Bioconjugate Chemistry

EDITORIAL: Thanks to Our Reviewers

It is a pleasure to acknowledge the contributions of the reviewers of manuscripts submitted in 2004 for publication in *Bioconjugate Chemistry*. Their unselfish service has been essential in the shaping of the fifteenth volume of the journal. The scientific community is fortunate that its members are willing to share their time and specialized knowledge in this way. The reviewers are listed on the following page.

REVIEWS

Next Generation, High Relaxivity Gadolinium MRI Agents†

Kenneth N. Raymond* and Valérie C. Pierre

Department of Chemistry, University of California, Berkeley, California 94720-1460 . Received July 27, 2004

Magnetic resonance imaging (MRI) has evolved into one of the most powerful techniques in diagnostic clinical medicine and biomedical research by enabling the acquisition of high resolution, three-dimensional images of the distribution of water in vivo (*1*). The strong expansion of medical MRI has prompted the development of a new class of pharmacological products, called contrast agents. These agents catalytically shorten the relaxation time of nearby water molecules, thereby enhancing the contrast with background tissues. In 1999, approximately 30% of all MRI scans used a contrast agent, most of which were based on gadolinium complexes (*1*). By now, this number has probably increased to between 40 and 50%. This utility has prompted research on improved Gd-based contrast agents, about which several reviews have recently been published (*1*−*15*).

Gd(III) is highly paramagnetic with seven unpaired electrons and a long electronic relaxation time, making it an excellent candidate as a relaxation agent. However, the very high in vivo toxicity of $[Gd(H_2O)_8]^{3+}$ requires that the metal be complexed by strong organic chelators before it is administered to patients. Current MRI agents require injection of gram quantities of Gd in order to obtain satisfactory contrast in the resulting image. With such large doses required for reasonable image enhancement, current contrast agents are limited to targeting sites where they can be expected to accumulate in high concentrations, such as in the blood stream. Ideally, second generation agents will be site-specific; much higher relaxivities will be required to account for the decrease in concentration that accompanies increased tissue specificity.

The image-enhancing capability of a contrast agent is directly proportional to its relaxation of neighboring water molecules by the paramagnetic ion; that is, to the relaxation rate increase, either longitudinal ($1/T_1$) or transverse ($1/T_2$). This effect includes both inner-sphere (from water molecules directly coordinated to the Gd) and outer-sphere contributions (from nearby, H-bonded waters). The latter are usually relatively small and are usually neglected. For Gd(III) complexes, the inner-sphere relaxivity primarily results from a dipolar contribution (through-space interactions due to the random fluctuations of the electronic field) and can be described by the Solomon−Bloembergen−Morgan equation. According to this theory, to increase the relaxivity, r_{1p}, of a Gd contrast agent, one has to design a ligand that will enable the complex to have a greater number of inner-sphere water molecules, q; an optimally short water residence time, τ_m; and a slow tumbling rate, $1/\tau_r$ (Figure 1) while maintaining sufficient thermodynamic stability. This is quite a challenge! The water residence time, τ_m, is probably the least understood and most important parameter that affects relaxivity. Indeed, it has been demonstrated that the relaxivity of a Gd^{III} complex will increase upon slowing down its molecular tumbling (increasing its molecular weight) insofar as its water residence time is close to optimal (*16*−*19*).

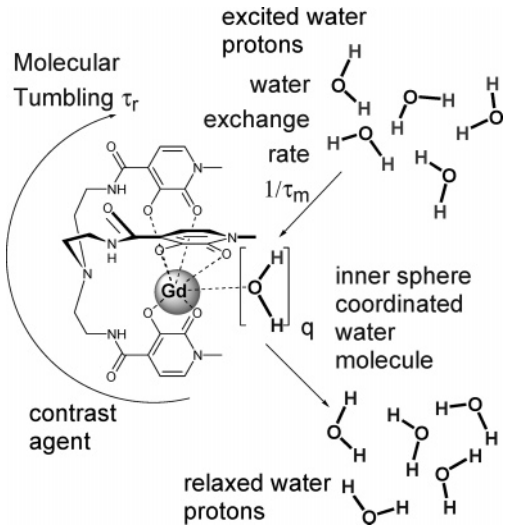

Figure 1. Parameters influencing relaxivity.

Considering the aforementioned properties, current commercial poly(amino-carboxylate) complexes (Figure 2) have several disadvantages (*1*). They have only one coordinated water molecule and fast tumbling rates due to their small size. Attempts to increase their relaxivities by grafting them on macromolecules (slowing τ_r) have led to mixed success due to the accompanying particularly slow water exchange rates, $1/\tau_m$, typically $0.5-5 \times 10^6$ s^{-1} (*1, 20, 21*). These water exchange rates are several orders of magnitude slower than the rate for $Gd(H_2O)_8^{3+}$ and far below levels necessary to achieve high relaxivity ($\tau_m \approx 20$ ns at 20 MHz). Because the fundamental properties of current commercial contrast agents are far from optimal, their resulting relaxivities are very low (~5 mM^{-1} s^{-1}), just a few percentage points of what is theoretically possible. Recent attempts to increase their water exchange rates by destabilizing their nine-coordinate ground state have resulted in less stable complexes (*20, 21*).

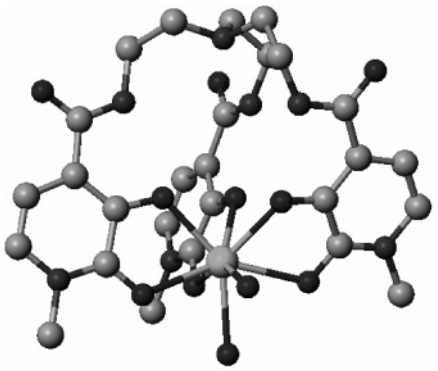

Figure 3. Crystal structure of Gd-TREN-1-Me-3,2-HOPO (**1**).

Gd(III) centers of poly(amino-carboxylate) complexes are coordinated by both oxygen and nitrogen atoms. This is more for synthetic convenience than design, given the high oxophilicity of lanthanide ions (*22*). We have reported a new family of MRI agents composed of all-oxygen donors and based on hydroxypyridinone (HOPO) and related ligands (Figure 4). The first of this family of compounds, Gd-TREN-1-Me-3,2-HOPO (Figure 3), showed particular promise due to its two coordinated water molecules and its fast, near-optimal water exchange rate (*23*). Its relaxivity of 10.5 mM^{-1} s^{-1} is more than double that of commercial contrast agents. Since then, the HOPO family has been extended to include complexes with varying chelating HOPO moieties, including mixed or heteropodal complexes and some complexes with varying caps. Their structures are shown in Figure 4, and their relaxivity and stability properties are given in Table 1. The water exchange rates and relaxivities of HOPO-based complexes are compared to those of commercial agents in Figures 5 and 6, respectively.

The fast, near-optimal water exchange rate is probably the most significant property of this family of complexes. The mechanism of exchange is probably similar to that of the aqua ion. Indeed both are eight-coordinate and both undergo rapid water exchange through an associative mechanism that goes through a nine-coordinate intermediate (Figure 8). This mechanism was recently supported by variable pressure NMR experiments that indicated that the reaction has a small negative activation volume ($\Delta V^{\ddagger} = -5 \pm 1$ cm^3 mol^{-1}) similar to that of the aqua complex ($\Delta V^{\ddagger} = -3.3$ cm^3 mol^{-1}) and indicative of an associative interchange process (*24*). Furthermore, shape analysis of the coordination sphere of the Gd(III) center in the crystal structure of Gd-TREN-1,2-HOPO indicates that the Gd(III) has a bicapped trigonal prism configuration (C.N. 8, Figure 8). Coordination of a new oxygen donor to form a tricapped trigonal prism (C.N. 9 intermediate) does not disturb the original geometry, indicating that this geometry may be predisposed for near optimal water exchange rates (*25*).

The water exchange mechanism of lanthanide aqua complexes are understood because of the classic studies of Merbach et al. (*26*). Earlier lanthanides (La to Nd) are nine-coordinate and exchange water through a dissociative mechanism whereas the heavier lanthanides (Gd to Lu) are eight-coordinate and exchange water through an associative mechanism. The fastest water exchange rates are observed for Sm and Eu for which the 8 and 9 coordination states are energetically identical. Given their fast water exchange rates, the same trend is expected for the HOPO based Gd(III) complexes. This is supported by the structure of La-TREN-1-Me-3,2-HOPO (Figure 9), which is a dimer in which one La is eight-coordinate with square antiprismatic geometry and the other is nine-coordinate with a monocapped square antiprismatic geometry (*27*). This demonstrates that the eight- and nine-coordination states are very close in energy and have similar geometries, which explains the fast water exchange rate observed for the corresponding Gd complex.

A typical NMRD (nuclear magnetic resonance dispersion) profile of a hydroxypyridinone-based complex, Gd-TREN-Me_2-5,4-HOPY (**3**), is shown in Figure 7. The relaxivity increases with decreasing temperature, a typical behavior for small molecular weight compounds for which the rotational correlation time is the limiting parameter. More significantly, at relevant magnetic field strengths the relaxivity peaks at high magnetic fields, typically between 20 and 100 MHz. This peak is a direct consequence of the fast water exchange rates of HOPO-based complexes: these rates are near optimal for high frequency MRI scanners. This behavior is opposite to that observed for commercial contrast agents, which have higher relaxivities at low magnetic fields (below 10 MHz) but significantly lower relaxivities at higher field strengths.

One of the disadvantages of the first hydroxypyridone-based Gd(III) complexes was their poor aqueous solubility. Given the high injection dosage needed to observe sufficient contrast in MR images, a water solubility of ~0.5 M is required. Modifications to improve solubility include the methoxy derivative, Gd-TREN-MOE−3,2-HOPO (**2**), cap in Gd-Ser_3-TREN-Me-3,2-HOPO (**7**), which has OH groups grafted onto the cap, and several

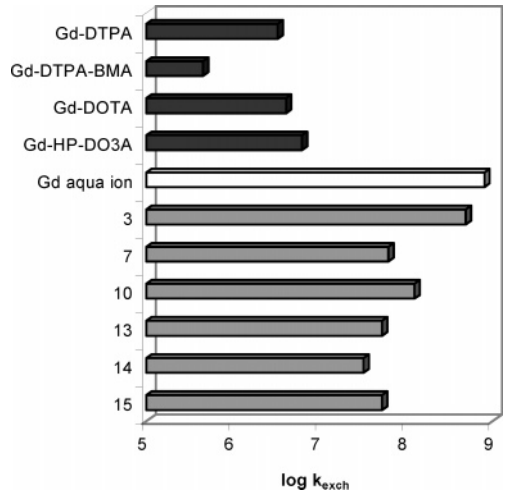

Figure 5. Water exchange rate of HOPO-based Gd complexes (grey) versus commercial agents (black).

isomers of HOPO such as Gd-TREN-6-Me-1,2-HOPO (**4**), Gd-TREN-1,2-HOPO (**5**), and the promising hydroxypyrimidine derivative, Gd-TREN-Me_2-5,4-HOPY (**3**). Mixed or heteropodal complexes containing two 1-Me-3,2-HOPO moieties and either a terephthalamide (**10**), a salicylamide (**11**), an isophthalamide (**12**), or a 1,2-HOPO moiety (**6**) have also been studied (*25, 27, 31, 33, 35, 36*). Fortunately, the addition of these small water-solubilizing moieties and the small variations in the chelating ring do not significantly change the water residence time ($\tau_m \approx 20$ ns), and all complexes demonstrate similar relaxivities ($r_{1p} \approx 9$ mM^{-1} s^{-1}). The exception is Gd-TREN-Me_2-5,4-HOPY (**3**) which not only demonstrates markedly improved solubility (up to 100 mM) but also a noticeably shorter water residence ($\tau_m \approx$ 2 ns), similar to that of the aqua complex (*33*).

The heteropodal HOPO/TAM (terephthalamide) complex offers the further advantage of being easily functionalized via its terminal acid group. Several poly(ethylene glycol) (PEG) derivatives (**13**, **14**, and **15**) bearing PEGs of different length have thus been synthesized. The resulting complexes demonstrate not only markedly improved water solubility but also provide the ability to fine-tune the water residence time (*28*). Addi-

tion of a PEG chain of MW ≈5000 g/mol increases the water residence time, τ_m, by a factor of 4.

The high toxicity of the Gd^{III} aqua ion (LD_{50} (mice) = 0.1 mmol/kg) requires that it be sequestered, and complexes that are kinetically labile must exhibit high thermodynamic stabilities (*29*). The stabilities of complexes with different number of protonation steps can easily and directly be compared in terms of their pMs (*30*). The stabilities of HOPO-based complexes are given in Table 1. As shown in Figure 11, they have stabilities comparable to commercial agents. Surprisingly, the more basic heteropodal HOPO−TAM complexes do not display

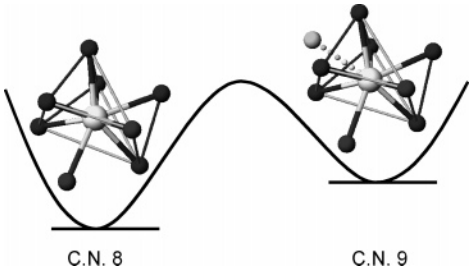

Figure 8. Proposed mechanism of water exchange for q = 2 hydroxypyridinone-based complexes (*25*).

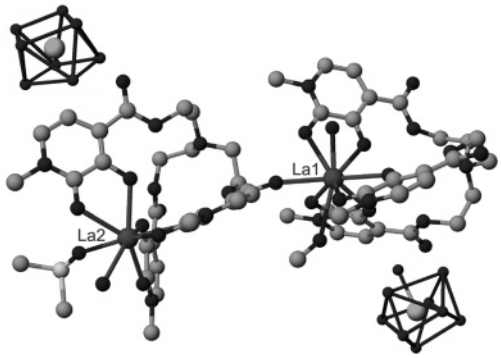

Figure 9. Crystal structure of La-TREN-1-Me-3,2-HOPO. La1 is nine-coordinate with monocapped square antiprismatic geometry while La2 is eight-coordinate with square antiprismatic geometry (*27*).

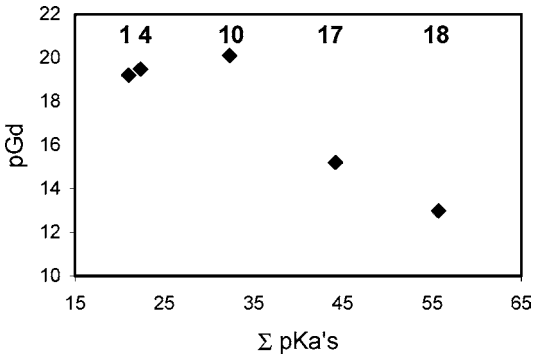

Figure 10. Stability of mixed hydroxypyridinone/terephthalamide Gd(III) complexes as a function of their basicity. 25 °C, pH 7.4, 0.1 M KCl, $[L]_{total}$ = 10 μM, $[Gd]_{total}$ = 1 μM (*31*).

the same linear relationship between stability and basicity that was observed for the more acidic commercial agents. As shown in Figure 10, the substitution of one hydroxypyridinone by one terephthalamide moiety (**16**) slightly increases the stability of the Gd(III) complex, while further substitution (**17** and **18**) significantly decreases the stability (*31*). This indicates that there is an optimal ligand basicity needed to achieve maximum stability, and that it is achieved by the presence of only one TAM moiety.

The TREN capping moiety is another important parameter in achieving high stability. Replacing the TREN cap by an expanded TRPN moiety (**9**) or inserting a glycine spacer (**8**) significantly reduces the stability of the resulting Gd(III) complex. As seen in both these data and the structures, internal H-bonding between the central capping N and the surrounding protons from the three amides noticeably increases the stability of the complexes (*32*).

All hydroxypyridinone Gd(III) complexes are acid sensitive. One HOPO podand protonates around pH 3, and the complex fully dissociates between pH 1 and 2.

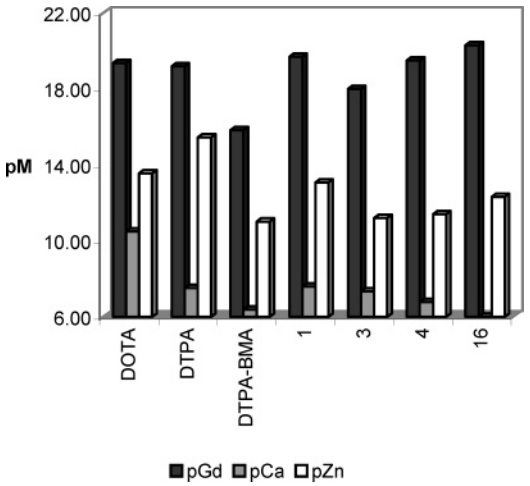

Figure 11. Selectivity of hydroxypyridinone-based ligands for Gd(III) over Ca(II) and Zn(II). 25 °C, pH 7.4, 0.1 M KCl, $[L]_{total} = 10\ \mu M$, $[M]_{total} = 1\ \mu M$ (*33, 34*).

As shown in Figure 7, this thermodynamic behavior, first observed by spectrophotometric titrations, is completely reflected in the pH dependence of the relaxivities (*33*). At pH 3, when one HOPO moiety protonates and dissociates, it is replaced by two water molecules, reflected by the doubling in relaxivity. The relaxivity then decreases toward pH 1 as the complex completely dissociates.

Selectivity is another important parameter to consider for kinetically labile complexes such as the HOPOs, which reach thermodynamic equilibrium with endogeneous cations during their in vivo lifetime. Indeed, it has been demonstrated that for such Gd(III) complexes, their toxicity is not directly related to their stability but rather to the selectivity of the ligand for Gd(III) over physiologically available metals such as Zn(II) (*29*). This selectivity may easily be determined by the difference in pM values between the two metal complexes (i.e. the selectivity for Gd(III) over Zn(II) is pGd-pZn). As shown in Figure 11, hydroxypyridinone ligands have higher selectivity for Gd(III) over Ca(II) and Zn(II) than commercial contrast agents (*34*).

CONCLUSION

Hydroxypyridinone-based Gd(III) complexes demonstrate significantly improved relaxivities due to their higher number of coordinated water molecules and near-optimal water exchange rates-several orders of magnitude faster than those of commercial agents. This optimal τ_m is reflected in the NMRD profiles, which typically show a peak of relaxivity at high magnetic fields where the relaxivities of commercial agents decrease. The fast water exchange is a result of an interchange associative mechanism in which the nine-coordinate intermediate is close in energy to the eight-coordinate ground state. This exchange rate can further be fine-tuned by grafting long poly(ethylene glycol) chains to the pendant acid of a mixed hydroxypyridinone/terephthalamide complex. These complexes also have high thermodynamic stability, and the ligands are more selective for Gd(III) over physiologically available cations such as Ca(II) and Zn(II) than current commercial agents.

Ligand-Carrying Gas-Filled Microbubbles: Ultrasound Contrast Agents for Targeted Molecular Imaging†

Alexander L. Klibanov*

Cardiovascular Division, University of Virginia, Charlottesville, Virginia 22908. Received April 24, 2004; Revised Manuscript Received December 8, 2004

INTRODUCTION

Molecular imaging is heralded as the solution to many problems of current medicine (*1*). It is supposed to offer convenient, universal, high-resolution, and affordable diagnostic imaging insight into the in vivo biological processes on the molecular and cellular level, aiding with personalized, targeted, and image-guided therapeutic interventions. Contrast agents usually suggested for molecular imaging are radioisotopes, paramagnetic materials, or fluorescent dyes, designed for SPECT/PET, MRI, or infrared optical imaging systems, respectively. Ultrasound as an imaging modality offers a cache of advantages over those techniques; therefore, development of molecular imaging contrast agent for ultrasound will result in many benefits.

Ultrasound imaging is (1) a real-time modality (routinely, 20−30 frames/s or more); (2) consistently used in image-guided biopsy and therapy, such as cryoablation, (3) inexpensive and popular; equipment is widely installed worldwide, and (4) portable: equipment can be taken to the bedside, ambulance, battlefield, or private practice office (including laptop and hand-held ultrasound units).

The concept of ultrasound contrast agent for molecular (targeted) imaging consists of using contrast particles with a specific ligand to the target receptors that are expressed in the area of disease. Targeted contrast is administered intravenously, circulates in the bloodstream, and accumulates in the area of interest via a ligand−receptor interaction. Free circulating agent clears from the bloodstream, and targeted agent signal is then used to demarcate the site and condition of the target diseased tissue (a simplified picture of such imaging is presented on Figure 1). Ultrasound imaging equipment is widely available. Contrast materials for intravenous use are already approved; therefore, targeted agents capable of molecular imaging represent a logical extension of the existing technology.

In this review, we will discuss the chemistry of the preparation of the most efficient targeted ultrasound contrast materials, techniques for ligand attachment, and application of these agents for molecular imaging. In this limited format it is not possible to provide the references to all the existing literature in the field; examples will be provided to demonstrate the general development trends.

Ultrasound Contrast Particle Design: Physical Considerations and Sensitivity. Ultrasound imaging is performed by signal processing of the reflections of sound waves sent toward the tissues within the body. For general clinical diagnostic imaging 1−10 MHz frequency ultrasound is used, which implies sub-millimeter to millimeter wavelength range and comparable spatial resolution. Higher frequencies, up to 20−50 MHz, provide much higher resolution (down to tens of micrometers) at the expense of penetration depth and are applied for imaging of specific organs, such as in ophthalmology, or in the intravascular probes. Lower frequency ultrasound, ∼1−3 MHz, allows deep penetration within the body. High frequencies provide limited penetration, only several millimeters. Ultrasound scattering by the tissues and borders between tissues is dependent on the mismatch of the acoustic impedance, i.e., difference between the product of the speed of sound in the medium multiplied by the density of that medium (*2*). Therefore, contrast agent particles which present the highest echo response would be the ones that possess the highest acoustic impedance mismatch between the bulk medium (blood has acoustic impedance quite close to water) and the particle microphase.

Several types of contrast particles have been suggested for ultrasound imaging, including liquid-core microemulsions and nanoemulsions (*3*), liposomes (*4*), and gas-filled microbubbles, with the average size of several micrometers (*5*−*7*). Gas-filled microbubbles offer the highest acoustic impedance mismatch and the highest recorded backscatter signals in ultrasound imaging (*2*, *8*). Liquid

contrast emulsion particles offer lower acoustic impedance mismatch but enhanced stability and prolonged circulation time (*3*). Multilamellar liposome-based agents were initially hypothesized to provide acoustic response due to their multilamellar lipid structure (*4*); later, it was shown that their acoustic response was caused by incorporated pockets of gas phase (*9*). Such liposomes offer acoustic response that is several orders of magnitude lower than that of microbubble-based agents (*10*). Overall, microbubbles offer the best detection sensitivity and some of these contrast agents are already approved for blood pool indications. Hence, the main focus of this review will be the discussion of the microbubble-based contrast materials, the specific chemistry of their preparation, ligand coupling, and actual molecular imaging applications.

Sensitivity of the detection of gas-filled microbubbles by ultrasound is quite high, even in comparison with other modalities suggested for molecular imaging. Typical approved intravenous human dose of ultrasound contrast microbubble material is at sub-milligram level. Actual detectable amount is considerably less. Experimental detection of *individual* microbubbles with diagnostic imaging clinical ultrasound systems has been reported (*8*, *11*). An estimated mass of the material contained in the shell and gas phase of an average microbubble is about a picogram; it can be clearly observed by ultrasound imaging of targeted microbubble in an in vitro model system (Figures 1 and 2). Within a certain microbubble concentration range, ultrasound backscatter response demonstrated linear dependence on concentration. Therefore, one can expect successful delineation of the areas of microbubble accumulation in the target tissues even if the number of actual targeted tracer particles is low (few thousands of selectively retained microbubbles definitely could be detected at the target area).

Additional imaging and postprocessing schemes can be applied to improve detection of targeted microbubbles on the background of normal tissue (the latter may be actually useful to pinpoint the location of the targeted bubbles in relation to anatomical markers and body structures). One important approach is image subtraction, when an image frame is acquired prior to contrast administration, and next one is obtained when targeted contrast accumulates in the area. Frames are aligned properly, and images are subtracted, so that the targeted contrast signal that constitutes the difference between the frames can be recognized easily. To aid in this procedure, targeted bubble destruction at high ultrasound intensity is often used (*12*). This way, there is no need to wait for many minutes from obtaining the original blank image to acquiring the "targeted" image, with the probe fixed at the same spot. After the "targeted" frame, all the targeted accumulated bubbles can be cleared by ultrasound irradiation, and the control frame is taken just a few seconds later (Figure 3A vs Figure 3C provide an in vitro model comparison). Another advantage of high-intensity destructive ultrasound imaging is a considerably higher acoustic response achieved in these conditions (Figure 3B). When nondestructive imaging of microbubble contrast is performed at a low ultrasound mechanical index (Figure 3A), the signal from targeted microbubbles is relatively low (arrow on the images pointing toward microbubble location), but quite visible and detectable as compared with control image where bubbles were destroyed, Figure 3C. When bubbles are irradiated with a higher-intensity ultrasound pulse, they are destroyed. Actual intensity and frequency of ultrasound pulses applied for bubble destruction and imaging may have to take into account the potential bioeffects of ultrasound (see below). During destruction, bubbles emit a bright acoustic flash at various frequencies. This signal can be detected by the imaging system very efficiently (Figure 3B). The microscopy image of the plate prior to insonation showed that only a small fraction (several percent) of the target surface is covered with targeted bubbles; just a few bubbles as observed optically (Figure 3D) are sufficient to obtain the high signal-to-noise ultrasound images. Overall sensitivity of the ultrasound for the detection of targeted contrast should be sufficient for molecular imaging.

Ultrasound Contrast Particle Design: Microbubble Preparation and Storage Stability. When microbubbles were first proposed as contrast agents, they did not carry a shell; such nonstabilized bubbles could survive only while they were surrounded by the aqueous medium, either normal saline (*13*) or viscous X-ray contrast (*14*). Such bubbles would fuse with each other and with the headspace air above the volume of the aqueous medium in the vial and rapidly disappear even prior to administration in the patient. An inadequate level of storage stability required in situ bubble generation in the immediate proximity to the patient location.

Improvement of microbubble formulation allowed the preparation of microbubbles stabilized with a lipid shell, typically, a lipid monolayer. Most often, lipids applied for microbubble coating possess a high transition tem-

perature (e.g., DPPC, 42 °C, or DSPC, 56 °C). Monolayers of such lipids are in gel phase and do not fuse as easily as do monolayers of fluid-phase lipids. Lipid-stabilized microbubbles possess somewhat improved stability over shell-free bubbles. To improve microbubble storage stability even further, we need to prevent direct contact between individual microbubbles and thus reduce the rate of shell fusion and bubble coalescence. This is achieved either by adding electrostatically charged molecules as a part of the microbubble shell (typically as 5−15 mol % of a negatively charged lipid within the bulk zwitterionic lipid) (*15*) or by grafting a surface brush of hydrophilic polymer, such as poly(ethylene glycol) (PEG) on the microbubble surface (*16*). PEG brush is similar to the coating of long-circulating liposomes, an established drug delivery system with prolonged circulation time and reduced uptake to Kupffer cells and macrophages. PEG-coated microbubble preparations can be stored for up to several years without a substantial loss of ultrasound contrast response, in our experience.

Actual microbubble preparation is typically accomplished by high-shear (such as probe-type sonication) dispersing of gas in the aqueous medium that contains lipids in a micellar or liposomal form. A most primitive but efficient dispersion apparatus consists of two disposable polypropylene syringes, partly filled with gas and aqueous lipid mixture and connected to each other via a partially closed stopcock (*17*). Liquid and gas are forced from one syringe to another by back and forth movement of the plungers; high shear and resulting microbubbles are generated in the narrow connector orifice. The size of the manufactured bubbles is dependent on the shear flow and also on the composition of the stabilizer lipid. A more sophisticated and widely applied method consists of sonication of the aqueous medium with a probe-type ultrasound disintegrator in the atmosphere of a desirable gas. When the gas is dispersed in the aqueous micellar medium, freshly generated contact surface between the gas and liquid phases is immediately coated and stabilized with the lipid monolayer to reduce surface tension. As individual microbubbles are closed up, they can no longer fuse with their neighbors due to the presence of the newly deposited shell. Typically, instead of air that was used in the early generation bubble preparations, fluorine-containing inert insoluble gases (such as decafluorobutane, octafluoropropane, or sulfur hexafluoride) are predominantly applied in the second generation microbubble materials (see Table 1 for the characteristics of some microbubble contrast agents available).

Commercially developed (nontargeted) microbubbles applied as the markers of circulating blood are stored usually as precursors, mostly dry preparations that

require addition of water for reconstitution prior to injection (*15*) and can only be used within several hours after reconstitution. However, some of the bubble preparations can withstand prolonged (years) storage in the aqueous phase; this requires a thicker shell, such as denatured albumin (*6*) or a shell composed of gel-phase lipid combined with PEG brush coating (*18*) to avoid microbubble fusion. Overall, storage stability of ultrasound contrast microbubble agents is now comparable with that of the agents used in other molecular imaging modalities, and cumbersome preparation or express delivery from the manufacturer to the hospital is not required.

Ultrasound Contrast Particle Design: Ligand Attachment Strategies. There are two general strategies for the attachment of the targeting ligand to the microbubble shell. In the first technique, the ligand is in a separate procedure coupled to the shell-forming molecule or its precursor (such as a lipid residue), to be used as an anchor to retain the ligand attached to the shell monolayer. The bioconjugate is then mixed with the bulk material suited for shell preparation, and bubbles are generated as described above. This approach works well for small organic molecule ligands, such as peptides, peptide mimetics, carbohydrates, hormones, and vitamins (such as biotin). Preparation of ligand−lipid conjugates has been perfected years ago and applied for ligand attachment to microbubbles either directly (*19*) or via a PEG spacer arm (*18*, *20*, *21*). The main advantage of this approach is the ability to perform the synthesis and product purification in the stepwise manner in the fully controlled conditions of an organic chemistry setup, ensuring high product yield and purity.

The second general approach to ligand conjugation with the bubble shell calls for covalent or noncovalent attachment of ligands to preformed microbubbles. This approach is most appropriate for the materials that are unstable in the conditions of continuous sonication, high-speed shear mixing, and resulting high temperatures, that are often associated with the preparation of microbubbles. Large protein molecules, such as antibodies or antibody fragments, are easily denatured in harsh conditions. To avoid denaturation of protein ligands, reactive moieties that are stable enough to withstand bubble preparation conditions can be incorporated in the shell first and then applied for the attachment of the protein ligand to preformed bubbles.

The groupings to achieve protein ligand binding can be suitable for covalent or noncovalent attachment. The noncovalent attachment strategies have been well developed, mostly with biotin−streptavidin-mediated techniques (Figure 4) (*12*). Conveniently, microbubbles can be rapidly purified from excess of free lipid, streptavidin, or biotinylated ligand, by repeated low-speed centrifugal flotation washes (e.g., 400*g* for several minutes). Respectively, after the first round of centrifugal washes during which the microbubbles are purified from excess lipid and biotin−lipid, microbubbles are dispersed in streptavidin solution. Streptavidin is used at an excess over the amount of available biotins on the bubble surface to avoid bubble cross-linking. After a brief incubation, the excess of free streptavidin is removed by flotation. Biotinylated antibody or other ligand is then added to complete the "sandwich" formation on the bubble surface (Figure 4). Coupling yield for the attachment of biotinylated ligands to microbubbles is reasonably high, and large excesses and losses of expensive ligand can be avoided.

Covalent attachment of antibody ligands to preformed microbubbles can be easily accomplished after a carboxylated lipid derivative has been incorporated in the bubble shell; typically, carboxylate is positioned on the outer terminus of a PEG polymer spacer, and the other terminus of PEG is grafted to the lipid anchor embedded in the shell (*22*). Carboxylate can be activated by a water-soluble carbodiimide, such as 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide in the presence of *N*-hydroxysulfosuccinimide, and resulting active ester can react with an amino group of an antibody or other protein ligand (Figure 5) (*23*, *24*). First, in mildly acidic conditions, the carboxylic acid residue is reacted with the carbodiimide with the formation of an unstable *O*-acylisourea. It is undesirable for this intermediate to be converted to the stable *N*-acylisourea, which would then be permanently attached onto the surface of the microbubble. *N*-Hydroxysulfosuccinimide is therefore added to convert *O*-acylisourea to *N*-hydroxysulfosuccinimide ester, which is reasonably stable in mild acidic environments, but would rapidly hydrolyze with the release of the unaltered carboxyl and *N*-hydroxysulfosuccinimide once the bubble preparation is placed in the mildly alkaline aqueous buffer solution containing the ligand that possesses primary amino groups used for coupling. Irreversible chemical modification of the bubble surface with undesirable *N*-acylisourea will thus be avoided.

The coupling yield of the targeting agent to microbubbles is determined by the rates of two competing

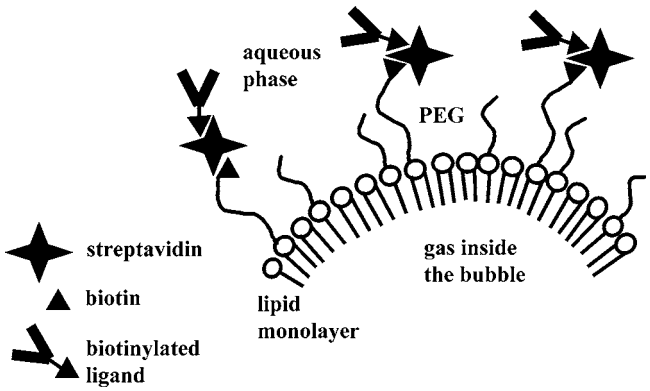

Figure 4. Design of biotinylated microbubble and attachment of biotinylated ligand via a streptavidin linker and PEG spacer arm.

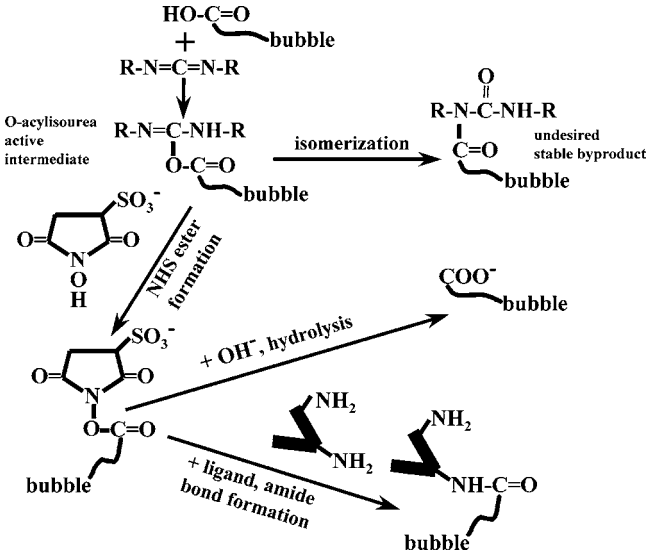

Figure 5. Coupling of amino-containing ligand to carboxyl-carrying microbubbles via water-soluble carbodiimide and *N*-hydroxysulfosuccinimide: the desired and side reactions.

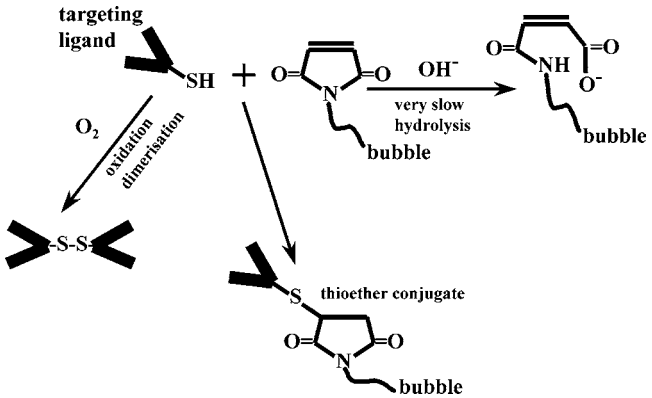

Figure 6. Coupling of thiol-carrying ligand to maleimide-carrying microbubbles: the desired and side reactions.

reactions, hydrolysis of *N*-hydroxysulfosuccinimide ester, and formation of amide bond between the ligand and activated carboxyl. The hydrolysis reaction is pseudo-first-order; the reaction rate constant is dependent on pH (faster at higher pH). The rate of coupling is also dependent on the concentration of primary amine in the deprotonated form (which depends on its p*K* and pH as well). Ligand coupling to active ester is a second-order reaction; the rate and the ligand coupling yield are both dependent on the concentration of reactants. While this coupling chemistry was successfully applied for antibody coupling to liposomal systems, where carboxylated lipid concentration was in the mM range (*24*), it is less than perfect for microbubble-based systems. The overall concentration of lipids that are needed to coat the surface of microbubbles is about 2 orders of magnitude less than a typical liposome lipid concentration, as is the concentration of activated carboxyl in the microbubble preparation. To achieve a decent ($\sim 10^5$ antibody per microbubble) level of coating, a large excess of the expensive antibody ligand has to be added (*22*); most of the antibody is not attached to the bubbles and wasted. To improve coupling yield, one needs to reduce the rate of side reactions of the activated derivative on the bubble surface without reducing the rate of the desired coupling reaction.

A different coupling strategy, attachment of thiol-carrying targeting ligands to the particle surface via maleimide (*25*) or vinyl sulfone, is widely applied in bioconjugate chemistry. Use of maleimide may provide good ligand coupling yield and slow degradation of the reactive group on the bubble surface (Figure 6). Maleimide-PEG-lipid can be easily incorporated in the monolayer shell, and thiol-carrying antibody can be simply added to react with maleimide with a formation of a thioether bond, which is exceptionally stable. The maleimide reactive group possesses much better stability than an NHS ester in the aqueous medium (*26*), and the rate of unproductive side reactions is greatly diminished; therefore, the yield of ligand coupling to the microbubbles can be improved considerably. An alternative side reaction in this case, oxidation of a thiol with atmospheric oxygen with the formation of disulfide bond, should not be a major problem, because microbubble handling should be performed in the perfluorocarbon atmosphere anyway. An additional benefit from the use of the thiol-maleimide approach, the ability to directionally attach the ligand to the bubbles, should also be taken into account. Protein ligands contain dozens of primary amino groups, and carboxylic acid coupling to those with amide bond formation is quite random. Some of the coupling sites may be located close to the binding site of the ligand, which would greatly reduce the affinity to the target receptor. If a single thiol residue is specifically introduced in a desired portion of the ligand, either by site-directed mutagenesis or by synthesis, oriented coupling to the bubbles will be achieved. The chance of ligand inactivation upon coupling via a single thiol will be greatly reduced.

The use of a flexible polymer spacer arm as a linker between the bubble surface and the ligand offers some advantage over a direct attachment of the ligand to the microbubble surface. The microbubble shell, especially one formed from gel-state phospholipids, does not offer rapid ligand mobility along the bubble surface. Therefore, the matching of ligand and receptor pairs along the contact area may require time that is not available during the brief contact between the bubble and the target surface in a flow-through scenario. Use of a flexible polymer tether (such as PEG) allows the ligand to rapidly interrogate the target surface and attach to the target receptors whenever available and in reasonable proximity to the microbubble surface. Additional benefit of placing the ligand on the PEG spacer becomes obvious when microbubbles also carry a grafted PEG polymer brush. If the ligand is attached directly to the lipid anchors, it may be hidden inside the polymer brush layer and become poorly accessible to the target receptor (*27*). When ligand is placed on the extended tether, especially if the length of the tether exceeds the thickness of the PEG brush, a "tiered brush" structure is created on the surface of the bubbles, where the thick brush layer of shorter PEG provides a stabilization coating, and longer polymer chains with tethered ligand are extended into the surrounding medium for efficient target receptor capture.

Ultrasound Contrast Particle Design: Biodistribution and in Vivo Behavior. Initial microbubble contrast preparations were quite unstable in the bloodstream; shell-free microbubbles could not even pass through the lung vasculature, and contrast imaging of myocardium was only possible after intraarterial administration (*13*). Since that time, ultrasound contrast materials' circulation time has improved greatly. Modern microbubble contrasts use appropriate lipid, polymer, or protein shells and can persist in the bloodstream for many minutes (up to 1 h for some preparations). This circulation time scale is quite sufficient to perform the task of targeted mapping of the receptors exposed to vascular lumen. For lipid monolayer-based microbubble design, generally, the coating made from longer-chain fully saturated lipid molecules (such as distearoyl phosphatidylcholine as compared with, for example, dimiristoyl phosphatidylcholine) ensures longer circulation time. In the early generation contrast agents, air was used as the gas phase. Use of low-solubility gases, e.g., decafluorobutane, further improves circulation time, because such gases exit the bubble and dissolve in the surrounding blood slower than oxygen or nitrogen. A lipid monolayer-coated bubble with decafluorobutane gas core can stay in the bloodstream for many minutes. During the circulation, especially while passing through the lung microcirculation, microbubbles gradually deflate and lose ability to scatter ultrasound; majority of the poorly soluble gas incorporated within the bubbles is exhaled within minutes after intravenous injection, which points to the lungs as the major bubble gas elimination site (*28*) (actual circulation and exhalation times depend on the specifics of the gas used).

Some of the microbubble preparations were retained nonspecifically in the vasculature, especially in the areas of inflammation (*29*, *30*); in part this may be caused by the activation of complement by some of the components

of the microbubble shell and triggered by the presence of electrostatically charged lipids on the bubble surface (*31*). Leukocytes, macrophages, and Kupffer cells have a tendency to capture these heavily charged microbubbles, especially the ones carrying phosphatidylserine (*32*). Presence of the PEG brush on the microbubble surface of charged bubbles reduces complement deposition only partially (*31*); therefore, it may be desirable to avoid surface charge in the microbubble formulations, especially if reduction of the nonspecific microbubble tissue uptake is desired.

In all of the imaging modalities used for targeted and molecular imaging, it is critical to achieve not only a high degree of accumulation of contrast material in the target and low accumulation in normal tissues, but also low level of circulating contrast in the bloodstream. For some of the intravenously injected targeted contrasts used in SPECT or MRI, such as antibodies, long-circulating liposomes, or high molecular mass polymers, it may take up to a day to clear from the bloodstream via liver or kidneys. Therefore, diagnostic imaging cannot be performed rapidly and repeated frequently to monitor treatment efficacy. In the case of ultrasound, circulating bubbles may clear from the bloodstream completely within a fraction of an hour, or even faster, depending on the particular shell design and gas core. We can speculate that the microbubbles that had attached to the target tissue should maintain their stability much better than the bubbles still in circulation. Targeted bubbles do not repeatedly pass through the lungs where most of gas exchange and bubble deflation seem to take place. In an in vitro setting, targeted bubbles can be maintained on the antigen-coated surface for at least a day. Even if the majority of the bubbles clears from the bloodstream and other tissues, and only a small fraction of the administered bubbles is retained at the target, high detection sensitivity should allow successful target detection and delineation. Thus, we can expect high target-to-blood ratio within 10−15 min after microbubble contrast administration (*12*), and in this situation further extending contrast circulation time may not bring any benefits for the timely completion of the imaging procedure and successful diagnosis.

Potential Safety Concerns Associated with Targeted Microbubble Systems. Contrast agents need to possess an excellent safety profile to be permitted for clinical use. Therefore, potential safety, toxicity, and side effect concerns affiliated with targeted microbubble agents need to be taken seriously and evaluated in detail. There are generally three groups of safety questions concerning microbubble contrast to be applied in molecular imaging: (1) the general reaction of the organism to contrast agent particles; (2) potential generation of immune response to particle components, such as targeting ligands; (3) ultrasound radiation bioeffects potentiation in the presence of microbubble agents in the living tissues.

Concerns regarding undesired reactions of the organism to the intravascular administration of particle agents had been raised many times over the past years, especially with liposomes (*33*). In some patients an undesired systemic hypersensitivity-type reaction to the particle administration might occur; agent infusion is then to be discontinued and antiinflammatory therapy performed (*34*). One likely explanation for these adverse events is based on the electrostatic surface charge of the particles that results in complement activation leading to the undesired systemic effects (*33*). The administered dose of ultrasound contrast agents is usually lower than the dose of therapeutic liposomes; therefore, the resulting undesirable effects are quite rare. For ultrasound contrast particles, addition of a PEG brush on particle surface might diminish complement-mediated events somewhat, but might not fully solve the problem (*31*) (similarly, liposome therapeutics described above that cause complement activation are PEGylated). The effective solution to this problem would be to formulate the agent without a substantial content of electrostatically charged components, which may be easily achievable for most of the particle systems by careful choice of ligands, coupling chemistries, and coupling anchors.

Concerns regarding immune response to targeted particles, i.e., development of antibodies against targeting ligands (such as full size antibody molecules) and other microbubble shell components, have been evaluated for liposome-based drug carrier systems and should not be very different for the targeted ultrasound contrast particles (*35*). The use of humanized/human antibodies, small antibody fragments, and small molecule ligands is expected to minimize development of secondary antibodies in patients. Monitoring of this issue will ensure safety of repeated clinical application of targeted contrast ultrasound particles.

The presence of gas bubbles may enhance the bioeffects generated by ultrasound (*36*). In clinical practice, the intensity of ultrasound radiation transmitted into the body of the patient by the transducer of the imaging system is strictly controlled and limited; mechanical index (MI) and thermal index quotients are constantly computed and restricted by the equipment according to applicable FDA guidelines (*37*). In vitro and in animal studies it has been shown that in certain conditions, a combination of microbubbles and ultrasound may cause RBC hemolysis (*38*), enhance transfection (a term "Sonoporation" was even coined (*39*)), and in some instances result in the rupture of microvasculature and formation of miniature petechial hemorrhages (*40*) that may actually be applied for enhancement of angiogenesis (*41*) and for drug delivery (*42*). The perceived degree, potential practical importance, and alleged dangers of the ultrasound bioeffects vary. Regarding hemolysis, even if we assume that a billion injected bubbles would in a worst-case scenario damage a billion RBCs (<0.3 mL of blood), the amount of released hemoglobin would be comparable with the background free hemoglobin normally present in blood. Regarding tissue and vascular wall damage, to achieve substantial petechia formation, several parameters of the studies had to be brought to certain levels at the same time. In some animal studies, the skin barrier had to be removed to achieve vascular bioeffects (therefore, we may expect that even a modest degree of attenuation by the tissues in the body would suppress capillary rupture). Microbubble concentration in the blood in those animal studies sometimes was orders of magnitude higher than used in clinic (*40*−*42*). In concurrence to that, bioeffects did not manifest themselves unless lower frequency ultrasound (e.g., ∼1−2 MHz transmit) was applied at high MI (1.0 and above). Intermittent pulsing (1 frame/s) was found to cause petechia formation whereas continuous (30 frames/s) imaging did not (*43*); possibly, intermittent pulsing allowed the microbubbles to reach the capillaries, where size of microbubble is close to the size of vascular lumen and bubble expansion in the sound field may cause maximal effect on the vessel wall. Ultrasound bioeffects at higher frequencies were generally suppressed. Care should be therefore taken to avoid a combination of undesirable conditions (such as

high energy intermittent pulsing at low frequencies) during targeted ultrasound contrast imaging.

Overall, microbubble-based contrast agents are approved for clinical use in many countries; hundreds of thousands of patients have received ultrasound contrast material, and so far, reported side effects from numerous clinical trials have been quite rare (certainly less than manifested in case of X-ray contrast media). When we combine available side effect information with its applicability to targeted bubble imaging paradigm, we may assume that it is unlikely to become a major problem. For targeted imaging, circulating bubbles will be removed to reduce target-to-blood ratio; therefore, we may not expect significant damage to capillaries as observed for circulating bubbles. Low MI and higher frequency imaging will likely be used for detecting targeted bubbles; therefore, bioeffects are not likely to present a significant issue in the ultrasound contrast molecular imaging. It is important to continue in-depth research and monitoring efforts in the area of microbubble-mediated bioeffects, so that patient safety is assured.

Ultrasound Contrast Materials in Molecular Imaging Applications. The general upper limit for the size of an intravascular particulate contrast agent, several micrometers, roughly the same size as red blood cells, is defined by the diameter of capillaries. These micron-size bubble particles would not be able to escape the circulation and enter the extravascular space. Submicron bubbles are mostly not very stable and not very echogenic. Therefore, targeting of micron-size bubbles directed to the receptors on intravascular entities is the most acceptable strategy. Receptors of interest, upregulated on the inner surface of endothelial layer of the vasculature, include proteins from integrin and selectin families. For instance, P-selectin and ICAM-1 are known to be upregulated on the surface of activated endothelium in the tissue that is undergoing inflammatory processes; selectin and integrin upregulation is applied by the body to direct leukocyte accumulation and transmigration into these areas. Leukocyte size and behavior in the blood flow is similar to that of the microbubble contrast agent, so it can be expected that targeting of microbubbles can be as successful as targeting of leukocytes in nature. Indeed, when a monoclonal antibody against P-selectin was attached to the microbubble surface via a PEG spacer and biotin−streptavidin linker technique, selective accumulation of microbubbles in the areas of inflammation and ischemia-reperfusion injury of mouse kidneys was demonstrated by intravital microscopy and ultrasound imaging (*12*), very similar to leukocyte capture and accumulation in those areas. Similarly, anti-ICAM-1 monoclonal antibody attached to the same biotinylated bubbles directed them to the vasculature of rejecting hearts in a heterotopic rat heart transplant model (*44*). Anti-VCAM-1 antibody on the bubble surface directs them to atherosclerotic plaques in animal models (*45*).

This targeting strategy also proved successful for imaging the areas of angiogenesis, which is an important phenomenon defining the process of tumor growth and metastases development (*46*) or could be induced on purpose as a therapeutic procedure for the improvement of the blood flow to ischemic myocardium or other tissues and organs (*47*). Biotinylated antibody against $\alpha_V\beta_3$, or a biotinylated 5.4 KD RGD disintegrin peptide echistatin, coupled to biotinylated microbubbles by the same technique as above, resulted in selective accumulation of targeted bubbles, but not the control bubbles, in the area of elevated surface density of $\alpha_V\beta_3$ on vascular endothelium, such as angiogenesis in a matrigel plug mouse model (*48*) or a tumor growth area in a glioma model in nude rats (*49*). Successful targeting of microbubbles via covalently attached RGD peptides to activated platelets has also been achieved as an approach to blood clot imaging (*20*, *21*).

Overall, a successful clinically suitable targeted microbubble contrast agent is not going to be based on streptavidin−biotin coupling technology due to the need of multiple washes and the use of a foreign, possibly immunogenic protein (streptavidin) in the design; that approach is most appropriate and convenient for early proof-of-principle animal studies, where biotinylated ligands, such as antibodies of a wide variety are easily available commercially. Most of the available monoclonal antibodies are also immunogenic, due to their rat or mouse origin, and the variety of nonimmunogenic human antibodies is still limited. Furthermore, antibodies or other large proteins may be denatured in the harsh conditions of sonication and high shear during microbubble preparation and have to be attached to the preformulated microbubble agents. The preferred strategy would be to obtain small molecule ligands against the desired selectin and integrin targets and attach them to the bubbles via a direct chemical linking, preferably via a PEG spacer arm. Such high-affinity ligands (peptides or peptide mimetics) are becoming available via combinatorial synthesis and library screening methods. High affinity small molecules with nM level K_d have already been identified (*50*). As compared with an antibody with its ~150 kD molecular mass, these molecules are much smaller in size and should easily withstand the conditions of microbubble preparation without loss of binding affinity.

Another advantage of small molecule ligands over antibodies is in the kinetics of the attachment of ligand to receptor. Antibody active site structure is oftentimes designed as a pouch; it binds to the target receptor slowly and holds it firmly, with overall low equilibrium dissociation constant K_d, despite low kinetic k_{on}. Small ligands, on the other hand, can rapidly bind to the target with high k_{on}, which is a great advantage for a situation where a microbubble that flows through the vasculature and bumps into activated endothelium has a very limited time to attach to it. In nature, leukocytes apply PSGL-1, a fast k_{on} ligand with a sialylated sulfated 19-amino acid active site on its N-terminus, to achieve rapid binding to endothelium, resulting in leukocytes slow rolling through the vessels even in high shear flow (*51*). This ligand makes leukocytes as well as model polystyrene beads roll (and even firmly stick) onto endothelial cells that possess high enough surface density of P-selectin. The use of such small ligands (as simple as sialyl Lewis X, or a glycosulfopeptide described above) on the surface of microbubbles, especially in combination with coimmobilized slow k_{on} ligands (such as antibodies) will allow firm adhesion despite rapid blood flow in high wall shear stress conditions (*52*, *53*). A small ligand will provide initial slowdown of the bubbles so that the antibody will obtain a better chance to attach to the target antigen, thus retaining the microbubble on the target surface firmly. We need to note, however, that these elaborate designs might only be necessary for some of the intended targets located in the areas of exceptionally high shear flow (such as vulnerable plaque when accessed from the artery side). For many of the proposed targets, such as tumor vasculature with relatively slow blood flow, existing simple single-ligand designs may be sufficient for successful microbubble targeting and retention.

CONCLUSION

The winning design of a targeted ultrasound contrast agent will most likely be based on a small molecule ligand attached to the shell of a gas-filled microbubble. Preformulated microbubbles will be stable on storage. They will require only a short resuspension procedure prior to the administration to patients. The bubbles will most likely be PEGylated, to improve storage stability, achieve optimal circulation time, and reduce nonspecific background accumulation in normal nondiseased tissues. The injected dose of the material is going to be in submilligram level (of which the ligand will constitute micrograms, quite comparable with PET or SPECT targeted nuclear medicine agents). Due to low dosage and proper shell composition, the possibility of undesirable patient side effects will be eliminated. Current ultrasound imaging technologies and equipment allow excellent sensitivity of microbubble contrast detection in the target tissues, with the capability to count individual bubbles with picogram mass. Targeted ultrasound contrast will find widespread application for imaging, image-guided biopsy, and image-guided therapy of cancer, as well as application for monitoring the status of tissues subjected to ischemia, inflammation, or rejection of transplanted organs.

ACKNOWLEDGMENT

The author is grateful to J.R. Lindner, S. Kaul, K. Ley, and J. Rychak, University of Virginia Cardiovascular Division, Cardiovascular Research Center and Cardiovascular Imaging Center, for support, help, and exchange of ideas. Support (in part) via DOE 43-14702, NIH DK63508, HL64381, and EIF Foundation is acknowledged. Mallinckrodt Inc. (Hazelwood, MO) is acknowledged for the donation of laboratory equipment to University of Virginia so this research could continue at UVA.

Improving the Integrity of Three-Dimensional Vascular Patterns by Poly(ethylene glycol) Conjugation

Sadhana Sharma,[†,§] Wei Tan,[‡,§] and Tejal A. Desai*[,∥]

Davis Heart & Lung Research Institute, The Ohio State University, Columbus, Ohio 43210, Beckman Institute, University of Illinois at Urbana−Champaign, Urbana, Illinois 61801, and Department of Biomedical Engineering, Boston University, Boston, Massachusetts 02215. Received May 16, 2004; Revised Manuscript Received August 16, 2004

Development of functional tissue-engineering constructs may require that multiple cell types be organized in controlled three-dimensional (3-D) microarchitectures with proper nutrient diffusion and vascularization. In the past few years, a variety of microscale techniques have demonstrated the ability to control protein and cell attachment in defined patterns. Nevertheless, maintenance of these patterns over time has been a significant challenge due to nonspecific protein adsorption and cell migration. To this end, we have investigated the effectiveness of poly(ethylene glycol) (PEG) thin films in maintaining the integrity of 3-D cellular patterns, using human umbilical vein endothelial cells (HUVEC) as a model system. These HUVEC constructs were created using extracellular matrix (ECM)-based microfluidic patterning. Our results indicated that PEG-conjugated substrates improve cell pattern integrity as compared to control silicon. The compliance multifactor (a measure of pattern integrity; higher value means lower pattern integrity) was about 3.66 ± 0.29 on day 5 for PEG-conjugated surfaces, compared with 8.23 ± 0.42 for control surfaces ECM-based microfluidic patterning coupled with stable PEG-conjugated surfaces may serve as a vital tool for vascularized tissue engineering.

INTRODUCTION

Damage or loss of an organ or tissue is one of the most frequent and costly problems in healthcare. Current treatment modalities include transplantation, surgical reconstruction, and mechanical devices such as kidney dialyzers. These therapies have revolutionized medical practice but have limitations. While transplantation is restricted by ever increasing donor shortage, mechanical devices cannot perform all the functions of a single organ, thus providing only temporary benefits (*1, 2*). The emerging and interdisciplinary field of tissue engineering offers to solve the organ transplantation crisis. The creation of functional tissue engineering constructs, however, requires the formation of well-defined biomimetic microenvironments that surround cells and promote controlled cell interactions, maintenance of three-dimensional (3-D) microarchitecture, and proper vascularization.

Vascularization is considered as the main technological barrier for building 3-D human organs, as effective organ perfusion is not possible without an endothelialized vascular tree (*3*). The extracellular matrix (ECM), serving as a natural scaffold and reservoir of signaling molecules in tissues, may provide 3-D biomimetic environments for proper growth of the cells, and hence vascularization. Chemical modifications of matrix components in vitro *may* allow ECM scaffolds to be tailored. Patterning of cells within a 3-D matrix provides an approach that allows for shifting from two-dimensional (2-D) patterned cell cultures to 3-D patterned "tissue"-like culture systems (*4, 5*).

Microfluidic patterning techniques provide ways to spatially control cells and design appropriate configurations of cells and materials for "engineered" products. Chiu et al. (2000) fabricated 3-D microfluidic systems and used them to pattern proteins and mammalian cells on a planar substrate. The channel structure, formed by a microstamp in contact with the surface of the substrate, limited migration and growth of the cells in the channels. Removal of the stamp, however, resulted in the spreading and growth of the different cell types (*6*). It was realized that nonselective adhesion and cell migration were the major reasons for the collapse of these patterns over time.

While the problem of long-term maintenance of 2-D cell patterns created using microcontact printing has been previously addressed, the stability of 3-D cellular patterns remains unexplored (*4*). We previously investigated the pattern integrity of 3-D micropatterns created using microfluidic patterning. Since the ECM naturally stabilizes tissue architecture in vivo (*7*), we used ECM components in microfluidic patterning for better main-

tenance of pattern integrity. We also demonstrated that the chemical addition of matrix components in vitro would allow the ECM scaffolds to be tailored for superior maintenance of HUVEC patterns (*4*). This method improved the integrity of 3-D HUVEC patterns on Petri dish for a period of two weeks.

PEGs are known for their ability to prevent protein adsorption and cellular adhesion (*8, 9*). Therefore, the use of covalently coupled and stable PEG films may be useful for the modification of surfaces for 3-D ECM microfluidic patterning. This may facilitate improved control over cell proliferation and migration and, in turn, pattern maintenance for longer durations. Previously, Branch et al. (2000) used PEG thin films as a background for 2-D neural patterning. However, these films degraded over time (<4 weeks) resulting in the loss of pattern (*10, 11*). In this study, we investigate the usefulness of PEG conjugation for maintaining the integrity of 3-D HUVEC patterns created using microfluidic patterning. The PEG films used in this study were developed using a one-step covalent coupling procedure (*12*). These PEG films were characterized and investigated for their stability over time (up to 4 weeks) (*13, 14*). Results suggested that these PEG thin films were effective in controlling protein and cell adhesion for the period investigated. In the present research effort, we have examined the effectiveness of PEG thin films in maintaining the integrity of 3-D HUVEC patterns. These HUVEC patterns were created using ECM-based microfluidic patterning with a collagen matrix.

MATERIALS AND METHODS

Preparation and Characterization of PEG-Conjugated Silicon Substrates. PEG-conjugated silicon substrates were created using a one-step covalent coupling procedure. This reaction scheme involves synthesis of PEG-$OSiCl_3$ (called PEG-silane) by reacting PEG with silicon tetrachloride in the presence of triethylamine (catalyst), followed by direct coupling of PEG-silane to a hydrophilized silicon surface. In the present study, PEG (MW: 1000) was coupled to 3-in. silicon wafers (⟨100⟩) using 10 mM of PEG concentration for 1 h. Ellipsometry, contact angle measurement, X-ray photoelectron spectroscopy (XPS), and atomic force microscopy (AFM) were used to analyze the PEG-conjugated surfaces. The details of this procedure have been described elsewhere (*12*).

Cell Culture and Microfluidic ECM-HUVEC Patterning. HUVECs (BioWhittaker, Walkersville, MD) were maintained in endothelial growth medium (BioWhittaker) containing 2% FBS, 2 mL of human fibroblast growth factor (hFGF−B), 0.2 mL of hydrocortisone, 0.5 mL of vascular endothelial growth factor (VEGF), 0.5 mL of human recombinant insulin-like growth factor (R3−IGF-1), 0.5 mL of ascorbic acid, 0.5 mL of human epidermal growth factor (hEGF), 0.5 mL of gentamicin-amphotericin B (GA-1000), and 0.5 mL of heparin in every 500 mL of endothelial basal medium. Cells with passage 3−8 were used in the experiments.

Collagen matrix was used in these experiments to create 3-D HUVEC patterns. This method involves microfluidic patterning of 3-D biopolymer matrices to provide microscale control over cellular microenvironments. The method of preparing prepolymer solution of collagen matrix has been described in detail elsewhere (*15*). The techniques of cell microfluidic patterning have also been demonstrated previously (*6*). Similar procedures were used in this study to pattern HUVECs. For injection, a 1-cm^3 syringe was used, but the needle was replaced with a smaller 26 gauge needle to fit the inner diameter of the tubing. To pattern cell-ECM assemblies, cell-ECM solutions were prepared. The concentration of cells without and within ECM solutions was 1×10^6 cells/mL. First a prepolymer solution, which polymerizes at 37 °C, was prepared on ice and then mixed with the cell suspension just before microfuidic delivery. The control and PEG-conjugated wafers were then immersed in water for 30 min and sterilized by immersion in 70 vol % ethanol for 20 min. Subsequently, they were rinsed in sterile deionized water and dried inside a sterile hood. HUVEC-ECM assemblies were then patterned into a straight microchannel using a PDMS mold (prepared as described in (*4*)). Figure 1 shows a schematic of the microfluidic patterning technique used in this study.

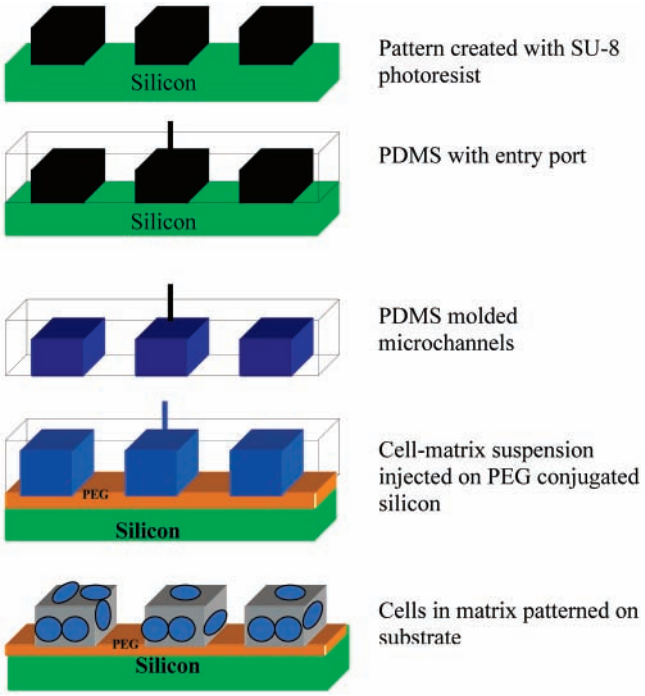

Figure 1. Schematic diagram for microfluidic cellular patterning.

For quantitative assessment of cell spreading, samples were monitored daily for 5 days after removing the PDMS template. Light microscopy was used to acquire images of cells and cell-matrices. Image-Pro Plus software (Media-Cybernetics, Carlsbad, CA) was used for image analysis. Matrix size, spreading area, and cell migration distance were measured by the software tools. In this study, the compliance multifactor was defined as the patterned cell area at time = t over the original patterned cell area at time = 0. Analysis of variance (ANOVA) was used to evaluate the results of compliance multifactor. The significance levels of the experimental data were analyzed with Microsoft (Redmond,WA) Excel.

RESULTS AND DISCUSSION

Surface Characterization of PEG-Conjugated Silicon Substrates. The thickness of PEG films was determined using variable-angle ellipsometry and was found to be 20 ± 0.93 Å. The hydrophilicity/hydrophobicity of the surface was determined by measuring water contact angle in air using the HALF-ANGLE measuring technique by a contact angle goniometer (Tantec Inc., Schaumburg, IL) before and after PEG-conjugation (Table 1). Surfaces with contact angles in the range of 20−60° are generally considered to be hydrophilic and show more

resistance to protein adsorption and cell adhesion. The water contact angle for these PEG films was ~42°, suggesting their hydrophilic nature. The presence of PEG on silicon surfaces was verified using XPS. Survey spectra, and high-resolution spectra of Si2p and C1s core levels were taken on silicon surfaces before and after conjugation of PEG. The XPS analysis demonstrated an increase in carbon and oxygen content, and a decrease in silicon concentration for the PEG-modified surface (Table 1). An increase in the intensity of the C−O peak in high-resolution C1s spectra further confirmed the presence of PEG on silicon substrate. Surface topography and uniformity of clean and PEG-conjugated surfaces were examined using a tapping mode AFM. The roughness of the surface was assessed by measuring the roughness parameter, R_{rms} (root-mean-square roughness). R_{rms} is defined as the root-mean-square average of the height (h) deviations taken from the mean data plane. It is expressed as: $R_{rms} = \sqrt{(1/N)\sum_{i=1}^{N}(h_i - \bar{h})^2}$. Here, h_i is the current height value, $\bar{h}$ is the height of the mean data plane, and N is the number of points within the box cursor. Table 1 shows RMS roughness parameters for control and PEG-conjugated silicon surfaces. Furthermore, PEG-conjugated silicon substrates were analyzed for their antifouling abilities using albumin and fibrinogen as model proteins. There was an approximately 80% reduction in fibrinogen adsorption and 90% reduction in albumin adsorption on PEG-conjugated surfaces (Table 1). The topography of fibrinogen-adsorbed control and PEG-conjugated surfaces was also examined using AFM. Figure 2 shows 3-D and section plots for 500 nm size scans of protein-adsorbed control and PEG-conjugated silicon. Irregularly defined and nonuniformly distributed peaks were seen in the 3-D image and section plot of protein on PEG-conjugated surfaces compared to control silicon surfaces. A closer examination of the section plots of control and PEG-conjugated surfaces indicated that protein was evenly adsorbed on control silicon surface as compared to random adsorption on PEG-conjugated surfaces. Detailed characterization of these surfaces is described elsewhere (*13*).

HUVEC-ECM Pattern Integrity on Control and PEG-Conjugated Silicon Substrates. Pattern integrity is defined here as the ability of cells to stay in the position where they were originally patterned. It is similar to the notion of pattern compliance which has been used elsewhere (*10, 11*), except that in this study it refers to a 3-D system. To examine the efficacy of PEG in maintaining pattern integrity, first ⟨100⟩ silicon wafers were coated with PEG as described earlier. The change in cellular micropattern width over time was used to evaluate pattern integrity. The width of the cell pattern was determined by drawing two parallel lines as the borders between which most of the cells (>95%) are located, neglecting outliers beyond the borderlines. In our previous paper (*4*), we investigated the influence of the channel size on the compliance and, therefore, defined compliance multifactor as the patterned cell area at time t over the original patterned cell area at $t = 0$, divided by channel size in order to eliminate that factor in the final compliance multifactor value. In this study, the compliance multifactor was defined as the patterned cell area at time = t over the original patterned cell area at time = 0. Smaller values of compliance multifactor mean better maintenance of the pattern i.e., greater pattern integrity. Cell number was estimated from micrograph image areas of 1 mm^2.

Figure 3 shows the results for the HUVEC-ECM patterns created on unmodified and PEG-modified silicon. The cells patterned on PEG-conjugated substrates

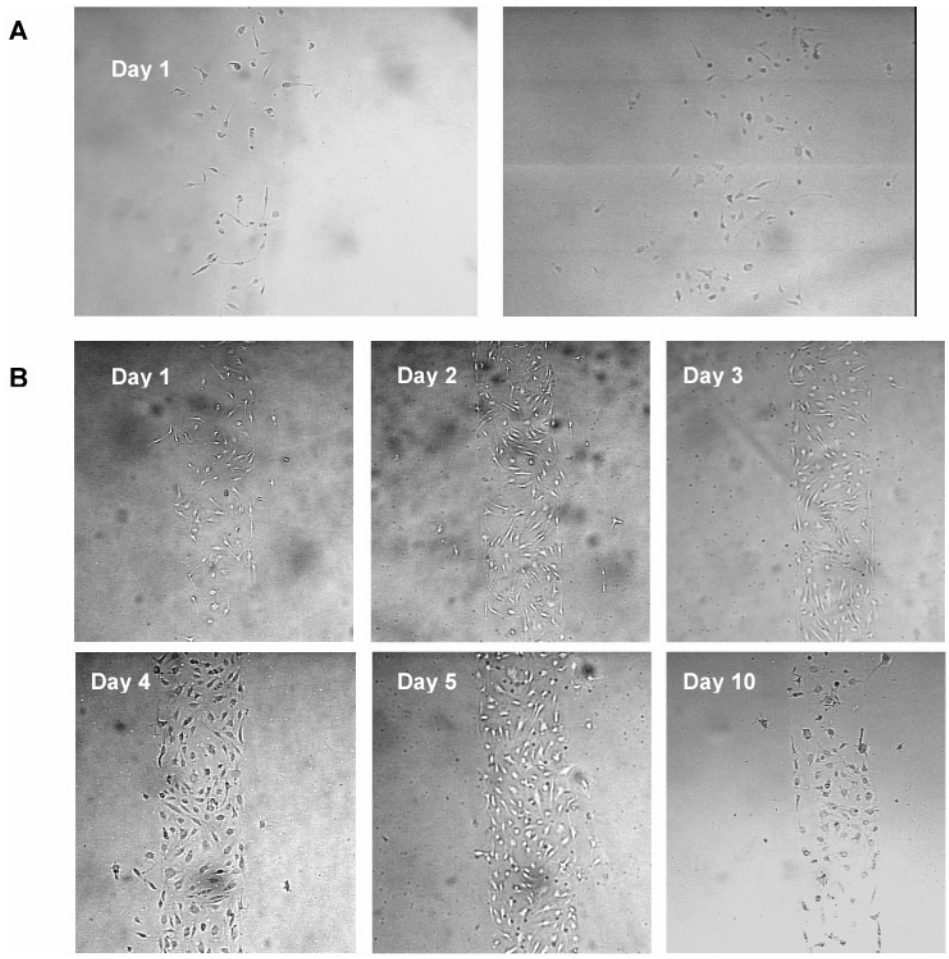

Figure 3. (A) Control silicon: pictures of cells cultured for 1−2 days. After 3 days, we had to take two frames to add images up to get the compliance multifactor; (B) PEG conjugated silicon: pictures of cells cultured for 1−5 days and day 10. After 10-day culture, cells apoptosized due to the overconfluency in the channel area.

displayed greater compliance with the original pattern, with a slower rate of pattern loss in the first 5 days of culture as compared to control silicon. For control silicon substrates, images from two frames were taken to obtain the compliance multifactor after 3 days. Cell migration and proliferation contribute to the loss of a cellular pattern over time. As compared to our previous study, here we used a different type of substrate, i.e., silicon instead of Petri dish. Because of the limited size of the silicon piece we used and higher compliance multifactor on the silicon piece than that on the dish surface, we could only follow the changes in control silicon sample till day 6 as compared to two weeks on Petri dish. While the compliance multifactor continued to increase for cells patterned on bare silicon, its value begins to plateau for PEG-conjugated silicon. On day 5, the compliance multifactor was about 3.66 ± 0.29 for PEG-conjugated surfaces, compared with 8.23 ± 0.42 for control silicon surfaces (Figure 4). Lower values of compliance multifactor for PEG-conjugated surfaces indicate the superior ability of PEG to maintain cell patterns for the period investigated.

In this study, we combined three different approaches: microfluidic patterning for spatial control, collagen matrix materials for chemical/ material control, and PEG in order to improve the pattern integrity. This model may also be useful for providing quantitative measurements of cell−matrix interactions, and eventually generating tissue-like structures in vitro. Our previous studies indicated that the modified collagen

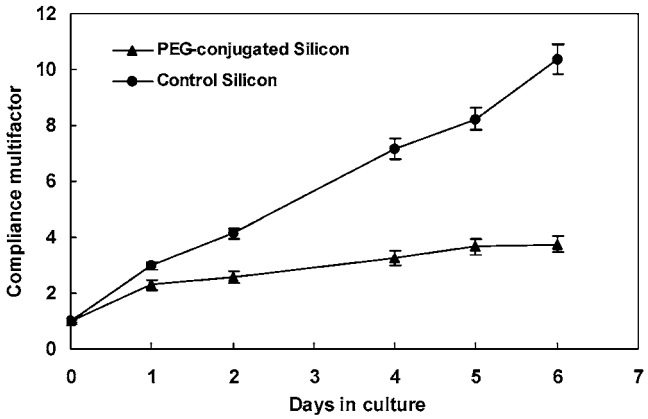

Figure 4. Compliance multifactor of HUVEC on control silicon and PEG-conjugated silicon wafers.

(collagen−chitosan or collagen−chitosan−fibronectin) matrices maintain cell pattern integrity better than the collagen-only matrix (*4*). Our future studies would, therefore, be directed toward combining modified collagen matrices with PEG-conjugated substrates to achieve compliance multifactor values (∼1) suitable for long-term culture.

Human Serum Albumin Bearing Covalently Attached Iron(II) Porphyrins as O_2-Coordination Sites

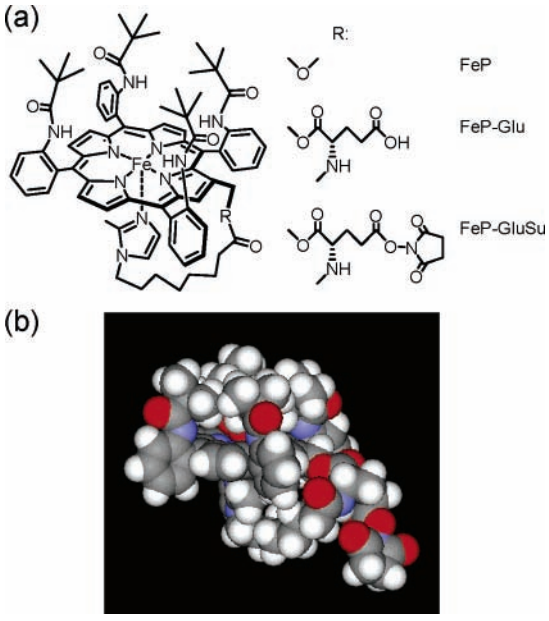
Rong-Min Wang,[†,‡] Teruyuki Komatsu,[†] Akito Nakagawa,[†] and Eishun Tsuchida*[,†]

Advanced Research Institute for Science and Engineering, Waseda University, 3-4-1 Okubo, Shinjuku-ku, Tokyo 169-8555, Japan, and Institute of Polymer, Northwest Normal University, Lanzhou 730070, China . Received June 17, 2004; Revised Manuscript Received September 25, 2004

Tetrakis{(α,α,α,α-*o*-pivalamido)phenyl}porphinatoiron(II) with a bifunctional tail possessing an axially coordinated imidazolyl group and a protein attachable succinimidyl(glutamyl) group (FeP-GluSu) has been synthesized. It can efficiently react with the lysine residues of recombinant human serum albumin (rHSA), giving a new albumin−heme conjugate [rHSA(FeP-Glu)]. MALDI-TOFMS showed a distinct molecular ion peak at *m/z* 70 643, which indicates that three FeP-Glu molecules were covalently linked to the rHSA scaffold. The binding number of FeP-Glu is approximately three (mol/mol) and independent of the mixing ratio. The CD spectrum and Native PAGE revealed that the albumin structure remained unaltered after the covalent bonding of the hemes. This rHSA(FeP-Glu) conjugate can bind and release O_2 reversibly under physiological conditions (pH 7.3, 37 °C) in the same manner as hemoglobin and myoglobin. The O_2-adduct complex had a remarkably long lifetime ($\tau_{1/2}$: 5 h). The O_2-binding affinity [$P_{1/2}^{O_2}$: 27 Torr] was identical to that of human red cells. Laser flash photolysis experiments gave the O_2- and CO-association rate constants and suggested that there are two different geometries of the imidazole binding to the central ion.

Human serum albumin (HSA), which is the major plasma protein component in our bloodstream, has no prosthetic group; however it nonspecifically captures many endogenous and exogenous compounds by weak interactions, *e.g.,* H-bond, ionic attraction, and hydrophobic interaction, namely noncovalent bonds (*1*−*3*). Synthetic heme, 2-[{8-*N*-(2-methylimidazolyl)octanoyl}-oxy]methyl-5,10,15,20-tetrakis{(α,α,α,α-*o*-pivalamido)-phenyl}porphinatoiron(II) (FeP, Chart 1 a) is also incorporated into recombinant HSA (rHSA), and the obtained albumin−heme (rHSA-FeP) hybrid can reversibly coordinate O_2 under physiological conditions (pH 7.3, 37 °C) (*4*). This O_2-carrying plasma hemoprotein could be of medical importance as a blood replacement composition (*4e*−*g*). Nevertheless, the major driving force of the heme-binding to albumin is a hydrophobic interaction; therefore, its binding constants (10^4−10^6 M^{-1}) are not high enough to maintain the heme concentration in the circulatory system for a long period (*4a*). The administration of the albumin−heme hybrid solution into rats demonstrated that the lifetimes of the heme was less than 6 h (*4e, 5*). To immobilize the heme group to the albumin scaffold more tightly and retain its O_2-transport efficacy, we have combined the O_2-coordination site FeP to the rHSA structure through a covalent bond. In this communication, we report, for the first time, the synthesis of a novel FeP analogue with a bifunctional branched-tail including an axially coordinated imidazolyl group and a protein-attachable succinimidyl(glutamyl) group (FeP-GluSu, Chart 1 a), and the properties of the rHSA conjugate bearing covalently linked FeP-Glu as a new O_2-carrying hemoprotein.

Chart 1. (a) 5,10,15,20-Tetrakis{(α,α,α,α-*o*-pivalamido)-phenyl}porphinatoiron Derivatives with a Bifunctional Tail Group. (b) Space-Filling Representation of the Oxygenated FeP-GluSu by Insight II (see ref 11)



As a functional side-chain of FeP, which directly makes a covalent bond to rHSA, we selected the succinimidyl group, because it selectively reacts with the NH_2 group of lysine in the range of pH 6.3−8.6 with high yield. The branched tail that includes the imidazolyl and succnimidyl groups via a glutamate junction was introduced into the parent porphyrin **1** (*6*) as shown in Scheme 1 (*7*).

First, Fmoc-L-Glu(g-*tert*-butyl ester) was bound to the OH group at the β-pyrrolic position of the porphyrin **1** by DCC. After removal of the Fmoc protecting group with piperidine, 8-*N*-(2-methylimidazolyl)octanoic acid was reacted with the obtained compound **3** in CH_2Cl_2, giving the imidazolyl-tailed porphyrin (**4**). The *tert*-butyl group was then removed by TFA, and the central iron insertion was carried out by the general $FeBr_2$ method to afford the iron-porphryin FeP-Glu. Finally, the reaction of *N*-hydroxysuccinimide with DCC gave the FeP-GluSu. All reactions can be performed at room temperature with high yields. The analytical data of all compounds described above were satisfactory obtained (*7*).

The FeP-Glu was converted to the ferrous complex by reduction in a heterogeneous two-phase system (toluene/aqueous $Na_2S_2O_4$) under an N_2 atmosphere (*6, 8*). The UV−vis absorption spectrum of the orange solution showed five-*N*-coordinated Fe(II) species (λ_{max}: 440, 531, 563 nm) via intramolecular imidazole binding (*6, 8, 9*). Upon exposure to CO, its UV−vis absorption immediately moved to that of the CO adduct complex. On the other hand, the dioxygenation was unstable at 25 °C, which is likely due to the presence of the neighboring glutamic acid proton.

The EtOH solution of the carbonyl FeP-GluSu (2 mL) was then injected into the phosphate-buffered solution of rHSA (8 mL, pH 7.3) (molar ratio 4/1), and the mixture was gently stirred for 1 h at room temperature. The solution was dialyzed against phosphate buffer (pH 7.3) to remove EtOH. The MALDI-TOFMS demonstrated a single molecular ion peak at *m/z* 70 643 (Figure 1). Attempts to measure the molecular weight of the rHSA-FeP hybrid, in which the FePs are noncovalently accommodated, failed using MALDI- and ESI-TOFMS; the molecular ion peak of rHSA (65 500) was only observable because the FePs are dissociated from the albumin during the ionization process (*10*). Therefore, we can conclude that the FeP-Glu is conjugated with rHSA

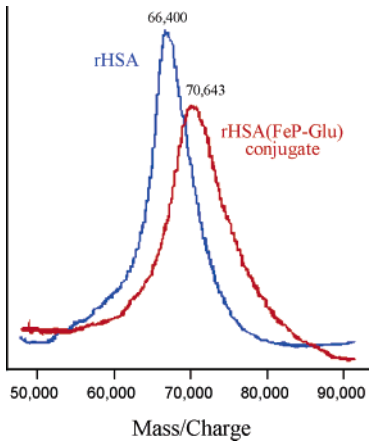

Figure 1. MALDI-TOFMS of the rHSA(FeP-Glu) conjugate. Matrix: 2,5-dihydroxybenzoic acid.

through amide bond formation. The average number of FeP-Glu in an rHSA was estimated to be 2.9−3.5, and this number is not dependent on the mixing molar ratio of FeP-GluSu/rHSA that ranged from 4 to 10. There are a total of 59 NH_2 groups in the rHSA structure, but only three of them are presumably active for the FeP-GluSu binding.

The conjugation of FeP-GluSu did not induce any change in the circular dichroism spectrum of rHSA in the 200−250 nm region. The Native PAGE of rHSA(FeP-Glu) also showed a single band with same migration distance of rHSA. Both results suggested that the secondary structure, molecular shape, and surface charge of albumin remained unaltered after the covalent binding of the hemes.

The UV−vis absorption spectrum of the rHSA(FeP-Glu) conjugate under an N_2 atmosphere showed a typical five-*N*-coordinated complex as seen in the toluene solution of FeP-Glu (Figure 2) (*4a,b, 6, 8, 9*). Upon exposure

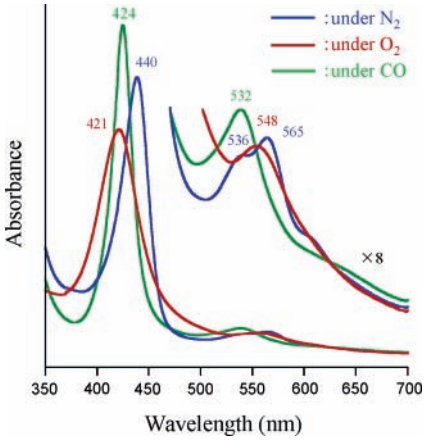

Figure 2. UV−vis absorption spectral changes of the rHSA-(FeP-Glu) conjugate in phosphate-buffered solution (pH 7.3) at 25 °C.

of this solution to O_2, the spectrum changed to that of the O_2-adduct complex under physiological conditions (pH 7.3, 37 °C) (*4a*−*c*). This dioxygenation was reversibly observed to be dependent on the O_2 partial pressure in the same manner as hemoglobin (Hb) and myoglobin. The half-lifetime of the O_2 adduct (ca. 5 h at 37 °C) was significantly longer than that of the noncovalent rHSA-FeP hybrid ($\tau_{1/2}$: 2 h) (*4d*). The covalent linkages of FeP-Glu to the protein scaffold obviously retarded the oxidation process of the central ferrous ion. Molecular simulation of the structure of FeP-GluSu revealed that the geometry of the imidazole ring against the porphyrin platform was perpendicular, which suggests that the spacer moiety between the imidazole and the porphyrin periphery does not produce an unfavorable distortion of the axial coordination and will not influence the O_2-binding behavior (see Chart 1b) (*11*).

The O_2-binding affinity [$P_{1/2}{}^{O_2}$] of the rHSA(FeP-Glu) conjugate was determined to be 27 Torr at 37 °C (*3b,c, 6, 7, 9, 10*), which is almost the same as that of the rHSA-FeP hybrid [$P_{1/2}{}^{O_2}$: 33 Torr] (*3b*−*d*) and identical to that of human red cells (*12*). The laser flash photolysis experiments provided the association rate constants of the O_2- and CO-bindings ($k_{on}{}^{O_2}$, $k_{on}{}^{CO}$) (*6, 8, 9a*). The absorption decays accompanying the O_2- and CO-recombination to the noncovalent rHSA-FeP hybrid were composed of two phases of the first-order kinetics, and the curves were fit by a double-exponential equation to determine k_{on} (fast) and k_{on} (slow) (Table 1) (*4c*). We supposed that the O_2- and CO-association to the FeP in the hydrophobic domains of the albumin was influenced by the molecular microenvironments around each O_2-coordination site, e.g., steric hindrance of the amino acid residue and difference in polarity (*4b*−*d*). The time dependence of the absorption change in the CO recombination to the rHSA(FeP-Glu) conjugate also showed double-exponential profile, but the rebinding process of O_2 obeyed monophasic decay. On the basis of studies on synthetic model hemes, it has been known that the proximal-side effect is the only primary factor which influences the association rate for CO but not for O_2 (*8, 9a*). We assume that there are two different geometries of the imidazole coordination and that each one shows the individual kinetics of the CO association. The covalent linkages between the axially coordinated imidazolyl side-chain and the albumin structure may provide an additional strain of the Fe−N(imidazole) bond and gives two conformations of the proximal-base binding. Since the $k_{on}{}^{O_2}$ value of rHSA(FeP-Glu) was nearly the same as the $k_{on}{}^{O_2}$ (fast) of the rHSA-FeP hybrid (Table 1), the FeP-Glu molecules are likely to locate on the surface of rHSA.

In conclusion, reaction of the newly synthesized tetrakis{(α,α,α,α-*o*-pivalamido)phenyl}porphinatoiron(II) with a proximal base and succinimidyl(glutamyl) group to rHSA produced a novel albumin conjugate bearing covalently attached heme groups as O_2-coordination sites. The molecular weight of rHSA(FeP-Glu) was directly measured by MALDI-TOF MS. In nature, one can find unique heme-linked proteins, e.g., cyctochrome *c*. The rHSA(FeP-Glu) conjugate presumably becomes a valuable model of these hemoproteins. The obtained rHSA-(FeP-Glu) can reversibly absorb O_2 under physiological conditions, and its O_2-binding affinity showed an identical value to that for human erythrocytes. These results suggest that this novel plasma protein may efficiently transport O_2 in the bloodstream as an O_2-carrier with a long circulation time.

It is well documented that guanidine nucleotide-coupled dopamine subtype 2 receptors (D_2) are configured in high and low affinity states for the dopamine agonist in vitro. However, it is still unclear whether these functional states exist in vivo. We hypothesized that positron-labeled D_2 agonist and Positron Emission Tomography can be used to probe these functional states noninvasively. Recently, we demonstrated in nonhuman primates that *N*-[^{11}C]propyl-norapomorphine (NPA), a full D_2 agonist, is a suitable tracer for imaging the high affinity states of D_2 receptors in vivo. We also developed kinetic modeling method to derive receptor parameters, such as binding potential (BP) and specific uptake ratios (V_3''). When coupled with a dopamine releasing drug, amphetamine, NPA was found to be more sensitive than antagonist tracers, such as [^{11}C]raclopride (RAC), to endogenous dopamine concentration changes (by about 42%). This finding suggests that NPA is a superior tracer for reporting endogenous DA concentration. In addition, the difference of the BP or V_3'' of NPA and RAC under control and amphetamine challenge conditions could be used to estimate the functional states of D_2 receptors in vivo. On the basis of our findings and the assumptions that NPA binds only to the high affinity states and RAC binds equally to both affinity states, we proposed that about 70% of the D_2 receptors are configured in the high affinity states in vivo.

INTRODUCTION

The hyperdopaminergic hypothesis of schizophrenia is well supported by compelling evidence such as that all antipsychotics are potent dopamine D_2 receptor antagonists and that hyperdopaminergic activities of schizophrenic patients are detectable by neuroimaging techniques. However, the functional states of the D_2 receptors in this disease are still unknown.

Like other guanine nucleotide protein (G-protein)-coupled receptors, D_2 receptors are configured into G-protein-coupled (GR) and -uncoupled (R) states, as proposed in the ternary complex model (*1*, *2*). In this model, dopamine (DA) or other D_2 agonists bind with high affinity to GR ($D_{2\ high}$) and low affinity to the low affinity states ($D_{2\ low}$). However, a D_2 antagonist will bind with equal potency to the high and the low affinity states. Therefore, an agonist tracer is needed to probe the $D_{2\ high}$ receptors in vivo. In addition, since DA binds with high affinity to the $D_{2\ high}$, an agonist tracer will be more sensitive to endogenous DA concentration changes, and hence it will be a superior tracer for reporting endogenous DA concentrations.

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) have been used successfully to study the competition between endogenous DA and radiotracers (*3*). These neuroimaging techniques involved a baseline scan followed by a drug challenge scan. The baseline uptake of the tracer (such as [^{123}I]IBZM or RAC) is first determined. Then, a DA enhancing drug, such as amphetamie (AMPH), is given. The drug leads to massive increases of DA in the synapse that compete with tracer binding and result in the decrease of tracer uptake. The difference of tracer bindings between these two scans becomes an index of synaptic dopamine concentrations.

The endogenous concentrations of DA at baseline and after AMPH challenge can be measured using microdialysis technique. A linear relationship exists between the changes of tracer binding (detected by IBZM SPECT or RAC PET scans) and the DA concentration (measured by microdialysis) (Figure 1) (*4*, *5*). With increasing doses of AMPH (0.3, 0.5, and 1 mg/kg), a 7-, 10-, and 15-fold increase in endogenous DA concentration and 20%, 30%, and 40% decrease of tracer bindings, respectively, were observed. The linear relationship of the AMPH dose response curve demonstrated that the decrease of tracer uptake is an index of endogenous DA concentration. It also revealed that a 40% increase in DA concentration only resulted in 1% decrease of [^{123}I]IBZM, and a 44% increase in DA concentration resulted in 1% decrease of RAC binding. The low sensitivity of antagonist to dopamine competition is observed. Examining the RAC PET images in Figure 1, one can easily appreciate the small 10% difference between the control (top image) and the AMPH (0.3 mg/kg, bottom).

Importantly, the AMPH challenge image paradigm has revealed that the decrease in tracer binding under the AMPH condition is more in the schizophrenic patients (−15%) than in the normal controls (−9%). This observation offered a direct evidence of hyperdopaminergic activity in schizophrenia. The role of noninvasive brain imaging technique in understanding the pathophysiology of schizophrenia has recently been reviewed (*6*).

Unfortunately, this image paradigm revealed a ceiling effect of 40% decrease of tracer binding by DA enhancing drugs (*3*). This is based on the results from eight nonhuman primates (five with RAC and three with IBZM) and 11 human studies (six RAC and five IBZM). In these studies, the decrease of tracer binding potential (which is the ratio of striatal uptake to tracers activity in the blood) ranged from 10% to 40% with doses of AMPH ranged from 0.2 to 1 mg for nonhuman primates and 0.2−0.5 mg for humans. One possible explanation of the ceiling effect is that antagonist tracers (such as IBZM and RAC) bind with equal affinity to both high and low affinity states. However, only the bindings to the high affinity states are vulnerable to endogenous DA challenge. The 40% ceiling effect suggested that 40% of the D_2 receptors are configured in the high affinity state. However, the best way to confirm the high and low affinity function states of D_2 receptors is to use agonist tracer.

Because DA agonist binds with high affinity to the high affinity states, it is expected that an agonist tracer will be more sensitive to endogenous DA concentration changes than that of an antagonist tracer. Therefore, an agonist tracer will be a superior probe for reporting endogenous DA concentration.

Since the early 1990s, two classes of D_2 agonists, apomorphine and aminotralin derivatives, have been evaluated as potential agonist PET tracers (Figures 2 and 3). In the aminotralin series, both 5- and 7-hydroxy-aminotetralin derivatives have been prepared and evaluated. In 1993, Zijlstra et al. reported two fluoropropyl derivatives of 5-hydroxy-2-aminotetralin, compounds **1** and **2** in Figure 2 (*7*). However, both tracers showed no selective bindings in vivo. In 1994, Halldin et al. evaluated [^{11}C]-7-hydroxy-2-*N*,*N*-dipropylaminotetralin (7-OH-DPAT, **7**, prepared by N-alkylation with [^{11}C]propyl iodide) as a potential ligand for D_3 receptor, and a striatum (target tissue) to cerebellum (reference tissue) ratio of 2.2 in monkey brain was reported (*8*). However, since the initial report, no detailed studies of 7-OH-DPAT were reported. Similarly, Brown et al. reported the preparation of [^{11}C]PHNO, **8**, via the formation of [^{11}C]-propionic amide followed by reduction, but in vivo evaluation of the tracer was never reported (*9*). More recently, Shi et al. reported that several 5-hydroxy-2-aminotetralin derivatives (both C-11 and F-18 labeled tracers, compounds **3** to **6** in Figure 2) have high affinity for the D_2 receptors (*10*−*13*). The agonist properties of these tracers were demonstrated by in vitro autoradiography using rat brain slices. When tissues were incubated in the presence of nonhydrolyzable guanine nucleotide, GppNHp, which converts the high to the low affinity states, tracer uptakes are completely blocked. Monkey PET studies of tracers **3** to **6** revealed a striatum/cerebellum ratios of about 2. Detailed evaluation of these tracers (particularly the optically active tracers) has not been reported.

For the apomorphine series (Figure 3), Zijlstra et al. evaluated both [^{11}C]apomorphine, **9**, and [^{18}F]fluoropropylnorapomorphine, **10**, in rodents (*14*, *15*). [^{11}C]Apo-

morphine had a striatum/cerebellum ratio of about 1.5, but the fluoro derivative did not show any specific uptake. Because of the low selective uptake, these tracers were not further evaluated. Halldin et al. reported two [^{11}C]-labeled *N*-propyl-nor-apomorphine (NPA) derivatives, 2-hydoxy-[^{11}C-propyl]NPA, **11**, and 2-O-[^{11}C]methoxy-NPA, **12**. Initial primate studies showed that comppound **11** (prepared by reacting the norpropyl precursor with [^{11}C]propyl iodide) had low brain uptake (*16*). On the other hand, 2-[^{11}C]methoxy-NPA, prepared by reacting 2-hydroxy-NPA with [^{11}C]methyl iodide, showed a moderate striatum/cerebellum ratio of 2 in monkey. Unfortunately, this tracer was not further characterized.

Interestingly, one of the best characterized D_2 agonist, *N*-propyl-norapomorphine (NPA), has not been the focus of PET tracer development. NPA is a full D_2 agonist with K_i values of 0.4 nM and 23 nM for the $D_{2\ high}$ and $D_{2\ low}$, respectively (*17*, *18*). It also has high affinity for another D_2 family receptors, the D_3 subtype ($K_i = 0.3$ nM). It has good D_2 selectivity over other receptors (K_i for D_1, 340 nM; α_2, 480 nM; all other receptors, >1 μM). More importantly it has been used in humans for treating Parkinson's disease. In addition, norapomorphine, the starting material for the radiolabeling of NPA, is commercially available. This greatly facilitated our preparation and evaluation of [^{11}C]-labeled NPA.

This article will focus on the use of [^{11}C]-labeled NPA for in vivo imaging of the high affinity states of D2 receptors. The sensitivities of an agonist verse an antagonist PET tracer to endogenous dopamine concentration changes will be presented.

EXPERIMENTAL PROCEDURES

Radiochemistry. [^{11}C]NPA was prepared according to our published procedure (*19*). Briefly, a two-step labeling procedure, N-propionylation of norapomorphine followed by LAH reduction, was used for the preparation of [^{11}C]NPA (*19*). This procedure yielded high specific activity (>1.5 mCi/nmol) and radiochemical purity (>95%) of NPA. [^{11}C]Raclopride was prepared from desmethyl raclopride and [^{11}C]methyl triflate with similar specific activity and radiochemical purity.

Baboon PET Imaging. Detailed procedures can be found in two published articles (*20*, *21*). Briefly, the baboon was anesthetized with isoflurane and body temperature maintained by a water blanket. After tracer injection, 120-min dynamic PET scans were started. For amphetamine challenge studies, amphetamine was given 5 min prior to tracer injection. Arterial blood samples were taken at different interval to get input function and to do metabolite analysis. Plasma free fraction was measured using ultrafiltration technique.

PET Image Analysis. Detailed description can be found in our published article (*21*). Briefly, the outcome measures are the tissue distribution volume (V_T), binding potentials (BP), and selective uptake ratios (V_3''). These terms are defined as follows:

$$V_T = C_{tissue}/C_{blood} \quad (1)$$

$$BP_{tissue} = V_{T\ tissue} - V_{T\ reference\ region} = \text{bound/free} = f_1 B_{max}/K_D \quad (2)$$

$$V_3'' = BP_{tissue}/V_{T\ reference\ region} \quad (3)$$

where C_{tissue} is the radioactivity in the tissue detected by PET scan, C_{blood} is the amount of the parent tracer in the plasma (determined by measuring the radioactivity in the plasma at different time point and corrected for the metabolites), B_{max} is the total receptor density, K_D is the tracer's affinity for D_2 receptors, and f_1 is the plasma free fraction of the tracer.

The effect of AMPH on tissue's selective uptake is calculated as the difference of the BP or V_3'' of the pre- and post-AMPH scans divided by the BP or V_3'' of the pre-AMPH scan as defined in eqs 4 and 5:

$$\Delta BP = (BP_{pre} - BP_{post})/BP_{pre} \quad (4)$$

$$\Delta V_3'' = (V_3''_{pre} - V_3''_{post})/V_3''_{pre} \quad (5)$$

Table 1. Reproducibility of $\Delta V_3''$ and ΔBP Following Amphetamine (0.5 mg/kg) in the Same Baboon

tracer	condition	$\Delta V_3''$, %	ΔBP, %
[^{11}C]raclopride	test	−26	−26
	retest	−25	−21
[^{11}C]NPA	test	−48	−41
	retest	−46	−52

RESULTS AND DISCUSSION

For the radiosynthesis of NPA, a two-step labeling procedure, N-propionylation of norapomorphine followed by LAH reduction, was developed (*19*). This procedure yielded high SA (>1.5 mCi/nmol) and radiochemical purity (>95%) of NPA. Biodistribution in rats showed a striatum/cerebellum ratio of 4.4 at 60 min post tracer injection.

Baboon PET scans showed moderate striatal uptakes and the striatum/cerebellum ratio reached 2.8 at 45 min post tracer injection, which is higher than any D_2 agonist PET tracer reported to date. More importantly, the uptake was blocked by haldol at an iv dose of 0.2 mg/kg. These results strongly suggest that NPA is a selective D_2 receptor PET ligand.

Recently, we demonstrated that a one-tissue-compartment kinetic modeling method with metabolite corrected arterial input function is suitable for deriving receptor parameters, such as the tissue distribution volume (V_T), binding potentials (BP) and selective uptake ratios (V_3'') (*20*).

Table 1 shows the $\Delta V_3''$ of RAC and NPA in the same baboon using a dose of 0.5 mg/kg AMPH. A decrease of 26% and 48% was observed for RAC and NPA, respectively (*21*). The reliability of this outcome measure under test and retest conditions is excellent. The $\Delta V_3''$ value is more consistent than the ΔBP value. The voxelwise V_3'' maps of RAC and NPA under control and AMPH conditions in the same baboon are shown in Figure 4. The large effect of amphetamine on NPA V_3'' is evident.

More detailed studies were then conducted in three additional baboons (*21*). Each baboon received both RAC and NPA and studied under control and AMPH treated conditions (3 doses: 0.3, 0.5, and 1 mg/kg). A total of 36 scans were performed. For these scans, there were no significant difference in injected dose, mass (both control and AMPH conditions), free fractions, clearance rate, and the reference tissue distribution volume ($V_{T\ CER}$). However, the $V_{T\ CER}$ did drop under AMPH conditions, which only results in underestimates of the true effect.

The AMPH dose effects on the $\Delta V_3''$ of RAC and NPA are shown in Figure 5. Under all doses examined, NPA consistently shows higher decreases of selective uptakes and the difference are significant in all doses examined. If we compare the AMPH effect on NPA (triangle) and antagonist tracers (RAC circle and IBZM square), one can clearly see that a ceiling effect (60%) is observed with NPA (Figure 6). Assuming that NPA binds only to the

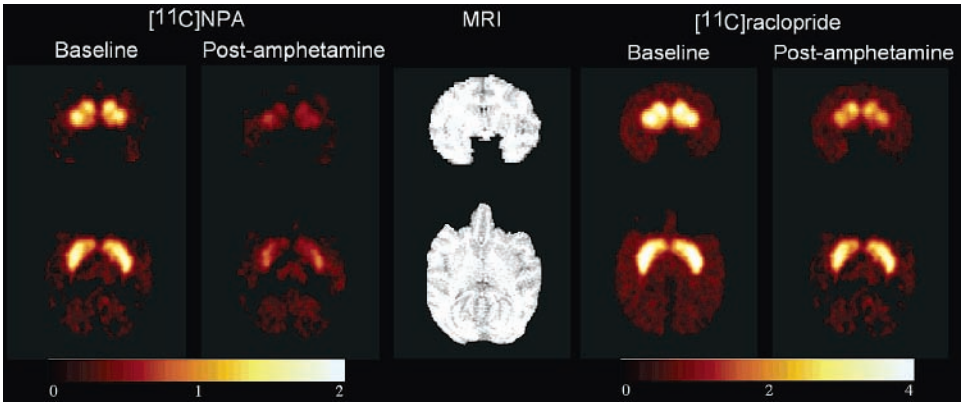

Figure 4. Voxelwise V_3'' maps of [^{11}C]NPA and [^{11}C]raclopride in the same baboon under control and post amphetamine (0.5 mg/kg) challenge conditions. The left panel is the [^{11}C]NPA V_3'' maps under baseline (left) and post amphetamine challenge (right). The middle panel is the MRI images of the baboon brain correspond to those of the PET images. The right panel is the [^{11}C]raclopride V_3'' maps under baseline (left) and post amphetamine challenge (right). In this paired study the displacement ($\Delta V_3''$) for [^{11}C] NPA and [^{11}C]raclopride are − 48% and − 26%, respectively.

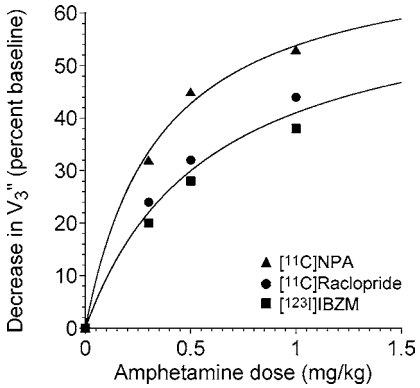

Figure 5. Effect of amphetamine on V_3'' of [^{11}C]NPA (solid triangle), [^{11}C]raclopride (solid circle), and [^{123}I]IBZM (solid square). The *X*-axis is the dose of amphetamine (mg/kg), and the *Y*-axis is the percent change of V_3'' ($\Delta V_3''$). The figure illustrates that the effect of amphetamine on agonist tracer ([^{11}C]NPA, K_{high} = 0.2 nM) is larger than antagonist tracers ([^{11}C]raclopride, K_D = 1.2 nM; and [^{123}I]IBZM, K_D = 0.4 nM). Its effect on antagonists is similar. These results imply that the agonist tracer is more sensitive to endogenous dopamine concentration changes than antagonist tracer.

$D_{2\ high}$, the percent of high affinity states (ratio of R_{high} to B_{max}) can be calculated from the ratios of ΔBP_{RAC} and ΔBP_{NPA} according to the following equation:

$$R_{high}/B_{max} = [\Delta BP_{RAC}/\Delta BP_{NPA}]\,(1 - \alpha) + \alpha \quad (6)$$

where α is the percent of receptor occupied by DA. Detailed derivation of the equations can be found in our recent paper (*21*).

Since only 60% of the NPA binding ($D_{2\ high}$) was displaceable by endogenous DA, this portion of $D_{2\ high}$ is defined as R_{HS} (synaptic high affinity states) and the rest of $D_{2\ high}$ as R_{HNS} (nonsynaptic high affinity states). This means that R_{HS} equals 60% of $D_{2\ high}$ that are not occupied by DA.

Our results showed a $\Delta BP_{RAC}/\Delta BP_{NPA}$ ratio of 0.7 (*21*). If we assume α equals 10% (i.e. 10% of the $D_{2\ high}$ is already occupied by DA), a R_{high}/B_{max} ratio of 0.73 was obtained from eq 6. It suggested that 73% of the D_2 receptors are configured in the high affinity state (i.e. $D_{2\ high}/B_{max}$ = 73%). Since we assume that 10% of the $D_{2\ high}$ are occupied by DA and we observed a maximum of 60% of NPA binding that can be displaced by endogenous DA, the percent of R_{HS} and R_{HNS} are calculated to be 38% (i.e. 0.6 × (0.73 − 0.1)) and 25%, respectively.

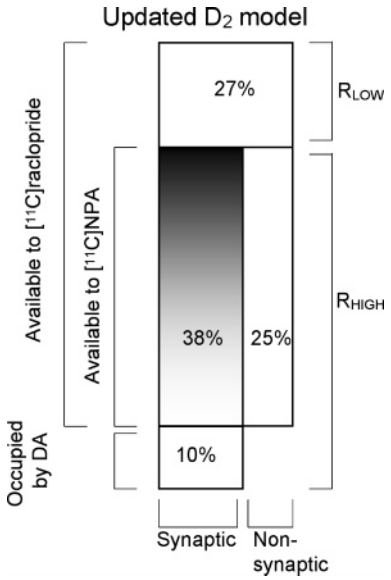

Figure 6. Revised model of D_2 receptors. The extended model (panel B) is derived from our present result. The new model divides the receptors into $D_{2\ high}$ and $D_{2\ low}$. An 10% of the $D_{2\ high}$ are assumed to be occupied by dopamine at baseline. Our result suggests that 40% of $D_{2\ high}$ are protected from dopamine challenge. Therefore, the $D_{2\ high}$ was further divided into synaptic and nonsynaptic compartments. Since we observed a 70% difference between the effect of amphetamine on [^{11}C]NPA and [^{11}C]raclopride, this suggests that 73% of the receptors are the $D_{2\ high}$. Thus we calculated the following proportion of receptors for the extended model: 10% occupied by dopamine at baseline, 38% of the R_{high} are vulnerable to dopamine challenge (synaptic $D_{2\ high}$), 25% of the R_{high} are protected from dopamine occupancy (nonsynaptic $D_{2\ high}$), and 27% are R_{low}.

On the basis of these results, we modified the original D_2 model, which suggests that only 50% of the D_2 receptors are configured in high affinity states, to the new model that 73% of the D_2 receptors are configured in the high affinity states ($D_{2\ high}$). We also proposed that, among the 73% of $D_{2\ high}$, 10% is already occupied by DA at baseline, 38% is the synaptic high affinity state that is vulnerable to AMPH challenge, and 25% is the nonsynaptic high affinity state that is not vulnerable to challenge.

Recently, we performed in vivo saturation binding studies in baboon with both NPA and RAC (unpublished results). From these experiments we obtained the in vivo K_D of 1.44 nM for RAC and 0.15 nM for NPA. The B_{max} obtained with RAC and NPA are 26 and 20 nM, respec-

tively. From these numbers, the percent of $D_{2\ high}$ is calculated to be 79%, which is remarkably close to the number we derived from the combined RAC and NPA studies.

In conclusion, we found that in vivo binding of NPA is more vulnerable to competition by endogenous DA than that of RAC (by 42%). NPA appears to be a superior probe to report on endogenous DA fluctuations. We also found that about 60% of the NPA bindings are vulnerable to endogenous competition (versus 44% for RAC), which agrees with previous findings in mice using [^{3}H]NPA (*22*). Assuming that, at tracer dose, NPA binds only to $D_{2\ high}$, our results implied that about 70% of D_2 receptors are $D_{2\ high}$. Recent saturation studies confirmed that NPA B_{max} (= R_{high}) is 70% of RAC B_{max}.

There is no doubt that neuroimaging techniques such as PET and SPECT are powerful tools to explore biochemistry in vivo. This technique depends on the successful development of appropriate tracers. It is obvious that chemists play a vital role in this field. Equally important is to establish collaborations among different disciplines that widen the scope of the application.

Received August 12, 2004; Revised Manuscript Received October 21, 2004

A clinically relevant photosensitizer, 3-devinyl-3-(1-hexyloxyethyl)pyropheophorbide-a (HPPH, a chlorophyll-a derivative), was conjugated with Gd(III)-aminobenzyl-diethylenetriaminepentaacetic acid (DTPA), an experimental magnetic resonance (MR) imaging agent. In vivo reflectance spectroscopy confirmed tumor uptake of HPPH−aminobenzyl-Gd(III)-DTPA conjugate was higher than free HPPH administered intraveneously (iv) to C_3H mice with subcutaneously (sc) implanted radiation-induced fibrosarcoma (RIF) tumor cells. In other experiments, Sprague−Dawley (SD) rats with sc implanted Ward Colon Carcinoma cells yielded markedly increased MR signal intensities from tumor regions-of-interest (ROIs) 24 h post-iv injection of HPPH−aminobenzyl-Gd(III)-DTPA conjugate as compared to unconjugated HPPH. In both in vitro (RIF tumor cells) and in vivo (mice bearing RIF tumors and rats bearing Ward Colon tumors) the conjugate produced significant increases in tumor conspicuity at 1.5 T and retained therapeutic efficacy following PDT. Also synthesized were a series of novel bifunctional agents containing two Gd(III) atoms per HPPH molecule that remained tumor-avid and PDT-active and yielded improved MR tumor conspicuity compared to their corresponding mono-Gd-(III) analogues. Administered iv at a MR imaging dose of 10 μmol/kg, these conjugates produced severe skin phototoxicity. However, by replacing the hexyl group of the pyropheophorbide-a with a tri(ethylene glycol) monomethyl ether (PEG-methyl ether), these conjugates produced remarkable MR tumor enhancement at 8 h post-iv injection, significant tumoricidal activity (80% of mice were tumor-free on day 90), and reduced skin phototoxicity compared to their corresponding hexyl ether analogues. The poor water-solubility characteristic of these conjugates was resolved by incorporation into a liposomal formulation. This paper presents the synthesis of tumor-avid contrast enhancing agents for MR imaging and thus represents an important milestone toward improving cancer diagnosis and tumor characterization. More importantly, this paper describes a new family of bifunctional agents that combine two modalities into a single cost-effective "see and treat" approach, namely, a single agent that can be used for contrast agent-enhanced MR imaging followed by targeted photodynamic therapy.

INTRODUCTION

For many years, in vivo imaging of human organs was largely dependent upon intravenous administration of radioactive molecules for nuclear scanning or nonradioactive iodinated chemicals for radiography (*1*−*4*). However, over the past decade, magnetic resonance (MR) imaging has become the method-of-choice for many procedures (*4*). Unlike nuclear scanning, conventional radiography or computed tomography, MR often relies on "contrast-enhancing agents" to improve inherent contrast between normal and diseased tissue. MR signal intensity or signal intensity differences (contrast) is dependent upon longitudinal (1/*T*1) and transverse relaxation rates (1/*T*2) of tissue protons. Agents containing paramagnetic ions have been shown to effectively alter 1/*T*1 and/or 1/*T*2 by changing the local magnetic field when they come in close proximity to water protons. The paramagnetic ion most widely used in this regard is gadolinium [Gd(III)] because of its seven unpaired electrons and large paramagnetic moment. At present, three similar Gd(III)-derived MR contrast enhancing agents have been approved by the Food and Drug Administration (FDA) for clinical use in the United States, the bis-*N*-methylglucamine salt of Gd(III)-diethylenetriamine pentaacetic acid (DTPA) (Magnavist, Berlex Laboratories, Wayne, NJ), the bis-*N*-methylamide of Gd(III)-DTPA (Omniscan, Amersham Health, Princeton, NJ), and the Gd(III) chelate of the 20-(2-hydroxypropyl) derivative of 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-1,4,7-tetraacetic acid (Prohance, Bracco Diagnostics, Princeton, NJ). All three of these agents are carboxylate-containing,

water-soluble complexes. While several agents look promising, no macromolecular MR contrast-enhancing agent has been approved for human use. Conventional MR contrast media rely on tumor enhancement secondary to altered tumor capillary permeability. The time course of tumor enhancement with these agents, therefore, is to a great extent dependent upon intravascular contrast agent concentration. As an administered MR contrast-enhancing agent clears from the circulation, tumor conspicuity may appear to increase due to rising tumor-to-background ratio. Thereafter, tumor MR signal intensity declines as nonbound contrast media clears from a given lesion. Typical plasma clearance rates for FDA approved agents are on the order of 15 min or less, thereby limiting the usable time frame for MR data acquisition, which can take between 5 and 15 min per acquisition. Moreover, several additional disadvantages exist for current FDA-approved MR contrast media. Because current FDA approved MR agents do not preferentially bind specific molecular targets, they cannot reliably differentiate neoplasm from inflammation. Finally, because the tumor selectivity of current MR contrast-enhancing agents is singularly dependent upon perturbations in normal vascular permeability, small foci of metastatic tumor cells, particularly those in minimally enlarged or normal-sized lymph nodes, may not be detectable by current methods. However, by selective or nonselective binding of a MR contrast-enhancing agent to a tumor target or by simply slowing in vivo tumor clearance rates, several improvements might be realized. For example, additional data sets or repeat MR acquisitions might be obtained, thereby enabling screening of additional body regions or more detailed MR characterization of specific locations.

Previously, gadolinium-based porphyrin contrast media, particularly gadoporphyrin-2, have been extensively studied and found to be necrosis-avid (*5*, *6*). Although such compounds may be useful for tumor imaging (5−30% tumor mass is commonly necrotic), a MR agent that targets living tumor cells, particularly those that are actively undergoing metabolic processes, would be superior. For the last several years, our laboratory has focused our research efforts on developing various long wavelength-absorbing photosensitizers (660−800 nm) derived from chlorophyll-a and bacteriochlorophyll-a for photodynamic therapy (PDT) (*7*−*14*). Among these compounds, HPPH is currently at Phase II human clinical trials and others are at various stages of preclinical studies (*15*, *16*). Because HPPH demonstrated both tumor avidity and limited skin phototoxicity (a major drawback with most of the porphyrin-based compounds), we were interested in studying HPPH as a "vehicle" for delivering gadolinium complexes to tumors. Our goal was to develop a single bifunctional agent that could be clinically utilized both as a MR contrast-enhancing agent and a photosensitizer for PDT.

EXPERIMENTAL PROCEDURES

^{1}H and ^{13}C NMR spectra were recorded on Bruker AMX-400 Spectrometer at 400.1 and 100.6 MHz, respectively. Unless otherwise stated, chemical shifts are reported in ppm and referenced to residual solvent resonance peaks ($CDCl_3$: for ^{1}H, 7.26 ppm and ^{13}C, 77.2 ppm; methanol-d_4: for ^{1}H, 3.31 ppm). UV−vis spectra were recorded on a Varian (Cary-50 Bio) spectrophotometer. Column chromatographic separations were performed over silica gel 60 (70−230 mesh) or neutral alumina (Brockmann grade III, ∼150 mesh).

HPPH−DTPA-*tert*-butyl Ester (3). A mixture of HPPH **2** (91 mg, 0.143 mmol), **7** (167 mg, 0.215 mmol), *N*,*N*′-dicyclohexylcarbodiimide (DCC, 35 mg, 0.170 mmol), and (dimethylamino)-pyridine (DMAP, 21 mg, 0.172 mmol) in dry dichloromethane (5 mL) was stirred at room temperature under nitrogen for 16 h. Water (1 mL) was then added, and the mixture was stirred for 15 min. The organic layer was separated, dried with Na_2SO_4, filtered, and concentrated. The residue was dissolved in minimum amount of dichloromethane (∼2 mL) and refrigerated for 1 h. It was then filtered, and the solid (1, 3-dicyclohexylurea) was washed with dichloromethane. The filtrate was concentrated and purified with column chromatography over neutral alumina (Brockmann grade III, ∼150 mesh) eluting with hexanes−EtOAc (v/v 3/1) and then hexanes−EtOAc (v/v 5/2). The fractions containing the product **3** were combined and concentrated. The residue was purified by another column chromatography over neutral alumina (Brockmann grade III) eluting with CH_2Cl_2-EtOAc (v/v 8/1) and then $CH_3OH-CH_2Cl_2$ (3%) to provide the title compound **3** (167 mg, 0.120 mmol) as a dark blue oil in 84% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 410 (117540), 505 (10650), 536 (10740), 604 (8950), 660 (54460). ^{1}H NMR ($CDCl_3$) δ 9.81 (1H, splitting s, H-5), 9.00 (1H, splitting s, H-10), 8.53 (1H, s, H-20), 7.24 (1H, br, CONH), 7.17 (2H, m, H-2′ and 6′), 7.05 (2H, m, H-3′ and 5′), 5.93 [1H, m, CH_3(O-hexyl)*CH*-3], 5.22 (2H, dd, AB system, J = 20.0 Hz, $COCH_2$-15), 4.60 (1H, m, H-18), 4.42 (1H, m, H-17), 3.78−3.17 (20H, m, H-1″, CH_3-2, CH_3-7, CH_3CH_2-8 and 5 × NCH_2CO_2C), 3.09−2.90, 2.90−2.52, 2.50−2.28, 2.24−2.03 [total 19H, m, CH_3-12, HNCO-CH_2CH_2-17, H-7′, 8′, 9′, 10′, 11′, CH_3(O-hexyl)CH-3], 1.82 (3H, d, J = 7.4 Hz, CH_3-18), 1.78 (2H, m, H-2"), 1.59 (3H, m, CH_3-CH_2-8), 1.40, 1.39, 1.37 [45H, each s, 5×-$OCOC(CH_3)_3$], 1.40 (2H, m, overlapped with *tert*-butyls, H-3"), 1.25 (4H, m, H-4″ and H-5″), 0.80 (3H, m, H-6″), 0.46 (1H, br, NH), −1.59 (1H, s, NH). ^{13}C NMR ($CDCl_3$): δ 196.5, 172.2, 171.5, 170.9, 170.7, 160.4, 155.6, 151.0, 149.2, 145.3, 141.7, 141.6, 140.0, 137.7, 136.3, 136.0, 135.9, 132.6, 132.5, 130.2, 129.8, 128.0, 119.7, 106.2, 104.1, 98.3, 98.2, 92.8, 80.9, 80.7, 73.1, 69.9, 63.2, 56.3, 56.2, 53.8, 53.1, 52.7, 51.9, 50.3, 48.4, 36.8, 34.0, 32.0, 30.4, 28.4, 28.3, 26.3, 25.0, 24.9, 23.3, 22.8, 19.6, 17.5, 14.2, 14.1, 11.7, 11.5, 11.2. MS (FAB) *m*/*z* 1397.9 (MH^+, 100). HRMS (FAB): Calcd for $C_{80}H_{117}N_8O_{13}$ (MH^+) 1397.8739; Found 1397.8750.

HPPH−DTPA (4). **3** (130 mg) was dissolved in trifluoroacetic acid (TFA, 3 mL). The solution was stirred at room temperature for 3 h. TFA was removed with under high vacuum at room temperature. The residue was dissolved in toluene (10 mL), and then the solvent was removed with rotavapor. The process was repeated three times to give **4** as dark blue powder. ^{1}H NMR (50% $CDCl_3$, 50% CD_3OD and one drop of C_5D_5N) δ 9.77 (1H, splitting s, H-5), 9.46 (1H, s, H-10), 8.60 (1H, s, H-20), 7.31 (2H, m, H-2′ and 6′), 7.01 (2H, m, H-3′ and 5′), 5.92 [1H, m, CH_3(O-hexyl)*CH*-3], 5.20 (2H, dd, AB system, J = 19.6 Hz, $COCH_2$-15), 4.62 (1H, m, H-18), 4.34 (1H, m, H-17), 3.81−2.23 (36H, m, H-1", CH_3-2, CH_3-7, CH_3-12, CH_3CH_2-8, HNCOCH_2CH_2-17, H-7′, 8′, 9′, 10′, 11′ and 5×-NCH_2CO_2C. Note: CH_3-2, CH_3-7, and CH_3-12 appeared at 3.37, 3.26, and 3.58, respectively), 2.12 [3H, d, J = 6.6 Hz, CH_3(O-hexyl)CH-3], 1.84 (3H, d, J = 7.2 Hz, CH_3-18), 1.72 (2H, m, H-2″), 1.69 (3H, t, J = 7.4 Hz, CH_3CH_2-8), 1.38 (2H, m, H-3″), 1.21 (4H, m, H-4″ and H-5″), 0.75 (3H, t, J = 7.2 Hz, H-6″). MS (ESI) *m*/*z* 1117.7 (MH^+, 100).

HPPH−DTPA-Gd Complex (5). To a solution of **4** (135 mg, 0.121 mmol) in pyridine (15 mL) was added a solution of $GdCl_3 \cdot 6H_2O$ (45 mg, 0.121 mmol) in deionized water (2 mL). The solution was stirred at room temperature for 3 h. Solvent was removed, and deionized water (10 mL) was added to the residue. A dark blue solid formed. The mixture was filtered and washed with water. The dark blue solid was collected and dried with high vacuum in a desiccator to provide **5** (141 mg) in 90% yield. Anal. Calcd for $C_{60}H_{75}N_8O_{14}Gd$: C, 55.84; H, 5.86; N, 8.69. Found: C, 56.71; H, 5.88; N, 8.37.

Compound 8. A mixture of **2** (228 mg, 0.358 mmol), di-*tert*-butyl iminodiacetate (132 mg, 0.538 mmol), DCC (89 mg, 0.431 mmol), and DMAP (53 mg, 0.434 mmol) in dry dichloromethane (6 mL) was stirred at room temperature under nitrogen for 15 h. Water (1 mL) was then added, and the mixture was stirred for 15 min. The organic layer was separated, dried with Na_2SO_4, filtered, and concentrated. 1,3-Dicyclohexylurea was removed as described in the preparation of **3**. The crude product was purified with column chromatography over neutral alumina (Brockmann grade III, ∼150 mesh) eluting with hexanes−EtOAc (v/v 1/1) to provide the title compound **8** (306 mg) as a

dark blue oil in 99% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 318 (25650), 410 (128140), 505 (11750), 536 (11750), 605 (9720), 661 (60760). ^{1}H NMR ($CDCl_3$) δ 9.79 (1H, s, H-5), 9.53 (1H, s, H-10), 8.53 (1H, s, H-20), 5.92 [1H, q, J = 6.6 Hz, CH_3(O-hexyl)*CH*-3], 5.22 (2H, dd, AB system, J = 20.7 Hz, $COCH_2$-15), 4.51 (1H, q, J = 6.9 Hz, H-18), 4.39 (1H, m, H-17), 4.03 (2H, splitting s, H-1′ or H-2′), 3.79−3.53 (9H, m, CH_3CH_2-8, 1× ring CH_3, H-1′ or 2′, H-1″), 3.39, 3.28 (each 3H, s, 2 × ring CH_3), 2.75, 2.47 (each 1H, m, $HNCOCH_2CH_2$-17), 2.42, 2.14 (each 1H, m, $HNCOCH_2$-CH_2-17), 2.12 [3H, two set of doublets, J = 6.6, 7.3 Hz, CH_3(O-hexyl)CH-3], 1.81 (3H, d, J = 7.6 Hz, CH_3-18), 1.75 (2H, m, H-2″), 1.72 (3H, t, J = 7.6 Hz, CH_3CH_2-8), 1.50−1.40 [11H, m, H-3″, 1 × $OCOC(CH_3)_3$], 1.23 (4H, m, H-4″ and H-5″), 1.04, 1.03 [9H, two singlets, 1 × $OCOC(CH_3)_3$], 0.79 (3H, m, H-6″), 0.43 (1H, br, NH), −1.72 (1H, s, NH). MS (FAB) *m/z* 864.4 (MH^+, 100). HRMS (FAB): Calcd. for $C_{51}H_{70}N_5O_7$ (MH^+) 864.5275; Found 864.5280.

HPPH−di-DTPA-*tert*-butyl Ester (10). Compound **8** (626 mg, 0.725 mmol) was dissolved in TFA (10 mL). The solution was stirred at room temperature for 2 h. TFA was removed, and the residue was dried with high vacuum. DCC (907 mg, 4.39 mmol), DMAP (268 mg, 2.19 mmol), **7** (2.21 g, 2.84 mmol), and dry CH_2Cl_2 (20 mL) were then added. The resultant mixture was stirred at room temperature under nitrogen for 20 h. Water (10 mL) was then added, and the mixture was stirred for 15 min. The organic layer was separated, dried with Na_2SO_4, filtered, and concentrated. 1,3-Dicyclohexylurea was removed as described in the preparation of **3**. The product was purified with column chromatography over neutral alumina (Brockmann grade III, ∼150 mesh) eluting with hexanes−EtOAc (v/v 1/2) to remove excess **7** and some other impurity and then eluting with CH_3OH−CH_2Cl_2 (3%) to give **10** (1.13 g) in 68.6% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 319 (21870), 411 (109150), 506 (9960), 537 (10010), 604 (8280), 660 (50080). ^{1}H NMR ($CDCl_3$) δ 10.59 (1H, br, 1 × CO*NH*-phenyl), 9.76 (1H, splitting s, H-5), 9.49 (1H, s, H-10), 8.46 (1H, s, H-20), 8.14 (1H, br, 1 × CO*NH*-phenyl), 7.65 (2H, m, 2 × phenyl H), 7.48 (2H, m, 2 × phenyl H), 7.23 (4H, m, 4 × phenyl H), 5.87 [1H, m, CH_3(O-hexyl)*CH*-3], 5.16 (2H, dd, AB system, J = 20.0 Hz, $COCH_2$-15), 4.40 (1H, m, H-18), 4.28 (1H, m, H-17), 4.07, 3.84 (4H, m, H-1′ and H-1″), 3.76−3.53 (7H, m, H-1‴, CH_3-12, CH_3CH_2-8), 3.53−3.28 (23H, CH_3-2 and 10 × NCH_2CO_2C), 3.25 (3H, s, CH_3-7), 3.10 (2H, m, H-3′ and H-3″), 2.98−2.15 (20H, m, $HNCOCH_2CH_2$-17, H-2′, 2″, 4′, 4″, 5′, 5″, 6′, 6″), 2.07 [3H, m, CH_3(O-hexyl)CH-3], 1.69 (8H, m, H-2‴, CH_3CH_2-8, CH_3-18), 1.61−1.28 [92H, m, H-3‴, 10 × $OCOC(CH_3)_3$], 1.20 (4H, m, H-4‴ and H-5‴), 0.76 (3H, t, J = 6.8 Hz, H-6″), 0.43 (1H, br, NH), −1.75 (1H, s, NH). MS (FAB) *m/z* 2274.0 (MH^+, 100). HRMS (FAB): Calcd for $C_{125}H_{189}N_{13}O_{25}$-Na ($MNa^+$) 2295.3814; Found 2295.3820.

HPPH-di-DTPA (11). 10 (30 mg) was treated with TFA (2 mL) as described in the preparation of **4** to provide **11** in quantitative yield. ^{1}H NMR (60% $CDCl_3$, 40% CD_3OD and one drop of C_5D_5N, TMS as internal standard) δ 9.83 (1H, splitting s, H-5), 9.57 (1H, s, H-10), 8.58 (1H, s, H-20), 7.68−7.37 (4H, m, 4 × phenyl H), 7.22−6.94 (4H, m, 4 × phenyl H), 5.92 [1H, m, CH_3(O-hexyl)*CH*-3], 5.13 (2H, dd, AB system, J = 19.8 Hz, $COCH_2$-15), 4.58−3.99 (6H, m, overlapped with water signal, H-18, H-17, H-1′ and H-1″), 3.84−2.20 (55H, m, H-1‴, CH_3-2, CH_3-7, CH_3-12, CH_3CH_2-8, 10 × NCH_2CO_2C, $HNCOCH_2CH_2$-17, H-2′, 2″, 3′, 3″, 4′, 4″, 5′, 5″, 6′, 6″), 2.12 [3H, m, CH_3(O-hexyl)CH-3], 1.85−1.63 (8H, m, H-2‴, CH_3CH_2-8, CH_3-18), 1.35 (2H, m, H-3‴), 1.22 (4H, m, H-4‴ and H-5‴), 0.76 (3H, m, H-6″). MS (ESI) *m/z* 1713.9 (MH^+, 100).

HPPH−di-DTPA-di-Gd Complex (12). A solution of **10** (700 mg, 0.308 mmol) in TFA (10 mL) was stirred at room temperature for 3 h. TFA was then removed with a ratovapor. The resultant residue was dissolved in pyridine (10 mL). A solution of $GdCl_3$·$6H_2O$ (230 mg, 0.619 mmol) in deionized water (2 mL) was added to above solution. The mixture was stirred at room temperature for 3 h. Solvent was removed, and deionized water (20 mL) was added to the residue. Dark blue solid formed. The mixture was filtered and washed with water. The dark blue solid was collected and dried with high vacuum in a desiccator to provide **12** (630 mg) in 99.5% yield. Anal. $C_{85}H_{107}N_{13}O_{27}Gd_2$. Calcd: C, 49.57; H, 5.24; N, 8.85. Found: C, 50.63; H, 5.10; N, 8.21.

Compound 14. Methylpyropheophorbide-a **13** (2.13 g, 3.88 mmol) was dissolved in HBr−AcOH (30%, 40 mL). The solution was stirred at room temperature for 2 h. HBr and acetic acid were removed under high vacuum. To the residue was added tri(ethylene glycol) monomethyl ether (5 mL) and potassium carbonate (2.0 g) and dry CH_2Cl_2 (20 mL). The mixture was stirred at room temperature for 1 h. It was then diluted with CH_2Cl_2 and washed with water and 5% $NaHCO_3$. The organic layer was dried with Na_2SO_4, filtered, and concentrated. The resultant residue was purified with column chromatography over alumina (Grade III) using CH_2Cl_2−acetone (v/v 9/1) as eluant to give D-20, which was crystallized from CH_2Cl_2−hexanes to provide pure **14** (1.50 g) in 54.2% yield. ^{1}H NMR ($CDCl_3$) δ 9.75 (1H, s, H-5), 9.50 (1H, s, H-10), 8.54 (1H, s, H-20), 6.02 [1H, q, J = 6.7 Hz, CH_3(O-PEG)*CH*-3], 5.18 (2H, dd, AB system, J = 19.8 Hz, $COCH_2$-15), 4.49 (1H, m, H-18), 4.30 (1H, m, H-17), 3.66, 3.62, 3,40, 3.28 (15H, each s, 3 × ring CH_3, $COOCH_3$, H-7″), 3.95−3.48, 3.40 (14H, m, CH_3CH_2-8, H-1″, 2″, 3″, 4″, 5″, 6″), 2.69, 2.55, 2.28 (1H, 1H, 2H, m, $CH_3OOCCH_2CH_2$-17), 2.15 [3H, two set of doublets, J = 6.8, 6.6 Hz, CH_3(O-hexyl)-CH-3], 1.82 (3H, d, J = 7.8 Hz, CH_3-18), 1.72 (3H, t, J = 7.6 Hz, CH_3CH_2-8), 0.43 (1H, br, NH), −1.72 (1H, s, NH). MS (ESI) *m/z* 735.9 (MNa^+, 100).

Compound 15. To a solution of **14** (1.5 g) in THF (80 mL) were added methanol (40 mL) and a solution of LiOH·H_2O (1.0 g) in water (20 mL). The mixture was stirred at room temperature for 4 h. It was then neutralized with 2% acetic acid (200 mL). The mixture was extracted CH_2Cl_2 (4 × 200 mL). The organic layers were combined and washed with water (5 × 400 mL), dried over Na_2SO_4, filtered, and concentrated. The resultant residue was crystallized with CH_2Cl_2−hexanes to provide **15** (1.46 g) in 99.3% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 320 (21230), 410 (106603), 505 (9822), 536 (9671), 604 (8160), 661 (49864). ^{1}H NMR ($CDCl_3$) δ 9.72 (1H, splitting s, H-5), 9.49 (1H, s, H-10), 8.51 (1H, s, H-20), 5.99 [1H, q, J = 6.4 Hz, CH_3(O-PEG)*CH*-3], 5.18 (2H, dd, AB system, J = 20.2 Hz, $COCH_2$-15), 4.47 (1H, q, J = 7.0 Hz, H-18), 4.31 (1H, m, H-17), 3.65, 3.37, 3,26, 3.25 (12H, each s, 3 × ring CH_3, H-7″), 3.89−3.45, 3.39 (14H, m, CH_3CH_2-8, H-1″, 2″, 3″, 4″, 5″, 6″), 2.69, 2.59, 2.29 (1H, 1H, 2H, m, $CH_3OOCCH_2CH_2$-17), 2.12 [3H, two set of doublets, J = 6.6, 6.7 Hz, CH_3(O-hexyl)CH-3], 1.80 (3H, d, J = 6.9 Hz, CH_3-18), 1.69 (3H, t, J = 7.7 Hz, CH_3CH_2-8), −1.72 (1H, s, NH). MS (FAB) *m/z* 699.2 (MH^+, 100). HRMS (FAB): Calcd for $C_{40}H_{51}N_4O_7$ (MH^+) 699.3757; Found 699.3730.

Compound 16. By following the procedure for the preparation of **8**, reaction of **15** (1.45 g, 2.07 mmol) with di-*tert*-butyl iminodiacetate (770 mg, 3.14 mmol) in the presence of DCC (650 mg, 3.15 mmol) and DMAP (382 mg, 3.13 mmol) provided **16** (1.60 g) in 83.3% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 318 (18008), 411 (92100), 505 (8335), 537 (8438), 605 (6895), 661 (43426). ^{1}H NMR ($CDCl_3$) δ 9.74 (1H, splitting s, H-5), 9.53 (1H, s, H-10), 8.53 (1H, s, H-20), 6.01 [1H, m, CH_3(O-hexyl)*CH*-3], 5.21 (2H, dd, AB system, J = 19.8 Hz, $COCH_2$-15), 4.50 (1H, m, H-18), 4.38 (1H, m, H-17), 4.02 (2H, splitting s, H-1′ or 2′), 3.68, 3.34, 3,29, 3.27 (12H, each s, 3 × ring CH_3, H-7″), 3.91−3.50, 3.42 (14H, m, CH_3CH_2-8, H-1″, 2″, 3″, 4″, 5″, 6″), 3.39 (2H, s, H-1′ or 2′), 2.74, 2.43, 1.94 (1H, 2H, 1H, m, $CH_3OOCCH_2CH_2$-17), 2.13 [3H, d, J = 6.7 Hz, CH_3(O-hexyl)CH-3], 1.80 (3H, d, J = 7.5 Hz, CH_3-18), 1.72 (3H, t, J = 7.5 Hz, CH_3CH_2-8), 1.47, 1.43 1.07, 1.03 [6H, 6H, 3H, 3H, each s, 2 × $OCOC(CH_3)_3$], 0.79 (3H, m, H-6″), 0.39 (1H, br, NH), −1.75 (1H, s, NH). MS (FAB) *m/z* 926.3 (MH^+, 100). HRMS (FAB) Calcd for $C_{52}H_{72}N_5O_{10}$ (MH^+) 926.5279; Found 926.5316.

Compound 18. By following the procedure for the preparation of **10**, compound **16** (3.70 g, 3.99 mmol) was treated with TFA (40 mL) to afford compound **17**. Without purification, reacting **17** with **7** (7.50 g, 9.63 mmol) in the presence of DCC (2.04 g, 9.89 mmol) and DMAP (1.22 g, 9.99 mmol) provided **18** (5.91 g) in 63.3% yield. UV−vis in CH_2Cl_2 [λ_{max} (ϵ)]: 318 (22525), 412 (112301), 505 (10336), 537 (10243), 605 (8528), 661 (51863). ^{1}H NMR ($CDCl_3$): δ 10.79 (1H, br, 1 × CO*NH*-phenyl), 9.72 (1H, splitting s, H-5), 9.45 (1H, splitting s, H-10), 8.76 (1H, br, 1 × CO*NH*-phenyl), 8.47 (1H, s, H-20), 7.71 (2H, m, 2 × phenyl H), 7.54 (2H, d, J = 7.9 Hz, 2 × phenyl H), 7.25 (2H, m, 2 × phenyl H), 7.20 (2H, d, J = 8.2 Hz, 2 × phenyl H), 5.96 [1H, m, CH_3-(O-hexyl)*CH*-3], 5.15 (2H, dd, AB system, J = 20.4 Hz, $COCH_2$-

MS (FAB) *m/z* 2336.1 (MH$^+$, 68), 2358.1 (MNa$^+$, 100). HRMS (FAB): Calcd for $C_{126}H_{191}N_{13}O_{28}Na$ (MNa$^+$) 2357.3818; Found 2357.3820.

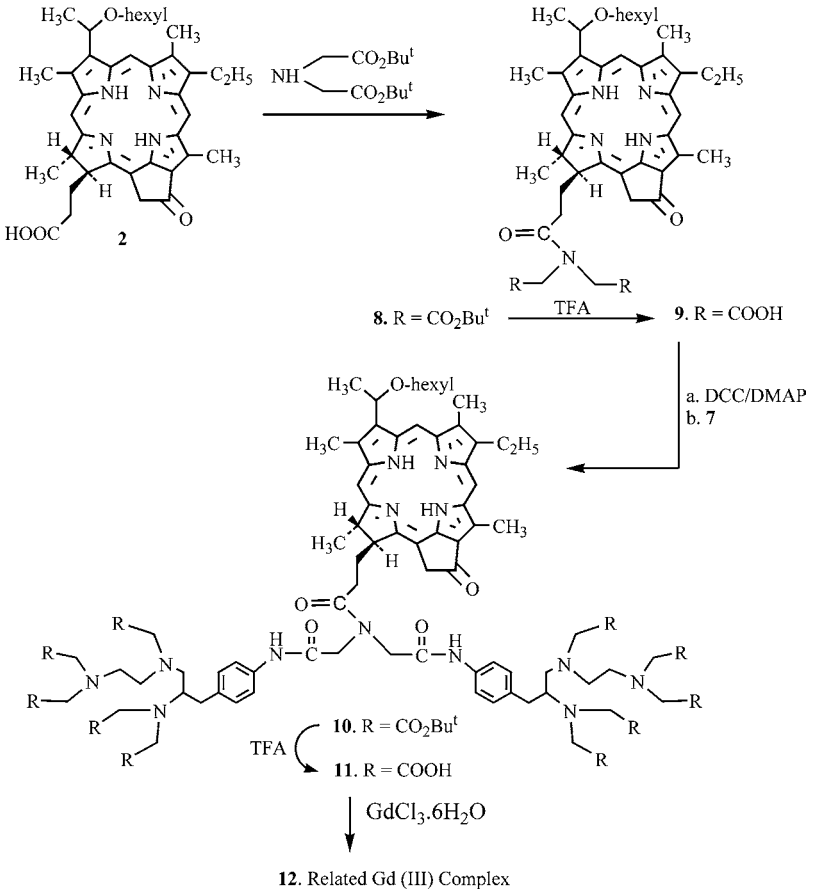
Gd(III) Complex 20. A solution of **18** (5.90 g, 2.52 mmol) in TFA (50 mL) was stirred at room temperature for 3 h. TFA was then removed under vacuum. The resultant residue was washed with water, dried under vacuum, and dissolved in pyridine (70 mL). To this solution was added a solution of $GdCl_3 \cdot 6H_2O$ (1.91 g, 5.14 mmol) in deionized water (5 mL). The mixture was stirred at room temperature for 2.5 h. Solvent was removed to dryness, and deionized water (100 mL) was added to the residue. The dark blue solid was washed several times with water (5 × 100 mL) and dried under high vacuum in a desiccator to provide **20** (5.20 g) in 97.1% yield. Analysis for $C_{86}H_{109}N_{13}O_{30}Gd_2$. Calculated: C, 48.69; H, 5.18; N, 8.59. Found: C, 48.91; H, 4.99; N, 8.85.

Formulation Procedure. To formulate the compound into the liposome mixture, a ratio of 2:1 60% lecithin to cholesterol (Sigma) by mass is dissolved into a minimal amount of dichloromethane in a large-mouthed test tube. The dichloromethane was then evaporated by purging nitrogen slowly while the test tube was kept warm by inserting the test tube in a warm water bath. The test tube was then placed into desiccator under high vacuum for 1 h in order to ensure total removal of the dichloromethane. The compound was weighed out in a ratio of 2:1 60% lecithin to compound by mass and placed into another large test tube. PBS (6 mL) (pH 7.2) was added to the compound and sonicated for 5−10 min. This mixture was then pipetted into the test tube with the liposome film and sonicated for 2 h. The solution must be surrounded by cold water since sonication produces heat. After 2 h the solution was filtered through a 0.45 μm filter into a plastic culture tube and wrapped in aluminum foil.

Whole Body MRI Imaging. Rats (female SD rats, three rats/group) with subcutaneously implanted Ward colon carcinomas (1 cm^3) were imaged in a 1.5 T magnetic resonance imaging system using a standard wrist coil (GE Horizon 5.8, GE Medical Systems, Milwaukee, WI). Preinjection imaging was T_1 weighted (TR = 500 ms, TE = 14 ms) in axial and coronal planes. Image thickness was 3 mm with a 1 mm interscan gap. Matrix size was 256 × 192 with 1.5 excitations and an 8 × 8 cm field-of-view.

***T*1/*T*2 Relaxivity Experiments:** The R1 and R2 relaxivity measurements were acquired on a General Electric 4.7T/33 cm horizontal bore magnet (GE NMR instruments, Fremont, CA)

Scheme 2



incorporating AVANCE digital electronics (Bruker BioSpec platform with Paravision version 2.1 acquisition software, Bruker Medical, Billerica, MA).

T1 relaxation rates (R1) were acquired for a range of contrast agent concentrations with a saturation recovery spin−echo (SE) sequence with a fixed TE = 10 ms and TR times ranging from 125 to 8000 ms (FOV = 32 × 32 mm, slice thickness = 1 mm, slices = 3, interslice gap = 2 mm, matrix = 128 × 128, NEX = 2). Signal intensities at each repetition time was obtained by taking the mean intensity within ROIs using Analyze 5.0 (Biomedical Imaging Resource, Mayo Foundation, Rochester, MN), and R1 and S_{MAX} were determined by nonlinear fitting of the equation:

$$S_{(TR)} = S_{MAX}(1 - e^{-(R1 \cdot TR)}) + \text{background noise}$$

using Matlab's Curve Fitting Toolbox (Matlab 6.5, MathWorks Inc., Natick, MA). Similarly, T2 relaxation rates (R2) were acquired with multi-echo, CPMG SE sequence with a fixed TR of 4500 ms and TE times ranging from 100 to 2000 ms. R2 and S_{MAX} were determined as described above using the equation:

$$S_{(TE)} = S_{MAX}(e^{-(R2 \cdot TE)}) + \text{background noise}$$

Animal and Tumor Systems. RIF-1 tumors were propagated in 6−9 week old female C3H/He mice. Tumors were obtained by subcutaneous injection of 2×10^5 RIF cells, prepared from established tumors by enzymatic digestion, into the right flanks of the animals. Prior to tumor-cell injection all hair was removed from the inoculation site by shaving and use of a commercially available depilatory, e.g. Nair. Tumors were used for experimentation when they reach a diameter of 5−6 mm and a width and thickness of ~4 mm.

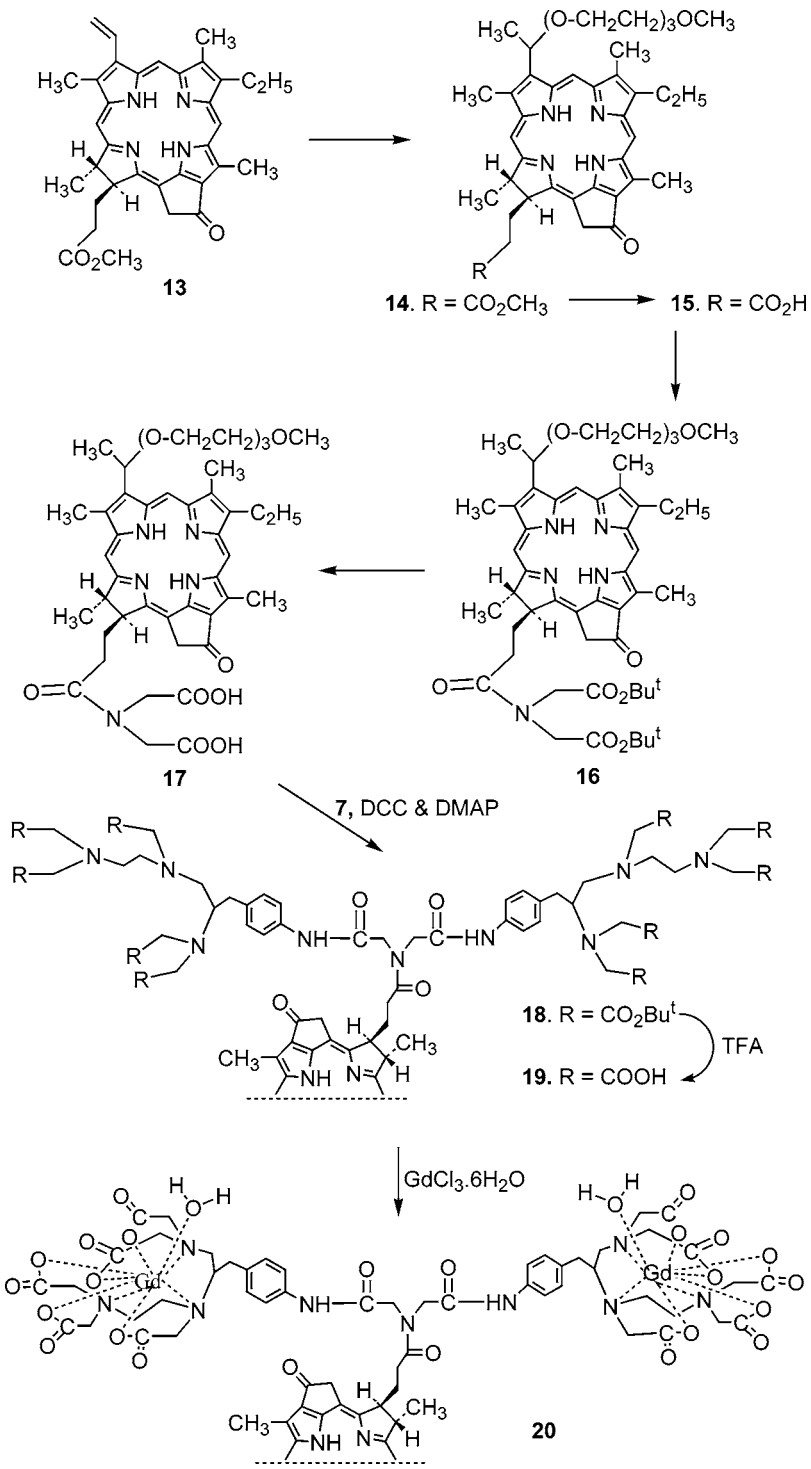
Light Sources. An 18-W argon laser pumping a dye laser (model 171/375; Spectra-Physics) using DCM dye (Exciton, Inc.) tuned to 665 nm wavelength filter was employed. The output beam was split using a custom-made eight-way beam splitter device coupled to 400 μm diameter optical fibers. Each fiber was terminated with a microlens of a focal length of 3.5 mm in order to supply an even light distribution over the treatment field. The power density (75 mW cm^{-2}) was measured by a thermopile power meter (Coherent), and treatment field size was typically 1 cm in diameter.

Assessment of Tumor Response and Cure. The tumor's length (the longest dimension) and width (perpendicular to the long axis) was measured with electronic calipers. The volume was calculated as $V = {}^1/_2(L \times W^2)$. The hours-to-endpoint (HTE; time to 400 mm^3) was calculated by linearly interpolating between the times just before and after this volume is reached, using log(tumor volume) for the calculations; this was done using Microsoft Excel-based software developed by the RPCIC Biomathematics Resource. Mice were routinely sacrificed just after their tumors reached the endpoint. For nonrecurrent tumors, animals were followed for at least 30 days from the time of treatment. Individual experiment included at least five mice. Toxic death was defined as deaths taking place within 48 h of treatment. Toxic deaths only occur after intense PDT treatments.

Mice were used to elucidate important questions regarding the PDT efficacy. The primary therapeutic endpoint was based on the time for tumor regrowth to 400 mm^3. These procedures fall into Class 1 (little or no pain and distress) or Class 2 (mild stress) categories. The designed toxicity endpoint, normal (foot) tissue damage, is a Class 3 procedure; early toxic death is a nondesigned toxicity endpoint. PDT experiments using these endpoints are covered in an approved Institute Animal Care and Use (IACUC) protocol.

Determination of Intracellular Localization by Fluorescence Light Microscopy. In our attempt to investigate the site(s) of localization of the conjugates, these compounds were coincubated in the RIF cells with Mitotracker Green (Molecular Probes, Eugene, OR) which target mitochondria. Briefly, 1×10^5 cells were plated on poly-L-lysine-coated coverslips and grown for 2 days. Cells were incubated with photosensitizer(s) for 4 or 24 h at 37 °C, 5% CO_2, in the dark, and then washed

Scheme 3



with fresh growth medium for 1 h to remove loosely bound drug, and gently rinsed with PBS immediately prior to microscopy (Zeiss Axiovert 200, Inverted Fluorescence Microscope, Carl Zeiss Inc., Germany). Localization was similar at both time-points. For the coincubation studies, Mitotracker Green (200 nM) was added 24 h before washing with PBS and examining by microscopy. Fluorescence was imaged with an AxioCam MRM monochrome digital camera. The images were captured and processed by MRGrab Software (Carl Zeiss, Inc., Germany). The cells were illuminated by a Fluoarc HBO 103 mercury vapor arc lamp filtered through a filter cube containing a 390−430 nm excitation filter, a 505 nm dichroic filter, and a 650−700 nm emission filter for detection of photosensitizers. Mitotracker Green was detected using a 450−490 nm excitation filter, a 495 nm dichroic, and a 500−550 nm emission filter. Images of photosensitizers and Mitotracker Green were taken in rapid succession.

RESULTS AND DISCUSSION

Chemistry. *HPPH Conjugated with One Gd(III)-Aminobenzyl-DTPA Complex.* For the preparation of the conjugate, methyl pheophorbide *a*, **1**, was isolated from *Spirulina pacifica* (*17*, *18*) and was converted into the corresponding 3-devinyl-3-(1-hexyloxy)ethyl-pyropheophorbide *a* (HPPH), **2**, by following the improved methodology developed in our laboratory. For the preparation of the MR agent, HPPH **2** was reacted with 4-aminobenzyl-

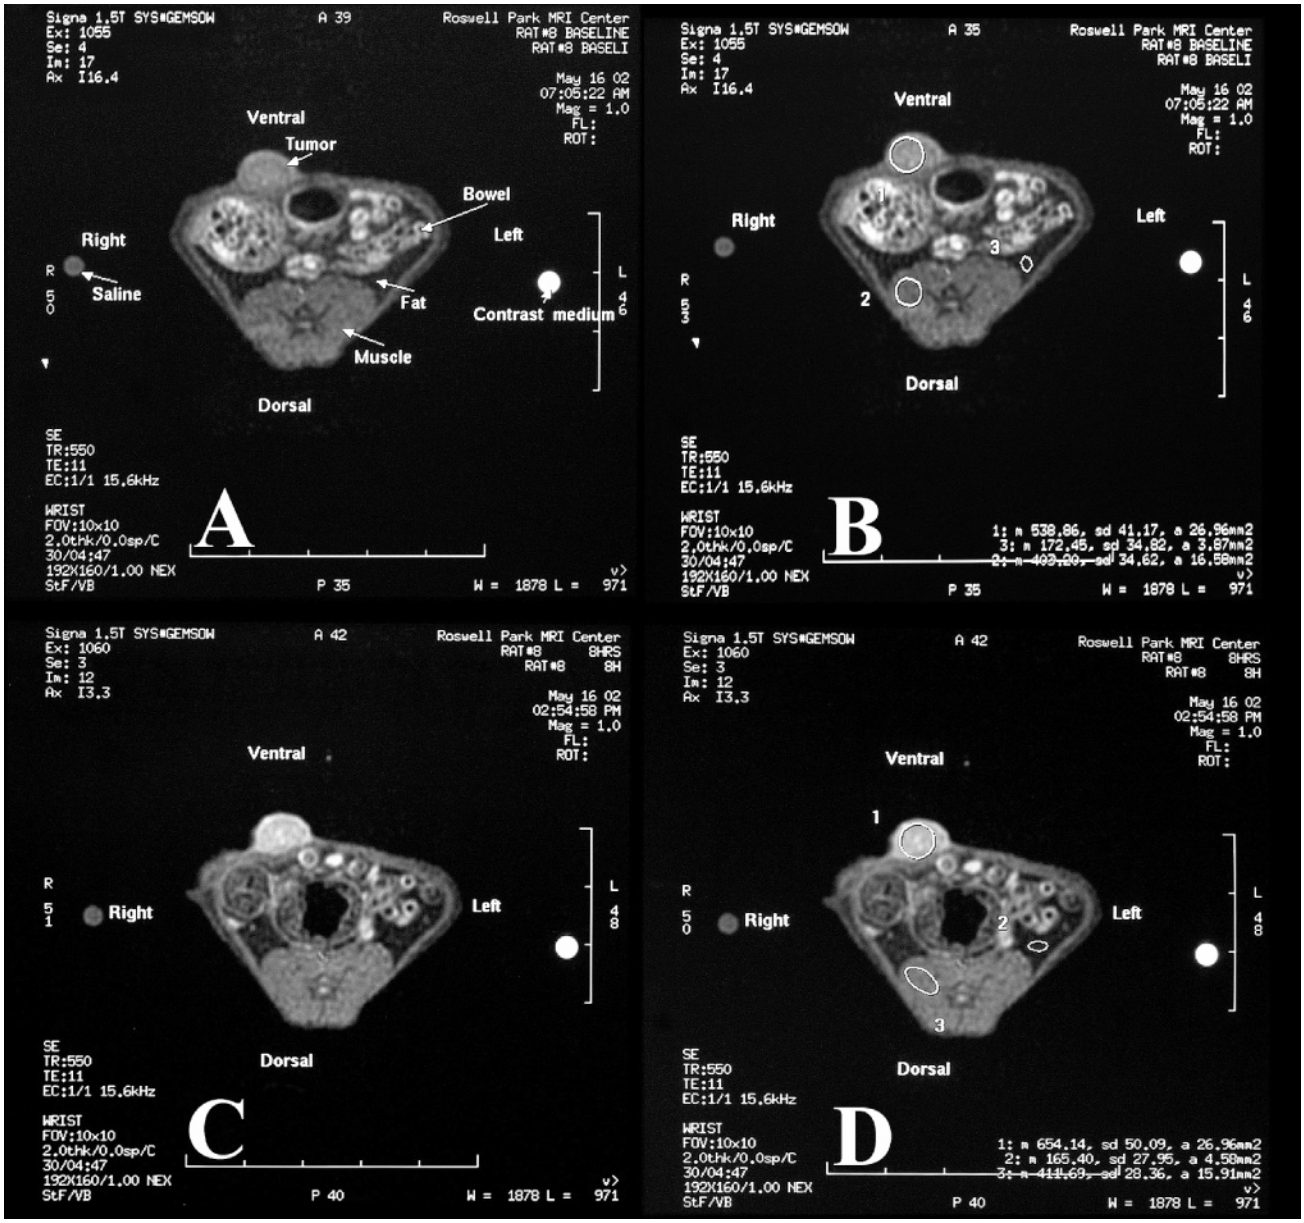


Figure 1. MRI images of tumors (Word Colon) implanted in rats (SD) from conjugate **20** (10 μmol/kg) before and at 8 h postinjection (for details see the text).

DTPA penta-*tert*-butyl ester **7** [which in turn was obtained in several steps from **6** by slightly modifying the methodology reported by Cummins et al. (*19*)] via the carbodiimide approach as illustrated in Scheme 1. For the preparation of the Gd(III) complex, the *tert*-butyl ester functionalities in **3** were converted into the corresponding carboxylic acid **4**, by reacting with trifluoroacetic acid (yield 100%). It was then dissolved in pyridine and reacted with gadolinium chloride hexahydrate dissolved in deionized water at room temperature for 2 h. The solvents were removed, and the residue was washed with deionized water several times and dried under high vacuum. The desired compound **5** was isolated (92% yield).

HPPH Conjugated with Two Gd(III)-Aminobenzyl-DTPA Complexes. The tumor avidity of any scanning agent, whether receptor-based (monoclonal antibodies, peptides) or porphyrin-based, generally improves only slightly by molecular redesign. An alternate approach for improving MR relaxivity would be to increase the number of Gd(III) atoms per molecule. Our approach was based on the hypothesis that HPPH conjugated with two or more Gd(III) chelates per molecule would further enhance tumor conspicuity and/or lower the dose required for MR imaging. For the synthesis of the desired conjugate, HPPH **2** was first reacted with di-*tert*-butyl iminodiacetate by following the carbodiimide approach as described for the preparation **3** (Scheme 1), and the intermediate amide analogue **8** was obtained (quantitative yield). The two *tert*-butyl functionalities present in the intermediate were cleaved on reacting with TFA, and the corresponding carboxylic acid **9** was isolated in quantitative yield. In a sequence of reactions, amide analogue **9** on reacting first with 4-aminobenzyl-DTPA **7** (Scheme 1) and then with TFA and $GdCl_3$ produced the desired compound **12** (90% overall yield). The structures of the intermediates and the final products were confirmed by ^1H NMR and/or mass spectrometry.

Di-Gd(III)-DTPA Conjugate of Pyropheophorbide-PEG. Previous SAR and QSAR efficacy studies on a series of alkyl ether analogues of pyropheophorbide-a (*8*) has shown that lipophilicity is one of the determinants for PDT. Therefore, to investigate the effect of hydrophilic substituent in tumor imaging, PDT efficacy, and skin

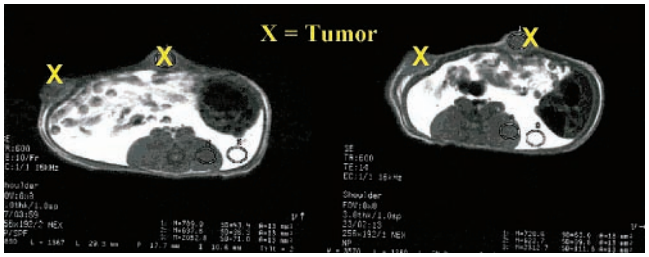

Figure 2. Tumor images rats implanted with Word Colon tumors) before (A) and 8 h postinjection (B) of Magnavist (1 mmol/kg).

phototoxicity, the hexyl ether group present at position-3 in compound **12** was replaced by a poly(ethylene glycol) methyl ether group by following the methodology depicted in Scheme 3, and conjugate **20** was isolated in good yield (see Experimental Procedures).

Body Tumor MR Imaging. *HPPH−Mono-Gd(III)-aminobenzyl-DTPA Conjugate **5**, HPPH−Di-Gd(III)-aminobenzyl-DTPA Conjugate **12**, and the Related PEG Derivative **20**.* Imaging was repeated at 1 and 24 h postinjection of Gd−HPPH **5** (11.25 μmol/kg) with identical imaging parameters (see Experimental Procedures). Region of interest measurements were obtained over the tumor paraspinal muscles and intraabdominal fat, using a workstation (GE Advantage Windows 3.1, GE Medical Systems, Milwaukee, WI). The tumor area of interest increased markedly, from 623 to 881 intensity units. The effect was striking both visually and quantitatively. Signal enhancement was largely restricted to tumor. The signal obtained from fat was essentially unchanged (1998 to 1939 intensity units), and muscle enhancement was minimal. The Gd−HPPH **5** was insoluble in water and required solubilization in 1% Tween-80/water solution, which represents a major barrier to human use because of its known toxicity at higher doses. Therefore, the formulation was revised to Gd−HPPH liposomal formulation (see Experimental Procedures), which has achieved a 25-fold increase in solubility.

To prove that the liposome preparation remains tumor-avid, we successfully produced images virtually identical to the Tween 80 formulation using 10 μmol/kg of conjugate **5**. We also observed that the "higher payload" tumor-avid double-Gd−HPPH compound **12** was equally soluble with liposomal capsulation and enhanced tumor signal. However, the effect was not linear (the signal enhancement was largely restricted to tumor, whose intensity rises markedly from 370 (pre-injection) to 582 (24 h) to 715 at 48 h postinjection.

No tumor enhancement with conjugate **20** over baseline was detected, either visually or quantitatively, at doses of 2.5 μmol/kg and 5.0 μmol/kg in rats. At a dose of 10 μmol/kg, the best enhancement of tumor signal relative to baseline developed 8 h after drug injection. A baseline supine transaxial image viewed from the caudal end (Figure 1, A) demonstrates transplanted tumor (1 cm^3) growing out of the ventral abdominal wall. Muscle, fat, and bowel were clearly defined. Baseline signal measurements (Figure 1B) of tumor, muscle, fat, and control tubes of saline and contrast medium were 538, 403, 172, 385, and 1684. Eight hours after intravenous injection of 10.0 μmol/kg of the Gd(III) complex of Pyro-PEG **20** (Figure 1C) the tumor was visually enhanced and the tumor signal measurement (Figure 1D) increased 22% to 654. Fat and muscle signal changed minimally, from 172 and 403 (baseline measurement) to 165 and 411 (after the conjugate injection), respectively. On the 8-h images, saline and contrast medium control tubes measured 359 and 1746, representing a variation of 15% and 5% respectively from baseline measurements, due to normal system "drift".

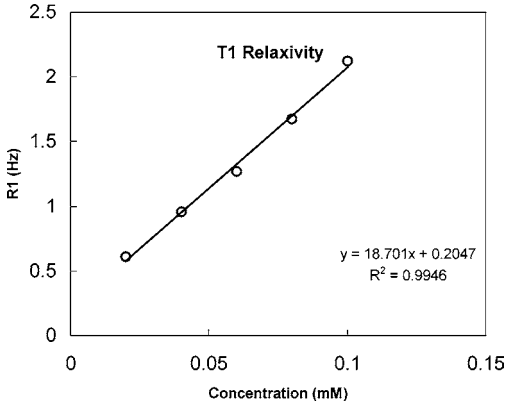

Figure 3. T1 relaxivity of conjugate **20**.

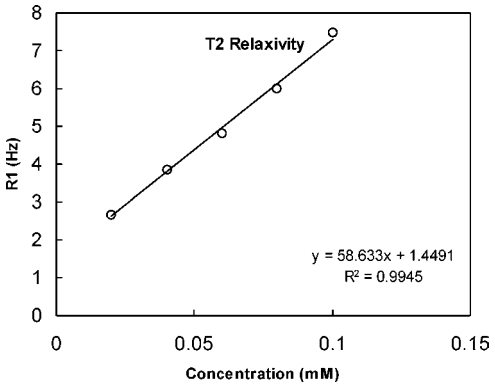

Figure 4. T2 relaxivity of conjugate **20**.

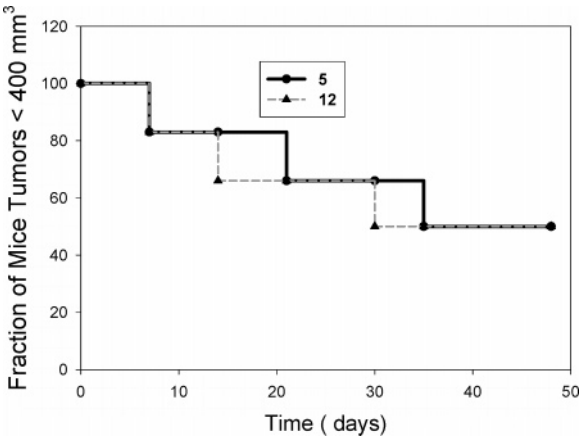

Figure 5. In vivo photosensitizing efficacy of DTPA conjugates **5** and **12** (liposomal formulation) at a dose of 0.47 μmol/kg in C_3H mice (six mice/group) implanted with RIF tumors. The 4−6 mm diameter tumors were exposed to light [130 J/cm^2 (75 mW/cm^2)] for 30 min from a tunable dye laser tuned to the maximum red absorption peak (λ_{max}665 nm)] 24 h postinjection. At day 50, 3/6 mice were tumor-free.

Comparative Study with Magnavist. At present, Magnavist [Gd(III) complex of DTPA] is a standard MRI agent that clinicians use on an almost daily basis. It, however, works by penetrating damaged tumor vascular beds and does not bind to tumor cells, so that when it rapidly clears from the circulation, the tumor concentration also falls rapidly. It has a very brief temporal "window" for MR imaging (5 to 10 min), and therefore to use Magnavist as a tumor-enhancing agent one must know where to image with MRI in advance as it clears

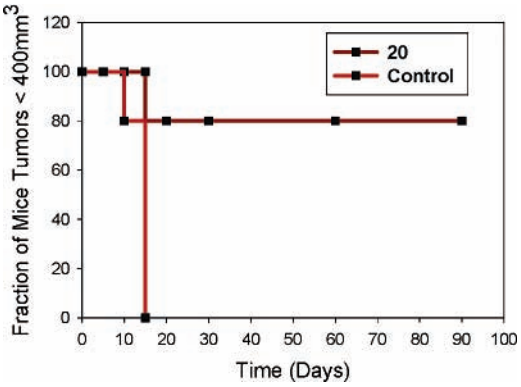

Figure 6. Mice (C3H/HeJ, six mice/group) bearing RIF tumors were treated with **20** (10 μmol/kg) with light (75mW, 135 J/cm^2) for 30 min at 8 h postinjection. Control: No light treatment. At day 90, 5/6 mice were tumor-free.

from tumors within minutes. In the present study, Magnavist was used to image tumors implanted in Fisher rats. The best images were obtained at 5, 10 min postinjection (data not shown). However, at 1, 4, 8, and 24 h postinjection, no tumor enhancement was observed (Figure 2, images at 8 h postinjection), whereas the lead compound (e.g. **20**) remains in tumors for a reasonable time, so that MRI could scan several large body areas and later treat transcutaneously by PDT.

T1 and T2 relaxivity of each compound was determined by taking the slope of linear least-squares fit of contrast agent concentration vs relaxation rate (for compound **20** see Figures 3 and 4). For comparison, relaxivity of Gd-DTPA (Magnevist, Berlex, Wayne, NJ) at 4.7 T was acquired under identical conditions. Compound **20** formulated in liposome demonstrated a relatively high T1 relaxivity of 18.70 $mM^{-1}\cdot s^{-1}$ at 4.7 T as compared to Gd-DTPA (3.25 $mM^{-1}\cdot s^{-1}$), as well as a high T2 relaxivity of 58.63 $mM^{-1}\cdot s^{-1}$.

*In Vivo Photosensitizing Efficacy of Liposome-Encapsulated Mono-Gd−HPPH Conjugate **5** and Di-Gd(III) Conjugate **12**:* The photosensitizing efficacies of the mono- **5** and di-Gd(III)-DTPA **12** were evaluated in C3H mice (six mice/group) bearing RIF tumors (*7*, *8*) at a dose of 0.47 μmol/kg. The compounds in liposomal formulation produced the same PDT efficacy (Figure 3). As can be seen, the presence of an additional Gd(III)-DTPA molecule did not inhibit PDT activity. By day 35 the effect of each compound was equal to 50% tumor cure (3/6 mice were tumor free and both formulations produced the same PDT efficacy (Figure 3). However, compound **12** at the tumor-imaging dose (10 μmol/kg), after light exposure (135 J/cm^2, 24 h postinjection), was found to be toxic and produced 100% mortality (without light exposure, no toxicity was observed).

*In Vivo Photosensitizing Activity of the PEG Analogue **20** at MR Imaging Dose.* Compound **20** at the tumor imaging dose (10.0 μmol/kg) was evaluated for PDT efficacy in C3H mice (10 mice/group) bearing RIF tumors under the light treatment conditions described for compounds **5** and **12** [130 J/cm^2 (75 mW/cm^2) for 30 min] at 8 h postinjection (tumor-imaging time). As can be seen from Figure 6, in preliminary screening, the PEG analogue **20** was found to be quite effective (80% of mice were tumor-free on day 90) and did not produce any mortality or adverse effects at the imaging dose before and after the light treatment. All treated mice showed normal behavior.

Skin Phototoxicity of the Conjugates and Advantages of the Related PEG Analogue. Conjugates **5**, **12**, and **20** (10 μmol/kg, the imaging dose) were injected (iv) individually to rats (three rats/group), and the foot was exposed to light (*18*). The feet of each rat (one exposed to light and another used as a control) response was observed daily. Skin response was significantly different for conjugates **5**, **12**, and **20**. Both **5** and **12** were found

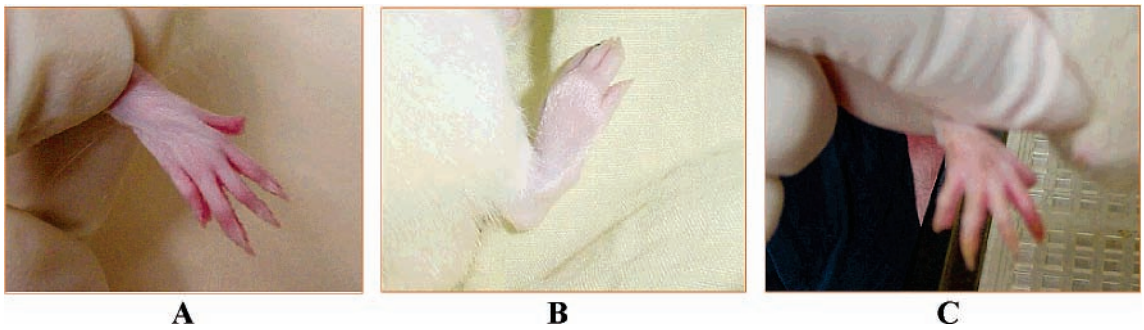

Figure 7. Foot response in female SD rats injected with 10 μmol/kg of compound **20** [A: before light exposure, B: light exposure at 24 h and C: at 96 h postinjection]. At 24 h, swelling of toes and at 96 h, light edema (almost normal) was observed (for details see the text).

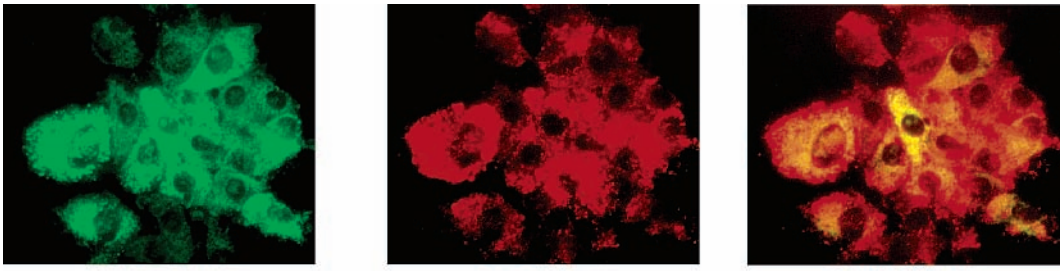

Figure 8. Comparative localization of Mitotracker Green (Mitochondrial marker) and conjugate **20** (1.0 μM) in RIF cells, determined by fluorescence light microscopy (false colors). Similar patterns were obtained from the mono- and di-Gd(III)-aminophenyl-DTPA conjugates **5** and **12** respectively (for details, see the text).

to be extremely phototoxic whereas compound **20** showed significantly reduced skin phototoxicity. The foot response was scored by following the literature procedure and was recorded as follows: At 24 h: 1.8 (moderate dry desquamation and swelling of toes); 72 h: 1.0 (erythema with edema and slight depilation); 96 h: 0.1 (light edema); 120 h: 0 (normal, no reaction) (Figure 7). Thus, initial mild-to-moderate phototoxicity resolved to some extent on day 4 and 5. Therefore, the introduction of a more hydrophilic group certainly helped in clearance of the drug from the skin, resulting in reduced phototoxicity.

Intracellular Localization. It has been shown by us and others that photosensitizers that localize in mitochondria are generally more effective than those that localize in lysosomes (*20*−*24*). Therefore, the localization characteristics of HPPH (localize in mitochondria) was compared with the related DTPA-Gd(III) conjugates including the PEG analogue (for details, see Experimental Procedures). The HPPH and the related DTPA-Gd(III) conjugates **5** and **12** and the PEG analogue **20** were found to localize in mitochondria. A representative example of the DTPA conjugate **20** is shown in Figure 8. Localization images by fluorescence light microscopy (see Experimental Procedures) were taken in rapid sessions. The results (Figure 8) indicate that Mitotracker Green and conjugate **20** localize to the same subcellular region, the mitochondria.

CONCLUSION

The preliminary data suggest that di-DTPA-Gd(III) conjugate **12** is a more effective MRI imaging agent than the related mono-DTPA analogue **5**. Therefore, for designing an improved imaging agent, it is advantageous to have two Gd(DTPA) moieties in the conjugates. However, for both HPPH conjugates (mono-DTPA-Gd(III) **5** and di-DTPA-Gd(III)) **12**, the imaging dose (10.0μmol/kg) produced severe skin phototoxicity. Interestingly, conjugate **20** in which the hexyl substituent (conjugate **12**) was replaced with PEG-monomethyl ether was found to be an effective MRI agent (at 8 h postinjection) at a dose of 10 μmol/kg, with enhanced in vivo photosensitizing efficacy and reduced skin phototoxicity. Measured T1 and T2 relaxivities for liposome-formulated Pyro-PEG-di-DTPA-Gd(III) contrast media **20** were significantly increased as compared to a commercially available mono-DTPA-Gd(III) MR contrast-enhancing agent and were consistent with theoretical values expected for a di-DTPA-Gd(III) conjugate (*25*).

Though the PEG conjugate is not entirely free from phototoxicity, the imaging and photosensitizing results obtained from our systematic synthetic design provides an excellent approach for developing improved bifunctional agents. These characteristics raise the concept of a single "see and treat" agent that could be injected intravenously to image the tumors by MRI and then treat them by exposing to light (PDT) introduced either endoscopically or by a thin fiber optic cable, following guided needle puncture. On the basis of these results, we extrapolate that an improved dual agent can be developed by (a) selecting those photosensitizers as substrates that possess higher tumor selectivity than HPPH, (b) the desired overall lipophilicity can be tuned by introducing mono- or di-PEG substituents at the peripheral position of the chromophore, (c) the depth of tissue penetration could further be increased by conjugating Gd(III)-DTPA with those photosensitizers that exhibit long-wavelength absorption near 750−800 nm. Such dual conjugates may have advantages in treating large and deeply seated tumors. These studies are currently in progress.

ACKNOWLEDGMENT

The authors are thankful to the NIH (CA 55791, 1 R21 CA109914-01), Oncologic Foundation of Buffalo, Roswell Park Alliance, and the shared resources of the Roswell Park Cancer Center Support Grant (P30CA16056) for financial support. We are thankful to Adam Sumlin, PDT Center, for his help in evaluating the foot-response assay (skin phototoxicity). The technical assistance provided by Schlossin and Carol Kaminskiin in tumor imaging is highly appreciated.

Wolfe Street, Baltimore, Maryland 21287. Received July 23, 2004; Revised Manuscript Received October 6, 2004

^{99m}Tc-labeled bombesin analogues have shown promise for noninvasive detection of many tumors that express bombesin (BN)/gastrin-releasing peptide (GRP) receptors. ^{99m}Tc-labeled peptides, however, have a tendency to accumulate in the liver and intestines due to hepatobiliary clearance as a result of the lipophilicity of the ^{99m}Tc chelates. This makes the imaging of lesions in the abdominal area difficult. In this study, we have synthesized a new high affinity ^{99m}Tc-labeled BN analogue, [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN, having a built-in pharmacokinetic modifier, DTPA, and labeled with ^{99m}Tc using a hydrophilic diaminedithiol chelator (Pm-DADT) to effect low hepatobiliary clearance. In vitro binding studies using human prostate cancer PC-3 cell membranes showed that the inhibition constant (K_i) for [DTPA^1, Lys^3(^{99}Tc-Pm-DADT), Tyr^4]BN was 4.1 ± 1.4 nM. Biodistribution studies of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN in normal mice showed very low accumulation of radioactivity in the liver and intestines (1.32 ± 0.13 and 4.58 ± 0.50% ID, 4 h postinjection, respectively). There was significant uptake (7.71 ± 1.37% ID/g, 1 h postinjection) in the pancreas which expresses BN/GRP receptors. The uptake in the pancreas could be blocked by BN, partially blocked by neuromedin B, but not affected by somatostatin, indicating that the in vivo binding was BN/GRP receptor specific. Scintigraphic images showed specific, high contrast delineation of prostate cancer PC-3 xenografts in SCID mice. Thus, the new peptide has a great potential for imaging BN/GRP receptor-positive cancers located even in the abdomen.

INTRODUCTION

Bombesin (BN), the first cancer cell autocrine peptide growth factor to be discovered (*1*), is a 14 amino acid peptide initially isolated from frog skin (*2*). The main mammalian members of the bombesin family of peptides are gastrin releasing peptide (GRP), a 27 amino acid peptide first isolated from porcine stomach (*3*), and neuromedin B (NMB), a 10 amino acid peptide first isolated from porcine spinal cord (*4*). Bombesin-like peptides produce many physiological activities that include stimulation of the release of numerous gastrointestinal hormones and peptides (*5, 6*), stimulation of pancreatic enzyme secretion (*7*), effects on the central nervous system (CNS) such as thermoregulation (*8*), and inhibition of thyroid-stimulating hormone (TSH) (*9*). Many tumors such as glioblastoma, small cell lung cancer, prostate, breast, gastric, colon, and pancreatic cancer (*10*−*18*) are also known to express cell surface receptors to bombesin-like peptides. The receptor system is accessible as a marker for the development of tracers for noninvasive detection and therapy of the cancers.

Radionuclides, such as ^{111}In, ^{125}I, ^{105}Rh, and ^{99m}Tc (*19*−*28*), have been used to label BN/GRP analogues for noninvasive in vivo imaging of BN/GRP receptor-positive cancers. Of these radionuclides, ^{99m}Tc is more advantageous because of its ready availability, low cost, excellent imaging properties (141 keV photon energy and 89% photon flux), favorable dosimetry, and high specific activity. Many ^{99m}Tc-labeled peptides, however, have a tendency to accumulate in the liver and intestines as a result of hepatobiliary clearance. Hepatobiliary clearance is the preferred excretion route because of the lipophilicity conferred on the labeled peptide by many Tc chelates. The high accumulation of radioactivity in the liver and intestines will jeopardize the imaging of BN/GRP receptor-positive cancers and their metastases in the abdominal area. Radiotracers with higher hydrophilicity tend to be excreted trough the urinary system (*29*−*31*), Strategies for decreasing abdominal accumulation have included the use of hydrophilic bifunctional chelating agents (BFCA) (*28*) or coligands (*32*). Recently, we reported the use of a built-in pharmacokinetic modifier in the form of diethylenetriaminepentaacetic acid (DTPA) to reduce hepatobiliary clearance (*33*).

In this study, we present a new high affinity, hydrophilic ^{99m}Tc-labeled BN/GRP analogue, [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN, having the build-in pharmacokinetic modifier, DTPA, at the N-terminus and labeled with ^{99m}Tc using a hydrophilic diaminedithiol (DADT) chelate, Pm-DADT (Figure 1), to direct its clearance through the urinary system. The design and synthesis of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN as well as its initial biological evaluation are discussed here.

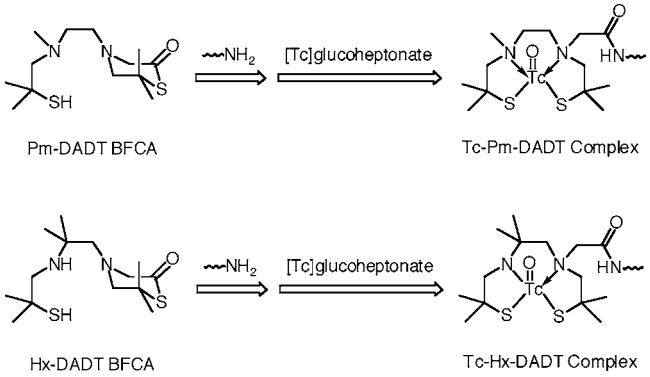

Figure 1. The structures of the diaminedithiol (DADT) bifunctional chelating agents (BFCA) and their Tc complexes. Reaction of the bifunctional chelating agents Hx-DADT and Pm-DADT with amine nucleophiles results in the release of a thiol group to complete the chelating core of the diaminedithiol chelating system for subsequent chelation of Tc from labile Tc complexes such as Tc-glucoheptonate.

MATERIALS AND METHODS

BN, neuromedin B, and somatostatin were purchased from Advanced ChemTech (Louisville, KY). [^{99}Tc]NH_4TcO_4 and [^{125}I-Tyr^4]BN were purchased from NEN Life Science Products (Boston, MA). [^{99m}Tc]$NaTcO_4$ was purchased as a solution in physiologic saline from Syncor (Timonium, MD). The Glucoscan kit was purchased from the Du Pont Radiopharmaceutical Division (Billerica, MA). All other chemicals were obtained from either Aldrich Chemical Co. (Milwaukee, WI) or Sigma Chemical Company (St. Louis, MO). Solvents and chemicals were reagent grade and used as received without further purification. Pm-DADT was synthesized according to our previously published procedure (*34*).

Male CD-1 mice were purchased from the Charles River Laboratories (Charles River, MA). The PC-3 cell line was obtained from the American Type Culture Collection (Rockville, MD) and grown in the Cell Culture Laboratory, School of Medicine, The Johns Hopkins University (Baltimore, MD). Amino acid analyses and MALDI mass spectral analyses were performed by AnaSpec, Inc. (San Jose, CA).

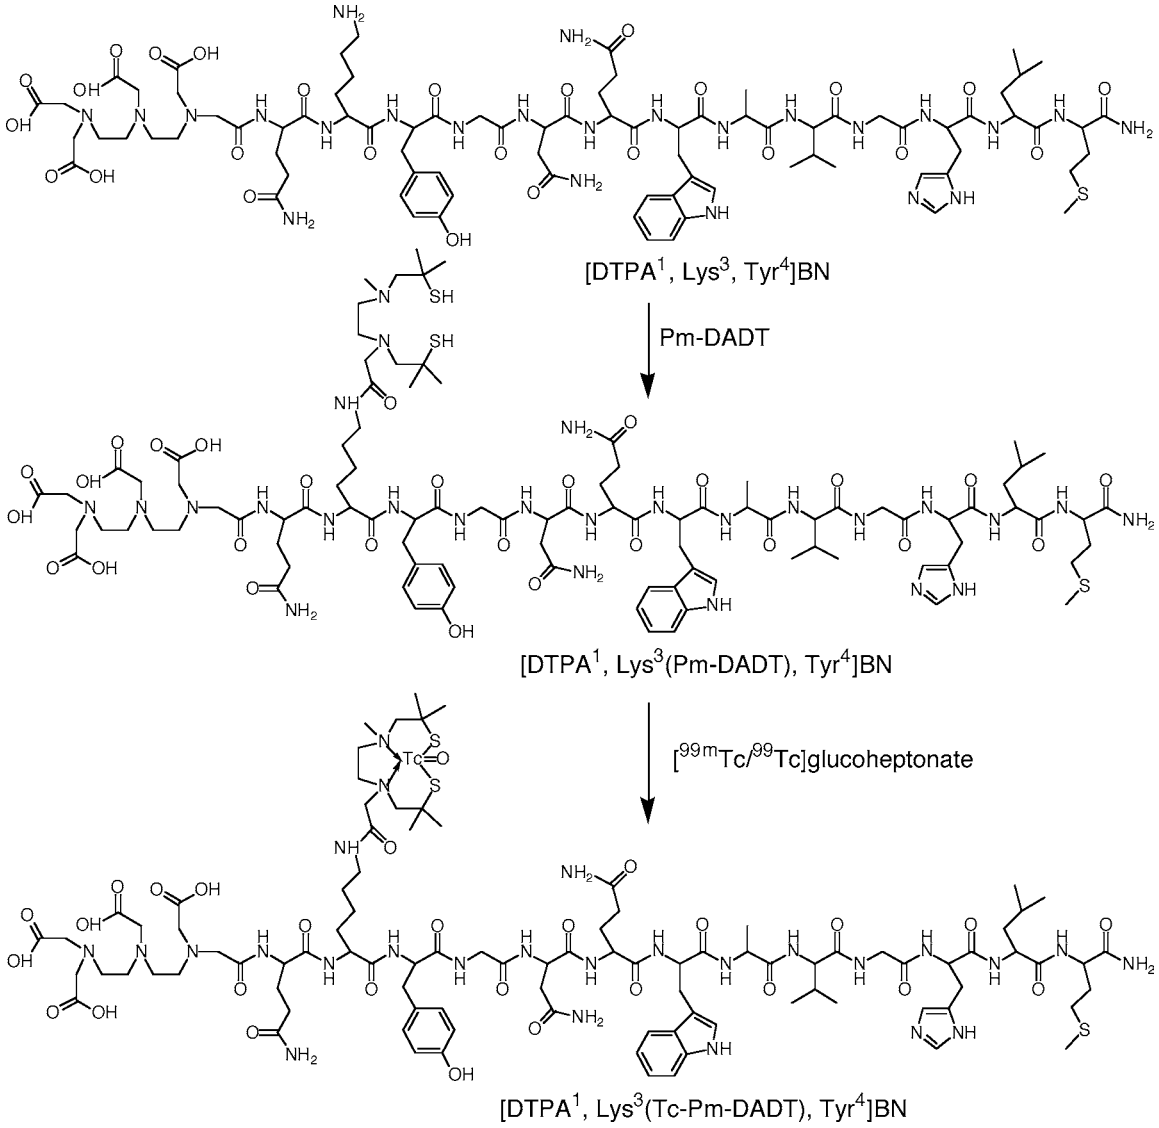
HPLC was performed with a Waters Chromatography Division (Milford, MA) HPLC System equipped with two model 510EF pumps, a model 680 automated gradient controller, a model 490 UV absorbance detector, and a Bioscan NaI scintillation detector connected to a Bioscan Flow-count System. The output from two channels of the UV detector and the output from the Flow-count system were fed into a Gateway 2000 P5−133 computer fitted with an IN/US System, Inc. (Tampa, FL) computer card. HPLC acquisition and analysis were performed with the Winflow software from IN/US. The semipreparative column (C18 Novapak cartridge, 25 mm × 10 cm, 6 μm), the analytical column (C18 Novapak cartridge, 8 mm × 10 cm, 4 μm), and the C18 Light Sep-Pak cartridge were purchased from Waters Chromatography Division. The G3000SW size exclusion column (silica, 7.5 mm × 30 cm, particle size 10 μm, pore size 25 nm) was purchased from TosoHaas (Montogomeryville, PA). HPLC solvents consisted of acetontrile containing 0.1% trifluoroacetic acid (solvent A) and water containing 0.1% trifluoroacetic acid (solvent B). Liquid scintillation counting for quantification of ^{99}Tc activity was performed on an LKB Wallac instrument model 1219 Rackbeta using Ecolume (ICN pharmaceuticals, Inc., Costa Mesa, CA) as cocktail. Filtration of in vitro assay mixtures was performed on a BRANDEL, 48M Harvester. ^{125}I activity on filters from in vitro assays and ^{99m}Tc activity of tissues from biodistribution and blocking studies were counted on an automated gamma counter (Pharmacia-Wallac model 1282). Analyses of in vitro binding assay results were performed using the EBDA/LIGAND programs from Biosoft (Milltown, NJ). ^{99m}Tc activity for synthetic reactions was measured in a Capintec CRC-7 Dose Calibrator.

Synthesis of [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN. The basic peptide sequence, [DTPA^1, Lys^3, Tyr^4]BN was assembled in an Advanced ChemTech 90 Tabletop Peptide Synthesizer using the *tert*-butyloxycarbonyl (Boc) protocol starting with Boc-L-methionine-*p*-methylbenzhydrylamine resin (3 g, 1 mmol/g). Coupling was performed for 30 min with DIC (9 mmol) and HOBt (9 mmol) using the appropriate Boc-protected amino acid (9 mmol) which included N^{im}-tosyl-His, N^{in}-formyl-Trp, *N*-γ-xanthyl-Gln, *N*-β-xanthyl-Asn, *O*-2,6-dichlorobenzyl-Tyr, and N^{ϵ}-2-chlorobenzyloxycarbonyl-Lys in methylene chloride/dimethylformamide (1:1). The coupling reactions were monitored with the nynhydrin test and was repeated if the test was positive. The Boc group was deprotected during each cycle with trifluoroacetic acid (25%) in methylene chloride. DTPA was conjugated at the last step of peptide assembly using the method of Mokotoff et al. (*35*). At the end of peptide assembly, cleavage and side chain deprotection were performed using anhydrous hydrogen fluoride (14 g) at 0 °C for 1.5 h in the presence of anisole (19.7 mmol). After removal of hydrogen fluoride using a slow stream of nitrogen, the residue was washed with ether, dried, and then extracted with 5% aqueous acetic acid (50 mL) and lyophilized. The lyophilized powder was dissolved in water (50 mL), and the solution was adjusted to pH 11 with 2.5 M NaOH. After 5 min, the solution was readjusted to pH 7 with 6 N HCl. The crude product was purified by HPLC using a linear gradient from solvent A (15%)/solvent B (85%) to solvent A (40%)/solvent B (60%) over the course of 50 min at a flow rate of 6 mL/min using the semipreparative column monitored on-line for UV absorption at 220 nm. Eluates containing the product with a retention time of 26.0 min were collected, pooled, and lyophilized. The purity of [DTPA^1, Lys^3, Tyr^4]BN was >95% as assessed by analytical HPLC. The yield of [DTPA^1, Lys^3, Tyr^4]BN was 968 mg (17%).

Pm-DADT was coupled to [DTPA^1, Lys^3, Tyr^4]BN according to Scheme 1. Pm-DADT·2HCl (9.9 mg, 27.2 μmol) and [DTPA^1, Lys^3, Tyr^4]BN (9.0 mg, 4.7 μmol) were dissolved in borate buffer (500 μL, 0.1 M, pH 9) and acetonitrile (500 μL), and the pH was readjusted to 9 with triethylamine. The mixture was incubated at room temperature for 3 h and then extracted with ether (3 × 2 mL). The aqueous fraction was chromatographed by HPLC with a linear gradient from solvent B (100%) to solvent A (80%)/solvent B (20%) over the course of 60 min at a flow rate of 6 mL/min using the semipreparative column monitored on-line for UV absorption at 220 nm. The product with a retention time of 30.8 min was collected, followed by lyophilization. The synthetic yield of [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN was 5.2 mg (50%). Amino acid analysis gave the expected amino acid ratios; calc/found Asn (1/0.88), His (1/1.14), Val (1/0.98), Leu (1/0.95), Lys (1/0.81), Gln(2/1.79), Gly (2/2.19), Ala (1/0.98), Tyr (1/1.09), Met (1/0.97). MALDI MS: calc MW for [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN, 2195.0; found $[M + H]^+$ 2195.1.

^{99m}Tc Labeling of [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN. ^{99m}Tc labeling of [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN was performed as depicted in Scheme 1. A glucoheptonate kit (Glucoscan) was reconstituted with water (1.0 mL). From this solution, [^{99m}Tc]glucoheptonate

Scheme 1. Synthesis of [DTPA^1, Lys^3(Tc−Pm-DADT), Tyr^4]BN



was prepared by addition of an aliquot (200 μL) to a [^{99m}Tc]pertechnetate solution (500 μL, 10−20 mCi), and the mixture was vortexed for 1 min. Then, the [^{99m}Tc]glucoheptonate solution (300 μL) was added to a solution of the [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN (0.5 μmol) in water (500 μL), and the mixture was vortexed for 1 min and incubated at room temperature for 10 min. The reaction was followed by HPLC using a linear gradient from solvent A (25%)/solvent B (75%) to solvent A (55%)/solvent B (45%) over the course of 60 min at a flow rate of 2 mL/min using the analytical column monitored on-line for UV absorption at 220 nm and scintillation for radioactivity. [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN was obtained as a single product peak with a retention time of 35.1 min compared with a retention time of 27 min for [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN, the unlabeled precursor. The yield was > 90%.

Preparation of the ^{99}Tc Analogue of [DTPA^1, Lys^3-(Pm-DADT)Tyr^4]BN. A solution of [^{99}Tc]glucoheptonate in water (20 μL, 20 mM) was added to a solution of [DTPA^1, Lys^3(Pm-DADT), Tyr^4]BN (0.8 mg, 0.36 μmol) in methanol (400 μL) and water (400 μL), and the mixture was incubated at room temperature for 10 min. A similar product was obtained as described above for the ^{99m}Tc analogue. The product was isolated by HPLC using the same conditions above for the purification of the ^{99m}Tc analogue. The yield of the product was 17%. MALDI MS: calc MW for [DTPA^1, Lys^3(^{99}Tc-Pm-DADT), Tyr^4]BN 2308.0, found $[M + H]^+$ 2307.8.

In Vitro Binding Assay of BN Analogues. In vitro binding studies were performed using a modified method of Reile et al. (*36*). Briefly, membrane protein (10 μg) was incubated at 25 °C for 35 min with [^{125}I-Tyr^4]BN (100 pM) in the presence or absence of various concentrations of BN, somatostatin, [DTPA^1, Lys^3, Tyr^4]BN, [DTPA^1, Lys^3-(Pm-DADT), Tyr^4]BN or [DTPA^1, Lys^3(^{99}Tc-Pm-DADT), Tyr^4]BN ranging from 10 pM to 10 μM in the assay buffer (50 mM Tris-HCl buffer, pH 7.4, containing 1 mg/mL bovine serum albumin (BSA) and 2 μg/mL bacitracin) (125 μL total volume). Nonspecific binding was determined in the presence of 1 μM bombesin. The reaction was terminated by rapid filtration through Whatman GF/B glass fibers presoaked for 30 min in the wash buffer (50 mM Tris-HCl buffer, pH 7.4, containing 1 mg/mL BSA). The filter was washed 3 × 5 mL with ice cold wash buffer. Radioactivity on the filters was counted using the automated gamma counter. The results of the assay were analyzed by the EBDA/LIGAND computer programs (*37*). The assays were performed in duplicate and the whole experiment was repeated three times.

Biodistribution of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN in Normal Mice. The HPLC-purified [DTPA^1,

Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN was isolated from the HPLC eluate by solid-phase extraction using the C18 Light Sep-Pak cartridge. The Sep-Pak cartridge was first washed with ethanol (5 mL) followed by a solution of ammonium acetate (0.05 M, 5 mL). The HPLC eluate containing [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN was diluted five times with ammonium acetate (0.05 M) and then passed through the Sep-Pak cartridge. The Sep-Pak cartridge was washed with an ammonium acetate solution (0.05 M, 5 mL) and then [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN was eluated with ethanol (300 μL). The ethanolic solution was diluted with physiologic saline to make the final injectate (10 μCi/mL) containing <0.5% ethanol.

Normal male CD-1 mice (average weight 31.6 ± 1.0 g) were used for the biodistribution studies. [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN (2 μCi, 200 μL) was injected into mice via the tail vein. At 15 min, 1, 2, and 4 h postinjection, four mice for each time point were euthanized by cervical dislocation. Major organs were dissected, weighed, and counted in the automated gamma counter with aliquots of the injectate as standards counted at the same time. The percent injected dose per organ (% ID/organ) and the percent injected dose per gram (% ID/g) were calculated. The % ID in blood was estimated with the assumption that the total blood volume is 6.5% of the body weight.

In blocking studies, each mouse received a subcutaneous injection of 700 μg BN, neuromedin B, or somatostatin in saline (100 μL) or saline vehicle (100 μL) 30 min before the intravenous injection of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN. One hour after the injection of the tracer, the mice were sacrificed and major organs were dissected, weighed, and counted as described above.

Stability Test of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN in Human Serum. The purified ethanolic solution (300 μL) of [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN was diluted with saline (3 mL), and then 100 μL of this diluted solution was mixed with 900 μL of human serum. The mixture was incubated in a 37 °C water bath. After 2, 4, and 6 h, an aliquot (100 μL) was removed and analyzed by HPLC.

The HPLC conditions were isocratic at a flow rate of 1 mL/min using the size exclusion column monitored online for UV absorption at 280 nm and scintillation for radioactivity. The eluent consisted of phosphate buffer (0.2 M, pH 7.15) containing 10% acetonitrile and 0.05% sodium azide. The serum proteins eluted at the retention time ranging from 5 to 10 min, and [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN eluted at the retention time of 13.2 min.

Scintigraphic Imaging of Prostate Cancer PC-3 Xenografts Using [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN. Male SCID mice (24.0−32.6 g) were injected subcutaneously with 10^6 PC-3 human prostate cancer cells in matrigel (0.3 mL) in one flank. The mice having palpable tumors after 8 weeks were used for imaging studies. HPLC purified [DTPA^1, Lys^3(^{99m}Tc-Hx-DADT), Tyr^4]BN (200 μCi) was injected through the tail vein. Each mouse was injected with HPLC purified [DTPA^1, Lys^3(^{99m}Tc-Pm-DADT), Tyr^4]BN (200 μCi) through the tail vein. For comparison, another group of mice were preinjected subcutaneously with 0.7 mg BN to block BN/GRP receptors in vivo 30 min before receiving radiotracer. At 12 h postinjection of tracer, the mice were anaesthesized with urethane and placed directly on the face of one crystal head of a Phillips IRIX VT camera fitted with a low energy high resolution parallel hole collimator and imaged. Image analysis was performed using the Odyssey FX 8.9C software. The target to nontarget ratio on the image was calculated from regions of interest drawn over the tumor area (target) and the contralateral region (nontarget) of each mouse image.

RESULTS AND DISCUSSION

The development of biomarkers for early detection of cancer is important in patient management. Because they are rapidly metabolized in blood, autocrine growth peptides such as bombesin/GRP, are not suitable as biomarkers for detection. The receptors, on the other hand, can be used as biomarkers for detection if suitable tracers could be developed for identifying them in vivo. In many instances, such as in small cell lung cancer (*38, 39*) and gastric cancer (*18*), there are practically no receptors present in surrounding normal tissue making this system amenable to good target to non target differentiation that can be taken advantage of in both imaging and therapy.

Currently, there is significant evidence of the presence of BN receptors in human biopsy samples of prostate, breast, stomach, colon, and small cell lung cancer (*17, 18, 40*−*44*). The incidence of high-density binding sites appears to be near 100% for prostate cancer (*17*) and small cell lung cancer (*42, 45, 46*). In breast cancer 63% of invasive ductal carcinoma and ductal carcinoma in situ as well as all lymph node metastases from the primary tumors express the receptor (*40*). The incidence is 57% for stomach cancer (*18*) and about 40% for colon cancer (*44*). Thus far, in a limited number of patients, the feasibility of imaging bombesin receptors in humans has been demonstrated (*24, 27*).

It is becoming increasingly evident that the BN/GRP receptor becomes expressed early in the process of carcinogenesis in a number of cancers that have been investigated. For example, pulmonary BN/GRP receptor levels in adult lung are extremely low or nonexistent under normal conditions. However, prolonged tobacco exposure, transformed cells, and lung cancer result in marked increases in pulmonary BN/GRP levels and the expression of their receptors (*45, 47*). In human prostate cancer tissue, a massive bombesin/GRP receptor overexpression has been demonstrated in prostatic intraepithelial proliferative lesions, a premalignant condition, and in prostatic carcinoma but not in normal tissues or other prostate hyperplasias (*17*). Similar results have also been reported for gastric cancer where a high density of receptors is present in gastric cancer and Menetrier's disease, a mucosal disorder known to be premalignant, but absent in the surrounding normal tissues (*18*). Such data are not only of biological significance but also provide a molecular basis for potential applications such as bombesin/GRP-receptor scintigraphy for biochemical characterization of the cancers with respect to the extent of bombesin/GRP receptor expression on the cells. The benefits of such characterization would include early diagnosis including the monitoring of high risk individuals such as heavy smokers, imaging of the extent of disease, and the selection of patients to benefit from therapies based on bombesin/GRP receptors.

For these reasons efforts continue to be made to develop ^{99m}Tc-labeled bombesin analogues for imaging neoplasia that express the receptor (*22*−*28*). Because the binding of Tc, an inorganic metal, to the peptide is weak, it is necessary to provide a Tc chelating site on the peptide that can bind Tc in a stable fashion. A number of chelating systems have been investigated for this purpose. We have been investigating the use of diaminedithiol ligands, in the form of the bifunctional

chelating agents depicted in Figure 1, as the carrier of the Tc label. DADT ligands have been shown to be one of the most promising chelators for labeling substrates with Tc and Re. The advantages of the ligand system include stable and well characterized complexes. DADT ligands have been used to label both proteins and peptides with Tc for applications such as cancer and inflammation imaging (*22, 34, 48, 49*).

Previously, we showed in model studies that the labeling of Lys^3-BN with ^{99m}Tc, using Pm-DADT as the bifunctional chelating agent resulted in reduced hepatobiliary activity compared to that of Hx-DADT (intestines and liver, 29% vs 96% ID, 3 h postinjection) (*22*). On chelation of the $[Tc(V)\text{-}oxo]^{3+}$ core using Hx-DADT derived ligands, the resulting TcO-Hx-DADT complex core (Figure 1) is neutral as a consequence of the deprotonation of two sulfhydryl and one secondary amine groups (*50*). In contrast, TcO-Pm-DADT (Figure 1) exhibits one positive charge due to the deprotonation of only the two sulfhydryl groups (*34*). Thus, in applying the two bifunctional chelating agents to label Lys^3-BN, a more hydrophilic product, $Lys^3(^{99m}Tc\text{-}Pm\text{-}DADT)BN$, is obtained from Pm-DADT, compared with $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)BN$ which is derived from Hx-DADT. The hydrophilicity of $Lys^3(^{99m}Tc\text{-}Pm\text{-}DADT)BN$ accounts for its lower accumulation in the hepatobiliary system. Recently (*33*), we also explored the use of DTPA as a built-in pharmacokinetic modifier to reduce the excretion of a ^{99m}Tc-labeled BN analogue, [$DTPA^1$, $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)$, Tyr^4]BN, through the hepatobiliary system. For this compound, Hx-DADT was used to chelate ^{99m}Tc. Compared to $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)BN$ (also labeled using Hx-DADT), the excretion of [$DTPA^1$, $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)$, Tyr^4]BN through the hepatobiliary pathway was greatly reduced (from 96% for $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)BN$ to 21% for [$DTPA^1$, $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)$, Tyr^4]BN), indicating the success of the pharmacokinetic modifier in modulating the biodistribution of [$DTPA^1$, $Lys^3(^{99m}Tc\text{-}Hx\text{-}DADT)$, Tyr^4]BN. These results showed that both the more hydrophilic TcO-Pm-DADT and the use of the pharmacokinetic modifier could independently lower the hepatobiliary clearance of the resulting ^{99m}Tc-labeled BN analogues. However, further reduction of the hepatobiliary clearance is necessary to lower the background radioactivity for better imaging of BN/GRP receptor-positive cancers and their metastases located in the abdominal area. In this study, therefore, we combined the two strategies of pharmacokinetic modifier and hydrophilic chelate in the same peptide in an effort to further lower the hepatobiliary accretion of the labeled peptide.

In the design of the target molecule, [$DTPA^1$, Lys^3-$(^{99m}Tc\text{-}Pm\text{-}DADT)$, Tyr^4]BN, we sought modifications only at the N-terminus of BN. The C-terminal octapeptide, which is required for receptor binding (*51*), was left intact in order to preserve high affinity binding to the receptor. Pyr at the N-terminus of BN was replaced by DTPA, which serves as the pharmacokinetic modifier. Arg at the third position of BN was replaced by Lys to provide the essential ϵ-amino group for coupling to the bifunctional chelating agent, Pm-DADT. Coupling of Pm-DADT at the Lys side chain which is placed at a distance from the receptor binding region was designed to minimize the interference of the Tc-chelate with the receptor binding site. Leu at the fourth position was also replaced by Tyr to facilitate the potential direct iodination of the resulting analogue.

The peptide backbone [$DTPA^1$, Lys^3, Tyr^4]BN was assembled using the Boc technology. Coupling of the bifunctional chelating agent, Pm-DADT, to [$DTPA^1$, Lys^3, Tyr^4]BN was performed at pH 9 using a Pm-DADT: [$DTPA^1$, Lys^3, Tyr^4]BN ratio of 6:1 (Scheme 1). After 3 h incubation at room temperature, the excess Pm-DADT was removed by extraction with ether and the [$DTPA^1$, Lys^3(Pm-DADT), Tyr^4]BN adduct purified by semipreparative reversed phase HPLC. Side chain protection was unnecessary since the indole and imidazole groups of Trp and His, respectively, are weak neucleophiles under the coupling conditions. The purified adduct was characterized by both mass spectrometry and amino acid analysis.

Table 1. Results of in Vitro Binding Studies of Bombesin Analogues to PC-3 Cell Membranes

compound	K_i[a] (nM)
bombesin	1.7 ± 0.6
[$DTPA^1$, Lys^3, Tyr^4]BN	3.1 ± 1.3
[$DTPA^1$, Lys^3(Pm-DADT), Tyr^4]BN	15.5 ± 1.2
[$DTPA^1$, $Lys^3(^{99}Tc\text{-}Pm\text{-}DADT)$, Tyr^4]BN	4.1 ± 1.4
somatostatin	>10000

[a] Values represent the mean ± SD ($n = 3$).

We prepared both no-carrier-added (^{99m}Tc) and milligram quantities (^{99}Tc) of the Tc-labeled BN analogue, [$DTPA^1$, Lys^3(Tc-Pm-DADT), Tyr^4]BN. These Tc derivatives were prepared in ligand exchange reactions by incubation of a mixture of [$DTPA^1$, Lys^3(Pm-DADT), Tyr^4]BN with [^{99m}Tc]- or [^{99}Tc]glucoheptonate at room temperature (Scheme 1). Only one product was obtained in both cases. The yield of ^{99m}Tc product was >90% after incubation for 10 min at room temperature as determined by HPLC. The ^{99}Tc product with 17% isolated yield was characterized by chromatographic comparison to the ^{99m}Tc analogue and mass spectrometry.

Both DTPA and the DADT chelating ligands can coordinate Tc. Therefore, a major issue in the design of [$DTPA^1$, $Lys^3(^{99m}Tc\text{-}Pm\text{-}DADT)$, Tyr^4]BN was the site of Tc chelation. The mass spectrometry results of [$DTPA^1$, $Lys^3(^{99}Tc\text{-}Pm\text{-}DADT)$, Tyr^4]BN indicated that only one [Tc-oxo] center was chelated to [$DTPA^1$, Lys^3(Pm-DADT), Tyr^4]BN. This could either be at the DADT or DTPA site. In the stability studies, only 6.8% of radioactivity was transferred to serum proteins even after 6 h incubation at 37 °C. This is an indication of the strong binding of Tc to the peptide, suggesting binding at the DADT site. The labeling of proteins with ^{99m}Tc via DTPA results in poor stability both in vitro and in vivo (*52*). Furthermore, we have shown in previous studies that in the presence of the benzylamine derivative of Pm-DADT, more than 100 fold excess DTPA cannot compete for the chelation of ^{99m}Tc (*34*). Taken together, the likelihood is strong that the ^{99m}Tc is chelated via the DADT ligand site rather than DTPA.

As a first step in the evaluation of the biological activity of [$DTPA^1$, Lys^3(Tc-Pm-DADT), Tyr^4]BN, we have investigated the ability of [$DTPA^1$, Lys^3(Tc-Pm-DADT), Tyr^4]-BN to bind to the BN/GRP receptor in human prostate cancer PC-3 cell membrane preparations according to a modified method of Reile et al. (*36*). These studies involved competitive binding experiments using the authentic BN receptor ligand [^{125}I-Tyr^4]BN. Results of analysis with the EBDA/LIGAND computer programs are shown in Table 1. The apparent affinities (K_i) of [$DTPA^1$, Lys^3, Tyr^4]BN (3.1 ± 1.3 nM) and [$DTPA^1$, $Lys^3(^{99}Tc\text{-}Pm\text{-}DADT)$, Tyr^4]BN (4.1 ± 1.4 nM) for the BN receptor were comparable to that of BN (1.7 ± 0.6 nM) itself. The unlabeled Pm-DADT adduct, [$DTPA^1$, Lys^3-(Pm-DADT), Tyr^4]BN, had slightly lower affinity (15.5 ± 1.2 nM). Somatostatin which does not bind to the receptor system had a $K_i > 10000$ nM.

Table 2. Biodistribution Results (% ID/organ)[a] of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN in normal Mice at Different Time Points

	15 min	1 h	2 h	4 h
blood[b]	5.07 ± 0.50	2.78 ± 0.50	1.52 ± 0.13	1.22 ± 0.07

[a] Values represent the mean ± SD ($n = 4$).

Results of the biodistribution studies of [DTPA[1], Lys[3]-(99mTc-Pm-DADT), Tyr[4]]BN in normal mice are summarized in Tables 2 and 3. [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN showed fast clearance from the blood pool (0.58 ± 0.05% ID/g, 4 h postinjection) in good agreement with our previous findings (*22*). However, the radioactivity excreted through the hepatobiliary system (liver and intestines, ~6% ID, 4 h postinjection) was much lower compared to the results of Lys[3](99mTc-Hx-DADT)BN (96% ID, 3 h postinjection), Lys[3](99mTc-Pm-DADT)BN (29% ID, 3 h postinjection) and [DTPA[1], Lys[3](99mTc-Hx-DADT), Tyr[4]]BN (21% ID, 4 h postinjection) from our previous studies (*22, 33*). These results indicated the success of the pharmacokinetic modifier, DTPA, and the combination with the hydrophilic Tc-Pm-DADT chelate, in reducing the radioactivity in the hepatobiliary system. Only small amounts of activity remained in the stomach and liver 4 h postinjection (0.43 ± 0.23 and 1.32 ± 0.13% ID, respectively). The pancreas, which expresses the BN/GRP receptor, showed significant uptake (7.71 ± 1.37% ID/g, 1 h postinjection) of radioactivity. This demonstrated the ability of [DTPA[1], Lys[3]-(99mTc-Pm-DADT), Tyr[4]] to target BN/GRP receptor expressing cells in vivo. The pancreas/blood, pancreas/muscle, and pancreas/liver ratios were highest at 4 h postinjection at 9.1, 50, and 7.1, respectively.

To determine if the distribution of [DTPA[1], Lys[3](99m-Tc-Pm-DADT), Tyr[4]]BN in vivo was specific, we conducted experiments in which bombesin, neuromedin-B, somatostatin, or saline vehicle was preinjected in normal mice prior to the administration of [DTPA[1], Lys[3]-(99mTc-Pm-DADT), Tyr[4]]BN. Results of these receptor blocking studies in vivo are shown in Table 4. The difference in the uptake of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN with and without subcutaneous injection of 700 μg of BN is significant in the pancreas (0.48 ± 0.07 vs 8.71 ± 0.99% ID/g) and intestines (0.68 ± 0.11 vs 2.20 ± 0.01% ID/g). Acini cells of the pancreas, submucosal layer of the small intestine, longitudal and circular muscle, and submucosal layer of the colon all have been shown to express BN/GRP receptors (*53, 54*). Neuromedin B (*55*), another mammalian analogue of BN, which shows moderate affinity (K_i, 150−350 nM against [^{125}I-Tyr[4]]BN) toward BN/GRP receptors in acini cells of rat pancreas partially blocked the uptake of radioactivity in pancreas (4.87 ± 0.06 vs 8.71 ± 0.99% ID/g). In contrast, biodistribution of the group with the preinjection of somatostatin, which does not bind to the BN/GRP receptor, was similar to that of the unblocked group. Thus, blocking in vivo followed the expected rank order with respect to the affinity of the blocking agents to the BN/GRP receptor in the pancreas. These results show the specificity of the uptake of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN in receptor rich tissue in vivo. Furthermore, [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN appears to have subtype selectivity on account of the limited ability of neuromedin-B to block its binding in vivo.

Table 4. Results (% ID/g[a]) of Blocking Studies in Normal Mice

	unblocked	bombesin[b]	neuromedin b[b]	somatostatin[b]
blood	1.34 ± 0.17	1.54 ± 0.19	1.59 ± 0.14	1.42 ± 0.16
heart	0.54 ± 0.11	0.55 ± 0.06	0.59 ± 0.05	0.51 ± 0.03
lung	1.40 ± 0.21	1.10 ± 0.14	1.20 ± 0.14	1.36 ± 0.11
kidneys	13.65 ± 0.61	14.32 ± 2.40	15.20 ± 1.18	12.26 ± 2.05
spleen	0.56 ± 0.16	0.57 ± 0.16	0.74 ± 0.12	0.80 ± 0.06
pancreas	8.71 ± 0.99	0.48 ± 0.07	4.87 ± 0.51	8.90 ± 1.51
intestines	2.20 ± 0.01	0.68 ± 0.11	1.88 ± 0.05	1.96 ± 0.30
stomach	3.09 ± 0.71	2.42 ± 0.47	3.28 ± 0.38	4.83 ± 0.59
liver	1.31 ± 0.16	1.39 ± 0.18	1.74 ± 0.08	1.55 ± 0.12
muscle	0.29 ± 0.03	0.34 ± 0.35	0.31 ± 0.01	0.30 ± 0.03

[a] Values represent the mean ± SD ($n = 4$). [b] 700 μg (in 100 μL saline) BN, neuromedin B, or somatostatin was injected subcutaneously 30 min before the injection of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN.

The incidence of the specific subtype of receptors present in human tumors has begun to be investigated. Preston et al. found the predominant subtype in stomach cancer was the BB_2. Recently, Reubi et al. (*46*) also studied the incidence of bombesin receptor subtypes in human tumors. They reported in their series of 161 human tumors that 12/12 prostate cancers, 41/51 breast cancers, and 5/5 gastrinomas expressed the BB_2 receptor subtype predominantly. The study confirmed previous studies that indicate that for prostate and breast cancers, the predominant subtype expressed in high density is the BB_2 subtype (*17, 40, 41*). Other tumors in this series such as small cell lung cancer (3/9) and renal cell carcinomas (6/16) also showed BB_2 receptor subtype expression. Lower incidence of expression of the BB_1 and BB_3 receptor subtypes were reported in bronchial carcinoids, renal cancer, Ewing sarcomas except intestinal carcinoids that showed 11/24 BB_1 receptors, and small cell lung cancer that showed 4/9 BB_3 receptors in this series. The results of our blocking studies suggest that [DTPA[1], Lys[3](99mTc-Pm-DADT) may be more specific for the BB_2 subtype, the predominant subtype expressed in many tumors. This is because neuromedin-B has higher affinity for the BB_1 receptor than the BB_2 receptor. Further work is ongoing in our laboratory to investigate the subtype specificity of [DTPA[1], Lys[3](99mTc-Pm-DADT) Tyr[4]].

In preliminary studies, we investigated the feasibility of imaging human prostate cancer PC-3 xenografts in SCID mice. In these studies, one group of mice were injected with unlabeled bombesin prior to the injection of the tracer to block the receptors while the other group

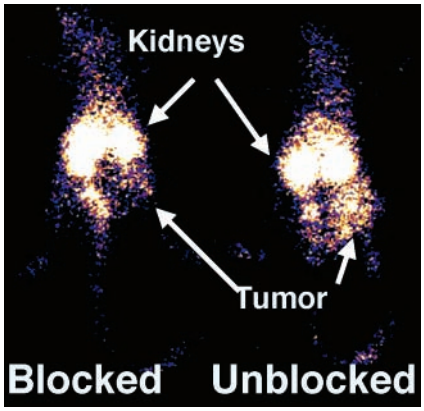

Figure 2. Representative images of human prostate cancer PC-3 tumors in SCID mice injected with [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN. Each mouse received a 200 μCi injection of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN. One group of mice received 700 μg of BN subcutaneously (blocked) and another group received saline vehicle (unblocked) 30 min before the intravenous injection of tracer. The mice were imaged at 12 h postinjection. The target/nontarget ratios were 2 and 10 for the blocked versus unblocked mice, respectively.

only received the tracer. Representative images obtained after 12 h postinjection are shown in Figure 2. The tumor could more clearly be seen in the mice that received no blocking dose of bombesin, whereas the tumors could barely be seen in the mice whose receptors were blocked. Analysis of regions of interest drawn over tumor areas compared to contralateral regions in the same mice showed that the target (tumor) to nontarget (contralateral region) ratios were 2 and 10 for the blocked versus unblocked mice, respectively. The results show that the binding of [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN in vivo in the tumor is specific and indicates the potential of the tracer for imaging prostate cancer.

In conclusion, the use of the built-in pharmacokinetic modifier, DTPA, combined with the hydrophilic Tc-Pm-DADT chelate, showed minimum abdominal accumulation and the ability to target BN/GRP receptor-positive tissues. This will enable [DTPA[1], Lys[3](99mTc-Pm-DADT), Tyr[4]]BN to be used for imaging BN/GRP receptor-positive cancers and their metastases located even in the abdominal area. DADT ligands are also capable of forming highly stable complexes with Re, the congener of Tc. Thus, the 186Re and 188Re analogues of [DTPA[1], Lys[3](Pm-DADT), Tyr[4]]BN would be directly applicable for the radiotherapy of many cancers. When used together, the Tc and Re analogues would represent a diagnostic and therapeutic pair of radiopharmaceuticals. The Tc analogues could then be used to select the patients that could benefit from therapy using the Re analogues.

Synergistic multivalent interactions can amplify desired chemical or biological molecular recognitions. We report a new class of multicarboxylate-containing carbocyanine dye constructs for use as optical scaffolds that not only serve as fluorescent antennas but also participate in structural assembly of the multivalent molecular construct. Three generations of carboxylate-terminating multivalent near-infrared carbocyanine probes from a dicarboxylic acid precursor dye (cypate) were prepared via its imino diacetic acid derivatives. Conjugation of the probes with D-(+)-glucosamine afforded dendritic arrays of the carbohydrates on an inner NIR chromophore core. All the multicarboxylate probes and their glucosamine conjugates have similar NIR spectral properties because conjugation occurred at distal positions to the inner chromophore core, thereby providing consistent and predictable spectral properties for their biological applications. Although light-induced photodamage equally affected the precursor dye, multicarboxylate probes, and their glucosamine derivatives, we observed that octacarboxylcypate (multivalent probe) was remarkably stable in different mediums at physiologically relevant temperatures relative to cypate, especially in basic mediums. Biodistribution studies in tumor-bearing nude mice show that all the glucosamine conjugates localized in the tumor but cypate was almost exclusively retained in the liver at 24 h postinjection. The tumor uptake does not correlate with the number of glucosamine tether on the multicarboxylate probe. Overall, the triglucosamine derivative appears to offer the best balance between high tumor uptake and low retention in nontarget tissues. These results suggest that multivalent molecular beacons are useful for assessing the beneficial effects of multivalency and for optimizing the biological and chemical properties of tissue-specific molecular probes.

INTRODUCTION

Optical imaging is attractive for studying molecular recognitions of chemical and biological importance because minute fluorescent tracers can be detected in homogeneous and heterogeneous media with existing laboratory instruments. For in vivo biological applications, near-infrared (NIR) fluorescent carbocyanine molecular probes are valuable for optical imaging because light in the 700−900 nm wavelengths propagates several centimeters in tissue (*1*, *2*). As a result, diseases in deep tissues can be monitored noninvasively by NIR optical methods. Additionally, NIR excitation also minimizes tissue autofluorescence that confounds spectral analysis in the visible wavelengths. Thus, development of NIR molecular probes with high specificity, selectivity, sensitivity, and stability are highly desirable.

