated animals. Specifically, no liver toxicity as indicated by elevated liver enzymes (ALT/AST) or kidney toxicity as indicated by elevated creatinine levels was observed. Platelets dropped to approximately 50% of untreated animals, a phenomenon not observed in nude mice. Additionally, in a histological evaluation, liver and lung tissue sections appeared to be essentially normal, with no necrosis or excessive lymphoid infiltrates observed (Figure 9). These are common toxicities associated with intravenous delivery of lPEI−DNA complexes (*16*).

Nude mice tolerated the treatment equally well; no significant differences in any blood parameter was measured between the CD−lPEI + AD−PEG particles and a D5W control (Table 2). The biodistribution of the p53 plasmid was measured by PCR in three animals that each received a 120 μg dose of plasmid delivered in particles containing CD−lPEI + AD−PEG. At 24 h postinjection, the liver, kidney, and lung had $4.6 \pm 2.1 \times 10^7$, $1.9 \pm 1.3 \times 10^3$, and $4.2 \pm 1.4 \times 10^4$ fg p53/mg tissue, respectively (tumor of treated animals and all tissues of D5W controls were below quantitation limits). Additionally, expression of p53 (mRNA expression measured by RT-PCR) was only observed in liver ($0.9 \pm 0.4 \times 10^4$ copies of p53 mRNA/mg tissue).

DISCUSSION

β-Cyclodextrin-grafted poly(ethylenimine) polymers were synthesized by reaction of a mono-tosylated cyclodextrin with PEI amines in an effort to impart the advantageous properties associated with cyclodextrins (low toxicity, high water solubility, inclusion complex formation ability) to PEI (Figure 1). Reaction via nucleophilic substitution is preferred for several reasons. First, grafting density can be easily controlled and high grafting levels (up to 16%) are readily obtained. Second, the activated cyclodextrins react with both primary and secondary amines; therefore, CD−lPEI can also be syn-

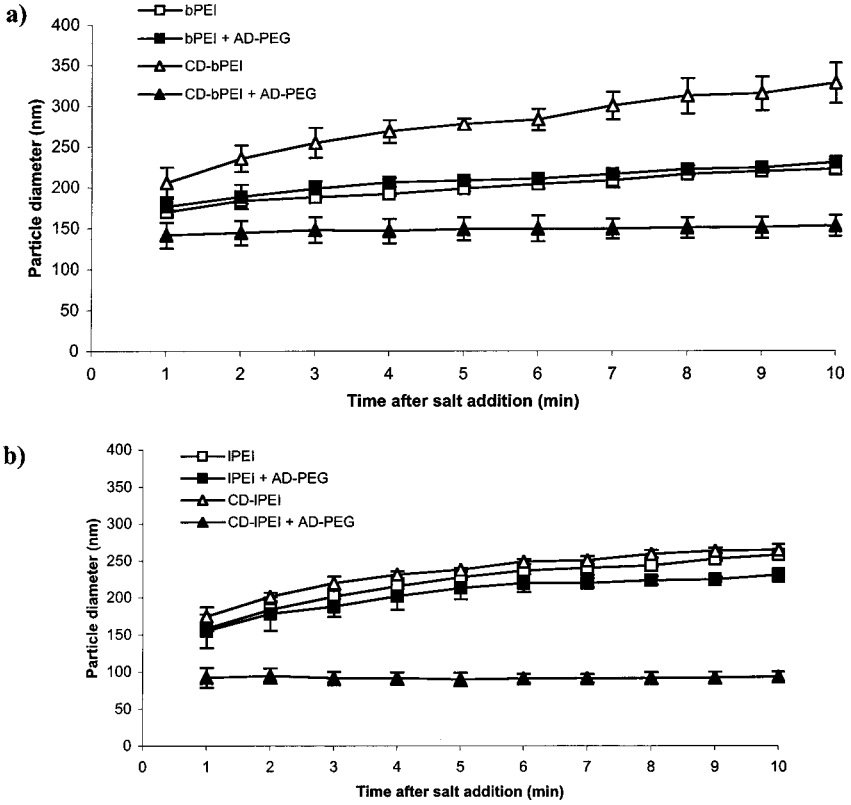

Figure 6. Salt stabilization of PEGylated CD−PEI polyplexes. Polyplexes were prepared at 10 N/P in 40 μL of water. PBS, pH 7.2. (1.2 mL), was then added and particle size monitored by dynamic light scattering for 10 min after salt addition. All measurements were conducted in triplicate and averaged for each time point. Particle diameters were measured as a function of time. (a) bPEI and CD analogues; (b) lPEI and CD analogues.

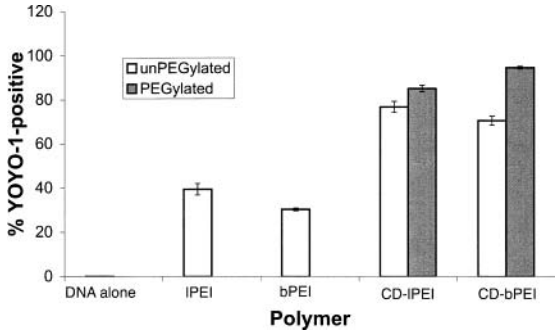

Figure 7. Comparison of plasmid uptake efficiencies of PEI and CD−PEI polymers. Polymers were complexed with YOYO-1-labeled plasmids at 10 N/P and exposed to PC3 cells for 15 min. Cells were washed with PBS and Cell Scrub buffer to remove surface-associated particles and analyzed for polyplex uptake by flow cytometry. Each value represents the mean ± SD of three experiments.

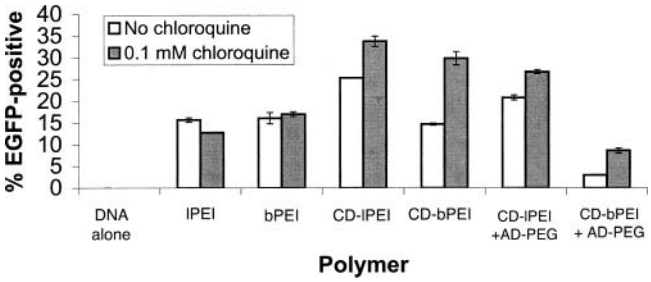

Figure 8. Comparison of transgene expression from PEI and CD−PEI polymers in the presence or absence of 0.1 mM chloroquine. Polymers were complexed with pEGFPLuc at 10 N/P and exposed to PC3 cells for 4 h in the presence and absence of 0.1 mM chloroquine. Cells were analyzed for EGFP expression by flow cytometry 48 h after initial transfection. Each value represents the mean ± SD of three experiments.

thesized. Finally, unlike reaction by reductive amination, this conjugation approach leaves the cyclodextrin intact and available for inclusion complex formation.

A series of CD−bPEI polymers with levels of CD grafting ranging from 5% to 16% of the PEI amines were synthesized (Figure 1, Table 1). The effect of CD grafting on the in vitro transfection efficiency and toxicity of CD−bPEI was determined by luciferase expression using transfection and MTT assays, respectively. Although all CD−bPEI polymers transfected PC3 cells, the efficiency was reduced as the CD grafting increased (Figure 2). At higher levels of CD grafting, dramatic reductions (up to 4 orders of magnitude) in luciferase expression were observed. Because all polymers condensed DNA to similar-sized particles (~100−160 nm), the CDs are unlikely interfering with DNA association and protection. Rather, high levels of CD conjugation may reduce endosomal release efficiencies by changing the pK_a profile of the PEI amines. Suh et al. report that the amines of CD-grafted dendrimer poly(ethylenimines) have substantially lower pK_a's than the parent polymers, requiring more acidic conditions for protonation (*23*). Cyclodextrin-modified PEI's possess substantially reduced buffering capacities from the unmodified PEI polymers (Figure 4). Because the high transfection efficiency of PEI is attributed to the buffering ability of the secondary amines in the acidic endosomes, any substantial shifts in the secondary amine pK_a is therefore likely to hinder or eliminate this endosomal release ability, thereby also reducing transfection efficiency.

Cyclodextrin grafting to bPEI also reduces polymer toxicity (Figure 3). Polymers with higher CD grafting densities have increased IC_{50}'s over the unmodified bPEI. For example, the IC_{50} of CD−bPEI with 16% grafting is

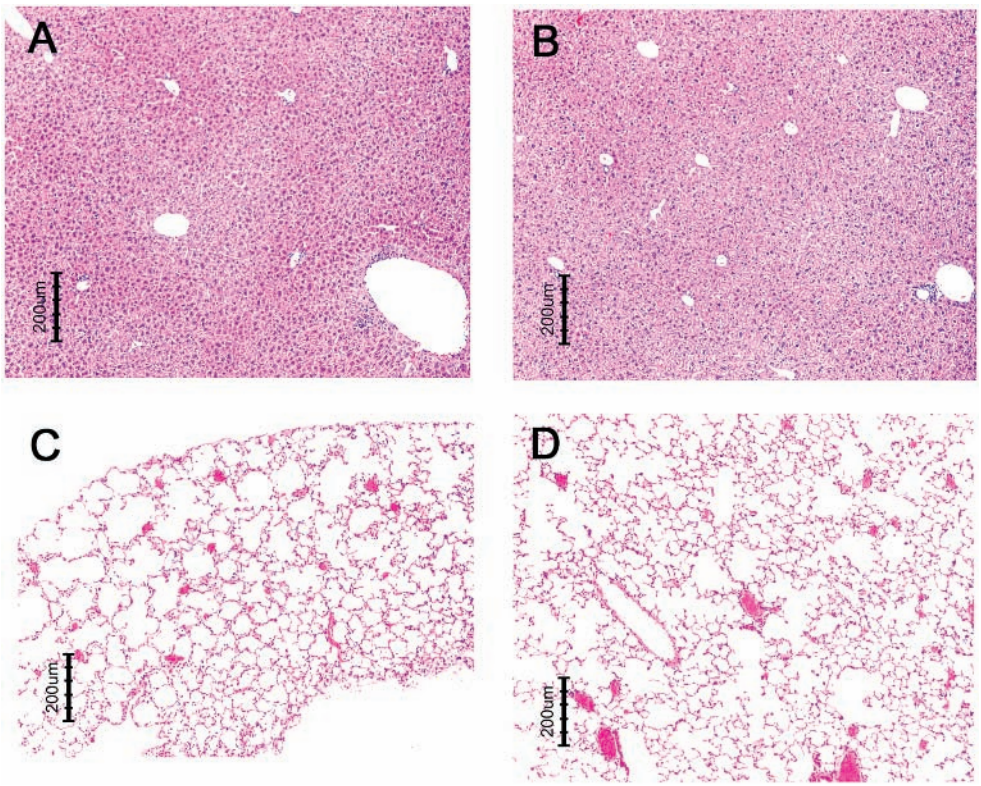

Figure 9. H&E stained tissue sections from nude mice treated with 120 μg of plasmid DNA formulated with CD−lPEI + AD−PEG. (A) Liver of treated animal; (B) liver of untreated animal; (C) lung of treated animal; (D) lung of untreated animal.

6.7 mM (concentration of amines), over 20-fold higher than bPEI (0.28 mM). The cyclodextrin grafting could reduce polycation toxicity by increasing polymer solubility, by capping primary amines, or by reducing binding affinity. Hydrophobic polymers tend to impart higher cell toxicity. Previous structure/function studies with other CD-polymers revealed reduced IC_{50}'s with less water-soluble polymers (*3*, *4*−*7*, *9*). Cyclodextrins are highly water soluble molecules, and linear, CD-containing polymers have very high water solubility. Indeed, the CD−bPEI-based polyplexes have higher critical flocculation concentrations than bPEI-based polyplexes. The CD-monotosylates also react with PEI primary amines. Lipids containing primary amines have been reported to disrupt PKC function, causing cell toxicity (*24*). One proposed mechanism of polycation toxicity has been interference with protein kinase activity after internalization. Removal of the primary amines may therefore reduce polymer toxicity if at least a portion of the toxicity is from this mechanism. PEI derivatives prepared by chemical modification of the nitrogen atoms, including galactosylated, mannosylated, and acetylated PEI synthesized by reactions with primary amines, have also demonstrated reduced toxicity over the parent polymers (*10*−*12*). CD−PEI may have decreased toxicity in a similar fashion. Cyclodextrin grafting can also mediate lower toxicity by decreasing nonspecific binding of PEI with proteins or cellular structures. In addition to converting primary amines to secondary amines, cyclodextrins are also large, bulky molecules that can sterically reduce nonspecific binding affinities.

It is interesting to note that Uekama and colleagues have noticed the opposite effect of cyclodextrin grafting on cyclodextrin-dendrimer conjugates (*25*, *26*). Their initial study demonstrated that α-, β-, and γ-cyclodextrin conjugation to polyamidoamine dendrimers increases transfection efficiency, with the proposed mechanism of enhancing endosomal release (*25*). α-Cyclodextrin-dendrimers were found to have the highest transfection efficiency and a subsequent paper focusing on these dendrimers reports increased transfection and toxicity with higher cyclodextrin substitution (*25*).

The best CD−bPEI for plasmid delivery was determined to have 8% PEI amine grafting. Similarly, the best CD−lPEI was synthesized with 12% grafting. The abilities of these polymers to complex and deliver nucleic acids were compared with bPEI and lPEI. CD−bPEI and CD−lPEI spontaneously condense plasmid DNA to small, spherical particles (Figure 5). Although polycation/DNA complexes can be reproducibly formulated with spherical morphologies in water solutions, complexes aggregate rapidly in the presence of salt. This rapid aggregation, along with serum protein or platelet interactions, can cause death in vivo by blockage of lung capillaries (*16*). For systemic administration, a vital concern is the stabilization of these polyplexes. We have demonstrated previously a particle modification approach based on inclusion complex formation between adamantane and cyclodextrin (*4*, *8*, *9*). Here, this methodology is extended to stabilize CD−PEI polyplexes against salt-induced aggregation. A solution of AD−PEG (at a 2 AD:1 CD ratio) was added to DNA to formulate stabilized particles. The adamantane assembles inside the CD cup, leaving the PEG to form a protective brush layer on the particle surface (Figure 5b). Polyplex morphology is not significantly changed by this method of PEGylation (Figures 5c and 5d). Particle stabilization by PEGylation was assessed by monitoring particle size in salt solutions as a function of time. Without PEGylation, PEI and CD−PEI polyplexes aggregate upon exposure to ionic solutions (150 mM strength), as indicated by the increase in particle diameter measured by light scattering (Figure 6). These polyplexes have high zeta potentials (∼30−40 mV, not shown). The addition of AD−PEG to PEI

particles does not prevent aggregation because the PEG remains free in solution, unable to associate with the particles. AD−PEG is able to stabilize CD−bPEI and CD−lPEI particles (zeta potentials ∼10 mV, not shown) by forming inclusion complexes with surface available cyclodextrins (Figure 6). The PEGylated particles completely form by self-assembly (electrostatic interactions between CD−PEI and DNA, guest−host hydrophobic interactions between adamantane and cyclodextrin) and can be formulated under several conditions. For example, stable particles can be prepared at a wide range of concentrations and volumes and with different formulation orders. Our preferred method involves first mixing the AD−PEG and CD−PEI polymers and then adding the solution to DNA because this procedure allows for particles to be formulated at high concentrations (if AD−PEG is added to preformed polyplexes, the concentration is limited by the critical flocculation concentration of the polyplexes).

The best CD−PEI polymers were tested for their ability to deliver plasmids to cultured cells (Figure 7). The labeled plasmids were complexed with PEI and CD−PEI polymers and exposed to PC3 cells for 15 min. Surface-associated polyplexes were removed, and DNA uptake was analyzed by flow cytometry. CD−PEI polymers deliver plasmids with higher efficiency than the parent PEI polymers (75% CD−lPEI vs 40% for lPEI and 70% for CD−bPEI vs 30% for bPEI). Additionally, PEGylation does not impede the uptake of CD−PEI delivery vehicles.

The transfection efficiencies of the CD−PEI polymers were compared to their parent PEI's by using the expression of EGFP (analysis by flow cytometry) in PC3 cells. lPEI and bPEI show approximately 15% EGFP positive cells, and this amount is not changed by the addition of chloroquine (Figure 8). These data are very consistent with literature reports. CD−bPEI reveals the same transfection results as bPEI in the absence of chloroquine, but in its presence, shows significantly enhanced transfection (Figure 8). CD−lPEI gives better expression than lPEI in both the presence and absence of chloroquine (Figure 8). It is possible that the greater than or equal to transfection of the CD−PEI's compared to the parent PEI's is due to their increased uptake (Figure 7). Of interest is the fact that chloroquine significantly enhances the transfection with the CD−PEI's while it does not with the parent PEI's, indicating that there are differences in the intracellular behaviors of the CD-containing and parent PEI's. While recent evidence does support the "proton sponge hypothesis" for enhanced transfection using polycation−DNA polyplexes containing proton buffering polyamines (*27*), it is likely that it is not the only factor contributing to the transfection efficiencies of PEI (*28*, *29*). Itaka et al. suggest that both lPEI and bPEI complexes rapidly escape endosomes but that the lPEI dissociates more readily from the plasmid DNA to enhance gene expression (*29*). The PEGylation of the CD−PEI delivery vehicles produces a reduction in the transfection, expecially for the CD−bPEI. Mishra et al. have shown that PEI-based polyplexes aggregate in culture media, enter cells as aggregates, and have high expression while PEGylated PEI-based particles enter cells as individual particles and give lower gene expression (*30*). It is most likely that the PEGylated CD−PEI particles are not aggregating prior to cell uptake as opposed to either unPEGylated CD−PEI- or PEI-containing polyplexes (Figure 6). Of significance is the observation that the PEGylated CD−lPEI particles can provide good transfection in the absence of chloroquine. This formulation has several desirable features for in vivo use: (i) reduced toxicity, (ii) stable in physiologic salt solutions, and (iii) good transfection efficiencies. This formulation was investigated in mice.

The low toxicity of the CD−PEI delivery particles compared to the PEI-based particles obtained from in vitro experiments was also observed in vivo. Tail vein injections in mice of up to 120 μg of DNA formulated with CD−lPEI + AD−PEG did not produce any acute toxicity. lPEI−DNA polyplexes at this dose are lethal to mice (*16*). Additionally, numerous blood chemistries (Table 2) suggest that this dose of CD−lPEI + AD−PEG + DNA is well tolerated. PEI−DNA complexes administered iv cause liver necrosis as well as red bood cell adhesion in the lung (*16*). Balb/c mice treated with CD−lPEI + AD−PEG did not show any of these symptoms and organs essentially looked normal (Figure 9). When lower doses of PEI−DNA are injected into the tail vein of mice, the main organ accumulating the DNA is the lung (*16*, *31*). This is likely due to aggregation of the polyplexes and their capture by the lung microvasculature. With PEGylated CD−lPEI−DNA particles, the aggregation rate is substantially reduced and they primarily accumulate in liver as opposed to lung (4 orders-of-magnitude larger amount in liver than lung). Additionally, gene expression is observed in the liver and is below detection limits in all other organs. Thus, the CD−lPEI + AD−PEG + DNA delivery vehicle provides an avenue for liver gene expression from a systemic administration.

Self-Assembling Nanocomplexes from Insulin and Water-Soluble Branched Polyesters, Poly[(vinyl-3-(diethylamino)-propylcarbamate-*co*-(vinyl acetate)-*co*-(vinyl alcohol)]-graft-poly(L-lactic acid): A Novel Carrier for Transmucosal Delivery of Peptides

M. Simon,[†] M. Wittmar,[†] U. Bakowsky,[‡] and T. Kissel*[,†]

Received September 9, 2003; Revised Manuscript Received May 6, 2004

The design of carriers for protein delivery that provide protection against enzymatic degradation and facilitate protein transport across epithelial surfaces, thus avoiding parenteral administration, remains a challenge. Self-assembling nanoscale protein/polymer complexes might present a promising approach. We synthesized water-soluble, amphiphilic polyesters, poly[(vinyl-3-(diethylamino)-propylcarbamate-*co*-(vinyl acetate)-*co*-(vinyl alcohol)]-graft-poly(L-lactic acid), containing a positively charged backbone, and studied the spontaneous formation of nanocomplexes (NC) with insulin. NC were characterized using dynamic light scattering, zeta-potential measurements, and atomic force microscopy (AFM). Insulin loading was determined with HPLC, and the binding constants were obtained by isothermal titration calorimetry (ITC). The NC formation was followed using nephelometric and light scattering techniques. Water-soluble, positively charged, branched polyesters with amphiphilic properties were obtained in a three-step polymer-analogous reaction. The degree of amine substitution, DS, in the PVAL backbone was varied between 0.04 and 0.5, and grafting this backbone with L-lactide increased the molecular weight from 18 kDa to 81 kDa. The polymer composition was optimized to facilitate NC formation with insulin resulting in a DS of 0.09 and a poly(L-lactide) side chain substitution of 0.5 with an average chain length of two lactic acids. Depending on polymer composition, stable NC of 200−500 nm diameter were formed with insulin, and the binding constants ranged from 4.7×10^5 to 9.5×10^6 M^{-1}. Positively charged surface charges ranging from +5 to +35mV and an insulin loading up to 98% of 33 IU/mL were obtained. The NC visualized by AFM revealed spheroidal particles with an entangled internal structure. It was demonstrated that this class of multifunctional polymers is capable of self-assembly with a peptidic substrate. The resulting nanosized complexes offer the potential for mucosal insulin/protein delivery and merit further investigations under in vivo conditions.

INTRODUCTION

Diabetes mellitus is the most common of the serious metabolic diseases and prevalence in Western societies is estimated to be about 1%. Long-term complications involving the eyes, kidneys, nerves, and blood vessels present a heavy burden for the health care system in western societies. The intensified insulin therapy for diabetic patients requires up to four subcutaneous injections per day to maintain adequate control of serum glucose levels. Compliance with such demanding dosing regimes is difficult for the patient and make the development of an alternative form of insulin administration clearly appealing.

Numerous attempts to deliver insulin by application routes avoiding injections have been reported in the literature. Peroral, pulmonary, and nasal insulin administrations fall into this category, but enzymatic lability and inefficient transport across mucosae provide formidable challenges and lead to low and variable bioavailabilities (*1*). The intranasal route is most attractive for chronic administration of peptides and proteins (*2*). However, nasal insulin absorption is low without coadministration of absorption enhancers which open the epithelial barrier and/or prolong the residence time in the nasal cavity. Promoters such as bile salts, chelating agents, or the surfactant laureth-9 have shown undesirable toxic side effects after chronic administration (*3*).

Proteins delivery systems relying on complexation and assembly of proteins with amphiphilic polymers could present an alternative to the absorption enhancers described above. These polymers form nanoscale complexes with proteins through electrostatic and van der Waals interactions, protecting them against loss of biological activity and increasing their transmucosal uptake. Several polymers such as chitosan (*4*), poly(glutamine) (*5*), poly(ethylenimine-*co*-polyester) (*6*), AB block-copolymers, e.g., PEO−poly(L-lysine) (*7*) or PEO−PLGA (*8*), polyacrylates (*9, 10*), or poly(L-lysine) derivates (*11*) have been proposed for insulin delivery.

Nanoscale delivery systems with strong bioadhesive properties seem to be a promising approach (*12*) because significant insulin uptake after nasal or oral administra-

tion without use of penetration enhancers was observed. Nanoparticles (NP) of insulin and chitosan were obtained in the size range of ca. 350 nm by ionotropic gelation, leading to blood glucose reduction in rabbits after nasal administration (*4*). Oral administration of insulin containing NP (~700 nm) from a fumaric and sebacic acid copolyanhydride resulted in a significant blood glucose reduction and strong adhesive NP/mucus interactions (*13*). For intranasal drug delivery polymers with positively charged groups such as chitosan, poly-L-lysines, or protamine has been demonstrated to increase bioadhesion and membrane permeability (*3*).

Another important concern is the fabrication of NP. Nanoencapsulation techniques often rely on formation of emulsions with subsequent solvent evaporation. Usually a high energy input is necessary to obtain nanoemulsions and hence NP. Under those conditions, protein stability is often compromised through temperature, pH, and shear stress at interfacial surfaces with organic solvents (*14*).

Therefore, a self-assembling system composed of an "intelligent" polymer designed for spontaneous complexation of a target-protein under gentle aqueous conditions might provide advantages over classic nanoencapsulation strategies. Since the pioneering work of Morawetz and Hugues (*15*), it is recognized that globular proteins can form stable complexes with polyelectrolytes. The association of proteins with polyelectrolytes can result in soluble complexes, complex coacervation, precipitation, or gelation of the resulting system (*16, 17*). The two most important parameters governing polymer/protein association in water are the hydrophobicity and the electrostatic interactions of the partners. Additional phenomena, such as gelation and retardation of precipitation, are thought to result directly from the presence of hydrophobic association in polyelectrolyte complexes (PEC) (*18*).

Optimal polymer properties for self-assembly with proteins are rarely found in naturally occurring macromolecules. We report here the design and characterization of new synthetic polymers with amphiphilic properties suitable as a self-assembling protein carrier system. By grafting L-lactide onto a hydrophilic, charge-modified poly(vinyl alcohol) backbone with covalently bound diethylaminopropylamine groups, amphiphilic biodegradable comb polyesters with lipophilic side chains were obtained. We hypothesized that insulin, dissolved at a pH above its point of isocharge (PI ~ pH 5.3), carries an overall negative charge (*19*) and will form PEC with the cationic polymers by electrostatic and hydrophobic interactions. This work is an extension of our experiments using negatively charged branched polyesters, namely SB−PVA-*g*-PLGA for transmucosal delivery of tetanus toxoid (*20, 21*).

EXPERIMENTAL PROCEDURES

Materials. Diethylaminopropylamine (purum, >98%), poly(vinyl alcohol) (PVA) (15000 g/mol; degree of polymerization 300 ($P = 300$); degree of hydrolysis 86−89%), carbonyl diimidazole, (CDI), (purum, 97%), *N*-methylpyrrolidone (NMP) (purum, absolute), and 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU) (puriss., absolute, over molecular sieves) were purchased from Fluka GmbH Germany and used as received. L-lactide-(S-grade) (Boehringer Ingelheim, Germany) was recrystallized twice from ethyl acetate. Tin(II) 2-ethylhexanoate (Aldrich, Germany) was used as received. Tetrahydrofuran (THF) (BASF, Germany) was dried over sodium and distilled under nitrogen before use. *N*,*N*-Dimethylacetamide (for HPLC, 99.8%) was purchased from Fluka and Lithium bromide (extra pure) was ordered from Merck. Human recombinant insulin powder (26.2 IU/mg) was a gift from Aventis Pharma AG (Germany). All other chemicals were of the highest analytical grade commercially available.

Polymer Synthesis. The synthesis was described in detail elsewhere (*22*). Poly[(vinyl-3-(diethylamino)propylcarbamate-*co*-(vinyl acetate)-*co*-(vinyl alcohol)]-graft-poly(L-lactic acid) were synthesized in a three-step synthesis. Briefly, amino functions were introduced to the PVA backbone using CDI linker chemistry followed by grafting of L-Lactic acid chains using a ring-opening polymerization in bulk. The products were purified by ultrafiltration and lyophilized.

Nomenclature. The source-based IUPAC nomenclature for these polymers is poly(vinyl 3-(diethylamino)-propylcarbamate-*co*-vinyl acetate-*co*-vinyl alcohol)-graft-poly(L-lactide). As abbreviation we used 'DEAPA' (diethylaminopropylamine) followed by the average number of amine-carrying monomer units per 'PVA' (poly(vinyl alcohol)) chain with a polymerization degree of 300. The grafting of PLLA with the average chain length, calculated from feeding, in parentheses follows (e.g., DEAPA-(26)-PVA_{300}-*g*-PLLA(2)). For simplification, the following code was selected: P for the DEA(P)A substitution, afterward the number of amine groups per PVA in parentheses, followed by number of the lactide amount from feeding and LL as index, indicating grafting with pure L-lactide side chains (e.g. $P(26)\text{-}2_{LL}$).

Polymer Characterization. ^1H and ^{13}C NMR spectroscopic data were collected using a JEOL Eclipse+ 500 and a JEOL GX 400 D at a frequency of 500 or 400 MHz for ^1H NMR and 126 or 101 MHz for ^{13}C NMR, respectively, at 50 °C in d_6-DMSO (euriso-top, <0.02% HDO+D_2O). 40 to 50 mg samples were used for each measurement. ^1H NMR was performed with 64 and ^{13}C NMR with 4096 scans.

Gel permeation chromatography (GPC) was performed using a SDV linearM column (8 × 300 mm, 5 μm, with precolumn 8 × 50 mm) from Polymer Standard Services (Mainz). The eluent was dimethylacetamide with an addition of 2.50 g LiBr/L and a flow rate of 0.5 mL/min at 60 °C. The GPC consisted of a Merck-Hitachi AS-2000A autosampler, an L-6000 pump, a Merck T-6300 Column Thermostat and Differential Refractometer Optilab DSP, a Wyatt DAWN Eos multiangle light-scattering detector (The d*n*/d*c* was calculated with total mass recovery, Dawn EOS calibrated against PMMA 200k) and a Duratec DDG-75 degasser. The molecular weights of the samples were determined (third-order fit) with the Wyatt Astra V4.73 Software.

Nanocomplex Preparation and Characterization. *Preparation of Insulin Nanocomplexes.* An insulin stock solution (2.50 mg/mL) was prepared in two steps. 1. The insulin powder was dissolved in 87% (V/V) 1.15×10^{-2} N HCl in 10.0 mL Pyrex tubes. 2. 13% (V/V) of 0.1 N tris-(hydroxymethyl)aminomethane solution was added resulting in a clear Tris-buffer with low ionic strength ($I = 0.01$) and pH 7.40. Polymer stock solutions in concentrations (Table 2) from 0.64 mg/mL for P(150) up to 7.0 mg/mL for $P(26)\text{-}3_{LL}$ were prepared in Tris-buffer. An equal volume of the stock solutions of insulin and polymer were mixed resulting in defined mass ratios (Table 2) of insulin/polymer 1: 0.26−2.8 (m/m) in the final NC-solution. The colloidal polymer−insulin complexes formed immediately after mixing by spontaneous self-assembly.

Particle Size and ζ-Potential. Average size and the size distribution of the NCs was investigated using photon

[a] Optimized mixing ratios, standard insulin concentration 1.25 mg/mL in NC solution. [b] Measured from 25 × 25 μm scale AFM images. [c] Determined by HPLC after filtration of NC with 0.22 μm. [d] Ratios at the turbidimetric/scattering extrema. [e] Molar insulin/polymer ratio: first value at extrema turbidimetry, second value at turning point ITC.

correlation spectroscopy (*21*) with a Zetasizer 4 equipped with an AZ110 cell (Malvern Instruments UK), a 4-mV laser source, a 64-channel correlator, and a multiangle photomultiplier. Each buffer solution was filtered through 0.2 μm Acrodisc filters (Gelman Laboratory), and measurements were performed in serial mode. The photon correlation spectroscopy (V.1.26 Software) was used to calculate particle mean diameter and width of the fitted Gaussian distribution. The ζ-potential of the NC suspension was determined by laser-Doppler-anemometry in distilled water (conductance 0.055 μs/cm) using the AZ 104 cell. The ζ-potential was derived from electrophoretic mobility of the NC. Each measurement was performed in triplicate.

Insulin Loading of Nanocomplexes. After centrifugation of the complex dispersions in 2.0 mL Eppendorf-Cups for 30 min at 14,000 rpm, the supernatant was filtered through 0.1 μm Millex (Millipore), and the insulin content was determined by high performance liquid chromatography (HPLC). HPLC was based on a LiChrosphere100 RP18 (5 μm), 250 × 4 mm column (Merck) with isocratic elution (65% H_2O + 0.1% TFA/35% acetonitrile 90/ H_2O 10 + 0.1%TFA (flow rate 1.0 mL/min) and detection of insulin by a fluorescence spectrophotometer (Ex 276 nm/ Em 600 nm). The HPLC system consisted of a T6300 column thermostat, a 6200A pump, a F1050 fluorescence spectrophotometer, an AS 2000A autosampler (Merck, Germany), and a vacuum degasser (Duratec). Data processing was performed with the Millenium^{32} software Version 3.05. (Waters).

Isothermal Titration Calorimetry. Microtitration calorimetry was performed using the MSC-ITC equipment from Microcal Inc. (Northampton). The cell volume was 1351 μL containing insulin, and the syringe volume was 250 μL with the respective polymer solution. All Tris buffer solutions were filtered with 0.2 μm Acrodisc filters, and the pH values in the final solutions were maintained at 7.40 to avoid pH compensation signals. The injection scheme was 14 × 15 μL every 190 s at 400 rpm at 25 °C, and data processing was performed with the software Microcal Origin 3.5. The measurements were carried out in triplicate.

NC Stoichiometry by Colloid Titration. Turbidimetric measurements were carried out according to the method of Kokufuta et al. (*23, 24*). A constant volume of 0.30 mL insulin stock solution (2.50 mg/mL) was mixed with an appropriate volume of polymer solution and filled up with Tris buffer to a constant volume of 3.30 mL to avoid dilution effects. Transmission data were recorded on a Shimadzu UV-160 spectrophotometer at 630 nm using Suprasil cuvettes with 10 mm path length. Scattering data were obtained in the same way as PCS at an angle of 90°. The extrema were read directly from curves after plotting the data points with B-spline connection using Microcal Origin 6.0 software. Determinations were carried out in triplicate.

Atomic Force Microscopy. The polymer/insulin NC were prepared as described above. After 20 min, the complexes were directly transferred onto a silicon chip by dipping into the NC solution. Atomic force microscopy was performed on a Digital Nanoscope IV Bioscope (Veeco Instruments, Santa Barbara, CA) as described elsewhere (*25*). The microscope was vibration-damped. Commercial pyramidal Si_3N_4 tips (NCH-W, Veeco Instruments, Santa Barbara, CA) on a cantilever with a length of 125 μm, a resonance frequency of about 220 kHz, and a nominal force constant of 36 N/m were used. All measurements were performed in tapping mode to avoid damage of the sample surface. The scan speed was proportional to the scan size, and the scan frequency was between 0.5 and 1.5 Hz. Images were obtained by displaying the amplitude signal of the cantilever in the trace direction, the height signal in the retrace direction, and the phase signal in retrace direction, both signals being simultaneously recorded. The results were visualized either in height, amplitude, or/and in phase modus. The phase mode permits assessment of material properties (viscoelastic properties). These are expressed as "brightness" of the AFM image.

RESULTS AND DISCUSSION

Synthesis and Structural Characterization of the Copolymers. Nanoscience is a rapidly developing area of research with considerable potential for drug delivery because cellular interaction and transport of nanoscale objects may offer new opportunities not available to larger devices. Especially NP based on hydrophilic/biodegradable polymers can be designed to provide particle characteristics, protease inhibition, and permeation enhancement for peptidic drugs.

To explore the potential of the NP approach, novel materials are necessary which allow formation of NP under mild conditions, such as self-assembly leading to nanocomplexes. We have designed amphiphilic charge-containing biodegradable copolyesters composed of a hydrophilic PVA backbone grafted with short hydrophobic lactic acid groups to complex proteins and peptides. Cationic carriers such as DEAE-dextran, chitosan, and poly(L-lysin) are suitable for complexation of a large number of negatively charged pharmacologically active agents, e.g. insulin, oligonucleotides, and DNA (*26*−*28*).

The use of CDI chemistry allows the modification of amine substitution in a broad range. We coupled amino groups to the PVA backbone and investigated the effect of different degrees of DEAPA substitution on complex formation with insulin. PVA is known as a nontoxic and biocompatible polymer which exhibits mucoadhesive properties and is therefore used in drug delivery (*29*). The degree of amino substitution was varied from moderate 13 (DS = 0.04), up to a highly substituted backbones with 150 (DS = 0.5) of the ca. 300 hydroxyl groups of PVA substituted (cf. Table 1). To introduce amphiphilicity in the PVA backbone, hydrophobic L-lactic acid side chains were grafted to the backbone in a second step to yield a brushlike and biodegradable copolyester structure. For a P(26) backbone (DS = 0.09), the highest possible lactic acid substitution while remaining water soluble was 1:3 (w/w). By combining hydrophilic backbones with hydrophobic domains, numerous benefits were reported in the literature such as increased drug loading, self-association, or complex stability (*18, 30, 31*).

The polyesters were characterized using ^{1}H NMR spectroscopy and gel permeation chromatography. A typical ^{1}H NMR spectrum (Figure 1) of these graft polymers show signals of both polymers, PVA, and poly(L-lactide). The ratio between end group and central group integrals depends on the side chain length and could be used to calculate the average chain length and the molecular weight (MW) of the sample. The reproducibility of the synthesis is demonstrated for two different batches of polymer P(26)-2_{LL} (Table 1) with similar degrees of substitution. It could be shown that the MW of the polyesters is increasing as expected. The polymer with the highest calculated side chain length, P(26)-3_{LL}, shows the highest molecular weight, and the polymer with the lowest lactic acid grafting, P(26)-1_{LL}, yields the smallest molecular weight of all polyesters. The molecular weights calculated from NMR spectra of all tested polymers are in good agreement with the number average molecular weights, M_n, obtained by GPC/MALLS. The only exception was P(26)-2_{LL}, which exhibited an apparent higher molecular weight measured by light scattering caused by a fraction of polymer aggregates. Otherwise, the elution time of P(26)-2_{LL} measured by a refractive index detector is in the range of the other polyesters (Figure 2), indicating a MW of the same order of magnitude.

Formation of NC with Insulin. Complex formation between proteins and polymers is influenced by a large

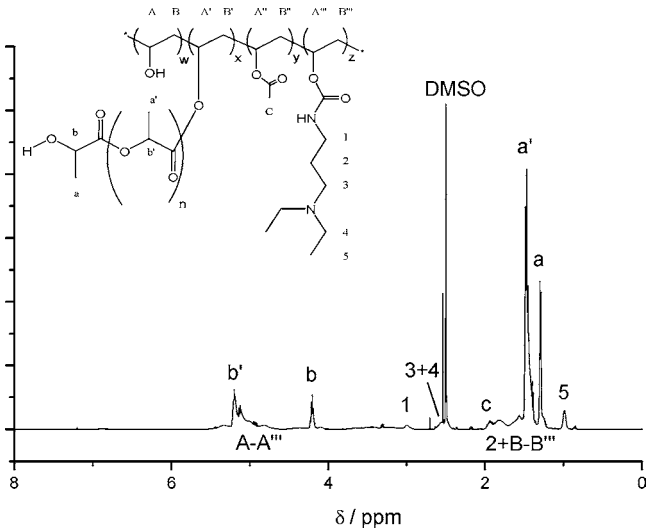

Figure 1. ^{1}H NMR of DEAPA(26)−(3) and the correlation of structure and signal. The lactide chains have four different signals. These are the multiplet of the methine central groups between 5.24 and 5.03 ppm, the multiplet of the methine end group between 4.25 and 4.15 ppm, the multiplet of the methyl central groups between 1.51 and 1.40, and the multiplet of the methyl end groups between 1.32 and 1.27.

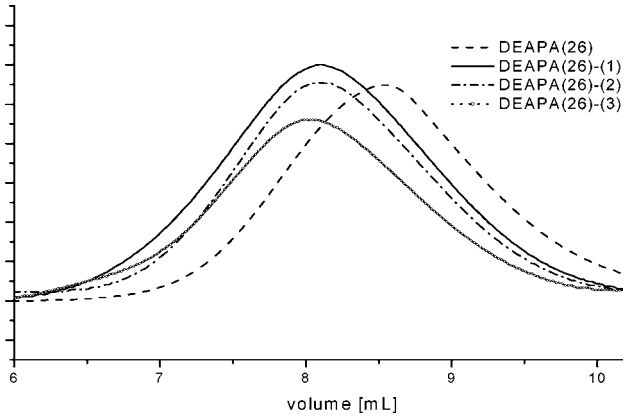

Figure 2. GPC signals of the refractive index detector of the polymers DEAPA-(26),-(26)-(1), -(2), and -(3). There is only a small difference between the three polyesters. The modified PVA shows a higher eluation volume.

number of parameters. Apart from mixing conditions (polymer concentration, rate of mixing, stirring), medium parameters (pH value, ionic strength, type of salt, polarity of solvent) and particularly the characteristics of the polyelectrolyte (molecular weight, polydispersity, branching, charge density) are known to play an important role. We investigated the complexation process in a systematic manner using turbidity as a simple and noninvasive measurement of NC formation (*32*). The formation of supramolecular structures leads to a corresponding increase in particle mass, which can be sensitively monitored by light scattering. In turbidimetric studies, the transmission of a light beam passing through a cuvette with a dispersion is given by $T = I/I_0 = \exp(-\tau l)$ where I_0 is the intensity of the light beam, I is the intensity after the cuvette of the length l, and τ is the turbidity. In nonabsorbing systems (630 nm), the transmittance is determined by the scattering of light. According to the Rayleigh theory, the scattered intensity is proportional to the square of the mass of the particles (*33, 34*). Turbidimetry monitors structural changes caused by the onset of association respectively particle formation. The characteristics of a turbidimetric curve for different

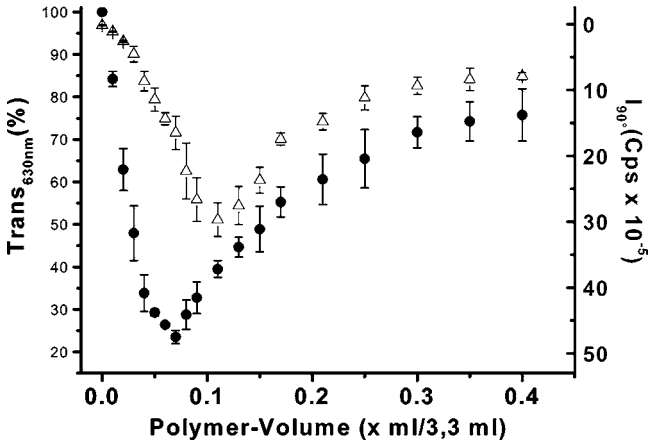

Figure 3. Turbidimetry (●) and scattering (△) of DEAPA(26) and insulin.

mixing ratios of a 3.2×10^{-5} mol insulin solution with increasing concentrations of polymer are shown in Figure 3. The graph does not represent a classic colloid titration because every data point was generated from a separate experiment with a constant volume of 3.30 mL to eliminate dilution effects. All polymers exhibited the same turbidimetric profile characterized by a sharp decrease of transmission and a sharp increase of scattered light at increasing polymer concentrations resulting in distinct minima and maxima. The turbidimetric profile suggests that at initially low polymer concentration, large and incoherent complexes are formed with an excess of insulin. These complexes condense to a more defined and compact structure at increasing polymer concentration, corresponding-to-mixing ratios at the extrema and the ascending part of the turbidimetric curve. Furthermore, addition of the same type of polymer to NC dispersion leads to a redistribution of the insulin to the new binding partner resulting in a decrease of scattering intensity and absorption. The NC size measurements as a function of the mixing ratios confirm this assumption (Figure 4). A transition to small-sized NC was achieved upon exceeding the described minima/maxima.

At a physiological pH human insulin carries two negative charges per molecule (*19*). The terminal tertiary amino groups of DEAPA are predominantly protonated at neutral pH, allowing calculation of charge ratios at the extreme values of the turbidity curves. The calculations are based on the total concentrations. In Figure 5, a linear relationship between the number of DEAPA groups in the backbone and the molecular ratio of insulin/polymer is shown. With higher degrees of amino substitution, increasing from 13 to 150, higher molar ratios between DEAPA and insulin with 1:7 up to 1:45 are observed. These data suggest that at the extreme values, approximately 1:1 charge ratios are observed (Table 2) and highlight the importance of electrostatic interactions. On the other hand, with increasing amounts of lactic acid grafting, no change in the molar ratio of insulin/polymer is observed. This suggests that the stoichiometry of the complexes is primarily determined by Coulombic interactions and that hydrophobic forces play a minor role.

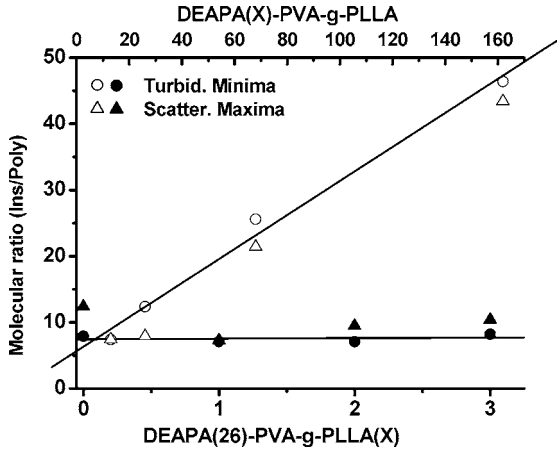

Figure 5. Turbidimetric and scattering extrema: correlation of molecular ratio and substitution degree of DEAPA (○, △) respective amount grafted lactide (●, ▲).

Under our experimental conditions, the NC demonstrated no tendencies of precipitation or macroscopic flocculation. The only exception is P(26)-3_{LL}-NC which tended to precipitate after ~1−2 h, possibly due to the high lactic acid grafting. It is very important to mention that turbidimetry does not provide information on the affinity between insulin and the different polymers. Therefore, isothermal microtitration calorimetry was performed.

Nanocomplex Characterization. Ideal nanocomplexes containing insulin should meet the following requirements: (i) particle sizes <500 nm to facilitate epithelial uptake (*35*); (ii) high positive ζ−potential to increase interaction with negatively charged cell surfaces (*36*); and (iii) high insulin loading. These parameters were determined at different points of the turbidimetric profile (Figure 4). It was found that the optimal range is located at the ascending part of the profile. This observation was made with all polymers and thus permitted a calculation and even a prediction of the optimal ratios of both binding partners (Table 2).

Using a simple mixing procedure and short incubation times, it was possible to obtain NC with an average diameter of ~200 to 500 nm. Within a homologous series of backbone composition, an increasing amount of lactic acid grafting ($0 < 1_{LL} < 2_{LL}$) led to more compact and smaller NC, pointing to the influence of hydrophobic interactions for the complex structure.

The degrees of amino substitution allowed variation of the positive surface charge of the NC. The observed ζ-potentials ranged from +3 mV at a low ('13') to + 35 mV with a higher degree of substitution ('150'). Furthermore, when the number of amino groups was kept constant at 26 and the lactic acid ratio was increased from 1_{LL} to 3_{LL}, the ζ-potential increased from +15 mV to +33 mV. This

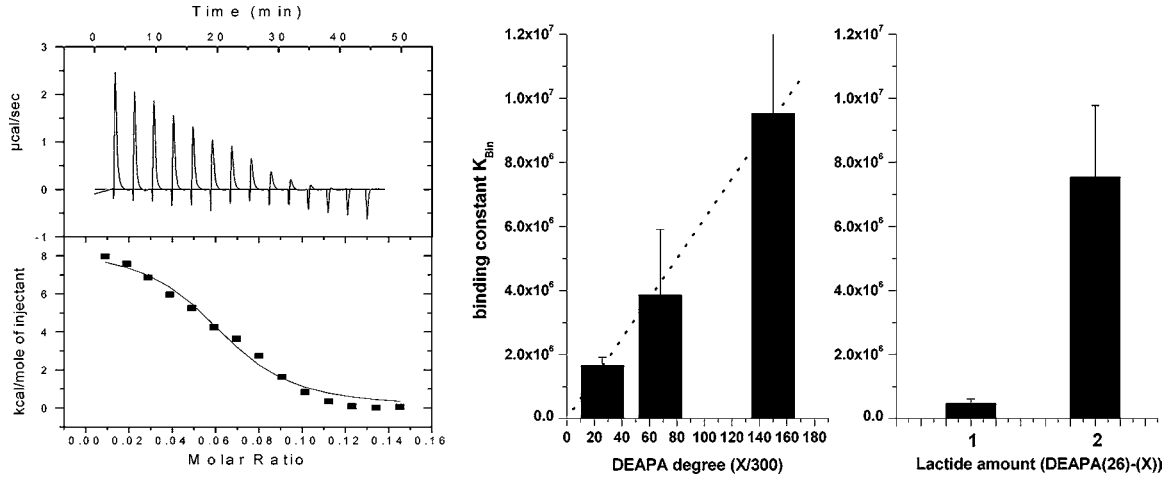

Figure 6. Left: MTC final plot of DEAPA(26)-(1)/insulin, right: correlation of binding constants for different amine substitutions (26, 68, 150) of PVAL and comparison of polyesters DEAPA(26)-(1) and-(2).

could be explained by increased internal hydrophobic interactions leading to a displacement of positive charges from the inner parts of the complex to the outer layer.

The high loading of insulin (Table 2) in NC was obtained either with high degrees of amine substitution or by a combination of medium charge density ('26') and a higher lactic acid grafting (2_{LL}, 3_{LL}). At the standard concentration of 1.25 mg/mL insulin (26.2 IU/mg), ca. 98% were bound in NC. A degree of amino substitution of 0.04 was insufficient for efficient insulin complexation.

The hydrophobic B-chain, C-terminal end plays an important role in the complexation behavior of insulin (e.g. self-association or fibrillation). The increased complexation capacity of the higher grafted polyesters possibly results from more pronounced hydrophobic interactions with these nonpolar residues of insulin. In the literature, the formation of complexes was even observed with partners of the same charge, namely serum albumin and hydrophobically modified anionic poly(acrylic acid) (*37*), pointing to the importance of hydrophobic interactions.

Microcalorimetry. Interactions between proteins and polymers and their assembly to NC, are the result of cooperative interactions of many weak inter- and intramolecular forces. Isothermal titration calorimetry (ITC) provides a tool to determine equilibrium constants and enthalpies under identical experimental conditions. From these data, entropy values and standard free energies can be derived, giving insight into the complexation reactions. The binding constant, K_{bin}, allows an assessment of the influence of polymer modifications on the affinity to a target-protein. The so-called "final plot" in Figure 6 displays the titration of insulin solution with P(26)-1_{LL} polymer. The peaks in the upper window represent the heat flow of the ongoing complexation reaction. This continues until only dilution effects of excessive polymer addition are detected within the last 3−4 peaks. The lower window represents the fit of the integrals according to the least-squares method. The binding constants ranged from 4.68×10^5 with P(26)-1_{LL} to 9.53×10^6 M^{-1} with P(150) (Figure 6 right).

An increase in the binding constant can be attained by two ways: First is with a higher degree of amine substitution, leading to a higher charge density. The binding constant increased almost linearly (correlation coefficient ~0.998) for P(26), -(68) and -(150). Second is by the introduction of short hydrophobic lactic acid side chains, which have to exceed a critical length to influence the complexation of insulin significantly. A strong increase of K_{bin} to 7.54×10^6 M^{-1} was seen when lactic acid grafting increased from (1_{LL}) to (2_{LL}), due to additional hydrophobic binding forces. It was not possible to investigate P(13) because of its weak complexation properties and P(26)-3_{LL} due to its precipitation tendency.

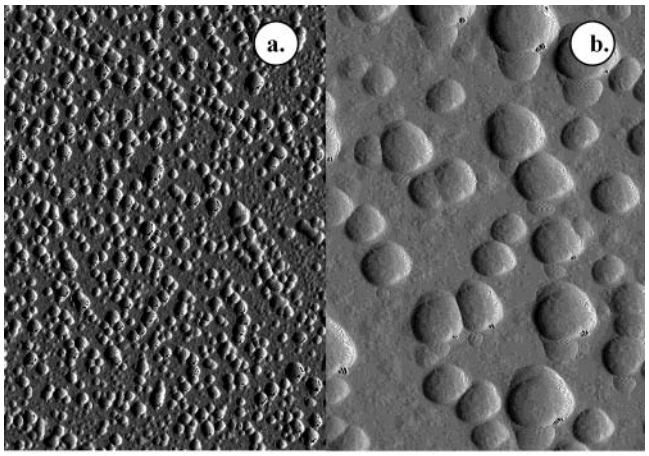

Figure 7. Tapping mode AFM images: Overview of DEAPA-(26)/insulin complexes: (a) 10.0 μm and (b) 2.0 μm scale.

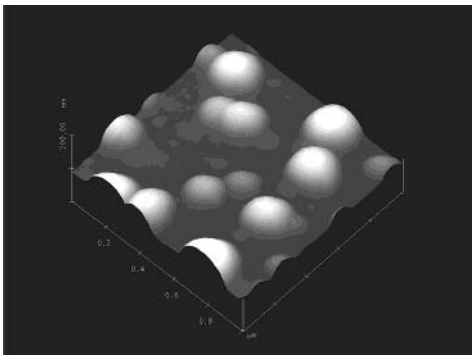

Figure 8. Three-dimensional structure of nanocomplexes.

For comparison, the binding constant for soluble insulin to crystals of cationic protamine/insulin (0.27 mg/100 IU) at pH 7.5 is (buffer dependent) $15.5-37.7 \times 10^5$ M^{-1} (*38*) and the strong binding of the two first hexacoordinated zinc atoms per insulin hexamer is in the magnitude of $1.9-4.7 \times 10^6$ M^{-1} (*39*), documenting a substantial affinity of insulin to the DEAPA polymers.

The calorimetric enthalpy change (ΔH) measured in an ITC experiment is the total change in enthalpy for the whole system. That means exothermic or endothermic

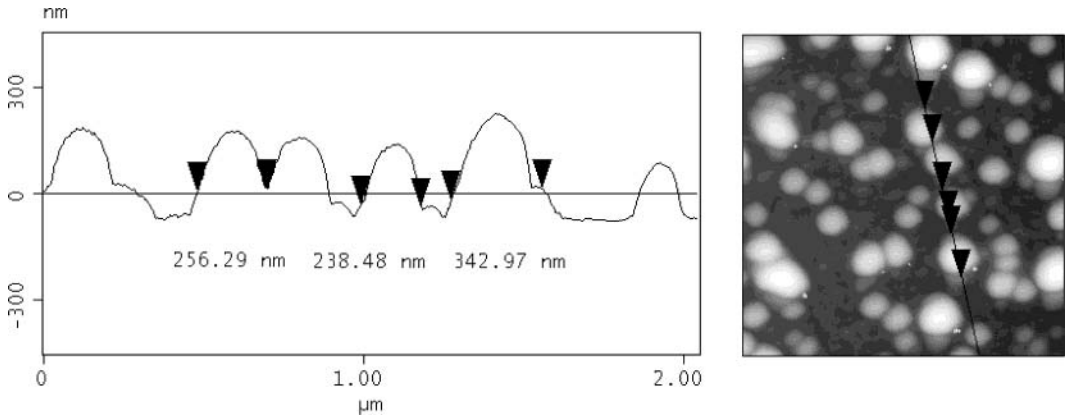

Figure 9. Cross-section for nanocomplexes from AFM line analysis.

events can be associated with conformational change of the reactants, ionization of polar groups, and interactions with the solvent. The determination of the true (intrinsic) enthalpy requires additional experiments in different solvents and should in this context not be discussed in detail. The driving force of complex formation is mainly the gain in entropy due to the liberation of the low molecular counterions. The derived entropy values for the complexation reactions ranged from 45 for P(26) to 255 kcal/mol for P(150). From a thermodynamic point of view, polyelectrolytes with stronger ionic groups and/or higher molecular masses are generally favored in complex formation (*33*).

Another parameter directly obtained by ITC is the stoichiometry of the binding partners at the turning point of the isotherm. This stoichiometry cannot be directly compared with turbidimetry due to different physicochemical principles. The thermodynamic stoichiometry of insulin/polymer was about two to three times higher than the molar ratios derived from turbidimetry (Table 2).

Visualization of NC. Atomic force microscopy (AFM) is a microscopic technique which allows the imaging of NC formulations independent of their composition under wet (physiological) conditions. Using AFM, in contrast to the electron microscopy, samples can be measured without preparation or fixation. AFM is an excellent method for imaging soft and flexible objects with high resolutions, allowing determination of particles sizes and surface morphology on a nanometer scale resolution. For size determination, all NC within a representative scan area ($25 \times 25\ \mu$m) were evaluated individually (Table 2). These data can deviate from the results of PCS measurements for several reasons. First, interaction of soft and flexible polymer NC with the surface of the silicon support can cause artifacts. The individual particle analysis allows exclusion of such artifacts.

In addition, the visualization and evaluation of NC enables us to investigate the stability of these particles. The morphology of spreaded surface films of the pure polymer solution exhibited a uniform appearance for all polymers. The polymers form globular structures with a high tendency to generate fractal structures. The size for the globuli ranged between 25 nm for P(26) (Figure 10/B) and 38 nm for P(26)-2_{LL}. The investigated polymer/insulin nanocomplexes showed average particle sizes between 274 nm (P(26)) and 434 nm (P(150)). These values are in excellent accordance with the results determined by PCS. A general overview of a NC distribution is seen in Figure 7 for P(26)/insulin. All particles were of round shape and stable; no tendency for agglomeration could be observed. Only the formulation of

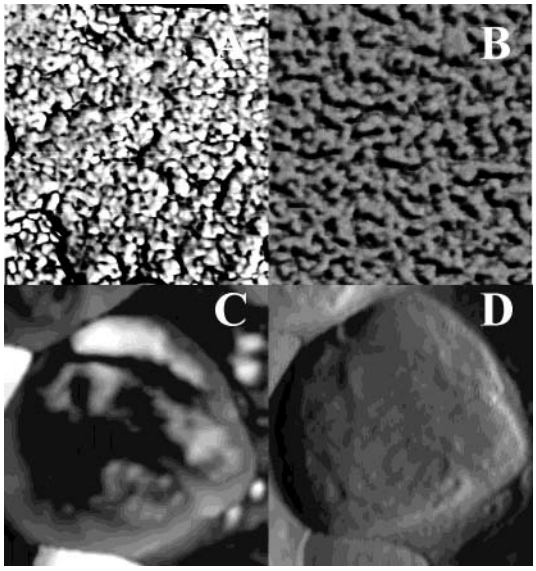

Figure 10. AFM phase mode: (A) Insulin (B) DEAPA(26)-polymer (C) NC of a/b, AFM Tapping mode: (D) surface structure of C.

P(26)-3_{LL} NC showed a very inhomogeneous particle distribution and the tendency of stack formation. In the case of P(26), two major subpopulations were observed. The smaller fraction had an average diameter of approximately 204 nm, and the larger fraction showed sizes between 300 and 400 nm. This feature also explains the differences in the size measurements between the used methods. The surface of the particle is very smooth; no breaks or cracks could be seen.

A general problem with soft objectives such as NC, even in the noncontact mode, is to obtain accurate height information. Often nanoparticles show a tendency to coalesce at the surface, leading to significant height differences and very flat structures (*40*). Under our experimental conditions, the NC exhibited a good aspect ratio between height and diameter (Figure 8) which was confirmed by a cross-section of 2 μm and additional height measurements (Figure 9).

A special technique of AFM is the so-called phase imaging mode measuring the material contrasts, depending on the stiffness or elasticity of the object (*41*). Differing material properties are presented in different color intensities in images of insulin (a) and DEAPA polymers (b) as shown in Figure 10. More rigid materials show a brighter image than softer materials. In the case of P(26), different bright areas within the particles could be observed (Figure 10/c). The areas were very small with

a size between 5 and 20 nm and can be discussed as a distribution of polymer/insulin nanostructures with different compositions. Brighter areas consist of domains with a higher content of insulin and were more rigid, while darker areas consist of regions with higher polymer content. The results of the AFM investigation are compatible with a spheroidal shape for the nanocomplexes and an entangled internal structure for insulin and DEAPA polymers.

CONCLUSION

A series of polymers was synthesized and characterized exhibiting a comblike structure. The variation of hydrophobicity by lactic acid side chain grafting and charged groups, at physiological pH, resulted in branched polyesters with a positively charged backbone offering multiple binding sites for the preparation of colloidal nanocarrier systems. It was possible to manipulate the hydrophilic−hydrophobic balance of these polyesters by factors such as molecular weight, PLLA chain lengths, and degree of amine substitution. Water solubility of these polymers allowed the self-assembling of small NC with narrow size distribution without any mechanic emulsification procedures and without the use of surfactants.

Insulin was complexed to a high extent, resulting in uniform particles with an entangled structure. The increase in binding affinity, drug loading, zeta potential, and the decrease in size could be correlated with a higher substitution degree of DEAPA groups and a higher lactic acid grafting of the backbone. The possibility of designing the polymer structure in a rational manner may provide significant advantage for generating nanocarriers for mucosal drug delivery. The potential of these NC for nasal delivery of insulin with in vivo models is currently under investigation in our laboratory.

Ltd., Yongin, Kyunggi, Korea. Received November 10, 2003

^{99m}Tc-Labeled diethylenetriaminepentaacetic acid (DTPA)-coupled neogalactosyl human serum albumin (GSA) is used as an imaging agent for asialoglycoprotein receptor of the liver. However, its labeling is inconvenient because it should be incubated for 30 min at 50 °C. In addition, the conjugated DTPAs can cause decrease of pI and denaturation of protein. Therefore, we developed an improved agent ^{99m}Tc-neolactosyl human serum albumin (LSA) which contains a terminal galactose. LSA was synthesized by conjugating lactose to human serum albumin by the formation of a Schiff's base and successive reduction with sodium cyanoborohydride. The number of conjugated lactose molecules per LSA was 40.7 ± 12.3. To simplify the labeling procedure, we used a direct labeling method that adopts a high affinity ^{99m}Tc binding site concept in antibody labeling. The produced LSA was reduced by β-mercaptoethanol to generate sulfhydryl groups and purified by PD-10 size-exclusion column. The number of generated sulfhydryl groups per LSA was 21.9 ± 3.0. Medronate and stannous chloride were added to the reduced LSA and freeze-dried. Finally, ^{99m}Tc-pertechnetate (37 MBq, 1 mL) was added to the vial and incubated for 10 min at room temperature. The labeling efficiency of ^{99m}Tc-LSA was higher than 98%, and the stability in human serum at 37 °C for 24 h was over 90%. Biodistribution study using balb/c mice and imaging study using SD rats showed high initial liver uptake and slow increase in the intestine due to hepatobiliary excretion after metabolism in the hepatocytes. Negligible spleen uptake was found while ^{99m}Tc-tin colloid showed significant amount of spleen uptake due to reticuloendothelial uptake. In conclusion, an improved agent, ^{99m}Tc-LSA, for imaging asialoglycoprotein receptor of the liver was successfully developed which showed a simple labeling procedure, high labeling efficiency, high stability, and high initial liver uptake.

INTRODUCTION

Traditionally, radiocolloids, e.g. ^{99m}Tc-tin colloid, ^{99m}Tc-sulfur colloid, ^{99m}Tc-phytate colloid, etc., have been used for imaging liver function (Stern et al., 1966; Arzoumanian et al., 1977). However, the images obtained by radiocolloids do not represent the function of hepatocytes which comprise 85% of the liver cells playing a key role in liver function. Rather, the images represent the function of the reticuloendothelial system which comprises only 15% of the liver cells playing a defensive role. Although, the function of hepatocytes could be indirectly estimated by measuring serum level of liver enzymes such as ALT and AST, direct estimation of liver function using functional imaging can provide more useful information.

Asialoglycoprotein receptors are known to exist on the mammalian liver (Ashwell and Morell, 1974) and play an important role in the hepatic metabolism of serum proteins (Ashwell and Steer, 1981). It has been reported that the asialoglycoprotein receptors exist on the surface of hepatocytes (Stokert and Morell, 1983), and it has also been suggested that quantitative imaging of asialoglycoprotein receptors estimates the function of the liver (Krohn et al., 1982; Lee, 1998; Miki et al., 2001).

A novel neogalactosylalbumin has been developed and labeled with ^{99m}Tc for imaging the liver (Krohn et al., 1980). Receptor-mediated binding to hepatocytes was also investigated both in vitro and in vivo (Vera et al., 1984a,b). Later preclinical studies proved the stability and safety of ^{99m}Tc-neogalactosylalbumin (Vera et al., 1985). However, it was necessary to develop a simpler and more convenient method, because the electrolytic labeling method used could not be performed practically in most clinical fields.

To make the labeling procedure simple, diethylenetriaminepentaacetic acid (DTPA)-conjugated neogalactosylalbumin (GSA) has been developed as an instant kit (Kubota et al., 1986). The GSA kit can be labeled with ^{99m}Tc more easily and consequently they are used widely for imaging liver function especially in Japan. The development and application of ^{99m}Tc-GSA has been published in an informative review (Stadalnik and Vera, 2001).

However, it is predicted that ^{99m}Tc would make less stable complexes with hard bases such as carboxyl or tertiary amine groups of DTPA, because it is a soft acid (Huheey, 1983). In fact, it has been reported that a

significant amount of ^{99m}Tc nonspecifically binds to antibodies instead of the DTPA residue when attempting to label DTPA-conjugated antibodies (Childs and Hnatowich, 1985). In addition, conjugation of DTPA to human serum albumin can lead to denaturation, polymerization, and decrease of isoelectric point. Conjugation of DTPA and galactose to the same protein molecule would make them compete with each other because both bind to the amino group.

In this paper, we introduced a direct labeling concept instead of conjugation of DTPA to human serum albumin. Thiol-containing antibodies, after reduction of disulfide bonds using a reducing agent such as β-mercaptoethanol, can be labeled directly with ^{99m}Tc (Schwarz and Steinsträsser, 1987; Mather and Ellison, 1990). Similarly, human serum albumin containing 17 intramolecular disulfide bonds should also be labeled with ^{99m}Tc directly after reduction with β-mercaptoethanol.

Another important aspect of this experiment is that the conjugated sugar is not a galactose but a lactose. Lactose is a disaccharide of galactose and glucose: 4-*O*-β-D-galactopyranosyl-D-glucose. The aldehyde group of the glucose residue and the amino group of human serum albumin form a reversible Schiff's base and are subsequently reduced into an secondary amine to form an irreversible covalent bond. Thus the galactose residues of neolactosylated human serum albumin (LSA) are intact even after conjugation and act as ligands of asialoglycoprotein receptors.

EXPERIMENTAL PROCEDURES

Materials and Instruments. Human serum albumin was purchased from Green Cross Corp. (Seoul, Korea) as a 20% solution in normal saline. For purification of neolactosylated human serum albumin (LSA), ready-made Sephadex G-25 columns were purchased as PD-10 columns from Pharmacia (Uppsala, Sweden). Disposable aseptic 0.22 μm filters were purchased from Millipore Company. ^{99}Mo/^{99m}Tc-generators were purchased from Du Pont Company. ITLC plates were purchased from Gelman Company. Tin colloid kits (0.15 mg of stannous fluoride and 1 mg of sodium fluoride) and human serum albumin (HSA) kits (50 mg of HSA and 0.5 mg of stannous chloride hydrate) for ^{99m}Tc-labeling were purchased from Daiichi Co. The particle size of ^{99m}Tc-tin colloid has been reported as 0.1−0.5 μm (McClelland et al. 2003). All the other reagents and solvents, if not specified, were purchased from Aldrich, Fluka, or Sigma and were used without further purification.

Radio-TLC chromatograms were obtained using a Bio-Scan System 200 imaging scanner. A gamma scintillation counter Cobra II model from Packard Canberra Company was used for counting radioactivity of organs in the biodistribution study. A gamma camera Sigma 410 model from Ohio-Nuclear equipped with a low-energy collimator was used for imaging rats.

Preparation of LSA. LSA was prepared using minor modification of the previously reported reductive lactosamination method (Lim et al., 1996; Wilson, 1978). The overall reaction procedure is described in Figure 1. In 50 mL of 0.2 M potassium phosphate buffer (pH = 8.0), 680 mg of human serum albumin was dissolved completely and 1 g of α-lactose was dissolved successively. One gram of sodium cyanoborohydride was added, and the solution was filtered using a 0.22 μm filter. The filtered solution was incubated at 37 °C with slow stirring for 14 days. The resulting reactant was centrifuged at 3000 rpm for 5 min to remove any precipitate. The supernatant was recovered and stored at −70 °C until used.

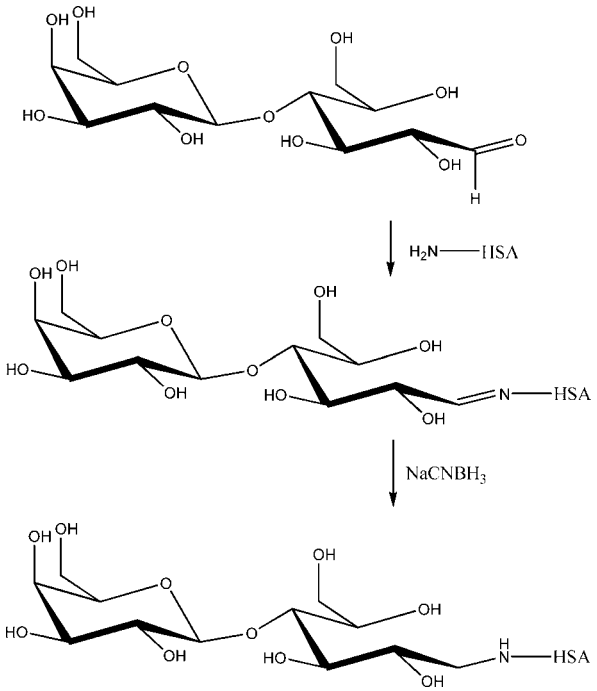

Figure 1. Conjugation of lactose to human serum albumin by reductive amination. The aldehyde group of glucose residue makes a Schiff's base with the amino group of human serum albumin, and then it is reduced to a stable amine by sodium cyanoborohydride.

Preparation of Disulfide-Reduced LSA (rLSA). Reduction of LSA was performed in a similar way with that of monoclonal antibody for labeling with ^{99m}Tc (Mather and Ellison, 1990). To 1 mL of the above prepared LSA, 40 μL of 0.3 M EDTA (pH = 8.0), 40 μL of 1 M sodium bicarbonate, and 50 μL of 1.5 M β-mercaptoethanol were added successively and incubated at 37 °C for 1 h. After purification of the rLSA using Sephadex G-25 column/phosphate-buffered saline (pH = 6.0), 0.3 mL of sodium medronate (1.25 mg/mL, pH 7.6, containing 68 μg SnF_2) was added. The solution was dispensed into vials as an aliquot containing 3 mg of protein and stored in a refrigerator after freeze-drying.

Determination of the Conjugation Number of Lactose. The conjugated number of lactose per molecule of human serum albumin was calculated by measuring galactose concentration from the absorbance at 485 nm using the phenol/sulfuric acid method (Dubios et al., 1956); since the secondary amine formed by reductive amination is acid-stable, only galactose is produced during the hydrolysis (Wilson, 1978).

Determination of the Number of Thiols. The number of thiol groups on an rLSA molecule was determined before addition of sodium medronate containing SnF_2. It was determined by measuring absorbance at 410 nm after 400 μL of sample was reacted with 2 mL of 0.1 M Ellman's reagent (5,5′-dithio-bis(2-nitrobenzoic acid). Serially diluted cysteine solution was used as a standard.

Labeling with ^{99m}Tc. To the above freeze-dried vial, 2−5 mL aliquot of generator-eluted ^{99m}Tc-pertechnetate was added and incubated at room temperature for 1−30 min. Unreduced LSA was also labeled using the same method for comparison. The labeling efficiencies were checked using ITLC/Umezawa (ethanol:10% ammonium acetate = 1:1) and 5% bovine serum albumin (BSA) impregnated paper chromatography/saline. Unbound ^{99m}Tc moved to the solvent-front, and LSA-bound ^{99m}Tc stayed at the origin on ITLC/Umezawa. All ^{99m}Tc activity

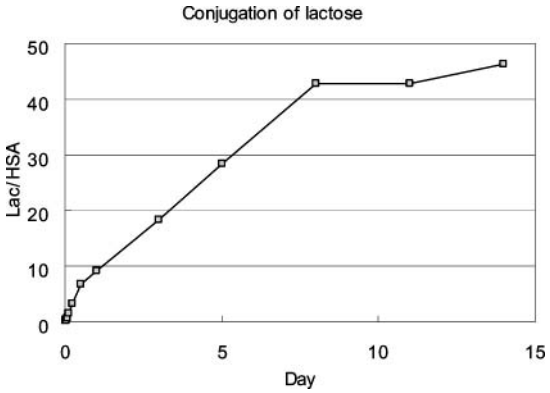

Figure 2. Number of lactose molecules conjugated to human serum albumin by incubation time. The conjugated number becomes maximized after incubation for 8 days at 37 °C.

except reduced hydrolyzed ^{99m}Tc moved to the solvent-front on 5% BSA-impregnated paper chromatography/saline.

Stability Test. Stability of the labeled LSA was checked at room temperature. Stability in human serum at 37 °C was also checked. The bound and free form of ^{99m}Tc was determined using ITLC/Umezawa and 5% BSA-impregnated paper chromatography/saline as described above. The pH of the reaction mixture during stability test was measured by pH paper.

Biodistribution Study in Mice. For biodistribution, 37 kBq of ^{99m}Tc-LSA was injected into each mouse (male, ICR, ~20 g, $n = 4$) through the tail vein. The mice were sacrificed at 10 and 60 min. The weight and radioactivity of the blood, muscle, fat tissue, heart, lung, liver, spleen, stomach, intestine, kidney, and bone from the sacrificed mice were measured using an electronic balance and gamma scintillation counter. The percentage of injected dose per gram tissue was calculated.

Imaging Study in Rats. For imaging, 7.4 MBq of ^{99m}Tc-LSA was injected into each rat (male, Sprague−Dawley, ~200 g) through the tail vein. Planar images of the rats in prone position after 15 and 30 min were obtained using a gamma camera equipped with a low-energy collimator. Imaging with ^{99m}Tc-tin colloid by the same procedure was performed for comparison.

RESULTS

Preparation and Characterization of rLSA. The entire procedure was performed in an aseptic manner to prevent bacterial growth. Excess lactose (lactose:HSA = 285:1) was added to make the reaction close to complete. The conjugated number of lactose to human serum albumin reached almost maximum after incubation at 37 °C for 8 days (Figure 2). The maximum number of conjugated lactose per human serum albumin was about 43. The average conjugated number after 11 days incubation was 40.7 ± 12.3.

For labeling with ^{99m}Tc, the LSA was reduced by β-mercaptoethanol. The remaining β-mercaptoethanol was removed by PD-10 size-exclusion column, and rLSA was obtained in phosphate-buffered saline (pH 6.0). The average number of sulfhydryl groups per rLSA measured by Ellman's reagent was 21.9 ± 3.0. For ^{99m}Tc labeling and stabilization, 0.3 mL of sodium medronate (1.25 mg/mL, pH 7.6, containing 68 μg SnF_2) was added, then dispensed into 3-mg protein aliquots and freeze-dried.

Labeling with ^{99m}Tc and Radiochemical Study. After labeling of rLSA with ^{99m}Tc, free ^{99m}Tc was determined by ITLC/Umezawa and colloid was determined by 5% BSA-impregnated Whatman No.1/saline (Figure 3).

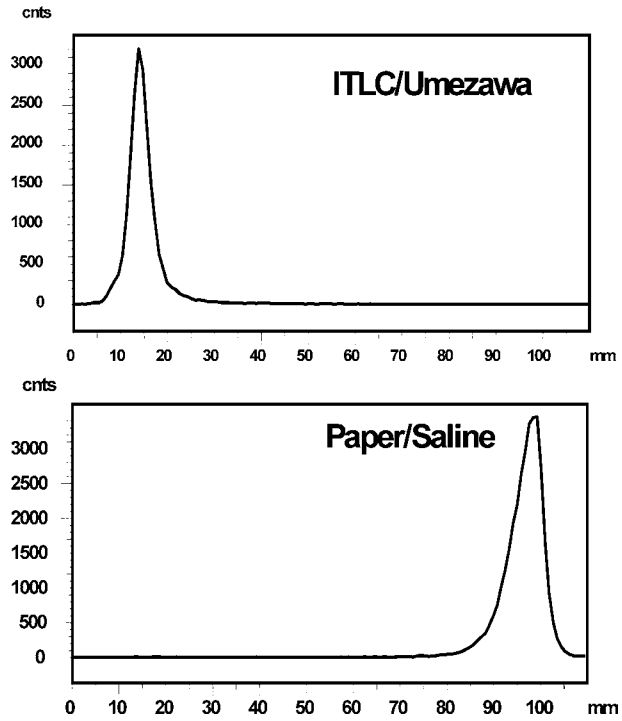

Figure 3. Determination of labeling efficiency. Labeled and colloidal ^{99m}Tc remains at the origin, and all the other activities move to the solvent-front by ITLC/Umezawa and all activities except colloidal ^{99m}Tc move to the solvent-front of the paper chromatography/saline.

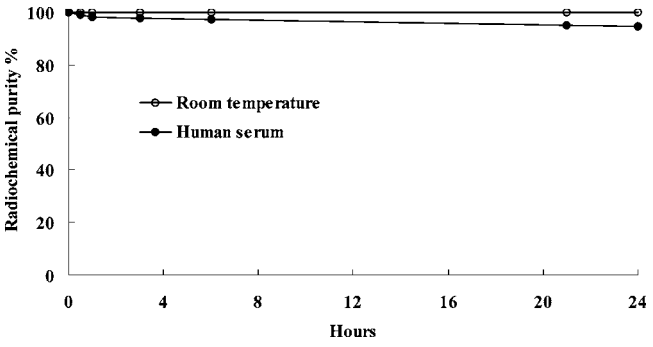

Figure 4. Stability test of ^{99m}Tc-LSA at room temperature and at 37 °C in human serum.

Table 1. Labeling Efficiency of ^{99m}Tc-LSA Determined by ITLC and Paper Chromatography

	added volume of ^{99m}Tc-pertechnetate[a]	
incubation time (min)	2 mL	5 mL
1	98.5	98.9
3	98.2	99.0
7	98.9	100
15	98.9	99.3
30	100	100

[a] The values denote labeling efficiency (%).

Labeling was finished in 1 min with >98% efficiency at room temperature (Table 1). The volume of ^{99m}Tc-pertechnetate, either 2 mL or 5 mL, did not affect the labeling efficiency.

The preparation of the ^{99m}Tc-LSA was stable for at least 24 h when stored at room temperature, and it was also stable in serum at 37 °C for 24 h (Figure 4).

Biodistribution Study in the Mice. ^{99m}Tc-HSA showed high blood pool activity. High activities in the liver, spleen, and kidney seem to be caused by high blood content in those tissues (Figure 5A). ^{99m}Tc-LSA ac-

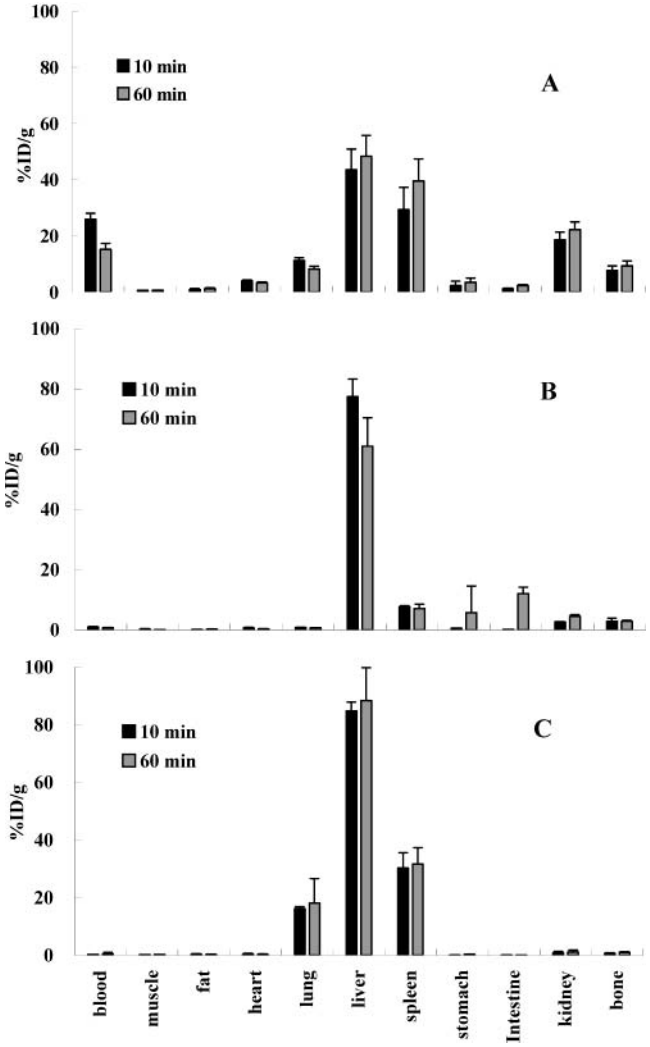

Figure 5. Biodistribution of ^{99m}Tc-HSA (A), ^{99m}Tc-LSA (B), and ^{99m}Tc-tin colloid (C) in mice (male, ICR).

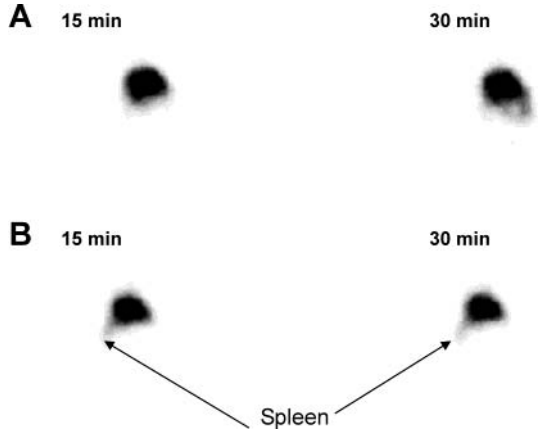

Figure 6. Imaging after injection of ^{99m}Tc-LSA (A) and ^{99m}Tc-tin colloid (B) in rats (male, Sprague−Dawley).

cumulated mainly in the liver and was excreted into the intestine slowly, which is evidence of specific uptake by the asialoglycoprotein receptor and successive metabolism (Figure 5B). ^{99m}Tc-Tin colloid, known to be taken up by the reticuloendothelial system, showed high accumulation in the liver, and the radioactivity was not excreted as expected (Figure 5C). It also showed high accumulation in the spleen. The radioactivity in the lung is due to capillary blockage by aggregated ^{99m}Tc-tin colloid. Very low radioactivity in the intestine indicates little or no metabolism in the liver (Figure 5C). Unlike ^{99m}Tc-HSA, both ^{99m}Tc-LSA and ^{99m}Tc-tin colloid showed very low blood activity due to rapid uptake by the liver.

Imaging Study in Rats. ^{99m}Tc-LSA was taken up by the liver quickly at 15 min, and some activity was excreted into the intestine at 30 min (Figure 6A). No spleen uptake was found. ^{99m}Tc-Tin colloid accumulated mainly in the liver, although some activity was found in the spleen. The activity did not change significantly with time (Figure 6B). These results were consistent with the biodistribution results in the mice.

DISCUSSION

Previously reported galactosylation method has a problem because it requires long preliminary steps for synthesis of precursor of galactosylation (Kudo et al., 1994). In addition the precursor, 2-imino-2-methoxyethyl-1-thio-β-D-galactose, is not suitable for long-term storage due to instability. So the precursor of the precursor, 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-galactose, is generally synthesized and used for synthesis of 2-imino-2-methoxyethyl-1-thio-β-D-galactose to conjugate to human serum albumin. On the other hand, lactose, the precursor of lactosylation, is commercially available at an economical price.

After reductive lactosaminylation, glucose residue of lactose is opened and reduced to a glucitol type linker which is neutral and hydrophilic. Generally, neutral and hydrophilic linkers are ideal for conjugation of haptens to proteins because they may not have much of an effect on the tertiary structure of the conjugated proteins.

Major advances in the labeling of proteins with ^{99m}Tc have been developed with monoclonal antibodies. Many bifunctional chelating agents for linking ^{99m}Tc and antibody have been used. Although DTPA was the first introduced bifunctional chelating agent for labeling antibodies with ^{99m}Tc, it was not used widely because of the problems previously discussed in the Introduction section. Another extensively studied bifunctional chelating agent was N_3S type compound (Kasina et al., 1998). Although this bifunctional chelating agent showed excellent radiochemical and biological properties, the labeling procedure was complicated because of prelabeling and postconjugating procedure. A preconjugation and postlabeling type bifunctional chelating agent, hydrazinonicotinic acid (HYNIC), has been developed to facilitate labeling (Abrams et al., 1990) and has been adapted by many researchers due to excellent labeling efficiency and simple labeling procedure (Schwartz et al., 1991; Blankenberg et al., 1999). The most up-to-date method of labeling proteins might be using tricarbonyl intermediate complex (Alberto et al., 1998; Egli et al., 1999). This method is currently widely studied by many researchers due to high labeling efficiency and high stability despite its two-step labeling procedure.

We applied a direct labeling method to label LSA with ^{99m}Tc, which has been studied for a long time. Direct labeling can be applied only to proteins containing disulfide bonds or sulfhydryl groups. Direct ^{99m}Tc-labeling method of HSA using stannous ion was first reported by Eckelman et al. in 1971. It has been found that preliminary reduction of proteins with stannous tartrate allows for labeling small amounts of proteins (Pettit et al., 1980). A specific labeling method to the high affinity sites of antibodies with ^{99m}Tc to acquire high stability after labeling has been reported (Paik et al., 1985). A practical method with higher than 90% labeling efficiency which employs preliminary reduction with β-mercaptoethanol

and using a weak chelator has also been reported (Mather and Ellison, 1990). The role of the weak chelator was the prevention of colloid formation and weak labeling to the antibodies. In this experiment, we used medronate as a weak chelator and found that colloid formation was completely suppressed, and labeled LSA was stable. Labeling efficiency was also very high (>98%) even after 1 min incubation at room temperature. It is a significant improvement compared to a commercialized GSA kit (neogalactosyl-DTPA-human serum albumin) which requires 30 min incubation at 50 °C for labeling.

Dosage of LSA was formulated as 3 mg/vial in this research. It has been reported that administration of 3 mg of ^{99m}Tc-GSA would be less extensively affected by the physiological asialoglycoprotein (Ha-Kawa et al., 1997). The number of total asialoglycoprotein receptors on the normal liver is $2.5-10 \times 10^{16}$. About 2.4×10^{16} molecules are in 3 mg of LSA. To evaluate the function of the liver, it is necessary to administer close to the saturation number of ligands. If the number of ligands is low, then the image will be normal even though the number of asialoglycoprotein receptors decreases.

Slow increase of radioactivity in the intestines after initial uptake in the liver is due to metabolism in the hepatocytes and successive hepatobiliary excretion. ^{99m}Tc-Tin colloid which is not metabolized showed constant biodistribution as expected. A blood pool imaging agent, ^{99m}Tc-HSA, showed high blood activity. Biodistribution and imaging study show well-correlated results in this experiment.

CONCLUSION

A new imaging agent for asialoglycoprotein receptors of the liver, ^{99m}Tc-LSA, was successfully developed. The new agent showed promising practicability with easy labeling, high labeling efficiency, high stability, and high liver uptake.

ACKNOWLEDGMENT

We would like to express our gratitude to Mr. Keagan H. Lee for his assistance in the English language for this manuscript.

Novel Procedures for Preparing ^{99m}Tc(III) Complexes with Tetradentate/Monodentate Coordination of Varying Lipophilicity and Adaptation to ^{188}Re Analogues

S. Seifert,* J.-U. Künstler, E. Schiller, H.-J. Pietzsch, B. Pawelke, R. Bergmann, and H. Spies

Forschungszentrum Rossendorf, Institut für Bioanorganische und Radiopharmazeutische Chemie, PF 510 119, D-01314 Dresden, Germany. Received December 5, 2003; Revised Manuscript Received March 22, 2004

Improved methods are presented for the preparation of ^{99m}Tc and ^{188}Re mixed-ligand complexes with tetradentate and monodentate ligands of the general formula $[M^{III}(L^m)(L^n)]$ (M = Tc, Re; $L^m = NS_3$ or NS_3COOH; L^n = isocyanide or phosphine). To avoid the undesired formation of reduced-hydrolyzed species of both metals, the preparation of complexes is performed in a two-step procedure. At first the Tc(III)− or Re(III)−EDTA complex is formed which reacts in a second step with the tripodal ligand 2,2′,2″-nitrilotris(ethanethiol) (NS_3) or its carboxyl derivative NS_3COOH (**a**) and the monodentate phosphine ligands (triphenylphosphine **L^1**, dimethylphenylphosphine **L^2**) or isocyanides (*tert*-butyl isonitrile **L^3**, methoxyisobutyl isonitrile **L^4**, 4-isocyanomethylbenzoic acid-L-arginine **L^5,** 4-isocyanomethylbenzoic acid-L-arginyl-L-arginine **L^6**, 4-isocyanomethylbenzoic acid-neurotensin(8−13) **L^7**) to the so-called '4+1' complex. Copper(I) isocyanide complexes are used for preparing the '4+1' complexes. That facilitates storage stability and allows kit formulations, and, moreover, enables the formation of ^{188}Re complexes in acidic solution. Only micromolar amounts of the monodentate ligand are needed, and that results in high specific activity labeling of interesting molecules. The lipophilicity of complexes can be controlled by introducing a carboxyl group into the tetradentate ligand and/or derivatization of the monodentate ligands. Furthermore, the carboxyl group enables the conjugation of biomolecules. As an example, the neurotensin derivative CN-NT(8−13) was prepared and labeled with ^{99m}Tc according to the '4+1' approach, and its behavior in vivo was studied.

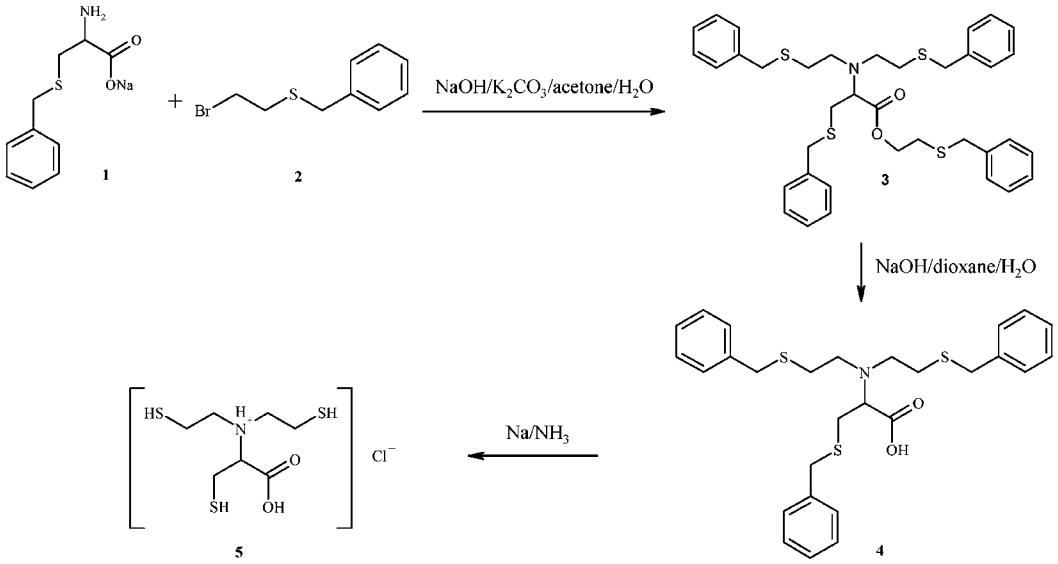
INTRODUCTION

Technetium and rhenium mixed-ligand complexes represent an important approach to the development of radiotracers for diagnostic and therapeutic application because of the many possibilities to vary their biobehavior. Such complexes contain the metal ion stabilized in an appropriate oxidation state by means of a suitable ligand framework, which only partially fills the coordination sphere. Examples are the technetium and rhenium tricarbonyl moiety $[M^I(CO)_3]^+$ (*1*), the "super-nitrido" $[Tc^V(N)(PNP)]^{2+}$ (PNP = tridentate aminediphosphine ligand) fragment (*2*), the substitution-inert $[Re^V(O)(L)]^{2+}$ moiety (L = bidentate functionalized phosphine) (*3*), and the $[M^V(O)(SES)]^+$ (SES = tridentate dithiol ligand; E = S, NR, O) group of the well-known '3+1' Tc and Re complexes (*4*, *5*). In all cases the coordination sphere of the metal ion is completed by substitution of mono-, bi-, or tridentate coligands, which may balance the charge of the complexes.

However, differences were observed in connection with the stability of the final complexes in vitro and in vivo. Especially the 3+1 complexes undergo a substitution reaction in vivo with the SH-group-containing molecules such as cysteine or glutathione (*6*−*9*). To overcome this problem, the search focused on stable mixed-ligand complexes of technetium and rhenium at other oxidation states than +V and led to the development of the so-called '4+1' and '3+2' Tc(III) complexes (*10*, *11*).

This class of technetium and rhenium mixed-ligand complexes at the oxidation state III with tetradentate/monodentate NS_3/isocyanide or phosphine coordination, the so-called '4+1' complexes, was described some years ago (*12*, *13*). Recently the synthesis and structural analysis of ^{99}Tc complexes with simple isocyanides was performed and a first way of the no-carrier-added preparation was investigated (*14*). Moreover, the '4+1' approach was used for preparing receptor-affine complexes which contain isocyanides with the receptor binding region 2-methoxyphenylpiperazine, derived from the selective receptor antagonist WAY 100 635 ([*N*-(2-(1-(4-(2-methoxyphenyl)piperazinyl)ethyl))-*N*-(2-pyridinyl)cyclohexanecarboxamide]) (*15*).

The trigonal-bipyramidal '4+1' Re and Tc complexes containing NS_3[1] and isocyanides or phosphines as coligands are stable against ligand exchange with cysteine or glutathione and in vitro in incubations with plasma as well as whole blood of rats and represent therefore an alternative to the '3+1' complexes concerning the possibilities of designing biologically interesting ^{99m}Tc- or ^{188}Re-labeled compounds (*14*).



In the present paper, we report on improved preparation methods for no carrier added '4+1' ^{99m}Tc and carrier

free '4+1' ^{188}Re complexes, present a kit preparation, demonstrate possibilities of "fine-tuning" the lipophilicity and biodistribution using the simple NS_3 ligand or a carboxyl group-substituted NS_3 ligand as tripodal ligands and isocyanides as well as various phosphines as monodentate ligands, and describe the possibilities of labeling of biomolecules.

EXPERIMENTAL PROCEDURES

Materials and Methods. EDTA was purchased from Riedel-deHaen. Isocyanides were obtained from Johnson Matthey GmbH, TBI from Alfa Products, and a commercial Cardiolite kit and MIBI from Bristol-Myers-Squibb. PPh_3 and PMe_2Ph were purchased from Aldrich. All solvents and commercially available substances were of reagent grade and used without further purification. The tripodal ligand NS_3 was prepared according to standard procedures starting from tris(2-chloroethyl)-amine hydrochloride (*16*). ^{99}Tc as NH_4TcO_4 was obtained from Amersham as a 0.3 M aqueous solution. $^{99m}TcO_4^-$ was eluted from a commercial $^{99}Mo/^{99m}Tc$ generator (Mallinckrodt). $^{188}ReO_4^-$ was eluted from a $^{188}W/^{188}Re$ generator (Oak Ridge National Laboratories, Oak Ridge, TN).

Thin-layer chromatography (TLC) and high performance liquid chromatography (HPLC) analyses were performed for controlling the identity, the radiochemical purity, and the stability of the preparations. For TLC studies, silica gel strips (Kieselgel 60, Merck) or cellulose strips (Merck) were used and developed with mobile phases of acetone and water. The strips were scanned with a Raytest Rita radioanalyzer. HPLC analyses were performed on a Perkin-Elmer device consisting of a Turbo LC System with a quaternary pump (Series 200 LC Pump), a Programmable Absorbance Detector Model 785A, and a homemade γ-ray detector (Bohrloch, NaI-(Tl) crystal). HPLC analyses were carried out with a Hypersil ODS column (250 × 4 mm) using a gradient eluant of methanol/0.01 M phosphate buffer, pH 7.4, and a flow rate of 1.0 mL/min or with a Zorbax 300SB-C18 column (5 μm, 250 × 9.4 mm, Agilent) using a gradient eluant of acetonitrile (A) with 0.04% TFA/water (B) with 0.05% TFA, gradient elution: 0−12 min 5 to 70% A, 12−15 min 70−90% A, 15−18 min 90% A, and a flow rate of 2.0 mL/min. The effluent from the columns was monitored by UV absorbance at 254 nm for ^{99}Tc or Re reference complexes or γ-ray detection for the ^{99m}Tc and ^{188}Re complexes. The following three methods were used for HPLC analyses of derivatized peptides and rhenium complexes thereof.

Method 1: Jupiter C-18 (5 μm, 300 Å, 250 × 4,6 mm, Phenomenex), 1 mL/min, rt, solvent A comprised water with 0.1% trifluoroacetic acid (TFA) and solvent B comprised acetonitrile with 0.1% TFA, gradient elution: 0−20 min 20 to 80% B, 20−40 min 80% B.

Method 2: Zorbax 300SB-C18 (5 μm, 250 × 9,4 mm, Agilent), 3 mL/min, r.t., solvent A comprised water with 0.1% TFA and solvent B comprised acetonitrile with 0.1% TFA, gradient elution: 0−20 min 20 to 80% B, 20−40 min 80% B.

Method 3: Zorbax 300SB-C18 (5 μm, 250 × 9,4 mm, Agilent), 2 mL/min, 40 °C, solvent A comprised water with 0.04% TFA and solvent B comprised acetonitrile with 0.05% TFA, gradient elution: 0−12 min 5 to 70% B, 12−15 min 70−90% B, 15−18 min 90% B.

Mass spectrometric analyses were carried out on a Micromass Tandem Quadrupole Mass Spectrometer (Quattro LC) operating in the MS mode. Mass spectral data were recorded at the negative and positive ESI mode using a cone voltage of 20 or 60 V. About 0.1 mg of the sample dissolved in 1.0 mL methanol/water (50/50) and 0.05% formic acid was infused at a flow rate of 5 μL/min. Nuclear magnetic resonance spectra were recorded on a 400 MHz Varian Inova 400 spectrometer. Chemical shifts are reported as δ in ppm relative to the residual solvent signal or TMS. IR spectra were recorded on the FTIR spectrometer IR 2000 (Perkin-Elmer) using KBr pellets.

Preparation of Copper Isocyanide Complexes. Copper isocyanide complexes were prepared as described for $[Cu(TBI)_4]Cl$ (17) to stabilize the ligands against oxidation and to generate a lyophilizable form of the ligands.

Preparation of NS_3COOH. The NS_3COOH ligand (**5**) was prepared from *S*-benzylcysteine (**1**) by reaction with 1-benzylsulfanyl-2-bromoethane (**2**) to give 3-benzylsulfanyl-2-[bis(2-benzylsulfanylethyl)amino]propionic acid 2-benzylsulfanyl ethyl ester (**3**), hydrolysis of the ester, and deprotection with sodium in liquid ammonia (Scheme 1).

S-Benzylcysteine **1** is commercially available (Arcos Organics), and 1-benzylsulfanyl-2-bromoethane **2** was

synthesized according to the method described by Trujillo and co-workers (*18*).

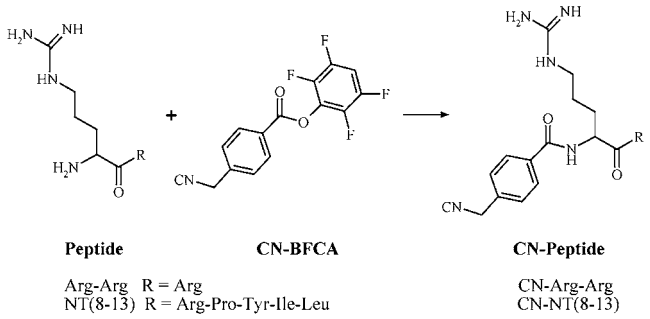
Preparation of 3-Benzylsulfanyl-2-[bis(2-benzylsulfanylethyl)amino]propionic Acid 2-Benzylsulfanylethyl Ester 3. Acetone (50 mL) was added to an aqueous solution of 0.01 mol (2.33 g) **1**, 0.04 mol (5.52 g) K_2CO_3, and 0.04 mol (1.6 g) NaOH. Afterward 0.05 mol (11.56 g) **2** dissolved in 10 mL of acetone was added dropwise at room temperature. The reaction mixture was stirred at room temperature for 6 days, and then the volume was reduced in vacuo. The remaining solution was extracted with diethyl ether. Removal of the solvent in vacuo gave a pale yellow oil which was purified by column chromatography (silica gel, *n*-hexane/ethyl acetate/triethylamine (75:25:0.1)). Yield: 38% pale yellow oil.

Analytical Data for ***3***. ^{1}H NMR: ($CDCl_3$): δ 2.37 (t, 4H), 2.63 (m, 8H), 3.73 (t, 1H), 3.65 (s, 6H), 3.73 (s, 2H), 4.16 (t, 2H), 7.26 (m, 20$H_{arom.}$). ^{13}C NMR: ($CDCl_3$): δ 29.7, 30.5, 31.7, 36.2, 36.4, 36.8, 51.4, 62.8, 63.8, 127.0, 127.1, 127.2, 128.5, 128.6, 128.9, 137.9, 138.2, 138.4, 171.3. ESI-MS (*m*/*z*) calcd (found): 663 (663) for $[M + H]^+$.

Preparation of 3-Benzylsulfanyl-2-[bis(2-benzylsulfanylethyl)amino]propionic Acid 4. A solution of 1 mmol (0.66 g) **3** in 10 mL of 1 N NaOH and 10 mL of dioxane was heated under reflux for 3 h. After cooling, 10 mL of acetic acid were added, and the reaction mixture was stirred at room temperature for another 1 h. Afterward it was extracted three times each with 10 mL $CHCl_3$. After drying over $MgSO_4$ and filtration, the organic solvent was removed in vacuo. The remaining oil was purified by column chromatography (silica, *n*-hexane/ethyl acetate (1:1)). Yield: 78% colorless oil.

Analytical Data for ***4***. ^{1}H NMR: ($CDCl_3$): δ 2.39 (t, 4H), 2.64 (m, 5H), 3.04 (dd, 1H), 3.30 (dd, 1H), 3.65 (m, 4H), 3.69 (s, 2H), 7.27 (m, 15$H_{arom.}$). ^{13}C NMR: ($CDCl_3$): δ 29.4, 30.1, 36.3, 37.6, 50.4, 64.2, 127.2, 127.3, 128.6, 128.7, 128.9, 137.9, 173.0.

Preparation of 2-[Bis(2-mercaptoethyl)amino]-3-mercaptopropionic Acid Hydrochloride 5. A solution of 0.4 mmol (0.2 g) **4** in 2 mL of dry THF was dropped to about 5 mL of liquid ammonia. Sodium was added in small portions until the solution remained deep blue for 15 min. The solvents were removed in an argon stream. To the white residue was added 5 mL water, and the solution was acidified with 1 N HCl (pH 2−3). The solution was extracted with ethyl acetate (3 × 5 mL). The combined organic phases were extracted with 1 N HCl (4 × 5 mL). Removal of the water in vacuo yielded 0.1 g (90%) of a colorless viscous oil.



Analytical Data for ***5***. ^{1}H NMR: (D_2O): δ 2.97 (t, 4H), 3.12 (dd, 1H), 3.23 (dd, 1H), 3.56 (m, 4H), 4.22 (t, 1H). ^{13}C NMR: (D_2O): δ 18.8, 20.8, 54.4, 67.0, 169.6. ESI-MS (*m*/*z*) calcd (found): 242 (242) for $[M + H]^+$.

Preparation of CN-NT(8−13), CN-Arg-Arg, CN-Arg. As an example for the labeling of interesting biomolecules following the 4+1 principle, isocyanide-derivatized peptides were prepared in the following way (Scheme 2).

Preparation of 4-Isocyanomethyl Benzoic Acid 2,3,5,6-Tetrafluorophenyl Ester (CN-BFCA). The CN-BFCA compound **C** was prepared by formylation of 4-aminomethyl benzoic acid to give **A**, esterification with 2,3,5,6-tetrafluorophenol, and converting **B** to **C**.

Preparation of 4-Formylaminomethyl Benzoic Acid (A). 4-Aminomethyl benzoic acid (7 g, 0.046 mol) was dissolved in 80 mL of formic acid and 50 mL of acetic anhydride and heated under reflux for 3 h. After removal of the solvent, the remaining white powder was washed with diethyl ether and recrystallized from 2-propanol. Yield: 90%.

Scheme 2

Preparation of 4-Formylaminomethyl Benzoic Acid 2,3,5,6-Tetrafluorophenyl Ester (B). A (6 g, 0.033 mol) was dissolved in 30 mL of *N*,*N*-dimethylformamide (DMF), and a solution of 6.9 g (0.033 mol) *N*,*N*′-dicyclohexylcarbodiimide in 15 mL of DMF was added at 0 °C. After the mixture was stirred for 20 min, 5.7 g (0.033 mol) of 2,3,5,6-tetrafluorophenol dissolved in 5 mL of DMF was added. The mixture was stirred for 4 h at 0 °C and overnight at room temperature. The formed precipitate was separated by filtration, the supernatant was evaporated, and the remaining product was recrystallized from chloroform and *n*-hexane. Yield: 70%.

Preparation of 4-Isocyanomethyl Benzoic Acid 2,3,5,6-Tetrafluorophenyl Ester (C). B (0.5 g, 1.5 mmol) was dissolved in 12 mL of anhydrous pyridine, and 430 mg (2.25 mmol) of *p*-toluenesulfonyl chloride was added. After being stirred for 1.5 h at room temperature, the mixture was transferred in a flask filled with ice. After of the ice was slowly melted, the precipitate was filtered off and washed with water until no pyridine smell was noticed. The product was purified by column chromatography on silica gel 60 using a mixture of *tert*-butyl methyl ether and *n*-hexane (5:2) as eluent. The product fraction was evaporated and recrystallized from chloroform and *n*-hexane. Yield. 45%. ^{1}H NMR: (DMSO-d_6): δ 5.09 (s, 2H), 7.66 (d, 2H_{arom}), 7.98−8.07 (m, 1H), 8.24 (d, 2H_{arom}). IR: 1759 cm^{-1} (st, C═O), 2167 cm^{-1} (m, C≡N).

Preparation of CN-NT(8−13), CN-Arg-Arg, CN-Arg. NT(8−13) (70%) (4.7 mg, 4 μmol) was dissolved in 400 μL of DMF and 1.2 μL (8 μmol) of triethylamine, and 1.2 mg (4 μmol) of CN-BFCA dissolved in 100 μL of DMF was added. Alternatively, 7.9 mg (15 μmol) of L-arginyl-L-arginine (63%) or 5.3 mg (25 μmol) of L-arginine dihydrochloride were dissolved in a mixture of 800 μL of DMF and 150 μL of water. Triethylamine (35 μL, 0.25 mmol) and 7.7 mg (25 μmol) of CN-BFCA were added to the L-arginyl-L-arginine solution, and 20 μL (0.15 mmol) of triethylamine and 4.6 mg (15 μmol) of CN-BFCA were added to the L-arginine solution. After being stirred for 4−6 h at room temperature, the solvent was removed. The residues were dissolved in a mixture of acetonitrile and water (1:1) and then purified by semipreparative HPLC (method 2). The product fraction was neutralized with aqueous ammonia (2.5%) immediately after collecting and lyophilized. Yields: 50−60%. The substances were checked by HPLC and ESI-MS. HPLC: t_R = 10.1 min for CN-NT(8−13), t_R = 4.9 min for CN-Arg-Arg, t_R = 5.6 min for CN-Arg (method 1). ESI-MS (*m*/*z*) calcd (found): 961 (961) for $[CN\text{-}NT(8-13)]^+$, 474 (474) for [CN-Arg-Arg]$^+$, 318 (318) for $[CN\text{-}Arg + H]^+$.

Preparation of Reference Rhenium Complexes. *[Re(NS$_3$)CN-BFCA].* CN-BFCA (170 mg, 0.54 mmol) dissolved in 4 mL of chloroform were added to 206 mg

(0.4 mmol) of [Re(NS_3)PMe_2Ph] dissolved in 4 mL of chloroform. The mixture was stirred at 50 °C for 1 h and then evaporated to give an oily residue which was washed with diethyl ether to obtain an olive-brown powder. The substance was crystallized from chloroform after adding of methanol and diethyl ether at −18 °C. Yield: 95%. ^{1}H NMR: (DMSO-d_6): δ 2.8−3.2 (broad s, 12H), 6.15 (s, 2H), 7.79 (d, 2$H_{arom.}$), 7.97−8.07 (m, 1H), 8.20 (d, 2$H_{arom.}$). IR: 1752 cm^{-1} (st, C═O), 1922 cm^{-1} (st, C≡N). ESI-MS (*m*/*z*) calcd (found): 690, 692 (690, 692) for $[M + H]^+$.

[Re(NS_3)CN$CH_2C_6H_4$COOH]. A solution of 13 mg (0.3 mmol) of LiOH·H_2O in 3 mL of water was added to 54 mg (80 μmol) of [Re(NS_3)CN-BFCA] dissolved in 5 mL of tetrahydrofuran. After being stirred for 2 h at room temperature, the mixture was acidified with concentrated HCl. The olive precipitate was separated by filtration, washed with water and recrystallized from acetonitrile and methanol. Yield: 70−80%. ^{1}H NMR: (DMSO-d_6): δ 2.8−3.2 (broad s, 12H), 6.07 (s, 2H), 7.62 (d, 2H_{arom}), 7.94 (d, 2H_{arom}). IR: 1685 cm^{-1} (st, C═O), 1988 cm^{-1} (st, C≡N). HPLC: t_R = 17.9 min (method 1), t_R = 16.8 min (method 3), ESI-MS (*m*/*z*) calcd (found): 542, 544 (542, 544) for $[M + H]^+$.

[Re(NS_3)CN-NT(8−13)], [Re(NS_3)CN-Arg-Arg], [Re(NS_3)CN-Arg]. NT(8−13) (70%) (4.7 mg, 4 μmol) was dissolved in 400 μL of DMF, 1.2 μL (8 μmol) of triethylamine, and 2.8 mg (4 μmol) of [Re(NS_3)CN-BFCA] dissolved in 100 μL of DMF were added. Alternatively, 3.2 mg (15 μmol) of L-arginine dihydrochloride and 7.9 mg (15 μmol) of L-arginyl-L-arginine (63%) were dissolved separately in a mixture of 500 μL of DMF, 100 μL of water, and 20 μL (0.15 mmol) of triethylamine. [Re(NS_3)-CN-BFCA] (10.3 mg, 15 μmol) dissolved in 100 μL of DMF was added to each reaction mixture. After being stirred for 4−6 h at room temperature, the solvent was removed. The residues were dissolved in a mixture of acetonitrile and water (1:1), purified by semipreparative HPLC (method 2), and lyophilized. Yields: 50−60%. HPLC: t_R = 14.9 min (method 1), 14.5 min (method 3) for [Re(NS_3)-CN-NT(8−13)]; t_R = 12.5 min (method 1), 13.1 min (method 3) for [Re(NS_3)CN-Arg-Arg]; t_R = 13.8 min (method 1), 14.1 min (method 3) for [Re(NS_3)CN-Arg]. ESI-MS (*m*/*z*) calcd (found): 1341, 1343 (1341, 1343) for $[Re(NS_3)CN\text{-}NT(8-13)]^+$; 854, 856 (854, 856) for $[Re(NS_3)CN\text{-}Arg\text{-}Arg]^+$; 698, 700 (698, 700) for $[Re(NS_3)CN\text{-}Arg + H]^+$.

[Re(NS_3)PMe_2Ph] and Re or ^{99}Tc references for the 4 + 1 ^{99m}Tc complexes were synthesized according to (3).

Synthesis Procedure for the '4 + 1' ^{99m}Tc Complexes. *^{99m}Tc-EDTA.* To a kit formulation containing 5 mg of EDTA, 5 mg of mannitol, and 0.08 mg of $SnCl_2$ in freeze-dried form under nitrogen was added 2−5 mL of eluate of a ^{99}Mo/^{99m}Tc generator, and the solution was allowed to stand for 5 min at room temperature. Radiochemical purity: >95% (TLC).

'4+1' ^{99m}Tc Complexes. *Method 1.* NS_3 or NS_3COOH (0.3 mg) and isocyanide (0.05 mg) or phosphine (0.05−0.1 mg) were dissolved in 0.5−1.0 mL of methanol and added to the ^{99m}Tc-EDTA solution using a syringe. The reaction mixture was heated at 75 °C in a glycol bath for 30 min. Radiochemical purity: 90−97% (HPLC and TLC).

Method 2. ^{99m}Tc-EDTA solution (2.0−5.0 mL) prepared as described above was added to a kit vial containing 0.1 mg of the tetradentate ligand and 0.05 mg of [Cu(isocyanide)$_4$]Cl. The solution was allowed to stand at room temperature for 30−45 min or was heated at 50 °C for 15 min. Radiochemical purity: 90−97% (HPLC and TLC). The identity of the species obtained was confirmed by comparison with the HPLC profiles of ^{99}Tc or Re analogues. For stability and biodistribution studies, the ^{99m}Tc preparations were purified by semipreparative HPLC, the organic eluants were evaporated in vacuo, and the complexes were redissolved in saline and 20% propylene glycol.

Synthesis Procedure for the '4+1' ^{188}Re Complexes. *^{188}Re-EDTA.* Perrhenate eluate (3−5 mL) from a ^{188}W/^{188}Re generator was added together with 0.5 mL of 0.1 N HCl to a kit vial containing 5 mg of EDTA, 5 mg of mannitol, and 1.0 mg of $SnCl_2$ in freeze-dried form under nitrogen. After 20−30 min at room temperature, the complex formation is finished. Yield: >95% (TLC).

'4+1' ^{188}Re Complexes. NS_3 ligand (0.3 mg) and phosphine (0.05−0.20 mg) or [Cu(isocyanide)$_4$]Cl (0.05 mg) dissolved in 0.5 mL of water and 0.5 mL of methanol were added with a syringe to the Re-EDTA preparation, and the solution was heated at 90 °C for 30 min or at 50 °C for 1 h. Radiochemical purity: 75−85% (HPLC and TLC).

Determination of Partition Coefficients. Partition coefficients of the model ^{99m}Tc and ^{188}Re complexes were determined by shake-flask method by mixing 0.5 mL of the complex solution (0.1 M phosphate buffer pH 7.4 with 20% propylene glycol) and 0.5 mL of octanol and shaking for 5 min. After centrifugation aliquots of both phases were counted and the partition coefficient calculated.

Stability Studies. The in vivo stability of [^{99m}Tc(NS_3)-CN-NT(8−13)] was studied using rat arterial blood samples at various time points (0.5, 3, and 24 min) after injection of 50 MBq of [^{99m}Tc(NS_3)CN-NT(8−13)]. Ethanol (150 μL) was added to 100 μL of the supernatants obtained after centrifugation (11000*g*, 3 min) of the blood samples to precipitate the blood cells. Than the samples were cooled at −60 °C for 5 min. After centrifugation, the supernatant was analyzed by HPLC. For in vitro experiments, 500 μL of rat blood and plasma were incubated with the ^{99m}Tc compound (2−5 MBq) at room temperature for 120 min. The samples were treated as described above and analyzed by HPLC. To identify the degradation products, their t_R values were compared with [^{99m}Tc(NS_3)CN-NT(8−13)], [^{99m}Tc(NS_3)CN-Arg-Arg], [^{99m}Tc(NS_3)CN-Arg], [Re(NS_3)$CNCH_2C_6H_4$COOH] and $^{99m}TcO_4^-$ or coinjection experiments were performed.

Biodistribution Studies. The animal studies were carried out according to the relevant national regulations using male Wistar rats (5−6 weeks old). The ^{99m}Tc complex solution (0.5 MBq) (0.5 mL) was injected into the tail vein under slight ether anesthesia. After the injection, the rats were sacrificed by heart puncture 5 and 60 min postinjection (pi). Selected organs were isolated for weighing and counting. The activity concentration in the tissue of organs was calculated in terms of percentage of injected total activity (dose) per gram tissue (% ID/g).

RESULTS AND DISCUSSION

To find out optimum preparation conditions and to study the possibilities of "fine-tuning" of lipophilicity and their consequences on biodistribution in rats, simple isocyanides and phosphines as well as ligands containing carboxyl or ether functionalities were used (Figure 1). Moreover, as an example for labeling of biomolecules the peptides NT(8−13) as well as Arg-Arg and Arg (as reference complex) were labeled with ^{99m}Tc using the '4+1' approach and its stability in vitro and in vivo was studied.

Preparation of the '4+1' ^{99m}Tc Complexes. When the '4+1' technetium-99m complexes were prepared by

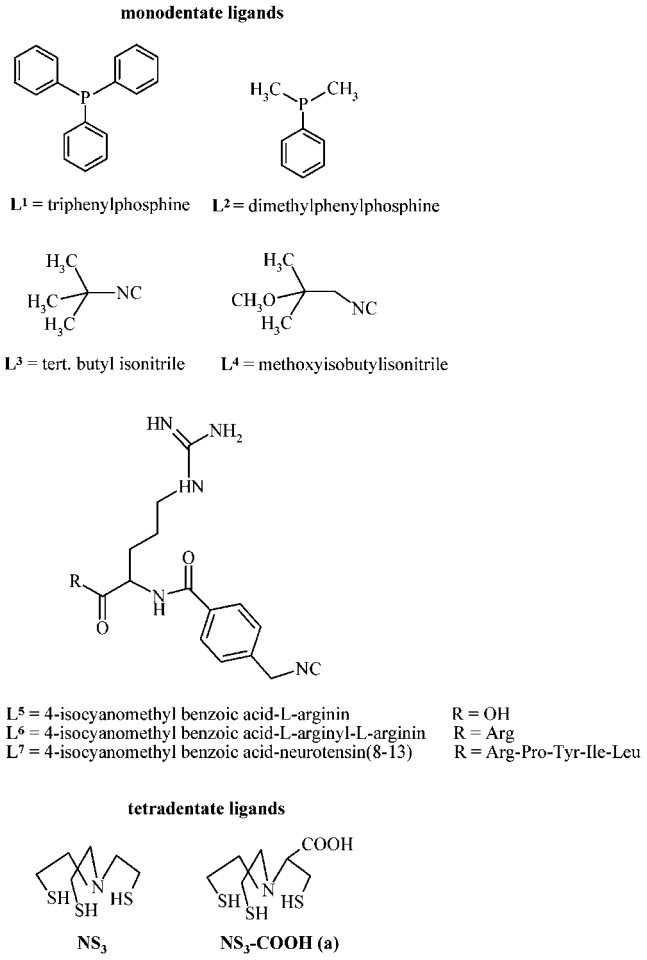


Figure 1. Structures of the ligands used for present studies.

a one-step procedure starting from pertechnetate with stannous chloride as reducing agent, more than 30% of reduced-hydrolyzed technetium was formed. These undesired large amounts of Tc hydroxide motivated us to search for a better reaction route. To avoid the formation of Tc hydroxide we prepared the '4+1' complexes in a two-step procedure. At first the ^{99m}Tc(III)-EDTA complex was formed, which in a second step reacts with both ligands to the desired '4+1' complex (Scheme 3).

To prepare the Tc-EDTA complex, a kit formulation was used. Five milligrams of EDTA, 5 mg of mannitol, and 0.08 mg of stannous chloride, which are contained in a vial in freeze-dried form and under nitrogen, are optimum amounts also for the complexation of high radioactive concentrations of technetium-99m (1−3 GBq/mL eluate). It was observed that the stability of such a Tc-EDTA preparation decreased when lower ligand concentrations were applied. Lower ^{99m}Tc activities (10−100 MBq/mL) need only 0.2 mg of EDTA and 0.01 mg of $SnCl_2$ for complete reduction of pertechnetate. The higher amounts of EDTA did not influence the ligand exchange reaction with the NS_3 ligand and the isonitrile or phosphine. We found that in order to prepare the intermediate complex it is also possible to use an EHIDA-kit (ROTOP Pharmaka GmbH) which contains 20 mg of the aminopolycarboxylic acid. In all cases >95% of the desired Tc-EDTA complex were formed and less than 1−2% of Tc hydroxide was detected by TLC.

In a second preparation step the ^{99m}Tc-EDTA complex reacts with optimized ligand amounts to the '4+1' complex. As an example, we studied the reaction of NS_3 and TBI with the Tc-EDTA complex and found that at high temperatures (30 min at 75 °C) 0.3 mg of NS_3 and 0.04 mg of TBI are sufficient ligand amounts to achieve a radiochemical purity of more than 95%. With 0.01 mg of TBI yields of about 70% were still obtained.

Table 1. Partition Coefficients Log *P* (octanol/0.1 M phosphate buffer, pH 7.4) of the '4+1' ^{99m}Tc and ^{188}Re Complexes (n = 3)

complex no.	log $P_{o/w}$ ^{99m}Tc	log $P_{o/w}$ ^{188}Re
1	1.83	1.78
1a	1.54	1.01
2	1.27	1.25
2a	1.10	0.96
3	1.28	1.14
3a	0.31	0.46
4	1.35	1.34
4a	−0.42	−0.27

A further improvement of preparation conditions was realized by using a copper(I) isocyanide complex instead of the free isonitrile ligand. That allows to prepare freeze-dried kit formulations. The complex $[Cu(TBI)_4]Cl$ was prepared and for optimum reaction conditions per vial 0.05 mg of the copper complex were lyophilized together with 0.1 mg of NS_3-oxalate. The Tc-EDTA solution was added with a syringe to the vial containing both of the ligands and the '4+1' ^{99m}Tc complex was formed with yields of >95% by incubation the reaction solution for 10 min at 50 °C. Reaction at room temperature requires a longer time of about 30 min.

Preparation of the '4+1' ^{188}Re Complexes. In principle, the preparation of the '4+1' ^{188}Re complexes followed the same two-step procedure as described for the technetium-99m complexes. At first the ^{188}Re-EDTA complex was prepared. Surprisingly, this was accomplished under relatively mild conditions with at least 1.0 mg $SnCl_2$. Lower Sn^{2+} concentrations or pH values >3 led to incomplete reduction of perrhenate. The addition of both ligands for the second step of reaction had to occur in the acidic solution. In the case of phosphines that was unproblematic. However, isocyanides are not stable under acidic conditions, but react with water to give the corresponding formamide and finally the amine. The use of copper isocyanide complexes widely prevents the degradation of isocyanides and thus allows the preparation of the corresponding '4+1' ^{188}Re complexes.

According to the optimized reaction conditions various '4+1' ^{99m}Tc and ^{188}Re complexes were prepared with the ligands listed in Figure 1, purified by HPLC, and characterized. We determined the influence of the carboxyl group of the NS_3COOH ligand on the octanol/water partition coefficient and the biodistribution of the complexes. Moreover, the biodistribution of ^{99m}Tc complexes with simple monodentate ligands (TBI, Me_2PhP) was compared with that of an ether group-containing ligand (MIBI). As examples for labeling of biomolecules two peptides and arginine were functionalized and labeled according to the '4+1' approach.

Comparison of the Log $P_{o/w}$ Values. Examination of the octanol/water partition coefficients suggests comparable high lipophilicity for ^{99m}Tc and ^{188}Re complexes with NS_3 and alkyl or aryl group-containing monodentate ligands. As shown in Table 1, the lipophilicity decreases at the introduction of a carboxyl group into the tetradentate ligand. Especially complexes with a small isonitrile (TBI) or an ether-derivatized monodentate ligand (MIBI) show increased hydrophilicity. The effect is less intensive using small phosphines as monodentate ligands.

Biodistribution of Complexes 2/2a−4/4a and 5 in Rats. Only ^{99m}Tc complexes were used to study the

[a] Values represent the means ± SD (n = 4) of the percent injected dose/gram.

biodistribution in rats. In case of ^{188}Re complexes the risk of reoxidation of Re(III) to Re(VII) is higher than for ^{99m}Tc complexes and can lead to other results. This will be subject of another study. In general, the low accumulation of radioactivity in the stomach and the thyroid indicates the stability of the chelate unit (data not shown). The change of lipophilicity of the ^{99m}Tc complexes caused by variation of the outer sphere of the complexes is reflected by their biodistribution in rats (Table 2).

The introduction of a carboxyl group in the NS_3 ligand results in an obvious decrease of lipophilicity of complexes, especially in the case of isocyanide complexes (Table 1). That results in a high renal excretion of these complexes. The washout from the liver is also accelerated. The remarkably high primary concentration of complexes **3a** and **4a** in the blood may be caused by an unspecific binding of these complexes to plasma proteins. Such a plasma protein binding was also observed by HPLC analyses of in vivo plasma samples prepared 60 min after injection. It was not found for complex **2a**.

The increasing uptake of complexes **2**, **3**, and **4** in the liver and kidneys over time could be the result of other accumulation mechanisms of the complexes in these organs, which will be subject to further analysis. As known from the Tc(I) isocyanide complexes [^{99m}Tc-(MIBI)$_6$]$^+$ and [^{99m}Tc(EIBI^{13})$_6$]$^+$ which both contain ether groups in the ligand molecules, the clearance of such a complex through the liver is enlarged in comparison with the [^{99m}Tc(TBI)$_6$]$^+$ complex (*19*, *20*). That difference is not observed for the '4+1' complexes **3** and **4**. Despite the ether group of the MIBI complex **4**, the liver uptake is higher and increases with time in almost the same manner as observed for **3**.

Since the main catabolite of the in vivo degradation of complex **7**, the complex **5**, showed high in vivo stability over 120 min, its biodistribution in Wistar rats 5 and 120 min pi was also determined. The elimination of **5** from the blood was comparable with that of complexes **2**, **2a**, and **4**. After fast accumulation of **5** in the liver the activity decreased to about 2.3% ID/g after 60 min, which is comparable with the activity concentration in the liver of the other ^{99m}Tc complexes.

Stability Studies. Stability studies in vitro and in vivo were performed with the NT(8−13)-containing complex **[^{99m}Tc]7**. Generally, catabolites of ^{99m}Tc-labeled biomolecules can be generated by proteolytic degradation, by other elimination processes or by derivatization of the chelate unit and/or the biomolecules by various enzymatic reactions in vivo. Preliminary studies have provided an indication of in vitro and in vivo stability of the used '4+1'

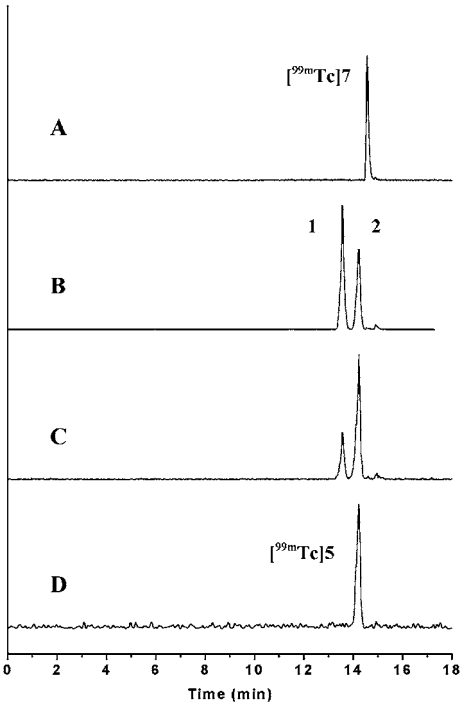

Figure 2. Catabolism of **[^{99m}Tc]7** in rats. (A) radioactive trace of complex **7**, (B) rat plasma sample, 0.5 min pi, (C) 3 min p.i., (D) 24 min pi; experiments were performed using a reversed-phase column (Zorbax 300SB-C18 (Agilent); 5 μm, 250 × 9.4 mm).

chelate unit (*3*). It is assumed that catabolites of **[^{99m}Tc]-7** are primarily formed by converting of the bound NT-(8−13). In vivo, NT(8−13) is extensively degraded by peptidases. That was also observed for the '4+1' ^{99m}Tc complex **7**. **[^{99m}Tc]7** was degraded so fast in vivo that already 0.5 min after injection the original compound was no longer detected in the plasma sample. **[^{99m}Tc]5** (catabolite 2) was identified by comparison with the Re reference complexes as the main degradation product in the plasma samples in vivo. It was the only ^{99m}Tc-labeled compound in the plasma 24 min after injection. Catabolite 1 was not identified, but it should be an intermediate product formed during the catabolism of complex **7**.

In vitro, 85−90% of **[^{99m}Tc]5** were detected after incubation with rat plasma for 120 min (Figure 2).

CONCLUSION

A novel two-step procedure allows "kitlike" preparations of '4+1' ^{99m}Tc and ^{188}Re complexes. In a first step, the metal(III)-EDTA complex is formed, which reacts in a second step with optimized ligand amounts to the desired '4+1' complex. Using oxalate salts of NS_3 ligands and copper isocyanide complexes or phosphonium salts as monodentate ligands, kit formulations can be prepared and reconstituted with pertechnetate or perrhenate in high yields. Only micromolar amounts of the monodentate ligand are needed and that results in high specific activity labeling of interesting molecules. The reduction of perrhenate has to be performed in acidic solutions and needs more quantities of EDTA and of the reducing agent stannous chloride, but not of the NS_3 ligand and the isocyanide or phosphine. Thus, high labeling yields are possible at low ligand concentration also with ^{188}Re. The lipophilicity of complexes can be controlled by introducing a carboxyl group into the tetradentate ligand and/or derivatization of the monodentate ligand. Moreover, the described approach allows the functionalization of a biomolecule with the tripodal as well as the monodentate ligand. The isocyanides and phosphines offer the possibility to vary the length and type of spacer for coupling the biomolecule. As an example, the neurotensin derivative CN-NT(8−13) was labeled with ^{99m}Tc according to the '4+1' approach and its behavior in vivo was studied. Although no stabilization effect after complexation of the peptide against peptidases was observed, the example demonstrates the usefulness of the '4+1' approach for high specific activity labeling of biomolecules under mild conditions with ^{99m}Tc and ^{188}Re.

ACKNOWLEDGMENT

We would like to thank Dr. Wunderlich (Klinik und Poliklinik für Nuklearmedizin, TU Dresden) for generously providing a ^{188}W/^{188}Re generator and Dr. S. H. Park (Division of Radioisotope Production and Application, HANARO center, Korea) for determination of partition coefficients.

Gastrin/CCK-2 receptors are overexpressed in a number of tumors such as medullary thyroid cancer (MTC) and small cell lung cancer (SCLC). Recently [D-Glu^1]-minigastrin (MG) has been radiolabeled with ^{131}I, ^{111}In, and ^{90}Y and evaluated in patients. This study describes the labeling and evaluation of MG with technetium-99m using two different labeling approaches: HYNIC as bifunctional coupling agent and (N_α-His)Ac as tridentate ligand for ^{99m}Tc(CO_3) labeling. Labeling was perfomed at high specific activities using Tricine and EDDA as coligands for HYNIC-MG and $[^{99m}Tc(OH_2)_3(CO)_3]^+$ for (N_α-His)Ac-MG. Stability experiments were carried out by reversed phase HPLC analysis in PBS, serum, histidine, and cysteine solutions, as well as rat liver and kidney homogenates. Receptor binding and internalization experiments were performed using CCK-2 receptor positive AR42J rat pancreatic tumor cells. Biodistribution experiments were carried out in nude mice carrying AR42J tumors by injection of ^{99m}Tc-labeled peptide with or without coinjection of 50 μg of minigastrin I human (MGh). HYNIC-MG and (N_α-His)Ac-MG could be radiolabeled at high specific activities (>1 Ci/μmol). For HYNIC-MG, high labeling yields (>95%) were achieved using Tricine and EDDA as coligands. Stability experiments of all ^{99m}Tc-labeled conjugates revealed a high stability of the label in PBS and serum as well as toward challenge with histidine and cysteine. Incubation in kidney homogenates resulted in a rapid degradation of all conjugates with <10% intact peptide after 60 min at 37 °C, with no considerable differences between the radiolabeled conjugates; a somewhat lower degradation rate was seen in liver homogenates. Protein binding varied considerably with lowest levels for ^{99m}Tc-EDDA/HYNIC-MG. Competition experiments of unlabeled conjugates on AR42J membranes versus [^{125}I-Tyr^{12}]-gastrin I showed high CCK-2 receptor affinity for all conjugates under study. Internalization behavior was very rapid for all radiolabeled conjugates in the order of ^{99m}Tc-(N_α-His)Ac-MG > ^{99m}Tc-EDDA/HYNIC-MG > ^{99m}Tc-Tricine/HYNIC-MG. In tumor-bearing nude mice the highest tumor-uptake was observed with ^{99m}Tc-EDDA/HYNIC-MG (8.1%ID/g) followed by ^{99m}Tc-Tricine/HYNIC-MG (2.2%ID/g) and ^{99m}Tc-(N_α-His)Ac-MG (1.2%ID/g) which correlated with kidney uptake (101.0%ID/g, 53.8%ID/g, 1.8%ID/g respectively). In this series of compounds ^{99m}Tc-EDDA/HYNIC-MG with its very high tumor/organ ratios except for kidneys seems to be the most promising agent to target CCK-2 receptors. Despite promising properties concerning receptor binding, internalization, and in vitro stability, ^{99m}Tc-(N_α-His)Ac-MG showed low tumor uptake in vivo.

INTRODUCTION

Cholecystokinin-2 (CCK-2, formerly CCK-B)/gastrin receptors have recently found increasing interest as targets for nuclear medicine applications. A high incidence of CCK-2 receptors has been found in human samples of medullary thyroid cancer (MTC), small cell lung cancer (SCLC), stromal ovarian cancers (*1*), and also in vivo in gastrointestinal neuroendocrine tumors, especially if somatostatin receptor scintgraphy is negative (*2*). Radiolabeled analogues of both CCK (*3*) and gastrin (*4*) have been developed. [DTPA-D-Glu^1]-minigastrin (DTPA-MG) radiolabeled with ^{111}In has shown promising properties for detection of CCK-2 receptor positive tissue in patients (*5*) and has been extensively evaluated clinically, radiolabeled with ^{90}Y even for therapeutic purposes in MTC (*6*). For diagnostic applications, technetium-99m still is the label of choice for routine applications due to its availability, low costs, low radiation dose for the patient, and optimal gamma-energy profile. Labeling approaches of peptides with ^{99m}Tc have to fulfill several criteria (*7*): labeling has to be achieved at high specific activities without interfering with the amino acid sequence responsible for receptor binding, and it has to ensure reasonably hydrophilic properties of the peptide resulting in predominant renal clearance and a high in vivo stability of the ^{99m}Tc complex. These criteria limit the numbers of available labeling approaches, and only a few have so far shown applicability in patient studies. Hydrazinonicotinic acid (HYNIC) is a bifunctional coupling agent for ^{99m}Tc-labeling of peptides and has been used to radiolabel a number of peptides such as somatostatin analogues (*8*) or GPIIb/IIIa antagonists (*9*). Figure 1. Molecular formulas of HYNIC and (N_α-His)acetic acid conjugated to [D-Glu]^1-minigastrin (MG).

the HYNIC labeling approach, technetium-99m is bound to the hydrazino group, and the other coordination sites are occupied by one or more coligands. A number of suitable coligands has been described, but it is also known that the choice of coligand can influence the stability and lipophilicity of the radiolabeled peptide and in the end the biodistribution (*10*). Another interesting approach to radiolabel peptides at high specific activities is the use of the technetium−carbonyl-core [$Tc(CO)_3$]. Alberto et al. described the one-step synthesis of the technetium−carbonyl aquaion [$^{99m}Tc(OH_2)_3(CO)_3]^+$ (*11*). This precursor has been shown to have a high affinity for histidine (His) and radiolabels peptides at very high specific activities (*12*). Further, the denticity of the $Tc(CO)_3$ coordinating ligand can influence the biological behavior of radiolabeled peptides, and tridentate ligands have advantages over bidentate systems (*13*). One promising tridentate derivative for peptide conjugation is (N_α-His)Ac that has shown suitable properties for ^{99m}Tc labeling after conjugation to a neurotensin derivative (*14*). We herein describe the labeling, in vitro characterization including receptor binding, and biodistribution of HYNIC and (N_α-His)acetic acid conjugated to [D-Glu]^1-minigastrin (MG, D-Glu-Glu_5-Ala-Tyr-Gly-Trp-Met-Asp-$PheNH_2$), Figure 1.

EXPERIMENTAL PROCEDURES

Materials. Reagents were purchased from Aldrich-Sigma Chemical Co. unless stated otherwise and used as they were received. [HYNIC-D-Glu^1]-minigastrin (HYNIC-MG) and [(N_α-His)Acetyl-D-Glu^1]-minigastrin ((N_α-His)Ac-MG) were synthesized by PiChem (Graz, Austria) with a purity of >95% as analyzed by reversed phase HPLC (RP-HPLC) and MS. [^{125}I -Tyr^{12}]-gastrin I was purchased from Perkin-Elmer Life Science (Boston, MA). Na $^{99m}TcO_4$ was obtained from a commercial ^{99}Mo/^{99m}Tc generator (ULTRATECHNEKOW, Mallinckrodt, The Netherlands).

Analytical Methods. *HPLC.* A Gynkotek M480 pump with a Spectra Physics Spectra Chrom 100 variable UV detector and Bioscan radiometric detection was used for RP-HPLC analysis. A Macherey & Nagl Nucleosil 120-5 C18 250 × 4.6 mm column, flow rates of 1 mL/min, and UV detection at 220 nm were employed with the following gradients:

Method 1: Acetonitrile (ACN)/0.1% trifluoroacetic acid (TFA)/H_2O: *t*: 0−3 min 0% ACN, 3−5 min 0−25% ACN, 5−20 min 25−40% ACN, 20−25 min 40−60% ACN, 25−28 min 60−0% ACN, 28−33 min 0% ACN

Method 2: 0.05 M Na acetate pH 5.4/ACN: *t*: 0−3 min: 0% ACN, 3−33 min: 0−100% ACN, 33−35 min: 100% ACN, 35−36 min: 100−0% ACN.

Purification by Solid-Phase Extraction (SPE). For purification of the radiolabeled peptide for stability studies, a SPE method was used. The radiolabeling mixture was passed through a C18-SEPPAK-mini cartridge (Waters, Milford, MA). The cartridge was washed with 5 mL of saline, and the radiolabeled peptide was eluted with 70% ethanol. This method efficiently removed all hydrophilic, nonpeptide bound impurities (mainly $^{99m}TcO_4^-$, ^{99m}Tc coligands).

^{99m}Tc-Labeling. *HYNIC-MG: Tris(hydroxymethyl)-methylglycine (Tricine) as Coligand.* In a rubber-sealed vial, 3 μg of HYNIC-MG was incubated with 0.5 mL of Tricine solution (70 mg/mL in water), 0.5 mL of $^{99m}TcO_4^-$ solution (>200 MBq), and 20 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) for 20 min at room temperature or 75 °C.

Ethylenediaminediacetic Acid (EDDA) as Coligand. In a rubber-sealed vial, 10 μg of HYNIC-MG was incubated with 0.5 mL of EDDA solution (20 mg/mL in pH 6−7), 0.5 mL of $^{99m}TcO_4^-$ solution (400 MBq), and 20 μL of tin-(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) for 30 min at room temperature and for 10 min in a boiling water bath.

Tricine/EDDA Exchange Labeling. In a rubber-sealed vial, 20 μg of HYNIC-MG was incubated with 1 mL of EDDA/Tricine solution (20 mg/mL Tricine, 10 mg/mL EDDA in pH 6−7), 1 mL of $^{99m}TcO_4^-$ solution (800 MBq), and 20 μL of tin(II) solution (10 mg of $SnCl_2 \cdot 2H_2O$ in 10 mL of nitrogen purged 0.1 N HCl) for 10 min in a boiling water bath.

