A Single-Step Method for the Production of Sugar Hydrazides: Intermediates for the Chemoselective Preparation of Glycoconjugates

Nicholas S. Flinn,* Martin Quibell, Tracy P. Monk, Manoj K. Ramjee, and Christopher J. Urch†

Amura Therapeutics Limited, Horizon Park, Barton Road, Comberton, CB3 7AJ, United Kingdom. Received February 15, 2005; Revised Manuscript Received March 10, 2005

The ability to selectively conjugate carbohydrate molecules to a protein is a key step in the preparation of conjugate vaccines, while facile methods for linking carbohydrates to polymers or solid surfaces to produce diagnostic probes and functional microarrays are also sought. Here, we describe a simple, single-step method of producing glycosylhydrazides from unprotected sugars, which were then linked in a controlled manner to a desired carrier, through an appropriate linker. The method was chemoselective and did not require coupling reagents, and the native pyranose form of the reducing end residue was retained. Initially, mono- and disaccharide hydrazides were produced from the corresponding reducing sugars and linked to BSA through a bifunctional linker. Final exemplification of the procedure was demonstrated by the preparation of a LewisY tetrasaccharide protein conjugate, which was recognized by a LewisY monoclonal antibody indicating the preservation of the natural conformation of the tetrasaccharide in the final construct. It is envisaged that this method will have general applicability to a variety of functionally diverse reducing sugars and provide a route to highly defined glycoconjugates, without the need for elaborate synthetic strategies.

INTRODUCTION

Bacterial derived polysaccharides presented as vaccines have already been effective in controlling certain types of pneumonia and meningitis (*1*, *2*), while "tumor-associated" carbohydrates unique to certain cancers, have also proved attractive as candidates for incorporation into therapeutic cancer vaccines (*3*−*7*). The promise of such subunit vaccines has been limited by their low immunogenicity, and to make polysaccharide vaccines broadly more effective, the polysaccharides require conjugation to "carrier proteins" (*8*), which are often prepared from bacterial sources themselves. The resultant conjugate vaccines tend to be highly immunogenic and confer long-lasting protection.

Conjugation of polysaccharides to a carrier protein, however, is by no means a simple task, given the polyfunctional nature and complexity of the molecules. Nonspecific approaches include the use of cyanogen bromide (CNBr) (*9*, *10*) and 1-cyano-4-dimethylamino-pyridinium tetrafluoroborate (CDAP) (*11*, *12*), which involve activation of hydroxyl groups on the polysaccharide and result in attachment through multiple sites. More controlled methods of conjugation utilize reductive amination, whereby the reducing end of the polysaccharide is reacted with an amine present on a bifunctional spacer molecule or on a protein to form a Schiff adduct, which is then reduced with sodium cyanoborohydride to form a physiologically stable bond (*13*, *14*). However, the ring opening of the reducing end residue, which occurs during reductive amination, may have a detrimental effect on the biological activity or immunogenicity of the carbohydrate, because the loss of structure ultimately equates to the loss of function (*15*).

A much improved approach involves the introduction of a primary amine at the reducing end terminus of an unprotected carbohydrate (*16*). The pyranose form of the reducing end terminus monosaccharide is preserved, and the new amine provides a useful handle for further elaboration that may lead to selectively defined glycoconjugates (*15*, *17*, *18*). Obviously, defined sugar conjugates may be obtained from a wholly synthetic approach; however, this chemistry is complex and is limited to short-chain-length oligosaccharides (<10 residues).

We have developed a chemoselective linker for controlled conjugation, particularly in the preparation of constructs where retention of structure and function is paramount (e.g., vaccines, functional arrays, etc.) (*19*). The methodology, which has already been applied to peptides, proteins, and small molecules, requires a hydrazide to be present, because conjugation proceeds through hydrazone formation (*20*). Herein, we describe a one-step method for the preparation of glycosylhydrazides directly from reducing sugars, without the need for elaborate synthetic manipulation or initial conversion to an amino derivative. Reaction of model mono- and disaccharides with the homobifunctional spacer adipic dihydrazide, produced the desired glycosylhydrazides in predominantly the β-pyranose form. These hydrazide-modified sugars were then conjugated to bovine serum albumin (BSA) in a selective manner, using our previously described linker technology (*20*). In a further exemplification of the methodology, a BSA conjugate of the LewisY tetrasaccharide (*21*, *22*) was also prepared and the conjugate was recognized by a LewisY-specific monoclonal antibody, demonstrating the retention of the native LewisY structure during the process. It is envisaged that the chemistries derived for these model systems could be extended to more complex saccharides and

provide a generalized method for the prederivatization of a range of complex glycans ready for chemoselective glycoconjugate production.

EXPERIMENTAL PROCEDURES

General Biochemistry. All reagents were of the highest commercially available quality and were used as received. Unless otherwise stated all chemicals and biochemicals were purchased from the Sigma Chemical Company (Poole, Dorset, U.K.). Unless otherwise stated, routine protocols were carried out at ambient temperature and kinetic experiments were carried out at 25 °C. Protein concentrations were determined using the Bradford reagent (Sigma) according to the instructions of the manufacturer using BSA as the standard. Absorbance measurements were either carried out in 384-well microtiter plates (Corning Costar 3702 plates, Fisher Scientific, Loughborough, U.K.), flat-bottomed 96-well plates (Spectra; Greiner Bio-One Ltd., Stonehouse, Gloucestershire, U.K.) or standard 1 mL quartz cuvettes, using a SpectraMax PLUS384 plate reader (Molecular Devices, Crawley, U.K.). Fluorescence measurements were carried out in either 384-well microtiter plates (Corning Costar 3705 plates, Fisher Scientific) or 96-well "U" bottomed Microfluor W1 microtiter plates (Thermo Labsystems, Ashford, Middlesex, U.K.). Fluorescence assays were monitored using a SpectraMax Gemini fluorescence plate reader (Molecular Devices). In all cases, SOFTmax Pro 3.1.2 software was used for data collection and handling (Molecular Devices). All spectra were collected at a resolution of 2 nm. Gel and membrane images were captured using a Hewlett−Packard C7710A scanner employing HP Precision ScanPro 3.02 software on default settings. Images were routinely scanned at a minimum resolution of 600 dpi in gray scale mode (32 bit). Images were marked with legends employing Powerpoint (Microsoft Corp., Seattle, WA). Image analysis and processing was carried out using ImageJ software (*23*).

General Chemistry. All solid-phase synthesis was performed using an "Fmoc/tBu" procedure (*24*) invoking standard solid-phase synthesis resin washing protocols. Standard Fmoc amino acids were obtained from Chem-Impex International (Wood Dale, IL) and Merck Biosciences (Nottingham, U.K.) with the exception of Fmoc *N*-ϵ-trimethyllysine, which was purchased from Bachem U.K. Ltd. (St. Helens, U.K.). 2-Chlorotrityl-resin (Product 04-12-2800) was obtained from Merck Biosciences (Nottingham, U.K.). PS-carbodiimide resin was obtained from Argonaut Technologies (Muttenz, Switzerland). All solvents were purchased from Romil (Cambridge, U.K.). Solid-phase syntheses were performed manually in a polypropylene syringe fitted with a polypropylene frit to allow filtration under vacuum. Analytical HPLC was performed on Agilent 1100 series instruments including a G1311A quaternary pumping system, with a G1322A degassing module and a G1365B multiple wavelength UV−vis detector. Data were collected and integrated with Chemstation 2D software. The analyses were performed on a Zorbax, 5 μm, C8 reverse-phase column (150 × 4.6 mm i.d.), at a flow rate of 1.5 mL/min, monitoring at 215 and 254 nm. Eluents used were (A) 0.1% trifluoroacetic acid in water and (B) 90% acetonitrile/10% eluent A and used to run a gradient starting at 10% B, increasing to 90% B over 7 min, holding for 1 min, returning to 10% B over 1 min, and then remaining at initial conditions for a further 4 min to allow column re-equilibration. Compounds were purified by semipreparative HPLC, using a Phenomenex Jupiter C4 reverse-phase column (250 × 10 mm i.d.) at a flow rate of 4 mL/min, using the equipment and eluents described above or by gel filtration, using BioGel P-2 resin (extra fine in 0.02 M ammonium bicarbonate, Bio-Rad Laboratories). The molecular ions of compounds were determined on an Agilent 1100 series LC/MSD electrospray mass spectrometer (ESI−MS). ^{1}H NMR was performed on a Bruker Avance (500 MHz, TXI probe with ATM) at 300 K.

Amine Determination. The amine concentrations were determined using fluorescamine (Fluram; Fluka) (*25*), employing Ac-Lys-NH_2 (Bachem) as the calibration control. Routinely, 10 μL of test sample was diluted into 85 μL of 100 mM sodium phosphate at pH 10 and 5 μL of 10 mM Fluram (in 100% acetonitrile) added. The Fluram solutions were freshly prepared prior to use. The reactions were mixed and incubated at ambient temperature for 30 min prior to measuring the fluorescence (390 nm, excitation; 460 nm, emission).

SDS−PAGE and Western Blot Analysis. The SDS−PAGE and Western blot components were obtained from Invitrogen, Paisley, U.K. For denatured protein analysis, samples were routinely analyzed by SDS−PAGE using the NuPAGE system employing 4−12% bis-tris NuPAGE gels and, unless otherwise stated, all gels were run in MES or MOPS running buffer. The POWEREASE system was used to carry out electrophoresis employing protocols embedded in the software of the unit. Proteins were visualized with SimplyBlue stain or SilverExpress stain kits according to protocols of the manufacturers. After staining, gels were dried using DryEase gel-drying solution and cellophane membranes.

For Western blot analysis of conjugates, the proteins were transferred from the gel onto PVDF membrane using the reagents and protocols of the manufacturer (Invitrogen). The PVDF membranes were blocked by gentle agitation in 50 mL phosphate-buffered saline containing 1% Tween 20 (PBST; Sigma) plus 1% (w/v) casein for 60 min. The recovered membranes were washed 3 times, by gentle agitation, in 50 mL of PBST for 5 min per cycle. After this, the membranes were incubated in 30 mL of PBST containing 1:100 dilution of mouse IgM LewisY monoclonal antibody (Alexis Corporation, SIG-317) for 60 min. After washing as before, the membranes were incubated in 30 mL of PBST containing 1:1000 dilution goat anti-mouse IgM, HRP conjugated antibody (Alexis Corporation, A90-101P) for 60 min, washed as before in PBST, and allowed to partially drip dry. Regions of peroxidase activity were visualized by addition of a 3,3′,5,5′-tetramethylbenzidine (TMB) liquid substrate (Sigma) onto the static membrane. After appropriate exposure, the membrane was recovered, washed in water, and air-dried prior to scanning, analysis, and storage.

ELISA assays were performed in immulon 2HB 96-well plates (Thermo Labsystems). Samples were introduced in PBS buffer and incubated overnight at 37 °C. Washing was performed 3 times with 200 μL of PBST, and the plate was blocked with 100 μL of PBST containing 1% casein (w/v) for 60 min. Primary and secondary antibodies (100 μL) were the same as those used for the Western blot analysis, both being incubated for 60 min at 37 °C with a PBST wash step in between. After a final PBST wash, peroxidase activity was visualized by addition of 100 μL of *o*-phenylenediamine (OPD; Sigma) and the reaction was quenched with 100 μL of 0.1 M sulfuric acid. Quantitation was by absorbance at 490 nm.

Diafiltration. Routinely, Amicon Ultra-4 ($\leq$4 mL) or Ultra-15 ($\leq$15 mL) centrifugal filter units (10 000 mwco; Millipore, Watford, U.K.) were used for diafiltration. Each cycle consisted of diluting the protein sample approxi-

mately 10-fold with exchange buffer and concentrating the sample by centrifugation back to its original volume. Cycles were repeated as required for quick and highly efficient equilibration/washing of protein samples. Routinely, six cycles were completed for each diafiltration step.

Synthesis of 5-[*N*′-(3,4,5-Trihydroxy-6-hydroxymethyltetrahydropyran-2-yl)-hydrazinocarbonyl] Pentanoic Hydrazide (3a). A mixture of glucose **1a** (90 mg, 0.5 mmol) and adipic dihydrazide **2** (recrystallized from water−acetonitrile) (870 mg, 5 mmol) in water (5 mL) and acetonitrile (5 mL) was heated at 80 °C. After 8 h, the mixture was evaporated under reduced pressure, water (2 mL) was added, and the mixture was evaporated under reduced pressure. Gel-filtration chromatography was performed twice to give **3a** (22 mg, 13%) as a white solid, following lyophilisation. ^{1}H NMR (D_2O) δ: 3.96 (d, 1H, J = 9.0 Hz), 3.77 (dd, 1H, J = 12.2, 2.1 Hz), 3.58 (dd, 1H, 12.2, J = 5.8 Hz), 3.38 (t, 1H, J = 9.1 Hz), 3.28 (ddd, 1H, J = 9.8, 5.9, 2.3 Hz), 3.22 (t, 1H, J = 9.3 Hz), 3.14 (t, 1H, J = 9.0 Hz), 2.11 (m, 4H), 1.47 (m, 4H). MS *m/z*: 337.2 (M + H^+), 359.2 (M + Na^+). Exact mass calculated for $C_{12}H_{24}N_4O_7$ (MH+), 337.1718; found, 337.1710 (δ −2.19 ppm).

Synthesis of 5-{*N*′-[3,4-Dihydroxy-6-hydroxymethyl-5-(3,4,5-trihydroxy-6-hydroxymethyltetrahydropyran-2-yloxy)tetrahydro-pyran-2-yl]hydrazinocarbonyl} Pentanoic Hydrazide (3b). A mixture of α-D-lactose monohydrate **1b** (180 mg, 0.5 mmol) and **2** (recrystallized from water−acetonitrile) (870 mg, 5 mmol) was heated in water (5 mL) and acetonitrile (5 mL) at 80 °C. After 8 h, the mixture was evaporated under reduced pressure, water (2 mL) was added, and the mixture was evaporated under reduced pressure. Gel-filtration chromatography was performed twice to give **3b** (182 mg, 73%) as a white solid, following lyophilisation. ^{1}H NMR (D_2O) for β isomer δ: 4.35 (d, 1H, J = 7.9 Hz), 4.03 (d, 1H, J = 9.0 Hz), 3.87 (dd, 1H, J = 12.2, 2.1 Hz), 3.83 (d, 1H, J = 3.3 Hz), 3.75−3.50 (m, 7H), 3.45 (m, 2H), 3.25 (t, 1H, J = 9.0 Hz), 2.14 (m, 4H), 1.51 (m, 4H). MS *m/z*: 499.2 (M + H^+), 521.2 (M + Na^+), 1019.3 (2M + Na^+). Exact mass calculated for $C_{18}H_{34}N_4O_{12}$ (MH^+), 499.2246; found, 499.2252 (δ +1.25 ppm).

Synthesis of *N*-[2-(*N*′-Acetylhydrazino)-5-[4,5-dihydroxy-6-hydroxymethyl-3-(3,4,5-trihydroxy-6-methyltetrahydropyran-2-yloxy)tetrahydropyran-2-yloxy]-6-hydroxymethyl-4-(3,4,5-trihydroxy-6-methyltetrahydropyran-2-yloxy)tetrahydropyran-3-yl]-5-hydrazinocarbonylpentamide (3c). A mixture of LewisY tetrasaccharide **1c** (3 mg as supplied by Sigma, 0.0044 mmol) and adipic dihydrazide **2** (recrystallized from water−acetonitrile) (7.7 mg, 0.044 mmol) in pH 4.75 sodium formate buffer (0.1 mL) was heated at 30 °C, and the reaction was monitored for product formation. After 6 days, the mixture was diluted with water (0.1 mL), frozen, and lyophilized. Gel-filtration chromatography (Bio-Gel P-2 Gel, extra fine, 0.02 M ammonium bicarbonate) gave the LewisY tetrasaccharide-adipic dihydrazide adduct **3c** (1.66 mg, 45%) as a white solid, following lyophilisation. ^{1}H NMR (D_2O) major isomer δ: 5.15 (d, 1H, J = 3.5 Hz), 4.97 (d, 1H, J = 3.9 Hz), 4.76 (brq, 1H, J = 6.0 Hz), 4.37 (d, 1H, J = 7.8 Hz), 4.13 (d, 1H, J = 4.6 Hz), 4.11 (brs, 1H), 3.86 (d, 1H, J = 10.3 Hz), 3.80−3.40 (m, 19H), 3.30 (m, 1H), 2.25−2.05 (m, 4H), 1.89 (s, 3H), 1.55−1.40 (m, 4H), 1.13 (d, 3H, J = 6.6 Hz), 1.10 (d, 3H, J = 6.6 Hz). MS *m/z*: 832.3 (M + H^+), 854.3 (M + Na^+). Exact mass calculated for $C_{32}H_{57}N_5O_{20}$ (MNa+), 854.3495; found, 854.3470 (δ −2.92 ppm).

Synthesis of 5-(4-Formyl-3-hydroxyphenoxy)pentanoic Acid 2,5-Dioxo-pyrrolidin-1-yl Ester (4) (AmLinker *N*-Hydroxysuccinimide Ester). Compound **4** was prepared as described previously (*20*).

Preparation of AmLinker−BSA (5). BSA (2 mg, 29 nmol) was dissolved in 0.1 M sodium acetate (1 mL, pH 7.25), to which 500 μL of a 15 mM solution of **4** (in 100% DMSO) was added, and the reaction was stirred at ambient temperature. The disappearance of free amine was monitored using Fluram titration and once complete (∼2−3 h) the reaction mixture was purified by diafiltration using 10 mM ammonium bicarbonate (pH 8) and the product analyzed by SDS−PAGE.

Preparation of Glucose, Lactose, and LewisY BSA Conjugates (6a−c, Respectively). The glucose, lactose, and LewisY conjugates (**6a−c**) were produced by stirring AmLinker−BSA (**5**) (1 mg, 14 nmol) with sugar hydrazides **3a**, **3b**, and **3c** in sodium formate (0.1 M; pH 4: 1 mL) containing between 10 and 30% DMSO (v/v) at room temperature, using 3−5 molar equivalents of sugar hydrazide over the molar equivalents of AmLinker coupled to the surface of the BSA. The reactions were monitored by UV at 318 nm and allowed to run until deemed completed (by the UV profile), which in general was 5−6 h. The conjugates were purified by diafiltration and characterized by SDS−PAGE.

RESULTS AND DISCUSSION

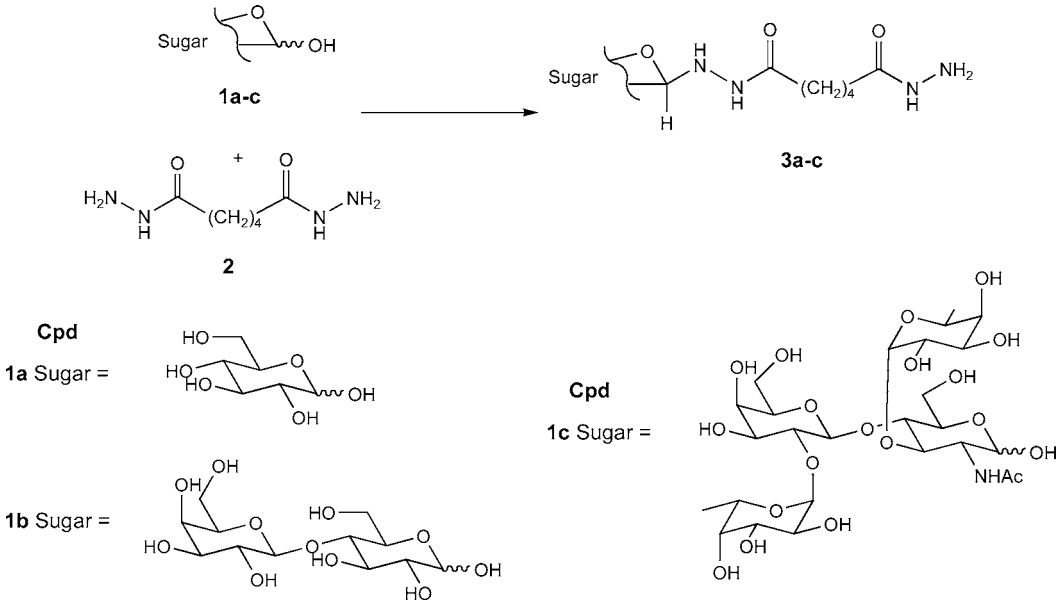
Synthesis of Hydrazide-Modified Sugars. We recently reported the development of a charge-balanced linker for the chemoselective conjugation of proteins, peptides, and small molecules (*20*) and were attracted by the potential wider application of the linkage technology to include the preparation of defined glycoconjugates. Because the linkage chemistry relies on hydrazone formation, it is necessary to introduce a hydrazide moiety into the carbohydrate of interest, before conjugation to a carrier or solid surface can be performed. With this in mind, a simple method of glycosylhydrazide production was sought that was selective, did not require elaborate synthetic protocols, and had the potential for application to increasingly complex saccharides. It was deemed imperative that the procedure should leave the pyranose form of the sugar intact and not disrupt its native ring conformation, and herein, we report our results.

Given the success of the well-precedented selective preparation of β-glycosylhydrazines from reducing sugars by treatment with hydrazine (*26*) and hydrazine derivatives (*27*), we sought to replicate the process replacing hydrazine with a hydrazide. Simple mono- and disaccharide sugars (**1a** and **1b**) were reacted with the commonly used bifunctional spacer adipic dihydrazide **2** (in excess) to yield the corresponding hydrazide-modified sugars (**3a** and **3b**) (Scheme 1).

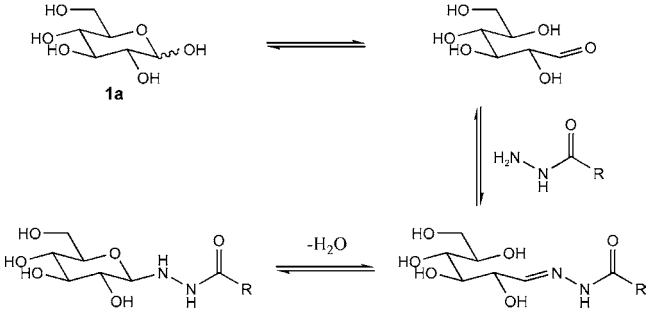
For sugars **1a** and **1b**, the reaction was performed at 80 °C for 8 h in a 50:50 mixture of water and acetonitrile (acetonitrile could be replaced with DMSO, without any detrimental effect), which usually resulted in a near quantitative yield of the hydrazide adduct. Further examples of glycosylhydrazides were also prepared from glucosamine, *N*-acetyl glucosamine, and glucuronic acid, to demonstrate the broad applicability of the method to structurally diverse sugars, although in these latter examples, the products were not isolated (*28*).

As a result of very high water solubility and the small differences in molecular weight between product and reactants, purification of the glucose monoglycosylhydrazide (**3a**) proved troublesome by gel-filtration chro-

Scheme 1



Scheme 2. Proposed Mechanism for the Glycosylhydrazide Formation



matography, with an isolated yield of only 13% being obtained despite the reaction being near quantitative. However, the higher molecular weight sugars were more amenable to gel-filtration chromatography. For example, when the lactose and LewisY derivatives (**3b** and **3c**) were purified by gel filtration, much higher isolated yields (73 and 45%, respectively) were obtained. In each reaction, the β isomer was the major product estimated at about 90% (but because of the proximity of the anomeric proton of the α isomer to the water signal in the NMR spectra, greater accuracy was not possible).

This selectivity of a reaction for an anomeric position bearing a hydroxyl group is important because it means that sugar conjugates can be made without the risk of decomposition of the saccharide. It also implies that the mechanism of reaction is via the open-chain sugar and is reinforced by the fact that the open imine form of the product can be identified in some cases by NMR, particularly before the reaction has gone to completion (shown in Scheme 2 for glucose **1a**).

After we demonstrated the feasibility of glycosylhydrazide preparation from simple unprotected sugars, a more complex and biologically relevant carbohydrate was sought as a final exemplification. Of particular interest was the LewisY tetrasaccharide (**1c**, Scheme 1), a carbohydrate specificity belonging to the A, B, and H Lewis blood group family, which is overexpressed on many carcinomas, including ovary, pancreas, prostate, breast, colon, and nonsmall cell lung cancers (*4*, *29*, *30*) and has been highlighted as a possible tumor vaccine candidate. A further attraction was the fact that monoclonal antibodies (mAb) specific for LewisY were commercially available, which was useful for determining whether the structural conformation of the LewisY was retained during the derivatization procedure and final conjugation process, because the LewisY mAb would presumably only recognize the native structure.

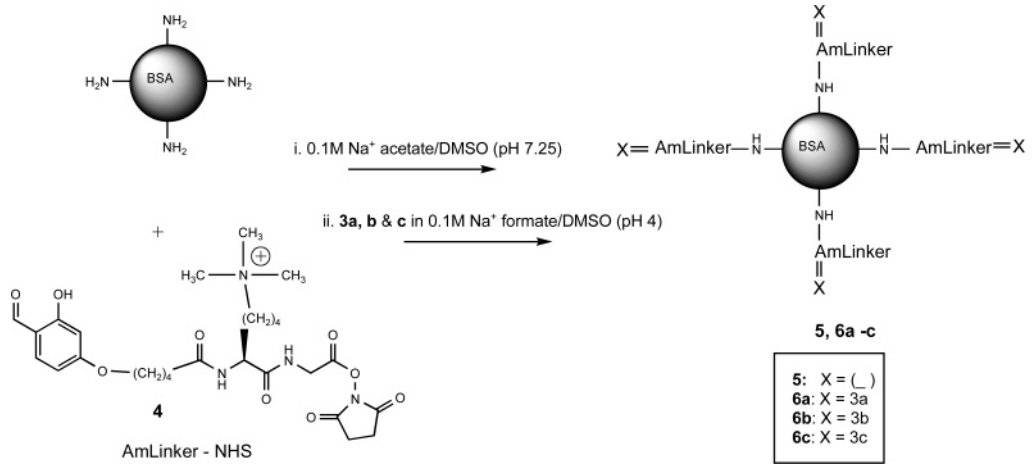
In the case of the Lewis Y tetrasaccharide, it was not possible to form the glycosylhydrazide under the conditions previously employed because of the practical difficulties of maintaining a small volume (0.1 mL) at 80 °C. Thus, it was necessary to find conditions that allowed equilibrium to be reached at a lower temperature on a reasonable time scale. This was accomplished by performing the reaction under mildly acidic conditions. Trial reactions using *N*-acetyl glucosamine and adipic dihydrazide **2** at 30 °C were essentially complete after 5 days. Thus, the Lewis Y tetrasaccharide **1c** and 10 equiv of adipic dihydrazide **2** were heated at 30 °C in pH 4.75 formate buffer for 6 days, at which point TLC (SiO_2 and MeOH) indicated complete conversion to the glycosylhydrazide. Characterization of the crude reaction mixture by ESI−MS and NMR indicated one major product. Gel-filtration chromatography gave the desired product **3c** in an isolated yield of 45%.

Because glycosylhydrazide formation can occur at mildly acidic to neutral pH, it is possible to modify reaction conditions such as pH and temperature to achieve optimal reaction rates while maintaining a stable environment for the reactants and product. This versatility should render the process applicable to a diverse array of complex carbohydrates, some of which may be chemically sensitive.

Carrier Protein Conjugation. With the glycosylhydrazides prepared, we next sought to use these derivatized sugars to produce protein−sugar conjugates. Thus, BSA, which is often exploited as a carrier protein for experimental conjugate vaccines, was derivatized by acylation with the *N*-hydroxysuccinimide ester of our linker **4** (AmLinker-NHS) to produce a BSA−AmLinker-derived carrier protein **5** (Scheme 3).

Using a modification of the general coupling conditions elucidated previously for peptide hydrazides (*19*, *20*), conjugation reactions were attempted with the AmLinker-modified BSA **5** and hydrazide sugars **1a** and **1b** to produce BSA−sugar conjugates of glucose and lactose

Scheme 3. Preparation of BSA Glycoconjugates via AmLinker



(**6a** and **6b** respectively). The process was monitored by the increase in absorbance at 318 nm, as described previously (*20*) (Figure 1A).

Characterization of the conjugates was accomplished by gel electrophoresis, which was employed to give an estimation of molecular weight. Figure 1B shows the slight increase in molecular weight between BSA and conjugates **6a** and **6b**.

Conjugation of **3c** to BSA−AmLinker **5** was carried out and monitored by UV at 318 nm (Figure 2) as stated previously for conjugates **6a** and **6b**, with the exception that only 3 molar equivalents of **3c** was used over **5**, because of the limited availability of the LewisY starting material.

After purification of the product by diafiltration, the LewisY−BSA conjugate (**6c**) was initially characterized by gel electrophoresis to assess molecular weight and loading (Figure 3A). Figure 3A clearly shows that the BSA−LewisY conjugate **6c** has an increased molecular weight of approximately 25 kDa when compared to the unmodified BSA protein. Modification of the BSA with 1 AmLinker molecule and the LewisY tetrasaccharide would lead to an increase of a little over 1 kDa. Thus, a molecular weight increase of 25 kDa would suggest a loading of ∼22−24 molecules of LewisY on every molecule of BSA (which represents the majority of surface-available linkage points). It was also observed that the glycoconjugate remained soluble in the buffer solution even though the protein had undergone substantial surface modification, indicating the benefits of the charge

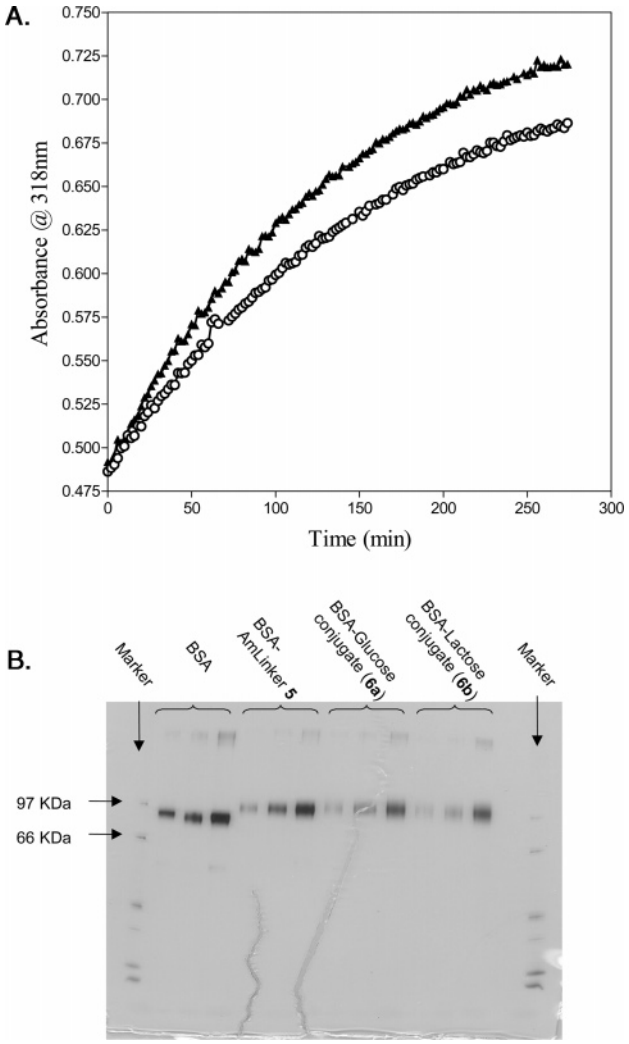


Figure 1. (A) Production of BSA glycoconjugates **6a** (○) and **6b** (▲). Glucose hydrazide (**3a**) and lactose hydrazide (**3b**) conjugation, to BSA−AmLinker (**5**) in 100 mM formate at pH 4.0 (with 20% v/v DMSO), monitored by a change in absorbance at 318 nm. (B) Characterization of conjugates **6a** and **6b** by SDS−PAGE.

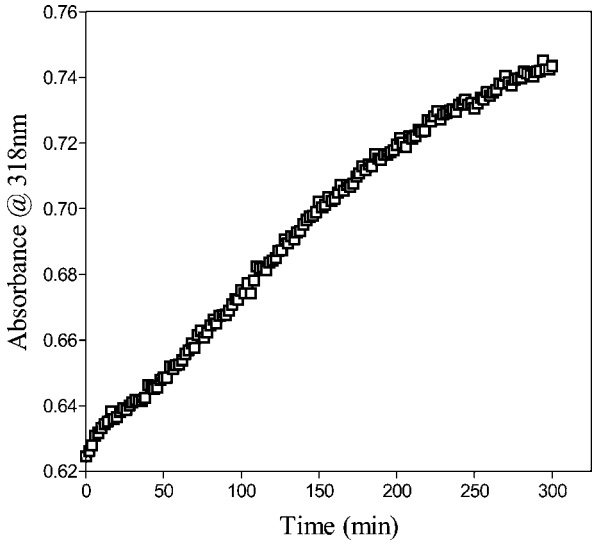

Figure 2. Production of BSA−LewisY conjugate (**6c**) (□). LewisY hydrazide (**1c**) conjugation to BSA−AmLinker (**5**) in 100 mM sodium formate at pH 4.0 (with 20% v/v DMSO), monitored by a change in absorbance at 318 nm.

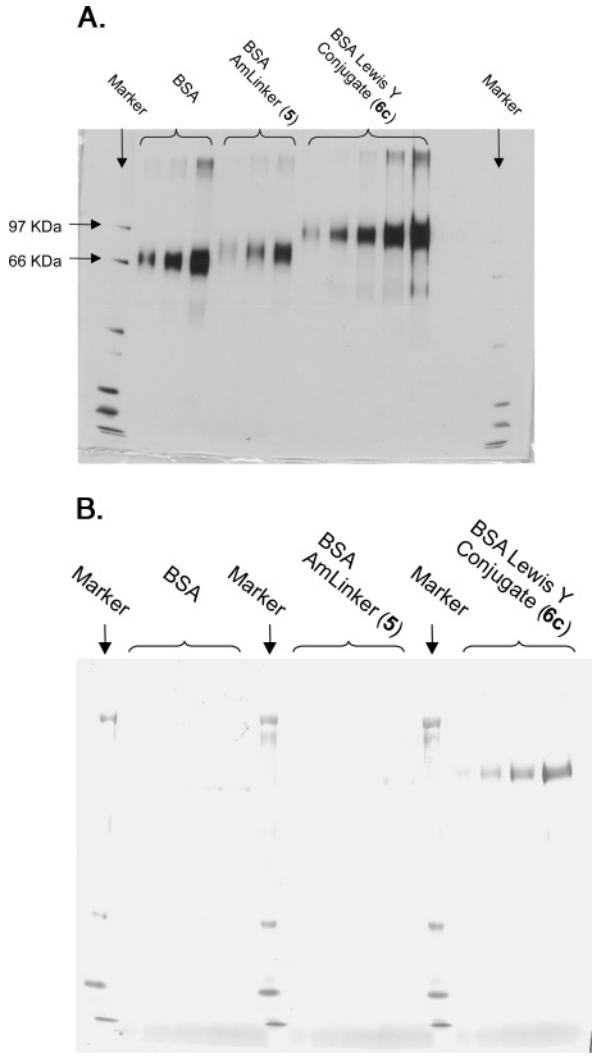

Figure 3. (A) Increase in molecular weight of BSA−LewisY conjugate (**6c**) shown by SDS−PAGE: The single band suggests an homogeneous conjugate preparation. (B) Western blot of BSA, BSA−AmLinker (**5**), and BSA−LewisY conjugate (**6c**) using a LewisY specific mAb and an anti-mouse IgM HRP labeled secondary antibody. Visualization was achieved with ″TMB. Rainbow markers were used to give molecular weight estimates.

compensation mechanism built into AmLinker, which replenishes the positive charge of the surface amine lost during its covalent modification (*20*).

To further characterize the conjugate, binding assays were performed using a LewisY-specific mAb to demonstrate that the LewisY tetrasaccharide was conjugated in a selective manner and remained structurally unperturbed. In the first experiment, a Western blot of a gel similar to that in Figure 3A was produced and exposed to the LewisY-specific mAb. After the blot was developed, it was clear that the mAb recognized the BSA−LewisY conjugate **6c** alone and not the BSA or the BSA−AmLinker **5** intermediate (Figure 3B).

To confirm that the LewisY-specific mAb recognized only the LewisY and not the BSA or AmLinker, an ELISA immunoassay was performed, whereby the BSA−LewisY conjugate **6c** was treated with 1 N hydrochloric acid (HCl) and then repurified by ultradiafiltration. Because one aspect of AmLinker is its reversibility (*20*), treatment with acid will remove any conjugated molecule while leaving the BSA−AmLinker preparation intact. Thus, the LewisY-specific mAb should no longer recognize this acid-treated sample after removal of the LewisY tetrasaccharide.

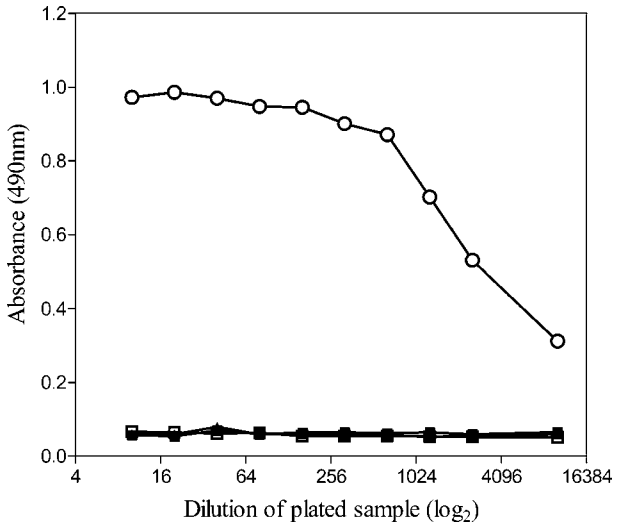

Figure 4. ELISA shows the specific recognition of the BSA−LewisY conjugate (**6c**) (○) with the LewisY specific mAb, whereas BSA (■), BSA−AmLinker (**5**) (▲), and the post-acid-treated BSA−LewisY conjugate (□) display no reaction. Visualization was achieved with an anti-mouse IgM HRP labeled secondary antibody and OPD and quantified by absorbance at 490 nm.

The samples were added to a microtiter plate and double-diluted in PBS, while PBS alone was used as the blank. After exposure to the LewisY-specific mAb, only the BSA−LewisY conjugate **6c** displayed binding, while the other samples, including the acid-treated BSA−LewisY conjugate, were not recognized by the mAb, as quantified by absorbance readings at 490 nm (Figure 4).

CONCLUSION

The synthetic study described herein successfully demonstrates that glycosylhydrazides can be prepared from their unprotected precursor reducing sugars in a single step reaction, employing simple solvents and without the need for aggressive activating reagents. These stable glycosylhydrazides may then be conjugated, via our proprietary linkage technology (AmLinker) (*20*) to any amine functionalized surface. The uncomplicated and selective manner in which the derivitisation and conjugation is performed permits the retention of the native pyranose structure of the reducing end sugar and leads to the enhanced prospect of producing functional conjugates. This is a primary consideration when designing and developing glycoconjugates for use as vaccines, diagnostic tools, or in high throughput screening strategies, where the loss of native conformation ultimately leads to an attenuation of biological activity.

Although exemplification of this feasibility study culminated in the production of glycoprotein conjugates, our AmLinker technology has already demonstrated applicability to the construction of functional peptide and small molecule arrays and protein conjugates (*19*). Thus, it is envisaged that the simple preparation of unprotected sugar hydrazides, described herein, utilizing an established dihydrazide spacer molecule, may be employed over a wide range of applications, where conjugation of mono-, di-, oligo-, or polysaccharides to a carrier molecule or solid surface would be desirable.

TECHNICAL NOTES

Probing for Integrin $\alpha_v\beta_3$ Binding of RGD Peptides Using Fluorescence Polarization

Department of Experimental Diagnostic Imaging and Department of Neuro-oncology, The University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030. Received September 29, 2004; Revised Manuscript Received March 1, 2005

Integrin $\alpha_v\beta_3$ is an adhesion molecule involved in tumor invasion, angiogenesis, and metastasis. There is substantial interest in developing novel agents that bind to integrin $\alpha_v\beta_3$. Here we report the synthesis and characterization of a fluorescent integrin $\alpha_v\beta_3$ probe and its use in a nonradioactive, simple, sensitive fluorescence polarization (FP) assay to quantify binding to integrin $\alpha_v\beta_3$. For assay validation, the FP assay was compared to a cell adhesion assay. In the two assays, probe binding to integrin $\alpha_v\beta_3$ showed a similar dependence on probe concentration. The FP assay was successfully applied to measure the binding affinity to integrin $\alpha_v\beta_3$ of several cyclic peptides containing the Arg-Gly-Asp (RGD) motif. The FP assay we describe here may be appropriate for high-throughput screening for integrin $\alpha_v\beta_3$-binding ligands used for anti-integrin therapy or noninvasive imaging of integrin expression.

INTRODUCTION

Integrins are heterodimeric transmembrane proteins that function principally as receptors for spatially restricted extracellular ligands (*1*). The α_v-integrins ($\alpha_v\beta_3$, $\alpha_v\beta_5$) play a critical role in tumor angiogenesis and are associated with tumor progression and metastasis (*2*−*4*). They are overexpressed on brain and melanoma tumor cells and newly formed tumor microvessels but not on normal cells and quiescent endothelial cells (*5*−*7*). Antibody, peptide, and peptidomimetic integrin $\alpha_v\beta_3$ antagonists have been shown to impair angiogenesis, growth, and metastasis of solid tumors (*8*−*10*). Furthermore, imaging the expression of α_v-integrins may allow determination of the optimal biological dose and schedule of integrin-targeted therapeutics and may allow monitoring of tumor responses to such therapeutics. Thus, there is substantial interest in developing novel agents that bind to α_v-integrins for both therapeutic and diagnostic purposes.

Existing in vitro methods for detecting integrin $\alpha_v\beta_3$ binding include a binding assay that uses immobilized integrin and a radiolabeled tracer (*11*, *12*), a competitive enzyme-linker immunosorbent assay (*13*), and surface plasma resonance (*14*). All of these methods, however, require immobilization of integrins on a solid surface.

A fluorescence polarization (FP) assay would be a more suitable assay for detecting integrin $\alpha_v\beta_3$ binding because FP is a homogeneous technology requiring only simple mix reagents and read format that can be easily automated (*15*). The technique has recently been introduced for high-throughput screening in the drug discovery process (*16*). FP depends on the excitation of a fluorescent molecule with plane-polarized light. This results in the emission of photons in the planes parallel and perpendicular to the excitation plane and confers information about the local environment of the fluorophore. Smaller molecules rotate faster and hence have smaller polarization values. Conversely, larger molecules (e.g., fluorescent probe bound to target) rotate more slowly and thus have bigger polarization values. Thus, the observed polarization value gives a direct measure of the molecular size of the analyte and the extent of tracer binding to macromolecules at constant temperature and viscosity. FP assays work well in colored and cloudy solutions. There is no need for radioisotopes, and there are no solid-phase artifacts. The technique does not require washing steps, and the system is easily automated.

To our knowledge, no fluorescence-labeled integrin $\alpha_v\beta_3$ ligands that could be used in an FP assay have previously been validated. Here we report the synthesis and characterization of a fluorescent derivative of the cyclic pentapeptide cyclo(Lys-Arg-Gly-Asp-phe) [c(KRGDf)]. We show that this probe tightly bound integrin $\alpha_v\beta_3$ and that its interaction with integrin $\alpha_v\beta_3$ was competed with by integrin ligands containing the Arg-Gly-Asp (RGD) motif.

EXPERIMENTAL PROCEDURES

Materials. All N^{α}-Fmoc-amino acids, 1-hydroxybenzotriazole (HOBt), benzotriazol-1-yl-oxy-tris-pyrrolidino-phosphonium hexafluorophosphate (PyBOP), and solid support linker [4-(4-hydroxymethyl-3-methoxyphenoxy)-acetic acid] (HMPA) were purchased from Novabiochem (San Diego, CA). Trifluoroacetic acid (TFA) was purchased from Chem-Impex International, Inc. (Wood Dale, IL). PL-DMA resin was purchased from Polymer Labo-

ratories (Amherst, MA). *N,N*-Diisopropylethylamine (DIPEA), triethylsilane (TES), 5(6)-carboxyfluorescein, tetrakis(triphenylphosphine)palladium ($Pd^0[P(C_6H_5)_3]_4$), *N*-methylmorpholine (NMP), and 1,3-diisopropylcarbodiimide (DIPCDI) were purchased from Aldrich Chemical Co. (St. Louis, MO). Integrin $\alpha_v\beta_3$ was purchased from Chemicon International, Inc. (Temecula, CA). All solvents were purchased from VWR (San Dimas, CA). A 96-well flat-bottom assay plate (black polystyrene) was purchased from Corning, Inc. (Corning, NY).

Analysis. Products were purified by reverse-phase high-performance liquid chromatography (HPLC), eluted with H_2O/acetonitrile containing 0.1% TFA, and validated by analytical HPLC and matrix-assisted laser desorption ionization (MALDI) mass spectrometry. Analytical HPLC was carried out on an Agilent 1100 system (Wilmington, DE) equipped with a Vydac peptide and protein analytical C-18 column (Anaheim, CA). Preparative HPLC was carried out on a Rainin Rabbit HP system (Walnut Creek, CA) equipped with a 25 × 2.5 cm Vydac C-18 column. MALDI was performed in the proteomics laboratory in the Department of Molecular Pathology at The University of Texas M. D. Anderson Cancer Center (Houston, TX).

Synthesis of Cyclic Peptides. RGD peptides were synthesized on a solid support. Briefly, PL-DMA resin (1 g) was treated with ethylenediamine (30 mL) overnight. HMPA linker (3 equiv) was attached to resin in the presence of DIPCDI (3 equiv) and HOBt (3 equiv). Peptides Fmoc-phe-X-Arg(Pbf)-Gly-Asp(resin)OAll, where X represents Lys(Boc), Glu(OBut), or Lys(Mtt), were synthesized using Fmoc solid-phase chemistry. The protecting groups of the amino acid side chains were *N-tert*-butoxycarbonyl (Boc) or 4-methyltrityl (Mtt) for Lys, *tert*-butyl (But) for Glu, 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl (Pbf) for Arg, and allyl (All) for Asp. Amino acids (3 equiv) were coupled stepwise in the presence of DIPCDI (3 equiv) and HOBt (3 equiv) coupling reagents. After removal of All and Fmoc protecting groups using $Pd^0[P(C_6H_5)_3]_4$ (3 equiv) in dichloromethane(DCM)/NMP/AcOH (37/1/2) and 20% piperidine in dimethylformamide (DMF), respectively, the cyclization was carried out on the solid support using PyBOP (3 equiv), HOBt (3 equiv), and DIPEA (6 equiv) as coupling agents to afford cyclo-[Lys(Boc)-Arg(Pbf)-Gly-Asp(resin)-phe], cyclo-[Glu(OBut)-Arg(Pbf)-Gly-Asp(resin)-phe), and cyclo-[(Lys(Mtt)-Arg(Pbf)-Gly-Asp(resin)-phe]. Mtt protecting group was removed by treatment with TFA/TES/DCM (1/2/97). To synthesize dimeric RGD peptide, Lys(Boc), Glu(OAll), phe, Asp(OBut), Gly, and Arg(Pbf) were successively attached to cyclo-[Lys-Arg-(Pbf)-Gly-Asp(resin)-phe] to form an undecapeptide Fmoc-Arg(Pbf)-Gly-Asp(OBut)-phe-Glu(OAll)-Lys(Boc)-cyclo-[Lys-Arg(Pbf)-Gly-Asp(resin)-phe]. After removal of All and Fmoc protecting groups, the second cyclization was carrier out on the solid support. Deprotection and cleavage of all these compounds from the solid support were carried out simultaneously by treatment with TFA/H_2O/TES (95/1/4) to afford c(KRGDf), cyclo(Glu-Arg-Gly-Asp-phe) [c(ERGDf)], or c(RGDfE)-K-c(KRGDf). All products were purified by reverse-phase HPLC and validated by MALDI mass spectrometry.

To synthesize the cyclic pentapeptide Ac-Ala-c(Cys-Asn-Gly-Arg-Cys)-Gly [Ac-A-c(CNGRC)-G], linear peptide Ac-ACNGRCG was first prepared using Fmoc solid-phase peptide synthesis. After removal of the peptide from the solid support by TFA/H_2O/TES (95/1/4), cyclization was achieved in NH_4OH aqueous solution (pH 9). The product was purified by reverse-phase HPLC and validated by MALDI mass spectrometry.

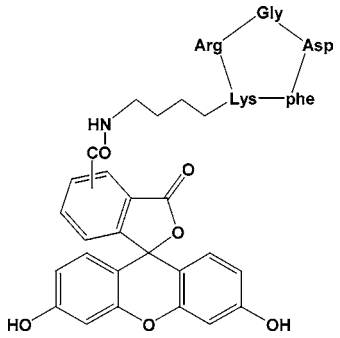

Figure 1. Structure of 5(6)-carboxyfluorescein−c(KRGDf) conjugate.

Conjugation of Fluorescein to c(KRGDf). Carboxyfluorescein (3 equiv) was coupled to c[Lys-Arg(Pbf)-Gly-Asp(resin)-phe] using DIPCDI (3 equiv) and HOBt (3 equiv) as the coupling agents. Deprotection and cleavage from the solid support were carried out simultaneously by treatment with TFA/H_2O/TES (95/1/4) to afford the target compound carboxyfluorescein-c(KRGDf) (FL-RGD) (Figure 1). The product was purified by reverse-phase HPLC and validated by MALDI mass spectrometry.

Fluorescence Polarization Assay. A solution of 200 μM FL-RGD or fluorescein in phosphate-buffered saline was diluted with Tris buffer (50 mM Tris, pH 7.4, 1 mM $CaCl_2$, 10 μM $MnCl_2$, 1 mM $MgCl_2$, 100 mM NaCl) to give a 100 nM stock solution. The reaction mixture (100 μL) in each well was composed of 10 nM FL-RGD probe (10 μL of 100 nM stock solution) and different concentrations of integrin $\alpha_v\beta_3$ (0 to 650 nM) in Tris buffer. The microwell assay plate was incubated at 29 °C for 0.5 h. Fluorescein alone (10 nM) and FL-RGD alone (10 nM) served as controls. FP was measured with a Tecan Polarion reader (Research Triangle Park, NC). The polarization value was expressed in millipolarization units (mP). The integrin titration data were analyzed using Graph-Pad PRISM software (GraphPad Software, Inc., San Diego, CA) with the one-site binding equation $FP = FP_{max}C/(K_d + C)$, where FP_{max} is the maximal FP value, C is the concentration of the protein, and K_d represents the dissociation constant.

Competitive displacement studies were performed with the integrin ligands c(KRGDf), c(ERGDf), and c(RGDfE)-K-c(KRGDf). The cyclic pentapeptide containing the Asn-Gly-Arg (NGR) motif, Ac-A-c(CNGRC)-G, was used as a negative control. Stocks of these compounds were made in phosphate-buffered saline at a concentration of 500 μM. The ligands were serially diluted in the assay buffer to concentrations ranging from 0.01 to 5 μM. The FL-RGD probe and $\alpha_v\beta_3$ were added at concentrations of 10 nM and 290 nM, respectively. The reaction mixture was shaken, and the FP values in mP were recorded. The mP values were plotted against the ligand concentration. The Polarion data were analyzed using Graph-Pad PRISM software with linear regression to obtain the concentration at which 50% inhibition of FL-RGD's binding to integrin $\alpha_v\beta_3$ was achieved (IC_{50} values).

Cell Adhesion Assay. Human melanoma M21 cells were obtained from Dr. David Cheresh (Scripps Research Institute, San Diego, CA). The cells were seeded in Dulbecco's modified Eagle's medium/F12 culture medium supplemented with 10% fetal bovine serum for 24 h. Cells (1×10^5) with different concentrations of c(KRGDf), c(ERGDf), c(RGDfE)-K-c(KRGDf), FL-RGD, or Ac-A-c(CNGRC)-G were added to vitronectin-coated microtiter wells under serum-free conditions and incubated at 37

[a] Reagents and conditions: (a) $Pd^0[P(C_6H_5)_3]_4$ (3 equiv), $CHCl_3$/AcOH/NMM (37/2/1, v); (b) 20% piperidine, DMF; (c) PyBOP/HOBt/DIPEA (3/3/6 equiv) in DMF; (d) TFA/H_2O/TES (95/1/4, v); (e) TFA/DCM/TES (1/97/2, v); (f) 5(6)-carboxyfluorescein (3 equiv) or Fmoc-Lys(Boc) (3 equiv), DIPCDI (3 equiv), HOBt (3 equiv) in DMF and DCM (1/1, v); (g) *p*-succinicamido-benzyl-DTPA penta-*tert*-butyl ester (2 equiv), PyBOP (3 equiv), HOBt (3 equiv), DIPEA (6 equiv) in DMF. SPPS, solid-phase peptide synthesis.

°C for 1 h. After washing steps, the bound cells were stained with 5% crystal violet, and then 0.1 M HCl was added to each well. The concentrations of crystal violet were determined by UV/Vis absorption at 627 nm. IC_{50} values were estimated from the dose−activity curves.

RESULTS AND DISCUSSION

Chemistry. Integrins bind extracellular matrix factors, such as vitronectin, that contain the RGD amino acid sequence, which appears to be critical in mediating the ligation signal, allowing endothelial cells to attach to the extracellular matrix and thus support endothelial survival and growth (*5*, *6*, *17*). Integrin antagonists and imaging agents are generally developed on the basis of cyclic peptides composed of five amino acids. One such agent, Cilengitide (c[RGDf(NMe)V]), has entered clinical phase II studies as a potent and selective integrin peptidic antagonist (*18*). Several radiolabeled peptides containing the RGD motif plus various combinations of two additional amino acids have been used for custom-made purposes such as iodination (tyrosine) or linkage of chelators (lysine) (*12*, *19*−*22*). Thus we selected c(KRGDf) peptide as the ligand for FP probe development.

We synthesized fluorescein-conjugated c(KRGDf) to use this agent as a probe for our FP assay. In addition, we synthesized the unconjugated monomeric peptides c(KRGDf) and c(ERGDf) and the dimeric cyclic peptide c(RGDfE)-K-c(KRGDf). All of these compounds were prepared by solid-phase peptide synthesis (Scheme 1). Starting from Asp attached to PL-DMA resin with HMPA linker coupled to the side chain of Asp, linear peptides were synthesized using an Fmoc strategy. The cyclization of pentapeptides was achieved on the solid support after selective removal of the N-terminal Fmoc and C-terminal All protecting groups to afford cyclo[X-Arg(Pbf)-Gly-Asp(resin)-phe], where X represents Lys(Boc), Glu(OBut), or Lys(Mtt). For the preparation of c(KRGDf), Boc was used as a protecting group for Lys. TFA was used to simultaneously cleave the peptide from the resin and remove the side chain protecting groups, yielding cyclic pentapeptides c(KRGDf) and c(ERGDf) (Scheme 1).

For preparation of the dimer c(RGDfE)-K-c(KRGDf) and FL-RGD, Mtt was used as the protecting group for Lys for the construction of cyclo[Lys(Mtt)-Arg(Pbf)-Gly-Asp(resin)-phe]. The side chain protecting group Mtt on Lys was selectively removed in diluted TFA without peptide cleaved from the resin. This allowed further elaboration for the second cyclic peptide or conjugation of carboxyfluorescein through the Lys unit on the solid support (Scheme 1). The physicochemical properties of the peptides synthesized are summarized in Table 1.

Fluorescence Polarization Assay. To demonstrate that the FP signal was a result of binding of FL-RGD with integrin, the FP assay was performed as a function of integrin concentrations with 10 nM probe in the assay. The FP signal rose from 40 mP (background mP value due to intrinsic polarization of the probe) to about 140 mP when the concentrations of integrin increased from 0 to 650 nM (Figure 2). This finding was expected because addition of more integrin would make more integrin available for complexing with the probe. The titration curve showed that the FL-RGD probe bound to integrin $\alpha_v\beta_3$. The dissociation constant (K_d) for FL-RGD−integrin

[a] Sample was eluted with H_2O and acetonitrile containing 0.1% TFA varying from 0% to 40% over 30 min. [b] Sample was eluted with H_2O and acetonitrile containing 0.1% TFA varying from 10% to 50% over 30 min.

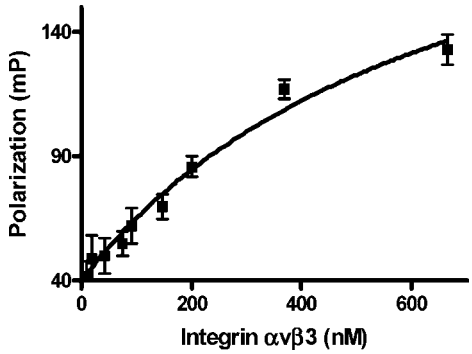

Figure 2. Titration curve for binding of FL-RGD probe to integrin $\alpha_v\beta_3$ as a function of $\alpha v\beta 3$ concentration. FP values (mP) were measured after incubation of FL-RGD (10 nM) and $\alpha_v\beta_3$ (0−650 nM) mixture at 29 °C for 30 min. The mP value obtained in the absence of $\alpha_v\beta_3$ (40 mP) represents the background mP value due to intrinsic polarization of the probe. Data are presented as mean values ± standard deviations from 3 independent experiments.

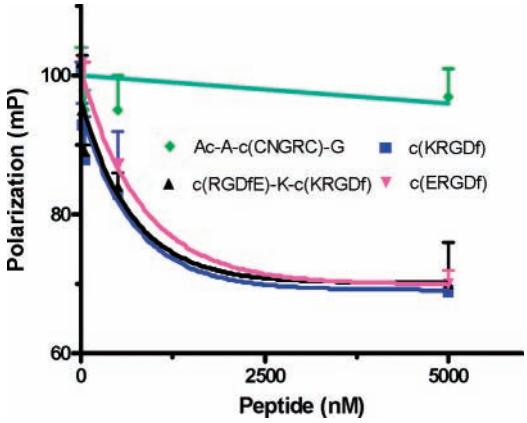

Figure 3. Titration curve for binding of FL-RGD probe (10 nM) to integrin $\alpha_v\beta_3$ (290 nM) in the presence of increasing concentrations of $\alpha_v\beta_3$ inhibitors. The NGR peptide [Ac-A-c(CNGRC)-G] is a negative control that does not bind $\alpha_v\beta_3$.

complex was 0.67 ± 0.15 μM as determined using GraphPad PRISM software with the one-site binding equation $FP = FP_{max}C/(K_d + C)$. The binding was fast; increasing the incubation time beyond 5 min did not have any effect on the FP signal (data not shown). These results showed that the FP assay with FL-RGD as a probe can be used to measure the binding affinity of ligands to integrin $\alpha_v\beta_3$.

To further demonstrate that the FP signal was dependent on formation of the RGD−integrin complex, the FP assay was performed as a function of concentration for several integrin inhibitors containing the RGD motif. Increasing the amounts of RGD peptides at fixed probe and integrin concentrations result in a decreased FP signal (Figure 3). The FP signal fell from about 105 mP to about 70 mP when the concentrations of the RGD peptide competitors increased from 0 to 5 μM. A window

Table 2. Comparison of IC_{50} Values Obtained from FP Assay and Cell Adhesion Assay[a]

cyclic peptides	FP IC_{50} (μM)	cell adhesion IC_{50} (μM)
carboxyfluorescein-c(KRGDf)		4.2 ± 0.27
c(KRGDf)	0.11 ± 0.003	5.0 ± 0.77
c(ERGDf)	0.28 ± 0.004	3.2 ± 0.16
c(RGDfE)-K-c(KRGDf)	0.11 ± 0.003	4.0 ± 0.32
Ac-A-c(CNGRC)-G	not available	not available

[a] Data are presented as mean values ± standard deviations from three independent experiments.

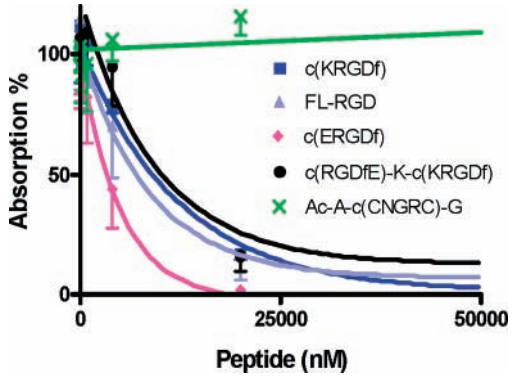

Figure 4. Adhesion of M21 human melanoma cells to vitronectin-coated microtiter wells in the presence of increasing concentrations of $\alpha_v\beta_3$ inhibitors. After washing steps, the bound cells were stained with 5% crystal violet, and then 0.1 M HCl was added to each well. The concentrations of crystal violet were determined by UV/Vis absorption at 627 nm. The percentage absorption values reported on the *y*-axis are relative to the absorption value measured in the absence of RGD peptides.

of about 35 mP was observed with peptide concentrations from 0 to 5 μM. Because of nonspecific binding, the FP value never dropped to the 40-mP background value observed in the absence of integrin inhibitors. IC_{50} values derived from linear regression of the competition curves for c(KRGDf), c(ERGDf), and c(RGDfE)-K-c(KRGDf) were 0.11, 0.28, and 0.11 μM, respectively. The NGR control peptide could not displace fluorescent probe from binding to integrin even at the maximal tested concentration of 5 μM (Figure 3; Table 2).

Cell Adhesion Assay. To validate the FP-integrin assay procedure, the FP assay was compared to a more standard functional assay that measures the inhibition of M21 tumor cell adhesion to extracellular matrix proteins. FL-RGD and the parent peptide c(KRGDf) gave similar IC_{50} values of 4.2 μM and 5.0 μM, respectively. These values are within the range of 3.2−5.0 μM for other RGD peptides, suggesting that FL-RGD is as efficacious as the parent peptide in inhibiting adhesion of tumor cells to vitronectin-coated microwells (Table 2). The number of attached cells decreased in a dose-dependent manner for all three unconjugated cyclic peptides containing the RGD motif as well as for FL-RGD (Figure 4). No inhibitory activity was observed for the NGR control peptide

(Figure 4). The IC_{50} values obtained from the FP assay paralleled the IC_{50} values obtained from the cell adhesion assay, albeit IC_{50} for integrin binding was approximately 10-times lower than IC_{50} for bioactivity. These data suggest that RGD peptides may possess nonspecific interaction with vitronectin in cell based adhesion assay. Nevertheless, both assays showed no significant differences among the three cyclic peptides containing RGD motif in their ability to bind integrin and inhibit cell adhesion (Table 2). We interpreted these findings as indicating that a similar binding affinity to integrin $\alpha v\beta 3$ resulted in a similar biological activity.

Binding Affinity of Various Cyclic RGD Peptides to Integrin $\alpha_v\beta_3$. The observation of no difference in integrin binding between c(KRGDf) and c(ERGDf) by FP assay confirms a previously reported finding that changing the amino acid X in c(XRGDf) does not significantly affect the binding affinity of cyclic RGD peptide to integrin (*23*). It has been proposed that multimeric constructs based on RGD peptide may lead to ligands with substantially increased binding affinity for integrin $\alpha_v\beta_3$ owing to the multivalency effect. Thumshirn et al. (*24*) observed 2.3- to 22-fold increases in IC_{50} values when monomeric peptides were compared to dimeric peptides linked together through a flexible oligomeric ethylene oxide linker. Janssen et al. (*25*) compared the IC_{50} of the radiolabeled monomer c(RGDfK) and dimeric E-[c(RGDfK)]$_2$ determined in immobilized human $\alpha_v\beta_3$ using an enzyme-linked immunosorbent assay. The affinity of the dimer for $\alpha_v\beta_3$ was 10 times the affinity of the monomer. In our hands, the dimeric peptide c(RGDfE)-K-c(KRGDf) did not show increased integrin binding as compared to the integrin binding of its individual monomers c(ERGDf) and c(KRGDf). It is possible that the distance and orientation between the two cyclic peptide rings could have affected the binding of the dimer to integrin receptors. With the integrin-binding FP assay validated, it is now possible to systematically investigate the effect of linker molecule on the binding of dimeric RGD peptide to integrin $\alpha_v\beta_3$. Work along this line is in progress.

Summary. In summary, the FP assay method should be advantageous compared to other methods reported in the literature for the measurement of integrin binding because the FP assay is a simple, one-step, nonradioactive assay that is performed in solution. We found that a fluorescent integrin $\alpha_v\beta_3$ probe based on the cyclic pentapeptide c(KRGDf) tightly bound integrin $\alpha_v\beta_3$ and that the probe's interaction with integrin $\alpha_v\beta_3$ was competed with by integrin ligands containing the RGD motif. The FP assay we describe here may be appropriate for high-throughput screening for integrin $\alpha_v\beta_3$-binding ligands used for anti-integrin therapy or noninvasive imaging of integrin expression.

Synthesis and Application of a Water-Soluble Near-Infrared Dye for Cancer Detection Using Optical Imaging

Wellington Pham, Zdravka Medarova, and Anna Moore*

Athinoula A. Martinos Center for Biomedical Imaging, Department of Radiology, Massachusetts General Hospital, Room 2301, Building 149, 13th Street, Charlestown, Massachusetts 02129.
Received December 15, 2004; Revised Manuscript Received March 14, 2005

A novel water-soluble 2-[2-(2-chloro-3-{2-[3,3-dimethyl-5-sulfo-1-(4-sulfo-butyl)-3*H*-indol-2-yl]-vinyl}-cyclohex-2-enylidene)-ethylidene]-3,3-dimethyl-1-(4-sulfo-butyl)-2,3-dihydro-1*H*-indole-5-carboxylic acid (dye **2**) was developed via an asymmetric approach. With an additional sulfonate group, the near-infrared feature of this dye exhibited a 2-fold increase in quantum yield compared to the previous generation. The current synthetic strategy provided a single carboxylic group as a handle for conjugation, thus allowing selectivity for bioconjugation. The stability of this dye was demonstrated by labeling peptides via solid-phase peptide chemistry. The in vivo optical imaging showed potential and broad applications of this dye in developing molecular-based beacons for cancer detection.

INTRODUCTION

The development of highly sensitive fluorescent dyes in combination with innovative optical techniques plays a pivotal role in the advancement of noninvasive imaging of human pathologic conditions. Fluorochromes attached to various ligands have been used for detecting nucleic acid hybridization, in drug discovery for sensing molecular interactions, and for deciphering biological pathways (*1*). Cyanine fluorochromes belong to a super-family of dyes that have attracted the most attention in molecular imaging recently, given the fact that the near-infrared (NIR) feature of the dye could theoretically be predicted and designed based on the length of the polymethine chain connecting the heterocyclic rings (*2*). The delocalization of a pair of electrons on an indole ring across the polymethine unsaturated bridge system defines the absorption maximum that corresponds to the transition from a ground state to an excited electronic state. For every double bond increase in the methine chain, there would be a 100 nm bathochromic shift as opposed to only 20 nm for every additional aromatic ring (*3*). Therefore, the absorption and emission wavelength of the cyanine dye can be tuned several hundred nanometers in the far-red region, though still maintain its compact structure compared to other types of dyes.

Optical imaging in the NIR region (700−900 nm) has a low absorption by intrinsic photoactive biomolecules and allows light to penetrate several centimeters into the tissue, a depth that is sufficient to image practically all small animal models (*1*). This technique, in conjunction with the development of a specific targeted molecular probe, not only allows detection of the enhanced contrasting signal, but also reveals specific molecular events associated with the disease state. Necessary features of fluorochromes for NIR in vivo imaging include water solubility, detectability in the NIR region, good quantum yield, stability in an array of different environments, and the availability of a handle for bioconjugation. Recently, we have described the development of cyclic polymethine dye **1**, in which the stability was remarkably improved by partially rigidizing two of the methine groups into a ring system (Figure 1). In addition, it has been observed that the ring not only increased the stability but also advanced the absorbance of the dye in the NIR region (*4*). The stability and diversity of dye **1** has been demonstrated in a first proof-of-concept study where it was used to label peptides and proteins in solid- and solution-phase chemistry, respectively (*5*, *6*). During the course of work, however, we realized that this first generation cyclic polymethine dye **1** had a few limitations. First, due to its intrinsic hydrophobicity, at the high concentrations needed for in vivo application (10−20 μM), a significant amount of organic solvent such as DMSO has to be applied in order to generate a homogeneous solution, thus becoming toxic to testing subjects. Second, despite the straightforwardness of the chemistry used to develop a symmetrical dye, the presence of two activated carboxylic acid moieties could easily lead to a cross-link reaction with amino groups on peptides or proteins. Third, the intrinsic hydrophobicity of the dye led to aggregation in an aqueous environment, which, in turn, caused fluorescence quenching and as a consequence a reduced quantum yield (*7*). We report herein on our efforts to overcome the above-mentioned obstacles and further optimize the optical properties of lead compound **1** for in vivo imaging.

MATERIALS AND METHODS

Apparatus and Reagents. Unless otherwise stated, reagents and solvents were obtained from commercial sources without further purification. Thin layer chromatography (TLC) was obtained from Polygram SIL G/UV_{254} plates (Bodman, Aston, PA) using reagent-graded solvents. Flash column chromatography was performed on silica gel 60 (230−400 mesh, Bodman). Reverse phase TLC was performed on Whatman KC 18F silica gel 60 Å (10 × 10 cm, Cat # 4803-425). All moisture- or air-sensitive reactions were carried out under a static argon atmosphere. Nuclear magnetic resonance (NMR) spectra were obtained with a Varian 400 MHz NMR in CD_3OD, DMSO-d_6 with TMS as an internal standard. The NMR signals were described with symbols s for singlet, d for doublet, t for triplet, m for multiplet, and br for broad. The chemical shifts are reported in parts per million downfield from tetramethylsilane, and coupling constants are reported in hertz. High performance liquid chromatography (HPLC) was performed on the Hitachi chromatograph equipped with diode array detector L-2450 and the LaChrom Elite software for performing 2-D intepretation. MALDI-TOF mass spectroscopy was performed by Tufts Core Mass Spectrometry Facility (Tufts University Medical School, Boston, MA). Absorption and emission spectra were determined using a Biomate spectrophotometer (Thermo Electron Spectroscopy Ltd, Cambridge, UK) and a Spex FluoroLog-3 spectrophotometer (Horiba Jobin Yvon, NJ) respectively. The molar extinction coefficient was obtained from HPLC-purified compound using Beer's law at 0.1−1.0 μM concentration of the dye. The relative fluorescence quantum yield was determined using the model:

$$\phi_{F(X)} = (A_s/A_x)\,(F_x/F_s)\,(n_x/n_s)^2\phi_{F(s)}$$

where ϕ_F is the fluorescence quantum yield, A is the absorbance, F is the area under the emission curve, and n is the refractive index of the solvents using in measurement (*8*). The subscripts s and x represent the standard and the unknown, respectively. Isocyanine green (ICG, Akorn, Inc. Decatur, IL) was used as a reference standard.

2,3,3-Trimethyl-3*H*-indole-5-sulfonic Acid (5). Glacial acetic acid (30 mL) was added to a mixture of 4-hydrazino-benzenesulfonic acid **4** (5.6 g, 30 mmol), methyl isopropyl ketone (4.6 mL, 43 mmol), and sodium acetate (5.0 g, 60 mmol) in a flame-dried round-bottom flask fitted with a reflux condenser. The brown suspension was refluxed for 18 h, the hot solution was filtered through the sintered glass filter to remove undissoved material followed by cooling to room temperature, and the brown solid product was precipitated in ether (70%); TLC: (2/1) CH_2Cl_2:CH_3OH, R_f = 0.53; λ_{max} (water) = 275 nm; ^{1}H NMR (DMSO-d_6, 400 MHz): δ 7.63 (1H, s, ArH), 7.56 (1H, d, J = 8.0 Hz, ArH), 7.34 (1H, d, J = 8.0 Hz, ArH), 2.20 (3H, s, CH_3), 1.82 (1H, s SO_3H), 1.23 (6H, s, $2CH_3$); ^{13}C NMR δ 189.1, 153.7, 145.2, 144.8, 125.2, 119.2, 118.2, 53.3, 22.5, 15.2

2,3,3-Trimethyl-5-sulfo-1-(4-sulfo-butyl)-3*H*-indolium (6). 1,2-Dichlorobenzene (50 mL) was added to a mixture of compound **5** (11.0 g, 46 mmol) and 1,4-butane sultone (4.9 mL, 48 mmol), and the mixture was heated to 110 °C for 12 h. The solid was triturated with 2-propanol triturate to provide a fine powder (68%), TLC: (2/1) CH_2Cl_2:CH_3OH, R_f = 0.18; λ_{max} (water) = 275 nm; ^{1}H NMR (CH_3OH, 400 MHz): δ 8.12 (1H, s, ArH), 8.04 (1H, d,d, J = 1.6, 7.0 Hz, ArH), 7.98 (1H, d, J = 8.4 Hz, ArH), 4.56 (2H, t, J = 8.0 Hz, CH_2N), 2.89 (2H, t, J = 7.4 Hz, CH_2SO_3), 2.13 (2H, m, CH_2), 1.85 (2H, m CH_2), 1.62 (6H, s, $2CH_3$); ^{13}C NMR δ 160.5, 145.7, 138.6, 136.0, 125.5, 119.5, 103.9, 74.6, 51.2, 43.5, 41.4, 29.8, 24.9, 22.7

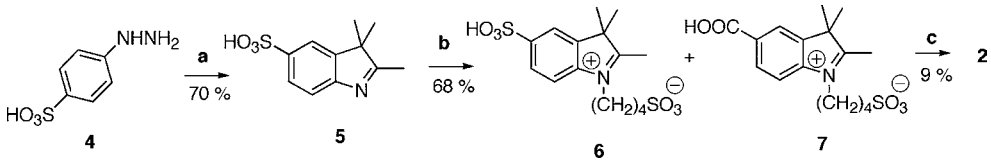
5-Carboxy-2,3,3-trimethyl-1-(4-sulfo-butyl)-3*H*-indolium (7). 1,2-Dichlorobenzene (20 mL) was added to a mixture of 2,3,3-trimethyl-3*H*-indole-5-carboxylic acid (2.72 g, 13.4 mmol) and 1,4-butane sultone (3.2 mL, 31 mmol), and the mixture was heated to reflux for 5 h. The solution was cooled to room temperature, and the solids were collected by filtration and washed with acetone to provide the brown product (2.7 g, 60%), TLC (2/1) CH_2Cl_2:CH_3OH, R_f = 0.25; λ_{max}(water) = 325 nm; ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.36 (1H, s, ArH), 8.14 (2H, s, ArH), 4.50 (2H, m, NCH_2), 2.88 (3H, s, CH_3), 2.52 (2H, t, J = 6.4 Hz, CH_2SO_3), 1.94 (2H, m, CH_2), 1.75 (2H, m, CH_2), 1.54 (6H, s, $2CH_3$); ^{13}C NMR δ 199.6, 166.4, 144.4, 142.3, 131.6, 130.7, 130.5, 124.9, 115.9, 54.5, 50.1, 47.6, 26.0, 22.0, 14.3

NIR Dye 2. A suspension of intermediate **6** (100 mg, 0.27 mmol), *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohexen-1-yl)methylene]aniline monhydrochloride (109.6 mg, 0.31 mmol), and sodium acetate (44.3 mg, 0.54 mmol) in absolute ethanol was refluxed for 4 h. The progress of the reaction was monitored by the disappearance of the absorption peak at 275 nm and the appearance of a strong peak at 650 nm. Intermediate **7** (92 mg, 0.27 mmol) was quickly added to the reaction flask and continued to reflux for 1 h. The solvent was reduced by using the rotor vapor. The residue was redissolved in water and purified by HPLC to provide the green, lyophilized solid (21.4 mg, 9.3%). Reversed phase TLC (1/1) water:CH_3OH, R_f = 0.72; λ_{max} (water) = 790 nm; ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.39 (1H, d, J = 14.8 Hz, CH of the bridge), 8.09 (1H, d, J = 13.6 Hz, CH of the bridge), 8.03 (1H, s, ArH of disulfonated indole ring), 7.93 (1H, d, J = 8.4 Hz, ArH of disulfonated indole ring), 7.85 (1H, s, ArH of monosulfonated indole ring), 7.70 (1H, d, J = 8.4 Hz, ArH of monosulfonated indole ring), 7.60 (1H, d, J = 8.4 Hz, ArH of disulfonated indole ring), 7.36 (1H, d, J = 8.8 Hz, ArH of monosulfonate indole ring), 6.66 (1H, d, J = 14.8 Hz, CH of the bridge), 6.20 (1H, d, J = 13.6 Hz, CH of the bridge), 2.75 (4H, br, $2(CH_2SO_3H)$), 2.50 (4H, partial overlapped by DMSO, 4H of cyclohexene), 1.7−19 (10H, br, m, CH_2CH_2, cyclohexene CH_2), 1.70 (6H, s, $2CH_3$ of disulfonated indole ring), 1.65 (6H, s, $2CH_3$ of monosulfonated indole ring). MS (MALDI-TOF) calcd (MH^+) 852.45, found 852. 42.

Synthesis of Probe 3. The peptide substrate, AREPPTRTFAYWG, with an aminohexanoic acid (AHA) moiety as a spacer on the N-terminus was synthesized using an automatic peptide synthesizer (PS 3, Protein Technologies, Inc.) by conventional Fmoc chemistry (0.1 mmol) using Rink amide resin (0.43 mmol/g) and HBTU/HOBT as the activating reagents. After completion of the peptide synthesis, the NIR dye **2** was coupled to the N-terminus of the AHA group. NIR dye **2** (71.3 mg, 0.084 mmol) was first initially activated with HBTU (44.6 mg, 0.12 mmol) and HOBT (16.2 mg, 0.12 mmol) in 1:10 of pyridine/DMF in the presence of argon for 2 h. The labeling product was charged with TFA/thioannisole/ethandithiol/anisole (90/5/3//2) to deprotect the acid-labile protective groups as well as the resin followed by C18 reversed-phase 2D-HPLC purification to afford a green product.

In Vivo Optical Imaging. Two million human pancreatic adenocarcinoma CAPAN-2 cells were implanted subcutaneously into athymic nude mice on the back adjacent to the upper thigh. When the tumors reached

Scheme 1. Synthesis of Asymmetric Water-Soluble NIR Dye 2[a]



[a] Reagents and conditions: (a) $(CH_3)_2CHCOCH_3$, acetic acid; (b) 1,4-butane sultone, 1,2-dichlorobenzene; (c) *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohexen-1-yl)methylene]aniline monohydrochloride, NaOAc, EtOH.

3−4 mm in diameter, the in vivo NIR fluorescence imaging experiments were performed. Animals were anesthetized with isoflurane and injected intravenously in the tail vein with 10 μM of probe **3** in Hanks Balanced Salt Solution (HBSS), pH 7.2, and subjected to NIR imaging 0.4, 0.2, 1, 2, 3, 6, 10, and 24 h postinjection. Imaging was performed using a whole-mouse imaging system (Imaging Station IS2000MM, Kodak Scientific Imaging System, New Haven, CT), equipped with a band-pass filter at 720 nm and a long-pass filter at 790 nm (Chroma Technology Corporation, Rockingham, VT). Images were analyzed using Kodak ID3.6.3 network version imaging software.

Fluorescence Microscopy. After completion of the in vivo imaging experiments, animals were sacrificed, and tumors were excised, snap frozen in liquid nitrogen, cut into 7 μm sections, and fixed in 2% paraformaldehyde. Sections were counterstained with DAPI to depict cell nuclei. Microscopy was performed using a Nikon Eclipse 50i fluorescence microscope equipped with an appropriate filter set (Chroma Technology Corporation, Rockingham, VT). Images were acquired using a CCD camera with near-infrared sensitivity (SPOT 7.4 Slider RT_{KE}; Diagnostic Instruments, Sterling Heights, MI) and analyzed using SPOT 4.0 advanced version software (Diagnostic Instruments, Sterling Heights, MI).

RESULTS AND DISCUSSION

Synthesis. To improve the limited physical properties of **1**, we performed the following modifications. First, to avoid cross-reaction with amino groups from targeted labeling entities and to increase water solubility, we replaced one of the carboxylic groups on the indole ring system by a sulfonic version (Scheme 1). Second, to produce the asymmetric dye, we employed a known procedure for a sequential, one-pot synthesis in the final step (*9*). It has been shown that an additional sulfonic group incorporated on the aromatic nucleus of the cyanine fluorophore not only enhanced water solubility, but also improved the quantum yield of the dye in a biological environment (*9*). The synthesis was commenced with Fischer indole condensation between hydrazino-benzene-sulfonic acid **4** and an isopropyl methyl ketone in acetic acid to yield intermediate **5** followed by alkylation of the indole ring with butane sultone in refluxing 1,2-dichlorobenzene to provide the water-soluble sulfonate analogue **6**. Finally, intermediate **6** was heated to reflux with *N*-[(3-(anilinomethylene)-2-chloro-1-cyclohexen-1-yl)methylene]aniline in ethanol in the presence of sodium acetate for 4 h, followed by an addition of intermediate **7** (*6*) to afford **2** in a modest yield (Scheme 1). During the course of work, we found that compound **7** was very susceptible to the condensation reaction, probably due to its better solubility in ethanol, and as a consequence, there was an equal formation of **1** as determined by 2-D HPLC and analyzed by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) spectrometry.

As we anticipated, the polarity of dye **2** was enhanced significantly by the incorporation of an additional sulfonate group while the absorption and emission maxima remained unchanged compared to the previous generation. The solubility of dye **2** was tested against former dye **1** at a high concentration (1 mg/100 μL) using solvents with a high dielectric constant such as DMSO, DMF, and water. Furthermore, the difference in polarity was confirmed by reverse phase HPLC where the retention time of dye **2** was 5 min earlier compared to that of **1**. We did not observe any new absorption band as an indication of dimerization or dye−dye interaction in addition to the major absorbance wavelength at 790 nm of the monomers (*7*) (Figure 2). The dye solutions in water followed Beer's law at a wide concentration range. NIR dye **2** in water had a molar extinction coefficient and quantum yield of 200 000 M^{-1} cm^{-1} and 0.18, respectively, compared to 180 000 M^{-1} cm^{-1} and 0.08 of compound **1** (*6*). The broad absorbance spectrum of dye **2** enabled excitation of the molecule several nanometers prior to the maximum excitation peak (λ_{max} = 790 nm) using a commercially available 720 nm excitation filter and collecting the emission light 50 nm away from the excitation wavelength by using a narrow-band emission filter at 790 nm. This strategy could eventually diminish the high background resulting from the cross-talk when the excitation and emission filters' wavelengths are too close (*10*).

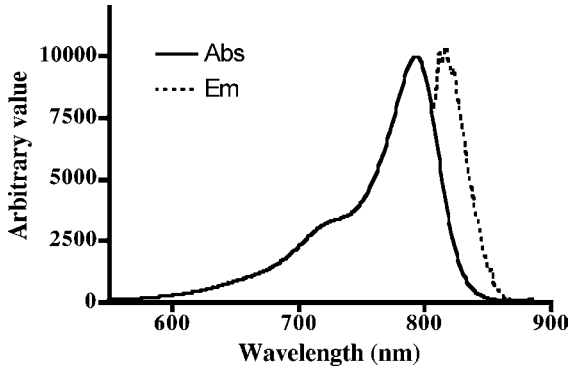


Figure 2. A normalized absorption and emission spectra of NIR dye **2** in water at 42 μM.

To prove the utility of the newly synthesized dye in vivo, we performed experiments that were based on our continued work toward the development of optical probes for early cancer detection. Underglycosylated mucin-1 tumor antigen (uMUC-1) is one of the early hallmarks of tumorogenesis in a wide variety of tumors. MUC-1 is overexpressed and underglycosylated on almost all human epithelial cell adenocarcinomas, including more than 90% of human breast cancers (*11*−*14*), ovarian (*15*−*17*), pancreatic (*18*), colorectal (*18*−*20*), lung (*21*, *22*), prostate (*23*), and gastric carcinomas (*24*, *25*). Moreover, MUC-1 expression has been demonstrated in nonepithelial cancer cell lines (astrocytoma, melanoma, and neuroblastoma (*19*)) as well as in hematological malignancies such as multiple myeloma and some B-cell non-Hodgkin lymphomas (*26*−*29*), constituting more than 50% of all cancers

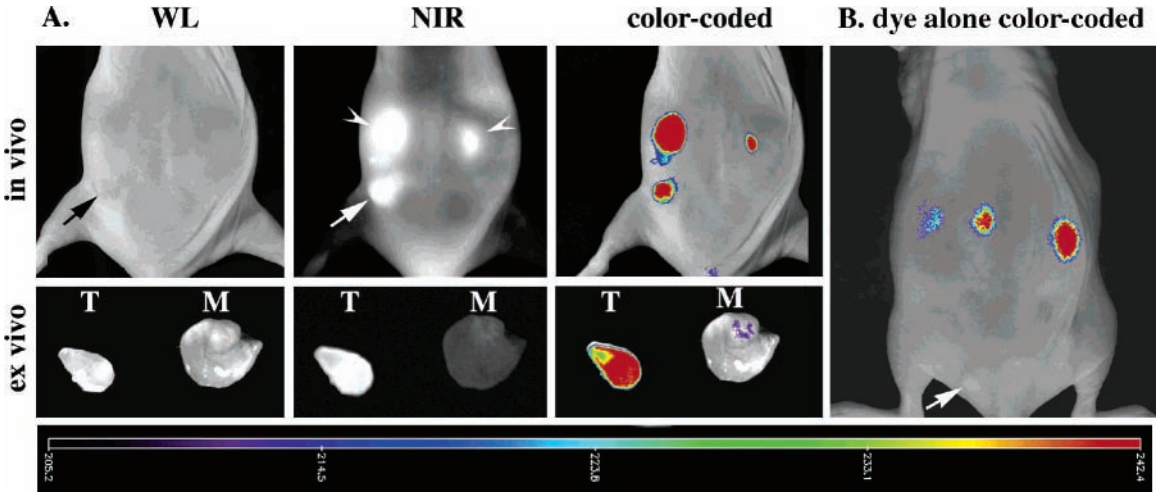

Figure 3. A. White light (WL), near-infrared (NIR), and color-coded map of mice bearing human pancreatic adenocarcinoma CAPAN-2 in vivo (top) and ex vivo (bottom). NIR fluorescence imaging was performed 24 h postinjection of 10 μM of probe **3**. Bright NIR fluorescence in the tumor (arrow) is the result of the accumulation of the probe labeled with dye **2**. Kidneys (arrowheads) showed systemic accumulation followed by clearance. Ex vivo images confirmed the signal coming from the excised tumor (T) compared to control muscle tissue (M). B. Color-coded map of tumor-bearing mice injected with unconjugated dye **2.** No accumulation of the unconjugated dye in the tumor (arrow) was detected.

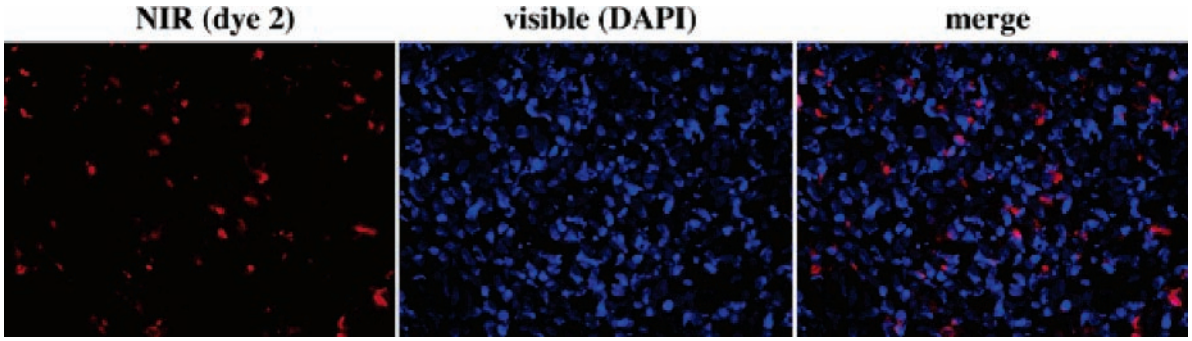

Figure 4. Dual channel fluorescence microscopy of the sections of excised tumor isolated from mouse 24 h after iv injection. Nuclear staining with DAPI was detected with a visible channel, while dye **2** as a component of probe **3** projected a strong signal in the NIR channel.

in humans (*30*). We have previously reported on the development of a multimodal (fluorescent and MRI) peptide-based imaging probe, targeting the uMUC-1 tumor antigen in a mouse model of human cancer (*31*). The peptide (EPPT peptide) targeting the uMUC-1 antigen was derived from the CDR3V$_\beta$ region of a monoclonal antibody raised against human epithelial cancer cells (*32*, *33*), and its sequence was determined (AREPPTRTFAYWG). The NIR fluorescence imaging experiments in our previous studies were performed on tumor-bearing mice using a Cy5.5-labeled probe. In the present study we used our newly developed dye **2** conjugated to an EPPT peptide, which showed specific accumulation in tumors expressing the uMUC-1 antigen (*31*). The peptide was derivatized with an aminohexanoic acid spacer (AHA), which concomitantly provided a sole amino terminal moiety for dye conjugation in solid-phase synthesis (*5*). The dye, activated in situ with *N*-hydroxybenzotriazole and 2-(1*H*-benzotriaole-1-yl)-1,1,3,3-tetramethyluronium (HOBT/HBTU) reacted with the aminated AHA-A-R(Pbf)-E(OtBu)-P-P-T(tBu)-R(Pbf)-T(tBu)-F-A-Y(tBu)-W(Boc)-G peptide with selectivity. During the course of our work, it turned out that the limited reagent of green color dye **2** could be used as an indicator to monitor the progress of the reaction; when the coupling reaction finished, the green color of the solution faded, while the resin turned green. The resin as well as the acidic labile side chain protection groups was deprotected in trifluoroacetic acid in the presence of scavengers to provide probe **3**. We observed no physical change in the dye property after peptide labeling.

In Vivo NIR Imaging and ex Vivo Microscopy. Tumor bearing animals were subjected to NIR imaging after intravenous injection of probe **3**. We detected a strong NIR fluorescent signal in the tumor 10 h after injection, and the signal continued to accumulate 24 h postinjection (Figure 3A). The NIR signal depicted from the tumor was of high intensity, readily distinguished from the background. After systemic distribution of the probe, there was a noticeable accumulation in the peripheral tissues (kidneys, spleen) followed by eventual clearance. Ex vivo images of the excised tumor (left) and muscle tissues (right) were obtained immediately after in vivo imaging. We observed a bright NIR signal coming from the tumors, whereas there was little signal from the muscle tissue. The ratio of fluorescence signal of the tumor versus muscle was 2.5 as determined by ROI analysis (Figure 3A). In contrast, animals injected with the same amount of unconjugated dye **2** did not show any signal in the tumors (Figure 3B). Other organs showed distribution similar to the conjugated dye. To confirm the presence of the probe in the tumor, we correlated our macroscopic observations with dual-channel fluorescence microscopy. NIR fluorescence was detected in tumor cell cytoplasm confirming the presence of the probe in the tumor tissue (Figure 4).

Overall, in this study we performed an improved development of NIR fluorescent dye **2** with enhanced

physical properties for in vivo imaging. First, we increased the overall hydrophilicity of the dye by adding a sulfonic moiety to its structure. Second, we eliminated the possibility of cross-linking with peptides/proteins during conjugation by removing one of the activated carboxylic acid group. Finally, we improved the quantum yield more than two times compared to the original dye **1**. Furthermore, we showed the suitability of dye **2** for in vivo NIR fluorescence optical imaging in a mouse model of human cancer. We confirmed our in vivo results with fluorescence microscopy where the dye was readily detectable on a cellular level. We anticipate that this modification of the NIR dye will be further used for conjugation with targeting molecules for in vivo optical imaging.

Identification and Mapping of Protein−Protein Interactions by a Combination of Cross-Linking, Cleavage, and Proteomics

Michael A. Trakselis,[†] Stephen C. Alley,*[,‡] and Faoud T. Ishmael[§]

Medical Research Council, Cancer Cell Unit, Hutchison MRC Research Centre, Hills Road, Cambridge CB2 2XZ, United Kingdom, Seattle Genetics, Inc., 21823 30th Drive Southeast, Bothell, Washington 98021, and The Pennsylvania State University, College of Medicine, Department of Medicine, H039, 500 University Drive, P.O. Box 850, Hershey, Pennsylvania 17033-0850. Received February 15, 2005; Revised Manuscript Received May 2, 2005

Protein−protein interactions are vital for almost all cellular functions, and many require the formation of multiprotein complexes. Identification of the macroscopic and microscopic protein interactions within these complexes is essential in understanding their mechanisms, both under physiologic as well as pathologic conditions. This review describes the current technology available to investigate interactions between proteins utilizing chemical cross-linking and site-directed cleavage reagents, outlining the necessary steps involved in identifying interacting proteins both in vitro and in vivo. Once interacting proteins are identified, more information about the architecture of the assemblies is necessary. Unique separation techniques coupled with cross-linking and mass spectrometry can now identify specific interaction sites and lead to the development of quaternary structural protein models. Furthermore, combination of these methods with proteomic approaches enables the identification and analysis of complex interactions in vivo. Finally, future directions in cross-linking methodologies are discussed.

INTRODUCTION

Protein−protein interactions are of extraordinary importance in biology. From multiprotein complexes, such as those found in DNA replication and RNA transcription, to transient interactions, such as those found in signal transduction networks, biological systems contain interaction networks that are critical for their function. The completed sequence information of a significant number of genomes and the availability of an increasing number of X-ray and NMR structures of key individual proteins have precipitated many advances in describing protein−protein interactions.

Numerous techniques have been developed to probe protein−protein interactions, with some methods providing very high structural resolution with low throughput, such as X-ray crystallography and multidimensional NMR, while others offer very high throughput with low structural resolution, such as phage display, yeast two-hybrid screens, and protein microarrays. Quantitative descriptions of the strength of protein−protein interac-

tions with low structural resolution can be determined by methods such as gel filtration, Biacore, and fluorescence spectroscopy. Chemical cross-linking does not have the throughput of techniques such as phage display or yeast two-hybrid systems, where libraries of interacting partners can be rapidly screened, nor does it provide information about the strength of an interaction, but it does allow higher resolution structural data to be generated where protein−protein interactions can be mapped to specific domains or amino acids. Most importantly, cross-linking allows noncovalent protein−protein interactions, which may be transient or dependent on specific physiological conditions, to be captured into long-lived covalent complexes that maintain structural information during subsequent purification, enrichment, and analysis.

Many protein cross-linking tools are commercially available, enabling wide access to investigation of protein−protein interactions. New reagents and mass spectrometry (MS)[1] have significantly increased the power of these tools and the ability to investigate more complicated systems, including protein−protein interactions in vivo. Interestingly, the two areas of protein cross-linking and proteomics have taken inspiration from each other, and several hybrid tools have emerged.

The investigation of protein−protein interactions may have several goals. The first may simply be the identification of two proteins that interact and may start with the two proteins in either purified form or in more complex mixtures. Detecting a new, higher molecular-weight band on an SDS−PAGE gel after cross-linking and Coomassie or silver staining is sufficient to identify an interaction between two purified proteins. However, the absence of a new band is not sufficient to exclude the possibility that two proteins do interact. This limitation is identical for many other techniques for investigating protein−protein interactions, in that the absence of a signal only excludes protein−protein interactions under the specific set of conditions used, which may be very different from those in vivo or lack additional factors necessary for forming the interaction. Detection of cross-links in the presence of many other proteins requires affinity tagging the protein or using antibodies against the protein for visualization. In the absence of these reagents, more sophisticated separation and/or visualization techniques, such as using affinity handles on the cross-linker or tandem mass spectrometry, will be required for identification of cross-linked proteins. Once interacting partners have been identified, the next goal may be to map the location of the interaction, which may also employ these sample visualization and identification tools with MS. Importantly, the yield from cross-linking and any separation technique employed must be high enough so that the subsequent MS analysis will be successful in identifying points of interaction. Significant effort in the choice of cross-linking reagent, scale-up, and/or cross-linking reaction optimization may be necessary in advance of MS investigation. Ultimately, sophisticated

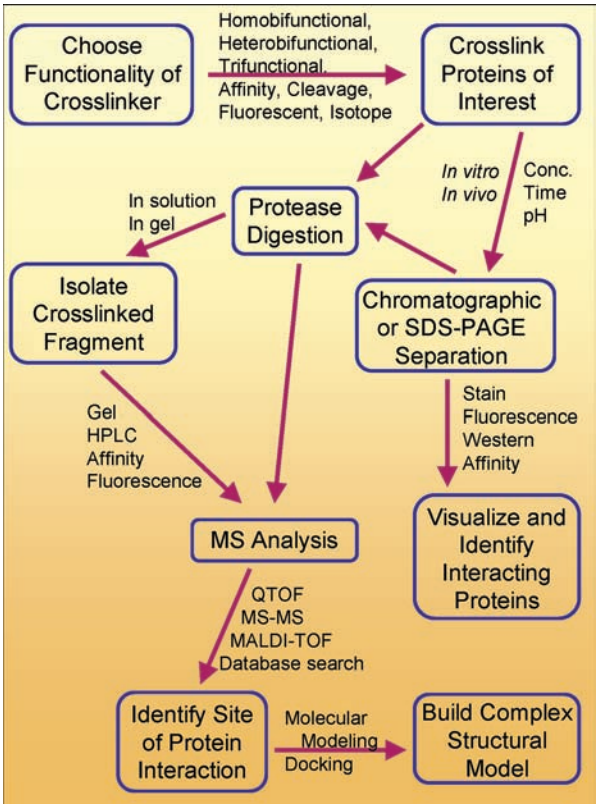

Figure 1. Cross-linking methodology flowchart demonstrating the procedures involved in identification of the specific site of cross-linking between two or more proteins and construction of quaternary complex models.

models of multiprotein complexes can be assembled from these results. Figure 1 characterizes the uses of cross-linking discussed above and outlines general strategies for the identification of specific protein interaction sites that can be used to develop quaternary protein models.

This review will illustrate the techniques that are currently being used in the identification of protein−protein interactions. Many commercially available reagents have been used in these studies, and novel probes and mass spectrometry techniques have come into play as the complexity of the multiprotein complexes under investigation have increased. Figure 2 provides an overview of the types of protein modification groups that are available. Modern mass spectrometry and proteomics techniques have significantly increased the scope of these studies and have begun to allow investigation of protein−protein interactions under more physiologically relevant conditions than for two purified and isolated proteins, including cell lysates and in vivo.

IDENTIFYING PROTEIN−PROTEIN INTERACTIONS

Homobifunctional and Heterobifunctional Cross-Linkers. The most common type of protein−protein interaction is the interaction of a protein with itself to form multimers. Often this can regulate the activity of the protein and provide a powerful switch between active and inactive forms. There are numerous techniques for studying oligomerization, and cross-linking provides the ability both to determine the degree of oligomerization and to map the network of interactions at the protein−protein interface. Many commercially available reagents can facilitate these studies by forming cross-links in proteins between pairs of lysines, lysines and aspartic or glutamic acids, lysines and cysteines, or pairs of

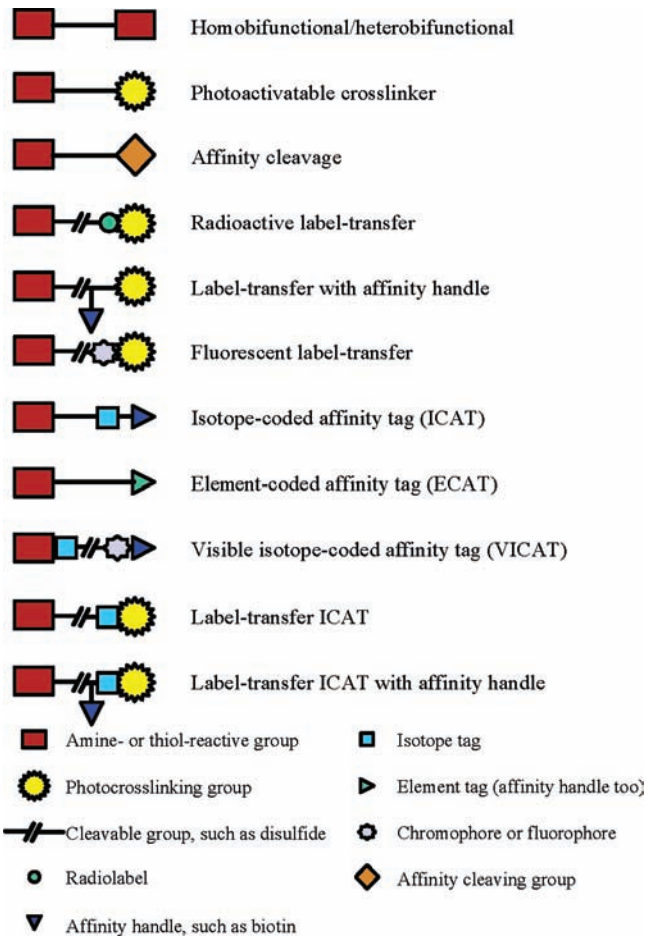

Figure 2. Schematic structures of the protein modification groups discussed in this review.

cysteines. The following examples show that these types of cross-links can be formed under a variety of biologically relevant conditions, including inside of cells and membrane preparations.

Cross-linking through the ϵ-amino group of lysines can demonstrate oligomerization due to the large number of lysines present on the surface of most proteins. It is highly likely that two lysines will be close to each other at the protein−protein interface and form cross-links. Szegedi and Garrow (*1*) used a 30-min incubation with glutaraldehyde to cross-link betaine-homocysteine methyltransferase (BHMT). Coupled with gel filtration, the oligomeric state of BHMT and several mutants could be assigned. Wild-type BHMT and some mutants were tetramers, while other mutants were dimers. Dimeric mutants were enzymatically inactive, demonstrating that the tetrameric form is required for activity.

Cysteines are less common on the surface of proteins, but can provide a higher resolution investigation of the protein−protein interface. Bunn and Ordal (*2*) made 30 single cysteine mutants (2 runs of 15 contiguous amino acids) of the homodimeric *Bacillus subtilis* chemoreceptor McpB, a member of a two-component signal transduction cascade. Using a 5-min incubation with copper-phenanthroline to oxidize properly orientated cysteines from each monomer to disulfides (a zero-length and reversible cross-link), contacts within the two α-helical transmembrane domains were mapped. Cross-linking was carried out using cells transformed with plasmids containing mutant *mcpB* and cross-links visualized by Western blots probed with anti-McpB antibodies. As would be expected for an α-helical bundle, cross-linking was maximized (up to 100% yield) at a spacing of n to n+3/n+4 in each domain, establishing the dimerization interface. However, cross-linking was also observed at amino acids on the opposite side of the α-helical bundle from the dimerization interface, leading the authors to suggest that in vivo, McpB can also exist as trimers of dimers.

The tether length of the cross-linker can be varied to map the distance between two cross-linked cysteines. Kaback and co-workers used 5 and 21 Å tether length bis-methane thiosulfonates to cross-link single cysteine mutants of *Escherichia coli* lactose permease (LacY). LacY is a membrane protein with 12 transmembrane helices and loops on the periplasmic and cytoplasmic sides of the membrane. Two hundred fifty transmembrane mutants (*3*) and 143 extramembrane mutants (*4*) were investigated for their importance in homodimer formation. Cross-linking was carried out for 3 min to 1 h using sonicated *E. coli* membrane suspensions made from cells transformed with plasmids containing mutant *lacY*, with anti-C-terminal antibodies used for visualization of cross-links on Western blots. Cross-linking yields of greater than 40% were observed for some mutants. Only 4% of the transmembrane mutants formed cross-links with the 5 Å cross-linker, while 53% of the extramembrane mutants formed cross-links with the 5 and 21 Å cross-linkers. Just over half of the extramembrane cross-links formed with only the 21 Å cross-linker. An interaction map of the homodimer interface was constructed from these results, with domains from both the periplasmic and cytoplasmic faces contributing significant contacts.

Photoactivatable Cross-Linking. Cross-links can also be formed between proteins using reagents that are activated by light. Heterobifunctional benzophenones and aryl azides can first be attached to proteins through lysines or cysteines, and then multiprotein complexes can be assembled under safe lighting conditions. Cross-links are only formed upon exposure to highly intense, short wavelength (250−350 nm) light. This offers the researcher a significant advantage, in that there is very good control for the start and end of cross-linking since light is the exclusive trigger for the cross-linking reaction. Photo-cross-linking times are generally shorter (5−15 min with aryl azides) than chemical cross-linking times, sometimes significantly shorter (down to 1 s with metal catalysis). However, photo-cross-linking can often be a process with poor yields and a diversity of possible products, especially with aryl azides, potentially making the identification of the location of photo-cross-linking very difficult. Numerous commercially available reagents, such as 4-maleimidobenzophenone (MBP) and *N*-5-azido-2-nitrobenzoyloxysuccinimide (ANB-NOS) (Figure 3), have been used to form photo-cross-links.

Giron-Monzon and co-workers (*5*) investigated the ATP-dependent activation of the *E. coli* mismatch repair exonuclase MutH by MutL by photo-cross-linking. MutL has 7 native cysteines, and these were first mutated to serine, leucine, or phenylalanine. Thirteen single cysteine mutants were then constructed and labeled with MBP. Complexes with MutH in the presence or absence of ATP, the nonhydrolysable ATP analogue ADPnP, and DNA were formed and then photolyzed for 10−30 min. An interaction map was then constructed, and a mechanism for the ATP dependence of the MutH-MutL complex formation could be determined.

Protein−protein interactions can also be studied by metal-catalyzed chemical- and photo-cross-linking. Chelated Ni(II) can be used to introduce zero-length cross-links by treating with an oxidant such as magnesium

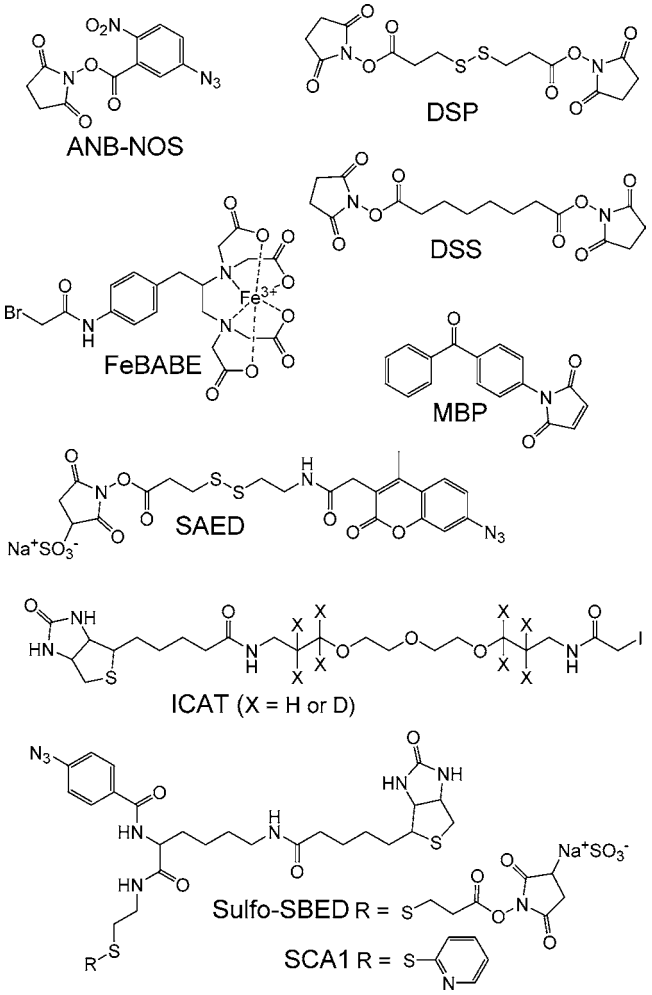

Figure 3. A selection of the structures of commonly used cross-linkers discussed in this review: *N*-5-azido-2-nitrobenzoyl-oxysuccinimide (ANB-NOS), dithiobis(succinimidyl propionate) (DSP), disuccinimidyl suberate (DSS), 1-(*p*-bromoacetmidobenzyl)-EDTA (FeBABE), 4-maleimidobenzophenone (MBP), sulfosuccinimidyl 2-(7-azido-4-methylcoumarin-3-acetamido)-ethyl-1,3′-dithiopropionate (SAED), isotope-coded affinity tag (ICAT), sulfosuccinimidyl 2-[6-(biotinamido)-2-(*p*-azidobenzamido)-hexanoamido]-ethyl-1,3′-dithiopropionate (Sulfo-SBED), and 1-[6-(biotinamido)-2-(*p*-azidobenzamido)-hexanoamido]-2-(2′-pyridyldithio)ethane (SCA1).

monoperoxyphthalic acid (*6*), while chelated Ru(II) (*7*) or Pd(II) (*8*) can introduce zero-length cross-links by photolysis in the presence of persulfate. Genetically encoded His_6-tags have been used for protein-bound Ni(II) chelators, while bodipy and porphyrins have been used for nonprotein bound chelation of Ru(II) and Pd(II), respectively. Depending on the system, photo-cross-linking times can be less than 1 s, and yields tend to be very high. Cross-linked amino acids are commonly tyrosines. These cross-linking reagents can also be used for affinity labeling with biotin-tyramine (*9*, *10*), which is chemically similar to tyrosine. The mechanisms of cross-linking and the protein complexes investigated with these reagents have been described in two excellent reviews (*11*, *12*).

Site-Directed Cleavage Agents. Instead of producing covalent cross-links, site-directed cleavage agents can be used to cleave a target protein at the point of protein−protein interactions. Iron-EDTA complexes have been used to generate hydroxyl radicals via a Fenton reaction and cleave both nucleic acids (*13*) and proteins. 1-(*p*-Bromoacetmidobenzyl)-EDTA (FeBABE) (Figure 3) can be attached to protein cysteines or 2-iminothiolane-modified amino groups and activated with iron, sodium ascorbate, and hydrogen peroxide. First demonstrated by internally cleaving bovine serum albumin (*14*), this technique generates peptide fragments that are not chemically damaged at their termini and can be Edman-sequenced to identify the location of cleavage. This site-directed cleavage agent can cleave peptide bonds within a protein or on interacting proteins as well as phosphodiester bonds of polynucleotides (Figure 4).

FeBABE has been used to study protein−protein interactions in the *E. coli* RNA polymerase holoenzyme. The stationary phase σ factor (σ^s) was mutated such that unique cysteines were independently placed at nine locations. The FeBABE−σ^s conjugates were assembled into the $\alpha_2\beta\beta'$ RNA polymerase holoenzyme, and cleavage was observed on the β and β' subunits, but not on the α subunit (*15*). In this study, visualization of the individual RNA polymerase subunits was accomplished by probing a Western blot with antibodies to the N-termini of each of the subunits.

In an extension of this method, FeBABE was used to map interactions between *S. cerevisiae* TFIIB and RNA ploymerase II. Five mutants of TFIIB containing unique, alkylatable cysteines were labeled with FeBABE and incubated with yeast nuclear extracts containing RNA polymerase II subunits individually genetically flag-tagged. The location of cleavage was determined using flag-tagged size standards from in vitro transcription/translation reactions of truncated RNA polymerase II subunit genes as templates (*16*). The use of genetically encoded flag tags removed the requirement for production of antibodies against all of the potentially cleaved proteins. In principle, any type of genetically encoded affinity tag, such as His-tags, GST-tags, or peptide sequences that are biotinylated during expression (*17*), could provide both purification and visualization handles for any recombinant proteins without the need to produce antibodies to these proteins.

Visualization Techniques: Label Transfer Agents. Tracking changes by mobility shift on by SDS−PAGE with Coomassie or silver staining to identify interacting proteins becomes quickly intractable as the number of proteins in the reaction mixture increases. Protein−protein interactions found within large complexes, such as those found in DNA replication and RNA transcription complexes, often occur in the presence of up to 50 polypeptides. To study these interactions, researchers have developed novel reagents to monitor protein−protein interactions. These reagents incorporate isotope or element tags to allow identification by mass spectrometry, radiolabels or fluorophores to enable identification of interaction partners, or affinity tags to allow both purification and identification. One powerful application of these techniques is label transfer (Figure 5).

Label transfer requires that a single protein of interest (A in Figure 5) is first modified with the label transfer agent. Second, the multiprotein complex is assembled in the presence of the labeled protein and cross-links are formed, typically by photolysis of reactive groups such as benzophenones or aryl azides. The identification of the interacting protein or proteins (B in Figure 5) is accomplished by separation by SDS−PAGE followed by autoradiography or visualization of the affinity tag (for instance, probing a gel with streptavidin−horseradish peroxidase to identify biotinylated proteins). The resolution of these techniques can be significantly enhanced by coupling with molecular biology: engineering of unique cysteines allows the label to be incorporated site-

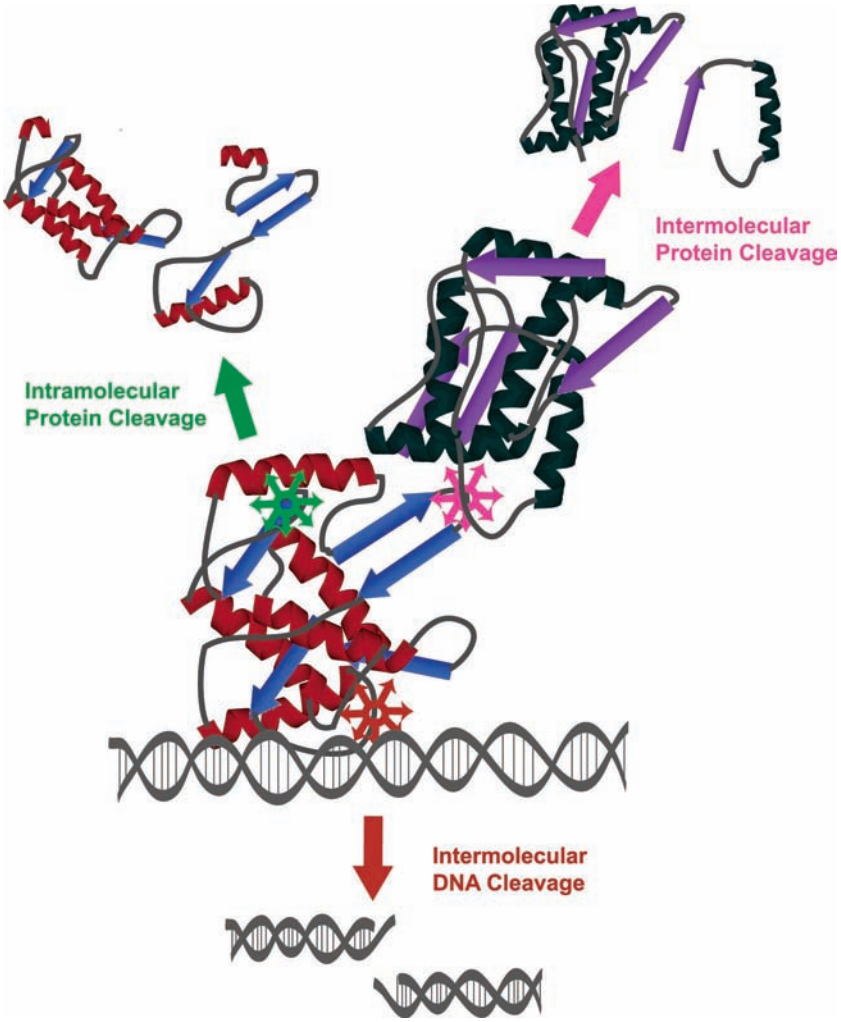

Figure 4. Site-directed cleavage agents such as FeBABE can be attached at site-specific cysteines or modified amines within a bait protein to detect intra- or intermolecular interactions. In the presence of ascorbate and peroxide, Fe^{3+} is reduced to Fe^{2+} and radicals cleave peptide bonds or phosphodiester bonds that are close in space. Detection of the resulting peptide or nucleic acid pattern can be analyzed by electrophoresis, Western blot, sequencing, or mass spectrometry and can provide information relating to the region of contact within the protein or the interacting complex.

specifically, and moving this unique cysteine around the protein enables interaction mapping.

Classically, label transfer used ^{125}I- (protein A-IgG) or ^{35}S- (gelatin-fibronectin) labeled reagents on lysine-reactive probes (*18*, *19*). Cleavage of the cross-linking group transfers the label to the interacting partner and was affected with DTT to cleave a disulfide or sodium dithionite to cleave an azo linkage. These early studies were enhanced when cysteine reactive probes were introduced. Chen and co-workers (*20*) incorporated ^{125}I-labeled *N*-(3-iodo-4-azidosalicyl)cysteine (IAC) into an engineered form of the catabolite gene activator protein (CAP). Following photo-cross-linking, label transfer, and DTT cleavage, the interaction of CAP, labeled in a region important for activation, was mapped to the carboxyl-terminal region of the α-subunit of RNA polymerase (RNAP) within the four-polypeptide RNAP. In the absence of the lac promoter DNA and/or CAP, no cross-linking or label transfer was observed, demonstrating the high specificity of the technique.

As an alternative to radioactive visualization, an affinity label-transfer reagent, sulfo-SBED (Figure 3) was developed at Pierce (*21*). This reagent transfers biotin from the labeled protein to the cross-linked interaction partner. Biotin is then used as a visualization reagent: Western blots of cross-linking mixtures following label transfer are probed with horseradish peroxidase to reveal cross-linked proteins. Sulfo-SBED is lysine reactive and has been used to study many protein−protein interactions. To increase the utility of this reagent, it has been converted to cysteine-reactive reagent by attaching a thiopyridyl group (SCA1, Figure 3) (*22*). This modified reagent has been used to track protein−protein interactions in the bacteriophage T4 DNA replication complex (four polypeptides in a ca. 350 kDa complex with DNA) (*22*) and a 1.8 MDa RNA transcription complex with at least 14 unique polypeptides (*23*). The benefit of these trifunctional reagents is the rapid identification of interacting proteins which only require photo-cross-linking and Western blotting with a universal reagent, without resorting to having to raise antibodies to every potential protein in the complex and running multiple Western blots with these custom reagents.

Sample Preparation: Proteomics and ICAT. The investigations described above involve labeling or making a mutant of a protein of interest before cross-linking. Studying protein−protein interactions in vivo generally does not allow for such modifications before crosslinking. Using these highly complex mixtures of proteins requires significant effort in sample preparation to identify interacting proteins. This can be accomplished after cross-linking by electrophoresis or chromatography, either with

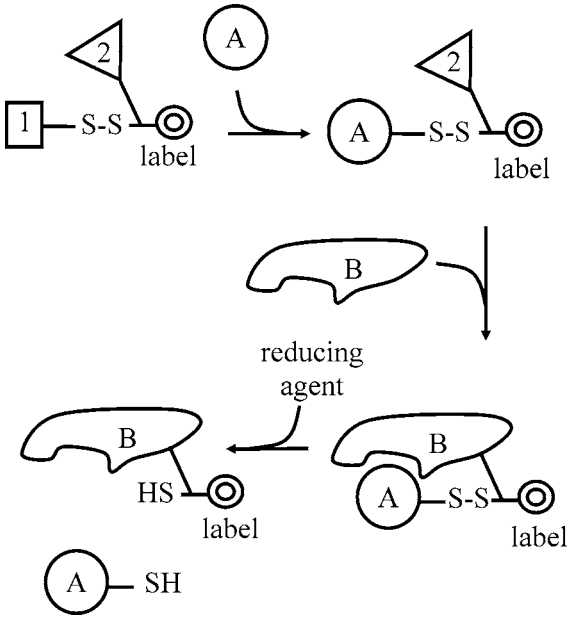

Figure 5. Label transfer cross-linking. Cross-linker consists of an amine or thiol reactive group (1), a photactivatable group (2), and a label (typically either a radioactive or biotin moiety). Protein A is first conjugated to the cross-linker at site 1. Protein B is then added and photo-cross-linked at site 2. Reduction of the disulfide bond with DTT results in the transfer of the label to protein B liberating free protein A. Separation of the protein mixture is performed by SDS−PAGE. Detection of the transferred label then occurs either by autoradiography or probing with streptavidin−horseradish peroxidase.

or without the benefit of affinity handles for enrichment and visualization.

The emergence of matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry within the past decade has greatly simplified the ability to identify proteins using an approach termed proteomics. Proteomics generally involves separating a mixture of proteins in a given system using techniques such as 2D gel electrophoresis followed by staining to detect protein bands. These bands are then excised, digested with a protease in-gel, and subjected to mass spectrometry. Each protein exhibits a specific digestion pattern with a given protease, which is manifested on MALDI as a specific mass fingerprint. This allows the identification of unknown proteins by comparing its digestion pattern to a database containing the proteolytic masses of known proteins. A variety of databases and algorithms have been constructed and developed to search for corresponding fragments within an organism's genome (*24*). The combination of these techniques with cross-linking has provided a powerful methodology to quickly determine interacting proteins in a complex.

This approach was exemplified by Bernhard et al. in the study of the transmembrane CD4 receptor (*25*). The authors used the homobifunctional lysine-lysine cross-linker DSP (Figure 3) to cross-link the proteins at the cell surface. Study of cell surface proteins and their associations with other proteins has traditionally been very difficult. In vitro analyses usually require removal of the protein from the membrane by proteolyitc cleavage, detergent-mediated release, or removal of the transmembrane domain by mutagenesis, all of which may alter its structure and function. However, the utilization of this cross-linker was beneficial because it allowed the protein to be studied in an in vivo setting, and the abundance of lysines on proteins in general allows for the maximal amount of cross-links between proteins in the complex. DSP also contains a disulfide linkage enabling cleavage of the linker if desired. The cross-linked proteins were released from the cell membrane and immunopreciptated using an antibody against the CD4 receptor to isolate only the cross-linked complex of interest. The cross-linker was then cleaved with a reducing agent to release the covalently linked complex, and the proteins were separated by SDS−PAGE. Individual bands were excised and digested, and the proteins were identified using MALDI MS. The authors were able to identify interacting proteins, including a trasferrin receptor, and a protein phosphatase, which provided valuable information about the function of the protein.

A similar technique was employed by Meunier and coworkers (*26*) in the study of chaperone proteins within the ER of mammalian cells. This group also used DSP to cross-link the proteins and followed with isolation by affinity purification, separation by 2D gel electrophoresis, and identification with MS. The interaction of an immunoglobulin with a chaperone complex was probed. These studies recognized a novel organization of chaperone proteins in a preformed complex and gave insight into its interaction with unfolded proteins. Because of the ability of DSP to cross the cell surface and permeate cells, these experiments were conducted in intact cells, further delineating the importance of this technique in studying in vivo systems.

Proteomics and mass spectrometry also benefit from enrichment and visualization tools. The first tools designed for these purposes include isotope-coded affinity tags (ICAT) (Figure 3) (*27*), which were designed to modify proteins with noncleavable biotin groups containing isotopic labels. Biotin allows enrichment of the sample before analysis, and the use of multiple isotope labels allows different states of the biological system to be encoded with each label. Mass spectrometry enables rapid identification of labeled proteins from their unique masses. Extensions of this method include element-encoded affinity tags (ECAT) (*28*) and visible isotope-coded affinity tags (VICAT) (*29*). ECAT reagents combine the element tag and affinity handle into a single DOTA functional group (anti-DOTA antibodies can be used for sample enrichment), while VICAT incorporates a visual chromophore for tracking during chromatography.

To extend these techniques for the investigation of protein−protein interactions, Trester-Zedlitz and coworkers (*30*) combined label transfer and ICAT in a modular system. Label-transfer reagents were built such that spacer lengths, chemical reactivities, affinity handles, cleavage sites, and isotope tags were varied so that they could be optimized to the multiprotein complex to be studied. The authors point out that a general method of interaction identification is probably not achievable due to the diversity of protein structure and reactive groups for label attachment. Building a modular toolbox will extend these techniques to a much greater number of proteins.

MAPPING SPECIFIC PROTEIN−PROTEIN CONTACT POINTS

Once two proteins have been identified as interacting partners by cross-linking, the specific site of interaction can be determined through mass spectrometry. MS analysis can be simplified exponentially if the digested cross-linked peptide can be isolated and purified first. Incorporation of either fluorescent probes or affinity handles into traditional cross-linkers aid tremendously in the isolation of the suitable adducts. Once the peptide of interest is isolated, analysis by a variety of MS

techniques reduce the old saying of "finding a needle in a haystack" to just finding the hay. An important caveat to this approach is that significant amounts of cross-linked products are needed for MS analysis. Therefore, efficient cross-linking and/or enrichment of a cross-linked species are necessary for successful identification. Various techniques including cross-linking conditions, fluorescent cross-linkers, affinity labels, and the ever increasing sensitivity of mass spectrometers all help to overcome this limitation.

Bromobimanes are the most widely used fluorescent cross-linkers. They are thiol−thiol cross-linkers and have the advantage that they only fluoresce upon conjugation. Therefore, the reaction progress can be monitored directly, simplifying analysis. They are also extremely stable in solution and have high thiol selectivity (*31*). Dibromobimane has been used successfully to cross-link and identify intramolecular thiols in myosin (*32*), lactose permease (*33*), and ATPase (*34*). A cleavable, fluorescent, photoactive cross-linking agent, sulfosuccinimidyl-2-(7-azido-4-methylcoumarin-3-acetamido)-ethyl-1,3′-dithiopropionate (SAED, Figure 3) has also been used to identify specific protein cross-links (*35*, *36*). The cross-linker is initially attached to amino groups of the protein of interest, then photo-cross-linked via an azide to residues on an interacting protein. The complex is then reduced, cleaving the disulfide within the cross-linker and transferring the fluorescent group to the interacting protein in a label transfer reaction (Figure 4). Protease digestion will then liberate a peptide with the fluorescent group identifying the interacting site. Other fluorescent dyes can be incorporated into trifunctional cross-linkers as the third arm to provide a tracer for peptide isolation. After digestion with trypsin or other proteases, these fluorescent protein fragments can be separated chromatographically or by SDS−PAGE and specifically analyzed by MS.

Another method of identification of cross-linked products is the use of affinity handles for enrichment of cross-linked products. The most common affinity handle is biotin, which can be specifically isolated using an affinity column composed of monomeric avidin or streptavidin beads. The previously described biotin cross-linkers, typically used in a label transfer reaction for visualization (*21*, *22*), can be used in addition to other trifunctional reagents (*30*, *37*) as affinity purification tools. After cross-linking two proteins, the biotin moiety is transferred to the cross-linked interacting protein with addition of a reducing agent. After protease digestion, isolation of a cross-linked fragment occurs by passing the entire protease digestion over an avidin affinity column. After washing, the cross-linked peptide with the biotin moiety is eluted with free biotin and isolated for MS analysis.

Upon isolation and purification of the cross-linked fragment, the mass of the individual peptide can be easily identified by MS through a single peak (*38*). Then the composition of the cross-linked peptide can be determined by comparison with the known sequence of the two interacting proteins. Advances in mass spectrometry have led to new methods of analysis including tandem mass spectrometry (*39*, *40*). This technique combines two rounds of MS analysis to identify the specific composition of a component. The first round separates the components based on mass, and the second round of MS breaks apart the individual peptides one amino acid at a time to yield a ladder of peaks identifying the sequence of a peptide. The mapping of specific protein−protein contact points by cross-linking along with individual structures of proteins and computer modeling will allow scientists to piece together protein complexes from a limited number of interaction points. As the sensitivity of MS detection and analysis increases, specific interactions in transient protein complexes should also become more clear.

USING CROSS-LINKING TO CREATE PROTEIN COMPLEX MODELS

Once interacting proteins in a complex are identified, with or without the determination of specific interaction points as described above, additional structural relationships and information about the architecture of the complex are necessary for a complete understanding of biological function. Sites of interaction or interfaces formed can be important in structure and function, and thus may be important in normal physiologic as well as pathologic processes, and generation of therapeutic agents. To reduce the bias and improve the resolution of the final model, a large number of cross-links should be formed across the interaction interface. Use of a homobifunctional lysine-lysine cross-linker allows the maximal amount of cross-linking due to the large number of lysines in proteins. Not only is there a greater chance that at least one of these lysines lie in or close to an interface, but the likelihood of multiple lysines at this site allows a map to be created of the interaction interface. In this way, unexpected or multiple modes of interaction may also be observed.

Young et al. (*41*) examined the intramolecular cross-links of fibroblast growth factor (FGF-2) which has a known three-dimensional structure. They were able to separate intramolecular cross-links from intermolecular cross-links by column chromatography or SDS−PAGE. Chromatographically separated fractions of the peptide digest of the intramolecular cross-links were then analyzed by MS. Cross-links were identified by analyzing the MS data with a custom software program, ASAP, and a model of the protein was generated. The data obtained were consistent with the crystal structure of FGF-2, with the interatomic distances experimentally determined by cross-linking close to the predicted distances. The structure of ubiquitin was also probed using a modified procedure in which the cross-linked protein was injected into an electrospray ionization (ESI)−Fourier transform (FT) mass spectrometer, and the cross-link positions were localized by multiple stages of fragmentation and mass spectrometry, instead of proteolysis followed by column chromatography and then MS (*42*). This approach, which yielded similar data, provided a simpler and quicker approach, which facilitates the application to high throughput experiments.

The structure of the yeast prohibin complex, a large multimeric assembly with chaperone-like activity was investigated without chromatographic separation techniques (*43*). The oligomer, which is composed of repeating heterodimers of a PHB1 and PHB2 subunits was cross-linked with DSP, digested with trypsin, and analyzed by either MALDI MS or ESI MS. The authors used a custom-made software tool, FindLink, to filter the data and identify cross-linked peptides. Since each protein contained multiple lysine residues close to the subunit interface, a total of nine heterodimeric cross-links were identified. This allowed a map of the subunit interface to be generated, and a model of the dimer was generated.

Similarly, a model of the signal recognition particle (FfH) and its receptor (FtsY) was built by chemical cross-linking with disuccinimydyl suberate (DSS, Figure 3) or bis(sulfosuccinimidyl) adipate (BSSA), proteolytic digestion, and tandem MS (*44*). In this study, they identified a total of nine separate intermolecular cross-linked

peptides. Using a novel model building approach which included geometric restraint optimization and macromolecular docking, they were able to identify a best fit for this complex based on the cross-linking data. After these findings, a partial crystal structure of the FfH−FtsY complex was determined and found to be in good agreement with the cross-linking model but lacked the M domain of FfH. Interestingly, four out of the nine cross-linked fragments provided information of the FfH M domain and provided new insights into its conformation relative to the rest of the complex which could not be determined in the crystal structure complex.

In a final example, the binding of calmodulin to mettilin, a polypeptide and principal component of honeybee venom, was also investigated without chromatographic separation techniques (*45*). The proteins were cross-linked with a number of different length amine−amine and amine−carboxylic acid cross-linkers, digested with trypsin, and analyzed by HPLC equipped with a high-resolution FT ion cyclotron resonance (ICR) mass spectrometer. The authors used distance constraints derived from the chemical cross-linking data in combination with computational methods three-dimensional structure models of the calmodulin−mettilin complex. From the numerous points of cross-linking obtained, an interface between the two proteins was mapped. The authors demonstrated for the first time that mettilin could bind to calmodulin in two different orientations (Figure 6).

The combination of cross-linking with mass spectrometric techniques used in proteomic identification has provided a powerful new tool to study the quaternary structure of multiprotein complexes. The development of tandem MS has allowed for more accurate identification and sequencing of peptides and the ability to detect femtomolar to nanomolar amounts of material, and increasingly sophisticated software tools may ultimately allow determination of cross-linking locations without the need for enrichment or separation techniques.

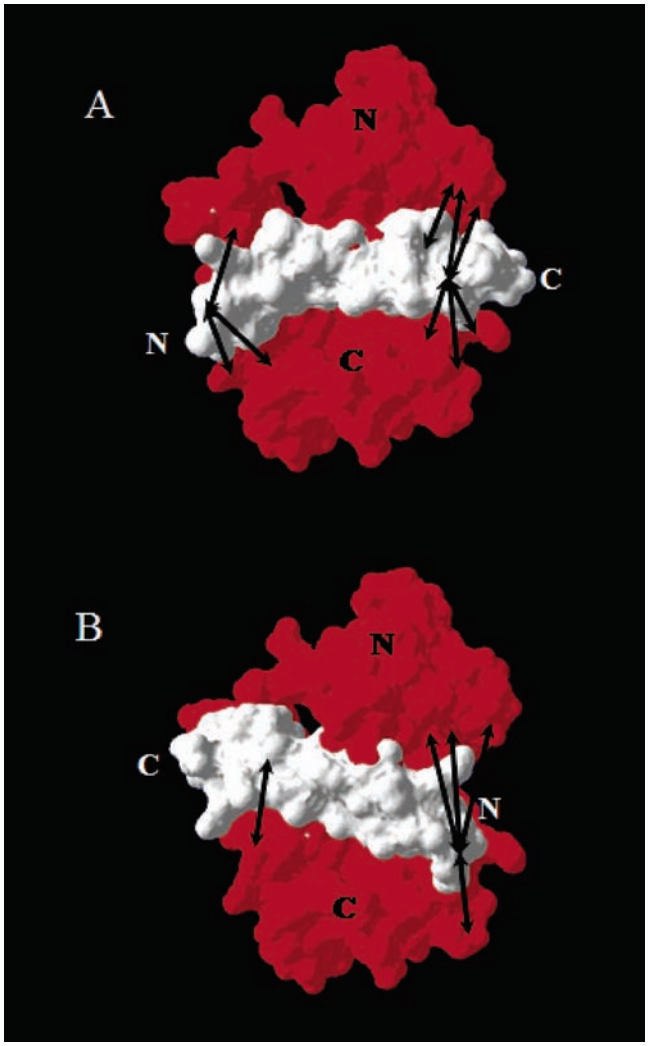

Figure 6. The complex between calmodulin (red) and mettilin (white) was analyzed using cross-linkers of different lengths. The arrows represent cross-links that were obtained and mapped. Calmodulin was found to bind mettilin in two different orientations, as shown in panels A and B. The amino- and carboxyl-terminal domains of calmodulin are labeled N and C, respectively. The amino and carboxyl termini of mettilin are similarly labeled.

FUTURE DIRECTIONS

Genetically Encoded Cross-Linking Agents. One of the challenges of site-specific modification of proteins with cross-linking agents is the necessity for a single alkylatable amino acid, typically cysteine. This can be accomplished by mutagenesis, but large proteins with numerous cysteines pose a significant challenge for constructing genes with multiple mutations. The alternative is to genetically incorporate noncanonical amino acids into proteins to provide the cross-linking group. Incorporation of noncanonical amino acids has been an accessible technology for decades, such as the incorporation of selenocysteine by adding this amino acid to the growth medium during protein expression. The native cysteine-tRNA synthetase can aminoacylate $tRNA_{cys}$ with selenocysteine under conditions when intracellular cysteine concentrations are low. The diversity of noncanonical amino acids that can be mischarged is low and unfortunately does not include cross-linking groups.

In the past few years, tRNA synthetases have been engineered to be able to aminoacylate tRNAs with an impressive number of noncanonical amino acids (*46*), including photo-cross-linking amino acids. Benzophenone is a very high efficiency photo-cross-linker and can be incorporated into proteins with the amino acid *p*-benzoyl-L-phenylalanine (pBpa). A library of *Methanococcus jannaschii* tyrosyl-tRNA synthetases was selected for the ability to aminoacylate a mutant tyrosine amber suppressor tRNA with pBpa. By engineering an amber codon into glutathione S-transferase and expressing in the presence on the mutant tRNA synthetase/tRNA pair and pBpa, site-specific incorporation of a benzophenone group was accomplished (*47*).

Alternatively, a mutant *E. coli* phenylalanine-tRNA synthetase has been engineered to allow incorporation of *p*-azidophenylalanine. Incorporation of this photo-cross-linking amino acid was accomplished using an *E. coli* phenylalanine auxotroph. Dihydrofolate reductase was successfully expressed with *p*-azidophenylalanine in place of phenylalanine (*48*). The disadvantage of this system is that all of the phenylalanines in the protein will be replaced, which is no more desirable than chemical modification of multiple cysteines. It has been shown, however, that the *E. coli* phenylalanine codon degeneracy can be broken with a mutant yeast phenylalanine tRNA specific for only one of the two phenylalanine codons (*49*). Site-specific incorporation of *p*-azidophenylalanine could be accomplished after making a mutant gene encoding for only one copy of the target codon, similar to the amber suppressing method above.

Expressing site-specific photo-cross-linking amino acids in proteins opens up the possibility of probing protein−

protein interactions in vivo without having to purify a target protein, incorporate the cross-linker, and reconstitute the protein complex. Expression of proteins with noncanonical amino acids in yeast (*50*) may also enable the opportunity of studying eukaryotic protein complexes using these technologies.

Identification of Variable Protein Complex Interactions. Rearrangements of protein complex composition are known to occur in response to extremes that alter the cellular environment, during normal processes throughout the cell cycle of an organism, or in the presence of pathologic disease. Already, microarray technology has detected these phenomena at the mRNA level, but this technology does not demonstrate what happens at the functional protein level. Assembly and disassembly of protein complexes occur in response to cellular signals. Formation of DNA replication factories, modulation of signal transduction complexes, transcriptional activation and repression, and translational protein/RNA complexes, as well as other multiprotein enzymatic machines, are all assembled and disassembled in response to cellular signaling. In vivo cross-linking in combination with antibody arrays designed for a specific biological area of interest coupled with mass spectrometry will provide a way to monitor changes in protein−protein interactions in response to certain cellular signals.

The ability to detect complex networks of interacting proteins has been limited in the past to focusing on single pairs of interacting proteins or a limited study of single branches of pathways. With the advances in the sensitivity, accuracy, and speed of mass spectrometers, there has been a trend toward automation of gathering and analyzing data. Mass spectrometers equipped with robotic machinery can prepare, process, and analyze a vast number of samples, enabling the development of high throughput approaches to proteomic analysis. These advances, combined with current experimental techniques including cell cycle synchrony, in vivo cross-linking, and immunoprecipitation arrays will allow for study of large complexes and protein networks.

The benefit of this combination of techniques is that it will provide for complete protein complex analysis in response to a variety of cellular signals. Protein complex assembly and disassembly can be followed over time. Most interestingly, promiscuous proteins involved in a number of protein complexes can be specifically examined to determine their appropriate complex association under various conditions or times. The results of these studies will produce a complex traffic map of protein interactions during normal cellular function as well as in response to changing cellular conditions. This map can then be exploited in the development of therapeutics designed to disrupt or alter the assembly or disassembly of specific protein complexes in response to specific cellular signals.

Rhenium-186-1-hydroxyethylidene-1,1-diphosphonate (^{186}Re-HEDP) has been used for the palliation of metastatic bone pain. Delayed blood clearance and high gastric uptake of radioactivity have been observed upon injection, due to the instability of ^{186}Re-HEDP in vivo. In this study, on the basis of the concept of bifunctional radiopharmaceuticals, we designed a stable ^{186}Re-mercaptoacetylglycylglycylglycine (MAG3) complex-conjugated bisphosphonate, [[[[(4-hydroxy-4,4-diphosphonobutyl)carbamoylmethyl]carbamoylmethyl]carbamoylmethyl]carbamoylmethanethiolate]oxorhenium(V) (^{186}Re-MAG3-HBP). As a precursor, [1-hydroxy-1-phosphono-4-[2-[2-[2-(2-tritylmercaptoacetylamino)acetylamino]acetylamino]acetylamino]butyl]phosphonic acid (Tr-MAG3-HBP) was synthesized by the conjugation of *N*-[(tritylmercapto)acetyl]glycylglycylglycine (Tr-MAG3) with the bisphosphonate analogue. After deprotection of the trityl group of Tr-MAG3-HBP, ^{186}Re-labeling was performed by reacting $^{186}ReO_4^-$ with $SnCl_2$ in citrate buffer. After purification by HPLC, ^{186}Re-MAG3-HBP showed a radiochemical purity of over 95%. To compare the stability of ^{186}Re-MAG3-HBP and ^{186}Re-HEDP, these ^{186}Re complexes were incubated in phosphate buffer. No measurable decomposition of ^{186}Re-MAG3-HBP occurred over a 24-h period, while only approximately 30% of ^{186}Re-HEDP remained intact 24 h postincubation. In biodistribution experiments, the radioactivity level of ^{186}Re-MAG3-HBP in bone was significantly higher than that of ^{186}Re-HEDP. Blood clearance of ^{186}Re-MAG3-HBP was faster than that of ^{186}Re-HEDP. In addition, the gastric accumulation of ^{186}Re-MAG3-HBP radioactivity was lower than that of ^{186}Re-HEDP. In conclusion, ^{186}Re-MAG3-HBP is expected to be a useful radiopharmaceutical for the palliation of metastatic bone pain.

INTRODUCTION

Malignant tumors, especially breast and prostate carcinomas, frequently metastasize to the bone (*1*). A prominent symptom caused by these metastases is pain, which has a significant impact on the patients' quality of life. Localized radiation therapy is an effective method for the treatment of bone pain (*2*); however, a common problem in patients with bone metastases is the development of multiple sites of metastasis, and so internal radiotherapy using specifically localized beta emitters is preferable. Recently, $^{89}SrCl_2$ has been used as a palliative agent for painful osseous metastases (*3*, *4*). However, ^{89}Sr is a pure beta emitter and has a relatively long half-life (50.5 d). These physical properties could be a disadvantage for clinical use.

Rhemium-186-1-hydroxyethylidene-1,1-diphosphonate (^{186}Re-HEDP) has also been proposed for the palliation of metastatic bone pain (*5*−*7*). ^{186}Re is a Group VII metal that decays with the emission of a beta particle with a maximal energy of 1.07 MeV. A 9% abundance gamma ray with energy of 137 keV is also produced in the decay process, enabling correlative imaging to be performed. Its relatively short physical half-life of 90.6 h accounts for high dose rates and allows for repeated treatments at short time intervals. Moreover, problems of radioactive waste handling and storage are

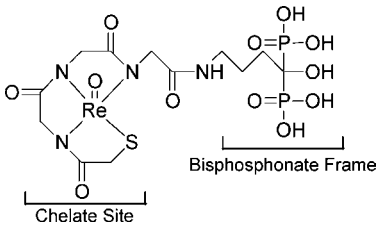

Figure 1. Chemical structure of Re-MAG3-HBP.

reduced. However, ^{186}Re-HEDP has showed delayed blood clearance and high gastric uptake. It has been reported that the unnecessary radiation in patients is due to the poor stability of the ^{186}Re complex in vivo leading to the generation of $^{186}ReO_4^-$ (*8*–*10*). Furthermore, a marked accumulation in bone is also a definitive requirement for a therapeutic drug in the palliation of metastatic bone pain. The accumulation of bisphosphonate analogues in the bone is responsible for the binding of hydroxyl groups of their phosphonate group to Ca^{2+} of hydroxyapatite (*11*). In the case of ^{186}Re-HEDP, since it is reasonable that some hydroxyl groups of HEDP bind to Ca^{2+} of hydroxyapatite and the rest coordinate rhenium, it is predictable that the coordination will reduce the inherent accumulation in bone of HEDP.

Thus, we planned the development of a novel ^{186}Re-labeled compound with a high affinity for bone and low accumulation of radioactivity in other organs. For this purpose, on the basis of the concept of bifunctional radiopharmaceuticals, we designed a stable ^{186}Re-mercaptoacetylglycylglycylglycine (MAG3) complex-conjugated bisphosphonate, [[[[(4-hydroxy-4,4-diphosphonobutyl)carbamoylmethyl]carbamoylmethyl]carbamoylmethyl]carbamoylmethanethiolate]oxorhenium(V) (^{186}Re-MAG3-HBP) (Figure 1). In this study, ^{186}Re-MAG3-HBP was synthesized and its stability and biodistribution were studied in comparison to ^{186}Re-HEDP.

MATERIALS AND METHODS

General. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Bruker AC-200 spectrometer (JEOL Ltd., Tokyo, Japan), and the chemical shifts were reported in ppm downfield from an internal tetramethylsilane standard. Fast atom bombardment mass spectra (FAB-MS) were obtained with a JMS−HX/HX 110 A (JEOL Ltd.). Ionspray mass spectra (IS-MS) were obtained with an API*III*E (Parkin-Elmer Sciex Instruments, Toronto, Canada). Electrospray ionization mass spectra (ESI-MS) were obtained with a LCMS-QP8000α (Shimadzu, Kyoto, Japan). ^{186}Re was supplied by the Japan Atomic Energy Research Institute (Tokai-mura, Japan) as perrhenate ($^{186}ReO_4^-$) (*12*). Cellulose acetate electrophoresis (CAE, Separax-SP; Joko Co. Ltd., Tokyo, Japan) was run in an electrostatic field of 0.8 mA/cm for 20 min in veronal buffer (I = 0.06, pH 8.6). TLC analyses were performed with silica plates (Merck Art 5553) using acetone as a developing solvent. Benzoyl-mercaptoacetylglycylglycylglycine (Bz-MAG3) was supplied by Daiich Radioisotopes Labs (Chiba, Japan). Other reagents were of reagent grade and used as received.

Synthesis of ^{186}Re-MAG3-HBP. ^{186}Re-MAG3-HBP (**10**) was synthesized according to the procedure outlined in Scheme 1.

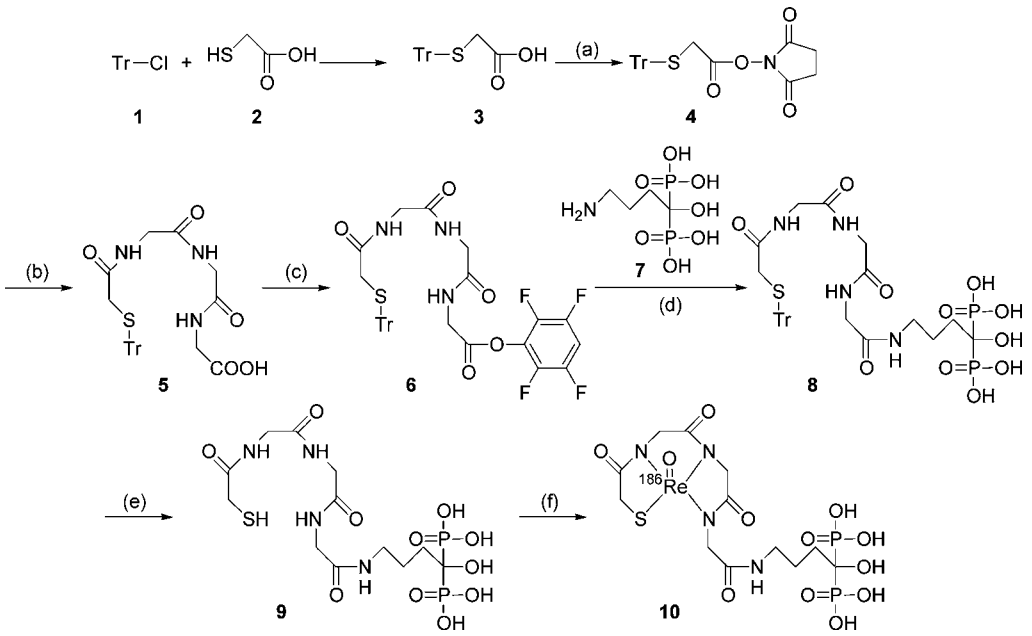
Tritylmercaptoacetic Acid (3). Mercaptoacetic acid (8.3 g, 90 mmol) and trityl chloride (25.0 g, 90 mmol) were dissolved in 45 mL of dimethylformamide (DMF). After the reaction mixture had been stirred at room temperature for 48 h, the solvent was removed in vacuo. The residue was dissolved in 100 mL of chloroform, and then 6 N NaOH was gradually added to the solution. The precipitated white crystals were collected and washed with distilled water to obtain compound **3** (22.3 g, 74.3%). ^{1}H NMR ($CDCl_3$): δ 7.43−7.19 (overlapped m, 15H), 3.03 (s, 2H). FAB-MS calcd for $C_{21}H_{18}O_2S$ $(M - H)^-$: *m/z* 333. Found: 333.

***N*-[(Tritylmercapto)acetyl]glycylglycylglycine (Tr-MAG3) (5).** Compound **3** (10.0 g, 30 mmol) was dissolved in 150 mL of chloroform, and *N*-hydroxysuccinimide (NHS) (3.45 g, 30 mmol) was added to the solution. Dicyclohexylcarbodiimide (DCC) (7.40 g, 36 mmol) in 25 mL of chloroform was added dropwise to the reaction mixture at room temperature. The reaction solution was stirred at room temperature for 18 h. The solvent was removed in vacuo. The residue was suspended in ethyl acetate. After filtration, the filtrate was evaporated in vacuo, and the residue was washed with hexane to obtain compound **4** (3.64 g) as the crude product. Glycylglycylglycine (0.73 g, 3.87 mmol) was dissolved in 22 mL of distilled water, and the solution was adjusted to pH 8.8 with 1 N NaOH. Compound **4** (2.00 g) was dissolved in 20 mL of DMF and was added dropwise to the glycylglycylglycine aqueous solution. After 3 h of stirring at 40 °C, the solvent was removed in vacuo. The residue was suspended in 30 mL of dilute hydrochloric acid (pH 2−3), and the aqueous mixture was extracted with chloroform. The organic layer was dried over anhydrous $CaSO_4$, and the solvent was removed in vacuo. The residue was purified by chromatography on silica gel using chloroform−methanol−acetic acid (50:10:1) as the eluent to obtain compound **5** (501 mg, 21.3%) as white crystals. ^{1}H NMR ($CDCl_3$): δ 7.23−7.44 (overlapped m, 15H), 4.13 (s, 4H), 3.65 (s, 2H), 3.47 (s, 2H). FAB-MS calcd for $C_{27}H_{27}N_3O_5S$ $(M + H)^+$: *m/z* 506. Found: 506.

4-Amino-1-hydroxybutylidene-1,1-bisphosphonate (7). Compound **7** was synthesized according to the procedure of Kiecykowski (*13*). Briefly, phthalic anhydride (29.6 g, 0.2 mol) was reacted with 4-aminobutyric acid (20.6 g, 0.2 mol) in 50 mL of acetic acid at 120 °C for 2 h. The reaction solution was cooled, and 300 mL of distilled water was gradually added to the solution. The precipitated white crystals were collected and washed with distilled water to obtain 4-phthalimidobutyric acid (40.5 g, 86.9%). ^{1}H NMR ($CDCl_3$): δ 7.82−7.89 (overlapped m, 2H), 7.76−7.65 (overlapped m, 2H), 3.77 (t, 2H), 2.43 (t, 2H), 2.02 (quin, 2H). FAB-MS calcd for $C_{12}H_{11}NO_4$ $(M + H)^+$: *m/z* 234. Found: 234.

4-Phthalimidobutyric acid (11.7 g, 50 mmol) was reacted with thionyl chloride (7.37 g, 62 mmol) in 50 mL of toluene and 50 μL of DMF at 50 °C for 1 h. The excess thionyl chloride was removed by distillation. The volume of the reaction mixture was reduced to 25 mL by distillation under a house vacuum (100 mmHg) at 80 °C. An additional 50 mL of toluene was added, and the mixture was distilled. The clear, colorless solution was used in the next reaction without further purification. Trimethyl phosphate (6.50 g, 53 mmol) was added, and the reaction solution was stirred at room temperature for 18 h. The reaction solution was used in the next reaction without further purification. Dimethyl phosphite (5.80 g, 53 mmol) was added to the reaction solution. Triethylamine (5.00 g, 50 mmol) was then added dropwise at 20 °C. During the addition of triethylamine, there was a rapid crystallization. After stirring for an additional 1 h, the reaction mixture was allowed to stand at 4 °C for 1 h. The precipitated white crystals were collected and washed with toluene to obtain tetramethyl 4-phthalimido-1-hydroxybutylidene-1,1-bisphosphonate

Scheme 1. Synthesis of ^{186}Re-MAG3-HBP[a]



[a] Reagents: (a) NHS, DCC; (b) glycylglycylglycine; (c) TFP, DCC; (d) Et_3N; (e) TFA, triethylsilane; (f) $^{186}ReO_4^-$, $SnCl_2$/citrate.

(10.2 g, 46.9%). ^{1}H NMR ($CDCl_3$): δ 7.81−7.86 (overlapped m, 2H), 7.70−7.75 (overlapped m, 2H), 3.81−3.89 (overlapped m, 12H), 3.72 (t,2H), 2.00−2.14 (overlapped m, 4H). FAB-MS calcd for $C_{16}H_{23}NO_9P_2$ $(M + H)^+$: *m/z* 436. Found: 436.

Tetramethyl 4-phthalimido-1-hydroxybutyliden-1, 1-bisphosphonate (1.00 g, 2.3 mmol) was hydrolyzed by the reflux in 5 mL of 6 N HCl for 18 h. The resulting suspension was cooled to 0 °C, and the phthalic acid was removed by filtration. The filtrate was concentrated. Compound **7** was crystallized by the addition of 1.25 mL of water and 1.88 mL of ethanol. After the suspension was cooled at 4 °C for 2 h, compound **7** (430 mg, 75.1%) was obtained by filtration and washing with 95% ethanol as white crystals. ^{1}H NMR ($NaOD/D_2O$): δ 2.88 (m, 2H), 1.85 (m, 4H). FAB-MS calcd for $C_4H_{13}NO_7P_2$ $(M + Na)^+$: *m/z* 272. Found: 272.

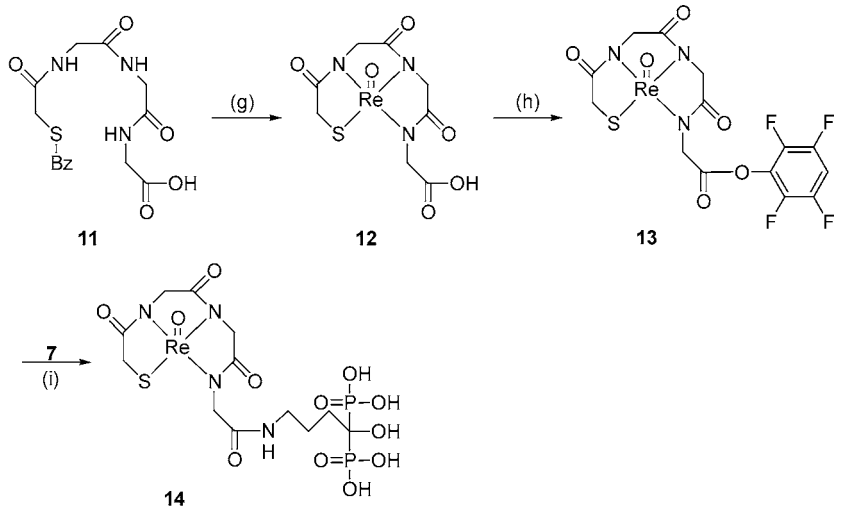
[1-Hydroxy-1-phosphono-4-[2-[2-[2-(2-tritylmercaptoacetylamino)acetylamino]acetylamino]acetylamino]butyl]phosphonic Acid (8) (Tr-MAG3-HBP). Tr-MAG3 (**5**) (100 mg, 0.198 mmol) and tetrafluorophenol (TFP) (38.8 mg, 0.220 mmol) were dissolved in 14 mL of chloroform. DCC (45.8 mg, 0.220 mmol) in 6 mL of chloroform was added dropwise to the reaction mixture at room temperature. After 1 h of stirring at room temperature, the solvent was removed in vacuo. The residue was then suspended in an adequate volume of ethyl acetate, DCC urea was removed by filtration, and the filtrate was evaporated in vacuo to obtain crude compound **6**. Compound **6** was used in the next reaction without further purification. Compound **7** (57.0 mg, 0.229 mmol) was suspended in 3 mL of distilled water, and triethylamine (139 mg, 1.37 mmol) was added to the suspension. After a few seconds of stirring at room temperature, the suspension became clear. Compound **6** was dissolved in 4 mL of acetonitrile and then added to the reaction mixture. Triethylamine (23.1 mg, 0.229 mmol) was then added, and the reaction mixture was stirred for 3 h at room temperature. This mixture was purified by reversed phase (RP)-HPLC performed with a Cosmosil $5C_{18}$-AR 300 column (10 × 150 mm; Nacalai Tesque, Kyoto, Japan) at a flow rate of 4.7 mL/min with a gradient mobile phase of 25% acetonitrile in water with 0.1% trifluoroacetic acid (TFA) to 40% acetonitrile in water with 0.1% TFA for 30 min. Chromatograms were obtained by monitoring the UV adsorption at a wavelength of 254 nm. The fraction containing compound **8** was determined by mass spectrometry and collected. The solvent was removed by lyophilization to provide compound **8** (50.3 mg, 34.5%) as white crystals. ^{1}H NMR (DMSO-d_6): δ 8.22 (t,1H), 8.18 (t, 1H), 8.10 (t, 1H), 7.81 (t, 1H), 7.25−7.36 (overlapped m, 15H), 3.63−3.76 (overlapped m, 6H), 2.98 (q, 2H), 2.85 (s, 2H), 1.67−1.85 (overlapped m, 4H). IS-MS calcd for $C_{31}H_{38}N_4O_{11}P_2S$ $(M + H)^+$: *m/z* 737. Found: 737.

[[[[(4-Hydroxy-4,4-diphosphonobutyl)carbamoylmethyl]carbamoylmethyl]carbamoylmethyl]carbamoylmethanethiolate]oxorhenium(V) (10) (^{186}Re-MAG3-HBP). The trityl group of Tr-MAG3-HBP was deprotected just before radiolabeling. Tr-MAG3-HBP (0.1 mg) was dissolved in 190 μL of TFA and 10 μL of triethylsilane and gently shaken. After removal of the solvent under a stream of N_2, 0.1 mL of 0.2 M acetate buffer (pH 3.0) was added to the residue. Stannous chloride (0.3 mg) in 0.1 mL of 0.1 M citrate-buffer (pH 5.0), and 0.1 mL of $^{186}ReO_4^-$ solution, were added to the MAG3-HBP ligand solution. The reaction mixture was vigorously stirred and allowed to react at 90 °C for 1 h. After the reaction mixture had cooled to room temperature, ^{186}Re-MAG3-HBP (**10**) was purified by RP-HPLC performed with a Cosmosil $5C_{18}$-AR-300 column (4.6 × 150 mm) at a flow rate of 1 mL/min with a mixture of 0.2 M phosphate buffer (pH 6.0) and ethanol (90:10) containing 10 mM tetrabutylammoniumhydroxide.

Synthesis of Nonradioactive Re-MAG3-HBP. Nonradioactive Re-MAG3-HBP (**14**) was synthesized according to the procedure outlined in Scheme 2.

[Mercaptoacetylglycylglycylglycine]oxorhenium-(V) (12) (Re-MAG3). A procedure reported previously was employed with slight modification (*14*). Bz-MAG3 (**11**) (300 mg, 817 μmol) was dissolved in 50 mL of acetonitrile−water (6:4). Stannous chloride (616 mg, 2.73 mmol) in 50 mL of 0.1 M citrate buffer (pH 5.0) and $KReO_4$ (228 mg, 789 μmol) in 50 mL of water were added to the Bz-MAG3 solution. The reaction mixture was stirred and refluxed for 1 h. After the reaction mixture

Scheme 2. Synthesis of Re-MAG3-HBP[a]



[a] Reagents: (g) $KReO_4$, $SnCl_2$/citrate; (h) TFP, DCC; (i) Et_3N.

had cooled to room temperature, Re-MAG3 was purified by RP-HPLC performed with a Cosmosil $5C_{18}$-AR300 column (20 × 150 mm) at a flow rate of 12 mL/min with a gradient mobile phase of 5% acetonitrile in water with 0.1% TFA to 30% acetonitrile in water with 0.1% TFA for 30 min. Chromatograms were obtained by monitoring the UV adsorption at a wavelength of 254 nm. The fraction containing compound **12** was determined by mass spectrometry and collected. The solvent was removed by lyophilization to provide Re-MAG3 (**12**) (70.8 mg, 18.7%) as purple crystals. ESI-MS calcd for $C_8H_9N_3O_6{}^{187}ReS$ $(M - H)^-$: *m/z* 461. Found: 461, $C_8H_9N_3O_6{}^{185}ReS$ $(M - H)^-$: *m/z* 459. Found: 459.

[[[[(4-Hydroxy-4,4-diphosphonobutyl)carbamoylmethyl]carbamoylmethyl]carbamoylmethyl]-carbamoylmethanethiolate]oxorhenium(V) (14) (Re-MAG3-HBP). To synthesize compound **13**, a procedure reported previously was employed with slight modifications (*15*, *16*). After Re-MAG3 (**12**) (10.0 mg, 21.6 μmol) was dissolved in 1 mL of acetate buffer (0.1 M, pH 6.0), TFP (4.15 mg, 25.0 μmol) in 100 μL of acetonitrile was added to the solution. HCl salt of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (48.5 mg, 25.1 μmol) and triethylamine (35.0 μL, 25.2 μmol) was added to the reaction mixture. After the pH was adjusted to about 6.0 with 1 N HCl, the mixture was stirred for 30 min at room temperature. The reaction mixture was diluted with water to a volume of 8 mL and purified on two conditioned Sep-Pak C18 cartridges (Waters, Milford, MA). For washing, 20 mL of water for injection, 30 mL of 20% ethanol in 0.01 M phosphate buffer (pH 7.0), 10 mL of water and 0.5 mL of ether were used. The active ester (**13**) was eluted with 2.5 mL of acetonitrile. Compound **7** (5.38 mg, 21.6 μmol) in 1 mL of 0.1 M borate buffer (pH 9.5), and triethylamine (15.0 μL), were added to the active ester solution. After the pH was adjusted to 9.0 with 1 N NaOH, the reaction mixture was stirred for 3 h at room temperature. This reaction mixture was purified by RP-HPLC performed with a Hydrosphere C18 column (20 × 150 mm, YMC, Kyoto, Japan) at a flow rate of 14 mL/min with a gradient mobile phase of 20% acetonitrile in water with 1% formic acid to 50% acetonitrile in water with 1% formic acid for 30 min. Chromatograms were obtained by monitoring the UV adsorption at a wavelength of 254 nm. The fraction containing compound **14** was determined by mass spectrometry and collected. The solvent was removed by lyophilization to provide Re-MAG3-HBP (**14**) (1.86 mg, 12.4%) as light purple crystals. ESI-MS calcd for $C_{12}H_{20}N_4O_{12}P_2{}^{187}ReS$ $(M - H)^-$: *m/z* 692. Found: 692 $C_{12}H_{20}N_4O_{12}P_2{}^{185}ReS$ $(M - H)^-$: *m/z* 690. Found: 690.

Preparation of ^{186}Re-HEDP. ^{186}Re-HEDP was prepared according to a published procedure (*9*) and used after confirmation of its radiochemical purity by TLC ($R_f = 0$) and CAE (3.5 cm anode from the origin).

In Vitro Stability. To evaluate the stability of ^{186}Re complexes in buffered solution, ^{186}Re-labeled compounds were diluted with 0.1 M phosphate buffer (pH 7.0) saturated with 95% O_2/5% CO_2, and the solutions were incubated at 37 °C. After 1, 3, and 24 h of incubation, the samples were drawn and the radioactivity was analyzed by RP-HPLC or TLC.

Biodistribution. After HPLC purification of ^{186}Re-MAG3-HBP, solvent exchange was performed using Sep-pak C18 cartridges eluted with ethanol. The ethanol was evaporated with a stream of N_2 gas, and the residue was dissolved in saline.

Biodistribution experiments were performed by intravenously administering ^{186}Re-labeled compounds into 6-week-old male ddY mice (27−30 g). Groups of five mice were administered 100 μL of each ^{186}Re-labeled compound prior to sacrifice at 10 and 30 min, and 1, 3, 6, and 24 h postinjection. Tissues of interest were removed and weighed, and radioactivity counts were determined with an auto well gamma counter (ARC-2000; Aloka, Tokyo, Japan).

Statistical Evaluation. Biodistribution data were compared using Students' *t* test; $p = 0.05$ was defined as the limit of significance.

RESULTS

^{186}Re-MAG3-HBP (**10**) was prepared according to the method shown in Scheme 1. The precursor (Tr-MAG3-HBP (**8**)) of ^{186}Re-MAG3-HBP was synthesized by coupling the carboxyl group of Tr-MAG3 (**5**) with the amino group of a bisphosphonate derivative (**7**). The trityl group of Tr-MAG3-HBP was deprotected by treatment with TFA and triethylsilane just before radiolabeling, and ^{186}Re-MAG3-HBP (**10**) was prepared by complexation with ^{186}Re using citrate/$SnCl_2$ as a reducing system. The radiochemical yield of ^{186}Re-MAG3-HBP was 76%. After purification by RP-HPLC, ^{186}Re-MAG3-HBP showed a radiochemical purity of over 95%.

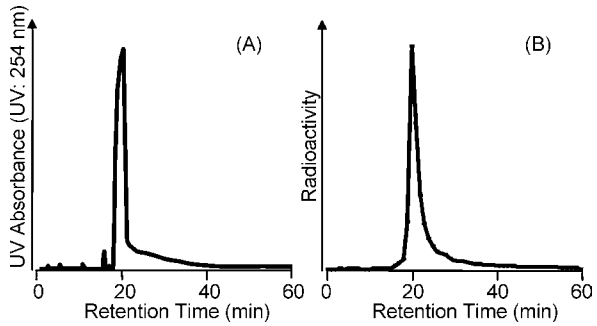


Figure 2. RP−HPLC chromatograms of (A) Re-MAG3-HBP and (B) ^{186}Re-MAG3-HBP after purification. Conditions: A flow rate of 1 mL/min with 10% ethanol in 200 mM phosphate buffer pH 6.0 containing 10 mM tetrabutylammoniumhydroxide.

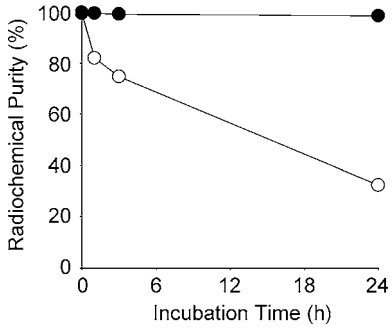

Figure 3. Stability of ^{186}Re-MAG3-HBP (closed circles) and ^{186}Re-HEDP (open circles) in buffered-solution.

Nonradioactive Re-MAG3-HBP (**14**) was synthesized by the coupling of Re-MAG3 (**12**) complexed previously with the bisphosphonate derivative (**7**), to exclude the possibility of complexation between rhenium or tin and the bisphosphonate structure (Scheme 2). Each RP-HPLC analysis of ^{186}Re-MAG3-HBP and Re-MAG3-HBP showed the same retention time (Figure 2). This indicates that the radiolabeled product proved identical to an authentic nonradioactive counterpart, and that ^{186}Re was chelated only with the MAG3 site.

Figure 3 shows the stability of ^{186}Re-MAG3-HBP and ^{186}Re-HEDP in buffered solution. After 24 h of incubation, about 95% of ^{186}Re-MAG3-HBP remained intact, whereas about 30% was intact in the case of ^{186}Re-HEDP.

The biodistributions of ^{186}Re-MAG3-HBP and ^{186}Re-HEDP in normal mice are presented in Tables 1 and 2, respectively. ^{186}Re-MAG3-HBP showed a rapid accumulation and long residence in the bone, and its uptake by the bone was significantly higher than that of ^{186}Re-HEDP. Furthermore, ^{186}Re-MAG3-HBP showed a faster clearance from the blood than did ^{186}Re-HEDP. Therefore, ^{186}Re-MAG3-HBP showed significantly higher bone:blood ratios of radioactivity than ^{186}Re-HEDP (Figure 4). Meanwhile, ^{186}Re-MAG3-HBP showed a significantly lower uptake by the stomach than ^{186}Re-HEDP.

DISCUSSION

The basic requirements of internal radiotherapeutic agents for the palliation of metastatic bone pain include excellent stability in vivo and marked accumulation in bone.

On the basis of the concept of bifunctional radiopharmaceuticals, we designed a ^{186}Re-labeled MAG3-conjugated bisphosphonate derivative (^{186}Re-MAG3-HBP, Figure 1). MAG3 was selected as the ^{186}Re-chelating group because it could form a stable, compact, and hydrophilic complex with ^{186}Re in high yield (*15*, *16*).

The result of in vitro stability experiments indicates that ^{186}Re-MAG3-HBP is more stable than ^{186}Re-HEDP. This result was reflected in the biodistribution. Namely, since accumulation in the stomach is an index of the decomposition of a Re-complex in biodistribution studies (*17*, *18*), a low level of ^{186}Re-MAG3-HBP in the stomach indicates good stability in vivo. The blood clearance could be also influenced by this stability. When calculated from the results of the biodistribution experiments, the rate of blood clearance of ^{186}Re-MAG3-HBP and ^{186}Re-HEDP was 49.7 mL/h and 15.6 mL/h, respectively. ^{186}Re-HEDP complex gave rise to $^{186}ReO_4^-$ in vivo, and the clearance from blood of $^{186}ReO_4^-$ was slower than that of ^{186}Re-HEDP (*9*). It is suggested that the more rapid clearance from the blood of ^{186}Re-MAG3-HBP is responsible for its stability, when compared with ^{186}Re-HEDP. This rapid clearance could lead to a decrease in the level of unnecessary radiation.

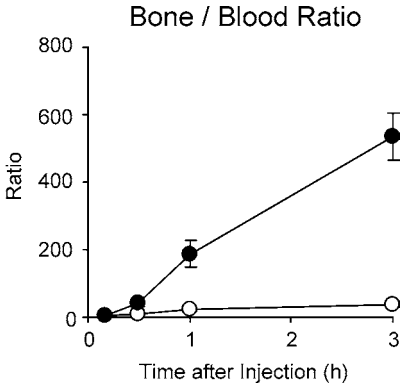

Figure 4. Bone blood ratios of radioactivity after injection of ^{186}Re-MAG3-HBP (closed circles) and ^{186}Re-HEDP (open circles) in mice.

The bone uptake of ^{186}Re-MAG3-HBP was compared with ^{186}Re-HEDP in mice. When expressed as %dose/g tissue × body weight in order to correct the difference in weight of the animals (*19*, *20*), the uptake of ^{186}Re-MAG3-HBP and ^{186}Re-HEDP in the femur 24 h after injection was 711% and 342%, respectively, while the uptake of ^{186}Re-MAG3-HBP was more than twice that of ^{186}Re-HEDP. Furthermore, bone uptake of ^{186}Re-MAG3-HBP was almost the same as that of ^{131}I-labeled arylalkylidenebisphosphonate reported recently (850%) (*19*). This ^{131}I-labeled bisphosphonate analogue was designed based on the same concept as ^{186}Re-MAG3-HBP, i.e., both compounds have a stable labeling site distinct from the bisphosphonate frame. Thus, the results obtained with the ^{131}I-labeled bisphosphonate support the usefulness of the drug design of ^{186}Re-MAG3-HBP based on bifunctional radiopharmaceuticals. In addition, $^{89}SrCl_2$ and ^{153}Sm-EDTMP were approved by the Food and Drug Administration for the treatment of painful osseous metastases, and the uptake value was 354% ($^{89}SrCl_2$, 24 h, mice) (*21*) and 580% (^{153}Sm-EDTMP, 24 h, rats) (*22*), respectively. Since the value of ^{186}Re-MAG3-HBP is higher than each of the values of $^{89}SrCl_2$ and ^{153}Sm-EDTMP, it is expected that ^{186}Re-MAG3-HBP will be of clinical use.