Several reports have successfully demonstrated the potential of NIR dye bioconjugates for imaging diseases in small animals (*3*−*5*). Recent studies have focused on developing dye conjugates of small bioactive molecules to improve rapid diffusion to target tissue, identify, and optimize new molecular beacons by combinatorial library and high throughput strategies and enhance in vivo stability of the compounds (*4*, *6*−*10*). Most of these studies were performed with carbocyanine-based molecular probes because of the exceptionally high biocompatibility and desirable spectral properties of indocyanine green (ICG), which is a member of this class of compounds (*7*, *11*). Because ICG itself does not readily react with biomolecules, we recently developed a reactive carbocyanine dye called cypate (**1**), which has similar spectral, blood clearance, and excretion profiles as ICG (*12*). Bioconjugates of cypate are not toxic to animals up $>10\ \mu$mol/kg body weight. Despite these successes, direct labeling of bioactive molecules to optimize the probes for clinical applications remains a challenge.

Synthetic dendrimers, nanoparticles, quantum dots, and other polyvalent compounds use synergistic multivalent interactions to amplify desired chemical or biological molecular recognitions (*13*−*15*). Labeling the multivalent materials at their reactive peripheral sites with fluorescent antennas provides a highly sensitive approach to track, visualize, and quantify different molecular interactions by optical methods. Although this strategy allows for conjugating multiple chromophores, the resulting molecular constructs may quench fluorescence, induce aggregation, disrupt bioactive conformations of adjacent small molecules, and destabilize the chromophore systems because of their exposure to harsh and metabolically active mediums.

Recently, we reported a new class of multicarboxylate-containing carbocyanine probes for use as optical scaffolds that not only serve as fluorescent antennas but also

participate in structural assembly of the multivalent molecular probes (*16*). The peripheral carboxylic acids that are distal to the chromophore core allow facile conjugation with biomolecules and retain the desirable NIR spectral properties of the dendritic molecule. Herein, we report the synthesis, spectral properties, stability, and biodistribution of multivalent NIR carbocyanine-based molecular probes. The results show that multivalent constructs have increased solution stability over the precursor dye in different mediums and physiologically relevant temperatures. Biodistribution of the glucosamine derivatives shows that the distribution of the compounds in target tumor does not correlate directly with the number of glucosamine moieties but reveals the potential of using multivalency to optimize molecular probes for different biomedical applications.

EXPERIMENTAL PROCEDURES

General. All solvents and chemicals were reagent grade and used without further purification. Benzotriazol-1-yloxy-tris(pyrrolidino)phosphonium hexafluorophosphate (PyBOP) and *N*-hydroxybenzotriazole (HOBt) were purchased from AnaSpec (San Jose, CA). Trifluoroacetic acid (TFA) and DIEA were purchased from Advanced ChemTech (Louisville, KY). Diisopropylcarbodiimide (DIC) and glutaconaldehyde dianilide monohydrochloride were purchased from Lancaster Synthesis (Windham, NH). Dichloromethane (DCM), *N*,*N*-dimethyformamide (DMF), methanol, and acetonitrile were from purchased from Fisher Scientific (Pittsburgh, PA). Other commercial chemicals were purchased from Aldrich (Milwaukee, WI). Mass spectra were obtained in dilute methanol solutions using Waters ZQ 4000 positive electrospray at cone voltage 67 V. All the compounds including the intermediates and final products were fully identified by ES-MS. The identity of final glucosamine conjugates were also confirmed by MALDI-TOF high-resolution mass spectrometry.

HPLC Purification and Analysis. HPLC analysis was performed on a Vydac C-18 column (250 × 4.6 mm) at a flow rate of 1.0 mL/min. Semipreparative HPLC was performed on a Vydac C-18 column (25 × 2.2 cm) at 9.5 mL/min. HPLC solvents consist of water containing 0.05% TFA (solvent A) and acetonitrile containing 0.05% TFA (solvent B). The elution protocol for analytical HPLC starts with 90% A for 1 min, followed by a linear gradient to 30% A over 20 min, held at 30% A for 5 min, continued to 10% A over 5 min, and finally returned to 90% A over 2 min. The elution profile was monitored by UV absorbance at 254 and 214 nm.

NMR Analysis. NMR spectra were recorded on a Varian Inova-600 (Varian Assoc., Palo Alto, CA) spectrometer, and the data were processed off-line with VNMR software. Proton and carbon chemical shifts were measured in ppm downfield from an external 3-(trimethylsilyl) propionic acid (TSP) standard. Proton spectra were obtained in DMSO-d_6 with a 5200-Hz spectral width collected into 32k data points using a 5.0 s preacquisition delay. Carbon spectra were obtained with a 27 000-Hz spectral width collected into 64k data points. The proton-detected heteronuclear multiple quantum coherence (HMQC) spectrum was recorded using a 0.5 s $^1H-^{13}C$ nulling period. The 90° ^1H pulse width was 9.5 μs, and the 90° ^{13}C pulse width was 14 μs. The proton spectral width was set to 5200 Hz and the carbon spectral width was set to 27 000 Hz. Phase sensitive 2D spectra were obtained by employing the Hypercomplex method. A 2 × 256 × 2048 data matrix with 64 scans per t1 value was collected. Gaussian line broadening was used in weighting both the t2 and the t1 dimensions. After 2D Fourier transform, the spectra resulted in 512 × 2048 data points, which were phase- and baseline-corrected in both dimensions.

UV−Vis and Emission Analysis. Absorbance spectra were measured on a Beckman Coulter DU 640 UV−visible spectrophotometer. Fluorescence spectra were recorded on a Fluorolog-3 fluorophotometer (JOBIN YVON/HORIBA, Edison, NJ). Stock solutions (1.0 mM) of the dye and its conjugates were prepared by dissolving each sample in anhydrous DMSO (99.99%). UV−vis and fluorescence measurements were carried out by sequentially adding 0.5−2.0 μL aliquots of the stock solutions via a micropipet into 3 mL of 20% aqueous DMSO solution or other solvents in a quartz cuvette. The mixtures were stirred briefly for equilibration prior to data acquisition.

1,1,2-Trimethyl[1H]-benz[*e*]indole-3-propanoic Acid. A mixture of 1,1,2-trimethyl-[1H]-benz[*e*]indole (40.0 g, 19.11 mmol) and 3-bromopropanoic acid (40.0 g, 26.15 mmol) in 1,2-dichlorobenzene (200 mL) was heated with stirring at 110 °C for 18 h. After the resulting mixture was cooled to room temperature, the precipitate was collected by filtration, followed by trituration in DCM to remove the unreacted material, and dried under vacuum to afford 1,1,2-trimethyl[1H]-benz[*e*]indole-3-propanoic acid (57 g, 82.4%). ESI-MS: 281.31 ($[MH]^+$).

Cypate (1). A solution of Ac_2O (1.20 g, 11.75 mmol) in DCM (5 mL) was added dropwise to a cooled, stirring suspension of glutaconaldehyde dianil monohydrochloride (2.84 g, 9.97 mmol) and DIEA (2.60 g, 20.11 mmol) in DCM (20 mL). The resulting clear solution was stirred for 1 h and added dropwise to a refluxing solution of 1,1,2-trimethyl[1H]-benz[*e*]indole-3-propanoic acid (8.2 g, 22.64 mmol) and sodium acetate (3.2 g, 39.01 mmol) in acetonitrile/water (95/5 mL). The mixture was refluxed for 16 h, cooled, filtered, and washed with acetonitrile, 5% HCl solution, and ethyl ether. About 6 g (85%) of **1** was obtained. ESI-MS: 625.34 ($[MH]^+$).

Tricarboxylic Acid-Containing Cypate Derivative (2). To a cooled solution of **1** (352.5 mg, 0.5 mmol) in DMF (15 mL) was added EDCI (114.6 mg, 0.6 mmol). After 20 min, HOBt (81.2 mg, 0.60 mmol) and di-*tert*-butyl iminodiacetate (147.0 mg, 0.60 mmol) were added. The mixture was stirred at room temperature for 2 h and concentrated. The residue was dissolved in DCM (35 mL), washed with HCl solution (1 M, 3 × 15 mL) and brine, and dried over $MgSO_4$. The filtrate was concentrated and purified by flash column chromatography using dichloromethane/methanol (100:6 v/v) to afford 154 mg (33%). ES-MS: 852.41 ($[MH]^+$).

The above compound (70 mg, 0.075 mmol) was dissolved in TFA (10 mL) and stirred for 1 h, concentrated, and dried to afford 59 mg of **2**, which was further purified by HPLC for both UV−vis and fluorescence assays. ES-MS: 740.28 ($[MH]^+$); HR-MS: 740.2987($[MH]^+$).

Tetracarboxylic Acid-Containing Cypate Derivative (3). The *tert*-butyl ester of **3** (348 mg, 60%) was prepared from **1** (352.5 mg, 0.5 mmol), EDCI (382.0 mg, 2.0 mmol), HOBt (270 mg, 2.0 mmol), and di-*tert*-butyl iminodiacetate (490.0 mg, 2.0 mmol), as described for **2** above. ES-MS: 1079.49 ($[MH]^+$).

The ester (200 mg, 0.17 mmol) was dissolved in TFA (30 mL) and stirred for 1 h, concentrated, and dried to afford 154 mg (97%) of **3**, which was further purified by HPLC for both UV−vis and fluorescence assays. ES-MS: 855.20 ($[MH]^+$).

Hexacarboxylic Acid-Containing Cypate Derivative (4). The *tert*-butyl ester of **4** (72.0 mg, 30%) was prepared from **2** (130 mg, 0.16 mmol), EDCI (275.1 mg, 1.44 mmol), HOBt (194.4 mg, 1.44 mmol), and a solution of di-*tert*-butyl iminodiacetate (352.8 mg, 1.44 mmol), as described for **2** above. ES-MS: 1422.60 ($[MH]^+$).

The ester (15 mg, 0.01 mmol) was dissolved in TFA (10 mL) and stirred for 1 h, concentrated, and dried to afford **4** (11 mg, 95%) which was further purified by HPLC for both UV−vis and fluorescence assays. ES-MS: 1085.23 ($[MH]^+$).

Octacarboxylic Acid-Containing Cypate Derivative (5). The *tert*-butyl ester of **5** (55.0 mg, 30%) was prepared from **3** (94 mg, 0.10 mmol), EDCI (229.2 mg, 1.20 mmol), HOBt (162 mg, 1.20 mmol), and a solution of di-*tert*-butyl iminodiacetate (196.0 mg, 0.80 mmol) in DMF (3 mL), as described for **2** above. (ES-MS: 1764.61 ($[MH]^+$).

The ester (25 mg, 0.0136 mmol) was dissolved in TFA (10 mL) and stirred for 2 h, concentrated, and dried to afford **5** (18 mg, 95%), which was further purified by HPLC for both UV−vis and fluorescence assays. ES-MS: 1315.21 ($[MH]^+$); HR-MS: 1315.5061($[MH]^+$).

Mono-D-(+)-glucosamine-Containing Cypate (6). To a cooled (−5 °C) solution of **1** (15 mg, 0.0213 mmol), HBTU (10.26 mg, 0.027 mmol), and HOBt (3.7 mg, 0.027 mmol) in DMF (5 mL) was added a solution of D-(+) glucosamine·HCl (12.0 mg, 0.054 mmol) and DIEA (14 mg, 0.108 mmol) in DMSO (1 mL). The mixture was stirred at room temperature for 2 h and added into ether (25 mL) with stirring. The precipitate was collected and purified by HPLC (10%-80% of A over 30 min) to afford 2.4 mg (13%) of **6**. ES-MS: 786.30 ($[MH]^+$); HR-MS: 786.4157 ($[MH]^+$).

Di-D-(+)-glucosamine-Containing Derivative of Cypate (7). We used a similar procedure described for **6** above to prepare **7** from **1** (15 mg, 0.0213 mmol), HBTU (25.8 mg, 0.068 mmol), HOBt (9.2 mg, 0.068 mmol), and a solution of D-(+) glucosamine·HCl (32.4 mg, 0.15 mmol) and DIEA (36.5 mg, 0.28 mmol) in DMSO (1 mL). The crude product was purified by HPLC to afford 6.6 mg (30%) of 7. ES-MS: 947.39 ($[MH]^+$); HR-MS: 947.5096 ($[MH]^+$).

Tri-D-(+)-glucosamine-Containing Derivative of Cypate (8). We used a similar procedure described for **6** above to prepare **8** from **2** (15 mg, 0.0183 mmol), HBTU (38.0 mg, 0.10 mmol) and HOBt (13.5 mg, 0.10 mmol), and a solution of D-(+) glucosamine·HCl (43.2 mg, 0.20 mmol) and DIEA (52.0 mg, 0.40 mmol) in DMSO (1.5 mL). Purification by HPLC afforded 6.0 mg (25%) of **8.** ES-MS: 1223.46 ($[MH]^+$); HR-MS: 1223.4759 ($[MH]^+$).

Tetra-D-(+)-glucosamine-Containing Derivative of Cypate (9). We used a similar procedure described for **6** above to prepare **9** from **3** (16 mg, 0.0171 mmol), HBTU (129.2 mg, 0.34 mmol), HOBt (46.0 mg, 0.34 mmol), and a solution of D-(+) glucosamine·HCl (73.5 mg, 0.34 mmol) and DIEA (129.0 mg, 1.0 mmol) in DMSO (1.5 mL). The mixture was purified by HPLC to afford 7.0 mg (26%) of **9**. ES-MS: 1499.41 ($[MH]^+$).

Hexa-D-(+)-glucosamine-Containing Derivative of Cypate (10). We used a similar procedure described for **6** above to prepare **10** from **4** (20 mg, 0.0172 mmol), HBTU (380.0 mg, 1.0 mmol), HOBt (135 mg, 1.0 mmol), and a mixture of D-(+) glucosamine·HCl (216.0 mg, 1.0 mmol) and DIEA (322.5 mg, 2.5 mmol) in DMSO (8 mL). The crude product was purified by HPLC to afford 7.3 mg (20%) of **10**. ES-MS: 2052.39 ($[MH]^+$), 1026.83 $[MH_2]^{2+}$; HR-MS: 2052.5934 ($[MH]^+$).

Octa-D-(+)-glucosamine-Containing Derivative of Cypate (11). We used a similar procedure described for **6** above to prepare **11** from **5** (20 mg, 0.0143 mmol), HBTU (380 mg, 1.0 mmol), HOBt (135 mg, 1.0 mmol), and a mixture of D-(+) glucosamine·HCl (432.0 mg, 2.0 mmol) and DIEA (516 mg, 4.0 mmol) in DMSO (12.0 mL). HPLC purification afforded 8.0 mg (21%) of **11**. ES-MS: 2606.49 ($[MH]^+$), 1302.47 ($[MH_2]^{2+}$); HR-MS: 2604.5407 ($[MH]^+$).

Solution Stability Studies. The stability of representative probes in four different media was monitored by UV−vis. The test solutions (10 μM) were prepared by adding stock solutions (1 mM, 30 μL) into 2970 μL of five different mediums: aqueous NaOH (0.01 M), aqueous HCl (0.01 M), PBS buffer (pH 7.2), 50% aqueous acetonitrile, and 50% aqueous acetonitrile containing 0.01 M DIEA. The solutions were kept at room temperature or incubated at 37 °C for analysis by UV−vis. The difference between the initial and subsequent absorbances of the solution at λ_{max} for each compound was used to determine their stability under different conditions.

Photostability Studies. Photostability studies were monitored by UV−vis at a probe concentration of 5.56 μM in 20% aqueous DMSO under three different conditions: in the dark (cuvette containing the solution was wrapped in aluminum foil), normal room fluorescent light (monitored at 24 h intervals for one week), and direct exposure to 60 W light bulb (sample was placed 30 cm from the light source and monitored at 0.5 h intervals for 8 h). Changes in the initial and subsequent absorbances of **1**, **5**, and **11** were recorded at the λ_{max} for each compound.

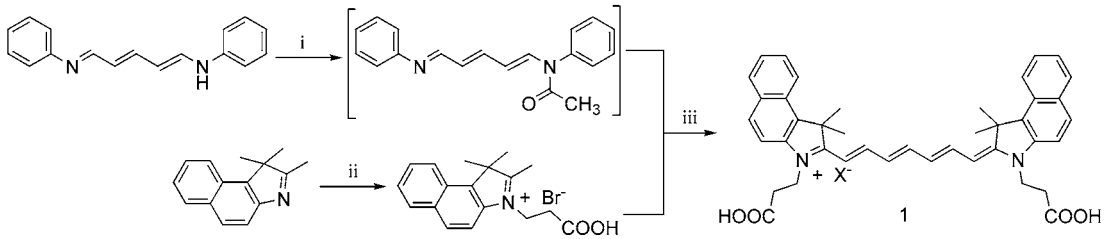
Biodistribution Assays. All animal studies were performed in compliance with the Guidelines for the Care and Use of Research Animals established by Washington University's Animal Studies Committee. To establish tumors, 1×10^7 CA20948 cells, grown in DMEM medium containing 10% fetal calf serum, were injected subcutaneously into the left flank of male nude mice. The CA20948 tumor typically grows to 3−5 mm between 14 and 21 days postinjection. The tumor bearing mice were anesthetized with ketamine/xylazine via intraperitoneal injection and each probe in 20% aqueous DMSO (0.3 μmol/kg body weight) was administered retroorbitally into the mice. At 24 h postinjection, the animals were euthanized and selected organs were removed, washed, and placed on a dark background for fluorescence imaging.

A noninvasive in vivo continuous wave fluorescence imaging apparatus was used to assess the localization and distribution of the probes, as described previously (*12*). Briefly, two 780 nm laser diodes were launched into fiber optic bundles to excite the probes and the emitted fluorescence was captured with a Photometrics CoolSnap HQ charge-coupled device (CCD) camera equipped with an 830 nm interference filter. We used two laser diodes to produce as much uniform illumination of the organs as possible. Images were acquired and processed using WinView software from Princeton Instruments. Tissue parts, instead of whole organs, were used to determine the relative fluorescence intensity in each organ to minimize problems associated with depth-dependent nonlinear fluorescence emission. A statistical program in the WinView package was used to estimate the mean fluorescence intensity per organ part.

RESULTS AND DISCUSSION

Synthesis. *Improved Synthesis of Cypate, the First Generation Dye.* The improved procedure is summarized

Scheme 1. Improved Synthesis of Cypate via Preacylation Approach[a]



[a] Reagents and conditions: (i) acetic anhydride/DIEA/DCM; (ii) 3-bromopropanoic acid/1,2-dichlorobenzene/110 °C; (iii) CH_3COONa/CH_3CN/H_2O/refluxed.

in Scheme 1. Cypate (**1**) was originally designed to mimic the absorption, fluorescence emission, excretion pathway, and blood clearance profiles of indocyanine green (ICG) because of the in vivo biocompatibility in humans and desirable spectral properties of ICG (*1*, *9*, *11*, *12*). Unlike ICG, **1** can serve as an optical scaffold for multivalent molecular designs because it contains two carboxylic acid functional sites for further derivatization. Initially, we synthesized **1** by a conventional method where a mixture of carboxypropyl benzoindole, glutaconaldehyde dianil monohydrochloride, and sodium acetate were refluxed in ethanol (*12*). Unfortunately, the isolated yield was low (<10%). Consequently, we explored alternative approaches to improve cypate synthesis by optimizing the reaction conditions (*6*, *12*, *16*).

Previous studies indicate that N-acetylation of the intermediate glutaconaldehyde may play an important role in the reaction of aldehydes with benzoindole to form tricarbocyanine dyes (*17*, *18*). This reaction is routinely performed in situ by using a mixture of acetic anhydride/acetic acid. However, the synthesis we conducted in acetic anhydride/acetic acid solution did not improve the yield of **1**. Therefore, we explored preacetylation of glutaconaldehyde with acetic anhydride prior to condensation with benzoindole intermediate at 110 °C to minimize the formation of byproducts generated at higher temperatures. As summarized in Scheme 1, the reaction of 1,1,2-trimethyl-[1H]-benz[*e*]indole and 3-bromopropanoic acid at 110 °C in dichlorobenzene afforded 1,1,2-trimethyl-[1H]-benz[*e*]indole-3-propanoic acid, which was conveniently purified by trituration in DCM and filtration to afford the compound in >80% yield. Reaction of glutaconaldehyde dianil monohydrochloride with acetic anhydride in the presence of triethylamine in DCM afforded acetyl glutaconaldehyde dianil. The solution was added to a refluxing mixture of 1,1,2-trimethyl[1H]-benz[*e*]-indole-3-propanoic acid and sodium acetate in ethanol at 70 °C. The resulting mixture was refluxed for about 16 h, concentrated, and washed with a solution of dilute HCl to afford the desired compound. Although this procedure improved the isolated yield of **1** over previous methods, the purification was still difficult because of the formation of solvent-mediated mono- and diethyl ester byproducts.

After conducting the reactions in different solvent systems, we found that a mixture of acetonitrile/water (7:3) eliminates the ester byproduct formation and significantly increased the isolated yield of **1**. The condensation reaction progressed smoothly at 70 °C in the aqueous acetonitrile solution, suggesting that the dye formation is favored by entropy and higher reaction temperatures are avoidable. The desired compound **1** was obtained in >80% yield by recrystallization. ES-MS, NMR, and HPLC analyses confirmed its identity and purity. The facile workup, non-HPLC-based purification, and gram-scale preparation attest to the importance of preacetylating glutaconaldehyde in reducing the formation of byproducts, making this protocol attractive for efficient large-scale synthesis of **1** and related compounds.

Synthesis of Multivalent Cypate Analogues. The synthetic procedure is summarized in Scheme 2 (*16*). Amide bonds are commonly used as a linker because of its facile formation, derivation to anchor different functionalities, high solution stability, and biocompatibility. For these reasons, we introduced multivalency on carbocyanine dye inner cores via multicarboxamide functionalities. Although the amide formation appears straightforward, we found the use of highly reactive coupling reagents such as HBTU, PyBOP, and HATU in the presence of organic bases such as DIEA lead to the decomposition of **1**, as identified by HPLC, UV−vis, and ES-MS. After evaluating the most commonly used coupling methods, we found that the relatively mild carbodiimide-mediated coupling of **1** and its derivatives with amine-containing compounds gives amide products in good yields. As identified by MS in some reaction mixtures, inactive *N*-acylurea byproducts were formed through O−N migration of the active *O*-acylurea intermediate (*19*). This migration can be minimized by adding HOBt to the reaction mixture, which also catalyzes the reaction. Therefore, we finally used a combination of EDIC/HOBt to prepare the multivalent compounds. Reaction of **1** with di-*tert*-butyl imino diacetate in the presence of EDCI/HOBt, followed by TFA-mediated deprotection, gave two of the second-generation multivalent probes (tri- (**2**) and tetra (**3**) carboxylate-containing derivatives). Further reactions of **2** and **3** with di-*tert*-butyl imino diacetate in the presence of EDIC/HOBt and subsequent TFA-mediated deprotection afforded two of the third-generation multivalent probes (hexa- (**4**) and octa- (**5**) carboxylate-containing derivatives (Scheme 2)). The compounds were purified and obtained in moderate to good yields as follows: **2** (33%), **3** (60%), **4** (30%), and **5** (30%). The NIR multivalent molecular probes were used to prepare dendritic arrays of diverse bioactive moieties on a carbocyanine inner core for molecular recognitions.

Dendritic Arrays of Glucosamine on Carbocyanine Core. Carbohydrates play important roles in molecular recognitions. These polyhydroxylated molecules typically enhance the intended biological event via multivalent interactions in glycoside clusters (*20*). To explore the potentials of the multivalent carbocyanines in molecular recognition studies, we constructed a library of multivalent glucosamine-containing carbocyanine conjugates as molecular beacons. Accordingly, a series of compounds including **6**, **7**, **8**, **9**, **10**, and **11** (Figure 1) were prepared by conjugating D-(+)-glucosamine with **1**, **2**, **3**, **4**, and **5** in the presence of HBTU/HOBT/DIEA in moderate yields (*16*).

HPLC Analysis. The purity and homogeneity of all the glucosamine conjugates were analyzed by HPLC. Figure 2 shows two RP-HPLC chromatograms of compound **5** and its conjugate **11**. Expectedly, conjugation of

Scheme 2. Synthesis of Multi-carboxylic Acid-containing Carbocyanine Dyes[a]

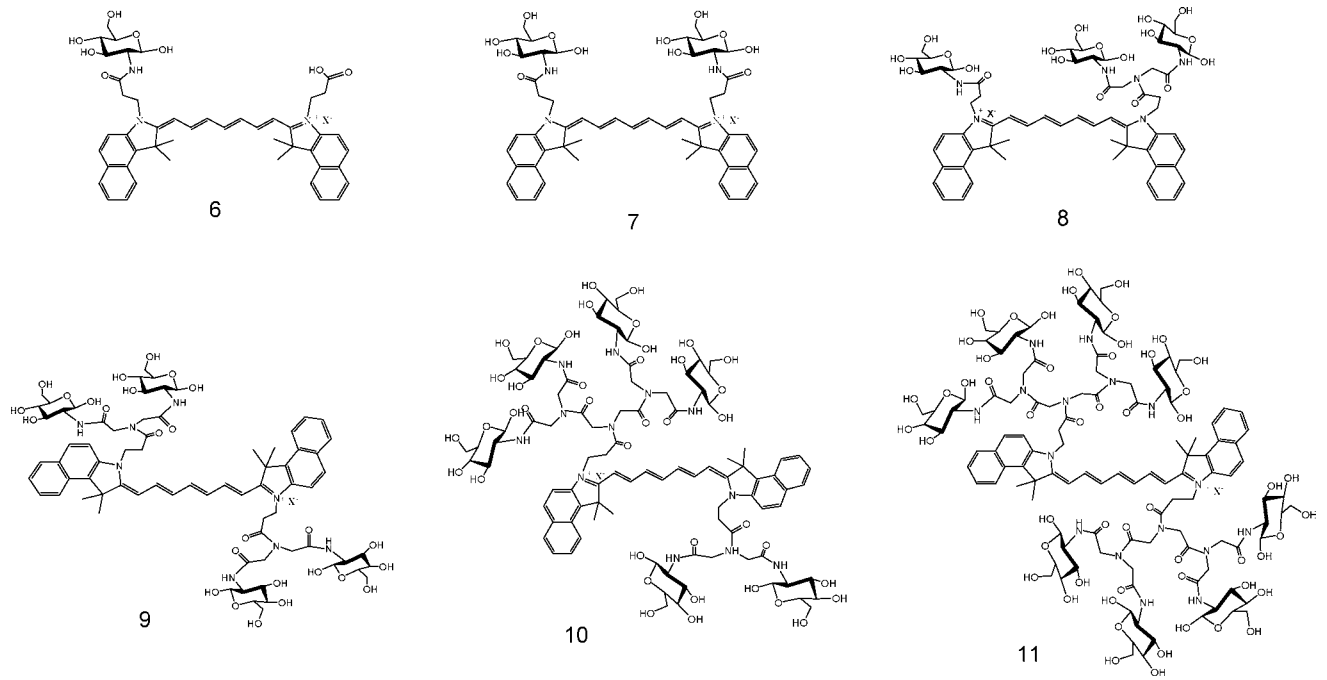

Figure 1. Structures of representative dendritic arrays of glucosamine on an inner NIR carbocyanine core.

the multivalent probes with glucosamine increases the hydrophilicity of the conjugate, as reflected in the shorter HPLC retention time compared with the precursor dye. The enhanced water solubility facilitates formulation of the probes in aqueous buffers for in vivo application.

NMR Analysis. ^{1}H and ^{13}C NMR analysis was performed on representative molecular probes **1**, **5**, and **11**. Structure of **1** was confirmed by proton 1D spectrum and 2D COSY and HMQC experiments. In Figure 3(A), the doublet at 6.45 ppm is assigned to the terminal protons at the conjugated double bond that are next to the indole ring. Spin propagation from the center proton (a in Figure 4(A)) toward the terminal proton (d in Figure 4A) further confirms the symmetrically conjugated seven-carbon double-bonded fragment. Assigned carbon resonances range from 104 to 156 ppm in HMQC (Figure 4B, a, b, c, d), indicating the conjugated double bonds are indeed present in **1**. Compounds **5** and **11** were identified by comparing their ^{13}C spectra with **1**. Additional resonances at 168−171 ppm and 47−50 ppm (Figure 5B) confirm the presence of octacarboxylic acid and 12 methylene groups, respectively, in **5**. Furthermore, the spectrum in Figure 5C indicates that the sugar carbons in **11** spans from 54 to 95 ppm. Comparison of the 2D HMQC spectra between **5** and **11** confirms the presence of glucosamine's anomeric H1′ protons at 4.92 and 4.43 ppm while those of H2′ to H6′ range from 3.02 to 3.59 ppm (Figure 6). Proton integration suggests that there is a 6:2 ratio between the

two H1′ resonances (Figure 3B) and further confirms **11** possesses eight sugar moieties in the structure.

Absorption and Emission Properties. The absorption and emission spectra of all the compounds evaluated are similar, with their maxima centered around 780 and 810 nm, respectively. Figure 7 shows the normalized absorption and emission spectra of **1**, **5**, and **11**. Expectedly, the spectral properties of the dendritic arrays are also similar to the precursor multivalent beacons in the same solvent because conjugation occurred at distal positions to the inner chromophore core. This feature demonstrates another advantage of this series of multivalent molecular probes in providing consistent and predictable spectral properties for biological applications. All the compounds have exceptionally high molar absorptivity in a variety of solvents (Table 1).

Solution Stability Studies. Understanding the stability of molecular probes in different solvent systems will guide researchers in selecting the appropriate medium to formulate the compounds, perform reactions, and optimize storage conditions for each probe. To this effect, we assessed the stabilities of **1** (precursor dye), **5** (carboxylic acid tethered multivalent dye), and **11** (dendritic array of glucosamine on the multivalent dye **5**) in different mediums and temperatures. Dilute NaOH and HCl were chosen to represent the mild basic or acidic conditions frequently encountered in diverse applications. Because we typically lyophilize the compounds in aqueous acetonitrile (ACN) and conduct reactions in DIEA-containing organic solutions, we also evaluated the stabilities of the probes in 50% aqueous ACN and 0.01 M DIEA solution in 50% aqueous ACN. Phosphate-buffered saline (PBS, pH 7.2) is conventionally used to formulate products for biological applications, and hence prolonged stability of the probes in PBS is highly desirable. The stabilities of the probes (10 μM) in different mediums were monitored by UV−vis at λ_{max} of each probe.

As with most carbocyanine dyes, all the compounds tested are relatively stable in acidic condition at room temperature (Figure 8) and 37 °C (Figure 9). Possibly, protonation of the "donor" tertiary amine of the benzoindole carbocyanine stabilizes the probes. Similarly, solutions of the probes in 50% aqueous ACN are exceptionally stable for up to 18 h at 37 °C. These results suggest that workup and storage conditions in acidic and aqueous

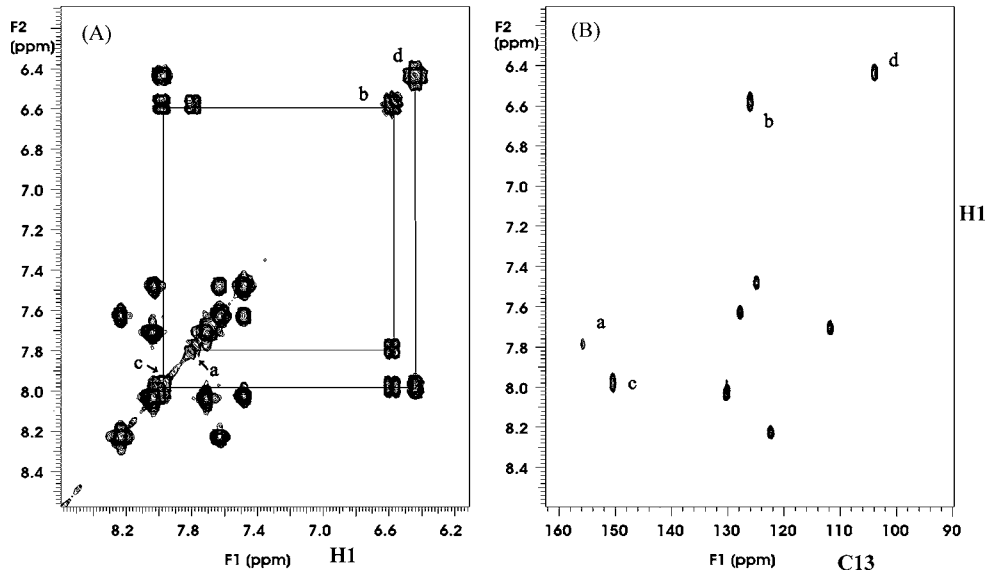

Figure 4. Expansions of the 600 MHz (A) COSY and (B) HMQC spectra of compound **1** in DMSO-d_6 at 25 °C. Same figure labels as in Figure 1.

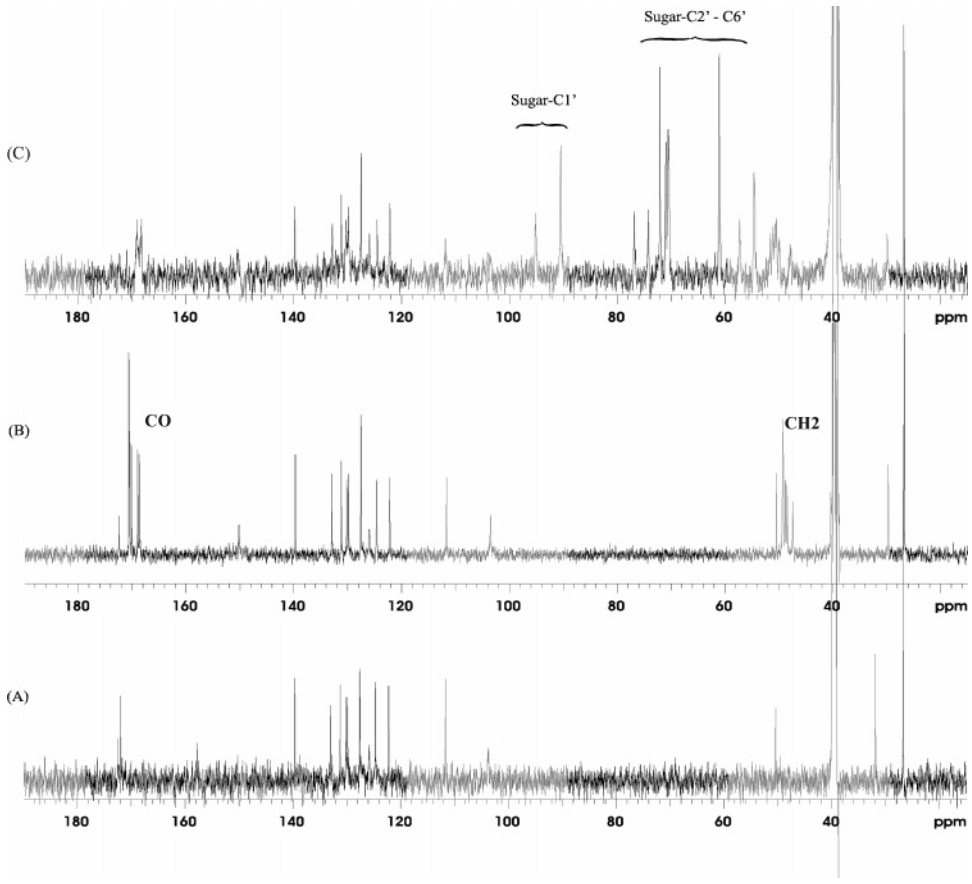

Figure 5. Carbon-13 spectra of (A) compound **1**, (B) compound **5**, and (C) compound **11** in DMSO-d_6 at 25 °C.

ACN mediums do not destabilize the chromophore system. In contrast, stabilities of the compounds in NaOH were different. While **5** was relatively stable in this medium up to 96 h, **1** and **11** were adversely affected. At 16 h, the percent absorbance of **1** in NaOH decreased to <80% and further dropped to <30% at room temperature after 96 h (Figure 8). A similar trend was obtained at 37 °C (Figure 9). This mild but progressive destabilization of **1** in NaOH may be due to the initial formation of the sodium carboxylate salt, followed by the generation of hydroxide zwitterions with the quartenary amine group of benzoindole. The strong basic hydroxide counterion can destabilize the conjugated π-system by abstracting acidic protons or reversing the aldehyde−trimethylbenzoindole condensation (Scheme 1). This inner salt effect by a strong basic counterion is supported by the minimal destabilization of **1** in the mild basic DIEA solution in aqueous ACN (Figure 9). Stability of **11** in basic mediums is abysmal and appears to correlate with the basicity of the medium, with stability in NaOH < DIEA solutions. This can be attributed to the hydrolysis of the glucosamine moieties under basic conditions, which gener-

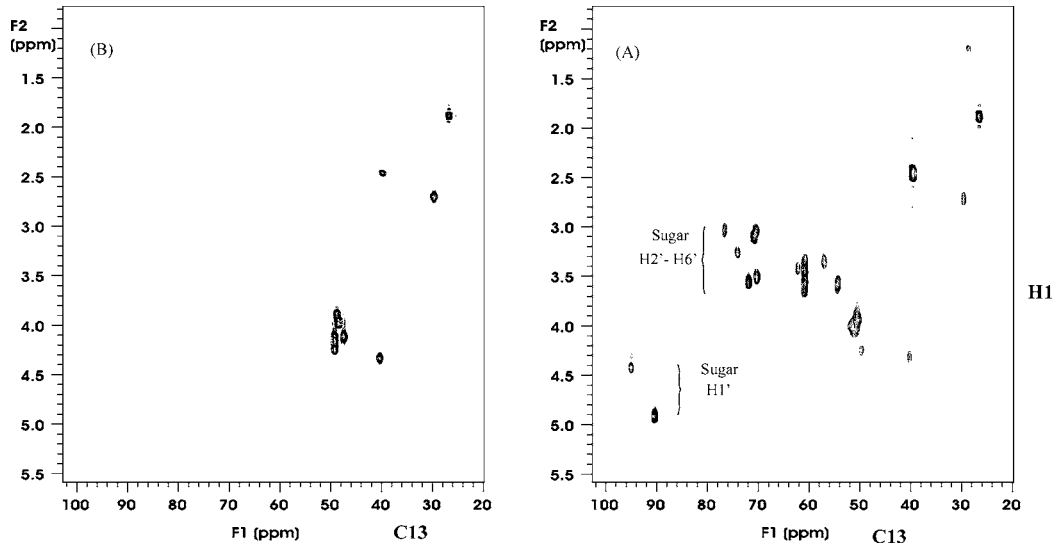

Figure 6. Expansions of the 600 MHz HMQC spectra of (a) compound **11** and (b) compound **5** in DMSO-d_6 at 25 °C.

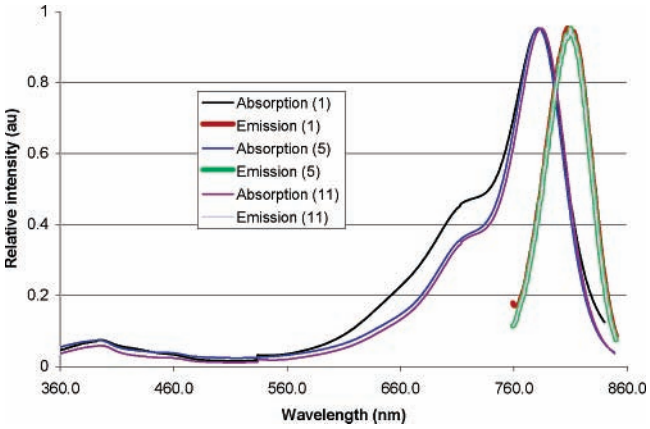

Figure 7. Normalized absorption and emission spectra of **1**, **5**, and **11** in 20% aqueous DMSO.

ates a mixture of byproducts that interfere with the spectral properties of the probe. Based on HPLC profile (not shown), the retention time of the byproducts (10.9 min), which increased in intensity as a function of time, is close to that of **5** (11.7 min) under the same HPLC condition, suggesting an incomplete hydrolysis of **11** toward the precursor probe **5**. However, **11** is most stable in PBS relative to **1** and **5** at room temperature after 96 h (Figure 8). This interesting observation indicates that the dendritic glucosamine probes can be formulated and stored in PBS for biological assays.

The results of the solution stability studies show that constructing multivalency on an inner chromophore core produced a robust NIR multivalent molecular probe (**5**) with exceptionally high stability in different mediums and at physiologically relevant temperatures, compared with the precursor dye (**1**). Stability of the dendritic array of biomolecules on the multivalent probes depends on the inherent stability of the biomolecule itself. In this study, the glucosamine cluster (**11**) is remarkably stable in acidic (dilute aqueous HCl) and buffered (PBS, pH 7.2) solutions but unstable under basic conditions.

Photostability Studies. Photostability studies were performed at a concentration of 5.56 μM in 20% aqueous

DMSO under three different conditions. A solution of the probe in a cuvette was (1) wrapped in aluminum foil and stored in a dark room, (2) placed on a laboratory shelf and exposed to normal fluorescent room light (condition A), and (3) exposed to a bright 60 W light bulb placed within 30 cm from the sample (condition B). UV−vis spectra were recorded at 0.5 h intervals for over 8 h under condition B and at 24 h intervals over one week for condition A. We found that the photophysical stability of all the molecular probes were identical. In the dark, the absorbance remained nearly constant for >1 week. Under fluorescent room light, no appreciable change in absorbance was observed for up to 24 h. However, the absorbance gradually decreased to 20% after 5 days. In contrast, all of the solutions were very unstable on exposure to bright light (Figure 10). The decrease in absorbance appears to follow a two-phase exponential model with a linear decay constant of about $-7.2\ s^{-1}$. The photostability data demonstrates that the multivalency does not protect the chromophore system from photodegradation and that the conventional storage in the dark is still recommended for the multivalent compounds. The observed decrease is probably due to photobleaching.

In Vivo Biodistribution. Glucose is the primary monosaccharide from carbohydrate digestion that is transported to cells to generate energy for normal physiological functions. Internalization of glucose in cells is typically mediated by glucose transporters (GLUTs) where it is phosphorylated by mitochondrial hexokinase (*21*). The metabolic fate of glucose hinges on the intricate interplay between extracellular glucose level, GLUTs and mitochondrial hexokinase. Abnormal, hypermetabolizing cells such as cancers, overexpress GLUTs to enhance this equilibrium-dependent glucose transport relative to normal surrounding cells. Therefore, molecules that are recognized by GLUTs but not further metabolized once internalized in cells accumulate in diseased tissues, thereby providing a method to image and treat pathologic tissues. This strategy is widely used to image hypermetabolizing cells by positron emission tomography after administering a radioactive glucose analogue, ^{18}fluorodeoxyglucose (^{18}FDG) to patients (*22*). Previous studies have shown that a fluorescent probe-labeled glucosamine derivative, 2-(*N*-(7-nitrobenz-2-oxa-1,3- diazol-4-yl)amino)-2-deoxyglucose (2-NBDG), is a viable nonradioactive method to monitor glucose transport and uptake in cells (*23*). More recent studies have shown that conjugation of glucosamine to NIR fluorescent dyes (*24*) or photosensitizers (*25*) results in high tumor uptake of the compounds. Although carbohydrates are known to interact strongly with their target via glycosidic clusters (*20*), these studies did not explore the potential beneficial effects of multivalency. Therefore, we evaluated the in vivo distribution of the NIR fluorescent dendritic arrays of glucosamine in highly proliferating pancreatic tumor (CA20948) bearing mice.

Each mouse received 0.3 μmol of the beacons per kg body weight of mouse via tail vein injection. The in vivo and ex vivo distribution of the molecular beacons were monitored by NIR fluorescence imaging using two collimated solid 780 nm laser sources for excitation and a CCD camera equipped with 830 nm interference filter to capture the fluorescence emission (*12*). At 24 h postinjection, the nude mice were sacrificed. Aliquots of blood and some major organs were harvested and washed with distilled water. The mean fluorescence count in each tissue was determined for each compound and normalized relative to 100% of the organ with highest fluorescence intensity (Figure 11). Negative control studies show that the precursor dye **1** was not retained in the tumor

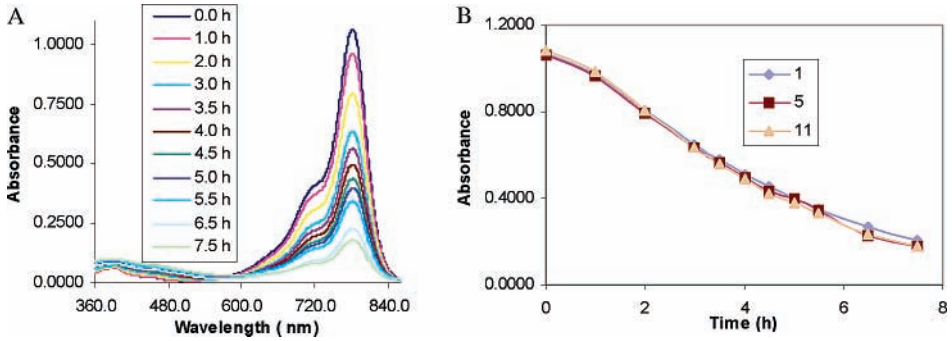

Figure 10. Spectra of the changes in the absorbance of **5** with time and (B) photostability of **1**, **5**, and **11** in 20% aqueous DMSO exposed to 60 W light bulb.

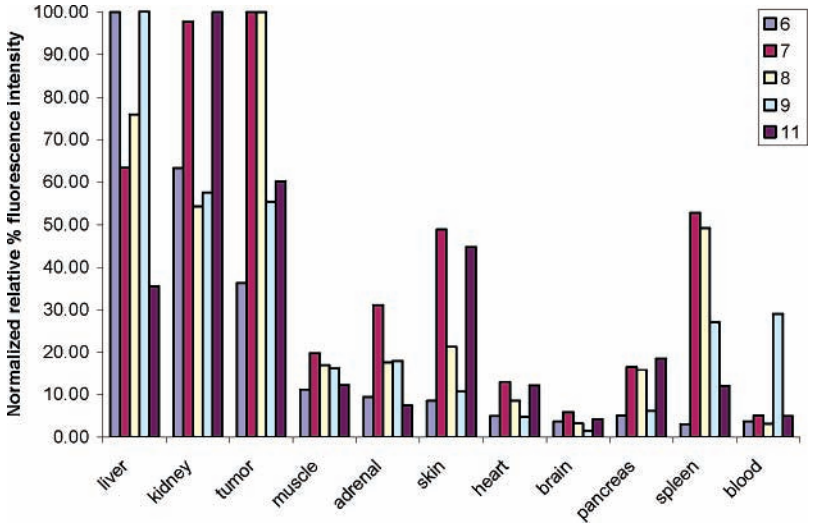

Figure 11. Biodistribution of dendritic arrays of glucosamine in CA20948 pancreatic tumor-bearing mice at 24 h postinjection of the probes.

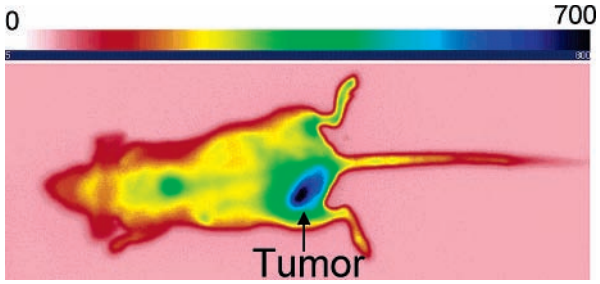

Figure 12. False color fluorescence image of compound **8** in CA20948 tumor-bearing nude mouse at 24 h postinjection of the probe.

but accumulated in the liver at about 1 h postinjection. This observation was also noted in previous studies with the same tumor model in male Lewis rats (*9*, *12*).

In contrast, all of the dendritic arrays of glucosamine were retained in the tumor up to 24 h postinjection (Figure 11). Compounds **7** and **8** have the highest tumor uptake at 24 h postinjection. However, the high retention of **7** in the skin increases background fluorescence, which is not desirable for noninvasive optical imaging. A significant amount of compound **9** is retained in blood at 24 h postinjection, making it the best agent for applications that require long-circulating probes with low skin uptake. The octaglucosamine probe (**11**) rapidly accumulates in the target tumor tissue within 6 h postinjection but at 24 h, the tumor uptake reduced to about 50% of the fluorescence intensity relative to the kidneys, which became the predominant retention organ. Surprisingly, the skin uptake of **11** was also high. Of all the glucosamine derivatives examined, the triglucosamine derivative (**8**) appears to have a good balance between high tumor uptake and decreased retention in nontarget tissues (Figure 12). Overall, there is an intricate relationship between the probe distribution and the multivalent compounds but the molecular basis for the selective uptake in some tissues is not clear at this time. Nonetheless, these results demonstrate that each compound can be used for different biomedical applications. For example, compound **9**, which is retained in blood for >24 h, could serve as a blood pool agent for monitoring blood flow and imaging blood vessels.

CONCLUSION

NIR carbocyanine dyes can effectively serve as optical scaffold for anchoring multiple functionalities and providing multivalency for molecular recognition studies. On the basis of the synthetic strategy developed, higher generations of the multivalent compounds are also accessible. Because the reactive functional groups are distal to the chromophore core, both multicarboxylate probes and their dendritic glucosamine derivatives have similar spectral properties, thereby improving data reproducibility and enabling the use of the same excitation source and filter for sample analysis. Photophysical stability studies show that neither the multivalent probes nor their corresponding dendritic array of biomolecules confer greater photostability to the chromophore core relative to the precursor dye. However, the multivalency appears to remarkably enhance the solution stability of the multicarboxylate probes in different mediums at physi-

ologically relevant temperatures. Overall, the stability studies provide guidance for reaction mediums and storage conditions. Biodistribution studies in tumor-bearing nude mice showed that all the glucosamine conjugates localized in the tumor but the precursor dye, cypate was almost exclusively retained in the liver. The pattern of probe distribution in various tissues suggests that each of the NIR fluorescent glucosamine derivatives could be useful for different but complimentary biological applications.

Maltose−polyrotaxane conjugates (Mal-PRXs), in which maltose-conjugated α-cyclodextrins (α-CDs) are threaded onto a poly(ethylene glycol) (PEG) chain capped with benzyloxycarbonyl-L-tyrosine, were characterized in terms of their molecular motion and the relation to multivalent interactions between the maltose moiety and concanavalin A from *Canavalia ensiformis* (Con A). Spin−lattice relaxation time (T_1) and spin−spin relaxation time (T_2) of α-CD C(1), maltosyl C(1), and PEG methylene protons in the Mal-PRXs revealed that the mobile motion of α-CDs in the polyrotaxane governed the molecular motion of maltosyl groups in α-CDs and threading PEG chain. The association constant (K_a) of the Mal-PRXs with 22, 38 and 53% of α-CD threading was 5.7×10^4, 1.1×10^6, and 5.3×10^5 (M^{-1}-maltose), respectively. The largest K_a value of the Mal-PRX with 38% of α-CD threading was well correlated with the T_1 and T_2 values of maltosyl groups and α-CD, suggesting that the mobile motion of maltose-conjugated α-CDs in the Mal-PRX contributes to the highest affinity with Con A. Initial rate of binding with Con A was also governed by the mobile motion of maltose-conjugated α-CDs. Therefore, we concluded that both highly molecular motion due to the mobile motion of maltose-conjugated α-CDs and multivalency of the Mal-PRXs contributes to inducing rapid Con A binding.

INTRODUCTION

Multivalent interactions between ligands and binding proteins have been extensively studied to obtain high association constants for targeting ligand−polymer conjugates to specific cells (*1*) and mimicking saccharide−protein interactions (*2*−*4*). Especially, saccharide−polymer conjugates enhance the interaction with concanavalin A (Con A), one of plant lectins from *Canavalia ensiformis*, resulting in the increased association constant (*5*−*7*). These effects are due to the multivalent interactions that are dependent on molecular weight (*8*), the number of ligands per one polymeric backbone (*9*), and flexibility of the polymeric backbone and linkers (*10*, *11*). In these factors, flexibility of the backbone and linkers is thought to be important because the flexible motion is considered to reduce steric hindrance of ligands toward the binding sites of lectins. Increasing the number of ligands per one polymeric backbone increases local density of the ligands, resulting in the enhanced opportunity of the multivalent interaction. Recently, architectural effects of the saccharide scaffolds on the multivalent interaction have been investigated (*12*) using linear neoglycopolymers (*9*), dendrimers (*13*, *14*), dendrigraft (*15*), nanoparticles (*16*), cyclic peptides (*17*), and cyclodextrins (CDs) (*18*, *19*). However, the increased local density and the number of saccharides often cause lectin recognition mismatching, so that reduction of the mismatching by the design of biomaterials is required to improve the multivalent feature.

To enhance the multivalent interaction, we have focused on mechanically locked structures of polyrotaxanes, in which many α-cyclodextrins (α-CDs) are threaded onto a poly(ethylene glycol) (PEG) chain capped with bulky end-groups (*20*). In our previous study, the mechanically locking structure of polyrotaxane is utilized for the conjugation of biotin (*21*, *22*) and a valyl-lysine dipeptide (*23*), and each conjugate is multivalently recognized by a streptavidin and peptide transporter, respectively. Moreover, maltosyl groups are successfully introduced to the polyrotaxane with a different number of α-CDs for multivalent interaction with Con A. When the threading percentage of α-CDs against the stoichiometric number was 38%, the highest mobility of maltosyl groups is observed, which demonstrates the highest relative potency of Con A-induced hemagglutination (*24*). Also, the maltose−polyrotaxane conjugate (Mal-PRX) with a highly mobile nature maintains water cluster structure that is clarified by Raman spectroscopy (*25*). Those findings suggest that the Mal-PRXs seem to be inert in aqueous solution, and the high mobility of maltosyl groups allows multivalent interaction. However, it has been unclear how the molecular motions of both α-CDs and PEG in the Mal-PRXs are related to the highly molecular motion of the maltosyl group. Moreover, the data of Con A-induced hemagglutination did not give us the direct binding aspects with Con A.

In this study, we examined Mal-PRXs in detail to understand the close relationship between whole molecular motions of the polyrotaxane backbone and multivalent binding with Con A. Molecular motion of maltosyl groups, α-CDs, and PEG in the Mal-PRXs was analyzed by spin−lattice relaxation time (T_1) and spin−spin relaxation times (T_2), and we discuss how the α-CD threading percentage in the Mal-PRXs affects the whole

molecular motion. Association constants (K_a) and initial binding rate of the multivalent interaction between the Mal-PRXs and Con A are estimated, and we also discuss in detail how the molecular motions of maltosyl groups, α-CDs, and PEG in the Mal-PRXs take part in the multivalent interaction.

MATERIALS AND METHODS

Materials. α-Cyclodextrin (α-CD) was purchased from Bio-Research Corporation of Yokohama (Yokohama, Japan). Poly(ethylene glycol) (PEG, M_n = 20 000), poly(acrylic acid) (PAA, M_n = 25 000) and *N,N*-diisopropylethylamine (DIEA) were purchased from Wako Pure Chemical Co. Ltd (Osaka, Japan). α,ω-Diamino PEG was synthesized according to previously reported method via tosylation, phthalimidation, and its hydorazine substitution (*26*). Benzotriazol-1-yloxytris(dimethylamino)phosohonium hexafluorophosphate (BOP reagent) and 1-hydroxybenzotriazole (HOBt) were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Benzyloxycarbonyl-L-tyrosine (Z-L-Tyr) was purchased from Kokusan Chemical Co., Ltd (Tokyo, Japan). Concanavalin A (Con A) from *Canavalia ensiformis* was purchased from Sigma Co. (MI). Fluorescein-labeled Con A was purchased from Vector Laboratories, Inc. (CA). Other chemicals used were of highest purity available.

Measurements. Gel permeation chromatography (GPC) was carried out using GPC columns TSK_{gel} G-5000H_{HR} + TSK_{gel} G-3000H_{HR} (Tosoh Co. Ltd., Tokyo, Japan) using DMSO (HPLC grade, Kishida Chemical Co. Ltd., Osaka, Japan) as the eluent. The eluent was detected with a chiral detector (OR-990, Japan Spectroscopic Co., Ltd., Tokyo, Japan). ^{1}H NMR spectra were recorded on a 750 MHz FT-NMR spectrometer (Varian, Unity plus, CA). Turbidity change at 420 nm was recorded on a UV−vis spectrometer (V-550, Japan Spectroscopic Co., Ltd., Tokyo, Japan). Fluorescent spectra were recorded on a spactrofluorometer (FP-777, Japan Spectroscopic Co., Ltd., Tokyo, Japan).

Synthesis of Maltose−Polyrotaxane Conjugates (Mal-PRXs, 1−3) (24). Polypseudorotaxanes (inclusion complex of α-CDs and α,ω-diamino PEG, M_n: 20 000) were prepared according to the previously reported procedure by Harada et al. (*20*). The number of threading α-CD was calculated to be ca. 120 from ^{1}H NMR spectra, comparing the integrations of the signals at 4.8 ppm (C(1)H of α-CD) with those at 3.5 ppm (CH_2 of PEG).

The synthetic method of Z-Tyr-terminated PRXs was followed by our previous report with some modifications (*24*). To introduce Z-L-Tyr as the terminal groups of polyrotaxanes, a condensation reaction was carried out. Z-L-Tyr (3.9 g, 12.4 mmol), BOP (5.5 g, 12.4 mmol), HOBt (1.9 g, 14.0 mmol), and DIEA (2.2 mL, 12.4 mmol) were dissolved in dry DMF (10 mL). The solution was added to a suspension of the polypseudorotaxane (85 g, 0.62 mmol) in a mixture of DMF and DMSO (40 mL), and the reaction mixture was stirred at room temperature for 6 h. Here, volume ratio of DMF and DMSO (DMF/DMSO) was varied so as to be 85/15, 90/10, and 100/0. After that, the mixture was poured into excess acetone to precipitate crude products and to remove BOP, HOBt, DIEA, and unreacted α,ω-diamino PEG. The precipitate was collected by centrifugation and washed with ethanol and pure water to remove impurities including free α-CDs. The resulting precipitate was dried in vacuo at room temperature to obtain Z-Tyr-terminated PRXs as white powders. By changing the DMF/DMSO from 85/15 to 100/0, the number of α-CDs was varied to be ca. 50, 85, and 120, respectively, which was calculated by ^{1}H NMR spectra. The obtained Z-Tyr-terminated PRXs were soluble only in DMSO.

To introduce carboxyl groups to hydroxyl group of α-CDs in Z-Tyr-terminated PRXs, carboxyethyl ester PRXs (CEE-PRXs) were prepared using the Z-Tyr-terminated PRXs according to our method (*24*). The Z-Tyr-terminated PRXs and succucinic anhydride (same mol. of hydroxyl groups in the Z-Tyr-terminated PRXs) were dissolved in dry pyridine and stirred at room temperature. The reaction mixture was poured into excess ether and washed with ether three times. The precipitate was collected by centrifuging and dried in vacuo to give the CEE-PRXs. The degree of substitution of CEE groups in the polyrotaxane was estimated from the ratio of the methylene peak of CEE (2.3 ppm) and C(1)H of α-CD (4.9 ppm) on ^{1}H NMR spectra. In this synthetic condition, all the primary hydroxyl groups were converted to the CEE, i.e., the number of CEE per one α-CD molecule was ca. 6.

Finally, maltosyl groups were introduced to CEE groups in the CEE-PRXs (Scheme 1). β-Maltosylamine (Mal-amine) was prepared by the method of Kobayashi et al. (*27*) (yield: 85%). The CEE-PRXs (concentrated of CEE: 3.0 mM) were dissolved in dry DMSO. A solution of BOP, HOBt, and DIEA in DMSO (6.0 mM each) was added to the solution. The reaction mixture was stirred at 25 °C for several minutes. Then, Mal-amine in DMSO was added (final concentration of Mal-amine: 8.8 mM) and stirred at 25 °C for 10 h. The solution was poured into an excess acetone, and then the crude products were purified by dialysis against water using Spectra/Por CE 6 (MWCO: 8000) to obtain the maltose-polyrotaxane conjugates (Mal-PRX, **1**−**3**) as white powders (yields: 70−80%).

In a similar manner, a maltose−α-CD conjugate (Mal-CD, **4**) and maltose−poly(acrylic acid) conjugates (Mal-PAA, **5**) were synthesized. α-CD (2.5 g, 2.6 mmol) and succinic anhydride (8.2 g, 54.6 mmol) were dissolved in dry pyridine (100 mL) and stirred for 24 h at room temperature. The reaction mixture was poured into excess ether. The precipitate was collected by centrifuging and dried in vacuo to give a crude product. The crude product was dissolved in distilled water. The solution was dialyzed in distilled water for 3 days using Spectra/Por CE (MWCO = 500) and then lyophilized to obtain CEE-α-CD (the number of CEE per one α-CD molecule was ca. 6). Finally, Mal-amine (2.0 mM) was introduced to the CEE-α-CD (concentrated of CEE: 3.8mM) in the presence of BOP, HOBt, and DIEA in DMSO (4.6 mM each) as well as the Mal-PRXs. As for the Mal-PAA **5**, Mal-amine (8.8 mM) was introduced to the PAA (concentrated of carboxyl groups: 7.0 mM) in the presence of BOP, HOBt, and DIEA in DMSO (17.5 mM each).

The degree of substitution of maltose in the polyrotaxane was calculated from the ratio of the C(1)H and C(1′) of maltose (2H, 5.3 ppm) and C(1)H of α-CD (1H, 4.9 ppm) on the ^{1}H NMR spectra. Average molecular weights of the Mal-PRXs **1**−**3** and the Mal-PAA **5** were calculated by ^{1}H NMR and GPC. As for the GPC, both the number average molecular weight (M_n) and the weight average molecular weight (M_w) were calculated from a calibration curve of pullulan standard. The M_w of the Mal-CD **4** was determined by MALDI-TOF mass spectrum using Voyager-DE2RP (PE Biosystems, Foster city, CA) in linear mode. Samples for mass spectrum were prepared by casting the matrix compound (2,5-dihydroxyacetophenone) with the Mal-CD **4** (0.2 mg/mL in water) onto the

5: ^{1}H NMR [750 MHz, D_2O containing 0.05v/v % *t*-BtOH ppm]: *δ* 8.1−7.3 (d, NH's), 5.3 (C(1)H and C(1′)H of maltose, d, 470 H), 4.2−3.2 (C(3)H, C(3′)H, C(5)H, C(5′)H, C(6)H, C(6′)H, C(4)H, C(4′)H, C(2)H and C(2′)H of maltose, m, 2820 H), 3.7 (CH of PAA, s, 87 H), 1.9 (CH of PAA, s, 174 H).

^{1}H NMR Spin−Lattice Relaxation Time (T_1) and Spin−Spin Relaxation Time (T_2). The Mal-PRXs were dissolved in 0.1 M phosphate buffer (pH 7.4, D_2O + 0.02 M NaH_2PO_4 + 0.08 M Na_2HPO_4 + 0.1 mM $CaCl_2$ + 0.1 mM $MgCl_2$). ^{1}H NMR spin−lattice relaxation times (T_1) C(1)H of maltosyl groups, C(1)H of α-CDs, and methylene of PEG were determined by inversion−recovery method, using the pulse sequence 180°− t−90°−acquire, where t is a variable delay. ^{1}H NMR spin−spin relaxation times (T_2) of C(1)H of maltosyl groups, C(1)H of α-CDs, and methylene of PEG were determined by the Carr−Purecell−Meiboom−Gill (CPMG) method. The ^{1}H CPMG spectra measurements were performed using the standard $\pi/2\text{-}[\tau-\pi-\tau]_n$ CPMG sequence at room temperature.

Fluorescent Assay for Multivalent Interaction between Mal-PRXs and Con A. Aliquots (1 μL) of a stock solution of the conjugates (0.75 mM as maltose units) were added every 15 min to a solution of fluorescein-labeled Con A (5.9×10^{-7} mmol/1.5 mL, 393 nM) in the PBS (pH 7.4) containing 0.1 mM $CaCl_2$ + 0.1 mM $MgCl_2$. Fluorescence intensity at 520 nm was measured with excitation at 490 nm at 25 °C.

Turbidity Assay. One mL of Con A dissolved in the PBS (0.8 mg/mL, 7.97 μM) was added to a cuvette. A solution of the 20 mM per maltose residue dissolved in the PBS was added. Absorbance at 420 nm was recorded for 20 min.

Inhibition of Con-A-Induced Hemaggulutination (24). To evaluate how the number of maltosyl groups per α-CD molecule in the series of Mal-PRXs, Mal-PRXs **1**−**3** with different number of maltosyl groups were prepared by changing the feed ratio of Mal-amine and CEE-PRXs (*24*). The concentration of Con A was fixed to be 4-fold minimum concentration required for hemagglutination of erythrocyte (*28*), Twenty microliters of a 3% erythrocyte (rat blood) suspension in a 0.1 M phosphate buffer (PBS, pH7.4) containing 0.1 mM $CaCl_2$ and 0.1 mM $MgCl_2$ was pipetted into each well of the 2-fold dilution series of Con A (20 μL) in 96-holes microtiter plate and incubated at 37 °C for 1 h. The minimum concentration of Con A was determined, and its 4-fold concentration was used for the following Con A-induced hemaggultination assay.

An aliquot (20 μL) of Con A (7.83 μg/mL) in the buffer was added to each hole of 96-holes microtiter plates. The malotose conjugates dissolved in the buffer with various concentrations were added to the each hole (20 μL) and incubated at 37 °C for 1 h. Then, 3% erythrocyte suspension (40 μL) was added to the holes and incubated at 37 °C for 1 h. Agglutination of erythrocytes was observed, and the minimum concentration (MIC) of maltose was determined. All the experiments were carried out triplicate.

RESULTS AND DISCUSSION

Synthesis, Characterization and Molecular Motion of Mal-PRXs. A variation of the Mal-PRXs **1**−**3** with different number of threading α-CDs (no. of CDs: 50, 85, and 120) and the same number of maltose (ca. 230−240) was prepared using PEG with M_n of 20 000 (Table 1). If α-CDs are stoichiometrially threaded onto a PEG chain, two ethylene glycol units should be included in each α-CD cavity (*20*). Since the stoichiometric number is ca. 227 for PEG with M_n of 20 000, the threading % of α-CDs in Mal-PRX **1**, **2**, and **3** were 22, 38, and 53%, respectively. The obtained data of M_n from the GPC were well consistent with those from ^{1}H NMR, suggesting that the M_n calibrated by pullulan did not include any artifacts of the instruments such as pressure variations.

Our previous studies of the Mal-PRXs regarding the molecular motion of maltosyl groups suggest that highly flexible motion of maltosyl groups in the Mal-PRX **2** dominates the multivalent recognition of Con A (*24*). However, it has been unclear that the relation between the molecular motion of maltosyl groups and mechanically locking structure between α-CDs and PEG. ^{1}H NMR relaxation studies of each component (maltose, α-CDs, and PEG in the Mal-PRXs **1**−**3**) can provide information of the mobility in solution, because the relaxation parameters have long been used to provide a dynamic description of biomacromolecules such as protein structures (*29*). Table 2 summarizes the results of T_1 and T_2 values of C(1)H of maltosyl groups, C(1)H of α-CD, and methylene groups of PEG in the Mal-PRXs **1**−**3**. T_1 has been used for analyzing molecular motion of CDs before and after including guest molecules (*30*), and longer T_1 values of CDs in the presence of guest molecules suggest the decreased molecular motion of CDs due to locating the guest molecules in the cavity. The Mal-PRX **1** (α-CD threading: 22%) and **3** (α-CD threading: 53%) were longer in the T_1 values of both C(1)Hs of maltosyl groups (2.31 and 2.42 s) and α-CD (3.85 and 3.63 s) than those of Mal-PRX **2** (α-CD threading: 38%) (1.46 and 3.09 s). Since the Mal-CD **4** showed smaller T_1 values (1.42 and 1.37 s) than the Mal-PRXs, the larger T_1 values of the Mal-PRXs **1** and **3** seem to indicate slower motion of both maltosyl groups and α-CDs. On the other hand, T_1 values of PEG showed similar motion (Table 2). Thus, the T_1 values were one of good parameters to discuss the molecular motion of Mal-PRXs. However, it is still difficult to image how the molecular motions of maltosyl groups, α-CDs, and PEG are related to each other. Since T_2 values are strongly influenced by heterogeneous conditions of magnetic fields, which is related to solubility, association, molecular motion, and so on, T_2 can also give us important information of molecular motion. The Mal-PRX **2** was much longer in the T_2 value of C(1)H of α-CD than the others. Similar tendency was observed for the T_2 value of C(1)H of maltosyl groups (Table 2). In addition, the Mal-PRX **2** exhibited almost the same T_2 as the Mal-CD **4** (*24*). Generally, slow molecular motions in magnetic fields show longer and shorter T_1 and T_2 values, respectively, while fast motions show both longer values. Therefore, the difference between T_1 and T_2 values ($T_1 - T_2$) should provide the real information of molecular motions: big difference between T_1 and T_2 values indicates slow molecular motions. As shown in Figure 1, $T_1 - T_2$ of both C(1)Hs of maltosyl groups and α-CDs in the Mal-PRX **2** was smaller than the Mal-PRXs **1** and **3**. On the other hand, $T_1 - T_2$ of C(1)H maltosyl groups in the Mal-PAA **5** showed the largest value of all the sample series. These results indicate that the mobile motion of α-CDs in the polyrotaxane governed the molecular motion of maltosyl groups in α-CDs, and the mechanically locking structure between maltose-conjugated α-CDs and PEG contributes to increasing the mobility of maltosyl groups. Contribution of α-CD-mobile motion was discussed from the relation between C(1)Hs of α-CDs and maltosyl groups or methylene groups of PEG (Figure 2). As mentioned above, T_2 values of C(1)H maltose was increased with C(1)H α-CDs, suggesting

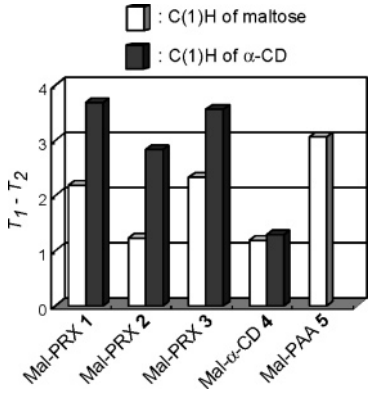

Figure 1. The difference between T_1 and T_2 values ($T_1 - T_2$) of C(1)H of maltosyl groups and α-CDs in the Mal-PRXs **1**−**3**, the Mal-α-CD **4**, and the Mal-PAA **5**.

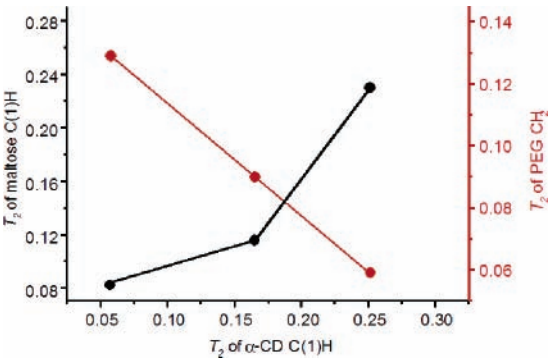

Figure 2. The relation of T_2 values of C(1)Hs of α-CDs with those of maltosyl groups and methylene groups of PEG.

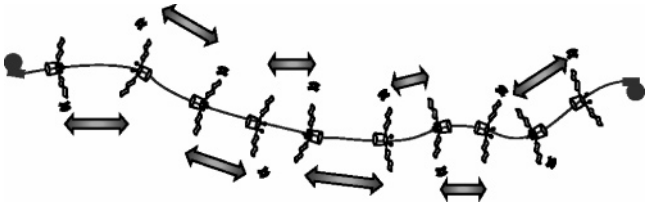

Figure 3. Image of molecular motion of the Mal-PRX **2** based on the results of ^{1}H NMR relaxation studies.

both the mobile motions are not independent. On the other hand, T_2 values of PEG methylene groups was inversely proportional to the values of C(1)H α-CDs, This means that PEG molecule existed in magnetically heterogeneous conditions with increasing the molecular motion of maltose governed by the mobile motion of α-CDs. Therefore, it can be speculated that the highest mobile motion of maltose-conjugated α-CDs in the Mal-PRX **2** is sliding along the PEG chain with diffusion of the Mal-PRX **2** itself (Figure 3). With increasing the α-CD threading % (the Mal-PRX **3**), some intra- and/or intermolecular hydrogen bonds between the maltose-conjugated α-CDs are likely to occur, resulting in the decreased motion of maltose-conjugated α-CDs and the increased motion of the exposed PEG. With a decrease of the α-CD threading % (the Mal-PRX **1**), it is supposed that the terminal Z-L-Tyr moieties intermolecularly associate, because an increase in hydrophilically modified α-CD threading in polyrotaxanes contributes to decreasing association number in water (*31*). Such an association may become slower the molecular motions of the Mal-PRX **1** in comparison with the Mal-PRX **2**.

Affinity of Mal-PRXs to Con A. Our previous results of Con A-induced hemagglutination of the Mal-PRXs (*24*) made us hypothesize that Con A bound effectively with

Table 3. K_a for the Binding of Con A with Mal-PRXs 1−3, Mal-α-CD 4, and Mal-PAA 5 at 25 °C

sample code	K_a ($\times 10^3$ M^{-1})
Mal-PRX,**1**	57
Mal-PRX,**2**	1100
Mal-PRX,**3**	530
Mal-CD, **4**	3.0
Mal-PAA,**5**	140
maltose	1.1[a]

[a] Determined by isothermal titration calorimetry (ITC). In ref 34, 1.2×10^3 M^{-1}.

maltosyl groups of the Mal-PRX **2** via highly molecular motion of maltosyl group. As mentioned in the previous section, highly mobile motion of α-CDs dominated the highly molecular motion of the maltosyl group in the Mal-PRX **2**. Therefore, determination of association constant (K_a) will provide us the direct evidence of the mobile effect on Con A binding. The K_a of the multivalent interaction between the Mal-PRXs and Con A was quantitatively determined by fluorescent assay using fluorescein-labeled Con A. The addition of an increasing amount of the Mal-PRXs decreased the fluorescent intensity of fluorescein at 520 nm. The decrement of fluorescence intensity ($\Delta F/F_0$) was plotted against the concentration per maltose unit of the conjugate. Apparent K_a was calculated by the following equation (*10*, *32*):

$$\frac{F_0}{\Delta F}[\text{maltose}] = \frac{F_0}{\Delta F_{max}}[\text{maltose}] + \frac{F_0}{\Delta F_{max} K_a}$$

where [maltose] was the concentration of maltose (M). The obtained K_a values of the multivalent saccharides (the Mal-PRXs **1**−**3** and the Mal-PAA **5**) were summarized in Table 3. The K_a values of the Mal-PRXs **1**−**3** and the Mal-PAA **5** (the number of maltose: 230−240) were 1−3 powers higher than those of monomeric compound (maltose), indicating the multivalent effect. The Mal-CD **4** displayed three maltosyl groups in one conjugate. The magnitude of the power in the Mal-CD **4** was the same with maltose, indicating that the oligomeric number of maltose conjugation is not effective for the affinity to Con A. The K_a values of the Mal-PRX **1**, **2**, and **3** were 5.7×10^4, 1.1×10^6, and 5.3×10^5 (M^{-1}-maltose), respectively. This result indicates that the K_a values of the Mal-PRX **1**, **2**, and **3** were 52, 1000, and 480 times higher than maltose. Since the number of maltosyl groups per one Mal-PRX molecule is similar level (230−240), the number of maltosyl groups in the Mal-PRXs should not be the main factor of the difference. The most considerable factors are local density of maltose and mobile motion of maltose-conjugated α-CDs in the Mal-PRXs. The K_a value of the Mal-PRX **1** seems to be too small compared with the Mal-PRX **3**, because the Mal-PRX **1** showed similar degree of the molecular motions with the Mal-PRX **3** (Figure 1). The number of maltose per one α-CD molecule in the Mal-PRX **1**, **2**, and **3** was 4.6, 2.9, and 2.0, respectively, so that the local density of maltosyl groups attached to α-CD molecule in the Mal-PRXs is the considerable factor. To evaluate the influence of the local density, the Mal-PRXs **1**−**3** with different number of maltosyl groups were prepared and examined the inhibition of Con A-induced hemagglutination. The hemagglutination assay is useful for the evaluation of the difference in the number of ligands (*11*). As shown in Figure 4, the relative potency, calculated from the minimum inhibition concentration, of the Mal-PRX **2** was increased with the number of maltosyl groups per one α-CD molecule and reached to the highest value

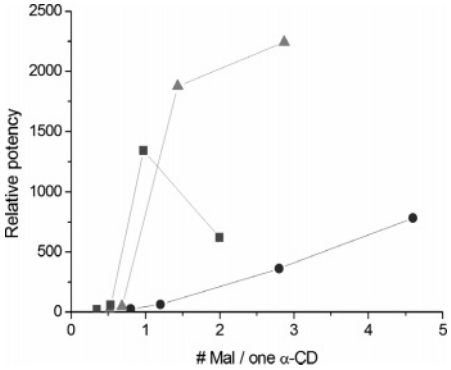

Figure 4. Dependence of hemagglutination inhibition on the number of maltosyl groups per α-CD. (closed circle): the Mal-PRX **1**. (closed triangle): the Mal-PRX **2**, (closed square): the Mal-PRX **3**.

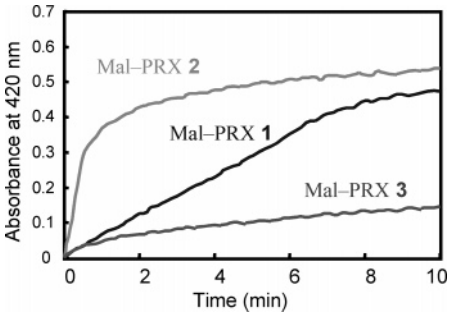

Figure 5. Time course of turbidity measurements in a 0.1 M phosphate buffer containing 0.1 mM $CaCl_2$ and 0.1 mM $MgCl_2$ (pH 7.4) at 25 °C. Concentration of Con A and the Mal-PRX was 7.97 μM and 20 mM maltose units, respectively.

at the 2.9 maltosyl groups per one α-CD molecule. The relative potency of the Mal-PRX **3** was increased with the number up to 1.0 and then was decreased with a further increase in the number. These results suggest that the decrease in the relative potency of the Mal-PRX **3** is due to steric hindrance: all the maltosyl groups cannot necessarily bind to the binding sites of Con A. However, such the steric hindrance in the Mal-PRX **2** was eliminated, presumably due to the highly mobile motion of maltose-conjugated α-CDs (Figures 1 and 2). On the other hand, the relative potency of the Mal-PRX **1** was smaller than the Mal-PRXs **2** and **3** and proportionally increased with the number of maltosyl groups per one α-CD molecule. This result suggests that the molecular motion of the Mal-PRX **1** do not reflect the inhibition of Con A-induced hemagglutination, and the steric hindrance from the number of maltose per one α-CD molecule was small. Presumably, intra- and/or intermolecular association of Mal-PRX **1** due to smaller number of threading α-CD as mentioned before exists, and therefore the Mal-PRX **1** showed the smallest K_a value.

Initial Rate of Binding with Con A. Turbidimetric assay is one of good methods to monitor the rate of lectin clustering with saccharide derivatives (*9*, *33*, *34*). After mixing the solution of the Mal-PRXs and Con A, the absorbance was increased with a certain rate and then slowly increased (Figure 5). The increased absorbance means the cross-linking of the Mal-PRXs with Con A under high concentrations of both the Mal-PRXs and Con A. It is known that a change in the initial rate of turbidity is directly related to Con A clustering mediated by saccharide-based multivalent polymers (*9*). From the initial binding curve in Figure 5, the absorbance of the Mal-PRX **2** was increased and reached to 0.3 within 0.6 min while the time to finish the initial binding of the Mal-PRX **1** and **3** was 7.5 and 0.7 min, respectively. Since the large value of the absorbance (turbidity) shows the formation of higher order and cross-linked structure (*9*), the Mal-PRX **2** is considered to be rapidly cross-linked with Con A with high order. The cross-linking between the Mal-PRX **2** and Con A was faster than the Mal-PRX **1**, but the extent of cross-linking seems to be the same level with the Mal-PRX **2**. This result indicates that the Mal-PRX **2** is superior to the Mal-PRX **1** in terms of rapid formation of the high order-cross-linking structure. On the other hand, the extent of cross-linking between the Mal-PRX **3** and Con A was very small (Figure 5). This result suggests that the Mal-PRX **3** is intramolecularly cross-linked with Con A compared with the Mal-PRXs **1** and **2**.

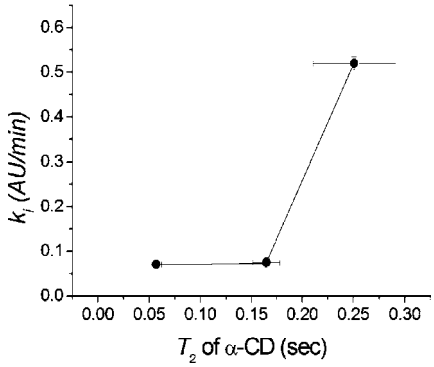

Figure 6. Initial rate of precipitation (k_i) as a function of T_2 values of α-CD C(1)H in the Mal-PRXs.

Table 4. Initial Rate of Con A Precipitation (k_i) Using Mal-PRXs

sample code	k_i (AU/min)
Mal-PRX, **1**	0.075 ± 0.011
Mal-PRX, **2**	0.52 ± 0.015
Mal-PRX, **3**	0.071 ± 0.004

To qualify the initial rate for binding, initial rate of the precipitation (k_i) was calculated using following equation:

$$k_i = \mathrm{abs}_{420}/\mathrm{min}$$

Table 4 shows the k_i of the Mal-PRXs **1**–**3**. The k_i of the Mal-PRX **2** showed the highest value, even in the same number of maltosyl groups per one conjugate with the Mal-PRXs **1** and **3**. Figure 6 shows the relationship between T_2 values of C(1)H of α-CD in each conjugate and k_i. Similar relationship between the T_2 values of C(1)H of maltosyl groups and Con A was observed (data not shown). Thus, the mobile motion of maltose-conjugated α-CDs in the Mal-PRX **2** contributes to the highest binding rate with Con A.

CONCLUSIONS

Maltose–polyrotaxane conjugates (Mal-PRXs) with the same number of maltose (230–240) and different α-CD threading percentage (22, 38, and 53%) were examined to clarify the molecular motion of the Mal-PRXs and those relations to Con A binding. ^{1}H NMR relaxation time analysis revealed that the mobile motion of α-CDs in the polyrotaxane governed molecular motion of the maltosyl group in α-CDs and threading PEG chain. The largest K_a value of the Mal-PRX **2** was well correlated with large T_1 and T_2 values of maltosyl groups and α-CD, suggesting that mobile motion of maltose-conjugated α-CDs in the Mal-PRX contributes to the highest affinity with Con A.

Highly mobile motion of maltose-conjugated α-CDs in the Mal-PRX **2** is likely to enhance initial rate of binding with Con A. Therefore, it is concluded that the mobile motion due to the mechanically locking structure plays a key role for inducing rapid multivalent interaction.

Received August 28, 2004; Revised Manuscript Received October 28, 2004

Human estrogen receptor-positive breast cancer cells typically display elevated levels of Myc protein due to overexpression of *MYC* mRNA, and elevated insulin-like growth factor 1 receptor (IGF1R) due to overexpression of *IGF1R* mRNA. We hypothesized that scintigraphic detection of *MYC* peptide nucleic acid (PNA) probes with an IGF1 peptide loop on the C-terminus, and a [^{99m}Tc]chelator peptide on the N-terminus, could measure levels of *MYC* mRNA noninvasively in human *IGF1R*-overexpressing MCF7 breast cancer xenografts in nude mice. We prepared the chelator-*MYC* PNA-IGF1 peptide, as well as a 4-nt mismatch PNA control, by solid-phase synthesis. We imaged MCF7 xenografts scintigraphically and measured the distribution of [^{99m}Tc]probes by scintillation counting of dissected tissues. MCF7 xenografts in nude mice were visualized at 4 and 24 h after tail vein administration of the [^{99m}Tc]PNA probe specific for *MYC* mRNA, but not with the mismatch control. The [^{99m}Tc]-probes distributed normally to the kidneys, livers, tumors, and other tissues. Molecular imaging of oncogene mRNAs in solid tumors with radiolabel-PNA–peptide chimeras might provide additional genetic characterization of preinvasive and invasive breast cancers.

INTRODUCTION

MYC was one of the first proto-oncogenes to be identified (*1*), and *MYC* was the first oncogene to be inhibited by antisense oligonucleotides, blocking the transition from G1 to S phase in normal peripheral blood mononuclear cells (*2*) and in promyelocytic leukemia cells (*3*). *MYC* mRNA and Myc protein are overexpressed in a variety of cancers, including breast (*4*), bladder (*5*), kidney (*6*), lung cancer (*7*), and lymphoma (*8*). *MYC* antisense oligonucleotides were able to ablate Myc protein levels in peripheral blood mononuclear cells of Eμ-*myc* transgenic mice (*9*), delay the onset of congenital lymphoma in Eμ-*myc* transgenic mice (*10*), and delay the proliferation of Eμ-*myc* lymphoma cells transplanted into congenic parental mice (*11*). Similarly, in patients with advanced solid tumors, a phase I trial of our *MYC* antisense oligonucleotide sequence, combined with cisplatin, revealed no significant toxicity at therapeutic doses, and displayed clinical responses in ovarian and colorectal cancer (*12*).

Myc is a nuclear phosphoprotein in the basic/helix-loop-helix/leucine zipper family of transcription factors that associates with Max to activate proliferative genes (*13*). Myc protein accelerates cells into S phase by induction of cyclin D1 (*14*), which increases shortly after estrogen induction of *MYC* mRNA expression in mammary cells (*15*) via an atypical estrogen response element (*16*).

As a corollary of *MYC* overexpression in breast cancers (*4*), *MYC* antisense oligonucleotides inhibited estrogen-stimulated MCF7 breast cancer cell proliferation, as well as the estrogen-independent MDA-MB-231 breast cancer line (*17*). Correspondingly, induction of *MYC* expression in antiestrogen-arrested cells mimicked the effects of estrogen by reinitiating cell cycle progression (*18*), while constitutive overexpression of Myc protein conferred resistance to antiestrogen treatment in human MCF7 breast cancer cells (*19*). In the cell signaling pathway, antisense inhibition of *MYC* mRNA in MCF7 breast cancer cells inhibited cyclin D1 expression and cell proliferation (*15*, *20*), even though *MYC* gene induction did not increase cyclin D1 expression. Thus, while cyclin D1 expression is dependent on Myc protein, *MYC* gene expression is not limited by cyclin D1.

Clinical examination and mammography, the currently accepted breast cancer screening methods, miss almost half of breast cancers in women younger than 40 years, approximately one-quarter of cancers in women aged 40–49 years, and one-fifth of cancers in women over 50 years old (*21*). The breast is the most common site of noncutaneous cancer in US women (*22*). Moreover, if an abnormality is found, an invasive diagnostic procedure must still be performed to determine if the breast contains atypia or cancer. Despite recent improvements in BI-RADS standardization of mammography (including the use of two views of the breast rather than one, spot compression, and digital images) that have improved sensi-

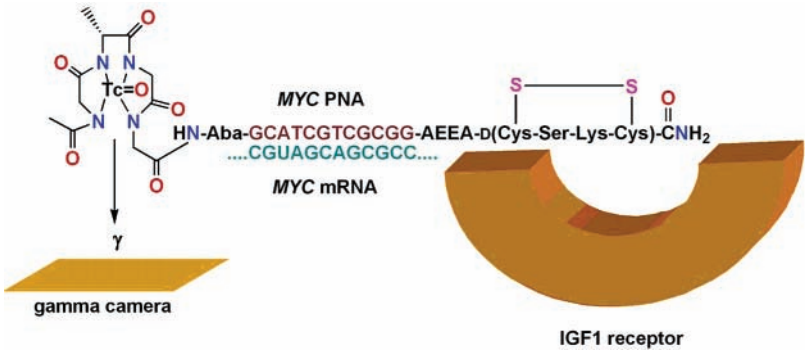

Figure 1. [^{99m}Tc]AcGlyD(Ala)GlyGlyAba-*MYC* PNA-AEEA-D(CysSerLysCys), WT4219, designed to bind to the receptor for IGF1, internalize, and hybridize with *MYC* mRNA. Scintigraphic imaging of γ-particles emitted upon decay of ^{99m}Tc might identify sites of high *MYC* mRNA expression.

tivity and specificity (*23*), 66−85% of women with suspicious mammograms who undergo surgery are found to have a benign abnormality (*24*). In many other patients recently determined to have a benign mammogram, clinical examination reveals a mass found to be malignant.

A noninvasive method to evaluate women for the presence of atypia and/or cancer of the breast would be very beneficial. SestaMIBI has demonstrated utility in imaging lesions in a dense breast, but is limited by the fact that other cell types with high mitochondrial activity avidly take up the tracer, leading to false positive results in breasts with inflammation/infection (*25*), false negatives due to sensitivity limits of the technology, in which tumors <8 mm in diameter are difficult to visualize (*26*), and the potential for false negatives with well differentiated, slowly growing tumors due to their lower mitochondrial content.

Recent evidence from gene expression profiling suggests that alterations in mRNA conferring the potential for invasive breast cancer are already present in preinvasive disease, supporting the rationale for this approach (*27*). However, transcription profiles of breast cancer tissue by microarray analysis have not yet identified detectable overexpression of those markers (*28*), and that approach requires an invasive biopsy. As a step in characterizing preinvasive disease, such as ductal carcinoma in situ, it might be helpful to identify sites of *MYC* overexpression externally, without a biopsy.

Therefore, we hypothesized that noninvasive imaging of a radiolabeled oligonucleotide hybridized to *MYC* mRNA inside breast cancer cells might identify sites of neoplastic transformation. Previously, a [^{99m}Tc]6-hydrazinonicotinate-conjugated *MYC* antisense oligonucleotide phosphorothioate failed to show differences in uptake among cell lines with high, normal, or low levels of *MYC* mRNA (*29*). Those negative results might have been due to nonspecific affinity of phosphorothioate oligonucleotides for proteins, limiting efflux of unbound label, and to destruction of the oncogene message being measured by RNase H attack on the RNA target due to hybridization of the labeled antisense DNA, or to lack of a receptor targeting ligand. While specific tumor uptake of [^{111}In]-*MYC* phosphorothioate (*30*) and [^{68}Ga]*KRAS* phosphorothioate (*31*) have been asserted, those reports have not been replicated as yet.

Morpholino phosphorodiamidates provide a useful alternative to phosphorothioates as hybridization agents, but suffer from poor uptake (*32*). However, radiolabeled morpholino oligonucleotides have exhibited good pharmacokinetic and tissue distribution properties (*33*). Avoidance of cytosines in morpholino sequences reduces renal accumulation (*34*), while conjugation of basic peptides elevates cellular uptake of morpholino oligomers (*35*).

To address those drawbacks, we turned to peptide nucleic acids (PNAs), which hybridize more tightly and more specifically to RNA than morpholino oligonucleotides (*36*, *37*), resist nuclease attack, and demonstrate antisense activity upon microinjection of PNAs into cellular nuclei (*38*). RNA hybridized to uncharged oligonucleotide derivatives, such as PNA, is not recognized by RNase H. Therefore, PNA does not catalyze degradation of its analyte, the bound RNA (*39*), but inhibits mRNA translation solely by hybridization arrest, and thus provides an opportunity for diagnostic application (*38*). The requirement for intracellular PNA microinjection, however, stems from their poor cellular uptake, which was reported to be 10 times less efficient than uptake of phosphorothioates in a variety of mammalian cells (*40*).

Cellular uptake of PNAs can be improved by the addition of ligands (*41*). Previously we observed that synthesis of an *IGF1R* PNA dodecamer with an N-terminal D-peptide analogue of IGF1, D(CysSerLysCys), provided cell-type specificity, and increased cellular uptake 5−10-fold in BALB/c3T3 cells transformed with human *IGF1R* (*42*) and in human *IGF1R*-overexpressing MCF7 breast cancer cells (*43*). Only background levels of uptake were seen with control cell lines or control peptides. In prostate cancer cells, for comparison, addition of dihydrotestosterone or a nuclear localization peptide to a *MYC* antisense PNA permitted some nuclear localization and Myc reduction in LNCaP cells expressing androgen receptor after 24 h exposure to 10 μM PNA (*44*). It appears that the use of a peptide analogue specific for a cell surface receptor is more effective than a steroid capable of binding to a cytoplasmic protein after unassisted uptake.

We have pursued this cell-specific approach to enable application of PNAs as gene expression diagnostics in vivo, developing methods for the synthesis of peptide−PNA−peptide chimeras, which exhibit the same melting temperatures with complementary RNA targets as do PNAs alone without peptides (*45*). For noninvasive scintigraphic imaging of oncogene mRNA in malignant lesions, we developed a method to label PNA−peptide hybridization probes with ^{99m}Tc by including a chelating peptide GlyD(Ala)GlyGlyAba (Aba = γ-aminobutanoate) (TP3654) (*46*) coupled by continuous solid-phase synthesis to the N-terminus of PNA-AEEA-D(CysSerLysCys) (AEEA = aminoethoxyethoxyaceate) (*45*). Fluoresceinyl-GlyD(Ala)GlyGlyAba−*CCND1* PNA-AEEA-D(CysSerLysCys) lowered cyclin D1 protein in *IGF1R*-overexpressing MCF7 xenografts in immunocompromised mice upon

intratumoral injection (*43*). The γ-emitting [^{99m}Tc]AcGlyD(Ala)GlyGlyAba−*CCND1* PNA-AEEA-D(CysSerLysCys) visualized *IGF1R*-overexpressing, *CCND1*-overexpressing MCF7 xenografts in immunocompromised mice at 12 and 24 h after intravenous administration. In all of those experiments, control PNA and peptide sequences were unable to produce similar images (*43*).

Because *MYC* mRNA is overexpressed in a broad spectrum of cancers, it might be a valuable target for diagnostic imaging in many cases. We report here imaging of *MYC* mRNA levels in human estrogen receptor-positive MCF7:IGF1R breast cancer xenografts in immunocompromised mice following intravenous administration of [^{99m}Tc]AcGlyD(Ala)GlyGlyAba-*MYC* PNA-AEEA-D(CysSerLysCys) chimera, designed to bind to the receptor for IGF1, internalize, and hybridize with *MYC* mRNA (Figure 1).

MATERIALS AND METHODS

Peptide−PNA−Peptide Synthesis. The peptide−PNA−peptide chimeras were assembled (Scheme 1), purified, and characterized as described previously (*45*). Briefly, the IGF1 analogue D(CysSerLysCys), or the mismatch control D(CysAlaAlaCys), was assembled by Fmoc coupling on NovaSyn TGR resin (0.2−0.3 mmol/g) (Novabiochem, San Diego CA) on an Applied Biosystems 430A peptide synthesizer. Then the linker Fmoc-AEEA and PNA monomers (Applied Biosystems, Foster City CA) were sequentially coupled to the N-terminus of the peptide-resin on an Applied Biosystems 8909 DNA synthesizer, running the manufacturer's PNA 2 μmol protocol. Finally, the chelator peptide Fmoc-GlyD(Ala)-GlyGlyAba (Novabiochem) was coupled to the N-terminus of the PNA−peptide using a long coupling cycle protocol (*45*), then acetylated. The cysteine residues were cyclized on solid phase with 10 equivalents of I_2 in Me_2NCHO for 4 h at room temperature (*45*).

The chimeras were cleaved and deprotected with 85% CF_3CO_2H, 5% CH_2Cl_2, 9.5% *m*-cresol, and 0.5% Et_3SiH for 2 h at room temperature (*45*), then purified by reversed phase liquid chromatography on a 10 × 250 mm Alltima C_{18} column eluted with a gradient linear 25 min. from 5% to 45% CH_3CN in aqueous 0.1% CF_3CO_2H, at 1 mL/min, at 50 °C, monitored at 260 nm. Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS, Ciphergen Corp., Fremont, CA) was carried out from an α-cyano-hydroxycinnamic acid matrix excited at 338 nm, and calibrated with porcine neuropeptide Y.

Cell Lines and Xenografts. Human MCF7:IGF1R estrogen receptor-positive breast cancer cells, clone 17, transformed to express 1×10^6 IGF1R/cell constitutively from a cytomegalovirus promoter (*47*) were maintained in DMEM plus 5% calf serum, 50 U/mL penicillin, 5 μg/mL streptomycin, 2 mM glutamine, and 7.5 nM 17-β-estradiol (Sigma) at 37 °C under 5% CO_2. For tumor induction, $5-6 \times 10^6$ cells in 0.2 mL of culture medium were implanted intramuscularly through a sterile 27 gauge needle into the thighs of female Balb/c nude mice obtained from NIH. Tumors were allowed to grow to no more than 0.5 cm in diameter. Each injection included 10 mg of Matrigel. A 60-day release pellet containing 4.5 mg of 17-β-estradiol (Innovative Research of America, Sarasota, FL) was implanted subdermally in each mouse. All animal studies were conducted in accordance with federal and state guidelines governing the laboratory use of animals, and under approved protocols reviewed by the Animal Care and Use Committee at Thomas Jefferson University. All animals were anesthetized by approved methods, and when required, the animals were restrained using methods and devices specifically designed to provide a minimum of discomfort to the animal. Animals were euthanized in a halothane chamber, con-

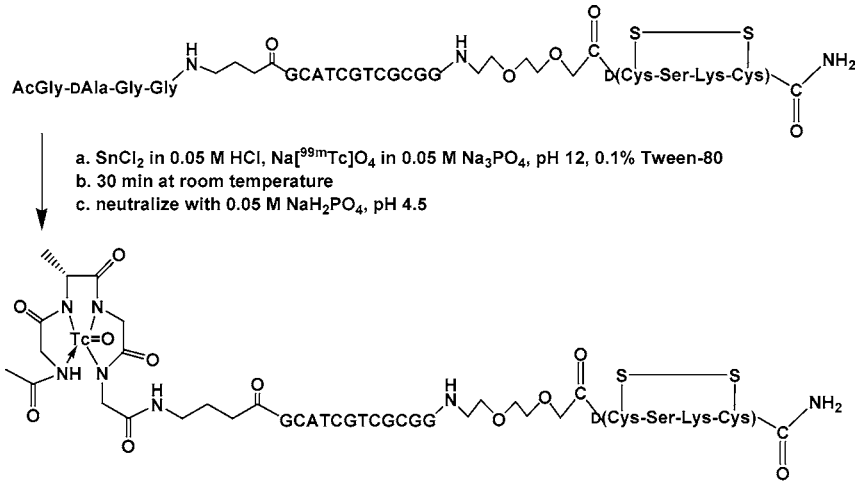

Scheme 2. ^{99m}Tc labeling of peptide-*MYC* PNA-peptides

sistent with USDA regulations and American Veterinary Medical Association recommendations.

Radiolabeling. Purified peptide−PNA−peptide chimeras were labeled with ^{99m}Tc (Scheme 2) essentially as described previously (*48*). Briefly, 20 μg of peptide−PNA−peptide chimera and 45−60 μg of $SnCl_2 \cdot 2H_2O$ were vortexed in 20 μL of 0.05 M HCl. Next, 12 mCi of $Na^{99m}TcO_4$ freshly eluted from the ^{99m}Tc generator with 200 μL of 0.15 M NaCl were vortexed with 600 μL of 0.05 M Na_3PO_4, pH 12, 0.1% Tween 80. The radionuclide mixture was then added to the peptide−PNA−peptide/$SnCl_2$ solution and incubated for 30 min at room temperature. Finally, the solution was neutralized by the addition of 1 mL of 0.05 M NaH_2PO_4, pH 4.5.

Reaction mixtures were analyzed to determine free ^{99m}Tc and chelated ^{99m}Tc by reversed phase liquid chromatography on a 4.5 × 250 mm reversed phase C_{18} microbond HPLC column (Rainin, Emeryville, CA) coupled to a UV detector, NaI (Tl) radioactivity monitor, and a rate meter. The column was eluted with a 28 min. gradient from 10% to 100% CH_3CN in aqueous 0.1% CF_3CO_2H, at 1 mL/min, at 25 °C. Unchelated free ^{99m}Tc (R_f 1.0) was also determined by instant thin-layer chromatography on silica gel (ITLC−SG, Gelman Sciences, Ann Arbor, MI) developed with methylethyl ketone. Colloid formation (R_f 0.0) was determined on ITLC−SG developed with pyridine/HOAc/H_2O (3:5:1.5). These preparations were stable at 22 °C for more than 4 h, as determined by HPLC, and were stable to challenges with 100-fold molar excesses of diethylenetriaminepentaacetic acid, human serum albumin, or cysteine.

Systemic Administration and Tissue Distribution of Labeled Probes. To assess chimera distribution and imaging, 7.4−11.1 MBq (0.2−0.3 mCi) of the [^{99m}Tc]-peptide−PNA−peptides in 0.2 mL of sterile 0.1 M Na_2HPO_4, pH 7, was administered to groups of five mice each through a lateral tail vein using a sterile 27 gauge needle. For the 24 h distribution, 29.6−34.2 MBq (0.8−0.9 mCi) of probe was administered. At 4 and 24 h postinjection, mice were lightly anesthetized, then imaged using a Starcam (GE Medical, Milwaukee, WI) gamma camera equipped with a parallel hole collimator. For each image, 300 000 counts were collected. Digital scanning of region-of-interest intensities with the interfaced Entegra computer (GE Medical) across each scintigraphic image from the tumor-free left flank to the tumor-bearing right flank provided quantitation of tumor images.

Mice were then euthanized, and tissues were dissected. These were washed free of blood, blotted dry, and weighed, and radioactivity associated with each tissue was counted in an automatic gamma counter (Packard Series 5000, Meridien, CT), together with a standard radioactive solution of a known quantity prepared at the time of injection. Results were expressed as percent of injected dose per gram of tissue (% I.D/g).

In Vivo Stability. Urine was collected up to 2−3 h postinjection from groups of 5 mice injected with [^{99m}Tc]-peptide−PNA−peptide probes for assessment of probe stability. The urine samples were combined, sedimented at 2000*g* for 10 min, filtered through Millipore HAWP 025 membranes with 0.22 μm pores, and analyzed by RP-HPLC as described in Radiolabeling above.

Statistical Methods. Statistical analysis of differences among groups was determined by applying the standard error of the mean, Student's *t* test, Kruskal and Wallis's one-way analysis of variance on ranks, or the Holm−Sidak pairwise multiple comparison procedure, using SigmaStat 3.0 (SPSS, Chicago, IL).

RESULTS

Peptide−PNA−Peptides. We prepared a cyclized peptide−PNA−peptide chimera AcGlyD(Ala)GlyGlyAba-GCATCGTCGCGG-AEEA-D(CysSerLysCys), WT4219, specific for *MYC* mRNA and the IGF1 receptor (Figure 1). Preparative RP-HPLC of the crude product yielded a main peak containing 98.05% of the absorbance at 260 nm (Figure 2A). The overall yield following preparative RP-HPLC was 27.2%. MALDI-TOF MS confirmed the identity of the main product peak at 4221.6 Da (Figure 2B). Similarly, we prepared a *MYC* PNA 4-mismatch control, AcGlyD(Ala)GlyGlyAba-GCATGTCTGCGG-AEEA-D(CysSerLysCys), WT4235, with 30.6% overall yield following preparative RP-HPLC (Figure 3A), and MALDI-TOF mass of 4234.7 Da (Figure 3B).

[^{99m}Tc]Peptide−PNA−Peptides. Twenty microgram aliquots of the *MYC* peptide−PNA−peptide antisense probe, WT4219, labeled well at 22 °C (Figure 4A). Free ^{99m}Tc was only 0.36%, and colloids were only 4.84%. The PNA mismatch, WT4235, labeled well also (Figure 4B). Free ^{99m}Tc was 0.99%, and colloids were 4.84%.

Systemic Administration. To test our hypothesis that a complementary [^{99m}Tc]peptide−PNA−peptide probe specific for *MYC* mRNA and the IGF1 receptor could visualize a *MYC*-expressing tumor, we administered approximately 0.5 mCi [^{99m}Tc]peptide PNA−peptide *MYC* probes to cohorts of five nude mice bearing approximately 0.5 cm MCF7:IGF1R xenografts to determine the specificity and sensitivity of scintigraphic imaging 4 h and 24

h after administration (Figure 5). We previously tested whether the PNA-free chelator plus IGF1 analogue control probe would bind to tumor cells expressing high levels of IGF1 receptor, which it did not (*43*).

To test whether a probe containing four central PNA mismatches would bind to tumor cells expressing high levels of IGF1 receptor and *MYC* mRNA, we administered the PNA mismatch control, WT4235. We did not observe tumor signals at 4 h or 24 h postinjection. Finally, to test whether the complementary probe with correct IGF1 analogue would bind to tumor cells expressing high levels of IGF1 receptor and *MYC* mRNA, we administered the PNA antisense chimera, WT4219. In this case, we observed faint tumor signals at 4 h and intermediate tumor signals at 24 h postinjection.

Digital scanning of the tumor site region-of-interest on the right flank vs the mirror image tumor-free region-of-interest on the left flank enabled quantitation of tumor images. The ratios of tumor site:control site intensities are plotted in Figure 6 as a function of time. One presumes that any ratio greater than 1 implies some preferential probe concentration. No tumor image was obvious in Figure 5 following administration of the PNA mismatch control, WT4235, which includes the IGF1 peptide analogue, but the digitized tumor site:control site ratio was 3.33 ± 0.30 at 4 h, and 2.72 ± 0.44 at 24 h. A faint tumor image was apparent in Figure 5 four h after administration of the antisense probe, WT4219, which correlated with the tumor site:control site ratio of 4.35 ± 0.58. At 24 h postinjection, the ratio increased to 7.01 ± 0.90.

Kruskal−Wallis one-way analysis of variance on ranks determined that the four groups were significantly different from each other ($p < 0.001$). When all four groups were compared by the Holm−Sidak method, the antisense group was not significantly different from the mismatch group at 4 h postinjection ($p = 0.244$). However, at 24 h postinjection, Holm−Sidak comparison revealed a statistically significant difference ($p < 0.001$) between the antisense group and the mismatch group. The test performed had a power of 0.985 with $\alpha = 0.050$.

In Vivo Stability. RP-HPLC of radioactivity in the combined 3-h urine sample from mice injected with [^{99m}-

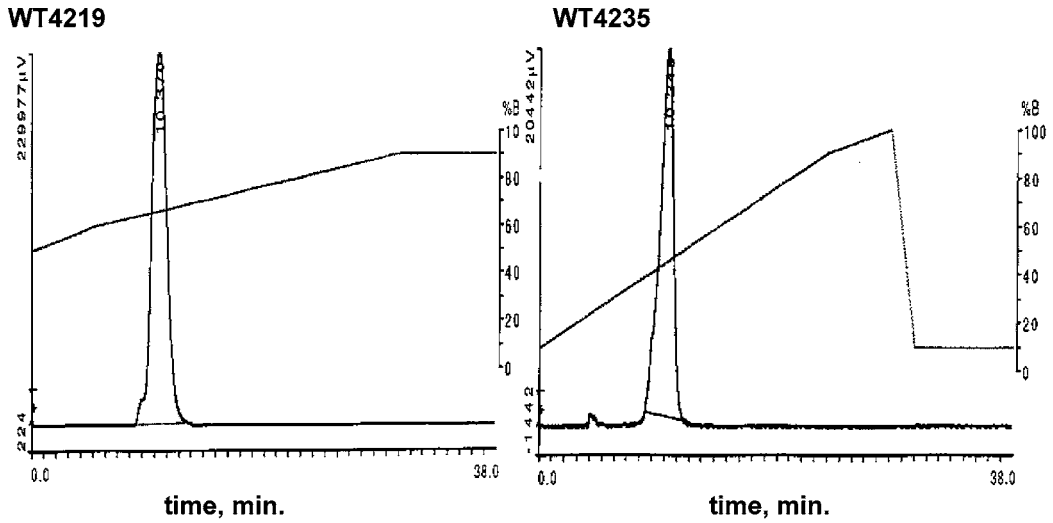

Figure 4. Analysis of [^{99m}Tc]peptide−PNA−peptides. An aliquot of each labeling reaction was analyzed by RP-HPLC on a 10 × 250 mm Rainin Microbond C_{18} column eluted with a 28 min gradient from 10% to 100% CH_3CN in aqueous 0.1% CF_3CO_2H, at 1 mL/min, at 25 °C. %B (CH_3CN) is shown on the right *y*-axis, and NaI (Tl) radiometric gamma emission is shown on the left *y*-axis. Left: antisense probe, WT4219. The single labeled peak eluted at 10.37 min. Right: mismatch probe, WT4235. The single labeled peak eluted at 10.25 min.

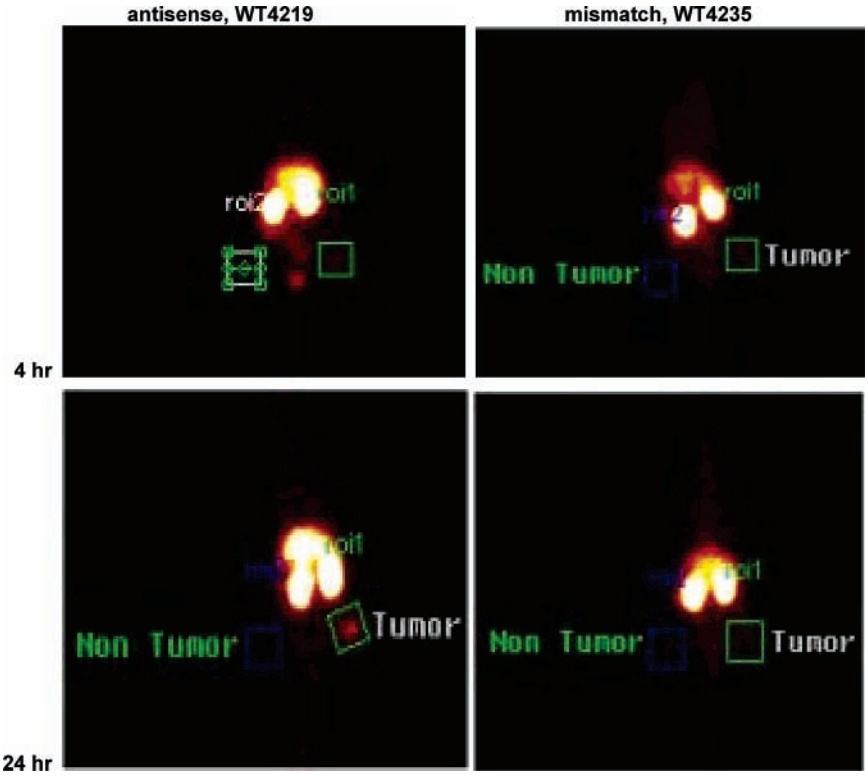

Figure 5. Scintigraphic images of γ−particles emitted by decaying ^{99m}Tc in immunocompromised mice carrying human MCF7: IGF1R ER+ breast tumor cell xenografts at 4 h and 24 h after injection of [^{99m}Tc]peptide−PNA−peptides. Left: [^{99m}Tc]*MYC* PNA antisense probe, WT4219; right: [^{99m}Tc]*MYC* PNA mismatch control, WT4235.

Tc]*MYC* antisense probe, WT4219, showed no void volume peak of free ^{99m}Tc, but only an intact probe peak at 10.7 min (Figure 7, left). RP-HPLC of radioactivity in the combined 2-h urine sample from mice injected with [^{99m}Tc]*MYC* mismatch probe revealed a void volume peak of free ^{99m}Tc, 44% of radioactivity, and a probe peak at 10.3 min with 56% of the radioactivity (Figure 7, right). Breakdown fragments of the peptide−PNA−peptide probe were not detected from either probe.

Tissue Distribution. Tissue distribution of each probe was measured in all subjects at 4 and 24 h after administration. Table 1 presents the data for the antisense group and the mismatch group at 4 h, while Table 2 shows the 24 h results. As the time after injection elapsed, the radioactivity in all tissues decreased, including that in the tumors. However, the tumor to blood and tumor-to-muscle ratios increased for WT4219 as time went on. This is consistent with the scintigraphic images in Figure 5 and the tumor (right)-to-muscle (left) image intensity ratios provided in Figure 6, which were higher than the tumor/muscle distribution ratios from scintillation counting for WT4219. While the tumors were readily detectable by scintigraphy with WT4219, but not with WT4235, the tumor distribution counts of % injected dose/g for the antisense group and the mismatch group were not remarkably different, except for the heart. The

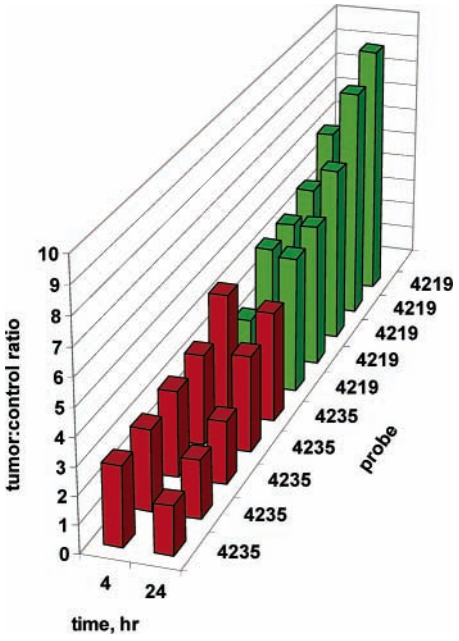

Figure 6. Tumor site:control site gamma intensity ratios after systemic administration of [^{99m}Tc]peptide−PNA−peptide chimeras for all subjects in Figure 5. red, [^{99m}Tc]*MYC* PNA mismatch control, WT4235; green, [^{99m}Tc]*MYC* PNA antisense probe, WT4219.

increased accumulation of the mismatch probe WT4235 in heart tissue invited a BLAST search with the WT4235 sequence for heart-specific or mitochondrial-specific murine mRNAs. Unfortunately, no complementary homologies were identified, so the concentration of mismatch probe in the heart remains unexplained.

The tissue distribution data indicated that renal excretion was the primary route of elimination and renal uptake was highest among all tissues, but the extent differed from agent to agent.

DISCUSSION

In this report we tested the feasibility of using a [^{99m}Tc]chelator peptide-*MYC* PNA receptor-targeting hybridization probe to image *MYC* mRNA at modest copy number in ER+ breast cancer cells that overexpress IGF1R, a receptor that is overexpressed is a high percentage of breast cancer cells.

Quantitative reverse transcription-polymerase chain reaction measurements of *MYC* mRNA in total MCF7:IGF1R cell RNA revealed 4-fold inhibition after preannealing with 0.1 μM N-Gly$_D$(Ala)GlyGlyAba-*MYC* PNA-Gly$_4$D(CysSerLysCys) probe before adding PCR primers, and 8-fold inhibition after preannealing with 1.0 μM probe (*39*). The *MYC* mismatch control had no effect, consistent with the hypothesis that the complementary PNA probe would bind strongly to the mRNA target. That probe was essentially the same as WT4219, except for substitution of Gly$_4$ for the AEEA linker (*39*). The specificity of RT inhibition implies that the peptide−PNA−peptides hybridize to their intended *MYC* mRNA target.

Previously, denaturing NaDodSO$_4$ gel electrophoresis (*43*) of a comparable [^{99m}Tc]peptide−*CCND1* PNA−peptide probe showed a radioactive band that co-electrophoresed with the main radioactive band from the [^{99m}Tc]*CCND1* probe labeling mixture. Similarly, fluorescence microscopy illustrated that the peptide−*CCND1* PNA−peptide probes were taken up inside MCF7:IGF1R breast cancer cells, if and only if the IGF1 peptide analogue sequence was correct (*43*), as was reported previously for p6 cells (*42*).

We carried out a variety of tests of the hypothesis that overexpression of *MYC* mRNA in MCF7:IGF1R breast cancer xenografts could be detected specifically and noninvasively by scintigraphic imaging of ^{99m}Tc-peptide−PNA−peptide probes. We previously measured *MYC* oncogene mRNA copy number in MCF7:IGF1R human breast cancer cells by quantitative reverse transcription-polymerase chain reaction (*43*). Comparison of threshold cycle numbers for *MYC* mRNA with those for TATA-box binding protein mRNA yielded an average ratio of 8 for MCF7:IGF1R cells over two logs of RNA template. On the basis of the previously reported TATA-box binding protein mRNA copies per breast cancer cell of 1000−2000 (*49*), we estimated approximately 8000 *MYC* mRNAs per MCF7:IGF1R cell. Assuming 8000 mRNAs per cell and 10^9 cells per gram of tumor, there would be an estimated 8×10^{12} mRNA copies available for binding in a 1 g tumor. Our data suggest that 0.1% of the injected [^{99m}Tc]-WT4219 antisense probe (specific activity 2 Ci/μmol) was associated with the tumors at 24 h. This suggests that approximately 3×10^{11} molecules of [^{99m}Tc]WT4219 were bound to the mRNA in a 1 g tumor, or about 4% of the *MYC* mRNAs, despite nonuniform distribution of radioactivity in the tumor. In a high specific activity or carrier-free preparation, this would be equivalent to 500 μCi of ^{99m}Tc, suggesting the possibility of up to 500 times greater sensitivity than we observed in this initial study.

To estimate the fraction of internalized PNA probes that could be hybridized to available *MYC* mRNAs in live tumor cells, one must begin with the observed T_m of approximately 80 °C for 2.5 μM peptide−PNA−peptide 12-mers with 2.5 μM RNA (*45*). A copy number of approximately 8000 *MYC* mRNAs per 1 pL cell translates to 13 nM, while the [^{99m}Tc]WT4219 appeared to be less than 1/10 of that, 1 nM. The T_m, the probe concentration, and the 13-fold excess mRNA concentration enable prediction (*36*) of virtually complete hybridization of available intracellular probe.

Interestingly, concentration of label in tumors was very faint at 4 h after injection of the antisense PNA *MYC* sequence with IGF1 analogue, WT4219, although the digital scan revealed detectable concentrations of label. We interpret that observation to mean that uptake, intracellular trafficking, hybridization of label, and efflux of unbound label are all slow processes that do not reveal a strong tumor signal at 4 h. Because labeled antisense PNA in the tumors could be visualized at 24 h, we hypothesize that 24 h was sufficient for unbound probe to efflux from cells and to be excreted. With respect to the hybridized label, bound PNA probe dissociates negligibly from complementary RNA by 12−24 h (*25*, *36*). In the end, we found that the MCF7:IGF1R xenografts that overexpress *MYC* mRNA could be imaged reliably and specifically at 24 h postinjection.

The [^{99m}Tc]*MYC* mismatch probe was also administered to immunocompromised mice to assess metabolism in vivo. Urinalysis by RP-HPLC (Figure 7), showing intact [^{99m}Tc]*MYC* antisense and mismatch probes, implied reasonable stability of the peptide−PNA agent in vivo, consistent with the hypothesis that a [^{99m}Tc]D-peptide−PNA would be resistant to proteases and nucleases in blood and tissues. In the case of the mismatch probe, free ^{99m}Tc void volume peak probably resulted from reoxidation of probe-bound Tc(III) to free Tc(VII) in the liver. The lack of a free ^{99m}Tc void volume peak in the case of the antisense probe is remarkable. One may speculate that the antisense probe was only excreted

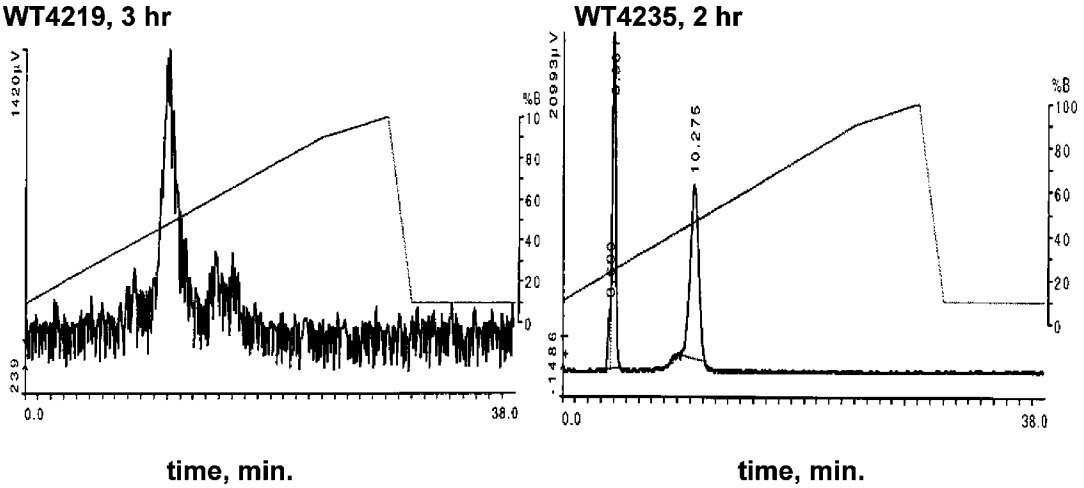

Figure 7. Analytical HPLC of [^{99m}Tc]peptide−PNA−peptide probes that were recovered from mouse urine 2−3 h after administration, chromatographed as in Figure 4 above. Left, [^{99m}Tc]*MYC* antisense probe, WT4219, 3 h after administration; right, [^{99m}Tc]*MYC* mismatch probe, WT4235, 2 h after administration.

upon the first pass through the kidney, and that antisense probes that distributed to tissues did not re-enter the bloodstream to be metabolized by the liver, at least up to 3 h.

The tissue distribution and urinalysis results were comparable to our previous observations with [^{99m}Tc]-GlyD(Ala)GlyGlyAba-GCATCGTCGCGG, WT4219 lacking the IGF1 analogue (*39*). The tissue distribution results were also comparable with those for [^{99m}Tc]-AcGlyD(Ala)GlyGlyAba−*CCND1* PNA-IGF1 analogues and controls (*43*). As noted above, a BLAST search with the mismatch sequence did not uncover any complementary cardiac or mitochondrial mRNAs.

Although there was no significant difference in tumor: muscle ratios between the *MYC* probe and its mismatch control, the MCF7:IGF1R xenografts were imaged clearly with WT4219, but not with WT4235. That is because the tissue distribution data report radioactivity in the entire excised masses, which include some surrounding normal tissue, the actively proliferating cells on the periphery of the tumors, and the necrotic cores. The radioactive *MYC* probes were predicted to concentrate in the actively proliferating cells. However, the surrounding normal tissues, which do not express human *MYC* mRNA, and the nectrotic cores, which exhibit poor uptake of macromolecules (*50*) and are not proliferating, were not dissected away before measuring tissue radioactivity. As a result, the apparent % uptake of ^{99m}Tc/g tumor was diluted by inclusion of extra nonproliferating tissue. Hence, the tumor/muscle ratios of *MYC* probe radioactivity were reduced to the range of the mismatch probe. This same difference between clear scintigraphic images and modest % uptake of ^{99m}Tc/g tumor was also observed earlier for [^{99m}Tc]GlyD(Ala)GlyGlyAba-vasoactive intestinal peptide, which revealed occult tumors in patients despite apparent tumor uptake of only 0.3% injected dose/g in xenografts in immunocompromised mice (*46*, *48*, *51*), and for [^{99m}Tc]AcGlyD(Ala)GlyGlyAba−*CCND1* PNA-IGF1 analogues and controls in MCF7:IGF1R xenografts (*43*). Digital scanning, however, of scintigraphic intensities determined the radioactivity per pixel in the tumor region-of-interest, revealing *MYC* mRNA expression in the actively proliferating cells on the periphery of the tumors. In this case, the necrotic centers presumably did not contribute to the measurement, eliminating the possibility of label dilution. Thus, the tumor/contralateral scintifigraphic intensity ratios in Figure 6 probably provided more accurate results than the scintillation counting tissue distribution ratios in Tables 1 and 2.

High grade renal cell carcinomas exhibit elevated cytoplasmic Myc protein, but not in the nuclei, and not in normal renal cells (*40*, *52*). Therefore, concentration of the PNA antisense probe WT4219 in the kidneys was probably not due to labeling of *MYC* mRNA in kidney cells, but to nonspecific binding to negative charges on renal parenchyma. Simultaneous L-lysine administration has been shown to reduce renal accumulation of [^{111}In]-DTPA-octreotide in rats (*53*). Preliminary results from a study underway in our laboratory with our [^{99m}Tc]*CCND1* probe administered to tumor-bearing mice are consistent with that report.

Our observation of scintigraphic imaging of *MYC* mRNA expression in xenografts could be applicable to

patients at risk for new or recurrent breast cancer, including those with a strong family history of breast cancer, or when standard detection techniques provide ambiguous results. Imaging of mRNA expression with chelator−PNA−peptide chimeras labeled with ^{99m}T, ^{64}Cu, or other radionuclides might also be applicable to other oncogenes or to other cell surface receptors.

Targeting altered expression of oncogenes provides the promise of specificity, ultimately leading to the elimination of diagnostic surgical biopsy. *MYC* overexpression is a common event in and highly associated with the presence of breast cancer. While not sufficiently sensitive to be used alone, noninvasive measurement of mRNA expression by one or more oncogenes to confirm the presence or absence of cancer by γ-particle emission or by positron emission tomography when an imaging study is abnormal provides a mechanism for more accurate diagnosis of breast cancer.

ACKNOWLEDGMENT

We thank Dr. Eva Surmacz for her advice and the gift of MCF7 cells that constitutively overexpress IGF1R, Zuping Qu for maintaining the MCF7 cells under a variety of conditions, Dr. Zhi-xian Lu for assembly of linear peptide-resin supports, and Dr. Richard Wassell for assistance in measuring mass spectra of peptide−PNA−peptides. This work was supported by DOE ER63055 to E.W. and NIH HL59769 to M.L.T.

Structure−Photodynamic Activity Relationships of Substituted Zinc Trisulfophthalocyanines

Nicole Cauchon, Hongjian Tian, Réjean Langlois, Carole La Madeleine, Stephane Martin, Hasrat Ali, Darel Hunting, and Johan E. van Lier*

Department of Nuclear Medicine and Radiobiology, Faculty of Medicine, Université de Sherbrooke, Sherbrooke, Québec, Canada J1H 5N4. Received June 30, 2004; Revised Manuscript Received October 20, 2004

To identify optimal features of metalated sulfophthalocyanine dyes for their use as photosensitizers in the photodynamic therapy of cancer, we synthesized a series of alkynyl-substituted trisulfonated phthalocyanines and compared their amphiphilic properties to a number of parameters related to their photodynamic potency. Varying the length of the substituted alkynyl side-chain modulates the hydrophobic/hydrophilic properties of the dyes providing a linear relationship between their *n*-octanol/water partition coefficients and retention times on reversed-phase HPLC. Aggregate formation of the dyes in aqueous solution increased with increasing hydrophobicity while monomer formation was favored by the addition of serum proteins or organic solvent. Trisulfonated zinc phthalocyanines bearing hexynyl and nonynyl substituents exhibited high cellular uptake with strong localization at the mitochondrial membranes, which coincided with effective photocytotoxicity toward EMT-6 murine mammary tumor cells. Further increase in the length of the alkynyl chains (dodecynyl, hexadecynyl) did not improve their phototoxicity, likely resulting from extensive aggregation of the dyes in aqueous medium and reduced cell uptake. Aggregation was evident from shifts in the electronic spectra and reduced capacity to generate singlet oxygen. When monomerized through the addition of Cremophor EL all sulfonated zinc phthalocyanines gave similar singlet oxygen yields. Accordingly, differences in the tendency of the dyes to aggregate do not appear to be a determining factor in their photodynamic potency. Our results confirm that the latter in particular relates to their amphiphilic properties, which facilitate cell uptake and intracellular localization at photosensitive sites such as the mitochondria. Combined, these factors play a significant role in the overall photodynamic potency of the dyes.

INTRODUCTION

Photodynamic therapy (PDT)[1] is an alternative treatment for cancer and several other medical conditions requiring a concerted action of a photosensitizer, oxygen, and light (*1*−*3*). Upon illumination with light of the appropriate wavelength (630−800 nm), the photosensitizer is excited to its triplet state and the excited photosensitizer interacts with its environment to produce highly reactive intermediates (for example, singlet oxygen, superoxide anion, and hydroxyl radical) that are cytotoxic and cause tumor regression either directly by cell inactivation (*4*, *5*) and/or indirectly by destruction of the tumor vascular microcirculation (*6*−*8*). PDT using Photofrin as a sensitizer has been approved for clinical treatment of many cancers worldwide, including cancer of the skin, mouth, esophagus, bladder, lung, breast, and some reproductive organs (*9*, *10*). Advantages of PDT over other conventional cancer therapies are that neither the photosensitizer nor the light used for its activation are toxic, allowing the treatment to target diseased tissue selectively while sparing surrounding healthy tissue.

The well-known limitations and drawbacks of Photofrin, i.e., chemical heterogeneity, relatively low absorption coefficient at the activation wavelength of 630 nm, and prolonged cutaneous photosensitivity, has led to an extensive search for new, well-defined sensitizers with highly effective photoactivity and less side effects (*11*). Many different classes of new sensitizers have been advanced for PDT and are under development at various stages of preclinical or clinical trials (*12*). Among the second-generation photosensitizers for PDT, phthalocyanines (Pc) have received particular attention due to the selective retention by tumor cells, lack of toxicity, and chemical and photochemical stability combined with a high molar absorption coefficient ($\epsilon > 10^5\ M^{-1}\ cm^{-1}$, 640−710 nm) in the clinically useful red part of the spectrum (*13*). Nonsubstituted Pc are extremely hydrophobic and insoluble in water. Sulfonation is a well documented method to render them suitable for use in biological systems. Sulfonated Pc are water soluble and have been shown to be effective photosensitizers to kill tumor cells in vitro and tumor regression in vivo. We have previously synthesized zinc, gallium, and aluminum Pc with various degrees of sulfonation by either condensation or sulfonation methods (*14*). Depending on the degree of sulfonation, Pc exhibit varying hydrophobic and hydrophilic

properties, affecting the tendency to aggregate, changing their ability to generate $^1O_2$ and resulting in very different photodynamic effects (*15*). Hydrophobic photosensitizers tend to aggregate in aqueous solution (*16*), decreasing their photodynamic activity while hydrophilic photosensitizers display decreased cell uptake (*17*), target less photosensitive sub cellular sites (*18*), and are rapidly cleared in vivo (*19*).

Many investigators have reported that photodynamic treatment induce lesions in mitochondria, lysosomes, golgi, membranes, and/or other organelles as well as essential biomolecules including DNA (*20*−*22*). Photosensitizers rarely reach the cell nucleus and accordingly this target is less important for photodynamic cytotoxicity. The cytoplasmic organelles constitute the more accessible targets for photosensitizers mainly owing to the permeability of cytoplasmic membrane. Mitochondria are the principal target for most photosensitizers and damage to this organelle quickly induces cell death by apoptosis (*9*). Deregulation or dysfunction of the mitochondria induces fast cell death due to respiratory failure. The Golgi apparatus is a specialized type of endoplasmic reticulum involved in the transport of macromolecules and degradation products. Damage to the Golgi disrupts protein synthesis/routing and excretion of breakdown products. The lysosomes are the excretory vesicles produced by the Golgi to eliminate undesirable compounds (exocytosis) and their rupture releases such materials together with harmful acidic hydrolases into the cytosol.

Cellular response to PDT-induced oxidative stress involves complex signal transduction pathways and alterations in gene expression leading either to repair of induced lesions, altered cell functions, or cell death (*23*). Even though specific damage to sub-cellular structures or functions has been demonstrated, it is difficult to show a clear causal relationship between intracellular damage and cell death (*24*). Furthermore, sensitivity to PDT differs a great deal among various cell types (*25*). Thus photodynamic activity depends largely on intracellular distribution patterns that in turn depend on both cell type and the nature of the photosensitizer. The relative contribution of these various factors to the overall photodynamic response remains to be elucidated.

Under in vitro conditions, amphiphilic photosensitizers are in general more photodynamically active than hydrophobic or hydrophilic molecules of the same class of compounds (*17*, *26*). It has also been suggested that favorable pharmacokinetics to ensure tumor selectivity and rapid systemic clearance is likewise related to the amphiphilic properties of the photosensitizer (*10*). Among the sulfophthalocyanine dyes, adjacently substituted, disulfonated compounds have the appropriate amphiphilic properties for optimal cell membrane penetration, resulting in high photodynamic activity both against tumor cells in culture and experimental animal tumors (*27*−*30*). However such derivatives are difficult to purify as single isomeric products. We have also demonstrated that addition of some hydrophobic groups onto the fourth benzyl ring of trisulfonated Pc can improve their amphiphilic properties resulting in an increase in cell uptake and in vitro photocytotoxicity (*31*, *32*). Woehrle and collaborators showed that introducing different lengths of alkyl chains to a series of positive-charged Pc tips the balance of the hydrophilic/lipophilic character of a Pc-based sensitizer (*33*). Pandey's studies on a series of purpurinimides containing alkyl substituents established that the overall lipophilicity did not affect singlet oxygen yields of the monomerized compound; however, the position of the alkyl groups was shown to play an important role in the in vivo efficacy of the photosensitizer (*34*).

Since the core of the Pc macro ring system is hydrophobic and peripherally attached sulfonate groups are hydrophilic, substituting different lipophilic alkyl chains onto a sulfonated Pc permits modulation of the amphiphilic properties of the dye. Using indole or pyrrole as a protecting group of the sulfonate substituent (*35*) in combination with the palladium-catalyzed cross-coupling reaction (*36*) allowed us to prepare a series of novel trisulfonated Pc substituted with different lengths of alkynyl carbon chains on the fourth, nonsulfonated benzyl ring (*37*). In this paper we compare their amphiphilic properties to tendencies to aggregate, cell uptake, intracellular distribution, and photocytotoxicity to arrive at structure−activity relationships.

EXPERIMENTAL PROCEDURES

Photosensitizers. The di- and trisulfonated zinc(II) Pc ($ZnPcS_{2a}$ and $ZnPcS_3$) were prepared via condensation of sulfonated precursors and purified by extensive C-18 reversed-phase HPLC fractionation (Waters Corp., Milford, MA; Column: RCM 8 × 10, Millipore, Milford, MA), using a linear gradient from 100% aqueous 5.0 mM phosphate buffer (pH 5) to 100% methanol over 30 min (1.5 mL/min) (*14*). A preliminary note on the syntheses of the substituted trisulfonated Pc ($ZnPcS_3C_{2-16}$) has previously been reported (*37*). Briefly, their preparation involves the synthesis of the indole-protected monoiodo $ZnPcS_3I$ (**3**) via the mixed condensation of 1-(3,4-dicyanophenylsulfonyl)indole (**1**) with 4-iodophthalonitrile (**2**) followed by facile purification over a silica gel column (Scheme 1). The protected monoiodo **3** was reacted with the different terminal alkynes under palladium/Cu(I)-catalyzed conditions to yield the series of protected $ZnPcS_3C_{2-16}$ (**4**−**8**) with different functionalized alkynyl substituents. After further purification over a silica gel column, the protected $ZnPcS_3C_{2-16}$ were hydrolyzed with lithium methoxide in methanol/THF to yield the pure alkynyl derivatives **9**−**13** in >85% yield.

2-Iodo-9,16,23-tris(1′-indolylsulfonyl)phthalocyanine Zinc(II) (3). 4-Iodophthalonitrile (**1**) (1 mmol), 1-(3,4-dicyanophenylsulfonyl)indole (**2**) (3 mmol), and zinc acetate (5 mmol) were ground together and heated at 200 °C for 2 h. The crude mixture was dissolved in $CHCl_3$ and purified by silica gel column chromatography eluted with 5% ethyl acetate in toluene to yield **3** as a dark blue solid in 20%. UV−vis ($CHCl_3$) λ_{max}/nm (log ϵ) 687.5 (5.26), 673.5 (5.26). ^1H NMR (DMSO-d_6) 9.2 (m), 8.8 (m), 8.4 (m), 8.22 (m), 8.18 (m), 7.9 (m), 7.4 (m), 7.2 (m), 6.7 (m).

General Procedure for the Coupling of 3 with Alkynes. Compound **3** (0.1 mmol) and alkyne (0.13 mmol) were dissolved under N_2 in anhyd THF (5 mL). To this were added $Pd(ph_3P)_2Cl_2$ (18 mg), CuI (18 mg), and triethylamine (9 mL), and the mixture was heated at reflux for 15−24 h. The products were purified by silica gel column chromatography and isolated in 85−90% yield.

2-Ethynyl-9,16,23-tris(1′-indolylsulfonyl) PcZn(II) (4): UV−vis ($CHCl_3$) λ_{max}/nm (log ϵ) 690 (5.26), 676 (5.26), 615 (4.65), 359 (4.90), MS (FAB) *m/z* calculated for $C_{61}H_{39}N_{11}O_6S_3Zn$ 1211.70, found, 1211.0.

2-(1′-Dodecyne)-9,16,23-trisulfosodium PcZn(II) (12): UV−vis (MeOH) λ_{max}/nm (log ϵ) 671 (5.30), 607 (4.51), 345 (4.81), MS Electron-spray) *m/z* calculated for $C_{44}H_{36}N_8O_9S_3Zn$ 982.38, found, 981.0 (M-1). ^{1}H NMR (DMSO-d_6) δ: 9.75 (m, 3H), 9.45 (m, 5H), 8.55 (m, 3H), 8.20 (m, 1H), 2.78 (t, 2H), 1.2−1.8 (m, 12H), 1.08 (t, 3H, CH_3).

2-(1′-Hexadecyne)-9,16,23-trisulfosodium PcZn(II) (13): UV−vis (MeOH) λ_{max}/nm (log ϵ) 678 (5.14), 607 (4.36), 356 (4.68), MS Electron-spray) *m/z* calculated for $C_{48}H_{44}N_8O_9S_3Zn$ 1038.49, found, 1037.8 (M-1). ^{1}H NMR (DMSO-d_6) δ: 9.68 (m, 3H), 9.42 (m, 5H), 8.55 (m, 3H), 8.18 (m, 1H), 2.72 (t, 2H), 0.9−1.81 (m, 26H), 0.82 (t, 3H, CH_3).

Formulation of Photosensitizers. To prepare the phosphate-buffered saline (PBS) dye solutions, a few mg of Pc were dissolved in 1% PBS (pH 7.4) and sonicated for a few minutes. The solution was filtered on Millex-GV 0.22 μm (Millipore, Ont.) under sterile condition. The final concentration of the dyes was determined by UV−vis spectroscopy after 50-fold dilution in methanol or dimethylformamide (DMF).

Lipophilic Properties of the Dyes. The hydrophilic and hydrophobic properties of the various Pc were determined by their retention time (t_R) on C-18 reversed-phase HPLC and by their partition coefficient (P) between *n*-octanol and water.

(a) Retention Time. Analytical HPLC was conducted on a Waters system composed of a model 600 pump, 2487 UV−visible detector, helium degasser, model 600 control-

ler, and a Rheodyne injector. The HPLC column consisted of a Radial-Pak cartridge (10 × 0.8 cm) filled with 4 μm Nova Pak C18 reversed-phase packing (Waters) and operated with a 1−30% linear gradient of methanol in aqueous 10.0 mM sodium phosphate buffer (pH 5.0) over a period of 30 min followed by isocratic elution with 100% methanol for 5 min, at 1.0 mL min^{-1}. Eluted Pc were detected by the absorbency of the monomeric dyes at 670−700 nm and t_R were calculated as the weighted average of the t_R of the regional isomers.

(b) Partition Coefficient. To 2 mL of the various sulfonated ZnPc solutions (50 μM) in PBS (pH 7.4) was added 2 mL of *n*-octanol. The mixture was vortexed for 2 min and then centrifuged 10 min (900 g) at room temperature to separate the phases. The concentrations of Pc in both phases was determined spectrophotometrically (U-2000, Hitachi) after diluting a sample 50-fold in DMF and measuring the absorbency at 340−360 nm (ϵ = 80 000 M^{-1} cm^{-1}). The Pc concentration found in *n*-octanol was then divided by that found in PBS to give the partition coefficient (*P*).

Spectral Properties. The stock $ZnPcS_3C_{2-16}$ and $ZnPcS_{3/2a}$ solutions in PBS were diluted to 5 μM in different media (methanol, DMF, PBS, 1% and 55% FBS in Waymouth, 1% CRM in PBS) and incubated for different time intervals (0, 1, and 24 h). The electronic spectra were recorded (U-2000, Hitachi, Japan) and evaluated for the degree of aggregation by calculating the absorbency of the monomer at about 675 nm and the aggregate about 635 nm from the deconvoluted spectra. The dye concentrations can be measured independently from their aggregation state by their absorbency at 340−360 nm (ϵ = 80 000 $M^{-1}cm^{-1}$).

L-Tryptophan Photooxidation (*38*). A solution of 1 mL containing ZnPcS (50 μM) and l-tryptophan (5 mM) in PBS with and without 1% CRM was irradiated in a glass test tube (16 × 100 mm). The light source consisted of a high-intensity xenon short arc 300 W lamp model LX300F (ILC Technology, Sunnyvale, CA). Light was fed through a liquid guide fiber optic (model 77556, Oriel Corp. Stratford, CT) and two filters LS-700 and LL-600 (Corion, Holliston, MA), thus transmitting light between 600 and 700 nm at a fluence rate of 150 mW cm^{-2} (measured with a Power-Energy meter model 365 with a sensor model 38-0101, Scientech, Boulder, CO). The solution was kept at 4 °C and bubbled with air to ensure O_2 saturation. After 2 and 4 min of illumination, 80 μL samples were collected and analyzed by HPLC to quantify the characteristic hydroperoxide products 3α-hydroperoxy-1,2,3,3α,8,8α-hexahydropyrrolo[2,3β]indole-2-carboxylic acid (HPPI isomers) (t_R HPPI = 13.5 and 18.0 min, t_R tryptophan = 30.0 min) derived from $^1O_2$ oxidation of tryptophan. The relative HPPI yield for each photosensitizer was measured from the HPPI chromatogram peak areas, taking the area produced by $AlOHPcS_4$ as 100%. HPLC analysis was done on a Radial Pak cartridge (10 × 0.8 cm) filled with 4 μm Nova Pak C_{18} reversed-phase packing eluted at 1.0 mL/min with a linear gradient of 0.1% trifluoroacetic acid (TFA) in water and methanol (0.1% TFA) over 30 min from (1 to 30% methanol). The UV−vis detector was set at 215 nm.

Cell Cultures. The cell line used was the EMT-6 murine mammary tumor line, maintained in Waymouth medium culture (Gibco, Burlington, Canada) supplemented with 15% fetal bovine serum (FBS), 1% glutamine, and 1% pen−strep (Gibco). This corresponds to a complete medium.

Cell Uptake of Dyes. The EMT-6 cells (1.5 × 10^5 cells per well) in 1 mL Waymouth's growth medium were incubated in 24 multiwell plates (Falcon) overnight at 37 °C under 5% CO_2. The medium was removed and the monolayer rinsed twice with 1% PBS and then overlaid with 500 μL of the dye solution (10 μM) in medium culture supplemented with 1% FBS. For the longer incubation times of 24 and 48 h, the medium was supplemented with 4% of FBS to reduce cell death. After the incubation, the dye solution was removed and the cells were washed twice with 1% PBS. The cells were lysed with 500 μL of 0.1 N NaOH. An aliquot (50 μL) was removed to determine cellular protein according to the Bradford method (Bio-Rad Protein Assay) (*39*). DMF (450 μL) and 1% PBS (100 μL) were added to the remaining cell lysate, the mixture was centrifuged for 30 min at 4 °C, 3500 rpm, and dye concentration in the clear supernatant was assayed by fluorescence spectroscopy (F-2000, Hitachi) (λ_{ex} = 608 nm, 5 nm band-pass, λ_{em} = 687 nm, 5 nm band-pass). Standard curves were made using cell lysates treated as above with known amounts of the appropriate Pc solution added. The results were expressed as nmole of Pc per mg of cellular protein.

Intracellular Distribution. The cell suspension (1 × 10^5 cells/mL) was plated onto glass cover slips and incubated for 18−24 h at 37 °C, 5% CO_2, to allow for cell adhesion. The medium was removed, and the cells were rinsed twice with PBS and then overlaid with 1 mL of the dye solution (10 μM) in medium culture supplemented with 1% FBS. After 3 h at 37 °C, the dye solution was removed and the cells were washed twice with PBS and twice more with low phosphate buffer (HBSS/HEPES). The cells were incubated at 37 °C under 5% CO_2 with different tracker dyes (Invitrogen Inc., Ontario, Canada) including SYTO 13 (10 nM, 1 h), Myto-Tracker green (150 nM, 45 min), Lyso-Tracker Green (200 nM, 1 h), TMA-DPH (5 μM, 1 h), and NBDC6 Ceramide (5 μM, 1 h). Only the latter dye needs to be rinsed three times with the same buffer where after new medium is added, and the cells are incubated for another 30 min. After the last incubation, all samples were washed twice with PBS and mounted for microscopic observations. Cells were examined with a scanning confocal microscope (NORAN Instruments Inc, Middleton, WI) coupled to an inverted microscope with a 100× oil immersion objective (Nikon). Specimens were excited by krypton/argon laser at 488 or 568 nm and emitted fluorescence was measured using barrier filters (525/25 nm band-pass or 590 nm long-pass, respectively). Optical sections were collected at 0.25-μm intervals with 10 μm pinhole aperture (minimal opening in order to yield a maximal confocal component). Digitized images of 512 × 480 pixels were obtained with 256 times line averaging and enhanced with Intervision software (NORAN Instruments Inc) on a Silicon Graphics O2-workstation (Mountain View, CA).

Cell Photoinactivation. Cell cultures were trypsinated to give a 1.5 × 10^5 cells/mL suspension of which 100 μL per well were plated in 96 multiwell plates and incubated overnight at 37 °C under 5% CO_2. One column did not receive cells to serve as a blank. Attached cells were rinsed twice with PBS and incubated with 50 μL of dye solution (1 μM) in Waymouth 1% FBS for 1 or 24 h. One control column was filled with dye-free Waymouth 1% FBS. The cells were then rinsed twice with PBS, refed with 100 μL of Waymouth 15% FBS, and exposed for varying time intervals to red light (10 mW cm^{-2} at 660−700 nm). Plates were incubated overnight at 37 °C under 5% CO_2. Cell survival was measured by a colorimetric method, using the tetrazolium salt MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Sigma).

[a] *P*: *n*-Octanol/water partition coefficient. [b] t_R: HPLC retention times of PcS (in minutes, weighted average of regional isomers) on a C-18 reversed-phase column. [c] The relative amount of hydroperoxide (HPPI) formed from the photooxidation of l-tryptophan using different PcS in PBS (with and without 1% CRM) is expressed relative to that obtained with a standard ($AlOHPcS_4$). The quantum yield for singlet oxygen production of $AlOHPcS_4$ is 0.4. [d] The monomer concentration was estimated from its molar absorbance at 675 nm after deconvolution analysis and expressed as % of total PcS (5 μM). [e] n.d.: No detectable HPPI formation. n.a.: not applicable.

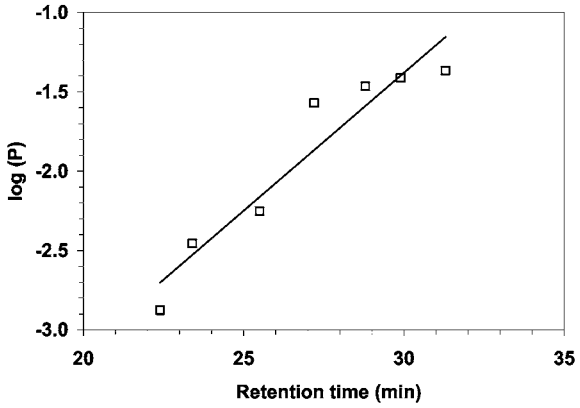

Figure 1. *n*-Octanol/water partition coefficient (log *P*) vs reversed-phase HPLC retention time (t_R).

Eight-fold replicates were run and experiments were repeated at least three times.

MTT Assay. This assay was adapted from the method described by Tada et al. (*40*). A stock solution of MTT at 0.5% in PBS was prepared and kept at 4 °C in the dark. The solution was diluted 5-fold in Waymouth 15% FBS, and 50 μL was added in each well. After 4 h incubation (37 °C, 5% CO_2), 100 μL sodium dodecyl sulfate (10% in 0.01 N HCl) was added to the wells to stop MTT reduction and to dissolve the blue formazan crystals produced by mitochondrial hydrogenases in living cells. After 24 h incubation, the plates were read on a microplate reader (Molecular Devices, Thermomax) for their optical densities at 570 nm. The survival curves were plotted as a function of light dose and LD_{90} values were calculated.

RESULTS

Lipophilic Properties of the Dyes. The retention times (t_R) of the substituted $ZnPcS_3C_n$ on reversed-phase HPLC and their partition coefficients (*P*) between *n*-octanol and water are summarized in Table 1. A plot of log *P* versus the retention time on HPLC shows a linear correlation (Figure 1). t_R values of the $ZnPcS_3C_n$ increase with increasing "*n*", i.e., the length of the alkynyl side chain, reflecting their increased lipophilicity. Addition of a six-carbon chain to the $ZnPcS_3$ to give $ZnPcS_3C_6$ (**10**) increases the t_R from 22.4 to 27.2 min, which is similar to the t_R of the adjacent substituted disulfonated $ZnPcS_{2a}$ (25.5 min), suggesting that their amphiphilic characters are comparable. The partition coefficients indicate however that the $ZnPcS_3C_6$ (**10**) is more lipophilic than the $ZnPcS_{2a}$.

Spectral Properties. The spectra of all dyes in PBS show a strong absorption peak at 460 nm, a characteristic peak of the monomer at 675 nm, and a characteristic peak for the aggregated dye at 630 nm (Figure 2). Aggregation of the monomers results in a blue shift of the Q-band, from 675 to 630 nm while the intensity of the absorption band at 460 nm remains constant (*15*, *41*−*43*). In Waymouth 1% FBS the intensity of the aggregate peak at 630 nm is decreased while the intensity of monomeric Q-band at 675 nm is increased. Augmenting the FBS concentration to 55% further increases the absorption peak at 675 nm. This suggests that binding of the Pc to FBS proteins facilitates the formation of monomers. In methanol and DMF the monomeric peak at 675 nm is prominent for most of the $ZnPcS_3$ derivatives. Addition of an emulsifier such as Cremophor EL (1%) to an aqueous solution of the dye likewise results in monomerization of the aggregates. Examples of the spectral shifts in different media are presented in Figure 2a−d.

To estimate the concentration of monomeric or aggregated Pc in different media, deconvolution spectra of the overlapping absorption peaks were generated. To this end, the spectra were analyzed by a Lorentzian non linear curve fit (*44*). Table 1 summarizes the monomer concentration (μM) of the various sulfonated ZnPc (5 μM) measured in five different media after an equilibrium period of 24 h. In all media a linear relationship between retention time (t_R) and the monomer concentration is evident with the highest percentage of monomers occurring for the hydrophilic $ZnPcS_3$ lacking the hydrocarbon side chain. Monomerization is minimal in PBS. The addition of 1% FBS has little effect, while 55% FBS results in a balance between the concentration of monomer and aggregate except for $ZnPcS_3C_{16}$ (**13**), which is not affected. In contrast the monomer concentration of $ZnPcS_{2a}$ increases by 5-fold upon addition of 55% FBS, approaching the monomerization level obtained in methanol. In methanol, the monomer concentration of all sulfonated ZnPc derivatives is higher than 2.3 μM, with the nonsubstituted $ZnPcS_3$ approaching near 100% monomerization.

L-Tryptophan Photooxidation. Upon excitation, phthalocyanine monomers generate $^1O_2$, which in turn can photooxidize lipids and amino acids such as L-tryptophan. L-Tryptophan photooxidation yields characteristic hydroperoxide isomers (HPPI) that can be quantified using HPLC. Singlet oxygen quantum yields ($\Phi\ ^1O_2$) can be established by comparison of the HPPI yields of the ZnPc with $AlOHPcS_4$ ($\Phi\ ^1O_2 = 0.43$) (*45*). Table 1 shows the HPPI hydroperoxide yields for the various

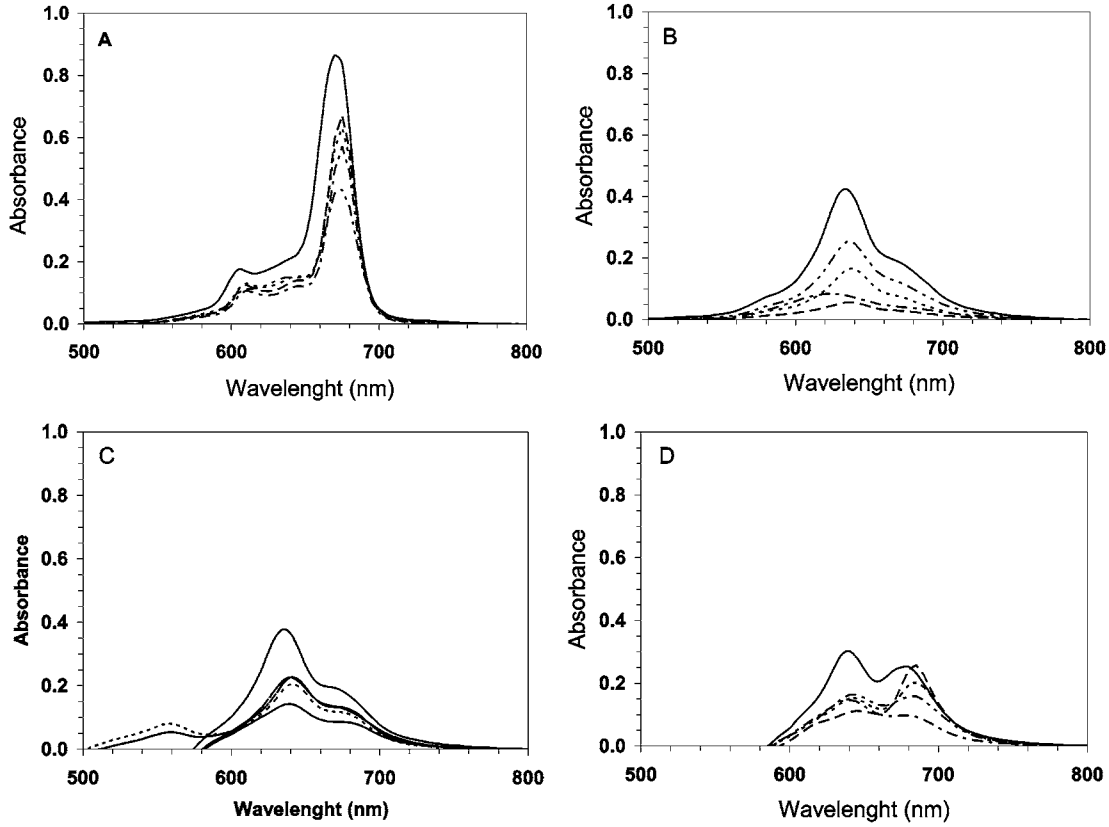

Figure 2. Absorption spectra of $ZnPcS_3$ (−), $ZnPcS_3C_2$ (− · · −), $ZnPcS_3C_6$ (· · · ·), $ZnPcS_3C_9$ (− − −) and $ZnPcS_3C_{16}$ (− · − ·) in different media. A: methanol, B: PBS, C: Waymouth's +1% FBS, D: Waymouth's +55% FBS.

ZnPcS derivatives together with their monomer concentrations. In PBS the photooxidation of l-tryptophan is greatly decreased when $ZnPcS_3$ is substituted with lipophilic chains to give $ZnPcS_3C_n$. This is in agreement with their absorption spectra that indicate that the $ZnPcS_3C_n$ are highly aggregated in this medium. However, addition of 1% CRM results in >60% monomerization revealing that all $ZnPcS_3C_n$ have similar capacities to generate $^1O_2$, which are higher than that of the reference dye AlO-$HPcS_4$.

Cell Uptake. Dye uptake by the EMT-6 cells as a function of incubation time is presented in Figure 3. The concentrations in nmole Pc per mg cell protein after 1 and 24 h incubation with 10 μM ZnPcS are shown together with cell survival after PDT with 1 μM ZnPcS as a function of the light dose required for 50% and 90% cell kill (LD_{50} and LD_{90}). After 1 h of incubation, $ZnPcS_3C_9$ (**11**) shows the highest uptake among the various $ZnPcS_3C_n$. Prolonged incubation of 24 h results in further increase of the dye concentration by about an order of magnitude. $ZnPcS_3$ substituted with longer aliphatic side chains ($n > 9$) are taken up by the EMT-6 cells to a lesser extent.

Intracellular Distribution. Figure 4a−e shows the intracellular localization of the ZnPcS derivatives (10 μM) in EMT-6 cells after 3 h incubation, together with the localization of different tracker dyes. The presence of the ZnPcS is evident from their red fluorescence (Figure 4, center images). The different tracker dyes are detected by their intense green fluorescence (left images), while colocalization with the ZnPcS results in a yellow fluorescence (right images). The ZnPcS are mainly localized in the cytoplasm: Mitochondria (Figure 4a), Golgi (Figure 4b), and lysosomes (Figure 4c), while almost excluded from the cell nucleus (Figure 4d). The sensitizers mostly cross the cytoplasmic membrane by passive diffusion; however, colocalization with the tracker dyes in Golgi and lysosomes indicates that part of the transport involves endocytosis. The latter is confirmed by the detection of ZnPcS as a punctuate pattern colocalized with membrane tracker dye (Figure 4e). The parent $ZnPcS_3$ and its analogue substituted with a short C2 chain exhibit a similar distribution pattern while substitution with the longer C12 and C16 chains reduces uptake in the cytoplasmic organelles. The most amphiphilic $ZnPcS_{2a}$, $ZnPcS_3C_6$ (**10**) and $ZnPcS_3C_9$ (**11**), show the highest accumulation in the mitochondria (Figure 4).

Photocytotoxicity. No dark toxicity toward EMT-6 cells was observed with any of the dyes under study up to 100 μM over a 24 h incubation period in Waymouth 1% FBS. LD_{50} and LD_{90} after 1 h and 24 h incubation with the dyes as a function of light dose (J cm^{-2}) are summarized in Table 2 and were derived from the corresponding survival curves (not shown). To directly compare cell uptake with photocytotoxicity of the $ZnPcS_3C_n$ series, the LD_{50}, LD_{90}, and cell uptake values vs retention time are shown on the same plots (Figure 3). The most photoactive dye is the $ZnPcS_{2a}$ followed by $ZnPcS_3C_6$ (**10**) and $ZnPcS_3C_9$ (**11**). The latter exhibit substantial higher photocytotoxicity than the parent $ZnPcS_3$ or the $ZnPcS_3C_n$ bearing the shorter ($n = 2$) or longer ($n = 16$) alkynyl side chain.

DISCUSSION

In this study we compare the hydrophilic/lipophilic properties of a series of structurally related sulfonated Pc dyes with a number of parameters that impact on their photodynamic potential. The lipophilic properties of the various $ZnPcS_3C_n$ were determined by two methods, *n*-octanol/water partition coefficient (*P*) and reversed-phase HPLC retention time (t_R). The first shows the

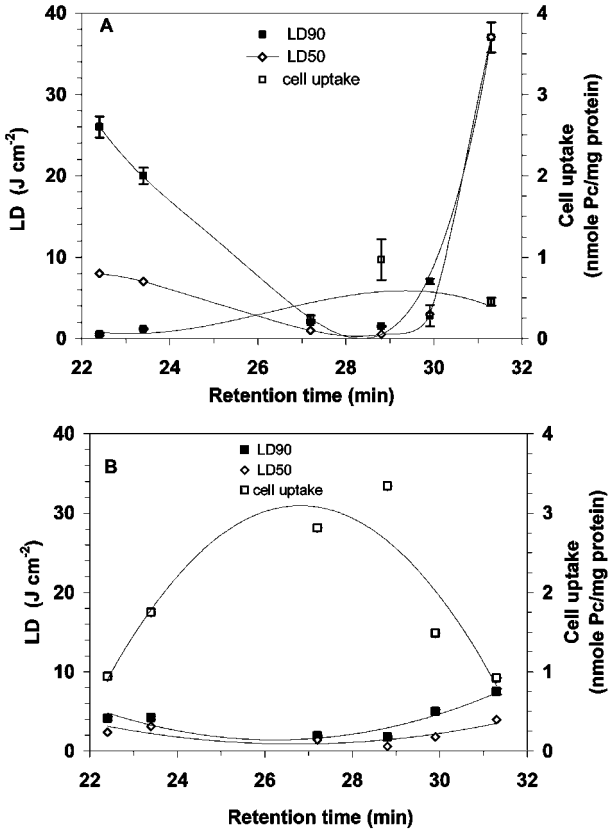

Figure 3. Comparison of EMT-6 cell phototoxicity (LD_{90} and LD_{50} in J cm^{-2}) and cell uptake (in nmol Pc/mg protein) of a series of ZnPcS derivatives as a function of their HPLC retention times, after (A): 1 h and (B): 24 h incubation periods.

preference of the dyes for organic solvent (*n*-octanol) and the second determines the strength of hydrophobic interactions. Both methods give a measure of the lipophilic properties of the dyes and the relationship between these two parameters was shown to be linear (Figure 1). Longer t_R correlate with a higher partition coefficient (log *P*) reflecting stronger lipophilic properties of a given dye.

Singlet oxygen ($^1O_2$) yields have shown to be inversely proportional to the extent of aggregation of a sensitizer (*15*, *43*). Tendency to aggregate is largely modulated by the ring substituents and the nature of axial ligands on the central metal ion. Monomeric Pc molecules with the identical central metal ion and varying degrees of sulfonation retain the same photochemical activity. Pc aggregation is easily detected by a 30−50 nm blue-shift of the Q-band around 675 nm to yield a broad and less absorption peak around 630 nm in the UV−vis absorption spectrum (*15*). Upon excitation with light, aggregated photosensitizers dissipate their energy through internal conversion to the ground-state rather than triplet formation with subsequent singlet oxygen production (*16*). Hydroperoxide (HPPI) formation from L-tryptophan by our ZnPcS in PBS increased proportionally with the monomer concentration (Table 1). The more lipophilic compounds with longer HPLC retention times aggregated more readily in aqueous solution, thus reducing their photochemical activities. When the Pc derivatives were solubilized in 1% Cremophor EL, HPPI formation of all $ZnPcS_3C_n$ derivatives surpassed that of the reference $AlOHPcS_4$ (Table 1). Margaron et al. reported similar findings using a series of ZnPc, where the most lipophilic compound, a tetraiodinated ZnPc entered the cells to a lesser extent due to low affinity for the plasma membrane (*26*).

It is generally believed that amphiphilic properties of photosensitizers play a significant role in their efficiency in photodynamic therapy (*46*). We previously reported that increasing the number of sulfonated groups on a metallo Pc led to a decrease in the photocytotoxicity under both in vitro and in vivo conditions, which coincided with decreased cellular uptake (*47*, *48*). The disulfonated dye bearing two sulfonated groups on adjacent benzyl rings was found to be the most photoactive derivative. On the other hand, it was reported that amphiphilic dyes interact with the lipid portion of plasma membranes (*49*), thereby facilitating their transport into the cell (*27*). It has also been reported that the same amphiphilic properties allows for more efficient binding to low density lipoprotein (LDL), which has been implicated in the transport of porphyrin-based sensitizers to tumor tissue (17). Amphiphilic properties of sulfonated Pc strongly correlate with their cell uptake and photocytotoxic potency (*26*). Our current data confirm that adding a lipophilic hydrocarbon side chain to $ZnPcS_3$ improves cell uptake (Table 2). However, adding longer chain lengths, e.g., $n > 9$ for $ZnPcS_3C_n$, results in a decrease in cell uptake providing a parabolic relationship between cell uptake vs retention time, inverse to that observed for phototoxicity vs retention time (Figure 3). This is particularly evident after a 24 h incubation period (Figure 3B). Comparing the LD_{90} of the $ZnPcS_3C_n$ with their relative cell uptake values, both after a 1-h and 24-h incubation periods, reveals a linear regression with higher cell uptake capacity correlating to lower photocytotoxicity (Figure 5). This phenomenon is particularly evident after the shorter 1-h incubation period. This confirms that variations in cellular phototoxicity between the dyes cannot simply be explained by differences in cell uptake. Instead, our data strongly suggest that variations in cell uptake rates and intracellular distribution pattern are responsible for differences in photoactivity.

On such account we examined possible correlations between amphiphilicity and tendencies to aggregate, which in turn could impact both on cell uptake kinetics and capacity to produce singlet oxygen as well as intra-

Table 2. Phototoxicity and EMT-6 Cell Uptake of a Series of ZnPcS Derivatives

[a] EMT-6 cells were incubated with ZnPcS (10 μM) for 1 h or 24 h and analyzed for dye content as described under materials and methods. Values are in nmole Pc per mg of cell protein (±SEM). [b] The LD_{50} or LD_{90} is the light dose (J cm^{-1}) required to induce cell survival by 50% or 90% after incubating EMT-6 cells with 1 μM dye for 1 h or 24 h.

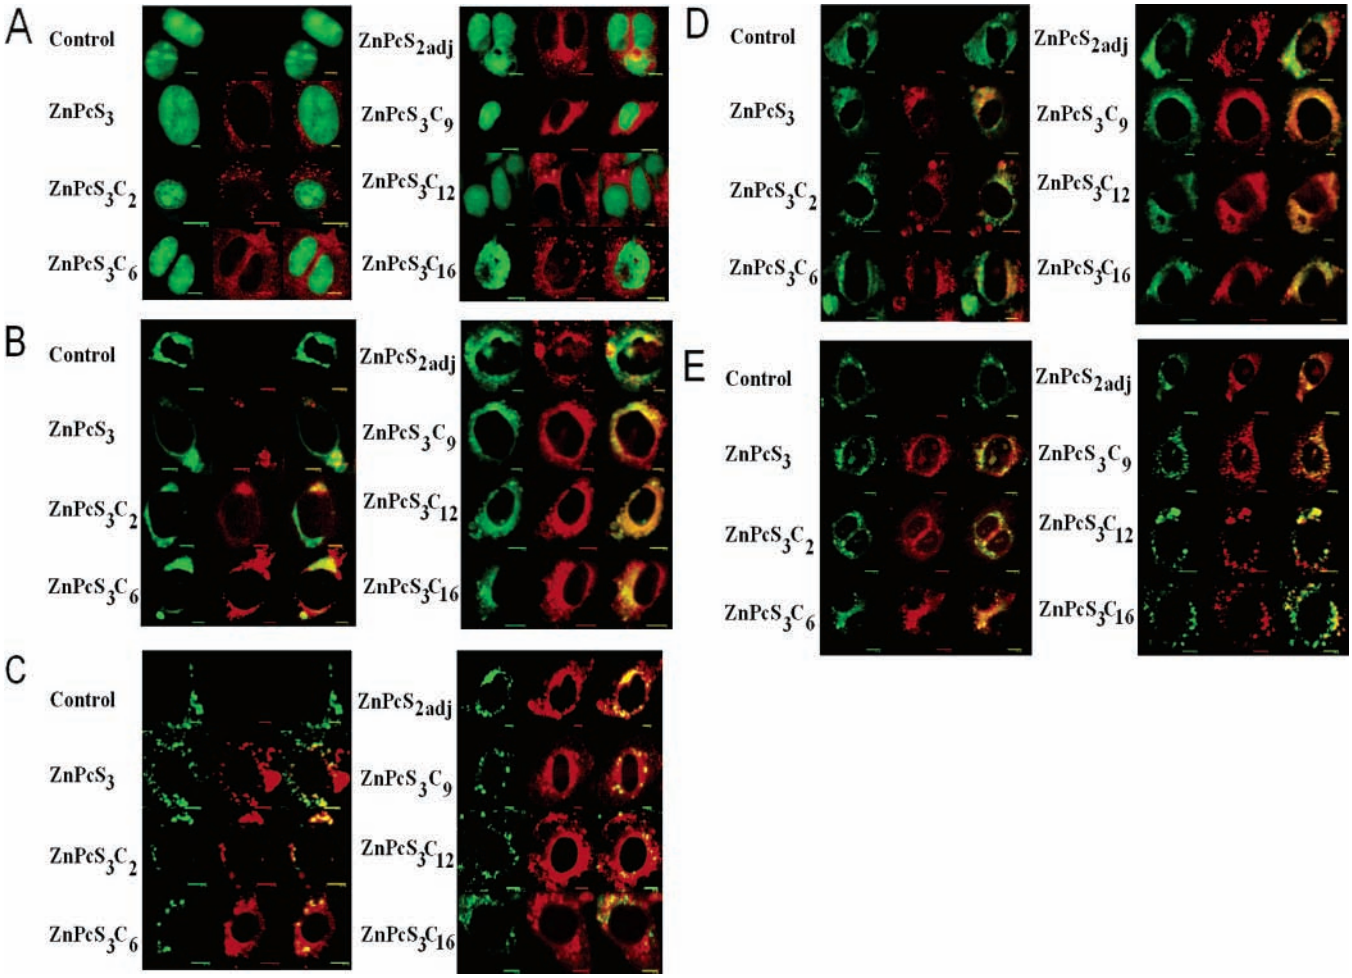

Figure 4. Comparative intracellular localization of ZnPcS derivatives (10 μM) in EMT-6 cells after incubation for 3 h (center images) with various tracker dyes (left images) and superimposed images (right images). A: nucleus (syto 13), B: mitochondria (mytotracker green), C: lysosomes (lyso-tracker green), D: golgi (NBD-6 Ceramide), and E: endocytose (TMA-DPH).

cellular localization pattern. Increasing hydrophobicity of $ZnPcS_3$ by the addition of lipophilic side chains affects the tendencies to aggregate in a milieu-dependent manner. In PBS or culture medium, with the addition of 1% FBS protein, aggregation remains high and similar for all derivatives tested (Table 1). These data show that the most hydrophilic parent $ZnPcS_3$ is in fact the least aggregated. Adding 55% protein to the medium breaks up the stacked ZnPcS aggregates resulting in doubling of the monomer concentration to ~20%. Only the $ZnPcS_3C_{16}$ is less affected by the added protein and its monomer concentration remains low (6%). In contrast $ZnPcS_{2a}$ interacts strongly with protein resulting in a 5-fold increase of the monomer concentration (>50%). In methanol monomerization is high, i.e., above 50% for most dyes tested. Of the five media the aqueous buffer fortified with 55% FBS most closely mimics the intracellular environment where the dyes localize, suggesting that a similar monomerization process occurs at the cellular level. This implies that amphiphilicity of the dye plays an important role in reaching optimal monomer/aggregated ratios at the target site, contributing to the desired phototoxic effects.

Longer side chains facilitate aggregation of the dyes resulting in loss of their capacity to generate singlet oxygen, a phenomena that is confirmed by their diminished capacity to photooxidize L-tryptophan to its characteristic HPPI hydroperoxide products (Table 1). Steric hindrance may also contribute to diminished cell uptake and loss of phototoxicity. Rosenthal et al. attributed the absence of significant uptake of the lipophilic tetraneopentoxy ZnPc to steric hindrance of the bulky neopentoxy groups (*50*). We previously demonstrated that adding long axial hydrocarbon chains to silicon naphthalocyanine increased their hydrophobicity, but that increased steric hindrance reduced cellular uptake resulting in reduced cellular phototoxicity (*51*).

However, differences between the intracellular localization patterns of the dyes may yet play the most important role in exerting their photodynamic action. The high reactivity of the cytotoxic singlet oxygen produced upon photoexcitation of the dyes limits their action range such that most of the photodamage occurs at the site where the dyes localize (*24*). The importance of intracellular localization relates to the many cytoplasmic targets, the extent of the damage generated, and the capacity of the cell to repair these injuries. The nucleus's DNA is prone to damage and as such is the first target to consider in cell death. However, access to the nucleus is limited due to the selectivity of the nuclear membrane. Our phthalocyanines, as well as other photosensitizers, tend to accumulate on the surface of the nuclear membrane without traversing this barrier (Figure 4A). Even though the nucleus is not directly affected by our phthalocyanines, its role in cell death after PDT is evident since damage at other intracellular sites initiates a cascade of biochemical reactions that affect the nucleus (*20*).

Our $ZnPcS_3C_n$ localize mainly at the mitochondria and Golgi apparatus (Figure 4B,C). There are, however, significant differences between the dye preparations with the most amphiphilic $ZnPcS_3C_6$ and -C_9 giving the highest colocalization with mitotracker green. Shorter or longer lipophilic side chains show reduced uptake. Furthermore, uptake by the lysosomes provides an active pathway to attack vital organelles as part of the overall photodynamic response. The relationship between the intracellular localization pattern of our ZnPcS and their photodynamic potency obviously does not constitute the only parameter to consider. Other factors that may play a role include the quantity of singlet oxygen produced, interaction between different organelles within the cell, the extent of damage, changes in permeability of the various membrane structures, cell uptake kinetics, etc. Evaluation of all such parameters is essential to establish a reliable structure−photodynamic activity relationship and experiments to this end are currently in progress.

In summary, the amphiphilic properties of trisulfonated ZnPc can be improved by introducing a lipophilic alkynyl chain to the Pc macro cycle. The amphiphilic properties of the $ZnPcS_3C_n$ play a key role in cell uptake and photocytotoxicity, and also affect the aggregation of sulfonated Pc in biological systems. Adding a C6−C9 linear carbon chain to $ZnPcS_3$ ($ZnPcS_3C_6$ and $ZnPcS_3C_9$) gave Pc that readily localized in the mitochondria and the Golgi apparatus resulting in comparable photodynamic activities as those reported for the amphiphilic, adjacent disulfonated $ZnPcS_{2a}$, which is considered as one of the most active sulfonated Pc-based photosensitizers for PDT. The advantage of these new derivatives over $ZnPcS_{2a}$ as potential photosensitizers for PDT lies in their chemistry: They are more easily prepared and purified to give well identified products.

ACKNOWLEDGMENT

Synthesis of a Lipid Conjugate of SO_3Le^a and Its Enhancement on Liposomal Binding to Activated Platelets

Feng Yan,[§] Jie Xue,[§] Junmin Zhu,[†] Roger E. Marchant,[†,*] and Zhongwu Guo[§,*]

Departments of Chemistry and Biomedical Engineering, Case Western Reserve University, 10900 Euclid Avenue, Cleveland, Ohio 44106. Received August 13, 2004; Revised Manuscript Received October 20, 2004

3′-O-Sulfated Le^a (SO_3Le^a) is one of the most potent natural oligosaccharide ligands of selectins. The specific interactions between SO_3Le^a and E-/P-selectins are critical in the inflammation process. This paper described an efficient synthesis of a lipid conjugate of SO_3Le^a and its combination with phospholipid and cholesterol to form SO_3Le^a-coated liposomes by the freeze-thaw and extrusion method. The size ($D = 78$ nm) and stability of the resultant glycoliposomes were comparable to that of liposomes without the glycoconjugate. It was further observed that the incorporation of SO_3Le^a into liposomes could significantly enhance their adhesion to activated platelets as a result of the specific binding between SO_3Le^a on the glycoliposome and the P-selectin on activated platelets. The glycoliposome constructs may be useful for antiinflammation or for targeted delivery of drugs to endothelial cells that express E- and P-selectins.

INTRODUCTION

Liposomes are colloidal structures consisting of a lipid bilayer and an encapsulated aqueous volume to locate useful components. Since the encapsulated volume and components are isolated from the outside environment, they are not easily disturbed until the liposome is disrupted. Consequently, liposomes have been studied extensively as drug delivery systems (*1*−*7*), in the hope of improving the stability, therapeutic efficiency, and pharmacokinetic properties of drugs while reducing their side effects. As drug delivery systems, liposomes have the advantage of being biodegradable and nontoxic, as well as the beneficial properties that their surface chemistry and lipid composition can be easily modified to address targeting requirements. Moreover, the high lateral mobility of liposome-associated molecules facilitates their formation of subdomains on liposome surface and enables the multivalent interactions between liposomes and cells.

In recent years, the cell surface glycocalyx has emerged as a useful model to create carbohydrate-modified liposomes, namely glycoliposomes, for the targeting of specific organs or tissues (*8*−*10*). An important discovery in this respect is that liposomes coated with different carbohydrates have distinct properties. For instance, by primarily inhibiting the uptake of liposomes into the reticuloendothelial system (RES) in liver and spleen, GM1 ganglioside enhances liposomal circulation lifetimes in vivo (*11*−*13*) in a manner comparable to that observed with the sterically stabilized poly(ethylene glycol) (PEG) liposomes (*14*, *15*). In contrast, trisialoganglioside GT1 liposomes were quickly cleared into the RES, due to the specific binding between GT1 and its receptors in RES (*16*). These results suggest that the recognition of special oligosaccharide epitopes by cells may play an important role in determining the in vivo fate of glycoliposomes (*10*, *14*). Consequently, glycoliposomes are extensively investigated for targeted drug delivery, taking advantage of their interactions with specific carbohydrate receptors on cells (*10*). This approach can give rise to highly selective and efficient delivery devices and further reduce the adverse systemic side effects of drugs.

Numerous carbohydrate recognition proteins are known to exist on mammalian cell surfaces (*17*−*22*). For the purpose of tissue targeting, the galactose- and mannose-binding receptors on hepatic cells have been broadly studied (*8*, *10*, *22*−*25*). Another important target is the selectins present on activated endothelial cells and platelets (*26*−*29*).

Selectins are a family of lectins that bind Lewis type carbohydrate antigens specifically (*30*, *31*). Three selectins have been identified, including E-, P-, and L-selectins. P- and E-selectins are expressed on activated vascular endothelial cells and platelets; L-selectin is expressed on activated leukocytes. The specific interactions between selectins and their ligands regulate the adhesion of leukocytes to endothelium, the first step of inflammation (*30*−*32*). Therefore, much effort is currently focused on the development of new therapeutic strategies for inflammatory diseases based on Lewis type antigens (*33*−*35*).

The natural selectin ligands, such as sialyl Lewis x (sLe^x **1**), sialyl Lewis a (sLe^a **2**), and 3′-O-sulfated Lewis a (SO_3Le^a **3**) (Figure 1), share a common recognition motif, namely the Lewis type antigen which is a fucosylated trisaccharide with a negatively charged species, e.g. a sialic acid or a sulfate unit, attached to the galactose 3-O-position.

It has been well established that Lewis type carbohydrates can interrupt the adhesion of leukocytes to the endothelium and thus inhibit the inflammatory process (*33*). Alternatively, the specific binding of Lewis type carbohydrates to endothelial cells can also be used for the selective targeting of the endothelium (*26*). To explore the promise of these applications, we synthesized the lipid conjugate of SO_3Le^a, one of the most potent natural ligands of selectin (*36*), incorporated the conjugate into

liposomes, and studied the properties of the resultant glycoliposomes. One objective of this work was to establish a practicable method to synthesize the lipid conjugates of Lewis type antigens with the lipid moiety linked to the carbohydrate reducing end. Another objective was to investigate the physical and biological properties of the glycoliposomes coated with a Lewis type antigen.

EXPERIMENTAL PROCEDURES

General Methods. NMR spectra were recorded on a 300 or 600 MHz NMR spectrometer with chemical shifts reported in ppm (δ) relative to Me_4Si (^1H), $CDCl_3$ (^{13}C), and $CFCl_3$ (^{19}F), respectively. Coupling constants (J) are reported in hertz (Hz). Thin-layer chromatography (TLC) was performed on silica gel 60 GF_{256} with detection by charring with phosphomolibdic acid in EtOH or 5% H_2SO_4 in EtOH. Commercial solvents and reagents were directly used without further purification.

***O*-(2,4,6-Tri-O-acetyl-3-*O*-chloroacetyl-*β*-D-galactopyranosyl)-(1→3)-2-deoxy-4,6-*O*-phenylmethylene-2-phthalimido-*β*-D-glucopyranosyl Azide (9).** A solution of TfOH (200 μL) in CH_2Cl_2 (2 mL) was added dropwise to a mixture of **7** (1.80 g, 2.86 mmol), **8** (0.80 g, 0.93 mmol), and NIS (0.62 g, 1.45 mmol) in CH_2Cl_2 (50 mL) at −10 °C. After the reaction was completed (monitored by TLC), saturated $NaHCO_3$ solution was added (30 mL). The organic phase was separated, and the aqueous phase was extracted with CH_2Cl_2 (50 mL). The organic solutions were combined and washed with $Na_2S_2O_3$ solution (2 × 25 mL) and dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure, and the residue was subjected to column chromatography to afford **9** (0.82 g, 55%) as a white solid. TLC: R_f = 0.25 (hexane and acetone, 3:2); ^1H NMR (300 MHz, $CDCl_3$): δ 7.94−7.77 (m, 4 H, aromatic), 7.49−7.23 (m, 5 H, aromatic), 5.60 (s, 1 H, C*H*Ph), 5.35 (bd, *J* 9.5 Hz, 1 H, H-1), 5.20 (d, *J* 3.4 Hz, 1 H, H-4′), 5.02 (dd, *J* 8.0, 10.4 Hz, 1 H, H-2′), 4.81 (dd, *J* 3.4, 10.4 Hz, 1 H, H-3′), 4.79 (dd, *J* 8.9, 9.7 Hz, 1 H, H-3), 4.56 (d, *J* 8.0 Hz, 1 H, H-1′), 4.40 (dd, 1 H, H-6a), 4.23 (dd, *J* 3.4, 10.4 Hz, 1 H, H-2), 4.03 (dd, *J* 8.3, 11.1 Hz, 1 H, H-6b), 3.88−3.72 (m, 6 H, H-4, 5, 6′a, 6′b, CH_2Cl), 3.50 (m, 1 H, H-5), 2.09, 1.93, 1.59 (s, 3 H each, 3 Ac); FAB-MS: Calcd for $C_{35}H_{35}ClN_4O_{15}$ (M^+) 787.1, Found 787.1.

***O*-(2,4,6-Tri-O-acetyl-3-*O*-chloroacetyl-*β*-D-galactopyranosyl)-(1→3)-6-*O*-benzyl-2-deoxy-2-phthalimido-*β*-D-glucopyranosyl Azide (10).** A freshly prepared saturated solution of HCl in diethyl ether (8 mL) was added dropwise to a suspension of **9** (1.0 g, 1.1 mmol) and $NaBH_3CN$ (0.78 g, 11.0 mmol) in THF (60 mL) at 0 °C. After **9** was completely consumed, solid $NaHCO_3$ (1.5 g) was added to quench the reaction. The mixture was stirred at room temperature for 5 min and then diluted with ethyl acetate (300 mL). After the organic solution was washed with saturated $NaHCO_3$ solution (2 × 150 mL) and brine (2 × 150 mL), it was dried over anhydrous Na_2SO_4. The solvent was removed under reduced pressure and the residue was separated by column chromatography to afford **10** (0.90 g, 90%) as a colorless foamy solid. TLC: R_f = 0.23 (hexane and acetone, 3:2); $[\alpha]_D$ −3.6 (*c* 1.0, $CHCl_3$); ^1H NMR (600 MHz, $CDCl_3$): δ 7.94−7.77 (m, 4 H, aromatic), 7.49−7.23 (m, 5 H, aromatic), 5.29 (d, *J* 3.6 Hz, 1 H, H-4′), 5.20 (d, *J* 9.6 Hz, 1 H, H-1), 5.12 (dd, *J* 9.8, 11.2 Hz, 1 H, H-2′), 4.84 (dd, *J* 3.6, 11.2 Hz, 1 H, H-3′), 4.65 (s, 2 H, CH_2Ph), 4.50 (dd, *J* 7.8, 10.8 Hz, 1 H, H-3), 4.40 (d, *J* 7.8 Hz, 1 H, H-1′), 4.50 (dd, *J* 9.6, 10.8 Hz, 1 H, H-2), 4.13−4.09 (m, 2 H), 4.00 (s, 1 H, OH), 3.95 (m, 1 H), 3.86−3.70 (m, 5 H), 3.67 (t, *J* 9.6 Hz, 1 H). 2.14, 2.09, 2.01 (s, 3 H each, 3 Ac); ^{13}C NMR (25 MHz, $CDCl_3$): δ 170.6, 170.3, 168.9, 166.6, 138.0, 134.8, 131.30, 128.56, 128.53, 128.47, 127.96, 127.92, 127.84, 127.76, 127.72, 123.9, 100.9, 85.6, 81.8, 77.75, 77.59, 77.2, 76.7, 73.72, 73.67, 73.63, 72.5, 71.2, 69.6, 69.1, 68.3, 66.8, 61.55, 61.52, 54.2, 40.21, 40.18, 20.63, 20.60, 20.57, 20.54, 19.79; FAB-MS: Calcd for $C_{35}H_{36}ClN_4NaO_{15}$ ($M - H + Na)^+$ 811.1, Found 811.2.

***O*-(2,4,6-Tri-O-acetyl-3-*O*-chloroacetyl-*β*-D-galactopyranosyl)-(1→3)-[*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-(1→4)]-6-*O*-benzyl-2-deoxy-2-phthalimido-*β*-D-glucopyranosyl Azide (11).** A mixture of **10** (0.070 g, 0.089 mmol), **6** (0.105 g, 0.23 mmol), and freshly activated MS 4 Å in CH_2Cl_2 (10 mL) and DMF (10 mL) was stirred at 20 °C for 2 h, whereupon $CuBr_2$ (0.070 g, 0.30 mmol) and Bu_4NBr (0.10 g, 0.32 mmol) were added. After the mixture was stirred at room temperature for 36 h, the solid material was filtered off and washed with CH_2Cl_2 (2 × 20 mL). The combined filtrates were washed with diluted aq HCl solution, saturated aq $NaHCO_3$ solution, and brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by flash chromatography to afford **11** (0.80 g, 78%) as a colorless foamy solid. TLC: R_f = 0.30 (hexane and acetone, 2:1); $[\alpha]_D$ −22.8 (*c* 1.0, $CHCl_3$); ^1H NMR (600 MHz, $CDCl_3$): δ 7.94−7.77 (m, 4 H, aromatic), 7.49−7.23 (m, 20 H, aromatic), 5.20 (dd, *J* 1.2, 3.6 Hz, 1 H, H-4′), 5.19 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 5.10 (d, *J* 9.6 Hz, 1 H, H-1), 5.02 (dd, *J* 8.4, 10.4 Hz, 1 H, H-2′), 4.98 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.88 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.84 (dd, *J* 3.6, 11.2 Hz, 1 H, H-3), 4.83 (m, 3 H, H-2″, H-4″, H-3″), 4.78 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.70 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.70 (m, 1 H, H-5″), 4.48 (dd, *J* 3.6, 10.6 Hz, 1 H, H-3′), 4.44 (s, 2 H, CH_2Ph), 4.20 (m, 4 H, H-5′, H-1′, H-2, H-1″), 4.08−3.93 (m, 3 H, H-4, H-6), 3.80 (m, 2 H, CH_2Cl), 3.74−3.64 (m, 3 H, H-5, H-6), 3.65 (m, 1 H), 1.99, 1.98, 1.71 (s, 3 H each, 3 Ac), 1.12 (d, *J* 6.2 Hz, 3 H, Fuc-6); ^{13}C NMR (25 MHz, $CDCl_3$): δ 170.3, 169.92, 169.19, 166.63, 138.71, 138.63, 138.23, 135.02, 128.78, 128.49, 128.47, 128.41, 128.33, 127.92, 127.71, 127.60, 127.56, 127.44, 127.01, 123.89, 100.4, 97.8, 85.3, 80.9, 77.9, 77.48, 77.06, 76.64, 76.27, 75.5, 75.05, 74.51, 73.94, 73.18, 72.73, 72.35, 72.3, 70.23, 67.5, 66.4, 66.1, 55.8, 40.3 20.63, 20.49, 20.38, 16.97; FAB-MS: Calcd for $C_{62}H_{65}ClN_4O_{19}$ (M^+) 1204, Found 1204.

***O*-(2,4,6-Tri-*O*-acetyl-*β*-D-galactopyranosyl)-(1→3)-[*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-(1→4)]-6-*O*-benzyl-2-deoxy-2-phthalimido-*β*-D-glucopyranosyl Azide (12).** After 16 h of refluxing, the mixture of thiourea (25 mg, 0.033 mmol), 2,6-lutidine (16 μL, 14 mg)

and **11** (80 mg, 0.066 mmol) in EtOH and CH_2Cl_2 (1:4, 50 mL) was concentrated in a vacuum. The residue was purified on a silica gel column to give **12** (64 mg, 86%) as a foamy solid. TLC: R_f = 0.27 (toluene and ethyl acetate, 2:1); $[\alpha]_D$ −9.7 (*c* 0.8, $CHCl_3$); ^{1}H NMR (600 MHz, $CDCl_3$): δ 7.94−7.77 (m, 4 H, aromatic), 7.49−7.23 (m, 20 H, aromatic), 5.07 (d, *J* 19.2 Hz, 2 H, CH_2Ph), 5.05 (d, *J* 9.6 Hz, 1 H, H-1), 4.91 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.83 (d, *J* 12.0 Hz, 1 H, CH_2Ph), 4.83−4.62 (m, 6 H, H-2″, H-4″, H-3″, H-3, H-2′, H-4′), 4.20 (t, *J* 9.6 Hz, 1 H, H-2), 4.14−3.87 (m, 7 H, H-5′, H-1′, H-4, H-1″, H-6′), 3.65−3.54 (m, 4 H), 3.16 (dd, *J* 3.6, 9.6 Hz, 1 H, H-3′), 2.00, 1.96, 1.68 (s, 3 H each, 3 Ac), 1.13 (d, *J* 6.2 Hz, 3 H, Fuc-6); ^{13}C NMR (25 MHz, $CDCl_3$): δ 171.7, 170.2, 170.1, 138.76, 138.60, 138.25, 138.06, 134.84, 128.79, 128.59, 128.49, 128.43, 128.34, 127.92, 127.75, 127.69, 127.6, 127.55, 127.50, 127.44, 127.05, 123.778, 100.2, 97.9, 85.4, 80.9, 78.0, 77.5, 77.07, 76.66, 76.27, 75.50, 75.05, 74.34, 73.97, 73.19, 72.52, 72.33, 71.78, 71.63, 70.56, 68.90, 66.88, 66.35, 60.18, 55.75, 29.8, 20.72, 20.64, 20.60, 17.02; FAB-MS: Calcd for $C_{60}H_{64}N_4O_{18}$ (M^+) 1128, Found 1128.

***O*-(2,4,6-Tri-*O*-acetyl-3-*O*-sulfo-*β*-D-galactopyranosyl)-(1→3)-[*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-(1→4)]-6-*O*-benzyl-2-deoxy-2-phthalimido-*β*-D-glucopyranosyl Azide (13).** While the mixture of **12** (70 mg, 0.062 mmol) and SO_3·NMe_3 (0.173 g, 1.24 mmol) in pyridine (15 mL) was stirred at room temperature, the reaction progress was monitored by TLC. When the reaction completed about 24 h later, the mixture was concentrated in a vacuum. The residue was dissolved in $CHCl_3$ (30 mL), and the solution was washed with brine, dried over Na_2SO_4, and concentrated under reduced pressure. Purification was performed on a silica gel column to produce **13** (54 mg, 72%) as a white foamy solid. TLC: R_f =0.28 (DCM and MeOH, 8:1); ^{1}H NMR (600 MHz, $CDCl_3$): δ 7.94−7.77 (m, 4 H, aromatic), 7.49−7.23 (m, 20 H, aromatic), 5.33 (dd, 1 H, H-4′), 5.07 (d, *J* 9.6 Hz, 1 H, H-1), 4.89 (d, *J* 11.4 Hz, 1 H, CH_2Ph), 4.80−4.59 (m, 6 H), 4.38 (m, 2 H, CH_2Ph), 4.17−4.07 (m, 3 H), 3.96−3.87 (m, 4 H), 3.65−3.60 (m, 4 H), 2.00, 1.94, 1.76 (s, 3 H each, 3 Ac), 1.13 (d, *J* 6.2 Hz, 3 H, Fuc-6); ^{13}C NMR (25 MHz, $CDCl_3$): δ 171.7, 170.2, 170.1, 138.76, 138.60, 138.25, 138.06, 134.84, 128.79, 128.59, 128.49, 128.43, 128.34, 127.92, 127.75, 127.69, 127.6, 127.55, 127.50, 127.44, 127.05, 123.778, 100.2, 97.9, 85.4, 80.9, 78.0, 77.5, 77.07, 76.66, 76.27, 75.50, 75.05, 74.34, 73.97, 73.19, 72.52, 72.33, 71.78, 71.63, 70.56, 68.90, 66.88, 66.35, 60.18, 55.75, 29.8, 20.72, 20.64, 20.60, 17.02; FAB-MS: Calcd for $C_{60}H_{63}N_4Na_2O_{21}S$ ($M - H + 2\ Na)^+$ 1253, Found 1253.

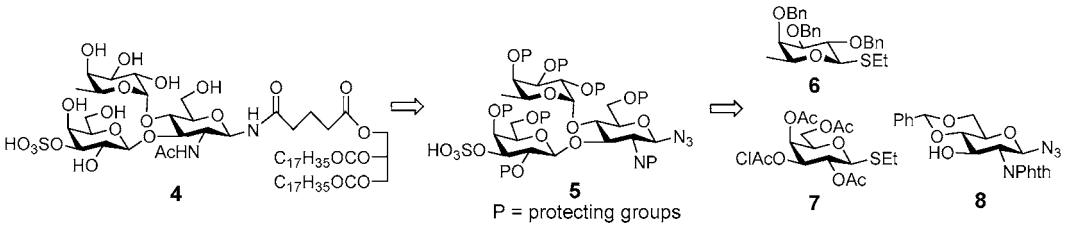
***O*-(3-*O*-Sulfo-*β*-D-galactopyranosyl)-(1→3)-[*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-(1→4)]-2-acetamido-6-*O*-benzyl-2-deoxy-*β*-D-glucopyranosyl Azide (5).** After the mixture of **13** (0.25 g, 0.21 mmol) and ethylenediamine (1 mL, 15 mmol) in BuOH (10 mL) was stirred at 90 °C overnight, the solution was concentrated in a vacuum, and the residue was dissolved in MeOH (20 mL). To this solution were added triethylamine (2.0 mL) and Ac_2O (1.5 mL) at room temperature. The mixture was stirred for 10 min and then condensed. Purification of the residue with silica gel column twice gave **5** (0.11 g, 52%) as a white foamy solid. TLC: R_f = 0.49 (DCM and MeOH, 8:1); $[\alpha]_D$ −27.5 (*c* 1.0, $CHCl_3$); ^{1}H NMR (600 MHz, $CDCl_3$−CD_3OD): δ 7.18−7.39 (m, 20 H, aromatic), 5.04 (d, *J* 3.0 Hz, 1 H, H-1″), 4.88 (d, *J* 11.4 Hz, 1 H), 4.78 (d, *J* 11.4 Hz, 1 H), 4.75 (d, *J* 10.8 Hz, 1 H), 4.72 (m, 1 H, 5-H″), 4.69 (d, *J* 11.4 Hz, 1 H), 4.58 (d, *J* 10.8 Hz, 1 H), 4.55 (d, *J* 9.6 Hz, 1 H, H-1), 4.50 (d, *J* 12.0 Hz, 1 H), 4.48 (d, *J* 11.4 Hz, 1 H), 4.39 (d, *J* 10.2 Hz, 1 H, H-1′), 4.38 (d, *J* 12.0 Hz, 1 H), 4.14 (d, *J* 2.4 Hz, 1 H), 4.10 (dd, *J* 9.6, 3.0 Hz, 1 H), 3.80−3.97 (m, 8 H), 3.65 (d, *J* 10.8 Hz, 1 H), 3.61 (m, 2 H), 3.43 (m, 2 H), 1.95 (s, 3 H), 1.12 (d, *J* 6.0 Hz, 3 H); MALDI-TOF-MS: Calcd for $C_{48}H_{58}N_4NaO_{17}S$ ($M - H + Na)^+$ 1016, Found 1015.

5-{*O*-(3-*O*-Sulfo-*β*-D-galactopyranosyl)-(1→3)-[*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-(1→4)]-2-acetamido-6-*O*-benzyl-2-deoxy-*β*-D-glucopyranosylamino}-5-oxopentanoic Acid 2(*R*,*S*),3-Dioctadecanoyloxypropanyl Ester (16). Lindlar's catalyst (20 mg) was added to a solution of **5** (50 mg, 0.05 mmol) in dry DCM and MeOH (1:1, 10 mL), and the mixture was stirred vigorously under a H_2 atmosphere at room temperature for 2 h. TLC showed a clean and complete reaction. The catalyst was filtered off, and the filtrate was directly applied to the next step without further treatment. Thus, to this solution were added **15** (74 mg, 0.1 mmol), HOBt (34 mg, 0.25 mmol), and EDC (96 mg, 0.5 mmol) at 0 °C, and the mixture was stirred at room temperature for 48 h, before it was concentrated in a vacuum. The residue was dissolved in diethyl ether, and the solution was washed with water, dried over Na_2SO_4, and finally condensed. Purification of the residue with a silica gel column gave the coupling product **16** (60 mg, 70%). TLC: R_f = 0.65 (DCM and MeOH, 8:1); ^{1}H NMR (600 MHz, $CDCl_3$−CD_3OD): δ 7.16−7.39 (m, 20 H, aromatic), 5.21 (m, 1 H, H-2^{gly}), 5.03 (br, 1 H, H-1″), 4.94 (d, *J* 8.4 Hz, 1 H, H-1), 4.88 (d, *J* 11.4 Hz, 1 H), 4.78 (d, *J* 11.4 Hz, 1 H), 4.72 (t, 1 H), 4.71 (d, *J* 10.8 Hz, 1 H), 4.69 (d, *J* 11.4 Hz, 1 H), 4.58 (d, *J* 10.8 Hz, 1 H), 4.43 (d, *J* 10.8 Hz, 1H, H-1′), 4.25−4.31 (m, 3 H), 4.09−4.14 (m, 5 H), 3.80−3.97 (m, 7 H), 3.61 (m, 3 H), 3.41 (t, *J* 9.0 Hz, 2 H), 2.33 (t, *J* 7.2 Hz, 2 H), 2.28 (t, *J* 7.2 Hz, 4 H), 2.20 (t, *J* 7.2 Hz, 2 H), 1.90 (s, 3 H), 1.86 (m, 2 H), 1.57 (m, 4 H), 1.23 (br, 56 H), 1.12 (d, *J* 6.6 Hz, 3 H), 0.83 (t, *J* 7.2 Hz, 6 H); ^{13}C/^{1}H NMR (150/600 MHz, HMQC): 103.0/4.43 (Gal-1), 97.5/5.03 (Fuc-1), 78.8/4.94 (Glu-1), 69.2/5.21 (Glycerol-2); MALDI-TOF-MS: Calcd for $C_{92}H_{139}N_2Na_2O_{24}S$ ($M - H + 2\ Na)^+$ 1734, Found 1733.

5-{*O*-(3-*O*-Sulfo-*β*-D-galactopyranosyl)-(1→3)-[*O*-α-L-fucopyranosyl)-(1→4)]-2-acetamido-2-deoxy-*β*-D-glucopyranosylamino}-5-oxopentanoic Acid 2(*R*,*S*),3-Dioctadecanoyloxypropanyl Ester (4). A mixture of **16** (25 mg, 14.8 μmol) and 10% Pd/C (25 mg) in DCM and MeOH (2:1, 3 mL) was stirred at room temperature in an H_2 atmosphere for 2 days. The solid material was filtered off through a syringe filter and washed with a mixture of MeOH and CH_2Cl_2 (1:1). The filtrates were combined and concentrated in a vacuum to afford **4** (22 mg, 95%) as a white solid. ^{1}H NMR (600 MHz, $CDCl_3$−CD_3OD): δ 5.21 (m, 1 H, Gly-H-2), 4.91 (d, *J* 9.0 Hz, 1 H, H-1); MALDI-TOF-MS: Calcd for $C_{64}H_{116}N_2Na_2O_{24}S$ ($M + 2\ Na)^+$ 1375, Found 1375.

Preparation of Liposomes. Liposomes were prepared by the extrusion method.[31] Briefly, desired volume of lipid stock solutions (20 mg/mL) in chloroform and methanol (3:1, v/v) (6.0 μmol of DSPC for DSPC liposomes, 0.55 μmol of DSPC with 0.05 μmol of PEG-DSPC for PEG liposomes, and 0.55 μmol of DSPC with 0.05 μmol of glycolipid **4** for glycoliposomes) was mixed with a cholesterol stock solution (10 mg/mL) in chloroform (0.154 mL, 4.0 μmol) in a 10-mL round-bottom flask. The total volume was made up to 1 mL by chloroform. The mixtures were deposited in a thin film on the interior of the flask by rotary evaporation under reduced pressure for 30 min, followed by drying in a vacuum oven at room-temperature overnight. Following addition of phosphate-buffered saline (PBS) (1 mL), lipid thin films were

Scheme 1



hydrated in 70 °C water bath for 30 min to obtain multilamellar vesicles (MLVs). MLV suspension was subjected to 3−5 freeze−thaw cycles, involving quenching in liquid nitrogen, followed by an immersion at 70 °C in a water bath. Unilamellar vesicles (ULVs) were produced by extrusion through Nucleopore track-etch polycarbonate membranes (Avanti Polar Lipids Inc.) with pore size of 100 nm for 10 times on an Avanti Mini-Extruder (Avanti Polar Lipids Inc.) operated at 75 °C. Then half of the liposomes thus obtained were extruded through 50-nm membranes for 10 more times by the same method. The extruded liposomes were stored at room temperature and followed by measuring the particle size and distribution.

Platelet Preparation. Whole blood (20 mL) was drawn from healthy, medication-free human donors into two 10-mL tubes each containing 1 mL of 3.8% sodium citrate anticoagulant, which was centrifuged at 800 rpm for 15 min to collect platelet-rich plasma (PRP). Platelets were obtained by centrifuging PRP at 1500 rpm for 15 min at 25 °C and resuspended in an equal volume of phosphate-buffered saline (PBS) containing 1% bovine serum albumin (BSA).

Fluorescence Microscopy. Fluorescence microscopy was used to characterize SO_3Le^a liposomes binding to platelets. Liposomes for use in fluorescence experiments were prepared by incorporating 1 mol % of nitrobenzodiazole (NBD)-modified phosphatidylcholine (NBD-PC, Avanti) with other lipids. PRP was incubated on collagen III coated glass coverslips in a multiwell cell culture plate at room temperature for 1 h. Then the coverslips were gently washed with PBS and incubated with NBD-labeled liposomes for 1 h, followed by washing with PBS and fixing in 4% paraformaldehyde. The coverslips were mounted onto glass microscope slides. The uniform distribution of platelets on coverslips was confirmed on a Nikon Diaphot phase-contrast microscope. Fluorescence micrographs were imaged on a Nikon Diaphot epifluorescence inverted microscope fitted with a Spot RT chilled CCD camera. All coverslips were run in triplicate, and multiple fields were examined for each coverslip.

RESULTS AND DISCUSSION

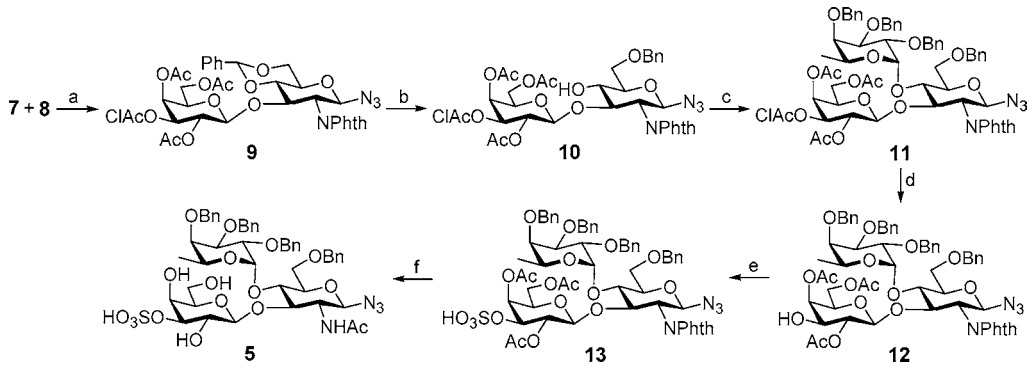
Synthesis of the Lipid Conjugate of SO_3Le^a. In the natural form, Lewis antigens are attached through their reducing ends to lipids and/or proteins. However, the semisynthetic lipid conjugates of Lewis antigens employed in previous studies (*26*, *27*, *37*) had the lipids attached to the 2-amino group of the glucosamine residue, as this position is easily distinguishable from the free hydroxyl groups of the oligosaccharides to enable a regioselective reaction affording well-defined products. Even though the resultant glycoliposomes showed promising properties (*26*, *27*, *37*), a problem with these glycolipids is that the artificial linkage may affect the conformations of the antigens and thereby their binding to selectins. Moreover, although several Lewis antigens including SO_3Le^a were synthesized previously (*35*, *38*−*43*), the reported syntheses did not focus on the conjugation of the antigens to other structures, and the reducing end of the synthetic antigens was usually capped by an unreactive group. Therefore, it would be generally useful to have a practicable method to prepare glycolipids of Lewis antigens with the lipid moiety on the carbohydrate reducing end.

Herein, we design to attach a lipid, 1,2-distearoyl-*sn*-glycerol, to the reducing end of SO_3Le^a via an amide bond using the glutaric group as a bifunctional linker (as shown in the structure of synthetic target **4**, Scheme 1). An important advantage of this design is that it may lead to a highly convergent synthetic procedure. Since an amino group is more reactive than a hydroxyl group, and a carboxylic compound can be conveniently and selectively attached to the amino group of a glycosylamine even in the presence of free hydroxyl groups (*44*), the introduction of the lipid chain can be achieved at the final stage of the glycolipid synthesis. In this case, an azido group that can be selectively reduced to a primary amine under mild condition can be used as a latent amino group. Moreover, since an azido group can withstand most transformations involved in carbohydrate synthesis, it may also serve as a protecting group of the oligosaccharide reducing end to further simplify the synthetic plan, especially in regard to protection tactics. Another useful property of the designed glycolipid **4** is that, compared to natural O-glycosides, a glycosyl amide is less susceptible to glycosidases, and consequently, **4** should be more stable under physiological conditions.

The retrosynthetic analysis of **4** (Scheme 1) results in an azido derivative **5** of SO_3Le^a as the logical key intermediate, whereas **5** can be further disconnected into three monosaccharide blocks **6**, **7**, and **8**. To facilitate the regioselective sulfation of the galactose 3-O-position at a later step, this position was protected by a chloroacetyl (ClAc) group that can be selectively removed in the presence of other acyl groups. Monosaccharide **8** is designed to have the azido group linked to its anomeric carbon.

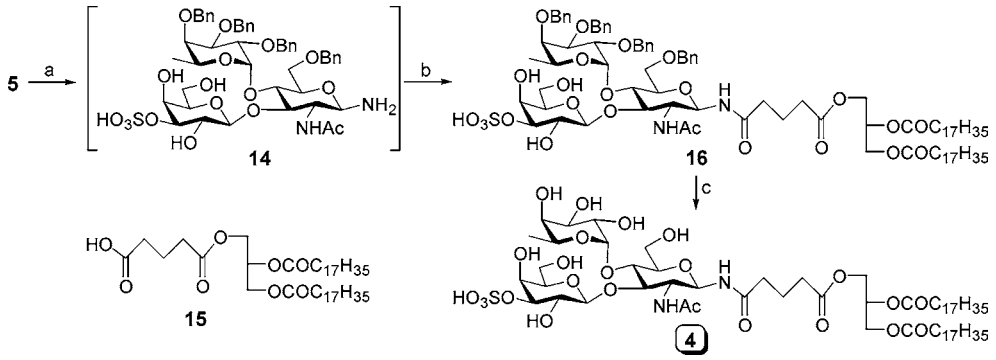
Scheme 2 outlines the synthesis of the key intermediate **5**. First, the glycosylation of **8** by **7** was accomplished with *N*-iodosuccinimide (NIS) and trifluoromethanesulfonic acid (TfOH) as promoters to form the β-linked disaccharide **9** (H-1: δ 5.35, J = 9.5 Hz; H-1′: δ 4.56, J = 8.0 Hz). Next, the benzylidene ring was regioselectively opened by reaction with sodium cyanoborohydride ($NaBH_3CN$) under a strong acidic condition to afford **10**. The fucosylation of **10** by **6** with tetrabutylammonium bromide and CuBr as promoters (*45*, *46*) gave the α-glycosylation product **11** in an excellent yield (78%) and stereoselectivity, while the same reaction with NIS and TfOH as promoters showed little stereoselectivity. After the chloroacetyl group of **11** was removed by thiourea, a sulfate group was introduced to the same position by reaction with sulfur trioxide trimethylamine complex ($SO_3{\cdot}NMe_3$) in pyridine. This reaction was very clean, and the product **13** could be readily purified by column

Scheme 2 [a]



[a] Reagents and conditions: (a) NIS, TfOH, MS 4 Å, CH_2Cl_2, −10 °C to room temperature, overnight, 55%; (b) $NaCNBH_3$, HCl, MS 4 Å, THF, 0 °C, 2 h, 90%; (c) **6**, CuBr, $(n\text{-}Bu)_4NBr$, DMF−CH_2Cl_2 (1:1), rt, 6 h, 78%); (d) thiourea, 2,6-lutidine, EtOH−CH_2Cl_2 (1:4), reflux, 16 h, 86%; (e) $SO_3{\cdot}NMe_3$, pyridine, rt, 24 h, 72%; (f) $H_2NCH_2CH_2NH_2$, butanol, 90 °C, overnight; then Ac_2O, MeOH, rt, 1 h, 50%.

Scheme 3 [a]



[a] Reagents and conditions: (a) H_2, Lindlar catalyst, MeOH−CH_2Cl_2 (1:1), rt, 2 h; (b) **15**, HOBt, EDC, MeOH−CH_2Cl_2 (1:1), rt, 48 h, 70% (two steps); (c) H_2, 10% Pd/C, MeOH−CH_2Cl_2 (1:2), rt, 48 h, 95%.

chromatography. The removal of the phthalyl and acetyl groups of **13** proved to be problematic. We first examined the reaction using hydrazine, but it afforded a very low yield of the expected product, presumably due to the involvement of the azido group. The deprotection was eventually achieved by heating **13** with ethylenediamine at 90 °C overnight, under which condition the sulfate group was unaffected. Subsequent acetylation of the resultant free amino group was performed in a one-pot manner to give the trisaccharide **5**. The two combined steps afforded a moderate yield (50%). It is worthy noting that the *O*-acetyl groups must be removed at this stage, or it would be impossible to remove the acetyl groups selectively after introducing the lipid moiety that also possesses ester bonds.

To facilitate the coupling of the sulfated trisaccharide **5** and the glycerol lipid via a glutaric group (Scheme 3), **5** was converted into a glycosylamine by selective hydrogenation under the influence of Lindlar catalyst. The resultant amine **14** was immediately treated with 1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride (EDC) and a glutarate of the lipid moiety **15**. The reaction proceeded smoothly to afford the expected glycolipid **16** in a good yield (70%) after column chromatography. Finally, global debenzylation of **16** was realized with 10% Pd/C in a hydrogen atmosphere, leading to the desired free glycolipid **4** that did not require further purification. The structures of the synthetic intermediates and the final product were verified by their NMR and MS spectra.

Properties of SO_3Le^a Modified Liposomes. The resultant glycolipid **4** was incorporated into liposomes in a 5% molar concentration, using 1,2-distearoyl-sn-glycero-3-phosphocholine (DSPC) and cholesterol in a molar ratio of 3:2, by a freeze-thaw and extrusion method (*47*, *48*). The liposomes were sequentially extruded through two membranes of 100 and 50 nm pore size, respectively. The resultant glycoliposome gave a mean vesicle size of 78 nm (Table 1), which is comparable to that of DSPC liposome (63 nm) and 5% mol PEG-modified

Table 1. Particle Size of Various Liposomes

	vesicle size (extrusion by 50 nm membrane)	
liposome[a]	D_v[b] ± SD[c] (nm)	PDI[d]
DSPC	63.3 ± 1.4	0.13
PEG	66.4 ± 1.4	0.12
SO_3Le^a	78.5 ± 1.5	0.20

[a] All liposomes were made with 60 mol % of total lipid and 40 mol % of cholesterol. [b] Average diameter. [c] Standard deviation. [d] Polydispersity index.

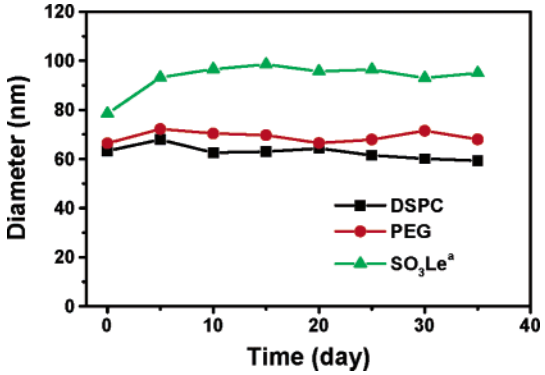


Figure 2. The size of different liposomes at room temperature.

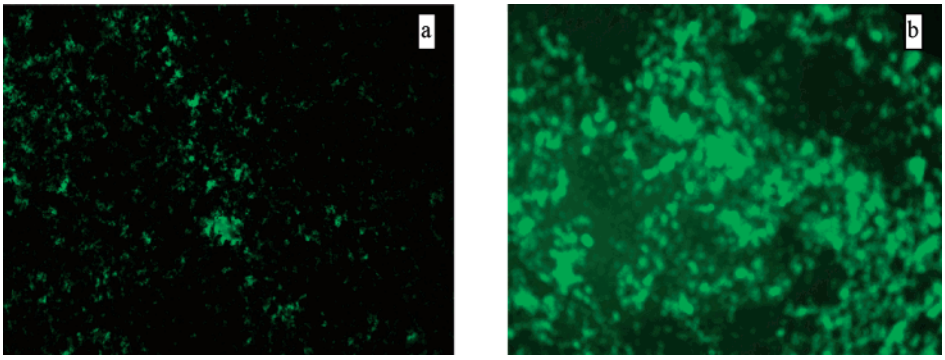

Figure 3. Fluorescence micrographs of platelets labeled with DSPC liposome (a) and SO_3Le^a liposome (b).

liposome (66 nm). The slightly larger size (by ca. 15−20%) of the former may result from the relatively large polar head of the glycolipid.

To investigate whether the increased size of SO_3Le^a-coated liposome would affect its stability, the three kinds of liposome were kept at room temperature for an extended period while the vesicle sizes were analyzed. We found that the size of the glycoliposome increased to about 98 nm at the initial stage but remained unchanged later on for at least one month (Figure 2). The results indicate that the stability of the glycoliposome was comparable to that of DSPC- and PEG-modified liposomes. It may suggest that the glycoliposome is stable enough for practical uses.

The binding of DSPC- and SO_3Le^a-coated liposomes to activated platelets was studied by the fluorescence microscopy method (*49*). The liposomes used in these experiments were prepared by incorporating 1 mol % of nitrobenzodiazole (NBD)-modified phosphatidylcholine which shows green fluorescence. On the other hand, since P-selectin is a component of the α-granule membrane of resting platelets and is only expressed on the activated platelet surface after α-granule secretion, we employed collagen coating on the coverslips to activate and adhere platelets (*50*) in order to observe the platelets more easily by the fluorescence microscope. Thus, the platelet-rich plasma was incubated on collagen III-coated glass coverslips in a multiwell cell culture plate at room temperature. The coverslips were then gently washed with PBS and incubated with NBD-labeled liposomes, followed by washing with PBS and fixing in 4% paraformaldehyde. Fluorescence micrographs of the coverslips were imaged, and the intensity of their green fluorescence from NBD label was calculated by Adobe Photoshop (Version 6.0). It was observed that the color intensity of SO_3Le^a-containing liposome-treated coverslips (Figure 3b) was at least 6.5 times higher than that of DSPC liposome-treated ones (Figure 3a). These results suggested that the SO_3Le^a-coated liposome had much higher binding to activated platelets than the DSPC liposome without SO_3Le^a. The significant increase in binding of the former to activated platelets is attributed to the specific interactions between SO_3Le^a on the glycoliposome and the P-selectin on activated platelets.

In summary, this paper has described an efficient method to prepare the lipid conjugate of SO_3Le^a with the lipid moiety attached to the reducing end of the carbohydrate chain through a bifunctional glutaric group. In the synthesis, the glycosidic azido derivative **5** of SO_3Le^a was employed as a key intermediate. This design facilitated a convergent synthetic procedure with the selective coupling of the lipid moiety to SO_3Le^a achieved at the final stage, which also significantly simplified the design of protection tactics. The strategies developed in this research may be applicable to the synthesis of other glycolipids. Our preliminary studies of the target glycolipid **4** indicate that it can form stable liposomes with DSPC and cholesterol, and the resultant glycoliposomes can bind to activated platelets effectively. These results suggest that SO_3Le^a-coated liposomes may be used to target endothelium for the selective delivery of drugs or be used as antiinflammatory agents via inhibition of the binding of lymphocytes to endothelial cells. These potential applications as well as the multivalent effects necessary for the selectin−carbohydrate ligand interactions are currently under further investigations.

Genome and Drug Research Center, Department of Applied Biological Science, and Faculty of Pharmaceutical Sciences, Tokyo University of Science, Noda, Chiba 278-8510, Japan. Received August 24, 2004; Revised Manuscript Received November 28, 2004

The application of resins normally used in solid-phase organic synthesis to the affinity capture of a mammalian DNA polymerase β (pol β) is reported. Lithocholic acid (LCA), an inhibitor of pol β, was immobilized on various solid supports, and the batch affinity purification of pol β from a mixture of proteins using these LCA-immobilized resins was examined. Of the resins tested, TentaGel was the most effective at purifying pol β and at resisting nonspecific absorption of proteins. The immobilized LCA recognized pol β specifically, which resulted in pol β binding to the resin. Using the LCA-immobilized resin, it was possible to purify pol β from a mixture of proteins. Furthermore, it was possible to concentrate pol β from a crude nuclear extract of human T lymphoma Molt4 cells. To facilitate the immobilization of compounds on TentaGel resins, we also designed and prepared photoaffinity beads containing a photoreactive group at the free termini of the TentaGel resin. The pol β inhibitors LCA, C_{18}-β-SQDG, and epolactaene were immobilized on the photoaffinity beads by photoreaction. The batch affinity purification of pol β from a protein mixture could be also achieved with these beads.

INTRODUCTION

DNA replication, repair, and recombination are important processes for all organisms. Many classes of DNA polymerases (pols) have been identified in multicellular eukaryotes, and recent investigations have revealed that eukaryotic cells contain at least 14 types of DNA pol (*1*). The purification of DNA pols is still a laborious and time-consuming endeavor. For example, a combination of many types of column chromatography (for example, phosphocellulose, human serum conjugated sepharose, rabbit IgG conjugated sepharose, and monoclonal antibody conjugated sepharose column chromatography) has been often used for the purification of DNA polymerase β.

One approach to studying the various roles of each of the DNA pols is to use inhibitors as tools and molecular probes to distinguish among the various DNA pols and to clarify their biological and in vivo functions. We previously identified a number of such inhibitors against DNA pols by screening both natural and synthetic products (*2*–*5*). Use of these inhibitors against DNA pols as molecular probes is also important for purifying DNA pols and for understanding their biological functions in detail.

Lithocolic acid (LCA), one of the bile acids, has been reported to promote tumorigenesis induced by *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine in rats (*6*–*8*) and to possess inhibitory activities against eukaryotic DNA pol α and β (*9*–*11*). We previously found that both the hydrophilic end (carboxyl group) and the hydrophobic region (steroidal skeleton) greatly influence the inhibitory activity of LCA, and that LCA binds to the 8-kDa DNA binding domain of DNA pol β (*11*). $^{1}H-^{15}N$ HMQC NMR analysis of the 8-kDa domain of pol β bound to LCA showed that LCA binds to the N-terminal 8-kDa domain of pol β as a 1:1 complex and interacts mainly with three amino acids (Lys 60, Leu 77, and Thr 79) in this domain (*10*, *11*). In addition, we previously prepared biotinylated LCA derivatives and developed affinity chromatography for the separation of DNA pol α and β from a mixture of the two proteins (*12*).