(N_α-His)Ac-MG. Carbonyl aquaion [$^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared as described previously (*15*). Briefly, in a rubber-sealed vial 4 mg of Na_2CO_3, 5.5 mg of $NaBH_4$, and 20 mg of NaK−tartrate were CO-purged for 15 min and reacted with 2.5 mL of $^{99m}TcO_4^-$ solution (3−4 GBq) for 30 min at 75 °C. Pressure from the evolving H_2 gas was balanced with a 20 mL syringe, and 1 M NaH_2PO_4 was added for neutralization. Quality control was performed by HPLC method 1.

Peptide Labeling. In a rubber-sealed vial 20 μg of (N_α-His)Ac-MG was incubated with 0.5 mL of Carbonyl precursor (800 MBq) for 30 min at 75 °C. Radiolabeled peptides were characterized and labeling yields determined by HPLC methods 1 and 2.

In Vitro Evaluation of Radiolabeled Peptides. Stability. The stability of the radiolabeled peptides in aqueous solution was tested by incubation of the reaction mixture purified by SPE at a concentration of 200−1000 pmol peptide/mL in phosphate buffer (pH 7.4), in a solution containing 10 000-fold molar excess of cysteine or histidine (pH 7.4) over the peptide and in fresh human plasma at 37 °C up to 24 h. After incubation, plasma samples were precipitated with acetonitrile and centrifuged (1750*g*, 5 min). Degradation of the ^{99m}Tc complexes was assessed by HPLC method 1.

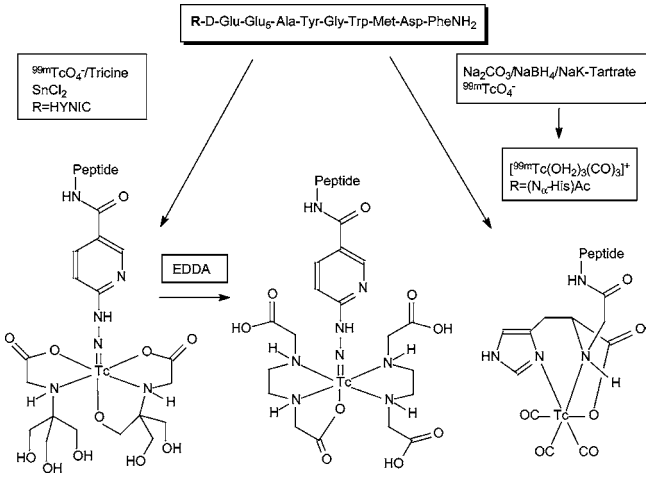
For protein binding assessment, the SPE-purified complexes were incubated at a concentration of 20−100 pmol peptide/mL in fresh human plasma at 37 °C and analyzed for up to 6 h by size-exclusion chromatography (MicroSpin G-50 Columns; Sephadex G-50). Protein binding of the ^{99m}Tc complex was determined by measuring column and eluate in a gamma counter.

For incubation in kidney and liver homogenates, kidneys or liver freshly excised from rat were rapidly rinsed and homogenized in 20 mM HEPES buffer pH 7.3 with an Ultra-Turrax T25 homogenator for 1 min at RT. The radiopeptides were incubated with fresh 30% homogenates at a concentration of 250−500 pmol peptide/mL at 37 °C for up to 2 h. Samples were precipitated with

acetonitrile, centrifuged (1750*g*, 5 min), and analyzed by HPLC method 1.

Receptor Binding Studies. The binding affinity of peptide conjugates was tested in a competition assay against [^{125}I-Tyr^{12}]-gastrin I. Rat pancreatic tumor (AR42J) cell membranes were used as the source for gastrin receptors. For membrane preparation, cells were homogenized three times for 10 s at 4 °C with an Ultra-Turrax T25 homogenator in 20 mM HEPES buffer pH 7.3/10 mM $MgCl_2$/10 μM bacitracin, and protein concentration was assessed to 50 μg/100 μL (Bradford assay). In a Multiscreen well plate (glass fiber filters; Whatman GF/C), 50 μL of competitor solution of increasing concentrations (0.001−1000 nM in 1% BSA/10 mM $MgCl_2$/10 μM bacitracin), 50 μL of radioligand solution (50 000 cpm in 1% BSA/10 mM $MgCl_2$/10 μM bacitracin), and 100 μL of membrane solution (50 μg protein/tube) were incubated in triplicates for 2 h at RT. Incubation was interrupted by filtration of the medium and rapid rinsing with ice-cold washing buffer (1 × 200 μL, followed by 1 × 50 μL 15 mM TRIS/139 mM saline pH 7.4), and filters were counted in a gamma-counter. IC_{50} values were calculated following nonlinear regression with Origin software (Microcal Origin 5.0, Northampton MA).

For saturation studies, similar to that described above for the competition assays on membranes, in a Multiscreen well plate, radiolabeled peptide conjugate of increasing concentrations (0.05−20 nM in 1% BSA/10 mM $MgCl_2$/10 μM Bacitracin) and AR42J membrane solution (50 μg protein/tube) were incubated in triplicate for 2 h at RT in a total volume of 200 μL. Nonspecific binding was determined in a parallel series containing 1 μM MGh. K_d values were calculated following nonlinear regression and Scatchard plot (linear regression) with Origin software (Microcal Origin 5.0, Northampton MA).



Internalization Studies. For internalization experiments, AR42J cells were seeded at a density of 1 × 10^6 cells per well in six-well plates (Greiner Labortechnik, Germany) and grown to confluency for 48 h. On the day of the experiment, cells were washed twice with ice-cold internalization medium prepared by RPMI1640 supplemented by 1% (v/v) fetal bovine serum. The cells were supplied with fresh medium (1.2 mL) and incubated with 300 000 cpm of the radiolabeled peptide (150 μL in PBS/0.5%BSA buffer, corresponding roughly to 200 fmol of total peptide) and either PBS/0.5%BSA buffer alone (150 μL, total series) or with 10 μM MGh in PBS/0.5%BSA buffer (150 μL, nonspecific series). The cells were incubated at 37 °C in triplicate for each time point of 5, 15, 30 min, 1 and 2 h incubation. Incubation was interrupted by removal of the medium and rapid rinsing with ice-cold internalization medium two times. Thereafter, the cells were incubated twice at ambient temperature in acid wash buffer (50 mM glycine buffer pH 2.8, 0.1 M NaCl) for 5 min, a period sufficient to remove over 90% of membrane-bound radioligand. The supernatant was collected, and the cells were rinsed with PBS/0.5% BSA (membrane bound radioligand fraction). Finally, cells were lyzed by treatment in 1 N NaOH and collected (internalized radioligand fraction). All fractions were counted in a gamma-counter, and mean specific values were calculated. The internalized fraction was expressed in relation to the total activity added (% of total) as well as in relation to the activity bound to the cells, i.e., internalized plus membrane bound fraction (% of bound).

In Vivo Evaluation of Radiolabeled Peptides. Biodistribution. All animal experiments were conducted in compliance with the Austrian animal protection laws and with approval of the Austrian Ministry of Science. Normal biodistribution studies were performed in Balb/c mice (Charles River, Germany). On the day of experiment, three mice received the radioactive conjugate (1 MBq/mouse, corresponding to 0.15−0.2 μg of peptide) intravenously injected into the tail vein, with or without coinjection of 50 μg of MGh. They were sacrificed by cervical dislocation 4 h postinjection. Different organs and tissues (blood, lung, heart, stomach, spleen, liver, pancreas, kidneys, muscle, intestine) were removed. The amount of radioactivity was determined with a gamma-counter. Results were expressed as percentage of injected dose per gram of tissue (%ID/g).

Tumor uptake studies were performed in nu/nu mice (Charles River, Germany). For the induction of tumor xenografts, AR42J cells were subcutaneously injected at a concentration of 10 × 10^6 cells/mouse, and tumors were allowed to grow until they had reached a size of 0.5−1 mL (10−15 days). On the day of the experiment, the animals were treated as described above. Tumors and other tissues (blood, lung, heart, stomach, spleen, liver, pancreas, kidneys, muscle, intestine) were removed. The amount of radioactivity was determined with a gamma-counter. Results were expressed as percentage of injected dose per gram of tissue (%ID/g), and tumor-to-organ, stomach-to-organ, pancreas-to-organ, and kidney-to-organ ratios were calculated.

Metabolic Stability. To evaluate the in vivo degradation of the conjugate, urinary excretion products were characterized by RP-HPLC (method 1).

Scheme 1. ^{99m}Tc-Labeling Routes of HYNIC- and (N_α-His)Ac-MG[a]

[a] Complex structures of ^{99m}Tc-Tricine/HYNIC-MG, ^{99m}Tc-EDDA/HYNIC-MG, and ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG according to refs 16, 17, and 13, respectively.

RESULTS

Radiolabeling. Radiolabeling of all peptide conjugates could be performed according to Scheme 1 at high specific activities (>70 GBq/μmol) with high yields. In the case of HYNIC-MG, only Tricine as coligand resulted in reasonable labeling yields, whereby two main peaks could be characterized by HPLC. At room temperature a shift to the more hydrophilic species over time was observed; by heating the reaction mixture at 80 °C for 15 min, only this peak was detected. Addition of monodentate ligands such as nicotinic acid to the reaction mixture did not significantly alter the HPLC profile. Therefore, ^{99m}Tc-HYNIC-MG prepared at higher temperature was chosen for further characterization. EDDA as coligand resulted in very low labeling yields even at elevated temperature;

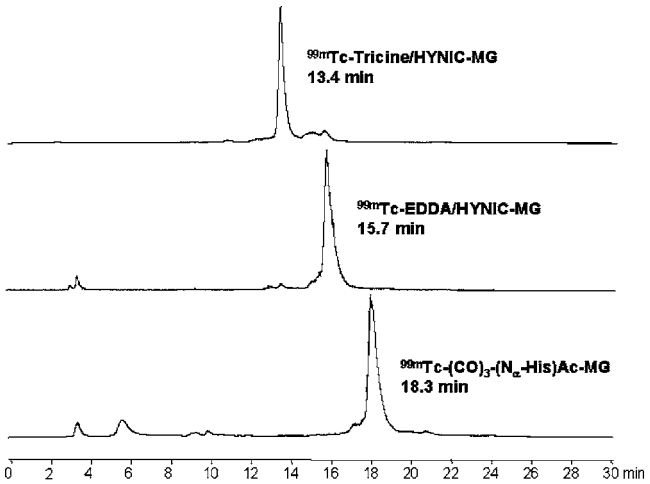


Figure 2. HPLC-radiochromatograms of the radiolabeled peptides (HPLC method 1).

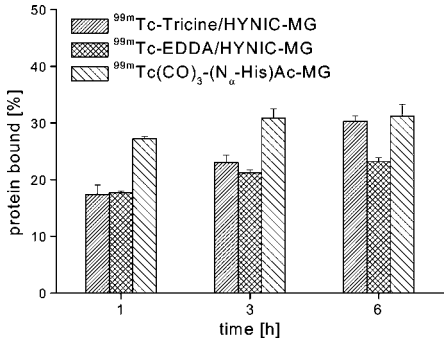

Figure 3. Protein binding over time determined by size exclusion chromatography (MicroSpinTM G-50 columns, Sephadex G-50).

Table 1. Retention Times of the Radiolabeled Peptides in Two Different HPLC Gradients

HPLC gradient	retention time (min)		
	^{99m}Tc-Tricine/HYNIC-MG	^{99m}Tc-EDDA/HYNIC-MG	^{99m}Tc(CO)$_3$-(N$_\alpha$-His)Ac-MG
method 1	13.4	15.7	18.3
method 2	14.3	14.9	15.8

however, using an exchange labeling approach from Tricine to EDDA and boiling the reaction mixture for 10 min, a single peak (^{99m}Tc-EDDA/HYNIC-MG) with distinct retention time on HPLC to the ^{99m}Tc-Tricine/HYNIC-MG complex was observed with labeling yields >90%. (N$_\alpha$-His)Ac-MG could be radiolabeled by addition of $[^{99m}Tc(OH_2)_3(CO)_3]^+$; high labeling yields >90% were achieved only when the concentration of peptide in the reaction solution was kept higher than 20 μM. In Figure 2 are shown typical HPLC-radiochromatograms of reaction mixtures of all three ^{99m}Tc-labeled MG derivatives. Retention times were different, utilizing two different HPLC gradients at different pH values (methods 1 and 2) and are summarized in Table 1. Lipophilicity as determined from the RP-HPLC retention behavior was increasing in the order ^{99m}Tc-Tricine/HYNIC-MG < ^{99m}Tc-EDDA/HYNIC-MG < ^{99m}Tc(CO)$_3$-(N$_\alpha$-His)Ac-MG.

Stability Studies. Plasma protein binding behavior at different time points is presented in Figure 3. At early time points, ^{99m}Tc(CO)$_3$-(N$_\alpha$-His)Ac-MG showed considerably higher levels compared to ^{99m}Tc-HYNIC conjugates. At later time points, ^{99m}Tc-Tricine/HYNIC-MG showed increasing values reaching levels comparable to ^{99m}Tc-(CO)$_3$-(N$_\alpha$-His)Ac-MG after 6 h incubation. Protein binding values of ^{99m}Tc-EDDA/HYNIC-MG were similar to its Tricine counterpart at 1 h with little change over time.

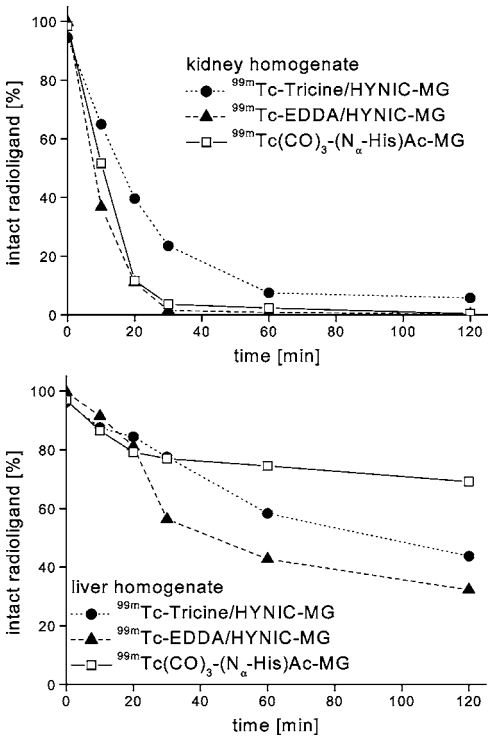

Figure 4. Stability of radiolabeld peptides in rat tissue homogenates: (a) kidney, (b) liver.

Table 2. Stability of the Radiolabeled Peptides in Aqueous Solutions

	0 h	1 h	2 h	4 h	24 h

phosphate	99.6	98.2	96.3	91.1	80.8
serum	98.9	98.8	98.4	96.7	94.6
cysteine	95.5	92.6	92.5	88.4	81.4
histidine	93.4	90.1	89.3	88.4	81.4
Intact ^{99m}Tc-EDDA/HYNIC-MG (%)					
phosphate	99.9	99.4	99.1	99.4	94.8
serum	99.7	99.3	96.6	97.4	90.9
cysteine	99.0	99.2	98.7	99.1	96.4
histidine	99.5	99.2	99.1	99.4	96.1
Intact ^{99m}Tc(CO)$_3$-(N$_\alpha$-His)Ac-MG (%)					
phosphate	98.8	99.6	98.7	99.2	96.8
serum	98.6	99.6	98.2	98.9	94.4
cysteine	98.5	99.8	99.4	99.9	96.2
histidine	98.7	99.7	99.9	99.9	97.6

Results from stability studies are summarized in Table 2. Incubation in PBS, serum, cysteine, and histidine for up to 24 h of SPE-purified peptides revealed high stability of all ^{99m}Tc-labeled peptide conjugates under investigation. Only ^{99m}Tc-Tricine/HYNIC-MG showed generally somewhat lower purity levels, especially after 24 h in all incubation solutions (80.8−81.4%) except serum.

Incubation in kidney homogenates resulted in a very rapid decrease of activity related to the original peptide peak (Figure 4a). After 30 min incubation, less than 10% intact peptide could be detected for ^{99m}Tc(CO)$_3$-(N$_\alpha$-His)-Ac-MG and ^{99m}Tc-EDDA/HYNIC-MG; for ^{99m}Tc-Tricine/HYNIC-MG, this value was reached only after 60 min incubation. After incubation in liver homogenates (Figure 4b), also a low stability of all three peptide conjugates was found with differences in the rate of decrease, reaching 69% for ^{99m}Tc(CO)$_3$-(N$_\alpha$-His)Ac-MG, 32% for ^{99m}Tc-EDDA/HYNIC-MG, and 44% for ^{99m}Tc-Tricine/HYNIC-MG after 120 min incubation time.

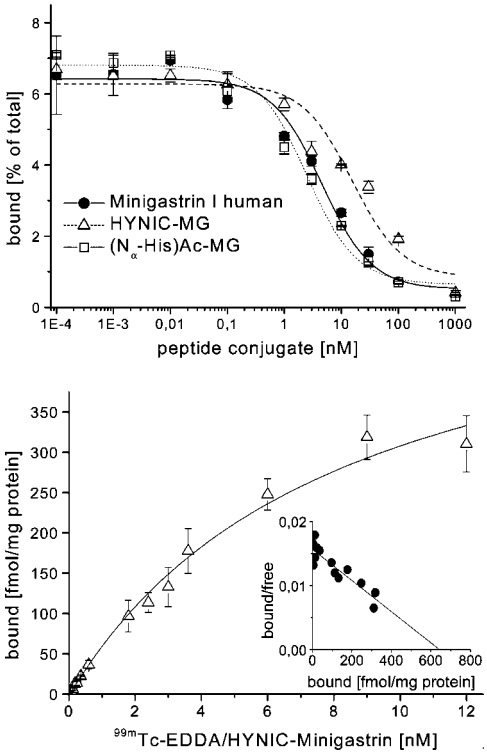

Figure 5. Receptor binding on AR42J membranes: (a) Displacement curves of [^{125}I-Tyr^{12}]-gastrin I using minigastrin I human (IC_{50} = 4.58 nM), HYNIC-MG (IC_{50} = 15.5 nM) and (N_α-His)Ac-MG (IC_{50} = 2.45 nM) as competitors (mean ± sd, n = 3). (b) Saturation curve and Scatchard plot of ^{99m}Tc-EDDA/HYNIC-MG (K_d = 10.3 nM, B_{max} = 647 fmol/mg protein).

Receptor Binding and Internalization. Both HYNIC-MG and (N_α-His)Ac-MG had a high affinity to the gastrin/CCK-2 receptor. Displacement of [^{125}I-Tyr^{12}]-gastrin I by the two peptide conjugates in comparison with unmodified MG is shown in Figure 5a. IC_{50} values for HYNIC-MG were somewhat higher (15.5 nM) compared to (N_α-His)Ac-MG (2.45 nM) and MG (4.58 nM). Saturation assay of ^{99m}Tc-EDDA/HYNIC-MG revealed high binding affinity of the ^{99m}Tc-labeled peptide with a K_d of 10.3 nM and a B_{max} of 647 fmol/mg protein (Figure 5b).

Internalization behavior on AR42J cells is summarized in Figure 6. All three ^{99m}Tc-labeled compounds showed a rapid internalization of cell-bound activity, reaching a plateau of more than 80% internalized fraction after 30 min incubation (Figure 6a). Looking at the percentage internalized activity of the total activity added, we observed differences (Figure 6b). ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG showed the highest percentage of internalized activity (reaching 13.7% after 120 min incubation), followed by ^{99m}Tc-EDDA/HYNIC-MG (10.1%) and ^{99m}Tc-Tricine/HYNIC-MG (7.0%).

Biodistribution and Tumor Uptake. Biodistribution in Balb/c mice 4 h pi revealed a rapid elimination from most organs and mainly renal excretion (Figure 7). Intestinal activity was minimal, varying from 1.18%ID/g for ^{99m}Tc-Tricine/HYNIC-MG to 0.44%ID/g for ^{99m}Tc-EDDA/HYNIC-MG, indicating low hepatobiliar excretion. However, great differences were observed in kidney uptake. ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG showed renal retention of 2.81%ID/g, whereas ^{99m}Tc-EDDA/HYNIC-MG and ^{99m}Tc-Tricine/HYNIC-MG accumulated to much higher levels in the kidneys with 127 and 73%ID/g, respectively. In animal urine only degradation products of the ^{99m}Tc-labeled peptide conjugates could be detected by RP-HPLC.

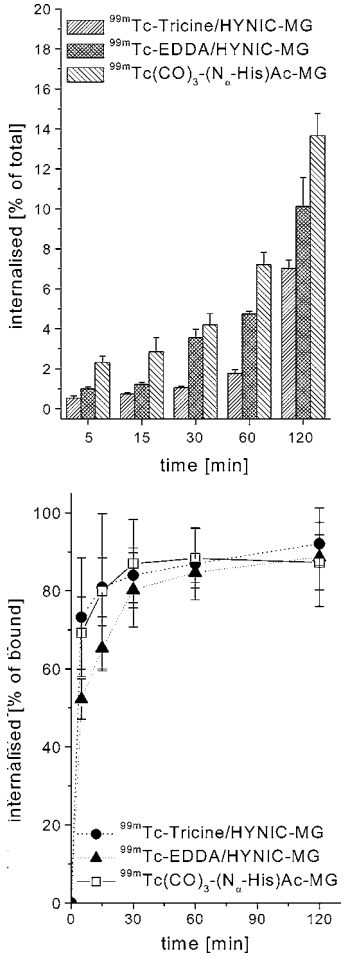

Figure 6. Time dipendent internalization of radiolabeled peptides in AR42J cells expressed as (a) % of total activity, (b) % of bound activity (mean ± sd, n = 3).

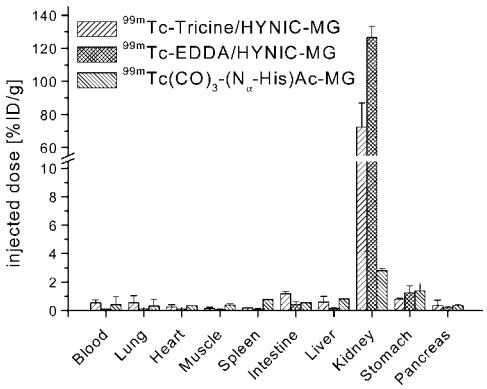

Figure 7. Normal biodistribution of the radiolabeled peptides in Balb/c mice 4 h after injection. Values are expressed as %ID/g = percentage injected dose/g tissue (means ± sd, n = 3).

Similar differences were also observed in a mouse tumor model. Results of biodistribution in nu/nu mice bearing AR42J tumor xenografts 4 h pi is summarized in Table 3. Whole body retention in this tumor model 4 h pi were 23.96 ± 4.02%ID for ^{99m}Tc-Tricine/HYNIC-MG, 38.96 ± 2.78%ID for ^{99m}Tc-EDDA/HYNIC-MG, and 2.38 ± 0.53%ID for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG. Again, low levels of intestinal activity and accumulation in other organs were detected (<1.2%ID/g), whereas kidney uptake varied from 101%ID/g for ^{99m}Tc-EDDA/HYNIC-MG, 53.8%ID/g for ^{99m}Tc-Tricine/HYNIC-MG, down to only

^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG	0.62	0.31	0.77	3.00	0.58	0.18	0.12	0.02	0.12	0.03

1.8%ID/g for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG. Tumor uptake also varied considerably from 8.09%ID/g for ^{99m}Tc-EDDA/HYNIC-MG, 2.18%ID/g for ^{99m}Tc-Tricine/HYNIC-MG, to only 1.2%ID/g for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG. Tumor uptake could be blocked by coinjection of 50 μg of MGh reducing values to 2.96, 1.23, and 0.73%ID/g, respectively; this reduction was significant for ^{99m}Tc-EDDA/HYNIC-MG and ^{99m}Tc-Tricine/HYNIC-MG ($p < 0.05$). A significant reduction of tissue uptake by coinjection of MGh was also observed in stomach for all three radiolabeled compounds, in pancreas for the ^{99m}Tc-HYNIC conjugates, and in kidneys for ^{99m}Tc-EDDA/HYNIC-MG.

Table 4 shows tumor/organ, stomach/organ, and pancreas/organ ratios (receptor positive organs) calculated from the mouse tumor model studies. Highest ratios for tumor and receptor positive organs (stomach and pancreas) were found in most cases for ^{99m}Tc-EDDA/HYNIC-MG and lowest for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG except for the kidney where this relationship was reversed.

DISCUSSION

Radiolabeling. Using both HYNIC and (N_α-His)Ac conjugated to [D-Glu^1]-MG, high labeling yields were achieved. Experiments were performed at high specific activities using small amounts of peptide conjugate (3−20 μg). In the case of HYNIC with Tricine as coligand, labeling was achieved directly. However, the presence of two major peaks dependent on the temperature and incubation time, the absence of multiple peaks as described for other peptides (*1*), and the failure to produce different complexes by addition of pyridine derivatives indicate some unique properties of this specific peptide. It could be argued that one of the carboxyl groups of the Glu-residues at the amino-terminus is involved in the complex formation resulting in a different species at higher temperature, a phenomenon that already has been described for ^{111}In-labeling of DTPA-MG (*5*). By addition of EDDA to the reaction mixture in a concentration of 5 mg/mL and heating the reaction solution, another complex formed in high yields. It could be shown for a somatostatin analogue that under these conditions Tricine as coligand is replaced by EDDA resulting in a more stable complex (*17*). Overall, radiolabeling of HYNIC-MG revealed some specific properties in the formation of technetium complexes. The characteristic feature of HYNIC-derivatized peptides, that by varying the coligand, different complexes were formed, was preserved. In contrast, radiolabeling of (N_α-His)Ac-MG resulted in a single peak independent of the reaction conditions. However, high labeling yields were dependent on a high concentration of the peptide in the reaction solution and not only on the specific activity (i.e. molar relation of peptide versus technetium). Therefore, comparably higher amounts of peptide (20 μg) were used to allow a volume (0.5 mL) potentially suitable in a clinical setting.

Complex Characterization and Stability Studies. All three complexes showed distinct retention times in different HPLC systems. In contrast to other peptides (*18*), with Tricine as coligand the lowest retention times were observed.

^{99m}Tc(N_α-His)Ac-MG showed the longest retention times, indicating the highest lipophilicity of all three complexes under study. This was underlined by its plasma protein binding behavior, showing the highest levels after a short incubation time. The observed tendency of increasing plasma protein binding over time for ^{99m}Tc-Tricine/

HYNIC-MG is a phenomenon already described for other HYNIC-peptide conjugates (*10*) and indicates a higher complex instability compared to ^{99m}Tc-EDDA/HYNIC-MG. Other experiments on the ^{99m}Tc-complex stability failed to reveal differences between the radiolabeled peptide conjugates. All complexes showed no major sign of complex degradation in different solutions; a somewhat lower stability for the Tricine-HYNIC derivative was observed. No considerable ligand exchange after challenge with amino acids could be detected. Especially the high stability of the ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG complex toward histidine indicates a high complex stability. It is known that the Tc(CO)$_3$ core has a very high affinity for His (*12*), and these findings underline the importance of a tridentate ligand coupled to the peptide for this labeling approach (*13*). In contrast to these results all ^{99m}Tc-peptide conjugates revealed a rather low stability independent of the labeling approach after incubation in kidney and liver homogenates. It can be assumed that this behavior is a result of an enzymatic cleavage of the peptide chain itself. This is underlined by the finding that on RP-HPLC various degradation products were observed with retention times different from low molecular ^{99m}Tc complexes such as ^{99m}Tc-cysteine or ^{99m}Tc-histidine (data not shown). This instability of the peptide toward enzymatic degradation is also confirmed by the observation that only degradation products could be detected in urine of mice injected with the radiolabeled conjugates. However, the high stability of the complexes in serum should be taken into account when judging the suitability of these radiolabeled MG derivatives to target receptor positive tumors in vivo.

Receptor Binding and Internalization. Derivatization of MG did not considerably impair receptor binding. Although HYNIC-MG showed lower IC_{50} values in comparison with unmodified MG, it still can be considered to have a high affinity to the gastrin/CCK-2 receptor. Of greater importance to judge the tumor targeting properties seemed to be the results from internalization studies. All compounds investigated showed very rapid internalization of surface-bound activity and very high uptake in receptor positive cells to a value up to 14%, levels comparable or even higher to high-affinity ^{99m}Tc-HYNIC−somatostatin conjugates in the same system (*8*). The highest levels of internalized activity were found for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG, and somewhat lower levels were found for both HYNIC conjugates, possibly reflecting a lower receptor affinity.

Biodistribution and Tumor Targeting Properties. Overall, all derivatives showed a rapid elimination with predominant renal excretion and low retention in blood and most tissues. However, considerable differences in the organ uptake were observed, both in normal and tumor-bearing mice. The differences between ^{99m}Tc-Tricine/HYNIC-MG and ^{99m}Tc-EDDA/HYNIC-MG in normal organ uptake reflect the known differences in complex stability between the coligands (*16*). In accordance with previous findings (*19*) all organs except kidney showed higher levels of activity for ^{99m}Tc-Tricine/HYNIC-MG, indicating higher unspecific retention of ^{99m}Tc. An unexpected finding was the great difference in kidney retention between ^{99m}Tc labeled HYNIC and (N_α-His)Ac-MG conjugates. Uptake of radiolabeled peptides in the kidney by a tubular reabsorption mechanism is a well-known phenomenon (*20*) and ideally should be as low as possible. A very high kidney retention was found both for ^{99m}Tc-Tricine/HYNIC-MG and ^{99m}Tc-EDDA/HYNIC-MG with over 50%ID/g, in accordance with the behavior of ^{111}In-DTPA-MG reported previously (*5*). This high kidney uptake is a usual observation with radiolabeled MG derivatives and is unlikely to be related to a specific interaction with the MG receptor but a result of tubular reabsorption. On the other hand, ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG showed kidney uptake levels of less than 3%ID/g both in normal and tumor-bearing mice. An explanation of this phenomenon with a complex instability in vivo, possibly in the kidney, seems unlikely, as no correlation with the in vitro stability experiments can be found. It also seems unlikely that other tridentate ligand systems such as (N_ϵ-His)Ac coupled to peptides, as recently described (*21*), would behave differently. This in vivo behavior could, however, result from a difference in charge of the complexes, assuming a less negatively charged ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG complex. It recently has been shown that reduction of the number of Glu-residues (negatively charged) in the gastrin sequence leads to lower levels of renal retention (*22*). Another option would be a rapid washout from the kidney, which is supported by the high in vitro stability and the much lower whole body retention observed for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG in comparison with the ^{99m}Tc-HYNIC conjugates. Unfortunately, the low kidney uptake of ^{99m}Tc-(CO)$_3$-(N_α-His)Ac-MG was also accompanied by a significantly lower specific uptake in stomach, pancreas, and especially tumor. Whereas ^{99m}Tc-EDDA/HYNIC-MG showed a promising high tumor uptake of more than 8%ID/g that could be reduced to less than 3%ID/g by coinjection of MGh, much lower levels of 1.2%ID/g were found for ^{99m}Tc(CO)$_3$-(N_α-His)Ac-MG, and although blocking with MGh reduced uptake, this reduction was not significant. Comparable results in other gastrin/CCK-2 receptor positive organs such as pancreas and stomach confirm this finding. Therefore, in this series, ^{99m}Tc-EDDA/HYNIC-MG seems to be the most promising agent for imaging gastrin/CCK-2 receptor positive tumors, showing very similar properties to ^{111}In-DTPA-MG, which already has been used successfully in patients (*23*). However, the high kidney uptake renders this compound developmental. Optimization of the peptide sequence leading to reduced kidney uptake without sacrificing tumor uptake should be attempted before patient studies are initiated.

CONCLUSION

This study describes for the first time a direct comparison of peptides radiolabeled with ^{99m}Tc via the HYNIC and the Tc(CO)$_3$ approach. Overall, MG derivatized with HYNIC and (N_α-His)acetic acid could be radiolabeled with ^{99m}Tc at high specific activities. Although only minor differences in vitro concerning stability and receptor binding were observed, the labeling approach significantly altered the biodistribution and tumor-targeting properties of the radiolabeled peptides. For these specific peptides, the HYNIC approach using a suitable coligand showed some advantages with respect to receptor specific uptake in vivo, partially outweighed by a very high kidney uptake. Further studies to improve tumor uptake and at the same time reduce kidney retention by optimizing the peptide sequence should be attempted.

ACKNOWLEDGMENT

This study in part was supported by the COST B12 Action "Radiotracers for the in vivo assessment of biological function" and by a "Gertrude Pfeiffer" scholarship of the Austrian Society of Nuclear Medicine. We specifically thank Prof. Hermann Dietrich for his help in the animal

tumor model as well as Ira Skvortsova, Gholamali Shabani Kakroodi, and Sonja Georgievska for their helping hands.

In Vitro and in Vivo Comparison of Human *Escherichia coli* Heat-Stable Peptide Analogues Incorporating the ^{111}In-DOTA Group and Distinct Linker Moieties

Michael F. Giblin,[||,†] Hariprasad Gali,[||] Gary L. Sieckman,[§] Nellie K. Owen,[||] Timothy J. Hoffman,[||,‡,§] Leonard R. Forte,[§,⊥] and Wynn A. Volkert[||,§,†,*]

Research Service, Harry S. Truman Memorial Veterans' Administration Hospital, Columbia, Missouri 65201, and Departments of Radiology, Pharmacology, Internal Medicine, and The Nuclear Sciences and Engineering Institute, University of Missouri—Columbia, Columbia, Missouri 65211. Received January 14, 2004; Revised Manuscript Received April 19, 2004

Three human *Escherichia coli* heat-stable peptide (ST_h) analogues, each containing a DOTA chelating group, were synthesized by SPPS and oxidative refolding and compared in in vitro and in vivo systems. One analogue, DOTA−F^{19}-ST_h(1−19), contains an N-terminal DOTA group attached via an amide bond linkage to an ST_h moiety which is essentially wild-type except for a Tyr to Phe alteration at position 19 of the molecule. A second analogue, DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), differs from the first in that asparagine residues in positions 1 and 4 have been altered to arginine residues in order to examine the effect of positively charged groups in the linker domain. A third analogue, DOTA−11AUN−F^{19}-ST_h(1−19), differs from the first in that it incorporates an 11-aminoundecanoic acid spacer group between the DOTA group and the first asparagine residue. In vitro competitive binding assays utilizing T-84 human colon cancer cells demonstrated that significant alterations to the N-terminal region of the ST_h molecule were well tolerated and did not significantly affect binding affinity of ST_h for the guanylyl cyclase C (GC-C) receptor. Internalization and efflux studies of the indium-labeled species demonstrated that inclusion of positive charge in the linker moiety inhibits internalization of the compound within tumor cells. The characteristics of the three analogues were compared in an in vivo model utilizing T-84 human colon cancer cell xenografts in SCID mice. Clearance of all analogues was rapid, primarily via renal excretion into the urine, with >89% ID excreted into the urine at 1 h pi for all analogues. The ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST_h(1−19) analogues both had longer residence times in the blood than did the ^{111}In-DOTA−F^{19}-ST_h(1−19) analogue, probably accounting for increased %ID/g values for tumors and nontarget tissues at 1 h pi. At 4 h pi, significant differences between analogues were only seen with respect to metabolic routes of excretion, indicating that increased blood residence time did not result in increased tumor residualization. Reduction of hepatic uptake of these compounds, however, could have significance in the development of agents for the imaging of hepatic metastases. The ability to manipulate in vivo pharmacodynamics and tumor uptake of radiolabeled ST_h peptides through modification of linker moieties is under continuing investigation in order to produce optimal imaging and therapeutic radiopharmaceuticals.

INTRODUCTION

Colorectal cancer is the third most common neoplasm and the second most common cause of cancer mortality in the United States (*1*). Colorectal cancer metastases most commonly localize to the pelvis, liver, and lungs, and the majority of patients who die from colon cancer have liver metastases (*2*). Improved ability to determine the location and extent of metastatic disease could have a significant impact on treatment planning for individuals with confirmed diagnoses of primary tumors. Since the early 1990s, several radioimmunoscintigraphic agents have gained approval in the United States or Europe for the imaging of colorectal carcinomas. Each of these agents when added to diagnostic protocols was shown to increase the sensitivity and/or specificity of diagnosis relative to the use of anatomical imaging (CT) alone (*3*−*8*). Two such agents, OncoScint CR/OV (Cytogen Corp., Princeton NJ) and HumaSPECT-Tc (Intracel Corp., Rockville, MD) are monoclonal antibodies of murine and human origin, respectively (*5*, *9*). A third, CEA-Scan (Immunomedics, Inc., Morris Plains, NJ), is a murine IgG1-derived Fab′ fragment (*3*, *10*). In general, the smaller size of Fab′ fragments relative to unmodified antibodies results in greater tumor penetration and more rapid blood clearance, thus reducing accumulation in nontarget tissues (*11*).

Extending the logic of reducing the size of targeted radiopharmaceuticals in order to improve their pharmacokinetic properties and reduce their immunogenicity, interest in using radiolabeled peptides as diagnostic and

therapeutic agents has rapidly increased over the past decade (*12*, *13*). Radiolabeled variants of somatostatin receptor targeting peptides are being used for imaging of neuroendocrine tumors and pulmonary masses (*12*). Analogues of bombesin (*38*−*41*), α-MSH (*42*−*45*), and numerous other receptor-avid peptides are under investigation for oncologic imaging of a variety of tumor types. Vasoactive intestinal peptide (VIP) and the *E. coli* heat-stable peptide (ST_h) are both under investigation as imaging agents for colorectal cancer (*14*, *18*−*24*). In a study directly comparing a ^{123}I-labeled VIP analogue with the approved agent OncoScint CR/OV, the labeled peptide was found to possess higher sensitivity in imaging intestinal carcinomas and metastatic spread (*15*). In principle, ^{123}I-labeled VIP produces an image by virtue of overexpression of its cognate receptor on the surface of colorectal cancer cells. However, VIP also targets receptors expressed in normal tissues such as the lung (*12*, *13*, *15*).

Guanylate cyclase C (GC-C) has been shown to be expressed on brush borders of intestinal epithelial cells, as well as on transformed human colon cancer cell lines such as the T-84 cell line (*16*, *17*). Importantly, GC-C is also expressed at much lower levels in normal human extraintestinal tissues (*18*, *46*−*48*). Circulation accessible when expressed on primary and metastatic colon cancer tissues, GC-C provides a uniquely specific target for receptor avid peptide radiopharmaceuticals (*18*−*24*). As normally expressed within the lumen of the gut, GC-C binds the endogenous peptides guanylin and uroguanylin, which act to regulate ion and fluid homeostasis and also may regulate epithelial cell turnover (*25*, *26*). Perhaps via gene transfer from vertebrate hosts, enteropathogenic strains of *E. coli* have evolved a homologous peptide, the human *E. coli* ST peptide (ST_h), which has the highest affinity for GC-C of any known ligand (*25*). The goal of the work presented here is to develop analogues of ST_h with N-terminal pendant DOTA chelating moieties that can deliver imaging and therapeutic radionuclides to primary and metastatic colon cancer tissues.

EXPERIMENTAL SECTION

All solvents were either ACS certified or HPLC grade solvents obtained from Fischer Scientific and used as received. The fmoc-Phe-Wang resin and fmoc-protected amino acids were purchased from Calbiochem-Novabiochem Corp (San Diego, CA) and the other peptide reagents from Applied Biosystems, Inc. (Foster City, CA). DOTA-tris (*tert*-butyl ester) was purchased from Macrocyclics (Dallas, TX) and fmoc-11-aminoundecanoic acid from Advanced ChemTech (Louisville, KY). $^{111}InCl_3$ was obtained from Mallinckrodt Medical, Inc (St. Louis, MO) as a 0.05 N HCl solution. Na^{125}I was obtained as a 10 μM NaOH solution from PerkinElmer (Boston, MA). All other reagents were purchased from Aldrich Chemical Co. Human colon carcinoma T-84 cells were obtained from American Type Culture Collection (ATCC) and maintained and grown for use in these studies in the University of Missouri Cell and Immunology Core facilities. Electrospray mass spectral analyses and amino acid analyses were performed by Synpep Corporation (Dublin, CA).

High Performance Liquid Chromatography (HPLC). High performance liquid chromatography (HPLC) analyses were performed on a Waters 600E system equipped with a Varian 2550 variable absorption detector, Packard Radiometric 150TR flow scintillation analyzer, sodium iodide crystal radiometric detector, Eppendorf TC-50 column temperature controller, and Hewlett-Packard HP3395 integrators. HPLC solvents consisted of H_2O containing 0.1% trifluoroacetic acid (Solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (Solvent B). Conditions: A Phenomenex Jupiter C-18 (5 μm, 300 Å, 4.6 × 250 mm) column was used with a flow rate of 1.5 mL/min. Gradient purification of compounds is achieved during a linear 30 min ramp from 20% B to 30% B, followed by column rinse and reequilibration.

Peptide Synthesis. Synthesis of linear peptides was carried out on a Perkin-Elmer Applied Biosystems Model 432 automated peptide synthesizer employing traditional Fmoc chemistry. Fmoc-Phe-Wang resin (25 μmol), Fmoc-protected amino acids with appropriate side-chain protections (75 μmol), and DOTA-tris (*tert*-butyl ester) (75 μmol) were used for the synthesis. Final products were cleaved by a standard procedure using a cocktail containing thioanisol, water, ethanedithiol, and trifluoroacetic acid in a ratio of 2:1:1:36 and precipitated into methyl *tert*-butyl ether. Yield of the reduced, linear peptides ranged between 50 and 70%. All peptides contained a tyrosine to phenylalanine substitution in position 19. This substitution was originally made to simplify the process of generating monoiodinated ST_h tracer labeled at tyrosine 5. Previous work (*23*) has suggested that this substitution has no effect on receptor binding affinity of ST_h.

Peptide Refolding. After cleavage and deprotection of the peptides, reduced linear species were oxidatively refolded by stirring a 0.1 mg/mL peptide solution in 0.1 M ammonium formate, pH 8.0, at room temperature for periods up to 5 days. Refolded peptides were purified by C18 RP-HPLC and characterized by ESI-MS. The lack of free thiols in refolded peptides was confirmed by Ellman's test. Additionally, the DOTA−F^{19}-ST_h(1−19) analogue was produced using an orthogonal deprotection scheme in which pairs of free cysteine residues were sequentially deprotected and oxidized using Trt, Acm, and tBu thiol protecting groups. Both oxidative refolding and orthogonal deprotection produced identical products as assessed by RP-HPLC retention time, ESI-MS, and receptor binding assay.

^{125}I Labeling. F^{19}-ST_h(1−19) was iodinated by a modified lactoperoxidase method. Briefly, 2 μg of peptide was suspended in 50 μL of 100 mM sodium phosphate buffer, pH 7.5, containing 2 μg of lactoperoxidase and 300 μCi of Na^{125}I. The reaction was initiated by addition of 2 μL of a 1:10,000 dilution 30% H_2O_2. The reaction was incubated 30 min at room temperature with occasional mixing and then diluted with distilled H_2O and purified to homogeneity by RP-HPLC.

Indium Labeling. For the synthesis of ^{111}In-labeled compounds, aliquots of $^{111}InCl_3$ (0.2−0.6 mCi, 7.4−22.2 MBq, 4−12 μL) were added to solutions of DOTA−F^{19}-ST_h(1−19) (25 μg), DOTA−R^{1,4},F^{19}-ST_h(1−19) (25 μg), or DOTA−11AUN−F^{19}-ST_h(1−19) (25 μg) in 0.4 M ammonium acetate (200 μL). The pH of the reaction mixture was adjusted to 5.8. The reaction mixture was incubated for 1 h at 80 °C. After 1 h, an aliquot of 0.002 M EDTA (50 μL) was added to the reaction mixture to complex unreacted $^{111}In^{3+}$. Radiolabeling efficiencies ranged between 60 and 80%. The resulting conjugates were purified to homogeneity by RP-HPLC. The ^{111}In-metalated conjugates eluted between 0.9 and 1.8 min before the associated nonmetalated species enabling collection of high-specific activity, no carrier-added ^{111}In−ST_h conjugates. All purified ^{111}In−ST_h conjugates were then concentrated by passing through a 3M Empore C-18 HD high

performance extraction disk (7 mm/3 mL) cartridge and eluting with 50% ethanol in 0.1 M NaH_2PO_4 buffer (500 μL). The concentrated fraction was then reduced in volume under a stream of $N_{2(g)}$ and finally diluted with 0.1M NaH_2PO_4 buffer, pH 7.0, to a final activity of approximately 2 μCi/100 μL.

Macroscopic quantities of indium complexes were synthesized by an analogous synthetic protocol. 0.2 mg DOTA−F^{19}-ST_h(1−19), DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), or DOTA−11AUN−F^{19}-ST_h(1−19), each in 100 μL 0.4 M ammonium acetate, pH 6.0, were added to 100 μg of indium chloride. Reactions were incubated at 80 °C for 1 h. The resulting indium complexes were purified by RP-HPLC and analyzed by ESI-MS.

In Vitro Cell Binding Studies. IC_{50}'s of DOTA−F^{19}-ST_h(1−19), DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), and DOTA−11AUN−F^{19}-ST_h(1−19) and the corresponding indium complexes were determined by a competitive displacement cell binding assay using ^{125}I-F^{19}-ST_h(1−19). Briefly 3×10^6 cells suspended in DMEM/F-12 media containing 15 mM MES and 0.2% BSA, pH 5.5, were incubated at 37 °C for 1 h in the presence of approximately 20 000 cpm ^{125}I-tracer and increasing concentration of the metalated and nonmetalated DOTA−ST_h conjugates. After the incubation, the reaction medium was aspirated, and cells were washed three times with media. The radioactivity bound to the cells was counted in a Packard Riastar gamma counting system. The % ^{125}I-F^{19}-ST_h(1−19) bound to cells was plotted vs increasing concentrations of F^{19}-ST_h(1−19), DOTA−F^{19}-ST_h(1−19), DOTA−$R^{1,4}$,F^{19}-ST_h-(1−19), and DOTA−11AUN−F^{19}-ST_h(1−19) (both metalated and nonmetalated) to determine the respective IC_{50} values. An ST_h analogue lacking tertiary structure by virtue of alanine substitutions for the six cysteine residues present in the wild-type molecule evaluated using this same system does not exhibit measurable binding to GC-C receptors (i.e., $IC_{50} > 10^{-6}$ M). For statistical considerations, three separate in vitro cell binding experiments with each analogue were performed in duplicate. IC_{50} calculations were performed using the four-parameter logistic model within the program grafit (Erithacus Software, Ltd).

Internalization/Efflux Studies. In vitro studies to measure rates of internalization and efflux of labeled compounds from T-84 human colon carcinoma cells were carried out as described previously (*22*). For measurement of internalization, 3×10^6 cells suspended in DMEM/F-12 media containing 15 mM MES and 0.2% BSA, pH 5.5, were incubated for varying times at 37 °C with ∼20 000 cpm ^{125}I-F^{19}-ST_h(1−19), ^{111}In-DOTA−F^{19}-ST_h(1−19), ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), or ^{111}In-DOTA−11AUN−F^{19}-ST_h(1−19). At designated times, binding media was aspirated and cells were washed 3× with 4 °C binding media and then washed 2× with 4 °C acid/saline solution (0.5 M NaCl, 1.2% CH_3COOH). The activity of the acid/saline rinse and the cell pellet were determined and represent surface and internalized activity, respectively. For efflux experiments, all samples were initially incubated for 1 h under the above conditions and then washed 3× with 37 °C binding media to remove free label. The initial (t0) sample was then washed 3× with 4 °C binding media and then 2× with 4 °C acid/saline wash. Subsequent timepoints were treated identically, with surface and internalized activity determined as above.

In Vivo Pharmacokinetic Studies of ^{111}In-ST_h Analogues in SCID Mice. Four- to five-week old female ICR SCID (severe combined immunodeficiency) mice were obtained from Taconic (Germantown, NY). The mice were housed five animals per cage in sterile micro isolator cages in a temperature- and humidity-controlled room with a 12-h light/12-h dark schedule. The animals were fed sterile rodent chow (Ralston Purina Company, St. Louis, MO) and water ad libitum. Animals were housed one week prior to inoculation of tumor cells and anesthetized for injections with isoflurane (Baxter Healthcare Corp., Deerfield, IL) at a rate of 2.5% with 0.4 L oxygen through a non-rebreathing anesthesia vaporizer.

Human colon cancer T-84 cells were injected on the bilateral subcutaneous (sc) flank with $\sim 5 \times 10^6$ cells in a suspension of 100 μL of normal sterile saline per injection site. T-84 cells were allowed to grow in vivo three to four weeks postinoculation, developing tumors ranging in sizes from 0.02 to 0.95 g. The biodistribution and uptake of ^{111}In-DOTA−F^{19}-ST_h(1−19), ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), and ^{111}In-DOTA−11AUN−F^{19}-ST_h(1−19) in tumor-bearing SCID mice were studied. The mice (average weight, 25 g) were injected with aliquots (50−100 μL) of the radiolabeled peptide solution (55−90 kBq) in each animal via the tail vein. Tissues, organs, and tumors were excised from animals sacrificed at 1 h and 4 h pi, weighed, and counted. Radioactivity was measured in a NaI counter, and the percent-injected dose per organ (%ID) and the percent-injected dose per gram tissue (%ID/g) were calculated. %ID in urine was obtained by combining activity measured in urinary bladder with activity measured on a cage lining of absorbent paper. Animal studies were conducted in accordance with the highest standards of care as outlined in the NIH guide for Care and Use of Laboratory Animals and the Policy and Procedures for Animal Research at the Harry S. Truman Memorial Veterans' Hospital and according to approved protocols.

RESULTS

DOTA−ST_h conjugates were synthesized by SPPS and oxidatively refolded for a period of up to 5 days in dilute aqueous solution at pH 8.0. The ST_h molecule possesses three disulfide bonds, arranged in a 1−4, 2−5, 3−6 array (Figure 1). Fifteen possible conformational isomers therefore exist for this molecule, depending on disulfide connectivity (*27*). Conformational isomers in which disulfide connectivity is incorrect generally lose activity in GC-C binding assays (*27*, *28*). In each case investigated here, the major product of the refolding process lacked free thiol residues as determined by Ellman's assay (*29*), had the appropriate mass by ESI-MS, and retained activity in a competitive binding assay utilizing ^{125}I-F^{19}-ST_h(1−19) radioligand and T-84 human colon cancer cells (Table 1). Additionally, the DOTA−F^{19}-ST_h(1−19) analogue was synthesized via a different route, utilizing orthogonal protection of cysteine residues such that disulfides were formed sequentially with intervening purification of folding intermediates (*23*). DOTA−F^{19}-ST_h-(1−19) synthesized in this manner was shown to be identical to the final product obtained from simultaneous cystine formation via oxidative refolding in aqueous solution, providing further evidence that the major product of this thermodynamically controlled process is indeed the correctly folded ST_h isomer.

The binding affinities of each analogue were compared in competitive binding assays using T-84 human colon cancer cells and an iodinated ST_h radioligand (Figure 2, Table 1). IC_{50} values for the metalated and nonmetalated analogues ranged between 2.9 ± 0.3 nM for the DOTA−F^{19}-ST_h(1−19) analogue and 6.0 ± 0.7 nM for the In-DOTA−11AUN−F^{19}-ST_h(1−19) analogue. Parallel stud-

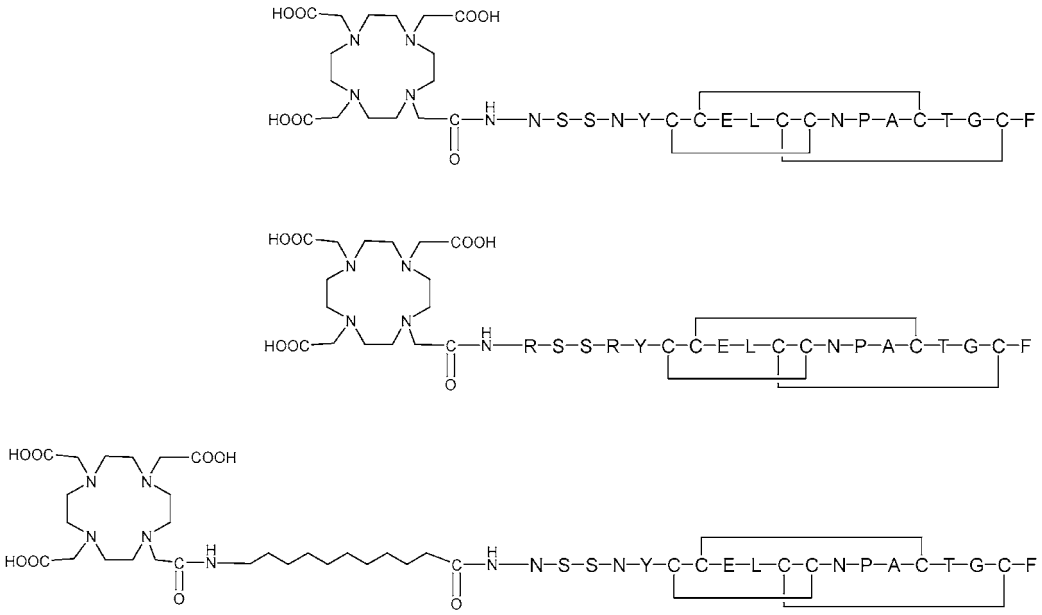

Figure 1. 1. Structures of DOTA−ST_h analogues. Top to bottom: DOTA−F^{19}-ST_h(1−19), DOTA−$R^{1,4}$,F^{19}-ST_h(1−19), DOTA−11AUN−F^{19}-ST_h(1−19).

Table 1. Calculated and Observed Molecular Weights (MW) and IC_{50} Values for ST_h Peptide Analogues

peptide	IC_{50} (nM)	MW (calcd)	MW (obsd)
DOTA−F^{19}-ST_h(1−19)	2.9 ± 0.3	2413.6	2412.6
In-DOTA−F^{19}-ST_h(1−19)	4.9 ± 2.8	2525.4	2525.1
DOTA−$R^{1,4}$,F^{19}-ST_h(1−19)	3.0 ± 0.2	2497.8	2497.0
In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19)	4.1 ± 3.3	2609.6	2609.5
DOTA−11AUN−F^{19}-ST_h(1−19)	3.8 ± 0.4	2595.9	2595.1
In-DOTA−11AUN−F^{19}-ST_h(1−19)	6.0 ± 0.7	2707.7	2707.8

ies with F^{19}-ST_h(1−19) demonstrated an IC_{50} value of 4.2 ± 0.8 nM for the species lacking the N-terminal DOTA moiety. These IC_{50} values are similar to results in the literature for the wild-type ST_h molecule (*16*, *30*), confirming that the binding affinity of the receptor targeting moiety is relatively unaffected by significant structural variations at the N-terminus of the molecule (*31*). Incorporation of In^{3+} into the DOTA moiety generally resulted in a less than 2-fold decrease in receptor binding affinity (Table 1).

DOTA−ST_h analogues were labeled with In-111 by heating a 0.2 mg/mL solution of peptide (pH 5.8) with $^{111}InCl_3$ at 80 °C for 1 h. After the labeling reaction was quenched with excess EDTA to sequester unbound $^{111}In^{3+}$, ^{111}In-DOTA−ST_h complexes were purified by C18 RP-HPLC. The impact of the different linker moieties on the relative hydrophobicities of the three molecules was clearly evident by RP-HPLC (Figure 3). Substitution of asparagine residues at positions 1 and 4 with arginine residues resulted in a decrease in hydrophobicity, while inclusion of the 11-undecanoic acid spacer greatly increased the hydrophobicity of the compound. All labeled analogues eluted earlier than their respective unlabeled congeners, allowing purification of high specific activity, no carrier added tracer.

Specific binding of all ^{111}In-labeled analogues was demonstrated in vitro using high specific activity ^{111}In-DOTA−ST_h conjugates and T-84 human colon cancer cells. In the absence of competing unlabeled ST_h, 9−15% of labeled analogue is associated with T-84 cells. In the presence of 1×10^{-6} M unlabeled ST_h, less than 3% of labeled ST_h is cell-associated. In general, specific binding of ^{111}In tracers exceeded NSB by 8−10-fold.

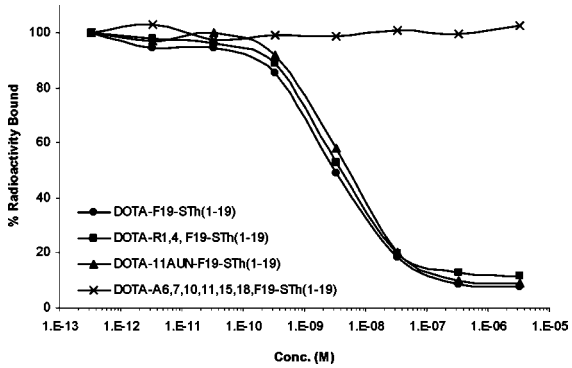

Figure 2. IC_{50} analyses using human T-84 colon carcinoma cells of DOTA−F^{19}-ST_h(1−19) (IC_{50} = 2.9 ± 0.3 nM), DOTA−$R^{1,4}$,F^{19}-ST_h(1−19) (IC_{50} = 3.0 ± 0.2 nM), and DOTA−11AUN−F^{19}-ST_h(1−19) (IC_{50} = 3.8 ± 0.4 nM). An analogue lacking tertiary structure due to alanine substitution of six cysteine residues showed no displacement in this assay.

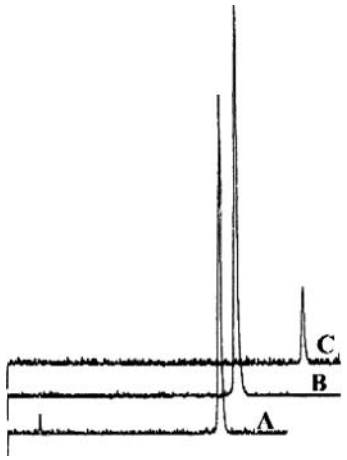

Figure 3. C18 RP-HPLC elution profiles of (A) ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19) (t_R = 15.9 min), (B) ^{111}In-DOTA−F^{19}-ST_h(1−19)) (t_R = 17.1 min), and (C) ^{111}In-DOTA−11AUN−F^{19}-ST_h(1−19)) (t_R = 22.3 min).

An important parameter that impacts the performance of radiopharmaceutical compounds in vivo is the degree to which these compounds are residualized within tumor

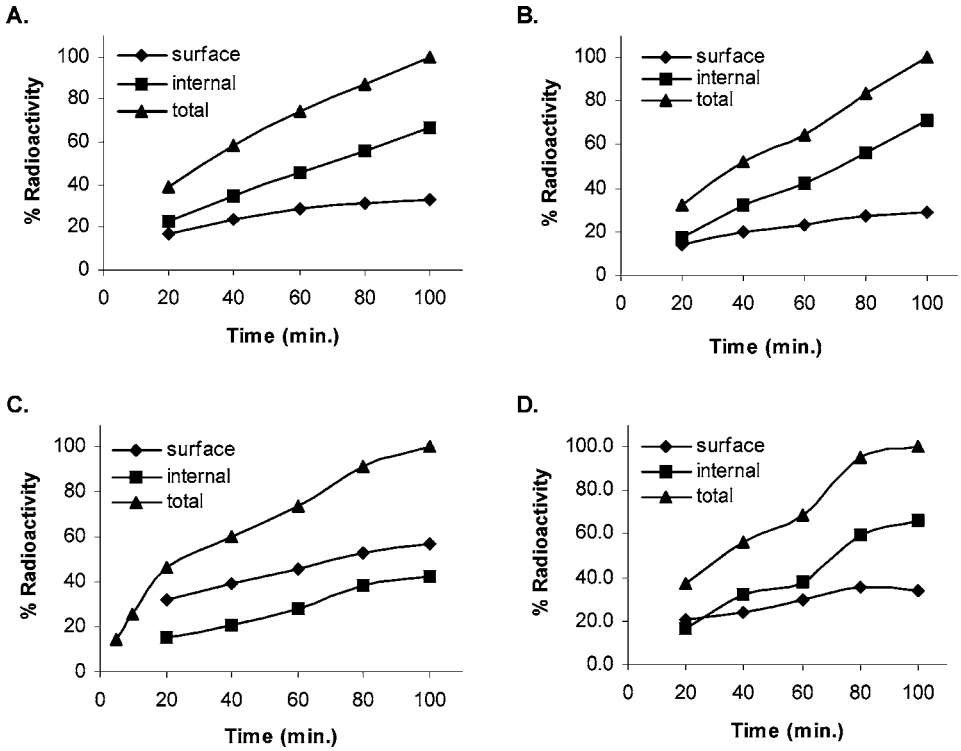

Figure 4. Determination of % internalized radioactivity in T-84 human colon carcinoma cells for (A) ^{125}I-F^{19}-ST$_h$(1−19), (B) ^{111}In-DOTA−F^{19}-ST$_h$(1−19), (C) ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19), (D) ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19).

cells. Residualization within tumor cells is a function of both the internalization rate and the rate of efflux of internalized peptide. Previous studies have shown that the GC-C receptor does undergo endocytosis following binding to ST$_h$ (*32*). As shown in Figure 4, both ^{111}In-DOTA−F^{19}-ST$_h$(1−19) and ^{125}I-F^{19}-ST$_h$(1−19) analogues are internalized by T-84 cells in vitro. For both, the degree of internalization of cell-associated radioactivity was similar, with approximately 60% of cell-bound radioactivity at 100 min. remaining cell-bound after incubation in pH 2.5, 0.5 M saline stripping buffer. Contrasted with this result, the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$-(1−19) analogue, bearing a net 2+ charge in the linker moiety, shows decreased internalization, with only ∼40% of cell-associated radioactivity internalized at 100 min. Results for the positively charged analogue indicate that the majority of cell-associated radioactivity remains surface bound (Figure 4C). Comparison of rates of efflux of labeled analogues (Figure 5) demonstrates that for both the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) species, internalized radioactivity is released from T-84 cells at approximately the same rate, with ∼90% of internalized radioactivity remaining cell-associated after a 3 h incubation at 37 °C. This indicates that once internalized, the ^{111}In-DOTA moiety is effectively trapped intracellularly. The higher amount of surface bound activity for the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$-(1−19) analogue resulted in a lower amount of total radioactivity retained for this analogue. The efflux rate for the ^{125}I-F^{19}-ST$_h$(1−19) species (Figure 5A) is lower than would be expected if the peptide was degraded intracellularly, releasing monoiodotyrosine. This is perhaps due to the proximity of the tyrosine residue to the extremely stable disulfide-stabilized core of the molecule, which may limit generation of monoiodotyrosine.

Biodistribution analyses of the three ^{111}In-labeled analogues were carried out in T-84 xenografted SCID mice. Biodistributions at 1 h pi are shown in Tables 2 and 4. For all analogues, radioactivity cleared rapidly from the bloodstream, with 89−93% ID in the urine at 1 h pi. The primary route of excretion of all analogues is via the kidneys into the urine (Table 2). Both the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and the ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogues showed significantly decreased urinary excretion and significantly increased blood activity at 1 h pi. Most nontarget tissues, as well as tumor tissue, showed increased %ID/g values for both analogues at 1 h pi, probably reflecting blood perfusion of both target and nontarget tissues.

Specificity of tumor uptake of ST$_h$ analogues has been demonstrated previously by coinjection of 4 mg/kg unlabeled ST$_h$ (*21*, *23*). Significant reductions in tumor uptake upon blocking were seen for labeled ST$_h$ analogues at 1 h postinjection with diverse linker moieties in both LS-180 and T84 human colon cancer tumor xenografts (*21*, *23*). Tumor uptake in these studies was reduced by coinjection of unlabeled peptide from 0.94 ± 0.31%ID/g to 0.46 ± 0.22%ID/g in an LS180/SCID model (*21*) and from 2.04 ± 0.3%ID/g to 0.81 ± 0.25%ID/g in a T84/SCID model (*23*). These 50−60% reductions in tumor uptake are comparable to reductions in uptake of radiolabeled bombesin in PC-3 human pancreatic cancer tumor xenografts by coinjection of unlabeled bombesin (*38*).

At 4 h pi, ∼95% of injected activity had been excreted via the renal/urinary route for all analogues (Table 3, 5). No significant differences in tumor uptake were seen between analogues at this time. The only significant differences between analogues related to kidney uptake and hepatic excretion. Uptake in the liver for both the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and the ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogues was significantly lower than for the ^{111}In-DOTA−F^{19}-ST$_h$(1−19) analogue at 4 h pi. Intestinal uptake for both was significantly higher, however. In addition, the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) analogue had the highest kidney retention of the three analogues, although the difference was only significant ($p < 0.05$) with respect to ^{111}In-DOTA−11AUN−F^{19}-ST$_h$-(1−19).

DISCUSSION

Research into the interaction between the heat-stable enterotoxin peptide and its cognate receptor GC-C has generated >100 synthetic analogues of the peptide, several of which have been investigated as imaging or therapeutic agents for colorectal cancers (*20*−*24*, *26*, *31*, *33*). In the work described here, we have appended a DOTA chelating moiety to the N-terminus of the ST$_h$ molecule via a series of hydrophilic and hydrophobic spacer groups. The DOTA chelating framework is capable of complexing a wide range of trivalent metals, including $^{90}Y^{3+}$, $^{111}In^{3+}$, $^{149}Pm^{3+}$, $^{153}Sm^{3+}$, $^{166}Ho^{3+}$, and $^{177}Lu^{3+}$. Such a broad array of radioisotopes suitable for complexation by DOTA will allow a single designed analogue to be used both for the imaging and treatment of colorectal cancers. For example, the 171 and 245 keV γ emissions of In-111 are suitable for SPECT imaging, while the particle emitting lanthanides provide a broad range of emission energies that could be appropriate for use therapeutically against either solid primary tumors or smaller distant metastases.

Our strategy for producing radiolabeled ST$_h$ analogues has been to covalently link the DOTA chelating moiety to the ST$_h$ peptide via a series of spacer groups. In the work described here, three highly dissimilar spacer groups were used. This illustrates the ability to generate a wide range of properly folded, bioactive ST$_h$ molecules with disparate physiochemical characteristics. Modulation of these characteristics can in turn significantly impact the pharmacokinetic properties of these compounds in vivo. Further, incorporation of such modifications at the N-terminus of ST$_h$ does not affect the binding affinity of modified analogues for the GC-C receptor. Three important physiochemical parameters that have

been altered in these experiments are the relative hydrophobicity of the molecules, their overall net charge, and the nature of the metabolites that could be formed upon intracellular degradation following internalization.

Although the ST_h molecule is extremely stable to both heat and proteolytic degradation (*23*, *34*), it is likely that the N-terminal tail of the molecule ($N^1S^2S^3N^4Y^5$-), which has a limited effect on receptor binding (*31*) and lies outside of the disulfide-stabilized core of ST_h, is vulnerable to enzymatic cleavage. Such cleavage, if occurring within the lysosome following cellular internalization, would probably result in formation of ^{111}In-DOTA−amino acid conjugates as have been shown to result from intracellular metabolism of labeled antibodies and glycoproteins (*35*−*37*). If intracellular metabolism does proceed along these lines for the analogues studied here, the ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19) molecule would yield a zwitterionic ^{111}In-DOTA−Arg fragment, while the ^{111}In-DOTA−F^{19}-ST_h(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST_h(1−19) analogues would each yield negatively charged fragments by virtue of the DOTA linkage to the N-terminal α amine.

The direct linkage of the ^{111}In-DOTA moiety to a positively charged arginine residue in the ^{111}In-DOTA−$R^{1,4}$,F^{19}-ST_h(1−19) analogue did result in increased kidney uptake. This is probably due to trapping of a zwitterionic ^{111}In-DOTA−Arg fragment within lysosomes of proximal tubule cells following pinocytotic reabsorption of the intact molecule during glomerular filtration in the kidney (*35*). Increased retention of this analogue within

T-84 cell tumor xenografts, however, was not observed at 4 h pi. This lack of increased tumor retention could perhaps be explained by the decreased rate of GC-C receptor-mediated internalization observed for this analogue (Figure 4). However, the ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogue also demonstrated decreased tumor retention, despite internalization and efflux rates similar to those of the ^{111}In-DOTA−F^{19}-ST$_h$(1−19) analogue. The reasons for these differences in residualization properties will therefore require further study.

The addition of the hydrophobic 11-aminoundecanoic acid spacer to the ST$_h$ molecule resulted in increased hepatic metabolism of the resulting compound. This modification also resulted in a faster rate of hepatic excretion, such that residual activity in the liver was ∼5-fold lower than for the analogue lacking the spacer at 4 h pi. The same trends were observed, albeit to a lesser degree, for the positively charged analogue, which had approximately half the liver activity of the analogue lacking spacer at 4 h pi. While radioactivity in the liver increased between 1 and 4 h pi for the ^{111}In-DOTA−F^{19}-ST$_h$(1−19) analogue, both the hydrophobic and charged analogues showed a decrease in liver activity over this period. It is important to note that for all three analogues, the total liver uptake is quite low. However, in the context of developing agents for imaging liver metastases of colorectal cancer, the ability to manipulate the timecourse of hepatic uptake and clearance could have significance.

While the increased rate of hepatic excretion of the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogues did result in lower background activity in the liver at 4 h pi, increased early hepatic metabolism of these compounds resulted in a large increase in background activity in the large and small intestines at this timepoint. Due to the generally rapid rate of elimination of these compounds from the bloodstream into the urine, this effect is most clearly seen by normalizing residual activity to the total amount remaining in the body at the given timepoint. For example, at 4 h pi, an average of 33.5% of activity remaining in the body is localized in tumor tissue using the ^{111}In-DOTA−F^{19}-ST$_h$(1−19) analogue. In contrast, only 6.9% and 7.6% of remaining activity is localized in tumor tissue for the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogues, respectively. Further, while only an average of 16.6% of remaining activity was localized to the intestinal tract for the ^{111}In-DOTA−F^{19}-ST$_h$(1−19) analogue at 4 h pi, 46.9% and 55.9% of remaining activity was localized there for the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) analogues, respectively.

CONCLUSION

This work demonstrates that a broad spectrum of N-terminally modified ^{111}In-labeled ST$_h$ molecules can be successfully synthesized which retain highly specific binding affinity for the GC-C receptor. Both the incorporation of highly charged and extended hydrophobic linkers had little effect on receptor binding affinity, yet had significant effects on the pharmacokinetics of these compounds in vivo. The more rapid liver metabolism of the ^{111}In-DOTA−R^{1,4},F^{19}-ST$_h$(1−19) and ^{111}In-DOTA−11AUN−F^{19}-ST$_h$(1−19) compounds relative to ^{111}In-DOTA−F^{19}-ST$_h$(1−19) could potentially allow superior images of hepatic metastases to be obtained in vivo. The lack of significant nontarget tissue uptake of ST$_h$ relative to other receptor-targeted radiopharmaceuticals clearly shows the potential of ST$_h$ analogues for use in the imaging and treatment of colon carcinoma. Future work will focus on the design of analogues optimized for both imaging and therapeutic applications.

Received January 30, 2004; Revised Manuscript Received April 21, 2004

A novel conjugate of a polysaccharide and a Gd(III) chelate with potential as contrast agent for magnetic resonance imaging (MRI) was synthesized. The structure of the chelate was derived from H_5DTPA by replacing the central pendant arm by a phosphinic acid functional group, which was covalently bound to the polysaccharide inulin. On the average, each monosaccharide unit of the inulin was attached to approximately one (0.9) chelate moiety. The average molecular weight is 23110 and the average number of Gd^{3+} ions per molecule is 24. The ligand binds the Gd^{3+} ion in an octadentate fashion via three nitrogen atoms, four carboxylate oxygen atoms, and one P−O oxygen atom, and its first coordination sphere is completed by a water molecule. This compound shows promising properties for application as a contrast agent for MRI thanks to a favorable residence lifetime of this water molecule (170 ns at 298 K), a relatively long rotational correlation time (866 ps at 298 K), and the presence of two water molecules in the second coordination sphere of the Gd^{3+} ion. Furthermore, its stability toward transmetalation with Zn(II) is as high as that of the clinically used $[Gd(DTPA)(H_2O)]^{2-}$.

INTRODUCTION

Paramagnetic metal complexes are widely used in clinical diagnostics as contrast agents for magnetic resonance imaging (MRI). They are used to enhance the contrast between normal and diseased tissue or to indicate blood flow and/or organ function (*1*, *2*). Nowadays, more than 30% of the examinations are performed after administration of a contrast agent. Paramagnetic contrast agents may improve the image contrast by enhancing the relaxation rate of water proton nuclei in their surroundings. The most commonly used paramagnetic metal ion in these contrast agents is Gd^{3+}, which is very efficient in enhancing relaxation rates by virtue of its seven unpaired electrons and its relatively long electronic relaxation time. The efficiency of an MRI contrast agent usually is expressed as the relaxivity, r_1, which is the enhancement of the water proton relaxation rate in s^{-1} mM^{-1} per Gd^{3+} ion. The relaxivity is governed mainly by the residence lifetime of water molecules coordinated in the first coordination sphere of the central metal ion, τ_M, by the complex reorientation time, τ_R, and by the longitudinal and transversal electronic relaxation times, τ_{s1}, τ_{s2} (*1*, *3*, *4*). Currently applied low molecular weight complexes, such as Gd^{3+} complexes of 1,1,4,7,7-diethylenetriaminepentaacetic acid (H_5DTPA) or 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (H_4DOTA), have their relaxivity limited by fast rotation and, therefore, a short rotational correlation time, τ_R. New generations of contrast agents with improved relaxivity and specificity are desired. There are possibilities to enhance the relaxivity by increasing the τ_R value. This can be achieved by, for example, covalent or noncovalent binding of a low molecular weight chelate to macromolecules (*3*) or by self-assembly of monomeric complexes into micelles or particulates (*5*).

The residence lifetime of the inner-sphere water molecule, τ_M, is a very important parameter in relation to the relaxivity of high molecular weight MRI contrast agents. Theory predicts that its optimal value is in the range of 20−50 ns at 298 K (*3*). The currently used contrast agents, such as the above-mentioned $[Gd(DTPA)(H_2O)]^{2-}$ and $[Gd(DOTA)(H_2O)]^{-}$, have τ_M values of 303 and 244 ns at 298 K, respectively, which is far from the optimum (*6*). Upon conjugation of these complexes to a macromolecule, the relaxivities may therefore be limited by this parameter. The water exchange rate can be enhanced by, for example, introducing negative charge (*7*) in the neighborhood of the Gd^{3+} bound water or by increasing its steric strain, which favors the dissociative mechanism of the water exchange (*8*−*12*). Previously, we reported on the low-molecular weight complex $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ (see Chart 1), which was designed on the basis of these ideas (*11*). It appeared to have a τ_M value of 92 ns, which is three times smaller than the currently used contrast agent $[Gd(DTPA)(H_2O)]^{2-}$. Furthermore, this complex has two second-sphere water molecules, which are contributing to the overall relaxivity. Here, we report on the synthesis of an analogous chelate (**8**) and its conjugate with the polysaccharide inulin (**L**, Chart 1). The relaxivity of both the parent chelate (**8**) and its conjugate and the parameters governing it are evaluated.

Chart 1. Molecular Structures of Ligands Discussed

EXPERIMENTAL PROCEDURES

Materials. Commercially available diethylenetriamine, phthalanhydride, ethyl chloroformate, and ethyl bromoacetate had synthetic purity and were used as received. Arsenazo III used for free-gadolinium tests was purchased from Aldrich Chemical Co. (Milwaukee, WI). The 10% Pd/C-catalyst for the hydrogenation reactions was obtained from Acros (Geel, Belgium). Inulin was obtained from Sensus Coöperatie Cosun U.A. (Roosendaal, The Netherlands) and had an average degree of polymerization (*dp*) of 25. This "long chain" fraction was obtained by recrystalization of inulin from water, thereby selectively removing the low-molecular-weight components. Paraformaldehyde was obtained by filtration of aged aqueous formaldehyde solutions and was dried in a desiccator over concentrated sulfuric acid. *p*-Nitrobenzyl phosphinic acid was prepared by alkylation of $P(CH(OEt)_2)(OSiMe_3)(OEt)$ with *p*-nitrobenzyl bromide followed by hydrolysis in aqueous HCl according to a procedure published elsewhere (*13*).

NMR Spectroscopy. ^{1}H (300 MHz), ^{13}C (75.5 MHz), ^{17}O (40.7 MHz), and ^{31}P NMR spectra (121.5 MHz) were recorded on a Varian INOVA-300 spectrometer using 5 mm sample tubes. Unless stated otherwise, NMR experiments were performed at 25 °C. Chemical shifts δ are given in ppm. For measurements in D_2O, *tert*-butyl alcohol was used as an internal standard with the methyl signal referenced to 1.2 ppm (^{1}H) or 31.2 ppm (^{13}C). Deuterium oxide (100%) was used as an external chemical shift reference for ^{17}O resonances. The ^{31}P chemical shifts were measured with respect to 1% H_3PO_4 in D_2O as an external standard (substitution method). The pH values of the samples were measured at ambient temperature using a Corning 125 pH meter with a calibrated microcombination electrode purchased from Aldrich Chemical Co. The pH values of the solutions were adjusted using dilute aqueous solutions of NaOH and HCl.

Mass Spectrometry. Mass spectra were obtained on a Q-tof 2 mass spectrometer (Micromass, Manchester, UK). Samples were dissolved in H_2O and injected at a rate of 5 μL/min. The cone voltage was 170 V (T = 80 °C); 850 spectra were accumulated. The reported mass corresponds to the most abundant isotopic peak.

Bis(phthaloyl)diethylenetriamine (1). This compound was synthesized according to a known procedure (*14*). ^{1}H NMR (DMSO-d_6), δ 2.76 and 3.59 (t, $^3J_{HH}$ = 6.3 Hz, 2 × 4H, CH_2), 7.80 (m, 8H, arom). ^{13}C NMR (DMSO-d_6), δ 37.14 and 46.10 (NCH_2CH_2N), 122.70, 131.59 and 134.07 (arom), 167.81 (*C*O).

Ethyl *p*-Nitrobenzylphosphinate (3). An excess of pyridine (3.45 g, 43.6 mmol) was slowly dropped to a suspension of *p*-nitrobenzylphosphinic acid (**2**) (*13*) (5.00 g, 24.9 mmol) and ethylchloroformate (3.47 g, 32.0 mmol) in $CHCl_3$ (200 mL) during a period of 2 h. The mixture obtained was stirred for 42 h at room temperature and then washed with water (3 × 150 mL). The organic layer was dried over Na_2SO_4 after which the solvents were evaporated off. The excess of chloroformate was removed by codistillation with toluene (2 × 50 mL) and dry ethanol (2 × 50 mL) to yield 5.25 g (92%) of **3** as a light yellow oil. ^{31}P NMR ($CDCl_3$), δ 33.39 (doublet of multiplets, $^1J_{PH}$ = 551 Hz). ^{13}C NMR ($CDCl_3$), δ 147.08 ($^5J_{CP}$ = 4.4 Hz, *C*-NO_2), 138.28 ($^2J_{CP}$ = 8.2 Hz, C_{arom}-CH_2), 130.80 ($^3J_{CP}$ = 6.0 Hz, arom), 123.83 ($^4J_{CP}$ = 2.7 Hz, arom), 63.10 ($^2J_{CP}$ = 7.1 Hz, OCH_2), 36.91 ($^1J_{CP}$ = 86.3 Hz, *C*H_2P), 16.21 ($^3J_{CP}$ = 6.0 Hz). ^{1}H NMR ($CDCl_3$) δ 8.2 (AA′BB′ system, 4H, arom), 7.20 ($^1J_{PH}$ = 554 Hz, 1H, P*H*), 4.15 (m, 2H, OCH_2), 3.42 ($^1J_{HP}$ = 19 Hz, 2H, CH_2P), 1.33 (m, 3H, CH_3).

Ethyl *N*,*N*″-Bis(phthaloyl)diethylenetriamine-*N*′-methylene(*p*-nitrobenzyl)phosphinate (4). Freshly prepared ethyl *p*-nitrobenzylphosphinate (**3**) (5.25 g, 22.9 mmol) was dissolved in a mixture of 100 mL of toluene and 30 mL of dry ethanol. Bis(phthaloyl)diethylenetriamine (**1**) (5.00 g, 13.8 mmol) was added, and the mixture was heated to reflux under a Dean−Stark trap. Paraformaldehyde (0.41 g, 13.8 mmol) was added portionwise during 1.5 h. After the addition was completed, the reaction mixture was refluxed for another 1.5 h. The solvent in the trap was removed, and a second portion of paraformaldehyde (0.41 g) was added. The mixture was then heated for 18 h at 100 °C. The excess of ethyl *p*-nitrobenzylphosphinate and the byproduct ethyl hydroxomethyl(*p*-nitrobenzyl)phosphinate were not removed, and the crude product was used in the next step without purification. ^{13}C NMR ($CDCl_3$), δ 16.98 (*C*H_3), 35.23 ($^1J_{CP}$ = 86 Hz, $O_2NC_6H_4CH_2$P), 35.80 (NCH_2CH_2-NPht), 53.05 (NCH_2P, $^1J_{CP}$ = 87); 53.63 (NCH_2CH_2NPht), 61.87 (POCH_2), 123.70, 131.19 and 134.53 (all Pht), 123.75, 132.53, 139.89, 147.27 (arom), 168.66 (*C*O).

Diethylenetriamine-*N*′-methylene(*p*-nitrobenzyl)-phosphinic-*N*,*N*,*N*″,*N*″-tetraacetic Acid (7). Hydrazine hydrate (2.00 g, 62.4 mmol) was added to a solution of crude **4** in dry ethanol (100 mL), and the mixture was refluxed for 6 h. After cooling, the precipitated phthalhydrazide was filtered off. The solvent was evaporated and water was removed by codistillation with dry ethanol. The crude product **5** was used in the next reaction step without further purification. All material obtained was dissolved in DMF (70 mL). $BrCH_2CO_2Et$ (20.04 g, 0.12 mol) and K_2CO_3 (15.12 g, 0.11 mol) were added to the solution obtained. After being stirred at room temperature for 24 h, the solids were filtered off and the mixture was diluted with a saturated solution of $NaHCO_3$ (70 mL). The product was extracted into toluene (150 mL). The organic layer was washed with a saturated solution of $NaHCO_3$ (3 × 100 mL) and with brine (100 mL). The organic phase was dried (Na_2SO_4), filtered and evaporated until dryness to give crude **6**.

All material obtained above was dissolved in 200 mL of diluted HCl (1:1). After being refluxed for 21 h, the mixture was filtered and evaporated to dryness. The residue was dissolved in water and poured onto a column of cation exchanger (Dowex 50, 200 mL, H^+-form). Nonbasic impurities were removed by elution with water

(~1 L). The crude product was eluted using a diluted ammonia (1:3) solution. The orange fraction obtained was evaporated to dryness, dissolved in water, and poured onto a column of an anion exchanger (Dowex 1, 250 mL, OH^--form). After being washed with water, some yellow-colored impurities were removed by elution with 10% acetic acid. The product was collected by elution with aqueous HCl (1:3). The fractions containing the product were evaporated to dryness. Trituration with 300 mL of acetone afforded a light yellow solid, which was filtered off, washed with acetone, and dried under vacuum. The product was recrystallized by dissolution in water with a minimal amount of ammonia and acidification with HCl to pH ~ 0. Overall yield (based on compound (**1**)): 5.61 g (70%). Elemental analysis showed that the compound contains a small amount of NaCl (calcd for **7**·$2H_2O$, $C_{20}H_{33}N_4O_{14}P$, $M = 584.47$) C 41.55 (41.10); H 5.63 (5.69); N 9.86 (9.59); Cl 1.01 (0.00). ^{31}P NMR (D_2O, pH = 0.5), δ 36.85. ^{13}C NMR (D_2O, pH = 0.5), δ 37.08 (d, $^1J_{CP} = 86$ Hz, $O_2NC_6H_4CH_2P$), 51.12 (PCH_2NCH_2), 51.65 (d, $^1J_{CP} = 80$ Hz, NCH_2P), 52.27 ($PCH_2NCH_2CH_2N$), 55.37 (NCH_2-CO), 124.05, 130.91 (d, $^3J_{CP} = 8.0$ Hz), 140.95 (d, $^2J_{CP} = 8.2$) and 146.66, (arom), 169.75 (*C*O). ^1H NMR (D_2O, pH = 0.5), δ 3.03 (d, $^2J_{HP} = 6.6$ Hz, $O_2NC_6H_4CH_2P$), 3.18 and 3.67 (m, CH_2 groups of skeleton and bearing phosphorus moiety), 4.01 (s, NCH_2CO); 7.38 and 8.08 (arom).

Diethylenetriamine-*N′*-methylene(*p*-aminobenzyl)-phosphinic-*N*,*N*,*N″*,*N″*-tetraacetic Acid (8). Compound **7** (0.5 g, 0.86 mmol) was dissolved in water (10 mL) with addition of a small amount of a solid LiOH. Hydrogenation catalyst (0.05 g of 5% Pd/C) was added, and the mixture was stirred under a H_2 atmosphere for 3 days. The reaction mixture was then filtered and purified by chromatography on a column of a strong anion exchanger (Dowex 1, AcO^--form, 25 mL). After washing with water, the product was eluted with HCl (1:3). The fractions containing the product were evaporated to dryness. The product was triturated using dry ethanol, collected by filtration, and dried under vacuum. Yield: 0.68 g (92%) Elem. anal. (calcd for (**8**)·$12H_2O$·HCl, $C_{20}H_{56}ClN_4O_{22}P$, M = 771.16) C 30.98 (31.15); H 5.26 (7.32); N 7.27 (7.27); Cl 2.08 (4.60). ^{31}P NMR (D_2O, pH = 0.5), δ 37.72. ^{13}C NMR (D_2O, pH = 0.5): 36.80 (d, $^1J_{CP} = 87$, $H_2NC_6H_4CH_2P$); 51.23 (PCH_2NCH_2); 51.65 (d, $^1J_{CP} = 90$, NCH_2P); 52.20 ($PCH_2NCH_2CH_2N$); 55.50 (NCH_2CO); 123.50, 128.73, 131.57 and 133.76 (arom); 169.96 (*C*O). ^1H NMR (D_2O, pH = 0.5), 3.05 (d, $^2J_{HP} = 6.9$ Hz, $H_2NC_6H_4CH_2P$), 3.18 and 3.39 (m, CH_2 groups of skeleton and bearing phosphorus moiety), 4.02 (s, NCH_2CO); 7.34 (arom).

Diethylenetriamine-*N′*-methylene(*p*-isothiocyanatobenzyl)phosphinic-*N*,*N*,*N″*,*N″*-tetraacetic Acid (9). Compound **8** (0.5 g, 0.65 mmol) was dissolved in water (5 mL), and the pH was adjusted to 2 by several drops of concentrated aqueous HCl. A solution of thiophosgene (80 mg in 3 mL CCl_4, 0.68 mmol, 1.05 equiv) was added in one portion, and then the mixture was stirred vigorously at room temperature for 48 h. The water phase was separated off and evaporated to dryness. Yield: 0.51 g. ^{31}P NMR (D_2O, pH = 0.5), δ 36.16. ^{13}C NMR (D_2O, pH = 0.5), δ 36.85 (d, $^1J_{CP} = 86$ Hz, $SCNC_6H_4CH_2P$), 49.38 (PCH_2NCH_2), 52.51 ($PCH_2NCH_2CH_2N$), 52.55 (d, $^1J_{CP} = 102$ Hz, NCH_2P), 57.29 (NCH_2CO), 126.00, 131.14, 134.24 and 134.99 (arom), 170.52 (*C*O); S*C*N was not observed, probably due to its very slow relaxation.

***O*-Cyanoethylinulin (11)** (*15*). Inulin (**10**) (dp 25, 5 g, 31 mmol of sugar units) was dissolved together with 0.26 g of NaOH (6.5 mmol) in water (8.9 mL, 0.49 mmol) by stirring at 45 °C. Then, acrylonitrile (3.28 g, 62 mmol) was added, and the mixture was stirred for 1 h at 45 °C. The mixture was diluted with water (20 mL) and neutralized by addition of 30% HCl (1 mL), followed by small amounts of $NaHCO_3$ (until CO_2 bubbles were observable). The reaction mixture was evaporated to dryness, and the residue was dissolved in 50% ethanol (100 mL). Salts were removed by membrane filtration (20 bar, UTC 60 membrane, Torey Industies Inc., Tokyo, Japan). The product was freeze-dried, and integration of the ^1H NMR spectrum showed the average degree of substitution to be 1.13. Yield: 5.70 g. ^1H NMR (D_2O), δ 2.6−2.9 (19% of overall intensity, CH_2CN); 3.5−4.4 (81% of overall intensity, remaining protons).

***O*-Aminopropylinulin (12)** (*16*)**.** *O*-Cyanoethylinulin (**11**) (1.00 g, 4.5 mmol) was dissolved in a mixture of liquid ammonia (100 mL) and dry ethanol (50 mL). Metallic lithium (0.53 g, 77 mmol) was added portionwise during 30 min at −50 °C. A deep blue color was visible for several seconds after each addition of the metal. The mixture was refluxed for 1 h. Then the ammonia was evaporated off over 3 h using a cold water bath, and the resulting mixture was diluted with water (50 mL). A stream of CO_2 was bubbled through the suspension to neutralize LiOH. The mixture was filtered and evaporated to dryness. The product was extracted with water (150 mL). Salts were removed by membrane filtration (UTC 60 membrane), and the filtrate was freeze-dried. The degree of substitution was determined by integration of the ^1H NMR spectrum to be 0.99. Yield: 0.88 g. ^1H NMR (D_2O, pH = 10.5), δ 1.5−2.0 (15% of overall intensity, $CH_2CH_2NH_2$), 2.6−2.9 and 2.9−3.1 (15% of overall intensity, $CH_2CH_2NH_2$); 3.4−4.3 (70% of overall intensity, remaining protons). ^1H NMR (D_2O, pH = 0), δ 1.5−2.0 1.65−1.85 (17% of overall intensity, $CH_2CH_2NH_2$); 2.8−3.0 (16% overall intensity, $CH_2CH_2NH_2$), 3.3−4.2 (67% of overall intensity, remaining protons). ESI-MS: *m*/*z*: 5676 (the mean value cossponds to dp ~ 26 with ds ~ 0.99). For MS data see Supporting Information (Figure S1).

Conjugate of Ligand 9 and *O*-Aminopropylinulin, L. *O*-Aminopropylinulin (**12**) (0.203 g, 0.93 mmol amino groups) was dissolved in water (7 mL), and the pH was adjusted to 9−10 with diluted KOH. Compound **9** (freshly prepared from 1.0 g of **8**, 1.30 mmol, 1.4 equiv) was added, and the reaction mixture was stirred at room temperature for 24 h. The reaction mixture was purified by gel chromatography (Sephadex G-25, 110 × 2 cm) using distilled water for elution. Four fractions of 100 mL were collected. The first two of them contained only inorganic salts and low molecular weight compounds and were discarded. The last two fractions containing the macromolecular material were freeze-dried. Yield: 0.91 g. ^{31}P NMR (D_2O), δ 34.18. ^1H NMR (D_2O), δ 2.0−2.2 ($CH_2CH_2NH_2$), 2.8−3.0 ($CH_2CH_2NH_2$), 3.1−3.3 (NCH_2CH_2N), 3.3−3.6 (NCH_2COOH), 3.7−4.2 (inulin *H*), 7.43 and 7.54 (arom). Comparison of the integrals of the aromatic protons and those of the sugar protons indicated that the degree of substitution was 0.86.

Gd(III) Complex of L, Gd_xL. In following text, for clarity, the abbreviation Gd_x**L** will be used for the final conjugate complex without specification of the number of metal ions per inulin molecule, the number of coordinated water molecules, and the charge. Ethylenediaminetetraacetic acid (H_4EDTA) (0.29 g, 1 mmol) was suspended in water (3 mL). Concentrated aqueous ammonia was added dropwise until all H_4EDTA was dissolved. Then, a solution of 0.22 g of $GdCl_3·6H_2O$ (0.59 mmol) in water (3 mL) was added, and the reaction mixture was stirred at room temperature. After 30 min,

all Gd(III) was complexed (as checked with Arsenazo III). A solution of **L** (0.10 g in 2 mL of water) was added, and the reaction mixture was stirred at room temperature for 36 h. The pH was not adjusted, and it had a value of 5.0.

The solution was then dialyzed (cellulose membrane, Sigma, retains mol. wt > 12 000). The water used in the dialysis was checked for the presence of Gd(III) by measuring its ^{17}O NMR shift. When the chemical shift of the water signal remained constant, the dialysis was terminated. The final solution was once again checked for the presence of free Gd(III) with Arsenazo III, and no free Gd(III) was detected. The solution of the Gd_x**L** complex was freeze-dried. Yield: 0.11 g of white hygroscopic solid. ESI-MS: *m*/*z*: 23110 (the mean value corresponds to dp ∼ 27 with ds ∼ 0.86 (number of Gd(III) complexes per sugar unit)). For the MS data see Supporting Information (Figure S1).

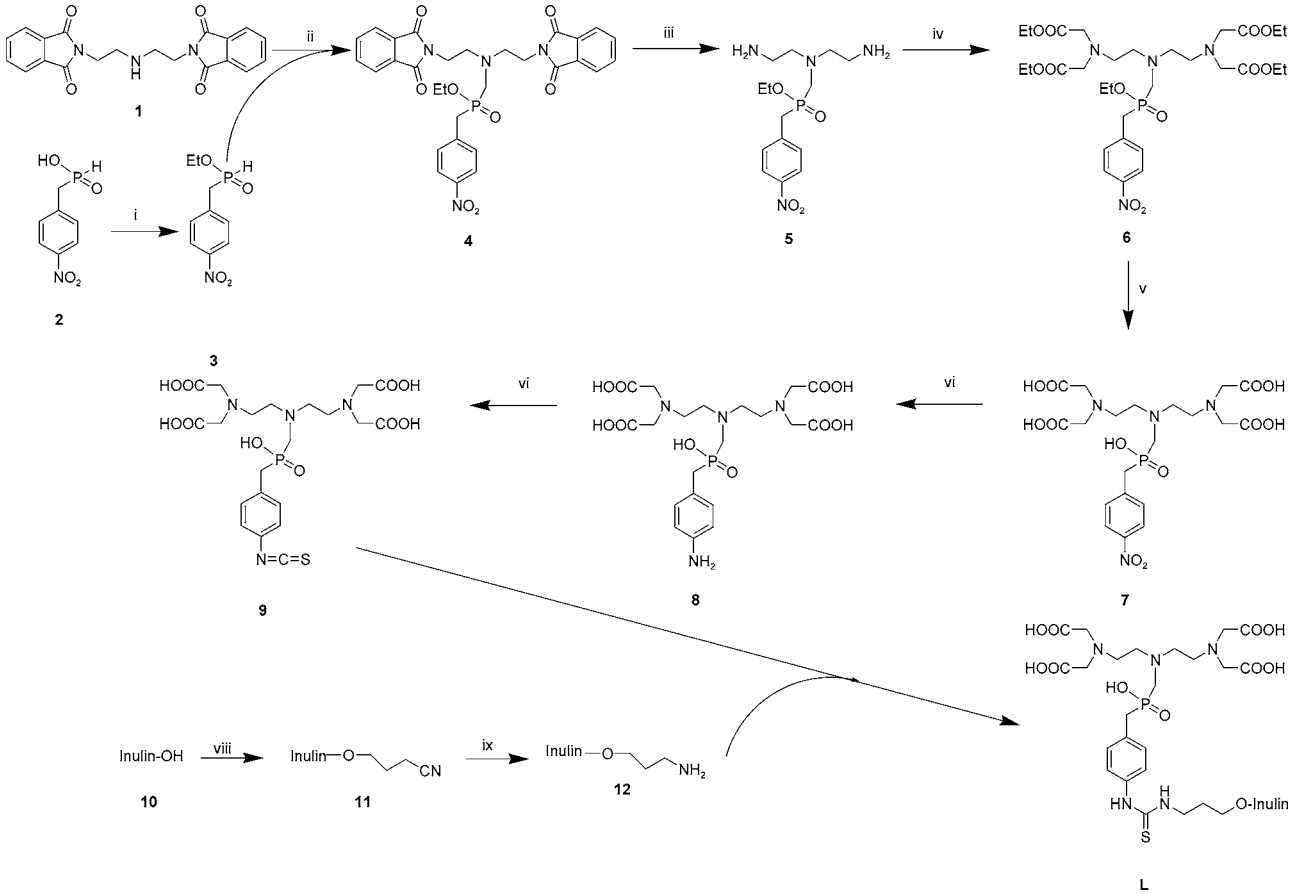
Variable Temperature ^{17}O NMR Study of the Gd_xL. A sample of the Gd(III) complex of **L** was prepared by dissolution of 0.0486 g of Gd_x**L** in 0.3621 g of deionized water. Then, 64 mg of ^{17}O enriched water (10% $H_2{}^{17}O$) was added, and the pH was determined to be 5.79. The exact concentration of Gd(III) was determined to be 82 mM from the bulk magnetic susceptibility shift, which was determined using the procedure described previously (*17*). All NMR spectra were acquired without frequency lock. To correct the ^{17}O NMR shift for a contribution of the BMS, the difference between chemical shifts of proton signals of *tert*-butyl alcohol in the paramagnetic sample and in pure water was applied according to the procedure described previously (*18*). Longitudinal ($1/T_1$) and transversal ($1/T_2$) relaxation rates were obtained by the inversion recovery method (*19*) and the Carr−Purcell−Meiboom−Gil pulse sequence (*20*), respectively.

Measurement of $1/T_1$ ^1H NMRD Profiles. The sample was prepared by dissolution of the freeze-dried complex Gd_x**L** in the appropriate amount of deionized water. The pH value was 7.11 and was not further adjusted. The exact concentration of Gd(III) was determined using the BMS method (*17*) and from proton relaxivity measurements at 20 MHz and 37 °C after complete hydrolysis in 25% HNO_3. The $1/T_1$ NMRD profiles were measured at 5, 25, and 37 °C at magnetic field strengths between $4.7 \cdot 10^{-4}$ T and 0.35 T using a Stelar SpinMaster FFC-2000 relaxometer. Measurements at 0.47, 1.42, and 7.05 T were performed on a Bruker Minispec PC-20 and Mq-60 and on a Bruker AMX-300 spectrometer and were included in the profiles. The experimental data were fitted simultaneously with ^{17}O NMR data employing a least-squares fitting procedure using the Micromath Scientist program version 2.0 (Salt Lake City, UT) as described previously (*21*, *22*).

Transmetalation. The stability of Gd(III) complex was determined using a transmetalation experiment with $ZnCl_2$ (*23*). This measurement was done using a buffered solution (phosphate buffer, total concentration 67 mM, pH 7) containing 2.5 mM of Gd_x**L** and 2.5 mM of $ZnCl_2$. The transmetalation was followed via the ^1H longitudinal relaxation rates of the water using the Bruker Minispec 20 MHz at 37 °C.

RESULTS AND DISCUSSION

Synthesis of the Conjugate of the Chelate and Its Gd(III) Complex. The conjugate of inulin and the carboxylic-phosphorus acid derivative of diethylenetriamine (**8**) was synthesized following the route outlined in Scheme 1. Inulin was chosen as a carrier for the chelating ligand, because its high flexibility allows the preparation of highly functionalized derivatives suitable for conjugation. In the present case the inulin was functionalized with *O*-aminopropyl groups by cyanoethylation of inulin with acrylonitrile and base, followed by reduction of the cyano groups with metallic Li in liquid ammonia/methanol at low temperature (*15*, *16*). A degree of substitution (ds, defined as the average number of substituents per monosaccharide unit; the theoretical maximum ds is three corresponding to three free hydroxy groups per sugar unit) of 1.0 was obtained. Previous studies have indicated that the cyanoethyl groups in *O*-cyanoethyl inulin are distributed uniformly along the inulin chain and that within each fructose unit, the 4-position is the most reactive toward cyanoethylation (*15*).



The Gd(III) chelating ligand (**8**) was prepared starting from *p*-nitrobenzylphosphinic acid (**2**). Its ethyl ester (**3**) was obtained by esterification using chloroformate and base, employing conditions published for phenylphosphinate (*24*). The phosphinic ester was attached to phthaloyl-protected diethylenetriamine by a Mannich-type reaction (*11*) to give intermediate **4**. Removal of the phthaloyl protective groups by reaction with hydrazine hydrate followed by alkylation with ethyl bromoacetate and hydrolysis of the ester groups gave nitro derivative **7**. The *p*-amino derivative **8** was obtained by hydrogenation with Pd/C as the catalyst. The latter compound was linked to *O*-aminopropylinulin (**12**) by means of a reaction with isothiocyanate to give macromolecular ligand **L**. The ds obtained was 0.86.

Attempts to prepare the Gd(III) complex by mixing aqueous solutions of the ligand and $GdCl_3$ followed by adjusting the pH failed. A precipitate was formed, which did not dissolve even after lowering the pH (4−5) and increasing the temperature to 50 °C. Therefore, the Gd(III) complex was prepared by a transmetalation reaction with NH_4[Gd(EDTA)]. Removal of the excess of this complex, free H_4EDTA, and salts by means of dialysis using a tubing with a cutoff of 12 000 Da afforded pure Gd(III) complex of **L**, Gd_x**L**. An ESI-mass spectrum showed that the average molecular weight is 23 110 Da, which means that the average dp is 27 and that on the average each molecule carries 24 Gd^{3+} ions.

Evaluation of the Relaxivity and the Parameters Governing It. To assess the efficacy of the novel macromolecular contrast agent, Gd_x**L**, we measured the longitudinal relaxation rate enhancements of water protons as a function of the Larmor frequency induced by this complex. In Figure 1, the resulting NMRD profile at 300 K is compared with that of the previously reported Gd(III) complex of the corresponding unconjugated chelate, $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ (*11*) and $[Gd(DTPA)(H_2O)]^{2-}$ (*6*).

The shape of the NMRD curve of the Gd_x**L** complex, particularly the maximum around 40 MHz, is characteristic for high-molecular-weight complexes and reflects the effect of the relatively low tumbling time of the complex (*1*, *3*). Clinically, MRI exams are performed at a magnetic field between 0.5 and 2 T (corresponding with ^1H Larmor frequencies of 20−85 MHz). The relaxivity of the novel contrast agent at these field strengths (20 s^{-1} mM^{-1} at 20 mHz and 37 °C) is considerably higher than that of the currently available contrast agents (<5 s^{-1} mM^{-1} at 20 MHz and 37 °C) and comparable or higher than the relaxivity of reported macromolecular conjugates. According to the literature data, macromolecular conjugates of a similar molecular weight, such as conjugates of H_5DTPA and poly(ethylene glycol) (*25*), H_5DTPA and polyethylene (*26*), and dendrimeric H_3DO3A derivatives

(*27*), have relaxivities in the range of 6 to 16 s^{-1} mM^{-1} at 20 MHz and 310 K. A comparable relaxivity was also found for the Gd^{3+} complex of another *O*-aminopropyl-inulin derivative with a very high degree of substitution (ds = 1.5), which was conjugated with H_3DO3A-squaric acid (about 20 s^{-1} mM^{-1} at 20 MHz and 310 K) (*22*). However, the relaxivities of conjugates of $Gd(DTPA)^{2-}$ to inulin have been found to be only slightly higher than that of $Gd(DTPA)^{2-}$ itself (*28*).

The overall relaxivity (r_1^{obs}) of the Gd(III) chelate can be described using a model that considers three different contributions: inner sphere (r_1^{IS}), second sphere (r_1^{SS}), and outer sphere (r_1^{OS}) (see eq 1).

$$r_1^{obsd} = r_1^{IS} + r_1^{SS} + r_1^{OS} \quad (1)$$

The inner-sphere contribution arises from the water molecule(s) coordinated directly to the Gd(III) ion, while the outer-sphere contribution involves all the solvent molecules diffusing along the complex. The term "second-sphere" concerns contributions arising from water molecules interacting via hydrogen bonds with the electronegative atoms of the ligand and therefore staying in the second coordination/hydration sphere of Gd(III). The inner-sphere contribution represents the most important term, and therefore most efforts toward improvement of new contrast agents are focusing on the optimization of this part. It is influenced by the chemical exchange of the water molecule (τ_M), the electron spin relaxation (τ_{S1} and τ_{S2}), and the reorientation of the Gd−H_w vector (τ_R) and is described by the Solomon−Bloembergen−Morgan equations (see Supporting Information) (*29*). The second-sphere contributions can be described by the same equations but with different values for some of the parameters. The outer-sphere contribution is usually described by the Freed equations (*30*).

The increase of the value of τ_R (by increasing the molecular weight of the paramagnetic complex) causes the increase of total relaxivity; however, τ_M then steps out to be the limiting factor. Therefore, the optimization

of the residence lifetime of the inner-sphere water turns out to be the crucial step. The optimum lies in the range of 20−50 ns at 298 K (*3*).

If second-sphere water molecules are present, they can also greatly influence the overall relaxivity because the structural arrangement (such as hydrogen bonds with the polar groups of the ligand) brings the second-sphere water protons close to the paramagnetic center, and therefore they are strongly relaxed.

The compound under study, $Gd_x\mathbf{L}$, is a modification of a previously published complex $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ (*11*), which is now covalently bound to the polysaccharide inulin. The structure of the Gd(III) chelate is derived from H_5DTPA where the central carboxylic group has been replaced by a phosphinate (see Chart 1). The presence of the more bulky phosphinate favors the dissociation of the inner-sphere water, causing a shorter τ_M (closer to the optimal value). The previously published parent molecule, $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$, had a residence lifetime of the inner-sphere water molecule at 298 K (τ_M^{298}) of 92 ns, which is three times shorter than that of the currently used contrast agents, such as $[Gd(DTPA)(H_2O)]^{2-}$ (303 ns). Furthermore, it also has two water molecules in the second sphere. To determine the parameters influencing relaxivity, ^{1}H NMRD profiles of $Gd_x\mathbf{L}$ were recorded at 278, 298, and 310 K (see Figure 2a) and were fitted together with the results of variable temperature of ^{17}O NMR measurements (see below).

^{17}O NMR relaxation rates and angular frequencies of the solution of the Gd(III) complex and an acidified water reference at different temperatures were measured, from which the reduced relaxation rates and chemical shifts were calculated ($1/T_{1r}$, $1/T_{2r}$, and $\Delta\omega_r$), using eqs 2 and 3,

$$1/T_{ir} = 1/P_m(1/T_i - 1/T_{iw}),\ i = 1, 2 \qquad (2)$$

$$\Delta\omega_r = 1/P_m(\omega - \omega_w) \qquad (3)$$

where P_m is the mole fraction of bound water and index w stands for the variable of the acidified water reference sample (see Figure 2b,c).

The calculated reduced relaxation rates and chemical shifts are listed in the Supporting Information (Table S1). The resulting NMRD and ^{17}O NMR data were fitted simultaneously with the set of Solomon−Bloembergen−Morgan equations, the Freed equations, and the set of equations usually used to predict the variable temperature ^{17}O NMR chemicals shifts and relaxation rates (*2*) (see Supporting Information). Simultaneous fitting has the advantage of putting constraints on the parameters. In total, 18 parameters have to be taken into account (see Table 1), and some of them are common for both sets of data.

The distance between the coordinated water oxygen and the Gd^{3+} ion (r_{GdO}) was fixed at 2.5 Å (*6*) and that between the coordinated water proton and Gd(III) (r_{GdH}) at 3.1 Å. For the second-sphere water molecule, this distance (r_{GdH}^{2S}) was fixed at 3.5 Å, whereas the number of second-sphere water molecules, q_S, was treated as an adjustable parameter. The activation energy of τ_V, E_V, had to be fixed during the fitting at 1 kJ mol^{-1}, since unrealistically small numbers were obtained if it was left variable. The hyperfine coupling constant ($A/\hbar$) was at the value that was measured for the parent molecule $[Gd(DT4AP^{Ph})]^{2-}$, -3.61×10^6 rad s^{-1} (*11*). The quadrupolar coupling constant ($\chi(1+\eta^2)^{1/2}$) was taken equal to that determined for the $[Gd(DOTA)(H_2O)]^-$ complex (5.2 MHz) (*32*). Furthermore, the values of the self-diffusion

coefficients of water at the various temperatures were calculated with the semiemperical equation of Hindman (*33*). Since the size of the $Gd_x\mathbf{L}$ complex is much larger than that of water, the self-diffusion constant ($D_{complex}^{298}$) would be much smaller than its value for water. Therefore, this parameter was neglected in the fittings. The distance of cloasest approach of a water molecule to Gd(III) was fixed at 3.5 Å.

A model with different rotational correlation times for ^{1}H NMRD and ^{17}O NMR (τ_R(H) and τ_R(O), respectively)

was used. There is a large difference in the concentrations (and, therefore, viscosities) of the samples for ^{17}O NMR (82 mM) and ^1H NMRD (1 mM) measurements (*34*), which, together with the fact that the two experiments are considering the rotations of two different vectors (Gd−O and Gd−H vectors), leads to two different values of τ_R (*32*).

A good fit for the NMRD and ^{17}O NMR data was obtained for the parameters listed in Table 1 (see Figure 2). For comparison the values of the parameters for the parent complex, $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ and for $[Gd(DTPA)(H_2O)]^{2-}$ are included in Table 1.

The simultaneous fits resulted in a value of $\tau_R^{298}(H) = 866$ ps and the ratio $\tau_R^{298}(O)/\tau_R^{298}(H) = 1.59$, which is in excellent agreement with the value reported by Dunand et al. (*32*). The rotational correlation time of Gd_x**L** ($\tau_R^{298}(H) = 866$ ps) is smaller than expected for a macromolecular compound, based solely on its molecular weight. From the Debye−Stokes−Einstein equation, it can be estimated that $\tau_R^{298} \approx 8$ ns for compounds in this molecular weight range (*35*). The relatively low τ_R-value for Gd_x**L** is probably due to some local mobility in the Gd_x**L** complex. The source of this mobility might be the aminopropyl-aminobenzyl linkage between the inulin backbone and the chelate that is probably rather flexible and allows additional motion of the chelate, which leads to a decrease in τ_R. Local mobility has been observed in many other macromolecular systems, including the Gd(III) complex of DO3A-squarate chelate linked to aminopropylinulin (*22*), which had a τ_R^{298} value of 735 ps.

The residence time of the inner-sphere water molecule (τ_M) is almost twice as high as that of $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$. This can probably be ascribed to the structural differences between the two chelates. While in the low-molecular-weight molecule, $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$, the phenyl group is directly attached to the phosphinate moiety, and here it is separated from it by a methylene group. Possibly, this results in somewhat less steric strain around the Gd(III)-bound water molecule and consequently an increase in the energy barrier in the dissociative mechanism and a larger τ_M. However, the τ_M^{298} value of the macromolecular complex (170 ns) is still substantially lower than that of commercially contrast agents, such as $[Gd(DTPA)(H_2O)]^{2-}$ (see Table 1) and its bisamides.

The temperature dependence of the relaxivity at constant magnetic field (20 MHz) shows a maximum at around 288 K (see Figure 3). The trend toward higher temperatures is decreasing, which means that τ_R is the limiting factor for relaxivity at temperatures above 288 K because of the increased tumbling rate at higher temperatures. At low temperatures the relaxivity increases with increasing temperature, which indicates that the influence of the increasing τ_R is competing with the limitation from τ_M. This could also explain the crossing of the NMRD curves at higher fields (see Figure 2a), where the relaxivity measured at 298 K is higher than the one measured at 278 K. At low temperature (<298 K) the relaxivity is limited by τ_M.

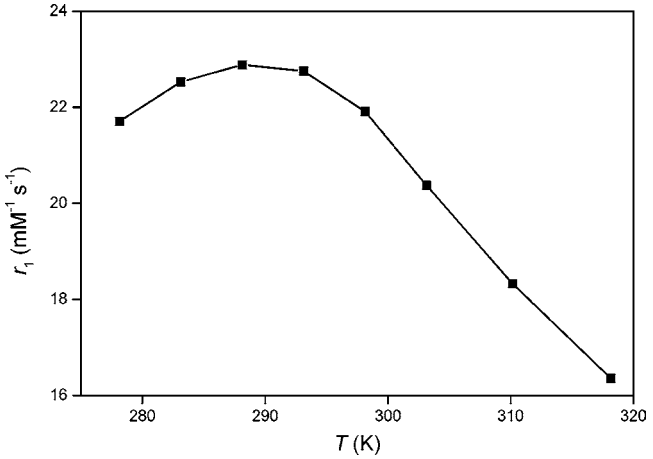

Figure 3. Proton longitudinal relaxivity at 20 MHz as a function of temperature for Gd_x**L**. The line is only a guide for the eye.

A good fit could only be obtained assuming the presence of two water molecules in the second coordination sphere of Gd(III). This is similar to what has been found previously for the low-molecular-weight analogue $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ (*11*). The residence time of the second-sphere water molecules ($\tau_M^{2s} = 32$ ps) is somewhat shorter but of the same magnitude as those for related ligands (*10*, *28*, *35*).

Transmetalation. The Gd(III) chelates can be sensitive to transmetalation by endogenous ions, such as Cu^{2+}, Ca^{2+}, and Zn^{2+} (*37*−*41*). The concentration of Cu^{2+} in blood is very small, about 1 μmol/L, whereas Ca^{2+}, on the other hand, has approximately 10 orders of magnitude lower affinity than Gd^{3+} toward organic ligands of the type of H_5DTPA (*42*). Out of the three metals mentioned, Zn^{2+} combines a rather high concentration (50 μmol/L) with a high affinity toward polyaminopoly-

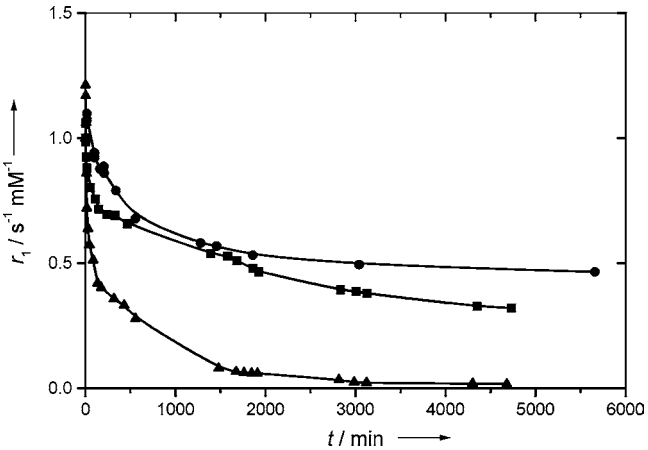

Figure 4. Evolution of the water proton paramagnetic longitudinal relaxation rate R_1^p vs time in 2.5 mM Zn^{2+} aqueous solution for Gd_x**L** (squares), $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ (triangles) and $[Gd(DTPA)(H_2O)]^{2-}$ (circles). The lines are only guides for the eye.

carboxylates. Therefore, this metal ion is able to replace a significant amount of Gd^{3+}, which may result in the release of the toxic Gd(III) aqua ion in the body (*42*). To investigate the kinetic stability of the macromolecular phosphorus containing complex, we performed a relaxometric study of its transmetalation with $ZnCl_2$. The mixture of Gd_x**L** and an equal amount of $ZnCl_2$ in phosphate buffer was monitored at 20 MHz and 310 K by measuring the proton longitudinal relaxation rate. Upon transmetalation of a paramagnetic Gd^{3+} ion by a diamagnetic Zn^{2+} ion in phosphate buffer, the released Gd^{3+} precipitates as $GdPO_4$ and does not contribute to the relaxivity anymore. Therefore, the overall relaxivity of the solution decreases upon time with a rate depending on the rate of transmetalation. This decrease in relaxivity is a good estimation of the kinetic stability of the Gd(III) complex. The result of this experiment is depicted in Figure 4, together with the curves previously measured for $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$ and for $[Gd(DTPA)(H_2O)]^{2-}$ (*6*,*11*). The kinetic stability appears to decrease in the order: $[Gd(DTPA)(H_2O)]^{2-}$ > Gd_x**L** ≫ $[Gd(DT4AP^{Ph})(H_2O)]^{2-}$. The novel macromolecular complex is, therefore, comparable in terms of kinetic stability with $[Gd(DTPA)(H_2O)]^{2-}$, which is being used clinically as an MRI contrast agent.

CONCLUSIONS

Replacement of the central pendant arm of the ligand in $[Gd(DTPA)(H_2O)]^{2-}$ by a phosphinic functional group has a positive influence on the residence water lifetime, τ_M, which is much closer to the optimal value for high relaxivity than that of the currently used contrast agents. The presence of two second coordination-sphere water molecules results in an increase of the relaxivity. Upon conjugation of these complexes to the oligosaccharide inulin, these parameters do not change much, and therefore in these conjugates, the increase in relaxivity thanks to the increase of the rotational correlation time, τ_R, is almost optimal. Only at temperatures below 288 K is the relaxivity limited by τ_M. The rotational correlation time is somewhat lower than expected on the basis of the molecular weight, which can be ascribed to local mobility, probably due to the flexibility of the tether. Further improvements may be achieved by more rigid linking groups and/or by decreasing of the local mobility through an increase of the degree of substitution of the inulin (*22*). The stability of the Gd(III) complex toward transmetalation with Zn^{2+} is comparable with that of $[Gd(DTPA)(H_2O)]^{2-}$.

ACKNOWLEDGMENT

This work was performed within the framework of the EU COST action D18: "Lanthanide chemistry for diagnosis and therapy". Thanks are due to the EU for financial support via a Marie Curie training site host fellowship (QLK5-CT-2000-60062) and to Grant Agency of the Czech Republic (203/02/0493 and 203/03/0168). J.K. thanks to the Grant Agency of Charles University (250/2003/B-Ch). We are very grateful to Dr. S. Laurent (University of Mons-Hainaut, Belgium) for measuring the mass spectra.

Solid-Phase Synthesis of Multiantennary Oligonucleotide Glycoconjugates Utilizing On-Support Oximation

Johanna Katajisto,* Pasi Virta, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received February 23, 2004; Revised Manuscript Received May 14, 2004

A novel method for preparation of multivalent oligonucleotide glycoconjugates on a solid support has been described. A pentaerythritol-based phosphoramidite (**1**) bearing two masked aminooxy groups has been used as the key building block. After conventional chain assembly, the aminooxy functions have been deblocked by a hydrazinium acetate treatment and subsequently oximated with fully acetylated 4-oxobutyl α-D-mannopyranoside. The conjugates obtained have been shown to withstand standard ammonolytic deprotection and cleavage from the support. Four different oligonucleotide glycoconjugates containing two, four, or six α-D-mannopyranosyl units (**12**−**15**) have been prepared to demonstrate the applicability of the procedure. The glycosyl residues only moderately retards hybridization of the oligonucleotide moiety.

INTRODUCTION

Multivalent carbohydrate−protein interactions play a crucial role in glycobiological recognition processes of both normal and malignant cells (*1*). The affinity of a single monosaccharide ligand to proteins (*2*−*6)* is usually low and, hence, a multipoint interaction with several covalently clustered sugar units is a prerequisite for efficient binding. These cluster effects have recently received considerable interest, since they offer a potential way to target drugs tissue- or cell-type specifically. The drug molecule may either be noncovalently complexed with a carbohydrate-based carrier or it may be covalently conjugated to an appropriate oligosaccharide construct designed to recognize a given cell-type. For these purposes, a variety of multiantennary glycoclusters *(7*−*15*) glycodendrimers (*16*−*18*), glycopeptides (*19*), cyclodextrin-based glycoclusters (*20, 21*), and glycopolymers (*22*−*25)* have been synthesized.

The glycocluster approach may also be expected to find applications in cell-specific targeting of antisense oligonucleotides, a novel class of chemotherapeutic agents that allow highly selective inhibition of gene expression (*26*). Enrichment of an oligonucleotide glycoconjugate or carbohydrate complex on the surface of a certain cell-type evidently leads to enhanced internalization of the conjugate by endocytosis. However, only few noncovalent carriers or covalent conjugates have been prepared. The examples available include electrostatic complexation of an oligonucleotide with glycosylated polylysine (*27*−*29),* chemical ligation to galactosylated polylysine (*30, 31*), a cholane scaffold (*32*), or a neoglycopeptide (*33*), on-support glycosylation with glycosyl trichloroacetimidates (*34*), and use of base moiety-glycosylated nucleoside phosphoramidites (*35*−*37*), and glycoside phosphoramidites (*38, 39*) as building blocks for the chain assembly. Recently, an elegant method for the solid-phase synthesis of oligonucleotide−glycocluster conjugates containing a tetraantennary construct at the 5′-terminus has been described (*40*). Building blocks derived from pentaerythritol has been used as branching units, and glycoside phosphoramidites for insertion of the 5′-terminal glycosyl groups. We now report on an alternative procedure for preparation of multivalent oligonucleotide glycoconjugates on a solid support. The key building block is a pentaerythritol-based phosphoramidite (**1**) that bears two masked aminooxy groups and additionally allows normal chain elongation (Chart 1). Accordingly, the distance between the site of attachment of the glycosyl groups may be tuned with additional nucleosidic or nonnucleosidic phosphoramidite building blocks. After exposing the aminooxy functions by removal of the phthaloyl protections, the support-bound oligonucleotide is reacted with the desired fully acetylated glycoside bearing an anomeric aldehyde tether (**2**) (Chart 1). The final deprotection and cleavage from the support is achieved by conventional ammonolysis. Four different oligonucleotide glycoconjugates containing two, four or six α-D-mannopyranosyl units have been prepared to demonstrate the applicability of the procedure.

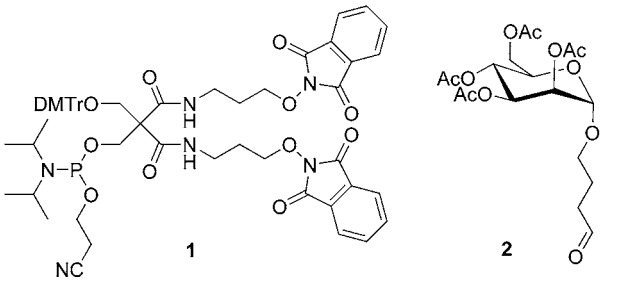
EXPERIMENTAL SECTION



General Methods and Materials. The NMR spectra were recorded at 200, 400, or 500 MHz in deuteriochloroform. The chemical shifts are given in ppm from internal TMS and the coupling constants in hertz. The mass spectra were recorded by ESI ionization. For detailed information, see Supporting Information.

High-Performance Liquid Chromatography (HPLC). The oligonucleotide conjugates were analyzed and isolated on an analytical ThermoHypersil C-18 column (4.6 × 150 mm, 5 μm, a gradient elution from 0 to 100% B in 30 min, flow rate 1 mL min^{-1}, buffer A = 0.05 M NH_4Ac (aq), buffer B = buffer A in 65% MeCN) and finally desalted.

Diethyl 2-Methoxy-1,3-dioxane-5,5-dicarboxylate (4). A catalytic amount of *p*-toluenesulfonic acid monohydrate was added to a mixture of diethyl 2,2-bis-(hydroxymethyl)malonate (**2**, 10.0 g, 45.4 mmol) and trimethyl orthoformate (6.5 mL, 59.0 mmol) in dry THF (60 mL). The mixture was stirred overnight at room temperature and then slowly poured into magnetically

stirred ice-cold aqueous $NaHCO_3$ (100 mL of 5% aq soln). The mixture was extracted with diethyl ether, washed with brine, and dried with Na_2SO_4. The solvent was removed under reduced pressure, and the residue was chromatographed on a silica gel column eluting with DCM. Compound **4** was obtained as a colorless oil in 94% yield (11.2 g). ^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.28 (s, 1H), 4.54 (d, 2H, J^2_{AB} = 10,5 Hz), 4.04−4.52 (m, 6H), 3.38 (s, 3H), 1.23−1.34 (m, 6H); ^{13}C NMR ($CDCl_3$, 50 MHz) δ 169.5, 167.4, 108.9, 62.8, 62.1, 52.8, 13.9; HRMS (ESI) $[M + Na]^+$ calcd 285.0945, obsd 285.0950.

***N,N*-Bis(3-hydroxypropyl)-2-methoxy-1,3-dioxane-5,5-dicarboxamide (5).** The mixture of compound **4** (7.00 g, 26.7 mmol) and 3-aminopropanol (160 mmol, 13.5 mL) was refluxed for 48 h. Compound **5** was isolated from the crude reaction mixture by silica gel chromatography (5% MeOH in DCM) in a 76% yield (6.5 g).^{1}H NMR ($CDCl_3$, 200 MHz) δ 5.29 (s, 1H), 4.50 (d, 2H, J^2_{AB} = 13.6 Hz), 4.18 (d, 2H, J^2_{AB} = 13.6 Hz), 3.61−3.73 (m, 4H), 3.38−3.55 (m, 7H), 1.73 (m, 4H); ^{13}C NMR ($CDCl_3$, 50 MHz) δ 169.6, 169.6, 109.8, 65.1, 59.6, 58.3, 53.2, 36.9, 18.3; HRMS (ESI) $[M + Na]^+$ calcd 343.1476, obsd 343.1469.

2,2-Bis(hydroxymethyl)-*N,N*-bis(3-phthalimidooxypropyl)malondiamide (6). Compound **5** (1.10 g, 3.43 mmol) was coevaporated twice with dry benzene. The residue, triphenylphosphine (1.98 g, 7.55 mmol), and *N*-hydroxyphthalimide (1.23 g, 7.55 mmol) were dissolved in dry THF (20 mL), and diethyl azodicarboxylate (DEAD) (1.17 mL, 7.55 mmol) was added dropwise. After stirring the reaction mixture overnight at room temperature, the consumption of **5** was complete according to TLC (5% MeOH in DCM). The solvent was removed under reduced pressure, and the residue was applied onto a silica gel column and eluted with a gradient from neat DCM to a 97:3 (v/v) mixture of DCM and *i*-PrOH. Purification of crude 2-methoxy-*N*,*N*-bis(3-phthalimidooxypropyl)-1,3-dioxane-5,5-dicarboxamide was seriously hampered by the presence of triphenylphosphine oxide formed during the reaction. The product still contaminated by some triphenylphosphine oxide exhibited ^{1}H NMR signals ($CDCl_3$, 200 MHz) at δ 7.45−7.84 (m, 8H), 5.27 (s, 1H), 4.56 (d, 2H, J^2_{AB} = 10.3 Hz), 4.20−4.31 (m, 6H), 3.58 (m, 4H), 3.36 (s, 3H), 2.01 (m, 4H), and ^{13}C NMR signals ($CDCl_3$, 100 MHz) at δ 169.4, 168.9, 163.7, 134.5, 132.0, 123.0, 109.7, 76.1, 64.9, 62.1, 53.1, 36.5, 27.5. The observed HRMS (ESI) $[M + Na]^+$ 633.1776 verified the identity of the compound (calcd 633.1803). To avoid further loss of the material by repeated purifications, the crude product was subjected to acid-catalyzed hydrolysis to remove the methoxymethylene protection. The crude sample was dissolved in 80% aqueous AcOH (20 mL) and left for 2 h at room temperature. The solution was evaporated to an oil and coevaporated with water. Purification by silica gel chromatography (0 to 5% MeOH in DCM) afforded **6** as a clear oil in a 15% yield (300 mg).^{1}H NMR ($CDCl_3$, 200 MHz) δ 7.72−7.91 (m, 8H), 4.26 (t, 4H, J = 5.7 Hz), 3.26 (q, 4H, J = 7.5 and 11.3 Hz), 2.01 (m, 4H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 169.5, 168.9, 163.6, 134.6, 131.8, 123.5, 65.0, 55.0, 36.4, 27.9; HRMS (ESI) $[M + H]^+$ calcd 569.1878, obsd 569.1896.

2-(4,4′-Dimethoxytrityloxymethyl)-2-(hydroxymethyl)-*N,N*-bis(3-phthalimidooxypropyl)malondiamide (7). Compound **6** (700 mg, 1.23 mmol) was dried by repeated coevaporations with dry pyridine and dissolved in dry pyridine (10 mL). 4,4′-Dimethoxytrityl chloride (417 mg, 1.23 mmol) was added, and the reaction mixture was left to stand overnight at room temperature. Pyridine was removed in vacuo, and the residue was subjected to DCM/aq 5% $NaHCO_3$ workup. The organic phase was dried with Na_2SO_4, and the oily residue was chromatographed on a silica gel (0 to 3% MeOH in DCM), giving **7** as a white solid foam in a 40% yield (440 mg). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 7.78−7.83 (m, 4H), 7.71−7.76 (m, 4H), 7.66 (t, 2H, J^3 = 6.4 Hz), 7.11−7.38 (complex, 9H), 6.80 (m, 4H), 4.18 (m, 4H), 4.10 (d, 2H, J^3 = 6.4 Hz), 3.81 (t, 1H, J^3 = 6.4 Hz), 3.75 (s, 6H), 3.46−3.62 (m, 6H), 1.96 (m, 4H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ 170.9, 163.5, 158.5, 144.3, 135.3, 134.5, 130.1, 128.9, 128.1, 127.9, 126.9, 123.6, 113.2, 86.5, 76.0, 65.1, 64,0, 58.7, 55.2, 36.4, 27.9; HRMS (ESI) $[M + Na]^+$ calcd 893.3004, obsd 893.3046.

2-Cyanoethyl 3-[(4,4′-Dimethoxytrityl)oxy]-2,2-bis[2-aza-1-oxo-5-(phthalimidooxy)pentyl]prop-yl *N,N*-Diisopropylphosphoramidite (1). Compound **7** (220 mg, 0.25 mmol) was predried overnight in vacuo over P_2O_5. 2-Cyanoethyl *N*,*N*-diisopropylphosphonamidic chloride (62 μL, 0.28 mmol) was added to a solution of **7** and triethylamine (175 μL, 1.26 mmol) in dry MeCN (2 mL) under nitrogen. The reaction mixture was left to stand at room temperature. The reaction was completed in 45 min, according TLC analysis (60% ethyl acetate in hexane). The reaction mixture was applied onto a short dried silica gel column, and the pure compound was isolated eluting with a mixture of ethyl acetate, hexane, and triethylamine (60:39:1, v/v/v). Phosphoramidite **1** was obtained as a white solid foam in a 85% yield (230 mg). ^{1}H NMR ($CDCl_3$, 200 MHz) δ 7.71−7.84 (m, 8H), 7.61 (t, 3H), 7.10−7.45 (complex, 9H), 6.80 (m, 4H), 4.03−4.45 (m, 4H), 3.69−3.78 (complex, 10H), 3.25−3.57 (m, 6H), 2.56 (t, 2H, J^2 = 7.2 Hz), 1.91−1.99 (m, 4H), 1.12 (t, 12H, J^2 = 7.2 Hz); ^{13}C NMR ($CDCl_3$, 50 MHz) δ 170.7, 163.3, 159.5, 144.1, 135.1, 134.3, 129.9, 128.7, 127.9, 127.7, 123.3, 113.1, 86.4, 75.9, 64.8, 64.5, 53.5, 59.4, 58.7, 58.3, 55.0, 43.0, 36.2, 27.9, 24.3, 18.7; ^{31}P NMR ($CDCl_3$, 200 MHz) δ 146.6; MS (ESI) $[M + Na]^+$ calcd 1093.4, obsd 1094.1.

4-Hydroxybutyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (9). α-D-Mannopyranosyl pentaacetate (**8**) (5.00 g, 12.8 mmol) was dried by repeated coevaporations with dry benzene. The residue was dissolved in dry MeCN (30 mL) together with 1,4-butanediol (1.10 mL, 12.8 mmol). Boron trifluoride etherate (4.82 mL, 38.4 mmol) was added under nitrogen, and the reaction was allowed to proceed at room temperature for 2 h. DCM was added, and the mixture was washed with water, dried with Na_2SO_4, and evaporated to dryness. Purification of the crude product on a silica gel column (ethyl acetate in hexane, 2/1, v/v) gave **9** as colorless oil in a 19% yield (1.05 g). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 5.33 (dd, 1H, J = 4.1 and 10.8 Hz), 5.29 (t, 1H, J = 10.8 Hz), 5.22 (dd, 1H, J = 4.3 and 1.6 Hz), 4.81 (d, 1H, J = 1.4 Hz), 4.28 (dd, 1H, J = 5.4 and 12.7 Hz), 4.10 (dd, 1H, J = 2.9 and 12.7 Hz), 3.58 (m, 1H), 3.73 (m, 1H), 3.68 (t, J = 5.4 Hz), 3.50 (m, 1H), 2,14, 2.10, 2.05 and 1.99 (each s, each 3H), 1.63−1.72 (m, 4H); ^{13}C NMR ($CDCl_3$, 100 MHz) δ

170.7, 170, 1, 169.9, 169.8, 97.6, 69.7, 69.1, 68.4, 68.3, 66.2, 62.5, 62.3, 29.4, 25.7, 20.7, 20.9, 20.8; MS (ESI) $[M + Na]^+$ calcd 443.1524, obsd 443.1516.

4-Oxobutyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (2). DMSO (2.70 mL, 38.1 mmol) was added dropwise under vigorous stirring to a solution of oxalyl chloride (1.67 mL, 19.1 mmol) in dry DCM (5 mL) at −60 °C under argon. The mixture was stirred for 30 min at the same temperature, after which a solution of **9** (1.00 g, 2.38 mmol) in dry DCM (10 mL) was slowly added to the reaction mixture, and the stirring was continued for 40 min at −60 °C. Triethylamine was added (7.91 mL, 57.1 mmol), and the solution was allowed to warm to 0 °C. The mixture was poured into vigorously stirred ice−water, and the aqueous phase was extracted with diethyl ether. The combined organic phases were washed with ice-cold aq HCl (1 mol L^{-1}), water, saturated $NaHCO_3$ and brine, dried with Na_2SO_4, and evaporated in vacuo. The residue was purified by silica gel chromatography eluting with a mixture of ethyl acetate and hexane (2/1, v/v). Compound **2** was obtained as a clear oil in a 60% yield (595 mg). ^1H NMR ($CDCl_3$, 500 MHz) δ 9.82 (s, 1H), 5.12−5.31 (complex, 3H), 4.80 (s, 1H), 4.28 (dd, 1H, J = 5.6 and 12.9 Hz), 4.12 (m, 1H), 3.95 (m, 1H), 3.75 (m, 1H), 3.50 (m, 1H), 2.58 (m, 2H), 2.16, 2.11 and 2.05 (each s, each 3H), 1.77−2.00 (complex, 5H); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 201.3, 170.6, 170.1, 169.9, 169.7, 97.5, 69.6, 68.9, 68.3, 67.9, 66.1, 62.4, 40.5, 22.3, 21.9, 20.9, 20.7, 20.4, 20.2; MS (ESI) $[M + Na]^+$ calcd 441.13673, obsd 441.13667.

Oligodeoxyribonucleotide Synthesis. The oligodeoxyribonucleotides were assembled on an Applied Biosystems 392 DNA synthesizer in 1.0 μmol scale using commercial 1000 Å CPG-succinyl-thymidine support and phosphoramidite chemistry. Phosphoramidite **1** was used as a 0.15 mol L^{-1} solution in dry MeCN, the coupling time being 600 s. After coupling of **1,** the detritylation was carried out by using two consecutive "#14 (acid solution) to column" steps (2 × 60 s) separated by a trityl flush step (5 s). Otherwise standard protocols were employed.

Synthesis of Oligonucleotide Glycoconjugates 12 and 13. Protected oligonucleotide sequences 5′-d(TTTXTTT)-3′ and 5′-d(TXTGACGATCTCAT)-3′, where X stands for the nonnucleosidic building block **1**, were synthesized as described above. The support-bound oligonucleotides were treated with 0.5 mol L^{-1} hydrazine acetate solution (0.124/4/1, $H_2NNH_2 \cdot H_2O$/pyridine/AcOH, v/v/v) for 30 min, washed with pyridine and acetonitrile, and dried. The supports were transferred to microcentrifuge tubes, a solution of the aldehyde tethered sugar ligand **2** (50 molar equiv in 200 μL of MeCN) was added, and the mixtures were shaken at ambient temperature for 4 h. The supports were filtered, washed with MeCN, dried, and treated with concentrated ammonia (33% aqueous NH_3, 7 h at 55 °C) to release and deprotect the resulting oligonucleotide glycoconjugates. Evaporation, dissolution in water, RP HPLC purification, desalting, and finally characterization by ESI-MS verified the formation of the expected conjugates **12** and **13** (Table 1).

Synthesis of Oligonucleotide Glycoconjugates 14 and 15. The conjugates **14** [sequence: 5′-d(TXTXTGACGATCTCAT)-3′] and **15** [sequence: 5′-d(TXTXTXTGACGATCTCAT)-3′] were prepared as described for **12** and **13** except for a prolonged reaction time of 16 h and larger excess of the sugar ligand (**2**) (100 or 150 molar equiv, respectively, in 200 μL of MeCN) used upon the oxymation step. The authenticity of **14** and **15** was verified by ESI-MS (Table 1).

Table 1. Properties of the Oligonucleotide Glycoconjugates

entry	oligonucleotide glycoconjugate	retention time (min)[a]	observed mass	calculated mass	purity, %[b]
1	12	13.7	2597.4	2597.9	84

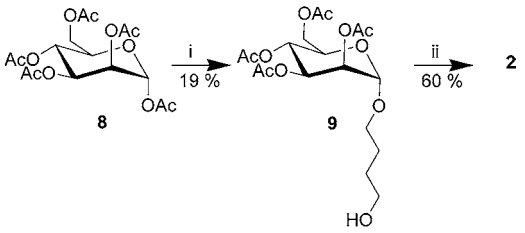
Melting Temperature Studies. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 2 UV−vis spectrometer equipped with Peltier Temperature controller by using a rate of 1 °C min^{-1} (from 15 to 90 °C). The experiments were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 100 mmol L^{-1} NaCl. The concentration of the oligonucleotide conjugate and its complementary sequence was 2 μmol L^{-1}.

RESULTS AND DISCUSSION

An aminoxy group is known to be a powerful nucleophile, in particular when an attack on a carbonyl carbon is concerned. The oxime linkage formed is stable over a wide pH range, and the conjugation reaction can be conducted under physiological conditions. The oxime linkage has been efficiently used for the chemoselective conjugation of fully unprotected peptides (*41*−*43*) and carbohydrates (*44*) with oligonucleotides in solution. Thus, it is somewhat surprising that the aminoxy-functionalized oligonucleotides have not been extensively utilized in solid-supported conjugation. A 5′-terminal aminoxy group has been introduced as a 2-[(2-ureido)-4-(2-phthalimidooxyethoxy)quinoline]ethyl (*43*), 11-phthalimidoxy-3,6,9-trioxaundecyl (*45*), or *N*-trityl-6-aminooxyhexyl phosphoramidite (*46*). The phthaloyl protection has been removed with hydrazinium acetate in pyridine and the trityl protection with acid, i.e., under conditions that do not cleave the normal succinyl linker. Aldehydes react readily with the exposed aminoxy group, affording fully protected oxime conjugates that may be cleaved from the support by normal ammonolysis (*45*). The phthaloyl protection strategy has been applied in the present study to obtain glycoconjugates on a solid-support.