In conclusion, we developed a highly stable ^{186}Re-labeled bisphosphonate, ^{186}Re-MAG3-HBP. This agent showed a marked accumulation in bone and rapid clearance from other tissues. Thus, ^{186}Re-MAG3-HBP is expected to be a useful radiopharmaceutical for the palliation of metastatic bone pain.

A New Platform for Oligonucleotide Delivery Utilizing the PEG Prodrug Approach

Hong Zhao,* Richard B. Greenwald, Prasanna Reddy, Jing Xia, and Ping Peng

Enzon Pharmaceuticals Inc., 20 Kingsbridge Road, Piscataway, New Jersey 08854. Received August 16, 2004; Revised Manuscript Received May 24, 2005

The oligonucleotide (oligo, ODN), Genasense (GS), an ODN currently waiting for FDA approval, was chosen as a model and modified with a 5′ or 3′ aminohexyl functionality (**1** and **4**, respectively) using solid-state synthesis. These amino derivatives were reacted with different releasable PEGs (rPEGs). The in vitro results of the PEG-modified oligos (Table 1) clearly show a substantial increase in rat plasma half-life and enhanced stability against a variety of nucleases, especially the predominant nuclease (PEII) in mammals, which is the main source of oligo degradation in cells. The advantage of using a PEG prodrug approach was further demonstrated by the pharmacokinetic (PK) results, which exhibited much greater C_{max}, plasma half-life, and area under the curve (AUC) for **3** compared to unmodified GS. A key step in the synthesis of ODN prodrug conjugates with a dye label was also accomplished successfully by employing dihydropyran derivatives of alcohols and acids as orthogonal protecting groups during the synthesis.

INTRODUCTION

Poly(ethylene glycol) (PEG) permanently bonded to oligodeoxynucleotides, generally as phosphate esters, has been synthesized by Bonora (*1*), Burchovich (*2*), Drioli (*3*) and several other groups to stabilize the rapidly metabolized oligo while enhancing, hopefully, cellular uptake (for reviews on this subject see Chirila (*4*) and Bonora (*5*)). PEG coupling to the 3′ and 5′ terminal positions showed more than a 10-fold increase in exonuclease stability, while maintaining in vitro activity (*6*). However anti-sense activity in vivo has yet to be demonstrated. This may in part be due to the inability of solid-phase methods to produce sufficient quantities of materials to test.

Other cases of oligos with 3′ or 5′ modifications including dyes, cholesterol (*7*), or other polymers (*8*) have shown enhanced antisense binding activities in vitro (*9*−*12*). Recently Agrawal et al. (*13*) have shown that conjugation of dyes, nucleotides, or oligomers through the 5′-position suppresses immunostimulatory activity of CpG containing ODNs, while conjugation at the 3′-position does not.

Construction of a pure, high molecular weight PEG prodrug by using the available NH_2 moiety obtained by introduction of an amino alkyl side chain at either the 3′ or 5′ terminal positions should provide a long-lived species and enhance oligo bioavailability using this long-circulating prodrug form. Kawaguchi (*14*) used a hexylamine linker at the 5′ terminus during the automated synthesis of a 15 base pair ODN and then permanently conjugated the basic NH_2 group to a low molecular weight (10 000 Da) branched PEG derivative, 2,4-(*O*-methoxypoly(ethylene glycol))-6-chloro-*S*-triazine. Unfortunately, purity was not defined, and a comparison of half-lives in human plasma in the presence of S1 nuclease demonstrated that the PEGylated mixture had marginally greater stability, while the free oligo with a phosphorothioate backbone showed the greatest stability. No PEGylation of the latter was reported.

PEG conjugation has been shown to enhance cellular uptake in vitro (*15*), thus making a PEG prodrug strategy particularly appealing since the native drug can be generated after cellular accumulation. The use of high molecular weight PEG (>20 000 Da) can control circulating half-life in plasma, while the linkage can be designed to release native oligo into the cell. In fact, application of this concept using phosphorothioate-based ODNs conceivably can provide constructs with outstanding stability. Therefore, to evaluate the effect of ODN−PEG conjugation on circulating half-life, drug delivery, and cellular uptake, we initiated a program that was based on the use of an aminohexyl modification at the 3′- and 5′-postions of different oligos to facilitate the reaction sequences. Preparation for future cellular uptake investigations of these PEG conjugates was also addressed by synthesizing a heterobifunctional rPEG with a releasable FITC conjugated oligo on one terminus and a fluorescent dye (Texas Red) on the distal end.

CHEMISTRY

The oligo, Genasense (GS), an ODN currently waiting for FDA approval, was chosen as a model and modified with a 5′ or 3′ aminohexyl functionality (**1** and **4**) using a solid-state synthesis. This amino derivative was reacted with releasable PEG (rPEG) based on 1,6-benzyl elimination (BE) (*16*) as shown in Schemes 1−3, and this reaction resulted in 50−80% isolated yield of the desired PEG prodrugs, **3**, **5**, **7**, **9**, and **11**. Conjugation with the bicin aliphatic linker (**16**) (*17*) proceeded readily and also gave similar yields to the BE aromatic product, **17** (Scheme 5). Unreacted oligo is easily recovered from these conjugation reactions and can be recycled to increase the overall yield. This is in contrast to the liquid-phase synthesis of a PEGylated mercaptoalkyl ester where the final yield of substituted oligo was reported (*11*) to be only 3%. As was the case with other small molecules, by variation of the trigger different rates of release could be obtained (*16*). In addition to **1**, which contains a phosphorothioate backbone, another model 4-mer oligo

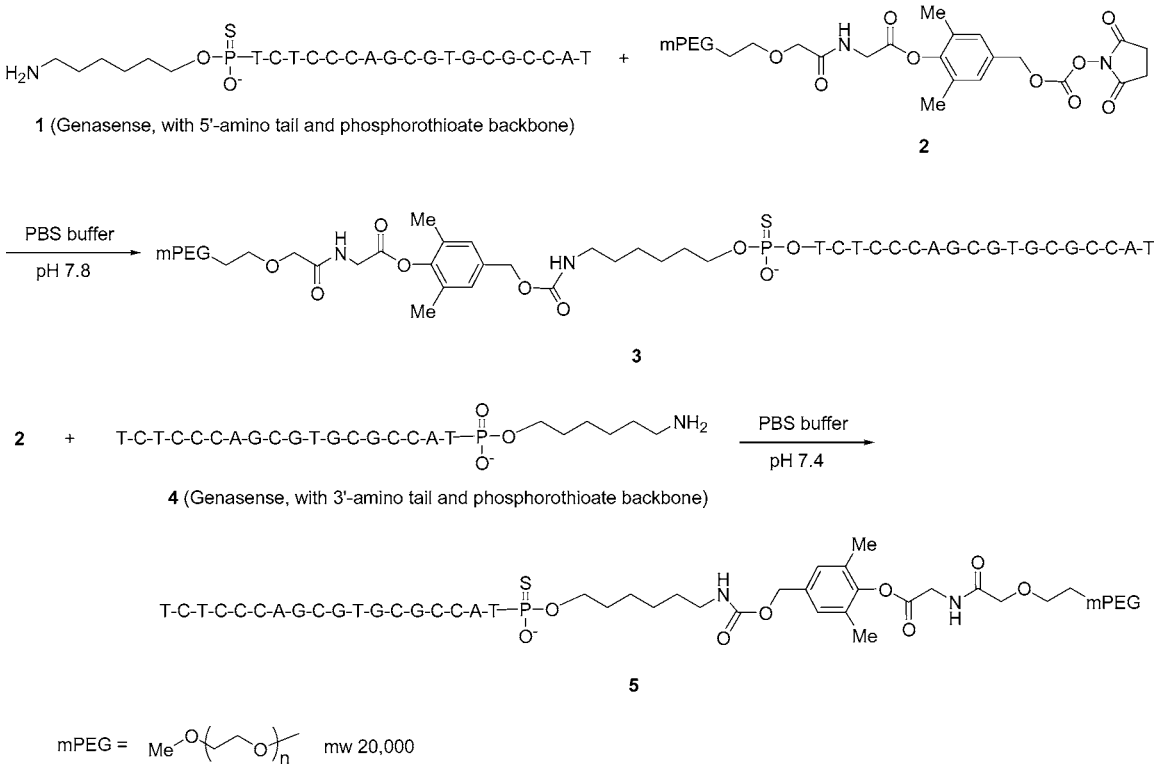
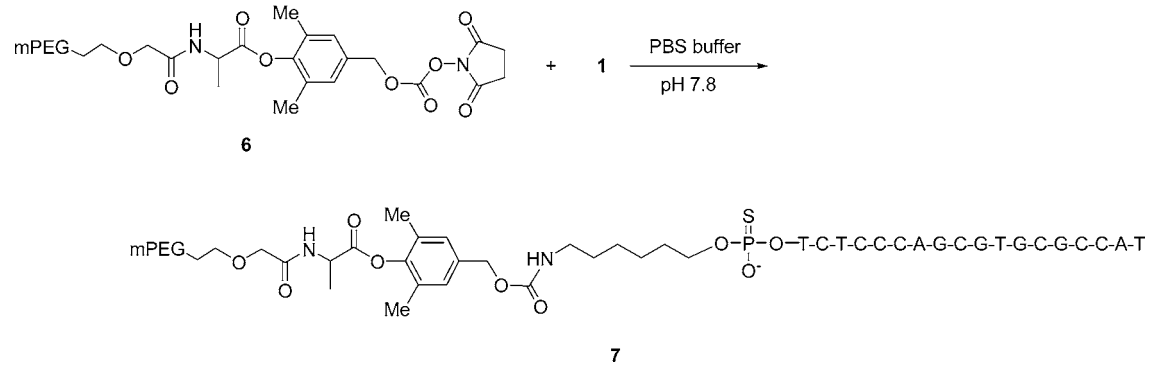


Scheme 2

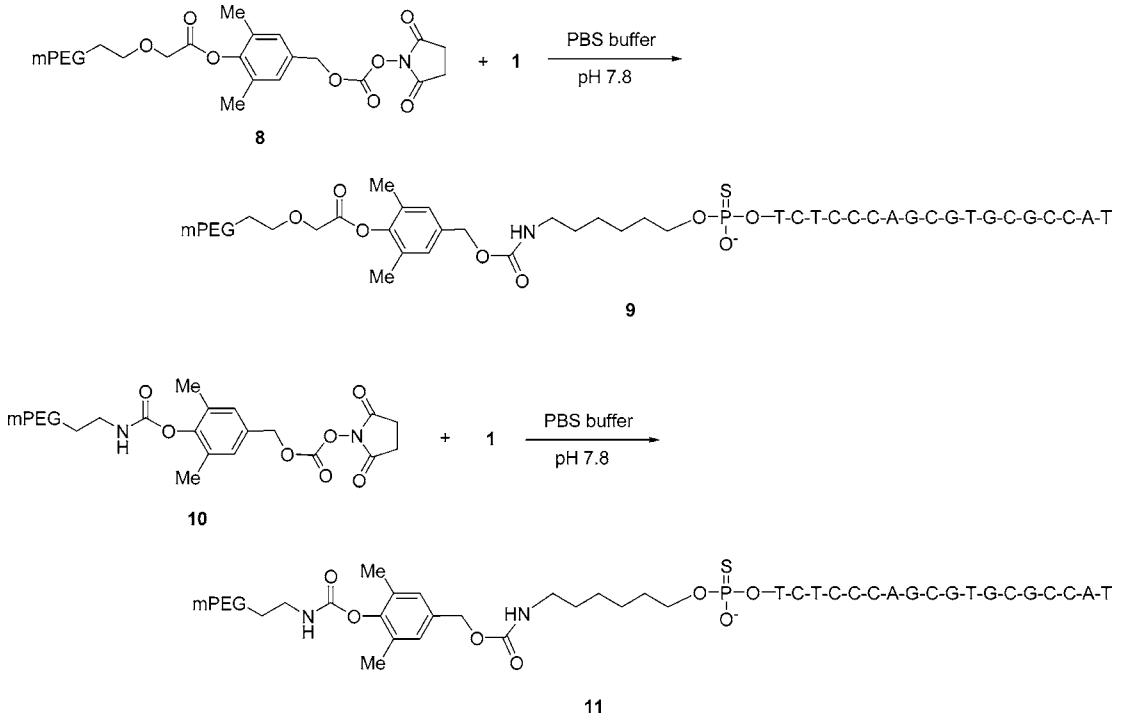


was prepared with a normal phosphate ester backbone, modified as the PEG prodrug (**15**, Scheme 4), and encouragingly, also demonstrated much greater in vitro stabilities (Table 1).

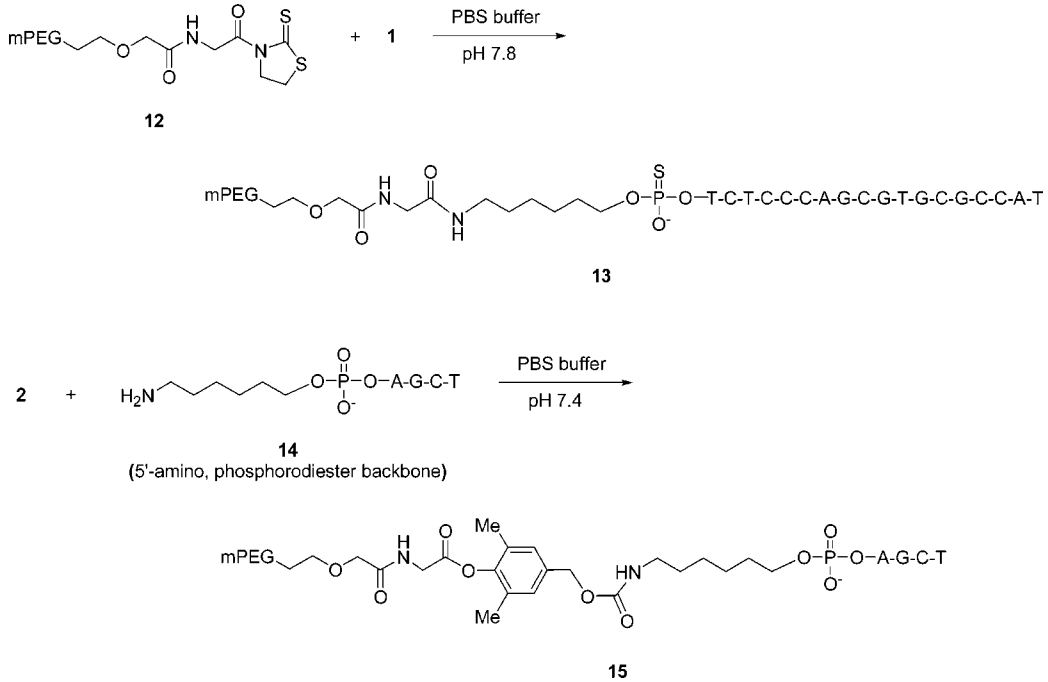
Cellular uptake studies of an rPEG−oligo conjugate should characterize the species produced using confocal microscopy analysis. To accomplish such a study, a heterobifunctional molecule would be required to provide two different types of substitutions at the termini of the PEG linker. Since the rPEG that was used in the first part of this investigation had a MW of 20 000 Da, it was decided to fix the variable of MW so that direct comparisons could be made. The synthesis of **35**, the first example of a high molecular weight (hMW) PEG heterobifunctional prodrug, was accomplished by the series of reactions shown in Schemes 6−8. Noteworthy in these sequences is the use of dihydropyran to form orthogonal protecting groups for the distal hydroxy and carboxy groups. The hMW α,ω-amino carboxy PEG derivative **24** was prepared by condensing the commercially available 3400 Da heterobifunctional derivatives **18** and **19** in the presence of DMAP to give heterobifunctional 6800 Da **20**, which was divided into two separate portions. The first segment was treated with TFA freeing the distal amino group and producing the amino acid salt **21**. The other functional unit was activated at the carboxy functionality by reaction with 2-mercaptothiazolidine (2-MT) to yield **22** in 90% yield. Reaction of **21** and **22** in the presence of DMAP resulted in the Boc-protected amino acid, **23**, which had a MW of 13 600Da. Compound **23** was deblocked with TFA and then reacted with **22**, which resulted in the hMW amino acid **24** (20 400 Da). It can be appreciated not only that further symmetrical condensations will double the MW each time but that the use of unequal MW portions will result in amino acids of intermediate molecular weights (MW). The introduction of the unsubstituted 1, 6-BE system was done as described earlier (*18*) for 2,6-dimethyl-4-hydroxybenzyl alcohol as shown in Scheme 7. Reaction of the carbonate *of p*-hydroxy benzaldehyde (**25**) with **24** formed the PEG aldehyde (**26**), which was reduced to the desired alcohol acid, **27**, with sodium borohydride.

Hussain and Truelove (*19*) have shown that the acyloxy derivatives of vinyl ethers (2-tetrahydropyranyl benzoate) undergo first-order hydrolysis with respect to the compound, independent of pH. However acetal derivatives of dihydropyran are only susceptible to acid-catalyzed hydrolysis (*20*). Since both types of dihydropyran deriva-

Scheme 3



Scheme 4



tives are formed under the same conditions, we reasoned that reaction of the heterobifunctional PEG alcohol acid (**27**) with dihydropyran should form both types of protecting groups simultaneously. With dry DCM and TsOH as catalyst, **27** provided the desired di-protected PEG species, **28**, in 95% yield. Dissolution of **28** in water at room temperature for 1 h removed the acyloxy ether but not the acetal moiety and provided an 88% yield of the desired monoprotected PEG acid, **29**. Conjugation of the free carboxyl group with Texas Red (**30**) in the presence of EDC resulted in the formation of the stable amide (**31**) in quantitative yield (Scheme 8). Finally, removal of the acetal from **31** was done with 50% acetic acid and gave the 1,6-benzyl alcohol−Texas Red derivative **32** in 89% yield. Activation of the OH group was done as described previously (*16*) by reaction with DSC to give **33**, followed by condensation with the aminohexyl derivative of GS with FITC labeling at the 3′ terminus resulting in the desired bifunctional substituted **35**. Inspection of **35** pinpoints the trigger (*16*) as an enzymatically labile phenolic carbamate (*21*, *22*). The ODN is attached distally as a stable aliphatic carbamate that releases only after the trigger hydrolyzes.

EXPERIMENTAL SECTION

General Procedures. All the conjugation reactions between PEG linkers and oligonucleotides were carried out in PBS buffer systems at various temperatures.

[a] PEI = phosphodiesterase I, 5′-exonuclease, kinetics done in pH 8.8 TEAA buffer at 37 °C; PEII = phosphodiesterase II, 3′-exonuclease, kinetics done in pH 6.5 TEAA buffer at 37 °C; nuclease P1 = endonuclease, kinetics done in pH 5.3 TEAA buffer at 37 °C. For all enzymes, 1 unit releases 1 μmol of oligonucleotide.

Extraction with organic solvents in general removed the unreacted oligonucleotides; further anion-exchange chromatography separated PEG−oligo conjugates from nonreacted excess PEG linkers to give pure products.

HPLC Methods. The reaction mixtures and the purity of intermediates and final products were monitored by a Beckman Coulter System Gold HPLC instrument employing a ZORBAX 300 SB C-8 reversed phase column (150 mm × 4.6 mm) or a Phenomenex Jupiter 300A C18 reversed phase column (150 mm × 4.6 mm) with a multiwavelength UV detector, using a gradient of 30−90% of acetonitrile in 0.5% trifluoroacetic acid (TFA) and 25−35% acetonitrile in 50 mM TEAA buffer with 4 mM TBACl at a flow rate of 1 mL/min. The anion-exchange chromatography was run on Bio-Cad 700E perfusion chromatography workstation from Applied Biosystems using either Poros 50HQ strong anion-exchange resin from Applied Biosystems or DEAE Sepharose fast-flow weak anion-exchange resin from Amersham Biosciences packed in an AP-Empty glass column from Waters. Desalting was achieved by using HiPrep 26/10 or PD-10 desalting columns from Amersham Biosciences.

ESI-MS Analysis. The composition and integrity of oligonucleotide (Genasense, **1**) in PEG−oligo conjugates were confirmed by electrospray ionization mass analysis using negative ion mode (Novatia LLC, Inc. Princeton, NJ) after base hydrolysis of each PEG−oligo conjugate. Releasable PEG−oligo conjugates were hydrolyzed using aqueous NH_3, lyophilized, and then sent for analysis. The samples containing released full-length oligonucleotide were flow-injected, and the obtained MS spectra were deconvoluted using ProMass software.

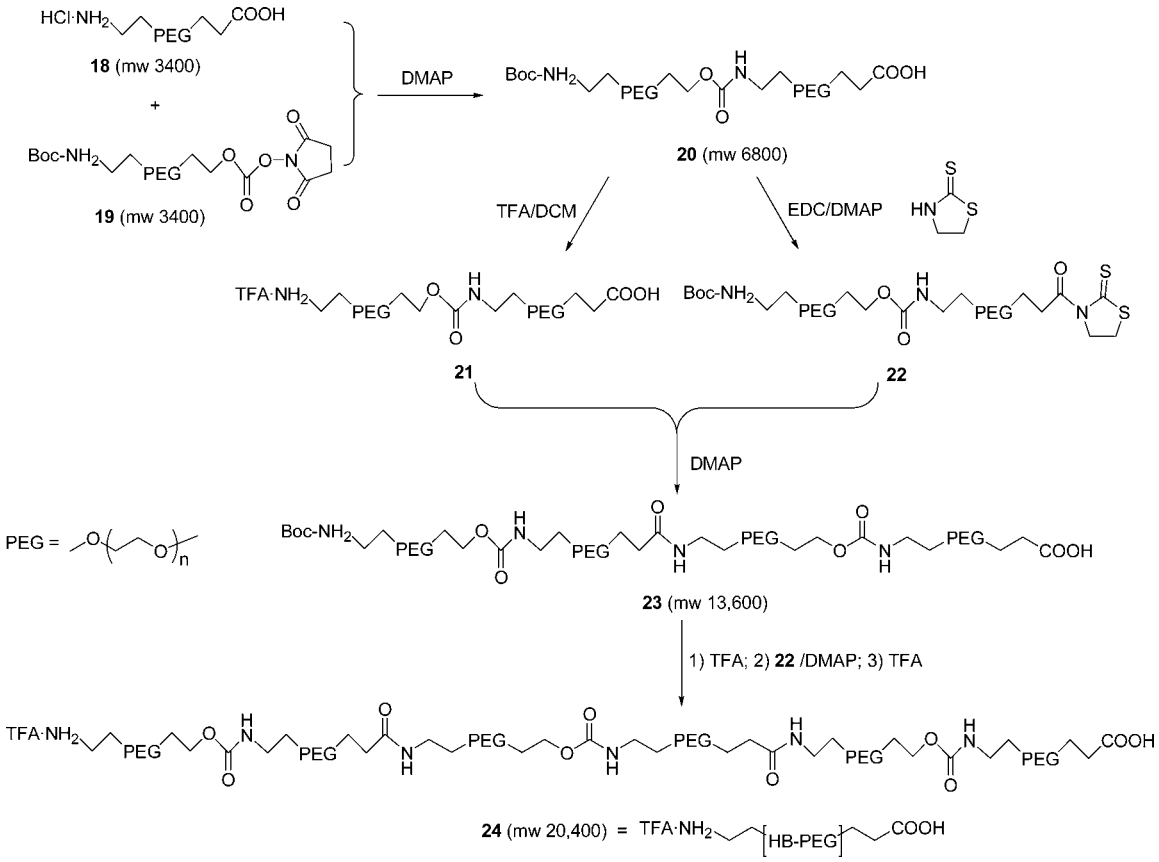
Compound 3. To a solution of compound **1** (25 mg, 3.9 μmol) in PBS buffer (5 mL, pH 7.8) was added **2** (600 mg, 39 μmol), and the mixture was stirred at room temperature for 5 h. The reaction solution was extracted with DCM (3 × 10 mL), the combined organic layers were dried ($MgSO_4$) and filtered, and the solvent was evaporated under reduced pressure. The residue was dissolved in double distilled water (5 mL) and loaded on a DEAE fast-flow weak anion-exchange column (27 mm × 250 mm, bed volume ≈ 50 mL), which was preequilibrated with 20 mM Tris-HCl buffer, pH 7.4. The unreacted PEG linkers were eluted with water (3−4 column volumes), and the product then eluted with a gradient of 0−100% 1 M NaCl in 20 mM Tris-HCl buffer, pH 7.4, in 10 min, followed by 100% 1 M NaCl in 20 mM Tris-HCl buffer, pH 7.4, for 10 min at a flow rate of 3 mL/min. The fractions containing pure product were pooled and desalted with an Amicon stirred cell concentrator using Ultracell membrane with a molecular weight cutoff of 5000, and the resulting solution was lyophilized to yield pure **3** (63 mg, 2.42 μmol, 60%). The analytical HPLC profile for purified compound **3** is shown in Figure 1; no free oligo impurity was detected. ESI-MS for released oligonucleotide: *m/z* 586.9 (42%) $[M - 10H]^{10-}$, 652.2 (100%) $[M - 9H]^{9-}$, 733.9 (88%) $[M - 8H]^{8-}$, 838.9 (68%) $[M - 7H]^{7-}$, 978.8 (46%) $[M - 6H]^{6-}$. M_{obsd} 5879.1; M_{calcd} 5879.8.

Compound 5. Compound **5** was made and purified in a similar way as **3** at a yield of 65%. Similar to **3**, analytical HPLC showed no impurity. ESI-MS for released oligonucleotide: *m/z* 586.9 (16%) $[M - 10H]^{10-}$, 652.2 (100%) $[M - 9H]^{9-}$, 733.9 (90%) $[M - 8H]^{8-}$, 838.8 (40%) $[M - 7H]^{7-}$, 978.8 (22%) $[M - 6H]^{6-}$. M_{obsd} 5879.0; M_{calcd} 5879.8.

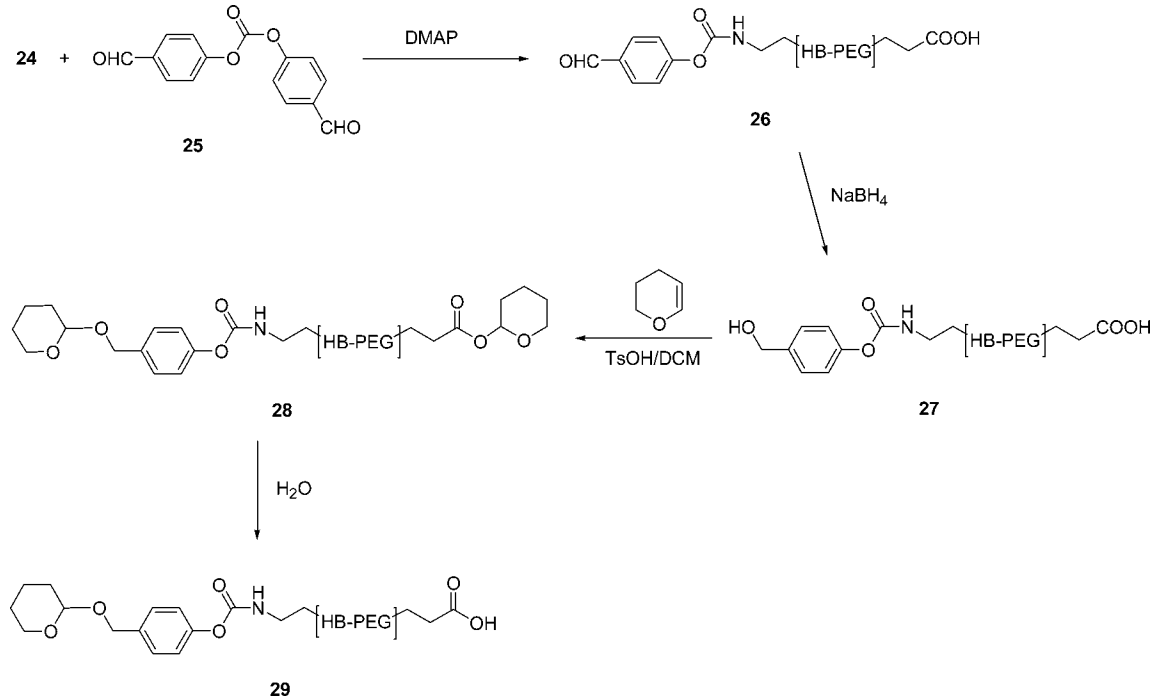
Compound 7. Compound **7** was made and purified in a similar way as **3** at a yield of 80%. Analytical HPLC showed no impurity. ESI-MS for released oligonucleotide: *m/z* 586.9 (54%) $[M - 10H]^{10-}$, 652.3 (100%) $[M - 9H]^{9-}$, 733.9 (59%) $[M - 8H]^{8-}$, 838.9 (30%) $[M - 7H]^{7-}$, 978.8 (27%) $[M - 6H]^{6-}$. M_{obsd} 5879.5; M_{calcd} 5879.8.

Compound 9. Compound 9 was made and purified in a similar way as **3** at a yield of 62%. Analytical HPLC showed no impurity. ESI-MS for released oligonucleotide: *m/z* 587.0 (39%) $[M - 10H]^{10-}$, 652.3 (100%) $[M - 9H]^{9-}$, 733.9 (76%) $[M - 8H]^{8-}$, 838.9 (61%) $[M - 7H]^{7-}$, 978.9 (41%) $[M - 6H]^{6-}$. M_{obsd} 5879.6; M_{calcd} 5879.8.

Scheme 6



Scheme 7



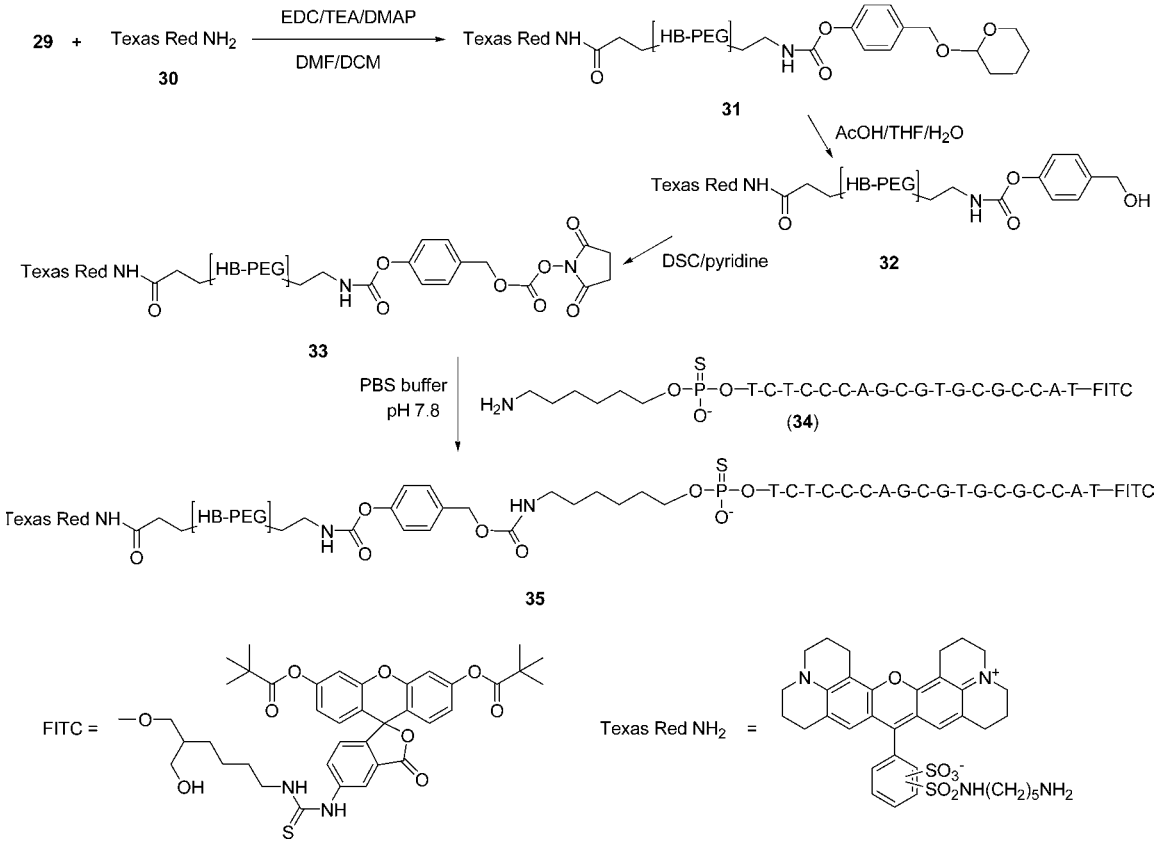
Compound 11. Compound **11** was made and purified in a similar way as **3** at a yield of 50%. Analytical HPLC showed no impurity. ESI-MS for released oligonucleotide: *m/z* 586.9 (60%) $[M - 10H]^{10-}$, 652.3 (100%) $[M - 9H]^{9-}$, 733.9 (58%) $[M - 8H]^{8-}$, 838.9 (34%) $[M - 7H]^{7-}$, 978.8 (26%) $[M - 6H]^{6-}$. M_{obsd} 5879.5, M_{calcd} 5879.8.

Compound 13. Compound **13** was made and purified in a similar way as **3** at a yield of 55%. Analytical HPLC showed no impurity. Hydrolysis study could not release free oligo due to the nature of permanent bonding in this compound.

Compound 15. Compound **15** was made and purified in a similar way as **3** at a yield of 50%. Analytical HPLC showed no impurity.

Compound 17. Compound **17** was made and purified in a similar way as **3** at a yield of 50%. Analytical HPLC

Scheme 8



showed no impurity. ESI-MS for released oligonucleotide: *m/z* 587.0 (65%) $[M - 10H]^{10-}$, 652.2 (100%) $[M - 9H]^{9-}$, 734.2 (45%) $[M - 8H]^{8-}$, 838.7 (31%) $[M - 7H]^{7-}$, 979.3 (10%) $[M - 6H]^{6-}$. M_{obsd} 5879.5, M_{calcd} 5879.8.

Compound 20. A solution of **18** (0.623 g, 0.180 mmol), **19** (0.623 g, 0.180 mmol), and *N,N*-(dimethylamino)-pyridine (DMAP, 0.110 g, 0.90 mmol) in dichloromethane (DCM, 20 mL) was stirred at room temperature for 12 h. The solution was washed with 0.1 N HCl (2 × 20 mL), dried ($MgSO_4$), and filtered, and the solvent was removed under reduced pressure; The product was crystallized from isopropyl alcohol (IPA, 25 mL) to give **20** (0. 910 g, 0.134 mmol, 74.3%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 171.91, 155.79, 155.30, 66.15, 63.32, 40.34, 39.91, 34.26, 28.02.

Compound 21. A solution of **20** (0.707 g, 0.104 mmol) in DCM/trifluoroacetic acid (TFA) (8 mL/4 mL) was stirred at room temperature for 3.5 h. The solvents were removed under reduced pressure, and the resulting solid was washed with ether to yield **21** (0.707 g, 0.104 mmol, 100%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 172.18, 155.94, 66.62, 66.32, 63.49, 40.49, 39.71, 34.46.

Compound 22. To a solution of **20** (0.910 g, 0.134 mmol), 2-mecaptothiazoline (2-MT, 0.0 319 g, 0.268 mmol), and DMAP (0.032.7 g, 0.268 mmol) in DCM (15 mL) cooled at 0 °C for 15 min was added 1-[3-(dimethylamino)-propyl]-3-ethylcarbodiimide hydrochloride (EDC, 0.0513 g, 0.268 mmol), and the reaction solution was allowed to gradually warm to room temperature and then stirred for 12 h. The PEG derivative was precipitated with ethyl ether, collected by filtration, and crystallized from IPA (19 mL) to give **22** (0.820 g, 0.121 mmol, 90.0%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 200.94, 171.73, 155.85, 155.36, 65.75, 63.37, 55.54, 40.37, 39.94, 38.73, 28.08.

Compound 23. To a solution of **21** (0.668 g, 0.098 mmol) in DCM (15 mL) was added DMAP to adjust the pH to 7.0. Compound **22** (0.677 g, 0.098 mmol) was added, and the reaction mixture was stirred at room temperature for 12 h. The solution was washed with 0.1 N HCl (2 × 20 mL), dried ($MgSO_4$) and filtered, solvent was removed under reduced pressure, and the residue was crystallized from IPA (25 mL) to give **23** (1.05 g, 0.077 mmol, 79.0%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 171.97, 170.72, 155.87, 155.36, 66.83, 66.24, 63.39, 40.40, 39.99, 38.74, 36.50, 34.34, 28.08.

Compound 24. A solution of **23** (4.50 g, 0.335 mmol) in DCM/TFA (30 mL/15 mL) was stirred at room temperature for 3.5 h. The solvents were removed under reduced pressure, and the resulting solid was washed with ether. The solid (4.30 g, 0.320 mmol) was dissolved in DCM (50 mL). To this solution was added DMAP (to achieve pH 7.0) and compound **22** (2.20 g, 0.320 mmol); the reaction mixture was stirred at room temperature for 12 h. The solution was washed with 0.1 N HCl (2 × 30 mL), dried ($MgSO_4$), and filtered, the solvent was removed under reduced pressure, and the residue was crystallized from IPA (25 mL) to yield BOC-protected PEG-acid (MW 20 400, 5.30 g, 0.260 mmol), which was treated with DCM/TFA (30 mL/15 mL) at room temperature for 3.5 h. The solvents were removed under reduced pressure, and the resulting solid was washed with ether to yield **24** (5.30 g, 0.260 mmol, 78%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 171.77, 170.60, 155.75, 66.73, 66.12, 63.28, 40.29, 39.86, 38.66, 36.41, 34.19.

Compound 26. To a solution of **24** (2.7 g, 0.134 mmol) in DCM (25 mL) was added DIEA until it reached pH 7.0. Compound **25** (72.6 mg, 0.269 mmol) was added, and the reaction mixture was stirred at room temperature for 12 h. The solution was washed with 0.1 N HCl (2 × 20 mL), dried ($MgSO_4$), and filtered, solvent was removed under reduced pressure, and the residue was crystallized from IPA (90 mL) to give **26** (2.11 g, 0.105 mmol, 78.1%).

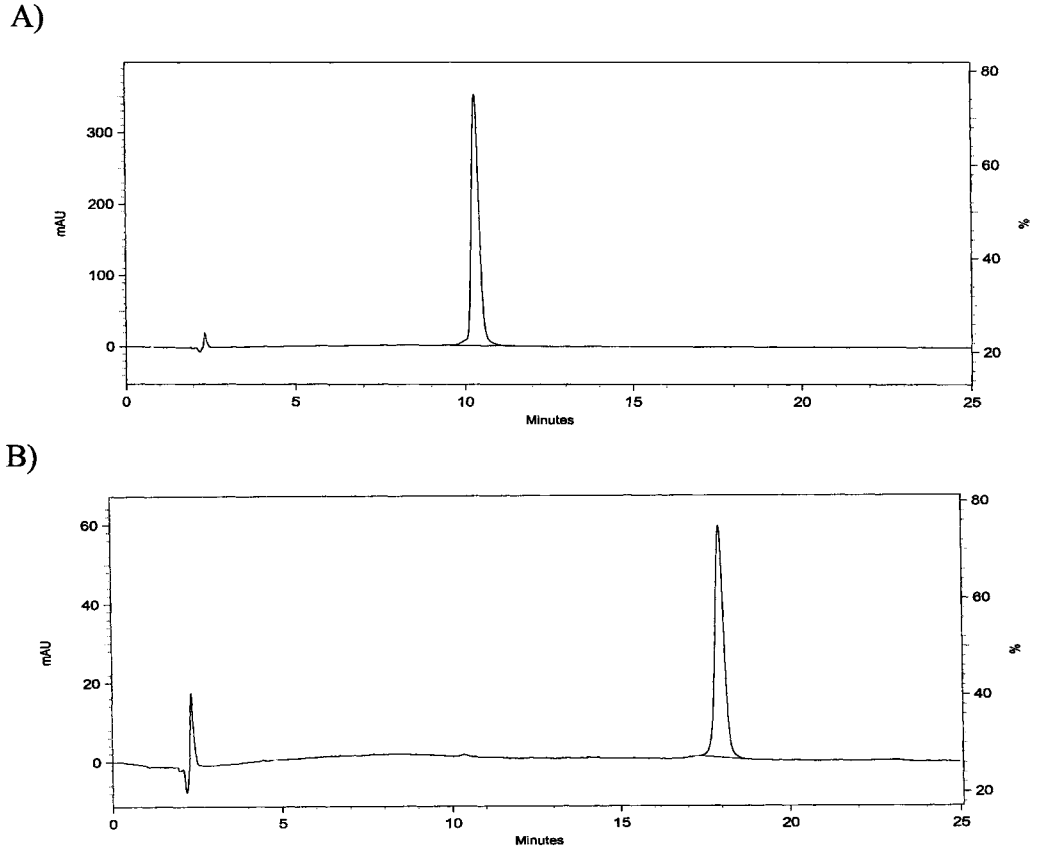


Figure 1. Analytical HPLC profile for (A) compound **1**, retention time 10.3 min, and (B) compound **3** (purified), retention time 17.9 min (UV detection at 260 nm).

^{13}C NMR (67.8 MHz, $CDCl_3$) δ *190.18*, 171.80, 170.63, 155.76, 155.36, 153.01, 130.74, 130.45, 121.40, 66.76, 66.15, 63.32, 40.61, 40.32, 38.69, 36.45, 34.23.

Compound 27. To a solution of **26** (2.1 g, 0.104 mmol) in MeOH (30 mL) cooled at 15 °C was added sodium borohydride (6.31 mg, 0.167 mmol), and the reaction solution was gradually warmed to room temperature and stirred for 2 h. This solution was treated with 1 N HCl to bring the pH to 6.5, the solvent was removed under reduced the pressure, and the residue was redissolved in about 20 mL of water. After the pH was adjusted to 2 with 1 N HCl, the aqueous solution was extracted three times with DCM. The organic fractions were combined, dried ($MgSO_4$), and filtered, solvent was removed partially under reduced pressure, and the residue was precipitated by addition of ether to give **27** (1.5 g, 0.074 mmol, 71.8%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 171.57, 170.40, 161.58, 155.61, 153.91, 149.4, 137.84, 126.79, 120.59, 66.58, 66.00, 63.23, 60.81, 40.34, 40.14, 38.51, 36.22, 34.08.

Compound 28. To a solution of **27** (1.56 g, 0.0774 mmol) and 3,4-dihydro-2*H*-pyran (DHP, 283 μL, 3.10 mmol) in DCM (20 mL) was added toluenesulfonic acid (TsOH, 3.68 mg, 0.019 mmol), and the reaction solution was stirred for 12 h at room temperature. The solution was filtered, and ethyl ether was added to precipitate the product. The crude product was crystallized from DMF/IPA (1:4, v/v) and DCM/ether (1:4, v/v) to yield **28** (1.49 g, 0.073 mmol, 95%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 170.37, 169.22, 155.56, 153.87, 149.64, 134.19, 127.81, 120.65, 97.94, 96.64, 91.70, 63.90, 63.02, 62.19, 61.25, 40.29, 40.08, 38.44, 36.16, 34.60, 29.87, 28.98, 28.45, 24.81, 24.54, 24.28, 22.77, 18.68, 17.82.

Compound 29. A solution of **28** (1.4 g, 0.073 mmol) in water (20 mL) was stirred for 1 h at room temperature. The solvent was removed under reduced pressure, and the residue was crystallized from DMF/IPA (1:4, v/v) and DCM/ether (1:4, v/v) to yield **29** (1.3 g, 0.064, 87.8%). ^{13}C NMR (67.8 MHz, $CDCl_3$) δ 171.56, 170.35, 155.55, 153.85, 149.62, 134.18, 127.80, 120.64, 97.91, 96.63, 63.92, 63.00, 61.22, 40.26, 40.06, 38.43, 36.12, 34.00, 29.85, 29.00, 24.78, 24.51, 22.74, 18.66.

Compound 31. To a solution of **29** (1.2 g, 0.059 mmol) in DCM (10 mL) was added the DMF solution (10 mL) of **30** (47 mg, 0.068 mmol) and 4 Å molecular sieves (1 g), and the reaction mixture was stirred for about 30 min before being cooled to 0 °C. Then TEA (179 μL, 1.29 mmol), DMAP (157 mg, 1.29 mmol), and EDC (200 mg, 1.05 mmol) were added, and the reaction mixture was stirred at room temperature for an additional 12 h. The solution was filtered, diluted with DCM, washed with water (2 × 20 mL) and 0.01 N $NaHCO_3$ (3 × 20 mL), dried ($MgSO_4$), and filtered, the solvent was removed under reduced pressure, and the residue was crystallized from 20% DMF in IPA three times to yield **31** (1.23 g, 0.059 mmol, 99%).

Compound 32. A solution of **31** (1.23 g, 0.059 mmol) in AcOH/THF/water (20:10:5 mL) was stirred for 12 h at room temperature. The solvents were removed under reduced pressure, and the residue was redissolved in DCM (20 mL). The solution was washed with water, dried ($MgSO_4$), and filtered, solvent was removed under reduced pressure, and the product was crystallized from 20% DMF in IPA to yield **32** (1.10 g, 0.053 mmol, 89%).

Compound 33. To a solution of **32** (1.1 g, 0.53 mmol) and DSC (0.108 g, 0.424 mmol) in DCM (20 mL) cooled to 0 °C was added pyridine (0.033 mL, 0.424 mmol), and the mixture was slowly warmed to room temperature and stirred for 12 h. The solvent was partially removed under reduced pressure, and the PEG compound was precipi-

tated with ethyl ether (50 mL). The crude product was crystallized from DMF/IPA (4 mL/30 mL) to give **33** (0.9 g, 0.43 mmol, 81%).

Compound 34. Compound **34** was made and purified in a similar way as **3** at a yield of 40%. Similar to **3**, analytical HPLC showed no free oligo impurity.

RESULTS AND DISCUSSION

The objectives of this study were to attempt to increase circulating half-life, drug delivery, and cellular uptake of ODNs aminohexyl-modified at the 3′- and 5′-positions by the synthesis of releasable PEG−ODN conjugates. To do so, we have developed a highly efficient method to synthesize and purify PEG−oligonucleotide conjugate. As illustrated by the synthesis of compound **3**, the purity of the final compound was checked both by analytical HPLC and by ESI-MS methods. From the HPLC chromatogram of both native oligonucleotide (Genasense) and PEG−oligo conjugate, we can clearly see that there is no free oligo in the final product (Figure 1). We then hydrolyzed the PEG−oligo conjugate to release the oligo and analyzed the mixture by ESI-MS. The data clearly show that full-length Genasense molecule was detected, which indicates that the Genasense in the PEG−oligo conjugate is intact. This was proven true for the rest of the PEG−oligo conjugates. The in vitro results of the PEG-modified oligos are summarized in Table 1 and clearly show a substantial increase in rat plasma half-life and enhanced stability against a variety of nucleases, especially the predominant nuclease (PEII) in mammals, which is the main source of oligo degradation in cells. The advantage of using an rPEG prodrug approach, resulting in a controlled continuous release of oligo and thus greater bioavailability, was further demonstrated by the pharmacokinetic (PK) results (performed using a previously described method) (*16*), which exhibited a much greater C_{max}, plasma half-life, and area under the curve (AUC) for prodrug **3** compared to non-PEGylated GS (Figure 2 and Table 2). Permanent PEG-conjugated oligo **13** showed greater PK results, as expected, but was not active in vivo (*23*).

Complete in vitro and in vivo activity test results derived from the PEG-conjugated oligos synthesized in this study will be reported in greater detail in a separate publication (*23*).

[a] A single iv bolus administration of 5 mg/kg of native oligo (**1**) equivalents of PEGylated oligo conjugate (**3**) in mice. [b] Separate study at 50 mg/kg dose.

The availability of a heterobifunctional rPEG with a releasable FITC-conjugated oligo on one terminus and a fluorescent dye (Texas Red) on the distal end now enables the question of cellular uptake of these compounds to be addressed. The results of this study will be presented shortly (*23*). These types of compounds or other nonpolymeric prodrug conjugates, which possess a permanent and a releasable dye at the distal termini, can be used for cellular uptake studies of ODNs providing detailed internalization information of delivered ODNs at subcellular levels.

CONCLUSIONS

rPEG linkers can be easily conjugated to aminoalkyl-ODNs in high yield to provide prodrugs that increase the stability of the oligo and provide a controlled release of the native drug. The facile purification of the rPEG conjugate makes this a very practical approach for prodrug scale-up, especially for (animal) studies that require large amounts of drug. The ease of variation of $t_{1/2}$ for the BE and bicin rPEG systems provides a versatile delivery platform for the intravenous administration of oligo drugs that addresses the issue of the low bioavailability of the ODN usually encountered and theoretically should permit PEG−ODN conjugates to be given at a lower dosage, thus avoiding spiking and subsequent toxicity problems. Synthesis of high MW heterobifunctional rPEG can also be done by a series of chain condensations starting from the more easily prepared low MW heterobifunctional compounds. Acetals

and acyl vinyl ethers (prepared simultaneously) can be employed as orthogonal protecting groups in PEG and other heterobifunctional molecules, thus permitting selective substitutions to be done at will.

Received September 21, 2004; Revised Manuscript Received April 18, 2005

Liposomes coated with poly(hydroxyethyl L-glutamine) (PHEG) show prolonged circulation times and biodistribution patterns comparable to PEG-coated liposomes. While PEG is a nondegradable polymer, PHEG is expected to be hydrolyzed by proteases. In this study the enzymatic degradability of PHEG both in its free form and grafted onto liposomes was investigated, using the proteases papain, pronase E, and cathepsin B. Enzymatic action was monitored with a ninhydrin assay, which quantifies amine groups formed due to hydrolysis of amide bonds, and the degradation products were characterized by MALDI-ToF mass spectrometry. PHEG, both in its free form and when grafted onto liposomes, showed degradation into low molecular weight peptides by the enzymes. Thus, we present a polymer-coated long-circulating liposome with an enzymatically degradable coating polymer, avoiding the risk of cellular accumulation.

INTRODUCTION

Liposomes are nanosized particles consisting of an aqueous volume enclosed by one or more phospholipid bilayers. Because of their biocompatibility and versatility they have been extensively studied as systems for the (targeted) delivery of small conventional drugs but also of macromolecules such as antigens, proteins, and DNA. Both lipophilic and hydrophilic compounds can be incorporated into liposomes, either in or absorbed to the lipid bilayer or in the aqueous compartment(s) (*1*–*4*). Intravenously injected liposomes are generally rapidly removed from the circulation, often hampering their ability to reach the aimed target site. This rapid elimination is due to recognition and capture by macrophages of the mononuclear phagocyte system (MPS), particularly those present in liver and spleen (*2, 3*). Surface modification with the hydrophilic polymer poly(ethylene glycol) (PEG) results in a decrease in uptake by the MPS and consequently in a prolonged circulation time (*2, 5*). Due to this MPS avoidance ('stealth') effect, PEG-liposomes are able to extravasate at pathological sites with areas of leaky endothelium, e.g. in tumors and inflamed tissues (so-called EPR effect (*6, 7*)). Besides PEG, several other polymers have been investigated for prolonging the circulation times of liposomes. Torchilin et al. studied vinyl-based liposome coatings (*8*), Woodle et al. studied poly(oxazoline) conjugates (*9*), and Maruyama et al. studied polyglycerol (*10*). Intravenously injected low molecular weight PEG (MW < 20 kDa) is rapidly cleared by the kidney (*11, 12*). However, its intracellular fate after uptake of PEG-coated liposomes is not known. PEG and the other polymers mentioned are not degradable by mammalian enzymes and therefore there is a risk of accumulation in cells in which the liposomes localize (e.g. macrophages), which in turn can lead to cell function impairment.

In a previous study we reported on two poly(α-amino acid)−lipid conjugates, namely poly(hydroxyethyl L-glutamine)−*N*-succinyldioctadecylamine (PHEG−DODASuc) and poly(hydroxyethyl L-asparagine)−DODASuc (PHEA−DODASuc), as stealth coatings for liposomes (structures shown in Figure 1). Indeed, liposomes coated with these polymers showed circulation kinetics and biodistribution patterns comparable to PEG-liposomes (*13*). The conjugates are based on modified L-α-amino acids and therefore have the potential to be degraded in vivo by proteases and peptidases. Poly(hydroxyethyl L-glutamine) (PHEG) has been investigated as biomaterial for different applications, and its enzymatic degradability has already been demonstrated (*14*–*21*). Relatively high molecular weight PHEG (MW = 25000−75000 Da) is cleaved into low molecular weight peptides by several proteolytic enzymes (e.g. papain, pepsin, pronase E, cathepsin B) of which the cysteine protease papain showed the highest activity (*17, 19*). Besides that enzymatic degradation reduces the risk of polymer accumulation inside cells, an enzymatically degradable coating polymer can also be used to trigger cellular uptake of the liposomes and/or release of the entrapped biologically active agent. To be more precise, in the extracellular space of tumors and inflamed tissues relatively high concentrations of proteases are present (*22, 23*). As just pointed out, long-circulating liposomes preferentially accumulate in such pathological tissues and 'stripping' of the polymer coating by enzymatic action can occur. As a result of the stripping process, surface properties (e.g. charge) and surface-associated targeting moieties that were initially shielded by the polymer coating become exposed (sheddable shielding) which may induce cellular binding and internalization.

In contrast to high molecular weight PHEG, the enzymatic degradation of low molecular PHEG as well

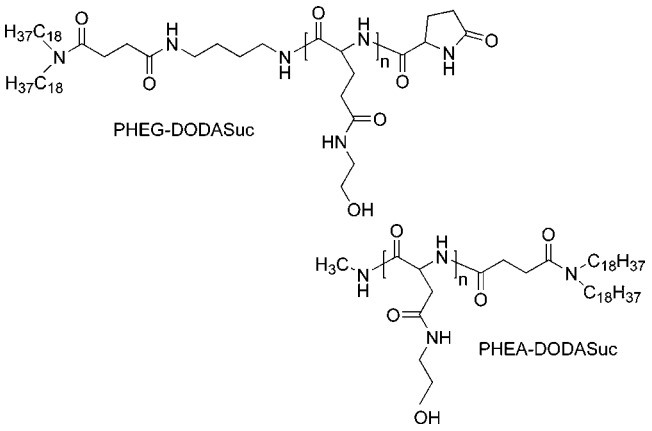

Figure 1. Structures of PHEG−DODASuc and PHEA−DODASuc.

as liposome-grafted PHEG has not been studied so far. The purpose of the present study was to investigate the enzymatic degradability of PHEG−DODASuc used as a coating for long-circulating liposomes and to identify the degradation products. Model enzymes, papain and pronase E, with specificities comparable to those of intra- and extracellular proteases, and the lysosomal cysteine protease cathepsin B, were used. All three enzymes are known to be capable of cleaving high molecular weight PHEG. Papain is a well-studied cysteine endopeptidase from *Carica papaya* latex with a broad catalytic specificity and is frequently used as a substitute for cathepsin B in degradation studies (*20, 21*). Pronase E, isolated from *Streptomyces griseus*, is composed of endo- and exopeptidases and therefore represents a natural mixture of proteases (*24*). Cathepsin B is a cysteine protease, which is present, for example, in mammalian lysosomes and is involved in protein turnover (*25*). It is also extracellularly present in pathological tissues such as tumors and sites of inflammation (*22, 23*).

The PHEG-conjugate was evaluated for enzymatic degradability both in its free form and grafted onto the surface of liposomes. Poly-L-glutamic acid was used as a control. Degradation of the free and grafted conjugate was assessed using a ninhydrin assay. Degradation products were analyzed by matrix-assisted laser desorption/ionization mass spectrometry (MALDI-ToF MS).

MATERIALS AND METHODS

Materials. PHEG−DODASuc (average MW = 3500 Da, determined by NMR and MALDI-ToF MS, corresponding with an average degree of polymerization of 16) was used in this study. Papain from papaya latex (33 units/mg in suspension, 28 mg protein/mL), cathepsin B from bovine spleen (lyophilized powder, 5.6 units/mg solid, 14 units/mg protein), Z-L-Lys-ONp hydrochloride, poly-L-glutamic acid (sodium salt, MW 1500−3000), ninhydrin, hydridantin, 2-methoxyethanol, α-cyano-hydroxycinnaminic acid, *n*-octylglucoside, and cholesterol were all purchased from Sigma-Aldrich Chemie BV, Zwijndrecht, The Netherlands. *N*-α-Benzoyl-D,L-arginine-*p*-nitroanilide (D,L-BAPNA) was obtained from ICN Biomedicals BV, Zoetermeer, The Netherlands. Pronase E (from *Streptomyces griseus*, 6−8 U/mg, lyophilized powder) was a product of Serva Electrophoresis GmbH, Heidelberg, Germany. Dipalmitoylphosphatidylcholine (DPPC) and poly(ethylene glycol)-distearylphosphatidylethanolamine (PEG2000-DSPE) were purchased from Lipoid GmbH, Ludwigshafen, Germany. All other reagents were of analytical grade.

Degradation with Papain. Thirty five microliters of the papain suspension was added to 965 μL of buffer (50 mM KH_2PO_4, 2.5 mM EDTA, 15 mM dithiothreitol, pH 6.5) to give a clear solution (32 U papain/mL). The solution was incubated for 1 h at 37 °C to activate the enzyme (*26*). The enzyme concentration was determined by UV spectroscopy at 278 nm (specific extinction coefficient $\epsilon_{\%} = 25.0$) (*27*). To determine the activity of papain, 50 μL of activated papain solution was added to 950 μL of 2 mM N-α-benzoyl-D,L-arginine-*p*-nitroanilide (D,L-BAPNA) solution in phosphate buffer (50 mM KH_2PO_4, 2.5 mM EDTA, pH 6.5). The formation of the product, 4-nitroaniline, was monitored spectroscopically at 410 nm.

The stability of papain was assessed by incubating the enzyme (400 μL of activated papain solution in 7.6 mL of phosphate buffer) at 37 °C for 120 h. At different time points the activity of papain was determined by mixing 500 μL of this solution with 500 μL of 2 mM D,L-BAPNA followed by the spectrophotometric analysis as described above. PHEG−DODASuc and poly-L-glutamic acid (pGlu) were dissolved in phosphate buffer (50 mM KH_2PO_4, 2.5 mM EDTA, pH 6.5) to a final concentration of 1 mg/mL. Activated papain (150 μL) was added to 2850 μL of the polymer solution. The mixtures were incubated at 37 °C. At different time points samples of 250 μL for ninhydrin analysis and of about 50 μL for mass spectrometric analysis were withdrawn. To inactivate the enzyme, the tubes were closed, heated for 5 min at 100 °C, and stored at −20 °C until analysis.

Degradation with Pronase E. Pronase E was dissolved to a concentration of 1 mg/mL in 10 mM HEPES (*N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid), 5 mM $CaCl_2$, pH 7.5. PHEG−DODASuc and pGlu were dissolved in the same buffer to a final concentration of 1 mg/mL. The pronase E solution (150 μL) was added to 2850 μL of the polymer solutions, which were subsequently incubated at 37 °C for 216 h. At different time points samples of 250 μL for the ninhydrin assay and samples for mass spectrometric analysis were withdrawn and heat inactivated as described for the papain samples. The samples were stored at −20 °C until further analysis.

Degradation with Cathepsin B. To assess the activity of cathepsin B, 1 mg of the enzyme was dissolved in 300 μL buffer (20 mM sodium acetate, 1 mM EDTA, 5 mM cysteine, pH 5). The substrate Z-L-Lys-ONp hydrochloride was dissolved in DMSO to a concentration of 2.3 mg/mL. Substrate solution (50 μL) and enzyme solution (10 μL) were added to 3 mL of acetate buffer. The generation of 4-nitrophenol was monitored spectroscopically over 5 min at 326 nm.

For studying the degradation of PHEG−DODASuc, cathepsin B was dissolved to a concentration of 16.5 mg/mL in buffer (50 mM sodium acetate, 1 mM EDTA, 10 mM dithiothreitol, pH 5.5). PHEG−DODASuc was dissolved in the same buffer without dithiothreitol to a final concentration of 1 mg/mL. Cathepsin B (150 μL) was added to 2850 μL of the polymer solution. The mixture was incubated at 37 °C for 144 h. Samples for ninhydrin and mass spectrometric analysis were withdrawn at different time points, and the enzyme was inactivated as described above. Samples were stored at −20 °C before analysis.

The activity of cathepsin B was also followed in time. Cathepsin B was incubated at 37 °C in buffer (50 mM sodium acetate, 1 mM EDTA, 10 mM dithiothreitol, pH 5.5) at a concentration of 0.825 mg/mL for 144 h. Samples of 10 μL were withdrawn at different time points and added to a mixture of 50 μL of the substrate solution and

3 mL of buffer (50 mM sodium acetate, 1 mM EDTA, pH 5.5). Formation of 4-nitrophenol was monitored spectroscopically at 326 nm.

Liposome Preparation. PHEG−DODASuc- and PEG−DSPE-liposomes were prepared by a film-extrusion method (*28*). In a typical experiment, a lipid mixture composed of DPPC/cholesterol/coating polymer (1,85:1:0.15 molar ratio; total lipid ≈100 mg) was dissolved in about 2 mL of a mixture of chloroform/methanol (1:1 v/v) in a 50 mL round-bottom flask. A lipid film was obtained by evaporation of the solvent under reduced pressure at 50 °C. After being flushed with nitrogen, the lipid film was hydrated in 4 mL of phosphate buffer (50 mM KH_2PO_4, 2.5 mM EDTA, pH 6.5), yielding a phospholipid concentration of 18.5 μmol/mL for the PHEG-liposomes and 20 μmol/mL for the PEG-liposomes. Liposomes were sized by sequential extrusion through two stacked polycarbonate filters (Poretics, 400, 200, 100, and 50 nm) with a high-pressure extrusion device. The liposomes were subjected to ultracentrifugation at 200000*g* (2 × 30 min, 4 °C) using a Beckman LE-80K Ultracentrifuge and redispersed in 4 mL of buffer (50 mM KH_2PO_4, 2.5 mM EDTA, pH 6.5).

Liposome Characterization. The mean particle size and polydispersity index of the liposome dispersions (10 times diluted with phosphate buffer) were determined by dynamic light scattering using a Malvern 4700 spectrometer. The zeta potential of the liposomes (diluted 1:100 in 5 mM HEPES buffer, pH 7.0) was determined using a Malvern Zetasizer 2000. Phospholipids were quantified spectrophotometrically according to Rouser et al. (*29*) after extraction of the lipids from the phosphate buffer with chloroform (*30*).

Degradation of Liposome-Grafted Poly(amino acid)−Lipid Conjugates with Papain. Activated papain in phosphate buffer (450 μL, 32 U/mL) was added to 8.55 mL of the dispersions of PEG−DSPE- and PHEG−DODASuc-liposomes. The dispersions were incubated at 37 °C and samples (250 μL) were taken periodically. The size and zeta potential of the liposomes were measured as described above. To separate the liposomes from the soluble degradation products, they were spun down by ultracentrifugation. In detail, 5 mL of phosphate buffer was added to the samples. Ultracentrifugation was done for 30 min at 200,000 g at 4 °C. The supernatant was collected, freeze-dried, stored at −20 °C and subsequently analyzed for degradation products by the ninhydrin assay. After 48 h of incubation, *n*-octylglucoside (150 mg) was added to 3 mL of the PHEG−liposome dispersion. Next, fresh papain (150 μL to 2850 μL of solution) was added. Samples of 250 μL were withdrawn at different time points, heat inactivated, stored at −20 °C and subsequently analyzed by the ninhydrin assay.

Quantitative ^{1}H NMR analysis of Papain-Treated PHEG-liposomes. PHEG-liposomes were incubated with papain as described above. After 48 h the papain-treated liposomes were separated from the soluble degradation products by ultracentrifugation (1 mL of liposome dispersion diluted with 5 mL of 5 mM NaCl, 200000*g*, 30 min, 4 °C). Next, the liposome pellet was dispersed in 1 mL of 5 mM NaCl and freeze-dried. The cake was dissolved in a mixture of $CDCl_3/d_6$-DMSO (2:1) and subsequently analyzed by ^{1}H nuclear magnetic resonance spectroscopy (NMR). Spectra were recorded with a Varian G-300 spectrometer (Varian, Palo Alto, CA) at 300 MHz. The number of accumulated transients was 32; the relaxation delay D1 was 10 s. The signals of the liposome mixture were assigned on the basis of chemical shift and intensity data and confirmed by homonuclear double resonance experiments. The relative amount of PHEG−DODASuc was quantified by comparing the integral values of proton signals of cholesterol and PHEG−DODASuc. The cholesterol signal chosen for calculation was at δ 5.2 (position: C6 at the double bond, corresponding to one proton) and the PHEG−DODASuc signal was at δ 3.45 (position: side chain-CH_2 next to OH, corresponding to 16 × 2 protons for $n = 16$). As a control formulation a sample of PHEG-liposomes that were not incubated with papain was prepared and analyzed as described above. A detailed description of this analytical method and its validation will be published elsewhere.

Ninhydrin Assay. When peptide bonds in peptides are cleaved due to action of the enzymes, primary amines are formed. The concentration of amines in the different samples was determined spectrophotometrically by the use of ninhydrin (*31*). The samples were thawed, and 1 M sodium acetate buffer (pH 5.5) was added to give a final volume of 1 mL. Next, 1 mL of freshly prepared ninhydrin solution (2.0 g ninhydrin and 0.3 g hydridantin dissolved in 75 mL of 2-methoxyethanol and 25 mL of 4 M sodium acetate buffer, pH 5.5) was added. The mixtures were vortexed and incubated for 15 min at 100 °C. After being cooled to room temperature, the samples were diluted with 5 mL of 50% ethanol in water, and the absorbance was read at 570 nm with a Perkin-Elmer Lambda 2 UV/vis spectrophotometer. Glycine (in 1 M acetate buffer) was used for calibration. The calibration curve was linear up to 0.5 μmol glycine/mL. Suitable controls containing only substrate or papain were run in parallel, and their readings were subtracted for plotting the degradation of the polymer-conjugates and controls.

MALDI-ToF Mass Spectrometry. α-Cyano-4-hydroxycinnaminic acid was used as a matrix and dissolved to a concentration of 10 mg/mL in 50% acetonitrile in water containing 0.1% trifluoroacetic acid. The samples were mixed with the matrix solution in a volume ratio of 1:3. Three times 1 μL of this mixture was put on a single position of the sample deposition plate and left at room temperature to allow solvent evaporation. Spectra of samples incubated with papain, pronase E, and cathepsin B were acquired with a Voyager-DE STR MALDI-ToF mass spectrometer (Applied Biosystems, Foster City, CA) operated in positive ion mode. Ionization was initiated with a nitrogen laser operating at 337 nm with a repetition rate of 7.6 Hz. Delayed extraction linear mode with an accelerating voltage of 20 kV was used and the acquisition mass range was 700−7000 Da. Calibration was done with a peptide mixture (900−3700 Da). MALDI-ToF spectra were analyzed with the Applied Biosystems Data Explorer Software.

RESULTS AND DISCUSSION

Enzymatic Degradation of PHEG−DODASuc Followed by the Ninhydrin Assay. *Papain Incubation.* The stability of papain was established using *N*-α-benzoyl-D,L-arginine-*p*-nitroanilide as substrate. It was shown that papain retained 50% of its activity after 72 h of incubation at pH 6.5 and 37 °C. The decrease in activity is likely caused by self-destruction, a phenomenon frequently observed for proteolytic enzymes with a broad specificity (*17*). The degradation PHEG−DODASuc and the control pGlu by papain was monitored by determination of the formed primary amine groups using the ninhydrin assay. The results are presented in Figure 2. During the first 10 h of incubation a strong increase

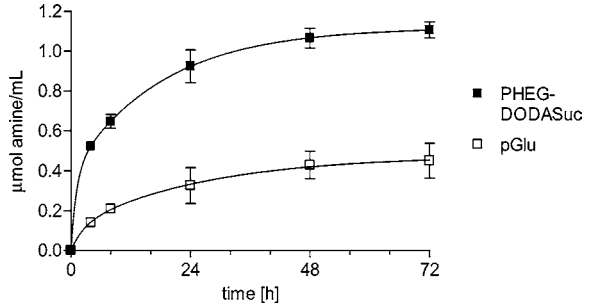

Figure 2. Time course of the concentration of primary amines in papain-incubated samples of PHEG−DODASuc (■) and poly-L-glutamic acid (□) as determined by the ninhydrin assay (average ± SD of three experiments). PHEG−DODASuc incubated in buffer without papain shows a constant concentration of amines in time.

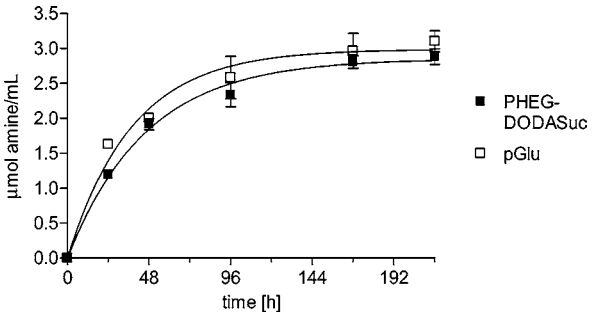

Figure 3. Time course of the concentration of primary amines in pronase E-incubated samples of PHEG−DODASuc (■) and poly-L-glutamic acid (□) as determined by the ninhydrin assay (average ± SD of three experiments).

in free amine concentration was observed for PHEG−DODASuc and pGlu, demonstrating that both relatively low molecular weight polymers are degraded by papain, as previously reported for their high molecular weight counterparts (*14*−*21*, *32*). Figure 2 also shows that a plateau value in amine concentration was obtained after 48−72 h. As mentioned, papain was still active after 72 h indicating that the degradation process did not stop due to inactivity of the enzyme. However, the activity of the enzyme might be inhibited by the formed degradation products. To investigate this, fresh papain was added after 48 h of incubation. No further increase in amine concentration was found, which shows that the obtained fragments cannot be further cleaved by the enzyme. The concentration of the formed amine groups in the PHEG−DODASuc sample after 72 h incubation (1.1 μmol amine/mL) corresponds with about four hydrolysis sites per molecule, yielding fragments with 3−4 amino acids. Fragments of 8−9 amino acids were formed after 72 h incubation of pGlu with papain. The modification of the glutamic acid side chain in PHEG with hydroxyalkylamine can be responsible for its higher enzymatic susceptibility (*16*).

Pronase E Incubation. Figure 3 shows the degradation profiles obtained when PHEG−DODASuc and pGlu were incubated with pronase E. This figure demonstrates that, in agreement with the findings of Pytela et al. for relatively high molecular weight PHEG (*19, 20*), the PHEG−conjugate as well as poly-L-glutamic acid are cleaved by this enzyme. On the basis of the plateau values of the amine concentrations, it is calculated that PHEG and pGlu are finally degraded into fragments of 1−2 and 2−3 amino acids, respectively. The higher susceptibility of PHEG for pronase E (final degradation fragments of 1−2 amino acids) as compared to papain (3−4 amino acids) is likely due to the fact that pronase E contains a cocktail of both endo- and exopeptidases.

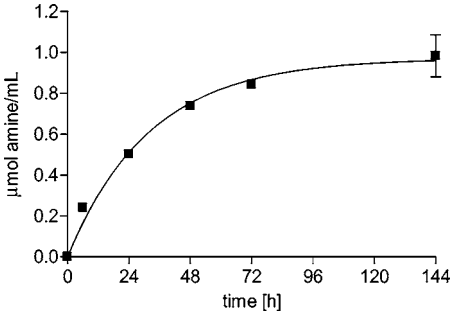

Figure 4. Time course of the concentration of primary amines in cathepsin B-incubated samples of PHEG−DODASuc as determined by the ninhydrin assay (average ± SD of three experiments).

Cathepsin B Incubation. Figure 4 demonstrates the degradability of PHEG−DODASuc by cathepsin B. The number of amine groups increases upon incubation, reaching its maximum value after 144 h. Unfortunately, the final fragment size could not be calculated since the concentration of primary amine groups in a control solution of cathepsin B only increased in time. Likely due to autodigestion, some of the peptide bonds in the enzyme are hydrolyzed, and the formed amine groups give a signal in the ninhydrin assay. In line herewith, an activity assay with a low molecular weight substrate showed that under the selected conditions the activity half-life of cathepsin B was about 30 h. Nevertheless, the concentration of amines in the samples with PHEG−DODASuc was always greater than in the control solution, demonstrating that this conjugate is a substrate for this enzyme. To get insight into the extent of PHEG−DODASuc degradation by cathepsin B, mass spectrometric analysis was done.

Mass Spectrometric Analysis of Enzymatically Degraded PHEG−DODASuc. Figure 5, 6, and 7 show representative mass spectra of papain-, pronase E-, and cathepsin B-degraded PHEG−DODASuc; Table 1 gives the peak assignments. In the spectrum of the nondegraded PHEG−DODASuc (Figure 5a), the peak distributions of the K^+- and the Na^+-adducts are present. The K^+-adduct is abundant since KH_2PO_4 was used in the degradation buffer. In the spectra of PHEG−DODASuc incubated with papain (Figure 5b and 5c), the high mass peaks originating from the nondegraded conjugate disappeared in time, and new peaks were observed. These new peaks have relatively lower masses and increase in their relative abundance in time (most pronounced at $t = 72$ h). A lactam group forms the terminus of the peptide chain in the native conjugate (Figure 1). The observed peaks in the degraded samples can be assigned to degradation fragments of the PHEG-conjugate without this lactam end group and a lower degree of polymerization. For example in the spectrum of the sample incubated for 8 h with papain (Figure 5b), masses of these fragments were between 1400 and 3000 Da, corresponding to fragment size of 4−13 amino acid residues. The observation that the resulting conjugates do not carry a lactam group indeed demonstrates that the peptide chain was hydrolytically cleaved, yielding PHEG−DODASuc (with an NH_2 terminus) and PHEG with COOH and lactam termini as degradation products. The latter products were not detected due to their low molecular weight. In the spectrum of the papain-degraded conjugate after 72 h incubation (Figure 5c) the peak population shifted to low masses of 1000−2300 Da, corresponding

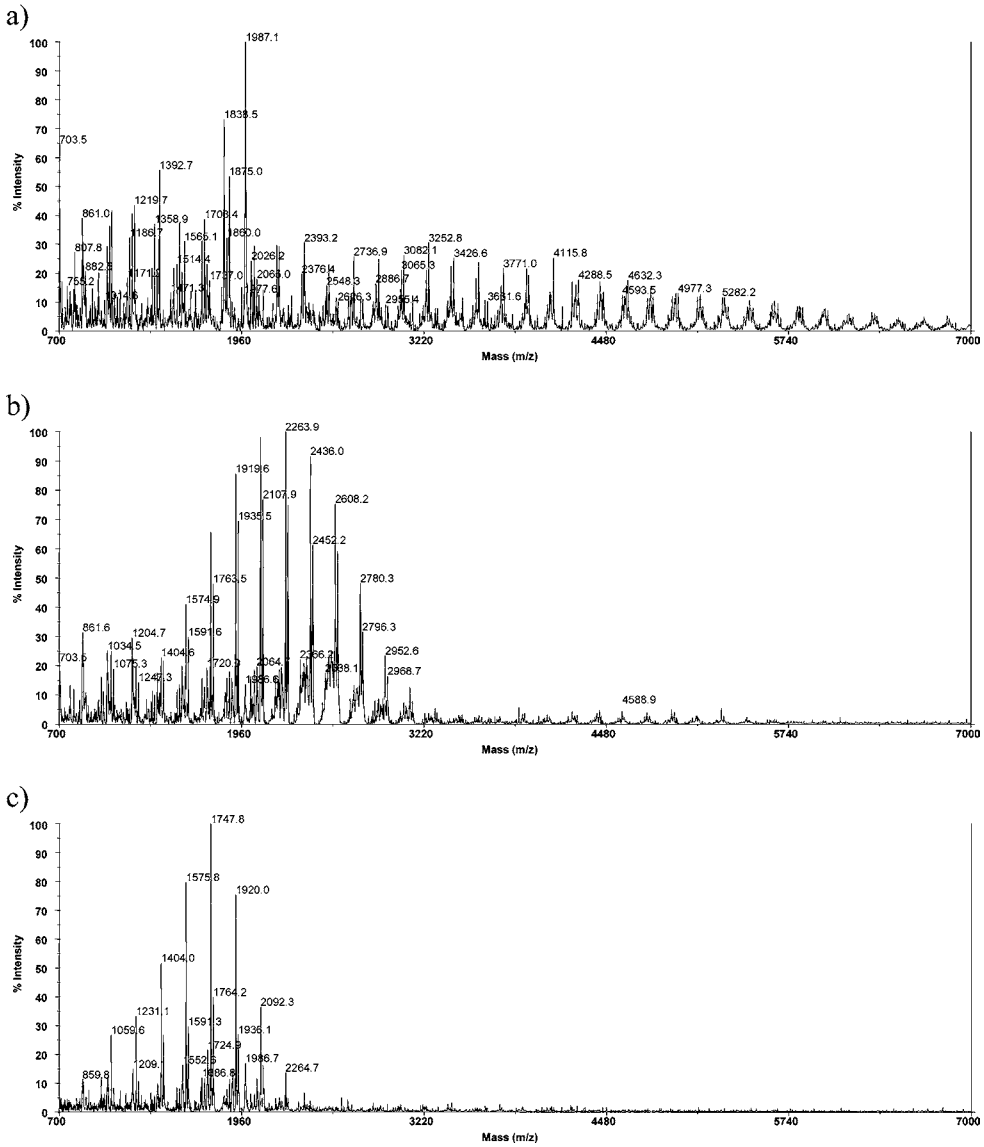

Figure 5. Mass spectra of PHEG−DODASuc (a) and after incubation with papain for 8 h (b) and 72 h (c).

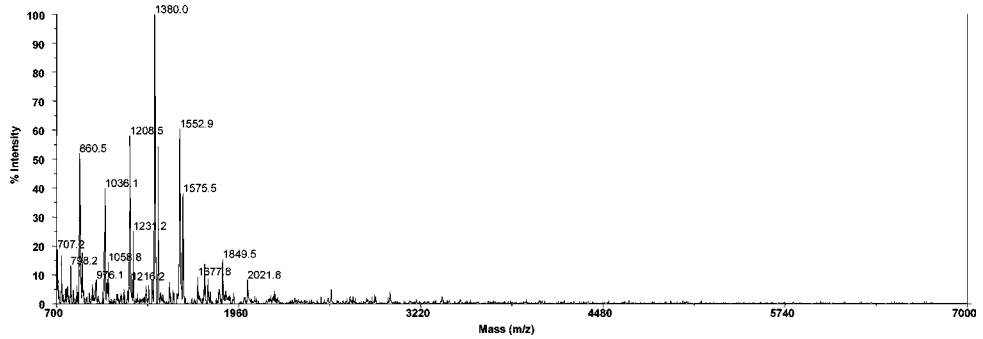

Figure 6. Mass spectrum of PHEG−DODASuc after incubation with pronase E for 216 h.

with fragments of 2−9 amino acids. Figure 6 shows the mass spectrum of PHEG−DODASuc incubated with pronase E. The peak population of the original conjugate disappeared, and peaks of Na^+-adducts of conjugate molecules without the lactam end group appear. Here the Na^+-adducts are the most abundant due to the choice of the buffer. The highest peak represents a fragment size of the DODASuc-anchor with 4 amino acids. Mass spectrometric analysis suggests a lower extent of degradation than the ninhydrin analysis (pronase E-catalyzed degradation of PHEG−DODASuc: compare fragments of 1−2 amino acids based on ninhydrin assay with those found with mass spectrometry analysis (2−5 amino acids)). It should be noted, however, that with the ninhydrin assay both fragments with and without the DODASuc-anchor are detected, whereas in the mass spectrum only the fragments with the anchor were observed. Obviously, the DODASuc-anchor prevents binding of the conjugate to the enzyme when a certain fragment size is achieved. Figure 7 shows the mass spectrum of PHEG−DODASuc degraded by cathepsin B after 144 h of incubation. The highest population of peaks

	3235.2	[DODASuc−$(PHEG)_{14}$-lactam+Na]$^+$
	4782.9	[DODASuc−$(PHEG)_{23}$-lactam+Na]$^+$
	2264.0	[DODASuc−$(PHEG)_9$+Na]$^+$
	3296.5	[DODASuc−$(PHEG)_{15}$+Na]$^+$
	4843.9	[DODASuc−$(PHEG)_{24}$+Na]$^+$

can be assigned to Na^+-adducts of degradation fragments without lactam endgroup. The peak population of the Na^+-adduct of the nondegraded conjugate is also present; however, their peak intensities are much lower than those of the degraded conjugate. Masses of the degraded fragments are between 1500 and 5000 Da, corresponding with conjugates of DODASuc with 5 to 25 hydroxylethyl L-glutamine residues. These results demonstrate that under the selected conditions PHEG−DODASuc is degraded by cathepsin B, however, not as considerable as observed with papain or pronase E. Because cathepsin B is rather unstable under the experimental condtions ($t_{1/2}$ = approximately 30 h), maximal fragmentation of PHEG−DODASuc is not achieved. It is therefore expected that under physiological conditions where the enzyme concentration is substantially higher (10−40 mg/mL in lysosomes (*25*), as compared to 0.8 mg/mL in this study) and its turnover is high, PHEG−DODASuc can be degraded further.

Degradation of PHEG Conjugate Grafted onto a Liposome Surface. Polymer-coated (PHEG/PEG) liposomes were prepared by the film-extrusion method. The loss of phospholipids during liposome preparation was approximately 30%; Table 2 shows the physical characteristics (size and charge) of the different liposome preparations. The PHEG-coated liposomes were slightly bigger than the PEG-liposomes. This is probably due to aggregate formation during the ultracentrifugation step (UC induced size increase of ≈30 nm, increase in polydispersity of ≈0.2). The negative values of the zeta potential of the different liposomes are probably due to the low ionic strength (5 mM HEPES, pH 7.0) at which the measurements were done (*33*).

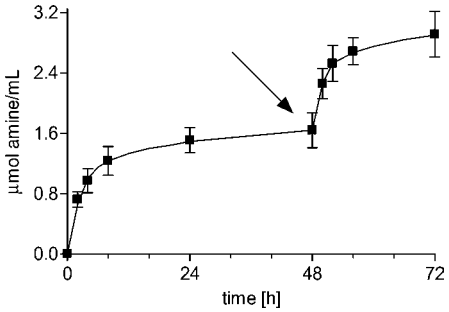

Figure 8. Time course of the concentration of amines in the papain-incubated samples of PHEG−DODASuc-coated liposomes as determined by the ninhydrin assay (average ± SD of three experiments). The arrow indicates the time point when liposomes were solubilized with *n*-octylglucoside and fresh papain was added.

Table 2. Liposome Characteristics

liposome type	mean diameter [nm]	polydispersity index	zeta potential [mV]
PHEG−DODASuc	158 ± 1	0.31 ± 0.03	−29 ± 1
PEG−DSPE	127 ± 1	0.07 ± 0.02	−35 ± 5

Figure 8 shows that the concentration of amines increased in time when liposomes grafted with PHEG−DODASuc were incubated with papain. This means that PHEG−DODASuc grafted onto a liposomal surface is still susceptible for degradation by papain and probably by other proteolytic enzymes. In agreement with expectations, PEG−DSPE coated on the liposomes was not degraded by this enzyme. For PHEG−DODASuc, a plateau in amine concentration was reached after approximately 24−40 h of incubation. In Figure 9 the size and zeta potential of the liposomes as a function of incubation time with papain are shown. For the PEG−DSPE coated liposomes, no significant changes in size and zeta potential upon incubation were observed. However, the PHEG−DODASuc-coated liposomes decreased around 20 nm in size during the first 5−10 h of degradation. The degradation of the conjugate on the liposome surface results in a smaller hydrodynamic diameter and is therefore a possible explanation, but this alone cannot be the reason for the observed drop in size. The end-to-end distance of the peptide part of the conjugate is approximately 6.5 nm; thus, a complete shedding of the peptide would result in a maximum size decrease of ≈13

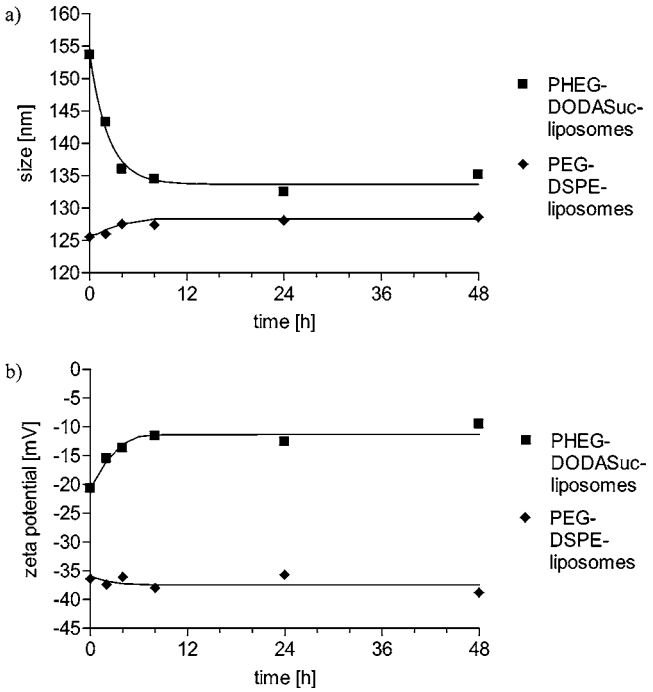

Figure 9. Size (a) and zeta potential (b) of PHEG−DODASuc liposomes (■) and PEG−DSPE liposomes (◆) as a function of incubation time with papain.

nm. As the polydispersity index of the PHEG-coated liposomes decreased from 0.3 to around 0.2 upon incubation with the enzyme, a dissociation of the aggregates, which were formed during ultracentrifugation, is likely to occur as well. The zeta potential of the PHEG-liposomes goes from −20 mV to about −10 mV. Mass spectrometry (Figure 5b/5c) demonstrates that after enzymatic digestion the formed DODASuc-peptide fragment has a terminal amine group (instead of the neutral lactam group of the nondegraded conjugate). This amine group is protonated at pH of 7.0 and likely responsible for the less negative zeta-potential. The progression of changes in size and zeta potential in time are in very good agreement with the progression of the amine content of the samples as seen in the ninhydrin degradation assay (compare Figures 8 and 9). The preparation method applied will result in the formation of unilamellar liposomes (*34*), with polypeptide conjugate present at both the inner and outer layer. It is likely that only the polypeptide present at the outside of the liposomal bilayer is accessible for enzymatic attack. When the liposomes were destabilized by *n*-octylglucoside after 48 h incubation with papain, formation of amines continued (Figure 8). This indicates that indeed only the polypeptide present at the outside of intact liposomes is degraded by papain.

According to the phosphate determination 70% of the initial phospholipid amount is recovered in the final dispersion. Assuming that therefore around 70% of the initial PHEG-conjugate amount is remaining in the liposome dispersions after preparation, the extent of degradation of surface grafted PHEG is the same as that of the conjugate in solution (final degradation products contain 3−4 amino acids). ^{1}H NMR-analysis of the liposome dispersion incubated with papain for 48 h showed that 63 ± 10% of the PHEG was still associated with the liposomal bilayer. As concluded from the data presented in Figure 8, PHEG present at the inside the liposome (≈50% of the totally present polymer) is not accessible for enzymatic attack. From the ^{1}H NMR analysis it can be derived that the PHEG fragment present at the outer layer of the liposomal membrane after enzymatic degradation contains 4−5 amino acid residues. This is in excellent agreement with the data of the enzymatic degradation of the PHEG-conjugate after mass spectrometric analysis.

In conclusion, this paper demonstrates that PHEG−DODASuc is enzymatically degradable even when it is attached to a liposomal surface, avoiding the risk of intracellular accumulation and making liposomes with a sheddable coating feasible.

Received November 13, 2004

Polymer–drug conjugates (polymer therapeutics) are finding increasing use as novel anticancer agents. Here a series of poly(ethylene glycol) PEG–doxorubicin (Dox) conjugates were synthesized using polymers of linear or branched architecture (molecular weight 5000–20000 g/mol) and with different peptidyl linkers (GFLG, GLFG, GLG, GGRR, and RGLG). The resultant conjugates had a drug loading of 2.7–8.0 wt % Dox and contained <2.0% free drug (% total drug). All conjugates containing a GFLG linker showed ~30% release of Dox at 5 h irrespective of PEG molecular weight or architecture. The GLFG linker was degraded more quickly (~57% Dox release at 5 h), and the other linkers more slowly (<16% release at 5 h), by lysosomal enzymes in vitro. In vitro there was no clear relationship between cytotoxicity toward B16F10 cells and the observed Dox release rate. All PEG conjugates were more than 10-fold less toxic (IC_{50} values > 2 μg/mL) than free Dox (IC_{50} value = 0.24 μg/mL). Biodistribution in mice bearing sc B16F10 tumors was assessed after administration of PEGs (5000, 10000, or 20000 g/mol) radioiodinated using the Bolton and Hunter reagent or PEG–Dox conjugates by HPLC. The ^{125}I-labeled PEGs showed a clear relationship between Mw and blood clearance and tumor accumulation. The highest Mw PEG had the longest plasma residence time and consequently the greatest tumor targeting. The PEG–Dox conjugates showed a markedly prolonged plasma clearance and greater tumor targeting compared to free Dox, but there was no clear molecular weight-dependence on biodistribution. This was consistent with the observation that the PEG–Dox conjugates formed micelles in aqueous solution comprising 2–20 PEG–Dox molecules depending on polymer Mw and architecture. Although PEG–Dox showed greater tumor targeting than free Dox, PEG conjugation led to significantly lower anthracycline levels in heart. Preliminary experiments to assess antitumor activity against sc B16F10 in vivo showed the PEG_{5000}linear (L)–GFLG–Dox and PEG_{10000}branched (B)–GLFG–Dox (both 5 mg/kg Dox-equiv) to be the most active with T/C values of 146 and 143%, respectively. Free Dox did not show significant activity in this model (T/C = 121%). Dose escalation of PEG_{5000}(L)–GFLG–Dox to 10 mg/kg Dox-equiv prolonged further animal survival (T/C = 161%). Using the Dox-sensitive model ip L1210 (where Dox displayed a T/C = 150% after single ip dose), the PEG_{5000}(L)–GFLG–Dox displayed a maximum T/C of 141% (10 mg/kg Dox-equiv) using a once a day (×3) schedule. Further studies are warranted with PEG_{5000}(L)–GFLG–Dox to determine its spectrum of antitumor activity and also the optimum dosing schedule before clinical testing.

INTRODUCTION

Early efforts to capitalize on lysosomotropic drug delivery (*1*) and tumor-specific uptake by the enhanced permeability and retention (EPR) effect (*2*) has generated antitumor polymer conjugates that have progressed into clinical trial (*3*–*6*). These first successes have led to an exponentially growing interest in the field of drug–polymer conjugates (polymer therapeutics) particularly as Phase I clinical studies with *N*-(2-hydroxypropyl)-methacrylamide (HPMA) copolymer–doxorubicin (Dox) showed a 4–5-fold decrease in Dox toxicity together with antitumor activity of the conjugate in chemotherapy refractory patients (*3*).

For many years, poly(ethylene glycol)s (PEGs) have been used to modify peptides and proteins (reviewed in refs 7, 8) in order to increase solubility, reduce immunogenicity, increase resistance to proteolysis and, in addition, provide a means to modulate pharmacokinetics (*8*). More recently, PEG conjugates containing antitumor drugs such as paclitaxel, camptothecin, and Dox have been described (reviewed in ref 9). A PEG–camptothecin conjugate has progressed to clinical trial (*10*).

To identify a PEG–Dox conjugate with improved tumor targeting and efficacy, a series of monomethoxy-PEG–peptide–Dox conjugates were prepared. PEGs of different (linear (L) or branched (B)) architecture and Mw (5000,

10000, or 20000 g/mol) were used together with a library of peptidyl linkers (GFLG, GLFG, GLG, Nle-GGRR, or Nle-RGLG) for covalent attachment of Dox to the carrier. The resultant conjugates were characterized in respect of their total and free Dox content and tendency to form micelles in aqueous solution. To aid selection of compounds for in vivo evaluation, the rate of Dox release by isolated lysosomal enzymes was established in vitro, and also their cytotoxicity was determined in vitro using a murine melanoma B16F10 model. To establish the effect of PEG molecular weight on tumor targeting, the biodistribution of ^{125}I-labeled PEGs of Mw 5000, 10000, and 20000 g/mol was studied at various times after intravenous (iv) administration to mice bearing established subcutaneous (sc) B16F10 tumors. Additionally, the biodistribution of PEG−Dox conjugates was followed using an HPLC method to detect Dox in tissues. Finally, the antitumor activity of the conjugates was investigated in a Dox-resistant model (sc B16F10) and a Dox-sensitive model (ip L1210). These models were chosen as they have been widely used to evaluate PK1 and other polymeric antitumor conjugates (*11*, *12*) and the mechanism of EPR-mediated targeting has been widely studied in the B16F10 model (*13*).

MATERIAL AND METHODS

Materials and Equipment. Linear monomethoxy-PEG of weight average molecular mass (Mw) 5000 and 10000 g/mol, linear PEG−norleucine-OSu (PEG−Nle-OSu) Mw = 5000 g/mol, branched PEG-OSu Mw = 10000 and 20000 g/mol were obtained from Shearwater Polymers (Huntsville, AL). Dox·HCl was purchased from Tide International LTD (China). 4-Nitrophenyl chloroformate, 1-cyclohexyl-3-(2-morpholinoethyl)carbodiimide methyl *p*-toluensulfonate (CMC), and *N*-hydroxybenzotriazole (HOBT) were obtained from Aldrich Chemie (Steinnheim, Germany). The solvents and other chemicals were of analytical grade from Merk (Darmstadt, Germany). 3-[4,5-Methylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), optical grade DMSO, and Bz-PVR-*p*-nitroanilide (NAp) were from Sigma, UK. The B16F10 cell line was kindly donated by Professor Ian Hart, St Thomas Hospital, London.

For pH titration, a radiometer autoburet ABU 80 (Copenhagen, Denmark) with titration TTT 80 and titrigraph REA 160 was used. UV−visible analyses were performed on a Perkin-Elmer Lamba 5 spectrophotometer. Analytical chromatography was performed using a liquid chromatograph LC 10 AS−SPD 10A VP UV−Vis detetctor (Shimadzu). Preparative size exclusion chromatography or ion exchange chromatography was carried out using Sephadex LH-20 or QAE-Sephadex A-50 columns (Pharmacia Biotech, Sweden), respectively. ^{1}H (200 Mz) NMR spectra were recorded in DMSO-*d*6 (Varian Gemini-200).

Solid-Phase Synthesis of Peptides. Peptides H-GFLG-OH·TFA, H-GLPG-OH·TFA, and HGLG- OH·TFA were synthesized by solid-phase peptide synthesis (SPPS) using the Merrifield procedure (*14*). Merrifield resin containing the first amino acid, Boc-G-OH, was preattached to the support (degree of substitution 1.04 mmol/g) and was used for synthesis of the desired peptide on a 5 mmol scale. Addition of the remaining amino acids was accomplished by repeated cycles of coupling and deprotection. Boc-amino acids (2-fold molar excess) were coupled to the peptide resin employing DCC as a condensation reagent. The peptides obtained were cleaved from the resin and deprotected by treatment with liquid HF and purified by preparative C_{18} reverse phase HPLC. Absorbed peptide was eluted by gradient elution. Eluant A was 0.1% TFA, and eluant B was acetonitrile. The gradient was run from 100% A to 60% B over 60 min. Fractions containing pure peptide were pooled and lyophilized.

Solution Synthesis of Hydrophobic Peptides. Boc-G-OSu was coupled to H-LG-OH in an active ester coupling to give Boc-GLG-OH. The tripeptide obtained was deprotected by treatment with 50% TFA/DCM (v/v) for 30 min. After evaporation of the solvents, the residue obtained was precipitated by addition of diethyl ether, and the precipitate was filtered. The tripeptide H-GLG-OH·TFA was purified as described above for the solid-phase produced peptides.

The tetrapeptide H-GLFG-OH·TFA was synthesized by reaction of Boc-GL-OSu with H-FG-OH using an active ester coupling to give Boc-GLFG-OH. The tetrapeptide obtained was deprotected by treatment with 50% TFA/DCM (v/v) for 30 min. After solvent evaporation the residue obtained was precipitated by addition of diethyl ether, and the precipitate was filtered. The product was purified as described above.

The tetrapeptide H-GFLG-OH·TFA was assembled by reaction of Boc-GP-OSu and HLG-OH in an active ester coupling to give Boc-GPLG-OH. The product was deprotected by treatment with 50% TFA/DCM (v/v) for 30 min. After solvent evaporation, the residue obtained was precipitated by addition of diethyl ether and the precipitate was filtered, and the product was purified as described above. The arginine-containing peptides H-GGRR-OH and H-RGLG-OH were also prepared by solid-phase synthesis in the same manner as described for the hydrophilic peptides, but in this case the side chain protection of arginine was achieved using a tosyl group.

Hydroxy-Terminated PEG−Peptide Conjugates. Linear monomethoxy-PEG-OH (Mw = 5000 g/mol or 10000 g/mol) (1 g, 0.2 mmol or 2 g, 0.2 mmol) was dissolved in 20 mL of toluene and dried by water−toluene distillation. To the water-free PEG-OH toluene solution were added ethylene chloride (2 mL) and 4-nitrophenyl chloroformate (80.6 mg, 0.4 mmol). The pH was brought to 8.0 by TEA (56 μL, 0.4 mmol). The obtained PEG-*p*-nitrophenyl carbonate was recovered by ether addition (300 mL) and the precipitate purified by crystallization from ethyl acetate. The peptide H-GFLG-OH (236 mg, 0.6 mmol) were dissolved in 4 mL of CH_3CN/H_2O (1:1) in the presence of TEA (84 μL, 0.6 mmol) and PEG-*p*-nitrophenyl carbonate (0.52 mg, 0.1 mmol) was added. The mixture was maintained at room temperature, under constant stirring of the solution, for 12 h. The pH of the solution was brought to 3.0, and the product was extracted into chloroform (five times, 50 mL each), concentrated, and precipitated with diethyl ether. The white solid product was collected by filtration and dried in vacuo (yield 467.3 mg, 0.086 mmol, 86%).

To characterize the product in respect to the carboxylic groups, the peptide was titrated with 0.01 N NaOH. The homogeneity was also assessed by HPLC chromatography using a Vydac C_{18} (250 mm × 4.6 mm) reverse phase column with UV detection at 226 nm. The gradient used water (A) and acetonitrile (B) as eluants (both containing 0.05% TFA) and was run from 10%(B) to 80%(B) over 40 min, and then the elution was maintained as isocratic for a further 10 min.

Carboxy-Terminated PEG−Peptide Conjugates. Branched monomethoxyPEG activated as succinimidyl ester (PEG-OSu) (Mw 10000 g/mol or 20000 g/mol) (1.03 g, 0.1 mmol or 2.03 g, 0.1 mmol) was added under stirring

to H-GPLG-OH (58.9 mg, 0.15 mmol.), H-GLPG-OH (58,9 mg, 0.15 mmol), or H-GLG-OH (36.8 mg, 0.15 mmol), dissolved in 2 mL of anhydrous DMSO. TEA 21 mL (0.15 mmol) was added to reach pH 8, and the reaction mixture was maintained under stirring at room temperature for 12 h. The solution was cooled, diluted with water, brought to pH 3 with 0.1 N HCl, and extracted with chloroform (five times, 50 mL each). After concentration under vacuum, the solution was precipitated with diethyl ether and dried. The precipitate was collected, dried in vacuo, and crystallized from ethanol (yield 467.3 mg, 0.086 mmol, 86%). The product was characterized by titration and by reverse phase HPLC as reported above.

In the case of peptides H-GGRR-OH and H-RGLG-OH the solvent of coupling was H_2O/acetonitrile (2:1) and the peptide was added at a molar excess, PEG−Nle-OSu:H-peptide-OH molar ratio = 1:6).

Synthesis of PEG−Peptide−Dox. Linear or branched PEG−peptides (526.5 mg,0.05 mmol) were dissolved in 2 mL of anhydrous DMF. Dox·HCl (43.5 mg, 0.075 mmol) and TEA (26 mL, 0.184 mmol) were dissolved separately in anhydrous DMF (3 mL), and the mixture was added to the PEG−peptide solution. 1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide methyl *p*-toluensolfonate (CMC) (63.5 mg, 0.15 mmol) in 1 mL of DMF and *N*-hydroxybenzotriazole (HOBT) (6.7 mg, 0.05 mmol) were added to the ice-cooled reaction mixture. The reaction mixture was left under constant stirring for 24 h at room temperature. After evaporation of the DMF, the residue was purified by gel filtration chromatography using a Sephadex LH20 resin with DMF as eluant. The fractions were analyzed for Dox by measuring absorption at 480 nm and using an iodine assay for free PEG (*15*). The PEG−Dox-containing fractions were pooled, and the solvent was evaporated. The red solid residue was redissolved in dichloromethane and added dropwise into diethyl ether (200 mL). The precipitate was collected and dried in vacuo, yielding the final conjugate (460 mg, 0.0415 mmol, 83%).

Measurement of Total Dox Content in PEG−Peptide−Dox Conjugates. PEG−peptide−Dox (8.4×10^{-4}) conjugates were dissolved in 1 mL of 1 N HCl and heated in a water bath at 50 °C for 2 h to yield doxorubicinone. The solution was cooled at room temperature, diluted by addition of 3 mL of DMSO, and analyzed within 2 h by HPLC using a Vydac C_{18} reverse phase column (250 mm × 4.6 mm) with UV detection at 480 nm. A gradient elution was used with water as eluant (A) and acetonitrile as eluant (B) (both containing 0.05% TFA). The gradient was run from 25% B to 30% B over 10 min, and then to 80% B over 5 min. Isocratic elution was then maintained for a further 15 min. Doxorubicinone was used as reference standard.

Solution Properties of PEG−Peptide−Dox Conjugates. A multiangle laser light scattering (MALS) photometer Dawn DSP-F from Wyatt (Santa Barbara, CA) was used in off-line batch mode to study the molecular properties (molecular weight, dimension, and aggregation number) of the PEG−peptide−Dox conjugates. The MALS photometer uses a vertically polarized laser, 632.8 nm of wavelength, and measures simultaneously by an array of photodiodes the intensity of the scattered light at 15 fixed angular locations ranging in aqueous solvent from 14.5° to 151.3°. Even though measurements were performed in static off-line mode a K5 flow cell was preferred to reduce the scattering volume. The solvent used was 0.15 M NaCl, and analyses were performed at room temperature. The calibration constant used to transform the photodiode voltage, i.e., the Rayleigh Factor $R(\theta)$, was calculated using toluene as a standard ($R(\theta)=1.406 \times 10^{-5}$ cm^{-1}), where θ denotes the angle between the detector and the primary incident light. The angular normalization of the different photodiodes was undertaken using a concentrated solution of bovine serum albumin (BSA) assumed to be an isotropic scatterer. Details of the MALS photometer have been described in detail elsewhere (*16*). It is well-known that three important parameters could be obtained from a MALS experiment in batch mode (Zimm plot): the weight-average molar mass M_w, the second virial coefficient A_2, and the *z*-average of the root-mean squares radius $\langle s^2 \rangle_z$, which denotes the gyration radius R_g. The specific refractive index increment, d*n*/d*c*, with respect to the solvent was measured by a KMX-16 differential refractometer from LDC Milton Roy (Riviera Beach, FL). The d*n*/d*c* value for the conjugates ranged from 0.131 to 0.135 mL/g. Each solution was filtered through a 0.2 μm filter.

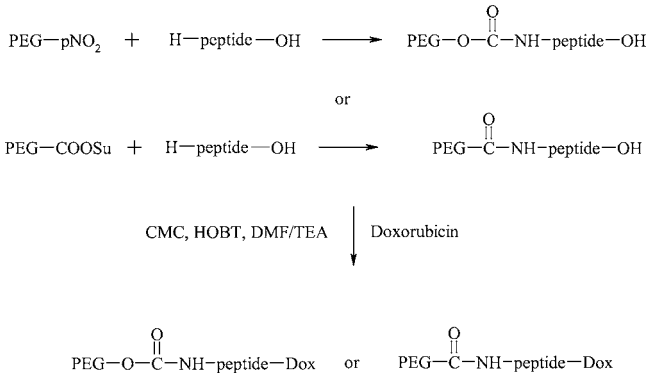
Evaluation of Dox Release by Isolated Lysosomal Enzymes. Experiments were carried out as described previously (*17*, *18*). Briefly, rat liver lysosomal enzymes (Tritosomes) were isolated according to the method of Trouet (*19*) and were standardized for activity by measuring their ability to degrade the substrate Bz-PVR-*p*-nitroanilide (NAp). Protein content of the tritosomes was also measured. The batch used here contained 0.96 mg protein/mL and had an activity 24.7 nmol NAp release/min/mg protein.

PEG−Dox conjugates were dissolved in 0.2 M citrate-phosphate buffer pH 5.5 containing Triton x-100 (0.2%v/v), reduced glutathione (5 mM), and EDTA (1 mM) to give a final concentration of 100 μg Dox-equiv/mL. Tritosomes (400 μL per mL of incubation mixture) were added to start the assay, and the sample was thoroughly mixed. All reagents were maintained at 37 °C throughout. Samples (100 μL) were taken over 5 h and immediately frozen in liquid nitrogen and stored frozen until analysis by HPLC.

A method previously described (*20*, *21*) was used as an initial step to extract free Dox from the PEG−Dox samples. However, some PEG−Dox was also transferred into the extraction solvent using this procedure. Therefore, after solvent evaporation, 0.5 mL of ethanol was added to the dry Dox residue in a 15 mL polypropylene centrifuge tube. After 30 s at 45 °C, the samples were vortexed for 5 s and placed on ice overnight to precipitate contaminating PEG−Dox conjugate. After this time, the sample was centrifuged (2000*g* for 15 min at 4 °C) and the supernatant containing Dox and the internal standard daunomycin (Dnm) was analyzed by HPLC. Isoproanol (29% in water) adjusted to pH 3.2 was used as a mobile phase, flow rate 1 mL/min, with a C_{18} Bondapack column (3.9 × 150 mm) using fluorescence detection. The free Dox recovery using this procedure was 85%, and the limit to detection for free Dox was ~10 ng.

Evaluation of in Vitro Cytotoxicity. The cytotoxicity of the PEG−Dox conjugates was assessed using the adherent murine B16F10 melanoma cell line as previously described (*22*). Cells were grown in RPMI medium supplemented with 10% fetal calf serum and seeded at a density of 10^4 cells per well in 96-well tissue culture plates. After 24 h, the medium was replaced and with serial dilutions of either Dox or the PEG−Dox added in fresh medium (100 μL). All stock solutions were filtered through a 0.22 μm membrane filter to ensure sterility. The cells were then incubated for 67 h at 37 °C. Then 20 μL of sterile MTT solution (0.5% w/v in PBS) was added to each well. After an additional 5 h incubation, the

Scheme 1



medium was removed and optical grade DMSO added to dissolve the insoluble formazan dye formed. Absorbance at 550 nm was measured using a microtiter plate reader and cell viability expressed as a percentage viability of cells incubated with medium alone.

Biodistribution of ^{125}I-Labeled PEGs and PEG−Dox in Mice Bearing sc B16F10 Tumors. *Tumor Model.* All animal experiments were conducted according to the United Kingdom Coordinating Committee on Cancer Research (UKCCCR) Guidelines (*23*). C57 black male mice were inoculated with 10^5 B16F10 tumor cells sc behind the neck. Once the tumor was palpable (∼50 mm^2), approximately 11 days later, ^{125}I-labeled PEGs or PEG−Dox was administered iv.

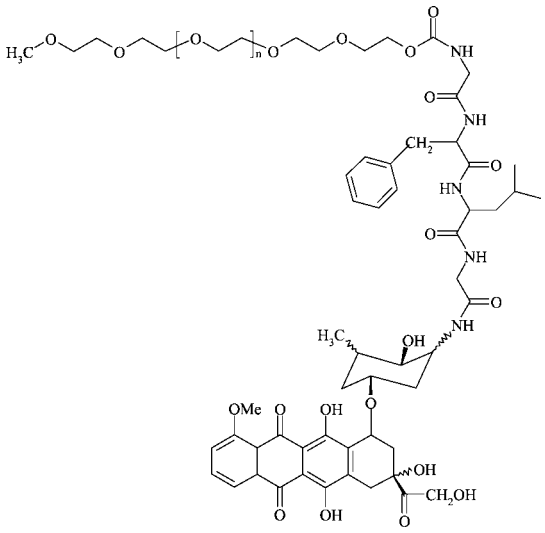
^{125}I-Labeled PEGs. Mono-amine-PEG 5000 g/mol (Shearwater), bis-amine-PEG 10, 000 g/mol (Fluka) and bis-amine-PEG 20 000 g/mol (Fluka) were labeled with [^{125}I]iodide using Bolton Hunter reagent. The crude reaction mixture was purified by elution through Sephadex G-25 gel filtration medium, and the purity in respect of free [^{125}I]iodide was assessed by paper electrophoresis. The specific activity of the products was 44, 50, and 42 μCi/mg for PEG 5000, 10000, and 20000 g/mol, respectively, and their purity > 99%. The ^{125}I-labeled PEGs were each diluted to give 5×10^6 cpm/mL before iv injection (dose ∼ 1.4 mg/kg). The mice were killed after 1 h, 5 h, or 24 h ($n = 3$), and a blood sample was taken before the tumor and organs were dissected. Blood and organs (after homogenization) were made up to a known volume and assayed for radioactivity. The biodistribution was expressed as a percentage of dose administered.

PEG−Dox Conjugates. Once the sc tumors had become palpable, PEG−Dox conjugates were injected iv at a dose of 5 mg/kg (Dox-equiv). After 1 h, the animals were killed and the organs were dissected as above. In this case an HPLC method (as described above) was used to quantify the total Dox content of blood and tissues. In this case the samples were subjected to acid hydrolysis before extraction and quantitation of Dox aglycone.

Antitumor Activity of PEG−Dox in the sc B16F10 and ip L1210 Models. *B16F10 Model.* C57 black male mice were injected with 1×10^5 B16 F10 murine melanoma cells sc as described above. They were then left for 10−12 days until tumor size reached between 9 and 25 mm^2. Animals were randomized into control and treatment groups ($n = 5$) and injected intraperitoneally (ip) with saline, Dox, or PEG−Dox according to the schedules and doses shown in the Results section.

L1210 Model. On day 0, 1×10^5 L1210 cells were injected ip into DBA2 mice. On day 1, the mice were randomized into control and treatment groups ($n = 5$). They were injected ip (either on day 1 only or on days 1, 2, and 3) with saline, free Dox or the PEG−Dox conjugate. The precise dose and schedule is shown in the Results section. In both cases animals were monitored daily for weight change, and for the B16F10 tumor model the tumor size was measured. Animals were humanely killed when their tumor burden reached the maximum allowable size according to the UKCCCR Guidelines (*23*).

Table 1. Structure and Composition of the PEG−Peptide−Dox Conjugates (a typical conjugate structure is shown)



compd	structure	total Dox content[a] (wt %)	free Dox content[a] (% total Dox)
1	linear PEG_{5000}−GFLG−Dox	3.0−7.4	0.53−1.41[a]
2	branched PEG_{10000}−GFLG−Dox	5.0	0.99
3	linear PEG_{10000}−GFLG−Dox	4.3	1.47
4	branched PEG_{20000}−GFLG−Dox	2.7	0.56
5	branched PEG_{10000}-GLFG−Dox	5.2	0.24
6	branched PEG_{10000}-GLG−Dox	5.8	0.62
7	linear PEG_{5000}−Nle-GGRR−Dox	8.0	1.57
8	linear PEG_{5000}−Nle-RGLG−Dox	6.4	0.89

[a] Varied in different batches. Total Dox content was evaluated by HPLC on the basis of doxorubicinone released after acid hydrolysis, while free Dox was evaluated on the HPLC of the untreated sample. The amount of unconjugated free PEG remaining in samples was not evaluated.

RESULTS AND DISCUSSION

Synthesis and Characterization of PEG−Peptide−Dox Conjugates. Three peptides H-GFLG-OH·TFA, H-GLFG-OH·TFA, and H-GLG-OH·TFA were synthesized using solid-phase and solution synthesis. The crude products were purified to homogeneity by preparative HPLC using a C_{18} derivatized silica column, and each peptide was characterized by analytical HPLC, amino acid analysis, and mass spectroscopy (MS). These analyses confirmed the proposed structure and also demonstrated that the two synthetic methods (solid phase and solution) were equally effective in giving pure products (by HPLC purity ranged between 99.3 −100%). The two hydrophilic arginine-containing peptides HGGRR-OH·TFA and H-RGLG-OH·TFA were synthesized using solid-phase synthesis only. Again purification was facilitated by reverse phase chromatography as described above. Analysis (HPLC, MS, and amino acid analysis) confirmed peptide structure, and the purity as assessed by analytical HPLC was >97%. Both hydrophobic and the more hydrophilic arginine-containing peptides were prepared in good yield (∼80% yield) using the methods described. Whereas solid-phase synthesis is preferred for rapid

synthesis of peptides on a small scale, in contrast, for large scale preparation, solution synthesis is frequently used as a less expensive alternative.

To prepare PEG−peptide−Dox conjugates, a sequential synthetic procedure was adopted. First the desired peptide linker was bound to PEG, and then Dox was conjugated via the amino glycoside to the peptide carboxylic group using CMC and HOBT as coupling agents (Scheme 1). This method was preferred to conventional PEG-supported liquid-phase synthesis in which the amino acids are added sequentially, as it allows the use of the same stock of peptide for binding to PEGs of different structure. Eight different conjugates were thus synthesized that differ in molecular weight and shape of the polymer (linear or branched PEG) and in composition of the peptide arm (Table 1).

In the first group of compounds (PEG−Dox **1**−**4**) the peptide H-GFLG-OH was retained, but PEGs with a linear or a branched form of Mw 5000 g/mol or 10000 g/mol were used (Table 1). In the second group of compounds (PEG−Dox **5**, **6**) the peptide composition was changed: First by reversal of FL to give LF (compare PEG−Dox **5** and PEG−Dox **1**−**4**) and then by deletion of F completely (PEG−Dox **6**). Finally two conjugates containing arginine in the linker were synthesized (PEG−Dox **7**, **8**). Arginine was inserted to increase the linker hydrophilicity with the aim of decreasing the tendency of Dox-induced micelle formation in water.

Different activation conditions were used when binding the various PEGs to peptides. For linear PEG terminating with an hydroxyl group, chloroformate activation was used to give a stable carbamate linkage between PEG and peptide (PEG−Dox **1** and **3**). In this case, aqueous−organic reaction conditions were used to give better dissolution of the peptide. However, it should be noted that a molar excess of peptide was needed to overcome the partial hydrolysis of the nitrophenyl group that takes place simultaneously to the aminolysis. The advantage of this procedure lies in the fact that unreacted PEG is hydrolyzed back to hydroxyl PEG and thus it cannot react with Dox in the following synthetic step. In contrast the branched PEGs had terminal COOH groups due to their unique method of synthesis (*24*). These PEGs were activated as hydroxysuccinimidyl esters and, since they are easily hydrolyzed by water, the reaction with the peptides was carried out in DMSO. Under these conditions, a large molar excess of peptide was not needed.

For the synthesis of the two arginine-containing peptides, a special Nle-containing PEG was used (*25*). The Nle residue is particularly useful, as it allows an easy analytical characterization of the products by amino acid analysis after acid hydrolysis. Arginine peptides were linked to the terminal COOH group of PEG−Nle-OH previously activated as succinimidyl ester. An aqueous−organic solution was needed since these peptides possess very low solubility in organic solvents. Also in this case a large molar excess of peptide over PEG was used to overcome the hydrolysis of the succinimidyl ester in this solvent mixture. In the PEG−Nle conjugates, the conjugate composition could be confirmed precisely by measuring the Nle:arginine ratio after acid hydrolysis, and the observed ratios were consistent with the theoretical. Dox conjugation to PEG−peptides was carried out in DMF also using CMC in the presence of HOBT (Scheme 1). Excess Dox was used to achieve complete reaction with the PEG−peptides. It is easier to separate the low molecular mass Dox from the large conjugate PEG−peptide−Dox than to remove excess PEG reagent of a similar molecular weight. Free Dox was removed using

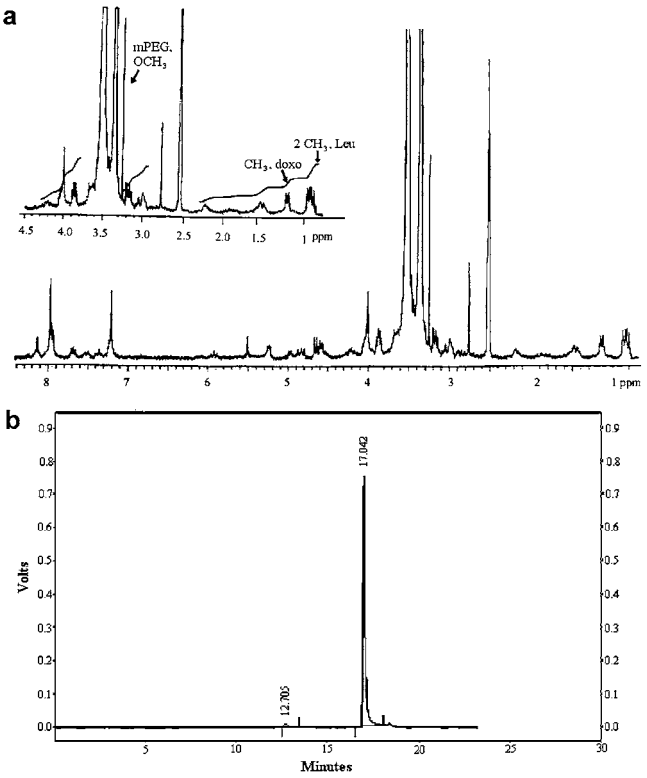


Figure 1. Characterization of PEG−Dox conjugates. Panel a shows an ^{1}H NMR spectrum of the linear PEG_{5000}−GFLG−Dox conjugate. The chemical shifts are shown in Table 2. Panel b shows a C_{18}-HPLC chromatogram of PEG−Dox 1 (UV = 226 nm). The major peak at t_R = 17.04 min is PEG−Dox 1 and free Dox is at t_R = 12.71 min. The chromatogram indicates the absence of unreacted PEG−AA (no peak at t_R = 16.01 min).

LH-20 Sephadex column chromatography with DMF as eluant. Only occasionally did a small amount of free Dox remain, and in this case a second chromatography run was needed to reduce the percentage free Dox in the product below 2.0% the total Dox content. The purity of the conjugates was assayed by C_{18}HPLC which could resolve conjugated and free Dox and any residual unreacted PEG−peptide. For example, the elution pattern of the PEG−Dox 1 is reported in Figure 1b. A trace of free Dox (∼0.5%) can be seen at t_R = 12.71 min and the major peak at t_R = 17.04 min corresponds to the conjugate. No evidence of unreacted PEG−AA (t_R = 16.01 min) could be seen.

The total and free Dox content of all conjugates is shown in Table 1. The peptide composition of each conjugate was confirmed by quantitative amino acid analysis after acid hydrolysis, and the amino acid ratios seen corresponded to the expected within the experimental error of the methods. ^{1}H NMR in DMSO was used to confirm product identity. A typical ^{1}H NMR spectrum (for the linear PEG_{5000}−GFLG−Dox conjugate) is shown in Figure 1a, and the chemical shifts ascribed to the polymer chain, Dox, and the spacer arm protons are reported in Table 2. The integral values of the methoxy group protons of the polymer chain and 2-methyl proton of leucine and 5′-methyl protons of Dox again support the assignment of a 1:1:1 composition of the PEG:peptide:Dox. For in vitro and in vivo experiments, total Dox content of the conjugates was calculated by UV absorption, since PEG has such as a high hydration tendency and it is not possible to remove the strongly bound water by azeotropic distillation due to the instability of Dox under these conditions. The presence of unreacted PEG would also have added to the error if weight % had been used.

Table 2. Proton Shifts Seen for the Linear PEG_{5000}−GFLG−Dox Conjugate during ^1H NMR (see also Figure 1)

Table 3. Determination of the Solution Properties of the PEG−Dox Conjugates Using Light Scattering

compound	apparent Mw (g/mol × 10^{-3})	R_g[a] (nm)	aggregation number[b]
PEG−Dox-1	120.0	23.3	20.1
PEG−Dox-2	33.6	29.7	3.0
PEG−Dox-3	33.1	15.6	3.0
PEG−Dox-5	28.4	13.0	2.6
PEG−Dox-6	30.6	16.8	2.8
PEG−Dox-7	54.7	45.6	9.1
PEG−Dox-8	35.2	21.3	5.9

[a] R_g gives the average radius of the molecule or aggregate. [b] The aggregation number indicates the approximate number of PEG−Dox molecules in the surpramolecular assembly.

Solution Properties of PEG−Dox Conjugates. Evaluation of the properties of the PEG−peptide−Dox conjugates in aqueous solution by light scattering showed clear evidence of conjugate aggregation (Table 3). The extent of aggregation was dependent on conjugate structure, and the linear PEG_{5000}−GFLG−Dox conjugate had by far the greatest tendency to form micelles that had an apparent Mw of 120000 g/mol which is equivalent to an aggregation number of ∼20. In general the other hydrophobic conjugates showed much lower aggregation tendency with an aggregation number of ∼3. Contrary to expectation, however, the more hydrophilic arginine-containing conjugates displayed a relatively high tendency to form micelles. These were composed of ∼6−9 PEG_{5000}−NleRGLG−Dox or PEG_{5000}−NleGGRR−Dox molecules, respectively. The tendency of polymer−drug conjugates to form unimolecular micelles (with bound hydrophobic drug forming the intramolecular core) or multimolecular micellar aggregates is important to note. It has been clearly shown that this phenomenon can limit access of activating enzyme and thus often determines the biological activity of these macromolecular prodrugs (*26*).

Lysosomal Enzyme-Mediated Release of Dox from PEG−Dox Conjugates. Incubation of the PEG−peptide−Dox conjugates **1**−**6** with tritosomes led to a linear initial release of Dox over 5 h (Figure 2; Table 3). It was evident that the amino acid sequence of the peptide spacer rather than PEG structure had the strongest influence on Dox release since conjugates **1**−**4**, which bore very different PEGs but had identical spacers, released similar quantities of Dox over 5 h. Branched PEG_{10000}-GLFG−Dox (conjugate **5**) displayed the fastest initial release rate. The tripeptide-containing linear PEG_{5000}-GLG−Dox (conjugate **6**) displayed a slower release rate. This pattern of degradation corresponds to the known susceptibilities of these linkers to degradation by lysosomal thiol-dependent proteases when the same sequences were used as side-chains in *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymer conjugates containing Dox (*27*). Interestingly, linear PEG_{5000}−GFLG−Dox released drug at the same rate as HPMA copolymer−GFLG−Dox when incubated with tritosomes, but much more quickly than a PEG−peptide block copolymer bearing GFLG−Dox side chains (*28*).

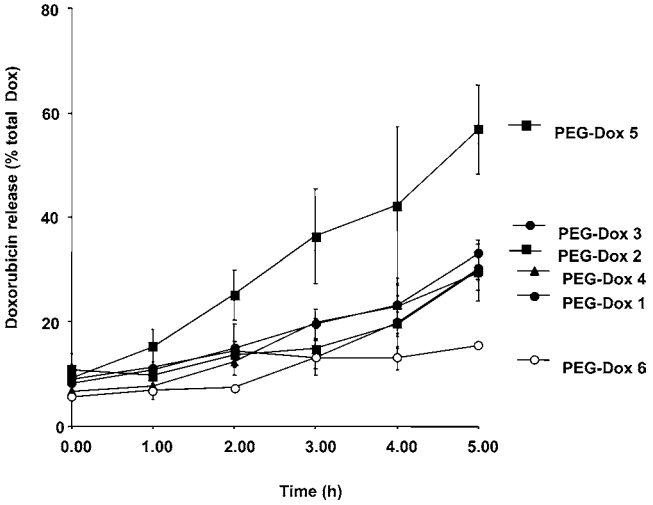

Figure 2. Release of Dox from PEG−peptide−Dox conjugates during incubation with isolated rat liver lysosomal enzymes (tritosomes). Each data point represents the mean ± SD of three separate experiments.

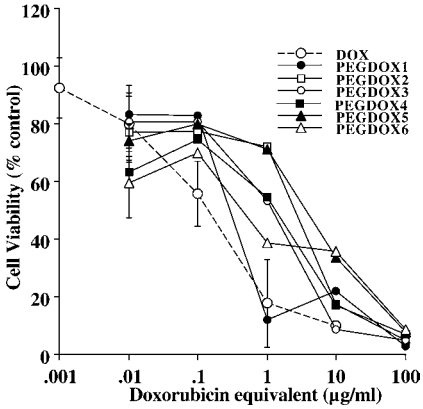

Figure 3. In vitro cytotoxicity of the PEG−Dox conjugates assessed using B16 F10 cells (MTT assay) after a 72 h incubation. Error bars represent the mean ± SD and $n = 4$−6.

The arginine-containing linkers displayed the lowest rate of release of free Dox, but this is most likely due to the specificity of the predominant lysosomal proteases rather than the micellerization of these conjugates.

In Vitro Cytotoxicity. The in vitro cytotoxicity tests (Figure 3; Table 4) showed the PEG−peptide−Dox conjugates to be 10−100 fold less toxic than free Dox (0.24 μg/mL) against B16F10 cells, an observation consistent with the slower rate of endocytic uptake and lysosomotropic activation as the rate-limiting step. Conjugates **1**−**4** having the GFLG linker displayed the greatest cytotoxicity ($IC_{50} = 4.6$−8.3 μg/mL). The low cytotoxicity of PEG−GLG−Dox conjugate **6** correlates well with its poor rate of enzymatic activation. However, it is difficult to explain the relatively low cytotoxicity of PEG−GLFG−Dox conjugate **5** as this contains the linker most susceptible to enzyme attack. Throughout the in vitro testing

Table 4. Summary of the Biological Properties of the PEG−Dox Conjugates

compound	release of Dox during incubation with tritosomes (% total Dox liberated) 5 h	24 h	IC_{50} (μg/mL)[a]	B16F10 model T/C (%)
Dox	N/A	N/A[b]	0.2	121

PEG−Dox 6	15.50 ± 0.53	37.6	105	N/A
PEG−Dox 7	3.08 ± 0.90	N/A	2.4	N/A
PEG−Dox 8	4.00 ± 1.03	N/A	3.8	N/A

[a] Assessed against B16 F10 cells over 72 h using the MTT assay. [b] N/A; not undertaken.

there seemed to be no clear correlation between PEG structure and cytotoxicity, and this is noteworthy that the free Dox content in each conjugate, even though the levels are low, can influence in vitro cytoxicity.

Biodistribution of ^{125}I-Labeled PEGs and PEG−Dox Conjugates. As would be predicted for water-soluble macromolecules (*29, 30*), the higher molecular weight ^{125}I-labeled PEGs remained circulating in the blood for longer due to decreased renal clearance after iv injection (Figure 4a; Table 5). This longer plasma residence time led to increased tumor targeting (Figure 4a; Table 5), but in many cases also gave increased normal tissue exposure (Table 5). Although the highest molecular weight PEG showed greatest tumor levels, comparison of the area under the curve values for each polymer indicated that PEG_{5000} had the most favorable

[a] Results represent the mean ± SD. $n = 3$.

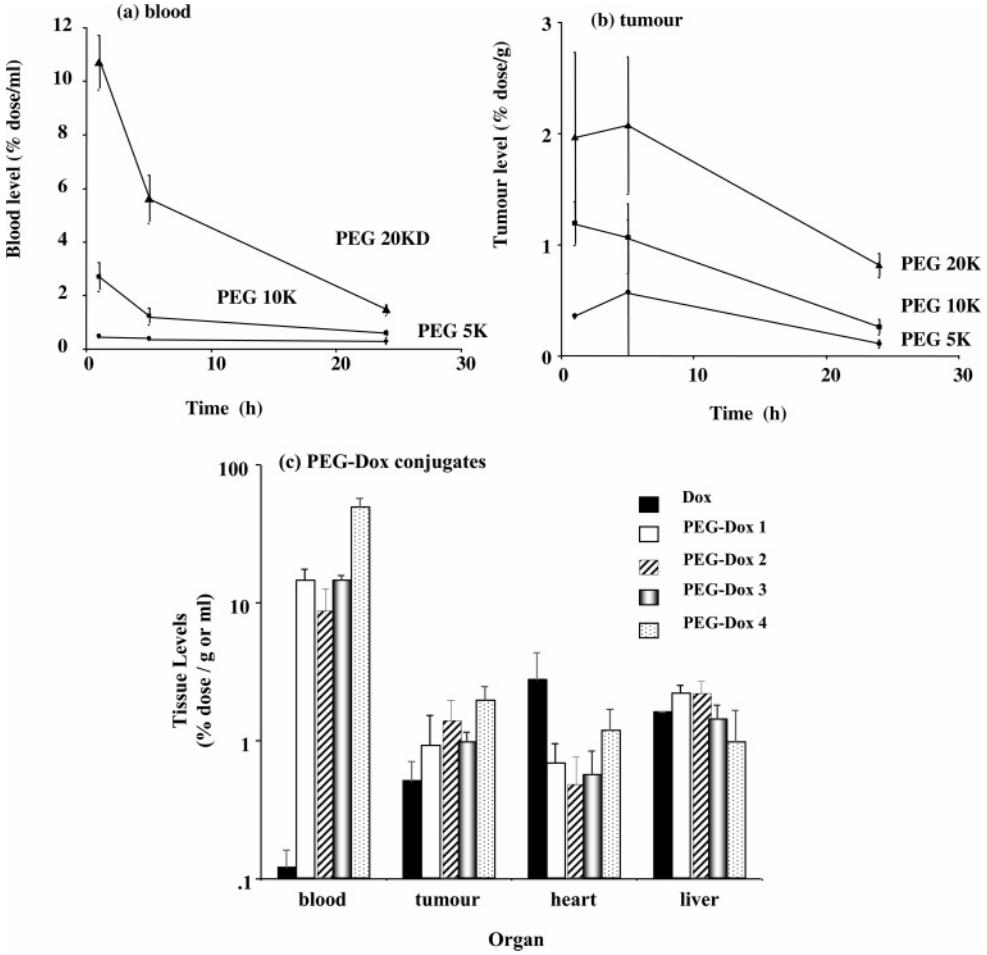

Figure 4. Biodistribution of ^{125}I-labeled PEGs and PEG−Dox conjugates after iv administration to mice bearing sc B16F10 tumors. Panel a shows the time-course of radioactivity detected in blood after administration of ^{125}I-labeled PEGs, panel b shows the time-course of radioactivity detected in tumor tissue and panel c shows the total Dox recovered in all tissues at 1 h after administration of PEG−Dox conjugates. (Analysis by HPLC). The data representmean ± SD where $n = 3-5$.

Table 6. Treatment of Mice Bearing sc B16F10 Murine Melanoma with Various PEG−DOX Conjugates

group	mean survival time (days)[a]	T/C × 100
saline	5.6	100
Dox	6.8	121
PEG−Dox 1	8.2	146[a]
PEG−Dox 2	7.5	132[a]
PEG−Dox 3	6.3	113
PEG−Dox 4	7.3	130[a]
PEG−Dox 5	8.0	143[a]

[a] In this aggressive B16F10 model it is usual to have statistical significance when T/C is greater than 125% and when the group size is $n = 5$, as was the case here.

tumor:heart ratio. Considering the known dose-limiting toxicity of Dox, this may be important. The radioactivity associated with ^{125}I-labeled PEGs in the liver were similar for PEG 10000 and 20000 g/mol, but were higher for PEG 5000 g/mol. and did not decrease in the same manner as in other tissues. Nevertheless, for all PEGs investigated, liver uptake was never more than 6% which is only a little higher than other water soluble polymeric drug carriers such as HPMA copolymers, for example. The variability in tumor accumulation of ^{125}I-labeled PEGs may be explained by the tendency of small tumors to accumulate more polymer than large tumors, a phenomenon shown previously with HPMA copolymer−Dox (*31*). Scatter plots of tumor uptake per gram against tumor weight showed that accumulation at 1 h was higher in smaller tumors (data not shown).

As a preliminary study, the biodistribution of the PEG−Dox conjugates, the levels of total Dox in blood, tumor, and the other principal organs, was examined at 1 h after iv injection. All the PEG−Dox conjugates showed a significantly longer plasma half-life than free Dox (Figure 4c). PEG−Dox 4 showed significantly higher blood levels than the other conjugates at 1 h. This is perhaps surprising as light scattering experiments suggested that PEG−Dox 1 had the highest apparent size and would suggest that the micellar aggregate of PEG−Dox 1 rapidly dissociates in blood. All PEG−Dox conjugates showed higher tumor Dox concentrations than free Dox and importantly lower heart levels (Figure 4c). It is important to note that the blood clearance and tumor targeting of the PEG−Dox conjugates was markedly different than seen for the corresponding molecular weight ^{125}I-labeled PEGs. This emphasizes the importance of monitoring biodistribution of each polymer−drug conjugate as well as the parent polymeric carrier.

Antitumor Activity of PEG−Dox Conjugates. An important factor leading to improved efficacy of polymer conjugates is tumor targeting by the EPR effect. Thus it is important to use solid tumor models to evaluate therapeutic potential of polymer conjugates. As we have used the B16F10 melanoma model to compare the activity of other anticancer conjugates that we have subsequently progressed into clinical trial (*32*−*34*), the antitumor activity of PEG−Dox conjugates was assessed using this model. It should be noted that this is a very aggressive tumor, and animals not treated usually die within 6−10 days of the tumor becoming palpable. First studies compared the activity of PEG−Dox conjugates 1−5 at a Dox dose of 5 mg/kg (Dox-equiv). Although Dox showed no significant antitumor activity, both PEG−Dox 1 and PEG−Dox 5 were active although the increase in survival was modest (T/C ∼ 145%) (Table 6). Antitumor activity would appear to correlate with the highest rate of Dox release in the presence of lysosomal enzymes (Table 4). Activity of PEG−Dox 1 was confirmed in a second experiment designed to examine the dose-dependency of activity. Although no clear dose−response was observed antitumor activity was evident, in this case a T/C of ∼ 160% was observed (Table 7).

The mouse leukemia L1210, grown as an ip ascites, is classically used to establish the activity of anthracycline derivatives. When PEG−Dox-1 was evaluated in this model, antitumor activity was observed, but survival was reduced in comparison to treatment with Dox alone (Table 8). Considering the differential pharmacokinetics of free Dox and PEG−DOX conjugates at the whole organism and cellular level, this observation is consistent with the need for EPR-mediated targeting to allow polymer conjugates to show therapeutic benefit. Additionally it is noteworthy throughout these experiments that the PEG−Dox conjugates were less toxic as evidenced by their lesser effect on animal weight loss (Figure 5).

CONCLUSIONS

Structure of PEG−peptide−Dox conjugates can be tailored to give a 1:1:1 stoichiometry of PEG chain, amino acid spacer, and anthracycline. This offers a unique

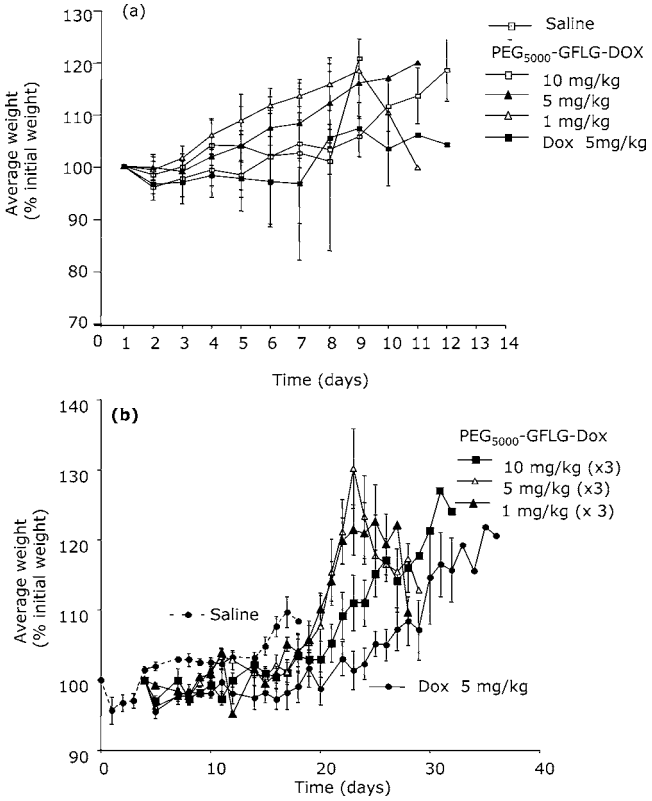

Figure 5. Effect of PEG–Dox conjugates on animal weight. The effect of PEG–Dox-1 and free Dox on the weight of mice during antitumor experiment. Panel a shows the weight change in C57 mice bearing a sc B16F10 tumor, and panel b shows the weight change in DBA2 mice bearing ip L1210.

opportunity to prepare anticancer polymeric conjugates of low polydispersity, which is advantageous compared to other pendant polymer conjugates. Solution properties are however complicated by the tendency of PEG–Dox conjugates to form multimolecular aggregates. The aggregation number was dependent on the nature of the PEG used (Mw and architecture), and further study of micellar stability is warranted before further development of such conjugates. The rate of Dox release on exposure to lysosomal enzymes was controlled by the peptidyl linker used, but the nature of the PEG carrier had little influence on this process. In vivo studies confirmed the effect of PEG Mw on the biodistribution of ^{125}I-labeled PEGs. However, the biodistribution of PEG–Dox conjugates was not clearly related to Mw or architecture of the carrier, but was probably governed by the nature and stability of the PEG–Dox aggregates formed. In all cases the PEG–Dox conjugates displayed greater tumor targeting than free Dox and also lower heart levels of the bound anthracycline. This justified evaluation of their antitumor activity in vivo. Experiments in mice bearing either a sc B16F10 tumor or and ip L1210 tumor confirmed the activity of selected PEG–Dox conjugates and also underlined the importance of the EPR effect as a means to enhance tumor targeting. PEG_{5000}–GFLG–Dox was selected as the lead candidate for further preclinical evaluation.

ACKNOWLEDGMENT

This work was supported by BE Project 97- 4133. We would like to thank Dr. Steve Stribbling for technical help with the in vivo experiments.

Received October 26, 2004; Revised Manuscript Received April 8, 2005

The influence of PEGylation on polyplex stability from poly(ethylene imine), PEI, and plasmid DNA was investigated both in vitro and after intravenous administration in mice. Polyplexes were characterized with respect to particle size (dynamic light scattering), zeta-potential (laser Doppler anemometry), and morphology (atomic force microscopy). Pharmacokinetics and organ accumulation of both polymers and pDNA were investigated using ^{125}I and ^{32}P radioactive labels, respectively. Furthermore gene expression patterns after 48 h were measured in mice. To elucidate the effect of different doses, all experiments were performed using ca. 1.5 μg and 25 μg of pDNA per mouse. Our studies demonstrated that both PEI and PEG−PEI form stable polyplexes with DNA with similar sizes of 100−130 nm. The zeta potential of PEI/pDNA polyplexes was highly positive, whereas PEG−PEI/pDNA showed a neutral surface charge as expected. The pharmacokinetic and organ distribution profiles after 2 h show similarities for both PEI and pDNA blood-level time curves from polyplexes at both doses indicative for significant stability in the bloodstream. A very rapid clearance from the bloodstream was observed and as major organs of accumulation liver and spleen were identified. PEG−PEI/pDNA complexes at a dose of ∼25 μg exhibit similar profiles except a significantly lower deposition in the lung. At the lower dose of ∼1.5 μg pDNA, however, for polyplexes from PEG−PEI, significant differences in blood level curves and organ accumulation of polymer and pDNA were found. In this case PEG−PEI shows a greatly enhanced circulation time in the bloodstream. By contrast, pDNA was rapidly cleared from circulation and significant amounts of radioactivity were found in the urine, suggesting a rapid degradation possibly by serum nucleases after complex separation. Regarding in vivo gene expression, no luciferase expression could be detected at ∼1.5 μg dose in any organ using both types of complexes. At 25 μg only in the case of PEI/pDNA complexes were significant levels of the reporter gene detected in lung, liver, and spleen. This coincided with high initial accumulation of pDNA complexed with PEI and a high acute in vivo toxicity. For PEG−PEI, initial accumulation was much lower and no gene expression as well as a low acute toxicity was found. In summary, our data demonstrate that PEG−PEI used in this study is not suitable for low dose gene delivery. At a higher dose of ∼25 μg, however, polyplex stability is similar to PEI/pDNA combined with a more favorable organ deposition and significantly lower acute in vivo toxicity. These findings have consequences for the design of PEG−PEI-based gene delivery systems for in vivo application.

INTRODUCTION

Nonviral gene delivery has proven its efficiency in numerous in vitro studies (*1*). The use of genes as therapeutic agents offers tremendous potential for the causal treatment of yet incurable diseases, especially viral infections and cancer (*2*). For systemic gene therapy, however, it is necessary to develop vectors with a low toxicity and sufficient stability and circulation time in the bloodstream in order to reach remote sites of the body, e.g. disseminated metastases. With cationic polymers, such as linear poly(ethylene imine), PEI (*3*, *4*), or methacrylates (*5*), in vivo transfection experiments have been reported using primarily luciferase encoding reporter genes. Also pharmacokinetic and organ distribution data have been obtained for different nonviral vectors, demonstrating rapid clearance of positively charged polyplexes from circulation (*6*−*8*).

To extend the blood circulation times of nonviral vectors, hydrophilic polymers, such as poly(ethylene glycol), PEG, or poly(*N*-(2-hydroxypropyl)methacrylamide) (pHPMA), have been coupled to polycations (*9*−*11*) to achieve hydrophilic shielding ("stealth" effect) similar to PEGylated liposomes (*12*). PEG-modified polycations have shown promising biophysical properties after complexation with p-DNA, such as a neutral zeta potential, very low cytotoxicity, and little or no tendency for aggregation (*9*, *11*, *13*). While the stability of polyplexes under in vitro conditions is well documented (*11*,

14), relatively little is known about polyplex stability in an in vivo situation.

Promising results have been obtained in animal studies with loco-regional administration of PEG-modified polymer/DNA complexes (*15*, *16*). Also repeated administration of PEG−PEI/DNA polyplexes led to a more prolonged transgene expression in the spinal cord as compared to PEI (*17*). By contrast, the fate of the constituents of polyplexes in the bloodstream after intravenous injection is incompletely understood, especially the influence of hydrophilic polymers, such as PEG. A comparison of poly(L-lysine) and PEGylated poly(L-lysine)/DNA complexes revealed significant DNA degradation in vivo for the PEGylated polymer indicative of polyplex disintegration (*7*). Further studies addressed pharmacokinetic profiles and organ distribution of either plasmid DNA *or* polymer after intravenous injection in mice (*9*, *11*). However, little is known about the quantitative distribution and blood level profiles of both complex constituents determined under the same experimental conditions and to what extent polyplexes retain their integrity in the bloodstream.

In this study we investigated blood level profiles and organ distributions of PEI/pDNA and PEG−PEI/pDNA polyplexes after intravenous injection into mice. To trace both complex constituents separately, two different radioactive labels for plasmid (^{32}P) and polymers (^{125}I) were used. To determine the influence of pDNA dose on blood level profiles and organ accumulation, we applied a total dose of 1.5 μg (0.075 mg/kg) and 25 μg (1.25 mg/kg) of plasmid DNA plus the corresponding amount of polymer per animal. Furthermore, we investigated gene expression profiles at both doses for PEI/plasmid and PEG−PEI/plasmid complexes, and we compared these with accumulation data of plasmid in major organs 30 min after injection and after 2 h.

EXPERIMENTAL SECTION

Materials and Animals. Endotoxin-free luciferase-encoding plasmid (pCMV-luc) was purchased from Plasmid Factory, Bielefeld, Germany. PEI 25 kDa was obtained from Sigma-Aldrich, Germany. PEI(25k)-*g*-PEG-$(2k)_{10}$ was synthesized as previously described (*18*). Male balb/c mice were purchased from Charles River, Germany.

Preparation of Polyplexes. Polymer solutions for complex formation were prepared in 79 μL of 150 mM NaCl with 10 mM HEPES buffer pH 7.4 and 36 μL glucose 5% pH 7.4. These mixtures were added to solutions of plasmid in 115 μL glucose 5% pH 7.4. All complexes used in this study were prepared at an N/P ratio of six.

Dynamic Light Scattering. Hydrodynamic diameters of polymer/pDNA polyplexes were determined by photon correlation spectroscopy. Plasmid (0.5 μg pCMV-Luc) in 25 μL of glucose 5%, pH 7.4 were complexed with the appropriate amount of polymer in 25 μL of glucose 5%, pH 7.4 each, as described above. Measurements were performed on a Zetasizer 3000 HS from Malvern Instruments, Germany (10 mW HeNe laser, 633 nm). Scattering light was detected at 90° angle through a 400 μm pinhole. For data analysis, the viscosity (0.88 mPa s) and the refractive index (1.33) of distilled water at 25 °C were used. The instrument was routinely validated using Standard Reference latex particles (AZ 55 Electrophoresis Standard Kit, Malvern Instruments). Each experiment was performed in quintuplet.

Measurement of Zeta Potential. Zeta-potential measurements were carried out in the standard capillary electrophoresis cell of the Zetasizer 3000 HS from Malvern Instruments at position 17.0. Measurements were performed in glucose 5%, pH 7.4, and all experiments were performed in quintuplet.

Radioactive Labeling of Polymers. Polymers were labeled employing *N*-succinimidyl-3-(4-hydroxy-3-[^{125}I]-iodo-phenyl)propionate (Amersham Pharmacia Biotech, Germany) according to the method of Bolton and Hunter as described earlier (*9*, *19*). Briefly: Polymers were dissolved in 0.1 M borate buffer pH 8.5, and the Bolton Hunter reagent was dissolved in DMSO. The polymer solution was added to the Bolton Hunter reagent solution, and the reaction was carried out for 60 min at room temperature. Purification was performed on a Sephadex G-25 column (PD10, Pharmacia, Germany), using an elution buffer containing 150 mM NaCl and 10 mM HEPES at pH 7.4.

Radioactive Labeling of DNA. Plasmid (pCMV-Luc) was radioactively labeled by incorporation of ^{32}P-dCTP (Readivue, Amersham Pharmacia, Germany) using a nick translation kit (Amersham Pharmacia, Germany) following a protocol provided by the manufacturer. Unincorporated nucleotides were carefully removed using Autoseq spin columns containing Sephadex G50 (Amersham Pharmacia, Germany) in two subsequent purification runs. Plasmid purity was verified via size exclusion chromatography using a PD-10 column and via ultracentrifugation using Microcon 10 spin columns (Amicon) via verification of absence of low molecular weight radioactive compounds. No significant amounts of free ^{32}P-dCTP were detected.

Pharmacokinetic Analysis and Organ Distribution. All animal experiments followed the "Principles of Laboratory Animal Care" (NIH publication #85-23, revised 1985) and were approved by an external review committee for laboratory animal care. Male balb/c mice with a body weight of 20−25 g were anaesthetized using Ketamine (Ketavet, Pharmacia & Upjohn, Germany) and Xylazine (Rompun, Bayer AG, Germany). Complexes of either ^{125}I-poylmer/plasmid or polymer/^{32}P-plasmid were injected as a bolus of approximately 100μL through the jugular vein. Two different doses, 1.5 μg of pDNA and 25 μg of pDNA, complexed with the corresponding amount of polymer to give a nitrogen-to-phosphate ratio of 6 were administered. Blood samples were obtained via a catheter in the common carotid artery, and urine was sampled by flushing the bladder with sodium chloride solution through a two-way catheter. After 30 or 120 min, mice were sacrificed and organs (liver, kidneys, lungs, spleen, cortex, heart, fatty tissue, vena jugularis, and cortex) were weighed and assayed for radioactivity. Radioactivity of the ^{125}I-polymer was measured on a 1277 Gammamaster (Perkin-Elmer Wallac, Germany). To assess the radioactivity from ^{32}P-pCMV-Luc, organs and blood samples were dissolved in 1 mL of Soluene 350 (Amersham Pharmacia, Germany). Subsequently, 200 μL of 30% sodium peroxide was incubated with the mixture for 30 min and then added to 15 mL of HionicFluor (Perkin-Elmer, Germany). Measurements were performed using a TriCarb liquid scintillation counter (Perkin-Elmer, Germany) with a counting time of 15 min and 1 min precount delay. Measurements of aliquots of complex solutions were used for both tracers to determine the injected dose of radioactivity. All experiments at low dose were performed in quadruplet; those at high dose were performed using eight animals.

In the case of PEI/pDNA complexes at both doses and PEG−PEI/pDNA complexes at ~25 μg dose, concentration−time curves from polymer and pDNA were fitted

to a two-compartmental model with the Software Kinetica 1.1 from Simed. The model used was $C(t) = Ae^{-\alpha t} + Be^{-\beta t}$, and the weighting applied was $1/(c_{calcd})^2$. Polymer concentrations in the samples were then calculated as percent of injected dose (%ID) or %ID/mL, respectively. Unpaired *t*-test was performed using Microcal Origin version 6.0 to compare blood levels of different polymers at corresponding time points. Differences were considered significant if two-tail $P \leq 0.05$.

Luciferase Expression in Vivo. Mice were anaesthetized as described above, and complexes containing either 1.5 or 25 μg of pCMV-luc were injected through the jugular vein in the same volume as described above. After 48 h mice were sacrificed and subsequently organs were removed. Liver, lung, spleen, kidneys, vena jugularis, cortex, and heart were dissolved in Lysis Buffer provided by Promega, Germany, and after centrifugation an aliquot of the supernatant was assayed for luciferase using a commercial kit and photon counting with a luminometer (Sirius Berthold, Germany). In vivo gene expression studies were performed in quadruplet.

RESULTS AND DISCUSSION

Size and Zeta Potential Measurements. At an N/P ratio of 6, both PEI 25 kDa and PEI(25k)-*g*-PEG(2k)$_{10}$ were capable of forming complexes with plasmid DNA. Polyplexes prepared with PEI 25 kDa displayed a size of 106 (±7) nm and a zeta potential of +26 (±2) mV. By contrast, PEG–PEI/DNA complexes reached a size of approximately 127 (±6) nm and a neutral zeta potential (0.5 ± 0.9 mV), indicating an efficient shielding of the cationic charge by grafted linear PEG chains. Compared to measurements obtained in 150 mM sodium chloride (*20*), complexes were significantly smaller when prepared in 5% glucose.

Atomic Force Microscopy (AFM). AFM images shown in Figure 1 as three-dimensional plots illustrate that both PEI and PEG–PEI formed defined, spherical complexes with plasmid DNA. Shape and size for both polyplex types appear to be similar and are in good agreement with previously published data (*18*, *20*). However, PEI/pDNA complexes seemed to be more uniform, more spherical, more compact, and smoother. PEG–PEI/DNA complexes were found to be flatter, and they showed a more irregular shape, suggesting that grafted PEG chains affected condensation of pDNA No free or only loosely complexed pDNA could be observed as described in earlier studies (*18*). Furthermore, DNA binding studies have been performed which indicated an efficient complexation of pDNA by PEI(25k)-*g*-PEG(2k)$_{10}$ (*20*). These observations suggest that these polyplexes could be suitable for in vivo evaluation.

Pharmacokinetic Analysis and Organ Distribution. Blood level profiles of polymers and pDNA are depicted in Figures 2–7. At a dose of approximately 1.5 μg of pDNA, none of the animals died during the experiments and no signs of acute toxicity were observed. Also at the higher dose of approximately 25 μg of pDNA, in the case of PEG–PEI/DNA complexes all animals survived without any signs of acute toxicity. However, after administration of unmodified PEI/pDNA complexes at a dose of 25μg of pDNA, two out of eight animals died within 30 min after injection, confirming previously published observations (*21*).

PEI/plasmid Polyplexes at Low Dose (Figure 2). Pharmacokinetic profiles obtained with PEI and plasmid DNA at a 1.5 μg dose displayed a very rapid clearance from the bloodstream. Curves fitted to a biexponential disposition equation by nonlinear curve fitting (Figure 2A) showed very steep alpha phases with a $t_{1/2\ alpha}$ of 4.9 min for the polymer and 3.4 min for pDNA (see Table 1). Subsequent beta elimination phases were very flat with $t_{1/2\ beta}$ of 120.0 and 132.6 min, respectively. After 30 min, less than 3% of the injected dose (polymer, as well as pDNA) per milliliter blood remained in blood circulation, approaching levels of approximately 1% ID/ml blood after 2 h. Comparison of pharmacokinetic data from plasmid DNA and PEI at 1.5 μg (Table 1) revealed very similar behavior especially within the first 30 min suggesting that PEI/DNA polyplexes remained intact to a substantial degree during blood circulation.

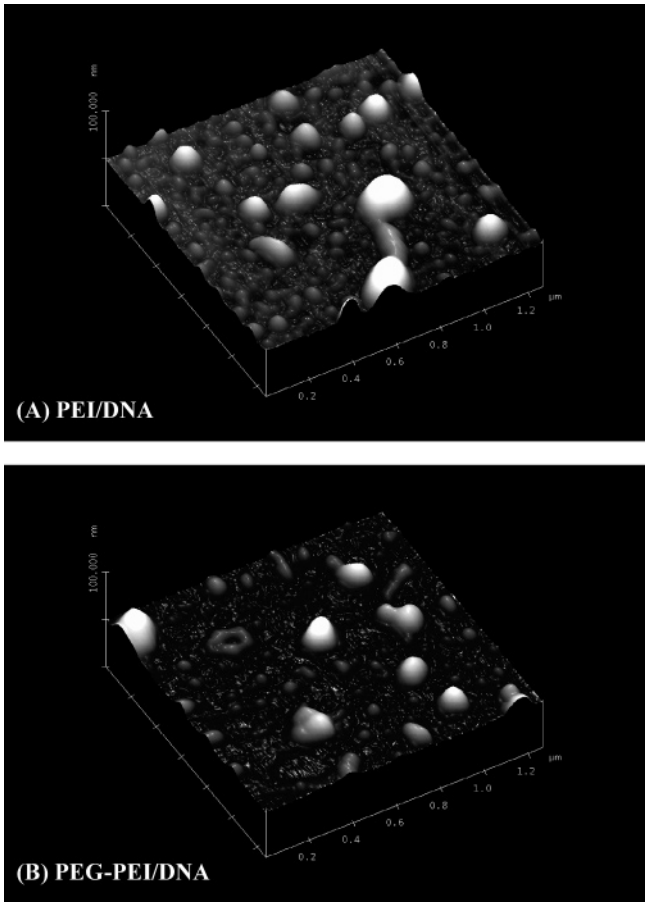

Figure 1. Complexes of PEI/DNA (A) and PEG–PEI/DNA (B) visualized by atomic force microscopy at N/P = 6 in 5% glucose. Images display defined structures of both complex types, and no free DNA could be observed in any image. Some larger aggregates are visible in both preparations.

The organ distribution of both PEI and pDNA at a 1.5 μg dose reached similar levels of radioactivity after 2 h in major organs, such as liver, kidney and lung (Figure 2B). These similarities provided additional evidence for polyplex stability in the bloodstream with concomitant uptake of both PEI and pDNA into tissues. Highest levels for polymer and pDNA were detected in the liver. Uptake probably occurred after opsonization of polyplexes as suggested by Planck et al. (*22*) with a subsequent rapid capture by mononuclear phagocytic cells. Organ deposition in the spleen showed approximately 3-fold higher accumulation of ^{125}I compared to ^{32}P. This fairly high accumulation in the spleen has been reported earlier for PEI 25 kDa polymer at a low dose (*9*) and was possibly caused by free polymer present at the N/P ratio used (*23*) or a minor degree of polyplex separation in the bloodstream.

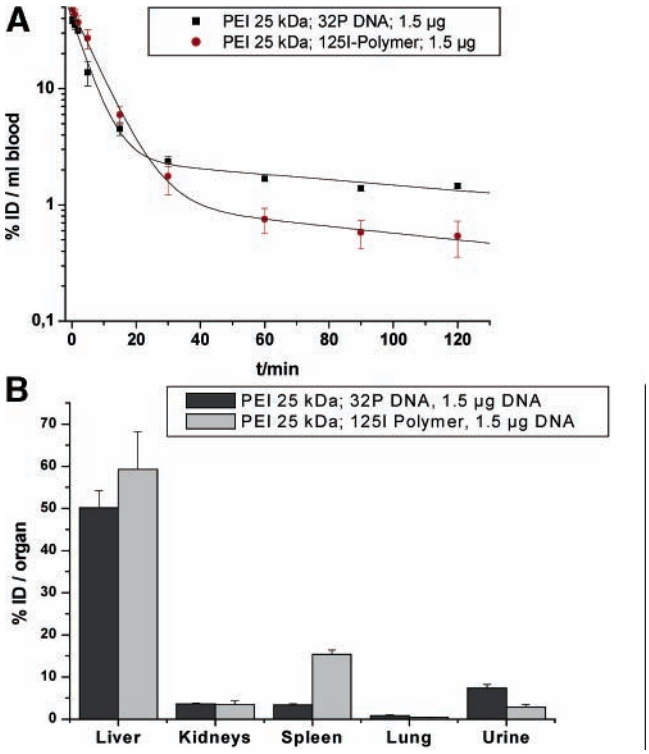

Figure 2. Blood level curves and organ accumulation after 2 h of PEI/pDNA at ~1.5 μg of pCMV-luc per mouse. A very rapid clearance of polymers and DNA from the bloodstream can be observed for polymer and pDNA.

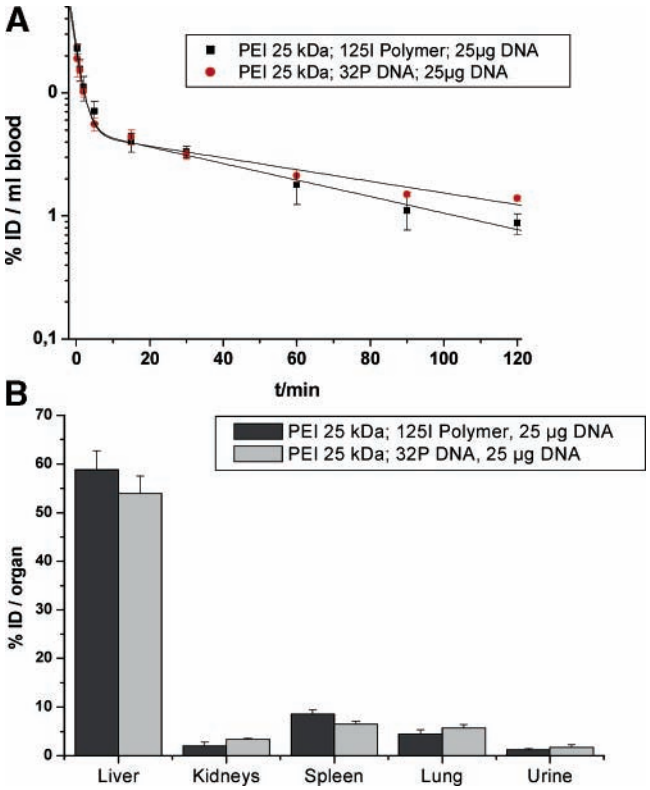

Figure 3. Blood level curves and organ accumulation after 2 h of PEI/pDNA at ~25 μg of pCMV-luc per mouse. Again a very rapid clearance from the blood stream can be observed for both complex constituents. Organ accumulation displays similar levels for pDNA and polymer. Compared to the low dose, a significantly higher level of accumulation was found in the lung.

Significant levels of radioactivity from ^{32}P were detected in the urine, in contrast to ^{125}I from the polymer. This difference most likely occurred as a result of polyplex separation followed by rapid pDNA degradation as described earlier (*24*). Uptake into the lungs is fairly low at 1.5 μg dose after 2 h (Figure 2B) and even at a 30 min no elevation in radioactivity were observed (data not shown). Due to the low dose formation of aggregates with e.g. erythrocytes was possibly reduced (*18*). Other tissues, such as heart, cortex, fatty tissue or the injection site in the jugular vein, did not exhibit significant levels of radioactivity from either polymer or pDNA after application of both PEI/DNA complexes (<1.5% ID). These findings were in good agreement with earlier studies (*9*, *25*).

PEI/plasmid Polyplexes at High Dose (Figure 3). At a 25 μg dose of DNA blood level profiles and organ distribution were rather similar to that at lower doses. Again a biphasic profile was found with $t_{1/2}$ alpha of 1.5 min and $t_{1/2\ \mathrm{beta}}$ of 45.9 min for polymer and $t_{1/2\ \mathrm{alpha}}$ of 1.4 min and $t_{1/2\ \mathrm{beta}}$ of 64.1 min for DNA (see Table 2). Clearance from the bloodstream occurred even more rapidly at the high dose. Furthermore, a significantly lower value for the area under the curve was found for polymer and pDNA compared to the lower dose (Tables 1 and 2). With respect to organ distribution, higher accumulation of radioactivity in the lung was detectable after 2 h for both pDNA and polymer (Figure 3B), possibly due to aggregate formation and subsequent entrapment in capillary bed of the lungs (*26*). After 30 min even higher accumulation of plasmid DNA in the lungs was found (Figure 6), compatible with initial accumulation and subsequent redistribution to the liver. This initial accumulation of polyplexes in the lung seemed to be responsible for the rapid death of about one-

PEI 25 kDa ^{32}P DNA	451 ± 19	17.8 ± 6.9	1.4 ± 0.4	4.6 ± 0,6	64.1 ± 9.1
PEG−PEI ^{125}I polymer	289 ± 91	15.1 ± 0.4	1.3 ± 0.5	4.2 ± 1.6	46.0 ± 16.2
PEG−PEI ^{32}P DNA	531 ± 118	11.6 ± 1.2	3.6 ± 2.4	3.9 ± 0.5	86.5 ± 24.6

[a] PEI/DNA data could be fitted to a two-compartment model. PEG−PEI/DNA, however, showed a different profile indicating complex separation.

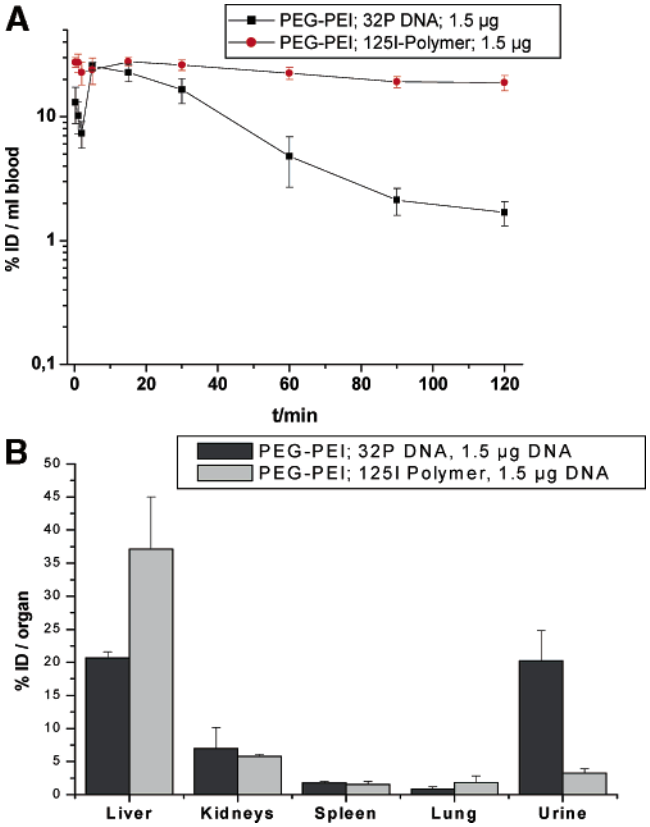

Figure 4. Blood level profiles and organ accumulation after application of PEG–PEI/pDNA complexes at a dose of ~1.5 μg of pDNA. Significant differences can be observed in blood level curves and organ depositions after 2 h, indicating a rapid separation of complex constituents at this low dose.

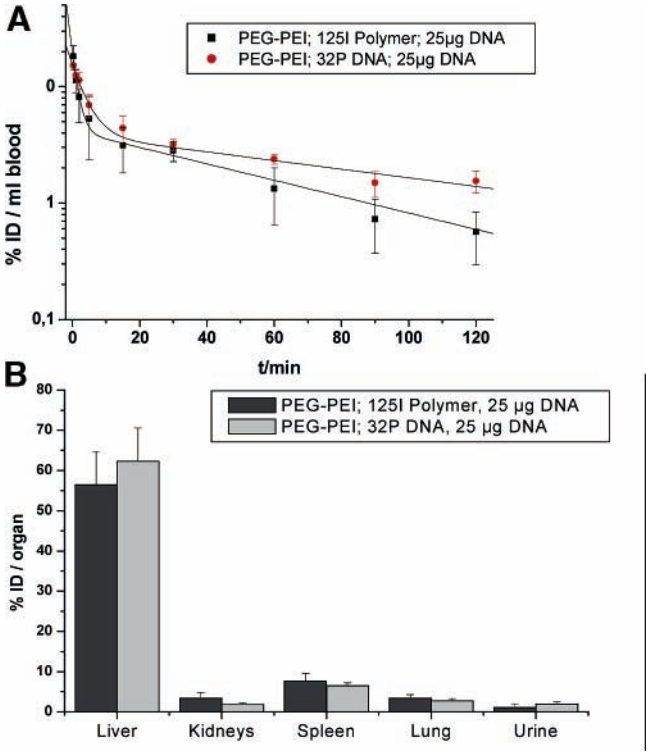

Figure 5. Blood level profiles and organ accumulation at 2 h from injection after application of PEG–PEI/pDNA complexes at a dose of 25 μg of pDNA per mouse. No enhancement of circulation time could be observed by using a PEGylated polymer; however, a significantly lower accumulation in the lung was observed compared to PEI/pDNA complexes at the same dose

fourth of laboratory animals. Measurements of radioactivity revealed enormous amounts of polymer and pDNA in the lungs of these animals, suggesting lung embolism as the most likely cause of death.

PEG–PEI/Plasmid Polyplexes at Low Dose (Figure 4). Blood level profiles and organ distribution data from PEG–PEI/DNA complexes at 1.5 μg yielded different results for the radioactive labels attached to the polymer (^{125}I) and plasmid DNA (^{32}P) (Figure 4A). While PEG–PEI displayed a rapid elimination phase initially, after approximately 5 min a plateau was reached at ~25 (% ID/mL). Blood level of PEG–PEI decreased marginally over the following 2 h. This long circulation of the PEG–PEI is thought to be caused by an efficient steric stabilization against opsonization by PEG and thus reduced uptake into the reticuloendothelial system of the liver. Another, less likely explanation could be the attachment of the PEG–PEI to, for example, cellular blood components as described earlier for cationic structures (*27*). Whereas the pharmacokinetic profile of PEG–PEI labeled with ^{125}I seemed to be attractive for intravenous delivery, the comparison with kinetic profile of ^{32}P labeled pCMV-Luc suggested a rapid dissociation of pDNA from polyplexes. After a maximum at 5 min at approximately 25% ID/mL, rapid clearance was observed. This maximum was possibly caused by an initial entrapment of pDNA or PEG–PEI/pDNA in the lung microvasculature with a subsequent time-delayed redistribution into the bloodstream as described earlier (*28*). After the maximum, the blood level of DNA decreased rapidly, reaching levels of less than 2% after 120 min.

Also organ distribution after 2 h showed differences between PEG–PEI and ^{32}P from pDNA (Figure 4B). While radioactivity from the polymer accumulated predominantly in the liver, reaching approximately 40% of injected dose, ^{32}P appeared in the liver at a significantly lower level (~20% ID). A high level of radioactivity of more than 20% ID from ^{32}P was found in the urine after 2 h. Since the size of plasmid DNA is far above the kidney threshold, this increase in urine levels was probably caused by degradation of pDNA or the ^{32}P label (*24*). Both pharmacokinetic profiles and organ accumulation support the conclusion that PEG–PEI/DNA polyplexes very likely undergo a rapid separation of polymer and DNA at this low dose. After separation, the PEG–PEI is taken up by the liver as described earlier (*9*) and a substantial amount of the injected dose circulates in the bloodstream, possibly attached to cellular blood components (*27*). Plasmid DNA, however, is probably degraded by serum nucleases rapidly after separation and degradation products are excreted.

PEG–PEI/Plasmid Complexes at High Dose (Figure 5). At a dose of 25 μg, DNA blood level profiles and organ distribution after 2 h are similar for PEG–PEI and pDNA. Again biphasic profiles were observed with a very rapid clearance from the bloodstream, displaying a $t_{1/2\ \mathrm{alpha}}$ of 1.3 min for the polymer and 3.6 min for the pDNA. Again a flat beta elimination phase follows with $t_{1/2\ \mathrm{beta}}$ of 46.0 min for the polymer and 86.5 min for pDNA. Interestingly there is no significant enhancement of the area under the curve for polymer or pDNA when PEG–PEI/pDNA complexes are compared to PEI/pDNA complexes (Table 2). Actually one intention of using PEG–PEI was to enhance circulation time. This effect could not be observed in this study with PEI(25k)-*g*-PEG(2k)$_{10}$. Organ distribution was similar at 25 μg for PEG–PEI and pDNA (Figure 5B). The majority of polymer and

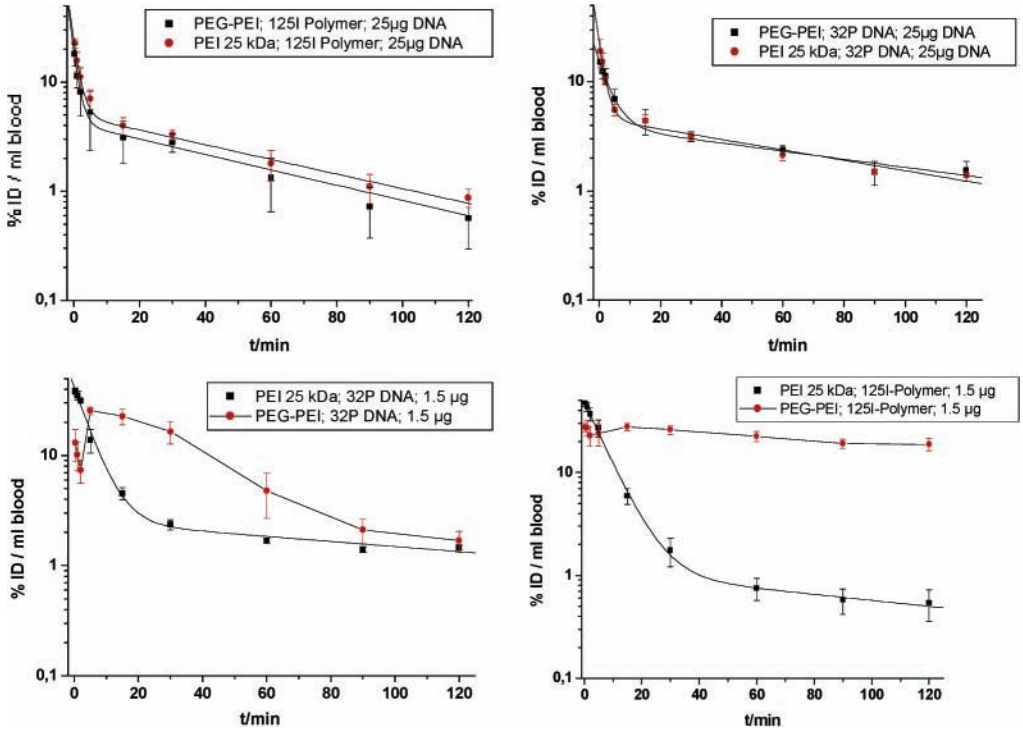

Figure 6. Comparison of blood level curves of PEI with PEG−PEI at two different doses and plasmid DNA complexed to PEI and PEG−PEI at two different doses.