Recently, small molecules have been immobilized on solid surfaces to facilitate the purification, and to profile the cellular activities, of their binding proteins (*13*–*18*). Several matrixes for affinity purification have been reported, including a glycidyl methacrylate (GMA)-covered GMA-styrene copolymer core (*15*), a poly(methacrylate) polymer (*16*, *17*), and a poly(ethylene glycol) dimethylacrylamide (PEGA) copolymer (*18*), among others.

Affinity purification of proteins is usually performed in aqueous solutions; however, the immobilization of bioactive compounds is usually performed in organic solvents. For this reason, we are interested in applying resins used for solid-phase organic synthesis to the development of methods for the affinity capture of proteins (*16*–*18*). Resins for solid-phase organic synthesis represent an ideal matrix for affinity purification because they are stable in both aqueous and organic media as well as under synthetic conditions (*16*, *17*, *19*). In addition to these attractive features, significant advances in solid-phase synthesis, coupled with improvements in solid polymer supports and linkers, have made it possible to attach structurally complex and diverse compounds onto

the resins. Herein we report the application of resins used for organic synthesis to the detection and purification of DNA pol β.

EXPERIMENTAL PROCEDURES

Compounds **2** and **5** were prepared according to the reported procedures (*12*, *20*−*22*). The determination of compound **2**, **5**, and LCA was performed by measuring ^{1}H NMR, ^{13}C NMR, IR, and MS data. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JNM-400 (Japan) or on a BRUKER DXR400 or DRX600 instrument (Germany). Chemical shifts were reported in δ, parts per million (ppm), relative to TMS as an internal standard or were calibrated by using residual undeuterated solvent as an internal reference. IR spectra were recorded on a JASCO FT/IR-410 spectrometer (Japan). Mass spectra were obtained on an ABI QSTAR Pulsar spectrometer equipped with an ESI ion source. UV irradiation was performed by an UM-453-A instrument (Ushio Inc., Japan). Column chromatography was carried out with Fuji Silisia PSQ100B silica gel (Japan). The immobilization of **2** and **5** on resins and cleavage of LCA from **3a** were checked by analytical thin-layer chromatography (TLC). TLC was performed on precoated Merck silica gel 60 F_{254} plates (Germany), and compounds were visualized by UV illumination (254 nm) or by heating the plates to 150 °C after spraying them with phosphomolybdic acid in ethanol. THF was distilled from sodium/benzophenone; CH_2Cl_2 was distilled from P_2O_5; and DMSO was distilled from CaH_2. All other solvent and reagents were obtained from commercial sources and used without further purification. Organic extracts were dried over $MgSO_4$, filtered, and concentrated by using a rotary evaporator. Involatile oils and solids were vacuum-dried.

Succinimidyl carbonate TentaGel resins (0.5 mmol/g) were purchased from Advanced ChemTech (USA); *p*-Nitrophenyl carbonate Merrifield resins (1.0 mmol/g) were obtained from Novabiochem (USA); and succimidyl carbonate Wang resins (1.0 mmol/g) were purchased from Aldrich (USA).

The fluorescein amine isomer II-immobilized resins were scanned for fluorescence by Xioskop2 plus, ebg 100 ISOLATED-2 and AxioCam HRm instrumentation (Carl Zeiss Co., Germany).

We used the following buffers: His-buffer A, containing 0.5 M NaCl, and 20 mM Tris-HCl (pH 7.9) buffer and 5 mM immidazole; His-buffer B, containing 0.5 M NaCl, and 20 mM Tris-HCl (pH 7.9) buffer and 60 mM immidazole; His-buffer C, containing 0.5 M NaCl, and 20 mM Tris-HCl (pH 7.9) buffer and 1 M immidazole; TEG buffer A, containing 50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10% (v/v) glycerol and 50 mM NaCl; TEG buffer B, containing 50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10% (v/v) glycerol and 1 M NaCl; TEG buffer C, containing 50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10% (v/v) glycerol and 100 mM NaCl; TEG buffer D, containing 50 mM Tris-HCl (pH 7.5), 1 mM EDTA, 10% (v/v) glycerol and 500 mM NaCl; sucrose buffer A, containing 50 mM Tris-HCl (pH 7.5), 50 mM NaCl, 1 mM EDTA, 5 mM 2-mercaptoethanol, 0.01% Nonidet-40, protease inhibitors (1 μg/mL leupeptin, 1 μg/mL pepstatin A, and 1 mM phenylmethylsulfonyl fluoride) and 0.25 M sucrose; and sucrose buffer B, containing 50 mM Tris-HCl (pH 7.5), 50 mM NaCl, 1 mM EDTA, 5 mM 2-mercaptoethanol, 0.01% Nonidet-40, protease inhibitors, and 1 M sucrose.

General Method for the Preparation of LCA-immobilized Resins. A suspension of each resin **1a**−**c** (1.0 equiv), 3-(3′-aminopropionyl)lithocholic acid (**2**) (1.2 equiv) and diidopropylethylamine (3 equiv) in DMSO-acetone-$CHCl_3$ (3:1:1, v/v) was stirred at 50 °C for 3 days. The processes of the reactions were checked by TLC. Each mixture was quenched by the addition of MeOH (1 mL) and then stirred at 50 °C for a further 1 h. Each mixture was filtered and washed with MeOH three times and dried in vacuo.

General Method for the Preparation of Methyl Carbonate Resins. A suspension of each resin **1a**−**c** (1 equiv) and K_2CO_3 (3 equiv) in MeOH was stirred at room temperature (rt) for 1 day. Each mixture was filtered and washed with MeOH three times. The resulting resins were dried in vacuo.

General Determination of the Amount of LCA on the Resins. A suspension of each LCA-immobilized resin (50 mg) and 1 N NaOH aq (0.5 mL) in THF−MeOH−H_2O (3:1:1 v/v, 2.5 mL) was stirred at room temperature for 1 day. The processes of the reactions were checked by TLC. Each mixture was filtered and washed with EtOAc three times. The filtrate was acidified to pH 1 and extracted with EtOAc three times. The organic layer was dried ($MgSO_4$) and evaporated. The residue was purified by silica gel chromatography to yield lithocholic acid (LCA). The determination of LCA was performed by measuring ^{1}H NMR, ^{13}C NMR, IR, and MS data.

Preparation of the Photoaffinity Beads. To a solution of TentaGel-CO_2Su (0.5 mmol/g, 56.0 mg) and **5** (20.0 mg, 0.056 mmol) in DMF (0.6 mL) was added *i*-Pr_2NEt (0.02 mL, 0.11 mmol) at room temperature. The mixture was then stirred for 34 h at room temperature. The processes of the reactions were checked by TLC. After filtration, the beads obtained were washed with MeOH three times to yield photoaffinity beads.

General Method for the Immobilization of Compounds on Photoaffinity Beads. A solution of photoaffinity beads (0.165 mmol/g, 30.0 mg) and substrate (5.0 μmol) in MeOH was stirred for 30 min. The solvent was removed under reduced pressure and the beads were dried in vacuo. After irradiation of the photoaffinity beads and substrate by a high-pressure mercury arc lamp for 1 h, the beads were washed with MeOH (3 times) and dried in vacuo.

Expression and Purification of Six Histidine Tagged-DNA Polymerase β (pol β) (*23*). The cDNA encoding pol β from *Rattus norvegicus* was cloned into the expression vector pET28b(+), and the *Escherichia coli* BL21 (DE3) was transformed with the vector. A single colony was used to incubate 600 mL of LB medium containing 1% glucose and 50 μg/mL of kanamycin at 30 °C. The cells were grown overnight and used to incubate 6 L of the same medium at 30 °C. After 3 h of growth, 1 mM IPTG was added. After 4 h of growth at 30 °C, the cells were harvested by centrifugation at 4000 rpm for 10 min at 4 °C in a HITACHI 10A rotor. The cells were resuspended in His-buffer A, sonicated 20 times for 20 s, and centrifuged for 30 min at 15 000 rpm in a HITACHI 20−2 rotor (Japan) at 4 °C. The supernatant was loaded onto His-Bind Resin preequilibrated with His-buffer A. The column was washed with His-buffer B, and the bound proteins were eluted with His-buffer C. The fraction containing the six-histidine-tagged pol β protein was dialyzed against TEG buffer (containing 50% (v/v) glycerol and 100 mM NaCl) and stored at −20 °C until use.

SDS−PAGE Analysis. Analyses by SDS−PAGE were generally done with 15% SDS−polyacrylamide gels and CBB staining. The eluted fractions of the resins from the nuclear extract were analyzed by SDS−PAGE (10−20% gel) and the gel was stained with silver.

Western Blotting Analysis (*24*). For Western blotting analysis, purified proteins were first resolved on SDS−PAGE gel (10−20%) and then transferred to nitrocellulose membranes and probed with a primary antibody, DNA polymerase β Ab-3 rabbit polyclonal antibody (Lab vision corporation, USA). Anti-rabbit IgG conjugated with horseradish peroxidase (VECTOR Laboratories, Inc., USA) was used as a secondary antibody. The antigen−antibody complex was visualized using Super-Signal West Dura (PIERCE). The chemiluminescence of the bands corresponding to human DNA polymerase β was quantified using Luminescent image analyzer, according to the manufacturer's instructions (LAS-1000 plus, Fuji Film, Japan).

Affinity Purification Using the LCA-Immobilized TentaGel, Merrifield, and Wang Resins. All procedures were performed at 4 °C. Each resin (20 mg), preequilibrated with TEG buffer A, was added to a solution (1.0 mL) of proteins (pol β, 8 nmol; hemoglobin, 15 nmol; trypsin inhibitor, 15 nmol; lysozyme, 15 nmol) in TEG buffer A, and the batch adsorption of proteins to the proteins was carried out overnight. Hemoglobin, trypsin inhibitor, and lysozyme were purchased from Wako Pure Chemical Industry (Japan). The resin was collected by centrifugation, and 800-μL aliquots of each supernatant (flow through) were kept for analysis. The resins were then washed 4 times with 800 μL TEG buffer A, and 800-μL aliquots of each supernatant (wash) were kept for analysis. Elution was performed 3 times with 100 μL of TEG buffer A containing 1% Tween20 and 80-μL aliquots of each supernatant (eluate) were kept for analysis. The resins were then boiled at 100 °C in 20 μL of SDS−PAGE loading buffer containing 1.25 mM DTT, 2.5% SDS, 100 mM Tris-HCl pH 6.8, 12.5% (v/v) glycerol and 0.01% BPB and 20-μL aliquots of each sample were kept for analysis.

Determination of the Amount of pol β bound To the Photoaffinity Beads Immobilized pol β Inhibitors (*25*). Each resin (10 mg) was suspended in 800 μL of TEG buffer and then 200 μL of pol β predialyzed against TEG buffer C was added. The batch adsorptions of proteins were carried out overnight. The amount of the His- tagged pol β protein bound to the beads was determined by Bradford assay, with absorbance measured at 595 nm.

Detection of pol β from Human T lymphoma Molt4 Cells by Using LCA-Immobilized TentaGel Resin. All procedures were performed at 4 °C. Frozen Molt4 cells (1 g) were crushed and suspended in 10 mL of sucrose buffer A. The Molt4 suspension was homogenized, and then centrifuged for 10 min at 9000 rpm in a HITACHI 20-2 rotor. The precipitate was then resuspended in 10 mL of sucrose buffer A. The suspension was layered in a thin band on top of 30 mL of sucrose buffer B, and then centrifuged for 30 min at 9000 rpm in a HITACHI 20-2 rotor. The precipitate was suspended in 5 mL of TEG buffer C containing 5 mM 2-mercaptoethanol, 0.01% Nonidet-40, and protease inhibitors, sonicated, and incubated on ice for 20 min, before being centrifuged for 20 min at 15 000 rpm in a HITACHI 20-2 rotor. The supernatant was further centrifuged for 30 min at 40 000 rpm in a HITACHI 70 Ti rotor (Japan).

The LCA-immobilized TentaGel resin (10 mg) and nonimmobilized one (10 mg), which were preequilibrated with TEG buffer C, were added to the supernatant (5 mg; 1.2 mL) to adsorb proteins. After incubation of the sample for 3.5 h, aliquots of the supernatant were removed and kept for the analysis. These resins were first batch washed five times with 1 mL of TEG buffer C for 10 min and 1-mL aliquots of each supernatant were kept. Next TEG buffer D (200 μL) was added to each resin, batch elution was carried out for 10 min, and 200-μL aliquots of each supernatant were kept. Then TEG buffer B (200 μL) was then added to each resin, batch elution was carried out for 10 min, and then 200-μL aliquots of each supernatant were kept for analysis. Finally, TEG buffer B (200 μL) containing 1% Tween20 was added to each resin, batch elution was carried out for 10 min, and 200-μL aliquots of each supernatant were kept.

RESULTS AND DISCUSSION

Initially, lithocholic acid (LCA) was immobilized on TentaGel resins (**1a**), Merrifield resins (**1b**), and Wang resins (**1c**). We previously found that the carboxyl group of LCA plays an important role in the inhibitory activity of LCA toward DNA pols (*11*, *12*). Therefore, LCA was immobilized on the resins with the 3-hydroxyl group rather than the carboxyl group (*12*). Treatment of carbonate resins **1a**−**c** and 3-(3′-aminopropionyl)lithocholic acid (**2**) with *i*Pr_2NEt in DMSO−acetone−$CHCl_3$ gave LCA-immobilized resins **3a**−**c** (Scheme 1). The amount of LCA immobilized was determined from the amount of LCA cleaved by hydrolysis from the resins. As a result, the amount of LCA immobilized on **3a**−**c** was 0.14, 0.48, and 0.10 μmol/mg of resin, respectively. Methyl carbonate resins **4a**−**c** were also prepared to examine the nonspecific binding of proteins.

To test the ability of these affinity resins, the maximum amount of pol β (*23*) binding to each resin (10 mg) was determined by monitoring absorbance at 595 nm (Figure 1). After **3a**−**c** (10 mg each) were equilibrated with a buffered solution of pol β (0.21 mg, 5.4 nmol), the amount of pol β that bound to the resins was determined by the colorimetric method reported by Bradford (*25*). From the amount of pol β that bound to **4b** and **4c** (0.014 and 0.012 mg, respectively), about 30% of the amount of pol β that bound to **3b** and **3c** was due to nonspecific binding. By contrast, only a small amount (0.003 mg) of pol β bound to **4a**; thus, the nonspecific binding of pol β to resin **3a** was far less (∼10%). We consider that the poly(ethylene glycol) (PEG) grafted on the TentaGel resin used in **3a** and **4a** prevented the nonspecific binding of pol β (*26*, *27*).

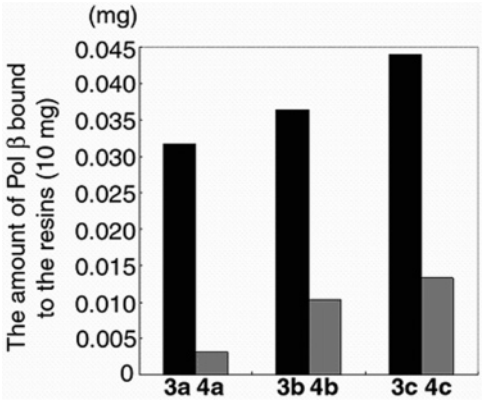

Figure 1. Pol β binding to resins **3a**−**c** and **4a**−**c**. Methyl carbonate resins (**4a**−**c**) were used as a negative control. The amount of pol β bound to each resin was determined by Bradford assay (*25*) by monitoring absorption at 595 nm.

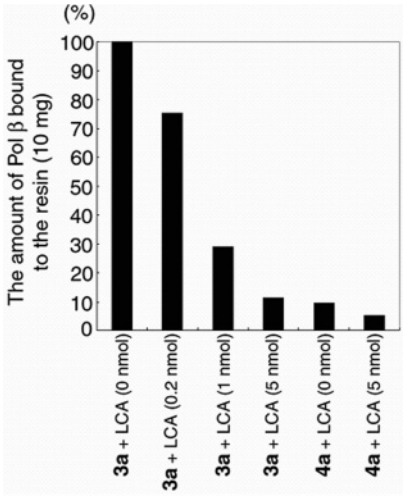

Figure 2. Inhibition of pol β adsorption to the resins by the addition of free LCA. The relative amount of pol β bound to **3a** in the absence and presence of increasing concentrations of free LCA was determined. The amount of pol β bound to **3a** in the absence of free LCA was arbitrarily taken to be 100%. Resin **4a** was used as a negative control.

The total amount of LCA that was immobilized on 10 mg of **3a** was 1.4 μmol, whereas the amount of pol β binding to 10 mg of **3a** was only 0.81 nmol (0.032 mg). The low absorption capacity of **3a** for pol β will be the low affinity between LCA and pol β. Our previous NMR experiments suggested that the 8-kDa domain of pol β binds to free LCA in a 1:1 ratio with a dissociation constant (K_D) of 1.56 mM (*10*). Use of resins bearing the higher affinity inhibitor against pol β will improve the absorption capacity, and the greater the amount of **3a** that is used, the greater the amount of pol β that will bind to **3a**. Indeed, 1.8 nmol (0.070 mg) of pol β was absorbed onto 20 mg of **3a** (data not shown).

To confirm that the LCA immobilized on the surface of **3a** specifically recognized pol β, we carried out competition assays of pol β adsorption to the resins in the presence of free LCA (Figure 2). The amount of pol β bound to **3a** in the absence and presence of increasing amounts of LCA was determined. The results showed that the greater the amount of free LCA that was added, the greater the amount of pol β that was unbound. This competitive inhibition of binding between **3a** and pol β by the addition of free LCA indicated that pol β bound to the LCA immobilized on **3a** in a specific manner.

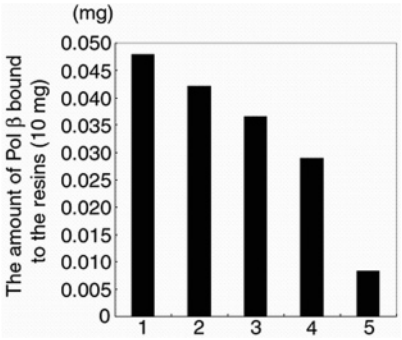

Figure 3. Relationship between the amount of LCA immobilized on **3a** and the amount of pol β bound to the resin. The amount of LCA immobilized on TentaGel resins was as follows: lane 1, 0.16 μmol/mg of resin; lane 2, 0.14 μmol/mg of resin; lane 3, 0.09 μmol/mg of resin; lane 4, 0.07 μmol/mg of resin; lane 5, 0.04 μmol/mg of resin.

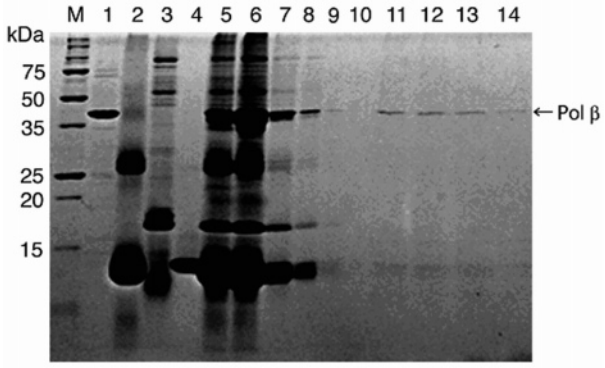

Figure 4. SDS−PAGE of input materials (pol β, hemoglobin, lysozyme, and trypsin inhibitor), flow-through, wash, elute, and resin during affinity purification with **3a**. Lane 1, pol β; lane 2, hemoglobin; lane 3, trypsin inhibitor; lane 4, lysozyme; lane 5, mixture of these proteins; lane 6, flow-through; lane 7−10, wash; lane 11−13, elute; lane 14, resin; M, molecular weight marker.

We next examined the relationship between the amount of LCA immobilized and the amount of pol β bound to the resin (Figure 3). Resins, **3a** with various concentrations of immobilized LCA (0.04 $\sim$ 0.16 μmol/mg resin), were prepared, and the amount of pol β bound to each resin was determined by Bradford assay. The amount of the LCA immobilized was determined by the amount of LCA cleaved by hydrolysis from the resins. The immobilization of **2** on **1a** under various conditions was also examined; however, the maximum concentration of immobilized LCA was found to be only 0.16 μmol/mg of resin. This low reactivity is probably due to the insolubility of **2** in organic solvents. In Figure 3, the amount of pol β bound to the resin is plotted against the decreasing amounts of immobilized LCA. It can be seen that the more LCA that was immobilized on TentaGel resins, the more pol β that bound to the LCA-immobilized TentaGel resins; however, pol β binding seemed to reach a maximum when the LCA immobilized reached a concentration of 0.16 μmol/mg of resin.

An example of the affinity purification of pol β from a mixture of proteins by **3a** is shown in Figure 4. After **3a** was equilibrated with a mixture of pol β, hemoglobin, trypsin inhibitor, and lysozyme, the resins were washed with TEG buffer A. Bound pol β was then eluted by the addition of 1% Tween20. Although the flow-through contained all of the charged proteins, which had various isoelectric points, pol β was certainly retained and purified by the LCA-immobilized resin. This result

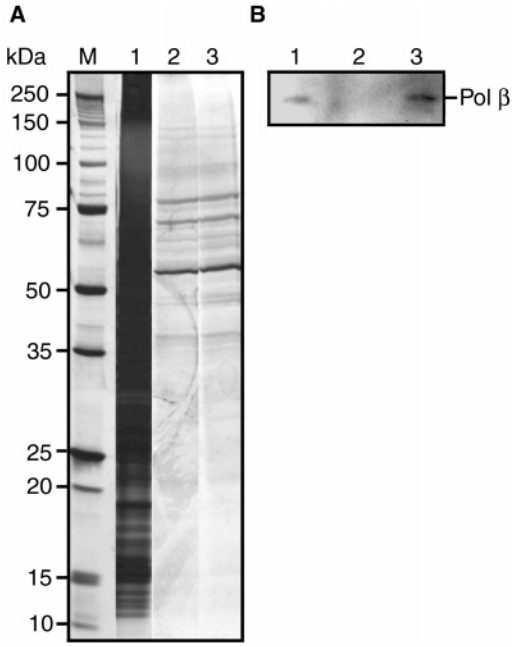

Figure 5. Partial purification of pol β from Molt4 nuclear extracts by the resin **3a**. (A) SDS−PAGE analysis of the eluted samples from the resin **3a** and **4a**. The gel was stained with silver: lane 1, nuclear extract; lane 2, elute from **4a** with TEG buffer B containing 1% Tween20; lane 3, elute from **3a** with TEG buffer B containing 1% Tween20; M, molecular weight marker. (B) Western blotting analysis for pol β. Proteins were transferred to a nitrocellulose membrane, and pol β was detected with anti-pol β polyclonal antibody. Lanes were the same as those for panel A.

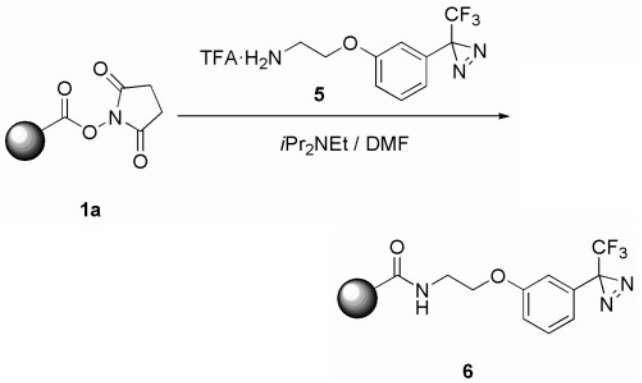
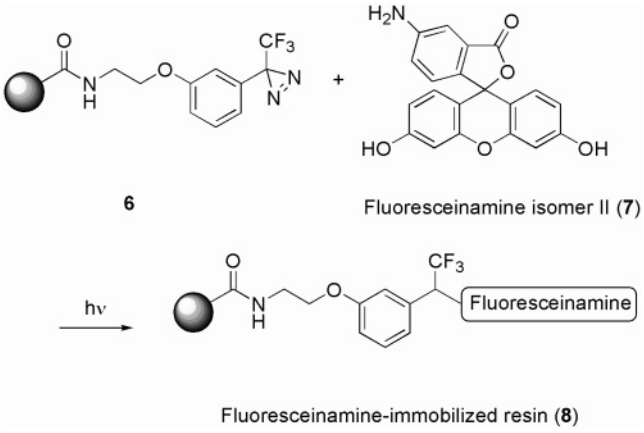
indicates that only pol β specifically bound to the LCA-immobilized resins.

To test whether the LCA-immobilized resins can retain pol β from many kinds of proteins, the capture of pol β from a crude nuclear extract of human T lymphoma Molt4 cells by using **3a** was examined (Figure 5). Resins **3a** and **4a** were respectively incubated with the nuclear extract (5 mg). After the resins were washed with TEG buffer C, TEG buffer D, and TEG buffer B, the bound fraction was eluted with 1% Tween20. Figure 5A shows SDS−PAGE analysis of the nuclear extract (lane 1) and the fractions eluted from **4a** and **3a** (lanes 2 and 3, respectively). Although the total proteins in the fraction eluted from **3a** was obviously less than those in the nuclear extract (lane 1 versus lane 3), it was difficult to identify the band corresponding to pol β. However, pol β was successfully detected by Western blotting using an anti-pol β polyclonal antibody (Figure 5B) (*24*). Thus, pol β was certainly retained from the crude nuclear extract by **3a** and eluted with 1% Tween20 (lane 3, Figure 5B). On the other hand, pol β was not detected by Western blotting in the eluted fraction from **4a** (lane 2, Figure 5B). These observations suggest that pol β specifically recognized LCA on the surface of **3a**. Furthermore, the signal intensity of the band in lane 1 was approximately equal to that in lane 3 in Figure 5B (lane 1/lane 3 = 100: 99). Unfortunately, it was unable to identify how pure the eluted fraction from the resin **3a** was because the amount of the proteins in the eluted fractions was too little to determine the protein concentration by Bradford assay. Indeed, several nonspecific binding proteins were observed in the eluted fraction, but it is possible to concentrate pol β from the crude nuclear extract by **3a**. These results suggest that a combination of the inhibitor-

Scheme 2. Preparation of Photoaffinity Beads (6)



Scheme 3. Photoaffinity Reaction of Photoaffinity Beads (7) and Fluorescein Amine Isomer II (8)



immobilized resins and classical column chromatography may facilitate the purification of pol β from a crude extract.

Nonspecific binding of proteins to **3a** would be due to hydrophobic interactions between proteins and the matrix of **3a** (*16*). As shown in Figure 1, LCA-immobilized Merrifield resins (**3b**) and Wang resins (**3c**) exhibited much more nonspecific protein binding. The matrixes of **3b** and **3c** are more hydrophobic than that of TentaGel (**3a**). Introduction of hydrophilic spacers on **3a** could reduce the nonspecific binding proteins (*15*, *17*).

To facilitate the immobilization of compounds on the resins, we prepared photoaffinity beads (**6**), that is, TentaGel resin beads with a photoreactive group at the free termini (*20*−*22*, *28*). Small molecules can be immobilized to such groups on a glass slide by a photolabeling reaction, as described in the small-molecules microarrays reported by Kanoh et al. (*28*) We therefore considered that, by using this methodology, small molecules, proteins, oligosaccharides, and DNA could be immobilized on the resin by UV irradiation. Photoaffinity beads (**6**) were prepared according to Scheme 2, in which a highly reactive carbene would be generated following the UV irradiation of **6** and would react with compounds in a nonspecific manner.

To check immobilization on the photoaffinity beads (**6**) following a photoreaction, the fluorescein amine isomer II (**7**) was immobilized on TentaGel resin by UV irradiation (Scheme 3). A solution of **6** and **7** in MeOH was stirred for 30 min at room temperature (rt). The solvent was removed under reduced pressure, and the beads were dried in vacuo. After irradiation of the solution of **6** and **7** by a high-pressure mercury arc lamp for 1 h, the beads were washed with MeOH (3 times) and dried in vacuo.

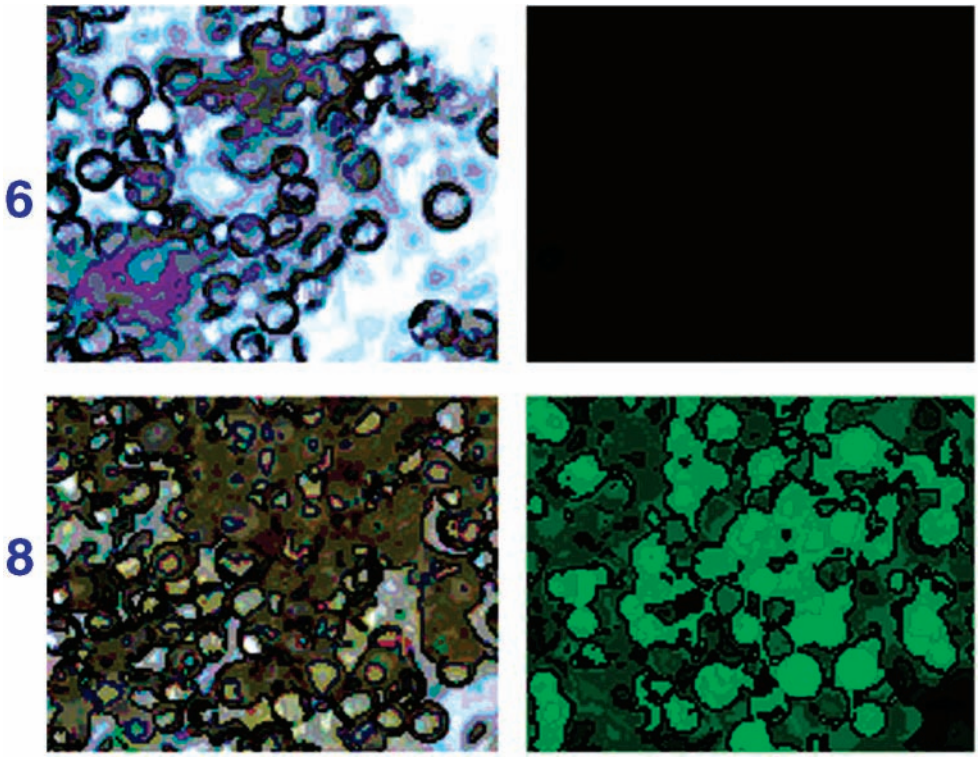


Figure 6. Microscopy (left) and the fluorescence (right) images of resins **6** and **8**.

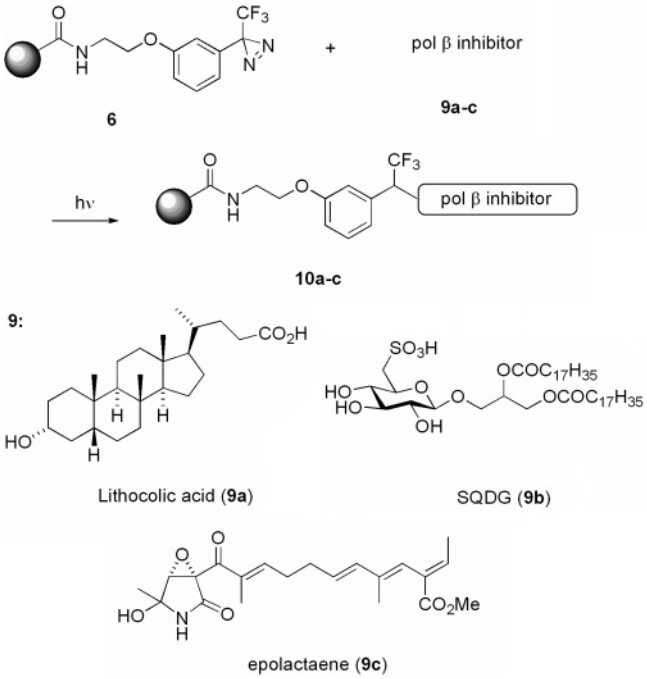
Scheme 4. Photoaffinity Reaction of Photoaffinity Beads (6) and pol β Inhibitors 9a−c



The resulting beads (**8**) were scanned for fluorescence by using a fluorescence microscope (Figure 6). The strong yellowish green fluorescence signals produced by **8** indicated that the fluorescein amine II (**7**) had been immobilized on the surface of resin **6** by the photoaffinity reaction.

Because LCA (**9a**), SQDG (**9b**) (*29*−*31*), and epolactaene (**9c**) (*32*−*34*) inhibit the activities of pol β in a dose-dependent manner, each of these molecules was immobilized on the photoaffinity beads (**6**) in the same way to obtain the inhibitor-immobilized TentaGel resins

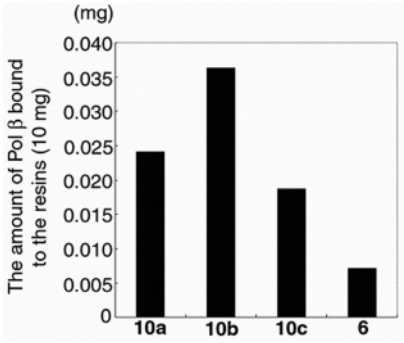


Figure 7. Amount of pol β bound to resins **10a**−**c**. Resin **6** was used as a negative control.

10a−**c** (Scheme 4). The maximum amount of pol β binding to **10a**−**c** (10 mg) was determined by monitoring absorbance at 595 nm (Figure 7). Whereas only 0.0075 mg of pol β bound to **6**, pol β was absorbed onto all of the inhibitor-immobilized resins. The amount of pol β bound to **10a**−**c** (10 mg) was 0.024, 0.037, and 0.019 mg, respectively. The immobilization of **9a**−**c** on **6** proceeded in a nonspecific manner; however, some of the immobilized **9a**−**c** did not lose the ability to bind pol β.

As mentioned above, the carboxylic group plays an important role in the interaction of LCA andpol β. Therefore, LCA was immobilized on **3a** through its 3-hydroxyl group. By contrast, LCA was immobilized in a nonspecific manner on **10a**−**c**. However, there was not much difference between the amount of pol β binding to **3a** and that binding to **10a** (0.032 mg for **3a**; 0.024 mg for **10a**). These findings show that the immobilization of protein inhibitors by a photoaffinity reaction will be effective not only for detecting the interactions between small molecules and proteins, but also for purifying proteins via these interactions.

Finally, the affinity purification of pol β from a mixture of proteins containing pol β, hemoglobin, trypsin inhibi-

tor, and lysozyme was also successfully achieved with photoaffinity beads **10a** and **10b** (Figure 8).

CONCLUSION

We report here the application of resins normally used in solid-phase organic synthesis to the affinity capture of DNA pol β. LCA, an inhibitor of a mammalian DNA polymerase β, was immobilized on Merrifield resins, Wang resins, and TentaGel resins, and the batch affinity purification of pol β from a mixture of proteins using these LCA-immobilized resins was examined. Among the resins, TentaGel resins were found to be the most effective for both purifying pol β and reducing nonspecific protein absorption. Furthermore, with the LCA-immobilized TentaGel resin, it was possible to concentrate pol β from a crude cell extract.

To facilitate the immobilization of compounds on TentaGel resins, we also designed and prepared photoaffinity beads containing a photoreactive group at the free termini of the TentaGel resin. The immobilization of compounds on the resins was easily achieved by UV irradiation. LCA, C_{18}-β-SQDG, and epolactaene, which all inhibit pol β, were immobilized on the photoaffinity beads by photoreaction. Pol β was successfully bound by all three of the immobilized pol β inhibitors. The batch affinity purification of pol β from a protein mixture was also achieved by the use of these resins.

We believe that these inhibitor-immobilized resins will facilitate the purification of pol β from a crude extract. As this methodology for the affinity capture of proteins is based on ligand−receptor interactions, it will be applicable to the affinity capture of other proteins based not only on small molecule−protein interactions but also protein−protein interactions, DNA−protein interactions, and so on. Studies of the use of resins in further proteomics applications are currently under way.

Synthesis and in Vitro Characterization of Organometallic Rhenium and Technetium Glucose Complexes against Glut 1 and Hexokinase

Roger Schibli,*[,†,‡] Cécile Dumas,[†] Jeannine Petrig,[†] Loredana Spadola,[‡] Leonardo Scapozza,[‡] Elisa Garcia-Garayoa,[†] and P. August Schubiger[†,‡]

Center for Radiopharmaceutical Science, ETH-PSI-USZ, Paul Scherrer Institute, 5232 Villigen PSI, Switzerland, and Department of Chemistry and Applied Biosciences ETHZ, 8093 Zurich, Switzerland. Received September 20, 2004; Revised Manuscript Received December 7, 2004

A series of nine organometallic technetium-99m and rhenium complexes of glucose are presented and characterized in vitro regarding their potential as surrogates of [^{18}F]-2-fluoro-desoxy glucose ([^{18}F]-FDG). The glucose derivatives are functionalized at positions C-1, C-2, C-3, and C-6. Different spacer lengths and chelating systems have been introduced at these sites. For the (radio)labeling, the organometallic precursors $[^{99m}Tc(H_2O)_3(CO)_3]^+$ and $[ReBr_3(CO)_3]^{2-}$ respectively have been used. The resulting complexes have been characterized chemically and radiochemically. The formation of uniform products has been observed on the macroscopic (Re) and no-carrier-added level (^{99m}Tc). The Tc-99m complexes revealed good inertness against ligand exchange (Cys and His) and excellent stability in physiological buffered saline as well as in human plasma over a period of 24 h at 37 °C. The rhenium complexes have been tested for competitive inhibition of the (yeast) hexokinase. Only for C-2 derivatized glucose complexes with extended spacer functionalities K_i values in the millimolar and sub-millimolar range have been observed. In silico molecular docking experiments supported these experimental findings. However, the competitive inhibitors are not recognized as a pseudosubstrate of hexokinase. The cellular uptake of all ^{99m}Tc-complexes into HT-29 colon carcinoma cells via Glut1 was generally low and unspecific independent of the position at the hexose ring, the chelating systems, or the overall charge of the corresponding metal complexes. The current results seem to preclude the use of these compounds as [^{18}F]-FDG surrogates primarily due to the low cellular uptake via Glut1.

INTRODUCTION

The radioactive labeled glucose analogue [^{18}F]-2-fluoro-desoxy glucose ([^{18}F]-FDG)[1] (^{18}F: β^+, $T_{1/2} = 109$ min) has gained tremendous relevance in clinical tumor diagnosis in recent years. [^{18}F]-FDG is taken up by tumor cells mainly by facile diffusion through the glucose transport protein Glut1. Phosphorylation of [^{18}F]-FDG to [^{18}F]-2-fluoro-desoxy glucose-6-phosphate ([^{18}F]-FDG-6-P) is accomplished by hexokinase (HK), and consequently [^{18}F]-FDG-6-P is metabolically trapped inside the cell. There is evidence that the phosphorylation via HK appears as the rate determining step in [^{18}F]-FDG accumulation in cancer cells, although this issue is controversially discussed in the literature (*1*−*3*). The clinical relevance of [^{18}F]-FDG prompted already some years ago the development of inexpensive and readily available ^{99m}Tc (γ; 150 keV, $T_{1/2} = 6.0$ h) labeled glucose analogues (*4*−*6*). Apart from the low costs of Tc-99m, a Re-186 (β^-; 1.1 MeV, $T_{1/2} = 90.6$ h) or Re-188 (β^-; 2.1 MeV, $T_{1/2} = 16.9$ h) labeled "FDG" analogue would open the opportunity for radiotherapy of various tumors with a simple and unspecific tracer. However, the ^{99m}Tc(V)-glucose complexes reported so far do not match the criteria and characteristics of FDG, such as active transport via Glut1 and phosphorylation via hexokinase. It can be speculated that this is due to steric reasons or the fact the transition metal coordination occurs via functional groups of the carbohydrate moiety important, for example, for substrate recognition.

Our group reasoned to employ the pendent approach for the radiolabeling of glucose to maintain its biological activity. For the radiolabeling, the organometallic precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ was chosen. Other than technetium and rhenium in high oxidation states such as +V/+III, the low-valent, organometallic M(+I)-tricarbonyl (M = Tc, Re) moiety reveals a low affinity toward hard donor groups such as hydroxyl functionalities (ubiquitous in carbohydrates) but a high affinity toward medium soft and soft donor functionalities.

Recently, several groups including our group have reported the preparation of organometallic glucose and glucosamine analogues of technetium and rhenium, respectively (*7*−*11*). However, until now there are no in vitro or in vivo results of such compounds reported, with respect to Glut1 and/or HK.

In this work, we present the biological characterization of a series of organometallic technetium- and rhenium-tricarbonyl complexes of glucose, derivatized at positions C-1, C-2, C-3, and C-6 with various chelating systems

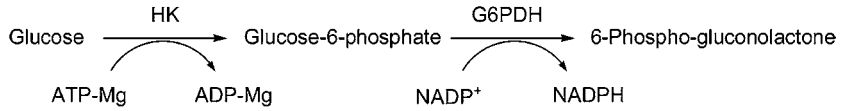
Scheme 1



(Scheme 3). The Tc-99m complexes have been tested for cell internalization and transport via Glut1 in HT29 colon carcinoma cells. The corresponding rhenium complexes were assessed for competitive inhibition of HK or pseudosubstrate activity. Results of molecular docking studies between the metal complexes and human HK-I are also reported.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals and enzymes were purchased from Fluka (Buchs, Switzerland) and used without further purification. The syntheses of the glucose derivatives **1**−**9** and the rhenium complexes **10**, **14**−**16** have been described elsewhere (*9*, *11*, *12*). $(NEt_4)_2$-$[ReBr_3(CO)_3]$ was synthesized according to previously published procedures (*13*). The IsoLink kit was used to prepare the radioactive precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ for the radiolabeling (*14*). All ^{99m}Tc glucose complexes have been prepared similar to the procedure published earlier (*9*). Na[$^{99m}TcO_4$] was eluted from a ^{99}Mo/^{99m}Tc generator (Mallinckrodt, Petten, The Netherlands) using 0.9% saline. UV/vis spectra were recorded on Beckman DU640 spectrometer. HPLC analyses were performed on a Merck-Hitachi L-7000-system equipped with an L-7400 tunable absorption detector, and a Berthold LB 506 B radiometric detector. HPLC solvents consisted of aqueous 0.05 M TEAP buffer, pH = 2.25 (solvent A) and methanol (solvent B). For the radiochemical analyses, a Macherey-Nagel C-18 reversed phase column (10 μm, 150 × 4.1 mm) was used. The HPLC system started with 100% of A from 0 to 3 min. The eluent switched at 3 min to 75% A and 25% B and at 9 min to 66% A and 34% B followed by a linear gradient 66% A/34% B to 100% B from 9 to 20 min. The gradient remained at 100% B for 2 min before switching back to 100% A. The flow rate was 1 mL/min. Human plasma samples were measured on a Superdex 10 size exclusion column. PBS was used as the mobile phase. The flow was set to 0.8 mL/min. Gamma samples were measured in a Packard COBRA II gamma counter. Scintillation analyses were performed on a Canberra Packard 1900TR beta counter.

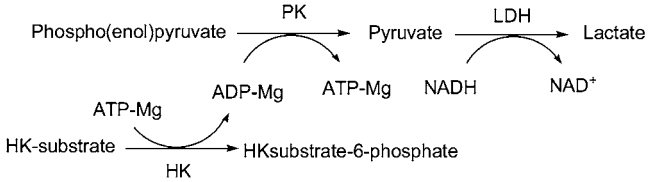
Preparation of the Tc-99m Complexes 10a−**18a.** To 250 μL of a 10^{-4} M solution of compounds **1**−**9** in physiological phosphate buffer (pH = 7.4), 250 μL of the neutralized IsoLink solution were added. The mixtures were heated at 75° C for 45 min. The reactions and products were analyzed by means of HPLC. Yields varied between 70 and 95%. The compounds were purified via HPLC for the in vitro tests.

Synthesis of Complexes 11b−**13b and Complexes 17b and 18b.** The complexes have been prepared similar to the method described for complex **10** in ref *9*. The disodium salt of ligands **2**−**4** was dissolved in water (5 mL) and 1 equiv of $(NEt_4)_2[ReBr_3(CO)_3]$ was added. After 2 h at 50 °C, the solvent was evaporated and the residue was dried overnight in a desiccator. The crude reaction product was redissolved in a minimum amount of methanol and applied on a SepPak C18 cartridge, preconditioned according to the manufacturer's protocol. Unreacted starting material and byproducts were eluted with H_2O. The final product was eluted with MeOH/H_2O (1:1). Analytical data for complex **11b**: ^{1}H NMR (CD_3OD, 25 °C): 5.49 (d, 0.5H), 4.65 (d, 0.5H), 4.10−3.54 (m, 10H), 3.54−3.00 (m, 4H), 2.40−2.01 (m, 2H); IR (KBr): 3444 br, 2024 vs, 1892 vs, 1650 vs, 1400 m, 1064 m cm^{-1}; MS (ES): *m/z* (%) 624 (100%) [M$^-$]. Analytical data for complex **12b**: ^{1}H NMR (DMSO-d_6, 50 °C) 5.24−5.17 (m, 0.3H), 5.04−4.99 (m, 0.5H), 4.86−4.81 (m, 0.2H), 4.51−4.45 (m, 0.4H), 4.29−4.15 (m, 0.6H), 4.02−3.50 (m, 8H), 3.50−3.31 (m, 2H), 3.31−3.14 (m, 3H), 1.84−1.70 (m, 2H), 1.70−1.54 (m, 2H), 1.51−1.26 (m, 8H); IR (KBr): 3432 br, 2020 vs, 1884 vs, 1656 m, 1640 w, 1630 m, 1390 m, 1034 m cm^{-1}; MS (ES): *m/z* (%) 692 [M$^-$] (100). Analytical data of complex **17b**: ^{1}H NMR (CD_3OD): δ 7.26 (d, 2 H), 7.12 (d, 2 H), 6.49 (s, 1 H), 3.87 (s, 6 H), 3.58−3.72 (m, 4 H), 3.75 (d, 2 H), 3.69−3.63 (m, 1 H), 3.34 (t, 1 H), 2.25−2.20 (m, 1 H), 1.78−1.72 (m, 1 H); IR (KBr): 3750 br, 2026 vs, 1896 vs, 1654 w, 1458 w, 1080 m cm^{-1}; MS (ES): *m/z* (%) 668 [M$^+$] (100). Analytical data of complex **18b**: ^{1}H NMR (CD_3OD) 5.94 (d, 0.5H), 5.09 (d, 0.5H), 5.07−5.02 (m, 1H), 5.01−4.96 (m, 1H), 4.70 (d, 0.5H), 4.54−4.39 (m, 0.5H), 4.39−4.28 (m, 0.5H), 4.17−3.92 (m,1.5H), 3.86−3.65 (m, 1H), 3.96 (d, 2H), 3.72 (d, 2H), 3.56−3.47 (m, 2H), 3.43−2.30 (m, 2H), 1.89−1.76 (m, 2H); IR (KBr): 3426 br, 2008 vs, 1892 vs, 1638 s, 1458 m, 1260 w, 1032 m cm^{-1}; MS (ES): *m/z* (%) 638 [M$^-$] (100).

Hexokinase Assay. A slightly modified procedure described by Roche-Applied-Science has been used to assess the inhibition effect of the rhenium complexes (*15*). Commercial yeast hexokinase has been used instead of human HK1. The phosphotransferase activity was followed spectrophotometrically (340 nm) in the presence of an excess of G6PDH at 37 °C (as depicted in Scheme 1). The assay was validated with 2-*N*-acetyl glucosamine, a known HK inhibitor. Stock solution of 10^{-2} M of the complexes **10b**−**18b** in TEOA (pH = 7.6) buffer have been prepared. Inhibition with respect to glucose was studied at three different concentrations. The reaction mixture contained 50−250 μL of the stock solution of the complexes in 0.1 M TEOA, 100 μL of 10 mM NADP, 50 μL of 0.66 mM ATP, 200 μL of 10 mM $MgCl_2$, 75−250 μL of 1 mM glucose, 5 μL of a stock solution of glucose-6-phosphate dehydrogenase (G6PDH; 140 U/mL), and 10 μL of a stock solution of HK (150 U/mL). The sample volume was matched to a final volume of 1 mL with 0.1 M TEAO buffer. Disturbance of the absorption of NADP$^+$ and NADPH were not detected at the applied concentrations of complexes.

Pseudosubstrate Assay. The PyK assay method has been described by Tietz and Ochoa (Scheme 2) (*16*). The

Scheme 2



assay was validated with D-glucose and 2-deoxy-D-glucose. Stock solutions of 10^{-2} M glucose and complexes **11b**−**13b** have been prepared in 30 mM phosphate

buffer. The substrate activity was tested at a concentration of 10^{-3} M of glucose and 10^{-3} M of complexes, respectively. Reactions were carried out at 37 °C and followed at 340 nm. A mixture of 590 μL of phosphate buffer 100 μL of glucose or complex solution, 10 μL of HK (150 U/mL), 150 μL of 10 mM $MgCl_2$, 50 μL of 1 mM ATP, 50 μL of phosphor(enol)pyruvate (8 mM), 65 μL of NADH (1.6 mM) and 35 μL of LDH (500 U/mL; freshly prepared) was incubated for 3 min at 37 °C. The reaction was launched by addition of 5 μL of freshly prepared PyK (170 U/mL) in phosphate buffer.

Measurement of Cell Uptake. Cellular uptake was assayed as previously described with few modifications (*17*). HT29 cells were grown in McCoy's 5A with 10% fetal calf serum (FCS). Confluent cells were placed in 12-well plates (106 cells/well) and allowed to attach overnight. Before the assay, cells were incubated for 5 h at 37 °C with McCoy's + 0.5% bovine serum albumin (BSA). Prior to the uptake studies, cells were preincubated with PBS + 1% BSA for 30 min at 37 °C. The assay was validated with [^{3}H]-2-deoxyglucose (2 μCi/mL, 160 nmol/mL). The effect of insulin, cytochalasin B, and D-glucose on [^{3}H]-2-deoxyglucose uptake was also tested. Cells were incubated for 30 min at 37 °C with insulin (0−100 nM), cytochalasin B (0−50 μM), and D-glucose (0−10 mM) before the 30 min incubation with [^{3}H]-2-deoxyglucose or the complexes **10a**, **15a**, and **17a** (Figure 4). For the Tc-99m complexes, the cells (106 cells/well) were incubated for 20 min at 37 °C with increasing concentrations of the different derivatives (0−1 MBq/mL, approximately 0−52 pM). The uptake was terminated by aspiration of the medium. Cells were washed three times with cold PBS and lysed with 1 N NaOH.

In Vitro Stability Tests. HPLC purified samples (100 μL) of the Tc-99m complexes were mixed with 900 μL of physiological phosphate buffer, human plasma, and 10^{-2} M solutions of cystein and histidine and incubated at 37 °C for 24 h. Aliquots were taken at 1, 4, and 24 h and analyzed via HPLC.

Computational Details. The analysis of the glucose binding site was carried out based on the crystal structure (resolution 2.8 Å) of HKI (*18*) using the program GRID (version 19) (*19*). The energy surface was calculated using H_2O as a probe, which contoured the space available in the active site for a ligand at 0 kcal/mol. The structure of the IDA complex moiety was taken from a reported crystal structure (*20*).

RESULTS AND DISCUSSION

Synthesis and Characterization of ^{99m}Tc and Re Complexes 10−18. The structure and composition of all tested rhenium complexes have been unambiguously characterized by means of ^{1}H NMR, IR spectroscopy, and/or mass spectrometry. The chemical analyses revealed that the metal-tricarbonyl center was in all cases tridentately coordinated via IDA- (**1**−**5** and **9**), picolylamine mono acetic acid (**6**), and histidyl (**7**), or via bisimidazolyl amino methane (**8**) chelates (Scheme 3). The resulting rhenium complexes showed high stability over a period of several weeks in aqueous media as evident from HPLC and NMR analyses. They were all soluble in aqueous media, which was essential to perform the in vitro experiments. However, complexes with chelating systems containing aromatic functionalities (**15b**−**17b**) and the complex **12b** with an octyl chain were less soluble in buffered systems than the complexes **10b**, **11b**, **13b**, **14b**, and **18b**.

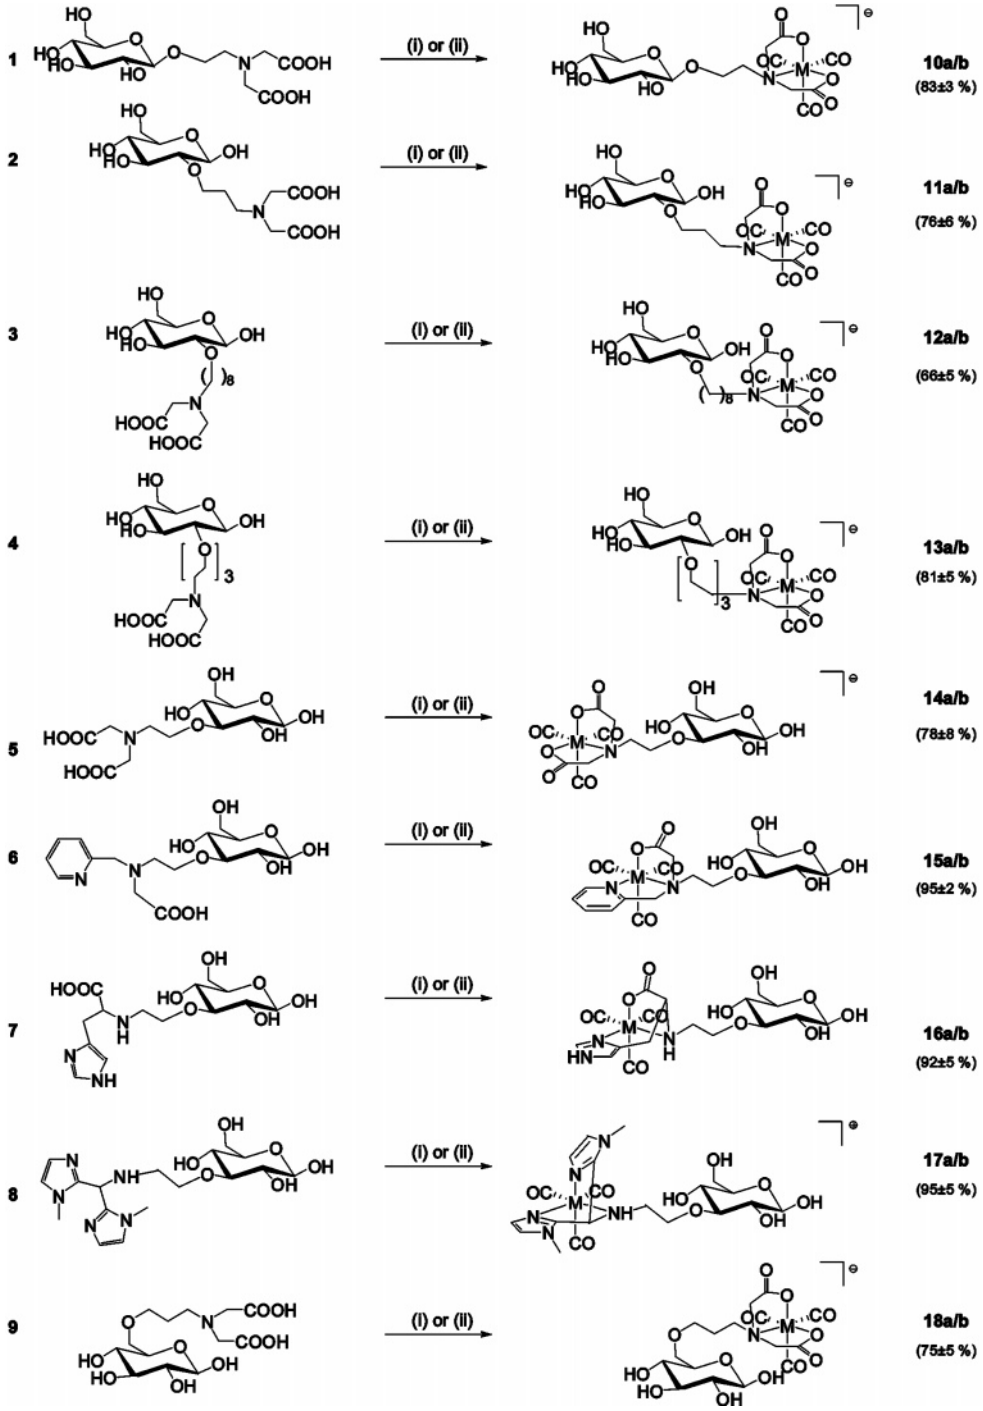
The glucose analogues **1**−**9** were reacted with the radioactive precursor $[^{99m}Tc(H_2O)_3(CO)_3]^+$ under physiological conditions. The formation of single products was observed in all cases. The yields of the labeling reactions were generally good (70−95%) but slightly depended on the nature of the chelating system. As previously reported by our group, chelating systems containing one or more aromatic amine functionalities (derivatives **6**−**8**) gave rise to higher yields than those with the IDA chelate at a ligand concentration of 10^{-4} M (*21*). However, we did not observe a significant dependence of the labeling efficiency either on the position where glucose was functionalized or on the spacer length. The HPLC analysis of the Tc-99m complexes **10a**−**18a** revealed similar retention times as for the corresponding rhenium complexes **10b**−**18b**. Thus, it can be concluded that Tc-99m complexes have the identical structure and composition as the analogous rhenium complexes.

Molecular Docking Studies. From high-resolution crystal structures of the enzyme dimer and monomer, it is evident that, for example, in yeast HK and human HK-I, the C-terminal and N-terminal domains are separated by a deep cleft (*18*, *22*). Glucose binds at the very bottom of the cleft and causes the small lobe of the molecule to rotate by 12° relative to the large lobe (*23*). Competitive HK inhibitors bind at the same site of the domain. The glucopyranose has to adopt a C-1 (chair equatorial) conformation. The C-3 and C-4 hydroxyl group of the sugar make specific interactions with the side chains of the protein. However, no direct interaction with side chains of the protein is observed for the OH group at position C-2. Thus, it is obvious that most of the known inhibitors of HK are C-2 functionalized, e.g., *o*-toluoyl glucosamine. Therefore, we performed molecular docking experiments with C-2 functionalized complexes. Simple alkyl spacers of different length were introduced between the sugar moiety and the Tc/Re-tricarbonyl entity. The molecules were manually docked into the active site. It was calculated that the introduction of a heptyl spacer would be sufficient to accommodate the metal entity in a large cavity at the outer surface of the protein without rearranging the glucose moiety in the active site. Figure 1 depicts the grid surface of the active site of HK in the "open" and the "closed" conformation with the corresponding glucose complex with a heptyl spacer.

Kinetic Studies of Rhenium Complexes 11b−18b against Hexokinase. The number of inhibitors for different types and subtypes of HKs (yeast, bovine brain, rabbit and human muscle) reported in the literature is rather limited. (i) Deoxy derivatives of hexoses which are competitive inhibitors with K_i values in the range of the K_m value of glucose (approximately 1 mM) (*24*, *25*). (ii) Hexose-6-phosphate analogues which inhibit human HK by interacting at regulatory sites (*26*). (iii) Glucosamine derivatives (*22*, *27*, *28*). However, to the best of our knowledge the inhibition of hexokinase by transition metal complexes and particularly organometallic glucose complexes has never been reported until now.

The complexes **10b**−**18b** have been tested for competitive inhibition of yeast hexokinase. Table 1 gives the inhibition constants of the different complexes. The kinetic data were calculated from Lineweaver−Burk plots ($1/v$ versus 1/[glucose]) and replots (slope versus concentration of inhibitor) with respect to glucose. Complexes **12b**, **13b**, **15b**, and **17b** competed with the substrate glucose for the active site of the enzyme however with variable efficiency. Two trends could be observed: (i) C-2 functionalized derivatives with a long alkyl and poly(ethylene glycol) spacer (**12b** and **13b**) exhibited low K_i values in the micromolar range (Table 1). For a comparison, the known HK inhibitor *N*-acetyl-

Scheme 3 [a]



[a] (i) M = ^{99m}Tc: $[^{99m}Tc(H_2O)_3(CO)_3]^+$, PBS, pH = 7.5, 45 min, 75 °C; (ii) M = Re: $(NEt_4)_2[ReBr_3(CO)_3]$, methanol or water, 2 h, 50 °C. (Yields given for ^{99m}Tc complexes only).

glucosamine revealed in our test system a K_i value of 3.26 ± 0.01 mM (literature value 2.72 ± 0.05 mM (*27*)). (ii) For the anionic complex **11b** functionalized at position C-2 with a short spacer and for the glucose complexes functionalized at C-1 and C-3 no or only moderate inhibition of the enzyme was detected independent of the overall charge of the complexes. These experimental data are in accordance with the results obtained during the above-mentioned molecular docking experiments.

It is worth mentioning that none of the metal-free glucose derivatives **1**−**9** showed inhibition of HK. Similar observations have been made with organometallic functionalized thymidine analogues toward human cytosolic thymidine kinase. Also in those cases only the corresponding rhenium-tricarbonyl complexes revealed inhibition of the targeted enzyme (*29*). It can be speculated that the neutralization of a negative charge at the chelating entity and/or the reorganization of the functional groups after complexation is the reason for this effect.

Evaluation of Pseudosubstrate Activity of Rhenium Complexes 12b and 13b. Theoretically complexes **10**−**17**, which have a free OH group at position C-6, may also act as pseudosubstrates and could potentially be phosphorylated by ATP. Thus, formation of ADP can be used as an indication for substrate and pseudosubstrate activity of glucose analogues. The C-2 functionalized rhenium glucose analogues **12b** and **13b** which exhibited reasonable K_i were qualitatively tested for pseudosub-

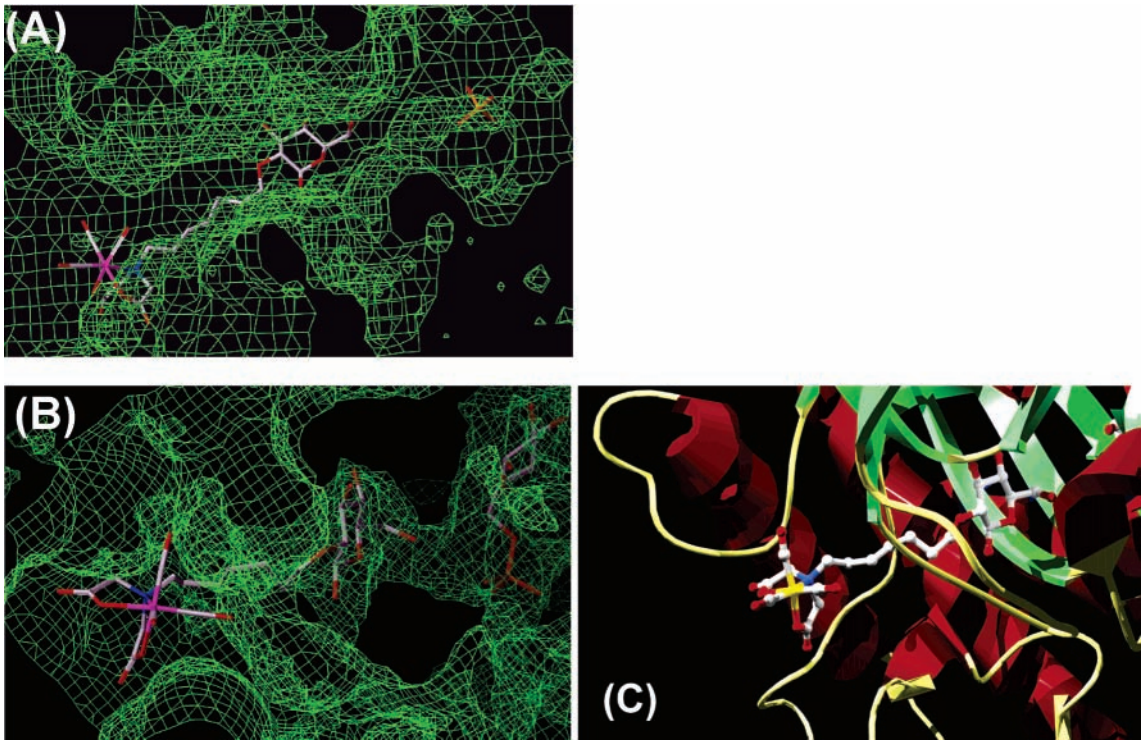


Figure 1. Catalytic site of HK: The green grids represent surface of the protein. (A) Active site of HK in the "open" conformation and (B) active site of HK in the "closed" conformation comprising a C-2 functionalized glucose "M(IDA)$(CO)_3$ complex" (M = Tc, Re) with a heptyl spacer; (C) ribbon representation of closed conformation.

Table 1. Inhibition Constants of Complexes 10b−18b with Respect to Yeast Hexokinase

complex	K_i [mM]	tested conc of inhibitor (mM)
10b	not detectable	1−2.5
11b	not detectable	1−2.5
12b	5.8 ± 0.9	1−2.5
13b	0.25 ± 0.01	1−2.5
14b	not detectable	1−7.6
15b	>100	1−2
16b	not detectable	0.1−2
17b	>100	1−3.8
18b	not detectable	0.1−2

strate activity. The formation of the ADP was measured via the ATPase assay ($\Delta Abs_{340nm}/\Delta t$ resulting from the oxidation of NADH is indirectly proportional to ADP formation). However, we observed only negligible activities for both Re complexes (Figure 2). By contrast, experiments with D-glucose and 2-deoxy-D-glucose revealed a significant rate of reaction as expected.

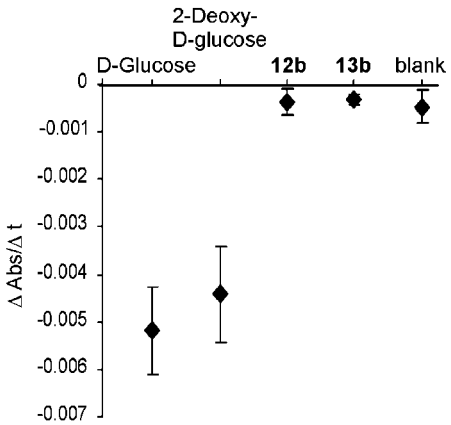

Figure 2. Rate of oxidation of NADH by LDH in the presence of HK, PyK, and complexes **12b**, **13b**, D-glucose, and 2-deoxy-D-glucose.

In Vitro Stability of Complexes 10a−18a. Previous to the cell experiments, all radioactive complexes **10a−18a** were tested in vitro in physiological phosphate buffer (pH = 7.4) and human serum at 37 °C for 24 h. Only minor decomposition of the complexes or back oxidation of the metal center to $^{99m}TcO_4^-$ (5−10%) could be observed during this time. The Tc-99m complexes were also challenged against the amino acids Cys and His. The complexes showed only insignificant transchelation or decomposition in the presence of Cys (<5%). Complexes with the IDA chelating moiety (**10a−14a** and **18a**) revealed minor ligand exchange in the presence of excess His (5−10%), whereas the complexes **15a−17a** were completely inert.

Cell Internalization Experiments via Glut1. It is well documented that Glut1 exists in two conformations and offers an extracellular as well as an intracellular binding site for D-glucose. Earlier it was reported that the OH groups at positions C-1, C-2, and C-3 of glucose interact with the transport protein at the extracellular binding site (*30*). The OH groups at positions C-4 and C-6 are described to be important for interaction with the intracellular binding sites. It was also reported that Glut1 tolerates some modification of the transported substrate. Speizer et al. reported that 6-deoxy-*N*-(7-nitrobenzyl-2-oxa-1,3-diazol-4-yl)amino glucose is transported via Glut1 (*31*) and recently, Zhang et al. published that pyropheophorbide 2-deoxyglucosamide functionalized at C-1 targets and transports via Glut1 (*32*).

We tested all our Tc-99m complexes for transport through the cell membrane via Glut1 and indirectly also for Glut1 interaction/inhibition. For these experiments, the colon carcinoma cell line HT29 has been used. The cells have been validated for exclusive overexpression of the sodium-independent Glut1 transport systems. For our tests, the cells have been incubated for 30 min at 37 °C with the freshly prepared and HPLC-purified technetium-99m complexes **10a−18a** and different amounts of

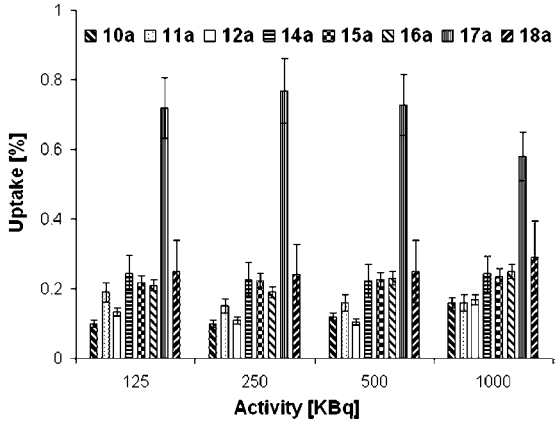

Figure 3. Dose-dependent cellular uptake of the complexes **10a**−**18a** in HT-29 colon carcinoma cells (after 30 min at 37 °C).

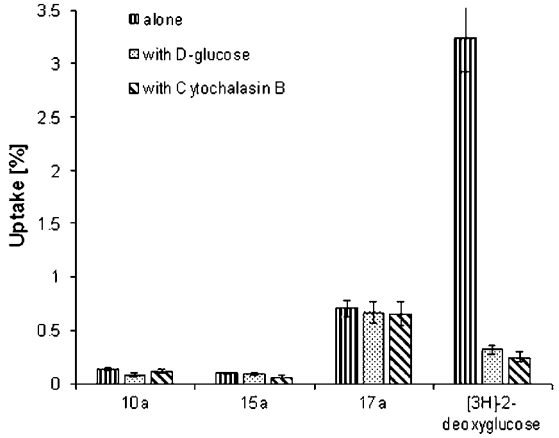

Figure 4. Cellular uptake of complex **10a**, **15a**, **17a**, and [3H]-2-deoxyglucose in the presence of 10 mM D-glucose or 50 μM cytochalasin B.

activity (125−1000 KBq). The results are depicted in Figure 3. Cellular uptake of the complexes **10a**−**16a** and **18a** ranged between 0.1 and 0.3% of total activity. Only complex **17a** revealed a significantly higher uptake (0.7 ± 0.08%). Compared to [^{3}H]-2-deoxyglucose (approximately 3 ± 0.38% after 30 min), the uptake was relatively low (Figure 4). In addition, the cellular uptake was not dose dependent.

The internalization of complexes **13a** (C-2), **17a** (C-3), and **18a** (C-6) was challenged in the presence of 10 mM D-glucose and cytochalasin B (50 μM), a potent Glut1 inhibitor, to verify specific transport via Glut1 or binding to Glut1. It was observed that within the standard deviation the internalization of the selected complexes was not affected by cytochalasin B (Figure 4). Therefore, it can be concluded that our complexes are not transported via Glut1. Since cytochalasin B is binding intracellularly, it still could be speculated that the complexes are interacting at the extracellular binding site of glucose (*33*, *34*). However, the fact that a large excess of D-glucose did not affect or reduce internalization of the complexes gives evidence that they do not compete for a common binding site. Unspecific uptake via passive diffusion rather than active transport via the sodium-independent Glut1 transporter can be postulated for all complexes based on these observations. Facilitated passive diffusion of the very lipophilic complex **17a** is presumably the reason for its increased (unspecific) internalization.

Almost simultaneously to our findings, Fischbarg and co-workers have recently published an improved three-dimensional structure of Glut1 by an evolutionary homology strategy based on the structure of glycerol-3-phosphate transporter from *Escherichia coli* (PDB 1PW4 (*35*)) (*34*). This model is still under investigation and validation, and the results should presumbaly be handled and interpreted with the necessary caution. A putative docking site of D-glucose was found near the extracellular opening of the transport channel as expected. According this model, D-glucose forms initially H-bonds with the pyranose oxygen (and lysine 38) as well as with the OH group at position C-6 (and glutamic acid 41), which is contrary to what was published earlier. The conserved QLS motif, which has been recognized earlier to be important for the selectivity of sugars transported (*36*), was also found near the entrance forming a tight bottleneck nearly impassable for compounds larger than glucose. Thus, it is very likely that our (and presumably any other) technetium glucose complexes are sterically too demanding for recognition at the extracellular binding site and/or transportation via Glut1. In addition, Fischbarg proposed that only one or two H-bonds are formed between the transporter and the substrate at any time, giving evidence for a rolling mechanism during substrate migration along the transport channel. It can be speculated that any modification preventing glucose from this rolling mechanism (as our modification of glucose with technetium complexes most likely do) will not be transported. Glut1 inhibitors such as forskolin and phloretin where found to form simultaneously three and five H-bonds, respectively, immobilizing these compounds and therefore blocking Glut1. Thus, it would eventually be interesting to target Glut1-overexpressing cancer cells with technetium complexes based on scaffold of a potent Glut1 inhibitor.

CONCLUSION

We have synthesized, radiolabeled, and characterized in vitro a series of organometallic technetium and rhenium complexes of glucose functionalized with different chelating systems at positions C-1, C-2, C-3, and C-6 of the hexose. The formation of well-defined and stable complexes has been observed in all cases. Competitive inhibitors were only found among glucose complexes functionalized at position C-2. Molecular docking experiments support this tendency. Other than [^{18}F]-FDG, the inhibitors are not phosphorylated by the enzyme in the presence of excess ATP. Furthermore, all tested complexes seem not to be recognized and transported via the Glut1 transporter. A critical evaluation of the data of our compounds preclude at the moment their use as [^{18}F]-FDG surrogates. The poor in vitro results do not currently justify further in vivo experiments with the presented technetium glucose complexes. However, it cannot be excluded that these compounds have the potential for other diagnostic (and therapeutic) indications or targets. Therefore, we are currently screening and evaluating other cellular transport systems such as Glut3 and SDGLT1-3, which show lower substrate specificity and are overexpressed on various cancer types.

ACKNOWLEDGMENT

We thank Judith Stahel for preparing the technetium-99m complexes and performing enzyme kinetic experiments. This work has been financially supported by Mallinckrodt-Tyco Inc.

Characterization of Site-Specific ScFv PEGylation for Tumor-Targeting Pharmaceuticals

Arutselvan Natarajan, Cheng-Yi Xiong, Huguette Albrecht, Gerald L. DeNardo, and Sally J. DeNardo*

University of California Davis Medical Center, Sacramento, California 95816. Received August 2, 2004; Revised Manuscript Received November 24, 2004

New radiopharmaceuticals are possible using site-specific conjugation of small tumor binding proteins and poly(ethylene glycol) (PEG) scaffolds to provide modular multivalent, homo- or heterofunctional cancer-targeting molecules having preferred molecular size, valence, and functionality. Residence time in plasma can be optimized by modification of the size, number, and charge of the protein units. However, random PEG conjugation (PEGylation) of these small molecules via amine groups has led to variations of structural conformation and binding affinity. To optimize PEGylation, scFvs have been recombinantly produced in a vector that adds an unpaired cysteine (c) near the scFv carboxy terminus (scFv-c), thus providing a specific site for thiol conjugation. To evaluate the general applicability of this unpaired cysteine for PEGylation of scFv-c, conjugation efficiency was determined for four different scFvs and several PEG molecules having thiol reactive groups. The effect of the PEG molecular format on scFv-c PEG malignant cell binding was also addressed. ScFvs produced as scFv-c and purified by anti E-TAG affinity chromatography were conjugated using PEG molecules with maleimide (Mal) or *o*-pyridyl disulfide (OPSS). Conjugations were performed at pH 7.0, with 2 molar excess TCEP/scFv and PEG-(Mal) or PEG-OPSS, using 5:1 (PEG/scFv). PEG-Mal conjugation efficiency was also evaluated with 1:5 (PEG/scFv). PEGylation efficiency was determined for each reaction by quantitation of the products on SDS−PAGE. ScFv-c conjugation with unifunctional maleimide PEGs resulted in PEG conjugates incorporating 30−80% of the scFv-c, but usually above 50%. Efficiency of scFv-c conjugation to both functional groups of the bifunctional PEG-$(Mal)_2$ varied between the PEG and scFv-c molecules studied. A maximum of 45% of scFv-c protein was conjugated as PEG-$(scFv\text{-}c)_2$ using the smallest PEG-$(Mal)_2$ (2 kDa). No significant increase in scFv-c conjugation was observed by the use of greater than a 5 molar excess of PEG/scFv-c. Under the same conjugation conditions, PEG as OPSS yielded less than 10% PEG-scFv-c. PEG-$(scFv)_2$ conjugates had increased binding in ELISA using malignant cell membranes, when compared with unmodified scFv-c. PEGylated-scFv binding was comparable with unmodified scFv-c. In summary, scFv-c can be PEGylated in a site-specific manner using uni- or bivalent PEG-Mal, either linear or branched. ScFv-c was most efficiently conjugated to smaller PEG-Mal molecules, with the smallest, 2 kDa PEG-Mal, usually PEGylating 60−90% of the scFv-c. ScFv-c conjugation to form PEG-$(scFv\text{-}c)_2$ reached greatest efficiency at 45%, and its purified form demonstrated greater binding than the corresponding scFv-c.

INTRODUCTION

Radiolabeled monoclonal antibodies (MAb) have proven to be effective therapy for some radiosensitive cancers (*1, 2*). Because of their large size, blood clearance and tumor uptake occur slowly, decreasing the tumor to marrow therapeutic index. Unless bone marrow support is provided, hematological toxicity precludes administration of sufficient radiopharmaceutical to deliver effective radiation to most solid tumors (*3, 4*). Recombinant production of selected single chain Fv antibody fragments (scFv) provides small molecules for new paradigms designed to enhance the therapeutic index of tumor-targeted or pretargeted radionuclide therapy (*5*−*7*). With advances in antibody engineering and phage-display, antibody fragments can be generated that have a high degree of target specificity and a range of binding affinities (*8, 9*).

Pharmacokinetic studies with radiolabeled scFvs have shown that their small size leads to rapid blood and renal clearance and insufficient opportunity for tumor uptake (*10, 11*). These small antigen-binding proteins can also serve as modules in multivalent tumor-targeting constructs designed to enhance radioimaging and therapy (*12, 13*). Poly(ethylene glycol) (PEG) polymers have the characteristics necessary to serve as scaffolds for these modules. PEGylation, the covalent attachment of PEG to other molecules, has become a validated drug delivery method, and several PEGylated drugs have been approved by the FDA. Better stability, decreased proteolysis, enhanced solubility, and longer circulation and body retention of PEGylated pharmaceuticals have led to their enhanced efficacy (*14, 15*).

PEGylation of biologically active drugs has historically been accomplished by covalent conjugation to available primary amines of lysine residues. Significant loss of target binding or biologic activity frequently resulted as a consequence of conformational change or steric hindrance (*16, 17*). Since small molecules such as scFv allow little room for error, an expression vector has been

engineered for the addition of a free cysteine (c) near the carboxyl end of the scFv (scFv-c), thereby providing a specific site for thiol conjugation of scFv-c produced in the vector (*18*). To determine the general applicability of scFv-c PEGylation, we evaluated the relative conjugation efficiency of several scFv-c with PEG molecules varying in size, structure, and thiol reactive groups, including mono- and bifunctional PEG molecules in linear and branched formats (Figure 1, Table 1). Evidence of a relationship between PEG structure, size, and the efficiency of scFv-c PEGylation was observed.

MATERIALS AND METHODS

Materials. Methoxy-PEG-maleimide (PEG-Mal) of 3.4, 5, 20, and 40 kDa and a bifunctional maleimide-PEG-Mal (PEG-$(Mal)_2$) of 3.4 kDa were purchased from Nektar Therapeutics (San Carlos, CA). PEG-Mal of 10 and 20 kDa, methoxy-PEG-*o*-pyridyl disulfide (OPSS) of 5, 10, and 20 kDa, and PEG-$(Mal)_2$ of 2 kDa were obtained from

Sunbio PEG-Shop (Anyang City, S. Korea). These were stored under N_2 atmosphere. Titrisol Iodine solution was obtained from EM Science (Gibbstown, NJ) and tris(2-carboxyethyl)phosphine hydrochloride (TCEP) from Molecular Probes (Eugene, OR). The Micro BCA Protein Assay Reagent kit was obtained from Pierce Biotechnology (Rockford, IL) and the RPAS purification module from Amersham Biosciences Corp (Piscataway, NJ). All other chemicals were obtained from Sigma-Aldrich (St. Louis, MO).

Production and Purification of scFv-c. Four MUC-1 positive scFv-c were selected from previously developed MUC-1 immune phage display scFv libraries (*19, 20*). MUC-1 is a high molecular weight glycoprotein molecule, composed of an extracellular domain with tandem repeats of 20 amino acids, a transmembrane region, and a cytoplasmic tail. In many epithelial cancers, the extracellular domain presents novel epitopes of shortened carbohydrate chains and exposed portions of the 20 amino acid tandem repeats, hence providing unique relatively tumor specific targets for antibodies (*20*). Anti MUC-1 scFv gene inserts were isolated by SfiI/NotI double digestion and ligated into the pCANTAB 5E Cys vector (*18*). Clones isolated from transformants after electroporation into *E. coli* HB2151 were sequenced to confirm the presence of the extra cysteine-specifying codon at the 3′ end of the scFv (scFv-c). In the scFv-c protein, cysteine (C) is transcribed from this vector codon, at the end of the linked Vh-Vl sequence, immediately after the amino acid sequence of the NotI insertion site (underlined) and before the E-TAG amino acid sequence (bold): (Vh-Vl...TKLELKRAAAC**GAPVPYPDPLEPRAA**) (*20*).

All the scFvs-c were produced in shaker flasks and purified as previously described (*18, 20*). Briefly, periplasmic extracts were prepared and affinity purified by anti E-Tag chromatography of the scFv-c proteins using the RPAS purification module and buffer-exchanged into phosphate-buffered saline (PBS) pH 7.4 (*18, 20*). The protein concentration (mg/mL) of each E-Tag purified scFv-c product was determined by using the micro BCA protein reagent kit. To ensure the scFv-c was in the monomeric form for conjugation, the scFv-S−S-scFv linkage from the unpaired thiol groups was prevented by addition of the reducing agent, TCEP, in 2-fold molar excess. As shown previously (*18*), nearly 100% reduction of that thiol group could be maintained in this manner with no evidence of effect on the two intramolecular disulfide bridges of the scFv-c. The advantage of TCEP as the reducing agent was stability over time in a broad pH range (5.0−8.0); however, increased signal in ELISA studies has been noted at these concentrations, so that samples with and without TCEP are evaluated.

Estimation of Maleimide Reactivity as PEG-Mal. To estimate the degree of functional maleimide groups available for conjugation in the PEG reagents, functional group analysis of the various PEG-Mal was carried out by adding up to a 5 M excess of cysteine to each PEG-Mal in 0.1 M sodium phosphate, pH 7, with 1 mM EDTA (Table 1, nos. 1−6). Free cysteine was then measure by reaction with DNTB as previously published (*21*). The results indicated that maleimide functional groups in all the PEG-Mal reagents were greater than 90% reactive toward cysteine and thus thiol groups.

PEGylation of scFv-c. The PEG to scFv molar ratio for conjugation reactions was initially studied with scFv-c as D5-c PEG-$(Mal)_2$ (2 kDa) at 2, 5,10, 20, and 50-fold molar excess of PEG. Since no increase in scFv conjugation was demonstrated in ratios over 5:1, PEGylation studies of all 4 scFv-c with the PEG-Mal and PEG-OPSS reagents was performed at a molar ratio of 5:1 (PEG: scFv). The reaction was carried out in 0.1M sodium phosphate buffer, pH 7.0, 2 mM EDTA, at 1−2 mg/mL scFv-c and 2-fold molar excess TCEP, and incubated under N_2 atm at 37 °C overnight (*22, 23*).

PEGylation efficiency was analyzed using separation of scFv-c and PEG-scFv species with SDS−PAGE (Novex XCell II) in 4−12% Bis-Tris NuPAGE gel and MES running buffer, according to the manufacturer's methods (*17, 22, 24*). Coomassie blue and barium iodide staining detected scFvs (free and conjugated) and PEG molecules, respectively, and comparisons were made to the molecular weight standards. Coomassie blue-stained proteins in the PAGE gels were digitally scanned for permanent images and quantitation of the bands. The gels were then rinsed with distilled water, and 5% barium chloride solution was added for 10 min and again rinsed and placed in 0.1 M Titrisol iodine solution for color development (*17, 25*) (Figure 2).

PEGylation yields were calculated from quantitation of the initial scFv-c compared to the resulting scFv-c as PEG-scFv conjugates vs unconjugated scFv-c. The relative amounts of each species in each reaction were obtained by calculations of digital information from densitometry performed on the scanned gel images and protein standards (Personal Densitometer S1, model PDS1, Molecular Dynamics Inc., Sunnyvale, CA), as previously described (*26*).

Western Blot Analysis of scFv-c E-Tag-Purified Products. The 4 scFv-c and separately BA1-c and the purified BA1-c PEG-$(scFv)_2$ products were evaluated with anti-E Tag by Western blotting. Two hundred and fifty nanograms of purified scFv-c and PEG-$(scFv)_2$ were subjected to SDS−PAGE, transferred onto a PVDF (polyvinylidine difluoride) membrane to which HRP-conjugated anti-E Tag (Amersham Biosciences) was added. After washings, reactivity was detected with the Super Signal (Pierce, Rockford, IL) substrate and exposed to chemiluminescent-sensitive film. Specific attention was given to the 17 and 19 kDa products seen on PAGE but not on Western with anti-E-Tag (Figure 3).

Protein N-Terminal Sequencing of the 17 and 19 kDa Fragments. After separation of the BA1-c protein forms by nonreducing SDS−PAGE, ~9.5 and 19 μg of BA1-c nonreduced scFv fragments, respectively, were loaded into two lanes of a 4−12% NuPAge gel (Invitrogen), and the proteins were electroblotted onto a PVDF membrane (Biorad, Hercules, CA) for direct N-terminal sequencing by Edman's degradation. This protein microsequencing was performed on an ABI Procise HT Edman Sequencer System (Perkin-Elmer/Applied Biosystems, Foster City, CA) at the Molecular Structure Facility at University of California−Davis.

Cell Lines and Cell Lysate Preparation. MUC-1 positive human breast adenocarcinoma MCF-7 cells (American Type Culture Collection (ATCC) Manassas, VA) were grown to 75% confluence in DMEM (Gibco, Invitrogen Corp., Carlsbad, CA) medium supplemented with 5% fetal calf serum (FCS) (Gibco, Invitrogen Corp.). MUC-1-positive DU145 human prostate cancer cells (ATTC) were grown to 100% confluence in RPMI-1640 medium (Gibco, Invitrogen Corp.) supplemented with 10% FCS.

Purification of PEG Conjugates. PEG-$(BA1)_2$ reaction mixture, as shown in the (Figure 3a, lane B) containing 250 μg of PEGylated protein, was purified by molecular sieving column chromatography on a 30 × 1.5 cm glass column (Bio-Rad, Hercules, CA) packed with sephadex G-75 (Sigma Chemicals, St. Louis, MO). The column was preconditioned in 100 mM sodium phosphate buffer pH 7.0 and operated at a flow rate of 0.3 mL/min. Fractions were collected (200 μL), and the PEG-$(scFv\text{-}c)_2$ (65 kDa) was eluted immediately after the void volume. ScFv-c (31kDa) and PEG-scFv-c (34kDa) eluted together at midcolumn volume.

Immunoreactivity. ELISA was used to determine immunoreactivity of PEGylated scFv against breast (MCF-7) and prostate cancer (DU145) cell membranes. Pro-Bind ELISA assay plates (Becton Dickinson Lab Ware, Franklin Lakes, NJ) were coated with 100 μL of cell lysate at 1 mg/mL. The wells were dried by warming the plates at 37 °C. Nonspecific binding was blocked with 200 μl/well of PBS/0.1% Tween 20 (Sigma-Aldrich) containing 3.0% nonfat dry milk (Bio-Rad, Hercules, CA) for 1 h at 37 °C. E-Tag-purified scFv-c, the reaction mixture of scFv-c and PEGylated scFv, and the purified PEG-$(scFv\text{-}c)_2$ were each studied in triplicate on three occasions, using 1 μg of scFv-c/well, a total volume of 100 μL/well (PBS/0.01% Tween 20/0.3% nonfat dry milk), and 1 h incubation at 37 °C. Following each incubation, the plates were washed six times with PBS containing 0.01% Tween 20. Anti-E-Tag-HRP MAb (100 μL) diluted to 1:4000 in PBS/0.1% Tween/0.3% nonfat milk solution was added and incubated in the same manner. Following the last wash step, the 2,2′-amino-bis-3-ethylbenzthiazoline-6-sulfonic acid (ABTS) substrate (Sigma-Aldrich), containing 0.3% H_2O_2, was added. As soon as color had developed, the content of each well was transferred to a new plate. Plates were read at $A_{405\ nm}$ (Dynex microplate reader, Chantilly, VA).

RESULTS

Evaluation of scFv-c Preparations. PAGE gels of the ETAG-purified products of each scFv-c in TCEP are illustrated in Figures 2. The major band, approximately 30 kDa, corresponds to the monomeric form of the scFv-c for CC6-c (Figure 2a), AD3-c (Figure 2b), D5-c (Figure 2c), and BA1-c (Figure 2d). Lower molecular weight recombinant products of AD-3-c, D5-c, and BA1-c can be seen approximating 17 and 19 kDa. These were demonstrated to have no E-Tag by Western Blot analysis, as exemplified by BA1-c (Figure 3). Minor bands at approximately 52 kDa were detected only in the initial BA1-c (Figure 2d) and were not studied.

PEGylation of scFv-c. PEGylation was studied using PEG with either of two thiol reacting groups, Mal or OPSS (*16, 27, 28*). Effective conjugations were only obtained with Mal as either PEG-Mal or PEG-$(Mal)_2$. The

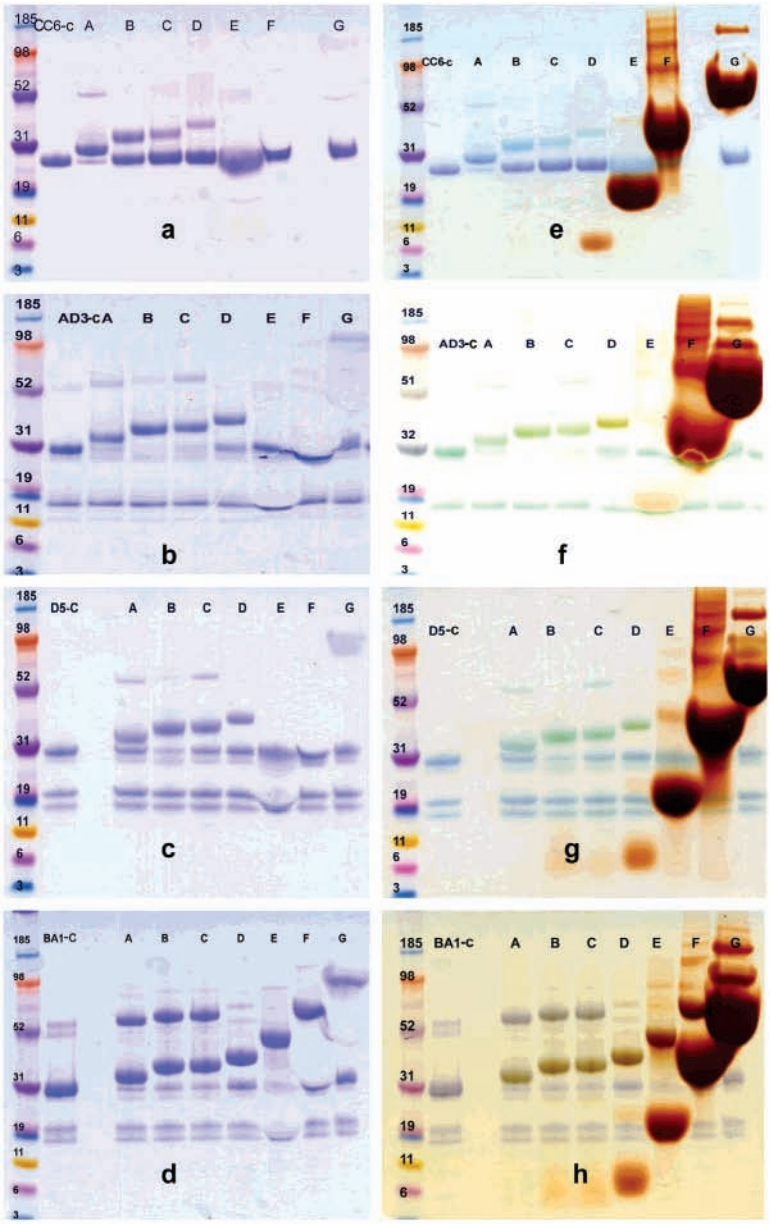

Figure 2. PEG-scFv conjugates on SDS−PAGE gel (4−12%) under reducing conditions. (Left) (a−d) Stained with Coomassie blue for protein identification. ScFv-c in each series of conjugation reactions, a: CC6-c, b: Ad3-c, c: D5-c, and d: BA1-c. (Right) (e−h) Stained with Coomassie blue for protein followed by barium iodide for PEG, allowing both scFv-PEG and PEG identification, e: CC6-c, f: Ad3-c, g: D5-c, and h: BA1-c. Lanes A and C are the results from PEGylation with PEG-$(Mal)_2$, 2 and 3.4 kDa; Lane B, NHS-PEG-Mal 3.4 kDa; and Lanes D−G PEG-Mal of 5, 10, 20, and (branched) 40 kDa. Note should be made that lanes D−G showed PEGylation with increasing PEG molecule size. The identification of PEG and scFv-PEG by barium iodide and Coomassie blue is shown in Figure 2e−h with three different colors: blue (scFv), green/gray (PEG-scFv), and brown (PEG), providing identification of various molecules to confirm the PEG-scFv conjugation. Lanes A to F (Figures a−d), with Coomassie blue staining, show gradual increase in molecular weight in accordance with the molecular weight of the PEG used in the conjugation.

PEG with OPSS was evaluated (5:1), PEG-OPSS/scFv, and resulted in less than 10% scFv conjugation. PEGylation with identical molar ratios of PEG-Mal to scFv-c (5:1) was much more effective with all scFvs (Figures2 and 4). The PEG-Mal conjugated 30−85% of the scFvs (Figure 4), and the percent of scFv that conjugated as bi-scFv on PEG-$(Mal)_2$ ranged from 15 to 35% for both 2 and 3.4 kDa PEG-$(Mal)_2$ polymers. ScFv BA1-c had the highest efficiency of bi-scFv-c conjugation to produce PEG- $(scFv)_2$ (Figure 4). Using the hetero-bifunctional PEG (3.4 kDa) (Table 1; no. 2) containing one Mal and *N*-hydroxysuccinimide (NHS), the latter for amine reactions, correlated with no effective production of bifunctional PEG-$(scFv)_2$ with CC6-c, AD3-c, or D5-c (Figure 2a,b,c; lane B), but BA1-c conjugated with the NHS group resulting in 40% of that scFv-c as PEG$(scFv)_2$, although the reactivity of NHS should be minimized at this pH (Figure 2d, lane B).

With different sizes of PEG, the PEGylation of scFv-c as one scFv-c per PEG resulted with scFv-c conjugation efficiency ranging from 45% to 75% (2 kDa), 30 to75% (3.4 kDa), 25 to 85% (5 kDa), and 10 to 70% (40 kDa) of the original scFv-c protein (Figure 4, blue bar). With PEG-$(Mal)_2$, 15 to 45% (2 kDa), and 15 to 40% (3.4 kDa), the initial scFv-c protein PEGylated as two scFv per PEG (PEG-$(scFv)_2$) (Figure 4, green bar). Conjugation efficiency with PEG varied moderately among the four scFv with BA1-c > AD3-c ≅ D5-c > CC6-c. The 10 and 20 kDa PEG-Mal PEGylated less than 5% of three out of the four scFv-c.

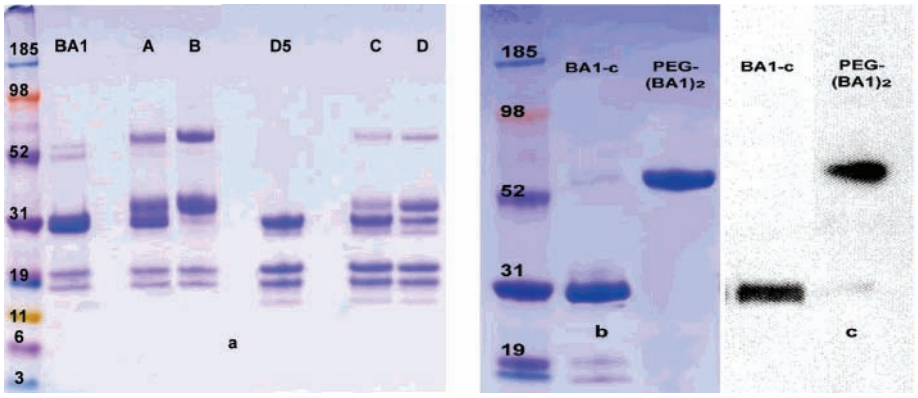

Figure 3. (a) SDS−PAGE reducing gel (4−12%) of 2 kDa PEG-$(Mal)_2$ conjugation reactions with two different scFvs, BA1-c and D5-c, using two different molar ratios of scFv/PEG: 5:1 (lanes A and C), and 1:5 (lanes B and D). It should be noted that bivalent PEG-$(scFv)_2$ product yield was not enhanced by multifold increase in scFv-c to PEG. (b) SDS−PAGE gel and (c) Western blot analysis of BA1-c compared to the purified PEG-$(BA1)_2$ product from the conjugation reaction mixtures seen in part b. The Western blot was performed using HRP-conjugated anti-E-TAG antibody. Bands at 17 and 19 kDa in parts a and b demonstrate no E-TAG binding on Western blot. Prior sequencing indicates that these represent an scFv fragment, with the protein sequence from the amino terminus of VH through the linker region.

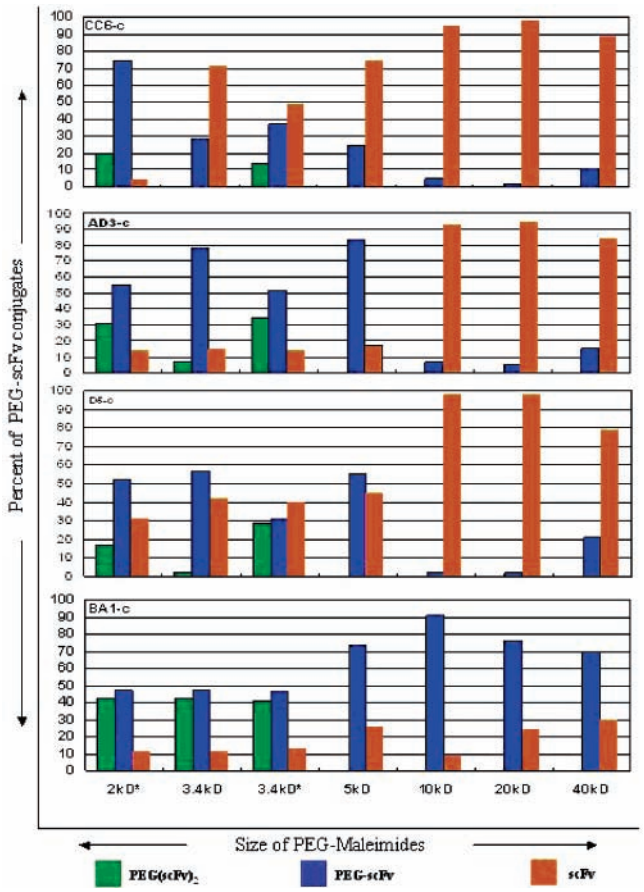

Figure 4. Yields of scFv-c and with PEG-Mal conjugation. The percent scFv-c protein conjugated by PEG-Mal (conjugation yield) calculated from densitometry of the Coomassie blue-stained PAGE gel images. Conjugation yield of scFv-c with PEG-$(Mal)_2$ and PEG-Mal are separately color-coded: green, PEG-$(scFv\text{-}c)_2$; blue, PEG-scFv-c; and orange, unconjugated scFv-c. The scFv-c protein percent yield as PEG-scFv conjugates are on the *x*-axis and PEG-Mal sizes are on the *y*-axis. * PEG-$(Mal)_2$. Panel of scFvs used in these studies were CC6-c, AD3-c, D5-c, and BA1-c, respectively.

The comparison of conjugation reactions of PEG-Mal molecules consisting of various molecular weights ranging from 2 kDa to 40 kDa (Figure 1) demonstrated higher efficiency scFv PEGylation with smaller PEG molecules and lower with larger PEG molecules (Figure 4). The percent yield of PEG-scFvs was 45 to 75, 30 to 75, 25 to 80, and 10 to 70% for 2, 3.4, 5, and 40 kDa PEGs, respectively. BA1 (scFv) had above 40% conjugation with all size of PEG-Mal. AD3 had an exceptionally high percent conjugation of 85% with 5 kDa PEG-Mal. However, unexpectedly 10 and 20 kDa linear PEG-Mal compounds did not react with CC6, D5, and AD3, but BA1 had greater than 75% conjugation. The 40 kDa PEG-Mal branched PEG (Figure 1) conjugated with all four scFv-c (Figures 2 and 4) (*29*). We speculate that this may be due to the influence of the location of the Mal in the branched polymer, as the 10 and 20 kDa were terminal on the linear molecule (*29, 30*).

SDS−PAGE Analysis of PEG-scFv and PEG-$(scFv)_2$ Products. The SDS−PAGE of protein by Coomassie blue is shown in Figure 2a−d. The identification of PEG and scFv-PEG by barium iodide and Coomassie blue is shown in Figure 2e−h with three different colors: blue (scFv), gray (PEG-scFv), and brown (PEG), providing identification of various molecules to confirm the PEG-scFv conjugation.

The SDS−PAGE gel (Figure 1e) of the PEG reagents stained with barium iodide showed decreased mobility of the PEG molecules of 2, 3.4, 5,10, 20, and 40 kDa with increased molecular size (*25*). Lanes A to E and F (Figures 2a−d), of Coomassie blue staining, demonstrated gradual increase in protein conjugate molecular weight (bands) in accordance with the molecular weight of the PEG (Figure 1) used in the conjugation.

The typical conjugation yield of PEG-scFvs varied between 20 and 80%. In Figure 2a−d, lanes A and C, we have used PEG-$(Mal)_2$ for the conjugation, which showed 15−45% PEG-$(scFv)_2$. Figure 2e−h, lanes A and C, supported this, as the light green/gray color of these bands confirmed bifunctional PEGylation. Figure 2d, lane G, demonstrated substantial PEGylation product of BA1-c and the branched PEG-Mal 40 kDa (98 kDa), while Figure 2a (lane G) of the scFv (CC6) showed less than 10% branched PEG-Mal 40 kDa conjugation product.

Lanes E and F for the 10 and 20 kDa linear PEG with the three scFvs (CC6, AD3, and D5) showed very faint bands for the PEGylation yield. Lane G of the Figure 2e−h did not demonstrate visible green color for PEGylation due to masking by the dark brown color by high concentrations of PEG. Data from these conjugations is presented in Figure 4.

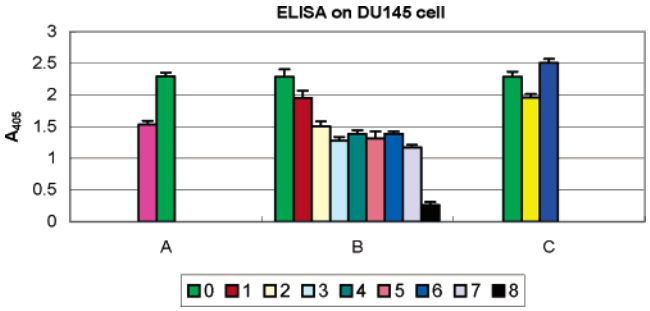

Figure 5. Comparison of MUC-1 binding by ELISA of BA1-c and its PEGylated products on DU145 cell lysate. Two micrograms of protein from each product were used. (A) BA1-c, no TCEP (pink) and BA1-c, with 2-fold molar excess of TCEP (green). (B) PEG-BA1 products (unpurified), code corresponds to conjugation reaction mixture tested i.e., 0 = BA1-c, 1 = 2kDa PEG-$(BA1)_2$, 2 = 3.4 kDa PEG-$(BA1)_2$, 3 = 3.4 kDa PEG-BA1, 4 = 5 kDa PEG-BA1, 5 = 10 kDa PEG-BA1, 6 = 20 kDa PEG-BA1 7 = 40 kDa PEG-BA1, and 8 = negative scFv-PEG control. (C) BA1-c with TCEP (green); 2 kDa PEG-$(BA1)_2$, unpurified (yellow); 2 kDa PEG-$(BA1)_2$, purified (blue). These data demonstrate that binding was generally retained after PEGylation. Further, binding of purified bifunctional 2kDa PEG-$(BA1)_2$ was increased over the original scFv-c with or without the TCEP addition. Since TCEP has demonstrated enhanced ELISA signal at the concentrations used; scFv-c with and without TCEP were controls in these binding studies. Reaction mixture samples had negligible TCEP because of buffer exchange/concentration and therefore no enhanced signal. The control BA1-c (pink), without TCEP, seen in A, represents a more appropriate comparison for PEG-scFv reaction mixture than the BA1-c with TCEP (green). PEGylated monofunctional scFv-c products demonstrated binding very similar to the initial BA1-c, and the binding of the bifunctional 2 kDa PEG-$(BA1)_2$ seen in C (blue) was enhanced. Graphs were derived from mean absorbance values normalized to background (no scFv). Corresponding standard errors (SE) from three experiments with triplicates in each of the three experiments are shown. Mean background values and SE was 0.11 (±0.009) for DU145 cell lysate.

PAGE and Western Blot Analysis. Figure 3a–c show the conjugation reaction mixture and purified product of BA1-c conjugated as PEG-$(scFv)_2$ analyzed by SDS–PAGE and anti E-Tag probing of the Western blot. SDS–PAGE of BA1-c show the two bands frequently seen, corresponding to 17 and 19 kDa, which did not appear with anti E-Tag probing of the Western blot, indicating that these two proteins have no E-Tag (Figure 3c).

Immunoreactivity. ELISA studies of in vitro binding to tumor cell membrane lysate were performed on the various PEGylation products, with varied results, particularly noted in samples with low PEGylation yield. Since the most efficient PEGylation with the various PEG structures was demonstrated with BA1-c (Figures 2 and 4), providing comparable samples for study, all of the BA1-c unpurified PEGylation products and the purified bivalent PEG-$(BA1\text{-}c)_2$ from conjugation with 2 kDa PEG-$(Mal)_2$ were selected for further study. ELISA results of these BA1-c PEGylation products seen on SDS–PAGE in Figure 2d demonstrated good binding with all univalent products and better binding with the bivalent PEG-$(BA1\text{-}c)_2$ (Figure 5). The purified PEG-$(BA1\text{-}c)_2$, in PBS with no TCEP, demonstrated the best results compared to the BA1-c with or without TCEP (Figure 5). Results on MCF-7 were remarkably similar and therefore are not shown.

DISCUSSION

Intact antibodies represent epitope specific, bivalent molecules that are used to specifically target a selected antigen for radiodiagnosis or therapy (*31*). If there is abundant antigen present, simultaneous or serial binding to two adjacent antigen molecules leads to increased "functional affinity" (avidity) and enhanced retention time on the target. Abundant antigen target on the malignant cell membrane is frequently found in cancer because of up-regulation of gene products. Univalent antibody fragments, such as Fab fragments or scFv, exhibit faster blood clearance and better tissue penetration and provide similar epitope-binding specificity and single valance affinity, but substantially lower avidity (*32*). The selection and production of target-specific scFv proteins is well established (*23*, *33*). The characteristics of the molecular format in which they can be used most effectively for tumor targeting depends on the diagnostic or therapeutic purpose so that the required molecular formats and pharmacokinetics vary. Small molecules, with rapid tissue penetration and clearance, provide high target to nontarget (T/NT) imaging agents for PET; larger heterofunctional formats, having longer blood and malignant cell residence, provide pretargeting molecules for multistep radioisotope therapy.

To increase avidity and to generate both homo- and heterofunctional molecules, Fab and scFv have been engineered previously into dimeric, trimeric, or tetrameric conjugates through the use of either chemical or recombinant technology (*33–35*). The work reported here addresses another more generally applicable approach to create multimeric scFv molecules for cancer targeting, by site-specific conjugation to functionalize PEG (*18*).

PEGylation has demonstrated the ability to increase in vivo bioactivity of a number of peptides, including asparaginase, interferon alpha, recombinant interleukin-2, tumor necrosis factor-alpha, cytokine conjugated toxin, and photodynamic agents such as chlorine polymers (*29*, *36–38*). The ability to control blood clearance based upon the selection of molecular size for PEGyated peptides has been demonstrated (*39, 40*). Increasing the "effective" molecular size of PEGylated recombinant interlecukin-2 from 40 kDa to 208 kDa increased the slow phase of plasma clearance, by more than 8-fold (*39*).

The FDA has approved a number of PEGylated proteins for imaging (*41*) and therapy (*38*, *42*). Other PEGylated compounds, to prolong circulation time and reduce immunogenicity, are in clinical trials (*43*). In general, PEGylation of proteins, including radiolabeled proteins, results in increased molecular size, increased blood retention, and decreased renal glomerular filtration (*44*). However, uptake of PEGylated proteins into renal tubular cells and hepatocytes, compared to non-PEGylated proteins, has been variable: increased (*45–47*), decreased (*48*), or unchanged (*49*). Conceptually, tumor to normal tissue concentration ratios can be enhanced for targeted radionuclide therapy with PEGylation of small tumor binding modules, but this has yet to be realized (*23*).

PEGylation also affords the opportunity to form multidentate versions of peptides and scFv through the use of branched or star PEG polymers, with the likelihood of increasing avidity and residence time on target sites (*50*). Studies of the effects of PEGylation on biodistribution of antibody fragments with linear PEG structures have shown that linear PEGylated fragments have prolonged circulation times and increased tumor uptake (*36, 39, 45, 50–53*).

In most cases, PEGylation has been performed by random conjugation with any of the many lysine residues of the protein. In small molecules, such as scFv, an

increased fraction of available lysine is located in or near the binding site (*17*). The resultant PEGylated proteins tend to be heterogeneous, composed of molecules having PEG conjugated at different positions, thus creating variable binding affinities (*17*). To overcome this major problem, an approach wherein the recombinant scFv production vectors encode an unpaired cysteine near the C terminus of any inserted scFv for site-specific PEGylation was devised; scFv-c from the pCANTAB 5E Cys vector was used to study thiol PEGylation in this report (*18*). The advantage of employing sulfhydryl-directed moieties in scFv engineering is that the four disulfide-bonded cysteines of the scFv framework needed for the structural configuration are completely buried by the molecular conformation, thus relatively protected (*19*). Unpaired cysteines are relatively unprotected and not naturally present, thus providing a unique site-specific target for conjugation of any scFv-c made in this manner (*54*).

In the PEGylation of scFv for developing tumor-targeting radiopharmaceuticals, efficient conjugation of thiol-reacting PEG to scFv-c is needed. Although the proof of principle of site-specific PEGylation has been previously published (*18, 23*), the general applicability and efficiencies of conjugation of various scFv-c with a panel of PEG molecules have not been demonstrated. Using four MUC-1 scFvs, having different target epitopes and sequences (*20*), the relative scFv-c thiol conjugation was evaluated with an array of functionalized PEG molecules. Focus was particularly made on linear uni- and bifunctional maleimide PEG molecules of varying molecular weights. In light of these studies, at least 60% (60−90%) of all four scFv could be conjugated with maleimide, demonstrating that the added cysteine provided an available SH for site-specific conjugation, as shown in Figures 2 and 4,

ScFv-PEG molecular size increased consistent with the size of PEG attached, as expected (Figure 2a−d). However, when the molecular weight of PEG-Mal increased above 5 kDa, PEGylation efficiency substantially decreased despite evidence of appropriate Mal reactivity on these larger PEG molecules. Steric hindrance of the Mal group by coiling of the linear PEG polymers may provide an explanation. With the 40 kDa branched polymer, better conjugation yield over the linear 10 and 20 kDa PEG may also be due to less steric hindrance of PEG on Mal interaction with the cysteine, since Mal is at the "v" branching point in this PEG configuration (Figure 1) (*29*).

Bifunctional conjugation was demonstrated with 2 and 3.4 kDa PEG bimaleimide. Using the same 1:5 scFv/PEG ratio with the (2 kDa and 3.4 kDa) PEG-$(Mal)_2$, 20, 30, 15, and 42% of the 4 scFv-c was conjugated as $(scFv)_2$-PEG, with 2−40% scFv-c left unconjugated. The efficiency of scFv-c reacting with Mal-PEG in all formats did seem to relate to the specific scFv-c, although three of four scFv-c demonstrated more complete conjugation with smaller and linear PEG-Mal molecules. Little or no divalent PEG-$(scFv)_2$, however, with the NHS-PEG-Mal was expected since NHS should not be conjugating at the pH used. This was the case with three of four scFvs. However, BA1-c did conjugate 40% of the BA1-c as scFv-PEG-scFv with NHS-PEG-Mal. This mixed bifunctional PEG formed a resultant PEG-$(BA1)_2$ that did bind tumor membranes well on ELISA (Figure 5). An available reactive group near the C-terminus of this scFv-c may be responsible.

The PEG-$(scFv)_2$ demonstrated improved binding to the cell membrane antigen when compared to the monomeric scFv-c. The improved binding of S−S linked homodimers (di-scFv) and PEG-$(scFv)_2$ over the univalent scFv-c or scFv would also be expected because of the increase in avidity with bivalent binding (*18, 55−57*). However, selected PEG-linked scFv bioconjugates are expected to be superior in vivo tumor targeting agents compared to di-scFv or diabody forms since (i) PEGylated proteins have shown enhanced stability in the circulation in vivo; (ii) increased molecular size should result in decreased rapid kidney clearance, as the threshold for first pass elimination is approximately 65 kDa (*58*); (iii) the addition of PEG is likely to decrease proteolysis at the tumor site (*42*).

In summary, 30-40% of the scFv-c protein from E-TAG-purified recombinant products was converted to malignant cell membrane binding PEG-$(scFv)_2$ in three of the four scFv-c studied. In these three studied, 50−90% could be conjugated as univalent PEG-scFv, with comparable malignant cell binding before and after PEGylation. These results provide further evidence that novel constructs for imaging and therapy can be developed from scFv-c modules through site-specific PEGylation.

ACKNOWLEDGMENT

U.S. Department of Energy Grant DE-FG01-00NE22944, National Cancer Institute Grant PO1 CA47829, and Department of Defense Grant DAMD17-01-0177 supported this work. We thank Trevor Peterson for excellent technical assistance to producing scFv for this work under a Society of Nuclear Medicine Extension and Research fellowship.

Received July 28, 2004; Revised Manuscript Received October 31, 2004

A novel intracellular pH-sensitive polymeric micelle drug carrier that controls the systemic, local, and subcellular distributions of pharmacologically active drugs has been developed in this study. The micelles were prepared from self-assembling amphiphilic block copolymers, poly(ethylene glycol)-poly(aspartate hydrazone adriamycin), in which the anticancer drug, adriamycin, was conjugated to the hydrophobic segments through acid-sensitive hydrazone linkers. By this polymer design, the micelles can stably preserve drugs under physiological conditions (pH 7.4) and selectively release them by sensing the intracellular pH decrease in endosomes and lysosomes (pH 5−6). In vitro and in vivo studies show that the micelles have the characteristic properties, such as an intracellular pH-triggered drug release capability, tumor-infiltrating permeability, and effective antitumor activity with extremely low toxicity. The acquired experimental data clearly elucidate that the optimization of both the functional and structural features of polymeric micelles provides a promising formulation not only for the development of intracellular environment-sensitive supramolecular devices for cancer therapeutic applications but also for the future treatment of intractable cancers with limited vasculature.

INTRODUCTION

The selective augmentation of drug concentrations in avascular tumor tissues is the most challenging issue of current cancer chemotherapy using macromolecular bioconjugates (*1*−*3*). Most anticancer drugs are pharmacologically effective but limited in their clinical applications due to serious toxicity and low water solubility; thereby, the altered biodistribution of these drugs has an important meaning not only to reduce the toxicity but also to improve therapeutic effects (*4*−*6*). For these reasons, interest has centered on the creation of drug carriers that safely and precisely deliver the appropriate amounts of active drugs to solid tumors (*7*−*10*). Indeed, several macromolecular drug carriers are under clinical trials or used practically, which include water-soluble polymer−drug conjugates (*11*), liposomal carriers (*12*), and polymeric micelles (*13*). However, even though these carriers have made significant advancements in cancer therapy, recent studies point out their antitumor activities are subject to change according to the cancer species with pathological, pharmacological, and biochemical differences (*14*).

There are three major reasons why the present macromolecular drug carriers have difficulties in clinical use. First, the carriers injected into the body encounter in vivo barriers such as nonspecific systemic accumulation and phagocytotic clearance by the host defense system (*15*). Second, even after the carriers accumulated in solid tumors avoiding these in vivo barriers, they still have to overcome the heterogeneous tumor microenvironments that are characterized by insufficient blood supply, disordered vasculatures, and diffusion-limited interstitum (*16*). Third, the carriers that successfully accessed the inside of tumor tissues should release the loaded drugs back into active forms in order to exert the antitumor effect (*17*). Among these reasons, poor permeability of the carriers inside the tumor tissues and low concentrations of active drugs throughout solid tumors become particularly serious problems (*18, 19*). For these reasons, understanding the correlation between the physicochemical properties of drug carriers and their behaviors in the body is very important, and the combination of these two features is required for the design of ultimate carriers (*20*).

In this article, we will report that such tantalizing problems may be overcome by a novel tumor-infiltrating drug carrier, the pH-sensitive polymeric micelle, whose structural and functional features were optimized for the intracellular drug delivery (Figure 1A). The micelle is a nanosized supramolecular assembly from the self-assembling amphiphilic block copolymers, poly(ethylene glycol)-poly(aspartate hydrazone adriamycin) [PEG-p(Asp-Hyd-ADR)]. The anticancer drug, adriamycin (ADR), is

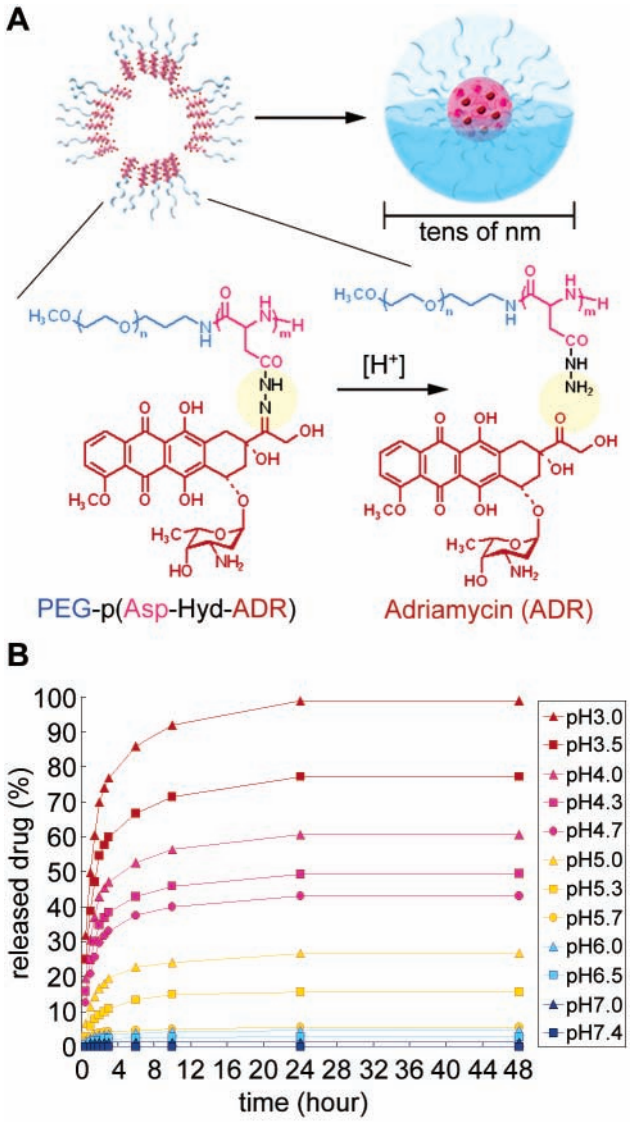

Figure 1. Preparation of tumor-infiltrating polymeric micelles with intracellular pH-sensitivity. (A) Micelles with tens of nm size diameter were prepared from self-assembling amphiphilic block copolymers, PEG-p(Asp-Hyd-ADR), in which the anticancer drug, adriamycin (ADR), was conjugated through acid-sensitive hydrazone linkers. (B) The micelles released the loaded drugs under acidic conditions below pH 6.0 corresponding to intracellular space, but remained stable under the conditions of vascular and extracellular space (pH 7.4−7.0).

conjugated to the core-forming segments through the hydrazone linkers that are stable under physiological conditions (pH 7.4) but cleavable under acidic intracellular environments in endosomes and lysosomes (pH 5−6). This carrier design allows the micelle to safely protect hydrophobic drugs from the host defense system in the body and to selectively exert cytotoxicity due to intracellular pH-triggered drug release, improving both the delivery effect and therapeutic efficacy of the drugs (*21*). Therefore, the characteristic in vitro and in vivo behaviors of the micelles would offer intriguing information taking into account the future design and development of bioresponsive supramolecular carrier systems for the intracellular trafficking of biologically active molecules.

EXPERIMENTAL PROCEDURES

Materials. β-Benzyl-L-aspartate was from Sigma and α-methoxy-ω-amino poly(ethylene glycol) (PEG; MW = 12 000) was from Nippon Oil & Fats, Japan. PEG was purified using an ion-exchange gel column (CM-Sephadex C-50, Amersham Pharmacia Biotech) prior to the synthesis of the block copolymers. Adriamycin hydrochloride-(ADR−HCl) was from Nippon Kayaku, Japan, and its purity was checked by reversed phase liquid chromatograpy (RPLC). Sephadex LH-20 gel was from Amersham Pharmacia Biotech, Sweden.

Cell Lines and Animals. A human small cell lung cancer cell line SBC-3 and murine colon adenocarcinoma 26 (C26) cells were from the National Cancer Center Research Institute, Japan, and cultured in a medium (DMEM, Sigma, St. Louis, MO) containing 10% fetal bovine serum in a humidified atmosphere with 5% CO_2 at 37 °C. CDF-1 mice (female, 6 weeks old) were from Charles River, Japan. The animals were cared for and all experiments were performed in compliance with the Guide for the Care and Use of Laboratory Animals as adopted and promulgated by the National Institutes of Health.

Preparation of the pH-Sensitive Polymeric Micelles. The self-assembling amphiphilic block copolymer, PEG-p(Asp-Hyd-ADR), was synthesized as reported elsewhere (*22*). Briefly, poly(ethylene glycol)-poly(β-benzyl-L-aspartate) (PEG-PBLA) was synthesized from the ring-opening polymerization of β-benzyl-L-aspartate *N*-carboxy-anhydride using PEG as a macro initiator, followed by substitution of the benzyl groups of PEG-PBLA with hydrazide groups for drug binding (see also Supporting Information). Unbound ADR was completely removed using Sephadex LH-20 gel, and the obtained polymers were redissolved in dimethylacetamide to prepare the micelle by a dialysis method.

Evaluation of Acid-Sensitive Drug Release from the Micelles. Reversed phase liquid chromatograpy (RPLC) analysis, using a μ-Bondasphere 5 μm C4-300A column (Nihon Waters, Japan), was used to assess the pH sensitivity of the micelle. The micelle with a 10 mg/mL concentration was incubated under various buffered conditions from pH 7.4 to 3.0 [20 mM phosphate buffer (pH 7.4−6.0), 20 mM acetate buffer (pH 5.8−3.0)], and time- and pH-dependently released drugs were measured from the peak intensity by a UV detector (485 nm).

Observations on Intracellular Drug Release and Localization of the Micelles. Multicellular tumor spheroid (MCTS) was prepared from a C26 cell line using a spheroid culture plate, Sumiloncelltight (Sumitomo Bakelite, Japan); 200 μm size MCTS were sorted and used for the experiments. Fluorescence images were observed using a confocal laser scanning microscope (LSM 510, Carl Zeiss, Germany) with a 20× objective (Plan-Apochromat, Carl Zeiss, Germany) and a 63× objective (C-Apochromat, Carl Zeiss, Germany) at excitation wavelengths of 488 nm (Ar laser) and 364 nm (UV laser) for ADR and Hoechst 33258, respectively. The concentrations of the micelles in the medium were adjusted to 10 μg/mL (ADR equivalent). All images were acquired and processed with the accompanying software.

In Vitro Growth Inhibition Assay. A tetrazolium dye method, called the MTT assay, was used to evaluate the growth-inhibitory effect of the micelle. Using 96-well culture plates, exponentially growing SBC-3 cells were seeded (2000 cell/well) and preincubated for 24 h, followed by coincubation with ADR and the micelle samples. After exposure for 3, 10, and 24 h, the medium was discarded and each cell was reincubated in fresh medium for another 24 h. The cells were then counted using a Bio-RAD Microplate Reader 550 (Bio-Rad Laboratories Inc.).

In Vivo Antitumor Activity and Body Weight Change of Mice. The antitumor activity of the micelles was evaluated with tumor bearing, 7-week-old, female SPF CDF1 mice (n = 6, Charles River, Japan). After implanting C26 cells 10 days earlier, injection of the samples took place using a volume of 0.1 mL/10 g body weight. The regimens of the micelles were scheduled by changing the administration dose (20, 40, and 60 mg/kg) three times with a 4-day interval, based on the optimized regimens of ADR as a control. However, in the case of ADR, only limited doses (5, 10, and 15 mg/kg) were applied to the mice due to the drugs toxicity. The mice were monitored daily, and tumor growth and body weights were measured at 2-day intervals. Tumor volume is calculated as follows: volume = $1/2 \times LW^2$ (L is the long diameter and W is the short diameter of a tumor).

Biodistribution and Pharmacokinetics. The CDF1 mice (n = 6), when the tumor volume reached ca. 100 mm^3, were injected with ADR and the micelles in a volume of 0.1 mL/10 g body weight for the experiments. The dose was either 10 mg/kg for ADR or the micelles (ADR equivalent). After the injection, blood, tumor, and major organs (heart, kidney, liver and spleen) were collected at 0.5, 1, 3, 6, 9, 24, and 48 h, followed by HPLC anaylsis (see Supporting Information for the detailed protocol).

Fluorescence Microscopic Observations of Solid Tumors and Their Peripheral Blood Vessels. The tumor-bearing mice were sacrificed at 24 h after the injection of the micelles with a 10 mg/kg dose. The intact tumor tissues with their peripheral blood vessels were harvested for macroscopic observations using a fluorescence microscope (Axiovert 200, Carl Zeiss, Germany) equipped with a 2.5× objective (Plan-Neofluar, Carl Zeiss, Germany) and a filter set15 (BP546/12, FT580, LP590, mercury lamp excitation, Carl Zeiss, Germany).

RESULTS

Preparation of the Intracellular pH-Sensitive Polymeric Micelles. The polymer backbone of PEG-p(Asp-Hyd-ADR) consisted of poly(ethylene glycol) (PEG) with a molecular weight of 12 000 g/mol for the hydrophilic shell-forming segment and 37 repeating units of polyaspartate (PAsp) for the core-forming segment (MW = 28 679), which were determined by gel permeation chromatography and ^{1}H NMR measurements. The 28 side chains in the PAsp block were replaced by hydrazide groups for the binding of the drugs. Adriamycin (ADR) was then conjugated to the polymer backbone through hydrazone bonds between the carbonyls at the C13 of ADR and the hydrazide groups of the PEG-p(Asp-Hyd) block copolymer. Even though the biological and chemical background of binding ADR to polymer backbone through hydrazone linkages has been delineated in our previous work (*22*) as well as many studies (*23*−*26*), it must be noticed that the hydrazone linkage is the most popularly used as pH-sensitive linkers due to the fact that this bond is quite stable at pH 7.4 but hydrolyzes under mild acidic conditions with pH 5−6. Therefore, to ensure that drug release from the micelles occurs only when acid-labile hydrazone linkers are cleaved, any unbound free ADR were completely removed in this study. These were confirmed by a reversed phase liquid chromatograpy (RPLC) analysis that is generally used for separating and purifying materials due to the differences in their hydrophobic properties (further details are described below). RPLC analysis showed the drug loading content of PEG-p(Asp-Hyd-ADR) was 42.5 wt % with respect to a single block copolymer chain. The obtained PEG-p(Asp-Hyd-ADR) block copolymers self-assembled into micelles in aqueous solutions; the prepared micelles had a 65 nm diameter, which was confirmed by dynamic light scattering measurements.

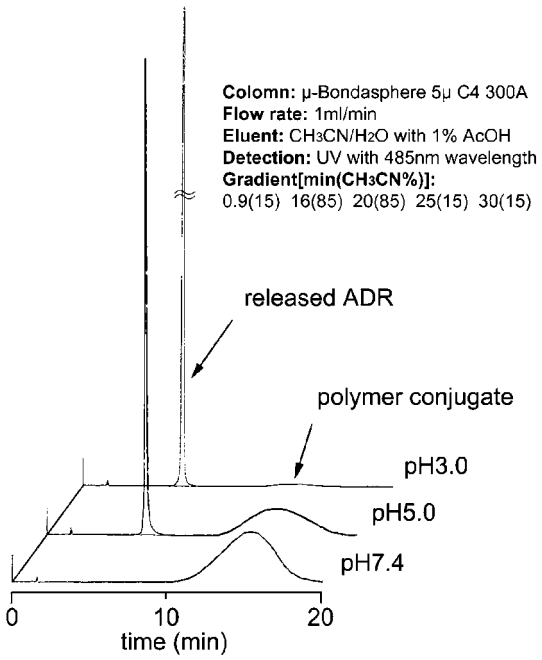

Figure 2. Acid-sensitive cleavage of drug-binding hydrazone bonds evaluated by reversed phase liquid chromatography (RPLC) analysis. RPLC separates free drugs and polymer conjugates due to the differences in their hydrophobic properties, demonstrating absence of free drugs at pH 7.4 possibly binding to polymer conjugates in a physical way. On the other hand, it clearly shows that the amount of released drugs increases under acidic conditions in which the drug-binding hydrazone linkers can be cleaved.

The Micelles Selectively Release the Loaded Drugs by Sensing a pH Decrease. To confirm the acid-sensitive drug release profile, the micelles were incubated under various pH conditions from 7.4 to 3.0, and the released drugs were measured using RPLC analysis. Figure 1B shows that the micelles released the loaded drugs time- and pH-dependently as the external pH decreased, while they were stable under physiological conditions at pH 7.4 for over 48 h. The results indicate the micelles should release the loaded drugs in the intracellular acidic regions (pH 5−6) such as endosomes and lysosomes in which the drug-binding hydrazone linkers can be cleaved most effectively. Chemical evidence for absence of free drugs and acid-sensitive cleavage of hydrazone linkers to induce drug release was also presented by RPLC analysis (Figure 2). As described above, ADR is conjugated to amphiphilic block copolymers through pH-sensitive hydrazone linkers. If the drugs were simply entrapped in the micelles by physical interaction instead binding to polymers via chemical linkers, a sharp peak corresponding to the free drug should be separated from drug−polymer conjugates by RPLC and appeared in the physiological condition (pH 7.4) where the acid-labile hydrazone bond remains stable. However, the peak from the free drug was not shown at pH 7.4 but gradually increased in acidic conditions while the broad peak from polymer conjugates decreased. Eventually, almost 100% of the drugs were released at pH 3.0, and on the basis of this, we calculated the drug loading content of polymer conjugate described above. These results demonstrate that acid-sensitive cleavage

Table 1. Growth Inhibitory Effects of the Micelles against Cancer Cells[a]

sample	exposure time (hour)	IC_{50}[b] (μg/mL±SD)	relative index[c]
ADR	3	0.041 ± 0.035	1.05
	10	0.048 ± 0.026	1.23
	24	0.039 ± 0.025	1
micelle	3	1.08 ± 0.12	27.69
	10	0.45 ± 0.061	11.54
	24	0.27 ± 0.038	6.92

[a] Eight independent experiments were carried out using a human small cell lung cancer cell line SBC-3 ($n = 8$). [b] IC_{50} denotes the inhibitory concentration of the drugs required for 50% reduction in cell population. Concentrations of the micelles are calculated with free ADR equivalents. [c] Relative index denotes the ratio between a control and the object for comparison. Here, we evaluated the growth inhibitory effect of the micelles by converting their concentrations with respect to ADR after a 24 h incubation as the control.

of hydrazone linkers between drugs and polymer chains obviously induced drug release.

Regenerated Drugs Were Pharmaceutically Active Inhibiting Cell Growth in Vitro. To verify whether the released drugs are pharmacologically active, an in vitro growth-inhibition test was carried out. The test revealed that the cytotoxic activity of the micelles was as high as 1/7-fold with respect to that of the free drugs after a 24 h exposure time (Table 1). Interestingly, the micelles showed delayed cytotoxicity that was drastically changed depending on the incubation time, which reflects that the drug release from the micelles took place and correlated with the cell metabolism.

The Micelle Infiltrates into the Avascular Tumor Model Multicellular Tumor Spheroids. Recently, it has been reported that the fluorescence quenching effect of the micelles provides a useful tool to observe the intracellular behaviors of the micelles (*22*). The fluorescence intensity of ADR, playing a role not only as an anticancer drug, but also as a fluorescence probe in this study, is quenched due to the locally increased high concentration in the micelle core; however, the fluorescence becomes detectable again as the micelles start to release ADR under acidic conditions. Consequently, the micelles emit intense fluorescence signals with the release of the entrapped ADR; a series of processes such as intracellular trafficking, drug release, and localization were able to be directly monitored in live cells accompanying the structural change. In the meantime, the multicellular tumor spheroid (MCTS) was used as an in vitro tumor model for the experiments because it is the most similar to avascular tumor regions of practical solid tumors in vivo that are characterized by limited accessibility of cell subpopulations (Figure 3). For example, MCTS reproduces adverse microenvironmental conditions of solid tumors in vivo such as hypoxia and nutritional depletion, and the extracellular matrix between tumor cells instead of intratumoral normal cell populations (*27*−*28*).

For these reasons, the intracellular behaviors of the micelles were observed within solid tumors using fluorescence quenching effect and the MCTS. The micelles were coincubated with the MCTS, and the change in the fluorescence intensity was monitored using a confocal laser scanning microscope (CLSM). The three-dimensional CLSM images demonstrated the time-dependent change in the fluorescence intensity of the micelle systems and their distributions throughout the MCTS with a 200 μm diameter depending on the incubation time (Figure 4A). The 200 μm diameter of MCTS was

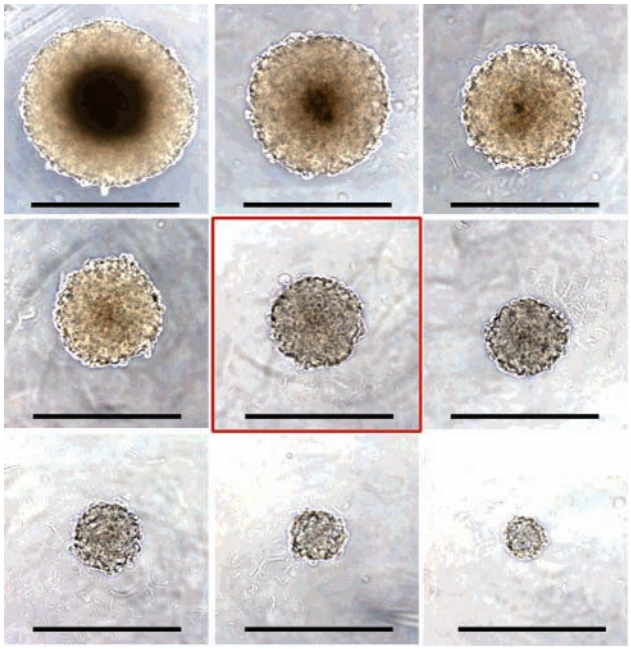

Figure 3. Preparation of multicellular tumor spheroid (MCTS). MCTS with diameter ranging from 100 to 500 μm was prepared from a C26 cell line. Among them, MCTS with a 200 μm diameter (red-edged) was used as an in vitro tumor model because it has the most suitable size for reproducing in vivo avascular tumor regions that are characterized by limited accessibility of cell subpopulations (bar = 500 μm).

determined as the most suitable size for the experiments, considering the fact that the maximum distance between the capillary blood vessels within avascular solid tumor is 200 μm or less (*29*). The fluorescence of the micelle system remained quenched at 1 h after incubation, but it was detected at 3 and 24 h. It is notable that most cell nuclei remained blue at 3 h. The images, therefore, suggest that the micelles began to intracellularly release the drugs but the released drugs were still localized in the cytoplasm. However, the intense fluorescence of ADR was eventually detected in most of the cell nuclei after 24 h. These results reflect that the micelles would access every cell in the avascular region of tumor tissues in vivo to release the drugs.

The Micelles Enter the Cell Interior and Release the Drugs. To get a better understanding of the intracellular distributions of the micelles and their released drugs, further observations of the MCTS coincubated with the micelles under high magnification were carried out using a 63× objective (Figure 4B). These images show clear evidence of the intracellular drug release from the micelles and accumulation of the released drugs in the cell nuclei. The localization of the ADR fluorescence in the cytoplasm after 3 h incubation is supporting our speculation that the micelles internalized the cells releasing the drugs. After additional incubation up to 24 h, the presence of the drugs both in the cytoplasm and cell nuclei was confirmed. When the same experiments were carried out with free ADR, all the cell nuclei in the MCTS became red within 1 h because the ADR with a low molecular weight rapidly penetrated into each cell, and we were not able to observe this unique time-dependent fluorescence change in intensity and its distribution. Therefore, it is obvious that the micelles are precisely functioning in the intracellular regions as we designed, and the possible drug release from the micelles in the extracellular regions is negligible.

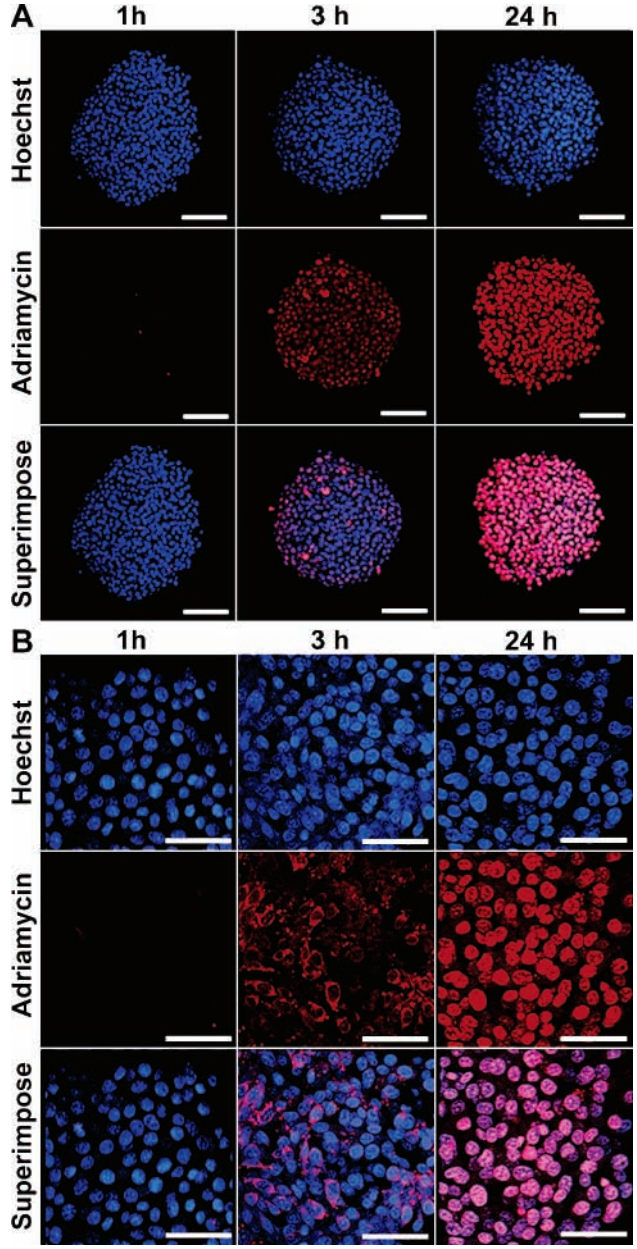

Figure 4. Observation of tumor permeability and intracellular drug release behaviors of the micelles. (A) CLSM observations showed the time-dependent change in the fluorescence intensities of ADR in the micelle system in MCTS. The images showed that the micelles can access the inside of the MCTS and release the loaded drugs (bar = 100 μm). (B) The intracellular drug release and localization of the micelles in each cell of MCTS were observed in detail using a high-magnification 63× objective. The images clearly demonstrated that the micelles internalized into the cells and released drugs, and that the released drugs eventually accumulated in the cell nuclei (bar = 50 μm).

The Micelles Suppress Tumor Growth in Mice with Enhanced Therapeutic Efficacy and Lowered Toxicity. The animal tests revealed that the micelles exerted an effective antitumor activity over a broad range of injection doses to suppress tumor growth in mice, showing some of the clear comparisons with ADR (Figure 5). In the case of ADR, tumor growth was suppressed with a 10 mg/kg dose, but the mice treated with a 15 mg/kg dose were dead due to the drug's toxicity. This corresponds well to the fact that the lethal dose of ADR killing 50% of the test animals within a designated period, called LD_{50}, is generally 12.7−13.2 mg/kg. On the contrary, the micelles were safely injectable up to a 40 mg/kg dose, while three of six mice were completely cured and there was no death among the treated mice. Notably, the body weights of the mice that slightly decreased during the micelle administration recovered, or even increased, on day 30 with respect to the controls (Table 2). Such behavior was not observed in the case of ADR, and the mice were emaciated with a 10 mg/kg dose that was the optimum dose for ADR to suppress tumor growth. Namely, the therapeutic efficacy of the micelles was significantly improved over that of ADR within this animal experiment setting, which distinguishes the micelles from ADR that has a narrow therapeutic window between 10 and 15 mg/kg. In the meantime, the tumor-suppressing antitumor activity of the micelles is shown from a 20 mg/kg dose. The micelles also extended the duration of tumor growth reaching a 5-fold initial tumor volume up to 22 and 28 days for the 20 and 40 mg/kg doses, respectively. These results indicate that the micelles achieved both enhanced therapeutic efficacy and a reduced toxicity of the loaded drugs, which are of great advantage to create effective and safe drug carrier systems.

Table 2. In Vivo Antitumor Activity of the Micelles against C26 Tumor-Bearing Mice

[a] Administrations were carried out three times with a 4-day interval, and doses were determined in free ADR equivalents. [b] Body weights were measured on day 30 after the first injection to compare the long-term toxicity between ADR and the micelles. Values are expressed as mean ± SEM. [c] Duration time to reach 5-fold initial tumor volume.

The Micelles Circulate for a Long Time in the Blood and Selectively Accumulate in Solid Tumors. Effective antitumor activity and low toxicity imply that the micelles are stable in the blood without drug release (or leakage); therefore, their systemic and local distribution may dominate the tumor-suppressing antitumor activity. To demonstrate this, we investigated the in vivo dispositions of the micelles in detail using a biodistribution study. The levels of the micelles in the blood, tumor, and major organs, such as the heart, kidney, liver, and spleen, are expressed as percentage of each dose at specific times after the intravenous injection (Figure 6A). As summarized in Table 3, the micelles circulated in the blood for a prolonged time, and the area under the concentration curve (AUC) of the blood was 15-fold greater than that of ADR. In particular, it is noteworthy that the AUC values of the micelles in the heart and kidney decreased as compared to ADR, indicating that their tumor selectivity (AUC_{tumor}/AUC_{organ}) increased 6- and 5-fold higher with respect to the heart and the kidney, respectively. Such tumor-selective accumulation of the micelles may reduce the side effects of ADR such as cardiotoxicity and nephrotoxicity. In the meantime, the micelles showed a relatively low uptake in the liver and spleen despite the long residence time in the blood in comparison with tumors. These results suggest that the micelles may rapidly evacuate from these reticular

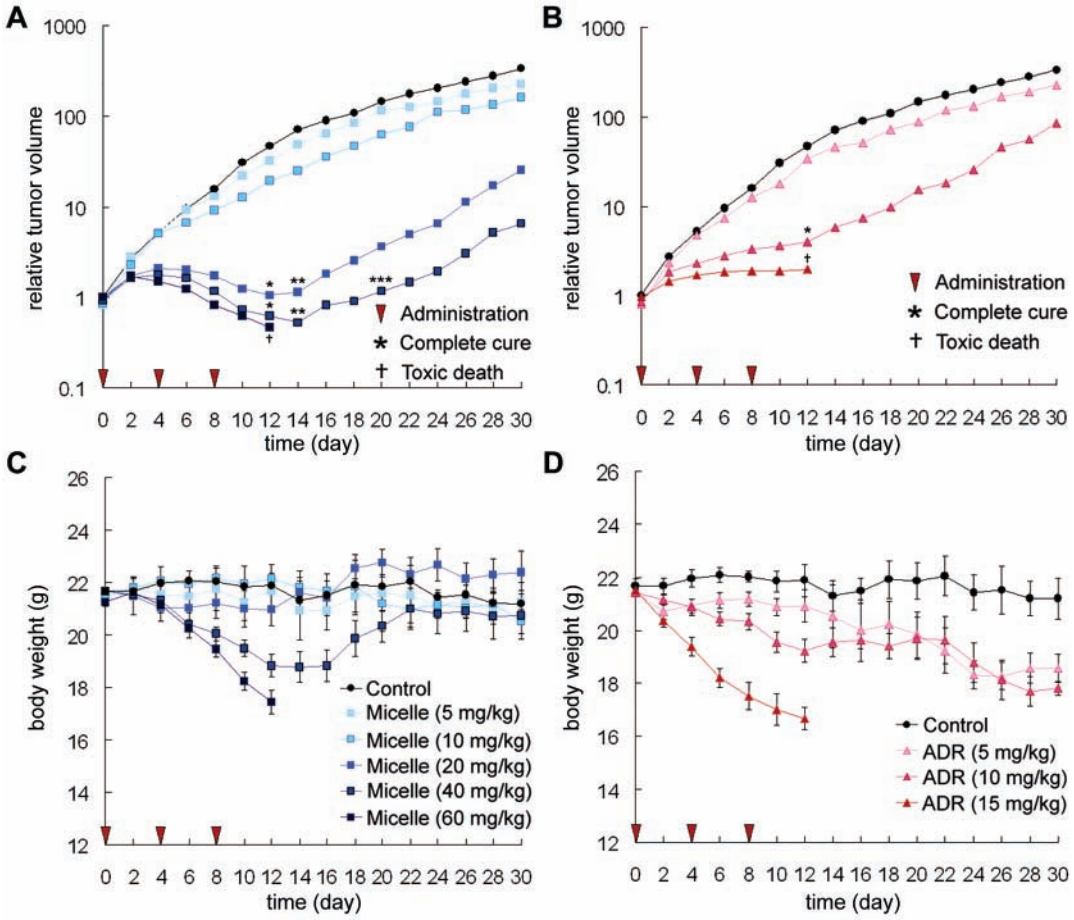

Figure 5. Tumor size and body weight changes of the treated mice. The figures show effective tumor-suppressing activity and low change in body weights over a broad range of injection doses of the micelles (A and C). To the contrary, ADR showed a narrow therapeutic window between 10 and 15 mg/kg does avoiding toxic death (B and D). Administrations were carried out three times with a 4-day interval into tumor bearing CDF1 mice (female, 6-week-old, $n = 6$). The micelle doses are shown as ADR equivalents. Values are expressed as mean and mean ± SEM for the tumor volume and body weight, respectively.

connective tissues without interacting with monocytes and macrophages that are responsible for engulfing and removing cellular debris, old cells, and unwelcome external invaders from the bloodstream. On the contrary, tumor tissues are characterized by a large vascular permeability and high interstitial diffusivity while a lack of lymphatic drainage is observed. This phenomenon is explained by the enhanced permeability and retention (EPR) effect, which significantly affects distributions of the macromolecules facilitating their access and accumulation in tumors (*30, 31*). Consequently, the micelles that accumulated in the solid tumors through the EPR effect can stay for a prolonged time. The biodistribution study, therefore, showed that the cytotoxicity of the micelles seems to depend on their retention time as well as in the accumulated amounts in each organ, which may be crucial in attaining both an effective antitumor activity and reduced toxicity in a single drug carrier system.

In vivo antitumor activity test showed that the micelles effectively suppressed tumor growth in mice over a broad range of injection doses while toxicity remained extremely low. On the other hand, the biodistribution study revealed that the micelles circulated in the blood for a long period of time and accumulated in normal organs as well as the tumors. These results are very interesting because the micelles showed organ-dependent differences in cytotoxicity. To elucidate this, we investigated the localization of the micelles in each organ by calculating the tissue-to-blood concentration ratio K_b (Table 4). The K_b value is defined as $[K_b = C_{tissue}/C_{blood}]$ where C_{tissue} and C_{blood} denote the tissue concentration and the blood concentration of the micelles, respectively. Each K_b value indicates distribution of the micelles in vascular space ($K_b < 0.1$), extracellular space ($0.1 < K_b < 0.5$), and intracellular space ($0.5 < K_b$) (*32, 33*). The data revealed that the micelles localized in the cell interior of tumor tissues but mainly distributed in the extracellular space of other organs after accumulation. It is in good accordance with our previous results published elsewhere (*34, 35*). We speculate that such drastic alterations might be due to the pathological differences in vasculatures and lymphatic drainages between organs. Consequently, even though the micelles accumulate in normal organs, they can be excreted from the body before releasing drugs. The organ-dependent cytotoxicity of the micelles, therefore, probably would depend on their retention time as well as the accumulated amounts in each organ.

The Micelles Regulate the Local Drug Distribution within Solid Tumors. In view of their tumor-specific accumulation and intracellular distribution, the micelles should release the drugs in solid tumors along with emitting fluorescence as we observed in the intracellular drug release experiment using MCTS. In contrast, if the micelles released the drugs slowly or not at all, the fluorescence of ADR would remain quenched. On the basis of this hypothesis, we observed the solid tumors and their peripheral blood vessels in mice after intravenous injection of the micelles using a fluorescence microscope (Figure 6B). The observations were carried out at 24 h after injection because the micelles needed to

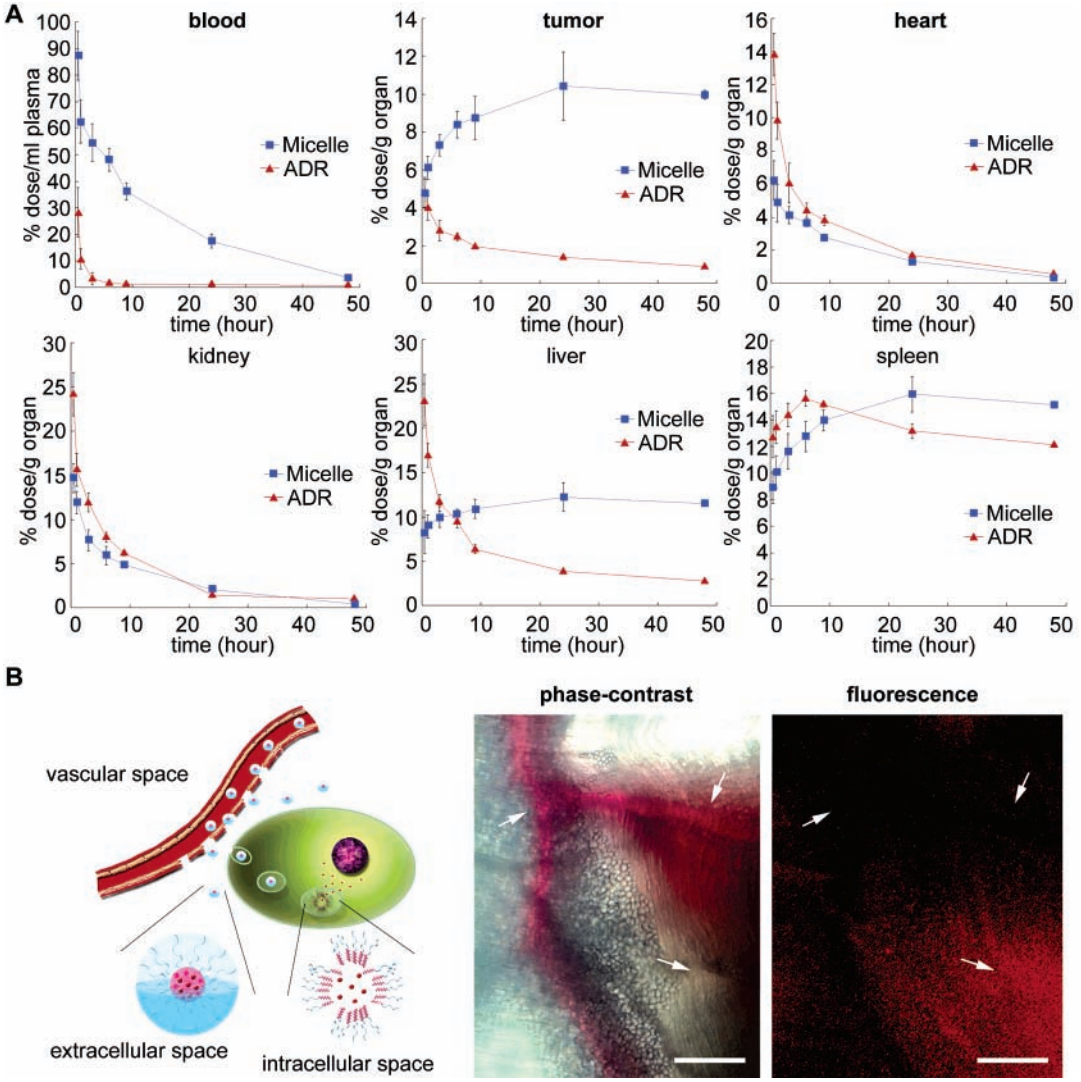

Figure 6. Tumor-specific accumulation of the micelles and locally increased drug concentrations. (A) Biodistribution study revealed the prolonged circulation in the blood and tumor-specific accumulation of the micelles. (B) Fluorescence microscopic observations of the solid tumor and its peripheral regions at 24 h after micelle injection demonstrate that the drug concentrations in the tumor tissues selectively increased due to the tumor-specific accumulation and controlled drug release from the micelles (bar = 500 μm).

Table 3. Tumor-Specific Accumulation of the Micelles

	AUC[a]		AUC ratio	tumor selectivity[b] (AUC_{tumor}/AUC_{organ})		tumor selectivity ratio $[(AUC_{tumor}/AUC_{organ})_{micelle}/(AUC_{tumor}/AUC_{organ})_{ADR}]$
	ADR	micelle	($AUC_{micelle}/AUC_{ADR}$)	ADR	micelle	
blood	58.86	858.54	14.59	–	–	–
tumor	49.59	210.21	4.24	–	–	–
heart	94.70	65.24	0.69	0.52	3.22	6.19
kidney	151.56	117.80	0.78	0.33	1.78	5.39
liver	176.15	261.17	1.48	0.28	0.80	2.86
spleen	341.38	329.66	0.97	0.15	0.64	4.27

[a] AUC denotes the area under a concentration curve that is obtained from the biodistribution study. Values are calculated based on the trapezoidal rule up to 24 h after intravenous injection. [b] Tumor selectivity of ADR and the micelles was determined by calculating the relative accumulated concentrations between the tumor tissues and each organ (AUC_{tumor}/AUC_{organ}). Their ratios indicate the change in the tumor selectivity of the micelles with respect to ADR.

accumulate in the tumor tissues enter the cells and release the drugs intracellularly as long as they were present in the blood. A phase-contrast image showed that the tumor blood vessels containing the micelles begin to leak into the extravascular compartment of the solid tumors (note the red color of the micelles). However, no fluorescence was detected at the corresponding part but in the limited regions of the solid tumor. Therefore, even though colloidal drug carriers are generally considered to localize in the limited peripheral regions of the solid tumors due to poor accessibility, we have confirmed that the micelles can infiltrate into tumor tissues after accumulation, thus increasing the local drug concentration. This conclusion is in good accordance with the results from the permeability testing of the micelles into MCTS.

DISCUSSION

This paper has revealed a new potency of the polymeric micelle drug carrier systems that they can directly deliver drugs to the interior of targeted cells in vivo by infiltrat-

Table 4. Tissue-to-blood Concentration Ratio (K_b) in Each Organ[a]

	organ

[a] K_b value is defined as [$K_b = C_{tissue}/C_{blood}$] where C_{tissue} and C_{blood} were the tissue concentration and the blood concentration of the micelles, respectively. Each K_b value indicates the distribution of the drugs in vascular space ($K_b < 0.1$), extracellular space ($0.1 < K_b < 0.5$), and intracellular space ($0.5 < K_b$).

ing into solid tumors. These findings provided a clear answer to the questions whether the nanosized supramolecular drug carriers can access the cells in the avascular region of the solid tumors without structural and functional breakdown, which is also crucial to other intracellular environment-sensitive macromolecular bioconjugates that are injected through the vein for tumor targeting.

For the past several decades, natural and artificial macromolecules have evolved into a very useful class of drug delivery media (*36*−*39*). However, their in vivo applications are not always successful because limited accessibility inside solid tumors causes stagnation of drug carriers at the periphery of the tumor vasculatures, inducing low concentrations of active drugs in the targeted tumor tissues (*40*). Such a poor delivery efficiency of active drugs to the solid tumors is considered a serious problem facing recent cancer therapy using drug carriers. In this regard, we considered that the intrinsic characteristics of drug carriers may play a critical role in determining their in vivo behaviors, such as tumor permeability, drug release property, and antitumor activity. To confirm this, a suitable carrier model is required that controls the release of drugs while its structural features are optimized for a tumor-targeting drug delivery, and we prepared a new type of drug carrier in this study by adding an intracellular pH-triggered drug release property to the polymeric micelle drug carrier system whose chemical and biological properties are clearly identified (*41*).

As shown in the experimental results, the prepared micelle behaves not only as a biocompatible nanosized drug carrier with a high drug-loading content but also as a bioresponsive device with intracellular pH-sensitivity to control the drug release. These characteristic behaviors suggest that the nanosized core−shell structure of the micelles seems important to take the best advantage of the PEG shielding, imparting both stability and fragility into a single carrier system. The micelles safely protect the loaded drugs and functional linkers by providing a nanocompartment in the core that is completely segregated from the external environments; they maintain a high water-solubility with the hydrophilic shell that prevents the adsorption of proteins and the adhesion of cells so as to circumvent the uptake by reticuloendothelial systems during blood circulation (*42, 43*). In the meantime, intracellular trafficking of the micelles in the solid tumors is evident, which indicates that PEG shielding of the micelle may behave as a kinetic barrier that regulates the condition of the molecular affinity interaction between the micelles and cell membrane according to the exposure or retention time. As explained by the EPR effect, solid tumors feature a large vascular permeability, high interstitial diffusivity, and poor lymphatic drainage; this is a fact that results in tumor-specific retention over a long period of time required for interacting with tumor cells. The retention time in each organ influences the intracellular trafficking of the micelles; thereby, any undesirable cytotoxicity to the normal organs is avoided. Consequently, the intracellular pH-triggered drug release property of the micelles should be the major reason for in vivo antitumor activity with low toxicity.

In conclusion, the intracellular pH-sensitive polymeric micelles exemplify the supramolecular drug carriers that control the systemic, local, and subcellular distribution of the active drugs. They show a higher bioavailability than free drugs, and therefore, the intracellular delivery of drugs would be the most effective and promising formulation for cancer chemotherapy with enhanced therapeutic efficacy and low toxicity. Moreover, the study reveals that the biocompatible structure and environment-sensitive functionality should be considered as a single event in order to realize the carrier systems that are related to these intracellular environments and material transports for the future treatment of cancers with avascular tumor tissue.

Role of Biotin-Binding Affinity in Streptavidin-Based Pretargeted Radioimmunotherapy of Lymphoma⊗

Kevin J. Hamblett,[†,⊥] Oliver W. Press,[§,||] Damon L. Meyer,[§,⊥] Don K. Hamlin,[‡] Don Axworthy,[§] D. Scott Wilbur,[‡] and Patrick S. Stayton*[,†]

One pretargeting approach to cancer radioimmunotherapy utilizes an antibody−streptavidin conjugate that is first localized to the tumor. A "clearing agent" is then administered to remove the excess bioconjugate from blood, followed by injection of the radiolabeled biotin therapeutic. In this study, the role of streptavidin−biotin affinity in this pretargeting system was investigated for the first time in vivo, with a reduced affinity, site-directed streptavidin mutant and with radiolabeled bis-biotin reagents. The S45A streptavidin mutant (SA-S45A), which displays a faster off-rate for biotin, was utilized with a bivalent biotin carrier that retains high avidity for the streptavidin mutant. Mice were fed either a normal or biotin-deficient diet, yielding serum endogenous biotin concentrations of 31 nM and 5 nM, respectively. Lymphoma-bearing nude mice pretargeted with 1F5 Antibody-SA-Wild Type (WT) bioconjugates produced ^{125}I-bis-biotin tumor concentrations of 2.2%ID/g and 7.0%ID/g in mice fed normal diets vs biotin-deficient diets. ^{125}I-bis-biotin tumor concentrations of mice pretargeted with 1F5-SA-S45A were 12%ID/g and 10%ID/g for mice fed normal and biotin-deficient diets, respectively. However, poor clearance of the 1F5-SA-S45A with the biotinylated clearing agent led to high normal organ concentrations of ^{125}I-bis-biotin. A galactosylated human serum albumin (HSA) modified with bis-biotin was then tested, and normal organ ^{125}I-bis-biotin concentrations were significantly reduced. Tumor-to-organ ratios achieved for 1F5-SA-S45A with the HSA-bis-biotin clearing agent in mice with high serum biotin were similar to those achieved with 1F5-SA-WT in mice with low serum biotin. These results demonstrate that exchange of bound endogenous biotin with lower affinity streptavidin mutants is possible, and that corresponding use of bis-biotin carriers can nearly eliminate the differences in therapeutic radioactivity at the tumor site in animals on normal vs biotin-deficient diets. The results also interestingly demonstrate, however, that improved clearance agents capable of removing the lower affinity streptavidin-antibody conjugate are needed to achieve comparable specificity in tumor to blood or normal organ ratios.

INTRODUCTION

Anti-CD20 antibody therapies have yielded high response rates in patients with B cell lymphomas (*1*). However, only 6% to 20% of patients achieve complete remissions, and few are cured using the antibody as a single agent. The therapeutic effectiveness of anti-CD20 antibodies can be enhanced by conjugating to radionuclides. This has been demonstrated in a recent randomized clinical trial that compared ^{90}yttrium-labeled ibritumomab tiuxetan (Zevalin), an anti-CD20 antibody, to rituximab (*2*). The radiolabeled anti-CD20 antibody achieved an overall response rate of 80% and complete remissions in 30% of lymphoma patients, compared with an overall response rate of 56% ($p = 0.002$) and a complete response rate of 16% ($p = 0.04$) with the nonradioactive anti-CD20 antibody (*2*). To further improve the response rates, myeloablative doses of radioactivity can be administered to further improve the response rates; however, this strategy subsequently requires stem cell transplantation (*3*).

A potential strategy for delivering higher levels of radioactivity to tumors without requiring myeloablative doses is multistep radioimmunotherapy (RIT) with pretargeting. One pretargeting approach consists of an antibody−streptavidin (Ab-SA) conjugate, a "clearing agent" to remove Ab-SA conjugate from the blood, and the radiolabeled biotin therapeutic. Clearing the excess Ab-SA conjugate from the blood has two significant advantages. First, the Ab-SA conjugate in the blood is quickly eliminated through the liver, limiting the nonspecific radiation exposure due to the presence of excess Ab-SA in the blood. Second, higher concentrations of Ab-SA can be injected because this nonspecific exposure is

bis-biotin-NCS

reduced, leading to higher concentration gradients and better tumor penetration of the antibody−streptavidin complex. Pretargeting has been shown to be an effective strategy for directing radioactivity to tumor xenografts in mice (*4*−*6*). Although SA-biotin pretargeting has demonstrated promise, the immunogenicity of SA and the presence of competing endogenous biotin represent potential limitations (*7*, *8*). Endogenous biotin binds and effectively blocks biotin-binding sites of SA due to its slow dissociation rate ($T_{1/2}$ = 6.5 h) (*9*). Mice are generally fed a biotin-deficient diet for several days prior to pretargeted radioimmunotherapy to reduce endogenous biotin concentration in serum (*7*, *10*). The extent of the endogenous biotin problem in humans is less clear, but patient dietary restrictions are difficult at best and even low levels of endogenous biotin can block available biotin-binding sites of streptavidin (*4*, *8*). Serum biotin levels also do not reveal the entire extent of endogenous biotin, as the liver has been suggested as a storage/release depot for biotin (*11*), and biotin levels in colon adenocarcinoma were found to be 3-fold higher than the surrounding tissue (*12*).

In this study we have investigated the role of the high affinity streptavidin binding in the pretargeting system. The high affinity of streptavidin for biotin provided the initial rationale for using this binding pair in pretargeting, but it conversely leads to the limitations associated with blocking by endogenous biotin. We have recently shown that SA-mutants can be used in combination with a bivalent biotin derivative to allow exchange of biotin, while retaining the high affinity with the bivalent biotin ligand in an in vitro binding system (*13*). Here we have characterized a site-directed mutant of SA in an anti-CD20 pretargeting system that exhibits lower affinity and a faster biotin off-rate than wild-type SA (SA-WT) (*9*, *14*−*16*). We report here an in vivo investigation using a mouse lymphoma xenograft system to determine whether this modified streptavidin−biotin system could circumvent blocking of biotin-binding sites by endogenous biotin while maintaining blood clearance capabilities and tumor targeting specificity. The study provided interesting insight into the tradeoff of high affinity in relation to endogenous ligand competition versus clearing agent effectiveness.

EXPERIMENTAL PROCEDURES

Reagent Preparation. SA-WT and SA-S45A were expressed, refolded, and purified as previously described (*9*, *15*, *16*). Conjugation of intact 1F5, an anti-CD20 antibody, to SA was performed as previously described (*5*, *17*). Briefly, Ab was reduced using DTT and SA was conjugated with SMCC in two separate reaction vials. Reduced Ab and maleimide-modified SA were reacted and then purified in two steps using iminobiotin and cation exchange columns. The Ab-SA conjugates were analyzed by HPLC and found to be >90% of the preparations had antibody:SA ratios of 1:1. ^{125}I-bis-biotin (Chart 1) was prepared and radioiodinated as previously described (Chart 1) (*13*).

To prepare the HSA-bis-biotin clearing agent, 0.3 mL of a 20 mg/mL in 50 mM sodium bicarbonate, pH 8.5, solution of HSA (6 mg, 0.09 μmol) was added to 0.15 mL of a 9.5 mg/mL solution of bis-biotin-NCS (1.4 mg, 1.5 μmol), shown in Chart 1, in the same buffer. The reaction mixture was slowly tumbled at room-temperature overnight. The entire mixture was then passed over a Sephadex G-25 column (PD-10, Phamacia, Piscataway, NJ) and collected in 0.9% saline. The protein containing fractions were combined, concentrated in a Centricon-30 (Millipore, Bedford, MA), and washed three times with 0.9% saline, concentrating between each wash. To the final volume of 0.25 mL was added 0.75 mL of 0.5 M sodium borate, pH 8.0, followed by 3 mg (9.6 0.09 μmol) of solid β-galactopyranosylphenyl isothiocyanate (Sigma, St. Louis, MO). The mixture was then allowed to tumble at room-temperature overnight before passing over a Sephadex G-25 column. The protein containing fractions were combined, concentrated, and washed three times with 0.9% saline, concentrating between washes.

Effect of Diet on Serum Biotin Levels. To measure the levels of biotin in serum, a competition assay was performed as previously described (*18*). Bovine serum albumin (BSA) mixed with biotinylated-BSA (100:1) at

a total protein concentration of 10 mg/mL was added to a 96-well plate at a total protein concentration of 10 mg/mL and allowed to incubate at room temperature for 1 h. The wells were washed three times with 10 mM Tris, 150 mM NaCl, 0.05% Tween 20 at pH = 7.5, referred to as TNTw buffer. Biotin standards or samples were added to the wells, followed by the addition of SA-HRP (1.25 mg/mL) (Zymed Laboratories, San Francisco, CA) at a 1:5000 dilution mixed with BSA at 1 mg/mL, and the mixtures were incubated at room temperature for 30 min. Wells were washed three times with TNTw buffer, followed by the addition of 0.1 M citric acid, 0.012% H_2O_2, and *o*-phenylenediamine dihydrochloride at a concentration of 1 mg/mL, pH = 4.5, which was incubated for 30 min at room temperature. The absorbance at 450 nm was measured for each well using a plate reader. The absorbance of biotin standards were plotted versus the logarithm of concentration. A standard curve was fit to a one-site competition model using Graphpad Prism version 3.02 for Windows, GraphPad Software, San Diego, CA (www.graphpad.com).

BALB/c nu/nu mice were separated into two groups of four mice each. Both groups were initially fed a normal diet (Irradiated Lab Diet #5053: Rodent Diet #20, [Purina, St. Louis, MO]). Mice were starved for 2 h at the same time every day, followed by retro-orbital phlebotomy. After the first blood draw, defined as time = 0, one group of mice was placed on a biotin-deficient diet (TD 81079 [Harlan Teklad, Madison, WI]), and the other group remained on the normal diet. Blood was removed for the next 4 days at the same time each day after a 2 h starvation. Blood was immediately collected into 1.5 mL tubes and allowed to clot. Blood samples were centrifuged at 4000 rpm for 3 min, the supernatant was removed, and the process was repeated. Supernatant was removed, and biotin concentrations were determined at various serum dilutions using the biotin assay described above. Serum samples for the mice at each time point were tested at three dilutions in order to obtain the most accurate reading range. Absorbance readings were used to calculate the corresponding biotin concentration in nmoles from the standard curve.

Effect of Streptavidin−Biotin System on Bis-Biotin Tumor Concentration on Normal or Biotin-Deficient Diets. BALB/c nu/nu mice (B & K Universal, Fremont, CA) were separated into two groups and fed either a normal or biotin-deficient diet. 10×10^6 Ramos lymphoma cells were injected subcutaneously into the flank of each mouse. One group of mice fed a biotin-deficient diet was injected with ^{125}I-bis-biotin ip, mice were sacrificed 24 h later, and tissues were harvested as described below. Upon the emergence of palpable tumors, the remaining mice were injected ip with 300 μg (6 nmol biotin binding sites) of either ^{131}I-1F5-SA-WT conjugate or ^{131}I-1F5-SA-S45A conjugate, labeled by the chloramine-T method. The mice were separated into four groups (n = 5), a normal diet and biotin-deficient diet for each 1F5-SA conjugate. Twenty-four hours after conjugate injection, 50 μg (6 nmol biotin) of a *N*-acetylgalactosamine-biotin (NAGB) clearing agent, graciously supplied by the NeoRx Corporation (*19*), was administered ip. ^{125}I-Bis-biotin (2.8 nmol biotin) was injected ip into the mice 3 h later, and the mice were sacrificed 24 h later. Organs were harvested and weighed, and the radioactivity was measured by a Cobra II gamma counter (Packard Bioscience). Tissue concentrations were calculated as the percent of injected dose per gram of tissue (%ID/g) and reported ± standard deviation. Statistical analysis was performed using the nonparametric Mann−Whitney test to compare groups.

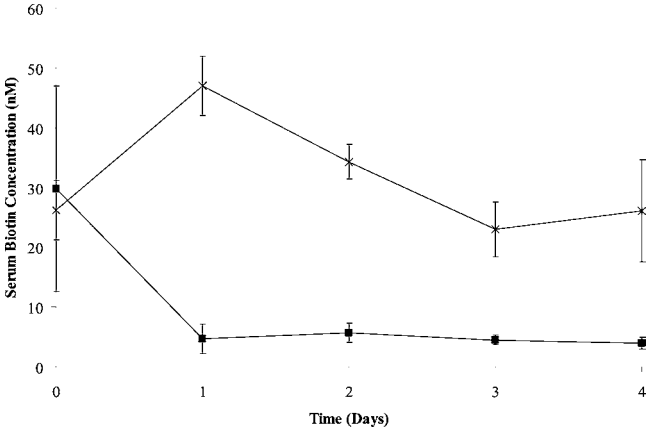

Figure 1. The effect of diet on serum biotin concentration. Mice were fed either a normal diet (×) or a biotin-deficient diet (■), with four mice per group. Blood samples were removed by a retro-orbital blood draw, and serum biotin concentration was measured using a biotin assay.

Pharmacokinetics of 1F5-SA Using Different Clearing Agents. Alternative clearing agents were investigated to improve the clearance of the mutant conjugate, 1F5-SA-S45A. Human serum albumin (HSA) was modified by conjugation of galactose residues and 2−2.5 equiv of bis-biotin molecules, to produce HSA-bis-biotin. Mice were fed a normal diet and separated into cohorts of four mice. Mice were injected ip with 75 μg (5.6 nmol biotin binding sites) ^{125}I-SA-S45A. At 4 h after the initial reagent, mice were injected ip with either 200 μg (11 nmol biotin) of HSA-bis-biotin, 100 μg of NAGB (12 nmol biotin), or 200 μg of HSA (control group). Blood samples were obtained at various time points throughout the experiment. The percent of injected dose per gram of blood (%ID/g) was calculated and plotted as a function of time.

Biodistributions in Mice Pretargeted with 1F5-SA, Cleared with a HSA-Bis-Biotin Clearing Agent. BALB/c nu/nu mice were injected with 10×10^6 Ramos cells subcutaneously in the right flank. Mice were fed either a normal or biotin-deficient diet. With the formation of palpable tumors, mice were injected with 300 μg (6 nmol biotin binding sites) of either ^{131}I-1F5-SA-WT or ^{131}I-1F5-SA-S45A. HSA-bis-biotin at a dose of 200 μg (11 nmol biotin) was administered 24 h later. Three hours later ^{125}I-bis-biotin (2.8 nmol biotin) was injected into the mice, and mice were sacrificed 24 h later. Tissue samples were collected, organs were weighed, and radioactivity was measured.

RESULTS

Assessment of Serum Biotin Concentrations for Normal vs Biotin-Deficient Diets. The serum levels of biotin were characterized for comparison between the normal mouse diets and the biotin-deficient diets. Prior to the determination of serum biotin levels, a standard curve was established using 11 different biotin concentrations ranging from 0.1 nM to 400 nM. The standards yielded a curve that was well fit to a one-site competition model after logarithmic transformation of the concentration. Mice that remained on the normal diet had serum biotin concentrations of 31 ± 5 nM. After beginning a biotin-deficient diet, serum biotin concentrations dropped to 4.7 ± 1.5 nM in 1 day as shown in Figure 1.

Effect of Streptavidin Affinity on Bis-Biotin Tumor Concentration with Normal vs Biotin-Defi-

cient Diets. A biodistribution study was conducted to test whether a bis-biotin therapeutic could be used in combination with a 1F5-SA-mutant conjugate to reduce the blocking of biotin-binding sites by endogenous biotin. SA-S45A has an affinity for biotin (2.1×10^{-10} M) (*14*) that is approximately 3 orders of magnitude lower than SA-WT (2.3×10^{-13} M) (*20*). Decreasing the affinity for biotin was expected to promote exchange of endogenous biotin, diminishing the blocking of biotin-binding sites by endogenous biotin on mice fed normal diets. The biodistribution of ^{125}I-bis-biotin was first measured in mice fed a biotin-deficient diet 24 h postinjection (Supporting Information). The concentration in all tissues was below 0.1%ID/g, indicating that the molecule does not localize nonspecifically to any of the tissues tested. Following this initial evaluation, a dual-label biodistribution experiment was conducted in mice on normal vs biotin-deficient diets. An outline of the injection times and groups used in both biodistribution experiments is shown in Scheme 1.

Tumor-bearing mice were split into two groups and fed either a biotin-deficient diet or a normal diet. These groups were further sub-divided and administered with either 1F5-SA-WT or 1F5-SA-S45A, with all groups injected with the NAGB clearing agent. The concentrations of the ^{131}I-1F5-SA conjugates in different tissues are shown in Figure 2A, 24 h after ^{125}I-bis-biotin administration. The blood concentration of ^{131}I-1F5-SA-WT was 17.7 ± 8.6%ID/g with the normal diet and 7.9 ± 6.0%ID/g for the biotin-deficient diet, indicating that endogenous biotin blocked the action of the biotin-based clearing agent. The blood concentration of the ^{131}I-1F5-SA-S45A conjugate was 21.4 ± 4.9%ID/g with the normal diet and remained relatively high at 14.2 ± 6.8%ID/g with the biotin-deficient diet. The high blood concentrations of ^{131}I-1F5-SA-S45A indicated suboptimal clearance of the low affinity mutant conjugate by the NAGB clearing agent. The concentration of ^{125}I-bis-biotin in different tissues at 24 h after injection is displayed in Figure 2B for the four groups of mice. The ^{125}I-bis-biotin concentrations at the tumors with 1F5-SA-S45A were 12 ± 4.6%ID/g and 10 ± 4.4%ID/g for normal vs biotin-deficient diets, respectively, whereas the concentrations with 1F5-SA-WT were 2.2 ± 1.1%ID/g and 7.0 ± 1.6%ID/g for normal vs biotin-deficient diets, respectively. These results demonstrate that the blocking of radiolabeled biotin by endogenous biotin observed in the 1F5-SA-WT system can be overcome with the lower affinity SA-S45A mutant. However, the concentrations of ^{125}I-bis-biotin in all normal organs was also significantly higher ($p < 0.05$) compared to mice receiving 1F5-SA-WT, due to the high blood concentrations of the 1F5-SA-S45A conjugate. The lower affinity of SA-S45A for biotin thus reduced the effectiveness of the NAGB clearing agent, necessitating the use of a new clearing agent with higher affinity to the mutant conjugate.

Effect of Different Clearing Agents on the Pharmacokinetics of SA-S45A and 1F5-SA-S45A. In initial pilot experiments, we assessed the efficiencies of modified clearing agents at removing unconjugated ^{125}I-SA-S45A from the circulation of mice fed a normal diet. The use of a divalent biotin-based agent was investigated based on the "avidity" effect previously demonstrated with the lower affinity streptavidin mutants (*13*). The NAGB clearing agent was tested at twice its usual dose (100 μg). Additionally, a galactosylated HSA-based clearing agent was constructed by conjugation with bis-biotin-NCS (see methods). Unmodified HSA was used as a control. Blood concentrations of ^{125}I-SA-S45A as a function of time are shown in Figure 3 for groups of mice injected with each clearing agent. HSA-bis-biotin reduced the blood concentration of ^{125}I-SA-S45A from 15.9 ± 2.8%ID/g to 1.0 ± 0.01%ID/g at 30 min after injection. The clearing results with the NAGB clearing agent showed a bimodal distribution where two mice showed no reduction in blood %ID/g, while two mice showed a reduction equivalent to that with the HSA-bis-biotin (leading to the average reduction from 16.8 ± 2.4%ID/g to 7.5 ($\pm$ 4.5−7.1) %ID/g, with the large standard deviation bars in Figure 3). Separate experiments showed that the NAGB clearing agent efficiency with the SA-S45A mutant streptavidin was sensitive to mouse diet, and the bimodal results most likely reflected that two of the mice had recently con-

Scheme 1. Schematic Depicting Time Course of Reagent Injections and Tissue Distribution in the Aminal Experiments[a]

[a] ^{131}I-1F5−SA was injected at time 0, followed 24 h later by clearing agent. Three hours later ^{125}I-bis-biotin was administered, and mice were sacrificed after an additional 24 h. Two biodistribution experiments were performed, and the reagents used in each group are listed in the table.

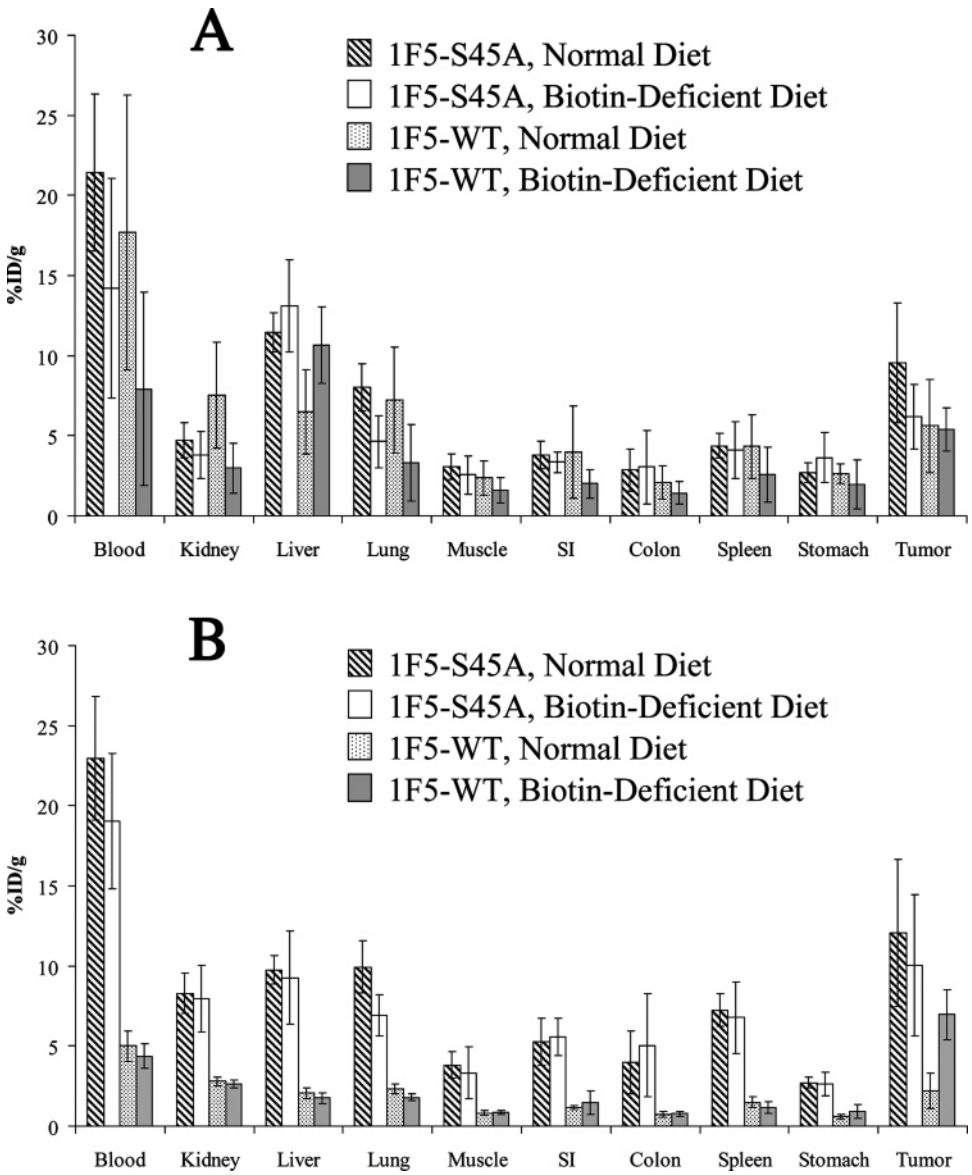

Figure 2. Tissue distributions of (A) ^{131}I-1F5-SA and (B) ^{125}I-bis-biotin in a pretargeting protocol using the NAGB clearing agent. ^{131}I-1F5-SA-WT and ^{131}I-1F5-SA-S45A were injected into mice on either normal or biotin-deficient diets. Twenty-four hours after the initial injection, the NAGB clearing agent was injected, followed 3 h later by administration of ^{125}I-bis-biotin. Mice were sacrificed 24 h after ^{125}I-bis-biotin injection, the tissues were harvested and weighed, and radioactivity was measured. The %ID/g of each tissue is shown for each group. From left to right in each column: 1F5-SA-S45A, normal diet; 1F5-SA-S45A, biotin-deficient diet; 1F5-SA-WT, normal diet; and 1F5-SA-WT, biotin-deficient diet. Average values are shown ± standard deviation.

sumed normal diet pellets. The HSA-bis-biotin was chosen for further studies to match best to the reduced affinity of the SA-S45A reagents under the broadest set of diet conditions.

Biodistributions in Mice Pretargeted with 1F5-SA and Cleared with HSA-Bis-Biotin. In a second biodistribution experiment, Ramos-bearing nude mice were split into two groups and fed either a biotin-deficient diet or a normal diet. These groups were further subdivided and administered with either 1F5-SA-WT or 1F5-SA-S45A. The HSA-bis-biotin clearing agent was used to determine if 1F5-SA-S45A in mice fed a normal diet could yield high ^{125}I-bis-biotin tumor concentrations and low ^{125}I-bis-biotin concentrations in the blood and normal organs. Figure 4A depicts the Ab-SA localization in each organ. The blood concentration of ^{131}I-1F5-SA-S45A 24 h after the ^{125}I-bis-biotin injection was 5.4 ± 3.0%ID/g with the normal diet and 4.4 ± 0.8%ID/g in the biotin-deficient group. 1F5-SA-WT exhibited a blood concentration of 9.7 ± 3.7%ID/g in mice fed a normal diet and 4.2 ± 2.7%ID/g in mice fed a biotin-deficient diet. ^{125}I-bis-biotin biodistributions are displayed in Figure 4B. Tumor concentrations of ^{125}I-bis-biotin 24 h after injection were 0.2 ± 0.03%ID/g for 1F5-SA-WT with the normal diet, and 0.1 ± 0.05%ID/g on the biotin-deficient diet. The tumor concentrations of ^{125}I-bis-biotin were 4.9 ± 3.2%ID/g and 3.4 ± 0.6%ID/g for 1F5-SA-S45A on normal vs biotin-deficient diets, respectively. Blood concentrations of ^{125}I-bis-biotin for 1F5-SA-S45A with the normal vs biotin-deficient diets were 2.5 ± 0.6%ID/g and 3.9 ± 0.7%ID/g, respectively. A comparison of tumor/normal organ ratios of the nonoptimized vs optimized 1F5-SA-S45A conjugate with the normal diet is compared to the optimized 1F5-SA-WT conjugate on the biotin-deficient diet in Figure 5. It can be observed that the bis-biotin clearing agent improves the overall performance of the 1F5-SA-S45A conjugate similar to the best 1F5-SA-WT conjugate system, with the advantage of attaining this performance on a normal biotin diet.

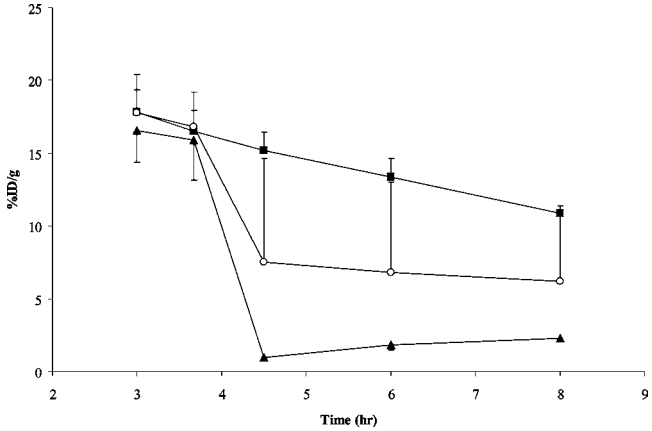

Figure 3. The effect of clearing agents on blood pharmacokinetics of SA-S45A. Three groups of mice ($n = 4$) were fed a normal diet and injected with ^{125}I-SA-S45A, and 4 h later the clearing agent was injected. Blood samples were removed at various time points, the radioactivity was measured, and %ID/g was calculated for each group: HSA control (■) NAGB (○), and HSA-bis-biotin (▲). Average values are shown ± standard deviation.

DISCUSSION

In this study, we have investigated the role of streptavidin affinity, modified therapeutic ligands, and clearing agents in a pretargeting system designed for treating B-cell lymphoma. In particular, the tradeoffs between the advantage of faster biotin off-rates for the rapid exchange of bound endogenous biotin with the biotinylated therapeutic, and the disadvantages of poorer therapeutic retention and blood clearance, have been clarified and initially optimized. The major conclusion is that the low affinity streptavidin mutant can be used with bis-biotin therapeutics of higher effective affinity (avidity) to achieve exchange of blocking endogenous biotin and excellent retention at the tumor. To achieve high tumor/normal organ ratios, it was also found that the clearing agent must be modified to the bis-biotin derivative in order to effectively clear the radiolabeled biotin therapeutic from the blood. When the optimized therapeutic and clearing agents were utilized with the lower affinity mutant, the performance of the pretargeting system with mice on normal diets reached that of the WT streptavidin system on biotin-deficient diets. In addition to providing useful insight into the role of biotin off-rates in pretargeting systems, this finding suggests that the engineered pretargeting system could reduce the impact of endogenous biotin and reduce the quantities of antibody−streptavidin conjugates needed to achieve effective radiation doses at the tumor site.

The bis-biotin strategy was based on previous in vitro work using SA affinity mutants and bivalent biotin ligands (*13*). The bivalent binding of optimized bis-biotin ligands raised their affinity with a site-directed SA-Y43A mutant to that comparable to biotin and wild-type SA. This property allows displacement of monovalent endogenous biotin due to the faster off-rate of the SA mutant, while maintaining the high affinity retention of the bis-biotin once it is exchanged. Initial evaluation of the Y43A streptavidin mutant used in the in vitro studies suggested that a faster off-rate was necessary in the in vivo pretargeting system, and thus the SA- S45A mutant was utilized in this study. The half-life of biotin dissociation from SA-WT is over 6.5 h at 37 °C, while for SA-S45A it is only 14 s. To test the impact of high and low biotin serum concentrations on wild-type and mutant SA biotin and bis-biotin systems, we conducted a series of experiments with mice possessing variable serum concentrations of endogenous biotin as a result of dietary manipulations. The biotin-deficient diets rapidly lowered the serum biotin concentration by 6-fold, from 31 nM to 4.7 nM. While a biotin-deficient diet was sufficient to reduce endogenous biotin serum concentrations 6-fold in mice within 1 day, in rats a 6-fold reduction of plasma biotin concentration took six weeks (*7*). Endogenous biotin levels in human plasma were reported between 1.3 and 2.2 nM (*10*, *21*), which is lower than reported above in nude mice (31 nM) and in rats (5.3 nM) (*7*). Tumor biopsies of patients in the clinic treated with NR-LU-10-SA (WT) revealed a reduction in the biotin-binding capacity over time, which was hypothesized to be due to blockage by endogenous biotin (*22*). As highlighted by Sharkey et al. (*23*), the presence of biotin storage sites may play a role in blocking biotin-binding sites. Development of cutaneous and neurological disorders in the aforementioned rats by 3−5 weeks suggests that reducing endogenous biotin levels in humans with such a diet would require close monitoring.

The tumor concentration of ^{125}I-bis-biotin in mice pretargeted with 1F5-SA-WT and low concentrations of endogenous biotin (biotin-deficient diet) was 7.0%ID/g compared to 2.2%ID/g in mice with high concentrations of serum endogenous biotin (normal diet). Tumor concentration of ^{125}I-bis-biotin was 12%ID/g in mice with high serum biotin concentrations treated with 1F5-SA-S45A, indicating endogenous biotin was unable to block the biotin-binding sites of 1F5-SA-S45A as it did 1F5-SA-WT. There was a concomitant increase in the concentrations of ^{125}I-bis-biotin in normal tissues, especially the blood. This finding highlighted an important tradeoff with the SA mutant: the normal biotin-based clearing agent also had an increased off-rate that prevented effective blood clearance. Biotinylated HSA modified with galactose residues was one of the first clearing agents used to remove Ab-SA conjugates from the blood (*4*). The same strategy was used to construct the multivalent clearing agent that was designed to exhibit the same increase in effective affinity through the avidity effect observed with the bis-biotin therapeutic. The HSA-bis-biotin clearing agent, used with the 1F5-SA-S45A conjugate and ^{125}I-bis-biotin, reduced normal organ concentrations in mice fed a normal diet to similar levels as those observed with the combination of the NAGB clearing agent, the 1F5-SA-WT conjugate, and ^{125}I-biotin in mice fed biotin-deficient diets (Figure 2). We have thus shown that the blocking of biotin-binding sites by endogenous biotin can be mitigated by using a SA-mutant with a lower affinity for biotin coupled with a bivalent bis-biotin therapeutic and clearing agent. Further optimization of the clearing agent and the streptavidin affinity will be necessary to fine-tune the composite activity and specificity (tumor-tissue ratios) further, but these results demonstrate the potential for engineering protein and ligands to optimize the overall pretargeting system.

ACKNOWLEDGMENT

We thank Dr. John Pagel and Dr. David Hyre for insightful discussions. Amphiphilic Core–Shell Nanoparticles with Poly(ethylenimine) Shells as Potential Gene Delivery Carriers

Junmin Zhu,[†] Angie Tang,[†] Lai Pang Law,[†] Min Feng,[†] Kin Man Ho,[†] Daniel K. L. Lee,[†] Frank W. Harris,[‡] and Pei Li*[,†]

Department of Applied Biology and Chemical Technology, and Open Laboratory of Chirotechnology of the Institute of Molecular Technology for Drug Discovery and Synthesis, The Hong Kong Polytechnic University, Hung Hom, Kowloon, P. R. China, and Maurice Morton Institute of Polymer Science, University of Akron, Akron, Ohio 44325-3909. Received April 29, 2004

Spherical, well-defined core–shell nanoparticles that consist of poly(methyl methacrylate) (PMMA) cores and branched poly(ethylenimine) shells (PEI) were synthesized via a graft copolymerization of methyl methacrylate from branched PEI induced by a small amount of *tert*-butyl hydroperoxide. The PMMA-PEI core–shell nanoparticles were between 130 to170 nm in diameter and displayed zeta-potentials near +40 mV at pH 7 in 1 mM aqueous NaCl. Plasmid DNA (pDNA) was mixed with nanoparticles and formed complexes of approximately 120 nm in diameter and was highly monodispersed. The complexes were characterized with respect to their particle size, zeta-potential, surface morphology, and DNA integrity. The complexing ability of the nanoparticles was strongly dependent on the molecular weight of the PEI and the thickness of the PEI shells. The stability of the complexes was influenced by the loading ratio of the pDNA and the nanoparticles. The condensed pDNA in the complexes was significantly protected from enzymatic degradation by DNase I. Cytotoxity studies using MTT colorimetric assays suggested that the PMMA-PEI (25 kDa) core–shell nanoparticles were three times less toxic than the branched PEI (25 kDa). Their transfection efficiencies were also significantly higher. Thus, the PEI-based core–shell nanoparticles show considerable potential as carriers for gene delivery.

INTRODUCTION

The search for a DNA carrier system that can provide safe and efficient gene delivery continues to be one of the most challenging tasks of gene therapy. A desirable vector must be able to protect DNA from enzymatic degradation, bind to target cells, cross the cell membrane, escape from the endosome, and release the therapeutic DNA or RNA resulting in gene expression. The vector should not be toxic or induce an immune response. For good systemic circulation in vivo, the size of the vector should be less than 200 nm in diameter and monodisperse (*1*, *2*).

In the past decade, viral and nonviral vectors have been extensively developed for DNA and oligonucleotide delivery. Viral vectors, although more efficient, are plagued by safety concerns, including virus replication and inflammatory reactions (*3*). With nonviral vectors, the efficiency of gene transfer to cells is very low due to the lack of receptor recognition, endosome escape, and poor nuclear targeting, but nonviral vectors are easy to manufacture on a large scale at an acceptable cost and have superior safety profiles and low immunogenicity. Targeting ligands can also be readily attached. Furthermore, the nonviral vectors can protect DNA from degradation by nucleases in the lysosome and bloodstream. Thus, nonviral systems are more amenable for use in commercial products (*4*).

Nonviral vectors that have been investigated include naked DNA, cationic lipids, liposomes, peptides, surfactants, polymers, dendrimers, polymeric particles, and other systems (*2*). Although many of these delivery systems have been evaluated in vivo, there is still no system that provides the efficacy, safety, and formulation stability required for clinical use. Thus, new nonviral gene delivery systems are continuously being developed in the hope that they will meet these stringent requirements.

Cationic polymers have received particular attention because they can condense with DNA via electrostatic interaction to form small particles, which protect the DNA from degradation and enhance uptake via endocytosis. Furthermore, they can be easily manufactured and conjugated to targeting ligands or intracellular trafficking enhancers (*5*). Of the various types of cationic polymers, linear and branched poly(ethylenimine)s are considered to be the most promising because they combine excellent transfection efficiency with high complex stability (*6*, *7*). The high transfection efficiency of PEI has been attributed to the so-called proton sponge effect (*8*). Since the amine groups on branched and linear PEI are not fully protonated at physiological pH after the PEI/DNA complexes enter the endo/lysosomal compartment, the PEI is able to buffer the acidic pH of the lysosome, protecting the DNA from degradation. Protonation of the PEI also results in an expansion of the polymeric network due to intramolecular charge repulsion. This causes an osmotic swelling/rupture of the vesicles, releasing the DNA into the cytoplasm. The positively charged PEIs are also endocytosed by the cells, thus facilitating endosomal escape. However, a major problem associated with PEI and many other cationic polymer–DNA complexes is their tendency for particle aggregation, resulting in the

formation of large particles (even μm-sized) with broad size distributions. The large particles have poor diffusion in vascular periphery and low internalization capacity to the cells *(9*, *10)*. Thus, the desirable in vivo vectors should be approximately 100 nm in diameter for good systemic circulation and effective endosytosis. Monodisperse vectors having homogeneous compositions are preferred, as they enable pharmacokinetic analysis of a single active species.

The objective of this work was to address the abovementioned problems through the use of monodisperse, amphiphilic core−shell nanoparticles with PEI shells as the gene carriers. The nanoparticles were prepared by our recently developed procedure (*11*, *12*) and treated with plasmid DNA. The resulting pDNA−nanoparticles complexes of approximately 100 to 120 nm in diameter were evaluated with regards to their morphology, physical and chemical properties, ability to protect and release the pDNA, cytotoxicity, and transfection efficiency.

EXPERIMENTAL PROCEDURES

Materials. Branched polyethylenimine with weight average molecular weight of 25 kDa (PEI25K) (waterfree) and 750 kDa (PEI750K) (50 wt % solution in water) were obtained from Aldrich. The phenolic inhibitor in methyl methacrylate (Aldrich) was removed by washing three times with 10% sodium hydroxide solution and then with deionized water until the pH of the water layer dropped to 7. It was further purified by vacuum distillation. *tert*-Butyl hydroperoxide (70% solution in water) was obtained from Acros. GIBCO Dulbecco's modified Eagle medium (DMEM) and Lipofectamine were purchased from Invitrogen Corporation. Poly(aspartic acid) (pASP, molecular weight based on viscosity of 8300 to 11 000 with a DP= 80) and in vitro MTT-based toxicology assay kit were obtained from Sigma. DNase I was purchased from Amersham (7500 units/μL). The human HeLa cell line was purchased from the American Type Culture Collection (ATCC, Maryland). LAR II Luciferase Substrate was from Promega. Freshly deionized and distilled water (ddH_2O) was used as the dispersion medium.

Synthesis of PMMA-PEI Core−Shell Nanoparticles. The PMMA-PEI core−shell nanoparticles were prepared according to our previously described method with minor modifications (*12*). PEI25K (0.84 g) was dissolved in water, and the pH of the solution was adjusted to 7 with 2 M HCl. Purified MMA (0.42 g) was added to the PEI solution in a water-jacketed flask equipped with a thermometer, a condenser, a magnetic stirrer, and a nitrogen inlet. After the solution was stirred under nitrogen for 30 min at 50 °C, *tert*-butyl hydroperoxide (0.25 mL of 1.0×10^{-2} M solution) was added dropwise. The mixture (total 30 mL) was heated at 80 °C for 2 h under nitrogen. The MMA conversion was then determined gravimetrically. The nanoparticles were carefully purified by repeated centrifugation of the dispersion at 13 000 rpm, followed by decantation. This procedure was repeated until conductivity of the supernatant was close to that of the water used. The nanoparticles were further purified by placing their final dispersion in a dialysis tube with a 50 K molecular weight cutoff (Spectra/PorCE) and dialyzed against 5 L of water, which was changed daily for one week at room temperature.

Characterization of Nanoparticles. Infrared spectra were recorded on a Nicolet 750 FT-IR spectrophotometer using KBr disks. Particle size and distribution were measured on a Coulter LS 230 Particle Size Analyzer. The diameters of the nanoparticle/pDNA (NP/pDNA) complexes and their zeta-potentials were determined with a Malvern Zetasizer 3000HS (Malvern, UK) in a 1 mM NaCl aqueous solution. The morphologies of nanoparticles were determined with a JEM 100 CX transmission electron microscope (TEM) with an accelerating voltage of 100 kV. Each sample was prepared by wetting a carbon-coated grid with a small drop of the dilute particle dispersion. The dry nanoparticles were treated with a small drop of 2% phosphotungstic acid (PTA) for 30 min and dried at room temperature. The morphologies of the PMMA-PEI nanoparticles and NP/pDNA complexes were examined with scanning electron microscope (SEM, Stereoscan 440, Leica). To prepare the samples, a drop of dilute latex dispersion was spread on to a glass surface and dried in a dust-free environment at room temperature. The dried specimen was then coated under vacuum with a thin layer of gold to a depth of ca. 5 Å.

Purification of Plasmid DNA. Commercially available plasmid DNA of pGL3-control (Promega) encoding the luciferase reporter gene was used in this study. This plasmid carries the SV40 promoter and enhancer that drive the firefly luciferase gene. The pGL3 plasmid was amplified in transformed JM109 *E.coli* cells in 5 mL of Luria Bertani agar broth supplemented with 50 μg/mL ampicillin (Sigma) at 37 °C. The mixture was gently shaken overnight at 225 rpm. The amplified plasmid DNA was purified using the Concert Rapid Plasmid Miliprep Kit (Life Biotechnologies). The concentration of pDNA was then measured by ultraviolet absorbance with a GeneQuant DNA/RNA Calculator at 260 nm (Pharmacia). The purity of the pDNA was confirmed using double restriction enzyme digestion with BamH1 and HindIII, followed by 0.8% agarose gel electrophoresis.

Nanoparticle/pDNA Complex Formation. The PMMA-PEI nanoparticle dispersions were diluted with ddH_2O to 1 mg/mL. Different amounts of the nanoparticle dispersion were mixed with 0.3 μg of pDNA in TE buffer, and the mixtures were incubated at room temperature for 20 min.

Gel Retardation Assay. pDNA binding to nanoparticles (i.e. complex formation) was studied by means of an agarose gel retardation assay. The agarose gel was prepared by dissolving 0.8% (w/v) agarose in 0.5× Tris−boric acid−EDTA (TBE) buffer containing 0.5 μg/mL ethidium bromide. The samples were mixed with appropriate amounts of 6× gel-loading buffer (Promega) and then loaded into the slots of the gel and subjected to electrophoresis at a voltage of 80 V for 40 min. The pDNA in the gel were visualized by ultraviolet transillumination and photographed by a Lumi-Imager. A 1 kb stepladder marker (Promega) was used as a DNA size marker.

Release of pDNA from Nanoparticles Complexes. The reversible nature of the nanoparticle/pDNA complexes was investigated through the addition of a polyanion, poly(aspartic acid) (pAsp). The complexes were incubated at room temperature with pAsp at a pAsp/pDNA molar ratio ranging from 10 to 100. Various incubation times were used (5, 10, 15, 30, 60, and 120 min), and the released pDNA was analyzed with 0.8% agarose gel electrophoresis.

DNase I Proection Assay. Nanoparticle/pDNA complexes [5:1 (w/w)] were incubated for 10 min at 37 °C with 1, 2, 3, 4, 6, 8, 10 unit/μL of DNase I (1 unit/μL), respectively. The DNase I was then inactivated by adding ethylenediaminetetraacetic acid (EDTA) (0.5 M, pH 8.0), followed by heating it at 80 °C for 2 min. The pDNA was then released from the nanoparticle complexes by pAsp

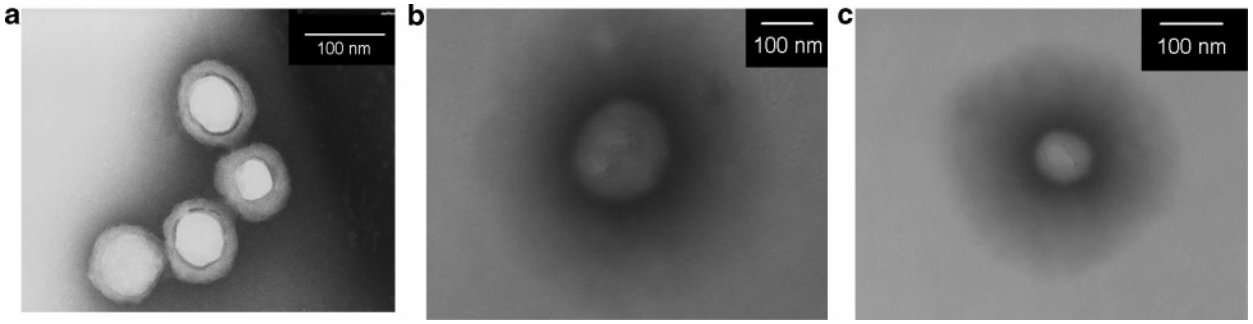

Figure 1. TEM micrographs of PMMA-PEI core−shell nanoparticles: (a) NP1, (b) NP1 at a high magnification, and (c) NP5 at a high magnification.

(molar ratio of pAsp to pDNA = 67:1), and its integrity was assessed by agarose gel electrophoresis.

Cell Culture. The human HeLa cells were cultured in DMEM medium with low glucose, supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS) at 37 °C under 5% CO_2. The cells were subcultured before reaching confluence, about every 7 to 8 days.

Cytotoxicity Assay. HeLa cells were seeded at 1.0 × 10^5 cells per well in 96-well plates using DMEM medium containing 10% FBS, 2 mM glutamine, 1 μg/mL insulin, 100 units/mL penicillin, and 100 μg/mL streptomycin and then incubated at 37 °C for 24 h under a 5% CO_2. After incubation, the medium was removed from the wells, and the cells were washed three times with 1× phosphate buffered saline (PBS) solution. Various concentrations of nanoparticles and PEI25K, ranging from 10 to 400 μg/mL, were prepared in the DMEM medium. 200 μL of the nanoparticle dispersion or PEI25K solution was added to each well and subsequently incubated with the cells for 16 h at 37 °C under 5% CO_2. The medium was then removed and replaced with 20 μL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) solution (5 mg/mL in PBS). The mixtures were further incubated at 37 °C for 4 h. The MTT solution was then carefully removed from each well, and 200 μL of MTT solubilization solution (containing 10% Triton X-100 plus, 0.1 N HCl in anhydrous 2-propanol) was added to dissolve the MTT formazan crystals. Plates were incubated for an additional 5 min before absorbances at 570 nm were determined spectrophotometrically using an ELISA microplate reader (Bio-Rad). The cell viability (%) was calculated according to the following equation:

$$\text{cell viability (\%)} = (A_{\text{sample}}/A_{\text{control}}) \times 100$$

where A_{sample} is the absorbance of the nanoparticles or PEI treated cells and A_{control} is the absorbance of the untreated cells. Each experiment was done in triplicate and repeated a minimum of three times.

Transfection Study. Cells were seeded at a concentration of 1.0 × 10^5 cells/well in six-well plates and incubated at 37 °C under 5% CO_2 for 24 h. Nanoparticle/pNDA and PEI25K/pDNA complexes of various nitrogen-to-phosphate (N/P) ratios were prepared. 200 μL of each complex suspension prepared, containing 1 μg plasmid, was added to each well. After incubation for 4 h at 37 °C under 5% CO_2, the medium was replaced by DMEM supplemented with 10% FBS and incubated for additional 20 h. The cells in each well were then washed with PBS (1 mL) and lysed with 500 μL of 1× Passive Lysis Buffer (PLB) with gentle shaking at room temperature for 15 min. 20 μL of the cell lysate was transferred into a luminometer tube containing 40 μL of LAR II Luciferase substrate. The relative luminescence unit (RLU) was measured with a Turner Designes TD-20/20 Luminometer (Promega).

Table 1. Preparation of PMMA-PEI Core−Shell Nanoparticles[a]

sample code	PEI (M_w, kDa)	MMA/PEI[b] (w/w)	D_v (nm)	D_n (nm)	D_v/D_n[c]	ξ-potential[d] (mV)

NP5	25	1:2	148	135	1.10	41

[a] The PEI and MMA were heated at 80 °C for 2 h in the presence of 0.08 mM TBHP. The pH of the reaction mixtures was 7, and solid content was approximately 4%. [b] Weight ratio of MMA to PEI charged. [c] D_n and D_v are the number and volume average particle diameters, respectively. D_v/D_n is the polydispersity index of the particle size distribution. [d] Zeta-potential was measured in 1 mM NaCl solution.

RESULTS AND DISCUSSION

Preparation of Core−Shell Nanoparticles with PEI Shells. A series of core−shell nanoparticles consisting of poly(methyl methacrylate) cores with branched poly(ethyleneimine) shells was prepared (Table 1). The procedure involved the *tert*-butyl hydroperoxide-initiated graft copolymerization of MMA from branched PEI in water at 80 °C. These particles include high and low molecular weight PEI shells and different shell thicknesses. Conversions of MMA monomer in all systems were around 90%. Small amounts of unreacted PEI, water-soluble copolymer and MMA monomer were removed from the particle dispersions through repeated centrifugation and decantation, followed by dialysis. The properties of the nanoparticles are summarized in Table 1. When the ratio of MMA to PEI was held constant (4:1 w/w), the use of lower molecular weight PEI resulted in slightly larger particle sizes. When the MMA to PEI ratio was decreased from 4:1 to 1:2, particle diameters decreased initially and then increased. This probably reflected the decrease in the diameter of the PMMA core followed by the increase in the thickness of the PEI shell. The nanostructures of the particles were examined with TEM (Figure 1). The micrographs clearly reveal that the nanoparticles are spherical and have well-defined core−shell nanostructures with very hairy PEI shells. The different core diameters and shell thicknesses were easily differentiated at high levels of magnification (Figures 1b and 1c). Furthermore, the nanoparticles all displayed positive surface charges of around +40 mV, regardless of the molecular weight of PEI or shell thickness. Such high positive zeta-potential of the PMMA-PEI core−shell nanoparticles indicated that these nanoparticles were

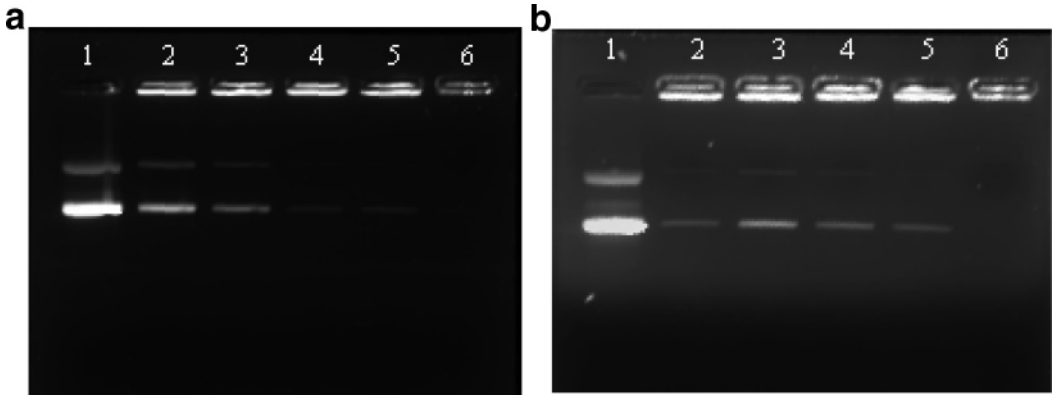

Figure 2. Ratio of nanoparticles to pDNA (w/w) required for complete complexation: (a) NP1/pDNA, Lane 1: pDNA; Lanes 2−6 are NP1/pDNA at weight ratios of 6:1, 8:1, 10:1, 12:1, and 14:1. (b) NP2/pDNA, Lane 1: pDNA; Lane 2−6 are NP2/pDNA at weight ratio of 30:1, 35:1, 40:1, 45:1, and 50:1.

very stable in aqueous and capable of condensing negatively charged pDNA.

Effect of the Molecular Weight of the PEI in the Shell on the Complexation of pDNA. DNA condensation onto a carrier is the first step in gene delivery. Thus, the effects of several parameters on the ability of the nanoparticles to complex with pDNA were examined. The effect of the molecular weight of the PEI shell was determined by incubating pDNA with various amounts of NP1 and NP2 nanoparticles. The amount of pDNA complexed with the nanoparticles was observed with agarose gel electrophoresis (Figure 2). When using the NP1 nanoparticles prepared from a high molecular weight of PEI (750 kDa), the pDNA was completely bound at nanoparticles to pDNA ratio of 14:1 (w/w) (Figure 2a). However, a ratio of 50:1 (w/w) was needed to bind all the pDNA with the NP2 nanoparticles, which were prepared with a low molecular weight PEI (25 kDa) (Figure 2b). Thus higher molecular weight PEI had much greater DNA binding capacity. Complicating this result is the fact that the molecular weight of PEI affects the transfection efficiency and the cytotoxicity *(13−15).* Although PEI with a molecular weight greater than 25 kDa provides high transfection efficiency, it is usually highly toxic, nonbiodegradable, and cannot be excreted. On the other hand, PEI carriers with molecular weights below 18K are not toxic, but have much lower transfection efficiency. Thus, even though the nanoparticles with high molecular weight of PEI shells bind DNA more effectively, the nanoparticles prepared from a low molecular weight of PEI (25 kDa) will probably have more potential for use in gene delivery.

Effect of the Thickness of the PEI Shell on Complexation with pDNA. To determine the effect of the thickness of the shell on the binding ability of the nanoparticles, a series of nanoparticles with an increase of shell thicknesses [MMA to PEI weight ratio of 4:1 (NP2), 2:1 (NP3), 1:1 (NP4) and 1:2 (NP5)] was prepared using PEI with a molecular weight of 25 kDa. The amount of nanoparticles necessary to completely complex a given amount of pDNA (0.3 μg) was then determined using agarose gel electrophoresis. Results in Table 2 show that the nanoparticles containing larger amounts of PEI were much more effective in complexing the pDNA. In fact, as the amount of PEI in the nanoparticle, i.e., the thickness of the shell, increased, the amount of nanoparticles required to complex the given amount of pDNA significantly decreased from 50:1 to 2:1. Thus, the NP5 nanoparticles were used for all subsequent studies.

Surface Properties and Stability of Complexed Nanoparticles. Surface charges of nanoparticles play a major role in controlling particle aggregation, which strongly affect the biodistribution and intracellular uptake in tissue (*16*, *17*). Since positive charges of nanoparticle surfaces decrease upon complexation of the negatively charged pDNA, the nanoparticles are expected to become less stable and more susceptible to aggregation as the amount of pDNA in the complex is increased. Thus, a study was carried out to determine the effect of pDNA loading on nanoparticle stability. Loading of pDNA was varied by complexing different amounts of the NP5 nanoparticles with a standard amount of pDNA at weight ratios of 2:1, 5:1, and 10:1. The stability of the complexes was determined with particle size measurement (Figure 3). Although the gel electrophoresis has indicated that NP5 nanoparticles could completely complex all the pDNA at the ratio of 2:1 (Table 2), the complexed particles were unstable and aggregated to form large particles with a mean size of 1612 nm (Figure 3b). However, the stability of the complexes could be greatly improved when increasing the nanoparticles to pDNA ratios to 5:1 or 10:1 (Figure 3 c and 3d). These complexed particles had mean sizes of 124 and 123 nm in diameter, which were smaller than the original NP5 particles (146 nm in diameter). The reduction of particle sizes was due to the negatively charged pDNA partially neutralizing the positively charged PEI shell. Thus the PEI shell became less water-soluble and shrunk. Measurement of surface charges of the complexes indicated that the zeta potential of the NP5 nanoparticles was reduced from +39.3 mM to +17.1 mV upon complexation with pDNA at a ratio of 5:1, confirming the electrostatic adsorption of pDNA on the PEI shell. Thus NP5 and pDNA complexation at weight ratio of 5:1 [estimated nitrogen to phosphorus (N/P) ratio = 5.5:1] was used for all the subsequent studies. The fact that the particle size of the complexes are around 100 nm with positive surface charges is very important for successful gene delivery because they provide good systemic circulation in vivo and facilitate cell uptake.

Table 2. Weight Ratios of Nanoparticles to pDNA Required for Complete Complexation

sample	MMA/PEI (w/w)	nanoparticle/pDNA (w/w) required to completely complex 0.3 μg of pDNA
NP2	4:1	50:1
NP3	2:1	20:1
NP4	1:1	12:1
NP5	1:2	2:1

The particle diameters and size distributions of the NP5 nanoparticles and their pDNA complexes were

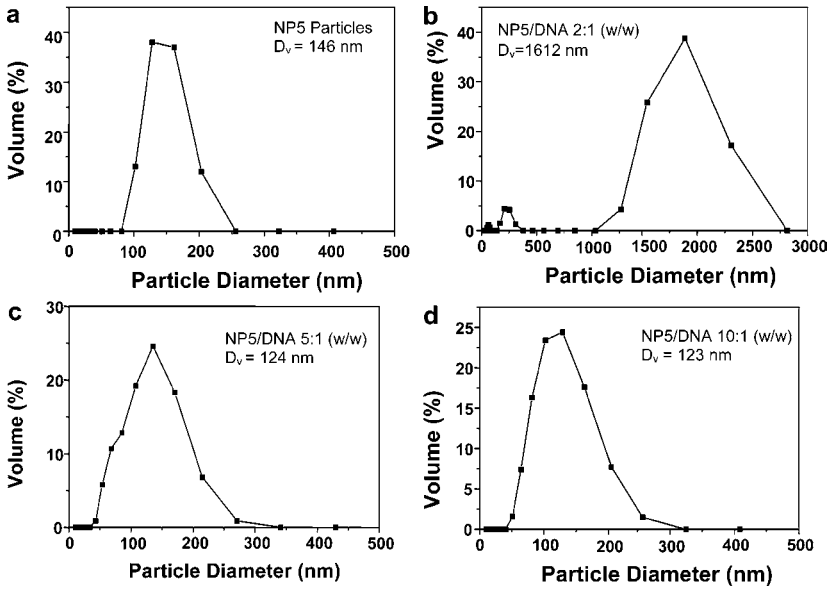

Figure 3. Particle diameters (Dv) of NP5 nanoparticles and NP5/pDNA complexes: (a) NP5 nanoparticles; (b) NP5:pDNA = 2:1 (w/w); (c) NP5:pDNA = 5:1 (w/w); (c) NP5:pDNA = 10:1 (w/w).

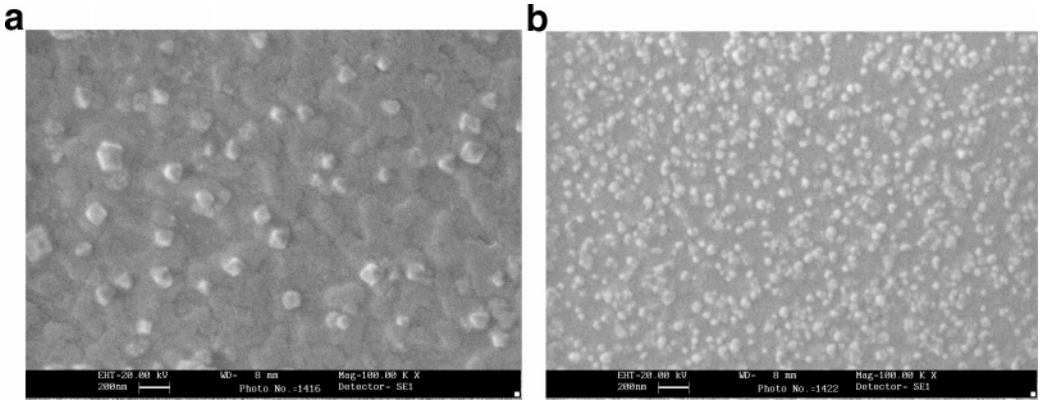

Figure 4. SEM micrographs of (a) NP5 nanoparticles, and (b) NP5/pDNA complexes at 5:1 ratio (w/w).

further studied with a scanning electron microscope (SEM) (Figure 4). The results confirmed that the average size of the NP5 nanoparticles was reduced to approximately 100 nm in diameter after complexing the pDNA. The monodispersity of the nanoparticles was also quite evident.