Synthesis of Phosphoramidite 1. Building block **1** was synthesized from commercially available diethyl 2,2-bis(hydroxymethyl)malonate (**3**), as outlined in Scheme 1. It has been shown previously (*47*) that compound **3** and its mono-4,4′-dimethoxytrityl (DMTr) derivative are decomposed by release of formaldehyde when treated with primary amines. Accordingly, **3** was converted to its di-*O*-methoxymethylene derivative (**4**) prior to aminolysis with 3-aminopropanol to obtain **5**. The free hydroxy functions of **5** were then subjected to a Mitsunobu reaction (*48*) using *N*-hydroxyphthalimide as a nucleophile and diethyl azodicarboxylate (DEAD) and triphenylphosphine as activators. After 24 h treatment, the starting material was entirely consumed and no side products were observed. Despite this, the purification of the desired di-*O*-phthalimido derivative turned out to be problematic. For this reason, the crude product was subjected to acid-catalyzed hydrolysis to remove the methoxymethylene protection. The resulting bis(hydroxymethyl) derivative (**6**) was then isolated by column chromatography, although in a relatively low 15% yield. One of the hydroxy groups of **6** was subsequently

protected as a DMTr ether (**7**). Standard phosphitylation of the remaining hydroxy function with 2-cyanoethyl *N,N*-diisopropylphosphonamidic chloride completed the synthesis of **1**.

Synthesis of the Mannosyl Ligand (2). Fully acetylated 4-oxobutyl α-D-mannopyranoside (**2**) was selected as the sugar ligand with which the solid-supported oximation was attempted. This compound was easily obtained via a two-step procedure (Scheme 2). Boron trifluoride etherate promoted glycosidation (*49*) of commercially available peracetylated α-D-mannopyranose (**8**) with 1,4-butanediol gave a 4-hydroxybutyl mannoside peracetate (**9**), which was then subjected to Swern oxidation (*50*) to obtain **2**. The synthesis was not optimized

Synthesis of the Oligonucleotide Glycoconjugates. To test the coupling efficiency of phosphoramidate **1** and the applicability of the developed protocol, a T_6 sequence containing an internally embedded **1** (**10**) was first assembled (Scheme 3). The standard phosporamidate protocol was applied, except that a prolonged coupling time (600 s) was used for the nonnucleosidic building block **1**. On the basis of the DMTr-cation assay (*51*), an acceptable 95% coupling efficiency was obtained. Next, the phthaloyl protections were removed by 30 min treatment with 0.5 mol L^{-1} hydrazinium acetate. The exposed aminoxy groups were then converted to stable oxime conjugates (**11**) by reacting them with the mannopyranosyl aldehyde building block (**2**). The conjugation reaction of the globally protected, hydrophobic species was performed in acetonitrile at room temperature. The reaction proceeded essentially to completion within 4 h to afford exclusively the support-bound oxime **11**. Standard ammonolytic treatment (33% aqueous NH_3, 7 h at 55 °C) released the crude oxime conjugate (**12**) in solution. No signs of hydrolysis or degradation products were observed consistent with previous results (*45*). RP HPLC analysis of the crude product showed the desired conjugate to be the main product (Table 1; entry 1, for the RP

HPLC chromatogram of crude **12**, see the Supporting Information). After RP HPLC purification, conjugate **12** was characterized by ESI-MS (Table 1; entry 1), which definitely proved the identity of the product.

The applicability of the protocol developed for the construction of multivalent oligonucleotide glycoconjugates was demonstrated by preparing three heterosequences (**13**−**15**) containing one, two and three nonnucleosidic units (**1**), i.e., two, four and six mannopyranosyl units, respectively. Essentially the same procedure was applied for the synthesis, except for the larger excess of the aldehydic sugar ligand **2** and prolonged reaction times used in the oxyamination step upon the synthesis of the larger conjugates (**14**, **15**). In all cases, a thymidine residue was inserted between the nonnucleosidic branching units to avoid unnecessary crowding and, hence, to

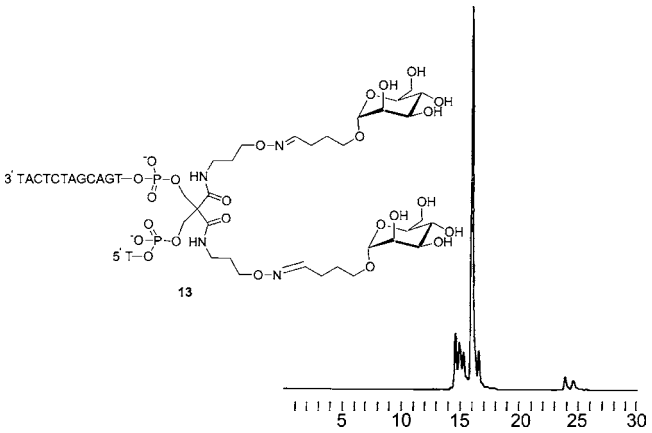

Figure 1. RP HPLC profile of crude **13** at 260 nm. For detailed chromatographic conditions, see Experimental Section.

ensure efficient coupling. RP HPLC analyses of the crude products showed that the expected conjugate was the main product in each case (Figures 1−3 and Table 1; entries 2−4). The authenticity of all products was verified by ESI-MS (Table 1; entries 2−4).

6-Aldehydo derivative of methyl α-D-mannopyranoside 2,3,4-tri-*O*-acetate was also prepared and used in the solid-supported oximation similarly to **2**. The oximation was successful, but upon the standard ammonolytic cleavage, the sugar ligand underwent dehydration to a 4,5-ene derivative, in all likehood because of conjugation of the 4,5- and 6,N-double bonds.

Melting Studies. Melting temperature (T_m) measurements showed that the oligonucleotide glycoconjugates obtained (**13**−**15**) form stable duplexes with complementary DNA oligonucleotides. Conjugates **13**−**15** were first hybridized with a complementary 12mer oligodeoxyribonucleotide in such a manner that the glycosylated 5′-terminus fell outside the duplex. The thermal stabilities of these duplexes were compared to that of a fully complementary 12mer duplex, which had a T_m value of 48.0 °C (Table 2; entry 1). Conjugate **13** showed es-

Table 2. Melting Temperatures of the Duplexes Formed by Hybridization of the Oligonucleotide Conjugates with Complementary DNA Sequences[a]

		DNA d(ATGAGATCGTCA)	DNA d(ATGAGATCGTCAAAAAAA)
entry	oligonucleotide or conjugate	$T_m \pm 0.5$ °C	$T_m \pm 0.5$ °C
1	d(TACTCTAGCAGT)	48.0	-
2	**13**	47.5	44.8
3	**14**	44.9	41.9
4	**15**	45.0	41.3

[a] For detailed T_m measurement conditions, see Experimental Section.

sentially unaltered T_m (Table 2; entry 2), while the larger conjugates **14** and **15** slightly decrease the stability (Table 2; entries 3−4). No substantial difference was observed between **14** and **15** (T_m = 45 °C for each). Similar results were obtained when the conjugates were hybridized with a complementary 18mer DNA carrying a A_7 sequence at the 3′-terminus, i.e. opposite to the glycosylated part of **13**−**15**. A melting point of 45 °C was observed for the hybridization of **13** (Table 2; entry 2), and slightly lower melting points of 42 and 41 °C for the hybridization of **14** and **15**, respectively (Table 2; entries 3 and 4). Accordingly, the duplex structure was not significantly disrupted.

CONCLUDING REMARKS

A nonnucleosidic phosphoramidate building block has been prepared and used for solid-supported synthesis of oligonucleotide glycoconjugates containing up to six sugar ligands. As shown by the set of synthesized conjugates, the protocol developed allows the construction of high molecular weight, multivalent glycoconjugates in a site-specific manner. The methodology enables variation of the number, site, and identity of the sugar ligands and hence meets the requirements for the creation of conjugate libraries. The synthesized oxime conjugates are highly water soluble and stable at physiological pH and, hence, applicable to biological screening.

ACKNOWLEDGMENT

The authors wish to thank Dr. Petri Heinonen for performing ^{1}H and ^{13}C NMR analysis on Bruker 400 and 500 NMR spectrometers.

Toxicity of Gold Nanoparticles Functionalized with Cationic and Anionic Side Chains

Catherine M. Goodman, Catherine D. McCusker, Tuna Yilmaz, and Vincent M. Rotello*

Department of Chemistry, University of Massachusetts, Amherst, Massachusetts 01003. Received March 2, 2004

The structure and properties of gold nanoparticles make them useful for a wide array of biological application. Toxicity, however, has been observed at high concentrations using these systems. MTT, hemolysis, and bacterial viability assays were used to explore differential toxicity among the cell types used, using 2 nm core particles. These studies show that cationic particles are moderately toxic, whereas anionic particles are quite nontoxic. Concentration-dependent lysis mediated by initial electrostatic binding was observed in dye release studies using lipid vesicles, providing the probable mechanism for observed toxicity with the cationic MMPCs.

The development of alternate drug delivery agents and drug scaffolds is an ongoing task in medicinal chemistry (*1*−*3*). The recent burst of research involving gold nanoparticles as transfection vectors (*4*−*6*), DNA-binding agents (*7*−*9*), protein inhibitors (*10*), and spectroscopic markers (*11*−*14*) demonstrates the versatility of these systems in biological applications. Gold particles display several features that make them well suited for biomedical applications, including straightforward synthesis (*7*), stability (*15*), and the facile ability to incorporate secondary tags such as peptides targeted to specific cell types to afford selectivity (*16*−*18*). These nanoparticle systems, however, have not been well evaluated to determine their interactions with cells beyond the designated functions.

Recently, we have shown that cationically functionalized mixed monolayer protected gold clusters (MMPCs) are capable of mediating DNA translocation across the cell membrane in mammalian cells at levels much higher than polyethyleneimine (PEI), a widely used transfection vector (*4*). At higher nanoparticle concentrations, however, transfection efficiency decreases due to cytotoxicity. While many available drugs display toxicity at sufficiently elevated concentrations (*19*−*20*), the toxicity of the nanoparticles was observed in this case at concentrations only 2-fold in excess of that found to have maximal transfection activity.

To provide insight into the origins of toxicity in MMPC systems, we fabricated cationic nanoparticle **1** and anionic particle **2**. (Figure 1). The quaternary ammonium-functionalized nanoparticle (MMPC **1**) is composed of the same monolayer components as those demonstrated to cause cytotoxicity in the mammalian cell cultures (*4*). The carboxylate-substituted nanoparticle (MMPC **2**) does not bind DNA (*7*) and was therefore not tested in the previous report. The negative substituents on the surface of MMPC **2** are not anticipated to interact with the cell membrane, given the overall negative charge of the lipid bilayer (*24*). The structure of the gold core and alkane thiol components, however, is identical to that of MMPC **1** and so should provide information relevant to the toxicity due to the particle structure and charge.

We utilized cells Cos-1 cells, red blood cells, and bacterial cultures (*Escherichia coli*) to probe the effect of the nanoparticles on cell viability. Further insight into the origin of toxicity was obtained using dye release studies using lipid vesicles. Dye release from these vesicles has been strongly correlated with the ability of amphiphilic polymers to lyse bacterial cells (*25*), providing an indication of whether membrane disruption is a significant factor in the mechanism of toxicity. Taken together, these studies provide insight into the origins of the toxicity observed, allowing design of new particles with an improved toxicity profile.

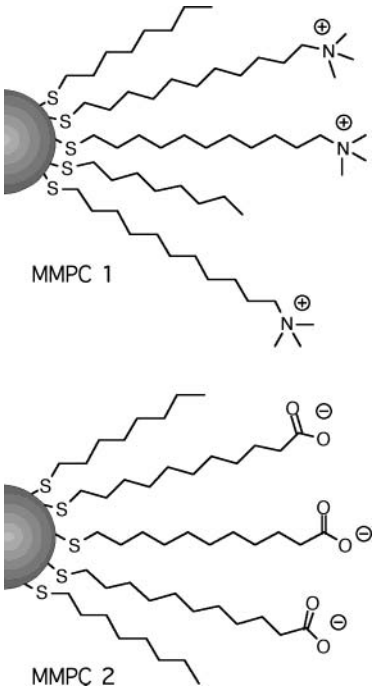

Figure 1. Schematic of the structures of MMPCs **1** and **2**. Each monolayer consists of approximately 70 charged thiols and 30 unsubstituted thiols.

MATERIALS AND METHODS

Colorimetric (MTT) kit for cell survival and proliferation was purchased from Chemicon International. Dulbecco's Modified Eagle Medium, L-glutamine, fetal bovine serum, trypsin, Trypan Blue stain (0.4%), and gentamicin

were purchased from Gibco. Tissue culture plates were purchased from Costar. Cos-1 cells purchased from ATCC. Acetic acid, ampicillin sodium salt, and sodium phosphate were purchased from EM. LB broth (Miller) and bacto-agar were purchased from DIFCO. Calcein, rhodamine 6G, 11-mercaptoundecanoic acid, and Triton X-100 were purchased from Sigma-Aldrich. Sodium chloride was purchased from Mallinckrodt. L-α-Stearoyl-oleoyl-phosphotidylcholine (SOPC) and L-α-stearoyl-oleoyl-phosphotidylserine (SOPS) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Ampicillin was dissolved in double distilled H_2O to yield stock solutions of 50 mg/mL, and aliquots were stored at −20 °C. All other materials were used as received. Gold nanoparticles were fabricated as previously described (*7*).

Cos-1 Viability Assay. Cos-1 cells were split to approximately 80% confluency in a 96-well culture plate the day preceding the assay. Cells were incubated at 37 °C in 7.5% CO_2 for 1, 2.5, 6, or 24 h with either MMPC **1** or **2** at 0.38, 0.75, 1.5, or 3 μM. Positive controls contained no nanoparticles. Following incubation periods, the media and nanoparticles were aspirated from the wells, cells were washed 2× with PBS, and fresh media was added. Following the MTT kit protocol, viability was measured by enzymatic reduction of the yellow tetrazolium MTT to a purple formazan, as measured using an EL808IU microplate reader (Biotek Instruments, Inc.) for absorbance readings (*26*). Mortality studies using Trypan Blue staining were performed using a modified procedure from the described above. In this case, the fresh media to harvest the cells was replaced by 20 μL of trypsin (0.25%), and 20 μL of Trypan Blue was added 5 min before counting cells on a hemocytometer.

Top Agar Assays. This procedure was adapted from a bacteriophage λ assay (*27*). BL21 (dE3) *E. coli* cells, transformed with a Pet16b vector encoding for ampicillin resistance and cellular retinoic acid binding protein I (*28*), were grown for 4−20 h in LB media with 0.1 mg/mL ampicillin. The OD of the cells at 600 nm was then measured and the relative concentration diluted to 0.5×10^{-4} absorbance using LB media or double distilled H_2O. A volume of 20 μL of the resultant cell solution was diluted with 0.55 mL of a LB-agar mix (25 g/L LB, 7.5 g/L agar) and 1−20 μL 833 μM MMPC solution and poured onto 3.5 cm LB-agar plates (25 g/L LB, 15 g/L agar, 0.1 mg/mL ampicillin). The plates were incubated overnight at 37 °C, and all resultant colonies were counted. The growth of the treated cells is reported relative to control plates.

Hemolysis Assay. This method was modified from a published procedure (29). In the studies, 40 μL of red blood cells from a healthy human donor were diluted with 10 mL of 10 mM Tris 150 mM NaCl buffer (pH 7) filtered with a 0.2 μm Acrodisc syringe filter (Pall Corporation, Ann Arbor, MI). The cell solution was centrifuged at 3000 rpm for 5 min, and the supernatant was poured off. Cells were washed until supernatant was clear, and the packed cells were resuspended in a final volume of 10 mL of Tris buffer. A volume of 80 μL of the resultant solution was incubated with 20 μL of MMPC solution (stocks ranging from 0.27 to 833 μM) with shaking for 30 min at 37 °C in a 96-well plate. Sample solutions were then diluted as necessary to allow quantification on an EL808IU microplate reader (Biotek Instruments, Inc.) at 405 nm with 5 s shaking prior to reading the sample. Nanoparticle absorbance was subtracted out according to the absorbance of the nanoparticles in buffer, and the resultant intensity due to detection of heme in solution was used to determine LC_{50} values.

Table 1. LC_{50} Values of MMPC 1 and 2 in Mammalian Cells and *E. coli*

	MMPC **1**, μM	MMPC **2**, μM
Cos-1	1.0 ± 0.5[a]	>7.37[b]
red blood cells	1.1 ± 0.1	72 ± 18
E. coli	3.1 ± 0.6	>28[c]

[a] LC_{50} value for MMPC **1** observed after 1 h of nanoparticle incubation. [b] Cells were 100% viable after 24 h of incubation with MMPC **2**. Higher concentrations of nanoparticles could not be completely washed from wells, and interfered with absorbance readings. [c] Higher concentrations could not be tested due to decreasing visibility of the colonies on the nanoparticle-doped agar.

Vesicle Leakage Assay. This assay was adapted from a previous report (*25*). Vesicles were prepared by evaporating the solvent from SOPC (0.55 mL 25 mg/mL solution in $CHCl_3$) or a mixture of SOPC/SOPS (0.5 mL 25 mg/mL:0.15 mL 10 mg/mL solution in $CHCl_3$, resulting in an 8.5:1 mole ratio) with a stream of N_2 (g). The dried lipids were resolubilized in 40 mM sodium phosphate buffer containing 100 mM calcein (further adjusted to pH 7 using NaOH and HCl) or 6.42 mM rhodamine. Three freeze−thaw cycles were then performed using a dry ice/acetone bath. The vesicles were then either sonicated gently two times for 10 min each using a 150T aquasonic sonicator (VWR), followed by an additional freeze−thaw cycle, or extruded using a 1 μm polycarbonate membrane (Avanti Polar Lipids, Inc) (*30*, *31*). Free fluorophore was removed by elution through a Sephadex 25 column with 90 mM sodium chloride and 10 mM sodium phosphate buffer adjusted to pH 7 or 7.4. Samples were prepared by diluting 0.2 or 0.3 mL of the collected vesicles to 2 mL using the sodium chloride buffer. The baseline fluorescence was corrected according to calibration of the nanoparticles with the fluorophore only or with Triton-lysed vesicles to control for light absorption by the particles. Components were added as aliquots of 1−10 μL of 0.005−10 mg/mL solutions, and the increasing fluorescence from vesicle lysis was monitored for 300 s at 515 nm ($\lambda_{ex} = 490$ nm) for calcein solutions and 554 nm ($\lambda_{ex} = 524$ nm) for rhodamine. The emission slit width was 1.5 or 3 nm. Complete leakage was caused by the addition of 50 μL 0.2% Triton X-100 in DMSO; the fluorescence intensity measured as a result was fixed at 100% vesicle lysis.

RESULTS AND DISCUSSION

MMPCs **1** and **2** were tested for toxicity in red blood cells, Cos-1 cells, and bacteria (*E. coli*). LC_{50} values determined in each case are shown in Table 1. Toxicity profiles for the two mammalian cells are virtually indistinguishable, while a 2- to 3-fold increase is required as a lethal concentration for the bacterial cultures. This modest increase may be due to the nature of the bacterial assay: use of a low-density cross-linked agar matrix will decrease the mobility of both the cells and nanoparticles, potentially altering slightly the manner in which the two components interact. Alternatively, the difference observed may be due to the increased protection provided by the outer membrane and cell wall surrounding the Gram-negative *E. coli* (*24*), requiring a higher nanoparticle concentration to fully rupture the bacteria.

The small variation in LC_{50} values observed suggests that the mechanism of toxicity is similar for the three cell types. This implies that the nanoparticles interact with the cells in a passive process, as the receptors and other related molecules active in energy-dependent processes are likely to be different for the separate species.

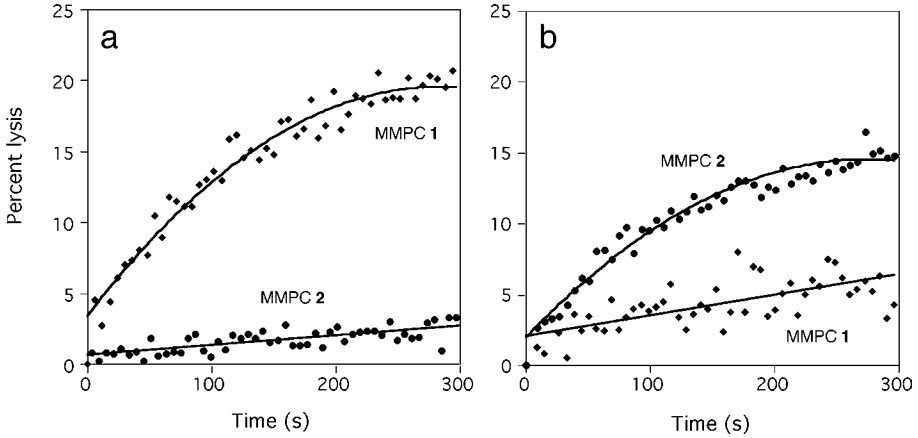

Figure 2. Comparison of MMPC **1** and **2** in disrupting vesicles with an overall negative (SOPC/SOPS; panel a) or neutral (SOPC only; panel b) charge. Nanoparticle concentration is 220 nM. Curves are meant to lead the eye.

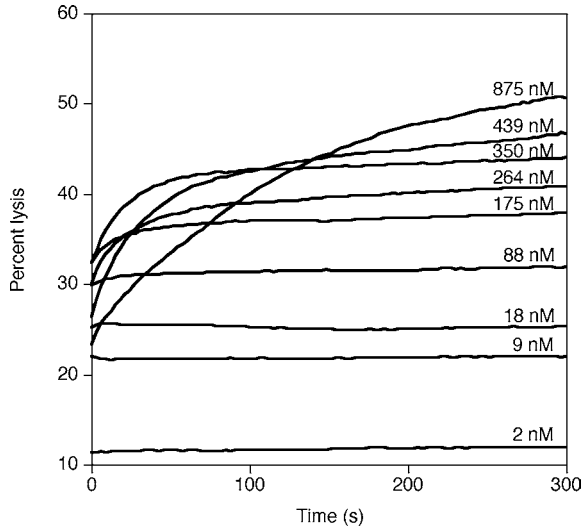

Figure 3. Concentration dependence of vesicle rupture by MMPC **1**. Higher concentrations could not be tested due to light absorption by the nanoparticles. Curves are meant to lead the eye.

Furthermore, the endocytic pathway is actively utilized by Cos-1 cells, but not erythrocytes, suggesting that toxicity is not caused by cellular uptake via endocytosis.[1] One mechanism anticipated to be similar in comparing the eukaryotic and prokaryotic samples is membrane adhesion or cell lysis by the nanoparticles. Certainly the specific lipids in the bilayer for each cell type are different in identity or percent composition, but all cell types feature an overall negative charge with both highly charged and amphiphilic substituents (*24*). MMPC **1** would be drawn to the negative membrane, whereas MMPC **2** would not be attracted as strongly. Once bound to the cell, the amphiphilicity of the mixed monolayer of MMPC **1** could induce a variety of further interactions.

To evaluate this potential mode of action, we performed a vesicle-disruption assay, in which a fluorescent dye is released from vesicles by molecules capable of interrupting the lipid bilayer. An increase in fluorescence in this assay is typically interpreted as an indication that a designed molecule may be antibacterial due to membrane leakage, as the bilayer is representative of the bacterial cell membrane (*25*). Two vesicle systems were examined, one composed of phosphotidylcholine (SOPC) and phosphotidylserine (SOPS) (net negative charge), and a second preparation of SOPC only (no net charge). MMPC **1** lysed the SOPC/SOPS vesicles more efficiently than MMPC **2** due to the electrostatic complementarity of the cationic substituents and the SOPS lipids (Figure 2a). In the case of the neutral SOPC vesicles, MMPC **2** showed higher levels of fluorophore release than MMPC **1**, although the intensity was less than that of MMPC **1** with the negatively charged vesicles (Figure 2b). This result demonstrates that the specific charge pairing of the nanoparticles and lipid bilayers mediates membrane interaction and lysis to release the fluorophore. This process is concentration dependent, as demonstrated by the increased lysis of the negative SOPC/SOPS vesicles observed with increasing concentrations of MMPC **1** (Figure 3). The reason for the decrease in lysis rate at higher MMPC concentrations is unclear and is currently under investigation.

In summary, we have demonstrated that the toxicity of the gold nanoparticles is related to their interactions with the cell membrane, a feature initially mediated by their strong electrostatic attraction to the negatively charged bilayer. We are currently designing nanoparticles with different properties to ameliorate the observed toxicity and will report our findings in due course.

[1] We cannot rule out the possibility of these more complex pathways of internalization when nanoparticles are in use as drug vectors.

ACKNOWLEDGMENT

We thank Joseph Simard for synthesis of the nanoparticles, Jennifer Habink for the generous donation of the *Escherichia coli* cell line, Renuka Sivendran for advice concerning the top-agar assay, Lachelle Arnt for assistance with the hemolysis assay, and Nandini Chari and Firat Ilker for assistance with the vesicle assay (Univeristy of Massachusetts). Transfection with Fluorinated Lipoplexes Based on New Fluorinated Cationic Lipids and in the Presence of a Bile Salt Surfactant

Caroline Boulanger, Christophe Di Giorgio, Jérôme Gaucheron, and Pierre Vierling*

Laboratoire de Chimie Bioorganique, UMR 6001 CNRS, Université de Nice Sophia-Antipolis, Faculté des Sciences, 06108 Nice Cédex 2, France. Received March 8, 2004; Revised Manuscript Received April 21, 2004

The synthesis of two fluorinated cationic lipids, which are analogues of frequently used synthetic gene carrier agents (including the cationic 2,3-dioleoyloxy-*N*-[2-(spermine-carboxamido)ethyl]-*N*,*N*-dimethyl-1-propanaminium (DOSPA) component of the commercially available liposomal Lipofectamine), and the disintegration and DNA accessibility (evaluated by the ethidium bromide (BET) intercalation assay) as well as the in vitro transfection efficacy of cationic lipoplexes formulated with these new lipids in conjunction with conventional or fluorinated helper lipids, in the absence or presence of sodium taurocholate (STC), a powerful anionic bile salt detergent, is reported. A higher stability, with respect to the STC lytic activity and DNA accessibility, of the fluorinated cationic lipoplexes as compared with their respective lipofectamine-based ones was demonstrated. Indeed, while the Lipofectamine lipoplexes were fully disintegrated at a [STC]/[lipid] molar ratio of 2000, only 40−60% of the DNA intercalation sites of the lipoplexes based on the fluorinated analogue of DOSPA were accessible to ethidium bromide. A higher transfection potential in the presence of STC was further found for the lipoplexes formulated with the fluorinated analogue of DOSPA as compared with the Lipofectamine preparation. For a STC concentration of 7.5 mM, lipofection mediated with these fluorinated lipoplexes was significantly higher (nearly 30- to 50-fold, $p < 0.05$) than with the Lipofectamine ones. These results confirm the remarkable transfection potential of fluorinated lipoplexes.

INTRODUCTION

Synthetic gene transfer systems based on (poly)cationic lipids, liposomes, or polymers (e.g. lipoplexes or polyplexes, respectively) have become very promising novel forms of molecular medicine (for recent reviews, see refs 1−8 and references therein). Although the gene expression levels obtained with these systems are transient and lower than with viral vectors, they present several advantages including low-cost and large-scale production, safety, and capacity to deliver large gene fragments. However, there is still a need for the development of gene transfer systems with improved and original properties. Progress in this field also requires systems which allow efficient gene expression in various biological fluids. In the field of gene transfer and gene therapy of cystic fibrosis and of cystic fibrosis-associated diseases for example, systems which enable efficient gene expression in the presence of various surfactants (pulmonary ones for the gene transfer to the respiratory epithelium, bile salts for the biliar epithelium) are required. Indeed, pulmonary surfactants constitute a barrier to transfection of the endobronchial airway (*9*). Such surfactants were also found to inhibit lipofection of various cell lines with cationic lipids (*9*−*12*).

In our laboratory, fluorinated cationic lipoplexes, i.e., lipoplexes resulting from the formulation of DNA with highly fluorinated cationic lipids (analogues of DOTMA, DMRIE, DPPES, and DOGS)[1] (*13*, *14*) and/or highly fluorinated helper lipids (analogues of DOPE) (*15*, *17*) (see structures in Figure 1), were shown to constitute very promising transfection systems. Such fluorinated cationic lipoplexes exhibited in vitro (*13*−*17*) and in vivo (*15*) a higher transfection potential than their conventional lipoplex counterparts and more particularly in the presence of a powerful anionic surfactant (*16*). Their remarkable transfection potency was attributed to the unique lipophobic and hydrophobic character of the fluorinated lipids used for their formulation, thus preventing DNA from interactions with lipophilic and hydrophilic biocompounds, and from degradation (*16*).

We report herein on the synthesis of F-DMAEA and F-DOSPA which are fluorinated analogues of frequently used synthetic gene carrier agents, i.e., GAP-DLRIE (*18*) and DOSPA (which is the cationic component of commercially available liposomal Lipofectamine) (*19*) (see structure in Figure 1), and on their ability to compact, transfer, and express DNA into cells in the absence or presence of a powerful anionic detergent (e.g. sodium taurocholate, STC, which is a model of bile salts). The

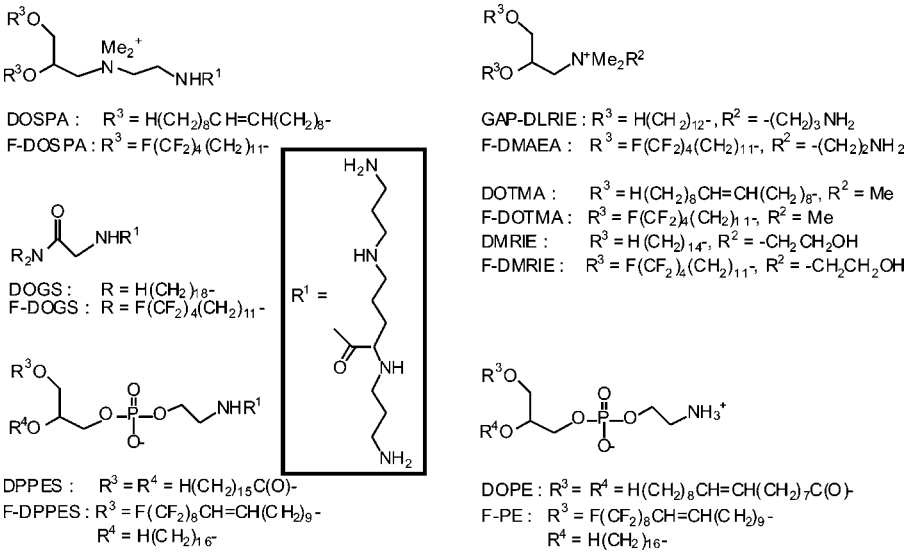

Figure 1. Chemical structure and code name of the fluorinated and conventional cationic and helper) lipids used and/or mentioned in this study. F-DOSPA, F-DMAEA, F-DOGS (*14*), F-DOTMA, F-DMRIE, F-DPPES (*13*), and F-PE (*15*, *17*) are fluorinated analogues of conventional DOSPA (*19*), GAP-DLRIE (*18*), DOGS (*25*), DOTMA (*26*), DMRIE (*27*), DPPES (*28*), and DOPE, respectively.

goals of this study were to extend the library of fluorinated cationic lipids that enable gene transfer and expression and to confirm or infirm the transfection potential of fluorinated cationic lipoplexes in the presence of surfactants (*16*). As the use of helper lipids (HL) enhances the transfection activity of most (poly)cationic lipids (including the fluorinated analogues of DOGS) (*14*, *17*), we report on the transfection efficacy of these new fluorinated cationic lipids (CL) used in conjunction with DOPE or F-PE, a fluorinated analogue of DOPE (see structure in Figure 1) which was found in vitro and in vivo to be a more efficient helper lipid than DOPE (*15*, *17*). In this paper, we show that, in the presence of STC, the cationic fluorinated F-DOSPA/F-PE lipoplexes display a greater stability with respect to detergent-triggered disintegration and DNA accessibility, and a significantly larger in vitro transfection potential than conventional lipoplexes formulated with Lipofectamine.

MATERIALS AND METHODS

General Experimental and Analytical Conditions. Most of the reactions were performed in anhydrous solvents under dry and oxygen-free nitrogen. Anhydrous solvents were prepared by standard methods. Purifications by column chromatography were carried out using silica gel 60 (Merck, 70−230 mesh) and chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), methanol (MeOH), or mixtures thereof as indicated. Unless noted otherwise, the ratios describing the composition of solvent mixtures represent relative volume. Advancement of the reaction was followed by thin-layer chromatography (TLC) on silica plates F254 (Merck). The following developing systems were used: UV light, $KMnO_4$, H_2SO_4/EtOH, Dragendorff reagent, ninhydrin reagent (Sigma). Tetra-*N*,*N*′,*N*″,*N*‴-(*tert*-butyloxycarbonyl)-spermine-5-carboxylic acid [(Boc)4SperCOOH] and *N*-[1-(2,3-di-11-(*F*-butyl)-undecyloxy)-propyl]-*N*-[2-hydroxyethyl]-*N*,*N*-dimethylammonium bromide [F-DMHEA] were synthesized according to published procedures (*13*, *14*). *rac*-3-[11-(*F*-Octyl)undec-10-enyl]-2-(hexadecyl)glycero-1-phosphoethanolamine, F-PE, was from our laboratory (*15*, *17*). 1,2-Dioleoyl-sn-glycero-3-phosphoethanolamine (DOPE) was purchased from Sigma. All other organic chemicals were purchased from Sigma, Aldrich, or Fluka. Lipofectamine was purchased from Invitrogen (Cergy Pontoise, France). ^1H, ^{13}C, and ^{19}F NMR spectra were recorded at 200, 50.3, and 188.3 MHz, respectively, on a Bruker AC-200. Chemical shifts were measured relative to $CHCl_3$ (δ 7.26 ppm) or CH_3OD (δ 3.31 ppm) for ^1H, relative to $CDCl_3$ (δ 77.1 ppm) for ^{13}C and expressed indirectly in relation to TMS, and relative to CCl_3F as internal reference for ^{19}F. The following abbreviations are used to describe the signal multiplicities: s (singlet), d (doublet), t (triplet), q (quadruplet), and m (multiplet). Chemical shifts are expressed in parts per million and listed as follows: shift in parts per million (multiplicity, coupling, integration, and attribution). Electrospray ionization mass spectrometry (ESI-MS) in positive mode was performed on a Finnigan MAT LCQ equipped with an atmospheric pressure ionization (API) source.

Synthesis of the Fluorinated Cationic Lipids. Synthesis of *N*-[1-(2,3-di-11-(*F*-butyl)undecyloxy)-propyl]-*N*,*N*-dimethyl-*N*-(2-aminoethyl)ammonium hydroxide [F-DMAEA].

To a solution of F-DMHEA (*13*) (600 mg, 0.6 mmol) in THF (20 mL) were added 0.7 mL of a freshly prepared 1.6 M solution of hydrazoic acid (HN_3, 1.1 mmol) in chloroform followed by 0.22 mL of a THF solution of diisopropyl azodicarboxylate (DIAC, 1.1 mmol) and then 10 mL of a THF solution of triphenylphosphine (0.52 g, 2 mmol) (*20*). The resulting mixture was stirred at 50 °C overnight. Water (1 mL) was added, and the temperature was maintained at 50 °C for 3 h. After evaporation in vacuo of the solvents, the residue was dissolved in dichloromethane. The organic phase was washed three times with water and then dried over Na_2SO_4. Flash chromatography of the residue obtained after evaporation over a silica gel column (60 g, from $CHCl_3$/MeOH 9/1 to $CHCl_3$/MeOH 8/2 and then $CHCl_3$/MeOH/NH_4OH 8/2/0.2) led to 0.27 g (0.27 mmol, 45%) of a white powder consisting into F-DMAEA as its hydroxide. TLC ($CHCl_3$/MeOH/NH_4OH, 8/2/0.2 v/v; H_2SO_4, Dragendorff, ninhydrin): $R_f = 0.35$. ^1H NMR ($CDCl_3$/CD_3OD): δ 1.02−1.31 (s large, 28H, $CF_2(CH_2)_2(CH_2)_7$); 1.31−1.55 (m, 8H, CF_2-CH_2CH_2, CH_2CH_2O); 1.90 (tt, ^3J = 8.3 Hz, $^3J_{HF}$ = 18.8 Hz, 4H, CF_2CH_2); 2.93−3.09 (m, 2H,CH_2NH_2); 3.09−3.19 (s large, 6H, CH_3); 3.23−3.61 (m, 10H, CH_2O, CH_2NCH_2); 3.80−3.95 (m, 1H, CH). ^{13}C NMR ($CDCl_3$/CD_3OD): δ 19.9 (t, $^3J_{CF}$ = 3.7 Hz, $CF_2CH_2CH_2$); 25.9, 26.0 ($CH_2(CH_2)_2O$); 28.9, 29.0, 29.2, 29.3, 29.4 ($CF_2(CH_2)_2(CH_2)_6$); 29.9 (CH_2-

CH_2O); 30.6 (t, $^2J_{CF} = 22.3$ Hz, CF_2CH_2); 35.4 (CH_2NH_2); 52.3, 52.9 (CH_3); 66.4 (CH_2NCH_2); 68.6, 69.3, 71.9 (CH_2O); 73.0 (CH).^{19}F NMR ($CDCl_3/CD_3OD$): δ −78.2 (3F, CF_3); −111.1 (2F, CF_2CH_2); −129.4 (2F, $CF_2CF_2CH_2$); −127.5 (2F, CF_3CF_2). MS (ESI+): $m/z = 907.6$ $[M]^+$, in agreement with the mass calculated for $[M]^+ = C_{37}H_{61}F_{18}N_2O_2$.

Synthesis of *N*-[1-(2,3-Di-11-(*F*-butyl)undecyloxy)-propyl]-*N*-[2-(sperminecarboxamido)ethyl]-*N*,*N*-dimethylammonium as a Trifluoroacetate Salt, [F-DOSPA]. To a solution of (Boc)4SperCOOH (*14*) (212 mg, 0.33 mmol) in 15 mL of CH_2Cl_2 were added *N*-hydroxysuccinimide (HOSu) (49 mg, 0.43 mmol) and dicyclohexylcarbodiimide (DCC) (88 mg, 0.43 mmol) with a few drops of THF. The mixture was stirred at room temperature during 12 h and was then cooled to 0 °C and filtered. Then, 270 mg (0.27 mmol) of F-DMAEA and 75 μL (0.54 mmol) of triethylamine were added, and the resulting mixture was stirred at room temperature during 12 h. The organic phase was washed with 5% sodium carbonate, 5% citric acid, and water until neutrality and then dried over Na_2SO_4. Flash chromatography over a silica gel column of the residue obtained after evaporation (20 g, CH_2Cl_2/MeOH: from 99/1 to 90/10 then CH_2Cl_2/MeOH/NH_4OH, 8/2/0.2 v/v) led to 200 mg (0.12 mmol, 46%) of a colorless oil consisting of *N*-[1-(2,3-di-11-(*F*-butyl)undecyloxy)propyl]-*N*-[2-(tetrabutoxycarbonyl-sperminecarboxamido)ethyl]-*N*,*N*-dimethylammonium hydroxide [F-DOSPA(Boc)]. TLC ($CHCl_3$/MeOH/ NH_4OH: 8/2/0.2; Dragendorff, ninhydrin): $R_f = 0.51$. ^{1}H NMR ($CDCl_3/CD_3OD$): δ 0.74−1.83 (m, 80H, $CF_2CH_2(CH_2)_9$, CH_3(Boc), CH_2CH_2N(H)Boc, CH_2CH_2NBoc, CH_2CHC(O)); 1.97 (tt, $^3J_{HH} = 7.5$ Hz and $^3J_{HF} = 19.1$ Hz, 4H, CF_2CH_2); 2.92−4.26 (m, 30H, $N(CH_3)_2$, CH_2O, CHO, CH_2N, CHC(O)NH). ^{13}C NMR ($CDCl_3/CD_3OD$): δ 20.1 (t, $^3J_{CF} = 3.7$ Hz, CF_2-CH_2CH_2); 26.1, 26.2 ($CH_2(CH_2)_2O$); 28.5 (CH_3(Boc); 29.1, 29.3, 29.4, 29.6, 29.7, 30.0 ($CF_2(CH_2)_2(CH_2)_6$, CH_2CH_2O, CH_2CH_2NBoc, CH_2CHNBoc); 30.8 (t, $^2J_{CF} = 22.3$ Hz, CF_2CH_2); 38.3, 44.0, 46.4, 46.7 (CH_2NBoc); 52.6 (CH_2-NHC(O)); 53.3, 53.5 ($N(CH_3)_2$); 60.6 (CHC(O)NH); 68.6, 69.5, 72.1 (CH_2O, $CHCH_2NCH_2$); 73.3 (CHO); 78.9, 79.6, 80.7 ($C(CH_3)_3$); 155.6, 155.7, 156.2 (C(O)). ^{19}F NMR ($CDCl_3/CD_3OD$): δ −81.6 (3F, CF_3); −115.1 (2F, CF_2CH_2); −125.0 (2F, $CF_2CF_2CH_2$); −126.6 (2F, CF_3CF_2). MS (ESI+): $m/z = 1536$ $[M]^+$, in agreement with the calculated mass for $[M]^+ = C_{68}H_{117}F_{18}N_6O_{11}$.

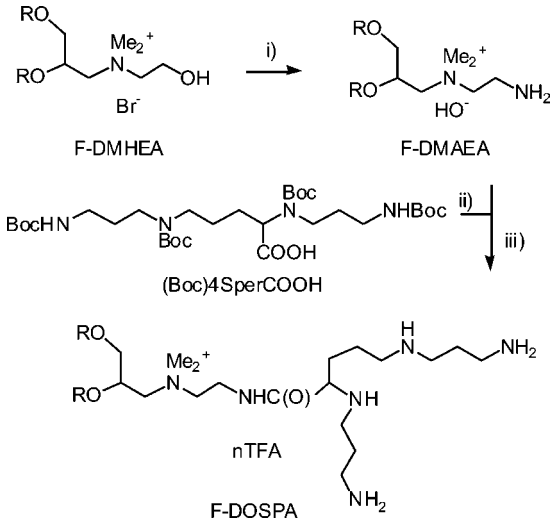
The Boc-deprotection of F-DOSPA(Boc) was quantitatively achieved in a large excess of a TFA/CH_2Cl_2 mixture during 1 h at room temperature. The excess TFA was removed by coevaporation with cyclohexane yielding F-DOSPA as a TFA salt (2.6 TFA according to ^{19}F NMR). ^{1}H NMR (CD_3OD): δ 1.22−2.29 (m, 48H, $CF_2(CH_2)_{10}$, CH_2CH_2NH, CH_2CHC(O)); 2.84−3.81 (m, 29H, $N(CH_3)_2$, CH_2O, CHO, CH_2N); 4.01−4.17 (m, 1H, CHC(O)NH). ^{13}C NMR (CD_3OD): δ 21.2 (t, $^3J_{CF} = 3.8$ Hz, $CF_2CH_2CH_2$); 23.1 (CH_2CHC(O)); 25.3 ($CH_2(CH_2)_2OCH_2$); 26.3 (CH_2-$(CH_2)_2$OCH); 27.2, 27.3, 28.6, 29.4, 30.1, 30.4, 30.5, 30.6, 30.7, 31.1 ($CF_2(CH_2)_2(CH_2)_6$, CH_2CH_2O); 31.6 (t, $^2J_{CF} = 22.4$ Hz, CF_2CH_2); 34.5 ($CH_2CH_2NH_2$); 37.8 (CH_2NHC-(O)); 38.5, 45.3, 45.9, 48.4 (CH_2NH, CH_2NH_2); 52.8, 53.1 ($N(CH_3)_2$); 61.6 (CHC(O)NH); 64.4, 67.4, 70.1, 70.2 (CH_2O, $CHCH_2NCH_2$); 72.8 (CHO); 163.1 (q, $^2J_{CF} = 34.5$ Hz, CF_3COO^-); 171.9 (C(O)NH).^{19}F NMR (CD_3OD): δ −77.2 (8F, CF_3COO^-); −83.0 (3F, CF_3); −116.1 (2F, CF_2CH_2); −125.9 (2F, $CF_2CF_2CH_2$); −127.7 (2F, CF_3CF_2). MS (ESI+): $m/z = 1135.7$ and m/2z = 568.6 in agreement with the calculated mass for $[M]^+ = C_{48}H_{85}F_{18}N_6O_3$ and $[M + H]^{2+}/2$, respectively.

Preparation of the DNA Complexes. The plasmid pTG11236 (pCMV-SV40-luciferase-SV40pA) used for the preparation of the DNA complexes and for transfection assays was produced by Transgène (Strasbourg, France). It is a plasmid of 5739 bp. The endotoxin content of the plasmid preparation was checked using a Limulus Amebocyte Lysat kit (Biogenic, France). This value was below 1 endotoxin unit/mg of plasmid, hence below the 5 e.u./mg of DNA recommended for in vivo protocols.The quantities of lipids used for the *N*/*P* 5 lipoplexes were calculated according to the DNA concentration of 0.1 mg/mL in the lipoplex preparation, the molar weight, and the number of amino groups in the selected cationic lipid (CL is F-DMAEA, F-DOSPA or DOSPA). The *N*/*P* ratio of 5 corresponds to the molar amount of CL necessary to have a ratio of five amino group nitrogens (for 1 mol CL) per one phosphate in the DNA (330 Da mean MW), as described elsewhere (*13*−*17*).

Liposomal dispersions containing CL and DOPE (or F-PE) as helper lipid (HL) at a [CL]/[HL] 60/40 molar ratio and at a CL concentration of 1.0 mg/mL in a 5% glucose solution were first prepared. Thus, for the preparation of *N*/*P* 5 F-DOSPA/HL/DNA complexes, 100 μL of a F-DOSPA solution (10 mg/mL in $CHCl_3$/MeOH 9/1) and 34.8 μL of DOPE or 54.7 μL of F-PE solutions (10 mg/mL in $CHCl_3$ or $CHCl_3$/MeOH 9/1, respectively) were transferred to a borosilicate glass tube. The solvents were evaporated in a Rotavap evaporation system (45 °C, 0.2 bar, 40 rotations/min). Then, 1.0 mL of a 5% glucose solution was added to the film obtained. The preparation was vortexed for 12 h and then sonicated for 5 min to yield a liposomal preparation. The F-DOSPA/HL/DNA lipoplexes were then formulated by adding 64.8 μL of the F-DOSPA/HL liposomal preparation to 85.2 μL of a DNA solution in glucose 5% (0.176 mg/mL) to reach a final DNA concentration of 0.1 mg/mL. This preparation was vortexed for 10 s and was used within 1 h for particle size measurements, agarose gel electrophoresis, ethidium bromide (BET) exclusion, and/or in vitro transfection experiments.

Measurement of the Size of the Lipoplexes. The average sizes were measured by photon correlation spectroscopy using a Coulter N4Plus particle size analyzer, as described elsewhere (*14*).

Agarose Gel Electrophoresis. Each sample of the above-described lipoplex preparation (0.5 μg of plasmid) was electrophoresed for about 30 min under 150 V, through a 0.8% agarose gel in TAE 1 x (Tris-acetate-EDTA) buffer and stained by spreading a 1 μL/mL BET solution in TAE buffer. The absence of BET-stained DNA bands after photographing on a UV transilluminator confirmed that all the DNA was complexed. Its integrity was confirmed by electrophoresis after disrupting the lipoplexes with a large excess of sodium dodecyl sulfate, following procedures described elsewhere (*14*).



Lipoplex Stability in the Presence of Sodium Taurocholate Dye-Exclusion Assays. The BET intercalation into the *N*/*P* 5 lipid-complexed DNA at a concentration of 15.0 μM for F-DOSPA or DOSPA (respectively 37.5 μM for F-DMAEA) and 15 μM DNA phosphate in the presence of various concentrations of STC (from 0 to 60 mM) was assessed by fluorescence monitoring at 2.5 μM BET which correspond to a BET:nucleotide ratio of 1:6. Under these conditions, the fluorescence of BET intercalated into DNA was found to be directly proportional to the percentage of accessible DNA (*21*). The above-described lipoplex preparation (0.1 mg DNA/mL) (75 μL) in a 5% glucose solution was added to 750 μL of BET (5 μM in a 5% glucose solution) and to 675 μL of STC in glucose 5% to reach a final concentration of STC in the 0−60 mM range. The resulting

preparations were incubated at 37.0 ± 0.5 °C in a thermoregulated cell with magnetic stirring for 10 min. Then, the fluorescence F was measured using a Perkin-Elmer Spectrofluorometer LS 50B (excitation at 306 nm, emission at 622 nm, and a 530 nm emission cutoff filter). The fluorescence signal, F_{max}, which corresponds to 100% BET intercalation, was determined for each detergent concentration tested on a 2.5 μM BET and naked DNA 0.1 mg/mL glucose solution. The fluorescence of each sample was corrected for the background fluorescence F0 of BET in the absence of DNA and in the presence of STC at each concentration tested. The percentage of accessible DNA to BET for each sample and for each detergent concentration was calculated from the equation $(F - F_0)/(F_{max} - F_0)$. This percentage can exceed 100% owing to diffusion background fluorescence resulting from the presence of lipospermine-based aggregates (in the present experiments F could not be corrected for this effect). The given means were calculated from at least three independent experiments.

In Vitro Transfection of A549 Cells. For in vitro transfection, A549 cells (epithelial cells derived from human pulmonary carcinoma) were grown 24 h before the experiments in Dulbeco-modified Eagle culture medium (DMEM) (Gibco-BRL), containing 10% foetal calf serum, FCS (Sigma), in 96-well plates (2×10^4 cells per well), in a wet (37 °C) and 5% CO_2/95% air atmosphere. Five microliters of CL/HL/DNA lipoplex preparation was diluted to 50 μL in DMEM. Ten minutes before addition to the cells, this dispersion was diluted with 50 μL of STC in DMEM to obtain the desired detergent concentration (from 0 to 17.5 mM). The cell culture medium was removed and replaced with this 100 μL of lipoplex/detergent/DMEM solution which corresponds to a DNA concentration of 0.5 μg and a lipid concentration of 15.1 μM for F-DOSPA and 37.9 μM for F-DMAEA in each well. After 4 and 24 h, 50 and 100 μL of DMEM supplemented with 30% and 10% FCS, respectively, were added. Forty-eight hours after transfection, the culture medium was discarded and the cells were washed twice with 100 μL of phosphate-buffered saline (PBS) and then lysed with 50 μL of lysis buffer (Promega, Charbonnières, France). The lysates were frozen at −40 °C awaiting for luciferase activity analysis. This measurement was done for 10 s on 10 μL of lysis mixture in a LB96P luminometer (Berthold, Evry, France) in dynamic mode, using the 'Luciferase' determination system (Promega) in 96-well plates. The total protein concentration per well was determined by the BCA test (Pierce, Montluçon, France). For cells grown in the absence of lipoplexes or STC, a well contained approximately 30−50 μg of proteins. Luciferase activity was calculated as femtograms (fg) of luciferase per milligram (mg) of proteins. The percentage cell viability of the lipoplexes (without or with STC) and of STC was calculated as the ratio of the total protein per well of the transfected cells (without or with STC) relative to that measured for untreated cells or for cells incubated with the detergent × 100%, respectively. The given means ± SEM were calculated from three independent experiments.

Statistical Analysis. Statistical tests were performed with STATGRAPHICS Plus5.1 software. Analysis of variance (Anova) was run on the logarithmic transformation of transfection levels (log10(fg luciferase/mg protein)) and on the cell viability to fit normal distributions of the data. One factor, i.e., the nature of the formulation, for a given amount of STC added (in the 0−60 mM range) was analyzed as source of the variation of cell viability percentages and of logarithmic transformation of the transfection levels using a one-way comparison procedure. The Tukey's honestly significant difference (HSD) method was used to discriminate among the means of cell viability percentages and the logarithmic transformations of luciferase expression levels.

Scheme 1. Synthetic Route to F-DMAEA and F-DOSPA[a]

[a] Reagents: (i) HN_3, PPh_3, DIAC; (ii) DCC, HOSu, CH_2Cl_2/THF; (iii) excess TFA/CH_2Cl_2. R represents $F(CF_2)_4(CH_2)_{11}$.

RESULTS AND DISCUSSION

Our main objectives were to extend the library of fluorinated cationic lipids and lipoplex formulations that enable gene transfer and expression (*13*, *14*) and to confirm the most promising transfection potential of fluorinated cationic lipoplexes in the presence of a powerful anionic surfactant (e.g. sodium taurocholate, STC) (*16*). Therefore, we (i) performed the synthesis of F-DMAEA and F-DOSPA, (ii) evaluated, as compared with control lipoplexes formulated with the commercially available DOSPA/DOPE Lipofectamine mixture, their ability to maintain, in the presence of STC, the integrity (in terms of DNA accessibility) of fluorinated lipoplexes they form, and (iii) explored their potential as gene transfer vectors and the impact of their hydrophobic and lipophobic character on detergent-triggered transfection inhibition.

The fluorinated F-DMAEA and F-DOSPA lipids were designed according to previous studies conducted in our laboratory on fluorinated analogues of DOGS (*14*, *16*). Their framework consists of a hydrophobic part which includes two $F(CF_2)_4(CH_2)_{11}$ chains. These chains were shown to lead to one of the most efficient gene transfer agent in the fluorinated DOGS series (*14*, *16*).

Synthesis. The synthesis of the fluorinated polycationic lipid F-DOSPA relies on F-DMAEA which himself relies on F-DMHEA precursor previously reported by our laboratory (Scheme 1) (*13*). The transformation of F-DMHEA into F-DMAEA consisted of a Mitsunobu reaction which converts the alcohol function into an amine (*20*). This was achieved by the use of hydrazoic acid (HN_3) in the presence of diisopropyl azodicarboxylate (DIAC) and triphenylphosphine. The conversion of F-DMAEA into F-DOSPA (isolated as its 2.6TFA salt as attested by ^{19}F NMR) was then performed using a conventional two-step coupling/deprotection procedure consisting into DCC/HOSu activation of tetra-*tert*-butoxycarbonylspermine-5-carboxylic acid (*14*) and condensation with F-DMAEA, followed by the quantitative removal of the Boc-protect-

ing groups with TFA. The chemical structure of the fluorinated F-DMAEA and F-DOSPA lipids was clearly attested by ESI/MS as well as by ^{1}H, ^{13}C, and ^{19}F NMR.

Lipoplex Formation and Characterization. The fluorinated lipoplexes were formulated at a *N*/*P* ratio of 5 with the fluorinated cationic lipid F-DOSPA or F-DMAEA in conjunction with a helper lipid (HL = DOPE or F-PE). These lipids were used at a molar ratio of 60/40 as for the control ones formulated with commercial Lipofectamine (i.e. DOSPA/DOPE 60/40). These studies were performed with pTG11236 plasmid also used for the detergent-triggered disintegration and the in vitro transfection assays (see below). The procedure applied for the lipoplex preparation relies on the dilution from liposomal CL/HL 60/40 dispersion in 5% glucose, using a *N*/*P* ratio of 5. All the lipoplex preparations consisted into a single population of stable DNA particles of mean diameters in the 120 (50) to 300 (150) nm range, as shown by light scattering measurements (data not shown). These formulations were also analyzed by gel electrophoresis (results not shown) which indicated the presence of fully complexed plasmid (not accessible to ethidium bromide intercalation). It should be mentioned that only *N*/*P* 5 lipoplexes were formulated and analyzed. We selected this *N*/*P* ratio as we found that in our transfection protocol and among the control *N*/*P* 0.8 to 10 Lipofectamine lipoplexes tested, the *N*/*P* 5 ones led to the highest level of luciferase expression (see Transfection section below).

Lipoplex Stability in the Presence of the Detergent. To evaluate the ability of the fluorinated lipids, as compared to Lipofectamine, to prevent lipoplex disintegration in the presence of surfactants, we examined the effects of STC on BET intercalation into the complexed plasmid. We used the fluorescence monitoring of BET intercalation into DNA which has been reported for characterizing DNA complexes (*21*) and applied for the first generation of fluorinated lipoplexes (*16*). When DNA is not accessible to BET, as in the *N*/*P* 5 lipoplexes, a fluorescence signal of very weak intensity (F0) corresponding to the free dye in solution is measured upon mixing BET with the lipoplexes. When surfactant-triggered dissociation of the lipoplexes occurs and all the BET intercalation sites of DNA become accessible, BET fluorescence is enhanced. For naked DNA, an approximately 40-fold fluorescence enhancement is obtained upon intercalation into DNA, the maximal fluorescence intensity (F_{max}) being measured for a BET:nucleotide ratio of 1:6. The intensity varies further linearly between F_0 and F_{max} for accessible DNA between zero and six nucleotides per BET. This allows the degree of DNA accessibility to be observed fluorometrically.

Figure 2 shows the evolution of the percentage of DNA accessibility to BET from the CL/HL (CL = F-DOSPA, or F-DMAEA; HL = DOPE or F-PE) and control Lipofectamine *N*/*P* 5 lipoplexes with the detergent/lipid [STC]/([CL]+[HL]) molar ratio. The percentage of DNA accessibility was seen to increase for all formulations when the STC concentration and, consequently, the detergent/lipid ratio were raised. However, lipoplexes formulated with the fluorinated or conventional pentaamino DOSPA were substantially more resistant to the lytic activity of STC than those formulated with the diamino F-DMAEA lipid. Indeed, for the F-DMAEA-based lipoplexes, a STC concentration of only 5 to 10 mM (which corresponds to a detergent/lipid molar ratio of 80−160) was sufficient to promote 80 to 100% of DNA accessibility (hence almost complete disintegration), whereas for the Lipofectamine and F-DOSPA-based lipoplexes and these STC concentrations (which correspond to detergent/lipid molar ratios of 200−400), only 40−45% of the DNA intercalation sites became accessible to BET. Furthermore, much higher STC concentrations (50 and 60 mM, respectively), which correspond to detergent/lipid molar ratios of 2000−2400, were necessary to disintegrate actively these latter lipoplexes. Interestingly, our data show further that the stability of the lipoplexes, with respect to the lytic activity of STC, is increasing along the sequence Lipofectamine < F-DOSPA/DOPE < F-DOSPA/F-PE, indicating that the higher the fluorination degree of the lipoplexes, the higher their stability. These results are in line with the pioneering study from this laboratory which highlighted a greater resistance to STC-triggered disintegration of lipoplexes formulated with fluorinated analogues of Transfectam (or DOGS) rather than with Transfectam itself (*16*). They confirm that the enhanced lipophobic and hydrophobic character of the fluorinated cationic or helper lipids, and consequently of the fluorinated lipoplexes they form, prevents these lipoplexes from disintegration by the detergent and, consequently, prevents DNA from degradation and from interactions with lipophilic and hydrophilic biocompounds. The main impact of the fluorinated lipids likely stems from the reduction of the detergent solubility into the film they form which surrounds DNA, owing to the very low miscibility between hydrocarbon (e.g. STC) and fluorinated lipids (*22*−*24*).

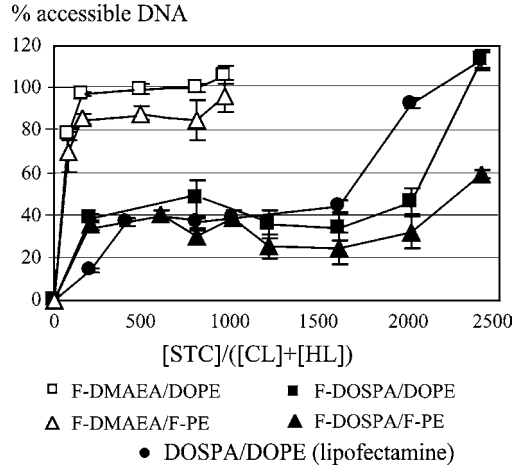


Figure 2. Evolution of the percentage of DNA accessibility to ethidium bromide (BET) from various lipoplexes with the [STC]/([CL]+[HL])] molar ratio (STC = sodium taurocholate; CL = cationic lipid = DOSPA, F-DOSPA, or F-DMAEA; HL = helper lipid DOPE or F-PE). The lipoplexes prepared in 5% glucose solution were made of the cationic lipids and helper lipids (structure shown in Figure 1) and plasmid pTG11236 (DNA) for a *N*/*P* ratio of 5 and for a [CL]/[HL] molar ratio of 60/40. The BET intercalation into lipid-complexed DNA at a concentration of 15.0 μM for F-DOSPA or DOSPA (respectively 37.5 μM for F-DMAEA) and 15 μM DNA phosphate in the presence of various concentrations of STC (from 0 to 60 mM) was assessed by fluorescence monitoring at 2.5 μM BET and at a BET:nucleotide ratio of 1:6. The given means ± SEM were calculated from at least three independent experiments. For more details, see Materials and Methods.

Transfection. The transfection potential of F-DOSPA and F-DMAEA with DOPE or F-PEhelper lipid was assayed in vitro on A549 cells, a commonly used cell model for in vitro gene delivery. These assays were performed by incubating the *N*/*P* 5 lipoplexes (at a DNA dose of 0.5 μg/well) with the cells in the presence of 10% fetal calf serum for 24 h and in the presence of increasing concentrations of STC (from 0 to 17.5 mM) and, consequently, of various detergent/lipid molar ratios (from 0

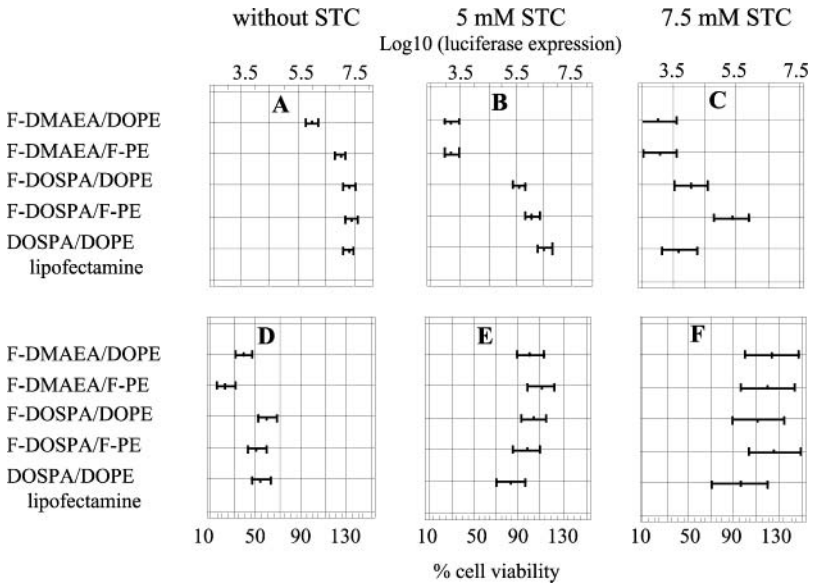

Figure 3. Means and 95.0% Tukey HSD intervals of the logarithmic transformation of transfection levels (log10(fg luciferase/mg protein); panels A−C) and of the percentage of cell viability (panels D−F) for the fluorinated F-DMAEA- or F-DOSPA-based *N*/*P* 5 lipoplexes coformulated with DOPE or F-PE, and for control *N*/*P* 5 formulations made with lipofectamine and incubated without STC (panels A and D), with 5 mM STC (panels B and E) or with 7.5 mM STC (panels C and F). Luciferase expression and percentage of cell viability were determined in A549 cells for a DNA dose of 0.5 μg per well. For the F-DMAEA-based lipoplexes, a STC concentration of 5 and 7.5 mM corresponds to a [STC]/[lipid] molar ratio of 80 and 120, respectively. For the (F-)DOSPA-based lipoplexes, a STC concentration of 5 and 7.5 mM corresponds to a [STC]/[lipid] molar ratio of 200 and 300, respectively. For more details, see Materials and Methods.

to 693 for (F-)DOSPA and 0 to 277 for F-DMAEA). Their transfection efficiency (expressed in femtograms (fg) of luciferase/mg of protein) was further evaluated as compared to naked DNA and to reference *N*/*P* 5 lipoplexes based on Lipofectamine. These conditions (*N*/*P* 5 and DNA dose of 0.5 μg/well) were shown to give the highest luciferase expression level and percentage of cell viability for the transfection of A549 cells with the control lipoplexes formulated with Lipofectamine among the *N*/*P* 0.8 to 10 ratio and DNA dose of 0.5 and 1 μg/well tested (data not shown). Cells treated with naked DNA under equivalent conditions showed expression levels of about 10^{2-3} fg of luciferase/mg of protein. The cell viability of the lipoplexes without and with STC at the different concentrations tested was also checked by determining the total protein amount per well of the transfected cells relative to that measured for untreated cells (for which the total protein amount per well is in a 30−60 μg/well range).

Figure 3 represents a variance analysis of (i) the logarithmic transformation of the transfection levels (panels A−C) and (ii) the percentage cell viability (panels D−F) obtained with the various *N*/*P* 5 lipoplexes without or with increasing amounts of STC. Although analysis was performed throughout the 0−17.5 mM STC concentration range, only data for a 0−7.5 mM STC concentration range are presented. For a STC concentration higher than 7.5 mM, cell toxicity of the lipoplexes and of STC was indeed too important to allow an unambiguous interpretation of the transfection results. However, it should be noted that in the presence of a STC concentration of 5 and 7.5 mM, cell viability of the lipoplexes was improved as compared with that of the lipoplexes alone (see Figure 3, panel E and F vs panel D). This indicates likely that, in this STC concentration range, STC neutralizes the deleterious effects on cells of the cationic lipids present in excess in the *N*/*P* 5 lipoplexes.

Concerning the transfection experiments performed in the absence of surfactant (Figure 3, panel A), our data show that the *N*/*P* 5 lipoplexes formulated with the fluorinated lipospermine F-DOSPA (whether used with DOPE or the fluorinated F-PE helper lipid) and the control Lipofectamine-based lipoplexes display comparable transfection efficiencies. This indicates that there is no benefit from using F-DOSPA/DOPE (or F-PE) instead of DOSPA/DOPE for transfecting A549 cells and is in line with the data obtained in our laboratory for fluorinated analogues of DOGS/DOPE (*14*). It can be further observed that the lipoplexes coformulated with the dicationic fluorinated F-DMAEA lipid and DOPE are less efficient for transfecting A549 cells than those formulated with the pentacationic lipospermine (F-)DOSPA and DOPE. Moreover, coformulation of the F-DMAEA lipoplexes with the fluorinated F-PE analogue of DOPE resulted in a substantial enhancement of transfection efficiency, confirming the remarkable transfection helper properties of F-PE (*15*, *17*). This transfection increase is however accompanied by a substantial decrease of cell viability (Figure 3, panel D). It should further be noticed that the *N*/*P* 5 F-DMAEA-based lipoplexes exhibit a lower cell viability than their respective lipospermine-based ones. This is likely related to the fact that, for a given *N*/*P* ratio, the concentration of the lipids in the transfection wells is 2.5-fold higher for a dicationic (e.g. F-DMAEA) than for a pentacationic lipid (e.g. (F-)DOSPA).

More importantly, concerning the transfection experiments performed in the presence of STC (Figure 3, panels B and C), and based on the stability study described in the precedent section, lipofection was expected to be inhibited by the detergent for all the lipoplexes but to a lesser extent (i) for any of the (F-)DOSPA lipoplexes as compared with the F-DMAEA-based ones, and (ii) for the fluorinated F-DOSPA lipoplexes as compared with the Lipofectamine controls and particularly with increasing the fluorination degree of the formulation. These were the observed trends as can be seen in Figure 3 (panels B and C vs panel A). Indeed, lipofection when mediated by the *N*/*P* 5 F-DMAEA-based lipoplexes was fully inhibited for a STC concentration of 5 mM which corresponds to a

[STC]/[lipid] molar ratio of 80. By contrast, only a 6-, 15-, and 50-fold inhibition of transfection ($p < 0.05$) was observed for the *N*/*P* 5 DOSPA/DOPE, F-DOSPA/F-PE, and F-DOSPA/DOPE formulations, respectively, although for these latter formulations a STC concentration of 5 mM corresponds to a higher [STC]/[lipid] molar ratio (i.e. 200). For a STC concentration of 7.5 mM (panel C), lipofection mediated with complexes formulated with both the fluorinated F-DOSPA and helper lipid F-PE was significantly higher than with Lipofectamine (nearly 50-fold, $p < 0.05$) or even with F-DOSPA/DOPE (nearly 30-fold, $p < 0.05$). It is thus the formulation displaying the highest fluorination degree of the formulations investigated here which possesses the largest lipofection potential in the presence of STC. That F-DOSPA/F-PE lipoplexes are more efficient for transfecting A549 cells than the F-DOSPA/DOPE ones illustrates again the remarkable helper properties of F-PE, a fluorinated analogue of DOPE.

The present study which demonstrates the improved lipofection capability of fluorinated lipoplexes in the presence of a powerful surfactant is in line with a previous study from this laboratory which was performed with *N*/*P* 5 lipoplexes made from fluorinated DOGS analogues (*16*). However, for these fluorinated DOGS formulations higher detergent concentrations (up to 17.5 mM vs 10 mM for F-DOSPA/F-PE) and higher [STC]/[lipid] molar ratios (up to 462 vs 400 for F-DOSPA/F-PE, data not shown) were necessary to inhibit lipofection of A549 cells. The lower cell transfection ability of F-DOSPA/F-PE (or DOPE) lipoplexes in the presence of STC as compared with that of the fluorinated DOGS analogues is likely related to the presence of the helper lipid (DOPE or F-PE) for the former formulations. STC displays a greater miscibility with DOPE and even with the mixed-chain F-PE (which contains a fluorinated and hydrocarbon chain) than with the fluorinated DOGS which contain two fluorocarbon chains (*22*−*24*). One expects therefore a lower stability (with respect to disintegration) in the presence of STC for the F-DOSPA/F-PE (or DOPE) lipoplexes than for the lipoplexes formulated only with fluorinated double-chain DOGS analogues.

Within the [STC]/[lipid] molar ratio range of 0−300, only subtle differences in disintegration of the (F-)-DOPSA-based lipoplexes were observed by the dye-exclusion assay (Figure 2), while more drastic differences were observed in transfection. This is due to the different experimental conditions employed for each assay type, as discussed elsewhere (*16*).

CONCLUSION

The extent of gene therapy using synthetic vectors depends on the development of new approaches to improve the features of lipoplexes aimed at facilitating their use in vivo. This study, which shows improved stability of fluorinated lipoplexes and higher levels of lipofection with fluorinated lipoplexes in the presence of surfactants, definitely confirms that fluorinated lipoplexes display a most promising potential as gene transfer vectors, and that they constitute a very attractive alternative to their more conventional homologues. The data reported here, together with the higher in vivo lung transfection efficiency found for fluorinated lipoplexes (*15*), suggest that their enhanced lipophobic and hydrophobic character prevents them from disintegration and, consequently, DNA from degradation and from interactions with lipophilic and hydrophilic biocompounds responsible for lipofection inhibition.

Fluorescent Vasotocin Conjugate for Identification of the Target Cells for Brain Actions of Vasotocin

Christine M. Lewis,[†] E. Kurt Dolence,[†,§] Zhaojie Zhang,[‡] and James D. Rose[†,‡,*]

Neuroscience Program, School of Pharmacy, and Department of Zoology and Physiology, University of Wyoming, Laramie, Wyoming 82071-3166. Received March 19, 2004; Revised Manuscript Received May 5, 2004

The effects of neuropeptides on the brain are a major focus of neuroendocrine research, and little progress has been made in the identification of the target neurons for many neuropeptides. Arginine[8]-vasotocin (AVT) is a neurohypophyseal peptide present in nonmammalian vertebrates that controls many neural and behavioral functions. Here we describe synthesis and functional characterization of an AVT-Oregon green conjugate **1** (AVT−OG **1**) that can be used in vivo to identify AVT target neurons. Application of AVT−OG **1** to the brainstem of an amphibian produces rapid, endosome-like internalization together with typical AVT-like neurophysiological effects. Thus, preparation of AVT−OG **1**, which preserves the peptide's neurophysiological effects, is useful as a fluorescent marker for AVT target neurons. Consequently, AVT−OG **1** conjugate will have considerable utility for analyzing the neural actions of AVT in the intact brain.

INTRODUCTION

Vasopressin-like and oxytocin-like peptides are members of a family of highly related neurohypophyseal nonapeptides that are present in all animals. Arginine[8]-vasotocin (AVT) is the specific peptide that serves antidiuretic and pressor functions in all vertebrate taxa except mammals, most of which produce arginine[8]-vasopressin (AVP) for these functions (*1*). These two neuropeptides differ only in that AVP has phenylalanine rather than isoleucine in position 3 (*2*). In addition to the antidiuretic and pressor effects of these neuropeptides, AVT and AVP appear to act in the vertebrate brain and spinal cord to mediate a diverse array of complex functions, particularly regulation of reproductive behaviors (*3, 4*). In addition, neural development and control of cellular responses to neuronal injury may be influenced by vasopressin-like neuropeptides (*5, 6*).

Numerous studies of mammalian and nonmammalian vertebrate species suggest that the neurobehavioral effects of AVT and AVP are mediated by V_1-like receptors in the central nervous system (*3, 7*−*10*). Agonist activation of G-protein-coupled receptors, such as the receptors mediating AVT and AVP behavioral effects, triggers a cascade of events, including internalization of the ligand−receptor complex (*11, 12*). This internalization may modulate cell responsiveness by causing the loss of receptors from the cell surface, making them inaccessible to continued ligand challenge (*13, 14*).

Current understanding of the cellular actions of vasopressin-like neuropeptides is very uneven, ranging from a detailed account of the target cells and mechanisms of action for antidiuretic functions involving the kidney, to much less complete mechanistic understanding of neural and behavioral actions. A limiting factor in elucidation of cellular mechanisms underlying neural−behavioral effects of vasopressin-like neuropeptides has been the absence of a means to identify the specific target neurons for AVT or AVP. Although receptors for these neuropeptides have been localized in certain neurons, the demonstration of receptors, per se, does not reveal the functional effects mediated by such receptors or even guarantee that histologically demonstrated receptors are functional. In addition, the diversity of structural and functional phenotypes of neurons in the brain, unlike structurally simpler peripheral target tissues such as the kidney, further complicates the matter of relating neuropeptide target cells to a role in neural function.

The purpose of the present paper is to document the preparation of a fluorescent Oregon Green 488 AVT conjugate **1** (AVT−OG **1**), validate its functional effects on neurons, and demonstrate its utility as a means of identifying the neuronal target cells for AVT. These steps in validating the utility of the fluorescent AVT conjugate will permit the use of this conjugate in the elucidation of this neuropeptide's mechanism of neurobehavioral action.

Research in this laboratory uses a comparatively simple model for analysis of the neurobehavioral actions of AVT. Roughskin newts (*Taricha granulosa*) exhibit a highly stereotyped pattern of mating behavior in which the male clasps the female with all four legs from a dorsal approach for a period of hours as an obligatory step in the courtship process leading to fertilization (*15*). It has been established that AVT is one of the hormones normally facilitating this behavior and the lower brainstem is the key brain region for AVT action in facilitating clasping (*4*). In addition, we have shown that the clasp-facilitating neural action of AVT appears to entail an enhancement of the responsiveness of medullary neurons to sensory stimuli applied to various locations on the body surface (*16*).

To visualize peptide internalization in endosome-like vesicles, previous studies of peripheral tissues have utilized fluorescent AVT (*17*), fluorescent AVP (*12*), and

Scheme 1. Synthesis of Oregon Green 488−[Arg^8]-Vasotocin Conjugate AVT−OG (1)[a]

[a] (a) 5′-Isomer Oregon Green 488, DMF, *N*OHSu, EDC·HCl, 21 h, 22 °C; (b) [Arg^8]-vasotocin, 0.1 M aq $NaHCO_3$, 24 h, 22 °C; (c) lyophilization; (d) C_{18} RP-TLC followed by preparative C_{18} RP-HPLC.

fluorescent receptor agonists or antagonists (*18*). However, the use of such conjugates has been confined to in vitro studies of nonneural cells (*11*, *12*, *14*, *17*−*20*). The most significant aspect of our use of this fluorescent vasopressin-like neuropeptide AVT−OG **1** is in vivo application to the brain in such a way that specific neuronal target cells can be visualized while the concurrent neuronal effects of AVT are neurophysiologically monitored. In addition, the fluorescent AVT−OG **1** that we are presenting appears to be comparable in neuropotency to unlabeled AVT and retains excellent fluorescence. Using this approach, we aim, for the first time, to connect the functional effects of AVT with the neuropeptide's specific target neurons and their structural characteristics. The analytic power of this in vivo use of the fluorescent neuropeptide AVT−OG **1**, particularly in the roughskin newt model, is considerable, in that it can also be used in conjunction with real-time techniques such as optical imaging of signaling events.

EXPERIMENTAL PROCEDURES

Synthesis of Oregon Green 488 Conjugated Arginine^8-Vasotocin 1 (AVT−OG 1) (Scheme 1). *Reagents.* Unless otherwise stated, reagents and solvents were obtained from commercial sources without further purification. Distilled deionized water was obtained from a Millipore NanoPure system. C_{18} reverse phase TLC was conducted using Merck RP-18 F_{254} glass-backed TLC plates. Preparative C_{18} RP-HPLC was conducted using a Phenomenex Juptiter 10 μm 300A 250 × 21.2 mm column while monitoring at both 254 and 494 nm with a flow rate of 1.0 mL/min. ESI mass spectrometry was obtained using a mixture of 50:50 CH_3CN:H_2O containing 0.1% TFA.

*Oregon Green 488−[Arg^8]-Vasotocin Conjugate (**1**) (AVT−OG **1**).* The 5′-isomer of Oregon Green 488 (0.5 mg, 1.1 μM, Molecular Probes) was dissolved in DMF (56 μL) in a foil-covered vial. To this solution was added 22 μL (2.2 μmol) of a stock solution of *N*-hydroxysuccinimide (0.1 μM in DMF) and 22 μL (2.2 μmol) of a stock solution of 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (0.1 μM in DMF). This mixture was stirred at 22 °C for 21 h. This active ester solution was transferred to the manufacturer's vial of [Arg^8]-vasotocin acetate salt (1.0 mg, 1.0 μM Sigma, free base MW 1050.2) dissolved in 100 μL of 0.1 M aq $NaHCO_3$ with the aid of 100 μL of DMF and 100 μL of 0.1 M aq $NaHCO_3$. The vial was covered with foil, and this mixture was stirred vigorously for 24 h at 22 °C. At this time, the mixture was transferred to a 25 mL pear shaped round-bottom flask with the aid of water, frozen, and lyophilized to afford a yellow film. This film was applied using 50:50 CH_3CN:H_2O containing 0.1% TFA to one 20 × 20 cm RP-18 F_{254} TLC plate and eluted with 40:60 CH_3CN:H_2O containing 0.1% TFA. The major yellow band (R_f 0.31) was removed by scraping and eluted with 50:50 CH_3CN:H_2O containing 0.1% TFA, and the solvents were removed by evaporation in vacuo. This material was further purified by gradient preparative RP-HPLC (5% CH_3CN:H_2O containing 0.1% TFA (5 min) followed by a gradient over 40 min to a composition of 80:20 CH_3CN:H_2O containing 0.1% TFA) (t_R = 26.3 min). This afforded 0.6 mg (41% yield) of **1** as a water soluble yellow film. ESI mass spectrometry calcd for $C_{64}H_{75}N_{15}O_{18}S_2F_2$ $(M + H)^+$ *m*/*z* 1444.5 found: $C_{64}H_{75}N_{15}O_{18}S_2F_2$ $(M + H)^+$ *m*/*z* 1444.3.

Neurophysiological Validation of the Physiological Activity of AVT−OG 1. Adult male roughskin newts (*Taricha granulosa*) were held in community tanks supplied with continuously flowing, aerated well water. The animals were fed chopped beef heart and maintained on a natural photoperiod. The University of Wyoming Animal Care and Use Committee approved all procedures involving animals.

Procedures used for recording and analysis of neuronal activity were similar to those previously reported (*16*) and will be only briefly described here. Newts were anesthetized by immersion in 0.1% MS-222 (tricaine methanesulfonate). The rostral medulla was surgically exposed, and the head was stabilized with a support system attached to the skull. After surgical preparation was complete, the newt was removed from the anesthetic and partially immersed in fresh, aerated well water with the skin covered by wet tissue paper to facilitate transcutaneous respiration. For electrophysiological recording, newts were immobilized by administration of 2% solution of gallamine triethiodide in Ringer's solution (0.2 mL, ip).

Recording began after sufficient time elapsed for the newt to recover from the anesthetic (approximately 2−4 h). Single neuron activity was recorded with 50 μm Diamel-insulated stainless steel microelectrodes (impedances of 100−500 kΩ) placed on the surface of the rostromedial medulla in the lower brainstem. At most recording sites, spikes were recorded simultaneously from two to five neurons. Two AVT-sensitive parameters of neuronal function were evaluated: spontaneous firing rates and responses to skin stimulation. Sensory responsiveness was tested by application of light pressure (4 s) to locations on the face, individual feet, and trunk with a cone-shaped probe mounted on a piano wire stylus to ensure constant force of stimuli. The stylus was fixed to a pressure transducer to record stimulus onset, duration, and offset. Stimuli were administered at 3 min intervals throughout each experiment. Prior to administration of a peptide or vehicle, four trials of stimulation were done to establish a baseline neuronal response. All newts received hormone or vehicle administration in 4 μL of physiological saline administered directly to the surface of the medulla via microsyringe.

Neuronal activity, pressure transducer recordings, and a voice narrative were recorded on videotape in pulse code-modulated format by means of a Neurodata Neurocorder for later analysis. Firing by individual neurons was identified with Spike II software (Cambridge Electronic Designs). The criterion required for identification of neuronal sensory responses and the assessment of hormone effects on neuronal sensory responses and activity levels were similar to those described previously (*16*). Changes in activity were assessed by comparison of prehormone and posthormone response magnitudes. In order for a neuron's spontaneous firing to be considered changed by AVT−OG **1**, or AVT, it's second-by-second firing rate after the neuropeptide application had to be above or below each of the four prepeptide samples of firing by at least 30%. Likewise for a neuron's response to a sensory stimulus to be considered increased, its second-by-second firing rate during a sensory stimulus after the neuropeptide application had to be above or below the four prepeptide records of firing during the same stimulus by at least 30%.

In addition to evaluating the neurophysiological effectiveness of AVT−OG **1**, we examined three aspects of the conjugate's internalization by neurons: time course, minimally effective dose, and specificity. To this end, 4 μL of physiological saline containing one of three doses of AVT−OG **1** (10 ng, 40 ng, or 80 ng), AVT (80 ng), or vehicle alone were administered to the surface of the medulla and rinsed at the end of 30 min ($n = 4$ newts for each group). To assess time course of internalization, two additional groups of newts ($n = 4$) received 80 ng of AVT−OG **1** for 5, 30, or 60 min prior to rinsing. Small numbers of additional newts received 80 ng of AVT−OG **1** for various exposure times between 5 and 60 min (e.g. 15, 45 min) to provide a more complete qualitative picture of the time course of internalization. These dosages of the peptide and application volumes of vehicle were based on previous neurophysiological and behavioral experiments showing that a 4 μL volume of solution containing AVT in these relative concentrations and applied directly to the surface of the medulla produced reliable neurophysiological effects (*16*). To determine the specificity of neuronal internalization of AVT−OG **1** the medulla was pretreated with 4 μL of physiological saline containing either unlabeled AVT or Manning compound (*21*, *22*), a V_1-receptor antagonist. For each treatment condition ($n = 4$), 1.76 mg of Manning compound (d(CH_2)$_5$-[Tyr(Me)^2]AVP), or physiological saline (VEH) was administered followed 30 min later by 80 ng of AVT−OG **1** in 4 μL of physiological saline.

Histological Localization of Fluorescent AVT−OG 1 Internalization by Neurons. After completion of each experimental treatment, the surface of the medulla was rinsed twice with ice cold PBS (1−4 °C), the newt was immediately decapitated, and the head was rinsed for 30 s twice in ice-cold PBS (1−4 °C) before being placed in ice-cold 30% sucrose−formalin (1−4 °C) for a minimum of 24 h. Brains were removed, embedded in Tissue Tek OCT compound, and transversely sectioned using a cryostat. Sections cut through the medulla were selected at 100 μm intervals, beginning just caudal to the cerebellum, thaw-mounted on microscope slides, and dried for a minimum of 8 h at room temperature.

Neuronal labeling by AVT−OG **1** was examined and digital images collected with a Leica TCS SP2 confocal laser-scanning microscope in the University of Wyoming Microscopy Core as well as with a conventional epifluoresence microscope (Olympus BX40, FITC filter set, and Optronics digital video camera system). Neuronal AVT−OG **1** internalization was determined by counting the number of nucleated neurons with 10 or more fluorescent endosomes in sections through the rostral medulla. This value is consistent with other studies in which endosomes have been counted for quantification of target cells (*13*, *17*−*20*). An endosome was defined as a spot of fluorescence greater than 0.1 μm but less than 0.5 μm in diameter (*12*). In each transverse section, neurons were counted from a zone extending from the lateral border of the medulla to the midline. This encompassed an area 1800 μm in width and 600 μm in depth in each section. Neurons were counted from sections every 100 μm in a zone extending from 0 μm to 2000 μm caudal to the posterior extent of the cerebellum. Numbers of labeled neurons were compared across treatment conditions with analysis of variance followed by Bonferroni critical value procedure.

RESULTS

Neuronal Internalization of AVT−OG 1. Application of AVT−OG **1** to the surface of the medulla produced a time- and dose-dependent internalization of fluorescence (Figure 1) that exhibited properties consistent with previously reported (*12*, *14*) demonstrations of neuropeptide internalization. When viewed by confocal microscopy, the intracellular labeling consisted of endosome-like foci of fluorescence approximately 0.2 μm in diameter (Figure 1b). The nuclei of labeled neurons were always devoid of labeling (Figures 1a and 1c).

The endosome-like uptake of fluorescence was evident in numerous medullary neurons of all sizes, particularly those in the medial reticular nuclei. The labeled neurons tended to be in clusters that were separated by unlabeled ones (Figures 1c and 1e). Fluorescently labeled cells were present at the lowest AVT−OG **1** dose examined (10 ng); however, these cells were present primarily at the most dorsal aspects of the tissue section examined. At both 40 ng and 80 ng doses, the number of labeled cells increased, but consistent labeling throughout the depth of the medulla appeared only after administration of 80 ng of AVT−OG **1** (Figure 2). Exposure of medullary neurons to AVT−OG **1** for durations of 5, 30, or 60 min revealed intracellular fluorescent labeling, but the pattern of labeling differed significantly across the three time intervals ($p < 0.01$) (Figure 3). At 5 min, labeled cells were present, but the mean number of cells for the group

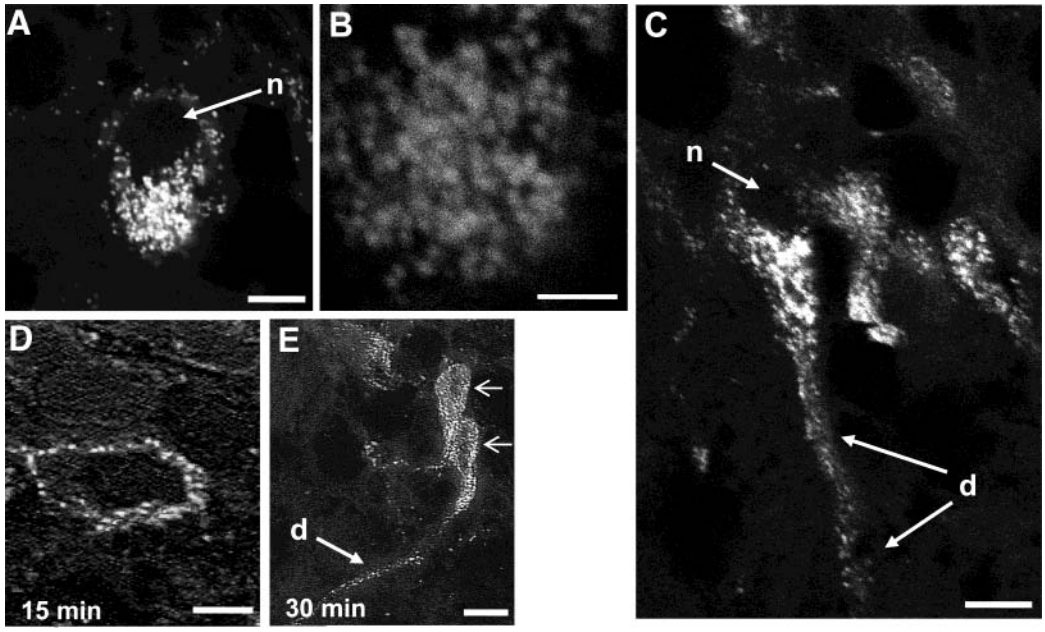

Figure 1. Confocal and epifluorescent images of rostromedial medullary neurons showing AVT−OG **1** internalization. (A and C) Single confocal optical scans (2 μm) illustrating the distribution of labeling within neurons. The cytoplasm of the cell body and a proximal dendrite (d) were intensely labeled but not the nucleus (n) (scale bar = 10 μm). (B) Confocal image of internalized AVT−OG **1** localized in puncta similar in size and appearance to endosomes (scale bar = 5 μm). (D and E) Epifluorescence images illustrating peripheral distribution of puncta in a neuronal cell body (D) at 15 min after AVT−OG **1** administration and redistribution of puncta throughout the cytoplasm of two neurons (E; small arrows) and a dendrite (d) at 30 min after AVT−OG **1** administration (scale bar = 10 μm).

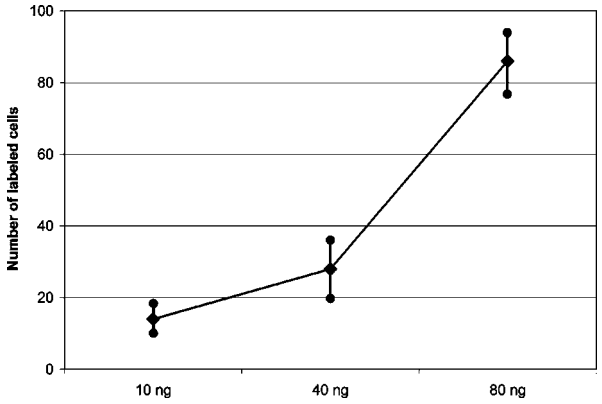

Figure 2. Mean number of labeled neurons in each group of newts as a function of dose after AVT−OG **1** administration (10 ng, 40 ng, or 80 ng) to the medulla. Neurons with AVT−OG **1** internalization were present at the lowest dose (10 ng) and the number of labeled cells increased substantially at the highest dose examined (80 ng).

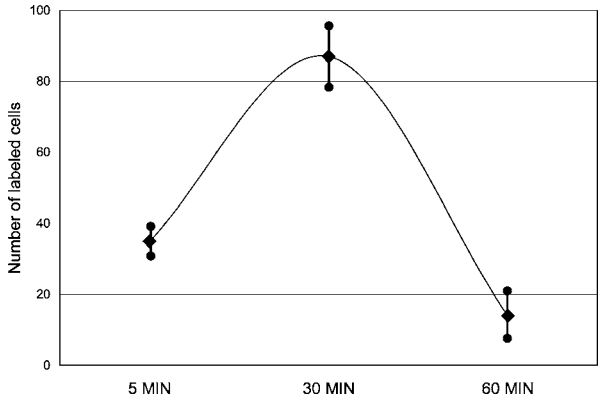

Figure 3. Mean number of labeled neurons in each group of newts as a function of time after AVT−OG **1** administration. AVT−OG **1** was applied to the medulla and rinsed after 5, 30, or 60 min. Neurons with AVT−OG **1** internalization were present at 5 min and the number of labeled cells peaked at 30 min.

of newts was significantly less (mean = 34.75) than at 30 min of exposure (mean = 85.75; $p < 0.01$) when the number of fluorescently labeled neurons was highest. Labeling was typically clustered at the periphery of the neuronal cell bodies at 15 min (Figure 1d) but at 30 min was distributed throughout the cytoplasm of each cell as well as proximal portions of primary dendrites (Figure 1e). Labeling of fine diameter processes thin enough to be axons was not evident. The number of fluorescently labeled cells peaked at 30 min and was significantly lower by 60 min of exposure (mean = 15.25).

AVT−OG 1 Internalization Is Specific and Blocked by AVT Receptor Ligands. Fluorescent labeling of medullary neurons appeared to be specific to AVT receptors in that it differed significantly across pretreatment competition conditions (Figure 4). Labeling was greatly diminished by pretreatment with either unlabeled AVT ($p < 0.01$) or Manning compound ($p < 0.01$), a specific V_1-receptor antagonist. Vehicle pretreatment had no effect on AVT−OG **1** internalization and Oregon Green, by itself, did not label cells.

AVT−OG 1 Internalization Is Associated with AVT-like Neurophysiological Effects. Application of AVT−OG **1** to the medulla produced changes in neuronal activity and sensory responsiveness (Figure 5) of the same types and magnitudes as previously seen with unlabeled AVT. For the AVT−OG **1** dose used in the present study (80 ng), most recorded neurons showed a pronounced increase in spontaneous firing within 3 min. Most of these neurons showed complete reversal of spontaneous firing to pretreatment values within 32−54 min of hormone administration. The majority (60.5%) of these neurons showed increased magnitudes of response to somatic sensory stimuli applied to various body locations after hormone administration. These changes in spontaneous activity and sensory responsiveness were

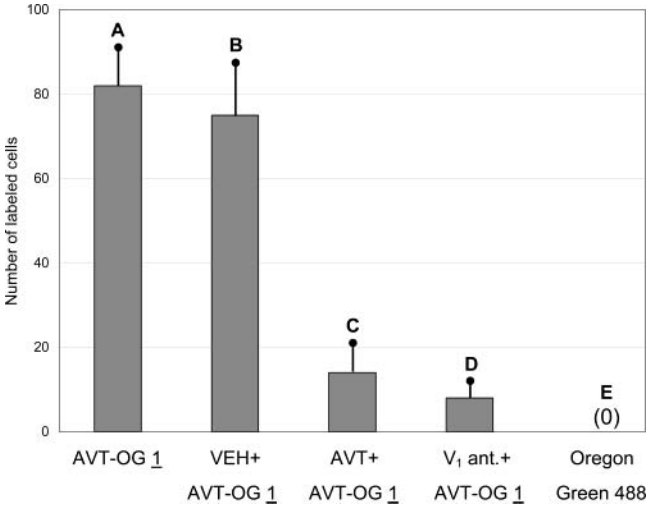

Figure 4. Competition of AVT−OG **1** neuronal labeling due to pretreatment with AVT or Manning compound. Unlabeled AVT or the specific V_1 receptor antagonist, Manning compound, administered immediately prior to AVT−OG **1**, significantly decreased the mean number of labeled cells, whereas vehicle pretreatment had no effect on AVT−OG **1** internalization. Significant differences were found in comparisons between A vs E, B vs C, and B vs D. Oregon Green 488 alone (E) did not produce any labeling.

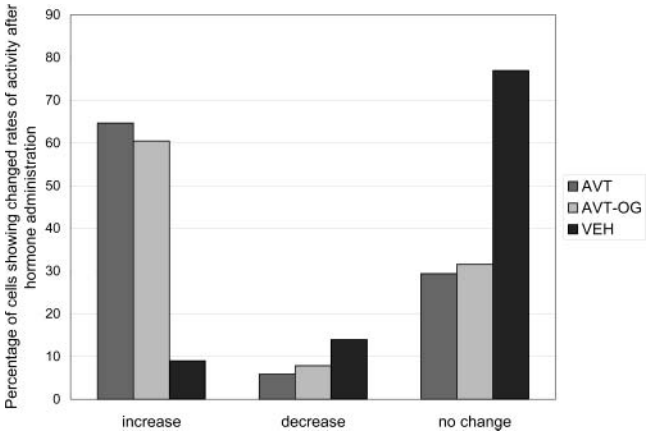

Figure 5. Both AVT and AVT−OG **1** caused significant increases in neuronal sensory responses rapidly after hormone administration. Sensory responsiveness increased in 22 of 34 neurons after administration of AVT and 23 of 38 neurons increased in sensory responsiveness after AVT−OG **1** administration. Changes of this magnitude were not seen after vehicle administration ($n = 22$).

not observed after vehicle application to the medulla (Figure 5). Collectively, these neurophysiological effects of AVT−OG **1** are essentially the same as those we have observed previously with unlabeled AVT, were similar to changes seen after administration of unconjugated AVT (Figure 5), and showed that the conjugate was functionally effective with a time course paralleling the process of internalization.

DISCUSSION

The fluorescent conjugate AVT−OG **1** described here provides a significant new tool for analysis of this neuropeptide's functions in cellular systems. One of the most active areas of investigation concerns AVT effects on brain functions, particularly those controlling behavior. Our results show that the AVT−OG conjugate **1** effectively labels target neurons for the neuropeptide and concurrently initiates the usual physiological actions of AVT. The potent enhancement of neuronal spontaneous activity and responsiveness to somatic sensory stimuli were essentially identical to results previously obtained (*16*) with a comparable dose of unlabeled AVT.

The cytological pattern of AVT−OG **1** uptake is consistent with an endosome-like pattern of internalization, like that previously described for toad bladder (*18, 19*) with an AVT agonist conjugate and for vasopressin agonist conjugates (*11, 12, 14*) in nonneuronal cells. The time course of AVT−OG **1** uptake and dispersal in endosome-like foci of fluorescence began in the perimeter of the cell body and progressed through the extranuclear cytoplasm of the neuronal somata and proximal dendrites. This pattern is also consistent with endosome formation.

Our results are compatible with a V_1 receptor-based process of AVT−OG **1** internalization. In the intact brain, competition by pretreatment with unlabeled AVT or a specific V_1 receptor antagonist blocked AVT−OG **1** uptake, thus verifying the specificity of action of the conjugate. In addition, the fact that Manning compound pretreatment produced very pronounced blockade of AVT−OG **1** uptake shows that the neurons in the newt medulla may have predominantly V_1 receptors. This result validates the utility of this conjugate **1** for investigations of neural effects of AVT due to the fact that V_1-like receptors mediate such neural effects (*4*, *7*).

In summary, this is the first use of a fluorescent AVT conjugate to investigate neuroendocrine function. In addition, we have verified that the AVT−OG conjugate **1** retains its receptor specificity and physiological effects. The availability of this fluorescent AVT makes new and analytically powerful investigations of neural and other cellular actions of AVT more feasible.

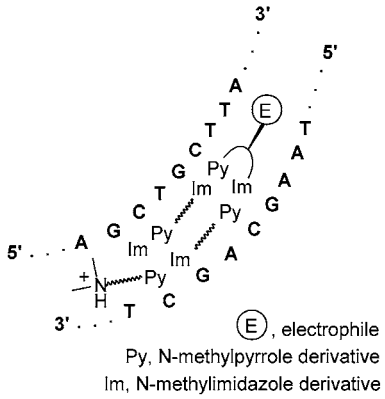
Conjugation of a Hairpin Pyrrole-Imidazole Polyamide to a Quinone Methide for Control of DNA Cross-Linking

Dalip Kumar, Willem F. Veldhuyzen, Qibing Zhou,† and Steven E. Rokita*

Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742. Received April 1, 2004; Revised Manuscript Received April 22, 2004



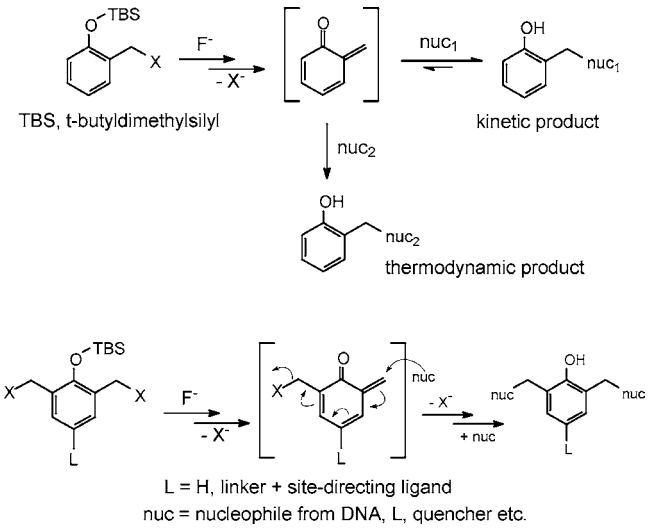
A series of quinone methide precursors designed for DNA cross-linking were prepared and conjugated to a pyrrole-imidazole polyamide for selective association to the minor groove. Although reaction was only observed for DNA containing the predicted recognition sequence, yields of strand alkylation were low. Interstrand cross-linking was more efficient than alkylation but still quite modest and equivalent to that generated by a comparable conjugate containing the N-mustard chlorambucil. Varying the length of the linker connecting the polyamide and quinone methide derivative did not greatly affect the yield of DNA cross-linking. Instead, intramolecular trapping of the quinone methide intermediate by nucleophiles of the attached polyamide appears to be the major determinant that limits its reaction with DNA. Self-adducts of the quinone methide conjugate form readily and irreversibly as detected by a combination of chromatography and mass spectroscopy. This result is unlike comparable self-adducts observed for oligonucleotide conjugates that form more slowly and remain reversible. Equivalent intramolecular alkylation of a polyamide by its attached chlorambucil mustard was not observed under similar condition. The presence of DNA, however, did facilitate hydrolysis of this mustard conjugate.

INTRODUCTION

Distamycin continues to inspire development of new compounds with a highly precise and predictable ability to recognize an extended series of base pairs in duplex DNA since its original discovery over 40 years ago (*1*). This natural product is composed of three *N*-methylpyrrole rings attached through amide bonds to create a molecule that complements the bend of DNA's minor groove and offers hydrogen bonding to its preferred target region rich in A/T pairs (*2*). Such selectivity has since been conferred to a number of reagents with covalent reactivity by conjugating the appropriate appendages to distamycin or related derivatives (*3*−*5*). Included in this series are a variety of alkylating agents. For example, a distamycin−benzoic acid N-mustard conjugate, tallimustine, was prepared and tested clinically as an anticancer drug candidate (*6*, *7*). Variations of tallimustine have also been synthesized and examined under a range of biological conditions (*8*−*11*). Other alkylating and cross-linking agents have similarly been attached to distamycin including a bis(hydroxylmethyl)pyrrole (*12*), a methyl alkyl sulfate (*13*), mitomycin (*14*), a pyrrolobenzodiazepine derivative reminiscent of tomamycin (*15*), and a cyclopropylpyrroloindole group related to CC-1065 and duocarmycin (*16*).

Once distamycin and its conjugates were found to bind as a dimer in the minor groove (*17*), polyamides containing the equivalents of a dimer structure were constructed (*18*). As predicted, these new hairpin-shaped derivatives bound tightly and precisely to chosen sequences of DNA. Inclusion of additional heterocyclic substituents allowed for distinct recognition of each base pair (*4*, *19*, *20*). Further derivatization of such compounds with cyclopropylpyrroloindole and chlorambucil appendages provided additional efficiency and selectivity for alkylating and cross-linking DNA (Scheme 1) (*21*−*23*). Success with the pyrrole-imidazole polyamides created an extremely attractive system for directing the chemistry of quinone methides to the minor groove of DNA.

Scheme 1



Quinone methides are highly electrophilic and transient intermediates that are implicated in alkylation of DNA by drugs such as mitomycin (*24*) and tamoxifen (*25*), food additives such as butylated hydroxytoluene (BHT) (*26*), and certain natural products (*27*, *28*). Our laboratory has prepared and studied a series of simple precursors and their bioconjugates that form *o*-quinone methide intermediates. Activation of these precursors is easily controlled by addition of fluoride, a species that is otherwise rarely encountered under chemical and biological conditions (Scheme 2). The products formed by quinone methide reaction with strongly nucleophilic groups in DNA tend to be unstable and readily reverse so that only adducts formed by the weakly nucleophilic exo amino groups of G and A are often isolated (nuc_1 vs nuc_2, respectively in Scheme 2) (*29*−*34*).

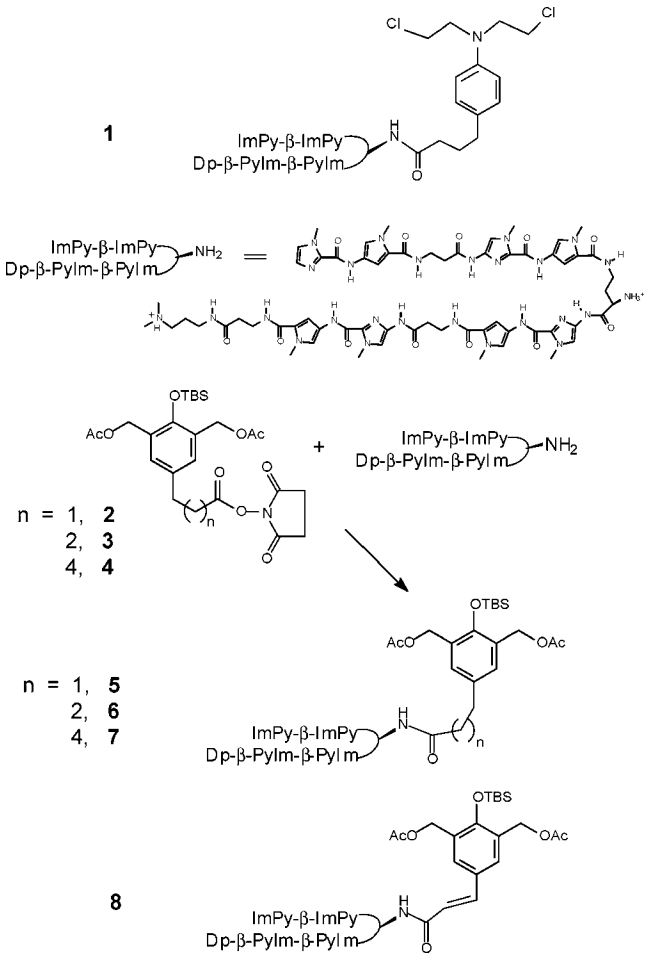
Scheme 2

The tendency for an *o*-quinone methide to accumulate only irreversible adducts can be overridden by attachment of a DNA ligand that is capable of maintaining close proximity between a reactive nucleophile−electrophile pair. Reversibility of addition is not affected by this strategy. Rather, diffusion of the regenerated intermediate is inhibited and consequently shielded from exposure to the weak nucleophiles forming irreversible adducts. This is best illustrated by the ability of a quinone methide−acridine conjugate to act as a highly efficient and persistent cross-linker of duplex DNA through reaction primarily at G N7 in the major groove, a site that would otherwise form only an unstable and transient adduct (*35*). The ratio of monoalkylation to cross-linking of this reagent is significantly smaller than that for an equivalent conjugate formed by chlorambucil. This desirably low ratio might also derive from the reversibility of quinone methide addition if the conjugate is able to migrate from sites allowing only monoalkylation to sites capable of cross-linking. Certainly, an equivalent reversibility in product formation is responsible for converting oligonucleotide−quinone methide self-adducts from inactive and undesirable side products to highly valuable target-promoted alkylating agents (*36*). A series of conjugates between a pyrrole-imidazole polyamide and quinone methide precursors has now been prepared and examined as described here to investigate whether a similar synergy could be realized between a distamycin-based ligand, a quinone methide intermediate, and the minor groove of DNA.

MATERIALS AND METHODS

General. Solvents, chemicals, and reagents were obtained in the highest purity commercially available and used without additional purification unless described below. Chlorambucil, 4-(4′-methoxyphenyl)butyric acid and monomethyl adipoyl chloride were purchased from ICN Biomedicals, Aldrich Chemical Co. and Fluka Chemical Corporation, respectively. Boc-*β*-alanine-Pam resin and (*R*)-2-Fmoc-4-Boc-diaminobutyric acid were purchased from Peptides International. Diisopropylethylamine (DIEA) and *N*,*N*-(dimethylamino)propylamine were distilled from calcium hydride (CaH_2) and stored over NaOH pellets. Fuming nitric acid was prepared by distillation of a 50:50 solution of concentrated sulfuric acid and 70% nitric acid. Dimethylformamide (DMF) was distilled from P_2O_5 and stored over molecular sieves, and acetonitrile was distilled from CaH_2. Pyridine was freshly distilled over NaOH pellets, and ethanol (EtOH) was dried by distillation over magnesium and iodine (10:1 w/w). Both methylene chloride (CH_2Cl_2) and toluene were distilled from CaH_2 prior to use. All aqueous solutions were prepared with water purified to a resistivity of 17.8−18.0 MΩ.



Silica gel for flash chromatography (230−400 mesh) was purchased from EM Sciences. Reverse phase C-18 chromatography was performed using analytical (Varian Microsorb-MV C-18, 300 C particle size, 250 mm × 4.6 mm) and semipreparative (Alltech Econosphere C-18, 10 um particle size, 250 mm × 10 mm) columns and a Jasco PU-980 HPLC equipped with a Jasco MD-1510 UV−Vis photodiode array detector.

^1H and ^{13}C spectra were recorded on a Bruker 400 MHz spectrometer. All NMR chemical shifts (δ) are reported in parts per million (ppm) and were determined relative to the standard values of the solvent (Cambridge Isotope Laboratories). Coupling constants (J) are reported in hertz (Hz). UV absorption spectra were obtained with a Hewlett-Packard 8453 UV−Vis spectrophotometer. Low resolution (LRMS) and high resolution (HRMS) mass spectra were determined on a VG7070E instrument using EI and FAB. Electrospray ionization mass spectrometry was performed with a Finnigan LCQ system equipped with a quadrupole ion trap.

Synthetic Procedures. *N*-Succinimidyl esters of 3-[4′-*tert*-butyldimethylsilyloxy-3′,5′-bis(acetoxymethyl)phenyl]-propionate (**2**), the related unsaturated derivative, and its conjugate **8** were prepared as described previously (*35*, *37*). The pyrrole-imidazole polyamide ImPy-*β*-ImPy-(R)*γ*-ImPy-*β*-ImPy-*β*-Dp and its chlorambucil conjugate **1** were synthesized as first reported by Wurtz and Dervan (*22*) (Scheme 3), and all of the monomeric components necessary for this were prepared as described by Baird and Dervan (*38*).

4-[4′-*tert*-Butyldimethylsilyloxy-3′,5′-bis(*tert*-butyldimethylsilyloxymethyl)phenyl]butanoic Acid (10a). Formaldehyde (37%, 11.1 mL) was added to an aqueous solution of NaOH (25%, 7.7 mL) containing *p*-hydroxyphenylbutanoic acid **9a** (2.0 g, 12 mmol) and methanol (6 mL) at 0 °C. The resulting mixture was heated to 37 °C, stirred for 48 h, and then diluted with acetone (80 mL). The orange aqueous phase was isolated, diluted with methanol (10 mL), and again added to acetone (125 mL). The resulting white precipitate was isolated by filtration, washed with acetone, and dried. This crude product (1.40 g, 4.93 mmol) was directly silylated by addition of DMF (15 mL), *tert*-butyldimethylsilyl chloride (TBS-Cl, 3.94 g, 26.1 mmol), and imidazole (4.00 g, 59.2 mmol). The reaction mixture was stirred at room temperature for 20 h, diluted with water (100 mL), and extracted with ether (3 × 50 mL). The organic phases were combined, dried with $MgSO_4$, and evaporated under reduced pressure. The residue was dissolved in methanol (40 mL), and potassium carbonate (2.0 g) was added in one portion. The solution was stirred for 40 min at room temperature, neutralized with 2 M HCl (150 mL), and extracted with ether (3 × 50 mL). The organic phase was dried ($MgSO_4$) and concentrated to yield a residue that was subject to silica gel flash chromatography using EtOAc/hexanes (1:9). The desired product was isolated as a colorless solid. Yield 56%; mp 78 °C. ^1H NMR ($CDCl_3$): δ 0.00 (s, 12H, $Si(CH_3)_2$), 0.07 (s, 6H, $Si(CH_3)_2$), 0.92(s, 18H, $C(CH_3)_3$), 1.01 (s, 9H, $C(CH_3)_3$), 1.92−1.96 (m, 2H, CH_2), 2.36 (t, J = 8.0 Hz, 2H, CH_2), 2.63 (t, J = 8.0 Hz, 2H, CH_2), 4.68 (s, 4H, CH_2), 7.16 (s, 2H, Ar−H). ^{13}C NMR ($CDCl_3$): δ 0.00, 18.4, 18.8, 26.0, 26.1, 26.2,

Scheme 3

33.3, 34.6, 60.6, 125.9, 131.5, 134.1, 146.2, 179.7. HRMS (FAB): calcd for $C_{30}H_{58}O_5Si_3$ $(M)^+$ 582.3592, found 582.2138.

4-[4′-*tert*-Butyldimethylsilyloxy-3′,5′-bis(acetoxymethyl)phenyl]butanoic Acid (11a). Solid ferric chloride (0.030 g, 0.19 mmol) was added to a stirred suspension of **10a** (0.33 g, 0.57 mmol) at 0 °C. The reaction mixture was maintained at this temperature and stirred for 0.5 h before adding ice-cold water (100 mL). This mixture was extracted with ether (3 × 10 mL). The organic layer was evaporated, and the residue was suspended in water (50 mL). This was extracted with hexanes (3 × 10 mL). The organic phase was dried with $MgSO_4$ and concentrated under reduced pressure. The resulting residue was subjected to silica gel column chromatography using EtOAc:hexanes (1:9), and the desired product (viscous oil) was isolated in 81% yield. ^{1}H NMR ($CDCl_3$): δ 0.17 (s, 6H, $Si(CH_3)_2$), 1.00 (s, 9H, $C(CH_3)_3$), 1.89 (m, 2H, CH_2), 2.08 (s, 6H, $COCH_3$), 2.35 (t, 2H, CH_2), 2.58 (t, 2H, CH_2), 5.05 (s, 4H, CH_2), 7.09 (s, 2H, Ar−H). ^{13}C NMR ($CDCl_3$): δ 18.9, 21.0, 25.8, 26.2, 33.3, 34.1, 61.9, 126.8, 130.3, 134.6, 149.6, 171.0. HRMS (FAB): calcd for $C_{22}H_{34}O_7SiNa$ $(M + Na)^+$ 461.1972, found 461.1962.

***N*-Succinimidyl 4-[4′-*tert*-Butyldimethylsilyloxy-3′,5′-bis(acetoxymethyl)phenyl]butanoate (3).** A mixture of **11a** (0.050 g, 0.11 mmol), *N*-hydroxysuccinimide (0.048 g, 0.42 mmol), and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC) (0.080 g, 0.42 mmol) in DMF (5 mL) was stirred at room temperature for 12 h. The reaction mixture was poured into cold water (100 mL) and extracted with ether (3 × 10 mL). The organic phase was dried with $MgSO_4$, and solvent was removed at reduced pressure. The resulting residue was subjected to preparative thin-layer chromatography using EtOAc:hexanes (2:3) to afford the desired product as a viscous oil. Yield 67%. ^{1}H NMR ($CDCl_3$): δ 0.17 (s, 6H, $Si(CH_3)_2$), 1.00 (s, 9H, $C(CH_3)_3$), 2.01−2.05 (m, 2H, CH_2), 2.09 (s, 6H, $COCH_3$), 2.60 (t, J = 7.0 Hz, 2H, CH_2), 2.09 (t, J = 7.0 Hz, 8.0 Hz, 2H, CH_2), 2.83 (s, 4H, CH_2), 5.06 (s, 4H, CH_2), 7.11(s, 2H, ArH). ^{13}C NMR ($CDCl_3$): δ −3.7, 18.6, 21.0, 25.60, 25.88, 26.22, 30.23, 33.77, 61.90, 127.00, 130.30, 134.00, 149.80, 168.40, 169.10, 171.0. HRMS (EI): calcd for $C_{26}H_{37}NO_9Si$ $(M)^+$, 535.2238, found 535.2227.

6-[4′-*tert*-Butyldimethylsilyloxy-3′,5′-bis(*tert*-butyldimethylsilyloxymethyl)phenyl]hexanoic Acid (10b). This was prepared equivalently to that described for **10a** starting from **9b** (0.52 g, 2.5 mmol). Yield 44%; mp. 82 °C. ^{1}H NMR ($CDCl_3$): δ 0.06 (s, 12H, $Si(CH_3)_2$), 0.13 (s, 6H, $Si(CH_3)_2$), 0.92 (s, 18H, $C(CH_3)_3$), 1.00 (s, 9H, $C(CH_3)_3$), 1.37−1.38 (m, 2H, CH_2), 1.59−1.67 (m, 4H, CH_2), 2.32 (t, J = 8.0 Hz, 2H, CH_2), 2.56 (t, J = 8.0 Hz, 2H, CH_2), 4.67 (s, 4H, CH_2), 7.13 (s, 2H, Ar−H). ^{13}C NMR ($CDCl_3$) δ 18.4, 18.72, 24.58, 25.94, 26.02, 28.67, 30.96, 33.96, 35.21, 60.6, 125.8, 131.2, 135.3, 179.7. HRMS (FAB): calcd for $C_{32}H_{61}O_5Si_3$ $(M - H)^-$ 609.3827, found 609.3826.

6-[4′-*tert*-Butyldimethylsilyloxy-3′,5′-bis(acetoxymethyl)phenyl]hexanoic Acid (11b). This was prepared equivalently to that described for **11a** starting from **10b** (025 g, 041 mmol). Yield 69% (viscous oil). ^{1}H NMR ($CDCl_3$): δ 0.18 (s, 6H, $Si(CH_3)_2$), 1.01 (s, 9H, $C(CH_3)_3$), 1.38−1.42 (m, 2H, CH_2), 1.57−1.71 (m, 4H, CH_2), 2.06 (s, 6H, $OCOCH_3$), 2.44 (t, J = 7.0, J = 8.0 Hz, 2H, CH_2), 2.54 (t, J = 8.0 Hz, 2H, CH_2), 5.06 (s, 4H, CH_2), 7.08 (s, 2H, Ar−H). ^{13}C NMR ($CDCl_3$): δ -3.8, 18.6, 21.0, 22.1, 23.9, 24.4, 25.8, 28.4, 30.9, 34.7, 35.0, 61.9, 126.6, 130.2, 135.7, 149.4, 169.2, 170.9. Polyamide−Quinone Methide Conjugate (5). A solution of *N*-succinimidyl-3-[4′-*tert*-butyldimethylsilyloxy-3′,5′-bis(acetoxymethyl)phenyl]propionate **2** (10 mg, 19 μmol) in CH_3CN (100 μL) was added to a solution of ImPy-β-ImPy-(R)γ-ImPy-β-ImPy-β-Dp (4 mg, 3 μmol) in DMF (320 μL). Reaction was initiated by addition of DIEA (200 μL) and stirred for 10 min at room temperature. The desired product was purified by preparative HPLC using a solvent gradient of 25% CH_3CN:0.1% (v/v) aq TFA to 50% CH_3CN:0.1% (v/v) aq TFA over 40 min (5 mL/min). Solvent was removed by lyophilization to yield a white powder (0.3 mg, 6%). This yield was measured by A_{306} based on the extinction coefficient of the polyamide-chlorambucil conjugate **1** (69 500 M^{-1} cm^{-1}) (*22*). LRMS (electrospray) *m/z* calcd for $C_{83}H_{111}N_{26}O_{18}Si$ $(M + H)^+$ 1787.8, found 1787.7.

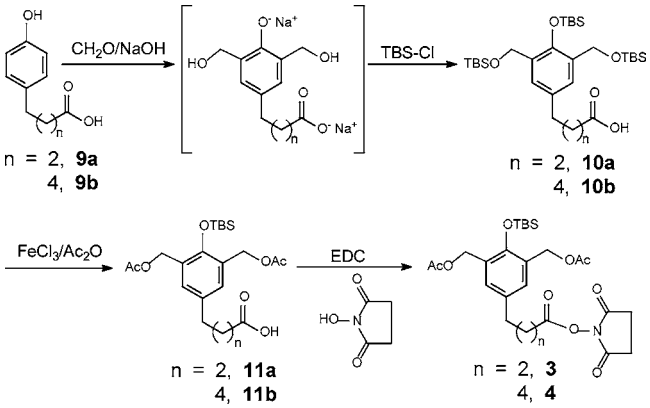
Polyamide−Quinone Methide Conjugate (6). This product was prepared equivalently to that described for conjugate **5** starting from **3** (4 mg, 8 μmol). Yield 3%;

LRMS (electrospray) *m*/*z* calcd for $C_{84}H_{113}N_{26}O_{18}Si$ $(M + H)^+$ 1801.8, found 1801.7.

Polyamide−Quinone Methide Conjugate (7). This product was prepared equivalently to that described for conjugate **5** starting from **4** (4 mg, 8 μmol). Yield 2%; LRMS (electrospray) *m*/*z* calcd for $C_{86}H_{117}N_{26}O_{18}Si$ $(M + H)^+$ 1829.8, found 1829.5.

DNA Preparation and Analysis. Oligonucleotides were synthesized by Invitrogen Life Technologies (Rockville, MD) and purified by gel electrophoresis under standard conditions (*39*). Oligonucleotides were labeled at their 5′ terminus with [γ-^{32}P]-ATP (New England Biolabs, Beverly, MA) as directed by the supplier. Typically, a 5′-[^{32}P] radiolabeled oligonucleotide (100 pmol, 640 nCi), its unlabeled equivalent (200 pmol), and its complementary strand (330 pmol) were annealed in a solution of Tris (20 mM, pH 7) by placing the mixture (total volume 200 μL) in a microfuge tube. The tube was placed in a water bath (90° C), and the bath and the tube were allowed to cool to room temperature over 3−4 h to afford a 2 μM solution of labeled duplex DNA.



DNA Alkylation and Cross-Linking by Polyamide Conjugates. Typically, 10 μL of the DNA solutions described above (2 μM, 20 mM Tris, pH 7) were mixed with water (2 μL) and a 15% aqueous acetonitrile solution (4 μL) of conjugate **1**, **5**, **6**, **7**, or **8** (15 μM) in a microfuge tube. After addition of 4 μL of a salt solution (15 mM NaCl, 10 mM $MgCl_2$, 5 mM $CaCl_2$, ± 5 mM NaF), the resulting mixture (20 μL, 10 mM Tris, pH 7) of DNA (1 μM), reactant (3 μM), and salts (3 mM NaCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, ± 1 mM NaF) was incubated (37 °C) for 12 h. Aliquots (3 μL) were removed from the reaction mixtures and combined with a formamide loading solution (10 μL, 0.05% bromophenol blue and 0.05% xylene cyanol FF) and analyzed by 20% polyacrylamide (19:1 acrylamide:bisacrylamide) gel electrophoresis under denaturing conditions (8 mM urea). DNA was detected and analyzed by phosphoimagery.

RESULTS AND DISCUSSION

Design and Synthesis of the Quinone Methide Precursors and Their Conjugates. A bis-functional precursor designed for cross-linking DNA through sequential formation of two quinone methide intermediates had previously been coupled to an acridine derivative and a triplex-forming oligonucleotide for delivery to the major groove (Scheme 2) (*35*, *40*). This same precursor has now also been attached to a pyrrole-imidazole polyamide for its complementary delivery to the minor groove. This new conjugate additionally allowed for comparison to a related derivative prepared previously by Wurtz and Dervan containing the N-mustard chlorambucil (**1**) (*22*) (Scheme 3). This original conjugate was designed to bind in the minor groove of helical DNA containing 5′-(A/T)GC(A/T)GC(A/T)-3′ and cross-link neighboring sequences with its N-mustard attached to a central γ-aminobutyric acid (*22*). Synthesis of the polyamide was first accomplished by manual solid-phase synthesis (*22*, *38*) and repeated in our laboratory in comparable yield. The N-mustard was also coupled to this polyamide as described by Wurtz and Dervan (*22*).

Coupling between the available quinone methide precursor **2** and the polyamide yielded a conjugate (**5**) that contained one less methylene unit in its linker than **1** (Scheme 3). Consequently, a series of additional quinone methide precursors were also prepared to more closely mimic the distance between the polyamide and its attached N-mustard in **1**. First, the alkyl chain connecting the polyamide and quinone methide precursor was extended by one carbon (**6**) to match the distance between the polyamide and aromatic ring of chlorambucil. Second, a longer extension (**7**) was generated to approach more closely the 11-atom distance between the polyamide of **1** and the site of nucleophilic addition by DNA on the N-mustard. In all cases, the linkers provided conformational flexibility for sampling numerous sites of potential reactivity. A contrasting analogue containing a conjugated vinyl linker was additionally prepared (**8**) as described previously (*37*) since this type of linkage had demonstrated great effectiveness in other polyamide conjugates (*16*, *41*, *42*).

Scheme 4

The activated esters **3** and **4** used for coupling to the polyamide were constructed using the same strategy developed for the original bis-functional quinone methide precursor **2** (*35*). The starting material **9a** was formed by demethylation of 4-(4′-methoxyphenyl)butyric acid, and **9b** was obtained from a Friedel−Craft acylation of phenol by monomethyl adipoyl chloride and subsequent Clemmensen reduction (*43*, *44*). These materials were hydroxymethylated with formaldehyde under basic conditions and then silylated with *tert*-butyldimethylsilyl chloride (TBS-Cl) under standard conditions to yield **10a**,**b** (Scheme 4) (*35*). The benzylic positions were selectively substituted with acetate by treatment with acetic anhydride and $FeCl_3$ (*45*), and finally the carboxylic acids were converted to their *N*-hydroxysuccinimide esters **3** and **4** in the presence of EDC. These activated esters were condensed with the polyamide in a mixture of CH_3CN, DMF, and DIEA to yield the desired conjugates capable of generating quinone methide intermediates. Analysis by reverse phase (C-18) HPLC indicated that all polyamide amine was consumed in the presence of the *N*-hydroxysuccinimide esters within 1 h and more than 50% had already reacted within the first 10 min. This analysis also indicated that the conjugate formed in yields of up to 65%. However, product recovery after reverse-phase chromatography was quite low and suggested problems with the final steps of isolation. This method of purification still generated sufficient material for the studies below, and consequently these procedures were not optimized. The molecular weights of each conjugate were confirmed by electrospray mass spectroscopy.

Alkylation and Cross-Linking of a Target DNA Using N-Mustard and Quinone Methide Conjugates. The original N-mustard chlorambucil conjugate **1** was targeted for selective reaction on either side of the TATA box of a HIV promoter and tested with a restriction fragment of DNA that offered a range of sequence variants (*22*). Indeed, the predicted sites were alkylated

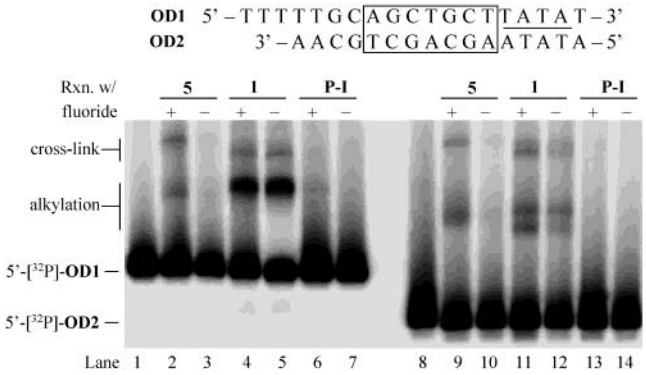


Figure 1. Alkylation and cross-linking of DNA by pyrrole-imidazole polyamide conjugates. 5′-[^{32}P]-**OD1** (30 nCi, 1.0 μM) and **OD2** (1.1 μM) (lane 1) or 5′-[^{32}P]-**OD2** (30 nCi, 1.0 μM) and **OD1** (1.1 μM) (lane 8) were incubated for 12 h (37 °C) in a solution of 5% aqueous acetonitrile (3 mM NaCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, 10 mM Tris, pH 7) in the added presence of conjugate **5** (10 μM, lanes 2, 3, 9, and 10), conjugate **1** (10 μM, lanes 4, 5, 11, and 12), or the polyamide ImPy-β-ImPy-(R)γ-ImPy-β-ImPy-β-Dp (**P**−**I**) (10 μM, lanes 6, 7, 13, and 14). Reactions were alternatively incubated in the presence of fluoride (1 mM NaF, lanes 2, 4, 6, 9, 11, and 13) or in its absence (lanes 3, 5, 7, 10, 12, and 14). The yields of alkylation and cross-linked products were determined relative to the total material per experiment.

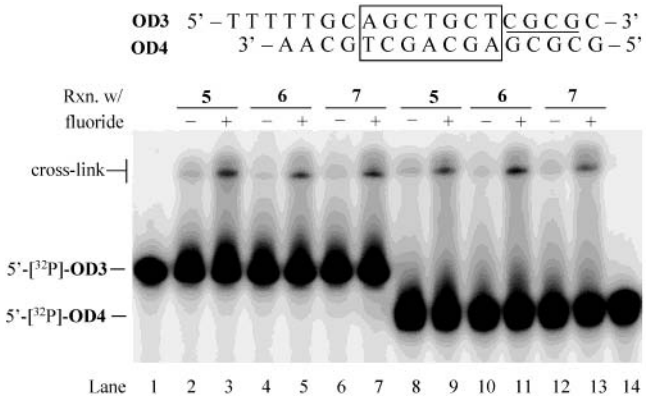

Figure 2. The effect of varying the linker length between a quinone methide precursor and its attached pyrrole-imidazole polyamide on the efficiency of DNA cross-linking. 5′-[^{32}P]-**OD3** (30 nCi, 1.0 μM) and **OD4** (1.1 μM) (lane 1) or 5′-[^{32}P]-**OD4** (30 nCi, 1.0 μM) and **OD3** (1.1 μM) (lane 14) were incubated for 12 h (37 °C) in a solution of 5% aqueous acetonitrile (3 mM NaCl, 2 mM $MgCl_2$, 1 mM $CaCl_2$, 10 mM Tris, pH 7) in the added presence of conjugate **5** (3 μM, lanes 2, 3, 8, and 9), conjugate **6** (3 μM, lanes 4, 5, 10, and 11), or conjugate **7** (3 μM, lanes 6, 7, 12, and 13). Reactions were alternatively incubated in the absence of fluoride (lanes 2, 4, 6, 8, 10, and 12) or in its presence (1 mM NaF, lanes 3, 5, 7, 9, 11, and 13). The yields of alkylation and cross-linked products were determined relative to the total material per experiment.

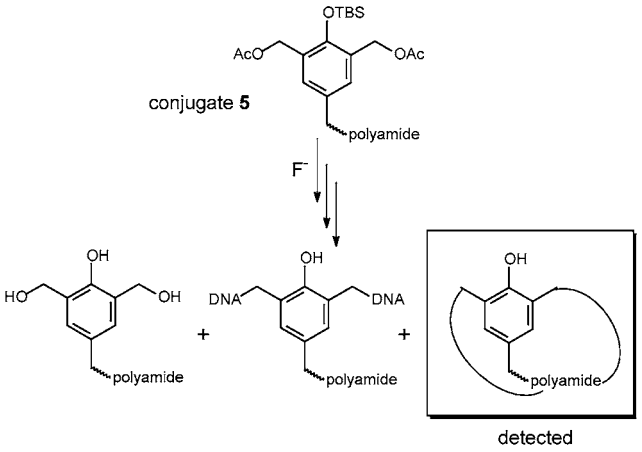
with greatest efficiency as expected for minor groove recognition. One of these sites has now been reproduced in the model formed by **OD1**·**OD2** to focus on the relative efficacy of alkylation by the contrasting electrophiles of a N-mustard and quinone methide. The length of **OD1** was extended beyond that of **OD2** to allow for easy differentiation of products formed by monoalkylation and interstrand cross-linking (bis-alkylation) using gel electrophoresis. Attempts to utilize the same ionic conditions as first reported by Wurtz and Dervan (*22*) led to precipitation after either KF or NaF (10 mM) was added to initiate quinone methide formation. Dilution of the NaCl (3 mM), $MgCl_2$ (2 mM), $CaCl_2$ (1 mM) and NaF (1 mM) was sufficient to avoid detectable precipitation. The initial precipitate was most likely due to the limited solubility of CaF_2. Although polyamides also exhibit low solubility, the conjugates described here appear to remain in solution at concentrations below 10 μM.

The chlorambucil- and quinone methide-containing conjugates **1** and **5** both yielded strand alkylation and cross-linking. Alkylation resulted in products that migrated in a strand specific manner (**OD1** vs **OD2**) and cross-linking resulted in a product that migrated equivalently regardless of which strand was labeled (Figure 1). Consistent with the mechanisms of each conjugate, fluoride was required to initiate reaction of the quinone methide precursor (Figure 1, lanes 2 and 9 vs lanes 3 and 10) whereas fluoride was not required for the N-mustard conjugate **1** (Figure 1, lanes 4, 5, 11, and 12). The slowly migrating products in both cases appear dependent on the reactive appendages since the polyamide alone did not generate equivalent species (Figure 1, lanes 6, 7, 13, and 14). Additionally, no reaction was detected when conjugate **5** was incubated with a DNA duplex formed by 5′-TTTTGCAGGTGGTGCCGC-3′ and a complementary strand that lacked the optimal sequence for polyamide recognition in the minor groove (5′-(A/T)GC(A/T)GC(A/T)-3′).

The expected site of reaction within **OD1**/**OD2** (*22*), 5′...TATA...3′/3′...ATAT...5′ adjacent to the polyamide binding site does not offer the preferred nucleophile for either a N-mustard or quinone methide. The intrinsic specificity of chlorambucil lacking a site-directing ligand is the N7 group of guanosine located in the major groove (*46*). Likewise, the most commonly reported adduct of simple quinone methides form with the 2-amino group of guanosine in the minor groove (*26*, *30*, *34*). Still, the N-mustard had been shown to alkylate the N3 position of A when held in the minor groove (*22*). Alkylation of the duplex by conjugate **1** proceeded in a yield of ∼18% for one strand (**OD1**, Figure 1, lanes 4 and 5) and ∼10% for the other (**OD2**, Figure 1, lanes 11 and 12). Cross-linking was less efficient (∼4%) but still detectable (Figure 1, lanes 4, 5, 11, and 12). The conjugate **5** containing the quinone methide precursor also reacted with this DNA after addition of fluoride and produced cross-linked DNA in a yield equivalent to that of the N-mustard (4%, Figure 1, lanes 2 and 9 vs 4, 5, 11 and 12). In contrast, strand alkylation by the quinone methide conjugate proceeded in only 5% and 8% yields for **OD1** and **OD2**, respectively (Figure 1, lanes 2 and 9). The DNA products formed by conjugate **1** generated strand fragmentation at A16 of **OD1** and A6 of **OD2** after heat treatment as expected for alkylation at their N3 positions (*22*). In contrast, no fragmentation was observed after comparable treatment of the DNA products formed by conjugate **5**. This suggests that reaction of the quinone methide may instead have involved the 2-amino group of G residues within the recognition site of the polyamide.

The efficiency of quinone methide-dependent cross-linking was next examined with an alternative DNA (**OD3/OD4**, Figure 2) that retained the polyamide recognition sequence but contained 5′-CGCG-3′ as a new target for reaction. This change placed a 2-amino of G proximal to the bound conjugate and supplied the preferred sequence (5′-CG-3′) for cross-linking in the minor groove by a quinone methide-like intermediate formed by mitomycin (*24*). Previously, the quinone methide precursor within conjugate **5** had been directed to the major groove by attachment to an acridine ligand with great success (*35*) although a related conjugate based on a triplex-forming oligonucleotide exhibited only modest activity (*40*). The major site of reaction, the N7 of G,



forms a reversible adduct. Alternative delivery of the quinone methide to the minor groove was expected to support high levels of reaction due to the potential advantages of localizing the quinone methide proximal to the 2-amino group of guanosine that generates a stable adduct irreversibly (*30*, *31*). Surprisingly, the quinone methide conjugate **5** also cross-linked its new target **OD3/OD4** with a low yield (~5%) and did not generate monoalkylation products detectably (Figure 2, lanes 3 and 9).

Many parameters could have impeded activity of the polyamide conjugate including the length and flexibility of the linker. While a long molecular spacer may allow access to many potential sites of reaction, the principle conformers of the spacer may not necessarily coincide with those most reactive. In contrast, a short and restricted spacer may stabilize a single conformer, but this may or may not necessarily represent the most reactive alignment. Certainly, the various linkers used for attaching N-mustards to ligands such as acridine (*47*) and triplex-forming oligonucleotides (*40*, *48*) dramatically affected target alkylation, and hence additional quinone methide conjugates were prepared for more precise comparison with the related polyamide−N-mustard conjugate **1**. The quinone methide conjugate **5** was extended by one carbon unit to form conjugate **6** containing the same four carbon link to the aromatic ring as that in the original N-mustard conjugate **1**. Another quinone methide conjugate **7** was prepared to mimic more closely the 11 atom spacing between the sites of ligand attachment and DNA alkylation of **1**. Surprisingly, neither change effected the apparent activity of the attached quinone methide. Conjugates **6** and **7** both cross-linked **OD3/OD4** in low yield (3−6%) and no monoalkylated derivatives were apparent in either case (Figure 2).

A short and rigid acrylamide linker has also been used to join various reactive appendages to the termini of distamycin-like ligands (*16*, *41*, *42*). The successes achieved with this design prompted construction of an equivalent quinone methide derivative (**8**) linked to the hairpin rather than terminal region of the polyamide as used previously (*37*). However, incubation of conjugate **8** under conditions equivalent to those used for conjugates **1** and **5**−**7** generated no observable alkylation or cross-linking of **OD3/OD4** (data not shown). This may reflect a decrease in the stability of the TBS-protected precursor relative to its saturated derivative **5** (*37*). Alternatively, the modest activity of the pyrrole-imidazole polyamide conjugates **5**−**7** and even the lack of reaction of **8** might instead have originated from a common characteristic shared by all of these quinone methide derivatives.

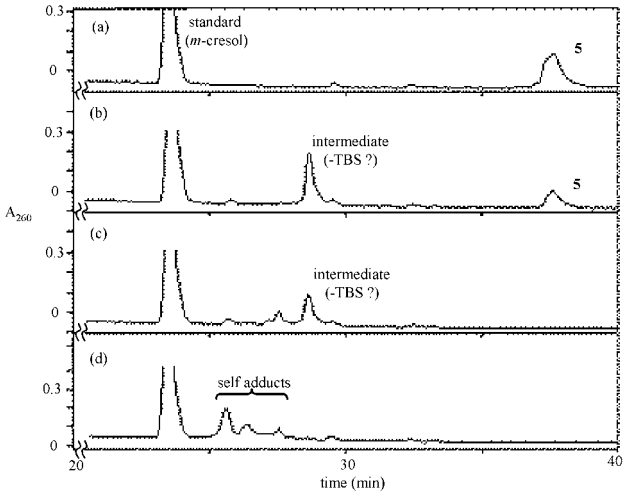
Intramolecular Trapping of the Quinone Methide Limits Its Reaction with DNA. Quinone methide intermediates are highly unstable and have the potential to react with a range of nucleophiles including those present in the attached site-directing ligand. Such intramolecular trapping would typically suppress reaction with the intended target, but the reversible nature of the quinone methide self-adducts formed with DNA allows subsequent transfer of the reactive intermediate from an intra- to intermolecular position (*36*). This process of reversible intramolecular trapping now serves a very beneficial role in an appealing new strategy for target promoted alkylation. The nucleophilic groups of the polyamide like those of DNA may also form intramolecular adducts with the attached quinone methide. Whether reaction with the polyamide suppresses or maintains target selective alkylation of DNA depends on the reversibility of possible self-adducts. The lack of efficient cross-linking and alkylation of DNA by the conjugates

Scheme 5

5−**8**, however, began to suggest that intramolecular adducts were forming and not capable of regenerating the quinone methide.