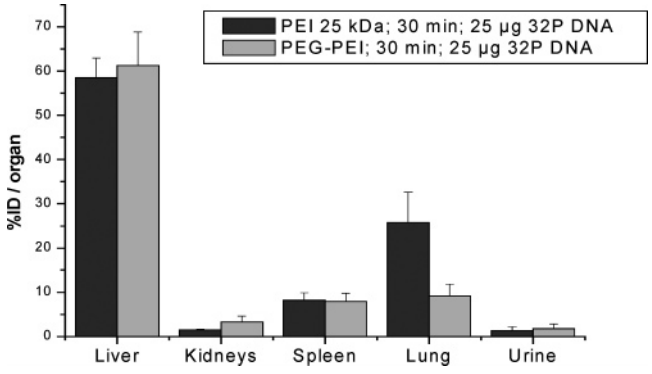

Figure 7. Organ accumulation of ^{32}P pCMV-luc from PEI/DNA and PEG−PEI/DNA complexes after 30 min using 25 μg of pDNA per mouse. A very high accumulation of pDNA can be observed for PEI/DNA complexes.

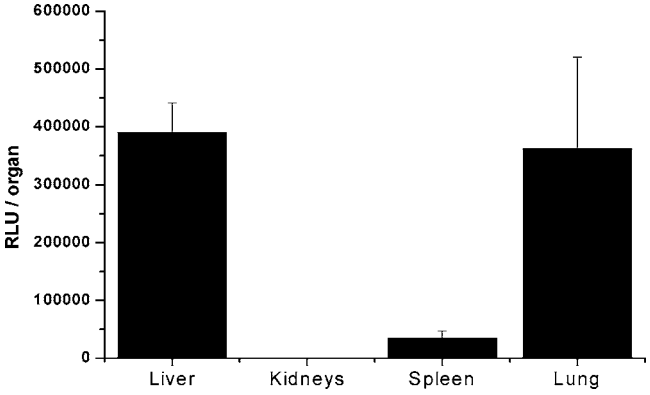

Figure 8. Gene expression pattern from PEI/pCMV-luc complexes after 48 h using ~25 μg of DNA. In the case of PEG−PEI/DNA complexes at ~25 μg and for both polymers at ~1.5 μg, no luciferase expression could be observed.

pDNA are sequestered into the liver very rapidly. Accumulation in the lung is significantly lower than that observed for PEI 25 kDa at 25 μg (Figures 3B and 7) possibly due to a lower level of aggregate formation caused by steric stabilization of complexes and a neutral surface charge provided by PEG-shielding. At this high dose much lower amounts of radioactivity were found in the kidneys and in the urine in contrast to the 1.5 μg data with PEG−PEI.

Comparisons of blood level profiles of PEI to PEG−PEI at two different doses and comparison of respective plasmid DNA curves are shown in Figure 6. At a high dose no significant differences were detected when comparing blood level profiles of pDNA complexed to either PEI or PEG−PEI. Polymer curves were very similar as well; however, in this case significant but not relevant differences were detected after 60 min. Again this indicates that PEGylation obviously does not extend circulation time of the polymer at this high dose. Concerning the low doses, however, blood level profiles were entirely different when comparing polymers among each other and respective pDNA levels such as previously described probably due to complex separation.

In Vivo Gene Expression in Mice (Figure 8). No gene expression could be detected in any organ for PEI and PEG−PEI at the low dose of 1.5 μg of DNA. This was not unexpected from results in the literature obtained with linear PEI (*26*). With the higher dose of 25 μg of pDNA, no luciferase expression was detected using PEG−PEI as a polycation. Using PEI 25 kDa, however, significant levels of luciferase expression were found in liver, spleen, and lung in accordance with the literature (*4*). Analysis of gene expression after 24 h revealed similar degrees of expression and profiles (data not shown).

Blood level profiles of polyplexes and organ distribution suggest that transfection of lung tissue is tightly associated with polyplex accumulation in the lung (*26*). Aggregates formed with cellular blood components or plasma proteins (*18*) obstructed fine lung capillaries, thus leading to a higher pressure in the microvasculature. This effect

may facilitate penetration of polyplexes across the endothelial barrier, leading to transfection of lung tissue even beyond the endothelia as described earlier (*29*, *30*). PEG−PEI/pDNA showed little or no tendency for aggregation with erythrocytes due to their neutral surface charge (*18*) and consequently accumulated to a lesser extent in the lung, preventing transfection of lung tissue in mice. This effect is expected and a prerequisite for active drug targeting.

Transfection using unmodified PEIs was accompanied by acute signs of toxicity, such as obstruction of lung vasculature (*21*, *26*). Massive damage in lung and liver tissue occurred as demonstrated by Chollet et al. (*26*). Therefore, unmodified PEI does not seem to be suitable for systemic transfection under in vivo conditions. Lung accumulation and toxicity of PEG−PEI/DNA complexes are much lower; therefore, this type of polymers appears to be more appropriate for in vivo use. A targeting moiety needs to be coupled to the polyplex to provide uptake into tumor tissues, e.g. transferrin (*31*) or epidermal growth factor for tumors (*32*).

Our data suggest that polyplexes of PEG−PEI and pDNA show a dose-dependent stability in circulation after intravenous injection. Rapid separation of pDNA from PEG−PEI polyplexes with subsequent degradation of DNA was not entirely unexpected, since PEGylated poly(L-lysine)/pDNA complexes were less stable against enzymatic degradation of DNA in vivo (*7*). The mechanism by which polyplexes are destabilized in a dose-dependent manner requires further investigations, especially to probe if there are threshold levels above which destabilization does not occur and to verify scalability across different species.

Also complexation and condensation of DNA by electrostatic interactions using polycations seemed to be influenced by the chain mobility of the polymer. This finding has consequences for the design of targetable nonviral vectors based upon polycations in which PEGylation is a requirement to avoid unspecific interaction with blood components. High grafting densities of PEG chains and relatively long PEG chains as in this case both destabilize PEGylated polyplexes under in vivo conditions. It worth mentioning that these instabilities were not detected with in vitro assays. Possibly high shear stress in the capillary beds of the lung compressed the hydrophilic coating layer leading to interactions of the positively charged core with blood components and the endothelial surface (*14*). Why separation of PEG−PEI polyplexes occurred as a saturable process merits further investigations. At higher doses PEG−PEI and pDNA remain associated and display a lower in vivo toxicity which suggests that optimization of polyplex composition, PEG−PEI structure, and the careful design of animal experiments could be promising strategies to exploit sterically shielded polyplexes for gene delivery.

Moreover, prolongation of PEG−PEI circulation in the bloodstream remains to be improved. In publications with PEGylated PEI, transfection under in vivo conditions was demonstrated; however, no pharmacokinetic evaluation was perfomed (*32*). Furthermore, all of these studies used doses of pDNA of 25 μg and above in mice (*21*, *31*, *32*). This translates into doses of almost 100 mg pDNA in humans, raising questions of practicability and potential safety of polyplexes. Therefore, polyplex formulations, which are effective at lower doses, remain an objective of high priority. A lateral stabilization of polyplexes, as described by Oupicky et al. (*33*), could improve the stability of PEG−PEI/pDNA to intravenous application of lower doses.

Apart from the obvious need to further optimize PEG−PEI polyplexes, this study highlights the necessity for more detailed mechanistic investigations of the behavior of "stealth" polyplexes under in vivo conditions. Testing of cytotoxicity in cell cultures is an important prerequisite to characterize polyplexes prior to animal studies. The lack of predictive power of in vitro assays for the performance of polyplexes in animals needs to be taken into account for further development of nonviral gene delivery systems. Moreover, the dose-dependent stability of polyplexes after intravenous injection raises questions about the possibility to separate transfection efficiency from toxic effects of polycations. Clearly more research into these issues and a standardization of animal protocols would be desirable.

ACKNOWLEDGMENT

Received November 9, 2004; Revised Manuscript Received April 29, 2005

There is a tremendous need to enhance delivery of therapeutic polypeptides to the brain to treat disorders of the central nervous system (CNS). The brain delivery of many polypeptides is severely restricted by the blood−brain barrier (BBB). The present study demonstrates that point modifications of a BBB-impermeable polypeptide, horseradish peroxidase (HRP), with lipophilic (stearoyl) or amphiphilic (Pluronic block copolymer) moieties considerably enhance the transport of this polypeptide across the BBB and accumulation of the polypeptide in the brain in vitro and in vivo. The enzymatic activity of the HRP was preserved after the transport. The modifications of the HRP with amphiphilic block copolymer moieties through degradable disulfide links resulted in the most effective transport of the HRP across in vitro brain microvessel endothelial cell monolayers and efficient delivery of HRP to the brain. Stearoyl modification of HRP improved its penetration by about 60% but also increased the clearance from blood. Pluronic modification using increased penetration of the BBB and had no significant effect on clearance so that uptake by brain was almost doubled. These results show that point modification can improve delivery of even highly impermeable polypeptides to the brain.

INTRODUCTION

Efficient delivery of therapeutic polypeptides across the blood−brain barrier (BBB) could result in improved diagnostics and treatment of diseases of central nervous system (CNS). Some examples include Parkinson's and Alzheimer's diseases (*1*−*3*), stroke (*4*, *5*), lysosomal storage diseases (*6*−*8*), and human obesity (*9*, *10*). The BBB is one of the most restrictive barriers in biology, which provides a formidable impediment for delivery of many polypeptides to the brain. Some peptides and regulatory proteins cross the BBB by saturable or nonsaturable mechanisms, whereas others cannot cross. Artificial hydrophobization of polypeptides with a small number of fatty acid residues (e.g., stearate or palmitate) was shown to enhance cellular uptake of these polypeptides in vitro (*11*). As a result of such modification, the polypeptide molecule remains water-soluble but also acquires lipophilic anchors that can target even very hydrophilic molecules to cell surfaces (*12*). The studies carried out in Russia over a decade ago have shown that modification of the Fab fragments of antibodies against gliofibrillar acid protein (GFAP) and brain-specific α-2-glycoprotein (α-2GP) with stearate moieties led to an increased accumulation of the modified Fab fragments in the brains of rats (*13*, *14*). Furthermore, a neuroleptic drug conjugated with stearoylated antibody Fab fragments was much more potent compared to the free drug. In comparison, fatty acylated Fab fragments of nonspecific antibodies did not accumulate in the brain but instead accumulated in the liver, while stearoylated Fab fragments of brain-specific antibodies displayed preferential accumulation in the brain. Subsequent studies using bovine brain microvessel endothelial cells (BBMEC) as an in vitro model of BBB demonstrated that stearoylation of ribonuclease A (approximately 13.6 kDa) increases the passage of this enzyme across the BBB by almost 9-fold (*15*).

Based on this foundation the present work focused on the development of optimal modifications of polypeptides to enhance their delivery to the brain. The studies reported here show that chemical modification of polypeptides with lipophilic and amphiphilic groups can increase the permeability of a model polypeptide, horseradish peroxidase (HRP), 40 kDa, across the BBB in vitro and in vivo. More specifically, modification of HRP with (1) stearoyl chloride or (2) Pluronic block copolymers (poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide)) increased the rate of transport of HRP across the BBB and enhanced accumulation of HRP within the brain. The paper reports for the first time conjugation of a protein with amphiphilic block copolymer moieties via biodegradable disulfide links and demonstrates that such a modification is most successful for enhanced polypeptide delivery to the brain.

EXPERIMENTAL PROCEDURES

Materials. Horseradish peroxidase type VI, MW 44 kDa (HRP), stearoyl chloride, sulfosuccinic acid bis(2-ethylhexyl)ester (AOT), dithiobis(succinimidylpropionate) (DSP), disuccinimidylsuberate (DSS), 4-methoxytrityl chloride (MTr-CL), 1,1′-carbonyldiimidazole, ethylendiamine, 2,4,6-trinitrobenzenesulfonic acid (TNBS), trifluoroacetic acid, acetone, dichloromethane, dimethylform-

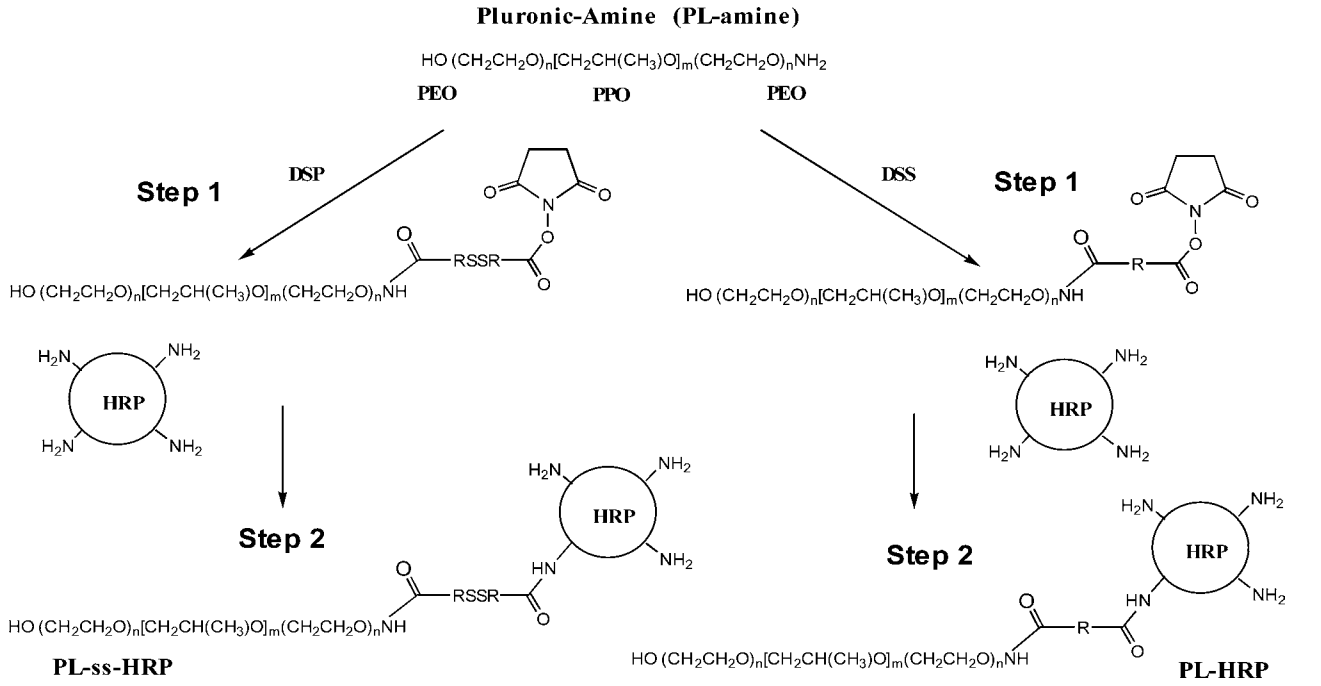
Scheme 1. Synthesis of Pluronic−HRP Conjugates[a]



[a] Step 1: Pluronic-amine is activated by bifunctional reagents (DSP or DSS) to obtain hydroxysuccinimide derivatives of Pluronic capable of reacting with the protein amino groups. Step 2: the excess of the reagents was removed by gel filtration, and the activated polymers were immediately reacted with HRP.

amide, anhydrous acetonitrile, and pyridine were obtained from Sigma-Aldrich Co. (St-Louis, MO). Pluronic P85 (lot no. WPOP-587A) and Pluronic L121 (lot no. WPAC-550B) were kindly provided by BASF Corp. (Parispany, NJ). All other reagents were of analytical grade.

Chemical Modification of HRP with Stearic Acid Chloride in Reverse Micelles. Modification of amino groups of HRP by stearoyl chloride was performed in the reverse micelle system of AOT in octane as described earlier (*12*). Briefly, HRP solution (2.5 mg/mL) in 0.1 M sodium borate buffer (pH 9.5) was mixed with a 10-fold volume excess of 0.3 M AOT solution in octane. The emulsion was vigorously shaken for 10 min until an optically transparent solution was obtained. Following a 2-hour incubation at room temperature, the protein was precipitated in a 5-fold volume excess of cold acetone (−20 °C) with subsequent centrifugation at 2000 rpm. The precipitate was washed three times with cold acetone, dried, and dissolved in 0.1 M borate buffer (pH 9.5). The product was purified of low molecular residuals by gel-permeation chromatography on a Sephadex G25 column (Amersham, Piscataway, NJ). The protein recovery was determined by BCA Pierce method (*16*). The modification degree (the number of fatty residues introduced in a protein molecule) of HRP was determined by titration of free amino groups with TNBS as described below.

Conjugation of HRP with Pluronic Block Copolymers. *Preparation of Monoamino Derivatives of Pluronics P85 and L121.* A Pluronic molecule contains two terminal hydroxyl groups, both of which can be used for conjugation with proteins. To obtain the monoamino derivative of Pluronic, one of the hydroxyl functions was protected with a 4-methoxytrityl (MTr) group. For this purpose, Pluronics (P85 or L121) were dried by coevaporation with anhydrous pyridine in vacuo at 50 °C. Then, the dried polymer was mixed with an equimolar amount of MTr-CL in anhydrous pyridine, and the obtained mixture was incubated at room temperature for 3 h. The reaction was stopped by addition of methanol, and pyridine was removed in vacuo by coevaporation with toluene. The monosubstituted product, MTr-Pluronic, was purified from nonmodified polymer and traces of bis-MTr-Pluronic by absorption chromatography on a Silicagel column (4.5 cm × 10 cm) in dichloromethane using stepwise elution with dichloromethane containing 2%, 5%, or 10% of methanol. Mono-MTr-Pluronic was dried by coevaporation with anhydrous acetonitrile in vacuo, and then incubated with 3-fold molar excess of 1,1′-carbonyldiimidazole in anhydrous acetonitrile for 4 h at 40 °C. Activated Pluronic was dissolved in ethanol and added dropwise to 10-fold excess of ethylenediamine in ethanol to obtain polymer with one side amino group as described elsewhere (*17*). The product was dialyzed against 10% ethanol to remove low molecular weight compounds. Removal of the MTr group from the polymer was achieved with 2% trifluoroacetic acid in dichloromethane. All synthetic steps have been controlled by thin-layer chromatography on Silicagel-coated plates using a dichloromethane/methanol (9:1) mixture as an eluent. Monoamino derivatives of Pluronics have been isolated by gel-permeation chromatography on the Sephadex LH-20 column (2.5 cm × 45 cm) in methanol as eluent. Colorimetric analysis of fractions with ninhydrine detected the presence of amino groups in the product. Amino-group content was analyzed by titration of the polymers with TNBS (*18*) and was equivalent to >45% substitution of all hydroxyl groups in Pluronics.

Conjugation of HRP with Monoamino Derivatives of Pluronics P85 and L121 via a Biodegradable Link (DSP method). To obtain a biodegradable link, HRP was conjugated with Pluronics through a reducible disulfide bond (Scheme 1). Pluronic-amine is activated by a bifunctional reagent, DSP, to obtain a hydroxysuccinimide derivative of Pluronic capable of reacting with the protein amino groups (step 1). Excess of the reagent was removed by gel filtration, and the activated polymers were immediately reacted with HRP (step 2). Briefly, monoamino derivatives of Pluronics were first dissolved

in methanol (70 μmol) and added dropwise to a stirred solution of DSP (0.2 mmol) in dimethylformamide at 25 °C. Following the 30-min reaction at room temperature, the DSP-modified Pluronic was purified by gel-filtration chromatography on a Sephadex LH 20 column in methanol. The product was concentrated in vacuo and dissolved in 20% ethanol. A solution of HRP (2 μmol) in 0.1 M borate (pH 9.5) was mixed with a DSP-modified Pluronic solution prepared earlier, and the homogeneous reaction mixture was incubated overnight at 4 °C. Modified HRP was precipitated in cold (−10 °C) ethanol, incubated at 4 °C for 30 min, and separated from the excess of DSP-modified Pluronic by centrifugation at 3000 rpm for 20 min at 4 °C. Brown precipitate was washed with cold ethanol and dried in vacuo. Pluronic−HRP conjugate was purified by cation-exchange chromatography on TSK CM-650M resin with 10 mM sodium acetate (pH 4.4), 10 mM NaCl, and 5% ethanol as an eluent. First, elution of Pluronic−HRP was performed with this eluent, and then a gradient of NaCl (from 0.01 to 0.15 M) was used for elution of residual (unconjugated) HRP. Collected fractions were desalted in dialysis tubes with a molecular weight cutoff of 20 kDa (SpectroPor, Fisher Scientific, Pittsburg, PA) against water overnight at 4 °C and freeze-dried. The obtained conjugate was analyzed for protein and salt contents using the analytical procedures described below.

Conjugation of HRP with Monoamino Derivatives of Pluronics P85 and L121 by Nonbiodegradable Bond (DSS method). To obtain a nonbiodegradable link, monoamino derivatives of Pluronics were conjugated with HRP similar to the method described above except using DSS, instead of DSP (Scheme 1).

Analysis of HRP Conjugates. *Protein Assay*. The BCA Kit from Pierce (Rockford, IL) was used to measure protein content in the obtained HRP conjugates. The obtained conjugates (1.0 mg/mL) were dissolved in water and mixed with coloring solutions according to the manufacturer's protocol. Mixtures were incubated for 30 min at 37 °C, and absorbance values were measured at 550 nm using a microplate reader Multiskan MCC/340 (Fisher Scientific, Pittsburgh, PA) as described elsewhere (*16*).

HRP Enzymatic Activity. The enzymatic activity of HRP in the obtained conjugates was assessed with *o*-phenylenediamine as described earlier (*12*). Briefly, conjugate solutions (0.1 mg/mL) were mixed in a 96-well plate with the solution of *o*-phenylenediamine (5 mg/mL) in 0.1 M citrate buffer (pH 5) containing 1 mg/mL bovine serum albumin (BSA), 0.1% Triton, and hydrogen peroxide solution (0.02%). After incubating the mixture for 5 min at 37 °C, the reaction was stopped by the addition of 0.5% sodium sulfite in 2 M sulfuric acid, and absorbance was measured at 550 nm using the microplate reader Multiskan MCC/340. The activities were related to HRP concentration in the sample.

Modification Degree. The modification degree of HRP (the number of fatty residues or Pluronic molecules introduced in a protein molecule) was determined by titration of the free amino groups of the protein with TNBS as described elsewhere (*18*). Briefly, solutions of native and modified protein (1 mg/mL) were mixed with 5% TNBS solution in 0.1 M sodium borate buffer (pH 9.5) in 96-well plate. Reaction mixtures were incubated for 1 h at 25 ° C, and absorbance was measured at 405 nm using the microplate reader. The degree of modification was calculated using following equation:

$$S_i = 4N_o(A_oN_o - A_i/N_i)/A_o \quad (1)$$

where N_o and N_i were protein content and A_o and A_i were amino group content in native and modified protein, respectively.

Binding of HRP Conjugates to the Brain Endothelial Cells. BBMEC were used as an in vitro model of the BBB in these studies. BBMEC were isolated from cow brains using mechanical and enzymatic disruption of brain matter coupled with gradient separation as described earlier (*19*). Cells were seeded onto collagen-coated, fibronectin-treated 24-well culture plates at a density of 50 000 cells/cm^2 and grown using media consisting of 45% minimum essential medium (MEM), 45% Ham's F-12 (F12), and 10% horse serum supplemented with antibiotics and heparin sulfate and used after reaching confluency (typically 10−12 days). All tissue culture media was obtained from Gibco Life Technologies, Inc. (Grand Island, NY). The BBMEC monolayers were incubated with unmodified HRP or the conjugates for various time points up to 120 min. Then, the cell monolayers were washed with 1% BSA in phosphate-buffered saline (PBS) and then washed in BSA-free PBS. The cells were then lysed in 1% Triton X100, and the net amount of the cell-bound enzyme was determined by colorimetric reaction with *o*-phenylenediamine in 0.1 M citrate buffer (pH 5) containing 0.1% Triton X100, 1 mg/mL BSA, and 0.02% hydrogen peroxide as described above. The amount of HRP was normalized by the amount of cell protein as determined by the Pierce BCA assay.

Transport of HRP Conjugates across BBMEC Monolayers. Isolated BBMEC were seeded on fibronectin- and collagen-coated polycarbonate membrane inserts (Transwell, Costar Permeability Supports, Cole-Parmer Instruments Co, Vernon Hills, IL, Contd.; pore size 0.4 μm; diameter 24.0 mm) at a density of 250 000 cells per insert and allowed to grow and differentiate for up to complete maturation of the monolayers (typically within 14 days). The trans-epithelial electrical resistance (TEER) of the monolayers was recorded as an index of cell viability and monolayer integrity. The TEER values of the confluent BBMEC monolayers were no less than 130.0 Ω·cm^2. Polycarbonate membrane inserts with confluent BBMEC monolayers were placed in Side-Bi-Side diffusion cells from Crown Bio Scientific, Inc. (Somerville, NJ) maintained at 37 °C, and the transport of HRP conjugates across cell monolayers was determined as described earlier (*20*). Briefly, for luminal to abluminal transport studies, the assay buffer at the luminal (apical) side was removed and replaced with the assay buffer containing solutions of the modified or native HRP (40 μg/mL). The solutions in the donor chamber also contained 1 nM H^3-mannitol as a paracellular marker (DuPont Corp., Boston, MA). At various time points, the solutions in the receiver chamber (at the basolateral side of the monolayers) and aliquots (20 μL) from the donor chamber (at the apical side of the monolayers) were removed for the determination of the HRP concentration. The enzyme activity of HRP was measured using the *o*-phenylenediamine method as described above. ^{3}H-mannitol concentrations were determined using Beckman LS 6000 IC liquid scintillation counter (Beckman Counter, Inc., Fullerton, CA). All transport experiments were conducted in triplicate. Apparent permeability coefficients (P_{app}) of the polypletides were calculated using the following equation:

$$P_{app} = \frac{1}{AC_0}\frac{dQ}{dt} \quad (2)$$

where dQ/dt is the flux across the cell monolayers, A is the surface area of the membrane, and C_0 is the initial concentration of the drug.

Localization of HRP Conjugates in BBMEC Monolayers. For this study, HRP conjugated with Pluronic P85 via the biodegradable DSP bond (Scheme 1) was used. The native and modified proteins were labeled with Alexa Fluor 594 protein labeling kit (Molecular Probes Inc., Eugene, OR) according to the manufacture's protocol. BBMEC grown on chamber slides (Fisher, St. Louis, MO) were incubated with Alexa-labeled native or P85-modified HRP (1 mg/mL) in assay buffer for 2 h at 37 °C. Following incubation, the loading solutions were removed, and cell monolayers were washed three times with ice-cold PBS containing 1% BSA and examined with a Zeiss LSM 410 confocal laser scanning microscope, CLSM (Goettinger, Germany). All pictures were taken at the same brightness and contrast.

In Vivo Transport of St−HRP and Pluronic−HRP Conjugates to the Brain. *Radioactive Labeling of HRP.* Native, Pluronic P85-modified, or stearoyl-modified HRP were labeled by the chloramine-T method (i.e., excluding the sodium metabisulfite treatment) (*21*). Briefly, 1 mCi of ^{131}I (New England Nuclear, Boston, MA), 10 μg of chloramine T, and 5.0 μg of protein were incubated together for 60 s. The reaction was halted by adding 10 μg of sodium metabisulfite. The iodinated materials were purified by filtration on Sephadex G10 (Sigma Chemical Co., St. Louis, MO) columns. Incorporation of the radioactive ^{131}I, as determined by TCA/brine precipitation, was greater than 90% for all materials, and the specific activities were estimated to be between 50 and 150 Ci/g of protein. Albumin was labeled with ^{99m}Tc with stannous tartrate (*22*) and purified on a column of Sephadex G-10.

Measurement of Unidirectional Influx Rates. Male CD-1 mice (Charles River Labs, Wilmington, MA) weighing 20−30 g were anesthetized with an ip injection of 40% ethyl carbamate. The left jugular vein and right carotid artery were isolated. A volume of 0.2 mL of 1% BSA in lactated Ringer's solution was injected into the jugular vein. The injection contained 1×10^5 cpm of a radioactively iodinated native or Pluronic- or stearoyl-modified HRP. Between 2 and 180 min after injection, blood was obtained from the carotid artery, and the mouse was decapitated. The brain was removed, the pineal and pituitaryglands were discarded, the remainder of the brain was weighed, and the levels of radioactivity were determined in a γ counter that could simultaneously count ^{131}I. The whole blood was centrifuged at 5000g for 10 min at 4 °C, and the level of radioactivity was determined in the resulting serum. The brain/serum ratio was calculated with the equation

$$\text{brain/serum ratio } (\mu\text{L/g}) = (\text{cpm/g of brain})/(\text{cpm}/\mu\text{L of serum}) \quad (3)$$

To adjust for clearance of the protein from the blood, exposure time (expt) was calculated from the equation

$$\text{expt} = [I_0^{\,t}\text{Cp}(J)\text{d}J]/\text{Cpt} \quad (4)$$

where Cpt is the level of radioactivity in serum at time t, and J is the dummy variable for time (*23*, *24*). Brain/serum ratios of the protein content were plotted against expt, and the regression line for the linear portion of the relation was calculated. The slope of this relation measures K_i and the intercept measures the distribution volume within brain at $t = 0$ (V_i in units of μL/g). Lack of a statistically significant relation between the brain/serum ratios and expt indicates either that the protein does not cross the BBB or that a steady state between the rate of influx and efflux has already been reached.

Calculation of the Percent of Injected Proteins Taken up by Brain. The clearance of the radioactively labeled native, Pluronic-modified, or stearoyl-modified HRP from blood was first characterized. The amount of radioactivity injected intravenously was divided by the level of radioactivity in serum to yield the percent of injected radioactivity present in 1 mL of serum (% inj/mL):

$$\%\ \text{inj/mL} = 100(\text{cpm of injected radioactivity})/(\text{cpm/mL of serum}) \quad (5)$$

To calculate the percent of the injected dose of the protein entering a gram of brain (% inj/g), % inj/mL was divided by 1000 to convert it to units of % inj/μL. The brain/serum ratios for the HRPs were corrected for vascular contamination by subtracting10 μL/g. The resulting brain/serum ratio was then multiplied by % inj/μL to yield % inj/g. The area under the curve (AUC) was calculated with Prism 4.0 software, which uses the trapezoidal method.

Capillary Depletion. To distinguish whether the native, stearoyl-modified, or Pluronic-modified HRP taken up by brain tissue was sequestered by the brain endothelial cells, which comprise the BBB or was transported fully across them into brain tissue, we performed capillary depletion with the protocol adapted to mice (*25*) from rats (*26*). CD-1 male mice anesthetized with ip ethyl carbamate received an iv injection of 0.2 mL of lactated Ringer's solution containing 1% BSA, 1×10^6 cpm of a radioactively labeled native, stearoyl-modified, or Pluronic-modified HRP, and 1×10^6 of ^{99m}Tc-labeled albumin. Blood from the abdominal aorta was collected. The thorax was then opened to expose the heart, both jugular veins were severed, the descending thoracic aorta was clamped, and 20 mL of lactated Ringer's solution was injected into the left ventricle of the heart within about 1 min. The cerebral cortex was removed 30 or 120 min after iv injection. The cerebral cortex was weighed and emulsified with a glass homogenizer (10 strokes) in 0.8 mL of physiological buffer (10 mM HEPES, 141 mM NaCl, 4 mM KCl, 2.8 mM $CaCl_2$, 1 mM $MgSO_4$, 1 mM NaH_2PO_4, and 10 mM D-glucose adjusted to pH 7.4). Dextran solution (1.6 mL of a 26% solution) was added to the homogenate, and the suspension was vigorously mixed and homogenized again (3 strokes). Homogenization was performed at 4 °C in less than 1 min. An aliquot of the homogenate was centrifuged at 5400g for 15 min at 4 °C in a Beckman TL-100 ultracentrifuge with a TLS-55 swinging bucket rotor. The pellet containing the brain vasculature and the supernatant containing the brain parenchyma were carefully separated. The levels of radioactivity in these fractions and in the aortic serum were determined in a γ counter. The fractions were expressed as volumes of distribution in μL/g, and the parenchymal fraction for HRP was corrected for vascular contamination by subtracting the value for the parenchymal fraction for albumin (P_v). The amount of HRP retained by brain capillaries (*5*) was measured by the volume of distribution for the vascular fraction from this experiment.

Statistical Analysis. All statistical tests were performed by Microsoft Excel XP program using the two-tailed heteroscedastic t-tests. A minimum p value of 0.05 was estimated as the significance level for all tests. SEM values for modified and native HRP accumulation and transfer levels were less than 10% of the mean.

RESULTS

Chemical Modification of HRP with Stearic Acid Chloride in Reverse Micelles. The HRP contains six amino groups available for chemical modification. To modify these groups with stearic acid residues, the enzyme was reacted with stearoyl chloride in the reverse micelle system of AOT in octane (*12*). Based on the titration of the remaining free amino groups of the protein with TNBS (see Experimental Procedures section), an average of 1.1 stearic acid residues per protein molecule was introduced onto HRP under these conditions. The solubility of the stearoylated HRP (St−HRP) was approximately 1 mg/mL, its RZ (absorbance ratio A_{403}/A_{280}) was 2.7, and the catalytic activity was 50% of the native HRP activity (RZ of native HRP was 3.0).

Conjugation of HRP with Pluronic Block Copolymers. Pluronics have a three-block ABA structure, where the A block is hydrophilic poly(ethylene oxide) (PEO) and the B block is a lipophilic poly(propylene oxide) (PPO) chain. Variations in the length of the blocks result in copolymers with different molecular masses and hydrophilic−lipophilic balances (HLB). We synthesized conjugates of HRP with Pluronic P85, a copolymer of intermediate lipophilicity, and Pluronic L121, a highly lipophilic copolymer. Initially monoamino derivatives of P85 and L121 were prepared as described in the Experimental Procedures section. These derivatives, "Pluronic-amine" were then conjugated to HRP using a two-step procedure shown in Scheme 1. First, Pluronic-amines were activated with DSP or DSS reagents. Second, the products of these reactions were linked to the amino groups of HRP. The DSP reagent was used to introduce a degradable disulfide linkage between the HRP and Pluronic molecules, while the DSS linkage was not degradable. To vary the number of copolymer chains per protein molecule, different excesses of activated Pluronic were used. The conjugation steps are described in greater detail in the Experimental Procedures section. The modified proteins were isolated by precipitation in cold ethanol and then purified by ion-exchange chromatography (Figure 1). TNBS analysis demonstrated that the products contained mainly mono- and bis-substituted protein. The fractions of unmodified HRP did not exceed 25%. The unmodified HRP was discarded, while the fractions of modified protein (peaks 1 and 2) were combined for each conjugate and used in subsequent studies. Overall, four conjugates with stable or degradable linkages and different modification degrees were synthesized as shown in Table 1. Residual activity of modified proteins was about 90−100%.

Binding and Transport of Stearoyl-Modified HRP across BBMEC Monolayers. The stearic acid was conjugated to the HRP molecule via a nonbiodegradable bond. The effect of this modification on the binding of HRP with brain endothelial cells was studied using BBMEC monolayers. The results are presented in Figure 2. Modification of HRP resulted in about a 3-fold increase of its binding with the BBMEC.

Figure 3 shows the effect of stearoyl modification on HRP transport across BBMEC monolayers from the apical to the basolateral side. As is seen in Figure 3, HRP modification increased the apparent permeability coefficient (P_{app}) about 1.6 times (3.8×10^{-7} cm/s) when compared with the nonmodified HRP (2.4×10^{-7} cm/s). Equally important, there were no changes in TEER or permeability of a paracellular marker, ^{3}H-mannitol, demonstrating that the integrity of the monolayers was not altered.

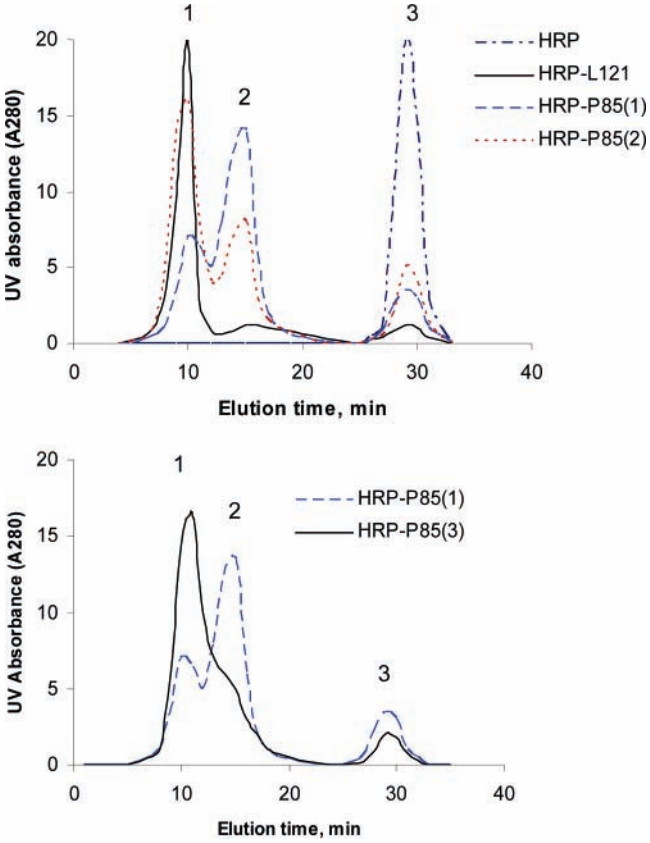


Figure 1. Chromatographic isolation of the HRP−Pluronic conjugates using TSK CM-650 column (2 cm × 15 cm) in NaCl salt gradient (0.01−0.2 M) (pH 4.5, elution rate 2 mL/min, detection at 280 nm). The peaks correspond to (1) bis-substituted HRP, (2) monosubstituted HRP, and (3) unmodified HRP. The substitution degree in each fraction was confirmed by the TNBS assay.

Table 1. Characteristics of HRP−Pluronic Conjugates

conjugate	Pluronic excess	type of link	modification degree[a]	residual activity, %[b]
HRP−P85 (1)	50	degradable	1.4	97
HRP−P85 (2)	50	stable	1.6	100
HRP−P85 (3)	70	degradable	2.0	89
HRP-L121	70	degradable	2.1	95

[a] Average number of Pluronic chains per HRP molecule determined using TNBS titration assay. [b] Compared to the native HRP, *o*-phenylenediamine reaction.

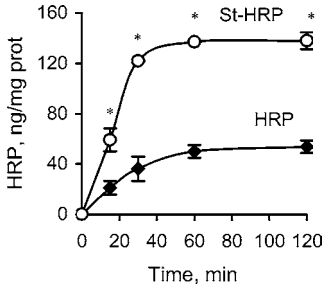

Figure 2. Binding of unmodified HRP and St−HRP with BBMEC monolayers. Data are mean ± SEM ($n = 4$). Asterisk (*) shows significant difference between HRP and St−HRP groups. Modification of HRP resulted in about a 3-fold increase of its binding with the cells.

Binding and Transport of Pluronic−HRP Conjugates across BBMEC Monolayers. Figure 4 presents the results of the study of binding of various Pluronic−HRP conjugates with BBMEC monolayers. The cells were

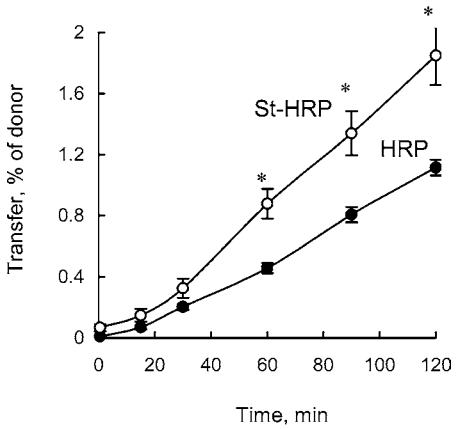

Figure 3. Apical to basolateral permeability of HRP and St−HRP in BBMEC monolayers. Data are mean ± SEM ($n = 4$). Asterisk (∗) shows a significant difference between HRP and St−HRP. Stearoyl modification of the protein results in about a 1.6-fold increase in its transport across the BBMEC.

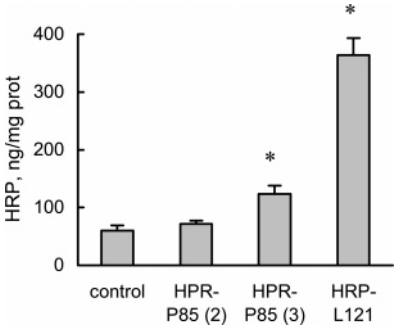

Figure 4. Binding of unmodified HRP and Pluronic−HRP conjugates (described in Table 1) with BBMEC monolayers at 60 min incubation. Results are mean ± SEM ($n = 4$). Asterisk (∗) shows a significant difference compared to HRP. Modification of HRP with Pluronic increases the binding (about 6 times for HRP−L121) of this protein with BBMEC.

incubated with unmodified HRP or the conjugates for 60 min, and the net amount of the cell-bound enzyme was determined as described above. There was practically no difference in binding between the unmodified HRP and the HRP−P85 (2) containing a nondegradable link. However, binding of conjugates containing the cleavable disulfide link, HRP−P85 (3) and HRP−L121, was increased significantly. The most pronounced effect (over 6-fold increase in binding) was observed in the case of the lipophilic Pluronic L121 conjugate. This result was consistent with our earlier report suggesting strong binding of this lipophilic block copolymer with the BBMEC membranes (*27*). HRP−P85 (3) displayed a only a 2-fold increase in cell binding compared to HRP.

The study of the permeability of various Pluronic−HRP conjugates across BBMEC was carried out in two steps. The initial experiment compared Pluronic−HRP conjugates with nondegradable and degradable links and unmodified HRP (data not shown). Modification of HRP with P85 via nondegradable link, HRP−P85 (2) resulted in about a 2-fold increase in the HRP transport. The conjugate containing a cleavable link, HRP−P85 (3), was transported almost 6 times faster than the unmodified HRP. Finally, the conjugate with the lipophilic Pluronic L121, also containing a cleavable linkage, displayed the highest rates of transport across the BBMEC monolayers. The rate of its transport was over 10-times higher than that of the unmodified HRP. Noteworthy, the amount of HRP transported across the BBMEC monolayers was determined using enzymatic reaction with the HRP

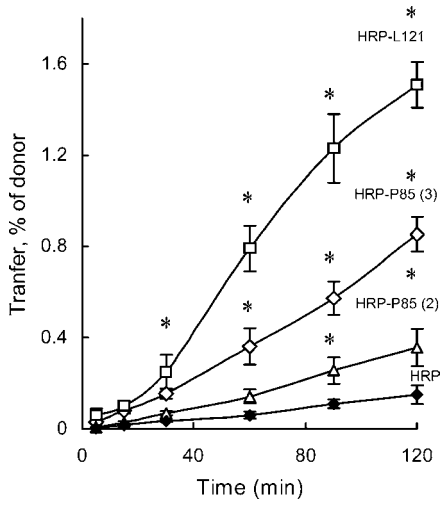

Figure 5. Apical to basolateral permeability of HRP and Pluronic−HRP in BBMEC monolayers. Data are mean ± SEM ($n = 4$). Asterisk (∗) shows significant difference between HRP and Pluronic−HRP groups. Conjugation of HRP with Pluronics via the biodegradable linkage resulted in the greatest increase (over 10-fold for HRP−L121) in permeability across the BBMEC.

substrate, *o*-phenylenediamine, suggesting that enzymatic activity of the protein was preserved during the transport across the cellular monolayers. Based on this experiment, Figure 5 compared conjugates of HRP with degradable links, HRP−L121 and HRP−P85 (3), as well as St-HRP and unmodified HRP. There were no changes in ^{3}H-mannitol permeability (not shown). At the same time, there were substantial differences in the permeability of different HRP samples increasing in the order HRP < HRP−St < HRP−P85 (3) < HRP−L121. Overall, conjugation of the enzyme with the highly hydrophobic Pluronic L121 via the biodegradable link resulted in the greatest increase in its transport across BBMEC monolayers. The P_{app} values were as follows: HRP 1×10^{-7} cm/s; St−HRP 3×10^{-7} cm/s; HRP−P85 (3) 7.8×10^{-7} cm/s; HRP−L121 10.4×10^{-7} cm/s. A separate experiment using HRP−P85 (3) labeled with Alexa FLUOR 594 determined that the amount of HRP associated with BBMEC monolayers was approximately 11.8% ± 0.3% at 60 min and 12.1% ± 0.4% at 120 min, while the amount of transferred enzyme was increasing in time reaching 3.6% ± 0.4% at 120 min.

Localization of HRP Conjugates in BBMEC Monolayers. Figure 6 shows confocal microscopy images of intracellular localization of a nonmodified protein, HRP (A, B), and HRP conjugated with Pluronic block copolymer P85 (C, D) in BBMEC monolayers. Pictures B and D represent fluorescent images; A and C represent differential interference contrast (DIC) and fluorescence images combined. HRP was linked to Pluronic P85 by a biodegradable disulfide linkage (conjugate HRP−P85 (3)). As is seen in the figure, unmodified HRP does not enter the barrier cells (A, B). Modification of the protein with Pluronic block copolymer drastically enhanced transport of HRP into the cells with accumulation in the cytoplasm, nuclei, and other cellular organelles (C, D).

Transport of St−HRP into the Brains of Mice. Figure 7 shows that linear relations existed between brain/serum ratios and exposure times for St−HRP ($r = 0.979$, $n = 7$, $p \ll 0.001$) to about 100 min and for HRP ($r = 0.959$, $n = 10$, $p \ll 0.001$) for over 250 min. This indicates passage across the BBB for both compounds and allows computation of K_i for those time periods. The K_i for St−HRP was 0.192 ± 0.018 μL/(g·min) and for HRP

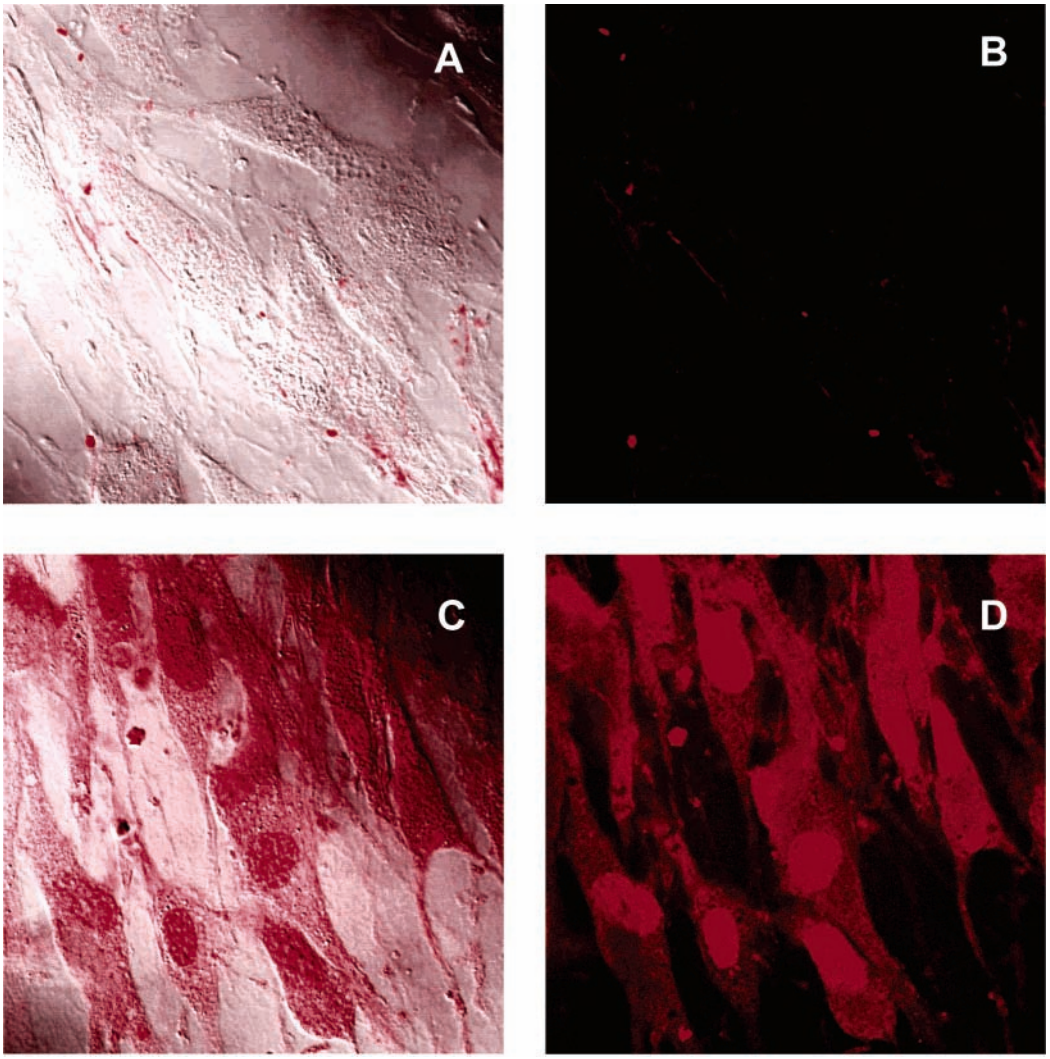

Figure 6. The confocal microscopy images showing the intracellular localization of Alexa-HRP (A, B), and Alexa-P85−HRP (C, D) in BBMEC monolayers. Pictures B and D represent fluorescent images; A and C represent differential interference contrast (DIC) and fluorescence images combined. HRP was linked to Pluronic P85 via a biodegradable disulfide linkage. The cells were exposed to Alexa-labeled native and modified HRP solutions for 2 h and washed with PBS. Modification of the protein with Pluronic L121 drastically enhanced transport of HRP into the cells with accumulation in the cytoplasm, nuclei, and other cellular organelles.

was 0.079 ± 0.008 μL/(g·min), a 2.4-fold difference. The two values differed from each other at the $p < 0.001$ level. The rate for HRP is only a little faster than the upper range usually measured for the entry of albumin.

Figure 8A shows the clearance of St−HRP and HRP from the blood. The half-time clearance (calculated with the first time point excluded for each compound) was 89.5 min for St-HRP and 79.6 min for HRP. The volume of distribution for St-HRP was 7.67 mL and for HRP was 5.93 mL. Statistical analysis showed that the slopes (half-time clearance rates) of these lines were not different, but that the intercepts (volume of distribution) were different: $F(1,1) = 7.65$, $p < 0.05$.

The percent of the injected dose taken up by brain (%inj/g) depends on two factors: the rate of entry into brain and the peripheral pharmacokinetics (such as half-time clearance rate and volume of distribution). Figure 9A shows the %inj/g for the first 180 min after injection of these compounds. St−HRP peaked higher and sooner. The ratio of the AUC for stearoyl-modified protein vs native protein (St−HRP/HRP) was 1.6 for the first 90 min of the experiment, but only 1.13 for the entire 180 min.

Figure 10 A,B shows results for capillary depletion after vascular washout and correction for albumin space with Tc−albumin for St−HRP and HRP. As is seen in Figure 10A (performed at 30 min), little or no St−HRP or HRP taken up by brain had been retained by capillaries but had all entered the brain parenchymal space. Two-way ANOVA showed significant effects for compound ($p < 0.001$), region ($p < 0.001$), and interaction ($p < 0.001$). Figure 10B shows parenchymal levels at 30 and 120 min. More HRP and St−HRP was found in the parenchymal compartment at 120 than 30 min, but at both times, entry favored St−HRP. A two-way ANOVA was significant for compound ($p < 0.05$) and time ($p < 0.05$) but not interaction.

Transport of HRP−P85 Conjugate into the Brain of Mice. Pluronic block copolymer with intermediate hydrophilic−lipophilic properties, P85, conjugated with HRP by biodegradable linkage (conjugate HRP−P85 (3), Table 1) was used for these studies. The unidirectional influx rate (K_i) for HRP−P85 was 0.0800 ± 0.0173 μL/(g·min) (regression line based on $n = 10$, $r = 0.853$, $p < 0.005$), and the K_i for HRP was 0.0206 ± 0.0081 μL/(g·min) ($n = 10$, $r = 0.669$, $p < 0.05$), a 3.9-fold increase, Figure 7B. The significant p values show that there was a statistically significant correlation between brain/serum ratios and exposure time and so indicates that both compounds crossed the BBB. The line for HRP−P85 was linear for about 180 min and for HRP for about

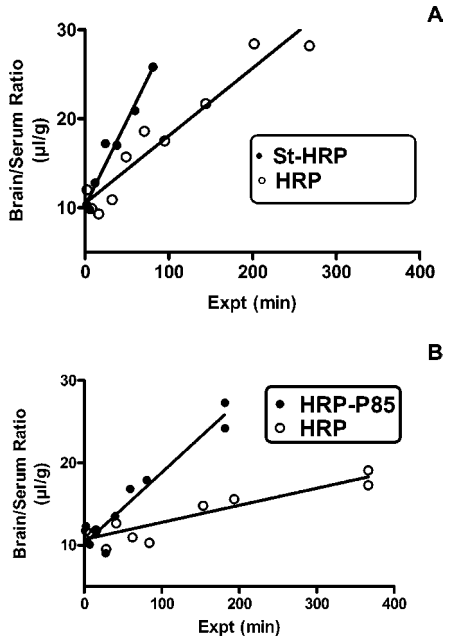

Figure 7. Comparison of blood-to-brain transport for St−HRP (A) and HRP−P85 (B) vs HRP. Modification of HRP increased K_i by 2.4-fold for St−HRP and by 3.9-fold for HRP−P85.

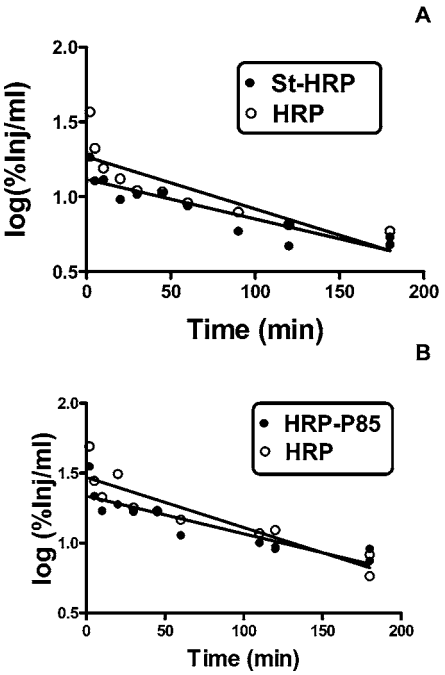

Figure 8. The percent of injected radioactivity present in 1 mL of serum (%inj/g) following injection of St−HRP and HRP (A) or HRP−P85 and HRP (B).

360 min. The K_i for HRP−P85 was about 3.9 times higher than the K_i for HRP, and this was significantly different: $F(1,16) = 9.27$, $p < 0.01$.

The half-time clearance from blood did not differ between the two compounds (Figure 8B), being 131 min for HPR−P85 and 94.5 min for HRP (2 min time points excluded). The volume of distribution after iv injection also did not differ between HPR−P85 (5.17 mL) and native HRP (3.82 mL).

Figure 9B compares the values for %inj/g for HRP−P85 and HRP. The curves differed little for the first 30 min, but thereafter, uptake of HRP−P85 exceeded that

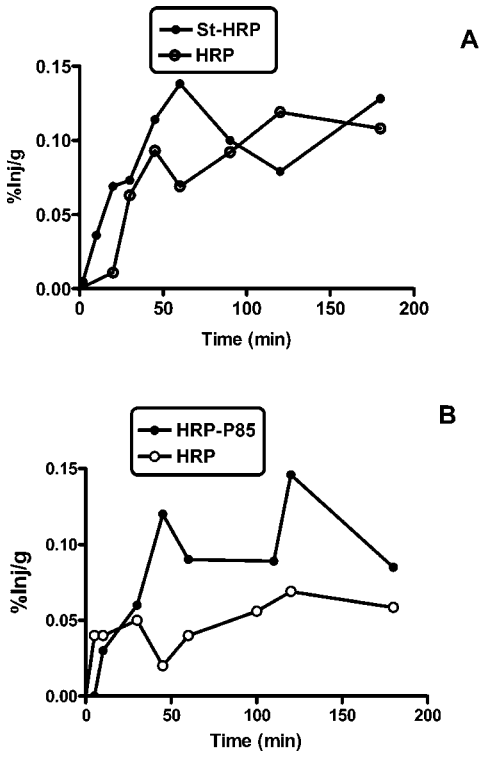

Figure 9. Modification of the protein with stearoyl or Pluronic moiety increased the AUC for brain uptake by 13% (St−HRP) and 82% (HRP−P85) during the 180 min of the experiment.

of HRP. The ratio of the area under the curve (HRP−P85/HRP) was 1.82.

Figure 10 shows results for capillary depletion after vascular washout and correction for albumin space with Tc−albumin. Figure 10C shows that at 30 min little or no HRP−P85 or HRP taken up by brain had been retained by capillaries but had all entered the brain parenchymal space. Two-way ANOVA test showed significant effects for region ($p < 0.05$) but not for compound or interaction. The lack of difference between these compounds is consistent with the %inj/g results, which showed HRP−P85 and HRP similar at that time point. Figure 10D shows parenchymal levels at 30 and 120 min. More HRP and HRP−P85 was found in the parenchymal compartment at 120 than 30 min, but at 120 min, entry favored HRP−P85. A two-way ANOVA test was significant for compound, time, and interaction all at the $p <$ 0.001 level.

DISCUSSION

Strategies for improving transport of therapeutic polypeptides to the brain are crucial for the successful applications of polypeptides for diagnostics and treatment of CNS diseases. The present in vitro and in vivo study demonstrates that point modifications of a model polypeptide, HRP, with lipophilic or amphiphilic groups greatly enhance the transport and accumulation of HRP in the brain. The key for such modifications is to achieve a delicate balance in hydrophilic−lipophilic properties of the modified polypeptides. On one hand, the modified polypeptide should be lipophilic to interact with and incorporate into the membranes of microvessel endothelial cells, but on the other hand, the protein should retain its high solubility in the blood stream. To accomplish this goal for stearoylated polypeptide, we used reverse micelles of a surfactant, AOT, producing microreactors and allowing a point conjugation of each polypeptide molecule

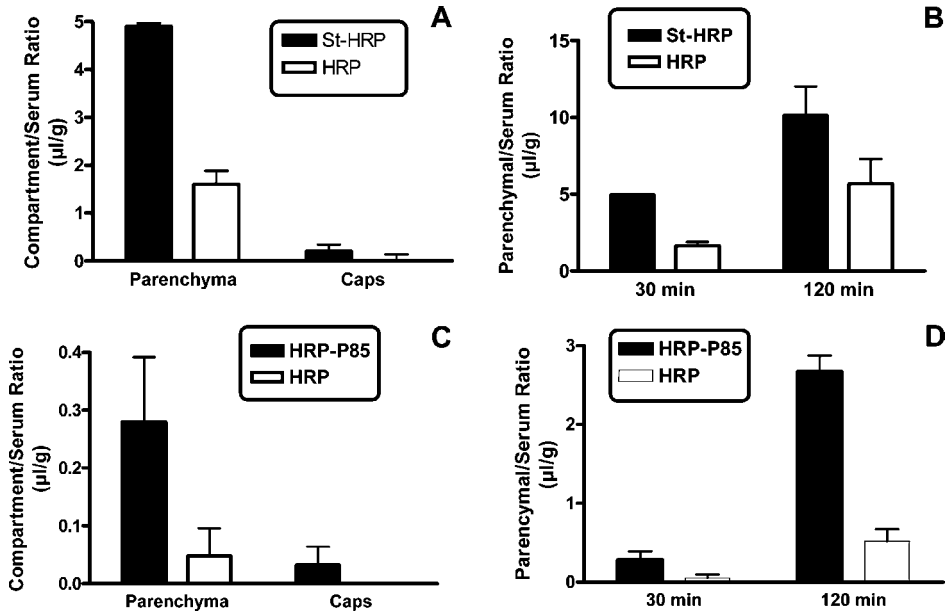

Figure 10. Capillary depletion compared for HRP and St-HRP (A,B) or HRP and HRP−P85 (C,D) 30 min after injection. Results show that all studied proteins crossed the BBB to enter the parenchymal compartment of the brain. The amount of native HRP (white bars, A−D), St−HRP (black bars, A and B), or HRP−P85 (black bars, C and D) retained in the brain is shown for capillaries and parenchyma (30 min after iv injection, A and C) or for parenchyma only (30 and 120 min after iv injection, B and D). Modification of HRP with stearoyl or Pluronic moiety significantly increased protein accumulation in the brain.

with 1−2 strearic acid residuals of the aliphatic chain. Based on the earlier reports (*11*, *15*, *28*), a stearic derivative was chosen as the most appropriate for this purpose. Consequently, total binding and transport of the stearoyl-modified HRP was increased about 2−3 times in the brain microvessel endothelial cells in vitro.

A similar principle was used in the case of a protein modification with Pluronic block copolymers; the designed conjugates had different balances between hydrophilic and lipophilic properties. Modification of HRP with Pluronic L121 was the most promising for the CNS delivery of the conjugate. The total binding and transport of Pluronic P85 and L121 modified HRP were increased up to 6 and 10 times, respectively, compared with the native HRP. A method of conjugation using biodegradable and nonbiodegradable links was also varied. As expected, the modification of the protein via a biodegradable link resulted in the most effective transport of the protein across the brain microvessel endothelial cell monolayers. We speculate that being highly hydrophilic the HRP molecule requires a highly lipophilic moiety to obtain the optimal hydrophilic−lipophilic balance of the conjugate. Such a lipophilic group has a tendency to remain associated with the cellular membrane as an anchor. Therefore, a biodegradable link allowed the polypeptide molecule to separate from its lipophilic moiety and enter the brain after the conjugate passed membranes of the barrier cells. Data obtained by confocal microscopy visualizes this effect. Modification of the protein with Pluronic P85 via biodegradable link drastically enhanced transport of HRP into the cells and its accumulation in the cytoplasm, nuclei, and other cellular organelles. We suggest that the protein conjugate was initially bound to the cellular membrane through the Pluronic moiety incorporated into the lipid bilayer followed by cleavage of the HRP molecule from the Pluronic anchors.

Another crucial point is to preserve the function of the modified protein (1) after the modification and (2) after the transport across the BBB. From this prospective, modification of HRP with Pluronic block copolymers was more preferable than conjugation with stearoyl moiety; Pluronic-based conjugates retained 90−100% of the native enzyme activity, whereas St−HRP retained only 50%. A considerable decrease in the enzymatic activity of St−HRP could be a result of the last step of the synthesis, when obtained conjugate was precipitated by ice-cold acetone. Nevertheless, all obtained conjugates retain their enzymatic activity during their transport across the BBMEC monolayers in vitro, as was detected by an HRP substrate, *o*-phenylenediamine.

In vivo studies found that (1) hydrophobization with stearoyl group or (2) amphiphilic modification with a Pluronic block copolymer had increased the rate of HRP penetration across the BBB and increased accumulation of HRP by the brain. In vivo studies of BBB permeability can differ from in vitro studies because clearance, serum protein binding, and tissue sequestration are factors that can influence in vivo results. Lipophilic modifications are especially notorious for increasing the ability of compounds to cross the BBB while decreasing the amount of compound accumulated by brain. This paradoxical effect occurs because lipophilic modification increases uptake by all tissues, not just brain, and so reduces the amount of the compound available for transport across the BBB. If the decrease in the amount of compound available for transport exceeds the increase in transport rate, the net effect is to decrease the amount of compound taken up by brain. Here we found that, in comparison to HRP, St−HRP had an increase in transport rate of 2.4-fold. However, volume of distribution as measured in Figure 8A was increased, indicating that there was increased uptake by other tissues. These two factors resulted in a net uptake by brain of St−HRP as measured by %inj/g of about 60% for the first 90 min after injection and an increase of about 13% over the entire study period.

Another problem with lipid modification as discussed above is that compounds can partition into cell membranes and become trapped there. For in vivo BBB, this results in material being retained by the capillaries and not being able to enter the brain parenchymal space. Here, the capillary depletion method was used to assess this possibility. It was found that although more St−HRP

than HRP was retained by capillaries, the vast majority of St−HRP entered brain parenchyma.

Overall modification with Pluronic block copolymers appeared to be more promising for HRP delivery to the brain. Permeation of the BBB in vivo was increased almost 4-fold with no statistically significant effects on peripheral pharmacokinetics or entry into the parenchymal space. The %inj/g was almost twice as great for HRP−P85 as for HRP.

CONCLUSIONS

This study indicates that simple and straightforward modification of polypeptides with lipophilic or amphiphilic groups can considerably increase the transport of HRP into the brain, while preserving the enymatic activity of HRP. A delicate balance between lipophilic and hydrophilic properties of the conjugate should be achieved to accomplish its efficient delivery into the brain. To achieve this balance, each unique polypeptide may require tailoring of the lipophilic moiety to match the hydrophilic−lipophilic characteristics of the native polypeptide.

Synthesis and Biological Evaluation of EC72: A New Folate-Targeted Chemotherapeutic

Christopher P. Leamon,* Joseph A. Reddy, Iontcho R. Vlahov, Marilynn Vetzel, Nikki Parker, Jeffrey S. Nicoson, Le-Cun Xu, and Elaine Westrick

Endocyte, Inc., 3000 Kent Avenue, West Lafayette, Indiana 47906. Received December 6, 2004; Revised Manuscript Received April 14, 2005

A novel folate conjugate of mitomycin C, herein referred to as EC72, was designed and evaluated for biological activity against FR-positive cells and tumors. EC72 was produced by coupling folic acid-γ-cysteine to 7-N-modified MMC via a disulfide bond. This water soluble conjugate was found to retain high affinity for FR-positive cells, and it produced dose responsive activity in vitro against a panel of folate receptor (FR)-positive cell lines. EC72's activity was considered to be targeted and specific for the FR since (i) excess folic acid blocked biological activity, and (ii) FR-negative cell lines were unresponsive to this drug. Initial in vivo tests confirmed EC72's activity in both syngeneic and xenograft models, and this activity occurred in the apparent absence of gross or pathological toxicity. These results are significant, since daily dosing of EC72 for more than 30 consecutive days yielded no evidence of myelosuppression or toxicity to major organs, including the FR-positive kidneys. The latter observation supports published data, indicating that the apically oriented kidney proximal tubule FRs function to salvage folates prior to their excretion and to return these molecules back into systemic circulation. Overall, EC72's performance in vitro and in vivo warrants further preclinical study before this novel targeted chemotherapeutic is considered for clinical investigation.

INTRODUCTION

Notwithstanding the noteworthy advances in its treatment, cancer persists as the second largest cause of death in America, with one in four deaths being caused by this disease (*1*). Chemotherapy remains the primary method of treatment for metastasized or disseminated cancers. Traditionally, chemotherapy regimens have been designed to administer the untargeted drug intermittently (e.g. once every three to six weeks) at its maximum tolerated dose followed by a recovery period. This approach has been used for over 50 years with dismal improvements in patient cure rates. One reason for this apparent failure is that this method of treatment is plagued by toxicity resulting from the nondiscriminate uptake of these poisons into proliferating cells of both normal and neoplastic tissue. Second, the kinetics of tumor tissue recovery is much faster than the kinetics of normal tissue recovery, thus making tumor elimination highly unlikely in response to infrequent drug administration. In theory, the normal tissue toxicity manifested by any drug should be decreased or eliminated if the pharmacophore were specifically targeted to the diseased cells. This alternative approach might also enable a more aggressive metronomic-style of dosing, which would be expected to produce better therapeutic outcomes because the tumor would never have the opportunity to "recover". As such, tumor-specific targeting of drugs remains one of the most important goals in cancer treatment today.

The vitamin folic acid is a ligand capable of targeting covalently attached bioactive agents quite specifically to folate receptor (FR)-positive tumors. The FR, which is a well-known tumor associated protein, can actively internalize bound folates via endocytosis (*2, 3*). It has been detected at very high levels in >90% of ovarian and other gynecological cancers, as well as at high to moderate levels in kidney, brain, lung, and breast carcinomas (*4*–*14*). Not surprisingly, the concept of "folate–drug targeting" has been effectively exemplified over the past 14 years using payloads as diverse as small radiopharmaceutical agents to large DNA-containing formulations (see (*15*) for a comprehensive overview of this technology).

Recent efforts from a small molecule research project led to the creation of a folate–mitomycin C (MMC) conjugate. This novel FR-targetable chemotherapeutic, named EC72, was constructed using disulfide linker technology to afford molecular separation of MMC from folate once this conjugate enters the endosomes of FR-positive cancer cells. As reported below, EC72 was found to produce encouraging in vitro and in vivo therapeutic activity in multiple FR-positive models, and these data warrant further preclinical study of this new investigational agent.

EXPERIMENTAL PROCEDURES

Materials. N^{10}-Trifluoroacetylpteroic acid was purchased from Eprova AG, Schaffhausen, Switzerland. Peptide synthesis reagents were purchased from Nova-Biochem (La Jolla, CA) and Bachem (San Carlos, CA). Folate-free RPMI media (FFRPMI) and PBS were obtained from Gibco, Grand Island, NY. ^{3}H-Thymidine and N^{1a}-(^{3}H-methyl)mitomycin K were purchased from Moravek Biochemicals, Brea, CA.

Synthesis, Purification, and Analytical Characterization of EC72 and ^{3}H-Methyl-EC72. Construction of EC72 began with the synthesis of the thiol containing folate linker, Pte-γGlu-Cys-OH, using a preloaded Fmoc-Cys(Trt) Wang resin and standard solid-phase techniques. The linker was purified on a preparative RP-HPLC system connected to a Novapak HR C18 19 × 300

mm column. A gradient method was used, starting with 99% mobile phase A (10 mM ammonium acetate buffer, pH 5.5) and 1% mobile phase B (acetonitrile) and reaching 50% B within 30 min at a flow rate of 15 mL/min. Fractions corresponding to the main peak (UV monitoring at 280 nm) were combined, and the acetonitrile was removed under reduced pressure. The rest was subjected to freeze-drying for 48 h to give the folate linker at >94% purity based on analytical HPLC (RT = 10 min) on NovaPak C18 3.9 × 150 mm column and using a gradient of solvents, starting with 99% mobile phase A (1 mM phosphate buffer, pH 6.5) and 1% mobile phase B (acetonitrile) and reaching 50% B within 30 min at a flow rate of 1.0 mL/min. ^{1}H NMR (300 MHz, DMSO-d_6): 1.87−2.93 (m,1H), 1.98−2.04 (m,1H), 2.10−2.15 (m, 2H), 2.54−2.68 (dd, J = 13.5 Hz, J = 5.6 Hz, 1H), 2.71−2.82 (dd, J = 13.5 Hz, J = 4.7 Hz, 1H), 4.05−4.08 (dd, J = 5.6 Hz, J = 4.7 Hz, 1H), 4.15−4.20 (dd, J = 8.2 Hz, J = 4.4 Hz, 1H), 6.61−6.63 (d, J = 8.7 Hz, 2H), 7.60−7.62 (d, J = 8.7 Hz, 2H), 8.61 (s, 1H).

The other reaction partner, pyridyldithioethylmitomycin C, was prepared by treating the commercially available 2-pyridyldithioethylamine with the vinylogous methyl ester in the quinone moiety of mitomycin A (*16*). The resulting 2-pyridyldithiol derivative was used for sulfenylation of the thiol group in Pte-γGlu-Cys-OH to provide EC72 (Pte-γGlu-Cys-SS-MMC). In brief, 100 mg (0.21 mmol) of Pte-γGlu-Cys-OH were mixed with 4.0 mL of HPLC-grade water, and the resulting suspension was bubbled with argon. While purging, the mixture was treated with 0.1 N sodium bicarbonate until the pH reached 7.0, at which time the solution turned clear yellow. One hundred twenty milligrams (0.24 mmol) of pyridyldithioethylmitomycin C dissolved in 3.0 mL of methanol was then added to the reaction vessel. The reaction mixture was stirred under argon for 1 h, after which methanol and some of the water were removed under reduced pressure. The resulting dark green suspension was filtered through a 0.45 μm filter to give a dark green solution; the sample was then loaded onto a preparative RP-HPLC system connected to a Novapak HR C18 19 × 300 mm column. A gradient method was used starting with 99% mobile phase A (10 mM ammonium acetate buffer, pH 6.3) and 1% mobile phase B (acetonitrile) and reaching 50% B within 30 min at a flow rate of 15 mL/min. Fractions corresponding to the main peak (UV monitoring at 280 nm) were combined, and the acetonitrile was removed under reduced pressure. The remaining material was subjected to freeze-drying for 48 h to yield 68 mg of final EC72 conjugate. EC72's analytical HPLC profile revealed 93% purity (t_R = 16.5 min) on a NovaPak C18 3.9 × 150 mm column, using a gradient of solvents starting with 99% mobile phase A (1 mM phosphate buffer, pH 6.5) and 1% mobile phase B (acetonitrile) while reaching 50% B within 30 min at a flow rate of 1.0 mL/min. The structure of EC72 was characterized by ^{1}H NMR (500 MHz, D_2O): δ 1.73 (s, 3H), 2.07−2.13 (m,1H), 2.28−2.32 (m,1H), 2.46−2.53 (m, 2H), 2,56−2.61 (m, 1H), 2.64−2.73 (m,1H), 2.90−2.96 (dd, J = 14.0 Hz, J = 8.3 Hz, 1H), 2.97−2.99 (m, 2H), 3.08−3.11 (dd, J = 14.0 Hz, J = 1.7 Hz, 1H), 3.25 (s, 3H), 3.46−3.49 (dd, J = 10.6 Hz, J = 4.4 Hz, 1H), 3.50−3.64 (m, 3H), 4.07−4.10 (d, J = 13.3 Hz, 1H), 4.16−4.21 (t, J = 10.6 Hz, 1H), 4.38−4.43 (m, 2H), 4.50 (s, 2H), 6.68−6.70 (d, J = 8.7 Hz, 2H), 7.62−76.4 (d, J = 8.7 Hz, 2H), 8.66 (s, 1H) and ES MS: $(m-H)^-$ 935.6, $(m+H)^+$ 937.4.

The synthesis of ^{3}H-methyl-EC72 was performed as described above except that N^{1a}-(^{3}H-methyl)mitomycin K (Moravek Biochemicals) was substituted for mitomycin A. The reaction mixture was condensed to 0.5 mL under reduced pressure, and the residue was purified by HPLC using the aforementioned conditions. The eluates containing ^{3}H-methyl-EC72 were collected and condensed to 1 mL under reduced pressure. The radiochemical purity was 98.5%, and the specific activity was 3.2 Ci/mmol.

Cell Culture. Cells were grown continuously as a monolayer using folate-free RPMI medium (FFRPMI) containing 10% heat-inactivated fetal calf serum (HIFCS) at 37 °C in a 5% CO_2/95% air-humidified atmosphere with no antibiotics. The HIFCS contained its normal complement of endogenous folates which enabled the cells to sustain growth in this more physiologically relevant medium (*3*). All cell experiments were performed using FFRPMI containing 10% HIFCS (FFRPMI/HIFCS) as the growth medium, except where indicated.

Folate Receptor Assay. A folate receptor (FR) assay was performed as previously described by Parker et al. (*14*), and all sample preparation procedures were performed at 4 °C. Briefly, tissue samples were homogenized in homogenization buffer (10 mM Tris, pH 8.0, 0.02 mg/mL each of leupeptin and aprotinin; 1 mL buffer per 50 mg of tissue). Membrane pellets were collected by centrifugation (40 000*g* for 60 min. at 4 °C) and resuspended in solubilization buffer (50 mM Tris, pH 7.4, 150 mM NaCl, 25 mM *n*-octyl-β-D-glucopyranoside, 5 mM EDTA, and 0.02% sodium azide). Insoluble material was removed by another centrifugation, and the total protein concentration of the supernatants was determined by the BCA method (Pierce Chemical Co.). Each sample was diluted to 0.25 mg/mL in solubilization buffer, and the solubilized FRs were concentrated by passing through Microcon-30 microconcentrators (30K molecular weight cutoff; Millipore Corporation). After a brief acid wash step to release endogenous folates, samples were neutralized and then allowed to bind ^{3}H-folic acid (120 nM ^{3}H-folic acid (Amersham) in 10 mM Na_2PO_4, 1.8 mM KH_2PO_4, pH 7.4, containing 500 mM NaCl, 2.7 mM KCl, and 25 mM *n*-octyl-β-D-glucopyranoside) or ^{3}H-folic acid competed with 120 μM unlabeled folic acid. The concentrators were washed three times with a detergent-based buffer (50 mM *n*-octyl-β-D-glucopyranoside, 0.7 M NaCl in PBS, pH 7.4). After the final wash, the retentates containing the solubilized FRs were recovered with PBS containing 4% Triton-X 100. The samples were then counted in a liquid scintillation counter (Packard Bioscience Co.). CPM values were converted to picomole of FR using the reagent's specific activity, and the final results were normalized with respect to the sample protein content.

Relative Affinity Assay. The relative affinity of various folate derivatives was determined according to the method described by Westerhoff et al. (*17*) with slight modification. Briefly, FR-positive KB cells were suspended into FFRPMI/HIFCS following exposure to 0.25% trypsin in phosphate-buffered saline (PBS) at room temperature for 3 min. Following a 5 min 800*g* spin and one PBS wash, the final cell pellet was suspended in FFRPMI (no serum). Cells were incubated for 15 min on ice with 100 nM of ^{3}H-folic acid in the absence and presence of increasing concentrations of folate-containing test articles. Samples were centrifuged at 10 000*g* for 5 min, cell pellets were suspended in buffer, transferred to individual vials containing 5 mL of scintillation cocktail, and then counted for radioactivity. Negative control tubes contained only the ^{3}H-folic acid in FFRPMI (no competitor). Positive control tubes contained a final concentration of 1 mM folic acid, and CPMs measured in these samples (representing nonspecific binding of label) were subtracted from all samples. Notably, relative

affinities were defined as the inverse molar ratio of compound required to displace 50% of ^{3}H-folic acid bound to FR on KB cells, and the relative affinity of folic acid for the FR was set to 1.

Kinetics and Specificity of EC72 Activity. KB cells were seeded in 12-well Falcon plates and allowed to form adherent monolayers (~50% confluent) overnight in FFRPMI/HIFCS. Thirty minutes prior to the addition of EC72, spent medium was aspirated from all wells and replaced with fresh FFRPMI. Note, designated wells received media containing 100 μM folic acid, and cells within the latter wells were used to determine the targeting specificity, since cytotoxic activity produced in the presence of excess folic acid (enables competition for FR binding) would signify the portion of the total activity that was unrelated to FR-specific delivery. Following a single rinse with 1 mL of media, cells were exposed to 100 nM of EC72 in 1 mL of FFRPMI/HIFCS for only 10 min at 37 °C (pulse). Cells were then washed three times with media and chased for 22, 46, or 70 h. Spent media was aspirated from all wells and replaced with fresh media containing 5 μCi/mL ^{3}H-thymidine. Following a 2 h 37 °C incubation, cells were washed three times with 0.5 mL of PBS, pH 7.4, and then treated with 0.5 mL of ice-cold 5% trichloroacetic acid per well. After 15 min, the trichloroacetic acid was aspirated and the cells solubilized by the addition of 0.5 mL of 0.25 N sodium hydroxide for 15 min. Four hundred and fifty microliters of each solubilized sample were transferred to scintillation vials containing 3 mL of Ecolume scintillation cocktail and then counted in a liquid scintillation counter. Final tabulated results were expressed as the percentage of ^{3}H-thymidine incorporation relative to untreated controls.

Dose-Dependent Activity. Cells were heavily seeded in 12-well Falcon plates and allowed to form nearly confluent monolayers overnight. Following one rinse with 1 mL of fresh FFRPMI/HIFCS, each well received 1 mL of media containing increasing concentrations of EC72 (four wells per sample). Cells were pulsed for 10 min at 37 °C, rinsed four times with 0.5 mL of media, and then chased in 1 mL of fresh media up to 72 h. Cells were incubated with ^{3}H-thymidine and processed as described above. Final tabulated results were expressed as the percentage of ^{3}H-thymidine incorporation relative to untreated controls.

Serum Stability. The stability of EC72 in human serum was determined by an in vitro assay which included a solid-phase extraction procedure for sample cleanup followed by HPLC analysis. EC72 was added to human serum at a 200 μM final concentration, and the sample was incubated in a 37 °C water bath for a total period of 24 h. Two hundred microliters of serum sample ($n = 3$) was removed 1, 2, 4, 8, and 24 h after initiation of incubation, and EC72 was recovered from serum by solid-phase extraction with Oasis HLB cartridges (1 cm^3/30 mg; Waters Corporation). First, 800 μL of 6 M guanidine (pH adjusted to 7.4 with 0.1 M NaOH) was added to each 200 μL serum sample to reduce nonspecific protein binding of the drug. Next, cartridges were conditioned with 1 mL of methanol and equilibrated with 1 mL of 6 M guanidine, pH 7.4. Samples (1 mL) were then loaded onto the cartridges followed by a wash with 5% methanol in water (1 mL). Finally, samples were eluted with 1 mL of methanol, evaporated to dryness, and reconstituted in 200 μL of phosphate-buffered saline, pH 7.4. Ten microliters of the reconstituted sample was injected on an HPLC equipped with a Sunfire C18 3.0 × 100 mm column, a UV detector at 280 nm, 10 mM ammonium acetate, pH 7.0 (mobile phase A), and acetonitrile (mobile phase B). EC72 was eluted with a gradient from 95:5 (A:B) to 60:40 (A:B) in 15 min. Percent recoveries were calculated based on the integrated peak areas assuming that a $t = 0$ serum extracted sample represented 100% recovery. The %RSD for each individual time point was <2%.

In Vivo Studies. Four to seven week-old mice (Balb/c or *nu*/*nu* strains) were purchased from Harlan Sprague Dawley, Inc. (Indianapolis, IN) and were maintained on a folate-free diet (Harlan diet #TD00434) for a total of three weeks prior to and beyond the onset of dosing. Syngeneic, FR-positive M109 tumor cells (0.5×10^6 per Balb/c mouse) or FR-positive KB cells (0.75×10^6 per *nu*/*nu* mouse) were inoculated in the peritoneal cavity and allowed to proliferate for 4 days. Sterile aqueous solutions of test article were dosed ip following a qdx7 or qdx5, 4 wk schedule, as indicated. Doses were 1800 nmol/kg for EC72 and MMC. Animals in the specificity cohort received 1800 nmol/kg EC72 plus 18 000 nmol/kg folic acid. Animal survival and health status were monitored daily, and activity data were reported as the percent survival (in days) of the treated cohorts relative to the untreated cohort.

Blood Clearance. Six week old female Balb/c mice received an 1800 nmol/kg intravenous dose of ^{3}H-methyl-EC72, and blood samples were taken with time. Approximately 100 μL of each blood sample were dissolved in a 1:1 mixture of Soluene-350 (Perkin-Elmer, Boston, MA) and 2-propanol, heated to 60 °C to solubilize, oxidized in 0.6% hydrogen peroxide, heated again to decolorize, mixed with scintillation fluid, and then counted for radioactivity. Data were fitted using a two-phase exponential decay algorithm ($r^2 = 0.999$; GraphPad Prism software, v. 4.02).

Toxicity Assessment. Balb/c mice bearing ip M109 tumors were treated daily with 1800 nmol/kg of test article administered ip. Animals were monitored daily and euthanized upon moribund condition (either from tumor burden or toxicity) using carbon dioxide asphyxiation. Blood samples were collected following the 30th dose and/or at time of euthanasia. Samples were collected via heparinized microhematocrit capillary tubes (Fisher) from the orbital sinus of animals anesthetized with diethyl ether. Blood samples collected at the time of euthanasia were done via cardiac puncture using 1 mL syringes fitted with 25 or 27.5 gauge needles. Blood was allowed to coagulate at room temperature for 30 min and then centrifuged at 6600*g* for 10 min at 4 °C. Sera were collected from these samples and then recentrifuged at the same rate for 6 additional min at 4 °C. Sera were frozen at −20 °C until shipment to Ani-Lytics, Inc. (Gaithersburg, MD) for analysis of AST-SGOT and blood urea nitrogen (BUN) levels. At the time of euthanasia, heart, lung, liver, spleen, kidney, intestine, skeletal muscle, and bone (tibia/fibula) were collected and immediately placed in 10% buffered formalin (Sigma-Aldrich). Preserved organs were sent to Animal Reference Pathology Laboratories (ARUP; Salt Lake City, Utah) for histopathologic tissue evaluation.

RESULTS

Folate-Targeted Chemotherapy. The mechanism of folate-targeted drug delivery is schematically shown in Figure 1. Cells expressing the FR protein bind folate−drug conjugates very tightly and endocytose them inside. Once internalized, the FR changes conformation and releases the conjugate inside the acidic milieu of the

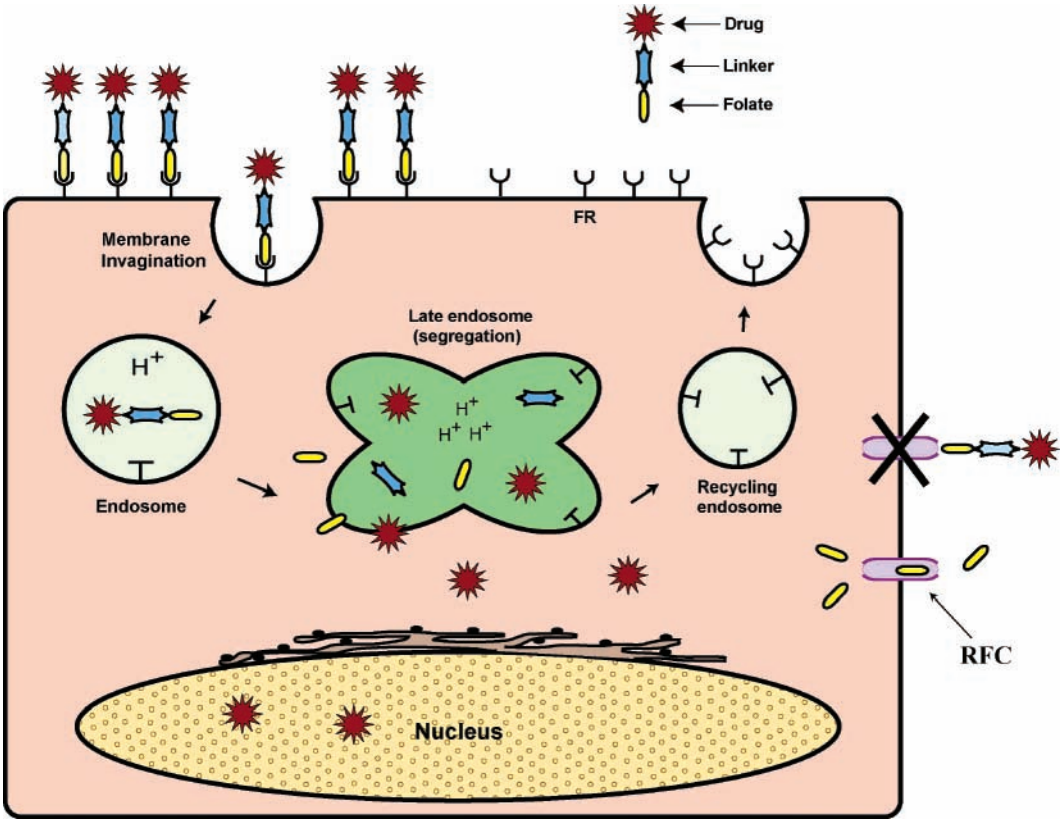

Figure 1. FR-mediated endocytosis of folate−drug conjugates. Exogenously added folate−drug conjugates bind specifically to the FR protein with high affinity. The plasma membrane invaginates around the conjugate:FR complex to form an endosome. As the lumen of the maturing endosome acidifies to ~pH 5, the receptor changes conformation and releases the conjugate. Eventually, the fates of the folate-based ligand, attached drug cargo, and the FR are determined during a sorting process within late endosomal elements. The reduced folate carrier (RFC), which unlike the FR is an anion transporter, can shuttle folate molecules inside the cell. Folate−drug conjugates, however, are not substrates for the RFC.

endocytic elements. Depending on the nature of the chemical linkage between them, separation of the folate and drug moieties can occur within these vesicular structures. Finally, the released drug diffuses across the vesicular membrane to exert its activity. Importantly, unmodified folates can also gain access to the cell cytosol via a membrane-resident anion transporter (reduced folate carrier). However, transport of folate−drug conjugates through this protein has not been experimentally observed (unpublished data).

EC72 Synthesis. The synthesis of EC72 is schematically shown in Figure 2. A thiol containing folate linker, Pte-γGlu-Cys-OH, was coupled in near quantitative yield to pyridyldithioethylmitomycin C to produce EC72 (Pte-γGlu-Cys-SS-MMC). It was purified by preparative reverse-phase HPLC and stored as a lyophilized powder. The structure of EC72 was confirmed by ^{1}H NMR spectroscopy and electrospray ionization mass spectroscopy.

Relative Affinity Assay. EC72 was first evaluated biologically using an in vitro relative affinity assay that measures a ligand's ability to directly compete with folic acid for binding to cell surface FRs. Importantly, a relative affinity value of 1.0 implies that the test article ligand has an affinity equal to that of folic acid for the FR. Likewise, values lower than unity reflect weaker affinity, and values higher than unity reflect stronger affinity.

Cultured KB or M109 cells were incubated with 100 nM ^{3}H-folic acid in the presence of increasing concentrations of nonradioactive folic acid or EC72. Following a 15 min incubation at 4 °C, cells were rinsed free of unbound material and counted for residual cell-associated radioactivity. The quantity of bound radioactivity was plotted against the concentration of unlabeled ligand, and IC_{50} values (concentration of ligand required to block 50% of ^{3}H-folic acid binding) were estimated. As shown in Figure 3, EC72 was experimentally determined to have an affinity of 0.59 relative to that of folic acid for human FRs (KB cells) and an affinity of 0.51 for murine FRs (M109 cells). Thus, chemical modification of folate with the mitomycin C drug motif only slightly altered the vitamin's intrinsic affinity for the FR.

Kinetics of EC72 Activity. Our initial in vitro activity study focused on determining a reasonable endpoint for measuring DNA synthesis inhibition. To accomplish this goal, monolayer KB cells were pulsed for 10 min with 100 nM of EC72 (in the presence and absence of excess folic acid) and then chased for various periods of time thereafter prior to labeling with ^{3}H-thymidine. Although such short pulse incubations are not commonly used when evaluating the in vitro activity of chemotherapeutic drugs (*18*), we felt that this approach was more meaningful for evaluating a targeted agent's activity in vitro since (i) a short incubation pulse should be effective for loading the cell surface receptors with a targeted agent, (ii) folate−drug conjugates are known to rapidly distribute throughout the body and clear from the bloodstream within the first couple of minutes (*19*), and (iii) tumors are not persistently bathed in the presence of drug. As shown in Figure 4, DNA synthesis activity in EC72-pulsed cells had progressively decreased with respect to the amount of chase time. Thus, a ~20% inhibition was measured after 24 h of chase time,

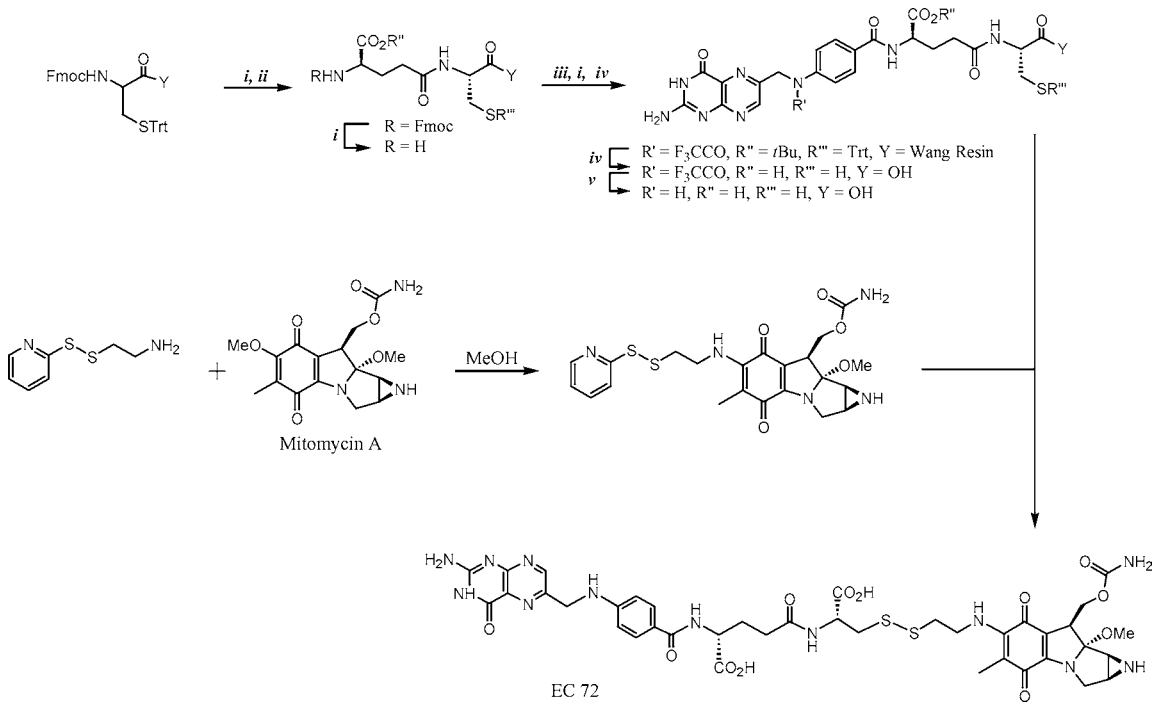

Figure 2. Synthetic route for EC72 (folate−disulfide−MMC). Bulk MMC is first converted into mitomycin A followed by vinylogous amidation to form a thiosulfonyl-ethyl−MMC intermediate. The intermediate is then reacted with Pte-γGlu-Cys to produce EC72. Reagents and conditions: (i) 20% piperidine, DMF; (ii) Fmoc-D-Glu-OtBu, PyBop, DIPEA, DMF; (iii) N^{10}-TFA-Pte-OH, DIPEA, DMSO; (iv) TFAA, $HSCH_2CH_2SH$, $^iPr_3SiH$; (v) H_4NOH, pH = 10.3.

whereas ∼75% inhibition resulted after 72 h. Although it is not shown here, chase times longer than 72 h typically did not produce any greater DNA synthesis inhibition. Importantly, the inhibitory activity manifested by EC72 was completely blocked at all chase times when cells were pulsed in the presence of excess folic acid, thereby confirming EC72's FR targeting specificity.

Dose-Dependent Activity. The activity of EC72 was next evaluated to determine its dose responsive properties. As shown in Figure 5A, EC72's activity was determined to be concentration dependent with an IC_{50} of ∼5 nM when cells were merely pulsed for a 10 min period. Importantly, similar results were obtained if cells were incubated for longer pulse times (2 h; see Figure 5B). Consistent with the data described above, EC72's activity was effectively blocked in the presence of excess free folic acid, indicating that the observed activity was folate-mediated. The latter result is significant, for it suggests that normal tissues that express little to no FR should not be affected by EC72.

A second line of evidence for EC72's specificity was obtained when a series of cell lines were screened in vitro. As shown in Table 1, EC72 was found to be active against only those cell lines that expressed the FR. Thus, DNA synthesis inhibition was measurable in the FR-positive KB, ID8, and M109 cell lines; however, no activity was measurable in the FR-negative 4T1 and A549 cell lines.

Serum Stability and Blood Clearance. Since EC72 contains an intramolecular disulfide bond which could be susceptible to cleavage in a biological matrix, its stability in human serum was investigated at 37 °C. As shown in Figure 6 Panel A, results from an HPLC-based solid-phase extraction method revealed that the percent recovery of intact EC72 decreased with time in the serum matrix with an estimated $t_{1/2}$ of ∼11 h. The relevance of this finding is emphasized by a follow up experiment which assessed the blood clearance of a structurally related analogue of EC72, e.g. a compound that contained a ^{3}H-methyl group on the mitomycin moiety's aziridine nitrogen (^{3}H-methyl-EC72).[1] Thus, an 1800 nmol/kg intravenous dose of ^{3}H-methyl-EC72 was given to Balb/c mice, and blood samples were taken with time to approximately measure the clearance rate. As shown in Figure 6 Panel B, ^{3}H-methyl-EC72 was rapidly removed from systemic circulation. After fitting the data using a two-phase exponential decay algorithm ($r^2 = 0.999$), the approximate half-lives of the alpha and beta phases were estimated to be 1 and 67 min, respectively. Importantly, similar rapid tissue distribution and elimination phenomena have also been observed for other folate−drug conjugates (*19, 20*), and it appears to be representative for this class of targeted small molecules. Taken together, the data in Figure 6 (Panels A and B) suggest that EC72 is likely to reach an FR-positive tumor in an intact form within minutes following an intravenous injection.

In Vivo Activity. (*a) Syngeneic Model.* EC72's activity was next evaluated in vivo. Four days after receiving an ip inoculation of syngeneic, FR-positive M109 tumor cells, animals received daily ip injections of 1800 nmol/kg EC72 or MMC (formulated in saline) following a qdx7, 4 wk schedule. Notably, animals in a specificity cohort received 1800 nmol/kg EC72 plus 18 000 nmol/kg of folic acid. As shown in Figure 7, untreated animals were all moribund by day-24 of the study and had to be euthanized. MMC-treated animals did not statistically live any longer than the controls; importantly, this effect was not due to the lack of antitumor activity, since MMC-treated animals did not present with a significant ip tumor burden upon necropsy. Instead, animals in this cohort apparently died from MMC-related toxicity (vide infra). Using an identical dosing regimen, EC72-treated animals had experienced a significant 185% increase in median survival time relative to the PBS control group ($p = 0.006$), and these

[1] Methyl-EC72 is essentially the porfiromycin analogue of EC72. When tested for activity against KB cells in the same experiment, the IC_{50}s were 5.7 nM and 7.7 nM for EC72 and methyl-EC72, respectively.

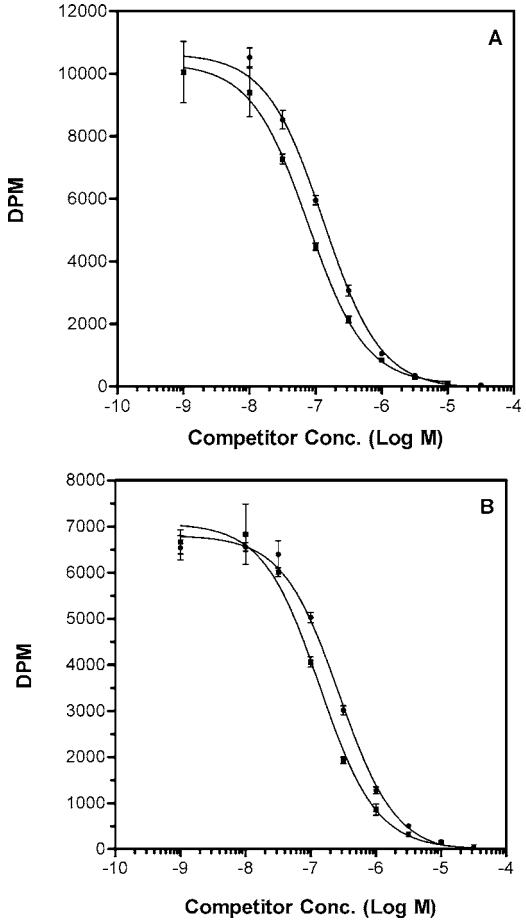

Figure 3. Relative folate receptor binding affinity of EC72. KB cells were incubated for 15 min on ice with 100 nM ^{3}H-folic acid in the presence and absence of increasing competitor concentrations: (■) folic acid; (●) EC72. Error bars represent 1 standard deviation ($n = 3$). A, human KB tumor cells; B, murine M109 tumor cells.

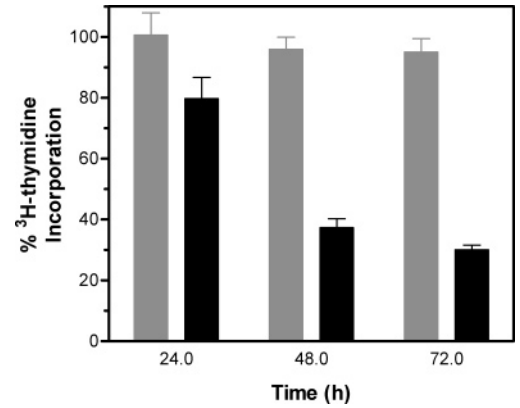

Figure 4. Kinetics of EC72 activity. Adherent KB cells were pulsed for 10 min with 100 nM EC72 in the presence or absence of 0.1 mM folic acid. Following a 22, 46, or 70 h chase in fresh media, cells were incubated with ^{3}H-thymidine for an additional 2 h and then counted for radiolabel incorporation into newly synthesized DNA, as described in Experimental Procedures. Black bars, EC72; grey bars, EC72 plus 0.1 mM folic acid. Data represent the average ± 1 SD ($n = 4$).

animals did not present with any noticeable toxicity (i.e. no weight loss or obvious physical change in behavior) during EC72 therapy. Furthermore, one of four of the EC72-treated animals emerged tumor-free by day-70 postinoculation. The antitumor effect of the EC72 conjugate was also found to be reduced to 112% increase in median survival when the drug was coinjected with a

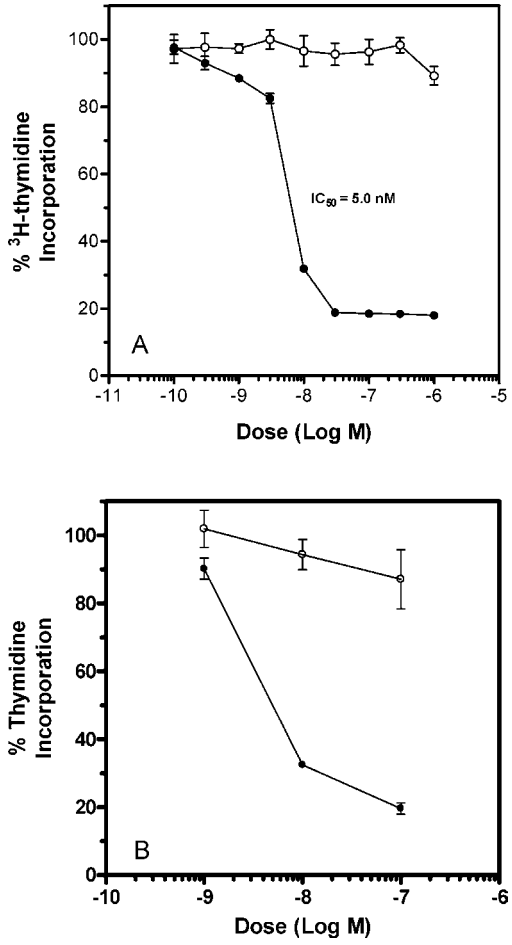

Figure 5. EC72 dose–response. KB cells were treated for 10 min (panel A) or 2 h (panel B) with increasing concentrations of EC72 in the presence or absence of 0.1 mM folic acid (as a competitor). Following a 70 h chase in fresh media, cells were incubated with ^{3}H-thymidine for 2 h and then counted for radiolabel incorporation into newly synthesized DNA, as described in Experimental Procedures. (●), EC72; (○), EC72 plus 0.1 mM folic acid. Data represent the average ± 1 SD ($n = 4$).

Table 1. EC72 Activity on Folate Receptor Positive and Negative Cell Lines[a]

cell line	origin	FR level (pmol/mg cell protein)	EC72 IC_{50} (nM)
KB	human, nasopharyngeal carcinoma	146	5
ID8	murine, ovarian carcinoma	45	100
M109	murine, lung carcinoma	45	100
4T1	murine, breast carcinoma	1.6	>1000
A549	human, lung carcinoma	1.3	>1000

[a] A panel of cell lines with varying levels of FR expression were treated for 10 min with increasing concentrations of EC72. Following a 70 h chase in fresh media, cells were incubated with ^{3}H-thymidine for 2 h and then counted for radiolabel incorporation into newly synthesized DNA, as described in Experimental Procedures. IC_{50} values were calculated from nonlinear fitted dose curves.

moderate, 10-fold excess of folic acid. Although the therapeutic difference between the +/− excess folate cohorts was obvious, the data only support a *p*-value of 0.065. However, different from the highly controllable receptor competition studies that are often performed in vitro (*15*), competition in vivo can be particularly challenging due to (i) nonequilibrium conditions, (ii) dissimilar pharmacokinetics between folic acid and a given folate–drug conjugate, and (iii) the fact that repeated doses of high excess folic acid (e.g. 100-fold over the

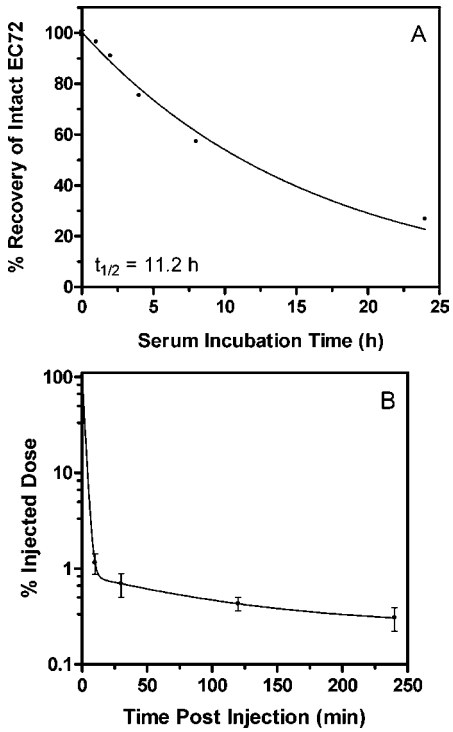

Figure 6. Serum stability and pharmacokinetics. Panel A, stability of EC72 in human serum at 37 °C ($n = 3$ with <2% %RSD). Panel B, blood clearance of ^{3}H-methyl-EC72 following an 1800 nmol/kg intravenous dose to Balb/c mice ($n = 3$).

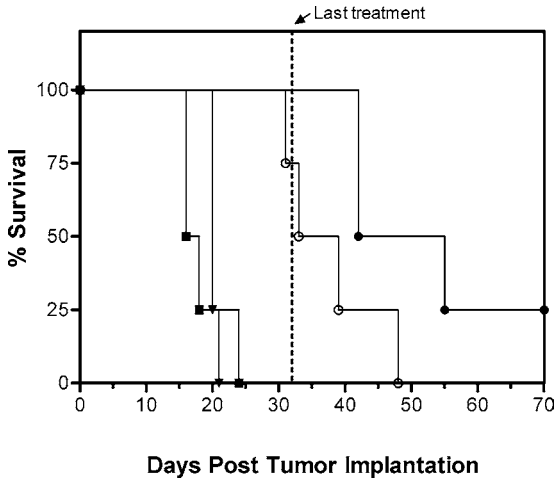

Figure 7. Antitumor activity of EC72 in a syngeneic model. 0.5×10^6 M109 cells were inoculated ip into each *Balb/c* mouse. Four days later, animals were treated intraperitoneally with (●) 1800 nmol/kg of EC72, (○) 1800 nmol/kg EC72 plus 18 000 nmol/kg of folic acid, or (▼) 1800 nmol/kg MMC following a qdx7, 4 wk schedule. A control cohort (■) was not treated. Animal survival was monitored daily ($n = 4$ animals per cohort).

folate−drug) cannot typically be given due to toxicity limitations related to the free vitamin itself (personal observations). Thus, the competition data presented in Figure 7 along with the lack of associated toxicity are believed to be evidence for tumor receptor targeting.

EC72's in vivo activity was also found to be dose responsive. As shown in Figure 8, untreated control animals all died by day 24 PTI. The lowest EC72 dose level of 100 nmol/kg failed to produce meaningful activity (43% ILS), whereas the 400 nmol/kg dose level yielded a 120% ILS. However, animals treated with 1800 nmol/kg responded the best, with one complete responder, and three of four partial responders (240% ILS overall).

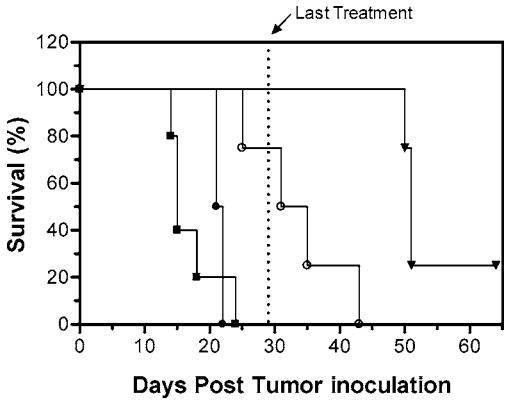

Figure 8. EC72 dose−response. 0.5×10^6 M109 cells were inoculated ip into each *Balb/c* mouse. Four days later, animals were treated intraperitoneally with (●) 100 nmol/kg, (○) 400 nmol/kg, or (▼) 1800 nmol/kg EC72 following a qdx5, 4 wk schedule. A control cohort (■) was not treated. Animal survival was monitored daily ($n = 4$ animals per cohort).

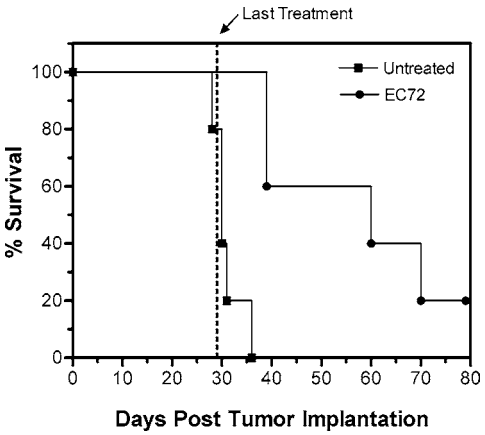

Figure 9. Antitumor activity of EC72 in a human tumor xenograft model. 0.75×10^6 KB cells were inoculated ip into each *nu/nu* mouse. Four days later, animals were treated intravenously with (●) 1800 nmol/kg of EC72 following a qdx5, 4 wk schedule. A control cohort (■) was not treated. Animal survival was monitored daily ($n = 5$ animals per cohort).

(b) Activity in the KB Xenograft Model. EC72 was also evaluated in the KB human tumor xenograft model. Except for using a qdx5, 4 wk regimen, experimental conditions were identical to those described above for the M109-Balb/c model. As shown in Figure 9, EC72-treated mice lived approximately twice as long (200% ILS; similar to the M109 model) compared to the untreated control animals, and one in five treated mice were long-term survivors. Furthermore, no evidence of test article-related gross or pathological toxicity was observed in these animals. Taken together, EC72 has proven to be active in both murine and human FR-positive tumor models.

(c) EC72 Toxicity. In a separate study, M109 tumor-bearing mice (4 days post ip inoculation) received daily ip injections of 1800 nmol/kg EC72 or MMC following a qdx7 schedule for up to 44 consecutive days. Blood samples were collected following the 30th dose and/or at time of euthanasia and then shipped to a contract laboratory for AST-SGOT and BUN quantitation. Major organs were also collected in both the EC72 and MMC mice, formalin fixed, and then shipped to a certified pathologist for examination (see Experimental Procedures). As described in Table 2, MMC-treated animals suffered from extensive myelosuppression, which is a characteristic side effect of MMC therapy (*21*). Although no visible tumors were identified in the peritoneal

Table 2. EC72 Toxicity[a]

test article	dose (nmol/kg)	schedule/ route	duration (days)	liver: AST-SGOT (normal: 72−288)	kidney: BUN (normal: 9−28)	pathological findings
MMC	1800	q1d, ip	21	1043 ± 921	74 ± 32	bone (tibia/fibula) was completely depleted of marrow cells loss of all spleen-derived marrow tissue; significant spleen weight loss heart, lung, liver, intestine, muscle tissue appeared normal
EC72	1800	q1d, ip	44	129 ± 34	31 ± 3.2	bone marrow (tibia/fibula) was normal spleen appeared normal; no tissue degeneration found kidney appeared normal; no tissue degeneration found heart, lung, liver, intestine, muscle tissue appeared normal

[a] Balb/c mice bearing ip M109 tumors were treated daily with 1800 nmol/kg of test article administered ip. All MMC-treated mice were moribund after receiving 21 doses, and they had to be sacrificed; however, major organs (including tibia/fibula and blood samples) were collected at the time of euthanasia. After 30 consecutive daily injections with EC72, blood was collected and AST-SGOT and BUN levels were measured. EC72-treated animals were sacrificed within 7 days following receipt of 44 consecutive daily injections. Major organs were then collected and pathologically evaluated concurrent with the organs from the MMC-treated animals. $N = 4$ animals per cohort.

cavities, all of the animals in this cohort died from apparent drug-related toxicity. In dramatic contrast, animals treated with EC72 displayed no evidence of myelosuppression or renal damage, as the spleen, tibia/fibula bone marrow, and kidneys all appeared microscopically normal to the experienced pathologist. In fact, none of the major organs examined from EC72-treated mice showed signs of tissue damage, and their BUN and AST-SGOT levels following 30 consecutive daily injections with high dose levels of the conjugate (1800 nmol/kg) were found to be within normal limits. Collectively, these results imply that the use of folate−drug conjugates may be an effective form of chemotherapy that does not cause unwanted injury to normal tissues, including the FR-positive kidneys. These data also support the hypothesis that the FR-positive kidney proximal tubules function primarily to shuttle scavenged folates or folate conjugates back into systemic circulation (via kidney-assisted transcellular reabsorption) rather than use them for localized biological consumption (*22*−*24*).

DISCUSSION

The objectives of this investigation were to design and test a folate-MMC conjugate for activity against FR-positive cells and tumors. One drug candidate, named EC72, was created whereby the vitamin folate was coupled to 7-N-modified MMC via a disulfide bond. Notably, due to previous successes with related folate−disulfide−drug constructs (*25*−*27*), the inclusion of the disulfide bond was predicted to be important for efficient release and therapeutic activity of the MMC moiety. EC72 was found to retain high affinity for FR-positive cells, and it produced dose responsive activity in vitro against numerous FR-positive cell lines. This activity was targeted and specific since (i) excess folic acid blocked activity, and (ii) FR-negative cell lines were unresponsive toward EC72.

EC72 proved to be active in both syngeneic and xenograft in vivo models, and this activity occurred in the apparent absence of gross or pathological toxicity. While these preliminary results are encouraging, only ∼25% of the animals in the treated cohorts were tumor free at the end of this study. Admittedly, it is possible that better responses might be obtained if higher dose levels are investigated (vide infra).

The untargeted MMC drug was found to effectively eliminate the ip tumors, but this activity was accompanied by lethal toxicity. Unfortunately, lower dose levels of free MMC were not investigated here, primarily because we wanted to directly compare the therapeutic and toxicological properties of free versus targeted MMC at equivalent dose levels. It is anticipated that lower dose levels of MMC would have provided therapeutic benefit along with lower and perhaps acceptable toxicity. However, given that (i) free MMC is very toxic to humans, (ii) its use is limited to very infrequent dose schedules because of this cumulative toxicity, and (iii) its preclinical activity in rodent models (i.e. high cure rate) was never clinically observed because patients could not withstand the level of toxicity that the rodents experienced, we feel that folate-targeted MMC (EC72) may be the better option for dosing humans with this drug class.

When comparing the in vivo activity of EC72 between our two tested models, similar therapeutic outcomes were observed. While these results are positive, and they do provide evidence for FR targeted activity, EC72 was predicted to have greater activity against the KB tumors since they express higher levels of FR protein per cell compared to the M109 tumors and the fact that the KB cells responded better to EC72 in vitro (see Table 1). Although no formal quantitation of tumor-associated drug was conducted in this investigation, it is possible that EC72's ability to penetrate KB tumors was somewhat compromised relative to the M109 tumors. In fact, such variances are to be expected, especially at the clinical level. But, an alternative explanation for the cause of this result could be that the two models were treated using slightly different schedules. Thus, M109 tumor-bearing mice received EC72 following a qdx7, 4 wk regimen, whereas KB tumor-bearing mice received EC72 following a qdx5, 4 wk regimen. Obviously, more consistent dosing would have favored the M109 tumor-bearing mice, even though the M109 tumors expressed less FR protein. Taken together, it is tempting to speculate that KB tumor-bearing mice might experience greater therapeutic activity if EC72 were dosed following the qdx7, 4 wk schedule.

On the basis of previous biodistribution studies using radiolabeled folate conjugates, we have determined that a dose level of ∼1800 nmol per kg body weight (mouse) is enough to saturate tumor-associated folate receptors following a single iv or ip injection (*28*). For that reason, we elected to use the 1800 nmol/kg dose level for both the M109 and KB in vivo model studies presented within. Notably, since it is very likely that the extent of tumor penetration will vary among different folate−drug conjugates, this parameter must be appropriately studied further. Until then, we pondered the significance of this dose level in the clinical setting. When translated to the human-equivalent dose (based on body surface area conversions), the mouse dose level of 1800 nmol/kg EC72 would be approximately 5.6 μmol/m^2. Interestingly, the

human dose level for MMC is 60 μmol/m^2 given in 6 to 8 week intervals (*29*). From an equivalency standpoint, and not withstanding the fact that EC72 is inherently less toxic than MMC, we estimate that a cancer patient could be safely treated >10 times within a 6 to 8 week cycle with "receptor-saturating" dose levels of EC72. Such a dose density, or metronomic, style of dosing may produce greater therapeutic outcomes. In regards to MMC, this targeted approach may also suddenly revitalize this old drug's clinical utility.

In conclusion, additional animal studies with EC72 are planned to better understand the effects of dose level and dose schedule. We also plan to study the effects of tumor growth rate and FR content on the overall observed antitumor response manifested by EC72 therapy. It is also important to study the effect of alternative dosing routes (ip versus iv or subcutaneous) as well as to vary the location of the tumor (i.e. ip versus subcutaneous). Since EC72 therapy appears to be rather safe, at least at the preclinical level, various combinations of EC72 plus other drugs should also be investigated for possible additive or synergistic responses. This is especially true for those drugs that cannot be dosed in combination with free MMC due to overlapping toxicities.

ACKNOWLEDGMENT

The authors wish to thank Dr. Philip S. Low for his valuable comments, and Dr. Alberto Gabizon for sharing his FR-positive M109 cell line.

A Peptide Carrier with a Built-In Vaccine Adjuvant: Construction of Immunogenic Conjugates

Dimitrios Krikorian, Eugenia Panou-Pomonis, Chryssa Voitharou, Constantinos Sakarellos, and Maria Sakarellos-Daitsiotis*

Department of Chemistry, Section of Organic Chemistry and Biochemistry, University of Ioannina, 45110 Ioannina, Greece. Received December 13, 2004; Revised Manuscript Received April 18, 2005

A multifunctional carrier combining B/T cell epitopes (i), a built-in vaccine adjuvant (ii), and a universal T cell epitope (iii) for the construction of potent and specific immunogenic conjugates is presented. The IL-1β(163−171) fragment known to reproduce the immunostimulatory and adjuvant effects of the whole IL-1β without possessing any of the pro-inflammatory properties of IL-1β was covalently anchored to the N-terminus of the Sequential Oligopeptide Carrier, SOC_n, formed by the repeating tripeptide unit Lys-Aib-Gly. A promiscuous T cell epitope derived from the tetanus toxin, TT(593−599), was also positioned in the carboxy terminus of SOC_n as a universal immunogen to provide broad immunogenicity. Selected B/T cell epitopes from the Sm and La/SSB autoantigens, against which is directed the humoral autoimmunity in patients with systemic lupus erythematosus and Sjögren's Syndrome, respectively, were coupled to the Lys-$N^{\epsilon}H_2$ groups of the carrier, and the formulated constructs were administered in animals following the conventional immunization protocol of complete/incomplete Freund's adjuvant. The induced immune responses were compared with that produced when the Sm- and La/SSB-reconstituted immunogenic conjugates were injected alone. High titers of specific antibodies recognizing the priming construct, as well as the cognate autoantigen, were obtained when administered alone without the assistance of Freund's adjuvant. It is concluded that our approach provides the conceptual and experimental framework for the development of multifunctional immunogenic conjugates eliciting enhanced, specific, and prolonged humoral response for usage as human vaccine candidates.

INTRODUCTION

Formulation of an effective immunogen that could elicit a potent immune response should incorporate B cell epitopes that mimic the three-dimensional conformation of the antigen and T cell epitopes resulting from the processed protein, both on the same carrier that links the major histocompatibility complex with the T cell receptor (*1, 2*). To achieve enhanced and prolonged humoral and cellular immune response, potent immunogens must be also administered in combination with adjuvants, e.g. incomplete Freund's, CRL1005, QS21, Montanide ISA-51, etc., although the precise mechanism of their action remains unclear, and severe skin toxicities, in some cases, have been reported. The only adjuvants currently approved by the Food and Drug Administration for use with human vaccines are alluminum salts, which, however, have low potency and problems associated with their formulation. To address this problem, adjuvants with low toxicity profiles as for example the granulocyte monocyte colony stimulating factor have been tested (*3, 4*). It has been also proposed that T cells provide "help" to B cells under genetic control. Recently, a number of so-called "promiscuous" T cell epitopes from tetanus toxin (TT), measles virus, or E6 transforming protein have been reported to be universally immunogenic (*5, 6*).

On the basis of the reported issues, an ideal immunogenic conjugate, and consequently an effective human vaccine, should combine specific B and T cell epitopes, adjuvants, and "promiscuous" T cell epitopes. The rational design of such a multivalent conjugate as vaccine candidate requires a synthetic carrier or template on which different peptides with various functionalities could be anchored. Development of synthetic carriers for anchoring immunogenic peptides and producing specific immune responses has been the stimulus of intensive efforts. Among others the lysine core matrix, the Pam_3-Cys-Ser (a palmitoyloxy lipopeptide), and the template-assembled synthetic protein (TASP)[1] deserve to be mentioned (*7−9*).

A new class of Sequential Oligopeptide Carriers, (SOC_n), for anchoring antigenic/immunogenic peptides has been successfully applied in our laboratory. The carrier, formed by the repetitive Lys-Aib-Gly moiety, was designed to display a predetermined 3D structure, so that the attached peptides could obtain a defined spatial

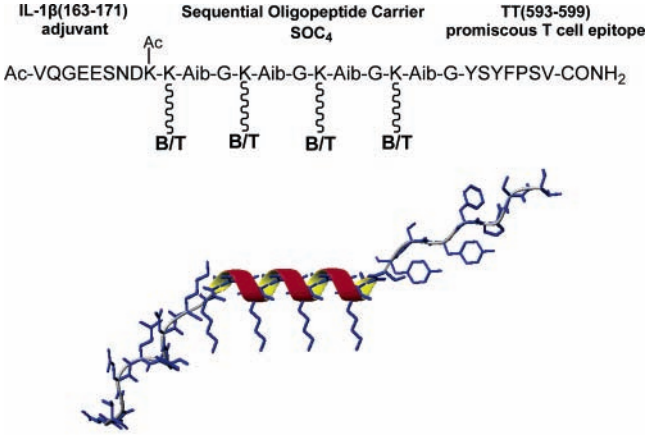

Figure 1. Schematic representation of a multivalent peptide carrier that incorporates an adjuvant, IL-1β(163−171), a promiscous T cell epitope, TT(593−599), and specific B and T cell epitopes anchored to the Lys-N$^{\epsilon}$N$_2$ groups of the sequential oligopeptide carrier (Lys-Aib-Gly)$_4$, SOC$_4$.

orientation. Conformational analysis showed that SOC$_n$ adopt a distorted 3_{10} helicoid structure, while the coupled epitopes preserve their original "active" structure. It has been concluded that the helicoid structure of SOC$_n$ helps the reconstitution and/or mimicking of the native forms of the epitopes, so that potent immunogens could be generated. SOC$_n$-conjugates induced high titers of specific antibodies recognizing the priming peptides, as well as the intact proteins, but not the carrier alone (*10*−*14*).

With the aim of contributing to the development of a carrier that could help to augment and improve the character and the quality of the humoral and cellular immune response, the SOC$_n$ carrier was elongated from the amino-terminus by the IL-1β fragment VQGEESNDK (163−171) as adjuvant. It has been reported that IL-1β-(163−171) is devoid of all pro-inflammatory effects of IL-1β but maintains the immunostimulatory activity of the intact cytokine (*15, 16*). A "promiscuous" T cell epitope deriving from TT, YSYFPSV (593−599), was also covalently attached to the carboxy-terminal group of SOC$_n$, as universal immunogen (*17*). B and T cell epitopes derived (i) from the Sm and (ii) the La/SSB antigens were coupled to the Lys-N$^{\epsilon}$H$_2$ groups of the carrier and the obtained conjugates were administered in animals without adding any adjuvant to test the induction of specific antibodies. The schematic representation of a multivalent peptide vaccine that incorporates an adjuvant IL-1β(163−171), a promiscuous T-cell epitope TT(593−599), and specific B and T cell epitopes is illustrated in Figure 1.

Epitope mapping of the Sm autoantigen revealed that the sequence PPGMRPP, found in three copies in the protein, represents the major B cell epitope of Sm, against which is directed the majority of autoantibodies in SLE patients (*18*). In this regard anti-Sm antibodies are considered as a disease marker for SLE (*19, 20*). Four copies of the PPGMRPP dominant B cell epitope of Sm were covalently anchored to the carrier and the potential of the reconstituted Sm conjugate, Ac-IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ (**2**) (Figure 2) to elicit specific immune response without usage of any adjuvant was examined.

La/SSB autoantigen is one of the molecular targets of humoral autoimmunity primarily in SS patients (*21*). In previous studies we have mapped the location of four B cell antigenic determinants of La/SSB (*22*), and we have investigated their ability to induce T cell responses against the La/SSB protein after animal injection (*23*). It was found that the sequence ANNGNLQLRNKEVTWEVLEG corresponding to the region 289−308 of La/SSB is an immunodominant T-cell and a minor B cell epitope. Two copies of the La/SSB (289−308) epitope were covalently linked to the 1st and 4th Lys-N$^{\epsilon}$H$_2$ group of SOC$_4$ to create a mimic of La/SSB. Animal immunization experiments were performed to validate the efficacy of the Ac-IL-1β-SOC$_4$-[Ac$_2$, (La/SSB)$_2$]-TT-NH$_2$ (**3**) conjugate (Figure 2) to induce high titers of specific antibodies without utilizing any adjuvant.

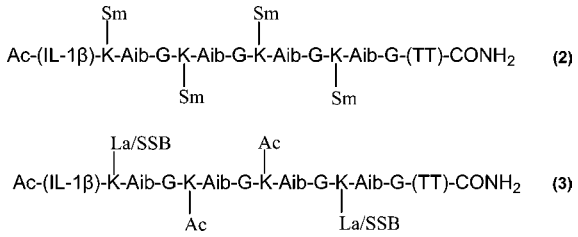

Figure 2. Schematic representation of conjugates Ac-IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ (**2**) and Ac-IL-1β-SOC$_4$-[Ac$_2$-(La/SSB)$_2$]-TT-NH$_2$ (**3**), where Sm: PPGMRPP, La/SSB: Ac-ANNGNLQLRNKEVTWEVLEG (289−308), IL-1β: Ac-VQGEESNDK (163−171), and TT: YSYFPSV (593−599).

The produced potent humoral immune response of both conjugates was compared with that obtained when each one of them was injected following the complete/incomplete Freund's adjuvant protocol. Our data suggest that the presented carrier could be employed in engineering potent immunogenic conjugates as human vaccine candidates.

EXPERIMENTAL PROCEDURES

Synthesis of the Ac-IL-1β-SOC$_4$-Ac$_4$-TT-NH$_2$ Carrier (1). The synthesis of **1**, where SOC$_4$ is (K-Aib-G)$_4$, was carried out manually by the SPPS procedure (*24*−*26*) using the MBHA resin (3 g, 0.13 mmol/g capacity). Lysine was introduced as Boc-Lys(Fmoc)-OH, serine as Boc-Ser(Bzl)-OH, tyrosine as Boc-Tyr(2,6-di-Cl−Bzl)-OH, and aspartic acid and glutamic acid as Boc-Asp(Obzl)-OH and Boc-Glu(Obzl)-OH, respectively. Synthetic procedure starts with the step by step couplings, to the resin, of the protected residues (Boc/Bzl) corresponding to the TT(593−599) fragment. The protocol of the synthesis was the following: (i) deprotection with 40% TFA/DCM (1 × 2 min, 1 × 13 min); (ii) washings DCM (3 × 1 min), MeOH (3 × 1 min), DCM (3 × 1 min); (iii) neutralization with 7% DIEA (2 × 2 min); (iv) washings DCM (3 × 1 min), MeOH (3 × 1 min), DCM (3 × 1 min); (v) couplings with three equivalent amino acid derivatives, 2.9 equiv of TBTU, 3 equiv of HOBt, 9 equiv of DIEA in DCM−DMF 4:1 or 1:4 (V/V) mixture depending on the solubility of Boc-amino acid derivatives (2 h); (vi) washings DCM (3 × 1 min), MeOH (3 × 1 min), DCM (3 × 1 min); (vii) ninhydrin assay (*27*). A similar protocol was applied for the sequential propagation of the Boc-K (Fmoc)-Aib-Gly moiety until the formation of the tetrameric SOC$_4$, oligopeptide. The IL-1β(163−171) fragment was inserted step by step following the Boc/Bzl strategy to obtain the protected carrier on the resin.

The N$^{\alpha}$-terminal Boc group (Boc-V) of the carrier was cleaved by 40% TFA in DCM and Val was N$^{\alpha}$-acetylated with Ac$_2$O (30 equiv of Ac$_2$O/pyridine, 20 min). Fmoc-protective groups of Lys-N$^{\epsilon}$H$_2$ were removed by 20% piperidine in DMF (1 × 2 min, 1 × 15 min, washings DCM, MeOH, DCM) followed by N$^{\epsilon}$-acetylation with Ac$_2$O. The peptide was cleaved from the resin support by liquid HF in the presence of phenol and anisole (HF−phenol−anisole = 10 mL:1 g:1 mL) for 30 min at −8 °C and 1.5 h at 0 °C and extracted with 2 M aqueous acetic

acid. The crude peptide (yield 90%) was purified by RP-HPLC using a Supelco Discovery C_{18} semipreparative column (250 mm × 10 mm, 5 μm, 300 Å). The purified peptide (yield 57%) was analyzed by RP-HPLC (t_R = 15.41 min), LC and ESI-MS (M + H^+ calculated/found 3181.5/3181.6).

Synthesis of the Ac−IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ Conjugate (2). Initially was synthesized, by the SPPS procedure, on the resin as the protected fragment of the carrier comprising TT and SOC_4, as already described for the synthesis of **1**, except that the fourth lysine was introduced as Alloc-K(Fmoc). After removal of the Fmoc protective groups from the Lys-$N^{\epsilon}H_2$ groups by 20% piperidine in DMF, synthesis of the Sm epitopes was carried out (Boc/Bzl) by the simultaneous attachment of each residue in four copies and afterward the N^{α}-Alloc group of Lys was eliminated under hydrostannolytic cleavage [$PbCl_2(PPh_3)_2$/Bu_3SnH/AcOH in DCM (0.03 equiv of $PbCl_2(PPh_3)_2$, 3 equiv of Bu_3SnH, and 3 equiv of AcOH for 30 min, washings DCM, MeOH, DCM] (*28, 29*), and the N-terminal sequence of IL-1β(163−171) was coupled step by step to the carrier. Arginine was introduced as Boc-Arg(Tos)-OH, while Met was used without side protection as Boc-Met-OH. Dimethyl sulfide was added to each cycle of Boc-removal (TFA/DCM/DMS: 40/59/1) after coupling of Boc-Met-OH to avoid oxidation of Met side chain. The peptide was cleaved from the resin by liquid HF in the presence of *p*-cresol and thiocresol as described for **1**. The crude material (yield 86%) was dialyzed against water (yield 33%) and purified by RP-HPLC using a Supelco Discovery C_{18} semipreparative column as for peptide **1**. The purified peptide (yield 24%) was analyzed by RP-HPLC (t_R = 10.12 min), LC and ESI-MS (M + H^+ calculated/found 5940.95/5940.90).

Synthesis of the Ac-IL-1β-SOC$_4$-[Ac$_2$, (La/SSB)$_2$]-TT-NH$_2$ Conjugate (3). Synthesis of the protected fragment of the carrier, incorporating TT(593−599) and SOC_4, was performed as for **1**, except that lysines at the 1st and 4th position of SOC_4 were introduced as Alloc-K(Fmoc) and Boc-K(Fmoc), respectively, while lysines at the 2th and 3rd position were inserted as Boc-K(Ac)-OH. After cleavage of the Fmoc protective group of lysine side chains, the synthesis of the La/SSB (289−308) epitope was carried out by the simultaneous coupling of each residue in two copies following the Boc methodology, except that lysine within the epitope sequence was introduced as Alloc-Lys(Fmoc)-OH. The $N^{\alpha}H_2$ terminus of the epitopes was acetylated, while after removal of the N^{α}-Alloc protective group of the carrier it was elongated to construct the IL-1β(161−173) N-terminal segment. The peptide was cleaved from the resin by liquid HF in the presence of phenol and anisole as described for **1**. The crude material (yield 91%) was dialyzed against water (yield 70%) and purified by RP-HPLC using a Supelco Discovery C_{18} semipreparative column as for peptide **1**. The purified peptide (yield 18%) was analyzed by RP-HPLC (t_R = 17.10 min), LC and ESI-MS (M + H^+ calculated/found 7619.43/7619.65).

Dialysis. Dialysis tubes, whice are cellulose membranes benzoylated in order to reduce the pore size, with a molecular mass cutoff of ∼1500, were obtained from Sigma (Deisenhofen, Germany). They were supplied in water pack containing 0.002% 1-hydroxypyridine-2-thione as preservative, and they were activated by heating in a solution of 0.1 M $NaHCO_3$ and 0.001 M ethylenediaminetetraacetic acid to just under boiling point.

LC-ESI-MS. LC-ESI-MS of Ac-IL-1β-SOC$_4$-Ac$_4$-TT-NH$_2$ (**1**), Ac-IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ (**2**), and Ac-IL-1β-SOC$_4$-[Ac$_2$-(La/SSB)$_2$]-TT-NH$_2$ (**3**) was performed using a Supelco Discovery C_{18} (250 mm × 4.6 mm, 5 μm, 300 Å) reverse phase column with a Waters instrument equipped with a Waters 616 pump and a Waters 2487 Dual λ absorbance detector. Eluent A was 0.1% TFA in water, and eluent B was 0.1% TFA in acetonitrile. A linear gradient for Ac-IL-1β-SOC$_4$-Ac$_4$-TT-NH$_2$ (**1**) and Ac-IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ (**2**) was 20% to 50% acetonitrile in 0.1% TFA at a flow rate of 1 mL/min and for Ac-IL-1β-SOC$_4$[Ac$_2$-(La/SSB)$_2$]-TT-NH$_2$ (**3**) was 20% to 40% acetonitrile in 0.1% TFA at a flow rate of 1 mL/min.

RP-HPLC. RP-HPLC purification was carried out on a Waters 4000 semipreparative instrument using a Supelco Discovery C_{18} (250 mm × 10 mm, 5 μm, 300 Å) column with the same linear gradient as LC-ESI-MS at a flow rate of 4.7 mL/min. Detection was carried out at λ = 214 nm.

Mass Spectroscopy. Positive ion electrospray ionization mass spectrometric (ESI-MS) analyses of Ac-IL-1β-SOC$_4$-Ac$_4$-TT-NH$_2$ (**1**), Ac-IL-1β-SOC$_4$-Sm$_4$-TT-NH$_2$ (**2**), and Ac-IL-1β-SOC$_4$-[Ac$_2$-(La/SSB)$_2$]-TT-NH$_2$ (**3**) were performed on a Micromass Platform LC-MS. Capillary and cone voltages were set to 3 kV and 45 V, respectively. Samples were dissolved in water/acetonitrile/trifluoroacetic acid (1/1/0.05 V/V/V).

Circular Dichroism. CD spectra were recorded at 25°C on a Jasco J-710 spectrophotometer using 0.1 cm path-length quartz cell and peptide concentration 10^{-4} M. Experiments were performed in TFE/H_2O mixtures (from 0 to 100%) and in SDS (concentrations ranged from 5 to 15 mM). Spectra were obtained with a 2 nm bandwidth, a scan speed of 4 nm min^{-1} and a time constant of 8 s. The signal-to-noise ratio was improved by accumulating four scans. To eliminate errors from instrumental drift, the baseline in air was recorded and subtracted after each scan. All CD spectra are reported in terms of ellipticity units per mole of peptide residue ($[\Theta]_R$ in deg cm^2 $dmol^{-1}$). The percentage helical content was estimated on the basis of the $[\Theta]_{222}$ nm values, in different environments, as described by Chen et al. (*30*) and using the CD deconvolution (CDNN program) described by Bohn et al. (*31*). Two parameters R1 and R2 described by Rozek et al. (*32*) were also used for analyzing the CD spectra. R1 is the ratio of the intensity of the maximum between 190 and 195 nm and the intensity of the minimum between 200 and 210 nm. R2 is the intensity of the minimum near 222 nm and the intensity of the minimum between 200 and 210 nm.

Rabbit Immunizations. New Zealand white rabbits were immunized, two for each peptide-conjugate, subcutaneously following three different protocols.

Protocol A: 1 mg of each conjugate in 500 μL of H_2O emulsified in 500 μL of CFA was injected on day 1, followed by boostings with 0.5 mg/500 μL H_2O emulsified in 500 μL of IFA with two weeks intervals. Animals were bled after two successive immunizations on day 21, after three injections on day 43, and after five injections on day 86.

Protocol B: 1 mg of each conjugate in 500 μL of H_2O emulsified in 500 μL of IFA was injected following the previous schedule. Animals were also bled after the sixth injection on days 108.

Protocol C: 1 mg of each conjugate in 1 mL of H_2O was injected following the schedule of protocol A adding neither CFA nor IFA. Animals were also bled after the sixth injection on days 108.

Mice Immunization. Mice (Balb/c) were immunized, three for each experiment, subcutaneously following two different protocols.

Protocol A: 50 μg of the conjugate (**3**) in 100 μL of H_2O emulsified in 100 μL of CFA was injected on day 1, followed by boostings with the same quantities of immunogen emulsified in 100 μL of IFA with two weeks intervals. Animals were bled after two successive immunizations.

Protocol B: 50 μg of immunogen in 200 μL of H_2O was injected following the previous schedule without adding CFA/IFA.

ELISA for Antisera. Ninety-six-well polystyrene plates (Nunc Immuno Plates, Denmark) were coated overnight at 4 °C with 10 μg/mL of each peptide-conjugate including the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 carrier in carbonate buffer, pH 9.6 (100 μL/well). After washings with PBS/pH 7.2, the nonspecific binding sites were blocked with 3% skim milk in PBS and the plates were incubated at room temperature for 2 h. Serum samples from preimmunized and postimmunized animals at dilutions, with blocking buffer, ranging from 1:100 to 1:50.000, were added, and the plates were incubated at 4 °C overnight. After extensive washings with PBS, the wells were incubated with anti rabbit anti-human IgG or goat anti-mouse IgG conjugated to peroxidase (Jackson Immunoresearch) at 37 °C for 1.5 h. Finally the plates were washed, 50 μL of substrate solution of TMB (1 mg/1 mL) and 50 μL of H_2O_2 (1 mL/1 mLH_2O) were added to each well, and the absorbance was measured at 450 nm.

RESULTS

Design and Synthesis of an Innovative Multifunctional Carrier Bearing B and T Cell Epitopes as Potential Immunogenic Conjugates. A new carrier combining (i) the tetrameric repeating unit (Lys-Aib-Gly)$_4$, SOC_4, for anchoring B/T cell epitopes from the Lys-N$^{\epsilon}H_2$ groups to induce specific antibodies, (ii) the IL-1β(163−171) fragment to improve the quality and prolong the immune response, and (iii) the TT(593−599) segment as universal immunogen, was constructed according to the principles of the step by step solid-phase peptide synthesis, following an othogonal system of N-protecting groups (Boc-, Fmoc-, and Alloc-). This approach allowed the formulation of reconstituted potent immunogenic conjugates in good yield and high purity as confirmed by ESI-MS and the corresponding LC. Molecular weights of the reported preparations ranged from 5940 to 7620, approaching the molecular mass of small proteins.

Conformational Study by CD. The CD spectra of the carrier in TFE/H_2O mixtures (10, 30, and 50%) showed a positive band at 192 nm and two negative bands at 208 and 222 nm typical of helical structure, which reaches maximum ellipticity at 100% TFE (Figure 3). It is presumed that trifluoroethanol favors the formation of a more ordered conformation by lowering the dielectric constant of the dissolving medium.

The effect of SDS, a membrane mimetic, on the conformation of the carrier was also studied. In phosphate buffer, pH 6, the CD spectrum exhibits weak helical characteristics. Upon addition of SDS, at concentration 5 mM, below the critical micelle concentration (CMC 8 mM) the typical characteristic bands of helical structure appeared, indicating that upon interaction with SDS even below CMC the helical character of the carrier is enhanced (*33*). The ellipticity remained practically unchanged at 10 and 15 mM SDS, suggesting that the micelle microenvironment at 5 mM is sufficient to induce maximum helical conformation to the carrier.

The percentage helical content of the carrier in phosphate buffers, 5 mM SDS and 100% TFE, calculated on the basis of the $[\Theta]_{222}$ value (*30*) and the CD deconvolution (*31*) was estimated to 6, 20, and 40%, respectively. Moreover, R1 parameter is close to −2 and R2 approximates 1, confirming the helicoid character of the carrier (*32*).

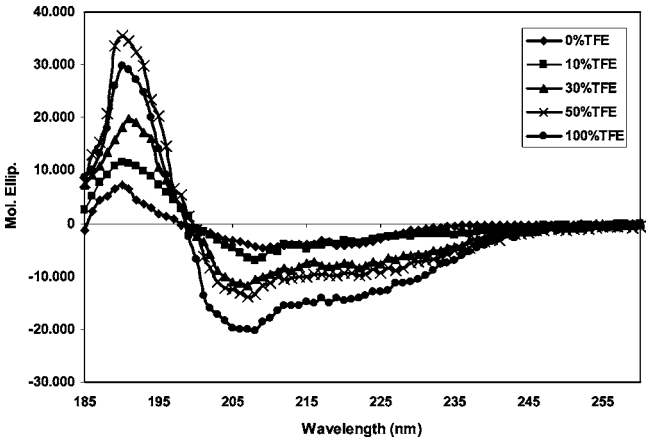

Figure 3. CD spectra of the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 (**1**) carrier in TFE/H_2O mixtures 10, 30, 50, and 100% TFE.

It seems likely that the helicoid features of SOC_4 (*10*−*14, 34, 35*) are conserved even after its amino and carboxy terminus elongation. One may assume that the persistence of the ordered secondary conformation of the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 carrier could optimize the B/T cell epitope presentation and help to the formation of functional reconstituted immunogenic conjugates.

Serological Study. Comparison of the Humoral Response in Rabbits Immunized with Three Different Approaches. Sera were collected before the initial immunization, as well as after two subsequent boosts and were tested against the immunizing conjugate. The reactivity of rabbit anti-sera to the Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 conjugate (**2**) following the CFA/IFA procedure increased gradually and remained at high levels after the third immunizatiuon. Dilution curves of sera in anti-Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 ELISA are shown in Figure 4A. Rabbits immunized with the Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 conjugate (**2**) and IFA raised specific antibodies recognizing the priming immunogen after the sixth boosting. Sera samples displayed high reactivity even at 1:50000 dilution (Figure 4B). Antibody specific response in rabbits immunized with Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 (**2**) alone, without administering neither CFA nor IFA was detected after the sixth injection and sera reactivity, as shown in anti-Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 ELISA tests, remained high even at 1:50000 dilution (Figure 4C).

Animals were immunized with Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 congugate (**3**) following the previous protocols, and sera were tested for the induction of anti-Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 antibodies in ELISA tests. The pattern of the sera reactivity was comparable with that observed when conjugate **2** was injected and the anti-conjugate **3** sera reactivity remained high (1:50000 dilution) even when conjugate **3** was injected alone without the assistance of adjuvant (Figure 5).

Usage of adjuvant is essential to induce strong and prolonged antibody responses although their function is not fully understood. Adjuvants incorporate two components. One is a substance designed to form a deposit protecting the antigen from rapid catabolism, and the other is a substance that stimulates the immune response nonspecifically by activating the antigen-processing cells

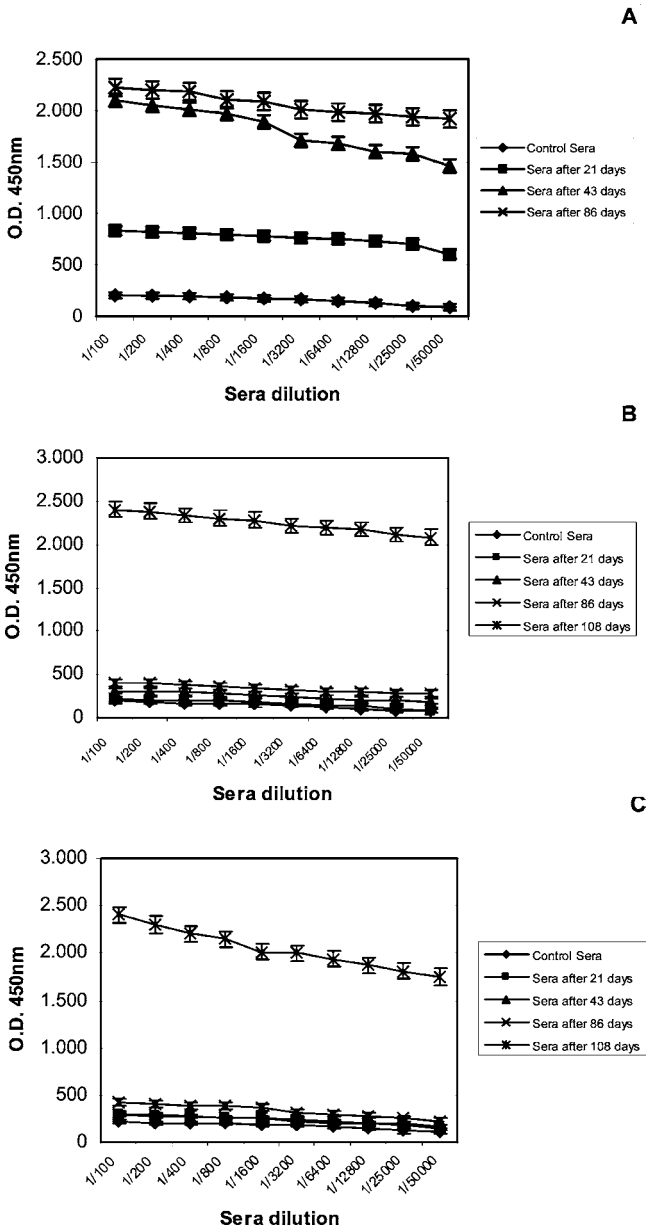

Figure 4. Binding of antisera to the Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 (**2**) conjugate. Antisera raised in rabbits immunized with CFA/IFA (A), IFA (B), and the peptide conjugate alone (C). Data shown as means of three independent experiments carried out in triplicate using a pool of the two rabbit sera that gave similar results when used independently. Control sera: preimmune.

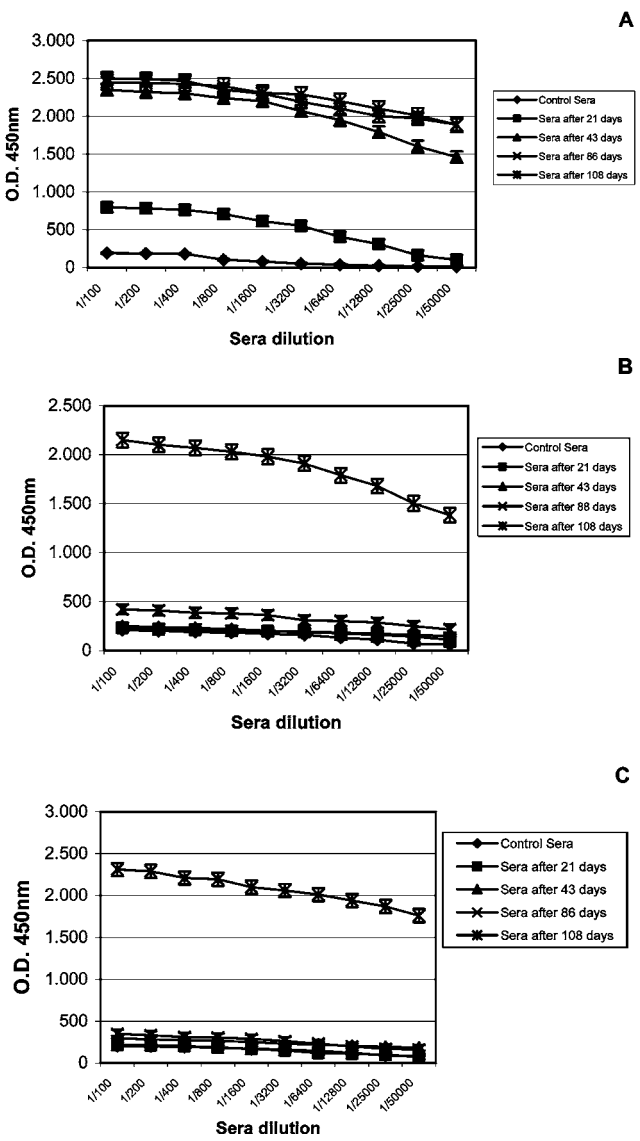

Figure 5. Binding of antisera to the Ac-IL-1β-SOC_4-[Ac_2,(La/$SSB)_2$]-TT-NH_2 conjugate (**3**). Antisera raised in rabbits immunized with CFA/IFA (A), IFA (B), and the peptide conjugate alone (C). Data shown as means of three independent experiments carried out in triplicate using a pool of the two rabbit sera that gave similar results when used independently. Control sera: preimmune

directly. Freund's adjuvant, which is the most commonly used adjuvant for research work, is a water-in-oil emulsion prepared with nometabolizable oils that contains heat-killed tuberculosis mycobacteria. The principal disadvantage of Freund's adjuvant is that it can cause a local inflammatory reaction at the site of injection and invoke very aggressive and persistent granulomas. To avoid these side effects, incomplete Freund's adjuvant, among others, has been proposed although severe skin toxicities have been reported in some cases (*3, 4, 36, 37*).

The profile of the antibody production when immunogens Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 and Ac-IL-1β-SOC_4-[Ac_2-(La/$SSB)_2$]-TT-NH_2 were injected alone leads to the assumption that incorporation of Aib, an enzymatic nondegradable residue, contributes to the slow release of epitopes thus resembling the proposed action of the nometabolizable oily constituents of IFA. On the other hand, the inclusion into the carrier of the IL-1β(163−171) fragment, known to reproduce the immunostimulatory and adjuvant functions of the whole IL-1β but not its numerous side effects (*15, 16*), assisted the generation of an enhanced and sustained immune response, as that of CFA, which is also site specific, as the produced antibodies, so far presented, recognize the priming immunogens.

Specificity of Antibody Recognition. To further assess the specificity of the generated antibodies when the constructed immunogens were injected to animals, the obtained antisera were tested against the carrier Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 (**1**) and SOC_4, Ac-[Lys(Ac)-Aib-Gly]$_4$, without bearing any peptide epitope. Antibodies raised against peptide-conjugate **2** are highly recognized by the priming peptide, but their recognition from the carrier, which incorporates the IL-1β and TT fragments, and SOC_4, when administered without adjuvant is negligible (Figure 6A). Similarly, antibodies raised against peptide-conjugate **3** without adjuvant exhibit negligible reactivity against the carrier compared to their high

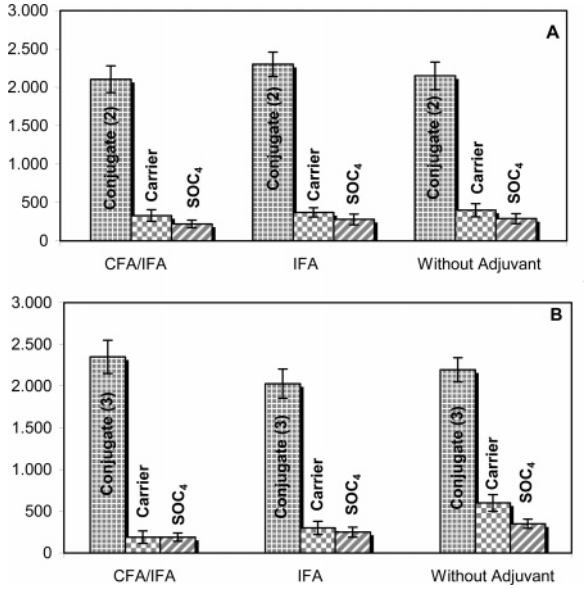

Figure 6. Comparison of the antisera reactivity of rabbits immunized with conjugate Ac-IL-1β-SOC_4-Sm_4-TT-NH_2 (**2**) against **2**, the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 carrier (**1**), and the SOC_4 carrier (A). Comparison of the antisera reactivity of rabbits immunized with conjugate Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 (3) against (3) the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 carrier (**1**), and the SOC_4 carrier (B). Peptide conjugates **2** and **3** were administered with CFA/IFA, IFA, and without adjuvant as indicated. Sera dilution: 1/800.

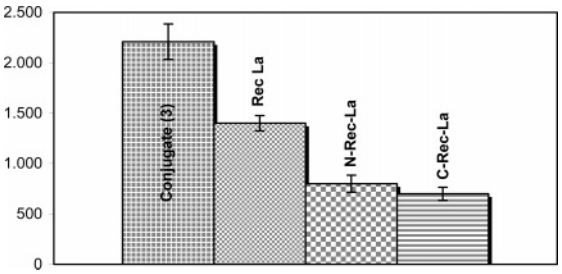

Figure 7. Comparison of the antisera reactivity of rabbits immunized (without adjuvant) with conjugate Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 (**3**) alone (without adjuvant) against **3**, recombinant La/SSB (Rec La), N-terminal recombinant La/SSB (N-Rec-La), and C-terminal recombinant La/SSB (C-Rec-La).

recognition by the priming peptide (Figure 6B). These findings indicate that the reported new immunogenic peptide-conjugates induce (without the assistance of adjuvant) a specific enhanced immunostimulatory response without producing nonspecific antibodies recognizing SOC_4 (*23, 38*) or the elongated by IL-1β and TT new carrier.

Rabbit antisera induced after immunization with peptide-conjugate **3** alone, without adjuvant, displayed significant reactivity (~60%) against recombinant La/SSB (*39*) and ~40% reactivity against the C-terminus and N-terminus of the recombinant La/SSB (*39*) compared to the anti-peptide-conjugate **3** antibody recognition (Figure 7). One may assume that immunizations using the conjugates presented in this study, without the addition of an adjuvant, results in polyclonal antibody response against the cognate protein or parts of it, as it was already mentioned when the conventional immunization protocol (CFA/IFA) was followed, suggesting the activation of antigen-specific B cells (*23, 41*).

In an attempt to validate the efficacy of our peptide-conjugates in species other than rabbits, immunizations were performed in mice, applying the peptide-conjugate

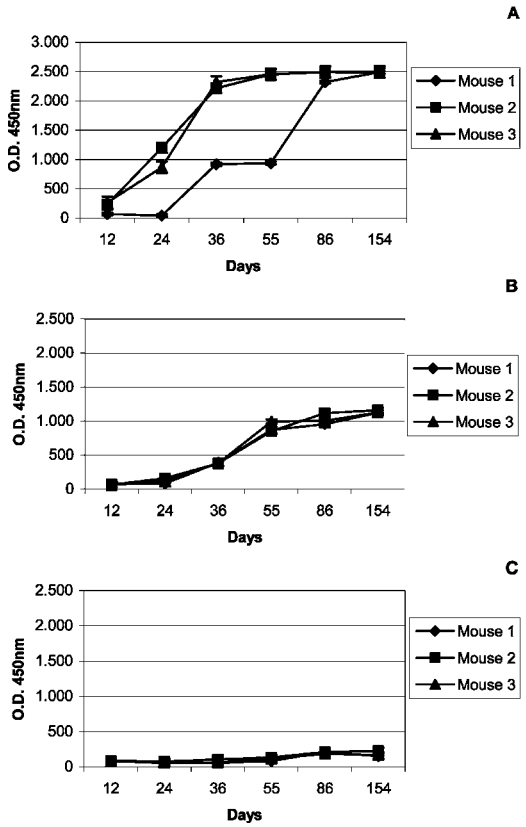

Figure 8. Binding of antisera to the Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 (**3**) conjugate at 1/500 dilution. Antisera raised in mice immunized with CFA/IFA (A) and the peptide conjugate alone without adjuvant (B). Data shown as means of three independent experiments carried out in triplicate using a pool of three mice sera that gave similar results when used independently. Control sera: preimmune (C).

3 following the CFA/IFA protocol and without the addition of adjuvant (Figure 8). Although rather lower titers of antibodies were produced when conjugate **3** was administered alone, the immunostimulatory response was specific for the priming peptide-conjugate, indicating the utility of the promiscuous T cell epitope, TT(593−599), in providing a broader spectrum of immunogenicity (*3, 5, 6*).

DISCUSSION

A new multivalent carrier combining B and T cell epitopes, a built-in adjuvant and a "promiscuous" T cell epitope as costimulatory molecules to formulate potential immunogenic conjugates is presented. Following the step-by-step solid-phase peptide synthesis principles and by applying orthogonal side-chain protections, it was feasible to synthesize two peptide-conjugates, as mimics of the Sm and La/SSB proteins, with accurate and unambiguous composition and structure without altering the initial properties of the conjugated epitopes. Moreover, is very probable that the helicoid features of the presented multifunctional carrier, as revealed by CD measurements, contribute to the conformation-dependent recognition of B cell epitopes of Sm and La/SSB proteins to elicit specific antibodies. In particular, the IL-1β(163−171) fragment was covalently linked to the N-terminus of the tetrameric Sequential Oligopeptide Carrier, SOC_4, as immunostimulator, while the TT(593−599) sequence was attached to the carboxy-terminus of SOC_4 as universal immunogen.

The reconstituted Sm and La/SSB immunogenic conjugates **2** and **3** respectively when injected in animals,

without the assistance of CFA/IFA, induced high titers of specific antibodies recognizing the priming peptide-constructs. The antibody reactivity remained high even at high sera dilution (1:50000), indicative of the potency and the good quality of the immune response. It seems likely that the inclusion of IL-1β(163−171) within the synthesized reconstituted immunogenic conjugates may substitute the immunostimulatory activity of Freund's adjuvant, while incorporation of Aib, an enzymatic nondegradable residue, in the repeating tripeptide unit of SOC_4 may replace the function of the nonmetabolizable oily constituents of the incomplete Freund's adjuvant.

Confirmation of the specificity of the generated antibodies, when the constructed immunogens are injected without the assistance of adjuvant, is further assessed from the fact that they do not recognize the Ac-IL-1β-SOC_4-Ac_4-TT-NH_2 carrier, which comprises the IL-1β, and the TT fragments and SOC_4. On the basis of these findings, it is presumed that the immune response is antigen driven, originated from the reported conjugates. It is of particular interest to underline the defined intramolecular spreading of the antibody response when epitope La/SSB(289−308) is injected in the form of Ac-IL-1β-SOC_4-[Ac_2-(La/SSB)$_2$]-TT-NH_2 without the assistance of Freund's adjuvant. The observed immunogenicity of construct **3** when injected in rabbits and mice implies that the inclusion of TT(593−599) in the reported carrier could help to overcome genetic restrictions of the T cell "help" to B cells.

Our study provides the conceptual and experimental framework to formulate multifunctional immunogens as human vaccine candidates without the adverse effects derived from the usage of adjuvants.

Complex Formation between a DNA Duplex and Lipid-like Spermine Derivatives: Hydrophobic Protection of DNA from One-Electron Oxidation

Huachuan Cao and Gary B. Schuster*

School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332. Received January 25, 2005; Revised Manuscript Received June 13, 2005

The one-electron oxidation of DNA leads to formation of a nucleobase radical cation that can migrate to a distant site where it is trapped by H_2O or O_2 to form a "damaged" guanine that is revealed as strand cleavage when the irradiated sample is treated with piperidine. We prepared a series of alkyl-substituted spermine derivatives and assessed their effect on the oxidative reactions of DNA induced by photoexcitation of a covalently linked anthraquinone derivative. The spermine compounds are polycations and bind nonselectively to DNA. When the spermine derivative is substituted with C_8 alkyl chains, it shows lipid-like properties. The reaction of the radical cation at guanine is affected by this lipid-like spermine. The distance dependence of the migration process becomes weaker, and the efficiency of strand cleavage is reduced. These results are attributed to the formation of a hydrophobic layer on the DNA that restricts access of H_2O to the nucleobase radical cation.

INTRODUCTION

The one-electron oxidation of DNA introduces a radical cation ("hole") that can migrate long distances before being consumed in an irreversible reaction that damages a nucleobase and results in strand cleavage upon subsequent treatment with piperidine (*1*). The mechanism of radical cation transport has been extensively studied. It is generally agreed that the hole hops adiabatically over distances greater than two or three base pairs and that it may tunnel from guanine to guanine over shorter distances (*2*−*6*). There has been less examination of the irreversible trapping reactions of these radical cations in DNA.

A pioneering study using isotope tracers showed that sensitized oxidation of 2′-deoxyguanosine in water solution leads to rapid deprotonation of the resulting radical cation and that subsequent reactions of the radical yield little 7,8-dihydro-8-oxo-2′-deoxyguanosine (8-OxoG) (*7*). In contrast, oxidation of guanine-containing duplex DNA in deoxygenated buffer solution was shown to give primarily 8-OxoG by reaction of a base-paired guanine radical cation with H_2O (*7*, *8*). Cullis (*9*) and Burrows (*10*) have shown that piperidine treatment of DNA that contains 8-OxoG does not lead to strand cleavage under the standard conditions. Clearly, formation of 8-OxoG by reaction of guanine radical cations with H_2O is not the only process that occurs in oxidized duplex DNA. In the experiments reported here, we probed the effect of an external hydrophobic "coating" around a DNA duplex on the efficiency of long-distance charge transport and on radical cation trapping by H_2O. We find that the hydrophobic layer increases the efficiency of charge transfer and inhibits trapping.

Our approach to limiting H_2O access to DNA was inspired by the extensive investigation of hydrophobic polycations that enable DNA transfection into cells (*11*−*13*). Microscopy, X-ray analysis, and fluorescence experiments show that these lipid-like materials cover the DNA surface and thereby facilitate migration through the hydrophobic cell membrane (*12*, *14*). We selected a set of derivatives for study that are built on a spermine tetracation core. In this case, the electrostatic interaction of the alkylammonium ions with the phosphate anions of DNA is the major driving force for formation of stable complexes (*15*). The lipid-like tetracations and the anthraquinone (AQ)-DNA duplex oligomer that we studied are shown in Figure 1.

EXPERIMENTAL PROCEDURES

The DNA oligonucleotides were synthesized on an ABI DNA synthesizer using standard solid-phase techniques. Phosphoramidites and 1.0 μM CPG columns were purchased from Glen Research. [γ-^{32}P]ATP was purchased from Amersham Bioscience. T4 polynucleotide kinase (T4PNK) was purchased from New England Biolabs and stored at −20 °C. DNA was deprotected in concentrated ammonium hydroxide and purified using reverse-phase HPLC on a Hitachi system equipped with a Dynamax C18 column. The molecular mass of the DNA was determined by electrospray ionization (ESI) mass spectrometry. The concentrations of the oligomers were determined from their absorbance at 260 nm. Duplex AQ-DNA solutions were prepared by combining equimolar amounts of the single-strand oligomers and annealing them at 90 °C with slow cooling to room temperature. UV melting and cooling curves were recorded on a Cary 1E spectrophotometer equipped with a multicell block, temperature controller, and sample transport accessory. CD spectra were recorded on a JASCO J-720 spectropolarimeter. Fluorescence measurements were recorded on SPEX 1681 Fluorolog spectrometer.

Synthesis of the C_nSp^{+4} "Lipids". The lipid-like compounds shown in Figure 1 all contain a spermine tetracation core and were prepared in seven steps. The synthetic route for these compounds was modeled on that for $C_{18}Sp^{+4}$, which was previously described (*16*). We found that replacement of tetramethylammonium chloride with sodium hydroxide to neutralize L-ornithine hydrochloride gave a better outcome. Details of the synthetic procedures will be reported elsewhere.

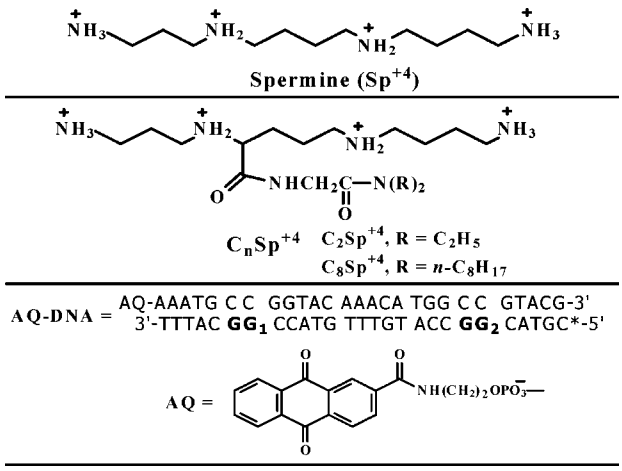

Figure 1. Structures of the spermine derivatives and the DNA oligomers used in this work. The ∗ indicates ^{32}P label.

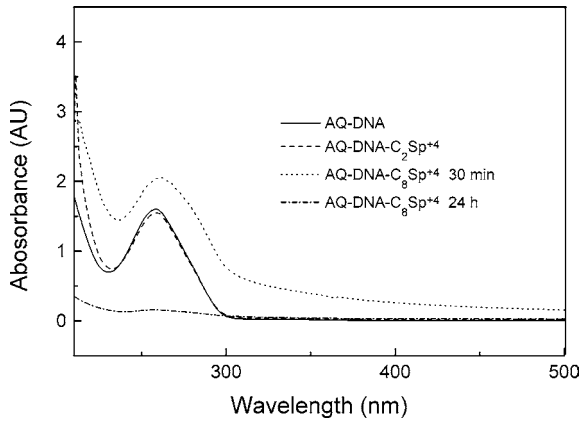

Figure 2. Absorption spectra of AQ-DNA in buffer solution at pH 7.0. The curves are recorded at various conditions as indicated. C_2Sp^{+4} and C_8Sp^{+4} are present at a charge ratio of 4.0.

Melting Temperatures. Melting temperatures were determined in quartz cuvettes sealed with tape. Samples contained duplex AQ-DNA (2.5 μM) in 10 mM sodium phosphate buffer (pH 7.0) and various concentrations of spermine or C_nSp^{+4}. The absorbance of the samples was monitored at 260 nm. The reported T_m values are the peaks in the first-derivative plots of melting profiles obtained by fitting the data with Microcal Origin software.

Fluorescence Spectroscopy. Emission spectra of ethidium bromide (EB, 10 μM) were obtained by exciting at 510 nm and monitoring the integrated emission intensity from 540 to 750 nm. Excitation spectra were obtained by monitoring the emission at 600 nm while scanning the excitation wavelength from 350 to 590 nm. The experiments were performed in a 1 cm path length quartz cuvette containing 1 mL of 2.5 μM AQ-DNA duplex in 10 mM sodium phosphate buffer at pH 7.0. Aliquots of solution containing spermine or C_nSp^{+4} were added to the DNA solution, and the fluorescence emission of the resulting solution was measured after incubation for 15 min.

Circular Dichroism (CD). CD spectra were measured between 200 and 400 nm as aliquots of solutions containing spermine or C_nSp^{+4} were added to an AQ-DNA duplex solution. Each spectrum was accumulated five times and smoothed, and the spectrum of the buffer solution was subtracted.

Cleavage Analysis by Radiolabeling and Polyacrylamide Gel Electrophoresis (PAGE). AQ-DNA was radiolabeled according to standard procedures at the 5′-end of the complementary strand with [γ-^{32}P]ATP and bacterial T4PNK. It was purified by 20% PAGE at 400 V. Samples for irradiation were prepared by hybridizing a mixture of unlabeled (2.5 μM) and radiolabeled (10 000 cpm) oligonucleotides in 10 mM sodium phosphate buffer (pH 7.0). Hybridized samples were incubated with various concentrations of spermine or C_nSp^{+4} as indicated for 30 min (total volume 30 μL) and then irradiated for 3 min at 30 °C in microcentrifuge tubes in a Rayonet photoreactor (Southern New England Ultraviolet Co., Barnsford, CT) equipped with eight 350 nm lamps. After irradiation, the samples were precipitated once with cold ethanol (100 μL) in the presence of glycogen (2 μL, 20 mg/mL), then washed with 80% ethanol (2 × 100 μL), dried (Speedvac, low heat), and treated with piperidine (100 μL of 1 M solution) at 90 °C for 30 min. After evaporation of the piperidine (Speedvac, medium heat), lyophilization twice with water (20 μL), and dissolution in denaturing dye solution (bromophenol blue, 4:1 v/v formamide in water), the samples (3000 cpm) were electrophoresed on a 20% 19:1 acrylamide/bisacrylamide gel containing urea (7 M) at 70 W for 90 min. The gels were dried, and the cleavage sites were visualized by autoradiography. Quantification of cleavage bands was performed on a Fuji phosphorimager.

Reaction of $^1O_2$ with AQ-DNA. A 10 μM solution of AQ-DNA, C_8Sp^{+4} and Rose Bengal (5 mM) was irradiated with light, >450 nm (only the Rose Bengal absorbs). After irradiation, the samples were worked up as described above (the Rose Bengal remains in the ethanol layer) and analyzed by PAGE.