When the branched PEI25K was complexed with pDNA using N/P ratios of 4.4:1, 5.5:1, and 11:1, bimodal particle size distributions were obtained in all cases. The diameters of the complexed particles ranged from 70 to100 nm, while those of the larger particles were between 400 and 650 nm. Thus, use of the core−shell nanoparticles as the carrier has obvious an advantage over the branched PEI with regards to the nanosize and monodispersity.

DNA Integrity and Release of pDNA from the Complexes. Physical integrity of the DNA after complexation is a prerequisite for biological activity of the DNA to mediate successful transfection. Disassembly of DNA from the carrier is another critical step in the final stage of gene expression. The disassembly reaction is believed to occur between the ionic complex of DNA with other anionically charged macromolecules or cellular components such as mRNA, sulfated sugars, and nuclear chromatin in the cell (*18*). Therefore, it is important to examine whether the pDNA remain intact after complexation and can be released through an exchange reaction with a polyanion. Figure 5 shows the results of releasing pDNA after incubating the complexed nanoparticles with poly(aspartic acid) (pAsp) for 2 h at room temperature. There was no pDNA band in Lane 2, indicating that the pDNA had formed a stable complex with NP5 nanoparticles. When 10 and 23 times excess

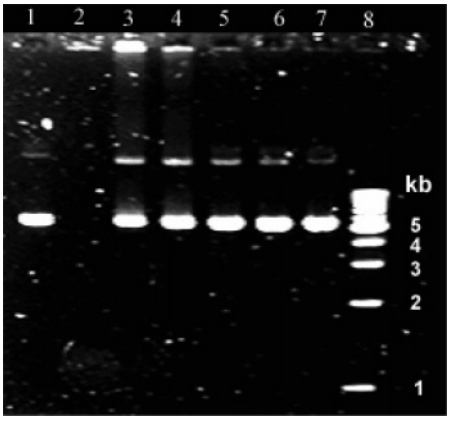

Figure 5. Release of pDNA from NP5/pDNA complexes by the addition of pAsp at various molar ratios. Lane: (1) plasmid DNA; (2) NP5/pDNA complexes at 5:1 weight ratio; (3−7) NP5/pDNA complexes with increasing proportions of pAsp (10, 23, 34, 45, and 55-fold excess of pAsp); (8) 1 kb DNA stepladder size marker. The band comigrating with the 5 kb size marker is the supercoiled form of pDNA, while the slower running and fainter band is the relaxed circular form.

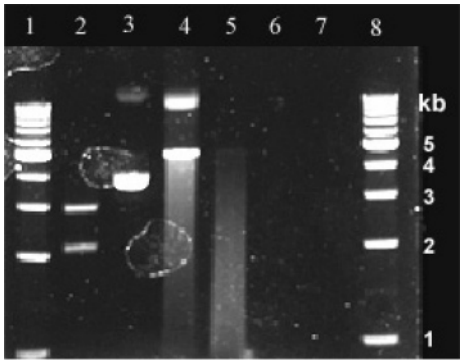

Figure 6. Determination of an optimal amount of DNase I to completely digest 0.3 μg of pDNA. Lane: (1 and 8) 1 kb DNA step ladder size marker; (2) double digestion of pDNA with BamH1 and Hind III for 90 min at 37 °C; (3) untreated plasmid DNA; (4−7) pDNA incubated with increasing amounts of DNase I [0.1, 0.5, 1, and 5 units].

of pAsp to pDNA (molar ratio) were used to release pDNA from the complexed particles (Land 3 and 4), both pDNA bands and smear appeared. Further increasing the molar ratios to 34, 45, and 55 could release all the pDNA from the complexes (Lane 5, 6, and 7). The nature of pDNA released was the same as the uncomplexed pDNA (Lane 1). These results clearly indicate that pDNA molecules remain intact after complexation and can be easily disassembled by polyanions. We also studied the minimum time required to completely release the pDNA from the complexed nanoparticles using 46-fold excess of pAsp and found that the pDNA could be all released within 5 min of incubation time.

Protection of pDNA against DNase I Digestion. For a useful gene delivery system, the carriers must be able to protect DNA from degradation by cellular nucleases abundant in serum and extracellular matrix. In this study, the extent of protection offered by the nanoparticles was investigated. Figure 6 showed that when naked pDNA (0.3 μg) was treated with 0.1 unit/μL of DNase I (Lane 4), a smear migrated ahead of the main band of the supercoiled pDNA, indicating some of the pDNA molecules were degraded. Increasing the DNase I concentration to 0.5 unit/μL could degrade most of the pDNA (Lane 5). Further increasing DNase I concentration to 1 or 5 unit/μL could completely degrade the pDNA (Line 6 and 7). When the same amount of pDNA (0.3 μg) was complexed with the NP5 nanoparticles and treated with 1 or 2 unit/μL of DNase I, no significant degradation of the pDNA was observed (Lanes 6 and 7, Figure 7). An increase of the intensity of the slower running band indicated the presence of more pDNA molecules in relaxed circular form. This change may be attributed to the fact that the DNase generates a single nick at one strand of the DNA, which can be repaired when they are inside the cell. The extent of the protection was further demonstrated using 3 to 10 unit/μL of DNase I to treat the NP5/pDNA complexes (Lanes 8−12, Figure 7). The majority of pDNA remained intact even though degradation became more and more apparent. The lack of complete protection against DNase I may be due to the degradation through surface erosion of DNA that is dynamically mobile on the particle shell. The porous nature of the nanoparticles shell layer also allowed the access of DNase, which could degrade the bounded pDNA (*19*). On the other hand, the level of nucleases in human serum at physiological conditions is approximately 0.1 unit/μL. At this level, the DNA complexed onto the nanoparticles should be totally protected against enzymatic degradation.

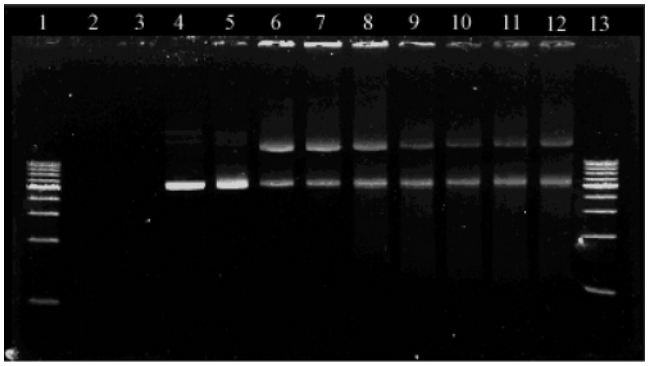

Figure 7. Protection of pDNA against DNase I after complexation with NP5 nanoparticles (NP5 to pDNA at a weight ratio of 5:1). Lane: (1 and 13) 1 kb step ladder size marker; (2) NP5 nanoparticles; (3) NP5/pDNA complexes; (4) plasmid DNA control; (5) pDNA released from the complexes without DNase treatment; (6−12) pDNA released from complexes treated with increasing amounts of DNase I [1, 2, 3, 4, 6, 8, and 10 units/μL].

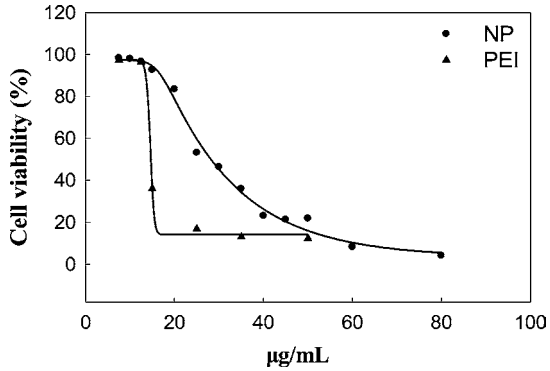

Figure 8. The percentage of viable cells at various concentrations for the NP5 nanoparticles (NP) and the free PEI (25kDa) polymer.

Cytotoxicity Study. The cytotoxicities of the PMMA-PEI core−shell nanoparticles (e.g. NP5) and the PEI25K polymer were compared using a cell viability assay (Figure 8). Various amounts of NP5 nanoparticles and PEI25K polymer were separately incubated with 1.0×10^5 HeLa cells (per well) in culture for 16 h at 37 °C. The cell viability was determined using MTT assay by measuring conversion of the MTT tetrazolium compound to formazan. The PMMA-PEI nanoparticles showed a significant reduction of cytotoxicity compared with the PEI (Figure 8). IC_{50} concentrations of the NP5 nanoparticles and PEI were 30 μg/mL and 10 μg/mL, respectively, indicating that the NP5 nanoparticles were three times less toxic than the PEI. In addition, a very sharp drop in the number of viable cells was observed with PEI, but much more gradual with NP5. This indicates that a much wider window between the beginning of metabolic down-regulation and the complete loss of viability is available with the nanoparticles. It should be noted that these cytotoxicity results were based on the use of nanoparticles and free PEI polymer. In general, the cytotoxicity of cationic carriers is reduced after complexation of the DNA (*8*). The cause of PEI cytotoxicity may be due to the multiple attachment of PEI to the cell surface, resulting in lysis of the cell (*20*, *21*). In our case, the PEI macromolecules are covalently linked to the PMMA particle surface. Thus, the number of possible PEI attachments to cell surfaces may be reduced, resulting in a lower cytotoxicity to the cell.

Transfection Activity. The effectiveness of PMMA-PEI core−shell nanoparticle (NP5) as carriers in gene

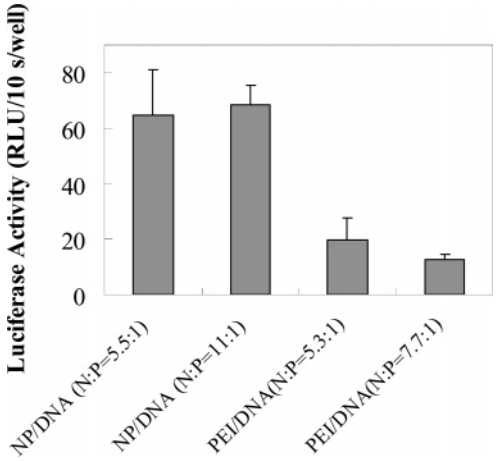

Figure 9. Transfection efficiency of NP5 and PEI25K at various N/P ratios in HeLa cells.

delivery was compared with PEI25K by assessing the level of expression of the reporter gene, firefly luciferase, carried into the HeLa cell in culture. The transfection efficiency was determined by the activity of firefly luciferase in relative luminescence units (RLU). Our results showed that the use of NP5 nanoparticles as carriers gave much higher transfection efficiency than that of PEI (Figure 9). For example, NP5/DNA complexes with N:P ratio of 5.5:1 were three times more efficient than PEI/DNA complexes with N/P ratio of 5.3:1. Increasing the N/P ratio of NP/DNA to 11:1 slightly enhanced the transfection efficiency. However, an opposite effect was observed with PEI/DNA complexes.

CONCLUSION

Various core−shell nanoparticles consisting of poly(methyl methacrylate) cores with branched poly(ethylenimine) shells were synthesized via a TBHP-induced graft copolymerization of methyl methacrylate from branched poly(ethylenimine). These core−shell nanoparticles were able to condense pDNA to form nanoparticle/pDNA complexes. Compared with the use of the branched PEI (25kDa) alone, PMMA-PEI core−shell nanoparticles formed much more stable complexed nanoparticles around 120 nm in diameter with a narrow size distribution. They were also three times less toxic than the branched PEI polymer and at least three times more efficient as gene carriers in transfecting cells. Although high molecular weight PEI (750 kDa) showed greater pDNA binding ability than the low molecular weight PEI (25 kDa), the cytotoxicity issue limited its potential application in gene delivery. Increasing PEI shell thickness using low molecular weight PEI (25 kDa) significantly increased the pDNA binding ability. The complexed pDNA remained intact and could be disassembled from the nanoparticle by the poly(aspartic acid). The PMMA-PEI core−shell nanoparticles also showed strong pDNA protection against enzymatic degradation. Thus, our PEI-based core−shell nanoparticles clearly demonstrate great potential as carriers for gene delivery. Studies of transfection efficiency with different cells and under different conditions, distribution of the nanoparticles inside the cell, and attachment of targeting ligands onto the nanoparticle surface will be the subjects of future investigation.

PEG-Modified Protamine with Improved Pharmacological/ Pharmaceutical Properties as a Potential Protamine Substitute: Synthesis and in Vitro Evaluation

Li-Chien Chang,[†,*] Hsiao-Feng Lee,[‡] Meng-Ju Chung,[†] and Victor C. Yang[§]

School of Pharmacy, National Defense Medical Center, Taipei, Taiwan, ROC, Industrial Science & Technology Network Inc., York, Pennsylvania 17404, and College of Pharmacy, The University of Michigan, Ann Arbor, Michigan 48109. Received January 15, 2004; Revised Manuscript Received September 4, 2004

Cardiopulmonary bypass (CPB) procedures are frequently associated with massive inflammatory responses, resulting in a high rate of morbidity and mortality in routine cardiac operations. One recognized attribute of these deleterious responses is the synergic effect of heparin and protamine, which elicit the activation of the complement system in vivo. To circumvent such toxic effects following protamine reversal of heparin anticoagulation in the CPB procedures, we proposed that poly(ethylene glycol) (PEG)-modified protamine could retain the heparin-neutralization ability and yet diminish the induced complement activation by the formed heparin−protamine complexes (HPC), thereby providing highly improved pharmacological properties. PEGylation of protamine was carried out by utilizing *N*-hydroxysuccinimidyl (NHS) conjugation chemistry. Size exclusion chromatography (SEC), reverse-phase high performance liquid chromatography (RP-HPLC), and matrix-assisted laser desorption mass spectrometry (MALDI-MS) were used to assess the conjugation stiochiometry, the purity of the conjugates, and the site of PEG modification, respectively. The heparin-neutralizing activity was determined by using heparin affinity chromatography and various biological assays including the plasma-activated partial thromboplastin time (aPTT), anti-Xa, and anti-IIa methods. The potency in inducing complement activation was examined in vitro using the CH_{50} hemolytic assay. The PEG-modified protamine was successfully synthesized with a PEG/protamine stiochiometry of 1:1. Only one conjugation site for PEG that was located at the N-terminal end of protamine was obtained. In the biological evaluations, the PEG-modified protamine displayed a full retention of the heparin-neutralizing ability of protamine and a significantly reduced activity in complement activation following its complexation with heparin. Results from studies of the particle size and zeta potential indicated that the PEG-modified protamine formed substantially smaller aggregates with heparin, rendering them less effective in triggering the size-dependent complement responses. As with protamine, PEG-modified protamine exhibited an enhanced aqueous solubility, therefore attaining significantly improved pharmaceutical properties. These preliminary results suggested that the PEG-modified protamine conjugate might serve as a potential protamine substitute with improved therapeutic and pharmaceutical properties in heparin reversal.

1. INTRODUCTION

Protamine is a low molecular weight protein (average MW: 4500 Da) rich in basic arginine residues. It is employed universally in the reversal of heparin anticoagulant activity following various surgical procedures including cardiopulmonary bypass (CPB), peripheral vascular surgery, and invasive cardiac angiography (*1*). It is estimated that more than 600 000 procedures are encountered in the mandatory use of these two drugs each year in the United States (*2*).

Despite decades of clinical use, safety concerns, however, have been remunerated on these two drugs. It has been widely reported that the synergic effects of heparin and protamine on the complement system would result in a variety of postoperative complications, such as increased pulmonary capillary permeability, anaphylactic reactions, organ failures (*3*, *4*), and ultimately many unpredictable deaths (*5*, *6*). Although intravenous administration of protamine alone could produce systemic hypotension, myocardial depression, and an increase in vascular permeability (*7*, *8*), it has been demonstrated clinically that the combined use of protamine and heparin actually triggers the activation of complement system that subsequently elicits more toxic responses (*9*, *10*). The quest for a better protamine alternative is therefore in profound scrutiny in recent years (*11*−*14*).

It has been recognized that inflammatory responses in CPB is, in large part, attributed to complement activation (*15*, *16*). Alleviation in complement activation has been shown to significantly diminish the CPB-associated inflammatory responses (*17*, *18*). On the basis of this reason, it has been hypothesized by us (*19*−*21*) and other investigators (*22*) that reduction of protamine-related complement activation is an effective method to improve the safety of CPB operations. Previously, we demonstrated that a chain-shortened low molecular weight protamine (LMWP) peptide with diminished

complement-activating ability elicited no toxic responses in a clinical dog model. This LMWP peptide, which was derived from thermolysin digestion of protamine, however, suffers with the shortcoming of yield (15%) that renders its prospect in comprehensive protamine substitution and as a universal heparin antidote. In this regard, the main objective of this study is to design an alternative approach in achieving a less toxic protamine substitute via the modification of protamine with the poly(ethylene glycol) (PEG) polymer.

It has been well documented that modification of a protein with PEG would help it elude the recognition by the immune system and retard the plasma clearance in vivo (*23*). Since the primary attribute of protamine toxicity lies in its cross-linking with the complement proteins (*11*), the major components of the immune system, it is of great interest to investigate if modification of protamine with PEG would attenuate the risk of protamine-mediated complement activation and enhance the safety of heparin/protamine therapies. Herein, we present a detailed investigation on this protamine PEGylation hypothesis, including synthesis, purification, characterization, and in vitro efficacy and toxicity evaluation of two PEG (PEG^{2000} and PEG^{5000}) modified protamine conjugates. The objective of this study is to demonstrate that the PEG-modified protamine would retain the original heparin-neutralizing ability of protamine, yet devoid of its complement-activating activity.

2. MATERIALS AND METHODS

2.1. Materials. Methoxypoly(ethylene glycol)-succinimidyl propionate (mPEG-SPA, 2000 and 5000 Da) was purchased from Shearwater Polymers (Huntsville, AL). Protamine sulfate (salmine, Grade X), human antithrombin III (A7388), and trifluoroacetic acid (TFA) were obtained from Sigma Chemical Co. (St. Louis, MO). Porcine intestine heparin (167 IU/mg) and S-2238 substrate were purchased from Pharmacia Hepar Inc. (Franklin, OH). HiTrap heparin affinity column was obtained from Amarshan Pharmacia Biotech Inc. (Piscataway, NJ). Freshly frozen human plasma in citrate was obtained from the American Red Cross (Detroit, MI). Acetonitrile was HPLC grade, and all solutions were prepared using distilled and deionized water (ddH_2O).

2.2. Preparation of PEG−Protamine Conjugates. Synthesis of the PEG (2000 or 5000 Da)−protamine conjugates was carried out by using the succinimidyl derivative of PEG propionic acid (PEG-SPA). In brief, a 10-fold molar excess of PEG-SPA (75 mmol) was allowed to react with protamine (7.5 mmol) in 5 mL of PBS (pH 7.5) buffer at room temperature for 2 h. The reaction mixture was then loaded on an Econo-Pac CM (Biorad) column preequilibrated with PBS. The column was washed with 10 volumes of PBS and then eluted with a linear NaCl gradient (0−2 M) in PBS. The appropriate fraction of PEG−protamine conjugate was collected, desalted, lyophilized, and then stored at −20 °C prior to use.

2.3. Characterization of PEG−Protamine Conjugates. Purified PEG−protamine conjugates were analyzed by size exclusion HPLC chromatography (SEC−HPLC, Shimadzu) equipped with a UV detector on a Tricorn Superdex Peptide (Amersham) column. For each measurement, the chromatography was performed with detection at 215 nm using an isocratic mobile phase of PBS with a flow rate of 0.7 mL/min.

Purity of the PEG−protamine conjugates was assessed by reverse-phase HPLC using an Alltech HPLC system equipped with a UV/VIS detector for continuously monitoring the absorbance of the eluent at 215 nm. A 4.6 × 250-mm, 5 μm Macrosphere (Alltech) C-4 column was equilibrated with 0.1% aqueous trifluoroacetic acid (solvent A) at a flow rate of 1.0 mL/min. Following sample injection (50 μL), a linear gradient of 2.0%/min solvent B (0.09% trifluoroacetic acid in acetonitrile) was applied to the column for a period of 50 min.

MALDI-TOF MS analyses were performed by the Protein and Carbohydrate Research Center at the University of Michigan using a Vestec-2000 Laser Tec Research laser desorption linear time-of-flight mass spectrometer. The matrix employed for all samples was α-cyano-4-hydroxycinnamic acid.

2.4. Bioactivity Measurements. Affinity of the PEG−protamine conjugates toward heparin was evaluated by using a heparin affinity chromatography. In brief, the purified conjugates were applied to a HiTrap heparin column (Pharmacia), and the affinity toward the immobilized heparin was determined from the elution time using a linear NaCl gradient (0−2 M) for 30 min. The flow rate was set at 1 mL/min, and the elution was monitored at 215 nm.

To comprehensively evaluate the heparin-neutralizing activity of PEG−protamine conjugates, three heparin assays routinely used in clinical laboratories including the activated partial thromboplastin time (aPTT), anti-Xa, and anti-IIa assays were employed. In brief, for the aPTT assay, 15 μL of heparin solution (5 U/mL) was mixed with 15 μL of sample solution containing various concentrations of protamine (0−30 μg/mL) or PEG−protamine conjugates (0−200 μg/mL), followed by the addition of 100 μL of actin cephaloplastin and 100 μL of plasma. After 3 min of incubation, 100 μL of 20 mM calcium chloride (preheated to 37 °C) were added and the clotting time was immediately measured using a fibrometer. For the anti-Xa assay, the procedure of Chang et al. (*19*) was followed. Briefly, 20 μL of heparinized human plasma (0.6 U/mL) was mixed with 75 μL of human antithrombin III (0.1 U/mL). After 2 min of incubation at 37 °C, 75 μL of factor Xa (4 nkat/mL), 75 μL of S-2222 substrate (1.9 mmol/mL), and 5 μL of protamine (or PEG−protamine conjugates) were added. Following 10 min of incubation, the absorbance of the solution was measured at 405 nm. The heparin-neutralizing ability of protamine (or PEG−protamine conjugates) was proportional to the absorbance increase at 405 nm. The protocol for measuring the anti-IIa activity was similar to that of anti-Xa except that factor IIa (thrombin) and S-2238 were used in replacement of factor Xa and S-2222, respectively. Details of this anti-IIa assay were described in a previous publication (*20*).

2.5. Complement Activation. Complement activation by protamine (or PEG−protamine) or heparin−protamine (or PEG−protamine) complexes was assessed by a modified hemolytic complement assay (*20*) using sensitized sheep erythrocytes (SRBC). In brief, 150 μL of diluted (1:60) serum containing an increasing concentration of protamine (or PEG−protamine) or heparin−protamine (or PEG−protamine) complexes, 75 μL of sensitized SRBC, and 150 μL of 0.02 M triethanolamine buffer saline (TBS) buffer containing 0.15 M NaCl were mixed together. The mixture was incubated at 37 °C for 60 min with occasional agitation. The reaction was then quenched by the addition of ice-cold TBS. After centrifugation, 200 μL of the supernatant were pipetted into the wells of a microplate, and the amount of released hemoglobin was determined at 541 nm using a microplate reader. The absorbance in the reaction mixture by adding TBS buffer

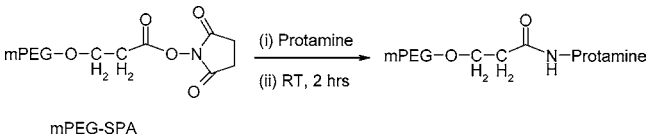

Figure 1. Scheme for chemical coupling of poly(ethylene glycol) (PEG) polymers to the N-terminal amino residues of protamine using methoxy(ethylene glycol)-succinimidyl propionate (mPEG-SPA).

and H_2O as the test samples was used as the control to represent 0% and 100% lysis, respectively. The degree of complement consumption (Y) was obtained from the equation:

$$Y = \left(1 - \frac{\text{test OD} - \text{TBS lysis OD}}{\text{H}_2\text{O lysis OD} - \text{TBS lysis OD}}\right) \times 100$$

2.6. Size and Charge of the Heparin−Protamine Complex (HPC). The heparin−protamine (or PEG−protamine conjugates) complexes (HPC) were prepared by mixing protamine (or PEG−protamine conjugates) with heparin (1U/mL). The dose of protamine used to form HPC was estimated based on the stiochiometric neutralization ratio of 1 mg protamine per 100 U of heparin (*24*), whereas the dose of PEG−protamine conjugates was determined by the ratio of achieving complete neutralization according to the aPTT assay. The solution was allowed to stand for 30 min at 20 °C to allow for a complete complex formation. The formed HPC were then examined for their size and zeta potential by using the HORIBA LB-500 (particle size) and ZetaPlus (zeta potential) analyzers, respectively. The particle size was presented as the effective mean diameter.

3. RESULTS AND DISCUSSION

3.1. Synthesis, Purification, and Characterization. Numerous methods for attaching PEG to a protein have been reported in the literature (*25*). Coupling reactions involving the amino groups of a protein and the monomethyl ester group of a modified PEG are the most widely used method. Among them, conjugation of a protein with the succinimidyl ester-modified PEG was shown to yield a linkage stable in most biological buffers and physiological conditions. For this reason, activated PEG-SPA (succinimidyl propionic acid) was selected to synthesize the PEG−protamine conjugates.

Conjugation was carried out under a slightly basic condition (pH 7.5). Normally, PEGylation of a protein occurs at the α-amino group of the N-terminal residue or the ϵ-amino groups of surface lysine residues when utilizing the *N*-hydroxysuccinimidyl (NHS) conjugation chemistry. Due to lack of lysine residues in the protamine sequence (*19*), the PEGylation reaction in our case is expected to occur only at the α-amino group, indeed, the imino moiety of the N-terminal proline residue of protamine (see Figure 1). Providentially, this conjugation process was actually preferred because it would allow for a site-specific 1:1 PEGylation of protamine at the N-end while preserving its intact structure for heparin neutralization.

To identify the PEGylation chemistry, the synthesized PEG−protamine conjugates were first examined by size exclusion chromatography (SEC). It can be seen in the chromatograms in Figure 2 that for either conjugation reaction (PEG^{2000}−protamine and PEG^{5000}−protamine) the desired mono-PEGylated protamine conjugates were predominantly produced and nearly homogeneous conjugates were obtained, suggesting that using the PEG-succinimidyl propionate reacted at a slightly basic pH could selectively produce N-terminally PEGylated protamines without branch reactions. The purity of the formed PEG−protamine conjugates was then assessed by using reverse-phase HPLC. As seen in Figure 3, only a single peak was eluted from the RP-column, indicating the production of highly pure (>95%) PEG−protamine conjugates. Although the PEG polymer did not absorb light at 215 nm, the separated PEG−protamine conjugate was not likely to contain un-reacted PEG simply because PEG possessed a very weak affinity to the ion exchange column.

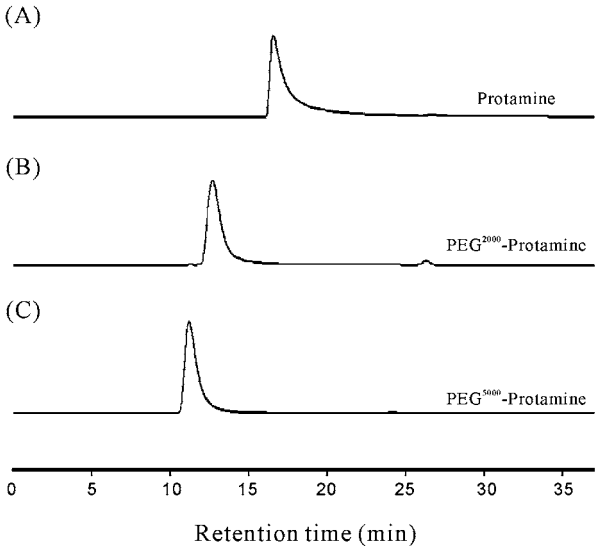

Figure 2. Size exclusion HPLC chromatograms of (A) protamine, (B) PEG^{2000}−protamine conjugate, and (C) PEG^{5000}−protamine conjugate. The PEG−protamine samples were prepurified by cationic ion-exchange chromatography as described in Materials and Methods.

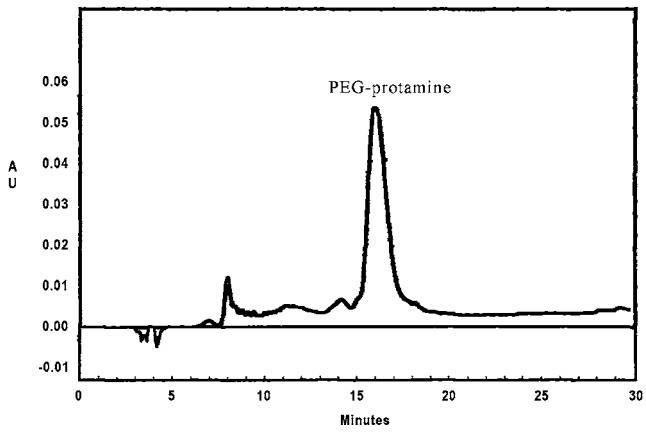

Figure 3. Reverse-phase HPLC chromatogram of PEG^{2000}−protamine conjugate. HPLC traces for PEG^{5000}−protamine conjugate were nearly identical to that of PEG^{2000}−protamine conjugate.

MALDI-TOF analysis was performed to further confirm the SEC results and to determine the molecular weight polydispersity of the formed PEG−protamine conjugates. As seen in Figure 4, the most probable mass peak was 6305.6 *m/z* for PEG^{2000}−protamine conjugate and 9970.5 *m/z* for PEG^{5000}−protamine conjugate, respectively, and in either spectrum a small double-charged mass (M^{2+}) peak was also present. Considering the molecular weight of protamine (4000−4300 Da (*19*)) and two PEGs (2000 and 5000), the obtained mass of the conjugates was very consistent with the calculated mass

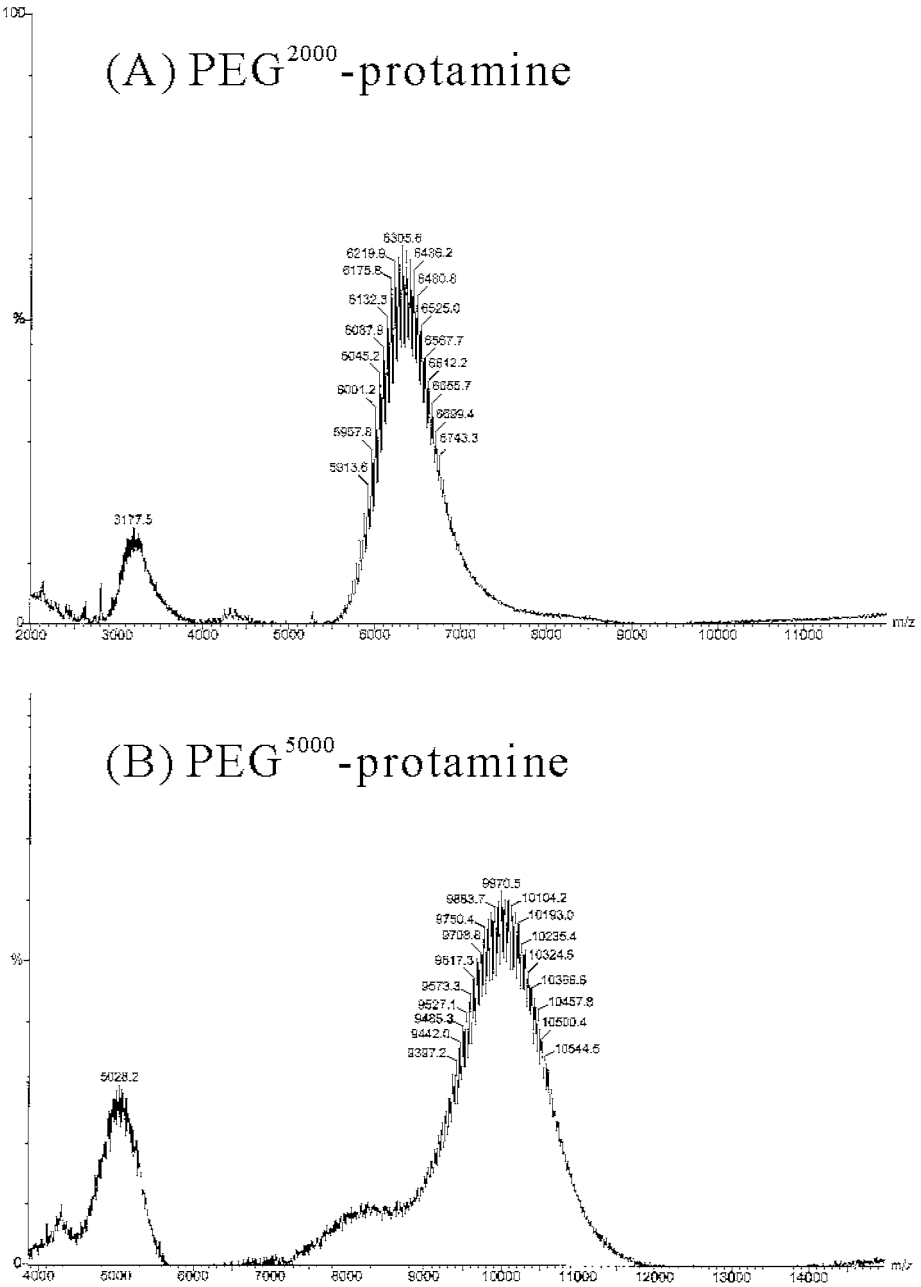

Figure 4. MALDI-TOF spectra of (A) PEG^{2000}−protamine and (B) PEG^{5000}−protamine conjugates. The molecular weight of protamine is about 4000−4300 Da (*19*). The most probable mass of PEG^{2000}−protamine and PEG^{5000}−protamine conjugates are 6305.6 and 9970.5 Da, respectively.

sum of individual molecules. Therefore, both the SEC and MALDI-TOF results clearly indicated that each protamine molecule was attached with only one PEG polymer chain with no intra- or intermolecular cross-linking being detected. Although the broad width of the peaks seen in both figures in Figure 4 suggested the polydispersity in molecular weight of the PEG−protamine conjugates, such a behavior was likely attributed to the polydispersity of the used PEG polymer rather than that of protamine, because the molecular weight distribution of protamine was relatively narrow (ca. 300 Da). Taken together, these data provided conclusive evidence that a homogeneous conjugation with a stiochiometry of 1:1 between PEG and protamine was achieved.

3.2. Binding Affinity and Neutralization Efficacy. It is well documented that the binding between protamine and heparin is primarily an electrostatic interaction. Both the structural integrity and charge density of protamine appear to be essential for its binding and neutralization activity toward heparin. In this regard, one could speculate that protamine modified by PEG at the N-terminal should preserve most of the heparin binding and neutralizing abilities. To validate this hypothesis, a previously established heparin affinity chromatographic method (*19*) was applied. Table 1 shows the elution ionic strength of the conjugates from a heparin column. As seen, while the original protamine was eluted

Table 1. Properties of PEG−Protamine Conjugates

compound	MW[a] (Da)	conjugation stoichiometry	heparin affinity[b] (NaCl concentration, M)
Protamine	4200	- -	~1.4
PEG^{2000}−Protamine	6400	1:1	~1.3
PEG^{5000}−Protamine	9800	1:1	~1.2

[a] Approximate value as determined by using MALDI-TOF mass analysis. [b] Elution concentration from a heparin affinity column.

with an ionic strength of 1.4 M NaCl, the PEG−protamine conjugates (PEG^{2000}−protamine and PEG^{5000}−protamine) were eluted at lower NaCl concentrations (i.e. 1.3 and 1.2 M, respectively), suggesting that the conjugation process might more or less impair the heparin-binding affinity of protamine. Nevertheless, it is well-known that protamine neutralizes heparin by its stronger affinity to heparin than antithrombin III (AT III). Therefore, the PEG−protamine conjugates should still possess a sufficient heparin-neutralizing ability, since the previous study revealed that AT III was eluted at a lower ionic strength (i.e. 0.75−1.3 M NaCl (*19*)) than those of the PEG−protamine conjugates.

It has been suggested that protamine may possess two active sites, one of which is utilized for heparin neutralization (*26*). Our previous investigation supported this speculation and further suggested that this site was near the C-terminal of the protamine molecule (*19*). In this regard, though most modification methods would result in loss of the biological functions of the parent protein, the N-terminal modification approach employed here might be able to achieve a maximum retention of the heparin-neutralizing ability of protamine. This is because the PEG polymer was conjugated to the N-terminal of protamine, and it was therefore not likely to exert any influence to the binding events that occurred at the C-terminal of protamine. To examine this postulation, a full spectrum of heparin biological assays, including the anti-IIa and anti-Xa chromogenic assays as well as the activated partial thromboplastin time (aPTT) method, was employed. As seen in Figure 5A, the dose required to achieve a complete neutralization of the anti-Xa activity was not significantly affected by PEG conjugation. For instance, each unit of heparin required 3 nmol of protamine to completely neutralize the anti-Xa activity, whereas it would require about 3.2 and 4.3 nmol of PEG^{2000}−protamine and PEG^{5000}−protamine conjugates, respectively, to achieve a full reversal. Interestingly, the sigmoid dose response curve of PEG^{2000}−protamine conjugate almost superimposed with that of native protamine, suggesting a complete retention by the conjugate of protamine's function in neutralizing heparin-induced anti-Xa activity. Figure 5B showed that the anti-IIa activity of heparin was also completely neutralized by protamine, PEG^{2000}−protamine, and PEG^{5000}−protamine conjugates at the protamine/heparin dose ratios of 2, 6.5, and 7 nmol/U, respectively. When comparing with the anti-Xa results seen in Figure 5A, however, PEG modification seemed to result in a larger reduction of the conjugates in protamine's function in neutralizing the anti-IIa activity of heparin. Altogether, the results implicated that conjugation of PEG at the N-terminal of protamine might offset the heparin-neutralizing functions of protamine more on the anti-IIa activity as opposed to the anti-Xa activity.

Heparin neutralization by protamine is often assessed by the activated partial thromboplastin time (aPTT) assay, a method that is used clinically to examine the effects on the intrinsic pathway of the hemostatic system. Figure 5C displays the dose-dependent profiles in the neutralization of heparin's aPTT activity by protamine, PEG^{2000}−protamine, and PEG^{5000}−protamine. As seen, the aPTT activity was completely neutralized by protamine at a protamine/heparin dose ratio of 1.8 nmol/U. On the other hand, this aPTT activity was also completely neutralized by PEG^{2000}−protamine and PEG^{5000}−protamine but at a higher protamine/heparin ratio of 2.3 and 3.9 nmol/U, respectively. Interestingly, the aPTT heparin-neutralizing ability seemed to be inversely proportional to the chain length of PEG, as the protamine conjugate of PEG^{2000} is more potent than that of PEG^{5000} with regard to the heparin neutralizing activity. This phenomenon could be accounted for the fact that the heparin neutralizing ability of PEG−protamine conjugates may be dependent on the size of PEG polymer chain which is presumably in relation to its yielded steric hindrance.

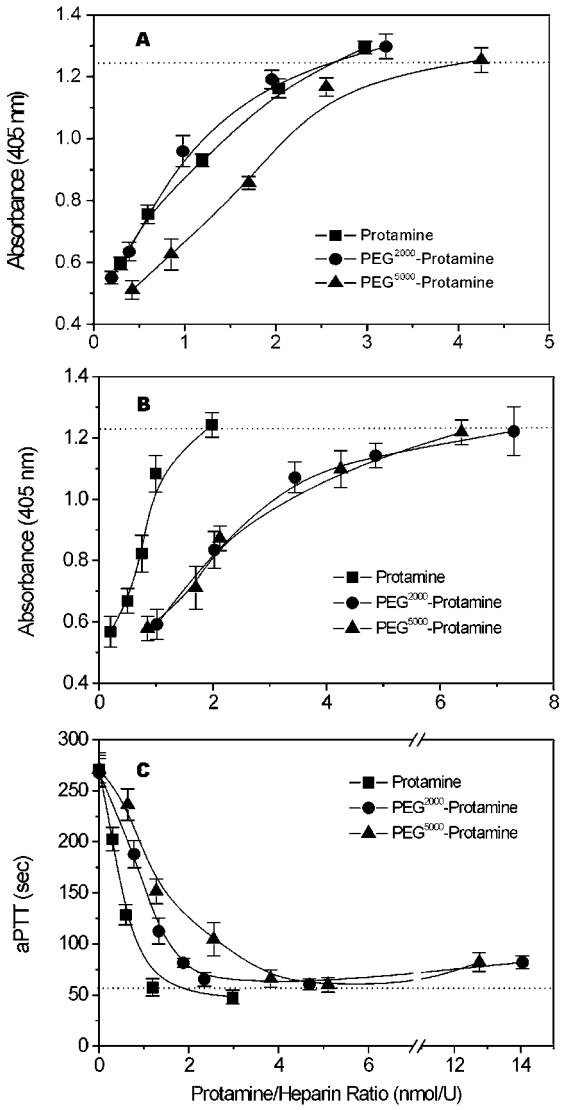

Figure 5. Neutralization of heparin by protamine, PEG^{2000}−protamine, and PEG^{5000}−protamine as measured by (A) anti-Xa, (B) anti-IIa chromogenic assays, and (C) aPTT clotting assay. Dotted line represents the control (i.e. 100% neutralization) for chromogenic assays and the baseline clotting time for clotting assay, respectively.

To further explain the impairment on the anti-heparin ability of the protamine conjugates by PEG modification, it is necessary to consider other factors such as the conjugation site of PEG and the specific binding affinity of protamine toward heparin. It is well documented that thrombin (factor IIa) binds heparin via an electrostatic interaction (*27*), whereas the anti-Xa activity of heparin is mediated by the specific binding of antithrombin III (ATIII) to the pentasaccharide sequence in heparin (*28*). For this reason, neutralization of the anti-Xa activity of heparin would probably require a specific sequence in protamine that possesses a unique heparin binding affinity in order to compete with AT III. If this assumption is true, our previous investigation indicated that this

specific heparin-binding domain evidently would be near the C-terminal of the protamine sequence. To this end, the N-terminal conjugation strategy employed in this study would be very keen in preserving the functions of the PEG−protamine conjugates in neutralizing the anti-Xa activity of heparin. For instance, while the doses required to neutralize the anti-Xa activity of heparin by protamine and the PEG^{2000}−protamine conjugate was about the same, the dose by the PEG^{5000}−protamine conjugate was increased by merely 1.5-fold. On the other hand, since the anti-IIa activity of heparin relies on a nonspecific binding by thrombin, any added PEG polymer chain on protamine would interfere with this nonspecific thrombin binding, resulting in a reduction of the conjugate in neutralizing the anti-IIa activity of heparin. As a consequence, both PEG^{2000}- and PEG^{5000}−protamine conjugates were significantly impaired in their abilities in neutralizing heparin-induced anti-IIa activity, and the doses required to neutralize such a heparin activity was increased by nearly identical 3.5-fold. Because the aPTT activity is mediated by the overall reactions of the coagulation proteins in the intrinsic pathway, it is of no surprise that the impairment on the aPTT neutralization by the conjugates was affected by both PEG conjugation and the chain length of the PEG polymers.

3.3. Complement Function. In general, protamine-induced toxicity is mediated by either a nonimmunological or an immunological pathway (*3*). For the former, the primary event is that the complement proteins bind either to Ig or directly to a particle surface and initiate deleterious complement responses. Therefore, measurements of complement consumption induced by this mechanism can be used as a key index to assess the toxicity of protamine and its PEG-derived analogues. Figure 6A showed the dose-dependent consumption of complement components by protamine and PEG^{5000}−protamine conjugate. As seen, protamine alone did not elicit any detectable complement consumption until its concentration was raised beyond 1 mg/mL, whereas about 30% of complement consumption was seen for the PEG^{5000}−protamine conjugate at a dose of 0.5 mg/mL. Nevertheless, these results did not seem to pose any clinical concern because the concentration was far beyond dose range (i.e. 0.01−0.05 mg/mL) employed clinically following a CPB procedure.

It has been reported that protamine by itself causes the depletion of the complement components in vitro only at a relatively high concentration (*9*). Coadministration of heparin and protamine, however, triggered a significant degree of complement responses at the much lower clinical dose range both in vitro and in vivo (*9*, *10*). Although the exact mechanism of complement activation by heparin and protamine remained unclear, related studies nevertheless suggested that activation of the complement system was mediated by formation of the heparin−protamine complexes, namely HPC. Indeed, this activation requires the HPC aggregates to reach a critical size in order to bind to C1q, the prelude of the activation event, as the binding of C1q moiety with other molecules is known to require the presence of repeating binding sites to bind the multiple heads of C1q molecule (*29*). Therefore, previously we demonstrated that the use of a chain-shortened low molecular weight protamine (LMWP) in HPC formation would significantly attenuate the HPC-induced complement activation in vitro (*20*), primarily due to the presence of an insufficient size or inappropriate structure of the formed HPC.

Following the same theory, protamine (or PEG^{5000}−protamine) was added to serum samples containing an increasing amount of heparin at the dose equivalent to the neutralization ratio (i.e. for each unit of heparin, 10 μg and 50 μg of protamine and PEG^{5000}−protamine were used, respectively, see results in Figure 5) to examine the effects of HPC on the complement system. Figure 6B showed that at a serum heparin concentration between 2.5 and 10 U/mL, which was the dose normally encountered during a cardiovascular surgical procedure, HPC produced by protamine and PEG^{5000}−protamine yielded 60−70% and 40% complement consumption, respectively. Although the CH50 method was a qualitative rather than a quantitative assay for measuring complement activation, the observed difference between these two HPC aggregates clearly suggested that the HPC by PEG^{5000}−protamine yielded significantly reduced complement activation. This phenomenon might be rationalized by the charge neutralization, and shielding effects of PEG on protamine abrogated the unwanted interactions of the formed HPC with complement proteins, alleviating the induced toxic side effects.

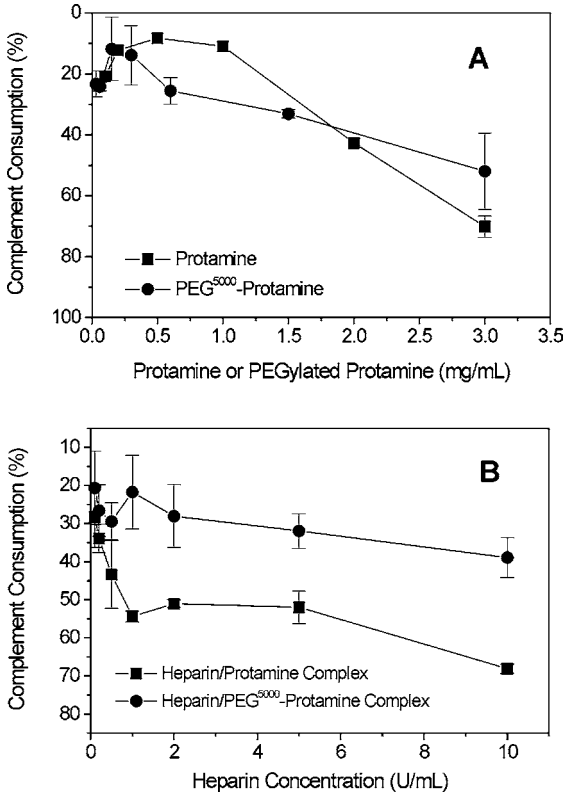

Figure 6. (A) Effects of protamine and PEG^{5000}−protamine alone on complement consumption. (B) Effects of heparin−protamine complexes and heparin-PEG^{5000}−protamine complexes on complement consumption. Complexes were prepared by the addition of protamine (or PEG^{5000}−protamine) to serum samples containing an increasing concentration of heparin at the respective neutralization ratio. That is, for each unit of heparin, 10 μg or 50 μg of protamine and PEG^{5000}−protamine conjugate, respectively, were added for the formation of heparin-(PEG^{5000}−protamine) complexes (HPC).

It has been shown that the CPB-induced inflammatory response can be significantly diminished via the reduction of complement activation. Clinical strategies aimed at reducing complement activation thus far include the use of corticosteroids (*30*), specific complement inhibitors (e.g. compstatin that inhibits the C3-mediated activation (*31*), and anti-properdin monoclonal antibody that would block the interaction of properdin and C3 convertase (*32*)). Although such strategies have been shown to be relatively useful, there still exist concerns of utilizing

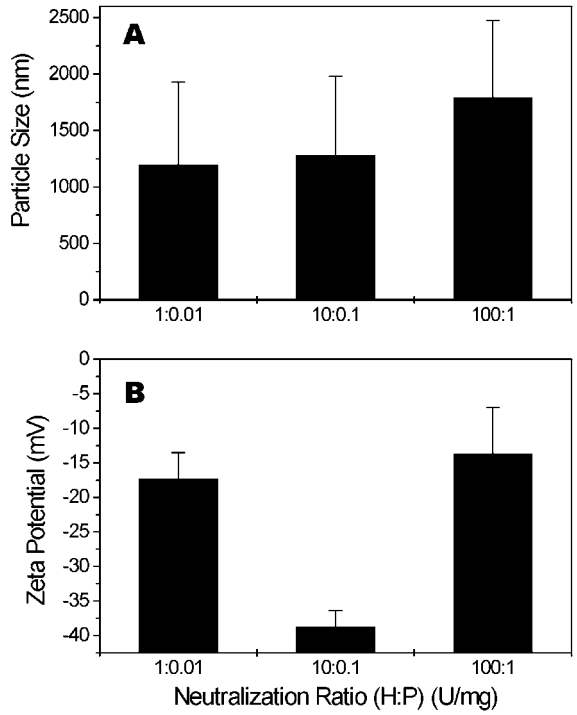

Figure 7. (A) Particle size and (B) zeta potential of the HPC aggregates formed by various amounts of heparin neutralized by their equivalent protamine. Data are presented as mean ± standard deviation.

these approaches, such as that compounds blocking the complement pathways may cause an increased susceptibility to pathogenic infection. Indeed, these drawbacks have already been reported in the literature with the use of soluble complement receptor 1 (sCR1) (*33*). In this regard, our approach by preventing the interaction with complement proteins instead of blocking the complement system should be more beneficial for use in clinical practice.

3.4. Particle Size and Zeta Potential. As discussed previously, complement activation by HPC was governed by their binding with C1q. Therefore, it deems necessary to further examine the particle size and zeta potential of the formed HPC aggregates. To determine the particle size and zeta potential of HPC, three concentrations (i.e. 1, 10, 100 U/mL) of heparin solution were mixed with appropriate amounts of protamine (or PEG−protamine conjugates) by using the previously determined neutralization ratios to yield the HPC aggregates. Figure 7 displayed the size distribution and zeta potential of the formed HPCs. As seen, while HPC aggregates with a mean size greater than 1000 nm occurred at all three test concentrations, the zeta potentials of these aggregates were −17.3, −38.7, and −13.7 for HPC formed with the heparin concentration of 1, 10, and 100 U/mL, respectively. Although the size of the HPC aggregates was sometimes influenced by the mixing speed (i.e. the size might be increased to 5000 nm if mixing of heparin and protamine was conducted more rapidly), the data nevertheless suggested that surface of the HPC aggregates was polyanionic; which was in good agreement with findings reported elsewhere (*34*). On the other hand, the aggregates produced by mixing heparin with PEG−protamine displayed a significantly reduced size, as in the range of ∼60 nm for heparin-PEG^{5000}−protamine complexes (data not shown). In fact, five out of the six measurements did not provide meaningful readings when using the light-scattering detection method, suggesting that the hydrophilic PEG polymer might help solubilize the HPC resulting in virtually no detectable aggregates when mixing heparin with the PEG−protamine conjugates. In concurrence, these PEG−protamine-derived HPC aggregates neither disclosed any meaningful value in the zeta potential measurement because soluble aggregates could not reflect light.

Introduction of PEG to a cationic carrier peptide as a block or graft copolymer is a well-known approach for stabilization of the cationic peptide and DNA complexes in gene delivery systems (*35*, *36*). While the cationic PEG−peptide conjugate hybrids with anionic DNA in an aqueous medium, the electrostatic interaction between anionic DNA segments and cationic counterparts is known to drive the formation of a polyelectrolyte complex inner core, whereas PEG segments constitute a PEG surrounding corona (*37*). In this regard, our result seemed to be in good agreement with this phenomenon that the cationic PEG−protamine conjugate interacted with anionic heparin to form such soluble micelle. As a consequence, the surrounding hydrophilic PEG segments of the core HPC aggregate could not only improve the aqueous solubility of the formed aggregate, but also protect the aggregate from serum protein binding, owing to the steric hindrance effect of the flexible PEG chains.

Rossmann et al. studied the composition of the heparin protamine aggregates in vitro and in vivo using different staining procedures and light or electron microscopy (*34*). The heparin−protamine complexes were described as particles of up to 500 nm in diameter, slightly oval, and sharply contoured. The surface of these aggregates was polyanionic, thus allowing them to bind strongly to scavenger receptor-bearing cells (e.g. macrophage) and trigger varying responses via the release of mediators such as thromboxane A2. Stehle et al. suggested that the amount, size, and charge density of the complexes were the determinants that evoke the deleterious complement responses (*38*). In this study, owing to the possible existence of the polyelectrolyte complex micelles structure between the cationic PEG−protamine conjugate and anionic heparin, a different mechanism by which the PEG−protamine conjugate could function might thus be as follow: First, PEG is a adhesion-resistant polymer that forms a flexible shield on the surface of HPC, avoiding the recognition by the immune system and binding with complement proteins. Second, the grafted hydrophilic PEG polymer enhances the solubility and reduces the size of HPC, therefore decreasing the magnitude of complement responses. (Note: the larger the HPC, the more significant the complement responses). In addition, the increased solubility of PEG−protamine conjugate would improve its stability, compatibility, and bioavailability, favorable pharmaceutical properties for dosage formulation. Overall, modification of protamine with PEG appears to be an attractive strategy to improve the pharmacological/pharmaceutical function of protamine for its important clinical application.

4. CONCLUSION

A simple approach via PEG modification of protamine was successfully used to create a potentially less toxic protamine alternative. On the basis of the selectivity of NHS conjugation chemistry and the unique composition of the protamine sequence, a mono-PEG molecule was covalently linked to the protamine N-terminal residue, producing a linear PEG−protamine conjugate. The conjugates maintain the high reactivity of protamine to heparin and graft the steric effect of PEG to the surface

of the HPC, therefore enabling an improved pharmacological activity. In addition, the grafted PEG polymer increases the solubility of HPC aggregates, a favorable pharmaceutical property for dosage formulation. Thus, it is rational to suggest that the PEG−protamine conjugate could be an effective, but less toxic, protamine alternative. While there is no real alternative for reducing heparin-inducing bleeding risks without inflicting patients with protamine-associated toxic effects presently, the PEG−protamine conjugate discloses many attractive pharmacological and pharmaceutical properties to be a safer heparin antidote. Additional studies focused on investigation of the complement inactivation mechanism, immunogenicity, and in vivo efficacy of the PEG−protamine conjugates are currently in progress in our laboratories.

Cationic Lipids with Increased DNA Binding Affinity for Nonviral Gene Transfer in Dividing and Nondividing Cells

Ajit S. Narang,[†] Laura Thoma,[†] Duane D. Miller,[†] and Ram I. Mahato[†,‡,*]

Departments of Pharmaceutical Sciences and Biomedical Engineering, University of Tennessee Health Science Center, Memphis, Tennessee 38163. Received July 27, 2004; Revised Manuscript Received September 30, 2004

Effect of headgroup structure on catonic lipid-mediated transfection was investigated with either a (i) tertiary amine, (ii) quaternary amine with a hydroxyl, or (iii) quaternary amine with mesylate as headgroups. Liposomes were formulated using cholesterol or dioleoyl phosphatidyl ethanolamine (DOPE) as colipids, and transfection efficiencies were determined in rapidly dividing colon carcinoma (CT 26) and rat aortic smooth muscle (RASM) cells as well as in nondividing human pancreatic islets using luciferase and green fluorescent protein expression plasmids, pcDNA3-Luc and pCMS-EGFP, respectively. Liposome/pDNA complexes were evaluated for DNA conformational state by circular dichroism (CD), DNA condensation by electrophoretic mobility shift assay (EMSA), particle size and zeta potential by laser diffraction technique, and surface morphology by transmission electron microscopy (TEM). Encouraging transfection results were obtained with the mesylate headgroup based lipid in liposome formulations with DOPE as a colipid, which were higher than the commercially available Lipofectamine formulation. We hypothesize that the additional hydrogen bonding or covalent interactions of the headgroup with the plasmid DNA, leading to higher binding affinity of the cationic lipids to pDNA, results in higher transfection. This hypothesis is supported by TEM observations where elongated complexes were observed and more lipid was seen associated with the DNA.

INTRODUCTION

Cationic lipid-based nonviral gene delivery system is an attractive approach for therapeutic gene transfer. Most cationic lipids have three parts: (i) a hydrophobic lipid anchor group, (ii) linker group, such as an ester, amide, or carbamate, and (iii) a positively charged headgroup, which interacts with pDNA, leading to its condensation (*1*, *2*). Among all the basic components of the cationic lipid, the type of headgroup has been shown to have a dominant role in transfection efficiency and toxicity. Three functional properties characterize the activity of any cationic liposome formulation: (i) efficient DNA condensation, (ii) increased cellular uptake due to interaction of positively charged complexes with negatively charged biological surfaces, and (iii) membrane fusion or transient membrane destabilization with the plasma membrane or the endosome to achieve delivery into the cytoplasm while avoiding degradation in the lysosomal compartment (*3*).

Since the introduction in 1987 of the transfection reagent Lipofectin, a 1:1 w/w mixture of the cationic lipid *N*-[1-(2,3-dioleoyloxy)propyl]-*N*,*N*,*N*-trimethylammonium (DOTMA) and dioleoyl phosphatidyl ethanolamine (DOPE) (*4*), many cationic lipids bearing either a single tertiary or quaternary ammonium headgroup or which contain protonatable polyamines linked to dialkyl or cholesterol anchors have been designed for transfection of a variety of cell types in culture (*5*, *6*). Commercially available cationic lipids used as liposome formulations or alone for gene delivery include DOTMA; 2,3-dioleyloxy-*N*-[2-spermine carboxamide] ethyl-*N*,*N*-dimethyl-1-propanammonium trifluoroacetate (DOSPA), 1,2-bis(oleoyloxy)-3-(trimethylammonio)propane (DOTAP), *N*-[1-(2,3-dimyristyloxy)propyl]-*N*,*N*-dimethyl-*N*-(2-hydroxyethyl)ammonium bromide (DMRIE), *3β*-[*N*-(*N*′,*N*′-dimethylaminoethane)carbamoyl]cholesterol (DC-Chol), and dioctadecyl amidoglyceryl spermine (DOGS, Transfectam). A few such compounds have also been used in initial clinical studies (*7*). However, many of the cationic lipids used in early clinical trials such as DC-Chol (*8*), DMRIE (*9*), and GL-67 (*10*), although effective in vitro, have proven inefficient in vivo, especially when compared with viral vectors.

Based on the structures of their cationic headgroups, cationic lipids can be classified into quaternary ammonium lipids, lipopolyamines, cationic lipids bearing both quaternary ammonium and polyamine moieties, amidinium and guanidinium salt lipids, and heterocyclic cationic lipids. A quaternary ammonium headgroup is widely used in many of the established cationic lipids such as DOTAP, DOTMA, and DMRIE, with the exception of Lipofectamine, which is a combination of both a polyamine and a quaternary cation. There are fewer lipids containing a primary, secondary, or tertiary amine headgroup. An example is DC-Chol, with a tertiary amino headgroup linked to cholesterol (*5*).

We have earlier studied the effect of cationic lipid structures, cationic lipid to colipid molar ratios, liposome size, charge ratio, and DNA dose on in vivo gene expression (*11*). Since liposome/plasmid complexes did not disperse well inside the solid tumor after local intratumoral injection (*12*) but showed beneficial effect in tumor regression (*13*), we later developed water soluble lipopolymers for gene delivery (*14*, *15*). Although water

soluble lipopolymers were effective in transfecting various cells, they were not effective in transfecting nondividing human pancreatic islets. Therefore, we decided to use Lipofectamine for gene delivery to human islets. We observed low transfection efficiency, possibly due to poor nuclear translocation, as the nuclear membrane remains intact in these cells at all times (*16*, *17*). This is also because islets are a compact cluster of ~1000 nondividing cells (*18*). To further enhance the transfection efficiency in both dividing and nondividing cells, we have designed novel cationic lipids based on C_{18} monounsaturated oleoyl esters of glycerol backbone to be used as liposomes. C_{18} chain length was selected based on the previous studies by various groups who have shown that carbon chain length significantly influences transfection efficiency, and C_{18} is the most commonly used and efficient in transfection (*3*, *11*, *19*). Moreover, smaller chain length lipids tend to provide more fluidity and weaker binding (*19*, *20*). Furthermore, introduction of unsaturation into carbon chain is known to give higher transfection (*21*).

MATERIALS AND METHODS

RPMI medium 1640 and trypsin−ethylenediaminetetraacetic acid (EDTA) were procured from Gibco, Invitrogen Corporation (Grand Island, NY). Dulbecco's phosphate-buffered saline (DPBS), heat-inactivated fetal bovine serum (FBS), and penicillin (10000 units/mL penicillin G sodium)−streptomycin solution (10000 μg/mL streptomycin sulfate) in 0.85% saline were purchased from Cellgro, Mediatech, Inc. (Herndon, VA). Luciferase Assay System, Luciferase Cell Culture Lysis Reagent 5X (CCLR), and Sca I restriction enzyme were procured from Promega Corporation (Madison, WI). QIAfilter plasmid maxi kit was purchased from Qiagen, Inc. (Valencia, CA); 96-well flat-bottom white LIA plate from Greiner Bio-One, Inc. (Longwood, FL); BCA protein assay kit from Pierce (Rockland, IL); Terrific Broth (Modified), Luria Agar (Miller's LB agar), glycerol, agarose, ethidium bromide aqueous solution (10 mg/mL), 2-propanol, absolute ethyl alcohol, sodium hydroxide pellets, oleoyl chloride, 2-bromoethanol, and various organic solvents including chloroform, acetone, ethanol, methylene chloride, phosphomolybdic acid spray reagent, and *N*,*N*-dimethylformamide (DMF) were purchased from Sigma-Aldrich Co. (St. Louis, MO). SURE-2 supercompetent cells were purchased from Stratagene, Inc. (La Jolla, CA), SOC medium from Invitrogen (Carlsbad, CA), 3-(dimethylamino)-1,2-propanediol, silica gel, and methanesulfonyl chloride from Aldrich Chemical Co., Inc. (Milwakee, WI), deuterated chloroform from Cambridge Isotope Labs, Inc. (Andover, MA), and cholesterol and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) from Avanti Polar Lipids, Inc. (Alabaster, AL). Carbon-coated 300-mesh copper grids were purchased from Electron Microscopy Sciences, Inc. (Fort Washington, PA). pCMS-EGFP plasmid was procured from BD Biosciences Clontech (Palo Alto, CA) and pcDNA3-Luc plasmid was a kind gift from Expression Genetics, Inc. (Huntsville, AL).

Synthesis and Purification. The synthesis scheme of tertiary, quaternary, and mesylate cationic lipids is shown in Figure 1. 3-(Dimethylamino)-1,2-propanediol (I) was reacted with oleoyl chloride (II) in anhydrous chloroform overnight at room temperature. The reaction mixture was extracted sequentially with 0.1 N sodium hydroxide, water and brine followed by dehydration in sodium sulfate and evaporation of chloroform in a rotary evaporator. Complete removal of starting materials was ascertained by ^{1}H nuclear magnetic resonance (NMR) spectroscopy using Bruker ARX-300 (Bruker Biospin

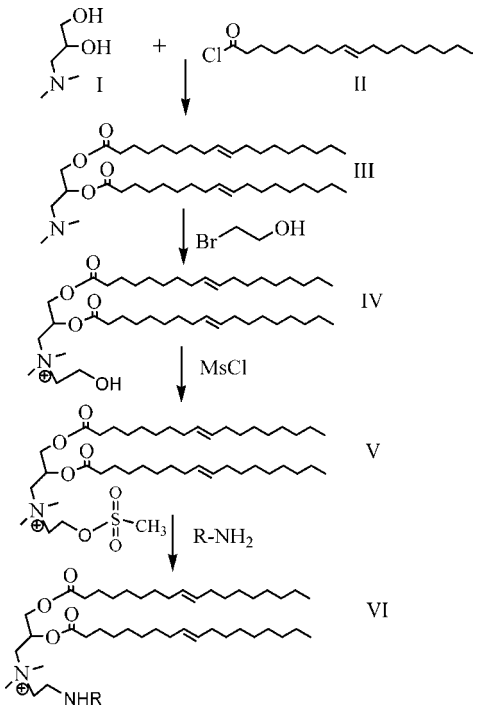

Figure 1. Synthesis scheme for 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP, III), 3-(*N*-2-hydroxyethyl dimethylamino)-1,2-dioleoylpropanediol (HE-DADP, IV), and 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP, V) cationic lipids starting with 3-(dimethylamino)-1,2-propanediol (I) esterification using oleoyl chloride (II), followed by quaternization using 2-bromoethanol and mesylation of the free hydroxyl group. EMS-DADP can be attached to various amine headgroups to yield transfection reagents with the structure (VI).

Corporation, Billerica, MA). The product, 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP, III), was dehydrated in a desiccator and stored at −20 °C (yield >90%). The quaternary amine compound, 3-(*N*-2-hydroxyethyldimethylamino)-1,2-dioleoylpropanediol (HE-DADP, IV), was synthesized by reacting (III) in 1:1 molar quatity in *N*,*N*-dimethylformamide at 105 °C for 24 h followed by solvent evaporation under high vacuum. Reaction conditions were optimized through ^{1}H NMR monitoring to minimize the formation of side products and maximize the reaction yield, which was 80%. The product was identified by both NMR and electrospray ionization-mass spectrometry (ESI-MS) using Bruker Esquire-LC Ion Trap LC/MS (Bruker Biospin Corporation, Billerica, MA). The mesylate derivative, 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP, V), was synthesized by reacting HE-DADP with methanesulfonyl chloride in the presence of triethylamine as the base, in methylene chloride on ice, followed by room temperature, for 3 h. Following characterization using thin-layer chromatography (TLC) using acetone/NaOH medium with spot visualization using phosphomolybdic acid/heat gun treatment, the reaction mixture was extracted using silica gel chromatography using acetone: 0.1 N aqueous NaOH (97/3) as the mobile phase. The Product eluted in the second fraction at an $R_f \sim 0.6$. purified product was identified by both NMR and ESI-MS.

Plasmid Preparation and Purification. Luciferase expression plasmid, pcDNA3-Luc, driven by cytomegalovirus (CMV) promoter, and enhanced green fluorescent protein (EGFP) expression plasmid, pCMS-EGFP, were transformed in SURE-2 supercompetent cells. Colonies were grown in 50 μg/mL ampicillin containing LB Agar

plates, followed by growth of single colonies in ampicillin containing terrific broth media. After sufficient bacterial growth, the cells were pelleted by centrifugation at 5000*g* and 4 °C for 20 min followed by plasmid extraction using QIAfilter plasmid maxiprep kit as per vendor's protocol. Plasmid purity was assessed by UV spectrophotometry ($A_{260/280} > 1.75$), agarose gel electrophoresis, and restriction digestion using *Sca I* enzyme.

Preparation of Liposomes and Lipid/Plasmid Complexes. Liposomes were prepared from a cationic lipid and a colipid (cholesterol or DOPE) at various molar ratios. Briefly, lipids were mixed in chloroform at desired molar ratios and evaporated to dryness in a 50-mL round-bottom flask using a rotary vacuum evaporator. Ethanol was used in the case of EMS-DADP due to the limited solubility of the mesylate compound in chloroform. The lipid film was hydrated in purified water to produce multilamellar vesicles, which were passed through an extruder (Lipex Biomembranes, Vancouver, Canada) using 100, 400, and 800 nm pore size polycarbonate membrane 10 times. The liposomes were stored at 4 °C as colloidal dispersions until used.

Plasmid and cationic liposomes were diluted separately to a volume of 250 μL with a final glucose concentration of 5% w/v, and then the DNA was added to the liposomes with mild mixing by pipeting. Complex formation was allowed to proceed for 45 min at room temperature. Lipid/plasmid complexes of different charge ratios were prepared by adjusting the stoichiometry of plasmid and cationic liposomes. The complexes were characterized for condensation efficiency, particle size, and ξ-potential as described previously (*11*, *22*, *23*). Briefly, complex formation and DNA condensation were determined using 1% agarose gel electrophoresis at 60V. The mean particle size of lipid/plasmid complexes was determined at 90° by dynamic light scattering using 90Plus Particle Sizer (Brookhaven Instruments Corp., Holtsville, NY). Particle size data is reported as a mean ± SD of three samples. ξ-Potential was measured by measuring electrophoretic mobility in aqueous solution at 25 °C and pH 7 utilizing a 30 mW laser and 0 to 3.2 kV/m field strength. The ξ-potential is reported as an average of 10 separate readings for a single sample.

Cell Culture and Transfection. Colon carcinoma (CT-26) and rat aortic smooth muscle (RASM) cells were cultured in 162 cm^2 flasks in RPMI 1640 media supplemented with 10% FBS and 1% penicillin/streptomycin antibiotic−antimycotic mixture. About 50 000 cells were plated in each well of 12-well cell culture plates. When the cells reached ~80% confluency (about 48 h after plating), cells were washed with cold Dulbecco's phosphate buffered saline (DPBS) and were incubated with cationic liposome/pDNA complexes in 500 μL serum free medium. At 6 h posttransfection, the culture media was replaced with serum containing media. In the case of EGFP expression plasmid, cells were incubated for additional 46−48 h and analyzed for transfection efficiency by fluorescence microscopy and flow cytometry. For luciferase expression plasmid, 48 h posttransfection the cells were washed with cold PBS and lysed in 500 μL of luciferase cell culture lysis reagent. Total protein was measured using BCA protein assay kit. Luciferase activity was measured in terms of relative light units (RLU) using a 96-well plate Labsystems Luminoskan RS luminometer (Albertville, MN). Human pancreatic islets were isolated, purified, counted, and cultured as described earlier (*16*, *17*). For transfection experiments, 1000 I.E. were suspended in 48-well plates and incubated for 12 h with pDNA/liposome complexes at the dose of 1 μg/well, followed by addition of more media and incubation at 37 °C in 5% CO_2 incubator for 48 h until cell lysis. $N = 6$ replicas were used for each sample.

Circular Dichroism. Circular dicrhroism (CD) spectra of plasmid DNA and pDNA/liposome complexes were obtaind using the Aviv 62A spectrometer (Lakewood, NJ). Samples were scanned through a wavelength range of 220−360 nm at 25 °C using a 0.5 mL quartz cuvette, with a path length of 1 cm. Each sample was scanned four times with an integration time of 5 s, and the values were averaged. Scanning was done at 1 nm steps, and the slit width was 1 nm. Liposome/pDNA complexes were prepared at 3/1 +/− charge ratio at 50 μg/mL pDNA concentration. Sample values were subtracted from those obtained for dextrose solution (for pDNA) or corresponding liposome solution in dextrose (for liposome/pDNA complexes) as blank.

Transmission Electron Microscopy. Liposome/pDNA complexes prepared at 3/1 (+/−) charge ratio were visualized by transmission electron microscopy (TEM) using 300-mesh carbon coated copper (Cu) grids, at 60 kV and magnifications ranging from 40 000× to 300 000×. Complexes were prepared at 3/1 charge ratio and 0.01 μg/μL pDNA concentration. Ten microliter complexes were loaded on the Cu grid for 2 min followed by blotting of the excess liquid and incubation for another 2 min with 1% uranyl acetate followed by blotting. The grid was air-dried for another 2 min and visualized under the electron microscope. Digital images were captured using the instrument software.

Statistical Analysis. Statistical significane of differences between samples was evaluated using one-way and two-way ANOVA using SPSS software (SPSS Inc., Chicago, IL) with Tukey's posthoc analysis. Significance level used for all studies was $p = 0.05$.

RESULTS

Syntheses and Purification. Tertiary amine (DADP, III), quaternary amine (HE-DADP, IV), and mesylate (EMS-DADP, V) derivatives of a two-chain fatty acid containing cationic lipid with only one positively charged headgroup were synthesized using dimethylaminoglycerol (I) as a template (Figure 1). Oleoyl chloride (II) was conjugated to the free hydroxyls of the glycerol backbone by esterification in chloroform followed by extraction in a series of aqueous solutions to give DADP. DADP was converted to HE-DADP by reaction with 2-bromoethanol in *N*,*N*-dimethylformamide, followed by mesylation in methylene chloride to yield EMS-DADP. Purity of the isolated compounds was assessed by both NMR and electrospray ionization-mass spectroscopy (ESI-MS). The mesylate compound was further converted to polyamine derivative (VI) using polyethyleneimine of low molecular weight (PEI 423) by simple heating.

NMR results of DADP are as follows (Figure 2a). ^{1}H NMR (300 MHz, chloroform-d_1): δ ~0.8−1.0 ppm (H of terminal (CH_3) of lipid chains (a)); δ ~1.2−1.7 (H of (CH_2) methylenes of lipid chains except the ones neighboring the double bond and the carbonyl (b)); δ ~2.0−2.1 (H of (CH_2) methylenes of lipid chains neighboring the double bond (c)); δ ~5.3−5.5 (H of (CH=) groups of lipid chains participating in double bond (d)); δ ~2.1−2.3 (H of (CH_3) methyl groups attached to the tertiary nitrogen (e)); δ ~4.3−4.4 (H of (CH_2) methylene of glycerol backbone (f)); δ ~2.2−2.4 (H of (CH_2) methylenes next to carbonyl on the lipid chains (g)); δ ~4.1 (H of (CH) from the glycerol backbone (h)); δ ~2.3−2.5 (H of (CH_2) methylene of the glycerol backbone connecting the amine (i)).

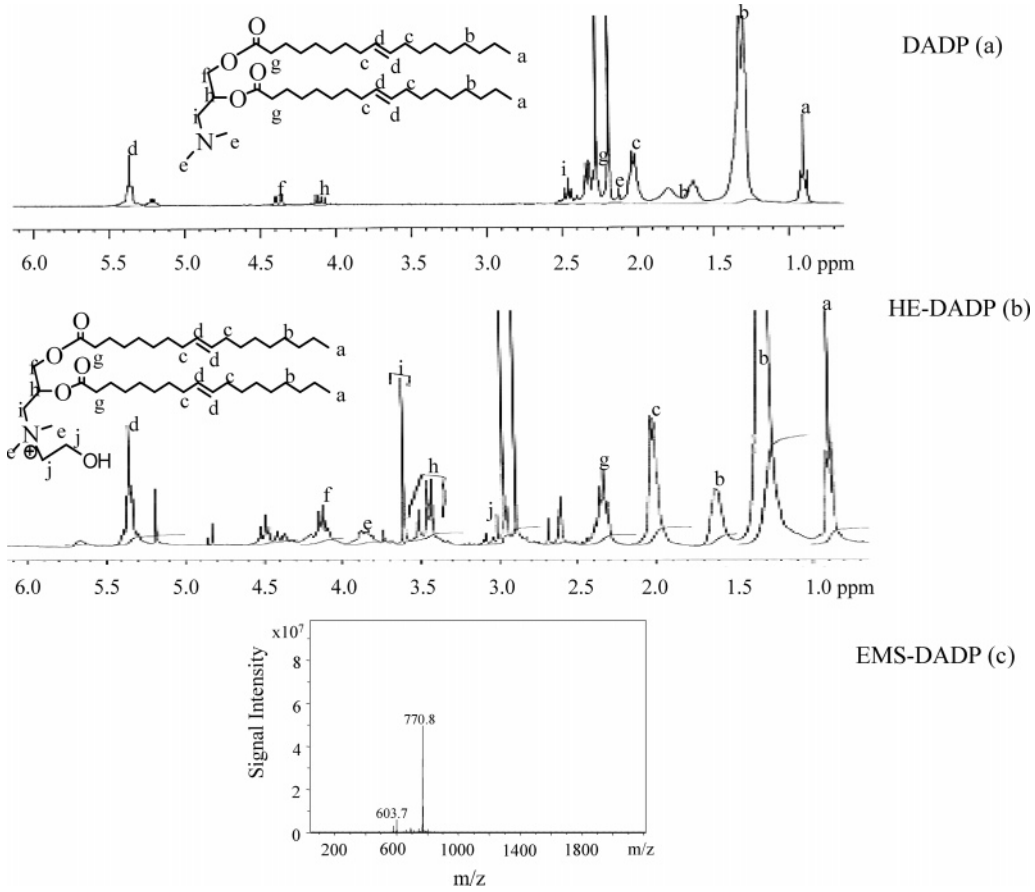

Figure 2. Proton nuclear magnetic resonance (NMR) spectra for 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP, III) and 3-(*N*-2-hydroxyethyl dimethylamino)-1,2-dioleoyl propanediol (HE-DADP, IV) and electrospray ionization (ESI) mass spectrum (MS) for 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP, V).

NMR results of HE-DADP are as follows (Figure 2b). ^{1}H NMR (300 MHz, chloroform-d_1): δ ~0.9 ppm (H of terminal (CH_3) of lipid chains (a)); δ ~1.2−1.7 (H of (CH_2) methylenes of lipid chains except the ones neighboring the double bond and the carbonyl (b)); δ ~2.1 (H of (CH_2) methylenes of lipid chains neighboring the double bond (c)); δ ~5.4 (H of (CH═) groups of lipid chains participating in double bond (d)); δ ~3.8−3.9 (H of (CH_3) methyl groups attached to the tertiary nitrogen (e)); δ ~4.1−4.2 (H of (CH_2) methylene of glycerol backbone (f)); δ ~2.2−2.4 (H of (CH_2) methylenes next to carbonyl on the lipid chains (g)); δ ~3.3−3.5 (H of (CH) from the glycerol backbone (h)); δ ~3.6 (H of (CH_2) methylene of the glycerol backbone connecting the amine (i)); δ ~2.9−3.1 (H of (CH_2) methylenes of hydroxy ethanol attached to the quaternary nitrogen (j).

EMS-DADP was also analyzed by NMR; however, the spectrum was too complicated to clearly distinguish product formation (data not shown). Hence, product formation and purity of EMS-DADP were assessed by the ESI-MS appearance of the molecular ion peak (770.8 corresponding to M. W. of 770, Figure 2c).

DNA Condensation. To determine the effect of cationic lipid headgroup structures, cationic lipid-to-colipid ratio, cationic lipid to pDNA charge ratio, and pH on DNA condensation, pDNA complexes were prepared by adjusting the stoichiometry of plasmid and cationic liposomes, using liposomes prepared from a cationic lipid (DADP, HE-DADP, or EMS-DADP) and a colipid (cholesterol or DOPE) at various molar ratios. Effective DNA condensation was achieved with cationic liposomes prepared using HE-DADP or EMS-DADP at charge ratios 3/1 and above, as no mobility of pDNA was observed at these charge ratios (data not shown). In contrast, DADP was relatively inefficient at DNA condensation, as some free DNA was seen even at 5/1 (+/−) charge ratio (data not shown). At a given charge ratio, cationic lipid to colipid molar ratios had little influence on DNA condensation (data not shown).

Formulation Factors Influencing Transfection Efficiency. The effect of various physicochemical parameters on in vitro transfection into CT-26 colon carcinoma cells was examined as a function of cationic lipid headgroup structure, colipid type, cationic lipid/colipid molar ratio, cationic lipid/DNA charge ratio, and liposome size.

The headgroup of most effective cationic lipids is either a polyamine or a quaternary amine, with the exception of Lipofectamine, which is a combination of both the motifs. Lipofectamine is composed of the cationic lipid DOSPA with colipid DOPE at 3/1 weight ratio. Since Lipofectamine gives one of the best transfection efficiencies and was used in our previous studies on gene delivery to human pancreatic islets (*16*, *17*), we compared the transfection efficiency of this commercially available reagent with our newly synthesized DADP, HE-DADP, and EMS-DADP lipid-based formulations. Transfection efficiency is reported as % relative light units (RLU) per mg of total protein content, expressed as a percentage of the transfection activity observed with Lipofectamine. Each bar in Figure 3 represents an average of six samples, with standard deviation being ≤10%.

The molar ratio of cationic lipid to colipid influences the surface chemistry of lipid/plasmid complexes and phase transition temperature of the liposomes. This may affect the plasmid uptake, opsonization, and endosomal

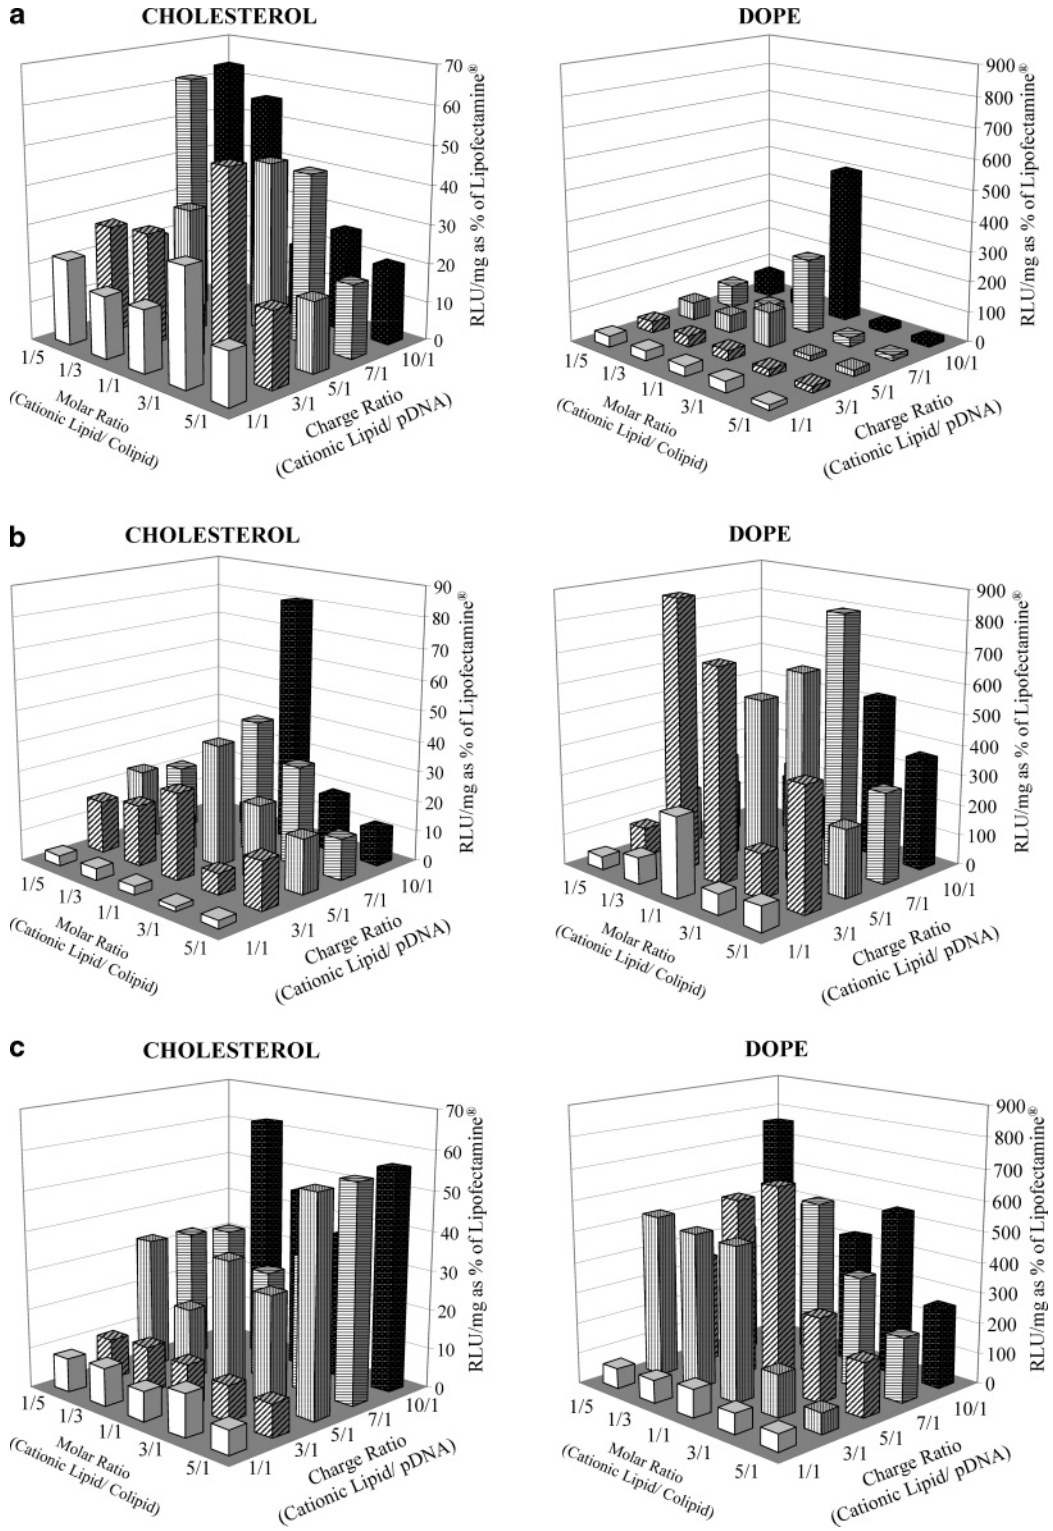

Figure 3. Transfection efficiency of liposomes prepared with 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP) (a), 3-(*N*-2-hydroxyethyldimethylamino)-1,2-dioleoylpropanediol (HE-DADP) (b), or 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP) (c) lipid derivatives prepared with cholesterol or DOPE as a colipid, as % relative light units (RLU) measured by luciferase assay, per mg of protein for $n = 6$. Transfection efficiency of Lipofectamine was considered 100% for comparison purpose.

release thus affecting the efficiency of gene expression. Most of the cationic liposome formulations incorporate colipids, but the colipid amount does not normally exceed 50% because of the need for high cationic lipid content to complex with and neutralize the large number of negative charges of DNA.

As shown in Figure 3, transfection efficiency was strongly influenced by the relative proportions of cationic lipid, colipid, and plasmid DNA. In general, at a fixed DNA concentration, the cationic lipid dose−response curves were bell-shaped due to the toxicity of cationic lipid at higher dose or charge ratios. The transfection efficiency of these cationic lipids was in the following order: DADP < HE-DADP < EMS-DADP. The use of cholesterol as a colipid showed poor transfection, while DOPE as a colipid gave higher transfection.

Transfection efficiency of DADP was higher for the 3/1 molar ratio of cationic lipid/colipid while decreasing on

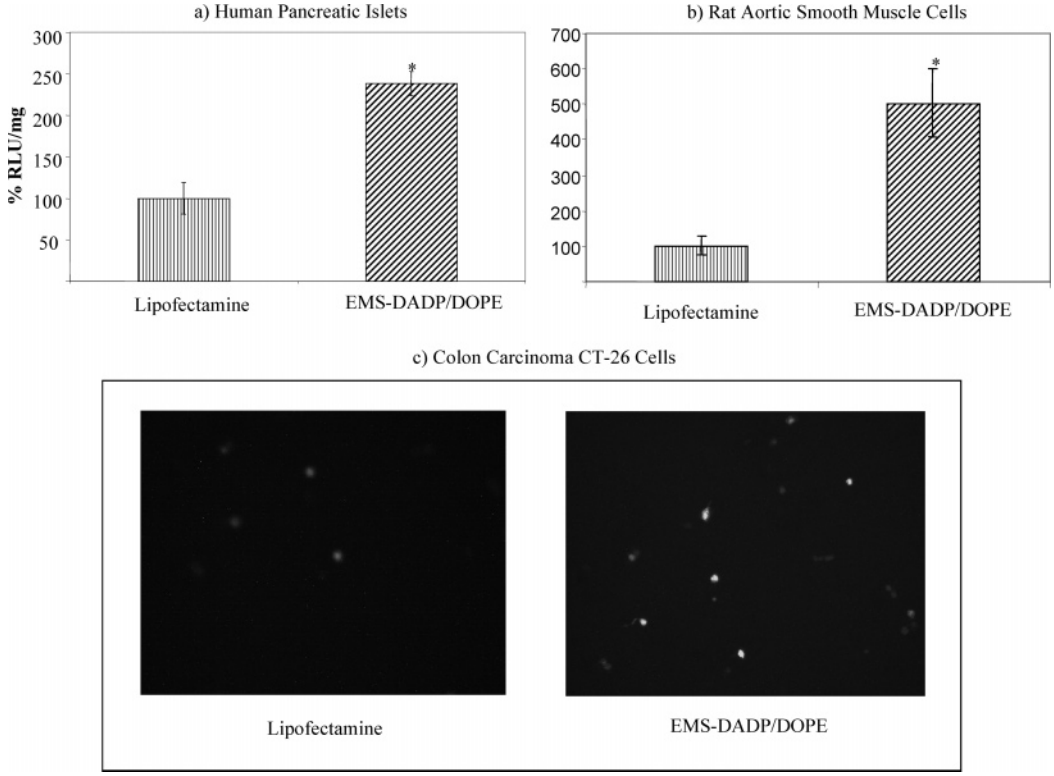

Figure 4. Transfection efficiency of pcDNA3-Luc/EMS-DADP (3/1, +/−) complexes in human pancreatic islets (a) and in rat aortic smooth muscle cells (b), by luciferase assay, and of pCMS-EGFP//EMS-DADP (3/1, +/−) complexes in colon carcinoma CT-26 cells (c), by fluorescence microscopy. (*) indicates statistically significantly ($p < 0.05$) differences in transfection efficiency by two-way ANOVA analysis.

either side, except for the 10/1 (+/−) cationic lipid/pDNA charge ratio for transfection. With respect to the influence of charge ratio, in liposomes with higher cholesterol content (1/5 and 1/3 molar ratios) transfection efficiency was higher with increasing charge ratios while liposomes with equal or less colipid content (1/1, 3/1, or 5/1 molar ratios) showed higher transfection efficiencies at intermediate charge ratios of 3/1 and 5/1.

HE-DADP showed a distinct trend of higher transfection activity at 1/1 molar ratio and decreasing trend with an increase in either the cationic or the colipid component of liposomes. However, the transfection efficiency of DADP, HE-DADP, and EMS-DADP was less when cholesterol was used as a colipid compared to Lipofectamine, with none of them exceeding 80% of the efficiency observed with Lipofectamine (Figure 3a). In contrast, transfection efficiency was signficantly higher for HE-DADP and EMS-DADP when DOPE was used as a colipid for liposome preparation. There was, furthermore, a clear trend of the transfection being dependent on the molar ratio of cationic lipid/colipid with 1/1 ratio giving higher activity than increasing the content of either component. HE-DADP and EMS-DADP/DOPE liposome/pDNA complexes, however, presented much higher transfection efficiency than DADP (∼2−5 times), as well as the commercially available reagent Lipofectamine (∼5 times) (Figure 3b). In the case of EMS-DADP/DOPE liposomes, the transfection activity was higher at higher molar ratios of DOPE.

We have previously reported that transfection efficiency of Lipofectamine/pCAGGS-hVEGF complexes into human islets is low and dependent on the incubation period of islets with the complexes (*16*, *17*). There are also reports of low transfection of Lipofectin/pDNA, Lipofectamine/pDNA, DOSPA:DOPE liposome/pDNA, and polyethylenimine (PEI)/pDNA complexes into intact mouse, rat, and porcine islets (*26*). Unlike the 3:1 w/w ratio Lipofectamine/pDNA used in the present study, Benhamou et al. (*24*) used relatively large amount of cationic lipid (DOTAP, complexes were formulated at 12/1 DOTAP/pDNA weight ratio). These authors also suggested that islet transfection is predominantly in the peripheral cells due to the relative inaccessibility of the central core cells to the vector. Low transfection efficiency in islets was also reported by Saldeen et al. (*25*) To compensate for low transfection efficiency, some workers transfect the dispersed islet cells, as opposed to intact islets, which gives higher transfection due to greater number of cells becoming exposed to the transfection agent after dispersion (*24*, *26*). This, however, often compromises the glucose response function of β-cells and will not be suitable for transplantation (*25*). In the present study, transfection efficiency was observed to be ∼2.5 times higher than Lipofectamine in the human pancreatic islets, and ∼5 times in RASM cells (Figure 4 a,b). In an attempt to further enhance transfection efficiency in human islets, we are in process of testing our lead formulations in conjunction with fusogenic peptides.

We also analyzed GFP positive CT-26 cells by flow cytometry after transfection with Lipofectamine and the lead formulation EMS-DADP/DOPE (1/1) complexed with pDNA at 3/1 (+/−) charge ratio. The results indicated that the transfection efficiency for EMS-DADP/DOPE liposomes was ∼1.5 times higher than Lipofectamine. Concurrent fluorescence microscopic observations of the same samples indicated higher levels of and difference in GFP expression. This could be because flow cytometric analysis would only capture cells that are relatively brightly fluorescent.

We and others (*3*, *11*, *27*) have shown that the transfection efficiency of larger size liposomes is higher than small size liposomes. To test the validity of this observa-

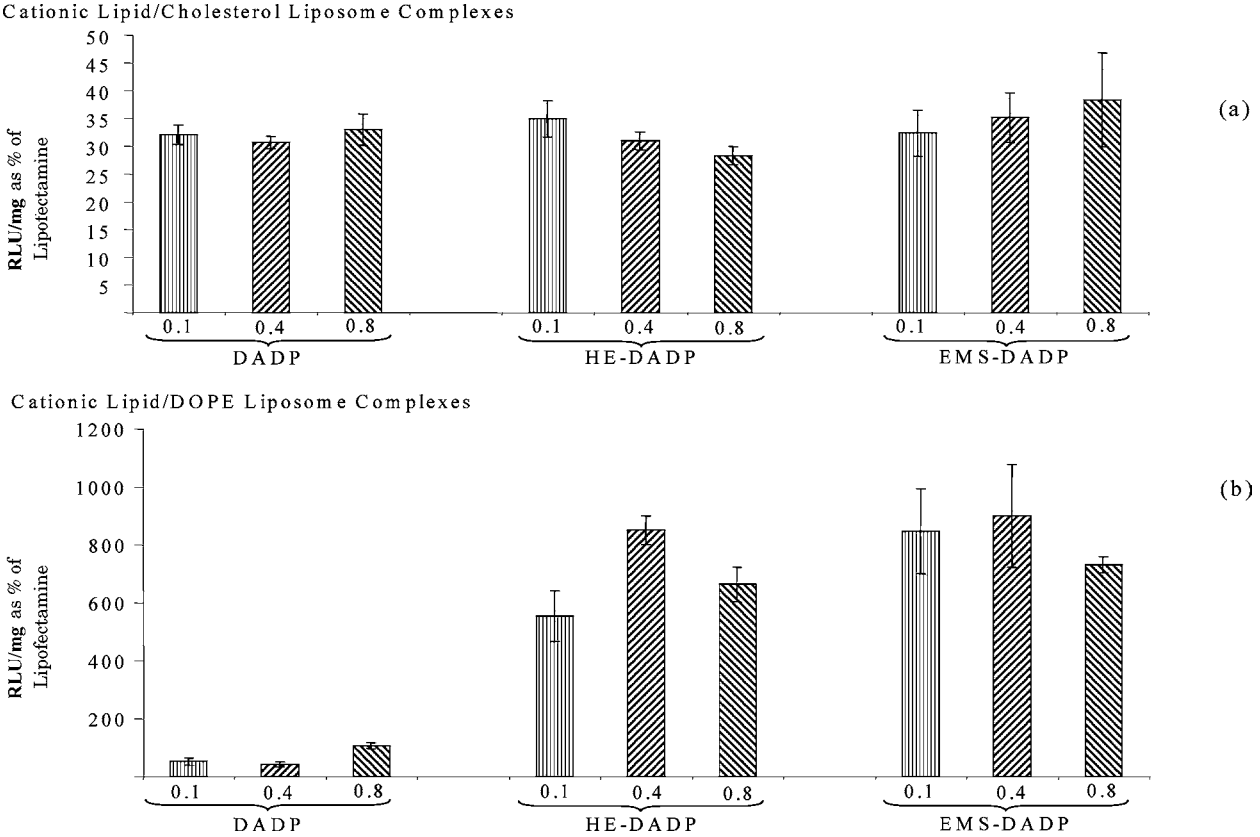

Figure 5. Effect of liposome size on transfection efficiency of pDNA/liposome complexes using DADP, HE-DADP, and EMS-DADP liposomes, extruded through 0.1, 0.4, and 0.8 μm polycarbonate membranes, using (a) cholesterol or (b) DOPE as a colipid. Transfection activity is expressed as % relative light units (RLU) measured by luciferase assay per mg of protein for $n = 6$. Transfection efficiency of Lipofectamine was considered 100% for comparison. There was no significant difference ($p = 0.05$) in transfection efficiency between different liposome size samples of the same lipid-based formulations.

tion with our novel lipids, we examined the effect of liposome size on transfection efficiency by extrusion of liposomes through 100, 400, and 800 nm pore size polycarbonate membranes and complex formation with pcDNA3-Luc at 3/1 (+/−) charge ratio (Figure 5). In the present study, liposome size did not show any significant effect on transfection efficiency for DOPE and cholesterol-based liposome/pDNA complex formulations, since 100, 400, and 800 nm extruded liposomes showed similar %RLU/mg total protein (Figure 5).

Particle Size and Zeta Potential. Particle diameter of liposome/pDNA complexes (Figure 6a) was ~500 nm for DADP and HE-DADP with both colipids, while EMS-DADP had a larger particle size (~1.0 μm with cholesterol as a colipid and ~1.8 μm with DOPE as a colipid). The particle size of complexes of all liposomes was larger than that of Lipofectamine and was closer to the membrane size used for extrusion of liposomes i.e., 400 nm (Figure 6a).

Zeta potential of liposome/pDNA complexes was ~ +40mV for both HE-DADP and EMS-DADP liposomes with either cholesterol or DOPE as colipids (Figure 6b). These were comparable to the zeta potential observed for Lipofectamine, ~ +45mV. The ξ-potential for complexes with DADP liposomes was, however, on the negative side (~−15mV). This was indicative of insufficient positive charge on the tertiary nitrogen to cause effective DNA condensation.

Circular Dichroism. Circular dichroism spectra were recorded for naked plasmid and lipid/plasmid complexes in 5% dextrose solution. Since dextrose is a chiral molecule, CD spectra of dextrose alone was subtracted from that of pDNA in dextrose solution to obtain the profile for pDNA. Similarly, the spectra of complexes were recorded with background normalization to the profiles of corresponding liposomes alone in dextrose solution. The spectra were recorded from 220 nm to 360 nm to observe changes in the conformation of pDNA arising from its interactions with the cationic lipids. The charge ratio of cationic lipids to pDNA as well as the molar ratio of cationic lipids to colipids was kept constant in order to delineate the differences arising from different structures of cationic lipids. The CD spectra of naked DNA and lipid/plasmid complexes are shown in Figure 7. The spectrum of naked DNA presented B-type DNA curve. The CD spectra of liposome/pDNA complexes indicated a significant change in DNA conformation being brought about by the interaction with cationic lipids. CD spectra of Lipofectamine/plasmid complexes were also recorded as a positive control. These data indicated that the difference in transfection efficiency obtained with these different liposome formulations could not be directly correlated to the change in DNA conforamation/winding of the duplex brought about by the cationic lipids.

Transmission Electron Microscopy. Morphology of lipid/plasmid complexes was visualized at magnifications of 40000 to 300000 under the transmission electron microscope after negative staining of DNA using uranyl acetate. The complexes formed with cationic lipids were compared with those formed with Lipofectamine (Figure 8a). The complexes with EMS-DADP had the tendency to be elongated and have more surface area than those formed with Lipofectamine, which were relatively compact. Furthermore, some incompletely condensed pDNA molecules could be visualized in these samples (Figure 8b), which indicated that a significantly higher amount

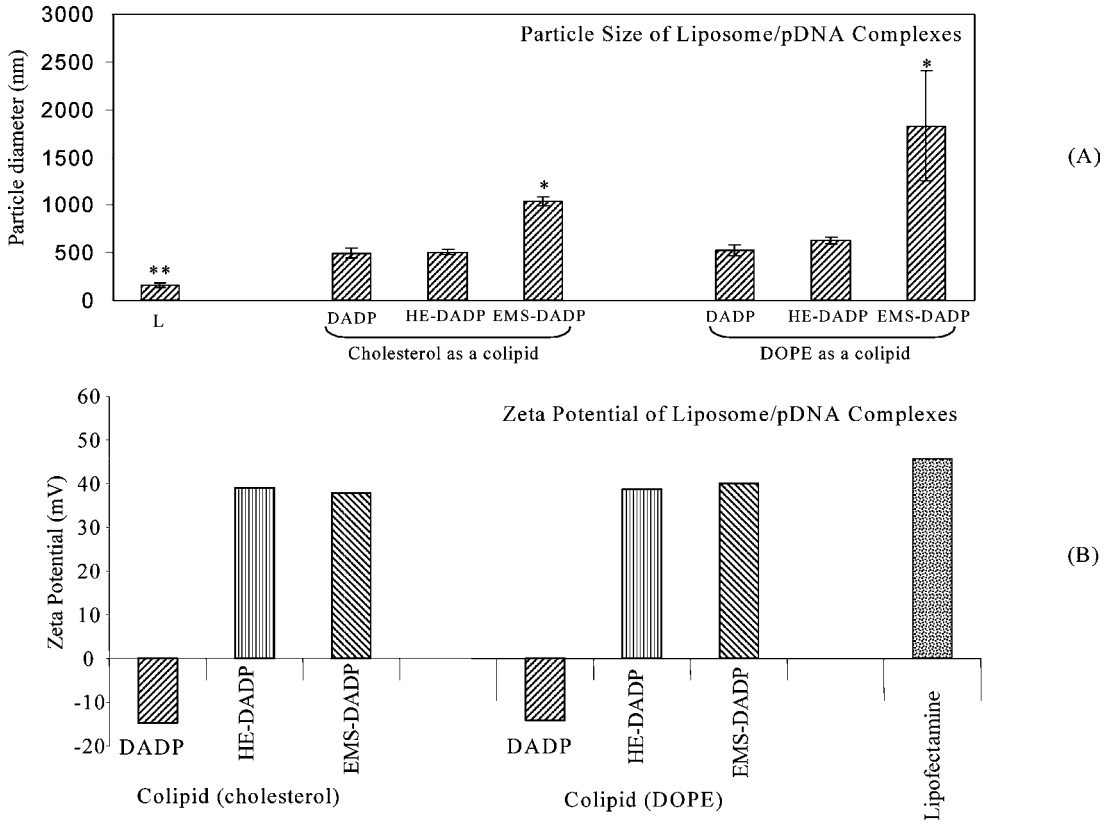

Figure 6. Particle size (a) and zeta potential (b) of liposome/pDNA complexes prepared at 3/1 (+/−) charge ratio using either 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP), 3-(*N*-2-hydroxyethyldimethylamino)-1,2-dioleoylpropanediol (HE-DADP), or 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP) as a cationic lipid and cholesterol or DOPE as a colipid at 1/1 molar ratio. Lipofectamine/pDNA complexes (3/1 molar ratio) were used as a control. (*) indicates statistically significant difference of these EMS-DADP samples from DADP, HE-DADP, and Lipofectamine. Lipofectamine (**) sample was significantly different from all other samples. Two-way ANOVA was used to assess statistical signficance of differences at $p < 0.05$ level. Significance tests could not be applied to the zeta potential data since it was based on only one sample readings.

of the lipids were attached to the DNA molecules in the case of EMS-DADP than Lipofectamine.

DISCUSSION

Cationic lipid structure, colipid type, lipid/DNA ratio, cationic lipid/colipid ratio, and liposome size have been shown to influence gene transfer efficiency both in vitro and in vivo (*2*, *3*, *11*). Here we report the effect of these parameters on the transfection efficiency of our newly synthesized cationic lipids in vitro. These lipid derivatives have two C_{18} oleoyl lipid chains attached to the glycerol backbone through an ester linkage. To the C-3 carbon of the glycerol backbone is attached either a tertiary or a quaternary amine as a hydrophilic headgroup. A review of research (*2*−*4*, *28*−*35*) and review (*36*−*42*) papers, and patents (US 5550289, 4897355, 5736392, 5527928, 5744625, 5892071, 5869715, 5171678, 5824812, 6251433, 6376248, 6051429, 6087325, 6143716, 6339069, 5736392, 5334761, and 6346516), revealed various design features and structure−activity relationships of cationic lipids. On the basis of this information, it was concluded that a two chain symmetrical C_{18} mono-unsaturated oleoyl ester chain based lipid conjugate would be the most suitable with a glycerol backbone connecting it to the cationic headgroup.

Significant differences were observed in the transfection efficiency of the three lipid derivatives prepared viz. DADP, HE-DADP, and EMS-DADP (Figure 3). The charge ratio of cationic lipid to pDNA, type of colipid, and molar ratio of cationic lipid to colipid affected the transfection efficiency of liposome/plasmid complexes. One possible reason for different transfection efficiency is the difference in their DNA condensing ability. Unlike most quaternary lipids currently being used for transfection, HE-DADP has an additional hydroxyl functionality separated from the quaternary amine by a two-carbon chain alkyl moiety that confers to it a distance of ∼ 5 Å. The hydroxyl group can participate in hydrogen bond formation as both a hydrogen bond donor and/or acceptor. The distance of the hydroxyl group from the quaternary amine correlates with the molecular distances within the DNA bases, indicating a possibility of concurrent hydrogen bond interactions along with electrostatic interactions, thus leading to better DNA condensation.

On the basis of the high transfection obtained with lipid/plasmid complexes prepared at 3/1 (+/−) charge ratio and 1/1 molar ratio of cationic lipid/colipid, we selected formulations of DADP, HE-DADP, and EMS-DADP with both cholesterol and DOPE as colipids for further studies. Plasmid DNA solution in water was used as a control. We hypothesize that the higher transfection efficiency of HE-DADP and EMS-DADP is due to stronger interactions between cationic lipid and plasmid DNA that originate in the presence of the hydroxyl functionality in HE-DADP and the methylsulfonate group in the case of EMS-DADP. The hydroxyl group has the potential for hydrogen bonding interactions both as a hydrogen bond donor as well as an acceptor. The position of the hydroxyl group on HE-DADP is such that it is only two carbons away from the positively charged nitrogen. Given the interaction of the positive nitrogen with the negative phosphate on the DNA backbone, which would bring the

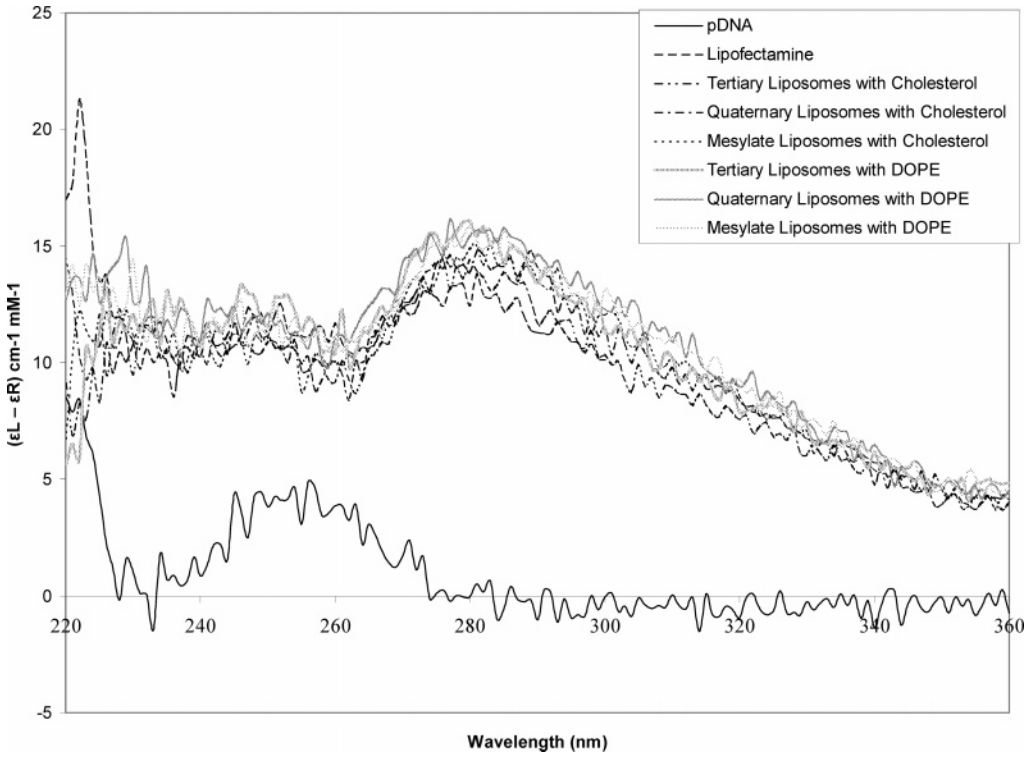

Figure 7. Circular dichroism (CD) spectra of lipid/plasmid complexes. Liposomes were prepared at 1/1 molar ratio of either 3-(dimethylamino)-1,2-dioleoylpropanediol (DADP), 3-(*N*-2-hydroxyethyldimethylamino)-1,2-dioleoylpropanediol (HE-DADP), or 3-(*N*-ethyl-2-methanesulfonyldimethylamino)-1,2-dioleoylpropanediol (EMS-DADP) as a cationic lipid and cholesterol or DOPE as a colipid. Complexes were prepared at 3/1 charge ratio of cationic lipid/colipid, and CD was recorded at a pDNA concentration of 50 μg/mL. The CD spectra has been compared to the profile for pDNA alone. Spectral profiles of liposomes with dextrose or of dextrose alone were subtracted as blank.

headgroup of the cationic lipid in close proximity to the DNA, the hydroxyl group possibly engages in hydrogen bonding interactions, either directly or through water bridge(s), with the neighboring polar or charged groups on the surface of DNA duplex. Multiple hydrogen bonding interaction of the cationic lipids with surface charged groups on the DNA double helix would be sufficient to significantly increase the overall strength of interaction between the lipid and the plasmid DNA.

In the case of EMS-DADP, the presence of the uncharged, bulky methanesulfonyl group above the quaternary amine headgroup is expected to hinder the electrostatic interactions between the positively charged nitrogen with the negatively charged phosphates on the DNA backbone. However, the transfection efficiency of EMS-DADP was not reduced compared to the quaternary compound, HE-DADP. Mesylates have been shown to alkylate DNA (*43*−*47*) and can react with amine functionalities in aqueous conditions at room temperature (*48*). Furthermore, the steric positioning of the mesylate group is expected to be close to the neighboring phosphates on the surface of double stranded DNA molecule, when the quaternary nitrogen forms electrostatic bonds with the anionic phosphates. The mesylate group, therefore, possibly forms a covalent bond or engages in hydrogen bonding interactions through the water bridges.

We have earlier evaluated in vivo transfection efficiency of cationic liposomes in mice after tail vein injection of lipid/plasmid complexes. Human growth hormone (hGH) gene expression level in the serum was about 6-fold higher when 400 nm extruded liposomes were used compared to 100 nm extruded liposomes (*11*). Ross et al. (1999) also observed a linear increase in lipoplex association, cellular uptake, and gene expression with increase in liposome size, composed of DOTAP as the cationic lipid and DOPE as the colipid (*49*). Also, Zelphati et al. (1998) have shown the transfection activity to be almost double for an increase in particle size from 100 nm to 400 nm (*50*). Felgner et al. (1994) have evaluated different particle size formulations of the cationic lipid DORIE, which is very similar to our lipid HE-DADP, and observed a 2-fold difference in the transfection efficiency of larger multilamellar vesicles and smaller unilamellar vesicles of these liposomes (*3*). In contrast, we did not observe a signficant (p 0.05, ANOVA) difference in transfection efficiency with increase in liposome size for all cationic lipids (Figure 5).

Zeta potential of the complexes has an important role in transfection efficiency by promoting adhesion of the complexes to the negatively charged cell membrane. The ξ-potential of lipid/plasmid complexes prepared using HE-DADP and EMS-DADP was ∼(+)40 mV, which was comparable to that for Lipofectamine/plasmid complexes (∼ +45 mV) indicating that higher ξ-potential was not the reason for higher transfection. The ξ-potential for complexes prepared with the liposomes of DADP was ∼ −15 mV. The low transfection efficiency of DADP could be correlated to negative zeta potential.

We have earlier shown that interaction with cationic lipopolymers significantly affects the conformation of pDNA, as inferred by CD, and that this is a function of +/− charge ratio used for the preparation of complexes (*14*). Therefore, in the present study, we have scanned pDNA and liposome/pDNA complexes over a range of 220−360 nm at a fixed charge ratio of 3/1 (+/−), to assess the comparative degree of change in conformational state of plasmid DNA with liposomes of different cationic lipids. The CD profile obtained for a given pDNA molecule depends on its sequence of base pairs, %AT content of bases, and the interactions among bases (*51*, *52*).

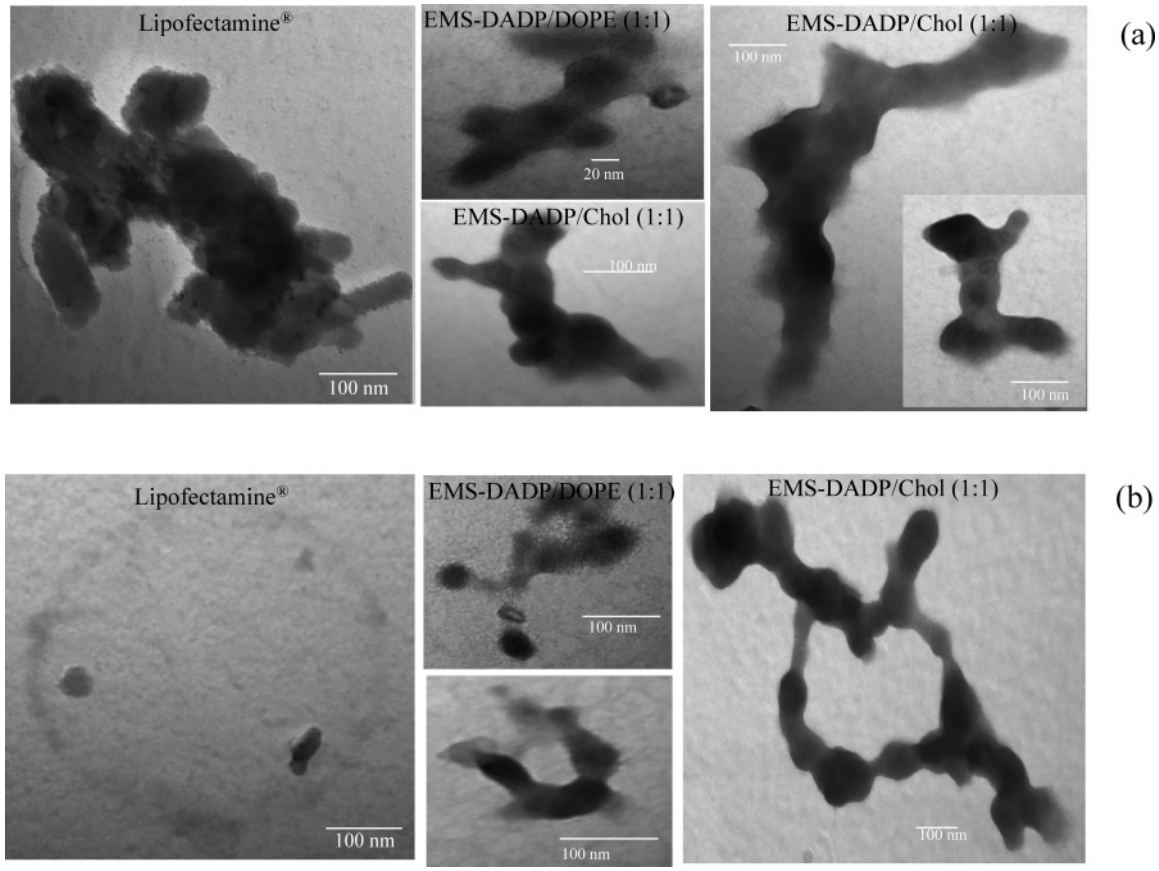

Figure 8. Transmission electron microscopy (TEM) images of cationic liposome/pDNA complexes and occasional uncondensed plasmid DNA when complexes were prepared at 3/1 (+/−) charge ratio using cationic liposomes prepared with 1/1 molar ratio of the cationic lipid with the colipid. Samples were prepared at the pDNA concentration of 0.01 μg/μL and negatively stained on carbon-coated copper grids using uranyl acetate aqueous solution. Complexes of the mesylate lipid with either DOPE or cholesterol as a colipid in liposome formulations have been compared with Lipofectamine.

Hence, the CD spectra of pDNA obtained in our current study was somewhat different than that obtained earlier (*14*) and seems closer to the poly [d(A-C-C). d(G-G-T)] two repeating trinucleotide polymer at 67% GC content shown by Gray et al. (*51*). The goal of our study here was to examine the relative difference in changes in conformation induced by different cationic lipids. The results (Figure 7) indicated a significant change in the conformation of pDNA upon complexation with the cationic lipids in the appearance of a significant positive peak ~ 280 nm, where there was a positive peak at ~ 255 nm in the naked pDNA and the disappearance of the slight negative peak at ~235 nm. However, the relative difference in the pDNA profile with different cationic lipids, including Lipofectamine, was insignificant. This indicated that the degree of conformational change/winding-up of the helix caused by the cationic lipids was similar in all cases examined.

The particle size data (Figure 6) as well as the results of transfection studies (Figure 3) implied the possibility that the higher in vitro transfection could be due to the aggregation/agglomeration of complexes. Therefore, we sought to visualize the complexes using transmission electron microscopy (TEM) to confirm the observations of particle size data and any possible aggregation of the complexes. The size, agglomeration, and structural geometry of the complexes has been shown to depend greatly upon the +/− charge ratio of the cationic polymer/liposomes to pDNA. Lower charge ratios of 1/1.2 to 1/1.3 were shown to form large-sized complexes and aggregates (*53*). Pitaard et al. (1997) had shown the progressive decrease in diameter and increase in compactness of complexes formed at (+/−) charge ratios of 0.3/1, through 1.65/1 to 6/1 (*54*). Rackstraw et al. (2002) had shown the increase in density and size of complexes formed at 1/1 to 5/1 charge ratio (*55*). The complexes were seen to be compact and spheroidal in all cases. Aggregate formation was also visible in some cases, especially at lower charge ratios. An interesting observation was reported by Thomas et al. (2003), with the deposition of a lot of lipid on the circular pDNA at an extremely high charge ratio of 150/1 (*56*). We have seen similar phenomena in the case of pDNA/EMS-DADP:DOPE liposome complexes but at a lower charge ratio of 3/1 (+/−).

The TEM of the pDNA complexes of Lipofectamine liposomes was also visualized as a control. Both complexes (Figure 8a) as well as occasional uncondensed pDNA (Figure 8b) could be seen. The observation of uncondensed DNA could be due to the relatively lower amount of liposomes used for pDNA condensation. The results indicated the size of most of the complexes to be in the range of the particle size data obtained using light scattering technique (Figure 6a). Furthermore, two significant differences were observed between Lipofectamine/plasmid and EMS-DADP:DOPE liposome/plasmid complexes. While the former appeared more compact in nature, the latter were more 'spread-out' and elongated, with higher surface area (Figure 8). The observation of elongated complexes indicated that the higher particle size obtained with the light scattering technique for EMS-DADP complexes could be due to the varying orientation of the elongated structures. This would also explain the significantly higher variability seen with the EMS-DADP/DOPE complexes in Figure 6a. The amount of lipid

attached to the plasmid DNA was seen to be significantly higher for EMS-DADP than for Lipofectamine complexes. This observation is in line with our hypothesis that the conformational placement of the hydroxyl or the mesylate group allows them to form additional bonding interactions with the DNA double helix, leading to a greater degree of attraction between the lipid molecules and the plasmid DNA. This results in more amount of lipid 'sticking' to the pDNA. This also explains the relatively elongated or spread-out nature of the complexes formed with EMS-DADP as being due to the packing of an excessive amount of material on the DNA duplex with a limited surface area.

The observation of uncondensed DNA could be due to the relatively lower amount of liposomes used for pDNA condensation. Although electrophoretic mobility of plasmid DNA was seen to be prevented at charge ratios of 3/1 and higher, effective charge neutralization might not result in formation of compact lipid/DNA complexes for all 100% molecules at 3/1 (+/−) charge ratio. Hence, some incompletely compacted pDNA molecules, which did have the lipid attached, were observed under the electron microscope at this charge ratio, although they were very few.

Bennett et al. (1997) have evaluated in vivo transfection efficiency and lipid hydration of a series of cationic lipids with variations in headgroup structures (*57*). Among other lipids, their lipid structure RI, which is the same as HE-DADP, was compared with its methoxy derivative (MEP) to evalute the difference in hydration and the role of hydrogen bonding interactions. They observed an increase in lipid hydration with increasing bulk of the polar headgroup with methoxy modification, which was attributed to reduced interactions with the colipid, DOPE. Thus, greater exclusion of interstitial water in the case of hydroxyl containing lipids due to intermolecular hydrogen bonding, would lead to reduced lipid hydration with increased tendency of liposomes to form nonbilayer structures. Such lipids were observed to be more active than the non-hydroxyl-containing lipids. The same lipid, HE-DADP, was also studied by Felgner et al. (1994) as DORI in their evaluation of a series of cationic lipid structures differing in headgroup as well as lipid domain structures (*3*). Addition of a hydroxyalkyl moiety on the quaternary amine in DORI was seen to give ~2-fold higher transfection than the non-hydroxyl group-containing lipid, DOTMA. Presence of polar hydroxyl functionality was postulated to affect hydrogen bonding associations with DOPE to form a heterodimer with different net charge dependent on the medium pH. The authors proposed that ion pair heterodimer formation with DOPE would help maintain the integrity of bilayer structure with changing pH, resulting in different aggregation and fusion properties of vesicles that impact intracellular trafficking. Hence, the hydrogen bonding potential of the hydroxyl functionality in the headgroup has been postulated to improve transfection efficiency either by destabilization of liposomes due to reduced hydration or maintaining the integrity of bilayer structure with changing pH.

Irrespective of the hypothesis regarding vesicle properties that influence transfection activity, cationic lipid interactions with the colipid DOPE were deemed important to the higher transfection efficiency of hydroxyl-containing cationic lipids by both Bennet et al. (*57*) and Felgner et al. (*3*). Felgner et al. also showed that an alternate colipid, dioleoyl phosphatidylcholine (DOPC), which had a permanently positively charged quaternary amine in the headgroup, which would display pH independent charge of the cationic lipid/colipid heterodimer. Lower transfection efficiency was seen with DOPC as a colipid in liposome formulations as compared to DOPE. Hence, the role of colipid remains very important to transfection efficiency because of its potential interactions with the cationic lipid. We expect that this should be true also for cholesterol versus DOPE as a colipid in our formulations.

Indeed, the transfection efficiency of EMS-DADP with DOPE-based liposomes is much higher than that with cholesterol based liposomes (Figure 3). The observation of higher amount of lipid attachment to plasmid DNA with mesylate lipid-based liposomes, however, is consistent with both types of colipids (Figure 8). This indicates that more lipid attachment is not the only mechanism involved. Literature also suggests that membrane fusion, promoted by lipid attachment to DNA, may not be the predominant mechanism for cell penetration (*58*). The predominant mechanism for membrane penetration is endocytosis rather than fusion. Membrane fusion and disruption, however, is a critical requirement for the next stage of endosomal escape. Higher affinity of the mesylate headgroup for DNA would also promote higher colipid attachment to pDNA because of the proximity of both lipids in the liposome formulation. Also, the attachment of DOPE as a colipid may be more than cholesterol because of zwitterionic nature of DOPE and its possible interactions with EMS-DADP as well as plasmid DNA. The fusogenic colipid DOPE is known to have significantly higher impact on endosomal disruption than cholesterol. Hence, we hypothesize that while higher lipid attachment may be protective for plasmid DNA and slightly enhancing cell penetration in the case of either colipid, higher transfection efficiencies are seen only with DOPE as a colipid because of its role in membrane fusion and disruption at the stage of endosomal escape. This is indicated by the significantly higher transfection efficiency of EMS-DADP liposomes having a higher molar content of DOPE in the liposomes (1/5, 1/3, and 1/1 EMS-DADP/DOPE molar ratios consistently give higher transfection than 3/1 and 5/1 molar ratios irrespective of the charge ratio used, Figure 3b). No such significant effect of colipid content was seen with cholesterol-based liposomes (Figure 3a). Hence, these cationic lipid formulations may be acting predominantly at a stage of endosomal disruption and prevention of lysosomal degradation instead of cellular internalization. These hypotheses will be the subject of our further investigations in this area.

The incomplete condensation observed at 3/1 (+/−) charge ratio may adversely impact in vivo gene expression of lipid/plasmid complexes. However, there is a need to maintain a delicate balance between transfection efficiency and toxicity. High charge ratios are known to efficiently condense DNA and increase transfection efficiency, but also increase cytotoxicity. Moreover, high charge ratios of cationic lipid to pDNA in complexes is known to cause complement activation after systemic administration (*59*). To minimize cytotoxicity, we will use 3/1 (+/−) charge ratio complexes for further evaluation of our novel lipids.

While our compounds with both polyamine and the quaternary amine were water-soluble and had lower transfection efficiencies than the commercially available Lipofectamine (data not shown), the HE-DADP and EMS-DADP showed unexpectedly higher transfection efficiencies. The cytotoxicity observed with these compounds, however, was not significantly higher than Lipofectamine, which was used as a positive control. We conclude that the possible reason for the higher transfection efficiency

observed with EMS-DADP lipsomes is due to increased lipid affinity for and attachment to the plasmid DNA.

Template-Directed Assembly and Characterization of Metallosalen–DNA Conjugates

Jennifer L. Czlapinski† and Terry L. Sheppard*

Department of Chemistry and The Robert H. Lurie Comprehensive Cancer Center, Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208-3113. Received October 17, 2004

Nucleic acid template-directed synthesis represents a powerful method for the encoded synthesis of new bioconjugates. Our laboratory previously reported a strategy for the synthesis of a new metal–DNA hybrid, metallosalen–DNA, by the DNA or RNA template-directed cross-linking of two salicylaldehyde-modified DNA oligonucleotides. The current manuscript describes the optimal assembly requirements and biophysical characterization of metallosalen–DNA conjugates containing nickel and manganese ions. Competitive assembly reactions demonstrated the template-directed nature of metallosalen–DNA formation. A single metallosalen–DNA conjugate was assembled selectively in the presence of two pairs of salicylaldehyde precursor strands and a single DNA template. Assembly reactions were sensitive to base pair mismatches in the pairing arms. Single base mismatches resulted in a loss of metallosalen–DNA conjugate yield. Metallosalen–DNA assembly yields depended on the identity and length of the template spacer, the reaction pH, and the type of metal and diamine utilized in the assembly reaction. Metallosalen–DNA conjugates were stable to a variety of conditions, including extended incubation at 50 °C. Nickel metallosalen–DNA remained unchanged after incubation at 80 °C for 24 h, while decomposition of manganese metallosalen–DNA was observed under the same conditions. Circular dichroism (CD) spectroscopy indicated that DNA duplexes containing internal metallosalen moieties adopted B-form double helices. UV thermal denaturation analysis demonstrated that 32-nucleotide duplexes containing internal metallosalen modifications displayed melting temperatures ~5 °C less than unmodified DNA duplexes.

INTRODUCTION

Metal ions are essential to nucleic acid structure and biochemistry. Nucleic acid duplexes and RNA tertiary structures are stabilized by metal ion binding (*1*, *2*), and numerous catalytic nucleic acids require divalent metal ions for their function (*3*, *4*). Despite a growing understanding of nucleic acid–metal interactions, the rational design or combinatorial discovery of metal-binding sites is still in its infancy. However, chemists have united the properties of metal ions with the coding abilities of nucleic acids by developing methods for the covalent conjugation of metal complexes to oligonucleotides. Early metal–DNA complexes involved the covalent attachment of EDTA to an oligonucleotide (*5*), for use in iron-mediated DNA cleavage. Since this discovery, numerous metal–DNA hybrids have been developed for applications ranging from nucleic acid cleavage (*6–12*) to DNA electron transfer studies (*13–19*). Other metal–DNA conjugates have been utilized as DNA hybridization probes and sensors (*20–23*) and for mechanistic studies of the anticancer drug, cisplatin (*24*). Recently, metal complexes have been utilized as scaffolds for metal-mediated DNA base pairs (*25–31*).

Metal–DNA hybrids have been synthesized by several methods. One common approach involved the conjugation of the metal complex to a functional group "handle" on a DNA oligonucleotide (*17–21*). A second procedure was based on the synthesis of oligonucleotides modified with metal ligands, followed by metal complexation (*5–8*, *22*). Metal complexes also have been inserted into oligonucleotides directly by DNA automated synthesis (*12–15*, *23*, *24*). In a recent advance, a DNA polymerase was used to incorporate a metal-containing nucleoside triphosphate into an oligonucleotide (*32*). Our laboratory became interested in template-directed synthesis as a new method for the assembly of metal–DNA hybrids.

In template-directed synthesis, substrate oligonucleotides bearing complementary reactive groups are brought into proximity by Watson–Crick base pairing with a nucleic acid template, which accelerates the selective formation of chemical bonds between the functionalized oligonucleotides. Initially, template-directed synthesis employed oligonucleotide strands containing chemically modified phosphate backbones (*33–35*). More recently, template-directed ligation reactions were expanded for the detection of DNA and RNA point mutations (*36*, *37*). Reversible chemical ligation strategies also have been developed (*33*, *38*) and adapted for the ligation of thymidine oligomers (*39*). Remarkably, DNA and RNA templates have directed the synthesis of a range of chemical structures across diverse reaction classes (*40–46*). In addition, nucleic acid mimics, including hexitol nucleic acids (*47*) and peptide nucleic acids (*48*, *49*), have demonstrated potential as templates in directed assembly reactions. More recently, template-directed synthesis has supported the construction of complex organic molecule–DNA conjugates (*50–52*), in some cases, with stereoselectivity (*53*) and in multistep transformations (*54*).

We recently reported a new metal–DNA hybrid, metallosalen–DNA, which was assembled by DNA or RNA

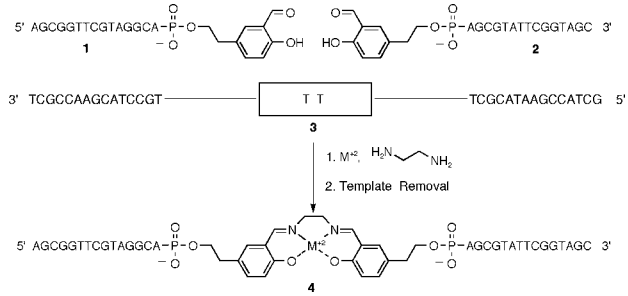
Scheme 1. Template-directed Metallosalen−DNA Conjugate Assembly.



template-directed synthesis (*55*, *56*). In our method, the metal complex was site-specifically incorporated into DNA by the diamine cross-linking of salicylaldehyde-modified DNA on an external template (Scheme 1). Two complementary DNA oligonucleotides were modified with a salicylaldehyde moiety at either the 3′- or 5′-end (**1** and **2**, respectively). The substrates were aligned on the template strand, and the addition of a diamine and a divalent metal ion led to the formation of a metallosalen−DNA hybrid. Herein we describe the variables that control optimal template-directed assembly of metallosalen−DNA conjugates containing nickel and manganese ions. Metallosalen−DNA assembly is controlled by the composition and length of template spacers that bridge the assembly site, reaction pH, the identities of the metal ion and diamine, and the presence of a complementary DNA template in the assembly reaction. Metallosalen−DNA conjugates form B-form DNA duplexes, as judged by circular dichroism (CD) studies, and their presence destabilizes a 32-oligonucleotide duplex by ∼5 °C in melting temperature.

EXPERIMENTAL PROCEDURES

General. All molecular biology reagents were purchased from Sigma. Metals for metallosalen−DNA conjugate formation were purchased from Aldrich as metal acetates, unless otherwise stated. T4 Polynucleotide kinase was obtained from US Biochemical, and [γ-^{32}P]-ATP (7000 Ci/mmol) was purchased from ICN. Radioactive bands in polyacrylamide gels were visualized using a Molecular Dynamics Storm Phosphorimager and quantitated using Molecular Dynamics ImageQuant software. 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), 2-(4-morpholino)ethanesulfonic acid (MES), and 2-(cyclohexylamino)ethanesulfonic acid (CHES) were purchased as molecular biology grade reagents from Sigma. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry was performed on a PerSeptive Biosystems, Inc. (Foster City, CA), Voyager-DE PRO Biospectrometry Workstation MALDI-TOF mass spectrometer as described (*55*).

DNA Synthesis, Deprotection, and Purification. Standard unmodified DNA oligonucleotides were synthesized by Integrated DNA Technologies (Coralville, IA). Modified oligonucleotides were synthesized on a Pharmacia Gene Assembler Plus at the 1.3 μmol scale using phosphoramidites with labile base protecting groups for the natural nucleotides, as described (*55*). All oligonucleotides were purified by reverse-phase HPLC (RP-HPLC), lyophilized, and resuspended in 0.5× Tris-EDTA buffer (5 mM Tris and 0.5 mM EDTA, pH = 7.5). Purified oligonucleotides were quantified by UV spectroscopy, as previously described (*55*).

5′-GCCGATACCACGCTCTTCACCGACGATTG-CCT-3′ (7). Oligonucleotide **7** was synthesized by Integrated DNA Technologies and purified by RP-HPLC.

Salicylaldehyde-Modified DNA Synthesis. Salicylaldehyde-modified DNA strands were synthesized by solid-phase DNA synthesis using standard methods for the natural nucleoside phosphoramidites and 2-(1,3-dioxan-2-yl)-3-benzoyloxyphenyl-4-ethyl-*O*-(2-cyanoethyl)-*N*,*N*′-diisopropylphosphoramidite (*55*) (**27**, 0.11 M solution in anhydrous CH_3CN). After synthesis, oligonucleotides were deprotected as described (*55*) and purified by RP-HPLC.

5′-AGGCAATCGTCGGTG-SAL-3′ (5). Oligonucleotide **5** was synthesized in the 5′-to-3′ direction using a dA-5′-CPG 500 solid support (Glen Research, 33.4 mg, 31 μmol/g loading, 1.03 μmol scale), using standard 5′-β-cyanoethyl nucleoside phosphoramidites and **27**. MALDI-TOF (*m/z*): $[M]^-$ calcd for **5**, 4860; found, 4860.

5′-SAL-GAGCGTGGTATCGGC-3′ (6). Oligonucleotide **6** was synthesized in the traditional 3′-to-5′ direction using standard 3′-nucleoside phosphoramidites (Glen Research, Ultramild) and **27** on a 1.3 μmol scale. MALDI-TOF (*m/z*): $[M]^-$ calcd for **6**, 4877; found, 4877.

5′-Radiolabeling. Oligonucleotide **1** or **5** (24 pmol) was radiolabeled as described (*55*). The reaction was purified by 20% PAGE, eluted from the gel slice (10 mM Tris-HCl, 200 mM NaCl, 1 mM EDTA, pH 7.5), and recovered by precipitation with two volumes of 2-propanol, which had been supplemented to 0.3 M NaOAc, pH 5.2. The oligonucleotide was redissolved in ddH_2O.

Mn Metallosalen−DNA Conjugate Formation Reactions (Mn-4 or Mn-8). A mixture of **1**−**3** (or **5**−**7**), each at 4 μM in 10 mM HEPES, pH 8.0 and 150 mM NaCl, were annealed by heating to 95 °C and slow cooling to RT over 2 h. Solutions of manganese acetate (2 mM) and ethylenediamine (EN, 500 μM) were added to give final concentrations of 400 μM $Mn(OAc)_2$ and 100 μM EN. Each strand was present in a final concentration of 2 μM. The solution was incubated at 37 °C for 1 h. Preparative scale reactions were performed on a 4 nmol scale in 50 mM HEPES, pH 8.0 and 150 mM NaCl. Conjugates were analyzed and purified by 20% polyacrylamide gel electrophoresis (PAGE) using TB buffer (89 mM Tris, 89 mM borate, no EDTA). The metallosalen−DNA complex was visualized using a handheld UV lamp and recovered by electroelution with TB buffer in a Schleicher & Schuell Elutrap (30 min, 200 V at RT). **Mn-4** or **Mn-8** were concentrated in a Millipore Microcon YM-3 filter, washed twice with 200 μL of ddH_2O, and eluted into 50 μL of ddH_2O for storage.

Ni Metallosalen−DNA Conjugate Formation Reactions (Ni-4 or Ni-8). Ni metallosalen−DNA formation reactions followed the same general procedure as for **Mn**; however, the $Ni(OAc)_2$ and EN had final concentrations of 300 μM and 150 μM, respectively, in a pH 6.5 buffer solution (10 mM MES and 150 mM NaCl). Preparative scale reactions required no changes in the reaction buffer.

Competitive Metallosalen−DNA Assembly. Two sets of reactions were prepared, one for formation of **Ni-4** and the other for **Mn-4**, using the buffer conditions listed above. For each metal, three reactions were performed: (1) a mixture of strands **1**−**3** (2 μM) with 20 fmol of radiolabeled **1**; (2) 2 μM each of **1**−**3** and **5**−**6** with 20 fmol of radiolabeled **1**; and (3) 2 μM each of **1**−**3** and **5**−**6** with 20 fmol of radiolabeled **5**. The appropriate amount of metal and diamine was added, and the reactions were incubated at 37 °C and analyzed by 20% PAGE using 1× TB as the running buffer.

Nonspecific Metallosalen–DNA Assembly. To assay for nonspecific metallosalen–DNA formation, a series of assembly reactions was performed for each metal ion. Two reactions were assembled for each time point: one that contained **1**–**3** (each at 2 μM) with 20 fmol radiolabeled **1**, and the other with 2 μM of **1** and **2** with 20 fmol radiolabeled **1**. Since assembly could not be quenched, the reactions were initiated in order of decreasing time. At the end of the time course, products were analyzed by 20% PAGE with TB as the running buffer.

Mismatch Metallosalen–DNA Formation. Reactions containing 2 μM each of **1**, **2**, template **3** or one of the mismatched templates **9**–**13**, and 20 fmol of radiolabeled **1**, were initiated under standard conditions. Reactions were performed with both $Mn(OAc)_2$ and $Ni(OAc)_2$ for each template and were assayed by 20% PAGE electrophoresis with TB buffer.

Metallosalen–DNA Formation with Diverse Metal Ions. Metal ion assays were performed using 2 μM each of **1**–**3** with 20 fmol of radiolabeled **1**. Each reaction was incubated for 1 h at 37 °C with 500 μM of metal salt and 250 μM of EN in 10 mM buffer at the required pH with 150 mM NaCl, as indicated by metal speciation data (*57*). $Cu(OAc)_2$ at pH 9.0 (CHES), $VOSO_4$ at pH 7.0 (HEPES), and $RhCl_3$ and $ZnSO_4$ at pH 7.5 (HEPES). Reaction products were analyzed by PAGE using 1× TB as the running buffer.

Metallosalen–DNA Thermal Stability and EDTA Decomposition. Radiolabeled **Mn-4** and **Ni-4** conjugates were prepared as described above. For thermal stability, solutions containing radiolabeled conjugate **4** were incubated at various temperatures (RT, 37 °C, 50 °C, and 80 °C), and reaction aliquots were taken over 48 h. The time points were analyzed by 20% PAGE with TB running buffer. For EDTA decomposition analysis, the radiolabeled conjugates were prepared in smaller quantities (2 μM strand concentrations) with 20 fmol of radiolabeled **1**. **Mn-4** and **Ni-4** formation reactions were treated with EDTA, pH 8.0 (final concentration: 0–40 mM) for 15 min at RT. Product decomposition was followed by 20% PAGE with TB as the running buffer.

Circular Dichroism Spectroscopy. CD spectra were recorded using a Jasco J-715 CD spectropolarimeter. Oligonucleotide duplex samples were prepared by mixing solutions of 1 μM of each strand in 10 mM sodium phosphate, 150 mM NaCl, pH 7.0. Spectra were recorded from 200 to 350 nm at 25 °C in a quartz cuvette (1 cm path length). The sample compartment was purged with inert atmosphere (N_2) during data acquisition. Each spectrum represents a baseline corrected average of four accumulations per scan, and all data were corrected by subtracting the buffer reference signal.

UV Thermal Denaturation Analysis. UV thermal denaturation data were acquired on a Cary 500 spectrophotometer equipped with a multicuvette thermoelectric controller in 1 cm quartz cuvettes. Solutions of 1 μM duplex oligonucleotides in 10 mM sodium phosphate, 150 mM NaCl, pH = 7.0 were annealed by heating to 95 °C for 5 min, then cooled to 25 °C over 2 h. The samples were degassed under vacuum for 3 min prior to melting analysis. The absorbance was measured at 260 nm as the samples were heated from 30 °C to 90 °C at 0.5 °C/min. Data sets for the downward transition from 90 °C to 30 °C also were collected at 0.5 °C/min; all melting profiles were fully reversible to within 1.0 °C. Melting temperatures (T_m) were determined from plots of dA_{260}/dT vs T as described (*58*) and are derived from replicate melting experiments using at least two independently prepared samples.

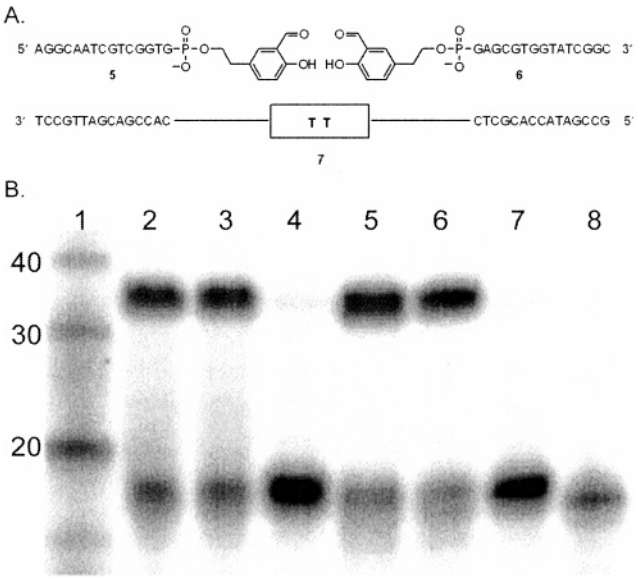


Figure 1. Metallosalen–DNA formation reactions for **Mn-4** and **Ni-4**. (A) SAL–DNA sequences **5** and **6** align on complementary template **7** to support assembly of **Mn-8** and **Ni-8**. Lane 2: All components: 400 μM $Mn(OAc)_2$, **1**, **2**, and template **3**, 100 μM EN, radiolabeled **1**. Lane 3: +SAL strands **5** and **6**. Lane 4: +**5** and **6**, -radiolabeled **1** and + radiolabeled **5**. Lanes 5–7: Analogous reactions to Lanes 2–4, but with 300 μM $Ni(OAc)_2$ and 150 μM EN at pH 6.5 for 24 h. Lane 8: Radiolabeled **1**.

RESULTS AND DISCUSSION

Generality of Template-Directed Metallosalen–DNA Synthesis. Our approach to metallosalen–DNA by template-directed synthesis was reported previously for the formation of **Mn-4** and **Ni-4**, as shown in Scheme 1 (*55*). We provided evidence that complementary template **3**, a diamine, and either manganese or nickel ions were required for the assembly of metallosalen–DNA **4** from **1** and **2**. To demonstrate the generality of template-directed synthesis of metallosalen–DNA, a second set of SAL–DNA precursors were prepared that varied the DNA sequences flanking the metallosalen–DNA. SAL–DNA sequences (**5** and **6**, Figure 1A) were synthesized, purified, and characterized by MALDI-TOF MS as described previously for **1** and **2** (*55*). Template-directed assembly reactions of metallosalen–DNA conjugates **Mn-8** and **Ni-8** from **5** and **6** and the complementary template **7** were analyzed by denaturing polyacrylamide gel electrophoresis (PAGE). When DNA **5** and **6** were hybridized to template **7** and incubated at 37 °C in the presence of 100 μM ethylenediamine (EN) and 400 μM $Mn(OAc)_2$, a new DNA product, corresponding to **Mn-8**, was produced in 50% yield. Similarly, **Ni-8** was prepared in 70% yield after 24 h, when 150 μM EN and 300 μM $Ni(OAc)_2$ were incubated with **5** and **6** in the presence of **7**. Metallosalen–DNA assembly required EN, divalent metal ion, and template **7** for optimal assembly, and **Mn-8** and **Ni-8** were produced in yields comparable to those of conjugates **4** (*55*). To confirm the identities of these new metallosalen–DNA hybrids, preparative syntheses (4 nmol) of **Mn-8** and **Ni-8** were performed with an RNA template. Purification of the conjugates was attempted by selective RNase H digestion of the RNA template as previously described (*55*). Although this strategy was effective for the purification of **Mn-4** and **Ni-4**, it was not reliable when applied to metallosalen–

DNA conjugates **Mn-8** and **Ni-8**. Thus, a more general method for the purification of metallosalen−DNA conjugates was developed, which utilized complementary DNA templates that were four nucleotides shorter than **7** (two nucleotides were removed from both the 5′- and 3′-ends). The shorter templates facilitated the separation of the desired metallosalen−DNA from the template strand by gel electrophoresis. Using this approach, **Mn-8** and **Ni-8** were purified by 20% PAGE, and their identities were confirmed by MALDI-TOF MS and base composition analysis (*55*) (see Supporting Information).

Template Specificity of Metallosalen−DNA Assembly. Given the sequence generality of metallosalen−DNA formation, further studies were performed to evaluate the effects of template specificity on the assembly reactions. To assay the template dependence of metallosalen−DNA conjugate assembly, a series of competitive assembly reactions were performed. Four noncomplementary salicylaldehyde-modified (SAL) oligonucleotides were combined with a template that was complementary to only one pair of SAL strands. Upon addition of a diamine and a divalent metal ion, only one metallosalen−DNA should be produced, dependent on the identity of the template strand present in the reaction. A series of reactions using the four SAL strands (**1**−**2** and **5**−**6**) and complementary DNA templates, **3** and **7**, respectively, were undertaken to assay metallosalen−DNA formation under competitive conditions. Three independent metallosalen−DNA reactions were performed and assayed by PAGE using radiolabeled SAL strands as tracers for the assembly of two different metallosalens, **4** and **8**. The first reaction was a typical assembly of **4** (Scheme 1) from SAL strands **1** and **2**, and template **3**, where radiolabeled **1** was used as a tracer. The second and third reactions contained four SAL strands, **1/2** and **5/6**, and the complementary template to **1** and **2** (oligonucleotide **3**). The second reaction, which included the radioactive tracer strand **1** (to track assembly of **4**), was designed to demonstrate that the correct templated conjugate, **4**, was formed even in the presence of other SAL oligonucleotides. The presence of labeled strand **5** in the third reaction was used to follow the assembly of **8** and show that strands **5** and **6** do not form metallosalen−DNA conjugate **8** in the presences of the "wrong" template (**3**).

Gel electrophoretic analysis of the competition reactions is shown in Figure 1B for metallosalen−DNA assembly with manganese and nickel ions. When **1** and **2** were hybridized to their complementary template **3** and incubated for 1 h at 37 °C in the presence of 100 μM EN and 400 μM $Mn(OAc)_2$, **Mn-4** was produced in 57% yield (lane 2). The addition of SAL strands **5** and **6**, which were noncomplementary to **3**, did not disrupt **Mn-4** formation (58%, lane 3). In the absence of labeled **1** (lane 4) and the presence of labeled **5**, no formation of **Mn-8** was observed. The assembly reactions performed with nickel provided similar results. When **1** and **2** were hybridized to complementary **3** and incubated for 24 h at 37 °C in the presence of 150 μM EN and 300 μM $Ni(OAc)_2$, **Ni-4** was produced in 73% yield (lane 5). The addition of unlabeled noncomplementary SAL oligonucleotides (**5** and **6**) did not alter the yield of **Ni-4** (72%, lane 6). However, when noncomplementary **1** was present as the labeled strand, no assembly of metallosalen−DNA **Ni-4** was observed (lane 7). Taken together, the results shown in Figure 1B demonstrated that metallosalen−DNA formation was template-directed, and that a single DNA template was capable of directing the synthesis of a unique metallosalen−DNA conjugate from a mixture of SAL−DNA strands.

Table 1. Mismatched Template Sequences and Yields for Mn-4 Formation Fidelity[a]

sequence		% yield **Mn-4**
5′-GCTACCGAATACGCTTTTGCCTACGAACCGCT-3′	(**3**)	64
5′-GCTACCGAATACGCTTT**G**GCCTACGAACCGCT-3′	(**9**)	58

[a] The bolded/underlined letter indicates the mismatched nucleotide; the nucleotide in bold italics is an additional base; and the underscore shows a missing nucleotide.

Nonspecific Metallosalen−DNA Assembly and Effects of Mismatched Base Pairs. To better assess how DNA templates enhance the rates of metallosalen−DNA assembly reactions, a measurement of the background rate of nonspecific metallosalen assembly was required. Nonspecific metallosalen−DNA assembly results from the cross-linking of two SAL−DNA strands in the absence of the corresponding DNA template. To monitor the nonspecific formation of metallosalen−DNA in reactions that lacked a template strand, the background rate of nonspecific metallosalen−DNA assembly was measured by following the formation of metallosalen−DNA product in a reaction containing only the two noncomplementary SAL−DNA strands in the presence of a diamine and a divalent metal ion, but in the absence of a template DNA. SAL strands **1** and **2** (including radiolabeled **1** as a tracer) were incubated under standard assembly conditions. For reactions with Mn(II), the nonspecific yield of material that comigrated with **Mn-4** was found to be 1% at 1 h. Nonspecific product formation increased gradually to 34% at 48 h of reaction. Although the yields of nonspecific conjugate formation increased at longer incubation times, template-directed **Mn-4** reactions typically were completed in 1 h (70% yield), which guaranteed that the major product of template-directed synthesis was the desired **Mn-4** under these conditions. As seen earlier (*56*), nonspecific assembly reactions with Ni(II) were considerably slower than those with manganese ions. No detectable nonspecific products were formed within 48 h, which was 24 h after templated **Ni-4** and **Ni-8** formations were generally complete. Thus, both manganese and nickel ion template-directed metallosalen−DNA assembly reactions were completed before significant amounts of nonspecific products were formed.

Numerous template-directed chemical ligation reactions have been shown to be sensitive to single base pair mismatches at or near the ligation site (*36*, *43*, *45*, *48*). As a result, the effect of base pair mismatches on metallosalen−DNA conjugate formation was assayed. A series of DNA templates (Table 1) for synthesis of metallosalen−DNA **4** (template a) or **8** (template b) were prepared that contained a range of mismatch types and sites: adjacent to the metallosalen assembly site (**9** and **10**), at the center of one metallosalen−DNA arm (**11**), an insertion of a dC nucleotide (**12**) or deletion of a single dG nucleotide (**13**) in the template strands.

Utilizing the conditions for **Mn-4** formation, the four mismatched templates **9**-**13** were hybridized with SAL strands **1** and **2** and incubated in the presence of 100 μM EN and 400 μM $Mn(OAc)_2$ at 45 °C for 1 h. Under these conditions, the mismatched templates led to lower yields of **Mn-4** (Table 1). The **Mn-4** yields with mismatched templates **9**−**13** were between 4 and 24% lower than with complementary template **3** (64%). When the mismatches were near the metallosalen formation site, the yields did not decrease significantly: **9** (58%, G·A

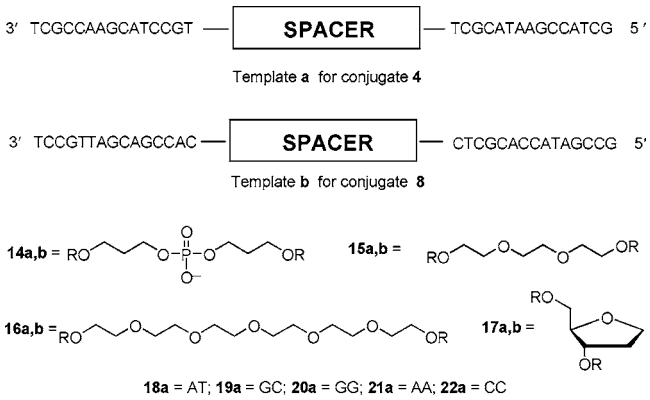

Figure 2. Template sequences and spacers used to evaluate the effects of spacer length and composition on metallosalen–DNA conjugate (**4** and **8**) formation. The spacer identities include a three-carbon linker (**14**), a nine-atom glycol linker (**15**), an eighteen-atom glycol linker (**16**), two D-spacers (**17**), and various dinucleotides: AT (**18**), GC (**19**), GG (**20**), AA (**21**), and CC (**22**).

mismatch) and **10** (60%, C·A mismatch). A more substantial decrease in yield occurred when the mismatch was centrally located within a DNA arm of the metallosalen (**11**, C·T mismatch, 55%) or with a single base insertion (**12**, 51%). The best discrimination was observed with a single base deletion (**13**, 40%).

The results in Table 1 indicate that metallosalen–DNA formation may not be sensitive to mismatches near central assembly site. Due to the lack of standard base pairing of the salicylaldehyde groups with bases in the templates and the likely requirement for flexibility at the assembly site, the loss of an additional base pair interaction by mismatch pairing may not perturb the assembly process. Nonetheless, there is a measurable decrease in yield for the other mismatched templates.

Effects of Template Spacers, Reaction pH, and Metal Ion Identity on Metallosalen–DNA Assembly Reactions. We previously established that efficient template-directed metallosalen–DNA assembly was dependent on several variables, including the identity of the template spacer nucleotides, the metal ion selected for the assembly reaction, and pH that was optimal for the selected metal ion (*55*). We now elaborate on the variables that affect the efficiency of template-directed metallosalen–DNA synthesis.

Other studies have revealed that the rate of bond formation in a template-directed reaction is relatively independent of the distance between the reactive partners (*51*). Thus, we evaluated the effect of the chemical identity and length of the central template spacer (See Scheme 1, Figure 1A) on the efficiency of metallosalen–DNA assembly reactions. Our initial report of metallosalen–DNA assembly (*55*) employed a DNA template with a central spacer consisting of two thymidine residues (TT, Scheme 1). We prepared a panel of template spacers to determine the effect of the chemical nature and the distance of the spacer groups on template-directed synthesis yields (Figure 2). Specifically, we examined spacers with flexible backbones (**14**–**16**), D-spacer abasic site analogues (**17**), and dinucleotides (**18**–**22**), which are shown in Figure 2. The optimal template for each metallosalen–DNA conjugate depended on the metal ion used in the assembly reaction and, in some cases, the oligonucleotide sequence. For example, significant template spacer effects were observed for assembly of manganese-containing metallosalen–DNA. For **Mn-4** assembly, optimal yields were achieved with template **3** (66%, TT spacer), followed by **14a** (51%, two three carbon spacers). The two glycol spacer templates, **15a** and **16a**, gave the next highest yields, at 49% each. The best template for **Mn-8** formation was the nine-atom glycol spacer in **15b** (61%), followed by **16b** (55%, eighteen atom glycol spacer), and **7** (50%, TT spacer). The rest of the templates gave similar yields of **Mn-8**: **17b** (two D-spacers, 25%) and **14b** (21%).

Table 2. Assembly Yields for Mn-4 and Ni-4 Metallosalen–DNA Conjugates with Different Nucleotide Spacer Templates

		% yield	
template	spacer	**Mn-4**	**Ni-4**
3	TT	77	86
18	AT	54	78
19	GC	66	72
20	GG	68	73
21	AA	71	76
22	CC	71	74

In contrast, more consistent results were observed for the assembly of the two different nickel-containing metallosalens. **Ni-4** and **Ni-8** formation was optimal with template spacers of similar type. For **Ni-8**, the original template **7** (TT spacer) exhibited the highest yield (70%). The next highest yielding template was **16b** (67%), while the rest of the templates yielded 30–40% less **Ni-8** than the standard thymidine dinucleotide template (**7**). The results for **Ni-4** were similar: the original template **3**, containing two thymidines, gave the optimal yield (69%). Other templates yielded between 12 and 62% less of the desired **Ni-4**, with **15a** yielding the least **Ni-4** (6%). In general, the formation of conjugates **4** and **8** was optimal when the templates contained natural nucleotides (T spacers, **3** or **7**) compared with the flexible organic spacers (**14**–**16**) and the abasic "D-spacers" (**17**). The organic spacers were chosen to provide flexibility and low steric demand at the assembly site. Likewise, templates with D-spacers were designed to maintain the natural helical pitch of the DNA backbone while eliminating steric hindrance at the assembly site by nucleotide bases. The results shown here were unexpected, given that templates that contained non-nucleotidyl spacers yielded 12 to 62% less metallosalen–DNA conjugate than the templates containing two natural thymidine residues.

With the successful formation of metallosalen–DNA conjugates using templates containing two thymidine spacers, other dinucleotide template spacers were evaluated: AT (**18a**), GC (**19a**), GG (**20a**), AA (**21a**), and CC (**22a**, Figure 2). Using **3** and the new templates **18a**–**22a**, the assembly reactions for **Mn-4** and **Ni-4** were examined, and the results are shown in Table 2. The yields for the metallosalen–DNA conjugates (**4**) with nickel and manganese ions showed comparable trends. Overall, template **3**, with its TT spacer, provided the maximal yield for the metallosalen–DNA conjugate **4** (77% for **Mn-4** and 86% for **Ni-4**). For templates **19a**–**22a**, which varied the identity of the internal dinucleotide spacer, results for **Mn-4** and **Ni-4** assembly reactions followed a similar trend: TT (**3**) ≫ AA (**21a**) ≥ CC (**22a**) > GG (**20a**) > GC (**19a**). Template **18a** (AT spacer) was unusual in that conjugate yields were dependent on the metal used. Template **18a** yielded 54% of **Mn-4**, which was lower than with the GC spacer (**19a**, 66%). However, yields of **Ni-4** with **18a** (78%) were similar to AA (76%, **21a**) and CC (74%, **22a**). We suggest that the differences may be accounted for by differential metal ion binding abilities of the spacer sites or by unique hydrogen bonding interactions with the salicylaldehyde moiety of

the SAL−DNA precursors. Evaluation of these hypotheses will require further structural studies of duplexes containing metallosalen−DNA. Nevertheless, Table 2 clearly shows that, of the templates screened, templates with two thymidine nucleotide spacers (**3** or **7**) are the optimal complementary strands for formation of the corresponding metallosalen−DNA derivatives.

A major reason for the initial selection of metallosalens as a target for template-directed synthesis was their ability to accommodate a variety of metal ions and diamines (*59*). To determine the range of metal ions and diamines that were able to support metallosalen−DNA assembly, a series of assays was performed using SAL strands **1** and **2** with template **3**. Metal ion assays were performed using concentrations of 500 μM of each metal and 250 μM of EN. The reactions were evaluated after 1 and 24 h of incubation at 37 °C and assayed by PAGE. Several water-soluble transition metals were assayed for their metallosalen−DNA formation ability, and the metal ions that supported metallosalen−DNA assembly were Mn(III), Ni(II), VO(II), Zn(II), Cu(II), and Rh(III) (see Supporting Information). As demonstrated previously, $Mn(OAc)_2$ and $Ni(OAc)_2$ provided the highest yields of metallosalen−DNA conjugates. Iron (II) also displayed early promise, but DNA aggregation has been observed above concentrations of 40 μM (*60*), which limited further studies. Copper(II) produced metallosalen−DNA conjugate in 36% yield, and the yields of **VO-4** and **Zn-4** were 15 and 21%, respectively. Formation of **Rh-4** proceeded poorly, in a maximal yield of 5%. Other studies have shown that metallosalen−DNA conjugate assembly reactions also accept Al(III) (*61*), opening the possibility for template directed synthesis of more diverse metallosalen−DNA conjugates.

All of the work described to date utilized ethylenediamine (EN) (*55*, *56*) as the cross-linker for the two precursor SAL−DNA strands. To explore the tolerance of the metallosalen−DNA assembly reaction to other diamines, two diamines were examined for metallosalen−DNA conjugation reactions: racemic *trans*-1, 2-diaminocyclohexane (CA) and 1,2-phenylenediamine (PA). CA was chosen because its molecular structure is more constrained than EN, while PA was selected to investigate formation with a rigid, achiral diamine. Utilizing the standard assembly conditions for **Mn-4** and **Ni-4**, the comparative ability of EN, CA, and PA to support metallosalen−DNA formation was assessed by gel electrophoretic studies. The yield of metallosalen−DNA, composed of different diamines, was dependent on the combination of metal and diamine used in the assembly reaction. For assembly with Mn(II), metallosalen−DNA yields for CA were similar to EN (54% and 55%, respectively), whereas the metallosalen derived from PA was formed in significantly lower yield (16%). The opposite trend occurred with nickel-metallosalen assembly: PA and EN yielded 44% and 40% of the metal−DNA respectively, while CA yielded 3% of the Ni metallosalen−DNA conjugate. These investigations suggested that use of diverse diamines should support the construction of a broad range of metallosalen−DNA backbones, including chiral diamine cross-linkers.

Physical Properties of the Metallosalen−DNA Conjugates. A second motivation for selection of metallosalen−DNA as a target for DNA template-directed synthesis was our interest in using metallosalen−DNA for applications in targeted DNA cleavage (*62*), catalysis, and materials design. As a result, we became interested in the inherent chemical and thermal stability of metallosalen−DNA and the stability of DNA duplexes containing metallosalen−DNA. To evaluate the metallosalen−DNA conjugates for thermal and chemical stability, radioactive samples of **Mn-4** and **Ni-4** were prepared using 0.4 nmol of **1**, **2**, template **3**, and a trace amount of radiolabeled **1** with the appropriate concentrations of metal and EN. The assembly reactions were incubated at 37 °C for 1 h (**Mn-4**) or 24 h (**Ni-4**) and purified by PAGE. The purified metallosalens, **Mn-4** or **Ni-4**, were subjected to various conditions, and the rates of decomposition were assayed by PAGE.

The effect of temperature on metallosalen−DNA stability was explored. At room temperature, there was no detected decomposition of **Mn-4** or **Ni-4** over several days. Incubation at higher temperatures also demonstrated little effect on the conjugates: no **Mn-4** or **Ni-4** decomposition was seen over 2 days at 50 °C. The degradation of **Mn-4** was slow (1−2% per h) at 80 °C and produced a product that comigrated with the SAL−DNA starting material. Thus, we hypothesized that the major decomposition mechanism was hydrolysis of the metallosalen. Conjugate **Ni-4** displayed no degradation at 80 °C over 24 h. Repeated thaws from −20 °C of nonradiolabeled **Mn-4** and **Ni-4** samples over several months to a year proceeded with no detectable loss of the conjugates.

Given the demonstrated thermal stability of conjugates **Mn-4** and **Ni-4**, we examined the stability of the metallosalen groups to the metal chelator, EDTA. Early in our investigations of template-directed metallosalen−DNA syntheses, EDTA was removed from all buffers to prevent removal of the metal from the salen ligand. The extent of metallosalen−DNA EDTA decomposition was assayed by incubation of **Mn-4** and **Ni-4** radiolabeled samples with increasing concentrations of EDTA (0−40 mM) for 15 min. The only visible products were the starting strand **1** and the metallosalen−DNA conjugate, **4**, suggesting that the major mechanism for decomposition was salen hydrolysis following metal removal. The **Mn-4** conjugate was stable in buffers containing up to 5 mM EDTA, above which the fraction of **Mn-4** remaining steadily decreased. At and above 40 mM EDTA, the amount of **Mn-4** remained at 6% of the starting amount. In contrast to the instability of **Mn-4**, **Ni-4** was stable to all EDTA concentrations examined, with no decomposition to component SAL−DNA strands being detected. Thus, the thermal and EDTA stability assessments of **Mn-4** and **Ni-4** indicated that nickel metallosalen−DNA conjugates were the more robust complexes, and the manganese metallosalen−DNA were more labile.

With the stabilities of the metallosalen−DNA conjugates established, the helical properties of the metallosalen−DNA conjugates **4** and **8** within duplex DNA were examined by circular dichroism (CD) spectroscopy. Metallosalen−DNA strands were hybridized to their complementary templates (**4•3** and **8•7**, TT spacers) in 10 mM sodium phosphate, 150 mM NaCl, pH 7.0. For comparison, all−DNA duplexes of templates **3** and **7** with complementary oligonucleotides (**23** and **24**, respectively) also were evaluated. Representative CD spectra for **Mn-4•3** and **Ni-4•3** and **3•23** are compared in Figure 3A. The spectrum of each duplex displays a positive band at 280 nm and a negative band at 250 nm, indicative of a B-form helix (*63*). All metallosalen−DNA conjugate duplexes provided similar CD spectra (see Supporting Information), indicating that the metallosalen does not disrupt B-form helicity.

The thermal stabilities of the metallosalen−DNA/template duplexes were evaluated by UV-thermal denaturation studies. Utilizing the same annealing conditions as the CD studies, the UV melting profiles were obtained

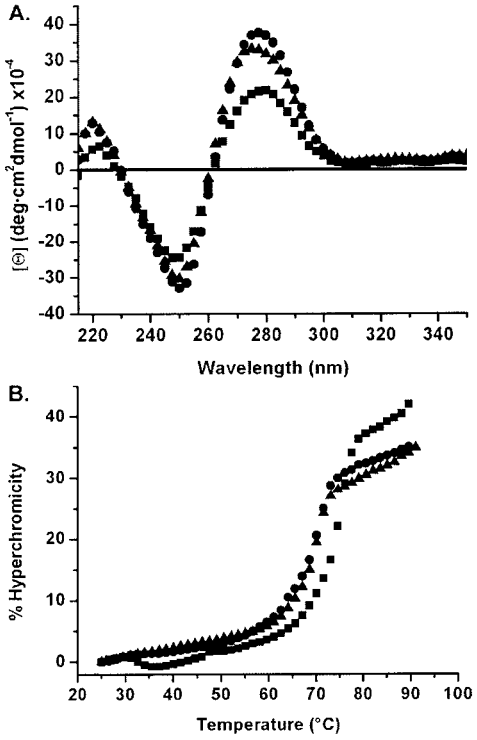

Figure 3. Biophysical properties of metallosalen–DNA **Mn-4•3** (circles) and **Ni-4•3** (triangles) duplexes compared to the control duplex of **3•23** (squares). (A) CD spectra of duplexes (1 μM each strand) in 10 mM sodium phosphate, 150 mM NaCl, pH 7.0. CD spectra were recorded at 25 °C. (B) UV thermal denaturation data were acquired under conditions identical to part A at 260 nm with a temperature ramp rate of 0.5 °C/min.

by heating the samples from 30 °C to 90 °C at 0.5 °C/min. The melting profiles of **Mn-4•3** and **Ni-4•3** and **3•23** are shown in Figure 3B. Metallosalen DNA conjugate duplexes of **Mn-4•3** and **Ni-4•3** demonstrated sharp melting transitions at 70.6 ± 0.1 °C and 70.5 ± 0.1 °C, respectively. The control duplex comprised of **3•23** displayed a slightly higher melting temperature (T_m) of 75.6 ± 0.3 °C. Thus, the replacement of two base pair interactions with the metallosalen led to a thermal stability loss of 5 °C in these duplexes. A similar decrease was observed in the **Ni-8** duplex T_m ($\Delta T_m = -6$ °C) compared with the unmodified duplex of **7•24**. Duplex **Ni-8•7** displayed a melting transition of 72.1 ± 0.5 °C compared to the T_m of 78.0 ± 0.1 °C for the control duplex **7•24.** The **Mn-8•7** duplex melted with a T_m of 69.1 ± 0.1 °C, but with a broad curvature, indicating a less cooperative denaturation profile. The UV-thermal denaturation studies indicated that the metallosalen of a metallosalen–DNA conjugate creates a minor destabilization of duplex DNA ($\Delta T_m = -5$ to -6 °C). The melting profiles of the conjugate duplexes were similar to unmodified duplexes **3•23** and **7•24** indicating that insertion of a metallosalen did not alter the mode of duplex denaturation. Although a duplex destabilization was expected with the replacement of two base pair interactions with a metallosalen, the disruption of duplex stability was relatively minor for these 32-nucleotide duplexes.

In conclusion, we have demonstrated the generality of template-directed metallosalen–DNA synthesis through the preparation and characterization of a new metallosalen–DNA conjugate (**8**). A second-generation purification methodology was developed that involved the use of shorter DNA templates, which permitted the isolation and characterization of four metallosalen–DNA conjugates. Our assembly approach for metallosalen–DNA conjugates was shown to be specific and template-directed, even in the presence of noncomplementary SAL–DNA strands. The optimal templates for efficient metallosalen–DNA conjugate synthesis contained dinucleotide spacers, usually TT, compared to flexible organic spacers or abasic site analogues. CD spectroscopy demonstrated that duplexes containing metallosalens adopted B-form helices, and UV-thermal denaturation studies indicated that the metallosalen destabilizes 32-mer duplexes by 5–6 °C. These studies establish the key features necessary for the template-directed syntheses and applications of metallosalen–DNA.

A nickel(II)–PNA bioconjugate was prepared by formation of a salicylaldimine complex with the amino terminus of a peptide–PNA hybrid with the sequence Arg-His-Gly-$[TACCTAGCAT]_{PNA}$-Arg-$CONH_2$. Hybridization to complementary oligodeoxynucleotides was demonstrated, and covalent adduct formation was observed upon addition of $KHSO_5$ as oxidant. In the absence of PNA, the reactivity of the phenolic radical generated as an intermediate was found to be G ≫ T ≫ C, A; by inclusion of the PNA delivery agent, cross-links between the two oligomers could be observed with T and C bases in the vicinity of the nickel complex, although G was still the most reactive site. The metal complex could be removed by treatment with EDTA following which the Schiff base linkage was readily hydrolyzed. The final result in this case is a salicylaldehyde moiety appended at the target site in DNA.

INTRODUCTION

Both nucleic acids and proteins are rich in nucleophilic sites as well as containing heterocyclic components susceptible to oxidation. Oxidation of either of the two biopolymers generates an electron-deficient site that can lead to covalent bond formation with a nucleophilic partner. For example, oxidative adducts to DNA bases include the well characterized addition of tyrosine's phenol group to both cytosine and thymine heterocycles as part of the molecular basis of DNA–protein cross-linking (*1*, *2*). Additionally, our laboratory has shown that a phenolic radical generated as part of a metallosalicylaldehyde complex undergoes facile addition to guanine forming a covalent adduct to RNA or DNA (*3*–*5*). Such a radical can be effectively produced with a nickel(II) salen complex (Scheme 1, M = Ni) whose one-electron oxidation is predominantly centered on the ligand rather than the metal (*6*). The N-terminal peptide sequence XXH (X = any amino acid) is also a good binding site for nickel(II) producing a redox-active complex and allowing conjugation of the complex to any peptide or protein sequence via elaboration of the C-terminus of XXH to include a DNA-binding sequence. Indeed, both metallosalens and metallopeptides have served as reactive components of bioconjugates for site-selective modification of DNA (*7*–*10*). By combining these two motifs, the ability of nickel(II) salen to form oxidative adducts (*11*) and the peptide features of the NiXXH complex (*12*), we designed the Ni(sal-XH) complex. In this complex, the minimal peptide unit is a dipeptide in which the second amino acid is histidine to provide a strong coordination site for the metal, and the first amino acid is any primary amine-containing α-amino acid (i.e. X ≠ proline) such that the amino terminus can form a Schiff base with salicylaldehyde (Scheme 1).

We previously reported the structure and properties of a prototype complex, Ni(sal-RH), the first tetradentate metal complex of a peptide-salicylaldimine (*13*). Crystallographic analysis showed the formation of a highly planar nickel(II) complex with coordination to the phenolate oxygen, the imine nitrogen, one deprotonated amide nitrogen, and an imidazole nitrogen with no additional axial ligands. An arginine residue at the N-terminal position enhanced both water solubility of the complex and its electrostratic interaction with DNA. Oxidation of the nickel(II) complex could be triggered in either of two ways, using the strong oxidant $KHSO_5$, or by adding a reducing agent, HSO_3^- to an aerobic aqueous solution of Ni(sal-RH). In the latter case, the nickel complex serves initially as a catalyst for in situ autoxidation of sulfite to HSO_5^- (*14*–*16*) and subsequently as a substrate for ligand-centered oxidation.

In the initial study, we found guanine bases in oligodeoxynucleotides exhibited the highest intrinsic reactivity with the Ni(sal-RH) complex under oxidative conditions (*13*), as was the case for other nickel salen-type complexes (*3*, *5*, *17*, *18*). Our subsequent goal was to explore the utility of Ni(sal-XH) as a DNA modifying agent under conditions where the salicylaldimine radical could be delivered site specifically to bases other than guanine. Targeted delivery of DNA alkylating agents has

been demonstrated for a variety of conjugates to distamycin analogues (*19*, *20*), and metallopeptides have been used for site-specific cleavage of nucleic acids via conjugation to proteins (*9*), distamycin-like polyamides (*21*), and PNA (*7*). In the present work, we examine the ability of PNA conjugates of the Ni(sal-XH) motif to covalently attach the salicylaldehyde unit to various bases of an oligodeoxynucleotide in order to demonstrate the utility of the Ni(sal-XH) to ultimately modify DNA with a unique aldehyde moiety.

Peptide nucleic acid (PNA) can serve as an ideal delivery agent to target specific sites in nucleic acids due to its exceptional properties for nucleic acid binding and ease of synthesis (*22*). PNAs have high binding affinity for DNA because of their neutral charge, and because PNA-DNA duplexes show higher melting temperatures than DNA–DNA duplexes, shorter sequences can be used to impart high stability to a duplex. PNA is less tolerant of base pair mismatches than is DNA; a single mismatch typically leads to an 8–20 °C lowering of the T_m in a PNA–DNA duplex ensuring higher sequence selectivity than for DNA–DNA duplexes (*23*–*25*). We therefore designed the Ni(sal-XH)–PNA conjugate, **1** (Scheme 2), that includes a PNA decamer conjugated to an N-terminal RHG peptide for formation of the appropriate redox-active nickel complex. Its reactivity toward complementary targets presenting any of the four natural bases in proximity to the metal complex was then examined.

EXPERIMENTAL PROCEDURES

Synthesis of NH$_2$-RHG-[TACCTAGCAT]-R-CONH$_2$. The PNA–peptide conjugate was prepared at a 0.1 mmol scale using Rink Amide AM resin (0.145 g) to build the conjugate. Fmoc- and Bhoc-protected monomers for PNA synthesis were purchased from Perseptive Biosystems; other protected amino acids were purchased from Nova-Biochem. The initial arginine at the C-terminus was coupled to the resin using standard peptide synthesis protocols. The solvent system was DMF, the activating agent was *N*-methylmorpholine in DMF, and the deprotecting agent was 20% piperidine in DMF. The peptide synthesizer was then switched to an NMP (*N*-methylpyrrolidine)-based solvent system (20% DMSO in NMP) (*26*) for addition of the Bhoc-protected PNA monomers. The activating agent was 10% DIPEA (*N*,*N*-diisopropylethylamine) and 10% lutidine in 20% DMSO/NMP, and the deprotecting agent was 30% piperidine in 20% DMSO/NMP. Each PNA monomer (0.1 mmol) was weighed into vials along with HBTU (0.3 mmol). An endcapping reagent (3 mL) was used that consisted of 5% acetic anhydride and 6% lutidine in 20% DMSO/NMP. The mixing times and activating/deprotecting steps reflected published protocols (*22*). Next, the solvent system of the synthesizer was switched back to DMF, as described above, to add the three N-terminal amino acids. Fmoc-Gly-OH, Fmoc-His(trt)-OH, and Fmoc-Arg(pbf)-OH were added sequentially using standard protocols. Endcapping was achieved using acetic anhydride. The final step was deprotection of the last amino acid without endcapping.

The PNA–peptide was cleaved from the resin using a cleavage cocktail of 95% trifluoroacetic acid, 4% *m*-cresol (necessary to cleave Bhoc protecting group) and 1% triisopropylsilane (a radical scavenger). The cocktail was shaken with the beads at room temperature for 1 h. The PNA–peptide conjugate was dried and washed three times with diethyl ether and then dried by evaporation. The sample was HPLC purified using an analytical C18 column (Viadac, 4.6 × 250 mm). The dried sample was dissolved in 35 mL of 0.1% TFA and filtered. A gradient from 100% solvent A (0.1% aqueous TFA) to 18% solvent B (acetonitrile) was used. The peak at 26 min. was analyzed by ESI-LC-MS (see Supporting Information) and showed a molecular mass at 3193.4 (calcd = 3193.7).

Synthesis and Purification of DNA Oligomers. Oligodeoxynucleotides were synthesized using standard automated solid-support chemistry protocols on an Applied Biosystems Model 392B synthesizer using the manufacturer's protocols. Gel electrophoresis on 20% polyacrylamide gels with 7M urea at 40 W provided the purified oligodeoxynucleotides. The purity of synthesized oligodeoxynucleotides was confirmed by mass spectral analysis on a Micromass Quattro II instrument.

Electrophoretic Mobility Shift Assays. The 14nt oligodeoxynucleotides were 5′-end labeled using T4 polynucleotide kinase and [(γ-^{32}P] ATP. Unreacted [(γ-^{32}P] ATP was separated from labeled oligonucleotides with MicroSpin G-25 columns (Amersham Pharmacia Biotech). DNA oligonucleotides were annealed to the PNA–peptide strand in 10 μL solutions of 10 mM NaH_2PO_4. The DNA concentration was kept constant (2.2 μM) while the PNA–peptide concentration varied from 0 to 2.2 μM. The resultant duplexes were applied to a 15% nondenaturing polyacrylamide gel and subjected to electophoresis at 2 W for 4.5 h in the cold box (4 °C). Radiolabeled duplex formation was quantified by storage phosphor autoradiography (Molecular Dynamics Storm 860).

Formation of the 1:DNA Duplexes. 5′-[^{32}P]-End-labeled oligodeoxynucleotides (3N14, N = A, C, G, T) were annealed to the PNA–peptide strand in 200 μL solutions containing 100 mM NaCl plus10 mM NaH_2PO_4 (pH = 8) to yield 1 μM solutions of DNA/PNA–peptide duplexes. Ni(sal)$_2$ was prepared by mixing stoichiometric amounts of Ni(OAc)$_2$ in 4:1 ethanol:water and salicylaldehyde in ethanol and collection of the precipitate. Approximately 1.5 mg of Ni(sal)$_2$ was added to each duplex solution and shaken overnight in the cold box at 4 °C. Excess amounts of Ni(sal)$_2$ were removed by filtration through SPIN-X columns, followed by washes with 100 μL of distilled H_2O (final volume = 300 μL). The solution volume was then reduced to 100 μL to yield 2 μM **1**:DNA duplex.

Cross-Link Formation. A 20-μL aliquot of 2 μM radiolabeled **1**:DNA duplex was added to 4 μL of 1 mM $KHSO_5$ in a 40-μL solution of 100 mM NaCl/10 mM NaH_2PO_4 (pH = 7) and incubated for 15 min at room temperature. Reactions were quenched by adding 2 μL of 20 mM EDTA and 2 μL of 50 mM HEPES followed by dialysis

overnight. Oxidized and unmodified **1**:DNA duplex was then treated with 0.2 M piperidine for 30 min at 90 °C. Both unmodified and oxidized **1**:DNA duplex not treated with piperidine were used as controls in these experiments. All reactions were lyophilized to dryness, resuspended in 4 μL of loading buffer, applied to a 15% polyacrylamide gel in the presence of 7M urea, and subjected to electrophoresis for 3 h at 40 W. Formation of the high molecular weight products was then monitored by storage phosphor autoradiography (Molecular Dynamics Storm 860).

Adduct Formation of Ni(sal-RH) with Plasmid DNA. Ni(sal-RH) was prepared as previously described (*13*). Reactions with the single-stranded plasmid from M13mp18 phage were conducted using 100 μM Ni(sal-RH) and 50 μM Na_2SO_3 using the same reaction and buffer conditions as for oligonucleotide work. Primer extension and PCR were performed using 5′-[^{32}P]-end labeled d(GTTTTCCCAGTCACGAC), the −40 primer relative to the Hind III restriction site, according to the procedure for the Thermo Sequenase cycle sequencing kit (Amersham). Analysis and imaging was conducted as described above.

RESULTS AND DISCUSSION

The peptide bioconjugate **1** was designed to comprise a 10-mer PNA sequence for hybridization to its complementary sequence in DNA along with the N-terminal XH motif for formation of the redox-active Ni(sal-XH) complex. A glycine spacer was added between the metal ligating peptide and the PNA sequence, and arginines were included at both the N terminus and the C terminus for additional water solubility and electrostratic interactions with DNA. Although lysine residues could also have served this purpose, they may have interfered with Schiff base formation at the amino-terminal site. Finally, the C terminus of the oligomer was left as a neutral amide rather than a carboxylate group by synthesis on Rink Amide resin, again for facilitating binding to DNA. The synthesis of the peptide−PNA portion of **1** was achieved through a combination of standard protocols for peptide and for PNA synthesis on solid support. The nickel salicylaldimine complex of the peptide could be prepared either before or after hybridization to the DNA complement. The completed synthesis of **1** was analyzed by ESI-MS (see Supporting Information) after HPLC purification of the peptide−PNA ligand.

The PNA conjugate **1** was tested for hybridization to DNA complements by both thermal melting studies and gel mobility shift analysis using the four oligodeoxynucleotides shown in Figure 1. Each of the 14-mers contained the 10-mer complementary sequence to the PNA segment at its 5′ end, a one-nucleotide spacer of deoxyadenosine, thought to be the least reactive of the four bases, and a trinucleotide NNN sequence at the 3′ end that would be oriented in proximity to the Ni(sal-RH) group and would serve as the target sites for oxidative adduct formation. T_m values were above 55 °C, and a gel shift experiment indicated tight binding between the PNA−peptide conjugate and each of the 3N14 complements. A representative assay is shown in Figure 2 for 3T14.

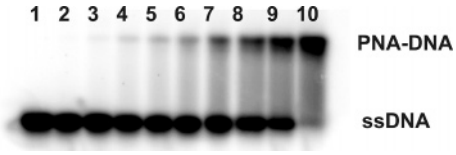

Figure 2. PNA−peptide binding examined by the gel mobility shift assay. In a total volume of 10 μL, a radiolabled DNA (3T14) was incubated with various amounts of a complementary PNA−peptide as described in the Experimental Procedures. The samples were analyzed on the 15% nondenaturing polyacrylamide gel. PNA concentrations in lanes 1−10 were 0, 0.011, 0.022, 0.034, 0.069, 0.14, 0.28, 0.55, 1.1, and 2.2 μM.

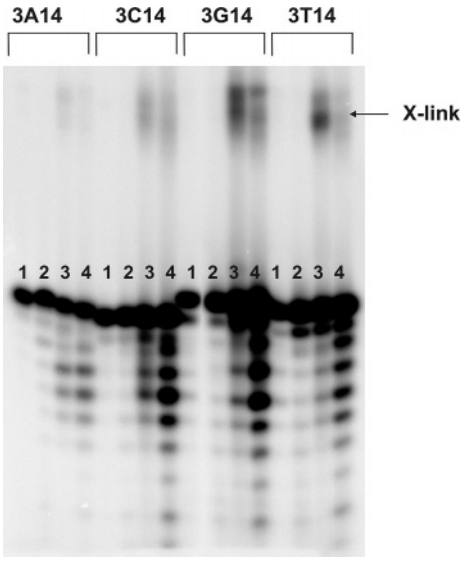

Figure 3. DNA−PNA cross-link formation after incubation DNA + bioconjugate **1** with $KHSO_5$ as described in the Experimental Procedures. For each series, lane 1 contains unoxidized DNA·**1** in buffer; lane 2 contains unoxidized DNA·**1** treated with 0.2 M piperidine; lane 3 − DNA·**1** incubated with 100 μM $KHSO_5$; lane 4 − DNA·**1** incubated with 100 μM $KHSO_5$ and treated with 0.2 M piperidine. All reactions were subjected to electrophoresis on a denaturing 15% polyacrylamide gel. The positions of the high molecular weight products are indicated by the arrow.

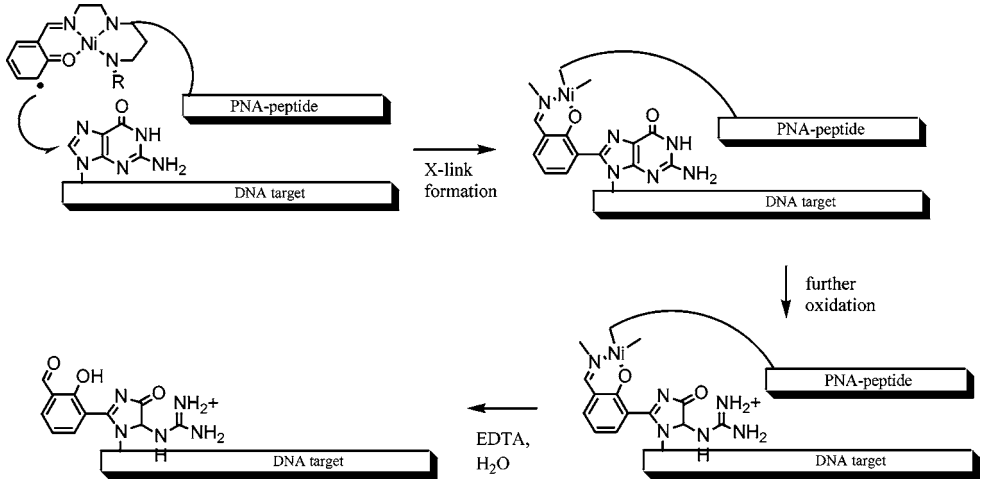
To assess the ability of the PNA−Ni(sal-RH) bioconjugate to form covalent cross-links to target oligodeoxynucleotides, we analyzed both oxidation and adduct formation by denaturing gel electrophoresis (Figure 3). For each of the DNA 14-mers containing the complement to the PNA sequence plus a 3′-NNNA overhang near the Ni(sal-RH) complex, the **1**:DNA duplex was treated with $KHSO_5$ to trigger oxidation of the nickel(II) complex. Because nickel−salicylaldimine complexes typically undergo ligand-centered oxidation, the resulting phenolic radical is expected to couple to one of the 3′ overhanging nucleotides. For each set of experiments, the first two lanes represent control studies without oxidant and −/+ piperidine treatment. Piperidine treatment would be expected to result in strand scission at sites of base oxidation and/or adduct formation (*27*). Lanes 3 and 4 show adduct formation and strand scission −/+ piperidine treatment, respectively.

It is clear from the results in Figure 3 that guanosine nucleotides retain the highest level of reactivity toward oxidative cross-link formation with thymidine also showing substantial adduct formation. The ability of dC to undergo adduct formation was apparent but small, while that of dA was almost nonexistent. Treatment of the

Scheme 3. Proposed Mechanism of Cross-Link Formation and Hydrolysis



cross-linked duplexes with piperidine led to some loss of intensity presumably due to strand scission as was previously shown for the parent complex, Ni(sal-RH) (*13*). In all cases, the overhanging nucleotides appear also to be subject to oxidative damage leading to strand scission as evidenced by the bands observed below starting material on the gel. This is likely due to the rather high concentration of $KHSO_5$ employed in the reaction (100 μM). Previously, we found that Na_2SO_3 could be used in place of $KHSO_5$ wherein the nickel complex served to catalyze in situ oxidation of sulfite to monoperoxysulfate, avoiding the use of excess oxidant (*13*); however, trials with Na_2SO_3 in the present system led to lower yields of cross-link formation as well.

On the basis of prior work in our laboratory and others, we propose the following mechanism of covalent adduct formation. First, the PNA strand hybridizes with DNA delivering the redox-active nickel complex to the vicinity of the 3′-overhang of the DNA target strand. Reaction with $KHSO_5$ as oxidant (or nickel-catalyzed autoxidation of Na_2SO_3) leads to ligand-centered oxidation generating a phenol radical on the salicylaldimine moiety. Radical attack at C8 of guanine (Scheme 3) or the 5,6 double bond of T or C leads to covalent adduct formation. The adducts appear to be sensitive to piperidine treatment, giving rise to strand scission at the site of cross-linking under Maxam–Gilbert conditions (Figure 3, lanes 4). In the case of guanine C8 phenolic adducts, we previously showed that the adducts were highly sensitive to further oxidation by a pathway analogous to that of 8-oxoguanosine, leading to a guanidinohydantoin derivative. This further oxidation product likely accounts for the additional high-molecular weight band observed by PAGE (Figure 3) under conditions where relatively high concentrations of oxidant were used. This was well characterized for the parent compound Ni(sal-RH) by ESI-MS analysis of the various adducts isolated from the gel (*13*). Furthermore, it was demonstrated that the peptide delivery vehicle could be released from its target by treatment with EDTA. Removal of the coordinating nickel ion presumably sensitizes the salicylaldimine to hydrolysis. The final product after EDTA treatment is therefore the original strand with a salicylaldehyde moiety tagging the site of adduct formation.

The extent of reaction at the various positions of the NNN overhang were analyzed after piperidine treatment. While all three positions were reactive, there was in each case a slight preference for reaction at the internal positions, N_{12} and N_{13}, as opposed to the final nucleotide,

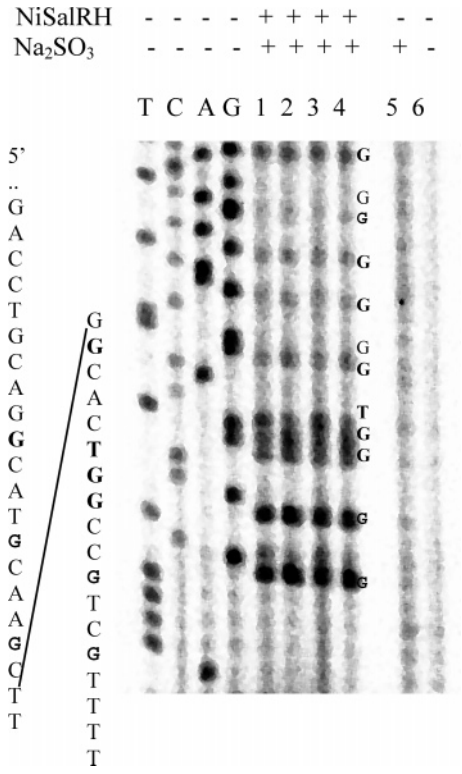


Figure 4. Primer extension analysis of single-stranded phage DNA (M13mp18) cross-linked to Ni(sal-RH). A portion of the sequence analyzed is shown at left with reactive sites in boldface. Lanes T, C, A, G are Sanger sequencing lanes of the single-stranded phage using ddATP, ddGTP, ddTTP, and ddCTP, respectively. Lanes 1–4 are reaction lanes. Cross-linking of Ni(sal-RH) with ss phage M13mp18 sterically inhibits Thermo Sequenase and hence primer extension stops before bases cross-linked to Ni(sal-RH). Control lane 5 demonstrates the effect of Na_2SO_3 in the absence of Ni(sal-RH). Control lane 6 is primer extension in the absence of Na_2SO_3 and Ni(sal-RH).

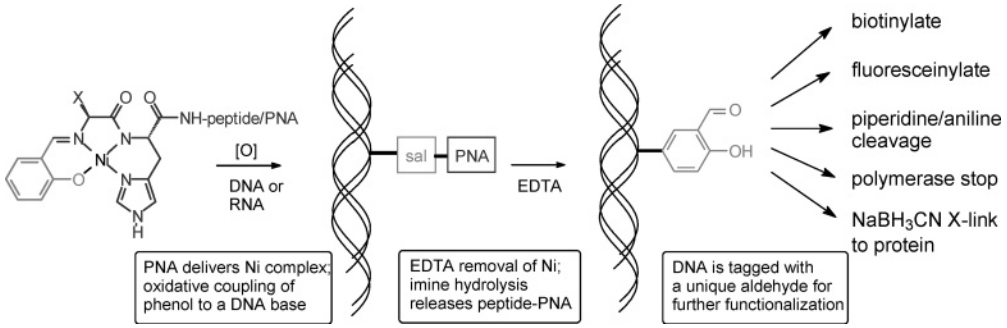
N_{14} (see Supporting Information), and the trend was the same for all bases except T, for which all three positions were equally reactive. An explanation consistent with these data is that bioconjugate **1** positions the reactive phenol radical nearest the bases that are 2–3 nucleotides beyond the complementary duplex region.

To examine whether the observed reactivity of the nickel salicylaldimine group with T or C, in addition to G, could be found in a larger sample of DNA, we analyzed the single-stranded plasmid M13mp18 with the parent complex, Ni(sal-RH), lacking the PNA delivery unit.

Scheme 4. Utility of the Ni(sal-XH) Motif in Bioconjugates for Delivery of an Aldehyde Functional Group to Specific Sites in DNA



Conditions were chosen under which we previously observed a high degree of adduct formation as opposed to simple oxidative damage. These conditions involved the use of relatively low concentrations of sulfite such that the strong oxidant HSO_5^- was only formed via nickel-mediated autoxidation, and the concentration of HSO_5^- remained negligible. Oxidative adduct formation was analyzed using Thermo Sequenase, an exonuclease-free thermostable DNA polymerase. Primer extension was inhibited by the presence of an adduct, and thus the bands analyzed in lanes 1−4 of Figure 4 represent adduct sites that are one nucleotide shorter than the dideoxy sequencing lanes for which insertion opposite the template base has occurred. The data shown represent a small segment of a larger analysis. In general, reactivity still was seen only at guanines; however, a small number of thymines were also observed to form adducts. These data is therefore in keeping with the assessment that the overall reactivity preference of the phenolic radical generated from the Ni(sal-RH) complex is G > T > C ≫ A.

CONCLUSIONS

We have demonstrated that a Schiff base complex of nickel(II) can be readily appended to a synthetic peptide−PNA conjugate for oxidative cross-linking to a complementary strand of DNA. Minimal requirements for the formation of the nickel complex are an N-terminal XH dipeptide motif in which X represents any α-amino acid with a primary amine available for imine formation with salicylaldehyde. The nickel(II) complex can then be prepared before or after conjugation of PNA to its DNA target. Oxidation with $KHSO_5$, or in situ formation of this oxidant by nickel-catalyzed sulfite autoxidation, leads to oxidative coupling between the phenol ring of salicylaldehyde and a DNA base. Although the intrinsic reactivity of the phenol radical is greatest toward guanosine (G > T > C > A), the reactivity of T and C is enhanced by delivery of the redox-active metal complex in proximity to these bases by the PNA conjugate. Even with delivery, however, adenine remains low in reactivity.

The ability to remove the metal complex and its PNA targeting agent by simple addition of EDTA is a further benefit of this design. The final result is a DNA strand whose targeted site bears a salicylaldehyde tag (Scheme 4). Such a unique aldehyde may be further functionalized with aldehyde reactive reagents leading to site-specific biotinylation, fluorescent labeling, or cross-linking to DNA binding proteins via reductive amination. Such features greatly expand the arsenal of metallo−PNA conjugates that has recently seen development in other laboratories as well (*28*−*33*).

Pasteur, B.P.28, 67037 Strasbourg Cedex 2, France. Received September 21, 2004; Revised Manuscript Received November 22, 2004

The feasibility of two-step radioimmunotherapy (RIT) of cancer by the Affinity Enhancement System (AES) has been demonstrated in experimental and clinical studies. This technique, associating a bispecific antibody and a bivalent peptide radiolabeled with iodine-131, has been developed to reduce toxicity and to improve therapeutic efficacy compared to one-step targeting methods. The use of AES with different beta-emitters such as rhenium-188, samarium-153, or lutetium-177 or alpha-emitters such as actinium-225 or bismuth-213 is now considered. Thus three new peptides, designed to allow for the coupling of a variety of bifunctional chelating agents BCA, were synthesized by associating two glycyl-succinyl-histamine (GSH) arms, which are recognized by the 679 monoclonal antibody (mAb-679), with different binding agents, such as *p*-nitrophenylalanine or *N,N*-bis(carboxymethyl)-4-*N*′-(9-fluorenylmethyloxycarbonyl)aminobenzylamine. Immunoreactivity and serum stability evaluation were performed for each synthesized peptide. One of the three peptides (**LM218**) proved to be more stable than the others, and three different BCAs were coupled to **LM218** (CITC-DTPA, CITC-TTHA, and CITC−CHXA″DTPA). One of these products, **LM218-BzTTHA** was radiolabeled with indium-111 without loss of immunoreactivity toward the mAb-679. These new peptides will allow pretargeted RIT with a large variety of radionuclides, to adapt the choice of the radionuclide (LET, half-life, penetrating emission) to the nature and size of targeted tumors.

INTRODUCTION

The targeting of cancer cells depends on the capacity of monoclonal antibodies to recognize antigens expressed at the surface of malignant tumors. These antibodies are used as vectors for radionuclides acting within the tumor mass. They were originally radiolabeled with a gamma emitter and used for diagnostic purposes in immunoscintigraphy (IS) of solid tumors (*1*). This concept was then extended to radioimmunotherapy (RIT[1]), using β- or α-emitters (*2*). However, this system often involves high irradiation of normal tissues, an undesirable effect due in part to the low uptake of monoclonal antibodies in tumor sites (0.01% ID/g tumor), which requires the infusion of large radioactivity doses (*3*), and the relatively slow clearance of excess activity (several hours). Pretargeting techniques allow substantial reduction of nonspecific irradiation of normal tissues. The Affinity Enhancement System (AES) is based on the use of a bispecific antibody (antitumor antigen x anti-hapten) and a radiolabeled peptide carrying two haptens (*4*, *5*). The principle consists of administering the bispecific antibody intravenously and to allow it to bind tumor cells. After a few days to allow elimination of excess free antibody, the radiolabeled bivalent peptide is injected, which is recognized by the bispecific antibody prelocalized in the tumor. Because of its small size, the peptide diffuses rapidly toward the target, and its clearance is much faster than that of a radiolabeled monoclonal antibody. The di-DTPA-TL peptide (Figure 1), which is bivalent with respect to the DTPA-indium hapten, has been used for immunoscintigraphy of colon cancer (*6*) and medullary thyroid carcinoma (*7*), and RIT of medullary thyroid carcinoma (*8*) and small-cell lung cancer (*9*) in association with the F6-734 (anti-CEA x anti-DTPA-indium) bispecific antibody. This peptide is currently tested in clinical trials for the therapy of CEA-expressing tumors (*10*) in association with the hMN14-734 (anti-CEA x anti-DTPA-indium) bispecific antibody. The di-DTPA-TL peptide allows radiolabeling with indium-111 on the DTPA groups and radiolabeling with iodine-131 on the aromatic ring of the tyrosine present in the linker peptide. A similar bivalent hapten based on DTPA-indium has been tested with the AES to target indium-111 to renal cell carcinoma in animals (*11*) and a derivative of this

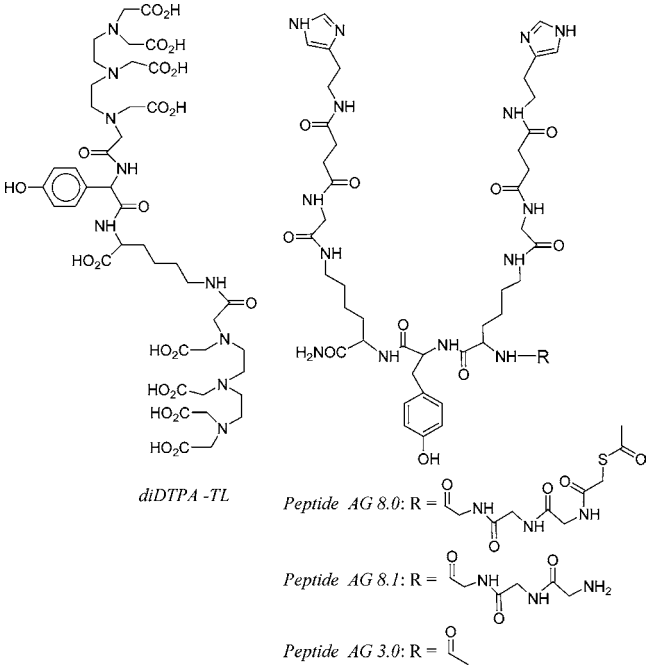

Figure 1. di-DTPA-TL, AG8.0, AG8.1 and AG3.0 Peptides.

peptide, designed to be labeled with technetium-99m and rhenium-188, has also been tested in animals in a colon cancer model (*12*). Peptides AG3.0 and AG8.1 (*13*) (Figure 1) in association with bispecific antibody F6-679 (anti-CEA x anti-GSH) allow direct radiolabeling with iodine-131 on the aromatic ring of tyrosine. Peptide AG8.0 was designed to allow radiolabeling with rhenium-188 and technetium-99m (*14*). However, in vivo targeting with rhenium-188 was not entirely satisfactory (*15*).

Iodine-131, the main radionuclide currently used in RIT, possesses satisfactory specific activity and is fairly easy to radiolabel. However, its radiophysical properties (low-energy β^- radiation, strong gamma emission, and long half-life) do not make it the best radionuclide for RIT applications (*16*). Radionuclides such as actinium-225, samarium-153, yttrium-90, lutetium-177, holmium-166, rhenium-186/188, and astate-211 possess very interesting properties. The possibility of labeling a peptide with each of these radionuclides would provide a therapeutic tool adaptable to different tumor targets. The intrinsic properties of each β- or α-emitter (physical half-life, linear energy transfer, range, energy) could be exploited as a function of the nature and size of the tumor targets to be destroyed. However, the use of these radionuclides within the AES requires their complexation by a bifunctional chelating agent (BCA) (*17*−*20*) coupled to the peptide. In this line of work Sharkey et al. (*21*) have tested in animals, in a colon cancer model, GSH containing peptides bearing a 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) that forms stable complexes with radionuclides such as lutetium-177, yttrium-90, and other radiometals.

The purpose of the present study was to design and synthesize new versatile peptides capable of being coupled to a variety of BCAs. This would allow iodine-131, which is currently used in RIT, to be replaced by other potentially more efficient radionuclides. An analogue of peptide AG8.1 was synthesized, which conserves the recognition properties of AG8.1 for mAb-679 (*22*) and bears a BCA coupling site. To this effect, an aromatic amine ($pK_a = 3$ to 5) was used, as a coupling site, allowing the coupling reaction to be carried out at pH 6, when the amine functions of imidazole ($pK_a = 7.1$) are not reactive. The introduction of a BCA on this new position is less susceptible to interfere in the recognition of the GSH site by mAb-679. On the other hand, the choice of an aromatic amine allows its transformation in isothiocyanate, so the coupling reaction to the BCA can occur either after activation of the peptide or activation of the BCA.

Three analogues of peptide AG8.1 have been synthesized: peptides **LM085**, **LM054**, and **LM218**. Their binding to mAb-679 was checked first, in comparison with that of peptide AG8.1, and their stability in serum was then evaluated. These tests showed that peptide **LM218** was the best candidate. **LM218** was coupled to several BCAs (CITC-DTPA (*17*), CITC-TTHA (synthesis nondescribed), and CITC−CHXA″DTPA (*18*, *19*)). One of the obtained bivalent peptides, **LM218-BzTTHA**, was radiolabeled with indium-111. The resulting radiolabeled product was fully immunoreactive toward mAb-679.

MATERIAL AND METHODS

General. All chemicals were of the highest purity commercially available (Sigma-Aldrich Company). Indium-111 was purchased from CIS bio international as a solution of indium-111 in HCl 0.05 M (specific activity: 370 MBq/μg; volumetric activity 370 MBq/mL). AG8.1 was kindly provided by Dr A. Gruaz-Guyon (Inserm, Paris, France) and mAb-679 by Dr. D. M. Goldenberg (IBC Pharmaceuticals, Inc. Morris Plains, NJ). The HPLC solvents were purchased from Carlo-Erba. TLC was performed using precoated Kieselgel 60 plates F_{254} (TLC plates, Carlo-Erba) and was visualized by UV or iodine. Silica gel (230−400 mesh, Carlo-Erba) was purchased from Merck. High-Performance Liquid Chromatography was carried out at 211 nm on a Waters 600 HPLC System using analytical reverse phase HPLC (SymmetryShield 5 μm RP-18 4.5 × 150 mm, Waters) and semipreparative reverse phase HPLC columns (SymmetryShield 7 μm RP-18, 19 × 300 mm, Waters). The elution solvents are as follows: solvent A: TFA/H_2O 0.1%; solvent B: acetonitrile. HPLC conditions will be given in details for each case. NMR spectra were recorded on a BRUKER AC 250 apparatus (250.133 MHz for ^1H). Chemical shifts are indicated in δ values (ppm) downfield from internal TMS and coupling constants (*J*) are given in Hertz (Hz). Multiplicities were recorded as s (singlet), d (doublet), t (triplet), and m (multiplet). Mass spectra were recorded using a Bruker Esquire LC electrospray mass spectrometer with methanol or water as carrier solvent. Competition curves and serum stability were performed in polypropylene tubes coated with mAb-679. The radiochemical purity was measured by thin layer silica gel chromatography, and the chromatograms were analyzed after exposure on a phosphorus screen (Molecular Dynamics, Sunnyvale, CA) using IPLab-Gel software (Analytics Corp., Atlanta, GA).

Synthesis: N_α-(Benzyloxycarbonyl)lysine Ethyl Ester (1). A suspension of N_α-(benzyloxycarbonyl)lysine (4.02 g, 14.3 mmol) in 600 mL of EtOH was saturated with HCl_g until total dissolution. The solution was stirred at room temperature for 4 h. After concentration to dryness, the residue was taken up in AcOEt and washed with 1 M NaOH. The organic layer was dried with Na_2SO_4, filtered, concentrated, and dried under reduced pressure. 3.74 g of yellow oil were obtained (85%).^1H NMR ($CDCl_3$): δ (ppm) 1.27 (t, 3H, $J = 7.1$ Hz); 1.31−1.92 (m, 8H); 2.65 (t, 2H, $J = 6.8$ Hz); 4.18 (q, 2H, $J = 7.1$ Hz); 4.35 (q, 1H, $J = 6.1$ Hz); 5.10 (s, 2H); 5.40 (d, 1H, $J = 6.1$ Hz); 7.33 (s, 5H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.5; 22.9; 32.8; 33.4; 41.1; 54.2; 61.7; 67.2; 127.0−128.4 (5C); 136.7; 156.3; 172.9. MS (ES^+) *m/z* 309 [MH^+].

Glycyl-N_α-(benzyloxycarbonyl)lysine Ethyl Ester (2). *N*-(*tert*-Butyloxycarbonyl)glycine *p*-nitrophenyl ester (3.59 g, 12 mmol) and **1** (3.74 g, 12 mmol) were dissolved in 20 mL of anhydrous THF under nitrogen atmosphere. After addition of triethylamine (0.72 g, 7.2 mmol), the solution was stirred at room temperature for 2 h and then concentrated to complete dryness. The residue was taken up in AcOEt and washed with 0.2 M HCl. The organic layer was dried with Na_2SO_4, filtered, and concentrated under vacuum. The residue was purified by column chromatography on silica gel eluting with dichloromethane−ethyl acetate (1:1) (R_f = 0.3) to give 4.25 g of *N*-(*tert*-butyloxycarbonyl)glycyl-N_α-(benzyloxycarbonyl)-lysine ethyl ester as a colorless oil (86%). ^{1}H NMR ($CDCl_3$): δ (ppm) 1.24 (t, 3H, J = 7.1 Hz); 1.30−1.81 (m, 15H); 3.24 (m, 2H,); 3.73 (d, 2H, J = 5.8 Hz); 4.15 (q, 2H, J = 7.1 Hz); 4.35 (m, 1H); 5.30 (bs, 3H); 5.43 (d, 1H, J = 8.1 Hz); 6.21 (m, 1H); 7.35 (s, 5H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.5; 22.8; 28.6 (3C); 29.3; 32.5; 39.3; 44.7; 54.1; 61.8; 67.3; 80.5; 128.4−128.9 (5C); 137.0; 156.5 (2C); 170.0; 172.8. MS (ES^+) *m/z* 466 [MH^+]. Trifluoroacetic acid (4 mL, 52 mmol) was slowly added to *N*-(*tert*-butyloxycarbonyl)glycyl-N_α-(benzyloxycarbonyl)lysine ethyl ester (4 g, 8.6 mmol) at 0 °C. The mixture was stirred for 2 h at 30 °C before the excess of TFA was evaporated in vacuo. The residue was taken up in CH_2Cl_2 and washed with 1 M NaOH. The organic layer was dried with Na_2SO_4, filtered, and concentrated to dryness. 2.75 g of compound **2** was obtained as a yellow oil (88%). ^{1}H NMR ($CDCl_3$): δ (ppm) 1.23 (t, 3H, J = 7.1 Hz); 1.31−1.81 (m, 8H); 3.19−3.27 (m+s, 4H); 4.15 (q, 2H, J = 7.1 Hz); 4.30 (m, 1H); 5.10 (s, 1H); 5.60 (d, 1H, J = 8.3 Hz); 7.33 (s; 6H). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.5; 22.9; 28.7; 32.4; 38.8; 45.1; 54.1; 61.8; 67.2; 128.4−128.9 (5C); 136.7; 156.4; 172.8; 173.2. MS (ES^+) *m/z* 366 [MH^+].

Succinylhistamine (2bis). Succinic anhydride (1.76 g, 17.6 mmol) was dissolved in 15 mL of anhydrous DMF, under nitrogen atmosphere. A solution of histamine (1.77 g, 15.9 mmol) in 25 mL of anhydrous DMF was added dropwise. The reaction mixture was stirred 1 h at room temperature. The DMF was removed under vacuum. Then 20 mL of ethanol was added, and the reaction mixture was chilled at 4 °C for a night. The white precipitate was filtered, washed with cold ethanol, and dried in vacuo. 2.83 g of a white solid was obtained (84%). ^{1}H NMR (CD_3OD): δ (ppm) 2.39 (m, 2H); 2.53 (m, 2H); 2.80 (t, 2H, J = 6.8 Hz); 3.42 (t, 2H, J = 6.8 Hz); 7.07 (d, 1H, J = 1.2 Hz); 8.12 (d, 1H, J = 1.2 Hz). ^{13}C NMR (CD_3OD): δ (ppm) 27.0; 32.7 (2C); 40.4; 118.4 (2C); 136.2; 175.6; 179.1. MS (ES^+) *m/z* 212 [MH^+].

Histaminosuccinylglycyl-N_α-(benzyloxycarbonyl)-lysine Ethyl Ester (3). To 1.055 g (5 mmol) of **2bis** dissolved in 20 mL of hot anhydrous DMF, was added, at 0 °C, 0.830 g (6 mmol) of *p*-nitrophenol, under nitrogen atmosphere. The reaction mixture was stirred 30 min at 0 °C before DCC (1.03 g, 5 mmol) was added. After 4 h at 0 °C a solution of **2** (1.83 g, 5 mmol) dissolved in 20 mL of anhydrous DMF was added slowly. The reaction mixture was stirred overnight at room temperature and then DMF was removed under vacuum. 15 mL of MeOH was added, and the reaction mixture was chilled at 4 °C for a night. After filtration of DHU, the filtrate was evaporated to dryness and purified by column chromatography on silica gel eluting with ethyl acetate and then methanol (R_f (MeOH) = 0.5). After crystallization in acetone, 1.09 g of white powder was obtained (39%). ^{1}H NMR (CD_3OD): δ (ppm) 1.20 (t, 3H, J = 7.1 Hz); 1.41−1.77 (m, 6H); 2.48 (m, 4H); 2.74 (t, 2H, J = 7.0 Hz); 3.18 (t, 2H, J = 6.9 Hz); 3.36 (t, 2H, J = 7.0 Hz); 3.79 (s, 2H); 4.11 (m, 3H); 5.07 (s, 2H); 6.82 (d, 1H, J = 1.1 Hz); 7.33 (s, 5H); 7.60 (d, 1H, J = 1.1 Hz). ^{13}C NMR (CD_3OD): δ (ppm) 14.8; 24.4; 28.1; 30.0; 32.1; 32.4; 32.5; 40.3; 40.8; 44.3; 55.9; 62.6; 67.9; 119.0 (2C); 129.1−129.8 (5C); 136.4; 138.5; 159.0; 172.1; 174.6; 174.9; 175.9. MS (ES^+) *m/z* 559 [MH^+].

Histaminosuccinylglycyllysine Ethyl Ester (4). Catalytic hydrogenation of **3** (558 mg, 1 mmol) in methanol (20 mL) over 10% Pd/C (0.3 equiv; w/w) was carried out at atmospheric pressure. After 4 h, the catalyst was filtered off (Celite) and the filtrate was removed under reduced pressure. 420 mg of a white solid was obtained (99%). ^{1}H NMR (CD_3OD): δ (ppm) 1.21 (t, 3H, J = 7.1 Hz); 1.43−1.80 (m, 6H); 2.50 (m, 4H); 2.64 (t, 2H, J = 7.0 Hz); 3.18 (t, 2H, J = 6.9 Hz); 3.37 (t, 2H, J = 7.0 Hz); 3.65 (m, 1H); 3.80 (s, 2H); 4.11 (q, 2H, J = 7.1 Hz); 6.72 (d, 1H, J = 1.1 Hz); 7.56 (d, 1H, J = 1.1 Hz). ^{13}C NMR (CD_3OD): δ (ppm) 14.8; 24.4; 26.1; 26.6; 28.0; 32.2; 32.3; 39.6; 40.7; 44.0; 55.7; 62.6; 119.2 (2C); 136.7; 172.2; 174.3; 174.7; 175.8. MS (ES^+) *m/z* 425 [MH^+].

Histaminosuccinylglycyl-N_α-(benzyloxycarbonyl)-lysine (4bis). Compound **3** (200 mg, 0.36 mmol) was dissolved in 1 mL of 1 M NaOH. After 2 h at room temperature, the mixture was evaporated in vacuo. The residue was taken up in 1 mL of water, and 1 M HCl was added until pH of the solution was 3. The solution was evaporated to dryness, and the white solid resulting was taken up in 1 mL of anhydrous MeOH. After 12 h at 4 °C, sodium chloride was filtered off and the filtrate evaporated. 189 mg of a white solid were obtained (99%). ^{1}H NMR (CD_3OD): δ (ppm) 1.39−1.78 (m, 6H); 2.37 (s, 4H); 2.99 (t, 2H, J = 6.1 Hz); 3.29 (m, 2H); 3.64 (m, 2H); 3.89 (m, 3H); 5.06 (s, 2H); 7.10 (s, 1H); 7.21 (s, 1H); 7.38 (s, 5H). ^{13}C NMR (CD_3OD): δ (ppm) 23.9; 26.1; 29.8; 30.1; 31.4; 32.3; 39.1; 40.0; 43.7; 55.5; 67.6; 118.2 (2C); 128.7 (2C); 129.0; 129.4 (2C); 135.8; 138.2; 159.0; 171.8; 175.4; 176.3; 176.7. MS (ES^+) *m/z* 531 [MH^+].

***N*-(*tert*-Butoxycarbonyl)-*p*-nitrophenylalanine *p*-Nitrophenyl Ester (5)**. To a solution of *N*-(*tert*-butoxycarbonyl)-*p*-nitrophenylalanine (200 mg, 0.64 mmol) and *p*-nitrophenol (98 mg, 0.70 mmol) in 5 mL of anhydrous THF was added dropwise, at 0 °C and under nitrogen atmosphere, a solution of DCC (133 mg, 0.64 mmol) in 10 mL of anhydrous THF. The reaction mixture was taken 4 h at 0 °C and 16 h at room temperature. DHU was filtered and washed with 5 mL of anhydrous DMF. The filtrate was evaporated to dryness, and the residue was taken up in 10 mL of anhydrous MeOH. After 4 h, the precipitated formed was filtered, washed with 10 mL of cold anhydrous MeOH, and dried in vacuo. 175 mg of a white solid was obtained (63%). ^{1}H NMR ($CDCl_3$): δ (ppm) 1.44 (s, 9H); 3.35 (m, 2H); 4.86 (m, 1H); 5.08 (d, 1H, J = 8.6 Hz); 7.23 (d, 2H, J = 9.2 Hz); 7.44 (d, 2H, J = 8.9 Hz); 8.23 (d, 2H, J = 8.9 Hz); 8.29 (d, 2H, J = 9.2 Hz). ^{13}C NMR ($CDCl_3$): δ (ppm) 28.2 (3C); 38.0; 54.4; 80.7; 122.1 (2C); 123.9 (2C); 125.4 (2C); 130.2 (2C); 143.3; 143.7; 174.3; 154.7; 158.6; 170.3. MS (ES^+) *m/z* 432 [MH^+].

Histaminosuccinylglycyl(*O*-ethyl)lysyl-*p*-nitrophenylalanine Hydrochloride (6). To a solution of compound **5** (158 mg, 0.37 mmol) in 1 mL of anhydrous DMF were added, under nitrogen atmosphere, **4** (204 mg, 0.48 mmol) and triethylamine (67 μL, 0.48 mmol). The reaction was stirred overnight at room temperature. After evaporation, the residue was taken up in 5 mL of $CHCl_3$ and washed three times with 5 mL of 0.5 M NaOH. The organic layer was dried over Na_2SO_4, filtered, and evaporated to dryness. The crude material was purified

by column chromatography on silica gel, eluting with ethyl acetate and then methanol (R_f (MeOH) = 0.5) to give 249 mg of a white solid (95%). To a solution of this compound (72 mg, 0.1 mmol) in 2 mL of acetone was added 700 μL of 3 M HCl. The reaction mixture was kept 4 h at room temperature. The solvents were removed, and the residue was dried under vacuum. 63 mg of a white solid was obtained (96%). ^{1}H NMR (CD_3OD): δ (ppm) 1.21 (t, 3H, J = 7.1 Hz); 1.32−1.78 (m, 6H); 2.40 (m, 4H); 2.68 (m, 2H); 3.01 (d, 2H, J = 7.4 Hz); 3.18 (t, 2H, J = 7.0 Hz); 3.37 (t, 2H, J = 7.2 Hz); 3.70 (s, 2H); 3.98 (t, 1H, J = 7.2 Hz); 4.02 (q, 2H, J = 7.1 Hz); 4.31 (m, 1H); 6.85 (s, 1H); 7.38 (d, 2H, J = 8.6 Hz); 7.67 (s, 1H); 8.07 (d, 2H, J = 8.6 Hz). ^{13}C NMR (CD_3OD): δ (ppm) 14.5; 23.9; 27.7; 28.6; 29.7; 31.9; 32.1; 39.3; 39.9; 40.5; 43.7; 53.8; 56.7; 62.3; 118.1 (2C); 124.4 (2C); 131.7 (2C); 136.1; 146.8; 148.3; 171.8; 173.3; 173.6; 174.5; 175.6. MS (ES^+) m/z 617 [MH^+].