Reaction between the quinone methide of conjugate **5** and its pyrrole-imidazole polyamide were consequently examined by HPLC and electrospray mass spectrometry in a manner equivalent to that used to detect the self-adducts of an oligonucleotide−quinone methide conjugate (*36*). Within 12 h, conjugate **5** was completely consumed in the presence, but not absence, of 10 mM KF under neutral conditions, and several new products were detected by HPLC. Each exhibited a *m*/*z* of 1554 which is consistent with loss of the silyl protecting group and substitution of both benzylic acetate groups with internal nucleophiles. No additional products were indicated by mass spectroscopy including no ions consistent with a single intramolecular substitution and addition of one water (*m*/*z* 1572), addition of two waters (*m*/*z* 1590), or other possible products (Scheme 5) (Supporting Information). HPLC-MS analysis was also repeated using very high concentrations of fluoride (1 M KF) in order to monitor the deprotected quinone methide precursor (− TBS) and its transformation to the self-adducts (Figure 3). Under these conditions, ~60% of conjugate **5** converted within 50 s to a transient intermediate that is consistent with its deprotected derivative. Within 5 min, signals of the self-adducts appeared and by 60 min the profile of self-adducts remained constant. Self-adduct formation within the polyamide conjugate occurred much more rapidly than that observed for related oligonucleotide conjugates (*36*). Both types of conjugates appear to form a diversity of self-adducts that likely result from reaction with various nucleophiles along the attached DNA ligand.

Generation of self-adducts of conjugate **5** would not necessarily preclude subsequent reaction with a target DNA as long as the adducts formed reversibly and the polyamide self-adducts could still recognize the target DNA. Conformational constraints created by intramolecular nucleophilic addition are likely to inhibit selective binding but affinity should be regained upon quinone methide regeneration. Without such regeneration, neither binding nor alkylation of DNA would likely be possible. First, the stability of the polyamide self-adducts in the presence of a stoichiometric concentration of duplex DNA (0.3 μM, **OD3/OD4**) was monitored over 3 days. No change in the profile or quantity of self-adducts was detected by HPLC, and concurrently no alkylation or cross-linking of DNA was detected by gel electrophoresis. Next, the self-adducts were incubated in the presence of



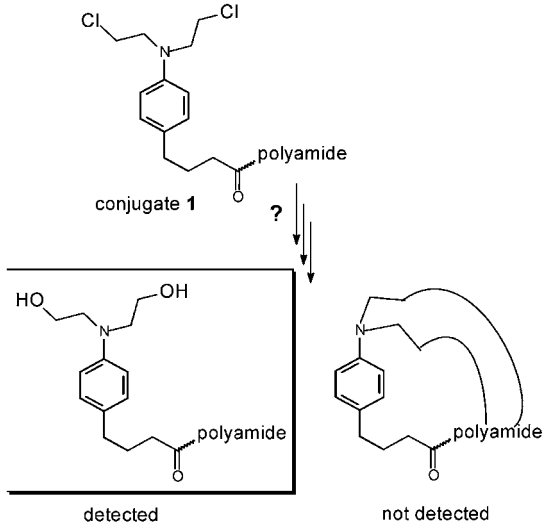


Figure 3. Formation of self-adducts from a quinone methide containing conjugate based on **5**. (a) Reaction of conjugate **5** in MES (10 mM, pH 7) and 16% acetonitrile was initiated by addition of KF (1.0 M) in the presence of a chromatographic standard *m*-cresol. Product formation was then monitored after (b) 50 s, (c) 5 min, and (d) 60 min by reverse phase (C-18) chromatography using a gradient of 5% to 70% acetonitrile in 0.1% aq TFA over 45 min at 1 mL/min.

Scheme 6

10 mM β-mercaptoethanol for 24 h, and again these adducts appeared inert. Thus, the polyamide self-adducts seem to form irreversibly and in high yield at the expense of DNA alkylation. The nonmethylated imidazole nitrogens most likely participate in self-adduct formation. This functional group is quite nucleophilic but does not exhibit a leaving group ability that is comparable to the functional groups of DNA already known to form quinone methide adducts reversibly (*31*, *33*, *34*).

N-Mustards have the potential to undergo reversible nucleophilic substitution as well, although such observations were not found in the literature. Accordingly, self-adduct formation by the polyamide−mustard conjugate **1** was investigated. Little consumption of conjugate **1** was observed after a 4 h incubation in the absence of **OD3/OD4**, and no self-adduct was detected in the presence or absence of this DNA (Supporting Information). However, ca. 60% of conjugate **1** was consumed in the presence of DNA over an equivalent period. This result can be attributed to DNA alkylation as evident by the change in chromatographic signals assigned to the DNA and hydrolysis of the dichloro mustard to its hydrolyzed diol product (Supporting Information). Thus, DNA appears to promote alkylation by and hydrolysis of the mustard containing conjugate without formation of self-adducts (Scheme 6).

CONCLUSION

The target selectivity of a quinone methide designed for cross-linking DNA was enhanced after its conjugation to a pyrrole-imidazole polyamide (*35*, *49*). However, reaction efficiency was only mildly enhanced. Yields of DNA cross-linking by the polyamide conjugates **5**−**7** were greater than similar reaction of the nonconjugated derivative at 20-fold higher concentration but still much lower than that of an acridine conjugate. The length of the linker used to attach the quinone methide to the polyamide did not affect target reaction in a significant manner. Instead, the conjugates were controlled by a dominant and irreversible formation of self-adducts by intramolecular nucleophilic addition to the transient quinone methide. A similar process was also suggested to explain a decrease in activity of mitomycin C when linked to an increasing number of *N*-methylpyrrole units (*14*). The propensity for generating intramolecular self-adducts will become advantageous rather than detrimental for target-directed alkylation once such self-adducts can be designed to form reversibly. Under these conditions, reaction selectivity, and efficiency can be achieved through a target-promoted mechanism (*36*)

ACKNOWLEDGMENT

We thank Drs. Qingping Zeng and Praveen Pande for their initial efforts on related bioconjugates. This research was supported in part by the National Institutes of Health (CA-81571).

TECHNICAL NOTES

Carbohydrate Conjugates for Molecular Imaging and Radiotherapy: ^{99m}Tc(I) and ^{186}Re(I) Tricarbonyl Complexes of *N*-(2′-Hydroxybenzyl)-2-amino-2-deoxy-D-glucose

Simon R. Bayly,[†,‡] Cara L. Fisher,[†,‡] Tim Storr,[†] Michael J. Adam,*[,‡] and Chris Orvig*[,†]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, British Columbia, V6T 1Z1, Canada, and TRIUMF, 4004 Wesbrook Mall, Vancouver, British Columbia, V6T 2A3, Canada. Received January 26, 2004; Revised Manuscript Received April 28, 2004

An approach to a new class of potential radiopharmaceuticals is demonstrated by the labeling of a glucosamine derivative with the tricarbonyls of ^{99m}Tc and ^{186}Re. The proligand H**L²** (*N*-(2′-hydroxybenzyl)-2-amino-2-deoxy-d-glucose) was produced by hydrogenation of the corresponding Schiff base and reacted with $[NEt_4]_2[Re(CO)_3Br_3]$ to form the neutral complex $[(\mathbf{L^2})Re(CO)_3]$ in 40% yield. ^{1}H and ^{13}C NMR spectra indicate that the $\{Re(CO)_3\}$ core is bound in a tridentate fashion via the amino N, phenolato O, and C-3 hydroxyl O atoms of the ligand. At the tracer-level, labeling of H**L²** with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ and $[^{186}Re(CO)_3(H_2O)_3]^+$ was achieved in aqueous conditions in 95 ± 2% and 94 ± 3% average radiochemical yields, respectively.

INTRODUCTION

2-[^{18}F]-Fluoro-2-deoxy-D-glucose (FDG) is the preeminent radiotracer used in positron emission tomography (*1*). Because the production of ^{18}F requires a cyclotron and the isotope has a short (110 min) half-life, its utility is somewhat limited compared to that of single photon emitters in nuclear medicine. By comparison, ^{99m}Tc, the isotope most commonly used in single photon emission computed tomography (SPECT), is produced in the form of $Na^{99m}TcO_4$ from a ^{99}Mo generator; hence, it is widely available and relatively inexpensive (*2*). The third row transition metal analogue of technetium, rhenium, has similar chemistry to that of technetium and has particle-emitting radioisotopes with physical properties applicable to therapeutic nuclear medicine (*3*). For these reasons, we seek a ^{99m}Tc SPECT tracer that will mimic the biodistribution of FDG and the therapeutic potential of the analogous rhenium compounds. Our approach is to attach to glucose a chelating ligand that, in a subsequent reaction, will bind the radioisotope ^{99m}Tc or $^{186/188}$Re. A metal-chelate could be preformed and then attached to glucose. To mimic the properties of FDG it is imperative that the effects of the tracer group on the properties of the glucose molecule are minimized. Existing ^{99m}Tc labeled glucose derivatives fail this criterion: they are either ionic or have relatively high molecular weight (i.e. carry two glucose moieties) (*4*).

We elected to use the versatile low valent *fac*-$\{M(CO)_3\}$ core (M = ^{99m}Tc^{I} or ^{186}Re^{I}), whose recent chemistry has been pioneered by Alberto and co-workers (*5*). The facially coordinated carbonyl ligands stabilize the Tc +1 oxidation state, obviating the elaborate, often macrocyclic, polydentate structures required to stabilize other intermediate oxidation states of Tc and Re. In neutral complexes with simple N,O donors the *fac*-$\{M(CO)_3\}$ core possesses intermediate lipophilicity, an advantage in living systems (*6*).

Glucosamine (2-amino-2-deoxy-D-glucose) is a highly attractive scaffold for a glucosyl ligand, because the amine acts both as a potential coordination site and as a useful target for further functionalization. Furthermore, there is much evidence in the literature to suggest that N-functionalized glucosamines show activity with GLUTs (glucose transporters) and hexokinase—the enzymes that are most closely associated with the metabolism of FDG—even when the functional group is large (*7*).

EXPERIMENTAL PROCEDURES

All solvents and chemicals (Fisher, Aldrich) were reagent grade and used without further purification unless otherwise specified. H**L¹** (*8*) and $[NEt_4]_2[Re(CO)_3Br_3]$ (*9*) were prepared according to previously published procedures. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AV-400 instrument at 400.132 and 100.623 MHz, respectively. Assigned chemical shifts for the compounds prepared are recorded in Table 1. Mass spectra (+ ion) were obtained on dilute methanol solutions using a Macromass LCT (electrospray ionization, ESI). Elemental analyses were performed at the University of British Columbia Chemistry Department by Mr. M. Lakha (Carlo Erba analytical instrumentation). HPLC analyses were performed on Knauer Wellchrom K-1001 HPLC equipped with a K-2501 absorption detector, a Kapintek radiometric well counter, and a Synergi 4 μm C-18 Hydro-RP analytical column with dimensions 250 × 4.6 mm. HPLC solvent consisted of 0.1% trifluoroacetic acid in water (solvent A) and acetonitrile (solvent B). Samples were analyzed with a linear gradient method (100% solvent A to 100% solvent B over 30 min).

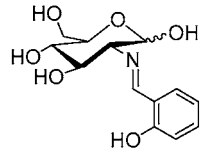
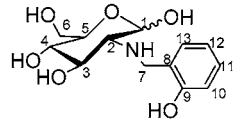
Synthesis. *N-(2′-Hydroxybenzyl)-2-amino-2-deoxy-*D*-glucose (H**L**^{2}).* H**L**^{1} (1.00 g, 3.53 mmol) was dissolved in MeOH (60 mL), and 10% Pd/C w/w (50 mg) was added. The mixture was stirred under a pressurized H_2 atmosphere (50 bar) for 24 h. The reaction mixture was clarified by filtration and the solvent evaporated to give H**L**^{2} (0.98 g, 98%). ESI-MS: 286 ([M + H]$^+$). Anal. Calcd for $C_{13}H_{19}NO_6 \cdot H_2O$: C, 51.48; H, 6.98; N, 4.62. Found: C, 51.50; H, 6.81; N, 4.60.



*Tricarbonyl(N-(2′-Hydroxybenzyl)-2-amino-2-deoxy-*D*-glucose)rhenium(I) (Re**L**^{2}(CO)$_3$).* [NEt$_4$]$_2$[Re(CO)$_3$Br$_3$] (200 mg, 0.26 mmol), H**L**^{2} (74 mg, 0.26 mmol), and sodium acetate trihydrate (40 mg, 0.32 mmol) were dissolved in H_2O (7 mL) and heated with stirring to 50 °C for 2 h. The solvent was then removed in vacuo and the residue dissolved in CH_2Cl_2 (10 mL) for 30 min. On standing, a brown residue was recovered by decanting off the solvent. This was purified to an off-white powder (58 mg, 0.10 mmol, 40%) by column chromatography (silica, 5:1CH_2Cl_2:CH_3OH). ESI-MS: 556, 554 ([M + H]$^+$), 578, 576 ([M + Na]$^+$). Anal. Calcd for $C_{16}H_{18}NO_9Re \cdot H_2O$: C, 33.57; H, 3.52; N, 2.45. Found: C, 33.55; H, 3.53; N, 2.75.

Radiolabeling. [^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ was prepared from a saline solution of Na[^{99m}TcO$_4$] (1 mL, 100 MBq) using an "Isolink" boranocarbonate kit generously donated by Mallinckrodt Inc. Due to the increased chemical inertness and lower redox potential of rhenium, [^{186}Re(CO)$_3$(H$_2$O)$_3$]$^+$ was not accessible by the kit preparation used for technetium. [^{186}Re(CO)$_3$(H$_2$O)$_3$]$^+$ was prepared by addition 4.5 μL of 85% H_3PO_4 to a saline solution of Na[^{186}ReO$_4$] (0.5 mL, 100 MBq), followed by addition of this solution to 3 mg of borane ammonia complex that had been flushed with CO for 10 min. The mixture was heated at 60 °C for 15 min and then cooled to room temperature. Labeling was achieved by mixing an aliquot of one of the above final solutions (0.5 mL) with a 1 mM solution of H**L**^{2} in PBS (pH 7.4, 1 mL) and incubating at 75 °C for 30 min.



Stability Evaluation. [(**L**^{2})^{99m}Tc(CO)$_3$(H$_2$O)] (100 μL, 10 MBq, 1 mM in H**L**^{2}) was added to 900 μL of either 1 mM histidine or 1 mM cysteine in PBS. The solutions were incubated at 37 °C and aliquots were removed at 1, 4, and 24 h, at which time HPLC analysis was run. Histidine labeling was achieved by adding a solution containing [^{99m}Tc(CO)$_3$(H$_2$O)$_3$]$^+$ to a 1 mM solution of histidine in PBS (pH 7.4, 1 mL) and incubating at 75 °C for 30 min. HPLC analysis confirmed the formation of a single radiolabeled product.

RESULTS AND DISCUSSION

The Schiff base formed by condensation of glucosamine with salicylaldehyde H**L**^{1} (Scheme 1) has been previously investigated as a ligand for transition metals, including ^{99}Tc(V) (*8*). Using the starting material [NEt$_4$]$_2$[Re(CO)$_3$Br$_3$] (*9*) as a "cold" surrogate for [M(CO)$_3$(H$_2$O)$_3$]$^+$ (M = ^{99m}Tc or ^{186}Re), we synthesized the complex [(**L**^{1})Re(CO)$_3$] (as observed by ESIMS (+)); however, both the imine and the complex are unstable to hydrolysis and proved to be unsuitable for aqueous radiolabeling chemistry.

To circumvent the hydrolysis problem, we reduced H**L**^{1} to the more hydrolytically robust amine phenol H**L**^{2} (*N*-(2′-hydroxybenzyl)-2-amino-2-deoxy-D-glucose, Scheme 1). Catalytic hydrogenation of H**L**^{1} provided H**L**^{2} in 98% yield, with sufficient purity for subsequent radiolabeling studies. The reaction of H**L**^{2} with [NEt$_4$]$_2$[Re(CO)$_3$Br$_3$] and NaOAc in H_2O produced the compound [(**L**^{2})Re(CO)$_3$] in 40% yield after column chromatographic purification. The molecular ion was identified as [((**L**^{2})Re(CO)$_3$) + H]$^+$ by ESIMS, and the formulation of the bulk sample was confirmed by elemental analysis. Comparison of the anomeric ratio (α/β) observed in the ^{1}H NMR spectrum (CD_3OD) showed a change from 1.9 for H**L**^{2} to 1.1 for the complex, indicating that complexation has decreased the difference in thermodynamic stability between the two anomers. For solubility reasons full NMR studies were carried out in DMSO-d_6 solution (Table 1). The ^{1}H NMR spectrum (DMSO-d_6) of the complex is highly convoluted, but the shifting and broadening out of the aromatic resonances compared to those of H**L**^{2} signify that the phenol "arm" participates, as desired, in the binding of the {Re^I(CO)$_3$} moiety. The splitting of the methine

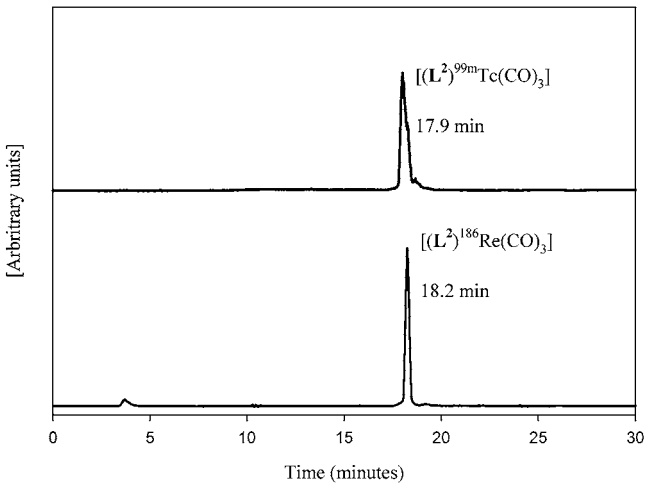

Figure 1. Radiation traces and retention times from HPLC analysis using a C18 column eluting with the gradient 100% 0.1% trifluoroacetic acid buffer to 100% acetonitrile over 30 min.

proton signals into two doublets for each anomer indicates the methine proton inequivalence on formation of the complex. Binding of the ligand N and O donor atoms incorporates the methine in a ring, rigidly holding the two protons in diastereotopic chemical environments. Signals due to the sugar C1 protons were shifted downfield in both anomers compared to those of H**L²**. Peaks due to the sugar C2 protons are also well-resolved and compared to those of H**L²** are also shifted slightly downfield in both anomers. Small extraneous peaks in the spectrum also indicate that at least one other minor species is present. When kept overnight in CD_3OD or DMSO-d_6 solution, samples of the complex become visibly brown and the relative intensities of these peaks increase, indicating that they arise from decomposition products. The signals do not correlate with the chemical shifts of uncomplexed H**L²**. Minor species are also detected by UV/visible spectroscopy in the HPLC of the complex and become more significant over time.

The $^{13}C\{^1H\}$ NMR spectrum (d_6-DMSO) of the complex was fully assigned for the α-anomer, and partially assigned for the β-anomer (Table 1). The Re carbonyls show three sharp resonances at 196−198 ppm as expected due to the lack of symmetry. In both anomers, peaks due to the phenol CO and the CH_2 linker are shifted significantly downfield from their values of H**L²**, giving a clear indication that the Re is bound both by the phenol O and glucosamine N (*10*). The C1 and C2 signals of both anomers are shifted upfield on complexation, presumably reflecting some slight conformational change in the hexose skeleton. The result of this could be destabilization of the α-anomer and hence the changed anomeric ratio compared to that of H**L²** itself. In the α-anomer the C3 signal has shifted downfield 7.4 ppm, suggesting that the C3 glucosamine hydroxyl is binding to the Re center in place of the predicted solvent molecule (*11*). Unfortunately, C3 for the β-anomer could not be assigned, due to the lower concentration of the anomer in DMSO solution. Less polar than water or methanol, DMSO is unable to stabilize the unfavorable dipole moments present in the β-anomer (*12*). It is unlikely that the stereochemistry at C1 can have any effect on the geometry-dependent propensity of the C3 hydroxyl to coordinate to Re, thus both anomers are predicted to bind Re in a similar tridentate manner.

Labeling H**L²** with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ and $[^{186}Re(CO)_3(H_2O)_3]^+$ was achieved in 95 ± 2% and 94 ± 3% average radiochemical yields, respectively, as measured by HPLC (Figure 1). The identities of the radiolabeled complexes were confirmed to be $[(\mathbf{L^2})^{99m}Tc(CO)_3]$ (t_R = 17.9 min) and $[(\mathbf{L^2})^{186}Re(CO)_3]$ (t_R = 18.2 min) by coinjection of the radiolabeled product with the authentic "cold" Re complex (t_R = 17.9 min.). To make a preliminary assessment of the potential in vivo stability of the ^{99m}Tc complex, cysteine/histidine challenge experiments were performed. In a typical test, the radiolabeled complex was incubated at 37 °C in aqueous phosphate buffer solution (pH 7.4) containing either 1 mM cysteine or 1 mM histidine, and aliquots were removed at 1, 4, and 24 h (Table 2). HPLC analysis showed the complex to be stable in either histidine or cysteine solution but only in the short term; by 4 h, less than 30% of the complex remained intact. Histidine-labeled $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was determined to be the major decomposition product of the histidine challenge experiments. The complex instability may be due to the relatively weak binding ability of the donor atoms, especially the secondary amino group and the carbohydrate hydroxyl. When considering modifications to increase complex stability, the fortuitous tridentate binding has directed us to investigate purposely tridentate ligands, and those containing binding groups with higher affinities for the soft $\{M(CO)_3\}$ center.

Table 2. Percentage of $[(L^2)^{99m}Tc(CO)_3]$ Remaining after Incubation at 37 °C in 1 mM Cysteine or Histidine for 1, 4, and 24 h

	% of $[(L^2)^{99m}Tc(CO)_3]$ remaining		
	1 h	4 h	24 h
incubation in cysteine	88	28	not detected
incubation in histidine	50	24	4

In summary, neutral, low molecular weight ^{99m}Tc- and ^{186}Re-labeled carbohydrate complexes were produced in high radiochemical yield from a simple functionalized glucosamine. H**L²** is in trials as a ligand for $^{62/64}Cu$ and $^{67/68}Ga$, and other carbohydrate-containing ligands for ^{99m}Tc and $^{186/188}Re$ are under study.

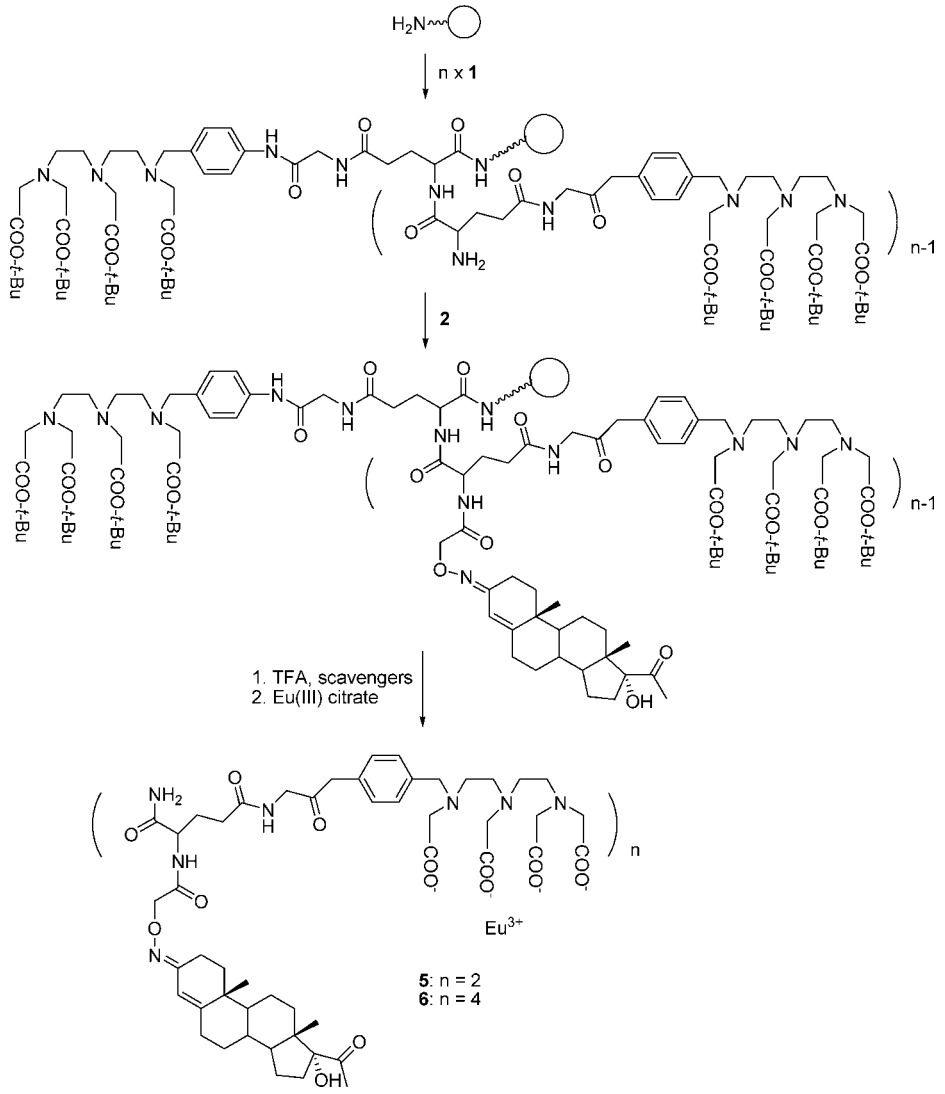
Up to four tetra-*tert*-butyl-1-[4-aminoacetamido)benzyl]diethylenetriaminetetrakis(acetato) derivatives of Fmoc glutamic acid (**1**) were attached to two steroids (17α-hydroxyprogesterone-3-*O*-carboxymethyloxime **2** and 1,3,5(10)-estratriene-3,16α,17*β*-triol-6-one-6-*O*-carboxymethyloxime, **3**)) on solid phase using an oligopeptide synthesizer. Upon deprotection and conversion to the corresponding europium(III) chelates, these steroid conjugates were used in DELFIA-based competitive fluoroimmunoassays. The more chelates conjugated to 17-α-hydroxyprogesterone, the more diluted antiserum could be used in an immunoassay for 17-α-hydroxyprogesterone, without any alteration of the measurement range. Hence, 17-α-hydroxyprogesterone tracers with several chelates are useful when a high serum dilution factor is desired i.e., when only a limited quantity of antiserum is available. The result demonstrates the suitability and usefulness of lanthanide(III) chelates as multilabels in bioaffinity assays.

INTRODUCTION

Steroids with additional functional groups are often needed for biological, microbiological and medicinal applications (*1*). For example, in competitive immunoassays, haptens coupled to a label molecule are used as tracers (*2*, *3*). Most commonly, a spacer arm with a reactive *ω*-substituent (amino or thiol) is introduced to the steroid structure before the labeling reaction, which is performed in solution between the hapten and an isothiocyanato, haloacetyl, or 3,5-dichloro-2,4,6-triazinyl derivative of the label molecule. Steroids tethered to a carboxylic acid group, in turn, are coupled to labels bearing an amino function using carbodiimide (*4*). The solution-phase labeling has been used in the preparation of haptens labeled with up to two europium(III) chelates (*5*). Because in all of these cases the labeling reaction is performed in the presence of an excess of an activated label or an activator, laborious purification procedures cannot be prevented. Especially, when attachment of several label molecules is needed, purification and characterization of the desired biomolecule conjugate may be extremely difficult. The purification problems can be avoided by performing the labeling reaction on solid phase. Hence, most of the impurities can be removed by washings when the biomolecule conjugate is still anchored to the solid support, and after release to the solution, only one chromatographic purification is needed.

Fluorescent label molecules attached to monomers for solid-phase synthesis are often organic dyes. Although organic chromophores can be utilized in several applications, these labels and labeled biomolecules suffer from many known drawbacks, such as Raman scattering, low water solubility, and especially concentration quenching. In addition, the sensitivity is compromised by the phosphorescence of the microtitration plates. Instead, the unique properties of lanthanide(III) chelates (*6*−*9*) such as long decay-time luminescence make them ideal labels for microtitration plate-based assays. Furthermore, large

Chart 1



Stokes shift and very sharp emission bands enable the simultaneous use of four lanthanides (i.e. Eu, Tb, Dy, and Sm). Thus, the heterogeneous DELFIA technique is widely applied in assays where exceptional sensitivity and robustness is required (*6*, *7*).

Quite recently, we reported a solid-phase method for the labeling of oligopeptides (*10*) and oligonucleotides (*11*, *12*). The approach involves synthesis of oligonucleotide and oligopeptide building blocks, which can be introduced to the biomolecule structure using commercial oligonucleotide and oligopeptide synthesizers by phosphoramidite and Fmoc chemistry, respectively. Upon comple-

Scheme 1. Labeling of Steroids on Solid Phase

tion of the chain assembly, the oligomer is deprotected and finally treated with the appropriate lanthanide(III) citrate to give rise to the desired biomolecule conjugate. Here the strategy is exploited in multilabeling of steroids using a peptide synthesizer. Accordingly, several tetra-*tert*-butyl-1-[4-aminoacetamido)benzyl]diethylenetriaminetetrakis(acetato) derivatives of Fmoc glutamic acid (**1**; Chart 1) were coupled to steroids tethered to a carboxyl acid function (**2**, **3**). Upon deprotection and conversion to the corresponding europium(III) chelate, these steroid conjugates were used in competitive fluoroimmunoassays based on DELFIA technology. The fluorescence signal was approximately proportional to the number of chelates attached to the steroids: the signal with 17-α-hydroxyprogesterone tethered to two or four europium(III) chelates was two and a half and five times higher, respectively, compared to the monolabeled derivative, **4**, demonstrating the suitability of lanthanide(III) chelates to multilabeling.

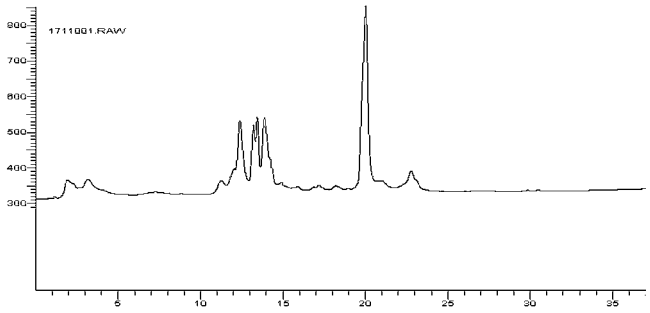

Figure 1. Reversed-phase HPLC profile (crude reaction mixture) of 17-α-hydroxyprogesterone labeled with four nonluminescent europium(III) chelates synthesized in the aid of block **1** and the steroid analogue **2** detected at 240 nm. The peak at t_R 20.06 min is the desired product. For chromatographic conditions, see Experimental Procedures.

EXPERIMENTAL PROCEDURES

General. The steroid compounds (**2** and **3**) were purchased from Steraloids (Newport, RI). The nonluminescent block, **1**, was synthesized as described previously (*10*). 17-α-OHP-3-CMO−Eu (**4**), rabbit anti-17-α-OHP antiserum, and the time-resolved fluorometer VICTOR^{2}V were products of PerkinElmer LAS. Anti-rabbit coated microtitration plates, blood spot standards, assay buffer, wash solution, and enhancement solution were from the DELFIA Neonatal 17-α-OH-progesterone kit 1244−039 (PerkinElmer LAS). HPLC analyses were performed on a PerkinElmer LC 2000 instrument using a reversed-phase column (LiChrocart 125−3 Purospher RP-18e, 5 μm). The mobile phase used was the following: Buffer A: 0.02 M TEAA (pH 7.5); Buffer B: A in 50% (v/v) acetonitrile. Gradient: from 0 to 1 min 95% A, from 1 to

Table 1. Tracers Synthesized and Their Observed and Calculated Molecular Weights

tracer[a]	$[M - nH]^{n-}/n$ calculated	$[M - nH]^{n-}/n$ observed
17-α-OHP-3-CMO-Eu_2 (**5**)	957.3 ($n = 2$)	957.7 ($n = 2$)
17-α-OHP-3-CMO-Eu_4 (**6**)	1143.3 ($n = 3$)	1143.5 ($n = 3$)
E3−6-CMO−Eu_2 (**7**)	944.2 ($n = 2$)	944.2 ($n = 2$)

[a] 17-α-OHP = 17-α-hydroxyprogesterone; E3 = estriol. CMO = carboxymethyloxime.

30 min from 95% A to 100% B. Flow rate was 0.6 mL min^{-1}. Electrospray ionization time-of-flight mass spectra (ESI-TOF MS) were recorded on an Applied Biosystems Mariner instrument on negative detection mode.

Synthesis of the Steroid Conjugates. The synthesis was performed in 10 μmol scale on an Applied Biosystems 433A instrument using Fmoc chemistry and recommended procedures (*O*-benzotriazol-1-yl-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU)/1-hydroxybentzotriazole (HOBt) activation; no capping), except the coupling time was increased to 2 h. 35 μmol of **1** was used in all coupling reactions. The last coupling was performed with 15 μmol of **2** or **3**. When the chain assembly was completed, the resin was treated with the mixture of crystalline phenol (75 mg), ethanethiol (25 μL), thioanisole (50 μL), water (50 μL), and trifluoroacetic acid (1 mL) for 3 h. The resin was removed by filtration, and the crude steroid conjugate was precipitated with diethyl ether. The precipitate was redissolved in water and treated with aqueous europium(III) citrate (5 equiv/ligand) Purification was performed on HPLC. The steroid conjugates were characterized on ESI-TOF mass spectrometry.

Time-Resolved Fluoroimmunoassays. The 17-α-hydroxyprogesterone derivatives synthesized were tested in a time-resolved fluoroimmunoassay. Standards (3.1 mm disks) punched from blood spots on filter paper were incubated in the wells of anti-rabbit coated microtitration plates with various concentrations of rabbit anti-serum to 17-α-hydroxyprogesterone and 300 pmol/L 17-α-hydroxyprogesterone-Eu tracers in a total volume of 200 μL, for 2 h. Bound and free 17-α-hydroxyprogesterone-Eu fractions were separated by washing, and bound Eu was measured, after addition of 200 μL of DELFIA enhancement solution, into which Eu dissociates and in which it forms highly fluorescent complexes. The fluorescence was measured in a 1420 Victor²V multilabel counter.

RESULT AND DISCUSSION

Tracer Synthesis. The present approach for solid-phase steroid derivatization is outlined in Scheme 1. Accordingly, two or four building blocks **1** were coupled to an amide resin in 10 μmol scale using Fmoc chemistry. A prolonged coupling time (2 h instead of 30 min) but otherwise standard conditions (3.5 equiv of **1**; HBTU/HOBt as an activator) were used. After the desired number of blocks was introduced, a steroid analogue tethered to a carboxylic acid function (1.5 equiv of **2** or **3**) was coupled using similar conditions. When the reaction was completed, the steroid conjugate was released from the resin and deprotected followed by precipitation from diethyl ether. Treatment of the deblocked conjugate with europium(III) citrate converted it to the corresponding lanthanide(III) chelate.

The labeled steroids were purified on reversed-phase HPLC and characterized on ESI-TOF mass spectrometry. A typical HPLC profile (crude reaction mixture) is shown in Figure 1 as an illustrative example. In all of the cases, the observed molecular weights were in accordance with the proposed structures (Table 1).

The DELFIA Assay. In the DELFIA assay set up for 17-α-hydroxyprogesterone, it is clearly seen that the signal goes up more than what is anticipated from the number of chelates attached to the steroid structure and that an increasing number of chelates makes the analytical sensitivity of the assay somewhat worse (Table 2). The shift of the standard curve to the right as well as the 5-fold increase in signal level when the number of Eu-chelates rises from 1 to 4 indicate that the antiserum has a higher affinity to tracers with more Eu-chelates. However, in 17-α-hydroxyprogesterone assays with these three tracers (**4**−**6**) the same sensitivity was observed when 17-α-hydroxyprogesterone antiserum and tracer dilutions were chosen to give the same signal in all three assays (Table 3). Thus, the more chelates conjugated to 17-α-hydroxyprogesterone, the more diluted antiserum could be used. Hence, 17-α-hydroxyprogesterone tracers

with several chelates are useful when a high serum dilution factor is desired i.e., when only limited quantities of antibody is available. This is usually the case in immunoassay applications for steroids of which many are widely used in clinical routine laboratories. Thus, when required, considerable amounts of antiserum can be saved and the lifetime of an assay prolonged by attachment of several chelates to the tracer. By contrast, if the labeling were performed using organic chromophores such as fluorescein or cyanine dyes, these dyes in close proximity will partially quench each other and further dilution of antiserum would be impossible.

In summary, a straightforward method for labeling of steroids on solid phase is demonstrated. Although an increasing number of biomolecule conjugates are nowadays synthesized entirely on solid phase (*13*), according to our knowledge, no method for solid phase labeling of steroids have been reported, excluding solid-phase synthesis of steroid−oligonucleotide conjugates. Although only labeling of carboxymethyloxime derivatives of estriol and 17-α-hydroxyprogesterone with several lanthanide(III) chelates is demonstrated, in all likelihood, the method is applicable to other haptens tethered to a carboxylic acid group as well.

Synthesis and Characterization of Dextran−Peptide−Methotrexate Conjugates for Tumor Targeting via Mediation by Matrix Metalloproteinase II and Matrix Metalloproteinase IX

Ying Chau, Frederick E. Tan, and Robert Langer*

Massachusetts Institute of Technology, Cambridge, Massachusetts 02142. Received April 4, 2004; Revised Manuscript Received May 30, 2004

We designed and synthesized new dextran−peptide−methotrexate conjugates for tumor-targeted delivery of chemotherapeutics via the mediation of matrix metalloproteinase II (MMP-2) and matrix metalloproteinase IX (MMP-9), both being widely known tumor-associated enzymes. A robust and flexible synthesis procedure and process monitoring chromatography assays were developed. The linker chemistry and the backbone charge were optimized to allow high sensitivity of the conjugates toward the targeted enzymes. The optimal conjugate carries Pro-Val-Gly-Leu-Ile-Gly as the peptide linker, and the charge on the dextran backbone is fully neutralized. In the presence of the targeted enzymes, the peptide was cleaved and peptidyl methotrexate was released, with a k_{cat}/K_m value of 1.21×10^5 M^{-1} s^{-1} for MMP-2 and 3.60×10^3 M^{-1} s^{-1} for MMP-9, respectively. Satisfactory stability of the new conjugates was demonstrated in serum containing conditions, suggesting the conjugates can remain intact in systemic circulation. These findings supported the tumor targeting capability of the new conjugates and warranted further investigation with in vivo study.

INTRODUCTION

Since conventional chemotherapy is nonspecific, it causes severe side effects and the treatment can be compromised due to dose-limiting toxicity. Recent advances in the understanding of tumor environment have prompted the current research to investigate a new approach to improve the biodistribution of chemotherapeutics. For tumors to survive, grow and metastasize, the expressions of a number of enzymes in high levels are required in the extracellular space. Among the many tumor-associated enzymes, we have selected to focus on matrix metalloproteinase II (MMP-2) and matrix metalloproteinase IV (MMP-9). These enzymes are extensively studied members of a family of zinc-dependent enzyme. They are elevated in a number of human epithelial cancers, including breast (*1*), prostate (*2*),colon (*3*), ovary (*4*), bladder (*5*) and gastric carcinoma (*6*). In fact, for tumor cells to invade and metastasize, the first barrier to overcome is the basement membrane (*7*, *8*) which is composed of type IV collagen and is susceptible to the degradation by MMP-2 and MMP-9. New functions of these MMPs have been recently reviewed (*9*). MMP-2 and MMP-9 can release growth factors sequestered in the extracellular matrix, expose binding sites for cell adhesion molecules, and activate growth factors and angiogenesis factors by cleaving their precursors. Their functions thus involve promoting tumor cell growth, upregulating angiogenesis and triggering tumor cell motility. They are either produced by the tumor cells or by the surrounding stromal cells, as extracellular or membrane-bound enzymes in the tumor's vicinity.

Polymer−drug conjugates are showing emerging potential in tumor targeting (*10*−*12*). The appropriate polymeric carriers are biocompatible and water-soluble. Covalent attachment of drug molecules to the macromolecular carrier solves the problem of poor solubility. Polymer of high molecular weight (with size near or above the renal excretion limit) is of special interest in tumor targeting due to two reasons. First, the half-life of the polymer−drug conjugates in the circulation is much longer than the free drugs. The decreased total body clearance of the polymer−drug conjugate increases the amount of drug delivered to the tumor site (*13*). Second, there is enhanced permeation and retention of the polymer−drug conjugates to the tumor site because solid tumor has leaky blood vessels and poor lymphatic drainage (*14*).

At the tumor site, as conjugates are internalized by nonspecific endocytosis, active drug molecules are released by either acid or intracellular enzymatic hydrolysis. However, fluid phase endocytosis is a slow process (*15*) and is not specific to tumor cells. Drug uptake by tumor cells can be enhanced by increasing the extent of binding of conjugates to the tumor cells. This route, selective endocytosis, has been investigated by the attachment of targeting ligands to the polymeric carriers (*10*, *16*−*19*). Alternatively, tumor uptake can be improved by increasing the extent of extracellular drug release in the tumor vicinity. This route is being explored in the current research by linking drug molecules to the polymeric carriers with peptide sequences. The specific peptide sequences are labile to the cleavage by tumor-associated enzymes in the extracellular space, enabling the release of drug molecules from the polymeric carriers.

The covalent attachment of a chemotherapeutic drug molecule to a peptide sequence susceptible to tumor-associated enzyme has produced prodrug that is activated by the enzyme of interest. Notably, the work on doxorubicin−peptide prodrug has demonstrated selective in vitro cytotoxicity for tumor cells producing prostate-specific antigen and in vivo antitumor efficacy (*20*). Sequences susceptible to cleavage by matrix metalloproteases (MMP) have also been used to increase tumor

selectivity of cytotoxins. Protective protein of anthrax toxin was mutated to contain a MMP recognizable sequence in order to be activated by the enzymes via a cleavage event on the cell surface (*21*). However, the tumor targeting efficiency of the above strategies is limited by the short circulation half-life of the active components.

We intend to combine the concepts of polymer−drug conjugate and peptide prodrug in our new conjugate and exploit the presence of MMP in tumor vicinity to release active drug molecules. We select dextran as the polymeric carrier because of its biocompatibility (*22*) and biodegradability (*23*). The hydroxyl groups on the dextran backbone provide possible functional sites for drug linkage. Previously, dextran of MW 70 000 was conjugated to doxorubicin via an acid-labile linkage for intratumoral delivery (*24*). Methotrexate is a folic acid analogue which inhibits dihydrofolate reductase and thus hinders the synthesis of RNA and DNA. Like most chemotherapeutic drugs, it is toxic to all fast growing cells. It is used as the model drug candidate in our conjugate. This molecule has been used for cancer treatment for many years and is effective against a number of tumors, including lymphoblastic leukemia in children, chriocarcinoma and related trophoblastic tumors in women, osteosacroma and carcinomas of the breast, head, neck, ovary and bladder. The major side effect is toxicity in gastrointestinal tract and bone marrow (*25*). Chemically, methotrexate has two carboxyl groups available for covalent linkage. The drug activity is relatively preserved when the gamma-carboxyl is chemically modified whereas the alpha-carboxyl has much less bulk tolerance (*26*). The peptide linker composition is based upon the work of Turk and co-workers (*27*) in which the authors constructed a combinatorial library of oligopeptides as MMP substrates. They scored all possible amino acids at each of the position from P4 to P4′. The highest-scoring amino acids without functional side chains are selected in our conjugate to form the optimal hexapeptide linker.

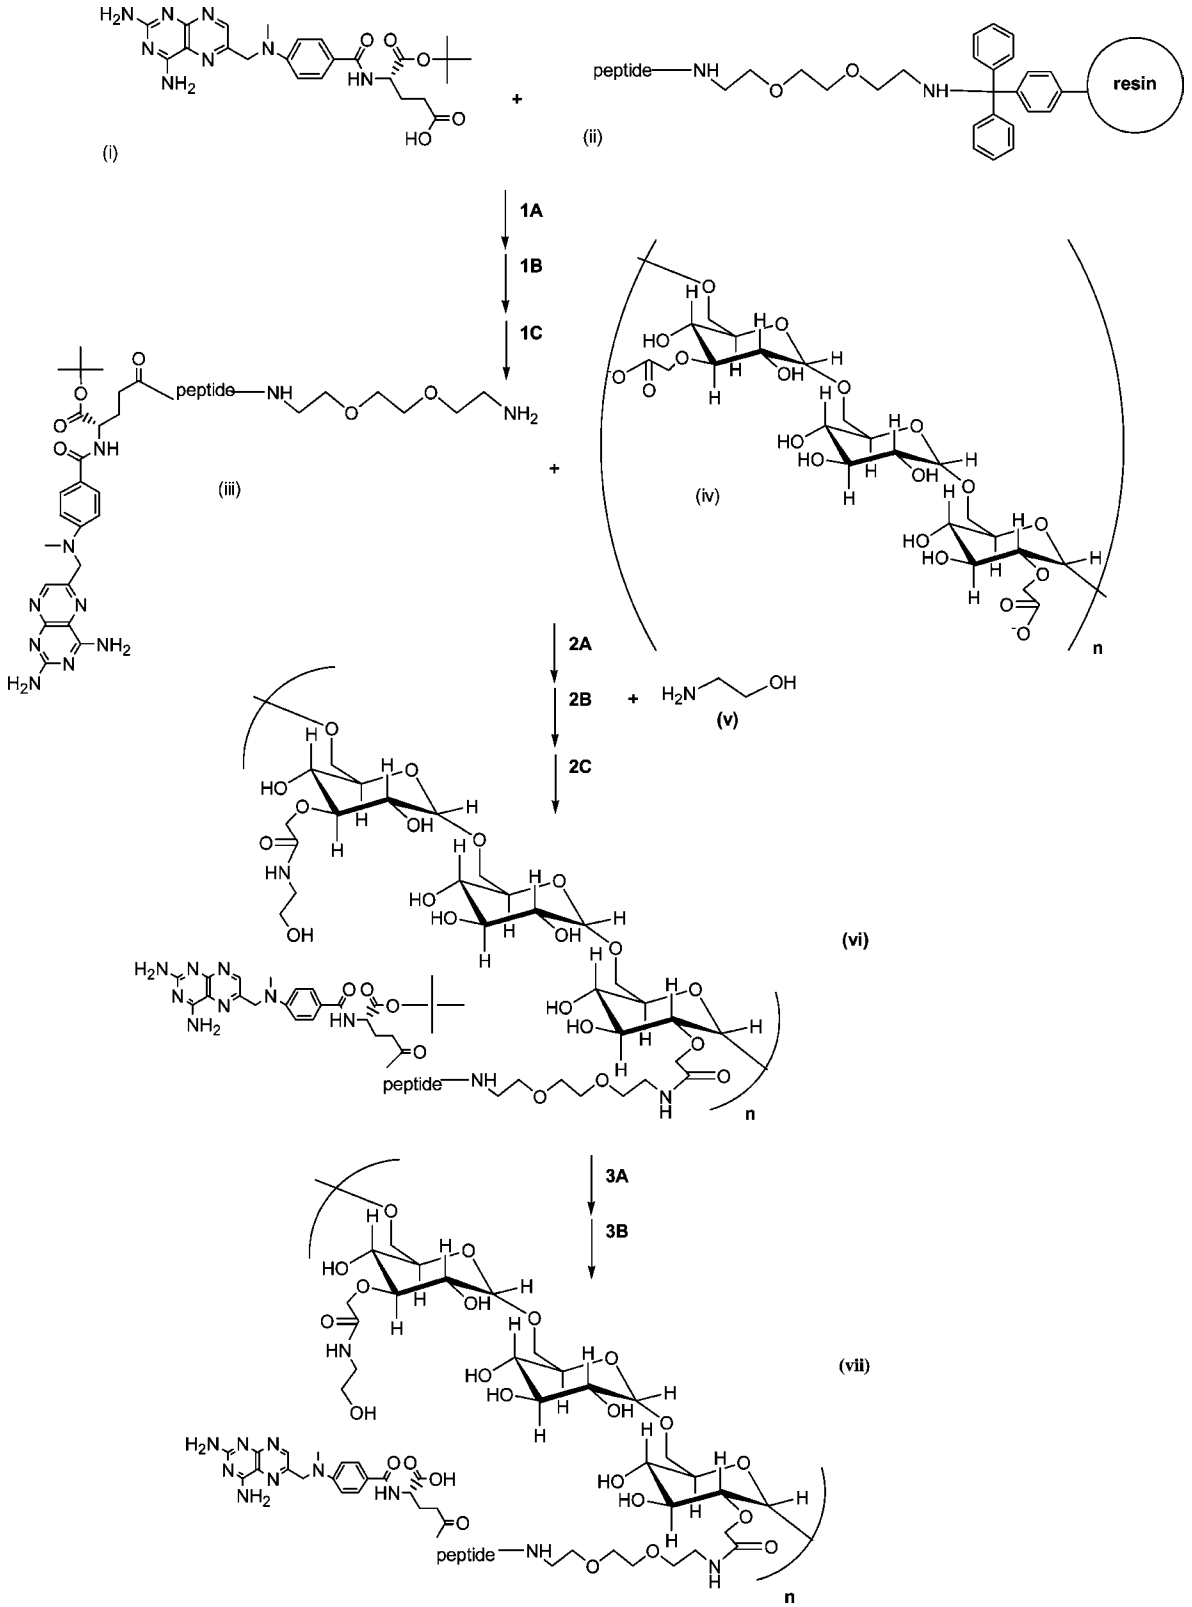
We report here a method to synthesize new dextran−peptide−methotrexate conjugates. The synthesis route is easily modified to prepare conjugates with different peptide linkers and different backbone charges. By tuning these parameters, the new conjugate is optimized in terms of sensitivity against MMP-2 and MMP-9. The conjugates also demonstrated excellent stability in serum-containing conditions, suggesting their capability to remain intact in systemic circulation.

EXPERIMENTAL PROCEDURES

Materials. Dextran T-70 with a nominal molecular weight of 70 000 was ordered from Pharmacia. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) and ethanolamine were obtained from Alfa Aesar. *O*-Bis(aminoethyl)ethylene glycol trityl resin, PyBop and HOBT were obtained from Nova Biochem. Glutamic acid-α-OtBu was purchased from Bachem. Trifluoroacetic acid (TFA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), acetonitrile (ACN), ethyl acetate, ether and 10× phosphate-buffered saline were obtained from EM Science. Methanol, sodium chloride and sodium phosphate were from Mallinckrodt. Tris was purchased from Boehringer Mannheim. Chloroacetic acid, *N*,*N*′-diisopropyl-(ethylamine) (DIPEA), BOP, 4-amino-4-deoxy-N^{10}-methylpteroic acid (APA), calcium chloride and phorbol 12-myristate 13-acetate (PMA) were from Sigma. Concanavalin A (ConA) was ordered from Calbiochem.

Purified active human MMP-2 and MMP-9 were purchased from Calbiochem. Precast protein gels with 10% gelatin and reagents for gelatin zymography were obtained from Biorad. Plasmocin was ordered from Invivogen. All other cell culture media and reagents as well as EDTA solution pH 8.0 were ordered from Gibco. Human tumor cell lines HT-1080 and BT-20 were obtained from American Type Cell Culture.

Preparation of Carboxymethyl Dextran (CM-dextran) (structure iv, Scheme 1). This procedure was based on the method by Nogusa for activating pullulan (*28*). Dextran T-70 (10 g) was dissolved in 100 mL of 6 N sodium hydroxide solution. Chloroacetic acid (30.2 g) was added to the solution and held at 70 °C for 2−3 h. Elevated temperature was necessary for this reaction. The reaction mixture was removed from heat and checked for pH. Acetic acid was used to neutralize the pH if necessary. The solution was then dialyzed against DI water using Spectrapor regenerated cellulose membrane with molecular weight cutoff at 3000−8000 for 2 days at 4 °C and lyophilized for storage. Degree of carboxymethyl substitution was determined by analysis of sodium content. Atomic absorption analysis to determine sodium content was performed by Quantitative Technologies Inc. (Whitehouse, NJ). The degree of substitution was consistently at 50% (±2%).



Synthesis and Purification of Methotrexate-alpha-OtBu (structure i, Scheme 1). Methotrexate-alpha-OtBu (MTX(OtBu)) was prepared from 4-amino-4-deoxy-N^{10}-methylpteroic acid (APA) and glutamic acid-α-OtBu using BOP as the conjugating reagent, following the procedure of Nagy (*29*). Crude MTX(OtBu) was precipitated by centrifugation in a 1:1 mixture of cold ether/ethyl acetate. The material was further purified by HPLC on a 95 mL C18 preparative scale column (Grace Vydac, Hesperia, CA) using a gradient from 0−100% acetonitrile with 0.2% TFA. The organic solvent in the product fractions was removed by rotoevaporation and the purified material was subsequently lyophilized. Product purity was confirmed to be ≥95% and the amount was quantified by the analytical scale reversed-phase HPLC. The average retention factor was 6.14.

Synthesis of Jeffamine−Peptide−Methotrexate-(OtBu) (structure iii, Scheme 1). Standard FMOC peptide synthesis in solid phase was carried out on *O*-Bis-(aminoethyl)ethylene glycol trityl resins by Biopolymer Lab at Massachusetts Institute of Technology. As in the conventional peptide synthesis, the peptide chain grew from the carboxyl to the amino terminal. After the last amino acid was loaded to the chain, FMOC was removed and the peptide with a free amino terminal was exposed whereas the carboxyl remained attached to the solid resin via a short six-carbon poly(ethylene oxide) spacer.

To couple MTX-α-OtBu to the amino terminal of the peptide chain, MTX-α-OtBu (2.5 equiv to the amount of peptide) was dissolved in DMF containing DIPEA (2.5 equiv). PyBop (2.5 equiv), HOBT (2.5 equiv) and additional DIPEA (2.5 equiv) were used to activate the γ-carboxyl of MTX-α-OtBu for about 15 min. More DMF was added such that the final concentration of MTX-α-OtBu was about 0.1 M. The mixture was combined with the resins loaded with peptide and stirred at room-temperature overnight. The reaction was confirmed for completeness the next day by ninhydrin test. Excessive reactants were washed away from the resins with DMF, DCM and methanol. The resins were then dried thoroughly.

Jeffamine−peptide−MTX(OtBu) was cleaved from trityl resins by suspending the resins in DCM containing 2% TFA for 10 min. This step was repeated three times. To collect all the cleaved product, the resins were further

Scheme 1. Schematics of the Synthesis Procedure of the New Dextran−Peptide−Methotrexate[a]

Reaction conditions and step yields*:* 1A: PyBop/HOBT/DIPEA coupling in DMF; 1B: dilute trifluoroacetic acid cleavage from resin.; 1C: reversed phase HPLC purification; typical yield for step 1= ∼70% yield. 2A: coupling with EDC in H_2O; 2B: charge neutralization by EDC/ethanolamine in excess; 2C: methanol precipitation; typical yield for step 2 = ∼40%. 3A: strong trifluoroacetic acid cleavage to deprotect *tert*-butyl group from MTX; 3B: diafiltration against DI water; typical yield for step 3 = ∼80%.

washed with DCM and methanol and the step was repeated until no further yellow color was observed (the yellow color was indicative of the presence of the MTX-(OtBu)-containing product). Organic solvent was subsequently removed by rotoevaporation from the collected product. The crude material was resuspended in water and purified by HPLC over a 0−100% acetonitrile gradient with 0.2% TFA using a 95 mL C18 preparative column. Product fractions were lyophilized after the organic solvent was removed by rotoevaporation. Product purity was found to be ≥95%, and the amount was quantified by analytical scale reversed phase HPLC.

The average retention factor on HPLC for MTX(OtBu)-Pro-Val-Gly-Leu-Ile-Gly-jeffamine was 6.71. Mass spectroscopy confirmed the identity of this intermediate product (structure iii in Scheme 1): Calc: 1177.3; Found: 1177.7. [^{1}H NMR (400 MHz, D_2O): δ 8.59 (s, H-7 of methotrexate, 1H), 7.62 (d, 3′,5′-H of methotrexate, 2H), 6.81 (d, 2′6′-H of methotrexate, 2H), 4.86 (s, H-9 of methotrexate, ∼2H, overlapping with H_2O), 4.33 (m, Hα of methotrexate, ∼1H, overlapping with H-2 of Pro) 1.8−2.0 (m,Hβ of methotrexate, 2H, overlapping with 3,4-H of Pro), 2.6 (m, Hγ of methotrexate, ∼2H), 1.41 (s, CH_3 of *tert*-butyl, ∼9H, overlapping with 3,4-H of Leu), 3.21 (s, CH_3-11 of methotrexate, 3H, overlapping with jeffamine EDR 148), 3.18−3.74 (m, H of jeffamine EDR 148, ∼12H, overlapping with H-5 of proline and CH_3-11 of methotrexate), 4.33 (m, H-2 of Pro, ∼1H, overlapping with Hα of methotrexate), 3.87−4.35 (m, H-2 of Val, Gly, Leu, Ile, Gly, 7H), 3.4−3.6 (m, H-5 of Pro, ∼2H, overlapping with jeffamine EDR 148), 2.1−2.3 (m, 3-H of Val, 3H of Ile, 2H), 1.8−2.1 (m, 3,4-H of Pro, 4H, overlapping with Hβ of methotrexate), 1.2−1.54 (m, 3,4-H of Leu, ∼3H, overlapping with CH_3 of *tert*-butyl), 0.78−0.93 (m, 3′,4-H of Val, 4′5-H of Leu, 3′4,5-H of Ile, 20H)].

The average retention factor of MTX(OtBu)-Gly-Ile-Val-Gly-Pro-Leu-jeffamine on our reversed-phase HPLC assay was 6.59. Mass spectroscopy confirmed the identity of this intermediate product (structure iii in Scheme 1): Calc: 1177.3; Found: 1177.1 [^{1}H NMR (400 MHz, D_2O): δ 8.59 (s, H-7 of methotrexate, 1H), 7.60−7.62 (d, 3′,5′-H of methotrexate, 2H), 6.78−6.80 (d, 2′6′-H of methotrexate, 2H), 4.85 (s, H-9 of methotrexate, ∼2H, overlapping with H_2O), 4.35 (m, Hα of methotrexate, ∼1H, overlapping with H-2 of Pro), 1.7−2.1 (m, Hβ of methotrexate, ∼2H, overlapping with 3,4-H of Pro), 2.45 (m, Hγ of methotrexate, 2H), 1.41 (s, CH_3 of *tert*-butyl, ∼9H, overlapping with 3,4-H of Leu), 3.20 (s, CH_3-11 of methotrexate, 3H, overlapping with jeffamine EDR 148), 3.16−3.74 (m, H of jeffamine EDR 148, ∼12H, overlapping with H-5 of proline and CH_3-11 of methotrexate), 4.35 (m, H-2 of Pro, 1H, overlapping with Hα of methotrexate), 3.84−4.25 (m, H-2 of Val, Gly, Leu, Ile, Gly, 7H), 3.3−3.5 (m, H-5 of Pro, ∼2H, overlapping with jeffamine EDR 148), 2.1−2.3 (m, 3-H of Val, 3H of Ile, 2H), 1.7−2.1 (m, 3,4-H of Pro, ∼4H, overlapping with Hβ of methotrexate), 1.1- - - 1.7 (m, 3,4-H of Leu, ∼3H, overlapping with CH_3 of *tert*-butyl), 0.74−0.88 (m, 3′,4-H of Val, 4′5-H of Leu, 3′4,5-H of Ile, 20H)]

Synthesis of Jeffamine−Methotrexate(OtBu) (iii′, structure not shown). The procedure was similar to above for the synthesis of (iii) except that no peptide was loaded onto the resin. MTX-α-OtBu was directly coupled to *O*-bis(aminoethyl)ethylene glycol trityl resin using the same protocol. Product found to be ≥ 95% by reversed-phase HPLC. The average retention factor of jeffamine−MTX(OtBu) was 5.81. Mass spectroscopy confirmed the identity of this intermediate product (iii′): Calc: 640.6; Found:640.6..

Synthesis and Purification of Dextran−Peptide−MTX (structure vii, Scheme 1). To couple jeffamine−peptide−MTX(OtBu) to CM-dextran, jeffamine−peptide−MTX(OtBu) (0.5 mMol) dissolved in DI water (1.9 mL) was combined with CM-dextran (4 g) dissolved in DI water (6.7 mL). EDC (4.7 g) was added to the mixture while stirring. The reaction was held overnight at room temperature. Another aliquot of EDC (4.7 g) was added the next day, and the reaction was held overnight to form CM-dextran−peptide−MTX(OtBu) (structure vi of Scheme 1).

To block the unreacted carboxymethyl groups on the dextran backbone, ethanolamine (30 mL) was first neutralized to pH 6−7 using 5 N HCl in dibasic phosphate buffer on ice. This mixture was added to (vi) followed by the reaction with EDC (47 g). It was held stirring at room-temperature overnight. The modified dextran−peptide−MTX(OtBu) was precipitated by centrifugation in methanol.

To remove the protection group OtBu, modified dextran−peptide−MTX(OtBu) was resuspended in 40 mL of strong trifluroacetic acid by vigorous stirring and held at room temperature for 3 h. This deprotection step was quenched by diluting the acidic mixture with 0.1 M phosphate buffer and neutralizing the pH with 5 N sodium hydroxide on ice. Extensive diafiltration was performed using Pellicon XL membrane cassettes of regenerated cellulose with 10 000 MWCO (Millipore, Billerica, MA) to remove excessive reactants and byproducts of the reaction. After purification, the product in the retentate was concentrated and then lyophilized for storage. The product purity was confirmed to be ≥99% by size-exclusion HPLC. The drug loading density was estimated by HPLC to be at 1.0 ± 0.2% (mol % per glucose unit).

Synthesis and Purification of Dextran−MTX (structure vii′, structure not shown). This procedure comprised of steps similar to those for the synthesis and purification of dextran−peptide−MTX (structure vii of Scheme 1), with the exception that jeffamine−MTX-(OtBu) was used instead of jeffamine−peptide−MTX-(OtBu).

Zeta Potential Measurement. Dextran and dextran−peptide−MTX conjugates were dissolved in DI water at 10 mg/mL. Measurement was performed with Zeta-analyzer (Brookhaven Instruments Co., Holtsville, NY).

Measurement of Kinetic Parameters for MMP-2 and MMP-9 Digestion of Conjugates. The kinetics of enzymatic digestion of the conjugates by MMP-2 and MMP-9 was modeled by the classical Michaelis−Menten equation:

$$\frac{1}{V_i} = \frac{1}{k_{cat}E_{total}} + \left(\frac{K_m}{k_{cat}E_{total}}\right)\frac{1}{S_o}$$

where V_i is the initial reaction velocity, S_o is the substrate concentration and E_{total} is the total enzyme concentration, including both bound and nonbound forms. K_m is the Michaelis−Menten constant and k_{cat} is the turnover rate of the substrate−enzyme complex to product. The ratio k_{cat}/K_m is widely used in the literature, termed as specificity constant, as a measure of how fast enzymatic digestion occurs. Conjugates of interest were dissolved in assay buffer (10 mM $CaCl_2$, 0.2 M NaCl in 50 mM Tris pH 7.5) at various concentrations: 5, 10, 20, 50 and 100 μM. For each substrate concentration, active MMP-2 or MMP-9 at a final concentration of 10 nM was added and the mixture was incubated at 37 °C. At specific time

points, the reaction mixture was quenched with EDTA solution at a final concentration of 20mM. The mixture was assayed by two-column size-exclusion HPLC (assay details are included in the next paragraph) and the cleavage product peak was quantified to calculate the reaction rate. Initial rate was defined as the rate for the cleavage of the first 20% of the conjugate. Triplicate measurements were made at each time point for each substrate concentration. Linear regression was performed on a double reciprocal plot of $1/V_i$ versus $1/S_o$ to determine the specificity constant k_{cat}/K_m.

HPLC Analytical Methods. *Reversed Phase Analytical Assay for Online Monitoring of Process Yield and Product Purity.* A silica C18 0.21 mm (ID) × 25 cm (L) column (Grace Vydac, Hesperia, CA) was connected to a HPLC solvent delivery system equipped with a UV detector (1100 series, Agilent Technologies, Palo Alto, CA). The method was run at 0.5 mL/min with mobile phase A as 0.2% trifluoroacetic acid (TFA) in water and mobile phase B as 0.2% TFA in acetonitrile. A sample of 10 μL was injected onto a preequilibrated column followed by 5 min of wash with mobile phase A. A gradient ramped from 0%B to 100%B in 20 min. Detection for methotrexate-containing moieties was made by UV absorbance at 307 nM. A calibration curve was constructed correlating the peak areas in the chromatograms and the concentrations of methotrexate standards.

Two-Column Size-Exclusion Assay for Enzyme Kinetics Study. A PW3000 7.8 mm (ID) × 30 cm (L) column followed by PW2000 7.5 mm (ID) × 30 cm (L) column (Tosohaas, Montgomeryville, PA) were connected to a HPLC solvent delivery system equipped with a UV detector (Agilent Technologies).The method consisted of an isocratic elution with 20% acetonitrile and 3.6× phosphate-buffered saline in water at 0.8 mL/min. Detection for methotrexate-containing moieties was made by UV detection at 307 nM or 390 nM. The default sample injection volume was set at 10 μL. A calibration curve was constructed correlating the peak areas in the chromatograms and the concentrations of methotrexate standards.

One-Column Size-Exclusion Assay for Online Monitoring of Process Yield and Product Purity. A PW3000 7.8 mm (ID) × 30 cm (L) column (Tosohaas) was connected to a HPLC solvent delivery system equipped with a UV detector (Agilent Technologies). The method consisted of an isocratic elution with 20% acetonitrile and 3.6× phosphate-buffered saline in water at 0.8 mL/min. Detection for methotrexate-containing moieties was made by UV detection at 307 nM. The default sample injection volume was set at 10 μL. A calibration curve was constructed correlating the peak areas in the chromatograms and the concentrations of methotrexate standards.

Maintenance of Cell Culture. Human tumor cells HT-1080 and BT-20 were maintained using DMEM low glucose media supplemented with 2 mM L-glutamine, 1× glutamine−penicillin−streptomycin (GPS), 25 μg/mL plasmocin, and 10% fetal bovine serum.

Zymography of Cell Conditioned Media. HT-1080 and BT-20 were grown to about 70% confluence before the growth media was exchanged to the serum-free media (DMEM low glucose containing 2 mM L-glutamine, 1× GPS, and 12.5 ng/mL of PMA) The culture was grown in serum-free media for another 3 days. Cell-conditioned media were analyzed with gelatin zymography according to a previously described procedure (*30*, *31*). Briefly, samples were separated with electrophoresis in a 10% polyacrylamide gel containing gelatin. After renaturing the gel in 2.5% Triton X-100 solution, it was incubated overnight in a development buffer to allow the digestion of the gelatin by MMP-2 or MMP-9. White clear bands in a blue background after Coomassie Blue staining indicated the presence of the enzymes.

In Vitro Digestion Experiments of Conjugates. To assess the stability of the conjugate MTX−PVGLIG−dextran (PVGLIG is the shorthand notation of the peptide Pro-Val-Gly-Leu-Ile-Gly) in serum-containing conditions, it was incubated at 37 °C and 5% CO_2 with various media for 24 h. The percentage cleavage of the conjugate was determined by the two-column size-exclusion HPLC assay.

To demonstrate that the specificity of release of peptidyl drug from the conjugate in cell culture was MMP-2 and MMP-9 dependent, HT-1080 and BT-20 were grown in 12-well-plates to about 80% confluence and growth media was exchanged to serum-free media containing 12 ng/mL of PMA or 10 μg/mL of ConA. PMA and ConA were used to activate pro-MMP-2 and pro-MMP-9 to their active forms. After 2 days, the conjugate MTX−PVGLIG−dextran was added to the cell culture and incubated for 6 h. Media samples were analyzed by two-column size-exclusion HPLC assay to determine the percentage peptidyl drug released from the conjugate.

Cytotoxicity Assay. (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide) assay (MTT assay) was used to measure the drug cytotoxicity according to a previously described procedure with modifications (*32*). Cells were seeded in serum-containing growth media to 96-well-plates at 10 000 cells/well. After 1 day, the growth media was exchanged to serum-free media and the drug solutions at specified concentrations were added. After another 2 days of drug exposure, MTT solution was added and the plates were incubated at 37 °C for 2 h, followed by overnight incubation with extraction solution (10% SDS in DMF/H_2O pH 4.7). Plates were read at 570 nM, and the readings of the absorbance corresponded to the number of living cells. Percentage survival was calculated using the formula listed in the website of National Cancer Institute (http://dtp.nci.nih.gov/branches/btb/ivclsp.html):

$$[(T_i - T_z)/(C - T_z)] \times 100 \text{ for concentrations for which } T_i \geq T_z$$

$$[(T_i - T_z)/T_z] \times 100 \text{ for concentrations for which } T_i < T_z$$

where T_z is the reading at time zero prior to the addition of drug solutions, T_i is the reading at the assay end-point at each of the drug concentration level, and C is reading at the assay end-point for the control growth (with no drug addition).

Growth inhibition of 50% (GI50) was calculated from $[(T_i - T_z)/(C - T_z)] \times 100 = 50$, which was the drug concentration resulting in a 50% reduction in the net increase in the number of viable cells (as measured by MTT assay) compared to control growth.

RESULTS

Synthesis of the New Conjugates. We have developed a robust process to synthesize and purify the new dextran−peptide−methotrexate conjugates. The process flowchart is shown in Scheme 1. To help us monitor and optimize the synthesis process, we have also established a reversed-phase and two size-exclusion HPLC assays.

The drug molecule to be attached to the new conjugate, methotrexate, has some bulk tolerance at the γ-carboxyl group. It is important that the α-carboxyl, the less

Table 1. Conjugation Yield of the Reaction Step between Carboxymethyl Dextran and Jeffamine−Peptide−MTX(OtBu), Varying the Amine and the Carboxyl Concentration

amine concn (M)	carboxyl concn (M)	conjugation yield (%)
0.02	0.66	76
0.02	0.18	41
0.02	0.09	29
0.02	0.02	15
0.01	0.66	25

tolerable functional group, is protected throughout the synthesis process. Thus methotrexate-alpha-(OtBu) (structure i, Scheme 1) was prepared from APA. This protected methotrexate was first conjugated to the peptide in a solid-phase reaction. Trityl resins were chosen as the solid-phase supports since the products synthesized on the resins could be released using a dilute acid thus leaving the *tert*-butyl group on methotrexate unaffected. This protection group was eventually removed in the last reaction step (step 3A, Scheme 1).

We have chosen a special trityl resin, *O*-bis(aminoethyl)ethylene glycol trityl resin (structure ii, Scheme 1), as the solid support. This enables the peptide to be attached to jeffamine, a short poly(ethylene oxide) chain. After detaching from the solid support, the peptide remains attached to jeffamine. Jeffamine aids in the coupling between the peptide−drug and carboxymethyl dextran (structure iv, Scheme 1). Our MMP-recognizable peptide sequence is composed of hydrophobic amino acids (Pro-Val-Gly-Leu-Ile-Gly). The protected drug MTX-α-(OtBu) also has limited aqueous solubility. On the other hand, carboxymethyl dextran is hydrophilic. In our attempts to couple peptide−drug to carboxymethyl dextran in the presence of EDC, we have found that the concentration of the amine component and the concentration of the carboxyl component are critical factors in determining conjugation yield. Table 1 lists the conjugation yield when we varied the amine or the carboxyl concentration in the coupling step, keeping all other reaction conditions identical. This observation is explained by the relatively short half-life of the EDC-activated carboxyl. If unable to encounter an amine component for reaction, the active ester becomes inactivated (*33*). Because of the hydrophilic character of the jeffamine spacer that improves aqueous solubility, higher concentration of jeffamine−peptide−MTX(OtBu) (structure iii, Scheme 1) can be attained and the conjugation in aqueous phase results in a reasonable yield (Step 2A, Scheme 1).

MMP-Mediated Drug Release Requires an Optimized Peptide Linker. We have prepared three different conjugates: (1) MTX−PVGLIG−dextran, with the peptide linker composition optimized for MMP-2 recognition; (2) MTX−GIVGPL−dextran, with a scrambled peptide linker; (3) MTX−dextran, without a peptide linker. The extents of drug release from these conjugates in the presence of MMP-2 and MMP-9 were compared in Figure 1 and Figure 2.

Similar trends were observed for both MMP-2 and MMP-9. MTX−PVGLIG−dextran conjugate released 89% of peptidyl methotrexate in the presence of MMP-2 and 61% in the presence of MMP-9 after 24 h. In contrast, conjugates without any peptide linker or carrying the scrambled peptide linker did not show any significant release. Without the MMP recognizable peptide linker, the conjugate was stable even in the presence of a high concentration of MMP-2 or MMP-9. We isolated the small molecular weight cleavage product from the digest of

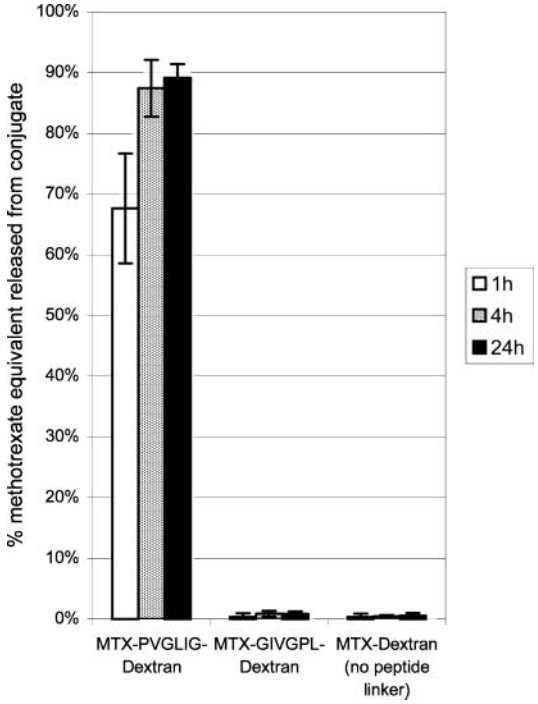


Figure 1. Extent of methotrexate equivalent released from different conjugates in the presence of MMP-2. Conjugates of different linkers were incubated with 10 nM of MMP-2 in assay buffer at 37 °C and measured for percentage cleavage at specified time points by size exclusion. Peptidyl methotrexate analogues were the expected products released from the dextran−peptide−methotrexate conjugates upon cleavage. Methotrexate was the expected product released from the dextran−methotrexate conjugate upon cleavage. Cleavage of the conjugate by MMP-2 was dependent on the linker composition.

MTX−PVGLIG−dextran on size-exclusion column and analyzed the product fraction by mass spectroscopy. The molecular weight found was 707.5 and was consistent with the notion that methotrexate−proline-valine-Gly (MTX−PVG) was the released product. This can be predicted by the scissile site of MMP-2 and MMP-9 on the peptide (*27*).

Preparation of Conjugates with Varying Backbone Negative Charges. To investigate the effect of the net charge on the dextran backbone, we prepared different conjugates by reacting the excess carboxymethyl with ethanolamine using different conditions. Ethanolamine is a simple, neutral and hydrophilic molecule (structure v and step 2B, Scheme 1). The charges on the resulting conjugates were characterized by its zeta potential. We first experimented with just carboxymethyl dextran (structure iv, Scheme 1) and found that the negative charge could be partially or fully neutralized using appropriate reaction conditions (Table 2).

By tuning the amount of EDC and ethanolamine, we prepared MTX−PVGLIG−dextran conjugates with varying negative charges and examined the charge effect on the kinetics of digestion by MMP-2 and MMP-9 (Table 3). As seen in Table 3, the charge on the conjugate backbone has a significant effect on the rate of MMP-2 cleavage. The value of k_{cat}/K_m is varied by an order of magnitude depending on the charge. The conjugate most sensitive to MMP-2 (Conjugate C) has its excess carboxymethyl groups completely masked by ethanolamine and is neutral in charge. It has a similar kinetic constant toward MMP-2 digestion as the optimal peptide found by Turk (*27*). In his report, Ile-Pro-Val-Ser-Leu-Arg-Ser has a k_{cat}/K_m value of 0.82×10^5 M^{-1} s^{-1}. On the other

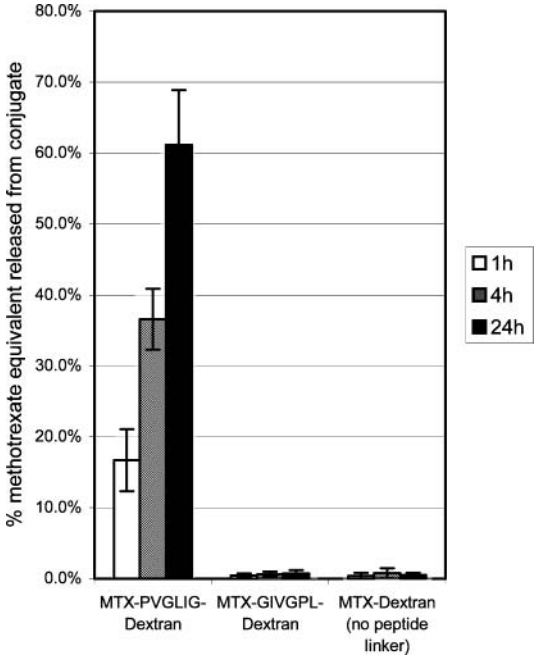

Figure 2. Extent of methotrexate equivalent released from different conjugates in the presence of MMP-9. Conjugates of different linkers were incubated with 10 nM of MMP-9 in assay buffer at 37 °C and measured for percentage cleavage at specified time points by size exclusion. Peptidyl methotrexate analogues were the expected products released from the dextran−peptide−methotrexate conjugates upon cleavage. Methotrexate was the expected product released from the dextran−methotrexate conjugate upon cleavage, if any. Cleavage of conjugate by MMP-9 was dependent on the linker composition.

hand, the kinetics of enzymatic digestion by MMP-9 was much less sensitive to the charge difference on our conjugate backbone. Taken together, the conjugate with its carboxymethyl groups masked and hence least negatively charged has the highest sensitivity toward MMP-2 and MMP-9.

Stability in Serum-Containing Conditions. We used fetal bovine serum and serum spiked with active human MMP-2 and MMP-9 to approximate the physiological conditions encountered by the conjugates in systemic circulation. In contrast to the conditions without serum, we found no significant cleavage even in serum spiked with high concentration of MMP-2 and MMP-9 (Figure 3). These results showed that the peptide linker within the conjugate was shielded from the exopeptidases in serum. Furthermore, the two MMPs were inactivated in serum.

Specificity of Release in Tumor Cell Culture. HT-1080 is a human fibrosacroma cell line that is known to express MMP-2 and MMP-9. BT-20, a human breast cancer cell line, is known to be negative in MMP-2 and MMP-9. These features were confirmed by zymography of the cell-conditioned media from these cell lines (Figure 4). In HT-1080 cell conditioned media, the prominent band at 68kD indicates the presence of active MMP-2 and the band at 86 kDa the presence of MMP-9. In BT-20 conditioned media, only a faint band is present at 72 kDa showing a relatively small amount of pro-MMP-2.

The conjugates MTX−PVGLIG−dextran were incubated for 6 h with these two types of cell culture. The digest showed no detectable cleavage of the conjugates in BT-20 culture. In contrast, 14% cleavage was observed in HT-1080 culture (Table 4). The in vitro experiments indicated that the extracellular release of peptidyl methotrexate from the conjugate was associated with the presence of active MMP-2 and MMP-9.

Cytotoxicity of the Released Peptidyl Methotrexate toward Tumor Cells. The released product from the new conjugate is a peptidyl methotrexate analogue (MTX−PVG) and has three amino acids attached to the free drug. The cytotoxicity of MTX−PVG was measured and compared with free methotrexate using MTT assay. For both tumor cell lines, HT-1080 and BT-20, peptidyl methotrexate was cytotoxic with GI50 on the order of 10 μM. Compared to free methotrexate, the potency of the drug was lowered by 2 orders of magnitude (Figures 5 and 6).

DISCUSSION

We have developed a robust and flexible synthesis procedure to prepare new dextran−peptide−methotrexate conjugates. Reaction and purification steps are monitored by HPLC to confirm high purity and reasonable yield. We have combined solid-phase and solution-phase synthesis to make the process more flexible. Peptide synthesis on solid supports is now a highly automated process, and peptide sequences of varying length or composition can be readily prepared in a short time. The advance of this current technology lets us accommodate any change in the peptide sequence for our conjugate's linker. This is valuable when we expand the current approach to target other tumor-associated enzymes, which are made up of a diverse group of proteases. A few examples include prostate-specific antigens (*34*), urokinase-type plasminogen activator (*35*), and cathepsin-L (*36*). We have also devised a method to modify the magnitude of negative charge on the dextran backbone, another factor that can be tailored to different enzymes of interest in order to optimize conjugate sensitivity. We have chosen a special trityl resin, *O*-bis(aminoethyl)-ethylene glycol trityl resin (structure ii, Scheme 1), as the solid support. This enables the ready incorporation of a 10-atom long jeffamine spacer adjacent to the specific peptide. Our original concept was to use the spacer to prevent steric hindrance posed by the dextran polymer backbone on the enzymatic cleavage of the specific peptide. This hydrophilic spacer is actually important in ensuring the robustness of the synthesis process. It improves the solubility of the peptide and hence increases the concentration of the amine component in the conjugation reaction, giving consistent and reasonable yield in this key reaction step.

We intend our new conjugates to release the active drug molecules in the presence of the tumor-associated enzymes MMP-2 and MMP-9. A peptide linker labile to enzymatic digestion is important to achieve this purpose. We selected the most preferable amino acids for MMP-2 from Turk's work (*27*) to fill the substrate positions from P3 to P3′. From our experience in developing dextran−peptide−doxorubicin conjugates (*37*), these six positions are necessary for recognition by MMP-2 and MMP-9. This observation is consistent with reports in the literature (*38*). We showed that the cleavage of the new dextran−peptide−methotrexate conjugate depended on the presence of the optimal peptide, as conjugates with scrambled peptide or no peptide linker did not respond to even a high concentration of MMP-2 or MMP-9 (Figures 1 and 2). Although the peptide PVGLIG shows a high cleavage rate by MMP-2 and MMP-9, this peptide is not sensitive exclusively to these two enzymes. Because of the similarity among members in the family of matrix metalloproteinases (*27*, *39*), this peptide is expected to be cleavable by other MMPs albeit with lower rates.

In our previous experience with dextran−peptide−doxorubicin conjugates, we observed that the rate of

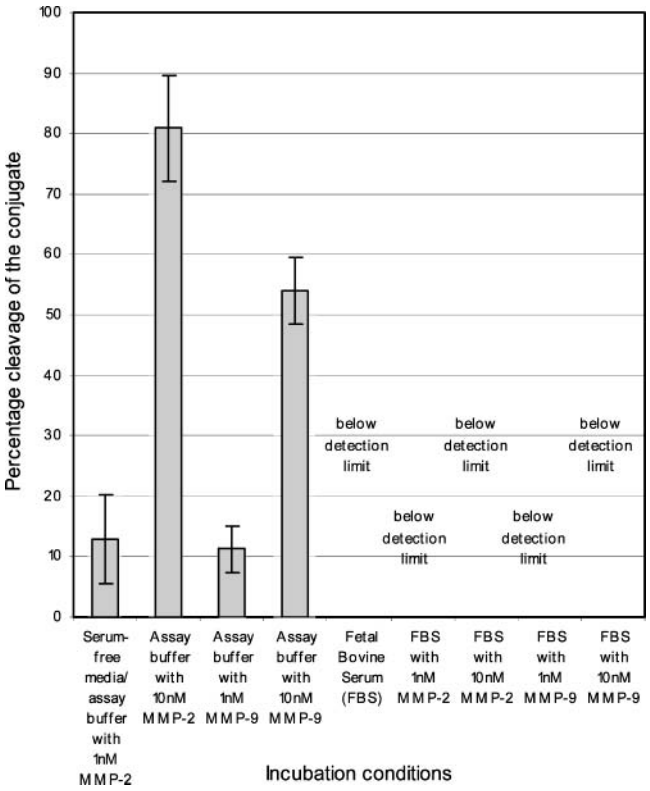

Figure 3. Stability of conjugate MTX−PVGLIG−dextran in various media conditions. Conjugates were incubated with the specified conditions for 24 h at 37 °C and assayed by size-exclusion HPLC to determine the percentage cleavage of the conjugate. The conjugate released peptidyl drug in serum-free conditions but remained intact in all the serum-containing conditions. The average values from three replicates with standard deviations as error bars are shown.

MMP-2 cleavage increased with higher ionic strength in the digestion media. In accordance with Debye−Hückel theory, we reasoned that this phenomenon could be explained by the electrostatic repulsion between the enzyme and the negatively charged conjugate (*37*). In the current report, we investigated the relationship between the negative charge on the dextran backbone and the enzyme kinetics of conjugate digestion. We confirmed our previous suspicion that MMP-2 was repulsive to negative charge. Blocking the excess negative charge on the dextran backbone improved the enzyme kinetics significantly (Table 3). Interestingly, MMP-9 is relatively insensitive to charge modification on the dextran backbone. MMP-2 and MMP-9 are similar in structure. Both

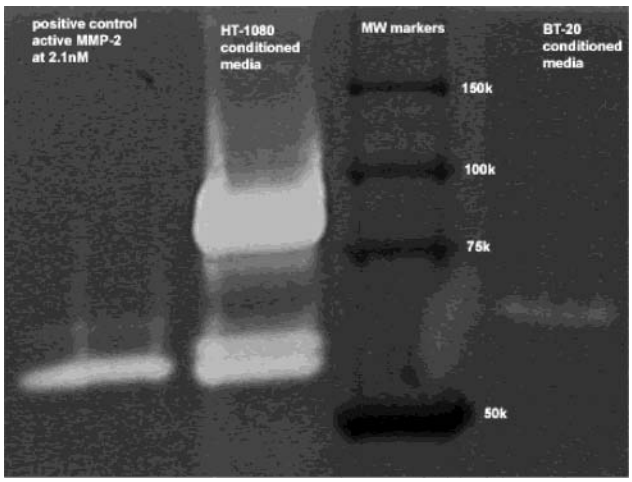

Figure 4. Gelatin zymography of HT-1080 and BT-20 cell conditioned media. The white bands in the dark backgrounds indicate the presence of gelatinases (MMP-2 and MMP-9). Active MMP-2 (68kD) and active MMP-9 (86kD) were expressed by HT-1080. Only a faint band of pro-MMP-2 (72kD) was found in BT-20.

have three repeats of fibronectin type II domain (*39*). Categorized together as gelatinases, these two enzymes are also reported to have similar biological substrates and specificity (*38*).We compared the amino acid sequences of the active form of human MMP-2 and MMP-9, taken from the Swiss-Prot database (P08253 and P14780 for their precursors). The net charge of MMP-2 is 10 times more negative than MMP-9. This difference is consistent with our current experimental observation that MMP-2 exhibits significantly more electrostatic repulsion toward the negatively charged dextran backbone.

Our new conjugates are intended for systemic delivery. To be able to target tumor sites, the conjugates must remain stable in the blood circulation and the drug molecules should stay attached to the polymer backbone prior reaching the tumor tissues. We demonstrated that our conjugates were satisfactory in meeting the stability

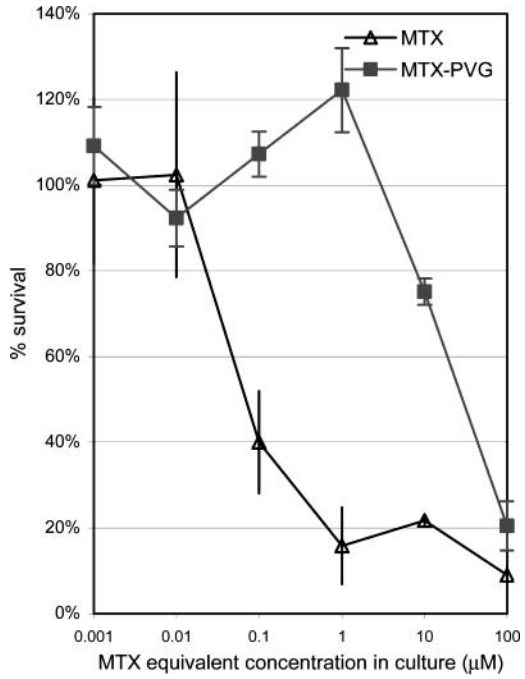

Figure 5. Cytotoxic effect of methotrexate and methotrexate-Pro-Val-Gly on HT-1080 cell culture measured by MTT assays. The average values of three replicates with standard deviations as error bars are shown.

criteria—they did not show any significant cleavage in serum-containing conditions (Figure 3). The peptide linker is covalently joined to the methotrexate molecule on one end and to the dextran backbone on the other, thus being protected from the exopeptidases present in the serum. Other than pure serum, we also tested the conjugate's stability in serum spiked with MMP-2 or MMP-9. These conditions are intended to mimic the physiological environments in which tumor growth is present in the body. When tumor tissues overexpress MMP-2 and MMP-9, the enzyme levels are also elevated in the blood stream (*40*). However, protease activities of these MMPs in the systemic circulation are greatly reduced because of the inhibition by serum proteins. One of these inhibitors is α2-macroglobulin, a large serum protein with molecular weight of about 800 kDa that offers the proteases a bait region. Once the bait region is cut, α2-macroglobulin changes shape to entrap the MMP (*39*). This inhibitory effect was clearly demonstrated in our experiments. While the conjugate MTX−PVGLIG−dextran was sensitive to MMP-2 or MMP-9 in assay medium that was serum free, releasing a significant amount of peptidyl methotrexate, it did not respond to the same enzymes at equivalent concentrations when serum was present.

We provided evidence that the conjugates were able to be cleaved in the tumor culture and the release of peptidyl drug was due to the presence of MMP-2 and MMP-9 (Figure 4 and Table 4). In these cell cultures, no serum was present. The absence of serum protein was intended to mimic the conditions in the tumor vicinity in vivo. Because of the large sizes of the serum protease inhibitors such as α2-macroglobulin, they are unable to cross the capillary endothelium and therefore are absent in the interstitial fluid. In the tumor tissues, the activities of MMP-2 and MMP-9 are not inhibited by serum proteins although they are regulated more specifically by tissue inhibitors of metalloproteinases (TIMPs) (*39*).

Because of the requirement of P3 to P3′ sites for substrate recognition by MMP-2 and MMP-9, the released product from the conjugate contains three amino acids attached to the free drug. Although methotrexate exhibits some bulk tolerance at the gamma-carboxyl site, we are concerned about the therapeutic effect of the released product. Cytotoxicity assays showed that the released product was still effective in inhibiting the proliferation of tumor cells but the potency was lower than the free methotrexate. This is the biggest concern of the current approach, namely, the drug is not released in the original free form. However, the loss in cytotoxicity in vitro may not translate to the loss in antitumor efficacy in vivo. The sensitivity of the new conjugates to the tumor-associated enzymes MMP-2 and MMP-9, as well as their capability of remaining stable in the systemic circulation, suggests that the new conjugates can passively and actively target the tumor tissue. We predict that these qualities will improve both the circulation half-life of the conjugate and the percentage dose accumulated in the tumor tissue. While these effects can bring about improvement in antitumor efficacy in vivo but cannot be measured in cell culture assays, further investigation in animal models is warranted.

ACKNOWLEDGMENT

The authors thank Dr. Sanyong Jon for the collection and the interpretation of NMR data. We are grateful for Dr. Dane Wittrup's advice on charge optimization of the conjugates and Dr. Marsha Moses's advice on biochemical characterization of MMP. Y. Bacteriorhodopsin Conjugates as Anchors for Supported Membranes

Manoj K. Sharma, Harsha Jattani, and M. Lane Gilchrist, Jr.*

Departments of Chemical and Biomedical Engineering, The City College of the City University of New York, 140th Street and Convent Avenue, New York, New York 10031. Received December 26, 2003; Revised Manuscript Received April 23, 2004

The sophistication of supported lipid bilayer membranes has increased steadily as new applications are being explored. In general, tethered lipids are used to anchor the lipid bilayer to the substrate. Here we describe a new type of anchoring system for supported lipid bilayers that is based on biotin−PEG_{3400}−bacteriorhodopsin conjugates. Amine-based coupling was used to construct the polymer conjugates, followed by fluorophore labeling to enable confocal imaging. The bacteriorhodopsin-based anchoring system was used to construct solid-supported vesicles from streptavidin-coated microspheres. This method could provide a new route for the stability enhancement of supported lipid bilayer membrane assemblies.

The means of constructing supported membranes for the immobilization of membrane proteins has progressed rapidly from simple physical adsorption of lipid bilayers to more sophisticated approaches involving polymer tethering (*1*−*6*). In the cases involving tether-supported membranes, a wide variety of tethering molecules have been employed, ranging from polymers to peptides (*1*, *5*). Thus far, primarily single lipid moieties connected at the end of tethers have been used to anchor membranes to solid supports (*7*−*10*). In the present study, our aim was to construct biotin−PEG_{3400}−bacteriorhodopsin (bR) conjugates and use them to anchor lipid bilayer membranes to streptavidin-coated microspheres.[1]

As our ultimate goal is to construct robust, supported membrane particles for immobilization of membrane proteins such as biocatalysts, the potential benefits of bacteriorhodopsin anchoring are multifold and linked to greater control over the stability of supported bilayers. Shown schematically in Figure 1, the use of bacteriorhodopsin (26.5 kDa without retinal) as a building block provides a means for more extensive anchor−membrane interactions relative to lipid-mediated tethering. The energetics of the removal of the tethered lipophilic moiety from the membrane are expected to be more highly unfavorable for the case of bR relative to a lipid anchor. This can be argued on the basis of anchor to membrane interaction surface area differences. Supported membrane assemblies on surfaces and particles fabricated in this fashion should exhibit greater stability under shear or processing flows. In addition, due to the increase in anchoring efficiency that could be obtained from the bR anchor, it is conceivable that fewer tethering points would be needed for a given supported membrane area. This would allow for greater native lipid areas for the introduction of membrane proteins into supramolecular assemblies of this type. A further benefit of bR anchoring is that reactive sites on the outer surface of the bR opposite the tether can be exploited to further stabilize the assemblies via cross-linking or by ligating large hydrophilic polymers such as glycans.

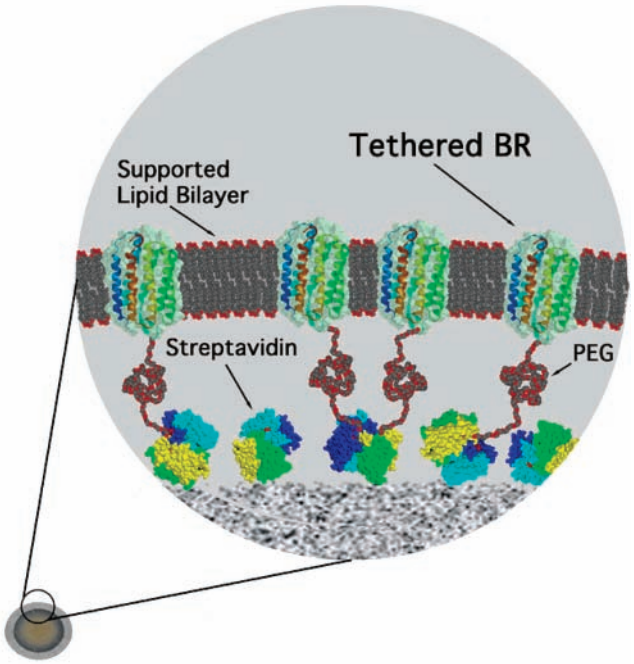

Figure 1. Schematic diagram of solid-supported vesicles that integrate bacteriorhodopsin conjugates as lipid bilayer membrane anchors.

There are a few precedents related to the present study that have involved bacteriorhodopsin or rhodopsin conjugation that warrant mention here. In one such study, Sirokman and Fasman explored the amine-based PEGylation of bR in conferring water solubility to the protein, providing an analysis of likely conjugation sites (*11*). In addition, their studies indicated that PEG_{5000}−bR retained similar proton-pumping activity relative to that

of unlabeled bR when the conjugate was reconstituted into lipid bilayers. In more recent work, Puu et al. utilized biotinylation of bR to allow for the localization of the protein in surface-deposited proteoliposomes, which was verified via AFM imaging of streptavidin−colloidal gold probes (*4*). Also related to the present study is the work of Bieri et al. in which rhodopsin that was biotinylated at the extracellular glycan moiety was used to tether the protein in a specific orientation in a biosensor microarray (*12*). While these studies demonstrate the feasibility of conjugation of bR and tethering via closely related rhodopsin, our work explores the first use of bR as a building block for a potentially improved means to anchor supported membranes.

This paper describes the construction and use of biotin−PEG_{3400}−bacteriorhodopsin conjugates in the formation of solid-supported membranes on particles. We have used amine-based coupling to conjugate biotin−PEG_{3400} to bR. The conjugates were characterized using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) after purification. The PEG−bR conjugate was further labeled with Texas Red to facilitate localization via fluorescence imaging. Supported membranes containing biotin−PEG_{3400}−bacteriorhodopsin were constructed through self-assembly onto streptavidin-coated beads to form solid-supported vesicles (SSVs). Confocal microscopy was used to image these supramolecular complexes, establishing the use of biotin−PEG_{3400}−bacteriorhodopsin as a membrane anchor.

MATERIALS AND METHODS

Materials. Bacteriorhodopsin was obtained as lyophilized powder of the Purple Membrane from *Halobacterium salinarum* strain S9 (Munich Innovative Biomaterials (MIB) GmbH, Germany). Biotin−PEG−SPA (MW 3400) was obtained from Nektar Therapeutics, Huntsville, AL. OG was obtained from Pierce Biotechnology Inc., Rockford, IL. Texas Red-X, succinimidyl ester, and β-BODIPY 530/550 C5−HPC were obtained from Molecular Probes, Eugene, OR. Sephadex G-50 was obtained from Amersham Biosciences Inc, Piscataway, NJ. Streptavidin-coated silica beads (3.18 μm diameter) were obtained from Bangs Laboratories Inc., Fishers, IN. Lipids POPC (egg, chicken), DOPG, and cholesterol (>98% pure) were purchased from Avanti Polar Lipids, Inc. Alabaster, AL. Bio-Beads SM-2 adsorbents were obtained from Bio-Rad Laboratories, Hercules, CA. Sequencing-grade trypsin (Bovine Pancreatic) was obtained from Roche Allied Science, Indianapolis, IN. RapiGest was purchased from Waters Corp., Waltham, MA.

Labeling of bR with Biotin−PEG and Texas Red. Purple membrane (3.45 mg bR) and biotin−PEG−SPA (38.2 mg) were each dissolved in 200 μL of 50 mM Na_2HPO_4 buffer stocks, pH 9.0 with 100 mM OG. The two solutions were mixed together and incubated at room temperature with gentle shaking for 2 h. TR-X succinimidyl ester stock (16.7 mg/mL) was prepared in DMSO and 30 μL was added to 200 μL of the reaction mixture. The remaining reaction mixture was saved for SDS−PAGE and MALDI-TOF-MS analysis after the addition of 15 μL of hydroxylamine (1.5 M) stop reagent. TR-X-containing reaction mixture was further incubated in the dark at room temperature for 2 h before the addition of 15 μL of hydroxylamine (1.5 M) stop reagent. Excess reactants were separated over a Sephadex G-50 column (1 cm × 50 cm) equilibrated with 50 mM Na_2HPO_4 buffer without any OG. bR fractions (labeled and unlabeled) collected from the first peak were pooled together and concentrated using Amicon Ultra-15 filters (30 kDa cutoff, 2800*g*, 30 min). bR aggregates formed on filter membrane were resolubilized using 100 mM OG. To achieve greater purification, traces of excess fluorescent probe TR and unattached biotin−PEG were further removed by another G-50 column. bR fractions from the first peak were pooled together again and exchanged with Hepes buffer A (Hepes, 20 mM; EDTA, 1 mM; NaCl, 100 mM, pH 7.5) using Amicon Ultra-15 filters (2800*g*, 30 min) in three rinse−spin cycles. The final retentate contained both labeled and unlabeled bR, was redissolved in 100 mM OG (25 μM protein, 600 μL total volume), and was stored at 4 °C until required.

Tethering of TR-Labeled Biotin−PEG−bR to Streptavidin-Coated Silica Microspheres. A 200 μL microsphere stock solution (~2 mg microspheres, biotin binding capacity 0.032 μg/mg microspheres) was washed three times with Hepes buffer A with 100 mM OG and centrifuged (200*g*, 10 min). After the third spin cycle the microspheres were mixed with 50 μL of the stock containing TR and biotin−PEG-labeled bR and incubated at room temperature for 3 h with gentle shaking. Biotin−PEG−bR tethered beads were centrifuged (200*g*, 10 min) to remove excess unattached bR complexes and rinsed with Hepes buffer A containing 100 mM OG. This wash−spin cycle was repeated three times to completely remove any nonspecifically adsorbed molecules from the microsphere surface.

Formation of Solid-Supported Vesicles. POPC, DOPG, and cholesterol were mixed in molar ratio 9:1:7 in chloroform (total lipid concentration 10 mg/mL). Green β-BODIPY 530/550 C5−HPC lipid probe was also added to the mixture at a ratio of 1:500 (probe:lipid). The lipid solution was subdivided in 250 μL parts in 4 mL vials and solvent was evaporated using a vacuum. The vials containing the lipid films were then stored under argon at −20 °C until required. For SSV preparation, one lipid formulation containing 2.5 mg of lipids was dissolved in 500 μL of Hepes buffer A with 100 mM OG. This lipid suspension was then used to resuspend the centrifuged biotin−PEG−bR tethered beads that were fabricated in previous steps. The mixture was incubated at 5 °C for 1 h. To remove detergent and form SSVs, 80 mg of wet Bio-Beads was added to the mixture kept at 5 °C with gentle shaking. After 3 h, a fresh lot of 80 mg of Bio-Beads was added and mixture was incubated for additional 2 h. Bio-Beads were then decanted from the solution containing regular and solid-supported lipid vesicles (SSVs). SSVs were centrifuged (200*g*, 10 min) and washed with Hepes buffer A.

Other Methods. MALDI-TOF mass spectrometry analysis was conducted at the Columbia University Protein Core Facility on a Perceptive Biosystems delayed-extraction reflector instrument. Trypsin digestion was carried out overnight at 37 °C in 0.5% RapiGest SF, at concentrations of bR and sequencing-grade trypsin of 0.5 and 0.05 mg/mL, respectively. The detergent was removed via ultrafiltration and a 10 min, 100 °C denaturing step preceded the digestion. SDS−PAGE was done on Bio-Rad Mini PROTEAN II apparatus using 4−15% *Linear Gradient Ready Gel* Tris-HCl Gels. Bio-Safe Coomassie stain from Bio-Rad Laboratories was used to detect protein bands. Gel densitomograms were obtained using a 16 bit Umax flatbed scanner, with image processing carried out using Igor Pro 4.0 (Wavemetrics, Inc). UV−Vis analysis was done on a Hitachi U-3010 spectrophotometer. The extent of fluorophore labeling was

determined by comparison of the Texas Red absorbance relative to protein concentration. Samples were imaged using a Leica TCS-SP four channel confocal microscope at the Mt. Sinai School of Medicine, using 488 nm excitation for β-BODIPY lipid probe and 568 nm for the Texas Red. The transmittance confocal channel was used to position the imaging plane at the center of the microspheres. Image analysis of confocal data was carried out with Igor Pro 4.0 (Wavemetrics, Inc).

RESULTS AND DISCUSSION

Our strategy to conjugate bacteriorhodopsin for anchoring membranes was adapted from the earlier work of Sirokman and Fasman (*11*) with a distinctly different aim. In our application, predominantly single-site labeling is desired. Furthermore, low yield is tolerable, because only the biotinylated bR conjugates will be assembled into the supramolecular complexes. Therefore, in contrast to the earlier bR PEGylation study, in which moderate double labeling was obtained, we did not employ two reaction cycles nor include nonreactive PEG to increase the reactivity of the protein (*11*). The first step of the conjugation was carried out at pH 9 at a 90-fold molar excess of biotin−PEG_{3400}−SPA. To enable fluorescence imaging of the biotin−PEG_{3400}−bR conjugates, an amine-based labeling (at 5-fold molar excess) with Texas-Red succinimidyl ester was conducted after PEGylation, also at pH 9. Separation of the excess reactants was carried out using gel filtration followed by ultrafiltration to remove all traces of Texas Red dye, thus minimizing artifacts in the confocal imaging studies. Figure 2 displays MALDI-TOF-MS traces of the bR starting material (trace A), the bR−PEG_{3400}−biotin conjugate (trace B), and the biotin-PEG_{3400}−bR−Texas Red conjugate (trace C). The inset of Figure 2 displays SDS−PAGE densitomograms that correspond to the MALDI-TOF-MS traces: bacteriorhodopsin starting material (trace A′), the bR−PEG_{3400} conjugate (trace B′), and the molecular weight markers (trace M). Traces B (MALDI-TOF-MS) and B′ (SDS−PAGE) each contain two peaks, a lower molecular weight peak from the unreacted bR and an additional peak of higher molecular weight that we assign to the conjugate. In trace B, we assign the conjugate peak (denoted by an asterisk (*)) to the broad band located approximately 3400 Da higher in molecular weight. A very weak band that appears to correspond to bR−(PEG_{3400}−biotin)$_2$ is evidenced near 34 100 Da in trace B. We assign this feature to a small amount of double labeling of bR. As MALDI-TOF characterization does not provide direct quantitative information about conjugate yield due to differences in desorption of various species, SDS−PAGE studies were also employed. SDS−PAGE densitomograms were obtained for separate bioconjugation trials. Multipeak fitting gave estimated yields of the bR−PEG_{3400}−biotin conjugates that ranged from 13 to 25%.

Figure 3 shows a schematic of the amino acid sequence of bR, with reference to the secondary structures of bR as determined by X-ray crystallography in recent work by Belrhali et al. (1999; PDB 1qhj) (*13*). The seven lysine residues are indicated by the circles, and the residues that comprise the transmembrane helices are located inside the rectangles. We note that the N-terminus is posttranslationally modified and does not contain a primary amine (*14*). The most likely polymer conjugation sites are Lys 129 and Lys 159 (indicated by arrows), as these are found on loops interconnecting the transmembrane helices and are solvent accessible to bulky reactants such as the SPA−PEG_{3400}−biotin employed here

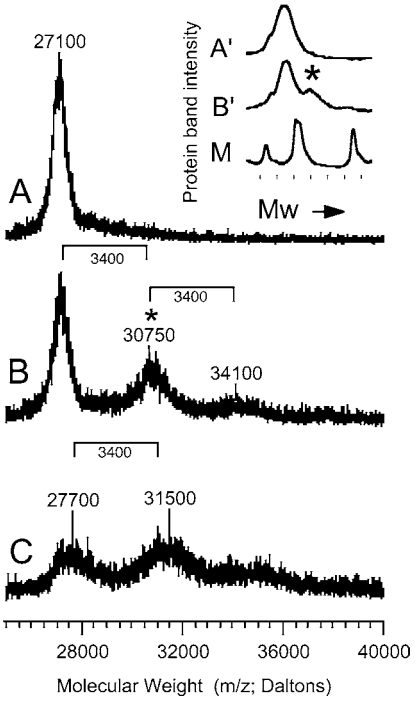

Figure 2. MALDI-TOF-MS and SDS−PAGE gel densitometry results for the biotin−PEG_{3400}−bacteriorhodopsin conjugate. Trace A was obtained from the bR starting material. Trace B was obtained from the biotin−PEG_{3400}−bR conjugate. The peak denoted by the asterisk (*) in the main figure and inset is assigned to the biotin-PEG_{3400}−bacteriorhodopsin conjugate. Trace C was obtained from the biotin−PEG_{3400}−bR−Texas Red conjugate. In the inset, SDS−PAGE gel densitometry results are shown for samples corresponding to traces A and B of the MALDI-TOF-MS results. Trace A′ was obtained from the bR starting material. Trace B′ was obtained from the biotin−PEG_{3400}−bR conjugate. Trace M was from the molecular weight markers (20, 25, and 37 kDa, left to right).

(*11*). Furthermore, in aforementioned studies carried out by Sirokman and Fasman with amine-reactive PEG_{5000}, chymotrypsin digestion studies were consistent with loop lysine labeling (*11*). Their findings were further bolstered by cogent arguments also based on the structure of bR. Early work with small-molecule labeling indicated that Lys 129 was the most likely site (*15, 16*).

To address this question directly, we have performed a trypsin digestion of the bR−PEG_{3400}−biotin conjugate, followed by MALDI-TOF-MS characterization of the resulting fragments. The degree of difficulty of trypsin fragmentation is especially high for membrane proteins such bR, as most cleavage sites are buried and, in addition, give rise to highly hydrophobic peptides (*14*). Furthermore, the addition of detergents to expose cleavage sites dramatically reduces trypsin activity. To obtain greater digestion yields, we employed a new, acid-cleavable denaturant (RapiGest SF, Waters Corp.) that does not greatly inhibit proteases and allows for higher trypsin reaction yields. In our experiments, run over a wide set of conditions, including ranges of RapiGest SF concentration and trypsin:bR ratio, we obtained peptides with missed cleavages almost exclusively. Table 1 lists the tryptic digest fragments detected that contain either K129 or K159. The corresponding MALDI-TOF-MS traces are shown in Figure 4. Trace A is from bR (control) and traces B and B′ (3 × B) are from the bR−PEG_{3400}−biotin conjugate. Prominent in trace A are the peaks at 17 578 and 24 856 *m*/*z*, assigned to 1−159 and 1−227, respectively, formed from loop site cleavage. Inspection of the bR−PEG_{3400}−biotin conjugate trace magnified 3× shows

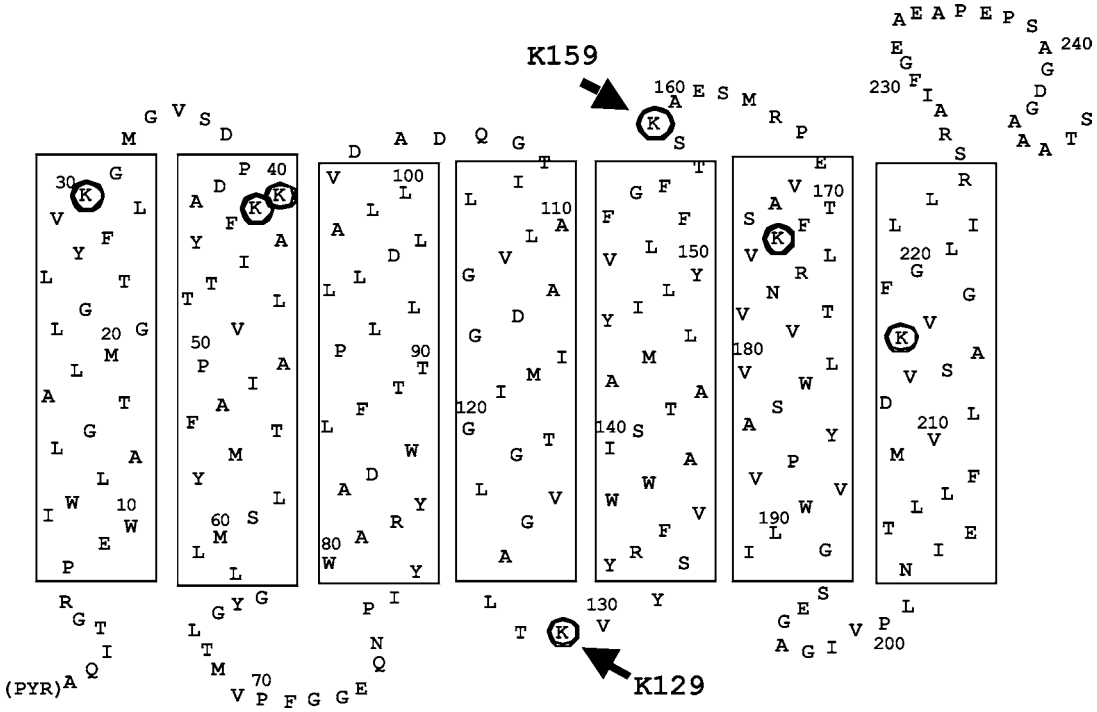

Figure 3. Schematic diagram of the structure of bacteriorhodopsin. The amino acid residues located in transmembrane helices are indicated by the rectangular boxes.

Table 1. Trypsin Fragments of Bacteriorhodopsin Detected That Contain Potentially Accessible Lysines

trypsin fragment no.	bR obsd (m/z)[a]	bR−PEG_{3400}−biotin observed (m/z)[a]	assigned sequence or conjugate (expected MW, species)
T6-7	3 566	3 600	130−159 (3 645, $[M + H]^+$)
T5-7	8 479	8 481	83−159 (8 470, $[M + H]^+$)
T1-7	9 025	9 017	1−159 (9 034, $[M + H]^{+2}$)
T1-7−PEG_{3400}−biotin		10 826	1−159−PEG_{3400}−biotin (9 034, $[M + H]^{+2}$)
T1-12	12 355	12 432	1−227 (24 882, $[M + H]^{+2}$)
T3-7	13 262	13 307	41−159 (13 198, $[M + H]^+$)
T1-7	17 578	17 662	1−159 (17 487, $[M + H]^+$)
T1-7−PEG_{3400}−biotin		21 200	1−159−PEG_{3400}−biotin (20 870, $[M + H]^+$)
T1-12	24 856	24 885	1−227 (24 882, M^+)
T1-12−PEG_{3400}−biotin		28 551	1−227−PEG_{3400}−biotin (28 282, $[M + H]^+$)

[a] The moderate errors in m/z relative to the expected MWs are attributed to external calibration of the spectra and some degree of amino acid side reactions such as methionine oxidation.

broad peaks shifted over by approximately 3400 Da from peaks assigned to sequences 1−159 and 1−227. These peaks are assigned to 1−159−PEG_{3400}−biotin and 1−227−PEG_{3400}−biotin conjugated fragments. The doubly charged 1−159−PEG_{3400}−biotin species was also detected as a broad peak centered at 10 826 m/z. We were unable to detect any other PEGylated species, including conjugates of 83−159 and 41−159, a consequence, presumably, of lower yields of intrahelical site cleavage that precluded detection. Due to the high yield of 1−159−PEG_{3400}−biotin species in the trypsin digest, we infer that the predominant PEG_{3400}−biotin conjugation site is K129, as PEG_{3400}−biotin labeling at K159 would be expected to inhibit trypsin due to steric hindrance.

The other five lysines are thought to be less solvent accessible and are the likely sites of conjugation of the hydrophobic Texas Red fluorophore. Evidence for successful fluorophore labeling was first seen in the SDS−PAGE gels, as the bands from bR labeled with Texas Red generated a different hue due to the colorimetric properties of this chromophore combined with the bromophenol blue protein stain. MALDI-TOF-MS of the biotin−PEG_{3400}−bR−Texas Red conjugate is shown in trace C of Figure 2. Two broad peaks with complex line shapes were evidenced, centered at approximately 27 700 and 31 500 Da. These features are shifted by over 600 Da from the corresponding peaks arising from bR and the bR−PEG_{3400}−biotin conjugate (found in trace B). These shifts are consistent with the successful conjugation of Texas Red (ligated molecular weight 702 Da) to a fraction of both the unreacted bR starting material and the bR−PEG_{3400}−biotin conjugate, giving rise to broad composite

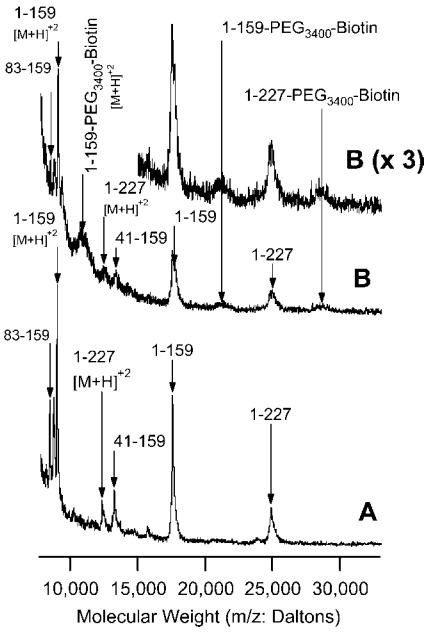

Figure 4. MALDI-TOF-MS results for the tryptic digest reaction products of the biotin−PEG_{3400}−bacteriorhodopsin conjugate. Trace A was obtained from a tryptic digest of the bR starting material. Trace B was obtained from a tryptic digest of biotin−PEG_{3400}−bR conjugate, conducted under the same conditions as in trace A. For closer examination, the region from 15 000 to 32 000 of trace B is shown magnified three times in the top trace.

peaks comprised of fluorophore-labeled and unlabeled molecules. Furthermore, UV−Vis analysis of the conjugate revealed that approximately 1−2 Texas Red fluorophores were conjugated to each protein molecule. This was based on protein concentration determined by UV absorption, combined with the Texas Red absorption intensity of the conjugate.

To demonstrate the use of bR in membrane anchoring, we have constructed solid supported vesicles (SSVs) based on streptavidin-coated silica microspheres (nominal size 3.18 μm). The first step in SSV assembly is to bind the biotin−PEG_{3400}−bR−Texas Red conjugates to the microspheres via biotin−streptavidin complex formation. In these experiments, the biotinylated conjugates were added in excess of a 1:1 molar ratio of the total number of streptavidin sites (from manufacturer's specifications) to aim for complete coverage. Removal of excess bR and bR conjugates is facilitated by the ease of settling the particles by low-speed centrifugation. To demonstrate formation of the supported bilayers on the particles, a green fluorescent phosphatidylcholine analogue (β-BODIPY 530/550 C5−HPC) was incorporated into the supported bilayer phospholipids. This reagent was incorporated in the formulation of negatively charged phospholipids (at a 1:500 probe:lipid ratio) that was combined with the bR-terminated particles. The phospholipids mixture also contained octyl glucoside detergent at 100 mM, which is above the concentration at which membranes become completely solublized and lipids form mixed micelles with detergent (*17, 18*). The final reconstitution steps were to form supported lipid bilayers on the particle surface upon removal of detergent by Bio-Beads (adsorbent), followed by centrifugation/washing steps to remove excess regular liposomes.

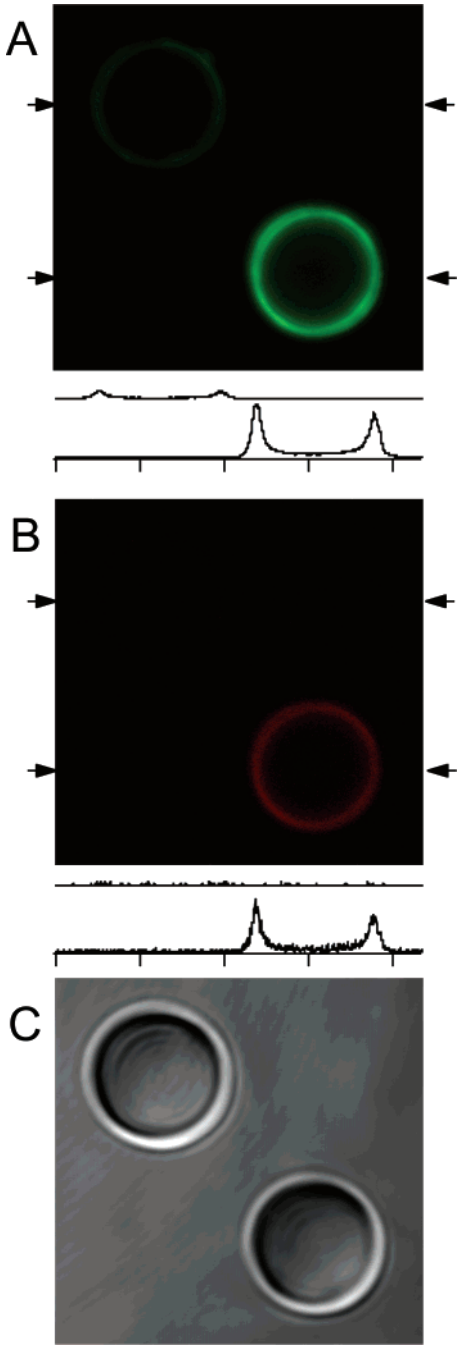

Figure 5. Confocal microscopy of solid-supported vesicles (SSVs) doped with a green fluorescent phosphatidylcholine analogue (β-BODIPY 530/550 C5−HPC) anchored by biotin−PEG_{3400}−bR−Texas Red conjugates. The images were obtained in a single *XY* imaging plane (~0.2 μm thickness) at the center of the particles. The top left particle is the nonspecific adsorption negative control, and the desired bR-anchored SSV particle is at the bottom right. The particles are each shown in three channels: β-BODIPY 530/550 (top panel A, excitation 488 nm, detection 500−570 nm), Texas red (middle panel B, excitation 568 nm, detection 580−660 nm), and reflectance mode (bottom panel C). Shown below the emission images are intensity profiles taken from horizontal slices bisecting the images at the positions of the arrows.

Confocal imaging results from a single *XY* plane obtained from bR-anchored, solid-supported vesicles (right, bottom) and a nonspecific adsorption control (left, top) are shown in Figure 5. These images were obtained from a region of the slide that contained both a (nonspecific adsorption) control particle and a desired bR-anchored SSV particle. The β-BODIPY 530/550 (green) emission

image is shown in panel A and the Texas Red emission image is shown below in panel B. For reference, the reflectance mode confocal image is given in panel C. Intensity profiles, taken horizontally from the images at the position of the arrows, are shown immediately below each dye emission image. At this resolution, the bR-anchored, solid-supported vesicle (right, bottom) exhibits colocalization of Texas Red and β-BODIPY 530/550 emissions in an approximately homogeneous ring around the particle. The presence of this pattern suggests that we have formed the bR anchored SSVs as intended in the design, with spatially overlapping emissions from the biotin−PEG_{3400}−bR−Texas Red conjugate and β-BODIPY 530/550 from the lipid layer. As a negative control, we also probed the nonspecific adsorption of β-BODIPY 530/550 containing lipids to the streptavidin microspheres under conditions similar to bR-anchored, SSV formation. In this case no tethering to the microspheres was employed. In general, nonspecific adsorption of the green fluorescent lipids was evidenced on average at lower levels than for the desired bR-anchored, solid-supported vesicles. This is reflected in the comparison of the intensities of representative particles shown in cross section in panel A. Moreover, the control microsphere in panel B (left, top) shows no Texas Red emission, as expected. This attribute was used to distinguish SSV particles from control particles on the same slide.

CONCLUSIONS

Bacteriorhodopsin−PEG_{3400}−biotin conjugates were constructed via primary amine coupling. The conjugates were characterized with MALDI-TOF-MS; single-site labeling occurred predominantly under these conditions. In cases in which the bR−PEG_{3400}−biotin conjugates were subsequently labeled with Texas Red for imaging, one or two sites per protein were tagged. Lysine 129, situated on an interhelical loop, was the most likely site for conjugation, as determined by trypsin digestion studies.

The confocal imaging results provide direct evidence that we have formed supported bilayers anchored with bacteriorhodopsin conjugates over a majority of the surfaces of the particles. In addition, β-BODIPY 530/550 containing lipid was localized on the particle surface, providing further evidence for supported vesicle formation mediated by the bR anchor formation. The present use of bR as an anchoring moiety may provide a new direction in the goal of enabling greater control over the stability of supported membranes positioned onto particles or onto surfaces. Continuing with this approach, we aim to fabricate particles that provide highly robust, yet nativelike microenvironments for the immobilization of membrane proteins. Further studies are currently underway to assess enhancements in stability relative to lipid tethering and to construct assemblies with varying amounts of bilayer tethering. In parallel, we are working to co-localize other membrane proteins in bR-anchored bilayers and examine retention of native function of the protein and activity in the assemblies.

ACKNOWLEDGMENT

Confocal microscopy was performed at the Mt. Sinai Medical School-Microscopy Shared Research Facility, supported, in part, with funding from NIH-NCI shared resources grant (1 R24 CA095823-01). Mary Ann Gawinowicz of the Columbia University Protein Core Facility is gratefully acknowledged for vital guidance in the tryptic digestion and MALDI-MS analysis.

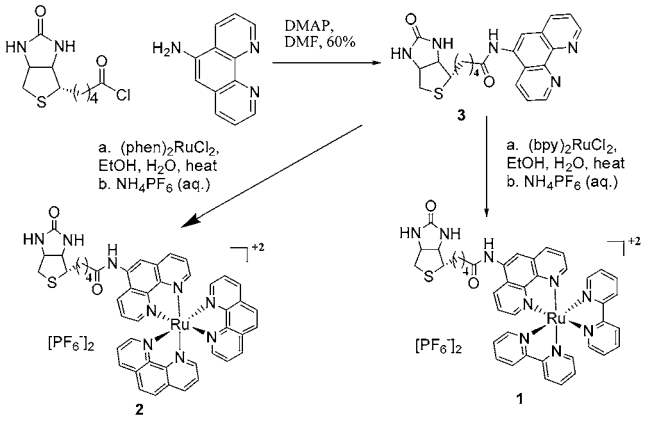
Ruthenium(II)−Phenanthroline−Biotin Complexes: Synthesis and Luminescence Enhancement upon Binding to Avidin

Mohamed Slim and Hanadi F. Sleiman*

Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, QC H3A 2K6 Canada.
Received March 31, 2004; Revised Manuscript Received July 22, 2004

We report the synthesis, characterization, and avidin-binding properties of two novel ruthenium complexes, $[Ru(bpy)_2(phen\text{-}biotin)][PF_6]_2$ **1** and $[Ru(phen)_2(phen\text{-}biotin)][PF_6]_2$ **2** (bpy = 2,2′-bipyridine; phen = 1,10-phenanthroline, phen-biotin = 5-(10-amidobiotinyl)-1,10-phenanthroline)). We demonstrate that both biotinylated compounds bind to avidin through their biotin moieties with high affinity and in a 4:1 ratio. The binding of compounds **1** and **2** to avidin results in an enhancement in luminescence intensity (∼1.4×, ∼1.6×, respectively), relative to the unbound biotinylated ruthenium complexes. This behavior is markedly different from biotinylated organic dyes, whose fluorescence is quenched upon binding to avidin. Thus, ruthenium−biotin complexes **1** and **2** can form the basis of new, simplified biotin−avidin assays, which involve luminescence detection of the relevant biotinylated molecule through cross-linking with avidin.

INTRODUCTION



The binding of biotin to (strept)avidin has found widespread applications in biomolecule detection, medical diagnostics, immunoassays, cytochemistry, and nanoscience (*1*−*7*). This is primarily due to the strength of the interaction between the ligand and the protein ($K_d = 1.3 \times 10^{-15}$ M) and to the presence of four binding sites for biotin on avidin, which in turn allows for the cross-linking of different biotinylated molecules (*1*). Bioanalytical applications based on the biotin/avidin interaction have typically used enzymatic reactions, radiolabeling techniques, and fluorescence for detection/visualization (*8*−*12*). Of these, fluorescence-based assays are some of the most straightforward and rapid detection techniques (*13*−*16*). The simplest design for these biotin−avidin assays would be covalent attachment of the fluorescent dye to biotin, followed by fluorescence detection of the relevant biotinylated molecule through cross-linking with avidin. However, biotinylated organic dyes have been shown to lose their luminescence intensity upon binding to avidin, likely through resonance energy transfer mechanisms (*17*−*22*). To overcome this problem, long spacers, such as poly(ethylene glycol), have been used to maximize the distance between the biotin-conjugated organic dyes and the avidin binding site (*17*, *18*). As a result of these difficulties, most fluorescence-based detection methods have relied on the more difficult conjugation of the organic dyes to the protein itself, rather than simple attachment to biotin (*18*, *19*).

Among many inorganic chromophores, ruthenium(II) bipyridyl or phenanthroline complexes have recently

Scheme 1. Synthesis of Ru(II)−Phenanthroline−Biotin Complexes 1 and 2

emerged as promising candidates for a variety of bioanalytical applications (*13*, *23*−*26*). These complexes present some unique photophysical properties, which distinguish them from their organic counterparts, including their chemical inertness and photostability, the tunability of their photophysical characteristics, the relative insensitivity of their photophysical properties to environmental changes, their large Stokes shifts, and their long excited-state lifetimes (*13*). We here report the facile synthesis of ruthenium complexes **1** and **2**, where a $(bpy)_2Ru(phen)^{2+}$ or $(phen)_3Ru^{2+}$ center is conjugated to a biotin moiety (bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline). Unlike organic dyes, binding of these Ru(II)−biotin complexes to avidin results in an enhancement in their luminescence intensity, thus making them useful tools for fluorescence-based biotin−avidin assays.

The synthesis of complexes **1** or **2** was carried out by first coupling 5-amino-1,10-phenanthroline (*27*, *28*) with the acyl chloride (*29*) derivative of biotin, to give the biotin−phenanthroline ligand **3**. The target complexes **1** and **2** were then obtained by refluxing ligand **3** with $Ru(bpy)_2Cl_2$ or $Ru(phen)_2Cl_2$ (*30*) in good yield (70−80%) and were isolated as their PF_6^- salts (Scheme 1) (*46*).

The UV/vis absorbance spectrum of ruthenium−biotin complexes **1** and **2** in CH_2Cl_2 shows bands at 450 nm, assigned to Ru(II) dπ−π* metal-to-ligand charge transfer (MLCT) transitions (Figure 1) (*46*). In addition, more intense bands at 250−300 nm were assigned to ligand-centered π−π* transitions. These absorbances and assignments are consistent with a number of related complexes in the literature (*13*, *30*). Steady-state emission spectra were recorded for complexes **1** and **2** in dichloromethane and showed strong luminescence at 589 nm for **1** and 580 for **2**, upon excitation of the MLCT band at 450 nm (Figure 1). The emission wavelength showed a slight increase with increasing solvent polarity, likely due to the stabilization of the MLCT state with polar solvents (*46*).

The binding properties of the Ru−biotin complexes **1** and **2** to avidin were first examined using the 4′-hydroxyazobenzene-2-carboxylic acid (HABA) assay (*32*, *46*). HABA can bind to avidin at the same binding site as biotin, with an association constant of 10^7 M^{-1} and with the same stoichiometry as unmodified biotin (4:1). Upon binding to avidin, HABA displays a new peak in its absorption spectrum at 500 nm. When biotin or biotinylated molecules are added, the displacement of HABA from avidin results in the reduction of this HABA−avidin absorption at 500 nm. The HABA−avidin complex was thus generated and was then titrated with the Ru−biotin complex **1**. An immediate decrease in the absorption at 500 nm was detected, and a new peak at ca. 450 nm, corresponding to the ruthenium complex **1**, was observed. The titration required exactly 4 mol equiv of complex **1** to avidin, after which no further changes in the absorption peak at 500 nm were detected (*46*). These results are consistent with immediate displacement of HABA from avidin and concomitant binding of Ru−biotin complex **1** to the protein. Similar results were obtained when the HABA−avidin complex was titrated with complex **2** (*46*). Thus, complexes **1** and **2** bind to avidin in a 4:1 ratio and with greater affinities than the HABA-avidin interaction.

To investigate the luminescence changes of complexes **1** and **2** in the presence of avidin, an avidin solution (in buffer A, containing 100 mM NaCl, 50 mM NaH_2PO_4, 1 mM EDTA, pH adjusted to 7.5 using NaOH) was titrated with complex **1** (16 μM), and luminescence at 615 nm was monitored (Figure 2, curve II). In addition, a blank buffer solution was titrated with complex **1** (16 μM, Figure 2, curve I). These experiments were repeated using complex **2** (Figure 3). Comparison of the titration curves I and II revealed that the luminescence of the Ru−biotin complexes is *enhanced* upon binding to avidin (*33*).

The emission intensity of the Ru−biotin complex **1** fully bound to avidin (4:1) ratio was measured to be ca. 1.4 times greater than unbound complex **1**, and complex **2** showed a greater enhancement of 1.6 (Figure 4). As a control experiment, the titration of avidin with $Ru(bpy)_3^{2+}$, which has similar structural and photophysical properties to complexes **1** and **2**, but lacks a biotin moiety, showed no detectable change in its luminescence intensity. Thus, complexes **1** and **2** bind to avidin through their biotin moiety in a 4:1 ratio and show luminescence enhancement as a result of this interaction. This is in marked contrast with the behavior of biotinylated organic

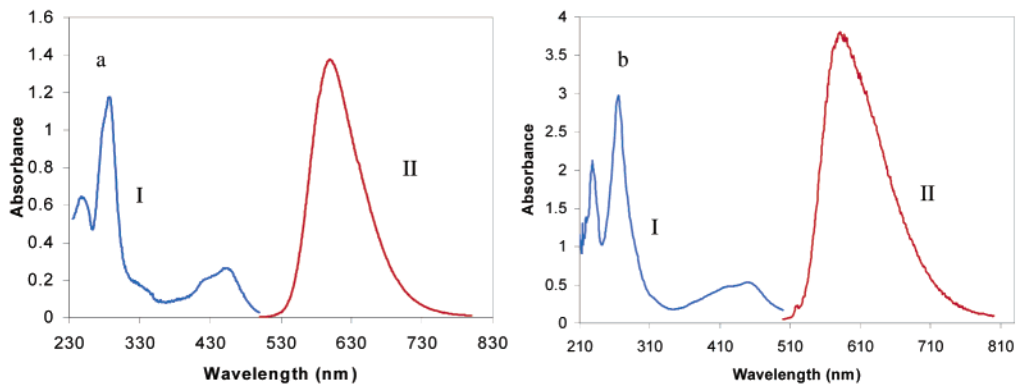

Figure 1. Electronic absorption (I) and emission (II) spectra of complexes **1** (a) and **2** (b) in CH_2Cl_2 at ambient temperature.

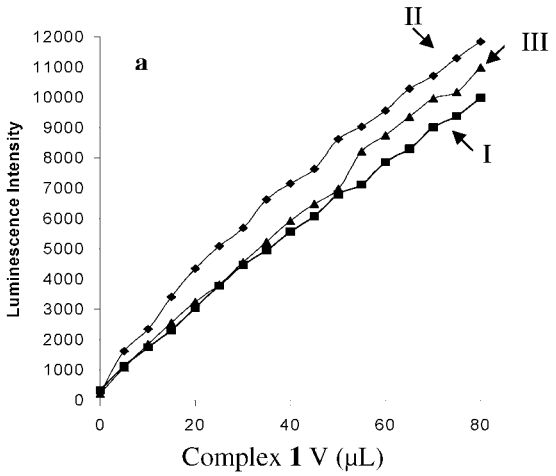

Figure 2. Luminescence titration curves for the titrations of (I) a blank buffer A solution with complex **1**, (II) an avidin solution (20 nmol) with complex **1**, (III) a preformed complex of avidin (20 nmol), and biotin (80 nmol) with complex **1** (16 M); the time delay between each addition was approximately 8 min.

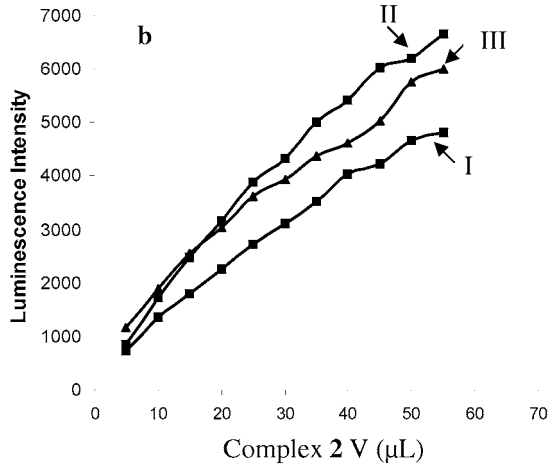

Figure 3. Luminescence titration curves for the titrations of (I) a blank buffer A solution with complex **2**, (II) an avidin solution (10 nmol) with complex **2**, (III) a preformed complex of avidin (10 nmol), and biotin (40 nmol) with complex **2** (16 M) the time delay between each addition was approximately 8 min.

fluorophores, whose fluorescence is quenched upon binding to avidin. The increase in luminescence intensity of the ruthenium complexes may be a result of the positioning of these chromophores in a more hydrophobic environment upon binding to avidin. Indeed, Ru(II) polypyridine complexes show a higher luminescence quantum yield in organic solvents, compared to water (*34*−*36*). Interestingly, preliminary experiments performed on the interaction of complex **2** with streptavidin, which is more hydrophobic and less positive in charge than avidin, showed a greater luminescence enhancement of ∼1.9 (*9*, *47*). To our knowledge, there is only one previous report describing a rhenium−biotin complex, which binds to avidin with luminescence enhancement (*37*). The tris-chelated Ru-complexes **1** and **2** are expected to display greater stability than the rhenium complex, which possesses monodentate pyridine and carbonyl ligands (*38*). In addition, ruthenium (II) bipyridine complexes are redox active, and can be used for electrochemiluminescence experiments, with a significant amplification of their luminescence signals (*41*).

To compare the avidin binding affinity of the Ru−biotin complexes to that of biotin itself, a complex of avidin−biotin in a 1:4 ratio was generated. This sample was then titrated with Ru−biotin complexes **1** (or **2**) (16 μM), and the luminescence intensity at 615 nm was monitored (Figures 2 and 3, titration curves III). Complex **2** showed consistently higher luminescence intensity than unbound Ru−biotin (curve I in Figure 3). This suggests partial displacement of biotin from avidin by molecule **2** and concomitant binding of this complex to avidin, resulting in an increase in its luminescence intensity. Complex **1**, on the other hand, showed similar luminescence intensity to that of unbound Ru−biotin, which increased only when relatively high concentrations were attained (curve III in Figure 2). Thus, the binding constant of complex **2** to avidin is likely higher than that of complex **1**. A similar preliminary experiment was performed with streptavidin, where 4 equiv of molecule **2** were added to a preformed streptavidin:biotin complex. In this case, an enhancement of ∼1.8 was noticed, consistent with an even greater binding affinity of complex **2** to streptavidin (*47*).

A final experiment was carried out, where a preformed complex of avidin−Ru−biotin in a 4:1 ratio was generated and then titrated with a solution of biotin (16 μM). The titration curves for both complexes **1** and **2** showed a steady decrease in luminescence intensity, until a ratio of biotin:avidin of approximately 4:1 was reached, upon which the luminescence intensity of the ruthenium complexes was unchanged with further biotin addition (*46*). This result is consistent with displacement of complexes **1** and **2** from avidin by biotin itself, suggesting that biotin binds to avidin with a higher affinity than complexes **1** and **2**. Thus, complexes **1** and **2** showed a relatively high binding affinity to avidin, albeit lower than biotin itself (K_d = 10^{-15} M), with a 4:1 binding stoichiometry and concomitant luminescence enhance-

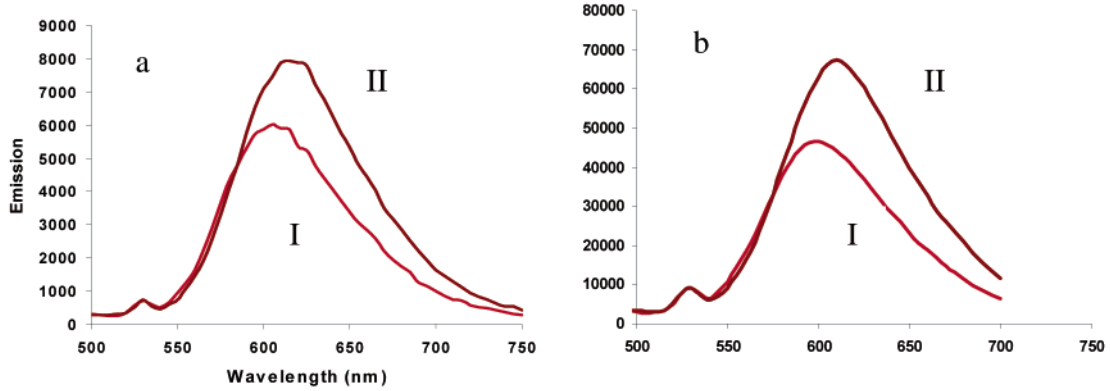

Figure 4. (a) Emission of complex **1** in buffer A (I) and in buffer A with avidin (II) (4:1 ratio). (b) Emission of complex **2** in buffer A (I) and in buffer A with avidin (II) (4:1 ratio).

ment. Interestingly, when a similar experiment was performed using streptavidin instead of avidin, the addition of 4 equiv of biotin to a preformed complex of streptavidin:molecule **2** did not cause any decrease in luminescence intensity, even after 12 h. This is consistent with little displacement of complex **2** from avidin by biotin and again suggests higher binding affinity of complex **2** to streptavidin, as compared to avidin (*47*).