RESULTS

Definition of the Charge Ratio. The experiments reported here were generally carried out in 10 mM sodium phosphate buffer solution at pH 7.0. Under these conditions, spermine (Sp^{+4}) and its derivatives C_nSp^{+4} have four positively charged ammonium groups, and the AQ-DNA duplex has 54 negatively charged phosphate groups. Thus, when the mole ratio of the AQ-DNA to spermine is 1:13.5, there is one positive charge on a spermine or a C_nSp^{+4} derivative for each negative charge on a DNA phosphate. We define this to be a charge ratio equal to 1.0.

Characterization of AQ-DNA Solutions in the Presence of Sp^{+4} and C_nSp^{+4}. DNA duplexes that are much longer than AQ-DNA examined in this work form aggregates and condensates with cationic lipids such as C_nSp^{+4} (*14*, *17*). We carried out experiments to assess the stability of solutions of AQ-DNA in the presence of Sp^{+4} and C_nSp^{+4}. The solutions were evaluated immediately after they were prepared and then monitored over time to determine whether they change during the course of the experiments reported here.

Absorption Spectroscopy. The absorption spectrum of AQ-DNA in solution was monitored in the presence of various concentrations of Sp^{+4} and C_nSp^{+4} (see Figure 2). Spermine and C_2Sp^{+4} do not affect the UV spectrum of AQ-DNA up to a charge ratio of 4.0. Similarly, solutions of AQ-DNA containing C_8Sp^{+4} up to a charge ratio of 2.0 were stable (a small, constant baseline increment is observed, which may indicate the formation of some small aggregates). In contrast, for C_8Sp^{+4} at a charge ratio of 4.0, the absorbance increases significantly (due to scattering) during the first few hours after the sample is prepared, and then there is a sharp decrease in absorbance attributed to precipitation of the AQ-DNA/C_8Sp^{+4}

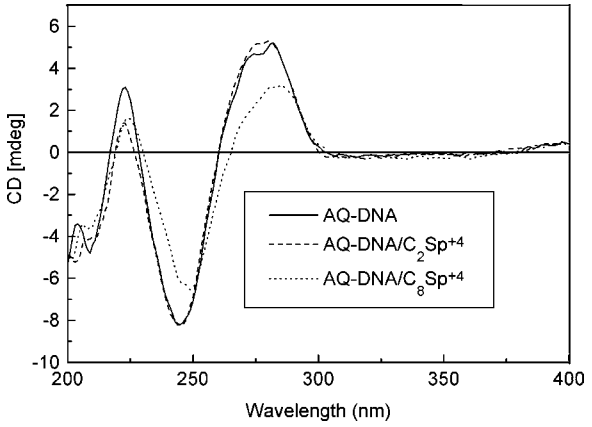

Figure 3. CD spectra of AQ-DNA in buffer solution at pH 7. C_2Sp^{+4} is present at a charge ratio of 2.0; C_8Sp^{+4} is present at a charge ratio of 3.0.

complex from solution. Consequently, we restricted our investigation of the effect of C_8Sp^{+4} on charge transfer in AQ-DNA to a charge ratio of 2.0 or less, where the solutions are stable.

Melting Temperature. We examined the melting behavior of AQ-DNA solutions in the presence of Sp^{+4} and C_nSp^{+4} to assess their interactions with the duplex. The melting temperature (T_m) of AQ-DNA is 58.4 °C. This value increases systematically with the addition of Sp^{+4} or C_nSp^{+4}. Spermine shows the most pronounced effect: an increase of 14 °C in T_m when the charge ratio of Sp^{+4} is 4.0. In contrast, for C_2Sp^{+4}, ΔT_m is 8.4 °C when the charge ratio is 4.0, and for C_8Sp^{+4}, ΔT_m is 4.0 °C at a charge ratio of 2.0.

Circular Dichroism Spectroscopy. As expected, the circular dichroism (CD) spectrum of AQ-DNA is indicative of normal B-form DNA (*18*). We monitored the CD spectra of AQ-DNA solutions containing Sp^{+4}, C_2Sp^{+4}, or C_8Sp^{+4} to assess the effect these additives have on the global structure of the duplex (Figure 3). The addition of Sp^{+4} or C_2Sp^{+4} to solutions of AQ-DNA up to a charge ratio of 4.0 did not significantly affect the CD spectrum. Similarly, there are only minor changes in the CD spectrum when C_8Sp^{+4} is added to AQ-DNA up to a charge ratio of 2.0. However at a charge ratio of 3.0, solutions containing C_8Sp^{+4} show a decrease in intensity and a slight red shift in the peaks with maxima at 220, 240 (negative), and 270 nm. This may indicate a change in the AQ-DNA secondary structure at relatively high concentrations of C_8Sp^{+4}.

Fluorescence Spectroscopy. We evaluated the effect of Sp^{+4} and C_nSp^{+4} on the fluorescence of ethidium bromide (EB) intercalated in AQ-DNA. It is well-known that the quenching of EB fluorescence by water is strongly inhibited when it is intercalated in DNA (*19*). In the absence of DNA, Sp^{+4} and C_nSp^{+4} have no measurable effect on the absorption or fluorescence emission or excitation spectra of EB. Figure 4 shows the normalized fluorescence intensity of the DNA−EB complex with various amounts of Sp^{+4} or C_nSp^{+4}. The addition of Sp^{+4} or C_2Sp^{+4} up to a charge ratio of 2.0 has only a modest effect on the emission intensity of EB. However, addition of C_8Sp^{+4} to the DNA−EB solution results in a nonlinear reduction in EB fluorescence intensity. There is only a moderate effect on EB fluorescence intensity up to a charge ratio of 1.0 for C_8Sp^{+4}, but the intensity decreases ca. 70% when the charge ratio is increased from 1.0 to 2.0. The absorption and emission spectra of the EB shift from those characteristic of intercalation to that of EB in solution when the charge ratio of C_8Sp^{+4} is increased

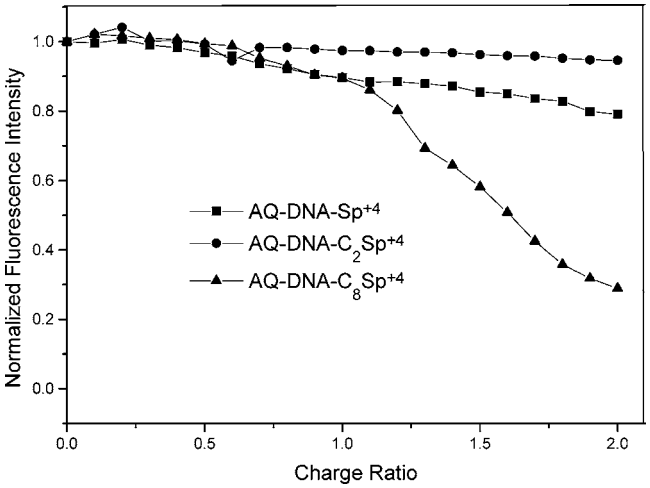

Figure 4. Fluorescence emission intensity of EB in buffer solution containing AQ-DNA and various amounts of spermine, C_2Sp^{+4}, and C_8Sp^{+4} as indicated.

from 1.0 to 2.0. However, the absorption of the AQ-DNA does not change meaningfully under these conditions, which indicates that the DNA/C_8Sp^{+4} complex is still in solution.

The effect of C_8Sp^{+4} on EB fluorescence can be understood as a competition between two equilibrium-controlled processes among DNA, EB, and the C_nSp^{+4} lipids (*20*). First, there is an equilibrium between the DNA−EB intercalated complex and free EB and DNA in solution. This equilibrium greatly favors intercalated EB in the presence of spermine and C_2Sp^{+4} up to a charge ratio of 2.0. The second equilibrium is association of Sp^{4+} and C_nSp^{+4} with AQ-DNA. Below a charge ratio of 1.0, association of C_8Sp^{+4} with AQ-DNA does not affect the intercalation of EB. But above a charge ratio of 1.0, C_8Sp^{+4} blocks the intercalation of EB into DNA, and the first equilibrium moves toward the side of free EB in solution. This is evidence for the formation of a special AQ-DNA complex in the presence of C_8Sp^{+4} above a charge ratio of 1.0. This effect is also detected in the analysis of radical cation transport in AQ-DNA.

Photoinduced Oxidative Damage in DNA−Lipid Complex. Numerous examinations of the one-electron oxidation of DNA have shown that a radical cation introduced at one location migrates through the DNA duplex (*21*, *22*). Some nucleobase sequences in the duplex, such as GG steps, serve as shallow traps where the radical cation reacts irreversibly with H_2O or O_2. Other nucleobase sequences serve as bridges between these traps. The radical cation resides briefly on the bridge but reacts there infrequently. The pattern of reactivity in DNA oligomers that have multiple GG steps has been shown to be controlled by the relative magnitudes of the rates for hopping (k_{hop}) of the radical cation from one GG step to another and that for the trapping reaction of the radical cation (k_{trap}) with H_2O or O_2. Thus k_{hop}/k_{trap} (defined as k_{ratio}) determines the observed pattern of reactivity in DNA oligomers containing multiple GG steps (*5*).

Reaction of a guanine radical cation with H_2O or O_2 forms oxidation products that result in strand cleavage when the sample is treated with piperidine or exposed to the enzyme formamidopyrimidine glycosylase (FPG) (*23*). The amount of strand cleavage is assessed by polyacrylamide gel electrophoresis (PAGE) and autoradiography. At low conversion (single hit conditions), it has been shown that the amount of strand cleavage is

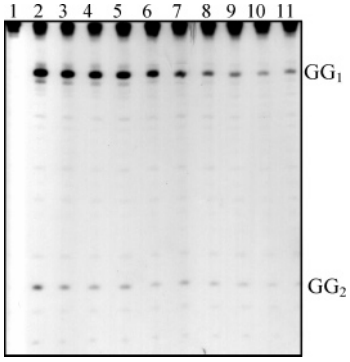

Figure 5. Autoradiogram from the irradiation (350 nm) of AQ-DNA in sodium phosphate buffer solution at pH 7 after treatment with piperidine: lane 1, dark control (no irradiation); lane 2, irradiation for 3 min, no added spermine derivative; lanes 3−11, irradiation (3 min) in the presence of added C_8Sp^{+4} with charge ratio equal to 0.1, 0.2, 0.35, 0.5, 0.75, 1.0, 1.3, 1.7, and 2.0, respectively.

proportional to the probability that the radical cation will occupy a particular GG site (*5*). Thus, this analysis provides a reliable means for assessing the relative magnitudes of k_{hop} and k_{trap}. We employed this method for analysis of the effect of Sp^{+4} and C_nSp^{+4} on radical cation migration and reaction in AQ-DNA.

AQ-DNA has two GG steps on the strand complementary to the one linked to the anthraquinone charge injector. The first step is labeled GG_1 and referred to as proximal because it is closer to the AQ. We refer to GG_2 as the distal step because it is farther from the AQ. Irradiation of the anthraquinone group at 350 nm forms an electronically excited state that is capable of the one-electron oxidation of the DNA. Subsequent reaction of the anthraquinone radical anion with O_2 forms superoxide ($O_2^{-\bullet}$) and leaves a radical cation in the DNA that can migrate until it is consumed in a trapping or annihilation reaction (*24*).

Irradiation of AQ-DNA in sodium phosphate buffer solution and subsequent treatment with piperidine (see Figure 5) or FPG reveals strand cleavage at both the proximal and the distal GG steps. As is typically the case, strand cleavage at the 5′-G of the GG step is greater than that at the 3′-G. And, as expected, there is more strand cleavage at the proximal site than at the distal site. This observation reveals that $k_{ratio} \leq 1$ for the nucleobase sequence of AQ-DNA.

We carried out a series of irradiation experiments in which solutions of AQ-DNA contained various concentrations of Sp^{+4} or C_nSp^{+4} up to a charge ratio of 2.0. Data from the addition of C_8Sp^{+4} are shown in Figure 5 in the form of an autoradiogram, and the results of several experiments are presented graphically in Figure 6. These data show that Sp^{+4} and C_2Sp^{+4} behave similarly up to a charge ratio of 2.0. That is, the relative amount of strand cleavage at the proximal and distal GG steps is unaffected, which indicates that k_{ratio} is unchanged by the addition of Sp^{+4} and C_2Sp^{+4} (*25*). The results are distinctly different for C_8Sp^{+4}. In this case, the relative amount of reaction at the distal GG step increases proportionally to the amount of C_8Sp^{+4} in solution, which at a charge ratio of 2.0 causes a 2-fold decrease in the relative reactivity of the proximal and distal GG steps (Figure 6a). Similarly, the total amount of strand cleavage observed is affected by the addition of Sp^{+4} or C_nSp^{+4}, but again the behavior of C_8Sp^{+4} is unique (Figure 6b). Addition of any of these spermine compounds reduces the sensitivity of the DNA to oxidative damage.

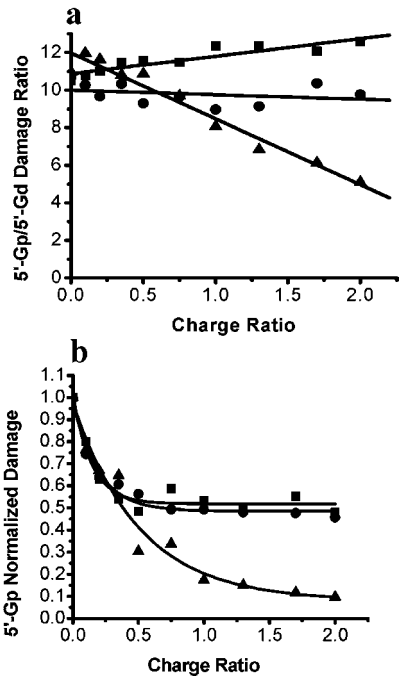

Figure 6. Plots of (a) proximal to distal damage ratio of AQ-DNA as a function of increasing charge ratio and (b) the amount of strand cleavage at the 5′-G of GG_1 as a function of increasing charge ratio: Sp^{+4} (■); C_2Sp^{+4} (●); C_8Sp^{+4} (▲).

However, this effect plateaus for Sp^{+4} or C_2Sp^{+4} at a charge ratio of ca. 0.5, but for C_8Sp^{+4}, this effect continues, and at a charge ratio of 2.0, the sensitivity of the DNA to oxidative damage is only 10% of its value in the absence of a spermine compound. We attribute this effect of C_8Sp^{+4} to a reduction of k_{trap} by the formation of a hydrophobic environment around the DNA duplex.

As noted above, absorption spectroscopy shows that the addition of C_8Sp^{+4} to AQ-DNA at a charge ratio of 2.0 causes a time-dependent change in the baseline that is indicative of aggregate formation. We carried out a control experiment designed to determine whether this affects the photooxidation reactions of AQ-DNA. Buffer solutions of AQ-DNA were incubated with C_8Sp^{+4} at a charge ratio of 2.0 for various periods of time before irradiation. After irradiation, the solutions were treated with piperidine and analyzed by PAGE and autoradiography. These experiments showed that the total amount of reaction at the GG steps of AQ-DNA and the ratio of proximal to distal strand cleavage are not affected by the incubation time with C_8Sp^{+4} up to 24 h (see Figure 7).

A second control experiment was designed to assess the sensitivity of the guanines in AQ-DNA in the presence of C_8Sp^{+4} to reaction with singlet oxygen ($^1O_2$). It is known that $^1O_2$ reacts with guanines in duplex DNA to form oxidation products that are revealed as strand cleavage by treatment with FPG (*26*). The addition of C_8Sp^{+4} up to a charge ratio of 2.0 had no effect on the reaction of AQ-DNA with $^1O_2$ (generated by irradiation of Rose Bengal with visible light greater than 450 nm). This suggests that the effect of C_8Sp^{+4} in the reaction of guanine radical cations that leads to strand cleavage involves a reagent not involved in the $^1O_2$ process, such as water.

DISCUSSION

As expected (*27*), irradiation of AQ-DNA in buffer solution causes reaction leading to strand cleavage at the GG steps. Treatment of the irradiated samples with

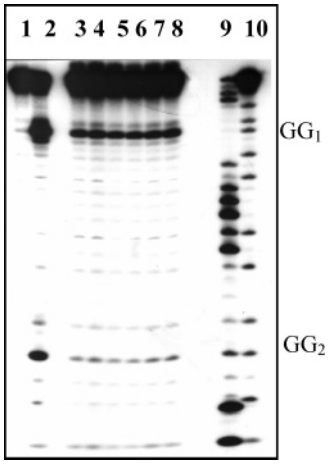

Figure 7. Autoradiogram of the denaturing gel for AQ-DNA incubated with C_8Sp^{+4} lipids (charge ratio of 2.0) for various incubation times. Lane 1 is sample w/o irradiation. Lane 2 is the sample w/o lipid. Lanes 3−8 correspond to sample incubated with C_8Sp^{+4} for 3 min, 30 min, 60 min, 6 h, 12 h, and 24 h, respectively, before 3 min of irradiation. The irradiated samples were treated with 1 M piperidine at 90 °C. Lanes 9 and 10 correspond to Maxam−Gilbert T and A/G sequencing lanes. All samples contain 2.5 μM DNA in 10 mM sodium phosphate buffer at pH 7.0. The minor band migrating slower than intact DNA in irradiated samples may be due to cross-linking.

piperidine leads to strand cleavage at the damaged guanines that is assayed by PAGE and quantified by phosphorimagery. Under the conditions of these experiments, the amount of strand cleavage at the proximal GG_1 step (ca. 20 Å from the AQ-linked terminus) is 11 ± 1 times greater than at the distal GG_2 step (ca. 70 Å from the AQ). These results are shown in Figure 5. The relative amount of reaction at GG_1 and GG_2 is controlled by the magnitude of the rate for radical cation hopping from GG_1 to GG_2 (and vice versa) compared with the rate for irreversible trapping of the radical cation by reaction with H_2O or O_2 (*5*, *28*). When k_{hop} and k_{trap} are of comparable value, $k_{ratio} \approx 1$, the amount of strand cleavage at sequential GG steps falls off approximately exponentially with distance, as is the case for AQ-DNA. Annihilation of the radical cation by back electron transfer (*29*) from superoxide in solution removes the radical cation from the DNA with no net reaction in competition with the trapping reactions that lead eventually to strand cleavage (*30*).

The addition of Sp^{+4} or C_2Sp^{+4} to the AQ-DNA solution before irradiation does not significantly affect the relative amount of proximal to distal strand cleavage detected (see Figure 6a). For example, at a charge ratio of 2.0 for Sp^{+4}, the amount of cleavage at GG_1 is 12 times that at GG_2, and for C_2Sp^{+4} it is 10 times. However, when C_8Sp^{+4} is present at a charge ratio of 2.0, the amount of cleavage at GG_1 is only 4 times greater than it is at GG_2. This finding reveals that in the presence of C_8Sp^{+4} (but not Sp^{+4} or C_2Sp^{+4}) the rate of irreversible trapping of the radical cation that leads to strand cleavage decreases relative to the rate of radical cation hopping; that is k_{ratio} increases, which results in relatively more reaction at the distal GG step (*5*, *28*).

Further evidence for the unique properties of C_8Sp^{+4} is revealed by monitoring the total amount of reaction at the 5′-G of the proximal GG step (see Figures 5 and 6b). Addition of either Sp^{+4}, C_2Sp^{+4}, or C_8Sp^{+4} up to a charge ratio of 0.5 to the AQ-DNA solution causes the amount of cleavage at GG_1 resulting from irradiation to decrease systematically until it reaches ca. 50% of that

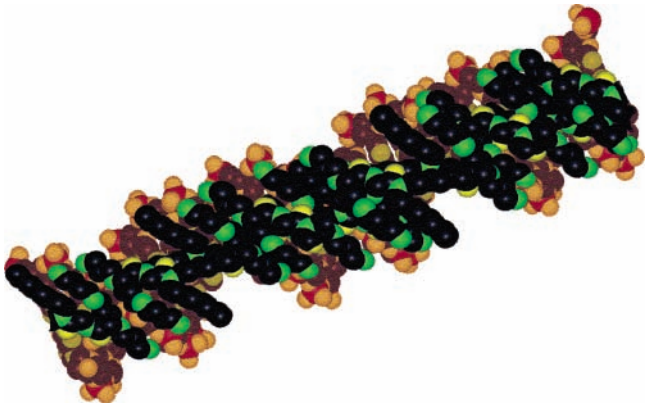

Figure 8. A schematic representation of AQ-DNA covered with 10 molecules of C_8Sp^{+4}. The ammonium groups of the spermine core have been aligned with the phosphates of the DNA. The C_8 chains are shown in black. These structures were minimized separately by molecular mechanics calculation.

observed in the absence of a spermine compound. Further additions of Sp^{+4} or C_2Sp^{+4} up to a charge ratio of 2.0 do not affect the amount of strand cleavage at GG_1. However, the amount of strand cleavage continues to decrease with increasing amounts of C_8Sp^{+4}, and at a charge ratio of 2.0, it is reduced to only 10% of its zero-spermine value. Clearly, radical cation hopping, trapping, or annihilation in DNA are affected when the polycations, Sp^{+4} or C_2Sp^{+4} replace Na^+, but there is an additional effect that protects the DNA oligomers from reaction observed only when the long alkyl chains of C_8Sp^{+4} are incorporated in the polycation.

The mechanism for the special protection of GG steps by C_8Sp^{+4} cannot be described precisely from the experiments reported here because the structures of the bound spermine complexes or soluble aggregates are not known accurately. Numerous experimental and theoretical studies have been directed toward elucidating the nature of spermine binding to DNA. It is generally agreed that a primary interaction is the electrostatic attraction between the negatively charged phosphate backbone of the DNA and the positively charged ammonium groups of spermine (*15*). However, polyamine binding sites in DNA have also been observed within both the minor and major groove of DNA (*31*−*33*), slightly favoring the minor groove in (A·T) rich tracks as shown in an experimental study (*34*). In addition, molecular dynamics simulations suggest that spermine binds in the major groove of GC-rich duplexes (*35*) and to the minor groove of AT-rich duplexes (*36*, *37*). Simulations also indicate that the presence of spermine significantly influences DNA hydration and the interaction of the sodium ions with DNA. These findings indicate that water molecules are expelled from the specific areas of DNA by spermine, which may affect k_{ratio} (*15*).

Both C_2Sp^{+4} and C_8Sp^{+4} have spermine-like polycation structures, and for this reason, we assume that they bind to DNA in the same way that spermine itself binds. In this case, it is possible to construct the model shown in Figure 8 for a complex between AQ-DNA and ten C_8Sp^{+4} molecules. One explanation for the unique properties of C_8Sp^{+4} is that the alkyl chains form a dense hydrophobic layer surrounding the DNA duplex that is absent from either the spermine or C_2Sp^{+4} complexes. This occurs because the hydrocarbon chains of C_8Sp^{+4} minimize adverse hydrophobic interactions by organizing to reduce the surface area they present to the aqueous solution. To accomplish this, the chains must interact with each other. We suggest that they form a compact layer on the

surface of the DNA oligomer. This coating should effectively reduce k_{trap} by impeding the ability of polar reagents such as H_2O to penetrate to the DNA and react with a nucleobase radical cation. The slower reaction at the proximal GG step gives the radical cation a greater probability of hopping to the distal GG steps, and this yields the lower 5′-G_p/5′-G_d ratio observed experimentally. The reduced rate for the reaction with water for the C_8Sp^{+4} complex similarly accounts for the special protective effect observed experimentally. In this case, the reactions that consume a radical cation in DNA without forming a product that leads to strand cleavage, such as reaction with superoxide, become more competitive in the AQ-DNA/C_8Sp^{+4} complex (*29*, *30*).

CONCLUSION

Spermine and the C_nSp^{+4} derivatives prepared and examined in this work form complexes with AQ-DNA. When $n = 2$, these complexes are stable in solution at high charge ratios. When $n = 8$, aggregation and precipitation occurs above a charge ratio of 2.0. Irradiation of the anthraquinone chromophore of AQ-DNA results in one-electron oxidation and the injection of a radical cation in the DNA oligomer. The radical cation migrates through the duplex and initiates reaction at GG steps that is revealed by strand cleavage. This charge hopping and reaction process is affected by the presence of spermine and the C_nSp^{+4} derivatives, but C_8Sp^{+4} is unique. This is attributed to the formation of a hydrophobic coating around DNA complexed with C_8Sp^{+4} that slows the reaction of the radical cation in DNA with water. These findings may have relevance to the protection of genomic DNA from oxidative damage.

ACKNOWLEDGMENT

We are grateful to the NSF and the Vasser−Woolley foundation for the financial support of this work. Dr. Sriram Kanvah prepared the DNA oligomers and assisted with the preparation of this manuscript. Dr. Abraham Joy also assisted in the preparation of this manuscript.

Cholesterol modified mono-, di-, and tetrameric oligonucleotides were synthesized and hybridized with antisense oligonucleotides to study their incorporation in cationic liposomes together with the influence of this dendrimeric delivery system on biological activity. Electrostatic interactions seem to play the most important role during complexation with cationic lipids. This oligonucleotide formulation gives a small but significant increase in the inhibition of P-glycoprotein expression in a cellular system.

INTRODUCTION

Antisense oligonucleotides are very powerful tools for inhibition of gene expression (*1*). The initial hurdles of enzymatic instability and poor hybridization strength of natural antisense oligonucleotides have been largely overcome by introducing chemical modifications. Delivery of oligonucleotides to target cells in vivo, however, is the major bottleneck for the widespread use of antisense oligonucleotides in therapy (*2*).

One of the potential solutions for this delivery problem is the use of liposomes (*3*). The antisense oligonucleotide (negatively charged due to the ionization of the phosphate backbone) interacts electrostatically with the cationic phospholipids forming the vesicles and is delivered to the cell by endocytosis. However, the number of oligonucleotides trapped into one complex is low. The delivery process can be improved by conjugation of the antisense oligonucleotide with cholesterol (*4*) or by the use of cholesterol for liposome formulations (*5*). A disadvantage of the first approach is that the cholesterol moiety is covalently attached to the oligonucleotide which influences the intracellular distribution of the antisense oligonucleotide.

Despite the efforts that have been made to characterize the formation of DNA-cationic liposome complexes (lipoplexes), the process is not yet completely understood. This is because multiple factors can influence their formation, such as the ratio between the number of negative charges in DNA and that of the positive charges in liposomes, the fluidity of the lipid bilayer, and the formation of lipid domains after DNA binding (*6*). Furthermore, the size instability was correlated with high transfection efficiency in vivo (*7*). The current view about the organization of lipoplexes comes from electron microscopy and X-ray diffraction studies (*8*, *9*). According to these, lipoplexes have a multilamellar structure with repeat distances equivalent to the thickness of a lipid bilayer and a single DNA double helix.

Here we investigated the approach of derivatization of an enzymatic labile sense−DNA with cholesterol and delivering the enzymatic stable antisense oligonucleotide as hybrid with this cholesterol−sense−DNA. As well as monomers, dimers and tetramers of sense−DNA were synthesized (Figure 1). Cationic lipids are used for the liposome formulation. This approach has the advantage that the enzymatic stable antisense oligonucleotide itself is not derivatized (i.e. its intracellular distribution and hybridization with its target is not influenced by a reporter group). The cholesterol-modified sense−DNA may stay locked in the endosomes and may be slowly degraded while the enzymatically more stable antisense oligonucleotide can diffuse into the cytoplasm and/or the nucleus (*10*). The synthesis was tested using an 11-mer as well as an 18-mer sense−DNA. For biological activity determination, we selected the 18-mer, as this length seems to be optimal for this purpose (*10*). The antisense oligonucleotide that is used as a model is a phosphorothioate 20 gapmer consisting of 2′-methyloxyethyl (2′-MOE) nucleotides in the flanks and phosphorothioate DNA in the middle (5′-CCAUCCcgacctcgCGCUCC-3′). The phosphorothioate DNA gap of eight nucleotides allows RNaseH to play a role in the mode of action of the antisense oligonucleotide. The phosphorothioate 2′-MOE flanks render the oligonucleotide stable against enzymatic degradation. This sequence has been demonstrated to inhibit P-glycoprotein expression in a cellular system (*11*).

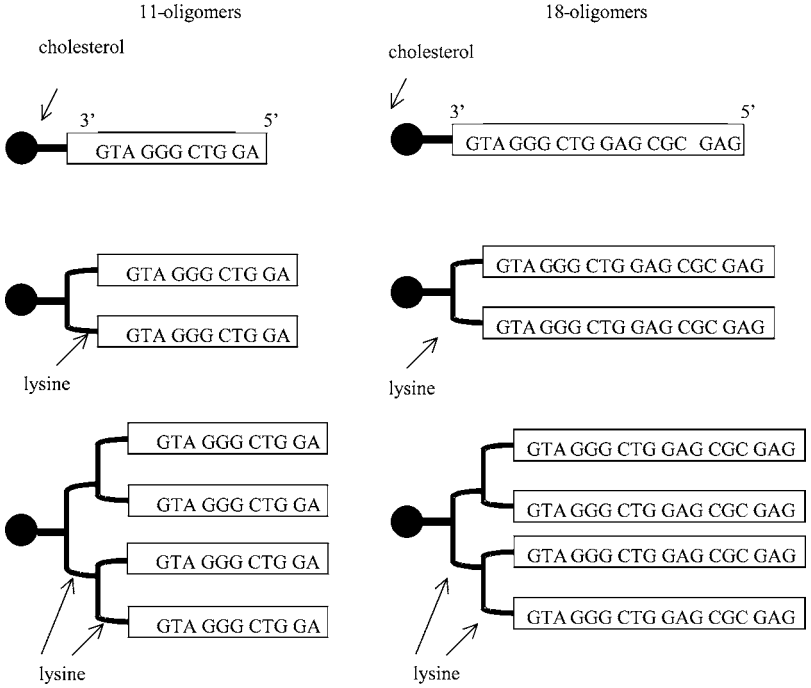

Figure 1. Schematic representation of monomeric and dendrimeric oligonucleotides (DNA) that were used to concentrate antisense oligonucleotides in cationic lipids for cellular delivery (as well, 11-mer as 18-mer oligonucleotides were evaluated as complexing agents for the antisense oligonucleotides).

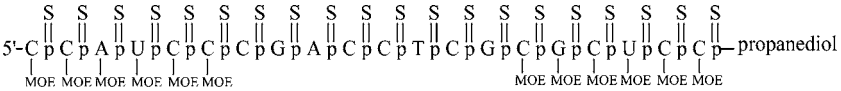

Figure 2. Structure of antisense oligonucleotide directed at mRNA that codes for the P-glycoprotein.

EXPERIMENTAL PROCEDURES

Chemistry. ^{1}H and ^{13}C NMR spectra were recorded at 200 MHz with a Varian Gemini 200 in $CDCl_3$. ^{13}C assignments were based on the usual shift increments and calculus values and where necessary confirmed by APT experiments. Assignments of quaternary carbons of the aromatic rings were based on comparison with other compounds and were mostly tentative. Electron impact mass spectra in positive (EI+) and negative ion mode (EI−) were acquired on a Kratos MS50TC mass spectrometer (Kratos, Manchester, UK), using MASPEC II data acquisition software (Mass Spectrometry Services Ltd., Manchester, UK). Electrospray ionization mass spectra in negative ion mode (ESI−) were recorded on a quadruple orthogonal acceleration/time-of-flight mass spectrometer (Q-TOf-2, Micromass, Manchester, UK). Absorption spectra were recorded with a Perkin-Elmer Lambda 40 spectrophotometer (Wellesley, MA) and fluorescence spectra with a Spex Fluorolog 3−22 fluorimeter (Jobin Yvon-Spex Instruments S. A., Inc., Edison, NJ). Precoated Machery-Nagel Alugram SilG/UV 254 plates were used for TLC, and spots were examined with UV light and a sulfuric acid/anisaldehyde spray. Column chromatography was performed on Acros silica gel (60−200 nm). Anhydrous solvents were obtained as follows: THF was refluxed on $LiAlH_4$ overnight and was distilled; dichloromethane (DCM) was stored on calcium hydride, refluxed, and distilled; pyridine, triethylamine (TEA), and *N*,*N*-diisopropylethylamine (DIEA) were refluxed overnight on potassium hydroxide and distilled. *N*,*N*-Dimethylformamide (DMF) was stored on activated molecular sieves (4 Å) for 3 days and was tested for absence of dimethylamine by the bromophenol test prior to use. DCM, DMF, acetic anhydride (Ac_2O), and pyridine were obtained from BDH (Poole, England). Piperidine, trifluoroacetic acid (TFA), diisopropylcarbodiimide (DIC), 1-hydroxybenzotriazole (HOBt), 1-methylimidazole (NMI), di-*tert*-butyl dicarbonate [$(Boc)_2O$], benzyl chloroformate, 9-fluorenylmethyloxycarbonyl chloride (FmocCl), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and *N*-methylmorpholine were supplied by ACROS (Geel, Belgium). 1-Hydroxy-7-azabenzotriazole (HOAt) and its tetramethyluronium derivative (HATU) were purchased from Perspective Biosystems. [2-(1*H*-bentotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate] (HBTU) from Advanced Chemtech. Benzotriazol-1-yloxytrispyrrolidinophosphonium hexafluorophosphate (PyBOP) was obtained from Advanced Chemtech. Diethyl azodicarboxylate (DEAD) and sodium hydride (NaH) were purchased from Sigma-Aldrich. *p*-[(*R*,*S*)-α-[1-(9*H*-fluoren-9-yl)methoxyformamido]-2,4-dimethoxybenzyl]phenoxyacetic acid (Fmoc-Rink linker) was supplied by Novabiochem. Lipofectamine 2000 was obtained from Invitrogen. PBS buffer (pH7.4) was obtained from Sigma. Oligonucleotide assembly was performed on an Expedite DNA synthesizer (Applied Biosystems) using phosphoramidites from Glen Research.

The 11 and the 18 oligonucleotide sense sequences without cholesterol, as well as the tetramethyl rhodamine (TMR)-labeled oligonucleotide antisense sequence, complementary to the gene encoding the P-glycoprotein (*11*), were obtained from Invitrogen. The phosphorothioate oligonucleotide from Figure 2 is a gift from ISIS.

Cholesterylacetaldehyde Diethylacetal (2). To a solution of cholesterol (5 g, 12.9 mmol, 1 equiv) in a mixture of anhydrous THF/DMF (1:1, 200 mL) were added NaH (3.2 g, 77.6 mmol, 6 equiv) and, after 5 min, bromoacetaldehyde diethylacetal (6.3 mL, 38.8 mmol, 3

equiv) under anhydrous conditions. A nitrogen-flushed reflux condensor was attached, and the mixture was heated at reflux for 18 h. The excess NaH was decomposed using MeOH/CH_2Cl_2 and mild shaking After evaporation to dryness, silica gel-based chromatographic purification was performed with a stepwise gradient of a hexane/EtOAc mixture (98:2 to 95:5) as eluent, yielding 4.3 g (8.56 mmol, 66.3%) of the title compound. ^{13}C NMR: δ = 140.97 (C-3), 121.58 (C-4), 101.46 (β-CH), 79.73 (C-1), 68.77 (α-CH_2), 62.09 (Et, CH_2O), 56.72 (C-7), 56.12 (C-10), 50.11 (C-14), 42.25 (C-11), 39.73; 39.45; 38.97 (C-2; C-12; C-24), 37.15 (C-16), 36.78 (C-15), 36.12 (C-22), 35.72 (C-20), 31.84 (C-5, C-6), 28.26; 28.13; 27.92 (C-17; C-9; C-25), 24.19; 23.73 (C-8; C-23), 22.73; 22.46 (C-26; C-27), 20.97 (C-13), 19.27 (C-18), 18.60 (C-21), 15.27 (Et, CH_3), 11.75 (C-19). Mass calcd for $[M + Cl]^-$ $C_{33}H_{58}O_3Cl_1$: 537.4074, found: (ESI−): 537.4094.

Cholesterylacetaldehyde (3). To a solution of **2** (4.1 g, 8.17 mmol) in CH_2Cl_2 (80 mL) was added 20 mL of TFA/H_2O (1:1), and the reaction mixture was stirred for 4.5 h at room temperature (complete conversion). NaOH (1 N) was used to neutralize the solution, and subsequently an extraction with CH_2Cl_2 was performed. The organic layer was dried over anhydrous $MgSO_4$, filtered, and evaporated in vacuo to dryness, yielding 3.45 g (8.07 mmol, 98%) of the title compound. ^{13}C NMR: δ = 201.70 (β-CH), 140.30 (C-3), 122.22 (C-4), 80.37 (C-1), 73.81 (α-CH_2), 56.69 (C-7), 56.12 (C-10), 50.08 (C-14), 42.25 (C-11), 39.70; 39.42; 38.76 (C-2; C-12; C-24), 36.97 (C-16), 36.72 (C-15), 36.12 (C-22), 35.69 (C-20), 31.81 (C-5, C-6), 28.10; 27.92 (C-17; C-9; C-25), 24.19; 23.73 (C-8; C-23), 22.70; 22.46 (C-26; C-27), 20.97 (C-13), 19.24 (C-18), 18.60 (C-21), 11.75 (C-19). Mass calcd for $[M]^+$ $C_{29}H_{48}O_2$: 428.3654, found (EI+): 428.3647.

Cholesterylacetic Acid (4). Compound **3** (3 g, 7.0 mmol) was dissolved in acetone (105 mL), and 1.5 mL Jones reagent (26.72 g CrO_3/23 mL concentrated H_2SO_4/H_2O to 100 mL) was added dropwise while the reaction mixture was cooled on ice. If necessary (TLC), more Jones reagent was added to completely convert **3** into its carboxylic acid. After 10 min, acetone and MeOH were added, the mixture was filtered, and the remaining filtrate was evaporated to dryness. The residual solid was purified by column chromatography on silica gel by elution with hexane/EtOAc/AcOH (8:2:0.1), yielding 2.1 g (4.76 mmol; 68%) of the title compound. ^{13}C NMR: δ = 173.54 (COOH), 140.00 (C-3), 122.46 (C-4), 80.46 (C-1), 65.16 (α-CH_2), 56.69 (C-7), 56.12 (C-10), 50.05 (C-14), 42.25 (C-11), 39.67; 39.45; 38.61 (C-2; C-12; C-24), 36.90 (C-16), 36.69 (C-15), 36.12 (C-22), 35.69 (C-20), 31.78 (C-5, C-6), 28.13; 28.01; 27.92 (C-17; C-9; C-25), 24.19; 23.73 (C-8; C-23), 22.73; 22.46 (C-26; C-27), 20.97 (C-13), 19.24 (C-18), 18.60 (C-21), 11.75 (C-19). Mass calcd for $[M]^+$ $C_{29}H_{48}O_3$: 444.3603, found (EI−): 444.3606.

Nα-Fmoc-Nϵ-cholesterylacetyl-lysine-O-Me (5). Compound **4** (1.7 g, 3.7 mmol, 1 equiv) and HATU (1.35 g, 4.07 mmol, 1.1 equiv) were suspended in 85 mL of dry DMF. To this suspension was added DIEA (1.3 mL, 7.4 mmol, 2 equiv), and the resulting solution was stirred for 2 h at room temperature. To this mixture was added a solution of Fmoc-Lysine-OMe.HCl (1.7 g, 4.07 mmol, 1.1 equiv) and DIEA (1.3 mL, 7.4 mmol, 2 equiv) in 15 mL of dry DMF, and stirring was continued at room temperature for 18 h. After evaporation, the residue was dissolved in EtOAc, and the organic phase was washed with HCl (1 N), water, saturated Na_2CO_3 solution, brine, and water. The organic layer was dried over sodium sulfate, filtered, and evaporated. The remaining oil was purified by chromatography using a mixture of CH_2Cl_2/MeOH (99:1) as eluent. Evaporation of the pooled fractions yielded 2.5 g (3.1 mmol, 84%) of compound **5**. ^{13}C NMR: δ = 172.66 (Lys, COOMe), 170.41 (CONH); 156.51 (OCONH), 144.04 (Fmoc, C-10/11), 141.73 (Fmoc, C-12/13), 140.12 (Chol, C-3), 127.68 (Fmoc, C-3/6), 127.04 (Fmoc, C-2/7), 125.07 (Fmoc, C-1/8), 122.28 (Chol, C-4), 119.97 (Fmoc, C-4/5), 80.39 (Chol, C-1), 67.47 (Fmoc, CH_2O), 66.52 (Chol, α-CH_2), 56.66 (Chol, C-7), 56.08 (Chol, C-10), 52.38 (Lys, CH_3O), 51.14 (Lys, α-CH) 50.01 (Chol, C-14), 47.22 (Fmoc, C-9), 42.24 (Chol, C-11), 40.61 (Lys, ϵ-CH_2NH), 39.67; 39.45; 38.82 (Chol, C-2; C-12; C-24), 36.93 (Chol, C-16), 36.69 (Chol, C-15), 36.12 (Chol, C-22), 35.69 (Chol, C-20), 32.26 (β-CH_2(Lys)), 31.80 (Chol, C-5, C-6), 29.62 (δ-CH_2(Lys)), 28.13; 28.01; 27.92 (Chol, C-17; C-9; C-25), 24.19; 23.73 (Chol, C-8; C-23), 22.73; 22.46 (Chol, C-26; C-27), 22.34 (γ-CH_2(Lys)) 20.97 (Chol, C-13), 19.27 (Chol, C-18), 18.63 (Chol, C-21), 11.74 (Chol, C-19). Mass calcd for $[M + Cl]^-$ $C_{51}H_{72}N_2O_6Cl_1$: 843.5078, found: (ESI−): 843.5049.

Nα-Fmoc-Nϵ-cholesterylacetyl-lysine (6). The cleavage of the methyl ester was carried as described in the literature (*12*). To compound **5** (1.5 g, 1.8 mmol, 1 equiv) in 20 mL of THF at 0 °C was added 0.2 N LiOH (18 mL, 3.6 mmol, 2 equiv), and the reaction was stirred for 40 min. To the reaction mixture, 50 mL of a biphase of 0.2 N HCl/EtOAc (1:1) was added, aqueous layer was extracted three times with EtOAc, and the combined organic layers were dried over $MgSO_4$, filtered, and evaporated to dryness. The remaining product was purified by column chromatography on silica gel with a CH_2Cl_2/MeOH mixture (95:5) as eluent, yielding 1.1 g (1.4 mmol, 77%) of the title compound. ^{13}C NMR: δ = 174.78 (Lys, COOH), 171.14 (CONH); 156.51 (OCONH), 144.01 (Fmoc, C-10/11), 141.37 (Fmoc, C-12/13), 140.06 (Chol, C-3), 127.71 (Fmoc, C-3/6), 127.07 (Fmoc, C-2/7), 125.10 (Fmoc, C-1/8), 122.31 (Chol, C-4), 120.00 (Fmoc, C-4/5), 80.46 (Chol, C-1), 67.31 (Fmoc, CH_2O), 66.52 (Chol, α-CH_2), 56.63 (Chol, C-7), 56.08 (Chol, C-10), 51.47 (Lys, α-CH) 49.98 (Chol, C-14), 47.19 (Fmoc, C-9), 42.24 (Chol, C-11), 40.58 (Lys, ϵ-CH_2NH), 39.67; 39.45; 38.82 (Chol, C-2; C-12; C-24), 36.90 (Chol, C-16), 36.69 (Chol, C-15), 36.12 (Chol, C-22), 35.72 (Chol, C-20), 32.26 (β-CH_2(Lys)), 31.80 (Chol, C-5, C-6), 29.62, 29.19 (δ-CH_2(Lys)), 28.16; 28.01; 27.92 (Chol, C-17; C-9; C-25), 24.19; 23.76 (Chol, C-8; C-23), 22.73; 22.46 (Chol, C-26; C-27), 22.34 (γ-CH_2-(Lys)), 20.97 (Chol, C-13), 19.24 (Chol, C-18), 18.63 (Chol, C-21), 11.74 (Chol, C-19). Mass calcd for $[M-H]^-$ $C_{50}H_{69}N_2O_6$: 793.5155, found: (ESI−): 793.5143.

Solid-Phase Synthesis. Peptide Synthesis. Synthesis of the conjugates was performed on the LCAA-CPG carrier. For each amino acid or compound to be coupled, different reaction conditions were applied. After every reaction, the solution was filtered and the beads were washed with DMF (two times), CH_2Cl_2 (2 times), and acetonitrile (two times). The beads were dried, and Fmoc- or MMTr- substitution levels were determined. Hereto, an accurately measured quantity of resin was suspended in exactly 25 mL of 20% piperidine in DMF or in a $HClO_4$/EtOH mixture (3:2), respectively. After 15 min the absorbance was measured at 300 nm for fulvene (or adduct) determination and at 475 nm for methoxytrityl cation detection (ϵ_{Fmoc} = 7500, ϵ_{MMTr} = 55000). If the coupling yields were unsatisfactory, a second coupling reaction was performed. Before each new coupling, the remaining amino groups were capped using 1.5 mL of 20% acetic anhydride in THF and 1.5 mL of 20% 1-methylimidazole and 40% 2,4,6-trimethylpyridine in THF for 15 min, and washed with acetonitrile and DMF. Fmoc-deprotection was carried out with a piperidine/

DMF mixture (2:8 v:v, 2 mL) for 5 min and washing for 15 min, while for MMTr-deprotection, 3% TCA in CH_2Cl_2 was used 3 to 4 times for 3 min, until no yellow color was detectable.

Coupling of Fmoc-sarcosine to LCAA-CPG was generally performed as described in the literature (*13*). To a solution of Fmoc-sarcosine (116 mg, 0.37 mmol, 4 equiv), HOBt (31 mg, 2.23 mmol, 2.5 equiv), and HBTU (88 mg, 0.23 mmol, 2.5 equiv) in 2 mL DMF was added DIEA (78 μL, 0.46 mmol, 5 equiv), and the mixture was shaken for 5 min. More DIEA (78 μL, 0.46 mmol, 5 equiv) was added, and the solution was then poured onto LCAA-CPG beads (1 g, 92 μmol, 1 equiv). The reaction mixture was occasionally shaken for 2 h. Coupling of MMTr-butyric acid was obtained by adding a solution of 4-OMMTr-butyric acid (*14*) (220 mg, 0.46 mmol, 5 equiv), HOBT/HBTU (88 mg, 0.23 mmol, 2.5 equiv), and DIEA (158 μL, 0.92 mmol, 10 equiv) in 2 mL of DMF. Following deprotection of MMTr, Fmoc-glycine was coupled to the 4-OH group of 4-OH-butyric acid by occasionally swirling the beads with a reaction mixture of Fmoc-glycine (273 mg, 0.92 mmol, 10 equiv), DIC (72 μL, 0.46 mmol, 5 equiv), and DMAP (17 mg, 13.8 μmol, 0.15 equiv) in DMF (2 mL).

The cholesterylacetamide **6** was attached to glycine by using a solution of **6** (0.29 mg, 0.37 mmol, 4 equiv), HBTU (140 mg, 0.37 mmol, 4 equiv), HOBt (49 mg, 0.37 mmol, 4 equiv), and DIEA (168 μL, 0.92 mmol, 10 equiv) in 1 mL of DMF. The mixture was shaken for 5 min before it was added to the Fmoc-deprotected support (yield: 90%).

For single oligonucleotide loading, 4-O-MMTr-butyric acid was coupled as a linker before starting oligonucleotide synthesis. For the branching-off purposes, Nα-Fmoc-Nϵ-Fmoc-lysine (4 equiv) was used. The protected lysine was attached to the support by adding a solution of HBTU (4 equiv), HOBt (4 equiv), and DIEA (10 equiv) in DMF. Subsequently, 4-O-MMTr-butyric acid was coupled. The amount of 4-O-MMTr-butyric acid used was always 4 times the amount of free NH_2 groups available for coupling.

Oligonucleotide Synthesis. Four different supports were used for assembly of the undeca- and octadecamers. The number of hydroxyl groups per gram of support was determined by detritylation and amounted to 48, 80, and 130 μmol/g for the supports **9**, **11**, **13**, respectively. The assembly of oligonucleotides was done on the Expedite following a standard 1 μmol protocol, using only 0.5 μmol of support and a 4 min coupling time. Following deprotection with AMA (methylamine−ammonia 1:1) for 2 h at 25 °C, the products were purified by gel filtration using 30% aqueous acetonitrile to avoid adsorption of the cholesteryl moieties to the support. Depending whether a single, double, or four chains of oligonucleotides needed to be coupled to the cholesterol moiety, one of the different supports **9**, **11**, **13** were used. The conjugates could be purified by RP-HPLC on PLRP−S (100 Å, 8 μM, 250 × 7 mm, Polymer Laboratories) with a CH_3CN gradient in 0.05 M ammonium acetate, pH 7.0. In general, in ascending order, tetrameric oligo-containing dendrimer eluted before the trimer, dimer, and monomer species. Analysis was accomplished by HPLC/MS on a capillary chromatograph (CapLC, Waters, Milford, CA). Columns of 150 mm × 0.3 mm length (LCPackings, San Francisco, CA) were used. Oligonucleotides were eluted with a triethylammonium-1,1,1,3,3,3-hexafluoro-2-propanol:acetonitrile solvent system, and the flow rate was 5 μL/min. Electrospray spectra were acquired on a quadrupole orthogonal acceleration/time-of-flight mass spectrometer (Q-Tof-2, Micromass, Manchester, U.K.) in negative ion mode. The scan time used was 2 s. The combined spectra from a chromatographic peak were deconvoluted using the MaxEnt algorithm of the software Masslynx 3.4 (Micromass). Theoretical oligonucleotide masses were calculated using the monoisotopic element masses for masses up to 8000 and using the average element masses for masses above 8000. The data are given in Table 1.

Table 1. Results of Mass Spectrometry Analysis of the Monomeric (10), Dimeric (12), and Tetrameric (14) Constructs

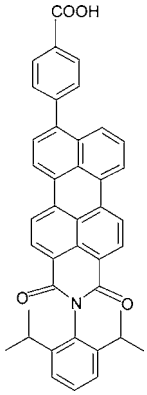

Figure 3. Structure of the perylene monoimide derivative used as a membrane probe.

Fluorescence Resonance Energy Transfer (FRET) Measurements. Lipofectamine 2000 was diluted in PBS (phosphate buffer saline, pH = 7.4) (Sigma) and was labeled with a perylene monoimide derivative (PMI-COOH) (Figure 3) in an approximate ratio of 1 fluorescent molecule for 250 lipid molecules. Hybridization between the antisense oligonucleotide labeled with TMR and the DNA with or without cholesterol was performed by heating appropriate amounts in PBS at 80° for 3 min, followed by cooling at room temperature for 15 min. Hybridized DNA was added in increasing concentrations to the Lipofectamine suspension. The fluorescence energy transfer between PMI-COOH and TMR was monitored by exciting the sample at 450 nm (where the direct excitation of TMR is minimal) and measuring the fluorescence quenching of PMI-COOH at the maximum emission peak (549 nm). The values were corrected for the nonlabeled DNA quenching of PMI-COOH fluorescence and for the TMR emission at 549 nm.

Cells. NIH 3T3 cells stably transfected with a plasmid containing the human *mdr1* gene (pSK1 MDR) were gift from M. M. Gottesman. The MDR-3T3 cells were grown in DMEM (Dulbecco minimal cututred media) medium containing 10% FBS (fetal bovine serum) and 60 mg/mL colchicine.

Treatment of Cells with Antisense Oligonucleotides. The experimental protocols were similar to those previously described (*11*). Briefly, MDR 3T3 cells were grown in 162 mm flasks to 95% confluency and then seeded onto six-well plates at 3×10^5/well in 10% FBS/DMEM and incubated 24 h. The cells were washed twice with PBS. Complexes between dendrimers and antisense

strand were prepared in 10 mM TRIS, 50 mM NaCI, 1 mM EDTA by heating the solutions at 80 °C and cooling to room temperature for 15 min. The complexation of the double stranded dendrimeric form of the antisense was done with Lipofectamine 2000 (Invitrogene) in OptiMEM according to standard procedure. The complexes were added to cells in 10% FBS/DMEM. The cells were incubated with complexes for 4 h. Then the cells were rinsed and further incubated for 68 h in 2% FBS/DMEM. All conditions were performed in triplicate. The P-glycoprotein percent shift is calculated from the lipofectamine 2000 control shift.

Pharmacological Effects of Antisense Treatment. Analysis of the pharmacological effects of dendrimeric delivery was based on a previously described assay (*15*) involving antisense inhibition of P-glycoprotein expression in mouse 3T3 cells stably transfected with the human *MDR1* gene. The cell surface expression of P-glycoprotein was determined by immunostaining and quantitation by flow cytometry, as described (*16*). Briefly, the MRK16 anti-P-glycoprotein antibody (Kamiya Biochemicals), which is directed against an external epitope, was employed as the primary antibody. After the incubation, the cells were washed twice in 10% FBS/PBS. The level of phycoerythrin (PE)-conjugated goat anti-mouse IgG (Sigma, St. Louis, MO was used as the second antibody) in viable cells (viability determined by light scatter) was quantitated using the Summit V3.0 software application (Cytomation Inc.) on a Becton Dickinson flow cytometer.

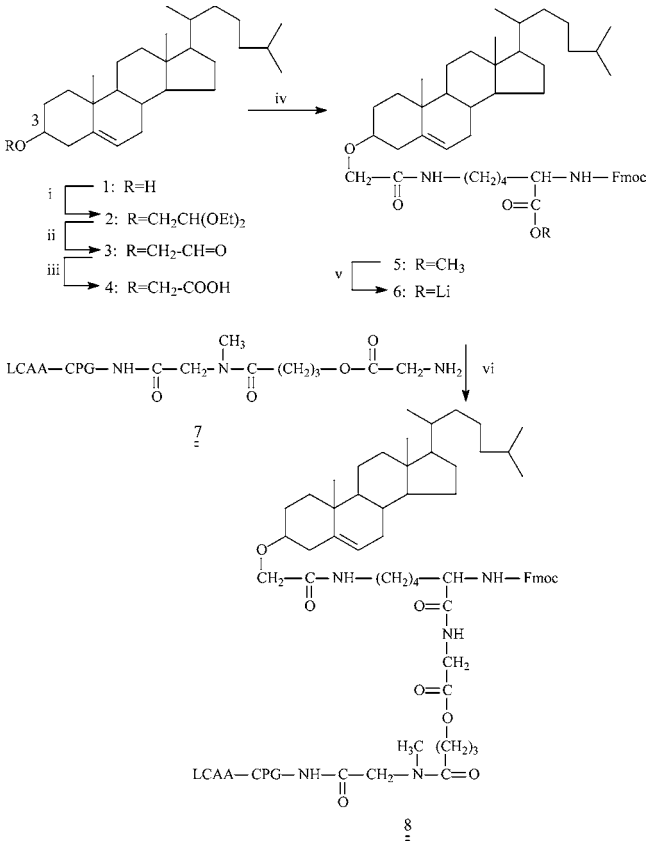
RESULTS AND DISCUSSION

Synthesis. For the synthesis of the monomeric, dimeric, and tetrameric cholesterol oligonucleotide conjugates, a strategy was used based on lysine chemistry. Lysine has an α- and ϵ-amino group, and binding of one lysine unit via its α carboxyl function to a solid support allows the two functional amino groups to be used for oligonucleotide synthesis.

Cholesterol (**1**) was derivatized at its C-3 hydroxyl group with a functional group that is stable against acid and base and that can be used for the formation of an amide bond (Scheme 1). Reaction of cholesterol with chloroacetic acid in the presence of NaH gives poor yields. Therefore, cholesterol was first reacted with the diethylacetal of bromoacetaldehyde in the presence of NaH in a mixture of THF/DMF for 18 h at 85 °C. In this way cholesterylacetaldehyde diethylacetal (**2**) was obtained in 70% yield. Reaction of **2** with Jones reagent resulted in the formation of the desired cholesterylacetic acid **4**, but the reaction went to completion only after 24 h, and multiple side products were formed. To avoid side reactions, the acetal was first hydrolyzed with trifluoroacetic acid in dichloromethane for 4 h, giving the aldehyde **3**. The oxidation of the aldehyde to the carboxylic acid with Jones reagent was completed after 10 min, giving a clean reaction product. The oxidation using hypochlorite was less effective.

Subsequently, Fmoc-Lysine-OMe was coupled with its free ϵ-NH_2-group to cholesteryl acetic acid using HATU, DIEA, and TEA (Scheme 1). Compound **5** was then deprotected by hydrolyzing the methyl ester with 0.2 N LiOH in THF/H_2O. The carboxylic acid of **6** could then be used to couple **6** to the solid support **7**. This solid support material was obtained by derivatization of LCAA-CPG with sarcosine. Subsequently, MMTr-O-butyric acid was attached to the sarcosine and detritylated

Scheme 1. Synthesis of Cholesterol-Conjugated Lysine on Solid Support[a]



[a] i: $BrCH_2CH(OEt)_2$, NaH, DMF/THF; ii: CF_3COOH aqueous in DCM; iii: CrO_3, H_2SO_4, CH_3COCH_3, H_2O; iv: Fmoc-Lysine-OMe HCL, HATU, DIEA, DMF; v: LiOH, THF, H_2O; vi: HBTU, HOBT, DIEA, DMF.

with trifluoroacetic acid. The free hydroxyl group was used for coupling with Fmoc-glycine with formation of a base-labile ester bond. After Fmoc deprotection, compound **6** was coupled to the solid support **7** using a mixture of HBTU, HOBT, and DIEA (Scheme 1). In this way, a cholesterol-derivatized lysine connected to a solid support via an ester bond was obtained, as general support for the synthesis of the desired oligonucleotide monomers (**10a**,**b**) and dendrimers (**12a**,**b** and **14a**,**b**).

The synthesis of the cholesteryl-lysyl oligonucleotide (monomer **10a**,**b**) is shown in Scheme 2. After Fmoc deprotection of **8**, coupling of MMTr-O-butyric acid, and MMTr deprotection, the solid material **8** was used for oligonucleotide synthesis with the phosphoramidite approach. An 11-mer and 18-mer were assembled with a sequence complementary to the antisense oligonucleotide.

Deprotection using AMA reagent (concentrated aq ammonia−aq methylamine 1:1) yielded **10a**,**b**. The conjugate was concomitantly removed from the solid support by cleavage of the labile ester group with formation of the methylamide (with 5% amide formation according to MS analysis).

Branching of the peptide linker was carried out by coupling of Fmoc-protected lys-OH on deprotected **8** (Scheme 3). After a second deprotection step and binding of hydroxybutyric acid, the solid support can be used for the synthesis of two oligonucleotides on the same cholesteryl derivatized peptide (Scheme 3). Repetition of the protocol of coupling Fmoc-protected lys-OH, Fmoc deprotection, and coupling of hydroxybutyric acid might lead to an exponential branching of the cholesterol-derivatized

solid support, enabling the assembly of multiple oligonucleotides on one cholesterol moiety. This is demonstrated with the branched dendrimer **14a**,**b** in Scheme 4. However, mass spectral analysis of the major fraction shows that only three of the four hydroxybutyryl moieties are used for oligonucleotide synthesis. The HPLC sample of the trimeric compound shows only a small fraction of the four-branched dendrimer. The three-branched molecule has an acetylated lysine moiety (although it is not clear if acetylation has occurred at the α-N or the ϵ-N of lysine). Apparently, steric hindrance or the occurrence of a side reaction hampers the formation of the four-branched construct. We were able, however, to isolate sufficient amounts of the tetrameric construct by chromatographic purification to carry out biological tests.

Using these three different supports, cholesterol oligonucleotide complexes were formed in a ratio of 1:1 (**10a**,**b**), 1:2 (**12a**,**b**), and 1:4 (**14a**,**b**), and the obtained products were used for hybridization with the antisense oligonucleotide followed by cationic liposome complexation. Although it is difficult to analyze the way the antisense oligonucleotides are associated to the sense-dendrimers, the stability of the complex was determined using melting experiments. In all cases, the melting point was above 70 °C, demonstrating that stable complexes are formed.

Lipoplexes Formation Followed by FRET. The dynamics of DNA−liposomes interaction can be monitored in a FRET experiment due to the sixth power dependence of the fluorescence energy transfer efficiency to the distance between donor and acceptor. The process can thus take place on distances of a few nanometers, meaning that only the DNA bound to the surface of liposomes will contribute to the variation of the measured signal. The FRET approach was used to investigate the association between DNA and liposomes with different compositions (*17*), to follow in time the changes in lipid−DNA interaction during lipoplex formation (*18*), or to monitor the oligonucleotide release into living cells (*19*). Theoretical calculations of FRET efficiency particularly applied for the geometry of lipoplexes were also developed (*20*).

In the context of our ongoing study of perylene monoimide derivatives in biological systems, this type of fluorescent molecule has been used in these experiments for several reasons. Due to its hydrophobic rylene core, the molecule is rapidly incorporated into a lipid bilayer, while the hydrophilic carboxylic group most probably anchors the molecule at the phospholipid−water interface. This dye was chosen instead of other fluorescent probes for membranes (e.g. diphenyl hexatriene DPH or its derivatives) because of the very high fluorescence quantum yield (almost 1) and the high photostability in hydrophobic environments of the PMI chromophore (*21*), making possible the detection of fluorescence intensity variations at very low concentrations ($10^{-8}-10^{-7}$ M). The molecule is practically devoid of fluorescence in water, so the dye that was not incorporated into liposomes does not contribute to the total intensity measured (ongoing study). In addition, the carboxylic group is negatively charged at the pH used for these experiments (pH 7.4), which makes the interaction with the positively charged lipids composing the Lipofectamine more efficient when compared to an indocarbocyanine dye with two long alkyl chains (DiI-C18) (data not shown). Third, the high spectral overlap between the PMI-COOH emission and TMR absorption (Figure 4) makes this dye pair very good for FRET measurements.

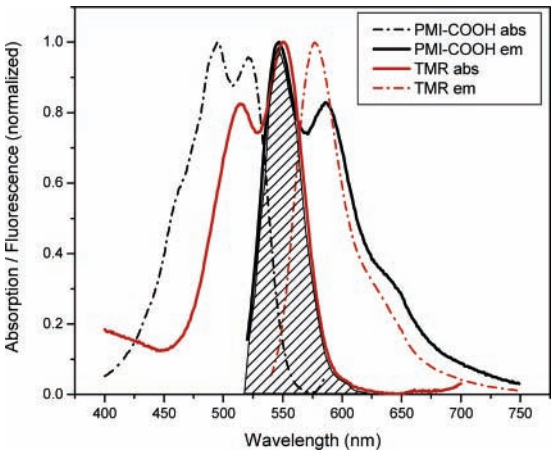

Figure 4. Absorption and emission spectra for PMI-COOH and TMR. The filled area represents the overlap between the emission spectrum of PMI-COOH and the absorption spectrum of TMR. The overlap integral calculated according to the Förster relation (*22*) is $J = 5.2 \times 10^{-13}$ cm^6 mmol^{-1} and the Förster radius is ≈60 Å.

The purpose of our experiments was to observe if cationic liposomes (Lipofectamine) are able to complex more antisense DNA hybridized with the cholesterol-modified sense sequence than the same DNA hybridized with the normal sense oligonucleotide (*10*). Lipofectamine suspension labeled with the donor (PMI-COOH) was kept at constant concentration in all experiments, while increasing acceptor concentrations (hybridized TMR−DNA) were added to the sample. Figure 5a and b show the averages and the standard deviations obtained from three independent experiments for each double strand type [naked DNA (11 DNA and 18 DNA) and cholesterol-modified monomeric (**10a**,**b**), dimeric (**12a**,**b**), and tetrameric (**14a**,**b**) DNA were evaluated]. The intensity of the donor in the presence of the acceptor (I_{DA}) was normalized to the initial intensity of the donor (I_D). Using a logarithmic scale, the first data points in each determination could be linearly fitted, and the values obtained for the slopes are given in Table 2.

As can be observed, hybridizing the 20-mer sequence with the cholesterol-modified sense 11-mer oligonucleotides (**10b**, **12b**, **14b**) shifts the slopes of the linear fitting toward higher values when compared to the unmodified sense sequence. Assuming that each TMR molecule acts as an independent acceptor even when two (**12b**) or four (**14b**) DNA oligonucleotides are linked in the same dendrimer, more donor molecules are quenched for the same DNA amount added to the system when cholesterol-modified sequences are used. Thus, the antisense oligonucleotide quantity bound to the liposomes is slightly higher in the case of cholesterol-modified sense oligonucleotides. The differences between the unmodified and the cholesterol-modified sequence are not very pronounced, but they are statistically significant. On the other hand, it seems that the number of oligonucleotides linked to the same cholesterol molecule does not influence the binding. When the 18-mer sense sequence is used for hybridization, no differences in the uptake in lipoplexes can be observed between the cholesterol-modified (**10a**, **12a**, **14a**) and the unmodified oligonucleotides. Another observation is that the slope values obtained for the 11- and 18-oligonucleotide sequence are not statistically different. Given the small length change from the 11 to the 18 sequences, we can conclude that the electrostatic interaction is the most important factor governing the formation of lipoplexes, while the much weaker hydrophobic interaction due to the presence of cholesterol may have a role in the case of short DNA sequences.

Table 2. Slopes for the Linear Fit of Data in Figure 5

DNA sequence	slope	DNA sequence	slope
11DNA	$(5.14 \pm 0.33) \times 10^6$	18DNA	$(5.68 \pm 0.54) \times 10^6$
10b	$(6.37 \pm 0.35) \times 10^6$	10a	$(5.85 \pm 0.30) \times 10^6$
12b	$(5.70 \pm 0.20) \times 10^6$	12a	$(5.94 \pm 0.42) \times 10^6$
14b	$(6.15 \pm 0.47) \times 10^6$	14a	$(5.82 \pm 0.43) \times 10^6$

The fact that we were not able to find significant differences in the liposome loading does not necessarily mean that a higher transfection efficiency in living cells cannot be obtained with the cholesterol-modified sequences. Previous studies reported a higher transfection efficiency obtained with cholesterol-modified oligonucleotides by themselves due to an increased binding to the cellular membranes (*23*, *24*). It seems thus possible that the uptake and the metabolization pathways, even when using a delivery agent, are different for the cholesterol-modified sequences when compared to the usual ones.

Biological Activity. The biological activity was determined using the 2′-MOE gapmer of phosphorothioate as the antisense strand (Table 3). The concentration was determined spectroscopically. When incubating the antisense oligonucleotide with Lipofectamine 2000, a maximum activity was obtained at 50 nM (giving 42.2% P-gp shift). Therefore, this antisense concentration was used in further experiments. When the cholesterol dendrimers

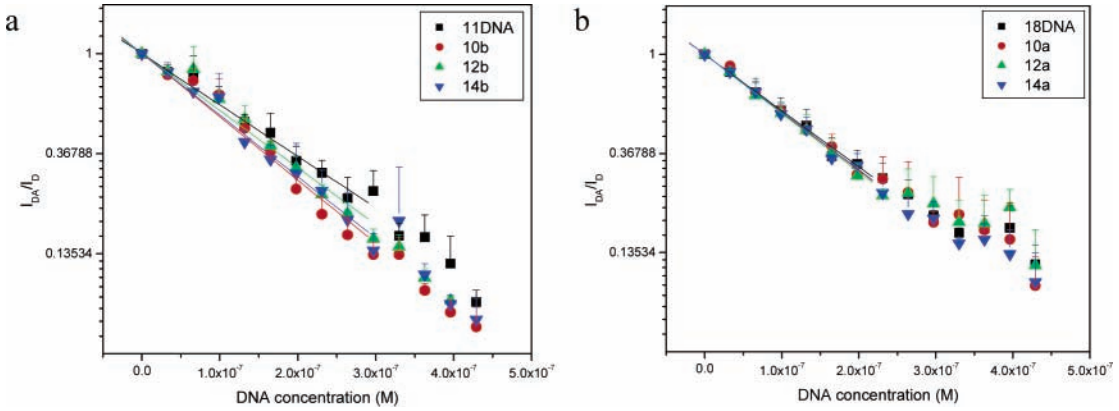

Figure 5. Quenching of PMI-COOH fluorescence (labeling Lipofectamine) using the 11 (a) and the 18 (b) oligonucleotide sequence for hybridization of the TMR-antigene sequence. The intensity of the donor in the presence of the acceptor (I_{DA}) was normalized to the initial intensity of the donor (I_D). Note that logarithmic scale was used. The first data points in each determination could be linearly fitted, and the values obtained for the slopes are given in Table 2.

Table 3. Percent Reduction of P-Glycoprotein Expression Level in Mouse 3T3 Cells by Dendrimer−Antisense Complexes[a]

	antisense alone	dimer 12a + antisense ratio 1:1	tetramer 14a + antisense ratio 1:1	dimer 12a + antisense ratio 1:2	tetramer 14a + antisense ratio 1:4
P-gp	62.8%	68.9%	70.5%	72.4%	74.0%

[a] NIH3T$_3$-MDR cells were transfected with the complexes of **12a** or **14a**, the antisense oligonucleotide, and Lipofectamine 2000. Results were obtained after 48 h incubation in 5% FBS. The ratio between **12a** or **14a** and the antisense oligonucleotide was 1:1, 1:2, and 1:4. The antisense oligonucleotide was always used at 50 nM concentration.

12a and **14a** were tested in complex with the antisense construct but without adding lipofectamine 2000, no significant effect was seen except after very long incubation time (72 h). This means that the dendrimers alone were not effective in delivering the antisense oligonucleotide. Significant effects were obtained when the dendrimers **12a** and **14a** were used in the presence of lipofectamine 2000 (Table 3). After 48 h incubation the antisense oligonucleotide gives 62.8% P-gp shift, while in the presence of the dendrimers and using 1:1, 1:2, or 1:4 molar ratios of dendrimer and antisense oligonucleotides (fixed at 50 nM), the P-gp shift varied from 68.9% to 74.0%. The effect is modest but significant. The biological activity is somewhat increased when the antisense oligonucleotides are more condensed (ratio 1:1 versus ratio 1:2 or 1:4).

CONCLUSION

Using a linker based on lysine chemistry, we were able to synthesize monomeric, dimeric, and tetrameric oligonucleotide constructs covalently linked to a cholesterol moiety. These monomeric and dendrimeric sense DNA were complexed with enzymatic stable antisense oligonucleotides targeting P-glycoprotein expression. Perylene dye was used to monitor uptake of the constructs in cationic lipids. In the case of 11-mer cholesterol-modified sense DNA, a higher amount of antisense oligonucleotide could be incorporated in the cationic liposomes than without cholesterol modification. However, this difference did not exist with the 18-mer cholesterol-modified sense DNA. Also the number of oligonucleotides linked to the same cholesterol moiety does not influence binding to the cationic lipids. In this case, electrostatic interactions seems to play the most important role during complex formations and longer sense DNA gives higher concentration of antisense DNA in the lipoplexes. The previously observed results of the better delivery of duplex oligonucleotide versus single-stranded oligonucleotides (*10*) may be partially explained by this phenomenon. However, dendrimer delivery of the antisense oligonucleotide using cholesterol-modified 18-mer sense DNA and lipofectamine resulted in a small but significant increase in biological activity. This increase in biological activity is, most probably, due to a difference in intracellular metabolism i.e., the kinetics with which the antisense oligonucleotide is delivered to its target mRNA.

ACKNOWLEDGMENT

We thank René De Boer for assistance with the mass spectrometric analysis, and Chantal Biernaux and Tom De Roeck for their excellent editorial help. Steven De Feyter is a postdoctoral fellow of the Fund for Scientific Research − Flanders. The Catholic University of Leuven (IDO/02/014) is acknowledged for financial support. Financial support from the University of North Carolina was provided by the grant P01GM59259 to R. L. Juliano. Synthesis and Bioconjugation of Diene-Modified Oligonucleotides

Rolf Tona and Robert Häner*

Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, CH-3012 Bern, Switzerland.
Received February 1, 2005; Revised Manuscript Received June 14, 2005

The preparation of diene-modified oligonucleotides as well as their properties and further derivatization are described. Self-complementary oligonucleotides containing a diene moiety in the loop region form stable, hairpin-like secondary structures. These hairpin mimics can be further derivatized via the Diels–Alder reaction. Diene modification in the stem region leads, in contrast, to a marked destabilization of the hairpin structure. No further reduction in stability is observed, however, upon conjugation of the stem-modified derivatives via the Diels–Alder reaction with an *N*-substituted maleimide dienophile.

INTRODUCTION

The hairpin is one of the most common secondary structural motifs found in nucleic acids (*1*). In RNA, it is an essential element for the assembly of higher order structures (*2*–*5*). By enabling the proper folding, the hairpin contributes to the many functional properties of RNA. Extra stable hairpins containing four bases in the loop (tetraloops) have emerged as a distinct class of hairpins forming highly specific interactions with tetraloop receptor sites (*1*, *6*, *7*). The hairpin motif is also found in DNA, although to a much lesser extent due to the intrinsic double-stranded nature of DNA. The requirements for the formation of DNA hairpins (*8*) and cruciform structures (*9*) in palindromic DNA sequences have been investigated in detail, and the involvement of such structures in the regulation of gene expression has been discussed (*10*, *11*). Furthermore, the hairpin loop also acts as a site of specific metal coordination (*12*–*14*). The central role of the hairpin as a structural and functional element has stimulated the design and synthesis of chemically modified hairpin analogues. Hairpin mimics can serve as tools for the investigation of structure and function of nucleic acids. In addition, they are increasingly gaining importance as building blocks for the construction of defined, nucleic acid-based molecular structures (*15*). Thus, the hairpin loop has been replaced with flexible oligoethylene glycol linkers (*16*–*18*) as well as with more rigid aromatic derivatives (*19*–*23*) and metal complexes (*24*–*26*). Furthermore, the construction of a stilbene-based hairpin mimic forming G-tetrades has been reported very recently (*27*).

The Diels–Alder reaction has been used for the derivatization (*28*–*30*) and immobilization (*31*) of nucleic acids. It was shown that oligonucleotides bearing a 5′-linked diene moiety react site-specifically with dienophiles without interference of the many functional groups present in RNA (*28*) and DNA (*29*, *31*). Despite its established chemoselectivity, however, the Diels–Alder reaction has hitherto not found widespread use for the purpose of DNA modification. Recently, we communicated the successful derivatization of a hairpin mimic with various functional groups (*32*). We showed that a 1,3-butadiene building block can serve as an excellent replacement of the hairpin loop. The so obtained diene-modified hairpin was amenable to derivatization via the Diels–Alder reaction with maleimide dienophiles carrying different pendant groups. We have subsequently extended these studies to the investigation of several aspects, such as the influence of changes in the 1,3-diene building blocks as well as the effect of placement of the 1,3-diene in the stem of the hairpin. Here, we report the synthesis and properties of these modified hairpins as well as their derivatization via the Diels–Alder reaction.

EXPERIMENTAL PROCEDURES

General. Reagents were purchased from Fluka, Sigma-Aldrich, or Acros and were used without further purification. Fluoresceine-derived maleimide **7** was purchased from Vector Laboratories, Inc. Reactions were monitored by thin-layer chromatography (TLC, Machery-Nagel precoated TLC plates SIL G-25 UV_{254}) using mixtures of ethyl acetate/hexane or dichloromethane/methanol. Compounds were visualized with UV light and/or dipping in permanganese- or cerium(IV) reagent followed by heating. Common workup consisted of sequential washing of the organic extract with water and brine, followed by drying over anhydrous sodium sulfate and evaporation under reduced pressure. Column chromatography (CC) was performed on silica gel (sds, SILICE 60 A C.C 40–63 μm). For tritylated compounds, TLC plates and silica gel columns were prepared with solvents containing 0.1% triethylamine. Melting points were recorded using a Büchi 510 apparatus (open capillaries, uncorrected values). ^{1}H (300 MHz), ^{13}C (75 MHz), and ^{31}P (122 MHz) NMR were recorded on a Bruker AC 300 and fitted with 1D WINNMR, and the chemical shifts (δ/ppm) were referenced to chloroform-*d* for ^{1}H and ^{13}C NMR and to phosphoric acid for ^{31}P NMR. Mass spectra were recorded on a VG Platform single quadrupole ESI-MS, Micromass Instruments, Manchester, UK.

Preparation of DNA Oligomers. The DNA oligomers were assembled on cpg solid supports (Transgenomic, Glasgow, UK) using an ABI 392 or an ABI 394 Nucleic Acid synthesizer from Applied Biosystems using the program for a 0.2 μmol synthesis except that the coupling time for modified phosphoramidites was extended to 5 min. Standard reagents and solvents for the phosphotriester method were used. Long chain aminoalkyl controlled pore glass (LCAA-CPG) solid supports with the

4,4′-dimethoxytrityl protected 3′-end nucleotide from Transgenomic (Glasgow, UK) were used. Synthesis involved repetitive cycles, each comprising (i) deprotection of the 5′-hydroxyl group by removing the 4,4′-dimethoxytrityl group with trichloroacetic acid, (ii) tetrazole activation and coupling of the following phosphoramidite, (iii) capping of nonprotected 5′-OH with acetic anhydride/1-methylimidazole, and (iv) iodine oxidation to the phosphotriester. The DNA oligomers were cleaved from the solid support using 25% aqueous ammonia hydroxide and then deprotected in the same solution at 55 °C for 15 h. After filtration through a 0.45 μm nylon syringe filter, the crude materials were purified with RP-HPLC using a LiChroCART 250-4 column from Merck (A: 0.1 M triethylammonium acetate in water, B: acetonitrile) at 40 °C. The dried oligonucleotides were desalted with Sep-Pak Cartridges (Waters) and analyzed with ESI-MS and denaturating polyacrylamide gel electrophoresis (PAGE) [Mini-PROTEAN 3 electrophoresis module (Bio-Rad Laboratories), 0.75-mm-thick 12% polyacrylamide, 1× TBE (Tris-borate-EDTA) and 10 M urea, 1× TBE as electrolyte]. Oligonucleotide concentrations were calculated from the absorbance at 260 nm with extinction coefficients calculated according to the program provided at http://paris.chem.yale.edu/extinct.html. For diene-modified and bioconjugated oligonucleotides, extinction coefficients of the respective unmodified sequences were used. Pure oligonucleotides were lyophilized and stored at −30 °C. The molecular weights of the purified oligonucleotides were determined by electrospray mass spectroscopy (see Table 1).

Bioconjugation Reactions. Diene-modified oligodeoxyribonucleotides were incubated in 10 mM sodium acetate buffer (pH 6.5) with 10 equiv of the maleimide derivatives at room temperature for 7 days. The absence of side reactions between maleimide and nucleic acid bases was monitored by MS analysis in control experiments. Fluoresceine-labeled oligodeoxyribonucleotides were purified by RP HPLC purification. The dried fractions were desalted via Sep-Pak Cartridges (Waters) and stored at −30 °C. The molecular weights of the purified conjugates were determined by electrospray mass spectroscopy (see Table 1).

Thermal Denaturation Experiments. UV melting curves were recorded on a Cary 3E UV/VIS spectrophotometer (Varian) equipped with a Cary Temperature Controller, a Sample Transport Accessory and a Multi Cell Block. Aqueous solutions of 2.5 μM oligomer, 10 mM Tris-HCl (pH 7.5), and 100 mM NaCl were used. The strands were allowed to anneal by heating at 85 °C for 1−2 min, followed by slow cooling to room temperature. The samples were heated at a rate of 0.5 °C/min, and the absorbance at 260 nm was plotted every 1 min. The percent hyperchromicity at 260 nm was plotted as a function of temperature. Melting temperatures were determined from the maximum of the first derivative of the melting curve (A_{260} against temperature); each T_m is the average of three independent experiments; exp error: ± 0.5 °C.

Molecular Modeling. The structures shown in Figure 1 were minimized using the amber force field (Hyperchem 7.0, Hypercube, Waterloo, Ontario).

General Methods. (A) Under argon, the diol (10 equiv) in absolute THF (1 mL/mmol) was added dropwise to a suspension of sodium hydride (4 equiv) in absolute THF (1 mL/mmol). After the sample was stirred for 15 h at room temperature, the dibromide, dissolved in absolute THF (1 mL/mmol), was added at room temperature and the reaction mixture was stirred for 1 h at 80 °C. The reaction mixture was then poured onto brine and extracted with EtOAc. After the sample was concentrated under reduced pressure, excess diol was evaporated under high vacuum in a kugelrohr oven (Büchi).

(B) The diol was dissolved in absolute pyridine (20 mL/mmol), and 4,4′-dimethoxytrityl chloride in absolute pyridine (0.8 equiv, 20 mL/mmol) was added dropwise over a period of about 2 h. After the sample was stirred at room temperature for 3 h, the reaction was quenched by the addition of water. The crude product was isolated by extraction with CH_2Cl_2 and concentrated using a rotary evaporator. To avoid decomposition of the product on silica gel, the column was prepared with eluent containing 0.5% triethylamine. Before addition of the crude product, the column was washed with pure eluent to remove surplus triethylamine.

(C) To a suspension of *N*,*N*-diisopropylammonium tetrazolide (2 equiv) and 2-cyanoethyl-bis(*N*,*N*-diisopropyl)amino phosphite (2 equiv) in absolute CH_2Cl_2 (5 mL/mmol), the alcohol (1 equiv) dissolved in absolute CH_2Cl_2 (10 mL/mmol) was added. After the sample was stirred at room temperature for 15 h, the reaction was quenched with saturated aqueous $NaHCO_3$ and extracted with CH_2Cl_2. To avoid decomposition of the product on silica gel, the column was prepared with eluent containing 0.5% triethylamine. Before addition of the crude product, the column was washed with pure eluent to remove surplus triethylamine.

1,6-Dibromo-hexa-2*t*,4*t*-diene (2). A solution of hexa-1,6-diene-3,4-diol (1.50 g, 13.1 mmol) in absolute diethyl ether (5 mL) was added dropwise to phosphorus tribromide (2.24 g, 9.0 mmol) in absolute diethyl ether (5 mL) at 0 °C. After the addition was complete, the mixture was allowed to warm to room temperature. After 3 h the reaction mixture was poured, slowly and under stirring, into ice−water. The mixture was carefully neutralized by the addition of saturated aqueous sodium carbonate solution. The mixture was extracted with diethyl ether and then purified by CC (EtOAc/MeOH, 19:1). The product is a strong lachrymator and should be handled in a fume hood (2.63 g, 11.4 mmol, 87%). ^{1}H NMR ($CDCl_3$) δ: 4.00 (d, 4 H, J = 7.7 Hz), 5.84−5.99 (m, 2 H), 6.21−6.31 (m, 2 H). ^{13}C NMR ($CDCl_3$) δ: 32.50, 130.86, 133.25. mp: (EtOAc) 85−87 °C.

2-[6-(2-Hydroxy-ethoxy)-hexa-2*t*,4*t*-dienyloxy]-ethanol (3a). 3a was synthesized according to general method A from **2** and ethylene glycol. The crude material was purified by CC (EtOAc/MeOH, 19:1). Yield: 24%, as a yellowish oil. ^{1}H NMR ($CDCl_3$) δ: 2.02 (s br, 2 H), 3.52−3.57 (m, 4 H), 3.73 (t, 4 H, J = 4.4 Hz), 4.05 (d, 4 H, J = 5.6 Hz), 5.71−5.80 (m, 2 H), 6.22−6.27 (m, 2 H). ^{13}C NMR ($CDCl_3$) δ: 61.92, 71.26, 77.24, 129.90, 132.03.

3-[6-(3-Hydroxy-propoxy)-hexa-2*t*,4*t*-dienyloxy]-propan-1-ol (3b). 3b was synthesized according to general method A from **2** and 1,3-propandiol. The crude

material was purified by CC (EtOAc/MeOH, 19:1). Yield: 24%, as transparent crystals. ^{1}H NMR ($CDCl_3$) δ: 1.78−1.86 (m, 4 H), 2.34 (s br, 2 H), 3.59 (t, 4 H, J = 56.0 Hz), 3.75 (t, 4 H, 6.0 Hz), 3.99 (d, 4 H, J = 6.0 Hz), 5.69−5.77 (m, 2 H), 6.16−6.26 (m, 2 H). ^{13}C NMR ($CDCl_3$) δ: 32.06, 61.95, 69.41, 71.24, 129.85, 131.88.

4-[6-(4-Hydroxy-butoxy)-hexa-2*t*,4*t*-dienyloxy]-butan-1-ol (3c). 3c was synthesized according to general method A from **2** and 1,4-butanediol. The crude material was purified by CC (EtOAc/MeOH, 19:1). Yield: 17%, as a yellowish oil. ^{1}H NMR ($CDCl_3$) δ: 1.60−1.67 (m, 8 H), 2.26 (s br, 2 H), 3.42 (t, 4 H, J = 5.9 Hz), 3.60 (t, 4 H, 3.0 Hz), 3.97 (d, 4 H, J = 5.6 Hz), 5.67−5.76 (m, 2 H), 6.15−6.25 (m, 2 H). ^{13}C NMR ($CDCl_3$) δ: 26.77, 30.11, 62.52, 70.24, 70.98, 129.83, 131.95.

2-(6-{2-[Bis-(4-methoxy-phenyl)-phenyl-methoxy]-ethoxy}-hexa-2*t*,4*t*-dienyloxy)-ethanol (4a). 4a was synthesized according to general method B from **3a** and 4,4′-dimethoxytrityl chloride. The crude product was purified by CC (EtOAc). Yield: 30%, as a transparent, viscous material. ^{1}H NMR ($CDCl_3$) δ: 1.80−1.87 (m, 4 H), 3.53−3.58 (m, 4 H), 3.76 (s, 6 H), 3.95−4.01 (m, 4 H), 4.07−4.14 (m, 2 H), 5.68−5.75 (m, 2 H), 6.18−6.23 (m, 2 H), 6.77−6.82 (m, 4 H), 7.18−7.31 (m, 7 H), 7.41 (d, 2 H, J = 7.0 Hz). ^{13}C NMR ($CDCl_3$) δ: 52.45, 54.18, 60.80, 68.70, 70.25, 84.96, 112.05, 125.64, 126.73, 127.22, 129.07, 130.25, 131.32, 135.35, 144.08, 157.38.

3-(6-{3-[Bis-(4-methoxy-phenyl)-phenyl-methoxy]-propoxy}-hexa-2*t*,4*t*-dienyloxy)-propan-1-ol (4b). 4b was synthesized according to general method B from **3b** and 4,4′-dimethoxytrityl chloride. The crude material was purified by CC (EtOAc/Hex, 2:3). Yield: 59%, as a transparent oil. ^{1}H NMR ($CDCl_3$) δ: 1.61−1.84 (m, 4 H), 1.97 (s br, 2 H), 3.08 (t, 4 H, J = 6.0 Hz), 3.48−3.56 (m, 4 H), 3.71 (s, 6 H), 3.90−3.95 (m, 4 H), 5.61−5.71 (m, 2 H), 6.10−6.20 (m, 2 H),6.72−6.77 (m, 4 H), 7.10−7.26 (m, 7 H), 7.35 (d, 2 H, J = 12 Hz). ^{13}C NMR ($CDCl_3$) δ: 30.60, 32.26, 55.33, 60.36, 62.07, 67.74, 69.45, 71.05, 71.43, 85.90, 113.12, 126.71, 127.82, 128.33, 129.62, 130.16, 130.62, 131.52, 132.25, 136.74, 145.46, 158.47.

4-(6-{4-[Bis-(4-methoxy-phenyl)-phenyl-methoxy]-butoxy}-hexa-2*t*,4*t*-dienyloxy)-butan-1-ol (4c). 4c was synthesized according to general method B from **3c** and 4,4′-dimethoxytrityl chloride. The crude material was purified by CC (EtOAc). Yield: 37%, as a beige solid. ^{1}H NMR ($CDCl_3$) δ: 1.64 (s, 8 H), 3.04 (t, 2 H, J = 5.8 Hz), 3.37 (t, 2 H, J = 6.0 Hz), 3.45 (t, 2 H, J = 5.7 Hz), 3.60−3.77 (m, 2 H), 3.77 (s, 6 H), 3.98 (dd, 4 H, J = 5.9 and 15.5 Hz), 5.68−5.77 (m, 2 H), 6.15−6.26 (m, 2 H), 6.78−6.82 (m, 4 H), 7.15−7.32 (m, 7 H), 7.41 (d, 2 H, J = 7.1 Hz). ^{13}C NMR ($CDCl_3$) δ: 26.71, 26.80, 30.25, 55.19, 62.78, 63.05, 70.22, 70.29, 70.89, 71.08, 112.95, 126.55, 127.68, 128.20, 129.54, 130.01, 130.45, 131.54, 132.15, 136.67, 145.36, 158.28.

Diisopropyl-phosphoramidous Acid 2-(6-{2-[Bis-(4-methoxy-phenyl)-phenyl-methoxy]-ethoxy}-hexa-2*t*,4*t*-dienyloxy)-ethyl Ester 2-Cyano-ethyl Ester (5a). 5a was synthesized according to general method C from **4a** and 2-cyanoethyl-bis(*N*,*N*-diisopropyl)amino phosphite. The crude material was purified by CC (EtOAc). Yield: 98%, as a transparent oil. ^{1}H NMR ($CDCl_3$) δ: 1.15−1.18 (m, 12 H), 1.54 (s, 2 H), 2.61 (t, 2 H, J = 6.4 Hz), 3.20 (t, 2 H, J = 5.1 Hz), 3.55−3.63 (m, 6 H), 3.77 (s, 6 H), 3.73−3.87 (m, 2 H), 4.06 (t, 4 H, J = 6.0 Hz), 5.71−5.78 (m, 2 H), 6.24−6.28 (m, 2 H), 6.77−6.82 (m, 4 H), 7.17−7.35 (m, 7 H), 7.45 (d, 2 H, J = 7.2 Hz). ^{13}C NMR ($CDCl_3$) δ: 20.27, 24.52, 24.59, 24.62, 24.68, 42.98, 43.14, 55.21, 58.38, 58.63, 62.53, 62.78, 63.24, 69.68, 70.00, 70.09, 71.24, 71.32, 77.44, 113.03, 126.64, 127.74, 128.21, 129.72, 130.07, 130.30, 131.44, 132.03, 136.33, 145.07, 158.37. ^{31}P NMR ($CDCl_3$) δ: 148.78. HRMS (ESI+): $C_{44}H_{60}N_2NaO_7P$: calc.: 727.3488 g/mol, found: 727.3497 g/mol.

Diisopropyl-phosphoramidous Acid 3-(6-{3-[Bis-(4-methoxy-phenyl)-phenyl-methoxy]-propoxy}-hexa-2*t*,4*t*-dienyloxy)-propyl Ester 2-Cyano-ethyl Ester (5b). 5b was synthesized according to general method C from **4b** and 2-cyanoethyl-bis(*N*,*N*-diisopropyl)amino phosphite. The crude material was purified by CC (EtOAc). Yield: 99%, as a transparent, glassy material. ^{1}H NMR ($CDCl_3$) δ: 1.09−1.19 (m, 16 H), 1.81−1.89 (m, 4 H), 2.58−2.63 (m, 2 H), 3.13 (t, 2 H, J = 6.2 Hz), 3.48−3.61 (m, 6 H), 3.71−3.85 (m, 2 H), 3.76 (s, 6 H), 3.97 (t, 2 H, J = 5.5 Hz), 5.67−5.76 (m, 2 H), 6.16−6.26 (m, 2 H), 6.77−6.83 (m, 4 H), 7.14−7.32 (m, 7 H), 7.41 (d, 2 H, J = 7.1 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.06, 20.31, 20.40, 22.99, 24.52, 24.61, 24.70, 30.44, 31.47, 31.57, 42.91, 43.08, 55.19, 58.19, 58.45, 60.22, 60.43, 60.66, 66.88, 67.60, 70.98, 71.05, 85.73, 112.97, 126.58, 127.69, 128.17, 130.01, 130.15, 131.60, 131.75, 136.57, 145.32, 158.31. ^{31}P NMR ($CDCl_3$) δ: 147.72. HRMS (ESI+): $C_{42}H_{58}N_2O_7P$: calc.: 733.3981 g/mol, found: 733.3971 g/mol.

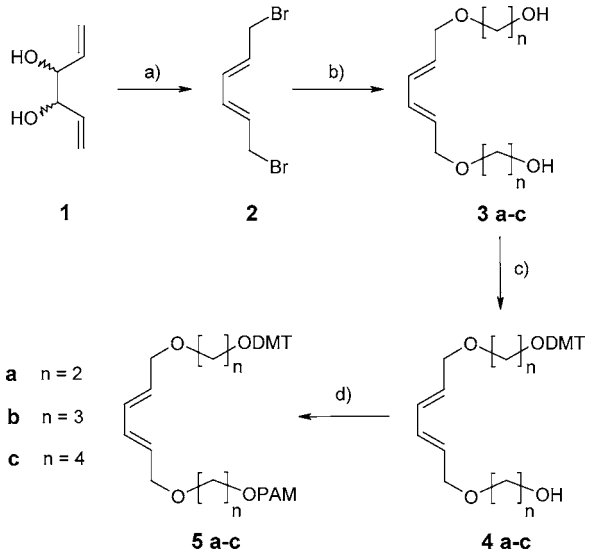
Diisopropyl-phosphoramidous acid 4-(6-{4-[bis-(4-methoxy-phenyl)-phenyl-methoxy]-butoxy}-hexa-2*t*,4*t*-dienyloxy)-butyl ester 2-cyano-ethyl ester (5c). 5c was synthesized according to general method C from **4c** and 2-cyanoethyl-bis(*N*,*N*-diisopropyl)amino phosphite. The crude material was purified by CC (EtOAc/Hex, 1:1). Yield: 97%, as a transparent oil. ^{1}H NMR ($CDCl_3$) δ: 1.14−1.17 (m, 14 H), 1.65 (t, 8 H, J = 3.0 Hz), 2.61 (t, 2 H, J = 6.4 Hz), 3.04 (t, 2 H, J = 5.8 Hz), 3.35−3.44 (m, 4 H), 3.51−3.74 (m, 4 H), 3.77 (s, 6 H), 3.96 (t, 4 H, J = 6.8 Hz), 5.68−5.77 (m, 2 H), 6.15−6.26 (m, 2H), 6.77−6.82 (m, 4 H), 7.15−7.32 (m, 7 H), 7.41 (d, 2 H, J = 12.2 Hz). ^{13}C NMR ($CDCl_3$) δ: 20.32, 20.41, 24.52, 24.60, 24.70, 26.31, 26.72, 28.02, 42.90, 43.07, 55.19, 58.17, 58.42, 63.05, 69.95, 70.26, 70.94, 77.21, 112.95, 126.55, 127.67, 128.19, 130.01, 130.09, 130.15, 131.69, 136.66, 158.29. ^{31}P NMR ($CDCl_3$) δ: 147.45. HRMS (ESI+): $C_{44}H_{62}N_2O_7P$: calc.: 761.4294 g/mol, found: 761.4283 g/mol.

RESULTS AND DISCUSSION

Synthesis of the different conjugated diene building blocks was accomplished as shown in Scheme 1. Thus, diol **1** was converted into the dibromide **2**, according to a literature procedure (*33*). Reaction with the corresponding α,ω-diols afforded the symmetrical diols **3a**−**c**, which were further transformed into the DMT-protected derivatives **4a**−**c**. Standard phosphitylation finally gave the phosphoramidites **5a**−**c**. The different phosphoramidite building blocks were subsequently used for the synthesis of the hairpin mimics **6a**−**c**, shown in Scheme 2, via automated oligonucleotide synthesis. All oligomers were purified by reverse phase HPLC and characterized by electrospray ionization time-of-flight (ESI-TOF) mass spectrometry. For comparison, the two hairpins $\mathbf{T_4}$ and $\mathbf{A_4}$, containing either four thymidine or deoxyadenosine nucleotides in the hairpin loops, were synthesized.

The stabilities of the different hairpin mimics were analyzed by thermal denaturation experiments. The denaturation curves showed a single, cooperative transition for all oligomers (data not shown). Furthermore, melting temperature (T_m) values were independent of the oligomer concentration, which indicates a unimolecular process, i.e., formation and melting of the hairpin structures. The different T_m values are summarized in Table

Scheme 1. Synthesis of Different Diene-Derived Phosphoramidite Building Blocks[a]



[a] Conditions: (a) PBr_3, rt (87%); (b) $NaO(CH_2)_nOH$, THF, 50 °C (30−43%); (c) 4,4′-dimethoxytrityl chloride, pyridine, rt (46%); (d) bis(*N*,*N*-di-*iso*-propylamino)-2-cyanoethylphosphoramidite, di-*iso*-propylammonium tetrazolide, CH_2Cl_2, rt (98%). PAM: 2-cyanoethyl-di-*iso*-propylaminophosphinoyl; DMT: 4,4′-dimethoxytrityl.

Table 2. T_m Values of Different Hairpins and Hairpin Mimics

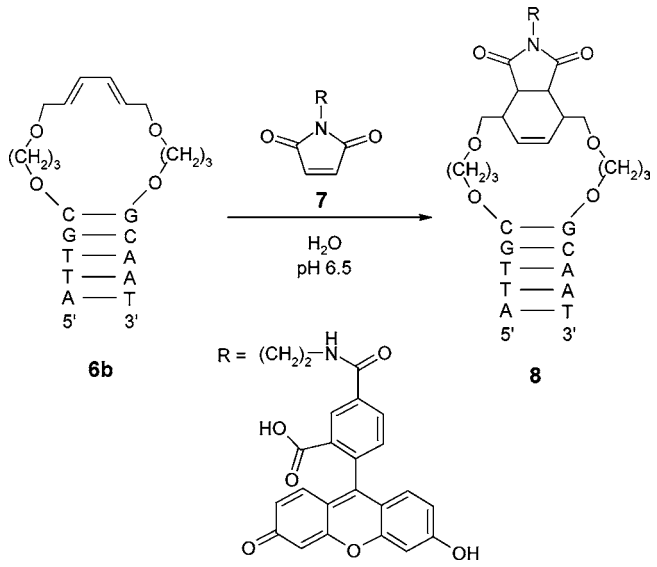
hairpin	T_4	A_4	6a	6b	6c	8
T_m [°C][a]	57.8	56.8	63.5	66.5	65.5	67.1[c]
ΔT_m [°C][b]		−1.0	5.7	8.7	7.7	9.3

[a] Conditions: oligomer concentration 2.5 μM, 10 mM Tris-HCl, 100 mM NaCl, pH 7.5; temp gradient: 0.5 °C/min. [b] Difference in T_m relative to T_4. [c] Value taken from ref *32*.

2. All diene-modified oligomers form more stable secondary structures than the control oligonucleotides T_4 or A_4. An increase in the T_m's of 6−9 °C was observed compared to the analogous hairpin containing a T_4 loop. Somewhat surprisingly, the size of the linkers connecting the diene moiety to the hairpin stem had a relatively small influence on the structural stability. The hairpin mimics **6a** and **6c** containing building blocks with two or four methylene units in the linker arms are only 3 and 1 °C less stable than **6b**, which contains three methylene units.

Since the loop region of the hairpin is crucial for intra- and intermolecular interactions, introduction of substituents at this site is desirable. We previously showed (*32*) that introduction of substituents can be readily achieved via the Diels−Alder reaction with maleimide-derived dienophiles, such as **7** (Scheme 3). The obtained conjugate

Scheme 3. Diels−Alder Reaction of 1,3-Butadiene-Based Hairpin Mimic 6b with Maleimide 7



forms a stable secondary structure. Thus, a T_m value of 67.1 °C was obtained for **8** (see Table 2) (*32*). Despite its relative bulkiness, the fluoresceine substituent is well tolerated. The circular dichroism (CD) spectra of **6b** and **8** were consistent with B-form DNA structures (data not shown). On the basis of all the information obtained, we derived models of **6b** and of the fluoresceine bioconjugate **8** (Figure 1). According to amber force field calculations (Hyperchem) (*34*), both possible diene conformations of **6b** (i.e., s-cis and s-trans) form a stable hairpin-like secondary structure. Since the s-cis isomer represents the relevant conformation for the subsequent Diels−Alder reaction, the hairpin mimic is presented in this orientation (Figure 1, middle). The model shows the nonnucleotidic linker on top of the helix, bridging the two nucleic acid strands. The plane of the diene is oriented parallel to the adjacent base pair, providing the proper arrangement for reaction with dienophiles. Thermal Diels−Alder reactions proceed through a concerted syn addition, leading to a cis geometry in the cycloadduct (*35*). Furthermore, the endo pathway is usually favored by far owing to a lowering of its transition state's energy as the result of a secondary π overlap (*35*). We can, thus, assume that the formation of the endo products is preferred in our experiments. Finally, the two faces of the dienophiles used in this study are homotopic. This leaves two unique ways in which the two partners can approach each other. The two faces of the diene are rendered diastereofacial by the chiral nucleic acid. Therefore, the two diastereomeric products shown in Figure 1 can be formed. In one diastereomer, the fluoresceine substituent (green) points into the minor groove (left), and in the other diastereomer, it is oriented toward the major groove. Thus far, we could not find any evidence that one of the diastereomers is formed preferentially. Analysis and purification of the products by HPLC did not result in the resolution or separation of the possible diastereomers. Furthermore, thermal denaturation experiments with the obtained product **8** showed no evidence of two separate transitions as a result of the presence of two diastereomeric hairpins of different structural stability.

The results demonstrate that the hairpin mimics containing diene modifications in the loop region, such as **6b**, are amenable to derivatization through the Diels−Alder reaction with maleimide-derived dienophiles. At-

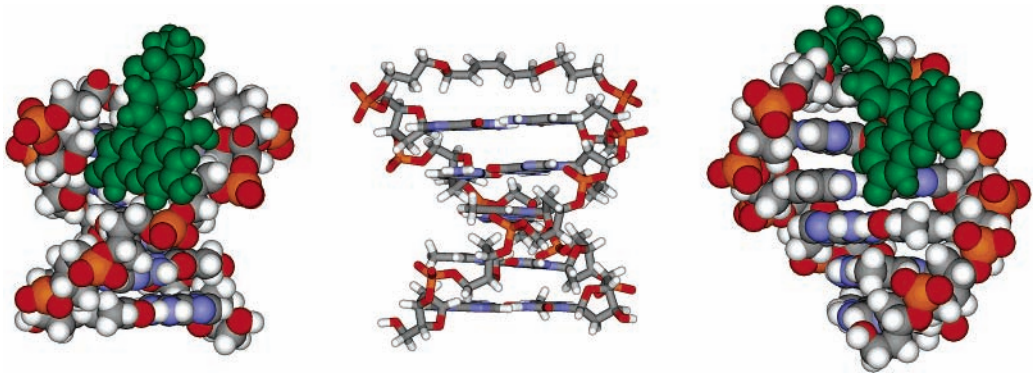


Figure 1. Optimized structures (HyperChem 7.0, amber force field) of the diene-modified hairpin mimic **6b** (middle) and the two possible diastereomeric products **8** arising from an endo Diels–Alder reaction with maleimide **7**. The two diastereomeric products have the fluorescein group (highlighted in green) pointing either into the minor groove (left) or into the major groove (right).

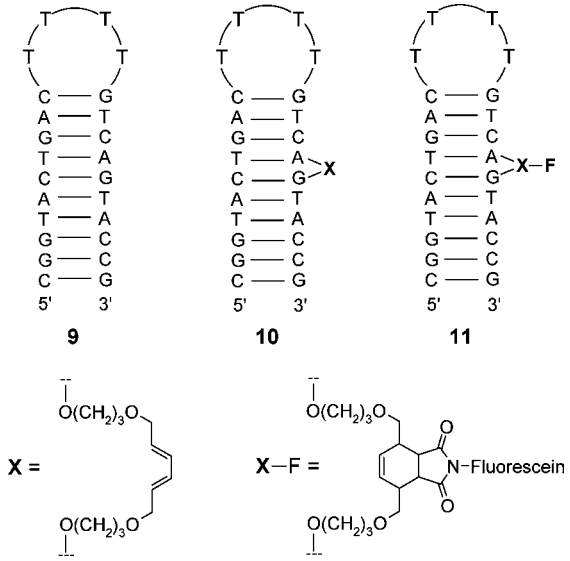
Scheme 4. Hairpins 10 and 11, Containing a Diene Modification or a Diels–Alder Adduct, Respectively, in the Stem[a]



[a] For the detailed structure of the fluorescein derivative see Scheme 3.

tachment of functional or reporter groups might, however, also be desirable in the stem part of a hairpin. Therefore, we investigated whether the approach of bioconjugation via the Diels–Alder reaction might be extended to the stem region of hairpin analogues. For this purpose, a hairpin analogue containing a diene building block in the stem was prepared. Again, the diene modification with three methylene units in the linkers was selected for incorporated into the hairpin oligonucleotide, this time, however, into the stem region. The unmodified hairpin **9** and the diene-containing analogue **10** are shown in Scheme 4. Treatment of **10** with the fluoresceine-substituted maleimide **7** under the same conditions as described above resulted in the formation of the Diels–Alder adduct **11**. The thermal denaturation data are summarized in Table 3. As can be seen, addition of a diene-building block into the stem region causes a strong destabilization of 14 °C. Subsequent Diels–Alder reaction of **11**, however, does not result in a further reduction of stability. In fact, the relatively bulky fluoresceine even reduces the destabilization to some extent (+2.5 °C). Thus, bioconjugation of hairpin analogues containing a diene modification in the stem can also be achieved via the Diels–Alder reaction. The resulting product is markedly destabilized. The destabilization is, however, a consequence of the insertion of an additional, nonnucleosidic building block rather than of the conjugation of the dienophile.

Table 3. T_m Values of Hairpins Modified in the Stem Region

hairpin	**9**	**10**	**11**
T_m [°C][a]	69.0	55.0	57.5
ΔT_m [°C][b]		−14.0	−11.5

[a] Conditions: oligomer concentration 2.5 μM, 10 mM Tris-HCl, 200 mM NaCl, pH 7.5; temp gradient: 0.5 °C/min. [b] Difference in T_m relative to **9**.

In conclusion, hairpin analogues containing diene modifications in the loop or in the stem regions have been synthesized. The hairpin mimics containing the diene modification in the loop region form stable secondary structures, which are relatively insensitive to the length of the synthetic linkers. The diene moiety is amenable to derivatization with an *N*-substituted maleimide, and the resulting conjugate adopts a remarkably stable secondary structure. On the other hand, derivatization with a diene in the stem region leads to a substantial reduction in stability. Subsequent Diels–Alder reaction with an *N*-substituted maleimide, however, occurs smoothly and does not result in any further destabilization.

Synthesis of 6′-*O*-Lissamine-rhodamine B-Glucosamine as a Novel Probe for Fluorescence Imaging of Lysosomes in Breast Tumors

Kristine Glunde,* Catherine A. Foss, Tomoyo Takagi, Flonne Wildes, and Zaver M. Bhujwalla

JHU ICMIC Program, The Russell H. Morgan Department of Radiology and Radiological Science, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205. Received February 19, 2005; Revised Manuscript Received May 17, 2005

Lysosomes contain multiple proteases, which play a crucial role in breast cancer invasion and metastasis. Noninvasive labeling of lysosomes in breast cancer cells and solid breast tumor models is therefore useful to study lysosomal trafficking and its role in invasion. We have synthesized a novel compound, 6′-*O*-lissamine-rhodamine B-glucosamine, to fluorescently label lysosomes, and evaluated the compound in human breast cancer cells in cell culture or in orthotopic human breast cancer models. We demonstrated that this novel compound biosynthetically labeled lysosomal proteins following addition to cell culture medium or following intravenous injection into mouse models of breast cancer. Fluorescence from 6′-*O*-lissamine-rhodamine B-glucosamine colocalized with several well-established lysosomal markers, such as lysosome-associated proteins 1 and 2 (LAMP-1 and -2) and CD63. We also demonstrated the feasibility of performing in vivo fluorescence imaging of 6′-*O*-lissamine-rhodamine B-glucosamine to image lysosomes in human breast cancer models.

INTRODUCTION

Lysosomes are membranous organelles of ~0.5 μm diameter, which contain several types of hydrolytic enzymes and maintain an acidic lumenal pH of ~5 (*1*). Lysosomes are the terminal degradative compartment of mammalian cells but are also involved in antigen processing (*2*), bone remodeling (*3*), the regulation of growth factors (*4*), and plasma membrane repair (*5*). Tumors with high metastatic potential, such as Lewis lung carcinoma (*6*), melanoma (*7*), and several breast cancers (*8, 9*), exhibit increased lysosomal enzyme expression and activity (*10*). Breast cancer cells can also contain intracellular large acidic vesicles (LAVs,[1] ≥ 5 μM in diameter), carrying endocytosed extracellular matrix (ECM) components (*11, 12*). Breast cancer invasion and metastasis, which is the most life-threatening aspect of malignant breast cancer, requires proteolytic enzymes to degrade ECM proteins (*13*–*15*). Cathepsins D, B, and L, which are sequestered in lysosomal vesicles (*16*), were shown to play a crucial role in cancer invasion and metastasis (*17*–*19*). Lysosomal trafficking may be an important parameter affecting lysosomal enzyme release and endocytosis of ECM proteins. Solid tumors contain hypoxic and acidic regions, which may affect lysosomal trafficking and the release of degradative enzymes by cancer cells (*20, 21*). Extracellular acidosis was shown to alter lysosomal trafficking in human breast cancer cells (*22*), which most likely facilitated lysosomal enzyme release. Effective techniques to fluorescently label lysosomes and optically image lysosomal trafficking in solid tumors are a prerequisite to study the role of lysosomes in breast cancer invasion and metastasis in tumor models.

In fixed tissues or cell specimens, lysosomes can be visualized by immunofluorescence staining using antibodies against a lysosomal protein of choice. Three well-established lysosomal marker proteins are lysosome-associated membrane proteins 1 and 2 (LAMP-1 and -2) (*23, 24*) and CD63 (*25*). LAMPs are highly abundant in lysosomal membranes and have been detected in most human tissues (*26*). Lysosomes in live cell cultures have been fluorescently labeled with substrates for lysosomal hydrolytic enzymes, such as fluorescent casein, which carry a fluorophore that is quenched before but fluoresces after cleavage (*27, 28*). Acidotropic fluorescent probes are a second class of lysosomal markers for live cell imaging, which accumulate in acidic organelles because of their matching pK_a values, e.g. neutral red (*29*), acridine orange (*30*), LysoTracker (*31*), and LysoSensor (*32*). Fluorescent probes such as fluorescent dextrans (*33*), that are endocytosed and accumulate in lysosomes, have been utilized to visualize lysosomes in live cell cultures. These techniques have limited specificity, since they label compartments based on characteristics not unique to lysosomes (*34*). We recently developed a technique to specifically label lysosomes biosynthetically in live breast cancer cell cultures using a dansylated glucosamine (*34*). This labeling technique is based on the fact that most lysosomal proteins, and particularly lysosomal membrane proteins, are highly glycosylated and frequently carry several N-linked glycans (*35*). These glycans consist of mannose, *N*-acetylglucosamine, fucose, galactose, and sialic acid moieties and are thought to protect lysosomal

proteins from degradation by lysosomal proteases (*36*). We previously synthesized and characterized 6-*O*-dansyl-GlcNH$_2$ (*34*), which localized to lysosomes by forming dansylated glycoproteins in live human mammary epithelial cells (HMECs) and live breast cancer cells. We demonstrated that biosynthetic labeling of lysosomes using 6-*O*-dansyl-GlcNH$_2$ is feasible for imaging lysosomes in live HMECs or breast cancer cells by confocal fluorescence microscopy (*34*).

In the present study, we synthesized and biologically characterized a novel fluorescently labeled glucosamine: 6′-*O*-lissamine-rhodamine B-glucosamine (6-*O*-liss-GlcNH$_2$) for in vivo studies in mice. This newly synthesized fluorescent compound is nontoxic and can be administered intravenously in tumor-bearing mice and subsequently localizes to lysosomes in tumors by accumulating in lysosomal proteins. The emission maximum of 6-*O*-liss-GlcNH$_2$ at 570 nm is suitable for in vivo optical imaging, since it lies within the window of low tissue absorption and autofluorescence. We assessed the uptake, relative distribution, and lysosomal localization of 6-*O*-liss-GlcNH$_2$ in MCF-7 and MDA-MB-231 breast cancer cells in cultures and in severe combined immune deficient (SCID) mice bearing MCF-7 and MDA-MB-231 tumors in the mammary fat pad.

MATERIALS AND METHODS

Cell Culture. Three human mammary epithelial cell (HMEC) lines representing different stages of malignancy were used in this study. MCF-12A, a spontaneously immortalized nonmalignant cell line established from MCF-12M mortal cells (*37*), was obtained from American Type Culture Collection (ATCC, Rockville, MD) and cultured in DMEM-Ham's F12 medium (Invitrogen Corporation, Carlsbad, CA) supplemented as described previously (*37*). MCF-7, an estrogen-positive lowly metastatic mammary epithelial cancer cell line, was obtained from ATCC (Rockville, MD) and cultured in EMEM medium (Mediatech, Inc., Herndon, VA) supplemented with 10% fetal bovine serum and antibiotics (*38*). An invasive and metastatic human mammary epithelial cell line, MDA-MB-231 was provided by Dr. R. J. Gillies (Arizona Health Sciences Center, Tuscon, AZ) and maintained in RPMI-1640 medium (Invitrogen Corporation, Carlsbad, CA) supplemented with 10% fetal bovine serum, 100 units/mL penicillin, and 100 μg/mL streptomycin (Invitrogen Corporation, Carlsbad, CA). The human breast cancer cell lines were originally isolated from pleural effusions of patients with breast cancer. All cells were kept at 37 °C in a humidified atmosphere of 5% CO_2 in air.

Tumor Model and Inoculations. MCF-7 or MDA-MB-231 cells were inoculated in the upper left thoracic mammary fat pad of five female severe combined immune deficient (SCID) mice. A quantity of 2×10^6 tumor cells was inoculated in a volume of 0.1 mL of Hanks balanced solution (HBSS, Sigma, St. Louis, MO) at a concentration of 10^6 cells/0.05 mL. An amount of 0.18 mg of 60-day release 17β-Estradiol Pellets (Innovative Research of America, Sarasota, FL) was subcutaneously implanted near the left shoulder of SCID mice inoculated with MCF-7 cells. Mice weighed between 19− 24 g, and tumor sizes ranged between 75 mm^3 and 375 mm^3 when experiments were performed. All experimental animal protocols were approved by the Institutional Animal Care and Use Committee.

Chemical Synthesis of 6′-*O*-Lissamine-rhodamine B-Glucosamine. All chemical reactions are shown in Figure 1. All reagents were purchased from Sigma unless otherwise noted and were of p.a. grade.

1-*O*-Boc, 2-*N*-Boc-β-D-glucosamine (2). Powdered sodium methoxide (500 mg, 9.98 mmol) and 6-(2-amino-2-deoxy-β-D-glucopyranosyl) ether (2.0 g, 9.28 mmol) were added to a baked 25 mL round-bottom flask along with 10 mL of dry methanol. The resulting suspension was stirred for 5 min at room temperature under argon and then filtered over scintered glass. The solid was washed with an additional 10 mL of dry methanol and transferred to a clean 25 mL round-bottom flask. Triethylamine (1.03 g, 10.2 mmol) and di-*tert*-butyl pyrocarbonate (2.23 g, 10.2 mmol) were added to the flask along with 10 mL of dry methanol, and the thick, white suspension was stirred at room temperature under argon for 10 h. Progress was monitored by silica gel thin-layer chroma-

tography (TLC) using 2-propanol/water/ammonium hydroxide (7:2:1 v/v/v) with ninhydrin (Fisher Scientific, Pittsburgh, PA) detection followed by baking. The starting material **1** displayed an R_f of 0.18. The *N*-Boc derivative displayed an R_f of 0.79. The reaction mixture was concentrated under reduced pressure and dissolved in 20 mL of dioxane/water (1:1 v/v). Triethylamine (1.03 g, 10.2 mmol), 4-(dimethylamino)pyridine (50 mg, 0.41 mmol), and di-*tert*-butyl pyrocarbonate (1.1 g, 5.1 mmol) were added, and the clear solution was stirred at room temperature under argon for 24 h. During this time, additional triethylamine (0.51 g, 5.1 mmol) and di-*tert*-butyl pyrocarbonate (1.1 g, 5.1 mmol) were added to the reaction. Progress was monitored by TLC using chloroform/ethyl acetate/methanol (5:2:1 v/v) with ninhydrin detection followed by baking. The *N*-Boc derivative displayed an R_f of 0.14, while the R_f of product **2** was 0.37. The reaction was concentrated under reduced pressure and **2** was purified by silica gel chromatography using chloroform/ethyl acetate/methanol (6:3:1 v/v) and resulted in a 48.2% yield.

6-*O*-Lissamine-rhodamine B-1-*O*-Boc,2-*N*-Boc-glucosamine (3). Dry 1-*O*-Boc,2-*N*-Boc-β-D-glucosamine (500 mg, 1.37 mmol) and Lissamine Rhodamine B sulfonyl chloride, mixed isomers (9-[4-(chlorosulfonyl)-2-sulfophenyl]-3, 6-bis(diethylamino)-xanthylium internal salt) (1 g, 1.78 mmol, Molecular Probes, Eugene, OR), were added to a baked 50 mL round-bottom flask along with dry pyridine (20 mL). The resulting purple suspension was stirred at room temperature under argon for 10 h. The reaction was quenched by addition of a piece of ice followed by removal of the pyridine under reduced pressure. Analysis of this material by TLC using methanol/methylene chloride (1:9 v/v) revealed the presence of product **3**, which exhibits an R_f of 0.6. The product was purified by silica gel chromatography using methanol/methylene chloride (2:8 v/v) to yield pure **3** at 62% yield.

6′-*O*-Lissamine-rhodamine B-glucosamine (4). Dry **3** (500 mg, 0.98 mmol) and dry trifluoroacetic acid (TFA) (10 mL) were stirred in a 50 mL round-bottom flask for 4 h at room temperature. The resulting bright red solution was then concentrated under reduced pressure to give a bright red oil. Analysis by TLC using methanol/methylene chloride (2:8 v/v) revealed the presence of **4**, which exhibits an R_f of 0.5−0.62 (mixed isomers). This oil was purified by silica gel chromatography using methanol/methylene chloride (2:8 v/v) and afforded final product **4** in 60% yield. ^{1}H NMR (500 MHz, CD_3OD): δ 8.68 (d, J = 0.91 Hz, 1H), δ 8.08 (dd, J = 7.94 Hz, 1.53 Hz, 1H), δ 7.38 (d, J = 7.94 Hz, 1H), δ 7.15 (d, J = 9.46 Hz, 2H), δ 7.01 (dd, J = 9.46 Hz, 2.44 Hz, 2H), δ 6.93 (d, J = 2.44 Hz, 2H), δ 3.67 (ddd, J = 7.33 Hz, 7.32 Hz, 7.02 Hz, 2H), δ 3.21 (ddd, J = 7.33 Hz, 7.32 Hz, 7.02 Hz, 5H), δ 1.30 (m, 20H). ^{13}C NMR (100 MHz, CD_3OD): δ 163.31 (q, J_{C-F} = 39.5 Hz), 159.87, 159.14, 157.58, 148.51, 146.48, 134.29, 133.52, 132.12, 129.02, 127.41, 115.91, 115.39, 97.41, 48.32, 47.28, 13.34, 9.71. Mass spectrum (FAB): m/z = 720 Da. Absorbance max (Beckman DU 7500) = 574 nm.

In Vitro Incubation with 6′-*O*-Lissamine-rhodamine B-Glucosamine. In cell cultures, different concentrations of 6-*O*-liss-$GlcNH_2$ (Figure 1, compound **4**) were tested in the range of 250 μM to 2 mM. A concentration of 500 μM 6-*O*-liss-$GlcNH_2$ was found to be sufficient for effective labeling. The time-course of 6-*O*-liss-$GlcNH_2$ uptake and localization to lysosomes was assessed in MCF-12A, MCF-7, and MDA-MB-231 cells grown on chamber slides. Cells were incubated for time periods of 2−96 h in cell culture medium containing 500 μM 6-*O*-liss-$GlcNH_2$. Cells were fixed with 3% paraformaldehyde as described previously (*22, 34*).

In Vivo Treatment with 6′-*O*-Lissamine-rhodamine B-Glucosamine. Female SCID mice bearing MCF-7 or MDA-MB-231 tumors were intravenously injected with 7.8 mg 6-*O*-liss-$GlcNH_2$ (7.8 mg in 0.1 mL saline, sterile filtered). At 2, 24, 48, and 72 h postinjection, tumors were optically imaged in vivo using a home-built small animal fluorescene imaging system, following which mice were sacrificed and tumor, blood, liver, kidney, and muscle tissue were harvested. Freshly cut 1-mm thick tissue sections of harvested organs and blood were placed on microscope slides (Fisher Scientific, Pittsburgh, PA), covered with CoverWell imaging chambers (Grace Bio-Labs, Bend, OR) and optically imaged using fluorescence microscopes. The remaining tumors were immediately frozen using Tissue-Tek O.C.T. Compound (Sakura Finetek U.S.A. Inc, Torrance, CA) and Tissue-Tek cryomolds (Miles Inc., Elkhart, IN) and liquid nitrogen.

In Vivo Optical Imaging of Breast Tumor Models. For in vivo imaging, the tumor region was shaved in anesthetized mice and the animal was lightly taped to minimize motion. A home-built small animal fluorescene imaging system equipped with a Mini Repro Camera Stand (Industria Fototecnica Firenze, Florence, Italy), a 300 W Gemini 300 high-intensity short arc light source with universal adaptor (Chiu Technical Corporation, Kings Park, NY), an optical fiber (Edmunds, Barrington, NJ), a filter cube containing a 510−560 nm band-pass exitation filter and a 575 nm long pass emission filter (Omega Optical, Inc., Brattleboro, VT), and a Nikon Coolpix 990 or Coolpix 5000 digital camera (Nikon, Tokyo, Japan) was used to obtain optical images of mice with tumor xenografts.

Ex Vivo Optical Imaging and Relative Distribution. Fresh tissue sections (1-mm thick) of tumor, liver, kidney, and muscle as well as blood were imaged ex vivo in imaging chambers using bright-field and epi-fluorescence (528−553 nm excitation, 565 nm emission) microscopy using a Nikon eclipse E400 or TS100 attached to a Nikon Coolpix 990 or 5000 digital camera. Exposure times were kept constant for all organ sections and blood. Low power images of whole organ sections were acquired using a 1× lens. High power images were acquired using a 40× or 100× lens. Image analysis was performed using ImageJ (National Institutes of Health, Bethesda, MD). Images were converted to 8-bit gray-scale, the organ section was outlined, fluorescence intensity was measured, and the median fluorescence intensity per pixel was calculated.

Immunofluorescence Staining. Tumors frozen in O.C.T. compound (Sakura Finetek U.S.A. Inc.) were sectioned at 15-μm thickness using a microtome cryostat (Microm Int., Walldorf, Germany) and attached to charged microscope slides (Fisher Scientific, Pittsburgh, PA). The 15-μm tumor sections were fixed using 3% paraformaldehyde. Fixed cells in chamber slides and fixed tumor sections were stained using monoclonal antibodies to LAMP-1 (H4A3), LAMP-2 (H4B4), or CD63 (ab1318, Abcam Inc., Cambridge, MA). hLAMP-1 and hLAMP-2 antibodies (*26*) were kindly provided by Dr. J. Thomas August, Johns Hopkins University, Baltimore, MD. LAMP-1, LAMP-2, and CD63 are three specific marker proteins localized in lysosomal membranes. Tumor sections and cells were incubated with a Cy5-labeled donkey anti-mouse secondary antibody (Jackson ImmunoResearch Laboratories, West Grove, PA), and cell nuclei were counterstained with Hoechst H-33342 (Molecular

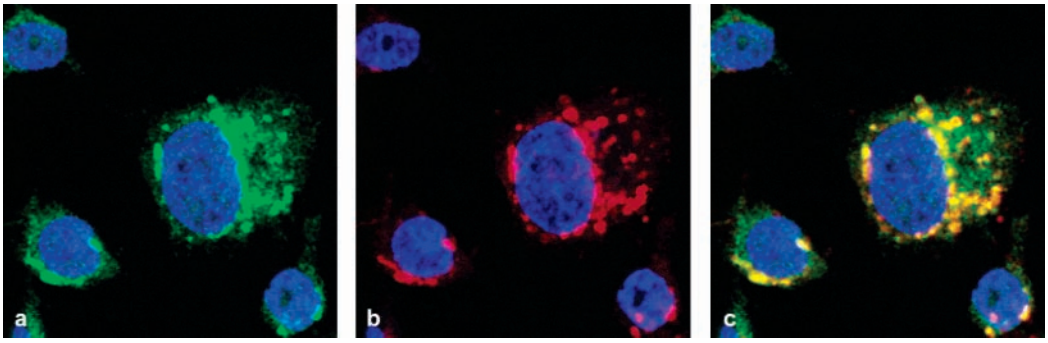

Figure 2. (a) Human MDA-MB-231 breast cancer cells exposed to 500 μM 6-*O*-liss-GlcNH_2 for 24 h. Fluorescence from (a) 6-*O*-liss-GlcNH_2 is displayed in green, and (b) CD63 immunofluorescence is displayed in red. Nuclei are displayed in blue. (c) The overlay of both images demonstrates the colocalization of 6-*O*-liss-GlcNH_2 and CD63, evident by the yellow color. The field of view of all images is 56.2 μm $\times$ 56.2 μm.

Probes, Eugene, OR) and mounted using Faramount aqueous mounting medium (DakoCytomation, Carpinteria, CA).

Confocal Laser-Scanning Fluorescence Microscopy. Fluorescence microscopy of fixed specimen was performed on a Zeiss LSM 510 META confocal laser-scanning microscope (Carl Zeiss, Inc., Thornwood, NY) using a Plan-Apochromat 63x/1.4 oil immersion lens (Zeiss) (The Johns Hopkins University School of Medicine Microscope Facility, Director Dr. Douglas B. Murphy). 6-*O*-liss-GlcNH_2 was excited with a 543 nm laser, and fluorescence emission was detected by a photomultiplier tube using a 565−595 nm band-pass filter. Simultaneously, H-33342 was excited with a 405 nm laser and the fluorescence emission was detected with a second photomultiplier by applying a 490 nm dichroic beam splitter and a 420−480 nm band-pass filter. Cy5 was excited simultaneously with a 633 nm laser and the fluorescence emission was detected with a third photomultiplier by using a 635 nm dichroic beam splitter and a 650 nm long pass filter, to achieve simultaneous detection of all three fluorophores. Confocal Z-sections of 1 μm thickness were imaged. Colocalization coefficients were measured using the LSM Software Release 3.2 (Zeiss).

Western-Blot Analysis. Cells were cultured in 100-mm tissue culture dishes until they reached 60−70% confluence. Following treatment with 500 μM 6-*O*-liss-GlcNH_2 for 2 or 4 days, cells were scraped and homogenized with lysis buffer containing protease inhibitors as previously described (*34*). A 50 μg amount of total protein was loaded in each lane of a 9% sodium dodecyl sulfate (SDS)-polyacrylamide gel, and proteins were resolved by electrophoresis (*34*). Approximate protein molecular weights were determined by comparison with a molecular weight marker (BenchMark, Life Technologies, Rockville, MD). Fluorescence and bright-field images were acquired for the resulting polyacrylamide gels using our home-built small animal fluorescence imaging system.

RESULTS

Chemistry. The novel compound 6′-*O*-lissamine-rhodamine B-glucosamine (6-*O*-liss-GlcNH_2, Figure 1, compound **4**) was synthesized in a three-step procedure analogous to the previously published synthesis of 6-*O*-dansyl-GlcNH_2 (*34*). As summarized in Figure 1, a Lissamine Rhodamine B group (*39*) was regiospecifically introduced to the 6′-hydroxyl group of 6-(2-amino-2-deoxy-β-D-glucopyranosyl)ether hydrochloride while the 2′-amino and 1′-hydroxyl groups were protected with *tert*-butyloxycarbonyl (Boc) groups (*34, 40*). The structure of

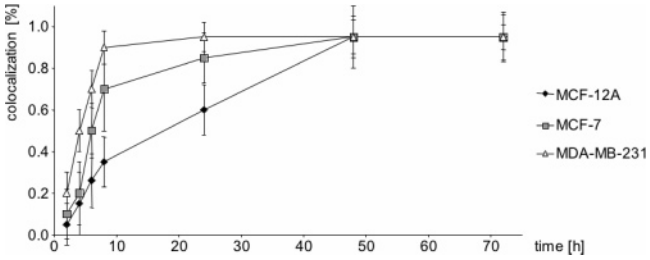

Figure 3. Time course of the colocalization coefficient. The colocalization coefficient (*y*-axis) of 6-*O*-liss-GlcNH_2 fluorescence with CD63 immunofluorescence increased gradually with increasing incubation time (*x*-axis) in MCF-12A HMECs, MCF-7, and MDA-MB-231 breast cancer cells. Colocalization was most rapid in MDA-MB-231 cells, followed by MCF-7 and MCF-12A cells. Values are mean $\pm$ standard error, $n = 15$, for each time point (five fields of view for three independent experiments each).

the final product 6-*O*-liss-GlcNH_2 was verified by ^{1}H and ^{13}C NMR spectroscopy and FAB-mass spectrometry (ppm- and *m/z*-values are given in Materials and Methods).

Uptake and Localization of 6-*O*-Liss-GlcNH_2 in Breast Epithelial and Cancer Cells. 6-*O*-liss-GlcNH_2 was taken up by MCF-12A HMECs and human MCF-7 and MDA-MB-231 breast cancer cells and significantly localized to lysosomes starting from ~8 h of incubation in MDA-MB-231 and MCF-7 breast cancer cells, and from ~24 h of incubation in MCF-12A HMECs. To assess the degree of lysosomal labeling from 6-*O*-dansyl-GlcNH_2, cells were fixed following 6-*O*-liss-GlcNH_2 incubation and costained with lysosomal markers CD63, LAMP-1, or LAMP-2. Representative fluorescence images of MDA-MB-231 breast cancer cells incubated with 6-*O*-liss-GlcNH_2 for 24 h in Figure 2a−c show that labeling from 6-*O*-liss-GlcNH_2 colocalized with the lysosomal marker CD63, as evident from the yellow color in the overlay image in Figure 2c. In Figure 3, the colocalization coefficient from 6-*O*-liss-GlcNH_2 and CD63 fluorescence was quantified from images derived from three independent experiments with each cell line, demonstrating the gradual increase in lysosomal 6-*O*-liss-GlcNH_2 staining. The fastest incorporation of fluorescent 6-*O*-liss-GlcNH_2 label into lysosomes occurred in MDA-MB-231 breast cancer cells, followed by MCF-7 cells and MCF-12A HMECs (Figure 3). Following 2−4 h of incubation, 6-*O*-liss-GlcNH_2 fluorescence was distributed over the cytoplasm of cells and concentrated in some bright nonlysosomal areas close to the nucleus (data not shown). Following 8 h of incubation in MDA-MB-231 cells, or 24−48 h in MCF-7 and MCF-12A cells, lysosomes were labeled up to a colocalization coefficient of 0.8−0.95 with

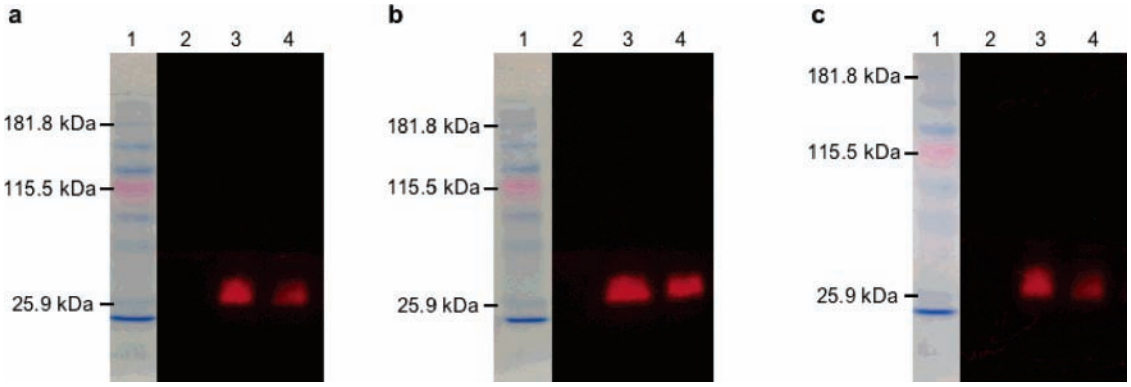

Figure 4. Fluorescence images of SDS−PAGE gels of protein lysates obtained from (a) MCF-12A, (b) MCF-7, and (c) MDA-MB-231 cells incubated with 6-*O*-liss-$GlcNH_2$ for 2 or 4 days. Bright-field images were acquired from the same field of view, and a molecular weight marker lane from bright-field images (lane 1) was copied into the fluorescence image to assign the molecular mass. Lane 1 contains molecular weight marker, lane 2 contains control cell lysate, lane 3 contains cell lysate following 2 days of incubation of cells with 6-*O*-liss-$GlcNH_2$, and lane 4 contains cell lysate following 4 days of incubation of cells with 6-*O*-liss-$GlcNH_2$. 6-*O*-liss-$GlcNH_2$ fluorescence is enriched in protein(s) of an apparent mass of 26−30 kDa following 2−4 days 6-*O*-liss-$GlcNH_2$ incubation.

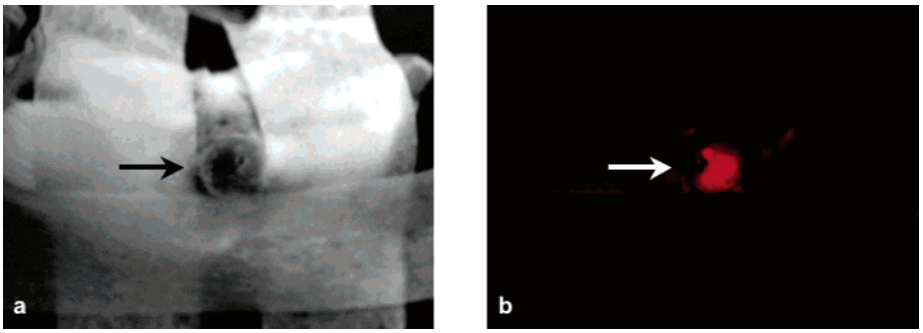

Figure 5. In vivo (a) bright-field and (b) fluorescence images of a representative MCF-7 tumor 2 h following injection of 7.8 mg of 6-*O*-liss-$GlcNH_2$ into the tail vein. Efficient delivery of 6-*O*-liss-$GlcNH_2$ to the tumor (tumor marked by arrow) is evident in these images.

respect to CD63 immunofluorescence (Figure 3), which corresponds to almost complete lysosomal staining. Comparable results were obtained with LAMP-1 and -2 immunofluorescence staining.

Protein Analysis. SDS−PAGE electrophoresis of lysates from 6-*O*-liss-$GlcNH_2$-treated cells was performed, followed by fluorescence imaging of these gels to determine the molecular weight of the protein(s) containing covalently bound 6-*O*-liss-$GlcNH_2$. As displayed in Figure 4, fluorescence imaging of these gels revealed that proteins with an apparent molecular weight of ∼26−30 kDa contained 6-*O*-liss-$GlcNH_2$-fluorescence. This fluorescent protein band was detected in MCF-12A HMECs as well as MCF-7 and MDA-MB-231 breast cancer cells (Figure 4).

Uptake and Localization of 6-*O*-Liss-$GlcNH_2$ in Tumor-Bearing SCID Mice. MCF-7 or MDA-MB-231 tumors in the mammary fat pad of female SCID mice were optically imaged in vivo at 2, 24, and 48 h following intravenous administration of 7.8 mg of 6-*O*-liss-$GlcNH_2$ via the tail vein. Figure 5 demonstrates that fluorescence from 6-*O*-liss-$GlcNH_2$ was detected in MCF-7 tumors at 2 h postinjection but not at 24 or 48 h postinjection. Similar results were obtained with MDA-MB-231 tumors. To assess the relative distribution of 6-*O*-liss-$GlcNH_2$ in selected tissues, bright-field and fluorescence microscopy were performed on freshly cut 1-mm sections from MCF-7 tumors, MDA-MB-231 tumors, liver, kidney, and muscle tissue as well as on blood. Although there was no detectable fluorescence at 24 and 48 h postinjection of 6-*O*-liss-$GlcNH_2$ in vivo, high-resolution fluorescence images of fresh tissue sections revealed that MCF-7 and MDA-MB-231 tumors contained 6-*O*-liss-$GlcNH_2$-fluorescence at 2, 24, and 48 h postinjection, as shown in Figure 6. Fluorescence intensity declined at later time points postinjection (Figures 6, 7). Tumoral 6-*O*-liss-$GlcNH_2$ fluorescence intensity was most pronounced in necrotic tumor areas, but also present in all other tumor regions, as evident from comparison of fluorescence with bright-field images (Figure 6a,b,f,g). High-power fluorescence images revealed that the staining pattern in viable tumor areas changed over time. At 2 h postinjection, 6-*O*-liss-$GlcNH_2$ was detected in the cytoplasm of tumor cells in viable tumor regions (Figure 6c,h). At 24 and 48 h postinjection, a punctate staining pattern from 6-*O*-liss-$GlcNH_2$ fluorescence was observed in viable tumor cells (Figure 6d,i). The liver contained detectable fluorescence intensity from 6-*O*-liss-$GlcNH_2$ only at 2 h postinjection but not at later time points (Figure 6j,k). A small amount of fluorescence intensity was detected in the kidneys at 2 h postinjection. Muscle and blood did not contain any detectable fluorescence from 6-*O*-liss-$GlcNH_2$ at the time points tested (data not shown). Figure 7 displays the time course of 6-*O*-liss-$GlcNH_2$ fluorescence intensity in all tested organs. MCF-7 and MDA-MB-231 tumors retained higher levels of 6-*O*-liss-$GlcNH_2$ fluorescence for a longer time than blood, liver, kidney, and muscle.

Lysosomal Localization of 6-*O*-Liss-$GlcNH_2$ in Tumor-Bearing SCID Mice. The subcellular localization of the tumoral 6-*O*-liss-$GlcNH_2$ staining pattern was assessed by immunofluorescence microscopy of MCF-7 and MDA-MB-231 tumor sections obtained following 6-*O*-liss-$GlcNH_2$ injection. Lysosomal staining with 6-*O*-liss-$GlcNH_2$ was evaluated by colocalization of 6-*O*-liss-$GlcNH_2$ with well-established lysososmal markers, such as CD63, LAMP-1, and LAMP-2. Figure 8 demonstrates

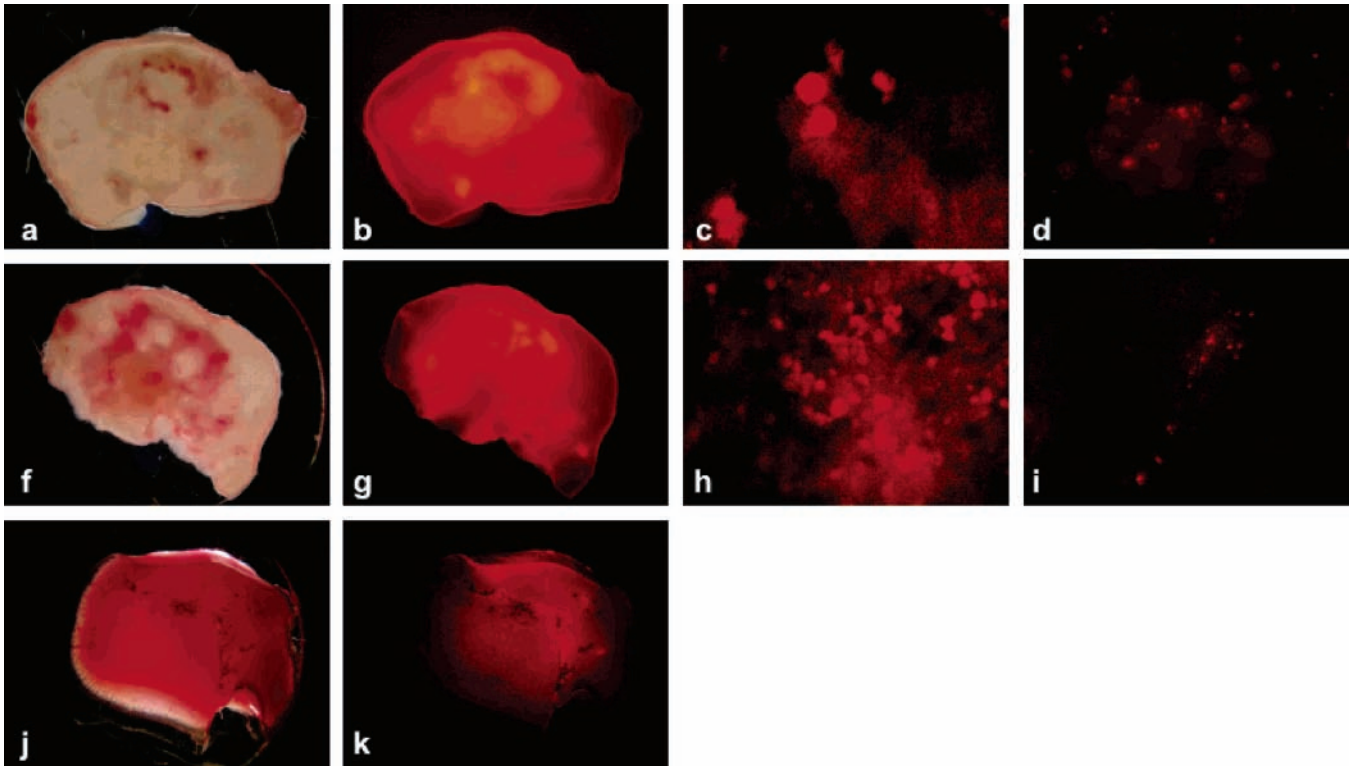

Figure 6. Ex vivo images of freshly cut 1-mm tissue sections (1× lens). Bright-field images of a representative (a) MCF-7 tumor section, (f) MDA-MB-231 tumor section, and (j) liver section and the corresponding 6-*O*-liss-GlcNH_2 fluorescence images of the (b) MCF-7 tumor section, (g) MDA-MB-231 tumor section, and (k) liver section are displayed. High-power (100× lens) fluorescence images of a representative (c) MCF-7 tumor section 2 h postinjection and (d) MCF-7 tumor section 24 h postinjection, as well as a representative (h) MDA-MB-231 tumor section 2 h postinjection and (i) MDA-MB-231 tumor section 24 h postinjection are displayed.

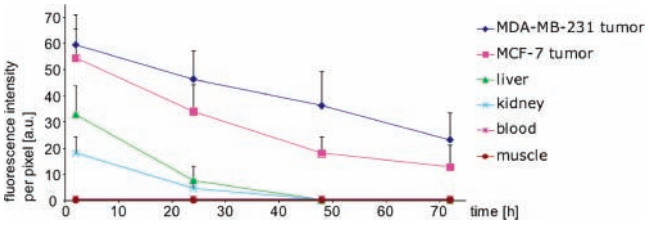

Figure 7. The time course of the mean 6-*O*-liss-GlcNH_2 fluorescence intensity per pixel is shown for MCF-7 tumors, MDA-MB-231 tumors, liver, kidney, muscle, and blood. Values are mean ± standard error, $n = 2-4$ for each time point.

that viable tumor regions from MCF-7 and MDA-MB-231 tumors contained lysosomal 6-*O*-liss-GlcNH_2-fluorescence at 24 h postinjection. This was evident from colocalization of 6-*O*-liss-GlcNH_2 displayed in green (Figure 8a,d) with CD63-staining displayed in red (Figure 8b,e), resulting in the yellow color from the overlay of both images (Figure 8c,f). Nuclei were counterstained and are displayed in blue. The colocalization coefficient for 6-*O*-liss-GlcNH_2 with CD63 fluroescence was 0.92 ± 0.09 ($n = 15$) in viable areas of MCF-7 tumors, as quantified using five sections from three tumors each. In MDA-MB-231 tumors, a colocalization coefficient of 0.96 ± 0.08 ($n = 15$) was observed in viable regions. Comparable results were obtained with the lysosomal markers LAMP-1 and LAMP-2 (data not shown). Necrotic tumor regions displayed abundant 6-*O*-liss-GlcNH_2 staining (Figure 8g) and, as anticipated, very little nuclear staining, since these tumor regions were not viable (Figure 8g–i). In addition, few yellow areas of colocalization were apparent in these necrotic areas (Figure 8i), indicating lack of lysosomal markers in these regions of dying cells (Figure 8g–i).

DISCUSSION

Here we have developed a novel compound, 6′-*O*-lissamine-rhodamine B-glucosamine, to perform noninvasive labeling of lysosomes in vivo and in vitro and to follow lysosomal trafficking in live breast cells and solid breast tumor models. This method will be useful to understand the relationship between lysosomal trafficking and the tumor microenvironment and its role in breast cancer invasion and metastasis.

The synthesis of 6-*O*-liss-GlcNH_2 is a relatively straightforward three-step procedure analogous to the synthesis of 6-*O*-dansyl-glucosamine (*34*). A Lissamine Rhodamine B group was regiospecifically introduced to the 6′-hydroxyl group of 6-(2-amino-2-deoxy-β-D-glucopyranosyl)ether hydrochloride while the 2′-amino and 1′-hydroxyl groups were protected with Boc (*tert*-butyloxycarbonyl) groups (*34, 40*).

Cell culture and animal studies are feasible using 6-*O*-liss-GlcNH_2, since it dissolves well in aqueous solutions. In cell culture studies, a concentration of 500 μM of 6-*O*-liss-GlcNH_2 in the cell culture medium resulted in clearly defined lysosomal fluorescence labeling in HMECs and breast cancer cells. In SCID mice bearing orthotopic breast tumor xenografts, administration of 7.8 mg of 6-*O*-liss-GlcNH_2 into the tail vein resulted in robust lysosomal fluorescence labeling of tumors. Lysosomes in HMECs, breast cancer cell lines, and tumors were specifically labeled by 6-*O*-liss-GlcNH_2 as verified by colocalization of 6-*O*-liss-GlcNH_2 fluorescence with CD63, LAMP-1, and LAMP-2, the latter three of which are well-established marker proteins for lysosomes (*23–26*). Lysosomal labeling of breast cancer cells in culture or solid tumors required relatively long incubation and postinjection uptake times of approximately 24 h. In in vitro cell culture assays, lysosomes in MDA-MB-231 breast cancer

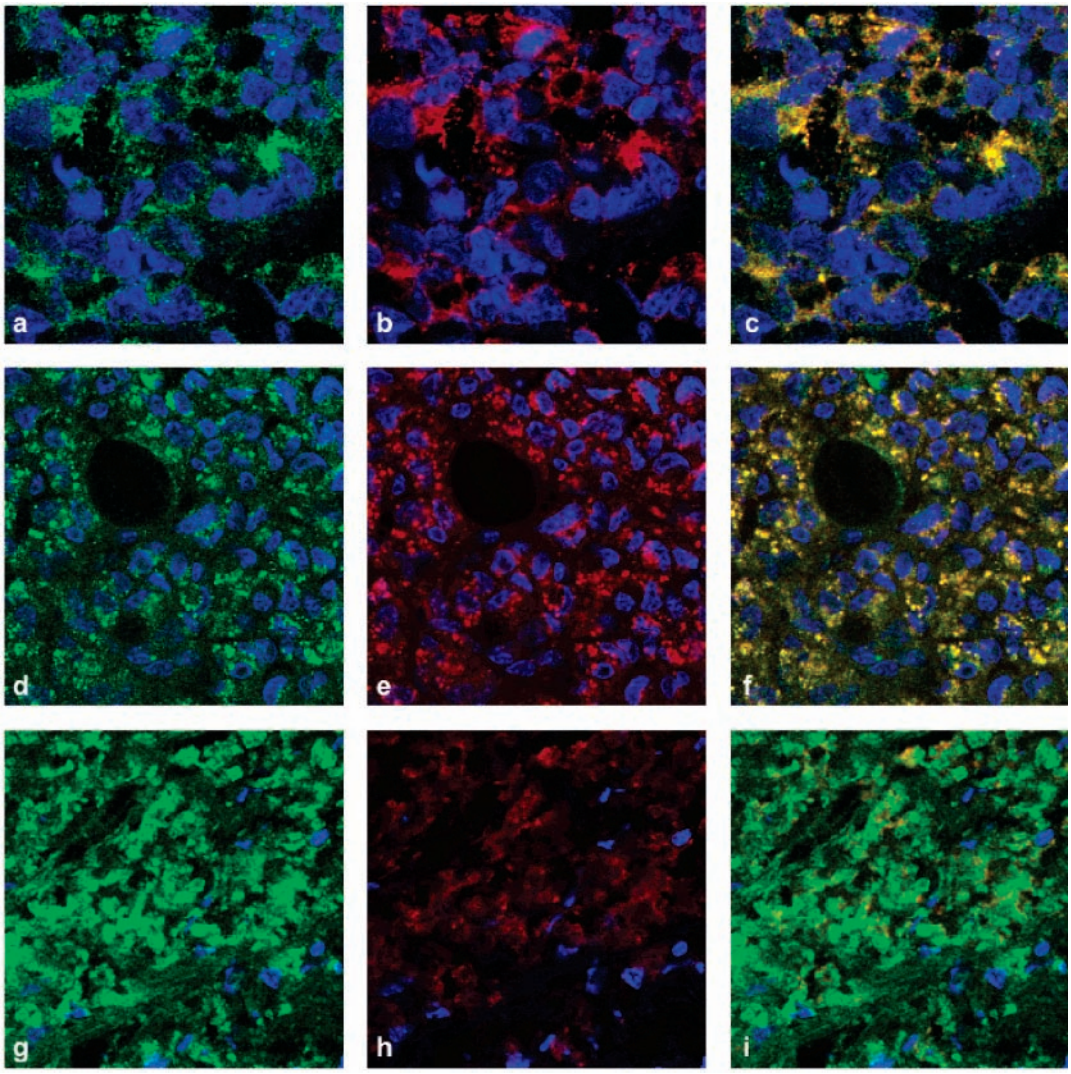

Figure 8. Confocal laser-scanning fluorescence images of (a−c) MCF-7 tumor sections and (d−f) MDA-MB-231 tumor sections. 6-*O*-liss-GlcNH_2 fluorescence images are displayed in green in a representative (a) MCF-7 tumor section and (d) MDA-MB-231 tumor section. The corresponding CD63 immunofluorescence images are displayed in red in the (b) MCF-7 tumor section and (e) MDA-MB-231 tumor section. 6-*O*-liss-GlcNH_2 and CD63 fluorescence images were overlaid for (c) MCF-7 and (f) MDA-MB-231 tumor sections, demonstrating strong colocalization of 6-*O*-liss-GlcNH_2 and CD63 as evident from the yellow color. (g−i) Representative confocal fluorescence images of necrotic regions from a MDA-MB-231 tumor, containing (g) strong 6-*O*-liss-GlcNH_2 fluorescence, and very little fluorescence from (h) lysosomes or (i) nuclei.

cells were labeled faster than lysosomes in MCF-7 and MCF-12A cells. At early incubation or postinjection uptake times, breast cancer cells exhibited a nonvesicular staining pattern. This observation is consistent with our earlier studies with the 6-*O*-dansyl derivative of glucosamine (*34*), where dansyl fluorescence was distributed over the cytoplasm of the cell and concentrated in some bright areas close to the nucleus following 5 h of exposure, and vesicular lysosomal staining appeared following 22 h or longer time periods of exposure (*34*). Similar to the analogous compound 6-*O*-dansyl-GlcNH_2, 6-*O*-liss-GlcNH_2 was most likely biosynthetically incorporated into highly glycosylated lysosomal proteins by passing through cellular sites of protein glycosylation. The lysosomal membrane contains several N-linked glycan-carrying proteins (*35*). N-Linked glycans are added cotranslationally to newly synthesized polypeptides in the endoplasmic reticulum (ER) and are extensively modified, as these glycoproteins mature and move through the ER and Golgi complex to their final destination in the cell (*41,* 42). Protein lysates of cells exposed to 6-*O*-liss-GlcNH_2 exhibited one major band at 26−30 kDa in optically imaged protein SDS−PAGE gels. Apparently, 6-*O*-liss-GlcNH_2 was utilized by breast cells in the biosynthesis of a glycosylated protein highly represented in lysosomes. However, 6-*O*-dansyl-GlcNH_2 was predominantly found in 70 kDa protein(s) (*34*). Although 6-*O*-liss-GlcNH_2 and 6-*O*-dansyl-GlcNH_2 both localized to lysosomes through biosynthetic incorporation into highly glycosylated lysosomal proteins, the difference in apparent molecular weight suggests that two distinct lysosomal proteins were labeled by these compounds. In contrast to commonly used less specific lysosomal probes utilized for live cell imaging, 6-*O*-liss-GlcNH_2 and 6-*O*-dansyl-GlcNH_2 (*34*) confer the advantage of being specifically targeted to lysosomes.

Systemic administration of 6-*O*-liss-GlcNH_2 in SCID mice revealed that this compound is nontoxic in SCID mice. 6-*O*-liss-GlcNH_2 is rapidly cleared from the blood stream within 2 h of intravenous administration, as demonstrated by a lack of 6-*O*-liss-GlcNH_2 fluorescence in the blood at 2 h postinjection. MCF-7 and MDA-MB-231 tumors were intensely fluorescent up to 24−48 h, while the liver and kidney contained moderate 6-*O*-liss-

$GlcNH_2$ fluorescence intensity at similar time points. Thus, 6-*O*-liss-$GlcNH_2$ was efficiently delivered to MCF-7 and MDA-MB-231 breast tumor xenografts in SCID mice. Although 6-*O*-liss-$GlcNH_2$ was detectable in these breast tumor models for more than 3 days, its fluorescence intensity declined over time, indicating elimination of 6-*O*-liss-$GlcNH_2$ from breast tumors. The fluorescence intensity from 6-*O*-liss-$GlcNH_2$ in these tumors was sufficient for tumor in vivo optical imaging at 2 h postinjection. Subcellular localization of 6-*O*-liss-$GlcNH_2$ to lysosomes in tumors required longer time periods. The highest colocalization coefficients of 6-*O*-liss-$GlcNH_2$ fluorescence with lysosomal markers CD63, LAMP-1, and LAMP-2 was detected at 24 h postinjection in viable tumor regions, suggesting that breast cancer cells in these viable tumor regions utilized 6-*O*-liss-$GlcNH_2$ in the biosynthesis of a glycosylated lysosomal protein. The intratumoral distribution of 6-*O*-liss-$GlcNH_2$ appeared to be inhomogeneous, exhibiting higher fluorescence intensity in necrotic areas. Necrotic areas did not contain viable cells, as evident from missing nuclear counterstaining in these areas. Thus, 6-*O*-liss-$GlcNH_2$ accumulation in necrotic tumor regions was nonspecific. While lysosomal localization of fluorescence from 6-*O*-liss-$GlcNH_2$ was most pronounced at 24 h postinjection, in vivo imaging of this fluorescence was not feasible with our system, because the fluorescence intensity was below the detection limit of this system. Images obtained by fluorescence microscopy of fresh tumor slices strongly suggest that intravital fluorescence microscopy or endoscopy of 6-*O*-liss-$GlcNH_2$-labeled lysosomes in solid breast tumor models will have sufficient resolution and sensitivity to detect lysosomal labeling in vivo.

The novel compound 6-*O*-liss-$GlcNH_2$ described here will be valuable not only to understand the role of lysosomes and lysosomal trafficking in breast cancer invasion and metastasis, but also to study cell and animal models of lysosomal diseases. 6-*O*-liss-$GlcNH_2$ itself, or analogous compounds, may, in the future, be utilized for detecting aberrant lysosomal trafficking in clinical settings. 6-*O*-liss-$GlcNH_2$ will prove useful for studying lysosomal storage diseases (*43*) such as Gauchers disease (*44*), as well as neurodegenerative diseases such as Alzheimer's disease (*45, 46*), which exhibit robust activation of the neuronal lysosomal system, namely, endocytosis and autophagy. Although 6-*O*-liss-$GlcNH_2$ may not be able to cross the intact blood−brain barrier (BBB), pathogenesis of increased BBB permeability has been demonstrated in Alzheimer's disease (*47*). 6-*O*-liss-$GlcNH_2$ may also be helpful for assessing host−parasite relationships such as that of *Trypanosoma cruzi* trypomastigotes (*48*), which involve participation of the host's lysosomes, and for following therapeutic targeting of lysosomes.

ACKNOWLEDGMENT

This work was supported by a Career Development Award to Dr. Kristine Glunde through P50 CA103175 (JHU ICMIC Program) and R24 CA92871. We thank Dr. Dmitri Artemov for building the small animal fluorescence imaging system and for technical support with this home-built system. We thank Dr. J. Thomas August for providing us with monoclonal antibodies against hLAMP-1 (H4A3) and hLAMP-2 (H4B4). We thank Dr. Douglas B. Murphy (Director, The Johns Hopkins University School of Medicine Microscope Facility) for technical support. We thank Mr. Gary Cromwell for maintaining the cell lines.

Synthesis and Characterization of Positively Charged Porphyrin−Peptide Conjugates

Martha Sibrian-Vazquez, Timothy J. Jensen, Frank R. Fronczek, Robert P. Hammer, and M. Graça H. Vicente*

Department of Chemistry, Louisiana State University, Baton Rouge, Louisiana 70803. Received February 28, 2005; Revised Manuscript Received May 26, 2005

The total syntheses of 14 porphyrin conjugates containing one to four positively charged amino acids and two distinct linkers are described. All conjugates were fully characterized using spectroscopic methods, and the X-ray structure of a porphyrin isothiocyanate precursor was obtained. In vitro studies using HEp2 cells show that these conjugates have low cytotoxicity ($IC_{50} > 250\ \mu M$) and that the extent of their cellular uptake depends significantly on the number, nature, and sequence of amino acids in the peptide, and on the presence of a centrally chelated metal ion. Metal-free conjugates bearing three consecutive arginine residues accumulated the most within cells. On the other hand, the preferential sites of subcellular localization were found to be independent from the number, nature, and sequence of amino acids in the conjugate, the linker, and coordinated metal ion; it is suggested, based on theoretical calculations, that the peptides in these conjugates fold over the porphyrin macrocycle in order to maximize intramolecular hydrophobic interactions.

INTRODUCTION

The biomedical applications of porphyrin-type macrocycles have been the subject of intense research in the past decades because of their unique photophysical and pharmacokinetic properties. In particular porphyrin derivatives have been investigated for use as sensitizers in the photodynamic therapy (PDT) and in the boron neutron capture therapy (BNCT) of tumors (*1*, *2*). PDT and BNCT are binary therapies for cancer treatment that involve the activation of a tumor-localized porphyrin sensitizer with light (in PDT) or low energy neutrons (in BNCT). These therapies have the potential to be highly localized to neoplastic tissue, since the cytotoxic species generated in PDT (mainly $^1O_2$) and BNCT ($^4He^{2+}$ and $^7Li^{3+}$) have short distances of travel through tissue. In fact the preferential subcellular site(s) of localization of porphyrin sensitizers are considered to be an important factor in determining their biological efficacy, as they define the primary site(s) of damage and can thus determine the mechanism(s) of cell death (*3*, *4*). Among the sensitizers, positively charged molecules are particularly interesting because they potentially target the most vulnerable intracellular sites, such as the cell mitochondria and nuclei (*4*−*6*) and have shown to cause effective DNA and RNA damage (*7*−*9*). Furthermore, cationic porphyrins are active in the photoinactivation of bacteria (*10*−*14*) and viruses (*15*, *16*).

With the aim to increase the biological effectiveness of porphyrin sensitizers and to broaden their application as fluorescent bioimaging agents, their conjugation to various proteins (*17*−*20*), peptides (*21*−*23*), oligonucleotides (*24*, *25*), and monoclonal antibodies (*26*, *27*) have been investigated in recent years. Several conjugation techniques have been reported, and the resulting bioconjugates have shown improved cell target ability and enhanced biological efficacy. In our continuing studies of structure−activity relationships in porphyrin macrocycles, we prepared 14 conjugates of a model porphyrin (**1**) to various positively charged amino acids and peptides containing lysine and arginine residues and investigated their cytotoxicity, cellular uptake, and sites of intracellular localization. Arginine (side chain $pK_a \sim 12.5$) and lysine ($pK_a \sim 9.4$) are amphiphilic amino acids that are protonated at physiological pH. Whereas lysine has a localized positive charge on its amino group, the guanidinium group has delocalized charge and is capable of forming multiple hydrogen bonds. Furthermore, the planar geometry and charge distribution of the guanidinium group is ideal for binding negatively charged groups, such as phosphates and carboxylates. Herein we report that porphyrin conjugates containing one to four lysine or arginine amino acid residues have low dark cytotoxicity and localize mainly in cellular vesicles and lysosomes, and that their cellular uptake depends significantly on the nature, number, and sequence of amino acid residues and the presence of a centrally chelated metal ion. Furthermore, we hypothesize that in such conjugates bearing small linkages between the porphyrin and peptide molecules, intramolecular forces favor a fold-over conformation of the conjugates, which might in part explain their similar sites of subcellular localization.

EXPERIMENTAL PROCEDURES

Syntheses. Unless otherwise indicated, all commercially available starting materials were used directly without further purification. Reactions under anhydrous conditions were performed in dried and distilled solvents under an argon atmosphere. All reactions were monitored by TLC using Sorbent Technologies 0.25 mm silica gel plates with or without UV indicator (60F-254). Silica gel Sorbent Technologies 32−63 μm was used for flash column chromatography. ^1H and ^{13}C NMR were obtained on either a DPX-250 or a ARX-300 Bruker spectrometer. Chemical shifts (δ) are given in ppm relative to $CDCl_3$ (7.26 ppm, ^1H; 77.00 ppm, ^{13}C) unless otherwise indi-

cated. Electronic absorption spectra were measured on a Perkin-Elmer Lambda 35 UV−vis spectrophotometer, and fluorescence spectra were measured on a Perkin-Elmer LS55 spectrometer. Mass spectra were obtained on an Applied Biosystems QSTAR XL, a hybrid QqTOF mass spectrometer with a MALDI ionization source using CCA as the matrix. HPLC separation and analysis were carried out on a Dionex system including a P680 pump and a UVD340U detector. Semipreparative HPLC was carried out using a Luna C_{18} 100 Å, 5 μm, 10 × 250 mm (Phenomenex) column and a stepwise gradient; analytical HPLC was carried out using a Delta Pak C_{18} 300 Å, 5 μm, 3.9 × 150 mm (Waters) column and a stepwise gradient (deprotected conjugates) or under isocratic conditions (protected conjugates). The samples were isolated and analyzed using the following solvents: buffer A (5% acetonitrile, 0.1% TFA, H_2O), buffer B (5% H_2O, 0.1% TFA, acetonitrile), and acetonitrile.

The Gasteiger−Huckel computational model and the Tripos Force Field parameters incorporated into the software package SYBYL 7.0 (Tripos, St. Louis, MO) were used for the energy minimization calculations. After initial minimization for each molecule, annealing was performed by heating the molecules to 500 K and then cooled to 0 K over a period of 1000 fs for 10 cycles. Following annealing, minimization was performed using the Powell descent series method. Solvation studies were performed by explicitly including water molecules in the calculation. The solute was solvated with one layer of water (TIP3P model) in a periodic box (46.46 × 46.46 × 46.46 Å), using the appropriate routine within SYBYL, and minimized within that box.

Conjugates 2a and 2b. Boc-L-Lys(Boc)OH (0.030 g, 0.0869 mmol) was dissolved in 0.5 mL of DMF.[1] To this solution were added HOBt (0.0133 g, 0.0869 mmol), DMAP (0.0010 g, 0.0086 mmol), Et_3N (0.0087 g, 0.0869 mmol), porphyrin **1** (0.050 g, 0.079 mmol), and EDCI (0.0166 g, 0.0869 mmol). The reaction mixture was stirred at room temperature for 48 h, after which 10 mL of distilled water and 5 mL of EtOAc were added. The two phases were separated, the organic phase was washed with distilled water (2 × 10 mL), dried over anhydrous Na_2SO_4, filtered, and the solvent was evaporated under vacuum. The protected conjugate was isolated by flash chromatography on silica gel using dichloromethane/methanol in the ratio 99/1. The protected conjugate **2a** was obtained in 96% yield as purple crystals. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (371,400), 515 (16,400), 551 (7,900), 590 (5,100), 646 (3,700). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.79−8.97 (9H, m), 8.13−8.25 (8H, m), 8.00 (2H, d, J = 8.49 Hz), 7.66−7.82 (9H, m), 5.46 (1H, d, J = 6.94 Hz), 4.71−4.73 (1H, m), 4.45 (1H, s), 3.22−3.27 (2H, m), 1.27−1.65 (24H, m), −2.76 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 170.99, 156.39, 142.13, 138.05, 137.65, 135.10, 134.52, 131.03, 127.61, 126.65,120.08, 119.56, 118.05, 55.40, 39.59, 31.44, 29.69, 28.49, 28.42, 22.70. LRMS (ESI) m/z 958.40 (M + H^+), calculated for $C_{60}H_{59}N_7O_5$ 958.45. Deprotection was accomplished in quantitative yield using TFA at room temperature for 4 h, following by evaporation of the TFA and washings with Et_2O. Conjugate **2b** was obtained as purple crystals, UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (282,300), 516 (16,300), 552 (7,900), 590 (5,100), 646 (3,800). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.83−8.86 (8H, m), 8.80−8.22 (8H, m), 7.93 (2H, d, J = 8.1 Hz), 7.66−7.74 (9H, m), 3.60 (1H, s), 3.21 (4H, s), 2.94 (2H, s), 1.29−1.46 (6H, m), −2.74 (2H, s). HRMS (ESI) m/z 758.3575 (M + H^+), calculated for $C_{50}H_{44}N_9OS$ 758.3607.

5-(4-Isothiocyanatophenyl)-10,15,20-triphenyl-porphyrin (5). To a stirred solution of porphyrin **1** (0.050 g, 0.0793 mmol) in freshly distilled dichloromethane (20 mL) was added 1,1′-thiocarbonyldi-2(1*H*)-pyridone (0.0369 g, 0.1587 mmol). The resulting mixture was stirred at room temperature for 2 h under an argon atmosphere, before being concentrated under vacuum. The residue was dissolved in dichloromethane and the product was isolated by flash chromatography on silica gel using dichloromethane as the eluent. The title product was isolated as purple crystals in 84% yield. HPLC t_R = 13.36 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (336,000), 515 (10,500), 548 (5,600), 589 (3,500), 645 (2,600). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.89−8.91 (6H, m), 8.81 (2H, d, J = 4.7 Hz), 8.19−8.26 (8H, m), 7.73−7.84 (9H, m), 7.62 (2H, d, J = 8.3 Hz), −2.74 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 142.49, 141.90, 136.89, 135.90, 135.02, 131.56, 128.26, 127.18, 124.53, 121.06, 120.88, 118.65. HRMS (ESI) m/z 672.2238 (M + H^+), calculated for $C_{45}H_{30}N_5S$ 672.2222. The crystal structure of the hemi-CH_2Cl_2 solvate of porphyrin **5** was determined, using data collected at T = 105 K with Mo Kα radiation on a Nonius KappaCCD diffractometer. Crystal data: $C_{45}H_{29}N_5S\cdot 0.5CH_2Cl_2$, triclinic space group P-1, a = 7.020(6), b = 10.789(8), c = 24.120(16) Å, α = 87.55(3), β = 85.04(3), γ = 85.86(7)° V = 1814(2) Å^3, Z = 2, R = 0.086 ($F^2 > 2\sigma$), Rw = 0.245 (all F^2) for 5075 unique data and 487 refined parameters. The solvent molecule is disordered about an inversion center. Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 263394. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, (fax: +44- (0)1223−336033 or e-mail: deposit @ccdc.cam.ac.uk).

4-[4-(10,15,20-Triphenyl-porphyrin-5-yl)-phenylcarbamoyl]-butyric Acid (6). Porphyrin **1** (0.1 g, 0.159 mmol) was added to a solution of glutaric anhydride (0.0543 g, 0.4769 mmol) in 2 mL of dry DMF at room temperature, and the final mixture was stirred at room temperature for 48 h. Distilled water (10 mL) was added, followed by 10 mL of EtOAc. The two phases were separated, the organic phase was washed with distilled water (3 × 10 mL), dried over anhydrous Na_2SO_4, and filtered, and the solvent was removed under vacuum. The title compound was purified on a silica gel plug using dichloromethane/methanol (99/1 to 90/10 ratios) for elution, in 100% yield. HPLC t_R = 21.34 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (336,000), 516 (16,900), 551 (7,900), 590 (5,100), 646 (3,800). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.8 (7H, s), 8.43 (7H, s); 7.71 (2H, s), 7.60 (10H, s), 2.63 (4H, s), 2.21 (2H, s), −2.79 (2H, s). HRMS (ESI) m/z 744.2865 (M + H^+), calculated for $C_{49}H_{38}N_5O_3$ 744.2896.

Conjugate 10. H-L-Lys(Boc)OtBu·HCl (0.0158 g, 0.0468 mmol) was dissolved in 500 μL of dry DMF under argon. To this solution was added Et_3N (0.0047 g, 0.0468 mmol),

[1] HOBt, 1-hydroxybenzotriazole; DMF, *N,N*-dimethylformamide; DMAP, 4-(dimethylamino)pyridine; Et_3N, triethylamine; CCA, α-cyano-4-hydroxycinnamic acid; EDCI, 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride; DCC, 1,3-dicyclohexylcarbodiimide; TFA, trifluoroactic acid; DIEA, *N,N*-diisopropylethylamine; TBTU, 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate; TIS, triisopropylsilane; DMSO, dimethyl sulfoxide; NHS, *N*-hydroxysuccinimide; Boc, *tert*-butoxy carbonyl; Z, benzyloxy carbonyl; Fmoc, fluorenylmethoxy carbonyl; HEPES, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid; PBS, phosphate-buffered saline; FBS, fetal bovine serum; MEM, modified eagle medium.

followed by porphyrin **5** (0.031 g, 0.0468 mmol). The reaction mixture was stirred at room temperature for 24 h, and then 10 mL of distilled water and 5 mL of EtOAc were added. The two phases were separated, the organic phase was washed with distilled water (2 × 10 mL), dried over anhydrous Na_2SO_4, and filtered, and the solvent was removed under vacuum. The title compound was purified by flash chromatography on silica gel using dichloromethane/methanol 98/2 for elution, in 93% yield. HPLC t_R = 6.94 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (301,600), 516 (14,000), 552 (7,000), 590 (4,500), 646 (3,400). ^{1}H NMR ($CDCl_3$, 250 MHz): δ 8.83−8.88 (6H, m), 8.20−8.24 (9H, m), 7.71−7.77 (11H, m), 5.19 (1H, s), 4.62 (1H, s), 3.16 (2H, d, J = 6.1 Hz), 1.27−1.63 (24H, m), −2.76 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): 180.10, 171.45, 156.07, 142.14, 140.69, 136.04, 134.54, 131.25, 127.75, 126.69, 122.13, 120.42, 120.29, 118.49,117.49, 32.12, 29.74, 28.40, 28.10, 22.30, LRMS (ESI) *m/z* 973.37 (M^+), calculated for $C_{63}H_{57}N_7O_4S$ 973.43.