LM054. To a solution of **4bis** (198 mg, 0.36 mmol) and *p*-nitrophenol (50 mg, 0.36 mmol) in 2 mL of anhydrous DMF was added, at 0 °C and under nitrogen atmosphere, a solution of DCC (74 mg, 0.36 mmol) in 6 mL of anhydrous DMF. After 4 h at 0 °C and a night at room temperature, **6** (234 mg, 0.36 mmol) and triethylamine (57 μL, 0.40 mmol) were added to the solution. The reaction mixture was stirred 8 h and then evaporated to dryness. The residue was taken up in 5 mL of anhydrous MeOH and chilled at 4 °C overnight. DHU was filtered and washed with cold MeOH, and the filtrate was concentrated to dryness. The crude product was purified by semipreparative HPLC at 211 nm. Semipreparative HPLC conditions: gradient: 0−15 min, 80%-50% A; 15−16 min, 50%-0% A; 16−24 min, 0% A; 24−25 min, 0%-80% A. Flow rate: 17 mL/min. Retention time: 9.43 min. 50 mg of pure product were collected (12%). ^{1}H NMR (CD_3OD): δ (ppm) 1.13 (t, 3H, J = 6.8 Hz); 1.22−1.75 (m, 12H); 2.38 (s, 8H); 2.77 (t, 4H, J = 6.6 Hz); 3.05 (m, 4H); 3.22 (m, 2H); 3.33 (t, 4H, J = 6.4 Hz); 3.53 (m, 1H); 3.72 (m, 1H); 3.86 (t, 1H, J = 7.0 Hz); 4.02 (q, 2H, J = 6.8 Hz); 4.25 (m, 1H); 5.10 (s, 2H); 7.21 (s, 5H); 7.22 (s, 2H); 7.38 (d, 2H, J = 8.6 Hz); 8.01 (d, 2H, J = 8.6 Hz); 8.67 (s, 2H). ^{13}C NMR (CD_3OD): δ (ppm) 14.5; 23.9; 24.0; 25.6 (4C); 29.6; 29.7; 31.7 (3C); 32.0; 32.5; 38.5; 39.3; 39.9; 40.0; 43.7 (2C); 53.8; 55.0; 56.6; 62.4; 67.8; 117.6 (2C); 124.4 (2C); 128.8; 129.1 (2C); 129.5 (2C); 131.7 (2C); 133.0 (2C); 134.8 (2C); 138.0; 146.4; 148.3; 158.5; 171.8; 171.9; 172.8; 173.3; 174.8; 174.9 (2C); 175.5 (2C). Analytical HPLC: gradient: 0−15 min, 80−50% A; 15−16 min, 50%-0% A; 16−24 min, 0% A; 24−25 min, 0%-80% A; flow rate 1 mL/min; retention time: 9.40 min. MS (ES^+) m/z 1130 [MH^+].

***p*-Aminobenzylamine Hydrochloride (7).** Catalytic hydrogenation of *p*-nitrobenzylamine hydrochloride (1.10 g, 5.8 mmol) in methanol (15 mL) over 10% Pd/C (10% w/w) was carried out at atmospheric pressure. After 3 h, the catalyst was filtered off (Celite) and the solvent was removed under reduced pressure. 900 mg of a yellow solid was obtained (98%). ^{1}H NMR (DMSO-d_6): δ (ppm) 3.82 (s, 2H); 5.27 (s, 2H); 6.58 (d, 2H, J = 8.3 Hz); 7.15 (d, 2H, J = 8.3 Hz); 8.19 (s, 2H). ^{13}C NMR (DMSO-d_6): δ (ppm) 43.3; 113.8 (2C); 120.7 (2C); 130.3; 149.2. MS (ES^+) m/z 123 [MH^+].

***N,N*-Bis(ethoxycarbonylmethyl)-4-aminobenzylamine (8).** A mixture of **7** (420 mg, 2.65 mmol), sodium carbonate (1.13 g, 10.6 mmol), potassium iodide (441 mg, 2.65 mmol), and ethyl bromoacetate (665 mg, 3.97 mmol) in acetonitrile (20 mL), under nitrogen atmosphere, was refluxed for 2 h. The insoluble materials were filtered off, and the solvent was removed under reduced pressure. The residue was purified on silica gel column using ethyl acetate-chloroform (1:1) as eluent to yield a yellow oil (469 mg, 60%). ^{1}H NMR ($CDCl_3$): δ (ppm) 1.25 (t, 6H, J = 7.1 Hz); 3.51 (s, 4H); 3.77 (s, 2H); 4.15 (q, 4H, J = 7.1 Hz); 6.61 (d, 2H, J = 8.5 Hz); 7.14 (d, 2H, J = 8.5 Hz). ^{13}C NMR ($CDCl_3$): δ (ppm) 14.8 (2C); 54.7 (2C); 58.1; 60.7 (2C); 115.3 (2C); 128.3; 131.0 (2C); 146.1; 171.9. MS (ES^+) m/z 295 [MH^+].

Disodium Salt of *N,N*-Bis(carboxymethyl)-4-aminobenzylamine (9). To 476 mg (1.6 mmol) of compound **8** in 500 μL of ethanol was added 3.20 mL of 2 M NaOH. The reaction mixture was stirred at 35 °C for 2 h and then concentrated to dryness. 452 mg of desired product was obtained as a pale orange solid (100%). ^{1}H NMR (D_2O): δ (ppm) 3.12 (s, 4H); 3.65 (s, 2H); 6.80 (d, 2H, J = 8.3 Hz); 7.16 (d, 2H, J = 8.3 Hz). MS (ES^+) m/z 239 [MH^+].

***N,N*-Bis(carboxymethyl)-4-*N′*-(9-fluorenylmethyloxycarbonyl)aminobenzylamine (10).** To 1.57 g (5.6 mmol) of compound **9** in a mixture of 10% Na_2CO_3 (15 mL) and dioxane (10 mL) was slowly added, at 0 °C, 1.5 g (5.6 mmol) of 9-fluorenylmethyl chloroformate. After 4 h at 0 °C and overnight at room temperature, the solvents were removed. 1 mL of H_2O was added to the residue followed by 3 M HCl until the pH rose to Congo. The obtained precipitate was filtered, washed with cold water, and dried under reduced pressure. 1.55 g of a white solid was obtained (60%). ^{1}H NMR (DMSO-d_6): δ (ppm) 3.71 (s, 4H); 4.17 (t, 1H, J = 6.7 Hz); 4.21 (s, 2H); 4.40 (d, 2H, J = 6.7 Hz); 7.25 (m, 8H); 7.59 (d, 2H, J = 6.9 Hz); 7.70 (d, 2H, J = 6.9 Hz). ^{13}C NMR (DMSO-d_6): δ (ppm) 46.9; 53.7 (2C); 56.9; 65.8; 118.4 (2C); 120.4 (2C); 125.3 (2C); 127.3 (2C); 127.9 (2C); 129.4 (2C); 132.5; 138.3; 141.0 (2C); 144.0 (2C); 153.6; 172.4 (2C). MS (ES^+) m/z 461 [MH^+].

***N′*-Fmoc-*N,N*-(histaminosuccinylglycyl-(*O*-ethyl)-lysyl-carboxymethyl)-*p*-aminobenzylamine (11).** To a solution of **10** (1.04 g, 2.26 mmol) in 5 mL of anhydrous DMF, was added, under nitrogen, CDI (878 mg, 5.42 mmol). When the effervescence stopped, a solution of **4** (2.3 g, 5.42 mmol) in 5 mL of anhydrous DMF was added. The reaction mixture was stirred at room-temperature overnight and then concentrated to dryness. The residue solubilized in 3 mL of MeOH was added dropwise at 0 °C in 100 mL of water. The precipitate was filtered, washed twice with cold water, and dried under vacuum. 2 g of a white solid was obtained (71%). ^{1}H NMR (CD_3OD): δ (ppm) 1.13 (t, 6H, J = 7.0 Hz); 1.18−1.79 (m, 12H); 2.40 (m, 8H); 2.66 (t, 4H, J = 7.0 Hz); 3.06 (t, 4H, J = 6.8 Hz); 3.27 (t, 4H, J = 7.0 Hz); 3.56 (s, 2H); 3.60 (s, 4H); 3.67 (s, 4H); 4.02 (q, 4H, J = 7.0 Hz); 4.15 (t, 1H, J = 6.5 Hz); 4.24 (m, 2H); 4.35 (d, 2H, J = 6.5 Hz); 6.72 (s, 2H); 7.13−7.33 (m, 8H); 7.49 (s, 2H); 7.57 (d, 2H, J = 7.2 Hz); 7.70 (d, 2H, J = 7.2 Hz). ^{13}C NMR (CD_3OD): δ (ppm) 14.5 (2C); 24.2 (2C); 26.0 (2C); 26.7 (2C); 27.2 (2C); 31.8 (2C); 32.1 (2C); 34.7; 40.1 (2C); 40.4 (2C); 43.7 (2C); 53.7 (2C); 58.2 (2C); 59.3; 62.4 (2C); 67.7; 118.1 (4C); 119.9 (2C); 121.0 (2C); 126.2 (2C); 128.2 (2C); 128.8 (2C); 131.2 (2C); 133.1; 136.0 (2C); 139.7; 142.6 (2C); 145.3 (2C); 155.8; 171.8 (2C); 173.5 (4C); 174.5 (2C); 175.5 (2C). LM085. Compound **11** (300 mg, 0.24 mmol) and 240 μL (2.3 mmol) of diethylamine were dissolved in 2 mL of anhydrous DMF. The reaction mixture was stirred under nitrogen atmosphere for 2 h and then concentrated. 10 mL of water was added to the residue. The aqueous layer was extracted four times with ethyl acetate (10 mL). The aqueous layer was then evaporated and dried under reduced pressure to yield desired compound as a white

solid (225 mg, 91%). ^{1}H NMR (CD_3OD): δ (ppm) 1.09 (d.t, 6H, J = 7.0 Hz); 1.36-1.75 (m, 12H); 2.38 (m, 8H); 2.63 (t, 4H, J = 7.0 Hz); 3,07 (t, 4H, J = 6.9 Hz); 3.25 (t, 4H, J = 7.0 Hz); 3.50 (s, 2H); 3.57 (s, 4H); 3.67 (s, 4H); 4.02 (q, 4H, J = 7.0 Hz); 4.24 (m, 2H); 6.57 (d, 2H, J = 8.4 Hz); 6.72 (s, 2H); 6.97 (d, 2H, J = 8.4 Hz); 7.48 (s, 2H). ^{13}C NMR (CD_3OD): δ (ppm) 14.5 (2C); 24.2 (2C); 27.6 (2C); 29.8 (2C); 31.8 (2C); 32.0 (2C); 32.1 (2C); 40.1 (2C); 40.4 (2C); 43.73 (2C); 52.8 (2C); 58.1; 59.4 (2C); 62.4 (2C); 116.4 (2C); 118.1 (4C); 129.5; 131.6 (2C); 135.7 (2C); 148.4; 171.8 (2C); 173.5 (2C); 173.6 (2C); 174.5 (2C); 175.5 (2C). Analytical HPLC: gradient: 0−5 min, 100% A; 5−35 min, 100%-0% A; 35−36 min, 0%-100% A; flow rate 1 mL/min; retention time: 15.0 min. MS (ES^+) *m/z* 1052 [MH^+].

LM218. Anhydrous $NH_{3(g)}$ was bubbled into a stirring solution of **11** (70 mg, 55 μmol) in 5 mL of MeOH. An ice bath was used to keep the solution at 5 °C. The formation of the product was monitored by electrospray mass spectra. Anhydrous $NH_{3(g)}$ was bubbled punctually until total reaction. The reaction mixture was reduced to dryness, the residue was taken up in 2 mL of water, and the aqueous layer was washed with $CHCl_3$ (5 × 5 mL). The aqueous layer was concentrated and dried under vacuum to give 40 mg of a yellow solid (74%). ^{1}H NMR (CD_3OD): δ (ppm) 1.17−1.82 (m, 12H); 2.50 (s, 8H); 2.74 (t, 4H, J = 6.6 Hz); 3.15 (t, 4H, J = 6.6 Hz); 3.34 (s, 4H); 3.39 (t, 4H, J = 7.1 Hz); 3.58 (s, 2H); 3.79 (s, 4H); 4.13 (m, 2H); 6.74 (d, 2H, J = 8.3 Hz); 6.89 (s, 2H); 7.13 (d, 2H, J = 8.3 Hz); 7.69 (s, 2H). ^{13}C NMR (CD_3OD): δ (ppm) 25.3 (2C); 28.8 (2C); 30.8 (2C); 33.7 (6C); 41.9 (2C); 45.5 (2C); 51.8 (2C); 56.1 (2C); 60.6; 62.0 (2C); 119.0 (2C); 119.9 (4C); 130.4; 133.7 (2C); 137.5 (2C); 148.8; 174.2 (2C); 176.5 (2C); 177.3 (2C); 178.3 (2C); 179.3 (2C). Analytical HPLC: gradient: 0−5 min, 100% A; 5−35 min, 100%-0% A; 35−36 min, 0%-100% A; flow rate 1 mL/min; retention time: 14.3 min. MS (ES^+) *m/z* 993 [MH^+].

General Procedure for LM218-BCA Coupling. A solution of **LM218**, BCA, and Et_3N in 500 μL of anhydrous DMF was stirred under nitrogen atmosphere for 16 h. The solvent was then evaporated, and the residue was purified by semipreparative reverse phase HPLC at 211 nm. Semipreparative HPLC conditions: isocratic, solvent A: 83%, solvent B: 17%. Flow rate: 17 mL/min.

LM218-BzDTPA. Using 6 mg (6.0 μmol) of **LM218,** 8 mg (12 μmol) of CITC-DTPA (17), and 5 μL (37.2 μmol) of triethylamine, 3 mg of pure **LM218-BzDTPA** was collected (Retention time: 6.4 min, yield = 30%). MS (ES^+) *m/z* 1533 [MH^+]. Analytical HPLC: gradient: 0−5 min, 100% A; 5−30 min, 100%-0% A; 30−40 min, 0%A; flow rate 1 mL/min; retention time: 16.5 min.

LM218-BzTTHA. Using 6 mg (6.0 μmol) of **LM218,** 9.4 mg (12 μmol) of CITC-TTHA (synthesis not described), and 8.3 μL (48.9 μmol) of triethylamine, 3.3 mg of pure **LM218-BzTTHA** was collected (Retention time: 6.7 min, yield 33%). MS (ES^+) *m/z* 1635 [MH^+]. Analytical HPLC: gradient: 0−5 min, 100% A; 5−30 min, 100%-0% A; 30−40 min, 0% A; flow rate 1 mL/min; retention time: 17.4 min.

LM218-CHXA″DTPA. Using 6 mg (6.0 μmol) of **LM218,** 8.5 mg (12.1 μmol) of CITC−CHXA"DTPA (*18*, *19*), and 7.6 μL (54.4 μmol) of triethylamine, 3 mg of **LM218-CHXA″DTPA** was collected (Retention time: 5.7 min, yield = 32%). MS (ES^+) *m/z* 1635 [MH^+]. Analytical HPLC: gradient: 0−5 min, 100% A; 5−30 min, 100%-0% A; 30−40 min, 0% A; flow rate 1 mL/min; retention time: 16.7 min.

Preparation of mAb-679-Coated Tubes. A series of 50 polypropylene tubes was coated by adding 0.5 mL of a solution of mAb-679 at 20 μg mL^{-1}. After 12 h incubation at 37 °C, the supernatant was removed and 0.5 mL of phosphate-buffered saline (PBS) supplemented with 0.5% bovine serum albumin (BSA) was added. Tubes were kept at 4 °C until used.

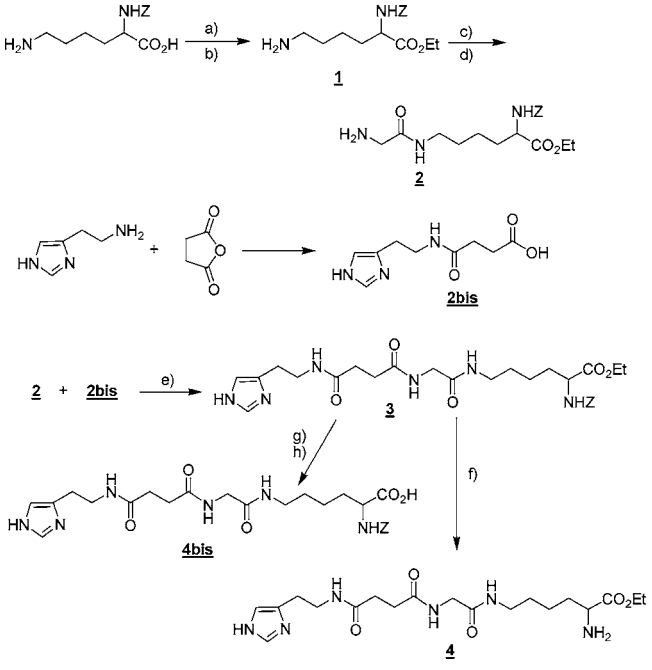
Preparation of AG8.1-^{125}I. AG8.1 was labeled with ^{125}I using chloramine-T (*23*). After labeling, the hapten was purified using a SepPak C_{18} cartridge (Millipore, Saint Quentin Yvelines, France) by successive injections of the labeling solution. The SepPak C_{18} cartridge was first eluted with 5 mL of 0.05% trifluoroacetic acid in water and then with 5 mL of a 3:2 mixture of 0.1 M phosphate buffer solution pH 7 and ethanol. Under these conditions, free ^{125}I was eluted in the acid aqueous phase and the radiolabeled hapten was eluted in the first 2 mL of the ethanol phase. The radiochemical purity of the purified solution was measured by thin layer silica gel chromatography using methanol as eluent. The immunoreactive fraction was determined by the percentage of activity of the mAb-679-coated tubes.

Competition Tests. For each competition test, peptide AG8.1 was used as a reference. The immunoreactivity tests of the synthesized peptides and AG8.1 peptide toward mAb-679 were performed in mAb-679-coated tubes. Two series of seven tubes were prepared for each peptide. In the first series, the tubes were charged with (1) a constant amount of AG8.1 peptide (0.2 pmol) radiolabeled with Iodine-125, (2) an increasing amount of cold AG8.1 peptide (C = 0, 0.25, 0.5, 1, 5, 10, and 100 pmol), (3) 200 μL of PBS/0.5% BSA for the **LM054** and **LM085** series or 250 μL for the **LM218** series. In the second series, the tubes were charged with (1) a constant amount of AG8.1 peptide (0.2 pmol) radiolabeled with Iodine-125. (2) an increasing amount of cold synthesized peptides **LM054**, **LM085**, or **LM218** (n = 0, 0.25, 0.5, 1, 5, 10, and 100 pmol), (3) 200 μL of PBS/0.5% BSA for the **LM054** and **LM085** series or 250 μL for the **LM218** series. After a night at 37 °C, the radioactivity of each tube was measured before (T) and after (B) three washes with 500 μL of PBS/1% Tween 20.

Serum Stability. Two solutions of AG8.1 peptide at 250 pmol/mL and 50 pmol/mL in serum and two solutions of **LM054**, **LM085**, or **LM218** peptide at the same concentrations were incubated at 37 °C. The immunoreactivity of each solution was determined at different times (0, 4 h, 24 h, 48 h, 144 h); for each point, 0.2 pmol of AG8.1 peptide radiolabeled with ^{125}I and 200 μL of the solutions of AG8.1 peptide in serum were incubated in a first series of mAb-679-coated tubes and 0.2 pmol of AG8.1 peptide radiolabeled with ^{125}I and 200 μL of the solutions of synthesized peptide (**LM054**, **LM085**, or **LM218**) in serum (50 pmol and 10 pmol) in another series of mAb-679-coated tubes. After 1.5 h of incubation at 37 °C, the radioactivity of each tube was measured before (T) and after (B) three washes with 500 μL of PBS supplemented with 1% Tween 20.

Radiolabeling of LM218-BzTTHA. 20 μL of a solution of $^{111}InCl_3$, 3.2 μL of sodium citrate/sodium acetate buffer 0.25 M/1.5 M pH 5.5, and 9 μL of a solution of **LM218-BzTTHA** at 20 pmol μL^{-1} were mixed and incubated 16 h at room temperature. A reference solution containing 20 μL of $InCl_3$ solution, 9 μL of H_2O, and 3.2 μL of sodium citrate/sodium acetate 0.25 M/1.5 M pH 5.5 buffer was also incubated 16 h at room temperature. The reference and the radiolabeled peptide were purified through a Sep-Pack C_{18} cartridge (Millipore, Saint-Quentin Yvelines, France) conditioned with sodium citrate buffer 0.1 M pH 5.5. The columns were first eluted with 5 mL of sodium citrate 0.1 M pH 5.5 buffer followed

Scheme 1. Synthesis of GSH Arms 4 and 4Bis[a]



[a] Reagents: (a) HCl gas, EtOH; (b) NaOH; (c) *N*(Boc)glycine *p*-nitrophenyl ester; (d) CF_3CO_2H; (e) *p*-nitrophenol, DCC; (f) H_2, Pd/C; (g) NaOH 1 M; (h) HCl 1 M.

by 5 mL of EtOH/sodium citrate buffer 0.1 M pH 5.5 10% and 5 mL of EtOH. Reference $InCl_3$ eluted in the first 5 mL of citrate buffer. **LM218-BzTTHA-^{111}In** eluted in the 5 mL of EtOH/sodium citrate buffer 0.1 M pH 5.5 and in the first 1 mL of EtOH.

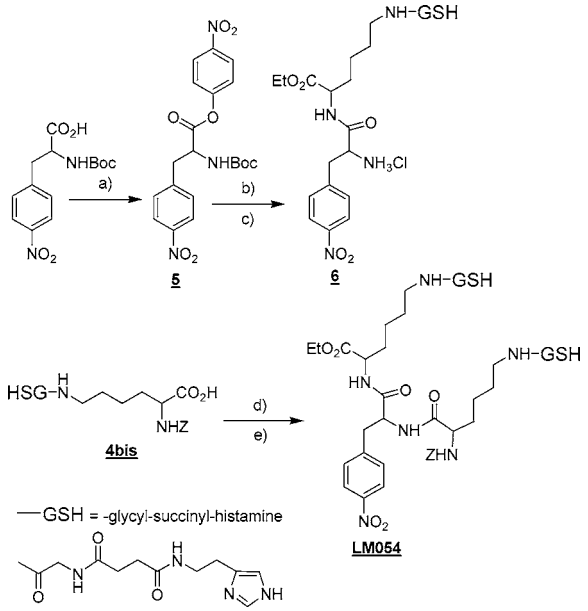
Immunoreactivity of LM218-BzTTHA-^{111}In. A series of mAb-679-coated tubes was loaded with increasing volumes (0, 2, 4, 6, 8, 10, 12, 15, and 20 μL) of the purified fraction of **LM218-BzTTHA-^{111}In**. Each tube was adjusted to a 250 μL volume with PBS/0.5% BSA. After 2 h at 37 °C, the radioactivity of each tube was measured before (T) and after (B) three washes with 500 μL of PBS/1% Tween 20.

RESULTS

Synthesis. Three peptides containing two GSH arms were synthesized. The GSH arms **4** and **4bis** were prepared by conventional peptide synthesis (*24*) (Scheme 1). Briefly, *N*(CbZ)-lysine ethyl ester **1** was obtained by esterification of commercial *N*(CbZ)-lysine by treatment with HCl gas in ethanol. Compound **1** was condensed with *N*(Boc)-glycine *p*-nitrophenyl ester with a 86% yield, followed by removal of the Boc group by TFA treatment (88%). **2bis** was obtained by coupling succinic anhydride to histamine. The condensation reaction between **2** and **2bis** was performed after activation of **2bis** with DCC/*p*-nitrophenol. Catalytic hydrogenation or basic hydrolysis of the resulting **3** yielded respectively intermediates **4** (99%) or **4bis** (99%). The synthesis of **LM054** was performed with an overall yield of 7% (Scheme 2). Compound **6** was obtained by coupling the activated ester **5** on compound **4**, followed by cleavage of the protective Boc group with TFA. Condensation between **4bis**, activated by *p*-nitrophenol in the presence of DCC, and **6** led to peptide **LM054** with a 12% yield after purification by semipreparative high-performance liquid chromatography (HPLC).

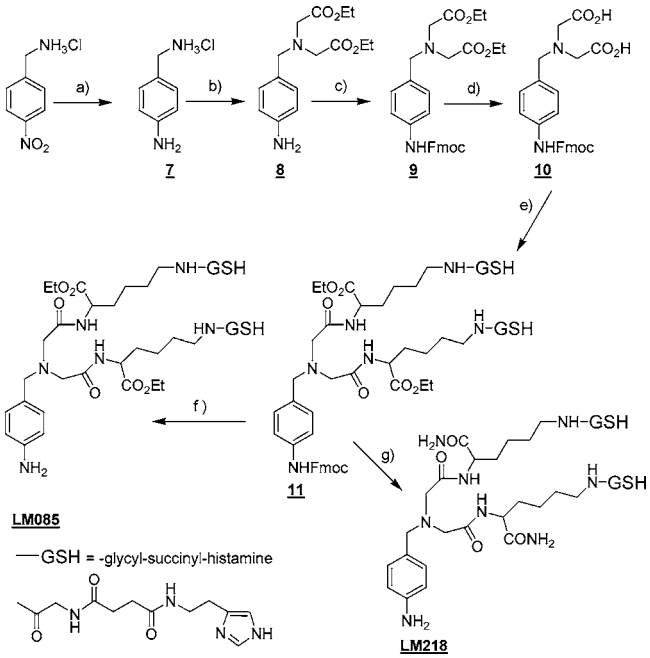
LM085 was synthesized with an overall yield of 22% (Scheme 3). The two acid functions of compound **10** were activated simultaneously by CDI and coupled with two

Scheme 2. Synthesis of LM054[a]



[a] Reagents: (a) *p*-nitrophenol, DCC; (b) compound **4**; (c) HCl 3 M; (d) *p*-nitrophenol, DCC; (e) compound **6**, Et_3N.

Scheme 3. Synthesis of LM085 and LM218[a]



[a] Reagents: (a) H_2, Pd/C; (b) Na_2CO_3, KI, $BrCH_2CO_2Et$; (c) NaOH 2 M; (d) FmocCl; (e) CDI (2.4 equiv); compound **4** (2.4 equiv); (f) Et_2NH; (g) NH_3 gas.

GSH arms (compound **4**). Compound **11**, obtained with a 70% yield, did not require HPLC purification. The cleavage of the Fmoc group performed in the presence of diethylamine gave **LM085**. **LM218** was synthesized with an overall yield of 16% (Scheme 3). $NH_{3(g)}$ treatment of previously described compound **11** allowed the substitution of the two ethyl ester functions into amide functions and the cleavage of the protective Fmoc group.

LM218-BzDTPA, LM218-BzTTHA, and **LM218-CHXA′DTPA.** The coupling reaction of peptide **LM218** with CITC-DTPA, CITC-TTHA, and CITC−CHXA′DTPA was achieved in anhydrous organic medium in the presence of triethylamine. Purification by semiprepara-

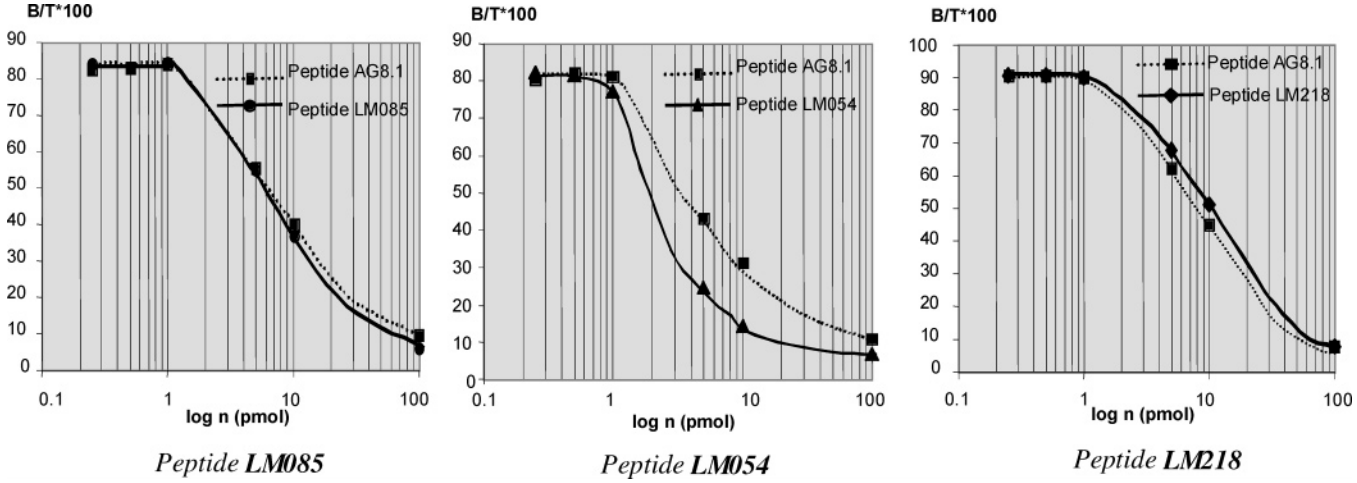


Figure 2. Competition tests. The synthesized peptides (**LM054**, **LM085**, and **LM218**) and peptide AG8.1 (reference) are compared in their ability to displace the fixation of a constant amount of tracer AG8.1-^{125}I on mAb-679-coated tubes. % of tracer AG8.1-^{125}I fixed on total amount introduced was plotted as a function of quantity of cold peptide (0.25 to 100 pmol).

tive HPLC allowed the expected conjugate to be obtained with an average yield of 30%.

AG8.1-^{125}I Radiolabeling. AG8.1-^{125}I was obtained with a 40% yield after addition of 253 MBq of iodine-125 to 11 nmol of AG8.1. The specific activity of AG8.1-^{125}I after purification was 11.1 MBq/nmol, with a radiochemical purity of 100% by chromatography. The immunoreactive fraction was measured between 85 and 90%.

Competition Studies (Figure 2). To evaluate the affinity of the synthesized peptides toward mAb-679, binding a trace amount of AG8.1-^{125}I to mAb-679-coated tubes was measured in the presence of increasing concentration of **LM054**, **LM085**, and **LM218**. The three synthesized peptides and AG8.1 itself showed similar competition curves with tracer AG8.1-^{125}I. Thus, it was considered that peptides AG8.1, **LM054**, **LM085**, and **LM218** had the same affinity for antibody mAb-679.

Serum Stability Tests (Figure 3). The serum stability of **LM054**, **LM085**, and **LM218** was studied by incubating each peptide at two different concentrations (250 and 50 pmol/mL) in human serum at 37 °C. Solutions of peptide AG8.1 at the same concentrations were used as references. The binding of a trace amount of AG8.1-^{125}I to mAb-679-coated tubes in the presence of 200 μL of the peptide solutions in serum was measured at selected time intervals, by incubation in mAb-679-coated tubes. Loss of immunoreactivity of the tested peptide results in a decreased competition toward the tracer AG8.1-^{125}I and in an increasing bound to total (B/T) ratio. AG8.1 remained stable for 48 h in the two series of tests. At 144 h, a loss of about 10% of immunoreactivity was observed for the 50-pmol/mL concentration. **LM054** at 50 pmol/mL lost 8% of its immunoreactivity in 4 h and 30% in 24 h. At 144 h, immunoreactivity was almost totally absent for both concentrations (250 and 50 pmol/mL). **LM085** retained its immunoreactivity at 4 h and lost 9% and 4% respectively for concentrations 50 and 250 pmol/mL at 24 h and 15% for both concentrations at 144 h. Until 24 h, peptide **LM218** showed practically the same immunoreactivity for mAb-679, as did peptide AG8.1. At 144 h, there were slight losses of immunoreactivity (6% and 3% respectively) compared to peptide AG8.1 for concentrations of 250 and 50 pmol/mL.

LM218-BzTTHA-^{111}In. Radiolabeling of **LM218-BzTTHA** was performed in sodium citrate/sodium acetate 0.25 M/1.5 M pH 5.5 buffer for 16 h at room temperature. A reference solution containing $InCl_3$ in the same buffer was also prepared. Purification of both solution on a Sep-Pack C_{18} cartridge (Millipore, Saint Quentin Yvelines, France) was performed, showing that free indium eluted in the first 5 mL of sodium citrate buffer 0.1 M pH 5.5, and **LM218-BzTTHA-^{111}In** in the 5 mL of EtOH/sodium citrate buffer 0.1 M pH 5.5 and in the first 1 mL of the EtOH fraction. The concentration of this last 1 mL fraction was evaluated to be 18 pmol mL^{-1}.

Immunoreactivity of LM218-BzTTHA-^{111}In. Conservation of the immunoreactivity of **LM218-BzTTHA** after radiolabeling was checked by introducing increasing amounts of **LM218-BzTTHA-^{111}In** in mAb-679-coated tubes. The EtOH fraction, estimated at 18 pmol mL^{-1}, was used. A series of nine mAb-679-coated tubes was loaded with 0, 2, 4, 6, 8, 10, 12, 15, and 20 μL of the EtOH fraction and adjusted to 250 μL with PBS/0.5% BSA. After 2 h at 37 °C, the radioactivity of each tube was measured before (T) and after (B) three washes with 500 μL of PBS/1% Tween 20. The B/T ratio was calculated. For each tube a constant immunoreactive fraction of 85% was found.

DISCUSSION

The original development of the AES pretargeting technology by Immunotech S.A. (Marseille, France) was performed in a large part as a collaboration with our laboratory (*25*, *26*). Later on, the advantage of bivalent haptens for pretargeting has been confirmed independently by Boerman and co-workers (*11*), and the AES was considered for RIT by IBC Pharmaceuticals (*10*). While the current clinical trials are still being performed using DTPA-indium bivalent haptens (Figure 1), the need for other haptens allowing a broader range of radionuclides to be used has been recognized. Thus, bivalent haptens of varying structures and lengths of the linker peptide chain using glycyl-succinyl-histamine (GSH) as the hapten have been synthesized (*13*, *14*, *27*). Peptide AG3.0 (Figure 1) proved to be the best candidate, both for its affinity for mAb-679 and its stability in vivo (*27*). In this peptide, the two GSH arms are linked together by a Lys-Tyr-Lys link, in which tyrosine allows direct radiolabeling with iodine-131. However, the physical characteristics of iodine-131 (low-energy β^- radiation, strong gamma emission, and long half-life) set limits to its use in RIT even using AES (*26*).

To circumvent this problem, the synthesis of heteropeptides recognized by mAb-679 (anti-GSH) and bearing

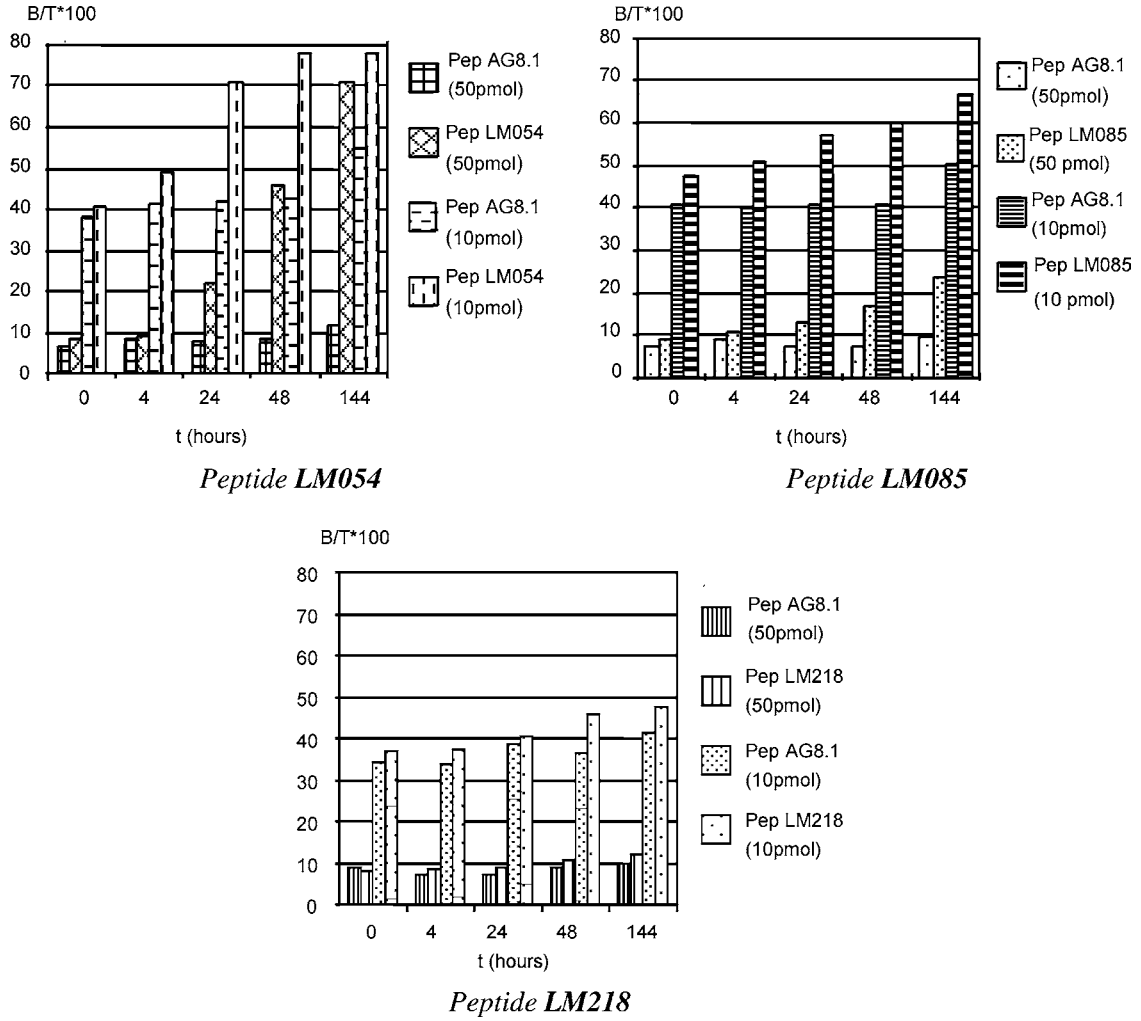

Figure 3. Serum stability. 50 pmol and 10 pmol of synthesized peptides (**LM054**, **LM085**, and **LM218**) and peptide AG8.1 (reference) were incubated in human serum at 37 °C. Aliquots of the serum solutions were put in competition with a constant amount of AG8.1-^{125}I in mAb-679-coated tubes. The percentage of bound AG8.1-^{125}I was plotted as a function of time of incubation for the two concentrations (50 and 10 pmol). Increased B/T corresponds to a loss of immunoreactivity of the tested peptide.

a site for coupling BCA's capable of forming a stable complex with a variety of radionuclides was undertaken. All three synthesized peptides showed good affinity toward mAb-679 (Figure 2). However, stability tests (Figure 3) showed that **LM054** was very rapidly degraded in serum at 37 °C, making it unsuitable for RIT. Thus, the synthetic process involving reduction of the nitro-aromatic function and/or cleavage of the benzyloxycarbonyl group was not carried on. The synthesis of a second peptide involved the coupling of the amine functions of compound **4** with the diacid [carboxymethyl-(4-nitrobenzyl)amino]acetic acid. Simultaneous activation of the two acid functions and subsequent coupling with two GSH arms (compound **4**) were performed with a good yield. Unfortunately, the final step involving catalytic hydrogenation of the nitro-aromatic function failed, producing side-products associated with benzylic rupture. To overcome this difficulty, another strategy was adopted by beginning the synthesis with an aromatic amino group protected by Fmoc. Reduction of the nitro group of the *p*-nitrobenzylamine followed by Fmoc-protection of the aryl amino group and N,N-dialkylation of the aliphatic amino group gave the diacid **10** in 70% yield. This intermediate reacted with two GSH arms to give, after removal of the Fmoc group, peptide **LM085** (Scheme 3). This compound precipitated in water and required no HPLC purification. Deprotection of the Fmoc group caused essentially no side reactions. Competition tests (Figure 2) showed that **LM085** and AG8.1 have the same affinity toward mAb-679. However, serum tests (Figure 3) were not satisfactory as **LM085** had poorer serum stability than AG8.1. To improve the serum stability and to mimic peptide AG8.1, the ethyl ester functions of **LM085** were replaced by amide functions. The treatment with NH_3 gas of compound **11** allowed both deprotection of the Fmoc function and afforded the amide functions (Scheme 3). The resulting compound **LM218**, like **LM054** and **LM085**, has the same affinity for mAb-679 as AG8.1, but also showed good serum stability for up to 144 h. As **LM218** met our criteria (satisfactory immunoreactivity and good serum stability), it was selected to validate the model. Thus **LM218** was coupled to three well-known BCAs, CITC-DTPA, CITC-TTHA, and CITC−CHXA″DTPA (Figure 4) in anhydrous organic medium. Unlike aqueous medium, in which a large excess of BCA is necessary, the anhydrous organic solvent allowed us to work with 2 equiv of BCA relative to the peptide. Finally, one of the conjugates, **LM218-BzTTHA**, was radiolabeled successfully with indium-111, and the immunoreactive fraction of the resulting radiolabeled product was measured as 85% or better.

There was a triple advantage in replacing the aliphatic amine function on the side chain of peptide AG8.1 by an aromatic amine function as the coupling site on the new

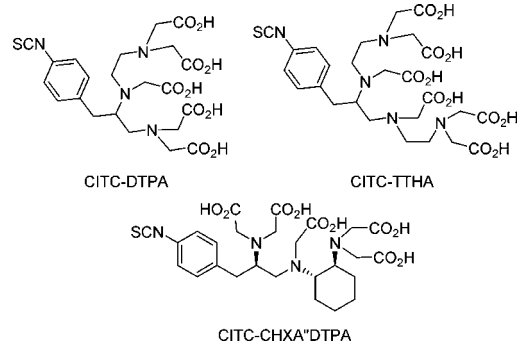

Figure 4. Chemical structures of CITC-DTPA, CITC-TTHA, and CITC−CHXA″DTPA.

peptides. First, the coupling of the BCA on this coupling site is less susceptible to interfere in the recognition of the GSH arms by mAb-679. Second, the low pK_a (3−5) of the aromatic amine allowed coupling to the BCA at a lower pH than with an aliphatic amine (pK_a = 9) and avoided undesirable interaction with the amine functions of imidazole (pK_a = 7.1). Third, the aromatic amine function can be easily activated after transformation to isothiocyanate (results not shown). This possible introduction of an isothiocyanate makes possible the coupling of BCA presenting aliphatic and aromatic amine functions.

In summary, a new bivalent peptide capable of binding mAb-679 was synthesized for applications in the Affinity Enhancement System. This peptide has been coupled to different BCAs and radiolabeled by indium-111, affording a radiolabeled product with excellent immunoreactivity toward mAb-679. These encouraging results indicate that this peptide could be used to couple a large variety of BCAs and thus to use a great variety of radionuclides for in vivo tumor pretargeting. Further studies are now in progress in this direction and will be reported in a future publication. AES-pretargeted RIT using radionuclides with better radiophysical properties than iodine-131 should prove even more efficient for tumor ablation and less toxic.

ACKNOWLEDGMENT

This work was supported by a grant from "La Ligue départementale Contre le Cancer de Vendée". The authors are indebted to Dr Anne Gruaz-Guyon for providing peptide AG8.1 and to IBC Pharmaceuticals, Inc., for the gift of mAb-679.

We succeeded in using 40 nm FRET (fluorescence resonance energy transfer) microspheres conjugated to antibodies as the fluorescent reporters to perform the multiplexing suspension array measurements on two simulants of biological threats, ricin (A chain) and a crude spore preparation of *Bacillus globigii* (Bg). The microspheres were impregnated with two types of fluorophores in equal number (~140 fluorophores in total per microsphere) and displayed bright PE-like fluorescence via a fluorescence resonance energy transfer mechanism. Activated microspheres (aldehyde groups) were directly coupled to antibodies and used to form sandwich-type immunoassays in a suspension array. For the crude preparations of Bg, the assay sensitivity using antibody-conjugated microspheres is an order of magnitude higher than that using the conventional fluorescent reporter, *R*-phycoerythrin (PE). Using the microspheres, Bg at the concentration of 5 ng/mL can be easily detected. For ricin, the assay sensitivity was similar to that obtained using PE as the reporter, but washing the reaction mixtures resulted in the fluorescence signals that were 2−3 times higher compared to those using PE. Ricin at a concentration of 1 ng/mL can be readily identified. Importantly, the two simulants do not interfere with each other in the multiplexing experiments. The 40 nm FRET microspheres are a new sensitive alternative as fluorescent reporters for detection in suspension arrays.

INTRODUCTION

Over the past 20 years, flow cytometry has become an indispensable measurement tool for clinical diagnostics and basic research. It is exquisitely suited to multiplexing analysis because the technology is capable of analyzing multiple wavelengths of emitted fluorescence from thousands of particles per second with excellent sensitivity (*1, 2*). When compared to conventional flow cytometers with multiple lasers for the respective fluorophores, the latest design of the suspension array flow cytometer (Luminex 100 from Luminex Corp.) provides high sensitivity, high throughput, and multiplex detection at a lower cost. The instrument is designed to take advantage *R*-phycoerythrin (PE) as the reporter. The suspension arrays utilize polystyrene microbeads (5.5 μm in diameter) that are impregnated with precise ratios of red and infrared fluorescent dyes yielding an array of 100 bead sets, each with a unique intensity address in the instrument. A 635 nm, 10 mW red diode laser excites the two classification fluorophores embedded in the microbeads, and a 532 nm, 13 mW yttrium aluminum garnet (YAG) laser provides the excitation of the fluorescent reporter PE. The immunoassays adopt a typical sandwich immunoassay format where antigen-specific capture antibodies are immobilized on the microbeads, antigen is then added and allowed to bind to capture beads, and the bound antigen is subsequently recognized by the biotinylated secondary antibodies that are identified by streptavidin-PE (*3*). Because the reporter fluorescence does not overlap with the classification signal, no fluorescent compensation is required.

High-throughput suspension arrays have been used for disease diagnostics (*4*) and for detections of biological threats because of the sensitivity, specificity, and multiplex capabilities (5, *6*). McBride and co-workers (*6*) have developed and tested a fully autonomous pathogen detection system for monitoring airborne biological threat agents. This system is designed to automate the sample collection, preparation, and multiplex detection of biological threat agents (bacteria, viruses, and toxins) using suspension arrays. The technological characteristics exhibit advantages over other immunoassay formats, such as enzyme-linked immunosorbent assay (ELISA) and time-resolved fluorescence (TRF) assays (*7*). To fulfill the need of the public health against the biological threats, it's important to develop simulants of biothreat agents for the purposes of rapid and accurate detection, remediation, and personnel training.

In the present study, two simulants of biological threats, ricin (A chain) and a spore preparation of *Bacillus globigii* (Bg), have been chosen as the model systems for detection using suspension arrays. Ricin, a glycoprotein toxin derived from castor plant beans, is one of the most poisonous naturally occurring substances known and has great potential for harm due to its wide availability and superior stability. The A chain portion of the ricin heterodimer has the enzymatic activity that binds and depurinates a specific adenine in the 28S subunit of ribosomes. The B chain portion of ricin is required for it to efficiently enter cells (*8, 9*). Bg is a nonpathogenic relative of *Bacillus anthracis* and the spore size and properties are similar to *Bacillus anthracis*

spores. The dormant spores can endure a wide range of extreme environmental stresses while retaining the capacity to rapidly return to vegetative growth (germination process) when environmental conditions are favorable (*10*). These two simulants (Bg and ricin A-chain) can safely be used as internal controls to increase the confidence of the results obtained from suspension arrays.

PE has an extremely high extinction coefficient and high fluorescence quantum yield and is widely used in conventional sandwich immunoassays. The Luminex 100 instrument was specifically designed to use PE as the fluorescent reporter. Since new types of brightly fluorescent reporter molecules are being developed continuously, the choice of the fluorescent reporter is likely to play an important role in increasing the sensitivity and reliability of immunoassays using liquid suspension arrays (manuscript in preparation). Although fluorescent microspheres (μm size) are widely used as standards for flow cytometry and fluorescence microscopy (*11*), nanometer-sized microspheres imbedded with fluorophores have been developed and conjugated to antibodies or streptavidin for immunology studies using flow cytometry, fluorescence microscopy, and ELISAs (*12*−*15*). These brightly fluorescent microspheres possess many advantages, such as high photostability and signal-to-noise ratio, environmental insensitivity, and incorporation of multiple dyes to make a set of probes that fluoresce at different wavelengths with a single excitation wavelength. In the present study, 40 nm FRET microspheres impregnated with two types of fluorophores were used as the fluorescent reporter for the sandwich assays detecting both ricin A chain and Bg simultaneously. We have focused on the application of these new FRET microspheres for multiplex assays and compared the results to PE, that is the reporter with the best sensitivity and greatest number of previous applications.

MATERIALS AND METHODS

An aqueous suspension of 40 nm FRET microspheres ($\sim 3.0 \times 10^{14}$/mL) with aldehyde functional groups on the surface was from Molecular Probes (Eugene, OR).[1] These microspheres are impregnated with two types of orange BODIPY dyes in equal number ($\sim$140 fluorophores in total per microsphere) and display bright PE-like fluorescence via a fluorescence resonance energy transfer mechanism. The dried preparation of *Bacillus globigii* (Bg, *Bacillus atropheus*) spores (lot Sept. 17, 2002) was obtained from U. S. Army Edgewood Chemical Biological Center (Edgewood, MD). The spore preparation gave an average of 1×10^5 colonies per μg of powder when suspended in water or buffer. Stock spore suspensions in PBS were stored at 4 °C. Ricin A chain (1 mg/mL, #L-1190, Vector Laboratories, Burlingame, CA) was diluted in PBS containing 5 mM dithiothreitol and 1% (w/w) BSA. Diluted solutions of the Bg spore and ricin A chain were prepared in PBS and used as the multiplex antigen samples. The polyclonal antibody against *Ricinus communis* agglutinin I & II was also purchased from Vector Laboratories. The antibody stock solution was prepared by adding 0.5 mL of water to obtain a final concentration of 2 mg/mL in phosphate buffer, pH 7.8 (10 mM phosphate, 0.15 M NaCl, 0.08% sodium azide, and sucrose). The polyclonal antibody against Bg was provided by Tetracore Inc. (Gaithersburg, MD) and was dissolved in phosphate-buffered saline, pH 7.4, (0.01 M phosphate, 0.138 M NaCl, 0.0027 M KCl, 0.05% (w/w) NaN_3) at a concentration of 3.6 mg/mL.

The immobilization of the polyclonal antibodies to Luminex carboxylated microspheres was accomplished through formation of a carbodiimide bond and carried out according to the manufacturer-recommended procedures. A FluoReporter Mini-Biotin-XX-Protein Labeling Kit from Molecular Probes was used for biotinylation of the antibodies, and the coupling reaction of biotins to the antibody was carried out according to the manufacturer-recommended procedures. The conjugation of the antibodies to 40 nm FRET microspheres was through the formation of an amide bond between amine groups of the antibodies and aldehyde groups on the surface of microspheres (*16*) and was carried out as follows. A 20 μL of antibody stock solution was diluted into 400 μL water, and then a proper volume of 40 nm FRET microsphere suspension was slowly added to the antibody solution. The labeling reaction carried out overnight with gentle vortexing. To prepare antibody-conjugated microspheres with different molar ratios between antibody and microsphere, the volume of microsphere suspension added was adjusted while the amount of antibody was kept constant. The agarose gel electrophoresis was used to detect the fluorescent products of the labeling reactions and help out finding of the optimal molar ratio of antibody and microsphere.

A commercial Luminex 100 instrument (Luminex Corp., Austin, TX) was used to perform the multiplexing sandwich assays detecting surrogates of biological threat agents, ricin A chain and Bg. Polyclonal antibodies coupled to specific Luminex beads (1500−3000 beads, 14 μL) were used for the primary analyte-capture step. After incubation with analytes (20 μL) for 20 min with gentle vortexing, the biotin-labeled antibodies (30 μL, 0.8 μg) were added and incubated for 20 min to form the sandwich-type complexes. PE-labeled streptavidin (10 μL, 1.5 μg) was then added as the conventional fluorescent reporter for the detection of ricin toxin and Bg. The final volume of the reaction mixture was 74 μL. On the other hand, microsphere-conjugated antibodies were utilized as an alternative, bright fluorescent reporter to detect the two analytes. The addition of the prior labeled antibodies combines the last two steps in conventional Luminex sandwich assays (Figure 1). When washing steps were employed, the assays were performed in 1.5 μL centrifuge tubes. The sandwich reaction mixtures were centrifuged at a g-force of 9000 for 2 min. The supernatant was discarded and 500 μL of blocking buffer, pH 7.4, (0.01 M phosphate, 0.138 M NaCl, 0.0027 M KCl, 1% (w/w) bovine serum albumin, 0.05% (w/w) NaN_3) was added. The centrifugation step described above was repeated, and the supernatant was again discarded. After the addition of 74 μL of blocking buffer, the reaction mixtures were vortexed and transferred to a 96-well plate (Model P, Corning Incorporated, Corning, NY) and prepared for detection. For the multiplexing sandwich assays, the blank signals were obtained in the absence of the antigens and were subtracted from the fluorescence signals of the sandwich complexes in the presence of the two analytes.

RESULTS AND DISCUSSION

The various steps of sandwich assays are illustrated in Figure 1. The analyte is recognized by the polyclonal

[1] Certain commercial equipment, instruments, and materials are identified in this paper to specify adequately the experimental procedure. In no case does such identification imply recommendation or endorsement by the National Institute of Standards and Technology, nor does it imply that the materials or equipment are necessarily the best available for the purpose.)

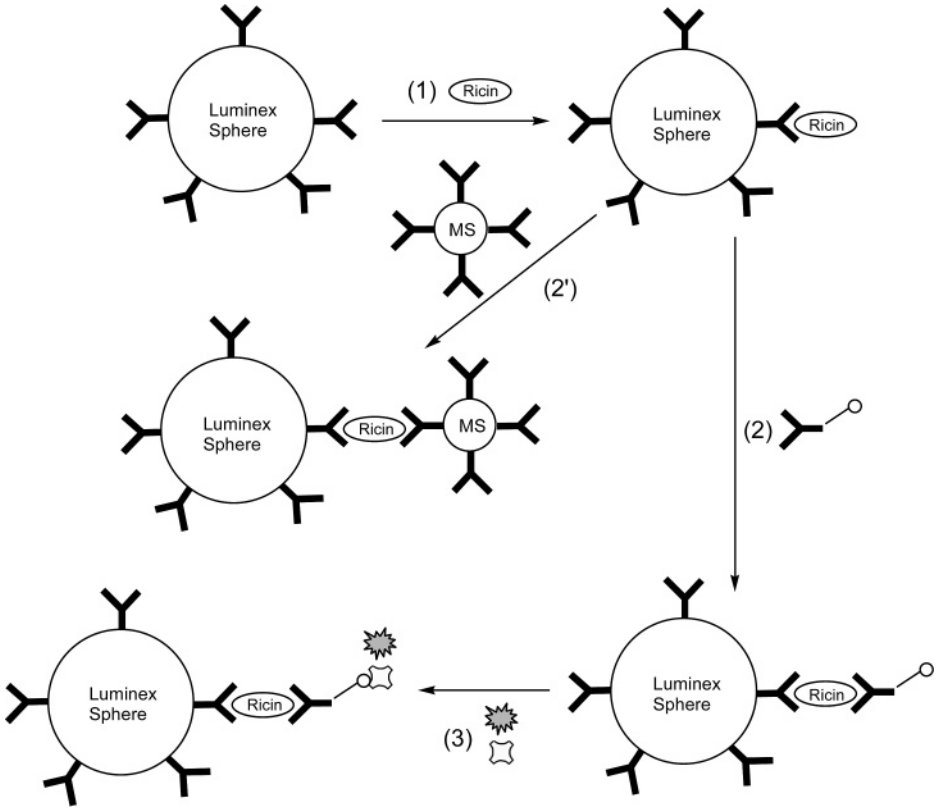

Figure 1. The schematic of immunological assays implemented in the study. As a first step, an analyte such as ricin A chain, for example, is bound to beads coated with a layer of polyclonal antibodies raised against ricin. Subsequently, biotinylated antibodies are added to the suspension in conventional immunoassays (2). Finally *R*-phycoerythrin (PE)-labeled streptavidin as the fluorescent reporter is added to the suspension to conclude the conventional sandwich assay (3). Alternatively, we have employed antibody-conjugated 40 nm FRET microspheres (MS) as the fluorescent reporter for the sandwich assay (2′). The 40 nm FRET microsphere is impregnated with as many as 140 fluorophores and is highly fluorescent compared to PE. The sizes of beads (5.5 μm) and 40 nm microspheres are not proportional in the illustration.

antibody immobilized on the surface of the beads (Step 1). Used in conventional immunoassays, biotin-labeled antibodies are subsequently bound to the analytes to form sandwich-type complexes (Step 2). Last, *R*-phycoerythrin (PE)-labeled streptavidin is added as the fluorescent reporter for intensity measurements by the instrument (Step 3). Alternatively, the antibody conjugated microspheres (40 nm in diameter) replaces the biotin-labeled antibodies and the strepavidin−PE steps in a single step (Step 2′). Since each 40 nm FRET microsphere, on the average, contains about 140 fluorophores, and a resonance energy transfer method (equal numbers of donor and acceptor) is used, about 70 fluorophores are sufficient for the final emission. It is known that a single PE is equivalent to ~20 fluorophores. Therefore, when the microspheres are used as the fluorescent label, in theory, the fluorescence signal should be about 3.5 times higher than that using *R*-PE as the fluorescent reporter. Since the 40 nm FRET microspheres are largely made of hydrophobic polystyrene, however, effort may be needed for preventing nonspecific adsorption.

Because of light scattering by the 40 nm polystyrene spheres, the absorbance of the dye molecules cannot be accurately measured through simple subtraction of the absorbance from the blank microspheres. The absorbance below 500 nm is affected by the light scattering. Wittmershaus and co-workers have measured the absorbance of different BODIPY dyes embedded in microspheres via the method of index matching (*17*). Given that the absorption of dye molecules impregnated in microspheres should be proportional to the fluorescence signal obtained at the same excitation wavelength when the emission wavelength is held constant (*18*), we measured the excitation spectrum of the dye-embedded microspheres. The excitation and emission spectra of the microspheres are shown in Figure 2. The maximal absorbance and fluorescence are at 538 nm and at 570 nm, respectively. These properties are ideal for applications using Luminex 100 instruments that are equipped with a 532 nm laser beam and a 575 ± 12 nm band-pass filter for the excitation and detection of fluorescent reporters, respectively. As shown in the inset of Figure 2, two types of BODIPY dyes are needed to maximize fluorescence signal for detections using Luminex 100 instrument**.** Upon excitation, the first BODIPY fluorophores whose emission spectrum shown as dash dot line in the inset will transfer its energy to the second BODIPY dye molecules (shown as dash line) via dipole−dipole interactions with ~95% transfer efficiency (*19*). Because these fluorophores are imbedded in the microspheres, their photostabilities are superior to the commonly used *R*-PE (*17*, *20*).

To minimize nonspecific adsorption of the microspheres to various hydrophobic assay components, the reactive aldehyde groups on the outer surfaces of the microspheres were saturated with antibodies. We have used agarose gel electrophoresis to detect the fluorescent products of the labeling reactions between antibodies and aldehyde microspheres. Figure 3 shows the gel electrophoresis of the conjugation reactions with various molar ratios of antibody and microsphere as well as pure reactive microspheres as a control (lane 1 in Figure 3A). Since the polystyrene microspheres are neutral on the outer surface, they hardly move into the gel. At relative low molar ratios of ricin antibody and microsphere from

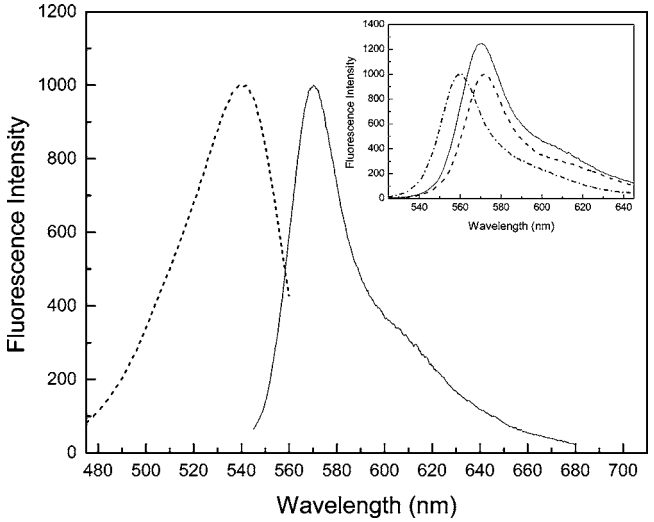

Figure 2. Normalized excitation (short dash line) and emission (solid line) spectra of the 40 nm FRET microspheres suspended in water. The fluorescence was monitored at 570 nm for the excitation spectrum and the excitation wavelength was set at 532 nm for the emission spectrum, respectively. The inset displays emission spectra (arbitrary units) of 40 nm microspheres with one type of BODIPY dye (dash and dash dot lines) and FRET microspheres imbedded with two types of BODIPY dye (solid line). The excitation wavelength was set at 490 nm for the spectral comparison. The Stokes shifts for both types of BODIPY dye are about 20 nm. The slits for excitation and emission monochromators were set at 4 nm for these measurements.

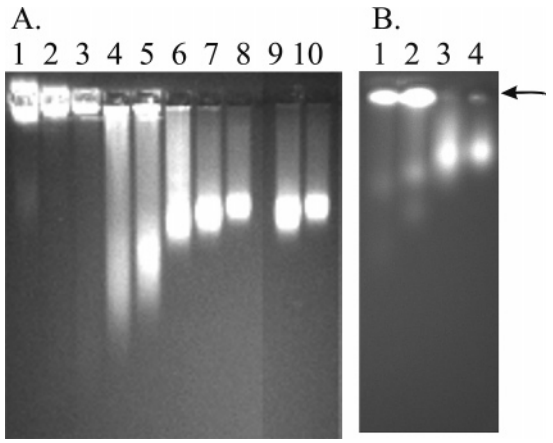

Figure 3. Agarose gel electrophoresis of microsphere preparations. The samples were electrophoresed for 3 h at 6 V/cm in 0.75% agarose using 0.5 × TBE buffer (45 mM TRIS, 45 mM boric acid, 1 mM EDTA, pH 8.3). Samples with diluted with 4% Ficoll 400 and a trace of bromphenol blue before loading. The arrow indicts the sample loading position. (A) The samples are microspheres (lane 1) and antibody-conjugated microspheres with various molar ratios of antibody against ricin and microsphere: 4:1 (lane 2), 8:1 (lane 3), 16:1 (lane 4), 24:1 (lane 5), 32:1 (lane 6), 48:1 (lane 7), 64:1 (lane 8), 48:1 from earlier preparation (lane 9), and 64:1 from earlier preparation (lane 10). (B) The conjugation reactions with four different molar ratios of antibody against Bg and microsphere: 32:1 (lane 1), 48:1 (lane 2), 64:1 (lane 3), 96:1 (lane 4). The gel was placed on a Dark Reader illuminator (output 400 nm to 500 nm, Clare Chemical Research, Denver, CO) and photographed using the supplied filter.

4:1 to 32:1 (Figure 3A: lane 2 to lane 6), not all microspheres are labeled with antibodies given that bare microspheres are seen near the loading well. At the ratios of 48:1 (Figure 3A: lane 7 and 9) and 64:1 (Figure 3A: lane 8 and 10), almost all the microspheres are conjugated with antibodies that are shown by the distinct

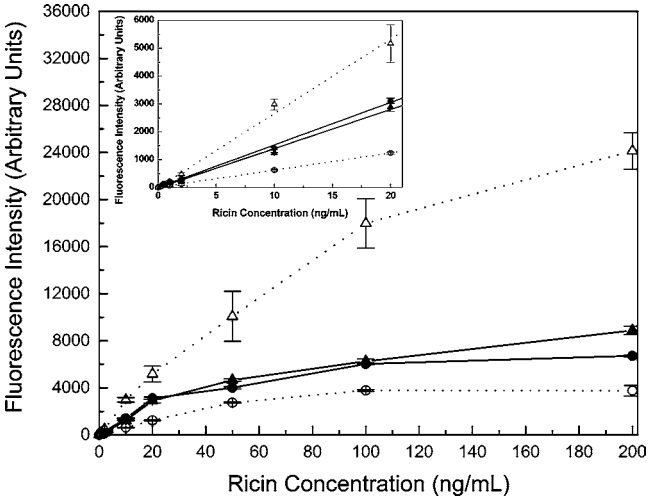

Figure 4. Standard curves of the immunoassays for ricin A chain generated by using two different fluorescent reporters, PE (circle and solid line) and antibody-conjugated microspheres with the molar ratio of antibody and microsphere of 48:1 (triangle and solid line), and implementing the two-step washing after completion of the sandwich complexes with the use of antibody-conjugated microspheres (open triangle and dot line) or PE (open circle and dot line). The error bars in the figure show the standard deviations obtained from multiple experimental repeats ($N = 4$). The inset shows the standard curves in the low concentration region of ricin A chain where the fluorescence signal corresponds linearly to ricin concentration. Various lines in the inset are the linear fitting curves.

fluorescent band that moved into the gel. The conjugation reactions (Figure 3A: lane 9 and 10) were made two weeks earlier than those (Figure 3A: lane 7 and 8), and the antibody-conjugated microspheres were stable as shown in the figure. Both ratios (48:1 and 64:1) were used to perform the sandwich assays and gave similar results.

Microspheres conjugated with the antibodies against Bg run more slowly in agarose gel than those labeled with anti-ricin antibodies (Figure 3B). At two ratios of Bg antibody and microspheres, 32:1 (Figure 3B, lane 1) and 48:1 (Figure 3B, lane 2), there were excess microspheres present near the loading wells and the coupling reactions were inefficient. With the increase of this ratio to 64:1 (Figure 3B, lane 3) and 96:1 (Figure 3B, lane 4), however, most microspheres were conjugated with antibodies, which could be visualized as a fluorescent band in the gel. The conjugated microspheres with the ratio of 64:1 were used for Bg to carry out the multiplexing experiments. The excitation and emission spectral shapes of these conjugated microspheres are the same as those shown in Figure 2.

Figure 4 displays the standard curves of the multiplexing immunoassays for ricin A chain in the presence of Bg using two different fluorescent reporters, PE (circle and solid line) and antibody-conjugated microspheres at the molar ratio of ricin antibody and microsphere of 48:1 (triangle and solid line). The two standard curves agree with each other. At low ricin concentrations ($\leq$20 ng/mL) the fluorescence signal reacts with ricin in a linear fashion, and at high concentrations of ricin ($\geq$20 ng/mL) the signal slowly approaches a plateau. Because of the possibility of the nonspecific adsorption by the microspheres, we further explored the effect of implementing a two-step washing step prior to the fluorescence detection. With the addition of the washing step, the standard curve with the use of antibody-conjugated microspheres (open triangle and dot line) was obtained with a highly improved sensitivity. In contrast, with the use of PE, the

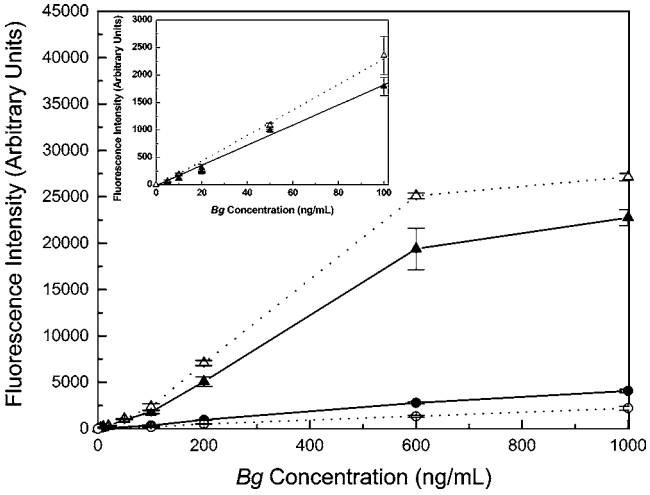

Figure 5. Standard curves of the immunological assays for *Bacillus globigii* (Bg) generated by using two fluorescent reporters, PE (circle and solid line) and antibody-conjugated microspheres with the molar ratio of antibody and microsphere of 64:1 (triangle and solid line), and employing the washing step after formation of the sandwich complexes in the presence of the antibody-conjugated microspheres (open triangle and dot line) or PE (open circle and dot line). The error bars show the standard deviations obtained from multiple experimental repeats ($N = 4$). The inset shows the standard curves in the low concentration region of Bg where the fluorescence signal responds to antigen concentration in a linear fashion. The two lines in the inset are the linear fitting curves.

assay sensitivity has dropped (open circle and dot line). The inset of the figure shows the standard curves in the low concentration region of the analyte where the fluorescence signal from the reporter responds linearly to analyte concentration. The larger slope of the linear fitting curve demonstrates the high sensitivity of ricin A chain detection by using the antibody-conjugated microspheres. The fluorescence enhancement achieved by the washing step is likely due to the minimization of the self-quenching between 40 nm dye-imbedded microspheres. As we anticipated, the fluorescence signals from the sandwich complexes with conjugated microspheres are 2 to 3 times larger than those using PE as the fluorescent reporter. Additionally, the presence of Bg did not interfere with the detection of ricin A chain since the fluorescence signals of the ricin sandwich complexes are about the same in the presence and absence of Bg (data not shown). The error bars in the figure show the standard deviations obtained from multiple experimental repeats.

The samples of Bg spores used in this study are crude preparations that would be representative of an environmental sample. The Bg samples must be constantly mixed to prevent settling during sampling and during the antigen capture step. The biological activity of these samples can be expressed in colony forming units ($\sim 1 \times 10^5$ colonies per μg), but comparison to other results done with different preparations of spores is not very meaningful because the total antigen content is not well defined in these samples. There is a real need for developing well-defined spore samples in both highly pure and crude forms. In the absence of standardized spore preparations, it makes the most sense to look at the relative differences in the detection limits when comparing the different reporters using the same samples.

The standard curves of the sandwich assays for Bg in the presence of ricin A chain are shown in Figure 5 with the use of two fluorescent reporters, PE (circle and solid line) and antibody-conjugated microspheres at the molar ratio of Bg antibody and microsphere of 64:1 (triangle and solid line). The assay sensitivity by using antibody-conjugated microspheres is much higher than that using the conventional PE. For instance, the fluorescence signals of the sandwich complexes at the Bg concentration of 5 ng/mL are distinctively above the signal of the negative control. However, with the use of PE as the reporter, the fluorescence signals of the formed complexes and of the negative control are about the same at the Bg concentration of 50 ng/mL. McBride and co-workers (*5*) showed that the sensitivity of Bg detection (using PE as the reporter) in suspension arrays was more than an order of magnitude higher compared to that using ELISAs.

We further explored the detection of Bg spores using the microspheres by adding a washing step. The fluorescence signals were only slightly improved by the washing step (open triangle and dot line) compared to the signals without the washing step (triangle and solid line). Similar to ricin assays shown in Figure 4, applying the washing steps with the use of PE as the reporter results in decrease of signals (open circle and dot line) when compared to the signals without the washing step (circle and solid line).

The high fluorescence signals obtained with the microspheres are likely attributed to several factors. As described earlier, each microsphere could emit, in principle, a ~3.5 times higher fluorescence signal than that of a single PE molecule. Additionally, because of the large size of Bg spore (~ 1 μm long and 0.7 μm wide) (*21*), it could be recognized by multiple polyclonal antibodies raised against Bg. With the use of microsphere-labeled antibodies, the signals of formed Bg complexes at high Bg concentrations are about 6 times higher than that using PE-conjugated antibodies (Figure 5). This implies that self-quenching between PE molecules is likely at high analyte concentration. The FRET microspheres coated with a layer of Bg antibodies may be less susceptible to self-quenching and therefore more versatile in recognizing the analyte (a crude spore preparation of Bg). The inset of the figure shows the standard curves in the low concentration region of the analyte where the fluorescence signal from antibody-conjugated microspheres responds to Bg concentration in a linear fashion. Using PE as the fluorescent reporter, the signals were hardly distinguishable from the background at the Bg concentration of 50 ng/mL.

CONCLUSIONS

To detect small amount of biological threats, it is critical to search for better fluorescent reporters that give brightest possible fluorescence for detection using high-throughput suspension arrays. In the present study, we have used 40 nm FRET microsphere-conjugated antibodies as the fluorescent reporters that emit about 3 times higher fluorescence than that of the conventional PE reporter used in suspension arrays to perform the multiplexing array experiments. In the case of Bg, the assay sensitivity using antibody-conjugated microspheres is an order of magnitude higher than that using the conventional PE without the implementation of the washing step. With the use of antibody-coupled microspheres, Bg at the concentration of 5 ng/mL can be easily detected. In the case of ricin A chain, the assay sensitivity is as good as that using PE as the fluorescent reporter without the washing step. While employing the washing step, however, the fluorescence signals of the sandwich complexes are 2−3 times higher than those using PE. Ricin A chain at concentration of 1 ng/mL can be readily

identified. Importantly, the two simulants do not interfere with each other in the multiplexing experiments. Thus, the present 40 nm FRET microspheres can be visualized as a unique class of fluorescence reporters for sensitive detections using suspension arrays.

Bolder BioTechnology, Inc., 4056 Youngfield Street, Wheat Ridge, Colorado 80033, BolderPATH, Inc., Campus Box 347, University of Colorado, Boulder, Colorado 80309. Received November 30, 2004

Recombinant interferon α-2 (IFN-α2) is used clinically to treat a variety of viral diseases and cancers. IFN-α2 has a short circulating half-life, which necessitates frequent administration to patients. Previous studies showed that it is possible to extend the circulating half-life of IFN-α2 by modifying lysine residues of the protein with amine-reactive poly(ethylene glycol) (PEG) reagents. However, amine-PEGylated IFN-α2 comprises a heterogeneous product mixture with low specific activity due to the large number and critical locations of lysine residues in IFN-α2. In an effort to overcome these problems we determined the feasibility of creating site-specific, mono-PEGylated IFN-α2 analogues by introducing a free (unpaired) cysteine residue into the protein, followed by modification of the added cysteine residue with a maleimide-PEG reagent. IFN-α2 cysteine analogues were expressed in *Escherichia coli* and purified, and their in vitro bioactivities were measured in the human Daudi cell line growth inhibition assay. Several cysteine analogues were identified that do not significantly affect in vitro biological activity of IFN-α2. Certain of the cysteine analogues, but not wild-type IFN-α2, reacted with maleimide-PEG to produce mono-PEGylated proteins. The PEG−Q5C analogue retained high in vitro bioactivity (within 3- to 4-fold of wild-type IFN-α2) even when modified with 20- and 40-kDa PEGs. Pharmacokinetic experiments indicated that the 20-kDa PEG−Q5C and 40-kDa PEG−Q5C proteins have 20-fold and 40-fold longer half-lives, respectively, than IFN-α2 following subcutaneous administration to rats. These studies demonstrate the feasibility of using site-specific PEGylation technology to create a long-acting, mono-PEGylated IFN-α2 protein with high specific activity.

INTRODUCTION

α-Interferons (IFN-α) comprise a family of at least 25 nonallelic genes and pseudogenes that encode proteins with 70% or greater amino acid identity (Henco et al., 1985; Blatt et al., 1996). IFN-α2 is the best-studied member of this family. IFN-α2 is a 19 kDa protein that exhibits antiviral, antiproliferative, and immunomodulatory effects on many cell types (Pestka and Langer, 1987; Gutterman, 1994). Recombinant IFN-α2 has proven useful for the treatment of a variety of human viral diseases and cancers (Gutterman, 1994). Recombinant IFN-α2 has a short circulating half-life and generally is administered to patients by daily or thrice weekly injections. Previous studies showed that it is possible to increase the circulating half-life of IFN-α2 by covalent modification of the protein with amine-reactive poly(ethylene glycol) (PEG) reagents, which typically attach to lysine residues or the N-terminal amino acid (Monkarsh et al., 1997; Wang et al., 2000; Bailon et al., 2001). A limitation of the use of amine-reactive PEGs for modifying IFN-α2 is the fact that IFN-α2 contains 10 (or 11, depending upon the subtype) lysine residues in addition to the N-terminal amino acid. Monkarsh et al. (1997) found that all 11 lysine residues in IFN-α2a are modified to varying extents using amine-reactive PEG reagents. In addition to these 11 positional isomers, amine-PEGylated IFN-α comprises a mixture of mono-, di-, and multiply-PEGylated species. The various positional isomers and mono- and multiply-PEGylated IFN-α2 species have different specific activities (Monkarsh et al., 1997). Amine-PEGylated IFN-α2 also has significantly reduced in vitro bioactivity (4- to 14-fold) compared to IFN-α2 (Monkarsh et al., 1997; Wang et al., 2000; Bailon et al., 2001), which increases the amount of protein required to treat patients. Loss of bioactivity is greatest when IFN-α2 is modified with large PEGs (e.g., 20- and 40-kDa PEGs), which are the most useful PEGs for extending the half-life of the protein, and when the protein is modified with more than one PEG (Monkarsh et al., 1997; Bailon et al., 2001). IFN-α2 contains several lysine residues that are located in regions of the protein believed to be important for receptor binding (Radhakrishnan et al., 1996). It is likely that modification of one or more of the critical lysine residues contributes to the loss of activity upon PEGylation of IFN-α2 with amine-reactive PEG reagents.

In an effort to overcome the heterogeneity and loss of activity problems associated with amine-PEGylation of IFN-α2, we tested the feasibility of using site-specific PEGylation (Goodson and Katre, 1990) to modify IFN-α2. Site-specific PEGylation involves introducing a "free" cysteine residue, that is, a cysteine residue not involved in a disulfide bond, into a target protein using site-directed mutagenesis, followed by covalent modification of the added cysteine residue with a cysteine-specific PEG reagent. A key technical challenge with this technology is the identification of a site(s) in the target protein where

a cysteine residue can be introduced and PEGylated without significantly affecting in vitro biological activity of the protein. In this report, we demonstrate the utility of this approach for creating a long-acting, highly potent PEGylated cysteine analogue of IFN-α2.

EXPERIMENTAL PROCEDURES

Cloning DNA Sequences Encoding IFN-α2 and IFN-α2 Cysteine Analogues. DNA encoding IFN-α2b (Henco et al., 1985) was amplified using the polymerase chain reaction (PCR) method from human genomic DNA (CLONTECH, Inc., Palo Alto, CA) using primers BB93 (5′-CGCGAATTCGGATATGTAAATAGATACACAGTG-3′) and BB94 (5′-CGCAAGCTTAAAAGATTTAAATCGT-GTCATGGT-3′). The PCR product was digested with *Eco*RI and *Hin*dIII and cloned into similarly digested plasmid pCDNA3.1(+) (Invitrogen Corporation, Carlsbad, CA), creating plasmid pBBT160. The IFN-α2 gene in pBBT160 was modified initially for cytoplasmic expression in *Escherichia coli* by using PCR mutagenesis to add a methionine codon immediately prior to the first residue (C1) of the mature IFN-α2 protein and to add a TAA stop codon following the carboxy-terminal residue, E165. In addition, *Xba*I and *Sal*I sites were added and a *Bgl*II site was eliminated to provide convenient restriction sites for subsequent mutagenesis. None of these alterations changed the amino acid sequence of IFN-α2. Primers used in this PCR reaction were BB99 (5′-CGCAAGCT-TCATATGTGTGATCTGCCTCAAACCCACAGCCTGG-GTTCTAGAAGGACCTTGATGCTC-3′) and BB100 (5′-CGCGAATTCTTATTCCTTACTTCTTAAACTTTCTTG-CAAGTTTGTCGACAAAGAAAAGGATCTCATGAT-3′). The PCR product was digested with *Hin*dIII and *Eco*RI and cloned into plasmid pCDNA3.1(+), creating pBBT164. The *Nde*I−*Eco*RI fragment of pBBT164 containing the met-IFN-α2 sequence was subcloned into pUC18 (Sigma-Aldrich, Inc., St. Louis, MO) to generate plasmid pBBT168.

A secreted form of IFN-α2 was created by fusing DNA encoding the *E. coli* heat-stable enterotoxin gene (STII) signal sequence (Picken et al., 1983) to the coding sequence of mature IFN-α2 via two sequential PCR reactions. The first reaction used forward primer BB101 (5′-GCATCTATGTTCGTTTTCTCTATCGCTACCAAC-GCTTACGCATGTGATCTGCCTCAAACCCACAGC-3′) and reverse primer BB100 with pBBT164 DNA. The PCR product was used as DNA template in a second PCR reaction, which used reverse primer BB100 and forward primer BB11 (5′-CCCCCTCTAGACATATGAAGAAGAA-CATCGCATTCCTGCTGGCATCTATGTTCGTTTTCTC-TATCG-3′). The PCR product was digested with *Nde*I and *Xba*I, and the ∼100 bp *Nde*I−*Xba*I fragment containing the STII leader sequence and amino-terminal 30 bp of IFN-α2 was purified and cloned into similarly digested pBBT168 DNA, creating pBBT177. The STII-IFN-α2 gene was subcloned as an *Nde*I−*Eco*RI fragment into expression vector pCYB1 (New England Biolabs, Beverly, MA), creating pBBT178.

Mutant IFN-α2 genes were constructed by site-directed PCR-based mutagenesis (Higuchi, 1990; Horton et al., 1993), using plasmid pBBT177 as the DNA template. PCR products were digested with appropriate restriction endonucleases and cloned into similarly digested pBBT177 DNA. Correct DNA sequences of all cysteine analogues were confirmed. The STII-IFN-α2 genes encoding the cysteine analogues were excised from the pUC18-based pBBT177 derivatives as *Nde*I−*Eco*RI fragments and subcloned into pCYB1 for expression in *E. coli*.

Expression and Purification of IFN-α2 and IFN-α2 Cysteine Analogues. pCYB1 plasmids encoding STII-IFN-α2 and STII-IFN-α2 cysteine analogues were transformed into *E. coli* strain W3110. Overnight cultures were diluted to an optical density at 600 nm of ∼0.02 in Luria Broth (LB) media, 100 mM MES (pH 5.5), containing 100 μg/mL ampicillin. Typically, cells were grown at 37 °C until the optical densities of the cultures reached 0.3−0.4. Isopropyl-β-D-thiogalactopyranoside (IPTG) was then added to a final concentration of 0.5 mM, and the induced cultures were shifted to 28 °C and incubated for about 16 h. Cultures were subjected to osmotic shock as described by Koshland and Botstein (1980). This procedure was modified for the IFN-α2 cysteine analogues to include 5 mM cystine in the osmotic shock buffers. The osmotic shock supernatant and pellet fractions were processed immediately or stored frozen at −80 °C.

IFN-α2 and certain IFN-α2 cysteine analogues were purified from the osmotic shock supernatants by S-Sepharose and Cu^{2+} immobilized metal affinity chromatography (IMAC) column chromatography (Voss et al., 1994; Khan and Rai, 1990). The osmotic shock supernatants were adjusted to pH 3 and centrifuged, and the supernatants were loaded onto a 5 mL HiTrap S-Sepharose column (Amersham Biosciences Corporation, Piscataway, NJ) equilibrated in 20 mM MES, pH 5.0. The bound proteins were eluted with a linear salt gradient from 0% to 100% 500 mM NaCl, 20 mM MES, 10% ethylene glycol, pH 5.0. Column fractions enriched for the IFN-α2 proteins were identified by nonreducing SDS−PAGE. These fractions were pooled and loaded onto a 1 mL Cu^{2+} IMAC HiTrap column (Amersham Biosciences Corporation) equilibrated in 40 mM sodium phosphate, pH 6.0, 1 M NaCl, 0.1% Tween 20. The IFN-α2 proteins were eluted with a reverse pH gradient from 5.5 to 4.1 in 40 mM sodium phosphate, 1 M NaCl, 0.1% Tween 20. Column fractions were analyzed by nonreducing SDS−PAGE, and fractions containing properly folded IFN-α2 protein and no visible contaminants were pooled and stored at −80 °C.

The osmotic shock pellets containing insoluble IFN-α2 cysteine analogues were treated with B-PER bacterial protein extraction reagent (Pierce Chemical Company, Rockford, IL) according to the manufacturer's directions. Insoluble material was recovered by centrifugation, washed with water, and solubilized in 5 mL of 6 M guanidine, 50 mM cysteine in 20 mM Tris base. The mixture was stirred for 30 min and then dialyzed overnight at 4 °C against 400 mL of 40 mM sodium phosphate, 150 mM NaCl, pH 8.0. The refold mixture was then adjusted to pH 3.0 and centrifuged, and refolded IFN-α2 proteins were purified from the supernatants by S-Sepharose and Cu^{2+} IMAC column chromatography as described above.

For larger scale production of the Q5C analogue, the osmotic shock step was omitted, and the protein was refolded from whole cells as follows. Frozen cells from 400 mL cultures were thawed and resuspended in 10 mL of 8M guanidine, 20 mM cysteine, 2% Tween 20, 20 mM MES, pH 3. After mixing for 3 h, the solution was diluted 20-fold, the guanidine concentration was adjusted to 0.6 M, urea and copper sulfate were added to final concentrations of 1 M and 40 μM, respectively, and the solution was adjusted to pH 6. The refold mixture was incubated for 1−2 days, adjusted to pH 3, and clarified by centrifugation. The refold mixture was diluted 4-fold with H_2O, and refolded Q5C protein was purified by S-Sepharose and Cu^{2+} IMAC column chromatography as described above.

PEGylation of IFN-α2 Cysteine Analogues. IFN-α2 proteins were incubated at room temperature with a 10- to 15-fold molar excess of Tris[2-carboxyethylphosphine] hydrochloride (TCEP, Pierce Chemical Company) and a 15- to 20-fold molar excess of 5 kDA maleimide PEG, 10 kDa maleimide PEG, 20 kDa maleimide PEG or 40 kDa branched maleimide PEGs (Nektar, Inc., Huntsville, AL) at pH 8.5 for 60 min. The PEGylation reactions were then diluted 10-fold with 20 mM MES, pH 5.0, adjusted to pH 3.0, and subjected to S-Sepharose column chromatography using the conditions described above.

In Vitro Bioactivity Measurements. The human Daudi B cell line (Horoszewicz et al., 1979; Evinger and Pestka, 1981) was obtained from the American Type Culture Collection (Rockville, MD) and maintained in RPMI 1640 media supplemented with 10% fetal bovine serum (FBS), 2 mM glutamine, 50 units/mL penicillin, and 50 μg/mL streptomycin (assay media). For bioassays, washed cells were resuspended at a concentration of 4×10^5 cells/mL in assay media, and 50 μL (2×10^4 cells) of the cell suspension was aliquotted per well of a flat bottom 96 well tissue culture plate. Serial 3-fold dilutions of the protein samples were prepared in assay media, and 50 μL of the diluted protein samples were added to the test wells. Protein samples were assayed in triplicate wells. Control wells contained media but no cells. A commercial wild-type IFN-α2 (Endogen, Inc.), and wild-type IFN-α2 prepared by us were analyzed in parallel to control for interday variability in the assay. Plates were incubated for 4 days at 37 °C in a humidified 5% CO_2 tissue culture incubator. Following the incubation period, 20 μL of CellTiter 96 AQueous One Solution Reagent (Promega Corporation, Madison, WI) was added to each well, and the plates were incubated at 37 °C in the tissue culture incubator for 1−4 h. Absorbance was read at 490 nm using a microplate reader.

Pharmacokinetic Experiments in Rats. Animal experiments were performed with the approval of BolderPATH's Institutional Animal Care and Use Committee. Groups of three male Sprague Dawley rats, weighing approximately 350 g each, received a single intravenous injection (lateral tail vein) of Roferon (recombinant *E. coli*-derived IFN-α2a, Roche), 10-kDa PEG−IFN-α2 Q5C, 20-kDa PEG−IFN-α2 Q5C, or 40-kDa PEG−IFN-α2 Q5C, each at a dose of 100 μg of protein/kg of body weight. At selected time points, blood samples (0.4 mL) were drawn from the rats into EDTA anticoagulant tubes. The blood samples were centrifuged, and the plasma samples were stored at −80 °C. A predose sample (0 h) was drawn 1 day prior to injection of the test compounds. Plasma levels of the test proteins were quantitated using human IFN-α2 ELISA kits (Pierce Chemical Company.). Serial dilutions of plasma samples from one animal in each test group were analyzed in the in vitro bioassay to identify dilutions that fell within the linear range of the ELISA (25.6−1000 pg/mL). Duplicate samples of appropriate dilutions of plasma samples from all rats were then analyzed in the ELISA. A subcutaneous pharmacokinetic experiment was performed in the same manner except that the protein samples were injected subcutaneously into the lateral sides of the rats. Pharmacokinetic parameters were analyzed using the WinNonlin software package (Pharsight, Inc., Mountain View, CA) using noncompartmental methods.

Biochemical Methods. Protein samples were analyzed by SDS−polyacrylamide gel electrophoresis (SDS−PAGE) on precast Tris−glycine polyacrylamide gels (Invitrogen Corporation, Carlsbad, CA) and stained with Coomassie Blue. 2-Mercaptoethanol was added to a final concentration of 1−5% (v/v) to reduce the proteins. Protein concentrations were determined using a Bradford protein assay kit (Bio-Rad Laboratories, Richmond, CA), using bovine serum albumin as the protein standard.

RESULTS

***E. coli* Expression, Purification, and Bioactivity of IFN-α2 and IFN-α2 Cysteine Analogues.** Human IFN-α2 has a compact globular structure, comprising five α helices joined by loops (Radhakrishnan et al., 1996; Klaus et al., 1997). The five α helices are termed A−E beginning from the N-terminus of the protein. The loop regions are referred to by the helices they join, for example, the A−B loop joins helices A and B. We constructed seven cysteine analogues in various nonhelical regions of IFN-α2. We constructed one cysteine substitution analogue in the amino-terminal region preceding helix A (Q5C), three cysteine substitution analogues in the CD loop (Q101C, T106C, E107C), and one cysteine substitution analogue in the carboxy-terminal region following helix E (S163C). We also constructed one cysteine addition analogue, *166C, that adds a cysteine residue following the carboxy-terminal residue, E165. In addition, we constructed the C98S analogue, which eliminates the nonessential C1−C98 disulfide (Morehead et al., 1984) and creates an unpaired cysteine (C1) in the region preceding helix A.

Wild-type IFN-α2 and IFN-α2 cysteine analogues were expressed as periplasmic secreted proteins in *E. coli* strain W3110 using the *E. coli* STII leader sequence, as described in Experimental Procedures. Voss et al. (1994) reported that correct processing of the STII secretion signal from IFNα2 was pH-dependent, being enhanced when culture pH was maintained at or below 6.7. Similarly, we found that Luria Broth medium buffered with 100 mM MES to a pH of 5.5 gave optimum yields of correctly processed IFN-α2 and IFN-α2 cysteine analogues (data not shown), and it was used routinely for expression of the proteins. Induced cell cultures were subjected to osmotic shock (Koshland and Botstein, 1980) to release the soluble contents of the periplasm. Approximately 25−50% of the correctly processed wild-type IFN-α2 protein was recovered in the supernatant fraction following centrifugation of the osmotic shock-treated cells. Wild-type IFN-α2 was purified from the osmotic shock supernatant by S-Sepharose column chromatography followed by affinity chromatography using a Cu^{2+} IMAC column (Figure 1). Purified wild-type IFN-α2 had a similar mean IC_{50} to a commercial IFN-α2 standard in the human Daudi B cell line growth inhibition assay (Figure 2 and Table 1). Relative IC_{50}'s for these proteins were consistent between experiments, although their absolute IC_{50} values varied by up to 2- to 3-fold in assays performed on different days; therefore comparisons between proteins were made on samples analyzed on the same days.

In contrast to wild-type IFN-α2, most IFN-α2 cysteine analogues were present in the osmotic shock supernatants at significantly reduced levels relative to wild-type IFN-α2 (data not shown). The cysteine analogues partitioned primarily into the osmotic shock pellets. Only the Q5C and S163C proteins were present at appreciable levels in the osmotic shock supernatants. These analogues were purified from the osmotic shock supernatants by S-Sepharose and Cu^{2+} IMAC chromatography as described for wild-type IFN-α2, with the exception that 5 mM cystine was added to the osmotic shock buffers. In

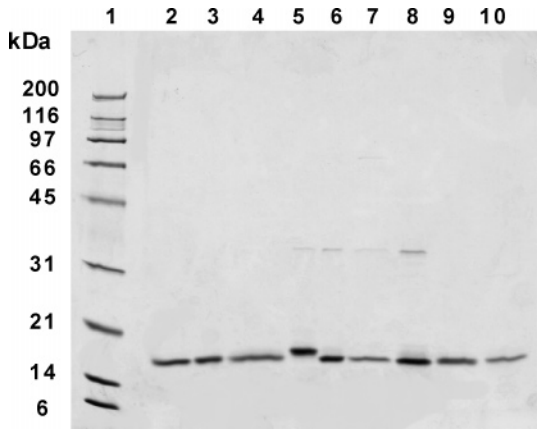

Figure 1. Nonreduced SDS−PAGE analysis of column pools of purified recombinant wild-type IFN-α2 and IFN-α2 cysteine analogues: lane 1, molecular weight markers; lane 2, wild-type IFN-α2 prepared by us; lane 3, Q5C soluble, periplasmically expressed; lane 4, Q5C, refolded; lane 5, C98S; lane 6, Q101C; lane 7, T106C; lane 8, E107C; lane 9, S163C; lane 10, *166C.

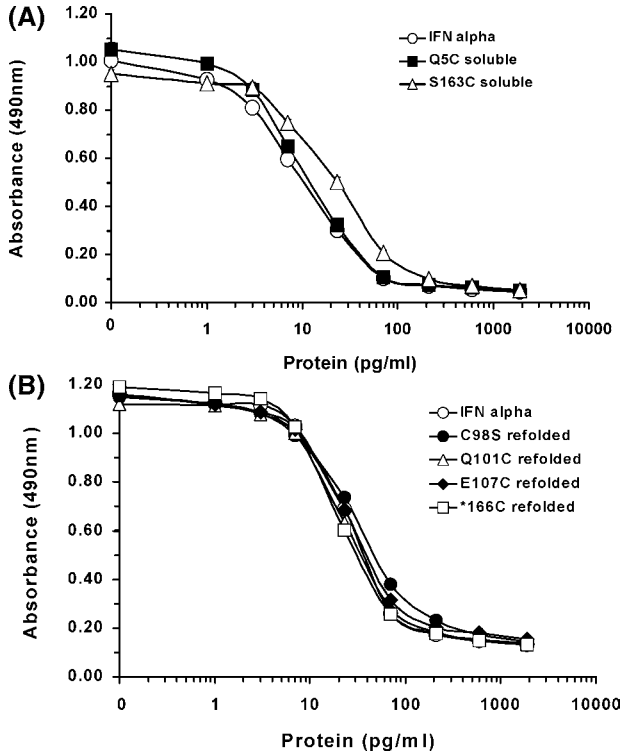

Figure 2. Dose response curves of IFN-α2 cysteine analogues and wild-type IFN-α2 for inhibiting proliferation of Daudi cells. Data are means of triplicate wells ± SD from representative experiments. SDs were less than 10% of the means. Proteins shown in the same panel were analyzed on the same days. Wild-type IFN-α2 used in the bioassay shown in panel A was prepared by us. Wild-type IFN-α2 used in the bioassay shown in panel B was purchased from Endogen, Inc. The Q5C and S163C proteins analyzed in panel A were purified from the soluble (supernatant) fraction of osmotic shock lysates; the C98S, Q101C, E107C, and *166C proteins analyzed in panel B were refolded from the insoluble (pellet) fraction of the osmotic shock lysates (see Experimental Procedures).

the absence of cystine, the cysteine analogues eluted in multiple fractions throughout the column gradients rather than as single peaks (data not shown).

SDS−PAGE analyses revealed that the C98S, Q101C, T106C, E107C, and *166C cysteine analogues expressed well but accumulated primarily in the osmotic shock pellets, suggesting that they were insoluble. When denatured and reduced these analogues comigrated with wild-type IFN-α2, indicating that the STII leader had been removed. Insoluble IFN-α2 cysteine analogues were refolded from the osmotic shock pellets and purified by S-Sepharose and Cu^{2+} IMAC column chromatography. The Q5C protein was recovered in both the pellet and the supernatant of the osmotic shock lysate and was purified from both sources. Nonreducing SDS−PAGE analysis of the purified Q5C, C98S, Q101C, T106C, E107C, S163C, and *166C proteins is shown in Figure 1. The cysteine analogues were recovered predominantly as monomers that comigrated with wild-type IFN-α2 under reducing and nonreducing SDS−PAGE conditions. The C98S analogue migrated with a slightly greater apparent molecular mass than the other INF-α2 analogues under nonreducing conditions, presumably due to the absence of the native C1−C98 disulfide bond (Morehead et al., 1984). Certain of the purified IFN-α2 analogues (C98S, Q101C, T106C, E107C) contained small amounts of disulfide-linked IFN-α2 dimers, which were apparent when the proteins were analyzed by nonreducing SDS−PAGE (Figure 1).

Table 1. In Vitro Bioactivities of IFN-α2 Cysteine Analogs

IFN-α2 protein	free cysteine location[a]	form assayed[b]	IC_{50} (pg/mL)[c]
IFN-α2[d]			13 ± 5
IFN-α2[e]		soluble	12 ± 4
Q5C	preceding helix A	soluble	13 ± 4
Q5C	preceding helix A	refolded	17 ± 3
C98S	preceding helix A[f]	refolded	28 ± 5
Q101C	C−D loop	refolded	18 ± 7
T106C	C−D loop	refolded	18 ± 0
E107C	C−D loop	refolded	18 ± 9
S163C	following helix E	soluble	27 ± 8
*166C	C-terminus	refolded	15 ± 6

[a] Based upon the IFN-α2 structure described by Radhakrishnan et al. (1996). [b] Soluble and refolded forms purified from the osmotic shock supernatant and pellet fractions, respectively. [c] Means ± SD for at least three assays for each protein except for the T106C analogue, which was assayed twice. [d] Wild-type IFN-α2 standard (Endogen, Inc.). [e] Wild-type IFN-α2 prepared by us. [f] Mutation creates a free cysteine (C1) in the region preceding helix A.

The Q5C, Q101C, T106C, E107C, and *166C proteins had in vitro bioactivities (IC_{50}'s) that were indistinguishable from that of wild-type IFN-α in the Daudi cell assay. In contrast, IC_{50}'s for the C98S and S163C proteins were consistently reduced about 2-fold relative to the IC_{50} of wild-type IFN-α2. Q5C recovered from the soluble periplasmic fraction and Q5C recovered from the insoluble fraction and refolded had IC_{50}'s equivalent to each other and to wild-type IFN-α2. These data are summarized in Table 1. Dose response curves for representative cysteine analogues are shown in Figure 2.

Preparation and in Vitro Bioactivity of PEG−Q5C. For PEGylation, the purified IFN-α2 cysteine analogues were reacted for 1 h at room temperature with TCEP and 5 kDa maleimide PEG at pH 8.5, as described in Experimental Procedures. Under these conditions, the Q5C analogue showed the greatest reactivity with the PEG reagent, yielding about 60% mono-PEGylated Q5C protein without detectable di- or tri-PEGylated protein (Figure 3). Control experiments (not shown) demonstrated that inclusion of a reducing agent such as TCEP in the PEGylation reaction was required for efficient PEGylation of Q5C and other IFN-α2 cysteine analogues. Wild-type IFN-α2 showed no detectable PEGylation under identical conditions, indicating that the native disulfide bonds of the protein are not disrupted by the

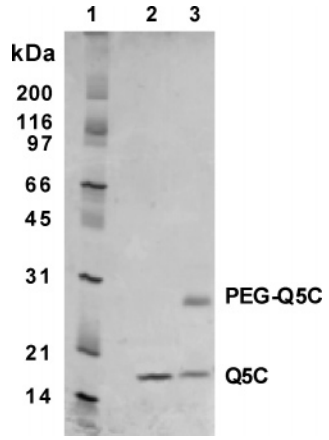

Figure 3. Nonreducing SDS−PAGE of Q5C and wild-type IFN-α2 PEGylation reaction products: lane 1, molecular weight markers; lane 2, wild-type IFN-α2 PEGylation reaction products; lane 3, Q5C PEGylation reaction products. Reaction conditions were as described in Experimental Procedures.

reaction conditions (Figure 3). The T106C, E107C, and S163C analogues also generated mono-PEGylated proteins using these PEGylation conditions, but the extent of PEGylation was less than that observed for the Q5C analogue (data not shown). The C98S, Q101C, and *166C proteins reacted only weakly with the PEG reagent under these conditions (data not shown).

The Q5C protein was modified at a larger scale with 5-, 10-, 20-, and 40-kDa maleimide-PEGs. PEG−Q5C was separated from unreacted Q5C protein by S-Sepharose column chromatography. A representative column elution profile for the 5-kDa PEG−Q5C PEGylation reaction mixture is shown in Figure 4A. The S−Sepharose column elution profile showed two major peaks. The early-eluting peak was determined to be mono-PEGylated Q5C by nonreducing SDS−PAGE (Figure 4B). The late-eluting peak was determined to be unreacted Q5C protein. Fractions containing PEG−Q5C and no visible unmodified protein were pooled and used for bioactivity measurements. Similar procedures were used to prepare Q5C modified with 10-, 20- and 40-kDa PEGs. Nonreducing SDS−PAGE of the purified PEG−Q5C proteins is shown in Figure 5.

When tested in the in vitro Daudi cell growth inhibition assay, bioactivity of the 5-kDa PEG−Q5C protein was reduced approximately 2-fold (IC_{50} of 22 ± 7 pg/mL; N = 3) compared to bioactivities of wild-type IFN-α2 (IC_{50} of 13 ± 6 pg/mL) and unmodified Q5C protein (IC_{50} of 13 ± 5 pg/mL) analyzed in the same assays (Figure 6A). Bioactitvities of the 10-, 20- and 40-kDa PEG−Q5C proteins were reduced approximately 3- to 4-fold relative to bioactivities of wild-type IFN-α and unmodified Q5C proteins analyzed in the same assays (Figure 6B and Table 2).

Pharmacokinetic Studies of PEG−Q5C Proteins. Circulating half-lives of the PEG−Q5C proteins were compared to that of wild-type IFN-α2 (Roferon, Roche) following intravenous and subcutaneous injection in rats. Circulating levels of the proteins were measured by ELISA. Following intravenous injection (Figure 7A), wild-type IFN-α2 cleared rapidly from the rats with a terminal half-life of 0.5 h, similar to what is reported in the literature (Bailon et al., 2001). In contrast, terminal half-lives for the 10-, 20-, and 40-kDa PEG−Q5C proteins were 22, 24, and 32 h, respectively. The initial distribution phase also appeared to be lengthened in the PEG−Q5C proteins relative to wild-type IFN-α2; however, not

Figure 4. enough early time points were sampled to obtain accurate values for the distribution phase.

Following subcutaneous administration (Figure 7B), plasma concentrations of wild-type IFN-α2 peaked 1 h after administration (10.2 ng/mL) and decreased to undetectable levels by 24 h postinjection. The terminal half-life was 1.2 h. In contrast, maximum plasma levels of the PEG−Q5C proteins were not attained until 10 h

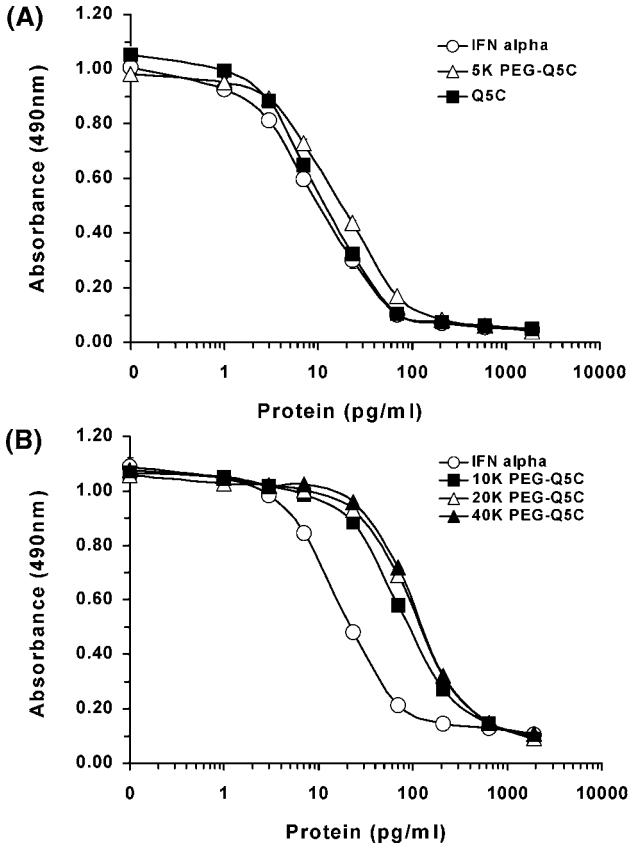

Figure 6. Dose response curves for PEG−Q5C proteins, unmodified Q5C, and wild-type IFN-α2 for inhibiting proliferation of Daudi cells: (A) comparison of the activities of commercial wild-type IFN-α2, Q5C, and 5-kDa PEG−Q5C; (B) comparison of the activities of commercial wild-type IFN-α2, 10-kDa PEG−Q5C, 20-kDa PEG−Q5C, and 40-kDa PEG−Q5C. Data are means of triplicate wells ± SD from representative experiments. SD were less than 10% of the means.

Table 2. In Vitro Bioactivities of PEG−Q5C Proteins

protein	IC_{50} (pg/mL)[a]
IFN-α2[b]	24 ± 5
IFN-α2[c]	29 ± 1
Q5C[d]	31 ± 2
10-kDa PEG-Q5C[d]	70 ± 0
20-kDa PEG-Q5C[d]	100 ± 7
40-kDa PEG-Q5C[d]	108 ± 11

[a] Means ± SD for at least three assays for each protein, except for the 10-kDa PEG−Q5C protein and our wild-type IFN-a2 protein, which were assayed twice. [b] Wild-type IFN-α2 standard (Endogen, Inc.). [c] Wild-type IFN-α2 prepared by us. [d] Q5C protein refolded from whole cells.

(10-kDa PEG−Q5C, 15.9 ng/mL), 24 h (20-kDa PEG−Q5C, 20.7 ng/mL), and 48 h (40-kDa PEG−Q5C, 33.3 ng/mL) postinjection (Figure 7B), and the PEG−Q5C proteins were cleared much more slowly than IFN-α. Terminal half-lives for the 10-, 20-, and 40-kDa PEG−Q5C proteins were 17, 27, and 48 h, respectively.

DISCUSSION

Our goal was to identify a site(s) in IFN-α2 where a cysteine residue can be introduced and PEGylated without significant loss of in vitro bioactivity. We focused mutagenesis efforts away from the presumptive receptor binding sites in IFN-α2, which have been localized to the N-terminal end of the A−B loop, helices C and D and the D−E loop (Uze et al., 1995; Rhadhakrishnan et al., 1996; Klaus et al., 1997; Roisman et al., 2001). The three

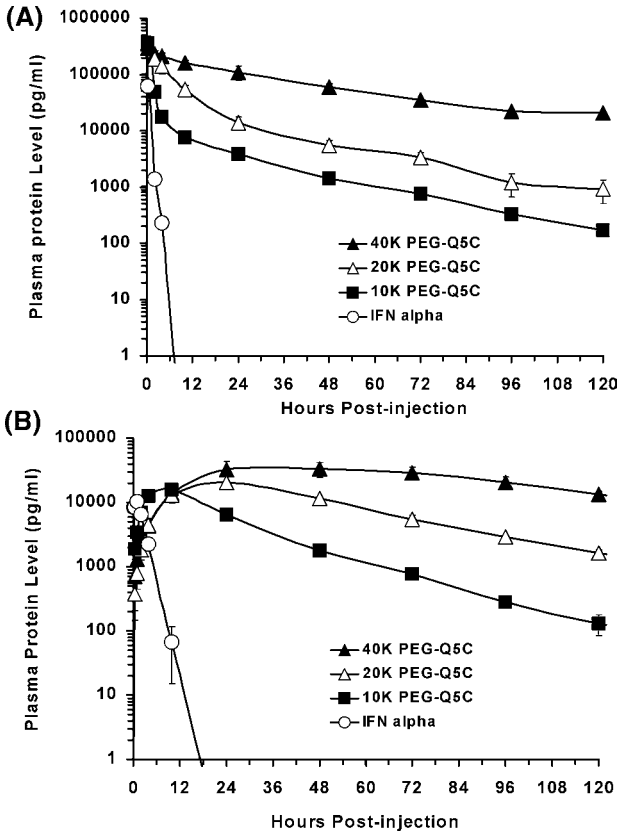

Figure 7. Changes in plasma protein levels following (A) intravenous and (B) subcutaneous administration of IFN-α2 (Roferon) and Q5C modified with 10-, 20-, and 40-kDa maleimide PEGs to rats. Protein levels were measured using human IFN-α2 ELISA kits. Data are means ± SD for three rats per group. SDs were generally less than 25% of the means.

regions chosen for mutational analysis, the region preceding helix A, the C−D loop, and the region following helix E, exhibit significant flexibility and high solvent exposure (Klaus et al., 1997). We found that the cysteine analogues analyzed in these regions retained complete (Q5C, Q101C, T106C, E107C, and *166C) or near complete (C98S, S163C) in vitro biological activity. Our data for the C98S analogue confirm previous studies indicating that the C1−C98 disulfide is not absolutely required for IFN-α2 bioactivity (Morehead et al., 1984; DeChiara et al., 1986). This is in contrast to the C29−C138 disulfide bond, which is required for IFN-α2 bioactivity (Morehead et al., 1984). We found that addition of cystine to the osmotic shock buffers and use of cysteine in the refold buffers was beneficial in improving recoveries of the IFN-α2 cysteine analogues from *E. coli*. We postulate that cystine/cysteine react with the free cysteine residues in the analogues to form a stable mixed disulfide that prevents or minimizes disulfide shuffling and aggregation of the proteins during subsequent column purification steps. This hypothesis is consistent with the finding that the purified cysteine analogues must be exposed to a reducing agent such as TCEP (presumably to reduce the mixed disulfide) for optimal reactivity with maleimide PEGs.

The Q5C protein was chosen for further study because it expressed well, displayed wild-type in vitro biological activity, and PEGylated efficiently. The mono-PEGylated Q5C protein could be purified readily from non-PEGylated protein by ion-exchange chromatography. The PEG−Q5C protein eluted as a single symmetrical peak, consistent with the PEG−protein having a homogeneous

structure. In contrast, amine-PEGylated IFN-α2 elutes as multiple peaks from ion-exchange columns due to heterogeneity resulting from the large number of positional isomers and multiply-PEGylated species (Monkarsh et al., 1997). In vitro bioactivity of the purified 5-kDa PEG−Q5C protein was within 2-fold of wild-type IFN-α2, whereas in vitro bioactivities of the Q5C protein modified with 10-, 20-, and 40-kDa PEGs were within 3- to 4-fold of wild-type IFN-α2. By contrast, in vitro bioactivity of IFN-α2 is reduced 4- to 5-fold when modified with 5-kDa amine-reactive PEGs and at least 14-fold when modified with 40-kDa amine-reactive PEGs (Monkarsh et al., 1997; Wang et al., 2000; Bailon et al., 2001). Thus, targeted attachment of PEG to IFN-α2 using site-specific PEGylation not only provides a structurally homogeneous product but also appears to yield a PEGylated IFN-α2 protein with higher specific activity than comparable amine-PEGylated IFN-α2 proteins. Pharmacokinetic studies showed that the circulating half-life of the Q5C protein varied depending upon the size of the attached PEG moiety, larger PEGs extending the half-life more than smaller PEGs. Attachment of a single 40-kDa PEG to the Q5C protein increased its half-life up to 40-fold relative to wild-type IFN-α2 following subcutaneous administration to rats. Modification of the Q5C protein with PEG also significantly slowed absorption of the protein from the injection site following subcutaneous administration, larger PEGs slowing absorption more than smaller PEGs. The half-life of the 40-kDa PEG−Q5C protein following subcutaneous administration to rats (48 h) is similar to that reported for IFN-α2a modified with a 40-kDa amine-reactive PEG following subcutaneous administration to rats (51 h; Bailon et al., 2001).

Two amine-PEGylated IFN-α2 products, PEG-Intron (Schering-Plough) and PEGASYS (Roche), are approved for use in humans. Both products have longer half-lives than IFN-α2, can be administered less frequently than IFN-α2 (once per week), and are more efficacious than IFN-α2 at treating hepatitis C (Craxi and Licata, 2003; Foster, 2003; Pedder, 2003). Clinical trials of these PEGylated IFN-α2 products in cancer patients are in progress (Choueiri et al., 2003). Although both products are prepared using amine-PEGylation technologies, the PEGylated proteins have quite different physical properties due to the PEGs used to prepare the proteins. PEG-Intron is modified with a 12 kDa linear PEG, whereas PEGASYS is modified with a 40 kDa branched PEG (Pedder, 2003). PEGASYS has lower activity than PEG-Intron in in vitro bioassays but a longer half-life than PEG-Intron in vivo (Gilbert and Park-Cho, 1999; Bailon et al., 2001; Pedder, 2003). The site-specific PEGylated Q5C protein described here is distinguished from PEG-Intron and PEGASYS by possessing both high in vitro bioactivity and a long half-life. Whether these unique features of PEG−Q5C will lead to a more potent or efficacious PEG-IFN-α2 product in vivo remains to be determined.

In conclusion, these studies demonstrate the feasibility of using site-specific PEGylation to create a long-acting IFN-α2 conjugate with high specific activity. Because of the shared structural features of members of the IFN gene family (IFN-α, IFN-β, IFN-γ, IL-10) information gained from these studies may prove useful for creating long-acting, site-specific PEGylated forms of other interferon species.

Transfection Activity of Polyamidoamine Dendrimers Having Hydrophobic Amino Acid Residues in the Periphery

Kenji Kono,* Hitoshi Akiyama, Toshinari Takahashi, Toru Takagishi, and Atsushi Harada

Department of Applied Materials Science, Graduate School of Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, Osaka 599-8531, Japan. Received September 10, 2004; Revised Manuscript Received December 1, 2004

We designed poly(amidoamine) dendrimers with phenylalanine or leucine residues at their chain ends. Thereby, we achieved efficient gene transfection of cells through synergy of the proton sponge effect, which is induced by the internal tertiary amines of the dendrimer, and hydrophobic interaction by the hydrophobic amino acid residues in the dendrimer periphery. Dendrimers having 16, 29, 46, and 64 terminal phenylalanine residues were prepared by the reaction of the amine-terminated poly(amidoamine) G4 dendrimer and L-phenylalanine using condensing reagent 1,3-dicyclohexylcarbodiimide. Transfection activity of these phenylalanine-modified dendrimers for CV1 cells, an African green monkey kidney cell line, increased concomitant with the increasing number of the terminal phenylalanine residues, except for the dendrimer with 64 phenylalanine residues, which showed poor water solubility and hardly formed a complex with DNA at neutral pH. However, under weakly acidic conditions, the dendrimer with 64 phenylalanine residues formed a complex with DNA, thereby achieving highly efficient transfection. In contrast, the attachment of L-leucine residues was unable to improve the transfection activity of the parent dendrimer, probably because of the relatively lower hydrophobicity of this amino acid. The phenylalanine-modified dendrimer exhibited a higher transfection activity and a lower cytotoxicity than some widely used transfection reagents. For that reason, the phenylalanine-modified dendrimers are considered to be promising gene carriers.

INTRODUCTION

Development of safe and efficient nonviral vectors is an important task in the field of gene therapy. Despite many efforts to develop nonviral vectors, their ability to transfect cells has yet to be improved (*1*, *2*). A variety of nonviral systems have been studied for this purpose. Cationic polymers offer some advantages such as a large diversity of molecular structures and freedom of molecular design (*3*, *4*). Cationic polymers can form stable complexes, so-called polyplexes, with DNA through electrostatic interactions. Positively charged polyplexes interact strongly with negatively charged cell membranes and are taken up by the cells through an endocytic pathway. However, many cationic polymers cannot achieve efficient transfection. A major cause is that, when internalized into the cell and taken up in the endosome, a large fraction of their complexes with DNA is delivered to the lysosome and is ultimately degraded there.

Nevertheless, several kinds of cationic polymers can mediate relatively efficient transfection of various animal cells. Poly(ethylenimine) (PEI) and poly(amidoamine) (PAMAM) dendrimers are among these polymers (*5*−*8*). These polymers possess many secondary and tertiary amino groups, which become protonated under weakly acidic conditions. These amino groups suppress the lowering of pH in endosomes and lysosomes by adsorbing protons and prohibiting their degradation in the lysosome. In addition, endosome buffering by these polymers is thought to induce osmotic swelling of the endosome interior, engendering rupture of the endosome and subsequent release of DNA into cytoplasm (*9*, *10*). Such a function of these secondary and tertiary amino groups of polymers is called the proton sponge effect (*6*).

PAMAM dendrimers are unique synthetic macromolecules with highly branched structure and globular shape (*11*, *12*). Molecular size of the dendrimers is increased stepwise via the repetition of a reaction sequence. Consequently, their size and structure are highly controllable and their molecular weight distribution is generally very narrow (*12*). Taking into account the high controllability of structure of the PAMAM dendrimers and their relatively high transfection activity, PAMAM dendrimers are highly attractive materials for the design of gene carriers. For that reason, many studies have been carried out to produce efficient gene carriers using PAMAM dendrimers as base materials (*13*). For example, Haensler and Szoka attempted to improve their transfection activity by conjugation of a pH-sensitive membrane-active peptide that destabilizes the endosomal membrane and promotes the escape of DNA into the cytosol (*5*). Arima and colleagues also prepared conjugates of PAMAM dendrimers with cyclodextrins, concluding that this conjugation greatly enhanced the transfection activity of PAMAM dendrimers (*14*, *15*). In addition, modification of PAMAM dendrimers with various molecules, such as a hydrophobic fluorescent dye (*16*) and poly(ethylene glycol) (*17*), demonstrably improves their efficiency for gene and oligonucleotide delivery.

Many studies have established that hydrophobic moieties affect transfection activity of cationic polymers (*18*−*22*). The hydrophobic nature of gene carriers will influence formation and stability of complexes between the

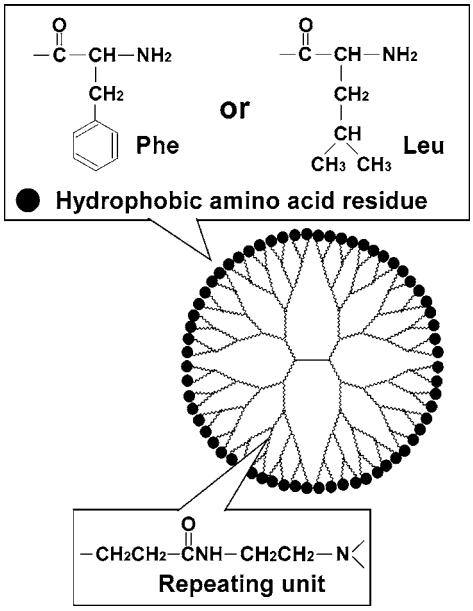

Figure 1. Structure of phenylalanine- or leucine-modified PAMAM G4 dendrimer.

carriers and DNA as it enhances interactions between the carriers and cells. In a previous study (*23*), we prepared PAMAM dendrons having two dodecyl groups. That study found that dendrons with hydrophobic moieties showed much higher transfection activity than PAMAM dendrimers of the same generation. That result suggests that introduction of an appropriate amount of hydrophobic moieties to the dendrimers can elevate their transfection efficiency.

In this study, we designed PAMAM G4 dendrimers having hydrophobic amino acid residues to produce efficient nonviral vectors that achieve cell transfection by synergistic actions of hydrophobic interactions and the proton sponge effect. We prepared PAMAM G4 dendrimers having phenylalanine or leucine residues at the dendrimer chain ends (Figure 1). Subsequently, we investigated their abilities to form a polyplex with plasmid DNA and to transfect CV1 cells, an African green monkey kidney cell line. The remarkable improvement of transfection activity of the PAMAM G4 dendrimer achieved by incorporation of phenylalanine is described.

EXPERIMENTAL PROCEDURES

General Methods. PAMAM (starbust) G4 dendrimer with an ethylenediamine core was purchased from Aldrich Chemical (Milwaukee, WI). *N*-(*tert*-Butoxycarbonyl)-L-phenylalanine (Boc-Phe) and *N*-(*tert*-butoxycarbonyl)-L-leucine (Boc-Leu) were obtained from Peptide Institute, Inc. (Osaka, Japan). 1, 3-Dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide were supplied from Tokyo Kasei Kogyo (Tokyo, Japan). Trifluoroacetic acid, triethylamine, 2-amino-2-hydroxymethyl-1,3-propanediol (Tris), and *N*,*N*-dimethylformamide (DMF) were from Kishida Chemical (Osaka, Japan). Dimethyl sulfoxide (DMSO) and ethidium bromide were from Wako Pure Chemical Industries (Osaka, Japan). Fetal calf serum (FCS) was from JRH Biosciences (Tokyo, Japan). Agarose was from Sigma (St. Louis, MO). Dulbecco's modified Eagle's medium (DMEM) was from Nissui Pharmaceutical (Tokyo, Japan). 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) was obtained from Dojin Laboratories (Kumamoto, Japan). Lipofectamine and SuperFect were purchased from Invitrogen (Carlsbad, CA) and Qiagen (Hilden, Germany), respectively. Plasmid DNA pCMV-Luc, which contains the cDNA of firefly luciferase driven by a human cytomegalovirus immediate-early promoter, was a gift from Dr. Kazuo Maruyama, Teikyo University.

Synthesis of Phenylalanine-Modified PAMAM G4 Dendrimers. The PAMAM dendrimers having varying numbers of phenylalanine residues at the chain terminals were prepared by the reaction of the amine-terminated PAMAM G4 dendrimers with varying amounts of Boc-Phe using *N*-hydroxysuccinimide and DCC and subsequent deprotection of Boc-Phe residues attached to the dendrimers using trifluoroacetic acid and thioanisole. A typical procedure was as follows: *N*-hydroxysuccinimide (44 mg, 0.380 mmol) and DCC (85 mg, 0.412 mmol) were added to Boc-Phe (84 mg, 0.317 mmol) dissolved in DMF (2 mL) and stirred for 7 h. Then, the PAMAM G4 dendrimer (46.9 mg, 3.30 nmol) and triethylamine (0.066 mL, 0.475 mmol) dissolved in DMSO (2 mL) were added to the solution and stirred for 7 days at room temperature. The obtained Boc-Phe-attached G4 dendrimer was purified with a Sephadex LH-20 column using methanol as the eluent. Boc groups of the dendrimer were removed by the treatment with trifluoroacetic acid (4 mL) and thioanisole (1 mL) at room temperature for 8 h. The dendrimer was purified by dialysis against distilled water and recovered by freeze-drying. Yield, 45.6 mg. Other Phe-modified dendrimers were prepared by the same procedure.

Synthesis of Leucine-Attached PAMAM G4 Dendrimer. *N*-Hydroxysuccinimide (102 mg, 0.883 mmol) and DCC (197 mg, 0.956 mmol) were added to Boc-Leu (170 mg, 0.735 mmol) dissolved in DMF (2 mL) and stirred for 3.5 h. Then, the PAMAM G4 dendrimer (108.9 mg, 7.66 nmol) and triethylamine (0.153 mL, 1.10 mmol) dissolved in DMSO (4 mL) were added to the solution and stirred for 8 days at room temperature. The obtained Boc-Leu-attached dendrimer was purified with a Sephadex LH-20 column using methanol as eluent. The deprotection of Boc-Leu-attached dendrimer and purification of the resultant dendrimer were carried out by the same procedure. Yield, 87.7 mg.

Agarose Gel Electrophoresis. The dendrimer−DNA polyplexes with varying N/P ratios were prepared by mixing plasmid DNA (1 μg) dissolved in 20 mM Tris-HCl buffer (5 μL) and the dendrimer dissolved in PBS (5 μL). After 10-min incubation at room temperature, the samples (10 μL) were electrophoresed on 0.6 wt % agarose gel in 40 mM Tris, 20 mM sodium acetate, and 2 mM EDTA buffer containing 1 μg/mL ethidium bromide at 100 V for 30 min. The ethidium bromide-stained bands were visualized and photographed using an Eagle Eye II Still Video System (Stratagene).

Transfection. For the preparation of dendrimer−plasmid DNA polyplexes, plasmid DNA (1 μg) dissolved in 20 mM Tris-HCl buffer (pH4.0−7.4, 50 μL) was mixed with the dendrimer dissolved in PBS of the same pH (0.2−5 g/l, 50 μL). The mixed solution was incubated for 10 min at room temperature to afford a polyplex with a given ratio of primary amino group of Phe-G4 to DNA phosphate (N/P ratio). The CV1 cells were seeded in 0.5 mL of DMEM supplemented with 10% FCS in 24-well culture plates at 5.0×10^4 cells per well the day before transfection. The cells were washed with PBS containing 0.36 mM $CaCl_2$ and 0.42 mM $MgCl_2$ [PBS(+)] and then covered with DMEM (1 mL). The polyplex containing plasmid DNA (1 μg) was added gently to the cells and incubated at 37 °C for 4 h. Then, the cells were rinsed with PBS(+), covered with DMEM containing 10% FCS,

and incubated at 37 °C. After 40 h, the cells were lysed by adding 50 μL of Luc-PGC-50 detergent (Toyo Ink, Tokyo, Japan). A 20 μL aliquot from each dish was used for one luciferase assay using a kit (Toyo Ink) and a Lumat LB9507 luminometer (Berthold, Bad Wildbad, Germany). The protein content of the lysate was measured by Coomassie Protein Assay Reagent (Pierce, IL) using bovine serum albumin as the standard. Transfection by Lipofectamine and Superfect was performed according to protocols recommended by the manufacturers.

Cytotoxicity. The cytotoxycity of complexes of the dendrimer, Lipofectamine, and Superfect with plasmid DNA was assessed by MTT assay (*24*). The cells were seeded in 1 mL of DMEM supplemented with 10% FCS in 12-well culture plates at 1.5×10^5 cells per well the day before transfection. The cells were washed with PBS (+) and then covered with DMEM (1 mL). The dendrimer−, Lipofectamine−, or SuperFect−DNA complex containing plasmid DNA (3μg) was added gently to the cells and incubated at 37 °C for 4 h. Then, the culture medium was carefully replaced with 0.5 mL of fresh DMEM containing 10% FCS, and 70 μL of MTT dissolved in PBS (5 mg/mL) was added to each well. After 4-h incubation at 37 °C, the medium was removed and the cells were solubilized in 500 μL of 2-propanol containing 0.1 M HCl. The number of viable cells was determined by absorbance at 570 nm. The cytotoxicity of the dendrimer, Lipofectamine, and Superfect without plasmid DNA was also measured by the same procedure.

RESULTS AND DISCUSSION

Design and Synthesis of Phenylalanine-Modified Dendrimers. The PAMAM dendrimers are currently considered to be extremely potent and promising nonviral vectors. These polymers can achieve efficient transfection of cells by the proton sponge effect, which induces suppression of gene degradation by lysosomal enzymes and promotes the transfer of DNA into the cytosol, resulting in transfection of the cells. This study prepared PAMAM dendrimers having hydrophobic amino acid residues because such dendrimers are expected to achieve an efficient transfection by a synergy of the proton sponge effect and hydrophobic interactions with cellular membranes.

We used phenylalanine for modification of PAMAM G4 dendrimers because this amino acid has a highly hydrophobic side group. We have already shown that amino acid molecules can be attached to terminal amino groups of the PAMAM dendrimers using condensing agent, DCC (*25*). Therefore, in this study, we combined phenylalanine with the dendrimer chain ends by the same method. Figure 2 depicts ^{1}H NMR spectra for the PAMAM G4 dendrimer (A), phenylalanine (B), and the dendrimer after reaction with 96 equiv of phenylalanine (C). Figure 2C shows that the spectrum of the dendrimer after the reaction exhibits signals corresponding to the PAMAM dendrimer and signals corresponding to phenylalanine, indicating that the amino acid residues are combined with the dendrimer. The number of phenylalanine residues attached to the dendrimer can be evaluated using the integral ratio of the signal at 2.2 ppm to 7−7.2 ppm. Table 1 lists the numbers of amino acid molecules added per dendrimer molecule for the reaction and the numbers of the amino acid residues combined to the dendrimer after the reaction. The number of phenylalanine residues combined to the dendrimer was controllable by adjusting the quantities of amino acids added for the condensation

reaction. When 96 equiv quantities of phenylalanine were reacted with the dendrimer, 64 phenylalanine residues were combined to the dendrimer, indicating that this Phe-modified dendrimer has a phenylalanine residue at every chain end. Consequently, we prepared four kinds of phenylalanine-modified dendrimers, (Phe)16-G4, (Phe)-29-G4, (Phe)46-G4, and (Phe)64-G4, which possessed 16, 29, 46, and 64 phenylalanine residues, respectively (Table 1).

Evaluation of Complex Formation with Plasmid DNA. The PAMAM dendrimers can form complexes efficiently with plasmid DNA through electrostatic interaction between the protonated primary amine of the dendrimer and negatively charged phosphodiester groups of DNA (*8*, *26*). Nevertheless, attachment of phenylalanine to the primary amine may affect the dendrimers' ability to form the complex with DNA. For that reason, we examined the influence of attachment of phenylalanine residues to the dendrimer on its ability of complex formation using agarose gel electrophoresis (Figure 3). In this experiment, the plasmid DNA was incubated with the dendrimer having varying numbers of phenylalanine residues for 10 min at pH 7.4, and electrophoresed on an agarose gel. Figure 3 shows that the free DNA band was not seen at the N/P ratio of 1 for the unmodified PAMAM dendrimer, indicating that all plasmid DNA molecules were associated with the dendrimer. However, for dendrimers having phenylalanine residues, the free DNA band can be observed at N/P ratios higher than 1. In addition, dendrimers having more phenylalanine residues needed a higher N/P ratio to complete their complex formation with DNA. For the fully phenylala-

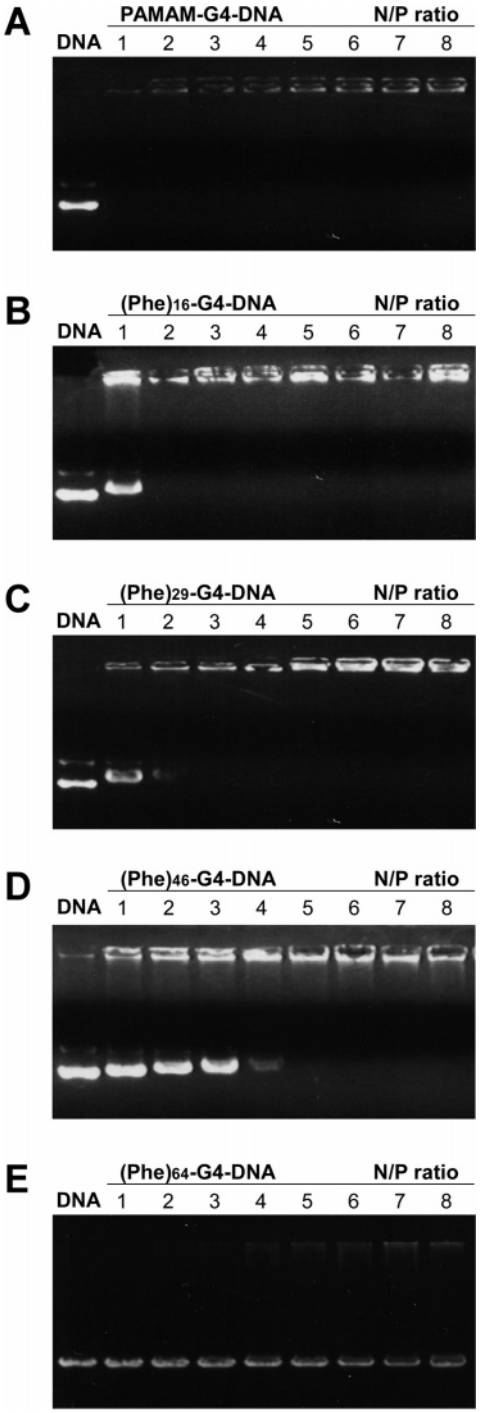

Figure 3. Agarose gel electrophoretic analysis for polyplex formation of PAMAM G4 dendrimers with varying numbers of phenylalanine residues: A, unmodified G4; B, (Phe)16-G4; C, (Phe)29-G4; D, (Phe)46-G4; E, (Phe)64-G4. Dendrimers and plasmid DNA were mixed at varying charge ratios and incubated for 10 min at room temperature. Then, the mixed solution was applied to the agarose gel and electrophoresed at 100 V for 30 min.

nine-substituted dendrimer, the free DNA band did not disappear, even at the N/P ratio of 8. These results emphasize that attachment of phenylalanine residues showed less ability to form a complex with DNA. Considering that protonation of the primary amino groups of the dendrimer occurs between pHs 7 and 10 (*27*) and the pK_a of α-amino group of phenylalanine is 9.1, these amino groups possess similar basicity. However, when combined to the dendrimer chain terminal, phenylalanine

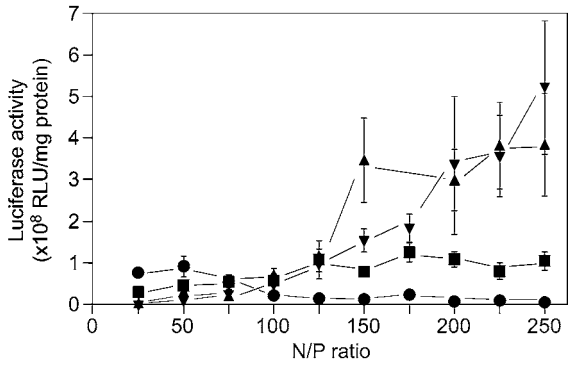

Figure 4. Luciferase activities of CV1 cells treated with polyplexes consisting of plasmid DNA and PAMAM G4 dendrimers with varying amounts of phenylalanine residues with varying N/P ratios: ■, unmodified G4; ●, (Phe)16-G4; ▲, (Phe)-29-G4; ▼, (Phe)46-G4 dendrimers. The cells (5×10^4) were treated with the polyplexes containing 1 μg DNA. Each point represents the mean ± SD ($n = 3$).

residues were able to form a hydrophobic environment in the periphery of the dendrimer, reducing protonation of their α-amino groups. Consequently, the phenylalanine-modified dendrimer showed smaller ability to form a complex with DNA.

Transfection Activity of Phenylalanine-Modified Dendrimers. Transfection activity of cationic polymer−DNA complexes varies depending on their composition. Therefore, we prepared dendrimer−DNA complexes at various N/P ratios and examined their transfection activity for CV1 cells. Figure 4 depicts luciferase activity of the cells treated with complexes consisting of plasmid DNA containing firefly luciferase gene and the dendrimers having varying numbers of phenylalanine residues. The (Phe)16-G4 dendrimer showed a similar or smaller transfection activity compared to the unmodified dendrimer. However, the dendrimer having 29 or 46 phenylalanine residues exhibited higher transfection activity. This result suggests that increased hydrophobicity enhances the transfection activity of the dendrimer. For that reason, it is expected that a fully phenylalanine-substituted dendrimer may exhibit the highest transfection activity among phenylalanine-modified dendrimers. Nevertheless, this dendrimer exhibited poor ability to form a complex with plasmid DNA, as mentioned above.

Transfection Activity of Phenylalanine-Modified Dendrimers at Acidic pH. Although the (Phe)64-G4 dendrimer hardly formed a complex with DNA at pH 7.4, it is possible that this dendrimer exhibits a higher ability to form the complex under acidic conditions because such conditions would enhance protonation of the amino groups contained in the (Phe)64-G4 dendrimer. Agarose gel electrophoresis was performed for mixtures of the dendrimer and DNA at various N/P ratios at pH 4−6 to examine the influence of pH on the ability of the dendrimer to form the complex. As shown in Figure 5, the N/P ratio at which the free DNA band disappears decreases with decreasing pH. This indicates that the ability of the dendrimer to perform complex formation increases with decreasing pH.

We next examined transfection activity of complexes prepared by mixing the (Phe)64-G4 dendrimer and plasmid DNA at varying N/P ratios at mildly acidic pHs. Figure 6A depicts luciferase expression of CV1 cells treated with these complexes. Transfection activity of these complexes was affected markedly by their composition. However, complexes with N/P ratios of 50−60 exhibited remarkably high transfection activity. We

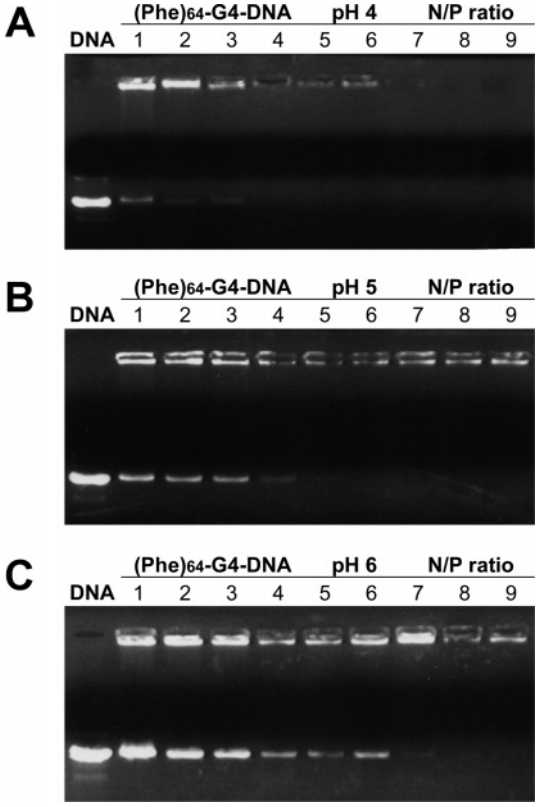

Figure 5. Agarose gel electrophoretic analysis for polyplex formation of (Phe)64-G4 dendrimer at pHs 4.0 (A), 5.0 (B), and 6.0 (C). The dendrimer and plasmid DNA were mixed at varying charge ratios and incubated for 10 min at room temperature. Then, the mixed solution was applied to the agarose gel and electrophoresed at 100 V for 30 min.

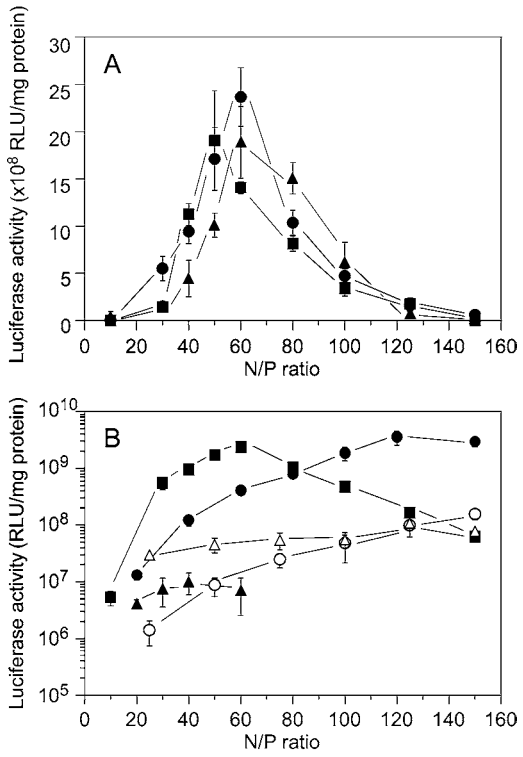

Figure 6. Influence of preparation pH on transfection activity of polyplex. (A) Luciferase activities of CV1 cells treated with (Phe)64-G4 polyplex with varying N/P ratios prepared at pHs 4.0 (■), 5.0 (●), and 6.0 (▲). (B) Luciferase activities of CV1 cells treated with (Phe)64-G4 (squares), (Phe)46-G4 (circles), and unmodified G4 (triangles) dendrimer polyplexes prepared at pHs 7.4 (open symbols) and 5.0 (closed symbols). The cells (5×10^4) were treated with the polyplex containing 1 μg DNA. Each point represents the mean ± SD ($n = 3$).

compared the (Phe)46-G4 dendrimer−DNA complex with the N/P ratio of 250 prepared at pH 7.4, which shows the highest activity among the polyplexes prepared at pH 7.4 (Figure 4), and the (Phe)64-G4 dendrimer−DNA polyplexes with the N/P ratio of 60 prepared at pH 5.0. The latter exhibited five times higher expression of luciferase gene, although the amount of the dendrimer contained in the latter polyplex was about one-fourth of that contained in the former polyplex. In addition, compared with the polyplex of the unmodified dendrimer, the (Phe)64-G4 dendrimer−polyplex exhibited about 30 times higher activity.

We further examined cell transfection by the polyplexes of (Phe)46-G4 or unmodified G4 dendrimer prepared at pH 5.0 and compared the result with that of the (Phe)64-G4 dendrimer-containing polyplex (Figure 6B). Thereby, we determined the influence of the pH of polyplex formation on transfection activity. The polyplex of the unmodified dendrimer showed decreased activity when prepared at pH 5.0. Because the charge density of the dendrimer is very high, DNA molecules might be bound very tightly to the dendrimer, resulting in the reduced transfection activity. However, regarding the (Phe)46-G4 dendrimer-containing polyplex, when prepared at pH 5.0, its activity increased 1 order of magnitude over that of the polyplex prepared at pH 7.4. A mildly acidic condition appears to moderately increase protonation of amino groups with reduced basicity in the dendrimer periphery; the resultant polyplex might show high transfection activity because of its hydrophobic nature and proton sponge effect. In comparison with the (Phe)64-G4−dendrimer polyplex, the (Phe)46-G4−dendrimer polyplex required a much higher N/P ratio. Consequently, that polyplex required a much higher amount of the dendrimer to achieve maximum activity, even though these polyplexes with the optimized compositions show approximately the same transfection activity.

Comparison between Phe-Modified and Leu-Modified Dendrimers. We first examined the effect of the attachment of L-phenylalanine on transfection activity of the PAMAM dendrimer. Next, L-leucine was used to modify the dendrimer as another hydrophobic amino acid. An excess of leucine was reacted with the PAMAM G4 dendrimer using DCC. The resultant dendrimer contained 63 leucine residues per dendrimer, as evaluated by ^{1}H NMR (Table 1). The ability of the (Leu)63-G4 dendrimer to form polyplexes was examined using agarose gel electrophoresis. The plasmid DNA was incubated with the leucine-modified dendrimer for 10 min at pH 7.4; then it was electrophoresed on an agarose gel. In contrast to the case of the (Phe)64-G4 dendrimer, no free DNA band was observed even at the N/P ratio of 1, indicating that the (Leu)63-G4 dendrimer has a much higher ability to form a polyplex with DNA (results not shown).

We examined the effect of attachment of leucine residues on transfection activity of the PAMAM dendrimer. CV1 cells were treated with the (Leu)63-G4 dendrimer polyplexes prepared at pH 7.4 and pH 5.0. Expression of luciferase in the treated cells was estimated, and the results were compared with the case of (Phe)64-G4 dendrimer polyplexes. We expected that incorporation of leucine residues to the chain ends of the dendrimer would elevate its transfection activity. How-

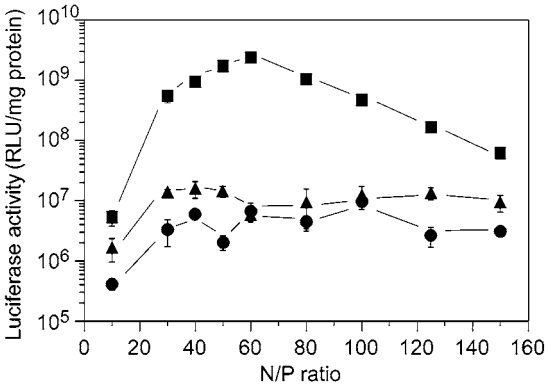

Figure 7. Comparison of transfection activity of luecine- and phenylalanine-modified dendrimers. Luciferase activities of CV1 cells treated with (Phe)64-G4 polyplex prepared at pH 5.0 (■) and (Leu)63-G4 polyplexes prepared at pHs 7.4 (▲) and 5.0 (●) containing 1 μg DNA with varying N/P ratios were shown in the figure. Each bar represents the mean ± SD (n = 3).

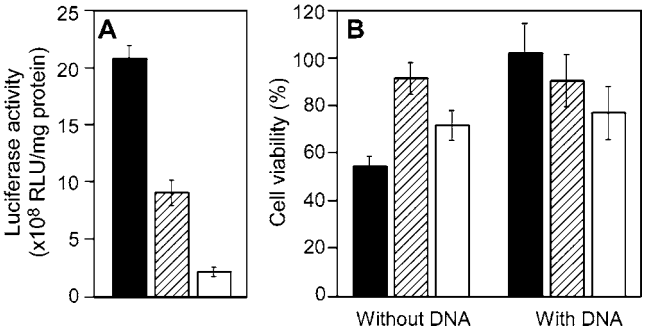

Figure 8. Comparison of transfection activity and cytotoxicity of (Phe)64-G4 dendrimer with widely used vectors. (A) Luciferase activities of CV1 cells treated with complexes of (Phe)-64-G4 dendrimers (closed bars), Lipofectamine (hatched bars), and SuperFect (open bars) containing 1 μg of DNA. Each bar represents the mean ± SD (n = 4). (B) Viability of CV1 cells treated with (Phe)64-G4 dendrimers (closed bars), Lipofectamine (hatched bars), and SuperFect (open bars) with or without plasmid DNA. Viability was expressed as the percentage of the untreated control cells. Each bar represents the mean ± SD (n = 3). The (Phe)64-G4 dendrimer polyplex with N/P ratio of 60 prepared at pH 5.0 was used.

ever, as shown in Figure 7, leucine residues did not increase its transfection activity at either pH compared with the unmodified dendrimer. Consequently, the (Leu)-63-G4 dendrimer−polyplexes exhibited a significantly lower activity than the (Phe)64-G4 dendrimer polyplexes.

As mentioned previously, we designed phenylalanine-modified and leucine-modified PAMAM dendrimers because we expected that these dendrimers express high transfection activity by synergistic actions of the proton sponge effect and hydrophobic interactions with cells. In fact, the attachment of phenylalanine increased the transfection activity of the parent dendrimer by about 2 orders of magnitude over that of the parent dendrimer (Figure 6). In contrast, the attachment of leucine showed no remarkable enhancement of dendrimer activity even though this amino acid is also hydrophobic. As a measure of hydrophobicity of the amino acid, Nozaki and Tanford used differences in free energy between a hydrophobic moiety of an amino acid in ethanol (or dioxane) and in water and showed that the free energies of transfer for phenylalanine and for leucine are 2500 and 1800 cal/mol, respectively (*28*), indicating that phenylalanine is more hydrophobic. We observed that (Phe)64-G4 dendrimer showed poor water solubility at pH 7.4, whereas (Leu)-63-G4 dendrimer was soluble in water at the same pH, although both dendrimers have essentially the same number of amino acid residues. This fact implies that the attachment of phenylalanine to the dendrimer lent a highly hydrophobic character to the dendrimer periphery. In fact, Meijer and co-workers reported that phenylalanine residues, when combined to the chain ends of poly(propylenimine) dendrimers, form a densely packed shell on the dendrimer surface (*29*, *30*). Therefore, the highly hydrophobic surface of densely packed phenylalanine residues of the dendrimer might enhance interaction of the dendrimer−DNA polyplexes and cellular membranes, engendering efficient transfection.

Recently, Shibata et al. reported that a random copolymer of L-lysine and L-phenylalanine translocates phospholipid membranes much faster than a poly(L-lysine) (*31*). This rapidity is probably attributable to the random incorporation of hydrophobic phenylalanine residues into the positively charged poly(lysine) chain. Those residues lowered the potential barrier in the hydrophobic region of the lipid membrane for the polypeptide translocation (*31*). Considering that observation, it is possible that the hydrophobic shell of phenylalanine on the dendrimer surface interacts strongly with the hydrophobic region of the cellular membranes and causes their destabilization, thereby enhancing translocation of the gene through the membrane.

Transfection Activity of Phe-modified Dendrimers and Some Vectors. We compared the respective activities of Lipofectamine and SuperFect, both of which are widely used and commercially available vectors, to evaluate the potential of phenylalanine-modified dendrimers as a gene carrier. We treated CV1 cells with (Phe)64-G4 dendrimer−DNA polyplex, Lipofectamine−DNA complex, and SuperFect−DNA complex; then we evaluated the cells' expression of luciferase. Figure 8A shows that the (Phe)64-G4 dendrimer polyplex induced about 2.3-fold higher and about 10-fold higher expression of luciferase, respectively, than Lipofectamine and SuperFect complexes that contained identical amounts of plasmid DNA.

The potential use of the phenylalanine-modified dendrimer as a gene carrier was also estimated from the viewpoint of cytotoxicity. Figure 8B depicts the viability of the cells treated with the (Phe)64-G4 dendrimer, Lipofectamine, and SuperFect, and their complexes with the plasmid DNA. The (Phe)64-G4 dendrimer itself was shown to be relatively toxic compared to these commercially available reagents. It is likely that the phenylalanine-modified dendrimer interacts strongly with the cell membranes and damages the cells because of the hydrophobic nature of the phenylalanine. However, in the form of the complex with DNA, the toxicity of the phenylalanine-modified dendrimer decreased remarkably. This decrease is attributable to the weakening of their strong interaction with cellular membranes by complexation with the hydrated DNA molecule. These results indicate that the phenylalanine-modified dendrimer can be considered as an efficient vector.

CONCLUSION

In this study, we prepared PAMAM G4 dendrimers having hydrophobic amino acid residues, which achieve an efficient transfection of cells through synergy of the proton sponge effect induced by the dendrimer tertiary amines and hydrophobic interaction by the amino acid residues. Transfection activity was not improved when leucine was attached to the dendrimer. However, the attachment of phenylalanine greatly increased the trans-

fection activity of the parent dendrimer. Activity of the fully phenylalanine-substituted dendrimer was shown to be higher than for some widely used vectors. Transfection activity of the PAMAM dendrimers is known to increase with generation (*5*, *8*). Therefore, the phenylalanine-modified dendrimers with higher generations may exhibit still higher activity than the present dendrimers. For this reason, the findings obtained in this study will engender the development of efficient gene carriers. We are currently studying the effect of dendrimer generation on transfection activity of phenylalanine-modified dendrimers.

A New Highly Efficient Photoreactive Analogue of dCTP. Synthesis, Characterization, and Application in Photoaffinity Modification of DNA Binding Proteins

Sergey V. Dezhurov,† Svetlana N. Khodyreva,† Ekaterina S. Plekhanova, and Olga I. Lavrik*

Institute of Chemical Biology and Fundamental Medicine, Siberian Division, Russian Academy of Sciences, Prospect Lavrentieva 8, Novosibirsk, 630090 Russia. Received September 7, 2004; Revised Manuscript Received November 30, 2004

A new base-substituted analogue of dCTP, *exo-N*-{2-[*N*-(4-azido-2,5-difluoro-3-chloropyridine-6-yl)-3-aminopropionyl]aminoethyl}-2′-deoxycytidine-5′-triphosphate (FAP-dCTP) has been synthesized and characterized. FAP-dCTP is an efficient substrate of mammalian DNA polymerase β in the reaction of primer elongation displaying substrate properties as an analogue of dCTP and dTTP. FAP-dCTP was used for the photoaffinity modification of mammalian DNA polymerase β. Two approaches to photoaffinity labeling were utilized. In one approach, photoreactive FAP-dCTP was first incorporated into radiolabeled primer−template, and photoreactive DNA was UV-irradiated in the presence of DNA polymerase β, which resulted in the polymerase labeling by photoreactive primer. In an alternate approach, FAP-dCTP was first UV-cross-linked to the enzyme; subsequently, radiolabeled primer−template was added, and the enzyme-linked FAP-dCTP was incorporated into the 3′-end of radioactive primer. This "catalytic" modification pathway was shown to be less specific in recognition of FAP-dCTP as an analogue of dCTP than dTTP. FAP-dCTP was used as substrate of endogenous DNA polymerases of HeLa cell extract to synthesize photoreactive DNAs for photoaffinity modification of cell proteins. UV irradiation results in modification of DNA binding proteins of cell extract. The level of photoaffinity labeling of protein targets in the cell extract was strongly dependent on the efficiency of synthesis of photoreactive DNA.

INTRODUCTION

The photoaffinity labeling technique in the study of DNA replication/repair machineries is based on UV-light-induced cross-linking of photoreactive DNA to proteins. The most easy-to-use way to synthesize photoreactive probes is the in situ introduction of photoreactive dNMP moieties into the 3′ end of a DNA primer via the activity of DNA polymerases with photoreactive dNTP analogues used as substrates. A wide range of base-substituted dNTP analogues containing photoreactive groups of different photoreactivity and spacers of various lengths have been synthesized and characterized (*1*−*3*). Photoreactive dNTP analogues have been shown to be effective substrates of viral, bacterial, and eukaryotic DNA polymerases. These analogues were widely applied in study of proteins belonging to DNA replication/repair machineries in the systems reconstituted from purified proteins (*4*−*6*) and in cell extracts (*7*, *8*). Photoreactive dNMP moieties varied substantially in their ability to form covalent cross-links with target protein depending on the type of photoreactive group used. The efficiency of covalent adduct formation may become a parameter restricting applicability of the method when applied in cell extracts for identification of unknown proteins because their concentrations are limited. Another factor that should be considered when photoreactive probes are synthesized in cell extracts via activity of the endogenous DNA polymerases is catalytic efficiency of dNTP derivatives since the concentrations of DNA polymerases are limited, which may restrict the yield of photoreactive DNA. It should be noticed that photoreactive dNTP analogues displayed different kinetic parameters in the primer elongation catalyzed by Pol β[1] (*9*). In our previous studies, we clearly recognized the factors that influence the efficiency of protein cross-linking. The most significant factors are the nature of photoreactive group and its position at the heterocyclic base. For example, among dUTP derivatives bearing substituents at the 5th position of the uridine ring, the most efficient in protein cross-linking was shown to be DNA containing FAP-dUMP moieties (*10*). As far as dCTP derivatives, the most efficient in protein cross-linking were FABO- and FABC-containing photoreactive DNA when these analogues were introduced opposite to an adenine of the template (*11*). As has been previously shown, dCTP derivatives

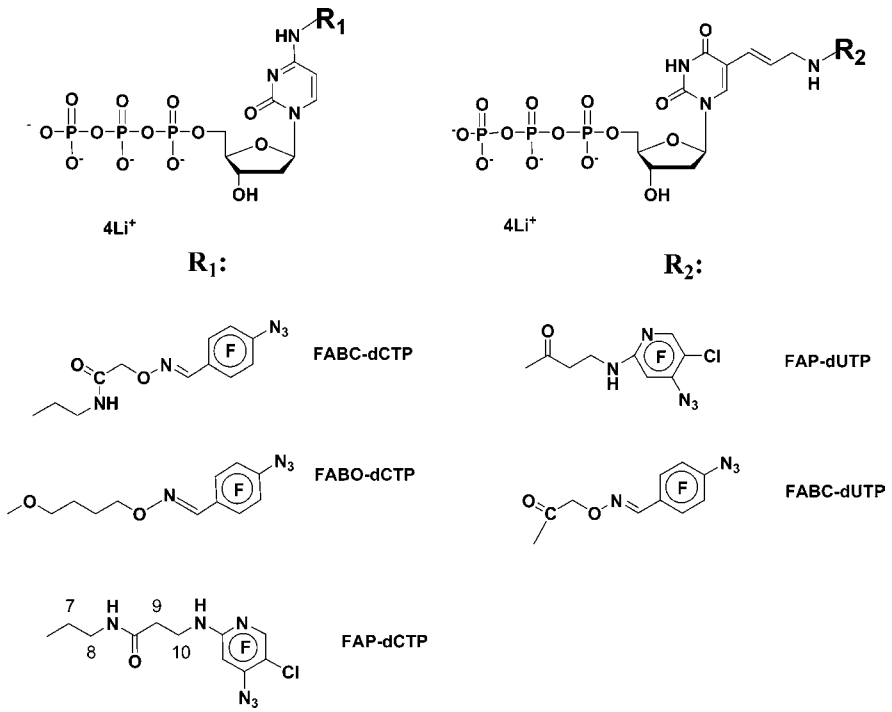

Figure 1. Structures of photoreactive analogues of dNTP.

were recognized by DNA polymerases as dTTP due to the shift of tautomeric equilibrium from the amino to the imino form cased by introduction of the photoreactive group (*9*). A characteristic feature of FABO- and FABC-dCTP derivatives is an electron-deficient atom of nitrogen, which is involved in π-system of the arylazido group (Figure 1).

Comparison of the efficiencies of photoreagent cross-linking to Pol β when DNA probes contain the same FABC group attached to either the 4th or 5th positions of the pyrimidine ring (moieties of FABC-dCMP and FABC-dUMP, respectively) clearly demonstrated that the former was more effective (*11*).

FAB-dCTP used to study the interactions of base excision repair proteins in mouse embryonic fibroblast extract with DNA intermediates synthesized in situ by endogenous DNA polymerases was efficiently incorporated in the primer (*12*). This analogue displayed rather good parameters in primer elongation catalyzed by Pol β but provided a low level of enzyme modification being incorporated in the primer chain. The main target for cross-linking of the photoreactive dCMP-containing primer was shown to be the complementary template chain (*9*). The corresponding efficiencies of the photoreactive primer cross-linking to Pol β and the template were 2% and 84%, respectively.

Thus, taking together all these data prompted us to synthesize a dCTP analogue substituted at the 4th position with a FAP group, which provided rather effective modification of Pol β as a part of a FAP-dUMP containing primer. We expected the new analogue to combine good substrate properties in DNA synthesis with effective cross-linking to proteins when introduced into DNA that would make it suitable for photoaffinity modification both in reconstituted systems and in cellular extracts. We tested FAP-dCTP as a substrate in the primer elongation catalyzed by Pol β and endogenous DNA polymerases of HeLa cell extract. Photoreactive DNA with FAP-dCMP moieties synthesized in situ was used for photoaffinity modification of Pol β and DNA binding proteins in the cell extract.

EXPERIMENTAL PROCEDURES

Materials. Ethylenediaminetetraacetic acid (EDTA), dCTP, glycine, Tris, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED), and Coomassie G-250 were from Sigma (St. Louis, MO); $MgCl_2$ and formamide were from Fluka (Buchs, Switzerland); β-mercaptoethanol was from Serva (Heidelberg, Germany); acrylamide, *N*,*N*′-methylenebisacrylamide, and urea were from ICN (Aurora, OH); γ-[^{32}P]ATP (>110 TBq/mmol) and T4 polynucleotide kinase were from Biosan (Novosibirsk, Russia). The ^{1}H, ^{19}F, and ^{31}P NMR spectra were recorded with a Bruker AM-400 spectrometer. UV spectra were recorded with UV 2100 Shimadzu (Kyoto, Japan).

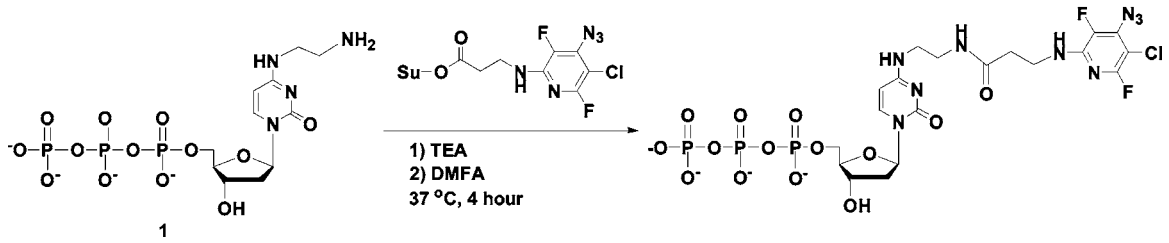
Oligonucleotides 5′-GGAAGACCCTGACGTT**G**CCCA-ACTTAATCGCC-3′ (36-mer template I), 5′-GGAAGAC-CCTGACGTT**A**CCCAACTTAATCGCC-3′ (36-mer template II), and 5′-GGCGATTAAGTTGGG-3′ (15-mer primer) Sibenzyme (Novosibirsk, Russia) were used for synthesis of photoreactive DNA. The primers were the 5′-end-labeled with [^{32}P] using T4 polynucleotide kinase and γ-[^{32}P]ATP (*13*) and then purified by denaturing PAGE in 7 M urea (*14*). The radioactive primer was mixed with the template at 1:1.5 molar ratio, and the DNA duplexes were formed by heating to 90 °C and slowly cooling to room temperature.

Recombinant rat DNA polymerase β (EC 2.7.7.7) was purified as described (*15*). Plasmid pRSET containing the cDNA of rat DNA polymerase β was the kind gift of Dr. S. H. Wilson (National Institute of Environmental Health Sciences, USA). HeLa cells were kindly provided by Dr. M. A. Zenkova (Institute of Chemical Biology and Fundamental Medicine, Novosibirsk). The whole cell extract was prepared as described (*16*).

FABO-dCTP and FABC-dCTP synthesized as described (*1*) were a generous gift of Dr. I. V. Safronov (Institute of Chemical Biology and Fundamental Medicine, Novosibirsk).

Synthesis and Characterization of FAP-dCTP. Synthesis of *exo*-*N*-{2-[*N*-(4-azido-2,5-difluoro-3-chloropyridine-6-yl)-3-aminopropionyl]aminoethyl}-2′-deoxyciti-

Scheme 1. Synthesis of FAP-dCTP



1

dine-5′-triphosphate (lithium salt) was carried out according to the standard method of the introduction of photoreactive groups (*1*). *N*-(4-Azido-2,5-difluoro-3-chloropyridine-6-yl)-3-aminopropionic acid *N*-hydroxysuccinimidyl ester (0.5 mmol) dissolved in DMFA (1 M, 500 μL) was mixed with 114 μmol (16 μL) of triethylamine and 0.4 mmol of triphosphate **1** (Scheme 1) dissolved in 2 mL of DMFA. When the reaction was completed (2 h, 37 °C), 50 mL of a 2% solution of $LiClO_4$ in acetone was added to the reaction mixture. The resulting precipitate was separated by centrifugation and washed with acetone and Et_2O. FAP-dCTP was purified by large scale HPLC using chromatographic complex Waters and column Lichroprep RP-18 (5−20 μm). Solvent was removed under reduced pressure; the residue was precipitated with a 2% solution of $LiClO_4$ in acetone and washed with Et_2O (61 mg, 20%). The purity of the analogue was 95% as estimated by analytical HPLC. The product was homogeneous according to TLC with $R_f = 0.21$ (dioxane−ammonia−water, 6:4:0.3); UV (H_2O) $\lambda_{max} = 237$ ($\epsilon = 26\,000$), $\lambda_{max} = 322$ ($\epsilon = 4000$), $\lambda_{min} = 280$ ($\epsilon = 1450$); NMR spectra (D_2O), ^{31}P (δ, ppm) −5.95 (d, $J = 20$ Hz, P_γ, 1P,), −10.21 (d, $J = 20$ Hz, P_α, 1P), −20.31 (t, $J = 20$ Hz, P_β, 1P), ^1H (δ, ppm) 2.2−2.4 (d, bs, H2′, 2H), 2.4−2.6 (t, bs, H9, 2H), 3.3−3.7 (m, H7, H8, H10, 6H), 4.1−4.3 (m, bs, H4′, H5′, 3H), 4.5 (s, H3′, 1H), 6.1 (d, H5, 1H), 6.4 (d, H1′, 1H), 7.9 (d, H6, 1H), ^{19}F (δ, ppm) 7.9 (d, $J = 23$ Hz, F5, 1F), 86.7 (d, $J = 23$ Hz, F2, 1F).

Mass Spectrometry. The mass spectra were recorded by MALDI-TOF mass spectrometer REFLEX III (Bruker Daltonics, Bremen, Germany), equipped with a single stage reflector giving an effective 3.0 m flight path and using the instrument's standard 337 nm nitrogen laser and microchannel plate detector. Range of operational parameters was 20 kV acceleration voltage, 0 ns extraction delay, and 90% grid voltage. Generally the extraction delay and grid voltage were set to optimize resolving power. Spectra were obtained as averages of 60 laser shots, and the laser energy was generally set 25% above the ionization threshold. The matrix was 3-hydroxypicolinic acid. Saturated solution of matrix (50 mg/mL) was prepared in 1:1 acetonitrile/water containing 1% diammonium hydrogen citrate.

Substrate Properties of FAP-dCTP. DNA synthesis catalyzed by Pol β was carried out in buffer containing 50 mM Tris-HCl (pH 8.8), 50 mM KCl, and 10 mM $MgCl_2$. In addition, the reaction mixture contained 1.5 μM template, 1 μM 5′-[^{32}P]-primer, and FAP-dCTP in variable concentrations (10−300 μM). The reaction was started by the enzyme addition to the final concentration of 20 or 2000 nM depending on the primer−template system and performed at 37 °C. Aliquots of 10 μL were taken out of the 200 μL reaction mixture at different time intervals (0.167−15 min) and quenched by the addition of loading buffer containing 80% formamide and 50 mM EDTA. After being heated (5 min, 90 °C), the samples were analyzed by electrophoresis in 20% PAG under denaturing conditions (*14*). Distribution of radioactivity in the gel was quantified using Molecular Imager (Bio-Rad, USA) and software "Quantity One". For each of the reaction mixtures, the efficiency of the primer elongation was determined. The data obtained were used for calculation of the K_m and k_{cat} values using the software Origin 6.0 (Microcal Software Inc., USA).

Determination of the Modification Rate Constant (k) and the Time of Half-Modification ($\tau_{1/2}$) of Pol β by Photoreactive Primers. The reaction mixtures for DNA synthesis (200 μL) contained standard components described above, but the concentration of Pol β and FAP-dCTP were 3 and 10 μM, respectively. The reaction mixtures were incubated for 30 min at 37 °C to introduce a photoreactive FAP-dCMP moiety into the 3′-end of the primer by the activity of Pol β. After primer elongation, the reaction mixtures were placed in water bath (25 °C). Photolysis was induced by UV light using a DRK-120 VIO-1 UV lamp ('LOMO', Saint Petersburg, Russia) supplemented with glass filter UFS-6 ($\lambda = 313-365$ nm) at a distance of 110 mm. During the irradiation, 15 μL aliquots were taken at definite time intervals (1−30 min). The reactions were stopped by adding the Laemmli loading buffer and heating at 90 °C for 5 min. The covalent adducts of Pol β with the [5′-^{32}P] DNA primer were separated from the free DNA primer and the products of template modification by 12% PAGE as described (*17*). Distribution of radioactivity in the gel was quantified as described above. The rate constants of modification (k) were calculated from the time dependence of the amount of modification products, assuming that the modification reaction is of the first order. The half-time of modification was calculated by the formula $\tau_{1/2} = (\ln 2)/k$, which corresponds to the formation of the half of the maximum amount of adducts under these conditions.

Determination of the Efficiency of Modification of Pol β (W_R). Pol β was cross-linked to photoreactive DNA as described in the previous sections by irradiation for the time $t \gg \tau_{1/2}$ (15 min). The covalent adducts of the [5′-^{32}P] DNA primer with DNA polymerase were separated from the other components of the reaction mixture by 12% PAGE (*17*). Distribution of radioactivity in the gel was quantified as describe above. The efficiency of modification was calculated from the equations $W_R = W_r/x$, $W_r = 100\%[A_1/(A_1 + A_2)]$ where A_1 is the amount of the primer covalently linked to Pol β, A_2 is the amount of the unbound radioactive DNA primer, and x is the part of extended primer. The A_1 and A_2 values were determined by counting the corresponding areas of the gel.

Determination of the Efficiency of DNA Template Modification. The modification of DNA template, which occurred along with the modification of Pol β, was determined quantitatively after the separation of the products by 20% PAGE under denaturing conditions (*14*). Distribution of radioactivity in the gel was quantified as describe above. The modification efficiency was calculated as the ratio of the template modification products to the total amount of the reactive [5′-^{32}P] DNA primer.

Catalytic Modification of Pol *β*. Modification of Pol β by the catalytic pathway was realized via initial UV irradiation of the enzyme in the presence of FAP-dCTP for the time $t \gg \tau_{1/2}$ followed by addition of primer−template and further incubation for 30 min at 37 °C. Concentrations of components were the same as for direct modification described in previous section.

Photoaffinity Modification of DNA Binding Proteins in Cellular Extract. Photoreactive dCMP moieties were incorporated in the primer by endogenous DNA polymerases of cell extract. The reaction mixtures (15 μL) contained standard components described above, but DNA duplex was 0.1 μM. One of the photoreactive dCTP analogues was added to the final concentration of 30 μM. The reaction mixtures contained 33 μg of total HeLa cell proteins. The reaction of incorporation of photoreactive dCMP residue was started by addition of cellular extract and allowed to proceed for 15 min at 37 °C. Two microliter aliquots were taken after completing DNA synthesis to analyze the efficiency of primer elongation. The rest of the reaction mixtures were placed on ice and irradiated for 15 min as described above. The efficiencies of primer elongation and cross-linking to proteins were quantified as described above.

RESULTS AND DISCUSSION

Characterization of FAP-dCTP. FAP-dCTP (Figure 1) was synthesized according to the standard method of the introduction of photoreactive groups (*1*) as shown in Scheme 1. FAP-dCTP was purified by large scale HPLC. The purity of the analogue was 95% as estimated by analytical HPLC. Data of NMR and UV spectroscopy confirmed the structure of the obtained compound.

Characterization of photoreactive derivatives of nucleoside triphosphates by MALDI-MS is poorly represented in the literature. We have found a single example, where the authors have determined MALDI-TOF spectra to characterize N_3dATP and a few nonnucleoside aryl azide derivatives (*18*). In the negative ion MALDI spectra of these ATP analogues, "fingerprint" peaks corresponding to [M − 10 − 1], [M − 12 − 1], [M − 16 − 1], [M −26 − 1], [M −28 − 1], [M − 41 − 1], and [M − 42 − 1] were observed. The model of a fragmentation of cited photoreactive compounds induced by ultraviolet laser has been suggested. It seems clear that [M − 28 − 1] corresponds to the nitrene and its isomers and [M − 42 − 1] indicates that it is possible for the azide to lose N_2 and N to form a free radical, for example. The MALDI-MS analysis for FAP-dCTP revealed analogous products [M − 1], [M − 41 − 1], and [M − 42 − 1], but the main peaks [M − 1], [M − 26 − 1], and [M − 28 − 1] were shifted (+7) in *m/z* values; these products represent the adducts containing Li^+ ions (Figure 2).

Substrate Properties. Substrate properties of FAP-dCTP in reaction of DNA primer elongation catalyzed by Pol β was characterized for two DNA duplexes, in which FAP-dCTP is incorporated either as a dCTP (PT1) or a dTTP analogue (PT2). Under conditions used, a single FAP-dCMP moiety was incorporated on both PT1 and PT2.

Data on kinetic parameters of primer elongation are listed in Table 1. It should be emphasized that on PT2 when FAP-dCTP was used as a dTTP analogue the efficiency of incorporation was substantially lower in comparison with PT1. In the former case, the concentration of Pol β in the reaction mixture was enhanced about 1000 times to register incorporation of the analogue. Since the concentrations of Pol β and template−primer

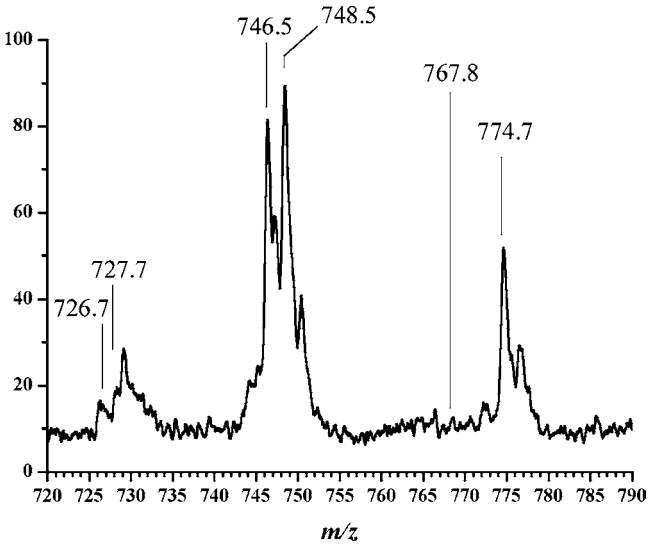


Figure 2. MALDI-TOF analysis of FAP-dCTP: peaks [M − 1], [M − 1 − 41], and [M − 1 − 42] (corresponding *m/z* values are 767.8, 727.7, and 726.7) and peaks of Li^+-containing adducts [M − 1 + Li], [M − 1 − 26 + Li], and [M − 1 − 28 + Li] (corresponding *m/z* values are 774.7, 748.5, and 746.5).

Table 1. Kinetic Parameters of Primer Elongation Catalyzed by DNA Polymerase *β*

case	k_{cat}, s^{-1}	$K_m \times 10^5$, M

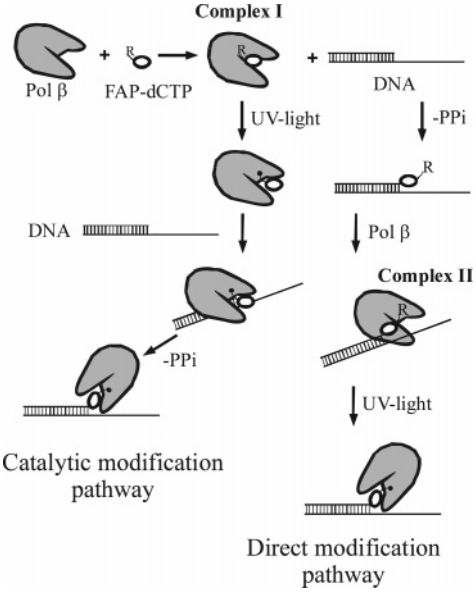
as analogue of dTTP (PT2)	0.005 ± 0.0005	3 ± 1.5

in this case were comparable, that is, the Michaelis−Menten approximation does not hold, the kinetic parameters of FAP-dCTP incorporation as an analogue of dTTP should be regarded only as a crude estimate.

K_m values for FAP-dCTP are rather close on both template−primer duplexes and differ insignificantly from K_m values for dCTP and dTTP, which were determined in refs *9* and *11*, respectively. K_m values for FABO-dCTP and FABC-dCTP were 10-fold higher than that of dCTP (*9*). When these analogues were used as dTTP, a 10-fold increase in K_m values in comparison with that for dTTP was also detected (*11*). Unlike dCTP derivatives bearing FABO or FABC groups, FAP-dCTP appears not to face steric hindrance in the interactions with the enzyme binding site. k_{cat} values for FAP-dCTP differ 65-fold depending on the template−primer duplex. When FAP-dCTP replaced dCTP, the k_{cat} value was in close agreement with that of dCTP (*9*). Thus, FAP-dCTP displays the best substrate properties among all photoreactive dCTP derivatives synthesized by us until now. When FAP-dCTP was used as dTTP the k_{cat} value was substantially lowered. DNA polymerase β appears to recognize FAP-dCTP in this case as an incorrect dNTP. Such a behavior conforms to the mechanism that is responsible for Pol β fidelity. DNA polymerase β provides dNTP selection mainly at the step of phosphodiester bond formation, but this enzyme can also discriminate between the correct and incorrect dNTP during stage of nucleotide binding (*19*).

Photoaffinity Modification of Pol *β*. We characterized all previously synthesized photoreactive dNTP analogues in their ability to cross-link Pol β when they were incorporated at the 3′ end of primers (*9, 10, 11*). To study the efficiency of FAP-dCMP-containing DNA as a photoreagent for protein modification, we used the same approach. We studied kinetics of the covalent attachment of photoreactive primer to Pol β. FAP-dCMP moieties were introduced in situ by Pol β using both template−

Scheme 2. Catalytic and Direct Pathways of Photoaffinity Modification of Pol β



primer duplexes PT1 and PT2. Molar ratio of template−primer duplex to Pol β and their concentrations provided practically complete binding of DNA duplex by Pol β. Under these conditions, the unproductive photolysis of photoreactive DNA in solution, which does not lead to formation of covalent adducts with Pol β, is minimized.

When FAP-dCTP was used as dCTP analogue, that is, on PT1, the efficiency of primer elongation prior to UV-irradiation was more than 90%. The kinetics of formation of covalent adducts of photoreactive primer with Pol β and the template strand fitted the exponential equation of the first order as was the case with other photoreactive dNTP derivatives (*10, 11*). We have estimated the rate constant of formation of covalent adducts and half-time of Pol β modification. The obtained values were shown to be similar to those for photoreactive primers with FAP-dUMP moiety bearing the same photoreactive group (*10*).

When FAP-dCTP was used as dTTP, that is, on PT2, the yield of cross-linking of photoreactive primer to Pol β was abnormal. The level of cross-linking (W_r) was 43% and exceeded the extent of conversion of the initial primer to the photoreactive form, which was less than 25%. This fact prompted us to propose that the additional amount of the covalent adducts of Pol β with the photoreactive primer was formed by an unusual pathway. The conventional pathway proceeds via prior incorporation of photoreactive dNMP moiety into the 3′ end of the primer followed by UV-light-induced cross-linking of photoreactive DNA to the protein. But, in the last unusual case, the process appears to proceed via the following steps (Scheme 2): first, cross-linking of photoreactive dCTP analogue to dNTP binding site of Pol β and, second, rather fast transfer of dNMP moiety onto the 3′ end of the primer from the dCTP analogue, which is covalently attached to the enzyme surface.

Such a way of Pol β labeling by using a similar photoreactive analogue of dCTP was suggested by us earlier (*20*). This pathway appears to provide the surplus in the level of covalent adduct formation.

To prove this proposal, we compared the rates of the primer elongation by Pol β and the cross-linking of the photoreactive primer to the enzyme. When FAP-dCTP was used as dTTP analogue, the rate of the primer elongation was approximately 10 times lower than the rate of cross-linking (data not shown). The rate of the primer elongation when FAP-dCTP was used as dCTP analogue was too high at the used concentration of Pol β to register the contribution of the second pathway. Thus, the more efficient covalent adducts Pol β−DNA primer formation appears to occur via saturation of dNTP binding site with the covalently attached dCTP analogue, from which a dCMP residue is transferred to the 3′ end of the primer.

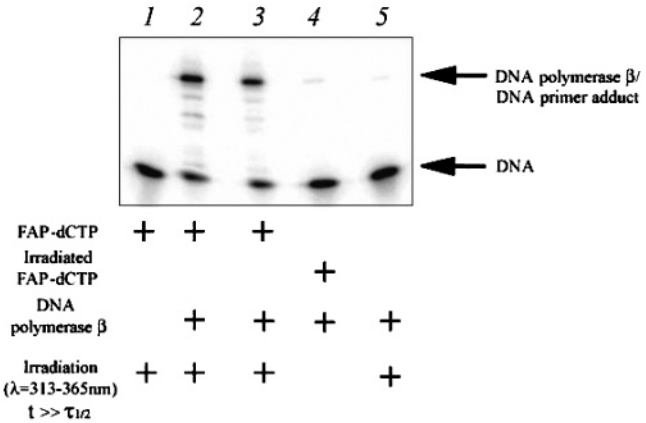


Figure 3. SDS−PAGE analysis of products of Pol β photoaffinity labeling: lane 1, no Pol β; lanes 2 and 3, direct and catalytic adduct formation, respectively; lane 4, FAP-dCTP irradiated (15 min) prior to addition to the reaction mixture; lane 5, no FAP-dCTP.

[a] Not determined. [b] Not applicable.

The additional argument for the proposed mechanism comes from the experiments where Pol β was UV-irradiated in the presence of FAP-dCTP with the reaction mixtures being devoid of DNA duplex during UV-irradiation. After completion of irradiation, the reaction mixtures were supplemented with DNA duplex and further incubated. The following analysis revealed the efficient formation of the covalent adducts. The data are presented in Figure 3. The amounts of DNA−protein adducts formed in each of the pathways are comparable, which speaks in favor of the essential contribution of catalytic labeling of Pol β in the total level of its modification.

Covalent fixation of a dNTP analogue in the active site of Pol β probably allows the enzyme to skip the stage of selection of the complementary dNTP. The transfer of the NAB-dUMP moiety from the dUTP analogue covalently fixed in the active site of Pol β onto the 3′ end of the oligonucleotide in a DNA duplex with a blunt end, that is, without a templating base, was shown by us earlier (*21*).

The data on the efficiency of Pol β modification are listed in Table 2. The relative efficiency (W_R) of cross-linking, that is, the part of photoreactive DNA primer cross-linked to Pol β, was the highest achieved so far with any photoreactive analogue used by us, although when FAP-dCTP was used as dTTP, the value of the relative efficiency is ill-defined due to the considerable contribution of catalytic modification of Pol β in the total level of the modification. Therefore, the W_R value (the amount of photoreactive primer cross-linked to Pol β normalized

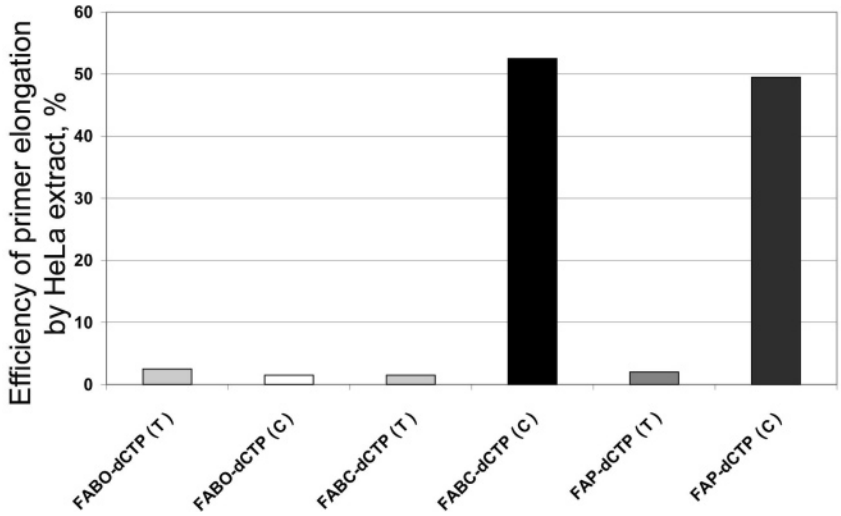

Figure 4. Efficiencies of incorporation of different dCTP analogues by endogenous DNA polymerases of HeLa cell extract. Letters in parentheses designate as what deoxynucleoside triphosphate dCTP or dTTP the analogue was used.

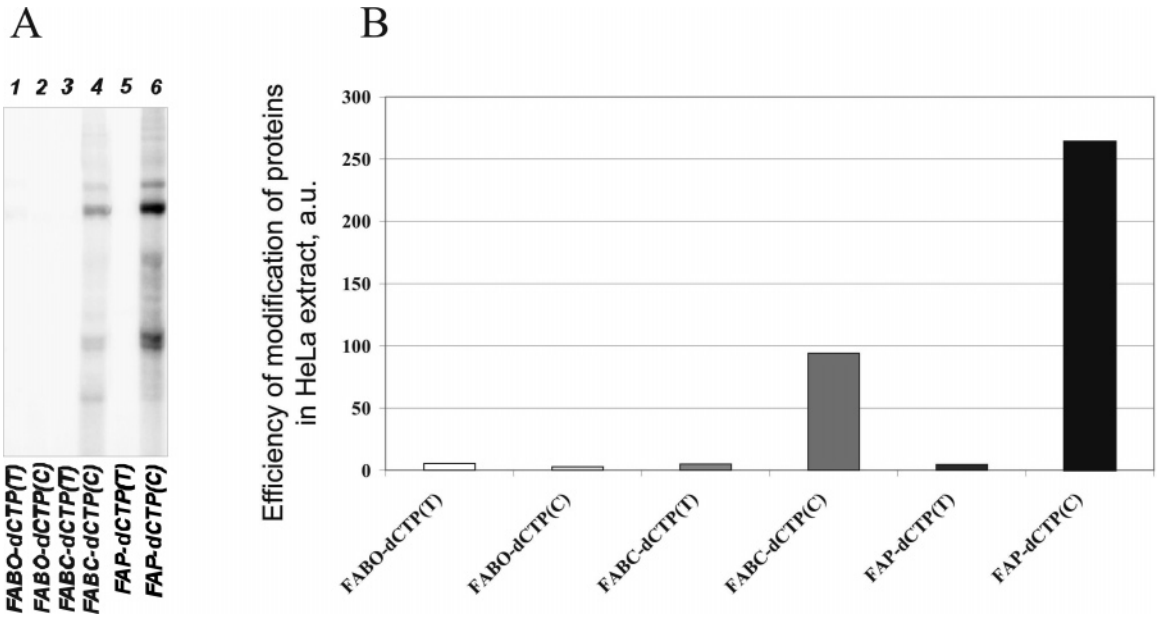

Figure 5. SDS−PAGE analysis (A) of products of photo-cross-linking of DNA binding proteins in HeLa cell extract by photoreactive DNAs synthesized in situ by endogenous DNA polymerases with different dCTP analogues as substrates and efficiencies of protein labeling (B) in HeLa cell extract by photoreactive DNAs (a.u. = arbitrary units). Letters in parentheses designate as what deoxynucleoside triphosphate dCTP or dTTP the analogue was used.

on the amount of the photoreactive primer synthesized prior to irradiation) is not shown in the Table 2. However, the W_r value directly determined from the experiment is rather high in comparison with the primers bearing other photoreactive dCMP moieties.

When FAP-dCMP was placed opposite an adenosine of the template chain, the modification of the template did not practically occurred. Location of FAP-dCMP moiety opposite the template guanosine residue resulted in less than 10% cross-linking of the photoreactive primer to the complementary template chain. The levels of the template modification containing A or G opposite FAP-dCMP correlates with the nucleophilicity of these bases. Rather low levels of the template modification were also observed in the case of FABC-dCMP and FABO-dCMP primers (*11*). Thus, these analogues can be considered as protein-directed reagents.

Thus, newly synthesized FAP-dCTP displays the best substrate characteristics among dCTP analogues in primer elongation catalyzed by Pol β and provides the highest level of Pol β modification achieved for any photoreactive dNTP derivatives synthesized and used by us until now.

Application of FAP-dCTP in Cell Extract. The most easy-to-use and adequate way to synthesize photoreactive probes is the in situ introduction of photoreactive dNMP moieties into DNA via activity of endogenous DNA polymerases using photoreactive dNTP analogues as substrates. In cell extracts, where the concentrations of DNA polymerases are rather low, the poor substrate properties of dNTP analogues may become the limiting factor in DNA synthesis, which, in turn, restricts the applicability of the analogue in these systems. We demonstrated good substrate properties of FAP-dCTP in the primer elongation catalyzed by Pol β, but in cell extracts the efficiency of incorporation of photoreactive moieties into DNA can be modulated by the presence of other DNA polymerases and proteins, which can influence the activity of Pol β. Therefore, the most adequate way to estimate the potential of the analogue as a reagent

for the in situ synthesis of photoreactive DNA probes in cell extracts is the direct measurement of the efficiency of its incorporation. We compared the efficiencies of incorporation of photoreactive dCMP moieties into DNA in HeLa cell extract using FAP-dCTP, FABO-dCTP, and FABC-dCTP as substrates. DNA containing FABO-dCMP and FABC-dCMP residues provide efficient cross-linking to Pol β, but corresponding dCTP analogues vary substantially in their substrate properties as dCTP or dTTP analogues in DNA synthesis catalyzed by Pol β (*9, 11*). Both FABC-dCTP and FABO-dCTP were used as dTTP to synthesize DNA probes for photoaffinity modification of proteins in HeLa cell extract (*11*). FABC-dCTP was shown to be less efficient in protein labeling than FABO-dCTP, but the data were not quantified. Here we quantitatively compare the levels of incorporation of these three analogues and efficiencies of photoaffinity modification of DNA binding proteins in HeLa cell extract by DNA synthesized in situ. The data on the efficiencies of analogue incorporation both as dCTP and dTTP by endogenous DNA polymerases in HeLa cell extract are presented in Figure 4.

FAP-dCTP and FABC-dCTP were rather efficiently incorporated as dCTP analogues, but considerably worse when used as dTTP. FABO-dCTP was rather inefficient in the extract both as dCTP and dTTP.

Photoreactive DNAs synthesized in situ were used for photoaffinity modification of DNA binding proteins in HeLa extract. A pattern of protein modification in HeLa cell extract is shown in Figure 5A. Quantitative estimation of the efficiencies of protein cross-linking to photoreactive DNA synthesized on the basis of different photoreactive dCTP analogues clearly demonstrates that the efficiencies are determined by the levels of analogue incorporation (Figure 5B). The yield of cross-linking products also depends on the type of photoreactive group. For example, FAP-dCTP and FABC-dCTP were incorporated as dCTP with comparable efficiencies, but DNA primer containing FAP-dCMP provided at least 2.5-fold higher level of protein labeling. Analogous dependencies of the efficiencies of protein labeling in HeLa cell extract on substrate properties of the analogues and the types of photoreactive groups were demonstrated for the set of photoreactive dUTP analogues (*11*).

The patterns of protein labeling were rather similar for all three analogues except the efficiency of cross-linking. Thus, the performance requirements for photoreactive dNTP analogues depend on the system, in which the analogues are planned to be used; and in the systems with limited DNA polymerase activities, the substrate characteristics of the analogues in DNA synthesis become very important. Taking together, the data clearly shows that newly synthesized FAP-dCTP possessing the best substrate and photochemical characteristics among the photoreactive dNTP analogues synthesized by us until now meets the requirements to be applied to the systems reconstituted from purified proteins and crude cellular extracts.

ACKNOWLEDGMENT

The work was supported by grants from the Russian Foundation for Basic Research, Project Nos. 04-04-48525, 03-04-48562, and 04-03-32490, and by a grant from HFSP, No. RG0007/2004-C104. We thank Dr. Vladimir Koval for recording the MALDI-MS.

Synthesis and Characterization of Poly(ethylene oxide)-*block*-poly(methylidene malonate 2.1.2) Block Copolymers Bearing a Mannose Group at the PEO Chain End

Peggy Studer,[†,‡] David Limal,[†,‡] Pascal Breton,[†] and Gérard Riess*[,‡]

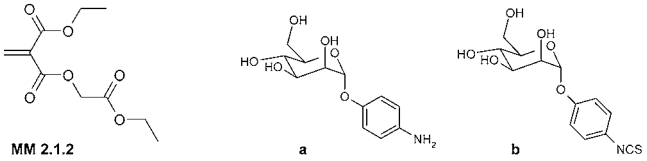
VIRSOL, 46 Rue Boissière, 75116 Paris, France, and Laboratoire de Chimie Macromoléculaire, Ecole Nationale Supérieure de Chimie de Mulhouse/Institut de Chimie des Surfaces et Interfaces, 3 Rue Alfred Werner, 68200 Mulhouse, France. Received August 13, 2004; Revised Manuscript Received December 3, 2004

A poly(ethylene oxide)-*block*-poly(methylidene malonate 2.1.2) block copolymer (PEO-*b*-PMM 2.1.2) bearing a mannose moiety at the poly(ethylene oxide) chain end was synthesized by sequential anionic polymerization of ethylene oxide (EO) and methylidene malonate 2.1.2 (MM 2.1.2), followed by a coupling reaction between its poly(ethylene oxide) amino- or aldehyde-end group and a sugar derivative. Different coupling procedures, either in organic media or in aqueous micellar solutions, were examined in order to optimize the poly(ethylene oxide) end-glycosylation yield. The micellar size of the functionalized block copolymers was determined by dynamic light scattering.

INTRODUCTION

There is a growing interest in the development of novel drug delivery systems to reach an increased bioavailability of drugs with controlled release profiles to the targeted cells and to reduce their side effects, especially in the field of cancer chemotherapy (*1, 2*). To this aim, biocompatible amphiphilic block copolymers, which have the tendency to self-assemble into micelles in a selective solvent, can be utilized as potential carriers for hydrophobic drugs or other bioactive molecules (*3*−*7*). The good water solubility properties, the biocompatibility, and the lack of immunogenicity of poly(ethylene oxide) (PEO) provide these nanostructures with a suitable outer corona of PEO that prevents protein adsorption and cell adhesion, which are the first steps before their uptake by the mononuclear phagocyte system and their rapid blood clearance (*8*). The drug release kinetics being affected by the drug/polymer interactions as well as by the polymer microstructure and erosion/degradation properties, the chemical composition, and architecture of the polymers have to be tailored to accommodate drugs with varying hydrophobicity, molecular weight, etc. The polymer matrixes and particularly the hydrophobic block have to be chosen in order to achieve the desired biocompatibility, polymer degradation and/or erosion, and drug release kinetics. The synthetic degradable polymers used for biomedical applications are typically poly(amino acids), poly(esters), and poly(anhydrides) with hydrolyzable bonds along the backbone (*9*). Another category of biocompatible polymers bears enzymatically cleavable side chains leading to water-soluble polymers through a bioerosion mechanism. These bioerodible polymers can be poly(cyanoacrylates) (PACA) (*10*) or poly(methylidene malonate 2.1.2) (PMM 2.1.2). The latter is prepared by polymerization of 1-ethoxycarbonyl-1-ethoxycarbonylmethylenoxycarbonyl ethene (MM 2.1.2, Scheme 1) and has been shown to be less toxic than PACA (*11, 12*).

Scheme 1. Structure of Methylidene Malonate 2.1.2 (MM 2.1.2) and of the Mannose Derivatives a and b



More recently, it has been proposed to introduce reactive groups on the surface of this kind of polymeric micelles and to use them as a basic system for active targeting (*4, 13*). Thus, PEGylation chemistry is retaining more and more attention in the field of biomedical materials (*14*−*16*). To improve the potential utility of polymeric micelles for drug targeting, Nagasaki et al. (*17*) reported the functionalization of the outer surface of the micelle by an easy and quantitative method allowing the synthesis of heterobifunctional poly(ethylene oxide) and block copolymers such as poly(ethylene oxide)-*b*-poly(D,L-lactide) (PEO-*b*-PDLLA), poly(ethylene oxide)-*b*-poly(dimethylaminoethyl methacrylate) (PEO-*b*-PDMAEMA) and many others. By using a sugar derivative as an initiator, the authors also developed a novel one-pot synthesis of PEO-*b*-PDLLA block copolymers bearing one sugar end-group, like glucosyl or galactosyl, at the PEO chain end (*18, 19*). Indeed, by an adequate protection of four out of five hydroxyl groups, a retained hydroxyl group can be used as an initiator for the monosaccharide-induced EO polymerization.

As the synthesis of nonfunctionalized PEO-*b*-PMM 2.1.2 is already known using diphenylmethylpotassium as an initiator (*20, 21*), the aim of this study was to develop a novel route to prepare functionalized PEO-*b*-PMM 2.1.2 block copolymers allowing the coupling of various ligands such as sugars (*22*), peptides (*23*), folic acid (*24*), fluorescent markers (*25*), etc. Our main purpose was to develop α-functionalized PEO-*b*-PMM 2.1.2 block copolymers and to demonstrate the reactivity of these

PEO end functions, so that the latter are enabled to carry out the ligand-anchoring with targeting agents such as a mannosyl residue. In the present study, a mannose moiety was conjugated through two different coupling procedures, either in aqueous micellar solutions or in organic solvents, to the α-amino and α-aldehyde reactive PEO end groups of the PEO-*b*-PMM 2.1.2 block copolymers, which were introduced during the initiation step.

EXPERIMENTAL PROCEDURES

Materials. All the reagents and chemicals used in this study were of the highest purity available. THF was purified using conventional methods (*20*). 2-Aminoethanol (Aldrich) was purified by distillation under CaH_2. The sodium phosphate buffer solution pH 7.0 was prepared as described by Yamamoto et al. (*13*). A 100 mL sodium carbonate buffer solution pH 9.5 was prepared as follows: 4.8 mL of a 0.2 M sodium carbonate solution and 20.3 mL of a 0.2 M sodium bicarbonate solution were diluted to 100 mL with distilled water. Methylidene malonate 2.1.2, prepared according to the Bru-Magniez et al. procedure (*26*), was kept under sulfur dioxide at −20 °C. Potassium naphthalide was prepared by the method of Scherf et al. (*27*), and its concentration (0.3 M) was determined by titration.

Preparation of the Sugar Derivatives. Sugar derivatives were prepared by combining different reaction steps described in the literature (*28*−*31*). (4-Aminophenyl)-α-D-mannopyranose **a** (Scheme 1) was obtained through a four-step synthesis (*29*). Briefly, mannose acylation according to Lerner et al. (*28*) consisted of the protection of the hydroxyl groups in positions 2, 3, 4, and 6 of α-D-mannopyranose, thus allowing the introduction on position 1 of the *p*-nitrophenyl group as described by Smits et al. (*30*). Deprotection of the hydroxyl groups was achieved on an Amberlyte resin, followed by a catalytic hydrogenolysis on Pd/C (*31*) that gave **a** with a global yield of 20%. As described by Monsigny et al. (*31*), (4-isothiocyanatophenyl)-α-D-mannopyranose **b** (Scheme 1) was obtained with a 94% yield by the reaction of **a** with thiophosgene.

Polymer Characterization. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ using a Bruker AC 250F spectrometer, respectively, at 250 and 62.9 MHz. Gel permeation chromatography measurements were performed by using a Waters 2690 Alliance system equipped with a sequence of Waters Styragel HR4, HR1 and HR0.5 columns and an internal RI Waters 410 detector (flow rate = 1 mL/min). THF was used as an eluant, and standards were poly(ethylene oxide) and poly(styrene).

Preparation and Characterization of the Polymeric Micelles. The procedure for micelle formation has been described previously (*20*). Briefly, 25 mg of copolymer was dissolved in 5 mL of a mixture THF/water 1/1 (v/v), and the polymer solution was transferred into a preswollen membrane SpectraPor 7 (molecular weight cut-off: 1000) and dialyzed against water for 24 h. The mean diameter of the polymeric micelles was determined by dynamic light scattering using a Coulter N4 Plus particle size analyzer (Coultronics).

Synthesis of α-Amino PEO-*b*-PMM 2.1.2 Block Copolymers (1) (Scheme 2). Polymerizations were carried out under nitrogen atmosphere in reactors equipped with a magnetic stirring device. As described by Mosquet et al. (*32*) for PEO, a typical procedure for the synthesis of the amino-bearing PEO-*b*-PMM 2.1.2 block copolymers **1** was as follows: 3.3 mL of potassium naphthalide solution (1 mmol) was added to 150 mL of dry THF containing 1 mmol (60 μL) of 2-aminoethanol to prepare the insoluble metalated alcoholate initiator. Afterward, this heterogeneous system was stirred for 5 min, and then 114 mmol (5 g) of EO was added via a sealed ampule to the THF solution containing the initiator. The polymerization of EO was carried out at 35 °C for 2 days. The PEO solution was then divided into two equivalent parts. The first one was deactivated by a small amount of methanol and kept for the determination of the molecular weight, the polydispersity, and the end functionality of the PEO thus prepared. A degassed MM 2.1.2 in THF solution (1 g/15 mL) was quickly introduced under efficient stirring into the second reaction vessel, resulting in the discoloration of the solution, and the reaction was carried out for an additional 1 h at room temperature. After the polymerization was stopped by the addition of a few drops of methanol, the mixture was then concentrated under reduced vacuum and finally precipitated

into a large amount of diethyl ether. The precipitated polymer was collected by filtration and dried under vacuum at room temperature (yield = 95%). *HO-PEO-NH_2 Homopolymer.* GPC (THF, PEO standards): number-average molecular weight (M_n) = 4470; weight-average molecular weight (M_w) = 5810; polydispersity index (I_p) = 1.30. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 2.85 (t, CH_2NH_2, 2H), 3.60 (m, CH_2 of PEO, 4H). ^{13}C NMR (62.9 MHz, $CDCl_3$, δ in ppm): 41.6 (CH_2NH_2), 60.1 (CH_2OH), 70.0 (CH_2 of PEO), 72,3 (CH_2 in β position of OH), 73.3 (CH_2 in β position of NH_2). End functionality = 98%. *PMM 2.1.2-b-PEO-NH_2 Copolymer.* GPC (THF, PS standards): polydispersity index (I_p) = 1.32. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 1.30 (m, CH_3 of PMM 2.1.2, 6H), 2.80 (m, CH_2 of the main chain of PMM 2.1.2, 2H), 3.60 (m, CH_2 of PEO, 4H), 4.10 (m, CH_2 of CH_2CH_3 of PMM 2.1.2, 4H), 4.50 (m, CH_2 of PMM 2.1.2, 2H). End functionality = 98%.

Synthesis of α-Acetal PEO-*b*-PMM 2.1.2 Block Copolymers (2) (Scheme 2). As reported by Yamamoto et al. (*13*) for PEO-*b*-PDLLA block copolymers, the synthesis of α-acetal-PEO-*b*-PMM 2.1.2 block copolymers **2** was as follows: 4.1 mL of potassium naphthalide (1.25 mmol) was added to 150 mL of dry THF containing 1.25 mmol (197 μL) of 3,3-diethoxypropan-1-ol to prepare the soluble metalated alcoholate initiator. After this mixture was stirred for 5 min, 114 mmol (5 g) of EO was then added via a sealed ampule to the THF solution containing the initiator. The polymerization of EO was carried out as described above. After dividing the solution into two equivalent parts, a degassed MM 2.1.2 in THF solution (4 g/15 mL) was quickly introduced under vigorous stirring into the second reaction vessel, and the reaction was carried out for an additional 1 h at room temperature. The polymerization was then stopped and the purification of the polymer was carried out as described before (yield = 95%). *HO-PEO-acetal Homopolymer.* GPC (THF, PEO standards): number-average molecular weight (M_n) = 4200; weight-average molecular weight (M_w) = 4960; polydispersity index (I_p) = 1.18. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 1.18 (t, CH_3, 6H), 1.88 (q, CH_2, 2H), 3.60 (m, CH_2 of PEO, 4H), 4.62 (t, CH, 1H). ^{13}C NMR (62.9 MHz, $CDCl_3$, δ in ppm): 15.3 (CH_3), 34.0 (CH_2), 60.1 (CH_2OH), 61.4 (CH_2 of CH_2CH_3), 61.5 (CH_2O), 70 (CH_2 of PEO), 72.3 (CH_2 in β position of OH), 100.5 (CH). End functionality = 98%. *PMM 2.1.2-b-PEO-acetal Copolymer.* GPC (THF, PS standards): polydispersity index (I_p) = 1.32. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 1.18 (t, CH_3, 6H), 1.30 (m, CH_3 of PMM 2.1.2, 6H), 1.88 (q, CH_2, 2H), 2.80 (m, CH_2 of the main chain of PMM 2.1.2, 2H), 3.60 (m, CH_2 of PEO, 4H), 4.10 (m, CH_2 of CH_2CH_3 of PMM 2.1.2, 4H), 4.50 (m, CH_2 of PMM 2.1.2, 2H), 4.62 (t, CH, 1H). End functionality = 95%.

Synthesis of α-Aldehyde PEO-*b*-PMM 2.1.2 Block Copolymers (3) (Scheme 2). An aqueous micellar solution of the acetal-PEO-*b*-PMM 2.1.2 copolymer **2** was prepared as described above, and the acetal group was transformed into an aldehyde group by acid treatment as follows: the aqueous solution of α-acetal-PEO-*b*-PMM 2.1.2 micelles was acidified to pH 2.0 by 1 N HCl added dropwise. After being stirred for 2 h at room temperature, the solution was neutralized by 0.1 N NaOH. The micellar solution was then desalted by dialysis against water. After 24 h, the micelles were then freeze-dried. *HO-PEO-CHO Homopolymer.* GPC (THF, PEO standards): number-average molecular weight (M_n) = 4290; weight-average molecular weight (M_w) = 5060; polydispersity index (I_p) = 1.18. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 2.67 (td, CH_2CHO, 2H), 3.60 (m, CH_2 of PEO, 4H), 9.77 (t, CHO, 1H). ^{13}C NMR (62.9 MHz, $CDCl_3$, δ in ppm): 43.6 (CH_2), 60.1 (CH_2OH), 64.6 (CH_2O), 70.0 (CH_2 of PEO), 72.3 (CH_2 in β position of OH), 201.0 (CHO). End functionality = 87%. *PMM 2.1.2-b-PEO-CHO Copolymer*. GPC (THF, PS standards): polydispersity index (I_p) = 1.30. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 1.30 (m, CH_3 of PMM 2.1.2, 6H), 2.67 (td, CH_2-CHO, 2H), 2.80 (m, CH_2 of the main chain of PMM 2.1.2, H), 3.60 (m, CH_2 of PEO, 4H), 4.10 (m, CH_2 of CH_2-CH_3 of PMM 2.1.2, 4H), 4.50 (m, CH_2 of PMM 2.1.2, 2H), 9.77 (t, CHO, 1H). End functionality = 95%.

24 h in order to remove the unreacted mannosyl derivatives and the salts and finally lyophilized. In organic solvent: Anhydrous DMF (25 mL) was added to 100 mg of **3**. Amounts of 5 and 10 mol equiv per polymer of **a** were then added to the mixture which was stirred for 1 h. Subsequently, 5 and 10 mol equiv per polymer $NaBH(OAc)_3$ were introduced into the reactor, and the mixtures were stirred for 24 h. The purification procedure was the same as described before. ^{1}H NMR (250 MHz, $CDCl_3$, δ in ppm): 1.30 (m, CH_3 of PMM 2.1.2, 6H), 1.85 (quin, CH_2, 2H), 2.80 (m, CH_2 of the main chain of PMM 2.1.2, 2H), 3.60 (m, CH_2 of PEO, 4H), 4.10 (m, CH_2 of CH_2CH_3 of PMM 2.1.2, 4H), 4.50 (m, CH_2 of PMM 2.1.2, 2H), 5.38 (d, H_{ano}, 1H), 6.53 (d, aromatics, 2H), 6.87 (d, aromatics, 2H) (Figure 1).

As described by Monsigny et al. (*33*), the sugar contents in the polymer samples were determined by a microscale colorimetric assay, in which the mannose residue reacts with resorcinol in the presence of 75% sulfuric acid solution. This easy-to-handle microplate assay has been found to be suitable to quantitatively determine the sugar content of samples. Note that we checked by GPC that the dialysis-purified polymer samples do not contain free mannosyl derivative.

RESULTS AND DISCUSSION

The synthesis of mannosylated PEO-*b*-PMM 2.1.2 block copolymers was carried out through the two following steps: (i) synthesis of α-amino or α-aldehyde PEO-*b*-PMM 2.1.2; (ii) coupling of the mannosyl derivatives to these α-functionalized copolymers.

The PEO precursor was analyzed by GPC using PEO standards for the determination of its molecular weight and polydispersity index. From the chemical composition of the purified copolymers determined by ^{1}H NMR, molecular weights of copolymers were calculated on the assumption that the block copolymer samples contained neither unreacted PEO nor PMM 2.1.2 homopolymer. In fact, it was clearly established from GPC profiles that copolymer samples did not contain a detectable amount of PEO homopolymer. The elimination of eventual traces of PMM 2.1.2 homopolymer from block copolymers was achieved by precipitation of the copolymerization reaction products into a large amount of diethyl ether, a well-known and good solvent of PMM 2.1.2.

The α-end functionalization yield was determined as following. The number-average molecular weight of the α-functionalized PEO homopolymer, which is the precursor for the preparation of the functionalized PEO-*b*-PMM 2.1.2 copolymers, was determined by GPC and allowed the calculation of the number *n* of ethylene oxide units per chain and thus per end group, whatever its functionality. The relative intensity of the signals corresponding to the α-end group protons as compared to that of the methylene protons of the PEO segment were obtained from the ^{1}H NMR spectra and allowed the determination of the number of functionalized end groups per *n* units and thus the calculation of the α-end functionalization yield. Calculations of α-functionalized PEO-*b*-PMM 2.1.2 copolymers **2**−**5** made use of ^{1}H NMR signals corresponding to the PMM 2.1.2 protons. Peaks corresponding to protons adjacent to or characteristic from amino, acetal, aldehyde, or mannosyl moieties were clearly observed in the spectra of the α-functionalized PEO homopolymers and/or of the PEO-*b*-PMM 2.1.2 block copolymers and enabled the easy determination of end functionalization yields. Furthermore, the chemical nature of the end group was confirmed by ^{13}C NMR (*29*), and the values obtained were in good agreement with those given by Zalipsky (*34*).

Synthesis and Characterization of α-Amino PEO-*b*-PMM 2.1.2 Block Copolymers 1. Most of them involving amino-protected initiators, different methods have been previously reported in the literature for the synthesis of α-amino PEO (*32, 35*−*38*). We selected the easiest one that consists of initiating the polymerization of EO by aminoethanolate as described by Mosquet et al. (*32*). These authors showed that due to the high reactivity of the potassium alcoholate with respect to those of the amino group, the ring opening reaction of ethylene oxide by the amino group is avoided in a dry aprotic medium like THF. In our study, the number-average molecular weight and polydispersity index were 4470 g/mol and 1.30, respectively, for the α-amino PEO, i.e., a degree of polymerization of 102. The weight-average molecular weight of the PMM 2.1.2 segment was estimated to be 1500 g/mol based on the molecular weight of the PEO segment and on the MM 2.1.2/EO ratio as determined by ^{1}H NMR. Probably due to the low solubility of the potassium 2-aminoethanolate in THF, the polydispersity index of the α-amino PEO is slightly higher than those obtained with soluble initiators (*32*). This MM $2.1.2_{(7)}$-$EO_{(102)}$-NH_2 copolymer thus prepared has an excellent α-amino end-functionality of 98% which was confirmed by acido-basic titration with NaOH. Moreover, the elemental analysis of the nitrogen content was in good agreement with the NMR/GPC data (*29*).

Synthesis and Characterization of α-Acetal PEO-*b*-PMM 2.1.2 Block Copolymers 2. The synthesis of α-acetal and α-aldehyde PEO homopolymers or corresponding copolymers has already been extensively described by Kataoka et al. (*39*−*42*). For the α-acetal PEO synthesized in the present study, the number-average molecular weight and polydispersity index were 4200 g/mol and 1.18, respectively. As expected, when soluble initiators are used, the polydispersity index value is lowered. The weight-average molecular weight of the PMM 2.1.2 segment was estimated at 6760 g/mol based on the molecular weight of the PEO segment and on the MM 2.1.2/EO molar ratio obtained from ^{1}H NMR data. This MM $2.1.2_{(30)}$-$EO_{(96)}$-acetal copolymer showed a good α-acetal end-functionalization yield of 95%, which was in agreement with those given by Scholz et al. (*41*).

Synthesis and Characterization of α-Aldehyde PEO-*b*-PMM 2.1.2 Block Copolymers 3. In water, core−shell-structured micelles were formed by the segregation of the hydrophobic PMM 2.1.2 blocks into the core, which is surrounded by a hydrophilic shell composed of PEO blocks. Thus, as confirmed by ^{1}H NMR, this structure prevents possible acidic hydrolysis of the PMM 2.1.2 esters, the MM 2.1.2/EO ratio being the same before and after the 2-h hydrolysis. The MM $2.1.2_{(30)}$-$EO_{(96)}$-CHO copolymer thus prepared showed an α-aldehyde end-

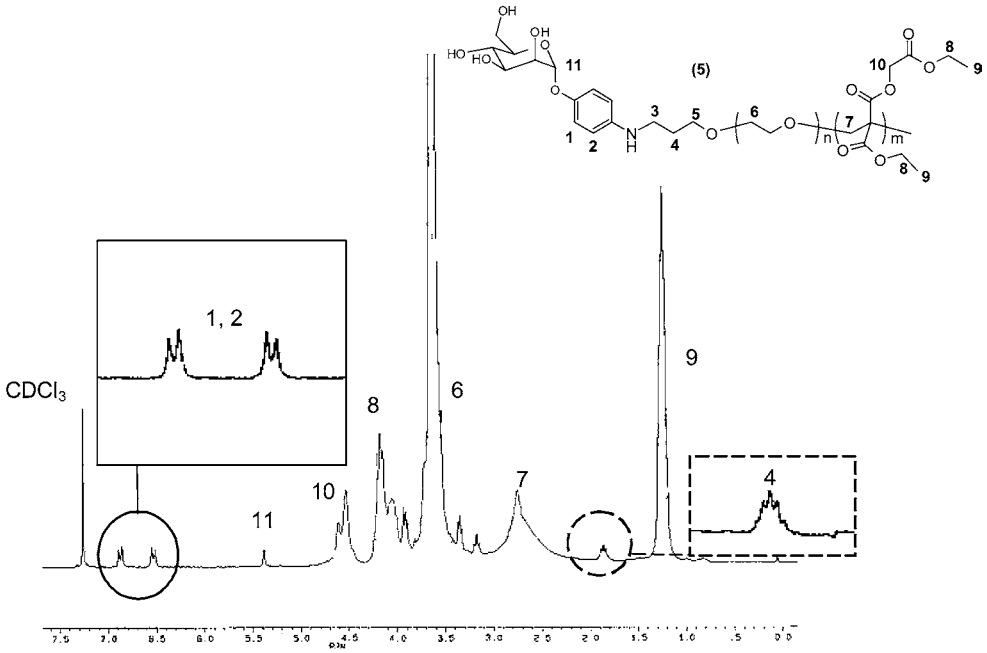

Figure 1. ^{1}H NMR spectrum of α-mannosyl-functionalized POE-*b*-PMM 2.1.2 **5** prepared by reductive amination.

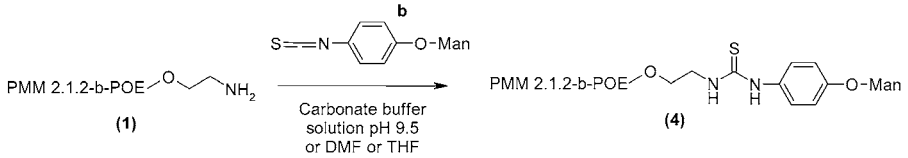
Scheme 3. Coupling Reaction between (4-Isothiocyanatophenyl)-α-D-mannopyranose b and the α-amino Ended Copolymer (1)



functionalization yield of 95%, similar to the previous one given above.

Coupling of Mannosyl Derivatives to α-Amino PEO-*b*-PMM 2.1.2 and to α-Aldehyde PEO-*b*-PMM 2.1.2 Copolymers 1 and 3. Mannosyl derivatives were conjugated to the α-functionalized PEO end, either by reaction of the amine function of **1** with the phenylisothiocyanate group of **b**, or by the reaction of the aldehyde function of **3** with the amino group of **a**. The bound mannosyl derivative content was determined by the resorcinol colorimetric method after free unreacted mannosyl derivatives were completely removed by dialysis. As mentioned by Yamamoto et al. (*13*), there might be about 5% mol equiv ligand per polymer being noncovalently linked to the block copolymer; hence, the measured mannosyl derivative content could include a small amount of physically adsorbed sugar. In fact, a GPC calibration test showed that less than 0.08% (w/w) of free mannose derivatives (either **a** or **b**) per purified copolymer sample could be detected, that corresponded to a maximum of 3% mol equiv per polymer of unbound mannosyl derivative, in considering a polymer sample with a weight-average molecular weight of 10000 g/mol (*29*). Furthermore, the accuracy of the coupling yields were confirmed by ^{1}H NMR analysis. The reaction conditions and the α-glycosylation yields are summarized in Table 1. No change in the GPC peak profile was observed by mannosylation of the precursor polymers.

Our goal was to implement a strategy to compare the efficiency of two different coupling reactions: (i) one using α-amino copolymers **1**; (ii) the other using α-aldehyde copolymers **3**.

H_2N-PEO-b-PMM 2.1.2 Block Copolymer. The coupling reaction (Scheme 3) was performed either in a heterogeneous buffer solution at pH 9.5 (micellar solution) or in a homogeneous medium such as THF or DMF. The results given in Table 1 show that, probably because of the better solubility of copolymer **1** in these solvents, the highest coupling efficiency were achieved in organic solvents and especially in THF.

OHC-PEO-b-PMM 2.1.2 Block Copolymer. The two most commonly used reductive amination methods differ in the nature of the reducing agent. In the first one, the catalytic hydrogenation involving platinum or palladium catalysts gives a mixture of products and has limited use especially in the presence of reducible functional groups. The second one utilizes hybride reducing agents such as borohydrides. The reductive amination between the α-aldehyde ended copolymer **3** and the amine-bearing mannosyl derivative **a** were carried out with two different reducing agents. The choice of the reducing agent was critical for the success of the reaction, since the latter must reduce imines selectively over aldehydes under the reaction conditions. In our procedure, the reductive amination was indirect, as the reaction involved the preformation of the imine intermediate followed by reduction in a subsequent separate step. Depending on the nature of the reducing agent, the coupling reaction (Scheme 4) was performed either in aqueous buffer solution pH = 7.0 as described by Yamamoto et al. (*13*) or in anhydrous DMF as suggested by Abdel-Magid et al. (*43*). The results given in Table 2 show that the reductive amination was an efficient procedure. In the presence of $NaBH_3CN$, which is a specific reducing agent in buffer solution, the coupling yields were similar to those of Yamamoto et al. (*13*) obtained for the coupling of amino acids with PDLLA-*b*-PEO-CHO. Note that excellent coupling yields could be reached with sodium

Scheme 4. Coupling Reaction between the (4-aminophenyl)-α-D-mannopyranose a and the α-Aldehyde Ended Copolymer (3)

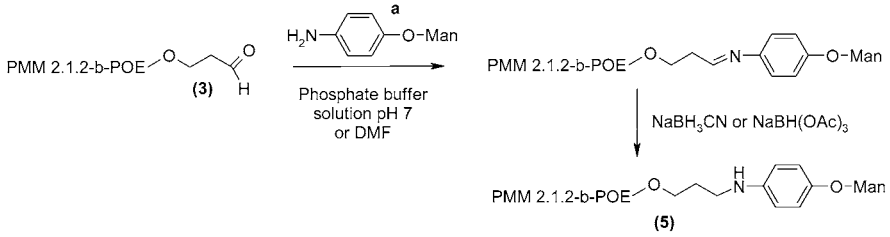


Table 3. Size of Micelles Obtained with Various α-Substituted Copolymers

copolymer	functionalization	average diameter in weight (nm)[a]
2	acetal	56.2 ± 2.3
3	CHO	56.2 ± 2.0
5	O-Man	56.0 ± 1.9

[a] Acetal-$EO_{(96)}$-MM $2.1.2_{(30)}$ block copolymer (end functionalization yield = 95%) was used as a starting material.

triacetoxyborohydride $NaBH(OAc)_3$ in DMF, this mild and selective reducing agent being suitable for reductive reactions to be carried out in organic solvents such as DMF as mentioned by Abdel-Magid et al. (*43*). Figure 1 shows the ^1H NMR spectrum of α-mannosyl-functionalized PEO-*b*-PMM 2.1.2 as a typical example.

From these results, it turned out that the synthesis of α-mannosyl-functionalized PEO-*b*-PMM 2.1.2 has preferably to be carried out in an organic medium such as THF or DMF which are common solvents of both sequences of the block copolymers. Furthermore, it appeared that the highest coupling yield (74−85%) is obtained in organic medium by reductive amination between α-aldehyde-ended copolymers **3** and amine-bearing mannosyl derivative **a**, this yield being quite comparable to those of 65% and 90% given by Nakamura et al. (*18*) and Yasugi et al. (*19*), respectively, which were obtained by initiating the polymerization with a protected monosaccharide residue. In addition, this procedure has a double-advantage: (i) compared to α-amino-functionalized copolymers **1**, α-aldehyde-functionalized copolymers **3** have been obtained with a lower polydispersity index; (ii) the amine-bearing mannosyl derivative **a** was produced in a four-step synthesis, whereas the phenylisothiocyanate-bearing mannosyl derivative **b** needed five steps.

Micellization of the α-Acetal, α-Aldehyde and α-Mannosyl-Functionalized PEO-*b*-PMM 2.1.2 Block Copolymers 2, 3, and 5. As the primary application of these α-substituted PEO-*b*-PMM 2.1.2 block copolymers consists of preparing polymeric colloidal vectors for drug delivery, it was of interest to determine their micellar characteristics. In aqueous media, these block copolymers self-associate, leading to spherical micelles with a PMM 2.1.2-made hydrophobic core surrounded by a corona of hydrated PEO segments. A typical example of micellar characteristics of α-substituted block copolymers with various end groups is given in Table 3, the composition and molecular weight of the copolymer being kept constant.

Dynamic light scattering studies indicated that, in our micellization procedure, the block copolymer leads to a monodisperse micelle population with an average diameter of 56 ± 2 nm, which is in agreement with the predicted value of 49 nm given by Larras et al. (*20*) for PEO-*b*-PMM 2.1.2 block copolymers. It was confirmed that the micelle diameter did not change, neither after the hydrolysis of the acetal group as pointed out by Kataoka et al. (*13*) nor after the coupling reaction with the mannosyl derivatives **a** or **b**.