In conclusion, we have generated a new class of ruthenium complexes, where $(bpy)_2Ru(phen)^{2+}$ or $(phen)_3Ru^{2+}$ centers are conjugated to a biotin moiety. These complexes bind to avidin and streptavidin through their biotin moiety with high affinity, in a 4:1 ratio, and with concomitant enhancement in their fluorescence intensity. This is in marked contrast with organic dyes, which lose their fluorescence upon binding to avidin. Thus, these new ruthenium−biotin complexes can form the basis of new, simplified biotin−avidin assays, which consist of cross-linking the unknown biotinylated molecule and the ruthenium−biotin complex to avidin, for luminescence detection. Ru(II) polypyridine complexes present other advantages over the currently used chromophores, including their photostability and resistance to photobleaching, and their large Stokes shifts, which allow many of these chromophores to be linked to the protein for signal amplification, without quenching their luminescence (*19*, *21*, *39*−*45*). Further work is in progress in our laboratory to extend the applications of these and related transition metal−biotin complexes to more selective bioassays.

Facile Synthesis of Chain-End Functionalized Glycopolymers for Site-Specific Bioconjugation

Sijian Hou,[†] Xue-Long Sun,*[,†] Chang-Ming Dong,[†] and Elliot L. Chaikof*[,†,‡]

Laboratory for Biomolecular Materials Research, Departments of Surgery and Biomedical Engineering, Emory University School of Medicine, Atlanta, Georgia 30322, and School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, Georgia 30320. Received March 19, 2004; Revised Manuscript Received June 22, 2004

A series of derivatized arylamine initiators were used to generate chain-end functionalized glycopolymers by cyanoxyl-mediated free-radical polymerization. Significant features of this strategy include the capacity to produce polymers of low polydispersity (PDI < 1.5) under aqueous conditions using unprotected monomers bearing a wide range of functional groups. In addition, the presence of a phenyl ring simplifies calculation of polymer saccharide content and molar mass by ^{1}H NMR. It is particularly noteworthy, however, that derivatized arylamine initiators in conjunction with the presence of a terminal cyanate group provide a convenient approach for synthesizing polymers with a variety of distinct functional groups at α and ω chain ends. In the process, the capacity to label glycopolymers or otherwise conjugate them to proteins or other molecules is greatly enhanced.

INTRODUCTION

Polymers containing carbohydrate moieties as pendant groups, referred to as "glycopolymers", have potential applications in medicine and biotechnology. In particular, glycopolymers potentiate multivalent protein−carbohydrate interactions, which lead to biomolecular recognition events that are dramatically different from those elicited by monovalent interactions (*1*−*3*). In the past decade, considerable efforts have focused on the application of living/controlled polymerization strategies for the production of glycopolymers that exhibit low fluctuation in size and composition. Examples include cationic polymerization (*4*−*7*), ring-opening polymerization (*8*, *9*), ring-opening metatheses polymerization (*10*, *11*), and nitroxide-mediated radical polymerization (*12*−*16*). Likewise, recent reports have also demonstrated the efficacy of transition metal-catalyzed atom transfer radical polymerization (ATRP) for the synthesis of carbohydrate-bearing polymers (*17*−*21*).

Recently, the potential utility of glycopolymers in bio- and immunochemical assays (*22*−*25*), as biocapture reagents (*26*, *27*), and as glycosurfaces (*28*, *29*) has been investigated by the addition of functional anchoring groups either pendant to the backbone or at the chain end. In this regard, a chain-end functionalized glycopolymer facilitates site-specific immobilization required for generating a uniformly oriented multivalent array of carbohydrates (*25*). However, the desire to generate glycopolymers with oligosaccahride units of increasing functional complexity poses a number of significant challenges, including a requirement for serial protection−deprotection steps or further polymer derivatization after initial synthesis. We have previously reported that cyanoxyl (OCN)-mediated free radical polymerization of unprotected glycomonomers can be conducted in aqueous solution, is tolerant of a broad range of functional groups including −OH, −NH_2, −COOH, and SO_3^- moieties, and can yield glycopolymers with low polydispersity (PDI < 1.5) (*29*−*31*). In the present study, we describe a straightforward approach to synthesize chain-end functionalized glycopolymers (Figure 1) using functionalized arylamine initiators in conjunction with cyanoxyl-mediated polymerization. As a model system, copolymerization of acrylamide with either lactose or sulfated lactose acrylamide monomer was performed. Notably, polyacrylamide-based neoglycoconjugates have been used as diagnostic reagents (*32*) or as solid-phase coatings in enzyme-linked immunosorbent assays (ELISA) (*22*, *33*).

EXPERIMENTAL PROCEDURES

Chemicals. *p*-Anisidine(4-methoxyaniline), 2-(4-aminophenyl) ethylamine, 4-aminobenzoic hydrazide, 4-aminophenylacetic acid, *N*-(9-fluorenymethoxycarbonyloxy) succinimide, piperidine, sodium nitrite, fluoroboronic acid (48% aqueous solution), sodium cyanate, tetrahydrofuran (THF), acrylamide (AM), peracetyl lactose, dimethylformamide (DMF), methanol, trifluoron boron in ether (BF_3·OEt_2), sodium azide, acryloyl chloride, platinum oxide, sodium methoxide, and triethylamine were used as received, unless otherwise specified. Lactose acrylamide monomer (**2**) and sulfated lactose acrylamide monomer (**3**) were synthesized as previously described (*31*).

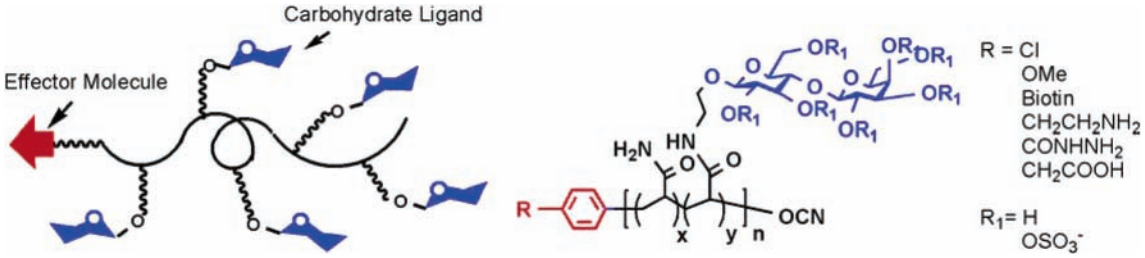

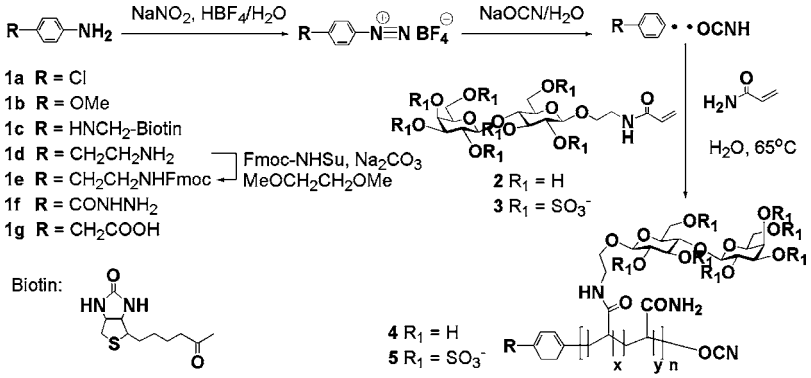

Figure 1. Schematic structure of chain-end functionalized glycopolymer.

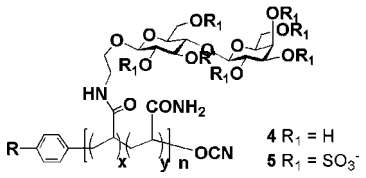
Scheme 1: Synthesis of Chain-End Functionalized Glycopolymers via Cyanoxyl-Mediated Free Radical Polymerization

(Scheme 1). In a three-neck flask, 6.03×10^{-5} mol of arylamine was reacted with 17 mg of HBF_4 (48 wt % aqueous solution, 9.04×10^{-5} mol) in 2 mL of water at 0 °C and under an Ar atmosphere. The diazonium salt $RC_6H_4N^+{\equiv}NBF_4^-$ was then generated by adding 5 mg (7.2×10^{-5} mol) of sodium nitrite ($NaNO_2$) to the reaction medium. After 30 min, a degassed mixture of 225 mg (6.03×10^{-4} mol) of glycomonomer (2/3), 171 mg (2.41×10^{-3} mol) of acrylamide, and 4 mg (6.03×10^{-5} mol) of NaOCN dissolved in 1 mL of water were introduced into the flask containing the diazonium salt. The polymerization solution was then heated to 65 °C for 16 h to yield statistical copolymers (**4**/**5**) after quenching the reaction and dialysis for 2 days at room temperature to remove inorganic salt and impurities. The conversions were determined by weight for the resultant glycopolymers.

Complex Formation of Biotin Chain-End Functionalized Glycopolymer with Streptavidin. The biotin chain-end functionalized glycopolymer **4c**/**5c** (1.33×10^{-4} mmol) dissolved in PBS (0.2 mL) was incubated with streptavidin (1.67×10^{-5} mmol) at room temperature for 2 h. UV−vis spectroscopy was performed before and after adding 4′-hydroxyazo-benzene-2-carboxylic acid (HABA, 1.33×10^{-4} mmol). All spectra were acquired on a Cary 50 Bio UV−visible spectrophotometer (Varian).

Conversion of Cyanate (OCN) of Glycopolymer 4b to a Hydroxyl End Group. Pyridine (0.5 mL) was added to a solution of glycopolymer **4b** (16 mg, 2.1×10^{-3} mmol) in water (2 mL). The mixture was stirred at room temperature for 2 h, followed by dialysis against water at room temperature for 2 days to remove excess pyridine and glutaconic aldehyde. Infrared spectra of **4b** and **6b** were acquired using a Digilab/BioRad FTS-4000 Fourier transform infrared (FT-IR) spectrometer (Randolf, MA) equipped with a wide band MCT detector, collected with 512 backgrounds scans, triangular apodization, and 4 cm^{-1} resolutions.



Synthesis of Fmoc-Protected Arylamine 1e. 2-(4-Aminophenyl) ethylamine (**1d**) (220 mg, 1.615 mmol) was dissolved in a sodium carbonate aqueous solution (10%, 7 mL) and was stirred 30 min at room temperature. A solution of *N*-(9-fluorenylmethoxycarbonyloxy) succinimide (Fmoc-NHS, 545 mg, 1.615 mmol) in 1,2-dimethoxyethane (7 mL) was slowly added, and the reaction mixture was stirred overnight at room temperature. A white solid in the reaction mixture was removed by filtration. The filtrate was evaporated to yield a residue, which was dissolved in ethyl acetate, washed three times with distilled water, and then concentrated. The resulting residue was purified by silica gel column chromatography using chloroform/methanol (95/5) as eluent to obtain **1e** (265 mg, yield 46%). ^{1}H NMR ($CDCl_3$) δ ppm: 7.75 (2H, d, J = 7.5 Hz), 7.6 (2H, d, J = 7.2 Hz); 7.40 (2H, t, J = 7.2 Hz), 7.30 (2H, t, J = 4.8 Hz), 6.95 (2H, d, J = 4.8 Hz), 6.60 (2H, d, J = 8.1 Hz), 4.40 (2H, d, J = 6.6 Hz), 4.2 (1H, t, J = 6.9 Hz), 3.4 (2H, m), 2.70 (2H, t, J = 6.9 Hz). MS/FAB, m/z: 358 $(M + Li)^+$.

Removal of Fmoc Protecting Group of Glycopolymer 5e. Fmoc-protected glycopolymer **5e** (50 mg) was dissolved in 3 mL of DMF. Piperidine (3 mL) was dropped into the polymer solution, which was stirred overnight at room temperature. The reaction mixture was dialyzed using a cellulose membrane for 2 days and then extracted three times using chloroform. The solution was freeze-dried using a lyophilizer to give glycopolymer **5d** (33 mg).

RESULTS AND DISCUSSION

Previous investigations have demonstrated that cyanoxyl (OCN)-mediated free-radical polymerization of acrylamide glycomonomers could be conducted in aqueous solution to yield glycopolymers of low polydispersity. In this polymerization scheme, cyanoxyl radicals are generated by an electron-transfer reaction between cyanate anions ($^-OC{\equiv}N$) from a NaOCN aqueous solution and aryl-diazonium salts ($RC_6H_4N{\equiv}N^+BF_4^-$) prepared in situ through a diazotization reaction of arylamine in water. In addition to cyanoxyl persistent radicals, aryl-type active radicals were simultaneously produced, and only the latter species is capable of initiating chain growth. Therefore, we hypothesized that chain-end functionalized

[a] Polymerizations were performed for 16 h at 65 °C. [b] Mass content of saccharide and molecular weight were determined by ^1H NMR analysis (in D_2O).

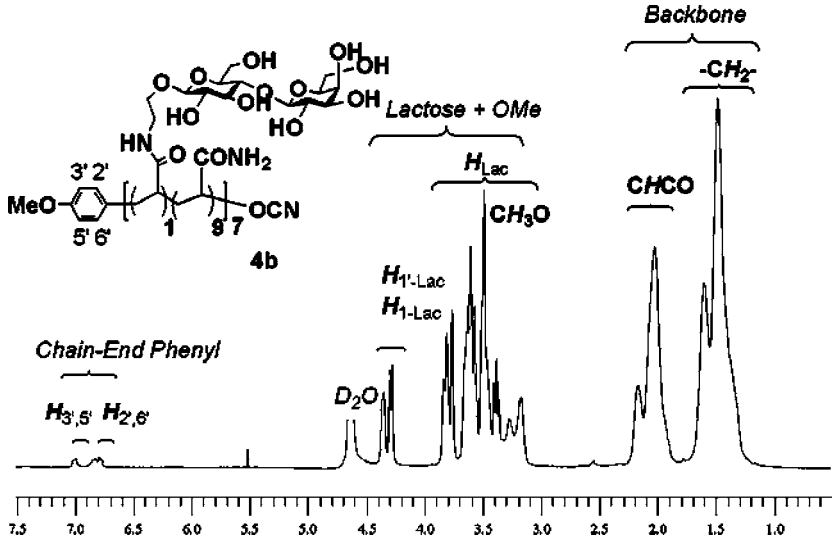

Figure 2. ^1H NMR spectrum of methoxyl phenyl chain-ended glycopolymer **4b** in D_2O.

glycopolymers could be obtained if functionalized arylamines could act as efficient initiators for polymerization. A series of 4-substituted phenylamines (**1a**−**1g**) were investigated as initiators of cyanoxyl-mediated copolymerization of nonsulfated and sulfated lactose acrylamide monomers (**2**/**3**) with acrylamide. Consequently, a series of chain-end functionalized glycopolymers of varying molecular weight were prepared by altering either monomer conversion or the initial ratio of monomer to initiator concentrations ($[M]_0/[I]_0$). As shown in Scheme 1 and summarized in Table 1, copolymerization of lactosyl acrylamide (**2**/**3**) and acrylamide generated a series of expected chain-end functionalized glycopolymers (**4**/**5**). Of note, carboxylic acid, amine, and hydrazine end groups will facilitate glycopolymer conjugation with amine-, acid-, and aldehyde-containing molecules, respectively, while the biotin end group facilitates glycopolymer binding to streptavidin (*29*), and the methoxyl phenyl end group provides an activated aromatic ring for radiohalogenation of the glycopolymer (*34*).

The resultant glycopolymers were characterized by NMR spectroscopy. It is noteworthy that the phenyl group at the end of the glycopolymer provides a convenient mechanism for calculating carbohydrate content and the molar mass through comparison of integrated phenyl proton peaks with those of carbohydrate and backbone protons, respectively. For example, as illustrated in Figure 2, comparison of the integrated signals produced from the chain-end phenyl protons ($H_{2',6'}$ and $H_{3',5'}$) with those due to the anomeric protons of lactose ($H_{1'-Lac}$ and H_{1-Lac}) and the backbone protons indicated that the average composition of the methoxylphenyl chain-end functionalized glycopolymer **4b** was seven lactose units and 63 acrylamide units with M_n of 7500. In addition, downfield shift of end phenyl protons $H_{2',6'}$ of resultant glycopolymers confirmed C−C bond formation between phenyl and the polymer backbone (Table 2).

When compared to chlorine-, methoxyl-, carboxylic-, and biotin-containing arylamine initiators, amine- and hydrazine-derivatized arylamines (**1d** and **1f**) afforded the corresponding glycopolymers (**5d** and **5f**) in lower yield. This may be a result of quaternization of the amino group, limiting subsequent radical formation. Therefore, Fmoc-protected arylamine (**1e**) initiated polymerization was investigated providing an amine-protected chain-end

functionalized glycopolymer (**5e**) in high conversion yield. ^{1}H NMR comfirmed that piperidine completely deprotected the Fmoc groups producing an amine chain-end functionalized glycopolymer.

High-affinity binding of biotin to streptavidin (ca. 10^{13-15} M^{-1}) has led to the use of streptavidin as a molecular adapter in diverse applications (*35*). For example, polymers with biotinylated end groups have been found to be significant for a self-organizing protein−polymer hybrid amphiphile that uses the molecular recognition between streptavidin and biotin (*36*). In the present study, glycopolymer-based noncovalent neoglycoproteins were produced by incubation of streptavidin with biotin chain-end functionalized polymers **4c** and **5c** (Scheme 2). The ability of biotin−glycopolymers to specifically bind streptavidin was accessed using a HABA−streptavidin assay (*37*). HABA ′ (λ_{max} 350 nm) changes color from yellow to red (λ_{max} 500 nm) upon binding to streptavidin (Figure 3, trial C). When HABA was added to a solution of streptavidin saturated with free biotin or biotin glycopolymers **4c** and **5c**, a red shift was not observed (Figure 3, trials D, E, and F). In contrast, a color change was noted when HABA was added to a solution of streptavidin with non-biotin-containing glycopolymers **4a** and **5a** (Figure 3, trials A and B). These results demonstrate glycopolymer−protein hybrid formation through specific binding of chain-end biotin of glycopolymers **4c** and **5c** to streptavidin. In principle, streptavidin has four free biotin-binding sites. However, the HABA assay revealed an average occupancy of 3.0−3.6 glycopolymer chains per streptavidin molecule. Full occupancy may be limited as a result of steric factors.

Another significant feature of cyanoxyl (OCN)-mediated polymerization is the presence of a terminal cyanate group at the opposing chain end (Scheme 1). Cyanate-based ligand immobilization via specific reaction with an amine group to form an isourea bond has proven to be a useful tool in bioconjugate chemistry (*38*, *39*). As such, the OCN end group provides a second feasible reaction pathway for conjugation of glycopolymers with amine-containing surfaces and molecules (*40*). Consequently, this scheme establishes a facile approach for producing α,ω asymmetric bifunctional chain-terminated polymers. Moreover, the potential to conjugate glycopolymers that have been selectively labeled with a chromophore, fluorophore, or radiotracer is apparent. It is also noteworthy that desired the cyanate group can be converted to a hydroxyl group (Scheme 3) by treatment with pyridine in water (*41*). IR spectroscopy demonstrated that the OCN absorption band at 2157 cm^{-1} disappeared after pyridine treatment of glycopolymer **4b** to **6b** thereby confirming complete hydrolysis of the cyanoxyl group. Further ^{1}H NMR of **6b** indicated that this hydrolysis reaction did not induce any further structural changes.

In summary, a straightforward approach for the synthesis of a series of α,ω chain-end functionalized glyco-

Scheme 3. Conversion of Terminal Glycopolymer Cyanate Group (OCN) to a Hydroxyl Moiety

polymers via cyanoxyl-mediated free-radical polymerization has been presented. Significantly, a variety of arylamine derivatives proved to be acceptable initiators for cyanoxyl-mediated free-radical polymerization yielding chain-end functionalized glycopolymers that can be successfully conjugated or otherwise linked to a variety of molecules or surfaces.

Novel Hyperbranched Dendron for Gene Transfer in Vitro and in Vivo

Pallab Banerjee, Wilfried Reichardt, Ralph Weissleder, and Alexei Bogdanov, Jr.*

Center for Molecular Imaging Research, Massachusetts General Hospital, Charlestown, Massachusetts 02129.
Received November 13, 2003; Revised Manuscript Received May 19, 2004

Novel hyperbranched dendron (HD) polymers were synthesized using a low molecular weight poly(ethyleneimine) core (BPEI). Using successive attachment of ethyleneimine moieties to the PEI core, the relative ratio of linear-to-branched structures was lowered from 1.17 to 0.70. We found that the more extensive branching of PEI enables the condensation of plasmid DNA into nanostructures with a size of 70−100 nm. The obtained complexes were stable at least for 3 weeks at 4 °C. The HD−DNA complexes prepared using secondary and tertiary amine-containing dendrons exerted a very low cytotoxicity in vitro during a coincubation with cells for 48 h. Using firefly luciferase as a marker of protein expression, we established that HD complexes were efficient in transfecting cells in the presence of serum. Under optimized conditions, the transfection activity at a nitrogen-to-phosphate (N/P) ratio of 6 was approximately six times higher than that of the commercially available polycationic transfection reagent. Bioluminescent imaging of in vivo gene expression using a luciferase reporter gene showed the increase of the signal in the liver and in submandibular lymph nodes in live mice. Our preliminary in vivo gene expression data demonstrates the potential of HD polymers as in vivo transfection agents that could be potentially useful for lymph node gene delivery.

INTRODUCTION

Nonviral gene transfer is frequently regarded as a potentially safer alternative to viral gene delivery (*1*−*5*). However, nonviral gene transfer to mammalian cells usually lacks the efficiency typical to that of viral transduction and requires substantial improvement (*6*). Nonviral delivery of DNA usually requires condensation with positively charged lipids or polycations to enable binding of polyionic complexes to plasma membrane and further internalization by the cells. The condensation ideally yields complexes that could release DNA after the internalization. In recent years several cationic polymers that readily form complexes with DNA (e.g. polylysine, poly(ethyleneimine), or various types of block and graft copolymers) have been investigated as potential nonviral vectors that enable transfer of DNA into mammalian cells (*7*−*12*). The binding of a polycation to DNA results in a formation of very compact colloidal complexes which are unstable in solution (*13*). Properties of these complexes that define their size and stability depend heavily on chemical structure as well as on physical properties of the polycation (*14, 15*).

As the use of synthetic carriers for DNA delivery expands beyond the traditional in vitro experiments, various polycations, including branched poly(ethyleneimine) (BPEI),[1] starburst polyamidoamine (PAMAM) dendrimers (*16*−*19*), and hyperbranched polymers (*20, 21*) are now being closely investigated. Some of the above polycations have shown high levels of gene transfer in mammalian cell culture. High transfection efficiency of BPEI and PAMAM compared to other polycations is explained by the "proton sponge" effect (*22*). This effect is supposedly caused by the protonation of tertiary amines present in the core of those polymers in the acidic milieu of endosomes. Godbey et al. (*23*) reported that the protonated form of branched PEI or PAMAM may perturb endosomes probably due to membrane disruption or as a result of osmotic effects (*23*). Haensler et al. (*16*) reported that dendrimers show a high level of transfection in a wide variety of cells in culture with low concomitant cytotoxicity. The transfection activity of PAMAM improved dramatically after random degradation by heat treatment in a solvolytic solvent (*24*), suggesting that polydisperse "fractured" dendrimers are more flexible than monodisperse PAMAM enabling "fractured" dendrimer to form compact complex with DNA. Interestingly, fractured dendrimers are able to swell when released from DNA (*24*). Recently, Lim et al. (*20, 21*) reported biodegradable hyperbranched poly(amino esters) with high transfection efficiency and low cytotoxicity in vitro.

The majority of PEI-mediated transfections utilize a low-branched polymer having a MW from 25 kDa to 800 kDa (*22, 25, 26*). Unfortunately, high molecular weight PEI has high cytotoxicity that limits the scope of potential applications in vivo. To decrease the cytotoxicity and to increase water solubility of DNA polymer complex, poly(ethylene glycol)-grafted PEI has been synthesized having lower transfection efficiency and low cytotoxicity at high N/P ratios (*27*). Alternatively, linear PEI (LPEI) has been suggested for in vitro and in vivo gene delivery (*28*−*30*)

since tertiary and secondary amine groups of LPEI causes less toxic effects than primary amines.

However, none of above nontoxic polycations appears to form sufficiently stable submicron complexes with DNA that could be useful for gene transfer in the presence of serum. The preservation of transfectability in serum is critical for in vivo gene delivery. Therefore, the goal of this research was to test a novel polymers that (1) would form nanosized, stable complexes with plasmid DNA, (2) would be efficient at low N/P ratios in the presence of serum, (3) would have low cytotoxicity, and (4) would be useful for in vivo gene delivery.

MATERIALS AND METHODS

Materials and Analytical Methods. Poly(ethyleneimine) (BPEI) (average molecular weight 10 kD) was obtained from Polysciences, Inc. (Warrington, PA) and purified by ultrafiltration using 30K NMWC cartridge (UFP-30, Amersham Biosciences). Gel permeation chromatography (GPC) was used to determine the molecular mass and molecular weight distribution. GPC analysis was carried out using PL aquagel-OH 40 8 μm column (Polymer Laboratories Inc, Amherst, MA) eluted at 1 mL/min with 100 mM ammonium acetate (pH 7) on Varian ProStar HPLC coupled with two detectors, UV−vis and differential refractive index (RI) detector at 30 °C. Molecular mass was measured using poly(ethylene oxide)s as standards. Twelve polyethylenoxide standards with molecular mass range from 5 kDa to 920 kDa were used for column calibration. The weight average molecular mass was computed from the refractive index data. Proton and ^{13}C NMR were recorded using D_2O solutions by Spectral Data Service (Champaign, IL) at 400 MHz for ^{1}H and 100 MHz for ^{13}C spectra, respectively. The quantitative ^{13}C were recorded using inverse gated decoupling pulse sequences. The spectra was obtained using ∼0.5 g/mL solution at 30 °C. The data were acquired with an 80° pulse and 10 s recycle delay. D-Luciferin was purchased from Xenogen (Alameda, CA).

Synthesis of PEI-Dendron. *Hyperbranched Dendron 2 (HD2).* Ten grams (0.086 mol) of 2-chloroethylamine hydrochloride (CEA, Acros, Pittsburgh, PA) was dissolved in 25 mL of water; 5 g (0.125 mol) of sodium hydroxide was added to this solution, stirred at the room temperature, and added dropwise into the condenser-equipped reaction flask containing a 10% water solution of 10 g of BPEI. The reaction mixture was stirred for 1 h at 50 °C. Sodium hydroxide solution (25%, 10 mL) was then added to the reaction mixture, and the temperature was raised to 90 °C, refluxed for 5 h, and stirred another 12 h at room temperature. The low molecular weight HD2 was purified by ultrafiltration using 30K NMWC cartridge (A/G Technology Co, Framingham MA) and freeze-dried. *Hyperbranched Dendrons 3 and 4 (HD3 and HD4).* HD2 (3.5 g) was reacted with 10 g of CEA in the presence of sodium hydroxide as described above. The purified product (HD3) was used in further experiments and as a core for HD4 synthesis. HD4 was prepared by repeating the procedure above using HD3 as a starting material.

Preparation of Dendron−DNA Complexes. The reporter plasmid, pCMV−Luc (3.2 MDa, 5.12kb), encoding firefly luciferase, was propagated in *E. coli*, DH5α and purified using Megaprep columns (Qiagen, Valencia, CA). Plasmid integrity was confirmed by gel electrophoresis in agarose. DNA concentration and purity were determined by measuring absorbance at 260 and 280 nm. The complex was prepared using 1 μg of pCMV−Luc plasmid DNA with varying amounts of polymers in TE buffer at pH 7.1 for 1 h before loading onto a 0.7% agarose gel. Ethidium bromide displacement titration studies were performed using F-4500 Fluorescence spectrophotometer (Hitachi, Danbury, CT). The excitation and emission wavelengths for ethidium bromide was 366 and 591 nm, respectively. Briefly, 10 μg of DNA and 2 μg of ethidium bromide solution (0.4 mg/mL) were mixed in 2 mL of TE buffer (pH 7.1). Polymer solution was added in 4−5 μL aliquots (1.06 mg polymer/mL). After adding polymer solution, the mixture was incubated at room temperature for 3 min for equilibration and the fluorescence intensity was measured. Two consecutive measurements were performed, and intensity values were averaged.

The size of the complexes was determined using Zetasizer 1000HSA (Malvern Instruments Inc, Southborogh, MA) using a 633 nm laser source at a fixed angle of 90°. Complexes were prepared in 0.25 M sucrose. All complexes were made by adding respective amount of dendron solution (∼3 mg/mL 0.25 M sucrose solution) to 20 μg/mL DNA in TE buffer. The particle size was measured using 500 μL of complex solution at 25 °C. Data were collected after two consecutive measurements. The change of particle size was measured for 3 weeks. All complexes were stored at 4 °C.

Cell Culture. COS-1 cells were propagated in Dulbecco's modified Eagle's medium with 4 mM L-glutamine, 1% penicillin−streptomycin, and 10% fetal bovine serum. Neuroprogenitor-derived cells, C17.2 (a generous gift of Dr. E. Snyder, Harvard Medical School), were propagated as described (*31*). Human umbilical venous endothelial cells (HUVEC) were cultured using EGM2 (Cambrex Bio Science, Baltimore, MD).

Transfection Experiments. HD polymers were dissolved in 0.25 M sucrosee solutions (∼3 mg/mL) and stored at 4 °C. Polymer−DNA complexes were formed by adding polymer solutions to DNA solutions. The maximum volume for the complex was adjusted to 50 μL by adding 0.25 M sucrose solution. Weight ratios of hyperbranched dendron-to-nucleic acid were based on the calculation of total charge present in each component, taking into account the molecular masses and degree of polymerization, i.e., the number of total nitrogen present in hyperbranched polymer vs the number of phosphates present in the nucleic acid. For example, 1 μg of plasmid DNA solution (0.74 mg/mL) was assumed to have 0.19×10^{16} negative charges. One microgram of HD4 solution (3.3 mg/mL stock solution in 0.25 M sucrose) was assumed to have 1.35×10^{16} positive charges. To obtain the theoretical charge ratio N/P = 1, we mixed 0.15 μg of HD4 solution, prepared by dilution polymer stock solution (3 mg/mL), with one μg of DNA (0.74 mg DNA/mL). We calculated N/P ratio assuming that total nitrogen (i.e. primary, secondary, and tertiary amines) contained within a single HD molecule, as well as all phosphates of DNA are taking part in the complex formation. Superfect cell transfection reagent (Qiagen, Valencia, CA) was used as a standard in our experiments. Superfect reagent and DNA complexes with Superfect were diluted using a 0.25 M sucrose solution.

Cell Transfection. Transfections with HD-plasmid DNA complexes were performed, and the results were analyzed using standard assay for luciferase activity expression (Luciferase assay reagent, Promega, Madison, WI). Various amounts of hyperbranched polymer in 0.25 M sucrose were added to the plasmid solution (0.5 μg of pCMV-luc DNA in 30 μL of 0.1 TE buffer), mixed, and incubated at room temperature for 30 min. Cells were plated at a density of 10 000 cells/well in 96-well plates,

24 h prior to transfection. Before the addition of complexes, medium was replaced by fresh 100 μL of serum-containing media. The complexes were then added to each well. The total volume did not exceed 150 μL/ well. The transfection was carried for either 4 or 48 h at 37 °C. In the case of 4 h transfection, the complete growth medium was replaced with the fresh serum-containing medium followed by another 48 h incubation. In the case of 48 h transfection, no medium change was performed. Luciferase activity in cell lysates was determined using Microlumat LB96P (EG&G Berthold) by adding 50 μL of luciferin substrate (Promega, Madison, WI) to 25 μL of cell lysate in each well using an automated injector (n = 3 independent experiments for each transfection reagent). Luciferase activity was integrated over 10 s with 2 s intervals. The protein concentration was measured in the rest of 25 μL of cell lysate using standard protein assay reagent Pierce-Endogen, Rockford, IL). Results were expressed in relative light units per mg of cell protein.

Transfection after Storage. The complexes of hyperbranched polymer were prepared at the same ratio as in the case of conventional transfection. Complexes were incubated 20 min at room temperature and then stored at 4 °C for 3 weeks. After 3 weeks, complexes were used for transfection, which was carried out in the same way as described above. As a control, freshly made complexes were used.

Cytotoxicity. Cells were plated at the same density as above at 24 h before the experiment. Medium was replaced by fresh 150 μL of serum-containing medium before the addition of complexes. Fifty microliters of complex solution was then added to each well and incubated at 48 h, 37 °C. Cytotoxicity assays (n = 4 experiments) were performed using standard CytoTox 96 Nonradioactive cytotoxicity assay (Promega, Madison, WI), i.e., a colorimetric method based on lactate dehydrogenase release (LDH). The absorbance at 490 nm was measured using a 96-well ELISA plate reader. The background absorbance was minimized using phenol red free cell growth media. Nontreated cells were used as controls. The percent cell death was calculated using the formula: % cytotoxicity = experimental LDH release (OD_{490})/maximum LDH release (OD_{490}).

Flow Cytometry. Various amounts of HD polymers in 0.25 M sucrose solution were added to the plasmid solution (1.5 μg of pCMV-GFP plasmid in 30 μL of 0.1 TE buffer (*32*), mixed, and incubated at room temperature for 30 min. Cells were plated at 40 000 cells/well in 12-well plates, 24 h prior to transfection. Before the addition of complexes, medium was replaced by fresh 800 μL of serum-containing medium. One hundred microliters of complex-containing solution was then added to each well. The total volume did not exceed 900 μL/well. After 4 h, the complete growth medium was replaced with the fresh serum-containing medium followed by another 48 h incubation. Cells were trypsinized and resuspended in 4% formalin−PBS solution for flow cytometry analysis (FACSCalibur, Beckton-Dickinson, Lexington, KY).

In Vivo CCD Camera Imaging of Luciferase Reporter Gene Expression. Hyperbranched polymers (HD4 and HD3) were used for complex formation with 50 μg of plasmid DNA at N/P 6.3 and 9.1, respectively, in 200 μL of 5% glucose containing 20 mM HEPES (pH 5.5). A complex with BPEI was obtained at N/P 6.3. The complexes were injected intravenously via the tail vein of 4−6 week old *nu*/*nu* mice. A negative control group of animals did not receive DNA injections. Animals (n= 3) were imaged for 7 d beginning at 1-day post iv injection. For imaging, animals were anesthetized ip using ketamine/xylazine. After anesthesia, the animals were injected ip with 200 μL of 4.5 mg/mL D-luciferin in saline. After 5 min, the animals were placed in the imaging chamber equipped with a CCD camera system (Roper Scientific, Trenton, NJ). A light image of the animal was obtained using polychromatic illumination. The luciferase activity within animal was then measured by recording the CCD photon counts for 15 min. Following data acquisition, postprocessing was performed using image display and analysis suite developed in IDL (Research Systems Inc., Boulder, CO). Regions of interest were defined using an automatic intensity contour procedure to identify bioluminescence signals with intensities significantly greater than the background. For visualization purposes, bioluminescence images were fused with the corresponding white light images in a transparent pseudocolor overlay, permitting correlation of areas of bioluminescence with the anatomy.

Ex Vivo Luciferase Activity. After the third day of imaging, HD4 complex-injected animals were sacrificed, and the major organs were harvested for luminescence analysis as in (*33*). The relative light measurements were normalized per organ weight. All results were reported as mean ± SEM.

Histology. Submandibular lymph nodes were dissected for histology 3 days postinjection. The tissue rinsed with PBS and frozen using Histo Prep (Fisher Scientific). Frozen sections (thickness, 6 μm) were cut and treated using anti- luciferase goat polyclonal antibody conjugated with horseradish peroxidase (AbCam, Cambridge MA) according to the manufacturer's protocol. The sections were counterstained using hematoxylin and eosin prior to mounting and microscopy.

RESULTS

Synthesis and Characterization. Hyperbranched PEI synthesis (Figure 1A) resulted in polymers that were characterized using ^{1}H and ^{13}C NMR (Figure 1B,C). Proton NMR spectra showed the characteristic 2.5−2.8 ppm peak due to the methylene group (CH_2) of the backbone (not shown). Since different amine substitutions could not be efficiently separated for quantitative analysis of ^{1}H NMR spectra, we used inversely gated decoupling pulse sequences to obtain ^{13}C spectra for quantitation (Figure 1B,C). All structural elements showed well-separated signals in the chemical shift range (37−58 ppm), peaks 1−8. Using the previously described (*34*, *35*) formula, we determined that commercially available branched BPEI has the ratio of secondary-to-tertiary amine of 1.17 (Table 1). The molecular mass of 9.5 kDa measured by GPC is in agreement with the 10 kDa value provided by the manufacturer. After the first round of reaction of HD polymer with 2-chloroethylamine, the molecular mass of the product increased to 11.7 kDa and PDI was 2.34 (HD2). The increase of molecular mass was due to the conjugation of approximately 50 ethyleneimine groups. In the case of dendron 3 (HD3, mol mass 13.7 kDa, PDI 2.32) and hyperbranched dendron 4 (HD4, mol mass 15 kDa, PDI 2.25), the number of ethyleneimine groups increased to 98 and 128, respectively. The final HD4 had the secondary-to-tertiary amine ration of 0.71. Since size exclusion chromatography (SEC) tends to underestimate the true molecular masses of branched polymers, the molecular masses measured in our studies (Table 1) were somewhat lower than the true molecular mass (*36*). Physical properties of the material changed from a liquidlike (low molecular weight branched PEI, BPEI) to a semisolid (HD4) at room temperature.

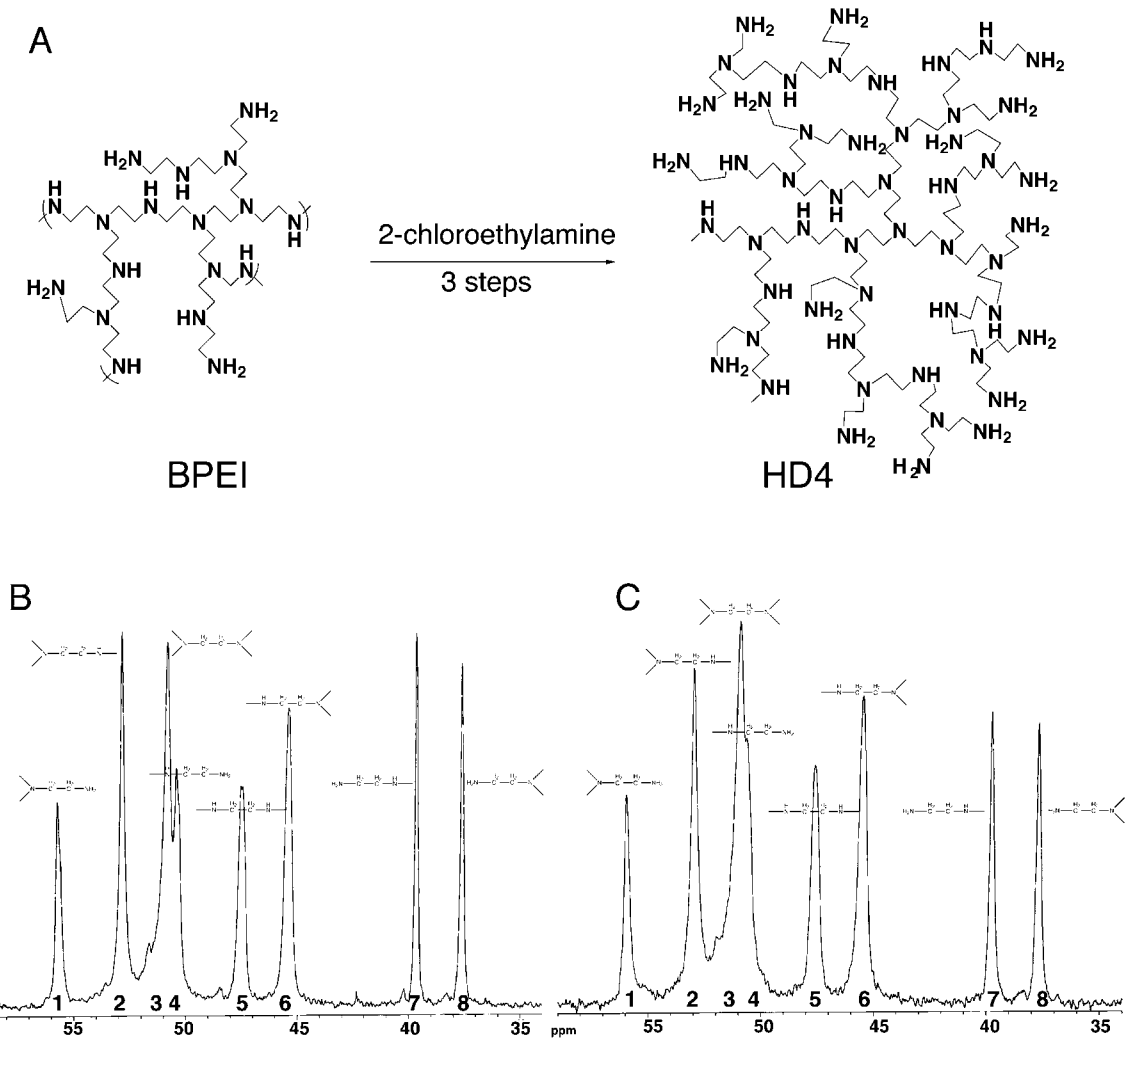

Figure 1. (A) A schematic representation of branched poly(ethyleneamine) BPEI and the hyperbranched dendron (HD4) obtained using consecutive aminoethylation of the core BPEI; (B) ^{13}C NMR spectrum of BPEI, (C) ^{13}C NMR spectrum of HD4. The spectra were analyzed as described in Results and Table 1.

Table 1. Properties of Branched Poly(ethyleneimine) and Hyperbranched Dendrons

polymer	MW[a] (KD)	PDI[b]	primary:secondary:tertiary amine[c]
BPEI	9.5	2.46	1.28:1.17:1
HD2	11.7	2.34	0.96:1.06:1
HD3	13.7	2.32	0.81:0.90:1
HD4	15	2.25	0.80:0.70:1

[a] MW = weight average molecular mass. GPC data was used for molecular mass determination. [b] PDI = polydispersity index. [c] Ratio of primary:secondary:tertiary amino groups calculated from ^{13}C NMR spectra.

Cytotoxicity. Figure 2 shows the cytotoxicity results obtained using branched PEI (BPEI) and synthesized hyperbranched dendrons. All cytotoxicity measurements were performed after 48 h of transfection with polymer−DNA complexes without medium changes. In all cases, the toxicity was low even after a 48-h incubation. For hyperbranched polymers in the moderate range of polymer concentrations (0.05 to 0.5 mg/mL), a maximum of 15% cell death was observed which is significantly lower than in the case of BPEI.

Complex Formation. The formation of complexes was monitored by fluorescence microscopy using ethidium bromide displacement method. At the N/P ratio of 2.30, the relative fluorescence decreased by approximately 50% for BPEI (Figure 3). In case of hyperbranched

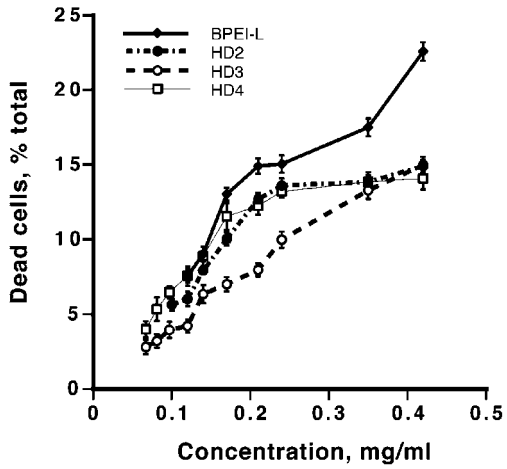

Figure 2. Polymer cytotoxicity measured in COS-1 cell culture as a function of concentration. Complexes were added to cells with growth medium and incubated for 48 h without changing the medium. Results represent the average of four independent experiments. Diamonds, BPEI; filled circles, HD2; open circles, HD3; squares, HD4.

dendron 2 (HD2), the same 50% decrease was achieved at N/P of 2.27. In the case of hyperbranched dendron 3 (HD3) a 50% fluorescence intensity decrease was observed at the N/P of 1.70, and for hyperbranched dendron 4 (HD4) a similar decrease was observed at N/P ratio of 1.23 (Figure 3). To investigate the mobility of complexes, we studied the interaction between the positively charged polymers and the plasmid at the different charge ratio using electrophoresis. Figure 4 shows the migration of DNA complexes obtained using different hyperbranched polymers. The migration of DNA was partially retarded by branched BPEI at N/P 4.4, and at the higher N/P ratios there was no detectable migration of the complex. In the case of hyperbranched dendron, the partial retardation of the migration was observed at N/P 2.9, 2.6, and 1.8, respectively, for HD2, HD3, and HD4 complexes. The electrophoretic migration of complexes stored for 3 weeks at 4 °C was almost unchanged (data not shown).

In isotonic sucrose and glucose solutions the particle size of DNA−BPEI complexes at all N/P ratios ranged between 50 and 120 nm. A similar behavior was observed for all HD complexes (Figure 5A). For HD4 complexes, particle size showed an increase from 90 to 160 nm when N/P ratio was decreased from 18 to 1. In the case of HD3 complex, the lowest particle size was observed at N/P ratio of 9.1, otherwise it varied slightly at different N/P. Figure 5B shows the stability of the complexes measured for 3 weeks. In 150 mM NaCl solution complexes were not stable and usually coagulated within 3 h. In the case of 5% glucose with 20 mM HEPES, complexes were more stable and usually smaller (approximately 40−60 nm) than in isotonic sucrose solution (data not shown).

Transfection Efficiency. To examine the potential of hyperbranched polymer for gene transfer to cells, we compared the transfection efficiency of BPEI and HDs with the standard commercially available dendrimer-based reagent (Superfect, Qiagen, Valencia, CA). Superfect (fractured dendrimer) is a very efficient transfection agent, especially in absence of serum in the cell culture medium (*24*). Since our main objective was to investigate the potential of hyperbranched polymers for the future in vivo gene delivery, we performed all transfections using 10% serum-containing media. The transfection efficiency was evaluated by luciferase reporter gene assay. We used various N/P ratio for optimization of the transfection efficiency of hyperbranched polymer and Superfect. Hyperbranched dendron 4 (HD4) showed a very high transfection efficiency compared to other polymers in the presence of serum. When transfection efficiencies of the different HDs and branched polymers were compared, we found that HD4-mediated transfection was very high at N/P ∼9 while BPEI showed maximum transfection efficiency at N/P ratio of ∼33. Transfection efficiency of HD at 4 h in absence of serum was at least 1 order of magnitude higher than transfection in the presence of serum (data not shown). To obtain the further insight into the cytotoxicity effect and transfection efficiency, we carried out the transfection for 48 h without changing cell culture media. Figure 6A shows the optimized N/P ratios based on 48 h transfection. Our data suggested that even after a prolonged coincubation, the transfection efficiency was still 5−6-fold higher than in the case of Superfect. All HDs as well as the branched PEI (BPEI) had higher transfection efficiencies in the presence of serum than with positive control transfection agent. The 48 h transfection data suggested that for HD4 at N/P = 6.3 the highest transfection has been achieved, whereas for BPEI the best results were achieved at N/P = 23.4 (Figure 6A). Transfection efficiencies of freshly prepared complexes and complexes stored for 3 weeks were then compared (Figure 6B). A comparison of transfection efficiencies at the optimized N/P ratios after a conventional 4 h transfection demonstrated that freshly prepared complexes have lower transfection efficiency than those stored for 3 weeks. At 48 h time point, HD4 and HD3 showed the highest transfection efficiency at N/P = 13 whereas the transfection efficiencies reached the highest levels at N/P ∼23 and 19 for HD2 and BPEI, respectively (Figure 6B). In all cases prolonged storage of complexes in sucrose solution resulted in ∼8-fold higher transfection efficiencies.

Flow ytometry. To test the transfection efficacy of hyperbranched polymers in cells other than COS-1, we tested transfection efficiency in neuroprogenitor-derived C17.2 cells and human endothelial cell cultures. We used green fluorescent protein as a marker (Table 2). Both HD4 and HD3 were capable of transfecting 20−25% C17.2 and HUVEC cells compared to 40% cells in the case of COS-1.

In Vivo Gene Expression. To test the in vivo gene delivery efficacy we relied on long-term transfection results in selecting N/P ratios. In preliminary experiments we determined that HD4 and HD3 showed the highest transfection efficiency at N/P 6.3 and 9.1, respec-

COS-1 were transfected by adding complexes in the presence of growth medium for 48 h. All results shown are the averages of three separate experiments obtained using complexes at the optimized N/P ratios. (B) In vitro luciferase activity in COS-1 cells transfected for 48 h using complexes that were either freshly prepared or stored for three weeks at 4 °C before use.

Table 2. Percent of Transfected Cells Measured Using Flow Cytometry

polymer[a]	COS-1[b]	C17.2[b]	HUVEC[b]
HD4	∼40	∼20−25	∼20−25
HD3	∼30−40	∼20−25	∼20−25

[a] Cells were transfected with pCMV-GFP -polymer complex as described in Materials and Methods. [b] Histograms were analyzed using CellQuest software (10 000 cells/analysis were used).

tively. These N/P ratios were chosen for preparing a complex with 50 μg of apyrogenic pCMV−Luc plasmid DNA in 20 mM HEPES/5% glucose solution. In the case of BPEI, we noticed that the complex prepared at the optimized N/P= 23 showed a profound toxicity after the injection. Since it is known that BPEI (molar mass 25 kDa) usually shows less toxicity and better transfection in animals at N/P 6−8 (*30*, *37*−*39*), in further animal experiments we selected N/P ratio of 6.3. Figure 7A shows the luciferase marker gene expression profile in vivo obtained by using noninvasive whole body bioluminescence imaging. We monitored the expression profile in the same group of animals repeatedly for 7 days. As pseudo-color maps demonstrate, gene expression was the highest in the case of HD4 complex. The major "hot spots" of luciferase expression were found in the liver and neck, as well as in the submandibular lymph node region. BPEI-based complex and "naked" DNA alone showed a much lower expression profile than hyperbranched dendron-based complexes. Figure 7B shows the change of photon counts over a period of 7 days. Both HD4 and HD3 showed the highest photon counts at 3−5 days either around the liver or in the neck regions. Figure 7C shows the luciferase assay performed in animals injected with the HD4-based complex. Luminescence measured over liver and lymph node regions showed a correlation with the gene expression profile obtained by luminescence imaging. Other organs did not show any measurable luciferase activity. Histology of lymph node frozen sections showed many immunoperoxidase-positive cells located on the periphery of lymph nodes, mainly around the follicle area (Figure 7D, image 1). The positive cells were absent in lymph nodes of control animals or in animals injected with plasmid DNA only (Figure 7D, image 2).

DISCUSSION

The compaction of DNA by positively charged molecules (e.g. polymers or lipids) into nanosized particles plays a crucial role for achieving high transfection efficiencies. Unfortunately, most of the polymer vectors reported so far are efficient mainly for in vitro cell transfection because of the inhibitive effects of serum and/or high in vivo toxicity. To reduce toxicity, several groups achieved limited success by using derivatization of polycations with poly (ethylene glycol) resulting in vectors with low cytotoxicity but also with lower transfection efficacy (*27*, *40*).

We hypothesized that the optimization of the balance between the cationic charge density of the polymer vector and phosphate groups of the DNA could potentially result in efficient DNA compaction and low cytotoxicity. We synthesized novel flexible hyperbranched polymers (dendrons, HD) by controlling branching of the initial PEI core polymers. Although hyperbranched dendrons and dendrimers are similar in that both are branched, other structural aspects are quite dissimilar (Figure 1). During HD synthesis, 2-chloroethylamine reacts with primary or secondary amines of the PEI core, resulting in a

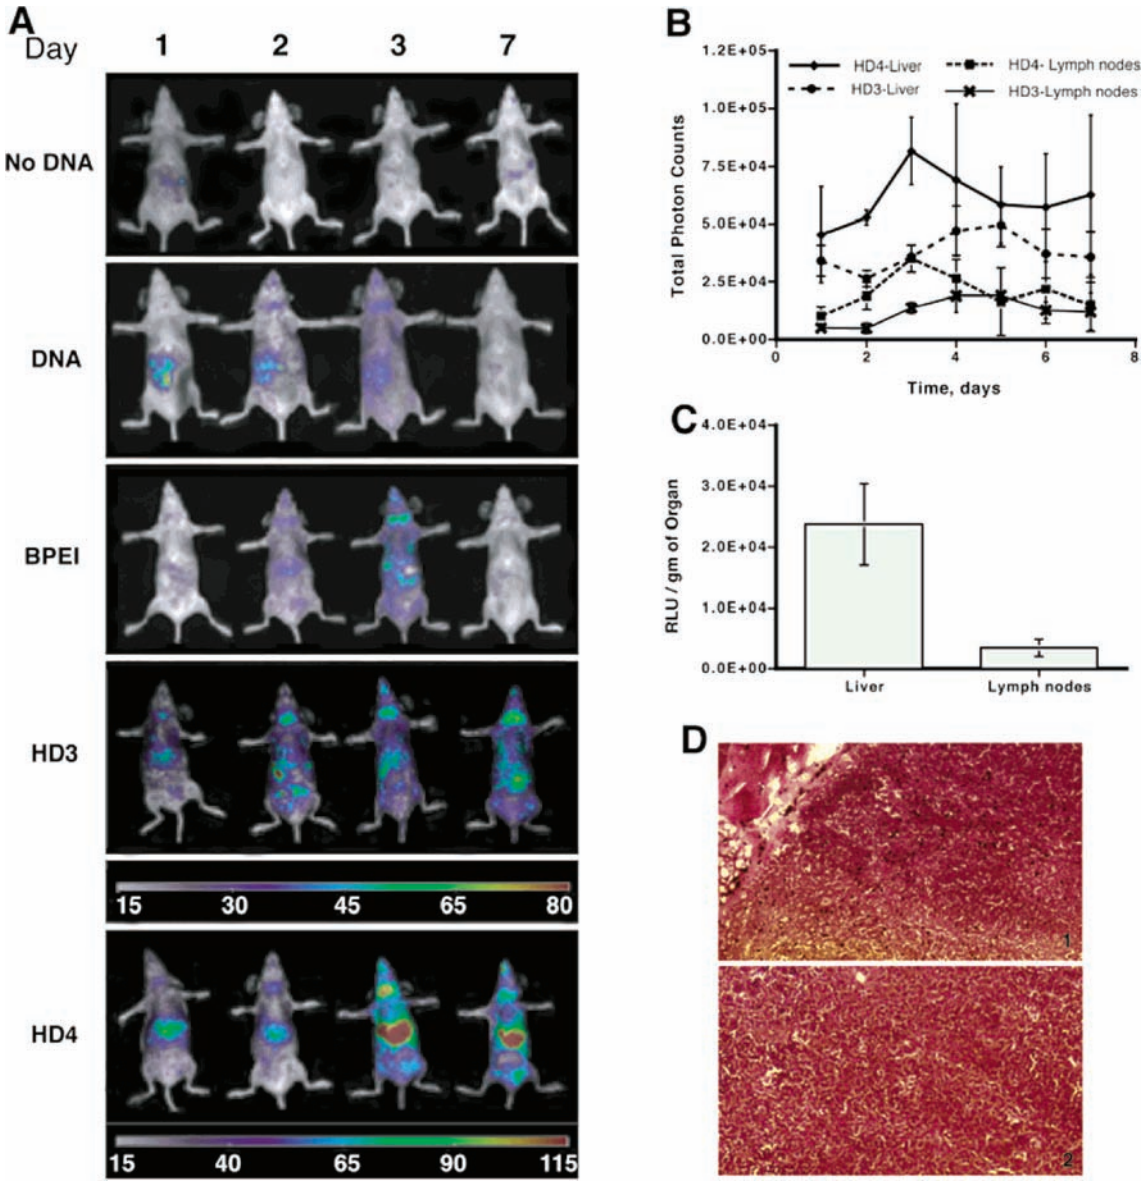

Figure 7. (A) Bioluminescence imaging of luciferase expression in living mice using a CCD camera performed at the time intervals indicated above the images. The image shows the best representative of the group ($n = 3$). Fifty micrograms pCMV−Luc was used for iv injections in all cases. All images were taken for 15 min and shown using two pseudocolor scales: one for HD4 and other for rest of the groups. (B) The change of the total photon counts integrated for 15 min imaging over 7 days in the case of HD4 and HD3 groups. The photon counts are averaged for three animals. Data presented as mean ± SD. (D) Immunohistology of lymph nodes after the administration of HD4/DNA complex (image 1) or naked DNA (image 2) intravenously. Fifty micrograms of DNA was used to prepare complexes at N/P 6.3. Animals were sacrificed 3 days after injection. Polyclonal goat anti-luciferase antibody−peroxidase conjugate was used to identify luciferase-positive cells followed by a hematoxylin/eosin counterstaining. Brown dots (image 1) represent luciferase-positive cells. Magnification, 30-fold.

random, treelike branched structure. As demonstrated previously, the reactivity of the chain end of a dendrimer is higher than the chain end reactivity of a hyperbranched polymer (*41*). To increase the rate of reaction between the functional end groups and chloroethylamine, we used a large excess of 2-chloroethylamine in alkaline conditions (*42*). The excess of 2-chloroethylamine or its cyclic byproduct (*43*, *44*) was removed later using ultrafiltration.

It is known that that highly branched, commercially available PEI with the high molar mass ranging from 25 kDa to 800 kDa have tertiary-to-secondary amine ratio of less than 0.75 (*35*). The above ratio measured in hyperbranched dendrons suggested that successive aminoethylation resulted in an increase of branching order (Table 1). Thus, the increased branching enables the incorporation of more secondary and tertiary amino groups than initially present in commercially available PEI core polymers. In HD4 this ratio is 2 times higher than in BPEI.

Partially hydrolyzed (∼53%) linear PEI (LPEI) has a lower toxicity than BPEI because of the high content of tertiary amines present in the backbone of LPEI (*45*). Therefore, we expected that the increase in branching, i.e., the increase of tertiary amine content, could result in a reduction of cytoxicity. In our experiments, hyperbranched polymers (HD2 to HD4) showed low toxicity (10% cell death, Figure 2). Better survival of cells in the presence of HD could be a result of a high secondary and tertiary amine content of HD polymer.

We further hypothesized that flexible architecture of HD polymers enables efficient condensation of plasmid

DNA (*46*). We found that the increase of ethyleneimine content in HD resulted in similar titration behavior of HDs in ethidium bromide displacement experiments with the exception of the position of the neutralizing point (Figure 3). Therefore, at any specific fixed concentration, different "generations" of HDs had different surface charges because of the branching order variations. This resulted in a measurable change of N/P ratio corresponding to a half-maximal displacement of ethidium bromide since more ethyleneimine moieties were present in HD than in BPEI. The hydrodynamic diameter of the complexes was approximately 100 nm and, in contrast to BPEI, the diameter increased at a much slower rate or remained almost constant over long periods of time (Figure 5). These results were relevant for further transfection experiments suggesting that the HD−DNA complex could tolerate the presence of serum proteins. This was not the case if a high molecular mass PEI was used in the presence of the serum (*22*).

It has been reported before that branched cationic polymers transfect cells because of the high buffering capacity of the amines present on these polymers, which leads to the release of DNA from the endosome (*16*, *22*, *47*). Such agents have been observed to induce osmotic swelling and lysis in response to the endosomal local pH drop (*48*). Hyperbranched dendrons contain all three different types of amine nitrogen, allowing the polymer to collapse, or to swell, depending on the magnitude of local pH change. This could explain the observation of a higher transfection efficiency of HD4 at low N/P ratios compared to a less branched core BPEI (Figure 6).

Since the complex of HD with plasmid vectors showed exceptional stability during storage, we decided to test whether during storage the complex retains the ability to transfect cells (Figure 6). Our results suggest that that the "aged" complex attains a more compact structure (*49*) which could help in preserving its transfection efficacy. Previous research suggested that DNA−carrier interactions can strengthen with time. For example, it is known that a time-dependent maturation process of lipid−DNA results in increased serum resistance (*49*, *50*). It is possible that during the storage, HD chains, due to segmental flexibility, could achieve strong multipoint interaction with negatively charged DNA, resulting in particles that are more compact (hydrodynamic diameter was approximately 10 nm lower than that of the complex formed immediately). A more compact structure would yield better stability in serum-containing medium, resulting in more efficient transfection.

Finally, we addressed the question whether stable complexes of plasmids with HD polymers would be efficient in gene transfer in vivo. Previously, in vivo bioluminescent imaging was used to detect gene expression after nonviral gene delivery (*51*). In our experiments, seven consecutive days of luciferase imaging suggested that HD4 could induce a prolonged gene expression, which reaches a maximum at 72 h in the liver and lymph nodes (Figure 7). Both HD4 and HD3 appear to be more efficient than either BPEI or "naked" DNA. Since complexes with HD bear a weak positive charge (zeta potential of HD4 complex at N/P $\sim$ 6.3 is 6.9 mV), we expected less interaction with blood components and lung endothelium. Indeed, we observed low expression of luciferase in the lung. Correlative luciferase activity measurements in tissue extracts (Figure 7C) and immunohistology pointed to expression of luciferase in the lymph node cells, with the majority of positive cells located on the periphery and around germinal centers (Figure 7D). The distribution of positive cells in the tissue argues for the ability of HD-based complexes to transfect organs located at the sites distant to the injection site, presumably because of the small size and weak positive charge.

In conclusion, we demonstrated that it is feasible to "tune" the molecular structure of PEI by attaching additional secondary and tertiary amino groups to commercially available ethyleneimine core. The "tuning" results in a substantial increase of transfection efficacy with the concomitant lower cytotoxicity in vitro. The advantage of HD polymers as gene delivery carriers are (1) the high transfection efficiency at low N/P ratios, (2) the formation of small stable complexes with DNA, (3) the tolerance of serum, and (4) overall low toxicity at the transfection conditions, as the amounts of HD needed to achieve high transfection efficiency were low. Finally, our preliminary in vivo studies suggested that HD-based complexes have a potential for transfection of lymph node cells in vivo.

Received May 1, 2004; Revised Manuscript Received July 6, 2004

With the impressive growth in gene sequence data that has become available, recombinant proteins represent an increasingly vast source of molecular components, with unique functional and structural properties, for use in biotechnological applications and devices. To facilitate the use, manipulation, and integration of such molecules into devices, a controllable method for their chemical modification was developed. In this approach, a trifunctional labeling reagent first recognizes and binds a His-tag on the target protein's surface. After binding, a photoreactive group on the trifunctional molecule is triggered to create a covalent linkage between the reagent and the target protein. The third moiety on the labeling reagent can be varied to bring unique chemical functionality to the target protein. This approach provides: (1) specificity in that only His-tagged targets are modified, (2) regio-specific control in that the target is modified proximal to the His-tag, the position of which can be varied, and (3) stoichiometric control in that the number modifications is limited by the binding capacity of the His-tag. Two such labeling reagents were designed, synthesized, and used to modify both N- and C-terminally His-tagged versions of the enzyme murine dihydrofolate reductase (mDHFR). The first reagent biotinylated the enzyme,while the second served to attach an oligonucleotide to yield a protein−DNA conjugate. In all cases, modification in this manner brings new functionality to the protein while leaving the enzymatic activity intact. The protein−DNA conjugate was used to specifically immobilize the active enzyme through DNA hybridization onto polystyrene microspheres, a step toward creating a functional protein microarray.

INTRODUCTION

Reagents and methods to selectively chemically modify proteins are becoming increasingly important for the study and utilization of protein functions and interactions, particularly due to the explosive growth in our knowledge of protein sequences from genome sequencing efforts and the drive to conduct proteomic research. Robust technologies for the rational chemical modification of proteins are needed for subsequent immobilization to create protein arrays for screening of function and interactions. The chemical attachment of prosthetic groups is also important for the creation of new protein-based biosensors and reporter molecules for life science research, biodetection assays, and therapeutics. Looking further ahead, controllable modification of proteins should help to foster a new era in biomaterials design and manufacture and semi-synthetic molecular engineering.

In general, when chemically modifying a protein, the goal is to introduce novel chemical functionality while preserving its native function and properties. Ideally, one would be able to covalently attach a precise number of unique chemical groups to one or more specific locations on the surface of any target protein in solution. This would provide maximal versatility and control over subsequent handling of the target while minimizing the likelihood of disrupting its native function. It is also important that the approach integrate with established technologies for recombinant protein production. Currently, the most general approach is to use electrophilic reagents that can react with nucleophilic groups on the surface of a target protein; however, this approach tends to yield a heterogeneous mixture of products since almost all proteins carry a number of nucleophilic groups on their surfaces. The thiol side-chain of cysteine is the most nucleophilic group that naturally occurs on a protein's surface and thiol-specific modifying reagents are numerous. Hence, to date, the best approach to engineer a site for selective chemical modification into a protein has been to genetically introduce a non-native cysteine at the desired site. After production and purification, the recombinant protein is covalently modified through thiol-specific chemistry. This approach is often successful, but can fail for a number of reasons. Foremost, the number and positions of native cysteines can be vitally important for the structural or functional integrity of many proteins; insertion of a non-native cysteine or removal of native cysteine can lead to misfolding or loss of function. Similarly, inappropriately modified native cysteines can lead to protein inactivation. This is particularly likely for enzymes that utilize a cysteine in their active site, including cysteine-based oxidoreductases, dehydrogenases, proteases, and some metal-binding proteins (*1*). Similar difficulties can arise from methods that rely on reaction between a terminal cysteine and a terminal thioester as typified by the native chemical ligation and expressed protein ligation approaches (*2*, *3*). In general, the site of modification by these elegant methods is restricted to a protein terminus; however, there are examples where multistep syntheses have permitted the introduction of modifications at internal positions (*4*, *5*). Oxidation-mediated protein labeling is also generally restricted to the termini (*6*−*8*). Another strategy to engineer sites for specific chemical modification in pro-

teins has been to develop expression systems that allow for the incorporation of unnatural amino acids that can serve as unique targets for covalent modification; however, these strategies have yet to prove widely applicable (*9*−*11*).

An alternative strategy to alter a protein's surface chemistry involves introducing unique non-native stretches of amino acids into a recombinant protein's native sequence (*12*). Such stretches of amino acids serve as integral "tags" that provide novel chemical functionality or can serve as targets for molecular recognition. A number of such tags have been described; they have been used principally for noncovalent immobilization or to allow antibody recognition. One notable exception has been the development of a tag that can serve as the target for novel biarsenical labeling reagents (*13*). Another genetic-engineering based approach is to link the sequence of two (or more) protein domains to yield novel recombinant "fusion" or "chimeric" proteins. In general, such tags have not provided a means for further covalent modification; however, recently a specific 207-amino-acid fusion tag has been developed that can serve as a site for selective covalent modification (*14*, *15*).

In protein research, the most versatile and widely used genetically encoded tag is the "polyhistidine" or "His-tag", which typically consists of a string of 2−6 consecutive histidine residues (*16*, *17*). Introduction of a His-tag at either the N- or C-terminus of a recombinant protein was first described as a convenient and generally nonperturbative means to facilitate purification of recombinant protein by immobilized metal-affinity chromatography. Functional His-tags can also be placed internally within the sequence of recombinant proteins, their sequences can be varied to include nonhistidine residues, and they can even take the form of engineered histidine "patches", consisting of histidines that are close in space though not in sequence within a folded protein structure (*18*−*23*). Immobilization takes place through coordination of two or more of the histidine residues with a metal ion (usually Ni(II)) that is incompletely coordinated by a substrate-attached chelating group such as nitrilotriacetic acid (NTA). Since its introduction, variants of this basic molecular recognition technology have been developed and utilized for a number of applications beyond protein purification; examples include sensitive target protein detection, protein structure studies, and protein immobilization for binding studies using surface plasmon resonance or atomic force microscopy (*24*−*28*). Since in its simplest form, as either an N- or C-terminal extension, the His-tag can be easily incorporated into expression vectors, genome-scale expression libraries of His-tagged proteins have been generated (*29*−*33*). In a groundbreaking study by Snyder and co-workers, 5800 different His-tagged yeast proteins, corresponding to about 80% of the yeast proteome, were expressed, purified, and arrayed on nickel-coated glass slides for subsequent probing (*32*). While this noncovalent immobilization served the purposes of the investigators, we reason that such arrays could be made more robust if the His-tag could serve as the target for covalent surface attachment. One solid-phase based approach to such affinity-directed covalent capture has been reported by Guisan and colleagues where His-tagged proteins have been bonded to chromatography resins that simultaneously carry metal-chelating groups and reactive epoxide groups (*34*).

We envision a broader use of the His-tag as a unique affinity target to direct proximal covalent bonding to a recombinant protein in solution. Solution-phase chemical modification is important to allow subsequent handling of the modified proteins and is required for the creation of protein-based reagents such as soluble therapeutic antibody−enzyme conjugates used in antibody-directed enzyme prodrug therapy (*35*). We judge the His-tag to have the best ensemble of features since as noted it is small relative to the size of most proteins of interest, it is generally nondisruptive to its host protein's structure and function, it can be placed at either terminus and even internally within its host's sequence, and it is widely used, particularly in the construction of expression libraries. Similar reasoning has led others to use the His-tag as a solution-phase target for the noncovalent tethering of bifunctional NTA-containing conjugates to protein (*36*, *37*). To direct covalent modification in solution, we have synthesized two different water-soluble trifunctional molecules based on shared design principles.

Ultimately, we envision this as a step toward the creation of encoded libraries of proteins (*38*) and a competitive technology for the creation of self-assembling protein arrays, engineered protein-containing molecular assemblies and nanostructures, and the integration of proteins into devices such as biosensors.

EXPERIMENTAL PROCEDURES

Instrumentation. The following instrumentation was used: an Agilent (Palo Alto, CA) 1050 and an 1100 HPLC system, each equipped with quartenary gradient pump, UV absorbance detector, fluorescence detector, and Chemstation software, a Cary 20 UV/vis absorbance spectrophotometer with kinetics software (Varian, Palo Alto, CA), a PerSeptive Voyager STR-DE Biospectrometry matrix-assisted laser deionization time-of-flight (MALDI-TOF) mass spectrometer (Applied Biosystems, Foster City, CA), a Micromass LCT electrospray ionization mass spectrometer (Waters Corp., Milford, MA), a DRX-500 nuclear magnetic resonance spectrometer (Bruker Biospin, Rheinstetten, Germany), a Perseptive Cytofluor 4000 microplate reader (Applied Biosystems), a Rotavaporator R-200 (Büchi, Flawil, Switzerland) with vacuum pump (Fisher Scientific, Hampton, NH), a Blak-ray B-100AP handheld long-UV lamp, a French-press, a Beckman preparative J-21 centrifuge (Beckman Coulter, Fullerton, CA), a Sorvall ultracentrifuge and tabletop low-speed centrifuge (Kendro, Asheville, NC), a tabletop 5415C microcentrifuge (Eppendorf AG, Hamburg, Germany), a mini-Protean II gel apparatus with Powerpac 300 power supply (Bio-Rad, Hercules, CA), and a Milli-Q water purification system (Millipore, Billerica, MA). The following columns were used: 250 × 4.60 mm Jupiter C4 packed with 5 μm beads, 250 × 10 mm Jupiter C4 packed with 15 μm beads, 250 × 4.60 mm Jupiter C18 packed with 5 μm beads, and a 250 × 10 mm Jupiter C18 packed with 10 μm beads with a 50 × 10 mm guard column. All Jupiter columns had 300 Å pores and were from Phenomenex (Torrance, CA). Also used: a 4.6 × 250 mm Zorbax GF-250 column with 4 μm beads (Agilent) and a HiPrep 16/60 Sephacryl S-100 HR column (Amersham Biosciences, Buckinghamshire, England).

Materials. DHFR expression plasmids, *Escherichia coli* host strains, Ni-NTA resins, and DAPase were all obtained from Qiagen (Valencia, CA). Bacterial culture media, IPTG, and ampicillin came from USBiological (Swampscott, MA). Buffers, salts, chemicals, biochemicals, and solvents were obtained from Sigma-Aldrich (St. Louis, MO) unless otherwise noted. Herring sperm DNA was from Promega (Madison, WI). HPLC solvents and methanol were purchased from EM Sciences (Hatfield, PA). *N*-(5-amino-1-carboxypentyl)iminodiacetic acid (NTA-

amine) came from Toronto Research Chemicals (North York, On., Canada). Sulfo-SBED, monomeric avidin, D-biotin, Immunopure HABA, Coomassie protein assay reagent, Gelcode Blue stain, and Gelcode SilverSNAP stain were from Pierce Chemical (Rockford, IL). β-Maleimido-proprionic acid was purchased from Molecular Biosciences (Boulder, CO). SPOS resin, PyBOP, and HOBt were from NovaBiochem (EMD Biosciences, San Diego, CA). Fmoc-Bpa-OH was purchased from Bachem (Bubendorf, Switzerland). NAP-10 gel filtration columns were from Amersham. Centricon Plus-20 PLGC devices and ZipTips came from Millipore. Precast minigels and protein electrophoresis standards were from Bio-Rad. Polymeric microspheres were from Polysciences (Warrington, PA). DNA-bind plates were from Corning (Corning, NY). Plastic, untreated, flat-bottom 96-well plates were from Nalge Nunc (Rochester, NY).

The following synthetic modified oligonucleotides were obtained from Integrated DNA Technologies (Coralville, IA); all linkers were C_6-type. Modifications included 5′-terminal thiol (SH-) groups, 5′-terminal amine (NH_2-) groups, 3′-terminal biotin, and terminal carboxyfluorescein (FAM) or hexachlorofluorescein (HEX) fluorophores.

Thiolated oligonucleotides used for protein labeling (the "sense" sequence is underlined):

$Oligo_{biotin}$: 5′SH-TTTTTCGTTGATAACCTGTCCATCTCTA-biotin

$Oligo_{FAM}$: 5′SH-TTTTTCGTTGATAACCTGTCCATCTCTA-FAM

Aminated oligonucleotides used to create capture surfaces:

Complementary: 5′ NH_2-TTTTTTTTTTAGAGATGGACAGGT

Noncomplementary: 5′ NH_2-TTTTTTTTTCCCTAAGAAGACGGA

Fluorescent oligonucleotides used to test capture surfaces:

FAM-sense: 5′ FAM-ACCTGTCCATCTCTA

HEX-anti-noncomplementary: 5′ HEX-TCCGTCTTCTTAGGG

Expression and Purification of N- or C-terminally His-Tagged Murine Dihydrofolate Reductase (His_6-mDHFR and mDHFR-His_6, Respectively) and Tagless Murine Dihydrofolate Reductase (mDHFR). To produce the His_6-mDHFR and mDHFR-His_6 proteins, competent *E. coli* (M15 [pREP4]) were separately transformed with the respective expression constructs pQE-40 and pQE-16 using the source company's protocols. The amino acid sequence of His_6-mDHFR differs from the sequence that can be obtained from the Swissprot database, DYR_MOUSE (accession number P00375), in that it has 14 additional residues at its N-terminus, MRGSHHHHHHGSGI-, has the C-terminal aspartate replaced by 17 residues, -GSRSACGTPGRPAAKLN, and has the cysteine in the seventh position replaced by a serine. The amino acid sequence of mDHFR-His_6 differs from DYR_MOUSE in that it has six additional residues at its N-terminus, MRGSGI-, has the C-terminal aspartate replaced by 10 residues, -GSRSHHHHHH, and has the cysteine in the seventh position replaced by a serine. Large-scale cultures were grown in LB medium containing neomycin (25 μg/mL) and ampicillin (100 μg/mL) at 37 °C, induced with 1 mM IPTG, harvested by centrifugation for 15 min at 6000 rpm in a Beckman J-10 rotor in a Beckman JA-21 centrifuge, frozen, and stored at −70 °C based on the Qiagen protocol. For protein purification 20−30 g of pelleted cells were resuspended and brought to a volume of 100 mL in lysis buffer (50 mM potassium phosphate (pH 8.9), 300 mM NaCl, 10 mM imidazole, 1× protease inhibitors). The cells were passed through a French press twice at a pressure of 1200−1600 psi. Cleared cellular lysate was obtained after centrifugation at 4 °C at 100000*g* for 1 h using an F-28/36 rotor in a Sorvall ultracentrifuge. Protease inhibitors were added at 1× concentration to the cleared lysate prior to loading onto a 10 mL Ni-NTA Superflow column. The column was preequilibrated in lysis buffer and peristaltically pumped at 1.2 mL/min at 4 °C. Following loading, the column was washed with 50 mL of low-imidazole buffer (20 mM imidazole, 300 mM NaCl, 50 mM potassium phosphate (pH 8.3)). Both His-tagged mDHFRs elute as a single peak at approximately 100 mM imidazole in a linear gradient of increasing imidazole. Peak fractions were pooled, dialyzed against mDHFR buffer (20 mM NaCl, 20 mM sodium phosphate (pH 7.6), 20% glycerol), and stored at 4 °C. Untagged mDHFR was generated from His_6-mDHFR by proteolytic digest with the enzyme DAPase followed by repurification on NTA-agarose resin according to the manufacturer's protocols.

Assay of Enzyme Activity in Solution. At room temperature, the oxidation of β-NADPH to $NADP^+$ that is coupled with reduction of DHFA to tetrahydrofolate (THFA) by mDHFR, was monitored as a decrease in absorbance at 340 nm with a Cary 20 UV/vis spectrophotometer (*39*). The reaction buffer, prepared immediately before use, consisted of either DHFA and β-NADPH at 67 μM with 13 mM β-mercaptoethanol and 1 mg/mL BSA, or DHFA and β-NADPH at 50 μM with 20 mM β-mercaptoethanol and 1 mg/mL BSA, in degassed 100 mM potassium phosphate buffer (pH 7.5). After recording the steady absorbance of 1 mL of the reaction buffer alone over 2 min, 1−2 μg of mDHFR or mDHFR−oligo conjugate was added to the cuvette, mixed by several inversions, and returned to the spectrophotometer. Changing absorbance at 340 nm was recorded for >10 min. Reaction velocities were determined from a 4-min linear portion of the recordings that typically began 30 s to 3 min after mixing. Activities were compared based on reaction velocity per microgram of added mDHFR.

Synthesis and Purification of NAB. The synthesis of NAB is shown in Scheme 2. NTA-amine (4 mg, 15 μmol) was dissolved/suspended in 1 mL of 50% anhydrous, deaminated dimethyl formamide (DMF), 50% anhydrous dimethyl sulfoxide (DMSO) containing triethylamine (TEA) (10 μL, 69 μmol). To this was added Sulfo-SBED (10 mg, 11 μmol) dissolved in 1:1 DMF/DMSO. The reaction was stirred under nitrogen overnight, in the dark, at room temperature. After the reaction, the mixture was reduced to a yellowish oily concentrate under high vacuum. The concentrate was redissolved in DMF or dimethyl acetamide (DMA) and purified by RP-HPLC using a C4 column (250 × 4.6 mm) pumped at 1 mL/min. Solvent A was water/0.01% trifluoroacetic acid (TFA) and solvent B was acetonitrile/0.01% TFA. The column was loaded and pumped for 10 min in 10% solvent B, followed by a brief linear gradient, from 10 to 27% solvent B over 5 min, then followed by 15 min at 27% solvent B. NAB elutes as the second major peak with a retention time of 28.5 min. Since NAB is light sensitive, preparative purification was conducted with the detector light sources turned off. Peak fractions were identified by UV absorbance spectroscopy of samples diluted into water. Peak fractions were pooled and dried down or used immediately in labeling reactions. The yield under these conditions was 50%.

Synthesis and Purification of NBzM. The solid-phase synthesis of NBzM is shown in Scheme 3. All steps were at room temperature unless otherwise noted. All

amine deprotection and coupling steps were monitored with the TNBS test as described in the NovaBiochem catalog (TNBS is 2,4,6-trinitrobenzenesulfonic acid). In a 25-mL manual peptide synthesis reaction vessel, Fmoc-Lys(Mtt)-Wang resin (2.75 g, 1.98 mmol) was swollen in dichloromethane (DCM) for 1 h. Fmoc deprotection was effected by six successive 15 min treatments of the resin with 20% piperidine in DCM. After deprotection, the resin was washed extensively with DCM. To the washed resin was added a 20-fold excess of *tert*-butyl-bromoacetate (6.4 mL, 40 mmol) with an equal amount of diisopropylethylamine (DIPEA) (7.2 mL, 41 mmol) and 2 mL of DCM. This reaction vessel was shaken at 350 rpm at 45 °C for 27 h. At this point, a TNBS test indicated that there were some residual free amines present on the resin beads. Fresh reagents were added and the vessel was further incubated at 45 °C with shaking for 18.5 h. The beads were washed successively with DCM, ethyl acetate, and DCM again. The Mtt group was removed by five 3-min treatments with 10 mL of 1% TFA, 5% triisopropyl silane (TIS) in DCM. After extensive washing with DCM, the beads were washed twice with 10 mL of 1:1 DCM/DMA. Fmoc-BPA-OH (1.95 g, 3.96 mmol), PyBOP (2.06 g, 3.96 mmol), HOBt (0.606 g, 3.96 mmol), and DIPEA (1.38 mL, 7.92 mmol) were added to the beads in 10 mL of 1:2 DCM/DMA. The beads were agitated with bubbling dry nitrogen for 17.5 h. Fresh reagents were added in half the previous amounts and allow to further react for 3 h. The beads were washed with DCM/DMA followed by DCM prior to Fmoc deprotection as previously carried out. After washing with DCM, the beads were washed twice with 10 mL of 1:1 DCM/DMA. β-Maleimido-proprionic acid (0.375 g, 2.22 mmol), PyBOP (1.155 g, 2.22 mmol), HOBt (0.340 g, 2.22 mmol), and DIPEA (780 μL, 4.44 mmol) were added to the beads in 12 mL of 1:2 DCM/DMA. The beads were allowed to react with agitation for ~48 h. After washing of the sample, an equivalent amount of fresh reagents were added and allowed to react for seven more hours. The beads were washed successively with DCM, ethyl acetate, methanol, DCM again, and dried briefly under vacuum. Products were cleaved from the resin with several 5-min treatments with 10 mL of 95% TFA, 5% anisole. The material was reduced to near dryness with rotary evaporation, precipitated with ice-cold diethyl ether, and dried under high vacuum.

The dried off-white material was dissolved in DMA and purified by semipreparative RP-HPLC over a Jupiter C18 column (50 × 10 mm guard, 250 × 10 mm main) pumped at 2.5 mL/min. Solvent A was water/0.01% TFA and solvent B was acetonitrile/0.01% TFA. The column was loaded in 10% solvent B and immediately linearly ramped up to 28.7% solvent B over 5 min. This was followed by a shallow linear gradient from 28.7 to 29.3% solvent B over 20 min, followed by a 5-min linear ramp to 95%. NBzM elutes as the forth major peak that starts to elute after 24 min. Peak fractions were pooled, dried by lyophilization, and stored dry in the dark. The yield, relative to the amount of Fmoc-Lys(Mtt) on the resin, was 12%.

Coupling of NBzM to Thiolated Oligonucleotides. Prior to reaction with NBzM, thiolated synthetic oligonucleotides were dissolved in Milli-Q water and reduced by overnight incubation with 2% TEA (v/v) and 50 mM DTT as recommended by the manufacturer. After reduction, thiolated oligonucleotides were separated from small molecules by gel filtration over a NAP-10 column preequilibrated with 50 mM sodium phosphate (pH 7.0), 300 mM NaCl. A 30-fold excess of dry, weighed NBzM was immediately added to the reduced thiolated oligonucleotide and allowed to react at room temperature overnight. Reduced thiolated oligonucleotide was almost entirely converted to NBz−oligo and was purified by RP-HPLC at neutral pH with a semipreparative C4 column (250 × 10 mm) pumped at 2.5 mL/min (*40*). Solvent A was 100 mM ammonium acetate (pH 7.0), and solvent B was pure acetonitrile. The column was loaded in 5% solvent B and immediately linearly ramped to 20% B over 30 min. NBz−oligo$_{FAM}$ elutes as the second major peak with a retention time of 25.2 min. MALDI-MS was used to confirm the mass of the NBz−oligo product. The peak fractions that contained the desired mass were pooled, lyophilized to dryness, and resuspended in sterile, Milli-Q water. The concentration of conjugate was determined by absorbance at 260 nm and a calculated extinction coefficient based on the nucleotide sequence and adjusted to account for the presence of benzophenone (*41*). Yields were typically ~50% relative to the amount of starting thiolated oligo. To charge the conjugate molecules with Ni(II), concentrated MOPS buffer, pH 7.9, was added to 20 mM followed by addition of $NiSO_4$ to 1.1-fold excess over the conjugate concentration (typically, 0.5−1 mM) (*24*). Ni(II) charged conjugates (Ni:NBz−oligo) were allowed to equilibrate at room temperature for several hours and then stored at 4 °C.

Photocrosslinking. For photoconjugation, purified target protein (10−200 μM) was preincubated from 1 to 12 h at 4 °C with an equimolar amount of trifunctional labeling reagent in 20 mM sodium phosphate (pH 7.6−8.0) and 300 mM NaCl. Following preincubation, the mixture was adjusted to 10 mM imidazole by addition of 1 M imidazole (pH 8.0) 30−60 min prior to irradiation. The reaction mixture, typically 50−500 μL, was contained in an uncapped microcentrifuge tube tightly sealed with Saran-wrap affixed by an elastic band. The tube(s) were placed in a cooled aluminum block and irradiated with long-UV light (Blak-Ray B-100AP lamp, ~365 nm) from above (~6 cm from source) at 4 °C for 3−18 h with stirbar agitation. This corresponded to an irradiation energy of 0.28−1.7 MJ/cm^2.

Purification of Protein Conjugates. Biotinylated protein conjugates, either NAB-labeled or NBz−oligo$_{biotin}$-labeled, were purified at room temperature by batch affinity chromatography using an Immunopure Immobilized Monomeric Avidin kit as per the manufacturer's instructions. Eluted biotinylated proteins were dialyzed, using Spectropore 10 kDa M_w cutoff membranes, extensively against 20 mM NaCl, 20 mM sodium phosphate, 20% glycerol for storage. After photoconjugation, mDHFR−oligo$_{FAM}$ conjugates were purified at room temperature by size-exclusion chromatography on a HiPrep 16/60 Sephacryl S-100 HR column installed on an Agilent 1100 series HPLC system equipped with a quartenary pump and UV−visible variable wavelength absorbance and fluorescence detectors. The column was equilibrated and run in 600 mM NaCl, 50 mM sodium phosphate (pH 7.6) at 0.25 mL/min. One-milliliter fractions were collected. Peak fractions were pooled and concentrated and exchanged into storage buffer by centrifugal ultrafiltration using Centricon Plus-20 PLGC devices in a room temperature tabletop centrifuge as per the manufacturer's instructions.

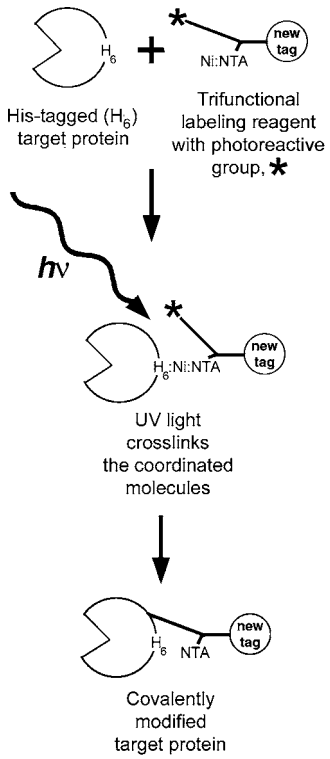
Absorbance Spectroscopy. All concentrations were determined based on absorbance measurements made with a quartz cuvette in a Cary-20 UV−visible spectrophotometer. The amount of biotin present in a pure sample of NAB was determined by a spectrophotometric assay using HABA and avidin (*42*). This quantity was

used along with absorbance measurements to determine a molar extinction coefficient at 270 nm, ϵ_{270}, of NAB in water. This extinction coefficient was used for all subsequent determinations of NAB concentration. Oligonucleotide concentrations were determined according to Beer's law based on absorbance at 260 nm and sequence-dependent calculated extinction coefficients provided by Integrated DNA Technologies. Pure mDHFR concentrations were determined from absorbance measurements at 280 nm in a quartz cuvette and a calculated extinction coefficient ($\epsilon_{280} = 25\,440$) based on amino acid content (*43*). mDHFR−oligo conjugate concentrations were determined by a microscale Bradford assay using a commercial Coomassie Protein Assay reagent and calibrated relative to staining of pure mDHFR with the same reagent; the oligo portion did not stain with this reagent.

Mass Spectrometry of Proteins, Oligos, and Conjugates. Protein samples were desalted using $ZipTip_{C18}$ devices as per the manufacturer's instructions. Proteins were eluted in ~2 μL, diluted to 10 μL in sinapinic acid solution (as per the instrument manual), and spotted directly onto a sample plate for interrogation with a Voyager-DE STR MALDI mass spectrometer. Oligonucleotides and NBz−oligo conjugates were desalted using $ZipTip_{C4}$ devices and spotted with 3-hydroxypicolinic acid as the matrix. For positive-ion ESI-MS, pure NAB, Ni:NAB, NBzM, and Ni:NBzM were dissolved in pure water, neutralized with ammonium bicarbonate buffer (pH 8.0), and diluted 5-fold with neat spectroscopic-grade methanol.

NMR. For NMR spectroscopy, approximately 22 mg of pure NBzM was dissolved in ~800 μL of DMSO-d_6. ^{1}H and ^{13}C NMR spectra were collected.

Polyacrylamide Gel Electrophoresis. Precast Tris-HCl Ready Gel mini-gels were run using a Mini-Protean II apparatus with a PowerPac 300 power supply at 200 V in 25 mM Tris, 192 mM glycine, and 0.1% SDS. For reducing conditions, protein samples were suspended and heat-denatured in 1× Laemmli buffer supplemented with 100 mM DTT; for nonreducing conditions no DTT was added. Prestained protein standards were either Precision- or Precision Plus-type from Bio-Rad. Carboxyfluorescein fluorescence from unstained gels was imaged, with a 2 s exposure, onto Polaroid type 667 film using a SYBR-Gold (Molecular Probes, Eugene, OR) gelatin filter with a Polaroid camera mounted over a UV transilluminator. Gels were stained using either GelCode Blue Stain or GelCode SilverSNAP.



Preparation of DNA-Modified Microplate Wells. The wells of DNA-bind plates were modified with aminated oligonucleotides as per the manufacturer's protocol. Oligonucleotides were used at a concentration of 200 pmol per well and were coupled over 3 h at 37 °C. Ethanolamine was used for blank wells and blocking. Plates were washed and stored in 50 mM sodium phosphate, pH 7.4, 150 mM NaCl and 0.02% sodium azide at 4 °C. Specificity of hybridization was confirmed with the fluorescent oligonucleotides FAM-sense and HEX-anti-noncomplementary.

Hybridization of Protein−Oligo Conjugate on Microplate Wells. mDHFR−oligo conjugate and unmodified mDHFR were diluted with water and 2× plate hybridization buffer (1.2 M NaCl, 120 mM sodium citrate, 0.02% Tween-20, 20 mM EDTA, 1 mg/mL Ac−BSA, 0.2 mg/mL Herring Sperm DNA, 100 mM TrisCl (pH 7.5)) to 500 nM in 1× plate hybridization buffer. Specificity of hybridization was confirmed by using the fluorescent oligonucleotides FAM-sense and HEX-anti-noncomplementary similarly diluted to 1 μM. Three separate 100 μL volumes of each sample type were dispensed into microplate wells modified with either 5′-aminated complementary, noncomplementary, or no capture oligonucleotide. On-plate hybridization occurred overnight at 37 °C in a shaking-platform incubator. After hybridization, supernatants were removed and saved, and the microwells were washed once with 200 μL of plate wash buffer (300 mM NaCl, 30 mM sodium citrate, 0.01% Tween-20, 50 mM TrisCl (pH 7.5)), again with 150 μL of the same buffer, and finally with 150 μL of 50 mM TrisCl (pH 7.5), 150 mM NaCl, 0.01% Tween-20. Each wash step was at 37 °C for 5 min. After washing, the microwells were filled with 100 μL of 50 mM sodium phosphate (pH 7.0), 100 mM NaCl, and the fluorescence was measured at room temperature with a Cytofluor 4000 fluorescence microplate reader. FAM fluorescence was measured using a 485/20 excitation filter and a 530/25 emission filter. HEX fluorescence was measured using a 530/25 excitation filter and a 620/40 emission filter.

Preparation of DNA-Modified Microspheres. Polybead carboxylate microspheres (4.34 ± 0.24 μm diameter) were modified with 5′-aminated oligonucleotides by one-step coupling as described by Weimer and colleagues (*44*). Briefly, ~81 mg of microspheres were washed twice with 10 mM NaOH, three times with Millipure water, three times with freshly prepared 100 mM MES (pH 4.7), and divided equally into three microcentrifuge tubes. After removing excess buffer, each of the ~27 mg portions of microspheres was resuspended to 600 μL with 100 mM 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDAC) in 100 mM MES (pH 4.7). At this point, 100 μL of 1 mM aminated oligonucleotide in water, or for blank microspheres, 100 mM ethanolamine in 100 mM MES (pH 4.7), was added to each portion of microspheres. The microfuge tubes of microspheres were then incubated in the dark, at room temperature, with mixing by rotation for ~72 h. This was followed by a 1 h exposure to 10 mM ethanolamine in 50 mM sodium phosphate, 1 mM EDTA (pH 8.5). The microspheres were washed 4 times with storage buffer (50 mM TrisCl, pH 7.5, 50 mM NaCl, 10 mM EDTA, 0.01% Tween-20, 0.02% sodium azide) and stored in the same buffer at ~25 mg/mL at 4 °C. The beads were characterized for their binding capacity by hybridization with fluorescently labeled complementary oligonucleotides and measurement of the residual fluorescence left in solution.

Hybridization of Protein−Oligo Conjugate on Microspheres. For mDHFR−$oligo_{FAM}$ conjugate hybridization experiments, three separate 50 μL aliquots (~1.25 mg) of each type of microsphere (bearing complementary, noncomplementary, or no DNA) were pelleted by centrifugation at 14 000 rpm at 4 °C in an Eppendorf 5415C microcentrifuge, resuspended, and incubated for 30 min with mixing, at room temperature in 100 μL of prehybridization solution (22.5 mM NaCl, 25 mM TrisCl (pH 7.5), 10 mM sodium phosphate, 2.5 mM EDTA, 0.01% Tween-20, 10% glycerol, 1 mg/mL acetylated bovine serum albumin (Ac−BSA)). Following repelleting of the sample, and removal of 40 μL of supernatant, the microspheres were resuspended with 20.4 μL of BSA buffer (25 mM NaCl, 50 mM TrisCl (pH 7.5), 5 mM EDTA, 0.02% Tween-20, 2 mg/mL Ac−BSA). To these suspensions was added 20.4 μL of mDHFR−oligo conjugate (100 pmol). Parallel incubations of conjugate without microspheres served as controls. Hybridization occurred at room temperature with mixing by rotation over 20 min. After hybridization and repelleting, supernatants (~40 μL) were removed carefully to avoid drying any of the microspheres. The microspheres were washed once

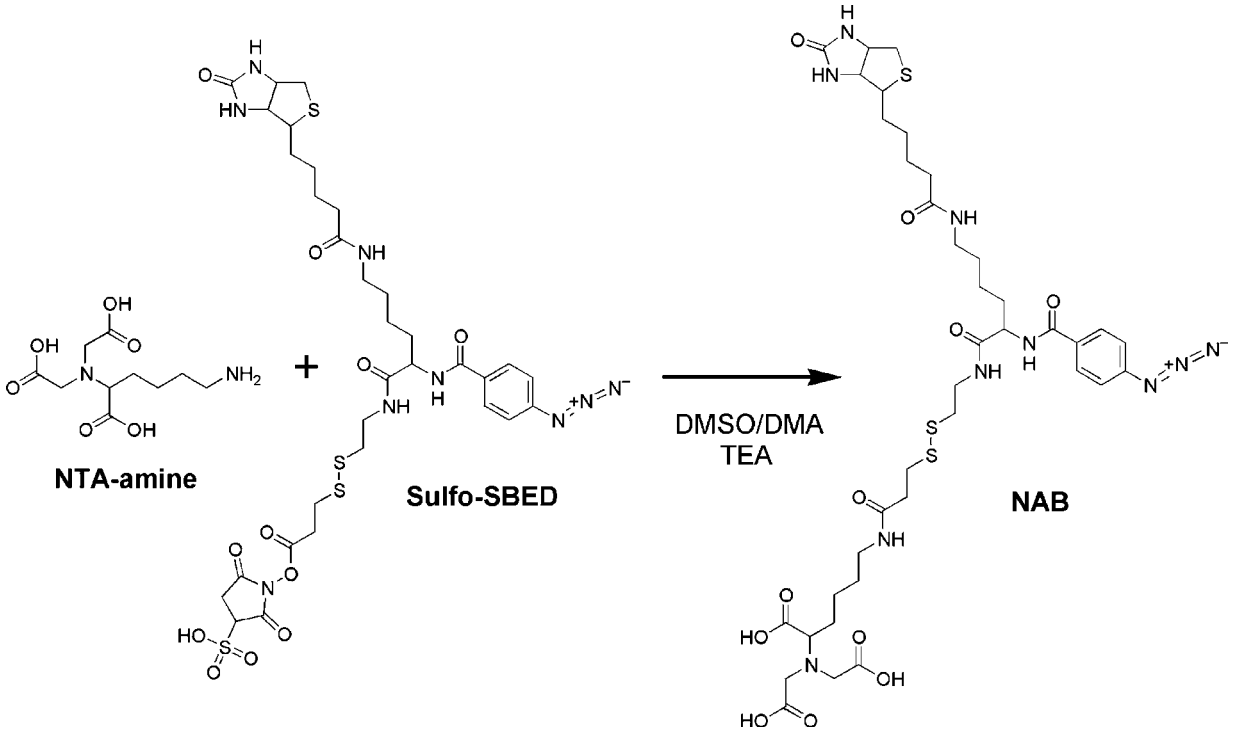
Scheme 1

for 5 min at room temperature with 100 μL of prehybridization solution, repelleted, and resuspended in 40 μL of fresh prehybridization solution after removal of the wash solution. The resultant ~50 μL suspensions of microspheres, along with 50 μL samples of supernatants, wash solutions, and control reactions, were pipetted into separate wells of a flat-bottom, untreated, 96-well microplate for fluorescence measurement and mDHFR activity assay with a Cytofluor 4000 fluorescence microplate reader. FAM fluorescence was measured using a 485/20 excitation filter and a 530/25 emission filter.

Assay of mDHFR Activity on Immobilized on Microspheres. All measurements were obtained at room temperature. After recording the FAM fluorescence, 50 μL of reaction buffer (100 μM β-NADPH, 100 μM DHFA, 20 mM β-mercaptoethanol in prehybridization solution) was added to the microplate wells. The final concentration of both substrate (DHFA) and cofactor (β-NADPH) was 50 μM, well above their sub-micromolar K_m values (*45*). Mixing of microspheres and substrates for 30 s every cycle was achieved using the instrument's built-in agitation mechanism. The fluorescence due to β-NADPH was periodically measured from each well at a frequency of once every 97 s (*46*). Fluorescence was measured using a 360/40 excitation filter and a 460/40 emission filter. Fluorescence measurements were averaged between three wells and background corrected for total fluorescence at $t = 8.1$ min. Linear fitting was error weighted and calculated using the program Origin 7.0 (OriginLab Corp., Northampton, MA).

RESULTS

The goal of this work was to develop reagents that can covalently label recombinant proteins selectively in solution. The strategy, involving a trifunctional labeling reagent that recognizes the His-tag, is illustrated in Scheme 1. First, the labeling reagent noncovalently coordinates to the His-tag on the protein through its Ni:NTA group. After this, long-wavelength UV light is used to create a covalent bond between the juxtaposed photoreactive group and protein surface. Affinity-driven docking of the labeling reagent ensures that the covalent bond is made proximal to the His-tag. Principal reaction products are expected to be selectively monofunctionalized proteins that retain native activity.



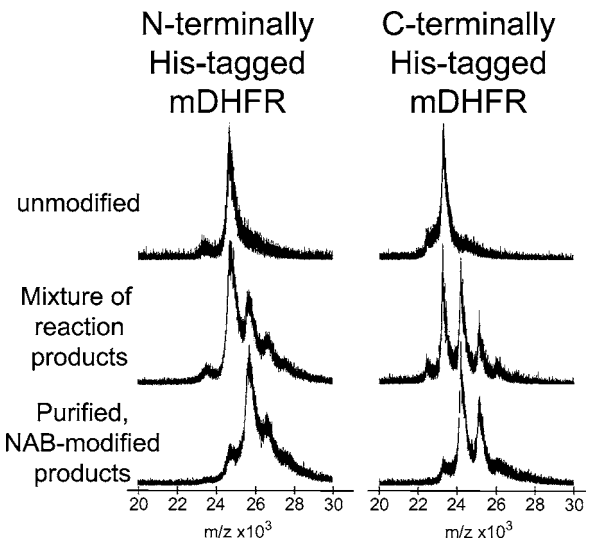
Design and Synthesis of NAB. To test whether a protein's His-tag could serve as a recognition element to guide a subsequent photoconjugation reaction, a trifunctional labeling reagent was synthesized in one step from commercially available precursors (Scheme 2). It is designated NAB since its three branches end in an **N**TA His-tag targeting group, a phenyl **A**zide photoreactive group, and a **B**iotin functional group. Electrospray ionization mass spectrometry (ESI-MS) of RP-HPLC purified NAB demonstrated masses at 925.3 and 947.3 corresponding to the protonated, $[M + H]^+$, and sodiated, $[M + Na]^+$, molecular ions. High-resolution ESI-MS of NAB following incubation with an excess of Ni(II) at pH 8.0 yielded a mass of 981.2538 as compared to an expected mass of 981.2567, corresponding to $[(M - 2H + Ni) + H]^+$ molecular ions; thus each NAB molecule can coordinate a Ni(II) ion to form a 1:1 complex. The molar extinction coefficient at 270 nm, ϵ_{270}, of NAB in water is ~26 900 M^{-1} cm^{-1} based on a quantitative assay of D-biotin.

Labeling of mDHFR with NAB and Characterization. NAB coordinated to Ni(II) was assayed for its capacity to selectively biotinylate His-tagged proteins. mDHFR was chosen as a test enzyme for modification by NAB. This small, ~23 kDa, monomeric enzyme is equally active when expressed with a His-tag at either its N-terminus or C-terminus and it is easily assayed in solution. A crystallographically determined model of the atomic structure of the highly homologous (87% sequence identity) human version of this enzyme shows that both termini occur at the surface of the molecule and are remote from its active-site (*47*). Thus, we reason that targeted modification of mDHFR guided by a His-tag at either the N- or C-terminus will leave the enzyme active.

Upon exposure to UV light, reactions of NAB with either N- or C-terminally His-tagged mDHFR (His_6-mDHFR and mDHFR-His_6, respectively) produce singly and doubly modified enzyme molecules. Under identical conditions, NAB fails to label untagged mDHFR. NAB-modified proteins could be detected by a small shift in mobility on nonreducing SDS−PAGE gels (data not shown). The covalent attachment of biotin to mDHFR could also be detected on Western blots (data not shown). Matrix-assisted laser desorption and ionization mass spectrometry (MALDI-MS) confirmed the presence of singly and doubly labeled species (Figure 1). Since a His-tag of six consecutive histidines was used, the occurrence of doubly modified mDHFR molecules may have resulted from the simultaneous or sequential coordination of two NAB molecules on a single His-tag; only two appropriately positioned histidine residues are necessary to coordinate a Ni:NTA moiety. We intend to test whether shorter His-tags change the distribution of modified products in future studies.

Characterization of NAB-Labeled mDHFR. NAB-labeled mDHFR remained active and its covalently attached biotin group was accessible by avidin. During purification by biotin-affinity chromatography, covalently NAB-labeled mDHFR remained immobilized on avidin-coated particles in the presence of 200 mM imidazole, a concentration sufficient to disrupt the noncovalent NTA:Ni(II):His-tag interaction. Elution of NAB-labeled mDHFR from the avidin-coated support yielded mixed popu-

Scheme 2



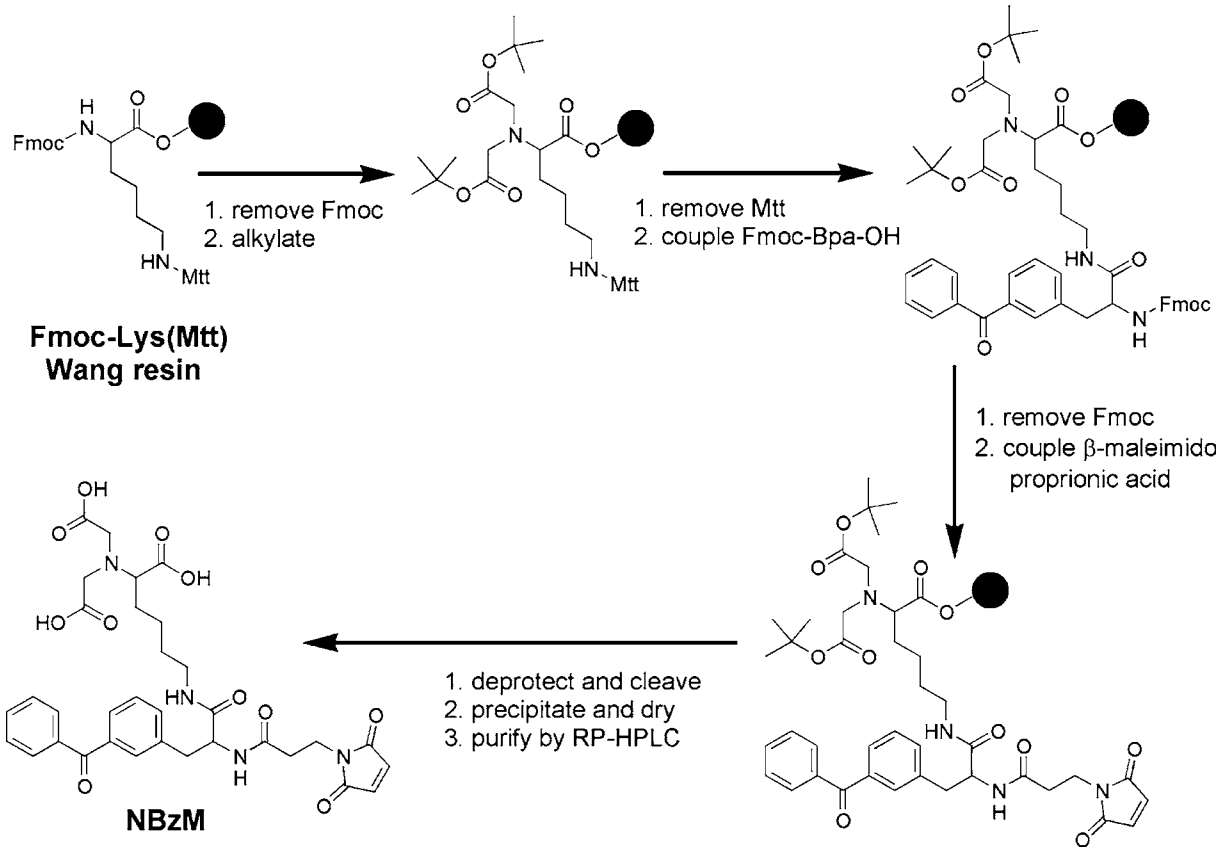


Figure 1. MALDI mass spectrometry of NAB-modified mDHFRs. Depicted are linear-mode MALDI-TOF spectra of both N- and C-terminally His-tagged versions of mDHFR prior to labeling with NAB (top), after labeling but before purification (middle) and after affinity purification of biotinylated species (bottom). Discrete peaks corresponding to singly and doubly modified mDHFR molecules are clearly present in both reactions demonstrating that labeling can be directed through a His-tag on either terminus of this enzyme. Affinity purification yields samples of almost entirely modified enzyme. The specific activity of both preparations remained close to that of the unmodified enzyme (see text).

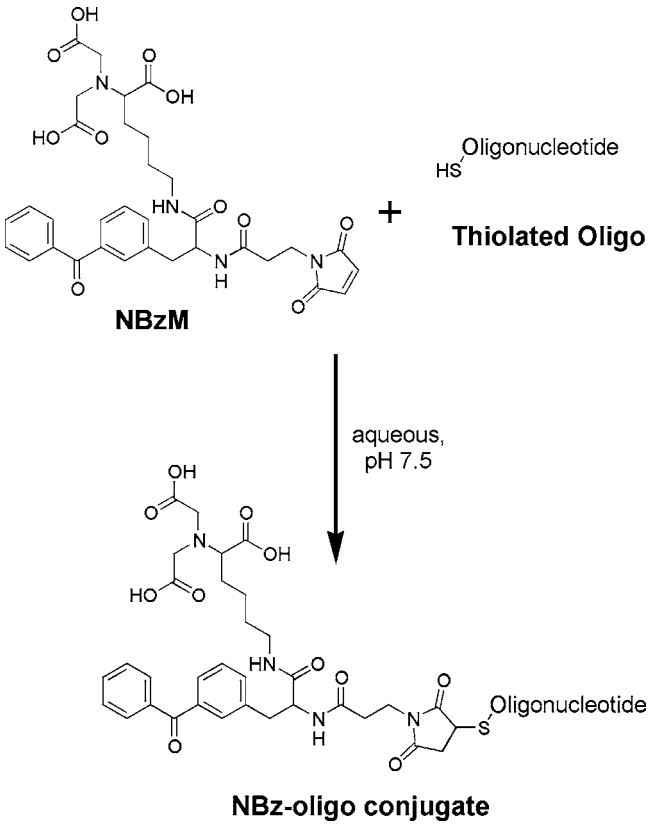
lations of singly and doubly modified protein molecules containing very little (<5%) unmodified protein (Figure 1). Under the conditions used, approximately 20% of the mDHFR molecules were labeled by NAB. The modified mDHFR molecules remained highly active; relative to unmodified controls, NAB−His_6-mDHFR retained 89% of its specific activity, and NAB−mDHFR-His_6 retained 96% of its specific activity ($n = 3$). No further efforts were made toward optimizing the yield of these conjugates.

Design and Synthesis of NBzM. To further explore the potential of the His-tag as a guide for the selective modification of proteins, we decided to design and test a more general trifunctional reagent. This reagent is called NBzM since its three branches end in an **N**TA affinity-directing group, a **B**enzophenone photoconjugating group, and a **M**aleimide functional group. The maleimide group provides a means to generate a series of related compounds since it can react specifically with a thiol-bearing compound under mild conditions. A straightforward solid-phase synthesis of this trifunctional molecule was developed as shown in Scheme 3. It should be noted that since introduction of the maleimide moiety occurs penultimate to cleavage, any of a variety of groups can substitute for it at this point to produce reagents attached to the same NTA-benzophenone molecular scaffold. Apart from replacement of the biotin group with maleimide, the structure of NBzM differs from NAB in three significant ways. Foremost, benzophenone was chosen as the photoreactive group since it is resistant to chemical reduction by thiols, and because its photolysis creates a reactive intermediate that, in the presence of oxygen, can decay back to the original photosensitive structure in the absence of covalent bond formation (*41*, *48*). Benzophenone has been used as the photoreactive group in many protein photolabeling studies (*49*). Second, the number of successive interatomic bonds between the photoreactive center and the tertiary nitrogen of NTA was shortened to 14 from 21. Simple modeling, where the mDHFR molecule is considered to be a sphere of uniform density, $\rho = 1.3$ g/cm^3, and the labeling compound is fully extended from a point on the protein surface, indicates that NBzM could form a covalent linkage near the His-tag in a region corresponding to ~15% of the surface area of mDHFR whereas the longer NAB could attach anywhere within an area of ~37% of the protein's surface. Finally, the disulfide bond that occurs in the NAB structure was eliminated.



Scheme 3

Pure NBzM is resolved as a single peak by analytical RP-HPLC. Hi-resolution ESI-MS of pure NBzM yielded a mass of 665.2481 as compared to an expected mass of 665.2459, corresponding to the protonated, $[M+H]^+$ molecular ion. Incubation with an excess of Ni(II) at pH 8.0 biased the ESI-MS peaks to a cluster starting at a mass of 721.3 corresponding to $[(M - 2H + Ni) + H]^+$ molecular ions indicating that NBzM can coordinate a Ni(II) ion to form a 1:1 complex. ^1H and ^{13}C NMR measurements in DMSO-d_6 are consistent with the structure of NBzM shown in Scheme 3.

Conjugation of NBzM to Thiol Oligos. We were particularly interested in testing whether NBzM could be used as a reagent for the preparation of protein−DNA conjugates. Protein−nucleic acid conjugates have been used as synthetic nucleases, as hybridization probes, for antisense directed delivery, for protein library encoding, for in vitro selection, and as immune stimulants (*50*−*56*). Protein−nucleic acid conjugates are also of increasing interest as elements for the production of self-assembling protein arrays (*57*−*59*). The overall strategy consists of first coupling NBzM through its maleimide group to a terminal thiol group on a synthetic DNA oligonucleotide (Scheme 4) then using the NTA group of this NBz−oligo molecule to guide a subsequent photoconjugation to a His-tagged protein. As determined by RP-HPLC and MALDI-MS, reduced thiolated oligos could be almost entirely converted to NBz−oligo conjugates by reaction with excess NBzM. Similar results were obtained with four different 5′- or 3′-thiolated oligonucleotides ranging from 15 to 28 bases in length. Ni(II) could be added to NBz−oligo conjugates at 1.1-fold excess over NTA groups; however, greater excesses were found to cause precipitation of oligos and the conjugates. Precipitation of DNA by Ni(II) has been observed and studied in other contexts (*60*−*62*). Given a stability constant of

Scheme 4

$10^{11.5}$ for the coordination of Ni(II) by NTA, when both Ni(II) and NBz−oligo are present at 10 μM, >99.99% of the conjugates will be coordinated to Ni(II) at equilibrium (*63*).

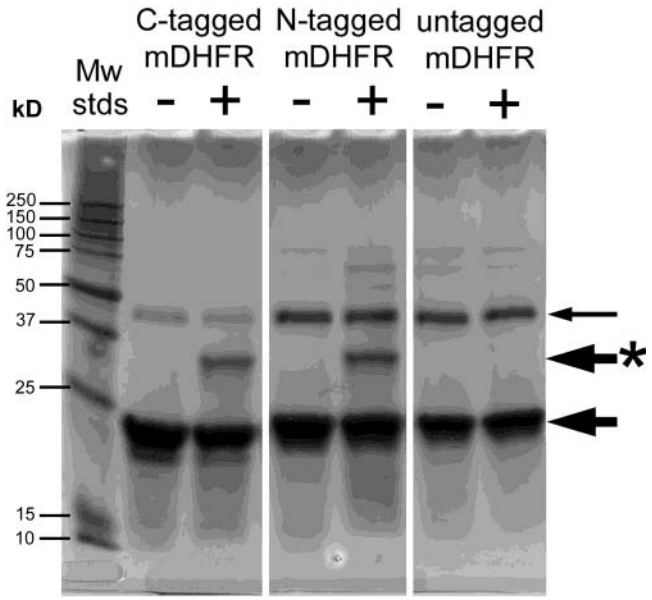


Figure 2. NBz−oligo labeling of mDHFR is selective for the presence of the His-tag. Hybrid molecules of covalently linked protein and DNA, the products of photoconjugation between NBz−oligo and His-tagged mDHFR in solution, are resolved as a discrete species on reducing and denaturing 12% polyacrylamide gels by SDS−PAGE. Shown are lanes from the same silver-stained gel (irrelevant lanes have been excised) where labeling reactions (+) between C- and N-terminally His-tagged mDHFRs are separated parallel to control reactions lacking NBz−oligo. The final two lanes are from reactions with mDHFR lacking a His-tag. The middle arrow, marked with an asterisk, indicates the position of the shifted species with a mobility equivalent to that of a 35 kDa protein. In similar experiments in which the oligo carries a terminal fluorophore, the fluorescence of this shifted band can be detected on unstained gels. The lower arrow indicates the mobility of the unmodified mDHFR molecules, with molecular masses ranging from 23.3 kDa for the C-tagged species to 24.7 kDa for the N-tagged species. All mDHFR preparations contain, to a variable extent, the ~50 kDa protein (small arrow) as a contaminant.

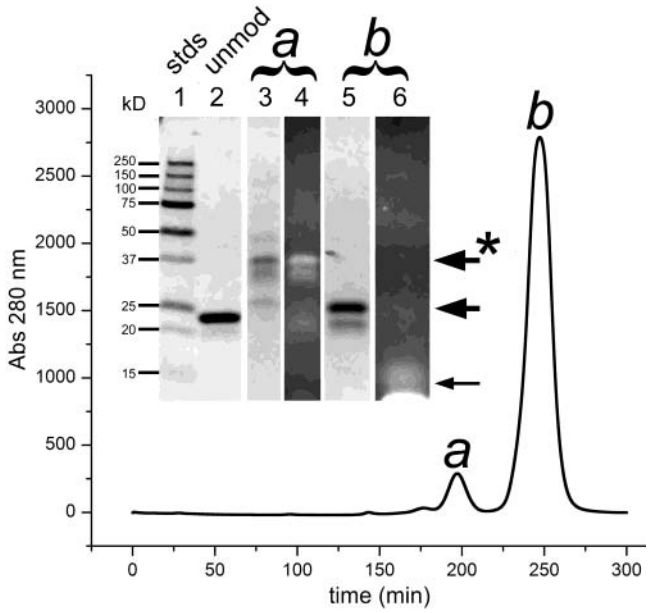

Figure 3. Size-exclusion chromatography allows purification of NBz−oligo-modified mDHFR. A 100 nmol scale reaction between C-terminally His-tagged mDHFR and the fluorescently labeled modification reagent NBz−oligo$_{FAM}$ was separated by high-resolution size exclusion chromatography. The elution profile is shown as a function of absorbance at 280 nm, a wavelength absorbed by protein and DNA. Collected fractions across peaks a and b were pooled separately and concentrated by ultrafiltration. The inset shows Coomassie-blue protein staining (lanes 2, 3, and 5) of reducing SDS−PAGE separations of unmodified C-tagged DHFR and the concentrated components of peaks a and b, respectively. Lanes 4 and 6, fluorescent images of the lanes 3 and 5, respectively, show the fluorescent species visible prior to staining. All lanes are from the same gel. Peak a is highly enriched with a fluorescent protein of high molecular weight (lanes 3 and 4): the NBz−oligo$_{FAM}$−mDHFR conjugate, indicated by the uppermost arrow labeled with an asterisk. Peak b appears to be a mixture of unmodified mDHFR (lane 5, middle arrow) and unattached fluorescent NBz−oligo (lane 6, lowest arrow). When assayed for mDHFR activity, peak a demonstrated a specific activity of about 80% that of unmodified mDHFR, while peak b had a specific activity equivalent to that of unmodified mDHFR.

Ni:NBz−Oligo Labeling of mDHFRs. NBz−oligo coordinated to Ni(II) was assayed for its capacity to label mDHFR. Reactions of Ni:NBz−oligo with both His$_6$-mDHFR and mDHFR-His$_6$ yielded protein molecules linked to a single oligo, while reactions with mDHFR lacking a His-tag showed no evidence of modification (Figure 2). Reactions between Ni:NBz−oligo and His-tagged mDHFR were significantly inhibited by the presence of either 150 mM imidazole or 5 mM EDTA (data not shown). Oligo-modified proteins could be detected by a significant shift in mobility on reducing SDS−PAGE gels (Figure 2). In all such labeling reactions, the NBz−oligo carried an additional label, either biotin or 6-carboxyfluorescein (FAM), linked to the end of the oligo opposite the NBz-group. When NBz−oligo$_{biotin}$ was used, biotin on the shifted protein was detected on Western blots (data not shown) and when NBz−oligo$_{FAM}$ was used, the fluorescence of the shifted protein was observed directly in the unstained gel (inset, Figure 3). No suitable conditions could be found to measure the molecular weight of these oligo−protein molecules by mass spectrometry.

Characterization of Oligo-Labeled mDHFR. Preparative-scale conjugation reactions were conducted between mDHFR-His$_6$ and either NBz−oligo$_{biotin}$ or NBz−oligo$_{FAM}$. Although the incorporation of biotin permitted significant enrichment of mDHFR−oligo conjugates over unmodified mDHFR through biotin affinity chromatography, size-exclusion methods permitted purification to near homogeneity (Figure 3). Under the conditions tested, NBz−oligo labeling yields were low, from 1 to 2%. In solution, purified mDHFR−oligo conjugates exhibited on average 72% (n = 4 preparations, ranging from 56 to 81%) of the specific activity of unmodified mDHFR indicating that the covalent attachment of oligo and subsequent manipulations did not greatly reduce the enzyme's native activity. When mDHFR−oligo conjugate molecules were incubated with either complementary or noncomplementary fluorescently labeled oligos in solution, analytical HPLC gel-filtration experiments showed the presence of new high-mobility species only with the complementary DNA (data not shown). This suggests that the mDHFR−oligo conjugate molecules could specifically hybridize with a complementary DNA oligonucleotide in solution. Under identical conditions, there was no evidence of hybridization to either of two different noncomplementary oligonucleotides.

To test whether the protein−oligo conjugates can be used to make self-assembling protein arrays their capacity to specifically hybridize to DNA-coated surfaces was assayed. For these experiments, the DNA portion of the conjugate was 28 bases long and linked to the mDHFR through its 5′ end. The 3′ end of the DNA consisted of a 15-base hybridization sequence termed "sense", end-

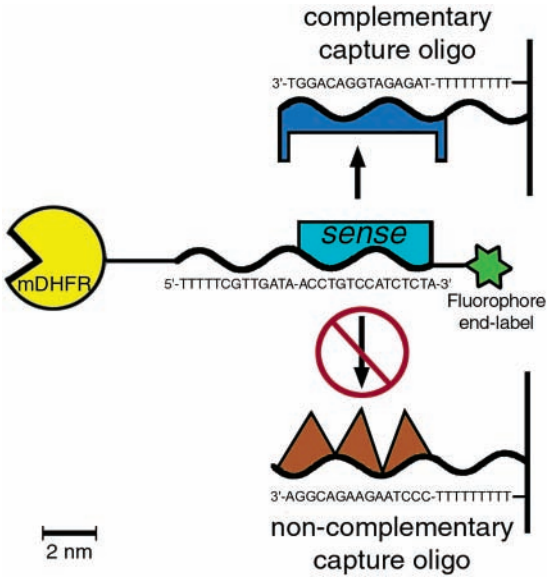

Figure 4. Scale cartoon of mDHFR−oligo conjugate used in hybridization experiments. The mDHFR−$oligo_{FAM}$ conjugate and its capture partners are depicted as fully extended molecules where the DNA segments have the length expected for duplex B-DNA. In the hybridization/immobilization experiments described, the conjugate is presented with either a complementary or noncomplementary capture strand that has been affixed through its 5′-end to a substrate. A 9-base spacer of thymidine residues links the capture sequences to the substrate to minimize crowding and to accommodate the fluorescent end-label of the conjugate. The nonspacer 15-base capture sequences are shown as shapes that either match or fail to match the shape of the conjugate 15-base "sense" sequence.

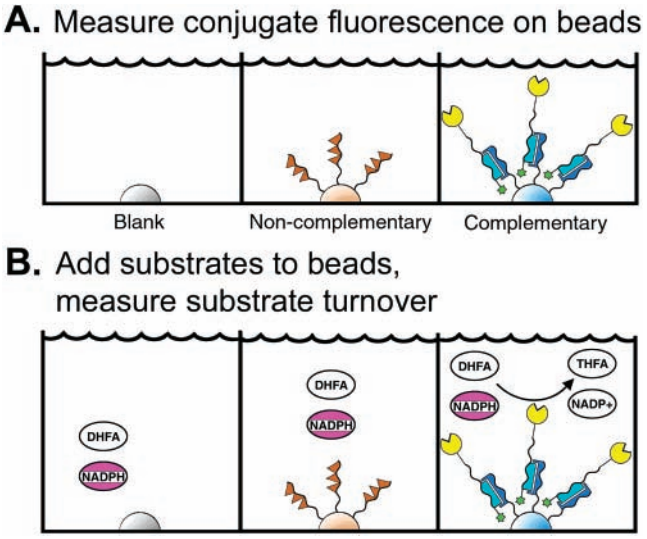

Figure 5. Schematic diagram of experiment to measure the enzyme activity of specifically immobilized conjugates. (A) The various microsphere types, either blank (non-DNA bearing), noncomplementary, or complementary beads are schematically shown in separate microplate wells under buffer, after having been incubated with mDHFR−$oligo_{FAM}$ conjugate (see Figure 4) and washed. The conjugate fluorescence is measured at this point. (B) A concentrated mixture of the substrate, DHFA, and cofactor β-NADPH are added to the wells. The enzyme mDHFR couples the oxidation of β-NADPH to $NADP^+$ with the reduction of DHFA to THFA.

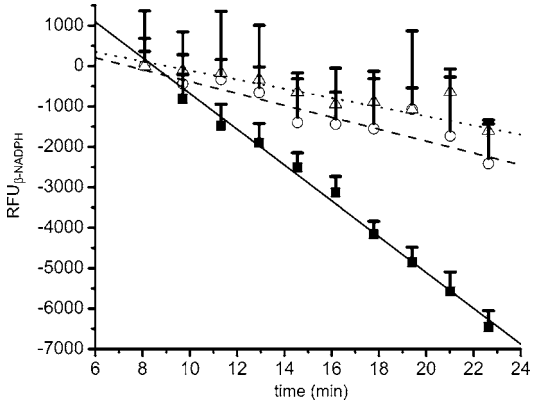

Figure 6. mDHFR immobilized through sequence-specific hybridization shows significant activity. Measurements of β-NADPH fluorescence were recorded as described in the methods and depicted in Figure 5. Filled squares, ■, correspond to complementary DNA-coated microspheres after hybridization to mDHFR−$oligo_{FAM}$ conjugate. Open circles, ○, correspond to noncomplementary DNA-coated microspheres after identical treatment. Open triangles, △, correspond to uncoated microspheres treated likewise. Linear least-squares fitting yielded the respective solid, dashed, and dotted lines. Subtracting the slope of the line for the unmodified beads from the slopes of the lines of the DNA-coated beads indicates that the activity difference due to sequence specificity is approximately 10-fold. Each datapoint is the average of measurements from three separate microwells. Error bars correspond to standard error of the mean. The mean background fluorescence of the first time-point used (t = 8.1 min after addition of substrates) was subtracted from all points for each dataset. Prior to the first time point used, there was significant scatter, most likely due to settling of the beads and inefficient mixing within the microplate reader.

labeled with a FAM fluorescent group (Figure 4). This design was chosen to allow the sense sequence to extend well away from the protein surface, to minimize self-complementarity, and to allow the conjugates to be directly detected by fluorescence measurements. To prepare surfaces that display capture DNA in the best orientation for hybridization, synthetic 5′-aminated oligos were coupled through primary amine-specific chemistry. Following the 5′-terminal amine, the capture oligo sequences consisted of nine deoxythymidine residues, which serve as an economical spacer sequence, followed by 15 bases that were complementary (5′-TAG AGA TGG ACA GGT-3′) or noncomplementary (5′-CCC TAA GAA GAC GGA-3′). To preserve the structure and activity of the mDHFR, the capture sequences were chosen to allow hybridization to their respective complementary sequences at room temperature at low ionic strength. The sequences were also selected to minimize self- and cross-complementarity. Specific hybridization of mDHFR−oligo conjugates could be observed on both oligo-modified flat plastic microwell surfaces and polymer microspheres. On microplate, noncomplementary wells captured only 12.1% as much conjugate, as measured by fluorescence, as did complementary ones (n = 3). Similarly, noncomplementary microspheres retained only 1.4% as much FAM fluorescence as compared to microspheres coated with complementary capture oligo (n = 3). Precise determination of the changes in fluorescence due to interaction with the microspheres is not within the scope of the current work.

To measure the enzymatic activity of the immobilized conjugates, the amount of mDHFR activity retained on microspheres after hybridization and washing was measured. In the assay, oxidation of the cofactor β-NADPH to β-$NADP^+$, which is coupled to the reduction of dihydrofolate (DHFA) to tetrahydrofolate (THFA), is monitored as a decrease in the fluorescence attributable to β-NADPH. The assay is depicted schematically in Figure 5. The amount of conjugate retained on the microspheres after hybridization was determined by measuring the FAM fluorescence of the supernatants and wash solutions

Table 1. Quantitative Results from Microsphere-Immobilized mDHFR−Oligo Conjugates

microsphere type	measured quantity of mDHFR−oligo remaining in solution (pmol)	calculated quantity of mDHFR−oligo retained on microspheres (pmol)	apparent mass equivalent activity, relative to nonimmobilized conjugate (pmol)
complementary	58.5	41.5	13.9
non-complementary	100	0	1.4

and comparing this to the fluorescence of known amounts of conjugate in the same buffer solution (Table 1). This was done because binding to the beads clearly altered the fluorescence of the conjugate molecules. By this measure, aliquots of 1.25 mg of complementary DNA-modified microspheres retained an average of 41.5 pmol of mDHFR−oligo conjugate, whereas equivalent aliquots of noncomplementary DNA-modified and unmodified microspheres failed to retain quantifiable amounts of conjugate. This value closely matches estimates of the binding capacity of the microspheres, 28−40 pmol/mg, as determined with fluorescent complementary oligonucleotides. Addition of the substrate DHFA and the cofactor β-NADPH at concentrations well above their respective K_m values allowed the activity of the immobilized mDHFR to be measured over time (Figure 6). With this assay, microspheres carrying specifically immobilized mDHFR showed approximately 10-fold greater activity than control microspheres (Table 1). The activity of the specifically immobilized mDHFR−oligo conjugate is 33.5% of that determined for an equivalent amount of conjugate in solution; this decrease may be due to nonideal mixing, molecular crowding and steric effects, or limits to substrate diffusion to a surface. No effort was made to optimize the kinetic behavior of the immobilized conjugate, nor was the long-term stability or reusability of the immobilized conjugate assessed.

DISCUSSION

This is the first report demonstrating the use of the His-tag as a guide for the covalent modification of a protein in solution. This approach has several advantages over conventional labeling methods in that (i) it utilizes the widely used His-tag, making it compatible with common expression systems and established libraries of His-tagged proteins, (ii) it presumably restricts the point of modification to the proximity of the His-tag, (iii) it restricts the stoichiometry of modification to yield largely 1:1 conjugates, (iv) the recognition element used, the His-tag, can be located at either protein terminus and possibly at internal sites, (v) a wide spectrum of modifications, from small molecules to macromolecules, are possible. We have shown that when this strategy is used to link a DNA oligonucleotide to a model enzyme, the protein's functionality remains intact both in solution and upon immobilization through sequence-specific hybridization. Thus, this technology may serve in the future creation of self-assembling, functional protein arrays.

With regard to the attachment of nucleic acid to protein for the creation of protein arrays, it should be noted that others have made progress using alternative methods. Such a goal was first expressed by Niemeyer and co-workers who chemically linked oligonucleotides to streptavidin (*64*). The oligo−streptavidin conjugate molecules were subsequently coupled to functional biotinylated antibodies through the strong noncovalent streptavidin−biotin interaction. Using this approach, the authors demonstrated the "translation", via hybridization, of a microtiter plate-based DNA array into a functional antibody array. Recently, the same group used expressed protein ligation to produce covalent conjugates between polyamide nucleic acid (PNA) and Ras protein and between PNA and the Ras binding domain of the c-Raf-1 protein (*59*). The authors showed that these C-terminally linked PNA−protein conjugates could hybridize to convert a simple glass-slide based DNA microarray into a protein array with retention of specific protein binding properties; however, no immobilized catalytic activity was demonstrated. Kuimelis and colleagues used mRNA−protein fusions to convert a DNA microarray chip to a simple protein microarray (*57*). The methodology described relies on in vitro translation and is restricted to fusions between the C-terminus of the protein and the 3′-end of its encoding mRNA. The array produced consisted of fragments of full-length proteins that were functional only in that they could be detected by specific antibodies. The approach we describe uses more readily produced biologically expressed full-length proteins, provides for modification in a variety of positions, and is compatible with many different sequences of the more chemically robust DNA or other nucleic acid analogues. Furthermore, the enzyme we immobilized was shown to retain catalytic activity.

More recently, Oleinikov and co-workers also used cell-free biosynthesis to produce lysine-biotinylated proteins (*58*). A series of steps allowed these researchers to produce protein−streptavidin−oligo conjugates that could be used to produce a simple self-assembled protein array. Importantly, both the proteins used, enhanced green fluorescent protein and the enzyme luciferase, retained their described functions. This approach is promising but also depends on the products of in vitro translation reactions. The biotinylation results we describe using the NAB reagent offer an alternative to this cell-free approach that could be easily integrated with their subsequent steps. The random incorporation of biotinylated-lysines by Oleinikov and colleagues eliminates the possibility of controlling the orientation of the proteins within the array. With our strategy, one can imagine varying the position of the His-tag in a given protein to control its resultant orientation upon modification and immobilization. Since protein arrays are sought largely as tools for the screening of molecular interactions, orientational control may prove very important. Further, orientational control is considered important for optimal functionality of immobilized enzymes (reviewed in ref *65*).

There are a number of ways that our results may be extended and improved. Foremost, greater efficiency of the photoreaction is expected if the affinity of the labeling reagent for the His-tag were to be increased. Drawing a lesson from the results of Ebright and co-workers, the affinity can be expected to be increased 10−100 fold simply by incorporation of two appropriately spaced NTA groups into the labeling reagent (*37*). Chemistries that yield covalent bonds other than through photolysis may increase efficiency as well. Combinatorial methods may allow co-optimization of the labeling reagent and variations of the His-tag that improve both specificity and affinity. Mapping the exact locations of protein modification produced with these reagents should shed light on their degree of regioselectivity. Other affinity-tag-directed cross-linking reagents are envisioned, such as one that incorporates glutathione to target the commonly used glutathione-*S*-transferase (GST) fusion tag. Use of this oligo-labeling strategy against a battery of proteins will allow a true self-assembling protein array, either bead- or chip-based to be demonstrated.

Of particular interest is the prospect of harnessing this molecular recognition based technology to achieve an unprecedented degree of control over the artificial assembly of molecular complexes. In recent years, it has become increasingly apparent that biological processes are mediated largely by exquisitely organized assemblies of functional macromolecules (*66*). Typically, such assemblies are multifunctional molecular machines capable of carrying out a series of physical and chemical transactions in a coordinated and efficient manner. Examples include the transcriptional apparatus that synthesizes RNA from genomic DNA in a highly regulated and processive manner, the ribosome which synthesizes proteins from mRNA also in a regulated and processive manner, and G-protein coupled receptor complexes which assemble and disassemble in response to signals at the cell-surface. In these systems, the identities, number, and relative orientations of the proteins are precisely defined, but by architectural rules that are currently poorly understood. The engineered assembly of proteins into higher-order multifunctional molecular machines requires a means to simplify these rules. Along these lines, significant progress in molecular assembly, programmed through the rules of nucleic acid interaction, has developed over the last two decades (see refs *67* and *68* for recent reviews). With this approach, remarkable molecular objects have been created from both DNA alone and protein−DNA conjugates. It is believed that the technology presented here may offer a predictable and practical means to modify recombinant proteins with precision sufficient to enable the design and assembly of novel multifunctional molecular machines held together and organized by structural elements such as nucleic acid. This or a similar approach, coupled with our ever-increasing knowledge of protein sequences, structures, and functions may form the basis for new engineered semi-synthetic biomolecular materials, catalysts, and nanobiotechnological devices.

ACKNOWLEDGMENT

This work was supported by NIH Grants F32NS11063 (G.D.M.) and GM57015 (N.L.A.). The authors thank John Greaves for help with mass spectrometry, Philip Dennison for NMR spectroscopy, Dennis Ta and Larry Vickery for help with molecular biology, J. Denis Heck for microarray support, Stephen Hou for help with bead-based fluorescence measurements, David van Vranken, Casey McComas, Josh Yoburn, and Frank Rossi for advice and help with organic synthesis, and Joseph Soughayer and Kwan Ng for helpful discussions.

Binding of annexin V or the C2A domain of synaptotagmin I to phosphatidylserine expressed on the surface of apoptotic cells can, when labeled with appropriate probe molecules, be used to detect the presence of apoptosis using radionuclide, magnetic resonance, and optical imaging techniques. The preparation of a biotinylated C2A−GST fusion protein is described, and its capability, when used in conjunction with fluorescein-labeled streptavidin, of detecting apoptotic cells by flow cytometry is compared directly with the performance of a commercial preparation of fluorescein-labeled annexin V. Biotinylated C2A−GST, when used in conjunction with streptavidin-conjugated superparamagnetic iron oxide nanoparticles or Gd−chelate−avidin conjugates, was shown to be capable of detecting apoptotic cells using T_2-weighted or T_1-weighted magnetic resonance imaging experiments, respectively.

INTRODUCTION

Apoptosis, or programmed cell death, is a highly regulated process that results in the selective elimination of cells during normal tissue homeostasis and differentiation (*1*). Apoptosis can also occur in tumors following chemotherapy, where the extent of apoptosis and the speed of onset have been shown to be good prognostic indicators for the outcome of treatment (*2*−*5*). For this reason we have been interested in identifying markers of tumor cell apoptosis that could be detected noninvasively in the clinic using magnetic resonance spectroscopy and imaging techniques (*6*, *7*). There are a number of markers that can be used to identify apoptotic cells, including morphological changes, DNA fragmentation, and caspase activation (*8*). A relatively early event in the process is the flipping of phosphatidylserine from the inner leaflet of the plasma membrane bilayer to the outer surface (*9*), which can be detected by binding of the protein annexin V to surface phosphatidylserine (*10*). This has led to the development of a number of annexin V based probes for detecting apoptotic cells, including technetium-labeled (*11*) and near-infrared fluorochrome-labeled-proteins (*12*), which have allowed the detection of apoptotic cells in vivo using radionuclide and optical imaging techniques, respectively. We have demonstrated previously that the C2A domain of the protein synaptotagmin I, which binds to negatively charged phospholipids in a Ca^{2+}-dependent manner, can be used to detect apoptotic cells in vitro using flow cytometry. We also showed that when labeled with superparamagnetic iron oxide nanoparticles (SPIO)[1] the protein domain could be used to detect apoptotic cells, in vitro and in vivo, using T_2-weighted magnetic resonance imaging experiments (*13*). We describe here the synthesis of a biotinylated protein that, when used in conjunction with appropriately labeled avidin or streptavidin molecules, which bind very tightly to biotin ($K_d \approx 10^{-15}$ M), can be used to detect apoptotic cells by flow cytometry or by T_1- or T_2-weighted ^{1}H magnetic resonance imaging. Flow cytometric detection of apoptotic cells using C2A was compared with detection using a commercial preparation of the more widely used annexin V.