Conjugate 11. The title compound was synthesized as described above for conjugate **10**, in 45% yield. HPLC t_R = 7.15 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (511,300), 516 (14,600), 552 (7,000), 590 (4,500), 646 (3,400). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.85−8.86 (8H, s), 8.23−8.26 (7H, m), 7.73−7.76 (10H, m), 7.25 (1H, s), 5.31 (1H, s), 4.89 (1H, s), 4.61 (1H, s), 3.22 (4H, s), 1.37−2.01 (39H, m), −2.72 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 180.30, 172.70, 156.07, 143.63, 137.34, 136.14, 132.77, 129.29, 128.25, 123.82, 121.84, 83.84, 80.76, 59.81, 41.77, 33.26, 31.27, 30.07, 29.67, 24.12. LRMS (ESI) *m/z* 1202.43 (M + H^+), calculated for $C_{71}H_{79}N_9O_7S$ 1202.50.

Conjugate 12. The title compound was synthesized as described above for conjugate **10**, in 35% yield. HPLC t_R = 9.78 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (343,700), 516 (19,600), 552 (9,600), 590 (6,000), 642 (4,700). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.86−8.94 (8H, m), 8.22−8.28 (8H, m), 8.06 (1H, d, J = 7.87 Hz), 7.76−7.77 (10H, m), 5.04 (1H, s), 4.66−4.83 (2H, m), 4.16 (1H, s), 3.19 (6H, s), 1.28−1.92 (54H, m), −2.74 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 181.21, 174.00, 171.77, 156.77, 142.60, 134.99, 131.56, 128.13, 127.11, 122.58, 121.65, 120.54, 82.17, 40.95, 40.30, 39.44, 31.48, 29.62, 28.52, 28.00, 22.82, 22.42, 21.73. HRMS (ESI) *m/z* 1430.7433 (M + H^+), calculated for $C_{82}H_{100}N_{11}O_{10}S$ 1430.7375.

Conjugate 13. Compound **10** (0.0442 g, 0.043 mmol) was added to a 10 mL round-bottom flask, previously purged with argon for 5 min, followed by 4 mL of TFA. The reaction mixture was stirred at room temperature for 4 h. TFA was evaporated under vacuum, 5 mL of Et_2O was added, and the suspension was transferred to a centrifuge tube. After centrifugation, the residue was washed with Et_2O (6 × 10 mL) to remove residual TFA and dried under vacuum. Yield 100%. HPLC t_R = 22.66 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (384,500), 515 (16,500), 551 (7,800), 590 (5,300), 646 (3,800). ^{1}H NMR ($CDCl_3$, 250 MHz): δ 8.83−8.88 (6H, m), 8.20−8.24 (9H, m), 7.71−7.77 (11H, m), 5.19 (1H, s), 4.62 (1H, s), 3.14−3.19 (2H, m), 1.27−1.63 (6, m), −2.76 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 180.10, 172.45, 156.07, 142.14, 140.69, 135.96, 134.96, 130.99, 127.71, 126.66, 122.29, 120.42, 120.29, 30.29, 29.69, 22.30, LRMS (ESI) *m/z* 817.34 (M^+), calculated for $C_{51}H_{43}N_7O_2S$ 817.32.

Conjugate 14. The title compound was deprotected as described above for conjugate **13** in quantitative yield. HPLC t_R = 15.71 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 419 (276,300), 516 (24,100), 551 (11,500), 590 (7,600), 646 (5,600). ^{1}H NMR (CD_3OD, 300 MHz): δ 8.50 (8H, s), 8.20−8.28 (9H, m), 7.76 (12H, s), 3.31−3.5 (4H, m), 1.25−1.96 (12H, m), −2.78 (2H, s). LRMS (ESI) *m/z* 945.48 (M^+), calculated for $C_{57}H_{55}N_9O_8S$ 945.41.

Conjugate 15. The title compound was deprotected as described for conjugate **13** in quantitative yield. HPLC t_R = 10.38 min. UV−vis (2:1 MeOH/$CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (280,600), 513 (15,700), 549 (8,700), 589 (5,900), 645 (4,600). ^{1}H NMR (CD_3OD, 300 MHz): δ 8.82−8.95 (7H, m), 8.55−8.57 (7H, m), 8.27−8.38 (2H, m), 8.05 (8H, s), 4.4−4.5 (1H, m), 3.99−4.02 (1H, m), 3.82−3.86 (1H, m), 2.94−3.01 (6H, m), 1.56−1.97 (18H, m). LRMS (ESI) *m/z* 1073.54 (M^+), calculated for $C_{63}H_{67}N_{11}O_4S$ 1073.51.

Conjugate 16. To a solution of porphyrin **6** (0.030 g, 0.043 mmol) in 500 μL of dry DMF were added DIEA (0.032 g, 0.2419 mmol), TBTU (0.0129 g, 0.0403 mmol), and HOBt (0.0062 g, 0.0403 mmol), followed by H-L-Lys-(Boc)OtBu·HCl (0.0136 g, 0.0403 mmol). The reaction mixture was stirred at room temperature for 24 h, diluted with 10 mL of EtOAc, and washed with water (3 × 10 mL). The organic extracts were combined, dried over anhydrous Na_2SO_4, and filtered, and the solvent was evaporated under vacuum. The protected conjugate was purified by flash chromatography on silica gel using 1% methanol/dichloromethane for elution. Yield 71%. HPLC t_R = 7.91 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 417 (359,200), 516 (12,200), 552 (6,900), 590 (4,400), 646 (3,300). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 9.12 (1H, s), 8.86−8.92 (7H, m), 8.16−8.24 (8H, m), 8.02 (2H, d, J = 8.29 Hz), 7.72−7.77 (9H, m), 6.43 (2H, d, J = 7.34 Hz), 4.65 (1H, s), 4.57 (1H, s), 3.15 (2H, t, J = 6.1 Hz), 2.62 (2H, t, J = 4.7, 5.9 Hz), 2.51 (2H, t, J = 5.86, 6.71 Hz), 2.25 (2H, m), 1.37−1.91 (24H, m), −2.74 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 172.88, 172.48, 171.66, 156.33, 142.13, 138.30, 137.53, 135.06, 134.53, 131.06, 127.68, 126.66, 120.01, 119.12, 117.76, 82.51, 79.51, 52.78, 39.83, 36.11, 34.74, 31.51, 29.81, 28.43, 28.05, 22.45, 22.01. HRMS (MALDI) *m/z* 1028.5081 (M^+), calculated for $C_{64}H_{66}N_7O_6$ 1028.5074. Deprotection as described above for conjugate **13** gave the title compound in quantitative yield. HPLC t_R = 16.28 min. UV−vis (9:1 MeOH/DMF) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (284,400), 513 (11,500), 551 (5,900), 587 (3,700), 645 (2,800). ^{1}H NMR (d_6-DMSO, 300 MHz): δ 8.79−8.90 (9H, m), 8.19−8.21 (10H, m), 7.79 (9H, m), 2.72 (2H, s), 2.43 (2H, s), 2.08 (2H, s), 1.3−1.93 (8H, m), −2.91 (2H, s). HRMS (ESI) *m/z* 872.3959 (M + H^+), calculated for $C_{55}H_{50}N_7O_4$ 872.3924.

Conjugate 17. Protected conjugate **17** was synthesized as described above for protected **16** and purified by flash chromatography on silica gel using 1% methanol/dichloromethane for elution. Yield 53%. HPLC t_R = 9.25 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (294,800), 516 (15,700), 552 (8,000), 590 (4,800), 646 (3,700). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.77−8.91 (7H, m), 8.04−8.24 (9H, m), 7.68−7.82 (9H, m), 6.84 (1H, d, J = 7.82 Hz), 6.72 (1H, d, J = 5.45 Hz), 5.03 (1H, s), 4.74 (1H, t, J = 6.05 Hz), 4.46−4.55 (2H, m), 3.13 (4H, s), 2.60 (2H, t, J = 6.21 Hz), 2.24 (2H, m), 1.18−1.90 (41H, m), −2.75 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 173.48, 172.42, 171.71, 171.29, 156.41, 142.15, 138.55, 137.42, 134.99, 134.51, 131.05, 127.66, 126.65, 120.06, 119.89, 117.82, 82.28, 79.31, 53.77, 52.90, 40.06, 39.39, 35.87, 34.60, 31.73, 31.22, 28.46, 28.43, 22.53, 22.31, 22.08. HRMS (ESI) *m/z* 1278.6389 (M + Na^+), calculated for $C_{75}H_{85}N_9O_9Na$ 1278.6368. Deprotection as described above for **13** afforded the title conjugate in quantitative yield. HPLC t_R = 12.82 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (336,000), 515 (10,500), 548 (5,600), 589 (3,500), 645 (2,600).^{1}H NMR (CD_3OD, 300 MHz): δ 8.82 (6H, s), 8.15

(7H, d, J = 6.76 Hz), 8.04 (2H, d, J = 8.20 Hz), 7.78 (8H, d, J = 7.45 Hz), 4.46 (1H, d, J = 6.74 Hz), 4.37−4.39 (1H, m), 3.01 (4H, s), 2.64 (2H, t, J = 7.03 Hz), 2.51 (2H, t, J = 7.01 Hz), 2.16 (2H, t, J = 7.21 Hz), 1.31−1.85 (12H, m). HRMS (MALDI) *m/z* 1000.4878 ($M + H^+$), calculated for $C_{61}H_{61}N_9O_5$ 1000.4796.

Conjugate 18. Protected conjugate **18** was synthesized as described above for protected **16** and obtained in 72% yield. HPLC t_R = 9.34 min. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 420 (241,600), 516 (15,000), 551 (7,300), 590 (4,600), 647 (3,500). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.51−8.90 (7H, m), 8.04−8.23 (8H, m), 7.74−7.76 (9H, m), 7.00 (1H, s), 4.97 (2H, s), 4.51 (2H, s), 3.14 (6H, s), 2.55−2.63 (4H, m), 2.24 (2H, s), 1.21−1.66 (54H, m), −2.75 (2H, s). ^{13}C NMR ($CDCl_3$, 62.5 MHz): δ 173.48, 172.42, 171.71, 171.29, 171.03, 156.27, 142.16, 138.55, 134.98, 134.52, 131.01, 127.67, 126.65, 120.06, 119.90, 117.92, 79.18, 53.75, 52.93, 40.08, 39.7, 31.70, 29.67, 28.44, 27.95, 22.43. HRMS (MALDI) *m/z* 1484.8077 ($M + H^+$), calculated for $C_{85}H_{106}N_{11}O_{12}$ 1484.8022. Deprotection as described above for **13** afforded the title conjugate in quantitative yield. HPLC t_R = 8.70 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 415 (225,100), 512 (12,100), 547 (6,200), 589 (3,900), 645 (3,000). ^{1}H NMR (CD_3OD, 300 MHz): 8.88 (7H, s), 8.21 (8H, d, J = 6.44 Hz), 8.06 (2H, d, J = 7.91 Hz), 7.82 (9H, d, J = 6.79 Hz), 4.32−4.37 (2H, m), 2.93−3.01 (6H, m), 2.65 (2H, t, J = 7.22 Hz), 2.51 (2H, t, J = 7.44 Hz), 2.17 (2H, t, J = 7.18 Hz), 1.2−1.83 (20H, m). ^{13}C NMR (CD_3-OD, 62.5 MHz): δ 174.82, 174.25, 156.95, 143.33, 136.16, 135.69, 129.64, 119.61, 40.60, 35.81, 32.38, 28.42, 28.11, 23.72. HRMS (MALDI) *m/z* 1127.5726 (M^+), calculated for $C_{67}H_{73}N_{11}O_6$ 1127.5745.

Zn(II) Conjugate 19. Under an argon atmosphere, conjugate **18** (0.005 g, 0.0044 mmol) and $ZnCl_2$ (0.0024 g, 0.0177 mmol) were dissolved in 2 mL of DMF. To this solution were added 0.1 mL of MeOH and 0.150 mL of pyridine. The final mixture was stirred at room temperature for 18 h, the solvent was removed under vacuum, and the residue was filtered through a silica gel plug. The title compound was obtained in quantitative yield. HPLC t_R = 20.52 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 422 (190,000), 557 (5,000), 595 (2,800). ^{1}H NMR (CD_3-OD, 300 MHz): 8.88 (7H, s), 8.21 (8H, d, J = 6.44 Hz), 8.06 (2H, d, J = 7.91 Hz), 7.82 (9H, d, J = 6.79 Hz), 4.32−4.37 (2H, m), 2.93−3.01 (6H, m), 2.65 (2H, t, J = 7.22 Hz), 2.51 (2H, t, J = 7.44 Hz), 2.17 (2H, t, J = 7.18 Hz), 1.20−1.83 (20H, m). LRMS (MALDI) *m/z* 1190.082 (M^+), calculated for $C_{67}H_{71}N_{11}O_6Zn$ 1190.488.

Sn(IV) Conjugate 20. Protected conjugate **18** (0.025 g, 0.0168 mmol) and $SnCl_2$ (0.083 g, 0.0437 mmol) were dissolved in 1 mL of pyridine. The reaction mixture was refluxed for 2 h, cooled to room temperature, and diluted with 10 mL of chloroform. The mixture was washed with water (3 × 20 mL), the organic extracts were combined and dried under anhydrous Na_2SO_4, and the solvent was evaporated under vacuum to give the protected Sn(IV) conjugate in quantitative yield. UV−vis ($CHCl_3$) λ_{max} (ϵ/M^{-1} cm^{-1}) 429 (308,000), 562 (12,700), 603 (9,400). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 9.17−9.27 (7H, m), 8.23−8.33 (7H, m), 8.12 (2H, d, J = 8.20 Hz), 7.81−7.89 (9H, m), 6.98 (1H, s), 5.50 (2H, s), 4.92 (2H, s), 3.12 (6H, s), 2.53 (4H, m), 2.23−2.27 (3H, m), 1.27−1.83 (54H, m). LRMS (ESI) *m/z* 1636.30 (M^+), calculated for $C_{85}H_{103}N_{11}O_{12}SnCl$ 1636.11. Deprotection as described above for conjugate **18** gave the title conjugate in quantitative yield. HPLC t_R = 9.91 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 422 (341,600), 557 (9,300), 597 (6,400). ^{1}H NMR (CD_3OD, 300 MHz): δ 9.21−9.43 (7H, m), 8.18−8.22 (8H, m), 8.04−8.08 (2H, m), 7.81 (9H, s), 4.23−4.32 (3H, m), 2.85 (6H, m), 2.52 (2H, t, J = 7.37 Hz), 2.37 (2H, t, J = 7.62 Hz), 2.01−2.07 (2H, m), 1.18−1.62 (18H, m). LRMS (MALDI) *m/z* 1280.84, 1245.27, calculated for $C_{67}H_{71}N_{11}O_6SnCl$ 1280.8988, $C_{67}H_{71}N_{11}O_6Sn$ 1245.46.

Solid-Phase Synthesis of Porphyrin Conjugates. Method A. Peptidyl resin (0.025 mmol) was added to a glass synthesizer, washed with DMF, and left to stand for 1 h, before being filtered. To the resin was added a 500 μL solution containing 0.05 mmol of porphyrin **6**, 0.150 mmol of DIEA, 0.05 mmol of HOBt, and 0.05 mmol of TBTU. The reaction mixture was stirred overnight at room temperature and then filtered to afford a dark purple resin. A fresh solution of porphyrin **6** (0.025 mmol) in DIEA, HOBt, and TBTU was added and the mixture stirred for an additional 12 h. After filtration, the resin was washed repeatedly with DMF until the filtrate was colorless and then with dichloromethane and methanol, before being dried under vacuum. Cleavage and deprotection was accomplished with 3 mL of a mixture of TFA/phenol/TIS/H_2O in 88/5/2/5 ratio, at room temperature for 4 h. The resin was filtered and washed with TFA (3 × 2 mL), and then the filtrates were combined and evaporated under vacuum to give a green residue. Addition of 5 mL of cold Et_2O gave a fine green precipitate which was centrifuged, washed successively with Et_2O, and dried under vacuum. Purification of the conjugates was accomplished by reverse phase HPLC using a Luna C_{18} semipreparative column (10 × 250 mm, 5 μm) and a buffer system of water/acetonitrile, both containing 0.1% TFA with a stepwise gradient from 40 to 75%. The fraction containing the conjugate was collected and lyophilized to yield pure conjugate. The purity of the peptides was >98% as obtained by HPLC on an analytical Delta Pak C_{18} column (3.9 × 150 mm, 5 μm).

Method B. Peptidyl resin (0.050 mmol) was added to a glass synthesizer, washed with DMF, and left to stand for 1 h, before being filtered. To the resin was added a 500 μL solution containing 0.150 mmol of porphyrin **5** and 0.300 mmol of Et_3N. The reaction mixture was stirred overnight at room temperature and filtered, a fresh solution of 0.050 mmol of **5** in Et_3N was added, and the mixture was stirred for another 12 h. After filtration, the resin was washed with DMF, dichloromethane, and methanol as described above and dried under vacuum. Cleavage and deprotection was carried out as described in Method A. The purification of the conjugates was accomplished by reverse phase HPLC using a Luna C_{18} semipreparative column and a water/acetonitrile buffer containing 0.1% TFA with a stepwise gradient from 40 to 95%. The fraction containing the conjugate was collected and lyophilized to yield the pure conjugate. The purity of the peptides was >97% as obtained by HPLC on an analytical Delta Pak C_{18} column.

Conjugate 21 was prepared as described in Method B. Yield 38%. HPLC t_R = 15.25 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (205,300), 512 (11,300), 547 (5,000), 590 (3,400), 645 (2,300). ^{1}H NMR (CD_3OH, 250 MHz): δ 8.72−8.77 (8H, m), 8.33 (1H, d, J = 7.42 Hz), 8.19−8.25 (10H, m), 8.03−8.09 (2H, m), 7.77−7.80 (9H, m), 7.42 (2H, s), 7.06−7.09 (3H, m), 3.15−3.19 (6H, m), 3.03−3.08 (2H, m), 1.4−1.6 (18H, m), −0.033 (3H, s). LRMS (MALDI) *m/z* 1284.72 (M^+), calculated for $C_{69}H_{80}N_{20}O_4S$, 1284.63.

Conjugate 22 was prepared as described in Method A. Yield 32%. HPLC t_R = 8.53 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (236,400), 515 (6,600), 548 (3,300), 588 (2,300), 645 (2,000). ^{1}H NMR (CD_3OH, 250 MHz): 8.71−8.76 (8H, m), 8.20−8.26 (10H, m), 8.03 (2H, t, J = 8.59 Hz), 7.69−7.80 (16H, m), 2.82−2.85 (6H, m), 2.50 (2H, t,

J = 6.85, 7.36 Hz), 2.35 (2H, t, J = 6.81, 7.95 Hz), 1.91 (2H, t, J = 7.97 Hz), 1.39−1.62 (19H, m), −0.04 (2H, s). HRMS (MALDI) *m/z* 1127.5897, calculated for $C_{67}H_{75}N_{12}O_5$1127.5893.

Conjugate 23 was prepared as described in Method A. Yield 52%. HPLC t_R = 12.56 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (227,300), 512 (9,900), 547 (6,600), 590 (3,300), 645 (2,300). ^{1}H NMR (CD_3OH, 250 MHz): δ 8.72−8.76 (8H, m), 8.28−8.32 (2H, m), 8.20 (10H, s), 8.11 (1H, d, J = 7.08 Hz), 8.00 (2H, d, J = 8.07 Hz), 7.68−7.76 (9H, m), 7.56 (1H, s), 7.37−7.43 (3H, m), 2.51 (2H, t, J = 6.84 Hz), 2.37 (2H, t, J = 6.9 Hz), 2.00 (2H, t, J = 7.38, 7.04 Hz), 1.40−1.63 (12H, m), −0.028 (2H, s). HRMS (MALDI) *m/z* 1211.6175 (M + H^+), calculated for $C_{67}H_{75}N_{18}O_5$, 1211.6168.

Conjugate 24 was prepared as described in Method A. Yield 45%. HPLC t_R = 9.13 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (235,900), 512 (7,000), 547 (3,500), 588 (2,400), 645 (2,100). ^{1}H NMR (CD_3OH, 250 MHz): δ 8.72−8.77 (8H, m), 8.32−8.34 (1H, d, J = 7.11 Hz), 8.19−8.25 (10H, m), 7.99−8.06 (2H, m), 7.78−7.90 (9H, m), 7.39 (1H, s), 7.06−7.12 (3H, m), 3.09−3.17 (6H, m), 3.06−3.09 (2H, m), 2.51 (2H, t, J = 7.91 Hz), 2.37 (2H, t, J = 7.40 Hz), 1.91 (2H, t, J = 6.45 Hz), 1.4−1.6 (18H, m), −0.03 (2H, s). HRMS (MALDI) *m/z* 1339.7168 (M^+), calculated for $C_{73}H_{86}N_{20}O_6$, 1339.7117.

Conjugate 25 was prepared as described in Method A. Yield 54%. HPLC t_R = 9.65 min. UV−vis (MeOH) λ_{max} (ϵ/M^{-1} cm^{-1}) 414 (263,300), 512 (7,800), 548 (3,800), 588 (2,500), 644 (2,000). ^{1}H NMR (7% D_2O/H_2O, 400 MHz): δ 8.68 (4H, d, J = 8.89 Hz), 8.43−8.56 (5H, m), 8.22 (2H, d, J = 9.31 Hz), 7.67 (2H, s), 7.55 (2H, broad s), 7.14−7.23 (4H, m), 4.28−4.33 (3H, m), 3.19−3.27 (6H, m), 2.98−3.02 (3H, m), 2.70 (2H, t, J = 8.44 Hz), 2.54 (2H, t, J = 9.40 Hz), 2.09−2.17 (2H, m), 1.25−1.87 (18H, m), −0.04 (2H, s). HRMS (MALDI) *m/z* 1340.7141 (M + H^+), calculated for $C_{73}H_{87}N_{20}O_6$ 1340.6264.

Cell Culture. The HEp2 cell line was purchased from ATCC. The cells were maintained in a 50:50 mixture of MEM:Advanced MEM (Gibco) and 5% FBS (Gibco) in a humidified, 5% CO_2 incubator at 37 °C. PBS, FBS, Triton X100, and trypsin were purchased from Gibco. All conjugate solutions were filter sterilized using a 0.22 μm Pal syringe filter.

Cytotoxicity. HEp2 cells were plated at a concentration of 10,000 cells per well on a Costar 96-well plate and allowed to attach overnight. Conjugate stock solutions were prepared in DMSO at a concentration of 50 mM. These stocks were diluted to give a final concentration of 500 μM in medium at 1% DMSO. Serial 2-fold dilutions were then made into medium containing 1% DMSO to give a concentration range of 500 μM down to 7.8 μM and maintaining the 1% DMSO concentration. The cells were then incubated 18 h in the dark. Cytotoxicity was measured using the Promega Cell Titer Blue assay, reading the fluorescent signal using a FluoStar Optima plate reader from BMG at 520 nm excitation and 594 nm emission.

Cellular Uptake. HEp2 cells were seeded as described above and then exposed to 10 μM conjugate in medium for 25, 12, 8, 4, 2, and 1 h time periods. At the end of the loading period, the medium was removed, and the cells were washed three times with PBS and solubilized with 0.25% Triton ×100 in PBS. The intracellular accumulation of conjugate was determined by measuring the porphyrin's fluorescence emission on a BMG FluoStar Optima plate reader using excitation/emission wavelengths of 410 and 650 nm, respectively. Cell numbers were measured using the CyQuant Cell Proliferation Assay (Molecular Probes).

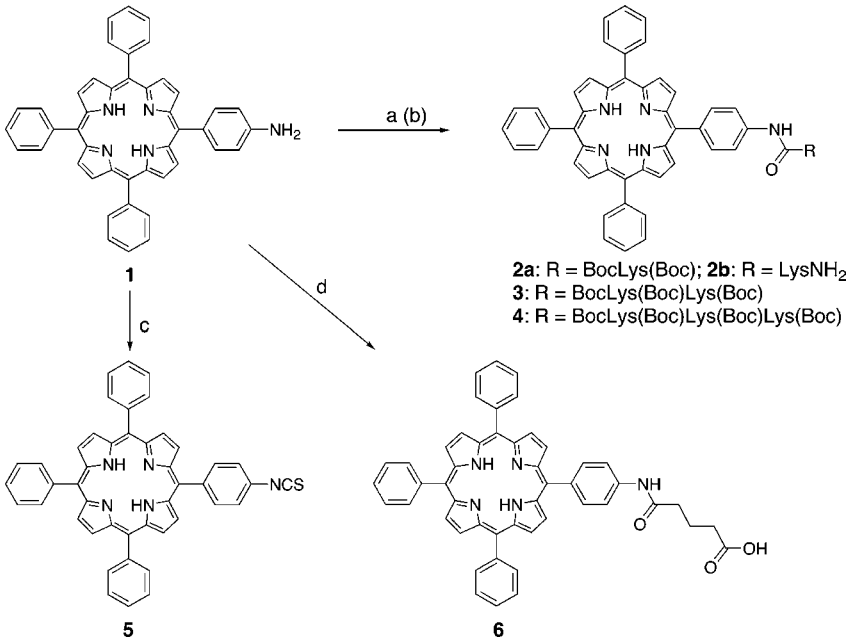
Intracellular Localization. HEp2 cells were seeded onto Lab-Tek II, two-chamber coverglass and incubated for 72 h. Conjugate was then added from a 10 mM stock solution in DMSO to reach a final concentration of 10 μM (the DMSO concentration never exceeded 1%). The cells were incubated overnight (18 h) and then washed with drug-free medium and given medium containing 50 mM HEPES pH 7.2. The coverslips were examined using a Zeiss Axiovert 200M inverted fluorescent microscope fitted with standard FITC and Texas Red filter sets (Chroma Technology Corp.). For colocalization experiments LysoSensor Green DND-189, MitoTracker Green FM and Hoechst 33342 (Molecular Probes) were used. The tracer compounds were diluted into medium to a final concentration of 50 nM (LysoSensor Green), 250 nM (MitoTracker Green) or 1 mg/mL (Hoechst), 10 min before microscopy. The cells were incubated concurrently with conjugate for 30 min (LysoSensor Green and MitoTracker Green) or 10 min (Hoechst) before washing and viewed by microscopy. In addition, three lipid mixtures of conjugates **22** or **23** were added to the cells prior to microscopy. Avanti transfection lipids, Cardiolipin (Avanti Polar Lipids) and Lipofectamine Transfection Reagent (Invitrogen) were used as the delivery vehicles. Since the Avanti lipids were provided in chloroform, the solvent was first removed under nitrogen before resuspension in sterile distilled water at 2 mg/mL. Lipofectamine was supplied in water and used as received. A mixture containing 2.5 μL of the lipid and 25 μL of serum-free medium was incubated for 15 min. Conjugates **22** and **23** (1 μL of 10 mM stock solution) were diluted into 25 μL serum-free medium, mixed with each lipid, and incubated for 45 min. The lipid mixtures were then diluted to 600 μL using serum-free medium, added to cells grown on Lab Tek chamber coverslips, incubated for 2.5 h, before adding 600 μL of medium containing 10% FBS (2×) and the cells incubated overnight. Microscopy was performed as described above.

RESULTS

The coupling of mono-aminoporphyrin **1** with protected amino acids and peptides was performed in either solution- or solid-phase, as described below. Mono-aminoporphyrin **1** was used as the starting material, because of its high solubility in organic solvents and easy synthesis on a multigram scale from *meso*-tetraphenylporphyrin (*28*). Porphyrins bearing *meso*-carboxyphenyl groups have also been used in such conjugation reactions (e.g. *29*) but these molecules are considerably less soluble than the amino derivatives and generally give low yields of the target conjugates. The Boc- and Z-protected peptides were obtained by either solution- or solid-phase syntheses, as previously reported (*30*, *31*). All compounds were completely characterized by spectroscopic methods, as described in the Experimental Section.

Solution-Phase Synthesis of Porphyrin Conjugates. Direct conjugation of **1** to Boc-L-Lys(Boc)OH using DCC/DMAP in dichloromethane (*32*) gave compound **2a** in 65% yield (Scheme 1). Under the same conditions, conjugates **3** and **4** were obtained in 40 and 18% yields, respectively. These yields could be improved to 96, 65, and 45%, respectively, when DMF was used as the solvent and HOBt/EDCI as the coupling agents (*33*, *34*). To further increase the conjugation efficiency, the amino group of **1** was converted into an isothiocyanate (*18*, *35*) by reaction of **1** with 1,1′-thiocarbonyldi-(2*H*)-pyridone,

Scheme 1[a]



[a] Conditions: (a) Boc-protected amino acid or peptide, DCC, DMAP, CH_2Cl_2, rt, 48 h (18−65%) or HOBt, EDCI, DMAP, Et_3N, DMF, rt, 48 h (45−96%). (b) TFA, rt, 4 h (100%). (c) 1,1′-Thiocarbonyldi-(2*H*)-pyridone, CH_2Cl_2, Ar, rt, 2h (84%). (d) Glutaric anhydride, DMF, rt, 24h (100%).

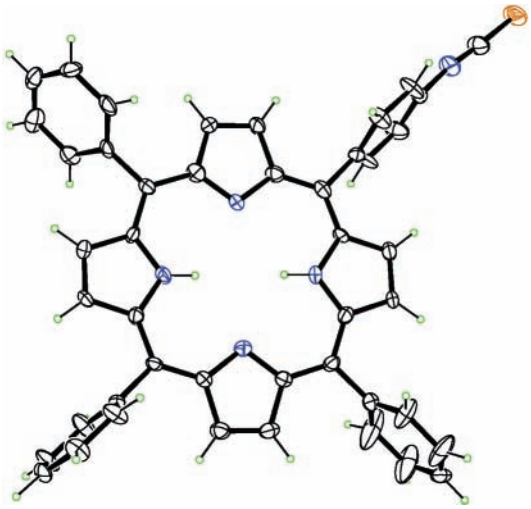


Figure 1. Molecular structure of porphyrin isothiocyanate **5**.

affording **5** in 84% yield (Scheme 1). The molecular structure of porphyrin **5** is shown in Figure 1. The porphyrin core is reasonably planar, having mean deviation of 24 atoms from their best plane only 0.062 Å, and maximum deviation 0.151(7) Å. The phenyl planes form dihedral angles with the porphyrin plane in the range 61.6(1)−82.4(2)° and that involving the ring carrying the isothiocyanate group is in the middle of that range, 76.1-(1)°.

Reaction of porphyrin **1** with glutaric anhydride gave carboxylic acid **6** in quantitative yield (Scheme 1). The use of porphyrin **6** in the conjugation reactions allowed us to study the effect of a five-carbon chain between the porphyrin and the positively charged peptides.

We investigated the conjugation of isothiocyanate **5** with various protected peptides under different reaction conditions and using both free amino terminus Z- and Boc-protected peptides (Table 1). No reaction took place in aqueous solution due to the poor solubility and limited stability of porphyrin **5** in water (Table 1, entry 1).

Table 1. Reaction Conditions for Coupling Porphyrin Isothiocyanate 5 to Protected Peptides

entry	protected peptide	solvent	% yield
1	HLys(Z)OH	DMSO/pH = 9.2, 0.1 M carbonate buffer	no rxn
2	HLys(Z)OBz	THF	90
3	HLys(Z)Lys(Z)OBz	THF	69
4	HLys(Z)Lys(Z)OBz	DMF	67
5	HLys(Z)Lys(Z)Lys (Z)OBz	DMF/$CHCl_3$, 2/1	63
6	HLys(Boc)OtBu	DMF	93
7	HLys(Boc)Lys(Boc)OtBu	DMF	45
8	HLys(Boc)Lys(Boc)Lys(Boc)OtBu	DMF	35

Although high yields of the conjugates were obtained with the Z-protected peptides (Table 1, entries 2−5), the deprotection to the corresponding free peptide conjugates was problematic. Indeed several deprotection methodologies were investigated, including catalytic hydrogenation (*36*), transfer hydrogenation (*37*), and dealkylation using Me_3SiI (*38*), but all were unsuccessful giving mixtures of partially deprotected conjugates. On the other hand, the Boc groups were easily cleaved in quantitative yield using TFA at room temperature (Scheme 2). The thus-obtained deprotected conjugates **13**−**15** were insoluble in water and mainly soluble in polar organic solvents such as $CHCl_3$, DMF, and DMSO.

Conjugates of porphyrin carboxylic acid **6** to Boc-protected peptides were synthesized in good yields using HOBt/TBTU in DMF, as shown in Scheme 3. A similar procedure has been recently reported for the coupling of a carboxy-functionalized porphyrin with the free amino terminus of a cyclic pentapeptide (*39*). Removal of the Boc group as described above produced conjugates **16**−**18** in quantitative yield. In contrast to the porphyrin isothiocyanate conjugates, compounds **16**−**18** are partially soluble in aqueous solutions and their water solubility increases with the number of amino acid residues on the peptide chain. In addition, the metallo-conjugates **19** and **20** were prepared using a similar route in quantitative yields, by either direct insertion of Zn-(II) into conjugate **18** using $ZnCl_2$ in DMF or by reaction

Solid-Phase Synthesis of Porphyrin Conjugates. The peptidyl PAL-PEG-PS resins used in the solid-phase synthesis of conjugates **21**−**25** reacted with porphyrin isothiocyanate **5** or with carboxylic acid **6** in the presence of, respectively, Et_3N or HOBt/TBTU/DIEA, as shown in Schemes 2 and 3 (*40*, *41*). Using this methodology, the deprotection and cleavage of the porphyrin−peptide conjugates from the solid support was achieved in a single step upon treatment with a mixture of TFA, phenol, TIS, and water in the ratio 88:5:2:5. The resulting conjugates **21**−**25** were obtained as the C-terminally amidated peptides, in 32−54% overall yields.

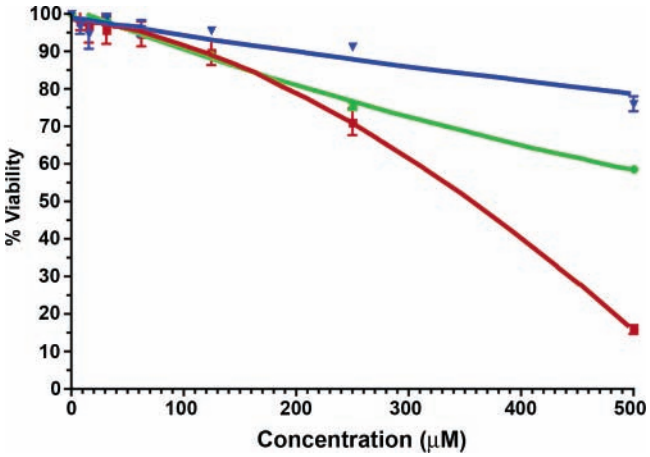

Figure 2. Dark cytotoxicity of conjugates **17** (green), **20** (blue), and **23** (red) toward HEp2 cells using a Cell Titer Blue assay.

Cellular Studies. The dark cytotoxicity and cellular uptake of representative porphyrin conjugates were investigated in human HEp2 cells (Figures 2 and 3). The cytotoxicity was assayed using a Cell Titer Blue assay

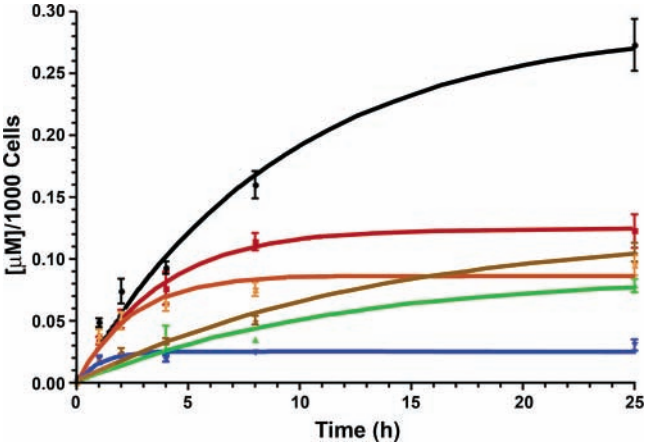

Figure 3. Time-dependent uptake of conjugates **15** (brown), **17** (green), **20** (blue), **23** (red), **24** (black), and **25** (orange) at 10 μM by HEp2 cells.

to evaluate the cytotoxicity of conjugates **17**, **20**, and **23**, at concentrations up to 500 μM, 18 h after exposure (*42*). The conjugates studied were the most water-soluble, and all showed low dark toxicity (IC_{50} > 250 μM) toward HEp2 cells (Figure 2). The time-dependent uptake of conjugates **15**, **17**, **20**, **23**, **24**, and **25** at a concentration of 10 μM in HEp2 cells was investigated. At this concentration all conjugates were nontoxic to the cells, as evaluated using the Cell Titer Blue assay (Supporting Information). Significant differences in the cellular uptake were observed, as seen in Figure 3, indicating that the number, nature, and sequence of amino acids, as well as the presence of a chelated metal ion affect the uptake of the conjugates. The di- and tri-lysine conjugates **17** and **15** show similar uptake kinetics, and at short time points (up to 4 h) there was no significant difference in their uptake by HEp2 cells. However after 25 h, the amount of tri-lysine conjugate **15** accumulated within cells is about 25% higher than that of the di-lysine derivative **17**. The Sn(IV) complex **20** is taken-up faster than **15** and **17**, reaching a plateau after about 2 h exposure time to cells. At longer time points (>4 h), the tri-lysine metal complex **20** is clearly the least accumulated within cells of all conjugates studied. On the other hand, the arginine-containing conjugates (**23**–**25**) were taken-up by HEp2 cells to a much larger amount (>50%) than the lysine derivatives at short time points (up to 4 h). After 25 h, conjugate **24** was clearly the one that accumulated the most within cells, followed by **23**, suggesting that at least three consecutive arginine residues are necessary for high cellular uptake.

The subcellular localization of all conjugates and starting porphyrins was also investigated in HEp2 cells. Figure 4 shows the fluorescent patterns observed for starting porphyrin **1** and conjugates **14**–**16**, **19**, **21**–**24** (supplementary data is available for all conjugates in the Supporting Information). All compounds were found to localize into vesicles, suggesting similar mechanisms of cellular uptake for all conjugates studied. Colocalization experiments were performed for all compounds using the organelle-specific fluorescent probes LysoSensor Green (lysosomes), MitoTracker Green (mitochondria), and Hoechst 33342 (nuclei). As shown in Figure 5 for conjugate **14**, the preferential sites of intracellular localization of **14** were the cell lysosomes. Similar observations were obtained for all other conjugates and for starting por-

phyrins **1** and **5** (Supporting Information). To investigate the effect of the route of delivery on cellular localization, three different transfection lipids, Avanti, Cardiolipin, and Lipofectamine, were used as delivery vehicles for conjugates **22** and **23**. Fluorescent microscopy revealed that all lipid mixtures transported the conjugates to the mitochondria of HEp2 cells (Supporting Information). We have previously observed that the use of liposomes as delivery vehicles can have a dramatic effect on the subcellular sites of accumulation of photosensitizers (*42*).

Molecular Modeling. Conformation analysis for conjugates **15**, **18**, **23**, **24**, and **25** was performed in a vacuum and, in the case of conjugate **18**, also in the presence of water. Only the minimum energy conformations were selected and those determined under vacuum are shown in Figure 6. All structures show a bend conformation of the peptides over the porphyrin ring, which is more pronounced in the case of the lysine derivatives bearing the five-carbon linker. In some cases (e.g. Figure 6a) additional stabilization was obtained via formation of an intramolecular bond between the N−H of a lysine residue and the porphyrin inner N−H. Furthermore, additional stabilization via hydrophobic interactions between the aliphatic chain of the lysine residue and the porphyrin aromatic system was observed (e.g. Figure 6b). Our results suggest that hydrogen bonding and hydrophobic interactions of the peptide chain with the porphyrin platform reduce the conformational entropy (by as much as 60 kcal/mol) as compared to the linear conformation. The water effects were evaluated only for conjugate **18**, and the minimum energy conformation found was similar to the vacuum structure shown in Figure 6b, with only a slight change on the position of the amine group of the lysine residues (see Supporting Information). It is, however, likely that in the presence of water, intermolecular forces (such as $\pi-\pi$ stacking of porphyrin macrocycles) predominate over the intramolecular interactions. Although the NMR chemical shifts of the Cα peptidyl protons can also be useful in the assignment of the secondary structure of peptides, we were not able to use this technique because of the overlap of these protons with those of the solvent.

DISCUSSION

The coupling of peptides to aminophenylporphyrin **1** via amide bond formation using traditional coupling reagents (DCC or EDCI) requires several days, due to the weak nucleophilicity of the aromatic amino group in pophyrin **1** and to steric factors, as previously observed (*43*). For example, while the coupling of porphyrin **1** with Boc-glycine produced the corresponding conjugate in 93% yield, the coupling with Boc-lysine under the same conditions resulted in 65% yield, and no conjugate was obtained in the presence of activated Boc-lysine with NHS. The reaction yields decreased with the increasing number of amino acid residues on the protected peptide, even under optimized coupling conditions (HOBt/EDCI/TBTU/DIEA in DMF). Slightly higher yields of the target conjugates were obtained upon conversion of the amino group of porphyrin **1** to a reactive isothiocyanate functionality (*18*, *35*), although steric factors still significantly influenced the reaction yields (Table 1). Using isothiocyanate porphyrin **5**, conjugates **13**−**15** were obtained in solution phase, in 35−93% yields. The free amino terminus Boc-protected peptides resulted in higher yields of the target conjugates, due to the easier cleavage of this protecting group compared with the Z-protected peptides. This result can be due, in the case of catalytic hydrogenation, to the poisoning of the palladium catalyst by the sulfur on the isothiourea group. The solution-phase conjugation of Boc-protected peptides to carboxylic acid porphyrin **6** containing a five-carbon spacer resulted in high yields of the target conjugates **17** and **18** that were independent from the size of the reacting peptide. The Zn(II)− and Sn(IV)−porphyrin conjugates were also prepared to investigate the effect of a centrally chelated diamagnetic metal ion on the cellular uptake and subcellular localization. In complexes **19** and **20** the amino groups on the lysine residues can potentially interact with the metal ion, especially in the case of the Zn(II) complex.

The solid-phase synthesis of C-amidated conjugates **21**−**25** proceeded considerably faster although lower yields were obtained compared with the solution-phase reactions. While the solution-phase conjugations are more time-consuming because they require rigorous isolation, purification, and characterization of the target compounds following each synthetic step, the conjugation to biomolecules built on a solid support allows a stepwise assembly of the conjugates with no isolation of interme-

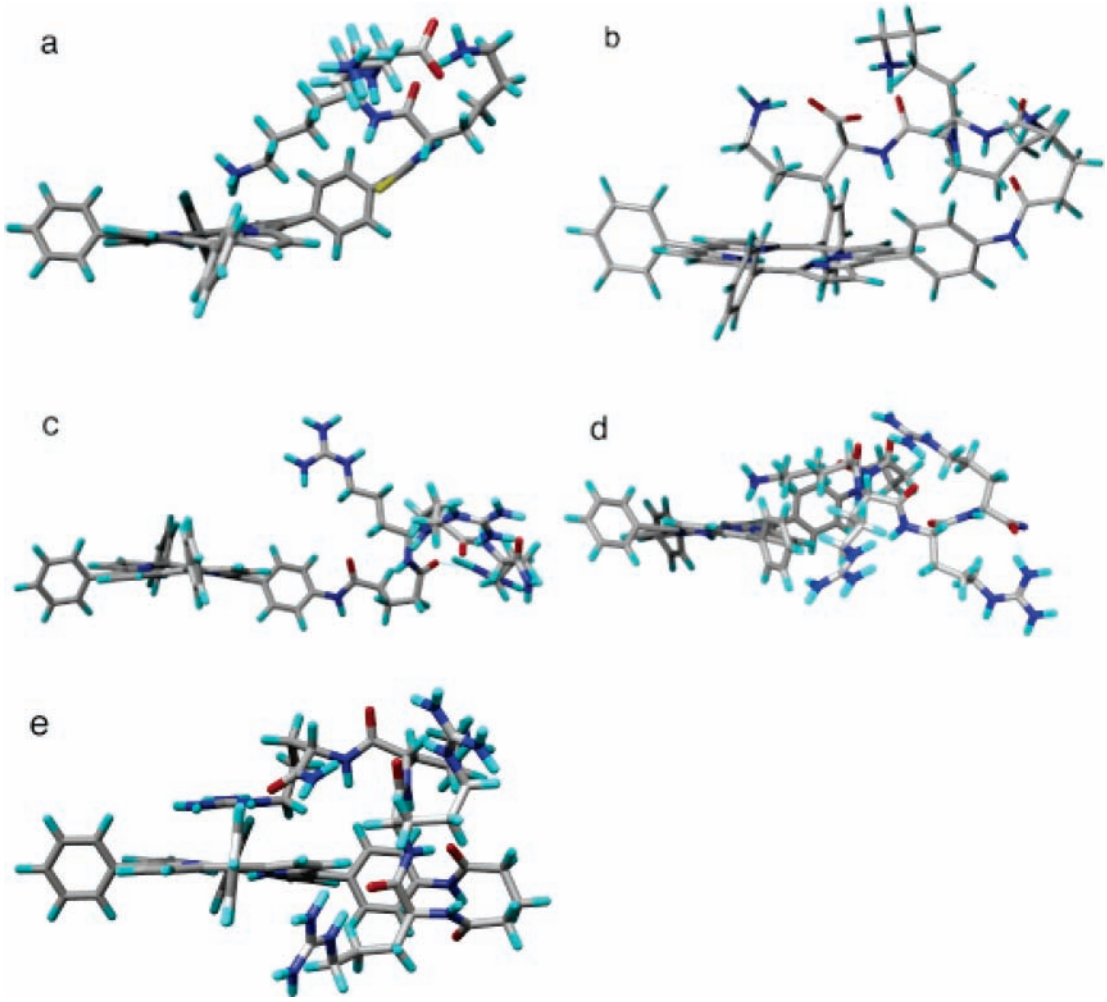

Figure 6. Energy-minimized conformations in a vacuum for conjugates (a) **15**, (b) **18**, (c) **23**, (d) **24**, and (e) **25**.

diates. The yields of the latter route are, however, lower because of poor solvation, increased intra- and intermolecular interactions in the growing peptide chains, and to porphyrin- or peptide-polymer adsorptions. Furthermore, in solid-phase synthesis various byproducts from either incomplete reactions, side reactions, or impure reagents usually accumulate on the resin during chain assembly, contaminating the final product and requiring HPLC purification; lower reactions rates are therefore observed as a result of secondary structures or aggregates formed with other peptide chains or with the polymer support.

The dark cytotoxicity of the most water-soluble porphyrin conjugates bearing two or three lysine or arginine residues was evaluated at concentrations up to 500 μM (Figure 2). All conjugates showed low dark toxicity (IC_{50} > 250 μM), and the least toxic was the Sn(IV) complex **20**, which was also the least accumulated within HEp2 cells at long exposure times (>2 h) (Figure 3). The cellular uptake of the conjugates depended significantly on the number, nature, and sequence of the amino acid residues, the chelated metal ion, and the C-termination (OH vs NH_2), i.e., on the overall molecular charge and its distribution. For all compounds studied, the metal-free conjugates showed similar uptake kinetics, and the amount of conjugate accumulated within cells was higher for those containing three consecutive arginine residues (Figure 3). It has been previously observed that peptides containing cationic amino acids, in particular arginine-rich peptides, have a unique ability to cross cellular membranes (*44*−*47*). This property is attributed to the unique structure of the positively charged guanidinium group and its ability to form bidentate hydrogen bonds with, for example, membrane-containing phosphate groups. Lysine-rich peptides usually show lower uptake compared with arginine peptides, and this uptake is dependent on the number of residues, suggesting that the overall charge is important but certainly not the only factor (*47*). In agreement with these studies our results show that a tri-lysine conjugate (**15**) is taken-up to a higher extent than a di-lysine derivative (**17**), that arginine-containing conjugates (e.g. **23** and **24**) rapidly and most effectively accumulate within cells, and that the amino acid sequence (LysArgArgArg vs ArgArgLysArg, i.e., conjugates **24** and **25**) plays an important role on the cellular uptake of these compounds. Furthermore, the presence of a centrally chelated metal ion (as in **20**) significantly changes the uptake kinetics, promoting higher uptake at low exposure times (<2 h), after which a plateau is reached and, unlike the metal-free conjugates, no significant amount of metalloconjugate is further taken-up by the cells.

The preferential sites of subcellular localization of aminophenylporphyrin **1** and its conjugates are the cell lysosomes (Figure 4), which suggest a similar mode of uptake for all molecules studied, probably involving an endocytic pathway and subsequent localization into the lysosomes. Similar observations have been recently reported for several cationic porphyrins with different degrees of lipophilicity (*48*). The presence of the short

peptide chain and the number, nature, and sequence of amino acids did not change the preferential subcellular sites of the porphyrin macrocycle (Figure 4a). However, in the presence of a lipid delivery vehicle, the main subcellular sites of localization were the mitochondria. Our results suggest that, in the absence of a carrier, these porphyrin−peptide conjugates do not assume distinct extended conformations for the peptidyl chains, either forming aggregates or assuming bend conformations in solution. The preferred conformations of peptides in aqueous media have been previously investigated using molecular dynamics (MD) computer simulations and are known to depend on the number, nature, and sequence of the amino acid residues on the peptide chain (*49*−*51*). For example, conformational studies of a tri-lysine peptide showed that this molecule does not adopt an extended or β-sheet conformation in water; instead it prefers to form an helix-type structure (*50*). Additionally, the electrostatic repulsion observed in MD in a vacuum between two positively charged arginine residues in close proximity was overcome by the presence of bridging water molecules (*52*). Our MD calculation studies of representative conjugates in a vacuum and in water show that the porphyrin ring influences the conformation of the peptide chain by providing extra hydrophobic and hydrogen bonding interactions that favor a bent (over extended) conformation of the peptide chains over the porphyrin ring (Figure 6). The hydrophobic and Coulombic interactions between the porphyrin and the peptides are presumably stronger that those between the short peptide chains, thus favoring a bundle structure for these conjugates. These results do not exclude the possibility of self-assembly of the conjugates in water (*53*) and can in part explain the similar intracellular patterns observed for all conjugates synthesized. Furthermore, our results suggest that a longer linker and longer amino acid sequences will likely favor an extended or β-sheet conformation for the peptide chains conjugated to a porphyrin macrocycle. It is worth noting that although no significant difference was observed in the in vitro subcellular localization of our conjugates, it is possible that their in vivo distribution following systemic administration is quite different, as it depends on multiple factors including the amount and nature of proteins and lipoproteins in the blood. It was recently reported that a porphyrin conjugated to a nuclear localizing sequence peptide has high affinity for low-density lipoproteins (*54*), but no results were reported on the preferential sites of subcellular localization of this conjugate. We anticipate that careful choice of the peptide chain and linker to the porphyrin macrocycle will lead to unique conjugates with ability for crossing cell membranes and localization in specific organelles.

ACKNOWLEDGMENT

The authors thank Martha Juban for peptide synthesis, Tracy McCarley for MS analyses, Guangyu Li for assisting with ^{1}H NMR analyses of porphyrin−tetrapeptide conjugates, and Jorge Escobedo for assisting with MD calculations. This work was supported by the National Science Foundation, grant number CHE-304833.

Supporting Information Available: Additional spectroscopic data including NMR for all compounds synthesized and synthetic routes to protected peptides and conjugates **3**, **4**, **7**−**9**, HPLC separation conditions, additional cytotoxicity data, fluorescence microscopy images, and MD minimized conformation for **18** in water. Nucleic Acid Complexing Glycosyl Nucleoside-Based Amphiphile

Jerome Arigon,[†] Carla A. H. Prata,[§] Mark W. Grinstaff,[§] and Philippe Barthélémy*[,†]

Faculté des sciences d'Avignon, 33 rue Louis Pasteur, F-84000 Avignon, France, and Departments of Chemistry and Biomedical Engineering, Metcalf Center for Science and Engineering, Boston University, Boston, Massachusetts 02215. Received February 4, 2005; Revised Manuscript Received April 25, 2005

A neutral amphiphile derived from uridine featuring two oleyl chains and one glucose for DNA binding was prepared using a convenient four-step synthetic route. The nucleic acid binding capabilities of this amphiphile were investigated by UV−vis, quasi-elastic light scattering (QELS), transmission electronic microscopy (TEM), gel electrophoresis, ^{31}P NMR, IR, and circular dichroism (CD). Amphiphile−nucleic acid complex formation is a consequence of the amphiphilic character of the molecule, phosphate−sugar, and nucleobase−nucleobase interactions. This work presents for the first time a glyco-nucleo-amphiphile capable of binding efficiently the nucleic acid double helix structure.

INTRODUCTION

The supramolecular assemblies observed between nucleic acids and different amphiphiles represent elegant examples of the role multiple noncovalent interactions have in governing structure and even function. These assemblies are of fundamental interest, as well as clinical importance, since some of these assemblies are used for the in vitro and in vivo delivery of DNA. The delivery of therapeutic nucleic acid offers the potential to treat diseases by replacing or inhibiting defective genes. The vast majority of DNA supramolecular assemblies are formed with molecular or macromolecular cationic amphiphiles including lipids, linear polymers, and dendritic polymers (*1*−*6*). One caveat with these cationic amphiphiles is that these systems are likely to interact with other biologics, since most proteins are also negatively charged at neutral pH. However, there are a few examples of DNA supramolecular assemblies formed with noncationic amphiphiles (*7*). Recently, neutral sugar- and poly(ethylene glycol)/uridine-based amphiphiles have been reported that complex DNA (*8*−*10*). The neutral glycosyl amphiphiles are particularly interesting since these compounds may provide a means to develop amphiphiles for selective biologic complexation. Such amphiphiles could be of interest for medical and biotechnological applications involving the manipulation or use of DNA or proteins.

With regards to the glycosyl amphiphiles, there are known examples of natural saccharides that bind nucleic acid. For example, S. Shinkai et al. have reported the molecular recognition between adenine, cytosine, and uracil in a single-stranded RNA and schizophyllan, a natural polysaccharide (*12*). It is known that when a given polyol structure, like a saccharide, is added to an aqueous solution containing DNA, the stability of the double helix can be affected. The effects observed depend on the polyol influence on the forces that stabilize the double helix, namely, hydrogen bonding, van der Waals forces, and electrostatic interactions. Consequently, the polyol can either stabilize or destabilize the duplex as evident by a change in the DNA denaturation temperature (T_m). G. Barone and co-workers have studied the effects of different small molecule polyols (i.e., glycerol, arabitol, D-mannitol, D-sorbitol, myo-inositol, etc.) on the thermal denaturation of DNA (*13*). The double helix destabilization was mainly attributed to the polyols interacting with the polynucleotide solvation sites. The polyols displace water molecules and alter the electrostatic interactions between the polynucleotide and its surrounding counterions. Consequently, when the concentration of polyols increases, the Coulombian repulsion between the negative charges of the phosphate groups increases leading to greater destabilization of the DNA double helix. Stabilizing contributions (polyols are less efficient than water in competing with the base−base interstrand hydrogen bonds) are counterbalanced by destabilizing electrostatic repulsions. A stabilization of the DNA double helix has been observed in the presence of a maltoheptaose amphiphile (*14*), where the saccharide promotes stabilization of the double helix versus single strand by the formation of DNA aggregates. This is likely due to the amphiphilic character of the polyols. To further explore the interactions between DNA and a neutral amphiphile, we have designed a noncationic amphiphile possessing both nucleoside and glycosyl moieties (Figure 1). Herein, we report the synthesis and physicochemical properties of this amphiphile as determined by UV−vis, quasi-elastic light scattering (QELS), NMR, IR, circular dichroism (CD), gel electrophoresis, and transmission electronic microscopy (TEM).

MATERIALS AND METHODS

General Experiments and Analytical Conditions. Unless noted otherwise, all starting materials were obtained from commercial suppliers and were used without further purification; the solvents were redistilled on calcium chloride, calcium hydride, potassium hydroxide, or sodium according to the solvent used. All compounds were characterized using standard analytical and spectroscopic data such as ^{1}H, ^{13}C NMR (apparatus BRUKER Avance DPX-300, ^{1}H at 300.13 MHz, ^{13}C at 75.46 MHz, and ^{31}P at 121.49 MHz) and mass spectrometry (instrument JEOL SX 102, NBA matrix). The NMR chemical shifts are reported in ppm relative to tetramethylsilane using the deuterium signal of the solvent ($CDCl_3$, MeOD) as a heteronuclear reference for ^{1}H and ^{13}C. The ^{1}H NMR coupling constants, J, are reported in hertz. TEM microscopy experiments were performed on a Philips CM 10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon-coated grids). Fluorescence spectra were recorded on a Hitachi F2500 using λ_{ex} = 320 nm and λ_{em} = 350−450 nm. The hydrodynamic radii (R_h) were determined at 25 °C using a Wyatt Mini-Dawn quasi-elastic light scattering (QELS) instrument. UV−visible studies were performed on a Perkin-Elmer Lambda 25 Peletier equipped, and circular dichroism was performed on a JASCO J-810 spectropolarimeter. The ^{31}P NMR experiments were performed on a BRUKER AC 250 at 121.49 MHz. The ^{31}P NMR chemical shifts (δP) are reported in ppm relative to phosphoric acid. FTIR spectra were recorded using a NICOLET Fourier transform spectrophotometer. Silica gel 60 (particle size 40−60 μm) was employed for flash chromatography. Thin layer chromatograms were performed with aluminum plates coated with silica gel 60 F_{254} (Merck). Varian silica gel reverse phase C18 MEGA BE-C18, 2GM, 12 mL was used.

Abbreviation. DOUGluc, 1-(2′,3′-dioleylcarbamoyluridine-5′)-β-D-glucopyranoside; HEPES, *N*-(2-hydroxyethyl)piperazine-*N*′-(2-ethanesulfonic acid); M.S., molecular sieves; EtBr, ethidium bromide; DMAP, (dimethylamino)pyridine; DCM, dichloromethane; DMF, dimethylformamide; AcOEt, ethyl acetate; SUV, small unilamellar vesicles; polyA−polyU, polyadenylic acid−polyuridylic acid; polyC−polyG, polycytidylic acid−polyguanylic acid; T_m, melting temperature; RT, room temperature; CDI, carbonyl diimidazole.

Materials. Calf thymus DNA (CAS no. 91080-16-9), pBR322 plasmid DNA (CAS no. 93384-17-9), polyadenylic acid−polyuridylic acid (CAS no. 24936-38-7], and polycytidylic acid−polyguanylic acid (CAS no. 90385-88-9) were obtained from Sigma. Buffer (0.02 M HEPES, 0.01 M NaCl) was prepared with distilled and filtered (0.22 μm) water, and the pH was adjusted to 7.4 with NaOH 0.1 M.

Synthetic Procedures. *2′,3′-Dioleylcarbamoyluridine (**2**).* 5′-Dimethoxytrityluridine **1** (1 g, 1 equiv), carbonyldiimidazole (1.22 g, 2.2 equiv), and a catalytic amount of DMAP were dissolved in 20 mL of anhydrous DMF. After 1 h at room temperature, oleylamine (4 mL, 7 equiv) was added, and then the reaction mixture was stirred for 12 h. DMF was removed under reduced pressure, and 20 mL of DCM was added. To this solution an excess of a 3% trichloroacetic acid solution in DCM was added, and the reaction mixture was stirred for 30 min at room temperature. After addition of methanol (3 mL), the organic layer was washed three times with 10 mL of water and dried over sodium sulfate. Compound **2** (0.54 g) was obtained after chromatography (DCM/MeOH 95/5). Yield: 36%. R_f: 0.32 (DCM/MeOH 95/5). ^{1}H NMR ($CDCl_3$) δ in ppm: 0.96 (s, CH_3), 1.2 (m, CH_2), 2.3 (m, CH_2), 3.2 (m, H5′), 3.92 (m, H4′), 4.2 (m, H3′), 4.95 (m, NH), 5.4 (m, H2′), 5.8 (d, CH, J = 8.1 Hz), 6.1 (d, H1′, J = 3.3 Hz), 7.85 (d, CH, J = 8.0 Hz), 8.6 (s, NH). ^{13}C NMR ($CDCl_3$) δ in ppm: 14 (s, CH_3), 27 (s, $CH_2\beta$), 30 (m, CH_2), 33 (m, $CH_2\alpha$), 42 (s, C−NH), 70 (m, C2,C3), 100 (s, CH), 131 (m, CH═CH), 133 (m, CH), 164 (m, CO carbamates), 170 (m, CO). MS FAB$^+$: [M + Na], m/z = 853.

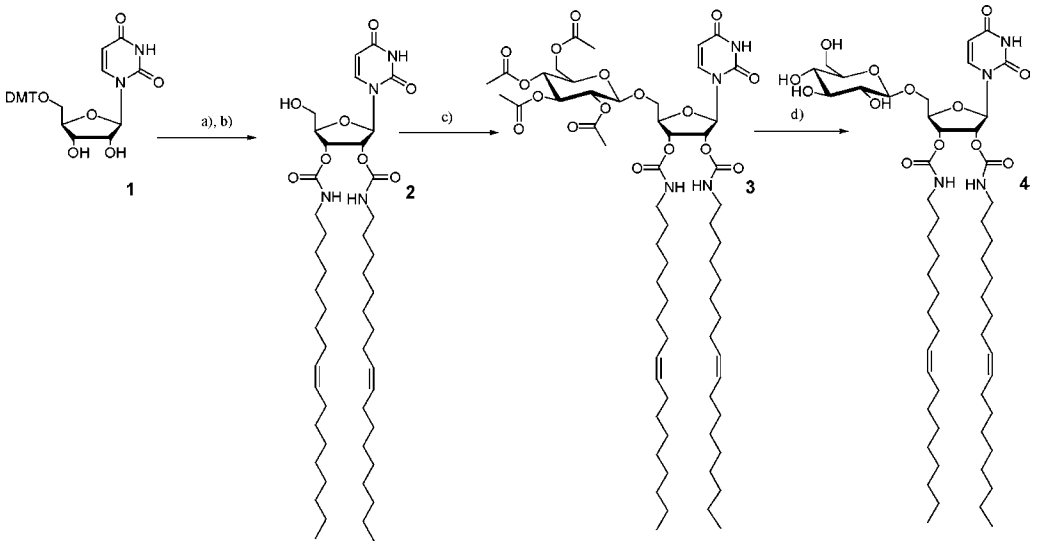
*1-(2′,3′-Dioleylcarbamoyluridine-5′)-2,3,4,6-tetra-O-acetyl-β-D-glucopyranoside (**3**).* 2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl trichloroacetimidate (0.2 g, 1.5 equiv) (*15*−*18*), 2′,3′-dioleylcarbamoyluridine **2** (0.2 g, 1 equiv), molecular sieves, and $BF_3{\cdot}Et_2O$ (0.18 g, 1.5 equiv) were dissolved in 10 mL of DCM. The reaction mixture was stirred for 4 h at room temperature. The product was obtained as a white solid (0.15 g) after chromatography (DCM/MeOH 95/5). Yield: 55%. R_f = 0.72 (DCM/MeOH 95/5). ^{1}H NMR ($CDCl_3$) δ in ppm: 0.96 (s, CH_3), 1.2 (m, CH_2), 2.0 (m, CH_3 acetyl), 3.1 (m, $CH_2\alpha$), 3.9 (m, H5′), 4.0 (m, H4′), 4.1 (m, H5), 4.2 (m, H6, H6), 4.7 (m, H3′), 4.85 (m, H2), 5.1 (m, H3), 5.5 (m, H4), 5.6 (d, H1β, J = 8.2 Hz), 5.65 (d, CH, J = 8.2 Hz), 6.1 (d, H1′, J = 3.0 Hz), 7.9 (d, CH, J = 8.1 Hz). ^{13}C NMR ($CDCl_3$) δ in ppm: 14 (s, CH_3), 20 (s, OAc), 27 (s, $CH_2\beta$), 30 (m, CH_2), 33 (m, $CH_2\alpha$), 42 (s, CH_2NH), 61−75 (m, C5,C3,C2,C3′,C4′,C5′), 97 (s, C1), 105 (s, CH), 131 (m, CH═CH), 133 (s, CH), 164 (m, CO carbamates), 170 (m, CO). MS FAB$^+$: [M + H], m/z = 1162.

*1-(2′,3′-Dioleylcarbamoyluridine-5′)-β-D-glucopyranoside (**4**).* 1-(2′,3′-Dioleylcarbamoyluridine-5′)-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**3**, 0.15 g) and a catalytic amount of sodium methoxide were dissolved in 10 mL of methanol. The reaction mixture was stirred for 4 h at room temperature. After evaporation of methanol under reduced pressure, the crude was purified by silica gel reverse phase column (DCM/MeOH 3/7) to afford the compound as a white solid (0.12 g). Yield: quantitative. R_f = 0.52 (DCM/MeOH reverse phase). ^{1}H NMR (CD_3OD) δ in ppm: 0.96 (s, CH_3), 1.3 (m, CH_2), 1.5 (m, $CH_2\beta$), 3.1 (m, $CH_2\alpha$), 3.3 (m, H6, H6), 3.7 (m, H3′, H4′), 3.8 (m, H5′, H2′), 4.3 (m, H5), 4.6 (s, H4), 4.8 (s, H3), 5.3 (m, CH═CH), 5.7 (d, H′β, J = 8.2 Hz), 5.8 (d, CH, J = 8.0 Hz), 6.2 (d, H1′, J = 3.0 Hz), 8.0 (d, CH, J = 8.1 Hz). ^{13}C NMR (CD_3OD) δ in ppm: 15 (s, CH_3), 27 (s, $CH_2\beta$), 30 (m, CH_2), 33 (m, $CH_2\alpha$), 42 (s, CH_2NH), 61−75 (m, C5,-C3,C2,C3′,C4′,C5′), 97 (s, C1), 105 (s, CH), 131 (m, CH═CH), 133 (s, CH), 162 (m, CO carbamates), 170 (m, CO). MS FAB$^+$: [M + Na], m/z = 1015. HRMS [M + Na] $m/z_{theoritical}$ = 1015.6551, $m/z_{observed}$ = 1015.6559. $[\alpha]_D^{20}$ = −7.26 (CH_3OH).

Critical Aggregation Concentration. For the measurements of critical micellar concentration, a stock solution of pyrene (0.5 mM) in ethanol was added to test tubes. The ethanol was evaporated by a stream of nitrogen and thereafter under vacuum for 1 h. Varying amounts of amphiphile stock solution in buffer were added to the tubes to give a final volume of 1 mL and a final pyrene concentration of 0.5 μM. The samples were incubated in the dark at 25 °C for 24 h with intermittent vigorous mixing. The fluorescence intensity (I_1, λ = 373 nm) was plotted as a function of the lipid concentration.

Thermal Denaturation and Circular Dichroism Studies. Samples were prepared in the following buffers: (i) 0.02 M HEPES, 0.01 M NaCl, pH = 7.4, and (ii) 0.02 M HEPES, 0.01 M NaCl, 0.01 M $MgCl_2$, pH = 7.4. Solutions at different ratios of polyA−polyU (1 mg/mL) or CT-DNA (1 mg/mL) to **4** were prepared in either sodium (i) or magnesium (ii) buffer and stirred for 10 min.

Scheme 1. Synthetic Route to Glucosyl Dicarbamate Uridine Amphiphile[a]



[a] Conditions: (a) CDI/DMAP in DMF 2 h, then oleylamine 12 h; (b) trichloroacetic acid in CH_2Cl_2 (yield$_{a+b}$ = 36%); (c) 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl trichloroacetimidate, M.S., and BF_3-Et_2O in CH_2Cl_2 (yield = 55%); (d) MeONa in MeOH (yield = quantitative).

The temperature was increased from 15 to 95 °C at 1 °C/min, and the absorbance at 260 nm was measured every 1 °C increments. Hyperchromicity = $A - A_0$, where A is the absorbance measured at $\lambda = 260$ nm and A_0 is the initial absorbance ($\lambda = 260$ nm) at 20 °C. T_m values were determined from first-order derivatives. CD spectra were recorded at 25 °C in rectangular quartz cuvettes of 0.1 cm; each spectrum was averaged from three successive accumulations and was baseline-corrected and smoothed using the software supplied by JASCO.

Quasi-Elastic Light Scattering (QELS). The R_h was measured at a 90° angle and $\lambda = 685$ nm using a flow cell. The solvent was filtered through a 0.02 μm membrane. The lipid and DNA solutions of desired concentrations were prepared and filtered through 0.2 μm pore size filter (Whatman) into the scattering cell. R_h measurements were realized at $t = 0$, 24, and 36 h of **4** (50 equiv per DNA phosphate) in the absence or presence of CT-DNA (1 mg/mL). R_h reported corresponds to the average of three experiments in aqueous HEPES buffer. Astra software (version 4.90.80) was used for data acquisition and analysis.

^{31}P NMR Studies and Job Plot. Na_2HPO_4 (3 mM) solution in D_2O−DMSO-d_6 (8:2) was added with different amounts of **4**, **2,** or D-glucose, and the mixtures were vortexed during 30 s. The chemical shifts (δP) of Na_2HPO_4 were measured by ^{31}P NMR. For the Job plot, the concentration of the mixture was kept constant at 3 mM.

Infrared Spectroscopy. PolyA−polyU (0.5 mg/mL) was mixed with DOUGluc **4** (1.5 mg) in H_2O and vortexed for 30 s; then the solution was freeze-dried. The solid obtained was mixed with KBr, and 64 scans were accumulated. In the case of D_2O experiments, the polyA−polyU/DOUGluc **4** and polyC−polyG/DOUGluc **4** mixtures are prepared in D_2O in the same conditions as for solid FTIR experiments, and the IR spectra are obtained directly from the D_2O solutions.

Agarose Gel Electrophoresis. Plasmid DNA (2 μL, 0.02 g/L in HEPES buffer) was added to various amounts of **4** at RT, and the mixture was vortexed during 30 s and left at RT for 36 h. Then the solutions were loaded into 1% (w/v) agarose gel at 60 V/cm in HEPES buffer. DNA was revealed with EtBr and visualized under UV light.

Transmission Electronic Microscopy (TEM). The samples were prepared with a solution of calf thymus DNA (1 mg/mL in HEPES buffer) and extruded (50 nm filter) HEPES buffer solution containing 50 equiv of DOUGluc **4** (for 1 equiv of phosphate DNA). This solution was vortexed and left for 36 h at RT prior to examination.

RESULTS AND DISCUSSION

The formation of amphiphile−DNA supramolecular assemblies is well-known in the case of cationic lipids; however, only a few examples of neutral amphiphiles that complex with DNA have been reported (*7*, *10*, *14*, *19*). To further increase the known types of DNA-binding neutral amphiphiles, we are designing amphiphiles that are based on a nucleoside and a sugar moiety. In this approach, the nucleoside and sugar derivative can provide sufficient interaction forces with DNA to form nucleic acid−amphiphile supramolecular assemblies. Consequently, we have synthesized the 1-(2′,3′-dioleylcarbamoyluridine-5′)-β-D-glucopyranoside and evaluated the ability of this neutral amphiphile to bind to nucleic acids using UV−vis, QELS, TEM, gel electrophoresis, ^{31}P NMR, FTIR, and CD.

Synthesis. The synthetic strategy is shown in Scheme 1 and involves four steps starting from 5′-dimethoxytrityluridine. The lipophilic intermediate **2** was obtained by coupling oleylamine to the 2′ and 3′ ribose secondary alcohols using CDI to afford carbamate linkages. The dimethoxytrityl protecting group was removed using trichloroacetic acid. Finally, the amphiphilic dioleyl nucleoside derivative **4** was obtained after addition of the glucose moiety via a trichloroacetimidate glycosylation and a deprotection step to remove the acetyl groups. Amphiphile **4** is soluble in water, whereas **2** possesses limited aqueous solubility and is soluble in DMSO.

Physicochemical Studies. The critical aggregation concentration (CAC) of **4** was determined using a fluorescence titration method (*20*, *21*). Thus, to determine the CAC value of our glycosyl nucleoside amphiphile, a stock solution of **4** was added to a pyrene-saturated solution (4×10^{-7} mol/L) at 298.2 K and stirred for 24 h to reach complete equilibrium between amphiphile and pyrene. The fluorescence emission was monitored at 394

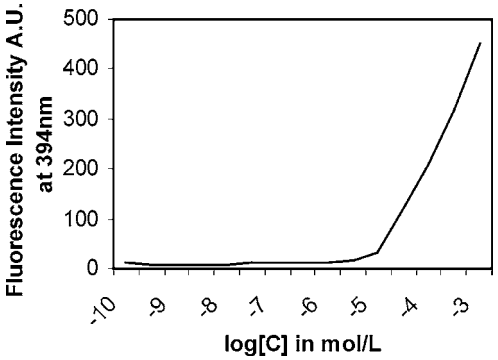


Figure 2. Measurements of pyrene fluorescence at 394 nm (λ_{ext} = 320 nm) versus log(c) in mol/L of compound **4**. CAC obtained was determined to be 1×10^{-5} mol/L.

nm (λ_{ext} was 320 nm). The CAC value for amphiphile **4** is 10^{-5} mol/L (see Figure 2). Note, that this value is similar in magnitude to CACs reported in the literature for mono- and dioleyl amphiphilic polyols or cationic derivatives of **4** suggesting that the nucleoside moiety does not significantly affect the CAC (*22*−*25*).

Nucleic Acid Thermal Denaturation. The nucleic acid binding capability of **4** was next evaluated by studying the thermal denaturation profile of a polyA−polyU double helix in the presence of varying amounts of glycosyl nucleoside amphiphile **4**. The denaturation profiles and corresponding first derivatives obtained in the absence or presence of magnesium are presented in Figure 3. Specifically, panels Ia, IIa, and IIIa of Figure 3 show the thermal denaturation profiles of polyA−polyU at 260 nm in the presence of compound **4**, glucose, and uridine, respectively. The first derivatives of the corresponding absorbances versus temperature are presented in panels Ib, IIb, and IIIb of Figure 3. Likewise, thermal denaturation experiments with polyA−polyU and amphiphile **4** in the presence of a magnesium buffer are shown in Figure 3, panel IVa. The corresponding first derivative is plotted in Figure 3, panel IVb. The DNA thermal denaturation results are summarized in Table 1.

In a HEPES buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M), the T_m measured for polyA−polyU is 43.4 °C. A positive shift, ΔT_m [$\Delta T_m = T_m$(**4** + polyA−polyU) − T_m-

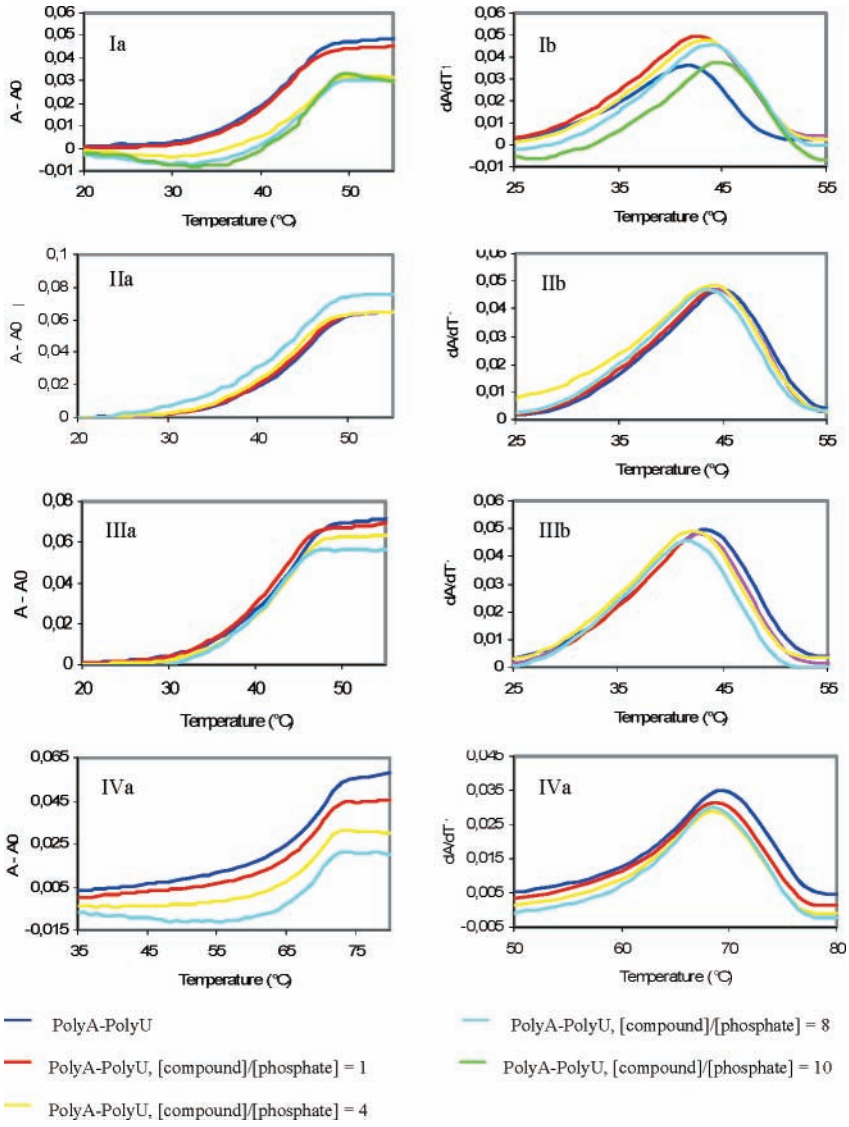

Figure 3. Hyperchromicity at 260 nm versus temperature of polyA−polyU in the presence of compound **4**, glucose, and uridine (respectively, panels Ia, IIa, and IIIa), first derivatives of absorbance versus temperature (respectively, panels Ib, IIb, and IIIb) in aqueous HEPES buffer 0.02 M, pH 7.4, NaCl 0.01 M). Same experiments with polyA−polyU and amphiphile **4** in the presence of magnesium (IVa) and their first derivatives (IVb) are also shown (performed in aqueous HEPES magnesium buffer 0.02 M, pH 7.4, NaCl 0.01 M, $MgCl_2$ 0.01 M).

Table 1. DNA Thermal Denaturation Results

amount of compd (equiv)	ΔT_m[a] (°C) **4** + polyA−polyU[b]	**4** + CT-DNA[c]	**4** + polyA−polyU + Mg[d]	uridine + polyA−polyU[b]	glucose + polyA−polyU[b]
1	1.3	1.5	−0.5	−0.6	−0.5
4	2.2	2.1	−0.7	−0.7	−0.9
8	2.6	2.3	−0.8	−1.7	−1.2
10	3.5	*e*	*e*	*e*	*e*

[a] ΔT_m (°C) = T_m of polyA−polyU + compound mixture − T_m of polyA−polyU (average of three experiments). The error in melting temperature (T_m) does not exceed 0.2 °C. [b] Aqueous HEPES buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M). T_m measured for polyA−polyU in this buffer is 43.4 °C. [c] Aqueous HEPES buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M). T_m measured for CT-DNA in this buffer is 72.3 °C. [d] Aqueous HEPES magnesium buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M, $MgCl_2$ 0.01 M). T_m measured for polyA−polyU in this buffer is 69.6 °C. [e] Not available.

(polyA−polyU)], of the polyA−polyU melting temperature is observed when compound **4** is added to the solution (Figure 3I) indicating a stabilization of the double helix ($\Delta T_m = 2.6$ °C, 8 equiv of **4** for 1 equiv of RNA phosphate). Note that the same phenomenon was observed with a calf thymus (CT) DNA ($\Delta T_m = 2.3$ °C, 8 equiv of **4** for 1 equiv of DNA phosphate). The ΔT_m increases as the number of amphiphile equivalents of **4** is increased suggesting that the stabilization of the double helix is not due to a one to one complex. Since these thermal denaturation experiments were performed with concentrations of amphiphile **4** higher than the CAC (1 equiv of **4** is 1.6×10^{-5} mol/L), the stabilization of the DNA double helix can be attributed to a DNA aggregation resulting from interactions between DNA and amphiphile aggregates.

As expected, in the presence magnesium the T_m-(polyA−polyU) is enhanced with a new value of 69.6 °C. It is well-known that magnesium ions increase T_m by binding to the phosphate backbone and stabilizing the double helix (*26*). When amphiphiles **4** is added to the Mg solution a decrease of the T_m(polyA−polyU) is noted. This small destabilization is consistent with the strong association of diols with the phosphate (*27*). In this case, sugar−phosphate associations compete with the Mg−phosphate complex inducing Mg displacement and consequently a decrease in double helix stability. To estimate the impact of the nucleoside and sugar moieties on the stability of polyA−polyU double helix, the denaturation experiments were performed in the presence of uridine and glucose (without added Mg). A negative ΔT_m was observed for both compounds (Figure 3, panels II and III). These negative values can be rationalized by the polyol interactions with DNA inducing an enhancement of the repulsion between the negative charges of the phosphate groups (*13*). These results underline the importance of the amphiphilic character and the aggregate formation in stabilizing the DNA double helix.

Quasi-Elastic Light Scattering (QELS) Studies. We evaluated the impact of the CT-DNA on amphiphile aggregation. The hydrodynamic radius (R_h) of the aggregates was measured at three time points (t = 0, 24, and 36 h), and Table 2 summarizes the values obtained. Amphiphiles (typical concentration 0.6 mM) were extruded through a 50 nm filter in buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M), DNA was then added to the aqueous solutions (DNA phosphate concentration 0.006 mM) containing the amphiphiles. Extruded amphiphile solutions exhibit stable aggregates with hydrodynamic radius of roughly 20 nm even after 36 h ($R_h = 19.8 \pm 0.3$) In the presence of CT-DNA after 36 h, the observed R_h increases to 42.6 ± 1.8 nm. It is reasonable to suggest that this size enhancement is due to the formation of new structures composed of amphiphiles and DNA.

Table 2. Hydrodynamic Radius (R_h, nm) of Amphiphiles and CT-DNA/Amphiphile Aggregates[a]

t (h)	DOUGluc (**4**)	DOUGluc (**4**) + CT-DNA
0	23.1 ± 1.2	22.1 ± 0.4
24	21.2 ± 0.3	22.2 ± 0.8
36	19.8 ± 0.3	42.6 ± 1.8

At t = 0, 24, and 36 h of **4** in the absence or presence of CT-DNA. Average of three experiments realized in aqueous buffer (HEPES 0.02 mM, pH 7.4, NaCl 0.01 mM). Value measured for CT-DNA alone (type XV activated, Sigma) is 3.0 ± 0.5 nm.

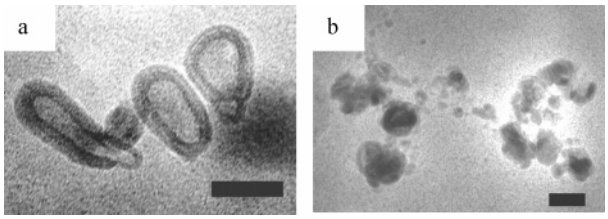

Figure 4. Transmission electronic microscopic (TEM) images of (a) small unilamellar vesicles obtained after extrusion of **4** through a 50 nm filter (bar = 50 nm) and (b) large aggregates (**4** equiv/CT-DNA = 50, bar = 100 nm).

TEM Studies. To confirm the impact of nucleic acids on amphiphile self-assembly, aqueous solutions of **4** were studied either in the absence or in the presence of CT-DNA by transmission electronic microscopy (TEM). As shown in Figure 4a, the extrusion of **4** through a 50 nm filter gives small unilamellar vesicles (SUV). The same solution was also studied after addition of calf thymus DNA. In agreement with the results obtained by QELS experiments, the presence of CT-DNA affects the supramolecular organization. A new population of larger aggregates is present in the solution. TEM images show a decrease in vesicle population and larger aggregates of roughly 100 nm (Figure 4b).

Gel Electrophoresis Studies. Electrophoresis gel shift is a convenient assay of DNA complexation. Thus, in light of the UV−vis, QELS, and TEM studies, agarose gel electrophoresis experiments were conducted by using plasmid pUC18 DNA. Increasing amounts (~0, 5, 10, 15, 25, 50, and 75 equiv based on the amphiphile **4**/phosphate, which correspond to the following concentrations: 0, 0.3, 0.6, 0.8, 1.4, 2.7, and 4.0 mM, respectively) of **4** were mixed with plasmid DNA (plasmid DNA phosphate concentration 0.06 mM) in HEPES buffer (HEPES 0.02 M, pH 7.4, NaCl 0.01 M). After incubation for 36 h at room temperature, the mixtures (20 μL) were loaded into a 1% agarose gel (HEPES 0.02 M, pH = 7.4, NaCl 0.01 M, EtBr 500 ng/mL) using a pipettor. The gel was run at constant power (60 V) and at room temperature for 2.5 h. The DNA−amphiphile complexation is readily monitored under UV. High amphiphile ratios

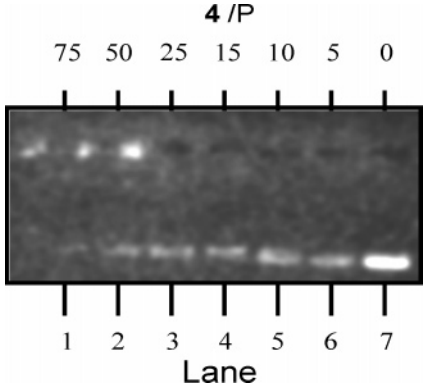

Figure 5. Electrophoretic gel shifts for the complex plasmid−**4**: from lane 1 to lane 7, decreasing amounts of **4** from 75 to 0 equiv.

(50−75 amphiphile/phosphate equiv) behave similarly, and the DNA is immobilized as typically shown in Figure 5. The glycosylated nucleoside amphiphile **4** immobilizes plasmid pUC18 DNA demonstrating the masking of DNA charges by the uncharged amphiphile aggregates.

^{31}P NMR and FTIR Studies. To determine whether the stabilization of the DNA double helix depends on both glucose−phosphate interactions and amphiphile self-organization, the binding of Na_2HPO_4 (guest, $[G]_t$ = total guest concentration) with glucose, **2**, and **4** (hosts, $[H]_t$ = total host concentration) were studied by ^{31}P NMR spectroscopy model systems. NMR titration of phosphate with sugars was performed by keeping the total phosphate concentration constant ($[Na_2HPO_4] = 3.0 \times 10^{-3}$ M) and gradually increasing the sugar derivative concentrations. These studies reveal that the complexation of the phosphate anion is occurring only in the case of the amphiphile. The ^{31}P NMR signal undergoes upfield shifts in the presence of **4** host until saturation is reached at $[H]_t/[G]_t$ ratios higher than 1 (Figure 6a), whereas no significant chemical induced shift is observed for glucose and compound **2**. Such a result indicates that both the glucose moiety and amphiphilic character are needed to induce the formation of a glucose−phosphate complex in aqueous media. Fifty percent complexation occurs for **4** host at $[H]_t/[G]_t = 0.5$ (Figure 6a), that is, at host concentration of $[H]_{50} = 1.5$ mM ($[G]_t = 3$ mM). The implication of $[H]_{50}$ is that $K_{min} = 1/[H]_{50} \approx 6 \times 10^2$ M^{-1} represents the lower limit of the binding constant of H for a molecule of G (where the equilibrium constant $K = [H-G]/[H][G]$, $H + G \rightleftarrows H-G$).[22] The binding affinity, K_{min}, obtained for **4** is slightly lower than those for the oligosaccharide clusters−phosphate complexes (10^3 M^{-1}) in aqueous media (*28*). A Job plot (*29*) for the binding of **4** and phosphate (Figure 6b) showed a maximum between $X = 0.5$ and $X = 0.6$, indicating a preference for 1:1 complexes over 2:1 complexes, which coexist in solution to a minor degree. From the NMR studies, the chemical induced shifts observed are due to phosphate anion coordination incorporated in the aggregate pools via hydrogen bonding. Indeed, in view of its amphiphilic nature, it is not surprising that host **4** forms aggregates, where the hydrogen bond forming anion may link to the sugar moieties. This is because the phosphate ion is associated with the sugar surface of the aggregates and a chemical induced shift is observed. Compound **2** does not possess a glucose moiety and therefore cannot bind phosphate anion. Consequently, the phosphate is not coordinated, and no significant chemical induced shifts are observed.

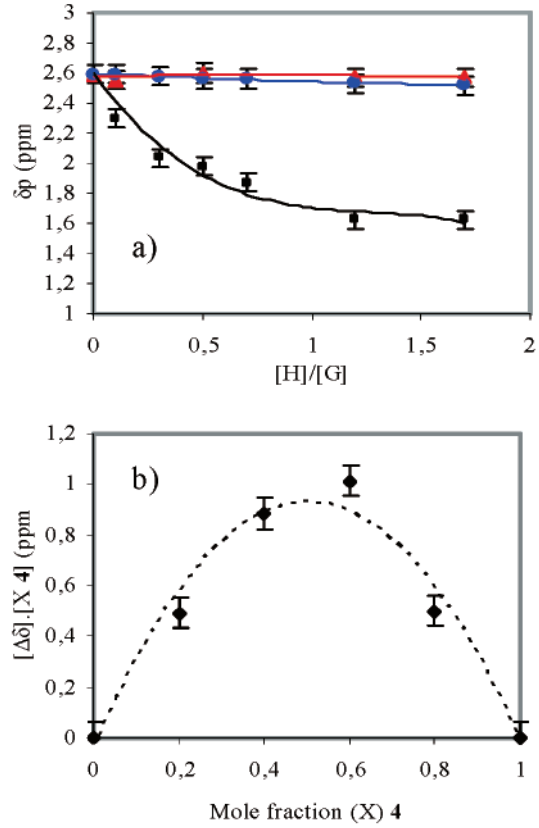

Figure 6. ^{31}P NMR titration (a) of phosphate (guest, [G] = 3 mM) with hosts ([H]) glucose (▲, red), compound **2** (●, blue), and compound **4** (■, black) at 25 °C in D_2O/DMSO-d_6 with δp in reference to external H_3PO_4 in D_2O ($\delta p = 0$) and Job plot (b) for the binding of **4** and phosphate. Concentration of **4** and of phosphate was held constant at 3 mM.

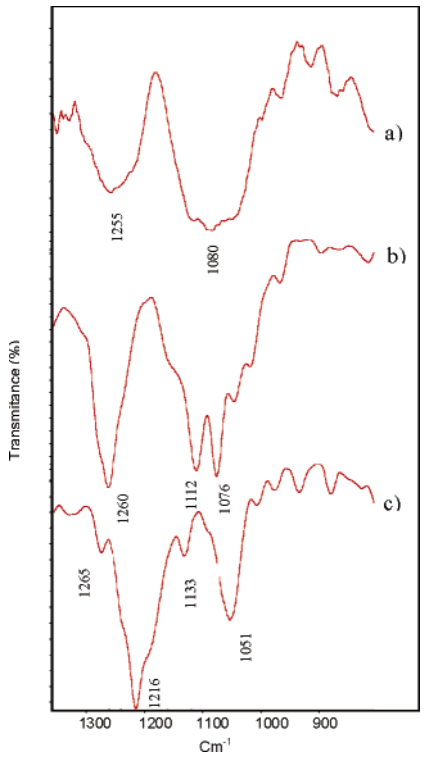

Figure 7. FTIR spectra of (a) polyA−polyU, (b) **4**, and (c) polyA−polyU/**4** 1:1 equiv in the region of 1350−800 cm^{-1}.

The infrared spectra of the polyA−polyU and the polyA−polyU/**4** (1:1 equiv) complexes in the region of

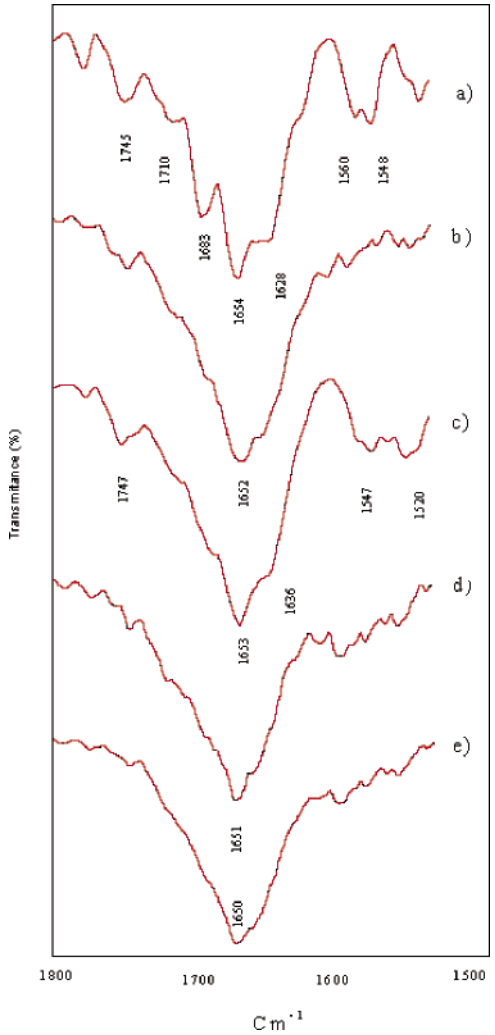

Figure 8. FTIR spectra in solution of (a) **4**/polyA−polyU (1:1), (b) polyA−polyU, (c) **4**, (d) **4**/polyC−polyG (1:1), and (e) polyC−polyG in the region of 1500−1800 cm^{-1}.

1350−800 cm^{-1} are shown in Figure 7. The band around 1080 cm^{-1} in the IR spectrum (Figure 7a) has been assigned to the symmetric PO_2^- stretching mode coupled with the C5′−O5′ vibrations (*30*), whereas the antisymmetric PO_2^- stretching vibrational band is observed around 1255 cm^{-1} (*31*). In the same region, **4** exhibits three bands at 1076 (C−O stretching primary alcohol), 1112 (C−O stretching secondary alcohol), and 1260 cm^{-1} (C−N−C=O vib) (*32*). The phosphate−sugar interactions are characterized by a shift of the antisymmetric PO_2^- stretch at 1216 cm^{-1}, which confirms the amphiphile−RNA complex formation (*33*).

FTIR spectra recorded in D_2O solutions in the region 1500−1800 cm^{-1} are presented in Figure 8. In the case of the mixture **4**/polyA−polyU (1:1) (Figure 8a), two additional bands at 1710 and 1683 cm^{-1} are observed. These absorptions are not observed for polyA−polyU (Figure 8b) and **4** (Figure 8c). According to Dagneaux et al., the absorption at 1712 cm^{-1} is assigned to a reverse Hoogsteen $C_2{=}O_2$ (thymidine, dT*dA-dT) stretching vibration (*34*). The band at 1683 cm^{-1} has been assigned to a $C_2{=}O_2$ stretch of additional base paired uridine (*35*). These results suggest that the base is also involved in the stabilization of the amphiphile/polyA−polyU complex via either Hoogsteen or reverse Hoogsteen nucleobase pairing with the uracil part of the amphiphile. A negative control using a mixture of **4**/polyC−polyG (1:1) is shown in Figure 8d. This FTIR spectrum, which does not show any change compared to polyC−polyG (Figure 8e), confirms the Hoogsteen or reverse Hoogsteen nucleobase pairing observed in the case of the **4**/polyA−polyU (1:1) mixture.

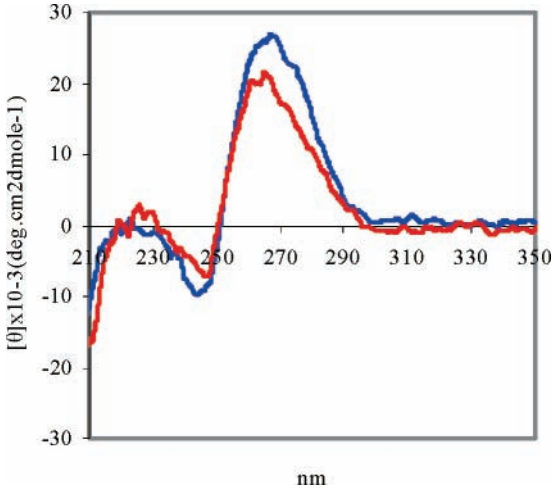

Figure 9. CD spectra of polyA−polyU (blue) and **4**/polyA−polyU (4:1) (red) at 25 °C.

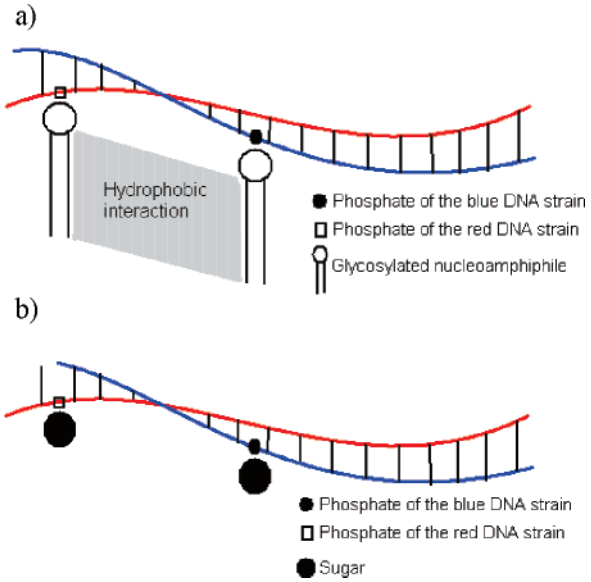

Figure 10. Interaction of (a) DNA−amphiphile, in which the presence of both hydrophobic interactions (amphiphiles−amphiphiles) and hydrogen bonding (sugars−phosphates) lead to a DNA double helix stabilization and (b) DNA−sugar, in which the sugar induces hydrogen bonding only, which gives a double helix destabilization.

Circular Dichroism Studies. The CD spectrum of polyA−polyU was recorded in the presence of **4**. The CD characteristics of the polyA−polyU/**4** complex are different from those of the polyA−polyU duplex. The CD spectrum of the polyA−polyU/**4** complex (red curve) and that of the polyA−polyU duplex (blue curve) are depicted in Figure 9. The RNA−**4** complex is characterized by a positive band at 260 nm and a negative band in the 245 nm region, and both of these bands have lower ellipticity values compared to that of the polyA−polyU duplex, which has a positive band in the 270 nm region, followed by a negative band at 245 nm. These results suggest that the polyA−polyU double helix structure is affected by the complexation with **4**. According to the circular dichroism investigations on U−A duplex and U*A−U triplex reported by Ray et al. (*36*), the lower ellipticity values observed in the case of **4**/polyA−polyU compared to

polyA−polyU duplex could be attributed to amphiphile U*A−U complex.

Proposed 4−DNA Complex. The molecular model for DNA−amphiphile assemblies formed with the glucosyl uridine amphiphile is proposed in Figure 10. In the case of amphiphile **4**, the stabilization of the double helix is due to concomitant phosphate−sugar and hydrophobic interactions (Figure 10a), whereas only phosphate−sugar interactions are responsible for DNA destabilization (*37*) by sugar or uridine (Figure 10b).

CONCLUSION

We describe here a new neutral DNA amphiphile for binding to nucleic acid and subsequent supramolecular assembly formation. The synthetic route to the glucosyl dioleyl uridine amphiphile is reported, which should provide easy access to other nucleoside-based sugar amphiphiles. A critical aggregation concentration of 10^{-5} mol/L for **4** was determined by using fluorescence probing methods. Thermal denaturation experiments of a polyA−polyU double helix in the presence of different amounts of **4** show a positive shift of ΔT_m indicating a double helix stabilization. The formation of amphiphile−nucleic acid complexes was confirmed by QELS, TEM, and gel electrophoresis studies. The ^{31}P NMR investigations reveal that the phosphate anion is associated with the sugar surface of the glucosyl dioleyl uridine amphiphile aggregates. Similarly, the PO_2^- stretch at 1216 cm^{-1} of the polyA−polyU/**4** (1:1 equiv) complex shows the presence of phosphate−sugar interactions. The bands at 1712 and 1683 cm^{-1} observed in aqueous solutions by FTIR and the lower ellipticity values measured by CD suggest that the uridine moiety of **4** is also involved in the stabilization of the amphiphile/polyA−polyU complex. All together, the results strongly support amphiphile−nucleic acid complex formation as a consequence of the amphiphilic character of the molecule, nucleoside, and phosphate−sugar interactions. This glycosyl nucleoside-based amphiphile demonstrates an alternative approach to forming stable nucleic acids supramolecular assemblies. These results expand the current repertoire of DNA complexing amphiphiles and provide further motivation for the design and evaluation of new amphiphiles.

(37) Sugars are polyols that displace water molecules and induce a modification of the electrostatic interactions between the polynucleotide and its surrounding counterions. Consequently, when the concentration of polyols increases, the repulsion between the negative charges of the phosphate groups is enhanced, and a gradual destabilization of the DNA double helix occurs.

Triplex-forming oligonucleotides (TFOs) are among the most specific DNA ligands and represent an important tool for specific regulation of gene expression. TFOs have also been used to target DNA-modifying molecules to obtain irreversible modifications on a specific site of the genome. A number of molecules have been recognized to target topoisomerase II and stabilize double-stranded cleavage mediated by this enzyme thus determining permanent DNA damage. Among these poisons, etoposide (VP16), a 4′-demethylepipodophyllotoxin derivative, is widely used in cancer chemotherapy. In the aim to design DNA site-specific molecules, three analogues of VP16 (**1**, **2**, and **3**), recently described (Duca et al. *J. Med. Chem.* **2005**, *48*, 596−603), were attached to TFOs, together with a fourth one, of which the synthesis is reported here. Two different oligonucleotides, differing by the length (a 16-mer and a 20-mer), and two different linker arms between the oligonucleotide and the drug were used. The coupling reaction between the drug and the TFO was further improved. For the first time, we also report the synthesis of TFO conjugates bearing two molecules of inhibitor linked to the same oligonucleotide end. In total, 16 new conjugates were synthesized and evaluated for their ability to form triple helices. The loss in triplex stability due to the conjugation of the TFO to compounds that do not interact with DNA is compensated by the presence of the ethylene glycol linker arm. This stabilization effect is more pronounced at the 3′ end than at the 5′ end. All conjugates form a stable triplex selectively on the DNA target at 37 °C and pH 7.2.

INTRODUCTION

Synthetic oligonucleotides can recognize short oligopyrimidine·oligopurine regions in double-stranded DNA via hydrogen bond formation with purine bases in the major groove, leading to a local triple helix (*1*−*3*). Triplex-forming oligonucleotides (TFOs[1]) are among the most specific DNA ligands, together with another class of small molecules represented by synthetic hairpin polyamides that bind to DNA in the minor groove (*4*). Triplex-based approaches are an attractive mean to achieve targeted gene regulation, gene manipulation, and directed mutagenesis in vitro and in vivo (*5*−*7*). Therefore, they represent an important tool for specific regulation of gene expression (*1*, *2*, *6*, *8*). In fact, TFOs have been described to modulate transcription in vitro and in cell culture for exogenous and endogenous genes (*9*−*11*), to inhibit DNA replication in cells (*12*), and to direct mutagenesis in vitro and in vivo (*13*). Furthermore, the sequence-specific recognition properties of TFOs can be exploited to direct DNA cleaving and alkylating agents to chosen DNA sequences (*14*). In fact, TFOs linked to the appropriate DNA modifying molecule are able to induce a permanent modification in the proximity of the triplex site (*7*, *15*, *16*). Interestingly, this strategy has been successfully used to target the action of topoisomerase I inhibitors, such as camptothecin (*17*−*19*).

Topoisomerases regulate DNA topology in cells and, therefore, are essential for many vital processes such as replication, transcription and chromosome segregation (*20*, *21*). Topoisomerases I and II represent privileged targets for a number of cytotoxic anticancer drugs, which stimulate strand cleavage by topoisomerases at a variety of sites. These drugs are called topoisomerase poisons or inhibitors (*22*, *23*).

Whereas topoisomerase I is a monomer and, thus, controls DNA topology by a single-strand breaking of DNA, eukaryotic topoisomerase II is an homodimer and acts by passing an intact DNA double helix through a transient double-stranded break (*21*). The DNA/topoisomerase II covalent complex, called the cleavage complex, is the key intermediate of the topoisomerase reaction. In this complex, each monomer of the enzyme is covalently linked, through a phosphotyrosine bond, to one strand of the duplex, to the 5′ phosphate of the 4-bp staggered DNA double-stranded break. This intermediate, which has normally a short lifetime, is stabilized by different molecules, such as etoposide or its derivatives,

which are topoisomerase II poisons. These poisons form a stable ternary complex drug/topoisomerase II/DNA and prevent DNA religation. Thereby, they induce breaks in the DNA strands whose accumulation causes cell death (*24*).

So, among the topoisomerase II poisons, some compounds are commonly used as anticancer drugs. Etoposide (VP16, Figure 1), a 4′-demethylepipodophyllotoxin (4′ DMEP) derivative, is one of these drugs and is used as frontline therapy particularly in the treatment of small cell lung cancer, testicular carcinoma, lymphoma and Kaposi's sarcoma (*25*, *26*). Although VP16 is widely used in chemotherapy, the molecular mechanism of action of this compound and, more generally, of this class of topoisomerase II poisons is not yet fully understood. Moreover, etoposide presents several limitations, such as moderate potency, poor water solubility, development of drug resistance, metabolic inactivation and toxic effects. For these reasons, the structure of VP16 has been extensively modified, thus increasing the information about its structure−activity relationships. In this context, it has been shown that the glucopyranose moiety in the 4-position of etoposide is not essential for activity and that other substituents, such as the aminoalkyl or arylamino chains induce a better antitopoisomerase II activity (*27*, *28*). Recently, we reported that some non glycoside 4′-demethylepipodophyllotoxin derivatives bearing a carbamate chain at the 4 position (4′-demethylepipodophyllotoxin-4-aminoalkyl carbamates, such as **1** and **3**, in Figure 1) strongly inhibit topoisomerase II and show antiproliferative effects in vitro and antitumor activity in vivo (*29*). A new 4′-DMEP derivative, bearing an aminobenzoyl group, has also been synthesized, resulting in an active topoisomerase II poison.

To increase the DNA sequence-specificity of these molecules that do not interact with DNA, we covalently attached these derivatives to TFOs, in a way similar to that performed with the topoisomerase I poisons camptothecin and rebeccamycin (*19*, *30*). Sixteen conjugates were synthesized and characterized, using two TFOs (differing by the length) and four VP16 analogues. These derivatives were attached to the 3′ or 5′ end of the TFO with two linker arms of different length (L_{18} and L_3). Conjugates bearing two molecules of poison at the same end of the TFO were also synthesized and characterized. The stability of the triplex formed by the conjugates was evaluated by gel retardation and DNase I footprinting assays.

EXPERIMENTAL PROCEDURES

Methods. ^{1}H NMR and NMR spectra were recorded in chloroform-*d* or methanol-d_4, on a Bruker spectrometer (300 MHz). For all oligonucleotides conjugates, mass determination was accomplished by electrospray ionization on a Q-STAR pulsar I (Appleura) and HPLC purifications were performed upon Agilent 1100 using a Xterra reversed phase C_{18} column (4.6 × 50 mm, 2.5 μm). Absorbance spectrophotometry was performed on a Uvikon 860 (Kontron).

Materials. All chemicals were purchased from Aldrich Chemical Co. All solvents were of analytical grade. 4-(*tert*-Butoxycarbonylaminomethyl)benzoic acid was prepared as previously reported (*31*). Human topoisomerase IIα was purchased from TopoGEN Inc. (Columbus, OH).

Oligonucleotides. All oligonucleotides were purchased from Eurogentec (Belgium). Concentrations were determined spectrophotometrically at 25 °C using molar extinction coefficients at 260 nm calculated from a nearest-neighbor model (*32*). The drug-tethered oligonucleotides were synthesized as described below. The nomenclature of the oligonucleotides and conjugates is as follows. The abbreviation TFO is preceded by a number referring to the length of the oligonucleotide and followed, if attached to the 3′ end, or preceded, if attached through the 5′ end, by the letter L (for linker) and the number of atoms in the linker (L_3 = ethylene glycol; L_{18} = hexaethylene glycol; L_{12} = 8-[(3-aminopropyl)-(7-carboxyheptyl)amino]octanoic acid), and, finally, by the denomination of the 4′-DMEP derivative. For example, 20TFO-L_{18}-**6** stands for the 20-mer TFO linked at its 3′ end through the hexaethylene glycol spacer to compound **6**. The orientation of the triple helix is defined as the orientation of the purine-rich strand of the duplex, the

TFO binding in the major groove in an orientation parallel to the oligopurine strand.

Topoisomerase II Poisons. The synthesis of compounds **1**, **2**, and **3** has been previously described (*29*). Starting material **4** was obtained as reported (*33*).

Synthesis of 4-β-(4-Boc-aminomethylphenyl)amido-4′-*O*-demethyl-4-deoxypodophyllotoxin (5). To a solution of **4** (1 g, 2.5 mmol) in anhydrous CH_2Cl_2 (75 mL), under inert atmosphere, were added 4-(*tert*-butoxycarbonylaminomethyl)benzoic acid (753 mg, 3 mmol), EDCI (575 mg, 3 mmol) and HOBt (405 mg, 3 mmol). The reaction mixture was further stirred at room temperature for 4 h. The medium was then taken up with CH_2Cl_2 (25 mL) and water (50 mL). The organic phase was extracted with H_2O (3 × 50 mL), then dried ($MgSO_4$) and filtered. This product was further purified by silica gel chromatography using CH_2Cl_2/methanol 20:1 as the eluent to give pure compound **5** in 70% yield. $R_f = 0.62$ (CH_2Cl_2/methanol 9:1), mp = 133−135 °C, ^{1}H NMR ($CDCl_3$) ∂: 7.71 (d, 2H, $J = 8.0$ Hz, Ph), 7.32 (d, 2H, $J =$ 7.7 Hz, Ph), 6.80 (s, 1H, 5-H), 6.53 (s, 1H, 8-H), 6.45−6.32 (m, 1H, 4-NH), 6.30 (s, 2H, 2′,6′-H), 5.97 (d, 2H, $J =$ 7.1 Hz, CH_2O_2), 5.50−5.38 (m, 2H, 4-H, 4′-OH), 5.00−4.88 (m, 1H, NH), 4.58 (d, 1H, $J = 3.2$ Hz, 1-H), 4.46 (t, 1H, $J = 8.0$ Hz, 11a−H), 4.30 (s, 2H, *CH*$_2$NH), 3.85 (t, 1H, $J = 9.6$ Hz, 11b−H), 3.77 (s, 6H, 3′,5′-OCH_3), 3.05−2.98 (m, 1H, 3-H), 2.95 (dd, 1H, $J = 4.6$, 14.3 Hz, 2-H); 1.44 (s, 9H, Boc); MS (CI) *m/z*: 650 $[M + NH_4]^+$.

Synthesis of 4-β-(4-Aminomethylphenyl)amido-4′-*O*-demethyl-4-deoxypodophyllotoxin (6). To a solution of **5** (700 mg, 1.1 mmol) in CH_2Cl_2 (10 mL) was added trifluoroacetic acid (TFA, 855 μL, 11.1 mmol). The reaction mixture was stirred for 5 h, and washed with a cold saturated aqueous $NaHCO_3$ solution then with water until pH 6−7. The organic extract was dried over $MgSO_4$ and concentrated in vacuo at 30 °C. The residue was purified by silica gel column chromatography using a CH_2Cl_2/methanol 10:1 mixture as the eluent to afford the pure compound **6** in 76% yield. $R_f = 0.17$ (CH_2Cl_2/methanol 9:1), mp = 178−180 °C, ^{1}H NMR (CD_3OD) ∂: 7.86 (d, 2H, $J = 8.0$ Hz, Ph), 7.46 (d, 2H, $J = 7.7$ Hz, Ph), 6.82 (s, 1H, 5-H), 6.51 (s, 1H, 8-H), 6.36 (s, 2H, 2′,6′-H), 5.93 (d, 2H, $J = 3.5$ Hz, CH_2O_2), 5.52−5.40 (m, 1H, 4-H), 4.58 (d, 1H, $J = 4.8$ Hz, 1-H), 4.42 (t, 1H, $J = 8.1$ Hz, 11a−H), 3.99 (s, 2H, *CH*$_2$NH), 3.83 (t, 1H, $J = 9.8$ Hz, 11b−H), 3.72 (s, 6H, 3′,5′-OCH_3), 3.38−3.22 (m, 1H, 2-H), 3.15−2.98 (m, 1H, 3-H); MS (CI) *m/z*: 550 $[M + NH_4]^+$.

Synthesis of the TFO-(4′-DMEP Derivative) Conjugates. The oligonucleotide conjugates were synthesized and purified according to previously reported procedures with little modifications (*34*). Compounds **1**, **2**, **3**, and **6** have been synthesized with an amino group in order to covalently link them to the phosphorylated poly(ethylene glycol) linker arm at the 3′ end (or the 5′ end) of the oligonucleotides (16TFO and 20TFO). The 3′ or 5′ phosphorylated oligonucleotide (300 μg) was first precipitated as hexadecyltrimethylammonium salt, then dissolved in 50 μL of dry DMSO. Solutions of 4-(*N*,*N*-dimethylamino)-pyridine (5 mg in 50 μL of DMSO, 41 μmol), dipyridyl disulfide (6.6 mg in 25 μL of DMSO, 30 μmol) and triphenylphosphine (7.9 mg in 25 μL of DMSO, 30 μmol) were added. After 15 min incubation at room temperature, the activated oligonucleotide was rapidly precipitated with 2% $LiClO_4$/acetone and resolubilized in water (50 μL). Triethylamine (3 μL) was added, followed by the drug solution (1 mg in 100 μL of a mixture H_2O/DMSO 40:60). After 2 h, the oligonucleotide was precipitated with 2% $LiClO_4$/acetone, rinsed with acetone, then dissolved in 50 μL of water. Reverse phase HPLC was used to separate the product from the initial oligonucleotide (5 → 40% CH_3CN in 0.2 M $(NH_4)OAc$). The product was eluted as a single peak absorbing at 310 nm (oligonucleotide) with retention times between 10 and 12 min. compared to 4−6 min for the initial 16TFO and 20 TFO, respectively. The average yield was 60%. Purity was 100%. 16TFO-L_{18}-**1**, **1**-L_{18}-16TFO MS (ES^+) *m/z*: 5971 $[M + H]^+$ (calculated: 5970), 16TFO-L_{18}-**2**, **2**-L_{18}-16TFO MS (ES^+) *m/z*: 5985 $[M + H]^+$ (calculated: 5984), 16TFO-L_{18}-**3**, **3**-L_{18}-16TFO MS (ES^+) *m/z*: 5957 [M + H] (calculated: 5956), 16TFO-L_{18}-**6**, **6**-L_{18}-16TFO MS (ES^+) *m/z*: 6003 $[M + H]^+$ (calculated: 6002), 16TFO-L_3-**6**, MS (ES^+) *m/z*: 5797 $[M + H]^+$ (calculated: 5796), 20TFO-L_{18}-**1**, **1**-L_{18}-20TFO MS (ES^+) *m/z*: 7234 $[M + H]^+$ (calculated: 7233), 20TFO-L_{18}-**6**, **6**-L_{18}-20TFO MS (ES^+) *m/z*: 7266 $[M + H]^+$ (calculated: 7265).

Synthesis of the TFO-L_{18}-$(6)_2$ Conjugates. Two molecules of compound **6** were attached to the 3′ phosphate of 16TFO-L_{18} and 20TFO-L_{18} using the same procedure as described above but repeating the reaction two times. The products were purified by HPLC (gradient: 0 → 80% CH_3CN in 0.2 M $(NH_4)OAc$). The average yield of the reaction was 45% and 100% purity. All conjugates were analyzed by UV spectroscopy, mass spectrometry and gel electrophoresis under denaturing conditions. 16TFO-L_{18}-$(\mathbf{6})_2$ MS (ES^+) *m/z*: 6545 $[M + H]^+$ (calculated: 6544), 20TFO-L_{18}-$(\mathbf{6})_2$ MS (ES^+) *m/z*: 7780 $[M + H]^+$ (calculated: 7779).

Synthesis of the 20TFO-L_{12}-$(6)_2$ Conjugates. Two molecules of compound **6** were linked to a trifunctional linker containing two carboxylic groups, the 8-[(3-aminopropyl)-(7-carboxyheptyl)amino]octanoic acid, and then coupled to 3′ phoshophorylated 20TFO.

Synthesis of 8-[(3-Boc-aminopropyl)−(7-carboxyheptyl)amino]octanoic Acid (8). 8-Bromooctanoic acid (240 mg, 1.1 mmol) was reacted with N-Boc-1,3-diaminopropane (87 mg, 0.5 mmol, **7**) in anhydrous acetonitrile (10 mL) for 48 h at 50 °C in the presence of K_2CO_3 (210 mg, 1.5 mmol). The solvent was removed under reduced pressure, and the reaction mixture was extracted with methanol/chloroform 9:1 (3 × 5 mL). Organic phases were combined and evaporated in vacuo. The crude product was washed with ether (3 × 5 mL) to afford a white solid in 78% yield. MS (ES^+) *m/z*: 459 $[M + H]^+$ (calculated: 458).

Synthesis of L_{12}-$(6)_2$ (9). To a solution of **6** (7 mg, 13 μmol) in anhydrous DMF were added **8** (2.3 mg, 5 μmol), DCC (3.6 mg, 17 μmol) and HOBt 1 M (17 μL, 17 μmol). The reaction mixture was stirred at room temperature for 12 h and then cooled in ether. This led to the formation of a yellow amorphous solid. The crude product was purified by reversed phase HPLC using an acetonitrile gradient (0 → 90% CH_3CN with 0.1% of TFA), and obtained in 16% yield. MS (ES^+) *m/z*: 1487 $[M + H]^+$ (calculated: 1486).

To a solution of this compound (0.6 mg, 0.4 μmol) in CH_2Cl_2 (50 μL was added TFA (50 μL). The reaction mixture was stirred at room temperature for 4 h. The mixture was concentrated in vacuo, and the crude product was purified by reversed phase HPLC using an acetonitrile gradient (0 → 90% CH_3CN with 0.1% of TFA) to give **9** with a 90% total yield. MS (ES^+) *m/z*: 1387 $[M + H]^+$ (calculated: 1386).

Synthesis of 20TFO-L_{12}-$(6)_2$. 3′-Phosphorylated oligonucleotide 20TFO (210 μg, 33 nmol) was first precipitated as hexadecyltrimethylammonium salt, then dissolved in 50 μL of dry DMF. Solutions of 4-(dimethylamino)pyridine (5 mg in 25 μL of DMF, 41 μmol),

dipyridyl disulfide (6.6 mg in 25 μL of DMF, 30 μmol) and triphenylphospine (7.9 mg in 50 μL of DMF, 30 μmol) were added. After 15 min of incubation at room temperature, **9** (0.6 mg, 430 nmol) was added. The mixture was kept at room temperature for 8 h. The oligonucleotide conjugate was then precipitated with 2% $LiClO_4$ in acetone, rinsed with acetone and purified by reversed phase HPLC using a linear acetonitrile gradient (0 → 80% CH_3CN in 0.2 M $(NH_4)OAc$). The average yield was of 40%. The oligonucleotide conjugate was characterized by UV spectroscopy, denaturing gel electrophoresis and mass spectrometry. 100% purity was obtained. MS (ES^-) *m/z*: 7776 $[M - H]^-$ (calculated: 7776).

Gel Retardation Assay. The oligopyrimidine strand of the 29-bp target duplex was 5′ end-labeled with [γ-^{32}P] ATP (Amersham) by T4 polynucleotide kinase (New England Biolabs) according to the manufacturer instructions.

Increasing concentrations (from 10 nM to 5 μM) of the triplex-forming oligonucleotides were added to 10 nM of the radiolabeled duplex in 10 mM $MgCl_2$, 50 mM NaCl, 50 mM HEPES pH 7.2, 10% sucrose and 0.5 mg/mL tRNA followed by sample incubation at 37 °C during 2 h. Electrophoresis was performed on a nondenaturing 15% polyacrylamide gel containing 10 mM $MgCl_2$ and 50 mM HEPES pH 7.2 at 37 °C. To quantify the formation of the triplex, the gels were dried and scanned with a Typhoon 9410 (Amersham Biosciences). The concentration of conjugate or TFO necessary to obtain 50% of formed triplex (C_{50}) was calculated, and a mean value corresponding to three to five different experiments is reported.

DNase I Protection Assays. The DNA template for DNase I protection assay on the oligopyrimidine-containing strand of the target was obtained by successive digestion of the plasmid described in (*18*) with *Pvu* II and *Eco* RI, yielding a 324-mer fragment suitable for 5′-end labeling by the T4 polynucleotide kinase (Biolabs New England) and γ[^{32}P]-ATP (Amersham) after shrimp alkaline phosphatase treatment, and purified as described. One microliter of DNase I (final concentration 0.03 mg/mL, Sigma) diluted in 1 mM $MgCl_2$, 1 mM $MnCl_2$, and 20 mM NaCl was added to the radiolabeled duplex (20 nM), preincubated previously for 1 h at 30 °C in 50 mM Tris-HCl, pH 7.2, 20 mM NaCl, 1 mM $MgCl_2$, 2 mM $MnCl_2$, in the absence or in the presence of the conjugates (final reaction volume 10 μL). The reaction was performed for 3 min at 20 °C and stopped by ethanol precipitation. The samples were resuspended in 95% formamide and heated at 95 °C for 4 min before being loaded onto a denaturing 8% polyacrylmide gel (19:1 acrylamide: bisacrylamide) containing 7.5 M urea in 1 × TBE buffer (50 mM Tris base, 55 mM boric acid, 1 mM EDTA). To identify DNase I footprinting, the gels were scanned with a Typhoon 9410 (Amersham Biosciences).

Topoisomerase II-Mediated DNA Cleavage Assay. Topoisomerase II poisoning by compound **6** was evaluated as previously described (*29*, *33b*).

The topoisomerase II poisoning by the conjugates was evaluated as the amount of DNA cleavage by topoisomerase II on a 5′-end radiolabeled 96-bp DNA fragment containing the triplex site. The 96-bp DNA fragment was prepared by 5′-[^{32}P]-end labeling of the *Eco*RI or *Not* II/alkaline phosphatase treated plasmid using γ-[^{32}P]-ATP and T4 polynucleotide kinase followed by treatment with *Not*II/*Eco*RI, yielding a fragment radiolabeled on the pyrimidine strand (Y) or on the purine strand (R), respectively. The detailed procedure for isolation and purification have been described previously (*18*). Fifty nanomoles of 96-bp radiolabeled DNA fragment was incubated for 1 h at 30 °C in 50 mM Tris-HCl pH 7.0, 120 mM KCl, 1 mM ATP, 10 mM $MgCl_2$, 0.5 mM DTT, 0.1 mM EDTA, and 30 μg/μL BSA in the presence of the TFO in order to form the triplex or of the drug at 5 μM (total reaction volume 10 μL). Human topo IIα (0.7 units) was added to the duplex preincubated as described above with either the TFO and/or the drugs followed by incubation for 20 min at 30 °C. After ethanol precipitation, all samples were suspended in 6 μL of formamide, heated at 90 °C for 3 min and then chilled on ice for 4 min before being loaded onto a denaturing 8% polyacrylamide gel (19:1 acrylamide:bisacrylamide) containing 7.5 M urea in 1 × TBE buffer (50 mM Tris-base, 55 mM boric acid, 1 mM EDTA) for 120 min at 65 W. To quantitate the extent of cleavage, the gels were scanned with a Typhoon 9410 (Amersham Biosciences). For the determination of cleavage levels, normalization relative to total loading was performed.

Molecular Modeling. Molecular modeling was performed by conformational energy minimization with Jumna program package (version 10.3) (*36*). The coordinates of DNA triple helices, which were derived from the previously published B-like triple helix, were used for the construction of triplex (*37*). The published atomic coordinates of yeast topoisomerase II (*38*) and of gyrase (*39*) were used to build the model.

RESULTS

Oligonucleotides and Topoisomerase II Poisons. The oligonucleotides chosen for this study are a 16-mer (16TFO) and a 20-mer (20TFO) containing 5-methyl-2′-deoxycytidine (M) and 5-propynyl-2′-deoxyuridine (P) (Figure 2A). These base modifications were previously shown to enhance triplex formation (*40*). 16TFO and 20TFO were already shown to form a stable triple helix on a 29-bp target sequence containing a 23-bp oligopyrimidine·oligopurine sequence at 37 °C, pH 7.2, 50 mM KCl, 10 mM $MgCl_2$ (Figure 2A) (*19*, *30*). The TFOs were covalently attached through three types of linker arms (L_3, L_{12}, and L_{18}) to derivatives of 4′-DMEP (Figure 2). Derivatives **1**−**3** have recently been synthesized and characterized (*29*). In these compounds the sugar of VP16 is replaced by an aminoalkyl chain linked to the C-4 of 4′-DMEP by a carbamate group (Figure 1). Compounds **1** and **2** bear a 4-*N*-(3-aminopropyl)carbamate chain or a 4-[*N*-(3-aminopropyl)-*N*-methyl]carbamate substituent, respectively. Compound **3** contains a 4-[*N*-(2-aminoethyl)]-carbamate chain and a supplementary modification on the lactone D ring, called retrolactone modification (*29*, *41*). Furthermore, we chose another 4′-DMEP derivative modified on the 4-position (**6**), containing a secondary aminomethylphenyl side chain with a primary amino group suitable for attachment to the TFO (Figure 1). This compound was designed on the basis of a family of 4′-DMEP derivatives, previously described by Zhou et al. (*42*), bearing aryl chains linked in the 4-position via an amide group. This family of compounds has shown good antitopoisomerase II activity. Compound **6** was synthesized starting from the 4-β-amino-4′-demethylpodophyllotoxin (**4**), prepared, as previously reported (*33*), by reaction with 4-(Boc-aminomethyl)benzoic acid in the presence of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide (EDCI) and 1-hydroxybenzotriazole (HOBt) (Scheme 1), to provide compound **5**, which, after deprotection, leads to **6** in a 76% yield. Compounds **1** and **3** are good topoisomerase II poisons (38% and 48% of inhibition at 20 μM, respectively, expressed as amount of linearized

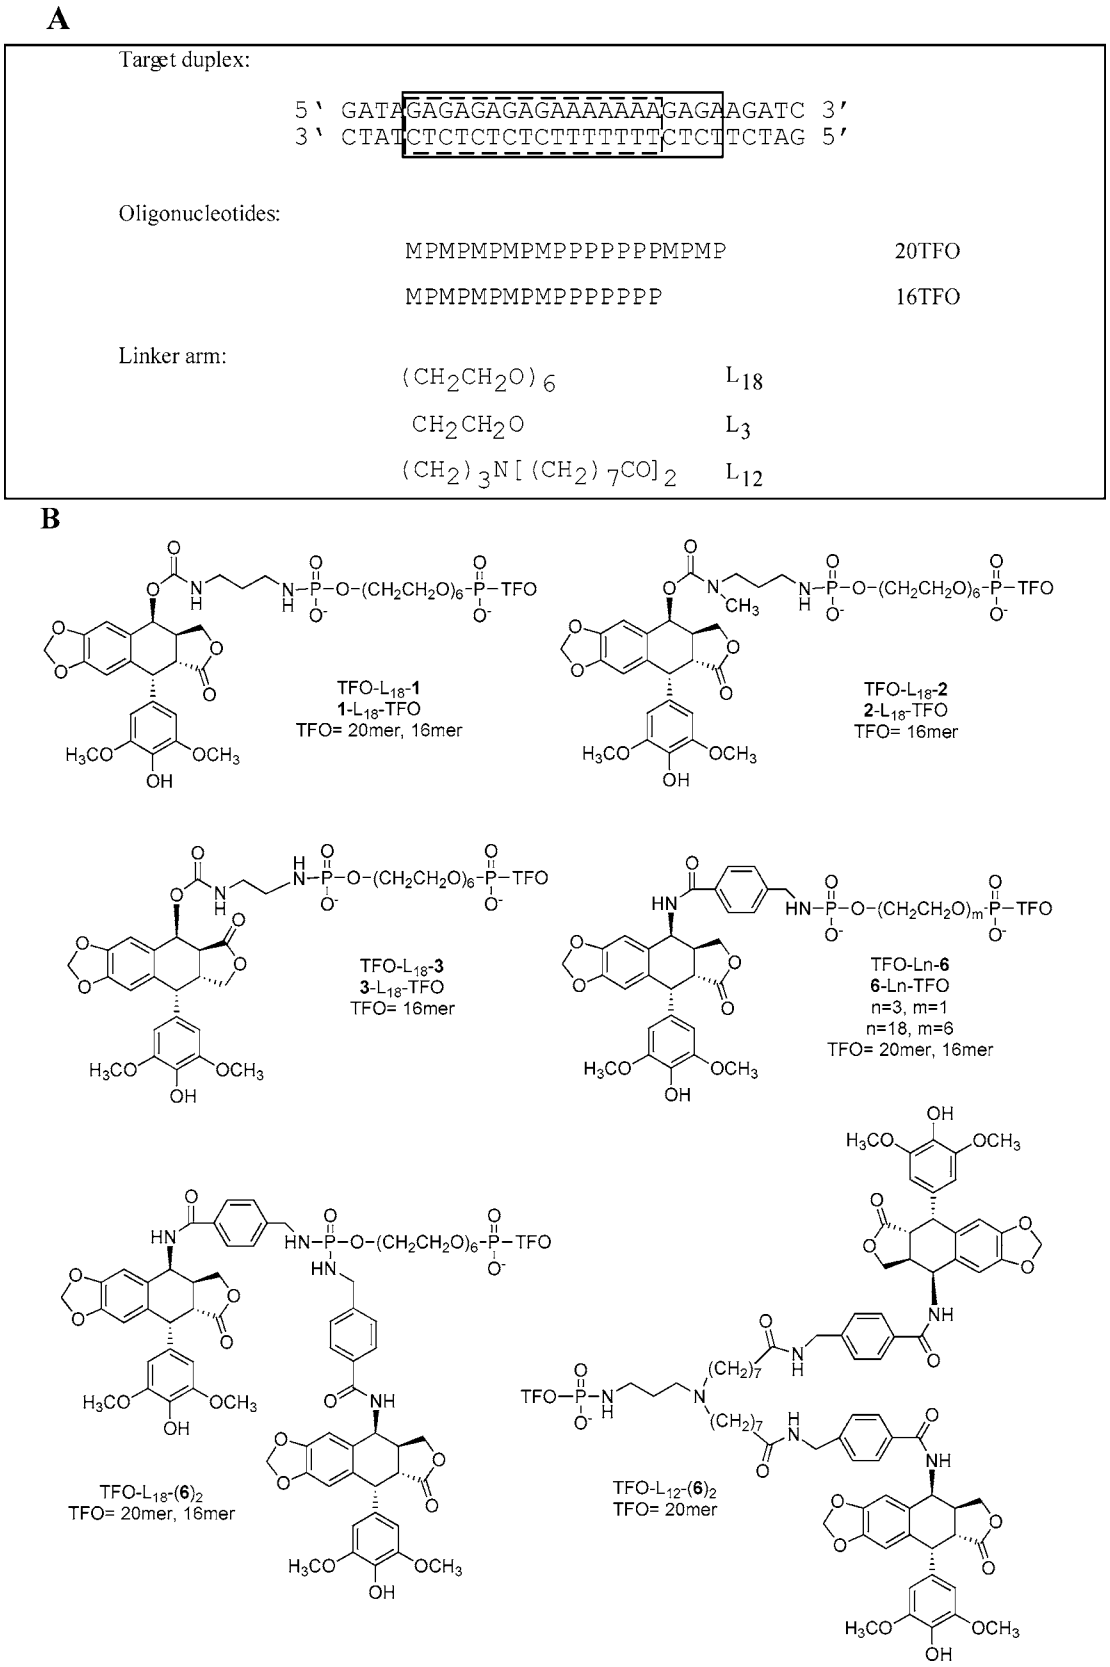

Figure 2. (A) Sequence of the 29-bp target duplex used for gel retardation assay and sequences of the TFOs (M = 5′-methyl-2′-deoxycytosine, P = 5-propynyl-2′-deoxyuracile) and chemical structure of the linker arms. The target sequences of 20TFO and 16TFO are surrounded. (B) Chemical structure of synthesized conjugates. The nomenclature of the oligonucleotides and conjugates is as follows: the abbreviation TFO is preceded by a number referring to the length of the oligonucleotide and followed, if attached to the 3′ end, or is preceded, if attached through the 5′ end, by the letter L (for linker) and the number of atoms in the linker, and finally the designation of the 4′-DMEP derivative.

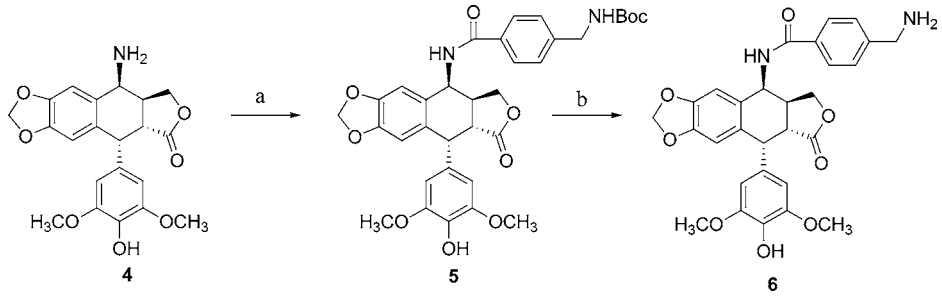
DNA formed upon reaction of supercoiled DNA with human topoisomerase II and compared to 50% at 20 μM for etoposide used as reference compound), whereas compound **2** is an example of an inactive derivative (8%

Scheme 1. Synthesis of Compound 6[a]



[a] Reagents: (a) 4-(*tert*-butoxycarbonylaminomethyl)benzoic acid, EDCI, HOBt, CH_2Cl_2; (b) TFA, CH_2Cl_2.

of inhibition at 20 μM) (*29*). Compound **6** was tested for its activity against topoisomerase II, showing a 25% of amount of linear DNA measured at 20 μM. All these compounds bear a primary amino group at the end of the secondary chain in order to bind them directly to the phosphate group at the extremity of the TFOs.

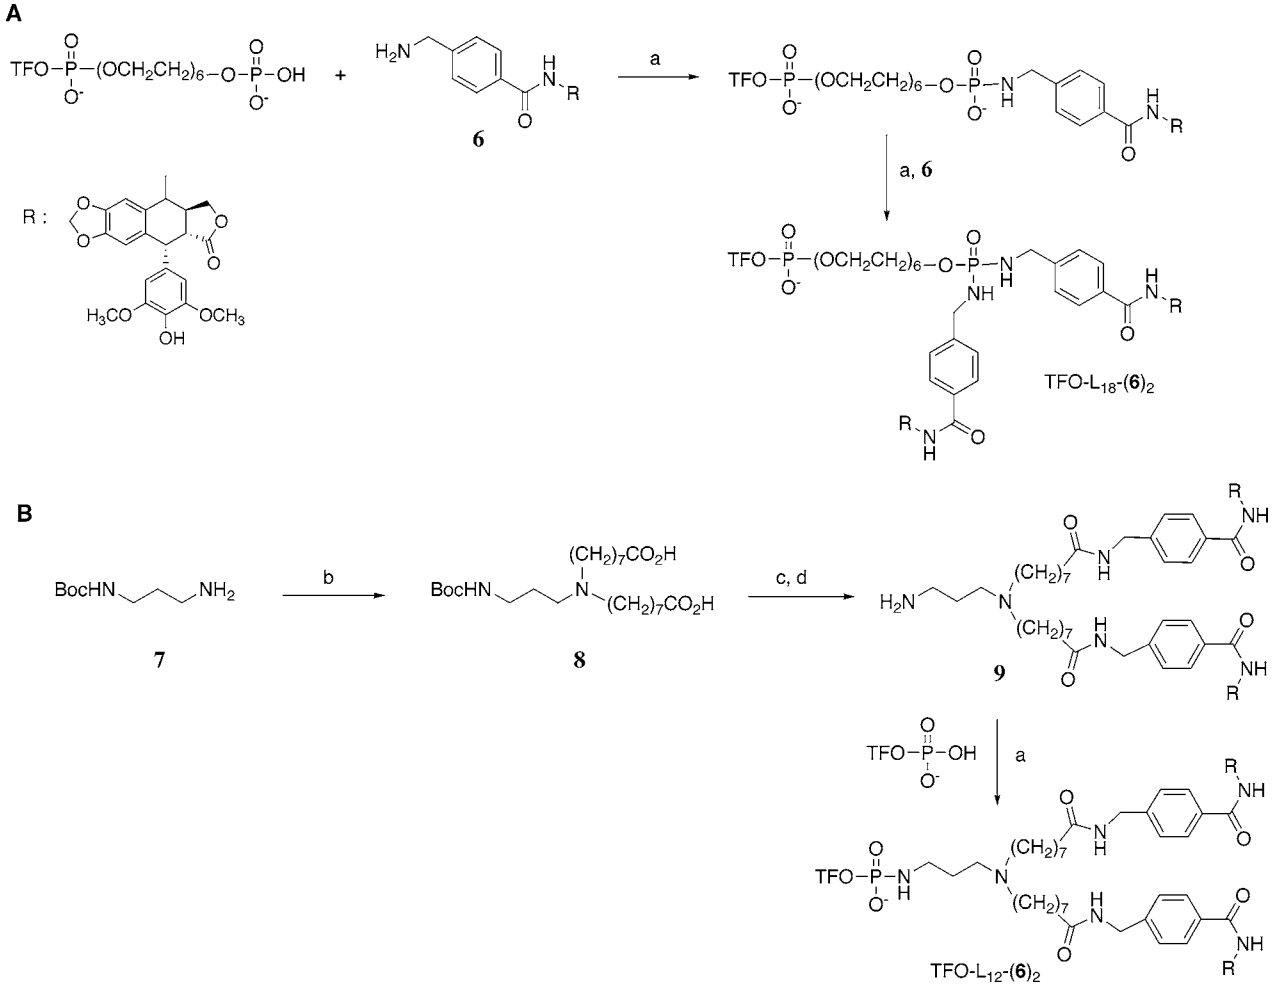
Synthesis of TFO−Topoisomerase II Inhibitors Conjugates. We covalently linked derivatives **1**, **2**, **3**, and **6** to the 3′ or 5′ end of the triple-helix forming oligonucleotides 16TFO and 20TFO. The first generation of conjugates bears one poison per TFO.

The chemical structure of these conjugates is depicted in Figure 2B and their synthesis consisted in the activation of the 3′ or 5′ phosphate group of the oligonucleotides in the presence of DMAP, PPh_3 and $(PyS)_2$, followed by the addition of the topoisomerase II inhibitors, as previously reported (*34*). The known procedure used DMSO as solvent for activation of the phosphate group and subsequent reaction with the amino group of the reacting molecule. However, upon use of this protocol, we observed, by HPLC and mass spectrometry, the formation of a secondary product containing both the topoisomerase II poison and a molecule of triphenylphosphine linked to the TFO. To avoid this side-reaction, the TFO activated by DMAP, PPh_3, $(PyS)_2$ in DMSO was rapidly precipitated in $LiClO_4$/acetone and the coupling reaction to the topoisomerase II poison was conducted in water. In this manner, triphenylphosphine was removed from the reaction mixture leading exclusively to the desired product with an average yield of 60%. Compounds **1**, **2**, **3**, and **6** were thus conjugated to 16TFO, and **1** and **6** to 20TFO, using hexaethylene glycol (L_{18}) as the linker arm. For the choice of the linker arm between the TFO and the poison, we were aware, from our study of TFO conjugates of topoisomerase I poisons, of the importance of optimizing its length. Therefore, we built a molecular model, based on the crystal structure and the model of the interaction of topoisomerases II with DNA (*39*, *43*). We docked two triple helices symmetrically on both sides of the topoisomerase II to evaluate whether there is steric clash in such a multicomponent complex. This model allowed us to evaluate the distance between the triplex and the catalytic tyrosines in the active site of topoisomerase II. The results suggested that an 18-atom linker would be the best length, and thus a hexaethylene glycol (L_{18}) was used to couple the VP16 derivatives to the TFOs. A shorter linker, ethylene glycol (L_3), was also used to conjugate compound **6** to the 3′ end of 16TFO, as a control.

In the second generation of conjugates, two VP16 analogues were attached to the same TFO. This is based on the hypothesis of Osheroff's group (*44*), concerning the stoichiometry of the complex formed by etoposide and topoisomerase II. In fact, eukaryotic topoisomerase II is constituted by a homodimer and thus bears two active sites containing two catalytic tyrosines. For this reason, Osheroff proposed that two molecules of etoposide are necessary to generate a double-stranded break and that one molecule of inhibitor leads to a single-stranded break. A conjugate bearing two molecules of topoisomerase II poisons at its end should thus be more efficient than the one bearing just one molecule. Furthermore, the comparison of the two types of conjugates should help to clarify the stoichiometry of the ternary complex formed during the inhibition of the enzyme. Only compound **6** was chosen to apply this strategy, because it gave better yields in the conjugation reaction and, once coupled to the TFO, it resulted more active against topoisomerase II than when compounds **1** and **3** were conjugated (data not shown). Two synthetic pathways were followed (Scheme 2): (1) the introduction of two compounds directly on the same terminal phosphate group of the hexaethylenglycol linker arm (L_{18}) at the 3′ end of the TFO or (2) the attachment of two molecules of **6** to a trifunctional linker arm (L_{12}), containing an amino group for the further coupling to the phosphorylated TFO. In the first pathway, the reaction is conducted as for the synthesis of the mono-conjugates, but it is repeated two times consecutively. We obtained conjugates 16TFO-L_{18}-(**6**)$_2$ and 20TFO-L_{18}-(**6**)$_2$ with 45% of average yield (Schema 2A). Following the second pathway, we prepared the linker starting from 3-*N*-Boc-1,3-propanediamine (**7**) and 8-bromooctanoic acid, which, in the presence of K_2CO_3 and in acetonitrile, gave the 3-*N*-Boc-aminopropane-1-iminodioctanoic acid (**8**) (Scheme 2B). Coupling of two molecules of **6** was achieved on the two activated carboxyl groups leading to product **9**. This latter, after deprotection of the Boc group by TFA in CH_2Cl_2, led to 3-aminopropane-1-aminodioctanoic acid (L_{12}) linked through the carboxyl groups to the amino group of **6**. Finally, the terminal amino group of **9** was reacted with the activated phosphate of the 20TFO to give 20TFO-L_{12}-(**6**)$_2$ as final product.

Triple Helix Formation by the Conjugates and Topoisomerase II Activity. In the second part of our study the capacity of all synthesized conjugates to form a triple-helix was evaluated. Triplex formation involves major groove binding of the oligonucleotidic part of the conjugates via sequence-specific recognition of the oligopurine strand of the duplex. The binding of the conjugated third strand to the duplex was analyzed by PAGE experiments. Increasing concentration of TFOs were incubated with 10 nM of radiolabeled target duplex in 50 mM HEPES pH 7.2, 10 mM $MgCl_2$, 50 mM NaCl at 37 °C for 2 h (Figure 3). The affinity of all conjugates and of the corresponding TFOs for the target 29 mer duplex was measured and expressed by C_{50} values, i.e. the concentration of TFO necessary to obtain 50% of triplex. Results are reported in Table 1.

Scheme 2. Synthesis of Conjugates Bearing Two Molecules of 6 at the Same End of the TFO by Methods A and B[a]



[a] Reagents: (a) DMAP, PPh_3, $(PyS)_2$, DMSO; (b) 8-bromooctanoic acid, K_2CO_3, CH_3CN; (c) **6** (2 equiv), DCC, HOBt, DMF; (d) TFA, CH_2Cl_2.

C_{50} of 16TFO and 20TFO are 0.46 μM and 0.32 μM, respectively. In the case of the 16mer, the introduction of a L_{18} linker arm at the 3′ end increased the affinity for the duplex, diminishing the C_{50} 4-fold. Interestingly, the shorter linker arm L_3 also increased the affinity. The stabilization induced by the linker arm was only 1.4-fold at the 5′ end.

In general, the conjugation of the poisons to the 16TFO caused, at both ends, a decrease in the affinity, with the exception of compound **3**, which bears the retrolactone modification. Furthermore, conjugation at the 3′ end was more destabilizing than at the 5′ end, even if the 3′ conjugates, however, remained 2 times more stable than the 5′ conjugates. The introduction of two molecules of topoisomerase poison **6** at the 3′ end caused an important loss in triplex affinity (about 40-fold less).

The 20 mer TFO, as expected, formed a more stable triple helix. The presence of a linker arm or the conjugation to VP16 analogues had little effect both at the 3′ and 5′ end. The presence of two molecules of **6** at the 3′ end remained, even in this case, very destabilizing with a loss in affinity of 4- and 7-fold for 20TFO-L_{18}-(**6**)$_2$ and 20TFO-L_{12} -(**6**)$_2$, respectively.

Noteworthy, for all conjugates, 100% of formation of the triple helice was always observed above 5 μM.

Evidence for the triplex formation was further confirmed by DNase I footprinting experiments as depicted in Figure 4. The 324-bp duplex fragment radiolabeled at 5′-end of the oligopurine-containing strand was incubated with the TFOs at 5 μM, and subjected to limited DNase I cleavage. DNase I cleavage was strongly inhibited at the target oligopyrimidine·oligopurine sequence and the footprint was clearly extended with the 20 mer TFOs compared to the 16 mer.

As shown in Table 2, all conjugates induce topoisomerase II-mediated DNA cleavage, at the exception of the conjugates of inactive compound **2** that remain inactives. Noteworthy, the experiments were carried out in conditions under which all conjugates form a stable triple helix. TFO conjugates of poison **3** resulted in the less active ones, while the comparison between 16TFO-L_{18}-**6** and 16TFO-L_3-**6** confirmed that the hexaethylene glycol (L_{18}) is the best linker arm. Finally, the double conjugates showed a comparable activity as the corresponding mono-conjugates.

DISCUSSION

Four 4′-demethylepipodophyllotoxin derivatives were chosen to be covalently attached to triplex-forming oligonucleotides (TFO). As in the case of TFO attached to topoisomerase I poison, these conjugates could be used to target topoisomerase II inhibitors to specific sequences on DNA.

Three of them (**1**, **2**, and **3**) were recently reported as part of a 4-substituted 4′-DMEP series bearing ami-

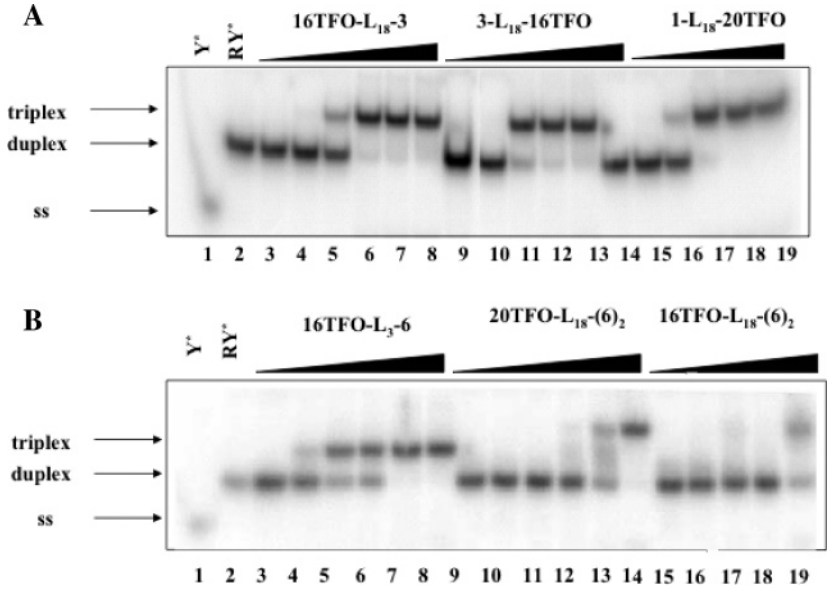


Figure 3. Triplex formation in PAGE experiments. 10 nM of the 29-bp target duplex (RY*, lane 2), 5′-end radiolabeled on the oligopyrimidine-containing strand (Y*, lane 1), was incubated for 2 h at 37 °C in 50 mM HEPES pH 7.2, 10 mM $MgCl_2$ and 50 mM NaCl in the presence of increasing concentrations of (A) 16TFO-L_{18}-**3** (0.01, 0.05, 0.1, 0.5, 1, 5 μM lanes 3−8), **3**-L_{18}-16TFO (0.01, 0.1, 0.5, 1, 5 μM, lanes 9−14), **1**-L_{18}-20TFO (0.01, 0.05, 0.1, 0.5, 1, 5 μM, lanes 15−19); (B) 16TFO-L_3-**6** (0.05, 0.1, 0.5, 1, 2, 5 μM, lanes 3−8), 20TFO-L_{18}-(**6**)$_2$ (0.05, 0.1, 0.5, 1, 2, 5 μM, lanes 9−14) and 16TFO-L_{18}-(**6**)$_2$ (0.05, 0.1, 0.5, 1, 5 μM, lanes 15−19), and then loaded on a 15% nondenaturing polyacrylamide gel. The shifts corresponding to single-stranded DNA (ss), duplex and triplex are indicated by arrows.

Table 1. C_{50} Values for 29R·29Y* TFO Triplexes[a]

TFOs	C_{50} (μM)
16TFO	0.46 ± 0.09
16TFO-L_{18}	0.11 ± 0.09
16TFO-L_{18}-**1**	0.47 ± 0.10
16TFO-L_{18}-**2**	0.30 ± 0.08
16TFO-L_{18}-**3**	0.17 ± 0.02
16TFO-L_{18}-**6**	0.39 ± 0.08
L_{18}-16TFO	0.33 ± 0.04
1-L_{18}-16TFO	0.74 ± 0.10
2-L_{18}-16TFO	0.65 ± 0.05
3-L_{18}-16TFO	0.33 ± 0.02
6-L_{18}-16TFO	0.59 ± 0.05
16TFO-L_3	0.14 ± 0.02
16TFO-L_3-**6**	0.20 ± 0.01
16TFO-L_{18}-(**6**)$_2$	4.1 ± 0.3
20TFO	0.32 ± 0.02
20TFO-L_{18}	0.27 ± 0.01
20TFO-L_{18}-**1**	0.38 ± 0.03
20TFO-L_{18}-**6**	0.32 ± 0.03
L_{18}-20TFO	0.30 ± 0.09
1-L_{18}-20TFO	0.27 ± 0.02
6-L_{18}-20TFO	0.48 ± 0.08
20TFO-L_{18}-(**6**)$_2$	1.3 ± 0.1
20TFO-L_{12}-(**6**)$_2$	2.2± 0.1

[a] The C_{50} values were calculated as the concentrations at which 50% of triplex is formed and an average value corresponding to three different experiments is reported. 29R·29Y (20 nM) was incubated at 37°C for 2 h with increasing concentrations of TFOs in 50 mM HEPES buffer (pH 7.2) containing 50 mM NaCl and 10 mM $MgCl_2$.

noalkyl chains in the 4-position linked by a carbamate group (*29*). In this series, some compounds showed an activity on topoisomerase II comparable to etoposide and even better activity in antitumor assays. The most active compounds contained an *N*,*N*-dimethyl group at the end of the side chain unsuitable for conjugation to TFOs. We thus designed **1**−**3** with a NH_2 group in the aim to conjugate them directly to the phosphate group at the end of the oligonucleotide. Compounds **1** and **3** are still active as topoisomerase II inhibitors, while compound **2** is an example of inactive compound. Interestingly, when **1** and **3** are conjugated to the TFO, they could eventually become more similar to most active compounds of the series because the terminal NH_2 is substituted by the phosphate group of TFO. In addition to these three drugs, we synthesized a new derivative of 4′-DMEP bearing an arylamino side chain linked in the 4-position via an amide group (compound **6**). The choice for such a chain is based on a work devoted to a series of derivatives previously synthesized by Zhou et al. (*42*) that were shown to be active topoisomerase II poisons.

All four VP16 analogues were conjugated to a 16mer TFO through a linker arm, a hexaethylene glycol (L_{18}), attached either at the 3′ end or the 5′ end. Analogues **1** and **6** were also linked, via the L_{18} linker arm, to a 20mer TFO directed against the extended oligopurine·oligopyrimidine duplex sequence. The previously described coupling reaction (*45*) was here further improved and carried out in a water/DMSO mixture in order to eliminate all secondary products and to obtain exclusively the desired product.

We investigate the influence on the triplex stability of: (i) the length of the TFO, a 16-mer vs a 20-mer, (ii) the linker arm, L_3 vs L_{18}, (iii) the modifications of the topoisomerase II poisons (compounds **1**, **2**, **3**, and **6**) and (iv) their position on the TFO, attachment to the 3′ end vs 5′ end. Triplex formation by the conjugates was evaluated by gel retardation assay that allowed us to obtain C_{50} values. The results were further confirmed by DNase I footprinting experiments.

Interestingly, the presence of the phosphorylated linker arm alone has a stabilizing effect in the case of 16TFO. The choice for such a long linker chain was based on reported data suggesting that topoisomerase II protected both strands of DNA over 25-bp region, in which the cleavage site was centrally located (*46*). In addition, Spizner et al. (*47*) have shown that the enzyme might need an accessible 10-bp double-helical region around the cleavage site to efficiently interact and cleave DNA. According to these observations, a relatively long linker, such as the L_{18}, should be the most appropriate in order

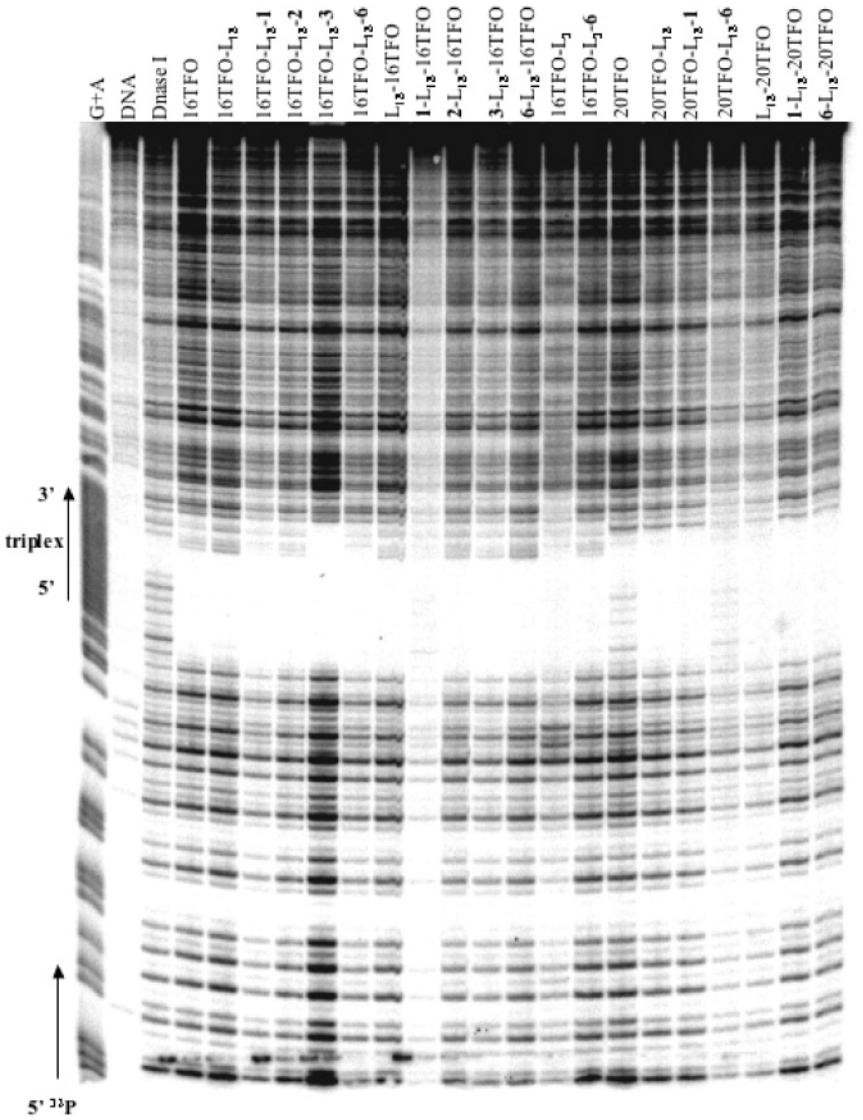

Figure 4. Sequence analysis of the DNase I footprinting experiments on the 324-bp target duplex radiolabeled at the 5′ end of the oligopurine strand in the presence of some TFO conjugates. Control TFOs and conjugates were added at 5 μM. The triplex site and its orientation are indicated by an arrow. Adenine/guanine-specific Maxam−Gilbert chemical cleavage reactions were used as markers.

to access the drug to the catalytic site of topoisomerase II and to prevent steric hindrance between the triple-helical structure and the enzyme.

Noteworthy, the tethered 4′ DMEP derivatives are now able to bind to DNA through the oligonucleotidic part of the conjugate and specifically to the triplex target (as shown by the DNase footprinting experiments). The tethering to the TFOs does not hamper the activity of the 4′ DMEP derivatives against topoisomerase II (Table 2). In the case of compound **2**, an example of inactive topoisomerase II poison, it remains inactive even when conjugated to the TFO. This is different from what is observed with camptothecin, a topoisomerase I poison, for which the conjugation of an inactive derivative to the TFO is able to convert it to an active topoisomerase I poison (*48*). Concerning triplex formation, the conjugation of the poison decreased, as expected, the affinity of the TFOs for the target duplex, the worst cases being the conjugates bearing two molecules of poisons linked to the same TFO end. This destabilization effect is more pronounced at the 3′ end than at the 5′ end, even if 3′ conjugates remain more stable than the respective 5′ conjugates. An exception is compound **3**, bearing the retrolactone, which was comparable in affinity to the 16TFO attached to the linker arm both in the 3′ end or 5′ end. The observed destabilization effect can be explained by the mechanism of action of these poisons. In fact, these molecules do not interact with DNA (*29*), but rather with the enzyme (*49*). The absence of interaction of these latter conjugates with DNA can explain, in part, the absence of stabilization of the triple-helical structure. Other topoisomerase II poisons families, such as amsacrines and antracyclines that intercalate into DNA, induce a stabilization of the triple-helical structure when conjugated to a TFO. In this context, it was shown that daunomycin strongly stabilized triplex formation when conjugated to the 5′ end (*10*, *50*); although no effect was observed at the 3′ end of the triplex (*10*). In the case of amsacrine (mAMSA), an acridine derivative inhibitor of topoisomerase II, a slight stabilization of the triplex structure was obtained when an amsacrine derivative was tethered to the 5′ end of the TFO (*51*). Linkage of the amsacrine derivative to the 3′-end of the TFO decreased triplex stability and the destabilizing effect was less pronounced with the conjugate containing a longer linker side chain (an hexaethylene glycol).

Interestingly, in this study, the 5′ end conjugates were 2-fold less stable than the 3′ end conjugates. This can be

[a] An average value corresponding to three different experiments is reported. [b] Drugs were evaluated at 50 μM, conjugates at 1 μM at the exception of the double conjugates that were evaluated at 10 μM.

explained, in part, by the fact that triplex formation seems to nucleate at the 5′ end of the triplex (*52*, *53*), and thus the presence of the drug at this end might interfere with the nucleation step and be more destabilizing. In agreement, the above-cited studies, together with previous ones (*54*), have demonstrated that the stabilizing effect of an intercalating drug is more important at the 5′ triplex/duplex junction than on the 3′ side.

Finally, in the case of the more stable 20TFO, very little differences were observed with the exception of the double conjugation that was very destabilizing for triplex formation, even if the effect was less than in the case of 16TFO. The higher affinity of the 20mer compared to the 16mer seems to abolish the differences due to the energetic penalty for the presence of the DNA-noninteracting molecule.

At last, we synthesized TFO conjugates containing two molecules at the same end, either both attached directly to the same phosphate at the end of the linker arm of the TFO (TFO-L_{18}-(**6**)$_2$), or each one attached to a linker arm further conjugated at the same phosphate at the extremity of the TFO (20TFO-L_{12}-(**6**)$_2$). These are the first examples of such a type of conjugates. All three double conjugates showed an important loss in triplex stability, but 100% of formation of triplex was still observed at pH 7.2 and 37 °C at high concentrations (>5 μM). Moreover, the importance of such conjugates resides in the fact that topoisomerase contains two subunits and thus two active sites (two Tyr^{804} for human topoisomerase II). This implies that there may be two sites available for the drug in every cleavage complex (*44*). These double-poison conjugates should represent a priori an important tool for the investigation of such a molecular mechanism. We observed, however, that their ability to stimulate DNA-cleavage on a 96-bp radiolabeled DNA fragment is comparable to that of the mono-conjugate (Table 2).

In conclusion, we synthesized a new poison of topoisomerase II derived from 4′-DMEP. This compound, together with other 4′-DMEP analogues previously reported, was conjugated to triplex-forming oligonucleotides with an average yield of 60%. We then evaluated the stability of the formed triplex and defined the best features for stability. Unexpectedly, the phosphorylated poly(ethylene glycol) linker arm increased the triplex stability and compensated for the presence of the 4′ DMEP derivatives that do not interact with DNA. The 20-mer conjugates form triplexes with comparable stability as the unlinked 20TFO. In the case of the 16mers, conjugation to the 3′ end is preferable to conjugation to the 5′ end. Finally, the conjugates retain the anti-topoisomerase II activity.

Received February 14, 2005; Revised Manuscript Received April 25, 2005

Hydrazinonicotinamide (HYNIC) forms stable coordination complexes with Tc-99m when reacted with Tc(V)oxo species such as Tc-mannitol or other Tc-polyhydric complexes. However, radio-HPLC of [Tc-For-MLFK-HYNIC] labeled via Tc-polyhydric ligands demonstrated multiple radiochemical species each with unique biodistribution patterns. This is likely due to the fact that Tc can bind to the hydrazino moiety, as well as polyhydric ligands, in a variety of coordination geometries. Tridentate ligands, such as bis(mercaptoethyl)methylamine (NS_2), may constrain the possible coordination geometries and improve overall stability. To investigate this, we synthesized NS_2, converted the [Tc-mannitol-For-MLFK-HYNIC] to the corresponding NS_2-containing complex [Tc-NS_2-For-MLFK-HYNIC], and compared its infection imaging and biodistribution properties with [Tc-mannitol-For-MLFK-HYNIC]. Conversion to the NS_2 complex was confirmed by HPLC which showed a single unique hydrophobic species with retention time greater than the [Tc-mannitol-For-MLFK-HYNIC] complex. Imaging experiments with both preparations were performed in rabbits with *E. coli* infections in the left thigh. Tissue radioactivity measurements demonstrated that compared to Tc-mannitol-peptide, accumulation of Tc-NS_2-peptide was lower in blood, heart, and normal muscle and higher in spleen, infected muscle, and pus ($p < 0.01$). These results indicate that the Tc-NS_2-peptide complex is chemically more homogeneous and exhibits improved infection localization and biodistribution properties. In an effort to model the interactions of the metal-HYNIC core with NS_2 and related ligand types, the reactions of $[ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ and $[^{99}TcCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$, effective structural analogues for the $\{M(NNC_5H_4NH_x)_2\}$ core, with NS_2, C_5H_3N-2,6-$(CH_2SH)_2$, $O(CH_2CH_2SH)_2$, and $S(CH_2CH_2SH)_2$ were investigated and the compounds $[M\{CH_3N(CH_2CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N]$ (M = ^{99}Tc (**5a**), Re (**5b**)), $[Re\{C_5H_3N$-2,6-$(CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]\cdot CH_2Cl_2\cdot 0.5MeOH$ (**7**), $[Re\{SCH_2CH_2)_2O\}(NNC_5H_4N)(NHNC_5H_4N)]$ (**8**), and $[Re\{(SCH_2CH_2)_2S\}(NNC_5H_4NH)(NHNC_5H_4N)]Cl$ (**9**) were isolated. Similarly, the reaction of $[ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ with the bidentate ligands pyridine-2-methanethiol and 3-(trimethlysilyl)pyridine-2-thiol led to the isolation of $[ReCl(C_5H_4N$-2-$CH_2S)(NNC_5H_4N)(NHNC_5H_4N)]$ (**10**) and $[Re(2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3)_2(NNC_5H_4N)(NHNC_5H_4N)]$ (**11**), respectively, while reaction with *N*-methylimidazole-2-thiol yielded the binuclear complex $[Re(OH)Cl(SC_3H_2N_2CH_3)_2(NNC_5H_4N)_2(NHNC_5H_4N)_2]$ (**12**). The analogous metal-(HYNIC-OH) precursor, $[ReCl_3\{NNC_5H_3NH(CO_2R)\}\{NHNC_5H_3N(CO_2R)\}]$ (R = H, **13a**; R = CH_3, **13b**) has been prepared and coupled to lysine to provide $[RCl_3\{NNC_5H_3NH(CONHCH_2CH_2CH_2CH_2CH(NH_2)CO_2H)\}\{NHNC_5H_3NH(CONHCH_2CH_2CH_2CH_2CH(NH_2)CO_2H)\}]\cdot 2HCl$ (**14**·2HCl), while the reaction of the methyl ester **13b** with 2-mercaptopyridine yields $[Re(2\text{-}SC_5H_4N)_2\{NNC_5H_3N(CO_2Me)\}\{NHNC_5H_3N(CO_2Me)\}]$ (**15**). While the chemical studies confirm the robustness of the M-HYNIC core (M = Tc, Re) and its persistence in ligand substitution reactions at adjacent coordination sites of the metal, the isolation of oligomeric structures and the insolubility of the peptide conjugates of **13**, **14**, and **15** underscore the difficulty of characterizing these materials on the macroscopic scale, an observation relevant to the persistent concerns with reagent purity and identity on the tracer level.

INTRODUCTION

The ability to incorporate readily available radionuclides with optimal decay characteristics into tracer molecules has been the foremost consideration in developing diagnostic radiopharmaceuticals. In this respect, technetium-99m is the ideal choice, and its use in nuclear medicine is well-established (*1*−*14*). This preferential use of ^{99m}Tc radiopharmaceuticals reflects the optimal nuclear properties of the isotope as well as its convenient availability from commercial generator columns. The half-life of ^{99m}Tc of 6 h and the absence of tissue-damaging corpuscular radiation allow the injection of activities of more than 30 mCi with low radiation exposure to the patient (*4*). The half-life is sufficiently long to carry out the labeling syntheses and the scintigraphic measure-

ments without significant losses in activity. Furthermore, the energy of the emitted photons of 140 keV is sufficient to study organs lying deep in the body and can be collimated so as to be detected effectively with NaI(T1) scintillation counters. Finally, the relatively stable ^{99m}Tc isotope may be used to develop technetium chemistry and to model technetium radiopharmaceuticals (*15*, *16*).

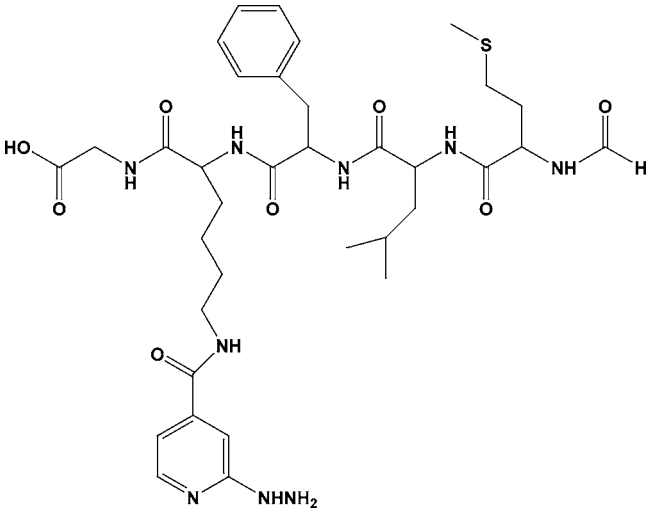
One approach to radiopharmaceutical design exploits radiolabeled biologically active compounds or drugs. For example, radiolabeled antibodies have been developed to target sites of cancer, cardiovascular, and other diseases (*1*−*3*, *17*). Similarly, the area of small-molecule receptor binding radiopharmaceuticals has witnessed significant development (*2*, *18*). These two strategies are conceptually related, differing only the size of the receptor binding molecule, which may be 1000 kD for antibodies and 2500 kD or less for small molecule receptor binding radiopharmaceuticals.

The use of bifunctional chelates offers one strategy for the linking of radioactive metal cations to macromolecules. The construction of effective radioimmunoconjugates requires selection of an appropriate metal radionuclide and organic chelating agent combination, along with the strategy and conditions for assembling the metal-chelating agent−antibody complex. The bifunctional ligand serves two purposes: to hold the metal radionuclide securely without leakage in vivo and to provide a sidearm for antibody linkage while maintaining maximum antibody integrity.

While numerous examples of labeled conjugates have been investigated, improved bifunctional ligands for efficient and stable incorporation of radiometallic nuclides under mild conditions must be developed to overcome the significant problems often associated with this technology, such as nonspecific binding of the radionuclide, protein denaturation under the conditions required for chelation of the metal, and slow kinetics of radionuclide-labeling. Our original efforts in technetium coordination chemistry (*19*) were directed toward this end and resulted in the development of a series of bifunctional hydrazine ligands which have proved effective and versatile linkers for labeling antibodies and fragments (*20*−*22*). Specifically, when *N*-oxysuccinimidylhydrazinonicotinamide is combined with a macromolecule such as a protein, polypeptide, or glycoprotein in neutral or slightly basic media, the protein-reactive part of the compound reacts with nucleophilic groups in the macromolecule, such as the amine groups of lysine residues, to yield a conjugate containing free hydrazine/hydrazide groups, referred to as HYNIC-protein. In fact, since our initial report of the labeling of polyclonal IgG with ^{99m}Tc-HYNIC (*19*), HYNIC has been employed as a bifunctional chelator for ^{99m}Tc-labeling of proteins (*23*), as well as small biomolecules including somatostatin analogues (*24*), liposomes (*25*), antisense oligonucleotides (*26*), folate receptor ligands (*27*), and polypeptides and other small molecules (*28*, *29*).

The versatility of this HYNIC-linker technology has also been demonstrated recently in the preparation of conjugates of chemotactic peptides, which bind to high affinity receptors on white blood cell membranes and thereby migrate to sites of infection (*30*). The advantages of this type of molecule over antibodies include smaller size and enhanced diffusibility to the extravascular space, faster blood clearance resulting in lower background radiation, the presence of well-defined receptor systems, and the ability to synthesize analogues of these peptides with varying size, charge, and linker properties (*31*).

Scheme 1. For-MLFK−(N$^{\epsilon}$-HYNIC)G



Specifically, For-MLF is a bacterial product that is known to initiate leukocyte chemotaxis by binding to high affinity receptors on the white blood cell membrane (*32*−*34*). These receptors are present on both PMNs and mononuclear phagocytes. As granulocytes respond to the chemoattractant gradient, the affinity of the receptors decreases as additional receptors are expressed, until the granulocyte reaches the site of inflammation, where the concentration of chemoattractant is greatest (*35*−*37*). Previous studies have demonstrated that many synthetic analogues of these small, *N*-formylmethionyl peptides bind to neutrophils and macrophages with equal to or greater affinity compared to the native peptide (*38*−*40*). On the basis of this information, it has been hypothesized that chemoattractant peptide analogues that can be readily radiolabeled with radionuclides suitable for external imaging might be effective agents for the rapid localization of focal sites of inflammation.