CONCLUSION

Well-controlled molecular weight α-amino and α-aldehyde-functionalized PEO-*b*-PMM 2.1.2 block copolymers were synthesized with high mean yields. These block copolymers were then successfully conjugated to a mannosyl derivative for the preparation of bioerodible nanocarriers with the aim of developing active tissue targeting strategies. Reductive amination of the α-aldehyde end-functionalized copolymer with amine-bearing mannosyl derivative in the presence of sodium triacetoxyborohydride in DMF appeared to be the most suitable functionalization procedure. A maximum of 85% of the PEO chain end was α-conjugated to mannosyl derivative without any change in the micellar size. Our studies result in a panel of novel macromolecular entities that can be used as starting materials on which to anchor various targeting ligands bearing various chemical functionalities. The latter can be adapted to the nature of the α-ending reactive function of the PEO-*b*-PMM 2.1.2 block copolymer, whereas the initiation process by a monosaccharide residue is limited to the sugar moiety only.

ACKNOWLEDGMENT

The authors gratefully acknowledge the financial support by Dr. Bru. We thank Drs. Nathalie Colin and Sophie Ruiz for their assistance in the determination of the copolymer-bound mannosyl derivative. We are grateful to Drs. Virginie Larras and Serge Sagodira for their helpful discussions.

Received March 23, 2004; Revised Manuscript Received July 20, 2004

The copolymer of styrene-maleic acid (SMA) was used to construct micelles containing pirarubicin (4′-*O*-tetrahydropyranyladriamycin, or THP) as a new anticancer drug formulation. The procedure for the preparation of the micelles was simple, the component consisting of only SMA and pirarubicin in a noncovalent association, possibly by hydrophobic interaction between the styrene portion of SMA and pirarubicin chromophore. This method ensures more than 80% recovery of pirarubicin by weight, and 60% of drug loading (by weight) was achieved. The micelles obtained (SMA−THP) showed high solubility in water and a constant pirarubicin release rate of about 3−4%/day in vitro. SMA−THP micelles had an average molecular size of about 34 kDa according to gel chromatography; this size is a marked increase from the 627.6 Da of free THP, which suggests the formation of a micellar structure. When albumin was added, the molecular size of the micelles increased to about 94 kDa, which indicates binding to albumin, a unique characteristic of SMA. SMA−THP micelle preparation had a cytotoxic effect (93−101%) on MCF-7 breast cancer cells and SW480 human colon cancer cells in vitro that was comparable to that of free THP. An in vivo assay of SMA−THP at doses of 20 mg/kg in ddY mice bearing S-180 tumor revealed complete tumor eradication in 100% of tested animals. Mice survived for more than 1 year after treatment with micellar drug doses as high as 100 mg/kg pirarubicin equivalent. This marked antitumor activity can be attributed to the enhanced permeability and retention (EPR) effect of macromolecular drugs seen in solid tumors, which enables selective delivery of drugs to tumor and thus much fewer side effects. Complete blood counts, liver function test, and cardiac histology showed no sign of adverse effects for intravenous doses of the micellar preparation. These data thus suggest that intravenous administration of the SMA−THP micellar formulation can enhance the therapeutic effect of pirarubicin more than 50-fold.

INTRODUCTION

Pirarubicin, (4′-*O*-tetrahydropyranyladriamycin, or THP[2]) is an anthracycline antibiotic that was developed during a search for less cardiotoxic agents among the 4′-O-substituted anthracyclines (*1*). Pirarubicin proved effective against hematological malignancies and was used for treatment of acute leukemias and malignant lymphomas, as well as breast cancer (*2*, *3*). The drug has both lipophilic and hydrophilic properties, which allows either intravenous (iv) or intraarterial injection with Lipiodol used as a carrier for treatment of liver metastasis and hepatocellular carcinoma (*4*). Unfortunately, THP lacks specificity for cancer cells, and its potent cytotoxicity, like that of many other low-molecular-weight cytotoxic anticancer agents, leads to severe side effects. As in most conventional chemotherapeutic drug regimens, this nonselective cytotoxicity is the primary reason for dose limitation.

We previously found that drugs of large molecular size, i.e., those of more than 40 kDa, preferentially accumulate in tumor tissue because of the unique characteristics of the tumor vasculature (*5*−*11*). Solid tumor tissue usually

[1]The definition of "micelles" may not be precisely as defined in polymer science; however, we deliberately use micelles as naïve definition. These SMA-micelles have a discrete size distribution in gel chromatography and by ultracentrifugation, and it is a complex of SMA and THP.

[2]Abbreviations: EPR, enhanced permeability and retention effect in solid tumor; THP, 4′-*O*-tetrahydropyranyladriamycin, which is also known as pirarubicin; SMA, copoly(styrene-maleic acid/anhydride); SDS, sodium dodecyl sulfate; EDAC, ethyldimethylaminopropylcarbodiimide; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; MALDI-TOF, matrix-assisted laser desorption−ionization/time-of-flight; H&E, haematoxylin and eosin.

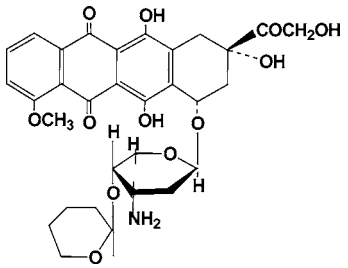

Figure 1. Chemical structure of pirarubicin (THP).

shows increased vascular density caused by angiogenesis, impaired lymphatic recovery system, and lack of a smooth muscle layer in the blood vessels. More important, functional augmentation of enhanced vascular permeability in tumor tissues has been identified and involves extensive production of vascular mediators such as bradykinin, nitric oxide, prostaglandins, matrix metalloproteinases, and vascular endothelial growth factor/vascular permeability factor, among others (*12*−*17*). We named this phenomenon the "enhanced permeability and retention (EPR) effect of macromolecular drugs in solid tumors" (*5*, *6*). In the present study, we developed micelles containing copoly(styrene-maleic acid) (SMA) and pirarubicin (THP) (Figure 1) with a large molecular size, to take advantage of the EPR effect and achieve tumor-selective drug delivery as well as an excellent therapeutic effect.

One advantage of using SMA for polymeric drug development relates to its noncovalent binding to albumin, which thus permits plasma albumin, one of the most biocompatible macromolecules, to serve as a secondary carrier of the drug (*18*). This SMA-micelle preparation takes advantage of the EPR effect. The amphiphilic nature of SMA enables a wide range of formulation possibilities, including an aqueous formulation for iv injection and an oily formulation for intraarterial or oral administration (*18*, *19*−*23*). With higher lipophilic nature, we demonstrated facilitated uptake into cells (*24*). In addition, we previously showed that when animals were treated with SMA conjugates, the SMA moieties conferred immunopotentiating activity (*25*−*28*); this result is in clear contrast to the immunosuppression caused by conventional small-molecular-size anticancer drugs.

We recently reported preparation and characterization of SMA−doxorubicin micelles, which showed marked tumor accumulation in tumor after iv administration compared with that obtained with free doxorubicin, i.e., a 13-fold increase in tumor uptake of drug and a 25-fold increase in the plasma level of drug (AUC) in a 24-h period (*29*). The SMA−doxorubicin micelle preparation produced a potent antitumor effect with fewer side effects at doses as high as 100 mg/kg of doxorubicin equivalent; in contrast, the parent drug had an LD_{100} of 10 mg/kg (*29*).

In this paper, we describe the preparation and characterization of SMA−THP micelles and the anticancer properties of this formulation.

EXPERIMENTAL PROCEDURES

Materials. Pirarubicin (also referred to as THP) was a generous gift from Meiji Seika Kaisha, Ltd, Tokyo, Japan. SMA as the anhydride form of a maleyl group with a mean molecular size of 1435 Da (M_w/M_n: 1.1), the range being between 901 and 1781 Da, was generously supplied by Kuraray Ltd, Kurashiki, Japan. Other reagents were of commercial reagent grade and were used without further purification.

Chemical Analysis. Visible/UV absorption was determined by use of a spectrophotometer (U-200, Hitachi Ltd., Tokyo, Japan). THP content was quantified via analysis of UV absorption at 487 nm. Fluorescence spectra were obtained by use of a fluorescence spectrophotometer (F-4500, Hitachi), excitation at 480 nm and emission at 450−750 nm. Infrared (IR) spectra were recorded with a JIR-6500w spectrometer (JEOL, Tokyo, Japan) using a KBr disk. Mass spectra were obtained by means of matrix-assisted laser desorption−ionization/time-of-flight (MALDI-TOF) mass spectrometry (Voyager System 6192, ABI, Foster City, CA).

Preparation of SMA−THP Micelles. Micelles were prepared as previously described in SMA−doxorubicin micelles preparation (*29*). Briefly, SMA (anhydrous) copolymer was hydrolyzed in 0.05 M NaOH. Hydrolysis produced an increase of 18 Da. Consequently, the mean molecular size of each repeating unit becomes 220 Da (Figure 2A). IR spectra showed the appearance of an OH signal at about 3400 cm^{-1} (Figure 2B, a, b).

To form the micelles, SMA powder was dissolved in water at pH 5.0 at 10 mg/mL, and then THP solution at a concentration of 10 mg/mL was added to this solution, followed by addition of the water soluble carbodiimide, ethyldimethylaminopropylcarbodiimide (EDAC), to 10 mg/mL. Resulting precipitates were washed and collected by centrifugation at 8000 rpm, solubilized, and then reconstituted in pH 7.0. The micelle solution (about 10 mg of THP/mL) was washed and concentrated to one tenth of the original volume by means of the ultrafiltration method with the Amicon ultrafiltration system (YM-10 membrane; cutoff molecular size of 10 kDa), which was repeated three times.

Sephadex G-50 and G-150 Gel Filtration. Size-exclusion chromatography with Sephadex G-50 Fine column (Pharmacia LKB, Uppsala, Sweden) was performed to separate the large-molecular-size SMA−THP micelles (with 0.2 M $NaHCO_3$, pH 8.2, as eluant, and a column size of Ø 3 × 52 cm), and the peak fraction was lyophilized. The powder thus obtained was subjected to IR and UV/visible spectroscopy.

To define the apparent molecular size of the micelles more accurately, various known globular proteins were used as standards. For this analysis, a Sephadex G-150 chromatography column of Ø 2.5 × 64 cm, with 0.25 M $NaHCO_3$, pH 8.2, as eluant, was used.

Release of Free Drug from the SMA−THP Micelles. To verify the release of free drug from SMA−THP micelles in vitro, 20 mg of the micellar preparation was dissolved in 5 mL of distilled water and placed in sealed dialysis tubes (M_r cutoff of 1000 Da; Spectrapor, Spectrum Laboratories Inc., San Diego, CA). The dialysis tubes were submerged in one of three different solutions: (a) 100% ethanol; (b) aqueous solution, pH 7.4; or (c) aqueous solution, pH 5.5. The dialysis tubes, with 25 mL of each solution above, were reciprocally shaken at 1 Hz for several days at 37 °C in the dark. Aliquots of dialysate solution were taken at predetermined time points, and the amount of THP in the dialysate was quantified by absorption at 487 nm.

In Vitro Cytotoxicity. In vitro cytotoxicity of SMA−THP micelles was determined by means of the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay (*30*) with human breast cancer MCF-7 cells and colon cancer SW480 cells, which were plated in 96-well culture plates (3000 cells/well). Cells were cultured overnight in Dulbecco's modified Eagle's medium with

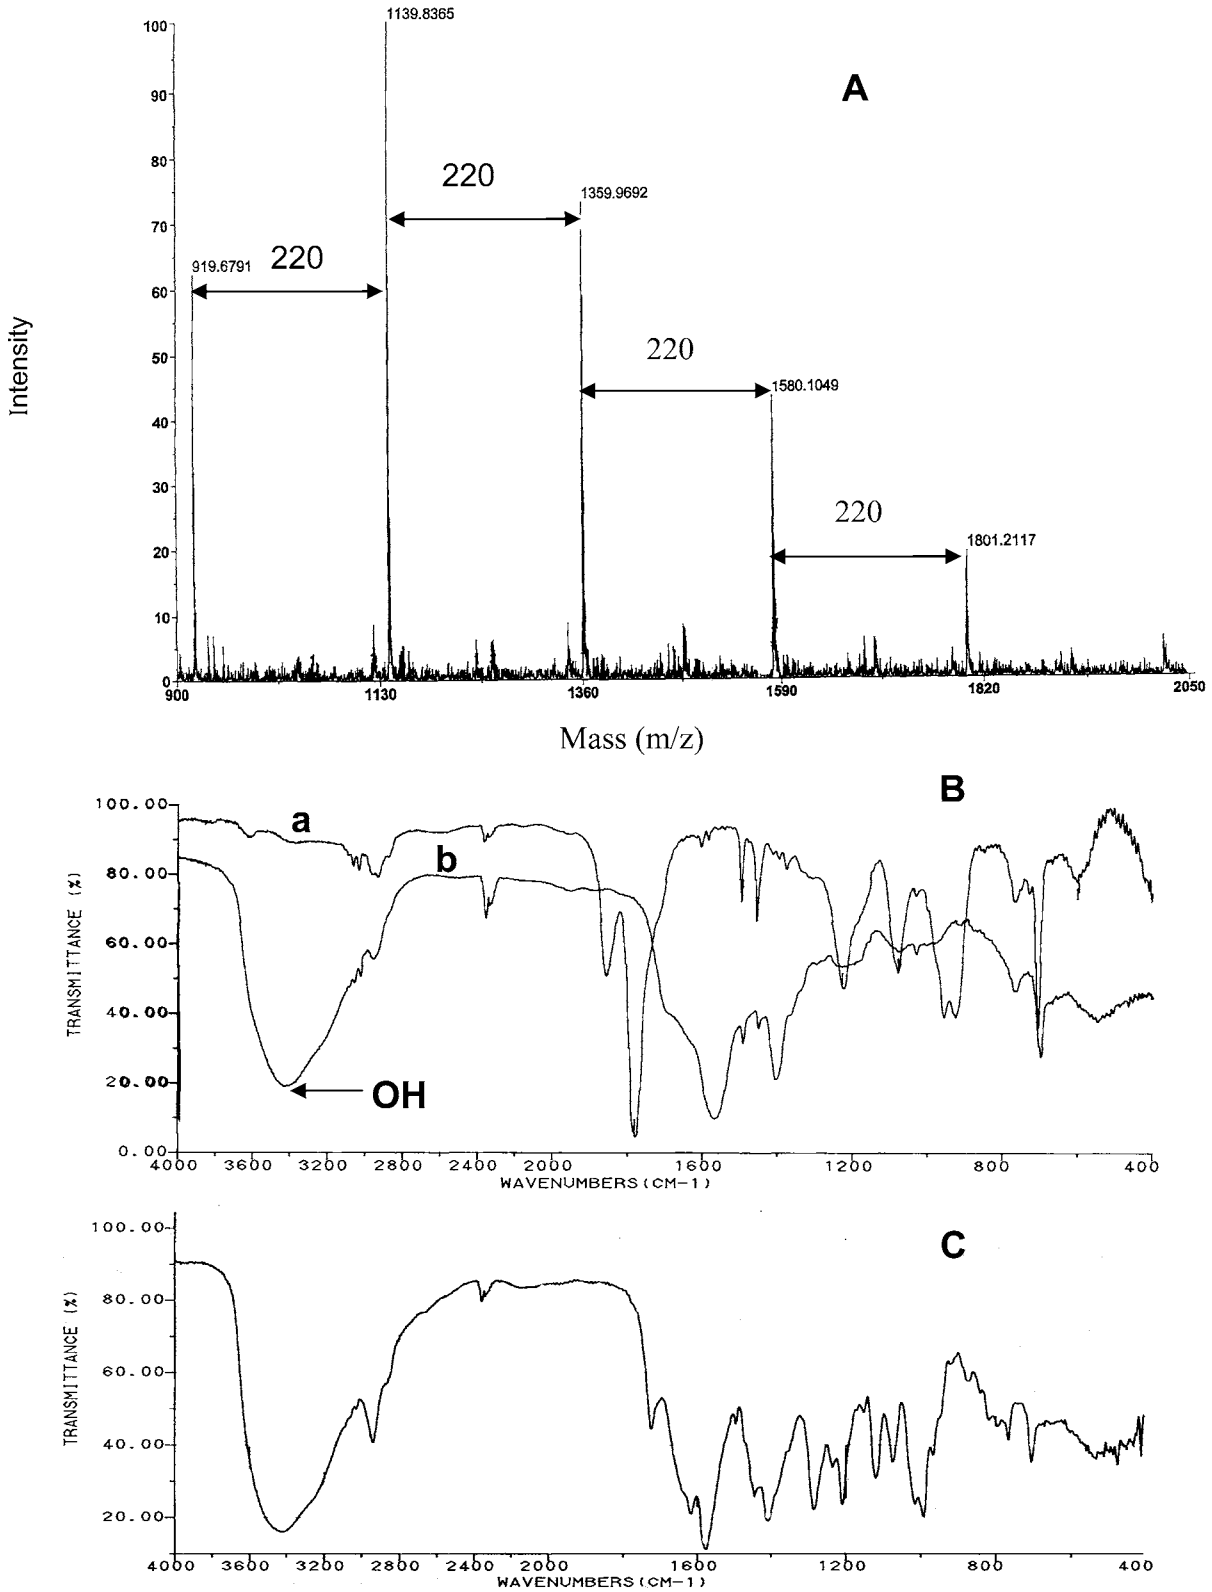

Figure 2. (A) MALDI-TOF mass spectra of styrene maleic acid. The increment of the molecular size of each unit from 202 to 220 Da clearly indicates integration of the H_2O molecule. (B) IR spectra of anhydrous SMA before (a) and after (b) hydrolysis. The appearance of a strong OH signal at 3434 cm^{-1} indicates hydrolysis of anhydrous SMA (a) to the water-soluble styrene-maleic acid (b). (C) IR spectrum of SMA−THP micelles.

10% fetal calf serum. The cells were then incubated in the presence of free THP or SMA−THP micelles for 3 days. Toxicity was quantified as the fraction of cells surviving relative to untreated controls.

Evaluation of the Antitumor Effect of SMA−THP Micelles in an Animal Tumor Model. Mouse sarcoma S-180 cells (2×10^6 cells), maintained as an ascitic tumor in ddY mice, were implanted subcutaneously in the dorsal skin of 6-week-old ddY mice each weighing 30−35 g. On day 7 after tumor cell inoculation, when tumor size was 5−7 mm in diameter but contained no necrotic areas, iv injections of free THP or SMA−THP micelles, in distilled

water at the desired concentration, were administrated into the tail vein in four equal doses every other day. Concentrations of the solutions were standardized via visible absorbance at 487 nm. All experiments were carried out according to the guidelines of the Laboratory Protocol of Animal Handling, Kumamoto University. Tumor growth was measured every 2 days by size of the tumors with a digital caliper, the tumor volume (V) being estimated by using the measured longitudinal cross section (L) and transverse section (W) according to the formula,

$$V = (L \times W^2)/2$$

The day of tumor implantation was set as day 0; the tumor volume was expressed in cm^3.

Side Effects of Treatment with SMA−THP Micelles. Mice with S-180 tumors of about 5−7 mm in diameter were used for this study. Either free THP or SMA−THP micelles were administered as described above. One, two, and three weeks after drug administration, 20 μL samples of blood were collected from the medial canthus for complete blood counts by means of an automated blood counter (F-800 Microcell Counter, Toa Medical Electronics, Kobe, Japan). For measurements of alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, and total creatine kinase, mice were killed 36 h after administration of either free drug or micellar THP, and 1 mL samples of blood were obtained from the inferior vena cava. Blood was kept at 0 °C until centrifugation at 4 °C, 3000 rpm for 15 min, and plasma was separated and stored at −80 °C until analyses by use of the Auto Analyzer system (Hitachi Ltd., Tokyo, Japan). At the time of blood collection, tissue specimens (heart, spleen, liver, and kidney) were also obtained; reperfusion with 20 mL of physiological saline containing heparin (5 units/mL) had been performed to remove blood components in blood vessels of the tissues. These tissue specimens were fixed in formalin and then embedded in paraffin and stained with hematoxylin−eosin (H&E).

Statistical Analyses. All data were expressed as means ± SD. Student's t-test was used to compare differences between experimental groups.

RESULTS AND DISCUSSION

Synthesis of SMA−THP Micelles. In the present study, we found that SMA, the styrene moiety of the amphiphilic polymer, formed a complex with pirarubicin (THP) to yield SMA−THP micelles. We also found that hydrolysis of SMA was essential for this complex formation: the hydrolyzed SMA was highly water-soluble and could form micelles rapidly. Treatment of anhydride acid of SMA with alkali resulted in the opening of the maleic anhydride ring in SMA via hydrolysis and the addition of an OH group, as evidencd by a 3400 cm^{-1} signal in the IR spectrum (Figure 2B,C) and an increase in the unit molecular size of SMA from 202 Da (styrene-maleic anhydride) to 220 Da (styrene maleate) because of the addition of 18 Da of H_2O (Figure 2A).

The loading efficiency of THP in the micelles was rather high: the micelles contained 60% (w/w) THP, as determined by spectroscopy and elemental analysis (i.e., N, C, and H content). The yield of drug from the micelles was more than 80% (by weight). It is most likely that the surface of the micellar outer shell has the polar, ionized carboxyl group of the maleic acid and the inner core consists mainly of the hydrophobic styrene group and pirarubicin chromophore.

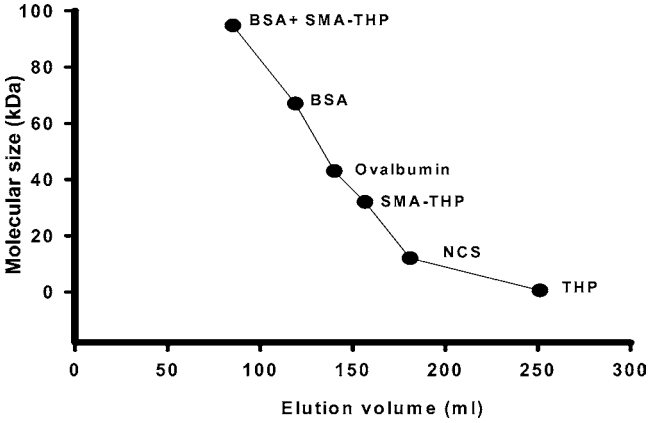

Figure 3. Average molecular size of SMA−THP micelles compared with standard molecular size markers. Sephadex G-150 Fine gel was used with a 2.5 × 64 cm column; each fraction was eluted with 0.2 M $NaHCO_3$, pH 8.2. BSA, bovine serum albumin; NCS, neocarzinostatin.

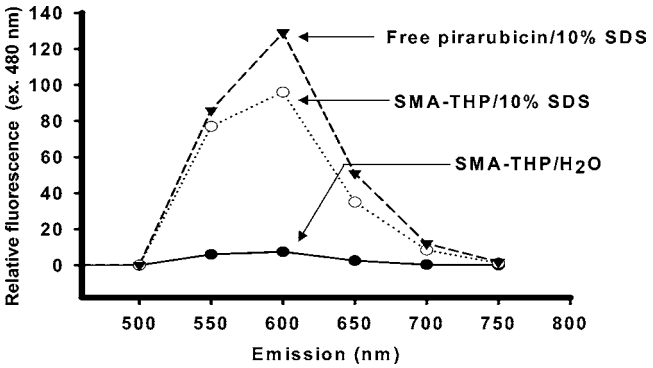

Figure 4. Change in fluorescence intensity of SMA−THP compared with that of free THP. SMA−THP micelles or free THP, each at 10 μM, was prepared in distilled water or in 10% SDS. Each solution was excited at 480 nm, and the resulting fluorescence emissions at 450−750 nm were recorded.

As shown in Figure 3, the SMA−THP micelles had a clearly increased molecular size compared with free pirarubicin. The average molecular size of the micelles was approximately 34 kDa (Figure 3), as determined by Sephadex G-150 column chromatography. The molecular size of the micelles increased to about 94 kDa when bovine serum albumin (40 mg/mL) was added, which indicates binding of SMA−THP to albumin (Figure 3).

Studies on Micellar Formation. Our initial intent regarding the SMA−THP complex was to induce covalent cross-links between the amino group of pirarubicin and the carboxyl group of maleic acid in SMA by treatment with EDAC, facilitated by a dehydration reaction to produce a carboamide linkage (*5*). However, this reaction did not proceed. In contrast, as described above, SMA and THP formed micelles, as evidenced, in part, by the ease with which free THP was liberated from the SMA−THP micelles without the use of harsh hydrolytic conditions, that is, by either ethanol or 10% sodium dodecyl sulfate (SDS) (Figure 4). IR spectroscopy of SMA−THP micelles showed the absence of signals corresponding to amide I and amide II, in contrast to other cases in our study (*31*). Furthermore, we found that other polyamines used instead of EDAC could serve a similar catalytic function for molecular orientation during formation of SMA micelles (not shown).

When excited at 480 nm, free THP showed intense fluorescence emission with a maximum peak between 550 and 600 nm (maximum at about 590 nm) (Figure 4). This

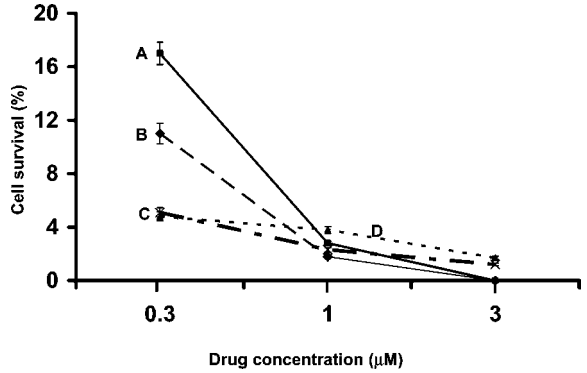

Figure 5. In vitro cytotoxicity of SMA−THP compared with that of free THP in MCF-7 and SW480 cells. (A) SMA−THP in MCF-7 cells. (B) Free THP in MCF-7 cells. (C) SMA−THP in SW480 cells. (D) Free THP in SW480 cells. Cells were exposed to free drug or to SMA−THP for 3 days. Cell viability was determined by the MTT assay. Values are means ± SD; n = 12.

fluorescence was almost completely quenched when the THP molecules were closely attached to or interacting with other aromatic molecules, the styrene moiety of SMA, in the binding pocket of albumin (or other proteins), or other high-affinity species (*32*). We thus anticipated that the energy transfer from the THP chromophore to aromatic residues of styrene in the micelles would result in efficient quenching and suppression of fluorescence. Figure 4 shows that, in fact, the fluorescence spectrum of the SMA−THP complex was markedly quenched when compared with that of the free drug, perhaps because the THP molecules form part of the core of the SMA−THP micelles, or are in very close contact with SMA (or styrene). The fluorescence intensity was restored when the micelles were disrupted by exposure to 10% SDS, which destroyed the micellar association between the anthracycline ring and the hydrophobic styrene residue of SMA.

Consequantly, Sephadex G-50 chromatography showed that SMA−THP exposed to 10% SDS had a distinctly smaller molecular weight equivalent to free THP, compared to the untreated micelles (data not shown).

Free Drug Release from SMA−THP Micelles. Free pirarubicin was released very slowly from the SMA−THP complex in aqueous media, about 3% per day at pH 7.4 and 4% per day at pH 5.5, which indicated higher stability of the micelles at neutral pH. When the solution outside the dialysis tubes was replaced by ethanol, the release rate increased markedly, which indicates that disruption of the micelles occurred, as described above. This stability of the micelles at physiological pH would thus prevent rapid release of free THP from micelles during circulation. The free drug would not be able to gain access to critical organs and tissues, which would be protected from the toxic effects of THP. Such stable micelles or macromolecular drugs will also benefit the functioning of the EPR effect for SMA−THP: the slower drug release rate during circulation than the rate of drug uptake into tumor ensured a greater antitumor effect without systemic toxicity.

In Vitro Biological Activity of SMA−THP Micelles. As shown in Figure 5, the cytotoxic effect of SMA−THP micelles on MCF-7 and SW480 cells was quite similar to that of free drug (93−101%) after 72 h of incubation. However, lower in vitro cytotoxicity is known for other polymeric anthracycline conjugates or complexes such as hydroxypropyl methacrylate copolymer-conjugated doxorubicin, (*33*, *34*). To explain the cause of

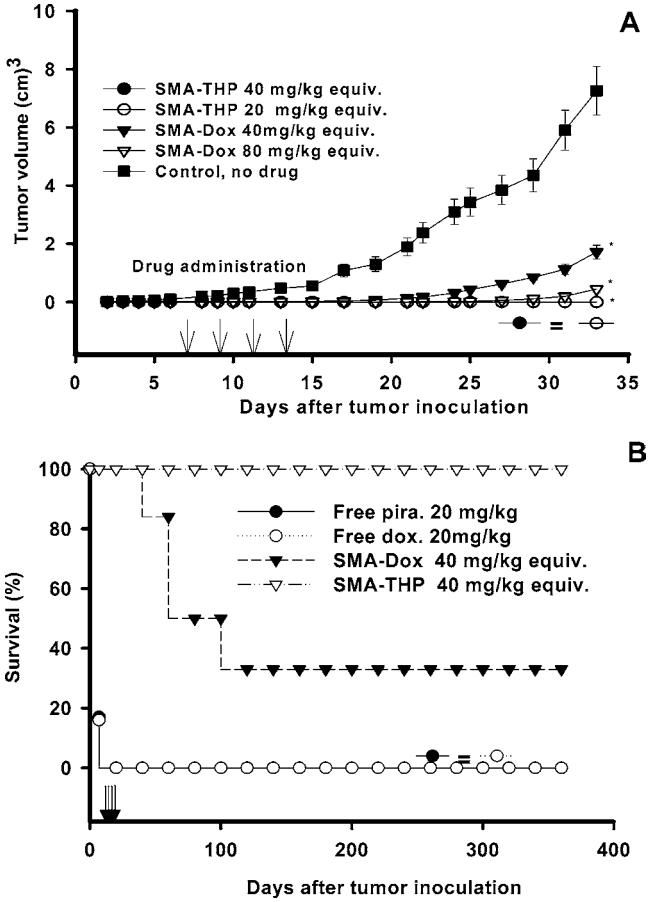

Figure 6. (A) Antitumor effect of SMA−THP micelles on implanted S-180 solid tumor in mice compared with that of control and SMA−doxorubicin micelles. Animals receiving similar dosage of free pirarubicin died within 1 week. Data are means ± SD for 12 tumors; *p < 0.001. (B) Survival of ddY mice after administration of both SMA−THP and SMA−Dox micelles compared with that after treatment with free drugs. Drugs were administered in four equal iv injections into the tail vein during a 1-week period. Observations continued for >1 year.

the similar in vitro cytotoxicity of the free drug and the micellar drug, we are currently investigating the possibility of receptor-mediated uptake, which may account for the high activity of the SMA−THP micelles. In addition to the endocytic mechanism by which most polymeric drugs operate, receptor-mediated uptake may occur: the one extra pyranyl residue in pirarubicin, compared with doxorubicin, may be involved in a receptor-mediated transport (*35*).

Antitumor Activity of SMA−THP Micelles in Vivo. For evaluation of antitumor activity tumor volume was measured in ddY mice bearing S-180 tumors for more than 30 days (Figure 6A), and survival of these mice was followed for more than 300 days as (Figure 6B). Treatment with SMA−THP micelles at two dosages, 20 and 40 mg/kg of free THP equivalent (given in four equal injections), completely suppressed tumor growth. All mice treated with SMA−THP micelles were tumor free. This finding is in great contrast to treatment with free THP, at 10 mg/kg total dose, which caused all mice to die within 1 week because of toxicity. In addition, mice given the 40 mg/kg of free THP equivalent dosage of the SMA−THP micelles demonstrated 100% survival for more than 300 days without any delectable tumor.

Potential Toxicity of SMA−THP Micelles. Tables 1 and 2 show results of blood assays and cardiac and liver function tests for mice receiving 33 mg/kg SMA−THP

Table 1. Blood Analysis for ddY Mice Receiving a Single Dose of 10 mg/kg Free Pirarubicin or 20 mg/kg Pirarubicin Equivalent as SMA−THP[a]

drug treatment	time when measured	hemoglobin (g/dL)	white blood cell count (cells/μL)	platelet count (/mm^3)
control		14.9 ± 1.3	8012 ± 1559	132.8 ± 15.3
free pirarubicin	1 week[b]	11.1 ± 2.6[c]	2533 ± 305[c]	67.6 ± 2.5[c]
SMA−THP	1 week	15.0 ± 2.5	6016 ± 1622	141.3 ± 16.1
	2 weeks	14.1 ± 1.6	5900 ± 2128	130.3 ± 10.9
	3 weeks	15.9 ± 0.4	6366 ± 1903	120.0 ± 32.5

[a] Values are means ± SD; n= 4. [b] Only one animal survived after the first week. [c] The difference from the control was statistically significant ($p < 0.05$).

Table 2. Liver Function and Cardiac Enzyme Assays for ddY Mice Receiving a Single Dose of 10 mg/kg Free Pirarubicin or 20 mg/kg Pirarubicin Equivalent Dose as SMA−THP[a]

drug treatment	CK (U/L)	LDH (IU/L)	ALT (IU/L)	AST (IU/L)
control	309 ± 42	260 ± 62.4	37 ± 12	81 ± 7.3
free pirarubicin	1704 ± 102[b]	634 ± 58[b]	53 ± 8.2	239 ± 18[b]
SMA−THP	381 ± 35	318 ± 42	58 ± 11	73.5 ± 6

micelles (20 mg/kg free pirarubicin equivalent) and for mice receiving 10 mg/kg free pirarubicin. The values obtained for mice receiving the micellar drug (33 mg/kg) were not statistically different from those of normal healthy mice. In contrast, animals receiving free pirarubicin showed serious side effects, with significant differences from the control group without drug on all measurements.

All S-180 tumor-bearing mice receiving a total dose of 166 mg/kg of the micellar preparation (100 mg/kg free pirarubicin equivalent), by four iv injections (41.5 mg/kg × 4) in 1 week, or 133 mg/kg as a single iv bolus, survived for more than 12 months. In contrast, mice receiving a total dose of 20 mg/kg free THP by four iv injections (5 mg/kg × 4) had a much reduced survival: 83% died within 1 week and the remaining 17% died within 3 weeks (Figure 6B).

The reduced toxicity of the micelles can be attributed to the EPR effect and tumor-selective drug targeting. This EPR effect is a molecular size-dependent phenomenon, which is seen for molecular sizes above M_r 40 000 (*8*, *9*). For example, molecular size of THP with biocompatible SMA, which binds with albumin, becomes larger (Figure 3). Such large macromolecules leak out of tumor vessels into tumor tissues (interstitium) and remain sequestered in the vicinity of the tumor as a result of anatomical and pathophysiological abnormalities of tumor tissues, i.e., by EPR effect (*5*, *8*, *11*, *36*−*41*). The dependence on molecular size of drug uptake into tumor is inversely correlated with the renal clearance of small molecular compounds (*5*, *8*−*11*). Therefore, the SMA−THP micelles, with an apparent molecular size in plasma of 94 kDa, will remain in circulation and, as a result of the EPR effect, lead to more selective targeting of drug to tumor.

Pathological examination of cardiac tissue by H&E staining showed extensive inflammation in animals receiving injections of free THP (5 mg/kg × 4), whereas tumor-bearing mice receiving SMA−THP (41.5 mg/kg × 4) showed no abnormalities. This high safety profile of these SMA−THP micelles can be attributed to the nature of the distribution of polymeric drugs (i.e., the EPR effect). In our previous work, we showed that SMA−doxorubicin micelles accumulated in tumors 13-fold more than that did free doxorubicin. Further more, doxorubicin delivered to cardiac tissue after administration of these micelles was only 8%. However, as is evident from results presented in Figure 6A and B, the new SMA−THP micelles had a far better antitumor effect, with even lower doses of the micellar drug, and produced longer survival; these effects may be attributed to better targeting of drug to tumor and improved accumulation of drug in tumor (*29*). This EPR effect-dependent distribution profile (high drug concentration in tumor but low drug level in normal tissues) ensures a higher margin of safety for normal organs and tissues, the end result being safer dose escalation of the SMA−THP micelle preparation, up to 15 times higher than the maximum tolerable dose of free pirarubicin.

In addition to its pharmacokinetic and pharmacodynamic advantages, SMA is known to confer immunopotentiating effects, such as activation of macrophages, T-cells, and natural killer cells, and induction of interferon (*25*−*28*). These immune system modifications can be considered another benefit of SMA-based micelles.

In summary, the present study described the preparation and characterization of SMA−THP micelles, the antitumor effect of this formulation, and preliminary safety data in mice. Further study of this micellar preparation is warranted.

ACKNOWLEDGMENT

The authors thank both Judith Gandy and Yukiko Koga for their valuable editorial help in the manuscript. This work was supported in part by Grants-in-Aid for Cancer Research to H.M. from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

Conjugation of DOTA Using Isolated Phenolic Active Esters: The Labeling and Biodistribution of Albumin as Blood Pool Marker

Walter Mier,*,† Johannes Hoffend,† Susanne Krämer,† Jochen Schuhmacher,‡ William E. Hull,‡ Michael Eisenhut,‡ and Uwe Haberkorn†

Department of Nuclear Medicine, Universitätsklinikum Heidelberg, INF 400, 69120 Heidelberg, Germany, and German Cancer Research Center, 69120 Heidelberg, Germany. Received November 28, 2003; Revised Manuscript Received September 28, 2004

A convenient method for the functionalization of proteins with DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) has been developed. For this purpose DOTA was converted into a series of different monoreactive activated phenolic esters. The esters were prepared in a single step from commercially available DOTA, using 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide or 1,3-dicyclohexylcarbodiimide as coupling agent. The resulting activated esters were isolated by HPLC, lyophilized, and stored for future applications. In solid form the compounds exhibit high hydrolytic stability. The reactions with proteins proceeded in good yields. The conjugation and subsequent radiolabeling of the 4-nitrophenol ester of DOTA with ^{67}Ga was investigated with rat serum albumin. A time-dependent biodistribution study in tumor bearing rats was conducted to demonstrate the integrity of the albumin conjugate. These results suggest that phenolic esters of DOTA represent versatile reagents to conjugate DOTA with proteins and other biomolecules in high yields.

Bifunctional chelating agents have been shown to be potent ligands for the labeling of molecules such as peptides and antibodies with radioactive isotopes or paramagnetic metals. As there is strong interest in the development of these agents, for example for the application of radioactive metals toward "targeted" diagnosis and therapy of cancer, a variety of bifunctional chelating agents have been synthesized and summarized in a review (*1*).

DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid) is known to complex a large number of main group and transition metal ions with extremely high stability constants, coordinating, for example, Y^{3+} with the four cyclic nitrogens and the three carboxylates. Because of their high stability constant, metal complexes of DOTA conjugates exhibit better in vivo stability than other chelates such as DTPA (diethylenetriaminepentaacetate).

Potential classes of molecules, which can be conjugated to the chelating agents, are peptides, saccharides, nucleic acids, and proteins. However, the convenient high yield protocols for the conjugation of chelating agents to biomolecules still need to be improved. These conjugation protocols are needed for diagnostic and therapeutic applications as well as for screening peptides in radiopharmaceutical research.

At present, the preferred derivatives of DOTA for the conjugation to proteins are the isothiocyanate *p*-isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid and esters of NHS (*N*-hydroxysuccinimide) that can be obtained by in situ activation (*2*). The in situ activation of the chelating agents leads to a mixture of mono- and multiply activated chelating agents which may react to more than one target molecule. As a consequence, the conjugation reaction is prone to the formation of intra- or intermolecular cross-links. To secure the formation of defined products, extensive efforts have been made to optimize the reaction conditions. Under these conditions, reactions with less than 1% of intermolecular cross-linked species are achievable (*3*). The reaction of more than one carboxylic acid of the chelating agent might lead to a decrease of complex stability. To optimize the in situ activation, the reaction mixture must contain a large excess of chelating agent (typically a 100-fold excess). This excess of chelating agent can nonspecifically aggregate to the target molecules. These aggregates may prolong the purification step and dissociate in vivo, leading to an undefined biodistribution of the label.

Another possibility is to generate spacer-modified chelating agents carrying active groups such as isothiocyanate for the conjugation with target molecules (*4, 5*). This approach necessitates a sophisticated, laborious synthesis of the precursor molecules. Advances have been made to develop spacer-modified linkers that allow the modulation of the pharmacokinetics of the chelator conjugates (*6, 7*). Several other methods for the specific conjugation of DOTA have been developed (*8*−*12*). Defined products of chelating agents with target molecules can be obtained by using selectively protected chelating agents (*13*). The remaining unblocked functional group can then be used for conjugation with the target molecule. However, the synthesis of the partially protected precursor is laborious, and after conjugation, a deprotection step is needed which leads to the denaturation of sensitive biomolecules, in particular in the case of proteins.

The application of activated monoesters represents an efficient method for the preparation of DOTA−protein conjugates. Because of the lability of these compounds, only limited information is available for the preparation, purification, and analysis of the active esters of DOTA.

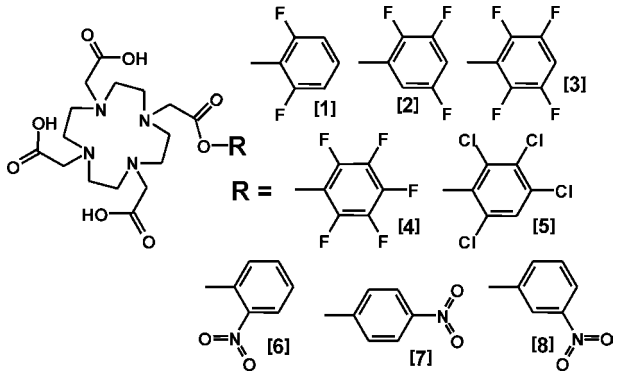

Figure 1. Chemical structures of the active esters of DOTA investigated.

Hitherto the NHS-ester and its water soluble derivative, the sulfo-NHS-ester, were the only active esters of DOTA described in the literature. During our investigations, an elaborate synthesis of the tetrafluorophenyl ester of DOTA was described (*14*). Other activated esters have not yet been reported. As compared to NHS-esters, phenolic esters (*15*, *16*) offer the advantage of an aromatic chromophore favoring UV detection during HPLC separation. These reasons prompted us to develop a straightforward synthesis of a DOTA monoester applicable for conjugation in solution or for solid-phase syntheses (*17*).

Because of the low solubility of unprotected DOTA under nonaqueous conditions, the reaction was conducted in aqueous solution containing acetonitrile using the water-soluble carbodiimide 1-ethyl-3-[3-(diamino)propyl]-carbodiimide × hydrochloride (EDAC) or diisopropylcarbodiimide as condensing agent. Another possibility is the synthesis using higher concentrations of the cosolvents such as acetonitrile or DMF. In this case, the carbodiimide *N*,*N*′-dicyclohexylcarbodiimide (DCC) can be used as a condensing agent. The highest yields of the phenolic esters could be obtained using stoichiometric amounts of DOTA, the substituted phenol and EDAC, or DCC.

The activated esters were obtained by dissolving 500 mg (1.24 mmol) of DOTA (Fluka, Taufkirchen, Germany) in 10 mL of water. A solution of 1.24 mmol of the particular phenol in 8 mL of acetonitrile was added. A solution of 255 mg (1.24 mmol) of *N*,*N*′-dicyclohexylcarbodiimide in 8 mL of pyridine was added dropwise with vigorous stirring. The reaction mixture was stirred for 90 min and concentrated to dryness under reduced pressure. The residue was taken up in 20% acetonitrile in water. The suspension was filtered to remove *N*,*N*′-dicyclohexylurea, and the filtrate was lyophilized. RP-HPLC (RP-select B column 10 μm, 250 × 10 mm Merck, Darmstadt, Germany) with a linear gradient from 0 to 60% acetonitrile (flow = 4 mL/min over 15 min) afforded the pure activated esters (34−65% yield) after lyophilization. Under these conditions, the monoactivated phenolic esters could be formed with surprisingly high selectivity. Compounds **1**−**8** (Figure 1) were characterized by analytical HPLC-chromatography and mass spectrometry. MALDI-MS or ESI-MS (*m*/*z*) for $[M + H]^+$: observed (calculated): **1** = 518 (517.49), **2** = 535 (535.48), **3** = 552 (553.47), **4** = 572 (571.47), **5** = 619 (619.29), **6** = 527 (526.51), **7** = 527 (526.51), **8** = 527 (526.51). The DOTA-bis-phenol-esters were the major byproducts formed under these conditions. The purification proved to be uncomplicated because the product eluted as a single peak. The HPLC profiles of a typical reaction mixture are shown in Figure 2A. The reaction mixture obtained with PNP and DCC is shown as a second example in Figure 2B. Using 2 equiv of DCC, the proportion of multiply activated species is strongly increased. The identity of the lyophilized compounds was further proven by NMR spectroscopy of **7**. This NMR analysis turned out to be complicated because several stable conformers result in broad signals at ambient temperature. At high temperature (373.5 K), a good resolution was achieved (Figure 3).

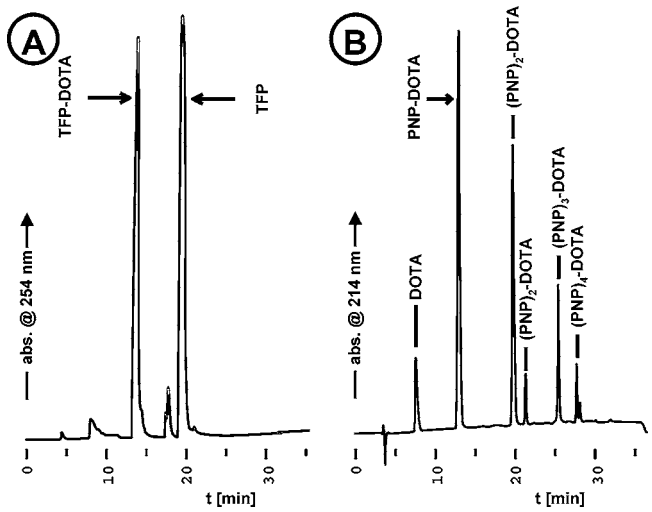

Figure 2. Reverse phase HPLC profiles of two representative reaction mixtures [A] TFP + EDAC and DOTA (1:1:1) and [B] PNP + DCC and DOTA (1:2:1) on a LiChrospher RP-select B 5 μm, 250 × 4 mm column (Merck, Darmstadt, Germany) using a linear gradient from 100% H_2O to 100% acetonitrile (both containing 0.1% TFA) in 30 min, flow rate: 0.7 mL/min).

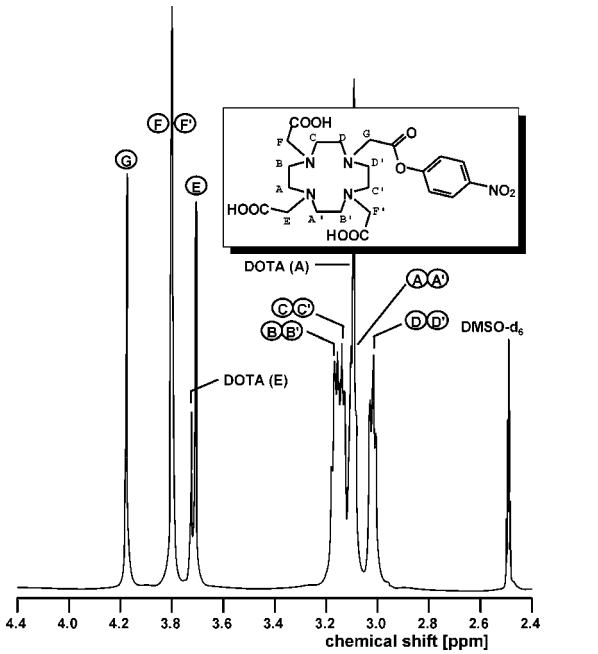

Figure 3. ^{1}H NMR spectrum (aliphatic hydrogens) of **7** in DMSO-d_6 at 80 °C. At high-temperature hydrolysis is observed to yield DOTA (signals A and E).

To characterize the feasibility of these esters, the rate of hydrolysis under different pH conditions was examined at room temperature. As the hydrolysis competes with the aminolysis (which leads to the amide-bonded product), this pH-dependent stability investigation allows the choice of appropriate reaction conditions for an active ester chosen. The comparison of the stability of **1**, **3**, and **7** and the NHS-ester of DOTA obtained from Macrocyclics (Dallas, TX) is shown in Figure 4. As expected, there is

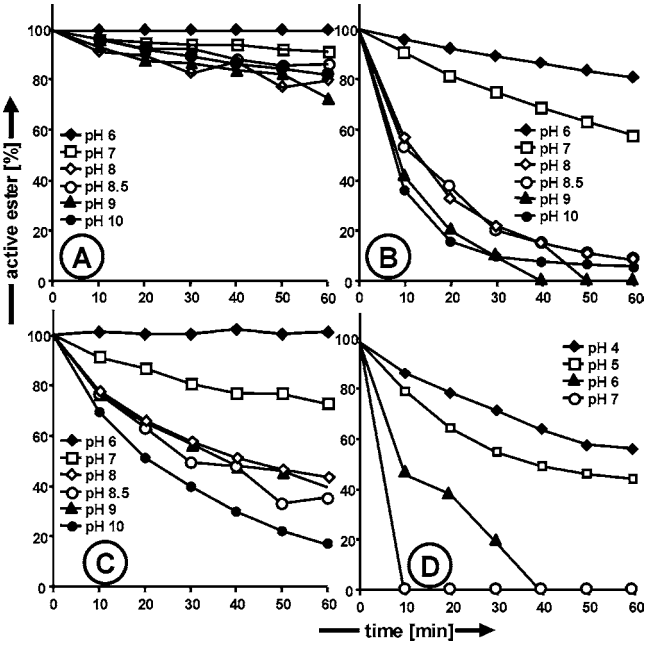

Figure 4. Stability of the phenolic esters **1** [A], **3** [B] and **7** [C] as compared to the NHS-ester of DOTA [D] in aqueous solution under a range of pH conditions. The active esters **1**, **3** and **7** were dissolved at a concentration of 1 mg/mL in borate buffer, the NHS-ester of DOTA was dissolved in citrate buffer. At various time points samples were taken and the concentration determined by RP-HPLC.

a substantial difference between the esters **1** and **3**. Whereas for **1** a relative high stability was found for pH values from 6 to 10, for **3** a slow cleavage was found even at neutral pH-values. The ester **7** revealed a stability profile which appears to be suitable for conjugation reactions at pH values from 7 to 9. The NHS-ester was rapidly hydrolyzed at neutral pH values.

The DOTA conjugation using active phenolic esters was utilized for the modification of rat serum albumin. Albumin was chosen because of the potential utility of albumin-derived radiotracers for making blood pool corrections for myocardial perfusion imaging as well as for the characterization of angiogenetic tumors.

The conjugation reaction was carried out by adding a solution of 10 mg of rat serum albumin (Sigma, Taufkirchen, Germany) in 0.1 M phosphate buffer pH 8.0 to 10 equiv of the lyophilized DOTA-phenolic ester (e.g. 875 μg of **7**). The components were mixed and incubated at room-temperature overnight. The conjugate was purified by gel filtration on a Superdex 75 column (Amersham Pharmacia, Freiburg, Germany) eluted with 0.05 M sodium phosphate 0.15 M NaCl buffer at pH 7. The eluted product was concentrated by 10 kDa molecular weight cutoff ultrafiltration membrane centrifugal filter devices (Amicon Ultra, Millipore). Protein concentrations were quantitated by the Bradford method (*18*).

The labeling was achieved by incubating the DOTA−albumin conjugate (obtained from **7**) with $^{67}Ga^{3+}$ chloride (Bristol-Myers Squibb) in 0.1 M ammonium acetate buffer pH 5 for 6 h at 42 °C. The labeling efficiency of the preparations was >90% as assessed by size exclusion HPLC under the conditions described above. Purification of the labeled compound by size exclusion HPLC led to a product typically with >98% of the radioactivity corresponding to ^{67}Ga-DOTA−albumin.

The number of functional chelates per albumin molecule was determined by isotopic dilution titration using trace amounts of $^{67}Ga^{3+}$ in the presence of a range of concentrations of 'cold' Ga^{3+} in 0.1 M ammonium acetate buffer pH 5.0. After 12 h at 42 °C, excess of DTPA was added and the amount of albumin-bound ^{67}Ga determined by TLC (ITLC−SG, Pall, Dreieich Germany) using 0.9% NaCl in water as the mobile phase. This analysis revealed that the conjugation of DOTA using **7** was effective with an approximate reaction-to-hydrolysis ratio of 1:4. A standard batch obtained from the reaction of 10 mg rat serum albumin with 760 μg of **7** (10 equiv of activated ester) resulted in approximately two functional DOTA chelates per albumin molecule.

The biodistribution of ^{67}Ga-DOTA−albumin was evaluated in male ACI rats bearing subcutaneous MH3924A Morris hepatoma (*19*). The experiments were performed in compliance with German laws relating to the conduct of animal experimentation. Tumor cells (4×10^6) were transplanted subcutaneously into the right thigh of male young adult ACI rats weighing 200−250 g and grown for approximately three weeks to a volume of 1.5 cm in diameter. A solution of ^{67}Ga-DOTA−albumin (2 MBq in 0.2 mL) was intravenously injected via the lateral tail vein. At selected times, rats were sacrificed and the radioactivity contained in the blood, heart, spleen, liver, kidney, muscle, brain, and tumor was measured in a γ-counter (Canberra Packard, Rüsselsheim, Germany) and expressed as a percentage of injected dose per gram of tissue (%ID/g) (Figure 5). Three rats were used for each

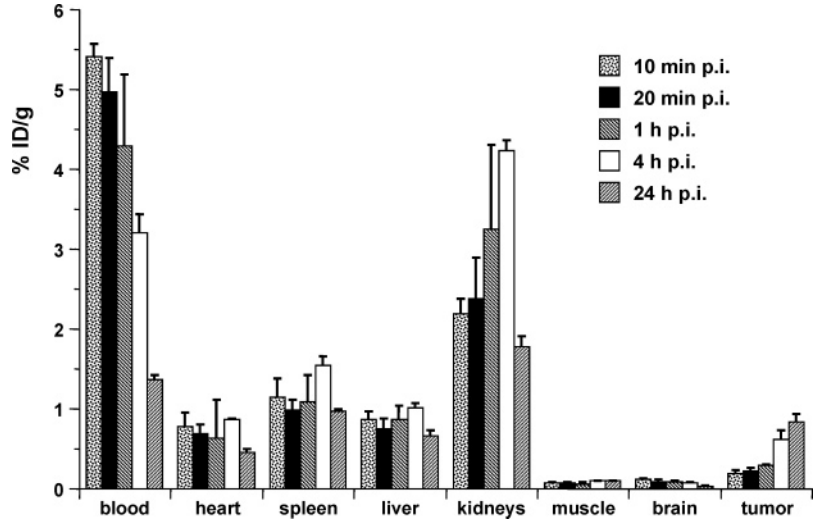

Figure 5. Time dependent organ distribution of ^{67}Ga labeled rat serum albumin in hepatoma-bearing rats.

time point. The data were in accordance with literature data obtained for both ^{125}I-labeled and ^{67}Cu-labeled benzyl-TETA albumin (*20*). As compared to ^{67}Cu-labeled benzyl-TETA-HSA a significantly lower liver uptake was observed (0.86%ID/g vs 2.37%ID/g) because of the intense hepatic metabolism and retention of copper radioisotopes.

Owing to the long circulation time, albumin can also be used as a high molecular weight carrier for drug delivery purposes. However, the biological half-life of albumin is known to be sensitive to high loading ratios (*21*). The best results were obtained with an approximate 1:1 cargo-to-albumin ratio (*22*). A higher number of molecules conjugated to albumin causes alterations of the secondary and tertiary structure, consecutively triggering the rapid sequestration by the monocyte−phagocyte system. The long circulation times allow albumin to passively accumulate in the tumor through the Enhanced Permeability and Retention (EPR) effect (*23*). This phenomenon is due to the increased permeability of tumor vasculature that permits large macromolecules to extravasate into the tumor tissue where they are retained due to an impaired reticuloendothelial/lymphatic clearance of macromolecules.

In summary, the method described here transforms the commercially available DOTA to useful active esters (**1** to **8**) which after purification can be stored and used for DOTA conjugation reactions. The stability of these active esters is suitable to optimize protocols for an efficient, controlled conjugation to proteins, peptides, and other molecules of biological interest, without the necessity of subsequent removal of protecting groups.

Coupling Biomolecules to Fullerenes through a Molecular Adapter

Marcello Capaccio, Vasilis G. Gavalas, Mark S. Meier, John E. Anthony,* and Leonidas G. Bachas*

Department of Chemistry and Advanced Carbon Materials Center, University of Kentucky, Lexington, Kentucky 40506-0055. Received June 15, 2004; Revised Manuscript Received December 12, 2004

A novel biotinylated fullerene has been synthesized to facilitate the attachment of biotin-conjugated proteins to C_{60} through the use of streptavidin as a molecular adapter. The strong biotin-streptavidin interaction enables the attachment of fullerenes to streptavidin and, because of the availability of four biotin-binding sites on streptavidin, to biotinylated biomolecules. The feasibility of this approach is demonstrated by using biotinylated alkaline phosphatase. Due to the insolubility of fullerenes in aqueous media, the immobilized enzyme can be eventually recovered by simple centrifugation with no significant loss in activity.

In recent years, fullerene derivatives have found applications in many fields of science and technology due to their special photophysical (strong absorption in the UV region and significant absorptions in the visible region) and electrochemical (electron accepting) properties (*1*−*3*). A variety of C_{60} derivatives have been successfully applied to biological/medical related studies (*4*−*8*). Moreover, C_{60} derivatives have some unique characteristics, related to the spherical shape and dimensions of the fullerene unit, which make them an attractive class of compounds from a biochemical point of view (*9*). For instance, the possibility of treating HIV with fullerenes has been explored by taking advantage of the complimentarily of C_{60} derivatives to structural features on HIV-1 protease, thus causing the inhibition of the enzyme (*10, 11*). An interesting example of coupling proteins and fullerenes was given in a recent report, in which the redox protein azurin was bound to a thiol-selective C_{60} derivative (*12*). Additionally, a biotinylated lipophilic fullerene was synthesized and used as a novel type of transmembrane anchor (*13*). Finally, C_{60} derivatized with a polyanionic dendrimer (*14*) or a histone-derived peptide (*15*) has been employed to form fullerene−protein conjugates through noncovalent interactions.

We are interested in using fullerene derivatives as building blocks to create hybrid biomolecule/fullerene nanoparticles as shown in Scheme 1. Moreover fullerenes, because of their insolubility in water and their nanosize dimensions, present advantages as immobilization supports for enzyme catalysts. Their nanometer size reduces substrate diffusion limitations that are commonly encountered with macroscopic support media. We recently described a method in which a mutant subtilisin was produced (by using molecular biology methods) and subsequently bound to a maleimidopropionyl C_{60} derivative (*16*). We now report a different strategy to attach fullerenes to biomolecules that involves the use of molecular adapters. This can be achieved through a two-step coupling procedure utilizing the strong affinity of streptavidin for biotin. Unlike prior approaches of pre-

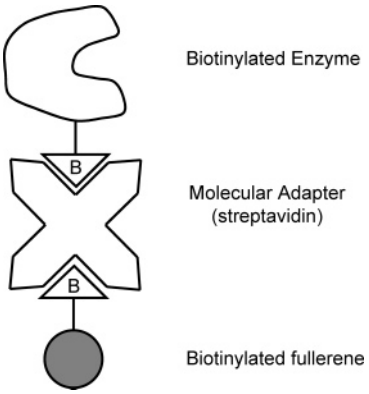
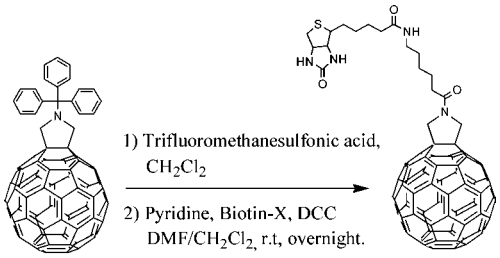


Scheme 2. Preparation of *N*-6-[(Biotinamido)-hexanoyl]-3,4-fulleropyrrolidine



paring fullerene−protein conjugates, where a fullerene derivative is reacted with functional groups on the protein of interest, this manuscript describes a versatile method to prepare these conjugates using a molecular adapter strategy.

A new biotinylated fullerene derivative, *N*-6-[(biotinamido)hexanoyl]-3,4-fulleropyrrolidine, **2**, was synthesized as in Scheme 2. *N*-(Triphenylmethyl)-3,4-fulleropyrrolidine, **1**, was synthesized and deprotected with trifluoromethanesulfonic acid as described previously (*12*, *17*). The biotin unit was added to a fulleropyrrolidine by dicyclohexylcarbodiimide (DCC) coupling of 6-((biotinoyl)-amino)hexanoic acid (biotin-X) with **1**. In particular, anhydrous pyridine (0.6 mL) was added to a sonicated suspension of **1** (40 mg in 10 mL of dry CH_2Cl_2). In a different flask, 37.2 mg (2 equiv) of biotin-X was dissolved in 8 mL of hot dry DMF and added to the suspension with stirring. A dicyclohexylcarbodiimide solution (21.4 mg in 2 mL of dry DMF, 2 equiv) was combined with the rest of the reactants at 0 °C. The reaction mixture was stirred for 30 min in an ice bath and then at room-temperature overnight. The solution was diluted with CH_2Cl_2 (30 mL) and filtered, and the filtrate was evaporated under reduced pressure. The solid residue was washed in a Soxhlet extractor first with water and then with benzene and finally with HPLC-grade pentane; after each washing step, the solid was oven-dried at 50 °C before washing it with the subsequent solvent. A brown powder was recovered from the dried thimble, and any residual solvent adhering to the solid particles was evaporated under reduced pressure. The residue was finally dried over P_2O_5 to yield *N*-6-[(biotinamido)hexanoyl]-3,4-fulleropyrrolidine (**2**, 37.3 mg, 65%). Brown solid; ^{1}H NMR (400 MHz, Me_2SO-d_6/CS_2/C_6D_6/1:1:0.5), δ 1.26 (m, 2H), 1.30 (m, 2H), 1.32 (m, 2H), 1.44 (m, 2H), 1.5 (m, 2H), 1.6 (m, 2H), 2.06 (t, 2H), 2.56 (d, 2H), 2.65 (t, 2H), 2.8 (m, 2H), 3.08 (m, 2H), 4.13, 4.3 (m, NH*CHCH*NH of bridge of biotin ring, 2H), 5.44, 5.54 (singlets, CH_2NCH_2 of pyrrolidine ring, 4H), 6.3, 6.41 (singlets, *NH*CO*NH* of biotin ring, 2H), 7.75 (t, CO*NH* of biotin side chain, 1H); *m/z* (MS-FAB) 1102 (M^-, 10%), 720 (C_{60}, 100%).

The mass spectrometric analysis shows the presence of a single biotin moiety (1102 (M^-)) in the biotinylated C_{60} (*N*-6-[(biotinamido)hexanoyl]-3,4-fulleropyrrolidine) product. This result is consistent with data obtained using a 2-anilinonaphthalene-6-sulfonic acid (ANS) displacement assay (*18*). ANS has distinct fluorescence emission and excitation spectra depending on whether it resides in the binding pocket of streptavidin. Thus, ANS could be used as a probe to evaluate the binding of biotinylated compounds to streptavidin since the wavelength of maximum emission shifts from 422 nm (ANS bound to streptavidin) to 468 nm (free ANS) upon displacement from the binding pocket of the protein. The change in fluorescence intensity at 468 nm was the same when a solution of preformed ANS/streptavidin complex was exposed to either a biotinylated fullerene solution or to an equimolar biotin solution. These data also indicate that, despite the modification of biotin at the carboxyl group, which has been shown to reduce its affinity for streptavidin (*19*, *20*), the interaction between the biotinylated fullerene and streptavidin is strong enough to displace ANS from the binding pocket of the protein.

The aminohexanoate spacer was incorporated between biotin and C_{60} to reduce the possibility of the fullerene affecting the streptavidin−biotin interaction. Indeed, it has been demonstrated previously that when bound to streptavidin, biotin lies well below the protein surface (*21*) and at a depth that is equivalent to the length of the aminohexanoate spacer (*22*, *23*).

Initially, the specificity of the binding between the biotinylated fullerene and streptavidin was determined using a fluorescein-conjugated streptavidin (SAV−FITC). A solution of SAV−FITC (2 mg/mL) was stirred with the biotinylated fullerene (0.7 mg) for 4 h at 4 °C, and then the solution was centrifuged to remove the fullerene with the attached SAV−FITC. The fluorescence signal of the supernatant was determined, which corresponded to unbound SAV−FITC. In parallel, two control experiments were performed. In one experiment, a solution of SAV−FITC (2 mg/mL) was stirred for 4 h with C_{60} (0.5 mg) at 4 °C; in a second experiment, a solution of SAV−FITC (2 mg/mL) was first stirred with an excess of biotin (10 min) to block the binding sites, and then with the biotinylated fullerene (4 h at 4 °C). In all cases, after the incubation step the solution was centrifuged to remove the bound SAV−FITC, and the fluorescence of the supernatant was recorded (proportional to the unbound protein). A fourth solution containing only SAV−FITC was stirred under the same conditions and used as a control as well. As shown in Figure 1, when SAV−FITC was incubated with the biotinylated fullerene, the amount of unbound protein was small compared to the control (Figure 1A,C). SAV−FITC did not bind to unmodified fullerene as verified by the insignificant change in the fluorescence signal in this case (Figure 1B,C). These results demonstrate that the attachment of the biotinylated fullerene to streptavidin takes place only through the biotin moiety and is not due to nonspecific interactions of the protein with the fullerene.

When the binding sites of SAV−FITC were blocked with regular biotin, the protein did not bind to the biotinylated fullerene, as confirmed by the emission spectrum (Figure 1D). This proves that the interaction of the biotinylated fullerene with the SAV−FITC occurs

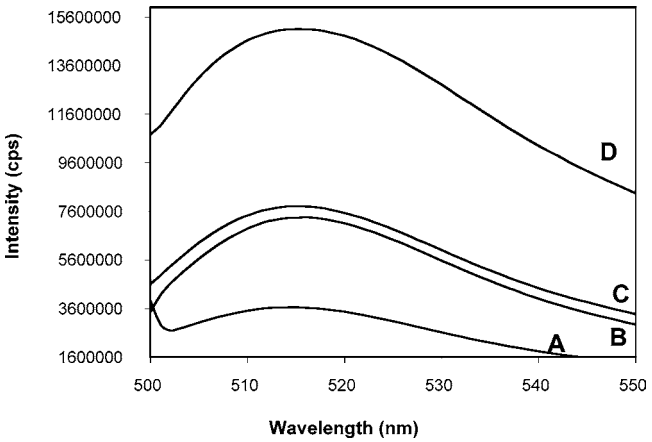


Figure 1. Fluorescence signal of supernatant solutions (λ_{ex} 490 nm) after the removal of the bound streptavidin−FITC by centrifugation. Supernatant derived from a stirred streptavidin−FITC solution: (A) with biotinylated fullerene, (B) with unmodified C_{60}, (C) untreated solution, and (D) with biotin to saturate the four binding sites first and then with biotinylated fullerene.

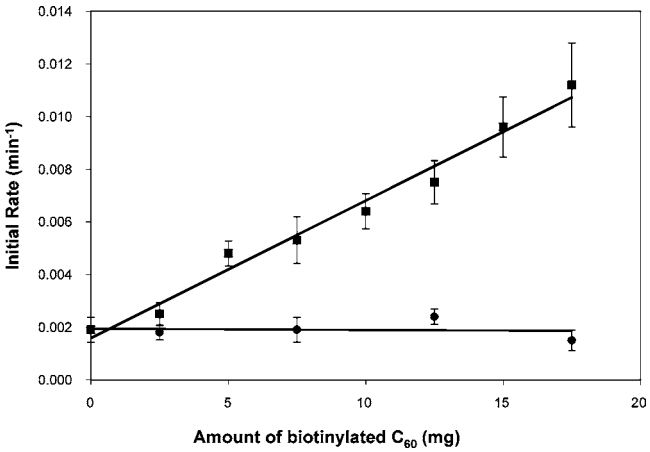

Figure 2. (■) Enzymatic activity (hydrolysis of *p*-NPP) of the hybrid fullerene−streptavidin−alkaline phosphatase nanoparticles. (●) Hydrolysis of *p*-NPP in the presence of the same amount of uncoupled biotinylated fullerene. Data are averages ± standard deviation ($n = 3$).

through the binding sites of the protein. Interestingly, in this case (Figure 1D) the signal increases upon biotin binding compared to the emission spectrum of unbound SAV−FITC (Figure 1C). This phenomenon has been observed previously with biotin binding to SAV−FITC (*24*) and has been attributed to the structural changes of SAV−FITC upon biotin binding (*21*).

The streptavidin−biotin interaction represents a very powerful means of attaching proteins to biotinylated fullerene. This approach becomes more universal if one considers the variety of biotinylated enzymes and streptavidin-conjugated enzymes that are commercially available or easily accessible through synthesis. We investigated the binding of biotinylated alkaline phosphatase to a streptavidin−biotinylated fullerene complex. Alkaline phosphatase catalyzes the hydrolysis of *p*-nitrophenyl phosphate (*p*-NPP) to give *p*-nitrophenol, which absorbs at 400 nm. The coupling reaction was performed by initially forming a complex between streptavidin and biotinylated alkaline phosphatase. In particular, a molar amount of biotinylated alkaline phosphatase, equivalent to saturating one of the four binding sites of streptavidin, was added to a solution of streptavidin in glycine buffer, pH 9.6. The 1:1 molar ratio was selected to limit any inhibitory effect of streptavidin on biotinylated alkaline phosphatase (excess of streptavidin commonly causes inhibition of biotinylated enzymes) (*23*) as well as avoid the formation of aggregates that could precipitate out of solution. After stirring for 10 min, an excess of biotinylated fullerene was added, and the suspension was sonicated at 4 °C. The suspension was then stirred overnight at 4 °C. At this point, the solid was recovered by centrifugation and washed three times with buffer to eliminate any unbound streptavidin. The solid was resuspended, and different amounts of the obtained suspension were added to a cuvette containing a solution of the *p*-NPP substrate. As a control experiment, the same amounts of unreacted biotinylated fullerene were added to a cuvette containing the same concentration of *p*-NPP. The results (Figure 2) verify that the biotinylated alkaline phosphatase was coupled to the fullerene through the streptavidin molecular adapter. Interestingly, we found that unlike suspensions of C_{60} that settle within minutes in water, the fullerene-immobilized enzyme remains in suspension for extended periods of time (several hours). This is an additional advantage of enzymes conjugated to fullerenes over those immobilized on more conventional (macroscopic) supports. It was also demonstrated that the fullerene-immobilized enzyme could be reused without any significant loss of activity. This was accomplished by combining previously used suspensions containing fullerene-immobilized enzyme. After centrifugation, the recovered solid was washed with buffer and its enzymatic activity was subsequently measured. No significant loss of activity was observed.

In conclusion, the biotin−streptavidin interaction enables the attachment of a fullerene to streptavidin and correspondingly to any available biotinylated biomolecules. This was demonstrated by using biotinylated alkaline phosphatase as a model enzyme. Overall, these studies show that streptavidin can be effectively utilized to connect biotinylated nanosized building blocks by taking advantage of its highly selective molecular recognition and affinity properties for biotin.

Preparation of a Gradient Biotinylated Polyethylene Surface To Bind Streptavidin–FITC

Moon Suk Kim,[†,§] Kwang Su Seo,[‡,§] Gilson Khang,[‡] and Hai Bang Lee*[,†]

Nanobiomaterials Laboratory, Korea Research Institute of Chemical Technology, P.O. Box 107, Yuseong, Daejeon 305-600, Korea, and Department of Polymer/Nano Science and Technology, Chonbuk National University, 664-14, Duckjin, Jeonju 561-756, Korea. Received June 16, 2004; Revised Manuscript Received February 1, 2005

A novel biotinylated gradient surface was designed to bind a streptavidin–FITC. The gradient polyethylene (PE) surface was prepared by a corona treatment with a power increase along the PE length, and successively, biotinylated gradient PE surface was prepared by the reaction of polyethylenimine (PEI) and biotin. Surface properties of the gradient PE surface changed according to PE length and chemical modification. The biotinylated gradient PE surface provided a continuous gradient of streptavidin–FITC through binding of avidin–biotin. The luminosity of fluorescence that corresponds to a streptavidin-bound FITC on the biotinylated gradient PE surface increased gradually on the surface along the PE length.

INTRODUCTION

When polymer materials are introduced in in vivo, they can act as a substrate for attaching extracellular matrix (ECM) proteins or cells but they simultaneously induce immunogenic responses (*1*–*4*). To prevent or decrease immunogenic responses, recent development of polymer materials has focused on the design of biomimetic materials that are able to recognize ECM or specific cell (*5*–*8*). The surface modification of materials was expected to be particularly useful in the design of biomimetic materials modified by bioactive molecules with biomolecular recognizable properties (*9*, *10*). The introduction of the bioactive molecules was usually performed by either physical or chemical reaction (*11*–*16*). The bioactive molecule-modified biomaterials can recognize the targetable receptor molecules that are present under biological conditions. The interactions between bioactive molecules and targetable receptors are also important for the design of biomimetic materials, because the evaluation of biomimetic materials can be affected by binding efficiency. The interactions are dependent on several factors such as the affinity between bioactive molecules and targetable receptors, the density of bioactive molecules, and the spatial distribution of bioactive molecules (*17*–*19*). Thus, the design of biomimetic materials that can selectively detect or identify targetable biomolecules as well as minimize nonspecific binding of biomolecules was a challenging subject; in addition, the designed biomimetic materials may offer the potential of biomedical applications such as biomolecular interactions (*20*–*22*), cell motility (*23*–*25*), and diagnostic studies (*26*, *27*).

However, the surface modification has some limitations. Since the surface modification has been performed on a uniform surface, the evaluation of the behavior of bioactive molecules on the biomaterial has been tediously conducted through several experiments.

a bioactive molecule is introduced on a gradient surface, the gradient bioactive molecule on the gradient surface can illustrate various results through a single experiment. This can be a powerful tool to evaluate the ability of bioactive molecules (*28*−*30*). However, there were few studies on the interaction between a gradient surface with a bioactive molecule and a targetable biomolecule.

The aim of our research was to develop a simple applicable method using gradient surfaces for biomedical applications. We present here the first approach for design of a novel gradient polyethylene (PE) surface by an incorporation of biotin and the binding of streptavidin−FITC on the biotinylated gradient surface.

RESULTS AND DISCUSSION

Corona discharge treatment is one of the useful methods for introducing functional groups and/or roughness onto a polymer surface. We recently reported the preparation of a gradient surface by radiofrequency corona discharge with knife-type electrodes and the applications as biomaterials (*31*, *32*). In this work, the chemical modification after corona discharge treatment was carried out as shown in Scheme 1. In the first step, the hydrocarbon backbone on the PE surface was activated to the carbon radicals form by the corona discharge treatment. The activated carbon radicals in the presence of oxygen provided a number of functional groups such as the hydroxyl group, ether, ketone, aldehyde, carboxylic acid, and carboxylic ester on the PE surface. Since the corona power gradually increased along the PE length, the density of functional groups gradually increased. To examine the surface property after corona treatment, the gradient PE surface was examined by water contact angle, Fourier transform infrared attenuated total reflectance (FTIR-ATR) spectroscopy, atomic force microscopy (AFM), and electron spectroscopy for chemical analysis (ESCA). The water contact angle of untreated PE surface was 99°, indicating a complete hydrophobic

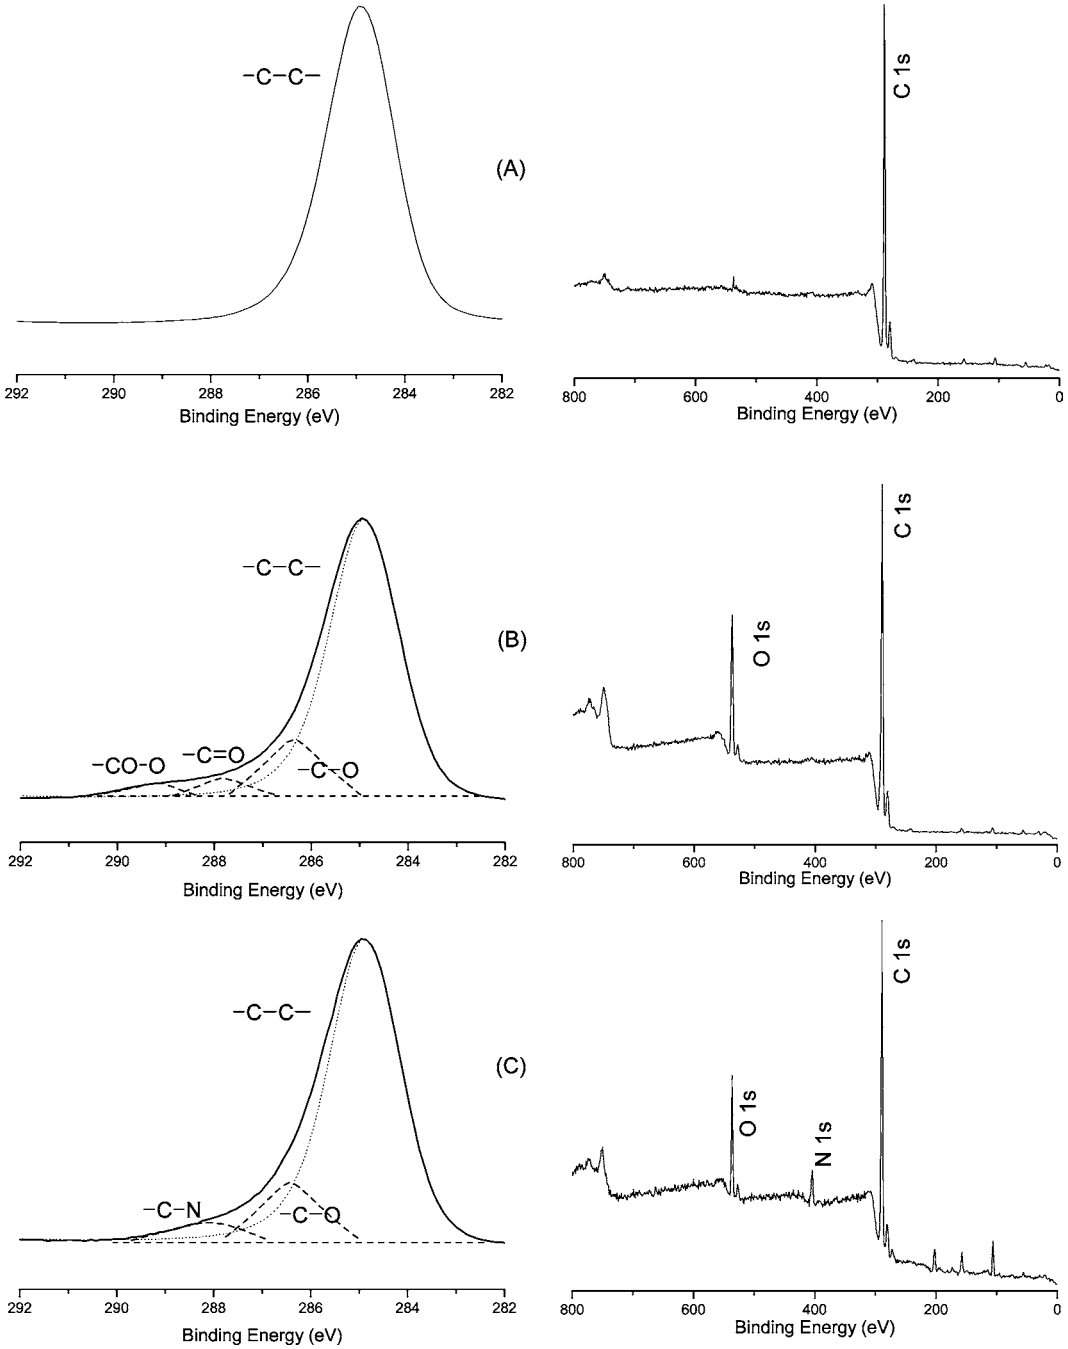

Figure 3. ESCA spectra of (A) untreated PE, (B) corona-treated PE, and (C) PEI-modified PE at the position 4.5 cm. (Left: carbon 1s core level spectra, Right: survey scan spectra).

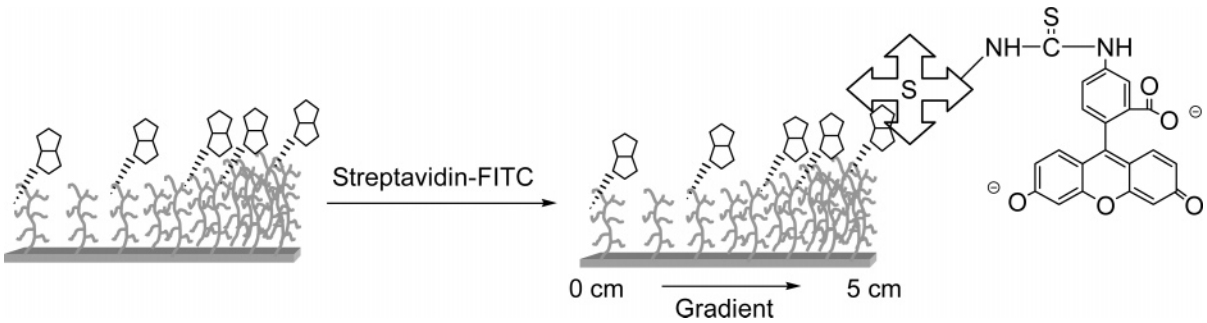
surface property. As shown in Figure 1A, the water contact angle of PE surface decreased gradually from 99° to 45−50° along the PE length with increasing corona power, indicating the gradual wettability change from completely hydrophobic to extremely hydrophilic. FTIR-ATR spectra showed a peak assignable to the C═O functional group at 1735 cm^{-1} and gradual peak intensity increase as the corona power increased (*33*). Figure 2 shows AFM images along the PE length after corona treatment. The PE surface exhibited a gradient roughness increase from 10 to 100 nm as corona power increases.

The chemical structure changes of the corona-treated PE surface were also investigated by ESCA (Figure 3). The untreated PE surface exhibited only a broad C1*s* peak at a binding energy of 285 eV (Figure 3A). After corona discharge treatment, new peaks assignable to ketone or aldehyde groups, hydroxyl or ether groups, and carboxylic acid or ester groups were observed at 287.9, 286.3 and 289.1 eV, respectively (Figure 3B). We confirmed the formation of various functional groups, especially the carboxylic acid group that can serve as reaction site on the PE surface. The carboxylic acid on the surface may chemically react with a functional group such as NH_2.

Polyamine compounds that have long spacers can be used for immobilization of the surface and consequently allow flexible and multifunctional sites on the surface in a biological environment. Thus chemical modification of the surface using polyamine was performed. First, the carboxylic group on the corona-treated PE surface was activated by *N*-hydroxysuccinimide (NHS) and EDC (*N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide). The activated carboxylic group reacted with the amine com-

Scheme 2



pounds such as 1,9-nonanediamine (ND) or polyethylenimine (PEI). In FTIR-ATR, the peak assignable to the C=O functional group almost disappeared at 1735 cm^{-1}, while a new peak was observed at around 1586 cm^{-1} after reaction with ND or PEI.

The ESCA spectrum of PEI modified on the gradient PE surface is shown in Figure 3C. A gradual increase in height of the C1*s* shoulder at 288.2 eV due to the C−N species within the PEI was observed along the PE length. In addition, 1s of nitrogen was observed at 399 eV in the survey scan spectrum (Figure 3C), and the intensity also gradually increased along the PE length, implying a nitrogen content increase on the PE surface (Table S1) (*34*). The results of FTIR-ATR and ESCA indicated that amine compounds were gradually modified on the gradient PE surface.

Among several binding systems, the binding affinity of the avidin−biotin interaction ($K_D \sim 10^{-15}$ M) is one of the highest to occur in nature as noncovalent bonding (*35*, *36*). Thus, we choose the binding system of avidin−biotin to design a gradient PE surface with a bioactive molecule. The amine-modified gradient PE surface was reacted with biotin that was preactivated by NHS and EDC. The new signal appeared at 1725 cm^{-1} after the reaction of biotin in FTIR-ATR spectrum (*33*). In the subsequent step, the gradient biotinylated PE surface was incubated in a solution of streptavidin−FITC (Scheme 2). The binding of the streptavidin−FITC to the gradient biotinylated PE surfaces was characterized by fluoresence microscopy. The fluorescence microscope image, which corresponds to a streptavidin-bound FITC bonded on the gradient biotinylated PE surfaces, is shown in Figure 4

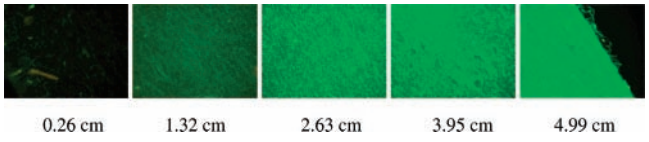


Figure 4. Change of fluorescence images on the gradient PE surface from 0 to 5 cm after the binding of streptavidin−FITC.

(*37*). The luminosity of fluorescence increased gradually on the surface when corona power for the surface increased along the length (*38*). Plotting of the length treated by corona versus the fluorescence intensity of the streptavidin−FITC reveals a gradient as shown in Figure 1B (*39*). The longer the length treated by corona, the smaller the water contact angle value and the stronger the fluorescence intensity , which could well explain the gradient PE surface.

In conclusion, we prepared a gradient PE surface using a corona treatment with power increase along the PE length and biotinylated gradient PE surface through the reaction of PEI and biotin. The biotinylated gradient PE surface provided a continuous gradient of streptavidin−FITC through recognizing their binding partners from solution. We believe that this method will be useful in the study of the analysis of functional bioactive molecules on the gradient surface through one experiment because the designed gradient PE surface is experimentally simpler than using a uniform surface.

A new method based on fluorescence imaging and flow cytometry was developed to investigate the transformation process of *Saccharomyces cerevisiae* AY. Yeast and fluorescent-labeled plasmid pUC18 were used as models of cells and DNA molecules, respectively. Binding of DNA molecules to yeast cell surfaces was observed. Factors influencing DNA binding to cell surfaces were investigated. It has been found that poly(ethylene glycol) (PEG) could induce DNA binding to yeast surfaces, while Li^+ showed a weak effect on the binding. When both Li^+ and PEG were used, synergetic effect occurred, resulting in the binding of pUC18 to the surface of more yeast cells compared with that in the presence of PEG or Li^+ only. It was also confirmed that heat shock, Li^+, and PEG all can increase the permeability of yeast cells. This simple method is helpful for understanding the process of yeast transformation and can be used to investigate the interaction of DNA with cell surfaces.

1. INTRODUCTION

The term "transformation" is used to describe DNA uptake in both prokaryotes and eukaryotes, as detected by consequent changes in phenotype (*1*). Genetic transformation of *Saccharomyces cerevisiae* was first reported in 1960 (*2*). Several methods for yeast transformation, such as spheroplast (*3*), Li^+ intact yeast cell, electroporation (*4*), glass beads (*5*), and biolistic (*6*), were developed.

Li^+ intact yeast cell transformation, which is a simple method with no special equipment required and with relatively high transformation efficiency, was first established by Ito in 1983 (*7*) and subsequently improved (*8*−*11*) and standardized (*12*). So, this method has been widely used.

The natural transformation process of bacteria usually includes three steps: first, DNA is bound to cell surfaces; second, the uptake of DNA by cells occurs; last, DNA molecules are integrated into chromosomal DNA or replicated as extrachromosomal genetic elements (*13*).

Although the details in the yeast transformation process are unknown, it can be supposed that the process involves the contact of DNA to yeast cells, the uptake of DNA by yeast cells, and the integration of DNA. Factors influencing these three steps will affect transformation efficiency. Some reports suggested that DNA could bind to yeast cell surfaces (*11*). It can be believed that factors facilitating DNA binding to cell surfaces will increase transformation efficiency. However, strong binding of DNA to the cell surfaces will result in reduced transformation efficiency (*11*). Increasing cell wall permeability to DNA enhanced transformation efficiency also (*14*).

Herein, DNA binding sites on yeast cell surfaces were observed, and factors that affect DNA binding to cell surfaces and cell permeability were explored in detail. Nevertheless, the integration of DNA molecules into chromosomal DNA cannot be studied by the current method. It is evident that this new method is helpful to understand the transformation process and can be promising in studying the transformation of other cells and the interaction of DNA with cells.

2. MATERIALS AND METHODS

Lithium acetate (LiAc), PEG4000, yeast extract, polypepton, Tris buffer, glucose, glass slides, and cover glass were all purchased from Sigma. YOYO-1 was a product of Molecular Probes. Plasmid pUC18 was obtained from Sino-American Biotechnology Co. Ultrapure water (18.2 MΩ) was prepared with a Labconco system and used throughout. *Saccharomyces cerevisiae* AY was obtained from Prof. Ping Shen's lab and used as a cell model. Before use, it was dispersed on a YPD plate (1.0% yeast extract, 2.0% polypepton, 2.0% glucose, 1.5% agar) and cultured for 2−3 days at 30 °C. Subsequently, a single colony was selected and dispersed on another YPD plate and cultured and then kept at 4 °C.

Plasmid pUC18 was labeled with YOYO-1 at a ratio of 50:1 (base pairs to YOYO-1) in the dark for 90 min at 4 °C immediately before use (*15*). At such a ratio of base pairs to YOYO-1, there is almost no free YOYO-1 because of its complete binding to DNA. A titration experiment demonstrated that addition of excess unlabeled DNA did not result in increase in fluorescence (*16*).

The Li^+ intact yeast cell transformation protocol was as previously reported (*1*). Yeast was precultured overnight in 5 mL of YPD (1.0% yeast extract, 2.0% polypepton, 2.0% glucose). A suitable volume of precultured cell suspension was added in 50 mL of YPD and incubated at 30 °C with shaking until cell growth reached the late logarithm phase. The cells were then harvested by centrifugation at 5000 rpm for 5 min, washed twice with ultrapure water, and resuspended in ultrapure water at 10^9 cells/mL. One hundred microliters of sample was centrifuged for 5 min at 5000 rpm, and the supernatant was discarded. The pellets were resuspended in 360 μL of transformation mixture (240 μL of 50% PEG4000 (w/v), 36 μL of 1.0 M LiAc, 50 μL of 2.0 mg/mL single-stranded carrier DNA, YOYO-1-labeled pUC18 DNA diluted to 34 μL with water). The cells in transformation mixture were incubated at 30 °C in the dark with shaking for 30 min, and then heat shocked at 42 °C in dark for 15 min.

Cells for experiments were dropped on glass slides and covered with a cover glass and then observed with a fluorescence microscope (FM) (Axiovert 200M, Zeiss) equipped with an oil-immersion objective (100× objective, Zeiss, N.A. = 1.25) or a confocal laser scanning microscope (CLSM) (TCS SP, Leica) equipped with an oil immersion objective (Leica, N.A. = 1.40). Cell samples were filtered with a 300 mesh filter and then diluted by several hundred times with 0.1 M Li^+-containing solution for cells in solution containing Li^+ or with ultrapure water for cells in Li^+-free solution before being analyzed with a flow cytometer (Beckman Coulter Epics Altra) coupled with a 488 nm Ar^+ laser and a 525 nm bandpass filter. The ultrapure-water-washed yeast cells were used as the negative control sample.

To examine yeast cell permeability, 10 μL of 10 μM YOYO-1 was added into 100 μL of water-washed cells, and then, Li^+, PEG, or both were added. The mixture was incubated at 30 °C with shaking in the dark for 30 min and then heat shocked at 42 °C in the dark for 15 min. At last, it was diluted and analyzed with a flow cytometer.

Atomic force microscopic (AFM) images of cell surfaces were obtained using an atomic force microscope (Picoscan, Molecular Imaging) in contact mode with a commercial MAClever type II probe (Molecular Imaging).

3. RESULTS AND DISCUSSION

3.1. Binding of DNA to Yeast Cell Surfaces. A widely used cell-impermeable fluorescent probe, YOYO-1, was used to label pUC18 plasmid DNA. After intercalation into double-stranded DNA, fluorescence intensity of YOYO-1 is enhanced by more than 1000 times (*17*). So, a very high ratio of signal-to-noise can be obtained using YOYO-1 to label DNA.

A commercial plasmid DNA, pUC18, was used to investigate the interaction of DNA with yeast cell surfaces, although it cannot be translated in yeast. Because pUC18 is short in strand length (2686 base pairs), each pUC18 molecule can only combine with a small number of YOYO-1 molecules (no more than 60 molecules) under our experimental conditions, the fluorescence of which is too weak to observe. When pUC18 molecules labeled with YOYO-1 are bound to cell surfaces, the fluorescence intensity is strong enough to observe since more labeled pUC18 molecules are concentrated on the surfaces.

The yeast cell wall acts as a barrier to DNA (*1*), and most DNA molecules are bound to the cell wall (*11*). So, all the fluorescence signals arose from DNA binding to cell surfaces, and the fluorescence of cells will indicate DNA binding to their surfaces. It was confirmed that the binding of YOYO-1 to DNA was of high affinity, thereby preventing the migration of YOYO-1 label from one DNA molecule to another (*17*, *18*). The addition of excessive single-stranded DNA does not affect the fluorescence of YOYO-1-labeled plasmid DNA.

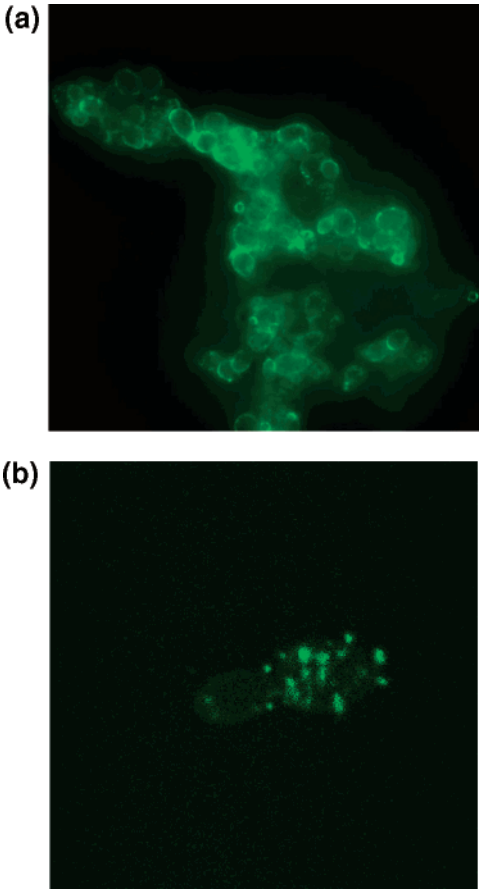

Figure 1. Fluorescence images of DNA binding to yeast cell surfaces: (a) a big field of view obtained by using a FM; (b) a small field of view containing two cells obtained by using a CLSM. Conditions were as follows: ca. 10^8 yeast cells treated with 20 ng of pUC18 stained with YOYO-1; image size ca. 80 × 80 μm^2 (a) and 25 × 25 μm^2 (b).

Because the cell wall of dead cells is not intact, YOYO-1-labeled DNA might diffuse into dead cells and make them fluoresce. So, the presence of dead cells will make difficult the judgment of DNA binding to cell surfaces. To ensure the reliability of experimental results, cells pretreated with the transformation mixture were labeled with methylene blue to determine whether the cells were dead (*19*). It was found that no more than 5% of cells were stained blue; that is, no more than 5% cells were dead.

Binding sites of DNA molecules on yeast cell surfaces were found (Figure 1). As the concentration of pUC18 increased, more pUC18 molecules would be bound to the cell surface. When 80 ng of pUC18 DNA was added into the mixture containing ca. 10^8 cells (the ratio of DNA molecules to cells was about 200:1), the DNA would be bound to the whole cell surface (Figure 2a). These results indicated that DNA binding sites on the surface of one yeast cell could be saturated in the presence of excessive DNA. Excessive pUC18 on the cell surfaces can be washed off (Figure 2b).

3.2. Factors Influencing DNA Binding to Yeast Cell Surfaces. Li^+ and PEG can facilitate DNA binding

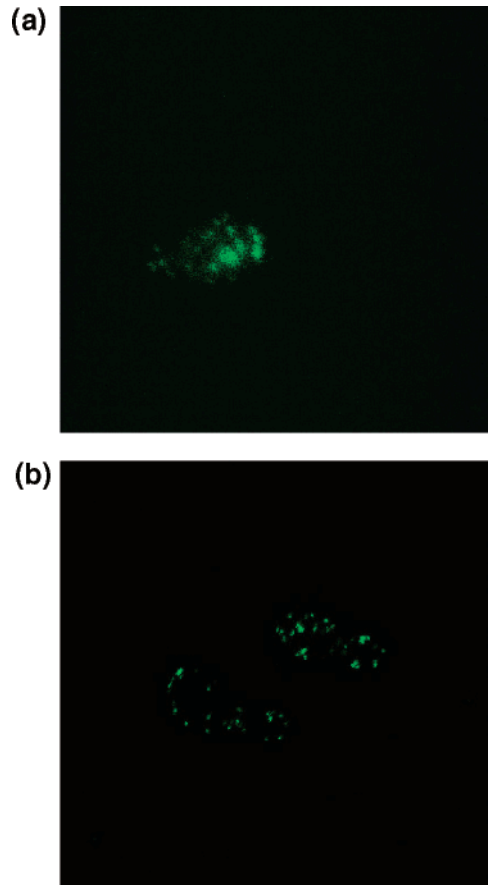

Figure 2. Fluorescence images of saturation of DNA binding to yeast cells. Conditions were as follows: ca. 10^8 yeast cells treated with 80 ng of pUC18 stained with YOYO-1 without washing (a) and with washing (b); 100× oil-immersion objective (N.A. = 1.40) (a) and 40× objective (N.A. = 0.70) (b); image size 25 × 25 μm^2 (a) and 40 × 40 μm^2 (b).

Table 1. Factors Influencing DNA Binding to Cell Surfaces

condition[a]	YOYO-1 labeled DNA	Li^+	PEG	PEG and Li^+	PEG, Li^+, and ss-DNA
a	1.2	6.1	9.8	44.8	
b	3.9	8.3	44.9	95.5	27.9
c	10.6	23.1	61.7	98.2	69.9

[a] Yeast cells (ca. 10^8) were treated with 4 (a), 20 (b), and 80 (c) ng of pUC18 stained with YOYO-1. Negative control sample was water-washed yeast cells.

to the yeast cell surface. Table 1 shows the percentage of fluorescent yeast cells treated with Li^+, PEG, or both in the presence of pUC18 of different concentrations. As mentioned above, the fluorescence of yeast cells was from labeled pUC18 on their surfaces; hence the percentage of fluorescent cells suggests the percentage of the cells with pUC18 bound on their surfaces. Li^+ can induce DNA binding to yeast cell surfaces, but its inducing effect was weak. PEG can induce DNA binding to yeast cell surfaces more strongly than Li^+. In our experiments, it was found that the use of both PEG and Li^+ in the transformation mixture could most strongly induce the binding.

The percentage of cells with bound pUC18 was 1.2%, 3.9%, and 10.6% in the presence of three different concentrations of YOYO-1-labeled pUC18 as listed in Table 1. But in the presence of Li^+, the percentage increased to 6.1%, 8.3%, and 23.1%, showing that Li^+ can induce DNA binding to yeast cell surfaces. As known,

Table 2. Transformation Frequency[a]

transformation frequency			
control	Li^+	PEG	Li^+ and PEG
0	0	5.12×10^{-5}	3.57×10^{-4}

[a] For details, see Supporting Information.

both DNA and the yeast cell surface are partly negatively charged (*20*); they will electrostatically repel. Li^+ can weaken such repulsion, inducing DNA molecules to be bound to yeast cell surfaces. Other cations, such as Na^+ and Cs^+, have been also used for yeast cell transformation (*7*, *8*), most probably due to their reduction of the repulsion between DNA and cell surfaces.

PEG has a strong effect on inducing DNA binding to yeast cell surfaces. In the presence of PEG, the percentages of cells with bound pUC18 on their surfaces increased to 9.8%, 44.9%, and 61.7% at three different labeled pUC18 concentrations (Table 1). It has been reported that PEG facilitates DNA deposition onto yeast cells (*11*). The effect of PEG may be attributed to its changing charges of cell surfaces (*7*). Such changes may induce both conformational changes and aggregation of cells (*7*). And it was also found that PEG could induce a drastic change in the conformation of plasmid DNA molecules (*8*). Perhaps both the conformational changes of DNA molecules and cell surfaces were propitious to the binding of DNA molecules to cell surfaces.

The use of both PEG and Li^+ induced DNA binding to yeast cell surfaces more effectively than PEG or Li^+ only. At three different concentrations of labeled pUC18, the percentage of fluorescent cells was 44.8%, 95.5%, and 98.2%, which might be attributed to a synergetic effect.

These results are exactly consistent with the transformation results (Table 2 and Supporting Information): in the presence of Li^+, PEG, or PEG plus Li^+, the transformation frequency was 0, 5.12×10^{-5}, and 3.57×10^{-4}, respectively.

Single-stranded carrier DNA can be bound more effectively to the yeast cell surfaces and occupy the DNA binding sites. It was reported that 500-fold excess single-stranded DNA decreased the strong binding of DNA to cell surfaces so that most of the plasmid was available for uptake, resulting in high transformation efficiency (*11*). Our results are in agreement with this. Single-stranded DNA decreased the percentage of cells with pUC18 bound to their surfaces from ca. 95% down to 28% in the case of ca. 20 ng of pUC18 in the transform mixture containing ca. 10^8 cells (Table 1).

3.3. Factors Influencing Cell Permeability. As mentioned above, the permeability of cells will affect the transformation for it can influence the cell uptake of DNA. Increasing cell permeability will result in high transformation efficiency. The factors influencing cell permeability were investigated with YOYO-1 by flow cytometry.

As a cell-impermeable reagent, YOYO-1 cannot pass through intact cell membranes, so it has been used to distinguish dead from living cells (*21*). Intact living yeast cells treated with YOYO-1 will not be fluorescent, but dead cells will be fluorescent. For our experiments, it was found that 19.1% (incubated at 30 °C), 73.1% (treated with Li^+), 83.1% (with PEG), and 99.4% (with Li^+ and PEG) of yeast cells were fluorescent (Table 3). However, methylene blue staining experiments showed that almost all of the fluorescent cells were alive. With increasing permeability of living cells, YOYO-1 can get into cells and be bound to the in-cell DNA, making living cells fluorescent. The cells that fluoresce should be permeable.

Table 3. Factors Increasing Cell Permeability[a]

percentage of permeable cells				
incubation at 30 °C	heat shock	Li^+	PEG	PEG and Li^+
19.1	36.1	73.1	83.1	99.4

[a] Negative control sample was water-washed yeast cells.

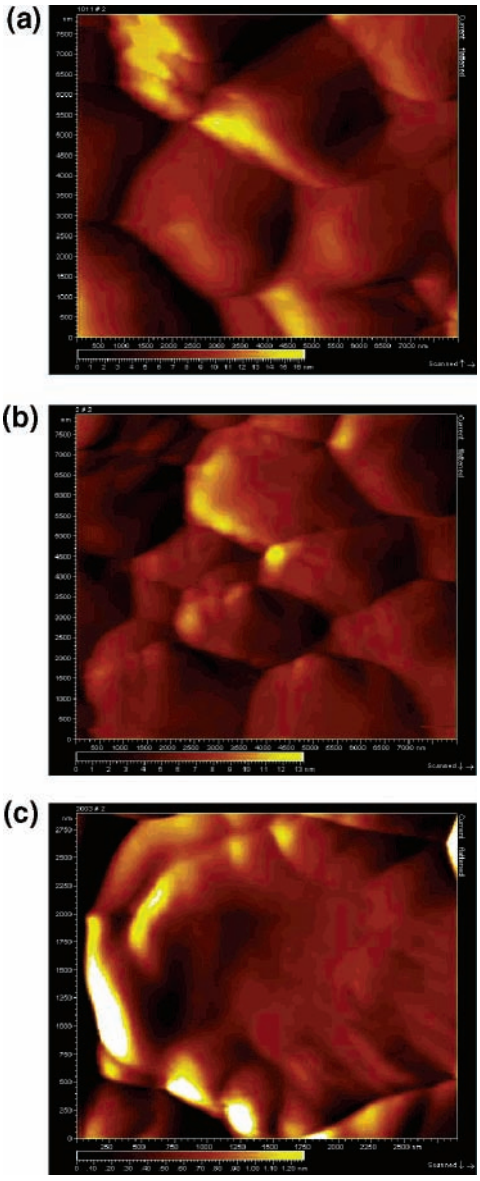

Figure 3. AFM images of some yeast cells (a), Li^+-treated yeast cells (b), and the cell wall of a Li^+-treated single yeast cell (c). Cell sample preparation was as follows: after being cultured and harvested, yeast cells were suspended at ca. 10^9 cells/mL in ultrapure water (a) or 0.1 M Li^+ solution (b, c) and subsequently incubated at 30 °C with shaking for 30 min, and then ca. 50 μL of cell sample was cast onto freshly cleaned slides (1.5 $\times$ 1.5 cm^2).

Treating with Li^+ can increase yeast cell permeability (*14*). Our results from AFM imaging (Figure 3) showed that cells treated with Li^+ had rougher surfaces than cells not treated with Li^+, indicating that the increase in cell permeability was perhaps attributed to the change of the cell surface structure. PEG is essential in yeast transformation (*7*, *8*). Many authors suggested that PEG was responsible for the adsorption of the DNA on the yeast cell surfaces. But our results revealed that PEG could also increase the cell permeability. Because PEG contaminates AFM probe tips seriously, cells treated with PEG cannot be studied by AFM. The use of both PEG and Li^+ can largely increase cell permeability probably due to synergetic effect. This result partly coincides with the transformation results. Although Li^+ can strongly increasing cell permeability, the transformation frequency was zero when only Li^+ was used to treat cells, which may be due to its weak effect on inducing DNA binding to cell surfaces.

Heat shock plays a significant role in transformation. It was reported that heat-shock proteins acted as molecular chaperones, protecting important structural proteins and enzymes from stress-induced degradation (*22*). Heat-shock-induced changes in the level of activities of specific proteins might affect either the transport of plasmid DNA from the cell membrane to the nucleus or elimination of cellular components that can degrade plasmid DNA (*11*). It was found, in our research, that heat shock caused 36.1% of cells to be permeable (19.1% for samples not treated with heat shock) (Table 3), suggesting that heat shock can also increase cell permeability.

4. CONCLUSIONS

A new way to study of yeast transformation process has been explored based on various techniques: fluorescence imaging to examine the DNA binding sites on yeast cell surfaces, flow cytometry to investigate the factors influencing DNA binding to cell surfaces and cell permeability, and AFM to observe cell surfaces to provide complementary information on the cell permeability.

Our research confirmed that there are DNA binding sites on yeast cell surfaces. At a high concentration of DNA, DNA binding sites will be saturated, and DNA molecules will adhere to the whole yeast cell surface.

Heat shock can apparently increase cell permeability. Li^+ is able to weakly promote DNA binding to yeast cell surfaces and strongly increase cell permeability. PEG can strongly induce DNA binding to cell surfaces and increase cell permeability, which are perhaps responsible for the increase of transformation efficiency. PEG can more effectively promote DNA binding to cell surfaces than Li^+. Use of both Li^+ and PEG will result in synergetic effect, which extremely strongly induces DNA binding to cell surfaces and increases cell permeability. Single-stranded carrier DNA is able to decrease strong binding of plasmid DNA to cell surfaces.

Kingshighway, Campus Box 8225, St. Louis, Missouri 63110, and Department of Chemistry, University of Illinois, 600 South Mathews Avenue, Urbana, Illinois 61801. Received September 21, 2004; Revised Manuscript Received December 30, 2004

Cyclopentadienyl tricarbonylmetal (CpTM, M = Re, ^{94m}Tc) complexes, some based on a typical nonsteroidal estrogen, were prepared with the aim of developing technetium- and rhenium-labeled imaging agents for estrogen receptor (ER) positive breast tumors. CpT[^{94m}Tc] compounds with simple cyclopentadienyl substituents were first synthesized using a modified double ligand transfer reaction. The in vivo biodistribution of one of these CpT[^{94m}Tc] complexes was determined by tissue dissection and microPET imaging. Novel C-ring substituted analogues of cyclofenil, a nonsteroidal compound known to bind the ER, were also prepared, and their ER binding was measured. Because of their low ER affinity, however, labeling and imaging studies of these compounds were not pursued. It is notable that the highest ER binding analogue, a CpTRe cyclofenil derivative, could be synthesized from the corresponding ferrocenyl cyclofenil analogue by the double ligand transfer reaction. This further demonstrates the versatility of the double ligand transfer reaction and indicates that the synthesis of technetium and rhenium radiolabeled agents for breast tumor imaging and therapy is also likely to be successful.

INTRODUCTION

Breast cancer continues to be the most common form of cancer and the third leading cause of cancer death among women in the United States (*1*). Early detection and accurate staging of cancer play key roles in the treatment planning and ultimate outcome of the patient. For breast cancer, proper staging includes the determination of the estrogen receptor (ER)[1] status, because this receptor is upregulated in many breast cancers. Breast tumors that have high ER levels, termed estrogen receptor positive (ER+) tumors, can often be successfully treated through hormone therapy with anti-estrogens. Some breast cancers express only low ER levels (ER−); these cancers generally have a poorer response to anti-estrogen therapy and usually require a more invasive treatment course (*2*). The high level of estrogen receptor expression in ER+ tumors can be exploited in imaging and therapy studies by the administration of ER-targeting compounds labeled with an appropriate radionuclide. Compounds that selectively bind to the receptor with high affinity yield higher activity accumulation in the ER+ tumor tissue than in surrounding nontarget and ER− tissues. Such imaging methods for in vivo assessment of the ER status of breast tumors are attractive because they simultaneously and noninvasively provide information on all tumor sites.

Previously, ER ligands have been labeled with fluorine-18 and other cyclotron-produced, short-lived radionuclides to develop in vivo imaging agents (*3*−*12*). For example, 16α-[^{18}F]fluoro-estradiol (FES) was used to image primary and metastatic breast tumors, and the FES images were shown to have value in predicting the clinical effectiveness of hormone therapy with tamoxifen, the most commonly used anti-estrogen drug (*13*, *14*). Short-lived, cyclotron-produced radionuclides, however, are expensive and are not widely available, which limits the utility of ER imaging agents such as FES for routine clinical studies.

The development of technetium- and rhenium ER-targeting compounds is attractive for several reasons. Compounds labeled with the inexpensive and widely available, single photon emission computed tomography (SPECT) technetium radionuclide, ^{99m}Tc ($t_{1/2}$ = 6.0 h, $E_{\beta+}$ = 140.5 keV, Iγ = 87.2%), could be used as ER imaging agents for routine clinical imaging studies. Rhenium, a nonradioactive congener of technetium, has very similar chemical and physical properties to technetium; in fact, rhenium complexes are commonly used to facilitate the development and characterization of technetium compounds. Rhenium also has two radionuclides that have been proven useful for therapy studies, ^{186}Re ($t_{1/2}$ = 3.71 d, $E_{\beta(\mathrm{avg})}$ = 0.36 MeV, $E\gamma$ = 137 keV) and ^{188}Re ($t_{1/2}$ = 16.8 h, $E_{\beta(\mathrm{avg})}$ = 0.77 MeV, $E\gamma$ = 155 keV) (*15*−*19*). Technetium and rhenium analogues of an ER-targeting compound could therefore be used in dual imaging/therapy studies. Furthermore, the replacement of the SPECT radionuclide, ^{99m}Tc, with the positron emission tomography (PET) radionuclide, ^{94m}Tc ($t_{1/2}$ = 52.0 min, β^+ = 70%, $E_{\beta+\max}$ = 2.44 MeV), could generate ER imaging agents for efficient screening and dosimetry calculations

of new Tc and Re compounds through the quantitation of PET images.

A number of attempts have been made to conjugate technetium and rhenium to estradiol, the natural ER ligand, to create agents suitable for imaging the ER in vivo (*20*−*31*). These steroid-based methods included both pendant and integrated approaches incorporate of the metal. In the pendant design, an inorganic or organometallic metal-containing moiety is covalently attached to the steroid; by contrast, the integrated approach involves replacement of part of the steroid backbone by a metal chelate. Many of these large, lipophilic complexes suffered from low receptor binding affinity, high nonspecific binding, and/or low complex stability, and were therefore not useful in imaging. For reasons that are not yet well understood, even those estradiol complexes with good in vitro binding to the ER did not give favorable tissue distribution in vivo.

The use of nonsteroidal ligands for the development of ER radiopharmaceuticals with organometallic radiometal tethers has also been investigated (*32*−*34*). An organometallic complex potentially useful in the development of ER imaging agents is cyclopentadienyl tricarbonylmetal (CpTM, M = Tc, Re). The CpTM unit (Figure 1) is small, has a lipophilic core of high chemical stability, and can be derivatized by altering the substituent (R) attached to the Cp ring. Wenzel et al. described the preparation of CpTM (M = ^{99m}Tc, Mn) via a quick and relatively mild transformation in which the reduction, carbonylation, and cyclopentadienylation of ^{99m}Tc was carried out in a one-pot reaction (Scheme 1) (*35*). We later studied the scope of this reaction and improved it by both increasing the yield through the use of a different reducing agent ($CrCl_3$ for $SnCl_2$) and by eliminating the Mn side-products of the original method by replacing the carbonyl donor ($Mn(CO)_5Br$ with $Cr(CO)_6$) (*36*). This method is termed a double ligand transfer reaction (DLT) because two different ligands (CO and Cp) on two different metal atoms (Mn/Cr and Fe) become transferred to a third metal atom (Tc/Re). Other methods have also been explored to synthesize the CpTM unit (*37*−*39*).

Jaouen et al. showed the potential of ER-targeting complexes containing the CpTM organometallic moiety by reporting the synthesis of a CpTRe β-ring substituted tamoxifen analogue that not only bound the ER, but also behaved as an anti-estrogen, with nearly identical efficacy as the active metabolite of tamoxifen (*33*). Cyclofenil is another nonsteroidal compound that has been shown to have good binding affinity for the ER (Figure 2a) (*40*). Muthyala et al. have reported several bridged bicyclic C-ring analogues of cyclofenil that have high ER binding affinity (*40*, *41*), as much as five times that of estradiol. This suggests that C-ring substitutions of cyclofenil with CpTM might also be possible without loss of ER binding affinity.

The overall goal of the work described herein was to investigate the synthesis of CpTRe and CpTTc compounds, including CpTM cyclofenil analogues, and to explore their potential use as ER imaging agents. As we are also developing methods for quantitative biodistribution studies derived from animal imaging sessions on microPET scanners, the PET radionuclide ^{94m}Tc was selected for labeling studies. We began our synthetic efforts by establishing labeling conditions for the production of CpT[^{94m}Tc] compounds with simple cyclopentadienyl substituents. To demonstrate that these model compounds could be obtained in sufficient yield, purity, and compatibility for use in animal studies, one of the compounds was used in microPET imaging and tissue dissection studies. To add an ER targeting component to the CpTM system, cyclofenil analogues with C-ring substitutions were synthesized and evaluated for their ability to bind the ER.

EXPERIMENTAL PROCEDURES

Materials and Chemical Methods. Reagents, solvents and deuterated solvents were purchased from Acros Organics of Fisher Scientific (Pittsburgh, PA), Aldrich (Milwaukee, WI), Fisher (Pittsburgh, PA), and Strem (Newburyport, NH). Methylene chloride and tetrahydrofuran were dried by a Solvent Delivery System (SDS) (neutral alumina columns) fabricated by J. C. Meyer (Irvine, CA), based on a design published by Pangborn et al. (*42*). All solutions were prepared using distilled, deionized water (Milli-Q; >18 MΩ resistivity). All air-sensitive reactions were carried out under nitrogen or argon atmosphere, using flame- or oven-dried glassware. Reaction progress was monitored by analytical thin-layer chromatography (TLC) on silica gel medium. Visualization was achieved either by UV light (254 nm) or phosphomolybdic acid indicator. Flash chromatography was performed using Woelm silica gel (0.040−0.063 mm) packing.

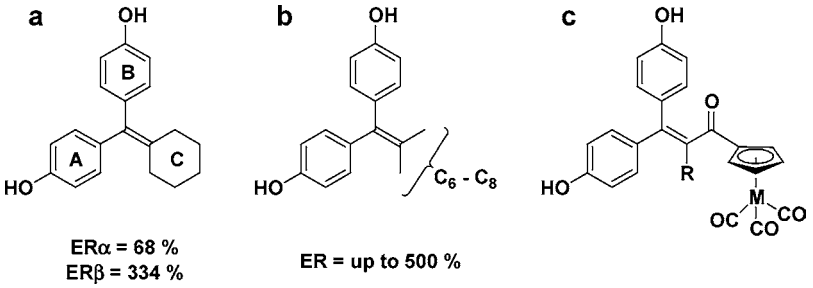

Figure 2. The structures of cyclofenil (**a**) (*39*), literature C-ring substituted analogues (**b**) (*39*−*40*), and proposed C-ring substituted CpTM analogues (**c**). The binding affinities listed are for the ER subtypes α and β and are relative to estradiol which is set as 100%.

^{1}H and ^{13}C NMR spectra were recorded on a Unity 500 Varian FT-NMR spectrometer. Chemical shifts (δ) are reported in parts per million downfield from internal tetramethylsilane and/or referenced from solvent resonances. NMR coupling constants are reported as absolute values in Hertz (Hz). Low resolution electron impact (EI) mass spectra and high-resolution EI mass spectra (HRMS) were obtained on Micromass 70-VSE. Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected.

A CS-15 cyclotron (Cyclotron Corporation, Berkeley, CA) with proton beam energy of 14.5 MeV was used for the in-house production of ^{94m}Tc. Methods for the production and purification of $^{94m}TcO_4^-$ have been described (*43*−*45*).[2] Briefly, ^{94m}Tc was produced by proton irradiation of an enriched molybdenum target, according to the ^{94}Mo(p,n)^{94m}Tc nuclear reaction. After irradiation, the ^{94m}Tc was separated from the molybdenum starting material by sublimation. The $^{94m}TcO_4^-$ was removed from the quartz sublimation apparatus either in dilute NaOH solution and was isolated using a Sep-Pak Light alumina N cartridge, or it was removed directly into MeOH and used without purification. Radioactive samples were counted in a radionuclide calibrator (Capintec, Inc., Ramsey, NJ) for determination of activity in millicuries and in a Beckman 8000 (Beckman Fullerton, CA) or a Cobra II (Packard, Meridian, CT) γ-counter for activity in counts per minute. Radionuclidic purity was determined by analysis on a Canberra multichannel analyzing gamma spectrometer (Canberra Industries, Inc., Meriden, CT). MicroPET imaging was performed on a microPET-R4 instrument (Concorde MicroSystems Inc., Knoxville, TN).

Acetylcyclopentadienyltechnetium-94m(I) Tricarbonyl (2a). Alumina purified $^{94m}TcO_4^-$ (5.50 mCi) in 0.5 mL saline was added to a pressure tube and evaporated to dryness with heat under a flow of argon. 1,1′-Diacetylferrocene (0.5 mg, 0.002 mmol), chromium(III) chloride (0.5 mg, 0.003 mmol), chromium hexacarbonyl (1 mg, 0.004 mmol), and 0.5 mL of dry methanol were added, and the tube was then sealed and heated in an aluminum bomb for a total of 45 min (30 min at 180 °C). After cooling to −78 °C, the tube was opened and the solvent evaporated with heat under argon, being careful not to distill off the product. The crude mixture was dissolved in ether and passed through a silica plug, then evaporated under an argon flow, leaving 1.07 mCi (65% decay-corrected). Purification was carried out by HPLC (C_{18} reverse-phase, 50% acetonitrile/50% water), and eluent fractions from 12 to 13.5 min were collected, as determined by the radioactive trace and by comparison to the mass peak of the nonradioactive rhenium analogue (*36*). The product was extracted into ether (x 3), and the combined organic layers were evaporated to give 439 μCi (45% decay-corrected, this was slightly lower than the usual yield of ∼55% and was likely due to loss of the pressure tube seal during heating). This material was dissolved in 10% DMSO/90% saline solution for injection. Note: the above procedure was also carried out using unpurified ^{94m}Tc, as a mixture of pertechnetate and technetium oxides (36% oxide content) in methanol. The isolated yield was 58% (decay-corrected) with greater than 95% purity based on HPLC analysis.

Methoxycarbonylcyclopentadienyltechnetium-94m(I) Tricarbonyl (2b). Alumina purified $^{94m}TcO_4^-$ (1.44 mCi) in 0.75 mL saline was added to a pressure tube and evaporated to dryness with heat under a flow of argon. 1,1′-Ferrocenedicarboxylate methyl ester (10.0 mg, 0.033 mmol), chromium(III) chloride (6 mg, 0.038 mmol), chromium hexacarbonyl (16 mg, 0.073 mmol), and 0.5 mL of dry methanol were added, and the tube was then sealed and heated in an aluminum bomb for a total of 45 min (30 min at 180 °C). After cooling to −78 °C, the tube was opened and the solvent evaporated with heat under argon, being careful not to distill off the product. The crude mixture was dissolved in acetonitrile and passed through a silica plug, then partially evaporated under an argon flow leaving 210 μCi (84% decay-corrected). An aliquot was purified by HPLC (C_{18} reverse-phase, 50% acetonitrile/50% water), and eluent fractions from 10.5 to 12 min were collected, as determined by the radioactive trace and by comparison to the mass peak of the nonradioactive rhenium analogue (*36*). The decay-corrected yield was 56%.

1,1-Bis-(4-methoxy-phenyl)-propan-1-ol (4). A 2 M THF solution of EtMgCl (1.34 mL, 2.68 mmol) was added to a solution of 4,4′-dimethoxybenzophenone (260 mg, 1.07 mmol) in dry THF (5 mL) at 0 °C. The solution was allowed to warm to room temperature over the course of 4−5 h, and a saturated solution of NH_4Cl (25 mL) was then slowly added. To this was added CH_2Cl_2 (25 mL), the phases were separated, and the aqueous phase was extracted with CH_2Cl_2 (2 × 25 mL). The combined organic phases were dried with $MgSO_4$, filtered, and concentrated under vacuum. The residual oil was purified by flash column chromatography (20:80 ethyl acetate:hexanes) to afford **4** as a pale yellow oil (136 mg, 47%). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 0.87 (t, 3H, J = 7.3 Hz), 1.99 (s, 1H), 2.25 (q, 2H, J = 7.3 Hz), 3.79 (s, 6H), 6.82−6.85 (m, 4H), 7.29−7.32 (m, 4H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 8.21, 34.63, 55.17, 77.93, 113.32, 127.33, 139.43, 158.25.

1,1-Bis-(4-methoxy-phenyl)-1-propene (5). *p*-Toluenesulfonic acid (5.5 mg, 0.029 mmol) was added to a solution of **4** (120 mg, 0.441 mmol) in benzene (30 mL), and the mixture was heated under reflux for 30 min. The solution was cooled, washed successively with saturated solutions of $NaHCO_3$ (2 × 30 mL) and NaCl (2 × 30 mL), then dried over $MgSO_4$, filtered, and concentrated under vacuum. The crude product was purified by flash column chromatography (20:80 ethyl acetate:hexanes) to give **5** as a white solid (104 mg, 93%), mp 100−101 °C (lit. mp (*46*) 97−100 °C). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 1.76 (d, 3H, J = 7.1), 3.80 (s, 3H), 3.85 (s, 3H), 6.03 (q, 1H, J = 7.1 Hz), 6.79−6.82 (m, 2H), 6.90−6.94 (m, 2H), 7.09−7.17 (m, 4H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 15.66, 55.18, 55.22, 113.37, 113.44, 122.13, 128.32, 131.15, 132.51, 136.11, 141.36, 158.37, 158.54. MS (EI): *m/z* 254 (M^+, 100%); HRMS calcd for $C_{17}H_{18}O_2$ 254.1307, found 254.1313.

3,3-Bis-(4-methoxy-phenyl)-2-methyl-1-phenyl-propenone (6). A solution of benzoyl chloride (37 mL, 0.32 mmol) in CH_2Cl_2 (1 mL) was slowly added to a small flask containing a mixture of **5** (54 mg, 0.21 mmol), aluminum-(III) chloride (85 mg, 0.64 mmol), and CH_2Cl_2 (5 mL) at 0 °C. The solution was allowed to warm to room-temperature overnight. A saturated solution of $NaHCO_3$ (10 mL) was added to quench the reaction and the resulting thick solution was passed through a Celite plug. The aqueous phase was separated and extracted with CH_2Cl_2 (3 × 10 mL). The combined organic phases were dried with $MgSO_4$, filtered, and concentrated under vacuum. The residual oil was purified by flash column chromatography (20:80 ethyl acetate:hexanes) to afford **6** as a pale yellow oil (41 mg, 54%). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.16 (s, 3H), 3.62 (s, 3H), 3.83 (s, 3H), 6.51−

[2] Bigott, H. M., Laforest, R., Ruangma, A. and Welch, M. J., unpublished results.

6.55 (m, 2H), 6.89−6.94 (m, 4H), 7.20−7.25 (m, 4H), 7.30−7.35 (m, 1H), 7.76−7.79 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 19.99, 54.96, 55.18, 113.04, 113.43, 127.99, 129.06, 131.27, 131.36, 132.27, 133.06, 133.47, 134.25, 137.08, 143.62, 158.88, 158.99, 201.59. MS (EI): *m/z* 358 (M^+, 100%); HRMS calcd for $C_{14}H_{22}O_3$ 358.1569, found 358.1564.

3,3-Bis-(4-methoxy-phenyl)-2-methyl-1-ferrocenyl-propenone (9). Pyridine (one drop) and oxalyl chloride (375 mL, 4.30 mmol) were slowly added to a suspension of ferrocenecarboxylic acid (200 mg, 0.869 mmol) in CH_2Cl_2 (6 mL) at 0 °C. The mixture was stirred for 30 min at 0 °C and another 30 min while warming to room temperature, during which time it became a clear rust color. The solvent was removed directly into a trap via cannulation, and the residue was dried for 2 h under vacuum. The ferrocene acid chloride residue (**8**) was dissolved in CH_2Cl_2 (7.5 mL), and the solution was slowly added to a flask containing a mixture of **5** (149 mg, 0.586 mmol), aluminum(III) chloride (272 mg, 2.04 mmol), zinc dust (1.77 g, 27.1 mmol), and CH_2Cl_2 (7.5 mL) at −78 °C. After 2 h, the mixture was stirred for 5 min with a saturated solution of $NaHCO_3$ (15 mL) and was then passed through a Celite plug to remove the zinc solids. The aqueous phase was separated and extracted with CH_2Cl_2 (3 × 10 mL). The combined organic phases were washed once with a saturated solution of NaCl, dried with $MgSO_4$, filtered, and concentrated under vacuum. The crude product was purified by flash column chromatography (3:97 ethyl acetate:methylene chloride) to afford **9** as a rust-colored solid (156 mg, 57%), mp 176−177 °C. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.23 (s, 3H), 3.66 (s, 3H), 3.85 (s, 3H), 4.18 (s, 5H), 4.28 (t, 2H, J = 1.9 Hz), 4.57 (t, 2H, J = 1.9 Hz), 6.56−6.60 (m, 2H), 6.91−6.94 (m, 4H), 7.14−7.17 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 20.68, 55.18, 55.40, 69.90, 70.36, 71.97, 78.84, 113.23, 113.63, 131.50, 131.63, 134.18, 134.37, 134.60, 142.06, 159.06 (x2), 205.93. MS (EI): *m/z* 466 (M^+, 55%); HRMS calcd for $C_{28}H_{26}O_3Fe$ 466.1231, found 466.1235.

3,3-Bis-(4-methoxy-phenyl)-2-methyl-1-(cyclopentadienylrhenium(I) Tricarbonyl)-propenone (10). A pressure vessel was charged with **9** (89 mg, 0.19 mmol), potassium perrhenate (56.6 mg, 0.196 mmol), chromium(III) chloride (60.0 mg, 0.379 mmol), and chromium hexacarbonyl (256 mg, 1.16 mmol). Dry methanol (0.5 mL) was added, and the tube was then sealed and heated in an aluminum bomb for a total of 75 min (60 min at 165 °C). After cooling to −78 °C, the tube was opened and the solution was transferred with CH_2Cl_2 (9 mL) to a separatory funnel and washed once with a saturated solution of NaCl (10 mL). The aqueous phase was separated and extracted with CH_2Cl_2 (2 × 10 mL). The combined organic phases were dried with $MgSO_4$, filtered, and concentrated under vacuum. The crude product was purified by flash column chromatography (3:97 ethyl acetate:methylene chloride) to give **10** as an off-white solid (34 mg, 29%). ^{1}H NMR (500 MHz, $CDCl_3$): δ = 2.12 (s, 3H), 3.76 (s, 3H), 3.84 (s, 3H), 5.10 (t, 2H, J = 2.1 Hz), 5.71 (t, 2H, J = 2.1 Hz), 6.71−6.75 (m, 2H), 6.89−6.93 (m, 2H), 7.00−7.04 (m, 2H), 7.10−7.14 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$): δ = 21.28, 55.20, 55.26, 84.35, 88.89, 94.49, 113.61, 113.65, 131.44, 131.68, 132.89, 133.04, 134.27, 143.15, 159.32, 159.67, 195.62, 211.53. MS (EI): *m/z* 616 (M^+, 33%); HRMS calcd for $C_{26}H_{21}O_6{}^{187}Re$ 616.0896, found 616.0893.

4,4′-(1-Propenylidene)bis-phenol (5a). To a solution of **5** (30 mg, 0.12 mmol) in CH_2Cl_2 (2 mL) was added $BF_3{\cdot}S(CH_3)_2$ (745 μL, 7.08 mmol) at room temperature. The solution was stirred for 4 h until the complete conversion to the diphenol, at which time the reaction was quenched with methanol (1 mL), and the solvent was removed under a stream of N_2. The rust orange-colored residue was partitioned between ethyl acetate (4 mL) and water (4 mL), and the mixture was stirred for 20 min. The aqueous phase was separated and extracted once with ethyl acetate (5 mL). The combined organic phases were quickly washed with saturated solutions of $NaHCO_3$ (10 mL) and NaCl (2 × 10 mL), dried over $MgSO_4$, filtered, and concentrated under vacuum. The crude product was dissolved in 40:60 ethyl acetate:hexanes (0.5 mL), passed through a plug of silica gel in a Pasteur pipet, eluted with 40:60 ethyl acetate:hexanes, and concentrated under vacuum to yield a nearly pure **5a** as a pale peach solid (18 mg, 69%). ^{1}H NMR (500 MHz, $(CD_3)_2CO$): δ = 1.68 (d, 3H, J = 6.9 Hz), 5.95 (q, 1H, J = 6.9 Hz), 6.70−6.75 (m, 2H), 6.83−6.87 (m, 2H), 6.95−6.99 (m, 2H), 7.01−7.05 (m, 2H), 8.25 (s, 1H), 8.34 (s, 1H). MS (EI): *m/z* 226 (M^+, 68%).

3,3-Bis-(4-hydroxy-phenyl)-2-methyl-1-ferrocenyl-propenone (9a). To a solution of **9** (19 mg, 0.041 mmol) in CH_2Cl_2 (0.68 mL) was added $BF_3{\cdot}S(CH_3)_2$ (257 μL, 2.44 mmol) at room temperature. The solution was stirred for 5 h until the complete conversion to the diphenol, at which time the reaction was quenched with methanol (1 mL), and the solvent was removed under a stream of N_2. The black residue was partitioned between ethyl acetate (4 mL) and water (4 mL), and the mixture was stirred for 15 min. The aqueous phase was separated and extracted once with ethyl acetate (5 mL). The combined organic phases were quickly washed with saturated solutions of $NaHCO_3$ (10 mL) and NaCl (2 × 10 mL), dried over $MgSO_4$, filtered, and concentrated under vacuum. Flash column chromatography (40:60 ethyl acetate:hexanes) gave nearly pure **9a** as a red rust-colored solid (15 mg, 54%). ^{1}H NMR (500 MHz, $(CD_3)_2CO$): δ = 2.18 (s, 3H), 4.17 (s, 5H), 4.27 (t, 2H, J = 1.9 Hz), 4.53 (t, 2H, J = 1.9 Hz), 6.50−6.53 (m, 2H), 6.78−6.81 (m, 2H), 6.85−6.89 (m, 2H), 7.09−7.13 (m, 2H), 8.27 (s, 1H), 8.49 (s, 1H). MS (EI): *m/z* 438 (M^+, 100%).

3,3-Bis-(4-hydroxy-phenyl)-2-methyl-1-(cyclopentadienylrhenium(I) Tricarbonyl)-propenone (10a). To a solution of **10** (19 mg, 0.031 mmol) in CH_2Cl_2 (1.0 mL) was added $BF_3{\cdot}S(CH_3)_2$ (162 μL, 1.54 mmol) at room temperature. The solution was stirred for 18 h, until the complete conversion to the diphenol, at which time the reaction was quenched with methanol (8 mL), and the solvent was removed under a stream of N_2. The deep red-colored residue was partitioned between ethyl acetate (5 mL) and water (5 mL), and the mixture was stirred for 30 min. The aqueous phase was separated and extracted once with ethyl acetate (5 mL). The combined organic phases were quickly washed with saturated solutions of $NaHCO_3$ (10 mL) and NaCl (10 mL), dried over $MgSO_4$, filtered, and concentrated under vacuum. The crude product was dissolved in 40:60 ethyl acetate:hexanes (0.5 mL), passed through a plug of silica gel in a Pasteur pipet, eluted with 40:60 ethyl acetate:hexanes, and concentrated under vacuum to yield a nearly pure **10a** as a yellow solid (4 mg, 22%). ^{1}H NMR (500 MHz, $(CD_3)_2CO$): δ = 2.05 (overlapped by solvent peak, should be s, 3H), 5.42 (t, 2H, J = 2.2 Hz), 5.92 (t, 2H, J = 2.2 Hz), 6.69−6.73 (m, 2H), 6.86−6.95 (m, 4H), 7.06−7.10 (m, 2H), 8.55 (s, 1H), 8.57 (s, 1H). MS (EI): *m/z* 588 (M^+, 9%).

Synthetic Notes of Diphenolic Compounds. The diphenolic compounds proved difficult to purify because they tended to decompose in solution and upon exposure

to light and heat. 2-D TLC verified that decomposition was not due to incompatibility with the silica gel. Therefore, when decomposition prevented typical column chromatography, short plugs of silica gel were instead used. This resulted in the isolation of nearly pure compounds that were then quickly used without further purification. The mechanism of decomposition (oxidative vs inherent structural instability) is uncertain since the formation of multiple new compounds with similar polarities is suggested by TLC, and the NMR spectra do not provide clear enough signals to identify these impurities. Methods attempted to stabilize the diphenolic compounds and to prevent oxidative decomposition failed. These included using either the radical scavenger, 3,5-di-*tert*-butyl-4-hydroxy-anisole (BHA), or the weak acid, acetic acid, during chromatography. As seen in the absence of these radical scavengers, decomposition was observed with mostly higher polarity compounds being formed. Decomposition was slowed by shielding the product from light, limiting its time in solution, and by storing it in vessels covered in aluminum foil, either on a high vacuum line or at −20 °C under N_2.

Estrogen Receptor Binding Affinity. Relative binding affinities (RBAs) were determined by competitive radiometric binding assays using [^{3}H]estradiol, following previously published procedures (*47*, *48*). The RBAs are expressed as a percentage, relative to estradiol binding being 100%. The receptor sources were lamb uterine cytosol, purified full-length human ERα, or purified full-length human ERβ (Pan Vera Inc., Madison, WI). The RBA values are reported as the average of two or more determinations ± the range ($n = 2$) or standard deviation ($n > 2$).

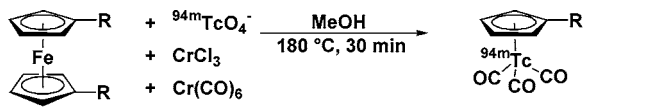
Biodistribution Study. All animal experiments were conducted in compliance with guidelines established by the Washington University Animal Studies Committee. Tissue distribution studies were performed on C57/Bl6 male mice. The mice were anesthetized with 1−2% isofluorane/oxygen, and a bolus injection of ∼10 μCi of **2a** (100 μL, 10% DMSO in saline) was administered via the tail vein. The animals were sacrificed by cervical dislocation at 2 h postinjection (pi). The tissues and organs were promptly removed and weighed, and the radioactivity of each sample was determined by a gamma counter.

PET Imaging. Positron emission tomography imaging was performed on a microPET-R4 system (Concorde Microsystems Inc, Knoxville, TN) which is based on the design of Cherry and colleagues (*49*). The microPET-R4 has a field of view of 8 cm axially by 11 cm transaxially and is capable of a spatial resolution of 2 mm and an absolute sensitivity of 920 cps/μCi in the middle of the field of view. Data were acquired in list mode and histogrammed into frames. Images were then reconstructed by Fourier Rebinning (FORE) followed by 2D-Filtered Back Projection (2D-FBP) with ramp filter cutoff at the Nyquist frequency, using data from all tilt angles (*50*). The microPET imaging study was carried out on a female C57/Bl6 mouse, anesthetized with 1−2% isofluorane/oxygen and placed in an immobilizing scanner support. Compound **2a** was administered as a bolus injection via the tail vein (175 μCi). Single position imaging was performed at five timepoints (5, 15, 30, 60 and 100 min pi), each consisting of 10 min static data collections.

RESULTS AND DISCUSSION

Design and Synthesis of Representative CpT-[^{94m}Tc] Systems (*51, 52*). Technetium-94m is a positron-emitting radionuclide that can be used in small animal PET imaging as well as standard tissue dissection biodistribution analysis. The relatively short half-life (52 min) of ^{94m}Tc must be considered when designing synthetic schemes utilizing this radionuclide. Ideally, the incorporation of ^{94m}Tc should be in the final synthetic step, and isolation and purification of the final compound should be rapid. To achieve conditions for the time-efficient and reproducible synthesis of CpT[^{94m}Tc] compounds, two model systems with simple cyclopentadienyl substituents were generated, CpT[^{94m}Tc]-$COCH_3$ (**2a**) and CpT[^{94m}Tc]-CO_2CH_3 (**2b**). Compounds **2a** and **2b** were made using a DLT reaction adapted from the reported synthesis of the analogous nonradioactive rhenium compounds, CpTRe-$COCH_3$ and CpTRe-CO_2CH_3 (*36*) (Scheme 2). The modifications made included increasing the reaction temperature from 160 to 180 °C, reducing the reaction time from 60 to 30 min, and purifying the reaction products by HPLC versus column chromatography. Each of these changes was aimed at minimizing synthesis and purification times to better suit the use of the short-lived ^{94m}Tc radiometal.

Scheme 2



1a R = $COCH_3$ **2a** R = $COCH_3$ (55%)
1b R = $COOCH_3$ **2b** R = CO_2CH_3 (56%)

In general, a pressure vessel was charged with a saline solution of $^{94m}TcO_4^-$, and the solvent was evaporated with heating under a flow of argon. At room temperature, the appropriate ferrocenyl compound, other nonradioactive reagents, and dry MeOH were added. The tube was sealed and heated at 180 °C for 30 min. Compounds **2a** and **2b** were shown to be radiochemically homogeneous and free from chemical impurities after purification by normal phase HPLC. As is typically the case, the characterization of the compounds was facilitated by comparison to the nonradioactive rhenium analogues. The yields reported in Scheme 2 (55% for CpT[^{94m}Tc]-$COCH_3$ and 56% for CpT[^{94m}Tc]-CO_2CH_3) were reasonably high. Additionally, considering that the reaction time was cut in half, these yields compared well to those reported for the rhenium compounds (60% for CpTRe-$COCH_3$ and 88% for CpTRe-CO_2CH_3) (*36*).

From these experiments, the observation was made that the volume of the $^{94m}TcO_4^-$ saline solution should be minimized. First, as the DLT reaction is most efficient with MeOH as the solvent (*36*), the use of a $^{94m}TcO_4^-$ saline solution required a time-consuming evaporation of the aqueous solvent and reconstitution of the residue in MeOH. Therefore, larger solution volumes required longer evaporation times, resulting in greater decay loss of ^{94m}Tc. Second, initial reaction attempts following the concentration of relatively large volumes of $^{94m}TcO_4^-$ in saline (1−3 mL) yielded salty reaction mixtures that, when filtered, caused appreciable amounts of the activity to become trapped in the filters. Optimization experiments for the isolation of $^{94m}TcO_4^-$ following the cyclotron production of ^{94m}Tc led to the development of a combination concentration and purification step.[2] Of the multiple columns and cartridges tested, the shortest processing times and smallest solution volumes were obtained using a Sep-Pak Light alumina N cartridge. In this way, highly concentrated and pure solutions of $^{94m}TcO_4^-$ in just 400 μL of normal saline were made and used in

the reactions. Consequently, the yields were improved from both shortened preparation times and reduced activity loss during filtration due to minimized salt content. The values reported in Scheme 2 are isolated yields and were achieved in reactions that followed the use of this method.

Methanolic solutions of $^{94m}TcO_4^-$ were also used in the DLT reactions of the CpT[^{94m}Tc] compounds. Here, the ^{94m}Tc activity was removed from the quartz distillation apparatus with hot methanol and the unpurified solution was quickly concentrated to the desired volume with heating under a flow of argon.[2] Similar decay-corrected isolated yields were obtained (i.e., 58% and 55% for **2a** from methanol and saline solutions, respectively), and the processing time from end of bombardment to end of synthesis was shortened. Although a direct comparison was not carried out, this suggests that the methanol recovery method would generate higher overall yields (i.e., in mCi), due to reduced ^{94m}Tc decay loss.

It should be pointed out that since no purification of the $^{94m}TcO_4^-$ was performed following the MeOH recovery, a technetium oxide radiochemical impurity (probably $^{94m}TcO_3$, see (*53*)) was present. Interestingly, this species did not appear to interfere with the DLT reaction. In fact, in one case, a methanolic solution of $^{94m}TcO_4^-$ that had an unusually high amount of $^{94m}TcO_3$ (36%) resulted in a 58% isolated yield of compound **2a**. It is unlikely that the $^{94m}TcO_4^-$ species alone reacted to give this yield as it was only 64% of the starting activity (a loss of only 6% would be remarkable). Rather, the technetium oxide impurity was likely also reduced and reacted with the ferrocene starting material.

To confirm the ability of technetium oxide to react in the DLT reaction, the analogous reaction was performed using rhenium(VI) oxide as the metal source. After heating for 1 h at 180 °C, followed by chromatographic purification, acetylcyclopentadienylrhenium(I) tricarbonyl was isolated in a yield of 87% while the methoxycarbonylcyclopentadienyl rhenium(I) tricarbonyl was isolated in 72% yield (experimental details not included). From this, one can conclude that both pertechnetate/perrhenate and technetium/rhenium oxide are suitable metal sources for the DLT reaction.

MicroPET Imaging and Biodistribution Studies of CpT[^{94m}Tc]-COCH$_3$ in Mice (*51, 52*). The simple cyclopentadienyl substituents and overall structure of the model CpT[^{94m}Tc] compounds prepared by the DLT reaction were not expected to target the ER. Nevertheless, to demonstrate the ability to synthesize adequate activity for animal imaging studies and in a chemical formulation compatible for safe iv administration into animals, compound **2a** was synthesized as discussed and used in both tissue distribution and microPET imaging studies of mice. Figure 3 shows a representative coronal microPET image slice of a C57/Bl6 mouse at 5 min pi of 175 μCi of **2a**. No significant differences in activity distributions were observed at later timepoints (out to 2 h pi) and are therefore not shown. This small, lipophilic compound shows high uptake in the liver and kidney area, as well as activity in the bladder, as would be expected in the hepatobiliary and renal clearance of such a compound. Tissue distribution studies of C57/Bl6 mice were also performed following low activity injections of compound **2a** (~10 μCi). These data, presented in Table 1, also show high activity in the clearance organs at 2 h pi.

Design and Synthesis of C-Ring Substituted Cyclofenil Analogues. The ligand binding pocket of the estrogen receptor has been shown to have a substantial amount of unoccupied space (~200 Å^3) when bound to estradiol, particularly in the middle of the ligand binding pocket, near the B and C rings (*54*) (Figure 4a). Several bridged bicyclic C-ring derivatives of cyclofenil have recently been reported to have high RBA for the ER (*40*, *41*), suggesting the potential of other C-ring modifications. Figure 4 shows the structural similarity of the cyclofenil analogues reported here compared to both estradiol and to an example of the reported bicyclic cyclofenil analogues.

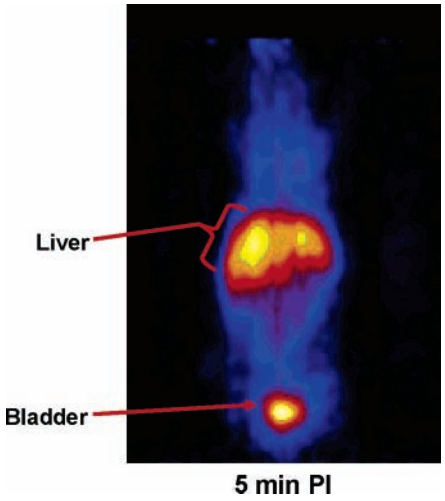


Figure 3. Representative coronal microPET image slice of a C57/Bl6 female mouse at 5 min post tail vain injection of CpT[^{94m}Tc]-COCH$_3$ (**2a**, 175 μCi). Liver and bladder are highlighted with arrows.

Table 1. Biodistribution of CpT[^{94m}Tc]-COCH$_3$ (2a) in Male C57/Bl6 Mice[a]

tissue	**2a**	tissue	**2a**
blood	0.22 ± 0.05	muscle	0.36 ± 0.29
lung	15.25 ± 1.55	fat	1.13 ± 0.80
liver	30.35 ± 2.22	brain	0.04 ± 0.02
spleen	0.17 ± 0.08	bone	0.77 ± 0.74

gallbladder	13.35 ± 2.54	testes	0.26 ± 0.22

[a] % Injected dose per gram at 2 h pi; values are reported as the mean ± SD; $n = 4$ for each time point.

The conditions for the incorporation of ^{94m}Tc into Cp-substituted CpT[^{94m}Tc] systems from the corresponding Cp-substituted ferrocene via the DLT reaction had been established (Scheme 2). We, therefore, sought to synthesize the DLT ferrocene precursor (**9**) necessary for the generation of the CpT[^{94m}Tc] cyclofenil analogue. A model synthesis, to produce a benzoyl cyclofenil analogue (**6**), was performed to assist in the development of effective synthetic conditions. The CpTRe cyclofenil compound (**10**), for characterization and RBA determination, was also synthesized. These syntheses, described briefly here, are detailed in the Experimental Procedures section.

Synthesis of the benzoyl model compound **6** began with the preparation of the known precursor **5**, as shown in Scheme 3 (*55*). Stirring the commercially available 4,4′-dimethoxybenzophenone **3** with the Grignard reagent ethylmagnesium chloride gave the alcohol **4** as the major product. Some formation of the alkene **5** was also observed. Dehydration was effected by refluxing the collected mixture of **4** and **5** in benzene with *p*-toluenesulfonic acid. Friedel−Crafts acylation of **5** with benzoyl chloride to yield the benzoyl cyclofenil analogue **6** was carried out by slow addition of benzoyl chloride to a cooled solution of **5** and aluminum chloride, followed by stirring

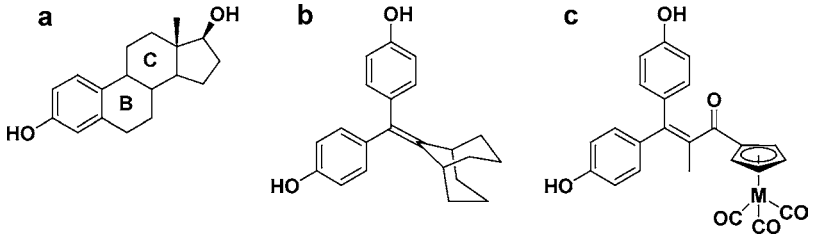

Figure 4. The structures of estradiol (**a**), a literature C-ring substituted analogue (**b**) (*40*), and a C-ring substituted CpTM analogue (**c**).

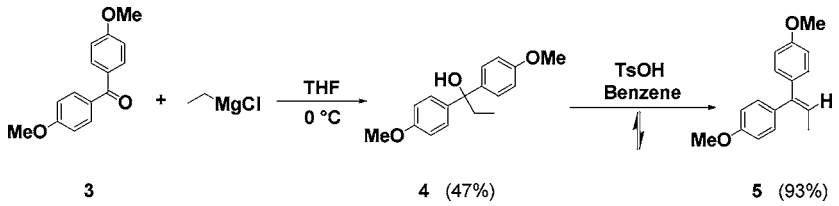
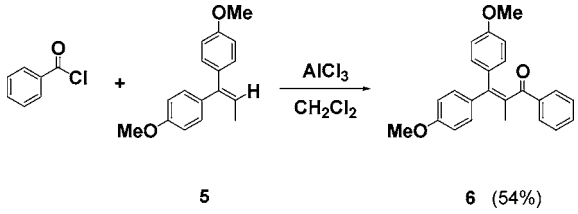
Scheme 3



Scheme 4



at room-temperature overnight. This gave **6** in 54% yield whereas other orders of addition and changing the Lewis acid resulted in poor yields (10−20%).

The ferrocene cyclofenil **9** analogue was prepared as outlined in Scheme 5. Conversion of the commercially available ferrocene carboxylic acid **7** to the ferrocene acid chloride **8** was quickly accomplished with oxalyl chloride (the use of thionyl chloride resulted in a thick black material) (*56*). Yields of this reaction were very high, provided that anhydrous conditions were strictly maintained. Initial efforts to synthesize **9** with Friedel−Crafts conditions based on the model reaction in Scheme 4 gave low and variable yields (<5−20%). The use of a large excess of Zn dust prevented the oxidation of the ferrocene and resulted in significantly increased and reproducible yields (*57*). The reaction time was also cut from 12 to 2 h, as the formation of the multiple side products worsened with time. The reduction in yield from this considerably shorter reaction time was found to be less than 5%. One of the side products was isolated and shown to be ferrocene anhydride, presumably from the reaction of the **8** with unreacted or hydrolyzed **7**.

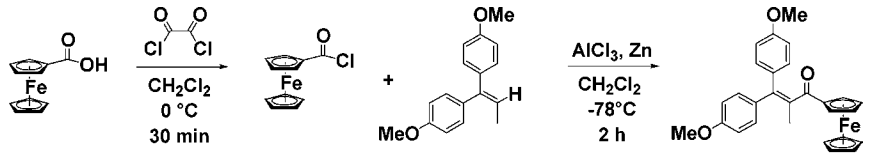
Scheme 6 illustrates the synthesis of the CpTRe cyclofenil compound **10** via a DLT reaction on **9**. The ferrocene precursor used here was monosubstituted, as opposed to the 1,1′-disubstituted precursors used in Scheme 2. We and others have reported that a carbonyl group must be directly attached to the Cp ring to effect the ring transfer (*36, 58*); therefore, the DLT reaction in Scheme 6 was predicted to react preferentially on the substituted Cp ring of **9**. As expected, we found no evidence of a ring transfer reaction occurring on the bare Cp ring. Other monosubstituted ferrocene precursors have been successfully labeled, though typically with yields much lower than with the 1,1′-disubstituted counterparts (*36*, *59*). Hence, the lower yield of the reaction in Scheme 6 relative to those in Scheme 2 was not surprising (the lower temperatures may also have accounted, in part, for the lower yields). Though modest, the yield of this reaction produced adequate material for characterization, deprotection and RBA studies; optimization of temperature and reaction time was not performed.

Structural studies of ER binding have indicated the need of a pharmacophore with two free phenols, similar to those of estradiol (spaced approximately 11 Å apart, (*54*)); therefore, good binding of the methyl ether protected compounds **5**, **6**, **9**, and **10** would not be expected, and deprotection conditions were investigated. This proved to be somewhat of a challenge. Deprotection of the phenolic methyl ethers using various reagents (BBr_3, BBr_3 with Zn, $AlCl_3$, $AlCl_3$ with EtSH) and reaction temperatures resulted in either no reaction or product decomposition. Under the conditions in Scheme 7, the deprotection of both phenols appeared, by TLC, to go to completion (*32*). However, the diphenolic compounds were difficult to isolate and purify, as they were found to be sensitive to heat, air and light to varying degrees. Nevertheless, the desired bisphenols **5a**, **9a**, and **10a** could be obtained in reasonable yields. The deprotected benzene compound was the most unstable and could not be prepared. Details and attempts to stabilize the compounds are given above in the Synthetic Notes of Diphenolic Compounds section.

Estrogen Receptor Binding Affinity Determination. Table 2 presents the binding affinity data of the cyclofenil analogues developed in this study. Binding affinities were determined by competitive radiometric binding assays with [^{3}H]estradiol, using cytosol preparations of lamb uterus (considered to be almost all ERα) or full-length human ERα and ERβ, as previously described (*47, 48*). Binding affinities are expressed relative to that of the standard, estradiol, as relative binding affinity (RBA) values, where the affinity of estradiol is 100%.

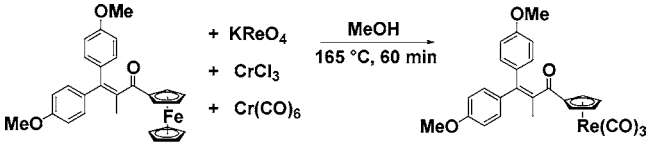
Binding affinities are presented for both the protected and deprotected compounds. As expected, the deprotected compounds (**5a**, **9a**, and **10a**) all gave significantly higher binding affinities than their protected counterparts (**5**, **9**, and **10**), ranging from 19- to 213-fold increases, which is a typical differential between phenols and their corresponding methyl ethers. The diphenolic alkene compound **5a** showed a small preference for the ERβ subtype, while the CpTRe cyclofenil analogue **10a** had a small preference for the ERα subtype, and the ferrocene cyclofenil analogue **9a** showed no subtype preference. The CpTRe cyclofenil analogue **10a** gave the highest RBA of

Scheme 5



7 **8** (90+%) **5** **9** (57%)

Scheme 6



9 **10** (29%)

Scheme 7

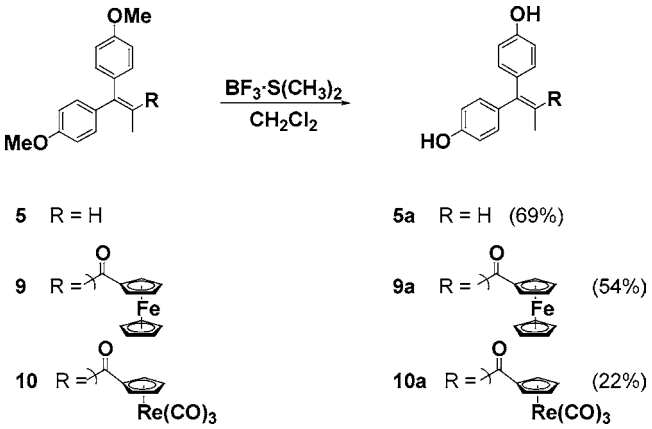


Table 2. Relative Binding Affinities (RBA) of Cyclofenil Analogues[a]

	RBA (%)		
ligand	cytosol	ERα	ERβ
estradiol	100	100	100
5	0.005 ± 0.001	0.006 ± 0.002	0.016 ± 0.004
6	0.004 ± 0.001	0.008 ± 0.002	<0.003
9	0.010 ± 0.003	0.014 ± 0.008	0.031 ± 0.004
10	0.014 ± 0.013	0.009 ± 0.006	0.034 ± 0.037
5a	0.274 ± 0.064	0.408 ± 0.109	1.399 ± 0.534
9a	0.648 ± 0.395	0.773 ± 0.205	0.868 ± 0.019
10a	0.357 ± 0.010	1.920 ± 0.467	0.634 ± 0.028

[a] Values are reported as the mean ± range ($n = 2$) or SD ($n > 2$) of 2−4 independent determinations. Under these conditions, the K_d for estradiol is 0.2 nM for ERα and 0.5 nM for ERβ.

nearly 2% that of estradiol for the ERα subtype. This value, although the highest in this study, is quite low compared with many of the reported ER-targeting compounds in recent literature (*25*, *32*, *41*). As the chemical and physical behavior of rhenium and technetium are very much alike, a CpT[^{94m}Tc] cyclofenil analogue, if synthesized, would also be expected to have a low affinity for the ER. Considering the low RBAs coupled with the handling difficulties of the free phenolic compounds, ^{94m}Tc labeling and imaging studies of these compounds were not pursued.

In conclusion, methods were developed for the rapid incorporation of the short-lived radionuclide ^{94m}Tc into two representative CpT[^{94m}Tc] systems (**2a** and **2b**) with sufficient yield, purity, and iv formulation compatability for animal studies. Qualitative analysis of the microPET images of compound **2a** match the tissue distribution studies of **2a**, suggesting that screening of new radiopharmaceuticals is possible with ^{94m}Tc and microPET. The synthesis of three C-ring substituted cyclofenil analogues was accomplished. Additionally, the conversion of the ferrocene analogue (**9**) into the CpTRe analogue (**10**) by the DLT reaction further demonstrated its utility for the synthesis of CpTM systems with both large and small cyclopentadienyl substituents. This predicts the use of this reaction for the successful incorporation of rhenium and technetium radionuclides into this and other cyclofenil analogues. While literature precedent suggested CpTM cyclofenil compounds as logical targets, the analogues synthesized in the present study had low relative binding affinities for the ER. A new direction may be to vary the C-ring bulk of the CpTM cyclofenil compounds, potentially leading to greater affinity for the ER. This may be accomplished, for example, by the use of a series of alkene precursors and/or extending the linker between the alkene and the ferrocene moieties. However, this approach may not resolve the handling difficulties of this class of diphenolic compounds.

ACKNOWLEDGMENT

We are grateful for support of this research through grants from the National Institute of Health (PHS 5R37 CA25836 [J.A.K.]) and the Department of Energy (DE FG02 84ER60218 [M.J.W.] and DE FG02 86ER60401 [J.A.K.]). Technetium-94m was produced at Washington University Medical School and partially funded through a National Cancer Institute grant (R24 CA86307). MicroPET imaging was partially supported by an NIH/NCI SAIRP grant (1 R24 CA83060). We thank the Small Animal Imaging Core of the Alvin J. Siteman Cancer Center at Washington University and Barnes-Jewish Hospital in St. Louis, MO, for additional support of the microPET imaging. The Core is supported by an NCI Cancer Center Support Grant (1 P30 CA91842). NMR spectra were obtained in the Varian Oxford Instrument Center for Excellence in NMR Laboratory at the University of Illinois. Funding for this instrumentation was provided in part from the W. M. Keck Foundation, the National Institutes of Health (PHS 1 S10 RR104444-01), and the National Science Foundation (NSF CHE 96-10502). Mass spectra were obtained on instruments supported by grants from the National Institute of General Medical Sciences (GM 27029), the National Institutes of Health (RR 01575), and the National Science Foundation (PCM 8121494). We also thank Kathryn Carlson at the University of Illinois for the binding affinity measurements and Eric Mull currently at Boehringer-Ingelheim for his assistance in the preliminary CpTM synthesis efforts.

Polymer–Oligonucleotide Conjugate Synthesis from an Amphiphilic Block Copolymer. Applications to DNA Detection on Microarray

Bertrand de Lambert, Carole Chaix,* Marie-Thérèse Charreyre, Alain Laurent, Arnaud Aigoui, Agnès Perrin-Rubens, and Christian Pichot

Unité Mixte CNRS/bioMérieux, Ecole Normale Supérieure de Lyon, 46 allée d'Italie, 69364 Lyon Cedex 07, France. Received August 30, 2004; Revised Manuscript Received January 3, 2005

An amphiphilic block copolymer poly(*tert*-butylacrylamide-*b*-(*N*-acryloylmorpholine-*N*-acryloxysuccinimide)) (poly(TBAm-*b*-(NAM/NAS)) and a random copolymer poly(NAM/NAS), synthesized by the reversible addition–fragmentation chain transfer (RAFT) polymerization process, have been used as support for oligonucleotide (ODN) synthesis, to elaborate polymer–oligonucleotide conjugates. In a first step, starters of ODN solid-phase synthesis were coupled to activated ester functions of polymers, and second, resulting functionalized polymers were covalently grafted onto hydroxylated controlled pore glass (CPG) support to further accomplish ODN synthesis. An efficient capping of residual hydroxyl functions of CPG was performed before synthesis, with both acetic anhydride and diethoxy-*N*,*N*-diisopropyl-phosphoramidite reagents, to suppress parasite-free ODN population present in conjugate crude material and resulting from syntheses directly initiated on silica beads. After purification, conjugates were evaluated in a DNA hybridization assay on a microarray, as macromolecules being able to favor capture of the target. Conjugate coating conditions were studied on the dT25/dA25 model. The role of the hydrophobic part (poly(TBAm)) of the conjugate synthesized with the block copolymer in the orientation of the conjugate after coating was revealed by spotting experiments achieved in a mixed solvent (DMF/H_2O). The use of block copolymer–dT25 conjugate afforded a significant sensitivity improvement of the hybridization assay.

INTRODUCTION

DNA biochip technology on microsystems has been intensively developed this past decade to answer the increasing need of DNA sequence multianalyses in reduced time and in small volumes. In a general manner, DNA microarrays are elaborated by two main methods: (i) in situ synthesis of oligonucleotides (ODNs) either by means of photolithographic techniques (*1*) or spotting robot device (*2*), (ii) mechanical deposition of presynthesized oligonucleotides via ink-jet printing technology (*3*). To develop low-density DNA probe microarrays, the latter strategy of ODN spotting appeared to be more suitable. By this technique and using a nanodroplet ink-jetting piezoelectric device, spot sizes can be varied between 150 and 250 μm and spot densities can reach 2500 spots/cm^2 (*4*).

DNA microarrays are elaborated with different sets of known oligonucleotide sequences (ODN probes) immobilized on precisely defined locations of a solid support. An important feature of a successful DNA microarray is a sensitive and discriminating detection of each event, for instance, hybridization of a complementary target sequence with ODN probes. Concerning the detection, fluorescence is the optical technique which offers the highest sensitivity because of a low background noise (*4*). After DNA target hybridization with the ODN probes, a positive signal arises from the labeled target (either by a fluorophore or by a specific enzyme which can convert a substrate into a fluorescent product).

To amplify the sensitivity of DNA detection, the use of polymers at the surface of the solid support has been reported in the literature. Acrylamide gels (*5*–7), dendritic structures (*8, 9*), and poly(pyrrole) films (*10*) favored the covalent immobilization of a high density of ODN probes (150–250 fmol/mm^2) which improved the capture of the DNA target.

Different strategies have been described to introduce these polymers in association with ODN probes onto the solid surface, to elaborate a DNA microarray by droplet spotting: (i) polymers can be deposited on the whole surface of the chip prior to spot the ODN probes (*5, 9*); (ii) ODN probes bearing polymerizable groups can be addressed individually on the chip surface, and the anchoring can proceed by copolymerization with comonomer mixtures (*6, 10*); (iii) polymer–ODN conjugates can be prepared in a first step prior to be spotted on the chip (*7*).

Our laboratory early focused on the elaboration of polymer–ODN conjugates which could improve DNA target capture efficiency and consequently enhance DNA detection sensitivity of these diagnostic assays. Reactive polymers such as poly(maleic anhydride-methyl vinyl ether) (*11*) and poly(*N*-vinyl pyrrolidone-*N*-acryloxysuccinimide) (*12*) were used to bind ODN probes, and the resulting conjugates were adsorbed onto the conical polymer support of a VIDAS instrument (bioMérieux Co.). To avoid the aggregation observed during the coupling reaction of the ODN to the polymer, as well as to control ODN amount and orientation onto the polymer chain, a new method of conjugate synthesis has been developed. Direct syntheses of oligonucleotides were performed from starters bound along the polymer chain further grafted on a solid support (controlled pore glass), either on poly(maleic anhydride-ethylene) (*13*) or on poly(*N*-acryloylmorpholine-*N*-acryloxysuccinimide) (*14*). This latter

method allowed us to synthesize conjugates with a high density of ODN per chain (up to 135 ODN per chain).

The adsorption of these conjugates produced from linear random copolymers results from nucleic base hydrophobic interactions with the polymeric support. In an attempt to control conjugate anchoring orientation on the solid support to favor ODN probe accessibility for DNA capture, we focused on the use of an amphiphilic block copolymer. The hydrophobic part of the resulting conjugate should adsorb preferentially onto the hydrophobic support, inducing an orientation of the hydrophilic part bearing the ODN probes toward the aqueous phase. The designed amphiphilic copolymer was the poly(*tert*-butylacrylamide-*b*-(*N*-acryloylmorpholine-*N*-acryloxysuccinimide)), poly(TBAm-*b*-(NAM/NAS)), containing both hydrophilic and reactive poly(NAM/NAS) block known to efficiently bind starters and an hydrophobic block poly-(TBAm). This latter block was chosen since TBAm is an hydrophobic monomer which polymerizes efficiently by the controlled radical polymerization technique used to synthesize the block copolymer, namely the reversible addition−fragmentation chain transfer (RAFT) polymerization process (*15*). Moreover, as TBAm is also an acrylamide derivative, it facilitates the synthesis of the second block (acrylamide and acrylate comonomers) from the poly(TBAm) block.

We aim at describing herein the direct synthesis of oligonucleotides from a block copolymer poly(TBAm-*b*-(NAM/NAS)) and a random copolymer poly(NAM/NAS), synthesized by RAFT process (*16, 17*). The use of these conjugates to elaborate DNA microarrays by ink-jet spotting techniques is studied, and the influence of the hydrophobic part of the conjugate on the performance of the diagnostic test is assessed.

MATERIALS AND METHODS

Reagents and Analyses. Controlled pore glass (CPG, 2000 Å mean pore diameter; 40−85 μm particle size; 9.2 m^2/g surface area) was ordered from Fluka. Anhydrous DMF (99.9%) was purchased from Aldrich. 6-(Trifluoroacetylamino)-1-hexanol (>98% from Fluka), (3-*O*-dimethoxytrityl-1,3-diol)-[(β-cyanoethyl)-*N*,*N*-(diisopropyl)]-phophoramidite (Spacer C3, Glen Research), DMAP (99% from Aldrich), hexa(ethylene glycol) (97% from Aldrich), triethylamine (99.5% from Aldrich), glycidyloxypropyltrimethoxysilane (97% from Fluka), and fluorescamine (Acros) were used as received.

Poly(TBAm-*b*-(NAM/NAS)) and poly(NAM/NAS) were synthesized as described in previous papers (*16, 18*). ODNs were synthesized on an Applied Biosystems DNA synthesizer (Model 394) by β-cyanoethyl phosphoramidite chemistry. Purity of the polymer−ODN conjugates was determined by aqueous SEC, using a Waters UltraHydrogel column 500 Å, a Kontron HPLC pump 422, a Kontron HPLC autosampler 465, and a Kontron diode array detector 440. The eluent was a phosphate buffer (0.1 M, pH = 6.8), at a flow rate of 0.5 mL/min. UV detection was achieved at 260 nm.

HPLC analyses of ODNs was performed on an Alliance Instrument from Waters, using XTerra RP 18 column with elution in acetonitrile/triethylammonium acetate buffer 0.05 M gradient (from 4.5% to 8.5% V/V) at 37°C. The flow rate was of 1 mL/min and UV detection was achieved at 260 nm.

Fluorescence measurements were carried out on a Perkin-Elmer LS50. ESI Mass Spectrometry analyses of starter **1** were performed on a Api 165 PE SCIEX instrument (Applied Biosystems). ^{1}H NMR spectra were recorded on an Avance 200 MHz Bruker spectrometer.

(3-*O*-Dimethoxytritylpropane-1,3-diol)−(6-aminohexyl) Phosphate (Starter 1) Synthesis. 84 mg (0.4 mmol) of 6-(trifluoroacetylamino)-1-hexanol were coevaporated with dry acetonitrile and dissolved afterward in 1 mL of this solvent. Then, 1.1 equiv (250 mg, 0.44 mmol) of (3-*O*-dimethoxytritylpropan-1,3-diol)-[(β-cyanoethyl)-*N*,*N*-(diisopropyl)] phosphoramidite (Spacer C3, Glen Research) and 1.3 equiv of ^{1}H-tetrazole (0.52 mmol of a 0.45 M solution/acetonitrile, Glen Research) were successively added to the solution and the mixture was stirred at room temperature during 3 h, under argon atmosphere. Then, 20 mL (5 equiv) of iodine solution (0.1 M in H_2O/pyridine/THF from Glen Research) was added, and the mixture was stirred during 30 min prior to concentrate the solution under reduced pressure. The residue was dissolved in CH_2Cl_2, and the organic phase was washed once with $NaHCO_3$, and twice with H_2O before evaporation to dryness in vacuo. Then, the residue was resuspended in KOH solution (0.2M in ethanol), and the deprotection reaction was achieved in 16 h at room temperature. After concentration in vacuo, the residue was chromatographed on a column of silica gel with (CH_2Cl_2/triethylamine 95/5) and methanol gradient to give starter **1** (70% yield). ^{1}H NMR ($CDCl_3$): 1.15−1.70 (m, 8H, $CH_2CH_2CH_2CH_2CH_2CH_2$); 1.33 (t, CH_3 TEA) 1.82 (m, 2H, $OCH_2CH_2CH_2O$); 2.71 (m, 2H, CH_2NH_2); 3 (q, CH_2 TEA); 3.05 (m, 2H, CH_2-ODMT); 3.70 (s, 6H, OCH_3); 3.84−3.90 (m, 4H, CH_2OPOCH_2); 6.70−7.35 (m, 13H, H Ar); 7.90−8.60 (large peak, NH_3^+). ESI mass analysis in negative mode: $[M - H]^- = 556.3$.

CPG Bead Functionalization. The functionalization step was adapted from a previous procedure published by Maskos and Southern (*19*). First, 1.38 g of underivatized CPG 2000 Å (Fluka) was suspended in chromic−sulfuric acid solution (saturated solution of chromium(VI) oxide in sulfuric acid (purity >95%)). After 3 h activation at 120°C, a large proportion of silane groups on the surface was in silanol form. Activated beads were filtered, carefully washed with water and acetone, and rapidly dried in vacuo prior to use for silanization.

To the beads suspended in 22.3 mL of dry toluene were added 6.8 mL of (glycidyloxypropyl)trimethoxysilane (Fluka) and 1.9 mL of triethylamine (Aldrich). The suspension was gently stirred overnight at 80 °C, then filtered, washed with anhydrous acetone, and dried during 2 h at 120 °C. In a second step, these beads were suspended in 5.52 mL of hexa(ethylene glycol) (Aldrich) with 3.1 μL of sulfuric acid (purity >95%), and the mixture was gently stirred at 80 °C overnight. Finally, the functionalized beads were carefully washed with anhydrous acetone and dried in desiccator.

Coupling of Starter 1 Kinetics onto Random and Block Copolymers. The same protocol was carried out for the two copolymers, poly(TBAm-*b*-(NAM/NAS)) and poly(NAM/NAS). First, 4 mg of block copolymer (or 3.65 mg of random copolymer) was dissolved in 500 μL of anhydrous DMF. In parallel, 3.1 mg of starter **1** (0.6 equiv in comparison with NAS units) was dissolved in 500 μL of the same solvent and added to the polymer solution containing 0.375 mg of DMAP (0.3 equiv). The mixture was stirred at room temperature during 10 days. At defined times, aliquots (10 μL) were withdrawn from the mixture and added to 240 μL of a fluorescamine solution (0.3 mg/mL in DMF) to follow the kinetics via primary amine titration. After 4 h storage in darkness, samples were analyzed by fluorimetry (λ_{em} = 392 nm, λ_{ex} = 463 nm). The fluorescence intensity was related to the concentration of starter **1** in the solution, using a calibration curve $I_{fluo} = f$([starter **1**]) previously obtained under

Table 1. Characteristics of the Block Copolymer, Poly(TBAm-*b*-(NAM/NAS)), and of the Random Copolymer, Poly(NAM/NAS)

sample	copolymer composition (mol %) (^{1}H NMR)	Mn (g/mol) (SEC/LS)	PDI
block: poly(TBAm-*b*-(NAM/NAS))	9/57/34	14000/103000[a]	1.4
random: poly(NAM/NAS)	60/40	71000	1.1

[a] Theoretical mass for the second block.

the same conditions. With this titration method of residual starter **1** in solution, the kinetics of the coupling reaction on the polymer have been obtained.

Grafting of Polymer–Starter 1 Conjugate onto Functionalized CPG Beads. After 10 days of the coupling reaction between copolymer and starter **1**, 150 mg of functionalized CPG beads was added to the mixture, and the grafting reaction was continued under gentle stirring during 5 additional days. Supports were then filtered and carefully washed with anhydrous DMF and anhydrous acetone prior to drying in vacuo for several hours.

ODN Synthesis on Polymer-Functionalized CPG Beads. Columns were loaded with 25 mg of polymer-functionalized beads and a standard 1 μmol β-cyanoethyl phosphoramidite coupling cycle was used for ODN syntheses on an Applied Biosystems 394 instrument. Before syntheses, different capping steps were studied. Ac_2O capping was either achieved directly on the instrument, i.e., three runs of 15 s of Ac_2O capping reagents (acetic anhydride/pyridine/THF; *N*-methylimidazole/THF) alternated with waits of 5 min, or in a flask, i.e., reaction with 1 mL of acetic anhydride in 1 mL of acetonitrile stirred during 120 min. An additional capping was achieved by 10 min reaction with diethoxy-*N*,*N*-diisopropyl-phophoramidite (DPP) 0.1 M or 0.5 M in acetonitrile directly on the instrument. Then, after washing the CPG with acetonitrile, an oxidation step was achieved with iodine (I_2/pyridine/H_2O). During syntheses, the stepwise yield of coupling reaction was automatically determined by dimethoxytrityl cations measurement. For the cleavage and deprotection step, ammonia (30% aqueous) was used for 16 h at 60°C. After concentration in vacuo, conjugates were resuspended in water and purified by filtration on Centricon (Millipore, cutoff of 100000 g/mol) and analyzed by SEC.

Microarray Setup. DNA microarray was elaborated from standard 96-well microplates. Capture probes (polymer–ODN conjugates or ODN) were diluted at 10 μM (ODN concentration) in a coating buffer (150 mM Na_2HPO_4/NaH_2PO_4, from 50 to 400mM NaCl, 1 mM EDTA, pH 7.4). The standard coating buffer used in the study contained 400 mM NaCl. Spotting of this solution in the microplate wells was carried out with a Biochip Arrayer (Perkin-Elmer), which is based on a submicroliter noncontact, drop-on-demand piezoelectric dispensing technology providing a typical spot diameter of 250 μm. Each probe was deposited in duplicate spots, following the circular format of the 96-wells microplate (Apibio microarray). After spotting of the capture probe solution and drying under controlled pressure and temperature, microplates were rinsed with PBS-Tween 20, 0.05%. Then, microarrays were dried in vacuo before storage.

OLISA Test: Capture and Detection Procedures. The fluorescent ODN target 5′CY3-dA25 was diluted in 30 μL of reaction buffer (0.1 M Na_2HPO_4/NaH_2PO_4, 0.5 M NaCl, 0.6% Tween 20, 2% PEG 4000, pH 7). The solution was incubated in the spotted well for 1 h at 37 °C. The well was rinsed twice with PBS-Tween 20, 0.05%.

Then, the array was imaged with the automated Apimager system (Apibio, Grenoble, France). Spot densities were analyzed by calculation of the mean gray level of each spot minus that of the corona surrounding the spot. Pixel densities were scaled from 0 (no signal) to 65 536 (saturating signal) and expressed in arbitrary units (a.u.).

RESULTS AND DISCUSSION

Polymer Synthesis and Characterization. The polymers used in this study were synthesized by a controlled radical polymerization technique, namely the reversible addition–fragmentation chain transfer (RAFT) polymerization, as described in recent papers from our laboratory (*17*, *20*). The RAFT polymerization of the *N*-acryloylmorpholine/*N*-acryloxysuccinimide comonomer pair was performed in the presence of either a dithioester to give a random (statistical distribution of each monomer) copolymer poly(NAM/NAS) (*18*) or a macrodithioester (chains of poly(*tert*-butylacrylamide) also synthesized by RAFT (poly(TBAm)) to produce a block copolymer poly(TBAm-*b*-(NAM/NAS)) (*16*). The two copolymers used in this study (Figure 1) were characterized by ^{1}H NMR and size exclusion chromatography with an on-line light scattering detector (SEC/LS) (*16*, *17*) (Table 1). Both copolymers are homogeneous in size (polydispersity index, PDI < 1.5) and present a long hydrophilic chain (M_n > 70 000 g mol^{-1}). In the block copolymer, the presence of the hydrophobic block of poly(TBAm) induces an amphiphilic behavior. For instance, a similar block copolymer poly(TBAm-*b*-NAM) of 14 000/90 000 g/mol has a critical micellar concentration (CMC) of 1 g/L.

Conjugate Elaboration Strategy. Polymer–ODN conjugates were obtained via a strategy of ODN direct synthesis from polymer chains previously grafted onto hydroxylated silica support, as displayed in Figure 2.

In a first step (A), the polymer was functionalized with a starter of ODN synthesis (starter **1**). The amine

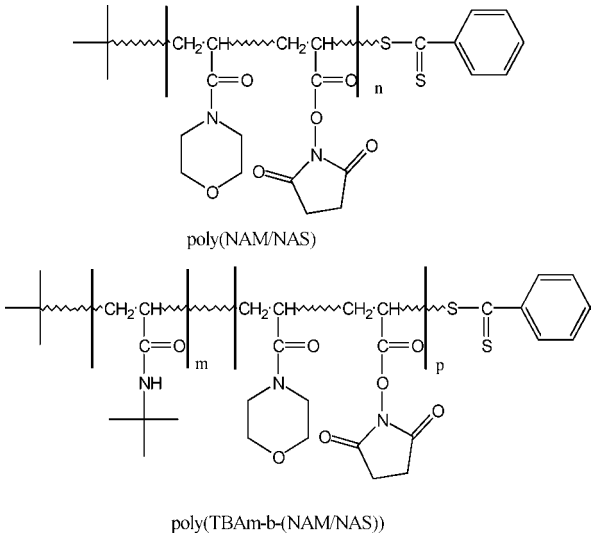

Figure 1. Random copolymer poly(NAM/NAS) and block copolymer poly(TBAm-*b*-(NAM/NAS)) structures.

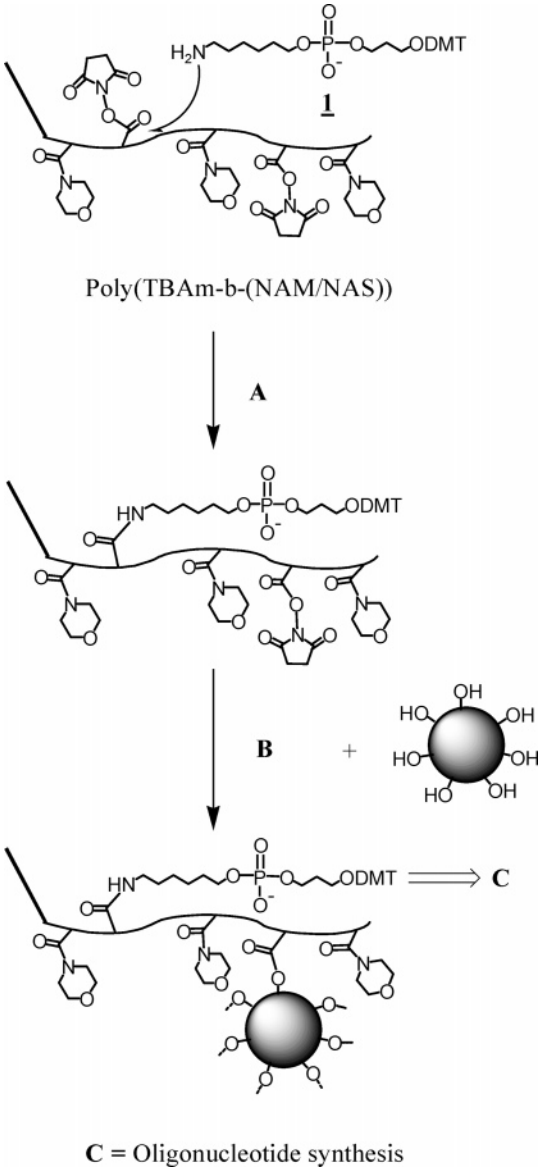

Figure 2. Strategy of conjugate synthesis; step A: Starter **1** functionalization of polymer; step B: grafting of (starter **1**−Polymer) onto HEG-CPG; step C: oligonucleotide synthesis.

function of **1** reacted with the activated ester of polymer. Then, in a second step, the starter-containing polymer was immobilized on CPG through reaction between hydroxyl groups from solid surface and some residual activated ester functions of the polymer (step B). As starter, **1** bears, on one extremity of its alkyl chain, a hydroxyl protected by a dimethoxytrityl (DMT) group. After DMT cleavage under acid treatment, the recovered OH group will be used to initiate oligonucleotide synthesis (step C).

*Starter **1** Synthesis.* Starter **1** structure was designed in order to avoid different hurdles encountered in this laboratory with other molecules elaborated for the same purpose: (i) a nucleotide analogue (5′-dimethoxytrityl-2′-deoxythymidine-3′-(6-aminohexyl phosphate)) which was described to react with maleic anhydride copolymers (*13*) or poly(NAM/NAS) copolymers (*14*) not only via the terminal amino group but also via the intracyclic amine function of the nucleic base, forming an unstable link (in ammonia) between polymer and starter, (ii) a neutral starter, DMT-O$(CH_2)_6NH_2$, efficiently coupled to poly(NAM/NAS) but appearing to inhibit further grafting reaction onto CPG (step B) (unpublished results). According to this latter observation, we aimed at introducing one phosphate group (bringing a charge) in the alkyl chain of the molecule, to restore the grafting ability of the resulting starter **1**−polymer conjugate onto hydroxylated silica support.

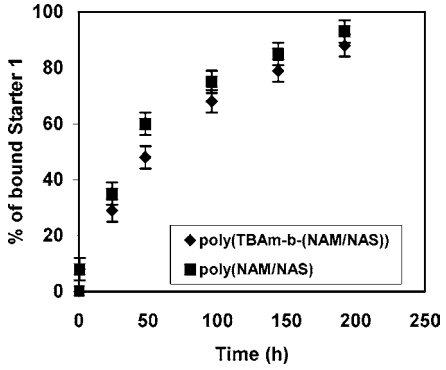

Figure 3. Kinetics of starter **1** coupling reaction to poly(TBAm-*b*-(NAM/NAS)) and to poly(NAM/NAS) (0.6 equiv of **1** per NAS units).

In this work, a new starter of DNA synthesis was designed (starter **1**, Figure 2) presenting at one extremity of its alkyl chain a primary amino function, at the other extremity a hydroxyl function protected by a dimethoxytrityl group, and a phosphate group included inside the chain.

Starter **1** synthesis was achieved via phosphoramidite coupling reaction with good yield (70%), as described in the experimental part.

*Coupling of Starter **1** to Block and Random Copolymers (Step A).* The coupling kinetics of starter **1** to polymer were investigated on both poly(TBAm-*b*-(NAM/NAS)) and poly(NAM/NAS). Conversions were determined by fluorimetry, as described in the experimental part. At different times, the amount of residual starter **1** was quantified using a specific titration of primary amine functions with fluorescamine. An excess of fluorescamine was used (> 5 equiv); preliminary studies showed that neither DMF nor polymers led to a reaction with fluorescamine.

The kinetics were followed with three different initial concentrations of starter **1** in solution, i.e., 0.6, 0.3, and 0.1 equiv of **1** per NAS units in the polymer (Figure 3, case of 0.6 equiv).

As a result, functionalization rates were similar for the two polymers. A reaction time around 8 days led to coupling yields higher than 95%. At this edge, residual starter quantification became difficult because of the too low concentration remaining in solution (sensitivity limit of the spectrofluorimeter). Then, 10 days were preferred to reach an optimized coupling yield (> 95%). Kinetics obtained with 0.3 and 0.1 equiv of **1** per NAS units were similar to the ones of Figure 3.

Grafting of Polymer−Starter Conjugate onto HEG-Functionalized CPG Beads (Step B). In the second step (B, Figure 2), the resulting polymer−starter **1** conjugate was grafted onto controlled pore glass (CPG) support (pore diameter of 2000 Å) which had been previously derivatized with hexa(ethylene glycol) (HEG), following protocols described by Maskos and co-workers (*19*).

As previously described (*14*), polymer grafting onto functionalized CPG was optimum after 5 days reaction. Grafting efficiency of the polymer−starter **1** conjugate was controlled through quantification of dimethoxytrityl groups released from starters **1** bound to polymer chain. The obtained amount of DMT cations released per gram

of support are reported in Table 2 (with different ratios of starter **1** introduced at the first step of the reaction).

Regarding results in Table 2, the higher the amount of starter **1** bound to the polymer chain, the higher the loading of conjugate onto CPG. In addition, functionalization yields were very similar for the two polymers indicating that the hydrophobic part of the block copolymer did not affect grafting reaction.

Oligonucleotide Synthesis on Polymer-Functionalized CPG Beads (Step C). Poly(TBAm-*b*-(NAM/NAS))- and poly-(NAM/NAS)-functionalized CPG beads were introduced in a DNA synthesizer (Applied Biosystems). Then, 25mer polythymidylates (dT25) were synthesized from the bound starters using standard 1 μM phosphoramidite cycle, as described in the experimental part.

Average coupling yield of thymidine synthon was estimated around 98% per cycle. After syntheses, standard ammonia treatment released the polymer–ODN conjugates which were analyzed by SEC. In both cases, chromatograms (at 260 nm) revealed the presence of two populations of nucleic acids (Figure 4).

The first population, eluted at 11.4 min for poly(TBAm-*b*-(NAM/NAS)) and at 12.55 min for poly(NAM/NAS), corresponded to the expected polymer–ODN conjugates. The same amount of conjugate was obtained in both cases (similar peak area on both chromatograms). An additional peak, eluted at 9 min, was observed for block copolymer conjugate which could result from a micellar aggregation of a part of the conjugate due to the hydrophobic block of the polymer. This observation confirmed the potential influence of the hydrophobic block on the conjugate structure in an aqueous medium.

The second population, eluted at 17.7 min, corresponded to free ODN. This parasite population directly initiated from HEG-CPG was systematically observed during conjugate syntheses, even with polymers of different nature, as for instance maleic anhydride copolymers (*13*, *21*).

The two populations were separated by filtration on Centricon membranes (cutoff of 100 000 g/mol). Conjugates were efficiently purified to almost 100% as confirmed by SEC analysis of the resulting material (Figure 5).

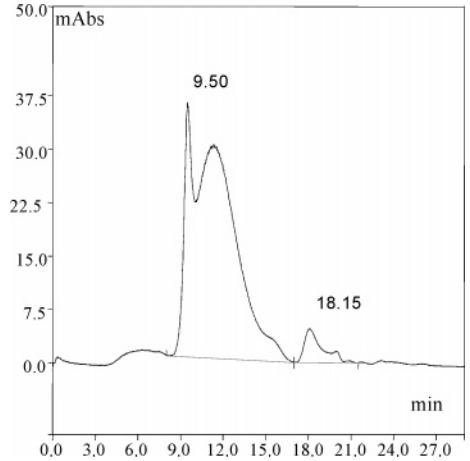

Figure 5. Poly(TBAm-*b*-(NAM/NAS))–dT25 conjugate SEC analysis after purification.

Parasite ODN Population Analysis. Aiming at investigating on the origin of parasite ODN population, a GACTGACT sequence model (including the four nucleotides) was synthesized from poly(TBAm-*b*-(NAM/NAS))-functionalized CPG. Prior to oligonucleotide synthesis, a capping step with acetic anhydride was achieved directly on the DNA synthesizer, as described in the experimental part, to mask residual hydroxyl functions on CPG surface. Under these conditions, coupling yields of the nucleotide phosphoramidites were satisfactory (DMT^+ quantification > 97% per cycle).

After ODN synthesis and release of the polymer–ODN conjugate in solution with ammonia, the parasite-free ODN population was recovered from membrane filtration and analyzed on reverse phase HPLC (Figure 6).

Amazingly, chromatographic analysis revealed a main population of ODN (eluted at 25.8 min) different from the expected GACTGACT oligonucleotide of which reten-

tion time was measured at 13.8 min (data not shown). This fraction was then collected and analyzed by MALDI-TOF MS. The main peak (m/z = 2753.28) corresponds to GACTGACT-3′-HEG product (calculated M − H = 2753.7 g/mol). This unexpected result suggested that a strong adsorption of HEG may occurred on CPG surface during its derivatization. Further experiments are in progress to better understand this HEG adsorption mechanism.

Capping Study on Polymer-Functionalized CPG. As unexpected ODN synthesis could be initiated from residual hydroxyl groups present on the surface of polymer-functionalized CPG, the acetic anhydride capping step performed in the synthesizer before ODN elongation appeared to be only partially efficient. Then, an additional capping step was evaluated with a more reactive reagent (diethoxy-*N*,*N*-diisopropylphosphoramidite, DPP) described to efficiently react with hydroxyl groups on silica surface (*22*). Best results were obtained when achieving successively Ac_2O capping and DPP (0.5 M in acetonitrile) capping directly inside the synthesizer. A total reduction of 93% of parasite ODN population was reached in these conditions on HEG-CPG.

This capping strategy was assessed on poly(TBAm-*b*-(NAM/NAS))-functionalized CPG, aiming at suppressing free ODN population during conjugate synthesis. Table 3 indicates resulting conjugate amount in solution (in percentage calculated from SEC peak areas) after different cappings of the support before dT25 ODN synthesis.

Compared to experiment 1 performed without capping, Ac_2O and further DPP capping reactions clearly reduced parasite-free ODN population. The best result was reached in experiment 4 (Ac_2O + DPP (0.5 M)). Nevertheless, free ODN peak disappearance was not as important as the one preliminary observed on HEG-CPG (reduction of 93% of parasite ODN synthesis). Two hypotheses can be suggested to explain such a difference: (i) the polymer−starter conjugate immobilized on the bead surface could reduce access of capping reagents to the hydroxyl groups, (ii) a part of the free ODN would not result from a parasite ODN synthesis on the bead, but from a partial degradation of the polymer−ODN conjugate in ammonia after ODN synthesis. It was then important to check the stability of the conjugate during its release from the CPG beads.

Stability Study of Polymer−ODN Conjugate in Ammonia. After ODN synthesis, ammonia treatment (NH_4OH 30%, 16 h, 60°C) was achieved on CPG directly to release the polymer−ODN conjugate in solution and to remove the base protecting groups. Conjugate stability in these conditions was studied by SEC. After 16 h of reaction in ammonia, around 25% of initial conjugate peak area has disappeared on the benefit of free ODN peak (data not shown). This study confirmed that a part of bound ODN were cleaved from polymer under basic treatment.

To avoid this degradation, we attempted to reduce the time of basic treatment from 16 h to 8 h. However, SEC analysis of crude material revealed an incomplete release of the conjugate from the CPG beads (only 80% of conjugate were recovered in solution compared to the amount released after 16 h reaction). According to degradation kinetics showing low difference between 8 h and 16 h of ammonia treatment, the standard treatment of 16 h at 60°C was preferred.

Purity Analysis of the Conjugate's Oligonucleotides. The above study revealed a conjugate degradation under basic conditions (aqueous NH_4OH 30%, at 60 °C) leading to a free ODN population in solution. Thus, to control the quality of the oligonucleotides obtained from direct synthesis on polymer chain, we applied these conditions to a prepurified poly(TBAm-*b*-(NAM/NAS))−dT25 conjugate (purity > 95%). After 48 h treatment, the cleaved ODNs were recovered and purified from residual conjugate by filtration on Centricon membrane (cutoff of 100 000 g/mol). Reverse phase HPLC analysis of the ODNs resulting from conjugate degradation is shown on Figure 7. A main peak is observed on chromatogram, eluted at 22.5 min, that corresponds to the full length oligonucleotide plus an additional fragment at its 3′ extremity resulting from the cleavage process. This chromatographic profile showing a main peak of full length dT25, and on the other hand, a low amount of truncated sequences (peaks between 8 and 22 min) attested to the good quality of oligonucleotides directly

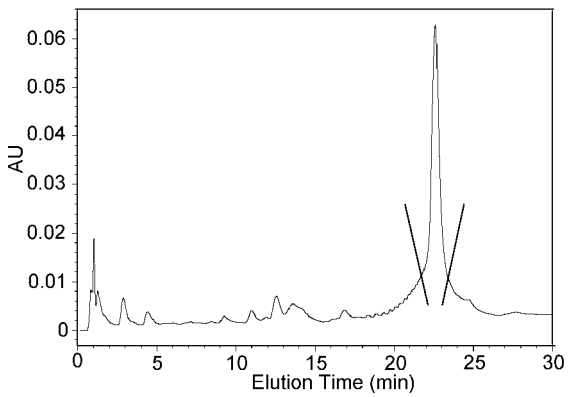

Figure 7. HPLC of ODNs bound to poly(TBAm-*b*-(NAM/NAS)); analysis achieved after conjugate degradation in ammonia.

synthesized onto polymer. To understand the conjugate degradation mechanism occurring in ammonia, the population eluted at 22.5 min during HPLC (Figure 7) was collected and analyzed by MALDI-TOF MS. The obtained mass (7681.56 g/mol) corresponded to a dT25−3′-O−PO_2−O-propanol (calculated M − H = 7680.7 g/mol). This surprising result suggested that the cleavage between ODNs and polymer chain in ammonia preferentially proceeded on the phosphate group of starter **1** instead of on the amide function binding the starter **1** to the polymer chain (Figure 2). In the literature, hydrolysis of phosphate diester groups of various molecules in basic medium was indeed described (*23, 24*). Two different cleavage mechanisms were reported, i.e., via a reaction on either C−O or P−O bound, which depended on the nature of the radicals borne by the phosphate. Results revealed that less sterically hindered phosphodiester groups were cleaved more rapidly, by an efficient nucleophilic attack on the carbon of C−O−P bound. When regarding the polymer−dT25 conjugate chemical structure in our case, the starter **1** phosphodiester group was less sterically hindered than the other phosphate groups of the oligonucleotide. This point could explain the specific cleavage observed on starter **1** phosphate diester linkage in aqueous ammonia, leading to conjugate degradation.

To conclude from the present results on conjugate elaboration, the strategy of direct synthesis of oligonucleotides from polymer can be applied to a block copolymer. In relation with the number of starter **1** bound to the polymeric chain, we can target conjugates with a broad range of ODN per chain (from 17 to 100). Prior to ODN synthesis, two capping steps must be performed on the functionalized CPG, with acetic anhydride and DPP reagents successively. This more efficient capping of residual hydroxyl groups from CPG beads allowed us to increase the amount of conjugate obtained in solution from 14.3% to 51% (percentages calculated in comparison with free ODN population). A slight degradation of conjugates was observed during the ammonia treatment. After investigation on the nature of the ODNs released from degradation, it seems that the cleavage preferentially proceeded on starter **1** phosphate diester group that linked ODN to polymer chain. HPLC analysis of ODN population recovered from conjugate degradation confirmed the good quality of oligonucleotides synthesized from the polymer. Conjugates were purified up to 95% prior to be used in hybridization assays in order to evaluate their performances in the capture phase.

Assessment of Polymer−ODN Conjugates in DNA Diagnostic Microarrays. Poly(TBAm-*b*-(NAM/NAS))−dT25 conjugates were evaluated in a microarray system based on a standard 96-well microtiterplate format functionalized in each well by 16 different spots. The Figure 8a shows the circular format of spots in the well. Biological species solutions are automatically deposited by droplet spotting technology (see experimental part). In a perspective of multidetection, the 16 spots could be addressed independently by ODN probes or proteins in order to develop in parallel oligosorbent and immunosorbent assays (*25*). In this work, we have evaluated conjugate ability to enhance signal of oligosorbent assay schemed in Figure 9.

Microarrays were functionalized by spotting either dT25 or copolymer−dT25 conjugates in phosphate buffer as described in Materials and Methods. It is worth noting that the concentration of free ODN or ODN bound to polymer in the case of conjugate were similar in spotting solutions. An assay performed with the poly(TBAm-*b*-(NAM/NAS))−dT25) conjugate is shown on Figure 8b. The picture corresponds to the resulting fluorescent signal obtained in the well after target hybridization. This experiment carried out at 10 nM of dA25-CY3 revealed that the assay run with conjugate was much more efficient (signal amplification × 5).

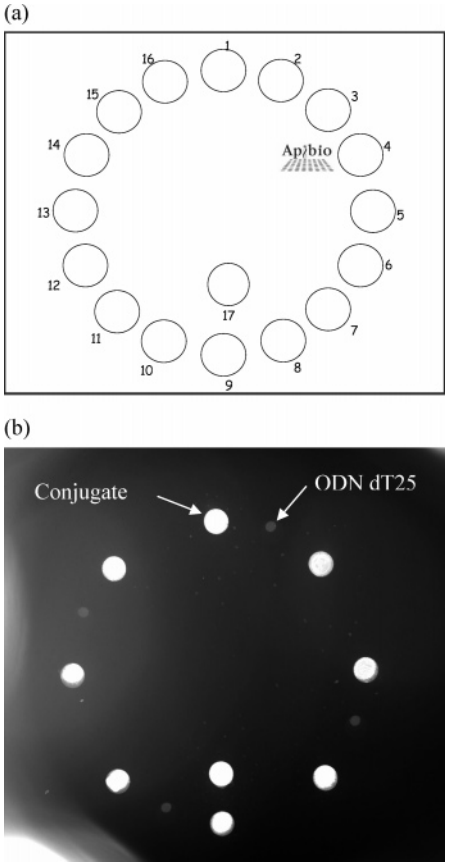

Figure 8. (a) Circular format of spots in wells of a microtiterplate from Apibio. (b) Circular microarray fluorescence resulting from 5′CY3-dA25 hybridization at 10 nM, after the spotting on surface of either ODN dT25 or poly(TBAm-*b*-(NAM/NAS))−dT25 conjugate at 10 μM (dT25 concentration) in standard buffer.

Influence of Salt Concentration in Spotting Buffer. Experiments were achieved in order to study the influence of salt concentration in coating buffer on the fluorescent signal obtained after target hybridization. Similar ODN concentration (10 μM) was used for both spottings of dT25 and poly(TBAm-*b*-(NAM/NAS))−dT25 conjugate solutions.

As shown on graph of Figure 10, variation of salt concentration in coating buffer clearly influenced the fluorescent signal resulting from hybridization with the target. Best results were obtained by spotting conjugates

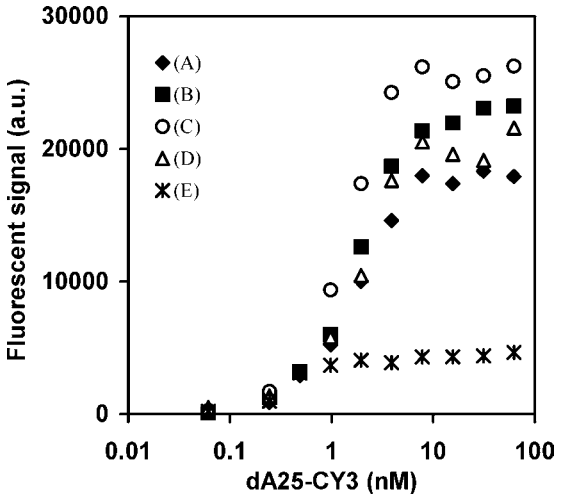

Figure 10. Influence of salt concentration in coating buffer (150 mM phosphate buffer, pH 7.4) on resulting fluorescent signal obtained in the assay. (A): [NaCl] = 400 mM, block copolymer−dT25 conjugate coating; (B): [NaCl] = 200 mM, block copolymer−dT25 conjugate coating; (C): [NaCl] = 100 mM, block copolymer−dT25 conjugate coating; (D): [NaCl] = 50 mM, block copolymer−dT25 conjugate coating; (E): [NaCl] = 400 mM, ODN dT25 coating.

in phosphate buffer (150 mM, pH 7.4) containing 100 mM NaCl. It is worth noting that the use of conjugate instead of oligonucleotide efficiently enhanced the fluorescent signal when dA25-CY3 concentration was higher than 1 nM. The use of conjugate increased dynamic range of dA25-CY3 detection (dynamic range from 0.2 nM to 1 nM using dT25 and from 0.2 nM to 10 nM using block copolymer−dT25 conjugate). To conclude from this study, phosphate coating buffer with 100 mM NaCl appeared to be good conditions for both conjugate anchoring on solid surface (salts suppress intermolecular electrostatic repulsions and so favor conjugate adsorption) and ODN probes expansion in solution. This latter parameter probably improves resulting accessibility of immobilized ODN probes for DNA capture.

Influence of ODN Number per Polymer Chain. According to the amount of starter **1** coupled to polymer chain, conjugates with different ODN numbers could be obtained. As described in Table 2, polymers were functionalized with three different amounts of **1** per NAS, i.e., 0.1, 0.3, and 0.6 equiv. Considering the coupling reaction yield of 95%, the number of ODN bound to the polymer could be estimated from the following equation:

$$f_{\mathrm{ODN}} = n_{(1)} \times Y \times N_{(\mathrm{NAS})}$$

with f_{ODN} the number of ODN per polymer chain, $n_{(1)}$ the equivalent number of starter **1**, Y the coupling yield of **1** to polymer, and $N_{(\mathrm{NAS})}$ the number of NAS units in the polymer chain ($N_{(\mathrm{NAS})}$ = 235 and 168 for block and random copolymers, respectively).

Taking into account the conjugate degradation in ammonia, we can estimate that 25% of ODN bound to polymer were cleaved during basic deprotection as described in the following equation:

$$F_{\mathrm{ODN}} = f_{\mathrm{ODN}} \times 0.75$$

with F_{ODN} the estimation of the final number of ODN per polymer chain. Calculated ODN number per chain (F_{ODN}) for the different polymer−ODN conjugates used in this study are mentioned on the graph of Figure 11. To evaluate the influence of ODN number per polymer chain

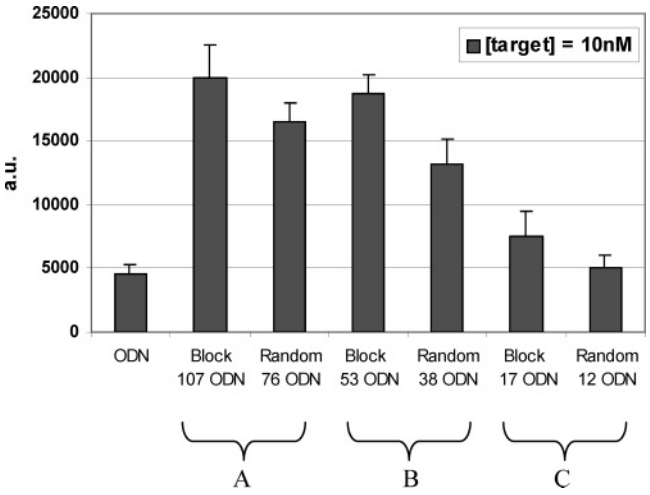

Figure 11. Influence of the number of ODNs per polymer chain on resulting fluorescent signal for block and random conjugates. Polymer functionnalization in conditions A: 0.6 equiv of **1** per NAS; B: 0.3 equiv of **1** per NAS; C: 0.1 equiv of **1** per NAS.

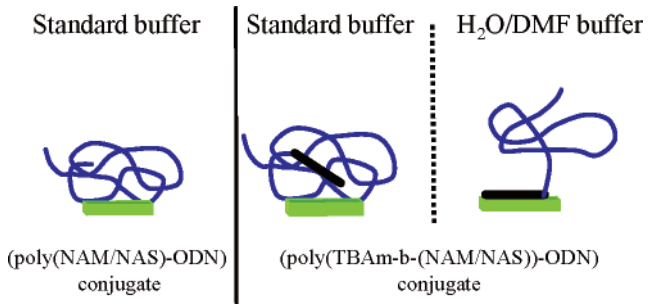

Figure 12. Schematic illustration of the hypothesis of conjugate conformation onto the solid support according to the nature of coating buffer.

on the fluorescent signal, the various conjugates were spotted on a microarray (Figure 11).

Efficient signal amplification was observed using conjugates from columns A and B, in comparison with free dT25. On the other hand, conjugates of column C, bearing a low amount of ODN, did not significantly amplify the signal. In conclusion from this study, a minimal amount of ODN per chain was necessary to impact the signal of the test on the microarray. Although experiments with conjugates of A and B columns led to quasi similar results, we can observe a slight enhancement of signal by using a block copolymer instead of a random copolymer.

Conjugate Spotting in Organic Solvent. We have demonstrated that the use of polymer−oligonucleotide conjugates instead of ODN for coating of microarrays improved DNA target capture from biological samples and thus enhanced fluorescent signal of the assays. But no significant difference was observed in the performances of the test, whether or not a block or a random copolymer was used. At this time, it was anticipated that aqueous buffer used for conjugate coating was not the best medium for favoring the solvation and the expansion of the hydrophobic block of poly(TBAm-*b*-(NAM/NAS)). In this medium, the poly(TBAm) may be hidden inside the hydrophilic part of conjugate and thus may have difficulties to access to solid surface (Figure 12). To validate our hypothesis and overcome the problem, coating of the conjugate was evaluated in a medium containing some organic solvent. The graph in Figure 13 shows signals obtained with poly(TBAm-*b*-(NAM/NAS))−ODN and poly-((NAM/NAS))−ODN coated in mixed media (20% DMF/

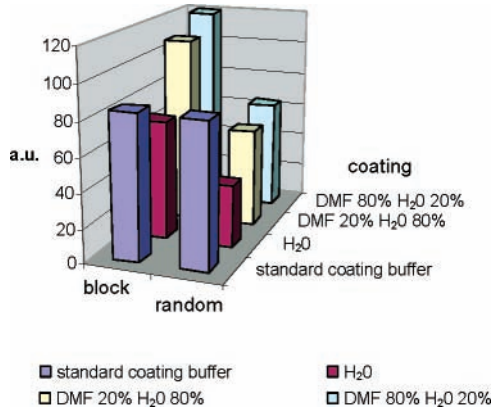

Figure 13. The influence of coating buffer on the sensitivity of the assay ([target] = 0.5 nM) for poly(TBAm-*b*-(NAM/NAS))–ODN (block) and poly(NAM/NAS)–ODN (random) conjugates (0.6 equiv of **1** per NAS).

80%H_2O and 80% DMF/20% H_2O), in comparison with data obtained in phosphate buffer and in Milli-Q water. The best results were observed for spots coated with poly(TBAm-*b*-(NAM/NAS))–ODN in organic mixtures. This would corroborate the above-mentioned hypothesis. The poly(TBAm) chain should indeed be well solvated so as to have the chance to interact with the solid surface during the coating step. It may be suggested that in DMF-rich solvent, the conjugate probably adopts a conformation favoring the anchoring on the surface via the hydrophobic arm, with a subsequent improvement of the capture probes accessibility. Finally, this would enhance the fluorescent signal of the DNA target detection.

CONCLUSION

An amphiphilic block copolymer poly(*tert*-butylacrylamide-*b*–*N*-acryloylmorpholine-*N*-acryloxysuccinimide) and a random copolymer poly(*N*-acryloylmorpholine-*N*-acryloxysuccinimide), synthesized by controlled radical polymerization (RAFT process) were used (number average molecular weights (Mn) of 14 000/103 000 g/mol and 71 000 g/mol, respectively) to elaborate polymer–ODN conjugates. A strategy of direct synthesis of ODN from the polymeric chain previously grafted onto solid support (controlled pore glass, CPG) was achieved. A preliminary step was performed to bind starters of oligonucleotide synthesis along the chain. For that purpose, (3-*O*-dimethoxytritylpropan-1,3-diol)-(6-aminohexyl) phosphate (starter **1**) was synthesized and characterized. The activated ester functions of the NAS units along the polymer chain efficiently reacted with the amino spacer arm of **1**, reaching coupling yield close to 100% after 10 days of reaction. Resulting polymer–starter **1** conjugates were grafted onto hydroxylated CPG beads and 25mer polythymidylates were synthesized from the functionalized polymer. Then, polymer–ODN conjugates were released in solution by ammonia treatment and analyzed by SEC. Two populations were observed on the chromatograms: one population eluted between 9 and 15 min, ascribed to polymer–ODN conjugate, and the other population eluted between 15 and 22 min, attributed to free ODN material. In an attempt to suppress this parasite ODN population resulting from syntheses directly initiated from hydroxylated CPG, the capping reaction of silica beads with diethoxy-*N*,*N*-diisopropylphosphoramidite (DPP) was studied. Performing DPP capping in addition to standard acetic anhydride capping reduced efficiently but not completely parasite ODN syntheses. Then, conjugates were purified by filtration on controlled pore size membrane up to 95% purity and evaluated in DNA hybridization assay as macromolecules being able to favor capture of the target. The microarray system used for the study was based on a standard 96-well microtiterplate format, presenting 16 different spots in each well. Conjugates were spotted by nanodroplet inkjetting technique. Both conjugates, elaborated from either block or random copolymers, enhanced signal of the DNA hybridization assay in standard spotting buffer (phosphate buffer with 400 mM NaCl). The role of the hydrophobic part (poly(TBAm)) of conjugate synthesized from the block copolymer was revealed by coating both types of conjugates in a mixed solvent (DMF/H_2O). In these conditions, poly(TBAm) block was more accessible for adsorption onto the surface of the well, inducing an orientation of the hydrophilic part of the conjugate (bearing ODN) toward the aqueous media. In conclusion, poly(TBAm-*b*-(NAM/NAS))–ODN conjugates spotting in a mixed solvent afforded a significant sensitivity improvement of hybridization assay performed with model dT25–dA25 on a microarray. Using this strategy, further experiments are in course with various biological models and will be reported in due time.

ACKNOWLEDGMENT

We wish to thank David Duracher and Thibault Martin from Apibio for the provision of oligosorbent microarrays spotted with conjugates.

Received September 3, 2004;
Revised Manuscript Received December 22, 2004

Two square planar derivatives of $Pt(en)Cl_2$ with intrinsic fluorescence in aqueous solution at room temperature, with quantum yields (Φ) 0.11 and 0.10, respectively, have been synthesized and characterized as [Pt(en)(CG)Cl] (Complex **1**) and [$Pt(en)(CG)_2$] (Complex **2**) (en = ethylenediamine, CG = cholylglycinate). Complexes **1** and **2** exchange just one ligand (chloride or cholylglycinate, respectively) when reacted with water or 5′-GMP to give the same chemical species. After reaction with DNA oligonucleotides or DNA plasmids, they show enhanced emission in the visible region, which lasts for long periods of time and makes them potentially useful DNA marker molecules. Incubation with nucleated blood cells followed by microscopic analyses revealed that they enter the cells within minutes of exposure, selectively stain the DNA, and persist after more than 48 h of exposure. Complexes **1** and **2** display cell cycle phase-independent cytotoxic activity against cisplatin-resistant CHO (Chinese hamster ovarian) tumor cells, with an early onset of their effects. Their slightly different biological effects, as compared to cisplatin, are considered to be linked to the bile acids and their vector properties and to the preferential formation of monoadducts.

INTRODUCTION

Cisplatin has become one of the most widely used anticancer agents, being especially effective in the treatment of patients with testicular and ovarian cancers as well as of hematologic malignancies, such as Hodgkins disease and childhood leukemias (*1*). Its severe toxicity and the development of resistance to the drug has led to the synthesis and evaluation of thousands of cisplatin analogues (*2*). In such complexes, leaving groups appear to influence solubility, toxicity, and both the tissue and intracellular distribution of the drug, while stable (carrier) am(m)ine ligands determine the structure of DNA adducts and cellular responses (*1*). The only analogues approved worldwide for patient treatment, the dicarboxylates carboplatin and oxaliplatin, appear to follow these rules (*2*, *3*).

Many and diverse biochemical and biophysical methods have been applied to elucidate critical aspects of the mechanisms of action of cytotoxic platinum complexes, in particular those of cisplatin (*4*). Platinum(II) complexes are considered to be nonfluorescent in solution at room temperature (except those carrying additional fluorophores), and, to the best of our knowledge, no intrinsically fluorescent cisplatin analogue with cytotoxic activity has been described so far. Recently reported approaches using platinum complexes with appended fluorophores have been only partially successful since, once inside the cell, fluorescence was not long-lasting (*5*). To achieve dynamic pictures of the biological effects of cisplatin analogues, it would be very interesting to have intrinsically fluorescent compounds with cytotoxic activity, especially against drug-resistant cell lines (*6*, *7*).

In recent years, we and others have explored the potential usefulness of bile acids as exchangeable platinum(II) ligands (*8*), which might reduce both toxicity and resistance owing to their lower lability (carboxylate vs chloride ligands), their amphipathic character, and their vectoriality (drug targeting) (*9*−*11*). In the present paper we describe for the first time two new intrinsically fluorescent square-planar platinum(II) complexes carrying one or two cholylglycinate ligands (**1** and **2**, Figure 1) that emit at room-temperature both once free in solution and after reaction with DNA. They were synthesized from $Pt(en)Cl_2$ using previously described protocols, and their reactions with different potential cellular ligands, such as water, GMP and DNAs of different sizes and sources, together with their fluorescence and cytotoxic properties have been studied. The implications on the cellular and biological effects of these compounds are also discussed.

EXPERIMENTAL SECTION

Chemicals. Dichloro(ethylenediamine)platinum(II), $Pt(en)Cl_2$, was purchased from Aldrich (St Louis, MO). Sodium cholylglycinate (NaCG), guanosine 5′-monophos-

phate (sodium salt; 5′-GMP), penicillin/streptomycin, sucrose, spermine tetrahydrochloride, trypsin, trypsin inhibitor, RNAse, Nonidet Np40, and propidium iodide were obtained from Sigma (St Louis, MO). HBSS (Hank's balanced salt solution), DMEM cell culture medium, L-glutamine, fetal calf serum, and sodium citrate were all purchased from Gibco BRL (Carlsbad, CA). Trisodium citrate and dimethyl sulfoxide were obtained from Merck (Darmstadt, Germany). All other reagents were of high purity and were used as purchased without any further purification. Oligonucleotides **I** (self-complementary) 5′-3′d(TATGATCATA), **II** (self-complementary) 5′-3′d(TGATCATGATCA), and **III** (single strand, non self-complementary) 5′-3′d(TTAGGGTTA) were purchased from Sigma Genosys (Cambridge, UK), with purification in reverse phase. Purified *Trichoderma harzianum* HH3-DNA (linear, 563 bp) was kindly provided by the Department of Microbiology (University of Salamanca, Salamanca, Spain), and the CH1cisR ovarian cancer cell line was kindly provided by Dr. J. M. Pérez (Madrid, Spain).

Analytical Methods. Chemical analyses for C, H, and N were performed on a Perkin-Elmer 2400 elemental analyzer (Applied Biosystems, Foster City, CA). Platinum was determined by atomic absorption on a Hitachi Z-8100 flameless graphite furnace spectrophotometer (Hitachi, Tokio, Japan) set at a wavelength of 265.9 nm, using the following temperature program: 90 °C (20 s), 100 °C (20 s), 800 °C (20 s), 1600 °C (30 s), 2800 °C (5 s), and 3000 °C (4 s). Infrared (IR) spectra were recorded in the 4000−200 cm^{-1} range on a Perkin-Elmer FT-IR 1730 instrument coupled to a Perkin-Elmer Data Station (Applied Biosystems). KBr pellets and spectrophotometric grade Nujol (Fluka, St. Louis, MO) or polyethylene disks (Aldrich) were used to record the spectra above and below 400 cm^{-1}, respectively. Electrospray ionization mass spectra (ESI-MS) were recorded on a Waters ZQ 4000 (Waters S.A., Milford, MA); positive and negative ion mass spectra were obtained by signal averaging of 25 consecutive shots; MALDI-TOF spectra were recorded on a Bruker, Reflex III (delayed extraction) instrument (Bruker, Karlsruhe, Germany) equipped with a nitrogen laser (λ = 337 nm, 3 ns pulse width). Electrical conductivity in solution was measured using a CDM2e conductimetry radiometer with a CDC-104 immersion cell (Radiometer, Copenhagen, Denmark). Temperature was controlled in a Unitherm water bath (Selecta, Barcelona, Spain) with a precision of ±0.01 °C. ^{1}H (400 MHz), ^{13}C (102.6 MHz), and ^{195}Pt (64.5 MHz) NMR spectra were obtained in D_2O, methanol-d_4 or DMSO-d_6 solutions on a Bruker DX400 instrument (Bruker, Germany). Carbon resonances were distinguished by DEPT-90 and DEPT-135 experiments. TMS was used as internal standard for ^{1}H and ^{13}C spectra. Using K_2PtCl_6 (δ = 0 ppm) as external standard, 300.000 scans, 2 s relaxation delay, and a 48 h acquisition time were used to obtain the ^{195}Pt spectra. Fluorescence measurements were performed in water at room temperature in a Shimadzu RF 5000 spectrofluorometer system (Shimadzu, Tokyo, Japan) equipped with a 150 W xenon lamp and a sensitivity unit. The optimal excitation wavelength was obtained from a fluorescence excitation spectra acquired at the optimal emission wavelength. Excitation and emission peaks were as follows: (1) free [Pt(en)(CG)Cl] and free [Pt(en)$(CG)_2$] in solution (301 nm, 384 nm) and (330 nm, 436 nm), respectively, (2) platinum complexes bound to oligonucleotides **I**, **II**, and **III** (352 nm, 437 nm), and (3) platinum complexes bound to HH3-DNA (350 nm, 437 nm).

Synthesis and Characterization of the Platinum Compounds. *Ethylenediaminechlorocholylglycinateplatinum(II), Pt(en)(CG)Cl*. Complex **1** was obtained by slowly adding a 1 mM NaCG solution to a 1 mM Pt(en)Cl_2 solution at 50 °C, with subsequent stirring for 24 h in the darkness (final pH = 5.6−5.7) (*10*, *12*). Liquid−liquid extraction on C18 cartridges yielded (after final methanol extraction) the newly formed platinum complexes (60% from the starting NaCG) free of excess unreacted Pt(en)Cl_2. Preparative TLC chromatography using butyl acetate/methanol 65/35 (v/v) gave complex **1** (R_f = 0.30, final yield 29%) as a yellow solid after evaporation to dryness in P_4O_{10}.

*Complex **1**, Pt(en)(CG)Cl*. Yellowish solid. Soluble in H_2O, MeOH, DMSO. Mp (with dec) = 173 ± 2 °C. EA Calcd. for $C_{28}H_{50}ClN_3O_6Pt$: % C 44.53; % H 6.67; % N 5.56; % Pt 25.83. Found: % C 45.16; % H 6.81; % N 5.52; % Pt 26.11. IR (ν, cm^{-1}): 3392, 1601, 1409, 542, 349. ESI-MS (*m/z*): 754.7 $[M]^+$, 741.4 $[M - Cl - H + Na]^+$, 718.6 $[M - Cl - H]^+$, 510.4 $[CG + 2Na]^+$, 488.4 $[CG + H + Na]^+$. ^{1}H NMR (CD_3OD) δ = 0.71 (3H, s; Me-18); 0.90 (3H, s; Me-19); 1.03 (3H, d, J = 6.5 Hz; Me-21); 2.53 (4H, bs; en); 3.37 (1H, m; H-3); 3.80 (1H, bs; H-7); 3.96 (1H, bs; H-12); 4.02 (2H, s; H-25). ^{13}C NMR (CD_3OD) δ = 188.6 (C- 26); 179.6 (C-24); 72.7 (C-12); 71.4 (C-3); 67.8 (C-7); 53.5 (C-25); 48.2 (en); 46.5 (C-17); 46.0 (C-13); 45.4 (en); 41.6 (C-5); 41.6 (C-14); 39.4 (C-8); 38.8 (C-4); 35.8 (C-20); 35.0 (C-1); 34.4 (C-6); 34.3 (C-10); 31.9 (C-22); 30.5 (C-23); 29.4 (C-2); 29.2 (C-11); 27.9 (C-16); 26.3 (C-9); 22.7 (C-15); 21.6 (C-19); 16.5 (C-21); 11.5 (C-18). ^{195}Pt NMR (D_2O) δ = −1970 ppm.