EXPERIMENTAL PROCEDURES

Protein Purification. *E. coli* BL21(DE3) cells transformed with a pGEX vector (Amersham Biosciences) expressing a C2A−GST fusion protein (*14*) were grown at 37 °C in 2xTY medium (2 L) supplemented with 50 μg/mL ampicillin until the A_{600} was between 0.5 and 0.8. The cells were then induced with IPTG (final concentration of 0.1 mM) and incubated for a further 3 h before harvesting by centrifugation at 6000*g* for 30 min. The cells were resuspended in 40 mL of BugBuster protein extraction reagent (Novagen) and incubated for 20 min at 25 °C. Cell debris was removed by ultracentrifugation at 20000*g* for 30 min, the supernatant was applied to glutathione sepharose 4B beads (Amersham Biosciences) preequilibrated with phosphate-buffered saline (PBS), and the protein was purified according to the manufacturer's instructions. The protein, which ran as a single band in sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE), was dialyzed against PBS and concentrated using a Vivaspin filter (Vivascience, Germany). The protein can be produced in very high yield using this system (∼40 mg/L *E. coli* culture), which is an advantage given the relatively large amounts required for magnetic resonance (MR) imaging experiments.

The C2A domain was prepared by thrombin cleavage of the fusion protein and purified using glutathione

sepharose 4B beads. Briefly, 400 μg of C2A−GST fusion protein were mixed with 10 units of thrombin in PBS and incubated for 20 h at 25 °C. Glutathione sepharose 4B beads were added to the reaction mixture and incubated for a further 10 min before the solution was centrifuged at 300*g* for 5 min to collect the supernatant, which contained the C2A domain. The bead-bound GST was eluted using a reduced glutathione solution.

Surface Plasmon Resonance Analysis. Liposomes were prepared from brain phospholipids (Avanti Polar Lipids Co.). Samples containing 2.6 μmol of a PS/PE/PC mixture (molar ratio 35:50:15) in chloroform were dried under a stream of nitrogen and resuspended in 2.6 mL of buffer (20 mM HEPES, 100 mM NaCl, pH 7.4) by vigorous vortexing. A milky suspension was created, indicating the formation of large multilamellar vesicles (LMV). Small unilamellar vesicles (SUV) were obtained by sonication of the LMV until the solution cleared. To determine the binding affinity of the C2A domain for the liposomes, surface plasmon resonance analysis was performed using a Biacore 2000 system (Biacore, Uppsala, Sweden) and L1 chips. The sensor chips were coated with 40 μL of a suspension of SUV containing 1 mM phospholipid at a flow rate of 5 μL/min. The resulting response was about 3000 RU. To remove any multilamellar material from the lipid surface, 5 μL of 50 mM NaOH was injected, which resulted in a stable baseline (∼2000 RU) corresponding to the lipid bilayer linked to the chip surface. The C2A domain was allowed to interact with the sensor surface for 10 min (association phase) at five different concentrations, increasing from 150 to 550 nM. All the experiments were conducted in a buffer containing 10 mM HEPES, pH 7.4, 150 mM NaCl, and 2 mM $CaCl_2$ at a flow rate of 5 μL/min and at 25 °C and were repeated three times. To regenerate the phospholipid bilayer surface after the dissociation phase, 10 μL of 50 mM NaOH solution was used. The binding data were evaluated using BIAevaluation software, version 3.1 (BIAcore AB, Uppsala, Sweden).

Biotinylation of the C2A−GST Fusion Protein. The protein was biotinylated using an *N*-hydroxysulfosuccinimide (NHS) ester derivative of biotin, which modifies primary amine groups. Since the Ca^{2+}-dependent PS binding sites on C2A contain two Lys residues (Lys200 and Lys236) (*20*), we sought to protect these by first binding the protein to an SP sepharose column. The protein binds tightly to the negatively charged SP sepharose resin in a Ca^{2+}-dependent manner, via binding sites that likely overlap those for PS. Purified C2A−GST (6 mg/mL, 1 mL) was loaded onto an SP column (HiTrap SP FF, 1 mL volume, Amersham Biosciences) equilibrated with HEPES-buffered saline containing 20 mM HEPES, pH 7.4, 150 mM NaCl, and 0.2 mM $CaCl_2$. After extensive washing, sulfoNHS−LC−biotin (Pierce) (1.8 mg/mL, 1 mL, 40-fold excess of biotin) in the same buffer was injected into the column and the flow-through fraction was collected and reinjected. After four cycles of reinjection, the column was left at 25 °C for 15 min and then washed with 10 bed volumes of HEPES−Ca^{2+} buffer. The biotinylated protein was eluted using buffer lacking $CaCl_2$ and containing 10 mM EDTA. The collected fractions were pooled and dialyzed against PBS for 24 h to remove EDTA.

The biotinylation sites in C2A−GST were investigated by cleaving the fusion protein at the thrombin cleavage site. To estimate the number of moles of biotin conjugated per mole of C2A−GST and to identify the region of the protein modified (C2A versus GST), the biotin-conjugated protein (0.4 mL of a 1 mg/mL solution in PBS) was mixed with a thrombin solution (10 μL of a 1 U/μL solution in PBS) and incubated at 25 °C for 20 h. The resulting mixture of two protein fragments and the intact fusion protein were analyzed by SDS−PAGE and MALDI-TOF mass spectrometry. The binding activity of biotinylated C2A−GST for PS was assessed using a liposome binding assay described previously (*21*). Briefly, the biotinylated protein was mixed with the liposomes and then centrifuged.

Flow Cytometry. Murine lymphoma cells (EL4) were grown in RPMI 1640 medium supplemented with 10% heat-inactivated fetal bovine serum, 2 mM L-glutamine, 100 U/mL penicillin, and 0.1 mg/mL streptomycin. The cells were treated with 15 μM etoposide for 16 h to induce apoptosis, collected by centrifugation, and then washed in ice-cold PBS. The washed cells were suspended in C2A-binding buffer (10 mM HEPES, 140 mM NaCl, 2.5 mM $CaCl_2$, pH 7.4), and the cell density was adjusted to 1×10^6 cells/mL. To 100 μL of cell suspension, 1 μL of biotin−C2A−GST protein (30 μM protein), 1 μL of propidium iodide (PI) (100 μg/mL), and 5 μL of streptavidin−FITC (Sigma) (1 mg/mL) were added, and the mixture was incubated for 5 min at 25 °C. The resulting mixture was then subjected to flow cytometry (FACScan, Becton Dickinson, U.K.). For each sample 20 000 cells were counted. Apoptosis was also detected using a commercially available preparation of annexin V-FITC (Molecular Probes), which was used according to the manufacturer's instructions.

Preparation of Contrast Agents and Magnetic Resonance Imaging. Avidin−GdDTPA conjugates were prepared as described in (*15*). Briefly, purified avidin (Sigma) was incubated with 20-fold excess DTPA anhydride (Sigma) for 24 h at 4 °C. After extensive dialysis against 100 mM sodium citrate buffer, pH 6.5, a 40-fold excess of $Gd(NTA)_2$ was added to the avidin−DTPA solution. After incubation for 24 h at 4 °C, the resulting mixture was dialyzed extensively against PBS and stored at −20 °C before use. The T_1 relaxivity of this modified protein at 9.4 T was about 60 mM^{-1} s^{-1}. For T_2-weighted ^1H MR imaging, commercially available strepavidin-conjugated SPIO nanoparticles were used (Miltenyi Biotec). Etoposide-treated cells were incubated with different concentrations (1.5, 4.5, 15 μM) of the biotinylated C2A−GST protein at 25 °C for 5 min. The protein concentration was determined by amino acid analysis. After being washed, cells were incubated with avidin−GdDTPA conjugates (80 μM protein) or streptavidin−SPIO nanoparticles (30 ng/mL of Fe) at 25 °C for 5 min. After washing, 10^7 cells were mixed with 50 μL of 4% bovine gelatin and then immediately loaded into a 5 mm NMR tube. T_1- (repetition time, TR = 0.2 s; spin−echo time, TE = 15 ms) and T_2- (TR = 4 s, TE = 40 ms) weighted ^1H MR images of the samples were acquired at 9.4 T using a two-dimensional spin−echo imaging sequence, a 25 mm diameter proton probe, and a Varian UnityPlus spectrometer.

RESULTS

Measurement of the Affinity of C2A for Phosphatidylserine-Containing Liposomes Using Surface Plasmon Resonance. Small unilamellar vesicles were immobilized on an L1 sensor chip, which allows retention of the lipid bilayer structure (*16*). A representative sensorgram is shown in Figure 1, showing the association of the C2A domain with phosphatidylserine on the surface of the sensor chip and its subsequent dissociation. The C2A domain bound to the surface of the

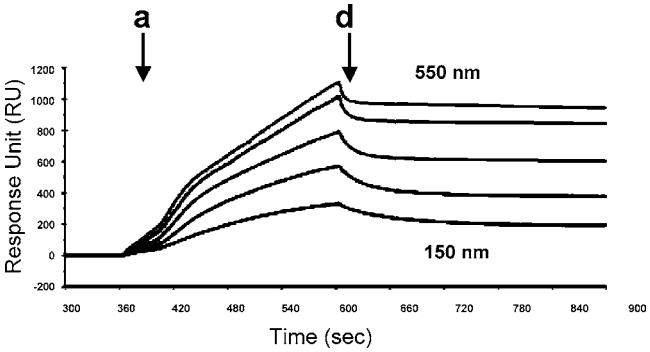

Figure 1. SPR sensorgram (relative response vs time) for the C2A domain. The L1 sensor chip was coated with PS-containing liposomes, and the C2A domain was injected at a series of increasing concentrations (150, 250, 350, 450, and 550 nM). The start of the association and dissociation phases are indicated by the symbols a and d, respectively.

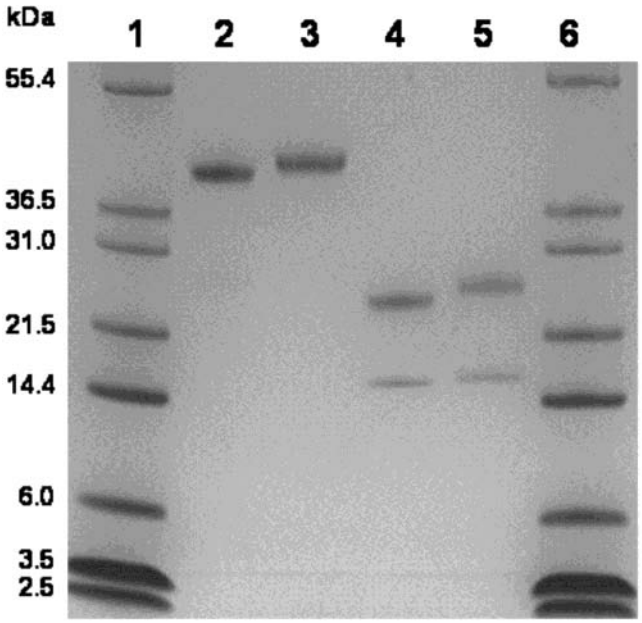

Figure 2. Analysis of the biotinylation of C2A−GST by SDS−PAGE: (1) size markers; (2) intact C2A-GST; (3) biotinylated C2A-GST; (4) thrombin-cleaved C2A−GST; (5) thrombin-cleaved biotinylated C2A-GST; (6) size markers. The relative molecular mass of GST is 26 kDa, and that of the C2A domain is 16 kDa. Both the GST and C2A bands from the biotinylated protein are retarded when compared to the unmodified protein, indicating that both domains of the fusion protein are biotinylated.

sensor chip in the presence of 2 mM $CaCl_2$ but had no affinity when free Ca^{2+} was depleted by the addition of 10 mM EDTA (data not shown). The calculated dissociation constant is in the nanomolar range ($(17.1 \pm 0.5) \times 10^{-9}$ M) and comparable to a value of 115×10^{-9} M for the binding of C2A−GST to a lipid monolayer (*17*) determined by surface plasmon resonance and to a value of 40×10^{-9} M for the binding of C2A to phospholipid vesicles (25% PS/75% PC) determined using intrinsic fluorescence measurements (*18*). However, the affinity of C2A for phosphatidylserine-containing membranes is lower than that of annexin V, for which a dissociation constant of $<0.1 \times 10^{-9}$ M was measured for its binding to phospholipid vesicles (20% PS/80% PC) at an ionic strength of 0.15 M (*19*).

Biotinylation of C2A−GST. The biotinylation sites in C2A−GST were investigated by cleaving the fusion protein at the thrombin cleavage site and analyzing the resulting two fragments and the intact fusion protein

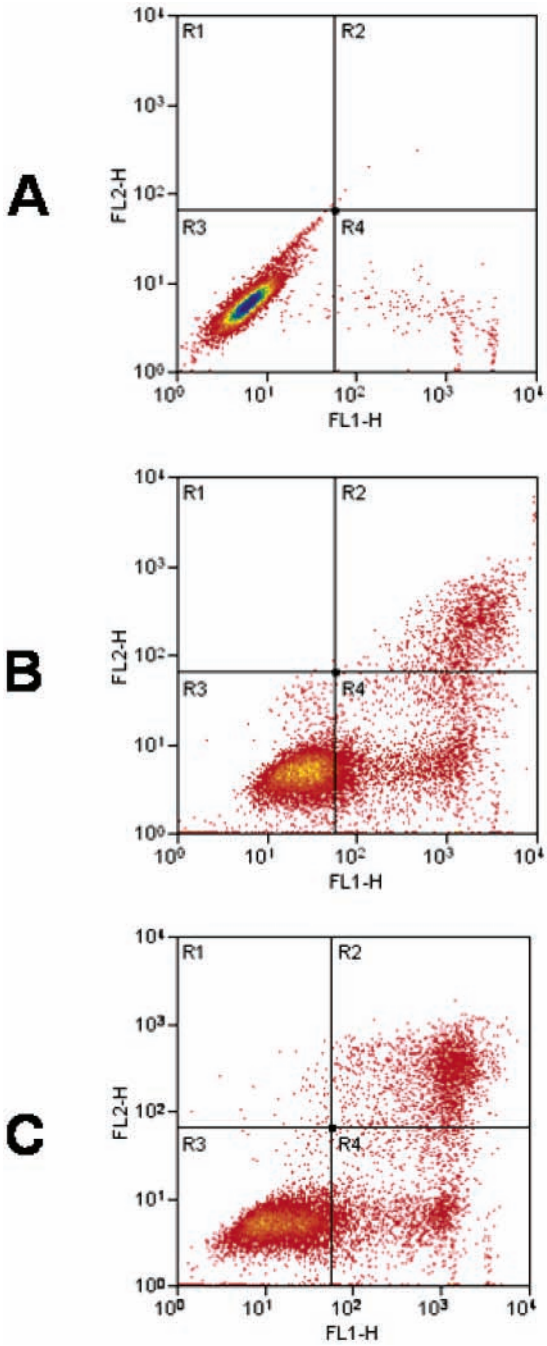

Figure 3. The capability of biotinylated C2A−GST to bind to apoptotic cells was assessed by flow cytometry: (A) apoptotic EL4 cells (1×10^6 cells/mL); (B) apoptotic EL4 cells (1×10^6 cells/mL) incubated with biotin−C2A−GST + streptavidin−FITC + PI; (C) apoptotic EL4 cells (1×10^6 cells/mL) + annexin V-FITC + PI.

using SDS−PAGE and MALDI-TOF mass spectrometry. As shown in Figure 2, the gel bands for biotinylated C2A−GST, C2A, and GST were retarded when compared with the unmodified proteins. MALDI-TOF mass spectrometry showed that GST contained between five and six biotin moieties and the C2A domain contained between zero and three. There are 14 lysine residues in C2A and 21 in GST. A liposome binding assay indicated that the modified protein was pulled down by the liposomes, demonstrating that it retained a strong binding affinity for PS (data not shown).

Flow Cytometry. The capability of biotinylated C2A−GST to detect apoptotic cells was assessed by using flow

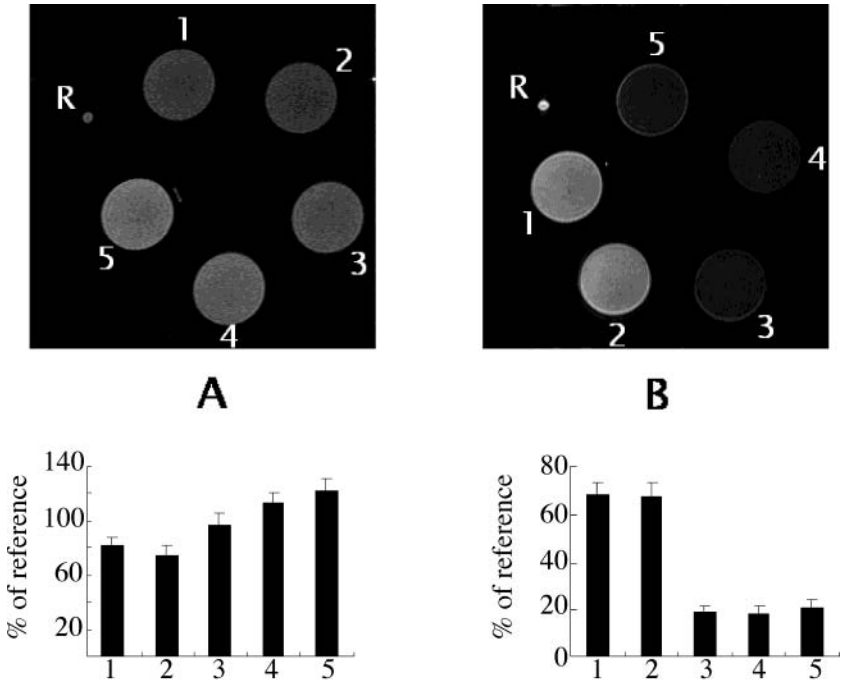

Figure 4. MR imaging of apoptotic cells in vitro. Apoptotic EL4 cells were incubated with biotin−C2A−GST at the specified concentration, washed, and then subsequently incubated with avidin−GdDTPA (80 μM protein) or streptavidin−SPIO (30 ng of Fe/mL), washed again, and then suspended in 4% gelatin in PBS and loaded into 5 mm diameter NMR tubes for T_1-weighted (A) or T_2-weighted (B) ^{1}H MR images. The tubes contained the following: (1) apoptotic cells; (2) apoptotic cells + avidin−GdDTPA (A) or streptavidin−SPIO (B); (3−5) apoptotic cells + biotin−C2A−GST + avidin−GdDTPA (A) or streptavidin−SPIO (B). The concentrations of biotinylated C2A−GST increased from tube 3 to tube 5 (tube 3, 1.5 μM; tube 4, 4.5 μM; tube 5, 15 μM). The signal intensities (mean pixel intensities ± SD) of the tubes relative to the reference (R) are shown at the bottom of each image.

cytometry in conjunction with fluoroscein-labeled streptavidin (streptavidin−FITC). Murine lymphoma cells (EL4) were induced to undergo apoptosis by treatment with etoposide and then stained with a combination of biotinylated C2A−GST, streptavidin−FITC, and propidium iodide (PI). PI stains the nuclei of necrotic cells. The same apoptotic cell preparation was also stained with FITC-labeled annexin V and PI for comparison (Figure 3). The annexin V-FITC was used according to the manufacturer's instructions. The biotinylated C2A−GST preparation allowed a distinction to be made between live cells (69%, quadrant labeled R3 in Figure 3B), apoptotic cells (21%, quadrant labeled R4 in Figure 3B), and necrotic cells (10%, quadrant labeled R2 in Figure. 3B). Despite the lower affinity of C2A for PS, similar results were obtained using annexin V, which detected 64% live cells, 16% apoptotic cells, and 20% necrotic cells (Figure 3C).

The single C2A domain was also biotinylated using the same conjugation procedure described above. The modified protein contained between two and six biotins, as determined by mass spectrometry. However, this protein showed no activity in the streptavidin−FITC flow cytometric assay most likely because the streptavidin−FITC interfered with binding of the biotinylated C2A to the cell membrane.

Magnetic Resonance Imaging. Figure 4 shows T_1-(A) and T_2-weighted (B) images obtained from apoptotic EL4 cells that had been incubated with biotinylated C2A−GST, washed, and then incubated with either avidin−GdDTPA or streptavidin-SPIO, before being washed again and then immobilized in gelatin. Apoptotic cells incubated with progressively increasing concentrations of C2A−GST and then either avidin−GdDTPA or streptavidin−SPIO showed progressively increasing or decreasing image intensities, respectively.

DISCUSSION

We had already shown that the C2A−GST fusion protein, when directly conjugated to SPIO nanoparticles, could be used to detect apoptotic tumor cells in vitro and in vivo using T_2-weighted magnetic resonance imaging experiments (*13*). Annexin V conjugated to a superparamagnetic complex has also been used for apoptosis detection by MRI (*22*). However, the SPIO label, although very sensitive to MRI detection, has two major limitations. The label is relatively large (we used particles 20−30 nm in diameter), which restricts extravasation of the agent from the vasculature into the tumor interstitium, and it gives rise to signal loss, or negative contrast in the MR image. Since there are many factors that can give rise to negative contrast in tumors, which show highly heterogeneous and temporally variable image contrast, this can make the label difficult to detect. Artemov et al. (*15*) have shown recently that they could detect the Her2-neu receptor in breast cancer cells with MRI by using a biotinylated antibody directed against the receptor in conjunction with either streptavidin−SPIO or avidin−GdDTPA conjugates in T_2-weighted or T_1-weighted imaging experiments respectively (*15*, *23*). This approach has the virtue that the imaging reagent is assembled in situ on the surface of the cell from smaller components, thus potentially overcoming the problems associated with the limited vascular permeability of larger agents, and in the case of the Gd conjugate, the agent gives rise to positive contrast in T_1-weighted images. Furthermore, it allows for the production of generic labeling agents based on avidin/streptavidin, which can be used in conjunction with specific, biotinylated, targeting agents. The experiments presented here (Figure 4) have demonstrated the feasibility of imaging apoptosis in vivo with a biotinylated targeting agent, C2A−GST, and a generic labeling agent based on either avidin or streptavidin conjugated to SPIO

or Gd−DTPA. Whereas SPIO gave relatively large decreases in image intensity in T_2-weighted images, the intensity increases produced by avidin−GdDTPA in the T_1-weighted images were more modest (Figure 4). For this reason it would be desirable to increase the amount and/or relaxivity of the Gd conjugates attached to the avidin/streptavidin. This may be achieved, for example, by attaching polyamidoamine dendrimers, conjugated to GdDTPA (*24*), to avidin/streptavidin. However, a drawback of the avidin/streptavidin system is the immunogenecity of these proteins (*25*), which may limit their application in the clinic. In this case, it may be preferable to conjugate high-relaxivity Gd-based agents directly to C2A−GST.

The formation of new blood vessels (angiogenesis) is a feature common to all solid tumors. The integrin receptor $\alpha_V\beta_3$, which is found on endothelial cells lining newly growing blood vessels at a higher density than on mature blood vessels, is being explored as a marker for tumor angiogenesis. Bitistatin, a member of the disintegrin family of polypeptides, has affinity for $\alpha_V\beta_3$ integrins. To determine whether radiolabeled bitistatin could target tumors, its biodistribution was tested in tumor-bearing mice. For initial validation studies, ^{125}I-bitistatin was injected into BALB/c mice bearing EMT-6 mouse mammary carcinoma tumors, a model that is highly vascular but which lacks $\alpha_V\beta_3$ directly on tumor cells. Tumor uptake reached maximal values (11.7 ± 4.6 %ID/g) at 2 h. Co-injection of 200 μg of unlabeled bitistatin reduced tumor uptake 62%, suggesting that the binding of ^{125}I-bitistatin is receptor-mediated. This work was extended to include the β^+-emitting radionuclide ^{64}Cu, which was attached to bitistatin via 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA). This modification did not significantly alter receptor binding in vitro. MicroPET images obtained with ^{64}Cu-DOTA-bitistatin showed that the tumor could easily be identified 4 h after administering the radiopharmaceutical. The biodistribution of ^{64}Cu-DOTA-bitistatin differed from the ^{125}I analogue, in that maximum tumor uptake was nearly 8-fold lower and took at least 6 h to reach maximal binding (1.6 ± 0.2 %ID/g). As with ^{125}I-labeled bitistatin, the ^{64}Cu conjugate showed a 50% reduction in tumor uptake with the co-injection of 200 μg of unlabeled bitistatin (0.8 ± 0.2 %ID/g). Competition studies with integrin-specific peptides indicated that the tumor uptake was related to both $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ integrin binding. To see if tumor uptake could be improved upon, ^{64}Cu was tethered to bitistatin using bromoacetamidobenzyl-1,4,7,-10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAD). Tumor uptake for ^{64}Cu-BAD-2IT-bitistatin was higher than the DOTA conjugate at all time points, reaching a maximum at least 6 h postinjection (5.2 ± 0.6 %ID/g); however, this was accompanied by higher uptake in nontarget organs at all time points. Radiolabeled ligands of this type may be useful in the targeting of tumor angiogenesis, but the choice of radiolabeling approach has a significant impact on the in vivo properties of the radioligand.

INTRODUCTION

Detecting cancer early enough to improve patient prognosis remains a difficult problem. Typically, solid tumors must be larger than 10 mm to be reliably detected by anatomic imaging techniques such as computed tomography (CT). In a similar fashion, traditional nuclear medicine techniques are limited to detection of larger tumors, so many lesions are missed. Thus, there is a need to develop new techniques for the early detection of tumors, so that treatment can be started earlier and improve patient prognoses. One of the ways this can be achieved is by targeting the evolving vasculature that nourishes a growing tumor.

As has been documented, the expansion of a tumor beyond a few cubic millimeters is dependent on the formation of new blood vessels (angiogenesis) to provide nutrients and oxygen needed by the growing tumor (*1*). The vasculature of the tumor differs from that found in the rest of the body in that it is relatively immature and contains large numbers of receptors involved in vessel growth (*2*). The unique character of tumor vasculature therefore would be a good target for pharmaceuticals in both the detection and treatment of a wide variety of cancerous tumors, as all solid tumors are dependent on angiogenesis. It is possible that targeting of tumor vasculature could allow monitoring of smaller tumors than can be detected with the present nuclear medicine radiotracers.

One marker of tumor angiogenesis that may be a suitable target is $\alpha_V\beta_3$, also known as the vitronectin receptor (*3*). It is a member of the integrin family of receptors which are involved in adhesion and signaling of many types of cells (*4*−*6*), and binds ligands containing an Arg-Gly-Asp (RGD) motif. Molecules containing this RGD motif are of interest as antagonists of angiogenesis. One such family of molecules is the disintegrins, which were first reported as $\alpha_{IIb}\beta_3$ antagonists isolated from the venoms of various snakes (*7*). These low molecular mass (5−9 kDa), cysteine-rich polypeptides are constrained by internal disulfide linkages into multiloop structures and

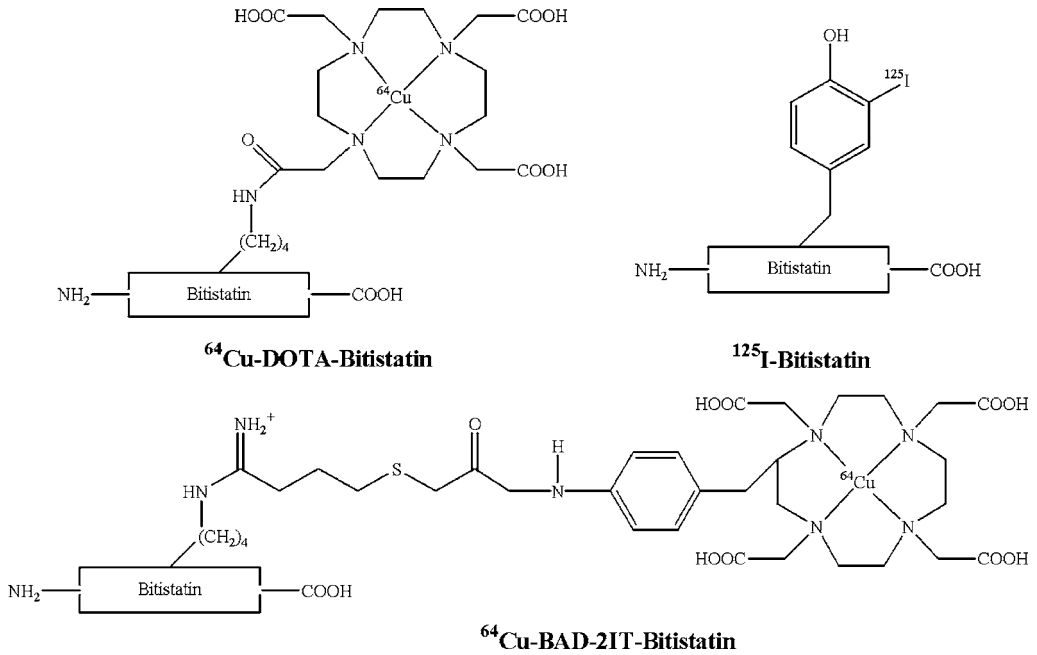

Figure 1. Structures of ^{64}Cu-DOTA-, ^{125}I-, and ^{64}Cu-BAD-2IT-labeled bitistatin.

are the most potent known inhibitors of integrin function. A common feature of the disintegrins is that they contain an RGD or analogous sequence at the apex of one of these loops.

The disintegrin bitistatin was selected for initial evaluation as a marker for tumor angiogenesis. When labeled with ^{123}I or ^{99m}Tc, bitistatin has been shown to be a promising agent for in vivo imaging of experimental pulmonary emboli (PE) and deep venous thrombi (DVT) (*8*−*11*). In a canine model, labeled bitistatin images were characterized by high uptake in thrombi and emboli and low background in muscle and most other tissues except for kidneys and spleen. Bitistatin has been shown to bind to both $\alpha_V\beta_3$ and $\alpha_{IIb}\beta_3$ integrins (*12*). We hypothesize that binding to both integrins may be advantageous, as bitistatin's reversible binding to $\alpha_{IIb}\beta_3$ on blood platelets may increase the blood residence time and therefore the bioavailability for delivery of radioligand to $\alpha_V\beta_3$ on endothelial cells. This approach differs significantly from previous studies that have focused on small cyclic RGD-containing peptides which were designed to have the highest possible affinity for $\alpha_V\beta_3$, while minimizing platelet binding with the lowest possible affinity for $\alpha_{IIb}\beta_3$ (*13*−*16*).

Molecular modeling studies have shown that the five lysine residues of bitistatin are located on the opposite side of the molecule from the putative binding domain (*10*). This suggests that bitistatin could be conjugated to bifunctional chelators (BFC) for labeling with radiometals without affecting the binding domain, and this has been successfully accomplished with Hynic modification for ^{99m}Tc labeling. The positron-emitting isotope ^{64}Cu ($t_{1/2}$ = 12.7 h, β^+ = 0.655 MeV (19.3%), β^- = 0.573 MeV (39.6%)) is an attractive radionuclide and has found use both as a diagnostic agent by utilizing the high sensitivity of PET imaging, and also as a radiotherapy agent (*17*). Large quantities of high-specific activity ^{64}Cu can be produced on demand using a biomedical cyclotron (*18*). In this study, bitistatin was first labeled with ^{125}I by direct radioiodination methods and then with ^{64}Cu to test whether it could be used for PET imaging of tumors.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals unless otherwise stated were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Water was distilled and then deionized (18 MΩ/cm^2) by passing through a milli-Q water filtration system (Millipore Corp., Milford, MA). Reversed-phase HPLC separation was achieved using a Dynamax C_{18}, 12 μm, 300 Å, 4.6 × 250 mm column (Rainin Instruments, Woburn, MA), eluted with a linear gradient of 0−60% acetonitrile in 0.1% trifluoroacetic acid over 30 min at a flow rate of 1.0 mL/min. FPLC analysis was performed using a Sephadex G-25 column equilibrated and eluted with 0.1 M NaCl/HEPES buffer pH 7.4 at a flow rate of 1 mL/min. ^{64}Cu was produced on a CS-15 biomedical cyclotron at Washington University School of Medicine, using published methods (*18*). Radioactivity was counted with a Beckman Gamma 8000 counter containing a NaI crystal (Beckman Instruments, Inc., Irvine, CA). Bitistatin was purified from the crude venom of Bitis arietans (Miami Serpentarium Laboratories, Punta Gorda, FL) by ion-exchange chromatography followed by RP-HPLC yielding a single peak (*8*, *19*). Mass spectrometry and partial amino acid sequence analysis were used to confirm the identity of bitistatin.

^{125}I-Bitistatin (Figure 1). Bitistatin (30 μg; 3.3 nmol) in 0.2 M Tris buffer, pH 7.8 was combined with 750 μCi ^{125}I (Perkin-Elmer Life Sciences, N. Billerica, MA) containing 1 nmol of NaI. The mixture was transferred to a tube containing 20 μg of IodoGen (Pierce Chemical Co, Rockford, IL). After 25 min at room temperature, the reaction was removed from the vial, diluted with saline, and allowed to stand for 5 min without addition of reductant. Unreacted ^{125}I was removed by gel filtration on a Econo-Pak 10DG column (Bio-Rad Laboratories, Hercules, CA) (*8*). The product had radiochemical purity of greater than 99% as determined by reversed phase HPLC.

^{64}Cu-DOTA-Bitistatin (Figure 1). The activation of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) and subsequent conjugation to bitistatin was carried out as described previously (*20*). Briefly, activa-

tion of DOTA with EDC (1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide) and sulfo-NHS (*N*-hydroxy-sulfo-succinimide) was carried out at 4 °C for 30 min. A 10-fold excess of DOTA and sulfo-NHS over EDC was used to ensure only one carboxylic acid moiety per DOTA was activated. The pH was then adjusted to 8.5 and enough bitistatin was added to generate a bitistatin:NHS-DOTA ratio of 1:100. The reaction vessel was then kept at 4 °C for 15 h, with continuous end-over-end mixing. The conjugated peptide was then purified using a Centricon-3 centrifugal filter (MW cutoff 3000; Millipore, Billerica, MA). The average number of DOTA units attached to bitistatin was found to be 1.76, as determined by TLC (*21*).

The conjugated bitistatin was labeled with ^{64}Cu as follows: bitistatin-DOTA (25−40 μg) was combined with $^{64}CuCl_2$ (6−8 mCi) in 0.03 M ammonium citrate buffer (pH 6.5), to give a total volume of 150 μL. The reaction mixture was heated at 55 °C for 40 min, after which diethylenetriaminepentaacetic acid (DTPA) was added to challenge nonbound radiometals. The radiolabeled peptide was purified with a Bio-Spin 6 column (Bio-Rad, Hercules, CA) centrifuged at 2500 rpm for 6 min. Using this method, specific activities of 250 μCi/g were typically obtained, with radiopurity of around 96% as determined by FPLC.

^{64}Cu-BAD-2IT-Bitistatin (Figure 1). The activation of bromoacetamidobenzyl-1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAD) (Macrocyclics, Dallas, TX) and subsequent conjugation to bitistatin was carried out as described previously (*22*). To a solution of bitistatin (0.1 M ammonium phosphate, pH 8.0) was added in this order: excess BAD in aqueous solution and freshly prepared 2-iminothiolane (2IT) in 50 mM triethanolamine hydrochloride, pH 8.7. The overall bitistatin/BAD/2IT ratio was 1:100:20, and the pH of the resulting solution was adjusted to 8.0. The reaction was then incubated at 37 °C for 40 min. The conjugated peptide was purified using a Centricon-3 centrifugal filter (MW cutoff 3000). The average number of BAD units attached to bitistatin was found to be 0.55, as determined by TLC (*21*).

The conjugated bitistatin was labeled with ^{64}Cu in a similar manner as the DOTA analogue. Briefly, BAD-2IT-bitistatin (120 μg) was combined with $^{64}CuCl_2$ (10−12 mCi) in 0.1 M ammonium citrate buffer (pH 6.5), to give a total volume of 150 μL. The reaction mixture was heated at 55 °C for 40 min, after which DTPA was added to challenge nonbound radiometals. The radiolabeled peptide was purified via gel filtration with a PD-10 column. Specific activities of 50 μCi/μg were obtained, with a radiopurity of 90% as determined by FPLC.

Stability of Radiolabel. To measure the in vivo stability of ^{64}Cu-DOTA-bitistatin in mice, plasma samples obtained at 1 h were purified by size exclusion chromatography and the fractions obtained were counted on a gamma counter. In an analogous in vitro experiment, ^{64}Cu-DOTA-bitistatin was incubated with human serum albumin (HSA) at 37 °C for 20 h, after which the solution was then separated by size exclusion chromatography to determine the amount of ^{64}Cu that remained bound to DOTA-bitistatin.

Inhibition of Platelet Aggregation In Vitro. Blood was obtained from aspirin-free human donors and anticoagulated with 0.1 vol of 3.8% sodium citrate. The blood was centrifuged at 160*g* for 12 min to obtain platelet-rich plasma (PRP). The concentration of platelets in human PRP was determined using a hemacytometer, and then diluted with the donor's own plasma to obtain a platelet concentration of 300 000/μL. For each measurement, 400 μL of adjusted PRP was placed in a cuvette and stirred at 37 °C. Vehicle (saline) or various concentrations of peptide was added in a volume of 10 μL and stirred at 37 °C for 1 min while recording light transmission. ADP was then added (final concentration 10 μM) to induce platelet aggregation. Platelet aggregation was determined by change in light transmission through the PRP, which was recorded for 5 min after ADP addition. The IC_{50} was determined (by least-squares fitting) as the concentration of peptide required to produce 50% inhibition of the response to ADP in the presence of the vehicle. Results were normalized to the results for the tetrapeptide Arg-Gly-Asp-Ser (RGDS).

Biodistribution Studies. All animal experiments were conducted in compliance with the Guidelines for the Care and Use of Research Animals established by Washington University's Animal Studies Committee. Biodistribution studies were carried out on female BALB/c mice (20−25 g) that had been implanted with 1×10^6 EMT-6 cells subcutaneously into the nape of the neck. This cell line was chosen as the resulting tumor is fast growing, and presumably contains vasculature that is rich in $\alpha_V\beta_3$ integrins, while the cells themselves are devoid of RGD binding receptors (*23*). EMT-6 murine mammary carcinoma cells were obtained from the Yale Cancer Center. Tumors were allowed to grow for 10 days after implantation of cells, after which time the animals received either 1 μCi of ^{125}I-bitistatin (1.1 pmol), 7 μCi ^{64}Cu-DOTA-bitistatin (3.1 pmol), or 5 μCi ^{64}Cu-BAD-2IT-bitistatin (11 pmol), in 125 μL of saline via lateral tail vein injection. In an analogous experiment to monitor the effect excess bitistatin would have on tumor uptake, 200 μg (22 nmol) of unlabeled bitistatin was injected into mice implanted with EMT-6 cells immediately prior to administering ^{125}I- or ^{64}Cu-DOTA-labeled bitistatin. This represents a 20 000- and 7100-fold increase over the mass of peptide injected with ^{125}I- and ^{64}Cu-DOTA-bitistatin respectively as compared to the nonblocked biodistribution studies. Animals were then euthanized at desired time points (30 min, 2 and 4 h for ^{125}I-bitistatin, 2, 4, and 6 h for ^{64}Cu-DOTA-bitistatin, 30 min, 2 h, 4 h, and 6 h for ^{64}Cu-BAD-2IT-bitistatin). Tissues and organs of interest were then removed and weighed and radioactivity was measured in a gamma counter. The percent dose per gram (%ID/g) was then calculated.

Because bitistatin can bind to both $\alpha_V\beta_3$ and $\alpha_{IIb}\beta_3$ integrins, a separate study was carried out to determine the effect blocking each integrin individually would have on tumor uptake. BALB/c mice bearing EMT-6 tumors were injected with 7 μCi of ^{64}Cu-DOTA-bitistatin (3.1 pmol) in 125 μL of saline via lateral tail vein injection. Immediately prior to injection of the radiopharmaceutical 40 μg (70 nmol) of the $\alpha_V\beta_3$-specific peptide cyclo[RGDfV] (*24*) (Bachem Bioscience Inc, King of Prussia, PA), or 55 μg (66 nmol) of the $\alpha_{IIb}\beta_3$-specific peptide eptifibatide (*25*) (GL Biochem (Shanghai) Ltd, Shanghai, China), was injected. After 2 h the animals were euthanized and their organs were counted.

Cell Binding Studies. The extent of platelet binding in vivo was assessed by collecting blood samples by cardiac puncture in mice pretreated with ^{64}Cu-DOTA-bitistatin and immediately layering over 100 μL of 30% sucrose in a microfuge tube. After centrifugation at 13000*g* for 5 min, the plasma was carefully removed by pipet to a clean tube for counting. The tip of the microfuge tube containing the cell pellet was snipped off into a second tube for counting. The percentage of total counts in the cell pellet was calculated.

To determine the extent of cell binding directly to EMT-6 cells, ^{64}Cu-DOTA-, ^{64}Cu-BAD-2IT-, and ^{125}I-bitistatin were incubated with EMT-6 cells in vitro. EMT-6 cells were suspended to a concentration of 5×10^6 cells/mL in PBS. Cell number was determined with a hemocytometer, and viability was determined by trypan blue exclusion. For the assay, the cell suspension was supplemented with $CaCl_2$ and $MnCl_2$ (final concentration 0.5 mM each), then radiolabeled bitistatin was added to a final concentration of 2 nM. Nonspecific binding was determined in the presence of 2.5 mM Na_4EDTA to chelate divalent cations which are needed for integrin function (*6*, *9*). After 1 h at 37 °C, 100 μL aliquots of the cell suspension were layered over 100 μL of a 30% sucrose solution in a microfuge tube. The cells were then pelleted from the media by centrifuging at 13000*g* for 3 min. The supernatant was transferred into a clean tube for counting and the tip containing the cell pellet was snipped from the microfuge tube and placed in a second tube for counting. Both supernatant and pellet were counted, and the percentage of the radioactivity associated with the cells was calculated. This was done in triplicate for each incubation condition.

MicroPET Imaging. Whole body microPET images were obtained on a microPET-R4 system (Concorde Microsystems, Knoxville, TN) (*26*). Imaging studies were carried out on BALB/c mice that had received an implant of EMT-6 cells (1×10^6 cells) in the nape of the neck ($n = 14$), with each mouse receiving 250 μCi of ^{64}Cu-DOTA-bitistatin (0.1 nmol). At each time point (4, 6, and 15 h) half of the animals were given 200 μg (22 nmol; 200-fold mass increase over ^{64}Cu-DOTA-bitistatin injected) of unlabeled bitistatin prior to the radiopharmaceutical to monitor the effect it would have on tumor uptake and clearance. The mice were imaged in pairs (blocked vs unblocked) side by side, and standardized uptake values (SUV) for the tumor, kidneys, and liver were obtained at all time points. The SUVs were determined by drawing regions of interest (ROI) around the target tissue to generate the radioactive concentration, which was decay corrected to the time of injection, multiplied by the mouse body weight (grams), and divided by the injected dose (nCi) to give the normalized tissue uptake to injected dose per body weight (*27*).

Statistical Methods. To compare differences between the ^{64}Cu- and ^{125}I-labeled bitistatin, a Student's *t*-test was performed. Differences at the 95% confidence level ($p < 0.05$) were considered significant.

RESULTS

Stability of ^{64}Cu-DOTA-Bitistatin. When ^{64}Cu-DOTA-bitistatin was incubated with HSA at 37 °C for 20 h, 90% of the radiopharmaceutical remained in its original form (no breakdown or plasma protein binding) (Figure 2). Size exclusion chromatography of plasma samples obtained from mice at 1 h did not contain enough radioactivity for accurate assessment by the in-line detector. However, subsequent counting of the fractions on a gamma counter showed that in both blocked and unblocked mice >95% of ^{64}Cu in mouse plasma samples was in the form of ^{64}Cu-DOTA-bitistatin. From these results, we can infer that ^{64}Cu-DOTA-bitistatin has a high in vivo stability in plasma.

Platelet Binding Studies. To determine whether conjugation of DOTA to bitistatin affected its ability to bind to $\alpha_{IIb}\beta_3$ integrin, DOTA-bitistatin and unmodified bitistatin were compared for their ability to inhibit human platelet aggregation via binding to $\alpha_{IIb}\beta_3$. The IC_{50}

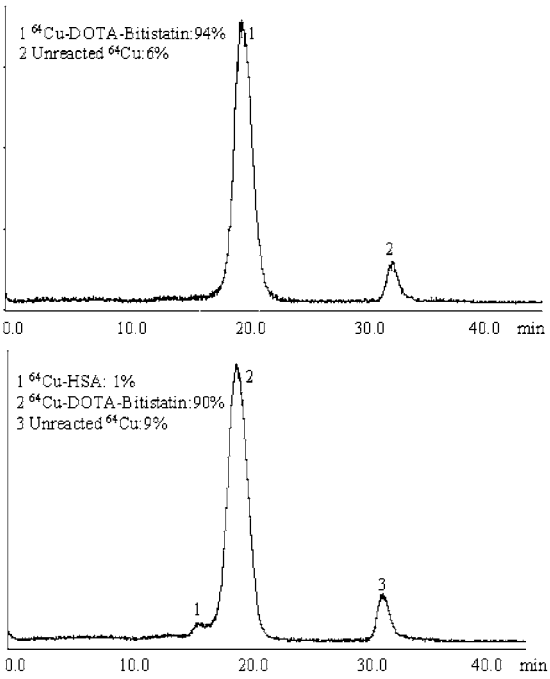

Figure 2. Radioactive profile of ^{64}Cu-DOTA-bitistatin before (top) and after (bottom) incubation in HSA for 20 h. The Sephadex G-25 column was eluted with 0.1 M NaCl/HEPES buffer, pH 7.4, at 1 mL/min.

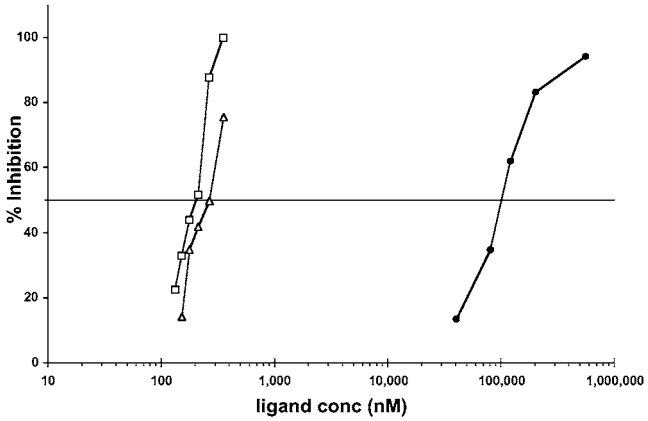

Figure 3. Inhibition of ADP-induced human platelet aggregation by unmodified bitistatin (open squares), DOTA-bitistatin (gray filled triangles), and Arg-Gly-Asp-Ser tetrapeptide (filled circles).

for inhibition of human platelet aggregation was 163 ± 27 nM for DOTA-bitistatin, compared with 140 ± 11 nM for the same lot of bitistatin before modification (Figure 3). There was no significant difference between these groups ($p = 0.46$).

Binding of ^{64}Cu-DOTA-bitistatin to platelets in vivo was found to be about 60% of the total blood activity in blood samples drawn at 1 h after injection. This is similar to the percentage of platelet binding of ^{125}I-bitistatin (64%) found in mice at 1 h. In mice which also received 200 μg of unlabeled bitistatin, the level of platelet-bound ^{125}I-bitistatin was reduced to 21%.

EMT-6 Binding Studies. Binding of ^{125}I-, ^{64}Cu-DOTA-, and ^{64}Cu-BAD-2IT-bitistatin to EMT-6 cells in vitro is shown in Figure 4. Binding of ^{125}I-bitistatin (6.4 ± 0.7%) was not significantly higher than nonspecific binding (4.3 ± 1.7%; $p = 0.22$). Similar results were found for both ^{64}Cu-DOTA-bitistatin (control 9.8 ± 0.8%, nonspe-

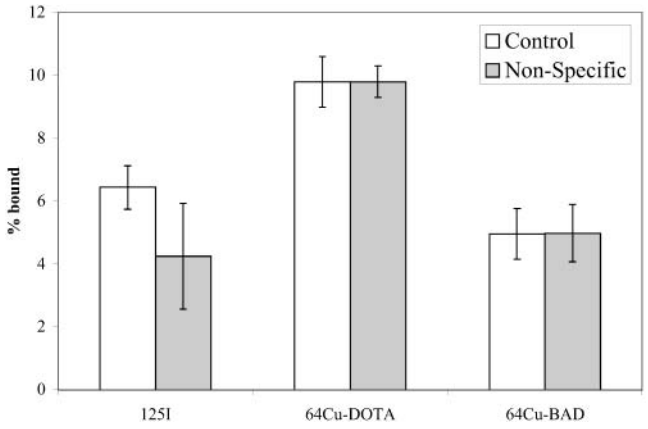

Figure 4. Binding of ^{64}Cu-DOTA-, ^{125}I-, and ^{64}Cu-BAD-2IT-labeled bitistatin to EMT-6 cells after incubation at 37 °C for 1 h. Nonspecific binding was determined in the presence of EDTA. Each point is based on triplicate samples, with error bars representing standard deviations.

Table 1. Biodistribution Data for ^{125}I-Bitistatin in BALB/c Mice Implanted with EMT-6 Tumors[a]

	30 min	2 h	2 h blk	4 h

cific 9.8 ± 0.5%; p = 0.94) and ^{64}Cu−BAD-2IT-bitistatin (control 5.0 ± 0.9%, nonspecific 5.0 ± 0.8%; p = 0.99).

Biodistribution Studies. For ^{125}I-bitistatin, tumor uptake reached a maximum at 2 h postinjection (11.7 ± 4.6 %ID/g) and then decreased (5.4 ± 2.0 %ID/g) after 4 h (Table 1). Co-injection of 200 μg of unlabeled bitistatin reduced tumor uptake at 2 h to 4.4 ± 2.8 %ID/g (p = 0.01), indicating receptor-mediated uptake. At 30 min, kidney uptake was high (57.6 ± 31.1 %ID/g) but cleared rapidly and after 4 h was 4.4 ± 0.7 %ID/g. As with other biomolecules directly radiolabeled with iodine, accumulation in the thyroid was observed.

In the studies undertaken with ^{64}Cu-DOTA-bitistatin, the biodistribution differed from that of the ^{125}I analogue in that the maximum tumor uptake was lower (1.6 ± 0.2 %ID/g, p < 0.001) and was achieved 6 h postinjection (Table 2). As with ^{125}I-bitistatin, the co-injection of 200 μg of unlabeled bitistatin reduced tumor uptake 2-fold

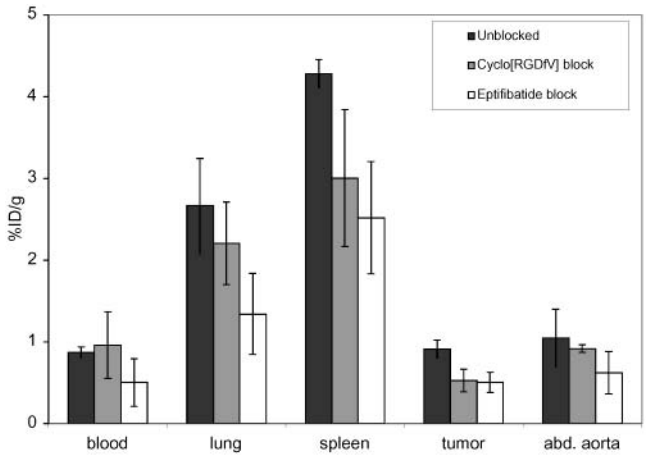

Figure 5. Comparative uptake of ^{64}Cu-DOTA-bitistatin in select organs, obtained from BALB/c mice implanted with EMT-6 tumors at 2 h. Control animals received only ^{64}Cu-DOTA-bitistatin, while blocked animals received either 40 μg of cyclo[RGDfV] or 55 μg of eptifibatide immediately prior to administering tracer. Data presented as %ID/g ± SD (n = 4).

(0.78 ± 0.18 %ID/g) at 6 h (p = 0.007). The clearance properties of ^{64}Cu-DOTA-bitistatin also differed significantly from those observed for the ^{125}I analogue. Initially kidney uptake was high (41.3 ± 4.7 %ID/g), and continued to increase up to 4 h (61.3 ± 6.2 %ID/g) before reaching a plateau.

Binding to integrins $\alpha_V\beta_3$ and $\alpha_{IIb}\beta_3$ was selectively blocked with the integrin specific peptides cyclo[RGDfV] and eptifibatide. A comparison of tissue uptake in selected organs is shown in Figure 5. Blocking of $\alpha_V\beta_3$ integrin with cyclo[RGDfV] had no effect on blood level (0.7 ± 0.2 %ID/g) or uptake in blood rich organs such as the lung (2.2 ± 0.5 %ID/g) or abdominal aorta (0.9 ± 0.1 %ID/g) at 2 h compared to controls. Tumor uptake however was significantly reduced (p = 0.009) to 0.5 ± 0.1 %ID/g, an approximate 2-fold reduction compared to control values. When the $\alpha_{IIb}\beta_3$ selective peptide eptifibatide was administered, significant reductions (p < 0.01) were seen in blood (0.6 ± 0.1 %ID/g), lung (1.3 ± 0.5 %ID/g), aorta (0.5 ± 0.2 %ID/g), and spleen (2.5 ± 0.7 %ID/g) levels at 2 h compared to the control mice. This was accompanied by a similar 2-fold reduction in tumor uptake (0.5 ± 0.1 %ID/g; p = 0.003), similar to the effect seen with cyclo[RGDfV]. Unexpectedly, kidney levels in the mice receiving eptifibatide (21.5 ± 6.2 %ID/g) was significantly lower (p = 0.01) than in mice that had not received competing peptide (36.7 ± 5.6 %ID/g) or in the mice that had received cyclo[RGDfV] (35.9 ± 9.9 %ID/g).

Because tumor localization of ^{64}Cu-DOTA-bitistatin was lower than expected, a different ^{64}Cu conjugate was tested to see if tumor targeting could be improved. Tumor uptake for ^{64}Cu-BAD-2IT-bitistatin was higher than the DOTA conjugate at all time points examined (p < 0.001), reaching a maximum 6 h postinjection (5.2 ± 0.6 %ID/g) (Table 3). At 6 h kidney and liver uptake had reached 221 ± 63 and 19.1 ± 4.1 %ID/g, respectively. Uptake in these nontarget organs was higher than those seen with the DOTA conjugate and substantially higher than those obtained for ^{125}I-bitistatin (p < 0.001).

MicroPET Imaging. Transaxial slices showing the localization of ^{64}Cu-DOTA-bitistatin in EMT-6 tumors as determined by microPET imaging are shown in Figure 6. Four hours after administering ^{64}Cu-DOTA-bitistatin no statistical difference (p = 0.98) in tumor SUV data was observed between the control (0.15 ± 0.03) and blocked mice (0.15 ± 0.03). It was not until 6 h postin-

Table 3. Biodistribution Data for ^{64}Cu-BAD-2IT-Bitistatin in BALB/c Mice Implanted with EMT-6 Tumors

jection that tumor uptake in the control and blocked animals were statistically different: SUV = 0.17 ± 0.02 and 0.09 ± 0.01, respectively (p < 0.02). After 15 h, tumor SUV in the control animals was 0.19 ± 0.01, while in the blocked animals tumor SUV was significantly lower (0.12 ± 0.01, p < 0.001). These data agree with qualitative examination of Figure 6, where blocking is observed at 6 and 15 h. Significant uptake of ^{64}Cu-DOTA-bitistatin in the liver and kidneys was observed at all time points.

DISCUSSION

Previous studies for the detection of angiogenesis have focused on small cyclic RGD-containing peptides which bind selectively to $\alpha_V\beta_3$ integrins, with the goal of minimizing platelet binding via $\alpha_{IIb}\beta_3$ (*13*−*16*). This approach usually results in fast blood clearance and is usually accompanied by low tumor uptake, possibly because of inadequate contact time with the target receptors. In this study, we have taken the opposite approach by utilizing a ligand that has affinity for $\alpha_v\beta_3$ integrins, allowing binding to receptors involved in angiogenesis and to $\alpha_{IIb}\beta_3$ integrins, prolonging the bioavailability of the radioligand.

A source of naturally occurring high-affinity ligands for integrins is found in the family of molecules known as disintegrins. These cysteine-rich peptides were first isolated from viper venoms and to date close to 50 have been isolated (*28*). Of these peptides, bitistatin was chosen as the targeting molecule for these studies, as previous work has shown that it binds to both $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$, and has been successfully used for in vivo imaging when directly radiolabeled with ^{123}I (*8*, *9*), or when labeled with ^{99m}Tc via hydrazinonicotinate (Hynic) linker (*10*, *11*). In studies in a canine model, labeled bitistatin exhibited high uptake in thrombotic lesions and very low uptake in most background tissues. Another characteristic of bitistatin is that it is displaced slowly from the activated $\alpha_{IIb}\beta_3$ receptor (*9*), and it was hoped that this slow off-rate would be observed on the $\alpha_v\beta_3$ integrin as well. It should be noted that other disintegrins have been reported to have higher affinity and selectivity for $\alpha_v\beta_3$ than bitistatin, and thus may be better for tumor angiogenesis targeting. Studies with these peptides are ongoing.

Both in vitro and in vivo studies were performed using EMT-6 murine mammary carcinoma cells. This cell line was chosen as the cells themselves are devoid of RGD binding receptors (*23*, *29*), while immunohistochemical staining of untreated EMT-6 tumors have shown a high concentration of vascular endothelial growth factor (VEGF) (*30*). This is important as it has been shown that VEGF directly activates $\alpha_v\beta_3$ leading to an increased concentration of this integrin on endothelial cells (*31*). It would be desirable to perform immunohistochemical staining of EMT-6 tumors to confirm the presence of $\alpha_v\beta_3$; however, at present the available antibodies for $\alpha_v\beta_3$ do not crossreact with murine tissue.

When the three labeled conjugates of bitistatin were incubated with EMT-6 cells, there was no significant binding of any of the conjugates above nonspecific levels, confirming that there is no integrin receptor binding of these conjugates to EMT-6 cells. Slight differences in the level of nonspecific binding were observed, however. The higher binding of the ^{64}Cu-DOTA-bitistatin conjugate may be explained by hydrogen bonding of the negatively charged carboxylate arms present on DOTA to positively charged moieties on the cell surface. It is possible that this was not seen for the BAD conjugate because the number of conjugates attached was 3-fold lower, 1.76 vs 0.55, respectively. In other investigations, the ability of bitistatin to bind to cells expressing $\alpha_v\beta_3$ has been demonstrated by the finding that ^{99m}Tc- or ^{125}I-bitistatin binds in vitro to cultured human endothelial cells and to two $\alpha_v\beta_3$ receptor positive tumor cell lines, and that this binding is completely abolished by competition with cyclo-[RGDfV] (*32*).

In most previously published studies, the ability of radiolabeled RGD-containing peptides to image tumor angiogenesis was obscured by the fact that the tumors were grown from cell lines that express $\alpha_v\beta_3$ directly on the tumor cells. In these cases, it was impossible to determine whether targeting was to the tumor vasculature or directly to the tumor cells themselves. In this study, we have provided evidence for targeting of tumor vasculature without targeting the tumor cells directly. This is likely to be a more challenging task, because the density of the target receptors may be much lower due to the lower number of tumor-associated endothelial cells compared to the number of tumor cells in the tumor mass.

The tumor uptakes achieved in this study (11.7 %ID/g at 2 h for ^{125}I-bitistatin and 5.18 %ID/g at 6 h for ^{64}Cu-BAD-2IT-bitistatin) compare favorably with uptakes of small RGD-containing peptides which have been evaluated in models employing $\alpha_v\beta_3$-positive tumor cell lines such as murine osteosarcoma, M21 melanoma, and OVCAR-3 ovarian carcinoma (*33*). It is notable that studies with an ^{18}F-labeled glycosylated cyclo[RGDfK], one of the most promising synthetic peptide radioligands, showed good uptake in $\alpha_v\beta_3$-positive M21 tumors in mice, but imaging showed no focal tracer accumulation in control tumors using $\alpha_v\beta_3$-negative M21-L cells (*34*). Although the tumor/background ratios obtained with bitistatin conjugates are not as high as have been reported with other tracers binding to tumor cell membranes and definitely could be improved upon, it is encouraging that adequate targeting to vasculature was achieved to enable focal imaging at 4−15 h.

Biodistribution studies carried out with ^{125}I-bitistatin in mice implanted with EMT-6 cells showed that maximum tumor uptake was observed 2 h postinjection, with elevated uptake in blood-rich organs such as the lung, spleen, and heart. This appeared to be related to receptor binding, as the co-injection of 200 μg of unlabeled bitistatin substantially reduced uptake in these organs. This work was then extended to positron emitting nuclides so that the sensitivity and high resolution of PET could be used to visually identify tumors. For these studies, ^{64}Cu was chosen due to its availability, energy of positron emission, and the stability of the final product. However, unlike iodine it must be attached via a bifunctional chelator (BFC) which is covalently bound to lysine side chains (*35*−*38*). 1,4,7,10-Tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) was chosen as the

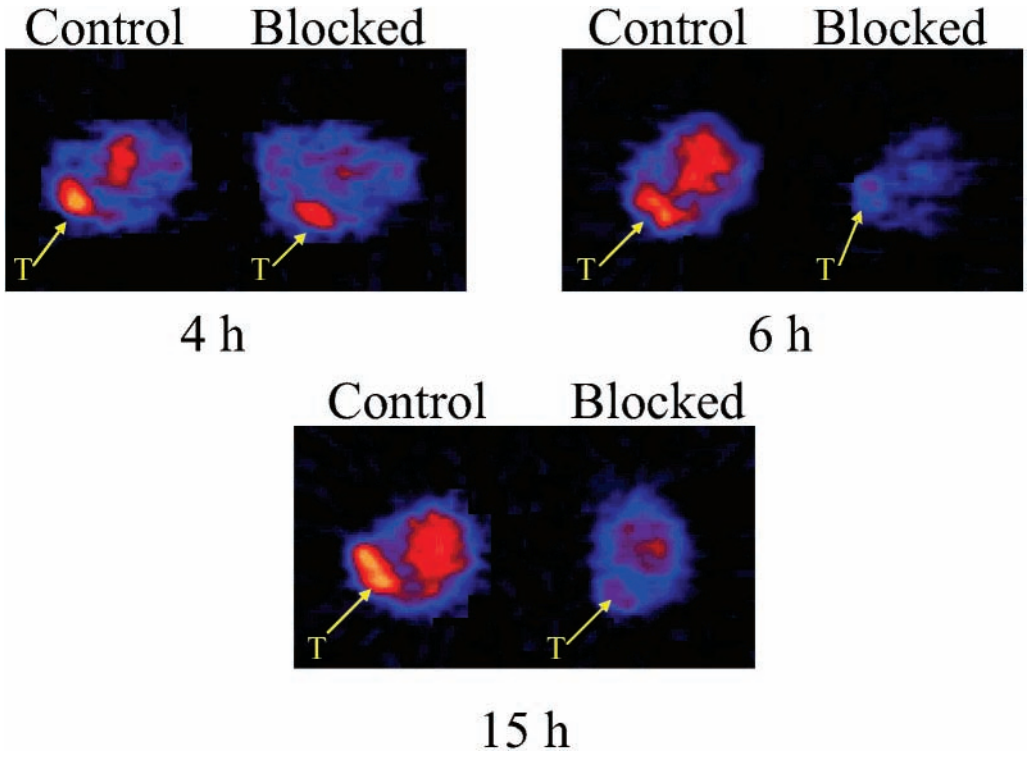

Figure 6. Transaxial images of BALB/c containing EMT-6 murine mammary carcinoma tumors 4, 6, and 15 h after tail vein injection of 250 μCi of ^{64}Cu-DOTA-bitistatin. Blocked mice were co-injected with 200 μg of bitistatin (T = tumor).

metal chelating agent due to its commercial availability and its flexibility to bind a variety of metal ions including Ga^{3+}, In^{3+}, and Y^{3+}. MicroPET images obtained with ^{64}Cu-DOTA-bitistatin showed that EMT-6 tumors could be identified after 4 h. As with ^{125}I-bitistatin, the co-injection of 200 μg of bitistatin reduced uptake in the tumor and blood-rich organs, indicating receptor mediated uptake. However, tumor uptake of ^{64}Cu-DOTA-bitistatin was 87% lower than the ^{125}I analogue and did not reach a maximum until at least 6 h postinjection. In addition, the percentage of ^{64}Cu-DOTA-bitistatin found in blood-rich organs was lower than observed for the ^{125}I analogue. This was surprising as the ^{64}Cu-DOTA conjugate appeared to be stable both in vitro and in vivo, with no significant change in potency for inhibition of human platelet aggregation by DOTA-bitistatin as compared unmodified bitistatin. Furthermore, although total blood levels for ^{125}I-bitistatin and ^{64}Cu-DOTA-bitistatin were different at 1 h postinjection, for both tracers a similar percentage of blood activity was bound to platelets in vivo at this time.

A possible explanation of this is that during conjugation of DOTA to bitistatin, some of the conjugation locations resulted in unfavorable alterations in bitistatin's receptor binding. These alterations may be more pronounced after labeling, which was not tested in the platelet assay in vitro. Conjugates that have impaired binding to platelets may leave the blood faster by renal clearance. At 1 h, if these forms have been substantially cleared, total blood activity would be lower, but the percent of total blood activity which is platelet-bound could be the same as for the ^{125}I-labeled bitistatin. Studies with site-directed mutagenesis to alter the locations of attachment of bifunctional chelating agents to bitistatin have shown that conjugation of Lys35 with Hynic followed by ^{99m}Tc labeling results in a slight loss of binding to $\alpha_{IIb}\beta_3$ (*39*). Unfortunately, we were unable to test for differences among the conjugates for binding to $\alpha_v\beta_3$ in vitro in this study because the EMT-6 cells do not express the receptor. Future studies with $\alpha_v\beta_3$ positive cells or purified integrin will need to be done.

These observations suggest that modification of lysine residues thought to be far from the binding domain could have an effect on bitistatin's pharmacokinetics. To investigate this further, the BFC bromoacetamidobenzyl-1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAD) was examined. This chelator was chosen because the copper binding domain of BAD is identical to DOTA, but the linker unit between the macrocycle and the lysine residue is longer, and any steric interactions that may occur are minimized. As with the DOTA conjugate, maximum tumor uptake did not occur until 6 h postinjection; however, tumor levels were 3−4-fold higher at all time points. This demonstrates that modifying the same lysine residues along the polypeptide backbone with differing conjugates can have a profound effect on the pharmokinetics, which alter not only receptor-mediated uptake but also uptake in clearance organs, as can be seen with elevated uptake in nontarget tissue compared to the DOTA analogue. Despite the increased tumor uptake compared to ^{64}Cu-DOTA-bitistatin, the overall tumor-to-tissue ratios obtained with ^{64}Cu-BAD-2IT-bitistatin were similar to those obtained with the ^{64}Cu-DOTA analogue (Table 4).

Kidney uptake and retention of both ^{64}Cu-DOTA- and ^{64}Cu−BAD-2IT-bitistatin was substantial. Initially, like ^{125}I-bitistatin, kidney uptake was high, but unlike the ^{125}I analogue they were retained and levels increased over time. The ^{125}I direct label was not as stable in vivo as evidenced by the thyroid uptake. It is possible that reaching maximal uptake in tumor at 2 h reflects the instability of the iodine label in blood preventing higher uptake beyond that time. More work is needed to select the optimal labeling method for best tumor targeting and background clearance.

Table 4. Comparison of Selected Tumor-to-Tissue Ratios (%ID/g) of ^{64}Cu-DOTA and ^{64}Cu-BAD-2IT-Labeled Bitistatin in BALB/c Mice Bearing EMT-6 Tumors

	^{6}4Cu-DOTA			^{64}Cu-2IT-BAD		
	2 h	4 h	6 h	2 h	4 h	6 h
tumor/blood	2.2 ± 0.5	2.1 ± 0.7	2.9 ± 0.2	3.4 ± 0.4	3.2 ± 0.7	3.5 ± 0.4
tumor/liver	0.4 ± 0.1	0.3 ± 0.02	0.3 ± 0.1	0.3 ± 0.03	0.3 ± 0.03	0.3 ± 0.02
tumor/kidney	0.03 ± 0.006	0.02 ±0.003	0.03 ± 0.008	0.02 ± 0.002	0.03 ± 0.01	0.03 ± 0.007
tumor/muscle	3.2 ± 1.5	4.3 ± 0.8	4.7 ± 0.8	4.0 ± 0.7	4.0 ± 0.3	4.9 ± 0. 9

These studies demonstrated that tumor uptake of ^{125}I- and ^{64}Cu-DOTA-bitistatin was dependent on binding both to $\alpha_v\beta_3$ integrins on endothelial cells and $\alpha_{IIb}\beta_3$ integrins found in circulating blood platelets. Selectively blocking $\alpha_v\beta_3$ with cyclo[RGDfV] or $\alpha_{IIb}\beta_3$ with eptifibatide, an antithrombotic drug, each reduced tumor uptake of ^{64}Cu-DOTA-bitistatin. Blocking with eptifibatide also led to reductions in radiotracer levels in blood and blood-rich organs such as spleen and lung. Blocking with cyclo-[RGDfV] led to reductions only in tumor and spleen, an organ that has previously been reported to take up $\alpha_V\beta_3$-targeted peptides (*13*). These data indicate that while tumor uptake is indeed mediated by $\alpha_V\beta_3$ receptor binding, the increased blood retention caused by binding to $\alpha_{IIb}\beta_3$ has an equivalently large effect, suggesting that the observed tumor uptake of labeled bitistatin is dependent on both $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ integrins.

Unexpectedly kidney uptake in the mice receiving eptifibatide was significantly lower ($p = 0.01$) than controls or in the mice that had received cyclo[RGDfV]. One possible explanation is that eptifibatide or some metabolite inhibits the tubular reabsorption of ^{64}Cu-DOTA-bitistatin, similar to the effect seen when an infusion of amino acids is given (*40*).

In summary, bitistatin, when directly labeled with ^{125}I or with ^{64}Cu via the BFCs DOTA and BAD was shown to accumulate in tumors in which the tumor cells themselves do not express $\alpha_V\beta_3$ integrin. Uptake was determined to be receptor-mediated by a combination of $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$ integrins. ^{125}I-bitistatin achieved a higher tumor uptake than bitistatin labeled with ^{64}Cu using a BFC. The biodistribution data suggest a different time−activity profile for uptake and washout of ^{125}I-bitistatin from the tumor as compared to its ^{64}Cu analogue. This along with the differing tumor and renal uptake for DOTA and BAD conjugated bitistatin suggest that modification of the side chains can have a dramatic affect on the distribution, stability, and clearance properties of radiolabeled bitistatin. Even though tumor uptake of ^{64}Cu-DOTA-bitistatin was significantly lower than that seen with ^{125}I-bitistatin, microPET imaging showed the tumor could be identified as quickly as 4 h. Therefore, radiolabeled ligands of this type may be useful in the targeting of tumor angiogenesis, but as demonstrated here the choice of radiolabeling approach has a significant impact on the in vivo properties of the radioligand.

ACKNOWLEDGMENT

The authors thank Jan E. Romano for purification of bitistatin and for performing platelet aggregation assays. Preparation of cells for implantation and uptake studies was done by Susan Adams. MicroPET imaging and evaluation was performed by John A Engelbach and Jerrel R. Rutlin, with biodistribution studies done with the assistance of Terry Sharp, Lynne Jones, and Nicole Fettig. This work was supported by NIH R24 CA86307 (M.J.W.), NIH R01 CA96792 (L.C.K.), and NIH R01 HL54578 (L.C.K.). We would also like to thank the Small Animal Imaging Core of the Alvin J. Siteman Cancer Center at Washington University and Barnes-Jewish Hospital in St. Louis, Missouri for additional support of the microPET imaging and the Statistics Core for statistical analysis. The Core is supported by an NCI Cancer Center Support Grant #1 P30 CA91842. The production of copper radionuclides is supported by a grant from the National Cancer Institute (CA86307).

The tumor targeting properties of a new drug carrier synthesized by bioconjugation of folic acid (FA) to β-cyclodextrins through a poly(ethylene glycol) (PEG) spacer (CD−PEG−FA) were investigated. Surface plasmon resonance demonstrated that CD−PEG−FA specifically interacts with immobilized folate binding protein (FBP) while the naked β-cyclodextrins do not display any specific interaction. In vitro studies demonstrated that CD−PEG−FA was devoid of cell toxicity. [^{3}H]-folic acid/CD−PEG−FA competition binding investigations performed with folate receptor overexpressing human epidermal carcinoma KB cells showed that CD−PEG−FA had about 14 times lower tumor cell binding capacity than free folic acid. The carrier cell trafficking properties were investigated using rhodamine-B as fluorescent probe, which possesses 3000 and 4580 M^{-1} inclusion constants for CD−PEG−FA and β-cyclodextrins, respectively. Cell-associated fluorescence measurements showed that CD−PEG−FA does not promote the rhodamine-B uptake into non-folate receptor expressing human lung carcinoma MCF7 cells while 19% higher accumulation in KB cells was found with respect to rhodamine-B loaded β-cyclodextrins. Confocal laser scanning microscopy indicated the presence of cytosolic red fluorescent spots after 2 h of incubation of KB cells with rhodamine-B included CD−PEG−FA. The fluorescent dye resided primarily in small spots, namely, endosomes and multivesicular bodies. At 1 h after pulsed incubation, wider red fluorescent cellular structures appeared as a fusion of previous structures.

INTRODUCTION

Cyclodextrins are cyclic oligosaccharides forming molecular inclusion complexes with a wide range of hydrophobic molecules. The ability to allocate active molecules into the oligosaccharide hydrophobic core offers several opportunities in drug solubility, stability, and bioavailability optimization (*1*−*3*). However, aside from γ-cyclodextrins, which have been used in parenteral drug administration, systemic application of natural cyclodextrins, namely α- and β-cyclodextrins, entails the risk of toxic effects such as hemolysis and nephrotoxicity (*4*−*5*). Aimed at reducing the toxicity and enhancing the biopharmaceutical properties of cyclodextrins, semisynthetic derivatives were prepared by introduction of hydroxyalkyl or sulfoalkyl functions or by conjugation to water-soluble polymers (*3*, *6*).

Although cyclodextrins possess interesting properties for delivery of therapeutics with high pharmacological activity, low therapeutic index, and poor physicochemical properties, they cannot be used for active drug targeting because they are devoid of any specificity for biological structures. To exploit cyclodextrins as targetable drug delivery systems, the oligosaccharide structure should be properly functionalized with targeting moieties such as peptides, hormones, vitamins, antibody fragments, etc.

Folic acid is a vitamin that binds selectively the folate receptor (FR), a glycosylphosphatidylinositol-anchored cell surface receptor that is overexpressed in many human tumors, including ovarian, endometrial, colorectal, breast, lung, renal, neuroendocrine carcinomas, and brain metastases (*7*). Upon receptor interaction, the folic acid−FR complex is taken up by cells and moves through many organelles involved in endocytic trafficking, providing for cytosolic disposition (*8*).

The folate receptor mediated endocytosis was largely investigated to expand the therapeutic value of drugs by increasing delivery to the target tissue as well as the target/nontarget tissue ratio. Examples of targetable drug delivery carriers functionalized by folic acid conjugation include radionuclide deferoxamine−folate complexes for radiopharmaceutical imaging, liposome−folate encapsulated drugs, liposome−folate encapsulated polylysine−DNA, cytotoxin−folate conjugates and folic acid decorated nanoparticles (*9*−*13*).

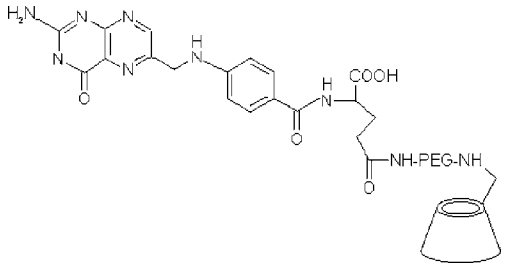
Recently, we synthesized a new targetable drug delivery system by folic acid conjugation to β-cyclodextrins through a 700 Da poly(ethylene glycol) (PEG) spacer arm. Preliminary studies demonstrated that the derivative possesses suitable properties for drug delivery: high solubility, ability to form inclusion complexes with few drug models, and negligible hemolytic activity (*14*).

In the present study the biological and biopharmaceutical properties of the new β-cyclodextrin−PEG−folic acid bioconjugate were investigated. The affinity of the bioconjugate for the immobilized folate binding protein (FBP) and for the cell membrane folate receptor was determined by Biacore and cultured tumor folate receptor overexpressing KB cells, respectively. The ability of the conjugate to be taken up by folate receptor overexpressing and nonexpressing cells was also investigated, and its intracellular localization was determined.

MATERIALS AND METHODS



β-Cyclodextrins, folic acid (FA), and *O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol) (Jeffamine or PEG) were purchased from Fluka Chemika (Buchs, Switzerland). Tissue culture products were obtained from GIBCO (Grand Island, NY).

Rhodamine-B and methylene blue were from Aldrich (Steinheim, Germany), and [^{3}H]-folic acid was from Amersham (Little Chalfont, U.K.). Folate binding protein (FBP) was furnished by Sigma (St. Louis, MO), FluorSave reagent was obtained from Calbiochem (San Diego, CA), fluorescein−DHPE was from Molecular Probes (Eugene, OR), and the Bio-Rad protein assay was from Bio-Rad Laboratories (Richmond, CA). Surface plasmon measurements were carried out with Biacore 3000 (Biacore AB, Uppsala, Sweden). CM 5 sensorchips and coupling reagents were furnished by Biacore.

Human nasopharyngeal epidermal carcinoma KB cells were cultured as a monolayer at 37 °C in a humidified atmosphere containing 5% CO_2 in folate-deficient Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% (v/v) heat-inactivated fetal calf serum, 2 mM glutamine, 100 IU/mL penicillin, and 100 μg/mL streptomycin. Lung human carcinoma MCF7 cells were cultured in normal RPMI-1640 medium, supplemented with 15% fetal calf serum, 2 mM glutamine, 100 IU/mL penicillin, and 100 μg/mL streptomycin. The folic acid concentration in the normal RPMI media was 2.26 μM. Cells were routinely treated with a 500 μg/mL trypsin and 200 μg/mL EDTA solution in Ca^{2+} and Mg^{2+} free phosphate buffered saline (PBS).

Synthesis of 6-Mono{folic acid-γ-[*O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]}-β-cyclodextrin. 6-Mono{folic acid-γ-[*O*,*O*′-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]}-β-cyclodextrin (CD−PEG−FA) was prepared according to a two-step procedure reported elsewhere (14). Briefly, 6-mono[*O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]-β-cyclodextrin (CD−PEG−NH_2) was prepared by reaction of 6-mono-(*p*-toluenesulfonyl)-β-cyclodextrin (0.995 g, 0.772 mmol) with *O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol) (53.34 mmol) in DMF (*15*). The mixture was refluxed for 8−9 h at 80 °C under argon. The 6-mono[*O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]-β-cyclodextrin conjugate was precipitated in 250 mL of acetone, washed several times with the same solvent, collected by centrifugation, and desiccated under vacuum. The final product was characterized by thin layer chromatography, NMR, and ESI-TOF mass spectrometry, and the iodine test and *p*-anisaldehyde were for PEG and cyclodextrin determination, respectively (*16*, *17*).

Chart 1. Main Isomer Formed by Bioconjugation Reaction of CD−PEG−NH_2 to Folic Acid (λ Carboxyl Folic Acid isomer): 6-Mono{folic acid-γ-[*O*,*O*′-bis-(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]}-β-cyclodextrin (CD−PEG−FA).

6-Mono{folic acid-γ-[*O*,*O*′-bis(2-aminopropyl)polypropylene glycol-*block*-poly(ethylene glycol)-*block*-polypropylene glycol]}-β-cyclodextrin was obtained by reaction of 6-mono-[*O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]-β-cyclodextrin (0.791 g, 0.438 mol) with the *N*-hydroxy-
succinimide ester of folic acid (2.884 g, 5.356 mmol) in 50 mL of anhydrous DMSO (*10*). TEA (320 μL, 0.2295 mmol) was added to the reaction mixture, and pH 9.0 was maintained by addition of the same base. The reaction mixture was stirred under dark and anhydrous conditions for 40 h. The solution was poured dropwise into 500 mL of cold acetone, and the precipitate was washed with 50 mL of the same solvent and dried under vacuum. The dry product was dissolved in 100 mL of 0.1 M borate buffer, pH 8.3, and fractionated by gel permeation chromatography using Sephadex G25 superfine column, eluting with 10 mM ammonium carbonate buffer, pH 8.0. The eluted volume was analyzed by UV at 363 nm, iodine test, and *p*-anisaldehyde. The bioconjugate was isolated and further purified by preparative RP-C18 column (2.5 cm × 22 cm), eluting in a gradient mode, using 10 mM ammonium acetate pH 6.5 (eluent A) and acetonitrile (eluent B). The peak corresponding to the conjugate was collected, concentrated, and analyzed by RP-C18 chromatography, UV−vis for folate determination (*18*), iodine test, mass spectrometry, and ^{1}H NMR.

The reaction procedure reported above yields two isomers where folic acid is conjugated at the α or λ carboxyl group of glutamate residue, respectively. According to the literature data (*19*), the conjugation takes place preferentially at the level of the λ carboxyl group. Chart 1 reports the chemical structure of the more abundant isomer (folic acid λ carboxyl derivative): 6-mono-{folic acid-γ-[*O*,*O*′-bis(2-aminopropyl)poly(propylene glycol)-*block*-poly(ethylene glycol)-*block*-poly(propylene glycol)]}-β-cyclodextrin (CD−PEG−FA).

Host−Guest Inclusion Constant Determination. Five sample series were prepared by addition of β-cyclodextrins (sample A), PEG (sample B), folic acid (sample C), β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture (sample D), and CD−PEG−FA conjugate (sample E) to 5 mL volumes of 10 mM phosphate buffer, 0.15 M NaCl, pH 7.2, containing 5 μM rhodamine-B. The solutions were prepared in order to obtain β-cyclodextrins/

rhodamine-B, PEG/rhodamine-B, folic acid/rhodamine-B, [β-cyclodextrins/PEG/folic acid]/rhodamine-B, or CD−PEG−FA/rhodamine-B molar ratios in the range of 0−200. The fluorescence of the samples was determined using a Perkin-Elmer LS 50 B spectrofluorimeter in a conventional 96-well plate. The instrument was set up using 2.5 nm excitation and emission slits, 543 nm excitation, and 580 nm emission wavelengths. Inclusion constants were calculated from fluorescence emission values according to the procedure reported in the literature (*20*, *21*).

Surface Plasmon Resonance Measurements. Surface plasmon resonance measurements were carried out using Biacore 3000. Cow milk folate-binding protein (FBP) was immobilized on the sensor chip surface of a carboxylated dextran-coated gold film (CM 5 sensor chip) activated according to the general procedure for immobilization by amine coupling recommended by the supplier (*22*, *23*). The flow channel of Biacore was equilibrated with HBS buffer (10 mM Hepes, 150 mM NaCl, 0.05% surfactant P20, pH 7.4), and then the following samples were successively injected into the system: (a) 0.1 M *N*-hydroxysuccinimide/0.4 M *N*′-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide solution (1/1, v/v) to obtain an activated carboxylated dextran; (b) 1 mg/mL of FBP in 100 mM potassium phosphate buffer, 4 mM mercaptoethanol, 10% v/v glycerol, pH 7.0; (c) 1 M ethanolamine, pH 8.5, to deactivate residual *N*-hydroxysuccinimidyl esters on the sensor chip. FBP immobilization was carried out using a flow rate of 5 μL/min. The receptor bound to the chip surface was 1.5 ng/mm^2 per channel. Four-hundred nanomolar samples of β-cyclodextrins or β-cyclodextrin-equivalent samples of β-cyclodextrins/PEG 1:1 molar ratio mixture or CD−PEG−FA solutions in HBS were injected in the Biacore flow channel at a flow rate of 30 μL/min and allowed to interact with the immobilized receptor for 3 min.

CD−PEG−FA in the presence of 10 μM free folic acid was also injected under the operative conditions reported above.

HBS solutions containing CD−PEG−FA in the range 50−400 nM were injected into the system and allowed to interact for 3 min to study the kinetic parameters of interaction.

Cytotoxic Assays. KB cells were seeded in 96-well tissue culture plates at a density of 5 × 10^4 cells/well. After 24 h, the culture medium was replaced with 200 μL of medium containing increasing concentrations (0−4 mM) of β-cyclodextrins, PEG, folic acid, β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture, or CD−PEG−FA. After 6 h of incubation, the medium was removed and the cells were washed three times with 200 μL of PBS, pH 7.4. An amount of 100 μL of a 0.25% (w/v) methylene blue in 50% (v/v) methanol/water solution was added to each well. After 30 min of incubation at room temperature, the plates were washed four times with PBS. The plates were dried at 55 °C for 30 min, and stained cells were immediately dissolved by addition of 200 μL/well of 0.1 M HCl. The absorbance was measured at 620 nm after overnight gentle stirring.

Cell Binding Studies. KB cells were seeded in 33 mm well culture plates at a concentration of 5 × 10^5 cells/well. After 24 h, the wells were washed twice with PBS, pH 7.4, and then the plates were incubated at 37 °C for 30 min with 1 mL of folic acid free DMEM medium containing 0.1 μM [^{3}H]-folic acid and CD−PEG−FA or β-cyclodextrins/PEG 1:1 molar ratio mixtures at concentrations ranging from 0 to 100 μM. After incubation, the plates were washed four times with PBS and the cells were lysed by overnight incubation with 1 mL/well aqueous solution containing 0.1% Triton-X100. The amount of radioactivity in the lysate was determined by addition of scintillation cocktail, and the radioactivity values were referenced to a standard radioactivity curve. All measures were carried out in triplicate. Plates preincubated with medium and serum without cells were used for residual plate radioactivity determination according to the procedure reported in the literature (*19*).

Cell Uptake Studies. KB or MCF7 cells were seeded in 33 mm culture wells (6 × 10^5 and 7 × 10^5 cells/well, respectively). After 24 h, the wells were washed with PBS, pH 7.4, and incubated with 1 mL of folic acid free DMEM containing free rhodamine-B (1 μM) or the same rhodamine-B concentration in the presence of β-cyclodextrins or β-cyclodextrins/PEG 1:1 molar ratio mixture or β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture or CD−PEG−FA (100 μM). After 2 h of incubation at 37 °C, the wells were washed four times with PBS and then subjected to addition of 300 μL of Ca^{2+} and Mg^{2+} free phosphate buffer containing 500 μg/mL of trypsin, 200 μg/mL of EDTA. The released cells were washed twice with PBS and lysed by overnight treatment with 0.667 mL of 0.1% Triton-X 100 water solution. The cell-associated rhodamine-B was determined by fluorescence analysis as reported above. The number of cells in the wells was estimated by a Bio-Rad protein assay, and the relative fluorescence obtained with the samples was normalized on the basis of the cell number.

Confocal Studies. KB and MCF7 cells (5 × 10^4 and 8 × 10^4 cells in 1 mL, respectively) were seeded into a 24-well culture plate containing one glass coverslip/well (1 mL of suspension per well). After 72 h, the wells were washed with PBS, pH 7.4, and the wells were incubated with 0.5 mL of a folic acid free DMEM medium containing 1 μM of rhodamine-B in free solution or in the presence of 100 μM β-cyclodextrins or 100 μM β-cyclodextrins/PEG 1:1 molar ratio mixture or 100 μM CD−PEG−FA. After 2 h of incubation, coverslips were taken, washed four times with cold PBS, placed in empty wells, and treated with 0.5 mL of 4% paraformaldehyde in PBS for 15 min at 4 °C. After two additional PBS washings, the cells on the coverslips were treated with 50 μL of a 20 μg/mL fluorescein−DHPE [*N*-(fluorescein-5-thiocarbamoyl)-1,2-dihexadecanoyl-*sn*-glycerol-3-phosphoethanolamine, triethylammonium salt] solution in PBS, washed three times with PBS, and mounted on glass slides by FluorSave reagent. Coverslips were maintained at 4 °C in the dark overnight and analyzed by a Zeiss LSM-510 confocal scanning laser microscope equipped with a 25 mW argon ion laser and an ×63 (oil) objective with a numerical aperture of 1.4. Green fluorescence was observed with a 505−550 nm band-pass emission filter under 488 nm laser illumination, and red fluorescence was observed with a 560 nm band-pass emission filter under 543 nm laser illumination.

For cell trafficking studies KB and MCF7 cell samples were treated according to the procedure reported in the previous section. The cells were incubated for 1 h with 0.5 mL of a folic acid free DMEM medium containing 1 μM of rhodamine-B and 100 μM CD−PEG−FA. After 1 h of incubation, the wells and coverslips were washed four times with PBS and incubated with 1 mL of folic acid free DMEM medium. At scheduled times, the coverslips were treated as reported above for cell fixing and analyzed by a Zeiss LSM-510 confocal scanning laser microscope.

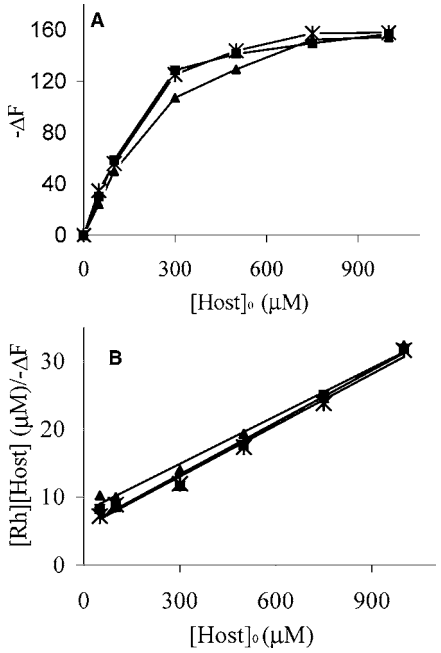


Figure 1. (A) Fluorescence quenching curve-fitting of rhodamine-B with β-cyclodextrins (×), β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture (■), and CD−PEG−folic acid (▲). (B) Modified Benesi−Hildebrand plots of rhodamine-B complexation with β-cyclodextrins (×), β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture (■), and CD−PEG−FA (▲).

RESULTS

Host−Guest Inclusion Constant Determinations. The formation of β-cyclodextrins and CD−PEG−FA inclusion complexes with rhodamine-B was investigated by fluorimetric titration (*24*).

Figure 1A shows the quenching profiles of rhodamine-B in the presence of different concentrations of β-cyclodextrins, β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture, and CD−PEG−FA. Figure 1B reports the quenching value elaboration used to calculate the inclusion constants of rhodamine-B for β-cyclodextrins, β-cyclodextrins in the presence of PEG and folic acid and CD−PEG−FA. The complex stability constants were determined according to the modified Benesi−Hildebrand equation (*20*, *21*) assuming a 1:1 rhodamine-B/cyclodextrin stoichiometry described by the following equation:

$$\mathrm{CDs} + \mathrm{RhB} \rightleftarrows \mathrm{CDs{\cdot}RhB}$$

$$\frac{[\mathrm{RhB}]_0[\mathrm{CDs}]_0}{F - F_0} = \frac{[\mathrm{CDs}]_0[\mathrm{RhB}]}{F_\infty - F_0} + \frac{[\mathrm{RhB}]}{(F_\infty - F_0)K_s}$$

where $[RhB]_0$ and $[CDs]_0$ are the initial guest (rhodamine-B) and host (β-cyclodextrin or CD−PEG−FA) concentrations, respectively, F_0 and F are the fluorescence intensities in the absence and in the presence of host, respectively, F_∞ is the fluorescence intensity limit when all rhodamine-B was included in the β-cyclodextrins, and K_s is the inclusion constants for 1:1 complex.

The complex stability constants of rhodamine-B for β-cyclodextrins, β-cyclodextrins/PEG/folic acid, and CD−PEG−FA were calculated to be 4580, 4500, and 3000 M^{-1}, respectively. Importantly, the calculated inclusion constant of rhodamine-B for β-cyclodextrins corresponds fairly to the value reported in the literature (*20*).

Surface Plasmon Resonance Measurements. The selective interaction of CD−PEG−FA with the cow milk folate binding protein (FBP) was investigated by surface plasmon resonance analysis.

The surface plasmon resonance profiles relative to β-cyclodextrins, β-cyclodextrins/PEG, and CD−PEG−FA reported in Figure 2 display a low signal/noise ratio typical of low molecular weight compounds, which elicit a weak signal. The signal variation (RU) at the injection time was due to irregularities induced by the injection of a solution with different refractive index compared to that of the solvent. To avoid this abnormality, the association curves were analyzed with a delay time of 9.9 s.

Despite the high noise, the surface plasmon resonance profiles reported in Figure 2A show differences among CD−PEG−FA, β-cyclodextrins, and the β-cyclodextrins/PEG mixture. The CD−PEG−FA bioconjugate elicits a signal due to a specific interaction with the FBP immobilized on the sensor chip, whereas the unconjugated β-cyclodextrins, either in the presence or in the absence of PEG, elicit a very weak signal indicating that no binding takes place.

The plasmon resonance signal/noise ratio did not allow for an accurate evaluation of the CD−PEG−FA apparent dissociation constant for FBP. However, the bioconjugate was estimated to have approximately 400 times lower affinity constant for FBP compared to the free folic acid value reported in the literature (*25*).

Specific binding of CD−PEG−FA to immobilized FBP was also demonstrated by injection of the conjugate in the presence of an excess of free folic acid (CD−PEG−FA/folic acid 1:25 molar ratio). The plasmon resonance profiles obtained with CD−PEG−FA in the absence or in the presence of free folic acid reported in Figure 2B indicate that the amount of CD−PEG−FA bound to FBP was sensibly lower in the case of folic acid co-injection, suggesting that the free folic acid competes with CD−PEG−FA for FBP binding.

Cell Toxicity Investigations. Aimed at setting up proper cell culture protocols for evaluating the cell binding and uptake, investigations were undertaken by incubation of PEG, folic acid, β-cyclodextrins, β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture, and CD−PEG−FA with folate receptor overexpressing KB cells or folate receptor nonexpressing MCF7 cells. As expected, samples containing free folic acid displayed enhanced cell proliferation while PEG did not have any effect on cell viability. Also, neither β-cyclodextrins nor CD−PEG−FA was found to affect the cell viability under the experimental conditions.

Competition Binding Studies. [^{3}H]-folic acid/CD−PEG−FA or [^{3}H]-folic acid/[β-cyclodextrins/PEG 1:1 molar mixture] binding competition studies were undertaken using KB cells to evaluate the CD−PEG−FA affinity for the cell folate receptor. The [^{3}H]-folic acid binding competition profiles reported in Figure 3 show that β-cyclodextrins/PEG do not compete with [^{3}H]-folic acid for the cell receptor. The maximal cell-associated radioactivity due to [^{3}H]-folic acid binding to the cell receptors was in fact retained at high [β-cyclodextrins/PEG mixture] concentrations (log [host], μM). In contrast, the cell-associated radioactivity decreased as the CD−PEG−FA concentration increased, indicating that the bioconjugate displaced the [^{3}H]-folic acid from the cell receptor. Since 50% of cell-associated radioactivity was obtained with 1.4 μM CD−PEG−FA and 0.1 μM [^{3}H]-folic acid, CD−PEG−FA was estimated to maintain 7% of the residual affinity for cell folate receptor.

Cell Uptake Investigations. Cell uptake studies were carried out by incubation of free rhodamine-B,

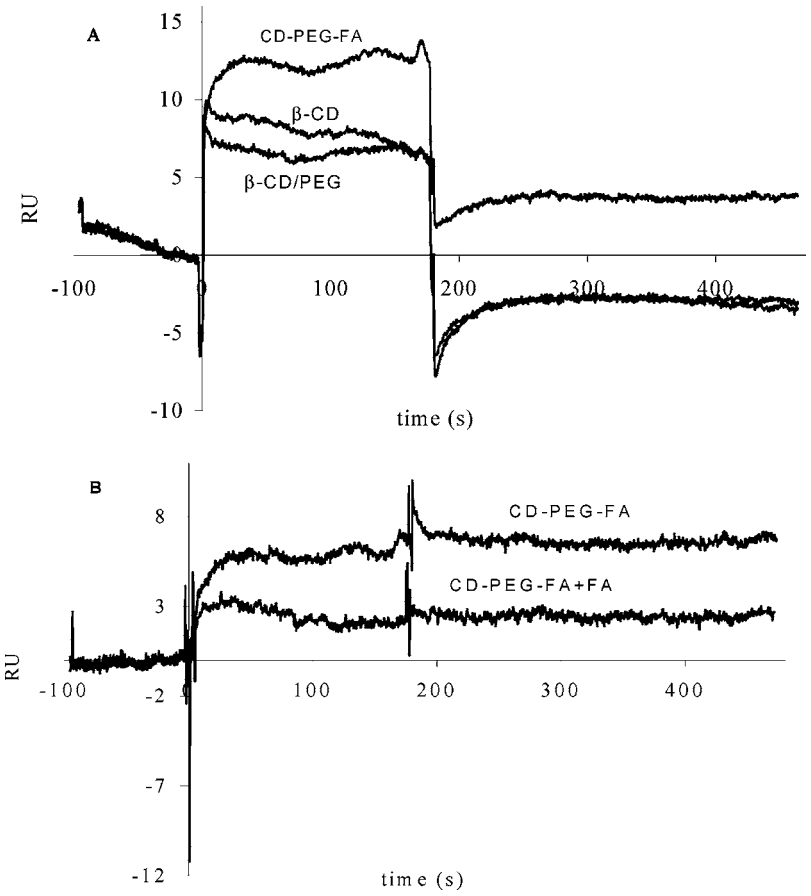

Figure 2. Surface plasmon resonance behavior of interaction with immobilized FBP: (A) binding profiles of CD−PEG−FA, β-cyclodextrins, and β-cyclodextrins/PEG 1:1 molar ratio mixture; (B) binding competition profiles in the absence and in the presence of free folic acid. RU = resonance units.

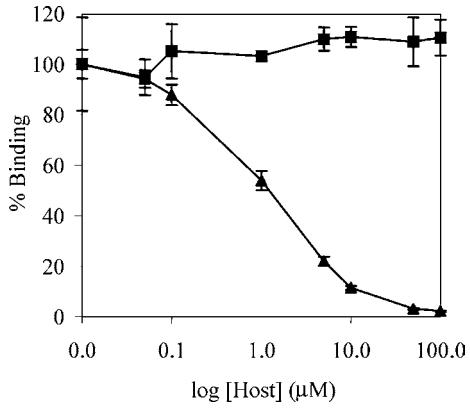

Figure 3. [^{3}H]-folic acid competition binding profiles of cellular folate receptor obtained with monolayer KB cells incubated with cyclodextrin/PEG 1:1 molar ratio (■) and CD−PEG−FA (▲). The mean values and standard deviations were calculated on the basis of five experiments.

rhodamine-B included in CD−PEG−FA, and various mixtures of the individual components (β-cyclodextrin, PEG, folic acid, and rhodamine-B) with folate receptor overexpressing KB cells or folate receptor not expressing MCF7 cells. According to the results reported in Figure 1A, 1:100 rhodamine-B/β-cyclodextrin molar ratio was chosen to guarantee over 90% of rhodamine-B inclusion into β-cyclodextrins or into CD−PEG−FA.

The enzymatic cell detachment procedure avoided fluorescence interferences due to unspecific rhodamine-B absorption on the plastic material. Rhodamine-B concentrations below 2 μM were used to prevent rhodamine-B related cell toxicity. Finally, methylene blue assay used to evaluate the cell viability avoided absorbance interferences observed with the MTT assay (*26*).

Figure 4A shows the KB cell-associated fluorescence values obtained after incubation with free rhodamine-B or rhodamine-B included in β-cyclodextrins/PEG, β-cyclodextrins/PEG/folic acid, and CD−PEG−FA. The data reported in the figure were obtained by subtracting the values obtained with rhodamine-B loaded β-cyclodextrins, which displayed the lower cell-associated fluorescence.

The increase of cell-associated fluorescence obtained with free rhodamine-B indicates that the passive penetration of the probe into the cells is prevented by inclusion into naked β-cyclodextrins. PEG and folic acid were found to enhance the cell uptake of rhodamine-B loaded β-cyclodextrins. The uptake of rhodamine-B loaded CD−PEG−FA was significantly higher ($P < 0.02$) compared to that under other experimental conditions: 19% higher with respect to rhodamine-B loaded β-cyclodextrins, 12% higher compared to free rhodamine-B, more than 10% higher compared to β-cyclodextrins/PEG and β-cyclodextrins/PEG/folic acid mixtures.

The bioconjugate selectivity for the folate receptor overexpressing cells was confirmed by using MCF7 cells, a human lung carcinoma cell line that lacks the folate receptor. The test was carried out under the same conditions reported above for the KB cell studies. Figure 4B shows that low cell-associated fluorescence is observed after incubation with free rhodamine-B and with rhodamine-B complexed with β-cyclodextrins/PEG or with β-cyclodextrins/PEG/folic acid, as well as after incubation with rhodamine-B loaded CD−PEG−FA. These results

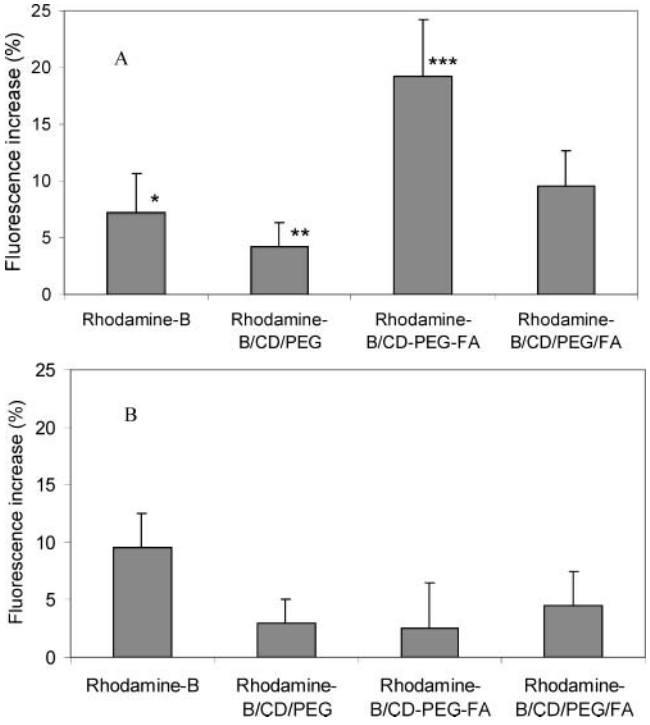

Figure 4. Rhodamine-B uptake by KB cells (A) and MCF7 cells (B). Fluorescence increase after cell incubation with free rhodamine-B and rhodamine-B complexed with β-cyclodextrins/PEG 1:1 molar ratio mixture, CD−PEG−FA, and β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture. The fluorescence increase is referenced to the values obtained with β-cyclodextrin complexed rhodamine-B. The mean values and the standard deviations were calculated on the basis of five experiments: $P < 0.02$ (***); $P < 0.05$ (**); $P < 0.5$ (*).

indicate that in this case the fluorophore was not taken up actively by cells.

Figure 5 shows the confocal laser-scanning microscopy images obtained after cell incubation with rhodamine-B loaded CD−PEG−FA and rhodamine-B loaded β-cyclodextrins/PEG/folic acid. The cell membranes were green-stained by fluorescein−DHPE, while red fluorescence was related to taken-up rhodamine-B.

Figure 5A shows that CD−PEG−FA promotes the rhodamine-B localization into KB cell tubular endosomal structures, some of them having a thickness of about 1−2 μm similar to those reported by other authors (*27*). Also, multivesicular bodies with predominant perinuclear fluorophore disposition were observed. Very weak diffuse fluorescence was detected in the cytosolic compartment and without localization into the nuclei. In contrast, the images obtained after KB or MCF7 cell incubation with free rhodamine-B, rhodamine-B loaded β-cyclodextrins/PEG, and β-cyclodextrins/PEG/folic acid mixtures or after MCF7 cell incubation with rhodamine-B loaded CD−PEG−FA did not show specific rhodamine-B localization into tubular endosomal structures and multivesicular bodies. In these cases, a diffused fluorescence in the cyctosolic compartment was observed. As an example, Figure 5B reports the image obtained with KB cells incubated with rhodamine-B loaded β-cyclodextrins/PEG/folic acid.

To get more information about intracellular trafficking of delivered rhodamine-B, KB cells were incubated for 1 h of pulse contact with medium containing rhodamine-B included CD−PEG−FA. Figure 5C shows that red fluorescence in dispersed cytosolic small spots, probably corresponding to small endosomes, was detectable soon after incubation. After 1 h, larger cytosolic fluorescent areas were observed (Figure 5D) indicating that the endosomes migrate and are localized in proximity of the Golgi apparatus as reported in the literature (*8*).

DISCUSSION

β-Cyclodextrins, folic acid, and PEG were properly assembled to obtain a supramolecular carrier system for active drug delivery. The delivery system was designed in order to exploit the physicochemical and biological properties of the various components; the β-cyclodextrin unit can host drugs with low solubility and stability, folic acid allows for active targeting to folate receptor over-expressing tumor cells, and PEG was used as a spacer between β-cyclodextrin and folic acid. PEG confers to the targeting moiety a certain flexibility that overcomes problems related to steric hindrance of β-cyclodextrin. Furthermore, PEG endows a derivative with higher solubility compared to the naked β-cyclodextrin or folic acid. The solubility of the new construct in water is, in fact, about 100 mg/mL, while the solubility of β-cyclodextrins and folic acid is 18.5 and 0.0016 mg/mL, respectively.

The bioconjugate was found to maintain high affinity for rhodamine-B used as the fluorescent probe in the present study. This result is in agreement with the data relative to estradiol already published (*14*). Similarly to estradiol, the rhodamine-B affinity constants for naked β-cyclodextrins and CD−PEG−FA were in the same order. However, the slight decrease in affinity obtained with CD−PEG−FA may be attributable to the chemical modification of the oligosaccharide ring or to the presence of the bound PEG that can interfere with the drug association, though the PEG and folic acid physically mixed with the β-cyclodextrins were not found to affect significantly the rhodamine-B affinity constant.

It should be noted that drugs with high-affinity constants are probably necessary to exploit the carrier properties of CD−PEG−FA because high drug/carrier affinity avoids the drug release before reaching the target. Aimed at selecting suitable drug models, an in silico drug design study is in progress.

Cell culture studies demonstrated that CD−PEG−FA was devoid of cytotoxicity, which represents a prerequisite for its pharmaceutical application. High cell viability was, in fact, observed by incubating both KB and MCF7 cells with high CD−PEG−FA concentration solutions. Also, previous studies demonstrated that this new derivative displays negligible hemolytic activity compared to the naked β-cyclodextrins, which confirms the good biocompatibility and low toxicity of this new macromolecular carrier.

The targeting properties of the bioconjugate were demonstrated by both the Biacore technique and cell culture investigations. Though the plasmon resonance signal/noise ratio did not allow for accurate affinity constant evaluation, CD−PEG−FA displayed a lower affinity for the cow milk folate binding protein compared to the free folic acid constant affinity reported in the literature (K_a = 50 pM). However, the free folic acid affinity constant reported in the literature was determined by using a different evaluation method with respect to the method adopted in this study. In the surface plasmon resonance assay, FBP is immobilized on a solid substrate while the affinity constant of free folic acid reported in the literature was evaluated by using FBP in solution, which prevents evaluation problems due to the solid matrix hindrance (*25*). Also, it is important to note that a certain decrease in affinity of the biocon-

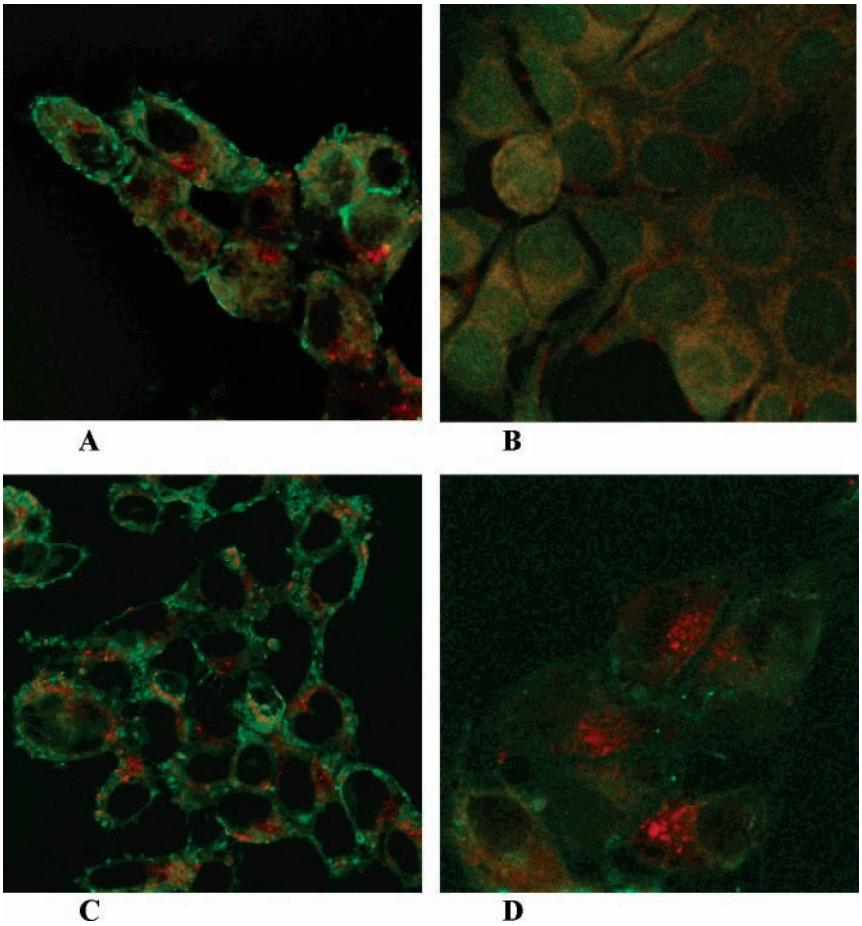

Figure 5. Confocal images obtained by incubation of 1 μM rhodamine-B with KB cells under different conditions: after 2 h of incubation with rhodamine-B loaded CD−PEG−FA (A); after 2 h of incubation with rhodamine-B loaded β-cyclodextrins/PEG/folic acid 1:1:1 molar ratio mixture (B); after 1 h of incubation with rhodamine-B loaded CD−PEG−FA (C); after 1 h from 1 h of incubation with rhodamine-B loaded CD−PEG−FA (D).

jugated folate was expected because about 20% of the folic acid was linked to PEG through the α-carboxylic group which is involved in the receptor recognition (*19*).

[^{3}H]-folic acid competition experiments performed using folate receptor overexpressing KB cells confirmed the specific recognition of CD−PEG−FA for the biological target. Although the folate affinity for the cell folate receptor decreased after conjugation to β-cyclodextrin−PEG, the conjugate was found to maintain high receptor affinity to guarantee its applicability in drug targeting similar to that reported for the folic acid−PEG 2000 Da bioconjugate used for liposome decoration (*19*).

The folate interaction with the folic acid receptor is known to promote a receptor-mediated internalization of the carrier into cells through a potocytosis pathway (*28*). The intracellular delivery of CD−PEG−FA was verified by cell culture studies using the fluorescent probe rhodamine-B. Confocal measurements showed that CD−PEG−FA provides for active transport of the probe into localized cell multivesicular bodies. Partial but unspecific rhodamine-B penetration was also observed when folate receptor overexpressing KB cells were incubated with free rhodamine-B or rhodamine-B loaded β-cyclodextrins/PEG or β-cyclodextrins/PEG/folic acid mixtures. Slight internalization was also obtained by incubation of folate receptor not-expressing MCF7 cells with free rhodamine-B, rhodamine-B included β-cyclodextrins/PEG/FA, or rhodamine-B included in CD−PEG−FA. Probably PEG partially disorganizes the biological membranes favoring passive rhodamine-B diffusion into the cells while folic acid promotes the rhodamine-B uptake from bulk solution by stimulating the cell potocytosic activity in folate receptor overexpressing cells.

Although the rhodamine-B uptake obtained using CD−PEG−FA was not massive, it was significantly higher compared to the other samples. Furthermore, it is worth noting that the simultaneous presence of folic acid and drug-loaded β-cyclodextrins in the same construct can guarantee the in vivo uptake of the carrier into the target cells where the drug can be released by environmental changes. The pH-induced ionization, for example, can take place in lysosomes or other cytosolic sites that display acidic pH and can provoke an affinity decrease that can result in drug release.

CONCLUSIONS

The supramolecular carrier obtained by β-cyclodextrins, PEG 700 Da, and folic acid bioconjugation possesses interesting properties for active tumor targeting. The copresence of the three components in the same construct enhances the drug solubility and stability and promotes drug targeting to the disease site, receptor recognition, and intracellular delivery. The drug release into the cells occurs by physical displacement, which represents a further advantage of this delivery system because chemical or enzymatic mechanisms usually required for drug release from polymer therapeutics often entail ineffective drug release.

Interestingly, the physicochemical and biopharmaceutical properties of this new class of bioconjugates can be optimized by the proper choice of the construct compo-

nents over a wide range of materials: cyclodextrins, polymeric spacer arms, and targeting moieties. Furthermore, according to the physicochemical properties of the drug and the target disease, tailor-made supramolecular carriers can be prepared.

C-Terminal Site-Specific PEGylation of a Truncated Thrombomodulin Mutant with Retention of Full Bioactivity

Chrystelle S. Cazalis,[†] Carolyn A. Haller,[†] Lisa Sease-Cargo,[†] and Elliot L. Chaikof*[,†,‡]

Laboratory for Biomolecular Materials Research, Departments of Surgery and Biomedical Engineering, Emory University School of Medicine, Atlanta, Georgia 30322, and School of Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, Georgia 30332. Received April 16, 2004; Revised Manuscript Received June 24, 2004

Addition of poly(ethylene glycol) to bioactive proteins (PEGylation) improves their plasma half-life, enhances stability against proteolytic cleavage, and may also decrease protein immunogenicity. Characteristically, PEGylation usually involves a reaction to available lysine amino groups, some of which may be within or near a bioactive site. Thus, most protocols are nonspecific and result in a loss of protein activity. We report herein a strategy for site-specific PEGylation of a thrombomodulin (TM) derivative at the C terminus. A truncated TM mutant consisting of epidermal growth factor (EGF)-like domains 4−6 was expressed in *Escherichia coli* with a C-terminal azido-methionine. The TM mutant was site-specifically conjugated to a methyl-PEG-triarylphosphine compound via the Staudinger reaction. Enzymatic activity of the TM construct before and after PEGylation was unchanged, which confirms the utility of this site-specific PEGylation scheme.

INTRODUCTION

Addition of poly(ethylene glycol) to bioactive proteins (PEGylation) increases both their molecular size and steric hindrance, which results in an increase of protein plasma half-life and resistance to proteolytic cleavage. In addition, protein immunogenicity may be decreased (*1*, *2*). Characteristically, PEGylation usually involves a reaction to available lysine amino groups, some of which may be within or near a bioactive site. Thus, most protocols are nonspecific and result in a loss of protein activity (*3*, *4*). For example, Han et al. (*5*) conjugated TM to PEG via trichlorotriazine as a coupling agent for immobilization onto a glass surface. Despite successful immobilization, reduced TM activity was noted presumably because of the alteration of protein conformation after PEGylation. To overcome the limitations of current conjugation strategies, several approaches have been proposed. Site-specific PEGylation can be achieved through the introduction of a cysteine residue in engineered proteins with a free thiol available for conjugation reactions (*6*, *7*). As a consequence, several PEG derivatives have been developed for that purpose (*8*−*11*). The efficacy of this approach is compromised, however, by a low yield of PEGylated protein and often by a substantial loss of activity if abnormal protein folding is induced by the introduction of the cysteine residue (*12*). As an alternative strategy, Yamamoto et al. (*13*) reported site-specific PEGylation of a lysine-deficient tumor necrosis factor-α (TNFα) at its N terminus. The corresponding bioconjugate showed higher bioactivity in vitro and greater antitumor potency than a randomly mono-PEGylated TNFα.

We report herein the use of a strategy for site-specific PEGylation of human thrombomodulin. This transmembrane protein is a critical regulator of the protein C pathway and represents a major anticoagulant mechanism that is operative under physiologic conditions in vivo (*14*, *15*). Thrombomodulin (TM) is a cofactor for thrombin-catalyzed activation of protein C, enhancing the rate of the reaction by 1000-fold (*16*). To closely mimic the TM structure as it appears at the cell surface (*17*, *18*) and consequently preserve its bioactivity, we investigated the PEGylation at the C terminus. Using a genetically directed synthesis in *Escherichia coli*, we first expressed a short TM construct containing epidermal growth factor (EGF)-like domains 4−6 and an azido-functionalized methionine analogue (*19*) as a C-terminal linker. The PEGylation was then achieved through Staudinger ligation (*20*) with a suitably engineered PEG derivative.

EXPERIMENTAL PROCEDURES

Materials. All chemical reagents were obtained from Sigma Chemical Corp. (St. Louis, MS). The methyl-PEG-amine 5000 was purchased from Netkar Corp. (Hunstville, AL). The *Bam*H I and Shrimp Alkaline Phosphatase enzymes were obtained from New England Biolabs, Inc. (Beverly, MA). The Quikchange Site-Directed Mutagenesis kit was from Stratagene (La Jolla, CA). *E. coli* strain B834 (DE3), plasmid pET-39b(+), S-Tag Rapid Assay kit, and Site-Specific Enterokinase Cleavage and Capture kits were from Novagen (Madison, WI). All plasmid purification kits were purchased from QIAGEN Inc. (Chatsworth, CA). The mouse monoclonal antibody to human TM was from COVANCE Corp. (Richmond, CA). Synthetic oligonucleotides were purchased from Integrated DNA Technologies, Inc. (Coralville, IA). Purified recombinant human PC and human α thrombin were from Haematologic Technologies Inc. (Essex Junction, VT). Human anti-thrombin, recombinant human TM

(soluble truncated form of TM that lacks the putative transmembrane and the cytoplasmic domains, with an approximate weight of 68 kD), and chromogenic substrate Spectrozyme PCa were purchased from American Diagnostica Inc. (Stamford, CT). All reagents for manipulating DNA and bacteria were sterilized by autoclave.

Instrumentation. MALDI−TOF mass spectrometry data were performed on an Applied Biosystem Voyager-DE STR Biospectrometry Workstation MALDI−TOF mass spectrometer using an 2-(4-hydroxy-phenylazo)-benzoic acid matrix. ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded at 600 MHz (^{1}H and ^{13}C) and 242 MHz (^{31}P) on a Varian INOVA in $CDCl_3$ (internal Me_4Si and H_3PO_4, respectively, δ ppm). Optical density was recorded on a Varian Cary 50 Bio UV−visible spectrophotometer.

Synthetic Gene Construction. A DNA fragment encoding for EGF (4−6) domains of human TM was obtained by polymerase chain reaction using primers 5′-TACCCTAACTACGACCTGGTG-3′ and 5′-TATGAGCAAGCCCGAATG-3′. Through a series of intermediate constructs, this fragment was used to generate a gene containing a leucine (Leu) substitution for methionine-388 (Met-388), N- and C-terminal *Bam*H I sites, and a C-terminal linker GlyGlyMet using site-directed mutagenesis. The final construct (TM_{GGM}) was then inserted using the *Bam*H I site of the expression plasmid pET-39b(+). All mutations were verified through sequence analysis.

Protein Expression and Purification. pET39b(+)-TM_{GGM} was transformed into the *E. coli* methionine auxotroph B834(DE3). M9 minimal medium (500 mL), supplemented with 1 mM $MgSO_4$, 0.4 wt % glucose, 1 mg/L thiamine chloride, 0.1 mM $CaCl_2$, kanamycin (30 mg/L), and all proteinogenic amino acids (40 mg/L), was inoculated with 20 mL of an overnight culture of the transformed cells. When the turbidity of the culture reached an OD_{600} of 0.8, protein expression was induced by addition of isopropyl-β-D-thiogalactopyranoside (IPTG) to a final concentration of 0.5 mM. After 5 min, the medium was exchanged to remove methionine, cells were sedimented (4000*g* for 20 min), and the cell pellet was washed twice with 200 mL of 1× M9 salts. Cells were resuspended in 500 mL of the M9 minimal medium described above, without methionine but supplemented with 100 mg/L of azido-functionalized methionine analogue (*19*). A culture lacking methionine served as the negative control. Cultures were grown for 4.5 h at 37 °C. The expression of the TM protein was analyzed by 4−20% gradient SDS−PAGE gel electrophoresis and visualized by Western blot analysis using a mouse monoclonal antibody to human TM. The target protein was expressed as a N-terminal Dsba enzyme fusion to a leader sequence containing an enterokinase cleavage site, hexahistidine, and S tags (protein TM_A). S-Tag Rapid Assay was used to quantify the protein concentration and therefore the expression yield, which averaged 17 mg/L of cell culture. TM_A was purified from the cell pellet by using immobilized metal-affinity chromatography on TALON resin (Clontech Laboratories, Inc.) under native conditions using an imidazole gradient for elution of the target polypeptide. The cells were first harvested by centrifugation at 4 °C at 10000*g* for 30 min and resuspended in 25 mL of lysis buffer (300 mM NaCl, 50 mM NaH_2PO_4, 10% glycerol, 1 mg/mL lysozyme, and 10 μg/mL PMSF at pH 8). After incubation on ice for 30 min, the cell lysate was clarified by centrifugation at 10000*g* for 20 min. The soluble extract was then loaded onto a column containing TALON metal-affinity resin (25 mL), which had been pre-equilibrated with lysis buffer. The weakly binding proteins were removed by rinsing the column with 125 mL of wash buffer (300 mM NaCl, 50 mM NaH_2PO_4, 10% glycerol, and 20 mM imidazole at pH 8). TM_A was eluted by the addition of 50 mL of elution buffer (300 mM NaCl, 50 mM NaH_2PO_4, 10% glycerol, and 250 mM imidazole at pH 8). The chromatographic fractions were analyzed by 4−20% gradient SDS−PAGE gel electrophoresis and visualized by Western blot analysis using mouse monoclonal antibody to human TM. The nitrocellulose membrane was developed using the ECL plus Western blotting detection kit (Amersham Biosciences, U.K.). Enterokinase cleavage removed the fusion tag and generated the target protein (TM_B). N-terminal sequencing, amino acid compositional, and mass analysis (SELDI−TOF) confirmed the integrity of TM_B, [mass detected (m/z) = 16 545.2 D (calculated = 16 540.1 D)].

Synthesis of Methyl-PEG-triarylphosphine (2). 1,3-Dicyclohexylcarbodiimide (DCC) (5.7 mg, 27 μmol) was added to a solution of phosphino reagent (**1**) (10.3 mg, 28 μmol) in anhydrous $CHCl_3$ (2 mL) at room temperature under argon. The mixture was stirred for 1 h, followed by the addition of methyl-PEG-amine [m-PEG-NH_2 (M_n = 5 kD)] (120 mg, 24 μmol) dissolved in $CHCl_3$ (2 mL). The mixture was subsequently agitated for 2.5 days under argon. The methyl-PEG-triarylphosphine conjugate was recovered by precipitation in cold diethyl ether (200 mL) and filtration. The precipitate was dissolved in water. The aqueous solution was filtrated and lyophilized to afford the final product with 50% substitution. The product was used in the Staudinger reaction without further purification. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 3.38 [s, 3H, OCH_3 (PEG)], 3.45−3.90 [m, 448 H, OCH_2 (PEG)], 7.47−7.55 (m, 6H), 7.67−7.70 (m, 5H), 7.91−7.94 (m, 1H), 8.12−8.13 (m, 1H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 40.0, 41.3, 52.5, 59.3, 70.2, 70.6, 71.1, 72.0, 128.5, 128.7, 128.8, 130.5, 131.0, 131.3, 132.0, 133.3, 134.1, 137.7, 138.1, 166.5, 166.7. ^{31}P NMR (242 MHz, $CDCl_3$) δ: −3.11. MALDI−TOF: 6034 D (calculated = 6014 D).

TM−PEG Conjugation. To a solution of TM_B in phosphate-buffered saline (PBS) at pH 7.4 (300−500 nM, 100 μL) was added a large excess (1 mg) of lyophilized methyl-PEG-triarylphosphine, and the mixture was subsequently heated at 37 °C for 36 h to obtain maximum conjugation. The mixture was divided in half and two sets of reactions were subjected to SDS−PAGE in parallel. Proteins from the first gel were transferred to nitrocellulose membrane and visualized by Western blot analysis using a mouse monoclonal antibody to human TM. This procedure monitored the presence of TM_B proteins that had reacted with the phosphine and were therefore PEG-labeled, as well as unreacted TM_B. The second gel was stained with barium chloride/iodine solutions to reveal PEGylated molecules only (*21*).

TM Enzymatic Activity Assay. A saturated concentration of TM_B in 20 μL of assay buffer (20 mM Tris-HCl at pH 7.5, 100 mM NaCl, and 2.5 mM $CaCl_2$) was incubated for 30 min at 37 °C with 10 nM human α thrombin and varying amounts of human protein C (0−8 μM). Reactions were quenched by addition of 5 μL of human antithrombin (10.7 μM) and incubation for 5 min at room temperature. The amount of activated protein C (APC) formed was determined by addition of 275 μL of Spectrozyme PCa (218 μM), followed by incubation for 20 min at room temperature. Spectrozyme PCa is a chromogenic substrate used for the quantification of APC in solution. A total of 1 mol of the substrate is hydrolyzed by APC producing 1 mol of *p*-nitroaniline (pNA). The pNA concentration was determined by UV spectro-

Figure 1. Schematic structure of the targeted truncated TM, whose amino acid sequence is encoded by the gene TM_{GGM}.

phometry at 407 nm using the equation

$$OD_{407nm} = -0.0014 + 0.0096[pNA] \quad (1)$$

where eq 1 was obtained by optical density measurements of pNA solutions of known concentrations. The corresponding rate (mol/min) of *p*-nitroaniline formed (R_{pNA}) was obtained by dividing the pNA concentration by the 20-min assay time.

A second standard plot was used to determine the APC concentration from R_{pNA}, where

$$R_{pNA} = -0.059 + 0.0671[APC] \quad (2)$$

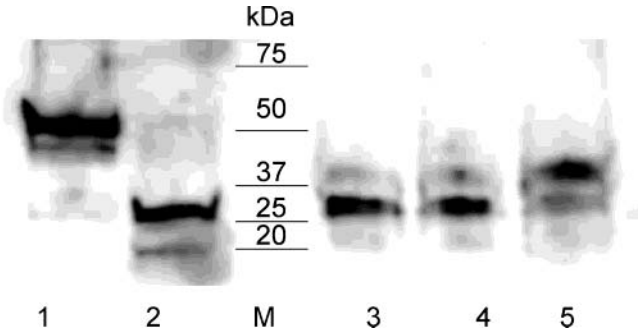
To obtain eq 2, commercial APC was dissolved in the assay buffer at various concentrations and incubated with Spectrozyme PCa for 20 min at room temperature. The corresponding rate (mol/min) of APC formed (R_{APC}) by the TM−thrombin complex was obtained by dividing the observed APC concentration by the 30-min assay time.

Values obtained for control experiments without TM were subtracted to give final rates of APC produced. Michaelis−Menten parameters (k_{cat} and K_m) were calculated from a plot of R_{APC} versus the protein C concentration.

RESULTS AND DISCUSSION

It is now well-established that the three consecutive EGF-like domains 4−6 (EGF4−6) of human TM exhibit full cofactor activity (*22*). The corresponding amino acid sequence contains only one methionine residue (Met-388), which is not vital for protein bioactivity (*23, 24*). In fact, prior studies have demonstrated that mutation of Met-388 to Leu results in a construct that is more resistant to oxidative inactivation and exhibits greater enzymatic activity than the native TM protein (*25*). Thus, we postulated that a truncated TM fragment containing EGF4−6 with the insertion of a C-terminal nonnatural methionine analogue would provide a good target for site-specific PEGylation. Indeed Kiick et al. (*19*) have recently reported the incorporation of an azide function into recombinant proteins via the use of a methionine analogue, which facilitated chemoselective modification by Staudinger ligation.

To create a short recombinant bioactive TM mutant, we first used the DNA fragment encoding for the amino acid sequence 349−492 to generate a gene containing a Met-388−Leu substitution and a C-terminal linker GlyGlyMet using site-directed mutagenesis (Figure 1). The final construct (TM_{GGM}) was then inserted in the expression plasmid pET-39b(+). This plasmid contains a leader gene sequence coding for the Dsba enzyme, which is a periplasmic enzyme catalyzing the formation and isomerization of disulfide bonds of expressed proteins. Therefore, we expected the target TM mutant to possess all disulfide bonds required for proper protein folding and enzyme activity. Expression under the induction of IPTG using the *E. coli* methionine auxotroph B834 (DE3)/pET39b(+)−TM_{GGM} in cultures depleted of methionine and supplemented with an azido-functionalized methionine analogue, azidohomoalanine (*19*), afforded the target protein as a N-terminal Dsba enzyme fusion



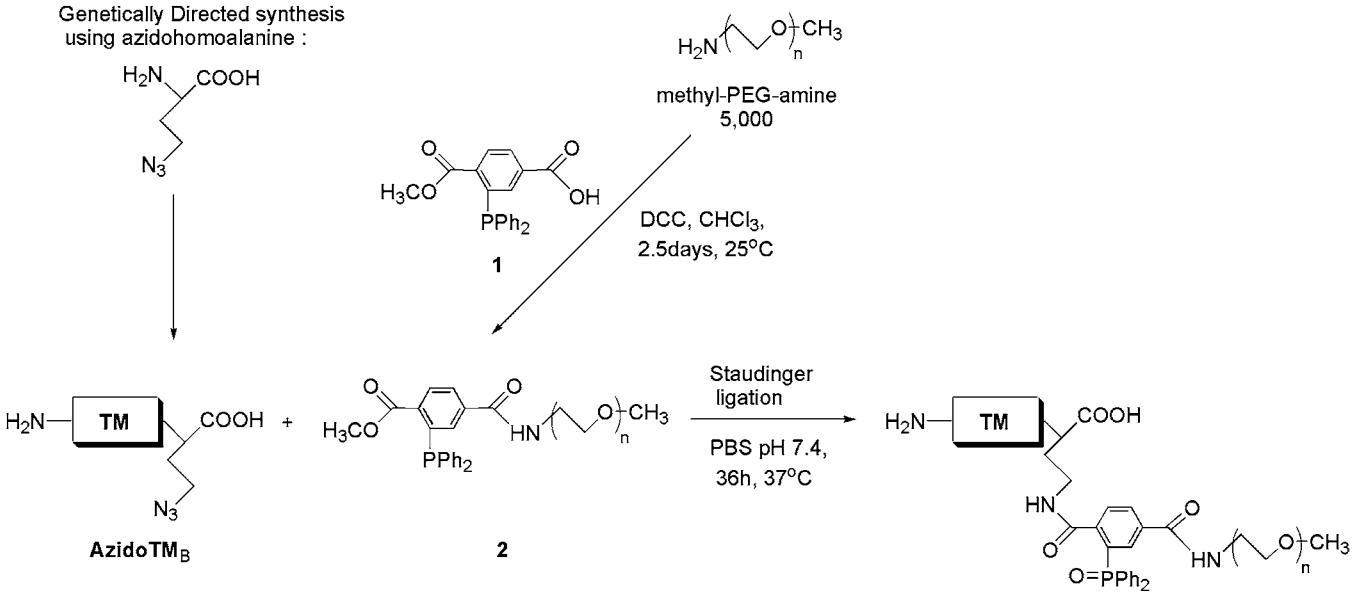


Figure 2. Western blot analysis of TM derivatives (4−20% SDS−PAGE gel). (1) Purified TM_A. (2) Enterokinase cleavage of TM_A leading to the target protein TM_B. (3−5) Conjugation of **2** to TM_B over time at 4, 8, and 24 h, respectively. M = molecular-weight marker proteins.

to a leader sequence containing enterokinase recognition sequence, hexahistidine, and S tags. Protein expression was monitored by SDS−PAGE analysis and visualized by Western blot analysis. The target protein was not observed in the negative control culture, whereas TM fused to the leader sequence (TM_A) was clearly detected in the positive control cultures supplemented with azidohomoalanine. The accumulation of TM_A was taken as preliminary evidence for incorporation of the nonnatural amino acid. TM_A was purified from the cell pellet by using immobilized metal-affinity chromatography with stepwise imidazole-gradient elution under native conditions. Enterokinase cleavage removed the fusion tag and generated the target proteins (TM_B). N-terminal sequencing, amino acid compositional, and mass analysis (mass detected = 16 545 D) confirmed the integrity of TM_B. TM_B was characterized by a band at 33 kD on Western blot analysis (Figure 2), which is consistent with prior reports that TM associates into dimers even under denaturing conditions (*25*).

Having expressed an azide-modified form of TM, we then investigated the selective Staudinger ligation of this protein with a methyl-PEG-triarylphosphine conjugate **2** (Scheme 1). We choose this ligation protocol to minimize the risk of side reactions that might alter the TM structure and activity. Indeed, in its classical form, the Staudinger reaction meets many of the criteria required of a chemoselective ligation in a cellular enviroment. The phosphine and the azide react rapidly, selectively, and in high yield, in water at room temperature. Kiick et al. (*19*) prepared a triarylphosphine compound **1** that was used for the preparation of a protein-flag conjugate, as well as for labeling cell-surface azide-bearing sialic acids with a biotinylated phosphine (*20*). In a similar manner, we used **1** in the synthesis of methyl-PEG-triarylphosphine conjugate **2**. The carboxylic acid group of **1** was reacted with the amino group of a commercially available derivative, m-PEG-NH_2 (5 kD), with amide-bond formation (Scheme 1). The incorporation of a phosphino group in PEG was assessed by ^1H, ^{13}C, and ^{31}P NMR, as well as by MALDI−TOF spectroscopy (Figure 3). The average molecular weight of 6034 D observed for the methyl-PEG-triarylphosphine conjugate **2** is consistent with an expected mass increase of 346 D, as a result of linking the phosphino compound **1** to m-PEG-NH_2 (average molecular weight observed = 5668 D).

The addition of m-PEG-NH_2 to **1** dramatically enhances the water solubility of the hydrophobic phosphino group. A large excess of lyophilized methyl-PEG-triarylphosphine conjugate **2** (1 mg) was added to 100 μL of an aqueous solution of TM_B in PBS at pH 7.4, and

Scheme 1. Synthesis of the Methyl-PEG-triarylphosphine Conjugate 2 and Its Conjugation to Azido-Functionalized TM_B

Staudinger ligation was performed at 37 °C for 24 h. The formation of the TM_B−PEG conjugate was followed by Western blot analysis of the reaction mixture over time (Figure 2). The gel shows a band at a higher molecular weight than the initial TM_B with a simultaneous disappearance of the TM_B band. These results indicate that the Staudinger reaction proceeded efficiently with incorporation of the PEG polymer into the TM construct. Because the reaction was not complete after 24 h, we allowed it to proceed for an additional 12 h. Western blot analysis (Figure 4a) and barium chloride/iodine staining (Figure 4b) of SDS−PAGE gels were performed in parallel to monitor the formation of the TM_B−PEG conjugate. Disappearance of the band characteristic of the unconjugated TM_B revealed that bioconjugation of TM_B to PEG was 100% complete. The SDS gel run in parallel under identical conditions but stained with barium chloride/iodine confirmed the presence of PEG in the bioconjugate. The presence of a low molecular-weight band represents unreacted methyl-PEG-triarylphosphine **2**.

Enzyme activity was assessed to determine the effect of PEGylation on TM cofactor activity (Table 1). We initially investigated the activity of the TM_A and TM_B mutants, as well as a commercial recombinant human TM mutant consisting solely of the extracellular domain (American Diagnostica Inc.). As previously noted, Clarke et al. (*23*) have reported that the Met-388−Leu mutation results in a 2-fold increase in k_{cat} for the activation of protein C by a thrombin−TM fragment complex. Although we were unable to observe this enhancement of activity, Michaelis−Menten parameters were similar for

TM_A and TM_B, as well as for the commercial human TM protein. We inferred that the generated TM mutants exhibited the requisite conformation and structure necessary for proper thrombin binding and protein C activation. Significantly, the incorporation of PEG into TM_B did not affect cofactor activity, indicating that this site-specific PEGylation scheme did not interfere with thrombin binding and protein C activation. Parenthetically, despite a concerted effort by our group, previous attempts to generate an enzymatically active truncated TM mutant with a C-terminal cysteine, as a potential bioconjugation site, were unsuccessful using both yeast and *E. coli* expression systems. We speculate that an additional terminal cysteine likely interfered with normal protein folding dependent upon the presence of native disulfide loops in the EGF sequences.

CONCLUSIONS

A human TM derivative containing EGF(4−6)-like domains designed with an azido-functionalized methionine C-terminal linker was successfully synthesized via a genetic engineering strategy. The protein exhibited bioactivity toward protein C that was comparable to native human TM. The TM construct was successfully conjugated to a novel engineered methyl-PEG-triarylphosphine compound via the Staudinger reaction under mild conditions. The cofactor activity assay before and after PEGylation was unchanged, confirming successful application of this site-specific PEGylation scheme. To our knowledge, this report is the first to describe site-specific PEGylation of a TM mutant with the retention of full bioactivity.

Novel Chemoselective Linkage Chemistry toward Controlled Loading of Ligands to Proteins through In Situ Real-Time Quantification of Conjugate Formation

Nicholas S. Flinn, Martin Quibell, William G. Turnell,§ Tracy P. Monk, and Manoj K. Ramjee*

Amura Therapeutics Limited, Horizon Park, Barton Road, Comberton, CB3 7AJ, United Kingdom

'Linkage chemistry', which encompasses the science of chemical attachment of a ligand molecule to a carrier moiety, plays a crucial role in a wide range of biochemical and biophysical disciplines. In particular, the production of synthetic vaccines, where quality assurance criteria are an essential part of the approvals procedure for development of medicines, is reliant upon reproducible linkage chemistries. Herein, we describe novel 2-hydroxybenzaldehyde-based quaternary amine containing chemoselective linkers that provide a simple and robust linkage process that overcomes the deficiencies present in state-of-the-art linkage chemistries. The 2-hydroxybenzaldehyde groups undergo a pH-dependent absorbance change that enabled its nondestructive quantification, even when covalently attached to a wide range of proteins. Additionally, formation of a hydrazone bond between the benzaldehyde group and a range of ligand hydrazides resulted in a second reversible absorbance change enabling the forward (ligand loading) and reverse (ligand release for analysis) reactions of ligand-loaded proteins to be monitored in situ and quantified in real time. Incorporation of the quaternary amine moiety into our improved linkage chemistries was found to increase the relative solubility of protein conjugates and enabled significantly higher loading of proteins with linker and subsequent ligands, while retaining aqueous solubility, when compared to standard methods.