We have developed chemotactic peptides which incorporate the ^{99m}Tc binding group HYNIC (hydrazinonicotinamide) (Scheme 1) (*20b*). This complex agent when added to the lysine extended C-terminus of the peptide sequence enabled robust labeling at high specific activity. Separation of the unlabeled peptide from the technetium-labeled peptide was easily achievable on HPLC and facilitated by the nature of the starting technetium complex. Animal studies with high specific activity, technetium-labeled HYNIC chemotactic peptides showed significant improvement over the In-111-DTPA peptides, and comparisons to the clinically accepted imaging agents such as In-111 white blood cells and In-111-IgG demonstrated greater target accumulation and lesion-to-normal tissue ratios exceeding that of the latter two agents (*20a*).

However, radio-HPLC of [^{99}Tc-For-MLFK-HYNIC], labeled using Tc-polyalkoxy ligand complexes, demonstrated multiple radiochemical species with unique biodistribution patterns (*20d*). This observation is likely a consequence of the tendency of Tc to bind to the hydrazino moiety, as well as polyalkoxy ligands, in a variety of coordination geometries (*41*). The recognition that the identity of the polyalkoxy coligand could dramatically influence the biological distribution of the ^{99m}Tc-labeled HYNIC-derivatized chemotactic peptides led to the development of a variety of potential coligands to increase the solution stability and minimize the number of isomers. Coligand development has focused on monodentate water-soluble phosphines (*21c*, *29a*), bidentate nitrogen−sulfur donors (*41*), and a variety of polydentate

alkoxy-based ligands (*20f*, *42*). However, tridentate ligands would ideally constrain the available coordination sites about the $\{M(\mu^2\text{-}NHNC_5H_3NR)(\mu^1\text{-}NNC_5H_3NR)\}^{2+}$ core. Furthermore, the affinity of this metal-bishydrazino core for nitrogen and sulfur donors suggests that tridentate ligands based on the bis(mercaptoethyl)methyamine (NS_2) prototype would effectively constrain the possible coordination geometries and improve overall stability. To investigate this hypothesis, we synthesized NS_2, converted the [^{99}Tc-mannitol-For-MLFK-HYNIC] to the corresponding NS_2-containing complex [Tc-NS_2-For-MLFK-HYNIC], henceforth [Tc-NS_2-HYNIC-peptide], and compared its infection imaging and biodistribution properties with [^{99}Tc-mannitol-For-MLFK-HYNIC]. HPLC, ROI analysis, and tissue radioactivity measurements indicate that the [Tc-NS_2-HYNIC-peptide] complex is chemically homogeneous and exhibits improved infection localization and biodistribution properties.

To provide a structural basis for the interaction of the {Tc-HYNIC} core with NS_2 and related ligand types, the reaction of $[MCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ (M = Tc, Re) with $CH_3N(CH_2CH_2SH)_2$ (NS_2), C_5H_3N-2,6-$(CH_2SH)_2$, $O(CH_2CH_2SH)_2$, and $S(CH_2CH_2SH)_2$, as well as the bidentate N,S-donor ligands pyridine-2-thiol, 3-(trimethylsilyl)pyridine-2-thiol, and *N*-methyl-imidazole-2-thiol, were investigated. The resulting thiolate derivatized complexes of the {M-HYNIC} core, $[M\{CH_3N(CH_2CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]$ (M = Tc (**5a**), Re (**5b**)), $[Re\{C_5H_3N\text{-}2,6\text{-}(CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]\cdot CH_2Cl_2\cdot 0.5MeOH$ (**7**), $[Re\{O(CH_2CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]$ (**8**), $[Re\{(SCH_2CH_2)_2S\}(NNC_5H_4NH)(NHNC_5H_4N)]Cl$ (**9**), $[ReCl(C_5H_4N\text{-}2\text{-}CH_2S)(NNC_5H_4N)(NHNC_5H_4N)]$ (**10**), $[Re(2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3)_2(NNC_5H_4N)(NHNC_5H_4N)]$ (**11**), and the unexpected binuclear species $[Re_2(OH)Cl(SC_3H_2N_2CH_3)_2(NNC_5H_4N)_2(NHNC_5H_4N)_2]$ (**12**), were characterized spectroscopically, and in the instances of **5b**, **7**, **9**, **10**, and **12** by X-ray crystallography. In addition, the 6-hydrazinonicotinic acid analogues $[ReCl_3\{NNC_5H_3NH(CO_2R)\}\{NHNC_5H_3N(CO_2R)\}]$ (R = H, **13a**; R = CH_3, **13b**) have been prepared, structurally characterized, and coupled to lysine to give $[ReCl_3\{NNC_5H_3NH(CONHCH_2CH_2CH_2CH(NH_2)CO_2H)\}\{NHNC_5H_3NH(CONHCH_2CH_2CH_2CH(NH_2)CO_2H\}]\cdot 2HCl$ (**14**·2HCl). The reaction of **13** with 2-mercaptopyridine provided the model compound $[Re(2\text{-}SC_5H_4N)_2\{NNC_5H_3NH(CO_2Me)\}\{NHNC_5H_3N(CO_2Me)\}]$ (**15**) whose structure has also been confirmed by X-ray crystallography. Attempts to prepare metalated conjugates of the For-MLFK-HYNIC either by reactions of rhenium precursors with For-MLFK-HYNIC or of **14** with For-MLF under appropriate conditions yielded only insoluble materials which could not be analyzed by NMR or mass spectrometry. These observations emphasize the difficulty of characterizing the metalated conjugates on the macroscopic scale, which has rendered the characterization of materials on the tracer scale problematic.

MATERIALS AND METHODS

Materials. Polystyrene-based *N*-α-9-fluorenylmethoxycarbonyl (Fmoc)-glycine-loaded SASRIN resin (0.69 mmol g^{-1}, 1% divinylbenzene, 200−400 mesh) was obtained from Bachem Inc. Fmoc-protected amino acids were purchased from NovaBiochem Inc., Bachem Inc., and Advanced ChemTech Inc.

N-Formyl-MLFK was prepared on an Advanced ChemTech 348Ω peptide synthesizer using a 40-well reaction vessel. Peptides were analyzed by electrospray mass spectrometry using a Micromass Quattro Ultima instrument in positive ion mode. Samples were dissolved in 50/50 acetonitrile/H_2O prior to analysis. Analytical HPLC was performed using a Varian Pro Star model 330 PDA detector, model 230 solvent delivery system and a C-18 Microsorb column (4.6 × 250 mm, 300 Å-5 μm). Semipreparative HPLC was carried out using a Varian Pro Star HPLC fitted with a model 320 μv-detector, a model 215 solvent delivery system, and a C-18 Microsorb column (10 × 250 mm, 300 Å-5 μm). The elution protocol for both analytical and semipreparative experiments was a linear gradient of 5% acetonitrile containing 0.1% TFA to 100% acetonitrile containing 0.1% TFA over 20 min. The flow rates were 1.0 mL min^{-1} and 4.2 mL min^{-1} for the analytical and semipreparative experiments, respectively. All analytical HPLC experiments were monitored at λ = 254 and 214 nm.

HYNIC acid and succinimidyl-6-tBOC-hydrazinopyridine-3-carboxylic acid were prepared by literature procedures (*20b*). Ammonium perrhenate (Aldrich), 2-mercaptoethyl ether (Aldrich), and triethylamine (Aldrich) were used as received without further purification. The synthetic precursor $[ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ was synthesized by published procedures (*43*) as was the pyridine-2-thiol-3-trimethylsilane (*44*). All the other chemical reagents were purchased from Aldrich and were used without purification.

Technetium-99m-pertechnetate (^{99}Mo/^{99m}Tc generator) and stannous glucoheptonate kits (Glucoscan) were obtained commercially from Dupont radiopharmaceutical division (Bilerica, MA). New Zealand white rabbits (2.5−3 kg) were purchased from Charles River Breeding Laboratories (Boston, MA).

Melting points were determined with a Thomas-Hoover capillary melting point apparatus and are uncorrected. TLC was performed on EM Science 250 μ Silica Gel F254 plates with fluorescent indicator and spots were detected with UV light. Mass spectra were measured on a JEOL JMS-D300 spectrometer.

NMR spectra were recorded on a General Electric QE 300 (^{1}H 300.10 MHz) spectrometer in CD_2Cl_2(δ 5.32) or $(CD_3)_2SO$ (δ 2.50). IR spectra were recorded as KBr pellets with a Perkin-Elmer Series 1600 FTIR. Elemental analysis for carbon, hydrogen, and nitrogen were carried out by Oneida Research Services, Whitesboro, NY.

CAUTION: ^{99}Tc is a weak β-emitter (293 keV). All experiments involving ^{99}Tc were performed in a laboratory designed for and devoted exclusively to the preparation of radioactive materials. Due to strong possibility of contamination, and current licensing regulations for our laboratory, ^{99}Tc-containing species were characterized only by X-ray crystallography and/or elemental analyses.

Preparation of *N*,*N*-Bis(2-mercaptoethyl)methylamine, $CH_3N(CH_2CH_2SH)_2$ (NS_2). All procedures were carried out under an atmosphere of purified dinitrogen. Bis(2-chloroethyl)amine hydrochloride (0.60 g, 0.33 mmol) was dissolved in 25 mL of DMF. Triphenylmethly mercaptan (2.00 g, 7.20 mmol) was added. This was followed by slow addition of 1,8-diazabicyclo[5.4.0]undec-7-ene (1.73 mL, 11.6 mmol) under a nitrogen atmosphere. The reaction was heated at 100 °C for 1 h. The solvent was evaporated, and the residue was dissolved in EtOAc. The solution was first washed with water, then brine, and was dried over sodium sulfate. The solvent was evaporated to give the crude product, which was purified by a short column pretreated with 10 mL of NEt_3 (10% EtOAc/hexane) to give 1.86 g (3.11 mmol, 94%) of bis(2-triphenylmethylsulfidoethyl)amine (**2**) as a yellow solid. IR (KBr, cm^{-1}): 3022 (w), 1596 (m), 1494 (m), 1444 (m), 1262 (w), 1155 (w), 1078 (m), 1031 (m), 919 (w), 804 (w),

758 (m), 734 (s), 700 (s), 658 (m), 620 (w), 605 (m), 493 (w), 468 (w).

Amine **2** (1.86 g, 3.11 mmol) was dissolved in 50 mL of DMF and 10 mL of acetonitrile. Formaldehyde (1.17 mL, 15.6 mmol) was then added. This was followed by the addition of sodium cyanoboron hydride (0.31 g, 4.98 mmol). Ten minutes later, 0.25 mL of acetic acid was added to neutralize the solution. The reaction was stirred at room temperature for 2 h before it was poured into 1 N NaOH (200 mL). The mixture was then extracted with 50% EtOAc/hexane. The organic extracts were combined and washed with brine and dried over sodium sulfate. The mixture was concentrated to give a crude product, which was purified by a short column to give bis(2-triphenylmethylsulfidoethyl)methylamine (**3**) (1.16 g, 1.87 mmol, 61%) as a white solid. IR (KBr, cm^{-1}): 3055 (2), 2345 (w), 1594 (w), 1490 (s), 1444 (s), 1285 (w), 1183 (w), 1034 (w), 742 (s), 700 (s), 622 (m), 565 (w).

Amine **3** (0.10 g, 0.16 mmol) was dissolved in 0.5 mL of methylene chloride. Trifluoroacetic acid (0.5 mL) was then added, and the solution turned yellow. Excess triethylsilane (0.16 mL, 0.98 mmol) was then added dropwise under an out flow of nitrogen, and the reaction turned colorless. The reaction mixture was evaporated to dryness. Hexane (0.5 mL) was added and then decanted. This was repeated three times. The residue was then vacuum-dried to give NS_2 as a white solid (0.04 g) which was used without further purification. IR (KBr, cm^{-1}): 1677 (m), 1596 (m), 1494 (m), 1444 (m), 1199 (s), 1078 (w), 1031 (m), 758 (m), 734 (m), 700 (s), 658 (w), 620 (w), 606 (m), 493 (w), 468 (w).

Chemotactic Peptides. *(a) For-MLFK(N$^{\epsilon}$-HYNIC).* N-For-MLFK was synthesized and purified by standard solid-phase techniques and conjugated with nicotinyl hydrazine to yield N-For-MLFK(N$^{\epsilon}$-HYNIC). The final product was characterized by UV, and mass spectrometry, amino acid analysis, f-MLF receptor binding affinity, and biological activity as previously reported (*20b*).

(b) For-MLFK(N$^{\epsilon}$-HYNIC)G. Fmoc-glycine-loaded SASRIN resin (150 mg/well, 0.69 mmol/g) was added to two wells of the reaction vessel (rv), suspended in DMF (2 mL/well), and shaken at 600 rpm for 1 min. The wells were subsequently filtered, suspended in THF (2 mL/well), shaken at 600 rpm for 1 min, and drained for 90 s. The THF wash was repeated two more times. The DMF wash was then repeated a final two times to complete the general wash cycle. This procedure was used between every deprotection and coupling step.

Fmoc deprotection was accomplished through the addition of a 20% v/v piperidine−DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 600 rpm. Following filtration, the process was repeated, shaking for 10 min. The deprotected resin-bound amino acid was washed using the general wash procedure and subsequently coupled to the next Fmoc-protected amino acid using a standard HBTU coupling technique.

Coupling reactions initially involved adding DMF (200 μL) to the active vessels followed by the addition of a 5-fold excess of the protected amino acid as a 0.5 M solution in DMF. Five equivalents of HBTU as a 0.5 M solution in DMF was then added followed by a 10-fold excess of DIPEA as 2.0 M solution in DMF. The reaction block was subsequently shaken for 80 min at 600 rpm. Following filtration, the resin was washed using the general washing procedure prior to the start of the next cycle. This procedure was repeated to afford the peptide, f-MLFK(N$^{\epsilon}$-Dde)G, while still attached to the resin.

Dde deprotection of f-MLFK(N$^{\epsilon}$-Dde)G was accomplished through the addition of a 2% v/v hydrazine−DMF solution to the active vessels (2 mL/well) and shaking for 5 min at 600 rpm. Following filtration, the process was repeated, shaking for 10 min. The epsilon free amine was then subjected to the general wash cycle and coupled to the HYNIC acid using the HBTU protocol described above, followed with a final wash prior to deprotection.

The peptide was cleaved from the resin support using a TFA cocktail containing EDT (2%), water (2%), and TIS (2%). The cleavage cocktail, cooled to 0° C, was added to the resin and the mixture allowed to warm to room temperature over 60 min. The suspension was filtered into cold diethyl ether and the resulting heterogeneous solution centrifuged at 3000 rpm and −5 °C for 10 min. The resultant pellet was washed with cold ether (3 × 25 mL), dissolved in distilled−deionized water, and lyophilized yielding a white solid. fMLFK(N$^{\epsilon}$-HYNIC)G: ESMS-(+ve) $m/z = 758.4$ (calculated 757.9), HPLC $t_R = 10.2$ min. The final product was characterized by UV and mass spectrometry, amino acid analysis, f-MLF receptor binding affinity, and biological activity as previously reported (*20b*).

Radiolabeling. *^{99m}Tc-Mannitol.* A solution of Sn(II) mannitol was prepared by dissolving 800 mg of mannitol (Aldrich) in dilute HCl followed by the dropwise addition of stannous chloride (1 mg in 0.1 cm^3 6 N HCl). The solutions were purged with nitrogen prior to and during manipulation. The pH of the final Sn(II) mannitol solution was adjusted to between 5 and 6 with NaOH. The final ligand concentration was ca. 80 mg/mL and the Sn(II) concentration [as $Sn(II)Cl_2$] was 100 mg/mL. The solution was filtered using a 0.22 mm Millex GS filter, and 0.5 mL aliquots were transferred to sterile rubber-stoppered glass vials, purged with N_2, and stored at −70 °C until use.

^{99m}Tc-mannitol was prepared by adding 2.0 mL of $\{^{99m}TcO_4\}^-$ in saline to a 0.5 mL aliquot of Sn(II) mannitol solution. The mixture was vortexed briefly and incubated at room temperature for 5 min before radiochemical analysis. The final concentration of radioactivity was 5−10 mCi/mL. Radiochemical analysis was performed by ITLC-sg with acetone and saline as the mobile phases. The R_fs of ^{99m}Tc-mannitol were 0.0 and 1.0 in acetone and saline, respectively. The potential impurities, unreduced TcO_4^- and reduced hydrolyzed TcO_2 have R_fs of 1.0 and 0.0 in these solvent systems.

^{99m}Tc-Labeling of Chemotactic Peptides. The following procedure was used to radiolabel the chemotactic peptide analogues with ^{99m}Tc. Twenty microliters of peptide solution (1 mg/mL in dimethyl sulfoxide) was transferred to a clean glass vial and diluted with 500 μL of 0.1 M acetate buffer (pH 5.2). ^{99m}Tc-mannitol solution (500 μL) was added and vortexed briefly, and the reaction mixture was incubated to room temperature for 1 h.

Peptide labeling was monitored by radio-HPLC using a C_{18}-reverse phase column (300 A, 5 μm, 4.5 mm × 25 cm, Vydac). The elution conditions were as follows: solvent A, 0.1% trifluoroacetic acid in water; solvent B, 0.1% trifluoroacetic acid in acetonitrile; gradient: 0% B to 100% B over 10 min; flow rate 2 mL/min. UV absorption was monitored at 260 and 400 nm with a flow-through spectrophotometer (Dynamax UV-D II, Rainin, Woburn, MA), and radioactivity was monitored using a radioisotope detector (Model 190, Beckman). The outputs of both detectors were recorded and analyzed using a dedicated HPLC controller/integrator (Dynamax HPLC method manager, Rainin, Woburn, MA).

Formyl-MLFK-HYNIC was labeled by incubating equal volumes of Tc-99m-mannitol with peptide [20 μg/mL] in 50 mM acetate buffer pH 5.2 for 1 h. Conversion to the

NS_2-containing complex was accomplished by addition of NS_2 [1 mg/mL DMSO] to the [Tc-mannitol-For-MLFK-HYNIC] solution at room temperature. Alternatively, $^{99m}TcO_4^-$ (1.0 mL) in acetate buffer was added to a solution of NS_2 (1 mg/mL in DMSO) and f-MLFK-HYNIC (10 μg/mL in acetate buffer, pH 5.2) in the presence of excess hydrazine sulfate as reducing agent. HPLC analysis of the purified material exhibited a profile identical to that of [^{99m}Tc-NS_2-HYNIC-peptide] as prepared by addition of NS_2 to [^{99m}Tc-mannitol-HYNIC-peptide].

Injectable solutions of radiolabeled peptide were prepared by isolating ^{99m}Tc-labeled from unlabeled peptide using a modification of the HPLC system described above. A semipreparative C_{18}-reverse phase column (300 A, 5 μm, 10 mm × 250 mm, Vydac, Hesperia, CA) was used, and the elution conditions were as follows: solvent A, 0.1% trifluoroacetic acid in water; solvent B, 0.1% trifluoroacetic acid in acetonitrile; gradient: 0% B from 0 to 2 min, 0% B to 100% B from 2 to 10 min; flow rate 4 mL/min. UV absorption and radioactivity were monitored as described above.

The peptide solutions were heated gently and dried under a stream of N_2 or rotary evaporated under vacuum. The residues were dissolved in 1 mL of absolute ethanol and diluted to an ethanol concentration of 10% with 0.9% NaCl for injection, USP. Sample of injectate were analyzed by HPLC using the analytical HPLC system described above.

Imaging Infected Rabbits. Groups of six male New Zealand white rabbits weighing 2−3 kg were anesthetized with ketamine and xylazine (15.0 and 1.5 mg/kg) and injected in the left posterior thigh muscle with 1.0 mL suspension of approximately 5×110^9 *E. coli*. Twenty-four hours after inoculation, rabbits with gross swelling in the inoculated thigh were injected intravenously through a lateral ear vein with 600−1000 mCi of HPLC purified [^{99m}Tc-mannitol-HYNIC-peptide], [^{99m}Tc-NS_2-HYNIC-peptide] (specific activity > 5000 mCi/μmol, separated from unlabeled peptide by HPLC as described above).

At 3 and 18 h after injection (hpi), the animals were anesthetized with ketamine/xylazine, and anterior images were acquired using a large field of view gamma camera (Technicare Omega 500, Solon, OH) equipped with a high resolution parallel hole collimator and interfaced to a dedicated computer (Technicare 560, Solon, Ohio). Images were recorded for a preset time of 5 min/view with a 15% window centered on the 140 keV photopeak ^{99m}Tc. Regions-of-interest (ROIs) were drawn over the area of infection, and the contralateral normal muscle and T/B ratios were calculated.

Biodistribution. After acquiring the final images, the animals were sacrificed with an overdose of sodium pentobarbital, and biodistribution was determined. Samples of blood, heart, lung, liver, spleen, kidney, adrenal, stomach, GI tract, testes, bone, bone marrow, normal muscle, infected muscle, and pus were weighed, and radioactivity was measured with a well type gamma counter (LKB model # 1282, Wallac Oy, Finland). To correct for radioactive decay and permit calculation of the concentration of radioactivity in each organ as a fraction of the administered dose, aliquots of the injected doses were counted simultaneously. The results were expressed as percent injected dose per gram (%ID/g), infected to normal muscle ratio and pus to normal muscle ratio.

Statistical Methods. The results of the imaging studies were evaluated by two-way analysis of variance (ANOVA) with a linear model in which peptide and time were the classification variable; T/B = Peptide + Time + Peptide × Time. The results of the biodistribution studies were evaluated by two-way analysis of variance (ANOVA) with a linear model in which organ and mannitol were the classification variables; %ID/g or %ID/organ = Organ + Peptide + Organ × Peptide. Post-hoc comparisons of peptide concentrations were performed by Duncan's new multiple range test (*45*). All results are expressed as mean ± SEM.

Syntheses of Model Compounds. *Preparation of [Tc{$CH_3N(CH_2CH_2S)_2$}(NNC_5H_4N)($NHNC_5H_4N$)] (**5a**).* A solution of [$TcCl_3$(NNC_5H_4NH)($NHNC_5H_4N$)] (0.02 g, 0.04 mmol), NS_2 (0.012 g, 0.08 mmol), and NEt_3 (0.016 g, 0.16 mmol) in 2 mL of methanol was stirred for 2 h. After filtration of the solution and evaporation to dryness, red-brown crystals of **5a** were isolated in 10−20% yield. Anal. Calcd for $C_{15}H_{20}N_7S_2Tc$: C, 39.1; H, 4.34; N, 21.3. Found: C, 38.7; H, 4.22; N, 21.2.

*Preparation of [Re{$CH_3N(CH_2CH_2S)_2$}(NNC_5H_4N)($NHNC_5H_4N$)] (**5b**).* A solution of [$ReCl_3$(NNC_5H_4NH)($NHNC_5H_4N$)] (0.025 g, 0.049 mmol) with bis(2,2′-ethanethiol)-*N*-methylamine (0.015 g, 0.098 mmol) and NEt_3 (0.03 g, 0.295 mmol) in 10 mL of methanol was stirred and refluxed for 2 h. The reaction mixture was filtered and evaporated to dryness. Dark brown crystals were grown by slow diffusion of pentane into a solution of **5b** in CH_2Cl_2 (Yield: 5%). Anal. Calcd for $C_{15}H_{20}N_7S_2Re$: C, 32.8; H, 3.64; N, 17.9. Found: C, 32.7; H, 3.81; N, 17.7.

*Preparation of C_5H_3N-2,6-$(CH_2SH)_2$ (**6**).* Compound **6** was prepared according to a modified literature synthesis described in ref 45. In a 100 mL Schlenk flask, a mixture of pyridine-2,6-methanethiol hydrochloride (5.00 g, 0.0285 m), thiourea (5.00 g, 0.0658 m) and 48% aqueous hydrobromic acid (28.80 g, 0.171 mol) was stirred and refluxed under an atmosphere of argon for 20 h. After cooling, a solution of NaOH (8.00 g, 0.200 mol) was slowly added. The mixture was refluxed for an additional 45 min. The resulting yellow solution was allowed to cool before extraction with methylene chloride. The extract was washed with a saturated salt solution (250 mL) and dried over sodium sulfate. Finally the solution was filtered and evaporated to a colorless residue (2.90 g, 59.3%). Due to its instability, compound **6** was made as needed and kept in a solution of CH_2Cl_2. IR (KBr, cm^{-1}); 1568 (s), 1269 (w), 1210 (w), 1064 (m), 995 (w), 814 (m), 751 (m).

*Preparation of [Re{C_5H_3N-2,6-$(CH_2S)_2$}(NNC_5H_4N)($NHNC_5H_4N$)]·CH_2Cl_2·0.5MeOH (**7**).* A solution of [$ReCl_3$(NNC_5H_4NH)($NHNC_5H_4N$)] (0.050 g, 0.098 mmol) with pyridine-2,6-dimethanethiol (0.050 g, 0.295 mmol) and NEt_3 (0.059 g, 0.591 mmol) in 10 mL of methanol was stirred and refluxed overnight whereupon the reaction mixture was filtered and evaporated to dryness. Dark red crystals of **7** were grown by slow diffusion of pentane into CH_2Cl_2 (Yield: 0.012 g, 21%). The material used for elemental analysis was heated at 80 °C under vacuum for 12 h. Anal. Calcd for $C_{17}H_{16}N_7S_2Re$: C, 38.9; H, 2.82; N, 17.2. Found: C, 38.6; H, 2.95; N, 16.9. IR (KBr, cm^{-1}): 1605 (s), 1546 (s), 1500 (m), 1460(m), 1451 (m), 1420 (s), 1300 (m), 1194 (s), 1052 (m), 1007 (w), 773 (m), 669 (w), 509 (w). ^{1}H NMR (MeOH-d_4, ppm): 4.50−4.85 (dd, J = 18 Hz, 4H), 6.55 (t, J = 5.4 Hz, 1H), 6.85 (t, J = 2.4 Hz, 1H), 7.22−7.42 (m, 3H), 7.50−7.80 (m, 3H), 7.90 (m, 2H), 8.50 (d, 1H).

*Preparation of [Re{$(SCH_2CH_2)_2O$}(NNC_5H_4N)($NHNC_5H_4N$)] (**8**).* A solution of [$ReCl_3$(NNC_5H_4NH)($NHNC_5H_4N$)] (0.050 g, 0.098 mmol) with bis(2-mercaptoethyl) ether (0.041 g, 0.295 mmol) and NEt_3 (0.059 g, 0.591 mmol) in 10 mL of methanol was stirred and refluxed overnight.

The reaction mixture was filtered and evaporated to dryness. Dark red crystals were grown by slow diffusion of pentane into a CH_2Cl_2 solution of the reaction residue. Anal. Calcd for $C_{14}H_{17}N_6OS_2Re$: C, 31.4; H, 3.17; N, 15.7. *Preparation of [ReCl(C_5H_4N-2-CH_2S)(NNC_5H_4N)($NHNC_5H_4N$)] (**10**).* A solution of [$ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)$] (0.050 g, 0.098 mmol) with pyridine-2-methylenethiol (0.100 g, 0.197 mmol) and NEt_3 (0.040 g, 0.396 mmol) in 10 mL of methanol was stirred and refluxed overnight. The reaction mixture was filtered and evaporated to dryness. Dark red crystals were grown by slow diffusion of pentane into a CH_2Cl_2 solution of the reaction residue. IR (KBr, cm^{-1}): 1654 (m), 1547 (m), 1496 (m), 1458 (s), 1421 (m), 1378 (m), 1294 (w), 1201 (m), 1055 (w), 1009 (w), 779 (w). ^1H NMR [$(CD_3)_2SO$]: 4.54 (d), 6.58 (m), 7.52 (d), 7.67 (d), 7.70 (m), 7.88 (m), 7.97 (m), 8.13 (m), 8.42 (d).

*Preparation of [Re(2-SC_5H_3N-3-$SiMe_3$)$_2$(NNC_5H_4N)($NHNC_5H_4N$)] (**11**).* A solution of [$ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)$] (0.050 g, 0.098 mmol) with pyridine-2-thiol-3-trimethylsilane (0.036 g, 0.197 mmol) and NEt_3 (0.039 g, 0.395 mmol) in 10 mL of methanol was stirred and refluxed overnight. The reaction mixture was filtered and the black precipitate was allowed to air-dry. Dark crystals were grown by slow diffusion of pentane into a CH_2Cl_2 solution of [$Re(C_8H_{12}NSiS)_2(NNC_5H_4NH)(NHNC_5H_4N)$] (0.055 g, 73% yield). Anal. Calcd for $C_{26}H_{33}N_8Si_2S_2Re$ (mol. wt. 763.2): C, 40.8; H, 4.32; N, 14.7. Found C, 40.3; H, 3.90; N, 14.3. IR (KBr, cm^{-1}): 1618 (m), 1565 (s), 1550 (s), 1459 (m), 1438 (w), 1422 (s), 1364 (s), 1299 (m), 1246 (m), 1213 (s), 1138 (m), 1014 (w), 847 (s), 761 (m), 654 (w), 642 (w). ^1H NMR (CD_2Cl_2): 0.42 (s), 1.52 (m), 1.701 (s), 3.17 (d), 6.67 (d), 6.75 (d), 7.08 (m), 7.56 (m), 7.60 (d), 7.75 (m), 7.91 (d), 8.71 (s).

*Preparation of [$Re_2(OH)Cl(SC_3H_2N_2CH_3)_2(NNC_5H_4N)_2$-($NHNC_5H_4N)_2$] (**12**).* *N*-methylimidazole-2-thiol (0.056 g, 0.49 mmol, in 3 mL chloroform) was added to a well stirred solution of [$ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)$] (0.1 g, 0.2 mmol) and triethylamine (60 mg, 0.6 mmol) in 20 mL of chloroform and was heated at reflux for 6 h. After cooling to room temperature, the greenish brown solution was extracted with water (5 × 30 mL), and the organic layer was dried over sodium sulfate. The volume was reduced to 5 mL, and the solution was passed through a silica gel column using 2:98 MeOH:CH_2Cl_2 solution as eluant. Yield: 0.090 g, 42%. ^1H NMR (δ (ppm), $CDCl_3$): 9.21 (d, J = 5.7 Hz, 1H), 9.11 (d, J = 5.7 Hz, 1H), 8.66−8.62 (m, 2H), 7.69−7.48 (m, 6H), 7.04 (d, J = 2.1 Hz, 1H), 6.96−6.88 (m, 3H), 6.81 (d, J = 7.5 Hz, 1H), 6.71−6.55 (m, 2H), 6.54 (d, J = 2.1 Hz, 1H), 6.38 (d, J = 0.8 Hz, 1H), 6.02 (d, J = 1.8 Hz, 1H), 3.50 (s, 3H), 3.23 (s, 3H), ^{13}C ($CDCl_3$): 166.90, 166.58, 166.02, 164.50, 161.07, 159.90, 155.05, 150.58, 150.25, 148.35, 139.43, 139.22, 138.33, 137.96, 128.63, 121.74, 121.44, 120.64, 119.58, 117.77, 117.37, 116.25, 116.06, 36.54, 35.22.

*Preparation of [$ReCl_3${$NNC_5H_3NH(CO_2R)$}{$NHNC_5H_3N$-(CO_2R)}] (R = H, **13a**; R = CH_3, **13b**).* A reaction mixture of [NH_4][ReO_4] (0.10 g, 0.37 mmol), 6-hydrazinonicotinic acid (0.25 g, 1.86 mmol) and 0.24 mL of aqueous 36% HCl (2 mmol) in 15 mL of MeOH was heated at reflux for 2 h. The solution was cooled to room temperature, and the brown precipitate was collected by vacuum filtration and washed with diethyl ether. The crude product was purified by flash chromatography over SiO_2 using MeOH:CH_2Cl_2:AcOH solution as eluant (20:80:1). Crystals were grown by slow evaporation of a solution of the purified product in MeOH:CH_2Cl_2 (1:1) solution. Crystallization afforded the methyl ester **12b**, rather than the free acid form (Yield: 60%). Anal. Calcd for $C_{14}H_{15}Cl_3N_6O_4Re$: C, 27.3; H, 2.53; N, 13.5. Found: C, 27.0; H, 2.42; N, 13.5. IR (KBr, cm^{-1}): 3394 (w), 2929 (w) 1630 (s), 1570 (s), 1544 (s), 1458 (m), 1281 (s), 1215 (s), 1130 (m), 1023 (w), 861 (w), 765 (m), 618 (w), 548 (w). ^1H NMR (δ (ppm), MeOH-d_4): 9.59 (d, 1H), 8.79 (d, 1H), 8.66 (d, 1H), 8.42 (d, 1H), 8.25 (d, 2H), 7.69 (d, 1H). ^{13}C (MeOH-d_4): 164.66, 163.23, 162.5, 152.6, 147.8, 144.01, 1142.94, 140.65, 138.55, 124.11, 121.45, 119.67. ESI-MS: (M^+H) 624.0, (M^+ + Na): 647.0.

*Preparation of [$ReCl_3${$NNC_5H_3NH(CONHCH_2CH_2CH_2$-$CH_2CH(NH_2)CO_2H$}{$NHNC_5H_3N(CONHCH_2CH_2CH_2$-$CH_2CH(NH_2)CO_2H$}]·2HCl (**14**·2HCl).* (a) A solution of [NH_4][ReO_4] (0.10 g, 0.37 mmol) and HYNIC-lysine (0.530 g, 1.49 mmol) in 15 mL of MeOH was heated at reflux for 2 h. The mixture was cooled to room temperature, and the resultant dark brown precipitate was collected by filtration, washed with diethyl ether (3 × 15 mL) and methanol and dried to give the product (Yield: 0.25 g, 78.8%). (b) Alternatively, the compound was prepared by the reaction of **12** (0.11 g, 0.18 mmol) and FMOC-lysine (α-N protected, 0.074 g, 0.20 mmol) in MeOH (15 mL). The insoluble dark brown precipitate was isolated in ca. 75% yield. Anal. Calcd for $C_{24}H_{34}Cl_3N_{10}O_6Re$: C, 30.3; H, 4.03; N, 16.5. Found: C, 30.2; H, 4.20; N, 16.7. X-Ray Crystallography. The crystals of **5b**, **7**, **9**, **10**, **12**, **13a**, and **15** were studied using a Bruker SMART diffractometer system using graphite monochromated Mo Kα radiation (λ(Mo Kα) = 0.71073 Å). Data collections for **5b**, **7**, **9**, **12**, **13a**, and **15** were carried out at low temperature while that of **10** was carried out under ambient conditions. The crystal parameters and other experimental details of the data collections are summarized in Table 1. A complete description of the details of the crystallographic methods is given in the Supporting Information. The structures were solved by direct methods (*46*). Neutral atom scattering factors were taken from Cromer and Waber (*47*), and anomalous dispersion corrections were taken from those of Creagh and McAuley (*48*). All calculations were performed using SHELXTL (*49*). Non-hydrogen atoms were refined anisotropically. No anomalies were encountered in refinements of any of the structures. Atomic positional parameters and isotropic temperature factors for the structures are presented in the Supporting Information.

RESULTS

Radiolabeling. The derivatized chemotactic peptide For-MLFK(N$^\epsilon$-HYNIC)G was prepared by solid-phase methods, as outlined in Scheme 2, while For-MLFK-(N$^\epsilon$-HYNIC) was prepared as previously described (*20b*).

After addition of $^{99m}TcO_4^-$ to each Sn(II)-mannitol solution, the desired Tc-mannitol complex was formed as

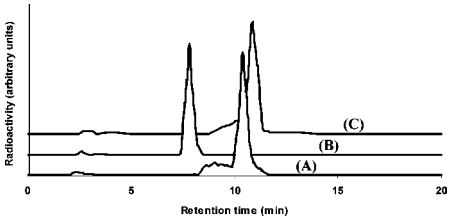

Figure 1. Radio-HPLC chromatograms of (A) [^{99m}Tc-mannitol-f-MLFK-HYNIC], (B) [^{99m}Tc(NS_2)(μ^2-$NHNC_5H_4N$)(μ^1-NNC_5H_4N)], and (C) [^{99m}Tc-NS_2-f-MLFK-HYNIC].

determined by radioanalytical thin-layer chromatography. The R_f values TEEP for the ^{99m}Tc-mannitol complex, determined by instant thin-layer chromatography-silica gel, were 1.0 and 0.0 in 25% NaCl and acetone:water (9:1), respectively. The ^{99m}Tc-mannitol complexes were >95% radiochemically pure. The R_f for the [^{99m}Tc-mannitol-HYNIC-peptide] complex determined by instant thin-layer chromatography silica gel were 0.0 and 1.0 in 25% NaCl and acetone:water (9:1), respectively. After a 1 h incubation of ^{99m}Tc-mannitol with a solution of f-MLFK-HYNIC, the corresponding [^{99m}Tc-mannitol-f-MLFK-HYNIC] was found in >90% radiochemical purity. The addition of NS_2 to the [^{99m}Tc-mannitol-HYNIC-peptide] structure affords the [^{99m}Tc-NS_2-HYNIC-peptide] complex.

Radio-HPLC analysis of the [^{99m}Tc-mannitol-HYNIC-peptide] complex demonstrated a unique chromatographic profile as compared with the [^{99m}Tc-NS_2-HYNIC-peptide] complex. HPLC analysis of the [^{99m}Tc-NS_2-HYNIC-peptide] showed a single unique hydrophobic species with retention time greater than that of the [^{99m}Tc-mannitol-HYNIC-peptide] starting material or of [^{99m}Tc{$CH_3N(CH_2CH_2S)_2$}](μ^2-$NHNC_5H_4N$)(μ^1-NNC_5H_4N)] as shown in Figure 1.

The complex [^{99m}Tc-NS_2-HYNIC-peptide] was also prepared by the reaction of $^{99m}TcO_4^-$ with NS_2, HYNIC-peptide, and excess hydrazine sulfate. After HPLC purification, radio-HPLC analysis revealed a chromatographic profile identical to that of species **C** of Figure 1, confirming that [^{99m}Tc-NS_2-HYNIC-peptide] does not contain mannitol as an additional ancillary ligand.

Imaging Results. At 3−4 h after injection both Tc-peptide preparations displayed similar biodistribution patterns. Both preparations displayed high concentrations of radioactivity in the lung, liver, spleen, and kidney. Concentrations were lower in muscle and gastrointestinal tract.

Region of interest (ROI) analysis of the scintigraphic images are summarized in Figure 2. Representative whole-body anterior images of rabbits at 3 and 18 h after injection of [^{99m}Tc-mannitol-For-MLFK-HYNIC] and [^{99m}Tc-NS_2-HYNIC-peptide] are shown. The data demonstrate that at early imaging times both preparations yield demonstrable accumulation of radioactivity in the injected areas with no significant difference between the two preparations. At later time points both preparations displayed an increased accumulation of activity at the site of injection with the [^{99m}Tc-NS_2-HYNIC-peptide] preparation increasing significantly greater that the [^{99m}Tc-mannitol-HYNIC-peptide]. Normal organ distribution was remarkably similar in samples taken at both 3 and 18 h for both preparations.

Direct Tissue Sampling. The concentrations of radioactivity for both peptide preparations at 18 h are summarized in Figure 3. Overall, the normal organ concentrations are remarkably similar except for heart and normal muscle where the [^{99m}Tc-NS_2-HYNIC-peptide] preparation was lower and in the spleen where it was higher. There was no significant difference in accumulation in GI tract.

Table 2 summarizes the concentrations (%ID/g) of both peptides in normal muscle, infected muscle, and pus. Significantly higher concentrations of [^{99m}Tc-NS_2-HYNIC-peptide] were found in infected muscle and pus ($p < 0.01$).

Infected muscle to normal muscle and pus to normal muscle ratios obtained from direct tissue counting are summarized in Figure 4. In both cases the ratios are significantly greater for [^{99m}Tc-NS_2-HYNIC-peptide] ($p < 0.01$). The average values of the tissue concentrations of [^{99m}Tc-mannitol-HYNIC-peptide] and [^{99m}Tc-NS_2-HYNIC-peptide] in the rabbit at 3 and 18 h after intravenous injection are shown in Table 3.

Model Compounds: Synthesis and Spectroscopic Characterization Compounds. Compounds **5** and **7**−**12** were all obtained in reasonable yields by reacting [$MCl_3(NNC_5H_4NH)(NHNC_5H_4N)$] (M = Tc, Re) with the thiolate ligand, adding base, and allowing the solution to reflux in methanol for 12 h. The syntheses exploit the versatile coordination properties of the hydrazino-2-pyridine ligand which facilitates the replacement of three chlorine atoms with a tridentate ligand of dinegative charge. To balance the charge, the pyridiniumdiazenido ligand is deprotonated so as to transform from the neutral zwitterionic diazene of the parent to a diazenido-(1−) form in the product. The removal of the pyridyl proton allows the rhenium complex to coordinate to the thiolate ligands and remain in the +3 state, which is the favored oxidation state under these conditions (*41*, *43*). By employing the structural versatility of [$ReCl_3(NNC_5H_5NH)(NHNC_5H_4N)$] and the chemical robustness of the {$M(NHNC_5H_4N)(NNC_5H_4N_x)$} ($x = 0, 1$) core, the thiolate complexes have been easily prepared and isolated.

The reaction of [$ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)$] with 3 equiv of bis(2,2′-ethanethiol)-*N*-methylamine in methanol and the presence of NEt_3 yields [Re{$CH_3N(CH_2CH_2S)_2$}(NNC_5H_4N)($NHNC_5H_4N$)] (**5b**) as a brown solid. Dark brown crystals were grown by slow diffusion of pentane into a mixture of **5b** in CH_2Cl_2. The chemistry of the analogous tridentate ligand, pyridine-2,6-dimethanethiol, was also investigated. Under similar reaction conditions employed in the synthesis of **5**, the resulting brown solid was identified as [Re{C_5H_3N-2,6-$(CH_2S)_2$}-(NNC_5H_4N)($NHCN_5H_4N$)]·CH_2Cl_2·0.5MeOH (**7**). The crude product was recrystallized by diffusing pentane into a mixture of **7** in CH_2Cl_2. The infrared spectrum of **7** exhibits strong to medium intensity bands at 1546 and 1500 cm^{-1} which are attributed to ν(N=N), suggesting the presence of multiple bond character. The spectrum also contains a series of bands in the 1600 to 1400 cm^{-1} range assigned to aromatic ring stretching modes ν(C=C) and ν(C=N). The ^{1}H NMR spectrum exhibited multiple ligand peaks between 6.9 and 8.6 ppm, attributed to the aromatic ring protons. In addition, the spectrum displays four sets of multiple peaks between 4.6 and 5.4 ppm attributed to the aliphatic thiolate carbon protons.

Substitution of the nitrogen donor of the thiol ligand $CH_3N(CH_2CH_2SH)_2$ with an oxygen donor provides the analogous (S−O−S) ligand, bis(2-mercaptoethyl) ether. Following an analogous synthetic procedure led to the preparation of [Re{$O(CH_2CH_2S)_2$}(NNC_5H_4N) ($NHNC_5H_4N$)] (**8**). Although dark red crystals of **8** were grown, these proved unsuitable for X-ray analysis due to severe twinning. The infrared spectrum of **8** displays a strong band at 1543 cm^{-1} in the region of ν(N=N), as well as multiple bands between 1400 and 1600 cm^{-1} attributed

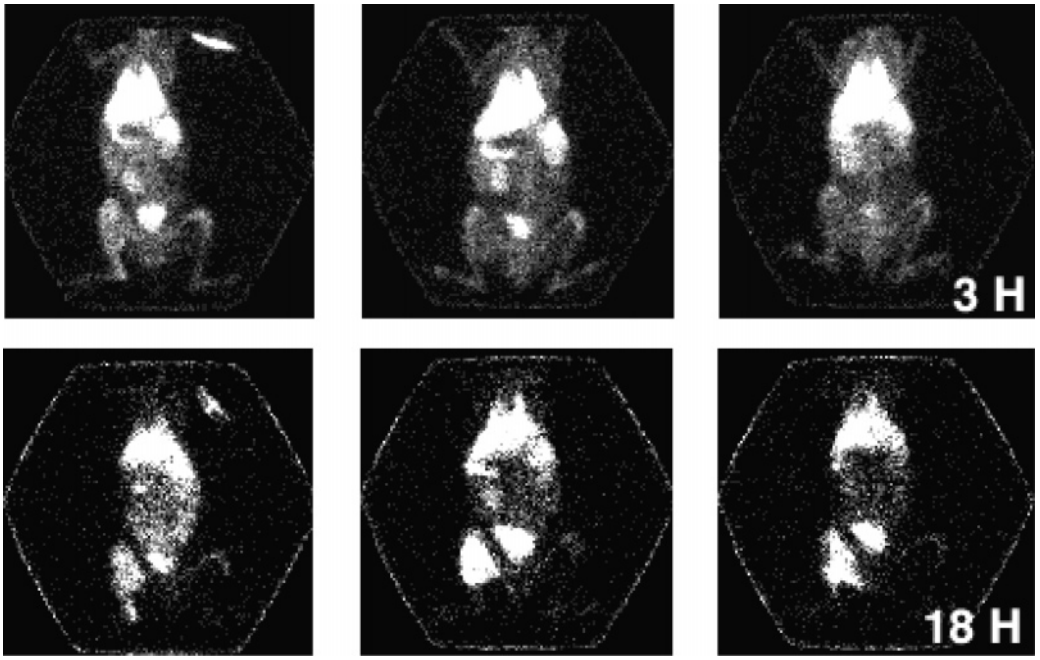

Figure 2. Representative whole-body anterior images of rabbits at 3 and 18 h after injection of [^{99m}Tc-mannitol-For-MLFK-HYNIC] and [^{99m}Tc-NS_2-HYNIC-peptide]. The animals were infected 24 h before radiopharmaceutical administration.

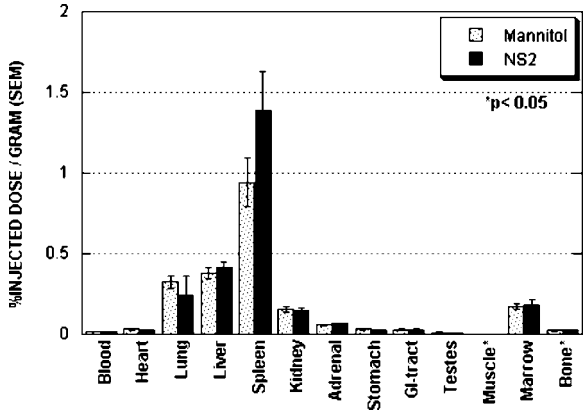

Figure 3. Average values of tissue concentration (% injected dose/g) of [^{99m}Tc-mannitol-HYNIC-peptide] and [^{99m}Tc-NS_2-HYNIC-peptide] in the rabbit at 18 h after intravenous injection (mean ± sem).

to ν(C=C) and ν(C=N). The ^{1}H NMR spectrum displays multiple aromatic protons between 6.7 and 8.4 ppm and peaks in the aliphatic region between 1.4 and 4.4 ppm.

However, substitution of the oxygen donor of $(HSCH_2CH_2)_2O$ with sulfur in the analogous (S−S−S) donor, bis-(2-mercaptoethyl) sulfide, followed by an analogous procedure as that used for the preparation of **8**, provided the cationic complex $[Re\{(SCH_2CH_2)_2S\}(NNC_5H_4NH)(NHNC_5H_4N)]^+$ as the chloride salt, compound **9**. The infrared spectrum of **9** exhibits the characteristic ν(N=N) band at 1539 cm^{-1}, and ν(C=N) and ν(C=C) bands in the 1425−1585 cm^{-1} range. The ^{1}H NMR spectrum exhibits a band at 4.32 ppm, assigned to the exchangeable α-nitrogen proton and the *N*-pyridyl proton which suggests some interconversion or equilibrium in solution.

An analogous bidentate, or "one-armed" derivative of **6**, the ligand pyridine-2-methanethiol was used to prepare $[ReCl(C_5H_4N\text{-}2\text{-}CH_2S)(NNC_5H_4N)(NHNC_5H_4N)]$ (**9**). Despite the use of 2 equiv of pyridine-2-methanethiol and exact reaction conditions employed to produce **5** and **7**−**9**, in the case of **10** the reaction results in the formation of the chloro derivative with retention of the metal-organohydrazine core. The resulting brown solid was recrystallized by diffusing pentane into a mixture of **10** in CH_2Cl_2. The infrared spectrum of **10** displays medium intensity bands at 1547 and 1496 cm^{-1} which are attributed to ν(N=N) of the organohydrazine ligands. The remainder of the spectrum is unexceptional.

The ligand pyridine-2-thiol-3-trimethylsilane was studied in order to evaluate the structural consequences of steric constraints. A solution of $[ReCl_3(\eta^1\text{-}NNC_5H_4NH)(\eta^2\text{-}NHNC_5H_4N)]$ with 2 equiv of pyridine-2-thiol-3-trimethylsilane and triethylamine in methanol was allowed to reflux for 12 h. The resulting black precipitate was obtained in high yields and allowed to air-dry. Dark red crystals of $[Re(2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3)_2(NNC_5H_4N)(NHNC_5C_5H_4N)]$ (**11**) were grown; however, once again poor crystal quality did not provide useful X-ray data. Elemental analysis confirmed that the rhenium organohydrazine core is preserved and that the rhenium-thiolate ratio is 1:2. This stoichiometry is similar to that previously observed for complexes of the $\{Re(NNR)_2\}^{n+}$ core with potentially bidentate thiolate ligands which form both mono- and bidentate attachments while preserving the {rhenium-bis-organohydrazino} core (eq 1).

$$[ReCl_3(NNC_5H_5NH)(NHNC_5H_4N)] + 2(2\text{-}HSC_5H_3N\text{-}3\text{-}SiMe_3) \Rightarrow [Re(\eta^2\text{-}2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3) \times (\eta^1\text{-}2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3) \times (NNC_5H_4N)(NHNC_5H_4N)]\ (\mathbf{11}) + 3\ HCl \quad (1)$$

The infrared spectrum of **11** possesses similar characteristics to the previously described compounds, with ν(N=N) stretches at 1565 and 1550 cm^{-1} and multiple bands between 1600 and 1400 cm^{-1} attributed to ν(C=C) and ν(C=N). It also displays a strong band at 847 cm^{-1} assigned to ν(Si=C). The room temperature ^{1}H NMR spectrum exhibits a broadened resonance for the $SiMe_3$ protons at 0.42 ppm as well as multiple peaks for the aromatic protons between 6.67 and 8.71 ppm.

Table 2. Concentrations of [^{99m}Tc-HYNIC-peptides] in Normal Muscle, Infected Muscle, and Pus Determined by Direct Measurements of Radioactivity, Mean ± SEM, $n = 6$

peptide	infected muscle[a]	pus	normal muscle[b]
[^{99m}Tc-mannitol-For-MLFK-HYNIC]	0.100 ± 0.0076	0.247 ± 0.049	0.0021 ± 0.0002
[^{99m}Tc-NS_2-For-MLFK-HYNIC]	0.180 ± 0.033	0.403 ± 0.098	0.001 ± 0.0001

[a] $p < 0.01$. [b] $p < 0.05$.

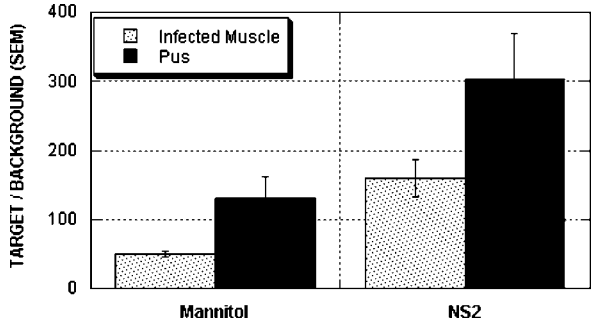

Figure 4. Average values of infected to normal muscle (open bars) and pus to normal muscle (solid bars) ratios at 18 h after injection of [^{99m}Tc-mannitol-For-MLFK-HYNIC and [^{99m}Tc-NS_2-HYNIC-peptide]. The rabbits were infected 24 h before radiopharmaceutical administration. Each value is the mean ± sem for six animals.

Table 3. Infected to Normal Tissue Ratios of [^{99m}Tc-mannitol-HYNIC-peptide] and [^{99m}Tc-NS_2-HYNIC-peptide] Determined by Region of Interest Analysis, Mean ± SEM, $n = 6$

peptide	3 h	18 h[a]
[^{99m}Tc-mannitol-For-MLFK-HYNIC]	3.906 ± 0.3155	11.886 ± 2.2053

[a] $p < 0.01$.

To evaluate the effectiveness of imidazole nitrogen donors in place of pyridine nitrogen, [$ReCl_3(\eta^1$-NNC_5H_4-$NH)(\eta^2$-$NHNC_5H_4N)$] was reacted with 2.5 equiv of *N*-methyl-imidazole-2-thiol in methanol. After isolation and purification, crystals of [$Re_2(OH)Cl(SC_3H_2N_2CH_3)_2$-$(\eta^1$-$NNC_5H_4N)_2(\eta^2$-$NHNC_5H_4N)_2$] (**12**) suitable for X-ray crystallography were obtained as dark green parallels parallelepipeds in moderate yield. The infrared spectrum of **12** displays medium intensity bands at 1549 and 1498 cm^{-1}, attributed to ν(N=N) of the organohydrazine ligands. In addition, a band at 642 cm^{-1} may be associated with the bridging oxo-group ν(Re−O−Re). The ^{1}H NMR spectrum is similar to that of **9** with aromatic and imidazole protons in the 6.00−9.21 ppm range and methyl resonances at 3.23 and 3.50 ppm. The unexceptional NMR spectrum confirms the diamagnetism of **12**, which may be formally considered a Re(III) species.

To confirm that the metal-organohydrazine core can support two peptide chains, the HYNIC derivative [$ReCl_3${$NNC_5H_3NH(CO_2R)$}{$NHNC_5H_3N(CO_2R)$}] (R = H, **13a**; R = CH_3, **13b**) and the lysine-coupled analogue [$ReCl_3${$NNC_5H_3NH(CONHCH_2CH_2CH_2CH_2CH$-$(NH_2)CO_2H$}{$NHNC_5H_3N(CONHCH_2CH_2CH_2CH_2CH$-$(NH_2)CO_2H$}]·2HCl (**13**·2HCl) were prepared. Compounds **13a** and **13b** were isolated from the reaction of [NH_4][ReO_4] with 6-hydrazinonicotinic acid and HCl in MeOH. In the course of the reaction, the hydrazinonicotinic acid was esterified to produce a mixture of **13a** and the methyl ester **13b**. The infrared spectrum of **13a** exhibited medium to strong intensity bands in the 1400−1630 cm^{-1} region, characteristic of ν(N=N) and ν(C=N).

The ^{1}H NMR spectrum of **13a** reveals a characteristic pattern of four aromatic peaks in the range 8.42−9.59 ppm associated with protons of the C5 and C6 ring positions of the pyridyl substituents in two distinct chemical environments of the [$ReCl_3(NNC_5H_3RNH)$-$(NHNC_5H_3RN)$] class of compounds. The detailed analysis of the spectrum will be provided for compound **14**.

The reaction of [NH_4][ReO_4] and HYNIC-lysine, prepared as previously described, in the presence of excess HCl in methanol solution provided **14**·2HCl in good yield. The methyl ester of **14**·2HCl was also found in the reaction mixture, albeit in low yield. The infrared spectrum of **14** is unexceptional with medium to strong bands associated with ν(N=N) and ν(C=N) appearing in the 1450−1630 cm^{-1} range.

The proton and carbon NMR spectra of **14** can be fully assigned on the bases of spin−spin structure, multiplicity, ^{1}H−^{1}H COSY, and ^{1}H−^{13}C HMQC experiments (Figure 5 and Table 4). Two sets of aromatic resonances associated with the two different pyridyl ring environments are observed. A numbering scheme is provided in the inset to Figure **5**. The two doublets at 8.21 ppm (J = 2.4 Hz) and 7.31 ppm (J = 9.0 Hz) are correlated and assigned to H-4 and H-5, respectively, of one pyridyl ring. Similarly, the doublets at 8.23 ppm (J = 2.4 Hz) and 7.68 ppm (J = 9.0 Hz) were assigned to H-4′ and H-5′ of the second pyridyl ring. The H-4/H-4′ peaks are assigned as the most downfield shifted as these protons are ortho to the amide group of the lysine and are also weakly coupled to H-2 or H-2′ at 8.97 (doublet, J = 2.1 Hz) and 9.27 ppm (doublet, J = 1.8 Hz). The corresponding ^{13}C NMR peaks are seen at 116.91 and 135.40 ppm for C-5 and C-4′ and 118.31 ppm and 137.13 pp, for C-6′ and C-5′, respectively. The C-3 and C-3′ resonances appear at 147.24 and 148.41 ppm, respectively.

The ^{1}H−^{1}H COSY experiment (Figure 6) allows assignment of the two triplets at 8.65 and 8.53 ppm as NH protons adjacent to the H-6a protons of the lysine residues. The H-6a/H-6a′ protons are assigned to the intensity four peak at 3.29 ppm. The ^{1}H−^{13}C HMQC data support this assignment, as there is no corresponding carbon resonance observed for these triplets.

The peaks in the aliphatic region were also assigned. Since the lysine residues are remote from the metal coordination site, no significant chemical shift differences were observed in either the ^{1}H and ^{13}C NMR spectra for the lysine substituents on the two HYNIC-lysine moieties. The most deshielded proton H-2a is adjacent to the carboxylic group and appears as a triplet with an integrated intensity of two protons, one from each lysine residue, at 3.81 ppm. Similarly, a single peak is found in the ^{13}C NMR spectrum at 52.34 ppm for the two magnetically equivalent C2 sites.

The proton resonances in the 1.36−1.50 ppm region are assigned to the two pairs of H-4a and H-5a protons, as indicated by their coupling and by the coupling to the H-6a protons at 3.29 ppm. The remaining peak at 1.73 ppm with an integrated intensity of four protons was assigned to the two pairs of H-3a protons. The related ^{13}C NMR peaks appear at 30.04, 28.88, and 22.04 for C-3a, C-5a, and C-4a, respectively. The ^{13}C resonances of the carboxylic acid carbon atoms appear as a single peak at 171.38 ppm with a characteristic doubling of the peak intensity compared to the two unique amide car-

bonyl carbon peaks at 163.98 and 160.23 ppm, which are inequivalent by virtue of their proximity to the chemically inequivalent pyridyl rings.

Model Compounds: X-ray Structures. The structure of $[Re\{CH_3N(CH_2CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]$ (**5b**) is shown in Figure 7. The geometry about the metal is distorted octahedral, with the rhenium(III) center

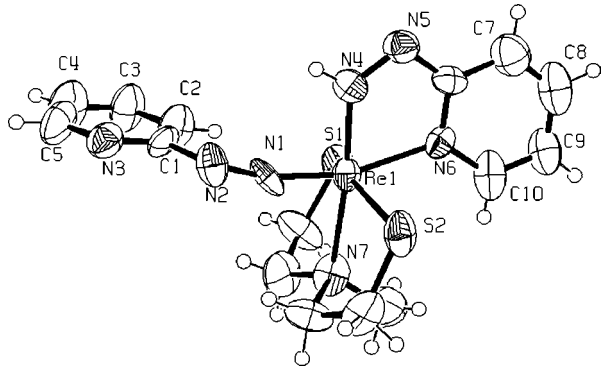

Figure 7. A view of the structure of **5**, showing the atom-labeling scheme and 50% thermal ellipsoids.

surrounded by two hydrazinopyridine ligands and one tridentate aminobisthiolate coordinated through two sulfur and one nitrogen donors. The hydrazino-2-pyridine ligands adopt two distinct binding modes: one binds exclusively through the α-nitrogen and is considered a diazenido(1−) ligand, while the second adopts a bidentate mode using the nitrogen donor of the pyridine ring as well as the α-nitrogen to chelate the metal as a neutral diazene species. The structural differences between these binding modes are quite evident in the internal bond lengths of the ligands. In the case of the diazenido(1−) ligand the Re−N1−N2 unit shows considerable multiple bond character with bond lengths of 1.78(2) Å and 1.26(2) Å for Re−N1 and N1−N2, respectively. The Re−N1−N2 bond angle is 165(2)°. In contrast, the neutral diazene species has Re−N4 and N4−N5 bond lengths of 1.94(2)

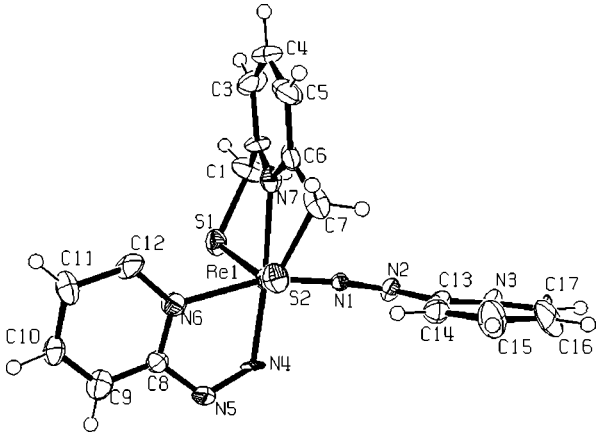

Figure 8. A view of the structure of **7**, showing the atom-labeling scheme and 50% thermal ellipsoids.

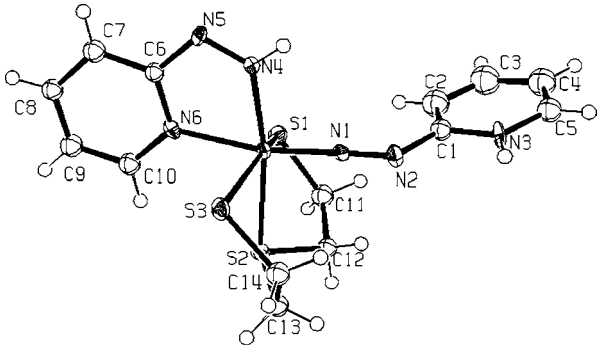

Figure 9. An ORTEP view of the structure of the complex cation of **9**, showing the atom-labeling scheme and 50% thermal ellipsoids.

Å and 1.36(2) Å, respectively. Furthermore, the Re−N6 and Re−N7 bond lengths of 2.16(2) and 2.28(2) Å, respectively, illustrate the range of Re−N single bonds and permit an internal comparison with the Re−N1 and Re−N4 multiple bonds. The average Re−S distance for **5b** is 2.39(1) Å, well within the range of other examples previously reported (*50*−*55*).

The structure of the analogous compound [Re{C_5H_3N-2,6-$(CH_2S)_2$}(NNC_5H_4N) $(NHNC_5H_4N)$] (**7**) consists of a six-coordinate rhenium(III) center with distorted octahedral geometry. The rhenium site is defined by a nitrogen from a monodentate diazenido(−1), two nitrogen donors from a bidentate neutral diazene, and two donor sulfurs and a nitrogen from the S−N−S tridentate thiolate as shown in Figure 8. The Re−N1(α-nitrogen) bond distance of 1.77(1) Å reflects the multiple bond character of the diazenido(1−) ligand and may be directly compared to the Re−N3 (pyridine nitrogen) bond length of 2.15(1) Å. Once again the chelating neutral diazene displays a short Re−N4 distance of 2.00(1) Å. The N1−N2 and N4−N5 bond lengths exhibit multiple bond character consistent with bond lengths of 1.25(2) Å and 1.28(2) Å, respectively (*56*). As anticipated the Re−S distances are similar to those observed in compound **5**, and all other metrical parameters are predictable.

Substitution of the NS_2 donor ligand of [Re{C_5H_3N-2,6-$(CH_2S)_2$}(NNC_5H_4N) $(NHNC_5H_4N)$] (**7**) by the S_3 donor $\{(SCH_2CH_2)_2S\}^{2-}$ provides [Re{$(SCH_2CH_2)_2S$} $(NNC_5H_4NH)(NHNC_5H_4N)$]Cl (**9**). As shown in Figure 9, the structure of the cationic complex consists of a six-coordinate rhenium(III) center with distorted octahedral geometry. In contrast to the structure of **7** which exhibits a monodentate diazenido(1−) ligand, the monodentate organohydrazino ligand of **9** is present as the protonated

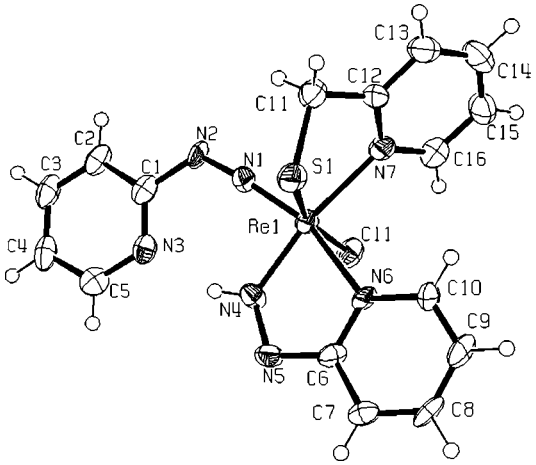

Figure 10. A view of the structure of **10**, showing the atom-labeling scheme and 50% thermal ellipsoids.

and neutral pyridinium-diazenido ligand. The coordination sphere is completed by the two nitrogen donors from the bidentate neutral diazene $(NHNC_5H_4N)$, and the three sulfur donors from the tridentate bis(2-mercaptoethyl)sulfide ligand. Since both organohydrazine ligands are formally neutral, the overall complex charge is +1, with the rhenium center formally in the +3 oxidation state. The Re−N1(α-nitrogen) bond distance of 1.760(9) Å reflects the multiple bond character of the pyridinium-diazenido ligand. The chelating neutral diazene exhibits unexceptional bond lengths of 1.972(8) Å and 2.129(8) Å for the Re−N4 (hydrazino-α-nitrogen) and Re−N6 (pyridine nitrogen) bonds, respectively. The Re-thiolate distances of 2.389(3) Å and 2.398(3) Å are significantly shorter than the Re-sulfide distance of 2.469(2) Å. All other metrical parameters are unexceptional.

The bidentate ligand pyridine-2-methanethiol displaces two chlorine donors of the precursor to form the chloro species [ReCl(C_5H_4N-2-CH_2S)$(NNC_5H_4N)$$(NHNC_5H_4N)$] (**10**), which are illustrated in Figure 10, and consists of a rhenium(III) center with distorted octahedral geometry defined by the sulfur and nitrogen donors of a chelating pyridine-2-methanethiol, the α-nitrogen of a monodentate pyridinediazenido(1-) ligand, the α-nitrogen, the pyridyl nitrogen of the chelating diazene, and a chloride donor.

The structure of the binuclear complex **12** is shown in Figure 11. The compound exhibits two inequivalent six-coordinate Re(III) sites, one with a $\{ReOClN_4\}$ coordina-

[a] $x = 0$, $n = 2$; $x = 1$, $n = 3$. [b] Values are averages over the two molecular cations of the asymmetric unit.

tion geometry and the second with $\{ReOS_2N_3\}$ coordination. The coordination at the Re1 site is defined by the multiply bonded nitrogen donor of the diazenido(1-) ligand, the α-hydrazine nitrogen donor and pyridyl nitrogen donor of the bidentate and neutral diazene ligand, a nitrogen donor of an N,S-bridging thioimidazole group, a terminal chloride, and a bridging hydroxy group. The Re2 site consists of the analogous diazene nitrogen and diazenido(1-) nitrogen donors, the thiolate sulfur of a terminal, monodentate mercaptoimidazole ligand, the sulfur donor of the bridging mercaptoimidazole and the hydroxide bridge. Consequently, there are two distinct *N*-methyl-2-imidazole-thiolate groups, one monodentate and bonding only through the sulfur, while the second is bidentate and bridging. Both Re sites exhibit the common $\{Re(III)(NNR)(NHNR)\}^{+2}$ core with unexceptional metrical parameters (Table 5).

The structure of $[ReCl_3\{NNC_5H_3NH(CO_2H)\}\{NHNC_5H_3N(CO_2H)\}]$ (**13a**), shown in Figure 12, is analogous to that of the previously reported $[ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ (*41*). The nitrogen donors adopt the conventional meridional geometry with the chloride ligands occupying the remaining coordination sites. The metrical parameters for the $[Re(III)\{\eta^1\text{-}NNC_5H_3NH(CO_2H)\}\{\eta^2\text{-}NHNC_5H_3N(CO_2H)\}]^{2+}$ core of **13a**, listed in Table 5, are unexceptional for compounds of this family.

The structure of the 2-mercaptopyridine derivative **15** of Figure 13 is analogous to that of $[Re(NNC_5H_4N)(NHNC_5H_4N)(SC_5H_4N)_2]$ and exhibits the common distorted six coordinate $\{ReS_2N_4\}$ geometry, with the sulfur donors in a transoid orientation. The metrical parameters for **14** are similar to those previously reported for $[Re(NNC_5H_4N)(NHNC_5H_4N)(SC_5H_4N)_2]$.

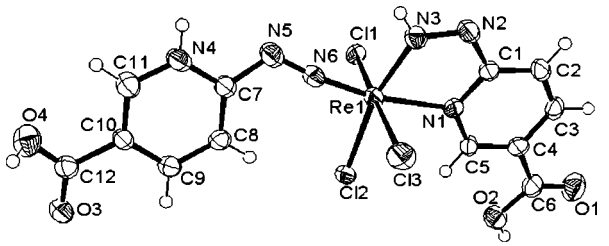

Figure 12. A view of the structure of **13a**, showing the atom-labeling scheme and 50% thermal ellipsoids.

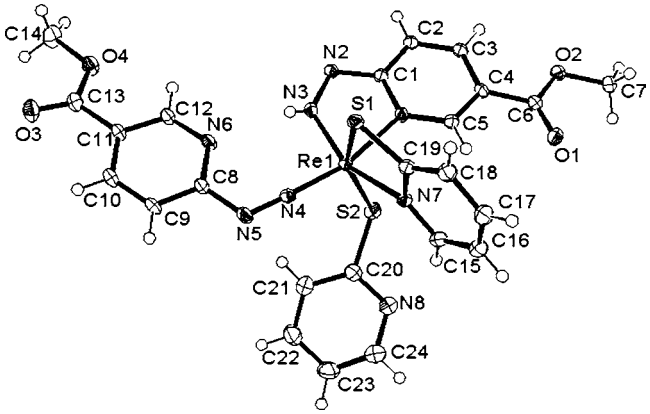

Figure 13. A view of the structure of **15**, showing the atom-labeling scheme and 50% thermal ellipsoids.

DISCUSSION

We have previously developed ^{99m}Tc-labeled HYNIC-chemotactic peptides for imaging focal sites of bacterial infections in a variety of animal models (*20b*). The results of these studies have shown that the radiometal-complexed peptides retain receptor binding affinity and biological activity in vivo, the HYNIC-chemotactic peptides are readily labeled with ^{99m}Tc at very high specific activities and are excellent radiopharmaceuticals for infection imaging. More recently, we demonstrated that the peptides localize at sites of infection predominantly by a specific f-MLF receptor-mediated mechanism (*20a*). These data indicate that ^{99m}Tc-labeled HYNIC-chemotactic peptides satisfy some of the criteria for "ideal" infection imaging agents: rapid localization and retention at the site of infection and concentrations in normal tissues which remain constant or decrease with time and displaying no biological effects.

As previous studies have demonstrated, ^{99m}Tc-mannitol gives superior imaging results when used as the starting species (or coligand) to label formyl-MLFK-HYNIC, as compared with other polyhydric coligands. However, radio-HPLC indicated the presence of several radioactive species. We are interested in producing [^{99m}Tc-HYNIC-peptides] as homogeneous radiochemical species in an effort to generate a well-defined chemical entity and simplify formulation and mechanistic studies.

With the aim of limiting radiochemical speciation of [^{99m}Tc-HYNIC-peptides] radiochemical species with more predictable radiochemical and biological properties, we previously investigated bidentate amino-thiol ligands,

pyrimidinethiols, and pyridinethiols as coligands. The effectiveness of mixed nitrogen/sulfur polydentate ligands in the design of ^{99m}Tc radiopharmaceuticals is well-documented for the N_3S (*57*), N_2S_2 (*58*), and even the NS_2 (*59*) and S_4 (*60*) donor sets. Previous work at the 'carrier' level showed these ligands form stable and reproducible complexes with Tc-hydrazinopyridine. To this end, we investigated the potential of pyrimidinethiols and pyridinethiols as coligands.

These ligands resulted in an improved radiochemical formulation by limiting the number of radiochemical species observed with reverse phase HPLC. However, the use of these ligands resulted in undesirable significant GI tract accumulation.

Tridentate ligands, such as NS_2, may constrain the possible coordination geometries and improved overall stability. To investigate this, we synthesized NS_2, converted the [^{99m}Tc-mannitol-For-MLFK-HYNIC] to the corresponding NS_2-containing complex [^{99m}Tc-NS_2-For-MLFK-HYNIC], and compared its infection imaging and biodistribution properties with [^{99m}Tc-mannitol-For-MLFK-HYNIC]. The biological distribution of the [^{99m}Tc-NS_2-HYNIC-peptide] was remarkably similar to that of the [^{99m}Tc-mannitol-HYNIC-peptide] in most tissues. Slightly greater concentrations were found in spleen and marrow though not significant. Less accumulation was noted in normal muscle ($p < 0.05$).

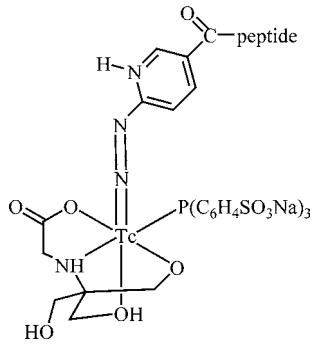
Perhaps most remarkable was the increase in accumulation in the infected muscle and pus. The [^{99m}Tc-NS_2-HYNIC-peptide] accumulated to almost twice the level of the [^{99m}Tc-mannitol-HYNIC-peptide] in these tissues ($p < 0.01$). This accounted for the much higher target/background ratios observed with gamma camera imaging. Target-to-background ratios are enhanced as well by reduction in normal muscle concentrations.

The improvement in target accumulation and background reduction has resulted in an improved entity for imaging infection. The reasons for this are not completely clear. However, based on the structural studies of the model compounds **5a** and **5b**, several mechanisms may be invoked to account for the superior biological properties.

First, the structures of the model coordination compounds suggest that the peptides (not the α-nitrogens atoms of the HYNIC moieties) adopt a trans orientation. This minimizes steric interface of the two peptides with each other and may allow either peptide access to the formyl-MLF receptor. If the peptides were cis to each other they may interfere with bonding to the receptor by interacting with each other or by sterically blocking the approach of the other to the receptor. This speculation has yet to be proven; however, the fact that the α-nitrogen of HYNIC will not coordinate trans to the α-nitrogen of a second HYNIC would dispose the peptides in a mutually trans arrangement.

Furthermore, the improvement in biological behavior may be derived from the likelihood that in vivo ligand substitution (via glutathione or cysteine) is unfavorable due to the tridentate nature of NS_2. Previous work with the bidentate pyridinethiol and pyrimidinethiol showed two pyridinethiol ligands attached to the metal core: one bidentate and one monodentate through the sulfur. The monodentate pyridinethiol is potentially labile due to the single attachment mode and the trans influence of the sulfur from the bidentate pyridinethiol. On the other hand, the NS_2 ligand may enhance the persistence of the complex by adopting a meridional coordination mode for a tridentate chelate.

Scheme 3. Proposed Structure of [Tc(tricineH_2)-{$P(C_6H_4SO_3Na)_3$}(HYNIC-peptide)]



The model studies not only confirm the persistence and chemical robustness of the {$Re(NNC_5H_4NH_x)(NH_yNC_5H_4N)\}^{n+}$ ($x = 0$ or 1; $y = 0$ or 1) core but also illustrate that the flexibility of the core with respect to protonation and overall charge allows the rhenium center to maintain the favorable +3 formal oxidation state in a variety of ligand environments. The chloride coligands of the $[ReCl_3(NNC_5H_4NH)(NHNC_5H_4N)]$ precursor are readily displaced by multidentate thiolate ligands to give chemically robust complexes while maintaining the {$Re(HNNC_5H_4N)(NNC_5H_4NH)\}^{+3}$ core. It is anticipated that the weakly coordinated polyhydric ligands commonly employed in tracer scale chemistry with Tc or Re would also be readily displaced by such effective chelators.

On the other hand, despite the robust nature of the Re- and Tc-HYNIC linkage and the persistence of the {$M(\eta^1\text{-}NNC_5H_3NR)(\eta^2\text{-}NHNC_5H_3NR)\}$ core on the macroscopic scale, definitive characterization of the Re complex with N-For-MLF(N^{ϵ}-HYNIC)K was not achieved as a consequence of the insolubility of the products if the reactions of ReO_4^- with N−For-MLF(N^{ϵ}-HYNIC) K or of **13a** with N-For-MLF. Consequently, unambiguous evidence for the 2:1 HYNIC-peptide:M formulation even on the macroscopic scale remains elusive. Since the alternative formulation with the Tc:HYNIC ratio of 1:1 cannot be totally eliminated, the improvement in target accumulation and background reduction of [^{99m}Tc-NS_2-HYNIC-peptide] may be the consequence of molecular volume and charge considerations, rather than involvement of two peptide pendants on the complex.

Furthermore, it is apparent from the general coordination chemistry of oxometalate species with organohydrazine ligands that the method of synthesis, as well as the nature of the coligands, can profoundly influence the identity of the product (*61*−*63*). For example, in the presence of phosphine ligands, chelating organohydrazine ligands yield monosubstituted complexes, such as $[MCl_2(NNCOC_6H_5)(PPh_3)_2]$ rather than materials with the {$M(\eta^1\text{-}NNC_5H_3NR)(\eta^2\text{-}NHNC_5H_3NR)\}^{2+}$ core (*64*, *65*). Consequently, it is not surprising that under different reaction conditions, the ^{99m}Tc complex [Tc(tricineH_2)-{$P(C_6H_4SO_3Na)_3$}(HYNIC-peptide)], shown in Scheme 3, has been proposed (*66*−*68*). While the mass spectrometry data and other details of the study are quite convincing for the Tc:HYNIC ratio of 1:1 in this case, the details of the structure are more controversial. Hydrazinopyridine is a highly effective chelating ligand, while the tricine amine, carboxylate and alkoxide donors are not particularly suitable for technetium in this oxidation state (*42*). It is more likely that the HYNIC subunit coordinates in a chelating fashion, displacing one of tricine donors. In fact, the mode of tricine coordination remains unresolved, as does the degree of deprotonation under physiological conditions. It is also noteworthy that all attempts to

prepare ^{99}Tc analogues of these phosphine derivatives on a macroscopic scale produced only intractable mixtures. Similarly, reactions of $\{M(\eta^1\text{-}NNC_5H_3NR)(\eta^2\text{-}NHNC_5H_3NR)\}^{2+}$ core model compounds of ^{99}Tc and Re with tricine yield uncharacterizable materials.

A final complication is the tendency of metal-organohydrazine complexes to form oligomers in donor solvents (*69*). This characteristic is reflected in the binuclear structure of **11**, as well as the tetranuclear species $[Re(\eta^1\text{-}NNC_4H_3N_2)(\eta^2\text{-}NHNC_4H_3N_2)(OCH_3)_2]_4$ and $[Re(\eta^1\text{-}NNC_5H_4N)(\eta^2\text{-}NHNC_5H_4N)(OH)_2]_4$ isolated from methanol and water, respectively (*70*).

CONCLUSION

In conclusion we have prepared model [Re(Tc)-NS_2-bis(HYNIC)] complexes and [^{99m}Tc-NS_2-peptides]. The model studies confirm that complexes with the $\{M(\eta_1\text{-}NNR)(\eta_2\text{-}NHNR)\}$ core, such as $[MCl_3(NNC_5H_4NH)(NHNC_5H_6N)]$ (M = Tc, Re), react smoothly with bis(mercaptoethyl)methylamine (NS_2) to yield $[M\{CH_3N(CH_2CH_2S)_2\}(NNC_5H_4N)(NHNC_5H_4N)]$. Complexes of this class are remarkable robust chemical species and, furthermore, demonstrate the persistence of the M-HYNIC core $\{M(\eta^1\text{-}NNR)(\eta^2\text{-}NHNR)\}$ under the conditions of this study. The NS_2 functions as a more effective coligand to this core than the commonly used polyhydroxylic ligands by virtue both of its geometric and steric constraints and of the strong preference of Tc(V) and Re(V) for thiolate coordination rather than alkoxy coordination. The coordination preferences of the thiolate donors dictate a meridional disposition of the NS_2 ligand about a metal site with the $\{M(\eta^1\text{-}NNR)(\eta^2\text{-}NNR)\}$ core. Consequently, substituents such as peptide chains attached to the HYNIC ligands will adopt a *transoid* orientation which may endow the material with enhanced biological properties. Thus, with respect to biological activity, the [Tc-NS_2-HYNIC-peptide] shows superior imaging and target accumulation as compared with less robust coligand systems we have previously studied.

On the other hand, while the HYNIC approach has proved successful in applications to infection imaging and appears to be a versatile technology for the labeling of a variety of biomolecules, it is now evident that, despite years of extensive investigations by a number of groups, HYNIC-based imaging agents are poorly characterized at the tracer level and, in some cases, even the ^{99m}Tc and Re analogues remain structurally elusive. Furthermore, since the synthesis of the HYNIC-peptide conjugate is quite involved and the coordination/coligand chemistry introduces additional synthetic and structural complexities, the commercial viability of the technology remains in question.

Gene Transfer Efficacies of Novel Cationic Amphiphiles with Alanine, β-Alanine, and Serine Headgroups: A Structure−Activity Investigation†

Joyeeta Sen and Arabinda Chaudhuri*

Division of Lipid Science and Technology, Indian Institute of Chemical Technology, Hyderabad-500 007, India.
Received February 16, 2005; Revised Manuscript Received June 3, 2005

Herein, we report on the relative in vitro efficacies of nine novel nonglycerol based cationic amphiphiles with increasing hydrophobic tails and the amino acids serine, alanine and β-alanine as the headgroup functionalities (lipids **1**−**9**, Scheme 1) in transfecting multiple cultured cells including CHO, COS-1, MCF-7, and HepG2. The gene transfer efficiencies of lipids **1**−**9** were evaluated using the reporter gene assays in all the four cell lines and the whole cell histochemical X-gal staining assays in representative CHO cells. In CHO, HepG2, and MCF-7 cells, cationic lipids with alanine (**4**−**6**) and β-alanine (**7**−**9**) headgroups were found to be remarkably more transfection efficient than their serine headgroup counterparts (**1**−**3**). Most notably, in CHO, HepG2, and MCF-7 cells, in combination with cholesterol as auxiliary lipid, the transfection efficiencies of the cationic lipids with alanine and β-alanine headgroups and myristyl and palmityl tails (lipids **4**, **5**, **7** and **8**) were significantly higher (2−3-fold) than that of LipofectAmine-2000, a widely used commercially available liposomal tranfection vectors. Surprisingly, in COS-1 cells, although cationic lipids with β-alanine headgroups (**7**−**9**) were strikingly transfection efficient (3−4-fold more efficacious than LipofectAmine-2000), the gene transfer properties of both their structural isomers (**4**−**6**) and their serine headgroup counterparts (**1**−**3**) were adversely affected. In summary, the present structure−activity investigation demonstrate that high gene delivery efficacies of cationic amphiphiles containing alanine or β-alanine headgroups can get seriously compromised by substituting the alanine or β-alanine with serine presumably due to the enhanced sensitivity of DNA associated with such serine-head-containing cationic lipids.

INTRODUCTION

Design of safe and efficacious therapeutic gene carriers still remains a critical challenge in gene therapy, the modality to combat myriads of inherited diseases, dreadful viral infections, and cancer. The gene transfer reagents currently in use can be broadly classified into two categories: viral and nonviral. Recombinant viral vectors, although remarkably efficient, suffer from numerous biosafety-related disadvantages (*1*−*3*). Viral vectors are capable of producing potentially replication-competent virus through recombination events with host genome and generating inflammatory and immunogenic responses against their structural components (*4*−*8*). In addition, viral vectors have a low insert-size limit for the therapeutic genes they can pack inside. Consequently, an increasing number of investigations are being reported on the development of safe and efficacious nonviral alternatives including cationic amphiphiles also known as cationic transfection lipids (*9*−*18*), cationic polymers (*19*, *20*), dendrimers (*21*−*23*), etc. Because of their least immunogenic nature, robust manufacture, ability to deliver large pieces of DNA, and ease of handling and preparation techniques, cationic amphiphiles are gaining increasing popularity as the alternative nonviral transfection vectors of choice for delivering genes into our body cells (*9*−*18*, *24*−*52*).

The molecular architectures of cationic amphiphiles consist of a positively charged water-loving (hydrophilic) polar headgroup region and a nonpolar hydrophobic tail region (usually consisting of either two long aliphatic hydrocarbon chains or a cholesterol skeleton) often tethered together via a linker functionality such as ether, ester, amide, amidine group, etc. Systematic structure−activity investigations are being pursued toward understanding how variations in each of these three lipid structural components influence the gene transfer efficacies of cationic amphiphiles continue to be an intensely pursued area of research in nonviral gene delivery (*12*, *16*, *27*, *31*, *34*, *38*, *40*, *41*, *47*−*52*). As part of our ongoing structure−activity program in the area of cationic lipid-mediated gene delivery (*12*, *16*, *17*, *47*−*52*), in the present investigation, we report on the relative in vitro efficacies of nine novel nonglycerol-based cationic amphiphiles with increasing hydrophobic tails and the amino acids serine, alanine and β-alanine as the headgroup functionalities (lipids **1**−**9**, Scheme 1) in transfecting multiple cultured cells including CHO, COS-1, MCF-7, and HepG2. As delineated below, the present structure−activity investigation demonstrates that high gene delivery efficacies of cationic amphiphiles containing alanine or β-alanine headgroups can get seriously compromised by substituting the alanine or β-alanine with serine presumably due to the enhanced sensitivity of DNA associated with such serine-head-containing cationic lipids. The transfection efficacy profiles of the presently described cationic lipids once again reiterate the proposition that gene transfer efficacies of cationic amphiphiles can be significantly modulated by minor structural variations in both the polar headgroup and hydrophobic tail regions of the lipid.

EXPERIMENTAL PROCEDURES

General Procedures and Materials. FABMS data were acquired by the liquid secondary ion mass spectrometry (LSIMS) technique using *m*-nitrobenzyl alcohol as the matrix. LSIMS analysis was performed in the scan range 100−1000 amu at the rate of 3 scans/s. ^{1}H NMR spectra were recorded on a Varian FT 200 MHz, AV 300 MHz, or Varian Unity 400 MHz. 1-Bromotetradecane, 1-bromohexadecane, 1-bromooctadecane, *n*-tetradecylamine, *n*-hexadecylamine, and *n*-octadecylamine were procured from Lancaster (Morecambe, England). The progress of the reactions was monitored by thin-layer chromatography on 0.25 mm silica gel plates. Column chromatography was performed with silica gel (Acme Synthetic Chemicals, India, finer than 200 and 60−120 mesh). p-CMV-SPORT-β-gal plasmid was a generous gift from Dr. Nalam Madhusudhana Rao. Lipofectamine was purchased from Invitrogen life technologies. Cell culture media, fetal bovine serum, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), poly(ethylene glycol) 8000, *o*-nitrophenyl-β−D-galactopyranoside, and cholesterol were purchased from Sigma, St. Louis, MO. NP-40, antibiotics, and agarose were purchased from Himedia, India. Unless otherwise stated, all the other reagents purchased from local commercial suppliers were of analytical grades and were used without further purification. COS-1 (SV 40 transformed African green monkey kidney cells), CHO (Chinese hamster ovary), HepG2 (human hepatocarcinoma), and MCF-7 (human breast adenocarcinoma) cell lines were procured from the National Centre for Cell Sciences (NCCS), Pune, India. Cells were grown at 37 °C in Dulbecco's modified Eagle's medium (DMEM)[1] with 10% FBS in a humidified atomosphere containing 5% CO_2/95% air. Purity of the final lipids **1**−**9** were determined by Analytical HPLC (Shimadzu Model LC10A) using a PARTISIL 5 ODS-3 WCS analytical column (4.6 × 250 mm, Whatman Inc., Clifton, NJ) in two different mobile phases. One solvent system (A) was methanol:water:trifluoroacetic acid in the ratio 75:25:0.05 (v/v) for 15 min with a flow rate of 0.8 mL/min. The other solvent system (B) was methanol:acetonitrile:water:trifluoroacetic acid in the ratio 65:10:25:0.05 for 15 min with a flow rate of 0.8 mL/min. Peaks were detected by UV absorption at 219 nm. All the target lipids (**1**−**9**) showed more than 95% purity. Typical retention times in mobile phase A were: 3.56 min (lipid **1**); 3.58 mins (lipid **2**); 3.60 min (lipid **3**), 3.59 mins (lipid **4**); 3.63 min (lipid **5**); 3.65 min (lipid **6**); 3.57 min (lipid **7**); 3.61 min (lipid **8**); 3.64 min (lipid **9**).

Synthesis. Lipids **1**−**9** were synthesized essentially applying the same synthetic steps as depicted schematically in Scheme 1. As a representative experimental detail, synthesis of lipid **2** is described below. For all the other lipids, only TLC, ^{1}H NMR, and mass spectral data are provided below. Due to extensive line broadening in ^{1}H NMR spectra of the final deprotected lipids (particularly in the region δ/ppm = 3−5), all the final lipids were characterized by LSIMS. However, ^{1}H NMR spectra of the BOC-protected immediate precursors for all the final

[1] Abbreviations used: BOC, *tert*-butyloxycarbonyl; Chol, cholesterol; DCC, dicyclohexylcarbodiimide; DCM, dichloromethane; DMAP, 4-(*N*,*N*-dimethylamino)pyridine; DMEM, Dulbecco's Modified Eagle's Medium; DMF, *N*,*N*-dimethylformamide; DOPE, 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine; FBS, fetal bovine serum; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; PBS, phosphate-buffered saline; TFA, trifluoroacetic acid.

lipids **1**−**9** (provided below) were in complete agreement with their assigned molecular structures.

Synthesis of *N,N*-Di-*n*-hexadecyl-*N*-methyl-*N*-[*N*′-(L-serinyl)aminoethyl]ammonium Chloride (lipid 2). *Step i (Scheme 1, Part A). Synthesis of N,N-Di-n-hexadecyl-N-[N-(Nα-BOC-L-serinyl)aminoethyl]amine.* Solid *N*-hydroxysuccinimide (0.08 g, 0.70 mmol) and DCC (0.16 g, 0.80 mmol) were added sequentially to an ice cold and stirred solution of *N*-*tert*-butyloxycarbonyl-L-serine (0.14 g, 0.70 mmol, prepared from L-serine and di-*tert*-butyl dicarbonate as described previously (*53*)) in dry DCM/dry DMF (9:1, v/v). After five minutes, *N*-(2-aminoethyl)-*N,N*-di-*n*-hexadecylamine (0.35 g, 0.70 mmol, a readily available precursor in our laboratory prepared as described previously (*48*)) and DMAP (catalytic) dissolved in dry DCM were added to the reaction mixture. The resulting solution was stirred at room temperature for 6 h, solid DCU was filtered, and the solvent from the filtrate was evaporated. The residue was taken up in ethyl acetate (100 mL) and washed sequentially with ice-cold 1 N HCl (3 × 100 mL), saturated sodium bicarbonate (3 × 100 mL), and water (3 × 100 mL). The organic layer was dried over anhydrous sodium sulfate and filtered and the solvent from the filtrate removed by rotary evaporation. The residue upon column chromatographic purification with 60−120 mesh silica gel using 3−4% methanol−dichloromethane (v/v) as eluent afforded 0.34 g (yield 71%) of the pure *N,N*-di-*n*-hexadecyl-*N*-[*N*-(*N*α-BOC-L-serinyl)aminoethyl]amine intermediate (R_f = 0.45, 10% methanol−dichloromethane, v/v). ^{1}H NMR (200 MHz, $CDCl_3$): δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{14}$]; 1.2−1.4 [m, 56H, (C*H*$_2$)$_{14}$]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 2.5 [t, 4H, N(C*H*$_2$-CH$_2$)$_2$]; 2.65 [t, 2H, NC*H*$_2$CH$_2$NHCO]; 3.3 [m, 2H, NCH$_2$C*H*$_2$NHCO]; 3.55 [dd, 1H, CH$_2$NHCOCH(C*H*OH)-NHBOC]; 3.9 [dd, 1H, CH$_2$NHCOCH(CH*H*OH)NHBOC]; 4.05 [m, 1H, CH$_2$NHCOC*H*(CHHOH)NHBOC]; 5.5 (m, 1H, Boc-N*H*); 6.8 [m, 1H, CH$_2$CH$_2$N*H*CO].

Step ii (Scheme 1, Part A). Synthesis of N,N-Di-n-hexadecyl-N-[N(Nα-BOC-L-serinyl)aminoethyl]-N-methylammonium Iodide. The intermediate obtained in step i above was dissolved in 3 mL of dichloromethane/methanol (2:1, v/v), and 3 mL of methyl iodide was added. The solution was stirred at room-temperature overnight. Solvent was removed on a rotary evaporator. The residue upon column chromatographic purification with 60−120 mesh size silica gel and 5−6% methanol in dichloromethane (v/v) as eluent afforded 0.22 g (54% yield) of pure *N,N*-di-*n*-hexadecyl-*N*-[*N*-(*N*α-BOC-L-serinyl)aminoethyl]-*N*-methylammonium iodide intermediate (R_f = 0.3, 10% methanol in dichloromethane, v/v). ^{1}H NMR (200 MHz, $CDCl_3$): δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{13}$]; 1.2−1.4 [m, 52H, CH$_3$(C*H*$_2$)$_{13}$]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.8 [m, 4H, N$^+$(CH$_2$C*H*$_2$)$_2$]; 3.05 [s, 3H, N$^+$C*H*$_3$]; 3.2−3.3 [m,4H, N$^+$(C*H*$_2$CH$_2$)$_2$]; 3.5 [m,2H, N$^+$C*H*$_2$CH$_2$NHCO]; 3.6−3.75 [m, 3H, N$^+$CH$_2$C*H*$_2$NHCO; dd, 1H, CH$_2$NHCOCH(C*H*OH)NHBOC]; 3.9 [dd, 1H, CH$_2$NHCOCH(CH*H*OH)NHBOC]; 4.15 [m, 1H, CH$_2$NHCOC*H*(CHHOH)NHBOC]; 6.0 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH$_2$CH$_2$N*H*CO].

Steps iii and iv (Scheme 1, Part A). Synthesis of N,N-Di-n-hexadecyl-N-methyl-N-[N′-(L-serinyl)aminoethyl]-ammonium Chloride (lipid 2). The intermediate obtained above in step ii (0.22 g) was dissolved in dry DCM (2 mL), and TFA (2 mL) was added at 0 °C. The resulting solution was stirred at room-temperature overnight to ensure complete deprotection. Excess TFA was removed by flushing with nitrogen to give the title compound as a trifluoroacetate salt. Column chromatographic purification using 60−120 mesh size silica gel and 12−14% (v/v) methanol−chloroform as eluent followed by chloride ion exchange chromatography (using amberlyst A-26 chloride ion-exchange resin) afforded 102 mg (57% yield) of pure lipid **2** (R_f = 0.3−0.4, 15% methanol in chloroform, v/v). LSIMS (lipid **2**): *m/z*: 611 [M + 1$^+$] (calcd for$C_{38}H_{80}O_2N_3$, 35%).

Lipids **1**, **3**−**9** were synthesized following the same four-step protocols as described above for the synthesis lipid **2** using the appropriate starting mixed amine (**I**, Scheme 1) and *N*-BOC-protected appropriate amino acids shown in Scheme 1. The TLC characteristics, ^{1}H NMR spectral data for the immediate precursor of the remaining final lipids, and the LSIMS data for the remaining final lipids are provided below.

Lipid 1. ^{1}H NMR (200 MHz, $CDCl_3$) of *N,N*-di-*n*-tetradecyl-*N*-[*N*-(*N*α-BOC-L-serinyl)aminoethyl]-*N*-methylammonium iodide (immediate precursor of lipid **1**, R_f = 0.3, 10% methanol in dichloromethane, v/v): δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{11}$]; 1.2−1.4 [m, 44H, CH$_3$(C*H*$_2$)$_{11}$]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.8 [m, 4H, N$^+$-(CH$_2$C*H*$_2$)$_2$]; 3.05 [s, 3H, N$^+$C*H*$_3$]; 3.2−3.3 [m,4H, N$^+$(C*H*$_2$-CH$_2$)$_2$]; 3.5 [m,2H, N$^+$C*H*$_2$CH$_2$NHCO]; 3.6−3.75 [m, 3H, N$^+$CH$_2$C*H*$_2$NHCO; dd, 1H, CH$_2$NHCOCH(C*H*OH)-NHBOC]; 3.9[dd, 1H, CH$_2$NHCOCH(CH*H*OH)NHBOC]; 4.15 [m, 1H, CH$_2$NHCOC*H*(CHHOH)NHBOC]; 6.0 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH$_2$CH$_2$N*H*CO]. LSIMS (lipid **1**): *m/z*: 555 [M + 1$^+$] (calcd for$C_{34}H_{72}O_2N_3$, 100%).

Lipid 3. ^{1}H NMR (200 MHz, $CDCl_3$) of *N,N*-di-*n*-octadecyl-*N*-[*N*-(*N*α-BOC-L-serinyl)aminoethyl]-*N*-methylammonium iodide (immediate precursor of lipid **3**, R_f = 0.3, 10% methanol in dichloromethane, v/v). δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{15}$]; 1.2−1.4 [m, 60H, CH$_3$(C*H*$_2$)$_{15}$]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.8 [m, 4H, N$^+$-(CH$_2$C*H*$_2$)$_2$]; 3.05 [s, 3H, N$^+$C*H*$_3$]; 3.2−3.3 [m,4H, N$^+$(C*H*$_2$-CH$_2$)$_2$]; 3.5 [m,2H, N$^+$C*H*$_2$CH$_2$NHCO]; 3.6−3.75 [m, 3H, N$^+$CH$_2$C*H*$_2$NHCO; dd, 1H, CH$_2$NHCOCH(C*H*OH)-NHBOC]; 3.9[dd, 1H, CH$_2$NHCOCH(CH*H*OH)NHBOC]; 4.15 [m, 1H, CH$_2$NHCOC*H*(CHHOH)NHBOC]; 6.0 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH$_2$CH$_2$N*H*CO]. LSIMS (lipid **3**): *m/z*: 667 [M + 1$^+$] (calcd for$C_{42}H_{88}O_2N_3$, 100%).

Lipid 4. ^{1}H NMR (200 MHz, $CDCl_3$) of *N*-[*N*-(*N*α-BOC-L-alanyl)aminoethyl]-*N,N*-di-*n*-tetradecyl-*N*-methylammonium iodide (immediate precursor of lipid **4**, R_f = 0.5, 10% methanol in dichloromethane, v/v). δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{13}$]; 1.2−1.4 [m, 44H, (C*H*$_2$)$_{11}$; 3H, NHCOCH-(C*H*$_3$)NHBoc]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.7 [m, 4H, N$^+$(CH$_2$C*H*$_2$)$_2$]; 3.2 [s, 3H, N$^+$C*H*$_3$]; 3.3 [m,4H, N$^+$(C*H*$_2$-CH$_2$)$_2$]; 3.7−3.9 [bs, 4H, N$^+$C*H*$_2$C*H*$_2$NHCO]; 4.05 [m, 1H, NHCOC*H*(CH$_3$)NHBOC]; 5.2 [m, 1H, BOC N*H*]; 8.2 [m, 1H, CH$_2$CH$_2$N*H*CO]. LSIMS (lipid **4**): *m/z*: 539 [M + 1$^+$] (calcd for$C_{34}H_{72}ON_3$, 100%).

Lipid 5. ^{1}H NMR (200 MHz, $CDCl_3$): *N,N*-di-*n*-hexadecyl-*N*-[*N*-(*N*α-BOC-L-alanyl)aminoethyl]-*N*-methylammonium iodide (immediate precursor of lipid **5**, R_f = 0.5, 10% methanol in dichloromethane, v/v). δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{13}$]; 1.2−1.4 [m, 52H, (C*H*$_2$)$_{13}$; 3H, NHCOCH(C*H*$_3$)NHBOC]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.7 [m, 4H, N$^+$(CH$_2$C*H*$_2$)$_2$]; 3.2 [s, 3H, N$^+$C*H*$_3$]; 3.3 [m, 4H, N$^+$(C*H*$_2$CH$_2$)$_2$]; 3.7−3.9 [bs, 4H, N$^+$C*H*$_2$C*H*$_2$-NHCO]; 4.05 [m, 1H, NHCOC*H*(CH$_3$)NHBOC]; 5.2 [m, 1H, BOC N*H*]; 8.2 [m, 1H, CH$_2$CH$_2$N*H*CO]. LSIMS (lipid **5**): *m/z*: 595 [M + 1$^+$] (calcd for$C_{38}H_{80}N_3O$, 100%).

Lipid 6. ^{1}H NMR (200 MHz, $CDCl_3$) of *N*-[*N*-(*N*α-BOC-L-alanyl]aminoethyl]-*N,N*-di-*n*-octadecyl-*N*-methylammonium iodide (immediate precursor of lipid **6**, R_f = 0.5, 10% methanol in dichloromethane, v/v). δ/ppm = 0.9 [t, 6H, C*H*$_3$(CH$_2$)$_{13}$]; 1.2−1.4 [m, 60H, (C*H*$_2$)$_{15}$; 3H, NHCOCH-(C*H*$_3$)NHBOC]; 1.4−1.5 [s, 9H, COOC(C*H*$_3$)$_3$]; 1.6−1.7 [m, 4H, N$^+$(CH$_2$C*H*$_2$)$_2$]; 3.2 [s, 3H, N$^+$C*H*$_3$]; 3.3 [m, 4H,

$N^+(CH_2CH_2)_2$]; 3.7−3.9 [bs, 4H, $N^+CH_2CH_2NHCO$]; 4.05 [m, 1H, $NHCOCH(CH_3)NHBOC$]; 5.2 [m, 1H, BOC N*H*]; 8.2 [m, 1H, CH_2CH_2NHCO]. LSIMS (lipid **6**): *m/z*: 651 [M + 1$^+$] (calcd for$C_{42}H_{88}ON_3$, 100%).

Lipid 7. ^{1}H NMR (200 MHz, $CDCl_3$) of *N*-[*N*-(*N*$^\alpha$-BOC-L-*β*-alanyl)]aminoethyl]-*N*,*N*-di-*n*-tetradecyl-*N*-methylammonium iodide (immediate precursor of lipid **7**, R_f = 0.5, 10% methanol in dichloromethane, v/v). *δ*/ppm = 0.9 [t, 6H, $CH_3(CH_2)_{11}$]; 1.2−1.4 [m, 44H, $CH_3(CH_2)_{11}$]; 1.4−1.5 [s, 9H, $COOC(CH_3)_3$]; 1.7 [m, 4H, $N^+(CH_2CH_2)_2$]; 2.45 [t, 2H, $COCH_2CH_2NHBOC$]; 3.3 [s, 3H, N^+CH_3]; 3.4−3.5 [bs, 6H, $N^+(CH_2CH_2)_2$, $N^+CH_2CH_2NH$]; 3.7 [bs, 4H, N^+-$CH_2CH_2NHCOCH_2CH_2NHBOC$]; 5.3 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH_2CH_2NHCO]. LSIMS (lipid **7**): *m/z*: 539 [M + 1$^+$] (calcd for$C_{34}H_{72}ON_3$, 100%).

Lipid 8. ^{1}H NMR (200 MHz, $CDCl_3$) of *N*-[*N*-(*N*$^\alpha$-BOC-L-*β*-alanyl)]aminoethyl]-*N*,*N*-di-*n*-hexadecyl-*N*-methylammonium iodide (immediate precursor of lipid **8**, R_f = 0.5, 10% methanol in dichloromethane, v/v). *δ*/ppm = 0.9 [t, 6H, $CH_3(CH_2)_{13}$]; 1.2−1.4 [m, 52H, $CH_3(CH_2)_{13}$]; 1.4−1.5 [s, 9H, $COOC(CH_3)_3$]; 1.7 [m, 4H, $N^+(CH_2CH_2)_2$]; 2.45 [t, 2H, $COCH_2CH_2NHBOC$]; 3.3 [s, 3H, N^+CH_3]; 3.4−3.5 [bs, 6H, $N^+(CH_2CH_2)_2$, $N^+CH_2CH_2NH$]; 3.7 [bs, 4H, N^+-$CH_2CH_2NHCOCH_2CH_2NHBOC$]; 5.3 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH_2CH_2NHCO]. LSIMS (lipid **8**): *m/z*: 595 [M$^+$] (calcd for$C_{38}H_{80}ON_3$, 100%).

Lipid 9. ^{1}H NMR (200 MHz, $CDCl_3$) of *N*-[*N*-(*N*$^\alpha$-BOC-L-*β*-alanyl)]aminoethyl]-*N*,*N*-di-*n*-octadecyl-*N*-methylammonium iodide (immediate precursor of lipid **9**, R_f = 0.5, 10% methanol in dichloromethane, v/v). *δ*/ppm = 0.9 [t, 6H, $CH_3(CH_2)_{15}$]; 1.2−1.4 [m, 60H, $CH_3(CH_2)_{15}$]; 1.4−1.5 [s, 9H, $COOC(CH_3)_3$]; 1.7 [m, 4H, $N^+(CH_2CH_2)_2$]; 2.45 [t, 2H, $COCH_2CH_2NHBOC$]; 3.3 [s, 3H, N^+CH_3]; 3.4−3.5 [bs,6H, $N^+(CH_2CH_2)_2$, $N^+CH_2CH_2NH$]; 3.7 [bs, 4H, N^+-$CH_2CH_2NHCOCH_2CH_2NHBOC$]; 5.3 [m, 1H, BOCN*H*]; 8.1 [m, 1H, CH_2CH_2NHCO]. LSIMS (lipid **9**): *m/z*: 651 [M + 1$^+$] (calcd for$C_{42}H_{88}ON_3$, 100%).

Cell Culture. COS-1 (SV 40 transformed African green monkey kidney cells), CHO (Chinese hamster ovary), HepG2 (human hepatocarcinoma), and MCF-7 (human breast adenocarcinoma cell) cell lines were procured from the National Centre for Cell Sciences (NCCS), Pune, India. Cells were cultured at 37 °C in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum, 50 *μ*g/mL penicillin, 50 *μ*g/mL streptomycin, and 20 *μ*g/mL kanamycin in a humidified atmosphere containing 5% CO_2.

Preparation of Liposomes. The cationic lipid and the colipid (Chol) in 1:1 mole ratio were dissolved in a mixture of chloroform and methanol (3:1, v/v) in a glass vial. The solvent was removed with a flow of moisture free nitrogen gas, and the dried lipid film was then kept under high vacuum for 8 h. A 5 mL amount of sterile deionized water was added to the vacuum-dried lipid film, and the mixture was allowed to swell overnight. The vial was then vortexed for 2−3 min at room temperature and occasionally sonicated in a bath sonicator to produce multilamellar vesicles (MLVs). MLVs were then sonicated in an ice bath (usually 45−60 s) until clarity using a Branson 450 sonifier at 100% duty cycle and 25 W output power. The resulting clear aqueous liposomes were used in forming lipoplexes.

Plasmid DNA. pCMV-SPORT-*β*-gal plasmid was a generous gift from Dr. Nalam Madhusudhana Rao (Centre for Cellular and Molecular Biology, Hyderabad, India) and was amplified in DH5α strain of *Escherichia coli*, isolated by alkaline lysis procedure, and finally purified by PEG-8000 precipitation as described previously (*54*). The purity of plasmid was checked by A_{260}/A_{280} ratio (around 1.9) and 1% agarose gel electrophoresis.

Transfection of Cells. Cells were seeded at a density of 15000 (for COS-1) and 20000 cells (for CHO, HepG2, and MCF-7) per well in a 96-well plate 18−24 h before the transfection. A 0.3 *μ*g amount of plasmid DNA was complexed with varying amounts of lipids (0.09−8.1 nmol) in plain DMEM medium (total volume made up to 100 *μ*L) for 30 min. The charge ratios were varied from 0.1:1 to 9:1 (±) over these ranges of the lipids. Immediately prior to transfection, cells plated in the 96-well plate were washed with PBS (2 × 100 *μ*L) followed by the addition of lipoplexes. After 3h of incubation, 100*μ*L of DMEM with 20% FBS was added to the cells. The medium was changed to 10% complete medium after 24 h and the reporter gene activity was estimated after 48 h. The cells were washed twice with PBS (100 *μ*L each) and lysed in 50 *μ*L of lysis buffer [0.25 M Tris-HCl (pH 8.0) and 0.5% NP40]. Care was taken to ensure complete lysis. The *β*-galactosidase activity per well was estimated by adding 50 *μ*L of 2X-substrate solution [1.33 mg/mL of ONPG, 0.2 M sodium phosphate (pH 7.3) and 2 mM magnesium chloride] to the lysate in a 96-well plate. Absorbance of the product *o*-nitrophenol at 405 nm was converted to *β*-galactosidase units by using a calibration curve constructed using pure commercial *β*-galactosidase enzyme. Each transfection experiment was repeated three times on three different days. The transfection values reported were average values from three replicate transfection plates assayed on three different days. The values of *β*-galactosidase units in replicate plates assayed on the same day varied by less than 20%. The day to day variation in transfection efficiency values for identically treated transfection plates was mostly within 2−3-fold and was dependent on the cell density and condition of the cells.

Toxicity Assay. Cytotoxicities of lipids **1**−**9** were assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay as described earlier (*37*). The cytotoxicity assay was performed in 96-well plates by maintaining the same ratio of number of cells to amount of cationic lipid, as used in the transfection experiments. MTT was added 3 h after addition of cationic lipid to the cells. Results were expressed as percent viability = [A_{540}(treated cells) − background/A_{540}(untreated cells) − background] × 100.

Zeta Potential (*ζ*) and Size Measurements. The sizes and the surface charges (zeta potentials) of liposomes and lipoplexes were measured by photon correlation spectroscopy and electrophoretic mobility on a Zeta sizer 3000HS_A (Malvern, UK). The sizes were measured in deionized water with a sample refractive index of 1.59 and a viscosity of 0.89. The system was calibrated by using the 200 ± 5 nm polystyrene polymer (Duke Scientific Corp., Palo Alto, CA). The diameters of liposomes and lipoplexes were calculated by using the automatic mode. The zeta potential was measured using the following parameters: viscosity, 0.89 cP; dielectric constant, 79; temperature, 25 °C; F(Ka), 1.50 (Smoluchowski); maximum voltage of the current, V. Measurements were done 10 times with the zero field correction. The potentials were calculated by using the Smoluchowski approximation.

DNase 1 Sensitivity Assays. Briefly, in a typical assay, 1.5 nmol of DNA (500 ng) was complexed with lipid using the indicated lipid:DNA charge ratios in 10 mM HEPES buffer (pH 7.4) in a volume of 40 *μ*L and the mixture incubated at room temperature for 30 min on a rotary shaker. Subsequently, the complexes were treated

with DNase I (at a final concentration of 1 ng/1.5 nmol of DNA) in the presence of 10 mM $MgCl_2$ and incubated for 20 min at 37 °C. The reactions were then halted by adding EDTA (to a final concentration of 50 mM) and incubated at 60 °C for 10 min in a water bath. The aqueous layer was washed with 50 μL of phenol:chloroform mixture (1:1, v/v) and centrifuged at 10 000 g for 5 min. The aqueous supernatants were separated, loaded (15 μL) on a 1% agarose gel, and electrophoresed at 100 V for 2 h. The bands were visualized with ethidium bromide staining.

X-Gal Staining. Cells expressing β-galactosidase were histochemically stained with the substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal) as described previously (*47*). Briefly, 48 h after transfection with lipoplexes in 96-well plates, the cells were washed two times (2 × 100 μL) with phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4) and fixed with 0.5% glutaraldehyde in PBS (225 μL). After 15 min incubation at room temperature, the cells were washed again with PBS three times (3 × 250 μL) and subsequently were stained with 1.0 mg/mL X-gal in PBS containing 5.0 mM $K_3[Fe(CN)_6]$, and 5.0 mM $K_4[Fe(CN)_6]$ and 1 mM $MgSO_4$ for 2−4 h at 37 °C. Blue colored cells were identified by light microscope (Leica, Germany).

RESULTS

Chemistry. Lipids **1**−**9** were prepared by conventional DCC coupling of the common precursor **I** (a readily available hydrophobic mixed primary-tertiary amine in our laboratory prepared as described previously (*48*)) and the appropriate BOC-protected amino acids (Scheme 1). The resulting intermediates were then subjected to quaternization with excess methyl iodide and BOC-deprotection with trifluoroacetic acid. The BOC-deprotected products afforded pure target lipids upon chloride ion exchange chromatography over Amberlyst-26 (Scheme 1). Minor variation in lipid structures were ensured by designing lipid pairs varying either only in structurally isomeric headgroup functionalities (e.g. lipid pairs **4** and **7**, **5** and **8**, and **6** and **9**) or by designing lipid pairs whose sole structural difference is substitution of a hydrogen atom in the headgroup side chain of one lipid by a hydroxyl functionality in the other (e.g. lipid pairs **1** and **4**, **2** and **5**, and **3** and **6**). Structures of all the synthetic intermediates and the final lipids shown in Scheme 1 were confirmed by ^{1}H NMR and LSIMS.

Transfection Biology. The in vitro gene transfer efficacies of lipids **1**−**9** were first measured by the reporter gene expression assay using equimolar cholesterol as colipid (cholesterol was found to be a more efficacious colipid than the other commonly used colipid dioleoyllphosphatidyl ethanolamine, DOPE, data not shown) and pCMV-SPORT-β-gal plasmid as the reporter gene across the lipid:DNA charge ratios 9:1−0.3:1. Figures 1−4 summarize the relative in vitro gene delivery efficacies of lipids **1**−**9** in transfecting CHO, HepG2, MCF7, and COS-1 cells, respectively. In CHO, HepG2, and MCF-7 cells, cationic lipids with alanine and β-alanine headgroups were, in general, found to be more transfection efficient than LipofectAmine-2000 (by about 2-fold in CHO and MCF-7 cells), a commercially available popular liposomal transfection kit (Figures 1−3, Parts B and C). Except in MCF-7 cells at 1:1 lipid:DNA charge ratio and in COS-1 cells, the sterylated lipids with alanine (lipid **6**) and β-alanine (lipid **9**) headgroups were found to be less efficient than their myristyl and palmityl

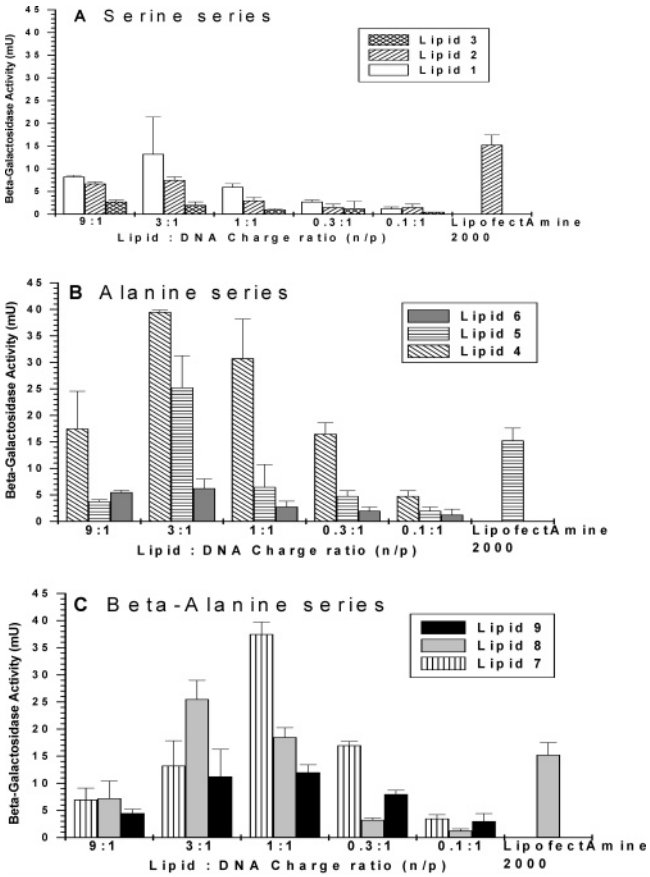

Figure 1. In vitro transfection efficiencies in CHO cells of lipids **1**, **2**, **3** (A); lipids **4**, **5**, **6** (B); and lipids **7**, **8**, **9** (C) using cholesterol as colipid (at lipid:cholesterol mole ratio of 1:1). Units of β-galactosidase activity were plotted against the varying lipid to DNA (±) charge ratios. The transfection efficiencies of the lipids were compared to that of commercially available LipofectAmine 2000. Transfection experiments were performed as described in the text. The transfection values shown are average of duplicate experiments performed on the same day.

analogues (lipids **4** and **5**, and **7** and **8**, respectively, Figures 1−4, parts B and C). However, unlike the previously reported high transfection efficacies of cationic lipids containing hydroxyalkyl headgroups (*31*, *40*, *41*, *49*, *50*, *52*), the cationic lipids with serine headgroups (lipids **1**−**3**) in spite of possessing hydroxymethyl headgroup functionalities were found to be less efficacious than their alanine (lipids **4**−**6**) and β-alanine (lipids **7**−**9**) analogues in transfecting all the four cells (Figures 1−4).

Unlike the comparable gene transfer efficacies of the cationic lipids with structurally isomeric alanine (lipids **4**−**6**) and β-alanine headgroups (lipids **7**−**9**) in CHO, HepG2, and MCF-7 cells (Figures 1−3, parts B and C), lipids **7**−**9** with β-alanine headgroups showed significantly higher transfection properties in COS-1 cells than its alanine analogues (Figure 4, parts B and C). In particular, at 3:1 lipid:DNA charge ratio, lipid **9** was found to be strikingly more efficient (>10-fold) than its alanine counterpart (lipid **6**) in transfecting COS-1 cells (Figure 4, parts B and C). The β-alanine lipid with a palmityl chain (**8**) were 3−4-fold more transfection efficient than LipofectAmine-2000 at lipid:DNA charge ratios of 3:1 (Figure 4, part C). The general transfection profiles for lipids **1**−**9** found in the above-mentioned reporter gene assays (Figures 1−4) were further confirmed by the whole cell histochemical X-gal staining assay. Representative X-gal staining patterns for CHO

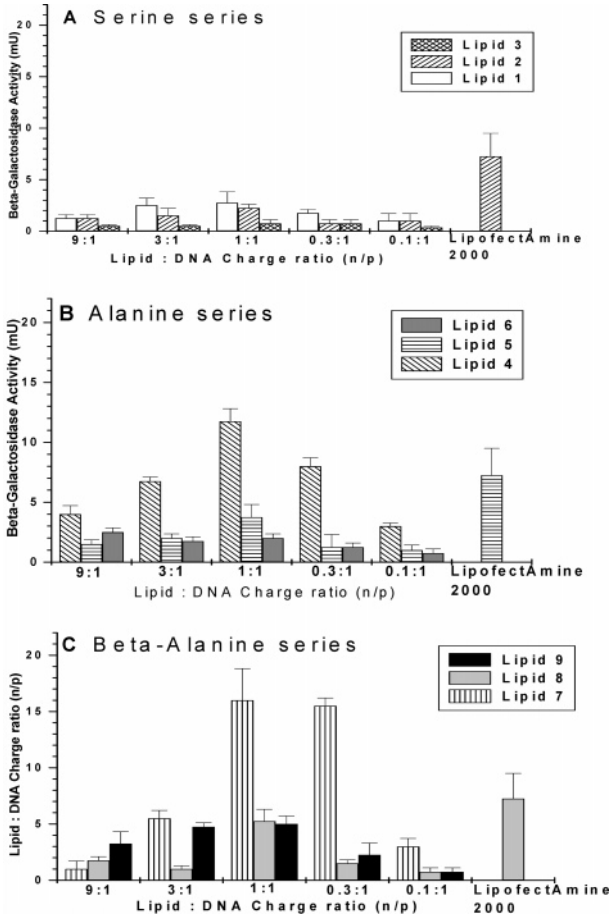

Figure 2. In vitro transfection efficiencies in HepG2 cells of lipids **1**, **2**, **3** (A); lipids **4**, **5**, **6** (B); and lipids **7**, **8**, **9** (C) using cholesterol as colipid (at lipid:cholesterol mole ratio of 1:1). Units of β-galactosidase activity were plotted against the varying lipid to DNA (±) charge ratios. The transfection efficiencies of the lipids were compared to that of commercially available LipofectAmine 2000. Transfection experiments were performed as described in the text. The transfection values shown are average of duplicate experiments performed on the same day.

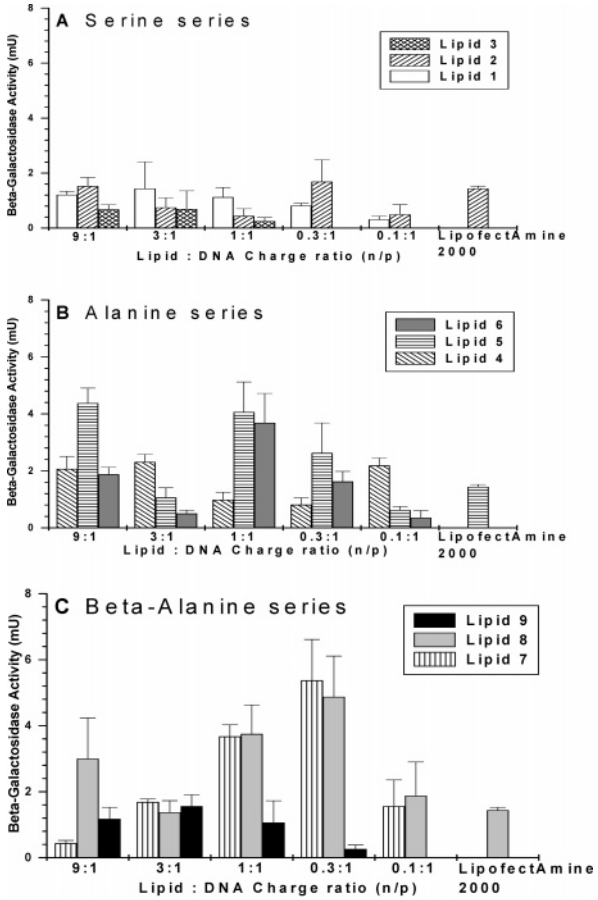

Figure 3. In vitro transfection efficiencies in MCF-7 cells of lipids **1**, **2**, **3** (A); lipids **4**, **5**, **6** (B); and lipids **7**, **8**, **9** (C) using cholesterol as colipid (at lipid:cholesterol mole ratio of 1:1). Units of β-galactosidase activity were plotted against the varying lipid to DNA (±) charge ratios. The transfection efficiencies of the lipids were compared to that of commercially available LipofectAmine 2000. Transfection experiments were performed as described in the text. The transfection values shown are average of duplicate experiments performed on the same day.

cells are shown in Figure 5 for lipids **1**, **3**, **4**, **6**, **7**, and **9** at both lipid:DNA charge ratios of 3:1 and 1:1.

Cell Viabilities. MTT-based cell viability assays were performed in representative CHO cells with lipids **1**−**9** as well as with the commercially available LipofectAmine across the entire range of lipid:DNA charge ratios used in the actual transfection experiments. Percent cell viabilities of lipids **1**−**9** were found to be high (more than 75%), particularly up to the lipid:DNA charge ratios of 3:1 (Figure 6). However, LipofectAmine was found to be less toxic than the present lipids, particularly at lipid:DNA charge ratios 9:1 and 3:1 (Figure 6).

Physicochemical Characterizations of Liposomes and Lipoplexes. Sizes and Zeta Potentials. The nanosizes and the global surface charges of the representative lipoplexes prepared with lipids **1**, **3**, **4**, **6**, **7** and **9** were measured using dynamic laser light scattering instrument equipped with zeta-sizing capacity across the lipid:DNA charge ratios of 0.1:1 to 9:1 in the presence of DMEM. Broadly speaking, the nanosizes of lipoplexes prepared using both transfection efficient (e.g. **4** and **7**) and transfection-incompetent lipids (e.g. **3** and **6**) similarly increased with increasing lipid:DNA charge ratios (up to 3:1) within the range 200−430 nm (data not shown). At the highest lipid:DNA charge ratios of 9:1, all the lipoplexes grew somewhat larger (around 600 nm). Interestingly, in the presence of DMEM, the global surface charges of both the inefficient as well as efficient lipoplexes prepared using lipid:DNA charge ratios of 1:1 or 3:1 were found to be either slightly positive (2−5 mV) or close to electroneutrality (Table 1).

Gel-Mobility Shifts. Toward understanding the role of lipid:DNA electrostatic binding interactions (if any) in modulating the in vitro transfection efficacies of lipids **1**−**9**, gel-mobility shift assays were performed using representative lipoplexes prepared with lipids **1** and **3** (serine head), **4** and **6** (alanine head), and **7** and **9** (β-alanine head) across the lipid:DNA charge ratios of 9:1 to 0.1:1. The band intensities of the free DNA (unassociated or loosely bound with lipoplexes) for all these lipoplexes were found to be remarkably diminished at lipid:DNA charge ratios of 3:1 and 9:1 (Figure 7), indicating that at such high lipid:DNA charge ratios, all the lipids were strongly associated with plasmid DNA. At lower lipid:DNA charge ratios (1:1−0.1:1), the band intensities of free DNA for all the lipoplexes increased significantly, the highest increase being observed with serine-lipids (lipids **1** and **3**, Figure 7, parts A−C).

DNase I Sensitivities. Toward obtaining insights into the relative accessibilities of the lipoplex associated DNA to DNase I, DNase I sensitivity assays were carried out using lipoplexes made with lipids **1**−**9** across the entire range of lipid:DNA charge ratios 0.1:1−9:1. After the free DNA digestion by DNase I, the total DNA (both digested

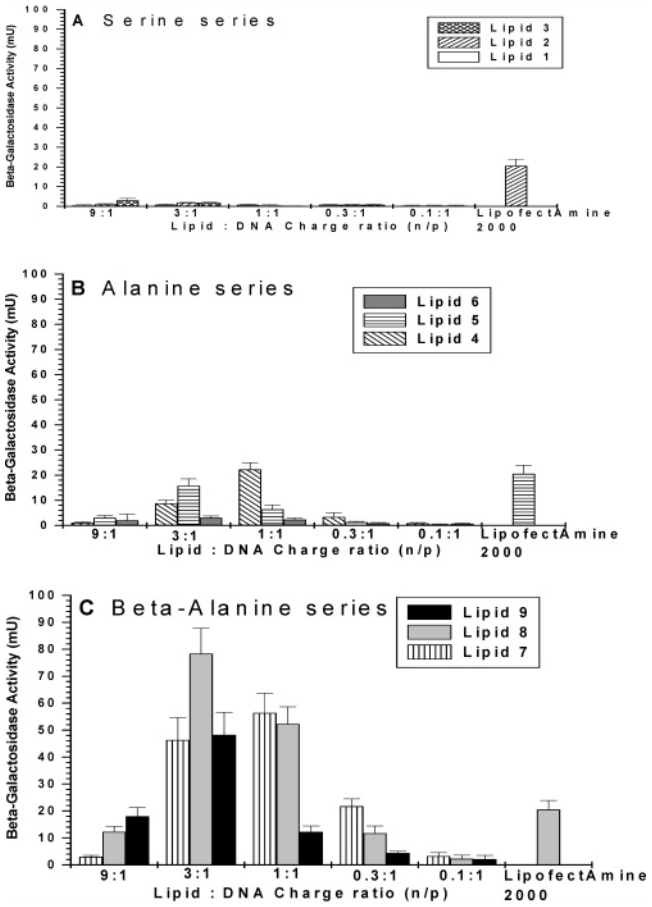

Figure 4. In vitro transfection efficiencies in COS-1 cells of lipids **1**, **2**, **3** (A); lipids **4**, **5**, **6** (B); and lipids **7**, **8**, **9** (C) using cholesterol as colipid (at lipid:cholesterol mole ratio of 1:1). Units of β-galactosidase activity were plotted against the varying lipid to DNA ($\pm$) charge ratios. The transfection efficiencies of the lipids were compared to that of commercially available LipofectAmine 2000. Transfection experiments were performed as described in the text. The transfection values shown are average of duplicate experiments performed on the same day.

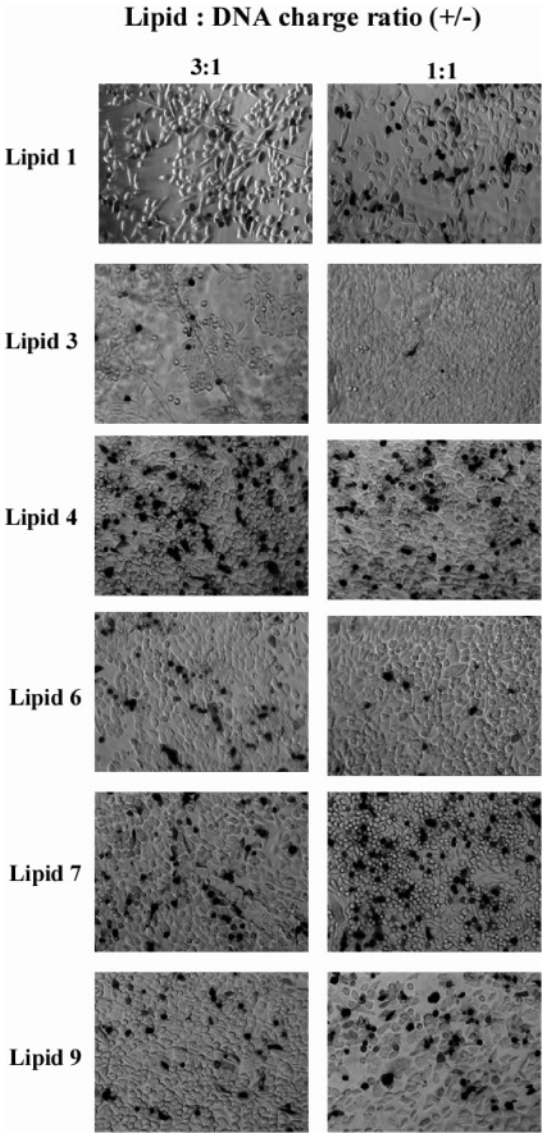

Figure 5. Histochemical whole cell X-gal staining of CHO cells transfected with lipids **1**, **3**, **4**, **6**, **7**, and **9** at lipid:DNA charge ratios of 3:1 and 1:1. Cells expressing β-galactosidase were stained with X-gal as described in the text.

and inaccessible DNA) was separated from the lipid and DNase I (by extracting with organic solvent) and loaded onto a 1% agarose gel. Resulting electrophoretic gel pattens in such DNase I protection experiments for representative lipoplexes prepared with lipids **1** and **3**, **4** and **6**, and **7** and **9** are shown in Parts A–C of Figure 8. In general, the band intensities of inaccessible and therefore undigested DNA associated with transfection incompetent lipids (**1** and **3** in particular) was observed to be significantly less than those associated with transfection efficient lipids (e.g. **4** and **7**, Figure 4, Parts A–C).

DISCUSSION

As a part of our ongoing structure–activity investigations in cationic lipid mediated gene delivery (*12*, *16*, *17*, *47–52*), in the present study, we have studied the influence of minor headgroup modifcations in liposomal gene delivery using nine novel cationic amphiphiles **1**–**9** containing simple aliphatic hydrocarbon chains (myristyl, palmityl, and stearyl) as hydrophobic tails and amino acids alanine, β-alanine and serine as their polar heads. Structurally speaking, lipid series **4**–**6** and **7**–**9** are very similar in nature. Except the headgroups of **4**–**6** being the structural isomers of lipids **7**–**9**, there are no differences between them. The only difference in the headgroup regions of lipids **1**–**3** and lipids **4**–**6** is that one hydrogen atom of the side-chain methyl groups of lipids **4**–**6** is substituted by one hydroxyl group in lipids **1**–**3**. Taking the high transfection efficacies of many previously reported cationic lipids containing a hydroxyalkyl headgroup (*31*, *40*, *41*) including our own (*49*, *50*, *52*) into account, we expected lipids **1**–**3** to be more transfection efficacious than lipids **4**–**6**. Surprisingly, lipids **1**–**3** turned out to be the most inefficient among all the lipids **1**–**9** (Figures 1–5). Findings in MTT-assay-based cell viability assays (Figure 6) ruled out the possibility of varying cell cytotoxicities playing any key role behind the compromised gene transfer efficacies of the serine lipids (**1**–**3**). The compromised transfection efficacies of lipids **1**–**3** in transfecting CHO, HepG2, MCF-7, and COS-1 cells across the entire lipid:DNA charge ratios of 0.1:9:1 (Figures 1–4, parts A) demonstrate that even minor structural substitution in the headgroup region can significantly lower the in vitro gene transfer properties of cationic amphiphiles. Such remarkable influence of minor headgroup modification in cationic lipid-mediated gene delivery is consistent with our recently reported findings on the dramatically superior transfer properties of a cholesterol-based cationic lipid with a β-alanine headgroup to its glycine counterpart (*47*). Findings in the

[a] ξ Potentials were measured by laser light scattering technique using Zetasizer 3000A (Malvern Instruments, UK). Values shown are the averages obtained from 10 (zeta potential) measurements.

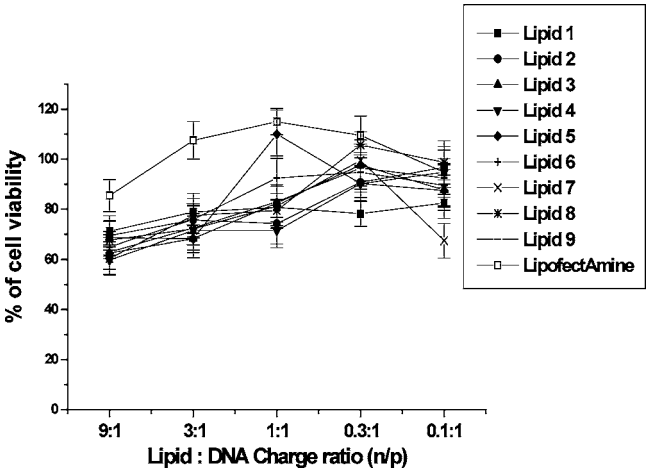

Figure 6. MTT-assay based cellular cytotoxicities of lipids **1**−**9** and commercially available LipofectAmine against representative CHO Cells. The percent cell viability values shown are average of duplicate experiments performed on the same day.

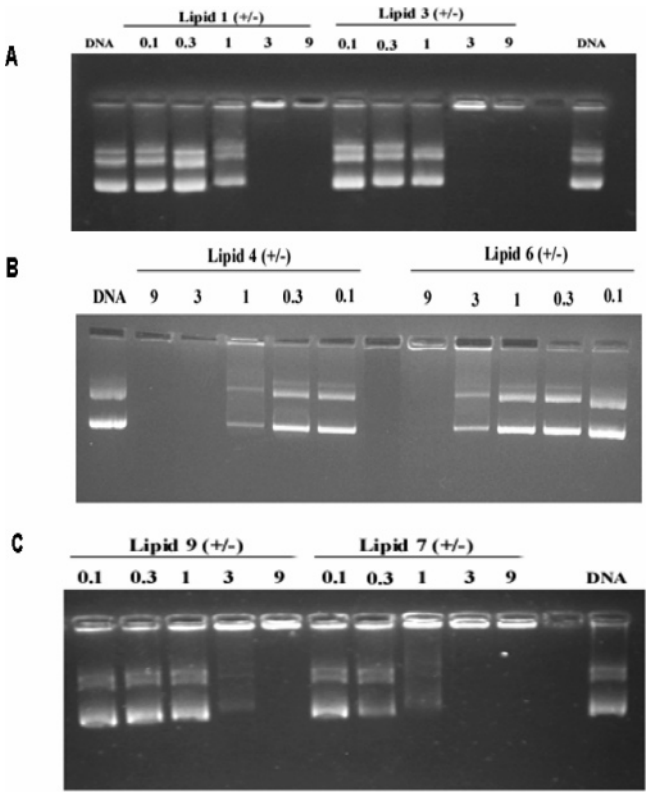

Figure 7. Electrophoretic gel patterns for lipoplex-associated DNA in gel retardation for lipid **1** and **3** (A), for lipid **4** and **6** (B), and for lipid **7** and **9** (C). The lipid:DNA charge ratios are indicated at the top of each lane. The details of treatment are as described in the text.

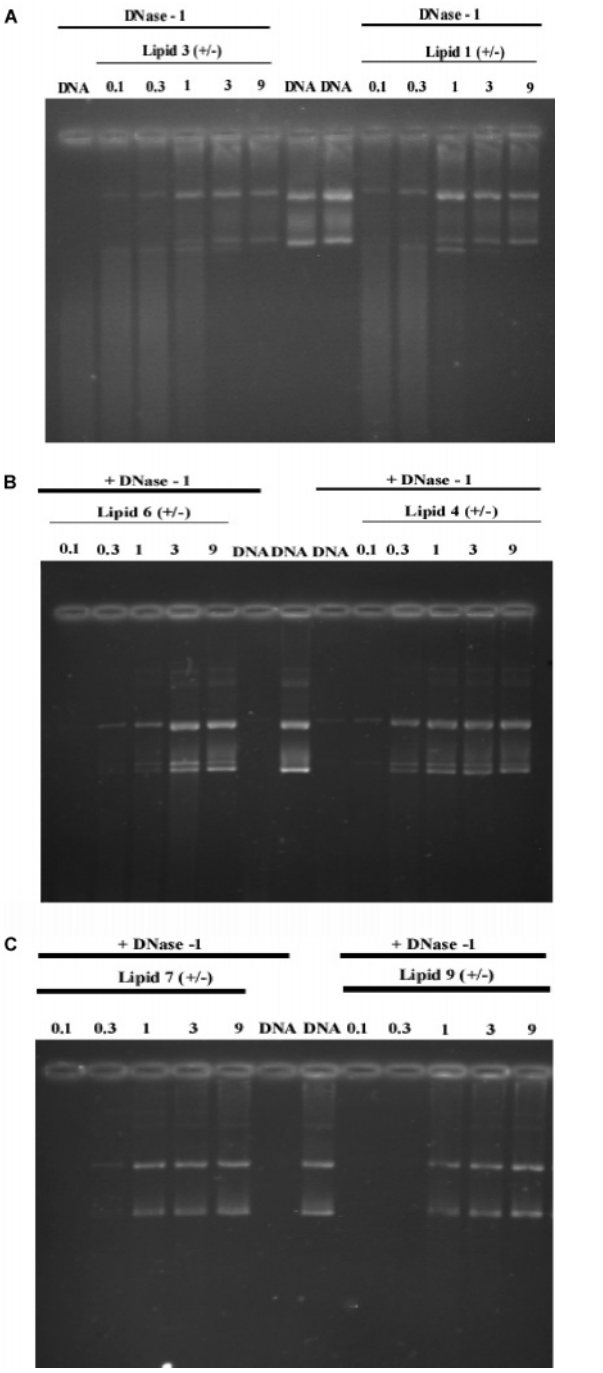

Figure 8. Electrophoretic gel patterns for lipoplex-associated DNA in DNase I sensitivity assay for lipids **1** and **3** (A), for lipids **4** and **6** (B), and for lipids **7** and **9** (C). The lipid:DNA charge ratios are indicated at the top of each lane. The details of treatment are as described in the text.

gel mobility shift assay indicate similar DNA-binding characteristics of lipids **1**−**9** (Figure 7). However, the electrophoretic gel patterns in DNase I sensitivity assays revealed pronounced sensitivities of DNA associated with lipoplexes of lipids **1**−**3** compared to DNA associated with lipids **4**−**9** (Figure 8). Thus, the findings summarized in Figures 7 and 8, taken together, support the notion that enhanced DNase I sensitivity of DNA associated with lipids **1**−**3** might play some important role behind their relatively poor gene transfer properties. However, the origin of such relatively pronounced DNase I sensitivities of the plasmid DNA associated with serine-lipids **1**−**3** across the entire lipid:DNA charge ratios of 9:1 to 0.1:1 remains elusive at this point of investigation.

The transfection profiles in COS-1 cells (Figure 4) provided the most convincing examples of dramatic headgroup influence in cationic lipid-mediated gene delivery. In COS-1 cells, although lipids **7**−**9** with β-alanine headgroups were found to be highly transfection efficient (lipid **8** at lipid:DNA charge ratios of 3:1 were 3−4-fold more transfection efficient than LipofectAmine-2000), gene transfer properties of lipids **4**−**6** containing their structurally isomeric alanine headgroups were observed to be significantly less (Figure 4, parts B and C). The strikingly enhanced gene transfection properties of lipid **9** with a β-alanine headgroup and a stearyl tail compared to lipid **6** with the same stearyl tail but a structurally isomeric alanine headgroup at 3:1 lipid:DNA charge ratio in COS-1 cells (Figure 4, parts B and C) demonstrate that in cationic lipid-mediated gene delivery even lipids with structurally isomeric headgroups can exhibit phenomenally contrasting transfection properties. The compromised transfection efficacies of all the present lipids at 9:1 lipid:DNA charge ratios (Figures 1−5) may partly originate from the big lipoplex sizes (>600 nm, data not shown). The global surface charge data summarized in Table 1 rules out the possibility of varying lipoplex surface potentials playing any key role behind the contrasting transfection profiles of the present lipids.

In conclusion, the present in-depth structure−activity investigation using nine novel cationic lipids with alanine, β-alanine, and serine headgroups demonstrates that high gene delivery efficacies of cationic amphiphiles containing alanine or β-alanine headgroups can get seriously compromised by substituting the alanine or β-alanine with serine, presumably due to the enhanced sensitivity of DNA associated with such serine-head-containing cationic lipids. The transfection efficacy profiles of the presently described cationic lipids once again reiterate the proposition that gene transfer efficacies of cationic amphiphiles can be significantly modulated by minor structural variations in both the polar headgroup and hydrophobic tail regions of the lipid.

ACKNOWLEDGMENT

Financial support received from the Department of Biotechnology, Government of India (to A.C.) is gratefully acknowledged. J.S. sincerely thanks the University Grant Commission (UGC), Government of India, for her doctoral research fellowship.

Albumin–Insulin Conjugate Releasing Insulin Slowly under Physiological Conditions: A New Concept for Long-Acting Insulin

Yoram Shechter,*,‡ Marina Mironchik,‡ Sara Rubinraut,§ Ayala Saul,‡,§ Haim Tsubery,‡,§ and Mati Fridkin*,§

Departments of Biological Chemistry and Organic Chemistry, Weizmann Institute of Science, Rehovot 76100, Israel. Received February 27, 2005; Revised Manuscript Received April 26, 2005

The covalent linkage of peptides or protein drugs to human serum albumin (HSA) greatly prolongs their lifetime in vivo but is pharmacologically irrelevant when it irreversibly inactivates them. We retain drug bioactivity by synthesizing a heterobifunctional reagent (MAL-Fmoc-OSu, 9-hydroxymethyl-2-(amino-3-maleimidopropionate)-fluorene-*N*-hydroxysuccinimide) that generates HSA–Fmoc–insulin on covalent conjugation to the amino group of insulin and the Cys-34 side chain of HSA. HSA–Fmoc–insulin is water-soluble and, upon incubation in aqueous buffers reflecting normal human serum conditions, slowly, spontaneously, and homogeneously hydrolyzes to release unmodified insulin with a $t_{1/2}$ of 25 ± 2 h. A single subcutaneous or intraperitoneal administration of HSA–Fmoc–insulin to diabetic rodents lowers circulating glucose levels for about 4 times longer than an equipotent dose of Zn^{2+}-free insulin. Following subcutaneous administration, onset of the glucose-lowering effect is delayed 0.5–1 h and persists for 12 h. Thus, we present a prototype insulin formulation possessing three desirable parameters: high aqueous solubility, delayed action following subcutaneous administration, and prolonged therapeutic effect.

INTRODUCTION

Most polypeptide drugs, in particular nonglycosylated proteins of molecular mass less than 50 kDa, are short-lived species in vivo, having circulatory half-lives of 5–20 min (*1*). The short lifetimes of proteins in vivo are attributed to several mechanisms, including glomerular filtration in the kidney and proteolysis at several levels (*2*). Insulin is degraded primarily in the liver through a mechanism defined as receptor-mediated endocytosis (*3*, *4*). This mechanism is an efficient route for terminating the action of the hormone after the levels of glucose and other nutrients have been normalized. Chemically modified insulins with negligible receptor binding affinities are therefore longer-lived species within the circulation; however, they are biologically ineffective (*5*).

IDDM[1] patients receive multiple daily subcutaneous administrations of "rapid" and long-acting insulins (*2*, *6*–*8*). Prolonged long-acting insulin preparations are needed to supply low basal levels of circulating insulin between meals and overnight, this being a physiological requirement for reducing triglyceride breakdown and suppressing hepatic glucose output under "resting" conditions (*9*–*11*).

Most long-acting insulins currently in use are suspensions of crystals, produced either by Zn^{2+} ions or by the addition of basic protamine. Such injected suspensions have decreased rates of absorption from the subcutaneous compartment to the circulatory system. Slow dissolution at the site of injection brings about the protracted effect (*2*, *12*, *13*). The application of subcutaneous infusion pumps was also introduced as a measure for controlled continuous supply of short-acting insulin (reviewed in ref *14*).

In recent years, major efforts have been devoted to prolonging the action of insulins that are soluble in aqueous buffered media. In one such innovative approach, two arginine moieties were covalently linked to insulin to raise the isoelectric point of the hormone. The derivative thus obtained (i.e., insulin-glargine) is formulated in a soluble form in a slightly acidic media and is crystallized and precipitated immediately after injection at the physiological neutral pH of the subcutaneous space (*15*–*17*).

Many versatile polymeric prodrugs have been developed for controlled drug delivery. Thus, conjugates of different drugs with polymeric carriers employing various chemical anchoring modes were developed, for example, hydrazones, esters carbamates, citraconyl, amides and acetals (reviewed in refs *18* and *19*). Noteworthy among the polymeric carriers are derivatives of poly(ethylene glycol) (*20*).

Albumin is long-lived in vivo. Similarly, drugs and endogenous substances that associate tightly with albumin have lower clearance rates than do the unbound substances and exhibit prolonged lifetime profiles in vivo (*21*). Long-chain-free fatty acids bind tightly to albumin ($K_a = 10^8\ M^{-1}$) (*22*), a fact that provided the impetus for

preparation of soluble fatty acid acylated insulins that could bind to serum albumin. However, the affinity of the insulin conjugates for albumin ($K_a \approx 10^5$ M^{-1}) was considerably less than that of the unbound long-chain-free fatty acids, and the conjugates exhibited only moderately prolonged actions in vivo (*23*−*25*).

A series of HSA−peptide conjugates have been recently prepared through formation of a stable covalent bond between maleimido-derivatives of biologically active peptides (e.g., atrial nutriuretic peptide (*26*), dynorphine (*27*), the Kringle 5 region of plasminogen (*28*)) and the mercapto moiety of the Cys-34 of HSA. This was undertaken with the aim of increasing the half-life of the peptide in circulation by reducing elimination through the kidney and concomitantly protecting it from proteolysis by plasma enzymes. The activities of the HSA-bound peptides, though significantly reduced as compared to the parent peptides, were found to be rather substantial. Moreover, the conjugates proved to be long-acting species.

Therapeutically, insulin differs from many other polypeptide drugs in the sense that overdosing may lead to severe hypoglycemia (*29*−*31*). To avoid that, only a limited dosage of insulin can be administered each time. Such a dosage is often insufficient to maintain the basal nighttime insulin level needed to avoid hyperglycemia at dawn (*6*−*8*). This therapeutic drawback can be overcome by engineering an insulin prodrug that is biologically inactive at the time of administration.

In this study, we aim to link insulin to HSA via a covalently stable bond. We expect such a nondissociable molecule to share the longevity of albumin in vivo. Because an extended surface area of the insulin molecule is engaged in receptor binding (*32*, *33*), we initially thought it unlikely that such a conjugate would be biologically (and therapeutically) active. Nevertheless, even an inactive, insulin−HSA chimera could be advantageous if the conjugate is capable of generating the active unmodified parent insulin with a desirable pharmacokinetic pattern. Our efforts in this latter direction are brought here in detail.

METHODS

Materials. Human (Zn^{2+}-free) insulin was donated by Novo Nordisk (Bagsvaerd, Denmark) and by Biotechnology General (Rehovot, Israel) and was used without further purification. D-[U-^{14}C]glucose (4−7 mCi/mol) was obtained from DuPont-NEN (Boston, MA). Collagenase, type I (134 U/mg), was purchased from Worthington (Freehold, NJ). 9-Fluorenylmethoxycarbonyl-*N*-hydroxysuccinimide (Fmoc-OSu) and di-*tert*-butyldicarbonate (t-Boc)$_2$O were obtained from Novabiochem (Laüfelfingen, Switzerland). MIB−NHS was obtained from Sigma-Aldrich (Rehovot, Israel). HSA was acquired from Omrix Biopharmaceutical Ltd. (Weizmann Science Park, Nes-Ziona, Israel). The protein was treated with 1 equiv of dithiothreitol for 20 min at pH 6.0 and then extensively dialyzed. This treatment removes any mixed disulfide form and any other removable protection from cysteine-34 of HSA (*34*). HSA prepared by this procedure contains 0.76 ± 0.03 mol of SH per mol of HSA as determined with DTNB (*35*). All other materials used in this study were of analytical grade.

HPLC analyses were performed using a Spectra-Physics SP-8800 liquid chromatography system with an Applied Biosystems 757 variable wavelength absorbance detector and a Spectra-SYSTEM and P2000 liquid chromatography system with a Spectra-SYSTEM AS100 autosampler and Spectra-SYSTEM UV1000, all controlled by a ThermoQuest chromatography data system (ThermoQuest Inc., San Jose, CA). The column effluents were monitored by UV absorbance at 220 nm. Analytical reverse phase HPLC was performed using a prepacked Chromolith Performance RP-18e column (4.6 mm × 100 mm, Merck KGaA, Darmstadt, Germany). The column was eluted with a binary gradient established between solution A (0.1% TFA in H_2O) and solution B (0.1% TFA in acetonitrile/H_2O; 3:1 v/v). Preparative separations were performed with a prepacked Vydac, RP-18, or RP-4 column (250 mm × 22 mm, Hesperia, CA).

Biological Methods and Procedures. Iodination of insulin and of HSA using [^{125}I] iodine was performed using the chloramine-T method (*36*). Rat adipocytes were prepared from the fat pads of male Wistar rats (100−200 g) by collagenase digestion (*37*). Lipogenesis (during which [U-^{14}C]glucose was incorporated into the lipids) was performed using the procedure of Moody et al. (*38*). Diabetes was induced by a single intravenous injection of freshly prepared streptozocin (STZ) solution (55 mg/kg of body weight) as per the method of Meyerovitch et al. (*39*). Rats were maintained at 24 °C under conditions of controlled lighting and were fed ad libitum. Blood samples for the analysis of blood glucose were taken from the tail veins and measured with a glucose analyzer (Beckman Instruments, Fullerton, CA) by the glucose oxidase method. Groups consisted of five Wistar rats weighing 170 ± 5 g. Data are presented as means ± SE.

Synthesis of 9-Hydroxymethyl-2-(amino-3-maleimidopropionate)-fluorene-*N*-hydroxy-succinimide (2). *9-Hydroxymethyl-2-(amino-3-maleimidopropionate)fluorene (**1**).* 3-Maleimidopropionic acid (1 g, 5.9 mmol) and DCC (0.69 g, 2.95 mmol) were dissolved in 10 mL of DMF and incubated for 4 h. *N*,*N*′-Dicyclohexylurea (DCU) was filtered off, and the anhydride thus formed (2.95 mmol) was dissolved in DMF (12 mL) and added to a suspension of 9-hydroxymethyl-2-amino fluorine (*36*; 0.4 g, 1.9 mmol) and $NaHCO_3$ (0.74 g, 8.85 mmol) in water. The homogeneous reaction mixture was stirred for 40 min, and product formation was monitored by analytical HPLC (Chromolith column, R_t = 4.46 min, 10−100% B over 10 min with a flow rate of 3 mL/min). The crude product was purified using preparative HPLC (RP-18 column, 10−100% B over 60 min with a flow rate of 12 mL/min). Yield, 57%, 1.08 mmol, 0.39 g. ESMS (calcd) 362.38 Da; ESMS (found) 362.42 Da (electrospray MS analyses were carried out with the Micromass Platform LCZ 4000).

*9-Hydroxymethyl-2-(amino-3-maleimidopropionate)-fluorene-N-hydroxysuccinimide (**2**)* was prepared according to the procedure of Albericio et. al. (*40*). Pyridine (0.17 mL, 2 mmol) was added dropwise to a stirred solution of 9-hydroxymethyl-2-(amino-3-maleimidopropionate)fluorene (0.37 g, 1.02 mmol) and triphosgene (0.425 g, 1.43 mmol, 4.2 equiv) in dry THF (10 mL). After 20 min, the precipitated pyridine hydrochloride salt was filtered off, and the THF was removed under vacuum. The oil obtained was dissolved in 10 mL of dry THF containing *N*-hydroxysuccinimide (0.61 g, 5.3 mmol). Pyridine (0.26 mL, 3.2 mmol) was then added, and the solution was stirred for 20 min. The precipitated pyridine hydrochloride salt was filtered off, and the THF was removed by vacuum. The oil obtained was dissolved in chloroform (100 mL) and washed with an aqueous $NaHCO_3$ solution (0.5 N, 3 × 50 mL), HCl (0.1 N, 3 × 50 mL), water (2 × 50 mL), and brine. The organic phase was dried over $MgSO_4$ and evaporated to give the desired product with a yield of 89% (0.9 mmol, 0.45 g). Analytical HPLC (R_t = 5.7 min, 10−100% B over 10 min with a flow rate of 3 mL/min) was used to ascertain the purity of the product.

ESMS (calcd) 503.13 Da; ESMS (found) for $[M + Na]^+$ = 526.38 Da and for $[M + K]^+$ = 542.30 Da.

Preparation of HSA–Fmoc–Insulin. To a stirred solution of Zn^{2+}-free insulin (5.9 mg, 1 μmol in 1.0 mL of 0.1 M phosphate buffer at pH 7.2) was added 505 μg (1 equiv) of MAL-Fmoc-OSu (50.5 μL from a fresh solution of MAL-Fmoc-OSu in DMF, 10 mg/mL). The reaction was carried out for 20 min at 25 °C. HSA (0.37 mL from a solution of 1.6 mM) was then added to a final concentration of 0.42 mM (0.6 mol/mol of insulin). The reaction was carried out for 2 h, and the mixture was then dialyzed overnight against H_2O at 7 °C. HSA–Fmoc–insulin was purified from unreacted insulin and from insulin–Fmoc–MAL that had not reacted with HSA by preparative HPLC (RP-4 column, Hesperia CA. 20–100% B over 60 min with a flow rate of 10 mL/min) The fractions corresponding to HSA–Fmoc–insulin, coeluted with HSA, were collected and lyophilized.

Preparation of HSA–BENZ–Insulin. This (irreversible) HSA–insulin conjugate was prepared under identical conditions to those used for HSA–Fmoc–insulin except that the hetrobifunctional agent used was *m*-maleimido-benzoate–*N*-hydroxysuccinimide ester (MIB–NHS). The reagent (32 μL from a fresh solution of MIB–NHS at 10 mg/mL) was reacted with insulin for 20 min at 25 °C prior to the addition of HSA (see above). HPLC-purified HSA–BENZ–insulin was characterized by MALDI-TOF MS. A mass of 72.432 kDa was found (calculated mass for 1:1 conjugate is 72.570 kDa).

RESULTS

Pharmacological Pattern of Subcutaneously Administered HSA in the Rat. ^{125}I-labeled HSA was administered subcutaneously to rats and the pharmacological pattern as a function of time was constructed by withdrawing blood aliquots at various time points and determining the TCA-precipitable counts for each aliquot. Subcutaneously administered HSA is a long-lived species in the rat circulatory system in vivo. It reached a peak value of 14 ± 1 h after administration and then declined with a $t_{1/2}$ of 41 ± 2 h (see appendix in Supporting Information). For comparison, we subcutaneously administered ^{125}I-insulin under similar experimental conditions. Insulin reached its peak value at 1 ± 0.1 h and then declined with a $t_{1/2}$ of 9.0 ± 1.0 h. Thus, subcutaneously administered HSA exhibits a substantially prolonged lifetime in vivo compared to insulin or any other nonglycosylated peptide or protein of molecular mass lower than 17 kDa (reviewed in ref *41*).

Engineering an HSA–Insulin Conjugate that Releases Insulin under Physiological Conditions. The covalent linking of insulin to HSA with MIB–NHS resulted in a nondissociable HSA–insulin conjugate having negligible biological potencies in vitro (subsequent paragraphs). We therefore designed and synthesized a heterobifunctional agent, consisting of an Fmoc-OSu derivative in which a maleimide group was attached to the flurenyl backbone. The steps involved in the synthesis of MAL-Fmoc-OSu and its structure are illustrated in Figure 1. Using MAL-Fmoc-OSu enabled us to link proteins via their amino side chains to the single cysteinyl residue of HSA. Previously we have found that Fmoc moieties linked to the amino side chains of peptides and proteins undergo slow hydrolysis in aqueous solutions under physiological conditions, generating the unmodified parent peptides and proteins (*41*, *42*).

The procedure described in detail in the Methods section was found optimal for coupling equimolar amounts of insulin to HSA. In brief, MAL-Fmoc-OSu is first reacted stoichiometrically with insulin for 20 min at pH 7.2, this being a pH value at which MAL remains chemically stable for several hours (*43*). Albumin is then added with a stoichiometry of 0.6 mol per mol of derivatized insulin in an attempt to reach a quantitative coupling of insulin–Fmoc–MAL to the cysteinyl-34 of this carrier protein. Unreacted insulin and insulin–Fmoc–MAL are removed by a semipreparative HPLC procedure.

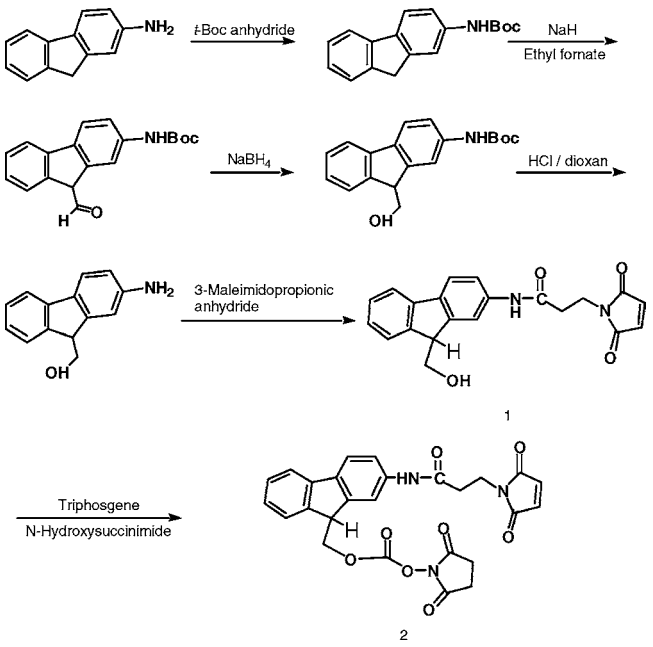

Figure 1. Schematic illustration of the synthesis and the structure of 9-hydroxymethyl-2-(amino-3-maleimido-propionate)-fluorene-*N*-hydroxysuccinimide (MAL-Fmoc-OSu). This heterobifunctional agent was used to conjugate HSA to insulin in the preparation of HSA–Fmoc–insulin.

General Features of HSA–Fmoc–Insulin. Table 1 summarizes several characteristic features of the HPLC-purified HSA–Fmoc–insulin that we prepared. It is a highly water-soluble derivative (>200 mg/mL) in buffered near-neutral solutions (pH 6–7) owing to the extreme solubility of the carrier protein (*44*). MALDI-TOF MS

Table 1. Chemophysical Features of HSA–Fmoc–Insulin

covalently linked insulin[a]		24 ± 3 μg/mg of HSA
solubility in aqueous buffer (pH 7.0)		>200 mg/mL
HPLC analysis retention time[a]		8.6 min
MALDI-TOF mass spectrum analysis[b] (m/z)	calcd	72.650 kDa
	found	73.189 kDa
molar extinction coefficient	calcd[c]	$\epsilon_{280} = 51.328$
		$\epsilon_{280}^{0.1\%} = 0.706$
	found	$\epsilon_{280} = 54.400$
		$\epsilon_{280}^{0.1\%} = 0.744$

[a] Determined by HPLC analysis following incubation of the conjugate in 0.1 M Na_2CO_3 (pH 10.3) for 4 h at 25 °C. Analytical HPLC procedures were carried out under the experimental conditions specified in the legend to Figure 3. Under these conditions, insulin elutes with R_t = 6.91 min and has a surface area of 187 000 ± 9000 mav/μg of insulin, and HSA (either free or linked to insulin) elutes with R_t = 8.1 min and has a surface area of 156 000 ± 7000 mav/μg of HSA. [b] MALDI-TOF MS analyses were carried out with the Bruker-Reflex-Reflection model. The molecular weight of HSA is calculated according to the amino acid composition of this carrier protein (ref *44*). [c] Molar extinction coefficient for HSA–Fmoc–insulin was calculated by combining the ϵ_{280} values of HSA (ϵ_{280} = 35 280, ref *37*), insulin (ϵ_{280} = 5800), and Fmoc (ϵ_{280} = 10 250).

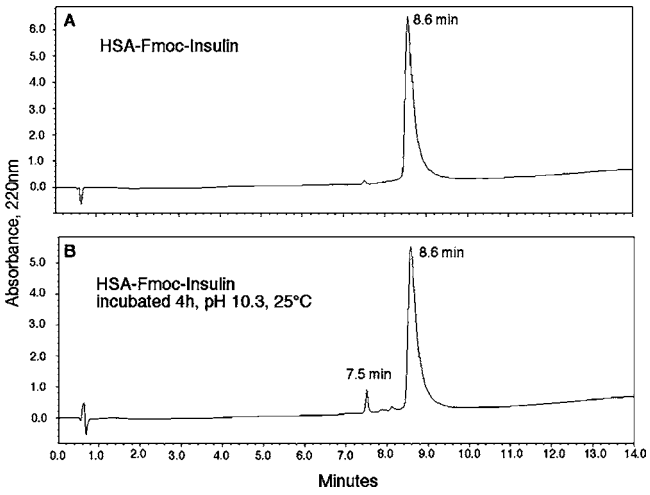

Figure 2. HPLC analysis of purified HSA−Fmoc−insulin before and after the release of insulin by hydrolysis: (A) purified HSA−Fmoc−insulin (100 μg loaded); (B) purified HSA−Fmoc−insulin following 4 h hydrolysis through incubation at pH 10.3, 25 °C. HPLC was conducted with a linear gradient from 0 to 100% of solution A (0.1% TFA) to solution B (acetonitrile−H_2O, 75:25 in 0.1% TFA) over 10 min and then 4 min in solution B, using a Chromolith RP 18e (100 mm × 4 mm) column at a rate of 3 mL/min. The effluent was monitored at 220 nm. Under the same experimental conditions, insulin elutes with $R_t = 6.91$ min and has a surface area of 187 000 ± 9000 mav/μg of insulin.

analysis revealed a molecular mass of 73.189 kDa (calculated mass for the 1:1 conjugate is 72.650 kDa). Analytical HPLC revealed that HSA−Fmoc−insulin coemerges with HSA as a single symmetric peak (Figure 2; retention time 8.6 min). A molar extinction coefficient of ϵ_{280} = 54 400 ($\epsilon_{280}^{0.1\%}$ 0.744) was found (calculated for 1:1 conjugate ϵ_{280} = 51 328). The HSA−Fmoc−insulin thus obtained contains 24 ± 3 μg of covalently linked insulin per mg of HSA as judged by HPLC analysis following the release of the covalently linked insulin from the conjugate by incubation at pH 10.3 for 4 h at 25 °C (Figure 2). In theory, 61 μg of covalently linked insulin per mg of conjugate is expected, based on 0.76 mol of SH per mol of HSA (experimental part). Thus our preparation of HSA−Fmoc−insulin appears to contain also HSA that is not linked to insulin.

Biological Potency of HSA−Fmoc−Insulin. Figure 3 shows the dose−response curve for native insulin and for HSA−Fmoc−insulin in a lipogenic assay in rat adipocytes. Based on the value of 24 ± 3 μg of covalently linked insulin per mg HSA in the conjugate (Table 1), HSA−Fmoc−insulin has 12.5% ± 3% of the biological potency of the native hormone (ED_{50} value = 2.4 ± 0.1 ng/mL versus ED_{50} = 0.3 ± 0.01 ng/mL for insulin, Figure 3). The covalent linking of insulin to HSA using the nonreversible agent MIB−NHS under similar experimental conditions (see Methods) yielded a conjugate having negligible potency (ED_{50} = 130 ± 10 ng/mL, being ~0.2% of the biological potency of insulin).

HSA−Fmoc−Insulin Releases Insulin upon Incubation under Physiological Conditions. Incubation of HSA−Fmoc−insulin at pH 10.3 for 4 h at 25 °C causes the covalently linked insulin to be released quantitatively from the conjugate (Figure 2B). In Figure 4A, HSA−Fmoc−insulin was incubated in 0.1 M phosphate buffer (pH 8.5, 37 °C), and the amount of insulin released from the conjugate as a function of time was quantified by HPLC analysis. At pH 8.5, the rate of Fmoc hydrolysis from Fmoc−protein conjugates is nearly identical to that obtained in normal human serum at 37 °C (*41*, *42*). As shown in the figure, insulin is released from the conjugate in a slow homogeneous fashion, having a half-life of 24 ± 3 h. After 80 and 150 h, the cumulative amount of free insulin reached 71% and 100%, respectively, of the initial HSA−Fmoc−insulin level.

Reactivation of HSA−Fmoc−Insulin upon Incubation. In Figure 4B, aliquots were withdrawn from incubated HSA−Fmoc−insulin (pH 8.5, 37 °C) at different time points and analyzed for their biological potencies in a lipogenic assay in rat adipocytes. As shown in the figure, the conjugate undergoes reactivation upon incubation in a nearly linear fashion. Thus, starting from 12% ± 3% at time 0, lipogenic potency is elevated to 31% ± 3%, 43% ± 4%, and 59% ± 5% following 10, 20, and 40 h of incubation, respectively. Upon 150 h of incubation, HSA−Fmoc−insulin regains its full biological potency (Figure 4B).

A Single Intraperitoneal or Subcutaneous Administration of HSA−Fmoc−Insulin Facilitates a Prolonged Glucose-Lowering Pattern in Mice. In Figure 5, we compare the glucose-lowering pattern of HSA−Fmoc−insulin (0.4 mg/mouse, corresponding to 9.6 μg of covalently linked insulin) to that of Zn^{2+}-free insulin (3 μg/mouse) following a single administration. For Figure 5A, administration was intraperitoneal, while in Figure 5B, it was subcutaneous. As shown in Figure 5A, HSA−Fmoc−insulin facilitates a prolonged and stable glucose-lowering pattern over a period of 14 h, exceeding

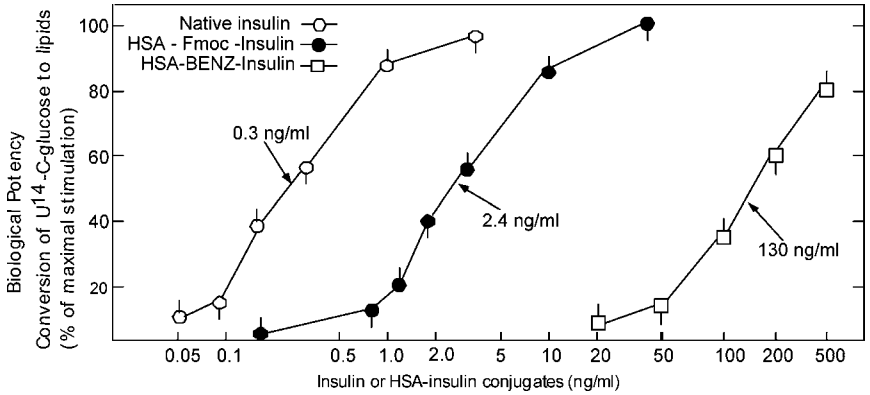

Figure 3. Dosage-dependent stimulation of lipogenesis in rat adipocytes. Lipogenesis was carried out for 2 h at 37 °C in plastic vials containing 0.5 mL of fat cell suspension (1.5 × 10^5 cells) and 0.2 mM [U-^{14}C]glucose in the presence or absence of the indicated concentrations of native insulin or HSA−insulin conjugates. Results are expressed as a percentage of maximal stimulation. Insulin (100 ng/mL) stimulated lipogenesis 4−5-fold above basal levels. HSA−Fmoc−insulin (1 mg/mL) was taken as containing 24 ± 3 μg of insulin per mg of HSA in this assay (see Table 1). The ED_{50} values for native insulin (0.3 ng/mL), for HSA−Fmoc−insulin (2.4 ng/mL), and for HSA−BENZ−insulin (130 ng/mL) are indicated with arrows on the figure.

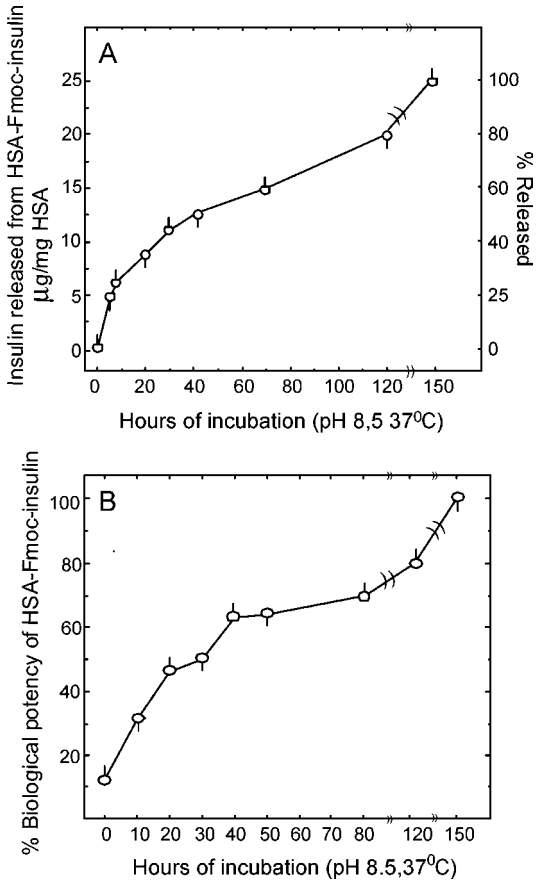

Figure 4. The rate of insulin release from HSA–Fmoc–insulin and reactivation of the conjugate upon incubation at pH 8.5, 37 °C. A solution of HSA–Fmoc–insulin (1 mg/mL) was incubated in 0.1 M phosphate buffer at pH 8.5, 37 °C. At the indicated time points, aliquots (100 μL) were analyzed by HPLC for the amount of released insulin (A) and for biological potency in rat adipocytes (B). Results are expressed as the amount of insulin released per mg of HSA–Fmoc–insulin. An aliquot of HSA–Fmoc–insulin exhibiting ED_{50} value = 3.0 ng/mL in a lipogenic assay was considered to have 10% of the native biological potency.

by about 4 times the duration obtained by the native hormone. Nearly the same glucose-lowering patterns were obtained following subcutaneous administration (Figure 5B). Again, the conjugate produced a prolonged and stable glucose-lowering pattern over many hours. A noticeable difference, however, is a delay of about 0.5 h until the fall in glucose level following subcutaneous administration of the conjugate commences (Figure 5B). This suggests that the rate of conjugate diffusion from the subcutaneous compartment into the circulatory system is considerably slower than that from the peritoneum. Indeed, diffusion and transportation rates of subcutaneously administered proteins across capillary membranes are known to decrease in proportion with increasing size of molecular radius (*21*, *45*).