Ethylenediaminebischolylglycinateplatinum(II), Pt(en)$(CG)_2$. Complex **2** was obtained using two different approaches: The first was identical to that described above, except that 2 equiv of NaCG was used, giving complex **2** (R_f = 0.24, 12% final yield). The second method was used in order to remove traces of complex **1**: a 1 mM solution of Pt(en)Cl_2 was reacted with an excess of $AgNO_3$ for 24 h; the precipitate formed was filtered out, and 2 equiv of NaCG was slowly added as a 1 mM solution. The subsequent procedures were identical to those described above for complex **1**. At the end, complex **2** gave a single TLC band (R_f = 0.24, 35% final yield).

*Complex **2**, Pt(en)$(CG)_2$*. Yellow solid. Soluble in H_2O, MeOH, DMSO. Mp (with dec) = 184 ± 2 °C. EA Calcd. for $C_{54}H_{92}N_4O_{12}Pt$: % C 54.76; % H 7.83; % N 4.73; % Pt 16.47. Found: % C 54.93; % H 7.78; % N 4.52; % Pt 17.01. IR (ν, cm^{-1}): 3429, 1617, 1384, 536. MALDI-TOF-MS (*m/z*): 1228.8 $[M + 2Na - 1]^+$, 1207.9 $[M + Na + 1]^+$, 1184.6 $[M + 1]^+$, 997.8 $[(NaCG)_2 + Na]^+$, 719.5 $[M - CG]^+$, 510.4 $[CG + 2Na]^+$, 488.4 $[CG + Na]^+$. ^{1}H NMR (CD_3OD) δ = 0.70 (3H, s; Me-18); 0.90 (3H, s; Me-19); 1.02 (3H, d, J = 6.5 Hz; Me-21); 2.48 (2H, bs; en); 3.35 (1H, m; H-3); 3.73 (2H, bs; H-25); 3.78 (1H, bs; H-7); 3.95 (1H, bs; H-12). ^{13}C NMR (CD_3OD) δ = 176.5 (C-26); 176.3 (C-24); 74.0 (C-12); 72.9 (C-3); 69.0 (C-7); 48.1 (C-17); 47.5

(en); 47.5 (C-13); 44.6 (C-25); 43.2 (C-14); 42.9 (C-5); 41.0 (C-8); 40.4 (C-4); 37.0 (C-20); 36.5 (C-1); 35.9 (C-6); 35.8 (C-10); 34.3 (C-22); 33.3 (C-23); 31.3 (C-2); 29.5 (C-11); 28.7 (C-16); 27.8 (C-9); 24.3 (C-15); 23.2 (C-19); 17.7 (C-21); 13.0 (C-18). ^{195}Pt NMR (D_2O) $\delta = -1420$ ppm.

NMR Reaction of Complexes 1 and 2 with 5′-GMP. One milligram of complex **1** (or complex **2**) was added as a solid to 0.5 mg (or 0.3 mg) of 5′-GMP sodium salt dissolved in 400 μL of 10 mM phosphate buffer in D_2O (pH = 7.2). Complex **2** immediately gave a clear solution, but complex **1** only dissolved after 24 h at 50 °C. ^{1}H NMR spectra at different time-points were recorded at 25 °C using a presaturation pulse to remove the residual solvent peak (spectral width = 8000 Hz). ROESY and DQF−COSY spectra of the final 1:1 complexes were also acquired at 25 °C.

Microscopic Analyses. Peripheral blood (PB) samples were collected from three healthy volunteers. Three 100 μL aliquots from each PB sample were incubated with 2 mL of an hypotonic solution (Quicklysis, Cytognos, Salamanca, Spain) for 10 min at room temperature to lyse nonnucleated red cells. After this incubation period, nucleated cells were centrifuged (5 min at 540*g*) and washed once in a phosphate-buffered saline (PBS) solution (pH = 7.6). Then, the cell pellet was resuspended in 50 μL of PBS and placed on a slide to which 50 μL of a solution of either complex **1** (5 μM) or complex **2** (5 μM) in water or just 50 μL of water was added. Fluorescence measurements were performed using an Olympus BX40 fluorescence microscope (Olympus, Hamburg, Germany) equipped with a mercury arc lamp using a 350 ± 25 nm band-pass excitation filter and a 400 ± 10 nm long pass emission filter. Fluorescence emission was captured through a CCD camera and printed in a 512 × 512 pixel picture.

Cytotoxicity Assays. The cytotoxic activity of the two newly synthesized platinum compounds **1** and **2** was evaluated in comparison with that of the most widely used platinum compound, cisplatin. To this end, CH1cisR ovarian cancer cells were cultured in parallel in the presence of different concentrations (0, 1, 2.5, 5, and 10 μM) of complex **1**, complex **2**, or cisplatin in DMEM medium supplemented with 10% fetal calf serum, 1% L-glutamine, and 1% penicillin/streptomycin. For the analysis of the cytotoxic activity, cells were harvested either prior to adding the platinum compounds or at 24 and 48 h after they were placed in culture. To harvest the cells they were incubated (5 min at 37 °C) with a solution containing 0.25% (w/v) of trypsin in Hank's balanced salt solution.

Evaluation of the cytotoxic activity was performed using conventional flow cytometry (FACScalibur, Becton/Dickinson Biosciences, San Jose, CA) techniques that allow the simultaneous measurement of cell death and cell proliferation. Briefly, harvested cells were centrifuged (5 min at 540*g*) and resuspended at a concentration of 10^4 cells/μL of 70% ethanol. After an incubation period of at least 30 min at 4 °C, cells were washed once in sodium citrate buffer−sucrose 250 mM, trisodium citrate 40 mM, 5% (v/v) dimethyl sulfoxide, 0.1% (v/v) Nonidet P40, 0.5 mM trishydroxymethylaminomethane, and 1.5 mM spermine tetrahydrochloride and resuspended in the same citrate buffer at a concentration of 10^4 cells/μL. To 10^6 cells in 100 μL, 1.5 mL of a solution containing 0.5 g/L of RNAse and 0.1 g/L of trypsin inhibitor in citrate buffer was added; after gently mixing, cells were incubated for another 10 min at room temperature. Once this incubation period had ended, 1.5 mL of a solution containing 0.42 g/L of propidium iodide in sodium citrate buffer was added, and another incubation for 15 min (room temperature) was performed in the darkness. Measurements of cell DNA contents were performed for at least 10^4 cells for each experimental condition.

Statistical Analysis. The equations for kinetic studies were adjusted to the experimental data by means of a nonlinear regression program available in the SIMFIT in the statistics package (Bardsley 1992 SIMFIT package 3.2. Department of Obstetrics and Gynecology, Manchester, UK).

For the calculation of the ratio of dead/apoptotic cells and the distribution of surviving cells in the different cell cycle phases, the ModFIT software program was used (Verity Software, Topsham, MA). The Mann−Whitney *U* test was used to estimate the statistical significance of the differences observed between groups. *P* values <0.05 were considered to be associated with statistical significance.

RESULTS

Structure of the Platinum Complexes 1 and 2. Both platinum complexes were characterized by a combination of spectroscopic techniques, since no crystals suitable for X-ray diffraction studies were available. In the MS, the peaks corresponding to platinated species were easily recognized due to six different isotopic masses for the metal (190, 192, 194, 195, 196, and 198). The observed molecular ions (754.7 for complex **1** and 1184.6 for complex **2**) are consistent with the molecular formulas $C_{28}H_{50}ClN_3O_6Pt$ (calcd. mass: 754.3) and $C_{54}H_{92}N_4O_{12}Pt$ (calcd. mass: 1183.64). Remarkable fragmentation peaks corresponded to the loss of a chloride from complex **1** or a cholylglycinate from complex **2** ($[M\mathbf{1} - Cl - H]^+ = 718.6$ and $[M\mathbf{2} - CG]^+ = 719.5$).

The ^{195}Pt NMR resonance for complex **1** is centered at −1970 ppm indicating a square planar complex with a PtN_2OCl environment, while the ^{195}Pt NMR signal for complex **2** is centered at −1470 ppm indicating a PtN_2O_2 square planar complex (*13*). The carboxylate ν_{as} and ν_s absorption bands in the IR spectra of complex **1** (1601 and 1409 cm^{-1}) and complex **2** (1637 and 1384 cm^{-1}) also point to monodentate binding of the cholylglycinate ligands (*10*). For complex **1**, a typical stretching vibrational mode of Pt−Cl at 349 cm^{-1} was observed (*10*, *14*).

The ^{1}H NMR and ^{13}C NMR spectra for complex **1** showed peaks corresponding to one cholylglycinate and to the ethylenediamine. The ^{1}H NMR and ^{13}C NMR spectra for complex **2** displayed peaks corresponding to two cholylglycinates and to the ethylenediamine. There is a single set of resonances for the two cholylglycinate ligands in complex **2** and the two ethylenediamine carbons of complex **2** are isochronous.

Both complexes are soluble in methanol and DMSO and dissolve over time in water, complex **2** being more water soluble than complex **1** (*14*). Aqueous solutions of both compounds showed a concentration-dependent, broad, and unstructured (*15*−*17*) fluorescence emission band (Figure 3), which persisted for weeks. The absorption spectra of these platinum compounds were typically formed by very intense charge-transference bands in the UV zone (Figure 2). These bands hide weaker d−d transitions located to greater wavelengths which did not show up at the concentrations used (10^{-4} M) in the registered absorption spectra.

The quantum yields (Φ) in water were calculated as being of 0.11 for complex **1** and of 0.10 for complex **2** (relative to quinine sulfate) (*18*).

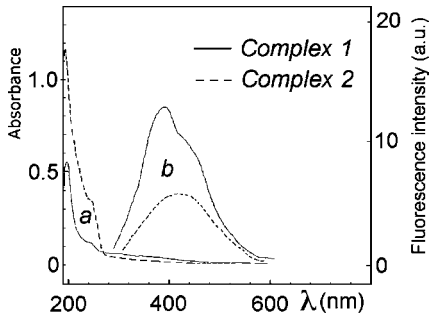

Figure 2

Figure 2. Electronic absorption (a) and emission (b) spectra at room temperature of platinum complexes in water solution ($c = 1 \times 10^{-4}$ M). Excitation wavelength: $\lambda_{ex} = 301$ nm (Complex **1**); $\lambda_{ex} = 330$ nm, (Complex **2**); fluorescence intensity in arbitrary units.

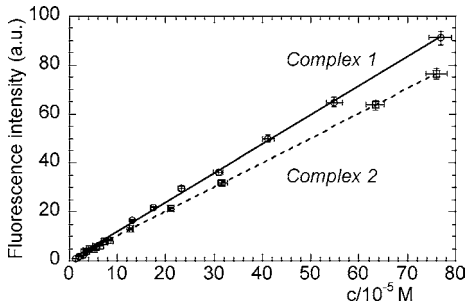

Figure 3. Concentration dependency of the fluorescence intensity of the platinum complexes. Concentrations are expressed in 10^{-5} M and the fluorescence intensity in arbitrary units (a.u.). Emission wavelengths for each complex were selected from the emission spectra (Figure 2) to achieve the maximal emission intensity: Complex **1**, $\lambda_{ex} = 301$ nm, $\lambda_{em} = 384$ nm; Complex **2**: $\lambda_{ex} = 330$ nm, $\lambda_{em} = 436$ nm. For each concentration series, small aliquots of a recently prepared aqueous solution of the corresponding complex were sequentially added to the cuvette, equilibrated for 10 min and measured at room temperature.

Kinetic Studies. Molar conductivities at 37 °C of complexes **1** or **2** (10^{-3} M solutions) were of 144 and 150 S cm^2 mol^{-1}, respectively, in agreement with a 1:1 electrolyte ratio. The hydrolysis kinetics at 37 °C in water and in solutions of increasing NaCl concentrations (4, 150, and 500 mM) were followed by the overtime variation in absorbance at 245 nm. The decay curve was adjusted to a pseudo first-order rate equation, $A = A_0e^{-kt} + C$, where A is absorbance at time t; A_0 is absorbance at time zero; k_{obs} is the rate constant (h^{-1}), and C is a constant term introduced to take into account the baseline variation and the absorption of other nonreacting species (Figure 4). The calculated values for the rate constants (k_{obs}) and the half-lives are summarized in Table 1.

Reactivity of Complexes 1 and 2 with 5-GMP. The reaction between complex **1** or complex **2** and 5′-GMP at 37 °C in a 1:1 molar ratio (10^{-4} M each) was followed by mass spectrometry (Figure 5). Briefly, unreacted 5′-GMP was quantified by peak integration (35 spectra) relative to an internal standard and comparison with a calibration curve (obtained by fitting different 5′-GMP standards to a straight line). Total 5′-GMP was estimated as the sums of the $m/z = 362$ [(5′-GMP) − H]$^+$ and $m/z = 384$ [5′-GMP) − H + Na]$^+$ ions (calibration curve: $0.999 > r^2 < 0.999$, $n = 4$, RSD = 0.3% − 0.03%). Both complexes reacted slowly since 5′-GMP consumptions greater than 95% took 187 and 124 h, respectively.

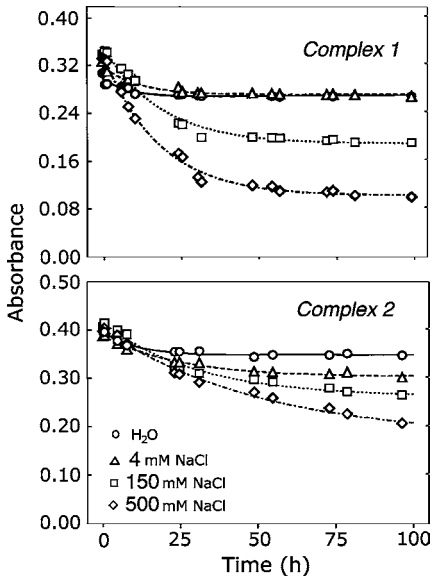

Figure 4. Absorbance vs time curves for complexes **1** and **2**. The hydrolysis reactions for complexes **1** and **2** were followed by monitoring the decay of the 245 nm absorption band at 37 °C. Increasing concentrations of sodium chloride (4, 150, and 500 mM) were selected to mimic the effect of different environments on the hydrolysis kinetics. The traces connecting the experimental data-points were drawn by SIMFIT and correspond to first order decays.

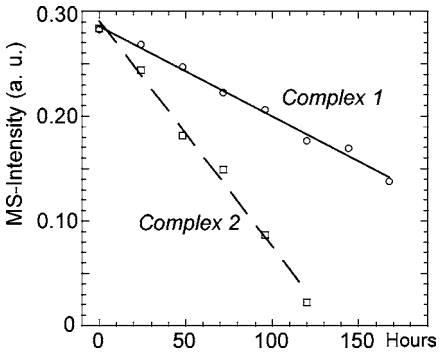

Figure 5. Effect of complex **1** and complex **2** on free 5′-GMP concentration according to time curves in the presence of complexes **1** and complex **2**. Free 5-GMP concentration was monitored by the MS-intensity measured at different time points (see text for details).

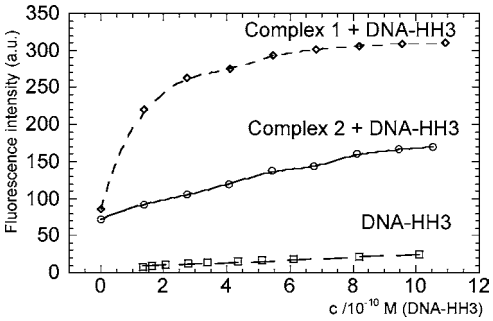

Figure 6. Fluorescence of the platinum complex **1** and complex **2** after incubation with HH3-DNA. Fluorescence intensity of increasing concentrations of HH3-DNA incubated for 24 h. with a 7.2×10^{-4} M solution of complex **1** in water and a 1.3×10^{-4} M solution of complex **2**. ($\lambda_{ex} = 350$ nm, $\lambda_{em} = 437$ nm.) The solutions remained fluorescent for periods of time longer than two months.

NMR monitoring of the reaction of complexes **1** and **2** with 5′-GMP revealed an over time decrease in the signal corresponding to the guanosine H8 proton (8.1 ppm),

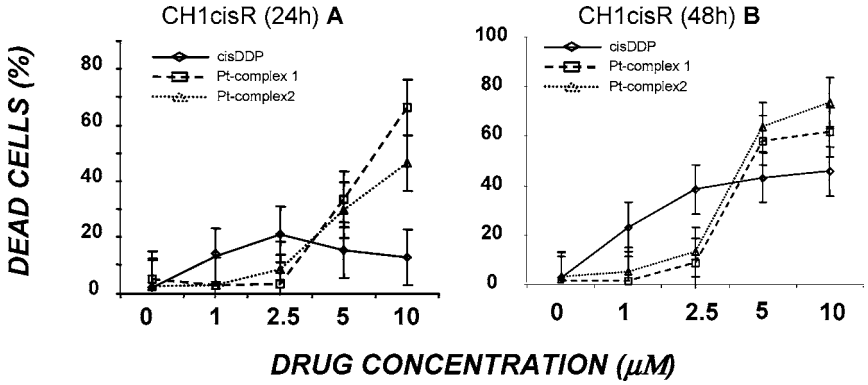

Figure 7. Cytotoxic activity of different doses of Pt complex **1** and complex **2** as compared to cisplatin against CH1cisR ovarian cancer cells after 24 h (panel A) and 48h (panel B) of culture. Results expressed as percentage of dead CH1cisR cells. Statistically significant differences ($p < 0.04$) were observed for the percentage of dead cells at 24 h for cisplatin as compared to both complex **1** and complex **2** at doses of 10 μM.

Table 1. Kinetic Parameters for Hydrolysis Reactions [$C = 10^{-4}$ M, 37 °C, final pH = 4.5 for Complex 1 and pH 6.0 for Complex 2]

	H_2O	4 mM NaCl	150 mM NaCl	500 mM NaCl
		Complex **1**		
k_{obs} (h^{-1})	$1.22 \pm 0.02 \times 10^{-1}$	$8.4 \pm 0.02 \times 10^{-2}$	$5.38 \pm 0.01 \times 10^{-2}$	$5.24 \pm 0.01 \times 10^{-2}$
$t_{1/2}$ (h)	5.68	8.23	12.88	13.22
		Complex **2**		
k_{obs} (h^{-1})	$0.93 \pm 0.01 \times 10^{-1}$	$0.39 \pm 0.02 \times 10^{-1}$	$0.32 \pm 0.02 \times 10^{-1}$	$0.19 \pm 0.01 \times 10^{-1}$
$t_{1/2}$ (h)	7.45	17.77	21.66	36.48

together with the appearance of a new resonance at 8.7 ppm (identical for both platinum compounds). The chemical shift changes for the sugar and the steroid moieties were less pronounced.

Fluorescence Properties of the Platinum Complexes 1 and 2 after Reaction with DNAs. All measurements were performed under the conditions employed for the microscopic experiments ($\lambda_{ex} = 350$ nm and $\lambda_{em} = 437$ nm) described below, to render the comparisons meaningful. The complexes were reacted separately with 5′-GMP, oligonucleotides **I**, **II**, and **III** (see Experimental Section) and HH3-DNA.

Incubation of 10^{-4} M [Pt(en)(CG)Cl] (**1**) and [Pt(en)-(CG)$_2$] (**2**) solutions with a 1:1 molar ratio of 5′-GMP led to fluorescence "quenching" . On the other hand, addition of increasing amounts of either oligonucleotides **I**, **II**, or **III** or HH3-DNA led, after 5 min, to an increase in fluorescence intensity higher than the sum of the fluorescence intensities of the individual components (*19*). The solutions remained fluorescent for periods longer than 2 months. No major differences in fluorescence emission were observed with increasing salt concentration (4, 150, and 500 mM of sodium chloride) when compared with aqueous solution (Figure 6).

Cytotoxic Activity of Platinum Complexes 1 and 2 and Microscopic Analyses. As shown in Figure 7, platinum complexes **1** and **2** displayed an important cytotoxic activity against the CH1cisR ovarian cancer cell line. This cytotoxic activity was already evident after 24 h of culture, and its maximum was reached for the highest doses assayed: 5 and 10 μM. Interestingly, after 24 h no significant differences were observed between the proportion of dead cells obtained with both complexes ($p > 0.05$). In contrast, the cytotoxic activity of these two complexes after 24 h of culture was significantly ($p < 0.04$) higher than that of cisplatin, this latter compound requiring longer periods of time (48 h) to reach identical cytotoxic effects, see Figure 7.

Analysis of the relative distribution of surviving cells in culture along the G_0/G_1, S and G_2/mitosis cell cycle

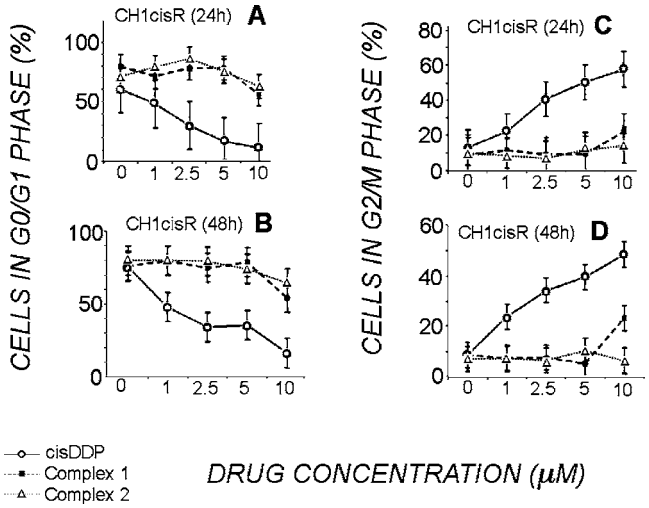

Figure 8. Cell cycle distribution of live CH1cisR (panels A to D) cells, after being cultured for 24 h (panels A, C), and 48 h (panels B, D), in the presence of Pt complex **1**, complex **2**, and cisplatin. Percentage value of G_0/G_1 cells is shown in panels A and B, and the proportion to G_2/M cells is displayed in the other panels (C and D). Statistically significant differences ($p < 0.03$) were found in the percentage of both G_2/M- and G_0/G_1-cell cycle phase cells cultured in the absence versus the presence of cisplatin at doses >2.5 μM for 24 and 48 h, except for the comparisons of the percentage of G_2/M cells treated with 2.5 μM cisplatin for 24 h.

phases showed that neither of the two platinum complexes synthesized induced a significant accumulation of cells in any specific cell cycle phase ($p > 0.05$). By contrast, cisplatin induced a dose-dependent accumulation of CH1cisR cells in the G_2/M cell cycle phases ($p < 0.03$), in line with previous findings (*20*). At identical doses, cisplatin requires that cells must have reached G_2, to enter apoptosis and finally die (*20*, *21*), see Figure 8.

PB nucleated cells incubated with either platinum complexes **1** or **2** became fluorescent after 10 min, mainly within the cells' nuclei, under microscopic analysis

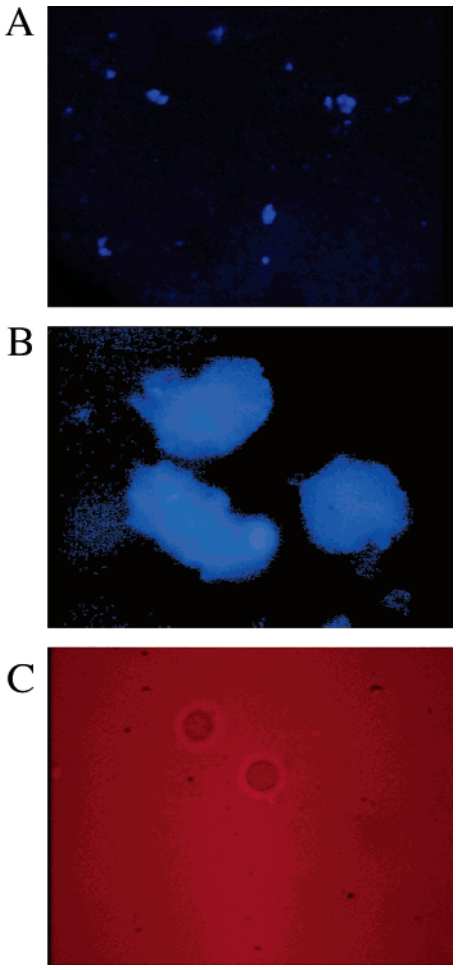

Figure 9. Illustrative photographs of the fluorescence emission observed after incubating peripheral blood nucleated cells with complex **1** (complex **2** leads to very similar photographs). Panel A shows a 20× magnification and panel B a 500× magnification. Panel C shows that these cells remained alive and did not incorporate propidium iodide.

(Figure 9). Cells treated with both platinum complexes remained fluorescent for more than five weeks.

DISCUSSION

The spectroscopic data for complex **1** and complex **2** agree with the expected [Pt(en)(CG)Cl] and [Pt(en)$(CG)_2$] square planar complexes, very similar to the closely related [$Pt(NH_3)_2$(CG)Cl] and [$Pt(NH_3)_2(CG)_2$] compounds we have recently described (*10*). Both complexes carry two putative leaving ligands, one chloride and one cholylglycinate for complex **1** and two cholylglycinates for complex **2**. The cholylglycinate ligands in both complexes are spectroscopically very similar, suggesting identical binding modes. Minor differences are seen for the atoms next to the Pt atom, the C-26 carboxylates and the ethylenediamine carbons and protons, which are isochronous in the NMR spectra of complex **2** but not in the asymmetric complex **1** (with different trans ligands: chloride and cholylglycinate). In complex **2**, the two cholylglycinates give rise to only one set of resonances, indicating a rapid rotation on the NMR time scale of the bile acids ring system, as would be expected for a freely rotating linear chain linking the Pt atom and the steroid skeleton.

Aqueous solutions of either complex show a persistent, concentration-dependent, broad, and unstructured fluorescence emission band. To the best of our knowledge, there are no previous reports of fluorescent platinum complexes in water at room temperature (other than those with attached fluorescent ligands) (*5*). The half-lives for the complexes measured in the kinetic studies (see Table 1) imply that both complexes are almost completely hydrolyzed after 48 h in pure water, but their solutions remain fluorescent.

Substitution of the chloride ion by water in cisplatin is the first kinetic step in its mechanism of action (*22*−*25*), prior to reaction with its final targets. Complexes **1** and **2** show higher aqueous solubility but slower kinetic profiles than cisplatin. The higher stability in water of complex **2** as compared to complex **1** relates to the substitution of the chloride ligand by the second carboxylate group (a worse leaving group). Such a substitution in cisplatin analogues (e.g. carboplatin and oxaliplatin) is considered to be responsible for their increased water solubility, as well as their reduced kinetic reactivity and toxicity (*1*). For complexes **1** and **2**, the higher the NaCl concentration, the longer their half-lives, as observed upon increasing NaCl concentrations from those observed in the cytoplasmic compartment (4 mM) to the plasma ones (150 mM). This behavior parallels that of cisplatin and accounts for its higher intracellular than extracellular reactivity (*1*).

The hydrolysis reactions of the two complexes follow single decay kinetics of increasing rates with decreasing NaCl concentrations (see Table 1). The two complexes initially hydrolyze to the same putative aquo-complex (*26*), $[Pt(en)(CG)H_2O]^+$, in agreement with the equivalent fragmentation peaks of the MS ($[M\mathbf{1} - Cl - H]^+ = 718.6$ and $[M\mathbf{2} - CG]^+ = 719.5$):

$$[Pt(en)(CG)Cl] + H_2O \rightarrow [Pt(en)(CG)H_2O]^+ + Cl^-$$

$$[Pt(en)(CG)_2] + H_2O \rightarrow [Pt(en)(CG)H_2O]^+ + CG^-$$

A second decay curve is not observed for either complex, even for very long reaction times. This observation suggests that there is only one replaceable ligand in these complexes, as opposed to cisplatin and its analogues, where two substitutions are seen from the kinetics of hydrolysis reactions. These double substitutions allow the formation of DNA bis-adducts, which are deemed important for the cytotoxic activity of cisplatin analogues (probably due to intra- and interstrand DNA cross-links) (*2*−*4*).

As a model system, the reaction of the complexes with 5′-GMP (cisplatin reacts with 5′-GMP to give mixtures of the mono- and the bisadducts) were studied by MS and NMR. The final time-points showed the [Pt(en)(CG)(5′-GMP)]$^+$ monoadduct with $m/z = 1082.5$, together with the residual unreacted complex. No platinated peak which could be ascribed to the generation of a [Pt(en)-$(5′\text{-GMP})_2]^+$ bis-adduct was detected, in agreement with the previously described kinetic studies. The ^{1}H NMR chemical shift changes are in agreement with the N7 platination of guanine. Guanine N7 is readily accessible in the DNA major groove and, owing to its high basicity among the four nucleotide bases, it is the major binding target on DNA for antitumor platinum complexes (*27*−*29*). Summarizing, complex **1** and **2** seem to have a single reactive ligand, the second one being inert or reacting much slower under the experimental conditions used, and they both lead to the same chemical species. The reaction of the complexes with 5′-GMP led to a substantial decrease in their fluorescence intensities. The endpoint

solutions gave, after correcting for the concentration differences, fluorescent intensities very similar to each other, as expected if they contain the same final products.

To determine the nature of the fluorescent species observed in the microscopic images described below, we further studied the reactivity of the complexes against different oligonucleotides and DNA structures by following changes in the emission spectra. A substantial increase in fluorescence intensity is observed, ascribed to the formation of monoadducts of the complexes with the guanine bases of the DNA. There was no fluorescence decay observed even for periods longer than 2 months, suggesting that the monoadducts are stable in vitro and do not evolve toward bis-adducts, even for oligonucleotide **III**, which bears three Gs in a row. The decreased fluorescence intensity of the 5′-GMP adducts and the increased emission attained with oligonucleotides and other DNAs is very fortunate, since it reduces the background fluorescence in microscopic images.

The microscopic studies confirmed that complexes **1** and **2** in individual cells mainly target the cells' nuclei, supporting their preferential binding to DNA. Interestingly, the increase in cell fluorescence was rapidly observed after 10 min, in keeping with the results described using oligonucleotides **I**, **II**, and **III**, and HH3-DNA. In addition, cells treated with both platinum complexes remained fluorescent for more than five weeks. Accordingly, both complexes emit enough fluorescence to allow unequivocal identification of cells containing the platinum complexes bound to their DNA and they remain stable. Such features, in a heterogeneous sample composed of a mixture of different cell subsets, would facilitate the visualization of individual cells containing platinum complexes inside by conventional microscopic techniques. This also indicates that even if cells containing platinum remained alive for relatively long periods of time they would not be able to rapidly eliminate such platinum complexes from the nuclei into the cytoplasmic compartment or the extracellular media. This would further facilitate a close analysis of the activity of these compounds through the possibility of identifying the cells targeted, provided that both platinum complexes do in fact retain cytotoxic activity.

The two synthesized platinum complexes showed a dose-dependent cytotoxic activity. Interestingly, once compared to cisplatin, both complex **1** and complex **2** showed significantly a higher cytotoxic activity at early time periods after they have been added to the cell culture, even in the absence of a high number of DNA bis-adducts. Since the formation of bis-adducts appears to be directly linked to the cytotoxic activity of cisplatin, our results suggest that the two platinum complex assayed might have formed other different type of adducts (*19*, *30*−*33*) which would also be capable of inducing cytotoxicity. The linkage of platinum compounds to bile acids would also help to explain the different pharmacokinetics observed for the two new complexes as compared to cisplatin. In addition, they exert their cytotoxic effects in the absence of significant accumulation of cells at a specific cell cycle phase.

Analysis of the relative distribution of surviving cells in culture along the G_0/G_1, S, and G_2/mitosis cell cycle phases showed that neither of the two platinum complexes synthesized induced a significant accumulation of cells in any specific cell cycle phase ($p > 0.05$). By contrast, cisplatin induced a dose-dependent accumulation of CH1cisR cells in the G_2/M cell cycle phases ($p < 0.03$), in line with previous findings (*20*). At identical doses, cisplatin requires that cells must have reached G_2, to enter apoptosis and finally die (*20*, *21*).

Such cell-cycle associated differences could be explained, at least to a certain extent, in terms of the formation of different adducts with the platinum complexes **1** and **2** as compared to cisplatin, which could lead to the occurrence of different interactions of the platinum compound once inside the cell. A potential advantage of the newly synthesized platinum complexes would rely on their potential cytotoxic effects on proliferating and resting tumor cells, provided the fact that this is not associated with an increase in normal tissue toxicity. Further studies are necessary to explore these potential advantages.

ACKNOWLEDGMENT

This work has been supported by grants from the Junta de Castilla y León (Grants SA 050/03 and SA073/02) and the D.G.I.-M.C.T. (PPQ2001-1977). We wish to thank the C.I.D.T.A. for allowing us to use their equipment, Dr. Anna Lithgow for acquiring the NMR spectra, Dr. César Raposo for the MS, N. Skinner for revising the manuscript, and Dr. José M. Perez for providing the ovarian cancer cell lines.

Polyphenylene Dendrimers as Scaffolds for Shape-Persistent Multiple Peptide Conjugates

Gueorgui Mihov,[†] Dörthe Grebel-Koehler,[†] Anke Lübbert,[†] Guido W. M. Vandermeulen,[†] Andreas Herrmann,[†] Harm-Anton Klok,[‡] and Klaus Müllen*,[†]

Max Planck Institute for Polymer Research Ackermannweg 10D-55128 Mainz, Germany, and Ecole Polytechnique Fédérale de Lausanne (EPFL) Institut des Matériaux, Laboratoire des Polymères Bâtiment MX-D, CH 1015 Lausanne, Switzerland. Received July 8, 2004; Revised Manuscript Received February 2, 2005

The present work describes synthetic concepts for the coupling of peptides to polyphenylene dendrimers (PPDs). Novel functionalized cyclopentadienones have been synthesized whose Diels−Alder cycloaddition with various core molecules leads to polyphenylene dendrimers possessing (protected) amino or carboxyl groups. In addition, the resulting functionalized molecules exhibit the characteristic shape-persistence and monodispersity of PPDs. Their functions have been used for the attachment of polylysine to the dendritic scaffold. Three different methods for the decoration of dendrimers with polypeptides are presented. First, polylysine segments are grafted from the surface of the dendrimers employing α-amino acid *N*-carboxyanhydride (NCA) polymerization. Second, the *C*-terminal carboxyl groups of protected polypeptides are activated and then coupled to the amino groups on the surface of the PPD. Finally, cysteine terminated, unprotected peptide sequences are attached to polyphenylene dendrimers utilizing the addition of the sulfhydryl group of a cysteine to the maleimide functions on the dendrimer surface. Moreover, Diels−Alder cycloaddition of suitably functionalized cyclopentadienons to a desymmetized core molecule allows the design of a dendritic scaffold with a specific number of different anchor groups on its periphery. These approaches are important for the tailoring of new, shape-persistent, polyfunctional multiple antigen conjugates.

1. INTRODUCTION

Dendrimers are monodisperse, highly branched macromolecules (*1*−*3*). Their synthesis involves either a convergent or divergent protocol, both implicating the creation of a core molecule and an iterative procedure for the construction of the dendrimer. The high number of functional groups and the well-defined structure make dendrimers attractive carriers for the design of nanoparticles with potential uses in clinical and diagnostic applications. Recent advances in the biomedical applications of various dendritic structures are reviewed by Stiriba et al. (*4*). The polyphenylene dendrimers (PPDs)[1] described here are unique shape-persistent and polyfunctional molecules bearing topologically isolated, noninterfering functional groups (*5*). This is essential for the active function of PPDs decorated with short peptide sequences because the bioactivity of the latter is strongly influenced by inter- and intramolecular chain interactions. The attachment of a defined number of oligopeptides onto PPDs has been inspired by the recent achievement of multiple antigen peptides (MAPs) (*6*).

MAPs are nanoparticles, which, when introduced to an organism, are able to trigger an immune response. In nature, the recognition of foreign bodies (antigens) by antibodies proceeds via the so-called key and lock principle, in which the shape of the antibodies' receptors is complementary to a given pattern on the surface of the antigen that is to be recognized. Complex antigens have a variety of epitopes on different parts of their surface, each of which can be recognized separately by a different antibody. Antigens of special interest are so-called immunogens that trigger an immune response, i.e., the production of antibodies.

Very often, the identifiable part for the antibody is a polypeptide segment. The attachment of several recognizable polypeptides to a nanoparticle is referred to as a MAP. These structures have proven to exhibit amplified immunogenicity and pave the way toward fully synthetic vaccines (*7*). Currently, MAPs are constructed by attaching the desired polypeptides to a dendritic matrix composed, most frequently, of branched polylysine. It has been shown that a stronger immunogenic effect may be achieved when the MAP system contains two different antigen peptides (*8*).

However, the oligolysine carriers do not possess a defined spatial structure, which is believed to have an unfavorable effect on their function (*6*). In fact, inter- and intramolecular interactions of the antigens may modify their secondary structure as well as limit their acces-

sibility. Therefore, the synthesis of nanosized peptide carriers comprising a well-defined structure and shape-persistence may provide improved MAPs. In this respect, the polyphenylene dendrimers are very promising templates due to their structural perfection and precise spatial definition of functional units in the center, in the dendritic scaffold, or at the periphery. Furthermore, they are chemically inert under the conditions of living organisms, which is another important prerequisite for biologically oriented applications.

In addition, the polyphenylene dendrimers can be synthesized not only as all-carbon structures but also using a strongly fluorescent perylenediimide core (PDI). Recently, we have described several synthetic approaches toward water-soluble and fluorescent PDI chromophores (*9*). The chromophore adds a further important property, namely, the possibility of facile optical detection of the dendritic conjugate, and such molecules may find diagnostic application. Thus, the aim of the present work is the development of reliable and expandable synthetic routes affording peptide-functionalized polyphenylene dendrimers with prospective application for attachment of antigen peptides onto a shape-persistent, polyphenylene scaffold. A further development is the synthesis of polyphenylene dendrimers bearing two different polypeptides. While we have recently described routes toward the synthesis of novel polyphenylene dendrimers with lysine and glutamic acid moieties anchored on the surface (*10*), we herein extend this idea by employing different synthetic approaches for the preparation of peptide−PPD conjugates. Polyphenylene dendrimers were functionalized with polylysine following three parallel routes. First, oligolysines were grafted directly from the surface of polyphenylene dendrimers employing α-amino acid *N*-carboxyanhydride (NCA) polymerization. Second, protected pentalysine moieties were coupled to PPDs via carbodiimide activation. Third, unprotected hexapeptides, composed of five lysine residues and a *C*-terminal cysteine, were specifically attached to the polyphenylene scaffold. This was achieved employing a Michael addition of the thiol containing peptides to maleimide functions on the dendrimer periphery. An important prerequisite for the synthesis of polyphenylene dendrimers decorated with two different peptide units is the creation of a core comprising two types of anchor groups, allowing the independent coupling of different peptide sequences.

2. EXPERIMENTAL SECTION

General Information. Unless stated otherwise, all solvents and reagents are commercially available and were used as received. ^{1}H NMR spectra were recorded on Bruker AMX 250, Bruker AMX 300, Bruker Advance DRX 500 or 700 spectrometers. Spectra were referenced to the residual proton signal of the deuterated solvent. Molecular weights were determined with matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) or field desorption (FD) mass spectrometry; MALDI-TOF mass spectra were recorded on a Bruker MALDI-TOF mass spectrometer, and FD mass spectra were recorded on VG Instruments ZAB 2 Se-FPD. Peptide syntheses were carried out on an Applied Biosystems peptide synthesizer model 433A. Ultraviolet-visible (UV−vis) spectra and fluorescence spectra were recorded using a Perkin-Elmer Lambda 9 and SPEX Fluorolog 2 spectrophotometer, respectively. Circular dichroism (CD) spectra were measured on a Jasco J-715 spectropolarimeter. Gel permeation chromatography (GPC) was performed at 60 °C with a setup consisting of a Waters 510 pump and a series of three styrene-divinylbenzene columns (300 × 8 mm) with pore sizes of 500, 10^5, and 10^6 Å (Polymer Standard Services, Mainz, Germany). The elemental analyses were carried out by the Microanalytical Laboratory of the University of Mainz (Germany).

The amino acids were free acids, and coupling was facilitated by the use of *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tertramethyluronium hexafluorophosphate (HBTU) and *N*-hydroxybenzotriazole (HOBt). Purity was checked using analytical reverse-phase high performance liquid chromatography (RP-HPLC, AKTA-Purifier, Amersham-Pharmacia Biotech). The column used was a reverse-phase C8 column (Sephasil peptide C8, volume 4.155 mL, 5 μm particle size). The synthesis of first- and second-generation dendrimers with maleimide functionalities **13a**−**d** and conjugates **38a**−**d** have been described previously (*10*). Compounds **1** (*11*), **2** (*12*), **3** (*13*), **4** (*14*), and **16** (*15*) were synthesized according published procedures.

Procedures. Compound 7a. 3-(4-Aminophenyl)-2,4,5-triphenylcyclopenta-2,4-dienone (**6a**) (1.4 g, 3.55 mmol), *N*-BOC-γ-aminobutyric acid (2.4 g, 17.71 mmol), *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC) (2.4 g, 17.71 mmol), and DMAP (1.3 g, 10.6 mmol) were dissolved in 50 mL of DMF and stirred for 48 h under an argon atmosphere. Thereafter, DCM (50 mL) was added, and the reaction mixture was washed twice with water. The organic phase was isolated, dried over magnesium sulfate, and filtrated, and the solvent was evaporated. The dried residue was purified by column chromatography with DCM/acetone (10:1) eluent to give **7a** as brown powder. Yield: 2.07 g (82.1%). FD (M^+): m/z = 585.5; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.43 (d, 2H, J = 8.48 Hz), 7.32−7.18 (m, 13H, arom.), 6.98 (d, 2H, J = 7.85 Hz), 6.87 (d, 2H, J = 7.89 Hz), 3.21 (q, 2H, J = 6.28 Hz), 2.23 (t, 2H, J = 6.28 Hz), 1.81 (t, 2H, J = 6.28 Hz), 1.44 (s, 9H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 199.6, 171.1, 171.0, 155.5, 154.5, 139.6, 139.5, 132.7, 130.7, 130.5, 129.7, 129.6, 128.8, 128.5, 128.0, 127.9, 127.5, 127.4, 126.8, 124.9, 124.1, 118.1, 117.9, 77.4, 33.7, 28.2, 25.3, 11.0; mp 106 °C.

Compound 7b. 3,4-Bis-(4-aminophenyl)-2,5-diphenylcyclopenta-2,4-dienone (**6b**) (1.1 g, 2.69 mmol), *N*-BOC-γ-aminobutyric acid (5.46 g, 26.9 mmol), EDC (5.16 g, 26.9 mmol), and DMAP (1.97 g, 16.1 mmol) were dissolved in 50 mL of DMF and stirred for 48 h under an argon atmosphere. DCM (50 mL) was added, the reaction mixture was washed twice with water, and the organic phase isolated, dried over magnesium sulfate, and filtrated, and the solvent was evaporated. The dried residue was purified by column chromatography with DCM/acetone (2:1) as eluent to give **7b** as brown powder. Yield: 1.54 g (73%). FD (M^+): m/z = 782.6; ^{1}H NMR (250 MHz, DMSO-d_6) δ_H 7.43 (d, 2H, J = 8.85 Hz), 7.30−7.13 (m, 10H, arom.), 6.83 (d, 2H, J = 8.53 Hz), 2.92 (q, 4H, J = 6.63 Hz), 2.26 (t, 4H, J = 7.27 Hz), 1.65 (p, 4H, J = 7.27 Hz), 1.35 (s, 18H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 199.8, 171.2, 155.8, 154.5, 139.8, 139.7,139.0, 130.0, 129.9, 128.2, 127.6, 127.1, 124.5, 118.2, 77.6, 34.0, 28.5, 25.5, 11.2.

Compound 8a. This compound was prepared analogously to **7a** using **6a** (1.4 g, 3.55 mmol), *N*-*Z*-γ-aminobutyric acid (3.37 g, 14.2 mmol), EDC (2.72 g, 14.2 mmol), and DMAP (1.04 g, 8.5 mmol) in 50 mL of DMF. The crude product was purified by column chromatography with DCM/acetone (10:1) as eluent to give **8a** as brown powder. Yield: 1.8 g (82%). FD (M^+): m/z = 619.4; ^{1}H NMR (250 MHz, DMSO-d_6) δ_H 7.44−7.12 (m, 20H, arom.), 6.96 (d, 2H, J = 7.9 Hz), 6.83 (d, 2H, J = 8.85 Hz), 4.99 (s, 2H), 3.01 (q, 2H, J = 6.64 Hz), 2.89 (t, 2H, J = 7.26 Hz), 1.75 (p, 2H, J = 6.63 Hz); ^{13}C NMR (75

MHz, DMSO-d_6) δ_C 199.7, 171.1, 156.1, 154.6, 154.5, 139.6, 139.5, 137.2, 135.8, 132.8, 130.7, 130.5, 129.8, 129.7, 128.9, 128.6, 128.4, 128.3, 128.0, 127.9, 127.7, 127.5, 127.4, 126.8, 125.0, 124.1, 118.0, 106.1, 65.1, 46.1, 33.6, 25.3; mp 80 °C.

Compound 8b. This compound was prepared analogously to **7b** using **6b** (1.1 g, 2.69 mmol), *N*-*Z*-γ-aminobutyric acid (6.39 g, 26.9 mmol), EDC (7.92 g, 26.9 mmol), and DMAP (1.97 g, 16.1 mmol) in 50 mL of DMF. The crude product was purified by column chromatography with DCM/acetone (2:1) as eluent to give **8b** as brown powder. Yield: 1.75 g (76.2%). FD (M^+): m/z = 853; ^{1}H NMR (250 MHz, DMSO-d_6) δ_H 7.44 (d, 4H, J = 8.53 Hz), 7.33−7.13 (m, 24H, arom.), 6.84 (d, 4H, J = 8.53 Hz), 4.99 (s, 4H), 3.02 (q, 4H, J = 6.32 Hz), 2.29 (t, 4H, J = 7.27 Hz), 1.65 (p, 4H, J = 5.95 Hz); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 199.8, 171.3, 171.2, 156.3, 154.5, 139.8, 139.7, 137.4, 131.0, 130.0, 128.5, 128.5, 127.9, 127.6, 127.1, 124.6, 118.3, 65.4, 46.4, 33.8, 25.3; mp 248 °C.

Compound 9. This compound was prepared analogously to **7a** using **6a** (0.7 g, 1.8 mmol), hexanedioic acid monomethyl ester (1.44 g, 9 mmol), EDC (1.72 g, 9 mmol), and DMAP (0.66 mg, 5.4 mmol) in 50 mL of DMF. The crude product was purified by column chromatography with DCM/acetone (50:1) as eluent to give **9** as brown powder. Yield: 0.830 g (85%). FD (M^+): m/z = 542; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.51−7.16 (m, 15H, arom.), 6.96 (d, 2H, J = 6.91 Hz), 6.85 (d, 2H, J = 8.5 Hz), 3.63 (s, 3H), 2.49−2.25 (m, 4H), 1.80−1.58 (m, 4H); ^{13}C NMR (75 MHz, CD_2Cl_2) δ_C 199.9, 179.0, 130.8, 130.7, 129.8, 129.0, 128.6, 128.5, 128.4, 127.9, 119.1, 51.9, 34.1, 24.8, 24.7.

Compound 14a. Compounds **3** (0.1 g, 0.085 mmol) and **7a** (0.597 g, 1.02 mmol) were dissolved in 31.5 mL of a *o*-xylene/toluene/DMSO mixture (5/5/2). The resulting solution was heated at 150 °C for 36 h under an argon atmosphere. The reaction mixture was precipitated in petroleum ether, and the crude product was purified by chromatography (silica gel, CH_2Cl_2/acetone 2:1) to give **14a.** Yield: 202 mg (70%). MALDI-TOF MS ((M + Na)$^+$): m/z = 3426; ^{1}H NMR (250 MHz, d^6-DMSO) δ_H 9.65, 9.59 (2H, NH), 7.91 (s, 4H, arom.), 7.42 (s, 4H, arom.), 7.33−6.66 (m, 98H, arom.), 2.89 (q, 8H, ^3J = 6.63 Hz), 2.69 (sept, 4H, ^3J = 6.32 Hz), 2.17 (q, 8H, ^3J = 7.27 Hz), 1.59 (p, 8H, ^3J = 7.27 Hz), 1.34 (s, 36H), 1.02 (d, 24H, ^3J = 5.68 Hz), ^{13}C NMR (125 MHz, DMSO-d_6) δ_C 170.4, 170.3, 170.3, 162.4, 155.3, 154.9, 153.2, 145.5, 141.3, 141.2, 141.1, 141.0, 140.4, 140.2, 139.8, 139.5, 139.4, 139.3, 139.2, 139.1, 139.0, 138.9, 138.8, 138.7, 137.5, 136.7, 136.6, 136.4, 136.3, 134.3, 134.0, 132.3, 131.0, 131.0, 131.0, 130.9, 130.8, 130.5, 130.2, 130.1, 129.3, 129.0, 127.3, 127.3, 126.6, 126.5, 126.3, 126.0, 125.4, 125.3, 125.2, 123.4, 122.5, 119.9, 119.7, 119.3, 118.5, 117.3, 117.0, 77.3, 33.6, 28.1, 25.2, 23.3.

Compound 14b. Compounds **3** (0.1 g, 0.085 mmol) and **7b** (1.07 g, 2.04 mmol) were dissolved in 42 mL of a *o*-xylene/toluene/DMSO mixture (5/5/2). The resulting solution was heated for 36 h at 150 °C under an argon atmosphere. The reaction mixture was precipitated in petroleum ether, and the crude product was purified by chromatography (silica gel, CH_2Cl_2/acetone 1:1) to give **14b.** Yield: 315 mg (88%). MALDI-TOF MS ((M + Na)$^+$): m/z = 4225; ^{1}H NMR (250 MHz, DMSO-d_6) δ_H 9.66, 9.61 (2s, NH), 7.90 (s, 4H, arom.), 7.43−6.68 (m, 94H, arom.), 2.88 (q, 16H, ^3J = 6.32 Hz), 2.69 (sept, 4H, ^3J = 6.31 Hz), 2.17 (q, 16H, ^3J = 7.27 Hz), 1.60 (p, 16H, ^3J = 7.27 Hz), 1.34 (s, 72H), 1.02 (d, 24H, ^3J = 5.68 Hz), ^{13}C NMR (125 MHz, DMSO-d_6) δ_C 170.4, 170.3, 170.2, 162.4, 155.3, 154.9, 153.2, 145.5, 141.2, 140.4, 139.4, 139.1, 139.0, 137.6, 136.7, 136.6, 136.4, 136.3, 134.4, 134.1, 132.3, 131.0, 131.0, 130.9, 130.5, 130.1, 129.3, 129.0, 127.3, 126.6, 126.0, 125.9, 125.4, 123.4, 122.5, 119.9, 119.7, 119.3, 118.5, 117.4, 117.1, 117.0, 77.3, 33.6, 28.2, 25.2, 23.4.

Compound 15a. Compound **14a** (0.2 g, 0.06 mmol) was dissolved in 4 mL of 50% trifluoroacetic acid in dichloromethane and stirred at room temperature for 2 h. The reaction mixture was added to saturated $NaHCO_3$ solution, and the precipitated product **15a** was filtrated and dried under reduced pressure. Yield: 172 mg (98%). MALDI-TOF MS ((M + Na)$^+$): m/z = 3023; ^{1}H NMR (500 MHz, DMSO-d_6) δ_H 7.93 (s, 4H, arom.), 7.45−7.42 (m, 6H, arom.), 7.31 (d, 4H, ^3J = 7.62 Hz, arom.), 7.17−6.68 (m, 92H, arom.), 2.70 (sept, 4H, ^3J = 6.41 Hz), 2.23 (q, 8H, ^3J = 7.63 Hz), 1.60 (p, 8H, ^3J = 6.72 Hz), 1.24 (s, NH), 1.04 (d, 24H, ^3J = 6.41 Hz); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 177.2, 171.0, 162.7, 155.0, 153.3, 145.5, 141.8, 141.2, 141.1, 140.5, 140.4, 139.9, 139.7, 139.6, 139.5, 139.4, 139.1, 138.9, 138.8, 137.6, 136.9, 134.3, 134.0, 133.5, 132.5, 131.2, 131.0, 130.6, 129.5, 127.7, 127.0, 126.7, 126.4, 125.8, 123.8, 122.6, 120.1, 119.5, 119.4, 118.9, 117.3, 116.9, 53.0, 44.3, 33.9, 28.4, 23.7.

Compound 15b. Compound **14b** (0.2 g, 0.05 mmol) was dissolved in 4 mL of 50% trifluoroacetic acid in dichloromethane and stirred at room temperature for 2 h. The reaction mixture was added to a saturated $NaHCO_3$ solution, and the precipitated product **15b** was filtrated and dried under reduced pressure. Yield: 158 mg (98%). MALDI-TOF MS ((M + Na)$^+$): m/z = 3423; ^{1}H NMR (250 MHz, DMSO-d_6) δ_H 7.92 (s, 4H, arom.), 7.44 (t, ^3J = 7.62 Hz, 2H, arom.), 7.39 (s, 4H, arom.), 7.31 (d, ^3J = 7.62 Hz, 4H, arom.), 7.19−6.69 (m, 88H, arom.), 2.70 (sept, ^3J = 6.72 Hz, 16H), 2.23 (q, ^3J = 7.63 Hz, 8H), 1.60 (p, ^3J = 6.72 Hz, 8H), 1.24 (s, NH), 1.04 (d, 24H, ^3J = 6.41 Hz); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 170.8, 166.8, 162.7, 155.0, 153.3, 145.5, 141.4, 141.2, 140.5, 140.0, 139.6, 139.1, 137.6, 136.9, 136.8, 136.6, 134.5, 134.2, 132.4, 131.3, 130.8, 130.6, 129.5, 129.3, 127.7, 126.9, 126.4, 125.7, 125.6, 123.8, 122.6, 120.1, 119.9, 119.3, 118.9, 117.3, 117.0, 114.0, 66.9, 33.6, 31.3, 28.4, 23.8.

Compound 17a. Compounds **16** (0.1 g, 0.036 mmol) and **8a** (0.797 g, 1.29 mmol) were dissolved in 9 mL of a tetraethyleneglycol/diphenyl ether mixture (1:1). The resulting solution was heated for 24 h at 170 °C under an argon atmosphere. The reaction mixture was precipitated in methanol, and the crude product was purified by chromatography (silica gel, CH_2Cl_2/acetone 1:4) to give **17a**. Yield: 197 mg (73%). MALDI-TOF MS ((M + Na)$^+$): m/z = 7640; ^{1}H NMR (300 MHz, DMSO-d_6) δ_H 9.64, 9.58 (2s, NH), 7.92 (s, 4H, arom.), 7.37−6.69 (m, 298H, arom.), 4.98 (s, 16H), 2.97 (br, 16H), 2.72 (sept, 4H, ^3J = 6.31 Hz), 2.20 (br, 16H), 1.63 (br, 16H), 1.02 (br, 24H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 170.5, 156.3, 156.1, 141.4, 141.2, 141.0, 140.4, 139.8, 139.3, 139.0, 138.4, 137.6, 137.1, 136.7, 136.6, 134.6, 134.2, 131.5, 131.1, 131.0, 129.5, 128.3, 127.8, 126.8, 126.4, 117.3, 116.8, 60.2, 60.1, 33.7, 28.8, 25.3, 23.9.

Compound 17b. Compounds **16** (0.12 g, 0.043 mmol) and **8b** (0.879 g, 1.03 mmol) were dissolved in 18 mL of a tetraethyleneglycol/diphenyl ether mixture (1:1). The resulting solution was heated at 170 °C for 24 h under an argon atmosphere. The reaction mixture was precipitated in methanol and the crude product purified by chromatography (silica gel, CH_2Cl_2/acetone 1:4) to give **17b**. Yield: 286 mg (71%). MALDI-TOF MS ((M + Na)$^+$): m/z = 9434; ^{1}H NMR (300 MHz, DMSO-d_6) δ_H 9.65, 9.59 (2s, NH), 7.90 (s, 4H, arom.), 7.31−6.43 (m, 298H, arom.), 4.98 (s, 32H), 2.98 (br, 32H), 2.71 (sept,

4H, ^3J = 6.31 Hz), 2.20 (br, 32H), 1.64 (br, 32H), 1.02 (br, 24H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 170.6, 156.1, 156.0, 141.5, 141.3, 140.9, 140.3, 139.7, 139.4, 139.0, 138.4, 137.5, 137.2, 136.8, 136.5, 134.6, 134.2, 131.6, 131.2, 130.9, 129.5, 128.3, 127.7, 126.7, 126.3, 117.3, 116.9, 60.2, 60.1, 33.6, 28.9, 25.2, 23.8.

Compound 18a. Compound **17a** (0.26 g, 0.035 mmol) was dissolved in 6 mL of trifluoroacetic acid and 210 μL of 5.7 M HBr in acetic acid was added. The reaction mixture was stirred at room temperature for 2 h and added to a saturated $NaHCO_3$ solution. The precipitate **18a** was filtrated and dried under reduced pressure. Yield: 215 mg (97%). ^{1}H NMR (300 MHz, DMSO-d_6) δ_H 7.95 (s, 4H, arom.), 7.03−7.80 (m, 246H, arom.), 2.04 (br, 16H), 1.82 (br, 16H), 1.43 (br, NH), 1.01 (br, 24H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 170.0, 162.7, 158.3, 157.8, 155.0, 153. 3, 145.5, 141.8, 141.3, 140.9, 140.3, 140.1, 139.9, 139.6, 139.3, 138.9, 138.6, 138.4, 137.9, 137.6, 137.1, 136.7, 136.2, 134.6, 134.3, 132.5, 131.9, 131.3, 130.9, 130.7, 130.6, 129.9, 129.5, 129.2, 129.0, 128.7, 128.3, 128.0, 127.7, 126.8, 126.6, 126.4, 125.5, 123.8, 122.6, 120.1, 119.3, 118.9, 117.3, 116.9, 115.3, 49.9, 32.8, 28.3, 23.7, 22.

Compound 18b. Compound **17b** (0.23 g, 0.025 mmol) was dissolved in 6 mL of trifluoroacetic acid and 280 μL of 5.7 M HBr in acetic acid were added. The reaction mixture was stirred at room temperature for 2 h and added to a saturated $NaHCO_3$ solution. The precipitate **18b** was filtrated and dried under reduced pressure. Yield: 170 mg (96%). ^{1}H NMR (300 MHz, DMSO-d_6) δ_H 7.90 (s, 4H, arom.), 7.69−6.44 (m, 238H, arom.), 2.29 (br, 32H), 1.76 (br, 32H), 1.40 (br, NH), 1.18 (br, 24H); ^{13}C NMR (75 MHz, DMSO-d_6) δ_C 170.7, 170.1, 162.7, 161.0, 158.8, 158.4, 157.9, 157.5, 153.3, 145.5, 141.3, 140.9, 140.3, 139.7, 139.4, 139.0, 138.4, 138.0, 137.6, 136.6, 136.1, 134.8, 134.4, 134.2, 132.5, 131.3, 130.6, 129.5, 128.6, 12.5, 128.2, 128.1, 128.0, 127.9, 127.7, 126.8, 126.4, 124.2, 123.2, 122.6, 120.2, 119.7, 119.3, 118.9, 118.7, 117.4, 117.0, 115.3, 47.6, 33.9, 32.9, 28.9, 23.8, 22.9.

Compound 19. Compounds **2** (0.100 g, 0.137 mmol) and **5b** (0.408 g, 0.55 mmol) in *o*-xylene (15 mL) were heated at 160 °C for 24 h under an argon atmosphere. The reaction mixture was concentrated to one-fourth of the initial volume, and the product was purified by precipitation from a mixture of methanol and water (7:1) to give a yellow powder. Yield: 0.250 g (84%). MALDI-TOF MS (M^+): m/z = 2159; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.72−6.70 (m, 78H, arom.), 6.61−6.49 (m, 8H, arom.), 6.34−6.21 (m, 8H, arom.), 1.18−1.05 (m, 42H); ^{13}C NMR (75 MHz, CD_2Cl_2) δ_C 166.3, 153.2, 132.2, 131.7, 131.4, 130.8, 130.4, 128.5, 128.1, 126.3, 123.3, 108.1, 90.3, 64.1, 19.0, 11.6.

Compound 20. To a solution of **19** (0.220 g, 0.102 mmol) in THF (20 mL) was added (*tert*-Bu)$_4$NF·3H$_2$O (0.130 g, 0.41 mmol). The reaction mixture was stirred for 5 h at room temperature. Water (20 mL) was added, and the product was extracted with DCM (3 × 15 mL). The organic phase was isolated, dried over magnesium sulfate, filtrated, and concentrated to 5 mL. The product was purified by precipitation from a mixture of methanol and water (7:1) to give a yellow powder. Yield: 0.160 g (85%). MALDI-TOF MS (M^+): m/z = 1848; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.74−6.70 (m, 78H, arom.), 6.62−6.50 (m, 8H, arom.), 6.35−6.22 (m, 8H, arom.), 3.12 (s, 2H); $_{13}$C NMR (75 MHz, CD_2Cl_2) δ_C 166.3, 153.2, 132.2, 131.8, 131.4, 130.8, 130.4, 128.5, 128.1, 126.3, 123.3, 85.7, 79.4, 64.1.

Compound 21. Compounds **20** (0.100 g, 0.054 mmol) and **9** (0.105 g, 0.204 mmol) were dissolved in *o*-xylene (15 mL) and heated at 160 °C for 24 h under an argon atmosphere. The reaction mixture was concentrated to one-fourth of the initial volume, and the product was purified by precipitation from methanol to give a yellow powder. Yield: 0.130 g (84%). MALDI-TOF MS (M^+): m/z = 2875; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.74−6.21 (m, 134H, arom.), 3.62 (s, 6H), 2.32−2.18 (m, 8H), 1.69−1.55 (m, 8H); ^{13}C NMR (75 MHz, CD_2Cl_2) δ_C 171.0, 168.1, 149.4, 149.0, 144.9, 144.6, 142.9, 142.5, 141.5, 141.3, 141.1, 140.7, 140.4, 140.2, 140.0, 139.7, 139.3, 136.5, 136.3, 135.9, 132.9, 132.3, 132.2, 130.8, 130.4, 130.1, 129.7, 129.2, 128.6, 128.5, 128.4, 128.2, 127.3, 126.7, 126.0, 120.2, 120.0, 118.3, 118.0, 114.2, 113.9, 63.9, 51.9, 37.6, 34.1, 25.3, 24.9.

Compound 22. To a solution of **20** (0.100 g, 0.035 mmol) in tetrahydrofuran (2 mL) was added an aqueous solution of LiOH (0.300 mL, 2.3 M), and the mixture was heated at 80 °C for 12 h under an argon atmosphere. The reaction mixture was added to distilled water, and the product was extracted with DCM (3 × 20 mL). The organic phases were collected, washed twice with water, and dried with $MgSO_4$, and the solvent was evaporated to give **22** as yellow powder. Yield: 0.093 g (94%). MALDI-TOF MS: m/z = 2847 g/mol (M^+), 2869 g/mol ((M + Na)$^+$); ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.75−6.15 (m, 134H, arom.), 2.16−1.55 (m, 16H); ^{13}C NMR (75 MHz, CD_2Cl_2) δ_C 169.0, 167.9, 149.2, 148.8, 144.8, 144.4, 142.7, 142.3, 141.8, 141.1, 140.9, 140.5, 140.3, 140.0, 139.9, 139.5, 138.5, 136.3, 135.7, 135.4, 132.7, 132.1, 131.6, 131.3, 130.9, 130.5, 130.3, 129.9, 129.7, 129.5, 129.1, 128.9, 128.6, 128.4, 128.3, 128.2,127.9, 127.5, 127.2, 126.5, 125.8, 120.6, 120.0, 119.8, 115.5, 114.2, 113.7, 63.8, 37.3, 30.1, 25.2.

Compound 23. Compound **22** (0.080 g, 0.032 mmol) was dissolved in THF (0.5 mL), and 2 N HCl (1 mL) added. After 10 min, the mixture was cooled with ice and concentrated HCl (0.5 mL) added. The mixture was stirred for 20 min, and the solvents were evaporated under high vacuum. The final product was isolated as a bright brown powder, which was used in the next step without additional purification. Yield: 0.055 g (89%).

Compound 24. Compound **23** (0.065 g, 0.034 mmol) and 4-(2,5-dioxopyrrol-1-yl)butanoyl chloride (0.085 g, 0.41 mmol) were dissolved in a mixture of DMF (5 mL) and triethylamine (0.5 mL). The solution was stirred for 6 h at RT under an argon atmosphere. The product was purified by precipitation in methanol to give a dark yellow powder. Yield: 0.080 g (92%). MALDI-TOF MS ((M + Na)$^+$) m/z = 2873 g/mol; ^{1}H NMR (250 MHz, CD_2Cl_2) δ_H 7.56−6.53 (m, 102H, arom.), 3.59−3.48 (m, 8), 2.45−2.12 (m, 16H), 1.95−1.65 (m, 16H); ^{13}C NMR (175 MHz, DMSO-d_6) δ_C 174.1, 170.9, 169.9, 162.2, 143.7, 141.2, 140.2, 140.0, 139.5, 139.0, 136.7, 136.4, 134.3, 132.9, 131.2, 130.0, 129.5, 128.5, 128.4, 127.6, 126.8, 126.6, 126.2, 125.4, 117.3, 116.9, 36.8, 35.7, 33.4, 30.7, 24.4, 24.1, 23.6.

Compounds 36a−d. The PDI dendrimers **15a**,**b** and **18a**,**b** together with 5 equiv of peptide and 20 equiv of HOBT and HBTU were dissolved in a minimum quantity DMF and treated with 50 equiv of diisopropylethylamine (DIPEA). The reaction was stirred for 5 days at room temperature, and the product afterward was precipitated from diethyl ether. The resulting powder contained dendrimer−peptide−conjugate and peptide. Purification by dialysis proved impossible, and thus the mixture was dissolved in TFA and deprotected with HBr in acetic acid by the method described above. The crude product was precipitated from diethyl ether and subsequent ultrafil-

[a] Notation: x, number of polypeptide chains per molecule; m, number of lysine residues per chain. The polydispersity (M_w/M_n) of the peptide−dendrimer conjugates is calculated from the gel permeation chromatography data, obtained in DMF against polystyrene standards.

tration in water [nominal molecular weight limits (NMWLs) 10 000] and freeze-drying yielded the products **36a**−**d**.

36a. Yield: 159 mg (61%). ^{1}H NMR (700 MHz, DMSO-d_6) δ_H 7.91−6.70 (m, 130H, arom. + NH), 4.26−4.23(br, 20H), 3.96−3.10 (m, NH), 2.69 (br, 40H), 2.22 (br, 8H), 1.67−1.23 (m, 120H), 1.05 (br, 24H), GPC (UV, $\lambda = 280$ nm; PS): $M_n = 15700$ g/mol, $M_w/M_n = 1.1$.

36b. Yield: 169 mg (48%). ^{1}H NMR (700 MHz, DMSO-d_6) δ_H 7.90−6.71 (m, 150H, arom. + NH), 4.26−4.19 (br, 40H, H_c), 3.51−3.0 (m, NH), 2.71 (br, 80H, H_e), 2.24 (br, 16H, Hb), 1.67−1.24 (m, 240H, H_d), 1.05 (br, 24H, H_a); GPC (UV, $\lambda = 280$ nm; PS): $M_n = 20100$ g/mol, $M_w/M_n = 1.1$.

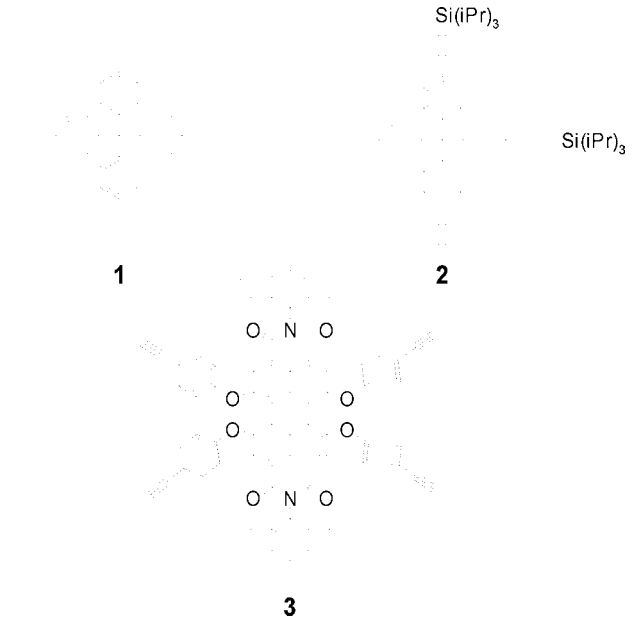
36c. Yield: 129 mg (52%). ^{1}H NMR (700 MHz, DMSO-d_6) δ_H 7.95−6.49 (m, 300H, arom. + NH), 4.26−4.20 (br, 40H, H_c), 3−64−3.08 (m, NH), 2.75 (br, 80H, H_e), 2.24 (br, 16H, Hb), 1.68−1.24 (m, 240H, H_d), 1.04 (br, 24H, H_a); GPC (UV, $\lambda = 280$ nm; PS): $M_n = 28600$ g/mol, $M_w/M_n = 1.16$.

36d. Yield: 131 mg (39%). ^{1}H NMR (700 MHz, DMSO-d_6) δ_H 7.95−6.45 (m, 340H, arom. + NH), 4.30−4.15 (br, 80H, H_c), 3.35 (br, NH), 2.74 (br, 160H, H_e), 2.26 (br, 32H, Hb), 1.68−1.04 (m, 504H, H_{d+a}); GPC (UV, $\lambda = 280$ nm; PS): $M_n = 35800$ g/mol, $M_w/M_n = 1.12$.

Polymerization. An argon-filled and thoroughly dried Schlenk-tube fitted with a drying tube was charged with a filtered (0.45 μm, PTFE) solution of the initiator (**15ab** and **18ab**) in dry dimethylformamide. A solution NCA in dry dimethylformamide was added via a syringe driven filter, so that the final NCA concentration in the mixture reaches approximately $c = 0.15-0.2$ g/L. The mixture was stirred under the exclusion of light for 5 days at room temperature, and the product was precipitated by dropwise addition of a 15-fold (v/v) excess of water. The precipitate was filtered through a glass frit, washed extensively with Et_2O to remove unreacted monomer, and dried under vacuum.

Deprotection of the Polymers. The polymer was dissolved in TFA, and a 4-fold excess (per lysine unit) of HBr in an AcOH solution (5.7 mol/L) was added. After 1 h reaction time, the product was precipitated by the addition of Et_2O. The precipitate was then filtered through a glass frit, purified via ultrafiltration against Milli-Q-water until a constant conductivity was reached, and finally lyophilized. The membranes used had NMWLs of 10 000 and 30 000 (regenerated cellulose), and 50 000 (polyethersulfone). All yields and molecular masses are listed in Table 1.

Scheme 1



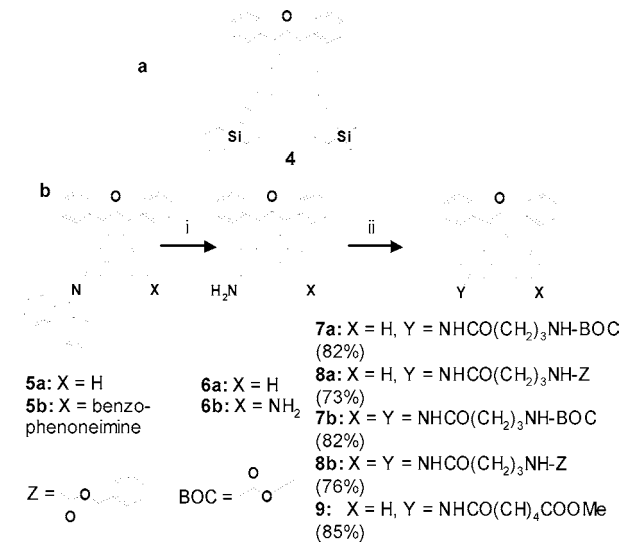
3. RESULTS AND DISCUSSION

The synthesis of polyphenylene dendrimers commences with a multi-ethynyl-substituted core molecule, namely, tetrakis-(4-ethynylphen-1-yl)-methane (**1**), its desymmetrized derivative **2**, as well as the PDI core **3** (Scheme 1).

We emphasize that the geometry of the core determines the overall shape of the resulting cascade molecules (*16*). The growth of each dendritic layer is based upon an iterative process including a Diels−Alder reaction and subsequent deprotection of ethynyl functions (*5*). Scheme 2a introduces a functionalized cyclopentadienone **4** used as A_2B-type branching agent (*16*). This molecule can act both as diene and after removal of the silyl protective groups from the ethynyl groups, as dienophile. In the [4+2]-cycloaddition between the cyclopentadienone and a free ethynyl group of the core molecule or the preceding dendrimer generation, a pentaphenylbenzene unit is formed under the extrusion of carbon monoxide (*17*−*19*).

3.1. Synthesis of Functionalized Cyclopentadienones. By using prefunctionalized cyclopentadienones **5ab**, **7ab**, **8ab**, **9** in the Diels−Alder reaction, polyphenylene dendrimers with chemical functions are obtained. These functions are either protected amino (**5ab**, **7ab**, **8ab**) or carboxyl (**9**) groups that can be readily converted into versatile anchor groups. The synthesis of the func-

Scheme 2[a]



[a] (a) A_2B-branching unit 3,4-bis-(4-triisopropylsilylethynylphenyl)-2,5-diphenyl-cyclopenta-2,4-dien-1-one **4**; (b) synthesis of functionalized cyclopentadienones; i: HCl, RT, THF; ii: corresponding *N*-protected amino acid or hexanedioic acid monomethyl ester, EDC, DMAP, DMF, RT.

tionalized cyclopentadienones is depicted in Scheme 2b. The preparation of the imino- (**5a**,**b**) and amino- (**6a**,**b**) functionalized cyclopentadienones has been described previously (*10*).

γ-Aminobutyric acid-functionalized building blocks **7ab**, **8ab** were obtained by EDC-catalyzed coupling of **6a**,**b** and the corresponding *N*-protected amino acid derivatives in DMF at room temperature. The products were purified by flash chromatography, and the structures were confirmed by ^{1}H NMR spectroscopy and FD mass spectrometry. Monocarboxy-functionalized cyclopentadienone **9** was synthesized analogously via a carbodiimide induced reaction of **6a** with hexanedioic acid monomethyl ester.

3.2. Synthesis of Polyphenylene Dendrimers. For the sake of brevity, the terminology introduced in Figure 1 will be used for the central dendritic polyphenylene units.

Scheme 3 summarizes the synthesis of amino- and maleimide-functionalized dendrimers. We have previously described the preparation of maleimide-decorated polyphenylene dendrimers **13a**−**d** (*10*). The Diels−Alder reaction of the functionalized cyclopentadienones **5ab** with either the core **1** or the octaethynyl-functionalized dendrimer **10** yielded the benzophenoneimino dendrimers **11a**−**d**. Subsequently, the complete cleavage of the protective groups was achieved with HCl in THF at room temperature, and the resulting amino dendrimers **12a**−**d** were reacted without additional purification with 4-(2,5-dioxo-pyrrol-1-yl)-butanoyl chloride to afford polyphenylene dendrimers with different numbers of maleimide anchor groups **13a**−**d**.

The synthesis of first-generation BOC-protected amino-functionalized PDI-dendrimers **14ab** proceeded via the Diels−Alder cycloaddition of **7ab** with the perylenediimide core **3.** The subsequent removal of the BOC groups with trifluoroacetic acid in dichloromethane (*20*) afforded

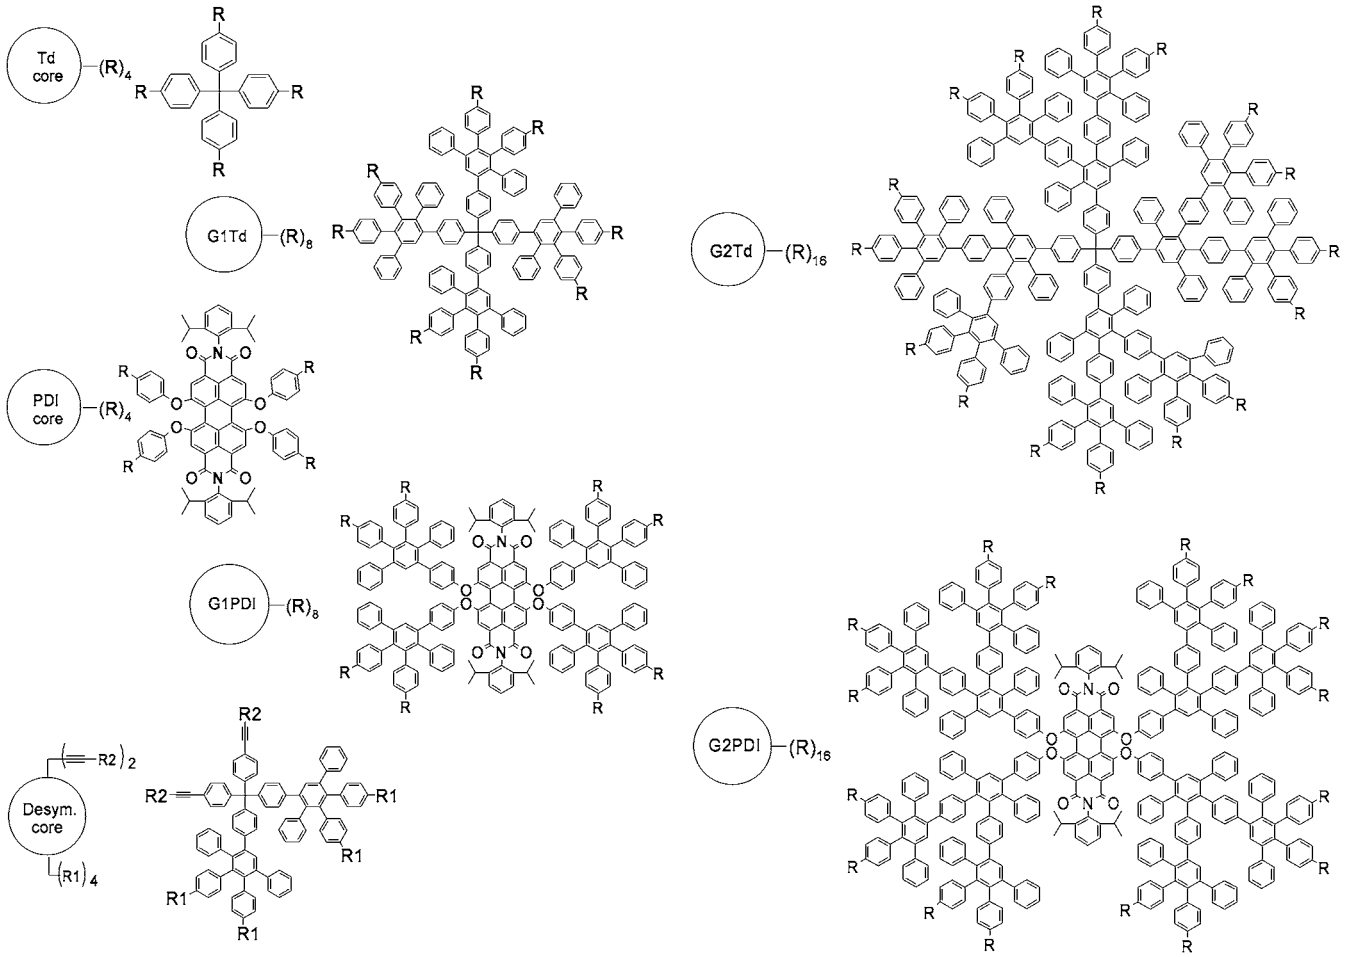


Figure 1. Symbols used to represent the polyphenylene scaffold of dendrimers in the schemes hereafter. The abbreviation in the circles shows the dendrimer generation and the central core unit.

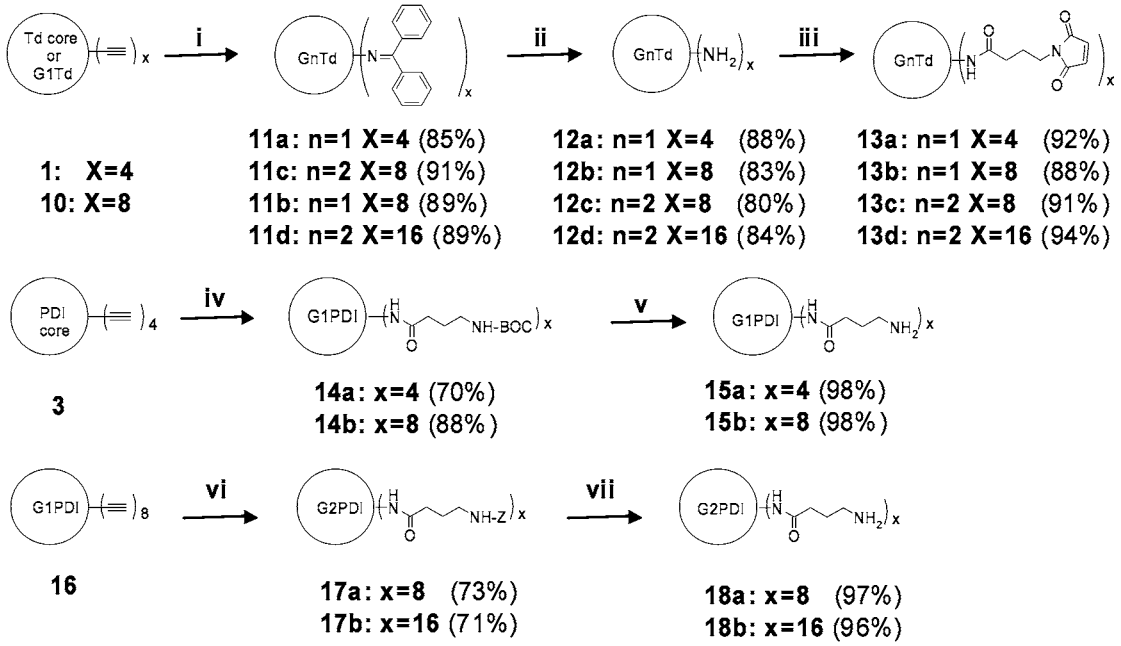
Scheme 3. Synthesis of Functionalized Dendrimers[a]



[a] (i) **5a/5b**, *O*-xylene, 150 °C; (ii) HCl, THF; (iii) 4-(2,5-dioxo-2,5-dihydropyrrol-1-yl)butanoyl chloride, DMF, triethylamine; (iv) **7a/7b**, *O*-xylene, toluene, DMSO, 150 °C; (v) TFA, DCM, RT; (vi) **8a/8b**, diphenyl ether, tetraethylene oxide, 170 °C; (vii) HBr, acetic acid. Notation: n, generation of the dendrimer.

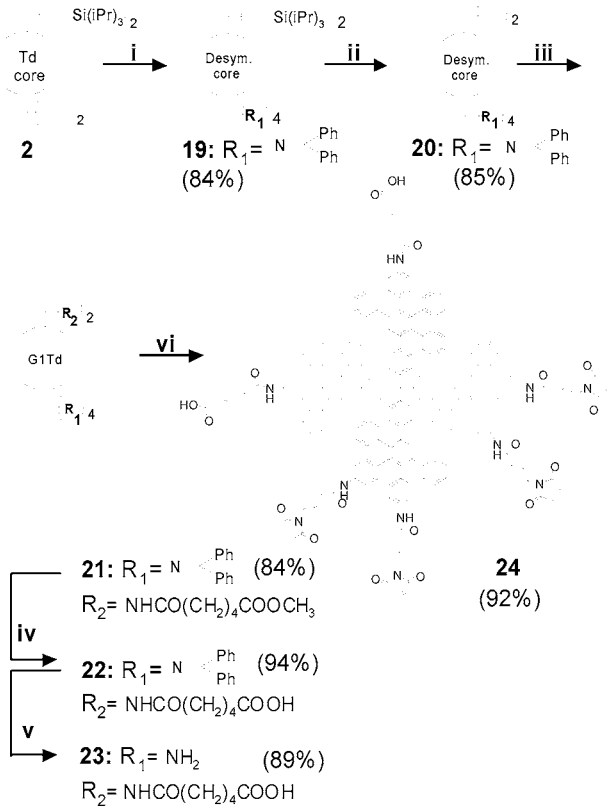
the amino compounds **15ab**. Employing the reagents **8ab** in a Diels–Alder reaction with **16** yielded the PDI dendrimers of the second generation **17ab**, which were readily converted to **18ab** by treatment with HBr in glacial acetic acid (*21*). The amino groups of compounds **15ab** and **18ab** are more stable against oxidation and more accessible for the coupling of polypeptides than amino groups of the aniline derivatives **12a–d**.

The synthesis of polyphenylene dendrimers possessing two different chemical functions is depicted in Scheme 4. First, cyclopentadienone **5b** was reacted with the diethynyl core **2** to afford compound **19**. After deprotection of the ethynyl groups, the subsequent Diels–Alder cycloaddition of **9** produced compound **20**. Note that **20** has both (protected) amino and carboxyl anchor groups. The ester groups were converted to free carboxyl groups by LiOH in THF at 80 °C (*22*), while the deprotection of the amino groups was achieved by HCl in THF. Finally, the maleimide groups were introduced via reaction with 4-(2,5-dioxo-pyrrol-1-yl)-butanoyl chloride in DMF at room temperature to obtain the bifunctional compound **24**.

3.3. Coupling of Polylysines to Polyphenylene Dendrimers. Scheme 5 gives an overview of the three synthetic routes toward peptide-decorated PPDs. Here we demonstrate the synthetic versatility of polyphenylene dendrimers as 3D carriers for the preparation of spatially defined bioactive conjugates. Three different strategies for peptide coupling were employed. We emphasize that the developed strategies are versatile and may be used for coupling of various oligopeptide fragments, according to the desired application.

3.3.1. Grafting of Protected Polypeptide from the PPD. The grafting of the polylysine from the surface of the polyphenylene dendrimers **15ab** and **18ab** was achieved by ring opening polymerization (Scheme 5a) of α-amino acid *N*-carboxyanhydrides (NCA). The ϵ-benzyloxycarbonyl-L-lysine *N*-carboxyanhydride (Lys(Cbz)-NCA) **25** was prepared following a literature procedure (*23–25*). **15a**,**b** and **18a**,**b** can be regarded as macroinitiators to which the corresponding amount of Lys(Cbz)-

Scheme 4. Synthesis of PPD Decorated with Different Anchor Groups[a]

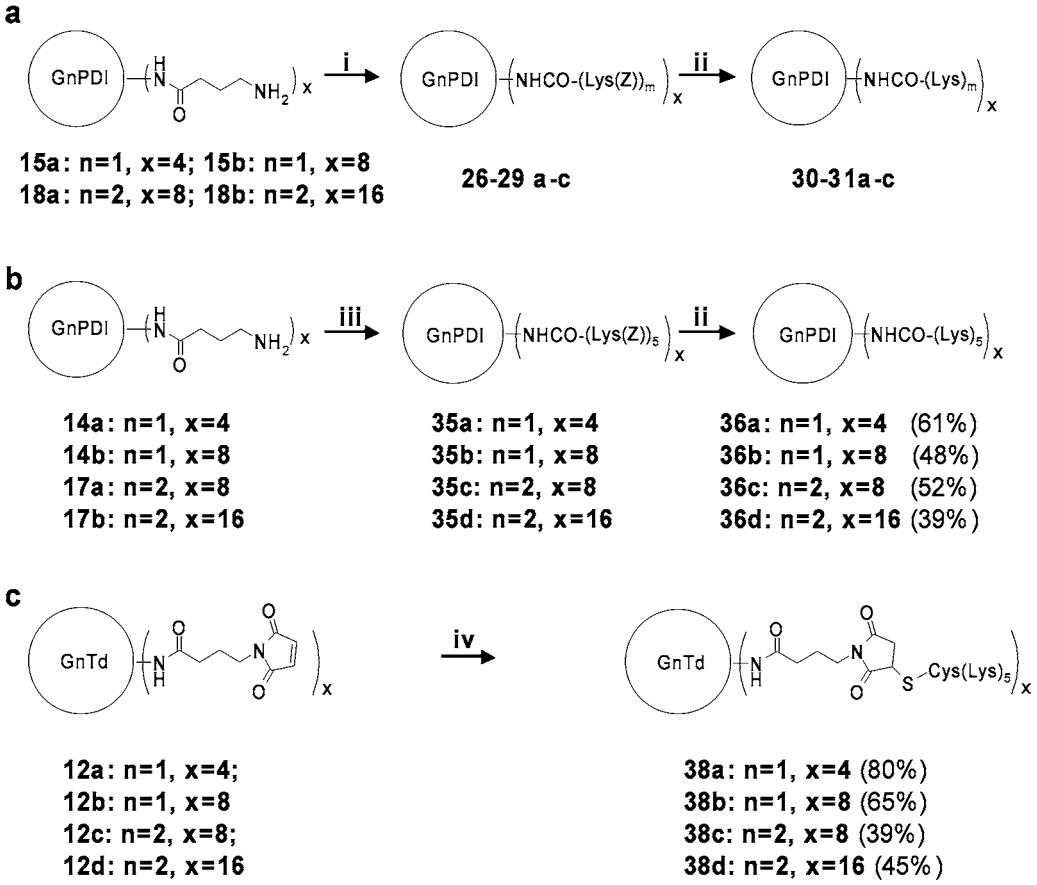


[a] (i) **5b**, *O*-xylene, 145 °C; (ii) $(t\text{-}Bu)_4NF{\cdot}3H_2O$, THF; (iii) **9**, *O*-xylene, 145 °C; (iv) LiOH, THF, 80 °C; (v) 2 N HCl, THF; (vi) 4-(2,5-dioxo-2,5-pyrrol-1-yl)-butanoyl chloride, DMF, triethylamine.

NCA was added, depending on the desired length of the peptide. The reaction proceeded in DMF at room temperature for 5 days.

The products **26a–c**, **27a–c**, **28a–c**, **29a–c** were precipitated in water. Unreacted monomer was removed

Scheme 5. Different Strategies for the Preparation of Peptide-dendrimer Conjugates[a]



[a] (i) ϵ-benzyloxycarbonyl-L-lysine *N*-carboxyanhydride (**25**), DMF; (ii) HBr, acetic acid; (iii) HOOC-(Lys(Z))$_5$-NHZ (**34**), HBTU, HOBT, DIPEA, DMF; (iv) HOOC-Cys-(Lys)$_5$-NH$_2$ (**37**), DMF. Notation: n, generation of the dendrimer; m, number of lysine residues per chain.

by extensive washing with Et_2O. Finally, the deprotection of the side chains of the lysine residues yielded **30a**−**c**, **31a**−**c**, **32a**−**c**, **33a**−**c** (Table 1). This reaction scheme permits control of the polypeptide length via the amount of the Lys(Cbz)-NCA added to the reaction. The dendrimers bear different numbers of polylysine chains of variable length (Table 1). These variable polypeptide lengths were used in the investigation of the secondary structure of the polylysine shell attached to a polyphenylene core (see section 2.4.). The Cbz-groups of the lysine residues were removed by HBr in glacial acetic acid, followed by precipitation in diethyl ether. To investigate the conjugates in salt-free solutions **30**−**33a**−**c** were purified via ultrafiltration in milli-Q water.

3.3.2. Attachment of Protected Pentalysine. In this case, the *C*-terminus of a Cbz-protected pentalysine **34** is coupled to the amino groups on the surface of the PDI dendrimers (Scheme 5b). The peptide was obtained by solid-phase peptide synthesis using standard Fmoc protecting group chemistry (*26*). The activation of the *C*-terminal carboxyl group of the peptides was achieved using HOBT, HBTU, and DIPEA as activating agents (*27*).

The dendrimers **15a**,**b** or **18 a**,**b**, peptide **34**, HOBT, HBTU, and DIPEA were allowed to react for 5 days in dry DMF under an inert atmosphere at room temperature. After precipitation of the sample in diethyl ether, the crude product was found to contain the target compounds **35a**−**d** and the unreacted polypeptide. Since purification at this stage was not possible, the Z-groups were removed by the same protocol as mentioned in 3.3.1. Subsequent utrafiltration in water (NMWLs 10 000) and freeze-drying yielded the water soluble conjugates **36a**−**d**. The structure and purity of these compounds were verified by means of ^{1}H NMR spectroscopy and gel permeation chromatography. The decoration of PDI dendrimers with preformed polypeptide sequences has the important advantage that no byproducts such as imperfect polypeptide chains occur. Note that the removal of such byproducts in the subsequent purification steps would be rather laborious (*28*).

3.3.3. Coupling of Unprotected Pentalysine. We also demonstrate a functionalization of the dendrimers with unprotected peptidesequences employing the Michael addition of the sulfhydryl group of terminal cysteine to the maleimide units on the dendrimer surface (Scheme 5c). Hexapeptide **37** is composed of a *C*-terminal cysteine and five lysine residues. The peptide was prepared via solid-phase peptide synthesis. The reaction of **13a**−**d** with **37** was performed in DMF at room temperature and the products **38a**−**d** were purified by dialysis and high performance liquid chromatography (HPLC). As for the method described in section 3.3.2, the absence of byproducts with wrong peptide sequences is a considerable advantage. Furthermore, in this case one circumvents the deprotection step(s), making this method especially convenient for coupling of polypeptide sequences sensitive to the deprotection procedures. It should be mentioned that the coupling via the SH group of the cysteine residue is not restricted to polypeptides.

3.4. Properties. 3.4.1. Circular Dichroism (CD). The intrinsic properties of proteins are achieved via secondary, tertiary, and quaternary structures. Therefore, a self-organization of the polypeptide shell attached

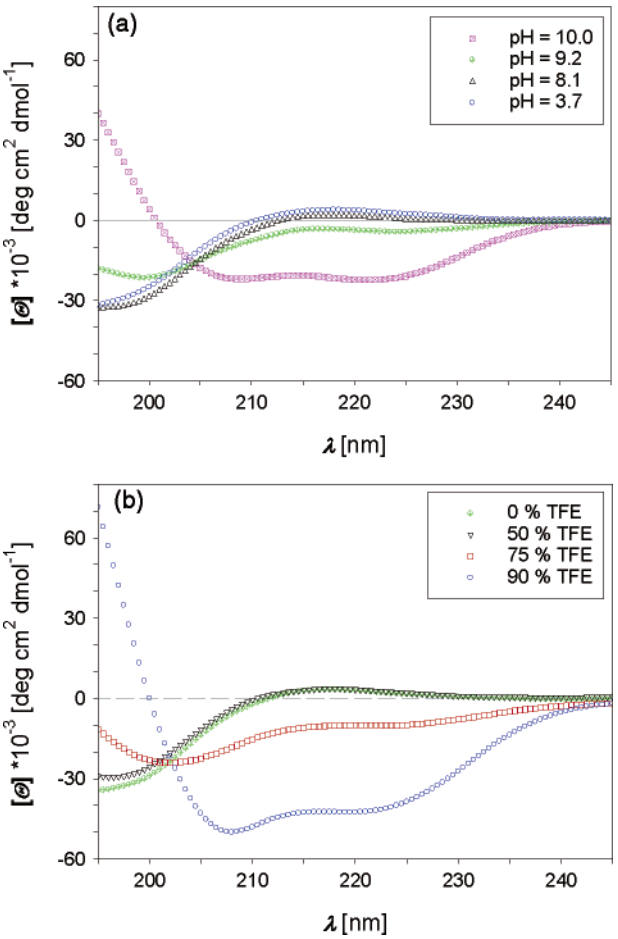


Figure 2. CD spectra of **30c** as a function of pH (a) and concentration of 2,2,2-trifluoro ethanol (b).

to a dendrimer core is essential for targeting bioproperties as for example antigen−antibody recognition. This motivated us to study the effect of either solvent or length of the peptides on the secondary structure of attached polylysine moieties.

PPDs bearing polylysine chains longer than six amino acid residues were investigated by CD spectroscopy. It is known that 2,2,2-trifluoroethanol (TFE) (*29*) as well as high pH (*23*) induce coil-to-helix transition in polylisine moieties. We employed these protocols to study how the polyphenylene scaffold affects the capability of the attached polypeptides of forming secondary structure. Figure 2 shows the CD spectra of **30c** (c = 1.1 μmol/L) as a function of pH (Figure 2a) and concentration of TFE (Figure 2b), respectively. The data are representative of all studied compounds **30a**−**c**, **31a**−**c**, **32a**−**c**, and **33a**−**c**, and the following conclusions can be drawn.

Below pH 9, the polypeptide chains form random coils. Above this pH value, the coils turn into helices. Above pH 10, however, the polypeptides begin to precipitate.

Coil-to-helix transformation can be induced by the exchange of the solvent, namely, when the concentration of TFE is above 75% vol.

The coil-to-helix transition with TFE as a solvent is induced because the intramolecular repulsion is suppressed (*29*−*31*). The same effect can be obtained by the basicity of the aqueous solution being increased (*23*). The helix content at pH 9.9 and in 90% TFE was calculated for all polylysine-decorated PPDs according to the method of Chen et al. (*32*−*34*). The mean residue ellipticity of a polylysine with 100% helix content at 222 nm was taken to be −37 600 deg cm^2 dmol^{-1} (*29*). The results are summarized in Table 2. For all studied compounds, the helix content at pH 9.9 is about 40% or above. Furthermore, the helix content determined in 90% TFE is higher than that determined at pH 9.9.

Table 2. Helix Content in Percent from the CD Spectra (80 μg/mL) in Water at pH = 9.9 and the Percentage in Comparison with the Measurements in a 90% TFE Solution

sample	generation	$m_{\mathrm{Lys,\,UV}}$	pH	α-helix [%]	$[\Theta]_{222}^{\mathrm{water}}/[\Theta]_{222}^{90\%\mathrm{TFE}}$ [%]
30a	$n = 1$ $x = 4$	9	9.9	43.6	78.2
30b		50	9.9	46.4	47.5
30c		85	10	60.6	53
31a	$n = 1$ $x = 8$	9	9.9	35.2	66.8

31c		76	9.8	47	45
32a	$n = 2$ $x = 8$	6	9.9	46.4	1133
32b		28	10	44.4	40.2
32c		41	9.9	43.2	42.5
33a	$n = 2$ $x = 16$	14	10	24.8	22.8
33b		41	9.9	80.6	71.2
33c		89	10.1	43.3	38

[a] Notation: $m_{\mathrm{Lys,UV}}$, number of lysine residues per chain, calculated by UV absorption of dendrimers.

The dissociation of polypeptide coiled coils and their organization into single-stranded helices are also evidenced by the ratio of the mean residue ellipticities at 222 and 208 nm (*33*, *35*). Figure 3a shows the ratio $[\Theta]_{222}/[\Theta]_{208}$ measured at pH 9.9 and in 90% TFE for all studied compounds. As evident from the plot, for polypeptide chains longer than 10 lysine residues, the ratio $[\Theta]_{222}/[\Theta]_{208}$ remains constant whatever the generation and number of polypeptide chains.

In water the ratio of the mean residue ellipticities at 222 and 208 nm is nearly one and indicates aggregation between the helices, whereas the value of the measurements in 90% TFE is around 0.8 points at dissociation. Shorter chains, comprising less than 10 residues, are less spatially organized and exhibit higher coil content, the latter being evidenced by the minimum in the ellipticity located in the region below 206 nm. An example is presented in Figure 3b where the CD spectra of **30a** and **30c** are compared.

The main conclusion from the CD data is that polypeptides attached on the dendrimers periphery are capable of forming secondary structures. This finding is essential for the design of synthetic multi-immunogens since the secondary structure of epitopes is responsible for the unique antigen−antibody recognition.

3.4.2. UV−Vis Absorption and Fluorescence. The compounds **30a**, **31a**, **32a**, and **33a**, each containing a PDI core, were characterized by UV−Vis and fluorescence spectroscopy. As an example, the absorption and emission spectra of **33c**, recorded in water and 90% TFE, are shown in Figure 4. Absorption and emission maxima in aqueous solution are at 580 and 614 nm, respectively, while a small bathochromic shift occurs when changing the solvent from water to 90% TFE with maxima at 597 (absorption) and 624 nm (emission).

For all compounds studied, the maxima of absorption are observed at 580−600 nm, being essentially independent of the dendrimer generation and number of peptide residues. Interestingly, the extinction in the less polar solvent water (58 000−88 000 cm^2 mol^{-1}) is lower than the extinction in TFE solutions (81 000−103 000 cm^2 mol^{-1}). All of the compounds **31**−**33** exhibit fluorescence. The emission maxima were detected at wavelengths between 615 and 630 nm upon excitation at 560 nm. The quantum yields in aqueous solutions of all compounds

were low (about 1%). Nevertheless, the optical properties (strong absorption at 580−600 nm and fluorescence in water) of the peptide-decorated PDI dendrimers allow their identification in complex mixtures of biological samples. These features are very important for in vitro/ in vivo studies and pharmaceutically oriented applications since at wavelengths greater than 550 nm cells and tissue usually do not show any chromophoric properties.

4. CONCLUSIONS

We have demonstrated the synthesis of new amino acid functionalized cyclopentadienones. Their Diels−Alder reactions with different core molecules lead to polyphenylene dendrimers functionalized with amino or carboxyl groups. Polylysine fragments were then coupled to these dendrimers employing three different methods.

(i) Grafting of the peptides from the surface of the dendrimer by applying the NCA polymerization strategy. This route affords a decoration of PPDs with polypeptides, connected via their *C*-terminus. Furthermore, the attached polypeptide chains are able to fold into defined secondary structures, an important prerequisite for the preparation of functional bioconjugates.

(ii) Carbodiimide coupling of a protected peptide. The C-terminal carboxyl groups of the peptides are activated employing HBTU/ HOBT and are attached to the surface amino groups of the dendrimers.

(iii) Specific attachment of unprotected peptide fragments under mild conditions via Michael addition of a thiol group of the terminal cysteine of the polypeptide to the maleimide of the PPD. This method allows both *C*- and *N*-terminal attachment of the polypeptide.

The resulting dendrimers have good solubility in water and combine shape-persistence with a controlled number of surface functions. Additionally, when perylenediimide PPDs are used as cores, absorption and fluorescence techniques can be employed for their identification.

By using an asymmetric core molecule and appropriately functionalized cyclopentadienones in a Diels−Alder reaction, we have obtained PPDs bearing two different functional groups. For example, compound **33**, a PPD bearing carboxyl and maleimide functions in isolated surface domains, is a scaffold for the creation of a conjugate possessing two different polypetide sequences.

We have recorded circular dichroism (CD) spectra of PPDs bearing different numbers of polypeptide chains of various degrees of polymerization. On the basis of these data, we have concluded that at pH 9.9, as well as in the presence of more than 75% TFE, the attached polypeptide is capable of forming an α-helical secondary structure. This fact is of particular importance for the design of MAP since the secondary structure is essential for the intrinsic properties of its distinct sites. In addition, conjugates synthesized with the perylenediimide core strongly absorb at 580−600 nm and are fluorescent in water.

Our synthetic methods are not restricted to oligolysines but may be easily adapted to the substitution of PPD with various polypeptide sequences. This opens the way to biofunctonalized compounds with perspectives as spatially defined MAPs with a hydrophilic shell formed of certain epitopes and chromophor-labeled shape-persistent scaffolds.

As more becomes known about the expression profiles of normal and cancerous cells, it should become possible to design antisense-based imaging agents for the early detection of cancer noninvasively. In this report, we rationally designed and synthesized three antisense and one sense hybrid PNA (peptide nucleic acid) to the unr mRNA that is highly overexpressed in a breast cancer cell line (MCF-7). The conjugates had a four-lysine tail at the carboxy terminus for cell permeation and a DOTA (1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid) chelating moiety at the amino terminal end for chelating ^{64}Cu for biodistribution and microPET imaging studies. Biodistribution of two ^{64}Cu-labeled conjugates with antisense and sense sequences (PNA50 and PNA50S) showed high uptake and long retention in kidney and low uptake and efficient clearance in blood and muscle in normal balb/c mice when administered intravenously or intraperitoneally. Intraperitoneal administration, however, gave a much slower release rate. MCF-7 tumors (100−320 mg) in CB-17 SCID mice were imaged with all four ^{64}Cu-labeled PNA conjugates by microPET, but the image contrast varied with different time points and different conjugates. Of the conjugates studied, ^{64}Cu-DOTA-Y-PNA50-K4 showed the best tumor image quality at all time points with a tumor/muscle ratio of 6.6 ± 1.1 at 24 h postinjection, which is among the highest reported for radiolabeled oligonucleotides. Our work further strengthens the potential of antigene and antisense PNAs to be utilized as specific molecular probes for early detection of cancer and ultimately for patient specific radiotherapy.

INTRODUCTION

Noninvasive imaging techniques are revolutionizing the way of understanding diseases at the cellular and molecular levels. Among the current available imaging modalities, positron emission tomography (PET) has demonstrated its great potential in the field of molecular imaging. The success of PET is due to its superior sensitivity and specificity in diverse applications and the ability to quantitatively analyze the regions of interest (*1*, *2*). Since the completion of human genome sequence, there has been considerable research interest in assessing gene expression through noninvasive molecular imaging approaches. Currently, the number of genes is estimated to be between 24 000 and 30 000 and that alternative polyadenylation and splicing could result in the formation of between 46 000 and 85 000 messenger RNAs (mRNA) (*3*). Of the various PET probes that have been developed to image gene expression in small animal models, oligodeoxynucleotides (ODNs) appear to be an inexhaustible gold mine for the development of new tracers with high specificity considering that an ODN with more than 12 bases could target a unique sequence in the whole human genome (*4*).

Naturally occurring ODNs cannot be directly used for nuclear imaging because they are rapidly degraded in vivo by endo- and exonucleases (*5*). Furthermore, ODNs can cause degradation of the target mRNA by RNAse H. To increase the in vivo stability of ODNs without significant alteration of their pharmacokinetics and targeting properties, many chemical modifications have been made to the sugar−phosphate backbone. Modifications include morpholino, phosphorothioate, phosphoroamidate, methylphosphonate, 2′- or 3′-modifications, 2′−4′ bridges (locked nucleic acid), and complete replacement of the backbone with an amide backbone (peptide nucleic acid or PNA) (*6*−*8*). PNAs are unique types of oligonucleotides, which were initially introduced by Nielsen et al. in 1991 as ligands for the double-stranded DNA recognition (*9*). They are synthetic DNA mimics featuring a chain with repeating N-(2-aminoethyl) glycine units instead of the sugar−phosphate backbone. Because of the structural characteristics (e.g., neutral and flexible), PNAs are resistant to in vivo enzymatic degradation and bind complementary DNAs or RNAs with high affinity and specificity even under low ionic strength (*10*). They also do not activate RNAse H degradation of mRNA. Recent work has shown that PNAs can be used as molecular hybridization probes (*11*), nuclear imaging tracers (*8*, *12*−*16*), and to control gene expression and splicing (*6*, *17*−*19*).

Using antisense PNAs as molecular imaging probes has a major obstacle in that they are not able to penetrate biologic membranes. To overcome this obstacle, researchers have resorted to drug delivery techniques such as

using cationic lipids (or polyamines) and liposomes (*20*−*23*), nanoparticles (*24*), and direct conjugation with monoclonal antibodies (*12*, *13*) or peptides (*6*, *25*−*32*), etc. Recently, it was reported that PNAs with four lysines at the C terminus (PNA-K4 oligomers) were able to penetrate cells in cell culture (*33*) and enter the cells of most organs of a mouse by their ability to restore correct splicing to an otherwise defective reporter gene (*6*).

To be useful as a probe, an antisense PNA must target a unique or a uniquely overexpressed mRNA in the disease cell. Analysis of mRNA expression levels within cancer cells by DNA chip or array analysis (*34*−*37*) and by serial analysis of gene expression (SAGE) (*38*, *39*) have revealed that there are many overexpressed mRNAs, some of which may be present in more than 50-fold greater abundance than in normal cells. To ensure good detection sensitivity and selectivity, a unique or uniquely overexpressed mRNA target should also be highly abundant, and initially we imagined that there would be a number of such candidate mRNA triggers already validated for antisense cancer therapy (*40*). Most of all the validated antisense targets for cancer have been picked, however, on the basis of biological function and not on abundance, and many of the target mRNAs turn out not to be uniquely overexpressed in the cancer cells as judged from an examination of SAGE databases. A search of the NCBI SAGE database for mRNAs that are uniquely overexpressed (>10-fold) and in high copy number in cancer cells identified the unr (upstream of N-ras) (*41*−*44*) mRNA as a potential target. The unr mRNA is more than 10-fold more highly expressed in the MCF-7 breast cancer cell line than it is in any normal tissue cell line, and that it is present in about 5000 copies per cell, making it an ideal initial target for imaging studies.

An additional criterion for the preparation of any PET probe is the ability to rapidly introduce the radionuclide at the last step in the synthesis and under conditions that do not damage the ligand. The important role of copper radiotracers in these regards has been well-recognized in the applications of PET imaging and radiotherapeutic agents in recent years. ^{64}Cu can be rapidly attached to a ligand by chelation to an appended high affinity chelator. Of the four copper radionuclides that can be used as PET imaging agents, ^{64}Cu has shown its versatility in diverse applications for PET imaging (*45*−*51*) and radiotherapy of cancer (*52*−*56*) due to its decay characteristics ($t_{1/2}$ = 12.7 h; β^+: 0.653 MeV, 17.4%; β^-: 0.578 MeV, 39%) and the ability to produce it in high yield and specific activity on a small biomedical cyclotron (*57*, *58*). In this study, we introduced a DOTA moiety to the N terminus of our designed PNAs so that they can be radiolabeled with ^{64}Cu, which enabled the in vivo visualization of our PNAs targeting MCF-7 tumor in mice via microPET and biodistribution studies.

EXPERIMENTAL PROCEDURES

Materials. DOTA-tris(*tert*-Butyl ester) was from Macrocyclics Inc. (Dallas, TX), and diisopropylethylamine (DIEA), trifluoroacetic acid (TFA), *m*-cresol, and diethyl ether (anhydride) were purchased from Aldrich (St. Louis, MO). α-N-9-Fluorenylmethoxycarbonyl (Fmoc)-protected amino acids [D-Lys(Boc)-OH and Tyr(tBu)-OH] were purchased from NovaBiochem (La Jolla, CA). O-(7-Azabenzo-triazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), Fmoc-XAL PEG-PS resin, PNA building blocks [Fmoc-A-(Bhoc)-OH, Fmoc-C-(Bhoc)-OH, Fmoc-G-(Bhoc)-OH, and Fmoc-T-OH], and other reagents and solvents for PNA and peptide synthesis were purchased from Applied Biosystems (Foster City, CA). UV spectral data were acquired on a Bausch and Lomb Spectronic 1001 spectrophotometer or Varian Cary 100 Bio UV−visible Spectrophotometer. Matrix-assisted laser desorption ionization (MALDI) mass spectra of PNA−peptide conjugates were measured on PerSeptive Voyager RP MALDI-time-of-flight (TOF) mass spectrometer using sinapinic acid as a matrix and calibrated vs insulin (average $[M + H^+] = 5734.5$) that was present as an internal standard. High-pressure liquid chromatography was carried out on a Beckman Coulter System Gold 126 with an array detector. Copper-64 was prepared on the Washington University Medical School CS-15 cyclotron by the ^{64}Ni(p,n)^{64}Cu nuclear reaction at a specific activity of 50−200 mCi/μg at the end of bombardment as previously described (*58*). Water was distilled and then deionized (18 MΩ/cm^2) by passing through a Milli-Q water filtration system (Millipore Corp., Bedford, MA). Diethylenetriaminepentaacetic acid (DTPA), ammonium acetate, and sodium chloride were purchased from Fluka Chemie AG (Buchs, Switzerland). Dry powder in foil pouches for the preparation of 10 mM phosphate buffer saline (PBS), pH 7.4, and 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES) were purchased from Sigma-Aldrich. Solvents (e.g., acetone, methanol, etc.) were purchased from Fisher Scientific (Pittsburgh, PA) and used as received. Saline (0.9% NaCl solution) was purchased from American Pharmaceutical Partners, Inc. (Schaumburg, IL). Centricons (YM-3: MWCO 3000 Da) were purchased from Millipore Corporation. Fast protein liquid chromatography (FPLC) and radio-FPLC were performed using an Amersham Pharmacia Biotech ÄKTA FPLC (Amersham Biosciences Corp., Piscataway, NJ) equipped with a Beckman 170 Radioisotope Detector (Beckman Instruments, Inc., Fullerton, CA). The Superdex 75 was bought from Amersham Biosciences Corp. PBS, trypsin/EDTA, and cell culture media and additives were purchased from the tissue culture support center of Washington University School of Medicine (St. Louis, MO). Fetal bovine serum (FBS), Earle's balanced salt solution (BSS), and insulin were bought from Sigma. Balb/c and CB-17 SCID mice were purchased from the Charles River Laboratories (Wilmington, MA).

Tissue Culture and Animal Model. The MCF-7 cell line was obtained from the American Type Culture Collection (ATCC, Manassas, VA). MCF-7 cells were grown in Eagle's minimum essential medium (MEM) with Earle's BSS and 2 mM L-glutamine modified to contain 1 mM sodium pyruvate, 0.1 mM nonessential amino acids, 1.5 mg/mL sodium bicarbonate supplemented with 10% FBS and 0.01 mg/mL bovine insulin. To establish MCF-7 human breast xenografts, each CB-17 SCID mice was implanted with a 60-day subcutaneous (s.c.) slow release estrogen pellet (1.7 mg 17β-estradiol/pellet; Innovative Research of America, Sarasota, FL) 48 h prior to the s.c. injection of MCF-7 cells into the nape of neck. Cultured MCF-7 cells were harvested from monolayer using PBS and trypsin/EDTA, and suspended in media with FBS. The cell suspension was centrifuged and resuspended in PBS at the concentration of 1×10^8 cells per milliliter. It was then mixed 1:1 with Matrigel and injected s.c. (1×10^7 cells per mouse, injection volume 200 μL) into the nape of the neck of CB-17 SCID mice (5−6 weeks of age). After the cell injection, the animals were monitored twice a week by general observations. The tumor was noticed to grow in the first week and allowed to grow five weeks to reach a palpable size for microPET imaging studies. The tumor weight was 100−320 mg as determined by post imaging biodistribution.

Synthesis of the DOTA-(D)-Y-PNA-K4 Conjugates. NH_2-Y-PNA-K4 conjugates were synthesized continuously on universal support XAL-PEG-PS resin on a 2 μmol scale with standard solid phase Fmoc off chemistry on an Expedite 8909 Synthesizer (Applied Biosystems) by loading the fifth and sixth building block channels with Fmoc-D-Lys and Fmoc-Tyr(tBu), respectively, and programming the sequence accordingly under standard automated PNA synthesis protocol. DOTA-tris(*tert*-butyl ester) (11.5 mg, 20 μmol) was dissolved in 100 μL of *N*-methylpyrrolidone, and then, 100 μL of HATU in dimethylformamide (DMF) solution (0.2 M) and 100 μL of base solution (0.2 M DIEA, 0.3 M 2,6-lutidine in DMF) were added, the mixture was introduced into the cartridge containing PNA-K4 resin manually with a syringe and pushed back and forth with a second syringe to agitate the resin suspension every 10 min for 1 h. Then, the resin was washed with DMF and dichloromethane and dried by passing nitrogen. Treatment of the resin with TFA/*m*-cresol (4:1) for 2 h at RT was used to cleave the conjugates and remove the side chain protective groups. Ethyl ether (8−10 volumes) was added to the TFA solution to precipitate the product as a yellow solid. The crude product was purified by reversed phase HPLC on a Microsorb C18 column (300 Å pore, 5 μm particle size, 4.6 × 250 mm) using a 5−70% linear gradient of solvent B (0.1% TFA in acetonitrile) in A (0.1% TFA in water) over 65 min at the flow rate of 1 mL/min. The effluent was monitored by absorbance at 260 nm and the major peaks were collected, concentrated to dryness in vacuum, and characterized by MALDI-TOF mass spectrometry.

Radiolabeling of DOTA-Y-PNA-K4 Conjugates with ^{64}Cu. Copper-64 chloride (typically in 0.1 M HCl) was converted to ^{64}Cu-citrate by adding an appropriate volume of 0.1 M ammonium citrate buffer (pH 7.0) to the $^{64}CuCl_2$ solution. Prior to labeling, the stock solutions of DOTA-Y-PNA-K4 conjugates were heated at 80 °C for 10 min to minimize aggregation and plastic wall sticky property of the PNA conjugates. To 200 μL of a DOTA-Y-PNA-K4 conjugate solution (40 μM), 20 μL of ^{64}Cu-citrate was added (2−4 mCi). The resulting solution was incubated at 60 °C for 1−2 h in a thermomixer (1000 rpm). After incubation, 5 μL of 10 mM DTPA solution was added to the ^{64}Cu-DOTA-Y-PNA-K4 solution. The solution was vortexed for a few seconds and left at RT for 10 min. It was then centrifuged at least two times through a Centricon YM-3 (MWCO 3000 Da) with 10 mM PBS buffer (pH 7.4) to remove the ^{64}Cu−DTPA complex and/or free ^{64}Cu-activity. The radiochemical purity (RCP) of the ^{64}Cu-labeled DOTA-Y-PNA-K4 conjugate was monitored by FPLC. The product was then diluted with 10 mM PBS buffer (pH 7.4) to prepare appropriate doses for biodistribution and microPET imaging studies.

FPLC Analysis. A 100 μL of analyte was injected into a Superdex 75 gel filtration column, which was then eluted with 20 mM HEPES and 150 mM NaCl (pH 7.3) buffer at an isocratic flow rate of 0.5 mL/min. The UV wavelength was preset to 280 nm, the radioactivity was monitored by an online Beckman radio-detector. Under these conditions, the retention times of the ^{64}Cu-DOTA-Y-PNA-K4 and DOTA-Y-PNA-K4 were ca. 31−35 min.

Biodistribution Studies. All animal studies were performed in compliance with guidelines set by the Washington University Animal Studies Committee. Copper-64 labeled DOTA-Y-PNA-K4 solutions were diluted with saline. Normal balb/c mice weighing 20−30 g (n = 3 per time point) were anesthetized with isoflurane and injected with 10−12 μCi of activity via the tail vein (i.v.) or ca. 55 μCi of radioactivity via intraperitoneal (i.p.) injection. The injected volume of activity per mouse was 100 μL. The mice were anesthetized prior to sacrifice (by decapitation) at each time point. Organs of interest were removed, weighed, and counted. Standards were prepared and counted along with the samples to calculate the percent injected dose per gram (%ID/g) and percent injected dose per organ (%ID/organ).

MicroPET Imaging Studies. The microPET imaging studies were carried out using the microPET R4 (rodent) scanner (Concorde Microsystems Inc., Knoxville, TN) (*59*). MCF-7 tumor-bearing CB-17 SCID mice were anesthetized with 1−2% vaporized isoflurane and injected with ca. 200−400 μCi of activity in 120 μL saline via the tail vein (^{64}Cu-DOTA-Y-PNA50, 210 μCi; ^{64}Cu-DOTA-Y-PNA50S, 347 μCi; ^{64}Cu-DOTA-Y-PNA5, 253 μCi; ^{64}Cu-DOTA-Y-PNA7, 361 μCi). At specific time points (1, 4, and 24 h) postinjection, the mice were reanesthetized and then immobilized in a supine position on custom-built support beds with attached anesthetic gas nose cones for data collection. Within 4 h p.i., the imaging collection time was 10 min; at 24 h p.i., the imaging collection time was 20 min.

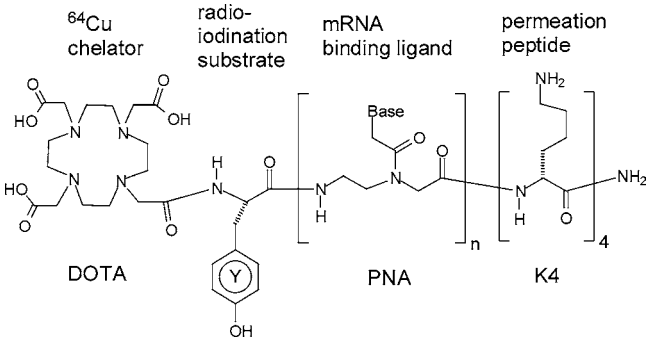
Radioactive tracer accumulation (^{64}Cu-labeled PNAs) in a targeted organ was measured using the standardized uptake value (SUV). The SUVs were obtained by the quantification of the regions of interest (ROIs) by viewing these areas in the selected tissues and averaging the activity concentration corrected for decay over the contained voxels (multiple image slices) at the time points p.i. (*60*).

$$\mathrm{SUV} = \frac{\text{radioactivity concentration in ROI } (\mu\text{Ci/cc})}{\text{injection dose } (\mu\text{Ci})/\text{animal weight (g)}}$$

After the microPET imaging at 24 h p.i., the animals were sacrificed and biodistribution studies were performed. The ratios of tumor to blood (T/B) and tumor to muscle (T/M) were calculated. The unpaired t-test on the biodistribution and microPET quantitation data was performed using Prism, v. 4.00 (Graphpad, San Diego, CA).

Assaying Unr mRNA Expression. Total RNA was extracted from MCF-7 cells and grafted mouse tissues with TRIzol (Invitrogen Corp., Carlsbad, CA). For the adult mouse tissues, samples were harvested and immediately submerged in RNAlater Tissue collection RNA stabilization solution (Ambion, Inc., Austin, TX) and then homogenized prior to mRNA extraction. Relative RT-PCR was carried out according to the manufacturer's procedures (Ambion). The cDNA was prepared with SuperScriptII reverse transcriptase (Invitrogen Life Technologies, Carlsbad, CA) and PCR was carried out with human-specific and nonspecific unr mRNA primers that were designed based on the available human and mouse unr sequences (gi:56117851, gi:16877279) along with QuantumRNA Classic I 18S Internal Standard competimer primer mix (1:1) as an internal control (Ambion). For human unr mRNA 5′-TGGGGGACATGGTCGAGTAT-3′ and 5′-ACATTCCACTGTGGCCCTG-3′ were used, and for both human and mouse unr mRNA 5′-AGCTTGTCCAAAGGCAAAG-3′ and 5′-AAGCCAAACTGATCTTTCACAC-3′ were used. PCR was performed with Pfx polymerase (Invitrogen) using a 3 min 94 °C preincubation followed by 24 cycles of 45 s 94 °C, 45 s at 56 °C for human-specific primers and 52 °C for the nonspecific primers, and 45 s at 68 °C. The samples were then kept at 68 °C for 2 min and then loaded into a 1% agarose gel and ethidium bromide stained.

Table 1. PNAs Used in PET Imaging Studies and Their Characterization by MALDI-TOF



PNA	site[a]	PNA sequence	calcd avg MW (M + 1)	observed (M + 1)
50	2848	TGGTGTGCTTTGTGGATG	6066.67	6068.95
7	673	TTTCCCAGTCCGTCGGTC	5876.54	5879.07

50S	sense	CATCCACAAAGCACACCA	5849.53	5852.87

[a] Start codon at 448.

RESULTS

Selection of the Antisense PNAs. The sequences of the antisense PNAs were selected by a procedure that will be described in greater detail elsewhere but in brief consisted of using a modification of a recently described RT-ROL (reverse transcriptase−random ODN library) method for mapping antisense binding sites on native mRNA (*61*). ODNs complementary to these sites were synthesized and their binding affinity for the unr mRNA determined. Hybrid PNAs corresponding to ODNs with the highest binding affinities and containing a C-terminal K4 (Lys_4) sequence and an amino terminal Cys-Tyr sequence were then synthesized, radioiodinated with ^{131}I on tyrosine, and their binding affinities determined. Three of these antisense PNAs and one sense PNA were selected for imaging studies: PNA50 with a K_d of 21 pM, PNA5 with a K_d of 22 pM, PNA7 with a K_d of 15 pM, and PNA50S (sense form of PNA50) with a K_d of >10 nM in 0.1 M NaCl, 50 mM EDTA, 2 mM cacodylic acid (Table 1). The sites on the mouse unr mRNA corresponding to the antisense PNA binding sites on the human mRNA are shown in (Table 2), two of which differ in sequence by two nucleotides (PNA50 and PNA7 sites), and one by only one nucleotide (PNA5 site). All the mouse sites have stretches of less than 14 nucleotides of complete complementarity to the PNAs, as compared to 18 for the human mRNA.

Synthesis of DOTA-Y-PNA-K4 Conjugates. The PNA conjugates (Table 1) were synthesized using standard automated solid phase Fmoc synthesis on an ABI 8909 DNA synthesizer with a PNA option (unfortunately, this synthesizer is no longer commercially available). The unnatural D-isomer of lysine was used to inhibit enzymatic degradation of the K4 permeation peptide unit. The DOTA group was added manually in the last step of the synthesis to the amino terminal ("5′-end") of the PNA via the commercially available tri-*tert*-butylester, and the HPLC purified products characterized by MALDI-TOF (Table 1).

Radiolabeling of DOTA-Y-PNA-K4 Conjugates. Four DOTA-Y-PNA-K4 conjugates were all successfully radiolabeled with ^{64}Cu in 0.1 M ammonium citrate buffer (pH 7.0) under mild conditions (at 60 °C for 1−2 h) in yields of 32−61% (decay corrected). After DTPA challenge of nonspecifically bound ^{64}Cu activity and Centricon YM-3 (MWCO: 3000 Da) separation, the radiochemical purity of the ^{64}Cu-labeled PNA conjugates was nearly 100% as determined by radio-FPLC: both the radioactivity and UV (280 nm) curves only showed a single strong peak with the same retention time in the range of 30−35 min. The ^{64}Cu-labeled PNA conjugates remained 100% intact after being kept in saline overnight.

Biodistribution of ^{64}Cu-DOTA-Y-PNA-K4 Conjugates in Normal Balb/c Mice. To better evaluate the in vivo kinetics of the ^{64}Cu-labeled PNA conjugates, the biodistribution studies were carried out with two different injection modes in normal balb/c mice: intravenous (tail vein) injection (i.v.) and intraperitoneal injection (i.p.).

Tail Vein Injection. The biodistribution data of ^{64}Cu-DOTA-Y-PNA50-K4 and ^{64}Cu-DOTA-Y-PNA50S-K4 in blood, liver, kidneys, and muscle are presented as percent of injected dose per organ (%ID/organ) at 20 min, 1 h, and 4 h postinjection (p.i.) in Figure 1. Both conjugates exhibited high kidney uptake and long retention. Within 1 h p.i., ^{64}Cu-DOTA-Y-PNA50-K4 showed slightly higher kidney accumulation (37.4 ± 1.8%ID/kidney at 20 min p.i. and 45.8 ± 0.7%ID/kidney at 1 h p.i.) than ^{64}Cu-DOTA-Y-PNA50S−K4 (35.6 ± 0.6%ID/kidney at 20 min p.i. and 42.3 ± 0.2%ID/kidney at 1 h p.i.). Out to 4 h p.i., ^{64}Cu-DOTA-Y-PNA50-K4 exhibited significant kidney clearance (36.1 ± 3.6%ID/kidney at 4 h p.i. $P < 0.02$ as compared to the value at 1 h p.i.), while a drastic accumulation was observed for ^{64}Cu-DOTA-Y-PNA50S-K4 (60.5 ± 3.6%ID/kidney at 4 h p.i. $P < 0.005$ as compared to the value at 1 h p.i.). In blood, liver, and muscle, the uptake of ^{64}Cu-DOTA-Y-PNA50-K4 was slightly lower than that of ^{64}Cu-DOTA-Y-PNA50S-K4 out to 4 h p.i. Both conjugates showed around 4%ID/organ of uptake in bone at 20 min p.i., but they were cleared to < 1%ID/organ at 4 h p.i. Negligible uptake was observed in lung, spleen, heart, and brain for both compounds (<1%ID/organ).

Intraperitoneal Injection. The biodistribution of ^{64}Cu-DOTA-Y-PNA50-K4 and ^{64}Cu-DOTA-Y-PNA50S-K4 via the intraperitoneal injection mode was performed in normal balb/c mice ($n = 3$) at 24 and 48 h p.i. The biodistribution data in selected organs are shown in

Table 2. Complementarity of PNAs Used in This Study to Human and Mouse mRNAs

PNA	mRNA	mRNA sequence with mismatches underlined	longest stretch of homology
PNA50	human unr	CATCCACAAAGCACACCAT	18
	mouse unr	CGTCCACAAAGCACATCAT	13
PNA5	human unr	AC̲AACAATGGACATAA̲TG	18
	mouse unr	ACAACAATGGACACAATG	13
PNA7	human unr	GACCGACGGACTG̲G̲GAAA	18
	mouse unr	GACCGG̲AGGACTGGGAAA	11
	mouse Slc37a3	A̲GAGG̲AC̲GGACTGGGAA̲G	14
	mouse pleckstrin	G̲C̲C̲TCACGGACTGGGAA̲A̲	13
PNA50S	human GALNT5	TC̲A̲TG̲TGCTTTGTGGATG	15

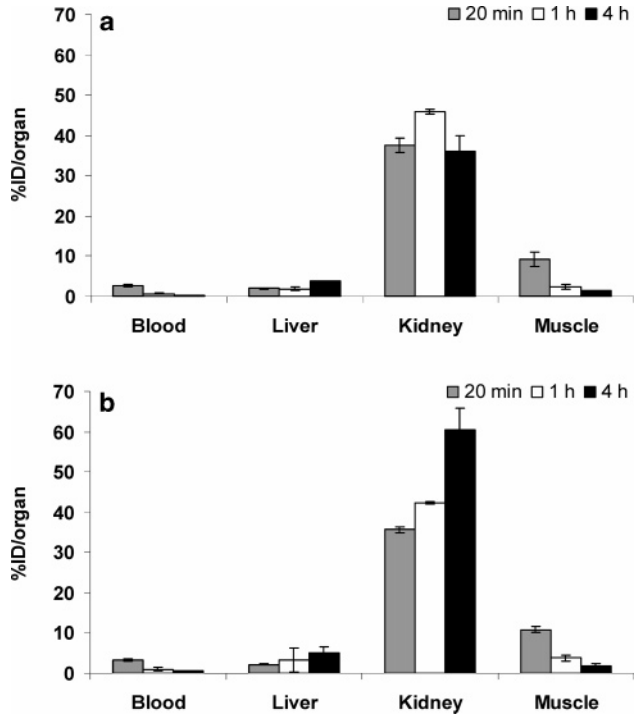

Figure 1. Biodistribution data of ^{64}Cu-DOTA-Y-PNA-K4 conjugates in selected organs of normal balb/c mice via the tail vein injection (n = 3). Injection dose: 10−12 μCi/100 μL. Upper: ^{64}Cu-DOTA-Y-PNA50-K4; lower: ^{64}Cu-DOTA-Y-PNA50S-K4. Data are present as %ID/organ ± SD.

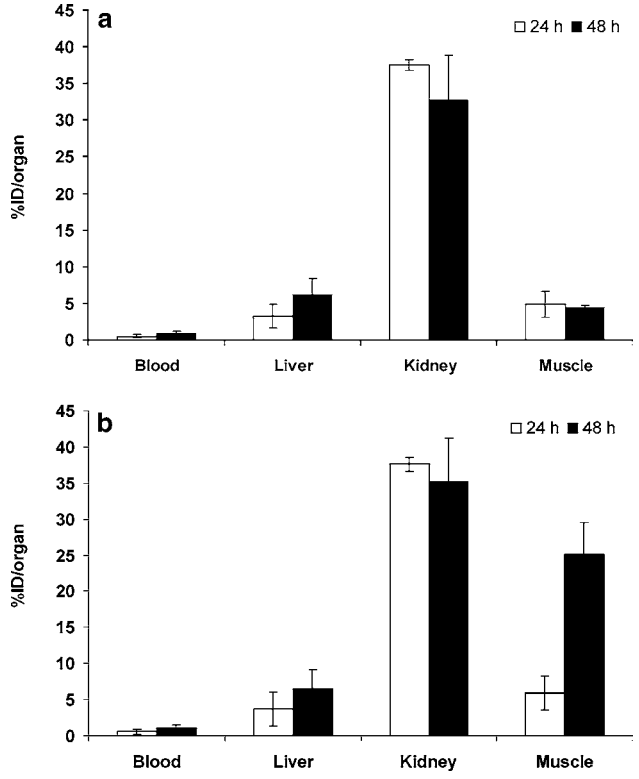

Figure 2. Biodistribution data of ^{64}Cu-DOTA-Y-PNA-K4 conjugates in selected organs of normal balb/c mice via intraperitoneal injection (n = 3). Injection dose: 55 μCi/100 μL. Upper: ^{64}Cu-DOTA-Y-PNA50-K4; lower: ^{64}Cu-DOTA−PNA50S-K4. Data are present as %ID/organ ± SD.

Figure 2. Both compounds exhibited similar uptake in kidney and liver at 24 h p.i. (^{64}Cu-DOTA-Y-PNA50-K4: 37.5 ± 0.7%ID/kidney and 3.2 ± 1.6%ID/liver; ^{64}Cu-DOTA-Y-PNA50S-K4: 37.6 ± 1.0%ID/kidney and 3.7 ± 2.4%ID/liver), which is comparable to the data of the i.v. mode at 20 min p.i. While no significant clearance was observed from kidney at 48 h p.i. for either compound (^{64}Cu-DOTA-Y-PNA50-K4: 33 ± 6%ID/kidney; ^{64}Cu-DOTA-Y-PNA50S-K4: 35 ± 6%ID/kidney), it is apparent that both conjugates were accumulating in liver out to 48 p.i. (^{64}Cu-DOTA-Y-PNA50-K4: 6.1 ± 2.1%ID/liver; ^{64}Cu-DOTA-Y-PNA50S-K4: 6.5 ± 2.6%ID/liver). Surprisingly, the muscle uptake of ^{64}Cu-DOTA-Y-PNA50S-K4 drastically increased from 5.9 ± 2.4%ID/muscle at 24 h p.i. to 25.0 ± 4.4%ID/muscle at 48 h p.i., while ^{64}Cu-DOTA-Y-PNA50-K4 maintained the same uptake level from 24 h (4.9 ± 1.8%ID/muscle) to 48 h p.i. (4.5 ± 0.2%ID/muscle). Both compounds exhibited low accumulation in other tissues (<1%ID/organ in lung, spleen, heart, and brain; < 2%ID/organ in blood and bone; and < 3%ID/organ in fat at 48 h p.i.).

MicroPET Imaging of ^{64}Cu-DOTA-Y-PNA-K4 Conjugates in MCF-7 Tumor Bearing Mice. The microPET imaging was performed in MCF-7 tumor-bearing CB-17 SCID mice with ^{64}Cu-DOTA-Y-PNA-K4 conjugates at 1, 4, and 24 h p.i. Of the four compounds, ^{64}Cu-DOTA-Y-PNA50-K4 exhibited visually the highest image contrast of the tumor, which was implanted in the nape of the neck, from 1 h out to 24 h p.i. (Figure 3a). Consistent with the biodistribution results, the microPET images (Figure 4) showed that the kidneys were the primary organ of accumulation of the PNA conjugates. As shown in Figure 3b, the solid tumor was also discernible from the surrounding tissues with ^{64}Cu-DOTA-Y-PNA50S-K4. The tumor was clearly imaged with ^{64}Cu-DOTA-Y-PNA5-K4 at 1 h p.i. (Figure 3c), but was not visible at either 4 or 24 h p.i. In contrast, ^{64}Cu-DOTA-Y-PNA7-K4 was able to give a fairly good image of the tumor at 24 h p.i. (Figure 3d) but not at the earlier time points.

The microPET images were analyzed by the quantification of radiotracer accumulation in the regions of interest (ROIs). The time−activity curves of the four PNA conjugates in the kidneys (represented by the left kidney), liver, and tumor are shown in Figure 5. It is apparent that the quantitative data are in agreement with the microPET images (Figures 3 and 4). The kidneys had the highest concentrations of all four compounds as shown by the standard uptake values (SUVs). The ^{64}Cu-labeled conjugates of PNA50, PNA50S, and PNA5 showed slow clearance from the kidneys and significant accumulation in the liver from 1 to 24 h p.i. While these three compounds exhibited similar uptake and retention in the kidneys and liver, ^{64}Cu-DOTA-Y-PNA7-K4 demonstrated significantly different behavior. In the kidneys, it showed the lowest uptake and the most efficient clearance out to 24 h p.i., whereas its liver concentration was the highest, at around five times those of other compounds at 1 h p.i., and remained at about the same level out to 24 h p.i. Copper-64-DOTA-Y-PNA50-K4 showed the highest SUV (0.076 ± 0.009) in tumor, followed by ^{64}Cu-DOTA-Y-PNA5-K4 (SUV: 0.034 ± 0.003) and ^{64}Cu-DOTA-Y-PNA50S-K4 (SUV: 0.018 ± 0.004) at 1 h p.i. While ^{64}Cu-DOTA-Y-PNA50-K4 exhibited rapid washout from tumor out to 4 h p.i., the accumulation level of ^{64}Cu-DOTA-Y-PNA50S-K4 remained steady within 24 h p.i. Consistent with the microPET images (Figure 3d), an appreciable amount of ^{64}Cu-DOTA-Y-PNA7-K4 accumulated in the tumor at 24 h p.i. (SUV: 0.031 ± 0.003).

Postimaging Biodistribution Data. The post imaging biodistribution experiments were carried out right after the microPET imaging at 24 p.i. The concentrations

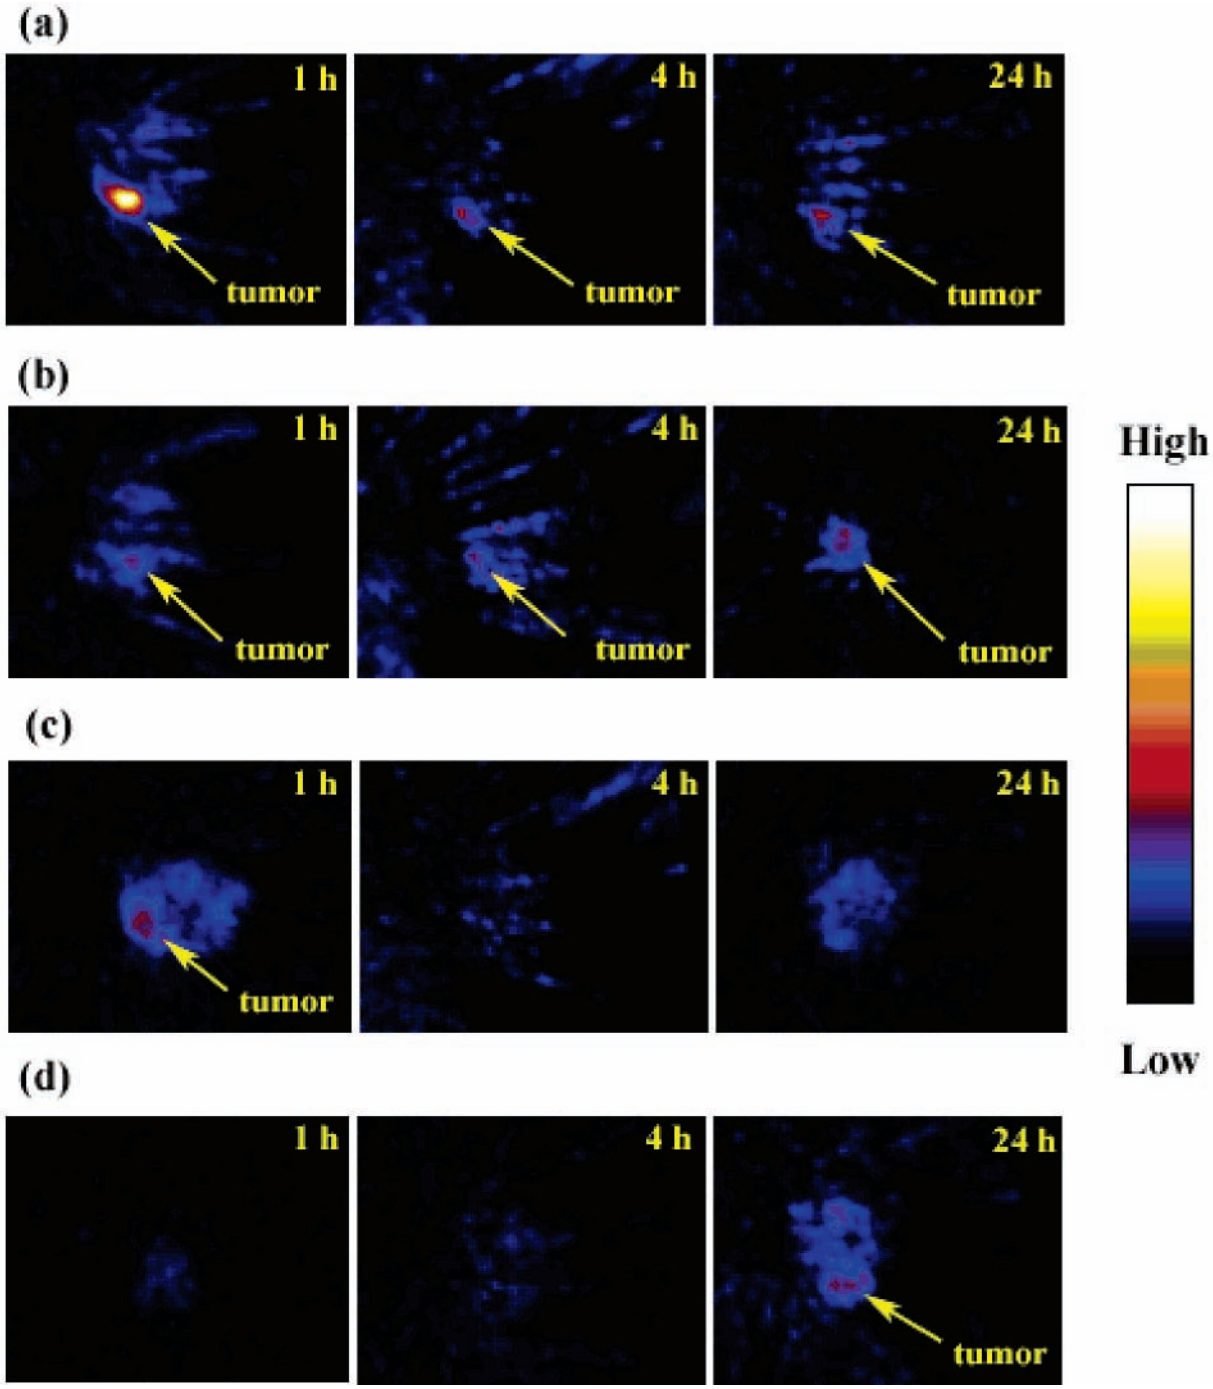

Figure 3. MicroPET transaxial images of ^{64}Cu-labeled PNA conjugates in MCF-7 tumor bearing CB-17 SCID mice. (a) ^{64}Cu-DOTA-Y-PNA50-K4 (injection dose: 210 μCi). (b) ^{64}Cu-DOTA-Y-PNA50S-K4 (injection dose: 347 μCi). (c) ^{64}Cu-DOTA-Y-PNA5-K4 (injection dose: 253 μCi). (d) ^{64}Cu-DOTA-Y-PNA7-K4 (injection dose: 361 μCi). The intensity of the images was decay-corrected and normalized to the injection dose.

of the four PNA conjugates in blood, liver, kidneys, muscle, and tumor were represented by percent of injected dose per gram of tissue (%ID/g) as shown in Figure 6. Copper-64-DOTA-Y-PNA50-K4 exhibited the highest concentration in the kidneys (280 ± 35%ID/g), followed by ^{64}Cu-DOTA-Y-PNA5-K4 (251 ± 50%ID/g), ^{64}Cu-DOTA-Y-PNA50S-K4 (174 ± 54%ID/g), and ^{64}Cu-DOTA-Y-PNA7-K4 (143%ID/g). While ^{64}Cu-DOTA-Y-PNA50-K4, ^{64}Cu-DOTA-Y-PNA50S-K4 and ^{64}Cu-DOTA-Y-PNA5-K4 showed similar low concentrations in the liver (5.6 ± 0.3%ID/g, 5.2 ± 2.2%ID/g, and 7.7 ± 1.1%ID/g, respectively), the concentration of ^{64}Cu-DOTA-Y-PNA7-K4 was much higher (28%ID/g). This observation is consistent with quantification of the microPET images. Although ^{64}Cu-DOTA-Y-PNA50-K4 and ^{64}Cu-DOTA-Y-PNA5-K4 showed similar tumor uptake (1.50 ± 0.11%ID/g and 1.35 ± 0.11%ID/g, respectively), the tumor/muscle (T/M) ratio of the former (T/M: 6.6 ± 1.1; $n = 2$) is about five times that of the latter due to the high concentration of ^{64}Cu-DOTA-Y-PNA5-K4 in muscle as shown in Figure 7. The T/M ratios of ^{64}Cu-DOTA-Y-PNA50S-K4 (3.0 ± 0.2; $n = 2$) and ^{64}Cu-DOTA-Y-PNA7-K4 (2.75; $n = 1$) are in between. Copper-64-DOTA-Y-PNA50-K4 also demonstrated the highest tumor/blood (T/B) ratio (T/B: 3.4 ± 0.0; $n = 2$) among the ^{64}Cu-labeled PNA conjugates at 24 h p.i.

Assay for Human and Mouse Unr mRNA Expression. To verify that the MCF-7 tumors were indeed

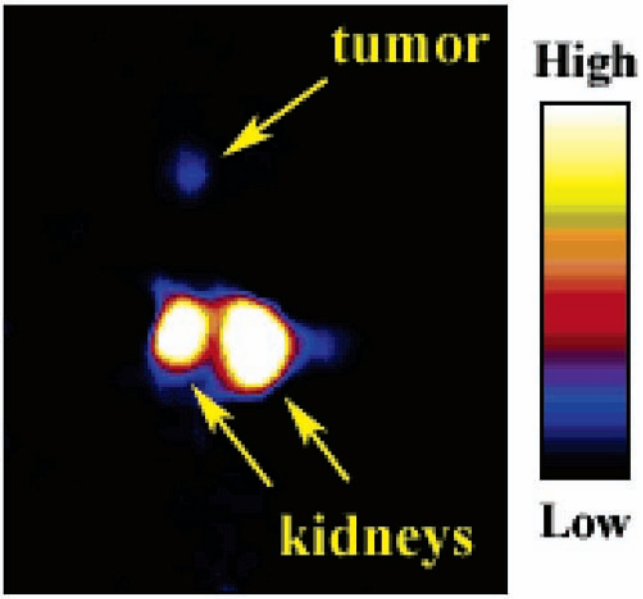

Figure 4. MicroPET coronal image of ^{64}Cu-DOTA-Y-PNA50-K4 in an MCF-7 tumor bearing CB-17 SCID mouse at 1 h p.i. The intensity of the images was scaled by max/min of frame.

producing human unr mRNA, unr mRNA expression was assayed by relative RT PCR using 18S rRNA as an internal control. Human unr mRNA-specific and nonspecific primers were designed based on the available sequences of human and mouse unr mRNA, and used to assay unr mRNA production in MCF-7 cells from tissue culture and from the tumor and other tissue specimens in a tumor-bearing mouse. The primers for the 18S RNA were nonspecies specific. As can be seen from Figure 8A, human unr mRNA was detected in the MCF-7 tumor in the mouse and was not detected in any other tissue samples. Use of the nonspecific PCR primers with the same tissue samples shows that mouse unr mRNA is produced in a number of tissues at variable levels (Figure 8B). The amount of unr mRNA detected with the human specific primers relative to the 18S rRNA is slightly greater in the tumor sample than it is in the MCF-7 cells from tissue culture, indicating that the expression level in the tumor is at least the same, if not more than it is in tissue culture. The amount of the unr mRNA detected with the nonspecific primers relative to the 18S rRNA is also slightly greater for the tumor than for the cultured cells indicating that the majority of the unr mRNA is being expressed by the MCF-7 cells.

DISCUSSION

Antisense oligonucleotides have been reported as nuclear imaging probes (PET and SPECT) in forms of unmodified oligomers or viral/nonviral carrier-oligomer conjugates (*8*, *14*, *15*, *62*). While the carrier systems could significantly enhance the tumor accumulation of oligonucleotides due to the increased payload of the carriers (*63*), a major concern is how to address the extent to which the biodistribution is determined by the carrier or the oligomer. Carrier-oligomer conjugates may also encounter the common difficulties of drug delivery systems, such as sequestration by reticulo-endothelial system (RES) and immunogenicity of the carriers (*8*). It is

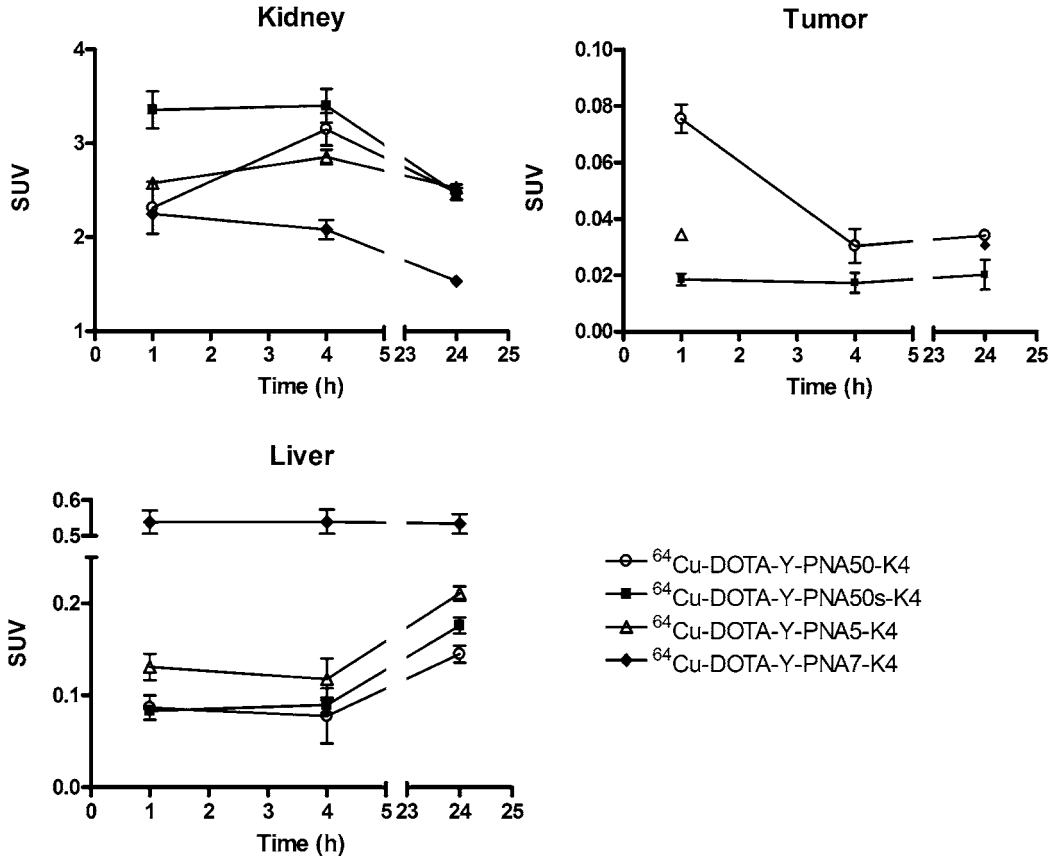

Figure 5. Time−activity curves of ^{64}Cu-DOTA-Y-PNA-K4 conjugates in MCF-7 tumor bearing CB-17 SCID mice. Data are obtained from averaging multiple microPET image slices in the selected organs and tumor and presented as mean SUV ± SD. Because of the low tumor to background contrast of ^{64}Cu-DOTA-Y-PNA5-K4 and ^{64}Cu-DOTA-Y-PNA7-K4, their SUV data in tumor are only obtainable at 1 and 24 h p.i., respectively.

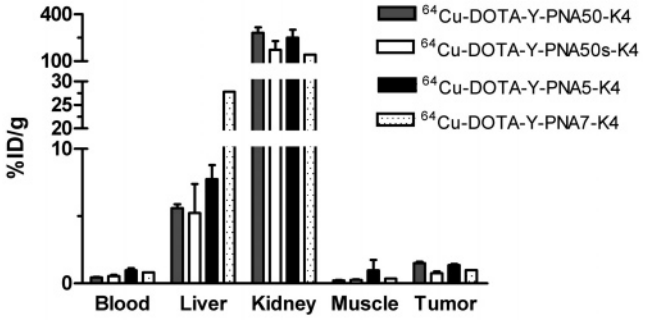

Figure 6. Biodistribution data of ^{64}Cu-DOTA-Y-PNA-K4 conjugates in MCF-7 tumor bearing CB-17 SCID mice post-microPET imaging at 24 h p.i. (n = 2). Data are present as %ID/g ± SD.

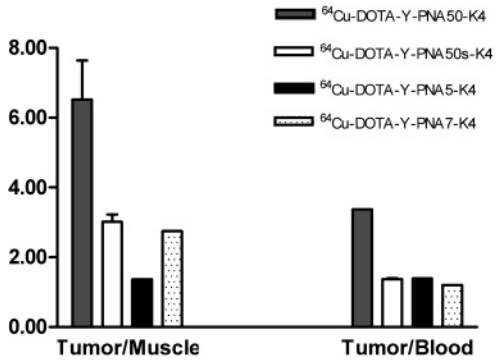

Figure 7. Ratios of tumor to muscle and tumor to blood of ^{64}Cu-DOTA-Y-PNA-K4 conjugates in MCF-7 tumor bearing CB-17 SCID mice at 24 h p.i. Data were calculated from biodistribution results of post-microPET imaging.

Lanes: 1, MCF-7 cells; 2, tumor; 3, muscle; 4, brain; 5, fat; 6, heart; 7, intestine; 8, kidney; 9, liver; 10, lung; 11, ovary; 12, spleen; and 13, uterus. The 18S PCR band is 488 nt, and the unr PCR band is 368 nt.

self-evident that unmodified or minimally modified oligonucleotides should be studied in-depth before they could be applied to the gene transfection or drug delivery systems for various proposes.

As a special class of oligonucleotide analogues, the biological behavior of PNAs has been extensively studied in vitro and in vivo since they were first proposed (*14*, *28*, *32*, *64*−*72*). In contrast, the utilization of PNAs as imaging probes of cancer for PET and SPECT is very limited, probably because the accumulation of the PNA imaging probes in the tumors could barely reach a detectable level. Recently, Sazani et al. reported that a PNA with four lysine at its N-terminus exhibited superior in vitro and vivo properties and sequence-specific activity compared to its analogue with one lysine (*6*, *33*).

Design of Cell Specific Imaging Probes. Our approach to the design of cell-specific PNA-based imaging agents is to: (1) identify an abundant, unique or uniquely overexpressed mRNA in the target cell, (2) identify high affinity antisense PNAs binding sites on the target mRNA, (3) covalently attach a permeation peptide to the PNAs that allows for reversible cell entry, and (4) attach a positron-emitting radionuclide with high specific activity to the PNA-permeation peptide conjugate. In our approach, the biological function of the mRNA is irrelevant, all that matters is that it is uniquely overexpressed and abundant in the target cell. As such this approach differs from other antisense approaches that often target oncogenes, which are only present in low copy number (<100). For this initial study we used SAGE analysis to identify the uniquely overexpressed (approximately 10-fold) and abundant unr mRNA in the MCF-7 cancer cell line (approximately 5000 copies/cell), and an RT-ROL assay to identify high affinity antisense binding sites on the mRNA. PNAs complementary to these sites were conjoined to the recently described permeation peptide Lys_4 (K4) (*6*, *33*) and the highest affinity PNA-K4 conjugates were linked to the ^{64}Cu binding ligand DOTA to create the MCF-7 cell-specific PET imaging agents.

As can be seen from Table 2, the antisense unr PNA sequences used also have partial complementarity to the mouse unr mRNA sequences and to some other mouse and human sequences. Though not determined in this study, the affinity of the PNAs to the mouse unr mRNA is expected to be diminished by the single and double mismatches, as well as by any changes in mRNA folding that would affect the accessibility of the antisense binding sites. Likewise, binding of PNA7 to two other mouse sequences is likely to be even more diminished by the presence of triple mismatches, even if these sites were accessible. While PNA50S was designed not to bind to the human unr mRNA, a search of the human genome revealed that it is complementary to the human GALNT5 mRNA. This mRNA is not likely to contribute to targeting of PNA50S to the tumor because it was not detected in the MCF-7 SAGE libraries, and has only been detected at very low levels in normal pooled brain and central retina SAGE libraries.

The labeling of DOTA-Y-PNA-K4 conjugates with ^{64}Cu was straightforward. The radiochemical yields were reasonably high, and a nearly perfect radiochemical purity was achieved after DTPA challenge of nonspecifically bound ^{64}Cu and centricon separation. The specific activity of the ^{64}Cu-labeled PNA conjugates was ca. 200 mCi/μmol (7400 MBq/μmol) at the injection time, which is the highest specific activity ever achieved for radiolabeled oligonucleotides (*62*, *73*, *74*) to the best of our knowledge. The radiolabeling conditions were optimized from the trials varying reaction temperature, time, pH, and media (data not shown).

Biodistribution of PNA Conjugates in Normal Mice. Concerned that our PNA conjugates might have rapid in vivo kinetics, we carried out biodistribution experiments in normal mice via i.v. and i.p. modes. The biodistribution via i.v. was performed within a short time period (4 h) postinjection, while the i.p. experiment was conducted at 24 and 48 h p.i. All four PNA conjugates showed high kidney uptake and long retention throughout time (Figures 1 and 2), no matter the injection mode. This observation is in agreement with McMahon's report on the in vivo behavior of PNAs (*75*). It differs, however, from what was observed for PNA50 and PNA50S lacking the DOTA group that were labeled at tyrosine with ^{131}I.

These PNAs showed predominant uptake in the liver (data not shown), indicating that the DOTA group influences the biodistribution properties of the PNA-K4 moiety.

While both PNA conjugates with unr mRNA antisense (PNA50) and sense (PNA50S) sequences exhibited a very similar pattern of tissue distribution within 1 h p.i., the conjugate with sense sequence showed a remarkably higher accumulation in kidney than its antisense counterpart ($P < 0.005$) at 4 h p.i. (Figure 1) which must be related to the differences in their base composition or sequence. As a result of the rapid pharmacokinetics of PNAs (*75*), our PNA conjugates showed a very low level of uptake in blood (<4%ID/blood) at the first time point of the i.v. biodistribution (20 min p.i.), and efficient clearance after then (Figure 1). The liver uptake was only around 5%ID/organ, which is similar to the levels previously reported for PNAs (*13*, *14*, *75*). The i.p. biodistribution showed the same profile as the i.v. experiment (Figures 1 and 2), which indicates that the tissue distribution of the PNA conjugates cannot be significantly altered by the administration modes.

Interestingly, the PNA conjugates with the sense sequence exhibited a significantly higher muscle accumulation at 48 h p.i. as compared to its antisense analogue ($P < 0.002$). It is possible that the sense PNA is complementary to the same or similar sequence found in mouse muscle, or that it shows some preferential affinity to some other biomolecule in muscle. A search of the mouse genome database, however, did not reveal any such homologous sequence (Table 2). As can also be seen from the table, all the antisense unr PNA sequences also show partial complementary to the mouse unr mRNA sequences, and to some other mouse and human sequences. The extent of binding to these sequences would depend on the folding of the mRNA and the effect of the mismatches, both of which are unknown at this time. The human GALNT5 has only been detected in a normal pooled brain and in a human central retina SAGE libraries at a level of 15 and 9 ppm, respectively, and is not present in the MCF-7 SAGE library, suggesting that any localization of PNA50S to the MCF-7 tumor is not due to the presence of another complementary mRNA.

Tumor Imaging with the PNA Conjugates. As shown in the microPET images (Figure 3), a tumor with a size of 100−320 mg in CB-17 SCID mice can be imaged with all four ^{64}Cu-labeled PNA conjugates. This is probably due in part to their high specific activity, which is about 5 times higher than that of the most recently reported ^{68}Ga-labeled oligonucleotide (*62*). The image contrast of the tumor at different time points varies greatly, however, with different compounds. At 1 and 4 h p.i., the tumor was not detectable with ^{64}Cu-DOTA-Y-PNA7-K4, whereas it gave a good tumor contrast at 24 h p.i. (Figure 3d). This behavior is what would be expected for an antisense PNA that slowly accumulates inside the tumor by binding to the target mRNA, which anchors the PNA within the cell, while PNA washes out from cells lacking the target mRNA. Interestingly, ^{64}Cu-DOTA-Y-PNA5-K4 behaved in the opposite way: it could only image the tumor at 1 h p.i. and not at either 4 or 24 h p.i. (Figure 3c). Both ^{64}Cu-DOTA-Y-PNA50-K4 and ^{64}Cu-DOTA-Y-PNA50S-K4 showed a tumor image at all the three time points, but the former conjugate exhibited a much higher tumor to background contrast, especially at 1 h p.i. (Figure 3a,b).

Quantitative analysis of the microPET images are in good agreement with the post imaging biodistribution data (Figures 5 and 6). This further confirmed the quantitation capability of microPET techniques in the field of molecular imaging. Copper-64-DOTA-Y-PNA5-K4 exhibited a similar tumor uptake to ^{64}Cu-DOTA-Y-PNA50-K4, however, the tumor was not discernible from the surrounding tissue at 24 h p.i. due to its relatively high accumulation in muscle and blood (Figure 6). This observation clearly demonstrates that the rapid and efficient clearance from blood and muscle is one of the essential criteria for a good imaging agent besides the high uptake in target organs. The comparatively high accumulation in muscle and blood may be due in part to targeting of the mouse unr mRNA, which differs by only a single nucleotide (Table 2) and appears to be present in muscle (Figure 8).

To the best of our knowledge, ^{64}Cu-DOTA-Y-PNA50-K4 has shown the highest and reproducible tumor/muscle ratio at 4 h (7.9 ± 3.3, data not presented) and at 24 h p.i. (6.6 ± 1.1) among the reported noncarrier bound oligonucleotides in the detection of cancer in vivo via nuclear imaging modalities (*14*, *62*). The tumor/muscle ratios for ^{64}Cu-DOTA-Y-PNA50-K4 are also 3.7 and 2.2 times greater than for ^{64}Cu-DOTA-Y-PNA50S-K4 at 4 and 24 h, respectively. The enhanced selectivity of ^{64}Cu-DOTA-Y-PNA50-K4 is consistent with selective binding of the PNA portion of the imaging agent to the unr mRNA inside the cell, though further studies will be needed to verify this. Further modification of the DOTA−PNA50 conjugate and others is under investigation to increase the selectivity of tumor targeting and to minimize accumulation in kidneys.

CONCLUSION

In conclusion, we have designed and synthesized four PNAs with a four-lysine tail at the C terminus, one with a sense sequence and three with antisense sequences for the unr mRNA, which is overexpressed in MCF-7 cell line. To evaluate their in vivo behavior and tumor-targeting property, we incorporated a DOTA moiety into the PNAs so that the conjugates can be radiolabeled with ^{64}Cu for biodistribution and microPET imaging studies in normal and MCF-7 tumor bearing mice. Of the PNA conjugates studied, ^{64}Cu-DOTA-Y-PNA50-K4 showed the best image contrast of MCF-7 tumor in CB-17 SCID mice, and its tumor/muscle ratio is reproducible and the highest among the radiolabeled oligonucleotides that have been reported for in vivo detection of tumor. On the other hand, the tumor/muscle ratio of ^{64}Cu-DOTA-Y-PNA50-K4 is only about 4-fold better at best than the corresponding sense sequence, indicating that factors other than sequence complementarity to the unr mRNA play a significant role in tumor localization. Likewise, the two other antisense PNA conjugates did not behave like ^{64}Cu-DOTA-Y-PNA50-K4, showing either higher uptake in muscle (^{64}Cu-DOTA-Y-PNA5-K4) or increasing contrast with time (^{64}Cu-DOTA-Y-PNA7-K4). While our studies further indicate that antisense PNAs have great potential to be developed as oncogene or mRNA specific probes for early diagnosis and treatment of specific cancers when ^{64}Cu is delivered in higher amounts (*52*−*56*), there is much to be learned about what governs distribution and localization kinetics of PNA conjugates in vivo.

ACKNOWLEDGMENT

We thank Nicole Fettig, John Engelbach, Lynne Jones, Susan Adams, and Terry Sharp for technical assistance in the biodistribution and microPET imaging studies and Jerrel Rutlin for quantitative analysis of the microPET

images. We also thank Xuan Yue for obtaining the MALDI-TOF of the PNAs. This research was supported by an NCI/NASA Biomolecular Sensors contract (N01-CO-27103). The copper-64 was provided by Washington University School of Medicine and partially funded through NCI Grant R24 CA86307 (M.J.W.).

Design of Phosphoramidite Monomer for Optimal Incorporation of Functional Intercalator to Main Chain of Oligonucleotide

Yun Shi, Kenzo Machida, Akinori Kuzuya, and Makoto Komiyama*

Research Center for Advanced Science and Technology, The University of Tokyo, 4-6-1 Komaba, Meguro-ku, Tokyo 153-8904, Japan. Received December 22, 2004

Chirally pure phosphoramidite monomers bearing 9-amino-6-chloro-2-methoxyacridine were synthesized from D- or L-threoninol and ω-aminocarboxylic acid, and incorporated into oligonucleotides. These acridine−DNA conjugates formed stable duplexes with complementary RNA because of intercalation of the acridine to DNA/RNA heteroduplexes. The stability of duplexes was not very dependent on either the chirality of the central carbon bearing the acridine or the length of the side chain. However, the ability for site-selective activation of the phosphodiester linkage in front of the acridine, which induced Lu(III)-promoted RNA scission, was strongly dependent on these two factors. The largest activation was achieved when the monomer unit was prepared from L-threoninol and 4-aminobutyric acid and the acridine was bound to the amino group. By attaching the more acidic 9-amino-2-methoxy-6-nitroacridine to this optimized scaffold, a quite effective acridine−DNA conjugate for site-selective RNA scission was obtained.

INTRODUCTION

To date, various conjugates of oligonucleotides with functional molecules (e.g., intercalating agents, fluorescent dyes, metal complexes, and others) have been prepared because of their attractive potentials for biological and biochemical applications (*1*−*4*). In many cases, functional molecules were tethered to either appropriate position in the nucleotide or the terminus of the main chain of the oligonucleotide. The introduction of functional molecules to the middle of main chain is also attractive, since these molecules can be placed at predetermined positions in helically structured duplexes and thus show various specific functions (*5*−*13*). One of the most important factors in this main chain modification is the design of a monomer unit that bears the functional molecules. Its structure must be optimized in order for the functional molecules to exert their designated roles satisfactorily.

Recently, we incorporated an acridine to the main chain of oligonucleotides and used these conjugates for site-selective scission of RNA (*14*, *15*). When these conjugates form heteroduplexes with complementary RNA, the acridine intercalates into the duplex and activates the confronting phosphodiester linkages of the RNA. As a result, these linkages are selectively hydrolyzed by metal ions such as lanthanide(III), Zn(II), and Mn(II). The RNA activation was ascribed to both acid catalysis by the ring nitrogen of acridine and the conformational change of the RNA backbone (*15*, *16*).

In those studies, the monomer unit for the introduction of acridine was prepared from 1,3-propanediol, which involves a prochiral carbon. The oligonucleotide additives were used as a mixture of two diastereomers derived from the chirality of this central carbon in the main chain. Accordingly, a detailed study on the relationship between the structure of the acridine−oligonucleotide conjugate and its RNA-activating ability was difficult. In this paper, a series of DNA conjugates bearing 9-amino-6-chloro-2-methoxyacridine are synthesized in chirally pure forms by using D- or L-threoninol as starting material (*17*). Thermodynamic stabilities of duplexes between these conjugates and their complementary RNA, as well as the mode of interactions of the acridine with these duplexes, are systematically studied, and their dependencies on the chirality of central carbon and the length of the side chain are quantitatively clarified. Furthermore, the RNA-activating abilities of these acridine−DNA conjugates (and thus the rates of the resultant site-selective RNA scission) are also investigated, since they should strongly reflect even subtle change in the interactions of the acridine with the confronting phosphodiester linkages.

EXPERIMENTAL PROCEDURES

Materials. The phosphoramidite monomers for the preparation of chiral acridine−DNA conjugates were synthesized from D- or L-threoninol, ω-aminocarboxylic acid, and acridine, as described in the Supporting Information. Details of the spectroscopic characterization of the products and the intermediates are presented there. The solvents used for their synthesis (pyridine, DMF, and dichloromethane) were sufficiently dried by molecular sieves. Unless noted otherwise, conventional 9-amino-6-chloro-2-methoxyacridine was used. Introduction of 9-amino-2-methoxy-6-nitroacridine to the phosphoramidite monomer (and thus to oligonucleotides) was achieved according to a preliminary communication (*16*). Other reagents and solvents were obtained from Glen Research Co., Tokyo Kasei Organic Chemicals, Aldrich Chemical Co., or Wako Pure Chemical Industries, Ltd.

Measurement of Melting Temperatures (T_m) of the Heteroduplexes between Acridine−DNA Conjugate and Its Complementary RNA. Melting profiles were measured on a JASCO V-530 UV/vis spectrophotometer. The absorbance at 260 nm was measured from 20 °C to 60 °C (only for DNA_2-S/RNA_2, from 5 °C to 60 °C) in a quartz cell of 1 cm path length with a heating

rate of 1.0 °C/min. The specimens contained DNA_2-**X** (1 μM), RNA_2 (1 μM), and NaCl (200 mM) in pH 8.0 Tris-HCl buffer (10 mM).

Spectroscopy. Fluorescence spectra were measured at 10 °C on a JASCO FP-750 spectrofluorometer with the excitation of the acridine at 346 nm. The specimens containing DNA_2-**X** conjugate (5 μM), Tris-HCl buffer (10 mM), and NaCl (200 mM) were titrated with 0.0, 0.5, 1.0, 1.5, and 2.0 equiv of RNA_2 (0−10 μM). The CD spectra were obtained on a JASCO J-820 spectropolarimeter at 10 °C in pH 8.0 phosphate buffer (10 mM); [DNA_2-**X**] = 0.5 mM, [RNA_2] = 0.5 mM, and [NaCl] = 200 mM in a quartz cell of 0.1 cm path length. For UV/vis absorption spectroscopy, a JASCO V-530 spectrometer was used.

Molecular Modeling. The Insight II/Discover 98.0 program package was used for conformational energy minimization. The acridine residue attached to the 36-mer DNA strand was built using the graphical program. In the energy minimization, neither water nor counterions were explicitly included, and their effects were simulated by a sigmoidal and distance-dependent dielectric function. The AMBER95 force field was used for the calculation. Computations were carried out on a Silicon Graphics Octane workstation with the operating system IRIX64 Release 6.5.

Assay of the Abilities of Acridine−DNA Conjugates for Lu(III)-Promoted Site-Selective RNA Hydrolysis. The site-selective RNA hydrolysis was carried out as described previously (*15*). The substrate RNA (RNA_1, 5 μM), labeled with 6-carboxyfluorescein (FAM) at the 5′-end, and the acridine−DNA conjugate (DNA_1-**X**, 10 μM) were dissolved in 10 mM Tris-HCl buffer (pH 8.0) containing NaCl (200 mM). The mixture was heated to 90 °C for 1 min, and slowly cooled to room temperature. Then, $^1/_{10}$ volume of an aqueous solution of $LuCl_3$ was added to the mixture (its final concentration was 100 μM). The mixtures were shielded from ambient light in order to avoid the possibility of any concurrent photoreactions (it later turned out that this procedure is not necessarily required). After a predetermined period of time at 37 °C, the reaction was quenched by 100 mM EDTA−2Na solution and analyzed on 20% denaturing PAGE. Quantitative analysis of the gel-electrophoresis patterns was carried out on a FUJIFILM FLA-3000G fluorescent imaging analyzer. The pseudo-first-order rate constants k_{obs} for the RNA scission were determined by conventional first-order plots.

RESULTS AND DISCUSSION

Acridine−DNA Conjugates for Site-Selective RNA Scission by Lu(III). The phosphoramidite monomers bearing 9-amino-6-chloro-2-methoxyacridine (**X** = **1D**, **1L**, **2D**, **2L**, **3D**, **3L**, **4D**, and **4L** in Figure 1) were synthesized from D- or L-threoninol and ω-aminocarboxylic acid. Thus, all of the eight 36-mer acridine−DNA conjugates (DNA_1-**X**), as well as 9-mer acridine−DNA conjugates (DNA_2-**X**) used for the spectroscopic studies, are chirally pure with respect to the configuration of the central carbon in the main chain. In **5D** and **5L**, the 6-chlorine atom of the acridine residue in **3D** and **3L** was replaced with a nitro group. In all the acridine−DNA conjugates, the **X** residue bearing the acridine is placed in front of U-19 in the substrate RNA_1.

Figure 2b shows typical gel-electrophoresis patterns for the RNA hydrolysis at pH 8.0 and 37 °C. In the absence of acridine−DNA conjugates, RNA_1 was almost randomly hydrolyzed by Lu(III) (lane 1). In their presence, however, RNA_1 was site-selectively hydrolyzed at U-19 as the target site (lanes 2−9). The phosphodiester linkage in the 5′-side of U-19 is the primary scission site (the lower bands designated by the arrow). This linkage is not cleaved at all when a modified DNA involving a 1,3-propanediol linker (in place of **X** in DNA_1-**X**) is used, and is efficiently hydrolyzed only with the use of the acridine−DNA conjugates (*15*). The following part of this paper deals with this scission.

5L	L-threoninol	3	-NO_2

Figure 1. The structures of acridine-bearing monomer units synthesized in the present study.

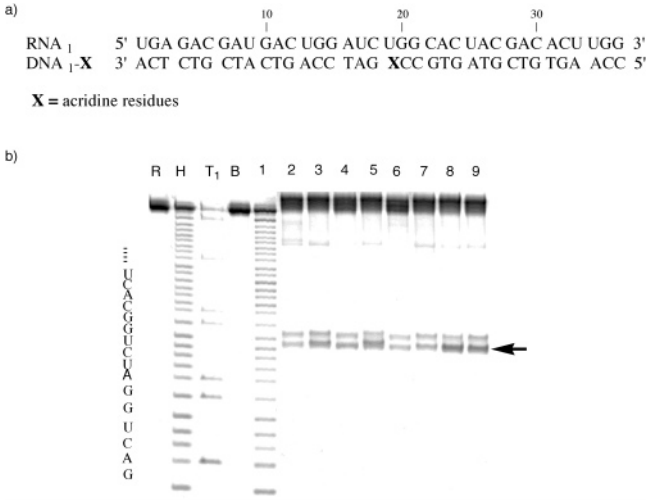

Figure 2. (a) Sequences of substrate RNA_1 and DNA conjugates used for the scission reaction. (b) PAGE for RNA_1 scission by Lu(III) in the presence of DNA conjugate bearing 9-amino-6-chloro-2-methoxyacridine. Lane 1, Lu(III) only; lane 2, with DNA_1-**1D**; lane 3, DNA_1-**2D**; lane 4, DNA_1-**3D**; lane 5, DNA_1-**4D**; lane 6, DNA_1-**1L**; lane 7, DNA_1-**2L**; lane 8, DNA_1-**3L**; lane 9, DNA_1-**4L**. At pH 8.0 and 37 °C for 4 h; [RNA_1] = 5 μM; [DNA] = 10 μM; [Lu(III)] = 100 μM; [Tris-HCl] = 10 mM; [NaCl] = 200 mM. All the scission fragments have 2′-(or 3′-)-phosphate termini, although their mobilities are slightly smaller than the corresponding fragment in lane 1 because of duplex formation with the acridine−DNA conjugates (see ref *18* for more details). R, RNA_1 only; H, alkaline hydrolysis; T_1, RNase T_1 digestion; B, control reaction in buffer solution.

Dependence of RNA-Activating Ability on Either the Chirality of the Central Carbon in the Main Chain or the Length of the Side Chain. First, the effect of side-chain length on the RNA-activating ability was examined for the L-series of conjugates, prepared using the phosphoramidite monomers derived from L-threoninol (**1L**, **2L**, **3L**, and **4L**). The numbers of methylene chains (n) in the side chain are 1, 2, 3, and 4, respectively. As presented in Figure 3a, the RNA-activating ability is notably dependent on the side-chain length. Of these four conjugates, DNA_1-**3L** is the most active (the

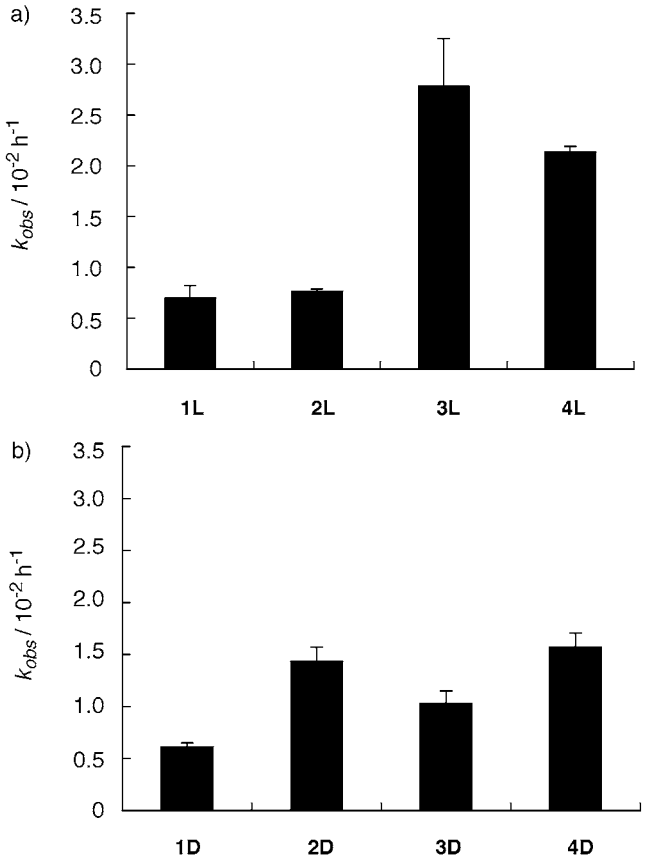

Figure 3. The pseudo-first-order rate constant k_{obs} for the site-selective scission of RNA_1 at the 5′-side of U-19 with (a) L-acridine−DNA conjugates and (b) D-acridine−DNA conjugates. The reaction conditions are the same as shown in Figure 2.

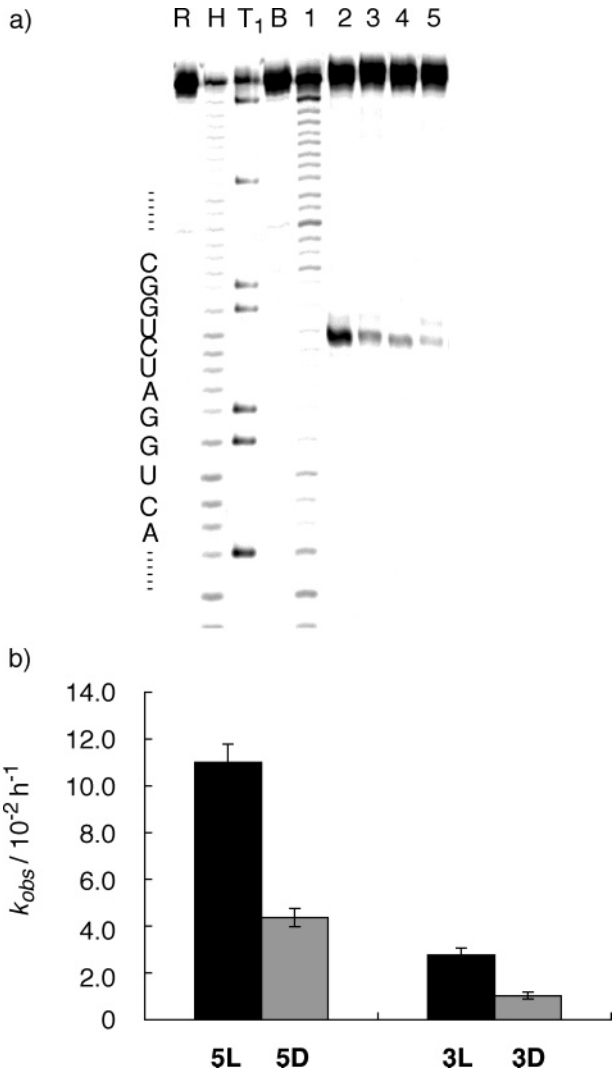

Figure 4. (a) Site-selective RNA_1 scission by Lu(III) in the presence of DNA conjugates bearing 9-amino-2-methoxy-6-nitroacridine (**5D** and **5L**). Lane 1, Lu (III) only; lane 2, with DNA_1-**5L**; lane 3, DNA_1-**5D**; lane 4, DNA_1-**3L**; lane 5, DNA_1-**3D**; R, RNA_1 only; H, alkaline hydrolysis; T_1, RNase T_1 digestion; B, control reaction in the buffer solution. The reaction conditions are the same as in Figure 2. The pseudo-first-order rate constants k_{obs} for the site-selective RNA_1 scission are presented in panel b.

pseudo-first-order rate constant k_{obs} for the RNA scission is 0.027 h^{-1}). This conjugate is about 4 times as active as DNA_1-**1L** and DNA_1-**2L**, and slightly exceeds DNA_1-**4L**. On the other hand, the RNA-activating ability of the D-series of acridine−DNA conjugates (**1D**, **2D**, **3D**, and **4D**) is less affected by the side-chain length (Figure 3b). In most cases (except for **2L** vs **2D**), the L-isomer is more active than the corresponding D-isomer. The difference is the largest when $n = 3$ (DNA_1-**3L** is 2.7 times as active as DNA_1-**3D**). Thus, the best monomer unit to bind 9-amino-6-chloro-2-methoxyacridine for the site-selective scission involves a trimethylene side chain on the central carbon of L-configuration and is prepared from L-threoninol and 4-aminobutyric acid.

Further Promotion of RNA-Activating Ability Using More Acidic Acridine. 9-Amino-2-methoxy-6-nitroacridine is more acidic than 9-amino-6-chloro-2-methoxyacridine (the pK_a values for the protonation at the ring nitrogen are 8.8 and 10.5, respectively). Since the present RNA activation is at least partially associated with acid catalysis by the protonated acridine, still greater RNA-activating ability is expected when 9-amino-2-methoxy-6-nitroacridine is employed (*16*). Accordingly, this acridine was introduced to the oligonucleotide having the scaffold which has been optimized above (the monomer unit prepared from L-threoninol and 4-aminobutyric acid). Exactly as designed, DNA_1-**5L** ($k_{obs} = 0.11$ h^{-1}) is 4.1 times as active as DNA_1-**3L** bearing 9-amino-6-chloro-2-methoxyacridine (Figure 4). By attaching a highly acidic acridine to the optimized backbone of oligonucleotides, an efficient RNA activator has been obtained.

Consistently with these results on the L-isomer, replacement of 9-amino-6-chloro-2-methoxyacridine in DNA_1-**3D** with 9-amino-2-methoxy-6-nitroacridine promoted the RNA-activating ability by 4.4-fold. The increase in the acidity of acridine induces almost the same magnitude of promotion for both D- and L-isomers, and thus DNA_1-**5L** is about 3 times active as DNA_1-**5D**.

Formation of Heteroduplexes between Acridine−DNA Conjugates and Complementary RNA. The T_m values of heteroduplexes between 9-mer acridine-modified DNA_2-**X** (5′-TGCCXGATC-3′) and its complementary 9-mer RNA_2 (5′-GAUCUGGCA-3′) are shown in Table 1. This RNA has the same sequence as the middle part (G15−A23) of RNA_1 used above for the site-selective scission by Lu(III), and the central U corresponds to the target scission site (U-19) in RNA_1. All the DNA conjugates form sufficiently stable duplexes with RNA_2. The T_m values are not very dependent on either the chirality of central carbon in the main chain or the length of the side chain (they take an A-type helix, as evidenced by the CD spectra in the 200−350 nm region: see the Supporting Information). Significantly, DNA_2-**X**/RNA_2 duplexes have considerably higher T_m values than the

DNA_2-S[e]	10.3	−27.1			

[a] Conditions: $[RNA_2] = 1\ \mu M$, $[DNA_2\text{-}\mathbf{X}] = 1\ \mu M$, [Tris-HCl] = 10 mM, and [NaCl] = 200 mM; heating rate, 1 °C/min. [b] The difference between the T_m of the heteroduplex and the value of completely complementary DNA_2-A/RNA_2 duplex. [c] $[RNA_2] = 0.0$ (for ss) or $7.5\ \mu M$ (for ds), $[DNA_2\text{-X}] = 5\ \mu M$, [Tris-HCl] = 10 mM, and [NaCl] = 200 mM at 10 °C; emission wavelength = 494 nm (excitation at 346 nm). [d] Both DNA_2-**5D** and DNA_2-**5L** are fluorescence-silent. [e] DNA_2-S involves a simple 1,3-propanediol linker in place of **X**, and thus has no acridine.

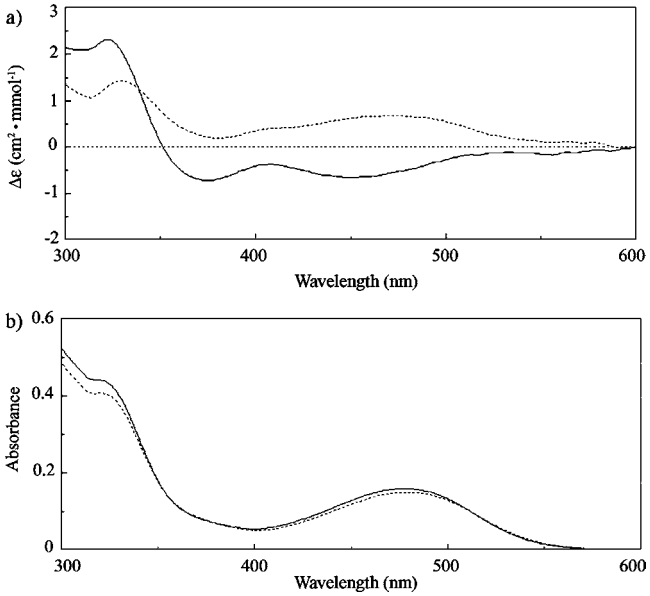

Figure 5. The CD spectra (a) and UV spectra (b) of the DNA_2-**5L**/RNA_2 duplex (solid line) and the DNA_2-**5D**/RNA_2 duplex (dotted line). Measurements were carried out at 10 °C in 10 mM phosphate buffer/200 mM sodium chloride (the T_m values of DNA_2-**5L**/RNA_2 and DNA_2-**5D**/RNA_2 duplexes under these conditions are 38.9 and 37.5 °C, respectively).

RNA_2 duplex of DNA_2-S in which the **X** residue in DNA_2-**X** is replaced by a simple 1,3-propanediol group. Compared with the completely complementary DNA_2-A/RNA_2 duplex, the DNA_2-S/RNA_2 duplex is less stable because of the removal of one A-U Watson−Crick base pair (T_m values are 37.4 and 10.3 °C, respectively). However, DNA_2-**X**/RNA_2 duplexes are mostly more stable than DNA_2-A/RNA_2 (ΔT_m is positive). Even the duplexes of DNA_2-**1L** ($\Delta T_m = -0.9$ °C) and DNA_2-**1D** ($\Delta T_m = -4.3$ °C) are far more stable than the DNA_2-S/RNA_2 duplex. It is strongly indicated that the acridine intercalates into the duplex and the corresponding energy gain sufficiently compensates the removal of one A-U pair. This argument is consistent with the finding by Kool (*1*) that stable duplexes are formed even when nucleobases are replaced by non-hydrogen-bonding aromatic residues.

Intercalation of the acridine into the heteroduplexes is further substantiated by the fact that the fluorescence from the acridine of DNA_2-**X** was notably quenched when it hybridized with RNA_2 (Table 1). For example, more than 90% of the fluorescence was quenched upon the formation of either the DNA_2-**3D**/RNA_2 or DNA_2-**3L**/RNA_2 duplex. Apparently, the acridine in the DNA_2-**X** deeply intercalates into the DNA_2-**X**/RNA_2 duplexes, and its fluorescence is quenched mainly by the adjacent guanine residues. The efficiency of fluorescence quenching is not very dependent on the chirality of the central carbon atom.

Effect of the Chirality of the Central Carbon in the Main Chain on the Position of Acridine. The CD spectra of DNA_2-**5L**/RNA_2 and DNA_2-**5D**/RNA_2 in the 420−520 nm region (due to the absorption of 9-amino-2-methoxy-6-nitroacridine) are entirely different from each other (Figure 5a), although their UV spectra are superimposed almost completely (Figure 5b). The sign of the induced CD is negative for DNA_2-**5L**/RNA_2 (solid line), whereas a positive CD is induced for DNA_2-**5D**/RNA_2 (dotted line). Apparently, the intercalating acridines take considerably different orientations depending on the chirality of the central carbon in the main chain. The molecular modeling in Figure 6 has substantiated this interpretation. Here, the intercalation mode of acridine is viewed from the 3′-side of RNA_1. In the DNA_1-**5L**/RNA_1 duplex (a), the side-chain portion first protrudes from the central carbon toward the major groove side, and then winds to the intercalating position. Thus the longitudinal axis of the acridine is rotated by about 80° counterclockwise with respect to the longitudinal axis of the Watson−Crick base pair in the 3′-side (the pair depicted in white). In DNA_1-**5D**/RNA_1 (b), however, the side chain runs more directly toward the intercalating position, and the corresponding angle between the two axes is only 30° counterclockwise. The difference of CD spectra between the D-isomer and the L-isomer (in Figure 5) is ascribed to this orientational difference (*19*). Almost the same structures were obtained for the DNA_1-**3L**/RNA_1 and DNA_1-**3D**/RNA_1 heteroduplexes involving 9-amino-6-chloro-2-methoxyacridine (data not presented).

On the basis of these analyses, the effect of chirality of the central carbon on the RNA-activating ability is tentatively ascribed to different orientation of intercalating acridine, which in turn induces a difference in local perturbation of the RNA backbone. In the heteroduplex between RNA_1 and DNA_1-**5L**, the conformation at the target scission site is probably more favorable for intramolecular nucleophilic attack of 2′O toward the P atom. It is noteworthy that the binding activity of the L-isomer to RNA_1 is comparable with that of the D-isomer (the T_m values of the DNA_2-**5L**/RNA_2 and DNA_2-**5D**/RNA_2 duplexes are almost the same: see Table 1). The fluorescence quenching efficiency for DNA_2-**3L**/RNA_2 is also almost the same as that for DNA_2-**3D**/RNA_2 (direct analysis on DNA_2-**5L**/RNA_2 and DNA_2-**5D** cannot be made since DNA_2-**5L** and DNA_2-**5D** are fluorescence-silent). There is no drastic difference in the overall structures of these two intercalation products. These facts further support the crucial role of orientation of the intercalating acridine for the present site-selective scission. The possibility that the L-isomer provides more efficient acid catalysis than the D-isomer is unlikely, since the increase in the acidity of acridine (exchange of 9-amino-6-chloro-2-methoxyacridine for 9-amino-2-meth-

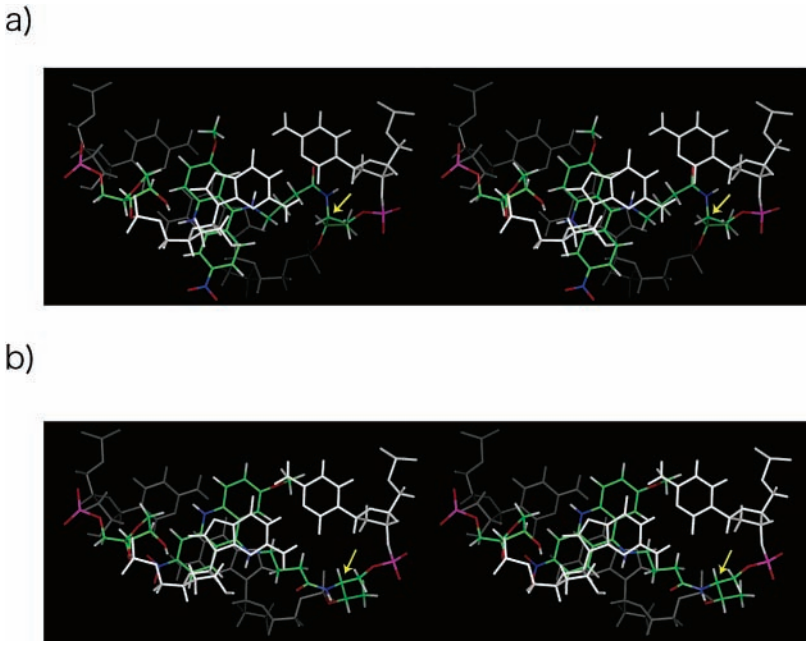

Figure 6. Molecular modeling of the duplex between RNA_1 and either (a) DNA_1-**5L** or (b) DNA_1-**5D**. The Watson−Crick base pair in white is located in the 3′-side of the central U (opposite the acridine (in green)) in RNA_1, whereas the gray one is in its 5′-side. The chiral carbons in the main chains of DNA_1-**5L** and DNA_1-**5D** are indicated by arrows. For the modeling, the nucleobase in front of the acridine was removed to simplify the calculation.

oxy-6-nitoroacridine) induces almost the same promotion effect for both isomers (Figure 4).

CONCLUSION

Using various phosphoramidite monomers, 9-amino-6-chloro-2-methoxyacridine has been incorporated into oligonucleotides in chirally pure forms (with respect to the configuration of central carbon in the main chain). All of these acridine−DNA conjugates form stable heteroduplexes with complementary RNA, and induce selective scission of the RNA by Lu(III) ion at the phosphodiester linkages in front of the acridine. The ability for the activation of confronting phosphodiester linkages strongly depends on both the chirality of the central carbon bearing the acridine and the length of the side chain. In most cases, the L-series of acridine−DNA conjugates are more active than the corresponding D-isomers. On the basis of CD spectroscopy, these results have been interpreted in terms of a subtle difference of orientation of the acridine in the RNA/DNA duplexes and the resulting different perturbation of the RNA backbone. Interestingly and importantly, these differences are not explicitly detected by either the T_m measurements or the fluorescence quenching experiments.

The optimized monomer unit for the RNA activation involves a trimethylene side chain on an L-configuration central carbon, and is prepared from L-threoninol and 4-aminobutyric acid. By combining this optimized monomer unit with the highly acidic 9-amino-2-methoxy-6-nitroacridine, a quite efficient acridine−DNA conjugate has been obtained.

The present systematic study has shown that the position and orientation of the intercalator in helical structures of DNA/RNA heteroduplexes can be regulated by the appropriate design of the monomer unit (chirality of the central carbon and the side-chain length). Thermodynamic stability of a "non-natural" heteroduplex involving this intercalator is not very dependent on the chirality of the central carbon. However, the functional properties (e.g., catalyses) are notably affected by the structure of monomer unit. These findings should be useful for rational design of various functionalized oligonucleotides in which intercalators take significant roles in a direct or indirect way.

Electrochemical Detection of Lesions in DNA

Amie K. Boal and Jacqueline K. Barton*

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received November 4, 2004; Revised Manuscript Received January 19, 2005

Electrochemical DNA-based sensors that exploit the inherent sensitivity of DNA-mediated charge transport (CT) to base pair stacking perturbations are capable of detecting base pair mismatches and some common base damage products. Here, using DNA-modified gold electrodes, monitoring the electrocatalytic reduction of DNA-bound methylene blue, we examine a wide range of base analogues and DNA damage products. Among those detected are base damage products O4-methyl-thymine, O6-methyl-guanine, 8-oxo-guanine, and 5-hydroxy-cytosine, as well as a therapeutic base, nebularine. The efficiency of DNA-mediated CT is found not to depend on the thermodynamic stability of the helix. However, general trends in how base modifications affect CT efficiency are apparent. Modifications to the hydrogen bonding interface in Watson−Crick base pairs yields a substantial loss in CT efficiency, as does added steric bulk. Base structure modifications that may induce base conformational changes also appear to attenuate CT in DNA as do those that bury hydrophilic groups within the DNA helix. Addition and subtraction of methyl groups that do not disrupt hydrogen bonding interactions do not have a large effect on CT efficiency. This sensitive detection methodology based upon DNA-mediated CT may have utility in diagnostic applications and implicates DNA-mediated CT as a possible damage detection mechanism for DNA repair enzymes.

INTRODUCTION

DNA is remarkably susceptible to chemical modification (*1*−*3*). Hydrolytic damage is the most common form of DNA base modification and often leads to deamination of cytosine and depurination. Oxidative damage results in a variety of base modifications, but 8-oxo-G is thought to be the most prevalent of these lesions. Nonenzymatic alkylation by endogenous and exogenous alkylating agents is also an important type of base damage (*2*). Modification of DNA bases can disrupt DNA replication and transcription by altering the base pairing properties of the DNA base and stalling the protein machinery associated with these processes. Base damage may also be an important indicator in the diagnosis and treatment of cancer, as high levels of damaged bases are often the result of exposure to carcinogens (*4*).

The base pair π-stack, formed when duplex DNA assumes a helical conformation, is capable of mediating charge transport (CT) (*5*−*9*). This chemistry is exquisitely sensitive to changes in base pair structure and dynamics; intervening mismatches in base pairing lead to a loss in the ability to transfer charge from an electron donor to an electron acceptor (*10*), as do bulges (*11*) or structural perturbations in base pair stacking induced by proteins (*12, 13*). While an in vivo role for DNA-mediated CT has yet to be established, it is interesting to consider that DNA-mediated CT may be involved in DNA damage and repair (*14*). Long-range DNA-mediated CT provides a potential route for funneling oxidative damage to specific regions of the genome and insulating alternate regions (*14, 15*). We have proposed that DNA repair proteins may take advantage of the sensitivity of DNA-mediated CT to DNA structural modifications in order to scan the genome for damage as an efficient long-range detection scheme (*14*, *16*).

The remarkable sensitivity of DNA-mediated CT to perturbations in base pair stacking and dynamics suggested that this chemistry could be applied in the design of sensors that detect base pair mismatches and damage products. Our laboratory has developed one such sensor for the detection of single base mutations in duplex DNA (*17, 18*). In this device, a monolayer of thiol-terminated DNA oligonucleotide duplexes is assembled on a gold surface; a redox-active intercalator bound near the top of the film acts as the probe of DNA CT chemistry. The DNA-mediated reduction of the intercalator is easily monitored electrochemically if the DNA is fully Watson−Crick base paired. However, the presence of a single base pair mismatch or other structural perturbation within the base pair stack attenuates intercalator reduction. This sensor is unique in that it does not exploit differences in hybridization thermodynamics to detect mutations, but instead differences in electronic coupling within the π-stack. Greater sensitivity to perturbations in the π-stack is attained by coupling the DNA-mediated reduction of the intercalative probe into an electrocatalytic cycle with an oxidant in solution capable of reoxidizing the intercalator. Figure 1 illustrates this cycle utilizing the intercalator methylene blue as the electrocatalyst for ferricyanide reduction. The integrity of the DNA π-stack is repeatedly probed via electron transfer in this catalytic cycle, and thus any perturbations in base pair stacking are amplified. Using this methodology, all single base mismatches in DNA, irrespective of sequence context or thermal stability, can be readily detected (*18*). Indeed recently, a full range of DNA-based biosensors have been developed (*19*, *20*).

Here we examine the scope of this methodology. We are interested in determining the primary factors governing the detection of DNA lesions by DNA charge transfer chemistry and the range of lesions that may be detected. How effective, for example, is this chemistry in detecting DNA methylation? Are base analogues

utilized as probes of nucleic acid processes or as therapeutics readily detected? We have already observed that the conformational distortions in synthetic oligonucleotides containing constrained sugar−phosphate backbones can be detected electrochemically (*21*), and this may be an important consideration in their application in antisense therapeutics. Perhaps most importantly, our understanding of the sensitivity and scope of DNA CT chemistry in the detection of lesions provides a foundation for the consideration of possible roles for DNA CT in mechanisms of DNA repair.

EXPERIMENTAL SECTION

Materials. All reagents for DNA synthesis were purchased from Glen Research (including all unnatural DNA base phosphoramidites). Methylene blue, ferricyanide, and reagents used in the synthesis of thiol-modified DNA were purchased from Aldrich in the highest available purity and used as received. All buffers were prepared with Milli-Q water and filtered with a sterile, 0.2 μm filter.

Preparation of DNA-Modified Electrodes. Oligonucleotides were prepared using standard phosphoramidite synthesis on an ABI 392 model DNA synthesizer. Oligonucleotide composition was verified by mass spectrometry. Thiol-modified duplexes were prepared using a solid-phase coupling procedure (*17*). The modified DNA was HPLC-purified on a semipreparative C18 column after either the amino modification or attachment of the disulfide moiety and again after the thiol deprotection. Thiol-modified DNA and the appropriate complementary strand were prepared in a 100 μM solution and annealed on a thermocycler. The resulting duplexes were self-assembled overnight (12−24 h) on polished (0.3 μm, 0.05 μm alumina) and etched (CV from +1575 mV to −250 mV, 20 cycles in 1 M H_2SO_4) bulk gold electrodes. $MgCl_2$ (100 mM) was added to the DNA solution prior to incubation to ensure a well-packed film. All DNA films were confirmed to be densely packed using a standard ferricyanide assay (*22*). At least three trials were performed for each base modification.

Electrochemical Analysis of DNA Films. Cyclic voltammetry and chronocoulometry experiments were carried out on a BAS CV50W model electrochemical analyzer. Experiments were executed in 50 mM NaCl, 5 mM sodium phosphate, pH 7, at ambient temperatures under an inert atmosphere. A three-compartment electrochemical cell was used with a Pt wire auxiliary electrode, 0.02 cm^2 gold working electrode, and saturated calomel reference electrode separated from the working electrode by a modified Luggin capillary.

Thermal Denaturation Studies. DNA duplexes (1.6 μM) were tested in 50 mM NaCl, 5 mM sodium phosphate, 100 mM $MgCl_2$, pH 7.0, in a quartz cell (with the exception of the lesions in group 4 which were analyzed in the absence of $MgCl_2$ and without the thiol tether). Absorbance at 260 nm was measured on a Beckman DU7400 spectrophotometer as the temperature decreased from 90 °C to 20 °C in a 0.5 °C/min linear gradient. Melting curves were fit to a sigmoidal function using ORIGIN software. The T_m is defined as the midpoint of these sigmoidal curves.

RESULTS

Methodology. Base lesions are incorporated into 15mer thiol-terminated duplexes using standard phosphoramidite chemistry, and the DNAs containing the base lesions are self-assembled into monolayers on gold electrodes. These DNA-modified electrodes are then investigated electrochemically using noncovalent methylene blue (MB) as a redox-active probe either directly or, in conjunction with ferricyanide, electrocatalytically. When MB is used as a direct probe, the DNA-modified electrodes are immersed in a buffered solution containing 2 μM MB. Note that it is the reduction of MB that is monitored using cyclic voltammetry from 0 to −650 mV; some of the lesions examined are easily oxidized but the conditions monitored here do not promote redox chemistry on the bases themselves. MB is also used as a catalytic reductive probe, when the DNA modified electrode is placed in a solution containing 2 mM ferricyanide and 0.5 μM MB. The redox activity of MB is then monitored primarily using chronocoulometry. In the experiments described here, charge is monitored for a period of 5 s while the potential steps from 0 to −350 mV.

The lesions investigated here encompass a wide variety of modifications to DNA bases. Some of these lesions occur physiologically as a result of enzymatic modification to DNA or as a result of oxidative and/or hydrolytic damage. Other lesions represent synthetic modifications to DNA bases, damage to bases that is the result of exposure to alkylating agents, bases used as therapeutics, and fluorescent bases commonly used as synthetic probes of DNA.

Group 1 Lesions. The group 1 lesions are all associated with DNA damage processes. O4-methyl-thymine (OMT) and O6-methyl-guanine (OMG) are methylation damage products occurring at sites involved in hydrogen bonding, and 5-hydroxy-cytosine (OHC) and 8-oxo-guanine (OG) are common oxidative damage products (*23*). The structures of these lesions are shown in Figure 2. DNA films containing OMG base paired with cytosine can be distinguished electrochemically, either with or without electrocatalysis, from those containing well-matched unmodified base pairs (Figure 2). OMT base paired with adenine can also be detected with and without electrocatalysis, but detection is greatly enhanced using electrocatalysis. As illustrated in Table 1, incorporation of these lesions into DNA duplexes also leads to dramatically reduced T_m values. It is noteworthy, however, that duplexes containing OMG have a lower T_m than those containing OMT, yet show less attenuation in MB reduction.

The oxidative damage products OG and OHC can also be detected electrochemically both with and without electrocatalysis (Figure 2). OG is examined here base paired with both A and C (OG:A and OG:C, respectively). In both base pairing contexts, OG is detectable when MB

is used as a direct probe. In the electrocatalysis experiments, OG is detectable when paired with C or A, but detection of OG:A is especially pronounced. OHC is also easily detectable with electrocatalysis. It is noteworthy that a higher background current is consistently observed in DNA films containing OHC; possibly this reflects a

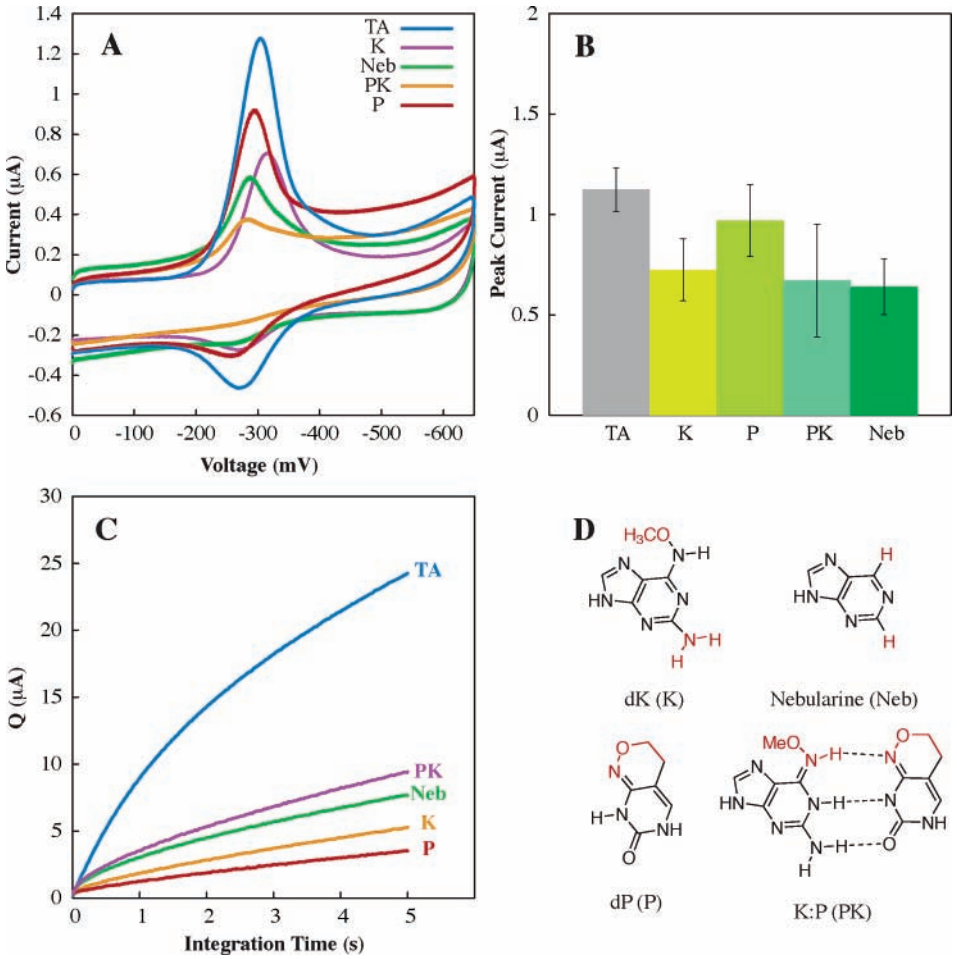

Figure 3. Electrochemical Detection of Group 2 Lesions. (A) Cyclic voltammetry without electrocatalysis. (B) Bar graph representing peak current attained in cyclic voltammetry experiments without electrocatalysis. (C) Chronocoulometry with electrocatalysis. (D) Structures of group 2 lesions. difference in film morphology. Note that all data, irrespective of film capacitance, were first background corrected.

As evident in Table 1, these lesions are somewhat thermodynamically destabilizing; duplexes containing these modifications have lower melting temperatures than unmodified duplexes (TA). Nonetheless, incorporation of these lesions in DNA films leads to a dramatic attenuation in CT efficiency.

Group 2 Lesions. Group 2 includes the synthetic base analogues, P and K, that function as degenerate bases; they can pair with either purine (P) or pyrimidine (K) (*24*). Nebularine (Neb) is a natural product that also has greater base pairing degeneracy than the natural purines (*25*). As illustrated in Figure 3, each of these lesions causes a profound decrease in DNA-mediated CT monitored with electrocatalysis. Significantly, P and K base paired to each other results in a higher charge accumulation when compared to P or K base paired to a natural base. As evident in Table 2, it is also interesting that the duplex with the highest charge accumulation (Q) with electrocatalysis has the lowest T_m. This result provides another indication that CT attenuation does not correlate with duplex melting temperature.

Group 3 Lesions. This group includes the therapeutic base 5-fluoro-uracil (FlU) (*26*), fluorescent bases, 2-aminopurine (2Ap) (*27*), and etheno-adenine (EA) (*28*), and synthetic base analogues 7-deaza-guanine (ZG) (*29*) and 7-deaza-adenine (ZA) (*30*). Group 3 represents structural modifications to DNA bases that are either completely synthetic (ZA, ZG, FlU, 2Ap) or the result of exposure to exogenous mutagens (EA).

Figure 4 illustrates, in DNA films containing these lesions, the reduction of MB without electrocatalysis as measured by cyclic voltammetry. None of these lesions are appreciably distinguished without electrocatalysis. Figure 4 also shows these data in bar graph form, further demonstrating that these lesions, within error, all have the same ability to facilitate CT as a fully matched duplex (TA). When MB is used electrocatalytically, ZA, ZG, and 2Ap are still not distinguishable. Interestingly, FlU or EA incorporation, examined through electrocatalysis, does lead to some attenuation in CT. Table 3 summarizes these data and shows melting temperatures for each duplex. All group 3 lesions, with the exception of EA, also show little deviation in melting temperature from a fully matched duplex.

Group 4 Lesions. Group 4 lesions, 5-methyl-cytosine (MC), N6-methyl-adenine (NA), and uracil (UA) are biologically relevant lesions that are the product of enzymatic methylation (MC and NA) or polymerase misincorporation (U base paired with A) (*31*−*33*). Each of these lesions is the result of the addition or subtraction of a methyl group in a location that does not appreciably hinder Watson−Crick hydrogen bonding ability.

Figure 5 shows the direct DNA-mediated reduction of MB (without electrocatalysis) measured by cyclic voltammetry. Without electrocatalysis, MB reduction is equivalent for DNAs containing these lesions when compared to a duplex that does not contain any lesions (TA). Figure

5 also shows these data as a bar graph, illustrating quantitatively that these lesions are not electrochemically detectable by this method. In addition, data from chronocoulometry experiments using electrocatalysis, our most sensitive assay, show that these lesions are not well detected even when MB is used as catalytic probe. These data are summarized in Table 4. Also shown in Table 4 are melting temperatures for these duplexes. It is note-

Table 3. Electrochemical Detection of Group 3 Lesions

Lesion	Sequence[a]	T_m (°C)	Q (μA) w/out electrocatalysis[b]	Q (μA) with electrocatalysis[c]
no lesion (TA)	SH – 5′ – AGT ACA GTC ATC GCG 3′ – TCA TGT CAG TAG CGC	60.0	1.27 ± 0.12	23.9 ± 1.7

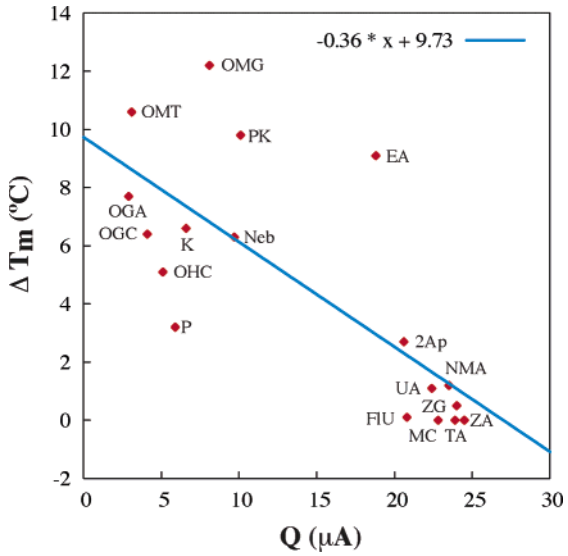

Figure 6. Plot of Q versus ΔT_m based upon data in Tables 1−4. The best linear fit is shown, although $R^2 = 0.57$.

versus the absolute change in T_m from well-matched DNA (TA) for each duplex. The parameter ΔT_m, rather than absolute T_m, is used to account for any differences in experimental conditions among measurements on the lesion-containing DNAs (see Table 4). As evident in the plot, little statistical correlation is observed between the CT efficiency and the thermodynamic stability of the duplex; the squared correlation coefficient for these data (R^2) equals 0.57. The electrochemical assay used here depends on different characteristics of the π-stacked DNA duplex rather than thermodynamic stability.

DISCUSSION

Electrochemical DNA-based biosensors offer a sensitive method for detecting a range of modified bases in DNA. Many of the lesions examined here are implicated in a variety of cancers (*34*−*36*), so that new assays for low levels of lesions that employ electrocatalysis may provide a novel, early diagnostic tool.

The results presented here also establish the general trends in how base modifications affect CT efficiency. Alteration of the Watson−Crick hydrogen bonding interface yields a profound loss in CT efficiency (OMT, OMG, Neb, P, and K), as does added steric bulk (P, K, OMT, and OMG). Base structure modifications that may induce base conformation changes (OG:A) also appear to diminish CT in DNA, as do those that place hydrophilic groups within the DNA helix (OHC). The presence or absence of methyl groups (MC, NMA, and UA) that do not disrupt hydrogen bonding interactions have little effect on CT efficiency. Little correlation between CT efficiency and thermal stability of duplex DNA containing a particular lesion is evident.

How are these lesions detected within the cell? The lesions examined here fall into three categories: oxidatively damaged bases, alkylated bases, and synthetic base analogues. The bases arising from oxidative or alkylation damage (OHC, OG, OMG, OMT) are all recognized by the cellular repair machinery. Enzymatic recognition by DNA repair systems is considered to involve similar factors that affect CT efficiency: hydrogen bonding patterns between the lesion and the opposite base, steric fit, the strength of the glycosidic bond, and base pair dynamics (*37*). OG is thought to be distinguished in part owing to protonation of the N7 nitrogen atom; N7 is not protonated in unmodified guanine (*38*). Repair of OG is also highly dependent on its base pairing environment. For instance, MutY, an enzyme that excises A from OG:A mispairs, can discriminate OG through stacking interactions involving an intercalated tyrosine coupled with hydrogen bonding of the OG to a serine (*39*). OHC is repaired by Endo III, a repair enzyme with a wide substrate specificity that targets oxidized pyrimidines (*40*). With this somewhat nondiscriminate enzyme, recognition is thought to involve both the lability of the lesion glycosidic bond and hydrogen bonding of the enzyme with the base opposite the lesion (*41, 42*). Direct damage reversal, where aberrant alkylation is transferred from DNA to a reactive cysteine in the repair protein, is the process that repairs O-methylation in DNA (*43*). OMT and OMG are recognized by methyltransferases and these enzymes likely recognize their substrates by sensing the instability of the lesion base pair (*44*). A consensus has not yet been reached regarding the exact protein/DNA interactions that determine specificity, but structural studies indicate that hydrophobic residues near the reactive cysteine may be involved in recognizing the site of alkylation (*45, 46*).

Many of these lesions associated with DNA damage have been previously reported as thermally destabilizing lesions (*47*−*49*), consistent with our findings here. Base modifications are also associated with dynamical changes in structure. OG is known to switch from the anti to the syn conformation while pairing with A (*50*). This conformational change is usually invoked as the basis for the mutagenic potential of OG (*51*), but it could also explain

the drastic CT efficiency attenuation observed with the OG:A base pair. O-methylation (OMG, OMT) is also known to alter Watson−Crick hydrogen bonding patterns (*48, 49*); OMG base paired with C does not form any hydrogen bonds unless C is protonated at the N3 position (*52*). OMT is similarly associated with increased flexibility at the lesion base pair (*49*), a property that, while linked to thermal instability and enzymatic recognition, may also be a factor in attenuation of CT efficiency. Synthetic lesions P, K, and Neb are not targeted by repair systems but can be thermally destabilizing (*24*, *53*).

Among the lesions not well-detected in this assay are ZA and ZG, purines where the nitrogen atom at the 7 position is replaced by a carbon atom. This modification is known to lower the redox potential of the base, but the 7-deaza modification is not thought to cause destabilization or altered base pairing and stacking interactions (*54*). 2-Aminopurine base paired with thymine is similarly found to be thermodynamically stable and well stacked in the helix; thus, it is not surprising that these three lesions are not easily detected using DNA CT (*5*, *55*). FlU, when base paired with adenine, is also thermodynamically stable and not a source of structural distortion (*56*). EA, a sterically bulky lesion, is only marginally detected here. Structural studies indicate that EA forms no hydrogen bonds with thymine and assumes a nonplanar conformation to accommodate the excess steric bulk of the lesion. Yet the lesion remains intrahelical, does not disrupt the structure of any flanking base pairs, and is purported to have stabilizing stacking interactions both with the bases above and below it and with the thymine opposite (*57*); perhaps these properties are sufficient to allow for some DNA-mediated reduction of MB in the presence of EA. Notably the poor coupling of EA in the base pair stack has been considered to account for the slow rate of base-base CT seen (*5*).

While O-methylation can be detected through CT, simple base alkylation, MC and NMA, cannot. Enzymatic methylation is generally thought to have a stabilizing effect on duplex DNA (*58, 59*). MC can lead to a higher melting temperature for DNA duplexes (*59*) and methylation at the 5 position on the pyrimidine ring, in general, is purported to reduce base pair opening rates (*60*). NMA, also not significantly thermally destabilizing, exhibits more favorable stacking interactions with bases above and below (*58*). Since methylation, if anything, further stabilizes a well-stacked conformation, then, our inability to detect methylation through DNA CT should not be surprising.

Given that DNA CT offers a sensitive strategy to detect a variety of DNA base lesions, might DNA CT chemistry play some role in DNA repair? While recent crystal structures provide some insight into how lesions may be structurally discriminated, in most cases, it is not well understood how DNA damage is first located within the genome; this is especially true in the case of base excision repair, the process that is responsible for removing single instances of base damage (*37*). The results described here certainly support the idea that DNA-mediated CT could potentially provide the foundation for a method of long range detection of DNA damage by repair enzymes. In this context, the detection of 5-hydroxy-cytosine and 8-oxo-guanine is especially significant as these are substrates for DNA repair glycosylases containing iron−sulfur cofactors that recently have demonstrated redox activity when bound to DNA (*16*).