INTRODUCTION

The covalent crosslinking of chemical and biological moieties is an essential process used in many diverse biophysical and biochemical applications (*1*−*4*). Each application requires the covalent attachment of an active moiety (i.e., a ligand) to a soluble or insoluble 'carrier' via an appropriately functionalized chemical linker. However, the diversity in the nature of the ligands (*4*−*8*) and carriers (*9,10*) has meant that each application has required an empirical solution for the successful production of conjugates. In this respect, perhaps one of the most challenging and yet promising areas has been the development of synthetic conjugate vaccines as medicines (*6*).

Small molecules and peptides, identified as epitopes for vaccine development, usually require conjugation to carrier proteins to provide a construct with which to provoke an immune response to the immunogen in vivo. An ideal vaccine construct would contain a high surface coverage of conjugated epitope on the carrier protein while retaining high aqueous solubility. Conjugation has traditionally been facilitated by the use of chemically reactive linkers, for which a number of reagents have been described (*11,12*). Although homobifunctional linkers were the first to be exploited, heterofunctional linkers became prominent as a means to circumvent ligand-to-ligand and carrier-to-carrier crosslinking. However, even with the improved control afforded by heterofunctional linkers, various practical issues, such as aqueous stability of the reactive species, conjugate solubility and stability, chemoselectivity, and ease of conjugate analysis still need to be solved empirically using laborious methods. Furthermore, the use of disulfide-bond constrained peptide loops as structural epitope mimics as well as the presence of certain functional groups within the epitope may also exclude the use of certain linkers since they provide sensitive or alternative reactive centers (*13*). To overcome these and other limitations, more selective aqueous compatible chemoselective linkage strategies have been developed. One such linkage chemistry is based on the formation of the acyl−hydrazone bond.

Hydrazides, being weak bases, form stable acyl−hydrazone bonds with an aldehyde functionality at mildly acidic pH (*14,15*). As such, hydrazone formation has been employed for various selective conjugation reactions (*16*−*19*) and this methodology has led to the development of a marketed product (Gemtuzumab Ozogamicin-Mylotarg) (*6*). Nevertheless, some basic practical issues remain for the routine production and quality assurance of conjugates. For example, highly loaded protein conjugates are in most cases unobtainable, due to the low and unpredictable solubility observed as the ratio of ligand to carrier protein increases (*20*). Additionally, the linkage created between the carrier protein and epitope would ideally be immunogenically inert and not involve residues or functionalities critical to epitope recognition (*13*). Also, for the production of medicines, quality assurance criteria are crucial as part of the FDA approvals procedure, for which some of the basic requirements are the quantitative assessment of linker loading of carrier as well as the extent of ligand coupling of the derivatized protein; both of which can be arduous tasks (*13*). These types of issues have made the production of synthetic vaccines a semi-empirical process, hampering the rapid development of

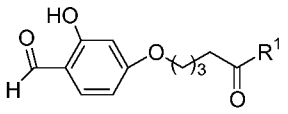
therapeutic vaccines. Therefore, the development of linkers that overcome the existing limitations would be of great benefit.

Here we describe the synthesis and characterization of 2-hydroxybenzaldehyde-based reversible chemoselective linkers that provide a number of practical advantages over conventional linkage technologies. First, the linkers could be quantified spectrophotometrically in a nondestructive manner in the absence or presence of various proteins. Second, elaboration of the protein-bound linker with a ligand via hydrazone formation resulted in a quantifiable absorbance change, enabling the forward (ligand loading) and reverse (ligand release for analysis) reactions of linker-loaded proteins to be monitored in situ. The linker was also designed to contain a quaternary amine moiety as a means of primarily compensating the loss of surface charge upon coupling of the linker onto the surface-exposed primary amines of proteins. This feature enabled relatively higher linker loading of proteins while retaining solubility.

EXPERIMENTAL PROCEDURES

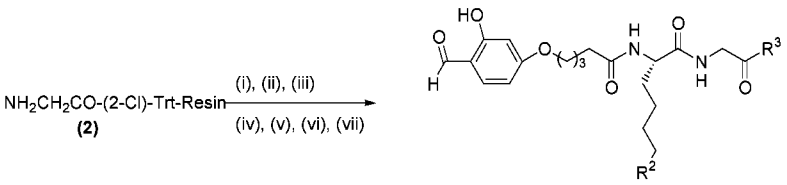
General Biochemistry. All reagents were of the highest commercially available quality and were used as received. Unless otherwise stated, all chemicals and biochemicals were purchased from the Sigma Chemical Company (Poole, Dorset, United Kingdom). Unless otherwise stated, routine protocols were carried out at room temperature and kinetic experiments at 25 °C. Protein concentrations were determined using Bradford reagent (Sigma) according to the manufacturer's instructions using BSA as the standard. Absorbance measurements were carried out in 384-well microtiter plates (Corning Costar 3702 plates, Fisher Scientific, Loughborough, United Kingdom), flat-bottomed 96-well plates (Spectra; Greiner Bio-One Ltd., Stonehouse, Gloucestershire, United Kingdom) or standard 1-mL quartz cuvettes, using a SpectraMax PLUS384 plate reader (Molecular Devices, Crawley, United Kingdom). Fluorescence measurements were carried out in either 384-well microtiter plates (Corning Costar 3705 plates, Fisher Scientific) or 96-well 'U' bottomed Microfluor W1 microtiter plates (Thermo Labsystems, Ashford, Middlesex, United Kingdom). Fluorescence assays were monitored using a SpectraMax Gemini fluorescence plate reader (Molecular Devices). In all cases SOFTmax Pro 3.1.2 software was used for data collection and handling (Molecular Devices). All spectra were collected at a resolution of 2 nm. Gel and membrane images were captured using a Hewlett-Packard C7710A scanner employing HP Precision ScanPro 3.02 software on default settings. Images were routinely scanned at a minimum resolution of 600 dpi in gray scale mode (32 bit). Images were marked with legends employing Powerpoint (Microsoft Corp., Seattle, WA). Image analysis and processing was carried out using ImageJ software (*21*).

General Chemistry. All solid-phase synthesis was performed using an "Fmoc/tBu" procedure (*22*) following standard solid-phase synthesis resin washing protocols. Standard Fmoc amino acids were obtained from Chem-Impex International (Wood Dale, IL) and Merck Biosciences (Nottingham, United Kingdom) with the exception of Fmoc *N*-ϵ-trimethyl-l-lysine, which was purchased from Bachem UK Ltd. (St. Helens, United Kingdom). The 2-chlorotrityl-resin (Product 04-12-2800) was obtained from Merck Biosciences (Nottingham, United Kingdom). The PS-carbodiimide resin was obtained from Argonaut Technologies (Muttenz, Switzerland). All solvents were purchased from Romil (Cambridge, United Kingdom). Solid-phase syntheses were performed manually in a polypropylene syringe fitted with a polypropylene frit to allow filtration under vacuum. Analytical HPLC was performed on Agilent 1100 series instruments including a G1311A quaternary pumping system, with a G1322A degassing module and a G1365B multiple wavelength UV−vis detector. Data were collected and integrated with Chemstation 2D software. Analytical HPLC analyses were performed on a Zorbax, 5-μm, C8 reverse phase column (150 × 4.6 mm i.d.), at a flow rate of 1.5 mL/min, monitoring at 215 and 254 nm. Eluents used were (A) 0.1% trifluoroacetic acid in water and (B) 90% acetonitrile/10% eluent A. They were used to run a gradient starting at 10% B, increasing to 90% B over 7 min, holding for 1 min, returning to 10% B over 1 min, and then remaining at initial conditions for a further 4 min to allow column reequilibration. Compounds were purified by semipreparative HPLC, using a Phenomenex Jupiter C4 reverse phase column (250 × 10 mm i.d.) at a flow rate of 4 mL/min, using the equipment and eluents described above. Compound molecular ions were determined on an Agilent 1100 series LC/MSD electrospray mass spectrometer.



Amine Determination. The amine concentrations were determined using fluorescamine (Fluram; Fluka) (*23*), employing Ac−Lys−NH_2 (Bachem) as the calibration control. Routinely, 10 μL of test sample was diluted into 85 μL 50 mM sodium phosphate; pH 10 and 5 μL 10 mM Fluram (in 100% acetonitrile) were added. The Fluram solutions were freshly prepared prior to use. The reactions were mixed and incubated at room temperature for 30 min prior to measuring the fluorescence (390-nm excitation, 485-nm emission).

SDS−PAGE and Western Blot Analysis. The SDS−PAGE and Western blot components were obtained from Invitrogen, Paisley, United Kingdom. For denatured protein analysis, samples were routinely analyzed by SDS−PAGE using the NuPAGE system employing 4−12% bis-tris NuPAGE gels. Unless otherwise stated, all gels were run in MES running buffer. For native protein analysis, samples were analyzed by PAGE using the NuPAGE system employing the 4−12% bis-tris NuPAGE gels, 7% NuPAGE tris-acetate, or 3−8% tris-acetate gels with the appropriate buffers. The POWEREASE system was used to carry out electrophoresis employing protocols embedded in the unit's software. Proteins were visualized with SimplyBlue stain kits or SilverExpress stain kits according to manufacturers' protocols. After staining, gels were dried using DryEase gel drying solution and cellophane membranes.



For Western blot analysis of conjugates, the proteins were transferred from the gel onto a PVDF membrane using the manufacturer's (Invitrogen) reagents and protocols. The PVDF membranes were blocked by gentle agitation in 50 mL phosphate buffered saline containing 1% Tween 20 (PBST; Sigma) plus 1% (w/v) BSA for 15 min. The recovered membranes were washed three times, by gentle agitation, in 100 mL PBST for 5 min per cycle. Following this, the membranes were incubated in 50 mL PBST containing a 1 in 5000 dilution of ExtrAvidin-

[1] Abbreviations: BSA, bovine serum albumin; HBV, hepatitis B virus; DCM, dichloromethane; DMF, dimethylformamide; DMSO, dimethyl sulfoxide; DTNB, 5,5′-dithio-bis-(2-nitrobenzoic acid); HEWL, hen egg-white lysozyme; HOBt, 1-hydroxybenzotriazole; HBTU, 2-(1*H*-benzatriazole-1-yl)-1,1,3,3′-tetramethyluronium hexafluorophosphate; NMM, *N*-methylmorpholine; OSu, *N*-hydroxysuccinamide ester; PBS, phosphate buffered saline; PFP, pentafluorophenol.

Peroxidase (Sigma) for 30 min, washed as before in PBST, and allowed to partially drip dry. Regions of peroxidase activity were visualized by addition of a 3,3′,5,5′-tetramethylbenzidine (TMB) liquid substrate (Sigma) onto the static membrane. After appropriate exposure, the membrane was recovered, washed in water, and air-dried prior to scanning, analysis, and storage.

Diafiltration. Routinely, Amicon Ultra-4 (≤4 mL) or Ultra-15 (≤15 mL) centrifugal filter units (10 000 mwco; Millipore, Watford, United Kingdom) were used for diafiltration. Each cycle consisted of diluting the protein sample approximately 10-fold with exchange buffer and concentrating the sample by centrifugation back to its original volume. Cycles were repeated as required for quick and highly efficient equilibration/washing of protein samples. Routinely six cycles were completed for each diafiltration step.

Synthesis of 5-(4-Formyl-3-hydroxyphenoxy)pentanoic Acid (*19*) **(Scheme 1: 1a).**Spray-dried potassium fluoride (8.4 g, 0.144 mol) and 2,4-dihydroxybenzaldehyde (10 g, 0.072 mol) were stirred vigorously at 60 °C for 20 min in anhydrous acetonitrile (150 mL). Methyl-5-bromovalerate (42.3 g, 0.216 mol) was added in one portion and the mixture brought to a gentle reflux for 5 h. The reaction was allowed to cool to room temperature and the solvent was removed in vacuo. The residue was partitioned between water (100 mL) and ethyl acetate (50 mL). The aqueous portion was washed twice more with ethyl acetate (2 × 30 mL) and the combined organic layers were back-washed with water, dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness. The resulting red oil was recrystallized from ether (30 mL) and heptane (20 mL). The methyl ester obtained was dissolved in tetrahydrofuran (120 mL) and stirred vigorously at room temperature. To this solution was added lithium hydroxide (3.7 g, 0.088 mol) dissolved in water (60 mL) and the mixture was stirred for 4 h. The solvent was reduced in vacuo and the resultant oily residue was diluted with water (30 mL), washed twice with methyl *tert*-butyl ether (2 × 50 mL), acidified to pH 2 with concentrated hydrochloric acid, and extracted with ethyl acetate (4 × 30 mL). The combined ethyl acetate fractions were dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness to give a white solid product. Yield: 9.86 g, 0.041 mol, 57%. ^{1}H NMR ($CDCl_3$) δ: 11.26 (2H, brs), 9.69 (1H, s), 7.41 (1H, d, J = 8.6 Hz), 6.51 (1H, dd, J = 8.6, 2.2 Hz), 6.40 (1H, d, J = 2.2 Hz), 4.02 (2H, t, J = 5.9 Hz), 2.44 (2H, t, J = 7.0 Hz), 1.84 (4H, m). mp: 88−91 °C. ESI−MS *m*/*z*: 239.1 (calc. for M + H^+ 239.08). HPLC retention time: 5.34 min.

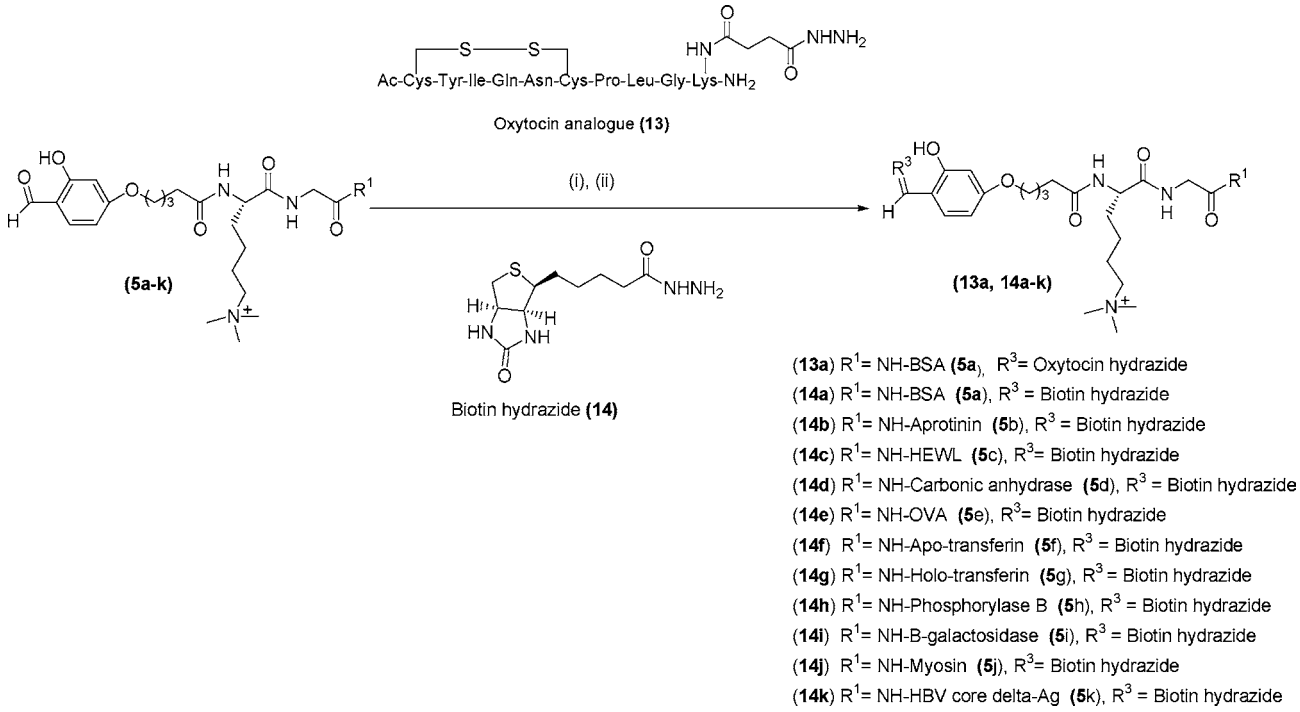
Synthesis of 5-(4-Formyl-3-hydroxyphenoxy)pentanoic Acid 2,5-Dioxopyrrolin-1-yl Ester (Scheme 1: 1b). PS-carbodiimide resin (**11**) (4.2 g, 5.5 mmol) was suspended in dichloromethane (45 mL) stirred for 5 min to swell the resin. Compound **1a** (1.0 g, 4.2 mmol) was added and dissolved in dichloromethane (10 mL); the resin mixture stirred for a further 20 min before the addition of *N*-hydroxysuccinimide (**12**) (0.46 g, 4.0 mmol) dissolved in dimethylformamide (4 mL). The reaction was then stirred and monitored by HPLC until completion (18 h). The resin was removed by filtration, the solvent was removed in vacuo, and the final product was recrystallized from 2-propanol. Yield: 1.3 g, 3.8 mmol, 92%. ESI−MS *m*/*z*: 336.1 (calc. for M + H^+ 336.1). HPLC retention time: 6.18 min.

Synthesis of {5*S*-(Carboxymethyl-carbamoyl)-5-[5-(4-formyl-3-hydroxyphenoxy)pentanoyl Aminopentyl}trimethylammonium (Scheme 1: 3). (a) Resin derivatized with a 2-chlorotrityl linker (0.19 g, 0.19 mmol), preloaded with glycine (**2**) (substitution: 1.0

mmol/g), was added to a polypropylene syringe fitted with a polypropylene filter frit (which allowed filtration of the resin under vacuum) and washed with DMF (5 × 5 mL) to swell the resin. *N*-α-Fmoc-Lys(Me)$_3$−OH (*9*) (0.25 g, 0.57 mmol) was dissolved in DMF (5 mL) along with 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU, 0.22 g, 0.57 mmol), 1-hydroxybenzotriazole (HOBt, 0.09 g, 0.57 mmol), and *N*-methylmorpholine (NMM, 125 μL, 1.14 mmol) and mixed thoroughly for 30 s, allowing in situ formation of the acyloxyuronium intermediate. This solution was then added to the glycyl resin and left for 6 h at room temperature with gentle agitation. After washing the resin with DMF (5 × 5 mL), the coupling procedure was repeated as above. Following washing of the resin with DMF (10 × 5 mL), the *N*-α-Fmoc group of the covalently attached trimethyllysine was removed by a 15 min treatment with 20% piperidine in DMF under continuous flow, followed by further washing of the resin with DMF (10 × 5 mL).

(b) 5-(4-Formyl-3-hydroxyphenoxy)pentanoic acid **(Scheme 1: 1a)** (0.14 g, 0.57 mmol) was double coupled to the trimethyl-L-lysyl-glycyl resin, using the same HBTU/HOBt activation protocol as described for *N*-α-Fmoc-Lys(Me)$_3$−OH, differing only in the reaction time (2 × 2 h). Following washing of the resin with DMF (10 × 5 mL), a final 20% piperidine in DMF treatment was carried out, to remove any unwanted ester that may have formed by reaction of the phenolic hydroxyl group with activated acid species, followed by a further DMF wash (10 × 5 mL).

(c) Final cleavage from the resin was performed by 5 × 5 min treatments of the peptidyl resin with 5% trifluoroacetic acid in dichloromethane (40 mL/g). The spent resin was removed by filtration and the pooled filtrate was concentrated by sparging with nitrogen. The crude product was precipitated and washed with cold methyl *tert*-butyl ether, before being redissolved in 30% aq. acetonitrile and lyophilized. The crude residue was purified by semipreparative RP-HPLC and the pure fractions were pooled and lyophilized to yield **3** (yield 35 mg, 0.075 mmol, 39%; HPLC retention time: 3.75 min). ^{1}H NMR (500 MHz, d_6-DMSO at 300 K): δ 1.21−1.75 (m, $OCH_2CH_2CH_2$ + $OCH_2CH_2CH_2$ + $NHCHCH_2CH_2$ + $NHCHCH_2CH_2$ + $(CH_3)_3N^+CH_2CH_2$, 10H), 2.19 (t, J = 7.20 Hz, CH_2CH_2CO, 2H), 3.01 (s, $CH_2N^+(CH_3)_3$, 9H), 3.19−3.24 (m, $CH_2N^+(CH_3)_3$, 2H), 3.66−3.80 (m, $NHCH_2$-CO, 2H), 4.02 (t, J = 6.10 Hz, OCH_2CH_2, 2H), 4.33 (m, $NHCHCH_2$, 1H), 6.46 (d, J = 2.30 Hz, $HOCCHCOCH_2$, 1H), 6.54 (dd, J = 2.25, 8.60 Hz, $CHCHCOCH_2$, 1H), 7.59 (d, J = 8.75 Hz, $CHCHCOCH_2$, 1H), 8.02 (d, J = 8.30 Hz, $NHCHCH_2$, 1H), 8.24 (t, J = 5.80 Hz, $NHCH_2CO$,-1H), 9.98 (s, *CH*O, 1H), 11.04 (s, *H*O, 1H), 12.30−12.80 (bs, COO*H*, 1H); calculated accurate mass for $C_{23}H_{36}N_3O_7$ (M^+): 466.2548, observed mass 466.2551 (+0.77 ppm).



Synthesis of {5*S*-(Carboxymethylcarbamoyl)-5-[5-(4-formyl-3-hydroxyphenoxy)pentanoylamino] pentyl}trifluoroacetic Acid (Scheme 1: 6). Synthesis of **(6)** was carried out in an analogous manner to **(3)** except that *N*-α-Fmoc-Lys(Tfa)−OH **(10)** was used in place of *N*-α-Fmoc-Lys(Me)$_3$−OH **(9)** (see above) (yield 49 mg, 0.095 mmol, 32%; HPLC retention time: 5.12 min). ^{1}H NMR (500 MHz, d_6-DMSO at 300 K): δ 1.20−1.70 (m, $OCH_2CH_2CH_2$ + $OCH_2CH_2CH_2$ + $NHCHCH_2CH_2$ + $NHCHCH_2CH_2$ + $CF_3CONHCH_2CH_2$, 10H), 2.15 (m, CH_2CH_2CO, 2H), 3.12 (m, $CH_2NHCOCF_3$, 2H), 3.65−3.78 (m, $NHCH_2CO$, 2H), 4.00 (t, J = 6.10 Hz, OCH_2CH_2, 2H), 4.27 (m, $NHCHCH_2$, 1H), 6.44 (d, J = 2.30 Hz, $HOCCH$-$COCH_2$, 1H), 6.53 (dd, J = 2.30, 8.70 Hz, $CHCHCOCH_2$, 1H), 7.58 (d, J = 8.75 Hz, $CHCHCOCH_2$, 1H), 7.93 (d, J = 8.25 Hz, $NHCHCH_2$, 1H), 8.17 (t, J = 5.90 Hz, $NHCH_2$-CO,1H), 9.37 (t, J = 5.50 Hz, $CH_2NHCOCF_3$,1H), 9.97 (s, *CH*O, 1H), 10.97 (s, *H*O, 1H), 12.51 (s, COO*H*, 1H); calculated accurate mass for $C_{22}H_{28}N_3O_8F_3$ (MNa^+): 542.1721, observed mass 542.1712 (−1.62 ppm).

Preparation of {5*S*-[(2,5-Dioxopyrrolidin-1-yloxycarbonylmethyl)carbamoyl]-5-[5-(4-formyl-3-hydroxyphenoxy)pentanoylamino]pentyl}trimethylammonium (Scheme 1: 4). Compound **3** (35 mg, 0.075 mmol) was dissolved in DMF (2 mL) and added to a stirred solution of PS-carbodiimide (**11**) (288 mg, 0.375 mmol) in DCM (10 mL). The mixture was stirred for 20 min before the addition of *N*-hydroxysuccinimide (**12**) (9 mg, 0.075 mmol) in DMF (1 mL). The reaction was then stirred at room temperature and monitored by HPLC until completion (5 h). The resin was removed by filtration, the solvent was removed in vacuo, and the compound was used without further purification (yield 38 mg, 0.068 mmol, 90%; HPLC retention time: 4.16 min). Calculated accurate mass for $C_{27}H_{39}N_4O_9$ (M^+): 563.2712, observed mass 563.2721 (+1.70 ppm).

[2S-[5-(4-Formyl-3-hydroxyphenoxy)pentanoylamino]-6-(2,2,2-trifluoroace tylamino)hexanoylamino]-acetic Acid 2,5-dioxopyrrolinin-1-yl Ester (Scheme 1: 7). Synthesis of **7** was carried out in an analogous manner to **4** except that **6** was used as the starting material (see above). The product was used without further purification (yield 55 mg, 0.089 mmol, 93%; HPLC retention time: 5.64 min). Accurate calculated mass for $C_{26}H_{31}N_4O_{10}F_3$ (MNa^+): 639.1884, observed mass 639.1885 (+0.07 ppm).

Synthesis of Oxytocin Analogue (Scheme 1: 13). The oxytocin analogue Acetyl-CYIQNCPLGK($COCH_2$-$CH_2CONHNH_2$)−NH_2 was synthesized manually using the Fmoc/*t*Bu protection strategy on TGR resin (0.25 g, 0.05 mmol, substitution: 0.2 mmol/g; Merck Biosciences). Coupling of the Fmoc amino acids was accomplished with an HBTU/HOBt method using DMF as the solvent, using 3 eq. of amino acid and coupling reagents with respect to the loading of the resin. The Fmoc group was removed by a 15-min treatment with 20% piperidine in DMF. The C-terminal lysine residue was introduced with Dde side-chain protection to allow orthogonal deprotection at a later stage in the synthesis. After Fmoc deprotection of the final residue, the N-terminus was acetylated using acetic anhydride (48 μL, 0.5 mmol) and diisopropylethylamine (43 μL, 0.25 mmol) in DMF for 2 h and the Dde protection of the lysine side chain was removed with 2% hydrazine in DMF for 15 min. The free amine of the lysine side chain was extended by reaction with succinic anhydride (50 mg, 0.5 mmol) and diisopropylethylamine (43 μL, 0.25 mmol) in DMF for 2 h and then hydrazine, coupled as a 10% solution in DMF using HBTU/ HOBt (in excess) for 3 h (A more efficient method to incorporate the hydrazide functionality has since been developed and involves the use of Boc-$NHNHCO(CH_2)_2COOH$ introduced onto the *N*-ϵ amine of lysine, using the HBTU/ HOBt protocols already described.). Final cleavage of the peptide from the resin was performed with 92.5% trifluoroacetic acid/2.5% triisopropylsilane/2.5% water/2.5% ethanedithiol (40 mL/g resin) for 75 min. The resin was removed by filtration and the filtrate was concentrated by sparging with nitrogen. The crude product was precipitated and washed with cold methyl *tert*-butyl ether (3 × 50 mL), before being redissolved in 50% (aq.) acetonitrile and lyophilized. The peptide was redissolved in ammonium bicarbonate (0.1 M, pH 8) to a concentration of 100 μM and oxidized using hydrogen peroxide (1.5

Scheme 2. Conjugation of Oxytocin Hydrazide or Biotin Hydrazide to a Wide Range of Protein Carriers

(i) 0.1 M sodium formate pH 4.5/DMSO. (ii) Dialysis.

eq) for 45 min. The reaction was monitored by LC−MS and by reaction with Ellman's reagent and was finally quenched with 10% (aq.) acetic acid (in excess). The mixture was lyophilized once more and the desired product was purified by semipreparative RP-HPLC (yield 24 mg, 0.019 mmol, 37%), ESI−MS *m/z*: 1291.3 (calc. for M + H^+ 1291.5), HPLC retention time 3.44 min.

General Method for Preparation of Linker-modified Proteins 1c, 5a−j, and 8. Aprotonin (cat # A4520), Hen egg-white lysozyme (HEWL; cat # L6876), carbonic anhydrase (cat # C2273), ovalbumin (OVA; cat # A7642), bovine serum albumin (BSA; cat # A7638), apo-transferrin (cat # T4382); holo-transferrin (cat #T4132); phosphorylase B (cat # P4649), β-galactosidase (β-gal; cat # G8511), and myosin (MYO; cat # M3889) were obtained from Sigma and made up to 1 mg/mL in either 0.1 M sodium acetate, pH 7.25, or 50 mM potassium phosphate, pH 9.3. The reactive amine concentration for each protein sample was determined and these data used as the basis for determining the reactive amine stoichiometry for each protein.

A fivefold excess over reactive amine content of **1b**, **4**, or **7** (from a 10 mM stock in DMSO) was added to an aliquot (200 μL) of each protein sample and the reactions were incubated at room temperature for 1−3 h followed by overnight incubation in the fridge (∼8 °C). Each reaction mixture was dialyzed against three changes of 1800 mL of either 10 mM ammonium bicarbonate, pH 8; 10 mM sodium acetate, pH 7.25; or 0.1 M sodium formate, pH 4.0, for 2 h, depending upon the desired application. The samples were recovered and stored in the fridge until required and, where necessary, were analyzed by SDS−PAGE.

General Method for Preparation of Protein Conjugates 13a and 14a−j (Scheme 2). A 5 molar excess of either oxytocin−hydrazide (**13**) or biotin−hydrazide **(14)** (Fluka cat # 14403; from a 10 mM stock in DMSO) over the reactive lysine content in the protein was added to the sodium formate dialyzed samples of each of the linker-derivatized proteins **5a−e** and **5h−j**. The DMSO concentration was then adjusted to 10−40% (depending upon the protein being used) and the samples were incubated at room temperature for 2−4 h and then stored overnight in the fridge (∼8 °C).

Since compounds **14f** and **14g** had been previously dialyzed into 50 mM potassium phosphate; pH 9.0 buffer, both compounds were mixed with equal volumes of 0.2 M sodium formate, pH 4.0, to obtain pH 4.5 for the conjugation reaction. The samples were then reacted with a 5 M excess of biotin−hydrazide, as above, at room temperature for 2 h and then overnight at ∼8 °C. After incubation, the reaction mixtures were recovered and each was dialyzed against 4 L of either 20 mM sodium acetate, pH 7.4, or 10 mM ammonium bicarbonate, pH 8, for 2 h at room temperature. The samples were recovered and stored in the fridge for further analysis.

Preparation of HBV Core Delta Ag-linker-Biotin Conjugate (14k). Recombinant HBV core delta Ag, strain ayw, was purchased from Advanced ImmunoChemical Inc., Long Beach, CA. To 75μL of a 1 mg/mL solution of HBVcore delta Ag was added 7.5 μL 0.5 M sodium phosphate, pH 9.3. The sample was mixed and, from this pool, an aliquot (55 μL) was removed and 5.5 μL of **4** (10 mM in DMSO) was added to it. The sample was then mixed again by pipetting and incubated at room temperature for 2 h to give linker-protein **5k**. After this incubation period, a further 27.5 μL was removed and 2 μL 2.65 M formic acid was added to the sample. The sample was mixed, 1.37 μL of 10 mM biotin−hydrazide was added, and the sample was incubated at room temperature for 60 min and then overnight at ∼8 °C. The protein samples were analyzed without dialysis.

Solubility Measurements of BSA-linker Constructs (1c, 5a, and 8). For measurement of solubility at pH 8, aliquots (1 mL) of the BSA-linker constructs **1c**, **5a**, and **8** in ammonium bicarbonate buffer were concentrated to approximately a fifth of their original volume by diafiltration and the protein concentration was determined. The concentration of constructs **1c** and **5a** was adjusted to 5 mg/mL while the concentration of construct

8 was adjusted to 4 mg/mL. Aliquots (40 μL) of each solution were transferred into the wells (in triplicate) of a 384-well microtiter plate and the samples were double diluted to produce a dilution series. The samples were allowed to equilibrate for 30 min at room temperature before the turbidity was measured at 650 nm. For measurement of solubility at pH 4.5, aliquots (1 mL) of the BSA-linker constructs in ammonium bicarbonate buffer were diafiltered for six cycles into 0.1 M sodium formate buffer, pH 4.5, and turbidity measurements were carried out as described above.

Monitoring the Conjugation of Biotin-hydrazide (14) to 5a and 5b. To an aliquot (100 μL) of ~1 mg/mL **5a** and **5b** in 0.1 M sodium formate, pH 4.5, was added 100 μL 10 mM biotin−hydrazide in 100 mM sodium formate, pH 4.5. The sample was mixed and then split into two 100 μL aliquots; one portion was used for collection of the absorption spectra and the other portion was used for concomitant sampling. These aliquots were quenched in sample-loading buffer (Invitrogen) followed by snap freezing in dry ice. Samples were stored at −20 °C and thawed as required prior to analysis by ELISA, SDS−PAGE, and Western blot.

ELISA Analysis of 14a and 14b. The enzyme-linked immunosorbent assays (ELISAs) of **14a** and **14b** were carried out as follows. Aliquots (1 μL) of each of the quenched samples were diluted into 500 μL 10 mM phosphate buffered saline (PBS; Sigma) and 100 μL of this was dispensed into a 96-well Immulon 2HB microtiter plate (Thermo Life Sciences, Basingstoke, United Kingdom). The plate was covered and incubated at 37 °C for 60 min, after which it was washed three times with 200 μL of PBS-Tween 20 (PBST). The wells were blocked by the addition of 100 μL PBST containing 1% (w/v) BSA followed by incubation at 37 °C for 60 min. The plate was washed as before, 100 μL of 1-in-5000 dilution of ExtrAvidin-HRP conjugate (Sigma) in PBST added to each well and incubated at 37 °C for 30 min. The plate was recovered and washed as before, was dried by shaking, and 100 μL OPD reagent (Sigma) was added to each well. The color was allowed to develop by eye; the reaction was stopped by addition of 100 μL 0.1 M sulfuric acid and the plates read at 492 nm.

General Method for Acid-catalyzed Cleavage of Hydrazone Bond. The acid-catalyzed release of the ligand, via cleavage of the hydrazone bond, was carried out by addition of HCl to a final concentration of 1 M. This was routinely facilitated by either addition of concentrated HCl or addition of an equal volume of 2 M HCl to an aliquot of sample.

RESULTS

Synthesis and Characterization of Linkers. Synthesis of the oxytocin analogue **13** and the linkers **1a**, **3,** and **6** proceeded smoothly using standard solution chemistry and Fmoc solid-phase techniques (*22*), to provide the desired compounds in good yield and purity. The linkers were stored as the free acids and the activated succinimidyl ester of the linkers (**1b**, **4**, and **7**) were freshly prepared when required.

The utilization of 2-hydroxybenzaldehyde within the linker provided a moiety that exhibited a pH-dependent change in its absorbance spectrum (Figure 1). The change in absorbance spectra as a function of pH produced three distinct regions of change with isosbestic points at 255 and 333 nm. The pK_a and wavelength maxima for the absorbance transitions were measured as 7.7 at 280 nm, 7.8 at 316 nm, and 8.3 at 364 nm (Figure 1 inset). Of

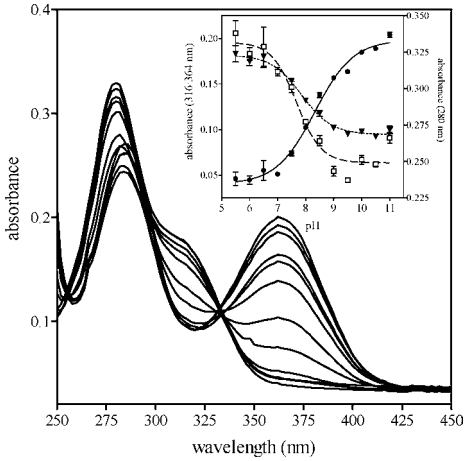


Figure 1. UV absorbance spectra of **3** (100 μM) as a function of pH. Spectra were collected with 100 μL of sample in 50 mM potassium phosphate buffer using Spectra 96-well plates. Inset: plot of the absorbance values versus pH at 280 nm (□), 316 nm (▼), and 364 nm (●). The lines represent sigmoidal fits to a single pK_a.

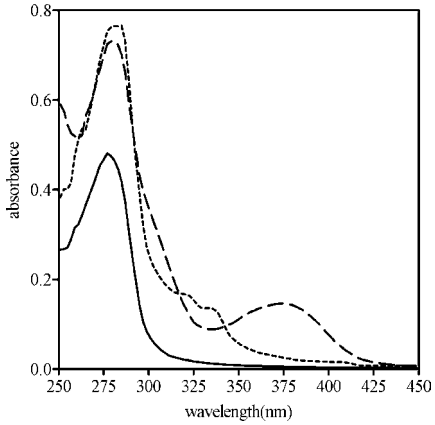

Figure 2. UV/visible absorbance spectra of 0.9 mg/mL BSA (solid line) and **5a** in 50 mM potassium phosphate, pH 9.5 (long-dashed line) and 0.1 M sodium formate, pH 4.0 (short-dashed line). Absorbance spectra were collected in 1-mL quartz cuvettes and background corrected using the respective buffers. Only one spectrum for BSA is presented since the spectra were superimposed in both buffers.

these absorbance transitions, the change at 364 nm proved to be the most accurate since the transitions at the other wavelengths were accompanied by spectral shifts. In 50 mM potassium phosphate, pH 10, compound **3** had a maximum extinction coefficient of 4685 $M^{-1}cm^{-1}$ at 364 nm ($\epsilon_{364\ nm}$ 4685 $M^{-1}cm^{-1}$), which routinely enabled as low as 5−10 μM of the linker to be quantified spectrophotometrically. Quantification could also be carried out in microtiter plates, making the system amenable to high throughput applications. Additionally, since proteins in general do not have any significant absorbance above 300 nm, this region of the spectrum also proved useful for quantification of the linker when covalently attached to a protein. Derivatization of BSA to produce linker-derivatized BSA (**5a**) demonstrated that linker loading could be quantified in situ without sample destruction (Figure 2). Although in most cases it was observed that, upon covalent attachment of **3** (*via* active ester **4**) to protein, the visible region absorbance maxima did not change significantly, in some cases slight shifts were observed (Figures 1 and 2). In all cases the extinction coefficient determined for compound **3** was used to calculate the protein-bound linker concentration. It was found that these calculated values were in good agree-

ment with titrations carried out for amine determination before and after linker derivatization. The novel linker **3** therefore provided a method for the nondestructive in situ quantification of linker loading of proteins, afforded by a simple change in buffer pH.

Derivatization of Proteins with Linker 3. To exemplify the practical applications of the linker for protein conjugation, in particular amine functionalization, the acid form of the linker **3** was activated to produce the active ester **4**. Although the NHS ester was used to exemplify much of the protein work, because of its favorable solubility properties, we found application of the pentafluorophenol (Pfp) ester to be comparable. Compound **4** was applied to a wide variety of proteins from viral, bacterial, plant, and animal sources ranging in molecular weight form from ∼6 to ∼300 kDa. Upon reaction, most of the proteins displayed slightly diffuse bands, most likely due to heterogeneous labeling of surface amines. In most cases the protein SDS−PAGE migration of the derivatized proteins were similar to the native proteins. Of the proteins tested, only phosphorylase B (∼97 kDa) and myosin (∼205 kDa) displayed a significant change in electrophoretic mobility upon derivatization, with derivatized phosphorylase B (**5h**) migrating significantly faster (∼60 kDa) and derivatized myosin (**5j**) migrating as a broad diffuse band (Figure 3). Dimeric (homo-) and multimeric (homo- and hetero-) proteins have also being derivatized using **4**, with varying results depending on the protein. In some cases the proteins did not migrate any differently to the underivatized proteins as judged by SDS−PAGE, whereas in other cases, especially with heteromultimeric proteins, marked differences were observed (data not shown). Similarly, an analysis of the native molecular weights of linker-derivatized proteins, as judged by gel permeation chromatography and native-PAGE, produced analogous trends in that linker-derivatized monomeric proteins generally displayed little or no change whereas multimeric proteins varied in their elution profile (data not shown). Once again, depending on the protein, HPLC analysis produced somewhat similar results. Nevertheless, in all cases the amount of conjugated linker could be quantified spectrophotometrically, even with proteins that had a significant UV/visible absorbance (e.g., holo-transferrin). Since the amount of linker could be quantified and related to the changes in migration or elution profiles, the extent of linker conjugation could easily be modified to optimize linker loading and yet minimize protein denaturation.

Elaboration of Linker-derivatized Proteins. During the characterization of the absorbance spectra of test samples, we observed marked differences between the spectra of a protein alone, a linker-derivatized protein (Figure 2) and a linker-hydrazone-protein conjugate (Figure 4A). Further investigation revealed that treatment of linker-derivatized proteins (e.g., BSA and aprotinin constructs **5a** and **5b**) with biotin−hydrazide (**14**), providing protein conjugates **14a** and **14b**, resulted in an increase in the absorbance spectra between ∼295 nm and ∼350 nm, with the maximum change being observed at 324 nm (Figure 4A).

To verify whether the absorbance changes were due to hydrazone formation, as a result of the reaction of biotin−hydrazide (**14**) with the aldehyde moiety of the linker, concomitant analysis of the reaction mixtures by absorbance, ELISA, SDS−PAGE, and Western blot were carried out (Figures 5, 6A, and 6B). The results clearly showed that as the absorbance at 324 nm increased (Figures 4A and 4B), the amount of biotin detected also increased (Figures 5 and 6B). Additionally the relative differences between the absorbance changes for the BSA **(5a)** and aprotinin **(5b)** samples were reflected in the final relative amounts of biotin detected (Figure 5). Additionally, the BSA and aprotinin samples were co-loaded onto the SDS−PAGE/Western blot gels to directly compare and relate the data to that from the ELISA analysis. It was clear that the observed absorbance

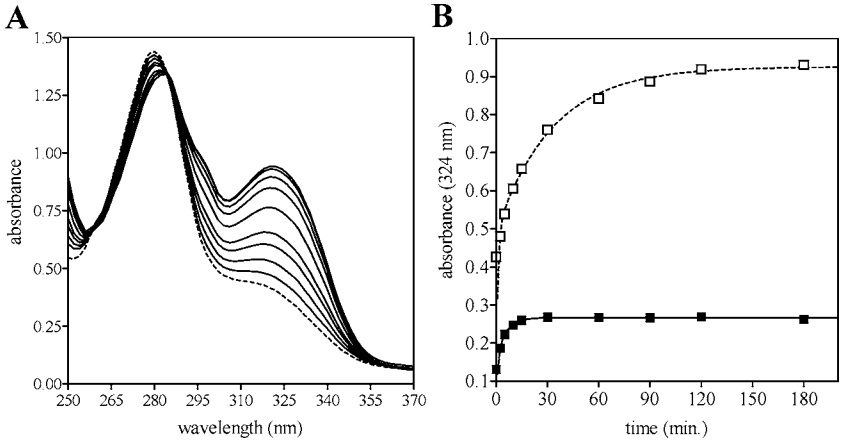

Figure 4. A: Time dependent change in UV/visible absorbance spectra of **5a** upon reaction with biotin−hydrazide (**14**) in 100 mM sodium formate, pH 4.0. **B**: Increase in absorbance at 324 nm while monitoring reaction of biotin−hydrazide (**14**) with **5a** (□) and **5b** (■). The solid lines represent nonlinear regression fits using two-phase exponential analysis.

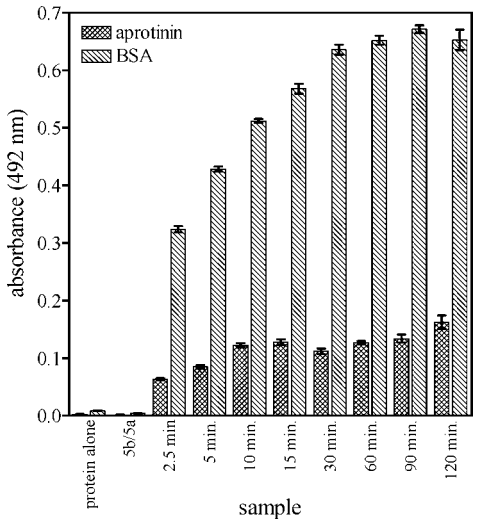

Figure 5. ELISA data for time-dependent elaboration of **5a** and **5b** with biotin−hydrazide (**14**). The respective samples as described in Figures 4 and 6 were used for this analysis.

changes upon addition of biotin hydrazide (**14**) to **5a** and **5b** were due to hydrazone formation (Analogous observations were also made when other linker-derivatized proteins were treated with a wide range of hydrazides (e.g., peptide−hydrazides, acetic acid hydrazide, BODIPY-hydrazide, etc.)). A repeat of the biotin conjugation reaction on a range of protein samples, followed by analysis by ELISA, SDS−PAGE, and Western blot (Figure 7), demonstrated that the conjugation chemistry was reproducible and that the hydrazone linkage was stable not only to the prolonged procedures associated with these protocols, but also to extensive dilution associated with the copious washing cycles. Thus, UV monitoring of the novel linker protein-bound constructs **5a**−**k** has provided a nondestructive real-time in situ method to follow the formation of the hydrazone bond during ligand conjugation processes.

The Effect of Positive-charged Linker (3) on Conjugate Solubility. Based on the hypothesis that charge balancing would enable relatively higher linker loading with the maintenance of conjugate solubility, one aspect of the design of the novel linker **(3)** was to incorporate a quaternary amine as a means to compensate for the loss of charge upon derivatization of the surface accessible amines, in particular the *N*-ϵ-amines of lysine residues. On this basis, the ability of the quarternary ammonium moiety of **3** to enhance the water solubility of protein conjugates, was tested along with comparable noncharged linkers (**1a** and **6**). With linker **1a**, it was not possible to obtain more than 55% loading (100% surface loading was determined by Fluram titration and equated to 22 mol amine per mol of diafiltered BSA (cat# A7638, Sigma) protein.) of BSA without catastrophic precipitation of the linker-derivatized product (**1c**$^{55\%}$) even with large-scale dilution, changing the buffer composition, or adding organic solvent (e.g., DMSO). A loading of 85% was possible with linker **6**, providing protein construct **8**, and this product could be solubilized by dilution or a change in buffer composition. An 85% loading of BSA was also achievable with linker **3**, providing protein construct **5a**, but with the added benefit of a superior solubility profile over the pH range tested (Figures 8A and 8B). Similarly, when **1c**$^{55\%}$, **5a**$^{85\%}$, and **8**$^{85\%}$ were elaborated with oxytocin−hydrazide (**13**), the conjugate **13a** was found to be the most soluble in PBS (data not shown).

Monitoring the Reversibility of the Hydrazone Bond. Having already established that conjugation of hydrazide derivatives to protein modified with novel linker **3** resulted in an absorbance change, we sought to use the same absorbance-based monitoring to assess the chemical reversibility of the reaction. This was demonstrated by treatment of conjugate **13a** with acid (1 M HCl final), which resulted in a return of the absorbance spectra to that observed prior to hydrazone formation, along with the concomitant release of ligand (**13**) from the protein conjugate. This time dependent release of the intact disulfide loop peptide (i.e., oxytocin−hydrazide (**13**)) could be spectrophotometrically monitored and the released product characterized by HPLC and mass spectrometry (Figure 9). Although the treatment with 1 N hydrochloric acid may be considered too harsh for more

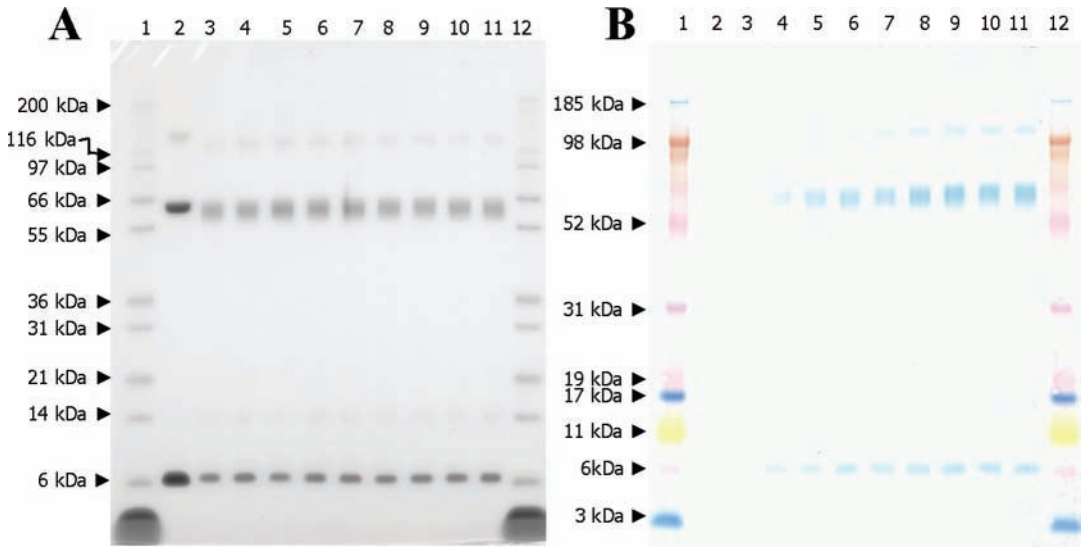

Figure 6. Concomitant SDS−PAGE (**A**) and Western blot (**B**) for time-dependent elaboration of **5a** and **5b** with biotin−hydrazide (**14**) as described in Figures 4 and 5. To directly compare the Western blot band intensities, the BSA and Aprotinin conjugates **14a** and **14b** were coloaded onto each of the gels. Lane 1 and 12: Mark 12 (SDS−PAGE) and Rainbow (Western) molecular weight markers; lane 2: untreated protein samples (BSA and Aprotinin); lane 3: **5a** and **5b** samples; lane 4: 2.5-min samples; lane 5: 5-min samples; lane 6: 10-min samples; lane 7: 15-min samples; lane 8: 30-min samples; lane 9: 60-min samples; lane 10: 90-min samples; lane 11: 120-min samples.

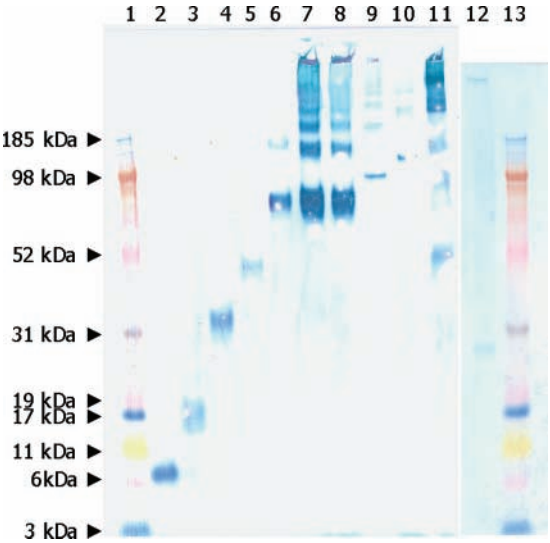

Figure 7. Western blot analysis of protein−biotin conjugates (**14a**−**k**). Lane 1 and 13, Rainbow molecular weight markers; lane 2 aprotinin−biotin (**14b**); lane 3, HEWL−biotin (**14c**); lane 4, carbonic anhydrase−biotin (**14d**); lane 5, OVA−biotin (**14e**); lane 6, BSA−biotin (**14a**); lane 7, apo-transferrin−biotin (**14f**); lane 8, holo-transferrin−biotin (**14g**); lane 9, phosphorylase B−biotin (**14h**); lane 10, β-gal−biotin (**14i**); lane 11, myosin−biotin (**14j**); lane 12, HBV core delta Ag−biotin (**14k**).

sensitive ligands and/or carriers, an added facet of the novel linker is the option to modify the acid liability by substitution within the aromatic ring (*24*−*26*). Also, since the acidolytic release feature was used simply to monitor the quality of the attached ligand, only a representative sample and not a full release of the ligand was required for analysis. A similar treatment of the conjugates **14a** and **14b** with acid (1 M HCl final) also resulted in a return of the absorbance spectra to that observed prior to hydrazone formation, along with the concomitant loss of the biotin label as judged by SDS−PAGE/Western blot analysis (data not shown).

DISCUSSION

Our initial goals in the design and synthesis of new linkage chemistry were to produce a chemoselective reagent that, when compared to existing methodologies, enabled controlled and relatively higher loading of proteins with ligands, while maintaining adequate aqueous solubility. When considering these requirements, the advantages afforded by aldehyde (*14*,*15*), benzaldehyde (*16*), and more specifically 2-hydroxybenzaldehyde (*19*) moieties as part of chemoselective reversible linkers has been well documented in the literature. However, in the first aspect of our design process, we have now demonstrated that known 2-hydroxybenzaldehyde chemistries further enable the in situ real-time spectrophotometric quantification of protein-linker formation and subsequent ligand-hydrazone formation in a nondestructive and reversible manner. The reaction monitoring is simple, is robust, and has been exemplified using a number of protein carriers and a variety of hydrazide-based ligands, illustrating the general wide utility of the process (Spectrophotometric changes upon protein−ligand interactions are known in nature; for example, enzymes that use a pyridoxal phosphate cofactor display characteristic absorbance changes associated with formation of different covalent adducts between substrate, cofactor and/or enzyme (*27*)).

In comparison to the existing nonspecific protocols of conjugation, which rely on post-reaction analysis using relatively laborious electrophoretic techniques (*11*, *12*), this simple but effective method of spectrophotometric monitoring permits fine control of the conjugation process, allowing immediate intervention to alter a reaction profile where necessary. In addition, the process is reversible under acidic conditions, thus enabling simple qualitative and quantitative quality control of the released ligand. This is particularly important, since the structural integrity of a ligand is paramount to its interaction with a target protein and any undesirable chemical modifications occurring during the conjugation process could result in a change or complete loss of recognition. These two features provide significant technical and practical advantages over the current state-of-the-art linkers.

In the second aspect of our design process, we have incorporated a quaternary amine as part of the linkage chemistry in the form of an N-ϵ-trimethyl-l-lysine residue. The incorporation of this moiety was based on the premise that linkers containing this group would compensate for the loss of protein surface charge that occurs upon derivatization of the surface amines of proteins, in particular the N-ϵ-amine of surface-exposed lysine residues. The use of quaternary amines as solubilizing agents has been well documented (*28*,*29*). One aspect of their use has been their incorporation into detergents and nondetergent solubilizing and renaturation agents (*29*).

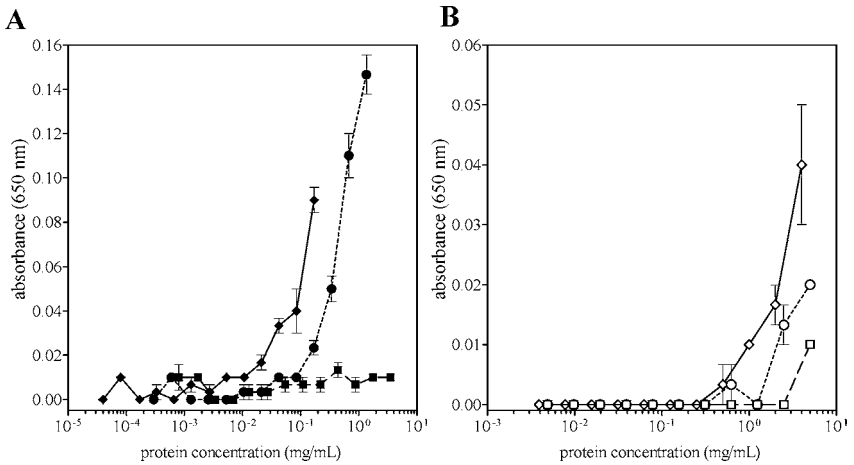

Figure 8. Relative solubility of linker-conjugated BSA samples tested in **A**: 100 mM sodium formate, pH 4.5 (left ordinate) for **5a**$^{85\%}$ (■), **1c**$^{55\%}$ (●), and **8**$^{85\%}$ (◆) and **B**: in 10 mM ammonium bicarbonate; pH 8.0 (right ordinate) for **5a**$^{85\%}$ (□), **1c**$^{55\%}$ (O), and **8**$^{85\%}$ (◇).

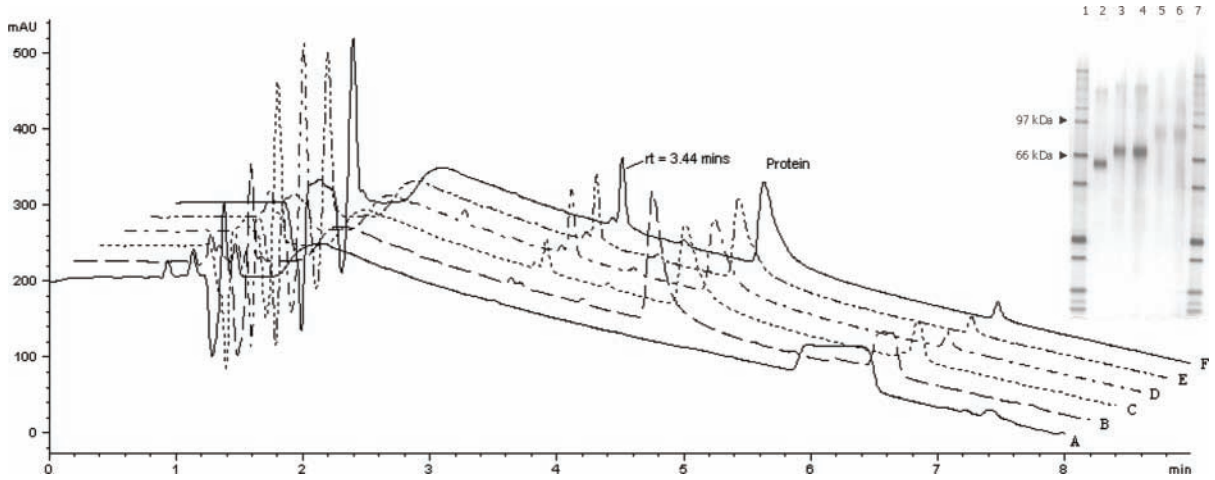

Figure 9. Time-dependent removal of oxytocin−hydrazide (**13**)from **13a**. Protein conjugate **13a** was acidified and aliquots were analyzed over time by HPLC (215 nm). The chromatograms relate to the blank buffer (negative) control (A), **13a** (positive) control (B), 15 min (C), 30 min (D), 45 min (E), and 60 min (F) incubation samples. The peak at 3.44 min was identified as free oxytocin−hydrazide (**13**) (ESI−MS *m*/*z*: 1291.3; calc. for M + H^+ 1291.5) and the inset shows the silver-stained gel of BSA (lane 2); **5a** (lanes 3 and 4) and **13a** (lanes 5 and 6).

Since protein solubility is a complex function of various factors (e.g., protein isoelectric point (p*I*), protein concentration, solvent temperature, surface accessible amino acids, solvation (hydrodynamic entropy), protein hydrophobicity, solvent pH, protein molecular weight, solvent ionic strength, protein conformation, etc.), the use of quaternary amines as protein solubilizing agents has primarily been empirical. Nevertheless, a resurgence of interest in the subject of protein solubility has been prompted by studies of protein crystallography and the underlying principles and themes have been extensively reviewed elsewhere (*30*−*33*). In relation to the role of surface-accessible lysine residues on protein solubility, various studies have been reported. For example, it has been demonstrated that chemical modification of surface lysine residues in goat serum albumin (GSA) with acetic anhydride increased the Stokes radii of the derivatized proteins, causing a change in protein conformation and a reduction in solubility (*20*). However, since acetylation of surface lysine residues by a neutral reagent would have also produced a change in surface charge, derivatization of the protein may have destabilized the native protein structure by increasing the electrostatic free energy of the protein and decreasing the favorable free energy of solvation associated with the positively charged amino acids (*20*). A major drawback to the chemical modification studies was that modifications were usually heterogeneous and uncontrolled. More recently, recombinant DNA technology, site directed mutagenesis, and protein crystallography have converged in order to better understand the criteria affecting protein solubility as a means to expedite protein crystallization. To this end, a number of studies have been carried out, not only to prevent protein precipitation but also to promote protein desolution as an aid to crystallization. For example, replacement of surface lysine with alanine in the cytosolic regulator RhoGDI resulted in a less-soluble protein, promoting protein crystallization (*34*). However, these studies were relatively focused on the production of material amenable to crystallization. Nevertheless, they show the importance of surface accessible lysine to solubility. A perhaps somewhat more comprehensive study was based on the selective replacement of glutamate and aspartate residues in ribonuclease Sa with lysine (*35*). Upon mutation, the more acidic isoelectric point for the wild-type protein (∼pH 3.5) was altered to ∼pH 6.5 for a three-lysine replacement mutant protein and ∼pH 10.2 for a five-lysine replacement mutant protein. The study concluded that the pH of minimum solubility varied with p*I* whereas the pH of maximum activity or stability did not (*35*). However, the data indicated that neither protein solubility nor the conformational stability was significantly affected by these changes. These and other studies only emphasize the difficulties in trying to rationalize the criteria that govern protein solubility other than categorizing gross effects. With this in mind we have not attempted to over-rationalize the effects of the quaternary amine on protein solubility other than to directly compare the relative solubility of conjugates using analogous linkers under the same conditions (Figures 8A and 8B). Our results clearly demonstrate that under similar conditions the quaternary amine enhances the solubility of protein-linker conjugates and, more importantly, protein-linker-carrier conjugates. We are in the process of fully characterizing the nature of this effect under a range of conditions employing an assortment of conjugates.

In summary, we have developed a chemoselective linkage technology, which enables highly loaded protein conjugates to be produced, while maintaining aqueous solubility. Spectral properties of the linker allow real-time monitoring of the conjugation reaction in situ and the reversible nature of the hydrazone bond under acidic conditions provides a simple means of quality control. This linker technology is now being used within applications such as conjugate vaccine production and the same basic design chemistry used in affinity purification strategies, micro-array design, and bio-active materials development.

Adapter Protein for Site-Specific Conjugation of Payloads for Targeted Drug Delivery

Marina V. Backer,*,† Timur I. Gaynutdinov,† Vimal Patel,† Brian T. Jehning,† Eugene Myshkin,‡ and Joseph M. Backer†

Rammelkamp Center for Research, Case Western Reserve University School of Medicine, Cleveland, Ohio 44109, and SibTech, Inc., Newington, Connecticut 06111. Received March 3, 2004; Revised Manuscript Received July 21, 2004

High-affinity interactions of two fragments of human RNase I (1−15-aa Hu-tag and 21−125-aa HuS adapter protein) can be used for assembly of targeting drug delivery complexes. In this approach, a targeting protein is expressed as a fusion protein with a 15-aa Hu-tag, while HuS is conjugated to a drug (or a drug carrier) creating a "payload" module, which is then bound noncovalently to the Hu-tag of the targeting protein. Although this approach eliminates chemical modifications of targeting proteins, the payload modules are still constructed by random cross-linking of drugs or drug carriers to an adapter protein that might lead to functional heterogeneity of the complexes. To avoid this problem, we engineered an adapter protein HuS(N88C) with an unpaired cysteine in position 88 that can be directly modified without interference with activity of assembled targeting complexes. HuS(N88C) binds Hu-tagged annexin V with K_D of 50 ± 6 nM, which is comparable to that of wild-type HuS. To demonstrate the utility of HuS(N88C) for developing uniform payload modules, we constructed a HuS(N88C)−lipid conjugate and inserted it into preformed liposomes loaded with a fluorescent dye. Targeting proteins, Hu-tagged vascular endothelial growth factor or Hu-tagged annexin V, were docked to liposomes decorated with HuS, and the assembled complexes delivered liposomes selectively to target cells.

INTRODUCTION

Efficient technology for loading drugs or drug carriers onto targeting proteins is necessary for targeted drug delivery (*1*). Currently, loading is largely based on random chemical conjugation of a cargo, such as drugs, drug carriers, or adapters for drug carriers, directly to targeting proteins. Chemical modifications of targeting proteins often damage their ability to bind to cellular targets, require expensive custom development, and yield heterogeneous preparations. To solve these problems, we have recently proposed to link a cargo to a standardized adapter protein that binds noncovalently to a docking tag engineered into a targeting protein (*2*). Our current adapter/docking tag pair is based on interactions between two fragments of human RNase I (*3*). As an adapter protein, we are using a 21−127-amino acid (aa) fragment of human RNase I, named HuS, while its N-terminal 1−15-aa fragment fused to a targeting protein serves as a docking tag, named Hu-tag. In the first application of this approach in vivo, we imaged a small mouse tumor using assembled complexes of Tc^{99m}-radiolabeled HuS and Hu-tagged vascular endothelial growth factor (*4*).

Although this approach eliminates chemical modifications of targeting proteins, assembled complexes are still structurally (and, potentially, functionally) heterogeneous because an adapter protein is still loaded via random cross-linking. Furthermore, random chemical modifications of adapter protein, particularly with large cargos such as liposomes or nanoparticles, decrease a proportion of molecules retaining full tag-binding activity. To solve these problems, we engineered an adapter protein with an unpaired cysteine in position 88, HuS(N88C), that can be directly modified without interference with activity of assembled targeting complexes. In this work, a PEGylated lipid was cross-linked to C88 in HuS(N88C), and the resulting conjugate was used to decorate liposomes (Figure 1). Hu-tagged vascular endothelial growth factor, or Hu-tagged annexin V, was docked to HuS−liposomes, and assembled complexes delivered liposomes selectively to target cells.

MATERIALS AND METHODS

Construction and Purification of Chimeric BH−RNase Mutants. Construction of chimeric $^{1-29}$B/$^{30-127}$H-RNase (BH-RNase) consisting of a 1−29 aa fragment of bovine RNase A and a 30−127 aa fragment of human RNase I has been described recently (*5*). The N88C and G68C amino acid substitutions were introduced separately in the pET29/$^{1-29}$B/$^{30-127}$H-RNase plasmid DNA by site-directed mutagenesis (Gene-Tailor site-directed mutagenesis kit, Invitrogen, Carlsbad, CA). The following primers were used for mutagenesis: 5′-TC ACT GAC TGC CGT CTT ACT TGC GGA TCC CGT T (sense, mutation underlined) and 5′-AGT AAG ACG GCA GTC AGT GAT ATG CAT AGA A (antisense) for the N88C mutation and 5′-AG AAG GTT ACC TGC AAA AAT TGC CAG GGT AAC TG (sense, mutation underlined) and 5′-ATT TTT GCA GGT AAC CTT CTC TTG GAA GCA A (antisense) for the G68C mutation. Both mutations were confirmed by sequencing. BH-RNase(G68C) and BH-RNase(N88C) were expressed in BL21(DE3) *Escherichia coli* (Novagen,

Madison, WI), refolded from inclusion bodies, and purified by ion-exchange chromatography on HiTrap SP Sepharose Fast Flow (1-mL prepacked columns, Amersham Biosciences, Piscataway, NJ) as described for BH-RNase (*5*). Free SH-groups in proteins were detected by reaction with *N*-(1-pyrene)-maleimide (Molecular Probes, Eugene, OR) as described (*6*). Briefly, *N*-(1-pyrene)-maleimide dissolved in DMSO was added to an assayed protein at the molar ratio of 10:1 and incubated for 1 h at RT (conditions yielding no modification in wild-type BH-RNase). The reaction mixture was analyzed by reverse-phase high-performance liquid chromatography (RP HPLC) on a C4 Alltech MACROSPHERE 300 5 μm column (150 mm × 4.6 mm) with elution at 0.75 mL/min with 0.1% TFA (v/v) and a linear gradient of acetonitrile (5−50% over 15 min) with detection at 216 and 340 nm.

Purification of HuS Mutants. To release 21−127-aa HuS(N88C) and HuS(G68C) proteins, the corresponding BH-RNase mutants were digested with subtilisin (Sigma, St. Louis, MD) at the protein to protease w/w ratio of 50:1. After a 1-hr digestion at 4 °C, the reactions were stopped by ice-cold TFA (a final concentration of 1%), and HuS mutants were purified by affinity chromatography on a column carrying CA-extended Hu-peptide (**CA**-KESRAKKFQRQHMDS synthesized by Genemed Synthesis, Inc., South San Francisco, CA) as described (*5*). Bound HuS mutants were eluted with 0.1 M citric acid, neutralized with 1 M Na_2HPO_4, and stored at −70 °C in small aliquots. Purified proteins were analyzed by RP HPLC on C18 Waters Nova-Pack 5 μm column (150 mm × 3.9 mm) with elution at 0.75 mL/min with 0.1% TFA (v/v) and a linear gradient of acetonitrile (5−50% over 20 min). The concentrations of HuS mutants were calculated using 216-nm integral absorption in HPLC profiles with bovine S-protein (Sigma) serving as a standard.

To obtain HuS(N88C) with a free C88 SH-group, BH-RNase(N88C) was incubated at 4 °C for 16 h in the presence of 1.5-fold molar excess of DTT and 0.5 M NDSB-221 (Novagen) followed by subtilisin digestion and affinity purification as described above. To assign the free SH group, deprotected HuS(N88C) was labeled with *N*-(1-pyrene)-maleimide (Molecular Probes) and digested with endopeptidase Arg-C (Roche) according to the manufacturer's instructions. The digest was separated on RP HPLC C4 column, and a single peak containing 87% of incorporated pyrene was collected and analyzed by electrospray mass spectrometry at Yale Cancer Center Mass Spectrometry Resources and the W. M. Keck Foundation Biotechnology Resource Laboratory (New Haven, CT).

Modification of HuS(N88C) with Poly(ethylene glycol)−α-Distearoyl Phosphatidylethanolamine−ω-maleimide (mPEG−DSPE−maleimide). Twenty milligrams of BH-RNase(N88C) was incubated at 4 °C for 16 h in the presence of 1.5-fold molar excess of DTT and 0.5 M NDSB-221 (Novagen) and then digested with subtilisin (w/w ratio of 50:1) for 2 h at 4 °C. Subtilisin digestion was stopped by ice-cold TFA (a final concentration of 1%), and the reaction mixture was loaded onto a HiTrap SP Sepharose column equilibrated with 20 mM NaOAc, 0.2 M NaCl, and 0.5% TFA. Subtilisin was completely removed from the column with 0.2 M NaCl, 20 mM NaOAc, while digested BH-RNase was eluted with 0.6 M NaCl, 20 mM NaOAc, pH 6.5. Eluted protein was incubated with mPEG−DSPE−maleimide (FW 3400, Shearwater Polymers, Huntsville, AL) at the molar protein-to-lipid ratio of 1:10 for 2 h at RT. The reaction mixture was then passed through a Hu-peptide affinity column. The mixture of HuS(N88C)−DSPE and unmodified HuS(N88C) bound to the column was eluted with 0.1 M citric acid, neutralized with 1 M Na_2HPO_4, and analyzed by RP HPLC on a Vydac Diphenyl (219TP5415) column (250 mm × 4.6 mm) with elution at 0.75 mL/min with 50 mM thriethylamine phosphate, pH 2.8, 20% 2-propanol with a linear gradient of acetonitrile (0−70% over 30 min). The eluted mixture was stored in liquid nitrogen in small aliquots.

Preparation of HuS−Liposomes. Liposomes containing 1,2-dioleoyl-s*n*-glycero-3-phosphocholine (DOPC, FW 786.15, Avanti, Alabaster, AL) and cholesterol (FW 386.7, Sigma) at the ratio of 65:35 (%) were prepared as described (2). A fluorescent dye, 8-hydroxypyrene-1,3,6-trisulfonic acid, trisodium salt (HPTS, Sigma), was added to the lipid hydration mixture at a concentration of 35 mM. Free HPTS was separated from liposomes by chromatography on Sepharose CL-4B (Sigma). The HPTS-loaded liposomes were incubated with 2.5 μM HuS(N88C)−DSPE at 37 °C for 16 h in a volume of 1 mL, and then passed again through Sepharose CL-4B column. The efficiency of HuS(N88C)−DSPE insertion was analyzed by RP HPLC on a Vydac Diphenyl (219TP5415) column (250 mm × 4.6 mm) with elution at 0.75 mL/min with 50 mM thriethylamine phosphate, pH 2.8, and 20% tetrahydrofuran with a linear gradient of acetonitrile (0−70% over 25 min). In four independent preparations, concentration of liposomal HuS(N88C) determined by RP HPLC was 2 ± 0.4 μM. The HPTS content determined fluorometrically at λ_{ex} = 485 nm/λ_{em} = 520 nm was 230 ± 30 μM. The phospholipid content was determined by the ferrithiocyanate method according to the protocol from Analytical Control Systems, Inc. (Fishers, IL). Briefly, chloroform, ferrithiocyanate reagent (23.03 g of ferric chloride hexahydrate and 30.4 g of ammonium ferrothiocynate per 1 L of water), and liposomes were mixed at vol/vol ratio of 2:2:0.1, vigorously mixed on a vortex for 60 s, and centrifuged to separate layers. Phospholipid content of the lower chloroform layer was determined by absorbance at 488 nm using DOPC as a standard. The liposomal phospholipid content was 6 ± 1.5 mM. The liposome average size of 93 nm (SD 11) at 26.3° and 105 nm (SD 14) at 35.2° was determined by DELSA 440SX (Coulter-Beckman, Miami, FL). Assembled liposomes retained the same HPTS concentration and ribonuclease activity of HuS after a 1-week storage on ice.

Construction of the pET/Hu$(G_4S)_3$ Vector. The pET29/Hu-tag vector (a derivative of the pET29a(+) bacterial expression vector, Novagen) for expressing recombinant proteins with an N-terminal Hu-peptide was described recently (*3*). To optimize the vector, a DNA fragment encoding an 8-aa linker between the Hu-tag sequence and the multiple cloning site (MCS) was replaced with a DNA fragment encoding a $(G_4S)_3$ peptide

as follows. Two single-stranded DNA fragments (synthesized by GeneLink, Thornwood, NY) were mixed in equimolar concentrations and annealed at room temperature (RT): 5′-pC GGT AGT GGT GGT GGC GGT TCA GGC GGA GGT GGC TC and 5′-pCAT GGA GCC ACC TCC GCC TGA ACC GCC ACC ACC ACT AC-C GGT AC. The annealed DNA fragment containing overhangs compatible with *Nco*I and *Kpn*I sites was ligated into *Nco*I−*Kpn*I of the pET29/Hu-tag vector. The *Kpn*I site has been destroyed then by site-directed mutagenesis (Gene-Tailor site-directed mutagenesis kit, Invitrogen) using primers: 5′- GT CAA CAC ATG GAC TCT GGT GGC GGC GGT AGT GGT GG (sense, mutation underlined) and 5′-ACC AGA GTC CAT GTG TTG ACG TTG AAA TTT TTT AGC (antisense). In the resulting pET/Hu$(G_4S)_3$ vector, an N-terminal 15-aa Hu-tag located immediately after the initiator methionine is connected to the MCS region via a $(G_4S)_3$ peptide linker.

Construction and Expression of Hu-Tagged Targeting Proteins. A 121-aa isoform of human vascular endothelial growth factor (VEGF) and human annexin V coding sequences were amplified by PCR using primers introducing *Nco*I sites (underlined) and cloned separately into the *Nco*I site of the pET/Hu$(G_4S)_3$ vector. VEGF was amplified from the pET29/Hu−VEGF plasmid (*3*) with primers 5′-CAC AAG CCA TGG CAC CCA TGG CAG AAG GAG GA (sense) and 5′-AC TAC CCA TGG TCA CCG CCT CGG CTT GTC AC (antisense). Human annexin V was amplified from the pPAP1-1.6 plasmid (kindly provided by Dr. J. Tait, University of Washington School of Medicine, Seattle, WA) with primers 5′-CAC AAG CCA TGG CAC AGG TTC TCA GAG (sense) and AC TAC CCA TGG TTA GTC ATC TTC TCC ACA GAG C (antisense). Clones with ORF correct orientations were selected by PCR using a T7-based sense primer. Both Hu-tagged proteins, Hu−VEGF and Hu−annexin, were expressed in *E. coli* strain BL21(DE3) (Novagen) grown in LB medium (Q-Biogen, Carlsbad, CA). The expression was induced by 1 mM IPTG at the optical density of 0.5−0.7 unit at 600 nm. After induction, the cultures were grown for 2 h at 37 °C with shaking at 300 rpm, then harvested by centrifugation. Hu−VEGF was refolded from inclusion bodies and purified as described (*3*). The yield of Hu−VEGF was 5 mg/L, purity was >95% by SDS−PAGE followed by SimplyBlue Safe Stain (Invitrogen), and dimer content was no less than 95% as estimated by nonreducing SDS−PAGE. Hu−annexin was expressed in a soluble cytoplasmic form and purified as described (*7*) with minor modifications. Briefly, bacterial pellets were resuspended in 50 mM Tris-HCl, 15 mM $CaCl_2$, pH 7.2, in the presence of Protease Inhibitor Cocktail Set II (Calbiochem, La Jolla, CA), then opened by sonication and centrifuged at 15 000*g* for 10 min. The pellet was resuspended in 50 mM Tris-HCl, 30 mM EDTA, pH 7.2, and centrifuged at 17 000*g* for 10 min. The supernatant containing Hu−annexin was dialyzed against 100 volumes of 20 mM Tris-HCl, pH 8.0, for 20 h. Hu−annexin was purified from the dialyzed supernatants by ion-exchange chromatography on HiTrap Q Sepharose Fast Flow (1-mL prepacked columns, Amersham). The yield of Hu−annexin was 15 mg/L, and purity was >95% by SDS−PAGE followed by SimplyBlue Safe Stain (Invitrogen). Both Hu−VEGF and Hu−annexin were stored at −70 °C in small aliquots.

Ribonuclease Activity. Ribonuclease activities of wild-type and mutant BH-RNases and reconstituted ribonuclease activities of assembled complexes were assayed as previously described (*2*, *3*, *5*, *6*). Briefly, varying amounts of RNase or preformed complex were added to a buffer containing 20 mM Tris-HCl, 100 mM NaCl, pH 7.5, 0.1 mg/mL poly C, and incubated for 5 min at RT. Ribonuclease activity was measured by 280-nm absorbance of the reaction mixtures cleared from TCA-precipitated material. One optical unit of TCA-soluble material released from poly C under these conditions was defined as one relative unit of ribonuclease activity.

HuS/Hu-tag Binding Assay. The equilibrium dissociation constant (K_D) values for complexes of HuS mutants and Hu-tagged proteins were determined as previously described (*3*, *5*, *6*). Briefly, HuS(N68C) and HuS(N88C) at final concentrations of 0.1, 0.2, or 0.3 nM were mixed separately with varying amounts of Hu−annexin. Reconstituted ribonuclease activity was measured as described above. Calculations of the K_D values were performed assuming that the initial rate of the hydrolysis is proportional to the concentration of reconstituted ribonuclease. DYNAFIT software was used for the global fitting with numeric iteration and calculation of the K_D values (*8*).

Hu-VEGF Assays. HEK293 human transformed embryonic kidney cells (CRL-1573) were from American Type Culture Collection (Rockville, MD). 293/KDR cells expressing 2.5×10^6 VEGFR-2/cell were described elsewhere (*9*). Cells were grown in DMEM with 10% fetal bovine serum (FBS), 2 mM L-glutamine, and antibiotics at 37 °C, 5% CO_2. HEK293 and 293/KDR cells were plated on 24-well plates, 17.5×10^4 cells/well, shifted to starvation medium (DMEM/0.5% FBS) 6 h later, and incubated in this medium for 16 h at 37 °C, 5% CO_2. For liposome binding experiments, cells were used directly after starvation. For VEGFR-2 autophosphorylation, cells after starvation were shifted to serum-free DMEM with 0.5 mM sodium vanadate for 20 min at 37 °C, then stimulated with Hu−VEGF for 10 min at 37° C, lysed, and analyzed by Western blotting using anti-phosphotyrosine RC20 conjugated to horseradish peroxidase (BD Transduction Labs, San Diego, CA).

Hu−Annexin Erythrocyte Binding Assay. The affinity of Hu−annexin for cell membranes with exposed phosphatidylserine was assayed by its ability to compete with FITC−annexin V (Sigma) for binding to erythrocytes as described (*7*, *10*). Briefly, 10^6 erythrocytes of stabilized human blood (4C Plus Cell Control, Beckman Coulter) were incubated with varying amounts of Hu−annexin in the presence of 5 nM FITC−annexin V in binding buffer (10 mM HEPES, pH 7.4, 136 mM NaCl, 2.5 mM $CaCl_2$) for 15 min at RT. Cells were spun down, resuspended in a binding buffer supplemented with 5 mM EDTA, and spun down again. FITC fluorescence in the supernatants was measured at $\lambda_{ex} = 485$ nm/$\lambda_{em} = 520$ nm.

RESULTS

BH-RNase(G68C) and BH-RNase(N88C) Mutants. On the basis of analysis of a 3D-structure of human RNase I (*11*), we have chosen two residues for introducing unpaired cysteines: N88 and G68. Modeling experiments with RNase I indicated that putative C68 and C88 would be oriented away from HuS domains involved in interactions with Hu-tag (Figure 2A) and therefore expected to be available for chemical cross-linking. Both mutant BH-RNases were expressed in BL21(DE3) *E. coli*, refolded from inclusion bodies, and purified to more than 95% pure proteins with yields of 22 mg/L for BH-RNase(G68C) and 45 mg/L for BH-RNase(N88C). Somewhat surprisingly, both mutants displayed decreased ribonuclease activity (Figure 2B) suggesting either subtle effects of the

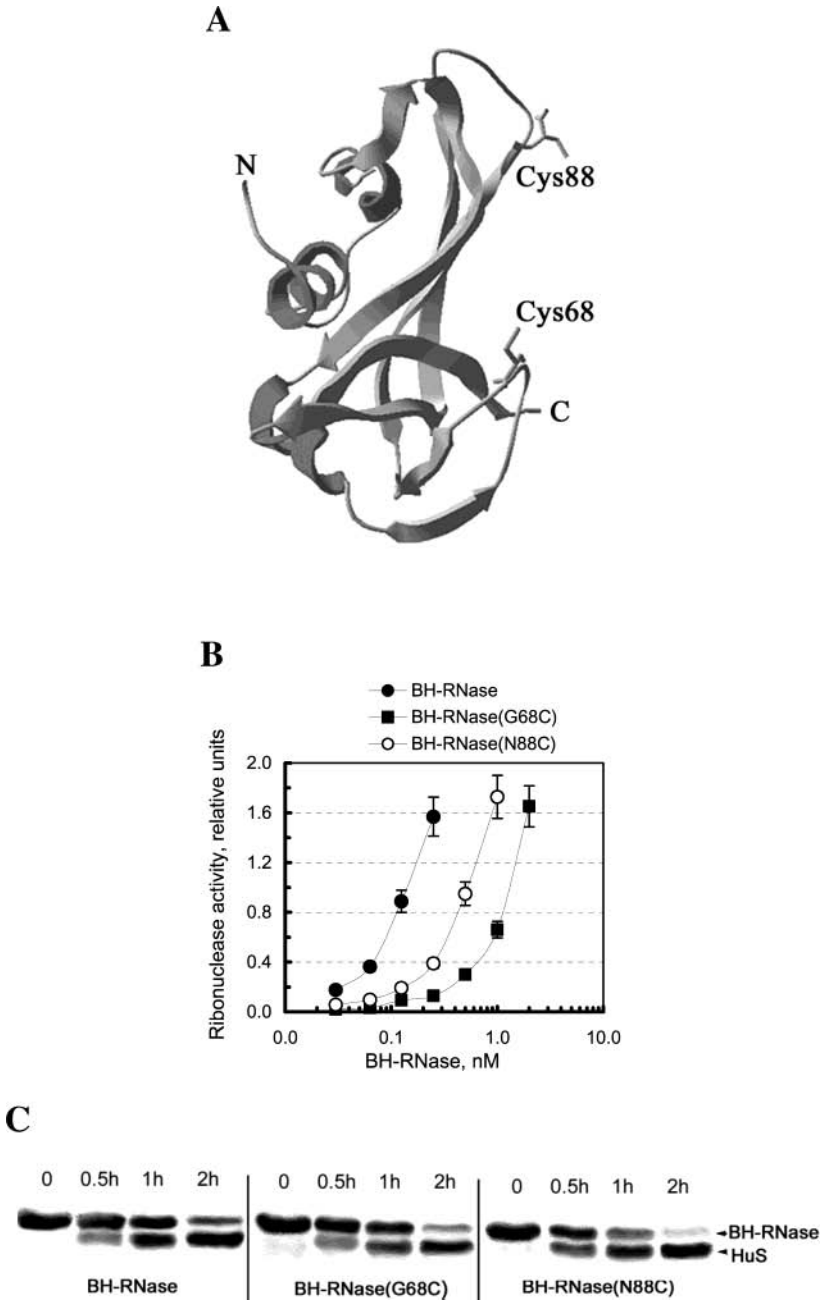

Figure 2. BH-RNase mutants with unpaired cysteines. In panel A, the backbone structure of human RNase I (1E21) is displayed with SWISS-PDB viewer. N- and C-termini and unpaired cysteines in positions 68 and 88 are indicated. Panel B presents the enzymatic activity of BH-RNase mutants. In panel C, wild-type HuS, HuS(G68C), and HuS(N88C) are released from the corresponding BH-RNases by limited digestion with subtilisin at the protease to BH-RNase w/w ratio of 1:50. Digestion reactions were incubated for 0.5, 1, and 2 h at 4 °C and analyzed then by reducing SDS−PAGE on 17.5% gels followed by Simply Blue Safe Stain (Invitrogen).

substitutions on the structure of the active center or the presence of the misfolded mutant BH-RNases in final protein preparations. However, the rates of subtilisin digestion for mutant proteins were comparable to that for wild-type BH-RNase (Figure 2C).

HuS(G68C) and HuS(N88C) Mutants. BH-RNase-(G68C) and BH-RNase(N88C) were digested with subtilisin and mutant HuS proteins were purified on a Hu-peptide affinity column as described for wild-type HuS (*5*). To characterize the affinity of purified mutant HuS proteins to Hu-peptide, we used Hu−annexin. A ribbon model of the HuS/Hu−annexin complex is shown in Figure 3A. Reconstituted ribonuclease activity in HuS/Hu−annexin mixtures was measured under conditions of equilibrium between free and bound HuS, and the data were used to calculate the equilibrium dissociation constant (K_D) values for these complexes as described (*3*, *5*, *6*). We found that affinities of HuS(G88C) and HuS-(N88C) to Hu−annexin were characterized by the K_D values of 123 ± 26 and 50 ± 6 nM, respectively (Figure 3B,C). Taking into account that BH-RNase(N88C) was recovered as a more active enzyme with a higher yield and its HuS(N88C) fragment displayed higher Hu-tag affinity comparable to that of wild-type HuS (K_D = 29 ± 3 nM (*5*)), further experiments were performed with this mutant.

Availability of C88 for Site-Specific Modification. Since BH-RNase(N88C) mutant was refolded in the presence of reduced/oxidized glutathiones (Red/Ox buffer), we have expected that an unpaired cysteine would be

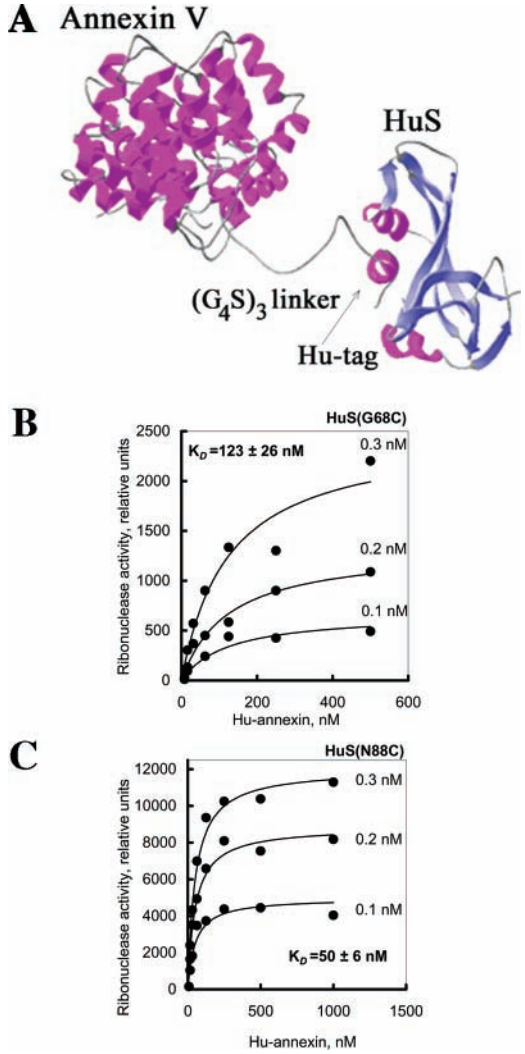

Figure 3. Affinity of HuS mutant proteins for Hu−annexin. Panel A shows the Hu−annexin/HuS complex. The Hu-peptide and $(G_4S)_3$ linker in random orientation were built using SWISS-PDB viewer and linked to the annexin V structure. The Hu−annexin/HuS complex was minimized using the SANDER module of the AMBER software package. Panels B and C show the affinity of HuS/Hu-tag interactions. Fixed amounts (0.1, 0.2, and 0.3 nM) of HuS(G68C) mutant (B) and HuS(N88C) mutant (C) were mixed separately with varying amounts of Hu−annexin. The K_D values for the resulting complexes were calculated as described (*5, 6*).

involved in a mixed disulfide with glutathione. Mixed disulfides were reported for other recombinant proteins with odd numbers of cysteines refolded in Red/Ox buffers including a mutant bovine S-protein with an engineered cysteine in position 122 (*6, 12*). Indeed, modification of freshly isolated BH-RNase(N88C) mutant protein with a sulfhydryl-directed reagent *N*-(1-pyrene)-maleimide indicated that only a fraction of unpaired cysteines was accessible for modification, varying from 5% to 35% in different preparations of BH-RNase(N88C). However, after a mild DTT treatment of BH-RNase(N88C) that did not affect RNase activity (1.5-fold molar excess DTT at 4 °C in the presence of 0.5 M NDSB-221 to prevent protein aggregation), the fraction of unpaired cysteines accessible for pyrene modification reached 95−98% indicating release from mixed disulfide (data not shown). To establish the position of a cysteine with a free SH-group, pyrene-modified HuS(N88C) was digested with endoproteinase Arg-C, and the digest was fractionated by RP HPLC. The major pyrene-containing peak (87% of incorporated pyrene) was found to be a single peptide with a mass of 951.43 as provided by electrospray mass spectrometric analysis. This mass corresponded to the theoretical mass of the expected peptide, Leu_{86}-Thr-Cys-(*N*-1-pyrene)-Gly-Ser-Arg_{92} (933.43 kDa) containing C88 modified with pyrene. The remaining pyrene (13%) was incorporated in several minor peaks that were not further analyzed.

Site-Specific Modification of HuS(N88C). To demonstrate utility of HuS(N88C) for developing uniform "payload" modules, we constructed a HuS(N88C)−lipid conjugate and inserted it into HPTS-loaded liposomes. Site-directed modification of C88 with mPEG−DSPE−maleimide included several steps. First, BH-RNase-(N88C) was "deprotected" from mixed disulfides (as described above). Second, it was cleaved with subtilisin, and subtilisin was removed from the reaction mixture by ion-exchange chromatography on an SP-column. Third, digested BH-RNase(N88C) was modified with mPEG−DSPE−maleimide, and the final product was purified on Hu-peptide affinity column (Figure 4A). The latter step removed undigested BH-RNase(N88C) and yielded a mixture of HuS(N88C)−DSPE conjugate and unmodified HuS(N88C). The extent of lipid modification of HuS-(N88C) eluted from affinity column varied from 70% to 85% as judged by RP HPLC analysis (Figure 4B). Two peaks of HuS−DSPE eluted at 23 and 23.6 min were products of conjugation with two forms of mPEG−DSPE−maleimide that are initially present in the reagent and the traces of which, eluted at 25 and 25.6 min, are still detectable in purified HuS−DSPE (Figure 4B). The mixture of HuS(N88C) and HuS(N88C)−DSPE conjugate retained the same ribonuclease activity after several months of storage in liquid nitrogen (data not shown).

For insertion in HPTS-loaded liposomes, the mixture of HuS(N88C)−DSPE conjugate and HuS(N88C) was incubated with liposomes for 16 h at 37 °C, followed by purification on Sepharose 4B and characterization of the size and composition as described in Materials and Methods. The efficiency of HuS(N88C)−DSPE insertion was determined by RP HPLC analysis of purified liposomes (Figure 4C, note that the RP HPLC system is different from the one described in Figure 4B; the peak eluted at 24 min corresponds to liposomal lipids). Based on this analysis, the amount of inserted HuS(N88C)−DSPE varied from 80% to 95% from experiment to experiment.

Hu-Tagged Targeting Proteins. The pET29/Hu-tag vector for bacterial expression of recombinant proteins with an N-terminal Hu-tag has been described recently (*3*). In the new pET$(G_4S)_3$Hu vector constructed for this work, a random 8-aa linker connecting Hu-tag and MCS region of the pET29/Hu-tag vector has been replaced with a standard $(G_4S)_3$ linker designed for fusion of heavy and light chains of monoclonal antibodies (*13*) and widely used since then for construction of single-chain recombinant antibodies (*14, 15*). Using the pET$(G_4S)_3$Hu vector, we have expressed two targeting proteins, Hu−VEGF and Hu−annexin.

Functional activity of Hu−annexin was determined as its ability to compete with FITC−annexin for binding to phosphatidylserine-displaying erythrocytes of stabilized human blood (*7*). In this assay, annexin is bound to erythrocytes in the presence of Ca^{2+} and released in the presence of EDTA. We found that Hu−annexin displaced FITC−annexin in a dose-dependent manner with IC_{50} of 11 ± 3 nM (Figure 5A). Since correct size recombinant

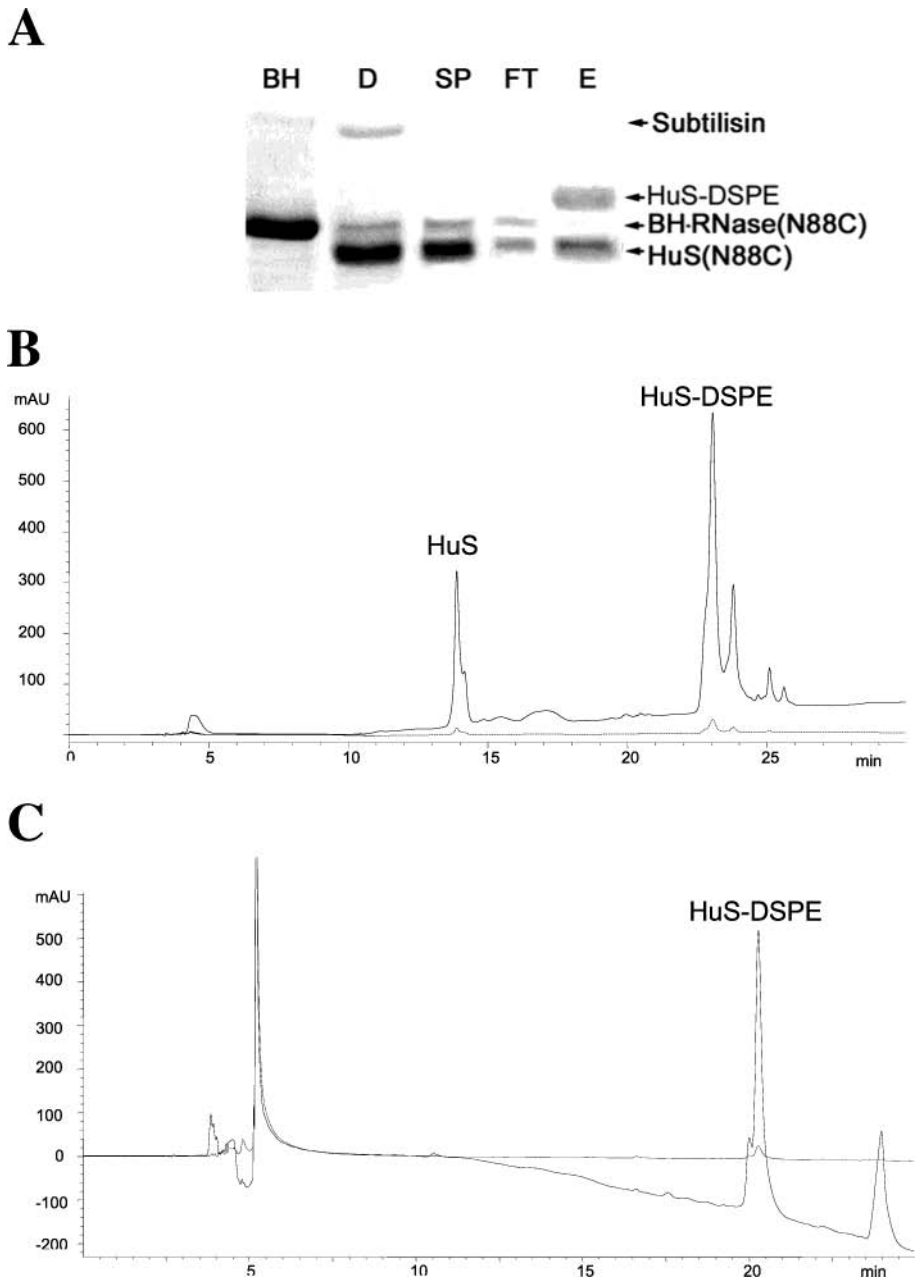

Figure 4. HuS88C−DPDE cross-linking and insertion into liposomes. Panel A shows SDS−PAGE analysis of HuS(N88C)−DSPE conjugate synthesis and purification: lane BH, BH-RNase(N88C); lane D, digestion of BH-RNase(N88C) with subtilisin; lane SP, SP-column purification; lane FT, affinity Hu-column flow-through; lane E, elution from affinity Hu-column. Samples were analyzed by reducing SDS−PAGE on 17.5% gels followed by Simply Blue Safe Stain (Invitrogen). In panel B, HuS(N88C)−DSPE was affinity purified and analyzed by RP HPLC (50 mM thriethylamine phosphate, pH 2.8, 20% 2-propanol with a linear gradient of acetonitrile 0−70% over 30 min). The yield of modified product was calculated as a ratio of integral peak intensities for HuS(N88C)−DSPE conjugate and unmodified HuS(N88C); in this case, modification is 77%. In panel C, the HuS(N88C)−DSPE conjugate was inserted in liposomes (16 h at 37 °C) and then analyzed by RP HPLC (50 mM thriethylamine phosphate, pH 2.8, and 20% tetrahydrofuran with a linear gradient of acetonitrile 0−70% over 25 min).

annexin V displayed a similar activity in this assay (IC_{50} of 9 ± 4 nM, (*7*)), we concluded that fusion of the Hu-tag did not disturb annexin V functional activity.

Functional activity of Hu−VEGF was tested in a VEGFR-2 autophosphorylation assay (Figure 5B). Hu−VEGF induced VEGFR-2 tyrosine autophosphorylation in 293/KDR cells, which was detectable at 0.04 nM Hu−VEGF and reached plateau at 0.4 nM (Figure 5B). Since similar activities were reported for the previous version of Hu−VEGF with a random 8-aa linker and also for recombinant human $VEGF_{165}$ (*3*), we concluded that the extension of the linker from 8-aa to 15-aa did not have detrimental effects on VEGF functional activity.

Targeted Delivery of HuS−Liposomes. Targeting proteins were mixed with HPTS-containing HuS−liposome at equimolar Hu-tagged protein to HuS ratio, and the HuS/Hu-tag association was detected by reconstituted ribonuclease activity. We found that dose-dependencies of ribonuclease activity of complexes with liposome-bound HuS were similar to that obtained with free HuS (Figure 6A). Targeting of HuS−Lip/Hu−annexin was tested in an erythrocyte binding assay. HuS−liposomes were used as a control for a nonspecific binding. We found that Hu−annexin/HuS−liposome complexes bound to erythrocytes in a dose-dependent manner, and the levels of binding

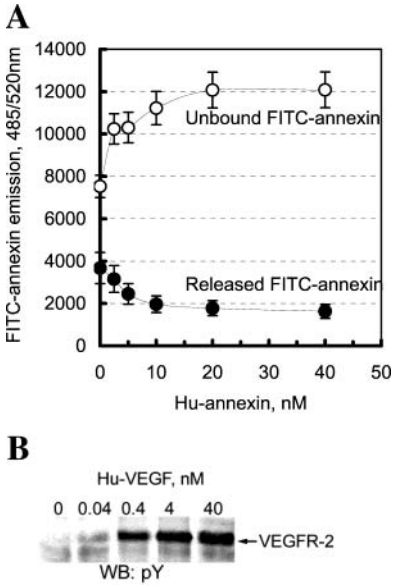

Figure 5. Hu-tagged targeting proteins are functionally active. In panel A, Hu−annexin competes with FITC−annexin for binding to erythrocytes with exposed phosphatidylserine. Unbound FITC−annexin was found in the supernatants after binding with erythrocytes; released FITC−annexin was found in the supernatants after resuspension of erythrocytes in EDTA-containing buffer. In panel B, Hu−VEGF activates VEGFR-2 in 293/KDR cells.

were significantly higher amounts than that for untargeted HuS−liposomes (Figure 6B).

Targeting of HuS−Lip/Hu−VEGF was tested in a binding assay with 293/KDR cells expressing 2.5×10^6 VEGFR-2/cell (9). HuS−liposomes were used as a control for a nonspecific binding. In addition, HEK293 cells lacking VEGFR-2 were used as a control for non-VEGFR-2-mediated binding. We found that 293/KDR cells internalized VEGF-driven HuS−liposomes significantly better than nontargeted HuS−liposomes (Figure 6C). In contrast, both targeted and nontargeted liposomes were internalized to the same extent by HEK293 cells lacking VEGFR-2 (Figure 6C).

DISCUSSION

To eliminate random chemical modification of targeting proteins currently used for targeted delivery of therapeutics and diagnostics, we have recently proposed to link a cargo to a standardized adapter protein that binds noncovalently to a docking tag engineered into a targeting protein (Figure 1). This approach however still yielded heterogeneous targeted drug delivery complexes because of a random cross-linking of a cargo to the adapter protein. Here we report development of a novel HuS(N88C) adapter protein for assembly of targeting drug delivery complexes (Figure 1). This mutant carries an unpaired cysteine in position 88 available for site-directed conjugations of drugs or drug carriers.

We have recently developed a high-yield system for production of HuS protein by subtilisin digestion of a chimeric recombinant BH-RNase containing an appropriate subtilisin cleavage site (*5*). BH-RNase is easily refolded into a functionally active conformation and yielded highly active HuS after subtilisin digestion. Therefore, to develop HuS mutants with unpaired cysteines, we mutated BH-RNase and then recovered HuS mutants by subtilisin digestion of the corresponding BH-RNases. The positions for the G68C and N88C substitutions have been chosen on the basis of 3-D structure of human RNase I (*11*) with the goal to minimize possible interference of cross-linked constructs with tag/adapter interactions. We report here that both mutant HuS proteins are readily recovered from the corresponding mutant BH-RNases by subtilisin digestion followed by affinity purification. We found that HuS(N88C) is a better candidate for further development because of its higher yield and higher affinity to Hu-tag, which is close to that of wild-type HuS (Figure 3 B,C (*5*)). A point mutation in position 88 of bovine RNase A was shown to decrease RNase affinity to ribonuclease inhibitor (RI) and enhances cytotoxic activity of RNase A (*16*). However, mutations in positions 88, 89, or 90 of highly homologous RNase I had little, if any, effect on cytotoxicity of this protein (*17*). Nevertheless, one could expect that cross-linking of bulky compounds to C88 still could decrease affinity of the reconstituted RNase to RI providing the assembled complexes with intrinsic cytotoxicity, which would be an additional benefit in a case of delivery of cytotoxic drugs.

Using maleimide chemistry, we cross-linked a PEGylated lipid to HuS(N88C). HuS−lipid conjugate was inserted into preformed unilamellar liposomes yielding 20−30 adapter proteins per liposome, which is consistent with previously published data on immunoliposome construction (*18*). HuS−liposomes readily bind Hu-tagged proteins as judged by reconstitution of RNase activity upon HuS/Hu-tag interaction. Furthermore, liposomes linked to HuS via C88 did not affect adapter/tag interactions, since complexes reconstituted with both liposomal and free HuS protein displayed similar ribonuclease activities. No significant interference with adapter/tag interactions was also observed in our preliminary experiments with various bulky constructs, such as magnetic beads (Dynal Biotech Corp., Lake Success, NY) or Dexferrum magnetic particles, (American Regent Lab., Shirley, NY) linked to HuS via C88.

Assembled drug delivery complexes might be developed for therapeutic applications only if their cargo does not interfere with targeting protein/receptor interaction. We report here that two different targeting proteins, Hu−annexin V and Hu−VEGF, significantly enhance HuS−liposome binding to the corresponding cells. Thus, liposomes do not interfere with binding of these targeting proteins to their cellular targets. Since annexin V and VEGF are vastly different proteins with even more different targets, we expect that HuS−liposomes developed in this work can be used as a standardized payload module for delivery by various targeting proteins. Although assembly of targeting complexes described in this work requires production of a modified adapter protein, this approach provides significant advantages over traditional drug loading via direct conjugation to targeting proteins. First, the same modified adapter would be suitable for assembly with different targeting proteins. Second, since the site-specifically modified adapter retains the ability to bind targeting proteins, we expect that various drugs or drug carriers can be cross-linked to C88 via standardized chemistries. We therefore expect that the benefits associated with the elimination of both the damage to the targeting proteins and the heterogeneity of the final products would stimulate acceptance of assembled complexes for targeted drug delivery. Experiments are in progress to establish whether selectivity provided by assembled targeting complexes is sufficient for therapeutic and diagnostic applications.

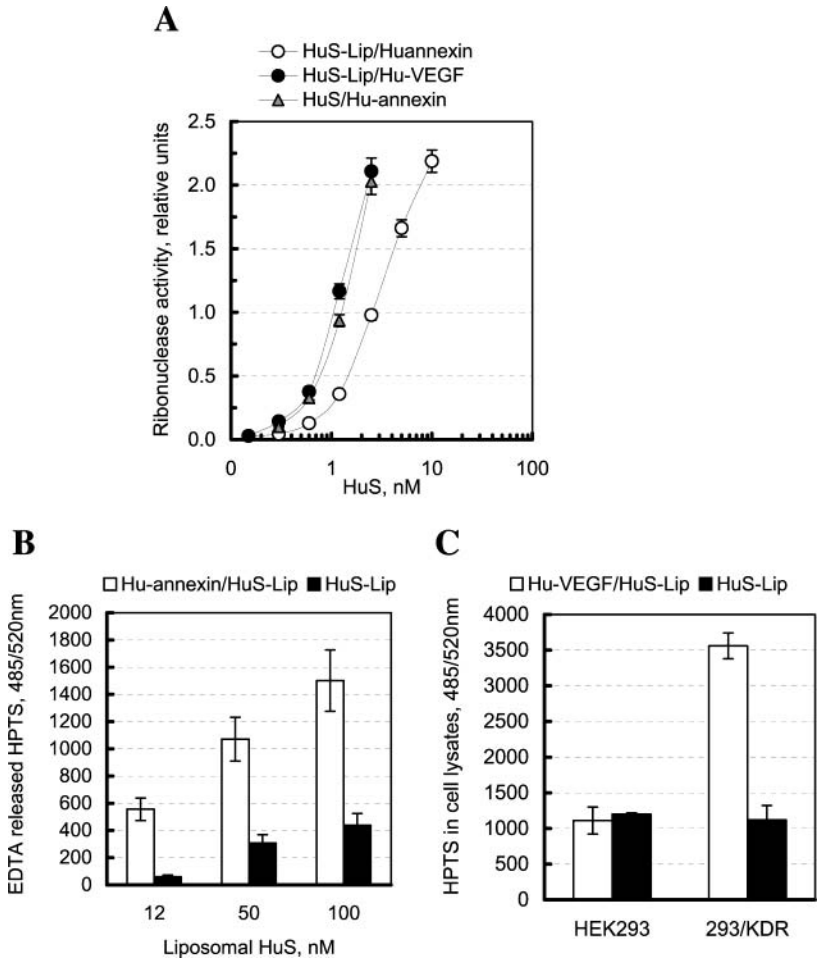

Figure 6. Targeted delivery of HiS−liposomes. Hu-tagged targeting proteins were mixed separately with HuS−liposomes at the liposomal HuS to Hu-tagged protein molar ratio of 1:1. For the liposome alone control (HuS−Lip), equal volumes of protein storage buffer were added to liposomes. All complexes were incubated on ice for 15 min and then added to cells. HPTS fluorescence was measured at λ_{ex} = 485 nm/λ_{em} = 520 nm. Liposome delivery experiments were done in duplicate and repeated twice. In panel A, Hu−annexin and Hu−VEGF bind HuS−liposomes with restoration of ribonuclease activity. In panel B, Hu−annexin-driven liposomes were added to erythrocytes in binding buffer at indicated liposomal HuS concentrations, incubated for 15 min at RT, and then spun down. The pellets were washed twice with binding buffer prior to resuspension in EDTA-containing buffer, then spun down again. HPTS fluorescence was measured in the supernatants. In panel C, Hu−VEGF-driven liposomes were added to starved HEK/293 and 293/KDR cells to final concentrations of 60 nM complex HuS/dimer VEGF. Cells were incubated 45 min at 4 °C and then moved to 37 °C to allow internalization of complexes. After 45 min at 37 °C, cells were washed twice with PBS and once with PBS containing 0.4 M NaCl and lysed in PBS with 1% NP-40. HPTS fluorescence was measured in the clarified cell lysates.

Synthesis and Characterization of a Photocleavable Cross-Linker and Its Application on Tunable Surface Modification and Protein Photodelivery

Funing Yan,[†,§] Liaohai Chen,*[,§] Qiling Tang,[†] and Rong Wang*[,†]

Illinois Institute of Technology, Chicago, Illinois 60616, and Argonne National Laboratory, Argonne, Illinois 60439. Received April 21, 2004; Revised Manuscript Received June 29, 2004

A heterobifunctional photocleavable cross-linker based on an *o*-nitrobenzyl ester moiety was synthesized. The cross-linker has *N*-hydroxysuccinimidyl and disulfide groups attached at each end and thus can anchor a protein to a gold-coated substrate surface. Steady-state spectroscopic studies suggest that the cross-linker undergoes a clean C−O fragmentation upon irradiation with a quantum yield of 0.1. Consequently, immobilized proteins (such as avidin or antibodies) on a substrate surface can be released efficiently (>95%) under UV irradiation (λ > 300 nm) without degrading the protein functionality. We also demonstrated protein delivery via bioconjugation of protein molecules to a gold-coated atomic-force microscope (AFM) tip. When the proteins are photoreleased from the AFM tip, they are delivered to the substrate surface as protein clusters of uniform size. This has been confirmed using both AFM and fluorescence microscopy. The application of bioconjugation in this study opens a new avenue for tunable surface modification and controllable protein delivery in studies of biological systems on the nanometer scale.

INTRODUCTION

Substrate surface modification with proteins is essential in bioassaying, bioengineering, and biotechnology (*1*). While many efforts are focused on the covalent linkage of proteins on a substrate surface (*2*, *3*), it is important to develop methods for detaching the anchored proteins from the substrate surface as desired. One of the practices commonly used to achieve this goal is the use of a reactive enzyme (*4*) to cleave the bond that holds the protein to the substrate surface. This approach may be cumbersome because it involves multiple steps and requires accommodation of enzyme working conditions. An alternative is to anchor proteins to a substrate surface using a photocleavable bond (*5*), so that the proteins can be detached by a photofragmentation reaction. Unlike the enzyme method, the photodetachment of proteins is clean and easy to carry out. No reagents are needed. More importantly, since light can be focused to a small spot (100−400 nm in diameter, depending on the diffraction limitation), the photofragmentation reaction can be achieved in a confined area, allowing detachment of proteins at a precise local position. Immobilization of proteins using a heterobifunctional and photoactivatable cross-linker will open new avenues for manipulating the attachment and detachment of biomolecules to a surface.

Among the photocleavable moieties used to cross-link proteins to a substrate surface, the *o*-nitrobenzyl group is popular due to unique properties that include stability under ambient light, clean cleavage upon exposure to UV irradiation, and fast fragmentation reactions (within nanoseconds) upon photoexcitation (*6*, *7*). This group has been used in myriad solid-phase synthesis, protein isolation, and protein purification experiments (*8*−*12*). In this paper, we report the development of a heterobifunctional photocleavable cross-linker that uses the *o*-nitrobenzyl ester moiety as a core. One terminal of the cross-linker, *N*-hydroxysuccinimidyl, allows a protein to be conjugated. The other terminal, a disulfide group, allows chemical bonding to a gold-coated substrate. The clean C−O photofragmentation was confirmed by our steady-state spectroscopic studies. Proteins (such as avidin or antibodies) anchored to a gold substrate surface by the cross-linker can be efficiently (>95%) photodetached under UV irradiation without degrading protein functions. We also demonstrated that proteins anchored to the AFM tip can be photodelivered to a substrate surface. As a complement to other protein delivery methods such as Dip-pen technology (*13*, *14*), the method developed in this paper allows for precise and controllable protein delivery.

EXPERIMENTAL SECTION

Materials. Reagent grade solvents were used without any purification unless specified; chemicals including 5-hydroxy-2-nitrobenzyl alcohol, 3,4-dihydro-2*H*-pyran, *p*-toluenesulfonic acid, *N*,*N*′-dicyclohexylcarbodiimide (DCC), thioctic acid, succinic anhydride, dimethyl aminopyridine (DMAP), N-hydroxy succinimide, and general organic solvents were purchased from the Sigma-Aldrich Chemical Co. (St. Louis, MO). THF was distilled before use. *N*-Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) and Alexa Fluoro 488 biocytin were purchased from Molecular Probes, Inc. (Benertin, OR).

Synthesis of Photolabile Cross-Linker. *Synthesis of 4-Nitro-3-(tetrahydropyran-2-yloxymethyl)phenol (**2**).* Nitrobenzyl alcohol (3.4 g, 0.02 mol) and *p*-toluenesulfonic acid (0.02 g, 0.1 mmol) were dissolved in 30 mL of dried THF. Under N_2 protection, 2.7 mL of 3,4-dihydro-2*H*-pyran was added dropwise. After the reaction was refluxed for 10 h, THF was evaporated under vacuum. The residue was chromatographed on silica gel using ethyl acetate/*n*-hexane (1:4) and yielded a white crystal-

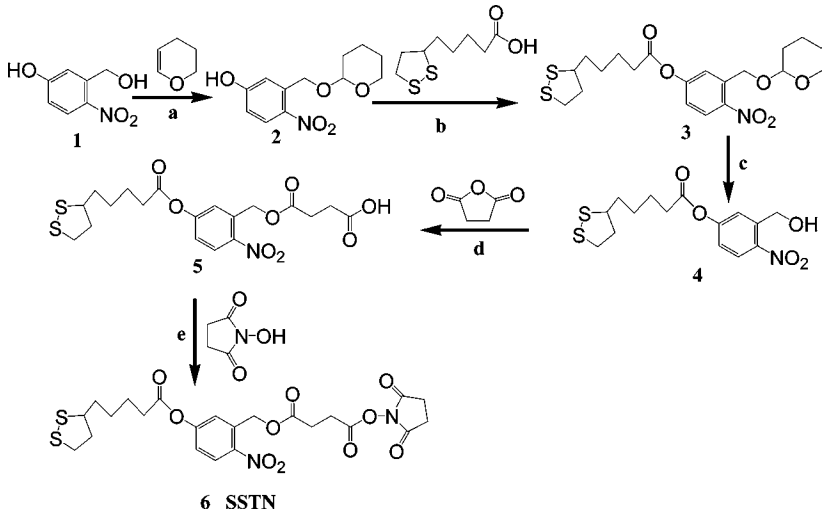
line solid. Recrystallization in ethyl acetate/*n*-hexane (1:1) resulted in 4.3 g of **2** (yield 86%). Mp 141−143 °C, ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.13 (d, 1H), 7.36 (d, 1H), 6.79 (d, 1H), 5.18 (m, 2H), 4.80 (t, 1H), 3.98 (m, 1H), 3.60 (m, 1H), 1.90 (m, 2H), 1.60 (m, 4H).

*Synthesis of 5-[1,2]-Dithiolan-3-ylpentanoic Acid 4-Nitro-3-(tetrahydropyran-2-yloxymethyl)phenyl Ester (**3**).* **2** (1.0 g, 4 mmol), thioctic acid (1.65 g, 8 mmol), and DCC (1.65 g, 8 mmol) were dissolved in 20 mL of dried THF. After the reaction was refluxed under N_2 protection for 12 h, the resulting suspension was filtered out and the THF was then evaporated under vacuum. The residue was chromatographed on silica gel using dichloromethane/*n*-hexane (5:1) to give 1.5 g of **3** (yield 85%). Yellow gel, ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.16 (d, 1H), 7.53 (d, 1H), 7.18 (d, 1H), 5.00 (m, 2H), 4.76 (t, 1H), 3.85 (m, 1H), 3.57 (m, 2H), 3.11 (m, 2H), 2.60 (t, 2H), 2.42 (m, 1H), 1.92 (m, 1H), 1.90−1.50 (m, 12H).

*Synthesis of 5-Thioctic Acid 3-Hydroxymethyl-4-nitrophenyl Ester (**4**)* **3**. (2.2 g, 5 mmol) was dissolved in dilute hydrochloride H_2O/THF solution (0.2 M, 1:2 V/V) and stirred overnight at room temperature. Then the mixture was poured into ethyl acetate followed by washing three times with 1% aqueous $NaHCO_3$ solution. After normal workup, the organic phase was chromatographed on silica gel using dichloromethane to give 1.6 g of **4** (yield 90%). Yellow gel, ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.20 (d, 1H), 7.58 (d, 1H), 7.20 (d, 1H), 5.01 (s, 2H), 3.60 (m, 1H), 3.18 (m, 2H), 2.61 (t, 2H), 2.40 (m, 1H), 1.78 (m, 4H), 1.58 (t, 2H).

*Synthesis of Succinic Acid Mono-[5-(5-[1,2]dithiolan-3-yl-pentanoyloxy)-2-nitrobenzyl] Ester (**5**).* **4** (0.7 g, 2 mmol), succinic anhydride (0.4 g, 4 mmol), and 4-dimethylaminopyridine (DMAP) (0.12 g, 1 mmol) were dissolved in 15 mL of dichloromethane and refluxed under N_2 protection for 10 h. The mixture was washed three times by distilled water followed by normal workup and chromatographed on silica gel using dichloromethane/methanol (9:1) to give 0.7 g of **5** (yield 75%). Yellow gel, ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.20 (d, 1H), 7.39 (d, 1H), 7.21 (d, 1H), 5.59 (s, 2H), 3.60 (m, 1H), 3.18 (m, 2H), 2.72 (t, 2H), 2.61 (t, 2H), 2.45 (m, 1H), 1.97 (m, 1H), 1.78 (m, 4H), 1.58 (t, 2H).

*Synthesis of Succinic Acid Succinimidyl Ester 5-Thioyloxy-2-nitrobenzyl Ester (SSTN) (**6**).* **5** (0.9 g, 2 mmol), *N*-hydroxysuccinimide (0.35 g, 3 mmol), and DCC (0.4 g, 2 mmol) were dissolved in 20 mL of dichloromethane. After the reaction was refluxed under N_2 protection for 12 h, the resulting suspension was filtered out and dichloromethane was then evaporated under vacuum. The residue was chromatographed on silica gel using dichloromethane/methanol (9:1) to give a white solid and recrystallized by ethyl acetate/*n*-hexane (6/1) to give 0.7 g of **6** (yield 65%). Mp 85−87 °C, ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.21 (d, 1H), 7.39 (d, 1H), 7.12 (d, 1H), 5.60 (s, 2H), 3.61 (m, 1H), 3.08 (m, 2H), 2.99 (t, 2H), 2.89 (t, 2H), 2.82 (t, 4H), 2.62 (t, 2H), 2.50 (m, 1H), 1.95 (m, 1H), 1.75 (m, 4H), 1.56 (m, 2H); ^{13}C NMR (500 MHz, $CDCl_3$): δ 24.34, 25.53, 25.53, 26.23, 28.62, 28.66, 34.03, 34.51, 38.50, 40.24, 56.24, 63.20, 121.71, 121.76, 126.96, 134.36, 144.12, 154.59, 167.57, 168.82, 168.82, 170.23, 170.92. Anal. Calcd: C 49.82, H 4.69, N 5.05, S 11.55, O 28.88, Found: C 50.05, H 4.69, N 5.17, S 11.08, O 28.82; MS (APCI): 589 (SSTN + Cl).



Instruments and Methods. TLC was performed with Analtech silica gel FG TLC plates (250 μm). Flash chromatography was carried out using Aldrich silica gel (60 mesh). ^{1}H NMR spectra were measured on a GE NMR-OMEGA (300 MHz), and ^{13}C NMR spectra were measured on a 500 MHz Bruker DMX. Elemental analysis was done by Atlantic Microlab Inc., Atlanta, GA. Mass spectra (GC/MS) were recorded at the University of Chicago.

A UV−vis absorption spectrometer was used to follow the changes in absorbance of SSTN fragmentation products during the photolysis. The UV−vis spectra were measured on a Hewlett-Packard 8453A diode-array spectrophotometer with a wavelength range from 190 to 1100 nm and a 1 nm bandwidth. The steady-state emission spectral measurements were carried out using 1 cm × 1 cm quartz cells in a PTI C60 spectrofluorimeter with a 75 W mercury lamp as an irradiation source. The detector was a thermoelectrically cooled photomultiplier. A right-angle configuration was used for emission and excitation. The protein-immobilized substrate was placed at an angle of 30° with respect to the excitation light in order to reduce the reflection of excitation light. The surface was covered with 30 μL of PBS during the measurement.

A multimode Nanoscope IIIa AFM (Digital Instruments, Santa Barbara, CA) was used to carry out and examine protein delivery. BSA or anti-human IgG antibody was immobilized on a gold-coated AFM tip via SSTN. The gold coating of the AFM cantilever was created using a thermal evaporator (Denton Vacuum, Moorestown, NJ). A gold-coated AFM tip (3 nm precoated titanium and 50 nm gold) was immersed in a 1.64×10^{-4} M SSTN solution in DMF at room temperature under nitrogen protection, generating a monolayer of SSTN on the tip via Au−S linkage, as routinely performed in the lab (*15*, *16*). After being thoroughly rinsed, the modified tip was immersed in a 10^{-6} M BSA or anti-human IgG antibody solution (in PBS buffer) overnight at room temperature under nitrogen protection. This allowed the chemical bonding of proteins onto the AFM tip. The unbound proteins were removed by thoroughly rinsing the tip in PBS and deionized water. For local functionalization of proteins at the tip end, we used an SSTN-modified AFM tip to approach a thin layer of protein solution on a mica surface. The approaching process was manually controlled using the positioner of the AFM setup and was carefully monitored using the optical microscope equipped with the AFM to allow only the tip end to contact the protein solution. After a 1-h incubation, the tip was withdrawn and thoroughly rinsed in PBS and deionized water to remove any unbound residue. A fluorescence microscope (Olympus IX-70) was used to confirm the local protein functionalization when a fluorescein-labeled anti-human IgG was employed. Photocontrollable protein delivery was performed on either a freshly cleaved mica microscope cover slide surface or a thoroughly cleaned glass microscope cover slide surface. AFM images were acquired in a contact mode using a triangular Si_3N_4 tip.

Photochemical Reactions. Photolysis was performed with a 3.6×10^{-4} M SSTN solution in CH_3CN using a quartz cuvette. The irradiation was carried out at room temperature using a 100 W high-pressure mercury lamp (Oriel Model 68700) with a UV 297 interference filter (Andover Corporation Optical Filter). Irradiation time-dependent photolysis was monitored by periodically taking the absorption spectra of SSTN to quantify the reaction quantum yield. To identify the photoreaction products, the sample was irradiated for 40 min. After the solvents were removed under vacuum, the residues were chromatographed on silica gel using chloroform to give yellow **7** in gel form (0.04 g, 60%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 9.85 (s, 1H), 8.12 (d, 1H), 7.45 (d, 1H), 7.05 (d,

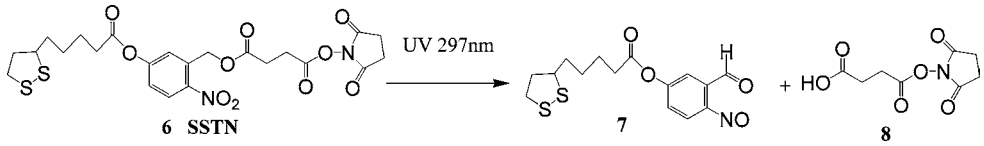
Actinometry and Quantum Yield Measurement. Potassium ferrioxalate actinometry was used as a reference to determine the incident light intensity (*17*). Potassium ferrioxalate was recrystallized from warm water in the dark and dried in a vacuum oven. The concentration of the ferrioxalate was 0.006 M in water. The photoreaction of potassium ferrioxalate was followed by UV−visible absorption. The amount of the product can be directly determined and then converted to determine the quantity of photons delivered (in Einstein). The quantum yield of the photoreaction of SSTN in acetonitrile can then be calculated using the following equation and the lamp flux value:

$$\varphi = \frac{\text{moles of product} \times C}{\text{lamp flux} \times \text{irradiation time (s)}}$$

The amount of product is determined by the absorbance change from UV−vis. C is a value that corrects the incomplete light absorption at the excitation wavelength. $C = 1/(1 - T)$, where T is the transmittance of SSTN before the irradiation.



Photocleavable Protein Immobilization. A microscope cover slide (Fisher) was used as a substrate. After being cleaned with H_2O_2/H_2SO_4 solution, the slide was coated with a 100 nm layer of gold on top of 10 nm of precoated titanium. The gold-coated slides were then immersed into SSTN/CH_3CN solution (3.6×10^{-4} M) overnight at room temperature under nitrogen protection (*5*). After being thoroughly rinsed using CH_3CN and then water, the substrates were then incubated in avidin solution (0.5 mg/mL in 0.1 M $NaHCO_3$, pH 8.5) for 4 h at room temperature. After being rinsed with PBS buffer, the avidin-immobilized substrates were immersed in an Alexa 488 biotin solution (2.56×10^{-4} M) for 1 h, followed by multiple rinsings of the substrate to remove any unbound biotin. The immobilization of avidin on the gold substrate surface was confirmed by the strong fluorescence of the coverslips (data not shown). To investigate the photocleavage of avidin from the substrate, emission spectra of the protein-functionalized surface after irradiation and thorough washing were recorded at 2-min intervals in PBS buffer solution. A control experiment was carried out by replacing SSTN with the conventional cross-linker succinimidyl 3-2(2-pyridyldithio)propionate (SPDP) under the same experimental conditions.

RESULTS AND DISCUSSION

Synthesis of Succinic Acid Succinimidyl Ester 5-Thioyloxy-2-nitrobenzyl Ester. The synthesis of succinic acid succinimidyl ester 5-thioyloxy-2-nitrobenzyl ester (SSTN, **6**) was achieved using 5-hydroxy-2-nitrobenzyl alcohol and thioctic acid (1,2-dithiolane-3-pentanoic acid) as starting materials (Scheme 1). The main challenge of this synthetic route was to selectively synthesize **4** without the competitive reactions of the two hydroxyl groups presented in **1** with thioctic acid. This was achieved using 3,4-dihydro-2*H*-pyran as the specific primary hydroxyl protection reagent. Since electrons on phenol oxygen are conjugated with π electrons and are strongly withdrawn by the nitro group, the electron density of the phenol group is much higher than that of the primary hydroxyl group. Therefore, the nucleophilic addition reaction in the first step should be highly selective toward the primary hydroxyl group when compared to the phenol group (*18*). In brief, the primary hydroxyl group of **1** was selectively protected by reacting with 3,4-dehydro-2*H*-pyran (*19, 20*) in the THF in the presence of *p*-toluenesulfonic as the catalyst (yield of 86%). Esterification of the phenol group with thioctic acid was carried out in THF using DCC as the catalyst and yielded nitrobenzyl thioctate derivative **3** (yield of 85%). Deprotection of the hydroxyl group was achieved in dilute hydrochloride H_2O/THF solution (0.2 M, 1:2 V/V), and then tetrahydropyran was removed to yield the primary hydroxyl group **4**, which further reacted with succinic anhydride in dichloromethane to yield 75% of hemisuccinic acid **5**. The final product was synthesized by esterifying **5** with *N*-hydroxysuccinimide in dichloromethane, using DCC as a catalyst with a yield of 65%. The overall yield was 32%. The structures of the final compound and the intermediate products were confirmed by ^{1}H NMR, ^{13}C NMR, mass spectrometry, and elemental analysis.

Photophysics and Photochemistry of the Cross-Linker. Steady-state spectroscopic studies revealed that SSTN contains a major absorption peak (n−σ*) at 274 nm. As with other nitro-aromatic molecules, SSTN has a very weak fluorescence peak at 427 nm. It has been established that α-substituted 2-nitrobenzyl photophore

Scheme 2. Photolysis of SSTN

can undergo a highly efficient and fast photofragmentation reaction (*21*). Indeed, upon irradiation ($\lambda = 297$ nm) of 7 mM of SSTN in deuterated chloroform, a thin-layer chromatograph experiment indicated that two major products were formed when visualized in an iodine chamber. To identify the photoreaction products, the reaction was followed using NMR spectroscopy. Benzyl hydrogen presented in SSTN exhibited a characteristic singlet peak at 5.60 ppm, which disappeared when the SSTN solution (3.6×10^{-4} M) was irradiated with 297 nm light. Another characteristic singlet peak centered at 9.85 ppm emerged as the photoreaction proceeded, suggesting a clean C−O bond cleavage and the formation of nitrosobenzaldehyde and succinic acid monosuccinimidyl ester. On the basis of TLC and NMR experimental results, we conclude that the reaction pathway is as shown in Scheme 2. The reaction scheme matches the reported reaction mechanism of the photolysis of other similar α-substituted 2-nitrobenzyl compounds (*21*).

The photofragmentation reaction can also be monitored using UV−vis absorption spectroscopy. As shown in Figure 1, the product nitrosobenzaldehyde **7** has a $\pi-\pi^*$ transition centered at 334 nm (the other product **8** has no absorption peak above 300 nm), 60 nm red-shifted when compared to the major absorption peak at 274 nm from the starting material. The occurrence of the photofragmentation reaction was made evident by the decrease of SSTN absorption at 274 nm and the increase of nitrosobenzaldehyde absorption at 334 nm.

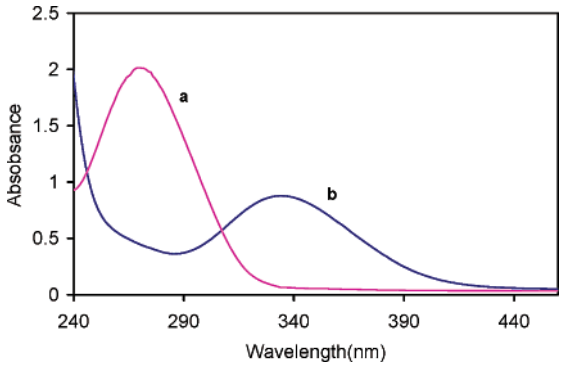


Figure 1. UV−vis spectra of **6** (3.0×10^{-4} M in acetonitrile) (a) and **7** (2.2×10^{-4} M in acetonitrile) (b).

Figure 2 demonstrates the absorption spectrum change of SSTN after the reaction solution (SSTN in acetonitrile, 9.0×10^{-5} M) was irradiated by 297 nm light for a short irradiation time (2-min interval). The insert of Figure 2 shows the absorption spectrum change of the SSTN solution (3.6×10^{-4} M) when irradiated for a longer time (30 min). The presence of an isosbestic point at 298 nm indicates a clean conversion from *o*-nitrobenzyl ester to nitrosobenzaldehyde. The progress of the reaction was followed quantitatively by noting the appearance of nitrosobenzaldehyde, as indicated by an absorption peak at 334 nm. A standard working curve for the absorption of pure nitrosobenzaldehyde as a function of concentration in the presence of the same concentration of starting material was used as a reference to quantify the product. The result of a control experiment, in which pure **7** in acetonitrile was irradiated using the same light source, suggests that **7** is very stable under the photoreaction conditions. Thus, the increase at 334 nm is correlated to the formation of **7**. After the photoflux using potassium ferrioxalate actinometry was determined, the quantum yield of the photoreaction with excitation at 297 nm was calculated to be 0.10 ± 0.04, comparable to the value reported in the literature (*22*). It was also found that the quantum efficiency remains the same in the degassed solvent; thus, oxygen most likely does not play any role in the photofragmentation reaction.

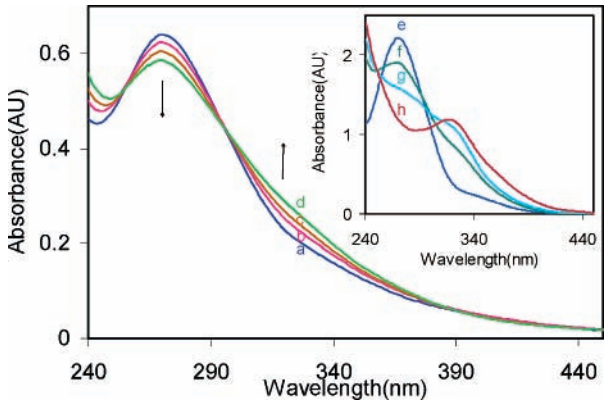

Figure 2. Absorption spectra of SSTN (9.0×10^{-5} M) under photolysis with shorter time interval. a: before irradiation; b: 2 min irradiation; c: 4 min irradiation; d: 6 min irradiation. Insert absorption spectra of SSTN (3.6×10^{-4} M) under photolysis with longer time interval. e: before irradiation; f: 18 min irradiation; g: 24 min irradiation; h: 30 min irradiation.

The mechanism of photolysis of *o*-nitrobenzyl alcohol derivatives (esters) involves a photoinduced intramolecular hydrogen abstraction and redox rearrangement that forms an *o*-quinonoid intermediate, followed by the release of the carboxylic acid and the formation of nitrosobenzaldehyde (*23*). Thus, the low quantum yield observed for the photoreaction is due to the low efficiency of the intramolecular hydrogen abstraction. Two approaches can be used to further increase photoefficiency: (1) introduce an additional *o*-nitro group to improve the chances of hydrogen abstraction by the excited nitro group; (2) introduce an α substitute to the photophore to enhance the efficiency of hydrogen abstraction and thus increase the overall reaction efficiency. Both approaches involve more steps to synthesize the desired cross-linkers. These approaches will be explored in our future study.

Photocontrollable Protein Surface Modification. We used the biotin−avidin model system to demonstrate phototunable protein immobilization using the SSTN cross-linker. The extremely high affinity of the biotin molecule to avidin protein (association constant of 10^{15} M^{-1}) has been well documented in the literature (*24*). As illustrated in Figure 3a, a monolayer of SSTN was self-assembled onto a gold-coated glass slide (*25, 26*). Nonspecifically bound SSTN was extensively washed away. After 4 h of incubation of the modified surface with avidin, the proteins were conjugated on the surface by the reaction of the amine groups of lysines in the avidin

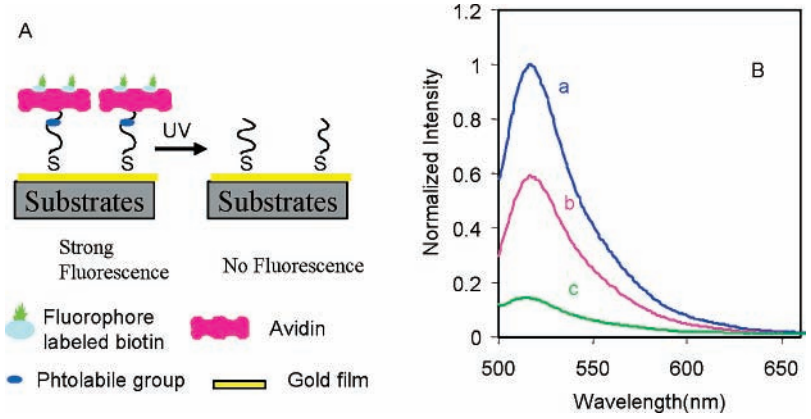

Figure 3. A. Scheme of photocontrollable protein immobilization. B. Fluorescence spectra of the substrates anchored with Alexa 488 biotin−avidin complex by photocleavable SSTN cross-linker, a: before irradiation; b: 2 min irradiation; c: 30 min irradiation.

with hydroxysuccinimidyl in the SSTN to form amide bonds. Again, any nonspecifically bound avidin was extensively washed away. As a control experiment, we also anchored avidin to a gold-coated substrate using succinimidyl 3-2(2-pyridyldithio)propionate (SPDP), a conventional cross-linker. Both substrates were then exposed to the Alexa-488-biotin solution (0.5 mg/mL) for 1 h, and unbound species were washed away with PBS buffer. Emission spectra of both substrates were recorded. The strong fluorescence at 520 nm indicated the formation of biotin−avidin complex on both substrates. Subsequently, both substrates were irradiated with UV light (297 nm) at 2-min intervals, followed by thorough washing steps (three times) before the recording of the fluorescence spectra of the substrates in the PBS buffer solution. Figure 3b demonstrates the changes to the normalized fluorescence intensities of the SSTN-immobilized substrate with different illumination times. The SSTN-immobilized surface lost its fluorescence almost completely after 30 min of UV irradiation. On the other hand, the fluorescence of the SPDP-immobilized surface decreased less than 10% after 30 min of UV irradiation and maintained this level with longer irradiation times (data not shown here).

Consistent with the result of photolysis of SSTN (shown in Figure 2), we conclude that the decrease of the fluorescence on the substrate is due to the break of the C−O bond of SSTN and the release of avidin−biotin-dye complex from the substrate to the solution. This is confirmed by the maintained, strong fluorescence on the SPDP-immobilized substrate even after long-term irradiation. Thus, we can establish that SSTN is an efficient photocleavable cross-linker that can be used to attach and detach protein molecules on a surface in a controllable fashion. Importantly, the 297 nm UV light does not alter the binding affinity between biotin and avidin, as demonstrated in the control experiment.