Glucose-Lowering Pattern of HSA–Fmoc–Insulin in STZ-Rats. Figure 6 shows the glucose-lowering pattern of the conjugate after a single subcutaneous administration in streptozocin-treated hyperglycemic rats. Here we have compared a conjugate dose (7 mg/STZ-rat) that is equipotent to the administered dose of Zn^{2+}-free insulin (20 μg/STZ-rat) at the time of administration. The dosage calculation was based on 24 ± 3 μg of covalently linked insulin per mg of HSA having 12% of the biological potency of the free hormone (Table 1, Figure 3). As shown in Figure 6, the glucose-lowering effect of HSA–Fmoc–insulin is about 2.6 times greater than that of the native hormone. A small decrease is seen shortly after administration (i.e., at 0.5 h). Circulating glucose levels then fall gradually, reaching a maximal decrease at 2–3 h after administration (190 ± 20 mg/dL). Hyperglycemia then reoccurs ($t_{1/2}$ = 4.7 h). The area under the curve of the saline-treated group, following HSA–Fmoc–insulin administration exceeds, by about four times, that obtained with native hormone (integrated from Figure 6). Thus, HSA–Fmoc–insulin is considerably more effective than insulin in lowering circulating glucose levels in insulin-deficient diabetic rats. Figure 6 also shows the glucose-lowering pattern obtained by subcutaneous administration of insulin-glargine. Since the latter insulin derivative was documented to be less potent than the native hormone (*15*), a higher dose (40 μg/STZ-rat) was administered. As shown, this dosage facilitates a glucose-lowering pattern that is nearly similar to that obtained following administration of HSA–Fmoc–insulin (Figure 6).

DISCUSSION

Long fatty-acid acylated insulins that are noncovalently associated with albumin, even with moderate affinity ($K_a = 10^5$ M^{-1}), are long-acting species in vivo (*23–25*). We wondered whether this would be equally valid if an insulin molecule were to be covalently linked to the carrier protein, particularly since HSA–peptide conjugates have been found to retain substantial parent-peptide activity (*26–28*). Since the linkage of insulin to HSA through the nonreversible linker MIB–NHS yielded

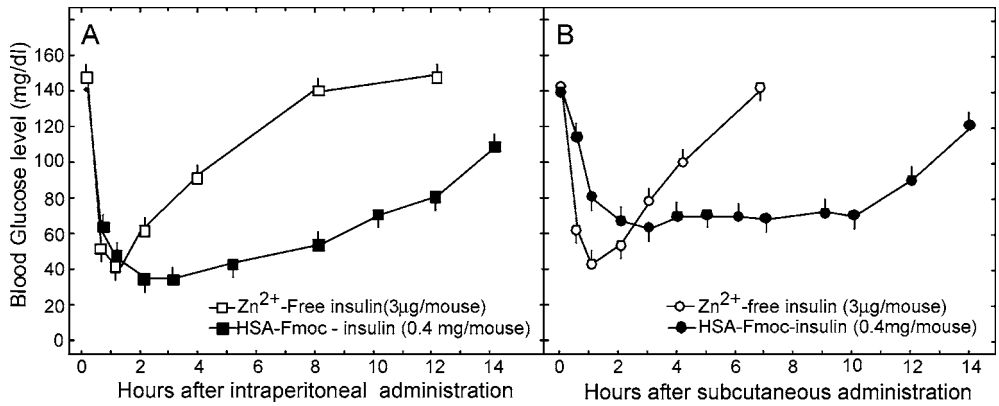

Figure 5. Circulating glucose levels in mice following a single subcutaneous or intraperitoneal administration of HSA–Fmoc–insulin. Mice were injected intraperitoneally (A) or subcutaneously (B) with Zn^{2+}-free insulin (3 μg/mouse in 0.2 mL saline) or HSA–Fmoc–insulin (0.4 mg/mouse). Blood glucose levels were determined at the indicated time points. Food was removed during the experiment. Each point is the arithmetic mean of n = 5 mice ± SE.

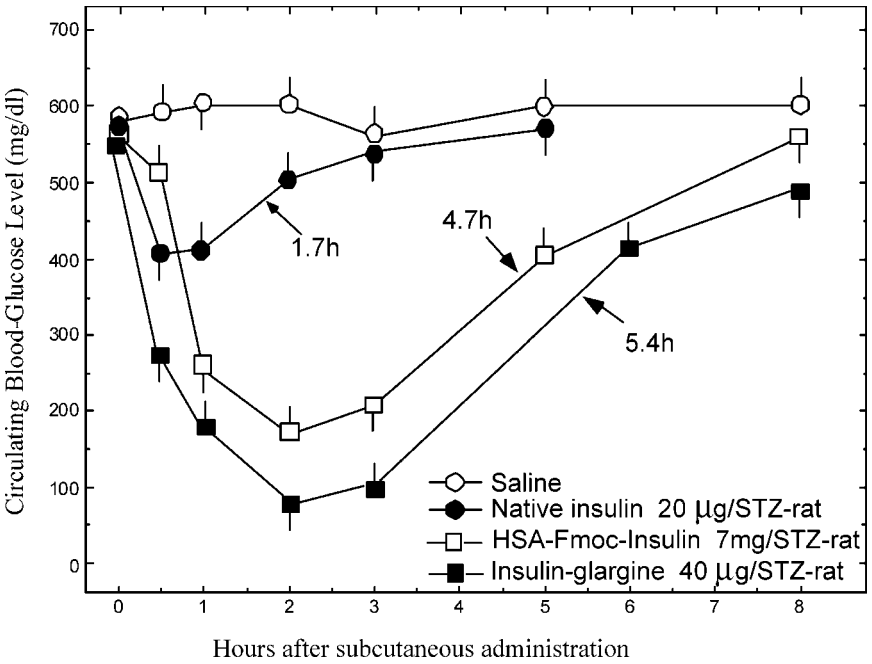

Figure 6. Effect of a single subcutaneous administration of HSA−Fmoc−insulin and of insulin-glargine on blood glucose levels in STZ-rats. STZ-rats received saline solution (control group), Zn^{2+}-free insulin (20 μg/STZ rat), HSA−Fmoc−insulin (7 mg/STZ-rat), and insulin-glargine (40 μg/STZ-rat). Blood glucose levels were determined at the time points indicated in the figure. Each point represents the arithmetic mean of the blood glucose levels of $n = 5$ rats ± SE. Insulin-glargine was diluted to a concentration of 0.2 mg/mL with 1 mM hydrochloric acid prior to injection. Each STZ-rat has received 0.2 mL subcutaneously.

an inactive conjugate (HSA−BENZ−insulin, Figure 3), we designed and synthesized the Fmoc-containing heterobifunctional reagent MAL-Fmoc-OSu (Figure 1). This development enabled us to link insulin (and potentially any other peptide or protein drug) via its amino groups to cysteine-34 of HSA.

HSA is likely to be linked to insulin through the α-amino side chain of Phe^{B1} (under investigation). The latter is considerably more exposed to alkylation, than the α-amino side chain of Gly^{A1} (*32*). At the low pH used for the conjugation (pH 7.2, methods), the ϵ-amino group of Lys^{B29} is fully protonated. Since the linkage between HSA and insulin is fully reversible and the rates of Fmoc-detachment from α- and ϵ-amino groups are similar as found in our previous studies (*41*, *42*), we expect that each new preparation of HSA−Fmoc−insulin would be similar with respect to its pharmacokinetic behavior.

In previous studies, we found that Fmoc moieties linked to proteins are detached in a slow and spontaneous fashion under aqueous physiological conditions generating the unmodified parental proteins (*41*, *42*). The rate of Fmoc hydrolysis is dictated exclusively by the pH, temperature, and protein concentration of the serum, three parameters that are maintained in mammals in strict homeostasis (*46*). We therefore anticipated that HSA−Fmoc−insulin would yield insulin in a rather similar manner.

HSA−Fmoc−insulin is an extremely water-soluble conjugate in which insulin has about 12% of the biological potency of the native hormone (Figure 3) in lipogenesis assay. We had expected it to have negligible activity given that an extended surface area of the insulin molecule is required for receptor binding (*32*, *33*). This activity, however, may stem from release of insulin from its conjugate during the assay, that is, incubation for 2 h at 37 °C in the presence of 20 mg/mL BSA. Indeed, such an explanation would be consistent with the inactivity of the stable covalent conjugate HSA−BENZ−insulin. Yet, upon incubation in aqueous solutions (i.e., pH 8.5, 37 °C), the covalently linked insulin is released from the HSA−Fmoc−insulin conjugate in a nearly homogeneous fashion over a prolonged period ($t_{1/2}$ = 24 ± 3 h) with the concomitant regeneration of insulin possessing full biological potency (Figure 4A,B). HSA−Fmoc−insulin facilitates prolonged glucose-lowering patterns in mice and in STZ-rats following a single subcutaneous or intraperitoneal administration (Figures 5 and 6). Based on administration of equipotent doses of insulin and of the conjugate at time 0, the glucose-lowering potency of HSA−Fmoc−insulin exceeds 3−4 times that facilitated by insulin in terms of longevity as well as efficacy, as judged by the $t_{1/2}$ values and the areas under the curves of the saline-treated rodents.

Lente and ultralente insulins, as well as insulin-glargine, are long-acting formulations following subcutaneous administration, because they are in a crystal form or crystallize in the subcutaneous tissue immediately after injection (*2*, *14*, *15*). Slow dissolution at the site of injection brings about the protracted effect. Our HSA−Fmoc−insulin is a soluble insulin preparation that exerts its prolonged glucose-lowering effect by a different principle, namely, by decreasing the clearance rate of the conjugates through the kidneys as well as by protecting the covalently linked insulin from proteolysis prior to its detachment from the conjugate. Therefore, the comparison to suspended formulations of insulin may be only partially representative. Nevertheless, we have also included in Figure 6 the glucose-lowering pattern of subcutaneously administered insulin-glargine, showing its nearly similar pattern to that obtained with HSA−Fmoc−insulin in STZ-rats (Figure 6). However, it is questionable whether the rat subcutis resembles the human subcutaneous tissue with regard to dissolution and diffusion of insulin-glargine from the subcutaneous compartment to the circulatory system.

The issue of potential immunogenicity of HSA−Fmoc−insulin deserves special consideration. Previously we found that an insulin derivative containing two rigid,

aromatic Fmoc moieties ($Fmoc_2$-insulin) is less immunogenic than the native hormone (*42*). Also, multiple injections of Fmoc-KLH conjugate to rabbits failed to yield antibodies against Fmoc (unpublished observations). It therefore appears that Fmoc is a poor antigen. However, because the HSA–insulin chimera is a new species, albeit combining two endogenous detachable proteins, its antigenicity should be carefully evaluated in future clinical studies.

In summary, taking insulin as a model, we have presented here the first prototype of an HSA–polypeptide/protein conjugate unique in its capability to release the covalently bound peptide/protein drug with a desirable pharmacokinetic pattern. Short-lived protein/peptide drugs can be turned into conjugates of molecular weight higher than 67 kDa and so resist clearance by kidney filtration (*1*). The covalently linked peptide/protein drug is then released by Fmoc hydrolysis, which returns it to its active state at a slow rate determined solely by the stable pH, temperature, and protein levels of the circulatory system. This new development is expected to extend the lifetime, bioavailability, and efficacy of existing peptide drugs and to extend the same in peptide drug candidates that may yet be discovered by genomics and proteomics.

ACKNOWLEDGMENT

Y.S. is the incumbent of the C.H. Hollenberg Chair in Metabolic and Diabetes Research established by the friends and associates of Dr. C. H. Hollenberg of Toronto, Canada. M.F. is the Lester Pearson Professor of Protein Chemistry. We thank Alexandra Singer for editing the manuscript. This research was supported by the Levine Institute of Applied Science and the Howard M. Siegler grant for Diabetes research.

One possible therapeutic approach to treat or prevent Alzheimer's disease (AD) is immunotherapy. On the basis of the identification of Aβ(4−10) (FRHDSGY) as the predominant B-cell epitope recognized by therapeutically active antisera from transgenic AD mice, conjugates with defined structures containing the epitope peptide attached to a tetratuftsin derivative as an oligopeptide carrier were synthesized and their structure characterized. To produce immunogenic constructs, the Aβ(4−10) epitope alone or flanked by α- or β-alanine residues was attached through an amide bond to the tetratuftsin derivative (Ac-[TKPKG]$_4$-NH$_2$) or to a carrier peptide elongated by a promiscuous T-helper cell epitope (Ac-FFLLTRILTIPQSLD-[TKPKG]$_4$-NH$_2$). The conformational preferences of the carrier and conjugates were examined by CD spectroscopy in water and in 1:1 and 9:1 TFE:water mixtures (v/v). We found that the presence of flanking dimers in the conjugates had no effects on the generally unordered solution conformation of the conjugates. However, conjugates with an elongated peptide backbone exhibited CD spectra indicative for a partially ordered secondary structure in the presence of TFE. Comparative ELISA binding studies, using monoclonal antibody raised against the β-amyloid (1−17) peptide, showed that conjugates with T-helper cell epitope in the carrier backbone exhibited decreased monoclonal antibody recognition. However, we found that this effect was compensated in conjugates comprising the Aβ(4−10) B-cell epitope with the β-alanine dimer flanking regions at both N- and C-termini. Results suggest that modification of the B-cell epitope peptide from Aβ with rational combination of structural elements (e.g. conjugation to carrier, introduction of flanking dimers) can result in synthetic antigen with preserved antibody recognition.

INTRODUCTION

Alzheimer's disease (AD), a progressive neurodegenerative disorder of the brain, is the most common form of dementia among the elderly. One of the pathological characteristics of AD is the accumulation and invariant deposition of β-amyloid peptide (Aβ) into extracellular toxic plaques in the brain, which is thought to be the cause of cognitive decline (the β-amyloid hypothesis of AD). One possible therapeutic approach of AD is immunotherapy, via active or passive immunization, with the aim of either increasing the clearance of Aβ from the brain or inhibiting its aggregation to amyloid plaques (*1*−*3*). It has been shown that active immunization with Aβ-(1−42) in transgenic mouse models of AD reduces both the accumulation of Aβ plaques in brain and associated cognitive impairment; no adverse effects were observed in these experiments (*4*−*7*). However, a therapeutic trial of immunization with Aβ(1−42) in humans was discontinued because several patients developed significant meningo-encephalitic cellular inflammatory reactions (*8*, *9*). An alternative strategy to the active immunization with the complete Aβ peptide might be the use of peptides that are not fibrillogenic/toxic and not identical to endogeneous Aβ, which should reduce the likelihood of these side effects (*10*).

Using the epitope excision method based on selective proteolytic digestion of the antigen−antibody complex in combination with high-resolution mass spectrometry (*11*), the N-terminal Aβ(4−10) sequence has been identified as the core epitope region recognized by therapeutically active antibodies raised against Aβ(1−42) and/or its oligomeric assemblies (*12*−*15*). Antibodies against the N-terminal regions of Aβ were able to invoke plaque clearance to the same degree as active immunization (*16*, *17*).

It is known that the administration of oligopeptide epitope rarely elicits appropriate immune responses (*18*). One approach to improve the immunogenicity of small peptides is the appropriate replacement of amino acid residues in the epitope core and/or the alteration of the flanking regions connected to the N- and/or C-terminal of the core (*19*, *20*). Another strategy for increasing the sensitivity of the immunogenic or antigen binding properties is the multiplication of copies of the same or defined number of different B- or T-cell epitopes (*19*). It has also been shown that general peptides incorporating helper T-cell determinants and B-cell epitopes in multiple copies in branched architecture (topology) were better immunogens (*18*). To achieve this, epitope peptides can be conjugated to appropriate carrier molecules such as keyhole limpet hemocyanine (KLH), bovine serum albu-

min (BSA), tetanus toxoid (TT), and purified protein derivatives (PPD). But these are not applicable in human therapy due to their immunological properties such as immunogenicity, cross-reactivity, and induction of tolerance (*21*−*23*). To overcome these drawbacks, synthetic polymers (*24*), branching lysine core (*25*), and sequential polypeptide (*26*) and carriers with discrete molecular mass and sequence (*27*) were developed and applied with success for preparation of antigens.

The first set of conjugates containing the β-amyloid-(4−10) epitope peptide was prepared in our laboratories using branched chain polymeric polypeptides with serine (SAK) or glutamic acid (EAK) at the branch terminating position (*28*). In these constructs the epitope peptide, elongated by $CysGly_5$ at the N- or Gly_5Cys at the C-terminus was attached to the chloroacetylated carrier via a thioether bond. A third construct contained polymeric carrier (EAK) and an epitope chimera in which a promiscuous T-helper cell epitope and the Aβ(4−10) epitope were joined by a dipeptide (Ahx-Cys) spacer (FFLLTRILTIPQSLD-AhxC-FRHDSGY). Comparative binding studies of the conjugates with a monoclonal antibody raised against amyloid protein beta-(1−17) showed that the chemical nature of the carrier has a significant influence on the antibody recognition. In addition we found that the presence of a T-helper cell epitope peptide in the conjugate resulted in lower antibody binding.

Recently a novel group of sequential oligopeptides based on tuftsin was developed in our laboratory (*29*). The oligotuftsin derivatives consisting of tandem pentapeptide repeat unit $[TKPKG]_n$ ($n = 2, 4, 6, 8$) derived from the canine tuftsin sequence TKPK extended by a C-terminal Gly. These compounds are nontoxic and nonimmunogenic and exhibit tuftsin-like biological properties, e.g. immunostimulatory activity and chemotactic activity on monocytes (*30*, *31*).

Considering the beneficial biological properties of the oligotuftsin derivatives and also their nonpolymeric structure, we prepared a new set of the Aβ(4−10) epitope conjugates to further investigate the effect of chemical structure on the antibody recognition of covalently attached epitope. These constructs are different from those reported earlier (*28*). Conjugates presented in this paper contain (a) sequential oligopeptide carrier instead of polymeric one, (b) amide linkage between the epitope and the carrier, and (c) Aβ(4−10) epitopes flanked by α- or β-alanine residues in contrast to the previously described versions, which possessed pentaglycine additions.

In this paper we report on the synthesis, structural characterization, and antibody binding properties of a new set of peptide-conjugates containing the Aβ(4−10) epitope with or without α- or β-alanine flanks (FRHDSGY, AAFRHDSGYAA, βAβAFRHDSGYβAβA) and a second generation of the tetratuftsin based carrier without (a) or with (b) promiscuous T-helper cell epitope of a hepatitis B surface antigen (Ac-$[TKPKG]_4$-NH_2, Ac-FFLLTRILTIPQSLD-$[TKPKG]_4$-NH_2) (Figure 1). Our results show that conjugates with T-helper cell epitope in the carrier backbone exhibited decreased monoclonal antibody recognition. However, we found that this effect was compensated in conjugates comprising the Aβ(4−10) B-cell epitope with β-alanine dimer flanking regions at both N- and C-termini. Results suggest that modification of the B-cell epitope peptide from Aβ with rational combination of structural elements (e.g. conjugation to carrier, introduction of flanking dimers) can result in synthetic antigen with preserved antibody recognition.

EXPERIMENTAL PROCEDURES

Materials. All amino acid derivatives and MBHA resin were purchased from Reanal (Budapest, Hungary) or NovaBiochem (Laufelfingen, Switzerland). Scavengers, coupling agents, and cleavage reagents (*p*-cresol, dithiothreitol (DTT), *N,N′*-dicyclohexylcarbodiimide (DCC), *N,N′*-diisopropylethylamine (DIEA), 1-hydroxybenzotriazole (HOBt), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), piperidine, trifluoroacetic acid (TFA), and hydrogen fluoride (HF)) were Fluka (Buchs, Switzerland) products. Acetic anhydride (Ac_2O) and solvents for synthesis and purification were delivered from Reanal (Budapest, Hungary).

Synthesis of Tetratuftsin Derivative. Ac-$[TKPKG]_4$-NH_2 (Ac-T20, **1**) was synthesized manually on a MBHA resin (1.04 mmol/g capacity) using the Boc/Bzl strategy. The following side-chain protected amino acid derivatives were used: Boc-Lys(ClZ)-OH, Boc-Thr(Bzl)-OH. The protocol was as follows: (i) DCM washing (3 × 0.5 min), (ii) Boc cleavage using 33% TFA in DCM (2+20 min), (iii) DCM washing (5 × 0.5 min), (iv) neutralization with 10% DIEA in DCM (4 × 1 min), (v) DCM washing (4 × 0.5 min), (vi) coupling 3 equiv of Boc amino acid−DCC−HOBt in DCM−DMF (4:1 or 1:4 depends on the solubility of amino acid derivatives) mixture (60 min), (vii) DMF washing (2 × 0.5 min), (viii) DCM washing (2 × 0.5 min), (ix) ninhydrin or isatin assay. After completion of the synthesis, the acetylation of the N-terminus was carried out with acetic anhydride (1 mL) and DIEA (1 mL) in DMF for 1 h. The peptide was cleaved from the resin by the aid of liquid HF in the presence of *p*-cresol and DTT as scavengers (HF−*p*-cresol−DTT=10 mL: 0.5 g: 0.1 g) for 1.5 h at 0 °C. The crude product was precipitated with diethyl ether; the filtrate was washed three times with diethyl ether and solubilized using 10% acetic acid before freeze-drying. The crude material was purified by RP-HPLC on a semipreparative C_{18} column and characterized by RP-HPLC, MALDI-FT-ICR mass spectrometry (Table 1), and amino acid analysis (data not shown).

Tandem Synthesis of Conjugates Composed of Oligotuftsin Derivatives and β-Amyloid(4−10) Epitope Peptides. Conjugates Ac-$[TKPK(H-FRHDSGY)G]_4$-NH_2(T20-A$\beta$$(4-10)_4$, **2**), Ac-$[TKPK(H-AAFRHDSGYAA)G]_4$-$NH_2$(T20-A$\beta$$(4-10\text{-}Ala)_4$, **3**), Ac-$[TKPK(H-\beta A\beta AFRHDSGY-\beta A\beta A)G]_4$-$NH_2$ (T20-A$\beta$$(4-10\text{-}\beta Ala)_4$, **4**), Ac-FFLLTRILTIPQSLD-$[TKPK(H-FRHDSGY)G]_4$-NH_2 (T20-T-cell-A$\beta$$(4-10)_4$, **5**), Ac-FFLLTRILTIPQSLD-$[TKPK(H-AAFRHDSGYAA)G]_4$-NH_2 (T20-T-cell-A$\beta$$(4-10\text{-}Ala)_4$, **6**), Ac-FFLLTRILTIPQSLD-$[TKPK(H-\beta A\beta AFRHDSGY\beta A\beta A)G]_4$-$NH_2$ (T20-T-cell-A$\beta$$(4-10\text{-}\beta Ala)_4$, **7**) containing amide bond between the carrier and the epitope peptide were

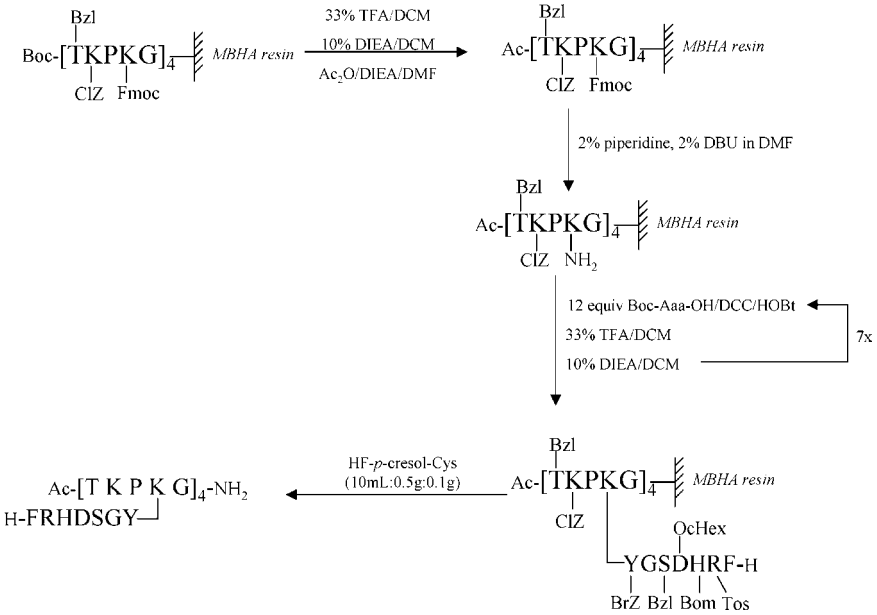

Figure 2. Outline of the synthesis of the Aβ(4−10) epitope peptide−tetratuftsin derivative conjugate (**2**) obtained by total synthesis.

prepared manually by tandem synthesis on a MBHA resin (1.04 mmol/g capacity) using the Boc/Bzl strategy (Figure 2). The following side-chain protected amino acid derivatives were used: Boc-Lys(Fmoc)-OH, Boc-Lys(ClZ)-OH, Boc-Thr(Bzl)-OH, Boc-Asp(OcHex)-OH, Boc-Ser(Bzl)-OH, Boc-Arg(Tos)-OH, Boc-Tyr(BrZ)-OH, Boc-His(Bom)-OH, and the syntheses were performed according to the protocol described above. After completion of the synthesis of the tetratuftsin derivative and its version elongated by T-cell epitope, the acetylation of the N-terminus was carried out with acetic anhydride (1 mL) and DIEA (1 mL) in DMF for 1 h. After removal of the N$^\epsilon$-Fmoc protecting group of Lys by 2% DBU, 2% piperidine in DMF for 2+2+5+15 min, the Aβ(4−10) epitope peptide with/without α- or β-alanine flanking region was built up on the ϵ-amino group of lysine by the Boc/Bzl strategy. A ratio of 12 equiv of Boc-amino acid derivatives and coupling reagents to the four Lys residues were used. The conjugates were cleaved from the resin by the aid of liquid HF in the presence of *p*-cresol and L-Cys (HF-*p*-cresol-Cys=10 mL:0.5 g:0.1 g) for 1.5 h at 0 °C. After their cleavage from the resin, the crude products (**2**, **3**, and **4***)* were purified by RP-HPLC on a semipreparative C_{18} column, while products (**5**, **6**, and **7***)*, on a C_4 column. The purified conjugates were characterized by RP-HPLC, ESI−FT-ICR mass spectrometry (Table 1), and amino acid analysis (data not shown).

Reverse Phase High Performance Liquid Chromatography (RP-HPLC). Analytical RP-HPLC was performed on a Knauer (H. Knauer, Bad Homburg, Germany) HPLC system using a Phenomenex Synergy C_{12}, column (250 × 4.6 mm I.D.) with 4 μm silica (80 Å pore size) (Torrance, CA) or Vydac C_4 column (250 × 4.6 mm I.D.) with 5 μm silica (300 Å pore size) (Hesperia, CA) as stationary phases. Linear gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) with eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile−water (80:20, V/V)) was used at a flow rate of 1 mL/min at ambient temperature. Peaks were detected at $\lambda = 220$ nm. The samples were dissolved in eluent A or in eluent A and B mixture (in case of compounds **5, 6**, **7**).

The crude products were purified on a semipreparative Phenomenex Jupiter C_{18} column (250 × 10 mm I.D.) with 10 μm silica (300 Å pore size) (Torrance, CA) or Vydac C_4 column (250 × 10 mm I.D.) with 10 μm silica (300 Å pore size) (Hesperia, CA). Flow rate was 4 mL/min. The same eluents as described above with an appropriate linear gradient (0 min 10% B; 5 min 10% B; 50 min 55% B in case of conjugates **2**, **3**, and **4** or 0 min 20% B; 5 min 20% B; 55 min 70% B in case of conjugates **5**, **6**, and **7**) were applied.

Amino Acid Analysis. The amino acid composition of the conjugates was determined by amino acid analysis using a Beckman Model 6300 analyzer (Fullerton, CA). Prior to analysis samples were hydrolyzed in 6 M HCl in N_2 atmosphere at 110 °C for 24 h.

Mass Spectrometry. MALDI−FT-ICR mass spectrometric analysis was performed with a Bruker APEX II

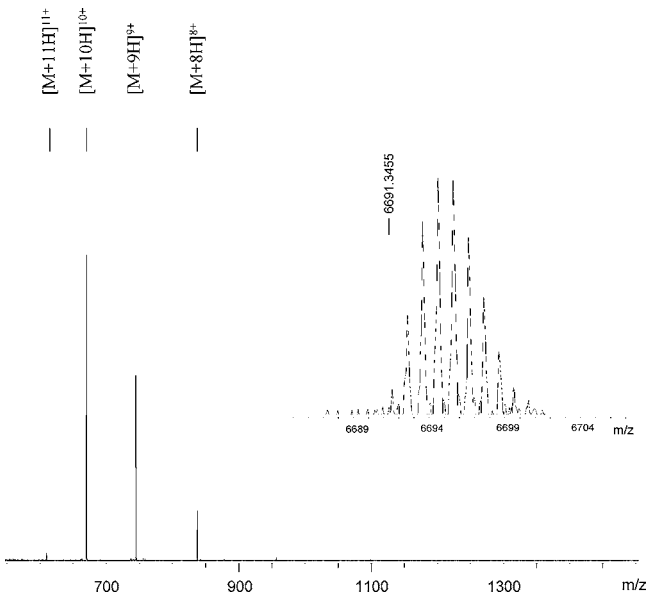

Figure 3. ESI−FT-ICR mass spectrum of T20(Aβ4−10-βAla)$_4$ (**4**). The insert shows the $[M + H]^+$ ion after deconvolution of the ESI−FT-ICR mass spectrum.

FT-ICR instrument equipped with an actively shielded 7T superconducting magnet, a cylindrical infinity ICR analyzer cell, and an external Scout 100 fully automated X−Y target stage MALDI source with pulsed collision gas (Bruker Daltonik, Bremen, Germany). The pulsed nitrogen laser is operated at 337 nm. A 100 mg/mL solution of 2,5-dihydroxybenzoic acid (DHB) (Aldrich, Steinheim, Germany) in acetonitrile:(0.1% trifluoroacetic acid in water) (2:1) was used as a matrix. A 0.5 μL amount of matrix solution and 0.5 μL of sample solution were mixed on the stainless steel MALDI sample target and allowed to dry. Calibration was performed with a standard peptide mixture with an *m/z* range of approximately 5000 (*32*).

ESI−FT-ICR MS were performed with the same Bruker Daltonik Apex II FT-ICR spectrometer (Bremen, Germany) equipped with a 7.0 T actively shielded superconducting magnet (Magnex, Oxford, UK), an APOLLO (Bruker Daltonik) electrospray ionization source, an API1600 ESI control unit, and a UNIX-based Silicon Graphics O2 workstation. Acquisition of spectra was performed with the Bruker Daltonik software XMASS and corresponding programs for mass calculation, data calibration, and processing. The masses of the singly charged ions were calculated by deconvolution of the multiply charged species (Figure 3). For sample preparation, 50% methanol, 2% acetic acid in water was used (*33*).

Circular Dichroism Spectroscopy. Circular dichroism (CD) spectra were recorded on a Jasco spectropolarimeter, model J-720 (Jasco, Espoo, Finland), at room temperature in quartz cells of 0.05 cm path-length, under constant nitrogen flush. The instrument was calibrated with 0.06% (w/v) ammonium-D-camphor-10-sulfonate (Katayama Chemical, Osaka, Japan) in water. Double distilled water and 1:1 and 9:1 mixtures (v/v) of trifluoroethanol (TFE) (Fluka, Buchs, Switzerland) and water were used as solvents. The concentration of the samples was 100 μM (in case of conjugates) and 200 μM (in case of Ac-T20). The spectra were averages of six scans between $\lambda = 190$ and 260 nm. Results are expressed in terms of mean residue ellipticity (deg cm^2 dmol^{-1}) after subtraction of the buffer baseline.

Enzyme-Linked Immunosorbent Assay (ELISA). ELISA studies were performed using the purified type IgG1 monoclonal antibody (mAb) 6E10 (Chemicon, Temecula, CA), raised against Aβ(1−17) as described (*28*). Briefly, a standard dilution of the mAb 6E10 ($c = 1$ mg/mL in PBS) and conjugates as coating antigens was used. Ninety-six-well ELISA plates (BioRad, Hercules, CA) were coated overnight at room temperature with 100 μL/well of conjugates (serial dilutions from 20 μM to 0.0001 μM of Aβ(4−10) epitope concentration). The antigen concentrations were expressed as the Aβ(4−10) epitope concentration, and they were the following: 20 μM, 6.66 μM, 2.22 μM, 0.74 μM, 0.246 μM, 0.082 μM, 0.027 μM, 0.0091 μM, 0.003 μM, 0.001 μM, 0.0003 μM, and 0.0001 μM. After coating, the wells were washed (0.05% Tween-20 v/v in PBS, pH = 7.5), and the nonspecific adsorption sites were blocked (5% BSA w/v in PBS). The mAb 6E10 at $c = 1$ μg/μL was diluted 4000 times in 5% BSA (Sigma-Aldrich, Steinheim, Germany) and added to each well (100 μL). After incubation at room temperature for 2 h and washing steps, 100 μL of peroxidase labeled goat anti-mouse IgG (Jackson Immuno Research, West Grove, PA) diluted 1000 times in 5% BSA was added to each well. After an additional incubation for 2 h and washing three times, 100 μL of *o*-phenylenediamine dihydrochloride (Merck, Darmstadt, Germany) in sodium phosphate-citrate buffer at $c = 1$ mg/mL and 2 μL of 30% hydrogen-peroxide (Merck, Darmstadt, Germany) per 10 mL of substrate buffer was added. After 5 min, the absorbance at $\lambda = 450$ nm was measured on a Wallac 1420 Victor^2 ELISA Plate Counter (PerkinElmer, Boston, MA). The concentration of the antigen, which gave an OD_{450} of 1 was calculated (Table 1).

RESULTS AND DISCUSSION

Synthesis and Structural Characterization of Aβ-(4−10) Epitope Peptide Conjugates. In this work we report on the synthesis and characterization of a new group of synthetic antigens, in which the β-amyloid(4−10) epitope peptide was attached through an amide bond to two sequential carriers, the tetratuftsin derivative consisting of four units of TKPKG pentapeptide and its analogue elongated by a T-helper cell epitope (FFLLTRILTIPQSLD). Both compounds were prepared by solid-phase methodology using Boc-chemistry and orthogonal protecting groups for lysine side-chains: Z(2Cl) in position 2 and Fmoc in position 4 of the pentapeptide unit. The Aβ(4−10) epitope peptide with/without α- or β-alanine flanking regions was connected to the ϵ-amino groups of lysine residues after selective removal of the N$^\epsilon$-Fmoc protecting group under alkaline conditions (Figure 2). After completion of the assembly of the 48−79-mer conjugates (**2**−**7**), the compounds were cleaved from the resin with HF in the presence of *p*-cresol and L-Cys. L-Cys was added to scavenge the formaldehyde derived from the Bom protecting group of His during the cleavage procedure. The compounds were purified by HPLC and characterized by RP-HPLC, high-resolution FT-ICR mass spectrometry (Table 1, Figure 3), and amino acid analysis. In contrast to antigens prepared by the attachment of epitopes with polymeric carrier through thioether bond as published by us earlier (*28*), these new set of conjugates have several advantages: (a) discrete molar mass, (b) structurally identical species, (c) the presence of amide bonds only. In addition these constructs were also different from previous ones since the flanking regions of the Aβ(4−10) epitope were Ala_2 or βAla_2 dimers instead of pentaglycine.

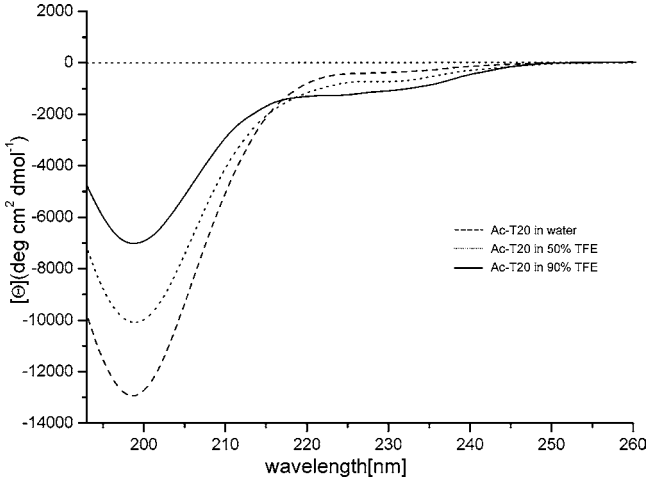

Figure 4. CD spectra of the acetylated tetratuftsin derivative (**1**).

Conformational Analysis by CD Spectroscopy. The conformational preferences of the carrier and epitope peptide conjugates in water and 1:1 and 9:1 TFE:water mixtures (v/v) was analyzed by CD spectroscopy. TFE is known to preferentially stabilize proteins and peptides in a helical conformation (*34*). The CD spectrum of the acetylated tetratuftsin derivative (**1**) recorded in water showed a strong negative $\pi-\pi^*$ band around 198 nm characteristic of unordered structure. The presence of TFE in the solvent mixture did not lead to spectral changes. The CD spectrum measured in 9:1 TFE:water mixture (v/v) reflects the predominance of random coil conformation, characterized by a negative maximum at 198 nm with a small shoulder at approximately 226 nm (Figure 4). Previous studies showed that nonacetylated tetratuftsin is very flexible, adopting a random coil conformation in water, TFE, and 1:1 TFE:water mixture (*29*). These results indicate that the acetylation of the tetratuftsin derivative does not change its conformational properties in solution.

The attachment of β-amyloid(4−10) epitope peptide with/without the α- or β-alanine flanking region to the carrier did not result in significant conformational changes of the carrier (Figure 5). The CD spectra of the Aβ(4−10) epitope peptide−tetratuftsin derivative conjugates recorded in water showed the presence of a negative maximum and an additional positive band around 220 nm which characterized the unordered structure. Compared to pure water as solvent, the CD spectra in 1:1 and 9:1 TFE:water mixture (v/v) showed only a small shift in the $\pi-\pi^*$ electronical transitions toward higher wavelengths and the presence of a small negative shoulder at 222 nm (n−π^* transition). A positive band around 220 nm could be detected only in case of conjugate **2**, and the presence of α- or β-alanine flanking regions in the structure of the conjugates **3** and **4** determined the disappearance of this additional band.

The conjugates **5**−**7** containing in their structure the T-helper cell epitope adopt a random coil conformation in water. Interestingly, in the presence of TFE, they adopt an ordered structure, which is more pronounced by increasing the content of TFE in the solvent mixture (the $\pi-\pi^*$ electronic transitions were shifted toward a higher wavelength, from 198 nm to 204−205 nm, and also the intensity of the n−π^* transition at 225 nm increased) (Figure 6). This indicates that the conformational preferences of the conjugates depend on their primary structure and that TFE enhances existing propensities and does not induce helix formation arbitrarily.

In contrast to the essentially unordered oligotuftsin based carrier, branched chain polymeric polypeptides used for the previous set of antigens (EAK and SAK) have ordered structure (*28*). We found that in both conjugate families the conformation of the carriers has a significant influence on the CD spectra of the respective conjugates. In case of branched polypeptide conjugates we detected high level of ordered structure (*28*). Similarly, conjugates with oligotuftsin derivatives displayed essentially unordered conformation (Figures 5 and 6).

Antigenicity of the Aβ(4−10) Epitope Peptide Conjugates against an Anti-Aβ-(1−17) Monoclonal Antibody. The β-amyloid(4−10) epitope−tetratuftsin derivative conjugates were compared for binding to an anti-Aβ-(1−17) monoclonal antibody by direct ELISA. The conjugates containing the Aβ(4−10) epitope in four copies or the free carrier were coated to ELISA plates. Subsequently mAb, peroxidase-conjugated second Ab, and OPD substrate were added and the absorbance was measured (Table 1, Figures 7A and 7B). The carrier itself did not show any reactivity with mAb (data not shown). On the basis of ELISA data, the influence of the flanking regions neighboring the B-cell epitope and the presence of T-helper cell epitope peptide in the backbone on the antibody binding were compared. The conjugates in which the B-cell epitope was flanked by two β-alanine residues at both N- and C-termini (**4**, **7**) showed the highest binding activity to the mAb (lowest amount of Aβ(4−10) epitope peptide to obtain an OD = 1: 0.06 μmol/L); no differences related to the presence of the T-helper cell epitope in the structure of conjugate **7** could be detected (Table 1). The Aβ(4−10)−tetratuftsin derivative conjugates had similar binding properties, and the presence of α-alanine dimer flanking regions had no significant influence on the antigenicity of B-cell epitope (**2**, **3**). Conjugates **5** and **6**, containing the T-helper cell epitope in the polypeptide backbone, bound to the antibody with similar intensities, but their antigenicity was lower in comparison with that of the constructs **2** and **3** (e.g. 0.28 for **5** vs 0.16 for **2**). We conclude that in the Aβ(4−10) epitope−tetratuftsin construct, the presence of α-alanine adjacent to the B-cell epitope had no marked effect on the antibody binding, whereas the β-alanine flanking region increased significantly the antibody recognition of Aβ(4−10) epitope.

The data presented here suggest that inclusion of appropriate flanks to the B-cell epitope (e.g. β-Ala) may increase the antibody binding of the epitopes attached to the tetratuftsin derivative. Elongation of the carrier backbone by a sequence of amino acids (T-helper cell epitope) only slightly decreased antibody binding to the B-cell epitope (0.16 vs 0.28; 0.14 vs 0.22), but the selection of appropriate flank in the B-cell epitope was able to compensate this effect (0.06 vs 0.06) (Table 1).

The coating ability of different conjugates with oligotuftsin-derived or polymer carriers is probably similar, but the coating itself may reduce the flexibility of the antigenic peptides and affect the binding. However, the data suggest that there is no significant influence on antibody recognition.

CONCLUSION

In this study we report on the preparation and structural and binding characteristics of synthetic antigen conjugates comprising the β-amyloid(4−10) epitope as

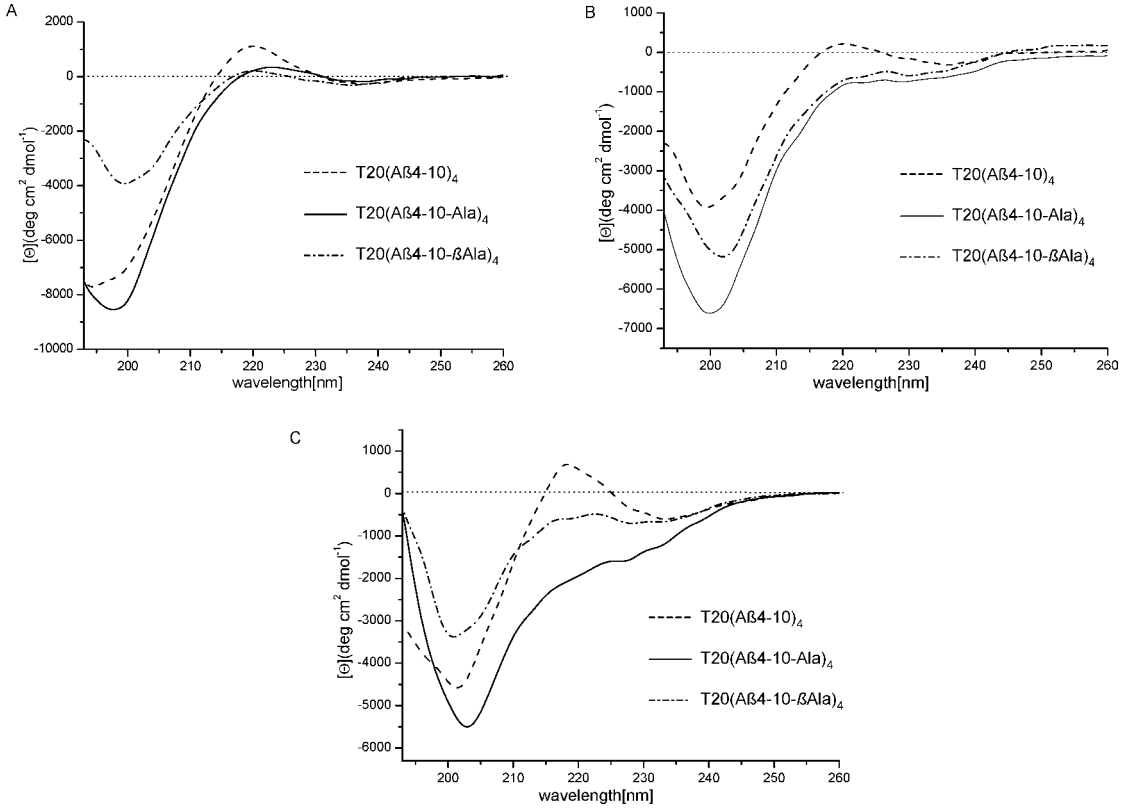

Figure 5. CD spectra of the Aβ(4−10)-tetratuftsin derivative conjugates in water (A) and 1:1 (B) and 9:1 (C) TFE:water mixtures (v/v).

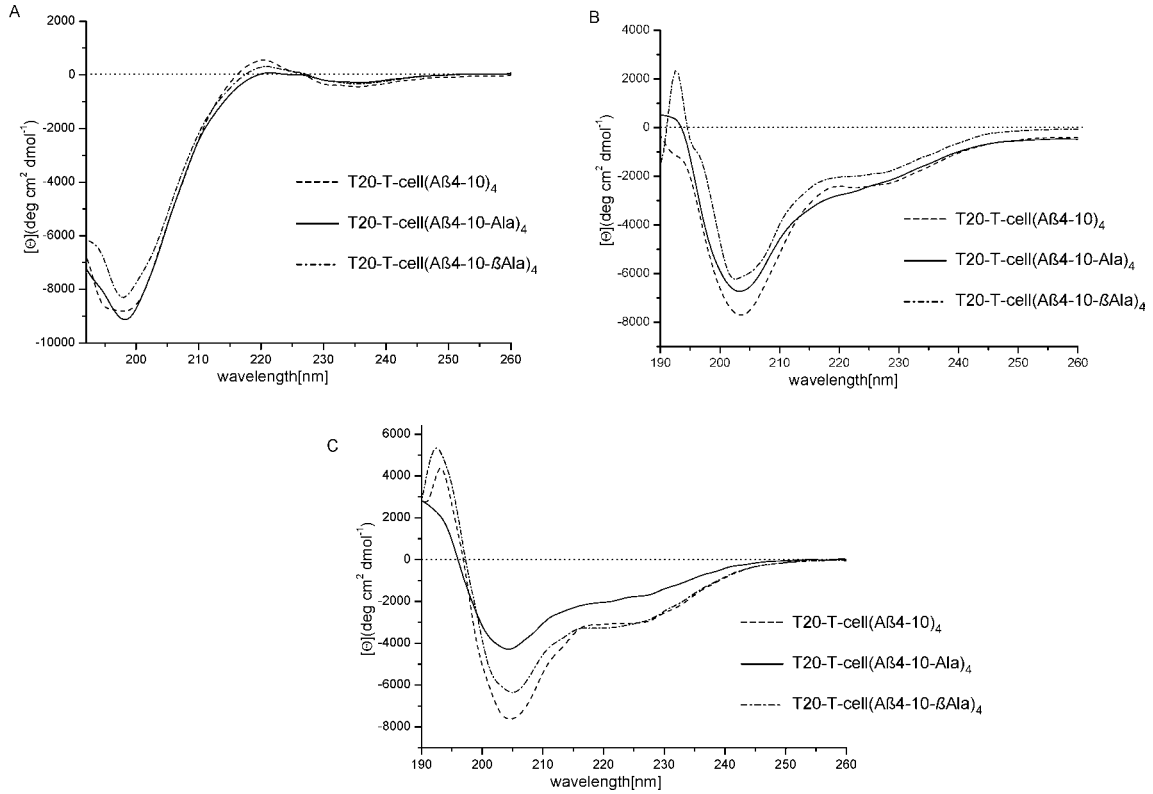

Figure 6. CD spectra of the Aβ(4−10)-tetratuftsin derivative−T-helper-cell epitope conjugates in water (A) and 1:1 (B) and 9:1 (C) TFE:water mixtures (v/v).

lead structures for new type of vaccines against Alzheimer's disease. Constructs with defined structures, in which the Aβ(4−10) epitope was attached through an amide bond to the tetratuftsin derivative as oligopeptide carrier, were successfully prepared by tandem solid-phase methodology. The alteration of the flanking regions connected to the N- and C-terminal ends of the Aβ(4−10)-epitope, e.g. by β-amino acid residues, resulted in increased binding. Comparative ELISA binding studies, using monoclonal antibody raised against the β-amyloid

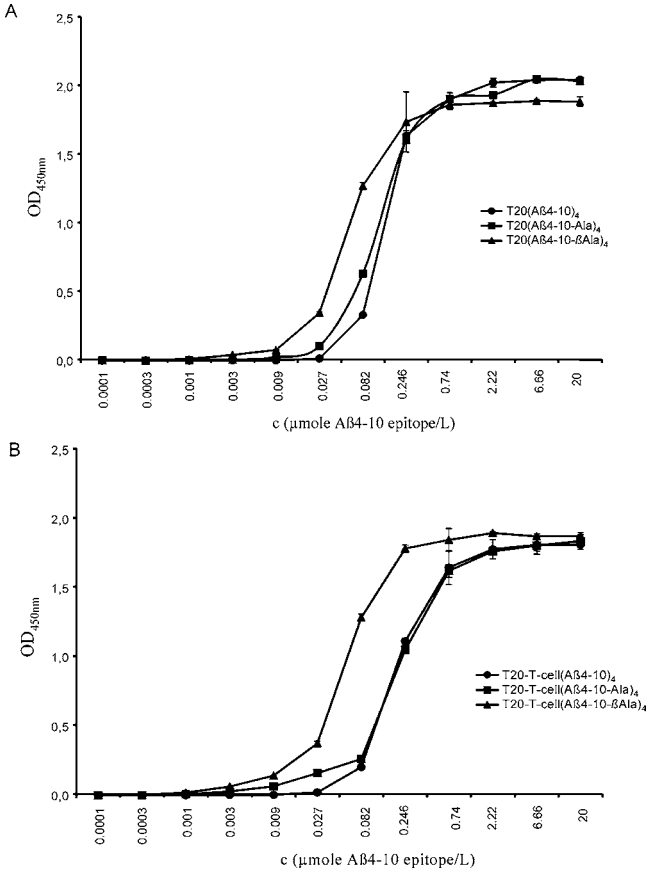

Figure 7. Binding of mouse anti-amyloid protein beta-(1−17) monoclonal antibody to Aβ(4−10) epitope peptide conjugates **2**−**4** (A) and to conjugates **5**−**7** (B), as measured by direct ELISA.

(1−17) peptide, showed that conjugates with a T-helper cell epitope in the carrier backbone exhibited decreased monoclonal antibody recognition. However, we found that this effect was compensated in conjugates comprising the Aβ(4−10) B-cell epitope with β-alanine dimer flanking regions at both N- and C-termini. Taken together, results suggest that modification of the B-cell epitope peptide from Aβ with rational combination of structural elements (e.g. conjugation to carrier, introduction of flanking dimers) can result in a T-cell epitope containing synthetic antigen with preserved, and even improved, antibody recognition. These findings can be utilized for the design of further optimized synthetic antigens. Corresponding immunization studies with Aβ(4−10) epitope conjugates based on these second generation tetratuftsin as well as on branched chain polymeric polypeptide (*28*) carrier are in progress in our laboratories.

ACKNOWLEDGMENT

This work was supported by grants from the Hungarian National Science Fund (OTKA No. T032425, T043576) and the Deutsche Forschungsgemeinschaft (Transregio-SFB Konstanz-Zuerich and Biopolymer-Mass Spectrometry). We thank Dr. Xiaodan Tian for constructive criticism and discussions of this work.

Comblike, Monodisperse Polypeptoid Drag-Tags for DNA Separations by End-Labeled Free-Solution Electrophoresis (ELFSE)

Russell D. Haynes,[†] Robert J. Meagher,[‡] Jong-In Won,[‡,§] Felicia M. Bogdan,[‡,⊥] and Annelise E. Barron*[,†,‡]

Departments of Chemistry and Chemical and Biological Engineering, Northwestern University, Evanston, Illinois 60208. Received December 28, 2004; Revised Manuscript Received April 24, 2005

The development of innovative technologies designed to reduce the cost and increase the throughput of DNA separations continues to be important for large-scale sequencing and genotyping efforts. We report research aimed at the further development of a free-solution bioconjugate method of DNA size separation by capillary electrophoresis (CE), in particular, the determination of an optimal molecular architecture for polyamide-based "drag-tags". We synthesized several branched poly(*N*-methoxyethyl glycine)s (poly(NMEG)s, a class of polypeptoids) as novel friction-generating entities for end-on attachment to DNA molecules. A 30-mer poly(NMEG) "backbone," comprising five evenly spaced reactive ϵ-amino groups, was synthesized on solid phase, cleaved, and purified to monodispersity by RP-HPLC. Three different comblike derivatives of this backbone molecule were created by (1) acetylating the ϵ-amino groups or (2) appending small, monodisperse NMEG oligomers (a tetramer and an octamer). Grafting of the oligo(NMEG)s was done using solution-phase amide bond formation chemistry. Once purified to total monodispersity, the three different drag-tags were studied by free-solution electrophoresis to observe the effect of branching on their hydrodynamic drag or "α" and hence their ability to separate DNA. Drag was found to scale linearly with total molecular weight, regardless of branch length. The octamer-branched drag-tag−DNA conjugate was used to separate ssDNA products of 50, 75, 100, and 150 bases in length by free-solution CE in less than 10 min. Hence, the use of branched or comblike drag-tags is both a feasible and an effective way to achieve high frictional drag, allowing the high-resolution separation of relatively large DNA molecules by free-solution CE without the need to synthesize very long polymers.

INTRODUCTION

The development of novel and improved technologies for DNA separation and analysis continues to be driven by a societal need to make sequencing and genotyping more cost-effective. Capillary electrophoresis (CE)[1] and capillary array electrophoresis (CAE) enable high-throughput DNA sequencing and genotyping separations by allowing the use of higher electric fields and greater automation than was possible with the traditional slab gel format. Both CE and CAE require the use of highly viscous polymer solutions (e.g., entangled solutions of linear polyacrylamide) as intracapillary DNA size-separation matrixes. In addition to their expense, these polymer solutions require the application of high pressure to be loaded into narrow capillaries, and generally DNA sequencing read lengths, with even the best polymers and CAE instruments, are limited to about 800 bases at best.

DNA separation cannot normally be achieved by electrophoresis in free solution, that is, in the absence of polymer networks, because the electrophoretic mobility of DNA molecules is independent of their chain length (*1*). It was theorized in 1992 that DNA could be separated by free-solution electrophoresis if one attached a monodisperse perturbing entity or "drag-tag" to DNA fragments of varying size (*2*). That is, it was predicted that the charge-to-friction ratio of DNA can be rendered size-dependent if a monodisperse drag-tag is covalently attached to one end of the DNA molecules to be separated, allowing the DNA chains to be separated by microchannel electrophoresis in a regular, size-dependent fashion. This approach, called end-labeled free-solution electrophoresis (ELFSE), has been under development for the past 10 years as a promising bioconjugate method of DNA sequencing and genotyping that could eliminate the need for viscous polymer solutions in capillary and chip electrophoresis of DNA (*3*−*5*). Experimentally, ELFSE with various types of drag-tags has been used to separate short oligonucleotides with high resolution (*6*, *7*), as well as long double-stranded DNA fragments (*8*). For DNA sequencing applications, ELFSE promises to provide faster separations and longer read lengths than matrix-based electrophoresis and should be particularly well suited for use in microfluidic devices (*5*, *9*, *10*).

The amount of drag created by the drag-tag can be characterized in terms of the parameter "α", which has the units of the hydrodynamic drag of a single base of

ssDNA (*4*). In circumstances and conditions likely to be present in this study, recent theoretical treatments of the electrophoretic mobilities of composite molecules from the Slater group (*11*, *12*) interpret α in terms of hydrodynamic "blobs". The effective friction coefficient α for a drag-tag can be estimated experimentally by measuring (simultaneously) the electrophoretic migration times of unconjugated, "free" DNA and of a drag-tag−DNA conjugate comprising the same DNA. The parameter α can then be calculated with the equation

$$\alpha = N\left(\frac{\mu_0}{\mu} - 1\right) \quad (1)$$

for a conjugate molecule consisting of N bases of DNA and a charge-neutral drag-tag with friction equivalent to α bases of ssDNA, having the electrophoretic mobility μ, where μ_0 is the electrophoretic mobility of unlabeled DNA (about 2.5×10^{-4} cm^2/(V·s) for the conditions herein) (*4*).

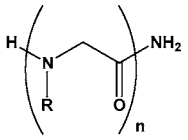
High-resolution ELFSE separations of DNA require the ideal drag-tag to be (i) totally monodisperse, (ii) of high enough molecular weight to impart sufficient drag to separate DNA analytes of varying size, (iii) water-soluble and polar but essentially charge-neutral (*13*), and (iv) resistant to nonspecific (band broadening) interactions with microchannel walls. Taken together, the various and in some cases contradictory design criteria make drag-tag design and synthesis a challenging problem in molecular engineering.

Natural proteins and viruses have been proposed as candidate drag-tags (*2*, *4*). This prediction was validated by the successful sequencing of ca. 110 DNA bases in 18 min by free-solution CE with the use of the protein streptavidin as a drag-tag (*14*). This result, although remarkable, highlighted some significant drawbacks of using natural proteins as drag-tags. For instance, the results indicated a problem with obtaining streptavidin in a truly monodisperse preparation and also showed that even a virtually charge-neutral protein can suffer from strong adsorptive interactions with the microchannel wall. These interactions result in band broadening and a decrease in peak resolution. Streptavidin is a tetrameric protein (*15*) (4×13 kDa, totaling 536 amino acid residues) that has numerous biochemical applications (*16*), but despite its relatively large size, it adopts a compact, globular conformation, resulting in a relatively low drag, equal to approximately 30 bases of DNA. This was the primary factor limiting read length in the study by Slater and Drouin (*14*).

Synthetic polymers have also been examined for use as ELFSE drag-tags. Poly(ethylene glycol) (PEG) is water-soluble, relatively nonadsorptive to glass, hydrophilic, and uncharged − all potentially ideal molecular properties for ELFSE. However, even PEGs with a low molecular mass such as 3400 g/mol (*17*) and an ultralow polydispersity index (M_w/M_n) of 1.01 are not sufficiently monodisperse for DNA sequencing or genotyping applications (*18*).

Poly-N-substituted glycines (polypeptoids) are non-natural, sequence-specific polymers based on a polyglycine backbone (*19*). This class of molecules may be synthesized on solid phase in high yield using a "sub-monomer approach," to include a myriad of different side-chain functionalities (*20*, *21*). After cleavage from the solid phase, they can be purified to monodispersity by reversed-phase high-performance liquid chromatography (RP-HPLC).

Table 1. N-Substituted Glycine (Peptoid) Side Chains



N-substituted glycine oligomer, or *peptoid*

R = Side chain	Designator
	NMEG = *N*-(methoxyethyl) glycine
	NABG = *N*-(butylamine) glycine

Vreeland et al. successfully employed a family of linear, poly(*N*-methoxyethyl glycine) peptoids (poly(NMEG)s) with PEG-like side chains (Table 1) as drag-tags for the ELFSE separation of short DNA oligonucleotides. Poly-(NMEG) drag-tags ranging in size from 10 to 60 monomers in length were used to separate 20- and 21-base ssDNAs (*6*), as well as single-base extension (SBE) reaction products between 19 and 24 bases in length (*22*). The longest polypeptoids used in these studies were 60 monomers in length, and were obtained in only modest yields by the divergent solid-phase peptide synthesis techniques used.

Aiming to improve upon this work, we hypothesized that the grafting of "branch" molecules onto a "backbone" would be an efficient convergent strategy for the synthesis of monodisperse, high-molecular weight drag-tags that could allow the separation of larger DNA. To test this idea, we designed a 30-mer poly(NMEG) "backbone" (Scheme 1) with five evenly spaced ϵ-amino sites to be grafted via a peptide bond-forming reaction with tetramer (**2**) and octamer (**3**) oligo(NMEG) peptoids possessing a terminal carboxylic acid (Scheme 2). The amino groups arrayed along the backbone of **1** could also be acetylated, yielding a set of three drag-tags with increasing branch length. We anticipated that the testing of these three different molecules as drag-tags for DNA separation by free-solution CE would provide valuable information regarding the relationship between chain architecture, molecular weight, and hydrodynamic drag (α). Grafting reactions could in theory be performed while the backbone molecule (**1**) is still on the solid-phase resin; however, for the coupling methodology to be more widely applicable for various classes of backbone molecules, we chose a solution-phase grafting strategy. In this research article, we describe how unbranched (acetylated), tetramer-branched, and octamer-branched comblike poly-(NMEG) peptoid drag-tags were synthesized, characterized, and evaluated. These drag-tags were attached to both 20- and 30-base DNA primers, and free-solution CE was used to analyze the electrophoretic mobilities of the bioconjugate molecules. We were able to observe and quantify the α values for each of these drag-tags. We also demonstrate the use of one of these drag-tags for the efficient separation of differently sized DNA fragments up to 150 bases long by CE in free solution.

EXPERIMENTAL SECTION

General Methods and Materials. The "sub-monomer" synthesis of the poly-N-substituted glycines or "polypeptoids" used in this work has been described previously (*23*). Scheme 1 depicts the protocol that was used to synthesize the polypeptoid molecules made for

Scheme 1. The Sub-Monomer Solid-Phase Polypeptoid Synthesis Protocol[a]

this study. All reactions were carried out on an ABI 433A automated peptide synthesizer (Applied Biosystems, Foster City, CA). All reagents used were purchased from Aldrich (Milwaukee, WI), unless stated otherwise. The mass spectra were recorded by MALDI-TOF (Voyager Pro DE, Perseptive Biosystems, Framingham, MA) and ESI (Waters Micromass Quattro II, Milford, MA). For synthesis details, see Supporting Information.

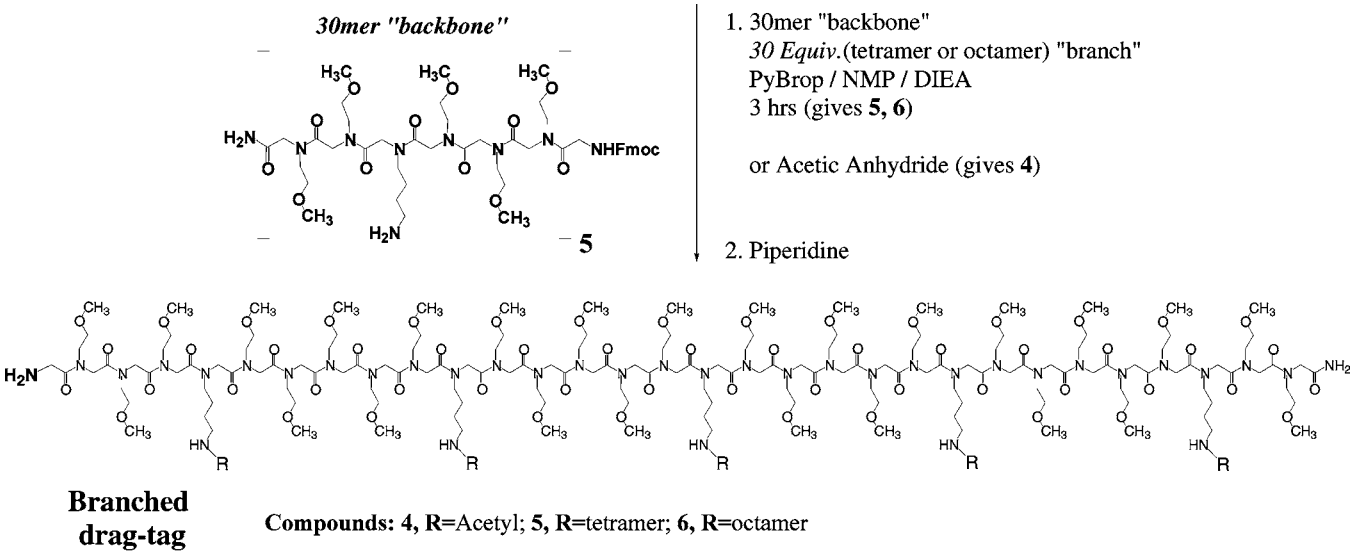
Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC). Analytical RP-HPLC was performed on a column with C18 packing (Vydac, 5 μm, 300 Å, 2.1 mm × 250 mm). The following conditions were employed, unless otherwise stated: a linear gradient of 10−40% B in A was run over 50 min at a flow rate of 0.5 mL/min (solvent A = 0.1% TFA in water; solvent B = 0.1% TFA in acetonitrile) at 58 °C; analytes were detected by UV absorbance at 220 or 260 nm or both. Preparative HPLC was performed on a Vydac C18 column (Vydac, 15 μm, 300 Å, 22 mm × 250 mm) using the same solvent and detection systems; analytes were eluted with a linear gradient of 10−40% B in A over 50 min at 12 mL/min.

Polypeptoid "Backbone" (Compound 1). *Synthesis Details*. Fmoc-Rink amide resin (Nova Biochem, San Diego CA. 0.30 mmol scale) was deprotected by treatment with piperidine in dimethylformamide (DMF) (20% v/v; 2 × 7 mL) in two consecutive 15-min treatments. The oligomer chain was then assembled with alternating cycles of the bromoacetylation step and amine displacement of the alkyl bromide moiety. Bromoacetylation was achieved by mixing the resin with bromoacetic acid (BAA) (1.2 M, 4.3 mL) in DMF and diisopropylcarbodiimide (DIC) (1 mL, 9.9 mmol). The mixture was vortexed for 45 min, the liquid was drained, and the resin was rinsed with DMF (4 × 7 mL). The resin was then mixed and vortexed (45 min) with either methoxyethylamine (1.0 M, 4 mL) or mono-Boc-protected diaminobutane (1.0 M, 4 mL) (*24*) in *N*-methylpyrrolidone (NMP) to introduce the methoxyethyl (NMEG) or butylamine (NABG) side chain moieties (Table 1). The liquid was drained, and the resin was rinsed with DMF (4 × 7 mL). These two reaction cycles were alternated until the polypeptoid was of the desired sequence and length. Finally, an Fmoc protecting group was installed on the amine terminus while the polypeptoid was still on the resin. This was achieved by adding Fmoc-glycine and DIC under the same conditions as used for the bromoacetylation step.

Finally, the polypeptoid was cleaved from the solid support by treatment with 95:2.5:2.5 trifluoroacetic acid (TFA)/triisopropylsilane (TIS)/water for 10 min. The polypeptoid was filtered through a fritted glass vessel to remove the solid support, diluted with water (50 mL), frozen (−80 °C), and then lyophilized. The product of the solid-phase synthesis was evaluated by analytical RP-HPLC. Preparative RP-HPLC was subsequently performed, and appropriate fractions were combined to afford the desired product (**1**) in pure preparation.

Tetramer "Branch" (Compound 2). Using the same methods described above, we synthesized this oligopeptoid using the "sub-monomer" approach (*23*) on a 0.30 mmol scale on Fmoc-Rink amide resin (Scheme 2a). Following procedures outlined above, four additions of the *N*-methoxyethyl glycine monomer were followed by the addition of an *N*-α-Fmoc-L-glutamic acid γ-*tert*-butyl ester (Fmoc-Glu(OtBu)-OH) residue, which involves the coupling of the amino acid to the terminal secondary amine. This coupling was achieved by dissolving the amino acid in NMP (1.0 M; 4 mL) with PyBroP (1.2 M) and DIEA (1.2 M). The Fmoc group at the N-terminus of the glutamic acid residue was subsequently removed using (20% v/v) piperidine in DMF, and the resultant primary amine was capped with acetic anhydride. This was achieved by immersing the resin in fresh acetic anhydride (neat) (Applied Biosystems, Foster City, CA), followed by agitation with occasional venting for 15 min. The resin was filtered and cleaved, as previously described. For the branch molecules, cleavage from the resin also resulted in deprotection of the *t*-butyl-protected glutamic acid side chain functionality, revealing the carboxylic acid group. The oligopeptoid was cleaved from the solid support, frozen, and lyophilized, as previously

Scheme 3. Solution-Phase Coupling Protocol for the Synthesis of Branched and Unbranched Drag-Tags (4−6) via Grafting of Oligopeptoids onto the Backbone Molecule (1)



described. The product of the solid-phase synthesis was evaluated by analytical RP-HPLC. Preparative RP-HPLC was performed, and appropriate fractions were combined to afford the desired tetramer (**2**). The product was identified by ESI mass spectrometry and analyzed by RP-HPLC.

Octamer "Branch" (Compound 3). The octamer branch molecule (Scheme 2b) was synthesized by preloading the Rink amide resin with Fmoc-Glu(OtBu)-OH as the first step using standard peptide chemistry. The Fmoc group on the glutamic acid residue was subsequently removed using (20% v/v) piperidine in DMF, followed by the addition of eight monomers of *N*-methoxyethyl glycine. The terminal secondary amine was acetylated, and the oligopeptoid was then cleaved from the solid support, frozen, and lyophilized, as previously described. Preparative RP-HPLC was performed, and appropriate fractions were combined to afford compound **3**. The product was identified by ESI mass spectrometry and was analyzed by RP-HPLC.

Backbone Acetylation (Compound 4). An "unbranched" 30-mer drag-tag was synthesized by the addition of neat acetic anhydride (1 mL) to the purified backbone molecule **1** (5.0 mg, 1.3 μmol) (Scheme 3). Excess acetic anhydride was removed in vacuo, and the reaction mixture was quenched with water (10 mL), frozen (−80 °C), and lyophilized. Preparative RP-HPLC was performed and appropriate fractions were combined to afford **4**. The product was identified by MALDI-TOF mass spectrometry and was analyzed by RP-HPLC.

Backbone Grafting Reactions (Compounds 5 and 6). *Typical synthesis protocol.* Tetramer **2** (25.5 mg, 39 μmol) and PyBroP (24.85 mg, 39 μmol) were added to a cooled solution (0 °C ice-bath) of backbone **1** (5.0 mg, 1.3 μmol) in NMP (1 mL) (Scheme 3). The resultant mixture was stirred under nitrogen for 5 min. The reaction mixture was stirred vigorously and diisopropylethylamine (DIEA) (5 mg, 39 μmol) was added dropwise via cannula under a positive nitrogen atmosphere. The reaction mixture was allowed to warm to room temperature, and the reaction was allowed to proceed for 3 h. NMP was then removed in vacuo, and the solution was diluted with deionized water (12 mL), frozen, and lyophilized. The grafting reaction was monitored by analytical RP-HPLC using a slightly different method than previously stated: A linear gradient of 10−60% B in A was run over 50 min at a flow rate of 0.5 mL/min (solvent A = 0.1% TFA in water, solvent B = 0.1% TFA in acetonitrile) at 58 °C on a C18 packing column (Vydac, 5 μm, 300 Å, 2.1 mm × 250 mm); analytes were detected by UV absorbance at 220 and 260 nm. Preparative HPLC was performed on a Vydac C18 column (Vydac, 15 μm, 300 Å, 22 mm × 250 mm) using the same solvent and detection systems; analytes were eluted with a linear gradient of 10−60% B in A over 50 min at 12 mL/min. Preparative RP-HPLC was performed, and appropriate fractions were combined. Compound **5** was then was treated with 20% (v/v) piperidine in methanol (1 mL) to remove the terminal Fmoc protecting group and stirred for 20 min. The solvent was then removed in vacuo, and the resulting material was repurified by RP-HPLC as previously described. The same conditions were used, and similar results were obtained for the grafting reaction with the octamer branch to produce compound **6**.

Sulfo-SMCC Conjugation. The drag-tags (**4**−**6**), displaying a free amine at the *N*-terminus, were dissolved in 0.1 M sodium phosphate buffer, 0.15 M sodium chloride, pH = 7.18. Sulfo-SMCC (sulfosuccinimidyl 4-[*N*-maleimidomethyl] cyclohexane-1-carboxylate) (Pierce Scientific, Rockford, IL, 10 mg/mL in water) was added to the drag-tag/buffer solution. This reaction mixture was agitated at room temperature for 1 h. The reaction was quenched by the addition of water (2 mL) and then purified by preparative HPLC using the conditions described above. The appropriate fractions were then combined.

Drag-tag−DNA Conjugation. Sulfo-SMCC-activated polypeptoid drag-tags were individually conjugated to 5′-thiolated, fluorescently labeled DNA oligonucleotides of lengths 20 and 30 bases (Integrated DNA Technologies, Coralville, IA). The 20- and 30-base DNA sequences were [5′-$\mathbf{X_1}$GT$\mathbf{X_2}$TTCCCAGTCACGACGTT-3′] and [5′-$\mathbf{X_1}$CC$\mathbf{X_2}$-TTTAGGGTTTTCCCAGTCACGACGTTG-3′], where $\mathbf{X_1}$ was a 5′ thiol modifier (C6 disulfide) and $\mathbf{X_2}$ was an internal fluorescein-labeled dT base. Both sequences are designed to be used as primers for an M13mp18 template; the 30-base sequence includes six nonhybridizing bases at the 5′ end. The thiol linkers were reduced by incubating 125 pmol of thiolated DNA with 5000 pmol of tris-(2-carboxyethylphosphine) hydrochloride (TCEP) (Acros Organics, Morris Plains, NJ) in a total volume of 10 μL

Table 2. Oligonucleotide Sequences Used as Primers for PCR Products of 50, 75, 100, and 150 bp

of sodium phosphate buffer (100 mM, pH 7.2) at 40 °C for 110 min.

Reduced DNA was conjugated to sulfo-SMCC-activated polypeptoids by mixing 500 pmol of polypeptoid with 12.5 pmol of the reduced DNA mixture (containing 500 pmol of TCEP) in a volume of 5−7 μL of sodium phosphate buffer (100 mM, pH 7.2). Conjugation reactions proceeded in the dark at room temperature for approximately 6 h before CE analysis.

Preparation of PCR Products. The 30-base thiolated, fluorescently labeled M13 oligonucleotide described above [5′−X$_1$CCX$_2$TTTAGGGTTTTCCCAGTCACGACGTTG-3′] was used as a forward primer. Four different 20-base oligonucleotides (Table 2) were purchased from IDT (Coralville, IA) and served as M13 reverse primers for generating PCR products of 50, 75, 100, and 150 bp in length. M13mp18 ssDNA obtained from Amersham Biosciences (Piscataway, NJ) was used as a template. PCR reactions using *Thermus aquaticus* (*Taq*) DNA polymerase were performed using an MJ Research DNA thermal cycler with 30 cycles of 95 °C for 1 min (denaturing), 55 °C for 1 min (annealing), and 72 °C for 2 min (elongation). The size of each PCR product (dsDNA) was confirmed via 3% agarose gel electrophoresis. The PCR products (with no additional purification) were reduced with Tris(2-carboxyethyl)phosphine (TCEP) and conjugated to drag-tags as described above for the DNA primers.

Free-Solution Capillary Electrophoresis. DNA−polypeptoid conjugates were analyzed by capillary electrophoresis with laser-induced fluorescence detection, using either a BioRad BioFocus 3000 single-capillary instrument (BioRad, Hercules, CA) or an Applied Biosystems Prism 3100 capillary array instrument (Applied Biosystems, Foster City, CA).

Oligonucleotide primers conjugated to polypeptoid drag-tags were analyzed by free-solution electrophoresis using the BioRad BioFocus instrument at 40−55 °C in 25-μm inner-diameter fused silica capillaries (Polymicro Technologies, Phoenix, AZ) cut to a total length of 25 cm (20.4 cm from inlet to detector). The running buffer was 1× TTE with 7 M urea (50 mM Tris, 50 mM TAPS, 2 mM EDTA, 7 M urea, pH = 8.5). Typical DNA sequencing conditions were used to keep the DNA in an unstructured state (7 M urea and a run temperature of 55 °C). The internal surface of the capillary was coated with an adsorbed layer of POP5 polymer (Applied Biosystems, Foster City, CA) using a low-viscosity 3% (v/v) aqueous dilution of the commercially available POP5 solution to reduce electroosmotic flow to negligible levels. Immediately prior to sample injection, the injection end of the capillary was dipped into deionized water to remove any residual buffer salts on the outer surface of the capillary. The samples were introduced into the capillary by pressure injection with pressure−time constants of 5−15 psi·s. Electrophoresis was conducted at 400 V/cm until all peaks had eluted with typical currents of 2.8 μA. Detection of the analytes was accomplished by excitation of the fluorescent label on the DNA using the 488 nm line of an argon-ion laser with emission detected at 520 nm.

Electrophoretic analysis of PCR products conjugated to polypeptoids was carried out in free solution using the Applied Biosystems Prism 3100 genetic analyzer with an array of fused silica capillaries of length 36 cm and inner diameter 50 μM. Analysis conditions were identical to those described above for the BioFocus experiments, except the electric field was 320 V/cm, and samples were introduced by an electrokinetic injection of 22 V/cm for 2 s. The PCR product−polypeptoid conjugates were diluted in deionized formamide (Applied Biosystems, Foster City, CA) and denatured at 95 °C for 5 min prior to electrophoretic analysis to yield single-stranded DNA−drag-tag conjugates.

RESULTS AND DISCUSSION

Branched Drag-Tag Design and Synthesis. Attaching large molecules onto a scaffold containing multiple grafting sites, and achieving full coverage, is a challenging proposition (*25*). For ELFSE applications, the grafting linkages need to be stable enough to withstand further conjugation reactions, purification steps, wide pH ranges, and the high temperatures used in thermal cycling. For this reason, we decided on peptide-bond linkages. We designed the backbone (**1**) to have regularly spaced, pendant ϵ-amino groups as attachment sites for tetramer (**2**) and octamer (**3**) branch molecules with terminal carboxylic acid groups. This is an attractive strategy as it allows for the convergent reaction between large molecules that have been prepurified to monodispersity. Although the resolving power of RP-HPLC could potentially allow for a subsequent removal of the incompletely grafted side-products, complete grafting is a desired outcome, because even slight impurities in the drag-tag are exposed by CE analysis and will limit its usefulness.

Indeed, early attempts in our lab to graft polyamide oligomers onto lysine-containing polypeptides resulted in a ladder of partially grafted products that ultimately proved too difficult to purify to monodispersity (*26*). In the present work, we have used poly(*N*-methoxyethyl glycine)s and their derivatives for both the backbone and branch structures and were able to produce highly monodisperse components in high yield. The structure of poly(NMEG) is consistent with recently proposed rules for creating chemical surfaces that are resistant to adsorption of proteins from solution. Specifically, it was found that surfaces presenting groups that are polar but uncharged and hydrophilic and contain hydrogen-bond acceptors (but not hydrogen-bond donors) are inert to adsorption of proteins from solution (*27*). We hypothesized that poly(NMEG), which has all of these structural features, would be resistant to adsorption from solution onto surfaces. This is a critical feature for capillary electrophoresis, where wall−analyte interactions are a major source of band broadening. Indeed, in previous ELFSE separations using streptavidin as a drag-tag, the interaction between streptavidin and the capillary wall was the primary factor limiting separation efficiency at high electric field strengths (*14*).

We had to design the drag-tag for two stages of conjugation: a grafting reaction that introduced the monodisperse branches and then a conjugation to DNA. To achieve this, the backbone molecule (**1**) was designed

Table 3. Peptoid Structures, Molecular Mass Confirmation, and Crude Purities

compound	peptoid oligomer	monomer sequence (amino-to-carboxy)	molar mass calcd/found	purity,[a] %
1	30-mer backbone	$FmocGly[(NMEG)_3(NABG)(NMEG)_2]_5NH_2$	3818.2/3819.3	77

3	octamer branch	$Ac(NMEG)_8Glu(OH)NH_2$	1108.6/1109.1	95

[a] As estimated by analytical reversed-phase HPLC of crude product. All compounds were purified to >99% homogeneity before conjugation reactions.

with a glycine group at the N-terminus (Scheme 1), and this resulted in a terminal amine protected with 9-fluorenylmethyloxycarbonyl (Fmoc). The Fmoc protecting group is orthogonal to the *tert*-butyloxycarbonyl (Boc)-protected *N*-butylamine (NABG) ϵ-amino groups along the backbone and, when removed (after grafting), exposes a free N-terminal amine for DNA conjugation. Cleavage from the resin using trifluoroacetic acid (TFA) also conveniently cleaves the Boc groups on the side chains without affecting the Fmoc-protected amino terminus.

The terminal Fmoc-glycine residue also facilitates purification. The increased hydrophobicity afforded by the inclusion of the Fmoc group dramatically increases the HPLC retention time, thus helping separate the desired product from impurities. Also, the UV absorbance of the Fmoc moiety allows for facile identification of the product peak at 260 nm by RP-HPLC. The Fmoc amino group can then be easily deprotected at a later point for conjugation to DNA prior to ELFSE analysis.

Backbone Synthesis. The backbone (**1**) was synthesized (Scheme 1) using commercially available materials and mono-Boc-protected diaminobutane, the latter synthesized and purified in-house according to literature procedures (*24*). RP-HPLC analysis revealed a single major product peak, approximately 77% by area (Table 3) (greater than 99% coupling efficiency per monomer residue). Compound **1** was obtained in pure form by preparative RP-HPLC, and its correct mass was confirmed by ESI mass spectrometry.

Branch Syntheses. The tetramer and octamer branches were both synthesized in excellent yield (Table 3) and purified to monodispersity by RP-HPLC. They were designed as oligo(*N*-methoxyethyl glycine) peptoids with terminal glutamic acid (peptide) functionalities. Previous unsuccessful attempts in our lab to make similar tetramer and octamer branches suitable for high-yield grafting involved using a terminal glycine unit to provide the reactive carboxylic acid group. Specifically, we had synthesized tetramer and octamer oligo(*N*-methoxyethyl glycine) peptoids on preloaded glycine Wang resin that revealed a C-terminal carboxylate upon cleavage. However, the carboxylate groups on these glycine-terminated drag-tags were apparently too sterically hindered for high-yield grafting reactions. In our hands, they failed to react efficiently with the ϵ-amino groups along the backbone. Attempts to graft with these branch molecules resulted in incomplete coverage and hence relatively low yields of the desired fully derivatized drag-tags (<30% crude yield). The tetramer-branched drag-tag obtained using this strategy was successfully isolated in sufficient quantity for conjugating to DNA, but in low overall yield and with a mass that differed for unknown reasons by ~200 g/mol from the correct target molar mass. Hence, the glycine-terminated branch design was abandoned in favor of glutamic acid-terminated branches; as described below, grafting of the backbone with these oligomers yields conjugates with the correct accurate masses.

With the intention of improving the coupling efficiency of the grafting reaction, glutamic acid-terminated oligomer branches were designed with the carboxylic acid functionality at the end of a longer, more flexible side chain. We designed the tetramer (**2**) to have the glutamic acid at the *N*-terminus and the octamer (**3**) with that group at the C-terminus (Scheme 2), since we did not know a priori which strategy was best or whether this would make a difference. Synthetically, the two branch designs differ only slightly but potentially enough to affect the monodispersity, since the acetic anyhdride capping of **1** takes place on a primary amine, while the capping of **2** occurs on a secondary amine. For both branch molecules, however, synthetic yields were high: RP-HPLC analysis revealed a single major product peak; yields were approximately 95% by area for both designs (Table 3). In addition, highly efficient grafting was achieved with both designs as described below (Figure 1).

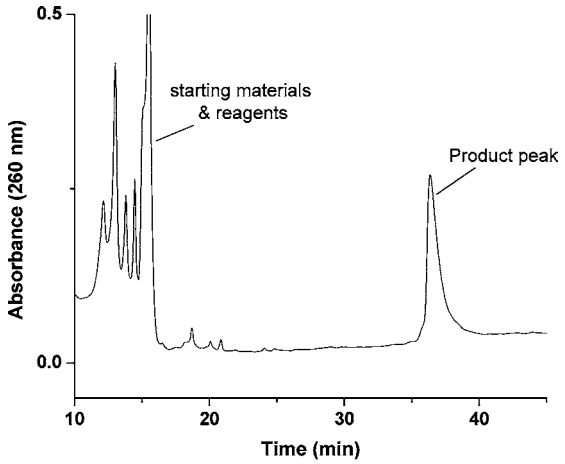

Figure 1. RP-HPLC chromatogram of the crude products of the grafting reaction between the tetramer branches (**2**) and the backbone molecule (**1**). HPLC conditions were C18 250 mm Vydac column, 58 °C, with 10−60% acetonitrile−water (0.1% TFA) over 50 min.

Grafting of Oligomeric Branches to the Polymeric Backbone. The "unbranched" or N-acetylated drag-tag (**4**) was synthesized by the addition of acetic anhydride to a solution of the backbone (**1**) in methanol. Removal of the solvents in vacuo, followed by RP-HPLC purification, afforded a single pure product. The Fmoc protecting group was then removed from the isolated product using piperidine; analysis of the products of this deprotection reaction gave a single peak by RP-HPLC. Compound **4** was collected as a white solid.

One of the most challenging aspects of this synthesis was to achieve complete reaction at all five amino sites on the backbone molecule with the tetramer and octamer branches. To generate a completely monodisperse product, we had to find the best way to couple several large molecules together while forming bonds that are extremely stable. Peptide bond linkages can be formed efficiently and were found to be sufficiently stable to withstand the further manipulations needed to make the drag-tag useable.

Finding the appropriate reagents and conditions to form five simultaneous peptide bonds in one reaction

Table 4. Drag-Tag Structures, Molecular Mass Confirmation, and α Values

compound	drag-tag	molar mass calcd/found	α(20)[a]	α(30)[b]
4	acetylated	4023.2/4023.5	7.9	7.9
5	tetramer-branched	6964.9/6964.6	12.5	13.7
6	octamer-branched	9266.1/9271.4	16.4	17.2

[a] For the 20-base DNA−drag-tag conjugate. [b] For the 30-base DNA−drag-tag conjugate.

initially proved difficult. Solvents including NMP and DMF were examined. Several peptide bond forming coupling reagents including PyBOP, HATU, and PyBroP were examined (*28*−*30*). Optimum results with respect to the efficiency of coupling were obtained utilizing a combination of NMP and PyBroP with DIEA (*26*). The use of freshly lyophilized chemicals and Aldrich "sure-seal" packaging (where available) and the employment of rigorous Schlenk techniques under a positive nitrogen atmosphere were found to be highly important factors in the achievement of complete grafting coverage of the backbone. The backbone molecule was found to be especially sensitive to air, because it possesses five free amines, which may react with carbon dioxide. After optimization of the reaction conditions, the RP-HPLC chromatograms for the analysis of the crude products of the grafting reactions show a single product peak, later identified by mass spectrometry to be the fully grafted comblike polymer. Under the described reaction conditions, the grafting reaction is highly efficient and goes to completion in only a few hours. Using 6 equiv of branch molecule per amino site on the backbone (30 equiv overall) was found to be sufficient to achieve complete grafting of all five sites. Preparative HPLC fractions were collected and lyophilized to afford a white solid. This protocol does expend a large quantity of the branch reagent, but to ensure that the reaction goes to completion (due to the strict monodispersity needs for ELFSE applications), the expense is deemed acceptable.

Isolated yields for the synthesis of these branched drag-tags are difficult to accurately quantitate since on the scale we performed them (5 mg of backbone), the masses of final product are low (ca. 1 mg). The crude yield as determined by RP-HPLC is ∼97% (Figure 1). However, to ensure complete monodispersity, only the product appearing in the central area of the RP-HPLC peak was carried on. The drag-tag conjugate molecules were found to have the correct masses by MALDI-TOF mass spectrometry (Table 4). As described above, the derivatized (branched) molecules were then treated with piperidine and further purified to afford drag-tags with free (and unique) primary amino groups at the N-terminus. These molecules were then ready for sulfo-SMCC activation to enable their conjugation to oligonucleotide primers.

Sulfo-SMCC Activation. The free-amine terminated drag-tags were reacted with the heterobifunctional linker sulfo-SMCC. This reagent consists of two reactive groups: a sulfo-NHS group (reactive toward primary amines) and a maleimide (reactive toward thiols), connected by a cyclohexyl-containing aliphatic linker. The primary amino terminus of the drag-tags reacts with the sulfo-NHS end of the linker. RP-HPLC was then used to remove excess sulfo-SMCC from the reaction mixture, resulting in a high yield (>95%) of drag-tag with a reactive maleimide for subsequent conjugation to thiolated oligonucleotides.

DNA Reduction and Conjugation to Polypeptoids. The 5′-thiolated DNA is obtained as the disulfide dimer, which must be reduced to yield free sulfhydryl groups. Complete reduction of the DNA is essential for obtaining a high yield of the desired conjugate molecule. DNA reduction conditions, involving a 40:1 molar ratio of tris(2-carboxyethyl)phosphine (TCEP) to thiolated DNA incubated at 40 °C for at least 90 min, were found to reliably reduce picomole amounts of disulfide-modified DNA with yields in excess of 80%. Dithiothreitol (DTT) may also be used for reduction at slightly alkaline pH, although in our experience a larger excess of DTT must be used with a significantly longer incubation at 40 °C to achieve a comparable level of reduction with these very small amounts of thiolated DNA. Solid-phase reducing agents (resin-bound DTT or TCEP) have given us inconsistent results.

Literature reports as to the reactivity of TCEP toward maleimides are varied (*31*−*33*). We have found that the presence of excess TCEP does seem to reduce the efficiency of the conjugation of thiolated DNA to maleimide-activated polypeptoids, and addition of maleimide-activated polypeptoid in slight excess relative to TCEP appears to give optimal conjugation yields (data not shown). Since the polypeptoids in this case are available in large quantities relative to the tiny amounts of DNA required for capillary electrophoresis analysis, the removal of excess TCEP by gel filtration or dialysis was not necessary. Conjugation yields were approximately 70% for polypeptoids conjugated to the 20-base DNA and closer to 95% for polypeptoids conjugated to 30-base DNA.

Free-Solution Capillary Electrophoresis Analysis of DNA−Drag-Tag Conjugates and the Determination of α Values. Capillary electrophoresis with laser-induced fluorescence detection is a powerful and sensitive analytical technique in which charged analytes are separated on the basis of differences in their charge-to-friction ratios or electrophoretic mobilities. Separations are carried out in narrow fused silica capillaries, which allow efficient heat removal and thus enable the use of higher electric fields than can be maintained in conventional slab gel electrophoresis. DNA separations are typically carried out in 50- or 75-μm inner diameter capillaries filled with a viscous polymer solution or sieving matrix. In this study, modifying DNA oligonucleotides with the drag-tags allowed the separation of DNA in free solution with no viscous polymer solution. The elimination of the polymer solution simplifies CE operations and allows the use of narrower capillaries (as small as 25 μm in inner diameter), which afford improved resolution.

The highly negatively charged DNA oligomer component of the drag-tag−DNA conjugates endows each of the bioconjugate molecules with a strong electromotive force during electrophoresis. The polypeptoid portion gives each molecule an additional amount of hydrodynamic drag. The analysis of the drag-tag−DNA conjugates by free-solution electrophoresis allows the determination of the frictional parameter α of the drag-tag, as described in the Introduction (eq 1).

The results of the electrophoretic analyses of the drag-tags conjugated to the 20-base oligonucleotide are shown in Figure 2, and α values calculated from the experiments are shown in Table 4. The acetylated 30-mer **4** gives an $\alpha \approx 8$, whereas the addition of tetramer and octamer branches increases α to about 13 and 17, respectively. Note that the 536-residue protein streptavidin gives an α value that is only twice that of the octamer-branched drag-tag (**6**), which comprises only 70 monomers. A high degree of monodispersity is a key property for drag-tags, and these drag-tags display excellent purity (>99% by area). Extremely monodisperse drag-tags are necessary

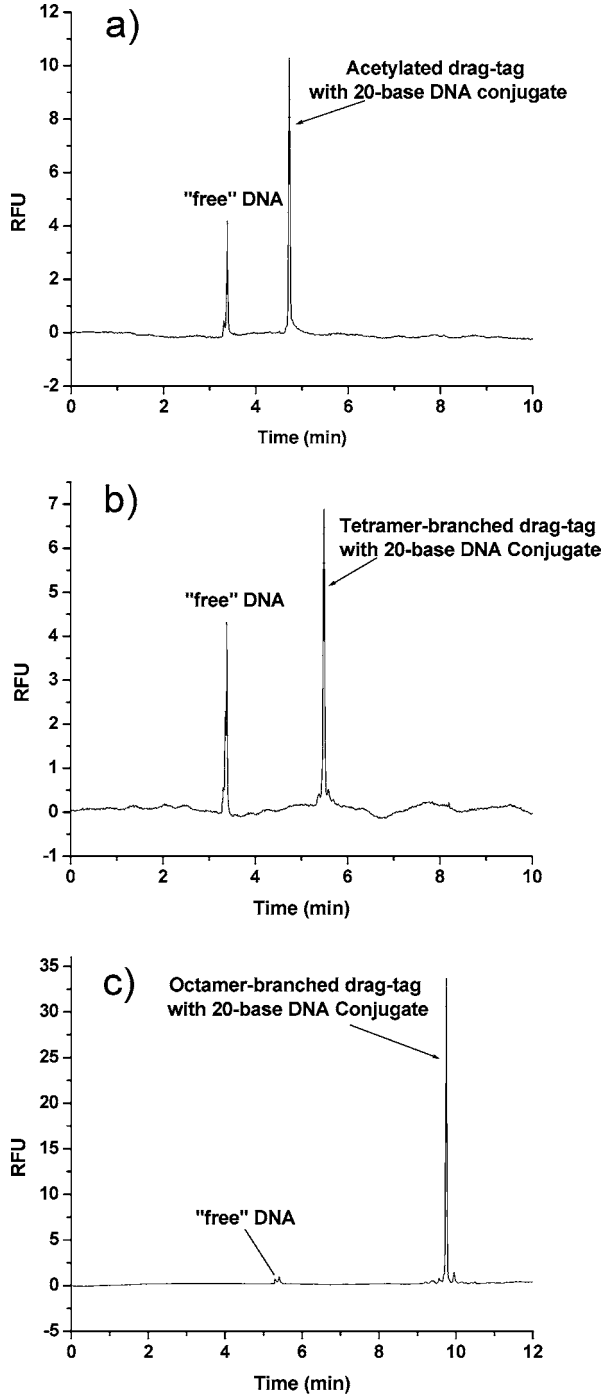

Figure 2. Free-solution capillary electrophoresis analysis of 20-base fluorescently labeled oligonucleotide conjugated to (a) an "unbranched" or acetylated 30-mer drag-tag (**4**), (b) a tetramer-branched drag-tag (**5**), and (c) an octamer-branched drag-tag (**6**). Separations were carried out on a BioRad BioFocus capillary electrophoresis instrument at 40 °C. The running buffer was 50 mM Tris, 50 mM TAPS, 2 mM EDTA, and 7 M urea, pH 8.5, mixed with a 3% (v/v) aqueous dilution of a POP5 solution as a wall coating agent. The fused silica capillary had an inner diameter of 25 μm and a total length of 25 cm (20.6 cm inlet to detector). Samples were introduced by hydrodynamic injection with a pressure−time constant of 5 psi·s. The electric field was 10 kV (400 V/cm) with a typical current of 2.8 μA. The fluorescent label was excited at 488 nm with emission detected at 520 nm.

for ELFSE analysis because impurities lead to multiple peaks for each size of DNA. Such extra peaks would confound the results of sequencing or other ELFSE separations demanding high resolution. These results

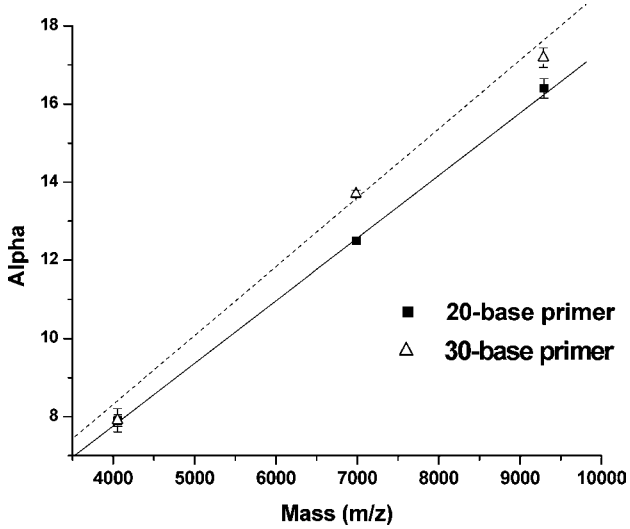

Figure 3. Plot of hydrodynamic drag or "α" against molecular weight for the 20-base and 30-base DNA−drag-tag conjugates (for all three drag-tags, **4**−**6**).

give us good confidence in the viability of making high molar mass peptoids for ELFSE applications.

Interestingly, the relationship between α and the molecular weight of the drag-tag for these poly(*N*-methoxyethyl glycine)-based molecules was found to be essentially linear (Figure 3). Table 4 shows the relative molecular weights and averaged α value for each of these drag-tag conjugates with two DNA primers of different length. This study shows that hydrodynamic drag is not simply a function of the length of the backbone. Rather, drag scales linearly with the total molecular weight or the total number of monomer units. This is in line with previous observations for linear polypeptoids (*6*) and suggests that the polypeptoids, whether branched or linear, adopt an "expanded" conformation in aqueous solution such that all of the monomer units are hydrodynamically exposed to the solvent during electrophoresis.

Separation of PCR Products. The octamer-branched drag-tag (**6**) was utilized in separating thiolated DNA products from a PCR reaction. PCR was used to generate double-stranded DNA fragments of 50, 75, 100, and 150 base pairs in size. The monodisperse, comblike polymer drag-tag **6** was conjugated to each of the fragments following the PCR reaction, and these conjugate products were successfully separated by CE in free solution, as shown in Figure 4a. The PCR products were denatured prior to analysis and analyzed under denaturing conditions, so the analysis represents single-stranded DNA−drag-tag conjugates. The PCR reaction products were not purified prior to analysis; hence there are some shorter products representing partially amplified PCR products shorter than 50 bases. We left these impurities in the mixture to demonstrate the ability of the drag-tag **6** to resolve small DNA with single-base resolution. The peaks for the 50-base and 75-base fragments are actually split into doublets, indicating the presence of two species (perhaps 50 and 51 and 75 and 76 bases). The reason for this could be due to the propensity of *Taq* polymerase to generate "stutter" or "shadow" bands, in this case possibly adding an extra base during the PCR reaction (*34*). Multiple closely spaced peaks are also present for "free" DNA (carrying no drag-tag). There are several different sizes of DNA present in the mixture, including some unreduced disulfide dimers, which may have slightly different mobilities, resulting in the spread of closely

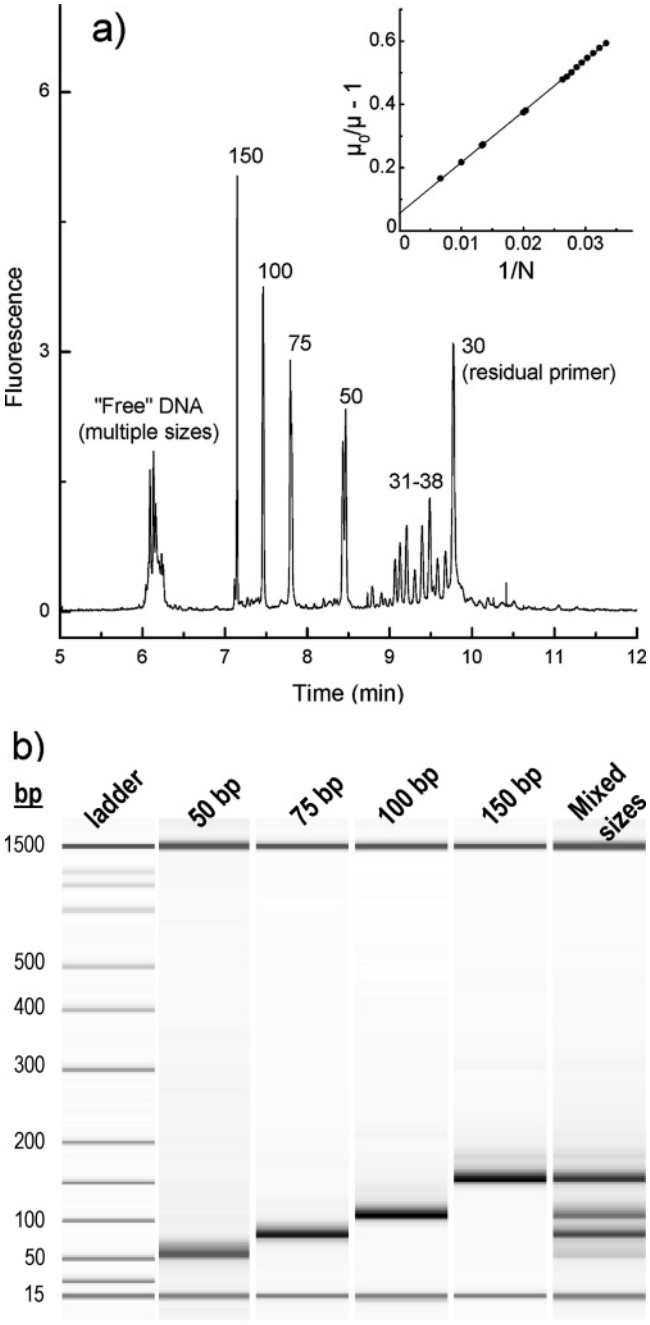

Figure 4. (a) ELFSE separation of 50-, 75-, 100-, and 150-base PCR products (and residual DNA impurities) conjugated to the octamer-branched drag-tag. Samples were denatured in formamide prior to injection. Analysis was performed in free solution on an ABI Prism 3100 instrument with a 36-cm long capillary array (55 μm i.d. capillaries) at 55 °C. The buffer was 50 mM Tris, 50 mM TAPS, 2 mM EDTA, and 7 M urea, pH 8.5, mixed with a 3% (v/v) aqueous dilution of a POP5 solution as a wall coating agent. An electrokinetic injection of ~22 V/cm for 2 s was used. The electric field during the run was ~320 V/cm with a typical current of ~8.5 μA per capillary. The inset is a plot of ($\mu_0/\mu - 1$) for each of the major peaks versus the number of DNA bases N (*4*). (b) Analysis of reduced, thiolated PCR products on Agilent 2100 Bioanalyzer using DNA 1000 sizing kit. Each sample lane includes 15 and 1500 bp markers.

spaced peaks centered around 6.1 min. For comparison, the separation of these PCR products was performed using a chip-based electrophoresis system (the Agilent 2100 Bioanalyzer) with a polymer solution to provide size-based separation of DNA. The correct sizes of the PCR products were confirmed by comparison to DNA size standards (Figure 4b). The DNA polydispersity around 50 bases correlates well with what was found using the ELFSE technique (compare Figure 4, parts a and b).

The inset of Figure 4 shows a plot of the mobility ratio, $\mu_0/\mu - 1$, versus number of bases for each of the major peaks in Figure 4, including the residual primer and impurity peaks. The tallest of the "free" DNA peaks at 6.13 min was chosen as the reference peak for μ_0. As can be observed by a simple rearrangement of eq 1, this plot should yield a straight line with slope equal to α. The resulting plot is highly linear ($R^2 = 0.9997$) with a slope of 16.15, in good agreement with the α values calculated from the separations of the 20-base and 30-base oligonucleotides. The intercept is slightly offset from zero; this may be the result of the fluorescein label, which contains a negative charge and thus slightly affects the electrophoretic mobility of both the conjugates (μ) and the free DNA (μ_0).

This separation of PCR products demonstrates the potential usefulness of branched polypeptoid drag-tags for a wide variety of genotyping or "DNA fingerprinting" applications that require size-based separation of DNA. The mixture shown here was intentionally not purified to demonstrate the resolving power of ELFSE for smaller oligonucleotides (the small impurities are easily separated with single-base resolution). This separation methodology could easily be adapted to analyze double-stranded PCR products as well. The highly monodisperse drag-tag and separation method used here offer excellent resolution and peak shape compared to the previous demonstrations of dsDNA separation by ELFSE using streptavidin (*8*), due to the true monodispersity and favorable chemical properties of these drag-tags. The octamer-branched drag-tag is likely too small for high-resolution separation of much larger PCR products or DNA sequencing fragments, but a similar methodology may be employed to construct much larger branched molecules, for example, using larger branches, a longer backbone, or both.

CONCLUSIONS

In this work, we have developed methodology for creating totally monodisperse, comblike, hydrophilic, and water-soluble copolymers, which were successfully synthesized and characterized. The peptide bonds between the branches and the backbone were formed most efficiently using an excess of glutamic acid-terminated branches and PyBroP as a coupling reagent. By conjugating the drag-tags to monodisperse DNA oligonucleotides 20 and 30 bases in length, we then evaluated these branched molecules by free-solution CE as ELFSE drag-tags in terms of their respective frictional parameters (α). The octamer-branched molecule was also used to successfully separate ssDNA fragments of varying lengths up to 150 bases.

The ELFSE studies of this family of branched drag-tag−DNA bioconjugates reveal a direct linear relationship between molecular weight and hydrodynamic drag. This information will prove useful in the future design of drag-tags for applications in free-solution CE. Achieving significant hydrodynamic drag for poly(NMEG) peptoids may be considered a direct function of molecular weight or the number of monomers, rather than simply the length of the backbone.

We intend to use this structural information about drag-tag design to generate drag-tags with tailored designs that allow the free-solution sequencing of hun-

dreds of bases of DNA. A comblike architecture appears to be an excellent design for drag-tags for the ELFSE technique.

ACKNOWLEDGMENT

We would like to thank Gary W. Slater for many helpful discussions regarding this project. This work was supported by the National Institute of Health and National Human Genome Research Institute (Grant No. 1RO1HG002918-01).

Water-Soluble Phosphines for Direct Labeling of Peptides with Technetium and Rhenium: Insights from Electrospray Mass Spectrometry

William E. P. Greenland[†] and Philip J. Blower*[,†,‡]

Biosciences Department, University of Kent at Canterbury, Canterbury, Kent CT2 7NJ, U.K., and Nuclear Medicine Department, East Kent Hospitals NHS Trust, Kent and Canterbury Hospital, Canterbury CT1 3NG, U.K.. Received March 4, 2005

Direct labeling of salmon calcitonin (sCT) is possible in one step using water-soluble phosphines (sulfonated triphenylphosphines) as the reducing agent both for disulfide and for pertechnetate. Phosphines were the most efficient reducing agent for disulfide bonds among those examined. The phosphines both reduced the pertechnetate to Tc(III), and contributed to the technetium coordination sphere in the labeled product. In contrast, the phosphines did not reduce rhenium below oxidation state V, nor did they participate in the rhenium coordination sphere in the labeled peptide. Instead, the expected oxorhenium(V) moiety was incorporated. Both Tc and Re labeling processes gave rise to dimers with two peptides linked by the metal center, as well as simple monomeric species. Positive mode electrospray mass spectrometry not only revealed the presence of phosphine bound to technetium and oxygen bound to rhenium in the metallopeptides but also revealed the oxidation states of the metals. Electrospray mass spectrometry is proving to be an exceptionally valuable technique for characterizing radiopharmaceuticals. Although the one-step direct labeling method described gives mixed products and poor receptor affinity when applied to the small peptide sCT, it might be readily adapted to monoclonal antibodies.

INTRODUCTION

The radiolabeling of peptides and antibodies with technetium and rhenium isotopes (Tc-99m, Re-186, Re-188) by direct methods (*1*–*5*) is an often-used but rarely understood process for producing diagnostic and therapeutic radiopharmaceuticals. The direct labeling approach exploits the presence of thiolate groups of cysteine side chains, usually generated by reduction of a disulfide bond, as the primary metal-binding groups. Its popular appeal stems from simplicity of execution, requiring no bifunctional chelator that may be costly or may necessitate considerable synthetic expertise. However, in most of the examples in which it has been used to date, it has many disadvantages. The structure of the conjugate is uncontrolled, unpredictable, and often unknown, and the in vivo stability may not be all that is desired. Much effort has therefore been invested in understanding the molecular structures and mechanisms involved (*3*, *6*–*10*). Nevertheless, with some exceptions (*11*), the structures remain poorly understood and unpredictable, and biological and clinical evaluations of several peptide and protein radiopharmaceuticals have been embarked upon without satisfactory understanding of their structure and properties. In the case of Tc and Re, coordination is commonly supposed to involve local nitrogen atoms from amide or amine groups in the peptide backbone or side chains, in addition to cysteine thiolates and a $[M{=}O]^{3+}$ (V) core, although spectroscopic evidence for this is sparse (*7*, *9*). The peptide conformation around the complex may well be heterogeneous. Also, because tetradentate ligands may coordinate in a bis(bidentate) mode due to the relatively low concentration of M compared to the ligand, peptide "dimers" linked by the metal are likely to exist (*12*).

The principal methods used to date to characterize peptide conformation and metal coordination have been ^{1}H NMR (*7*), electronic spectroscopy (*7*), and extended X-ray absorption fine structure (EXAFS) spectroscopy (*9*). A ^{1}H 2D nuclear Overhauser effect spectrometry (NOESY) NMR study of the somatostatin analogue RC160 labeled with Re has been reported. The perrhenate was reduced with stannous citrate, and the disulfide bond was reduced with ascorbate. The authors concluded that the peptide conformation was not grossly modified by labeling and that the Re was six-coordinate with a coordination sphere that, surprisingly, included only one of the two available thiolates but made no comment on the oxidation state of the rhenium (*7*). These conclusions are at variance with expectations from the known coordination chemistry of rhenium (*1*), which suggest that the complex is more likely to be a square pyramid with a $Re{=}O^{3+}$ core (*13*). EXAFS spectroscopy of model Re and Tc complexes with cysteine-containing peptides was more consistent with the latter model, suggesting a range of motifs all based on the $Re{=}O^{3+}$ core, including monomeric peptide$-N_3S[Re{=}O]$ (*13*), "homodimer" (peptide$-NS)_2$-[Re=O], and "heterodimer" (peptide$-N_2S$)(peptide$-$S)-[Re=O] (*4*, *9*). Thus, additional techniques must be brought to bear to improve understanding of these metal–peptide complexes in individual cases. In this paper, using salmon calcitonin (sCT) as a model peptide, we show that mass spectrometry, in particular with electrospray ionization, can offer additional structural insight to complement these methods. We also report a one-step method for simultaneous reduction of pertechnetate and

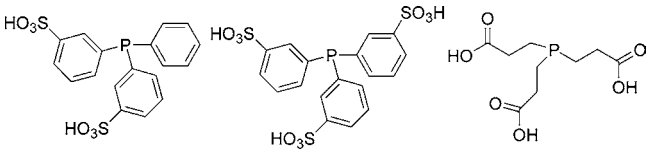

Figure 1. Structures of water-soluble phosphines used in this and related work: left to right, TPPDS (*21*, *22*), TPPTS (*21*, *22*), and $P(CH_2CH_2COOH)_3$ (tris(carboxyethyl) phosphine) (*23*).

peptide disulfide bonds using the water-soluble phosphines triphenylphosphine disulfonate (TPPDS) and triphenylphosphine trisulfonate (TPPTS) (see Figure 1).

Salmon calcitonin is a 32-amino acid neuropeptide with a disulfide loop. It has higher affinity for human calcitonin receptors than human calcitonin and is more stable in vivo. Calcitonin receptors are particularly abundant (ca. 10^6 per cell) in osteoclasts. They have recently been detected in various tumors and tumor-derived cells, including human ovarian small cell carcinoma, breast cancer, prostate cancer, and neuroblastoma, as well as bone tumors (osteoclastoma) and bone cancers and metastases with increased osteoclast activity (*14*, *15*). A suitably labeled calcitonin analogue might therefore have applications in imaging bone diseases and cancer.

MATERIALS AND METHODS

Instant thin layer chromatography (ITLC) was performed using two 1 cm × 8 cm strips (ITLC SG, Gelman Sciences) spotted with ~2 μL of the test solution. Before the spots dried, they were developed in either 1% saline (system I) or 1% saline/acetone/acetonitrile (2:1:1) (system II). The ITLC strips were scanned using a Bioscan Mini-Scan at 0.25 mm s^{-1}. Gamma photons were detected with a Bioscan Flow-Count scanner with a Bioscan B-FC-3200 detector. Data were collected and analyzed using LabLogic Laura GC Ram version 1.3b(104) software. ^{99m}Tc activity was measured using a calibrated CRC-35R ionization chamber and reader from Capintec Inc.

Two HPLC systems were employed in this work. System A comprised an LKB 2152 controller, a 2150 pump, a 2151 variable wavelength monitor, a Bioscan Flow-Count γ detector, a 100 μL injection loop, and LabLogic Laura data collection and analysis software. System B (hyphenated with an electrospray mass spectrometer) was a Hewlett-Packard 1100 system with a G1323A control unit, a 200 μL injection loop, a G1312A pump, a G1314 variable wavelength monitor, and Finnigan Corp Qual Browser software, version 1.2. Electrospray mass spectrometry (ES-MS) was performed on a Finnigan Mat LCQ ion trap mass spectrometer in tandem with HPLC system B described above. Spectra of eluting peaks were acquired in the *m/z* ranges 150−2000 for small organic molecules, 500−4000 for purified peptides, and 150−4000 for reaction mixtures. Calibration was checked with 20 μg of sCT or sCTA (sCTA is an analogue of sCT with arginine in place of lysine-11 (*14*)). The ES-MS system was set up for soft ionization (capillary temperature 220 °C, capillary voltage 19 V), and spectra were analyzed in positive ion mode. Control and data collection were performed using Thermo Quest Corp Tune Plus version 1.2 SP1 software. The analysis was performed using Finnigan Corp Qual Browser version 1.2 software. The *m/z* spectra from selected UV or ion count peaks were summed and interpreted.

Salmon calcitonin (sCT) was synthesized by standard solid-phase peptide synthesis methodology as described previously (*14*, *15*). TPPDS and TPPTS were synthesized as described previously (*16*). Stannous chloride dihydrate was obtained from Aldrich, U.K. Acetic acid and ethanol were obtained from BDH, U.K., and dH_2O (HPLC grade) was obtained from Fisher, U.K. $Na^{99m}TcO_4$ was eluted from a $^{99}Mo/^{99m}Tc$ generator (Mallinckrodt) with 0.9% saline. An acidic saturated stock solution of $HReOCl_4$ in ethanol was prepared as described previously (*17*). $NH_4{}^{99}TcO_4$ (318.2 MBq/g) was obtained from Amersham, U.K., dissolved in water, and filtered to remove traces of black insoluble material prior to use.

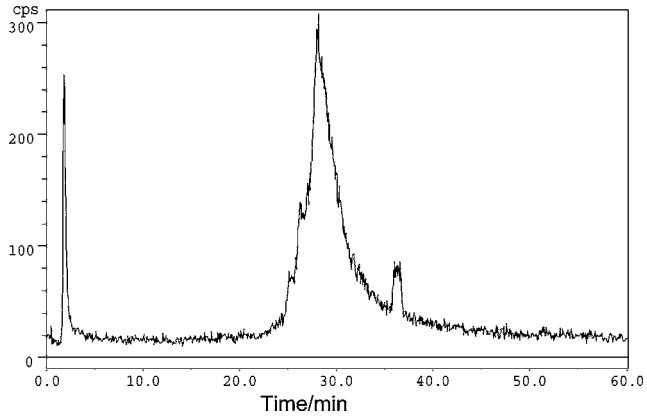

Figure 2. HPLC, with γ detection, of Tc-99m−sCT labeled using the one-step method at low specific activity (20 μg of peptide). Pertechnetate elutes between 1 and 2 min.

One-Step Labeling of sCT with ^{99m}Tc. To a solution of TPPDS (5.0 mg mL^{-1} in 10 mM acetic acid, pH 3.3, 20 μL) in a polypropylene microcentrifuge tube was added 20 μL of $Na^{99m}TcO_4$ eluate (63 MBq) followed by sCT (20 μg or 2 μg; that is, 20 μL of 1.00 or 0.1 mg mL^{-1} solution in 10 mM acetic acid, pH 3.3). A control with 20 μL of 10 mM acetic acid, pH 3.3, in place of the peptide solution was also prepared in an identical manner to test for ^{99m}Tc−TPPDS complexes being misinterpreted as labeled peptide. The reaction mixture was heated at 70−75 °C for 45 min, then removed from the polypropylene reaction tube. The radioactivity of both the reaction mixture and the empty tube was measured. The reaction mixture was analyzed by ITLC as described above and by RP HPLC (system A with a 150 mm × 2.1 mm Hamilton PRP1 10 μm column and a 25 mm × 2.1 mm Hamilton PRP1 10 μm guard column). The binary solvent system comprised solvent A (0.1% trifluoroacetic acid in water) and solvent B (0.085% trifluoroacetic acid in acetonitrile) at a flow rate of 0.5 mL min^{-1} with a linear gradient defined by the following points (min, %B): 0, 5; 2, 5; 5, 20; 45, 50; 55, 100; 56, 5; 60, 5. The UV detector was set at 210 nm. This radiopharmaceutical was used without purification in a qualitative cell binding assay as previously described (*14*, *15*).

Reduction of sCT with TPPDS and Other Reducing Agents. To a solution of TPPDS or TPPTS (0.1 mL of 1.0 mg mL^{-1} in 10 mM acetic acid, pH 3.3) was added a solution of sCT (0.1 mL of 1.0 mg mL^{-1} in 10 mM acetic acid). The solution was incubated at room temperature for 30 min, then analyzed by HPLC and ES-MS (HPLC system B with a Hamilton PRP1 column, 150 mm × 2.1 mm, 5 μm). The binary solvent system comprised solvent A (0.1% trifluoroacetic acid in water) and solvent B (0.085% trifluoroacetic acid in acetonitrile) with a linear gradient defined by the following points (min, %B, mL min^{-1}): 0, 5, 0.5; 2, 5, 0.5; 20, 100, 1.0; 21, 5, 1.0; 25, 5, 0. The UV detector was set at 214 nm. This solution, referred to henceforth as "prereduced-sCT" ($sCTH_2$), was used subsequently to study conjugates with technetium (using Tc-99) and rhenium synthons as described below.

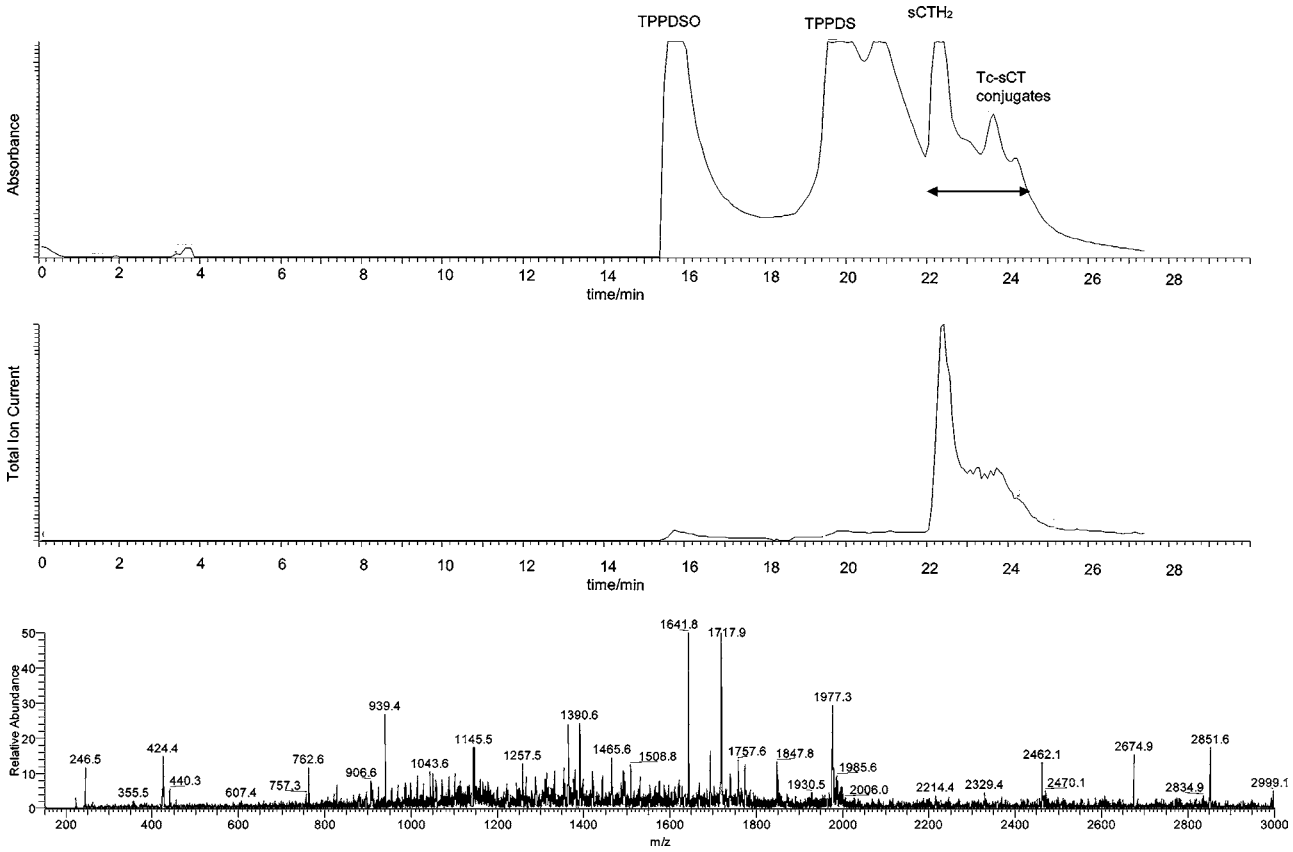

Figure 3. HPLC−ES-MS of sCT treated with TPPDS and $^{99}TcO_4^-$. The top panel shows the HPLC (UV detection) trace. The identity of the principal species in each peak was determined from its ES-MS spectrum. The phosphine TPPDS and its oxide TPPDSO eluted early, followed by unmodified $sCTH_2$ and finally Tc−peptide conjugates. The middle panel shows the total ion count detected in the mass spectrometer during ES-MS of the HPLC effluent. The bottom panel shows the summed ES-MS spectra of all peptide-containing fractions (indicated by the double arrow in the chromatogram, top). See Table 3 for assignments.

Table 1. Binding of ^{99m}Tc−sCT to MCF7 Breast Cancer Cells

high sp. ac.	1	present	0	58.2 (16)	3.1
high sp. ac.	1	present	1	18.7 (2.2)	
high sp. ac.	1	absent	0	16.7 (2.5)	1.3
high sp. ac.	1	absent	1	13.2 (2.3)	
sCT-free	0	present	0	22.5 (3.5)	0.9
sCT-free	0	present	1	23.7 (4.3)	
sCT-free	0	absent	0	10.7 (2.1)	0.9
sCT-free	0	absent	0	12.0 (3.8)	

[a] High sp. ac. means 2 μg of sCT; low sp. ac. means 20 μg of sCT. [b] Concentrations of sCT and ^{99m}Tc were adjusted during labeling to ensure that comparable activity was present in 1 nM sample added to cells. [c] Controls with wells containing no cells were employed to check for nonspecific binding to plastic. [d] Unlabeled sCT was added as an inhibitor in some cases to determine nonspecific binding. [e] Bound activity means activity bound to cells, well, or both after removal of supernatant. [f] Counts per minute (cpm) bound in the absence of cold sCT divided by cpm in the presence of 1 μM sCT.

The untreated sCT solution was analyzed similarly and served as a nonreduced control for studies of the reaction with technetium and rhenium synthons. Other reducing agents were examined in a similar manner, replacing the TPPDS solution with the same volume of TPPTS, 2-mercaptoethanol, stannous chloride, or ascorbic acid solution, each at 1 mg mL^{-1} in 10 mM acetic acid.

Reaction of "Prereduced sCT" with Rhenium. "Prereduced sCT" solution (50 μL, prepared using TPPDS as described above) was mixed with a solution of $HReOCl_4$ (saturated solution in ethanol diluted 100-fold with ethanol, 10 μL) and analyzed after 1 h at room temperature by HPLC−ES-MS using the same conditions as described above for "prereduced sCT".

Reaction of "Prereduced sCT" with Technetium. "Prereduced sCT" solution (100 μL, prepared using TPPDS or TPPTS as described above) was mixed with ammonium pertechnetate (20 μL of 1.0 mg mL^{-1} solution in physiological saline) and immediately analyzed by HPLC using the same conditions as described above for "prereduced sCT". In an alternative method, to aid reduction in a sample with a lower concentration of TPPDS, the sample was analyzed on a PRP1 HPLC column that had been pretreated with stannous chloride

[a] Calculated as the average molecular mass with isotopes at natural abundance, against sCT and sCTA (*14*) as calibrants. Their molecular mass was defined in the same way.

(100 μL of 1 mg mL^{-1} solution in 10 mM acetic acid, loaded onto and washed through the column using solvent A).

RESULTS

Labeling of sCT with ^{99m}Tc using the one-step method with water-soluble triarylphosphines TPPDS and TPPTS (Figure 1) was performed at two different peptide concentrations to evaluate the potential of the method for producing high specific activity labeled peptide. The labeling was investigated by ITLC using two parallel systems (I and II, see Materials and Methods) to determine free pertechnetate and reduced hydrolyzed Tc-99m. In system I, pertechnetate migrated with the solvent front ($R_f = 1$), while "reduced hydrolyzed technetium" and labeled peptide remained at the origin ($R_f = 0$). In system II, pertechnetate migrated with the solvent front ($R_f = 1$), while "reduced hydrolyzed technetium" remained at the origin ($R_f = 0$), and labeled peptide migrated with intermediate R_f values (0.2−0.5). When 2 μg of peptide was labeled, 18% of radioactivity migrated as pertechnetate, and when 20 μg peptide was labeled, 6% migrated as pertechnetate. No significant "reduced hydrolyzed technetium" was detected. Analysis by HPLC (system 1) was qualitatively in agreement with ITLC (see Figure 2). Labeled peptide eluted as a broad multiple peak between 23 and 32 min, indicative of a heterogeneous labeled product. Pertechnetate eluted at 1−2 min, and the radioactivity within this peak increased from 6% for 20 μg to ca. 20% for 2 μg of peptide. When peptide was omitted from the mixture, only pertechnetate eluted from the HPLC column. The heterogeneity of the labeled peptide was in agreement with multiplicity of peaks corresponding to Tc−peptide conjugates seen by HPLC−MS of carrier-level samples (see below and Figure 3).

Receptor affinity of the Tc-99m-labeled peptide was investigated using a semiquantitative MCF7 breast cancer cell binding assay as previously described (*15*) (see Table 1). Tracer concentrations of labeled sCT (1 nM) showed binding to cells that was inhibited by 1 μM unlabeled sCT, indicating some specific receptor binding, but the specific-to-nonspecific ratio (indicated by the ratio of bound counts in the absence and presence of cold sCT) was very modest indeed (ca. 3). This is a consequence of high nonspecific binding to both cells and plastic and low specific binding affinity due to poor radiolabel stability or adverse effects of labeling on peptide structure.

As well as nonspecific binding to the plastic multiwell plates used in the assay, a significant fraction of the radioactive products from the reaction remained bound to the polypropylene reaction tube in which labeling was performed. This behavior may be associated with the presence of a Tc-99m−TPPDS intermediate, since the binding is diminished by increasing the sCT concentration. The binding can be reduced by the addition of 0.01% Triton X100 surfactant, but it has not been determined how this affects the radiolabeled peptide as a whole. Nonspecific binding to these plastics is not observed with calcitonin labeled using the HYNIC method (*15*). A $^{99m}TcO_4^-$ sample exposed to the same reaction conditions but without TPPDS or peptide showed less than 1% binding to the polypropylene reaction tube.

A relatively high concentration of the phosphine was required (5 mg mL^{-1}), as well as heating, for reasonable radiochemical yields to be obtained. Lower concentrations of phosphine were able to reduce the peptide efficiently but led to high pertechnetate levels, while higher phosphine concentration led to formation of a cloudy precipitate on combination with peptide.

The role of the water-soluble phosphine in reduction of the peptide disulfide bond was investigated by HPLC

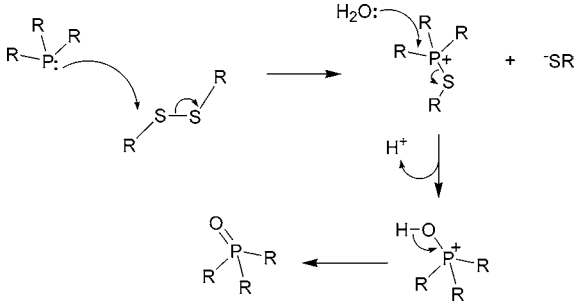
[a] Calculated as the average molecular mass with isotopes at natural abundance, against standard calibrant sCT and sCTA (*14*), the molecular mass of which was defined in the same way. [b] Based on the more abundant ^{187}Re isotope, not the average. The ^{185}Re peak is detected within the envelope but not reported separately.

and ES-MS, in comparison with other conventional disulfide bond reducing agents including 2-mercaptoethanol, stannous chloride, and ascorbic acid. The phosphine and phosphine oxide eluted as broad peaks at 15−22 min and were detected in the ES-MS at *m/z* 424 and 440. Untreated (unreduced) calcitonin eluted as a single sharp peak at 23.4 min using the HPLC conditions described above. ES-MS of this peak showed only the expected molecular ions (see Table 2) and a peak at 3432 in the deconvoluted spectrum. After treatment with TPPDS for 30 min at room temperature, the peptide eluted as a sharp peak slightly earlier (22.5 min) than the untreated peptide with *m/z* peaks corresponding to a peptide 2 Da heavier than untreated peptide (Table 2) and only a peak at 3434 in the corresponding deconvoluted mass spectrum. No other species were detected (e.g., no phosphine adducts, see Discussion section). This HPLC and ES-MS analysis is consistent with efficient and quantitative reduction of the disulfide bond. By contrast, treatment of sCT with stannous chloride under these conditions gave HPLC−ES-MS results corresponding to only unreduced peptide; heating to 90 °C for 30 min produced only a small shoulder in the HPLC profile corresponding to the reduced peptide. Traces of reduced peptide were detected in the ES-MS. None of the eluted fractions gave ES-MS peaks assignable to tin adducts of the peptide. This was true also if the peptide was prereduced with TPPDS before treatment with stannous chloride. Treatment of sCT with 2-mercaptoethanol gave a modest yield (ca. 20%) of reduced peptide, while the majority of peptide eluted within the 23.4 min peak. Ascorbic acid similarly gave variable but incomplete reduction under these conditions (20−90%).

The species formed on reductive labeling of sCT with pertechnetate using TPPDS was investigated using macroscopic amounts of ammonium [^{99}Tc]pertechnetate.

Scheme 1. Probable Mechanism of Oxidation of Disulfide by Tertiary Phosphine

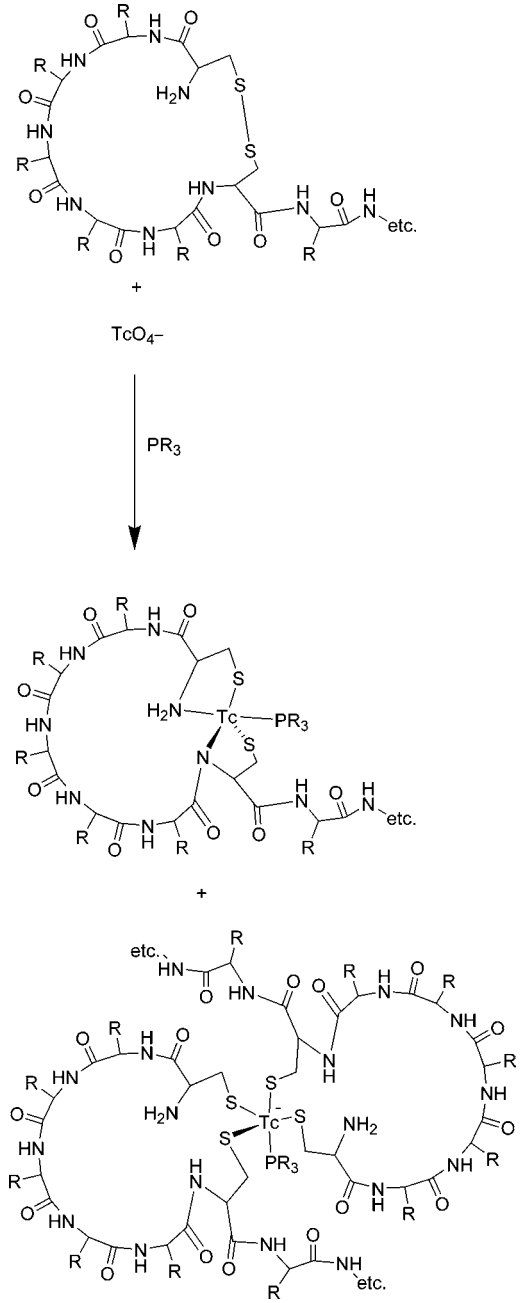


The increased levels of TPPDS required to reduce the larger quantity of pertechnetate compared to the no-carrier-added reaction caused precipitation from solution. Nevertheless, modified peptide conjugates (see Table 3) were detected in the HPLC eluate by UV absorbance and ES-MS. Ions with the same *m/z* but with improved signal-to-noise ratios were obtained by using a smaller concentration of phosphine with pertechnetate reduction supplemented by passing through a $SnCl_2$-treated column.

The peaks eluting at 22−25 min (Figure 3) gave ES-MS results (Figure 3) in which several peptide species were detected (Table 3), including reduced peptide (3434), an adduct of one sCT with one Tc and one TPPDS (3952), and an adduct comprising two sCT molecules with one Tc and one TPPDS (7387). The *m/z* values contributing to these deconvoluted peaks are given in Table 3. No ions with *m/z* corresponding to Tc−peptide conjugates without phosphine or with tin were observed. Analogous results were obtained with TPPTS in place of TPPDS (Table 3). The multiplicity of the Tc-containing HPLC peaks, coupled with the observation of only two different molecular mass conjugates in the ES-MS, indicates that in addition to monomers and dimers, isomeric forms of one or both of these species must be present.

Labeling of the "prereduced sCT" with Re(V) was achieved for ES-MS analysis by treating "prereduced sCT" with $ReOCl_4^-$ with TPPDS still present. HPLC−ES-MS analysis (Figure 4) revealed peaks eluting between 22.7 min (reduced peptide) and 24.0 min (Table 4). ES-MS revealed several species including reduced peptide (3434), an adduct comprising one sCT, one Re, and one O (3634), and an adduct comprising two sCT molecules, one Re, and one O (7066−7069). The *m/z* peaks contributing to these values are listed in Table 4, and the spectra are shown in Figure 4. No adducts containing TPPDS were detected in the ES-MS. Unreduced sCT mixed with $ReOCl_4^-$ showed only peaks corresponding to unmodified peptide both in the HPLC and ES-MS.

Scheme 2. Simultaneous Reduction of Disulfide and Pertechnetate by Water-Soluble Phosphine (PR_3 = TPPDS or TPPTS)[a]



[a] The reaction shows possible monomeric and dimeric topologies for coordination of Tc(III) by reduced peptide that among others may account for the observed ES-MS (the multiplicity of HPLC peaks indicates that more than one isomer is present).

DISCUSSION

Use of the water-soluble phosphines TPPDS and TPPTS provides a convenient, single-step direct labeling method for incorporating Tc-99m into disulfide-containing peptides. Water-soluble phosphines have been used successfully on previous occasions both for disulfide bond reduction (*18*−*20*) and as an ancillary ligand for HYNIC-linked technetium (*21*, *22*). For example, $P(CH_2CH_2COOH)_3$ (see Figure 1) was successfully used to generate thiol groups in a monoclonal antibody prior to Re-188 labeling (*23*). However, the labeled sCT conjugate produced by the single-step method has poor calcitonin receptor affinity and high nonspecfic binding or "stickiness" and does not have a homogeneous structure. Rather, it consists of isomeric forms of both monomeric and dimeric species. This behavior contrasts with the sCT conjugate labeled via a HYNIC bifunctional chelator, which gave a single sharp HPLC peak under similar conditions and retained excellent receptor affinity and stability (*15*). These water-soluble phosphines, however, emerge from this study as highly efficient reducing agents for the disulfide bond in peptides. In this respect, they are preferable to stannous chloride, ascorbic acid, and 2-mercaptoethanol, all of which have been used to reduce protein and antibody disulfide bonds previously (with conflicting conclusions about their efficacy (*24*−*32*)) but all of which failed to reduce the disulfide bond of sCT fully under similar conditions. The phosphines are less efficient, however, in the reduction and temporary coor-

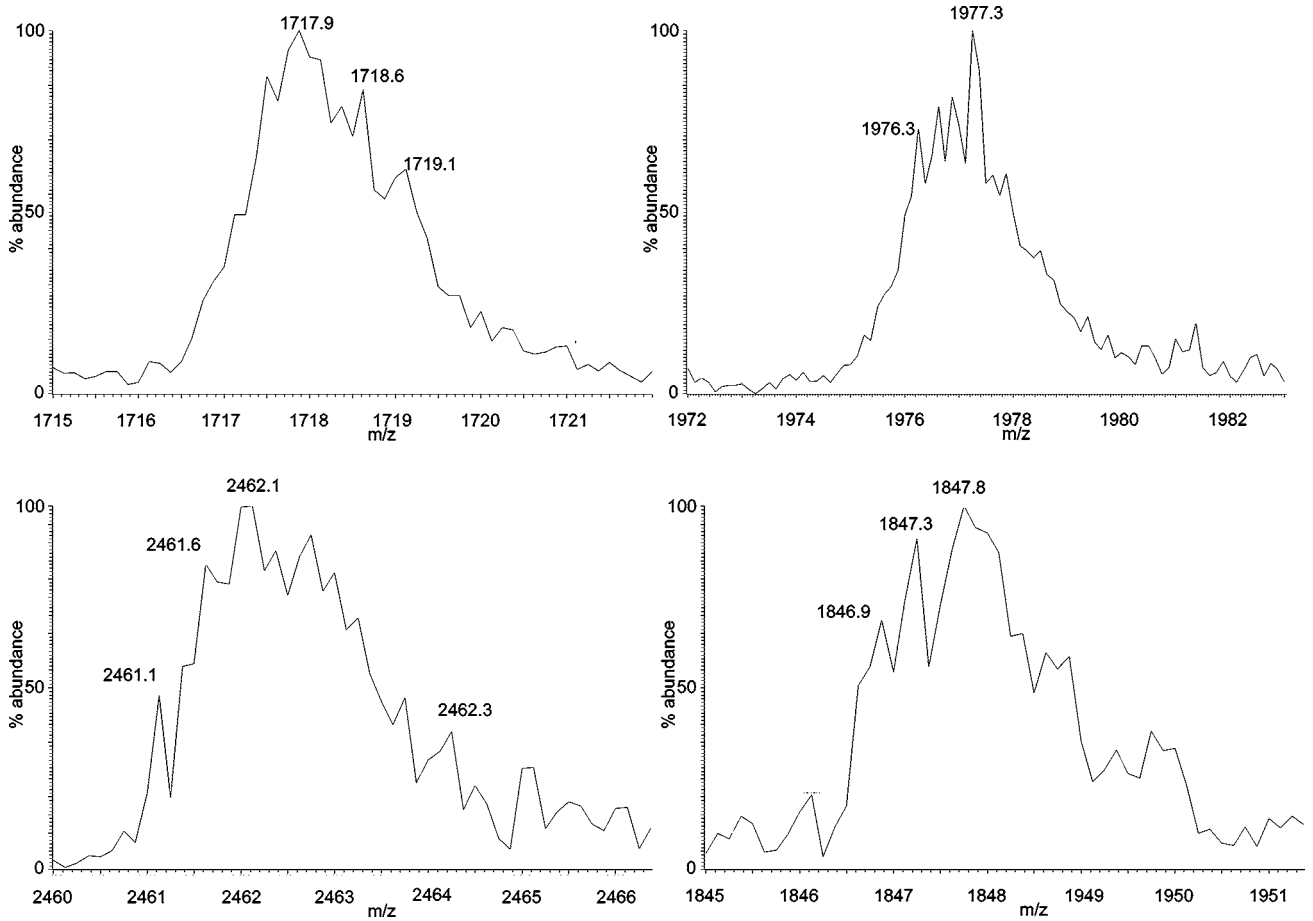


Figure 5. Expansion of peaks in the ES-MS of ^{99}Tc-labeled sCT: *m/z* = 1717.9 (top left, assigned as $sCTH_2$), 1977.3 (top right, assigned as $[sCTH_2 + (Tc\text{-}3H) + TPPDSH_2 + 2H]^{2+}$), 2462.1 and 1847.8 (bottom left and right, assigned as $[2sCTH_2 + (Tc\text{-}3H) + TPPDSH_2 + 3H]^{3+}$ and $[2sCTH_2 + (Tc\text{-}3H) + TPPDSH_2 + 4H]^{4+}$, respectively). The best fit to these peak values indicates that the technetium is in oxidation state III.

dination of the technetium, although TPPTS has been used previously in this capacity (*33*). This role requires higher concentration of phosphine, which in some instances resulted in precipitation of insoluble intermediates.

The application of electrospray mass spectroscopy illuminates several aspects of the labeling chemistry. First, it can address the question of the presence of stable intermediates in the reduction of the peptide bonds. For example, phosphine−thiolate adducts $[PR_3SR]^+$ are known to be formed during reduction of the disulfide bond (presumably as a result of the initial nucleophilic attack by phosphine on the disulfide, see Scheme 1). This intermediate is presumed to hydrolyze rapidly to the phosphine oxide under the aqueous reaction conditions but is otherwise sufficiently stable to be structurally characterized by crystallography (*34*). ES-MS revealed no evidence for such a species among the products of the reduction reaction. There is evidence in the literature that thiolate groups, generated by reduction of peptide in the presence of stannous ion, are able to chelate Sn(II) or Sn(IV) to a significant degree (*6*, *31*). However, no evidence for such chelates was detected in the ES-MS of the stannous reduction products.

Because of the prevalence of the Tc(V) and Re(V) oxo cores in chelates based on tetradentate ligand designs with SN3 or S2N2 donor sets (*1*), it is commonly supposed that this core is present when cysteine-containing peptides bind to technetium. This is possibly justified (although supported by very little direct evidence) when transfer ligands, such as glucoheptonate, that favor the Tc(V) oxidation state are employed (*9*). However, it is clear that great care must be exercised in making such assumptions generally: in the present case, there is no evidence for the presence of the Tc(V)oxo core. Instead, a Tc−phosphine core is shown by ES-MS to bind to the peptide, as shown in Scheme 2. The presence of such a large, hydrophobic group attached to the cysteine-containing domain (which is known to be critical for receptor binding (*35*, *36*)) of the peptide may be a major contributor to the loss of receptor affinity. Moreover, the ES-MS reveals the presence of dimeric species (containing two sCT peptides linked by a Tc−phosphine core, indicated by the peak in the deconvoluted spectrum at 7386), accounting for at least one of the several possible species suggested by the broad HPLC peak. This behavior is also observed in the TPPTS analogue, which shows the corresponding peak at 7465.

Careful inspection of the shift in *m/z* values of the various peaks in the ESMS upon Tc-labeling permits conclusions to be drawn about the oxidation state of the metal, by virtue of the number of protons it displaces from the peptide. The relative molecular mass of the $TcTPPDSH_2$ fragment (containing fully protonated sulfonic acid groups) is 521. The reduced peptide shows a *m/z* peak at 1718.1 ($[sCTH_2 + 2H]^{2+}$) and 1145.5 ($[sCTH_2 + 3H]^{3+}$). After incorporation of Tc the corresponding peaks shift to 1977.3, a shift of 259.2 (corresponding to a change in mass of 518.4, see Figure 5). This mass change is best accounted for as the result of replacement of $3H^+$ by $TcTPPDSH_2^{3+}$, that is, the Tc complex is probably in oxidation state III, and certainly between II

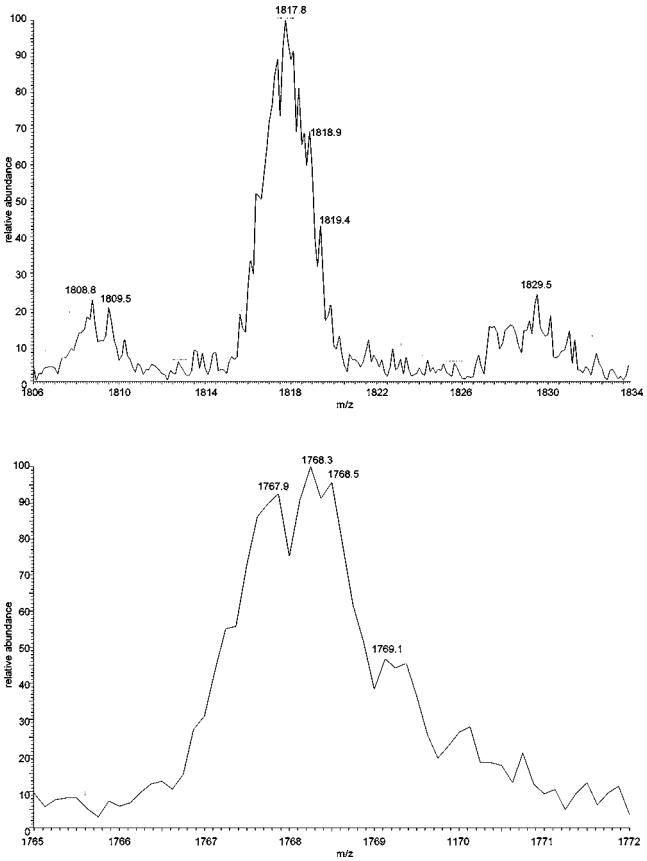

Figure 6. Expansion of peaks in the ES-MS of Re-labeled $sCTH_2$: $m/z = 1817.8$ (top, assigned as $[sCTH_2 + (ReO\text{-}3H) + 2H]^{2+}$) and 1768.3 (assigned as $[2sCTH_2 + (ReO\text{-}3H) + 4H]^{4+}$). The best fit to these peak values indicates that the rhenium is in oxidation state V.

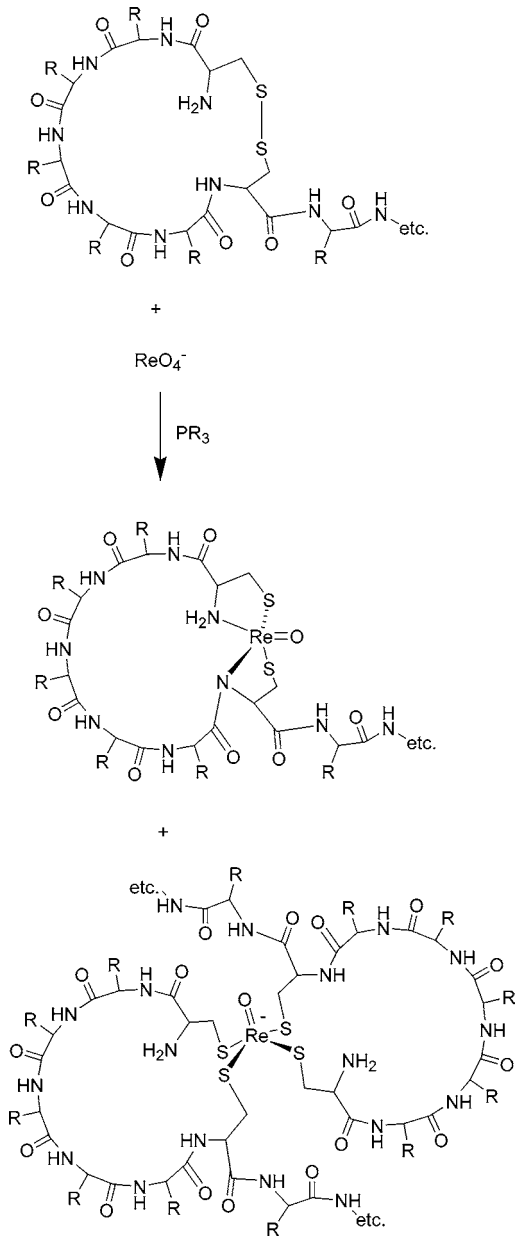
and IV. This estimate of the oxidation state is supported by similar analysis of the dimeric $[(sCTH_2)_2(TcDPPDSH_2) + 3H]^{3+}$ and $[(sCTH_2)_2(TcDPPDSH_2) + 4H]^{4+}$ peaks in the spectrum and of the ES-MS of the products of the analogous reaction with TPPTS (Table 4). Because of the width of the isotope distribution envelope and statistical noise in the spectra, this type of analysis requires very precise determination of the *m/z* for the peaks (see Figure 5), which was obtained by combining the results of several analyses involving different samples. Errors due to approximation of the isotope distribution, using the average molecular weight as the predictor of the highest peak in the envelope, are canceled both by the measurement of *m/z relative* to a standard of similar molecular weight and by the measurement of *m/z* shifts from the unmodified peptide, rather than relying on absolute *m/z* values. Full mathematical modeling of mass spectra (*14*, *37*, *38*) was therefore not necessary.

It is well-known that electron-transfer processes may occur during the electrospray ionization process, especially with redox-active analytes such as transition metals; therefore it is not possible to be completely certain that the observed oxidation states are those that exist in solution. However, the conclusions are consistent with the known coordination chemistry of technetium. Phosphines readily reduce technetium below Tc(V), to give oxidation states from Tc(I) to Tc(IV) (*39*, *40*), most often Tc(III) (*41*). Tc(III) complexes with phosphine and thiolate ligands in the coordination sphere are well-known (*42*−*44*). A common structure for both rhenium(III) (*45*, *46*) and technetium(III) (*42*−*44*) is the trigonal bipyramidal pentacoordinate complex with three anionic

Scheme 3. Reaction of $ReOCl_4^-$ with Reduced Peptide in the Presence of Water-Soluble Phosphine (PR_3 = TPPDS)[a]



[a] The reaction shows possible monomeric and dimeric topologies for coordination of Re(V) by reduced peptide that among others may account for the observed ES-MS (the multiplicity of HPLC peaks indicates that more than one isomer is present).

ligands in the equatorial positions and a phosphine or other ligand in one or both of the axial positions. Some possibilities are shown in Scheme 2, although without other forms of spectroscopic evidence (e.g., EXAFS, NMR) no conclusions can be drawn about which is the most likely product.

The direct labeling method was also investigated with rhenium, but because harsher conditions are generally required to reduce rhenium than technetium, the metal was presented in prereduced form ($HReOCl_4$). This species is known to undergo hydrolysis in the presence of water but neverless proved suitable for the formation of rhenium−peptide conjugates analyzable by ES-MS. Analysis of the rhenium−sCT conjugate by HPLC−ES-MS revealed HPLC peaks eluting at 22.7 min (reduced sCT) and a broad peak at 24 min. Despite the pres-

ence of excess phosphine in the reaction mixture, the latter gave ES-MS showing no sign of phosphine incorporation into the conjugate. Rather, it was consistent with the presence of the expected oxorhenium(V) core bound to $sCTH_2$ (3634). In addition, ions at *m/z* 2355.9 and 1768.3, assignable to dimers with two sCT molecules linked by the ReO^{3+} core, were detected. Again, the precise shifts in the *m/z* values resulting from labeling can be used to identify the rhenium oxidation state. The $[sCTH_2 + 2H]^{2+}$ peak at 1717.8 is shifted to 1817.8 (Figure 6), corresponding to an increase in molecular mass of 200. This in turn corresponds to replacement of $3H^+$ by ReO^{3+} (calculated on the basis of the most abundant isotope Re-187). Thus, with the minor reservations mentioned above for the Tc-labeled species, we conclude that the spectrum is consistent with rhenium having oxidation state V. Thus, in contrast to the technetium reaction, the presence of TPPDS neither reduces the rhenium below oxidation state V, nor contributes to the rhenium coordination sphere. Although it is not possible to define with certainty which residues within the peptide are bound directly to the rhenium, it seems certain that at least one of the cysteine thiolates is involved, since no adducts are observed unless the peptide is prereduced. It is possible that a number of isomeric forms exist, perhaps including those shown in Scheme 3. Other spectroscopic techniques such as EXAFS and high-field NMR may help to distinguish these possibilities, although such analysis would be hampered by the presence of mixtures of isomeric species.

SUMMARY

Phosphine is the most efficient reducing agent for disulfide bonds among those examined. Direct labeling of sCT is possible using water-soluble phosphine as the reducing agent both for disulfide and for pertechnetate, but the method gives mixed products and poor receptor affinity. This raises serious doubts about the acceptability of direct labeling of peptides in general, unless it can be shown by detailed spectroscopic methods that the product is structurally homogeneous and stable. Although this direct labeling method is unsuitable for sCT and probably other small disulfide-containing peptides, it may prove to be readily adaptable for application to larger vehicles such as monoclonal antibodies. The phosphine both reduces the pertechnetate and contributes to the technetium coordination sphere. In contrast, the phosphine does not reduce rhenium below oxidation state V, nor does it participate in the rhenium coordination sphere in the labeled peptide. Instead, the expected oxorhenium(V) moiety is incorporated. Both Tc and Re labeling processes give rise to dimers linked by the metal center, as well as simple monomeric species. Positive mode ES-MS of the metallopeptides not only revealed the presence of phosphine bound to technetium and oxygen bound to rhenium but also revealed the oxidation state of the metal in each case. ES-MS is proving to be an exceptionally valuable technique for characterizing radiopharmaceuticals, and when combined with other techniques (NMR and EXAFS, in particular), it can contribute to detailed structural characterization of metallopeptides, especially as recent technology offers sensitivity approaching carrier-free concentrations (*21*). Indeed, it may be argued that HPLC−ES-MS characterization should now be regarded as essential before it is permissible to embark on in vivo evaluation of small labeled peptides either in animals or in humans.

ACKNOWLEDGMENT

We thank Zeina Nasif, Elaine Cheung, K. Howland, and J. Hardy for technical assistance, Dr. Mathias Glaser for $HReOCl_4$ and Dr. Sushumna Prakash for TPPDS and TPPTS. We thank BBSRC for a studentship to W.E.P.G.

Oxoazabenzo[*de*]anthracenes Conjugated to Amino Acids: Synthesis and Evaluation as DNA-Binding Antitumor Agents

Nathalie Dias,[†] Jean-François Goossens,[‡] Brigitte Baldeyrou,[†] Amélie Lansiaux,[†] Pierre Colson,[§] Alberto Di Salvo,[∥] Jeanne Bernal,[∥] Agnes Turnbull,[∥] David J. Mincher,[∥] and Christian Bailly*[,†,⊥]

INSERM U-524 et Laboratoire de Pharmacologie Antitumorale du Centre Oscar Lambret, IRCL, 59045 Lille, France, Laboratoire de Chimie Analytique, Faculté des Sciences Pharmaceutiques et Biologiques, Université de Lille 2, 59006 Lille, France, Biospectroscopy and Physical Chemistry Unit, Department of Chemistry and Natural and Synthetic Drugs Research Center, University of Liege, Sart-Tilman, 4000 Liege, Belgium, and Napier University, School of Life Sciences, 10 Colinton Road, Edinburgh EH10 5DT, UK .
Received March 7, 2005; Revised Manuscript Received May 6, 2005

We report the synthesis of an original series of oxoazabenzo[*de*]anthracenes conjugated to an amino acid: Ala, Phe, Pro, Lys, or Gly (**4a**−**e**, respectively). The compounds, derived from 1,8-dihydroxyanthracene-9,10-dione, were studied for DNA binding and cytotoxicity. Melting temperature, fluorescence quenching, and surface plasmon resonance methods all indicated that the lysine derivative **4d** binds to DNA much more strongly that the Pro, Ala, and Gly conjugates whereas the Phe analogue showed the lowest DNA binding capacity. These compounds form intercalation complexes with DNA, as judged from electric linear dichroism and topoisomerase I-based DNA unwinding experiments. Preferential binding of **4d** to defined sequences such as 5′-CTAAAGG and 5′-ATGC was evidenced by DNase I footprinting. This Lys conjugate was found to be over 20 times more cytotoxic to CEM human leukemia cells than the other conjugates, with an IC_{50} in the submicromolar range. A high antiproliferative activity, likely attributable to the enhanced DNA binding capacity, is maintained despite the incapacity of the compound to stabilize topoisomerase−DNA covalent complexes. The cell cycle effects of **4d** consisted in an S phase accumulation of cells coupled with a pro-apoptotic action (appearance of hypodiploid sub-G1 cells) which were confirmed by measuring the inhibition of BrdU incorporation into DNA and labeling of phosphatidylserine residues with annexin V-FITC by means of flow cytometry. Altogether, the work provides interesting structure−activity relationships in the oxoazabenzo[*de*]anthracene−amino acid conjugate series and identifies the lysine derivative **4d** as a promising candidate for further in vivo evaluation and drug design.

INTRODUCTION

DNA topoisomerase enzymes are the targets of many clinically important anticancer drugs. Topoisomerase II was recognized as an important therapeutic target during the development of a number of drugs including doxorubicin, mitoxantrone, and etoposide, while camptothecin analogues were shown to inhibit topoisomerase I (*1*). Inherent structural lability problems associated with the camptothecins have stimulated the growth in developing new topoisomerase I inhibitors with diverse structures (*2*). Research efforts to overcome the clinical limitations of topoisomerase inhibitors remain intense (*3*).

The majority of these agents (topoisomerase 'poisons') are cytotoxic via stabilization of the normally transient, covalently bound cleavable complex formed between DNA and enzyme. Drug-stabilized DNA−enzyme complexes (ternary complexes) are believed to be lethal upon DNA replication when irreversible double-stranded DNA breaks are formed, causing various chromosomal aberrations culminating in cell death (*4*, *5*). The development of resistance to topoisomerase-targeting drugs, however, presents a major clinical problem; resistance commonly is manifested as classical multidrug resistance, caused by overexpression of the *mdr1* and *MRP* gene products, leading to increased efflux of drug from the cell, thereby reducing cytotoxic efficacy (*6*). Furthermore, acquired drug resistance characterized by alterations in individual topoisomerase expression resulting from antitopoisomerase drug therapy additionally limits clinical applications (*7*).

For the majority of topoisomerase inhibitors, DNA binding properties are crucial determinants of the pattern of topoisomerase enzyme inhibition in addition to their cytotoxic properties. We have previously noted (*8*) that key examples of spacer-linked anthraquinone−amino acid conjugates, capable of binding to DNA by intercalation of the planar aminoanthraquinone ring system, interact with topoisomerase I and topoisomerase II with selectable isoform specificity and have in vivo activity against experimental colon cancer (*9*). The foregoing anthraquinones have been shown to favor inhibition of topoisomerase II, in common with many compounds that bind strongly to DNA by intercalation, and, not unlike the dual topoisomerase I and II inhibitor, DACA, type I and II enzyme preference is influenced by the nature of the cationic side chain and nuclear substitution pattern (*10*).

In the present study, we postulated that the grafting of an additional ring onto the anthraquinone skeleton

4e	H	H	Gly

could modulate the DNA-binding properties and consequently the pattern of topoisomerase enzyme inhibition. To this end, a 1,3-oxazine ring was annealed onto the anthraquinone nucleus (Scheme 1) to afford the tetracyclic, oxa-aza-benzo[*de*]anthracene fused template ring system (**2**). This intermediate spacer compound was esterified to afford a series of amino acid conjugates (**4a**−**e**). It was anticipated that the angular disposition of the spacer-linked, cationic amino acid conjugate side chains would not be precluded from functioning as DNA minor groove-directed components. Additionally, it was recognized that the oxa-aza-benzo[*de*]anthracene formation would effectively mask one of the quinone carbonyl groups, potentially eliminating deleterious effects of quinone bioreduction, and that the conjugates might share common transport mechanisms with structurally related DNA-binding benzo[*e*]pyrimidines, some of which have been observed to overcome multidrug resistance protein-mediated drug efflux (*11*, *12*). In this paper, we report the synthesis and complete characterization of the DNA-binding properties of five oxa-aza-benzo[*de*]anthracene−amino acid conjugates (**4a**−**e**), together with a first evaluation of their biological activities. This work identifies the lysine derivative **4d** as a sequence-selective DNA-intercalating agent endowed with potent cytotoxic and pro-apoptotic activities. The structure−activity relationships are discussed.

EXPERIMENTAL SECTION

Synthetic Chemistry. Metal-promoted direct nuclear alkylamination of 1-hydroxyanthracene-9,10-dione (*13*) and 1,4-dihydroxyanthracene-9,10-dione (*14*) have been reported for which the metal ion was proposed to function as an effective oxidizing agent via formation of a metal chelate complex between the quinone carbonyl and an α-hydroxy group.

The key intermediate oxa-aza-benzanthracene (**2**) was synthesized in good yield via the amination at the C-9 carbonyl group of 1,8-dihydroxyanthracene-9,10-dione (**1**) with 3-amino-1 propanol followed by a copper(II) ion-promoted oxidative cyclization to form the 1,3-oxazine ring (Scheme 1).

Ester-linked amino acid conjugates of **2** were prepared by dicyclohexylcarbodiimide (DCC) coupling of N-^{t}Boc-protected amino acids, in the presence of 4-(dimethylamino)pyridine (DMAP), to afford the intermediate adducts **3a**−**e**. Standard removal of the ^{t}Boc-protecting groups with trifluoroacetic acid (TFA) gave the trifluoroacetate salts of the alanine (**4a**), phenylalanine (**4b**), proline (**4c**), lysine (**4d**), and glycine (**4e**) conjugates (Scheme 1).

Materials and Methods. N-^{t}Boc-protected amino acids and coupling reagents were commercially available from Novabiochem (Nottingham, UK), and 1,8-dihydroxyanthracene-9,10-dione (**1**) was from Aldrich (Poole,

UK). ^{1}H NMR spectra were recorded at 200 MHz [Bruker] in DMSO-d_6 or $CDCl_3$ as appropriate. Mass spectra were recorded using a Bruker Esquire 3000 spectrometer with electrospray ionization in positive or negative mode [ES (+) or ES (−)] or by fast atom bombardment [FAB (+)]. Chromatography was performed on silica gel 60 [Merck] with dichloromethane−ethyl acetate (4:1).

2-(2-Hydroxyethyl)-11-hydroxy-2*H*-3-oxa-1-aza-benzo[*de*]anthracen-7-one (2). To a solution of 1,8-dihydroxyanthracene-9,10-dione (**1**) (2.0 g; 8.2 mmol) in pyridine (80 mL) was added copper(II) bromide (3.7 g; 16 mmol). 3-Aminobutan-1-ol (50 mL) was then added dropwise, and the mixture was stirred at room temperature for 3 h. The reaction mixture was concentrated under reduced pressure and treated with water (200 mL) and concentrated hydrochloric acid to pH 2 (for 30 min) to decompose the copper chelate complexes of the product. The solution was neutralized with saturated sodium bicarbonate, and the resulting solid was removed by filtration. The solid was extracted with dichloromethane, dried ($MgSO_4$), concentrated under reduced pressure, and applied to a silica gel flash chromatography column. Elution with dichloromethane−ethyl acetate (4:1) gave the title compound (**2**) as a chromatographically homogeneous orange-yellow solid in 60% yield, mp 114 °C. ^{1}H NMR (DMSO-d_6) δ: 2.2 (2H, q, CH_2); 3.8 (2H, t, CH_2O); 4.8 (1H, s, OH); 6.2 (1H, t, H-2); 7.25−7.4 (2H, m, H-4, −10); 7.65−7.8 (4H, m, H-5, -6, -8, -9); 13.3 (1H, s, 11-OH). FAB(+) MS: *m/z* 296 $[M + H]^+$.

2-(*N*-*tert*-butoxycarbonylamino)propionic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo-[*de*]anthracene-2-yl)ethyl Ester (3). N-^{t}Boc-Ala-OH (0.4 g; 2.2 mmol) and DCC (0.4 g; 2 mmol) were added to a solution of **2** (0.6 g; 2 mmol) in dichloromethane (50 mL) containing DMAP (20 mg), and the mixture was stirred at room temperature for 12 h. Precipitated dicyclohexylurea was removed by filtration, and the solution was washed with saturated sodium bicarbonate, dried ($MgSO_4$), and evaporated, in vacuo to afford a solid residue. The latter was redissolved in dichloromethane−ethyl acetate (4:1; 20 mL) and chromatographed on silica gel in the same solvent mixture. Fractions containing the major product were combined, filtered, and evaporated to a solid residue that afforded the yellow crystalline title compound (**3**) from ethanol in 57% yield, mp 105−107 °C. ^{1}H NMR (DMSO-d_6) δ: 1.35−1.45 (12H, m, unresolved ^{t}Boc + CH_3); 2.35 (2H, q, CH_2); 4.3 (1H, q, α-CH); 4.5 (2H, m, CH_2O); 5.05 (1H, br s, N*H*CO); 6.1 (1H, t, H-2); FAB (+) MS *m/z* 467 $(M + H)^+$; 489 $(M + Na)^+$.

2-Aminopropionic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo[*de*]anthracene-2-yl)ethyl Ester Trifluoroacetate (4a). The N-protected alanine conjugate **3** (0.25 g; 0.5 mmol) was dissolved in dry trifluoroacetic acid (20 mL) and left at room temperature for 25 min. The solution was evaporated and re-evaporated from ethanol to afford a viscous residue that crystallized from ethanol−diethyl ether to afford the alanine conjugate trifluoroacetate salt (**4a**) (quantitative). ^{1}H NMR (DMSO-d_6) δ: 1.4 (3H, d, CH_3); 2.4 (2H, q, CH_2); 4.0 (1H, q, α-CH); 4.5 (2H, m, CH_2O); 6.2 (1H, t, H-2); 7.25−7.4 (2H, m, H-4, −10); 7.6−7.8 (4H, m, H-5,-6, -8, -9); 8.5 (3H, br s, NH_3^+); 13.2 (1H, s,11-OH). ES(+) MS *m/z* 367 $[RNH_3]^+$, 389 $[RNH_2 + Na]^+$; ES(−) *m/z* 113 $(CF_3{\cdot}COO^-)$.

2-Amino-3-phenylpropionic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo[*De*]anthracene-2-yl)ethyl Ester Trifluoroacetate (4b). The phenylalanine conjugate (**4b**) was prepared by an identical sequence to that described for (**4a**) except that N-^{t}Boc-phe-OH replaced N-^{t}Boc-Ala. ^{1}H NMR (DMSO-d_6) δ: 2.3 (2H, q, CH_2); 3.2 (2H, m, CH_2Ph); 4.3- (1H, m, α-CH); 4.55 (2H, m, CH_2O); 5.9 (1H, t, H-2); 7.2−7.4 (7H, m, H-4, −10 + Ph); 7.6−7.8 (4H, m, H-5, -6, -8, -9); 8.6 (3H, br s, NH_3^+); 13.2 (1H, s, 11-OH). ES(+) MS *m/z* 443 $[RNH_3]^+$, ES(−) *m/z* 113 $(CF_3{\cdot}COO^-)$.

Pyrrolidine-2-carboxylic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo[*de*]anthracene-2-yl)ethyl Ester Trifluoroacetate (4c). The proline conjugate (**4c**) was prepared by an identical sequence to that described for (**4a**) except that N-^{t}Boc-pro-OH replaced N-^{t}Boc-Ala. ^{1}H NMR (DMSO-d_6) δ: 1.8−2.1 (3H, m, γ-CH_2 + β-CH); 2.3 (1H, m, β-CH); 2.5 (2H, q, CH_2); 3.2 (2H, m, δ-CH_2); 4.3−4.55 (3H, m, CH_2O + α-CH) 6.25 (1H, t, H-2); 7.25−7.4 (2H, m, H-4, −10); 7.6−7.8 (4H, m, H-5, -6, -8, -9); 9.2 (2H, br s, NH_2^+); 13.2 (1H, s, 11-OH). ES(+) MS *m/z* 392 $[RR'NH_2^+]$; ES(−) MS *m/z* 113 $(CF_3{\cdot}COO^-)$.

2,6-Diaminohexanoic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo[*de*]anthracene-2-yl)-ethyl Ester Bis-α,ϵ-trifluoroacetate (4d). The lysine conjugate (**4d**) was prepared by an identical sequence to that described for **4a** except that N-^{t}Boc-lys(N-^{t}Boc)-OH replaced N-^{t}Boc-Ala. ^{1}H NMR (DMSO-d_6) δ: 1.3−1.7 (4H, m, δ-CH_2, γ-CH_2,); 1.8 (2H, m, β-CH_2); 2.4 (2H, m, CH_2); 2.75 (2H, t, ϵ-CH_2); 4.0 (1H, t, α-CH); 4.5 (2H, m, CH_2O); 6.3 (1H, t, H-2); 7.3−7.4 (2H, m, H-4, −10); 7.65−7.8 (4H, m, H-5, -6, -8, -9); 8.15 (6H, br s, α,ϵ-NH_3^+); 13.25 (1H, s,11-OH). ES(+) MS *m/z* 425 $[R(NH_2)NH_3^+]$; ES(−) *m/z* 113 $(CF_3{\cdot}COO^-)$.

2-Aminoethanoic Acid 2-(11-Hydroxy-7-oxo-2,7-dihydro-3-oxa-1-aza-benzo[*de*]anthracene-2-yl)ethyl Ester Trifluoroacetate (4e). The glycine conjugate (**4e**) was prepared by an identical sequence to that described for (**4a**) except that N-^{t}Boc-gly-OH replaced N-^{t}Boc-Ala. ^{1}H NMR (DMSO-d_6) δ: 2.4 (2H, q, CH_2); 3.9 (2H, s, α-CH_2N); 4.5 (2H, m, CH_2O); 6.2 (1H, t, H-2); 7.25−7.4 (2H, m, H-4, −10); 7.6−7.8 (4H, m, H-5,-6, -8, -9); 8.25 (3H, br s, NH_3^+); 13.2 (1H, s,11-OH). ES(+) MS *m/z* 353 $[RNH_2^+]$; ES(−) *m/z* 113 $(CF_3{\cdot}COO^-)$.