Conclusions. Electrocatalysis at well-packed DNA films as measured by chronocoulometry is an effective detection technique for biologically relevant lesions and base analogues. This work points out the general trends in base modification that impact charge-transfer efficiency in DNA. These include modifications that lead to decreased or altered base pairing at the lesion site, modifications that add excess steric bulk, alterations that result in burial of polar groups, and modifications with the potential to induce conformational changes. Successful detection of common base damage products with this DNA CT based technique has important implications for the use of DNA-mediated CT as a damage detection mechanism for DNA repair enzymes.

Supramolecular Gene Delivery Vectors Showing Enhanced Transgene Expression and Good Biocompatibility

Xintao Shuai,† Thomas Merdan,† Florian Unger, and Thomas Kissel*

Department of Pharmaceutics and Biopharmacy, Philipps-University of Marburg, Ketzerbach 63, D-35032 Marburg, Germany. Received June 30, 2004; Revised Manuscript Received January 23, 2005

Soluble supramolecular inclusion complexes were formed by threading α-cyclodextrin (α-CD) molecules over poly(ethylene glycol) (PEG) and poly(ϵ-caprolactone) (PCL) chains of ternary block copolymers of PEG, PCL and polyethylenimine (PEI). Characteristic shifts of PCL absorptions in FTIR, ^{1}H NMR and UV spectra strongly suggest that α-CD is threaded over PEG and PCL blocks. Due to the reduced hydrophobic interaction between PCL blocks, the resulting supramolecular complexes displayed a dramatically increased solubility, in comparison with the ternary block copolymers. Their ability to complex DNA was almost as efficient as that of branched PEI 25 kDa, as shown in the ethidium bromide fluorescence quenching experiments. Resulting DNA polyplexes displayed a size of around 200 nm and a neutral surface charge. Microscopy studies in 3T3 fibroblasts revealed an efficient cellular uptake. Transfection efficiencies of inclusion complexes were in the same order of magnitude as PEI. In contrast to PEI a 100× lower toxicity was observed by MTT-assay, allowing the administration of nitrogen-to-phosphate ratios of up to 20. These new gene delivery systems merit further characterization under in vivo conditions.

INTRODUCTION

Various nonviral gene delivery systems consisting of DNA and polycations, dubbed as "polyplexes", have been investigated (*1*−*3*). Poly(ethylenimine), PEI, has attracted considerable interest due to its high positive charge density and consequently strong DNA binding. Another beneficial feature of PEI is the "proton-sponge effect", which is thought to facilitate endosomal/lysosomal escape of DNA into the cytoplasm (*4*). PEI with molecular weights >2000 Da seems to be necessary for effective gene delivery (*5*−*7*). PEI and PEI/DNA complexes were found to be cytotoxic in molecular weight and composition dependent manner due to their electrostatic interactions with negatively charged cell membranes (*5*, *7*).

Copolymers of PEI with hydrophilic macromolecules forming DNA polyplexes with neutral surface charge have extensively been investigated recently (*8*−*12*). Most studies utilize nonionic hydrophilic polyethers, e.g. poly(ethylene glycol) (PEG), as a building block to generate block or graft copolymers with linear or branched PEIs. When these copolymers were mixed with pDNA in aqueous solution, the cationic PEI segment of the copolymer first binds DNA via electrostatic interactions and then the neutralized polyions aggregate to form an insoluble core. The nonionic water-soluble PEG chains act as a hydrophilic shell stabilizing the resulting nanoscale polyelectrolyte complexes (*8*). Polyplexes thus prepared show a lower positive surface charge compared to PEI, and consequently less cytotoxicity was observed. Unfortunately, the transfection efficiency was also decreased.

We recently synthesized a new type of ternary block-copolymers by grafting diblock copolymers of PEG and PCL onto branched PEI. Intensive hydrogen bonding between PCL and PEI blocks was noted in the bulk materials, and solubility was strongly affected by composition, i.e., block length and graft density. DNA polyplexes formed with soluble copolymers or copolymers possessing a high critical micelle concentration (cmc) showed significant transfection efficiency under in vitro conditions. By contrast, those copolymers with a high graft density and long PCL blocks showed very poor gene expression. In the latter case, access and binding of DNA to PEI was seriously hindered by hydrophobic PCL chains surrounding the hydrophilic PEI head. Hydrogen bonding between PCL and PEI blocks is also believed to be an impediment for the DNA complexation with PEI (*13*). Therefore, breaking of hydrogen bonds between PCL and PEI as well as the dissolution of PCL block in aqueous media seem to be key factors for improving gene transfection efficiency of these copolymers.

In this publication, we present an unusual way to dissolve the PCL blocks of the ternary copolymers in aqueous solution by including them inside the α-cyclodextrin (α-CD) cavities. α-CD is a cyclic oligosaccharide consisting of six glucose units (*15*). One of its distinctive characters is its amphipathy, i.e., it possesses a hydrophobic cavity of 4.5 Å in diameter with a hydrophilic outer layer supporting many hydroxyl groups (*15, 16*). Supramolecular inclusion complexes (ICs), organized by noncovalent interactions, can be formed by threading α-CD molecules onto various polymer chains (*17*−*23*). The driving force for the threading process is probably due to intermolecular hydrogen bonding between neighboring CDs, as well as steric compatibility and hydrophobic interactions between host and guest molecules. It has been demonstrated that α-CD forms inclusion complexes with both poly(ethylene glycol) (PEG) (*17, 18*) and PCL (*24*−*28*) chains. In most cases, a full coverage of individual polymer chains with α-CD bracelets leads to crystalline water-insoluble inclusion complexes. In

dilute solutions a partial coverage of PEG or PCL chains with α-CD can be achieved. In the latter case, inclusion complexes with PCL may be completely soluble in water.

Here we investigate supramolecular physicochemical and biological properties of supramolecular inclusion complexes as carriers for gene delivery.

EXPERIMENTAL SECTION

Materials. ϵ-Caprolactone (from Aldrich) was purified by vacuum distillation over CaH_2. Monomethoxyl-poly(ethylene glycol) (MPEG) (Aldrich) was dried by azeotropic distillation with dry toluene. The PEI with a molecular weight of 25 kDa (abbreviation: PEI25k) was a gift from BASF (Germany). This PEI is a highly branched molecule. Its contents of primary, secondary, and tertiary amine units are 42%, 33%, and 25% respectively. α-CD was purchased from Aldrich and vacuum-dried at 40 °C prior to use.

Diblock copolymers of PCL and PEG were synthesized by ring-opening polymerization of ϵ-caprolactone and then grafted to PEI, as described in our recent publication (*13*). The chemical structures of these copolymers and threading of α-CD are shown in Figure 1. Molecular characteristics of polymers used in this study are shown in Table 1. To prepare inclusion complexes, the predetermined amount of α-CD aqueous solution (e.g. 5 mg/mL, 20 mL) was added stepwise to the copolymer micelle solution (e.g. 4.2 mg/mL, 15 mL) in a glass vial immersed in an ultrasonic water bath at room temperature. Sonication was applied for 30 min during and after the addition of the α-CD solution. The mixed solution was then stirred magnetically overnight at room temperature, frozen at ∼−40 °C, and then freeze-dried to yield a powdered sample (*30*).

pCMV−Luc encoding for luciferase as a reporter gene was purchased from Plasmid Factory, Bielefeld, Germany. NIH/3T3 (Swiss mouse embryo) cell line was purchased from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). Cells were cultured according to the protocols suggested by the supplier.

Cell Culture. NIH/3T3 cells (DSMZ#: ACC 59) were cultured under conditions recommended by the supplier in Dulbecco's modified Eagle medium containing 10% fetal bovine serum.

Spectroscopic Measurements of Copolymers and Inclusion Complexes. FTIR spectral studies were carried out using a Nicolet 510P FTIR spectrometer with a resolution of 2 cm^{-1}. Powder samples were compressed into KBr pellets for FTIR measurements. ^1H NMR spectra were recorded on a JEOL GX 400 D spectrometer in deuterated water (D_2O) at room temperature. UV spectra of solution samples were recorded on a Shimadzu UV-160 UV−visible recording spectrophotometer.

Ethidium Bromide Exclusion Assay. DNA condensation was measured by the decrease in ethidium bromide fluorescence, as described earlier (*31, 32*). The assay was performed in 96-well plates in triplicate using 8 μg of salmon testes DNA was dissolved in 79 μL of water and 50 μL of 60 mM Tris buffer pH 7.4 were added to each well. Volumes were adjusted to 300 μL using water. Subsequently, appropriate volumes of 0.05 mg/mL polymer solutions were added to yield N/P ratios between 0.2 and 4. After 10 min 20 μL of a 0.1 mg/mL ethidium bromide solution were added. Wells were mixed thoroughly, and the fluorescence was measured using a fluorescence plate reader with an excitation wavelength at 518 nm and an emission wavelength of 605 nm.

Polyplex Formation. Luciferase plasmid (pCMV-luc) and the appropriate amount of polymer or inclusion complex were dissolved separately in 0.9% sodium chloride solution of pH = 7. The two solutions were mixed by vigorous pipetting, and complexes were allowed to interact for 10 min before use. Polyplexes were prepared for transfection experiments with 4 μg of plasmid in 300 μL of NaCl 0.9% and the appropriate amount of polymer or conjugate in 300 μL of sodium chloride solution (0.9%, pH = 7).

Photon Correlation Spectroscopy. Hydrodynamic diameters of the DNA/polymer complexes were determined by photon correlation spectroscopy. Measurements of micelle solutions were performed on a Zetasizer 3000 HS from Malvern Instruments, Herrenberg, Germany (10 mW HeNe laser, 633 nm). Scattering light was detected at 90° angle through a 400 μm pinhole at a temperature of 25 °C. For data analysis, the viscosity (0.88 mPa·s) and the refractive index (1.33) of distilled water at 25 °C were used. The instrument was routinely calibrated using Standard Reference latex particles (AZ 55 Electrophoresis Standard Kit, Malvern Instruments). Measurements were analyzed by the CONTIN algorithm. Values given are the means of 5 runs of 60 s ± standard deviation.

Zeta Potential Measurements. pCMV−Luc plasmid (16 μg) was complexed with the appropriate amount of polymer in 800 μL of NaCl 150 mM as described above. Zeta-potential measurements of polyplexes formed at N/P 7 were carried out in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at position 17.0 at 25 °C. Sampling time was set to automatic. Average values were calculated with the data of 5 runs.

Fluorescent Labeling of PEI and DNA for Confocal Laser Scanning Microscopy Experiments. Polymer or inclusion complexes (20 mg) were dissolved in 2 mL 0.1 M sodium bicarbonate solution at pH 9. Oregon Green 488 carboxylic acid succinimidyl ester (1 mg, Molecular Probes) was dissolved in 200 μL of dimethyl sulfoxide and added dropwise under stirring to the polymer solution. The mixture was stirred in the dark for 3 h at room temperature before the labeled polymer was purified by ultrafiltration in an Amicon cell (regenerated cellulose membrane, molecular weight cut off 10 000) and washed with 0.1 M borate/1.0 M sodium chloride solution pH 7.5. The washing procedure was performed until no absorption was detectable at 488 nm in the cell outflow. As a final step, the buffer was exchanged with distilled water. Plasmid (pCMV−Luc) was labeled with Cy3 using a commercial kit (Mirrus Label It, Mobitec, Göttingen, Germany). Procedure was performed according to the manufacturer's manual.

Confocal Laser Scanning Microscopy Experiments. A Zeiss Axiovert 100M microscope coupled to a Zeiss LSM 510 scan module was used. NIH/3T3 cells were seeded at a density of 50 000 cells per well in 8-well chamber slides (Lab Tek, Nunc, Wiesbaden, Germany). After 24 h the medium was removed and complexes of 0.5 μg of Oregon Green-labeled polymer or the appropriate amount of inclusion complex and 0.5 μg Cy3 labeled plasmid were added in new medium. After an additional 4 h, medium was removed again and cells were washed four times with phosphorus buffered saline (PBS). Fixation of cells was done by incubation with 400 μL of paraformaldehyde solution 3% in PBS for 20 min. Cells were washed again for four times and incubated for an additional 20 min with a 0.1 mg/mL DAPI (4′,6-diamidino-2-phenylindole, dihydrochloride) (Molecular Probes, Leiden, The Netherlands) solution in PBS. For excitation of DAPI fluorescence, an Enterprise UV laser with an excitation wavelength 364 nm was used. Excitation of Oregon Green was performed using an argon laser with an excitation wavelength of 488 nm and for excitation of Cy3 a helium−neon laser with an excitation wavelength of 543 nm was used.

In Vitro Cytotoxicity Using MTT Assay. L929 mouse fibroblasts were grown in Dulbecco's modified Eagle's medium (DMEM) (Gibco, Germany) supplemented with 10% fetal calf serum (Cytogen, Germany), 2 mM glutamine, penicillin (100 U/ml) and streptomycin (100 μg/mL; both Invitrogen, Germany).

In vitro cytotoxicity of the polymers was evaluated using the MTT assay as described previously (*5*). L929 cells were seeded into 96-well microtiter plates (Nunclon, Nunc, Germany) at a density of 8000 cells/well. After 24 h the culture medium was replaced with 100 μL/ well of serial dilutions of polymer stock solutions in antibiotic-free DMEM ($n = 4$). After an incubation period of 24 h, MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Sigma-Aldrich, Germany) was dissolved in phosphate buffered saline at 5 mg/mL and 20 μL were added to each well reaching a final concentration of 0.5 mg MTT/ml. After an incubation time of 4 h, unreacted dye was removed by aspiration and the purple formazan product was dissolved in 200 μL/well dimethyl sulfoxide and quantified by a plate reader (Titertek plus MS 212, ICN, Germany) at wavelengths of 570 and 690 nm. The relative cell viability [%] related to control wells containing cell culture medium without polymer was calculated by [A] test/[A] control × 100. Poly(ethylene imine) 25 kDa (BASF, Germany) was used as a positive control.

Transfection Experiments. Transfection experiments were performed with 4 μg of pCMV−Luc. NIH/3T3 cells were seeded in 12-well plates at a density of 50 000 cells per well. After 24 h, medium was removed and complexes were added in 1.5 mL of fresh media. Media was exchanged again after 4 h, and cells were incubated for a further 44 h. Luciferase gene expression was quantified using a commercial kit (Promega) and photon counting with a luminometer (Sirius, Berthold). Results in relative light units per second (RLU/s) were converted into ng luciferase by creating a calibration curve with recombinant luciferase (Promega). Protein concentration in each sample indicating cell viability was determined using a BCA assay. All experiments were performed in triplicate and data were expressed in ng luciferase per mg protein.

RESULTS AND DISCUSSION

Formation of Soluble Inclusion Complexes. Among the three copolymers listed in Table 2, only the copolymer containing the shortest PCL blocks (PCL of molecular weight 580) shows a high solubility in water. The other two copolymers showed a distinct critical micellization concentration (cmc) (*13*). To form an inclusion complex, the α-CD solution of predetermined concentration was added stepwise to the dilute micellar solution of the ternary block copolymer under sonication. During this process, dynamic light scattering (DLS) measurements were employed to monitor the micelle dissolution upon dilution and addition of α-CD. When the turbid solution became transparent upon addition of an aqueous α-CD solution, nanoparticles were no longer detectable by DLS measurement, suggesting the dissolution of micelles.

The effect of added α-CD on the solubility of the copolymers depends largely on the copolymer compositions, as illustrated in Figure 2. A soluble inclusion complex was obtained when the weight ratio of α-CD and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ reached a critical value of 1.66. In contrast, a soluble inclusion complex was obtained as well when the weight ratio of α-CD and PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ reached 0.78. It is known that the cavity depth of α-CD molecules is 7 Å, which is equal to the length of approximately 0.86 repeat units of PCL or approximately 2 repeat units of PEG (*36*). Therefore, even if only the PCL blocks of the copolymer were fully covered by α-CD molecules, the PEI contents in PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$, PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ should be

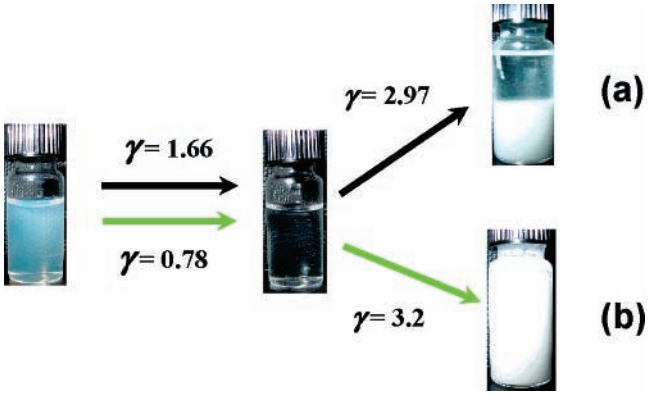

Figure 2. Phase transition phenomena of PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ (a) and PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ (b) upon adding α-CD solution. γ is the weight ratio of added α-CD and copolymer.

approximately 43%, 24% and 27%, respectively. The actual PEI content of complexes shown in Table 2 is close to (40% vs 43%, and 26% vs 27%) or much higher (34% vs 24%) than these values. Since PEG may also form an inclusion complex with α-CD, apparently the copolymer side chains (PCL-*b*-PEGs) were only partially covered by α-CD molecules in these soluble inclusion complexes. Interestingly, a white precipitate was formed when the weight ratio of α-CD and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ reached 2.97 at which the α-CD amount is sufficient to cover ~92% of total side chains (i.e. total length) of both PCL and PEG blocks. However, a gel was formed when the weight ratio of α-CD and PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ reached 3.2 at which α-CD can cover ~76% of total side chains. These results are reasonable because the inclusion complex of cyclodextrins and polymer may form insoluble crystals and these insoluble crystals may cross-link the highly branched polymer in solution, as reported by Yui et al. (*35*).

The threading of α-CD molecules onto the copolymer PCL blocks was illustrated in Figure 3 and demonstrated spectroscopically. Figure 4 shows an expansion of the FTIR spectra covering the carbonyl bands of a diblock copolymer of PCL and PEG (MPEG-*b*-PCL), its corresponding ternary copolymer and inclusion complex with α-CD. The inclusion complex powder sample was obtained by freeze-drying of the aqueous sample solution and was allowed to crystallize at room temperature for one month before the FTIR measurements. It is known that the expanded $\nu_{C=O}$ absorption band of the semicrystalline PCL is very indicative of the PCL phase structure in the FTIR measurements (*27*, *28*). In agreement with these reports, the PCL carbonyl absorption band (s, $\nu_{C=O}$) of PCL-*b*-MPEG can be well resolved into a peak at 1726 cm^{-1} and a prominent shoulder at 1736 cm^{-1}, corresponding to the carbonyl absorption of the crystalline and the amorphous PCL phases, respectively. The carbonyl absorption of the crystalline phase (1726 cm^{-1}) is much stronger than that of the amorphous one, suggesting high PCL crystallinity in the diblock copolymer. Upon grafting onto PEI, the absorption of crystalline PCL at 1725 cm^{-1} becomes weak, while the absorption of the amorphous PCL at 1736 cm^{-1} appears as the main peak, as shown in spectrum b. These results indicate that the crystallization of PCL blocks has been suppressed but not completely eliminated in the copolymers. By contrast, as shown in spectrum c, the C=O absorption of crystalline PCL regions completely disappears, and only the C=O absorption of noncrystalline PCL blocks is detected in the spectrum of the ICs. These results suggest that PCL

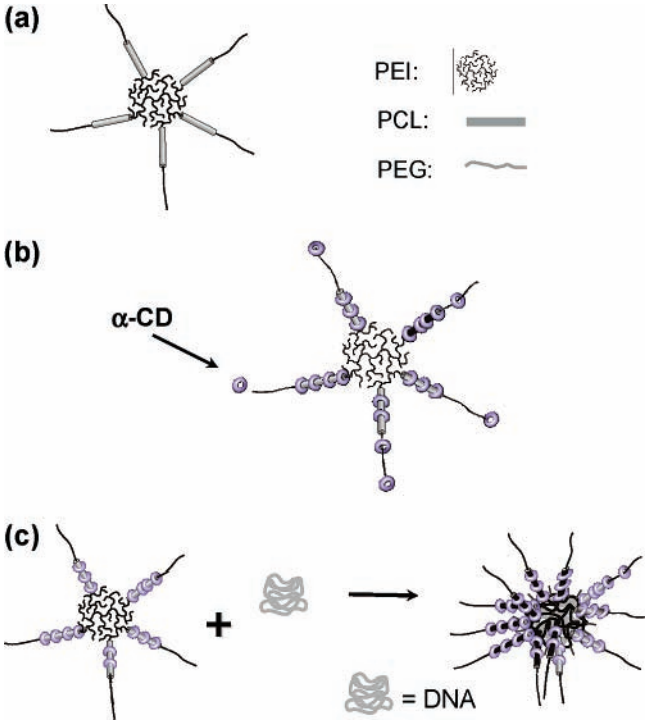

Figure 3. Schematic copolymer structure (a), formation of inclusion complex (b) and formation of polyplex (c).

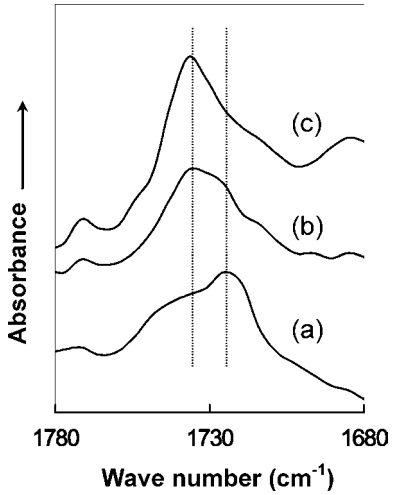

Figure 4. FTIR spectra of hydroxyl-terminated diblock copolymer PCL2k-*b*-MPEG2k (a), PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ (b) and inclusion complex of α-CD and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ (c).

chains, individually inserted into α-CD channels, were not able to fold and aggregate in order to form any PCL crystals.

^{1}H NMR spectroscopy further corroborates the preferential complexation of PCL block with α-CD. In Figure 5 the ^{1}H NMR spectra of PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ and inclusion complex of α-CD and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ are shown. Unfortunately, PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ has too low solubility (i.e. cmc) and does not show good resonance signals in the ^{1}H NMR measurement. Therefore, we have to turn to the highly soluble PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ for ^{1}H NMR measurement and compare its ^{1}H NMR signals with those of the soluble inclusion complex. The soluble copolymer PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ in deuterated water showed clear PCL resonance signals at 1.44, 1.66 and 2.4 ppm, Figure 2a. ^{1}H NMR spectra of copolymer micelles did not show

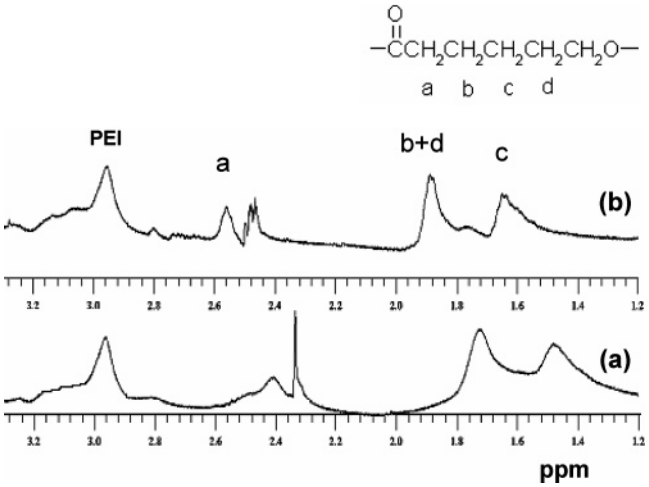

Figure 5. ^{1}H NMR spectra of PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ (a) and soluble inclusion complex of α-CD and PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$ in D_2O (b).

detectable resonance signals of PCL blocks due to the suppressed chain mobility (data not shown). When the micelles were dissociated upon addition of α-CD, clear PCL resonance signals were observed in the ^{1}H NMR measurements. However, these resonance signals of PCL blocks showed significant downfield shift upon forming the inclusion complex with α-CD, as shown in Figure 5b. These results are consistent with previous reports in which similar downfield shifts were observed when polymer chains were included inside CD cavities (*29*, *37*).

It was reported that protonated poly(iminooligomethylene)s may form soluble inclusion complexes with α-CD and result in the similar downfield chemical shift of oligomethylene signals. However the threading process was very slow at room temperature. In our work, PEI block signal did not show downfield shifts upon mixing with α-CD even after several days at room temperature. A model study with PEI25k showed the same results. Thus apparently, PEI does not form an inclusion complex with α-CD at room temperature. The different behavior of PEI and poly(iminooligomethylene)s may be due to the fact that the reported poly(iminooligomethylene)s contain long oligomethylene chains which are known to form an inclusion complex with α-CD. Indeed, polyethylene is known to form an inclusion complex with α-CD (*38*). In addition, the branched structure of the used PEI might be another reason that it cannot form inclusion complex with α-CD. It is well-known that PEG can also form inclusion complexes with α-CD. However, ^{1}H NMR signals of the PEG blocks of the copolymer complexes listed in Table 2 did not show any significant downfield shifts. These results suggest that the α-CD molecules have preferably formed an inclusion complex with the PCL block in these complexes, in case that the α-CD molar amount was stoichiometrically insufficient for the whole side chain (MPEG-*b*-PCL-) inclusion, as discussed in Figure 2.

Formation of an inclusion complex between α-CD and PCL block was confirmed by UV measurements as well. As shown in Figure 6, upon adding α-CD, the UV absorption peak of the PCL carbonyl of the soluble PEI25k-g-(PCL580-*b*-PEG5k)$_{2.9}$ showed a clear red-shift from 216 to 226 nm due to the interaction between α-CD and the included PCL chain. The other two copolymers are not soluble and form micelles in aqueous solution. Therefore, they are not suitable for the UV study.

The stability of these inclusion complexes still remains unclear. One concern is that α-CD molecules may unthread the copolymer chains and form inclusion complexes with competing ligands present in the cell culture media and blood plasma. So far there is no experimental evidence to substantiate this concern.

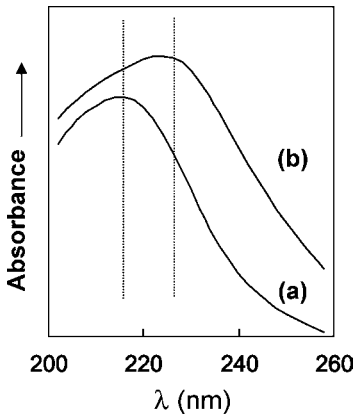

Figure 6. UV spectra of PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ (a) and its inclusion complex (b) in water.

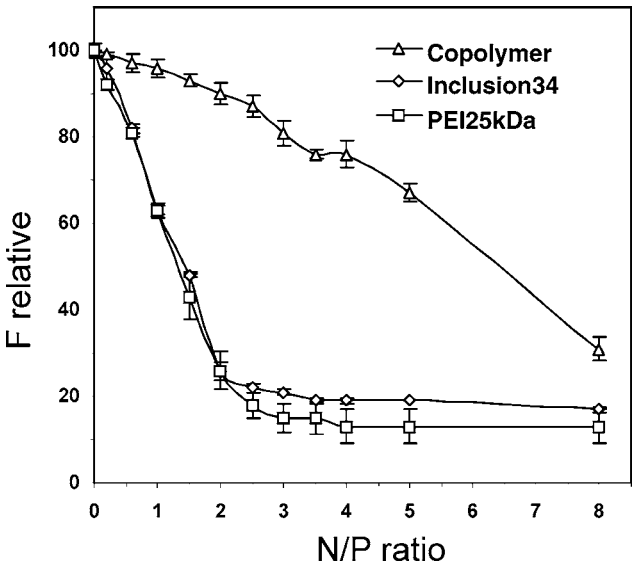

Figure 7. Condensation potential of PEI25k, PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ and its inclusion complex with α-CD, as determined by EtBr assay.

Ethidium bromide (EtBr) exclusion assay for DNA condensation. Fluorescence of ethidium bromide added to polyplex solutions was determined to monitor DNA condensation. While free ethidium bromide in solution only shows weak fluorescence, fluorescence intensity strongly increases when it intercalates with DNA. If the DNA is condensed by a polycation, EtBr cannot intercalate with DNA any more. Therefore, condensation of DNA by polycations can be monitored by the decrease of EtBr fluorescence. As shown in Figure 7, increasing amount of PEI25k and inclusion complex both led to a significant decrease in relative fluorescence intensity from 100% to 26% until N/P ratio reached 2. By contrast, the relative fluorescence intensity was only slightly decreased to 90% at this N/P scale when DNA was condensed with PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$. Similar data were obtained for other inclusion compounds and their CD-free counterparts. Apparently, PEI and the inclusion complexes are much more efficient for DNA condensation, in comparison to the non-α-CD-complexed copolymers.

Size, Zeta-Potential and Biocompatibility of Polyplex Polyplexes. The particle size and ξ-potential of various pDNA/copolymer complexes formed at an N/P

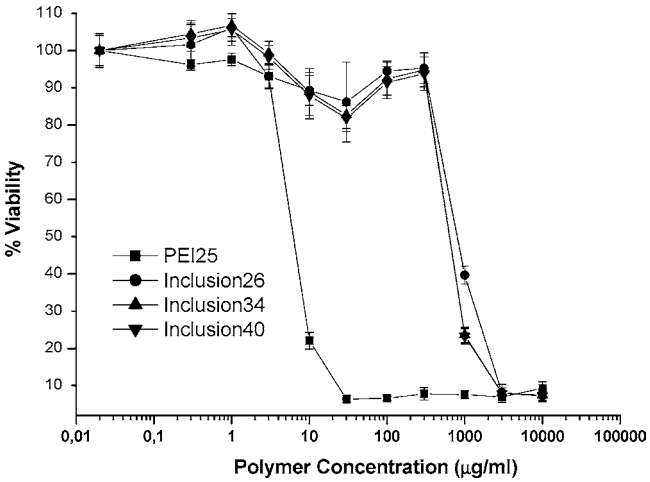

Figure 8. Estimation of cytotoxicity employing an MTT-assay. An about 100-fold less cytotoxicity of inclusion complexes can be observed compared to PEI 25 kDa.

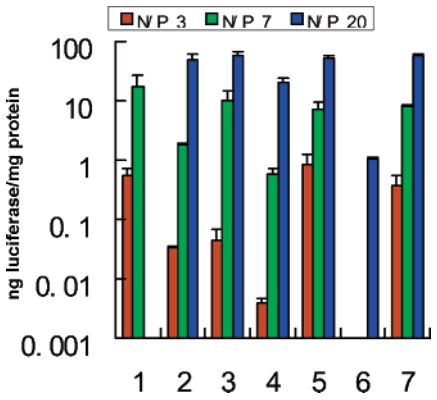

Figure 9. Transfection efficiency of polyplexes to 3T3 cells based on (1) PEI25k, (2) PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$, (3) inclusion complex of PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$, (4) PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$, (5) inclusion complex of PEI25k-*g*-(PCL2k-*b*-PEG2k)$_{2.8}$, (6) PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ and (7) inclusion complex of PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$.

ratio of 7 are summarized in Table 2. PEI25k formed the smallest polyplexes of approximately 160 nm in diameter. It is noteworthy that threading of α-CD does not increase the particle size of polyplexes, i.e., polyplex sizes detected are all around 200 nm no matter whether α-CD was incorporated or not. As expected, the $\xi-$potential of the polyplexes with PEI 25k are very high (21mV), suggesting highly positive charge on the particle surface. In contrast, polyplexes based on both copolymer and inclusion complexes possess approximately neutral surfaces (−3.5 to 1.4 mV $\xi-$potential).

In Vitro Cytotoxicity Using MTT Assay. Estimations of cytotoxicity by determining protein content after transfection could be confirmed using an MTT cytotoxicity assay. Figure 8 shows data obtained by a MTT assay comparing cytotoxicity of inclusion complexes to PEI 25k. A dramatically reduced toxicity could be observed which is about 100 times lower compared to PEI25k. This notion was also supported by the viability of 3T3 cells observed during the transfection experiments, as shown in Table 3. At N/P ratios of 3 and 7, cells remained viable when transfected with complexes based on the copolymers and their inclusion complexes. By contrast, cell viability dropped to 80% and 69%, respectively, when transfected with the PEI25k-based polyplex. As the N/P ratio reached 20, all cells were killed. However, cells retained about 50% of their viability when transfected with copolymer-based polyplexes. Furthermore, cell viability is even higher (>80%) when cells were transfected with inclusion complex-based polyplexes at N/P 20. A part of this reduced toxicity is probably due to the neutral surface charge of complexes; however, our data suggest also that cyclodextrin further improves biocompatibility.

Gene Transfection Efficiency of Polyplexes. The transfection efficiency to 3T3 cells with polyplexes based on three copolymers and their inclusion complexes is shown in Figure 9. Although PEI25k-*g*-(PCL580-*b*-PEG5k)$_{2.9}$ was soluble in a wide concentration range and showed quite good performance in DNA condensation and transgene expression (*13*), threading of α-CD onto the PCL blocks may further enhance the gene transfection of this copolymer-based polyplex by further reducing the hydrophobic hindrance of DNA binding to PEI blocks. Effect of incorporating α-CD on the transgene transfection of polyplexes of other two copolymers appears to be more significant. Surprisingly, at N/P 3 and 7, although PEI25k-*g*-(PCL1.2k-*b*-PEG2k)$_{5.1}$ did not transfect the cells at all, the polyplex based on the inclusion complex of this copolymer exhibited excellent transfection efficiency.

Intracellular Uptake of Polyplexes. After incubating the NIH 3T3 fibroblasts for 3 h, a typical confocal laser scanning microscope image of an inclusion complex containing polyplex is shown in Figure 10. The micrograph demonstrates the efficient internalization of polyplexes, despite their neutral surface charge. Both DNA and copolymer colocalize in punctuate vesicles, probably in the lysosomal compartment. The mechanism by which the polyplexes escape from the endo/lysosome is presently under investigation. Most likely, the PEI component of the copolymer acts as proton sponge, while inclusion complex formation modulates complex solubility and cytotoxicity. No significant differences could be observed between the subcellular distribution of IC-containing polyplexes compared to PEI25k (data not shown).

CONCLUSION

Upon formation of inclusion complexes between α-CD and preferably the PCL blocks of the ternary copolymers, the copolymers lost their amphipathy and became more hydrophilic. This effect not only led to an increase in water solubility of copolymers but also favored the access and binding of DNA. Consequently, enhanced gene transfection efficiency was detected in transfection ex-

Dendrimers have emerged as promising multifunctional nanomaterials for drug delivery due to their well-defined size and tailorability. We compare two schemes to obtain methylprednisolone (MP)–polyamidoamine dendrimer (PAMAM-G4-OH) conjugate. Glutaric acid (GA) was used as a spacer to facilitate the conjugation. In scheme A, PAMAM-G4-OH was first coupled to GA and then further conjugated with MP to obtain PAMAM-G4–GA–MP conjugates. This scheme yields a lower conjugation ratio of MP, presumably because of lower reactivity and steric hindrance for the steroid at the crowded dendrimer periphery. In scheme B, this steric hindrance was overcome by first preparing the MP–GA conjugate, which was then coupled to the PAMAM-G4-OH dendrimer. The ^{1}H NMR spectrum of the conjugate from scheme B indicates a conjugation of 12 molecules of MP with the dendrimer, corresponding to a payload of 32 wt %. In addition, conjugates were further fluorescent-labeled with fluoroisothiocynate (FITC) to evaluate the dynamics of cellular entry. Flow cytometry and UV/visible spectroscopic analysis showed that the conjugate is rapidly taken up inside the cell. Fluorescence and confocal microscopy images on A549 human lung epithelial carcinoma cells treated with conjugates show that the conjugate is mostly localized in cytosol. MP–GA–dendrimer conjugate showed comparable pharmacological activity to free MP, as measured by inhibition of prostaglandin secretion. These conjugates can potentially be further conjugated with a targeting moiety to deliver the drugs to specific cells in vivo.

INTRODUCTION

Dendrimers represent a relatively new class of well-defined monodisperse macromolecules with striking features such as controlled structure, globular shape, and a high density of "tunable" surface functional groups in their periphery (*1–5*). A variety of dendrimers have been synthesized and tailored for diverse applications (*6*). Encapsulation of drugs in PEGylated dendrimers led to increased circulation time (*7, 8*). Various strategies have been devised to load dendrimers with drug molecules, genetic materials, targeting agents, dyes, and imaging agents either by encapsulation, complexation, or conjugation (*9–15*). Although investigation of cellular delivery of drugs using dendrimers is at an early stage, these nanomaterials offer several advantages when compared to liposomes and microparticles. Their multiple, surface functional groups can be easily modified to potentially attach a large number of drug molecules, ligands, and antibodies, making them ideal vehicles for targeted drug delivery. They have been shown to be rapidly internalized into cells. Thus, they are promising nanovehicles in several therapeutic areas, where the target is intracellular (*16–21*). The present investigation demonstrates the potential of dendrimers as promising vehicles for delivering steroids to lung epithelial cells.

A critical issue in dendritic drug delivery systems is achieving a high drug payload. However, the payload that each polymer can carry typically depends on the total number of reactive groups. For example, a linear PEG molecule with two reactive end groups can be conjugated to two drug molecules, whereas, for the same molecular weight, hyperbranched polymers (HBPs) such as dendrimers with multiple reactive end groups can be conjugated to several drug molecules (*17*). Genes, targeting agents, and imaging agents have been linked with dendrimers to increase therapeutic efficacy. In most cases, achieving adequate drug loading has been a challenge. It may be possible that some of the dendrimer–drug conjugates show less therapeutic activity compared to free drug, due to relatively low drug payload and the lack of drug release from conjugate. This is especially true for the anticancer agents such as doxorubicin and methotrexate (*18*).

Despite the fact that dendrimers possess a high density of surface functional groups for chemical modification, the nanoscale architecture of a dendrimer (~10 nm) causes steric hindrance for covalent conjugation of drugs in general, and large steroid molecules in particular. This results in typical drug payloads of less than 10% for high molecular weight drugs (*1*). Achieving high drug payload for steroidal drugs ($M_w \sim 374.5$ Da) is challenging, since both the dendrimer and the steroid exhibit steric hindrance for covalent conjugation. Therefore, the main focus of this study was to (i) synthesize dendrimer–drug

conjugates with relatively high steroidal drug payload, (ii) demonstrate the potential of such conjugates to deliver high drug concentrations inside the cells, and (iii) evaluate their pharmacological activity.

We have previously investigated PAMAM-G4-NH_2 dendrimer−ibuprofen complexes involving ionic interaction between surface amine groups of the dendrimer and carboxyl groups of ibuprofen. The complexes demonstrated rapid cell entry into A549 human lung epithelial carcinoma cell lines and showed antiinflammatory activity by suppressing the COX-2 gene in the in vitro studies (*19*). But, since complexation or encapsulation of drug is a weak ionic interaction, the concern arises that the drug may decouple in vivo before it reaches the target site. Unlike these complexes, covalently conjugated drugs will be more stable at physiological pH, making them more suitable for in vivo applications. We have earlier reported dendrimer−ibuprofen conjugates with high payload using PAMAM G4-OH-terminated dendrimer (*20*).

The suitability of a dendrimer for delivering drug will depend on its molecular weight, generation number, end functionality, and charge. The polycationic systems show toxicity and higher elimination rate from the circulation. Anionic systems exhibit reduced uptake of molecules in cultured cells and are rapidly removed via the scavenger receptor in animal models (*21*). Conjugation of drug, targeting moiety, or imaging agent to the dendrimer also depends on the physicochemical properties of the agent to be coupled. This is especially true for a steroidal drug such as methylprednisolone. Covalent and noncovalent conjugations of drugs, genetic materials, and lipids to dendrimers have previously been reported (*22*). The conjugation of bulkier molecules such as steroids to dendrimers aims to address the issues of drug reactivity, stability, and most importantly the steric hindrance. To synthesize high payload drug−dendrimer conjugates using steroids, it is essential to overcome the steric hindrance and low reactivity of the drug molecule. The methodology reported here is an attempt to increase the payload of MP with dendrimer by increasing reactivity and at the same time minimizing steric hindrance.

Methylprednisolone (MP) is a corticosteroid, 6α-methyl-11β,17α,21-trihydroxy-1,4-pregnadiene-3,20-dione. It decreases inflammation by stabilizing leukocyte lysosomal membrane and has a greater antiinflammatory potency than prednisolone. The corticosteroid has three OH groups at 11β, 17α, and 21. The hydroxyl group at C21 is a primary OH and therefore is most favorable for the covalent conjugation with terminal COOH groups of the dendrimer. Previously, MP has been conjugated with dextran by using succinate as a linker (*23*). The ester bond so formed was enzymatically hydrolyzed in rat blood. However, the rate of hydrolysis was very slow, corresponding to a half-life of ~25 h of MP in dextran−MP conjugates.

In this paper, we evaluate synthetic approaches for obtaining MP−dendrimer (PAMAM G4-OH) conjugate with a high drug payload. We report conjugation of MP to PAMAM G2.5-COOH terminal dendrimer and PAMAM G4-OH terminal dendrimer using glutaric acid as a spacer. In addition, fluoroisothiocynate (FITC) was covalently linked with free MP and MP−dendrimer conjugate to investigate the cellular transport of free and dendrimer-conjugated MP. The dynamics of cell entry of the conjugate was studied using A549 human lung epithelial carcinoma cell line. Flow cytometry and UV/visible spectroscopy were used to follow the time-dependent transport of FITC-labeled MP and dendrimer−MP into lung epithelial cells. Fluorescence and confocal microscopy were used to visualize the cellular localization of the conjugate. In vitro pharmacological activity of the conjugate was demonstrated by measuring the prostaglandin (PGE_2) levels in cell supernatant.

EXPERIMENTAL SECTION

Materials and Methods. PAMAM-G-2.5-COOH (M_w ~ 6,267 Da, 32 end groups), PAMAM-G4-OH (M_w ~ 14,279 Da, 64 end groups) dendrimers, methylprednisolone USP (M_w ~ 374.5 Da), and dicyclohexylcarbodiimide (DCC) were purchased from Aldrich. Glutaric acid (M_w ~ 132 Da) (Matheson Coleman and Bell Co.), fluorescent probe fluoroisothiocynate (FITC) (Fluka), Interleukin (IL-2β) and lipopolysaccharide (LPS) (Sigma), ELISA kit for prostaglandin estimation (Cayman Chemical), and dialysis membrane of molecular weight cutoff of 3500 Da (Spectra Pore) were purchased. Dimethyl sulfoxide (DMSO), dimethyl formamide (DMF), methanol, and diethyl ether were purchased from Fischer Scientific. All other chemicals used were analytical grade.

Synthesis of PAMAM-G2.5-COOH−MP Conjugates. PAMAM-G2.5-COOH (0.088 g, 0.014 mmol) and MP (0.168 g, 0.449 mmol) were dissolved in anhydrous dimethyl sulfoxide (DMSO). (On the basis of the molecular weights, this corresponds to a molar ratio of dendrimer to MP of 1:32, one drug molecule for each dendrimer end group). To this solution was added DCC (0.093 g, 0.45 mmol) as a coupling agent. The reaction was carried out at room temperature for 3 days and filtered to remove dicyclohexylurea (DCU). The solution was further dialyzed (dialysis membrane of molecular weight cutoff = 3500 Da) against DMSO for 24 h to remove unreacted methylprednisolone. The contents from dialysis bag were dried under vacuum and characterized by ^{1}H NMR (*24*).

Conjugates Were Prepared Using Two Different Synthetic Strategies. (1) GA was first conjugated to PAMAM-G4-OH dendrimer, and then this conjugate was coupled with MP (scheme A).

(2) GA was first conjugated to MP, and then the conjugate was coupled with PAMAM-G4-OH (scheme B).

Scheme A. *A.1: Synthesis of PAMAM-G4-OH−Glutaric Acid Conjugates.* PAMAM-G4-OH (0.300 g, 0.021 mmol) and glutaric acid (0.180 g, 1.34 mmol) were dissolved in anhydrous dimethyl sulfoxide (DMSO). This corresponds to a mole ratio of dendrimer to GA of 1:64, with one GA molecule for every OH end group on the dendrimer. DCC (0.276 g, 1.33 mmol) was added as a coupling agent and stirred continuously for 2 days at room temperature. The resulting solution was filtered to remove DCU obtained as a byproduct during the reaction. The filtrate was dialyzed extensively with anhydrous DMSO (dialysis membrane of molecular weight cutoff = 3500 Da) for 24 h to remove unreacted glutaric acid. The contents from the dialysis bag were dried under vacuum. Repurification was carried out using diethyl ether, and the conjugate was dried under vacuum. ^{1}H NMR revealed that 50 molecules of GA are conjugated per dendrimer.

A.2: Synthesis of PAMAM-G4-OH−Glutaric Acid−Methylprednisolone Conjugates. PAMAM-G4−glutaric acid conjugate (0.12 g, 0.00574 mmol) and MP (0.1 g, 0.287 mmol) were dissolved in anhydrous dimethyl sulfoxide (DMSO). (The ratio of dendrimer−GA conjugates (50 molecules of GA per dendrimer) to MP was 1:50). To this solution was added DCC as a coupling agent, and the mixture was stirred continuously for 3 days. The DCU obtained was removed by filtration and was then dialyzed extensively with anhydrous DMSO

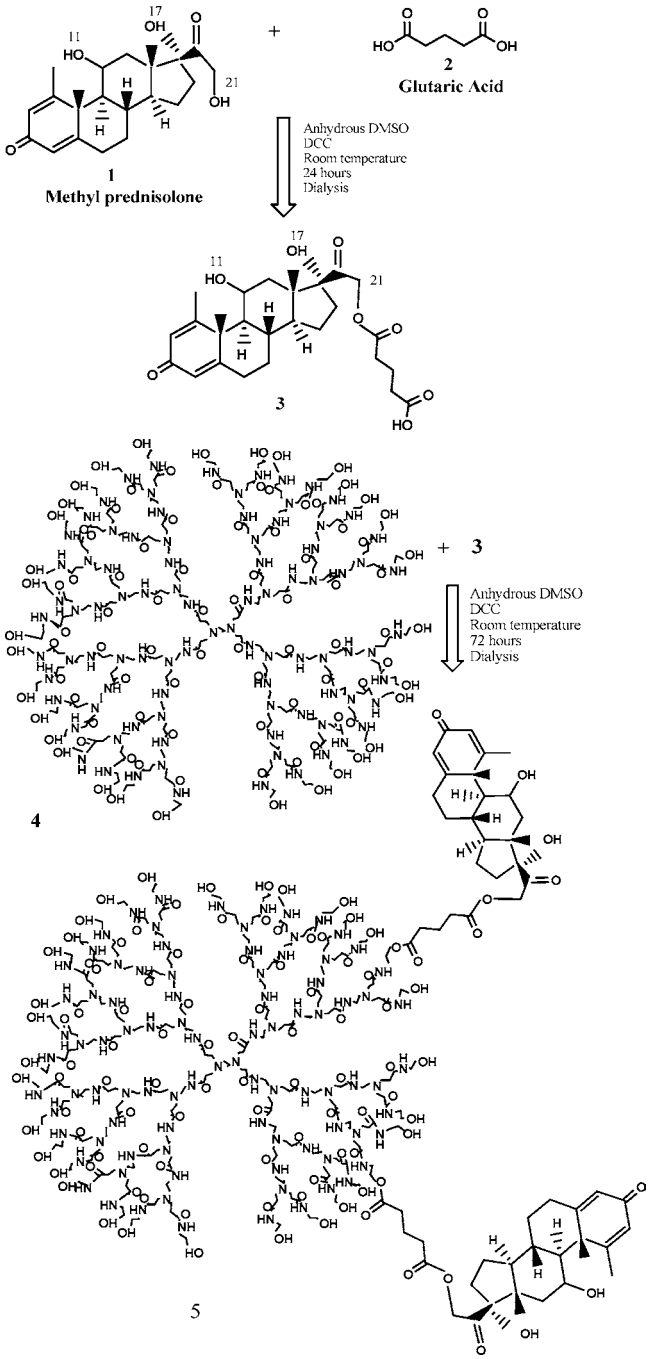

Figure 1. Schematic for dendrimer−glutaric acid−methylprednisolone conjugate synthesis multiplets corresponding to ring structure of methylprednisolone.

(dialysis membrane of molecular weight cutoff = 3500 Da) for 24 h to remove unreacted MP−glutaric acid and DCC. The contents from the dialysis bag were dried under vacuum to obtain the conjugate. ^{1}H NMR was used to characterize the conjugate. The conjugation ratio was extremely low (one molecule of MP per dendrimer). Therefore, the synthetic approach was changed as described below.

Scheme B. *B.1: Synthesis of Glutaric Acid−MP Conjugates (Figure 1*). MP (0.1 g, 0.265 mmol) and GA (0.036 g, 0.26 mmol) were dissolved in anhydrous DMSO. Dicyclohexylcarbodiimide (DCC) (0.056 g, 0.26 mmol) was added as a coupling agent to the above solution. The reaction was carried out for 24 h at room temperature and filtered to remove DCU obtained as a byproduct during this reaction. The filtrate was evaporated under vacuum to obtain MP−glutarate conjugate.

B.2: Conjugation of PAMAM-G4-OH Dendrimer to MP−Glutarate (Figure 1). PAMAM-G4-OH (0.032 g, 0.0024 mmol) and MP−glutaric acid conjugate (M_w ∼506) (0.077 g, 0.152 mM) were dissolved in anhydrous dimethyl sulfoxide (DMSO). (This corresponds to a mole ratio of dendrimer to MP−GA of 1:50). DCC (0.056 g, 0.26 mmol) was added as coupling agent, and the reaction was stirred for 3 days and filtered to remove DCU. The filtrate was dialyzed against anhydrous DMSO for 24 h (dialysis membrane of M_w cutoff = 3500 Da) to remove unreacted MP−glutaric acid conjugate, free MP, free GA, and DCC. The solvent was removed from the contents of dialysis bag, and the conjugate was evaporated under vacuum. The conjugate was characterized using ^{1}H NMR (Figure 2).

Conjugation of FITC to MP and PAMAM-G4-Dendrimer−GA−MP. MP (0.1 g, 0.265 mmol) and FITC (0.011 g, 0.28 mmol) or dendrimer−GA−MP (M_w ∼ 20 351 Da) (0.020 g, 0.00078 mmol) and FITC (0.01 g, 0.26 mmol) were dissolved in anhydrous DMSO (This corresponds-to-mole ratio of dendrimer to FITC 1:10). Dicyclohexylcarbodiimide (0.0054 g, 0.265 mmol) was added as a coupling agent for conjugation of FITC to MP and (0.00284 g, 0.014 mmol) for conjugation with dendrimer−GA−MP. The reaction was carried out for 24 h at room temperature and filtered to remove DCU. The FITC−dendrimer−GA−MP conjugate filtrate was dialyzed against anhydrous DMSO for 24 h (dialysis membrane of molecular weight cutoff = 3500 Da) to remove unreacted FITC and DCC. In addition, free FITC was removed by using excess acetone. The absence of free FITC in the conjugates was verified by thin-layer chromatography (TLC), using chloroform and methanol (1:1) as solvents (*25*). The conjugates were dried under vacuum to obtain FITC-labeled conjugates.

Cell Culture. Human lung carcinoma epithelial cell line A549 was obtained from Children's Hospital of Michigan Cell Culture facility and used for the cell entry and activity studies. Cells were incubated in RPMI 1640 (Gibco-BRL) cell culture medium supplemented with 10% fetal calf serum (FCS) and 1% penicillin−streptomycin at 37 °C with 5% CO_2 in a cell culture incubator. The cells were subcultured every 48 h and harvested from subconfluent cultures (60 to 70%) using 0.05% trypsin (Sigma-Aldrich).

Cell Entry of Fluorescent-Tagged Conjugate. A549 cells were seeded at 2×10^5 cells/mL and cultured on 60 × 15 mm culture plates using RPMI 1640 cell culture medium supplemented with 10% fetal calf serum (FCS) and 1% penicillin. When the cells were 60% confluent, they were treated with FITC-labeled MP or FITC-labeled dendrimer−GA−MP conjugate. The supernatant was removed at times 0, 5, 10, 15, 20, 240, and 360 min, and the amount of FITC present in the supernatant was estimated by measuring the UV/visible absorbance at 490 nm for FITC−MP and 498 for FITC−MP−dendrimer conjugate and quantified with a calibration curve (of known concentrations of FITC−MP and FITC-labeled MP−dendrimer conjugates) using appropriate supernatant as blank solution. The pH of the cell supernatant remained unchanged throughout the experiment.

After removing the cell supernatant at each time point, the cells were washed with phosphate-buffered saline (PBS), trypsinized, and centrifuged at 1500 rpm for 5 min to obtain a cell pellet. The cells were then rinsed with PBS buffer, spun down twice, resuspended in PBS, and subsequently analyzed using a flow cytometer (FACS

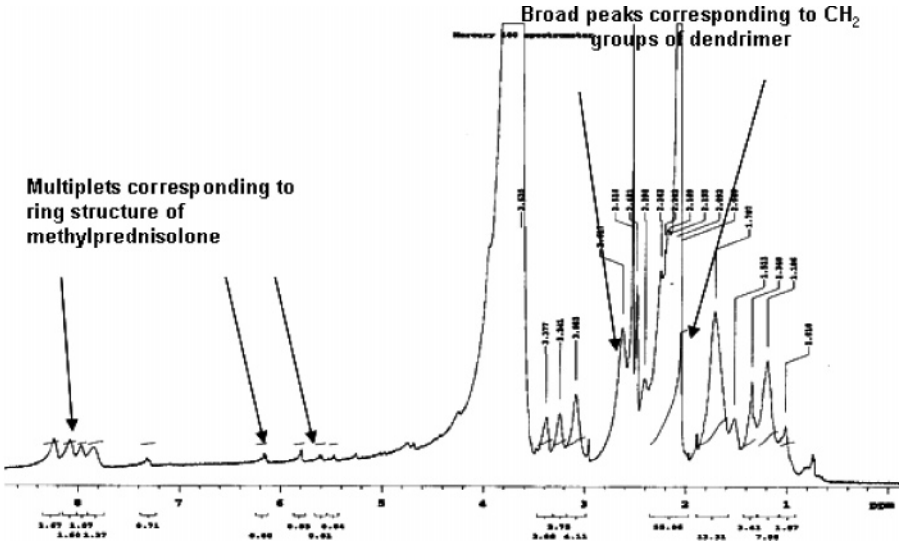

Figure 2. ^{1}H NMR spectrum of dendrimer–glutaric acid–methylprednisolone conjugates.

caliber, Becton Dickinson) by counting 10 000 events. (The mean fluorescence intensity of the cells was calculated using the histogram plot).

Fluorescence Microscopy. The procedure for cell culture and drug treatment was the same as described in previous section. After treatment with the conjugates for 2 h, the cells were washed with phosphate-buffered saline (pH 7.4). A few drops of the buffer was added before observing under the fluorescence microscope (Leica DM1L inverted microscope) using a magnification of 400×. Images were captured and stored using SensiCam-QE 12 bit monochrome camera and Camware 3.1 software, respectively.

Confocal Laser Scanning Microscopy. The procedure for cell culture and drug treatment was the same as described in previous section. After treating A549 cells for 2 h with FITC-labeled free dendrimer or MP conjugated dendrimer, the cells were washed with phosphate-buffered saline (pH 7.4). A few drops of the buffer and antifade reagent (Molecular Probes) was added before observing under the confocal microscope (Zeiss LSM 310) using a magnification of 63 × 1.2. The emission and excitation wavelengths were 488 and 518 nm for FITC.

Pharmacological Activity of Dendrimer–MP Conjugates. A 549 lung epithelial cells (2×10^5 cells/mL/well) was seeded in 24-well plates and allowed to grow overnight in RPMI medium supplemented with 10% FCS and 1% penicillin and streptomycin. When the cells were 60% confluent, the medium was removed and washed with serum-free medium (SFM). Each well was treated with 500 μL of SFM, and prostaglandin (PGE_2) secretion was induced by addition of lipopolysaccharide (LPS) and interleukin (IL- β2) to each well. After 30 min, either 5 μg of free MP or dendrimer–GA–MP conjugate (5 μg equivalent of MP) in ethanol was added. Control treatments with solvent, polymer, and positive control with no treatment, and negative controls without PGE_2 induction, were also studied. The supernatant was removed after 4 h and analyzed for PGE_2 concentration using a commercial ELISA kit. Results were represented as percent inhibition of PGE_2 compared to positive control.

RESULTS AND DISCUSSION

1. Design and Synthesis of Dendrimer–Drug Conjugates. To obtain dendrimer–drug conjugates with high drug payload, it is important to (1) decrease the steric hindrance of the surface functional groups, which are very close to each other. (This could be complicated by the potential back folding of end groups as explained below), and (2) increase the reactivity of the steroidal drug molecule and the dendrimer surface functional groups. Recently we have reported a high payload (on an average 53 molecules of drug per hyperbranched polymer) for the highly reactive and conformationally stable ibuprofen (*20*).

The hydrodynamic radius (R_h) of generation 4-poly-(glycerol succinic acid) (PGLSA-OH) dendrimers was estimated by quasielastic light scattering (QELS) method to be 7 nm (*6*). The authors reported the encapsulation of one Reichardt's dye per dendrimer molecule. As a consequence, R_h of the dendrimer reduced from 7 to 4 nm, suggesting the collapse of aliphatic dendrimer around the dye. Therefore, the factors that affect drug loading in dendrimers include (1) potential collapse of aliphatic groups and lowering of R_h in organic solvents, and (2) reduced *distance* between the two peripheral reactive groups. In addition, the reactivity of dendrimers may not be significantly high for direct covalent conjugation with drugs, especially with conformationally unstable and bulkier steroidal drugs such as MP. Such drugs have low reactivity, higher molecular weight, and steric hindrance.

The objective of present work was to obtain high payloads of MP with PAMAM dendrimers using DCC as a coupling agent. Therefore, we designed two synthetic approaches for conjugating MP with the dendrimer (schemes A and B). For comparison, the drug (MP) was conjugated directly to PAMAM G2.5-COOH dendrimer. The resulting conjugate had one drug molecule per dendrimer. In the first approach (scheme A), glutaric acid was incorporated as a flexible spacer, first by coupling it to OH end groups of PAMAM G4 dendrimer. This would present the highly reactive COOH group of the flexible GA spacer at the dendrimer surface, potentially relieving part of the crowding effect at the surface. The resulting dendrimer–glutarate conjugate was then linked to 21-OH group of MP. The drug loading to dendrimer molecule was estimated using ^{1}H proton integration method (*24*, *25*). However, ^{1}H NMR revealed the incorporation of only one MP molecule per mole of dendrimer. This suggests the presence of steric hindrance and low reactivity of the GA-modified dendrimer conjugate with MP. Therefore, the synthetic approach was slightly modified. In the second approach, the spacer molecule (GA) was first attached to MP, in an attempt to enhance the reactivity

of MP (scheme B). The reaction of glutaric acid to MP (Figure 1) is more favorable to primary hydroxyl group at 21, compared to C_9 (secondary) and C_{11} (tertiary) positions (*23*). MP was first linked to GA and further conjugated with OH groups of G4 dendrimer. ^{1}H NMR spectrum (Figure 2) shows the multiplets between δ 2.0 to 4.0 ppm, which correspond to the presence of 985 protons of CH_2 of PAMAM-G4-OH. Multiplets between δ 5.0 to 8.2 ppm correspond to four protons of the aromatic ring of methylprednisolone. The integration ratio of PAMAM-G4-OH to multiplets of methylprednisolone is 0.047, suggesting that 46.78 protons ($0.047 \times 985 = 46.295$) of methylprednisolone are present. Since four protons correspond to one molecule, on an average, 12 molecules of MP were incorporated per dendrimer molecule. The high payload of MP (32%) per dendrimer indicates that conjugation of a small spacer molecule such as glutaric acid increases the reactivity of MP molecule. In addition the MP−spacer conjugate overcomes the steric hindrance at the dendrimer surface for the large steroid. The resulting ester bond in the conjugate can potentially be hydrolyzed in the cell by lysosomal enzymes.

To study the cellular transport of the conjugates, FITC was conjugated to free MP and MP−GA−dendrimer conjugate using DCC as a coupling agent. Unreacted FITC was removed by membrane dialysis using DMSO for 24 h. Any remaining trace amount of free FITC was removed by an additional repurification step using excess acetone. The absence of free FITC in the conjugate was verified by thin-layer chromatography (TLC), using chloroform and methanol (1:1) as solvents (*25*). The proton integration ratio of MP−GA−dendrimer conjugate was compared to the additional protons arising from FITC molecules in MP−GA−dendrimer-FITC conjugate. ^{1}H NMR reveals that on an average of six FITC molecules are conjugated to MP−GA−dendrimer conjugate (^{1}H NMR not shown).

2. In Vitro Evaluation of Dendrimer−GA−MP Conjugates. When the conjugates were dissolved in DMSO and kept in a dialysis bag, no drug release was evident even after several hours, as verified by HPLC and UV/visible spectroscopy. To demonstrate the therapeutic potential of dendrimer−GA−MP conjugates, we evaluated these conjugates in A549 human lung epithelial carcinoma cell lines. The cells were treated with FITC-labeled-MP or dendrimer−GA−MP−FITC conjugate. Cell supernatant was analyzed for a period of 4 h by UV/visible spectroscopy, to estimate FITC concentration and the cellular uptake. As seen in Figure 3a,b, based on UV/visible analysis of the cell supernatant, ~85% of MP−FITC and 35% of dendrimer−GA−MP−FITC conjugate entered the cell within 1 h. The cellular entry of free and dendrimer-conjugated MP was further confirmed by flow cytometry by measuring the intracellular fluorescence intensity. By flow cytometry (Figure 3a,b), it was found that ~50% of free MP and 65% of dendrimer−GA−MP was inside the cell. The discrepancy between the UV/visible spectroscopy measurements (for extracellular concentration) and flow cytometry (for intracellular concentration) can be attributed to the adsorption of drug molecules on the cell surface. When the extracellular concentration is measured by UV/visible spectroscopy, it does not take into account the molecules that are adsorbed onto the cell and those that are internalized. Since the cells were repeatedly washed with PBS (to remove any adsorbed molecules on the cell surface) after removing the cell supernatant, flow cytometry would be more indicative of measuring fluorescence

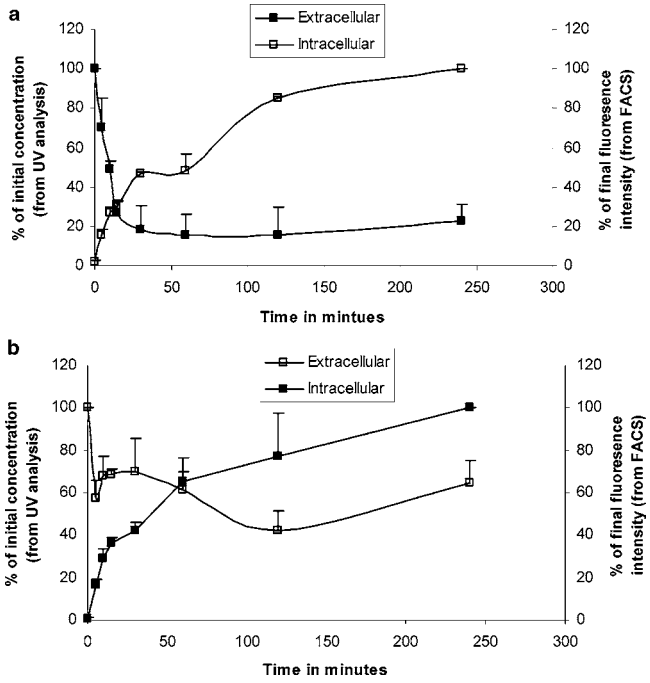

Figure 3. Decrease in FITC concentration in the cell supernatant (from UV/visible spectroscopy shown with open squares on the left-hand *y*-axis) and increase in the FITC intensity inside the cell (calculated from mean fluorescence intensity using flow cytometry and is shown with closed squares on the right-hand *y*-axis) for (a) MP−FITC and (b) dendrimer−GA−MP−FITC conjugate.

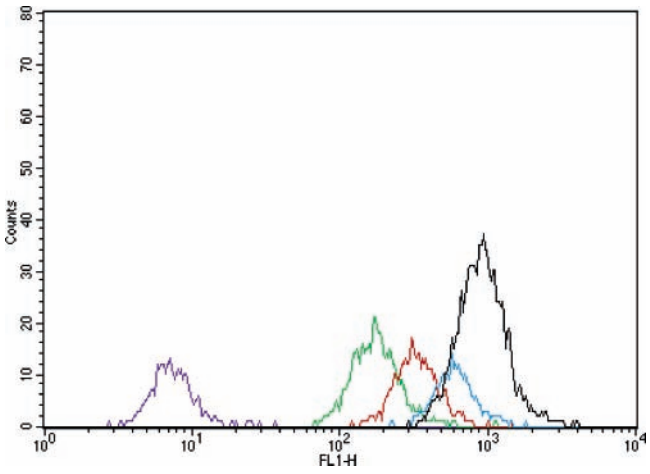

Figure 4. Fluorescence activated cell sorter analysis of the cell entry dynamics of methylprednisolone−glutaric acid−dendrimer−FITC conjugate in A549 lung epithelial cell line shows rapid internalization of the conjugates within 5 min. The log of FITC absorption intensity (FL1-H on *x*-axis) is plotted against the number of cells (counts on *y*-axis). Key: violet, 0 min; green, 5 min; red, 15 min; light blue, 60 min; black, 240 min.

intensity of only those molecules that are internalized into the cell. This is further demonstrated in Figure 4, where rapid internalization of the MP−GA−dendrimer conjugate is noted within 5 min and the fluorescence intensity gradually increases over a period of 4 h. From the present findings, it appears that the measurement of intracellular fluorescence intensity using flow cytometry might be a better method to follow the transport of free drug or drug−polymer conjugates.

At the end of 2 h, the cells were observed under fluorescence microscopy to identify the cellular localization of the free and drug conjugated dendrimer (Figure 5a−c). The cells without FITC showed no fluorescence

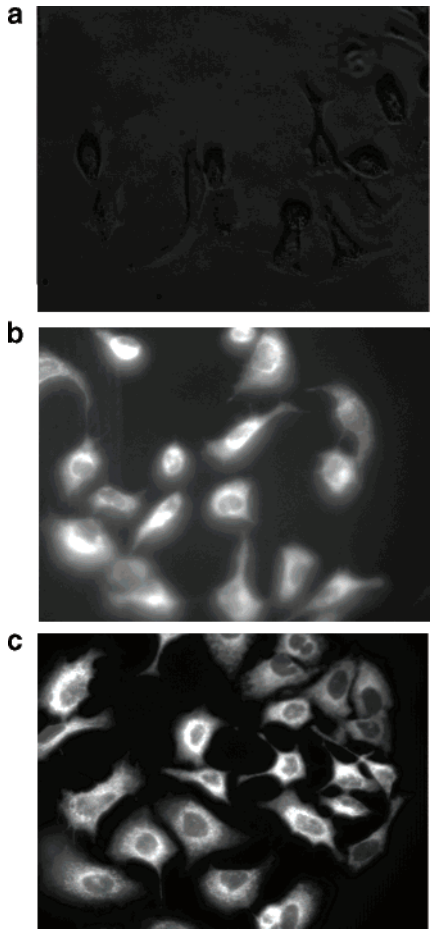

Figure 5. Fluorescence microscopic images (magnification 400×) of A549 cells 4 h of treatment with (a) control (no treatment), (b) FITC-labeled methylprednisolone, and (c) FITC-labeled dendrimer−GA−methylprednisolone conjugate.

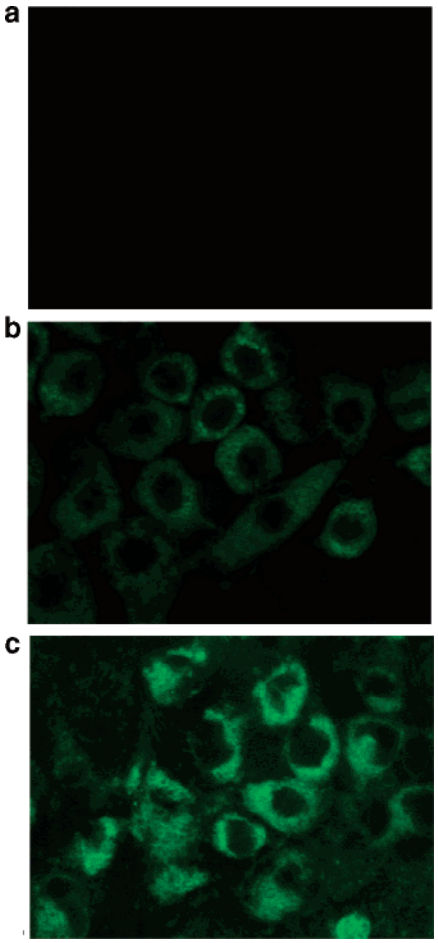

Figure 6. Confocal microscopic images (magnification 63 × 1.2) of A549 cells after 2 h of treatment with (a) control (no treatment), (b) FITC-labeled dendrimer, and (c) FITC-labeled dendrimer−methylprednisolone conjugate. The conjugates appear to be mainly localized in the cytoplasm.

as expected (Figure 5a). Both free and drug conjugated dendrimer were mainly found to be localized in the cell cytoplasm (Figure 5b,c). Further, this was substantiated from confocal microscopic images in Figure 6b,c, where the fluorescence is seen mostly in the cytoplasm. This suggests that the free dendrimer and MP−dendrimer conjugate are mainly localized in the cytosol in the cell.

Epithelial cells are known to possess anionic charge, and charged dendrimers such as PAMAM-NH_2-terminated dendrimers can be transported across the cell by electrostatic interactions (*14*, *26*). However, PAMAM-G4-OH terminal dendrimers are not charged and hence may be transported by selective absorptive endocytosis mechanism. It appears that the free MP enters the cells faster than the MP−dendrimer conjugate. From the results, it appears that the efficiency of the endocytosis mechanism is influenced by the molecular size and further studies are required to understand the cellular uptake mechanism. Simple passive diffusion of drug molecules (which is the case with free MP) across the cell membrane is a less efficient means to deliver drugs into the cells, as the drug molecules can diffuse in and out of the cell depending on the concentration gradient. Unlike passive diffusion, the endocytotic uptake of cells (in case of MP−dendrimer conjugate) is unidirectional; hence, the drug is not only more efficiently transported but is also retained at the site of action inside the cell. For MP, cytoplasmic delivery is required, since it exerts the pharmacological action by binding to the glucocorticoid receptors in the cytoplasmic compartment (*27*).

Antiinflammatory activity of free and dendrimer-conjugated MP was evaluated in vitro using A549 cells, which were pretreated with lipopolysaccharide and interleukin (IL-2β) to induce prostaglandin synthesis. Neither the free dendrimer nor the solvent showed any PGE_2 suppression. Dendrimer−GA−MP conjugate inhibited prostaglandin synthesis to the same extent ($p > 0.05$) as free MP (Figure 7) after 4 h of treatment. The results indicate that the conjugate was able to enter the cell and produce the desired pharmacological action. From these results, it appears that high drug payload in the dendrimer conjugate produces a high local drug concentration inside the cell to elicit a significant therapeutic response. At this point, it is unclear whether the MP is released from the dendrimer conjugate inside the cell or if the drug is effective even in the conjugated form. However, once the conjugate enters the cell, it is conceivable that the acidic pH and the enzymes in the endosomes would eventually hydrolyze the ester bond in the conjugate to release the free drug in the cytosol (*28*). Based on the previous report on dextran−MP conjugate, the hydrolysis process is likely to take much longer than the time frame used in current studies (*23*). Therefore, we may tentatively conclude that the conjugate may not have released the drug appreciably in 4 h. Nevertheless, the high payload drug conjugate show significant therapeutic activity. It may be possible that the conjugate may slowly release the drug over a sustained period providing therapeutic effect over longer times. Further studies are underway to investigate the stability of dendrimer−drug

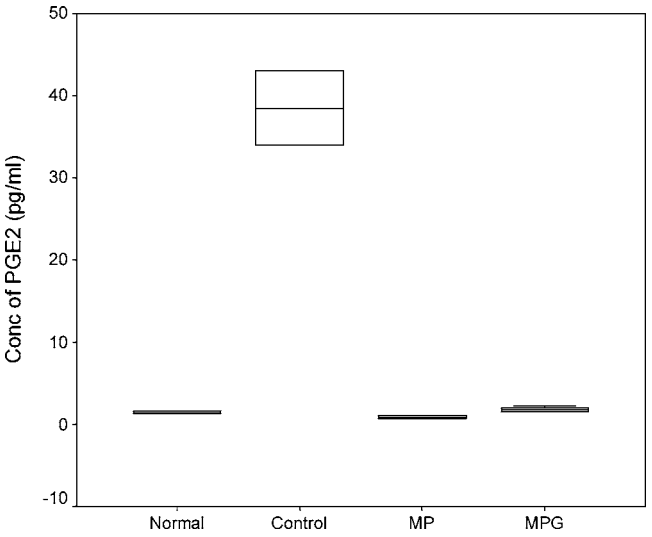

Figure 7. Box plot showing prostaglandin (PGE_2) concentration in the cell supernatant for different treatments ($n = 4$). Normal indicates the cells with no induction of prostaglandin synthesis. Control represents cells with prostaglandin induction with LPS+IL1β but with no drug treatment. MP and MPG indicate the cells, which were induced with LPS+IL1β to secrete prostaglandin and were treated for 4 h with free methylprednisolone and dendrimer−GA−MP conjugate, respectively. The cells treated with MP/MPG-suppressed prostaglandin secretion, and the PGE_2 levels were comparable to normal cells. Induced cells treated with dendrimer and solvent alone were similar to that of control (not shown). This indicates that the pharmacological activity of the conjugated MP has remained similar to that of the free drug.

conjugate at various pHs and in the presence of enzymes to understand the intracellular hydrolysis of the conjugate.

MP is used in the treatment of asthma, but systemic therapy is associated with severe side effects such as gastrointestinal hemorrhage, hypertension, endocrine, metabolic disturbances, immune suppression, and neuropsychiatric disturbances. (*29*). However, when both MP and a targeting ligand are conjugated to dendrimer, it may not only deliver the drug efficiently to the target site inside the cell, but also reduce the systemic side effects. By achieving a high local drug concentration at the target site, one could overcome the systemic adverse effects of free MP and improve the therapeutic efficacy significantly with a reduced dose. Current studies are ongoing to deliver the dendritic conjugate 'directly' to the lung through intranasal administration, in an in vivo lung inflammation model in mice (*30*). Furthermore, as the conjugates are expected to be stable in blood, it would achieve more sustained drug levels leading to reduce dosing frequency. Hence, the advantages of using dendrimers for delivery of MP would include (i) a high local concentration of MP in the lung through high drug payload (example, 12 MP molecules in a ~6 nm diameter spherical dendrimer), (ii) superior residence time in the lung enabled by the dendrimer (unpublished data), and (iii) slow hydrolysis of the ester bond enabling sustained delivery inside the cell.

CONCLUSIONS

A dendrimer−MP conjugate with a relatively high payload (12 steroid molecules per dendrimer) was prepared by first attaching glutaric acid to MP, then conjugating GA-MP to PAMAM-G4-OH dendrimers. This allowed us to (1) overcome the steric hindrance at the dendrimer surface for the large steroid molecule, and (2) improve the stability and reactivity of MP. The conjugate entered the cell rapidly and achieved a high local drug concentration to elicit the desired pharmacological action. It appears that, at least over the time period of this study, the conjugates are localized primarily in the cytosol, as imaged through fluorescence and confocal microscopy. The conjugate showed comparable therapeutic activity to the free drug, even at short times, where the drug may not have released from the dendrimer.

Affinity Enhancement Bivalent Morpholino for Pretargeting: Initial Evidence by Surface Plasmon Resonance

Jiang He,* Guozheng Liu, Jean-luc Vanderheyden, Shuping Dou, Rusckoswki Mary, and Donald J. Hnatowich*

Division of Nuclear Medicine, Department of Radiology, University of Massachusetts Medical School, 55 Lake Avenue North, Worcester, Massachusetts 01655. Received November 22, 2004; Revised Manuscript Received January 31, 2005

Pretargeting with bivalent effectors capable of bridging antitumor antibodies has been reported to provide superior results by affinity enhancement. Morpholinos (MORFs) and other DNA analogues used for pretargeting are ideally suited as bivalent effectors since they are easily synthesized and the distance between binding regions, likely to be a determinant of binding, may be adjusted simply by lengthening the chain. The goal of this investigation was to synthesize a bivalent MORF and to determine by surface plasmon resonance (SPR) whether the bivalent MORF exhibited bimolecular binding and whether the MORFs showed improved in vitro hybridization affinity in its bivalent form compared to its monovalent form. An 18 mer amino-derivitized MORF was made bivalent by dimerizing with disuccinimidyl suberate (DSS) in 1-methyl-2-pyrrolidinone (NMP) with *N*,*N*-diisopropylethylamine (DIEA) followed by purification by ion exchange chromatography. The in vitro hybridization affinity of bivalent compared to monovalent MORF was then measured by SPR. For these measurements, the complementary biotinylated cDNA was immobilized at coating densities that provided an average spacing of 20−100 Å and used to investigate the influence of this spacing on binding of the bivalent MORF with its binding regions separated by 25 Å. The yield of bivalent MORF was as high as 45%, and the structure was confirmed by MALDI-TOF mass spectroscopy. When the sensograms obtained by SPR were analyzed using different binding models, the evidence was consistent with bimolecular binding of the bivalent MORF. The dissociation rate constant of the bivalent compared to monovalent MORF was more than 10-fold lower at 2.14 compared to 0.27×10^{-5} (1/s) ($p < 0.05$), and since the association rate constants were similar at 8.53 and 5.64×10^5 (1/M·s) ($p = 0.08$), the equilibrium constant for hybridization to the immobilized cDNA of the bivalent compared to the monovalent MORF was almost 20-fold higher at 3.99 compared to 0.21×10^{10} (1/M) ($p < 0.05$). In addition, qualitative evidence for bivalent binding of the bivalent MORF was apparent in the lower concentrations necessary to saturate the cDNA. Finally, the stoichiometry interpretation of the binding data provided estimates of the fraction of bivalent MORF binding bimolecularly. Under one set of conditions, this value was 20%. In conclusion, a bivalent MORF was easily synthesized by dimerization of a monovalent MORF. A lower dissociation rate constant and higher equilibrium constant was measured by SPR for the bivalent compared to monovalent MORF in their binding to an immobilized cDNA. These results show that bimolecular binding was occurring in the case of the bivalent MORF and suggest that bivalency may be superior to monovalency in MORF pretargeting applications.

INTRODUCTION

While conventional immunoscintigraphy using monoclonal antibody promises to provide reliable noninvasive detection and localization of tumor, it still often provides marginal results in that image interpretation is often obscured by nonspecific accumulations of radioactivity in bone marrow, liver, in the vascular system, and other organs. As such, alternative methods with superior target/nontarget ratio are needed. Arguably one of the more attractive alternative approaches involves pretargeting (*1*). Preclinical studies of pretargeting have clearly demonstrated efficacy, and early clinical trials in several laboratories are providing encouraging results. These studies usually involve procedures based on the interaction of biotin with (strept)avidin, bispecific antibodies with a radiolabeled hapten, and oligonucleotides with their complement (*1*−*3*).

Even though (strept)avidin can be immunogenic, especially when conjugated to antibodies, and endogenous biotin can interfere, recent developments in avidin derivatives and biotin dimers or trimers are providing encouraging results (*4, 5*). However, the alternative approach using bifunctional antibodies as the first injectate and bivalent haptens (i.e. effector) as the second injectate has occasionally provided excellent results in animals with high tumor/normal tissue ratios and absolute tumor accumulations (*6*−*8*). These successes have been attributed in large part to affinity enhancement resulting from the bridging of two antibodies on the tumor surface by the radiolabeled bivalent hapten effector (i.e. "affinity enhancement system" or AES). The bivalent haptens used successfully include Ac-Lys(In-DTPA)-Tyr-Lys(In-DTPA)-Lys(TscG-Cys-)-NH_2 (*6, 9*), Janus bivalent hapten (*10*), pGlu-Leu-Tyr-Glu-Asn-Lys(DTPA)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu and DTPA-Gly-

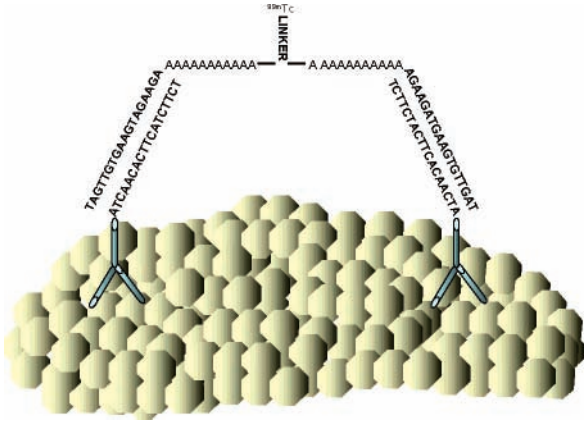

Figure 1. Artist's conception of a bivalent MORF bridging two complementary MORFs immobilizaed on a tumor cell.

Glu-Leu-Tyr-Glu-Asn-Lys(Ac)-Pro-Arg-Arg-Pro-Tyr-Ile-Leu (DTPA-Gly-NT) (*11*), and Ac-Phe-Lys(-DTPA)-Tyr-Lys(DTPA)-NH_2 (*12*) and have been variously radiolabled with ^{99m}Tc, ^{188}Re, ^{125}I, ^{131}I, ^{111}In, and most recently ^{68}Ga for radioimmunodetection and radiotherapy of tumor models (*13*−*21*). From these studies, it may be estimated that about 25 Å between the binding sites has been successfully used previously. Furthermore, a recent publication has shown that a bivalent receptor binding agent showed a 200-fold increase in affinity as the spacer between binding sites varied from 4 to 20 carbon atoms (i.e. 5−25 Å) (*22*).

This laboratory has previously reported encouraging results in tumored mice with pretargeting but using DNA and its analogues (collectively: oligomers). Instead of bifunctional antibodies, an antitumor antibody conjugated with a phosphodiamidate morpholine (MORF) serves as the first injection while the radiolabel is administered later on the complementary MORF (i.e. cMORF) as effector (*23*−*26*).

One advantage of using oligomers for pretargeting is the ease with which bivalent effectors for AES targeting may be constructed and the ease with which the molecular dimension separating the binding sites may be shortened or elongated. To accomplish the first goal of preparing the bivalent effector, MORFs with a primary amine were purchased and dimerized as described below. In future studies, the dimensions between binding sites will be investigated by purchasing the MORFs with additional bases in the chain.

The concept is shown schematically in Figure 1. In this investigation, we describe an initial test in which one bivalent MORF was synthesized and investigated for its properties of hybidization compared to its monovalent form. To measure these properties, a biotinylated cDNA was immobilized on a sensor chip at two concentrations, and, by surface plasmon resonance (SPR), the hybridization properties of MORF were measured in its bivalent form and compared to its monovalent form.

MATERIALS AND METHODS

All 18 mer MORFs and cMORFs [collectively: (c)MORFs] whether biotinylated or amine modified on the 3′ equivalent end were purchased prepurified (Gene-Tools, Corvallis, OR) and were used as received. The MORF base sequence was 5′-equivalent-TCT-TCT-ACT-TCA-CAA-CTA-linker-primary amine. The linker for amine modification was $-C(O)OCH_2C_6H_4CH_2NH_2$. The base sequences of the cMORFs were complementary with the linker and primary amine also on the 3′ equivalent end. The molecular weights were 6164 and 6422 Da. Biotinylated (c)DNA having the same sequences as the (c)MORF were purchased from Qiagen Inc. (Valencia, CA) and were also used as received. Disuccinimidyl suberate (DSS) was purchased from Pierce (Rockford, IL). Anhydrous dimethylformamide (DMF), *N*-methyl-2-pyrrodinone (NMP), and diisopropylethylamine (DIEA) were purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals were reagent grade and were used without purification.

Preparation of Bivalent MORF. About 1.5 mg (0.25 μmol) of amino-derivitized MORF was dissolved in 1.0 mL of 1-methyl-2-pyrrolidinone (NMP). A 0.125 μmol of disuccinimidyl suberate (DSS) in NMP solution at 2 mg/mL was added and followed by 0.66 μmol of *N*,*N*-diisopropylethylamine (DIEA). This mixture was incubated at room temperature for 2 days. The bivalent MORF was purified by Q Sepharose ion exchange chromatography. The collected fractions of bivalent MORFs were passed through a PD-10 column in 50 mM phosphate buffer. The molecular weight of the product was confirmed by MALDI-TOF before storage at freezer temperatures for future use.

Chromatography. Ion Exchange (IE) HPLC was performed on a HiTrap Q HP column (Amersham Biosciences, Uppsala Sweden) using 0.01 N NaOH (solvent A) and 0.01 N NaOH in 2 N NaCl (solvent B) at a flow rate of 1.0 mL/min going from 100% A to 70% A over the 30 min. Before each analysis, the column was stabilized with 0.01 N NaOH, and after each analysis the column was cleaned with solvent B. For small scale of preparative purification, samples were loaded on the column by several injections in running solvent A but without exceeding the column's maximum binding capability. The bivalent MORF was collected in fractions during the gradient elution.

Surface Plasmon Resonance Measurements. The surface plasmon resonance analysis (SPR) was performed on a BIAcore 2000 (BIAcore, Piscataway, NJ) instrument operating at room temperature. In these measurements DNAs rather than MORFs were immobilized because of earlier difficulties in immobilizing biotinylated (c)MORFs. Several 5−10 μL amounts of biotinylated(c)DNAs at 20 nM were each added to a separate new streptavidin−dextran-coated sensor chip (SA) at a flow rate of 20 μL/min until a response of about 100 (±10) or 500 (±30) response units (RU) was reached. The absence of mass transfer effects was confirmed by running separately one concentration of free MORFs at three different flow rates (10, 30, and 75 μL/min) and demonstrating identical response and curve shape for both concentrations. When the identical measurement was performed on a sensor chip to which DNA was added to a response of 750 RU, evidence of mass transfer effects was observed, and accordingly this chip was not used in subsequent studies. Solutions of free monovalent and bivalent MORF were prepared at eight concentrations from 0.0 to 500 nM in the same running buffer (10 mM HEPES, 150 mM NaCl, 3.4 mM Na_2EDTA, 0.005% P20, pH 7.4) and injected separately onto the active (cDNA) or control (DNA) surface. Dissociation was followed for 25 min or 4 h. The chip surface was regenerated by injection of 100 mM HCl. To correct for nonspecific binding and refractive index changes, the control responses were subtracted from those obtained from the active surface. A minor baseline drift resulting from a slow dissociation of the complex on the active and control surfaces was eliminated by also subtracting sensograms obtained following the injection of running buffer (*27*).

In the first series of experiments, samples of monovalent and bivalent MORFs were run at seven concentrations on both the 100 and 500 RU chips and with a dissociation time of only 25 min. In the second series of experiments, all seven concentrations were again run but with a dissociation time of 4 h to obtain more accurate values for the dissociation rate constants. To conserve instrument time, the longer analysis was performed only on the 100 RU chip. Each measurement was repeated four times, and, as mentioned above, each sample was run on both the cDNA and DNA chips at the same surface density so that results with the latter could be use to correct for bulk refractive index changes (*27*).

Sensorgram Kinetic Analysis. Sensorgram curves were evaluated using numerical intergration algorithms (BIAevaluation 3.0, BIAcore, Piscataway, NJ). The algorithm may be programmed for simple monomolecular 1:1 Langmuir interactions of a monvalent analyte or for a bivalent analyte binding monomolecularly (i.e. A+L→AL where A is the analyte, in this case MORF, and L is immobilized ligand, in this case cDNA) or binding bimolecularly (i.e. AA+L→AAL and AAL+ L→LAAL). In addition the algorithm may be programmed to analyze globally (i.e. all analyte concentrations considered together to provide one value for each of the two rate constants, association and dissociation) or locally (i.e. each analyte concentration considered separately to provide one value for each of the two rate constants for each analyte concentration). In addition, in the case of bimolecular binding, the bimolecular binding algorithm can provide one value for each of the two rate constants for the first and second binding. An added complication in the case of bivalent analyte binding is the possibility that the binding may be either monomolecular or bimolecular and thus cannot be accurately modeled. To emphasis this fact, the rate constants in this report for bivalent MORFs are referred to as "apparent". Finally, the program provides for each analysis a Chi2 (χ^2) value which is a statistical measure of how closely the model fits the experimental data. In general, χ^2 values lower than about 10 signify a good fit. In each of these investigations comparing monovalent to bivalent MORFs, the concentrations were adjusted to the same molarity of analyte and therefore the MORF molarity of the bivalent analyte was twice that of the monovalent analyte.

Stoichiometry of Bivalent MORF Binding. The BIAcore instrument measures the mass of molecules bound to the sensor surface. Thus, the stoichiometry of the surface molecular complex (i.e. the number of analyte molecules per ligand molecule) can be determined using eq 1:

$$\text{stoichiometry} = (R_{A(max)} \times MW_L)/(MW_A \times R_L) \quad (1)$$

where MW refers to molecular weight of the analyte (MW_A) and immobilized ligand (MW_L) while R refers to the response in RU of the analyte (R_A) and the ligand (R_L). $R_{A(max)}$ refers to the maximum response (i.e. binding capacity) of R_A for any ligand concentration R_L (i.e. either 100 or 500 RU) and can be obtained by analyzing locally the sensograms obtained at different analyte concentrations (*4, 28, 29*). If the stoichiometry value provided by eq 1 for monovalent MORF is fixed at 1.00, pure bimolecular binding of the bivalent MORF must provide a stoichiometry value of 0.50. To eliminate uncertainties related to ligand concentration in this investigation, the monovalent and bivalent MORFs were compared on the same sensor chips (and thus at the same MW_L and R_L) and the stoichimetry of the bivalent MORF is expressed as a ratio of that of the bivalent over the monovalent MORF.

RESULTS

Preparation of Bivalent MORF. To prepare the bivalent MORF, the amine derivatized MORF was dimerizing with disuccinimidyl suberate (DSS) for 2 days in the presence of 1-methyl-2-pyrrolidinone (NMP) and *N*,*N*-diisopropylethylamine (DIEA). The IE HPLC UV profile for the reaction mixture is shown in Figure 2C with peaks at 10.8, 11.8, and 13.9 min that are thought to represent the excess native MORF (shown in Figure 2A), DSS modified but monovalent MORF and the desired bivalent MORF, respectively. To help confirm these identifies, MORF was also reacted with succinic anhydride to give a compound similar to the DSS modified but monovalent MORF especially in the negative charge (Figure 2B). In this way, the remaining peak at 13.9 min was identified as the bivalent MORF (Figure 2D). Changing from alkaline solution to phosphate buffer or water was performed on a PD-10 column. Correct structure of the bivalent MORF was confirmed by MALDI-TOF MS (calculated MW: 12466; found: 12474 ± 8).

Sensorgram Kinetic Analysis. Figure 3 is a composite presenting typical sensorgrams for the monovalent and the bivalent MORFs obtained at 40 nM concentration with cDNA immobilized at 100 RU. The figure shows that the dissociation of bivalent MORF is slower compared to monovalent MORF and almost imperceptible over the 23 min dissociation period, a result of its high binding affinity. To measure more accurately the dissociation rate constant, the binding studies were repeated with a 4 h dissociation period. The measurement was performed for both surface densities of 100 and 500 RU and at seven concentrations of the monovalent and bivalent MORF from 0.5 to 500 nM. The results for different models and fitting method (globally or locally) are reported in Tables 1−3. Table 1 presents a comparison of the results obtained in the analysis of sensograms obtained with the monovalent and bivalent by the simpler 1:1 Langmuir interaction algorithm with global fitting. Table 2 presents analysis of the same data by the 1:1 Langmuir interaction algorithm but with local fitting. Finally Table 3 presents an analysis of only those sensograms obtained with the bivalent MORF using local fitting but with the bivalent algorithm rather than 1:1 Langmuir interaction algorithm. In each case, the χ^2 value is included as a statistical measure of how closely the model fits the experimental data.

As shown in the table, by globally fitting using a 1:1 Langmuir interaction algorithm, the association rate constants are similar for both monovalent and bivalent MORF. However, there is a significant difference in dissociation rate constants providing an equilibrium constants 15−20 times higher for the bivalent MORF at both cDNA densities.

A key step in interpreting the BIAcore results may be the separation of the dissociation rate constants into fast and slow phases since that may provide a method of distinguishing bimolecular binding of the bivalent MORF from monomolecular binding (*30, 31*). In the case of bivalent MORF, monomolecular binding should provide the same dissociation behavior as monovalent MORF while bimolecular binding should show different and slower dissociation kinetics. As described below, by inspection of the dissociation curves, the fast phase was defined as completed by 2 min following the end of the injection while the slow phase continued thereafter. The results are presented in Table 1 as k_d of fast and slow phases.

As shown in Table 2, a more complicated analysis again using the 1:1 Langmuir interaction algorithm but with local fitting has provided a better fit with more reasonable χ^2 usually less than 8. As shown, for the bivalent MORF the highest affinity at the 100 RU density was found in the concentration range of 80−160 nM while at density of 500 RU the highest affinity started at 250 nM.

Table 3 presents the apparent kinetics rate constants of bivalent MORF at different concentrations under condition of 100 RU DNA density and using the bivalent binding model instead of the 1:1 Langmuir interaction algorithm. The bivalent model considers the association and dissociation of the first and second bindings separately. Using a bivalent model to locally fit the sensorgrams of bivalent MORF has generally produced even lower χ^2 values and therefore a superior fit.

Figure 4 A and B presents sensograms of the monovalent and bivalent MORFs at different concentrations and at one cDNA density. Interpretation of the senso-

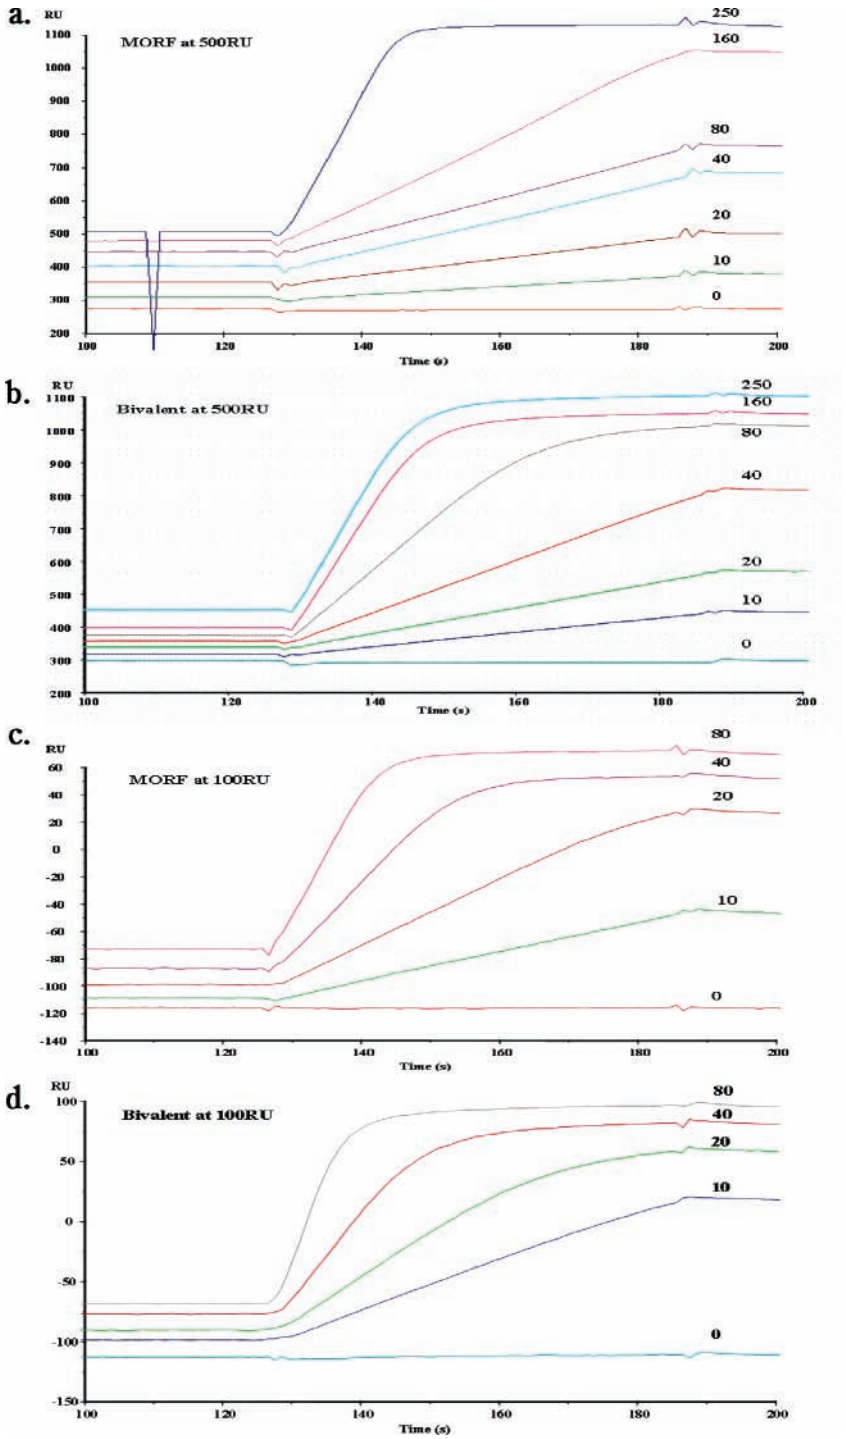

Figure 4. Sensograms at 500 RU cDNA density of the monovalent (panel A) and bivalent MORF (panel B) and at 100 RU cDNA density of the monovalent (panel C) and bivalent MORF (panel D) at the concentrations shown. The MORF concentrations of the bivalent MORF are twice the analyte concentrations. Concentraions are all in nM.

grams involves inspection of the behavior during injection (125 to 185 s). In the absence of saturation, the response will increase linearly throughout the entire period of the injection. In the presence of saturation, the response will level off before the end of the injection. Examples of both may be found in the sensograms of the bivalent MORF (Figure 4B). When injected at concentrations of 40 nM or less, the response increases linearly throughout while at higher concentration, the response becomes horizontal before the end of the injection and does so earlier with increasing concentration. The monovalent MORF clearly reaches a steady response more rapidly than bivalent MORF at this cDNA density and also does so at the lower cDNA density (Figure 4C and 4D). The sensograms may also be inspected for the shape of the curves as saturation approaches. In the case of the monovalent MORF, incapable of bimolecular binding, the sensograms shows a relatively abrupt change from increasing to horizontal response (Figure 4A and 4C). By contrast, the bivalent MORF shows a slower transition as evidence that more complex binding is occurring probably involving both monomolecular and bimolecular binding.

Stoichiometry of Bivalent MORF with Immobilized cDNA. The results of applying eq 1 to the sensograms showed that at both cDNA densities, the ratio of stoichiometry values for the bivalent over the monovalent

MORF is approximately 0.85 at all concentrations. Since this value is between the 1.0 for pure monomolecular binding and 0.5 for pure bimolecular binding, these results imply that the bivalent MORF under all conditions exhibits a mixture of monomolecular and bimolecular binding.

DISCUSSION

In this investigation, SPR was used to study the behavior of a bivalent MORF compared to its monovalent form during hybridization to immobilized cDNA. The bivalent MORF, AA, may bind to one cDNA ligand, L, to form the complex AAL, or it may bridge two ligands to form the complex LAAL. The probability of monomolecular binding (AAL) compared to bimolecular binding (LAAL) will depend on the molecular dimensions of the bivalent analyte and the concentration (spacing) and flexibility of the ligand molecules on the immobilized surface (*32*). Since bimolecular binding may be expected to provide higher hybridization affinities (equilibrium constants) than monomolecular binding, bimolecular binding of bivalent analytes may be expected to be favored under favorable conditions.

By inspection of the sensograms, it is possible to conclude that bimolecular binding of the bivalent MORF was observed in this investigation. The slower dissociation kinetics of the bivalent compared to the monovalent MORF (Figure 3) may be best explained by bimolecular binding of the bivalent MORF leading to slower dissociation. Additional evidence is provided by examination of the dissociation rate in Table 1. As is evident from the Table, the dissociation rate is largely independent of cDNA density in the case of the monovalent MORF but shows a strong dependence on the cDNA density in the case of the bivalent MORF. At the lower cDNA density, monomolecular binding of the bivalent MORF is favored as a result of the larger spacing between cDNAs. The fraction of the bivalent MORF binding bimolecularly may be expected to increase with increasing cDNA density (and therefore decreasing spacing), and therefore the dissociation rate will decrease as shown.

Finally, the sensograms may be inspected for the shape of the association/dissociation phase during injection. At the higher 500 RU cDNA density, saturation (evident by a horizontal response before the end of the injection) required concentrations greater than 40 nM for the bivalent MORF while saturation was not achieved for the monovalent MORF at less than 160 nM. Even considering that the MORF concentration of the bivalent MORF is half that of the monovalent MORF at the same analyte concentration, it is apparent that higher concentrations are required to achieve saturation in the case of the monovalent MORF presumably because the bivalent MORF is capable of bridging cMORFs by bimolecular binding.

Evidence of bimolecular binding is also apparent in the results of applying eq 1 to estimate the stoichometry of binding. Since the response by SPR increases linearly with the molecular weight of the analyte, it should be possible to distinguish between monomolecular and bimolecular binding in the case of the bivalent MORF. Monomolecular binding of the bivalent MORF will provide a response related to its molecular weight that is double that of bimolecular binding for the same number of cDNAs bound. But in the case of bimolecular binding, the response between monovalent and bivalent MORF for the same number of cDNAs will be lower as bivalent MORF bridges two binding sites. This analysis is based on the assumption that the larger bivalent MORF shows no steric hindrance to cDNA binding monomolecularlly compared to the smaller monovalent MORF. There is therefore a different response at the same number of cDNA binding sites for pure bimolecular binding and pure monomolecular binding in the case of bivalent MORF that can be used to estimate the fraction of bivalent MORF that is binding bivalently. To correct for variations in cDNA density and MORF concentrations, the results of stoichiometry analysis have been presented as a ratio. Thus, pure monomolecular binding would results in a stoichiometry value of 1.00 while pure bimolecular binding would results in a value of 0.50. That the results are fairly constant at about 0.79−0.93 regardless of cDNA density or MORF concentration indicates that a substantial and fairly constant fraction of the bivalent binding is bimolecular under all conditions. A value of 0.8 corresponding to the binding of about four bivalent MORF to five cDNAs or only one of four bivalent MORF binding bimolecularily or 25%. In this manner it may be estimated that less than 20% of bivalent MORF was binding bimolecular under the conditions in this study.

Evidence for bimolecular binding may also be apparent from sensorgram analysis using numerical intergration algorithms (BIAevaluation 3.0, BIAcore, Piscataway, NJ). In this investigation, the dissociation curves were analyzed by separately considering a fast and a slow dissociation phase. Dissociation of the bivalent MORF will involve both the dissociation of monomolecular bound bivalent MORF similar to that of the monovalent MORF and the dissociation of biomolecularily bound MORF unique to the bivalent MORF (*30, 31*). In case of the bivalent MORF, monomolecular binding should therefore provide the same dissociation behavior as monovalent MORF while bimolecular binding should show different and slower dissociation kinetics. In this study, the fast phase was defined as completed by 2 min following the end of injection while the slow phase continued thereafter. The k_d values for both phases are reported separately in Table 1 for both monovalent and bivalent MORF. In general, low cDNA density and higher MORF concentrations will not favor bimolecular binding, in the first instance because of the greater spacing between cDNAs and in the latter instance because the cDNAs are more likely to be saturated with MORF bound monomolecularly (see below). As evident in the table, at both cDNA densities, the k_d fast values are similar for monovalent and bivalent MORF (indicating monomolecular binding) while the k_d slow values for the bivalent MORF are significantly smaller ($p = 0.03$) at both densities (indicative of bimolecular binding). Thus, these results suggest that the bivalent MORF is binding bimolecularally at least in part.

The evidence presented above confirms that bimolecular binding was observed. It is then possible to examine the influence of bimolecular binding on the rate and equilibrium constants of hybridization. Bimolecular binding would be expected to result in lower dissociation rate constants and higher equilibrium constants. The results of analyzing the sensograms obtained in this investigation confirm that this is the case. As shown in Table 1, by globally fitting using a 1:1 Langmuir interaction algorithm, an important differences in dissociation rate constants is apparent between monovalent and bivalent MORF providing an equilibrium constant about 15−20 times higher for the bivalent MORF. Reanalysis using local fitting provided separate equilibrium constants for each MORF concentration. As shown in Table 2, in the

case of 500 RU cDNA density, the equilibrium constants for monovalent and bivalent MORFs are similar at concentrations below about 160 nM while at higher concentrations, the equilibrium constant for the bivalent MORF is approximately 2−8 times higher. The results of reanalyzing the data obtained at 100 RU cDNA density also shows similar equilibrium values at concentrations of 80 nM or less and about 9 times higher values for the bivalent MORF at concentrations of 80 and 160 nM. For reasons not understood, the trend reverses at higher concentrations with the monovalent MORF exhibiting higher equilibrium constants than the bivalent. Thus higher equilibrium constants and therefore affinity enhancement only occurred over a particular range of analyte concentrations in our bivalent MORF system instead of at all low concentrations as in other multivalent systems (*30*−*34*). This observation may be due to conformation changes during association of both the long, linear, and flexible cDNA linear ligands and MORF analytes and the complexity of oligomer hybridization itself involving many base pairs.

Table 3 presents the results of reanalyzing the results obtained for the bivalent MORF at each concentration but only at the 100 RU cDNA density. This analysis was capable of calculating separately an apparent first and second association and dissociation rate constants. As shown in the table, the apparent first association rate constant for all concentrations are similar ($(1-7) \times 10^5$ 1/M·s), indicating similar behavior in the first binding step regardless of concentration as is reasonable for consistent monomolecular binding. Furthermore, the first association rate constant is much larger (i.e. more rapid first association) compared to second association rate constant as is reasonable since bimolecular binding requires reorientation. Therefore, high concentrations of bivalent MORF will tend to saturate cDNA sites with monomolecular binding first, reducing the chances for bimolecular binding and therefore reducing the equilibrium constant. This phenomenon may be expected to be more pronounced at lower cDNA concentrations.

It is important to point out that in the sensogram analysis, quantitative evaluation was made difficult by the high cDNA densities required in this investigation to achieve bimolecular binding. These high densities can result in mass transport effects and, furthermore, can complicate the analysis by permitting rebinding during dissociation. In this investigation it was possible to prevent mass transport complications by adjusting the flow rate to be in a range where the response was shown to be flow-rate-independent. However, it was not possible to eliminate rebinding effects, and thus rebinding contributed partially to the resulting kinetic analysis. However, as rebinding would be hindered under conditions of ligand saturation, the fact that bivalent MORF saturated the cDNA at much lower concentrations than monvalent MORF would imply more favorable affinity of bivalent MORF than estimated in this study.

In this investigation, affinity enhancement was observed for the bivalent MORF on chips with cDNA densities as low as 100 RU. The RU unit can be approximately converted to mass of protein in the dextran layer by the relation 1 RU = 1 pg/mm^2 (*35*). With a new SA chip at 10000 RU in strepavidin, there are 10000 pg SA/mm^2 or 1.66×10^{-13} mol SA/mm^2. Using an 18 mer biotin-cDNA (MW ∼ 6K) as the ligand and assuming binding to all four sites of strepavidin, the maximun binding capacity of biotinylated cDNA may be estimated as 4.11 ng cDNA/mm^2 or 6.64×10^{-13} mol cDNA/mm^2 which corresponds to 4000 RU of cDNA. Initially in this study, 100 RU, 500 RU, and 750 RU of cDNA were immobilized which correspond to a 82, 25, and 17 Å distance between two neighboring cDNA. However, at a practical coating density of 750 RU, the effects of mass transport limitation were evident (data not shown), and for this reason only the 100 RU and 500 RU coating densities were used for further studies. It may be surprising that the 82 Å average spacing between cDNAs at 100 RU density did allow bimolecular binding for the bivalent MORF with about 25 Å between two MORF. This could be explained both by the relatively long 17-atom linker by which the cDNA is tethered to the chip via the biotin group and that the MORF itself is about 61 Å long. The bivalent MORF may be expected to have a large access range.

CONCLUSION

A synthesis of bivalent MORF has been described. The bivalent MORF exhibited significant enhanced affinity compared to monovalent MORF as demonstrated by BIAcore measurements. These results suggest that bivalency may be superior to monovalency in MORF pretargeting applications. Studies using less flexible ligand immobilization, lower coating density, and bivalent MORF with different length of linker will be necessary to optimize the influence of affinity enhancement of bivalent MORFs in pretargeting applications.

ACKNOWLEDGMENT

Financial support for this investigation was provided, in part, by the National Institutes of Health (CA79507 and CA 94994). The authors are grateful to Dr. Yongfu Li of Gene-Tools, Inc. (Corvallis, OR) for advice on the MORF purification.

An Anti-MUC1 Antibody–Calicheamicin Conjugate for Treatment of Solid Tumors. Choice of Linker and Overcoming Drug Resistance

Philip R. Hamann,* Lois M. Hinman, Carl F. Beyer, Lee M. Greenberger, Clara Lin, Delores Lindh, Ana T. Menendez, Rosalyn Wallace, Frederick E. Durr, and Janis Upeslacis

Wyeth Research, 401 N. Middletown Road, Pearl River, New York 10965. Received August 26, 2004; Revised Manuscript Received December 3, 2004

The anti-MUC1 antibody, CTM01, has been chosen to target the potently cytotoxic calicheamicin antitumor antibiotics to solid tumors of epithelial origin that express this antigen. Earlier calicheamicin conjugates relied on the attachment of a hydrazide derivative to the oxidized carbohydrates that occur naturally on antibodies. This produced a "carbohydrate conjugate" capable of releasing active drug by hydrolysis in the lysosomes where the pH is low. Conjugates have now been made that are formed by reacting a calicheamicin derivative containing an activated ester with the lysines of antibodies. This gives an "amide conjugate" that is stable to hydrolysis, leaving the disulfide that is present in all calicheamicin conjugates as the only likely site of drug release from the conjugate. As previously shown for the carbohydrate conjugate, this amide conjugate of CTM01 produces complete regressions of xenograft tumors at doses of 300 μg/kg (calicheamicin equivalents) given three times. This indicates that hydrolytic drug release is not necessary for potent, selective cytotoxicity for calicheamicin conjugates of CTM01. Although the unconjugated calicheamicins are in general less active in cells expressing the multidrug resistance phenotype, both in vitro and in vivo results of studies reported here suggest that the efficacy of the calicheamicins toward such tumors is unexpectedly enhanced by antibody conjugation, especially for the "amide conjugate". These hydrolytically stable conjugates are also active toward cisplatin-resistant ovarian carcinoma cells as well. Such studies indicate that the calicheamicin amide conjugate of CTM01 may have potential for the treatment of MUC1-positive solid tumors, including some types of resistant tumors.

INTRODUCTION

The calicheamicins are highly potent antitumor antibiotics of the enediyne family. Originally isolated from a broth extract of the soil microorganism *M. echinospora* ssp. *calichensis*, they were detected in a screen for potent DNA damaging agents (*1*). The parent of this family of xenobiotics, calicheamicin γ_1^I (**1**, Figure 1), associates with the minor groove of DNA and, following reduction with glutathione (*2*), causes sequence-specific, double-stranded DNA cleavage (*3*, *4*). Due to their mode of action and potency, several analogues of the calicheamicins have been tested in preclinical models as potential antitumor agents. Their development as single agent therapies has not been pursued because of delayed toxicity that limits the therapeutic dose range for treatment. However, their potency makes them appealing candidates for antibody-targeted chemotherapy, where limits in antigen expression make the potency of the cytotoxic agent crucial (*5*–*9*). Even when antigen expression appears to be high enough to allow for the use of less potent agents in animal models (*10*), clinical success has not yet been achieved.

The murine monoclonal antibody CTM01, also known as CT-M-01 or 7F11C7 (*11*), is an internalizing IgG_1 that recognizes the MUC1 antigen present on a broad spectrum of solid tumors of epithelial origin. The MUC1 antigen is a glycoprotein that is expressed on the nonvascular surface of normal epithelial cells, where it is normally inaccessible from circulation. It is present in under-glycosylated form on the nonvascular as well as the vascular surface of a number of epithelial cancer cells, such as breast, lung, ovarian, and colon carcinomas, thereby making it accessible for targeting. This antigen undergoes cycling between the surface and the interior of the cell and carries any bound antibody with it into the cell (*11*). Our results with CTM01 as well as numerous other antibodies suggest that they must be internalized to make effective targeting agents for the calicheamicins (*12*, *13*). CTM01 was selected after comparison of this antibody with a panel of anti-MUC1 monoclonal antibodies (*14*). Successful targeting to tumors in human subjects has been demonstrated (*15*).

The activity of a series of calicheamicin analogues conjugated to CTM01 has previously been described (*16*, *17*). From these studies, the feasibility of conjugating calicheamicin to oxidized carbohydrates on antibodies was established. Using these carbohydrate conjugates, the correlation between the potency of structural analogues of the calicheamicins and their therapeutic potential as conjugates was investigated. Linker variations were also examined in an effort to optimize the therapeutic window for such conjugates. From these studies, NAc-gamma calicheamicin DMH[1] (***3***, Figure 1), which contains a modified aminosugar residue and a disulfide

that is sterically hindered by two methyl groups, was chosen as the optimal drug for conjugation.

The carbohydrate conjugate of the anti-CD33 antibody, P67.6, was previously shown to be more efficacious than the corresponding amide conjugate (*18*), presumable due to the need for hydrolytic release of the calicheamicin from the antibody in the acidic lysosomes. In this report, the carbohydrate and amide conjugates of the CTM01 antibody are compared against a variety of tumors of epithelial origin. In contrast to the results with P67.6, both of these classes of conjugates exhibit potent, selective cytotoxicity. However, the amide conjugates show enhanced activity against tumors expressing multidrug resistance (MDR). These studies suggest the hypothesis that attaching a cytotoxic agent, such as calicheamicin, by way of a serum stable linker to an internalizing carrier protein may help to bypass normal membrane-based mechanisms of drug resistance. There is precedence for this with other types of conjugates (*19*), although further research with various drugs and antibodies would be required to adequately define this possibility. Good activity versus a cisplatin-resistant ovarian carcinoma line is also demonstrated.

The amide conjugate selected has been in clinical trials for ovarian cancer (*20*−*22*) as well as lung cancer (unpublished) with only limited evidence of activity. This is in contrast to gemtuzumab ozogamicin (Mylotarg) (*23*), which is an anti-CD33 calicheamicin conjugate approved for AML. The differences that may be responsible for the lesser activity include the presence of circulating antigen (*24*), possible detrimental effects of the predose of native antibody given in an attempt to clear the circulating antigen (*25*), differences in the linkers used (*18*), possible differences in resistance mechanisms (*26*), possible insufficient targeting of the conjugate to large solid tumors, etc. It is also possible that choosing a different tumor type, dosing patient after surgical removal of the primary tumor, or use in combination would show activity. Ongoing efforts may help to clarify these issues. Preclinical data on two more calicheamicin−antibody conjugates have recently been reported (*12*, *13*). Clinical experience with these two conjugates will also expand our understanding of the important issues that need to be addressed in order to make successful chemoimmunoconjugates.

EXPERIMENTAL PROCEDURES

Monoclonal Antibodies. CTM01 is a murine IgG_1 that recognizes the MUC1 (PEM) antigen (*11*). CTM01 was produced and purified from tissue culture supernatants by Celltech. MOPC-21 is a secreted murine myeloma IgG_1 that does not bind to any known antigen (*27*) and was also produced and purified from tissue culture supernatants by Celltech. Lym-1 is a murine IgG_1 reactive with human B-lymphocytes (*28*) and was produced and purified from tissue culture supernatants by Techniclone. These last two antibodies were used as controls.

The radioimmunoassay used for the determination of the immunoreactivity of the conjugates has been described previously (*16*), and involves competition with ^{125}I-labeled CTM01.

Antibody Conjugates. The synthesis of the carbohydrate conjugates (**4**) of NAc-gamma calicheamicin DMH have been reported previously (*16*). Drug loadings of 2 to 3 mol of calicheamicin per mole of antibody were seen and free calicheamicin (predominantly structure **3**) was normally 1−3%.

The procedures for the synthesis of amide conjugates (**7**) have also been published (*18*). Drug loadings of 2 to 3 mol of calicheamicin per mole of antibody were seen and free calicheamicin (predominantly structure **5**) was normally 0.5−1%.

All conjugates were characterized as monomeric by analytical gel-exclusion chromatography (aggregate < 3%) and loading was determined by the ratio of UV absorption at 280 nm (protein) and 333 nm (calicheamicin) as reported (*16*, *18*). Neither conjugation procedure significantly affected the immunoaffinity of the conjugates reported in this paper versus the starting native antibodies, as determined by competitive binding with antibody that had been radiolabeled with ^{125}I-Bolton−Hunter reagent, as detailed below.

Cells and Culture Methods. A549 is a NSC lung carcinoma, ATCC# CCL 185. Raji is a Burkitt's lymphoma cell line, ATCC# CCL 86. OVCAR-3 is an ovarian carcinoma line, ATCC# HTB161. A2780 is an ovarian carcinoma. A2780DDP was derived from A2780 by exposure to cisplatin (*29*) and was a gift from K. L. Scanlon. Lu-78 is a lung carcinoma (*30*). MX-1 is a breast carcinoma line obtained from the NCI. MX-1E was derived from the MX-1 breast carcinoma by exposure to

progressively higher concentrations of gamma calicheamicin and has elevated levels of Pgp. KB8.5 is an MDR cell line derived from the KB oral epidermoid carcinoma (ATCC# CCL17) and was a gift from Drs. Pastan and Gottesman at the NCI. SW620 is a colon carcinoma. SW620R was derived from SW620 by incubation with 20 ng/mL of adriamycin. S1 B1-20 cells were derived from a subclone of LS174T, designated S1, by selection in the presence of bisantrene. The methods used for cell culture have been described previously (*16*).

Photoaffinity assays were performed to determine the tendency of calicheamicin to bind to p-glycoprotein (Table 3.) One hundred micrograms of enriched plasma membranes from S1 of S1-B1-20 cells was incubated in 4 nM IAAP (^{125}I-iodoarylazidoprazosin, 2200 Ci/mmol; DuPont-NEN) with or without test agent as previously described (*31*). S1-B1-20 cells overexpress Pgp and have the MDR phenotype. After 1 h incubation at 25 °C and UV irradiation (5 min, 4 °C), material was solubilized in Laemmli sample buffer and resolved on SDS−PAGE. Gels were dried and subjected to autoradiography. Radioactive bands that contained IAAP bound to Pgp were identified, cut from the gel, and counted in a gamma counter. Binding of calicheamicin to Pgp caused an inhibition of this binding and, hence, lowered the amount of radioactivity associated with the Pgp.

In Vitro Cytotoxicity Assays. Two different assays were used to evaluate cytotoxicity in cell culture: a 1-h limited exposure to treatment and continuous exposure. For both assays, concentrations of the test substances were all normalized to equivalents of calicheamicin (NAc-gamma DMH or NAc-gamma DMA, both 1478 Da) and a medium control was included. All samples were run in triplicate. For the 1-h assay, viable cells (10^5/0.2 mL) were aliquoted into 15 mL test tubes which contained 0.2 mL of the sample to be tested at the appropriate concentration. Tubes were vortexed and incubated at 37 °C. The pellets were washed twice after 1 h with 8 mL of medium and 1 mL of medium was added to each pellet. The cells were then vortexed and 0.2 mL of suspended cells was removed and placed in a well of a 96-well plate (2×10^4 cells). For the continuous assay, triplicate 0.1 mL aliquots of cell suspension were added to microtiter wells already containing 0.1 mL aliquots of sample. For both assays, the cells were incubated for 3 days, at which time 0.1 mL of supernatant was removed and replaced with 0.2 μCi of [^{3}H]thymidine in 0.1 mL of fresh medium. Incubation was resumed for an additional 24 h at which point the cells were harvested and counted. Growth inhibition curves of each drug or conjugate were plotted and the IC_{50} value (concentration of drug equivalents needed for 50% [^{3}H]thymidine uptake inhibition) of each sample was determined.

In Vivo Tests for Antitumor Activity. The cell lines were passaged as ascites tumors in athymic mice or in tissue culture, and, for each experiment, 8×10^6 cells were routinely implanted subcutaneously. Tumors were allowed to become established for 4 days or longer to achieve a size of 50−300 mg prior to dosing ip at the indicated doses on days 1, 5, and 9 after staging. There were five or six mice per test group and 10 in the buffer-treated control group. Tumor mass was determined by measuring the tumor length and width once weekly for at least 28 days post tumor staging. Antitumor activity was defined by the ratio of tumor size of the treated animals and those of the controls (T/C). An agent was considered active if it had a sustained T/C of at least 58% with greater than 65% survivors. A therapeutic ratio (TR) was defined as the maximum tolerated dose/minimum effective dose (MTD/MED) and used as a measure of the therapeutic window for the conjugates or drugs tested.

RESULTS

Carbohydrate and Amide Conjugates of CTM01. Calicheamicin was conjugated to CTM01 by two methods. One method involved oxidizing the naturally occurring carbohydrates of the antibody and reacting the resultant aldehydes with a calicheamicin derivative referred to as NAc-gamma calicheamicin DMH (**3**). (See Figure 1 for structures.) This method gave a "carbohydrate conjugate" containing a hydrazone bond that is hydrolytically labile, especially at the low pH found in lysosomes (*32*, *33*). The second method involved reacting the ϵ-amino groups of lysines on the antibody with a calicheamicin derivative referred to as NAc-gamma calicheamicin DMA, OSu ester (**6**). This method gave an "amide conjugate" which does not have a bond that is hydrolytically labile under physiological conditions. Both of these conjugates contain a disulfide bond that can react with glutathione (or other cellular thiol) to release the calicheamicin from the antibody.

Comparative in Vitro Activity. Previous work showed that carbohydrate conjugates of calicheamicin and CTM01 (**4**) are potently and selectively cytotoxic toward MUC1-expressing cell lines in tissue culture (*16*). Table 1 shows representative data for a comparison of that conjugate with the amide conjugate. Both these conjugates, as well as unconjugated NAc-gamma calicheamicin (**2**), were incubated with either the antigen-positive MX-1 line or the antigen negative Raji cell line for either 1 h or continuously as indicated. Cytotoxicity of the two conjugates and an unconjugated calicheamicin derivative is compared using IC_{50}s expressed in equivalents of calicheamicin (NAc-gamma calicheamicin DMH, ***3***).

With a 1-h drug exposure period, the conjugates are 5 to 12-fold more cytotoxic toward the antigen expressing MX-1 cells than NAc-gamma calicheamicin (**2**) and at least 100-fold less cytotoxic than compound **2** toward the antigen negative Raji cells. Each of the conjugates, therefore, shows about 1000-fold selectivity for the target

Table 2. In Vitro Selectivity of the CTM01 Amide Conjugate versus a Conjugate of a Nonbinding Control Antibody

[a] Selectivity = IC_{50}(MOPC-21 conjugate) ÷ IC_{50}(CTM01 conjugate).

versus nontarget lines when corrected for the difference in drug sensitivity. With continuous exposure (four-day), the amide conjugate retains this selectivity, although all the IC_{50}s are shifted to far lower values. However, the carbohydrate conjugate loses much of its selectivity due to increased activity on the antigen negative line, presumably due to extracellular hydrolytic release of the calicheamicin derivative in the medium. Some selectivity is still retained if the difference in sensitivity of the two cell lines with respect to NAc-gamma calicheamicin (**2**) is considered.

Comparative in Vitro Activity. In vitro specificity of the CTM01 carbohydrate conjugate with respect to a nonbinding control conjugate has previously been demonstrated (16). The selectivity of the CTM01 amide conjugate was likewise confirmed in a series of experiments in which it was compared with an isotype-matched amide conjugate, prepared with the nontargeting antibody MOPC-21. In vitro cytotoxicity comparisons of the CTMO1 and MOPC-21 amide conjugates and NAc-gamma calicheamicin (**2**) were made in a number of different MUC1-expressing cell lines. MUC1 expression was determined by the ability of the cells to selectively bind radiolabeled CTM01. As shown in Table 2, both the A2780DDP line as well as the ZR-75-1 line show selectivity comparable to that seen previously with CTM01 carbohydrate conjugates.

Comparative in Vivo Activity. Previous work has shown that carbohydrate conjugates of CTM01 were active in multiple xenograft tumor models with long-term, tumor-free survivors being common (*16*). Significant growth inhibition of many MUC1 expressing tumors was also seen with the CTM01 amide conjugate, also with long-term, tumor-free survivors. In the experiment shown in Figure 2, treatment of athymic mice bearing 50 mg subcutaneous tumors with the CTM01 amide conjugate produced dose-dependent growth inhibition of a non small cell lung tumor, Lu-78. The CTM01 amide conjugate was active over a 6-fold dose range and produced complete regressions of the tumor in 10 of 12 animals treated at the two highest doses of 200 and 300 μg/kg given three times. In contrast, a comparable conjugate prepared with the nonbinding MOPC-21 antibody failed to produce sustained inhibition of the tumor growth at the maximum tolerated dose of 300 μg/kg. NAc-gamma calicheamicin (**2**) was included in this test as a control and was lethal at doses greater than 25 μg/kg and produced no sustained responses at nonlethal doses. Similar results were obtained for all treatments in a repeat experiment with tumors that were approximately 300 mg in size at dosing (data not shown).

Pronounced antitumor effects have been observed with both the CTM01 carbohydrate and amide conjugates in additional MUC1-expressing xenograft tumors, including two ovarian carcinomas, OVCAR-3 and A2780 (data not shown). These conjugates were active against these

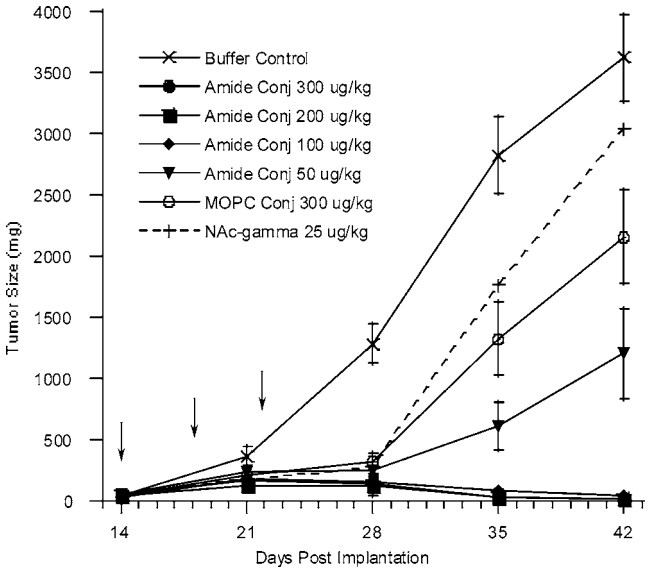

Figure 2. Time-course of the response of Lu-78 xenograft tumors to the CTM01 amide conjugate (**7**), to a similar control conjugate (**7**) made with the nonbinding MOPC-21 antibody, and to treatment with a representative calicheamicin derivative alone. Athymic mice were implanted sc with Lu-78 cells and then dosed when tumors were approximately 50 mg in size. The doses indicated were given on days 14, 18, and 22, as indicated by the arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. There were no deaths in any group, except for one with NAc-gamma calicheamicin. Error bars are SEMs and were omitted for NAc-gamma calicheamicin (dosed at the MTD) for clarity.

subcutaneous tumors in nude mice over a 4- to 6-fold dose range, expressed in terms of drug equivalents, with an MED of 50 μg/kg/dose × 3 doses and an MTD of >300 μg/kg × 3. As with the Lu-78 study shown in Figure 2, the top nonlethal dose of NAc-gamma calicheamicin (**2**) was lower than the MED for the conjugate and at that dose no sustained antitumor effects were seen with this or other unconjugated calicheamicin derivatives.

Figure 3 shows a comparison between an amide and carbohydrate conjugate of CTM01 on the more difficult to treat nonsmall cell lung carcinoma A549 where the carbohydrate conjugate showed somewhat reduced antitumor effects at lower doses and thus was effective over only a two to 3-fold dose range, instead of the four to 6-fold range seen with the amide conjugates.

In Vitro MDR Results. Screening of the calicheamicin family in vitro indicated that these compounds can serve as substrates for Pgp and thus might be less active against tumors expressing the MDR phenotype. Table 3 shows the results of photoaffinity labeling experiments with Pgp comparing calicheamicin with the known substrate vincristine. A 50-, 500-, and 5000-fold excess of gamma calicheamicin effectively inhibited the photoaffinity labeling of Pgp with 4 nM [^{125}I]-iodophenylazidoprazosin. These data indicate that calicheamicin binds to Pgp nearly as well as vinblastine.

Because of the assumed detrimental consequences of MDR on the clinical use of calicheamicin conjugates, the CTM01 amide conjugate has been compared in tissue culture against a parental cell line and a subclone expressing Pgp. In Table 4, the cytotoxicity of NAc-gamma calicheamicin (**2**) toward the antigen-expressing tumor line, SW620, and its adriamycin-resistant subclone, SW620R, are compared. The MDR ratio as defined in the table is a measure of the reversal of resistance quinidine exhibits on the SW620R cell line corrected for the effects of quinidine on the SW602 parental line. A

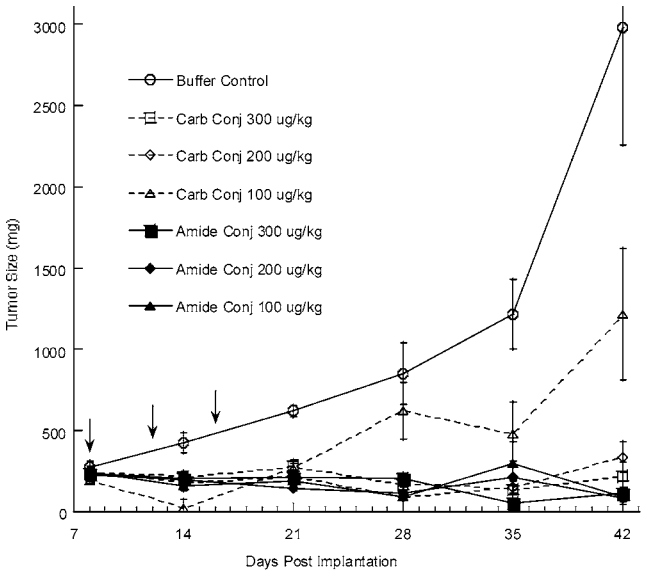

Figure 3. Response of A549 xenograft tumors to the CTM01 amide (**7**) and carbohydrate (**4**) conjugates. Athymic mice were implanted sc with A549 cells and then dosed when tumors were approximately 250 mg in size. The doses indicated were given on days 8, 12, and 16, as indicated by the arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs.

Table 3. Photoaffinity Labeling of Pgp in the Presence of Gamma Calicheamicin

drug	concn (μM)	vs control, %	±SE[a]	no. exp.
vinblastine	0.2	27	±16	2
	2.0	3.8	±1.7	6
	20	1.8	±1.6	8
gamma calicheamicin (**1**)	0.2	43		1
	2.0	12.3	±5.2	4
	20	1.9	±1.6	2

Table 4. In Vitro Cytotoxicity of the CTM01 Amide Conjugate and a Nonbinding Control Conjugate versus Adriamycin-Resistant Cells

	IC_{50}, ng/mL cal equiv				
	SW620		SW620R		
sample	−Q[a]	+Q[a]	−Q[a]	+Q[a]	ratio[b]
NAc-gamma calicheamicin (**2**)	0.7	0.18	64.5	2.9	5.7
CTM01 amide conjugate (**7**)	1.0	0.25	3.6	0.6	1.5
Lym-1 amide conjugate (**7**)[c]	294	91.0	>500	401	>0.4

[a] −Q, +Q = without or with 1.2 μg/mL quinidine added. [b] Ratio = IC50(−Q, SW620R)/IC_{50}(+Q, SW620R)/IC_{50}(−Q, SW620)/IC_{50}(+Q, SW620). [c] Nonbinding control conjugate.

high ratio results from a large shift in the IC_{50} relative to that seen in the parental line and implies a high degree of MDR resistance, while a ratio of one would imply no resistance, as far as quinidine at this concentration is able to reverse it. The higher ratio for NAc-gamma calicheamicin confirms the role of Pgp in the SW620R cell lines. The much lower ratio for the CTM01 amide conjugate indicates that MDR is significantly less important for this conjugate.

In Vivo MDR Results. The human epidermoid xenograft tumor, KB8.5, has the MDR phenotype (*34*) and also expresses the MUC1 antigen. In the study described in Figure 4, a comparison was made of the carbohydrate and amide conjugates of CTM01 over a 6-fold dose range. In this study, NAc-gamma calicheamicin DMH (**3**) and

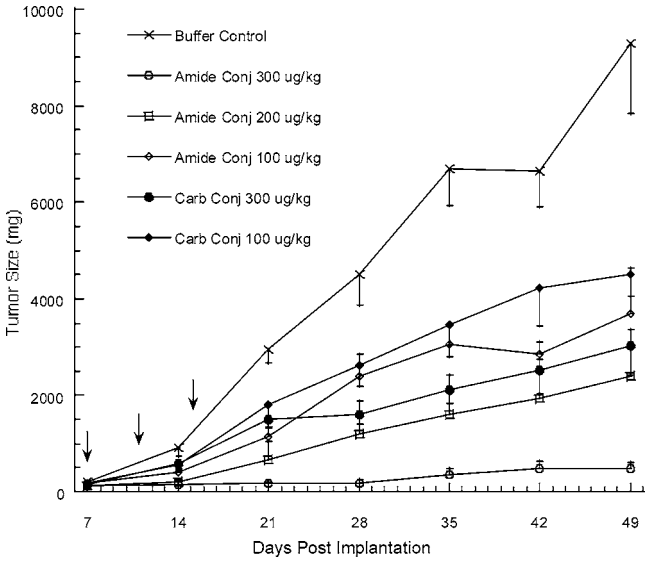

Figure 4. Response of MDR-resistant KB8.5 xenograft tumors to the CTM01 amide (**7**) and carbohydrate (**4**) conjugates. Athymic mice were implanted sc with KB8.5 cells and then dosed when tumors were approximately 200 mg in size. The doses indicated were given on days 7, 11, and 15, as indicated by the arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs and are given in the negative direction for buffer and the carbohydrate conjugate and in the positive direction for the amide conjugate. (The 200 μg/kg dosing group for the carbohydrate conjugate was omitted due to unusually large variability in that group.)

NAc-gamma calicheamicin DMA (**5**) were included as controls (data not shown). At the maximum tolerated doses of 200 μg/kg given three times, NAc-gamma calicheamicin DMA was completely ineffective while NAc-gamma calicheamicin DMH showed only marginally significant activity. The CTM01 amide conjugate showed pronounced activity over a 4-fold dose range of 100 to 400 μg/kg with two deaths seen in the 400 μg/kg treatment group (not plotted) and with no deaths at lower doses. In contrast, the carbohydrate conjugate was uniformly toxic at the 400 μg/kg dose (not plotted) and showed more modest activity at the 100 and 300 μg/kg doses.

In Vivo Platinum Resistance. The choice between the CTM01 amide and carbohydrate conjugates has also been examined with respect to the potential cross resistance to cisplatin-resistant tumors using the ovarian carcinoma line A2780 and its cisplatin-resistant subclone A2780DDP. Selective in vitro activity against the cisplatin-resistant line was shown in Table 2. Both the CTM01 amide and carbohydrate conjugates gave long-term tumor-free survivors in xenograft experiments with the parental A2780 ovarian line at the maximum tolerated dose and also at 50% of the usual maximum tolerated dose (data not shown). Although these conjugates are less effective against the cisplatin-resistant A2780DDP line, the amide conjugate was still significantly active over a 6-fold dose range of 50 to 300 μg/kg and produced dose-dependent inhibition of the tumor growth (Figure 5). In comparison with the CTM01 amide conjugate, the CTM01 carbohydrate conjugate caused more deaths at the 300 μg/kg dose (three deaths out of six animals versus none), was equally effective at the 150 μg/kg dose, and was somewhat less effective at the 50 μg/kg dose.

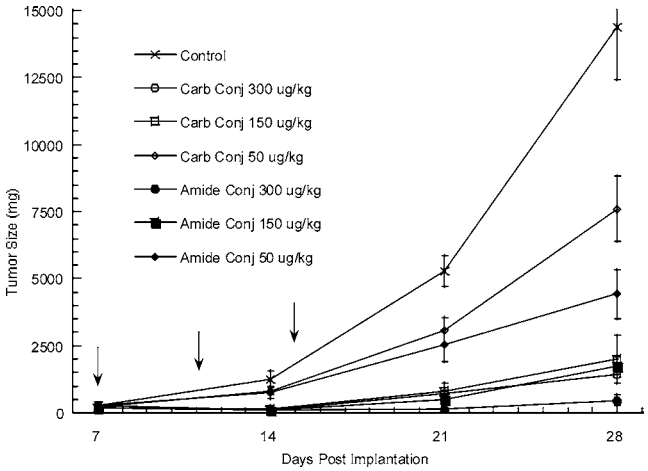

Figure 5. Response of cisplatin-resistant A2780DDP xenograft tumors to the CTM01 amide (**7**) and carbohydrate (**4**) conjugates. Athymic mice were implanted sc with A2780DDP cells and then dosed when tumors were approximately 250 mg in size. The doses indicated were given on days 7, 11, and 15, as indicated by the arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs.

DISCUSSION

The MUC1 antigen is a glycoprotein that is expressed on the nonvascular surface of normal epithelial cells, where it is normally inaccessible from circulation. It is also present in under-glycosylated form on the nonvascular as well as the vascular surface of a number of epithelial cancer cells, such as breast, non small cell lung, ovarian, and colon carcinomas. Successful targeting of the CTM01 antibody to tumor sites in human subjects has been demonstrated (*15*). MUC1 undergoes cycling between the surface and the interior of the cell (*11*) and carries the bound CTM01 with it into the cell. Our results with CTM01 as well as with a number of other antibodies suggest that drug conjugates must be internalized to be effective targeting agents.

Our previous reports on conjugates prepared with CTM01 concerned carbohydrate conjugates which were designed to release the drug in the acidic lysosomes by acid-catalyzed hydrolysis. The amide conjugates described herein have equivalent activity to that of the carbohydrate conjugates in many in vitro and in vivo test systems (e.g., Figures 2 and 3). These data show that the hydrolytic release inherent in the carbohydrate conjugates offers no known advantage for calicheamicin conjugates of CTM01. This stands in marked contrast to calicheamicin conjugates of another antibody, the anti-CD33 P67.6, which require hydrolytic release of the drug for optimum activity (*35*).

The mode of release for the amide conjugates is presumed to be disulfide exchange with reduced glutathione (*2*), which is at 100-fold higher concentrations inside most cells than in circulation (*36, 37*). This disulfide exchange is closely tied to the triggering of the calicheamicins that is required for the double-stranded DNA cleavage (*2*). Unfortunately, the potency of the calicheamicins and the consequential low concentrations of drug in cells required to produce cytotoxicity has precluded attempts to determine the site or rate of release of any calicheamicin derivatives from the CTM01 conjugates in cellular systems.

Although the CTM01 amide conjugate is in many cases equivalent to the carbohydrate conjugate, there are circumstances where the amide conjugate is superior. The in vitro data from Table 1 clearly shows that when cells are exposed to the carbohydrate conjugate for extended periods of time, there is an erosion of the selectivity, presumably due to the slow, extracellular, hydrolytic release of the cytotoxic calicheamicin derivative. This is consistent with the somewhat increased toxicity of the CTM01 carbohydrate conjugate over that of the CTM01 amide conjugate in numerous xenograft experiments as well as in preclinical toxicology assessments (data not included). Similar observations were made in earlier work that showed that increasing the stability of the disulfide decreased the toxicity of the conjugates (*17*). The toxicity seen with the less stable disulfides is presumed to be due to premature reductive release of a cytotoxic calicheamicin derivative in circulation.

The CTM01 amide conjugate also retains its selectivity in vitro when compared with a nonbinding control conjugate. This is shown in Table 2 for the nonbinding MOPC-21 antibody versus two different cell lines.

An important issue in the development of a potential therapy for solid tumors is the effect of resistance that might inherently exist or may have developed to previous chemotherapies. It is clear from the binding data in Table 3 that the calicheamicins are recognized by Pgp. The data in Table 4 further shows that cells which display the MDR phenotype are cross-resistant to calicheamicin, and that this resistance is reversed by standard reversal agents, such as quinidine. It has also been shown that incubating the MX-1 cell line with sublethal concentrations of gamma calicheamicin created a resistant subclone, MX-1E, that overexpressed Pgp. These MX-1E cells were cross-resistant to vincristine and adriamycin.

As shown in Figure 4, Pgp-mediated resistance is another circumstance where the amide conjugate is superior to the carbohydrate conjugate. The KB8.5 tumor line has an 8.5-fold increase in Pgp expression (*38*). These data, together with the in vitro studies described above, support the conclusion that a significant increase in sensitivity to the calicheamicins is achieved in resistant cells by conjugation of the drug to an internalizing antibody, especially through a stable amide linker.

Due to the presumed importance of glutathione in the chemistry of calicheamicin and its conjugates, it was of interest to examine cisplatin-resistant cell lines, where glutathione levels tend to be increased (*39*). Preliminary data suggest that the higher intracellular levels of glutathione may actually promote cleavage of the disulfide bond in calicheamicin conjugates and activate the drug. This may partly explain why the CTM01 amide conjugate is quite active against the A2780DDP cell line in vivo as shown in Figure 5. This is in spite of the fact that the calicheamicins are DNA active agents and that the A2780DDP cell line tends to be resistant to most DNA-damaging agents, in part due to a 2-fold increase in intracellular glutathione levels (*40*, *41*).

For the antibody P67.6, a site of hydrolytic release was necessary and the corresponding amide conjugate had much lower selectivity and potency (*18*). This is in stark contrast to the results in this report. An explanation of these somewhat contradictory results will require detailed studies on the mechanism of antibody processing for both antibodies in their respective target cell lines. One possibility that might be speculated is that the carbohydrate conjugates release the calicheamicin closer to the surface, allowing for easier access to the Pgp pump, while the amide conjugates may undergo the release of the calicheamicin at an unknown site closer to the DNA than the cell surface, thereby avoiding the Pgp pump to some extent. Another possibility is that the derivatives

released from the carbohydrate conjugates, NAc-gamma calicheamicin DMH, may simply be pumped better than the unknown derivative or derivatives released from the amide conjugate. However, the most important conclusion from the P67.6 and CTM01 calicheamicin conjugates is that one optimal design of conjugate does not exist for all antibodies. Each antibody must be examined separately, and a variety of different types of conjugates must be tried in order to individually optimize a specific delivery system.

In the case of P67.6, the incorporation of a site of hydrolytic release was crucial for the success of the conjugate. This site helped make the conjugate a potent and selective agent targeted toward CD33 positive cells in cell culture, xenograft experiments, and ex vivo models of AML. Subsequent optimization of the design of a hydrolytically labile linker resulted in the "hybrid" linker found in the approved antibody targeted chemotherapeutic agent gemtuzumab ozogamicin (Mylotarg) for use in AML (*42*, *43*). In contrast, the amide conjugate of CTM01 is every bit as potent and selective as the CTM01 carbohydrate conjugate against many tumor lines both in vitro and in vivo. However, the amide conjugate more successfully overcomes MDR resistance in a xenograft model of a cell line that overexpresses Pgp. There is precedence for overcoming MDR resistance by intracellular delivery of cytotoxic agents with the delivery of doxorubicin via folate-targeted liposomes (*44*). In addition, the amide conjugate of CTM01 is effective against a cisplatin-resistant cell line.

In conclusion, the calicheamicin conjugates, especially the "amide conjugate", show significant promise for targeted delivery. Through the process of antibody conjugation, a potent cytotoxic agent can be converted into an effective antitumor agent, with a significant therapeutic window for treating solid tumors in preclinical models. A conjugate made with a genetically engineered human version of CTM01 has been in clinical trials (*20*, *21*) (see the Introduction for discussion) and is the subject of another report (*45*).

ACKNOWLEDGMENT

We thank George Ellestad and May Lee for helpful discussions about calicheamicin chemistry. We are also grateful to Lucy Colina for her help with the biological testing of the conjugates and to Martha Godwin and J. Philip James for their assistance in conjugate preparation and purification.

Murine CTM01 is an internalizing murine IgG_1 monoclonal antibody that recognizes the MUC1 antigen expressed on many solid tumors of epithelial origin. Calicheamicin conjugates of this antibody have previously been shown to be potent, selective antitumor agents in preclinical models. A conjugate has now been made with a genetically engineered human version of this antibody, hCTM01. The hCTM01 is an IgG_4 isotype, has an immunoaffinity approximately 30% higher than mCTM01 by competitive RIA, and is efficiently internalized into target cells. The hCTM01−NAc-gamma calicheamicin DM amide conjugate, referred to as CMB-401, shows targeted killing of MUC1-expressing cells in vitro and produces pronounced dose-related antitumor effects over an 8-fold dose range against a MUC1-expressing, ovarian xenograft tumor, OvCar-3. The specificity of CMB-401 was confirmed by comparing its antitumor effects with those of an isotype-matched nonspecific conjugate against the MX-1 breast carcinoma. CMB-401, given either ip or iv, was highly active in these models in single and multiple dose regimens and gave complete regressions at the highest doses examined with good overall therapeutic ratios. CMB-401 also gave good antitumor effects at similar doses with a cisplatin-resistant MUC1-expressing cell line.

INTRODUCTION

The calicheamicins are highly potent antitumor antibiotics of the enediyne family. Originally isolated from a broth extract of the soil microorganism *M. echinospora* ssp. *calichensis*, the calicheamicins were detected in a screen for potent DNA damaging agents (*1*). The parent of this family of xenobiotics, calicheamicin γ_1^I (**1**, Figure 1), associates with the minor groove of DNA and, following reduction with glutathione (*2*), causes sequence-specific, double-stranded DNA cleavage (*3*, *4*). Due to their mode of action and potency, several analogues of the calicheamicins have been tested in preclinical models for their usefulness as antitumor agents. Their development as single agent therapies has not been pursued because of delayed toxicities that limit the therapeutic dose range for treatment. However, their potency makes them appealing candidates for antibody-targeted chemotherapy, where limits in antigen expression make the potency of the cytotoxic agent crucial.

The murine monoclonal antibody CTM01, also known as CT-M-01 or 7F11C7 (*5*), is an internalizing IgG_1 that recognizes the MUC1 antigen present on a broad spectrum of solid tumors of epithelial origin. The MUC1 antigen is a glycoprotein that is expressed on the nonvascular surface of normal epithelial cells, where it is normally inaccessible from circulation. It is present in underglycosylated form on the nonvascular as well as the vascular surface of a number of epithelial cancer cells, such as breast, lung, ovarian, and colon carcinomas, thereby making it accessible for targeting. This antigen undergoes cycling between the surface and the interior of the cell (*5*) and carries any bound antibody with it into the cell. Our results with CTM01 as well as numerous other antibodies suggest that they must be internalized to make effective targeting agents for potent drugs such as the calicheamicins (*6*, *7*). CTM01 was selected for development after comparison of this antibody with a panel of anti-MUC1 monoclonal antibodies (*8*). Successful targeting of this antibody to tumors in humans has been demonstrated (*9*).

A series of conjugates of the calicheamicins and mCTM01 have previously been described (*10*, *11*). Initial examination of the structural requirement for the calicheamicin portion of the molecule led to the selection of the carbohydrate conjugate **4** which contains NAc-gamma[1] calicheamicin as the calicheamicin core, a disulfide stabilized by two adjacent methyl groups, and a hydrazone linkage to the oxidized carbohydrates of the antibody as a site of hydrolytic release (*10*). Further work showed that the inclusion of the hydrazone was necessary for the anti-CD33 antibody, P67.6, for potent, selective cytotoxicity (*12*). However, for CTM01, including this hydrolyzable bond was not necessary for activity, and the lysine-linked conjugate **7**, referred to as the mCTM01 amide conjugate, was equivalent or even superior in all preclinical models that were examined, especially against resistant cell lines (*13*).

CTM01 has now been fully humanized by genetic engineering as an IgG_4 isotype (*8*) in order to decrease immunogenicity and permit repeated administration in

humans. This fully humanized antibody, hCTM01, has been evaluated for its potential for targeted therapy by examining its ability to bind to and internalize into target cells. The potency and selectivity of the amide conjugate of hCTM01, referred to as CMB-401, in in vitro and in vivo tumor models is also described.

CMB-401 (**7**) has been in clinical trials for ovarian cancer (*14*−*16*) as well as lung cancer (unpublished) with only limited evidence of activity. This is in contrast to gemtuzumab ozogamicin (Mylotarg) (*17*), which is an anti-CD33 calicheamicin conjugate approved for AML. The differences that may be responsible for the lesser activity include the presence of circulating antigen (*18*), possible detrimental effects of the predose of native antibody given in an attempt to clear the circulating antigen (*19*), differences in the linkers used (*12*), possible differences in resistance mechanisms (*20*), possible insufficient targeting of the conjugate to large solid tumors, etc. It is also possible that choosing a different tumor type, dosing patients after surgical removal of the primary tumor, or use in combination would show activity. Ongoing efforts may help to clarify these issues. Preclinical data on two more calicheamicin−antibody conjugates have recently been reported (*6*, *7*). Clinical experience with these two conjugates will also expand our understanding of the important issues that need to be addressed in order to make successful chemoimmunoconjugates.

EXPERIMENTAL PROCEDURES

Antibodies. The mCTM01 used in these studies was produced and purified from tissue culture supernatants by Celltech (Lot 122 88JC00-01). The fully humanized version of CTM01 was prepared by Celltech (*8*). hP67.6, an IgG_4, anti-CD33 antibody that served as a nonbinding antibody control (*21*), and MOPC-21, also a nonbinding control (*22*), were also prepared by Celltech.

Antibody Conjugates. The synthesis of the carbohydrate conjugates (**4**) of NAc-gamma calicheamicin DMH have been reported previously (*10*). Drug loadings averaged between 2 and 3 mol of calicheamicin per mole of antibody and free calicheamicin (predominantly structure **3**) was normally 1−3%.

The procedures for the synthesis of amide conjugates (**7**) have also been published (*12*). Drug loadings of 2 to 3 mol of calicheamicin per mole of antibody were seen and free calicheamicin (predominantly structure **5**) was normally 0.5−1%.

All conjugates were characterized as monomeric by analytical gel-exclusion chromatography (aggregate < 3%) and loading was determined by the ratio of UV absorption at 280 nm (protein) and 333 nm (calicheamicin) as reported (*10*, *12*). Neither conjugation procedure significantly affected the immunoaffinity of the conjugates reported in this paper versus the starting native antibodies, as determined by competitive binding with antibody that had been radiolabeled with ^{125}I-Bolton−Hunter reagent, as detailed below.

Cell Lines. MX-1 is a human ductal breast carcinoma cell line obtained from the National Cancer Institute. MCF-7 is a human breast adenocarcinoma, pleural effusion. ZR-75-1 is a human breast carcinoma. Raji is a Burkitt's Lymphoma cell line, ATCC # CCL 86. A2780 (*23*) is an ovarian carcinoma, and A2780DDP (*24*) was derived from A2780 by exposure to cisplatin and has enhanced DNA repair. The ovarian adenocarcinoma tumor OvCar-3 was obtained from the ATCC line HTB 161 and was passaged as an ascites tumor in nude mice.

Culture Methods. The basic methods used are as published previously (*10*). Cells were propagated in RPMI 1640 medium containing 5% fetal calf serum, 5 μg/mL insulin and transferrin, 5 ng/mL selenium, and 50 μg/mL gentamicin. Cultures were maintained in a humidified, 5% CO_2 incubator at 37 °C and were subcultured once or twice a week as needed. For in vitro cytotoxicity tests, streptomycin (50 μg/mL) and penicillin (50 U/mL) were incorporated into the medium.

Relative immunoaffinity of the antibodies and conjugates was measured by a competitive radioimmunoassay (RIA) in which several dilutions of the test sample were competed with iodinated CTM01 for binding to live cells. For each assay, 10^6 A2780DDP cells in 0.1 mL were incubated with 0.05 mL of 4 μg/mL ^{125}I-CTM01 (specific activity about 0.3−0.5 μCi/μg) and serial 4-fold dilutions of the test samples, the highest concentration being 200 μg/mL. After a 1 h incubation at 0−4 °C, the cells were washed three times with cold Dulbecco's phosphate-buffered saline (PBS) and transferred to fresh tubes and counted. Binding inhibition curves were plotted and calculated IC_{50} values for each conjugate were compared with that of the unmodified control antibody as a relative measure of retention of immunoaffinity.

Determination of Antibody Internalization by Target Cells. The acid-dissociation method (*25*) has been

adapted to quantitatively assess internalization of mCTM01 and hCTM01 by the human breast carcinoma cell line, MCF-7, and the cisplatin-resistant human ovarian carcinoma cell line, A2780DDP. Cells were collected by trypsinization and washed; viable cells were enumerated by Trypan Blue exclusion, and the suspension was adjusted to 5×10^6 viable cells/mL in medium (RPMI-1640 containing 5% heat-inactivated fetal calf serum and 0.02 M HEPES, pH 7.4). This suspension was chilled on ice, and ^{125}I-labeled antibody (labeled with Bolton-Hunter reagent; specific activity about 0.5 mCi/mg) was added to give a final concentration of 1−2 mg/10^6 cells. This suspension was distributed to two sets of duplicate tubes at 0.5 mL/tube. One set of tubes (control) was kept on ice throughout the incubation period; the other set was immediately transferred to a 37 °C water bath. At various times, the cell suspensions in duplicate tubes from each set were diluted with 2.5 mL of cold medium and centrifuged. The supernatants were decanted, and the cell pellets were washed with 3 mL of cold medium. The supernatants were decanted again, and the pellets were resuspended in 0.5 mL of 0.05 M glycine and 0.10 M NaCl, pH 2.8. These suspensions were incubated for 20 min at room temperature and then centrifuged. The acid supernatants were carefully removed and transferred to clean tubes; the pellets were resuspended in 0.5 mL of medium and also transferred to clean tubes. The radioactivity associated with cell pellets and acid supernatants was determined by gamma counting. This method is based on the finding that molecules of CTM01 that are bound to the outer plasma membrane of cells are released by exposure to isotonic pH 2.8 buffer, whereas internalized antibody molecules are not released. Thus, it is possible to distinguish between surface-bound and internalized CTM01 by this technique. Over time, there is a shift of radioactivity from the acid supernatants to the cell pellets for samples incubated at 37 °C but not for the controls incubated on ice. From the acid-stable, cell-associated cpm in the experimental samples (corrected for the small, constant, acid-stable cpm in the control samples) and the specific radioactivity of the antibody, the number of molecules of antibody internalized per cell (net uptake) is plotted vs time of incubation.

In Vitro Cytotoxicity Assays. To evaluate the cytotoxicity of drug or conjugate samples, viable cells (10^5/0.2 mL) were aliquoted into 15 mL test tubes which contained 0.2 mL of the sample to be tested at the appropriate concentration. Concentrations were all normalized to ng/mL calicheamicin equivalents (cal equiv). Tubes were vortexed and incubated at 37 °C for 1 h, and the pellets were washed 3 times with 8 mL of medium. One milliliter of medium was added to each pellet, the cells were vortexed, and 0.2 mL was removed and placed in a well of a 96-well plate (2×10^4 cells). Alternately for continuous exposure, cells were plated without removing unbound test article by washing. These cells were incubated for 3 days, at which time 0.1 mL of supernatant was removed and replaced with 0.2 mCi of [^{3}H] thymidine in 0.1 mL of fresh medium. Incubation was resumed for an additional 24 h at which point the cells were harvested and counted. Growth inhibition curves of each drug or conjugate were plotted, and the IC_{50} value (concentration of drug equivalents needed for 50% [^{3}H]thymidine uptake inhibition) of each sample was determined.

In Vivo Tests for Antitumor Activity. The cell lines were passaged in tissue culture or as ascites tumors in nude mice (OvCar-3). For each experiment, 8×10^6 cells were implanted subcutaneously into athymic mice. Tumors were staged for 4 to 10 days to achieve a size of

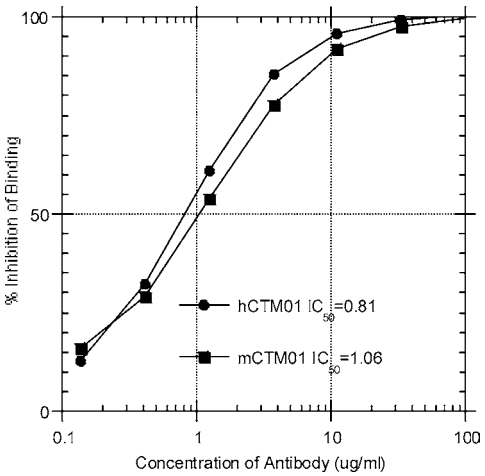

Figure 2. Competitive radioimmunoassay for mCTM01 and hCTM01. Affinity of the humanized antibody relative to the murine antibody is 1.3.

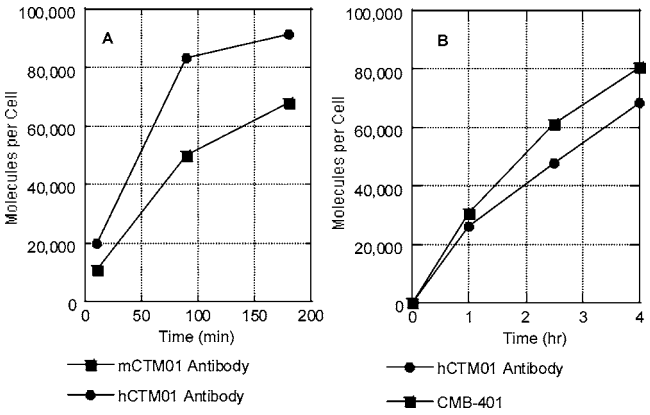

Figure 3. Internalization by MCF-7 (A) and A2780DDP (B) human cell lines. Frame A shows the effect of humanization on uptake, while frame B shows the effect of conjugation to make CMB-401 (**7**) on uptake of humanized antibody.

100−150 mg prior to treating ip at the indicated dose levels on days 1, 5, and 9 after staging. There were five or six mice per test group and 10 in the buffer control group. Tumor mass was determined by measuring two tumor dimensions once weekly for at least 28 days post-tumor staging. Antitumor activity was defined as a sustained 58% minimum inhibition of mean tumor mass (NCI standard criteria) compared with untreated controls in groups with greater than 65% survivors. A therapeutic ratio was defined as the maximum tolerated dose/minimum effective dose (MTD/MED) and used as a measure of the therapeutic window for the conjugates or drugs tested.

RESULTS

Relative Affinities of mCTM01 and hCTM01. The affinities of the murine and humanized versions of CTM01 were compared using ^{125}I-labeled mCTM01 in a competition assay. As shown in Figure 2, the binding data follow a normal curve and show that hCTM01 has ∼30% increased affinity with respect to the murine antibody.

Internalization of mCTM01, hCTM01, and CMB-401. Internalization of the two CTM01 antibodies and CMB-401 was examined on two cell lines using a modification of the acid-dissociation method. The increased affinity of the genetically engineered antibody resulted in increased internalization into the MCF-7 cell line, as shown in Figure 3A, and these results confirmed the observation (*5*) that MUC1 is efficiently internalized. In

Table 1. In Vitro Cytotoxicity of CMB-401 and the mCTM01 Amide Conjugate

	IC_{50}, 1 h[a]			IC_{50}, 4 days[a]		
sample	MX-1	Raji	index[b] specificity	MX-1	Raji	index[b] specificity
CMB-401	14.9	>500	>1000	0.05	>100	>70000
mCTM01 conjugate[c]	54.2	>500	>300	0.61	>100	>6000
NAc-gamma cal.	>20	0.53	**1**	1.08	0.03	**1**

[a] IC_{50}s are given in ng/mL cal equiv, doses of antibody are approximately 40-fold higher. [b] The specificity index is defined as (IC_{50} of conjugate of Raji/IC_{50} of conjugate on MX-1) ÷ (IC_{50} of NAc-gamma on Raji/IC_{50} of NAc-gamma on MX-1). [c] Same conjugate as CMB-401, but with murine antibody.

Table 2. In Vitro Activity of the CMB-401 and the MCTM01 Amide Conjugate

	IC_{50} (ng/mL)		
sample	A2780DDP	ZR-75-1	MCF-7
CMB-401	1.8	9.8	17
mCTM01 conjugate[d]	2.4	ND[b]	20
MOPC-21 conjugate[e]	189	ND[b]	305
hP67.6 conjugate[e]	ND[b]	331	ND[b]
NAc-gamma calicheamicin	0.056	0.038	1.8
selectivity index[c]	105	34	18

[a] IC_{50}s are given in ng/mL cal equiv, doses of antibody are approximately 40-fold higher. [b] ND = not determined. [c] Selectivity index = IC_{50}(MOPC-21 or hP67.6 conjugate) ÷ IC_{50}(CMB-401). [d] Same conjugate as CMB-401, but with murine antibody. [e] Same conjugate as CMB-401, but with indicated antibody.

this example at least 50 000 molecules per cell were internalized within the first hour of incubation at 37 °C. Figure 3B shows that the A2780DDP cell line had a slightly lower rate of internalization for hCTM01, but that CMB-401 was internalized at least as well, indicating that conjugating calicheamicin to the antibody does not interfere with internalization.

Comparative Activity of CMB-401 and the Corresponding Murine Conjugate in Vitro. The mCTM01 amide conjugate and CMB-401 routinely had drug loadings of 2 to 3 mol of calicheamicin per mole of antibody and retained >80% of their immunoaffinity (data not shown). The in vitro activity of CMB-401 was compared with that of the mCTM01 amide conjugate. The MX-1 breast line was used as the antigen-positive cell line and Raji as an antigen-negative control cell line with either 1-h exposure or continuous (4-day) exposure to conjugate. Additionally, the activities of all the conjugates were compared with that of unconjugated NAc-gamma calicheamicin (**2**). As summarized in Table 1, CMB-401 had lower IC_{50}s and higher specificities in both the 1-h incubation and continuous exposure protocols than seen with the mCTM01 amide conjugate.

To evaluate the selectivity of these amide conjugates for other MUC1-expressing tumor cell lines, an in vitro comparison of CMB-401 with a nonspecific antibody conjugate, prepared with identical calicheamicin chemistries, was made. In this study, the mCTM01 amide conjugate and CMB-401 along with both NAc-gamma calicheamicin (**2**) and the nonbinding control conjugate of the murine IgG_1 monoclonal antibody, MOPC-21, or the isotype-matched conjugate of hP67.6 were all tested against two human breast and one ovarian tumor cell lines. As the data in Table 2 indicate, both the mCTM01 amide conjugate and CMB-401 were equivalently active against the MUC1-expressing cell lines, with IC_{50}s in the 10 ng/mL of cal equiv dose range. The specificity of CMB-401 ranged from 20 to 100 with respect to a nonbinding conjugate. Table 2 also shows that both CTM01 amide conjugates were at least as potent on the cisplatin resistant cell line A2780DDP as on the other two cisplatin sensitive cell lines.

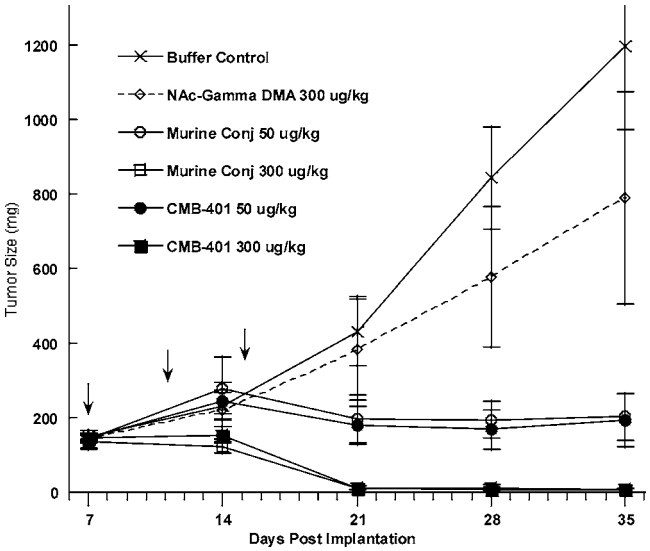

Figure 4. Response of OvCar-3. Xenograft tumors were treated with CMB-401 (**7**), the murine conjugate (**7**), or a representative calicheamicin derivative (**6**) alone. Athymic mice were implanted sc with OvCar-3 cells and then dosed when tumors were approximately 150 mg in size. The doses indicated were given on days 7, 11, and 15, as indicated by the arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs.

In Vivo Efficacy of CMB-401 versus OvCar-3. As shown in Figure 4, the mCTM01 amide conjugate and CMB-401 were both highly effective against the OvCar-3 ovarian carcinoma xenograft at doses ranging from 50 to 300 μg/kg cal equiv given three times each, with four out of five animals tumor-free in each of the 300 μg/kg treatment groups. This experiment was done with tumors staged to 150 mg prior to treatment. The conjugates were still effective at doses as low as 50 μg/kg, indicating a therapeutic ratio (MTD/MED) ≥ 6. In contrast, neither the NAc-gamma calicheamicin (**2**, not shown) nor the NAc-gamma calicheamicin DMA (**5**, shown) used as controls, gave substantial antitumor effects at the MTD. The dose−response behavior of the conjugates in this experiment is described in Figure 5. With both conjugates, 13 of the 25 treated animals were tumor-free at day 28 of the test as indicated in the figure. Native antibody itself has no effect in this or any other xenograft experiment that has been performed.

Evaluation of Specificity and Efficacy in Vivo versus MX-1. As shown in Figure 6, CMB-401 was compared with a conjugate prepared with the isotype-matched, genetically engineered IgG_4 antibody, hP67.6, that does not target to MX-1, conjugated to the same calicheamicin derivative. In this study, the two conjugates were administered ip on days 11, 15 and 19 post tumor implantation. At doses ranging from 150 to 450 μg/kg cal equiv per injection the specific hCTM01 amide conjugate was active while the nontargeting hP67.6 conjugate had comparatively modest activity (T/C = 43%) at the top dose tested.

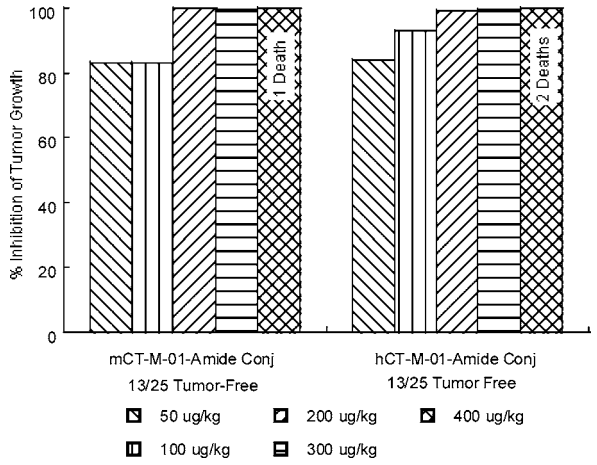

Figure 5. Dose−response of the OvCar-3 ovarian xenograft tumors. Athymic mice were implanted sc with OvCar-3 cells and then dosed with the conjugates (**7**) when tumors were approximately 150 mg in size. The doses indicated were given on days 7, 11, and 15 and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Data shown is for day 28.

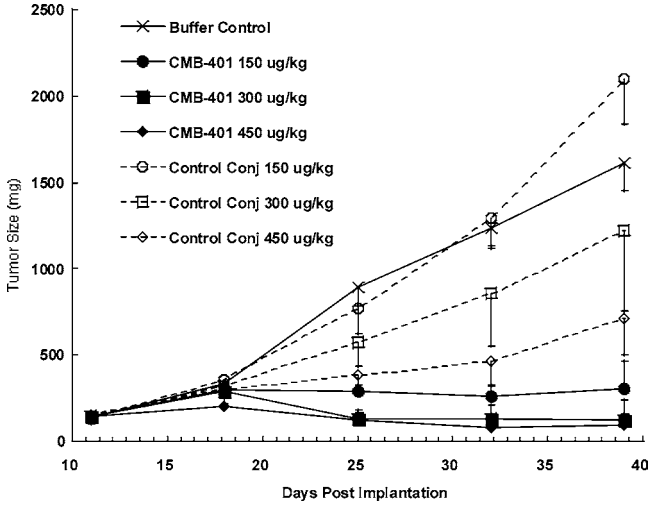

Figure 6. Response of the MX-1 breast xenograft tumors. Athymic mice were implanted sc with MX-1 cells and then dosed with the conjugates (**7**) when tumors were approximately 150 mg in size. The control conjugate is an identical conjugate made with the nonbinding, isotype-matched antibody, P67.6. The doses indicated were given on days 11, 15, and 19 and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs and are given in the negative direction for the control conjugate and in the positive direction for CMB-401.

Evaluation of Dose Schedule and Route of Administration. The MX-1 breast carcinoma was used to examine both route of administration and dose schedule for CMB-401. Figure 7 shows no difference in the activity of CMB-401 administered ip as a larger bolus injection versus the standard three doses separated by 4 days. There was also no significant difference in activity between the conjugates as a function of route of administration, ip versus iv, regardless of whether the conjugate was given as a bolus or as split doses (bolus iv not shown in graph for clarity).

DISCUSSION

The feasibility of conjugating calicheamicin to oxidized carbohydrates on antibodies has previously been demonstrated (*10*). Using these carbohydrate conjugates, the

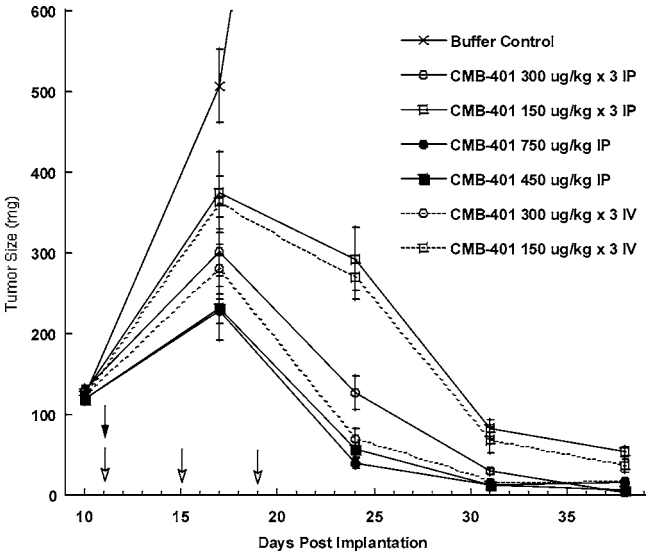

Figure 7. Effect of changing the fractionated dose IP to either a fractionated dose iv or to a bolus dose IP. Athymic mice were implanted sc with MX-1 cells and then dosed with CMB-401 (**7**) when tumors were approximately 150 mg in size. The doses indicated were given either on day 11, as indicated by the solid arrow (single dose), or on days 11, 15, and 19, as indicated by the open arrows, and are given in calicheamicin equivalents. The corresponding concentration of antibody is 40-fold greater. Error bars are SEMs.

correlation between the potency of calicheamicin analogues and their therapeutic potential as conjugates was investigated, and linker variations were also examined in an effort to optimize the therapeutic window for the conjugates. From these studies, the mCTM01 carbohydrate conjugate (**4**), which contains an NAc group, a disulfide that is sterically hindered by two methyl groups, and a hydrazone that allows for hydrolytic drug release, was chosen as the optimal drug for conjugation. Although incorporation of the NAc group lowered the potency of the conjugate somewhat, it significantly improved the therapeutic index. Increasing the stability of the disulfide is thought to decrease premature release and triggering of the calicheamicin in circulation. The hydrazone linkage was originally thought to be required for efficient drug release, as is the case for conjugates of other antibodies (*12*).

The site of hydrolytic release was subsequently removed by attaching an appropriate calicheamicin derivative to the epsilon-amino groups of lysines (*11*). The mCTM01 amide conjugate (**7**) is not only as efficacious as the hydrazone conjugate in many in vitro and in vivo tumor models, but also shows enhanced activity over the hydrazone conjugate against tumors overexpressing P-glycoprotein-mediated multidrug resistance (MDR) (*13*). These studies suggest the hypothesis that attaching a cytotoxic agent, such as calicheamicin, by way of a serum stable linker to an internalizing carrier protein may help to bypass normal membrane-based mechanisms of drug resistance. There is precedence for this with other types of conjugates (*26*), although further research with various drugs and antibodies would be required to adequately define this possibility. The amide conjugate also shows good activity versus a cisplatin-resistant ovarian carcinoma line. That this conjugate has activity equal to or greater than that of the CTM01 carbohydrate conjugate indicates that the hindered disulfide offers ample means for release of the drug intracellularly, presumably through interaction with glutathione and other reduced thiols (*2*). Preliminary experiments indicate that the reaction rate

of a model calicheamicin disulfide with glutathione is consistent with reasonable stability in circulation where glutathione concentrations are lower, but sufficient reactivity to allow for release of an active calicheamicin derivative intracellularly where glutathione concentrations are 100-fold higher (*27*, *28*). Specifically, about 2% reaction of the calicheamicin was seen at 0.02 mM glutathione in pH 7.4 phosphate buffer, which approximates the conditions in circulation, and 55% reaction was seen at 2 mM, which approximates the concentrations seen in cells.

The next step in the development of the CTM01 calicheamicin conjugates has been the replacement of the murine antibody with a genetically engineered human antibody that should be much less immunogenic in patients. The data presented in this report demonstrate that the resultant hCTM01 amide conjugate is well-behaved and is equivalent or superior to the corresponding murine version in all preclinical models. Good binding and internalization of this and all other calicheamicin conjugates is felt to be crucial for good activity. Binding and internalization has been shown to be unaffected by the change from mCTM01 to hCTM01 and by conjugation to calicheamicin. In fact, both the native hCTM01 antibody as well as its conjugate bind and internalize better than the murine counterparts.

In vitro*,* CMB-401 is potently cytotoxic with IC_{50}s in the 0.05 to 17 ng/mL cal equiv range and is highly selective with specificity indices of 20 to over 70 000, depending on the cell line and assay conditions. Specificity has been demonstrated both versus a nontargeted cell line and a nontargeting conjugate on various cell lines. The reason for modest selectivity in some cases is unknown; however, the activity in xenograft models reaffirms the potential of these conjugates. CMB-401 exhibits good stability in vitro as demonstrated by the retention of specificity seen after 4 days of the continuous exposure to conjugate at pH 7.4 and 37 °C.

In vivo, CMB-401 is virtually indistinguishable from the murine counterpart. The MED for multiple experiments falls in the range of 25 to 50 μg/kg cal equiv while the MTD ranges from 300 to 400 μg/kg, in each case being given three times spaced by 4 days. The therapeutic window in multiple experiments is always > 6. CMB-401 produced regressions of well established (150 mg) OvCar-3 ovarian xenograft tumors with long-term, tumor-free survivors being common not only at the MTD, but often at lower doses as well. Good activity is maintained over a 10-fold dose range in some experiments. The targeting of CMB-401 is demonstrated by its superior activity with respect to a conjugate made from the hP67.6 antibody which does not target the MX-1 breast xenograft. The nontargeting conjugate shows only modest in vivo activity at a dose that is almost 10 times the MED for CMB-401. Such modest activity is likely due to the tendency of xenograft tumors to accumulate macromolecules, but is significantly less than seen with the targeting antibody, where internalization takes the calicheamicin into the cell.

Experiments which examine the dosing schedule show that similar activity is seen with a higher bolus dose instead of three fractionated doses spaced 4 days apart. This is somewhat surprising, because chemotherapeutics are often fractionated to maximize effect while minimizing toxicity. Administration iv was seen to give the same results as the more normally used ip administration. Data from previous experiments also show that the CTM01 conjugates are as potent, both in vitro as well as in vivo, on the MUC1-expressing, cisplatin-resistant cell line A2780DDP as against the cisplatin-sensitive target cell lines (*11*). These observations were important since clinical evaluation of CMB-401 activity was initially made in ovarian carcinoma patients who had relapsed following cisplatin-based chemotherapy (*14*, *15*).

CMB-401 is a very potent antitumor agent, being routinely effective and nontoxic in the dose range of 50−300 μg/kg cal equiv. This potency is crucial considering that uptake of antibody conjugates by solid tumors in humans is low, typically in the range of 0.001−0.01% injected dose/g. The potential of the calicheamicins for targeted delivery with a fully humanized anti-MUC1 antibody has been demonstrated in preclinical models. The lack of sufficient activity in clinical trials (see the Introduction for discussion) was disappointing, but it gives us additional incentive to explore the many other properties a chemoimmunoconjugate and the tumors it targets must possess for ultimate success.

pH-Responsive Copolymer Assemblies for Controlled Release of Doxorubicin

Elizabeth R. Gillies and Jean M. J. Fréchet*

Center for New Directions in Organic Synthesis, Department of Chemistry, University of California, Berkeley, California 94720-1460. Received June 26, 2004; Revised Manuscript Received December 13, 2004

pH-Responsive drug carriers have the potential to provide selective drug release at therapeutic targets including tumors and in acidic intracellular vesicles such as endosomes and lysosomes. We have developed a new approach to the design of acid-sensitive micelles by incorporating hydrophobic acetal groups on the core block of a micelle-forming block copolymer. Hydrolysis of the acetals at mildly acidic pH is designed to reveal polar groups on the core-forming block, thus changing its solubility and disrupting the micelle, triggering drug release. The anticancer drug doxorubicin (DOX) was encapsulated in these pH-sensitive micelles, and the acetal hydrolysis rates and DOX release rates were determined in the pH range of 4.0 to 7.4 and were compared to those of control systems. The micelle disruption was investigated by dynamic light scattering. The in vitro toxicities of the empty and DOX-loaded micelles were determined, and the intracellular fate of the encapsulated DOX was compared to free DOX using fluorescence confocal microscopy.

INTRODUCTION

In recent years there has been increased interest in the development of drug delivery systems to improve the properties, increase the effectiveness, and reduce the harmful side effects of therapeutic molecules. Micelles formed by the assembly of amphiphilic block copolymers in aqueous solution have been investigated as potential drug carriers and offer many attractive characteristics (*1*−*3*). For example, these nanocontainers are capable of encapsulating hydrophobic drugs in their core, thus improving the drug's water solubility. In addition, the size of copolymer micelles, typically between 20 and 100 nm, is effective in avoiding rapid renal exclusion, but is also small enough to avoid undesirable uptake by the reticuloendothelial system (*4*). Therefore, the circulation of the micellar carrier and encapsulated drug is prolonged, but since the micelles are composed of polymer chains that are small enough to be eliminated by renal filtration, the eventual disintegration of the micelle will allow the polymer to be excreted. This is important since the long-term build-up of polymer in the body could lead to toxicity. The size and prolonged circulation of copolymer micelles also facilitates their passive accumulation at pathological sites such as tumors where the vasculature has increased permeability (*5*). This selective targeting of the drug carrier is ideal in terms of increasing the effectiveness and lowering the systemic toxicity of the drug payload.

An important issue determining the effectiveness of a micellar drug carrier is the ability to control the location and time over which drug release occurs. This challenge has motivated the development of micelle systems that are designed to release their drug load in a controlled manner, upon arrival at the target site. For example, temperature has been used to modulate drug release from thermoresponsive micelles (*6*, *7*), while ultrasound has been reported to trigger drug release from Pluronic micelles (*8*, *9*). Both these approaches require the presence of external stimuli, but it is also possible to exploit naturally occurring changes in the physiological environment. Change in acidity is a particularly useful stimulus to consider in the development of drug carriers because of the numerous pH gradients that exist in both normal and pathophysiological states. For example, it is well documented that the extracellular pH of tumors is slightly more acidic than the blood and normal tissue (*10*−*12*). In addition, it is proposed that micelles are taken up by cells via an endocytosis process (*13*, *14*). Although the endocytic pathway begins near the physiological pH of 7.4, it drops to a lower pH of 5.5−6.0 in endosomes and approaches pH 4.5−5.0 in lysosomes (*15*). Therefore, polymeric micelles that are responsive to pH can be designed to selectively release their payload in tumor tissue or within tumor cells.

Several different approaches have been taken to the development of pH-sensitive micelles (*16*). One approach is to incorporate "titratable" groups such as amines or carboxylic acids into the block copolymers such that the micelle formation is altered by the protonation of these groups. However, only a few of these systems have been demonstrated to undergo transitions in the physiologically relevant pH range of 5.0−7.4 and have the proven capacity to encapsulate drugs (*17*−*21*). Another approach that remains less explored is to incorporate acid degradable linkages into the copolymer for the direct attachment of drugs to the copolymer backbone or such that degradation of the linkage provides sufficient structural change in the polymer to trigger drug release. The groups of Park (*22*) and Kataoka (*23*) have demonstrated the first approach by attaching the anticancer drug doxorubicin (DOX) to the micelle-forming copolymer by an acid-sensitive hydrazone linkage. Heller and co-workers have developed micelles based on poly(ethylene oxide)(PEO)-polyortho ester block copolymers where the core-forming polyortho ester block degrades under acidic conditions (*24*, *25*).

We have recently introduced a new approach to acid-sensitive micelles using PEO−dendrimer hybrids as backbones (*26*, *27*). The approach involves the attachment of hydrophobic groups to the periphery of the core-forming dendrimer block by an acid-sensitive acetal linkage. The system is designed such that upon hydrolysis of the linkage and loss of the hydrophobic groups, the core-forming block becomes hydrophilic, thus destabilizing the micelle and enabling escape of the drug from its encapsulating micellar compartment. The stepwise synthesis and controlled multivalency of the PEO-dendrimer backbone afford a high degree of control over the polymer structures. This has allowed us to tune properties such as the rate of micelle disruption, the critical micelle concentration (CMC), and the size of the micelles by adjusting the length of the PEO block, the generation and chemical structure of the dendrimer block, and the method for attaching the hydrophobic acetals to the polymer (*27*). Here we describe the application of this new approach for the development of a pH-responsive delivery system for DOX. DOX is an ideal candidate for incorporation into this micelle system because it has previously been shown to benefit from the increased circulation time, tumor targeting, and decreased systemic toxicity provided by drug delivery systems such as liposomes (*28*−*30*), polymeric micelles (*31*, *32*), and polymer−drug conjugates (*33*, *34*). The loading and pH-dependent release of DOX from micelles based on a PEO−dendritic polyester hybrid are described here. Investigations of the micelle degradation by dynamic light scattering (DLS) and UV−visible spectroscopy are also described, and preliminary in vitro studies of the DOX-loaded micelles are reported.

MATERIALS AND METHODS

Preparation of DOX-Loaded Micelles. Copolymers **1** and **4** were synthesized as previously reported (*26*, *35*). DOX was loaded into the copolymer micelles using a modification of the previously reported oil/water emulsion method (*31*, *36*). With sonication, DOX (0.75 mg) was dissolved in 0.15 mL of chloroform with 3.0 equiv of NEt_3. This solution was added dropwise to a stirred solution containing 2.5 mg of copolymer in 5 mL of water. The resulting emulsion was stirred overnight in the dark at room temperature, open to the atmosphere allowing the chloroform to evaporate. Insoluble, free DOX was removed by centrifugation at 2000*g* for 5 min. Soluble, free DOX was removed from the micelles by ultrafiltration (triplicate) using a membrane with a molecular weight cutoff of 30 000 g/mol (Amicon YM30). DOX loading was quantified by absorbance using a UV−visible spectrometer (CARY 50 Conc) (*37*). Fluorescence spectra of DOX and DOX-loaded micelles were obtained at a concentration of 10 μg/mL DOX equiv using an ISA/SPEX Fluorolog 3.22 equipped with a 450 W Xe lamp, double excitation and double emission monochromators, and a digital photon-counting photomultiplier. An excitation wavelength of 490 nm was used, and the emission spectra were recorded from 510 to 700 nm.

Determination of Acetal Hydrolysis Rates. A solution of DOX-loaded micelles was adjusted to a buffer concentration of 0.1 M at the desired pH (pH 4.0, 5.0: acetate; pH 6.0: citrate; pH 7.4: phosphate). A micelle concentration of approximately 0.5 mg/mL was used. The samples were stored at 37 °C, and formation of the 2,4,6-trimethoxybenzaldehyde hydrolysis product was detected over time by measuring the absorbance of the sample at 290 nm in a quartz cuvette having a path length of 1 mm. To determine the absorbance at 100% hydrolysis, a drop of concentrated HCl was added to the sample to effect complete hydrolysis.

Determination of DOX Release Rates. A solution of DOX or DOX-loaded micelles (approximately 20 μg/mL DOX equiv) was added to a Slid-A-Lyzer dialysis cassette (Pierce) with a molecular weight cutoff of 10 000. The solution was dialyzed at 37 °C against 0.1 M buffer of the required pH (pH 4.0, 5.0: acetate; pH 6.0: citrate; pH 7.4: phosphate). The solution was removed periodically from the dialysis cassette and the absorbance at 490 nm was measured, then the solution was returned to the dialysis cassette. The amount of released DOX was determined by the decrease in absorbance of the solution in the dialysis cassette.

Dynamic Light Scattering. Micelle sizes were determined by dynamic light scattering using a Zetasizer Nano ZS (Malvern Instruments) equipped with a 4 mW He−Ne laser at 633 nm. Copolymer concentrations were 1 mg/mL in the appropriate 0.1 M buffer (pH 5.0: acetate; pH 7.4: phosphate). The samples were incubated at 37 °C in the temperature-controlled instrument and size measurements were taken automatically every 20−30 min. over a period of 72 h.

Cell Cytotoxicity Assay. MDA-MB-231 breast cancer cells were cultured by the UC Berkeley Cell Culture Facility in a medium consisting of Dulbecco's Modified Eagle medium (DMEM), containing 10% FBS. The cytotoxicity of the empty micelles, DOX-loaded micelles, and free DOX were determined using the MTT assay (*38*). Cells were seeded onto a 96-well plate at a density of 1.6×10^4 cells per well in 100 μL of medium and incubated overnight (37 °C, 5% CO_2). The medium of each well was then replaced by 100 μL of new medium (DMEM, 10% FBS, 1% penicillin−streptomycin) containing various concentrations of micelles, DOX-loaded micelles, or free DOX. The tests were conducted in replicates of four for each concentration. The cells were incubated for 72 h, the medium was aspirated, and 100 μL of fresh medium was added, followed by 20 μL of MTT solution (5 mg/mL). The cells were incubated for 4 h, and then the medium was carefully aspirated. To the resulting purple crystals was added 200 μL of DMSO, followed by 25 μL of pH 10.5 glycine buffer (0.1 M glycine, 0.1 M NaCl). The optical densities at 570 nm were obtained using a SpectraMAX 190 microplate reader (Molecular Devices). Optical densities measured for wells containing cells that received no polymer or drug were considered to represent 100% growth.

Laser Scanning Confocal Microscopy. MDA-MB-231 cells (4.8×10^5 cells per well) were seeded onto a six-well plate containing collagen I-coated coverslips (round, 2.2 cm diameter, BD Biosciences). After incubation overnight (37 °C, 5% CO_2), the medium was carefully aspirated and replaced with 2.0 mL of medium (DMEM, 10% FBS, 1% penicillin−streptomycin) containing 1.0 μg/mL DOX equiv of DOX-loaded micelles or free DOX. The cells were incubated for 24 h, and then the medium was carefully removed. The wells were each rinsed twice with 3 mL of PBS. Two milliliters of 1% paraformaldehyde was added, and the cells were fixed for 10 min. The solution was aspirated, the wells were rinsed three times with PBS, and then the coverslips were transferred to glass slides. Images were obtained using a confocal laser scanning microscope (LSM 510, Carl Ziess Inc.) using a 40× objective and an excitation wavelength of 543 nm (He−Ne laser).

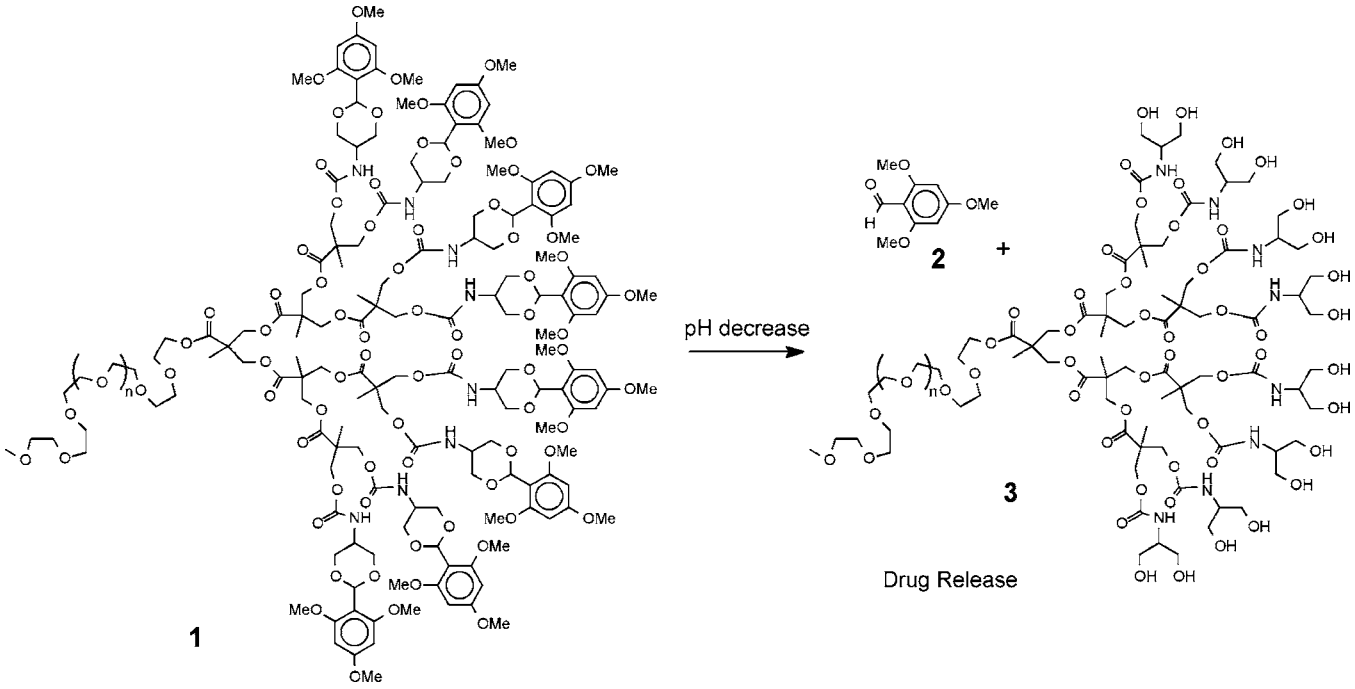

Figure 1. Hydrolysis of acetals on the dendrimer periphery of the micelle-forming copolymer **1** leads to a solubility change designed to disrupt micelle formation and trigger the release of drug.

RESULTS AND DISCUSSION

Preparation of DOX-Loaded Micelles. Copolymer **1** (Figure 1), composed of a 10 000 MW PEO block and a third generation polyester dendrimer with cyclic acetals of 2,4,6-trimethoxybenzaldehyde attached to the periphery was prepared as previously reported (*27*). As illustrated in Figure 1, hydrolysis of the cyclic acetals on the dendrimer periphery releases 2,4,6-trimethoxybenzaldehyde (**2**) and reveals polar 1,3-diol moieties on the dendrimer periphery to provide **3** after complete hydrolysis. This change in solubility of the dendrimer block is designed to trigger the disruption of the micelle and release of drug. Of the various polymers prepared in previous studies, **1** was selected for development of a DOX delivery system because of the ideal micelle size of 27 nm, a CMC of 40 mg/L, and the relatively rapid rate of micelle degradation (*27*).

DOX was loaded into micelles of **1** by an oil/water emulsion method similar to that described previously by Kataoka and co-workers (*31*, *36*). Chloroform was used as the organic phase, and 3 equiv of NEt_3 was used relative to DOX, as the drug is known to partition most effectively into the chloroform phase and into the micelle upon deprotonation of the glycosidic amine (*31*). Using 30 wt % of DOX relative to copolymer, a drug loading of approximately 12 wt % was typically obtained after centrifugation to remove insoluble free DOX particles and ultrafiltration to remove soluble unencapsulated DOX. DOX loadings were determined according to absorbance using UV−visible spectroscopy (*37*). As shown in Figure 2, that DOX is encapsulated in the micelles is supported by the significant attenuation in fluorescence (>20 times) observed for DOX-loaded micelles relative to a solution of free DOX of the same absorbance. This fluorescence attenuation has been observed previously for micellar DOX solutions and is attributed to fluorescence self-quenching of the drug molecules, which are within close proximity at the micelle core (*36*, *37*).

Hydrolysis of Acetals at the Micelle Core. A cyclic acetal composed of 2,4,6-trimethoxybenzaldehyde and the 1,3-diol moiety of serinol was selected as the pH-sensitive

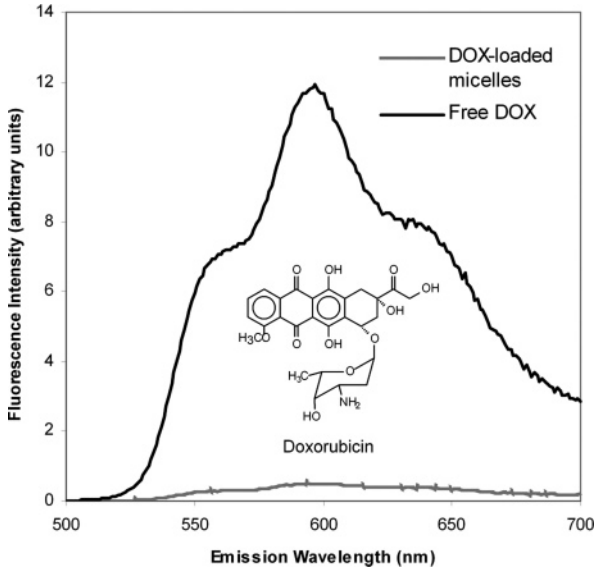

Figure 2. Fluorescence quenching of DOX-loaded micelles compared to free DOX (normalized for absorbance).

linkage for this system. While cyclic acetals are known to hydrolyze quite slowly in comparison to noncyclic acetals (*39*), the introduction of electron-donating methoxy groups at the ortho and para positions on the aromatic ring accelerates the hydrolysis rate significantly. We have also found that when these acetals are incorporated into the core block of a micelle-forming copolymer, the hydrolysis half-life is strongly dependent on the chemical environment at the micelle core. For example, while the half-life for a water-soluble low molecular weight model compound containing the same acetal is 1 h at pH 5, and several days at pH 7.4 (*27*), the rate is slowed to 50% hydrolysis after 4 h at pH 5.0 for micelles of copolymer **1** (*27*). This rate can be accelerated by the incorporation of hydrophilic spacers between the acetal and the dendrimer periphery that make the micelle core more hydrophilic, or slowed further by use

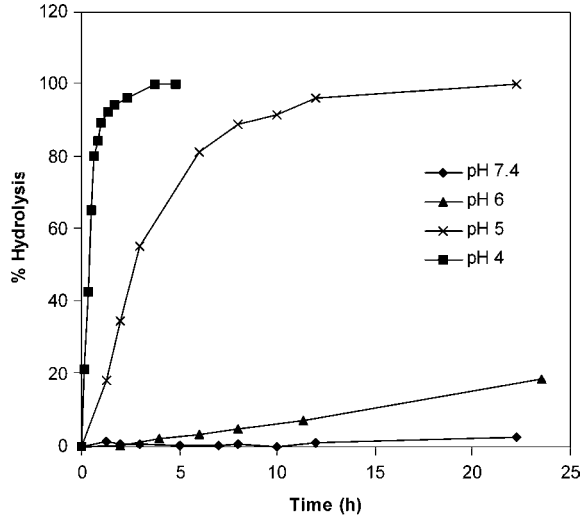

Figure 3. Hydrolysis rates of the acetals in DOX-loaded micelles of copolymer **1** at pH's ranging from 4 to 7.4.

of an even more hydrophobic linkage between the acetal and dendrimer or increasing the generation of the hydrophobic dendrimer block, making the dendrimer core more hydrophobic (*27*). Therefore, we were interested in the effect on the hydrolysis rate of incorporating DOX into the micelle core. The acetal hydrolysis rates at pH's ranging from 4 to 7.4 were investigated for the DOX-loaded micelles of copolymer **1**. Production of 2,4,6-trimethoxybenzaldehyde upon hydrolysis was detected by its absorbance at 290 nm. As shown in Figure 3, the amount of hydrolysis at pH 7.4 is quite negligible over a period of 24 h, while approximately 20% hydrolysis occurs at pH 6 over the same time period. At pH 4.0, the rate is rapid, with 50% hydrolysis after less than 30 min and at pH 5.0 the rate is very similar to that of the empty micelles with 50% hydrolysis after approximately 3 h. Therefore, the incorporation of DOX into the micelle core has only a small effect on the acetal hydrolysis rate. This may be because the hydrophobic aromatic portion of the DOX molecule is balanced by the hydrophilic glycosidic fragment, thus giving only a small change in the overall polarity of the micelle core.

pH-Dependent Release of DOX from the Micelles. The release of DOX from the micelles at different pH's was investigated using a dialysis procedure. A solution of the DOX-loaded micelles in a dialysis cassette was dialyzed against 100 mM buffer of the desired pH and the solution in the cassette was sampled at various times over a 72 h period to determine the amount of DOX remaining in the micelles. As shown in Figure 4a, a significant amount of DOX is released in a pH-dependent manner in the pH range of 4.0−6.0, while at pH 7.4 the system is very stable with less than 10% of the DOX released over 72 h.

As a control, the release of free DOX from a dialysis cassette was investigated at pH 5.0 and pH 7.4. As illustrated in Figure 4b, the release rates are very similar at both pH's, with essentially complete release after less than 10 h. This is consistent with the expected rate of diffusion for low molecular weight molecules across the dialysis membrane. Additionally, the release of DOX from micelles formed from copolymer **4** (Figure 5a) was also investigated as a control. In contrast to the highly sensitive cyclic acetals on the dendrimer periphery of **1**, the simple benzylidene acetals of **4** do not undergo hydrolysis at mildly acidic pH (*40*). Copolymer **4** was prepared as previously reported (*35*), and the micelles were prepared and loaded with DOX as described above for micelles of copolymer **1**. As shown in Figure 5b, the release rates of DOX from these micelles at both pH 5.0 and pH 7.4 are significant, with somewhat faster release at pH 5.0 as observed previously by Kataoka and co-workers using a pH-insensitive micelle system based on a PEO-poly(benzylasparate) block copolymer (*31*). These results indicate that the release of DOX from micelles is generally pH-dependent to some degree due to the increased aqueous solubility of DOX at mildly acid pH; However, the pH-sensitive micelle system based on copolymer **1** shows a stronger dependence of the release rate on pH (i.e. a greater difference between the rates at pH 7.4 and pH 5.0), suggesting that the hydrolysis of the pH-sensitive acetals likely plays a role. In addition, the increased stability of the pH-sensitive system at pH 7.4 is advantageous so that DOX will not be released during blood circulation, thus avoiding the undesirable organ accumulation and toxicity associated with the free drug. The slower release rate at pH 7.4 for micelles of **1** versus **4** highlights the fact that subtle changes in the polymer structure have a significant effect on the compatibility

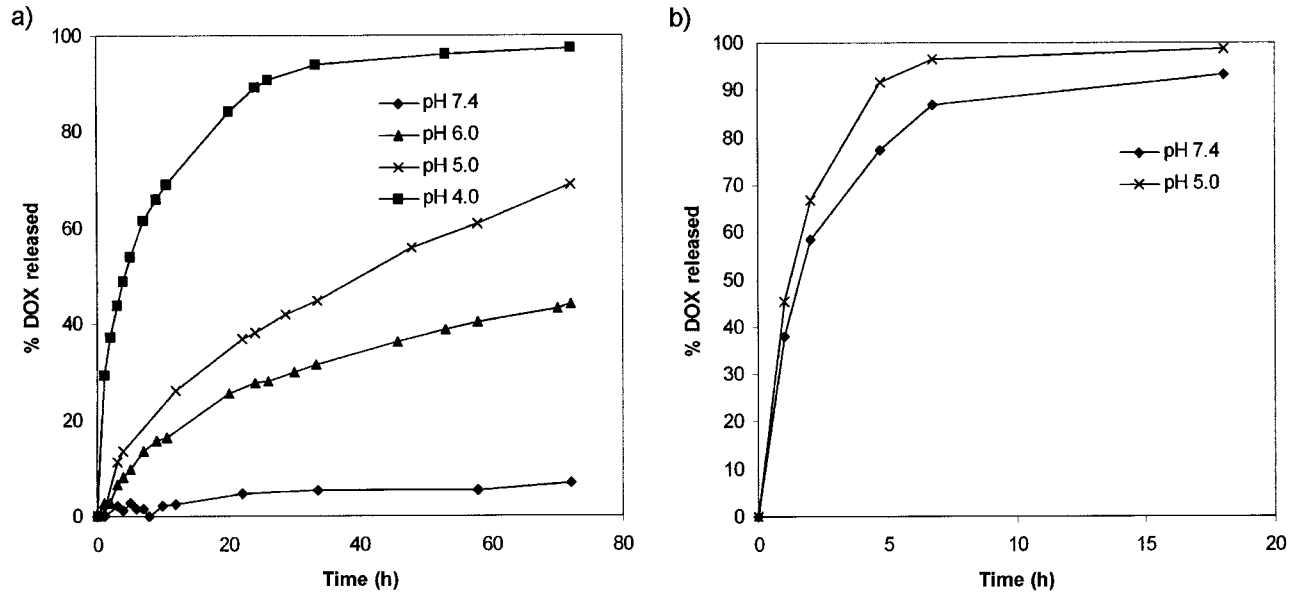

Figure 4. (a) pH-Dependent release of DOX from micelles of copolymer **1**. (b) Release of free DOX from a dialysis cassette.

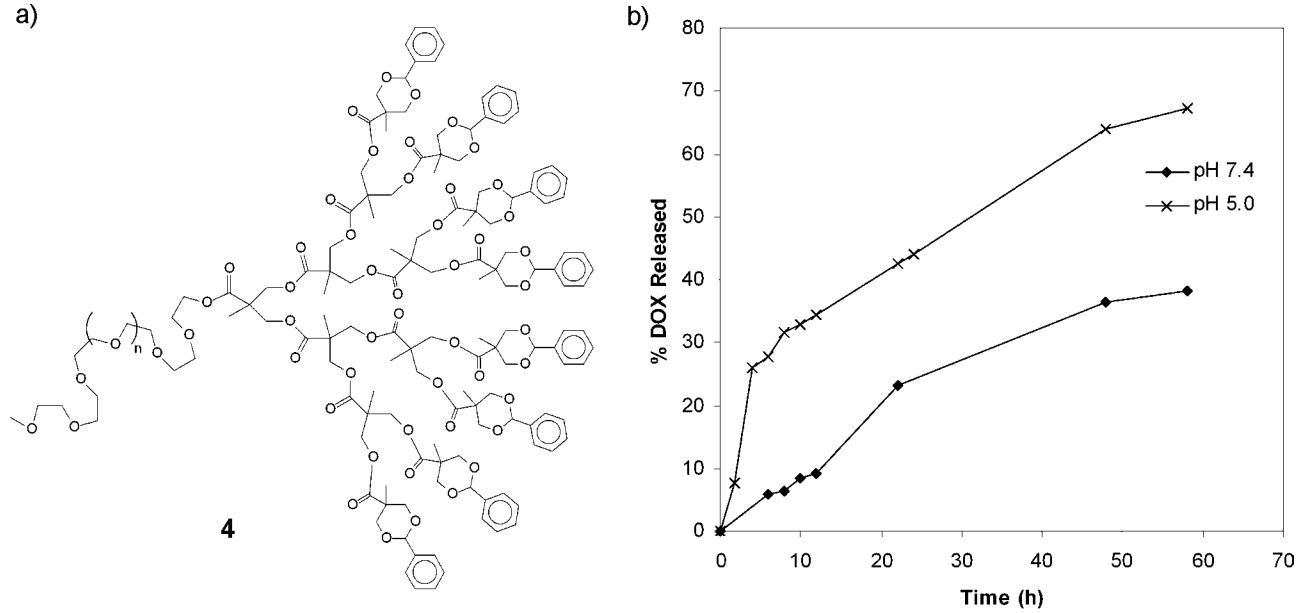

Figure 5. (a) Chemical structure of copolymer **4** forming micelles that are not pH-sensitive at mildly acidic pH. (b) Release of DOX from the pH-insensitive micelles.

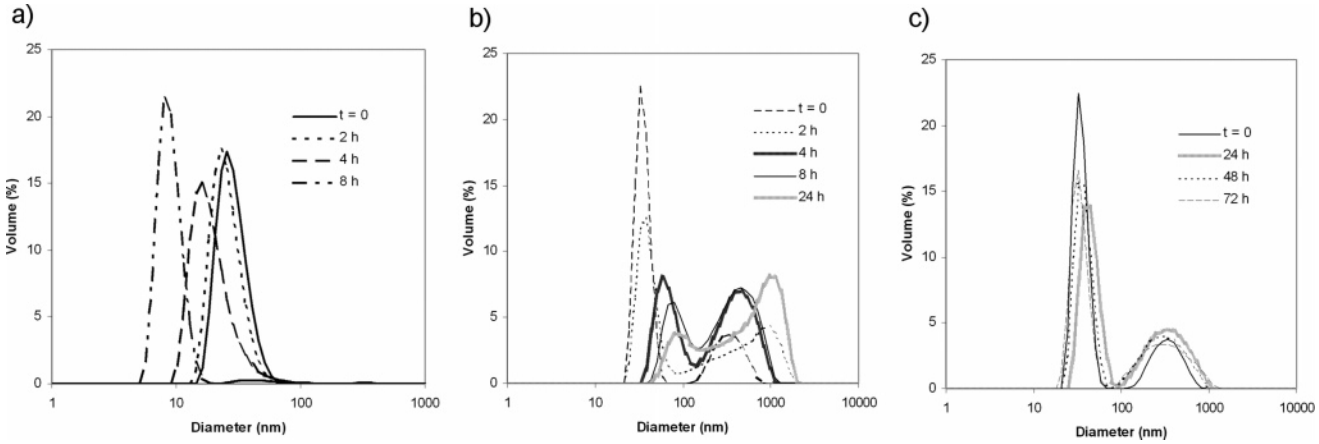

Figure 6. Dynamic light scattering measurements on micelles of copolymer **1**: (a) Degradation of empty micelles at pH 5.0. (b) Disruption of DOX-loaded micelles at pH 5.0. (c) Stability of DOX-loaded micelles at pH 7.4.

of the micelle core with the drug, thus altering the drug's overall release rate, and making the design of ideal model systems challenging. While exhibiting high stability under neutral conditions, the release of DOX from micelles of copolymer **1** at pH 5.0 is somewhat faster than that reported for other micelle systems where DOX is covalently bound to the polymer by a pH-sensitive linkage (*22*, *23*). Therefore, overall these results indicate that the pH-sensitive DOX-loaded micelles of **1** have characteristics ideal for the selective release of DOX in mildly acidic physiological environments.

Investigation of Micelle Degradation by Dynamic Light Scattering. Although DOX is steadily released from the micelles of copolymer **1** at mildly acidic pH, the release rates are generally slower than the acetal hydrolysis rates. Furthermore, even after 100% acetal hydrolysis, not all of the DOX is immediately released. Therefore, we were interested in probing the degradation of the DOX-loaded micelles by dynamic light scattering (DLS) to determine the time dependence of the micelle size. While the empty micelles have an initial volume average diameter of 27 nm, the DOX-loaded micelles are somewhat larger with a diameter of 35 nm and a small fraction of aggregates in the size range of 200−400 nm is observed. As shown in Figure 6a, the size of the empty micelles decreases over several h at pH 5.0, consistent with the disintegration of the micelles into soluble copolymer molecules. In contrast, over several h at pH 5.0, the size of the DOX-loaded micelles increases and the fraction of aggregates in the population becomes greater as shown in Figure 6b. This aggregation probably occurs upon disruption of the micelles due to acetal hydrolysis and is facilitated by the tendency of DOX to form aggregates by π-stacking. The lack of appearance of a population with a size less than 10 nm indicates that after acetal hydrolysis, the copolymers are probably associated with the aggregates rather than being dissociated in solution. It is likely that some DOX release occurs during rearrangement of the micelles to aggregates, while the remainder of the release over a longer time period occurs from the aggregates and is assisted by the increased water solubility of DOX at acidic pH upon protonation of the glycosidic amine. At pH 7.4, the micelles are stable over several days, with no significant changes in the size distribution over this time period (Figure 6c).

In Vitro Investigation of DOX-Loaded Micelles. Preliminary in vitro studies were conducted to compare the toxicities of the empty micelles, DOX-loaded micelles, and free DOX in MDA-MB-231 breast cancer cells using

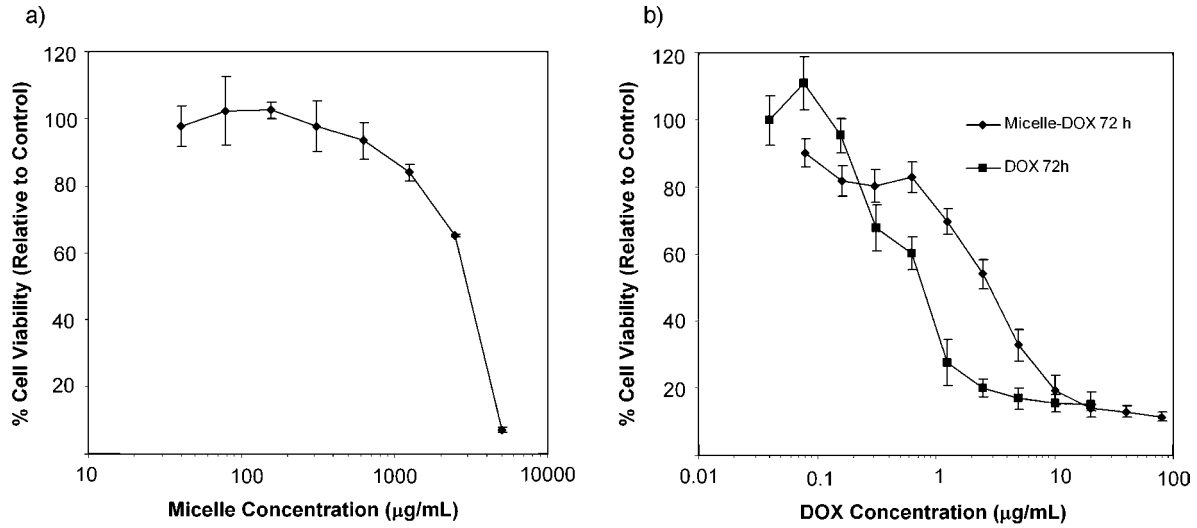

Figure 7. In vitro toxicity of (a) empty micelles and (b) free DOX and DOX-loaded micelles of copolymer **1** with MDA-MB-231 cells after a 72 h incubation (MTT assay).

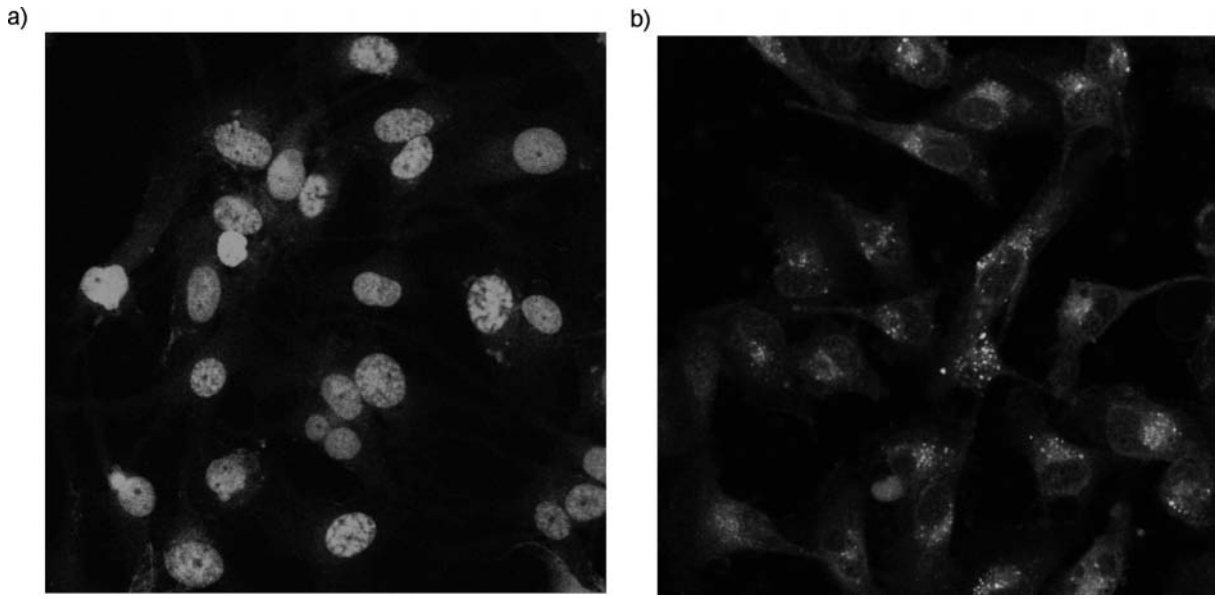

Figure 8. Laser scanning confocal microscopy images of (a) DOX and (b) DOX-loaded pH-sensitive micelles incubated with MDA-MB-231 cells for 24 h.

the MTT assay (*38*). As shown in Figure 7a, the empty micelles of copolymer **1** are nontoxic at concentrations up to 1 mg/mL, with an IC_{50} of approximately 2 mg/mL. The toxicity of the DOX-loaded micelles was investigated at a constant, nontoxic copolymer concentration of 0.2 mg/mL, and the concentration of DOX was varied. As shown in Figure 7b, above 1 μg/mL DOX equiv, the DOX-loaded micelles were toxic and an IC_{50} of approximately 3 μg/mL was determined. For comparison, the toxicity of free DOX was also investigated and the IC_{50} was found to be about 0.8 μg/mL. The fact that the micelle formulation is toxic, with an IC_{50} on the same order of magnitude as free DOX is consistent with the release of free and active DOX in the cells and is encouraging for the therapeutic potential of the system. The somewhat lower toxicity of the micelle system may result from the gradual release of DOX within the cell and from differences in the released drug's cellular localization relative to the free drug. However, the potential for the selective accumulation of the micelle system in tumor tissue by the enhanced permeation and retention effect may enhance its overall therapeutic efficacy in vivo relative to free DOX (*5*).

The intracellular localization of both free DOX and DOX-loaded micelles was investigated using confocal microscopy. As shown in Figure 8a, cells exposed to free DOX show significant accumulation of DOX in the nucleus after 24 h, consistent with the results of previous studies (*41*). In contrast, cells exposed to DOX-loaded pH-sensitive micelles have a punctate fluorescence that is concentrated in the cytoplasm after 24 h as shown in Figure 8b. These observations are important for several reasons. First, the absence of DOX fluorescence in the nucleus suggests that the micelles are stable in the presence of cells and serum-containing cell medium, as the rapid destabilization of the micelles in the extracellular environment and subsequent release of DOX outside the cell would be expected to result in an image similar to that observed for free DOX. In addition, the fluorescence in the cytoplasm suggests that the DOX-loaded micelles are indeed taken up by cells, and its punctate nature is consistent with the localization of the drug in subcellular organelles. While it is not possible with these data to determine the precise mechanism of cellular uptake or localization of the DOX-loaded micelles or the released drug, comparisons with similar images

previously reported for both pH-sensitive DOX-loaded micelles (*23*) and polymer-DOX conjugates (*42*) suggest that the fluorescence may be associated with organelles such as lysosomes, mitochondria, and the golgi apparatus. While one important mechanism of action of DOX involves DNA intercalation (*43*), other mechanisms have also been proposed, including the inhibition of mitochondrial function (*44*), thus explaining the toxicity of this and other delivery systems that do not lead to the accumulation of DOX in the nucleus. More in vitro studies with these DOX-loaded pH-sensitive micelles will be necessary in order to further explore their mechanism of cell uptake and intracellular trafficking.

CONCLUSIONS

In summary, the anticancer drug doxorubicin was encapsulated in pH-sensitive micelles formed from a PEO−dendritic polyester copolymer with acid-labile acetal groups on the core-forming dendrimer periphery. It was found that the acetal groups undergo hydrolysis and that DOX is selectively released at acidic pH's such as those encountered in tumor tissue and in endocytic vesicles including endosomes and lysosomes. In comparison with a non-pH-sensitive micelle control, the release of DOX from the pH-sensitive system was much more dependent on pH, although the release of DOX at acidic pH is clearly to some degree due to its increased aqueous solubility. Dynamic light scattering studies revealed that while the pH-sensitive micelles are stable at pH 7.4, acetal hydrolysis at acidic pH results in disruption of the micelles and rearrangment to form larger aggregates. In vitro toxicity studies revealed that the empty micelles are relatively nontoxic, while DOX encapsulated in the micelles has a toxicity quite similar to that of the free drug. Laser scanning confocal microscopy images support the localization of DOX in intracellular organelles in contrast to free DOX, which is localized in the cell nucleus after 24 h. This suggests that the DOX-loaded micelles are indeed taken up by cells and that the mechanism of action of the released drug may differ from that of the free drug. Future in vitro and in vivo studies will further explore the biological properties of these micelles. Thus far, these new pH-responsive drug carriers show promise for the controlled release of therapeutics in mildly acidic physiological environments.

ACKNOWLEDGMENT

We thank the National Institute of Health (GM 65361 and EB 002047) and the U.S. Department of Energy (DE-AC03-765F00098) for support of this research. We thank Ann Fisher and Young Kwon for help with in vitro studies. The Center for New Directions in Organic Synthesis is supported by Bristol-Myers Squibb as a Sponsoring Member and Novartis Pharma as Supporting Member.

Equinatoxin II is a pore forming toxin produced by the sea anemone *Actinia equina*. It is able to kill very unspecifically most cell types by the membrane-perturbing action of an amphiphilic α-helix located at its N-terminal. A normally active N-terminal mutant, containing one single cys in the amphiphilic α-helix, becomes totally inactive when it is bound to avidin via a biotinylated linker. By choosing, as a linker, a peptide containing a tumor protease cleavage site, we were able to construct an enzymatically activable conjugate which should be selective for tumor cells. The introduced cleavage site was designed in order to be digested by both cathepsin B and matrix metalloproteases (MMPs). We confirmed that this conjugate could be activated in vitro by cathepsin B and MMPs. After having measured the enzymatic activity of fibrosarcoma and breast carcinoma cells, we analyzed the cytotoxic effect of the conjugate on the same lines and on human red blood cells (HRBC) as controls. We found that the conjugate was activated, at least in part, by the tumor cell lines used, whereas it was inactive on HRBC. That the activation process was dependent on the enzymatic action of cathepsin B and MMPs, was indicated by three lines of evidence: (1) binding occurred normally on all type of cells including HRBC which however were insensitive being devoid of enzymes; (2) the cytotoxic effect correlated with the amount of cathepsin B activity expressed by the cells; (3) conjugate activation was reduced by specific inhibitors of cathepsin B and MMPs. These results demonstrate the possibility of tumor cell killing by a pore-forming toxin conjugate specifically activated by tumor proteases.

INTRODUCTION

Immunotoxins and mitotoxins are chimeric molecules in which specific ligands are coupled to toxins. If the ligand moiety is specific for a tumoral cell line, the chimeric toxin can kill those cells selectively. Several reviews describe the construction and the activity of chimeric toxin produced by genic fusion or chemical linking to either antibodies (immunotoxins) or growth factors (mitotoxins) (*1*, *2*).