Photocontrollable Protein Delivery. Photocontrollable protein immobilization on an AFM tip provides an opportunity to deliver protein molecules to a desired location on a substrate. As shown in Figure 4a, we anchored BSA on a gold-coated silicon nitride cantilever using an SSTN cross-linker. The surface of the freshly cleaved mica was imaged using this tip in air contact mode. As shown in Figure 4b, the surface is flat and lacks any features. While the tip was maintained at the same location, UV irradiation (297 nm) was applied to the cantilever for 30 min. The same area of mica surface was then imaged by the same tip (image is shown in Figure 4c). Numerous particles with an average diameter of 50 ± 10 nm and average height of 4 ± 1 nm appeared on

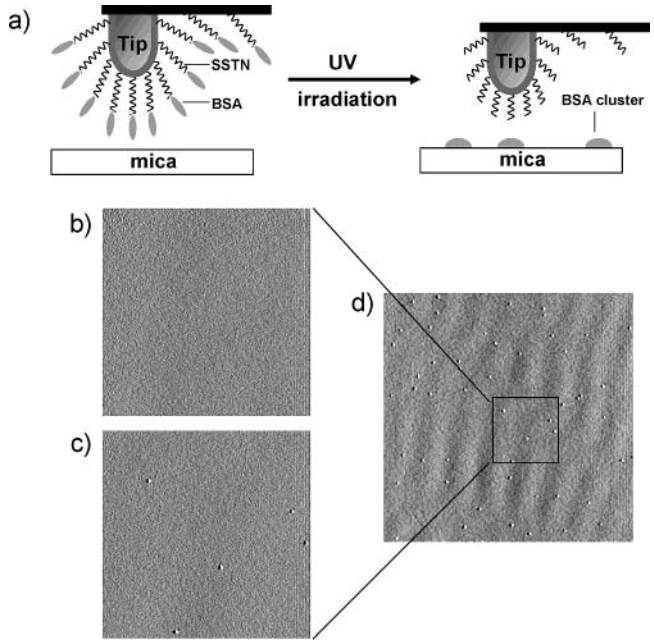

Figure 4. (a) Schematic illustration of AFM tip functionalization with BSA and photocleavage of BSA from the tip. (b) 5 μm × 5 μm contact mode image of newly cleaved mica surface before UV irradiation. (c) 5 μm × 5 μm image collected at the same region with the same tip right after UV irradiation for 1 h. (d) 18 μm × 18 μm image under the same conditions as c.

the surface. A larger scale image (Figure 4d) illustrates the distribution of the particles with uniform size. Note that the wavy parallel lines are result of optical interference due to the flatness of the mica surface and are not surface-relevant features. A control experiment was performed under the same conditions, except that UV irradiation was removed by keeping the sample in the dark for the same time period. In this case, a featureless mica surface was revealed using the AFM. This indicates the particles we observed in Figure 4c are BSA delivered from the AFM cantilever upon photocleavage of SSTN. BSA has an ellipsoidal structure with a short axis of 4 nm and a long axis of 14 nm. Thus, the particles appearing on the mica are clusters of single-layered BSA lying down on the substrate. Each cluster contains approximately 35−50 BSA molecules. High-resolution images indicated that there were no individual protein molecules present on the surface other than the clusters. To further confirm that the species dropped on the substrate are proteins, we used fluorescein (FITC)-labeled anti-human IgG antibody to repeat the experi-

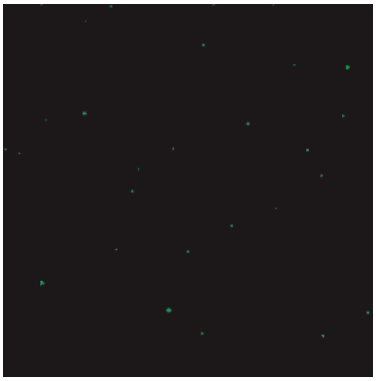

Figure 5. Fluorescence image of clusters of fluorescein-labeled anti-human IgG delivered from an AFM tip.

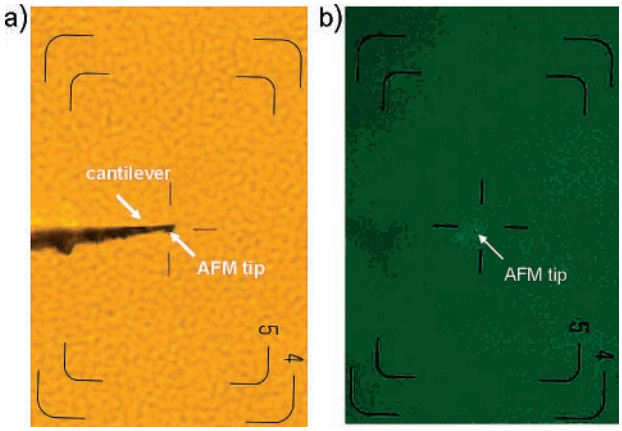

Figure 6. (a) Bright field image of an AFM tip; (b) fluorescence image of the AFM tip modified with FITC-labeled anti-IgG.

ment. Again, the AFM images showed that the antibody fell to the substrate as clusters with a uniform diameter of 70 ± 10 nm. Since the approximate size of intact IgG is 15 nm × 8 nm, each cluster may contain ~32−42 IgG molecules. Taking advantage of the fluorescein label of the antibody molecules, we were able to identify the protein clusters on the substrate using the fluorescence image, as shown in Figure 5.

It was a surprise to observe that proteins fell to the substrate as uniform clusters. We propose that after photocleavage, the proteins remain on the surface of the cantilever due to surface adhesion. Protein−protein attraction drives the proteins to accumulate and form clusters. When the proteins accumulate to a certain size, the gravity of the protein cluster is comparable to the adhesive force and the cluster falls to the substrate. A detailed mechanism is currently under investigation in our labs.

Because tip modification was achieved by incubating the cantilever in protein aqueous solution, proteins were immobilized on the entire cantilever (Figure 4a). When UV irradiation was applied, numerous protein clusters were delivered onto the surface. To accurately control the location of protein delivery, we modified protein molecules exclusively at the tip end. This was achieved by precisely controlling the tip to approach the protein solution, allowing only the tip end to contact the solution for incubation. The success of local tip modification was confirmed by examining the fluorescence image of a tip modified by fluorescein-labeled anti-human IgG antibody in this manner. Figure 6 shows the optical image (Figure 6a) and the fluorescence image (Figure 6b) of the AFM tip on its cantilever, achieved subsequently at the fixed tip position. Fluorescence was detected exclusively at the

Figure 7. Single BSA cluster delivered by AFM tip (4 μm × 4 μm).

tip end. After this tip was exposed to UV irradiation, a single protein cluster was observed at the position right underneath the tip, as shown in the AFM image (Figure 7) acquired using the same tip right after protein photocleavage. The conclusion is 2-fold: (1) proteins can be precisely delivered to a desired position; (2) an AFM tip can serve for both protein delivery and local imaging to examine the consequence of protein delivery.

A challenging task in bioscience is to directly monitor a protein function at local regions in their natural environment. This creates an urgent requirement for a general approach for delivering a ligand to a precise position, with a precise quantity. Our protein delivery approach employed UV light as a remote switch to control both timing and the position of protein delivery. To the best of our knowledge, this is the only approach that can offer the capability to deliver uniform small granules of proteins to a substrate. We also demonstrated that the same tip can be used after photocleavage to image the same local area, which is critical to achieving information on the nanometer scale. Using this approach, we expect to be able to deliver ligand clusters to a cell surface. Guided by the specific interaction via force mapping (*15*, *16*, *27*) using the ligand-functionalized tip, cell membrane receptors will be registered. The ligand will then be delivered to a receptor-rich area in order to in-situ monitor the living cell's localized response to the ligand−receptor binding on the nanometer scale. The feasibility has been demonstrated by our preliminary study in a model system involving the interaction between cholera toxin B oligomer (CTB) and its receptor ganglioside GM1. This approach will open an avenue for answering questions such as how individual ligand−receptor interactions trigger the cell signaling pathways in a living cell and why an inhibitor needs to be delivered to certain protein complexes in order to block protein activity.

CONCLUSION

A photocleavable cross-linker, succinic acid succinimidyl ester 5-thioyloxy-2-nitrobenzyl ester (SSTN), was synthesized in five steps using 5-hydroxy-2-nitrobenzyl-alcohol and thioctic acid (1,2-dithiolane-3-pentanoic acid) as starting materials. Upon photoexcitation, SSTN undergoes a fragmentation reaction to produce carboxylic acid and nitrosobenzaldehyde with a quantum yield of 0.1. SSTN can covalently anchor protein molecules to a gold-coated substrate, and those protein molecules can subsequently be efficiently (>95%) released under UV irradiation. By immobilizing the protein molecules on a gold-coated AFM tip, the protein molecules can be delivered as uniform clusters to the substrate via photolysis, and subsequently imaged at the same local region. Thus, this approach provides an important tool for tunable surface modification and precise protein delivery on the nanometer scale. We also expect that the results obtained in this study will lead to a new avenue

for generating protein patterns. In this case, the cross-linker will function as a "photoresister". When irradiation is applied to the protein-functionalized surface through a conventional photomask, as used in photolithography, the corresponding protein patterns can be easily generated.

Reduction of Methemoglobin via Electron Transfer from Photoreduced Flavin: Restoration of O_2-Binding of Concentrated Hemoglobin Solution Coencapsulated in Phospholipid Vesicles

Hiromi Sakai, Yohei Masada, Hiroto Onuma, Shinji Takeoka, and Eishun Tsuchida*

Advanced Research Institute for Science and Engineering, Waseda University, Tokyo 169-8555, Japan. Received April 9, 2004; Revised Manuscript Received July 31, 2004

Ferric methemoglobin is reduced to its ferrous form by photoirradiation either by direct photoexcitation of the heme portion to induce electron transfer from the surrounding media (Sakai at al. (**2000**) *Biochemistry 39*, 14595−14602) or by an indirect electron transfer from a photochemically reduced electron mediator such as flavin. In this research, we studied the mechanism and optimal condition that facilitates photoreduction of flavin mononucleotide (FMN) to $FMNH_2$ by irradiation of visible light, and the succeeding reduction of concentrated metHb in phospholipid vesicles to restore its O_2 binding ability. Visible light irradiation (435 nm) of a metHb solution containing FMN and an electron donor such as EDTA showed a significantly fast reduction to ferrous Hb with a quantum yield (Φ) of 0.17, that is higher than the method of direct photoexcitation of heme ($\Phi = 0.006$). Electron transfer from a donor molecule to metHb via FMN was completed within 30 ns. Native-PAGE and IEF electrophoresis indicated no chemical modification of the surface of the reduced Hb. Coencapsulation of concentrated Hb solution (35 g/dL) and the FMN/EDTA system in vesicles covered with a phospholipid bilayer membrane (Hb-vesicles, HbV, diameter: 250 nm) facilitated the metHb photoreduction even under aerobic conditions, and the reduced HbV restored the reversible O_2 binding property. A concentrated HbV suspension ([Hb] = 8 g/dL) was sandwiched with two glass plates to form a liquid layer with the thickness of about 10 μm (close to capillary diameter in tissue, 5 μm), and visible light irradiation (221 mW/cm^2) completed 100% metHb photoreduction within 20 s. The photoreduced $FMNH_2$ reacted with O_2 to produce H_2O_2, which was detected by the fluorescence measurement of the reaction of H_2O_2 and *p*-nitrophenylacetic acid. However, the amount of H_2O_2 generated during the photoreduction of HbV was significantly reduced in comparison with the homogeneous Hb solution, indicating that the photoreduced $FMNH_2$ was effectively consumed during the metHb reduction in a highly concentrated condition inside the HbV nanoparticles.

INTRODUCTION

Photoinduced electron transfer is an essential reaction in biological systems especially during photosynthesis by the chlorophyll−protein complex (*1*). Hemoproteins such as hemoglobin (Hb) and myoglobin (Mb) are originally not related to the photoreaction in a biological system; however, photoexcitation and the resulting electron transfer reactions have been extensively studied (*2*−*6*). In our previous report, we clarified the mechanism of reduction of ferric methemoglobin (metHb) to its ferrous form by the direct excitation of the porphyrin N band in the UVA region (*7*). The reduction proceeds by charge transfer from the porphyrin ring to the central ferric iron to form the porphyrin π cation radical and ferrous iron by the N band excitation, and the contribution of the amino acid residues in the globin chain as an electron donor or an electron pathway. Another photochemical process to reduce metHb is an electron transfer from photochemically reduced flavin derivatives. The precise photoreduction mechanism of a flavin derivative to its reduced form has been extensively studied (*8*−*10*), and this has contributed to the understanding of the mechanism of the electron transfer of flavoproteins (*11*−*17*) and their function in the biological systems such as bacterial photosynthesis (*18*) and visual organs (*19*). Irrespective of the flavoproteins, the photoreduction of metMb and metHb by the externally added photoreduced form of the flavin mononucleotide (FMN) was first reported by Brwon and Synder (*20*) and Yubisui et al. (*21*, *22*), respectively.

We have paid special attention to the reduction of hemoproteins that will be applicable to Hb-based artificial red cells (*23*). We focus on the liposome-encapsulated Hb; a concentrated Hb solution is encapsulated in phospholipid vesicles to form Hb-vesicles (HbV)[1] with a particle size of about 250 nm (*24*, *25*). Ferrous state Hb binds oxygen to form HbO_2; however, it gradually converts to ferric metHb and superoxide anion and loses its oxygen binding property both in vivo and in vitro (*26*). A series of thiols was studied as a reductant for metHb,

which is coencapsulated in the vesicles (*27*, *28*). As a result, the functional half-life of the Hb-vesicles is doubled by coencapsulation of the DL-homocysteine and active oxygen scavengers (*27*, *29*). To retard metHb formation, bioconjugation of enzymes such as catalase or superoxide dismutase (SOD) (*30*) and coencapsulation of RBC enzymes including the metHb reductase system, carbonic anhydrase, SOD, or catalase (*29*, *31*) have also been reported.

To restore the O_2 binding property of HbV, we tested utilization of the photoreduction system: the indirect excitation of an externally added electron mediator (*32*), or the direct excitation of metHb absorption in the UV region (*7*). In this study, we have made significant efforts to find out a condition that facilitates metHb reduction by a photoreduced flavin mononucleotide (FMN), because this system was well characterized by Everse (*32*), and the advantages of this system are visible light irradiation and high quantum yield (*9*, *10*). We analyzed the influence of electron donors to FMN, dissolved gases, etc., to find the facilitating condition and elucidate the mechanism for the facilitation of the metHb photoreduction in the HbV nanoparticles, a structure similar to that in red blood cells (RBCs), and this may also help understand the underlying mechanism of the reaction of NADPH-flavin reductase and metHb in RBCs.

EXPERIMENTAL PROCEDURES

Preparation of metHb. Carbonylhemoglobin (HbCO) was purified from outdated donated blood offered by the Hokkaido Red Cross Blood Center as previously reported (*33*, *34*). MetHb was prepared by reacting HbCO with an excess amount of potassium ferricyanide. The unreacted ions and ferrocyanide ions were removed twice by stirring with a mixed bed ion-exchange resin (Bio Rad AG 501-X8), and the solution was then permeated through 0.22 μm-filters (Advantec Co.). The metHb conversion was 99.8% measured by the cyanomethemoglobin method.

Chemicals. Amino acids (Met, Gln, Arg, Glu, Phe, Lys, Tyr, and Trp) were purchased from the Kanto Chem. Co (Tokyo). Peptides (Met-Met and Met-Gly) were from Sigma, and saccharides (mannitol, maltotriose, dextran, glucoseamine, glucron amide), methanol, citric acid sodium salt, ethylenediamine tetraacetic acid (EDTA), and diethylenetriamine pentaacetic acid (DTPA) were from the Kanto Chem. Co. All the chemicals were used without purification.

Photoreduction of FMN in the Presence of an Electron Donor. Three milliliters of phosphate-buffered saline (10 mM PBS, pH 7.4) with an electron donor (e.g., amino acids, peptides, sugars, as listed above, 20 mM) was sealed in a cuvette (2 mm width) with a butyl rubber cap. The solution was bubbled with N_2 for 30 min. A stock solution of FMN prepared in the dark was added at a concentration of 10 μM. The light source was a super high-pressure mercury lamp (USH-250D, 250W, Ushio Co., Tokyo) with a cutoff filter (L-42 and HA-50, Hoya Co., Tokyo) to obtain a single beam with the maximum wavelength of about 435 nm, which is close to λ_{max} of FMN (450 nm). The cuvette was located 2.5 cm away from the light source, and the light intensity was 221 mW/cm^2 that was measured with a power meter (PSV-3102, Gentec Co.). The conversion of the reduction, FMN to $FMNH_2$, was calculated from the reduction of absorbance at 450 nm, measured with an UV/vis spectrophotometer (V-560, Jasco, Tokyo).

Photoreduction of metHb in the Presence of FMN and an Electron Donor. Three milliliters of phosphate-buffered saline (10 mM PBS, pH 7.4) with an electron donor and FMN was sealed in a cuvette (2 mm width) with a butyl rubber cap. The solution was bubbled with N_2 gas for 30 min. A concentrated metHb stock solution deaerated by a gentle N_2 flowing in another bottle (about 3 mM, 10 μL) was injected into the cuvette. This procedure avoided bubbling of a metHb solution that might induce foaming and metHb denaturation. The final concentration of heme was 0.1 mM. The cuvette was exposed to the same visible light (435 nm) as described above. The conversion of the metHb reduction was calculated from the ratio of the Soret band absorption at 405 nm (λ_{max} of metHb) versus 430 nm (deoxyHb) or 415 nm (HbO_2).

A laser flash photolysis system (Tokyo Instr. Co.) was used for the transient spectrum measurement of the reduction of FMN and the succeeding metHb (*7*). The sample solutions were excited at 450 nm with a Pulsed Nd:YAG laser (SL803G-10, Spectron Laser Systems, Ltd.) equipped with an optical parametric oscillator. One irradiation time was 5−8 ns (fwhm) and the interval was 100 ms. A total of 100 accumulations were collected to get an acceptable signal-to-noise ratio. The transient spectra were recorded between 350 and 550 nm using a spectrophotometer (MS257, Oliel Instr. Co.) equipped with an ICCD detector (DH520−18F−WR, ANDOR Technol. Co.). A sample solution was placed in a 10 mm quartz cuvette and purged with N_2. The fastest time point of the measurements was 30 ns. A solution of FMN (100 μM)/Met (20 mM) in a 10 mM phosphate-buffered saline (pH 7.4), and a solution of FMN (5 μM)/Met (20 mM)/metHb ([heme] = 10 μM) in the phosphate-buffered saline were tested.

Quantum Yield Measurement. The ferroioxalate actinometer of $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ was used to measure the quantum yield (Φ) of metHb photoreduction (*7*, *35*, *36*). In the actinometer, Φ of the photoreduction of Fe^{3+} to Fe^{2+} was assumed to be 1.11 (*35*), and this value was used to calculate the total photons absorbed by the sample solution and Φ of the metHb photoreductions.

Isoelectric Focusing (IEF) and Native Polyacrylaminde Gel Electrophoresis (Native-PAGE). IEF and native-PAGE were performed on PhastGel IEF 3−9 (pH 3−9) and PhastGel Gradient 8−25 (PAGE content, 8−25%) (Amersham Pharmacia Biotech), respectively, with the PhastSystem (Pharmacia). The photoreduced Hbs in N_2 and air in the presence of FMN/EDTA was compared with metHb and the purified HbO_2.

IEF. Forty microliters of sample (1 mg/mL) per one lane was applied on the gel. This was focused and then stained with PhastGel Blue R (Coomassie brilliant blue) in the development unit of the PhastSystem. The marker was the p*I* calibration kit 3−10 (Pharmacia).

Native-PAGE. The samples were applied on the gel and the electrophoresis was automatically performed. The gel was stained with PhastGel Blue R. The marker was HMW Kit E (Parmacia).

Restoration of Oxygen Binding Property. The photoreduced deoxyHb solution ([heme] = 20 mM, [FMN] = 5 μM, [EDTA] = 10 mM) in an Ar atmosphere was bubbled with oxygen, and the UV/vis spectroscopy was measured. The photoreduced Hb solution was permeated through a column of Sephadex G-25 (Pharmacia) to remove FMN, the oxygen equilibrium curve of the obtained Hb solution was obtained at 37 °C with a Hemox Analyzer (TCS Products Inc.), and the oxygen affinity (P_{50}) and Hill number were measured. The Hb samples were diluted in a Hemox phosphate buffer (TCS Products Inc.).

Preparation of Hb-Vesicles Coencapsulating FMN and EDTA, and the Photoreduction of metHb. HbVs were prepared as previously reported (*24*, *34*, *37*). The purified HbO_2 solution (35 g/dL, [heme] = 21.7 mM) contained FMN (5, 10, or 50 mM) and EDTA (10, 20, 30, 50, or 200 mM), this was mixed with the lipid mixtures, and the resulting multilamellar vesicles were extruded through filters to regulate the vesicular size. The lipid bilayer was composed of a mixture of 1,2-dipalmitoyl-*sn*-glycero-3-phosphatidylcholine (DPPC), cholesterol, and 1,5-*O*-dihexadecyl-*N*-succinyl-L-glutamate (DHSG) at the molar ratio of 5/5/1 (Nippon Fine Chem. Co., Osaka), and 1,2-distearoyl-*sn*-glycero-3-phosphatidylethanolamine-*N*-PEG_{5000} (PEG-DSPE, NOF Co., Tokyo) (*38*). Thus the vesicular surface was covered with PEG chains. The molar composition of the DPPC/cholesterol/DHSG/PEG-DSPE was 5/5/1/0.033. HbVs were suspended in a physiologic salt solution at [Hb] = 10 g/dL. The suspension was incubated in the dark at 40 °C for 48 h to facilitate the metHb formation and to prepare metHbV. The concentrations of FMN, EDTA, and heme of Hb in HbV, expressed as $[FMN]_{in}$, $[EDTA]_{in}$, and $[heme]_{in}$, respectively, are assumed to be identical to the fed concentrations for the HbV preparation.

Photoreduction of metHbV was performed in the same manner with a metHb solution in a relatively diluted condition ([heme] = 10 μM) in a 2 mm quartz cuvette. At a higher concentration ([heme] = 5 mM) under aerobic condition, the suspension of metHbV was sandwiched between two glass plates. The optical path length was 10 μm.

Measurement of H_2O_2 in the metHb Photoreduction. The reaction of *p*-hydroxyphenyl acetic acid (PHA) and H_2O_2 to generate a fluorescent dimer, 6,6′-dihydroxy (1,1′-biphenyl)-3,3′-diacetic acid (DBDA), was used to detect H_2O_2 generated during the metHb photoreduction in the metHbV and metHb solutions. During the photoreduction of metHb or metHbV ([heme] = 20 μM in a cuvette) in the presence of FMN (5 μM)/EDTA (50 μM), 1 mL of sample was pipetted out and immediately mixed with horseradish peroxidase (Sigma, 3.7 μM), and PHA (5.8 mM). The mixture was ultracentrifuged in a tube with a filter (Cut off Mw. 30 kDa, Ultrafree, Amicon) at 12 000 rpm for 20 min to remove Hb or HbV and to obtain the filtrate solution. The fluorescence of the filtrate was measured with a fluorometer (JASCO, Ex: 317 nm, Em: 404 nm). The calibration curve was obtained by analysis of a diluted standard H_2O_2 solution (Kanto Chem., Co).

RESULTS

Photoreduction of FMN with an Electron Donor. Figure 1 shows the time course of the conversion of FMN to $FMNH_2$ by irradiation of visible light (435 nm). FMN primarily converts to the photoexcited triplet FMN* and this reacts with two electron donors (D) to generate $FMNH_2$. The reduction can be confirmed by the decrease in the absorption of the characteristics peaks at 370 and 450 nm. Without an addition of an electron donor, photoreduction gradually proceeds (baseline, initial reduction rate = 12 μM/min) (Table 1). A ribityl group in a FMN molecule of itself can be an electron donor. However, further irradiation should induce decomposition that was evident from the phenomena that the spectroscopic curves did not coincide at the isosbestic point. A significantly fast reduction was observed by the addition of EDTA and DTPA that were 88 and 84 times faster than the condition without the addition of an electron donor. Among the amino acids, Met showed the fastest

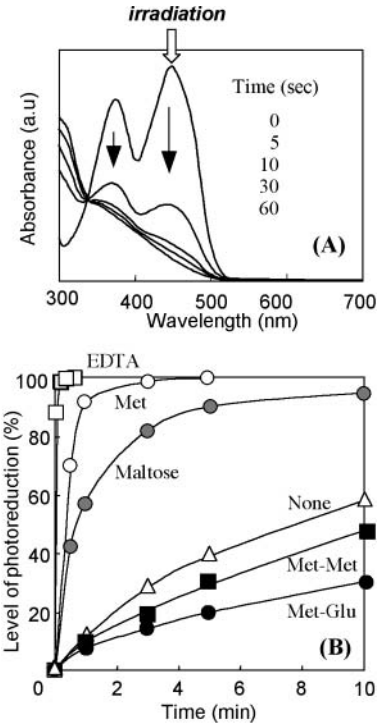

Figure 1. (A) Time course of the spectral changes during the conversion of FMN to $FMNH_2$ in the presence of EDTA (20 mM) by visible light irradiation (435 nm). The characteristic two peaks disappeared with the photoreduction conversion. (B) Time course of the conversion of FMN to $FMNH_2$ with various electron donors. EDTA and Met showed fast photoreduction rate. On the other hand, Met-Met and Met-Glu retarded the reaction. [FMN] = 100 μM, [electron donor] = 20 mM, pH = 7.4, in N_2 atmosphere.

Table 1. Initial Rates of the Photoreduction of FMN to $FMNH_2$ with Various Electron Donors (10 mM)

electron donor	mw	initial reduction rate (μM/min)	comparison with baseline
EDTA	292	1056	88
DTPA	393	1008	84
Met	149	140	11.7
Met-Met (10 mM)	280	5	0.2
Met-Met (20 mM)	280	10	0.8
Met-Glu	278	7	0.6

reduction rate (140 μM/min, 12 times faster than the baseline), while Arg, Phe, Lys, Glu, and Gln showed moderate facilitation. On the other hand, Tyr and Trp showed slower rates of photoreduction. Unexpectedly, Met-Met and Met-Glu lowered the reduction rate. As for the saccharides, mannitol, maltotriose, dextran, glucosamine, and glucron amide showed similar facilitation at the same glucose units. However, they are much slower than Met and EDTA. The presence of H_2 gas

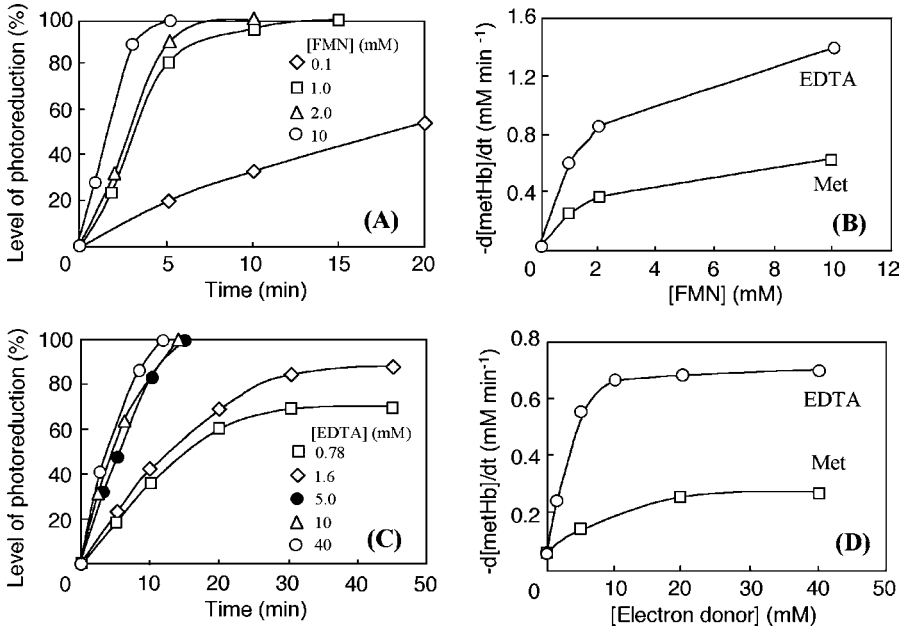

Figure 2. Influence of the concentrations of FMN and EDTA on the rate of metHb reduction. The time course of the level of photoreduction and the initial reaction rates are summarized. (A, B): Influence of the FMN concentration at a constant [EDTA] (20 mM). [FMN] was at 0.1, 1.0, 2.0, or 10 mM. (C, D): Influence of [EDTA] at the constant [FMN] (1.0 mM). [EDTA] was at 0.78, 1.6, 5.0, 10, or 40 mM. The data for the Met addition were inserted as a reference. [heme] = 3.1 mM.

slightly facilitated the reduction. Citric acid and methanol showed a slight facilitation. From these results, EDTA and Met were mainly studied as electron donors.

Reduction of metHb by the Photoreduced FMNH_2. The reduction of metHb by the photoreduced FMNH_2 was evident from the spectroscopic change of λ_{max} in the Soret and Q-bands. The influence of the concentration of FMN was examined at constant concentrations of metHb (5 g/dL, [heme] = 3.1 mM) and EDTA (20 mM) (Figure 2A). The presence of 100 μM FMN showed 50% reduction of metHb at 20 min; however, 1 mM FMN completed the reduction at 15 min. The influence of the EDTA concentration was examined at constant concentrations of metHb ([heme] = 3.1 mM) and FMN (1.0 mM) (Figure 2B). Without EDTA, the metHb photoreduction proceeded since a ribityl group of FMN and probably globin of Hb can be an electron donor. When the EDTA concentration was less than that of the heme concentration, the reduction rate was very slow, and the reduction could not be completed. However, 5 mM EDTA and higher showed a faster rate and the reduction was completed within 15 min. Similar results were obtained with Met; however, the initial rates were much slower than with EDTA.

The transient spectrum of the photoreduction of FMN in the presence of Met after laser flash irradiation showed the reduction of the absorbances at 445 and 373 nm at 30 ns, and the spectral profile was the same at 5 ms (data not shown here). Therefore, the photoreduction of FMN to FMNH_2 was completed within 30 ns. In the presence of metHb, a total of 30 ns was enough to observe the reduced deoxyHb (λ_{max} = 430 nm) and the spectrum was the same for 5 ms.

The influence of the presence of O_2 was examined (Figure 3). The metHb photoreduction in the presence of EDTA and FMN in the N_2 atmosphere completed the reduction within 15 min. The metHb photoreduction under the aerobic conditions became slightly slower, and the level of reduction reached 95% and then showed a plateau. In the case of the addition of Met, the reduction was completed within 40 min in the N_2 atmosphere that

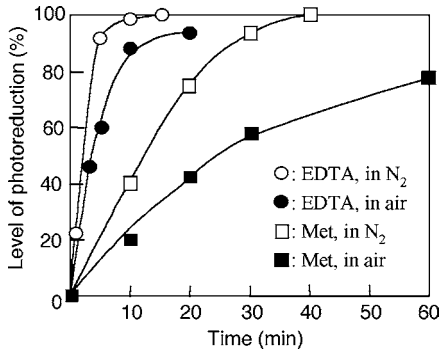

Figure 3. The influence of the presence of O_2 on the rate of photoreduction of metHb ([heme] = 3.1 mM) with FMN (1.0 mM) and an electron donor (20 mM) at pH 7.4. The data for Met addition (1.0 mM) were also inserted as a reference. The presence of O_2 retarded the metHb photoreduction.

was much slower in comparison with the EDTA addition. Under the aerobic condition, the reduction in the presence of Met was significantly slow and did not reach 80% at 60 min.

Native-PAGE of the photoreduced Hb both in the N_2 and aerobic atmospheres showed identical bands with the normal oxyHb and meHb (Figure 4A). Even though the Mw of Hb is 64.5 kDa, it showed a higher relative Mw than albumin (67 kDa) as one of the markers in the Native-PAGE in the absence of sodium dodecyl sulfate, SDS, because the surface charge of the protein directly affect on the traveling distance during the electrophoresis. IEF of the photoreduced Hbs showed the presence of HbO_2 at pI = 7.0 as a dense band and a weak band at pI = 7.2 of a partially reduced Hb (Figure 4B). There was no band at 7.4 that corresponds to metHb.

The oxygen dissociation curve of the photoreduced Hb was identical with that of the normal HbO_2 (Data not shown here). The P_{50} and Hill number of the photoreduced Hb were 10.5 Torr and 1.8, respectively, and they were almost identical with the normal HbO_2 (11 Torr and 1.7, respectively).

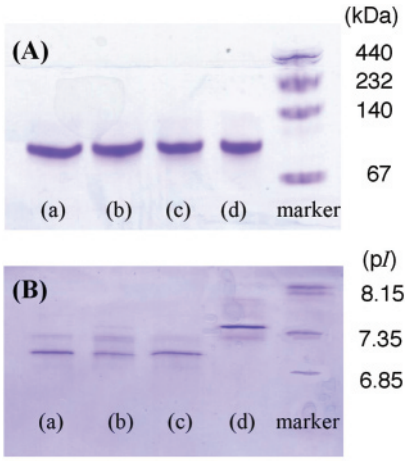

Figure 4. Native-PAGE (A) and IEF (B) of the photoreduced Hb in the presence of EDTA and FMN both in N_2 and aerobic atmospheres: (a) photoreduced Hb in N_2, (b) photoreduced Hb in air, (c) oxyHb, (d) metHb. In A, there was no change in the molecular weight of the Hb subunits. Since Native-PAGE does not include sodium dodecyl sulfate, the surface property of the protein directly affect on the traveling distance during electrophoresis. Therefore, Mw of Hb (Mw = 64.5 kDa) seemed much larger than albumin marker (Mw = 67 kDa). In B, the band at 7.4, which corresponded to metHb, almost disappeared in lanes a and b. No other bands were observed.

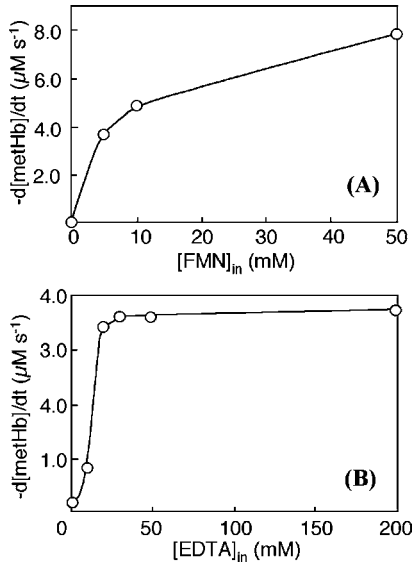

Figure 5. Influence of the concentrations of FMN and EDTA inside HbV on the initial rate of metHb reduction. (A) Influence of $[FMN]_{in}$ at the constant $[EDTA]_{in}$ = 20 mM. (B) Influence of $[EDTA]_{in}$ at the constant $[FMN]_{in}$ = 5 mM. [heme] = 10 μM in the cuvette, $[heme]_{in}$ = 21.7 mM. When $[EDTA]_{in}$ was higher than $[heme]_{in}$, the initial rate of metHb reduction was plateau.

Reduction of metHb in Hb-Vesicles. At first a diluted metHbV suspension ([heme] = 10 μM in a cuvette; $[heme]_{in}$ = 21.7 mM) was tested for photoreduction to analyze the kinetics. The initial rate of metHb reduction increased with increasing $[FMN]_{in}$ at a constant $[EDTA]_{in}$ (20 mM); however, the initial rate at $[FMN]_{in}$ = 10 mM was lower than twice that at $[FMN]_{in}$ = 5 mM (Figure 5A). At a constant $[FMN]_{in}$ (5 mM), increasing the $[EDTA]_{in}$ significantly facilitated the metHb photoreduction, however, the photoreduction rate did not increase above 20 mM (Figure 5B). This critical concentration is almost identical to $[heme]_{in}$ (21.7 mM). From these results, the rate-determining step of this system should be the electron transfer from an electron donor to the photoexcited FMN.

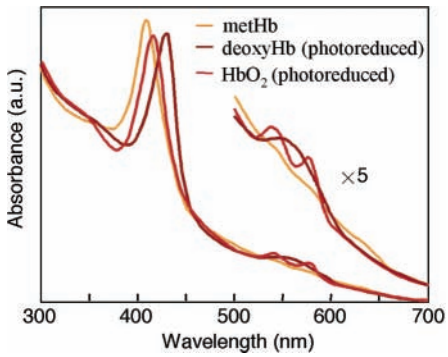

Figure 6. UV−visible spectra of HbV before irradiation (metHb), after photoreduction (deoxyHb), and its oxygenated form (HbO_2). $[EDTA]_{in}$ = 50 mM, $[FMN]_{in}$ = 5 mM, $[heme]_{in}$ = 21.7 mM. These spectra indicate the successful restoration of O_2-binding property of HbV.

The absorption spectra of the metHbV and the photoreduced HbV (λ_{max} = 430 nm) are shown in Figure 6. Due to the light scattering effect of the HbV particles, the turbidity was higher at a lower wavelength (*39*). Bubbling with an O_2 gas in a photoreduced HbV solution reversibly converted deoxyHb to HbO_2 with a characteristic shift of λ_{max} from 430 to 415 nm, indicating that the oxygen binding ability was successfully restored.

The concentration of [heme] in an HbV suspension for the intravenous infusion should be estimated to about 3−6 mM, which is significantly higher in comparison with 10 μM in a cuvette for the absorption spectral analysis. To test the photoreduction at a practical Hb concentration, a metHbV suspension ([heme] = 5.0 mM) was sandwiched between two glass plates and irradiated with visible light. The photoreduction proceeded quite promptly (Figure 7). Due to the thin liquid layer (ca. 10 μm in thickness), the effect of light scattering seen in Figure 6 is minimized. At the constant $[FMN]_{in}$ (5 mM) condition, the $[EDTA]_{in}$ of 10 and 20 mM were not enough to complete the reduction. At $[EDTA]_{in}$ = 50 mM, the photoreduction was significantly fast and the reaction was completed within 20 s with the characteristic λ_{max} of deoxyHb (430 nm). At $[FMN]_{in}$ = 100 mM and $[EDTA]_{in}$ = 20 mM, the initial reduction rate was the fastest; however, the reduction was not completed which was evident from the fact that the absorption at 430 nm in the Soret band was not high enough. The value of $[EDTA]_{in}$ should at least be higher than $[heme]_{in}$ (21.7 mM).

Quantum Yield of the Photoreduction Reactions. Table 2 summarizes the quantum yield, Φ, of various photoreduction conditions. The combination of metHb/FMN/EDTA showed the highest value (0.17) in an Ar atmosphere at [heme] = 0.1 mM. This was about 28 times higher than that for the photoreduction by the direct excitation of the N-band irradiating by near UV light (365 nm, Φ = 0.003−0.006) (*7*), and 4 times higher than the condition without an electron donor (0.04). In the case of HbV that coencapsulates FMN and EDTA, the concentrations of the components in the cuvette were much smaller, however, the concentrations in the nanoparticles (HbV) are much higher and the Φ for HbV was also very high (0.09−0.11). Probably due to the light scattering effect of HbV, Φ for HbV is slightly lower than that for the homogeneous Hb solution, but significantly higher than that for the N-band excitation (0.003−0.006).

Measurement of H_2O_2 in the metHb Photoreduction. Visible light irradiation to metHb([heme] = 20 μM)/FMN(5 μM)/EDTA(50 μM) under aerobic conditions

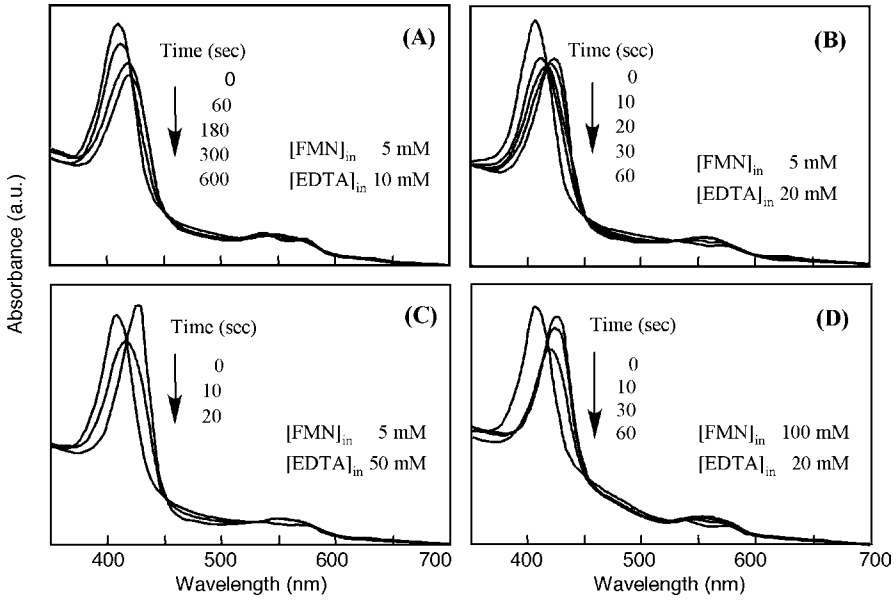

Figure 7. UV−visible spectral changes of HbV in a liquid layer sandwiched between two glass plates during photoreduction under aerobic conditions. The thickness of the layer was approximately 10 μm. Condition (C) ($[FMN]_{in} = 5$ mM, $[EDTA]_{in} = 50$ mM) showed the fastest rate of photoreduction, and the reaction was completed within 20 s. The arrows indicate the decrease in absorbance at 405 nm of MetHb with irradiation time.

Table 2. Quantum Yield (Φ) of Photoreduction of metHb and metHbV

	heme (mM)	FMN (mM)	electron donor (mM)	condition	λ_{ex} (nm)	Φ
metHb	0.1	0.01	EDTA (20)	in Ar	435	0.17
	0.1	0.01	Met (20)	in Ar	435	0.11
	0.1	0.01	no addition	in Ar	435	0.04
metHbV	0.01 (21.7)[a]	2.3×10^{-3} (5)[a]	EDTA (9.2×10^{-3}) (20)[a]	in Ar	435	0.09

produced H_2O_2, and the fluorescent intensity of DBDA ($\lambda_{em} = 404$ nm) significantly increased (Figure 8a). The amount of H_2O_2 reached 40 μM at 120 s (Figure 8b). Irradiation to FMN alone produced 100 μM H_2O_2 for 120 s without any formation of $FMNH_2$. We confirmed that the irradiation to metHb alone did not produce H_2O_2 (data not shown here). The level of metHb photoreduction was less than 20% at 120 s (Figure 8c). A significant suppression of H_2O_2 generation was confirmed for the irradiation to metHbV and the H_2O_2 generation decreased to less than 20 μM, and the level of metHb photoreduction reached 50% at 120 s. A further increase in the level of photoreduction to 80% was confirmed when the partial oxygen pressure in the cuvette was regulated to 40 Torr; however, the amount of H_2O_2 could not be significantly reduced.

DISCUSSION

We found for the first time that the coencapsulation of concentrated Hb solution and the FMN/EDTA system in phospholipid vesicles (HbV) significantly facilitated the reduction of metHb by visible light irradiation (435 nm). This was evident from the Φ of the reaction, i.e., 0.17 for the Hb solution and 0.10 for the HbV suspension. The lowered Φ for HbV in comparison with that for a Hb solution is probably due to the light scattering of the illuminated visible light due to the particle of HbV (diameter, 250 nm) (*39*). However, they are much higher than that for the metHb photoreduction via direct photoexcitation of the N-band of the porphyrin ring in the UVA region (Φ = 0.006) (*7*). Even though the concentrations of the components in the cuvette were much lower for HbV than for the homogeneous Hb solution as shown in Table 2, the concentrations inside HbV were significantly higher and this condition facilitated the desired reactions (photoreduction of FMN and metHb) and suppressed the unwanted side reactions (generation of active oxygen species).

The reaction mechanism is that the photoexcited triplet FMN* rapidly receives an electron from the donor molecule, EDTA, to transform to the semiquinone followed by disproportionation to the two electron reduced form, $FMNH_2$. They are effective reducing agent to offer an electron to metHb. According to Yubisui et al., $FMNH_2$ reduces metHb with the rate constant of 5.5×10^6 M^{-1} s^{-1} (*22*), which is significantly faster than do glutathione (rate constant = 2.5×10^{-3} M^{-1} s^{-1}) (*27*) and ascorbic acid (3.0×10^{-3} M^{-1} s^{-1}) (*22*). The transient spectrum of the reduction of metHb by the photoreduced form of FMN demonstrated the completion of the reaction at 30 ns. Our result may be plausible because it is reported that a flavocytochrome showed complete photoreduction within 100 ns (*14*), measured by a laser flash-induced transient absorption difference spectra. The externally added FMN should more freely access to the protoporphyrin IX (heme) in the Hb molecule and would show a faster electron transfer. It is reported that the direct chemical conjugation of flavin to the propionic acid residue of heme significantly facilitates the electron transfer from flavin to heme in a reconstituted myoglobin (*40*, *41*). Therefore,

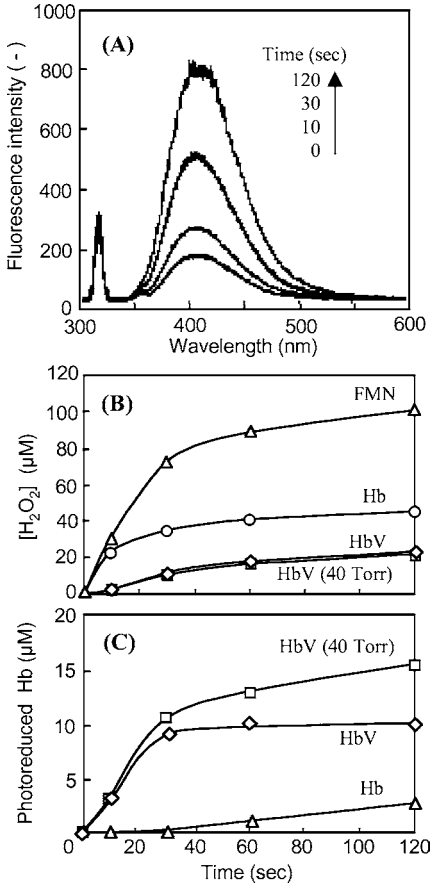

Figure 8. Detection of H_2O_2 using the fluorescence of DBDA during the photoreduction of Hb and HbV in the presence of FMN and EDTA. (A) An example of the fluorescence spectroscopy of the DBDA. The fluorescence intensity (λ_{em} = 404 nm) increased with time during the photoreduction of metHb solution under aerobic conditions (pO_2= 150 Torr). (B) Time course of the generation of H_2O_2 during the photoreduction of Hb and HbV under aerobic conditions (pO_2= 150 Torr), and HbV at pO_2 = 40 Torr. Irradiation to FMN alone was also tested as a reference (top curve) that produced 100 μM H_2O_2 for 120 s. Liberation of H_2O_2 from HbV was significantly suppressed in comparison with Hb solution. (C) The levels of metHb photoreduction during the measurement of H_2O_2 generation. The concentrations of heme (20 μM), FMN (5 μM), and EDTA (50 μM) in the cuvette were identical between the metHb solution and HbV suspension. For HbV, $[heme]_{in}$ = 21.6 mM, [FMN]in = 5 mM, and $[EDTA]_{in}$ = 50 mM.

two propionic acid groups of a heme that directly face the outer aqueous phase of an Hb molecule should contribute to the electron transfer from the externally added FMN to the heme.

The side reaction of $FMNH_2$ is the reaction with O_2 to generate singlet O_2 ($^1O_2$) or H_2O_2 (*11*, *42*), due to the low redox potential of reduced flavin (E_m = −209 mV). However, according to the quantitative measurement of H_2O_2, photoreduction of metHbV significantly reduced the side reaction in comparison with the metHb solution. This effect is due to the highly concentrated condition inside metHbV: the photoexcited FMN* readily reacts with EDTA to generate $FMNH_2$, and it also readily reacts with concentrated metHb inside the HbV nanoparticle. However, for the complete removal of H_2O_2, further coencapsulation of catalase would be effective (*29*) in the presence of O_2. Of course, in the absence of O_2, only the metHb reduction proceeds.

We tried to find other optimal electron donors instead of EDTA, because it has been reported that the oxidized and decomposed EDTA elements contain acetaldehyde that might react with the lysine residues on a protein molecule (*10*), and EDTA is a strong chelator of Ca^{2+} as an anticoagulant and may require caution when using a large dosage. We confirmed that Met was effective secondary to EDTA, as reported by other researchers (*9*, *32*). Arg was also effective, but it was not stable against oxidation during incubation under aerobic conditions at 37 °C for 3 days. Met was stable against oxidation. However, the small amino acid, Met (Mw = 149), gradually leaks out from the HbV across the phospholipid bilayer membrane (data not shown). To minimize the leakage of an electron donor, larger molecules, Met-Met and Met-Glu, were tested. Unexpectedly, they did not show any contribution as an electron donor and retarded the reduction of FMN. The ribityl phosphate group in the FMN molecule can be an electron donor, because the photoreduction of FMN proceeds without the addition of an electron donor. The retardation by the peptides should be probably due to some interaction of these peptides with the ribityl phosphate group that may hinder the electron transfer to the isoalloxazine ring. Other amino acids such as Phe and Lys, and saccharides such as mannitol or maltotoriose, are effective as an electron donor; however, their reduction rates of FMN were much lower in comparison with EDTA. Interestingly, methanol and gaseous H_2 also showed facilitation. DTPA, a structure similar to EDTA, showed an effectiveness comparable with EDTA. EDTA is a well-known electron donor, and its larger size (Mw = 292) and four negative charges prevent leakage from the vesicles. We could not find a more effective electron donor in our study, but confirmed that IEF and native-PAGE did not demonstrate any change in the chemical modification of the photoreduced Hb in the presence of EDTA/FMN, and the O_2 binding property was successfully restored. Therefore, we tested coencapsulation of FMN/EDTA in HbV for the other studies.

When HbV is intravenously infused for the substitution of blood, the concentrations of Hb and the heme of HbV in plasma should reach 5 g/dL and 3.1 mM, respectively, or higher (*43*). These are much higher than the experimental conditions in Figures 1−4, and it is impossible to test such a highly concentrated solution in a cuvette because of the strong light scattering by the particles and absorption by Hbs. We thus tested sandwiching the solution with two glass plates, thus making a thin liquid layer between the glass plates. The thickness of the liquid membrane is approximately 10 μm, about twice the capillary diameter in in vivo peripheral tissues. Irradiation of visible light onto the liquid membrane of HbV coencapsulating FMN and EDTA showed significantly fast rates for the metHb photoreduction. Especially, the coencapsulation of FMN (5 mM) and EDTA (50 mM) completed the metHb photoreduction within only 20 s. This significantly fast photoreduction system would be applicable to the transcutaneous irradiation of visible light to the body for the rejuvenation of HbV when the metHb content increased after the infusion of HbV.

In our study we established an efficient photoreduction system in a nanoparticle as shown in Figure 9. The illuminated visible light excites FMN to convert it to FMN*, and this reacts with an electron donor and transforms to $FMNH_2$, that subsequently reduces ferric metHb to its ferrous form. The reduced Hb can then reversibly bind O_2. Irrespective of the blood substitutes, one advantage of coencapsulation in a nanoparticle is that the concentrations of the components in the vesicles (nanoenvironment) are very high. Accordingly, the desired reactions are significantly accelerated and the

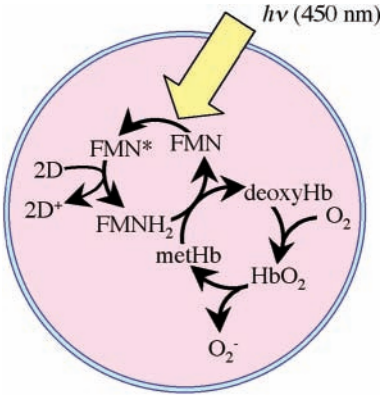

Figure 9. MetHb photoreduction system in a nanoparticle (HbV) using FMN and an electron donor (D), and recovery of the O_2-binding property.

unwanted side reaction is minimized in comparison with the homogeneous solution. To completely eliminate the side reaction of $FMNH_2$ and O_2, photoreduction under anaerobic conditions or coencapsulation of a radical scavenger, such as catalase, would be effective (*29*, *30*). RBC contains NADPH-flavin reductase to reduce metHb (*21*), and the reduced form of flavin is susceptible to react with O_2 as a side reaction. However, our results imply that the highly concentrated condition in RBCs and well-organized radical scavenging system should contribute to the effective metHb reduction in RBCs.

Highly Efficient Technetium-99m Labeling Procedure Based on the Conjugation of *N*-[*N*-(3-Diphenylphosphinopropionyl)glycyl]cysteine Ligand with Poly(ethylene glycol)

Roberta Visentin,† Gianfranco Pasut, Francesco Maria Veronese,* and Ulderico Mazzi*

Department of Pharmaceutical Sciences, University of Padova, 35131 Padova, Italy. Received April 28, 2004; Revised Manuscript Received June 30, 2004

The PN_2S *N*-(*N*-(3-diphenylphosphinopropionyl)glycyl)cysteine ligand was conjugated to methoxy-poly(ethylene glycol)-amino (mPEG-NH_2) 5 and 20 kDa to yield PN_2S(Trt)-PEG_{5000} **1** and PN_2S(Trt)-PEG_{20000} **2**, and then detritylated to PN_2S-PEG_{5000} **4** and PN_2S-PEG_{20000} **5**. When an acidic solution of $^{99m}TcO_4^-$ is added to **4** or **5** in solid form, a quantitative yield in a single labeled species, ^{99m}Tc-labeled PN_2S-PEG_{5000} **9** and ^{99m}Tc-labeled PN_2S-PEG_{20000} **10**, respectively, is obtained. The reaction occurs in less than 15 min at room temperature for **4** and 35 °C for **5**. This labeling procedure avoids the use of an external reducing agent, and it is based on the amphiphilic properties of PN_2S-PEGs. Once in water, **4** and **5** self-assemble in micelles, which catalyze the metal reduction by means of an electron pair transfer from the phosphorus to technetium. The $[^{99m}TcO]^{3+}$ species is then coordinated, and at micelle level, both the (P)ON_2S and the PN_2S coordinations are possible, as demonstrated by reacting ^{99m}Tc-gluconate and $ReOCl_3(PPh_3)_2$ with **4** and **5** and with the oxidized analogous (P)ON_2S-PEG_{5000} **6**. Compounds **9** and **10** exhibited a high stability both in vitro and in vivo. Biodistribution studies in mice also indicated that PN_2S linking and ^{99m}Tc labeling do not modify PEG behavior in water and in vivo since the polymer dictates the fate of the conjugate.

INTRODUCTION

In the last decades, a large number of techniques have been developed to label biomolecules with ^{99m}technetium and $^{186/188}$rhenium (*1*, *2*). In the most popular approach, namely, the bifunctional approach, the radionuclide is bound to the targeting molecule by means of a bifunctional chelating agent (BFCA) (*3*, *4*). The BFCA comprises a donor atom set to strongly coordinate the radiometal and a functional group to be covalently attached to the targeting molecule, either directly or through a linker. Among the available BFCAs, *N*-(*N*-(3-diphenylphosphinopropionyl)glycyl)-*S*-tritylcysteine, bearing a PN_2S set, was previously labeled with ^{99m}Tc leading to the penta-coordinated $^{99m}TcO[PN_2S]-OH$ (*5*). The labeled compound exhibited high stability in human plasma and in vivo, although the biodistribution was characterized by high hepatobiliary excretion, due to the lipophilicity of the complex. This suggested the need for chemical modification of the ligand to achieve a pharmacokinetics that favors renal clearance.

Attempts to overcome the problems related to radiopharmaceutical in vivo behavior may include the use of polymeric linkers acting as pharmacokinetic modifiers. Among the available polymers, poly(ethylene glycol) (PEG) is the most successfully used in pharmaceutical science (*6*, *7*). Thanks to its unique characteristics, like absence of immunogenicity and toxicity and high solubility either in aqueous or in organic solvents, PEG is extensively used for conjugation to proteins, peptides, and small drugs. It is able to transfer its properties to the conjugated molecules, and the products usually become less antigenic, less immunogenic, and more soluble with respect to the parent molecules. PEGylation also prevents recognition by antibodies and degradation by proteolitic enzymes and decreases renal clearance of small water-soluble molecules, prolonging the half-life of biomolecules. More recently, it was demonstrated that PEG gives to drugs passive tumor targeting by enhanced permeability and retention (EPR) effect (*8*).

These considerations prompted us to synthesize a novel class of PEG conjugates bearing the PN_2S chelating agent (PN_2S-PEGs) and to investigate the coordination with ^{99m}technetium and cold rhenium. During this study, a new labeling method based on the amphiphilic character of PN_2S-PEGs and avoiding the use of an external reducing agent was discovered. In vivo studies are also reported to evaluate the change to the biodistribution of ^{99m}Tc-complex afforded by PEGylation.

EXPERIMENTAL SECTION

Materials. All chemicals were reagent grade and used without further purification. Amino acids and reagents were purchased from Novabiochem (Laufelfingen, Switzerland) and Fluka (Sigma-Aldrich, Milan, Italy); 3-diphenylphosphinopropionic acid succinimide ester was provided from Argus Spechem S.a.s. (Prato, Italy); mPEG-NH_2[1] (MW 5 and 20 kDa) were purchased from Nektar Co. (Huntsville, AL). Rhenium was purchased from Sigma-Aldrich (Milan, Italy) as $KReO_4$, and the precursor $ReOCl_3(PPh_3)_2$ was synthesized according to the literature procedure (*9*). The synthesis of the *N*-[*N*-(3-diphenylphosphinopropionyl)glycyl]-*S*-trityl-L-cysteine (PN_2S-(Trt)-OH) ligand was performed according to the previously reported procedure (*10*). The syntheses of ligands

and complexes were carried out under an argon atmosphere using solvents degassed and tested for peroxides before use.

Solvents for syntheses and analysis and HPLC eluents were purchased from Fluka (Sigma-Aldrich, Milan, Italy) and Carlo Erba Reagenti (Div. Antibioticos, Milan, Italy); MilliQ water was obtained from a Millipore system (Millipore, Vimodrone, Milan, Italy). $CDCl_3$ for ^{1}H NMR, ^{13}C NMR, and ^{31}P NMR analysis was purchased from Sigma-Aldrich (Milan, Italy).

$Na^{99m}TcO_4$ was eluted from a commercial Drytec Sorin ^{99}Mo/^{99m}Tc generator (Nycomed Amersham Sorin, Saluggia, Vercelli, Italy). *Caution!* ^{99}Tc is a weak β^--emitter ($E = 0.292$ MeV, $t_{1/2} = 1.12 \times 10^5$ years). All manipulations were carried out in laboratories approved for low-level radioactivity use. Handling milligram amounts of ^{99}Tc does not present a serious health hazard since common laboratory glassware provides adequate shielding and all work is performed in approved and monitored hoods and gloveboxes. Bremsstrahlung is not a significant problem due to the low energy of the β^- particles; however, proper radiation safety procedures must be followed at all times, and particular care should be taken when handling solid samples.

Analytical Methods. ^{1}H NMR spectra were obtained on a Bruker 300 MHz spectrometer, and chemical shifts (ppm) were referenced to tetramethylsilane (TMS). ^{31}P NMR were recorded on a Bruker AC-200 spectrometer using 85% aqueous H_3PO_4 as external reference. Multiplicities were reported as s (singlet), d (doublet), dd (doublet of doublets), t (triplet), q (quadruplet), m (multiplet), and b (broad signal).

RP-HPLC analysis was performed on a LKB−Bromma system (Pharmacia, Cologno Monzese, Italy) comprising a binary LKB 2249 programmable gradient pumps controlled by a gradient controller 680 automated equipped with a LKB−Bromma 2140 tunable absorbance detector (Pharmacia, Cologno Monzese, Italy) set at 215 nm, a Beckman model 170 radioisotope detector system (Beckman, Milano, Italy), and a data module integrating recorder. The UV chromatograms were elaborated by using the WAVESCAN EG software (Pharmacia, Cologno Monzese, Italy), and the UV−RA (radioactive) chromatograms were elaborated by using the PE Nelson 900 series interface software (Pharmacia, Cologno Monzese, Italy). For analytical injections, a Hamilton PRP-1 column (4.1 mm × 250 mm, Alltech Italia, Sedriano, Milan, Italy) was used with a 20 μL injection loop and equipped with a Hamilton PRP-1 precolumn (Alltech Italia, Sedriano, Milan, Italy). The elution method consisted of a linear gradient (0−3 min, 20% solvent B; 3−28 min, 20−60% solvent B; 28−30 min, 60−100% solvent B; 30−33 100% solvent B; 33−35 min, 100−20% solvent B) using a mobile phase of 0.1% TFA in water (solvent A) and 0.05% TFA in MeCN (solvent B) at a flow rate of 1 mL min^{-1}.

Mass spectra were obtained on a Voyager-DE matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry system (PerSeptive Biosystems Inc, Framingham, MA). Data for 2 ns pulses of the 337 nm nitrogen laser were averaged for each spectrum in a linear mode, and a positive ion TOF detection was performed using an accelerating voltage of 25 kV. Synapinic acid was used as matrix.

Labeling efficiency and radiochemical purity (RCP) were assessed by reverse-phase high-performance liquid chromatography (RP-HPLC) and thin-layer chromatography (TLC). The RP-HPLC peak of the labeled compound was recovered, and the activity of the collected fraction was measured with a dose calibrator M2361 Messelektronik (Dresden, Germany). RCP was expressed as the percent of injected activity. TLC was performed on Merck silica F_{254s} plates. Ten microliters of the sample was applied at the application point 1 cm from the bottom and eluted over a distance of 7 cm from the bottom. Plates were then cut 4 cm above the application point and the activity of each part was measured using the above-mentioned dose calibrator. The absence of free pertechnetate ($^{99m}TcO_4^-$) in ^{99m}Tc-gluconate solution was assessed using acetone as eluent ($^{99m}TcO_4^-$ $R_F = 1$; ^{99m}Tc-gluconate $R_F = 0$; ^{99m}Tc-colloid $R_F = 0$), whereas determination of reduced-hydrolyzed ^{99m}Tc (colloid) in the same solution was performed using saline (^{99m}Tc-gluconate $R_F = 0.9-1$; ^{99m}Tc-colloid $R_F = 0$). The percentage of colloid (C) was calculated with the following formula: $C = [(A_{Tot} - A_{gluc})/A_{Tot}] \times 100$. Radiochemical purity of ^{99m}Tc-labeled PEGylated compounds was determined by eluting the TLC with saline ($R_F = 0.5$) and calculated with the following formula: $RCP = [(A_{Tot} - A_{gluc})/A_{Tot}] \times 100 - C$. Alternatively, the absence of ^{99m}Tc colloid was verified by subsequent analysis of the labeling mixture via HPLC to ensure a quantitative elution of activity from the column.

PN_2S(Trt)-PEG_{5000} (1). To a chilled solution (4 °C) of PN_2S(Trt)-OH (198 mg, 0.30 mmol) in CH_2Cl_2 (10 mL) were added NHS (51 mg, 0.45 mmol) and DCC (185 mg, 0.90 mmol). The mixture was warmed to room temperature and stirred for 5 h under an argon atmosphere. Then $mPEG_{5000}-NH_2$ (1.00 g, 0.20 mmol) previously dissolved in CH_2Cl_2 (4 mL) and TEA (41 μL, 0.30 mmol) were added. The reaction was left to proceed for 10 h at room temperature. The mixture was then filtered, and the solution was dropped into EtOAc (150 mL) and cooled at 0 °C for 3 h. On cooling, the product precipitated, and the excess of PN_2S(Trt)-OH remained in solution. The product collected on a funnel was dried under vacuum and purified by recrystallization from EtOAc. Yield: 90% (1.01 g, 0.18 mmol). ^{1}H NMR ($CDCl_3$): 2.24−2.85 (m, $P(CH_2)_2$, Cys-βCH_2), 3.38 (s, OCH_3, PEG), 3.64 (bs, $(OCH_2CH_2)_n$, PEG), 4.25 (m, Cys-αCH), 7.24−7.52 (m, ArH). ^{31}P NMR ($CDCl_3$): −14.49. MALDI-TOF MS: bell-shaped spectrum centered at 5701 Da (theory 5642 Da). HPLC: $t_R = 24.73$ min.

PN_2S(Trt)-PEG_{20000} (2). The same procedure was followed as for the synthesis of compound **1**, except for the following changes: PN_2S(Trt)-OH (49 mg, 0.07 mmol); NHS (13 mg, 0.11 mmol); DCC (45 mg, 0.22 mmol); TEA (9 μL, 0.07 mmol); $mPEG_{20000}-NH_2$ (1.00 g, 0.05 mmol). Yield: 91% (0.94 g, 0.04 mmol).^{1}H NMR ($CDCl_3$): 2.32−2.87 (m, $P(CH_2)_2$, Cys-βCH_2), 3.42 (s, OCH_3, PEG), 3.71 (bs, $(OCH_2CH_2)_n$, PEG), 7.20−7.47 (m, ArH). ^{31}P NMR ($CDCl_3$): −14.74. MALDI-TOF MS: bell-shaped spectrum centered at 20 986 Da (theory 20 642 Da). HPLC: $t_R =$ 23.48 min.

(P)ON_2S(Trt)-PEG_{5000} (3). The procedure for the synthesis of compound **1** was followed, except for the following changes: (P)ON_2S(Trt)-OH (203 mg, 0.30 mmol).

[1] Abbreviations: CH_2Cl_2, dichloromethane; $CHCl_3$, chloroform; DCC, *N*,*N*′-dicyclohexylcarbodiimide; EtOAc, ethyl acetate; EtOH, ethanol; Et_2O, diethyl ether; $KReO_4$, potassium perrhenate; mPEG-NH_2, methoxy-PEG-amino; MeCN, acetonitrile; Na-gluconate, sodium gluconate; $mPEG_{5000}-NH_2$, methoxy-PEG-amino MW 5 kDa; $mPEG_{20000}-NH_2$, methoxy-PEG-amino MW 20 kDa; $Na^{99m}TcO_4^-$, sodium pertechnetate; PBS, phosphate buffer solution; NHS, *N*-hydroxysuccinimide; $ReOCl_3(PPh_3)_2$, *trans*-oxotrichloro bistriphenylphosphine rhenium(V); saline, physiological solution (0.9% NaCl); $SnCl_2$, tin(II) chloride; TEA, triethylamine; TFA, trifluoroacetic acid.

Yield: 94% (1.06 g, 0.18 mmol). ^{1}H NMR ($CDCl_3$): 2.48−2.90 (m, $P(CH_2)_2$, Cys-βCH_2), 3.37 (s, OCH_3, PEG), 3.68 (bs, $(OCH_2CH_2)_n$, PEG), 4.32 (m, Cys-αCH), 7.17−7.88 (m, ArH). ^{31}P NMR ($CDCl_3$): 33.46. MALDI-TOF MS: bell-shaped spectrum centered at 5700 Da (theory 5658 Da). HPLC: t_R = 24.75 min.

PN_2S-PEG_{5000} (4). Compound **1** (100 mg, 1.7×10^{-2} mmol) was dissolved in CH_2Cl_2 (1 mL) and TFA (7 mL). Triethylsilane was added until the solution became colorless, and the final mixture was stirred for 45 min. TFA was removed under vacuum, and the resulting residue was crystallized as a white powder upon addition of cold EtOAc. Yield: 92% (88 mg, 1.6×10^{-2} mmol). ^{1}H NMR ($CDCl_3$): 2.31−2.89 (m, $P(CH_2)_2$, Cys-βCH_2), 3.25 (s, OCH_3, PEG), 3.68 (bs, $(OCH_2CH_2)_n$, PEG), 4.56 (m, Cys-αCH), 7.38−7.64 (m, ArH). ^{31}P NMR ($CDCl_3$): −15.02. HPLC: t_R = 19.53 min.

PN_2S-PEG_{20000} (5). The procedure was followed as in the synthesis of compound **4**, except for the following changes: compound **2** (100 mg, 0.5×10^{-2} mmol); TFA (15 mL). Yield: 90% (89 mg, 0.4×10^{-2} mmol). ^{1}H NMR ($CDCl_3$): 2.27−2.78 (m, $P(CH_2)_2$, Cys-βCH_2), 3.36 (s, OCH_3 PEG), 3.72 (bs, $(OCH_2CH_2)_n$, PEG), 7.35−7.51 (m, ArH). ^{31}P NMR ($CDCl_3$): −14.91. HPLC: t_R = 20.02 min.

$(P)ON_2S-PEG_{5000}$ (6). The same procedure for the synthesis of compound **4** was followed, except for the following change: compound **3** (100 mg, 1.7×10^{-2} mmol). Yield: 89% (85 mg, 1.5×10^{-2} mmol). ^{31}P NMR ($CDCl_3$): 36.76. HPLC: t_R = 19.77 min.

$ReO[PN_2S]$-PEG_{5000} (7). To a solution of **4** (250 mg, 4.6×10^{-2} mmol) in degassed CH_2Cl_2 (5 mL) was added a solution of $ReOCl_3(PPh_3)_2$ (38 mg, 4.4×10^{-2} mmol) in the same solvent (3 mL). TEA was added to the mixture to pH 9, resulting in a reddish-brown solution. The final complex was crystallized by adding Et_2O to the solution previously concentrated under vacuum. HPLC: t_R = 21.34 min. UV−vis (nm, $CHCl_3$): 507. ^{1}H NMR ($CDCl_3$): 2.28−2.99 (m, $P(CH_2)_2$), 3.23 (s, OCH_3, PEG), 3.71 (bs, $(OCH_2CH_2)_n$, PEG), 4.30 (dd, ^3J = 11.1, Cys-βCH, anti isomer), 4.51 (d, ^3J = 20.4, Gly-CH, anti isomer), 4.71 (d, ^3J = 21.0, Gly-CH, syn isomer), 4.82 (d, ^3J = 20.4, Gly-CH, anti isomer), 4.88 (d, ^2J = 21.0, Gly-CH, syn isomer), 5.25 (d, Cys-αCH, anti isomer), 5.66 (dd, ^3J = 8.4, Cys-αCH, syn isomer), 7.40−7.74 (m, ArH).

$ReO[(P)ON_2S]$-PEG_{5000} (8). To a solution of **6** (50 mg, 0.9×10^{-2} mmol) in degassed CH_2Cl_2 (3 mL) was added a solution of $ReOCl_3(PPh_3)_2$ (7 mg, 0.9×10^{-2} mmol) in the same solvent (2 mL). TEA was added to the mixture to pH 7, resulting in an orange solution. The final complex was crystallized by adding Et_2O to the solution previously concentrated under vacuum.

^{99m}Tc-labeled PN_2S-PEG_{5000} (9). $^{99m}TcO_4^-$ solution freshly eluted from generator was acidified to pH 2 (0.1 M HCl). One hundred microliters of the solution (1−2 mCi) was added to compound **4** (2 mg, 3.7×10^{-4} mmol) in a 1.5 mL eppendorf vial, and the final mixture was kept at room temperature for 10−15 min. Labeling yield > 95%. HPLC: t_R = 21.19 min.

^{99m}Tc-labeled PN_2S-PEG_{20000} (10). The same procedure was followed as in the synthesis of compound **9**, except for the following changes: compound **5** (8 mg, 3.9×10^{-4} mmol); incubation at 37 °C for 10−15 min. Labeling yield > 95%. HPLC: t_R = 21.91 min.

^{99m}Tc-gluconate. ^{99m}Tc-gluconate was prepared by adding 100 μL of freshly eluted $^{99m}TcO_4^-$ (5−10 mCi) to 10 μL of 0.01 M Na-gluconate (saline) and 1 μL of 0.1 M $SnCl_2$ (0.1 M HCl). The product was purified by Sep-pak chromatography. HPLC: t_R = 2.05 min.

$^{99m}TcO[PN_2S]$-PEG_{5000} (11). To a sample of compound **4** (2 mg, 3.7×10^{-4} mmol) was added a solution of purified ^{99m}Tc-gluconate (50 μL, 1−2 mCi) diluted with absolute EtOH (250 μL). The pH was increased to 9−10 by addition of 0.1 M NaOH, and the mixture was kept at 37 °C for 45 min. Labeling yield > 95%. HPLC: t_R = 20.96.

$^{99m}TcO[PN_2S]$-PEG_{20000} (12). The labeling of compound **5** (8 mg, 3.9×10^{-4} mmol) was performed following the same procedure described for the synthesis of compound **11**. Labeling yield > 95%. HPLC: t_R = 21.45.

$^{99m}TcO[(P)ON_2S]$-PEG_{5000} (13). The labeling of compound **6** (2 mg, 3.7×10^{-4} mmol) was performed following the same procedure described for the synthesis of compound **11**. Labeling yield > 95%. HPLC: t_R = 20.67.

Light Scattering Measurements. The tendency of **4** and **5** to self-associate in micellar aggregates in aqueous solutions was evaluated by dynamic light scattering (DLS) experiments performed at 25 °C using a Nicomp 170 computing autocorrelator (Pacific Scientific, Silver Spring, MD) equipped with a Spectra Physics Stabilite 2017 (Spectra Physics, Mountain View, CA; polarized argon laser 496 nm). A solid sample of the compound was directly dissolved in PBS (pH 4, 7.4, and 10) or in saline (pH 2, 0.1 M HCl) to a final concentration of 20 mg/mL for **4** and 80 mg/mL for **5**. DLS analysis was also employed to assess the presence of micellar aggregates in the labeling mixtures containing compounds **9** and **10**.

Critical Micellar Concentration. Critical micellar concentration of **4** and **5** was evaluated by fluorescence experiments using pyrene as fluorescence probe following a literature procedure (*11*). An amount of PEGylated compound was added to a volumetric flask, and degassed saline (pH 2, 0.1 M HCl) was added to give a final concentration of 20.0 g/L. The solution was diluted to yield stock solutions at different conjugate concentrations from 20.0 to 0.05 g/L. A known amount of pyrene in acetone was added to each of a series of 10 mL volumetric flasks, and the acetone was removed by evaporation. The amount of pyrene was chosen to give a final concentration of 6×10^{-7} M, close to the saturation solubility of pyrene in water at 22 °C, or 1.2×10^{-7} M. To each flask, a stock solution (10 mL) of PEGylated compound was then added. The closed flasks were heated for 3 h at 65 °C to equilibrate pyrene and micelles and subsequently allowed to cool overnight in the dark at room temperature. For measurements, 3 mL of each solution was placed in a quartz cuvette, and the fluorescence (λ_{ex} = 339 nm) and excitation (λ_{em} = 390 nm) spectra were recorded on a Shimatzu RF-540 spectrofluorophotometer at 25 °C and accumulated with an integration time of 1s/0.5 nm.

Specific Activity Determination. To $^{99m}TcO_4^-$ solution freshly eluted from generator (100 μL, 1−2 mCi) was added a standard solution of $^{99}TcO_4^-$ (^{99}Tc is the carrier) in saline (9 μL). The final mixture was acidified to pH 2 (0.1 M HCl) and added to **4** (2 mg, 3.7×10^{-4} mmol) in a 1.5 mL eppendorf vial. The solution was kept at room temperature for 10−15 min. The experiment was performed using 3.95×10^{-2}, 3.95×10^{-3}, and 3.95×10^{-4} M $^{99}TcO_4^-$ solutions to have a ^{99}Tc/PN_2S-PEG_{5000} molar ratio of 1:1, 1:10, and 1:100. The specific activity was determined with the following formula: specific activity = A (MBq)/PN_2S-PEG_{5000} (μmol), where A is the activity when no free $^{99m}TcO_4^-$ is detectable in the labeling mixture assuming the whole Tc (^{99m}Tc and ^{99}Tc) present in the solution as ^{99m}Tc, since ^{99m}Tc and ^{99}Tc are chemically indistinguishable. The amount of generator eluate ^{99m}Tc being negligible, A can be calculated by using the following formula: $A = [(n_{Tc}N_{AV})/N_t] \times 37$, where n_{Tc} =

^{99}Tc moles, N_{AV} = Avogadro's number (6.022×10^{23}), N_t = number of ^{99m}Tc atoms that correspond to 1 mCi of activity (1.16×10^{12}), and 37 is the conversion factor between mCi and MBq (1 mCi = 37 MBq).

In Plasma Stability. The stability of **9** and **10** was evaluated in human plasma. Aliquots of the labeling mixture (30 μL, 500 μCi) were diluted with freshly prepared human plasma from healthy donors (250 μL) and incubated at 37 °C for various times (1, 2, 4, and 6 h). After incubation, protein fractions in the samples were precipitated with MeCN/EtOH (1/1, 50 μL) and centrifuged (4 °C, 6000 rpm). After repeated precipitation and centrifugation, the supernatant was analyzed by RP-HPLC. Data are expressed as percentage of activity corresponding to intact complex and are means ± SD of five experiments. The stability was assessed in the presence and in the absence of micelles. To reach a final concentration of **4** and **5** in the plasma sample under the critical micellar concentration, the labeling mixture was conveniently diluted before incubation.

In Vivo Biodistribution. Compounds **9** and **10** were studied in vivo. All animal experiments were carried out in accordance with national regulations. Male Swiss mice (25−28 g) were from our department. Animals were anaesthetized by intraperitoneal injection of 100 μL of a solution containing tiletamine hydrochloride/zolazepam hydrochloride (1/1, 40 mg/kg) and xilazine (2 mg/kg). The biodistribution was evaluated by intravenous administration of labeled compounds via the tail vein (n = 3). Before injection, the labeling mixture was neutralized (1 M NaOH) and diluted with saline to a final concentration in PEGylated compound of 5 and 20 mg/mL for **4** and **5**, respectively. The biodistribution was evaluated by administration of about 700 μCi/100 μL. Scintigraphic images were collected using a YAP-camera, a γ-camera optimized to perform experiments on small animals with a spatial resolution of 1.0−1.2 and a 40 × 40 mm^2 field of view (*12*). Acquisition of images started 5 min post-injection and images of 1 min were acquired for a total time of 40 min and 3 h after administration of **9** and **10**, respectively. Collected images were elaborated in 10 min images using the Scion Image program. After scintigraphic analysis, tissues and organs were excised from the sacrificed animals and weighed, and the radioactivity counts were determined with a dose calibrator. The blood was withdrawn from the heart through a syringe immediately after sacrifice and counted. Data are expressed as percentage of injected dose (% ID) and of injected dose per gram of tissue (% ID/g). The activity in whole blood was estimated assuming a blood volume of 6.5% of the total body weight.

RESULTS AND DISCUSSION

Synthesis of PEGylated Ligands. The PEGylation of the PN_2S(Trt)-OH ligand and of the oxidized analogous (P)ON_2S(Trt)-OH was achieved at the level of the cysteine carboxylic group, following DCC/NHS activation in dichloromethane to couple to mPEG-NH_2 5 and 20 kDa. PN_2S-(Trt)-PEG_{5000} **1**, PN_2S(Trt)-PEG_{20000} **2**, and (P)ON_2S(Trt)-PEG_{5000} **3** (Figure 1) were obtained in high yield (>90%).

The conjugates showed high solubility in water where both PN_2S(Trt)-OH and (P)ON_2S(Trt)-OH and detritylated derivatives were insoluble. The purity and the identity of the products were assessed by RP-HPLC, MALDI-TOF spectrometry, ^{1}H NMR, and ^{31}P NMR. Laser desorption mass spectrometry gave a bell-shaped spectrum centered at 5701 Da for **1**, at 20 986 Da for **2**, and at 5700 Da for **3** with a family of adjacent peaks at 44 ± 1 Da (the ethylene oxide unit) due to the polydispersity of PEG. The ^{31}P NMR spectra showed a singlet at −14.49 ppm for **1** and at −14.74 ppm for **2**, characteristic of a phosphine phosphorus, and at 33.46 ppm for **3**, confirming the presence of completely oxidized phosphorus. The ^{1}H NMR signals of the PN_2S or (P)ON_2S set protons were detectable despite the broadness of PEG methylene signal, the ligand proton resonances being upshielded or deshielded with respect to PEG chemical shifts. The RP-HPLC chromatogram, as revealed at 215 nm, showed a single homogeneous peak at 24.73, 23.48, and 24.75 min for **1**, **2** and **3**, respectively.

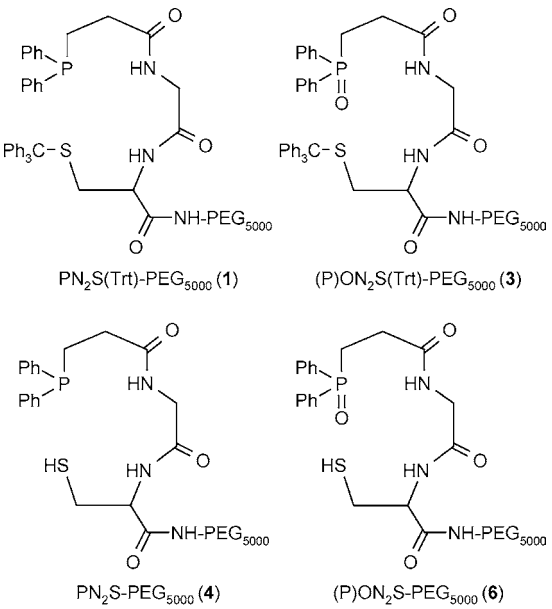

Figure 1. Structures of PEGylated PN_2S (**1**) and (P)ON_2S (**3**) ligands and structures of detritylated derivatives (**4** and **6**) used for ^{99m}Tc-labeling and Re-coordination studies.

To perform the complexation reactions with ^{99m}technetium and $^{185/187}$rhenium, the conjugates were detritylated with trifluoroacetic acid and triethylsilane (*13*) to yield PN_2S-PEG_{5000} **4**, PN_2S-PEG_{20000} **5**, and (P)ON_2S-PEG_{5000} **6**. The products were crystallized from degassed ethyl acetate to avoid the oxidation of phosphorus or the dimerization of cysteine. The purity of compounds was assessed by RP-HPLC, showing a single homogeneous peak at 19.49, 20.02, and 19.77 min for **4**, **5**, and **6**, respectively.

Direct Labeling of $PN_2S-PEGs$. The use of phosphine ligands as reducing agents for $^{99m}TcO_4^-$ is reported in the literature (*14*, *15*), but the reaction usually requires harsh conditions in terms of time and heating. Instead, it was observed that when an acidic solution of $^{99m}TcO_4^-$ (pH 2) is added to compound **4** or **5** in solid form, a quantitative yield in a single labeled species, **9** and **10**, respectively, is obtained, and the reaction occurs in less than 15 min at room temperature for **4** and 35 °C for **5**. The chromatograms depicted in Figure 2 are related to the labeling of **4** 10 min after TcO_4^- addition. The peak revealed by UV at 19.49 min, the same of **4** before labeling, indicates the stability of PEGylated PN_2S ligand under reaction conditions. The unique peak in the RA chromatogram at 21.19 min indicates the radiochemical purity of the labeled compound **9** and the absence of free $^{99m}TcO_4^-$ ($t_R \approx 3$ min). The higher retention time observed for **9** is in agreement with the increased lipophilicity of the labeled species due to metal coordination. Compound **9** is not assessable by UV detector since ^{99m}Tc concentration in the labeling mixture is in the range of picomoles.

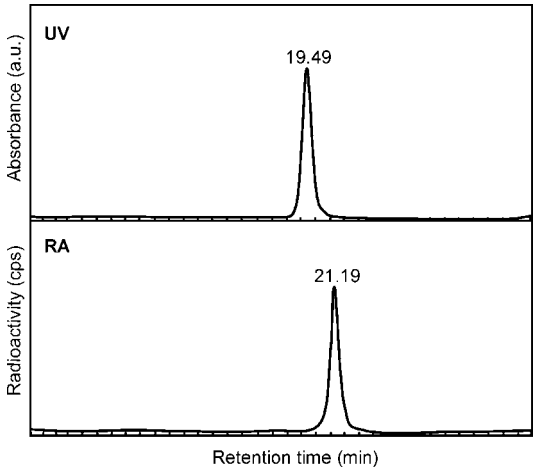

Figure 2. Direct labeling of PN_2S-PEG_{5000} **4**. RP-HPLC analysis of the labeling mixture 10 min after addition of TcO_4^- (pH 2) to solid **4** at room temperature is presented. The peak in the UV chromatogram is related to compound **4**. The RA chromatogram indicates the presence of a single labeled species **9** and the absence of free TcO_4^- ($t_R \approx 3$ min).

Table 1. Dynamic Light Scattering Analysis (25 °C, λ = 496 nm) of PN_2S-PEG_{5000} 4 (20 mg/mL) and PN_2S-PEG_{20000} 5 (80 mg/mL) in Saline (pH 2, 0.1 M HCl), PBS (pH 4, 7.4, and 10), and the Labeling Mixture (pH 2) Leading to ^{99m}Tc-Labeled PN_2S-PEG_{5000} 9 and ^{99m}Tc-Labeled PN_2S-PEG_{20000} 10, Respectively[a]

pH	**4**	**4**[b]	**5**	**5**[b]
2	316.7	125.7	2854.4	2057.3
4	325.2		3029.1	
7.4	318.8		2757.6	
10	391.6		2591.9	

[a] Values represent the mean diameter (nm) of micellar aggregates. [b] Labeling mixture.

Similar chromatograms were obtained when the direct labeling of compound **5** was performed.

It was observed that no labeling takes place if $^{99m}TcO_4^-$ is added to the unconjugated PN_2S-OH ligand or to a mixture of the ligand and mPEG-NH_2 non-covalently bound. Furthermore, the presence of phosphorus as phosphine and the integrity of the PN_2S set are essential, since the labeling does not occur when the conjugate is oxidized to **6** or dimerized through a disulfide bridge.

It was also found that the mixing conditions of TcO_4^- with the PEGylated ligand are very critical: the reaction is faster when the TcO_4^- solution is added to PN_2S-PEG in solid state than when the two reagents are solubilized separately and mixed. In this case, the labeling was still incomplete after 1 day.

A reasonable explanation of all these results is that the reduction and coordination of the metal take place thanks to a micellar catalysis due to self-aggregation of PN_2S-PEGs in water.

In fact, the conjugates have an amphiphilic character, the PN_2S moiety being highly lipophilic and the polymeric PEG chain being highly hydrophilic, and it is well-known that micelles can catalyze redox reactions (*16*). Light scattering measurements indicated that **4** and **5** effectively aggregate in water solutions to yield micelles (Table 1) with a cmc in the range 1−0.5 g/L. The cmc was determined in acidic saline to resemble the labeling reaction conditions using pyrene as a fluorescent probe in the presence of increasing concentrations of PN_2S-PEG conjugate (*11*). The characteristic feature of pyrene excitation spectra, namely, the (0,0) band shift from 334 to 337 nm upon probe partition into the inner core of micelles, was considered to be indicative of cmc achievement (Figure 3).

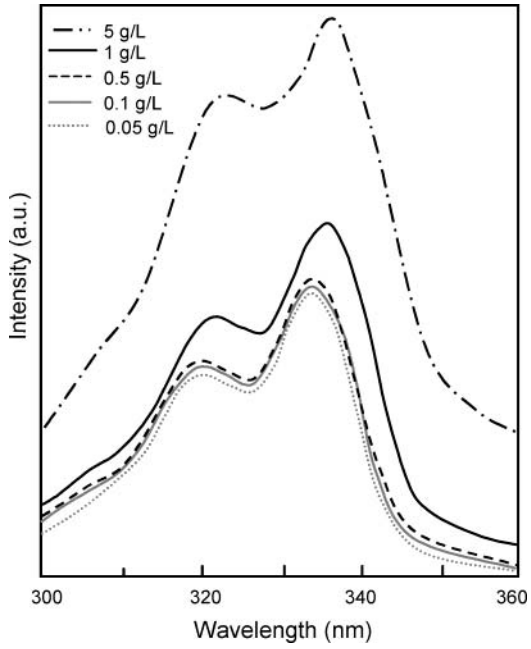

Figure 3. Determination of critical micellar concentration of PN_2S-PEG_{5000} **4** using physically entrapped pyrene as a fluorescent probe. The excitation spectra of pyrene, monitored at 390 nm in saline (pH 2) at 25 °C in the presence of increasing concentrations of **4**, show the shift in the (0,0) band as pyrene partitions between aqueous and micellar environments.

PN_2S-PEG micelles were found to easily disassemble by dilution. By dilution of the concentrated solutions below the cmc just before fluorescence analysis, the shift of the (0,0) band from 337 to 334 nm was observed, in agreement with a rapid disaggregation of micelles.

Micelles were also present in the labeling mixtures (Table 1), and the micellar state of the conjugate is necessary since no technetium labeling was obtained below the cmc. On the other hand, when $^{99m}TcO_4^-$ is added to previously solubilized PN_2S-PEG, the reaction occurs but at much lower rate since the PN_2S moiety, forming the inner lipophilic core of the already shaped micelles, is not available for the reduction and coordination of the metal. However, since micelles are in fluxional equilibrium with monomers, $^{99m}TcO_4^-$ can still be loaded into micelles where the redox reaction rapidly takes place, but this internalization process is slow and difficult to complete.

Furthermore, the catalytic effect mediated by micelles explains the efficiency of the labeling reaction, quantitative in less than 15 min, and the possibility to perform the reaction at acid pH. This pH, although favoring the redox reaction, is not as convenient as the alkaline usually required for the deprotonation of peptide ligand amides (*17*).

Finally, the metal is not simply entrapped into micelles as $^{99m}TcO_4^-$ but is strictly bound to PN_2S-PEG by coordination followed by reduction, since $^{99m}TcO_4^-$ is not released through micelle dissociation below the cmc, as detected under HPLC conditions.

In conclusion, we may state that when $^{99m}TcO_4^-$ is added to the solid **4** or **5**, the conjugate dissolves, associating into micelles, while the anion $^{99m}TcO_4^-$ binds to the phosphine phosphorus through an electrostatic interaction, since at acidic pH the phosphorus is present as phosphonium, as depicted in Figure 4.

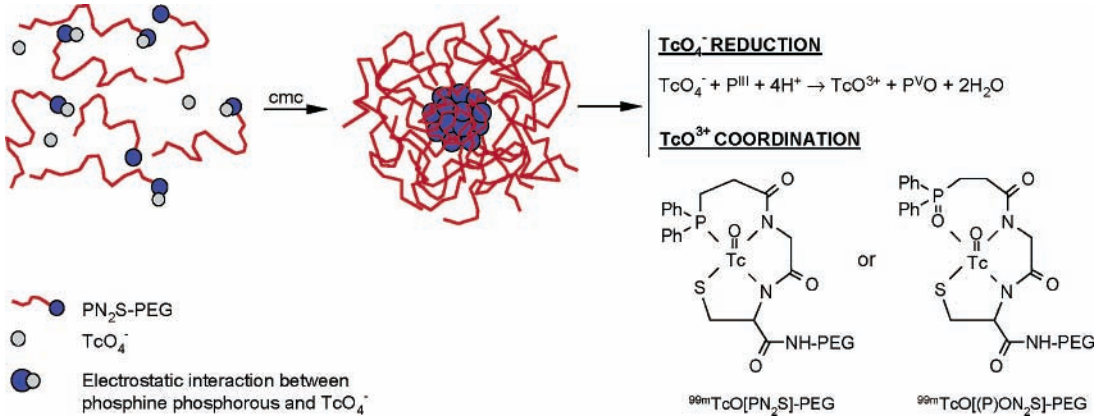

Figure 4. Direct labeling of PEGylated PN_2S ligands. A drawing of the mechanism of ^{99m}Tc reduction−coordination mediated by PN_2S−PEG micelle aggregation with the two possible coordination species is shown.

The Coulombic interaction favors the metal accumulation in the micelle environment where the reduction reaction occurs by means of an electron pair transfer from the phosphine phosphorus to technetium to give the $[^{99m}TcO]^{3+}$ species. It is presumed that the ligand acts as a formal two-electron reducing agent in the presence of $Tc^{VII}O_4^-$ and that, upon reduction of Tc^{VII} to Tc^V, the P^{III} center is oxidized to the corresponding phosphine oxide, P^V. The reduction is then followed by the coordination. The $[^{99m}TcO]^{3+}$ core could be coordinated by the same ligand molecule involved in the redox reaction by means of the new (P)ON_2S set, or alternatively, it could be coordinated through the PN_2S set of a second ligand molecule not involved in the reduction and included in the same micelle.

Transchelation Labeling of PN_2S−PEGs. To evaluate the above-reported coordination hypotheses, both **4** and **5** and the oxidized analogous **6** were employed in the labeling reaction with ^{99m}Tc-gluconate. In this case, the reaction involves the reduction of $^{99m}TcO_4^-$ to $[^{99m}TcO]^{3+}$ by Sn(II) in the presence of sodium gluconate to form the intermediate ^{99m}Tc-gluconate, which later exchanges with the ligand of interest to give the final complex.

Preliminary studies indicated the need to purify ^{99m}Tc-gluconate from technetium-hydrolyzed species leading to unspecific absorption to PEG chain. On the other hand, no interaction between ^{99m}Tc-gluconate and mPEG-NH_2 was observed.

The labeling reaction carried out by the addition of ^{99m}Tc-gluconate to **4** or **5** dissolved in water or in the solid state at a final concentration above the cmc was found to proceed but with a slow rate, since it was still incomplete after 4 h. This indicated that micelles interfere with the exchange ligand reaction, since the PN_2S moiety, which forms the lipophilic core, is less available for the coordination. This was not the case for the reaction carried out in water/EtOH 1:5 (v/v) to avoid micelle formation, a condition that yielded in 35−45 min to a single homogeneous peak detected by HPLC at 20.85 and 21.45 min for **4** and **5**, respectively. The peaks were attributed to ^{99m}TcO[PN_2S]-PEG_{5000} **11** and ^{99m}TcO[PN_2S]-PEG_{20000} **12** obtained from the transchelation between ^{99m}Tc-gluconate and the PN_2S set. The reaction performed using compound **6** led to analogous results with a single labeled species detected at 20.67 min. In this case, the $[^{99m}TcO]^{3+}$ core is supposed to be coordinated by the (P)ON_2S set with the phosphine oxide oxygen bound to the metal center instead of the phosphine phosphorus, leading to the ^{99m}TcO[(P)ON_2S]-PEG_{5000} complex **13**.

These results confirmed that at micelle level both coordinations may take place.

Rhenium Coordination Studies. To further confirm the two coordination possibilities, PEGylated PN_2S and (P)ON_2S were reacted with rhenium. In analogy to a previously reported method for the synthesis of the ReO-[PN_2S]-OMe complex (*10*), the reaction of **4** was performed in dichloromethane using $ReOCl_3(PPh_3)_2$ as rhenium^V oxo starting material. As observed with the PN_2S−OMe ligand, the solution, initially orange-green, turned to reddish-brown by triethylamine addition to reach alkalinity. This demonstrated that PN_2S−PEG_{5000} coordinates $[ReO]^{3+}$ leading to the pentacoordinated complex ReO[PN_2S]-PEG_{5000} **7**. The ^{1}H NMR analysis indicated that both the syn and the anti ReO[PN_2S]-PEG_{5000} complexes are formed, although the HPLC did not separate the two isomers. In the range 4−6 ppm, the signals related to cysteine (Cys) and glycine (Gly) protons were clearly assigned and found to be close to those detected in the syn and anti ReO[PN_2S]-OMe spectra. The Cys α protons were detected at 5.25 and 5.66 ppm for anti and syn isomer, respectively. As for the ReO-[PN_2S]-OMe anti isomer, the splitting pattern of anti isomer Cys α proton appeared as a doublet, indicating that it was at a nearly right angle to one of the β protons, thereby giving no coupling constant. On the other hand, syn isomer Cys α proton appeared as a doublet of doublets indicating that the torsion angles between the Cys α and β protons were different from those in the anti isomer. The Gly α proton signals were detected as two doublets (4.51 and 4.82 ppm, anti isomer; 4.71 and 4.88 ppm, syn isomer), with a geminal coupling of 20.4 and 21.0 Hz for anti and syn isomer, respectively. The β protons of the Cys residue were overlapped to the broad signal of PEG methylene, except for one detected as a doublet at 4.30 ppm and related to anti isomer. Different from ReO[PN_2S]-OMe isomers, always obtained in a 1:1 molar ratio, PN_2S−PEG coordination reaction led to a preference for the anti isomer (70−75%). It is reasonable that the presence of the PEG chain favors, by steric hindrance, one of the diastereomers.

The $ReOCl_3(PPh_3)_2$ precursor was reacted also with oxidized **6**, and the ReO[(P)ON_2S]-PEG_{5000} **8** complex was obtained and found to be stable both in the solid state and in solution. The yield was significantly lower than that achieved with **7**, and unfortunately, we did not succeed to remove the large amount of unreacted PN_2S−PEG_5 by diethyl ether crystallization. This made a good characterization of the product impossible, since in the ^{1}H NMR spectrum the strong intensity of PEG OCH_3 and

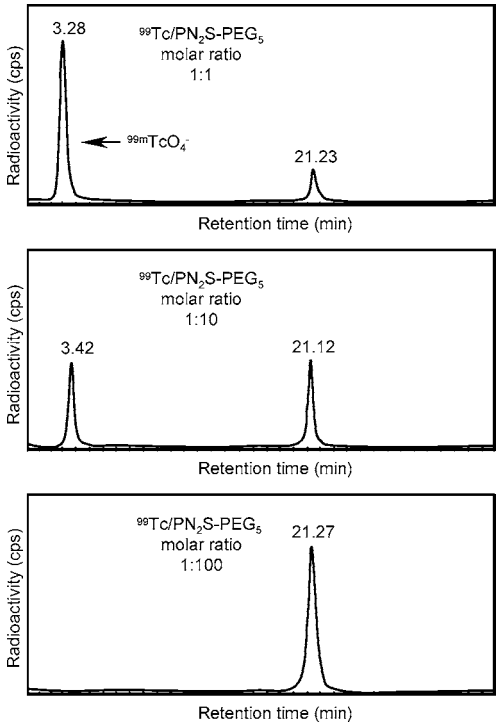

Figure 5. Direct labeling of PEGylated PN_2S ligands: determination of ^{99m}Tc-labeled PN_2S-PEG_{5000} specific activity through carrier added (^{99}Tc) experiments. At the ^{99}Tc/PN_2S-PEG_{5000} molar ratio 1:100, the $^{99m}TcO_4^-$ peak disappears suggesting that all the pertechnetate present in the labeling mixture ($^{99}TcO_4^-$ and $^{99m}TcO_4^-$) is reduced and coordinated. A 1.9 TBq/μmol specific activity was calculated considering the whole Tc present in the solution as ^{99m}Tc.

$CO(CH_2)_2-CO$ signals at 3.27 and 3.62 ppm, respectively, hampered the detection of the peaks related to coordinated Gly-Cys moiety. On the other hand, the same coordination events, initial green solution, which changed to orange by addition of TEA, were observed by reacting the $(P)ON_2S-OMe$ ligand with $[ReO]^{3+}$ as for $(P)ON_2S-PEG_{5000}$ (unpublished results).

In agreement with the results obtained with ^{99m}Tc-gluconate, rhenium-oxo studies confirmed that at micelle level both the PN_2S and $(P)ON_2S$ coordinations are possible.

Specific Activity Determination. The specific activity of **9** was evaluated by means of carrier-added experiments.

Different amounts of $^{99}TcO_4^-$ were added as carrier to $^{99m}TcO_4^-$ solution. The final mixtures were acidified to pH 2 and added to **4** in the solid state. The solutions were kept at room temperature for 10−15 min. The experiment was performed in triplicate using 3.95×10^{-2}, 3.95×10^{-3}, and 3.95×10^{-4} M $^{99}TcO_4^-$ solutions to have a ^{99}Tc/PN_2S-PEG_{5000} molar ratio of 1:1, 1:10, and 1:100. Figure 5 indicates that, when the molar ratio was in the range 1:1−1:10, the labeling reaction did not occur completely, since $^{99m}TcO_4^-$ is still detectable at about 3 min. Instead, at the molar ratio 1:100, the $^{99m}TcO_4^-$ peak disappeared, and it was assumed that all of the pertechnetate present in the labeling mixture ($^{99}TcO_4^-$ and $^{99m}TcO_4^-$) was reduced and coordinated. Based on the fact that ^{99m}Tc and ^{99}Tc are chemically indistinguishable, the specific activity was calculated considering the whole Tc present in the solution as ^{99m}Tc, yielding the considerably high value of 1.9 TBq/μmol.

In Vitro Plasma Stability. The in plasma stability of **9** obtained through the direct labeling procedure was evaluated by incubation at two concentrations, above and below the PN_2S-PEG_5 critical micellar concentration. The results depicted in Figure 6 demonstrated that **9** incubated in absence of micelle exhibited a stability analogous to those already observed for unPEGylated $^{99m}TcO[PN_2S]$-OH and $^{99m}TcO[PN_2S]$-OMe (*5*), while in the presence of micelles, the degradation was markedly reduced. As for the unPEGylated labeled compounds, the decomposition of **9** is due to the release of TcO_4^- and not to byproducts of backbone fragmentation, as demonstrated by RP-HPLC analysis. These experiments demonstrated that PEGylation did not affect the ability of the coordination set to stabilize $[TcO]^{3+}$ toward oxidation or exchange reactions and that micelles further protect the complex by inclusion in the inner core.

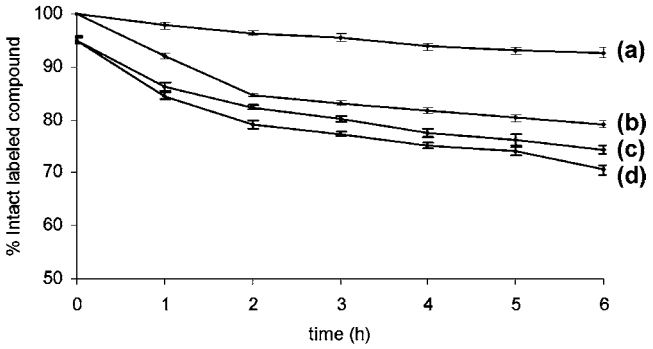

Figure 6. In human plasma stability of ^{99m}Tc-labeled PN_2S-PEG_{5000} **9** after incubation at 37 °C at a concentration above (a) and below (b) the PN_2S-PEG_{5000} cmc, compared with the stability of unPEGylated $^{99m}TcO[PN_2S]$-OMe (c) and $^{99m}TcO[PN_2S]$-OH (d). Values represent the means ± SD ($n = 5$) of the percentage of intact labeled compound.

In Vivo Biodistribution. The labeled compounds **9** and **10** obtained by direct labeling were studied in vivo to evaluate stability, blood residence time, and biodistribution. In Figure 7, the scintigraphic images related to the their biodistribution are depicted.

Scintigraphic images related to **9** were collected for 40 min and showed a rapid and efficient clearance from the bloodstream mainly by the urinary system, also confirmed by ex vivo counting of activity in organs and tissues (Table 2). Those data indicated that the biodistribution of labeled PN_2S-PEG_{5000} is analogous to that reported in the literature for free PEG_{5000} (*18*, *19*) and that the PEGylation of the PN_2S ligand drastically reduces its clearance through the hepatobiliary route (*5*).

For the biodistribution of **10**, the image acquisition time was extended to 3 h. A slow clearance from the blood pool was found, in agreement with a high retention of activity in organs and tissues, as confirmed by the ex vivo counting (Table 3). Also in this case, the biodistribution of labeled PN_2S-PEG_{20000} was similar to that reported for free PEG_{20000} (*18*, *19*), demonstrating that PN_2S linking and labeling do not modify the polymer behavior and that the polymer dictates the fate of the conjugate.

The observed biodistribution of both $^{99m}Tc-PN_2S-PEG$ 5000 and 20000 strictly correlates with that of the unmodified PEG with the same molecular weight, indicating that the excreted species are monomeric. This is also in agreement with the high degree of dilution in the blood pool, which causes micelle disaggregation.

The low activity found in the stomach and the recovery of unmodified labeled conjugates in urine further demonstrated the high affinity of the coordination set for technetium and the stability toward degradation, also due to the shielding effect afforded by PEG to enzymatic

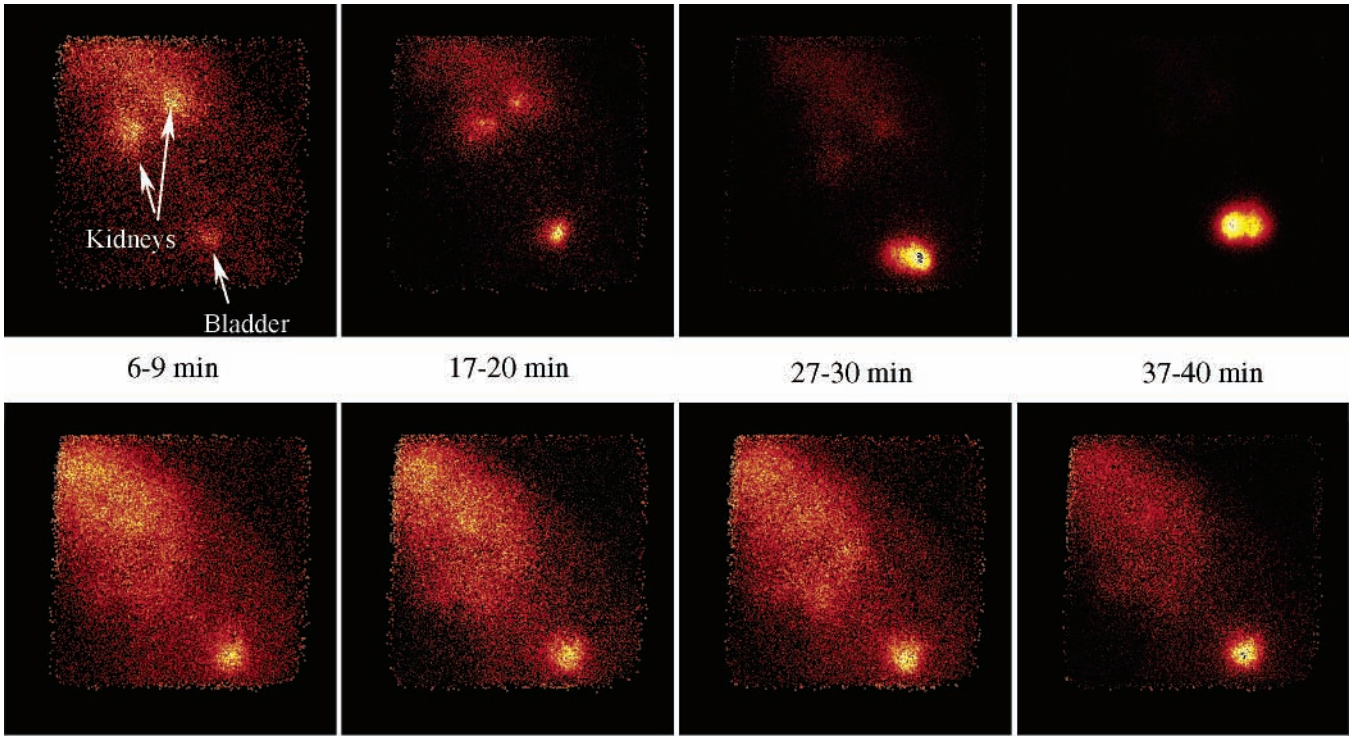

Figure 7. Scintigraphic images related to in mouse biodistribution of ^{99m}Tc-labeled PN_2S-PEG_{5000} **9** (top) and ^{99m}Tc-labeled PN_2S-PEG_{20000} **10** (bottom) obtained through the direct labeling method.

cleavage of amide bonds or hydrolysis by water often observed in PEG−peptide drugs.

CONCLUSIONS

The PEGylation of the PN_2S ligand allows a new simple, clean, and efficient ^{99m}Tc-labeling procedure and avoids the use of an external reducing agent. The mechanism of labeling is based on a supramolecular assembly of the PN_2S−PEG conjugates in aqueous solution to yield micelles that favor the reduction and coordination of technetium. The labeling does not modify the polymer behavior in water, and PEG may still convey to the labeled conjugates its pharmacokinetic properties, thanks also to the great in vivo stability of the complex. This novel method can therefore represent an useful tool to further improve the potential of technetium-99m in diagnosis and of rhenium-186/188 in radiotherapy through the labeling of targeting biomolecules conjugated to the PN_2S set via a bifunctional PEG. Studies are now directed to (i) verify the accumulation of monofunctional PEG conjugates in solid tumors exploiting the EPR effect taking advantage of the high steric hindrance of the molecules and (ii) evaluate the new labeling procedure in bioconjugates with the PN_2S set bound to specific targeting peptides using heterobifunctional PEGs.

ACKNOWLEDGMENT

The work originated from collaboration within the program COST-B12 WG-5. Gianfranco Pasut was supported by University of Padova Grant CPDG034599 “Progetto Giovani Ricercatori 2003”. The authors thank Dr. Fabrizio Mancin for assistance with light scattering analysis, Dr, Lorena Giovagnini for ^{31}P NMR spectra, Mr. Michele Bello for scintigraphic images elaboration, and Dr. Guido Bordignon for MALDI-TOF spectrometry.

Received April 13, 2004; Revised Manuscript Received July 13, 2004

Glucose oxidase (GO) was encapsulated in the liposomes composed of POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) to increase the enzyme stability through its decreased inhibition because of hydrogen peroxide (H_2O_2) produced in the glucose oxidation. The GO-containing liposomes (GOLs) were completely free of the inhibition even in the complete conversion of 10 mM glucose at 25 °C because the H_2O_2 concentration was kept negligibly low both outside and inside liposomes throughout the reaction. It was interestingly revealed that the H_2O_2 produced was decomposed not only by a slight amount of catalase originally contained in the commercially available GO but also by the lipid membranes of GOL. As compared to the GOL-catalyzed reaction, the free GO-catalyzed reaction more highly accumulated H_2O_2 because of the more rapid glucose conversion despite containing free catalase, leading to the completely inhibited GO before reaching a sufficient glucose conversion. This suggested that only the liposomal catalase could continue to catalyze the H_2O_2 decomposition. The effect of the glucose oxidation rate, i.e., the H_2O_2 production rate on the liposomal GO inhibition, was also examined employing the various GOLs with different permeabilities to glucose present in their external phase. It was concluded that the liposomal GO free of the inhibition could be obtained when the GOL-catalyzed H_2O_2 formation rate was limited by such a suitable lipid bilayer as POPC membrane so that the rate was well-balanced with the sum of the above two H_2O_2 decomposition rates. The highly stable GOL obtained in the present paper was shown to be a useful biocatalyst for the prolonged glucose oxidation.

INTRODUCTION

Glucose oxidase (GO)-catalyzed glucose oxidation producing gluconic acid and hydrogen peroxide (H_2O_2) has been utilized for glucose quantification (*1*, *2*), sterilization (*3*, *4*), textile bleaching (*5*), removal of oxygen from foods (*6*) and a large-scale production of gluconic acid (*7*). Immobilization of GO in the various solid supports has been studied for increasing physical stability and reusability of the enzyme (*1*, *2*, *5*−*7*). However, it is usually difficult to obtain the stable glucose oxidase free of the product (H_2O_2) inhibition to the enzyme in a prolonged glucose oxidation (*8*). Even though catalase is added to the reaction solution for catalyzing the decomposition of H_2O_2, the inhibitory effect to catalase also needs to be taken into consideration (*9*). Therefore, the key to develop a durable and biocompatible system for the prolonged glucose oxidation is considered to be regulating the behavior of H_2O_2 produced throughout the reaction period with such a biological mean as maintaining the initial activities of both enzymes.

We have studied liposomes (phospholipids vesicles) in modulating the reactivity and selectivity of the liposomal enzyme to the externally added substrates (*10*, *11*), refolding denatured enzyme in the presence of liposomes (*12*), and using the liposomal enzyme in a gas−liquid two-phase flow in a bubble column (*13*). These contributions are for developing the nanoscaled biofunctional materials applicable to bioprocesses. These unique features of liposomes are mainly attributed to the selective permeability of the membranes to substrate molecules (*10*, *11*, *13*) and the electrostatic and hydrophobic interactions between partially unfolded enzyme and lipid bilayer membranes (*12*, *14*). On the basis of such functions of liposomes as above, we recommended the liposomal GO as a stable biocatalyst for the air oxidation of glucose in an external loop airlift bioreactor. In particular, it is practically important that the commercially available GO encapsulated in liposomes can catalyze a prolonged air oxidation of glucose with remarkably higher stability than free GO (*13*). This indicates that the enzyme inhibition because of H_2O_2 produced in the oxidation is effectively suppressed in the liposomal system. However, the mechanism for this phenomenon has so far remained unclear.

In the present paper, a mechanism for an increase in the stability of liposomal GO is examined on the basis of the quantitative determination of the H_2O_2 produced in the glucose oxidations catalyzed by the different types of liposomal GO under the various conditions. The results obtained clearly show that an appropriate liposomal encapsulation of GO can give an extraordinary stable system for the simultaneous glucose oxidation and H_2O_2 decomposition with negligible formation of the inhibited enzymes.

EXPERIMENTAL PROCEDURES

Materials. GO from *Aspergius niger* (EC 1.1.3.4, 429 units/mg, $M_r \cong 180\,000$, pI = 4.44) was purchased from Sigma (St. Louis, MO). The GO from Sigma was nominally low in catalase, with the catalase content of less than 0.1 units/mg protein according to the specification. GO (147 units/mg) was also obtained from Toyobo Co. Ltd. (Osaka, Japan). POPC (1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine) with purity more than 99% was from Avanti Polar Lipids Inc. (Alabaster, AL). β-D-Glucose, H_2O_2 solution (35.1%), 3-AT (3-amino-1,2,4-triazole), DLPC (L-α-phosphatidylcholine, dilauroyl), DMPE (L-α-phosphatidylcholine, dimyristoyl), and sodium cholate were from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

Preparation of GO-Containing Liposomes (GOL). The GOL was prepared by the extrusion technique as reported previously (*10*), essentially based on the method of Mayer et al. (*15*) as follows. The lipid (30−100 mg) was at first solubilized in chloroform in a round-bottom flask followed by removal of the solvent by using a rotary evaporator. This procedure was repeated twice using diethyl ether as the second solvent. The lipid film obtained was dried under reduced pressure (<10 Pa) using a freeze dryer (FRD-50M, Asahi Techno Glass Corp., Funabashi, Japan) in the dark for 2 h to remove the residual solvent in the lipid layers. The dry lipid film was hydrated with 50 mM Tris-HCl/100 mM NaCl buffer (pH 7.4) (denoted as Tris buffer) containing 1.3 mg/mL GO. The water used for the Tris buffer preparation was deionized to remove metal ions by passing through an ion-exchange resin column. The multilamellar vesicles (MLVs) formed were frozen at −80 °C in dry ice/ethanol and thawed at 35 °C 7 times to transform a fraction of the small liposomes into the larger MLVs. The MLVs were extruded through the two stacked polycarbonate membranes with a nominal pore diameter of 100 nm using an extruding devise (Liposofast from Avestin Inc.) (*16*). Nonentrapped GO molecules were separated from the GOL using the gel-permeation chromatography (GPC) with a sepharose 4B column ($\phi 1 \times 20$ cm). The dehydration−rehydration vesicle method (DRV) (*17*−*19*) was used for preparing the various GOLs with different GO contents in liposomes as follows. The next freezing and drying treatment was performed for the GOL prepared as described above except that the GOL was not passed through the GPC column. The dry liposome−GO mixture obtained was rehydrated with a smaller quantity of deionized water than that in the first hydration. The GO content in the GOL was altered by changing the amount of water used in this rehydration step. Then, the GOL was frozen and thawed and extruded again followed by the same GPC treatment as above to obtain the GOL with different GO content. The lipid concentration was measured enzymatically using a kit from Wako Pure Chemical Industries, Ltd. In the following, the GOL stands for the GO-containing POPC liposomes without the DRV treatment unless otherwise described.

Determination of Activity of Liposomal and Free GO. Enzymatic activity of GO was measured by using the same colorimetric method (*20*) as reported previously (*10*). The activity efficiency (*E*) of the liposomal GO was defined as the observed GOL activity ([lipid] = 75 μM) with the external addition of 10 mM glucose at 25 °C relative to the intrinsic one measured after solubilization of the liposomes with an excess amount of cholate.

Glucose Oxidation Catalyzed by Liposomal and Free GO. The glucose oxidation was performed in the Tris buffer at the reaction volume of 2.0−3.0 mL in a glass test tube capped with cotton. The reaction was initiated with the GOL ([lipid] = 1.0 mM, and [GO] = 2.7 μg/mL) or free GO (2.7 μg/mL) at the initial glucose concentration of 10 mM in a water bath thermostated at 25 ± 0.3, 27 ± 0.3, or 40 ± 0.3 °C. An aliquot of the reaction solution was withdrawn periodically for quantification of the remaining glucose and accumulated H_2O_2 concentrations (see below). The glucose conversion was calculated from the remaining glucose concentration relative to the initial one. The reaction was also carried out in the presence of catalase inhibitor 3-AT at 250 mM. Prior to the reaction with it, either free GO or the GOL was incubated with 3-AT at 25 °C overnight.

Measurement of the Glucose Concentration in the Reaction Solution. The glucose concentration in the reaction mixture was measured either enzymatically or by the Somogyi−Nelson method. The former and latter methods were performed by using the kits from Toyobo Co. Ltd. (Osaka, Japan) and Nacalai Tesque, Inc. (Kyoto, Japan), respectively. The enzymatic method was used for the sample containing a negligible amount of H_2O_2 because it essentially measures H_2O_2 produced from glucose. The Somogyi−Nelson method was used for quantification of glucose in the presence of a relatively high concentration of H_2O_2 in the absence of lipids, i.e., in the reaction catalyzed by free GO. In the case of the reaction catalyzed by the liposomal GO with a high concentration of H_2O_2 accumulated, the glucose concentrations measured with the enzymatic method above were corrected using a calibration curve based on the separately measured H_2O_2 accumulated in the reaction mixtures (see below).

Measurement of the H_2O_2 Concentration in the Reaction Solution. H_2O_2 was quantified based on the oxidation of 3,3-dimethoxybenzidine dihydrochloride (*o*-dianiisidine) with H_2O_2 catalyzed by horseradish peroxidase (HRP) as follows. A total of 50 μL of a H_2O_2-containing sample with the GOL was mixed with 1450 μL of the Tris buffer solution (pH 7.4) to give the final concentrations of 5.0 μM for HRP and 3.3 mM for *o*-dianiisidine. To the above sample, 10−40 mM cholate was added for complete solubilization of liposomes to release the H_2O_2 in liposomes and to decrease the turbidity of the assay solution. The value of A_{460} was then measured immediately using a spectrophotometer (UV-1200, Shimazdu, Japan) in a quartz cell with a 0.5-cm optical length at 25 °C. Decomposition of H_2O_2 in the presence and absence of the various additives was measured at 25 °C for the initial H_2O_2 concentration of 10 mM in the Tris buffer (pH 7.4) of 0.5−3.0 mL in volume in a glass test tube capped with cotton. Then, the time course of the H_2O_2 concentration was measured with the enzymatic method as described above.

Determination of the Remaining Activity of Liposomal GO. The remaining GO activity in the GOL was measured after separating the GOL from the reaction mixture by using the GPC. The GO activity in the GOL fractions was measured after complete liposome solubilization with 40 mM cholate. The remaining GO activity was calculated as the enzyme activity detected in the GOL fractions relative to that determined for the GOL before the glucose oxidation.

RESULTS AND DISCUSSION

Characteristics of Prolonged Glucose Oxidation Catalyzed by Liposomal GO. The mean number of active GO molecules in a GOL used in the present paper

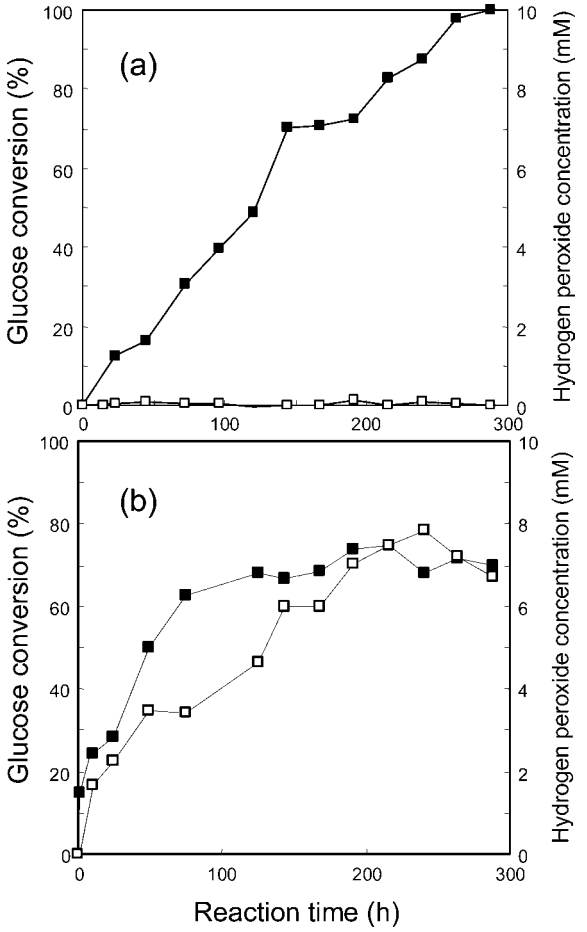

Figure 1. Time course of glucose conversion (■) and H_2O_2 concentrations (□) in glucose oxidation catalyzed by (a) GOL ([POPC] = 1.0 mM, and $[GO]_{overall}$ = 2.7 μg/mL) and (b) free GO ([GO] = 2.7 μg/mL). The initial glucose concentration was 10 mM in 50 mM Tris-HCl/100 mM NaCl buffer (pH 7.4) at 25 °C. The GO from Sigma was used.

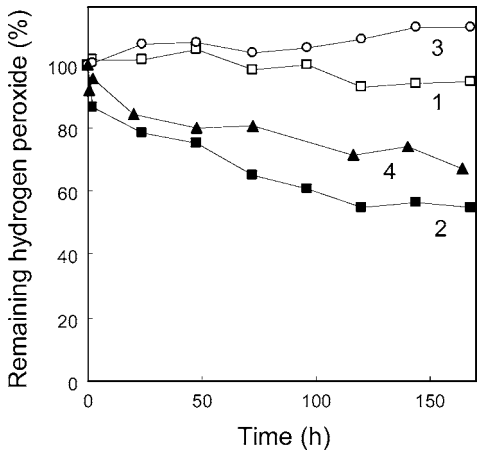

Figure 2. Time course of H_2O_2 concentrations in (1) 50 mM Tris-HCl/100 mM NaCl buffer (pH 7.4), (2) the Tris buffer containing free GO from Sigma ([GO] = 1.3 mg/mL), (3) the buffer containing 1.3 mg/mL free GO from Sigma plus 250 mM 3-AT, and (4) the buffer containing free GO from Toyobo Co. Ltd. ([GO] = 1.3 mg/mL) without 3-AT. All of the experiments were carried out under the initial H_2O_2 concentration of 10 mM at 25 °C.

was 1.7, unless otherwise stated. The values could be determined with the assumptions that the mean liposome diameter is 115 nm (*12*), the bilayer thickness of the POPC liposomes is 3.7 nm, and the mean area of the POPC headgroup is 0.72 nm^2 (*21*). The liposomal GO was found to have the initial apparent activity efficiency *E* of 0.03, that is, to show a very low reactivity with the external addition of glucose because of the limited permeability of glucose through the POPC membranes. Figure 1 shows the typical time courses of the GOL- and free GO-catalyzed glucose oxidation. The initial reaction rate catalyzed by the GOL (Figure 1a) is lower in comparison with that by free GO (Figure 1b). This corresponds to the small *E* value of the GOL. The critical difference in the observed time courses between the GOL- and free GO-catalyzed reactions is that almost no H_2O_2 is accumulated in the former case (Figure 1a), while the H_2O_2 concentration increases with increasing glucose conversion in the latter case (Figure 1b). The GO activity remaining in the GOL was 97% at the reaction time reaching almost complete conversion of glucose. Therefore, negligible GO leakage was found to occur during the reaction, suggesting that the high membrane integrity of the liposome was maintained throughout the reaction. The reason for such a remarkably stable GO activity of the GOL during the prolonged glucose oxidation (for 300 h) is that the H_2O_2 concentration even inside liposomes is kept low enough to give almost no inhibitory effect of H_2O_2 produced on the liposomal GO activity. In contrast, the free GO-catalyzed reaction is stopped because of the formation of an almost completely inhibited GO by H_2O_2 accumulating at a high concentration (*8*) even though unconverted glucose still remains, as seen in the result of Tzanov et al. (*5*). In the following, the highly stable liposomal GO free of the inhibition is analyzed and discussed in detail.

Activity of Free Catalase Contained in GO. Figure 2 shows the time courses of the H_2O_2 decomposition reaction in the four different Tris buffers (pH 7.4) at 25 °C. As shown in the figure, the self-decomposition of H_2O_2 in the Tris buffer (pH 7.4) is negligible (run 1) in agreement with the result of Qiang et al. (*22*). This suggests that the effect of trace metal ions such as Fe^{2+} and Cu^{2+} possibly contained in the water used or on the wall of the glass test tube can be negligible because these metal ions may cause the H_2O_2 decomposition through the formation of radical species such as a hydroxyl radical (*23*). The above result shows that the self-decomposition of H_2O_2 plays a rather minor role in the H_2O_2 behavior observed in the GOL-catalyzed reaction (Figure 1a). It is also seen in Figure 2 that the decomposition of H_2O_2 is enhanced in the free GO solutions (runs 2 and 4 for the GO from Sigma and Toyobo Co. Ltd., respectively). The H_2O_2 decomposition in the solution of free GO from Sigma was inhibited completely by the addition of 250 mM 3-AT (run 3). No decomposition of H_2O_2 was also observed in the solution of free GO from Toyobo Co. Ltd. in the presence of the same concentration of 3-AT (data not shown). Because 3-AT is a typical inhibitor for catalase (*9*, *24*), these results mean that the commercially available GO contains catalase as an impurity. The GO activity in the presence of 3-AT at 250 mM was approximately 90% of the original GO activity. It should be noted that pretreatment of the GOL incubated with 3-AT overnight gives almost completely inhibited catalase in liposomes with negligible GO leakage and deactivation of the GOL because of a sufficiently high permeability of 3-AT through the POPC bilayer membranes. The catalase activity in the free GO is seen to be deactivated progressively even in the absence of 3-AT leading to the stopping of the H_2O_2 decomposition reaction (run 2). This means

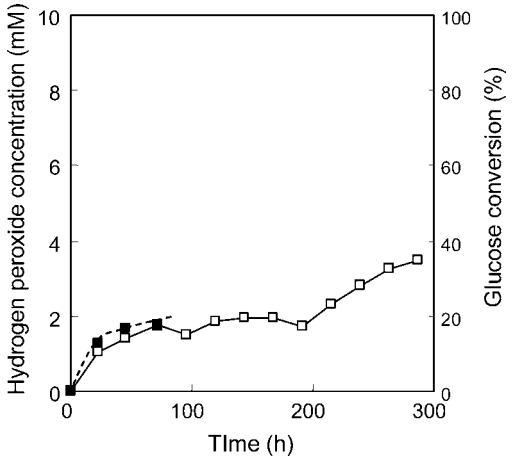

Figure 3. Time course of H_2O_2 concentration (□) and glucose conversion (■) in glucose oxidation catalyzed by GOL ([POPC] = 1.0 mM, and $[GO]_{overall}$ = 2.7 μg/mL) in the presence of 250 mM 3-AT under the initial glucose concentration of 10 mM in the Tris buffer (pH 7.4) at 25 °C.

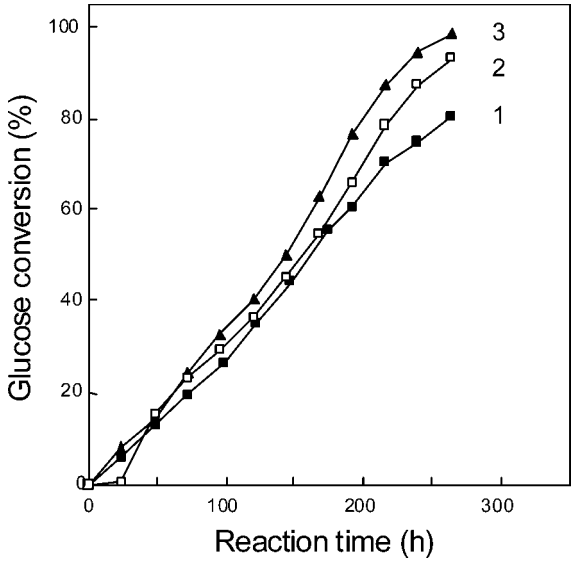

Figure 4. Time course of glucose conversion in glucose oxidation catalyzed by the GOL ([POPC] = 1.0 mM) with the different number of GO molecules in a liposome of 8.9 (1), 4.9 (2), and 2.1 (3). The initial glucose concentration was 10 mM in the Tris buffer (pH 7.4) at 25 °C. The remaining GO activities of the three GOLs at 250 h were 76% (1), 73% (2), and 94% (3). The GO from Sigma was used.

that a relatively high concentration of H_2O_2 causes the deactivation of catalase as reported previously (*9*).

Effects of Catalase Contained in GO on GOL-Catalyzed Glucose Oxidation. The GOL reaction was carried out in the presence of 250 mM 3-AT. Figure 3 shows the time courses of the H_2O_2 produced and the glucose conversion during the GOL-catalyzed glucose oxidation reaction. It is seen in the figure that H_2O_2 is accumulated with an increasing reaction time in contrast to the case of the reaction without 3-AT (Figure 1a). Therefore, it is evident that the liposomal GO is highly stabilized at least through the H_2O_2 decomposition catalyzed by the liposomal catalase. In Figure 3, the amount of glucose converted is slightly higher than that of H_2O_2 accumulated in the initial stage of the reaction. The result together with that of Figure 1a reveals that the liposomal catalase plays a crucial role in decomposing H_2O_2 produced. In Figure 3, the reaction rate is remarkably lowered with an increase in the amount of H_2O_2 accumulated because of its inhibitory effect on the activity of liposomal GO under an extremely limited supply of glucose to the enzyme in liposomes. The very low glucose concentration relative to the H_2O_2 concentration may lead to an almost complete inactivation of GO in liposomes in an earlier stage of the reaction as shown in Figure 3. On the other hand, no sufficient catalase activity is observed in the free GO-catalyzed reaction in the presence of catalase contained in GO, i.e., without addition of 3-AT (Figure 1b). Free catalase is thus suggested to be unstable in a sufficiently high concentration of H_2O_2 in agreement with the result shown in Figure 2 (run 2). The factors that may cause a significant difference in the activity stability between the liposomal and free catalase are considered to be as follows. First, the encapsulation of catalase in liposomes should affect the stability of the enzyme molecular structure essential for catalytic activity of catalase as reported for the other liposomal enzyme system (*25*). Because catalase requires four subunits to express its activity, the dilution-induced dissociation of the tetrameric catalase into subunits occurs in the case of free catalase (*26*). The liposomal encapsulation of an even very low concentration of catalase as in the case of the present GOL preparation, however, results in preventing effectively the tetrameric catalase from the dissociation, that is, giving the liposomal catalase with its high conformational stability. Considering that the amount of catalase is much lower than that of GO and one liposome contains approximately two GO molecules, only a very small fraction of the GOLs should contain a catalase molecule. Because H_2O_2 is much more permeable through the liposome membranes than glucose, the H_2O_2 produced in the catalase-free GOL is readily released into the bulk aqueous phase to be accessible to the liposomes containing catalase. Second, an interaction of liposomes with H_2O_2 possibly induces a change in the chemical stability of H_2O_2. Our preliminary study on the H_2O_2 stability in the GO-free liposome suspension suggests that the presence of intact lipid membranes causes a slightly enhanced decomposition of H_2O_2; i.e., liposomes possess a weak catalase-like function (Yoshimoto et al., unpublished results). The detailed mechanism for this phenomenon is unclear at the moment. Third, the relatively slow H_2O_2 formation in the GOL because of the limited glucose permeability through liposome membranes should have relevance to the H_2O_2 behavior and hence to activities of both GO and catalase in the liposomal system. This is because the amount of H_2O_2 accumulated should be determined by the kinetic balance between the formation and decomposition of H_2O_2. Concerning this point, the various GOLs, which differed in the GO content in liposomes, as well as the membrane permeability to glucose, were prepared and their performances were examined in the glucose oxidation as described below.

Effects of the Glucose Oxidation Rate on H_2O_2 Behavior. Figure 4 shows the time courses of the glucose conversion catalyzed by the various GOLs with the different mean numbers of GO molecules (*2*−*9*) in a GOL in the presence of catalase as an impurity, i.e., without addition of 3-AT. It can be seen in the figure that the initial rate of glucose conversion is not significantly dependent on the GO content in the GOL. This means that the permeation of glucose through the POPC membranes is the rate-controlling step in the GOL reaction in agreement with the results reported previously (*10*). The remaining GO activity was more than 70% for these GOLs (see the caption of Figure 4). The GOLs prepared

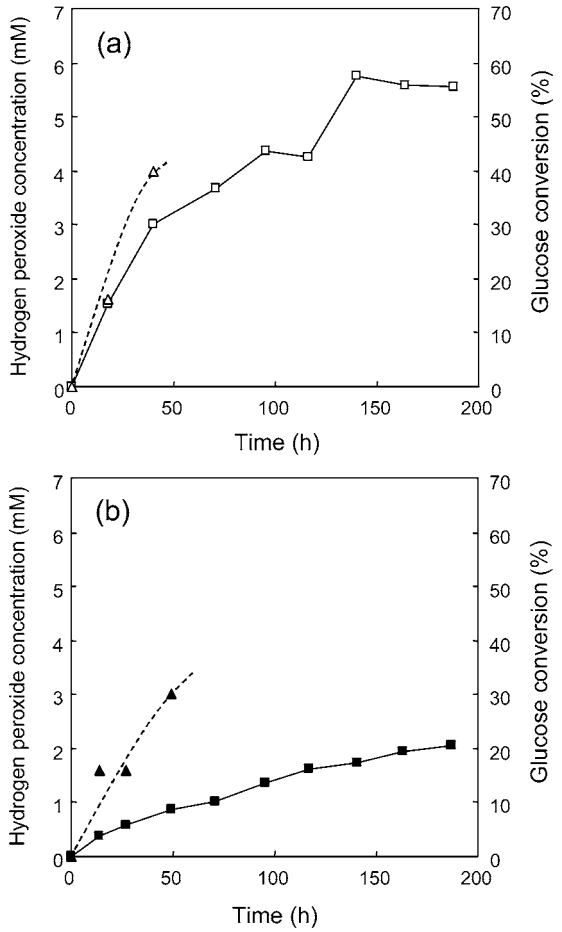

Figure 5. Time courses of H_2O_2 concentration (□ and ■) and glucose conversion (△ and ▲) in glucose oxidation catalyzed by (a) the GOL with DLPC membranes at 25 °C and (b) the GOL with POPC membranes at 40 °C. The initial glucose concentration was 10 mM in the Tris buffer (pH 7.4). The lipid concentration in the reaction was 1.0 mM. The GO from Sigma was used.

by the DRV method tend to show a slightly lower remaining activity. This may be because the GO molecules are partly trapped in the outer surface of the GOL membranes prepared by the DRV method. Such GO molecules may lead to the decreased stability of GO during the glucose oxidation as suggested by the low stability of free GO in the glucose oxidation (Figure 1b). From a practical point of view, the rate of the GOL reaction to consume glucose should be increased while keeping a sufficient GO stability in the GOL. Thus, the membrane permeability of the GOL to glucose was modulated. Figure 5 shows the H_2O_2 formation as well as the glucose conversion in the reaction catalyzed by the GOLs with the *E* values being different from the above GOL with POPC membranes at 25 °C without 3-AT. It can be seen in Figure 5a that the reaction catalyzed by the GOL with the DLPC membranes having much higher permeability to glucose ($E = 0.56$) than that with the POPC membranes ($E = 0.03$) results in the enhanced accumulation of H_2O_2 with an increasing reaction time. The initial rate of glucose conversion is seen to be high because of the considerably higher membrane permeability and hence higher activity efficiency of the liposomal enzyme. In this case, the liposomal catalase could not function enough because the initial production rate of H_2O_2 is significantly high. Consequently, the rate of glucose conversion will be significantly lowered in the later stage of the reaction because of the increasing inhibitory effect of H_2O_2 accumulated on the liposomal GO, as suggested in the reaction catalyzed by the free GO (Figure 1b). H_2O_2 was also accumulated in the reaction catalyzed by the GOL with POPC membranes at 40 °C, corresponding to the optimal temperature for GO activity as shown in Figure 5b. In the figure, the initial rate of glucose conversion is higher than that at 25 °C (Figure 1a) because of the enhanced membrane permeability of glucose at the higher temperature. In addition, the amount of glucose converted is seen to be higher than that of H_2O_2 accumulated, showing that the liposomal catalase decomposed a considerable amount of H_2O_2 produced. In the later stage of the reaction, however, the reaction rate should be lowered as opposed to the case at 25 °C because of an increase in the H_2O_2 concentration with time. Furthermore, Table 1 summarizes the results on the glucose oxidation catalyzed by the GOL with the POPC/DMPE membranes. The DMPE-incorporated GOL was used for the covalent immobilization of GOL into the chitosan gel beads (*13*). It can be seen in the table that the GOLs prepared have the *E* values of 0.07−0.10 and are stable enough to give a sufficient glucose conversion. For all of the cases, almost no H_2O_2 accumulation is observed at the reaction time of 240 h when the high glucose conversion indicated is obtained. These results suggest that the rate of the H_2O_2 formation catalyzed by the liposomal GO should be limited by keeping the *E* value of the GOL adequate enough to decompose the H_2O_2 produced ($E \leq 0.10$) when using the commercially available GO. In other words, the productivity of H_2O_2 in the GOL reaction can be controlled on the basis of the *E* value. The GOL with the POPC membranes at 25 °C showed such a suitable *E* value as the rate of the H_2O_2 formation catalyzed by the liposomal GO, which was well-balanced with that of the H_2O_2 decomposition catalyzed by the catalase contained as an impurity in the commercially available GO and lipid membranes. Therefore, the H_2O_2 concentration in the GOL is considered to be maintained low enough to cause no enzyme deactivation or possibly even activation of the enzyme (*27*). It was previously reported that the GOLs could be used for sterilization in the presence of glucose by producing H_2O_2 on the cell surface (*3*, *4*). The liposomal GO producing H_2O_2 was also utilized for quantification of a high concentration of glucose (*1*, *2*). In these cases, the membrane permeability to glucose corresponding to the *E* value in the present paper may be increased because of an interaction of the liposomes with the cell or solid surface so that the produced H_2O_2

Table 1. Glucose Oxidation Catalyzed by GOLs with POPC/DMPE Membranes[a]

lipid composition (POPC/DMPE in molar ratio)	number of GO molecules in a liposome	initial *E* value	reaction time (h)	H_2O_2 accumulated in the reaction solution (mM)	glucose conversion (%)	remaining GO activity (%)
100:0	2.2	0.07	240	0.1	84	94
95:5	2.0	0.08	240	0.09	85	87
90:10	2.1	0.10	240	0.1	78	82

[a] The GO used was from Toyobo Co. Ltd. The glucose oxidation was performed at 27 °C under the initial glucose and lipid concentrations of 10 and 1.0 mM, respectively.

can be accumulated enough as suggested by the results shown in Figure 5.

CONCLUDING REMARKS

The results obtained in the present paper are summarized as follows. (1) The GOLs efficiently catalyzed the prolonged glucose oxidation to give almost complete conversion of the initially added 10 mM glucose with negligible inhibition of GO due to the H_2O_2 produced because little H_2O_2 was accumulated throughout the reaction. (2) The GOL-catalyzed glucose oxidation with the catalase inhibitor 3-AT revealed that the catalase originally contained in the commercially available GO played a significant role in decomposing the H_2O_2 produced in the reaction. For the free GO-catalyzed reaction, H_2O_2 was significantly accumulated despite the presence of catalase as an impurity. Therefore, it was suggested that the liposomal encapsulation of both GO and catalase was effective to obtain a remarkably stable enzyme system for the glucose oxidation as well as H_2O_2 decomposition. (3) The activity of the commercially available GO with catalase as an impurity encapsulated in the POPC liposomes at 25 °C was suggested to be highly stabilized because the H_2O_2 formation catalyzed by the liposomal GO was kinetically balanced well with the H_2O_2 decomposition catalyzed by the catalase in liposomes as well as the lipid membranes of GOL. The glucose oxidation catalyzed by the GOL with a sufficiently high membrane permeability to glucose resulted in the H_2O_2 accumulation. In the liposomal reaction system, it was shown that the liposome membranes play a crucial role in regulating the activity of encapsulated catalase for an effective H_2O_2 decomposition.