Absorption Spectroscopy and Melting Temperature Studies. Absorption spectra and melting curves were measured using an Uvikon 943 spectrophotometer coupled to a Neslab RTE111 cryostat. Titrations of the drug with DNA, covering a large range of DNA-phosphate/drug ratios (P/D), were performed by adding aliquots of a concentrated DNA to a ligand solution at constant concentration (20 μM). The T_m measurements were performed in BPE buffer pH 7.1 (6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM EDTA). The temperature inside the cuvette (10 mm path length) was increased over the range 30−100 °C with a heating rate of 1 °C/min. The "melting" temperature T_m was taken as the midpoint of the hyperchromic transition.

Fluorescence Measurements. A competitive displacement fluorometric assay with DNA-bound ethidium was carried out to evaluate the binding properties of the tested drugs (*15*, *16*). Fluorescence data were recorded at room temperature with a SPEX Fluorolog fluorometer. Excitation was set at 515 nm, and fluorescence emission was monitored over the range of 550 to 700 nm. Experiments were performed with an [ethidium]:[DNA] molar ratio of 12.6:10 and a drug concentration range of 0.01 to 100 μM in a BPE buffer pH 7.1. C_{50} values for ethidium displacement were calculated using a fitting function incorporated into Prism 3.0, and the apparent equilibrium binding constants (K_{app}) were calculated as follows:

$K_{app} = (1.26\ \mu M/C_{50}) \times K_{ethidium}$, with $K_{ethidium} = 10^7\ M^{-1}$

Surface Plasmon Resonance. The experimental procedure has been recently described in details (*17*, *18*). Measurements were performed in HBS-EP buffer sterile filtered and degassed, which was obtained from Biacore (0.01 M HEPES pH 7.4, 0.15 M NaCl, 3 mM EDTA, 0.0005% Surfactant P20). The hairpin oligonucleotide d(biotin- CGAATTCGTCTCCGAATTCG) (hairpin loop underlined) was purchased (PAGE purified) from Eurogentec (Belgium).

Electric Linear Dichroism (ELD). Calf thymus DNA (Pharmacia) was deproteinized with sodium dodecyl sulfate (protein content <0.2%) and extensively dialyzed against 1 mM sodium cacodylate-buffered solution pH 7.0. ELD measurements were performed with a computerized optical measurement system using the procedures previously outlined (*19*). All experiments were conducted with a 10 mm path length Kerr cell having 1.5 mm electrode separation. The samples were oriented under an electric field strength varying from 1 to 14 kV/cm. Unless specified, 10 μM of the tested drug was incubated with 200 μM of DNA. This electrooptical method senses only the orientation of the polymer-bound ligand: free ligand is isotropic and does not contribute to the signal (*19*).

Topoisomerase I Inhibition. The experimental procedure has been previously detailed (*20*). Supercoiled pKMp27 DNA (0.2 μg) was incubated with 4 units of human topoisomerase I (TopoGen Inc.) at 37 °C for 1 h in relaxation buffer (10 mM Tris-HCl pH 7.9, 100 mM NaCl, 1 mM EDTA, 0.1% BSA, 0.1 mM Spermidine, 5% Glycerol) in the presence of varying concentrations of the drug under study. Reactions were terminated by adding SDS to 0.25% and proteinase K to 250 μg/mL. DNA samples were then added to the electrophoresis dye mixture (5 μL) and electrophoresed in a 1% agarose gel at room temperature for 2 h at 120 V. Gels were stained with ethidium bromide (1 μg/mL), washed, and photographed under UV light.

DNase I Footprinting. The complete procedure has been recently detailed (*21*). Briefly, the 117 and 265 bp DNA fragments were prepared by 3′-[^{32}P]-end labeling of the *Eco*RI-*Pvu*II double digest of the pBS plasmid (Stratagene) using α-[^{32}P]-dATP (Amersham, 3000 Ci/mmol) and AMV reverse transcriptase (Roche). The labeled digestion products were separated on a 6% polyacrylamide gel under nondenaturing conditions in TBE buffer (89 mM Tris-Borate pH 8.3, 1 mM EDTA), and the requisite band of DNA was excised and crushed in water. Then, the labeled DNA was precipitated with ethanol and resuspended in a solution containing 10 mM Tris pH 7.0 and 10 mM NaCl. Samples (2 μL) of the labeled DNA fragments were incubated with 6 μL of the buffered solution containing the ligand at the appropriate concentration. After 10 min incubation at room temperature to ensure equilibration of the binding reaction, the digestion was initiated by the addition of 2 μL of a DNase I solution whose concentration was adjusted to yield a final enzyme concentration of about 0.03 unit/mL in the reaction mixture. After 3 min, the reaction was stopped by freeze-drying. Samples were lyophilized and resuspended in 5 μL of a 80% formamide solution containing the tracking dyes. The DNA samples were then heated at 90 °C for 4 min and chilled in ice for 4 min prior loading.

DNA cleavage products were resolved by gel electrophoresis under denaturating conditions (8% acrylamide containing 7 M urea). After electrophoresis, gels were soaked in 10% acetic acid for 10 min, transferred to a Whatman 3MM paper, and dried under vacuum at 80 °C. Molecular Dynamics 425E PhosphorImager was used for data analysis. Each resolved band was assigned to a particular bond within the DNA fragments by comparison of its position relative to sequencing standards generated by treatment of the DNA with dimethyl sulfate followed by piperidine-induced cleavage at the modified guanine bases in DNA (G-track).

Cell Culture and Survival Assay. Human CEM leukemia cells were obtained from the American Tissue Culture Collection. Cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2 in RPMI 1640 medium, supplemented with 10% fetal bovine serum, 4.5 g/L glucose, 10 mM HEPES, 1 mM sodium pyruvate, penicillin (100 IU/mL), and streptomycin (100 μg/mL). The cytotoxicity of the tested compounds was assessed using a cell proliferation assay developed by Promega (CellTiter 96 AQueous one solution cell proliferation assay). Briefly, 2×10^4 exponentially growing cells were seeded in 96-well microculture plates with various drug concentrations in a volume of 100 μL. After 72 h incubation at 37 °C, 20 μL of the tetrazolium dye was added to each well, and the samples were incubated for a further 1.5 h at 37 °C. Plates were analyzed on a Labsystems Multiskan MS (type 352) reader at 492 nm.

Cell Cycle Analysis. For flow cytometric analysis of DNA content, 0.7×10^6 cells in exponential growth were treated with graded concentrations of the tested drug for 24 h and then washed with 1 mL of PBS. After centrifugation, the cell pellet was resuspended in 1 mL of cold ethanol for 1 h at 4 °C. The ethanol was removed, and the pellet was washed with 1 mL PBS and then incubated for 30 min in a solution containing 50 μg/mL PI and 100 μg/mL RNase. Samples were analyzed on a Becton Dickinson FACScan flow cytometer using the CellQuest software, which was also used to determine the percentage of cells in the different phases of the cell cycle. PI was excited at 488 nm, and fluorescence analyzed at 620 nm on channel Fl-2.

Externalization of Phosphatidyl Serines. Surface exposure of phosphatidyl serine (PS) by CEM cells was measured by cytometry by adding Annexin V-FITC to 0.7×10^6 cells per sample according to the manufacturer's specifications (Becton Dickinson, San Jose, CA). Simultaneously, the cells were stained with propidium iodide (50 μg/mL). Excitation was set at 488 nm, and the emission filters used were 515−545 (green, FITC) and 600 (red, PI). Data analysis was performed with the CellQuest software.

Bromodeoxyuridine (BrdU) Incorporation. Cells (0.7×10^6) were cultured in complete RPMI 1640 medium with the tested drug at different concentrations for 24 h prior to harvesting and then pulse labeled with 10 μM BrdU for 60 min in complete medium. Cells were pelleted, washed twice with PBS containing 0.1% sodium azide, and then fixed in ethanol 70% for 1 h at 4 °C. Cells were washed once again with PBS and then denatured in 2 N HCl for 15 min at 37 °C (or 30 min at room temperature) under gentle stirring. pH was adjusted by short incubation (5 min) in 3 mL 0.1 M $Na_2B_4O_7$, pH 8.5 before centrifugation (5 min, 500 g, 4 °C). The cell pellet was then washed with 5 mL of buffer containing PBS, 0.05% Tween, and 0.1% BSA (bovine serum albumin fraction V), resuspended in 100 μL of this buffer, and then incubated with the fluorescein isothiocyanate (FITC)-conjugated anti-BrdU monoclonal antibody (Becton Dickinson, San Jose, CA) for 30 min at room temperature in

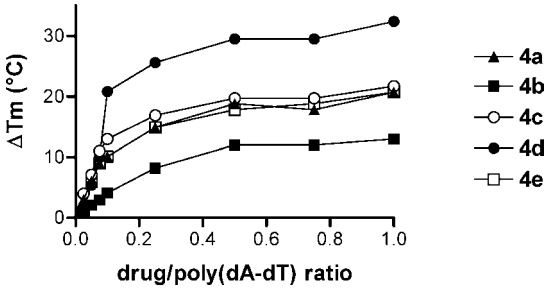

Figure 1. Melting temperature variation ΔT_m ($T_m^{\text{drug–DNA complex}} - T_m^{\text{DNA alone}}$, in °C) of the poly(dAT)$_2$ DNA after incubation with various compounds. The T_m measurements were performed at different drug/DNA-phosphate ratios. The poly(dAT)$_2$ concentration was fixed at 20 μM while the drug concentration varied from 0.5 to 20 μM. T_m measurements were performed in BPE buffer pH 7.1 (6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM EDTA), in 1 cm quartz cuvettes at 260 nm with a heating rate of 1 °C/min. The T_m values were obtained from first-derivative plots.

Table 1. Binding to DNA and Cytotoxicity

compd	ΔT_m (°C)[a]	K_{app} (10^7 M^{-1})[b]	IC_{50} (μM)[c]
4a	5.9	0.38 ±0.04	5.56 ±0.78
4b	4	<0.01	5.61 ±2.35
4c	4.9	0.54 ±0.09	3.52 ±0.44
4d	15.5	5.06 ±0.67	0.13 ±0.06
4e	6.8	0.75 ±0.04	2.97 ±0.05

[a] T_m measurements were performed in BPE buffer pH 7.1 (6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM EDTA) using 20 μM drug and 20 μM calf thymus DNA (nucleotide concentration) with a heating rate of 1 °C/min. [b] Apparent binding constant measured by fluorescence ($n = 3$). [c] Drug concentration (μM) that inhibits CEM leukemia cell growth by 50% after incubation in liquid medium for 72 h.

the dark. Cells were counterstained with 10 μg/mL of propidium iodide and treated with RNase (1 μg/mL). For the negative controls, the pellet was incubated with the antibody but not with BrdU. Samples were analyzed on a Becton Dickinson FACScan flow cytometer using the CellQuest software.

RESULTS

Affinity for DNA. Two complementary approaches were used to compare the affinity of the drugs for DNA. First, we measured the capacity of the compounds to protect the polynucleotide poly(dAT)$_2$ against heat denaturation. Under our experimental conditions, the AT polymer melted at 42 °C and this T_m value was increased in the presence of the different compounds. Figure 1 shows the concentration dependence on the ΔT_m ($T_m^{\text{complex}} - T_m^{\text{DNA}}$) values for the different poly(dAT)$_2$-drug complexes. It is already clear at this point that the nature of the amino acid substituent on the oxoazabenzo[*de*]anthracene chromophore strongly modulates the capacity of the drug to interact with DNA. The Phe derivative **4b** is considerably less efficient than the Lys derivative **4d** at stabilizing the duplex structure of DNA and the three other compounds bearing an uncharged Pro, Ala, or Gly residue showed similar behavior, intermediate between those of the charged Lys compound and the aromatic Phe conjugate. The extent of stabilization was very high with the Lys compound, reaching 30 °C at a drug/nucleotide-DNA ratio of 0.5 which represents a considerable stabilization of the double helical structure. Similar experiments were also performed with calf thymus DNA at a single drug/nucleotide ratio of 1 and the ΔT_m values are collated in Table 1. Here again, the Lys derivative **4d** proved to be the most potent compound in the series to protect DNA from heat-induced melting.

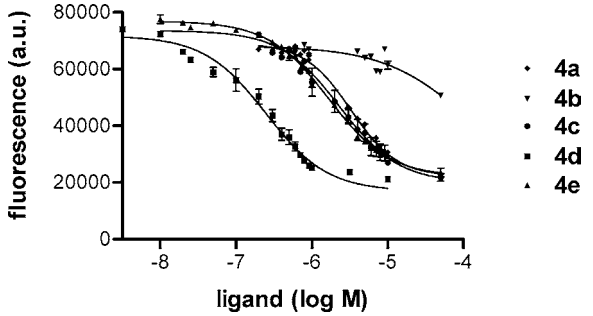

Figure 2. Dose-dependent quenching of the fluorescence of ethidium bromide bound to DNA in the presence of increasing concentrations (0.01 to 100 μM) of the tested compounds. Measurements were performed in BPE buffer, with an excitation wavelength of 515 nm and an [ethidium]:[DNA] molar ratio of 1.26. These ethidium displacement curves were used to calculate the apparent equilibrium binding constants (K_{app}) given in Table 1.

In a second phase, binding affinities for all five compounds were quantitated by means of fluorescence, using a well-established quenching assay based on the displacement of the intercalating drug ethidium bromide (EB) from calf thymus DNA. In this competition assay, binding of the tested compound to DNA leads to the removal of EB molecules inserted between the base pairs, and the resulting EB molecules not bound to DNA become much less fluorescent than the bound EB molecules because of the surrounding water molecules which quench the fluorescence. This conventional displacement assay is useful to calculate the concentration of the competing drug molecule required to reduce the EB fluorescence by 50%, and this value was then used to calculate the binding constant K_a for each conjugate (Table 1). The measured K_a values agree very well with the ΔT_m values. Compound **4b** poorly competed with EB for binding to DNA whereas **4d** was considerably more efficient than the other conjugates at displacing EB molecules from their intercalation sites. The quenching plots shown in Figure 2 indicate than **4d** is at least 200 times more efficient than **4b** and roughly 10-fold more potent than the Gly, Pro, and Ala conjugates. These three latter compounds exhibit comparable effects on the binding of EB to DNA, and this is in complete agreement with the ΔT_m data. The quantitative analysis of the binding plots gave a K_a value of 5×10^7 M^{-1} for UB368, 10 times higher than that calculated for the Pro derivative **4c**. In terms of DNA binding affinity the compounds rank in the order **4d** ≫ **4e** > **4c**, **4a** ≫ **4b**. As one would have expected, the linkage of a cationic Lys residue is thus highly favorable compared to an uncharged amino acid. On the opposite, the attachment of an aromatic phenyl ring is detrimental to the DNA interaction of the oxoazabenzo[*de*]anthracene moiety.

The binding of the compound showing the highest affinity for DNA, **4d**, was investigated further by absorption spectroscopy and surface plasmon resonance (SPR). The UV–visible titration spectra of **4d** with calf thymus DNA show both strong hypochromic and bathochromic effects (Figure 3a). The drug absorption bands centered at 282 and 393 nm are both strongly decreased upon addition of DNA, and a significant red shift (17 nm) occurs in the 400 nm band corresponding to the tetracyclic oxoazabenzoanthracene ring. SPR measurements were performed with a 20-mer hairpin oligonucleotide presenting the duplex sequence CGAATTCG. This oligonucleotide equipped with a biotin group at the 5′-end was immobilized on the sensor surface through streptavidin–biotin coupling. To provide a signal directly pro-

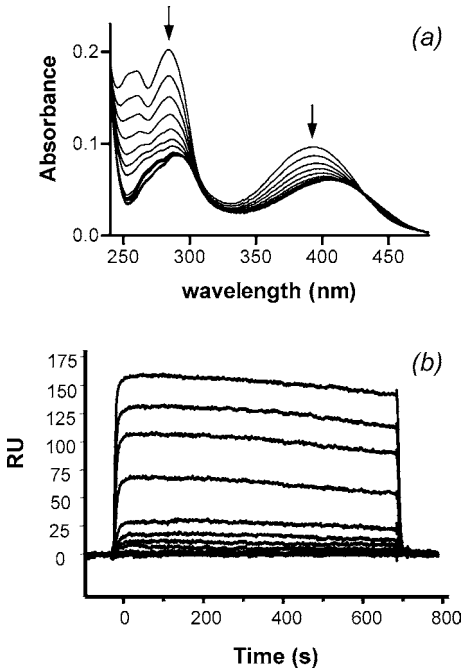

Figure 3. (a) DNA titration of **4d**. To 1 mL of drug solution at 20 μM were added aliquots of a concentrated calf thymus DNA solution. The phosphate-DNA/drug ratio increased from 0 to 20 (top to bottom curves, at 280 nm). Measurements were performed in BPE buffer pH 7.1 (6 mM Na_2HPO_4, 2 mM NaH_2PO_4, 1 mM Na_2EDTA). Spectra are referenced against DNA solutions of exactly the same DNA concentration and were adjusted to a common baseline. (b) SPR sensorgrams representing the binding of **4d** to the AATT hairpin oligonucleotide in HBS-EP buffer (BIA Certified from BIACORE, containing 0.01 M HEPES, 0.15 M NaCl, 3 mM EDTA, 0.005% polysorbate 20 (v/v), pH 7.4), at 25 °C. The concentration of the unbound ligand in the flow solution varies from 1 nM in the lowest curve to 10 μM in the top curve.

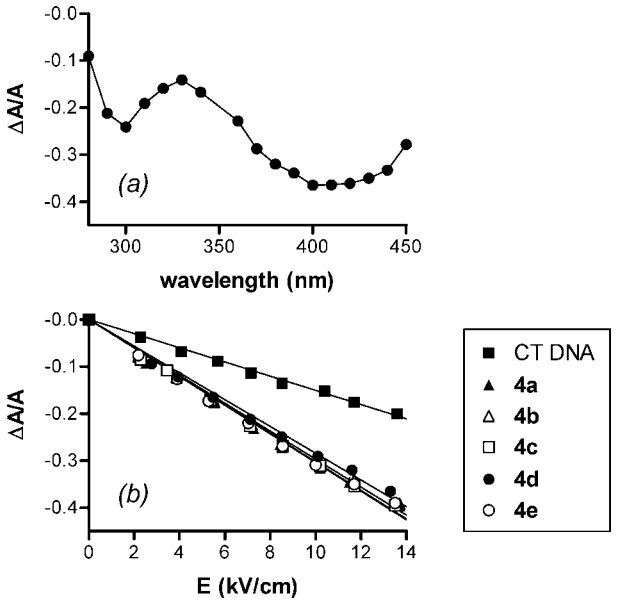

Figure 4. (a) Electric linear dichroism spectrum of the DNA-bound **4d**. $\Delta A/A$ was measured at 13.6 kV/cm, with a nucleotide/drug ratio of 25 (250 μM DNA, 10 μM drug). (b) Dependence of the reduced dichroism $\Delta A/A$ on the electric field strength for the different compounds bound to calf thymus DNA. Measurements were performed at 400 nm for the drug−DNA complexes and at 260 nm for the DNA alone. All measurements were performed at room temperature (20 °C) in 1 mM sodium cacodylate buffer, pH 7.0.

portional to the amount of bound compound, the reference response of an oligonucleotide-free blank cell was subtracted from the response in the channel with the target oligonucleotide. A set of SPR sensorgrams at different concentrations of **4d** binding to the CGAATTCG sequence is shown in Figure 3b. A concentration-dependent interaction was detected but the binding is very fast, and as a result, the kinetic parameters could not be measured. The association of the compound with the duplex oligonucleotide reaches a steady-state plateau in a few seconds. The dissociation of this cationic intercalating agent from DNA is also rapid and easily obtained just by injection of buffer solution. The binding affinity was measured from the steady-state SPR binding data. The plot or RU versus **4d** concentration (not shown) and the fitting of the binding results with a one site model gave a macroscopic binding constant of 1.56×10^6 M^{-1}. The difference with the binding constant determined by the fluorescence assay accounts for the higher ionic strength buffer used in the SPR experiments (HBS-EP buffer which contains 150 mM NaCl) compared to the fluorescence method (BPE buffer containing 16 mM NaCl).

Mode of Binding to DNA. Electric linear dichroism (ELD) experiments were performed to define the orientation of the compounds with respect to the DNA helix. In these experiments, the DNA is oriented in an electric field and the respective orientation of the molecules bound to DNA is probed using a linearly polarized light. The ELD spectrum of **4d** bound to calf thymus DNA is presented in Figure 4a. The reduced dichroism $\Delta A/A$ is negative in the drug absorption band. The 350−450 nm negative band reflects the orientation of the drug chromophore along the electric field. For each compound, we measured the reduced dichroism as a function of the electric field strength because the intensity of the ELD signal is a function of the degree of alignment of the DNA molecules in the electric field (Figure 4b). These measurements were performed in a low ionic strength buffer (1 mM Na cacodylate, as required for the ELD experiments due to the high electric field applied to the solution) at a high DNA−drug ratio (P/D = 25) to ensure that all drug molecules are bound to DNA. Strongly negative and equally intense signals were obtained with all compounds. There was no difference between the amino acid substitutions. The identical negative reduced dichroism values measured with the different compounds at 400 nm in the absorption band of the oxoazabenzoanthracene chromophore reflect a common orientation of the planar ring system perpendicular to the helix axis (or electric field direction), as expected for an intercalative binding. The higher $\Delta A/A$ values measured with the drug−DNA complexes compared to naked DNA most likely reflects drug-induced stiffening effects which would favor the orientation of the DNA molecules in the electric field. This phenomenon is commonly seen with intercalating agents (*22*, *23*).

We also used a DNA unwinding assay based on the relaxation of supercoiled plasmid DNA in the presence of topoisomerase I to compare the DNA binding properties of the amino acid conjugates. Supercoiled DNA was treated with topoisomerase I in the presence of increasing concentrations of the tested drugs. The DNA relaxation products were then resolved by agarose gel electrophoresis (Figure 5). Compound **4b** shows relatively small effect on the relaxation of DNA by topoisomerase I whereas the other compounds totally inhibit the relaxation of the DNA. Here again, the effect is more pronounced with **4d** compared to the other compounds (compare the 5 μM lanes in Figure 5). These results, showing that the compounds unwind closed circular duplex DNA, are

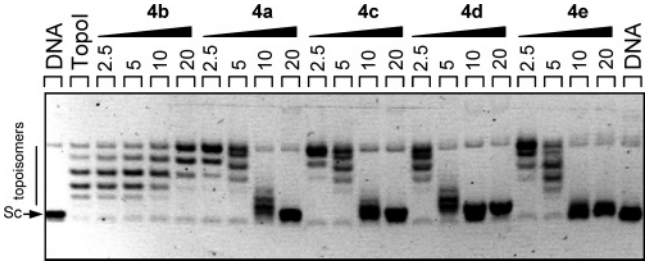

Figure 5. Effect of the compounds on the relaxation of plasmid DNA by human topoisomerase I. Native supercoiled DNA (0.2 μg) (lane DNA) was incubated with 3 units topoisomerase I in the absence (lane Topo I) or presence of the tested compounds at the indicated concentration (μM). Reactions were stopped with sodium dodecyl sulfate and treatment with proteinase K. DNA samples were separated by electrophoresis. The agarose gel was subsequently stained with ethidium bromide (1 μg/mL) and photographed under UV light. Sc, supercoiled DNA.

consistent with the intercalative binding mode. It is useful to mention at this point that the compounds affect topoisomerase I activity via DNA intercalation but they do not inhibit the catalytic activity of the enzyme. In parallel experiments (not shown), we observed that the drugs do not promote DNA cleavage by topoisomerases I or II. The intensity of the band corresponding to nicked DNA (for topoisomerase I) and linear DNA (for topoisomerase II) was not amplified in the presence of these oxoazabenzoanthracene derivatives.

Sequence Selectivity. The DNase I footprinting methodology was employed to compare the sequence selectivity of the compounds. Two DNA restriction fragments of 117- and 265-bp, both derived from the plasmid pBS, were prepared by 3′-end radiolabeling with ^{32}P. With each fragment, the products of digestion by DNase I in the absence and presence of the test drugs were resolved by polyacrylamide gel electrophoresis. Typical DNase I digestion patterns observed in the absence and presence of the tested compounds are illustrated in Figure 6. Significant differences between the control lanes and the drug-containing lanes can easily be seen. Well-resolved footprints are detected with **4d** and to a lower extent with the other compounds. The extent of DNase I protection is directly dependent to the affinity of the drug for DNA. The Phe derivative **4b** practically does alter the DNase I cleavage profiles. The Pro, Ala, and Gly derivatives appear to bind to the same type of sequences as the Lys analogue but with a reduced affinity. A typical example can be seen with the 117-bp

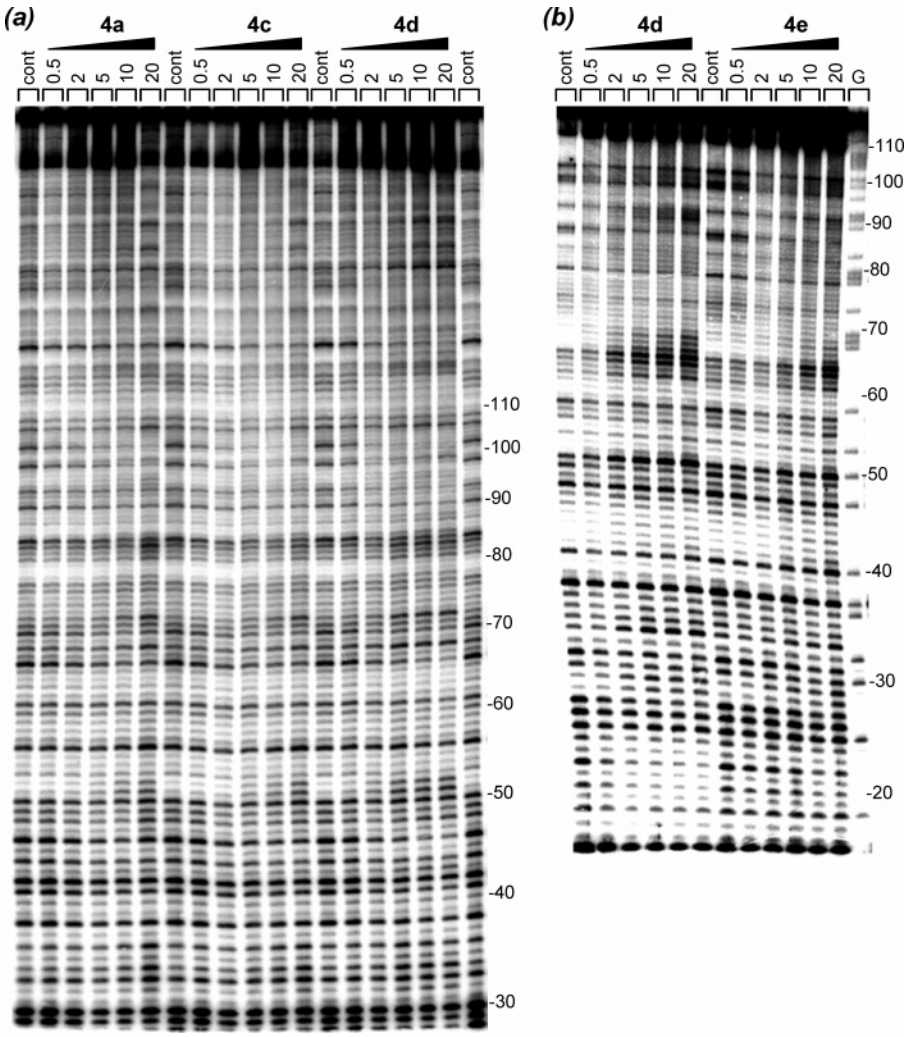

Figure 6. DNase I footprinting of the tested compounds on (a) the 265-bp and (b) the 117-bp *Eco*RI-*Pvu*II DNA restriction fragments from plasmid pBS. In both cases, the DNA was 3′-end labeled with [α-^{32}P]dATP in the presence of AMV reverse transcriptase. The products of nuclease digestion were resolved on 8% polyacrylamide gels containing 7 M urea. Control tracks (cont) contained no drug. The concentrations (μM) of the tested drug are shown at the top of the appropriate gel lanes. Tracks labeled "G" represent dimethyl sulfate−piperidine markers specific for guanines. Numbers on the right side of the gels refer to the standard numbering scheme for the nucleotide sequence of the DNA fragment.

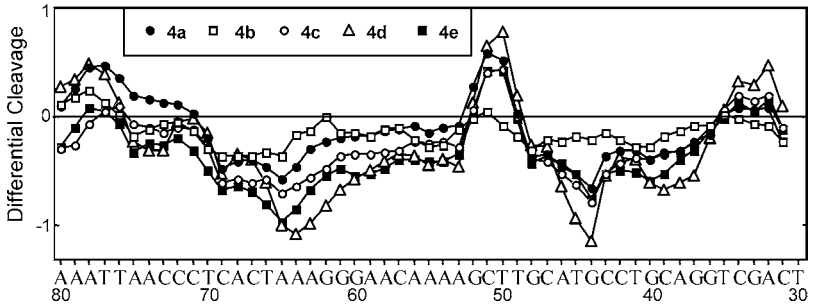

Figure 7. Differential cleavage plots showing the susceptibility of the 265bp fragment to DNase I cutting in the presence of the tested compound (10 μM each). Negative values correspond to a ligand-protected site and positive values represent enhanced cleavage. Vertical scales are in units of $\ln(f_a) - \ln(f_c)$, where f_a is the fractional cleavage at any bond in the presence of the drug and f_c is the fractional cleavage of the same bond in the control, given closely similar extents of overall digestion. Only the region of the restriction fragment analyzed by densitometry is shown.

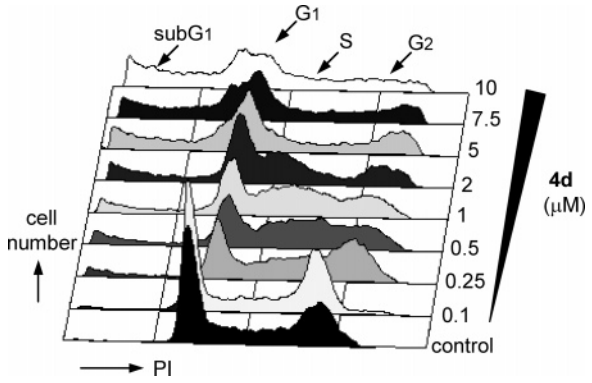

Figure 8. Cell cycle distribution determined by flow cytometry in CEM cells treated for 24 h with graded concentrations of **4d**. Cells were analyzed with the FACScan flow cytometer. Results show a typical experiment that has been repeated at least three times.

fragment where a solid footprint develops around nucleotide position 20 with **4d**, but there is almost nothing with **4e**. The difference between the two drugs is also clearly visible in terms of drug-induced enhanced DNase I cleavage, such as around position 64 where **4d** strongly promotes the activity of the enzyme, most likely as a result of intercalation-induced perturbation of the double helix structure (*24*). A densitometric analysis of the different patterns was performed to estimate the location and relative strength of binding at particular DNA sites. Figure 7 shows the differential cleavage plots for the 265-bp DNA fragment in the presence of the five compounds. The dips in these plots (negative values) indicate sites of protection from DNase I cleavage, whereas peaks (positive values) indicate regions of drug-induced enhancement of nuclease cleavage. The binding sites are broad and contain mixed sequences of AT and GC bp. Compound **4d** protects the sequences 5′-CTAAAGG and 5′-ATGC from DNase I cleavage. The recognized sequences are neither GC-rich nor do they contain exclusively AT bp. No clear preferential binding sequence could be deduced.

Cytotoxicity and Cell Cycle Effects. A tetrazolium-based assay was applied to determine the drug concentration required to inhibit the growth of CEM human

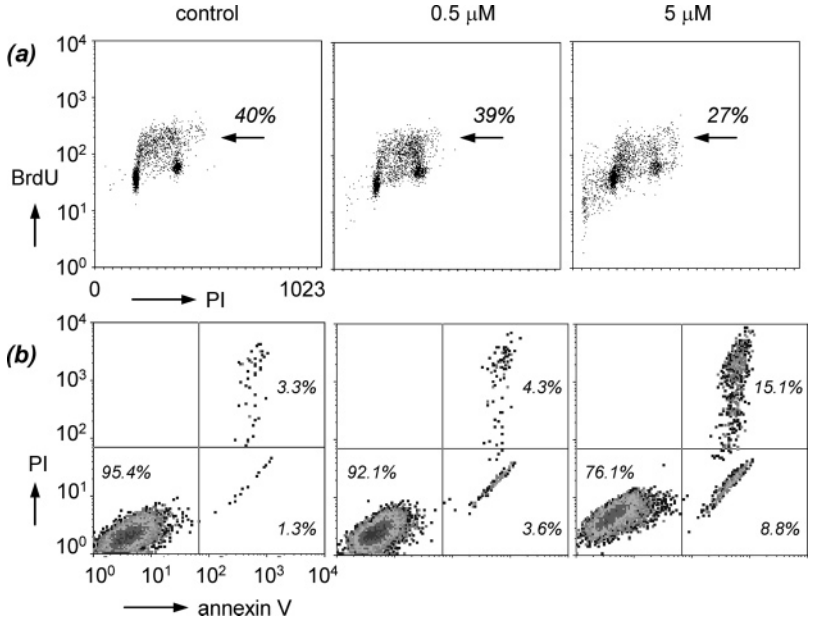

Figure 9. (a) Contour plots showing the reduction of bromodeoxyuridine incorporation in CEM cells treated with **4d**. Cells were treated for 24 h with the drug (0.5 or 5 μM) prior to labeling with the BrdU−FITC conjugate for 30 min and counterstained with propidium iodide (PI). In each case, the percentage of $BrdU^+$ cells is indicated. Drug-induced externalization of phosphatidylserine residues. CEM cells were treated with 0.5 or 5 μM **4d** for 24 h and then stained with propidium iodide (PI) and an annexin V-FITC conjugate specifically detecting the exposure of phosphatidylserine (PS) residues at the cell surface. Fluorescence intensities are shown as log scales. In each case, the percentage of annexin-V^+/IP^- cells (lower right square) and annexin-V^+/IP^+ cells (upper right square) is given (± 3%). Results show typical experiments that have been repeated twice.

leukemia cells by 50% (IC_{50}) after incubation in the culture medium for 72 h. Interestingly, the Lys derivative **4d** proved to be considerably, 20 to 40-times, more cytotoxic than the other amino acid derivatives (Table 1). This may be an indication that its superior affinity for DNA contributes to its enhanced cytotoxicity. Flow cytometric analysis of propidium iodide-labeled CEM cells revealed that **4d** induces a slight accumulation of cells in the G2/M phase at low concentrations and then in the S phase at higher concentrations, concomitant to a decrease of the G0/G1 cell population (Figure 7). The percentage of cells in the S phase increases from 22 to more than 40% upon treatment of the CEM cells with 1 μM **4d** for 24 h. The Phe derivative showed absolutely no effect on the cell cycle progression (not shown). To get a more precise view of the effect of **4d** at the S phase level, cells were labeled with bromodeoxyuridine (BrdU), a thymidine analogue which is incorporated into newly synthesized strands of DNA. As shown in Figure 9a, much fewer $BrdU^+$ cells, labeled in S-phase at the time of treatment, were detected after 24 h incubation with **4d** compared to the control cell population. The Lys derivative was the most potent compound in the series at inhibiting the incorporation of BrdU into DNA. The enhanced DNA binding capacity of **4d** likely accounts for the potent inhibition of DNA synthesis which is probably at the origin of the increased cytotoxicity of this Lys derivative.

Drug-Induced Apoptosis. During the cell cycle measurements, in parallel to the S block, a characteristic hypo-diploid DNA content peak (sub-G_1) was detected with **4d**. The effect is dose-dependent (Figure 8). The progressive generation of cells having a hypodiploid DNA content is usually characteristic of apoptosis and reflects fragmented DNA. These cell cycle analysis suggested that CEM leukemia cells accomplish apoptosis under treatment with **4d**. Therefore, to investigate further this question, we performed a biparametric cytofluorimetric analysis using propidium iodide and annexin V-FITC which stain DNA and phosphatidylserine (PS) residues, respectively. Annexin V is a Ca^{2+}-dependent phospholipid binding protein with high affinity for PS. After the drug treatment, CEM cells were labeled with these two dyes and washed, and the resulting red (PI) and green (FITC) fluorescence was monitored by flow cytometry. As indicated in Figure 9b, the percentage of annexin V positive cells slightly increased upon treatment with **4d**. At 5 μM, about 9% of the cells stained positively with annexin V, and this cell population characteristic of an early stage of apoptosis always remained <12% even with a higher drug concentration (data not shown). Rapidly, we detected the accumulation of cells doubly stained in green with annexin V and in red by PI corresponding to late stages of apoptosis and/or dead or necrotic cells. The loss of membrane asymmetry and the ensuing increased accessibility of PS residues to annexin V-FITC is a good criteria indicating that **4d** induces apoptosis but the effect is relatively modest and this compound can probably also cause cell death via a nonapoptotic pathway.

DISCUSSION

The oxoazabenzo[*de*]anthracene-amino acid conjugates reported here derive from a previous series of anthraquinone-amino acid conjugates endowed with potent cytotoxic activities and topoisomerase inhibitory properties. In an effort to enhance the cytotoxic activity of the molecules, it was hypothesized that the expansion of the planar chromophore could favor DNA binding and recognition and possibly promote the biological activity. This hypothesis was only partially validated. Indeed, it appears that the conversion of the anthraquinone nucleus into a tetracyclic oxa-aza-benzo[*de*]anthracene-fused ring system abolishes the capacity of the compounds to function as topoisomerase poisons. None of the compounds reported here efficiently stabilize topoisomerase−DNA covalent complexes, be it with topoisomerase I or topoisomerase II. However, the DNA binding properties and cytotoxic potential are preserved. The amino acid conjugates maintain DNA intercalation properties, and one compound in the series, the lysine derivative **4d**, appears to be a potent DNA binder and displays marked cytotoxic and pro-apoptotic activities. This cationic compound strongly binds to DNA, as evidenced by several spectroscopic techniques, forms intercalation complexes and preferentially recognized certain sequences. Nevertheless, the sequence selectivity is relatively modest, as it is generally the case with intercalating drugs. At the cellular level, **4d** inhibits DNA synthesis during the S phase of the cell cycle. This is potentially linked to its DNA binding properties. The compound shows submicromolar activity against the leukemia cell line. Although apoptotic cells have been identified upon treatment with **4d**, it seems that this compound can provoke cell death by different processes, not restricted to apoptosis. Compound **4d** is certainly a valid candidate for further pharmacological studies, with complementary tumor cell lines and in vivo tumor models.

The structure−activity relationships are relatively straightforward. The incorporation of a Lys amino acid with a cationic side chain strongly promotes DNA binding whereas the addition of a neutral amino acid results in a much weaker DNA interaction. The introduction of a hydrophobic amino acid appears to be detrimental to DNA interaction. Although this is not always the case (Phe derivative could favor DNA intercalation as well), it is common to observe that this type of relationship between compound hydrophobicity or charge and the DNA binding strength. More surprising is the positive relationship between DNA affinity and cytotoxicity. Compound **4d** has turned out to be a very cytotoxic compound, and the cell data (S phase arrest, inhibition of BrdU incorporation) suggest that the enhanced cytotoxicity is linked to the DNA binding activity. This is not so common. Apparently the cationic nature of the compound is not an obstacle for its cellular penetration. **4d** is over 20 times more cytotoxic than the other amino acid conjugates. It will therefore be interesting to pursue the synthesis of other cationic oxoazabenzo[*de*]anthracene conjugates equipped with other basic amino acids (e.g. arginine) or polyamine side chains, to exploit the polyamine transport system that is frequently overexpressed in tumor cells (*25*−*29*). The design of drugs linked to Lys-containing di- and tripeptides is also considered. In the past, we also successfully elaborated peptide−intercalator conjugates encompassing one or two Ser-Pro-Lys-Lys (SPKK) motifs (*30*−*32*). The same motif could also be adequate to optimize the activity of the oxoazabenzo[*de*]anthracene ring system. The molecule **4d** provides interesting opportunities to develop novel DNA-targeted anticancer agents.

Arginine-Rich Peptide Conjugation to Morpholino Oligomers: Effects on Antisense Activity and Specificity

Michelle H. Nelson, David A. Stein, Andrew D. Kroeker, Susie A. Hatlevig, Patrick L. Iversen, and Hong M. Moulton*

AVI BioPharma, Inc., Corvallis, Oregon 97333. Received April 3, 2005; Revised Manuscript Received June 9, 2005

Noncharged antisense compounds, such as phosphorodiamidate morpholino oligomers (PMOs), do not readily enter mammalian cells in culture. A simple and effective means for cellular delivery of PMOs is through their conjugation to arginine-rich peptides. Understanding the effect of peptide conjugation on the efficacy, toxicity, and specificity of PMOs is important to the successful application of this antisense delivery method. We investigated the effects of conjugation of arginine-rich peptides to PMO on the thermal stability, efficacy and specificity for targeted RNA of the resulting compound. In vitro translation assays showed that (1) R9F2−PMO generated antisense activity 3−25-fold higher than corresponding nonconjugated PMO, (2) the level of antisense activity enhancement by R9F2−PMO over a corresponding nonconjugated PMO is related to the GC content of the PMO sequence, (3) R9F2 conjugation reduced the minimum length of a PMO required to inactivate a target RNA from 20 bases to 14 bases, and (4) nonspecific effects of R9F2−PMO occur at lower concentrations than corresponding PMO alone. Thermal stability of heteroduplexes of PMO and complementary RNA were increased by conjugation of PMO to R9F2 peptide, likely accounting for the increased specific antisense activity of conjugated over nonconjugated PMO. A cell-culture based assay demonstrated that while conjugation to unnatural peptides increased PMO efficacy without causing nonspecificity at concentrations ≤10 μM, only L-peptide conjugation retained high specificity at higher concentrations. This study demonstrates that conjugation of PMO to an arginine-rich peptide generally increases the binding affinity of the PMO to complementary RNA and increases its antisense potency. Additionally, it is shown that the enzymatic stability of an L- or unnatural peptide used for PMO conjugation affects the antisense properties of the resulting compound.

INTRODUCTION

Antisense compounds can be powerful reagents for the exploration of gene function and have potential for therapeutic applications. The efficacy of an antisense compound depends on its biological stability, delivery to intracellular targets, binding affinity with target nucleic acids, and sequence specificity. Phosphorodiamidate morpholino oligomers (PMOs) (*1*, *2*) are a modified structural type, an oligonucleotide mimic with morpholine rings replacing the deoxyribose of DNA coupled by nonionic intersubunit linkages (Figure 1). This noncharged backbone structure is resistant to enzymatic degradation (*3*, *4*) and has higher RNA binding affinity than DNA (*5*). In eukaryotic cells, PMO can work as a translational or RNA splicing blocker or both by base-pairing to complementary target RNA and sterically blocking access of other biomolecules to a target sequence (*2*, *6*).

We have previously reported the successful delivery of PMOs by short arginine-rich peptides (ARPs) such as HIV Tat and R9F2, resulting in the correction of the pre-mRNA missplicing of mutant human β-globin (*7*, *8*) and inhibition of the replication of coronaviruses (*9*, *10*) and several flaviviruses (*11*, *12*) in cell culture. Successful ARP-mediated intracellular delivery of a PMO requires covalent conjugation, rather than merely the simultaneous presence of PMO and ARP in the cell culture media

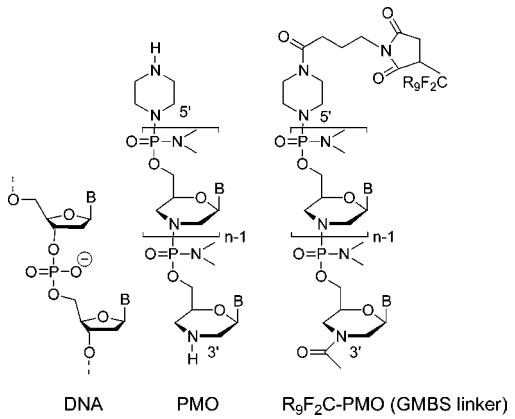

Figure 1. Structure of DNA, PMO, and R9F2C−PMO (PPMO) conjugate.

(*8*). Important issues in the development of this PMO delivery system, for both research and therapeutic applications, include understanding the influences that ARP conjugation has on the antisense efficacy, cytotoxicity and target specificity of the PMO. This will facilitate the design of peptide sequences, selection of amino acids, and conjugation chemistry, as well as interpretation of "gene-knockdown" experimental data. In this study, we investigated the following: (1) the effect of conjugation of PMO to an ARP, R9F2 on antisense activity and specificity in both in vitro translation and cell culture assays, (2) the effect of enzymatic stability of a conjugated ARP on antisense efficacy and specificity of a PMO, and

EXPERIMENTAL PROCEDURES

Peptides, PMOs, and Peptide−PMO Conjugates. The nomenclature and sequences of ARPs and PMOs are listed in Table 1. PMOs or fluorescein-tagged PMOs were synthesized at AVI BioPharma as described elsewhere (*1*, *7*, *13*). R9F2 and RXR peptides were synthesized at AVI BioPharma and the D-R9F2 peptide was synthesized by Global Peptide Services (Ft. Collins, CO). The purity of all peptides was >90%. The conjugation, purification and analysis of peptide−PMO conjugates were carried out as described previously (*7*, *8*). Each peptide was conjugated to the 5′-end of a PMO through the GMBS (*N*-[γ-maleimidobutyryloxy]succinimide ester) linker (Pierce, Rockford, IL) unless otherwise specified. The specific gene target of a PMO is written as a subscript. For example, PMO targeted to the human c-*myc* gene is designated as PMO_{CMYC}. The R9F2, RXR, or D-R9F2 peptide conjugated PMOs are designated as PPMO, (RXR)PMO, or D-PPMO, respectively. The chemical structures of PMOs and PPMOs are shown in Figure 1.

In Vitro Translation Assays. The coding sequence for firefly luciferase was subcloned into the multiple cloning site of plasmid pCiNeo (Promega, Madison, WI) at the *Sal*I and *Not*I sites. Subsequently, complementary oligonucleotides of sequences identical to those in West Nile virus (WNV), the cytochrome P450 3A2, a three-nucleotide mutant P450 3A2, human c-*myc*, or a segment of IRES sequence from hepatitis C virus (HCV) were duplexed and subcloned into the *Nhe*I and *Sal*I sites. The WNV leader sequence replaces the start codon of the luciferase gene with sequence encoding bases −29 to +16 relative to the A of the AUG translation initiation codon of the WNV polyprotein gene (bases 68−113, Genbank accession no. AF196835), including the complete −13 to +9 target site for the WNV PMO. The CYP3A2 leader sequence replaces the start codon of the luciferase gene with sequence encoding bases −31 to +16 relative to the A of the AUG translation initiation codon of the rat CYP3A2 gene (bases 43−90, Genbank accession no. U09724), including the complete −2 to +18 target site for the CYP3A2 PMO. The CYP3A2/3MP leader sequence is identical to the CYP3A2 leader except three guanine bases are replaced with three thymine bases. Relative to the A of the ATG, these thymine bases are −2, +4, and +9. The c-*myc* leader sequence replaces the start codon of the luciferase gene with sequence encoding bases −14 to +14 relative to the A of the AUG translation initiation codon of the c-*myc* gene (bases 4053−4081, Genbank accession no. AY214166), including the complete −6 to +14 target site for the c-*myc* PMO. The HCV IRES leader sequence includes bases 249−287 (Genbank accession no. NC_004102) of the HCV genome. The translational start site of luciferase is functional in this construct, and the sequence includes the complete target site of the HCV IRES PMO.

RNA was produced from these plasmids (pCN(WNV)-luc, pCN(3A2)luc, pCN(3A2/3MP)luc, pCN(myc)luc, and pCN(HCV−IRES)luc) after linearization with *Not*I, using the T7 polymerase-based MEGAscript kit and protocol (Ambion, Austin, TX). In vitro translations were carried out using transcribed RNA at a final concentration of 1 nM in each reaction with 12 μL of nuclease-treated rabbit reticulocyte lysate (Promega) and either PMO or water. After 1 h of incubation at 37 °C followed by 15 min at room temperature, 10 μL of the translation reaction mixture was combined with 50 μL of luciferase assay reagent (Promega) according to the manufacturer's instructions. Light emission was read on an FLx800 microplate luminometer (Bio-tek, Winooski, VT). Reactions were assayed for relative light units with the KC Junior program (Bio-tek) by using the luminescence function with a sensitivity setting of 125. Twelve reactions were assayed at one time, including water control reactions in the first and last wells of each row. The relative light units produced by each reaction were normalized to the mean of all control reactions and expressed as percent inhibition of luciferase translation. IC_{50}'s, the concentrations resulting in 50% inhibition, were derived from inhibition curves using GraphPad Prism 4.0 software (San Diego, CA).

Cell Culture Assay. The HeLa pLuc 705 (*8*, *14*) cell line (Gene Tools, Philomath, OR) was cultured in RPMI 1640 supplemented with 2 mM L-glutamine, 100 μg/mL streptomycin, 100 U/ml penicillin, and 10% fetal bovine serum (FBS) (Hyclone, Ogden, UT). The correction of pre-mRNA missplicing was carried out as described previously (*8*).

Thermal Stability. Thermal stability of a PMO hybridized to its complementary RNA target sequence was determined as described previously (*15*) with the following modifications. The PMO and the RNA were each present at a concentration of 2.5 μM. The solution was heated to 95 °C (with the exception of 100 °C for the PMO_{CMYC}/RNA and $PPMO_{CMYC}$/RNA samples) and cooled to 25 °C at a rate of 0.2 °C/min in a Cary 1 UV−vis spectrometer with a temperature controller (Varian, Mulgrave, Victoria, Australia). The absorbance was recorded at 260 nm. The T_m value was taken as the maximum of the first derivative of the absorbance vs temperature plot using Cary WinUV software (Varian).

Enzymatic Stability of Conjugates. PMO_{705} conjugated to R9F2, (RXR)R9F2, or D-R9F2 (each at 61 μM) and 10 units of proteinase K (Sigma, St. Louis, MO) were incubated in 100 μL of reaction buffer (50mM Tris-HCl, 5mM CaCl, pH 7.4) for 5 min at 37 °C. The reaction was stopped by placing the tube in crushed dry ice and then storing at −80 °C until analysis by matrix-assisted laser desorption ionization time-of-flight mass spectrometry

(MALDI TOF MS). Intracellular stability of a conjugate was determined as described below. The culture media was removed from about 50% confluent HeLa pLuc 705 cells in a T-175 flask and replaced with 20 mL of fresh medium containing 10 μM of a conjugate. Cells were treated for 24 h. The treatment medium was removed, and the cells were washed with 20 mL of PBS, trypsinized with 7 mL of trypsin for 7 min at 37 °C, and neutralized with 18 mL of FBS-containing medium. The suspension was pelleted, washed with 500 μL of PBS, then pelleted and resuspended in 200 μL of ice-cold water containing protease inhibitor cocktail (Roche Diagnostics). Each sample was then subjected to three freeze−thaw cycles with a crushed dry ice/ethanol bath and a room-temperature water bath. Ice-cold acetonitrile (600 μL) was then added to precipitate cellular proteins and debris. Samples were placed on ice for 15 min and then centrifuged for 5 min at 5000*g*. The supernatant was lyophilized. Each sample was brought up in 25 μL of water and analyzed by MALDI TOF MS.

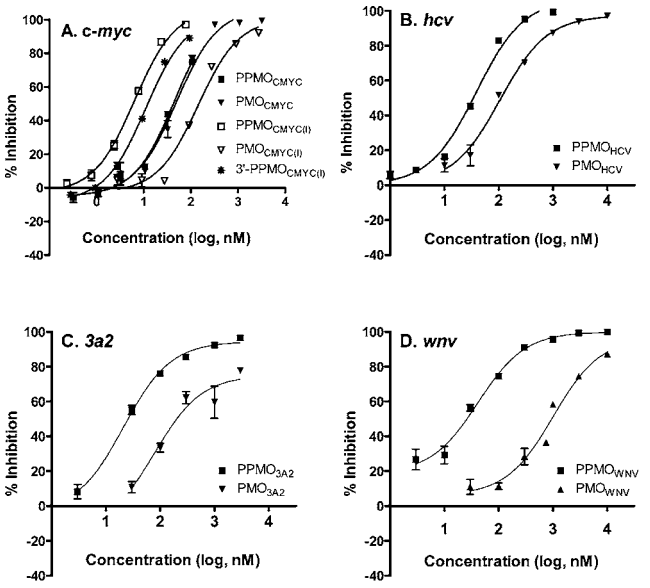
Data Process and Statistical Analysis. Data were plotted and analyzed using GraphPad Prism 4.0 software (GraphPad Software, San Diego, CA).

RESULTS

R9F2 Conjugated PMO Is More Potent Than Corresponding PMO in an In Vitro Translation Assay. Inhibition of targeted gene expression by PMO and PPMO was determined by cell-free in vitro translation assays using rabbit reticulocyte lysates. In each case the PMO was complementary to targeted RNA produced by in vitro transcription from chimeric plasmids containing the luciferase reporter gene fused downstream from sequence of human c-*myc* (c-*myc*), the rat cytochrome P450 3A2 (3A2), hepatitis C virus (HCV), or West Nile virus (WNV). Figure 2A−D represents the antisense activity of five PMO and six PPMO against their respective RNA targets at various concentrations. The five PMO used were PMO_{CMYC}, $PMO_{CMYC(I)}$, PMO_{HCV}, PMO_{3A2}, and PMO_{WNV}. The six PPMO used in this study included the five PMO described above conjugated to R9F2 at their 5′-ends and $PMO_{CMYC(I)}$ with R9F2 conjugated at its 3′-end (3′-$PPMO_{CMYC(I)}$). The antisense activity of PMO or PPMO is represented as the percent inhibition of luciferase reporter relative to a vehicle control versus concentrations. In each graph of Figure 2, a log dose versus response curve of PMO was compared to that of the corresponding PPMO in inhibition of target RNA c-*myc* (Figure 2A), HCV (Figure 2B), 3A2 (Figure 2C), and WNV (Figure 2D).

Concentration-dependent inhibition was observed for all PMO and PPMO against complementary targets. The concentration required to achieve 50% inhibition of target/reporter expression (IC_{50}) was used to quantitatively compare the effectiveness of PPMO to PMO. In each case (except c-*myc*), the PPMO was more efficacious than its corresponding PMO, as reflected by a lower IC_{50} value (Figure 2E). However, the magnitude of difference in inhibitory activity between a PMO and its corresponding PPMO varied among PMO sequences. The efficacies were essentially the same for $PPMO_{CMYC}$ and PMO_{CMYC} (IC_{50} at 46 and 50 nM, respectively), 3-fold higher for $PPMO_{HCV}$ compared to PMO_{HCV} (IC_{50} at 38 and 106 nM, respectively), 7-fold higher for $PPMO_{3A2}$ than PMO_{3A2} (IC_{50} at 21 and 140 nM, respectively), and 25-fold higher for $PPMO_{WNV}$ than PMO_{WNV} (IC_{50} at 40 and 1011 nM, respectively) (Figure 2E).

We hypothesized that ARP conjugation would provide a greater activity enhancement for a PMO with lower



E. IC_{50}(nM)

RNA Target	PPMO	PMO	PPMO(I)	PMO(I)	3′-PPMO(I)
c-*myc*	46	50	7	143	10

3a2	21	140	ND	ND	ND
wnv	40	1011	ND	ND	ND

Figure 2. In vitro translation assays show that an R9F2-conjugated PMO is more potent than the corresponding PMO. Chimeric RNAs containing the coding sequence of luciferase fused downstream from the sequence from c-*myc* (A), HCV (B), 3A2 (C), or WNV (D) were used to program rabbit reticulocyte lysate in vitro translation reactions. Each graph shows the relationship between the log concentrations of PPMO or PMO and antisense activity, represented as % inhibition of the reporter luciferase compared to a vehicle-only control. Each data point was an average ± the range of means of two independent experiments each consisting of triplicate samples. The data were also represented as IC_{50} (E), the compound concentration required for 50% inhibition. $PMO_{CMYC(I)}$ contained three inosines, replacing three guanines in the PMO_{CMYC} sequence. 3′-$PPMO_{CMYC(I)}$ is a $PMO_{CYMC(I)}$ with the R9F2 peptide conjugated to its 3′-end. All other PPMOs had R9F2 peptide conjugated to the 5′-end.

RNA binding affinity. To specifically test this, the RNA binding affinity of PMO_{CMYC} was purposely reduced by replacing the three guanine (G) bases at positions 8, 9, and 10 with three inosines (I) bases. The inosine-substituted PMO_{CMYC}, either without ($PMO_{CMYC(I)}$) or with the peptide conjugation ($PPMO_{CMYC(I)}$), was compared to nonsubstituted PMO_{CMYC} in inhibition of c-*myc*−luciferase expression (Figure 2A). The replacement of G with I increased the IC_{50} of PMO_{CMYC} from 50 to 143 nM (Figure 2E). Conjugation of the R9F2 peptide to the 5′- or 3′-end of $PMO_{CMYC(I)}$ lowered the IC_{50} value of $PMO_{CMYC(I)}$ from 143 nM to 7 or 10 nM, respectively (Figure 2E).

Conjugation to the R9F2 Peptide Reduces the Minimum Inactivating Length of PMO. Having shown that a PPMO generally has greater antisense activity than the corresponding PMO, we investigated whether R9F2 peptide conjugation would allow a decrease in the length of the PMO necessary to attain a given IC_{50}. Several truncated PMO_{3A2} (Table 2B) and the corresponding PPMO were tested against the 3A2 leader−luciferase RNA in the in vitro translation assay. These PMO/PPMO had 18, 16, 14, and 12 bases, derived by removing one, two, three, and four bases, respectively, from each end of the 20 base starting PMO_{3A2}/$PPMO_{3A2}$

Table 2. Conjugation of R9F2 Peptide Reduces the Minimum Inactivating Length of PMO:[a] (A) Data Are Represented as IC_{50};[b] (B) Sequence Alignment of PMO_{3A2} with 20, 18, 16, 14, and 12 Bases

[a] PMO or PPMO of different lengths targeted to 3A2 RNA were assayed for inhibition of luciferase reporter expression in two in vitro translation assays. The chimeric RNA contained the luciferase gene fused downstream from either the targeted sequence of CYP3A2 or the targeted sequence of CYP3A2 with three mutations. [b] Each IC_{50} was obtained from a dose/response curve constructed using the data from two independent experiments each consisting of triplicate samples. [c] Sequences of perfectly matched RNA (GGATGGACCTGCTTTCAGCT) and 3-mismatched RNA with mismatched bases boldface (**T**GATG**T**ACCT**T**CTTTCAGCT).

(Table 2B). As the IC_{50} values show in Table 2A, PMO became markedly less inhibitory as its length decreased. The IC_{50} value for the 14mer PMO_{3A2} was ≥15-fold greater than the 20mer PMO_{3A2} (3000 and 140 nM, respectively). However, shortening the PMO length had less effect on PPMO with IC_{50} values increasing by only 5-fold for the 14mer $PPMO_{3A2}$ compared to the 20mer $PPMO_{3A2}$ (97 and 21 nM, respectively). The 14mer $PPMO_{3A2}$ had an inhibition curve nearly identical to the 20mer PMO_{3A2} (data not shown), indicating that conjugation to the R9F2 peptide shortened the PMO_{3A2} length requirement by six bases to attain the IC_{50} of the nonconjugated PMO.

Shortening PMO Length Does Not Increase Nonspecificity of PPMO. The panel of various lengths of 3A2 PMO and corresponding PPMO was assayed against the $3A2_{3MM}$−luciferase RNA to determine the effect of the R9F2 peptide on the specificity of each of these PMO sequences. $3A2_{3MM}$ RNA had three mismatched bases in relation to the PMO_{3A2} sequence (Table 2). None of the nonconjugated PMO_{3A2}, at concentrations up to 3000 nM, inhibited the expression of three-mismatched RNA, while the corresponding PPMO generated IC_{50} values between 500 and 1000 nM (Table 2). However, unlike the results from the perfectly matched 3A2 RNA, which generated increasing IC_{50} values with decreasing PMO length, the IC_{50} of PPMO tested against mismatched RNA did not depend on PMO length. PPMO caused a similar degree of nonspecificity regardless of the length of the PMO component, suggesting that the observed nonspecific inhibition was entirely dependent on the molar concentration of R9F2 present.

PPMOs Have Greater Off-Target Effects Than PMOs. The target specificity of a PMO compared to its corresponding PPMO was assessed by comparing inhibitions of nontarget RNAs in three in vitro translation assays. The HCV−, 3A2−, and WNV−luciferase plasmid-derived RNAs were challenged with some or all of the following PMOs or PPMOs: (1) two random sequences (PMO_{Ran1} and PMO_{Ran2}), (2) a sequence targeted to a mutated site of human β-globin intron 2 (PMO_{705}), and (3) PMO_{CMYC}, PMO_{3A2}, and PMO_{WNV}. None of the PMOs or PPMOs had sequences containing significant identity with any of the RNAs used. None of the unrelated PMOs, at concentrations up to 10 μM, inhibited luciferase expression of any of the three plasmid generated RNAs (Figure 3). The unrelated PPMO caused little or no inhibition at concentrations <1 μM but did cause various degrees of inhibition at ≥1 μM (Figure 3). The concentration that caused inhibition and the level of those inhibitions varied among both the PPMOs and target RNAs. $PPMO_{Ran2}$ at 3 μM caused 91%, 83%, and 70% inhibition of WNV, 3A2, and HCV reporter expression, respectively. $PPMO_{705}$ had little inhibition of WNV expression at 3 μM, but the same concentration caused 50% inhibition of 3A2 expression. $PPMO_{3A2}$ at 1 μM had no inhibition of WNV expression, but conversely $PPMO_{WNV}$ inhibited 3A2 expression by 60%. Free R9F2 peptide alone had no inhibition against 3A2 RNA up to 3 μM.

Enzymatic Stability of PPMOs. RXR and D-R9F2 peptides were designed to be more resistant to enzymatic degradation than R9F2 peptide. RXR peptide was made of L-arginine and the unnatural amino acid, 6-aminohexanoic acid, and D-R9F2 peptide consisted of D-amino acids (Table 1). The enzymatic stability of the fluorescein-tagged PMO_{705} (PMO_{705}−Fl) conjugated to each of the three peptides was determined by treating a conjugated compound with proteinase K and by applying a conjugate onto cells and then retrieving cellular contents for analysis. Mass spectrometry analysis (Figure 4) showed that the R9F2 portion of the $PPMO_{705}$−Fl was mostly degraded by proteinase K after 5 min of treatment, as indicated by the change in mass-to-charge ratio (*m/z*) from 8333 to 6633, corresponding to the loss of 1700 Da, that is, the mass of nine arginines and two phenylalanines. Neither (RXR)PMO_{705}−Fl nor D-$PPMO_{705}$−Fl was degraded by this enzyme after 5 min of treatment. However, the $(RXR)_4$ portion of (RXR)PMO_{705}−Fl was partially degraded after a 2-h treatment, while D-$PPMO_{705}$−Fl remained completely stable (data not shown). The major component retrieved from the cells treated with $PPMO_{705}$−Fl or (RXR)PMO_{705}−Fl had a *m/z* of 6632, which corresponds to mass of the cysteine−GMBS−PMO_{705}−Fl portion of each conjugate, indicating that the R9F2 or $(RXR)_4$ portion of each conjugate has been removed by cellular enzymes (Figure 4).

Effect of an ARP on Antisense Activity and Specificity of PPMO in a Cell-Based Assay. Effects of conjugation to an ARP on the antisense activity and specificity of PMO was further characterized in cell culture using the previously described "positive read-out" splice-correction assay (*8*, *14*). This was addressed by examining a series of compounds consisting of one of several ARPs with differing enzymatic stabilities conjugated to one or all PMOs that were exactly, partially, or noncomplementary to their RNA targets. PMO_{705} is complementary to a region of human β-globin pre-mRNA intron 2 that contains a mutation at position 705. $PMO_{705-2MM}$ and $PMO_{705-4MM}$ are partially complementary to the PMO_{705} target with two or four mismatched bases (Table 1), respectively. $PMO_{705-SCR}$ is a noncomplementary scrambled sequence of PMO_{705}. Five additional noncomplementary PMOs unrelated to the RNA target were used in this experiment: PMO_{IHNV}, PMO_{HCV}, $PPMO_{3A2}$, PMO_{WNV}, and PMO_{CMYC}. Three different ARPs, R9F2, RXR, and D-R9F2, were conjugated to some or all of the above PMOs.

Activity of a PPMO in the splice-correction assay was evidenced by increased luciferase reporter signal over

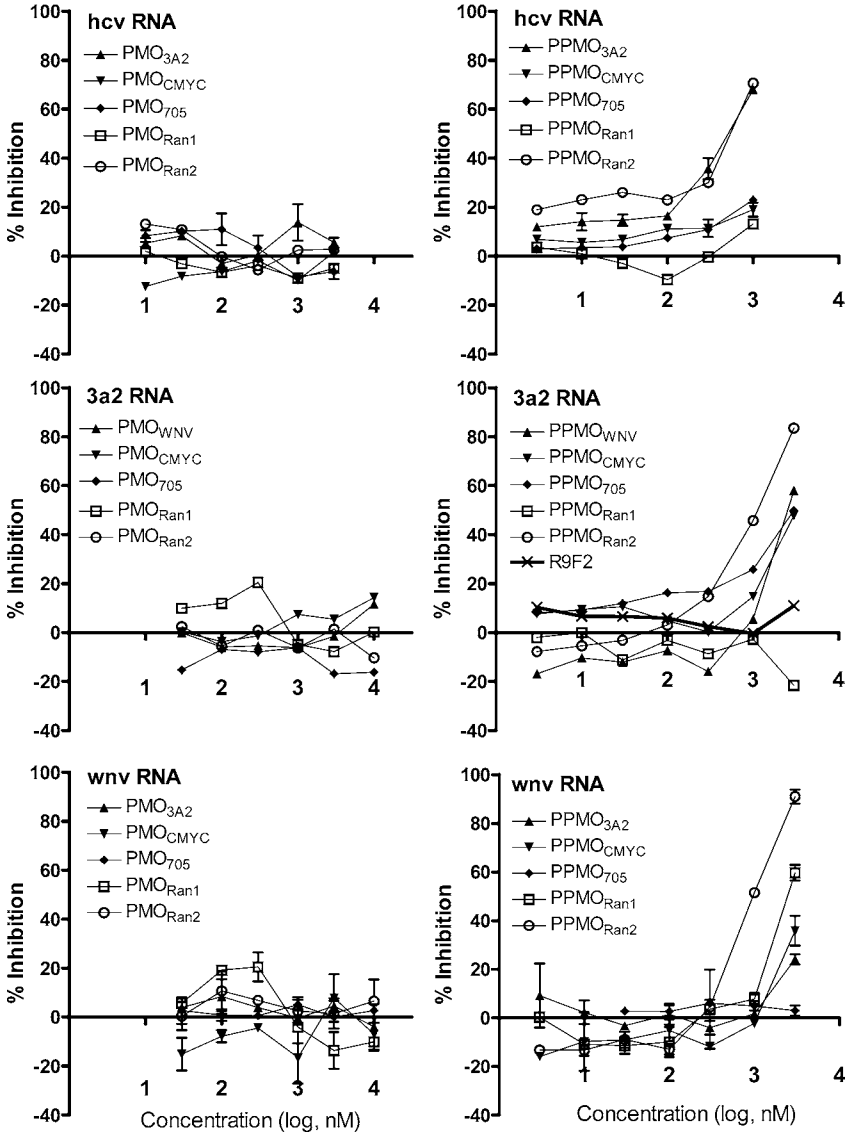

Figure 3. In vitro translation assays show that PPMOs have greater off-target effects than PMOs at concentrations >1 μM. PMOs (left panels) their corresponding PPMOs (right panels) or peptide alone (R9F2, right middle panel) were assayed for inhibition of luciferase reporter expression of HCV (top), 3A2 (middle), or WNV (bottom) RNA. Each PMO has a noncomplementary sequence to the challenge-RNA. Each graph shows the relationship between the log concentrations of PPMO or PMO and nonspecific activity, represented as % inhibition of the reporter luciferase compared to a vehicle-only control. Each data point was an average ± the range of means of two independent experiments each consisting of triplicate samples.

background. $PPMO_{705}$ corrected splicing and up-regulated luciferase reporter expression over background (Figure 5A,B). At treatment concentrations up to 10 μM, none of the five unrelated PPMOs resulted in an increased luciferase level (Figure 5A). Neither the partially complementary PPMOs ($PPMO_{705-2MM}$ or $PPMO_{705-4MM}$) nor the noncomplementary scrambled PPMO ($PPMO_{705-SCR}$) generated luciferase activity at concentrations up to 20 μM. (Figure 5B).

We hypothesized that cellular proteases might rapidly degrade the R9F2 portion of a PPMO after cell entry. The degradation of the peptide component could eliminate the peptide-associated nonspecificity documented in the results from the in vitro translation assays (Figure 3). To test this, the exactly-, partially-, or noncomplementary scrambled PMO was conjugated to the RXR or D-R9F2 peptide. Both (RXR)PMO_{705} and D-$PPMO_{705}$ had 2-fold higher specific antisense activity than $PPMO_{705}$ (Figure 5). (RXR)PMO_{705} or D-$PPMO_{705}$ at 5 μM caused cells to produce the same amount of luciferase as $PPMO_{705}$ at 10 μM. Nonspecific effects were not observed with RXR and D-R9F2 conjugated PMOs at concentrations <10 μM but were observed at higher concentrations. Specifically, cells treated with RXR-conjugated four-mismatched PMO and scrambled PMO at concentrations up to 20 μM did not produce luciferase activity above the background levels, whereas the cells treated with RXR-conjugated two-mismatched PMO at ≥10 μM did (Figure 5C). At concentrations ≤10 μM, neither of the mismatched or noncomplementary scrambled PMOs conjugated to D-R9F2 produced significant luciferase activity. However, the mismatched or scrambled D-PPMO did generate some nonspecificity at 20 μM, as indicated by the inappropriate production of luciferase (Figure 5D).

PPMO/RNA Heteroduplexes Have Higher Thermal Stability Than the Corresponding PMO/RNA Heteroduplexes. Having observed that ARP conjugation to a PMO increased antisense activity as well as caused nonspecificity at high concentrations, we hypothesized that the binding of PPMO and RNA is strengthened by interactions between peptide and RNA. The melting temperature (T_m) of a PMO/RNA heteroduplex

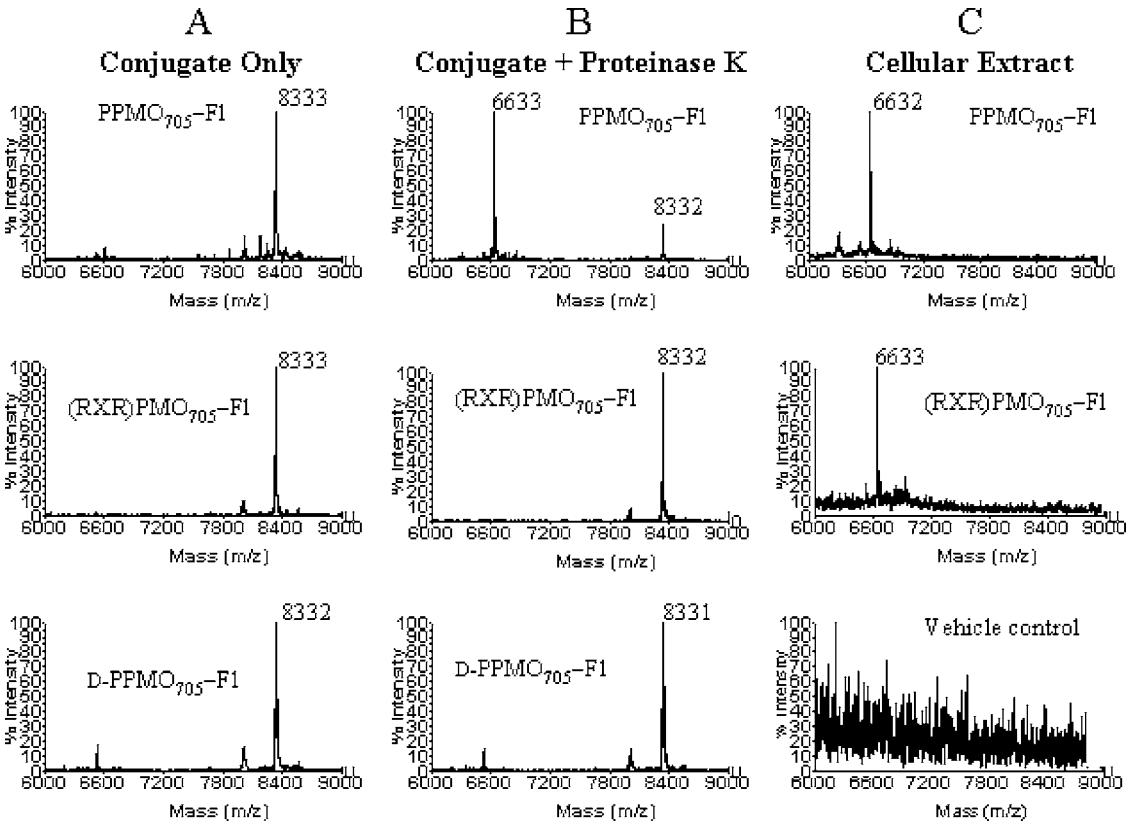

Figure 4. Enzymatic stability of peptide−PMO conjugates. The mass spectra of the fluorescein-tagged $PPMO_{705}$, $(RXR)PMO_{705}$, or D-$PPMO_{705}$ are shown: (A) no treatment performed on the conjugates; (B) the conjugate treated with proteinase K; (C) cellular extract of HeLa cells treated with $PPMO_{705}$ (upper), $(RXR)PMO_{705}$ (middle), or vehicle control (lower).

reflects the strength of the interaction between the two molecules of the duplex. T_m of a heteroduplex of PMO/RNA was compared to that of the corresponding PPMO/RNA. As shown in Table 3, T_m of the heteroduplexes of PMO_{CMYC}, PMO_{WNV}, or PMO_{705} with each of their complementary RNAs was 88.7, 74.8, or 74.1 °C, respectively. All corresponding PPMOs exhibited higher T_m's than the PMOs with values of 90.1, 78.8, and 80.1 °C, respectively. The differences in T_m between PMO/RNA and PPMO/RNA heteroduplexes were statistically significant ($p < 0.001$) as analyzed by the *t*-tests of GraphPad Prism software.

DISCUSSION

Throughout this study, we found that the antisense potency of PMO can be increased by conjugation to an ARP. This was demonstrated by the lower IC_{50} values of PPMOs than corresponding PMOs at inhibiting targeted RNA translation (Figure 2) and by a decrease of the inactivating length of PMOs (Table 2) in in vitro translation assays. These results were complemented by the demonstration in cultured cells that PMOs conjugated to less-degradable ARPs exhibited an increase in sequence-specific antisense activity compared to PMOs conjugated to a degradable ARP (Figure 5C,D). At higher concentrations, ARP conjugation to PMO caused greater nonspecific activity than the corresponding PMO alone. This conclusion was based on two specific observations: first inhibition of the translation of unrelated RNA in the in vitro translation assays by PPMO (Figure 3) and second inappropriately corrected pre-mRNA splicing in cultured cells when less degradable peptides were conjugated to partially complementary or noncomplementary scrambled PMO_{705} at concentrations ≥ 10 μM (Figure 5C,D). This nonspecificity was not observed in cell culture with PMO conjugated to the degradable peptide R9F2 at concentrations up to 20 μM.

We hypothesize that the increased antisense activity and nonspecificity of PPMOs compared to PMOs could be due to the following: the interactions between peptide and RNA strengthen the binding of peptide-conjugated PMOs to the targeted RNA, the peptide portion of the PPMO may provide additional steric blocking of the RNA, thus further hindering access of the RNA target to other biomolecules and thereby causing a higher degree of translation inhibition, or both. The thermal stability of the PPMO/RNA heteroduplexes was greater than that of PMO/RNA (Table 3), indicating that the binding strength between a PMO and its target RNA is enhanced by the presence of a conjugated ARP. An ARP conjugation accelerates the rate of association of a DNA oligo to its complementary DNA by 164-fold (*16*). The guanidine headgroups of an ARP have favorable binding with phosphate groups through bidentate hydrogen-bonding and electrostatic interactions (*17*, *18*). An ARP likely increases the association rate and decreases the dissociation rate of a PMO for its RNA, which accounts for the enhanced potency and off-target effects.

We investigated whether the peptide portion of PPMO provides additional interference with mRNA-binding translational components by comparing the activity of two PPMOs with the R9F2 peptide conjugated to either the 3′-end or the 5′-end of $PMO_{CMYC(I)}$ in an in vitro translation assay. The IC_{50} values of 3′-end and 5′-end conjugated $PMO_{CMYC(I)}$ were not much different from each other (Figure 2E). The data suggests that the peptide portion of PPMO does not increase potency of a PMO by interfering with a specific translational component.

The degree to which conjugation to an ARP increased PMO potency varies with the PMO sequence. This

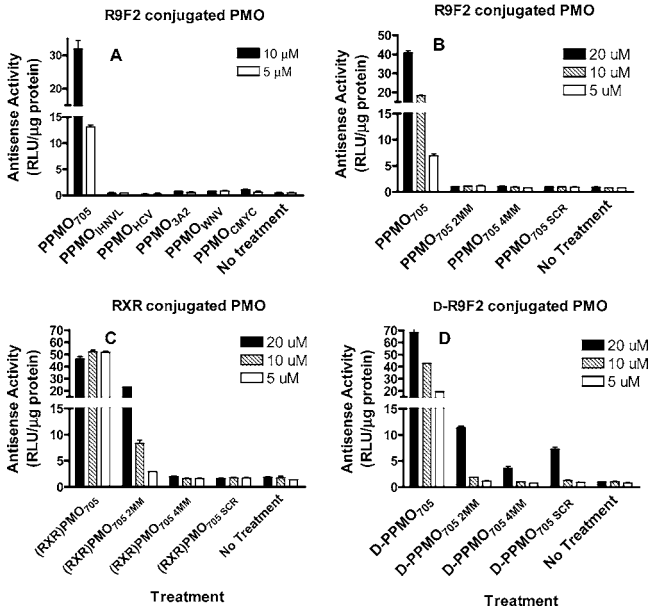

Figure 5. Antisense activity and specificity of PPMO in a cell-based splice-correction assay. R9F2-, RXR-, or D-R9F2-conjugated PMOs that were exactly (PMO_{705}), partially ($PMO_{705-2MM}$, $PMO_{705-4MM}$), or noncomplementary to the RNA target were tested in the splice-correction assay with HeLa pLuc 705 cells. Noncomplementary PMOs included PMO_{705} with scrambled bases ($PMO_{705-SCR}$) and PMOs that were unrelated to the RNA target (PMO_{IHNVL}, PMO_{HCV}, PMO_{WNV}, PMO_{CYP3A2}, and PMO_{C-MYC}): (A) $PPMO_{705}$ and unrelated PPMOs; (B) $PPMO_{705}$, $PPMO_{705-2MM}$, $PPMO_{705-4MM}$, and $PPMO_{705-SCR}$; (C) (RXR)-PMO_{705}, (RXR)$PMO_{705-2MM}$, and (RXR)$PMO_{705-SCR}$; (D) D-PP-MO_{705}, D-$PPMO_{705-2MM}$, D-$PPMO_{705-4MM}$, and D-$PPMO_{705-SCR}$. Cells were treated with a conjugate for 24 h in culture medium and then assayed for luciferase activity. Activity of a peptide−PMO conjugate in the splice-correction assay is indicated by increased production of the luciferase reporter over background level (no treatment). Data are represented as relative light units normalized to micrograms of total protein (RLU/μg of protein). Each data point was an average ± the range of means of two independent experiments each consisting of triplicate samples.

Table 3. PMO Conjugation to the R9F2 Peptide Increases the Thermal Stability of PMO/RNA Heteroduplex as Indicated by the Melting Temperatures of PMO or the Corresponding PPMO Heteroduplexed with Complementary RNA[a]

	PMO		PPMO		
	mean (SD), °C	n	mean (SD), °C	n	ΔT_m, °C
c-*myc* RNA	88.7 (0.1)	6	90.1 (0.5)	6	1.4
WNV RNA	74.8 (0.1)	6	78.8 (0.4)	6	4.0
705 RNA	74.1 (0.5)	5	80.1 (0.4)	5	6.0

[a] The data are reported as an average of the T_m, the standard derivation (SD), number of determinations (n), and the difference in T_m (ΔT_m) between the PPMO and PMO.

appears to correlate with the GC content and length of the PMO. PMOs with lower GC content had greater increases in T_m and greater decreases in IC_{50} after peptide conjugation. $PMO_{705(20mer)}$, PMO_{WNV}, and PMO_{CMYC} have GC contents of 40%, 45%, and 65%, respectively. Conjugation to the R9F2 peptide caused 6.0, 4.0, and 1.4 °C increase in T_m, respectively. PMO_{CMYC} and PMO_{HCV}, both with a high GC content of 65%, were least affected by peptide conjugation. PMO_{WNV}, with a GC content of 45%, the lowest among all PMO tested in the in vitro translation assays, was much affected by peptide conjugation, with a resultant 25-fold decrease in IC_{50} (Figure 2E).

To further verify the correlation between the GC content of PMO and the increase in efficacy generated by peptide conjugation, the inosine-substituted PMO_{CMYC} ($PMO_{CMYC(I)}$) and $PPMO_{CMYC(I)}$ were compared with the unsubstituted PMO_{CMYC} and $PPMO_{CMYC}$ in an in vitro translation assay. Unlike Watson−Crick pairing with perfect pairing geometry and triple hydrogen bonds between a G and a C, interaction between an I and a C form a wobble base pair with double hydrogen bonds. The inosine substitutions reduced the GC content of PMO_{CMYC} from 65% to 50% and decreased efficacy as shown by the increased IC_{50} value from 50 to 143 nM. $PMO_{CMYC(I)}$ had lower target binding affinity than PMO_{CMYC} as indicated by an 11 °C reduction in T_m (data not shown). Peptide conjugation had little effect on the IC_{50} of PMO_{CMYC} but caused significant change for $PMO_{CMYC(I)}$ with a 23-fold increase in efficacy compared to the corresponding PMO. This is consistent with the observed trend that PMOs with lower GC content have a larger IC_{50} shift upon conjugation.

ARP conjugation caused a greater increase in antisense activity for shorter-length than for longer-length PMOs. Reduction of the PMO_{3A2} length from 20 bases to 14 bases decreased its potency by 15-fold (Table 2). Conjugation to R9F2 peptide caused a larger increase in antisense potency for PMO_{3A2} 14mer than for PMO_{3A2} 20mer, evidenced by a 31- or 10-fold decrease in IC_{50} values, respectively (Table 2). Taken together, we conclude that the increase in antisense activity afforded by peptide conjugation depends, at least in part, on the intrinsic potency of the PMO to which it is conjugated, with a greater antisense enhancement effect when conjugated to a less potent PMO.

All PMOs tested in these studies exhibited a high degree of specificity (Figure 3); however, at higher concentrations, the ARP-conjugated PMOs exhibited considerable nonspecificity (Figures 3 and 5C,D). The electrostatic and hydrogen-bonding interactions between an ARP and RNA are not sequence-specific. When a high concentration of the PPMO was used, this nonspecific binding likely became more prominent and resulted in increased off-target effects. The degree of peptide-caused nonspecificity differed among various PPMOs against the same noncomplementary RNA target and also among a single PPMO against various RNA targets. There appears to be little correlation between the potency of a nonconjugated PMO and the degree of nonspecificity observed.

The nonspecificity observed in cell culture with (RXR)-PMO_{705} and D-$PPMO_{705}$, but not with $PPMO_{705}$ (Figure 5), is likely due to their relative stability toward proteases. Although cellular proteases degraded the R9F2 or $(RXR)_4$ portion of $PPMO_{705}$ or (RXR)PMO_{705} (Figure 4), the degradation rate for D-R9F2 and RXR peptide is likely significantly slower than that for L-R9F2. This conclusion is supported by the data of proteinase K or trypsin treatment. Treatment of $PPMO_{705}$ with proteinase K (Figure 4) or trypsin (data not shown) rapidly degraded L-R9F2, while the same treatment had slower effect on the (RXR)−PMO conjugate and had no effect on the D-R9F2−PMO conjugate. The intracellular rates of degradation of these conjugates are currently under investigation.

When an ARP is conjugated to a PMO for applications in cell culture or in vivo, several factors should be considered: (1) the intrinsic toxicity of the peptide, (2) the type of amino acids (e.g., D vs L) used in peptide synthesis, (3) the linker chemistry employed between peptide and PMO, and (4) experimental treatment conditions (e.g., concentrations of compound, duration of treatment, tissue culture conditions). ARPs have concen-

tration- and cell type-dependent cellular toxicity (*7*, *8*). Conjugating PMOs to a less degradable peptide made of unnatural amino acids through a noncleavable linker enhances specific antisense activity at lower concentrations but causes some nonspecificity at higher concentrations. The degree of nonspecificity caused by ARP conjugation depends on PMO sequences and RNA targets. To avoid the misinterpretation of cellular toxicity and nonspecific effects as an antisense effect, it seems advisable to use more than one irrelevant sequence control oligomer (preferably of roughly the same GC content and length) conjugated to the same peptide as the specific antisense compounds.

ACKNOWLEDGMENT

We thank Drs. Jon D. Moulton and Dan Mourich for critical reading of the manuscript. We are grateful to the chemistry team at AVI BioPharma for synthesis, purification, and analysis of peptides and PMOs.

Polyaspartamide Gadolinium Complexes Containing Sulfadiazine Groups as Potential Macromolecular MRI Contrast Agents

Guo-Ping Yan,*,† Mai-Li Liu,‡ and Li-Yun Li‡

School of Materials Science and Engineering, Wuhan Institute of Technology, Wuhan 430073, P. R. China, and State Key Laboratory of Magnetic Resonance and Atomic and Molecular Physics, Wuhan Institute of Physics and Mathematics, The Chinese Academy of Sciences, Wuhan 430071, P. R. China. Received February 1, 2005; Revised Manuscript Received May 16, 2005

Both diethylenetriaminepentaacetic acid (DTPA) and sulfadiazine (SD) were incorporated into polyaspartamides with different side chains, including poly-α,β-[*N*-(2-hydroxyethyl)-L-aspartamide] (PHEA), poly-α,β-[*N*- (3-hydroxypropyl)-L-aspartamide] (PHPA), poly-α,β-[*N*-(2-aminoethy1)-L-aspartamide] (PAEA), poly-α,β-[*N*-(4-aminobuty1)-L-aspartamide] (PABA), and poly-α,β-[*N*-(6-aminohexyl)-L-aspartamide] (PAHA). The polyaspartamide ligands containing DTPA and SD groups were further reacted with gadolinium chloride to give the corresponding macromolecular gadolinium complexes. Experimental data of ^{1}H NMR, IR, UV, and elemental analysis exhibited the formation of the polyaspartamide ligands and gadolinium complexes. Relaxivity studies indicated that the macromolecular chelates possess higher relaxivities than that of the clinically used Gd-DTPA. MR imaging showed that the macromolecular chelate PAEA-Gd-DTPA-SD greatly enhanced the contrast of MR images of hepatoma in the lower limb of mice and provided prolonged intravascular duration. Thus the polyaspartamide gadolinium complex containing SD groups is expected to be used as the potential macromolecular MRI contrast agents for hepatoma in mice.

INTRODUCTION

Magnetic resonance imaging (MRI) is a noninvasive clinical imaging modality, which relies on the detection of NMR signals emitted by hydrogen protons in the body placed in a magnetic field. MRI contrast agent is a unique class of pharmaceutical that enhances the image contrast between normal and diseased tissue and indicates the status of organ function or blood flow after administration by increasing the relaxation rates of water protons in tissue in which the agent accumulates (*1*−*3*).

The clinically used MRI contrast agents, for example, gadolinium diethylenetriaminepentaacetic acid (Gd-DTPA), are small ionic molecules that can diffuse freely through the extracellular space and are excreted rapidly by the kidney. Their biodistribution is nonspecific although Gd-DTPA works well in the brain and spinal cord (*4*, *5*). The binding of small gadolinium complex to a macromolecule has been shown to provide a mechanism of proton relaxation enhancement through longer rotational correlation times. The macromolecular MRI contrast agent thus obtained may show prolonged intravascular retention due to the bulky molecular volume, resulting in the clinical use as a blood pool contrast agent. In addition, when a tumor-targeting group is attached to this macromolecular metal chelate, it can be endowed with tumor-specific property (*3*, *6*).

Polyaspartamide is a water-soluble, biologically well-tolerated synthetic polymer with a protein-like structure that was used as a plasma extender and a drug carrier because it is nontoxic, nonantigenic, and degradable in living systems and modified readily by the reaction with the side chain (*7*, *8*). As reported, antiviral drugs and antiinflammatory agents were covalently linked to poly-α,β-[*N*-(2-hydroxyethyl)-D,L-aspartamide] (PHEA) forming drug−polymer conjugates capable of increasing drug stability and bioavailility. Therefore polyaspartamide can be used as polymer carriers for MRI contrast agents (*9*−*12*).

Sulfadiazine derivatives were reported to be concentrated into Walker carcinoma or Yoshida sarcoma by a factor of about 2−3 compared with the uptake in the liver (*13*−*14*). Previously we have used sulfadiazine (SD) as a tumor-selective group and evaluated Gd-DTPA derivatives containing SD groups as the potential tumor-specific contrast agents. The biodistribution and MRI studies indicated that the incorporation of SD into Gd-DTPA increased their uptake by hepatoma and Ehrlich ascites carcinoma in mice, and the gadolinium complexes exhibited tumor-selective properties (*15*).

In this work, the polyaspartamide ligands were synthesized by the incorporation of both DTPA and SD into polyaspartamides with different side chains. The ligands were further reacted with gadolinium chloride to give the corresponding polyaspartamide gadolinium complexes (Scheme 1). The polyaspartamide ligands and gadolinium complexes were characterized by ^{1}H NMR, IR, UV, and elemental analysis. Relaxivity and magnetic resonance imaging of hepatoma (H_{22}) in mice were evaluated.

EXPERIMENTAL PROCEDURES

Instrumentation and Materials. The compounds prepared were characterized using a Spectrum One infrared spectrophotometer, a Lambda Bio40 UV/Vis spectrophotometer, a Varian Mercury-VX300 NMR spectrometer, and a Carlo Erba 1106 analyzer. The molecular weight and polydispersity of polyaspartamide were measured by GPC [software version millemmium 32, Waters

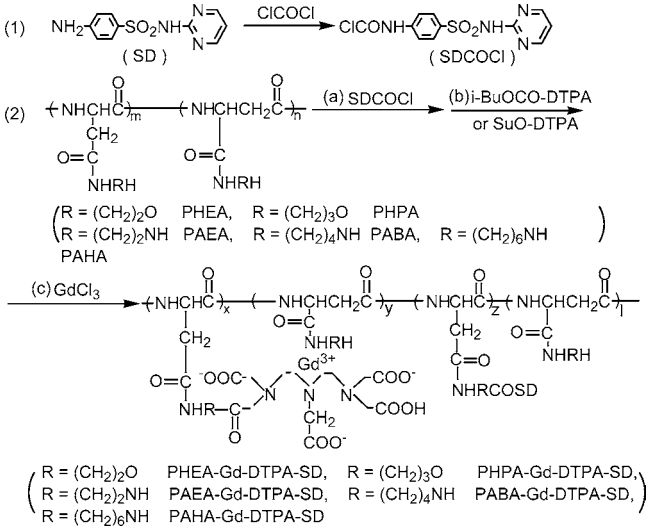
Scheme 1. Synthetic Route to Polyaspartamide MRI Contrast Agents



2960D separation module, Ultrahydrogel 2000 column, poly(Ethylene Glycol) standard, 0.1 M KH_2PO_4 solvent, 0.5 mL·min^{-1} flow, 35 °C column temperature and 30 °C detector temperature]. The concentration of the paramagnetic species [Gd^{3+}] was measured by an ICP Atomscan-2000 spectrometer. The solvent longitudinal relaxation time (T_1) for gadolinium complexes in distilled water was determined by a Varian Mercury-VX300 NMR spectrometer. MR image was performed on a 4.7 T BIOSPEC 47/30 MR Scanner (Bruker Medical, Ettlingen, Germany). KunMing mice bearing with hepatoma (H_{22}) in the right lower limb (weight: 30 ± 2 g) were provided by the Department of Pharmacy (School of Medicine, Huazhong University of Science and Technology, China) and were cultured according to the method described in the literature (*16*). Hepatoma (H_{22}) cells were provided by the China Center for Type Culture Collection of Wuhan University, China.

All the chemicals and solvents were of analytical grade. The solution of phosgene in toluene (2.0 M) (*17*), DTPA active ester including DTPA mono(carbonyloxyisobutyl ester) (i-BuOCO-DTPA) and DTPA mono(hydroxysuccinimidyl ester) (SuO-DTPA) (*18*), poly-α,*β*-[*N*-(2-hydroxyethyl)-L-aspartamide] (PHEA), poly-α,*β*-[*N*-(2-aminoethyl)-L-aspartamide] (PAEA), poly-α,*β*-[*N*-(3-hydroxypropyl)-L-aspartamide] (PHPA), poly-α,*β*-[*N*-(4-aminobutyl)-L-aspartamide] (PABA), and poly-α,*β*-[*N*-(6-aminohexyl)-L-aspartamide] (PAHA) (*19*) were prepared according to the literature.

Synthesis of Polyaspartamide Ligands. *Synthesis of PHEA-DTPA-SD and PHPA-DTPA-SD.* Sulfadiazine (SD, 1.0 g, 4 mmol) was dissolved in 20 mL of *N*,*N*-dimethylformamide (DMF) and 5 mL of pyridine. The mixture was added slowly to a solution of phosgene in toluene (10 mL) with rapid stirring at −10 °C to −5 °C. The reaction was stirred for 2 h at this temperature and a further 2 h at 0 °C under an argon atmosphere. After filtration, a brown solution of SDCOCl in DMF was obtained.

The solution of SDCOCl (4 mmol) in DMF obtained above was added slowly to a solution of PHEA (1.58 g, 10 mmol) in 40 mL of DMF and 8 mL of triethylamine with rapid stirring at 0 °C. The reaction was stirred for 4 h at 0 °C and a further 24 h at room temperature. After filtration, the filtrate was collected and cooled to −5 °C. The solution of DTPA mono(carbonyloxyisobutyl ester) (i-BuOCO-DTPA, 3.82 g, 8 mmol) in DMF (20 mL) was added dropwise to the filtrate at −5 °C. The reaction was continued stirring for 4 h at −5 °C and a further 48 h at room temperature. The resultant mixture was filtered and precipitated with ethanol and ethyl ether. The precipitate was reprecipitated from DMF using ethanol and ethyl ether, filtered, and dried under vacuum to yield a white polyaspartamide ligands containing DTPA and SD groups PHEA-DTPA-SD (M_1) (2.0 g, 30.1%). ^{1}H NMR (D_2O, δ, ppm): 8.1−7.7 (C_6H_4, $C_4N_2H_2$), 4.5, 4.2, 4.0 (CH, CH_2), 3.7(CH_2CO), 3.4−3.3(NCH_2CH_2N), 3.2, 3.0, 2.8, 2.6−2.4 ($NHCH_2$, CH_2); IR(KBr, cm^{-1}): 3426.6 (OH), 2975.7−2492.1 (C−H), 1711(COO), 1634.7(CONH), 1397.2, 1172.5(S=O), 1154.6(C−N), 1094.2 (C−O), 907.2, 840.3, 803.8(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 272.9.

The polyaspartamide ligands containing differing amounts of DTPA linked to polymeric repeat units were synthesized by the same method to give the following results PHEA-DTPA-SD (M_2, 28%) and PHPA-DTPA-SD (32%).

PHEA-DTPA-SD (M_2): ^{1}H NMR (D_2O, δ, ppm): 8.1−7.7 (C_6H_4, $C_4N_2H_2$), 4.5, 4.2, 4.0 (CH, CH_2), 3.7(CH_2CO), 3.4−3.3(NCH_2CH_2N), 3.2, 3.0, 2.8, 2.6−2.4 ($NHCH_2$, CH_2); IR(KBr, cm^{-1}): 3436.1(OH), 2975.4−2492(C−H), 1710(COO), 1637.4(CONH), 1474.2, 1433.9(C_6H_4, $C_4N_2H_2$), 1397.9, 1171.5(S=O), 1229.1(C−N), 1036.2 (C−O), 910.7, 849.1, 804.4(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 272.9.

PHPA-DTPA-SD: ^{1}H NMR (D_2O, δ, ppm): 8.2−7.7-(C_6H_4, $C_4N_2H_2$), 4.5, 4.2, 4.0 (CH, CH_2), 3.7(CH_2CO), 3.4−3.2(NCH_2CH_2N), 3.0, 2.8, 2.6−2.4 ($NHCH_2$, CH_2); IR(KBr, cm^{-1}): 3434.4(OH), 2975.3−2491.9(C−H), 1713(COO), 1636.0(CONH), 1474.5, 1434.1(C_6H_4, $C_4N_2H_2$), 1397.9, 1171.3(S=O), 1229.4(C−N), 1036.2 (C−O), 909.8, 849.1, 804.4(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 268.

Synthesis of PAEA-DTPA-SD, PABA-DTPA-SD and PAHA-DTPA-SD. The solution of SDCOCl (4 mmol) in DMF obtained above was added slowly to a solution of PAEA (1.57 g, 10 mmol) in 100 mL of distilled water and 8 mL of triethylamine with rapid stirring at −5 °C. The reaction was stirred for 4 h at −5 °C and a further 24 h at room temperature. After filtration, the filtrate was collected and cooled to −5 °C. The solution of DTPA mono(hydroxysuccinimidyl) ester (SuO-DTPA, 3.92 g, 8 mmol) in DMF (20 mL) was added dropwise to the filtrate at −5 °C. The reaction was continued stirring for 4 h at −5 °C and a further 48 h at room temperature. The resultant mixture was filtered and precipitated with ethanol and ethyl ether. The precipitate was reprecipitated from distilled water using ethanol and ethyl ether, filtered, and dried under vacuum to yield a white polyaspartamide ligands containing DTPA and SD groups PAEA-DTPA-SD (M_1) (2.1 g, 31.2%). ^{1}H NMR (D_2O, δ, ppm): 8.0−7.6 (C_6H_4, $C_4N_2H_2$), 4.5, 4.2, 4.0 (CH, CH_2), 3.7(CH_2CO), 3.4−3.1(NCH_2CH_2N), 3.0−2.8, 2.8−2.4, 2.4−2.2($NHCH_2CH_2NH$); IR(KBr, cm^{-1}): 3433.4(NH_2), 3071.2−2932.3(C−H), 1711(COO), 1644.4, 1545.4(CONH), 1435.3-(C_6H_4, $C_4N_2H_2$), 1398.7, 1171.7(S=O), 1321.5(C−N), 1090.3(C−O), 912.4, 849.1, 800.4(C_6H_4, $C_4N_2H_2$); UV-(H_2O, nm): 301.8.

The polyaspartamide ligands containing differing amounts of DTPA linked to polymeric repeat units were synthesized by the same method to give the following results PAEA-DTPA-SD (M_2, 29.2%), PABA-DTPA-SD (33%) and PAHA-DTPA-SD (33.5%).

PAEA-DTPA-SD (M_2): ^{1}H NMR (D_2O, δ, ppm): 8.0−7.6 (C_6H_4, $C_4N_2H_2$), 4.5, 4.2, 4.0 (CH, CH_2), 3.8(CH_2CO), 3.6−3.2(NCH_2CH_2N), 3.2−3.0, 2.8, 2.6−2.4 ($NHCH_2CH_2$-NH); IR(KBr, cm^{-1}): 3398.2(NH_2), 3057.3−2927.6(C−H), 1709(COO), 1648.1, 1535.3(CONH), 1432(C_6H_4, $C_4N_2H_2$),

1394.8, 1174.0(S=O), 1236.9(C−N), 1088.1(C−O), 909.1, 848.1, 800.4(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 301.8.

PABA-DTPA-SD: ^{1}H NMR (D_2O, δ, ppm): 8.1−7.6 (C_6H_4, $C_4N_2H_2$), 4.5, 4.1, 4.0 (CH, CH_2), 3.7(CH_2CO), 3.4−3.3(NCH_2CH_2N), 3.0, 2.8, 2.6−2.4 ($NHCH_2$, CH_2); IR(KBr, cm^{-1}): 3445.2(NH_2), 2975.6−2491.8(C−H), 1708.6(COO), 1634.8, 1535.3(CONH), 1473.9, 1434.0(C_6H_4, $C_4N_2H_2$), 1397.9, 1171.1(S=O), 1226.8(C−N), 1036.1(C−O), 909.1, 849.6, 805.0(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 268.5.

PAHA-DTPA-SD: ^{1}H NMR (D_2O, δ, ppm): 7.9−7.7 (C_6H_4, $C_4N_2H_2$), 4.5, 4.1, 4.0 (CH, CH_2), 3.8(CH_2CO), 3.5−3.3(NCH_2CH_2N), 3.0, 2.8, 2.6−2.4, 2.2 ($NHCH_2$, CH_2); IR-(KBr, cm^{-1}): 3436.2(NH_2), 3063.9−2934.2(C−H), 1714-(COO), 1641.7, 1541.5(CONH), 1435.3(C_6H_4, $C_4N_2H_2$), 1395.5, 1177(S=O), 1229.1(C−N), 1047.9(C−O), 907.8, 850, 804(C_6H_4, $C_4N_2H_2$); UV(H_2O, nm): 291.

Preparation of Polyaspartamide Gadolinium Chelates. The polyaspartamide gadolinium complexes with differing amounts of Gd-DTPA linked to polymeric repeat units and differing polymers were synthesized according to the following standard procedure. PHEA-DTPA-SD (M_1, 1.08 g, 5 mmol) was dissolved in 20 mL of distilled water and gadolinium chloride ($GdCl_3$, 1.98 g, 7.5 mmol) was added. The mixture was stirred for 1 h, adjusted with 2 M NaOH solution to pH 5, and continued to stir for 12 h at room temperature. After dialysis, the dialyzed solution was evaporated and the solid residue was dried under vacuum to yield polyaspartamide gadolinium complex PHEA-Gd-DTPA-SD (M_1, 1.18 g, 73.5%). PHEA-Gd-DTPA-SD (M_2, 65%), PHPA-Gd-DTPA-SD (74%), PAEA-Gd-DTPA-SD (M_1, 77%), PAEA-Gd− DTPA-SD (M_2, 71%), PABA-Gd-DTPA-SD (72%) and PAHA-Gd-DTPA-SD (68%) were similarly synthesized.

PHEA-Gd-DTPA-SD (M_1): IR(KBr, cm^{-1}): 3445.2(OH), 2932.2(C−H), 1659.0, 1642.0 (COO, CONH), 1542.1(C_6H_4, $C_4N_2H_2$), 1411, 1155(S=O), 1261.8(C−N), 1059.8(C−O), 930.8, 868.2, 801.0(C_6H_4, $C_4N_2H_2$). Elem. Anal.(%) found (calcd): C 42.40(42.70), N 15.59(15.70), H 5.73(5.69). The average mole ratio of attached Gd-DTPA and SD to all polymeric repeat units (mol %): Gd-DTPA 7.93 (as determined by an ICP Atomscan-2000 spectrometer), SD 0.57 (as determined by ^{1}H NMR); UV(H_2O, nm): 272.9.

PHEA-Gd-DTPA-SD (M_2): IR(KBr, cm^{-1}): 3431.3(OH), 2927.7(C−H), 1646.9, 1658.3, 1555.6(COO, CONH), 1542.1, 1435.5(C_6H_4, $C_4N_2H_2$), 1409.4, 1091.8(S=O), 1265.6(C−N), 1057.2(C−O), 931.8, 867, 801(C_6H_4, $C_4N_2H_2$). PAHA-Gd-DTPA-SD: IR(KBr, cm^{-1}): 3434.2(NH_2), 3078.9, 2933.7, 2860.8(C−H), 1658.3, 1647.0, 1601, 1542.3-(COO, CONH), 1473.2, 1437.3(C_6H_4, $C_4N_2H_2$), 1399.3, 1121.4(S=O), 1322.4, 1270.9(C−N), 1092.8(C−O), 930.5, 866.5, 800.8(C_6H_4, $C_4N_2H_2$). Elem. Anal.(%) found (calcd): C 51.48(51.78), N 17.56(17.66), H 7.81(7.79). The average mole ratio of attached Gd-DTPA and SD to all polymeric repeat units (mol %): Gd-DTPA 8.86 (as determined by an ICP Atomscan-2000 spectrometer), SD 2.59 (as determined by ^{1}H NMR); UV(H_2O, nm): 291.

Relaxivity. In the absence of solute−solute interactions, the solvent relaxation rates are linearly dependent on the concentration of the paramagnetic species ([M]); Relaxivity, r_1, is defined as the slope of this dependence (*2*):

$$(1/T_1)_{obsd} = (1/T_1)_d + r_1[M]$$

where $(1/T_1)_{obsd}$ is the observed solvent relaxation rate in the presence of a paramagnetic species, $(1/T_1)_d$ is the solvent relaxation rate in the absence of a paramagnatic species. In this experiment, the concentrations of the paramagnetic species [Gd^{3+}] were measured by an ICP Atomscan-2000 spectrometer. The solvent longitudinal relaxation time (T_1) for gadolinium complexes were carried out on a 10^{-3} M solution of gadolinium complexes in distilled water. Thus r_1 for gadolinium complexes in distilled water could be calculated.

MR Imaging. KunMing mice bearing hepatoma (H_{22}) in the right lower limb (weight: 30 ± 2 g) were anesthetized with 10% urethane solution (10 mL/kg), positioned prone and fixed to a polystyrene cradle with adhesive tape to minimize the motion. After performing nonenhanced MR imaging, a solution of PAEA-Gd-DTPA-SD (M_1, 0.1 mmol/kg) in 0.9% sodium chloride was injected via the tail vein. Coronal images of the right lower limb were obtained with a T_1-weighted spin−echo sequence [Repetition time (TR) 500 ms, echo time (TE) 15 ms, the field of view is 40 mm, with an image matrix of 128×128. Six slices were taken and slice thickness was 2 mm, with a 1 mm interslice gap.].

Statistical Analysis. Six T_1-weighted image slices were taken for the hepatoma in the right lower limb of each mouse. The top and bottom slices were not included in the data analysis to prevent confounding partial volume effects at the edges of the tumors. The average

relative signal intensities (pre-injection and postinjection at different times) within the region of interest were normalized to the water label background ($RI_{background}$) at each of the imaging conditions. The percentage of contrast enhancement in the signal from the tumors was calculated according to the following

$$\text{enhancement (\%)} = 100\%\ (RI_{post} - RI_{pre})/(RI_{pre} - RI_{background})$$

RESULTS AND DISCUSSION

A series of water-soluble polyaspartamide ligands PHEA-DTPA-SD, PHPA-DTPA-SD, PAEA-DTPA-SD, PABA-DTPA-SD, and PAHA-DTPA-SD were synthesized and their gadolinium complexes were also prepared. The ^{1}H NMR and UV spectra showed the characteristic peaks of benzene group, indicating that sulfadiazine was covalently bound to polyaspartamide (Table 1). The IR spectra of the free polyaspartamide ligands showed characteristic absorption peaks of carboxyl with 1715−1630 cm^{-1}, while these peaks disappeared and strong absorption peaks with 1660−1540 cm^{-1} were present in IR spectra of their gadolinium complexes. Thus the results exhibited the formation of gadolinium complexes. Moreover, the average mole ratio of attached DTPA to polymeric repeat units increased and the amount of gadolinium ion in the polyaspartamide complexes became larger as the mole ratio of DTPA active ester/(polymeric repeat units) in feed in the reaction process increased.

Macromolecular MRI contrast agents usually exhibit more effective relaxation rates than that of the low molecular weight metal complexes alone and improve the relaxivity per gadolinium atom due to a slowly tumbling systems and an increase in rotational correlation time. Table 2 illustrated that polyaspartamide gadolinium chelates containing SD groups possessed higher relaxivities than that of Gd-DTPA.

The T_1-weight images of hepatoma at various points in time are shown in Figure 1. Compared to those mice receiving no injection of MRI contrast agent, the signal intensities (SI) of the tumors in mice injected with PAEA-Gd-DTPA-SD (M_1, 0.1 mmol/kg) were obviously enhanced, the irradiated portion of the tumors was brighter and the demarcation became clearer during the detection time, while those of the surrounding tissues, such as the muscle in the lower limb, showed a little change.

Two hours after injection with PAEA-Gd-DTPA-SD (M_1), the signal in hepatoma in mice were still enhanced

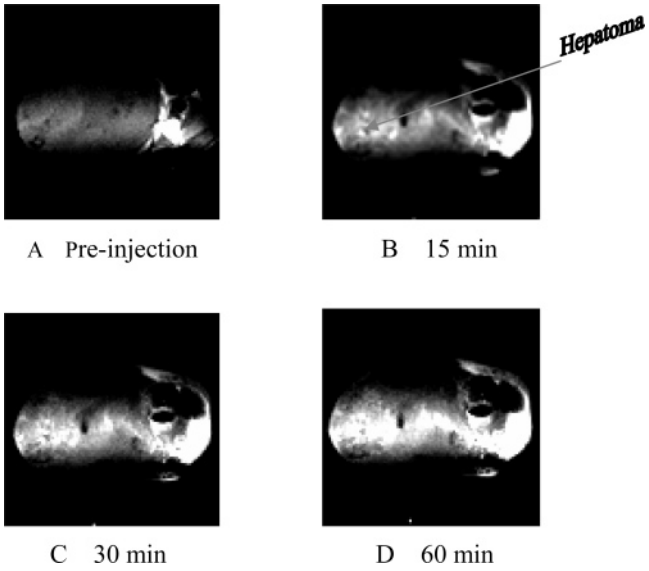

Figure 1. A is the T_1-weighted image of the right lower limb of mice with H_{22} receiving no MRI contrast agent; B, C, and D are the T_1-weighted images of the right lower limb of mice with H_{22} which received injection with PAEA-Gd-DTPA-SD (0.1 mmol/kg) after 15 min, 30 min, and 60 min, respectively.

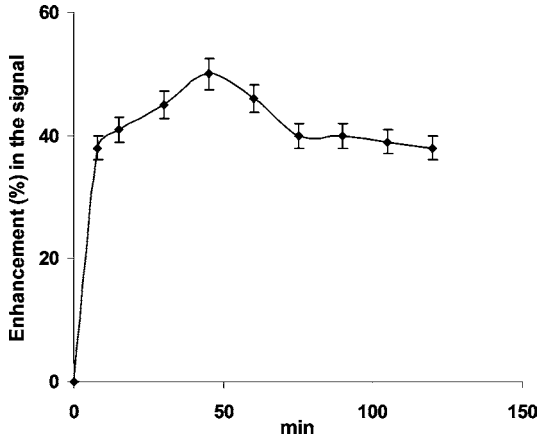

Figure 2. Signal enhancement (%) of the tumors in mice at different times after injection with PAEA-Gd-DTPA-SD (M_1, 0.1 mmol/kg).

by 138%, indicating it had a prolonged intravascular duration time in tumors of approximately 2 h (Figure 2). Thus the polyaspartamide gadolinium chelates containing SD groups could provide the prolonged enhancement of the tumors (Figure 2).

In summary, polyaspartamide gadolinium complexes containing sulfadiazine groups possess higher relaxation effectiveness than Gd-DTPA. MR imaging showed that PAEA-Gd-DTPA-SD (M_1) greatly enhanced the contrast of MR images of hepatoma in the lower limb of mice and provided prolonged intravascular duration. Thus the polyaspartamide gadolinium chelate is expected to be used as the potential macromolecular MRI contrast agents for hepatoma in mice.

Received March 9, 2005; Revised Manuscript Received June 13, 2005

A carboxyl-terminated *N*-isopropylacrylamide/vinyl laurate (VL) copolymer was prepared and coupled with chitosan (molecular weight = 2000) to produce a chitosan–NIPAAm/VL copolymer (PNVLCS) vector. The aqueous solution of PNVLCS displayed an obvious thermoresponsive behavior with a lower critical solution temperature (LCST) about 26 °C. The transmission electron microscopy (TEM) showed that the size of PNVLCS/DNA complexes varied with charge ratios (+/−), and the smaller nanoparticles were formed at higher charge ratios. DLS revealed that the size of complex particles was dependent on temperature. The results of temperature-variable circular dichroism (CD), UV, and electrophoresis retardation indicated that at lower charge ratios, DNA in the complexes assume a B conformation, whereas increasing charge ratios caused B → C type conformation transformation; the dissociation–formation of PNVLCS/DNA complexes could be tuned by varying temperature: at 37 °C, the collapse of PNIPAAm in PNVLCS was favorable for the formation of compact complexes, shielding more DNA from exposure; at 20 °C, the hydrated and extended PNIPAAm chains facilitated the unpacking of DNA from PNVLCS, increasing the exposure of DNA. PNVLCS was used to transfer plasmid-encoding β-galactosidase into C_2C_{12} cells. The level of gene expression could be controlled by varying incubation temperature. The transfection efficiency of PNVLCS was well improved by temporarily reducing culture temperature to 20 °C, whereas naked DNA and Lipofectamine 2000 did not demonstrate the characteristics of thermoresponsive gene transfection.

INTRODUCTION

In the past decade, much progress has been made in the study of chitosan (CS)-based nonviral vectors for gene transfection, and many encouraging results have been acquired (*1*–*4*). To further improve gene transfection level, a variety of strategies were reportedly employed recently, such as coupling deoxycholic acid (*5*), galactose (*6*), poly(vinyl pyrrolidone) (*7*), and urocanic acid (*8*) to chitosan. Although there were reports supporting that the modification of chitosan could really increase the transfection efficiency of chitosan–DNA complexes, and there was even in vivo study on using chitosan as a vector for gene therapy (*9*, *10*), the transfection efficiency of chitosan is relatively lower compared with that of liposome (*11*, *12*).

Like conventional polycationic vectors, chitosan forms polyelectrolyte complex (PEC) with DNA through electrostatic interaction between primary amino and phosphate groups. The strong electrostatic interaction is favorable for the formation of PEC, but on the other hand, it prevents gene dissociation from its carrier in nucleus, impeding the access of RNA polymerase to DNA so that gene expression level is decreased (*13*).

To weaken the electrostatic attraction of chitosan with DNA, long hydrophobic alkyl side chains were incorporated into chitosan, and transfection efficiency was increased with elongating the length of side chains. It was considered that the hydrophobic chains promoted the cell entry and the unpacking of genes from alkylated chitosan vector (*14*), but the alkylated chitosans were insensitive to environment, so gene expression could not be controlled by varying external stimuli. To fulfill this objective, Hennink's team explored the feasibility of thermosensitive poly(*N*-isopropylacrylamide)(PNIPAAm) copolymer as a smart gene delivery vector (*15*). They merely investigated the influence of temperature on the stability of the complexes, but not on temperature-dependent gene transfection. Recently, Kurisawa et al. reported a thermoreversible terpolymer vector, poly(*N*-isopropylacrylamide (NIPAAm)-*co*-2-(dimethylamino)-ethyl methacrylate DMAEMA)-*co*-butyl methacrylate (BMA)) (*16*). It was found that at a temperature above LCST of this copolymer, a tight copolymer/pCMV-lacZ plasmid DNA complex was formed, which was beneficial for the cellular uptake and protection of DNA from DNase attack. While lowering incubation temperature below LCST, the gene dissociated from its carrier, improving gene transfection even with small doses of DNA. Both branched and linear polyethyleneimines (PEI) have been extensively used to transfect a variety of cells in vitro and in vivo (*17*, *18*). But its significant toxicity has been a bottleneck for its clinical application (*19*, *20*). Türk et al. prepared temperature-sensitive PNIPAAm-*b*-PEI copolymers (*21*). The copolymerization with PNIPAAm reduced the cytotoxicity of branched PEIs with higher molecular weights, and PNIPAAm/PEI25L (linear PEI with molecular weight of 25 kDa) did not show any

significant toxicity. At body temperature, this copolymer vector could ferry more DNA into Hela cells. In particular, PEI25L obtained the most successful gene expression with low toxicity. Novel smart gene vectors of poly(L-lysine)-*graft*-poly(*N*-isopropylacrylamide) were also designed by Oupický et al. (*22*). It was demonstrated that the structural density and surface charge of the copolymer/DNA complexes could be adjusted by temperature. Moreover, it increased as the PNIPAM grafts collapsed above their phase transition temperature. In addition, more DNA tended to be released from polyelectrolyte complexes in the presence of PNIPAAm with addition of heparin.

To our best knowledge, research work on controllable gene expression of chitosan-based vectors has not been reported yet in the literature to date. In this study, we synthesized carboxyl-terminated NIPAAm/vinyl laurate (VL) random copolymer and coupled PNIPAAm/PVL to chitosan to generate a thermoresponsive CS−NIPAAm/VL (PNVLCS) copolymer vector. The PNVLCS was investigated as temperature-sensitive transgene vector for the first time. The temperature-dependent physicochemical properties of PNVLCS−DNA complexes were elucidated in detail. This copolymer vector was applied to the mediation of plasmid DNA transfection into C_2C_{12} cells, and the control of gene expression was examined at varied temperatures.

EXPERIMENTAL SECTION

Materials. *N*-Isopropylacrylamide (NIPAAm, Aldrich Chemical. Co.) was purified by recrystallization in hexane and dried in vacuo at 25 °C. Vinyl laurate (VL) was purchased from Fluka. The chain transfer agent, thioglycolic acid (TGA) (Sigma) was utilized to include carboxylic acid ends to the copolymer chains. The initiator, 2,2′-azoisobutyronitrile (AIBN) was recrystallized from methanol. Chitosan (degree of deacetylation = 80.3%, molecular weight = 2 kDa) was supplied by Qingdao Haihui Bioengineering Ltd. China. The water-soluble activating agent, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDAC) was obtained from Sigma. Plasmid pTracer-CMV/Bsd/*lacZ* and Lipofectamine 2000 reagent were provided by Invitrogen. Ethidium bromide (EB) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TEMED) were provided by Fluka. All other reagents used were analytical grade and used as received.

C_2C_{12} cells were maintained in Dulbecco's Modified Eagles Medium (DMEM, Sigma) supplemented with L-glutamine, penicillin/streptomycin, and 10% fetal bovine serum. Cells were incubated at 37 °C in a humidified atmosphere containing 5% CO_2 and used at appropriate degrees of confluence.

Synthesis of Copolymers. First, the carboxylic acid-terminated copolymer of NIPAAm and vinyl laurate (PNVLCOOH) was synthesized by a free radical polymerization in THF. *N*-Isopropylacrylamide(2.0 g), vinyl laurate(0.98 g), TGA (50 μL), and AIBN (20 mg) were dissolved in THF (25 mL). Polymerization was conducted under nitrogen-atmosphere, in a sealed reactor placed into a thermostated oil bath at 65 °C for 8 h. Once cooled to room temperature, the solution was added to excess amount of diethyl ether to precipitate PNVLCOOH. To remove the impurities in precipitated copolymer, dissolution−precipitation procedure was repeated three times, and the resultant precipitate was dried in a vacuum overnight.

Second, PNVLCOOH was coupled to chitosan (CS) by the reaction of the carboxylic acid groups activated with EDAC with the amine groups of chitosan. Chitosan (2.2 g) was dissolved in TEMED/HCl buffer (pH4.8, 25 mL) at 10 °C, and PNVLCOOH(1.5 g) was added to the solution. After 0.21 g of EDAC was added, the solution was stirred at 10 °C for 10 h. For purification, the solution of copolymer was raised to 28 °C, and the precipitate was collected by centrifugation (15000 rpm for 5 min) at 28 °C. Other water-soluble impurities in precipitate were removed by dialysis (MWCO 3500) against deionized water for 5 days at 4 °C. The final copolymer (PNVLCS) was recovered by lyophilization of the dialyzed solution.

PNVLCS/DNA Complexes Formation. To ensure that chitosan in PNVLCS was positively charged, PNVLCS was dissolved in 0.1 M sodium acetate/0.1 M acetic acid buffer (pH 5.4) to form a solution of 1.0 mg/mL, and 0.1 mg/mL of DNA solution was prepared in the same way. A series of PNVLCS/DNA complexes at various charge ratios were prepared by mixing PNVLCS solutions with a DNA solution, vortexing for 15 s, and incubating for 30 min at 37 °C prior to characterization use. It was noted that during complex preparation, the volume of DNA was constant and the volume of PNVLCS solution was varied to adjust the theoretical charge ratio (+/−) (molar ratio of amine to phosphate groups). All complexes for the characterization below were prepared in terms of this method unless otherwise statement.

FTIR Analysis. The solutions of chitosan, PNVLCOOH, and PNVLCS were poured into freshly cleaned plastic dishes and maintained in a vacuum overnight at 50 °C for film formation. FTIR spectra of the samples were measured over 4000−800 cm^{-1} on a Bio-Rad FTS 135 spectrophotometer.

^{1}H NMR Spectroscopy. To estimate the composition ratios of copolymers, ^{1}H NMR spectra of PNVLCOOH and PNVLCS were measured at ambient temperature with a Varian UNITY plus-400 NMR spectrometer using D_2O as a solvent.

Gel Permeation Chromatography (GPC). The molecular weights and molecular weight distributions of PNVLCOOH and PNVLCS were determined by gel permeation chromatography(GPC Waters 510/M32) using water as a mobile phase. Monodisperse polystyrene (Polymer Laboratories Inc., MA) was used for calibration. GPC analysis showed $\overline{M}_n$ = 3079, PDI = 1.66 (PNVLCOOH) and $\overline{M}_n$ = 4715, PDI = 1.37 (PNVLCS). Noted that the measured molecular weight is lower than theoretical value, 5079. This discrepancy is probably from polystyrene calibration standard and aggregation of NIPAAm−VI chains.

Determination of LCST of Polymer Solution. The variation in the turbidity of 1.0 wt % aqueous copolymer solutions was monitored as a function of temperatures at a fixed wavelength of 500 nm on a UV PC2501 UV−vis spectrophotometer equipped with a circulating water bath. The LCSTs were taken at the inflection point in the curves of optical density versus temperature.

Transmission Electron Microscopy(TEM). The morphology and size of PNVLCS/plasmid DNA complexes at different charge ratios (+/−) were observed using a JEOL JEM-100CXII TEM. First, one drop of the complexes was deposited on carbon-coated grids. After 5 min on the grids, 1.5% phosphotungstic acid (PTA) was added immediately to negatively stain the complexes for additional 5 min, and then the complexes were recorded on films with TEM.

Dynamic Light Scattering (DLS). Particle size of PNVLCS/DNA complexes was measured by dynamic

light scatting (DLS). DLS measurement was carried out with an argon ion laser system tuned at 514 nm. The complex solutions were filtered through a 0.45 μm filter (Millipore) directly into a freshly cleaned 10 mm-diameter cylindrical cell. The intensity of autocorrelation was measured at a scattering angle (θ) of 90° with a Brookhaven BI-9000AT digital autocorrelator at room temperature. When the difference between the measured and the calculated baselines was less than 0.1%, the correlation function was accepted. The mean diameter was evaluated by the Stokes−Einstein relationship. In this experiment, particle size of complexes was determined at 20 and 37 °C, respectively.

Circular Dichroism (CD). Samples were prepared at various PNVLCS/DNA charge ratios with DNA concentration of 40 μg/mL. Then the solutions were diluted with 0.1 M sodium acetate/0.1 M acetic acid buffer to a final DNA concentration of 1.1×10^{-4} M. CD spectra were collected in a 1 cm path length cuvette using a J-7150 spectropolarimeter in a range of wavelengths of 320−180 nm at 20 and 37 °C, respectively. Measurements were performed with a speed of 20 nm/min and a resolution of 0.5 nm. The spectra were corrected by subtracting the background of sodium acetate/acetic acid buffer, and three spectra were accumulated and averaged for each sample. The CD signal was converted to molar ellipticity [θ], deg·cm^2/dmol.

Temperaure-Variable UV. Temperaure-variable UV spectrophotometer was used to analyze the formation and dissociation of PNVLCS/DNA complex. The complexes at various charge ratios (+/−) were prepared by mixing different amount of PNVLCS solution with 3 μL of plasmid DNA solution. The total volume of the complexes was adjusted to 1 mL before incubation. The absorbance of the complexes at 20 °C and 37 °C was separately recorded at 260 nm on UV-2501PC spectrophotometer. The solvent was used as blank reference.

Gel Retardation Assay. PNVLCS/DNA complexes with varied charge ratios were prepared as mentioned above. The complex formation was carried out for 30 min at 20 and 37 °C, respectively. Aliquots of the complex solutions were loaded onto 0.6 wt % agarose gel (100V), and DNA bands were visualized by ethidium bromide staining. These gel assays were performed at temperature below and above LCST of PNVLCS solution for 20 min.

In Vitro Gene Expression. Preparation and Purification of Plasmid. Plasmid pTracer-CMV/Bsd/*lacZ* was amplified in *E. coli* and then prepared and purified using Wizard Purification Plasmid DNA Purification System (Promega). DNA concentration and purity were assessed via UV optical intensity at 260 nm and 280 nm. The plasmid DNA was stored at −20 °C until transfection experiments.

Cell Transfection. C_2C_{12} cells, a mouse myoblast cell line derived from mouse skeletal muscle, were used in this experiment considering that (1) this cell line has been shown to be a suitable host for stable transfection of exogenes (*14*); (2) C_2C_{12} myoblast has proved to be capable of synthesizing some osteogenesis factors (*23*) and secreting the hormone or growth factors (*24*). Thus for our future gene therapeutic application, a target gene will be delivered into muscle cells within the cavum articulare by PNVLCS vector to treat cartilage injury.

C_2C_{12} cells were seeded at a concentration of 6×10^4/mL, 0.5 mL/well, in 24-well plate. These wells were then incubated at 37 °C in 5% CO_2 for 24 h in DMEM supplemented with fetal bovine serum (FBS) and antibiotics. Before transfection the medium in each well was removed, and rinsed with fresh DMEM (without FBS and antibiotics). Then the transfection solutions (containing PNVLCS/DNA complexes described above) were placed in each well and left in the CO_2 incubator. Three hours later, the medium containing complex solution was removed and then incubated in fresh DMEM medium supplemented with FBS and antibiotics at different temperatures and times: (1) 45 h at 37 °C, and (2) 18 h at 37 °C + 3 h at 20 °C + 24 h at 37 °C.

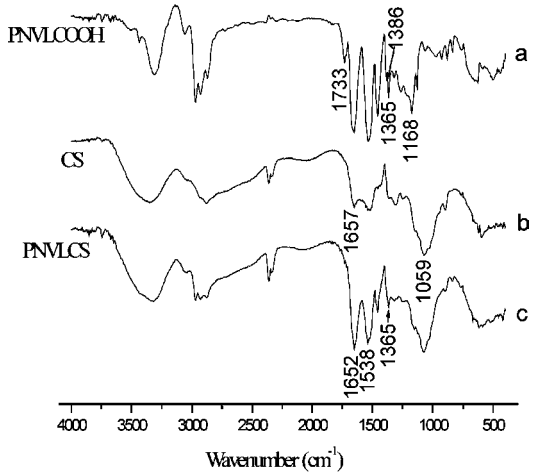

Figure 1. FTIR spectra of PNVLCOOH (a), chitosan (b), and PNVLCS (c).

After the incubation was finished, the activity of β-galactosidase in transfected cells was determined using β-Galactosidase Enzyme Assay System with Reporter Lysis Buffer (Promega, Madison, WI). The cells were washed twice with PBS and harvested with reporter lysis buffer. The β-galactosidase activity in transfected cells was measured at wavelength 450 nm by plate-reader of Labsystem using *o*-nitrophenyl-β-D-galactopyranoside (ONPG) as substrate. Cell lysates and a series of protein standard solutions prepared with bovine serum albumin (BSA) were subjected to BCA Protein Assay (Pierce, Rockford, IL) to quantify the total amount of protein in the transfected cells. The transfection efficiency was evaluated as the β-galactosidase expression level per microgram of cellular protein harvested (milliunit/mg protein). For comparison, the naked DNA and Lipofectamine 2000 were used as controls. The ratio of Lipofectamine 2000 to DNA was 2 μL/1 μg according to the recommended protocol. Each transfection experiment was carried out in triplicate.

Statistical Analysis. Both Student's t-test and one-way ANOVA with post hoc tests were used to evaluate the thermoresponsive transfection efficiency with $P < 0.05$. The transfection efficiency at constant 37 °C was treated as a control.

RESULTS AND DISCUSSION

Characteristics of PNVLCS Copolymer. The FTIR spectra of the PNVLCOOH, chitosan, and PNVLCS are given in Figure 1. As shown in Figures 1a and 1c, the amide peaks of NIPAAm units appear at 1650−1660 cm^{-1} (C=O stretching, amide I), 1530−1540 cm^{-1} (N−H bending, amide II), and 3420−3550 cm^{-1} (N−H stretching). A C=O stretching peak (related to carboxylic acid unit and ester unit of vinyl laurate) appears at 1730−1740 cm^{-1} in Figure 1a. This peak decreases when the copolymerization between PNVLCOOH and CS occurred (in Figure 1c). The bands at 1365 and 1386 cm^{-1} are attributed to the deformation of the two methyl groups in isopropyl groups (*25*). In the chitosan spectrum (Figure

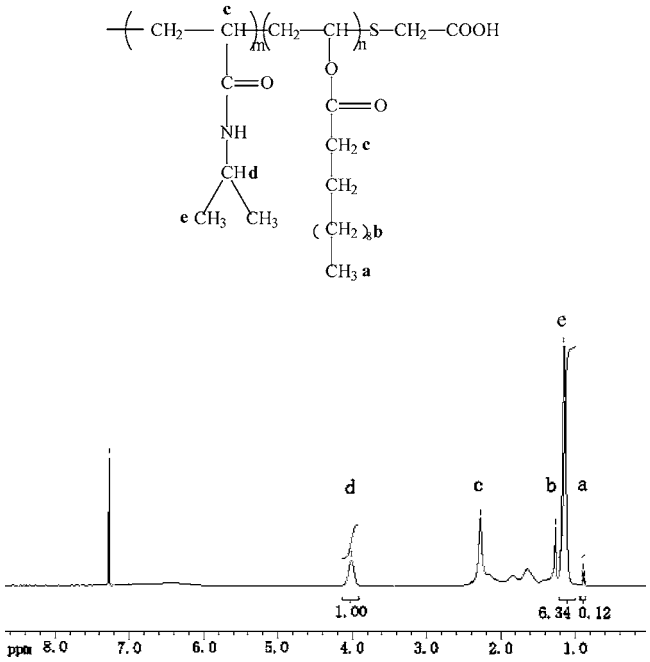

Figure 2. ^{1}H NMR spectrum of PNVLCOOH (in D_2O). The composition ratio(NIPAAm/VL, mol/mol) of PNVLCOOH is determined by comparing the peak areas of d and a in the spectrum.

1b), the characteristic absorbance of amide I is around 1657 cm^{-1}, and C−O stretching peak of pyranose ring is at 1029−1071 cm^{-1} (*26*), whose appearance in Figure 1c indicates the introduction of the chitosan unit into the copolymer chain.

The ^{1}H NMR spectrum of PNVLCOOH is depicted in Figure 2. It is evident that the peaks of NIPAAm and VL are well resolved (*27*, *28*), so the composition ratio (NIPAAm/VL, mol/mol) of PNVLCOOH is determined by comparing the peak areas of d and a in ^{1}H NMR spectrum, which represent the proton of the isopropyl CH in NIPAAm and the CH_3 of laurate (*28*), respectively. The calculated NIPAAm/VL composition ratio is 25:1, suggesting that only partial VL monomer reacted with NIPAAm supposedly due to its low reactivity caused by its steric hindrance of long alkyl chain (the actual feed ratio is 4:1). Noted that in Figure 2, the structure of PNVLCOOH does not necessarily reflect the single case of chain transfer; statistically, thioglycolic acid is likely to attach to the NIPAAm end. Herein, only one case is presented.

In our study, hydrophobic vinyl laurate was used to lower the LCST of the copolymer so that the formation and dissociation of PNVLCS/DNA complexes can be easily modulated by controlling temperature. It was also expected that incorporation of a small quantity of laurate vinyl could increase the cellular entry of PNVLCS vector. In addition, we will focus on the effect of charge ratios of vector to DNA on the properties of the complexes.

In ^{1}H NMR spectrum of PNVLCS (Figure 3), there still appear some feature peaks of NIPAAm (*29*), but the signal peaks of VL cannot be differentiated. The peaks at 2.702, 3.449, and 4.434 ppm are assigned to the H-2, H-3, and H-1 of chitosan (*30*). The signals of H-4, H-5, H-6 of chitosan cannot be resolved due to overlapping with those of NIPAAm. Combining the results of FTIR and NMR, it is reasonable to consider that chitosan has been coupled to PNVLCOOH.

In designing chitosan−NIPAAm/vinyl laurate, we first considered the LCST of the resultant copolymer solution.

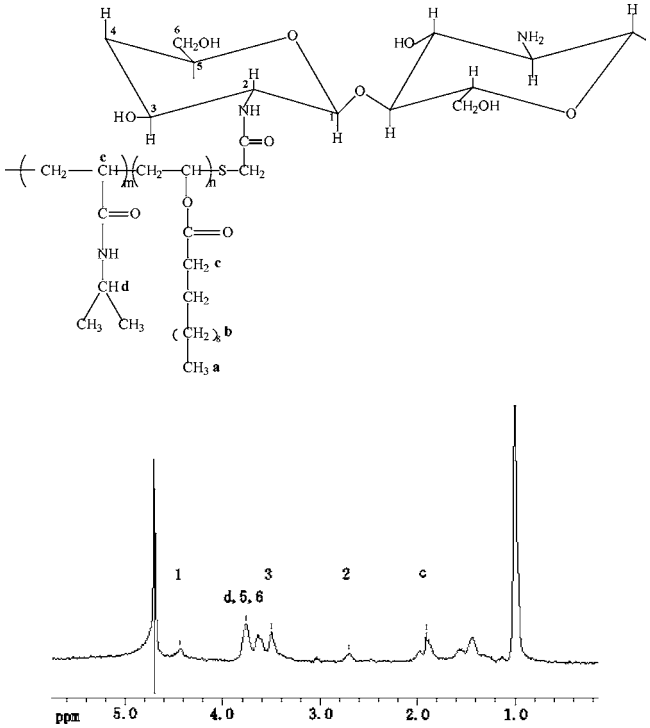

Figure 3. ^{1}H NMR spectrum of PNVLCS (in D_2O).

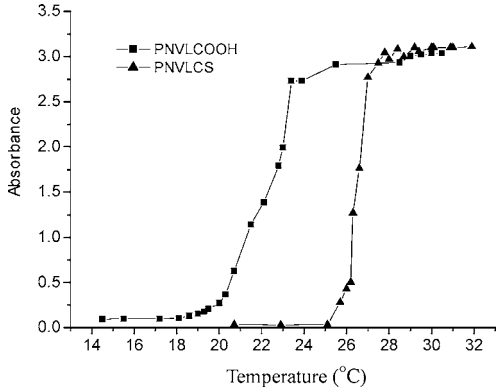

Figure 4. Absorbance versus temperature plots obtained for 1.0 wt % aqueous solutions of PNVLCOOH and PNVLCS. The LCSTs were taken at the inflection point in the curves of optical density versus temperature.

Figure 4 presents the variation in the turbidity of PVLCOOH and PNVLCS solutions as a function of temperature. From the figure, it is seen that there exist sharp changes of absorbance in both cases of PNVLCOOH and PNVLCS solutions. Obviously, introducing hydrophobic laurate moieties to the PNIPAAm chains causes a significant decrease in LCST from 32 °C to 20 °C. While the influence of hydrophilic carboxyl-capping on LCST can be neglected. In comparison, the LCST of PNVLCS solution is increased to 26 °C when PNVLCOOH is coupled with hydrophilic chitosan chains.

Physicochemical Properties of PNVLCS/DNA Complexes. The representative TEM images of PNVLCS vector and PNVLCS/DNA complexes with varied charge ratios are exhibited in Figure 5. The complexes at the selected charge ratios display globular shape, and the average sizes of globules in TEM images are summarized in Table 1. Somewhat surprisingly, PNVLCS also appears micelle-like morphology, and its average diameter is as high as 118 nm. In our previous work on thermoresponsive transition behavior of vinyl laurate-

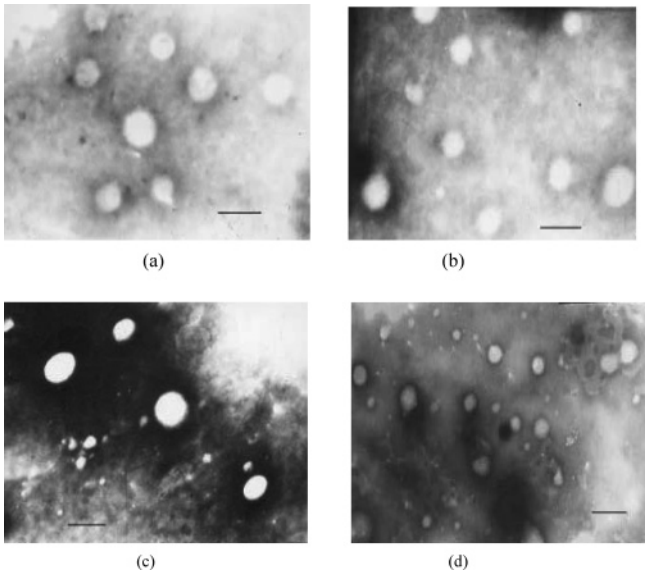

Figure 5. TEM images of PNVLCS (a) and PNVLCS/DNA complexes at charge ratios of 1:2 (b), 1:1 (c), and 5:1 (d). The scale bars = 200 nm. 1.5% phosphotungstic acid (PTA) was used as a negative staining agent.

Table 1. Particle Size Obtained from TEM Images

complex charge ratio (+/−)	diameter (nm)
PNVLCS	118 ± 10
1:8	100 ± 9
1:2	121 ± 15
1:1	148 ± 29
2:1	87 ± 23
5:1	83 ± 13
15:1	67 ± 14

Table 2. Mean Diameters of PNVLCS/DNA Complexes at 20 and 37 °C[a]

	mean diameter (nm)	
complex charge ratio (+/−)	at 20 °C	at 37 °C
1:8	87 ± 11	92 ± 15
1:2	158 ± 24	202 ± 23
1:1	146 ± 22	141 ± 17

[a] Values are the results of three measurements and are denoted as mean ± SD.

modified PNIPAAm copolymer solution (*28*), we found that incorporation of VL moieties could facilitate hydrophobic aggregation of chains far below the LCST. Therefore, NIPAAm/VL-coupled hydrophilic chitosan copolymer is inclined to form a larger micelle-like structure even at room temperature.

With the increment of charge ratio, the size of complexes increases and reaches a maximum at 1:1. Interestingly, with a further increasing charge ratio up to 15:1, the size of complex shows a decreasing trend. The size of complex is dependent on the interplay of hydrophobic and electrostatic interactions between DNA and PNVLCS. At lower charge ratio, the self-aggregation from hydrophobic alkyl chains of VL in PNVLCS causes a slight increase in the size of complex. Whereas at higher charge ratio, more compact complexes may be resulted from the strong electrostatic attraction.

To study the effects of temperature on the size of PNVLCS/DNA complexes, DLS experiment was performed at 20 °C (lower than LCST) and 37 °C (higher than LCST). In our experiment, we only selected three charge ratios, 1:8, 1:2, and 1:1 (Table 2). In the cases of 1:8 and 1:2, the mean diameter of complexes is increased

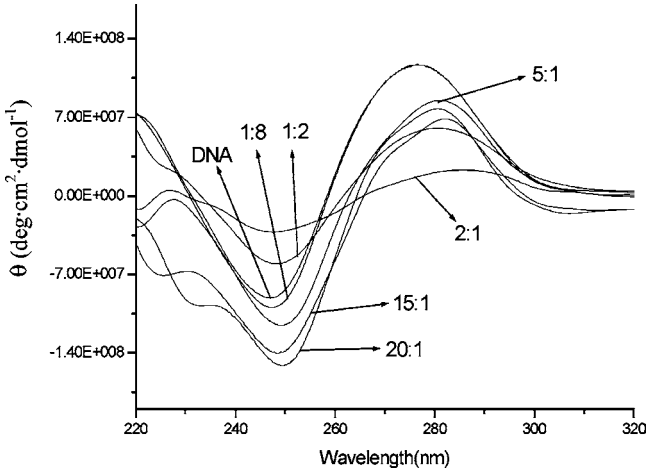

Figure 6. CD spectra of DNA and PNVLCS/DNA complexes at different charge ratios (at 20 °C). In each complex solution, the concentration of DNA is 1.1×10^{-4} M. The spectra were corrected by subtracting the background of sodium acetate/acetic acid buffer (pH 5.4), and three spectra were accumulated and averaged for each sample.

while temperature is raised from 20 to 37 °C. For charge ratio of 1:1, the diameter is diminished to a measurable extent while temperature is increased. The temperature-dependent change in the size of complex could be ascribed to two opposite factors. On one hand, at temperature above LCST, PNIPAAm chains collapse to form highly compacted structure, but meanwhile the hydrophobic chains are prone to self-aggregate. In some range of charge ratios, the aggregation plays a dominant role, rendering the size of complexes larger; at other charge ratios, the role of aggregation is marginal, and instead the collapse of PNIPAAm chains in combination with electrostatic attraction facilitates the formation of dense complexes, that is, a smaller size of particles.

The CD spectra of PNVLCS/DNA complexes with various charge ratios determined at 20 °C are illustrated in Figure 6. The positive and negative ellipticities centered around 275 and 245 nm arise from the DNA itself, revealing a type of double-stranded structure of DNA. The free DNA shows a typical CD spectrum for B-type DNA conformation.

At 1:8 charge ratio, the peak intensity remains nearly unchanged compared to that of free DNA; with the increase of charge ratio, the molar ellipticities of the DNA are suppressed, and the positive band at 275 nm is red-shifted. Interestingly, one can see two distinct variation trends of DNA conformation in the selected range of charge ratios. From 1:8 to 2:1, DNA in these complexes assumes a B conformation. A similar result was reported in our previous work on chitosan/DNA complexes (*31*), but the Cotton patterns observed with charge ratios from 5:1 to 15:1 demonstrate that the DNA changes from B to C conformation. The B−C type transformation was also reported in PLL-*g*-dextran/DNA complex system (*32*). We also recorded the CD spectra for the above series of PNVLCS/DNA complexes at 37 °C. The variation trend of CD pattern is identical to that at 20 °C. Though at the temperature above LCST, a heavy syneresis of PNIPAAm occurs, we see no B−A type transformation.

Figure 7a displays the CD spectra of complexes with varied charge ratios at 20 and 37 °C. It should be pointed out that at 37 °C, the intensity of free DNA is slightly decreased. To isolate the thermoresponsive phase transition, the difference in the CD intensity caused by temperature has been subtracted in the data treatment. It

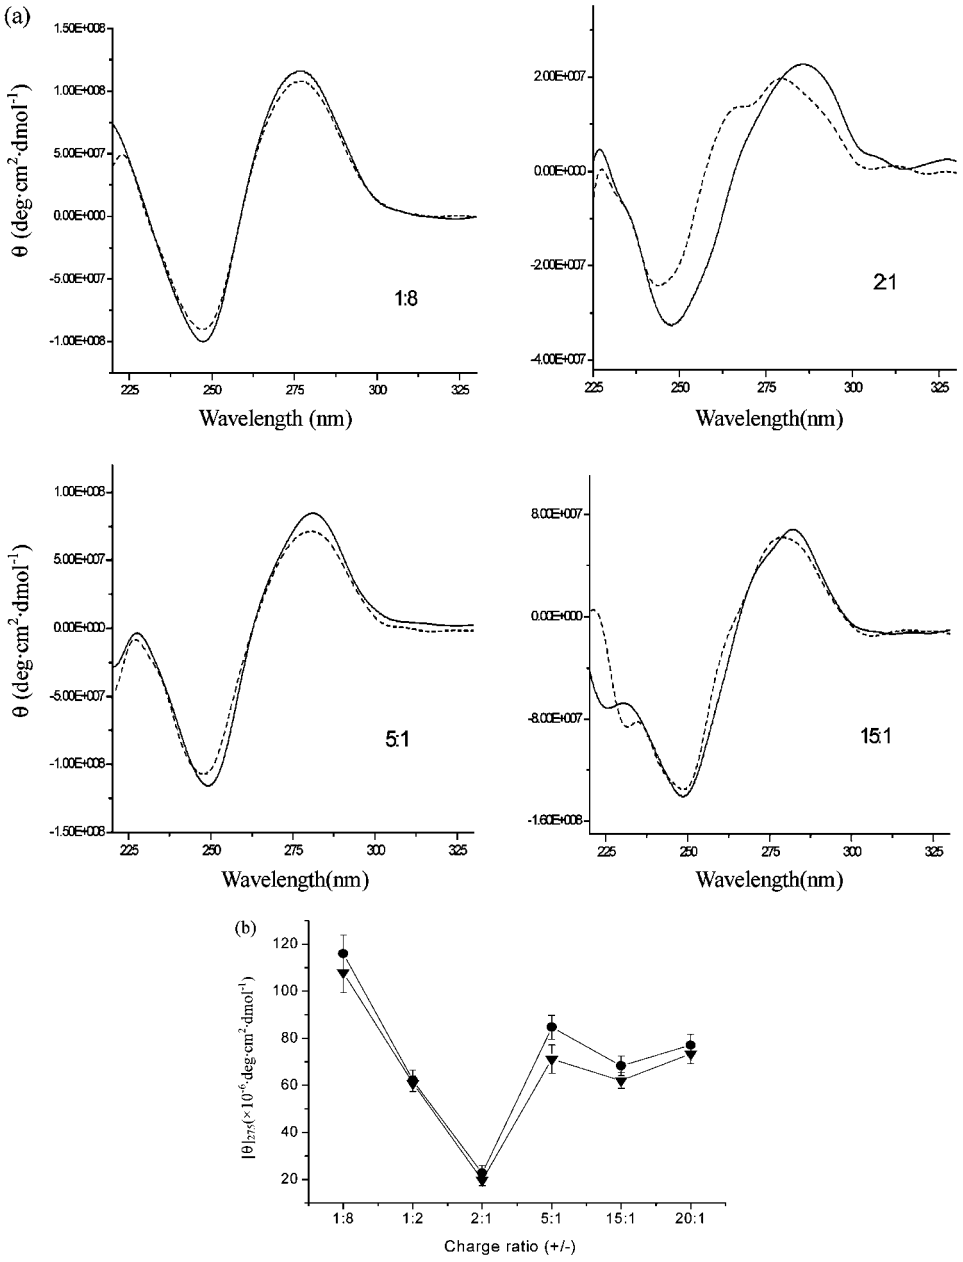

Figure 7. Effect of temperature-induced phase transition of PNVLCS on CD spectra of complexes. (a) Representative CD spectra of complexes at various charge ratios. (Solid line: 20 °C; dash line: 37 °C). The difference in the intensity of CD caused by temperature has been subtracted to eliminate the influence of the decrease in the intensity of free DNA at 37 °C. (b) Dependence of $[\theta]_{275}$ on charge ratios determined at 20 and 37 °C. (●): 20 °C; (▼): 37 °C.

is clearly seen from the figures that the CD intensity decreases to a certain degree when the temperature is increased from 20 °C to 37 °C. To give a clear observation of the effect of temperature-induced hydrophobicity on the CD signal, we plotted $[\theta]$ values of the CD signal at 275 nm determined at 20 and 37 °C versus charge ratios (Figure 7b). Obviously, the values of $[\theta]_{275}$ at 20 °C are greater than at 37 °C. It has been confirmed that at temperatures below LCST, PNIPAAm chains are hydrated; thus a loose structure of PNVLCS/DNA complex is formed in this case, rendering more DNA exposure, while at 37 °C, the PNIPAAm chains in PNVLCS collapse due to heavy dehydration. The collapsed chains tightly cover the surface of complex, protecting DNA from exposure. Therefore, the CD signals are suppressed at an elevated temperature.

To further verify the influence of thermoresponsive phase transition of PNVLCS on the packing−unpacking of DNA in the complexes, temperature-variable UV was performed. Figure 8 shows the change in OD_{260} of free DNA and the complex solutions at 20 and 37 °C versus charge ratios. As shown in the figure, OD_{260} of free DNA is constant at these two temperatures. At the selected temperature, DNA is not denatured, so the direct influence of temperature on the variation in the absorbance of naked DNA can be rationally neglected. We can see that after complexing with PNVLCS vectors, the OD_{260} values decrease relative to that of free DNA. It is not hard to figure out that with the addition of PNVLCS, DNA is condensed in polyelectrolyte complexes, which reduces the exposure of base-pairs; hence the OD_{260} decreases. Figure 8 also provides other useful information that all the OD_{260} values at 37 °C are lower than those at 20 °C. As aforementioned, while the temperature is raised to 37 °C, the PNIPAAm chains in PNVLCS collapse to tightly bind to the surface of complexes, resulting in more

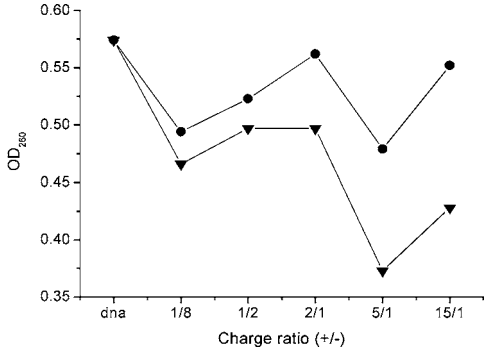

Figure 8. Change in OD_{260} of free DNA and PNVLCS/DNA complex solutions at 20 and 37 °C versus charge ratios. (●): 20 °C; (▼): 37 °C.

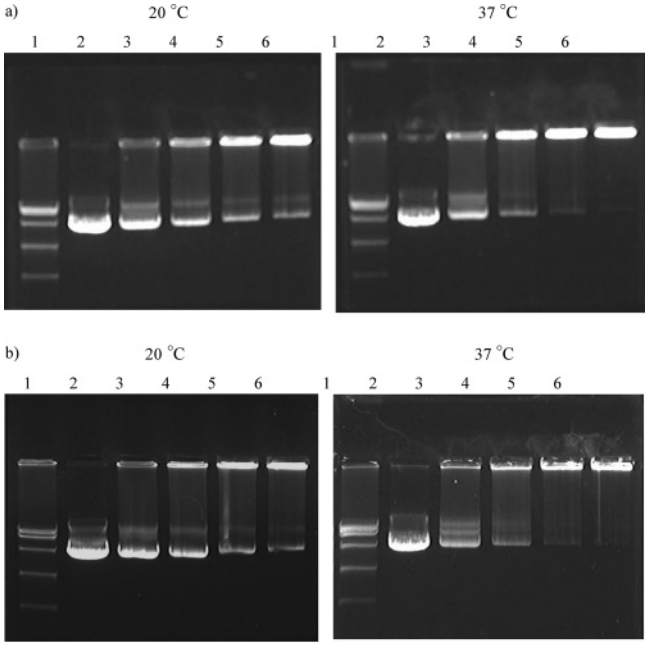

Figure 9. Electrophoresis of PNVLCS/DNA on agarose gels. (a) PNVLCS/DNA complexes were formed at 20 °C or 37 °C, and run at about 15 °C. (b) PNVLCS/DNA complexes were formed at 20 °C or 37 °C, and run at about 37 °C. Lane 1: DNA marker; lane 2: plasmid DNA; lane 3: +/− = 1/2; lane 4: 1/1; lane 5: 2/3; lane 6: 2:1.

compact structure of complexes, and consequently protecting DNA from exposure. This result is in good agreement with that of CD above. It is noted that the variation in OD_{260} is reversible upon increasing or decreasing temperature. It is safe to say that at temperature above LCST, more DNA molecules are trapped in PNVLCS/DNA complex compartments owing to the combined electrostatic and hydrophobic interactions. This is important for the cellular entry of complexes as well as hindrance for the attack of nuclease. Additionally, the temperature reversibility of PNVLCS can be used to adjust the packing and unpacking of gene in its vector, by which a controllable gene expression could be realized by simply varying temperature.

To examine the dependence of PNVLCS/DNA complexes on temperature, a temperature-variable electrophoresis was carried out. In experiment, we prepared the complexes at 20 and 37 °C, and the electrophoresis assay was performed at 15 and 37 °C, respectively (Figure 9). One can see that the migration of PNVLCS/DNA complexes is reduced with increasing charge ratio from 1:2 to 2:1 and much more DNA is restricted into gel slots. A

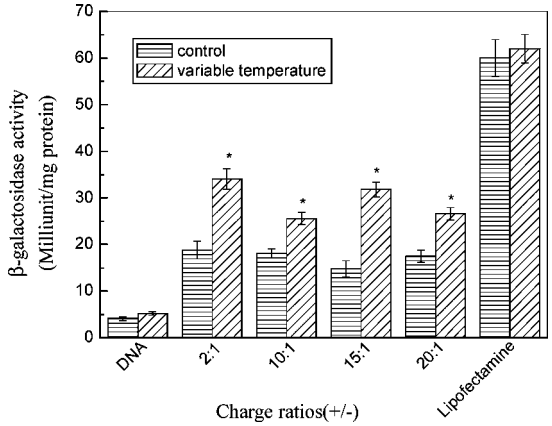

Figure 10. Thermoresponsive transfection efficiency of PNVLCS/DNA complexes at different charge ratios. The transfection level at constant 37 °C was used as a control. Data are shown as mean ± SD ($n = 3$). $P^* < 0.05$ (compared to the control).

complete retardation of DNA occurs at charge ratio of 2:1 (complex formed at 37 °C). These retardations are indicative of neutralization of negatively charged plasmid DNA as well as large size complex formation. A close inspection of temperature influence discloses that in the case of PNVLCS/DNA complexes formed at 20 °C, DNA cannot be retarded completely. Even at 2:3 and 2:1 charge ratios, a small quantity of DNA complex can still migrate out of slots. But the complexes of the same charge ratios formed at 37 °C can impede the DNA migration significantly; all DNA is retained in gel slot at 2:1 charge ratio. It is further confirmed that not only electrostatic interaction but also temperature change exerts an effect on the formation of PNVLCS/DNA complexes. For complexes formed above LCST (at 37 °C), greater retardation is achieved, implying the formation of more stable complexes at higher temperature.

In addition, in gel retardation assay run at varied temperatures, an interesting phenomenon is shown. The bands of complexes with charge ratios of 2/3 and 2/1 run on a agarose gel in liquid of 15 °C is brighter, while they become dimmer at the same charge ratios when liquid temperature is 37 °C. This fact suggests that the complexes formed at initial stage are just metastable. When the complexes are immersed in electrophoresis liquid of 37 °C, the PNIPAAm chains continue to collapse, causing more compact structure of the complexes in which DNA is shielded to a maximum extent.

Thermoresponsive Gene Transfection of C_2C_{12} Cells. The transfection efficiency was evaluated in C_2C_{12} cell lines using pTracer-CMV/Bsd/*lacZ* plasmid encoding β-galactosidase(β-gal). We adopted two routes to examine the thermal regulation of transfected gene expression; one is the constant temperature approach: the culture temperature was kept at 37 °C; the other is the variable temperature approach: the transfected cells were incubated for 18 h at 37 °C, 3 h at 20 °C, and an additional 24 h at 37 °C. Figure 10 displays the dependence of transfection efficiency achieved with naked DNA, PNVLCS and Lipofectamine 2000. As shown in the figure, the β-gal activities of PNVLCS obtained with variable temperature approach are 1.42−2.27 times that of constant 37 °C case. t-test analysis demonstrates a significant difference between variable temperature route and the control (constant 37 °C). In comparison, although the transfecion efficiencies of naked DNA and Lipofectamine 2000 are marginally enhanced, no significant difference is observed. In addition, with the variable temperature method, the β-gal activities of PNVLCS are

raised 5−8-fold to that of naked DNA. Note that the level of gene transfection mediated by PNVLCS is only up to 50% that of Lipofectamine 2000, but the order of magnitude is the same.

The thermoresponsive transfection efficiency should be attributed to the change of affinity between PNVLCS vector and DNA. From the analysis above, the phase transition of PNVLCS plays an important role in the formation and dissociation of the complexes responding to the change of temperature. At body temperature (37 °C), the PNIPAAm chains in PNVLCS become dehydrated and exist in a collapsed form, leading to compacted complexes. This tight form could be internalized easily via endocytosis and protects DNA from degradation by DNase during transportation into cells. After 18 h incubation at 37 °C, the transfected cells were lowered to 20 °C and incubated for 3 h. Below LCST, the PNIPAAm moieties in PNVLCS copolymer are hydrated and become loose and extended, which could promote dissociation of complexes or gene exposure, aiding in the accessibility of RNA polymerase, and consequently gene expression is increased.

It is necessary to point out that the timing for post-transfection at 37 °C and lowering the incubation temperature is critical for realizing the objective of gene expression control. An improper choice of timing might deteriorate transfection efficiency due to declined cell vitality in low-temperature surroundings and/or premature dissociation of genes in the endosome. In our experiment, although the timing cannot be guaranteed optimum, at least it is effective for improving gene expression.

CONCLUSIONS

A thermoresponsive chitosan−NIPAAm/VL copolymer (PNVLCS) vector was synthesized by coupling chitosan to carboxyl-capped NIPAAm/VL copolymer. The LCST of PNVLCS aqueous solution was ca. 26 °C. At lower charge ratios (+/−), DNA in the complexes remained in B conformation; while B → C type conformation transformation occurred at higher charge ratios. The affinity between DNA and PNVLCS could be tuned by varying surrounding temperature. At temperatures above LCST, tight and stable complexes were formed due to the collapse of PNIPAAm chains in PNVLCS. Reducing temperature below LCST facilitated the dissociation of PNVLCS/DNA complexes, resulting in the exposure of more DNA molecules. The level of gene expression could be thermally controlled and increased by lowering incubation temperature to 20 °C when PNVLCS/DNA complexes were applied to C_2C_{12} cells, which was attributed to the effective unpacking gene from PNVLCS at temperature below LCST. In contrast, the naked DNA and LipofectamineTM 2000 did not show temperature-sensitive behavior in mediating gene transfection, but the transfection level of PNVLCS was still inferior to that of Lipofectamine 2000, leaving much to be desired.

DNA-Directed Coupling of Organic Modules by Multiple Parallel Reductive Aminations and Subsequent Cleavage of Selected DNA Sequences

Morten Nielsen,[§] Vita Dauksaite,[†] Jørgen Kjems,[†] and Kurt V. Gothelf*[,§]

Department of Chemistry, Langelandsgade 140, and Department of Molecular Biology, C. F. Møllers Allé, Building 130, Aarhus University, 8000 Århus C, Denmark. Received March 15, 2005; Revised Manuscript Received April 29, 2005

A new method for DNA-directed assembly of organic modules by multiple parallel reductive aminations is presented. Linear oligonucleotide-functionalized modules (LOMs) consist of a rigid oligo(phenylene ethynylene) backbone with two salicylaldehyde termini, and each terminus is conjugated with an oligonucleotide sequence. The stability of the tetrahydrosalen-linked modules toward elevated temperature, low pH, nucleophiles, and metal chelators is studied and compared to the analogous metal−salen-linked modules. A linear oligonucleotide-functionalized disulfide-linked module (LOSM) containing cleavable linkers between the organic module and the two DNA sequences is coupled by DNA-directed reductive aminations to nonmodified LOM modules. This enables selective cleavage of the DNA strands of a central module in a structure consisting of three modules, and the reactions are analyzed by electrophoresis and ^{32}P-labeling of one of the DNA sequences of the central LOSM.

INTRODUCTION

DNA-directed synthesis has in just a few years evolved from chemical ligation to being an advanced tool for controlling chemical reactivity. This is obtained by the encoding of organic compounds with DNA sequences to react only with other compounds connected to complementary sequences (*1*−*3*). Liu and co-workers have demonstrated this principle to be applicable to a series of organic reactions ranging from acylation reactions to palladium-catalyzed cross-couplings (*4*, *5*). Several fascinating applications of DNA-directed chemistry have already been reported such as new DNA sequence detection methods (*6*−*8*), PNA-templated drug release (*9*−*11*), combinatorial synthesis and selection of libraries of potential drug candidates (*12*), and discovery of new organic reactions (*13*).

We have applied DNA-directed reactions for the assembly and coupling of multiple organic modules in parallel to form macromolecular nanostructures with predetermined connectivity (*14, 15*). The applied building blocks were rigid linear oligonucleotide-functionalized modules (LOM) and tripoidal oligonucleotide-functionalized modules (TOM) (*14, 16*). The LOM module shown in Figure 1A consists of an oligo(phenylene ethynylene) backbone and contains salicylaldehyde-derived termini to which two 15-nucleotide DNA sequences are attached (*16*). In former studies by us (*2, 14, 15*), and by others (*17, 18*), DNA-directed couplings of salicylaldehydes have been performed by metal salen formation using manganese acetate and ethylenediamine (EDA) (Figure 1B). DNA-directed formation of Ni−salen (*17, 18*) and Al−salen (*15*) have also been reported, and we have found that a variety of metal salts of Co, Fe, Cu, and U form metal−salen products in DNA-directed couplings.

EXPERIMENTAL PROCEDURES

Synthesis of LOMs and LOSMs. The linear oligonucleotide-functionalized modules (LOMs) and disulfide-modified modules (LOSMs) were prepared by incorporation of linear module (LM) phosphoramidites into oligonucleotides by standard automated oligonucleotide synthesis (DNA Technology, Aarhus, Denmark) according to previously published procedures (*14*−*16, 19*). The DNA sequences are given in Table 1.

Dimerization and Trimerization. A solution (10 μL) of the two or three LOM modules (5 μM each) in 100 mM KCl, 50 mM EPPS (pH 8.0 or pH 5.0) were heated to 60 °C for 5 min and cooled slowly to room temperature in a water bath. The coupling reactions were performed by addition of either 0.25 mM ethylenediamine, 1 mM $Mn(OAc)_2$ (for the salen formation at pH 8.0), or 0.25 mM ethylenediamine and 10 mM $NaCNBH_3$ (for the reductive amination at pH 5.0) and incubation for 2 h at 30 °C. Analysis of the reaction products was performed by electrophoresis at 90 V in 7.5% polyacrylamide gels (30:1.6) in 50 mM Tricine (pH 8.1) and 8 M urea. Samples were loaded in 8 M urea without heating and addition of dyes. Gels were fixed in 50% (v/v) ethanol, stained with ethidium bromide, and photographed in UV light.

Stability Testing. Dimers of LOMs coupled via a Mn−salen bond or via a tetrahydrosalen bond was prepared as described above. Stability tests were performed by subjecting the prepared complexes to heat (75 °C for 1 h), acid (acetate buffer, pH 3.8, 200 mM, 5 μL, 75 °C for 1 h)), amine ($MeNH_2$, 40% aq solution, 2 μL, 75 °C for 1 h), and EDTA (EDTA, pH 7.0, 100 mM, 5 μL, 75 °C for 1 h). Analysis of the reaction products by electro-

phoresis at 90 V in 7.5% polyacrylamide gels (30:1.6) in 50 mM Tricine (pH 8.1), 8 M urea. Samples were loaded in 8 M urea without heating and addition of dyes. Gels were fixed in 50% (v/v) ethanol, stained with ethidium bromide, and visualized by fluorography.

Radioactive Labeling. LOSM-5 (5 μM) was labeled with 24.2 pmol of gama-^{32}P-ATP (Amersham, 7000 Ci/mmol) in 50 μL of T4 polynucleotide kinase buffer using 2 μL of T4 PNK (10 U/μL) for 1h at 37 °C. The labeled oligonucleotide was purified on MicroSpin G-50 columns (Amersham Biosciences).

Disulfide Cleavage. Couplings of **LOM-4**, **LOSM-5**, and **LOM-6** to the desired dimers or trimers were performed as described previously. The disulfide cleavage was performed by addition of tricine buffer (pH 8.1, 2 μL, 500 mM) and tris(2-carboxyethyl)phosphine (TCEP) (pH 7.0, 5 μL, 50 mM) and incubation at 35 °C for 2 h. Traditional analysis of the reaction products was performed by electrophoresis at 90 V in 7.5% polyacrylamide gels (30:1.6) in 50 mM Tricine (pH 8.1), 8 M urea. Samples were loaded in 8 M urea without heating and addition of dyes. Gels were fixed in 50% (v/v) ethanol and stained with ethidium bromide. The wet gel was visualized by fluorography or autoradiography for 15 min and analyzed using Imagequant Software (Biorad).

RESULTS AND DISCUSSION

The metal−salen coupled macromolecular structures obtained in this manner are susceptible to hydrolysis at pH < 6 and other conditions. Consequently, we have investigated the DNA-directed double reductive amination of salicylaldehydes in the presence of EDA to form tetrahydrosalen (Figure 1B). This amine-linked structure is expected to be much more stable than the corresponding imine-linked metal−salens. The tetrahydrosalen is also an excellent ligand for various metals, which will ensure the ordered structure of the linkage between the modules (*20*). Incorporation of metals in the tetrahydrosalen will also maintain the potential conductivity of the macromolecules (*15*).

The results from the coupling experiments between two LOMs or three LOMs under various conditions for Mn−salen formation and reductive amination are shown in the PAGE gel in Figure 1C. Dimerization reactions of **LOM-1** and **LOM-2** are shown in lanes 1−5. Mn−salen formation proceeds quantitatively at pH 8, whereas no conversion is observed at pH 5. Importantly, reductive amination also proceeds almost quantitatively and in the presence of $Mn(OAc)_2$. In the absence of reductant and metal, but in the presence of EDA, the expected imine intermediate does not have the stability to withstand the

reaction conditions or the conditions for denaturing electrophoresis since only starting material is observed at pH 5 (lane 5). The same observation has been made at pH 8 (*14*). Trimerization of **LOM-1**, **LOM-2**, and **LOM-3** showed a similar trend (lanes 6−8). To probe the expected increase in stability of the tetrahydrosalen (HS)-linked **LOM-1**−**LOM-2** dimer compared to the corresponding Mn−salen (MS), we have submitted the products to various harsh conditions. The MS dimer is relatively stable toward heating at 75 °C for 1 h although some hydrolysis is observed (Figure 1D, lane 4). The HS dimer is inert to these conditions (lane 5). Treatment with acid (pH 3.8) for 1 h at 75 °C completely hydrolyzes the MS dimer whereas the HS dimer remain inert (lanes 6 and 7). Methylamine (10 mM, 75 °C for 1 h) also cleaves the MS dimer, but only partly decomposition of the HS dimer is observed (lanes 8−9). We have observed that the presence of EDTA in buffers leads to decomposition of the MS dimer (lane 10). Probably EDTA is capable of capturing the metal from MS−salen, and the resulting salen decomposes in situ or during gel electrophoresis. This is supported by the observed inertness of the HS dimer toward EDTA (lane 11).

The increased stability of the linkages between organic modules in the nanostructures described above encouraged us to investigate the selective cleavage of DNA sequences from macromolecular DNA organic hybrid assemblies. In a previous report we have described the synthesis and cleavage of disulfide-linked oligonucleotides in the LOSM module (*15*). The LOSM module contains two $(CH_2)_6$−S−S−$(CH_2)_6$ spacers between the organic module (LM) and the two 15-nucleotide DNA sequences. It was observed that the Mn−salen linkage in LOM dimers was labile to the reagent used for disulfide cleavage: tricarboxyethylphosphine (TCEP). Al−salen-linked dimers were stable toward TCEP, and we demonstrated that the 15-nucleotide DNA sequences were cleaved off a LOSM Al−salen dimer, but we were unable to identify the organic residue (*15*).

In contrast, tetrahydrosalen-linked LOM dimers were completely stable toward TCEP. We have therefore applied the reductive amination for couplings between LOMs and LOSM to induce a partial cleavage of DNA strands from the products (Figure 2A−E). Since the LOSM module contains a chain of 17 additional atoms between the organic module and the oligonucleotides, the reacting salicylaldehydes are not optimally positioned to form the annealed LOM−LOM couple. This is illustrated in Figure 2C. However, the coupling between **LOM-4** and **LOSM-5** to give the dimer **D1** proceeded in high yield, as it appears from denaturing gel electrophoresis (Figure 2A and 2D, lane 5). The release of two of the four DNA sequences in **D1** was performed by cleavage of the disulfides with TCEP. Analysis of this reaction by PAGE

using ethidium bromide staining and fluorography did not give a clear picture of the outcome of the reaction (Figure 2D, lane 6). We observed a strong band at around 30 nucleotides whereas the band at 15 nucleotides is weak, indicating cleavage of the dimer in LOM and LOSM monomers rather than cleavage of disulfides. It is, however, well-known that short ssDNA sequences bind ethidium bromide poorly and give rise to weak bands (*21*). The conjugated organic backbone in monomeric LOMs and in structures such as **D1** is highly fluorescent, which will contribute to the stronger signal at 30 nucleotides. To obtain a clearer picture of this reaction we have radiolabeled the LOSM module at the 5′-end of the oligonucleotide with ^{32}P and analyzed the reaction by autoradiography (2E, lanes 5 and 6) (*21*). It is clear from this gel that the radiolabeled 15-nucleotide sequence is released in high yield (2E, lane 6). The mobility of the organic residue strongly indicates that the nonlabeled disulfide-linked DNA sequence has also been released (2D, lane 6). In the second reaction sequence (Figure 2B), **LOM-4**, **LOSM-5**, and **LOM-6** undergo DNA-directed coupling to form trimer **T1** in high yield, and the major product has a mobility in PAGE which corresponds well with a trimer (2D, lane 7). The weaker bands result from slight discrepancies in the stoichiometry between the three species involved. Incubation of **T1** with TCEP for 2 h in tricine buffer leads to the major product observed in Figure 2D, lane 8. The low mobility of this product initially led us to believe that the disulfide cleavage had failed. From the autoradiography (2E, lane 8) it is clear, however, that the radiolabeled 15-nucleotide DNA sequence had been cleaved and, as shown in the previous experiment, the nonlabeled disulfide-linked DNA sequence was also cleaved by TCEP. The mobility of the 60-nucleotide product **T2** in PAGE was unusual low compared to the other 60-nucleotide product **D1** (2D, lane 5). This can, however, be explained by the different environment of the DNA. In product **D1** the two central DNA sequences are complementary and, due to the covalent bond between the modules, forms in principle a 30-nucleotides hairpin structure (*18*), which may only be partly denatured in 8 M urea. Product **T2** contains four noncomplementary sequences, and this reduces the mobility in PAGE. It is well-known that, for example, a 30-nucleotide hairpin structure has a much higher mobility in denaturing PAGE than a 30-nucleotide ssDNA sequence. We believe that this is also the reason for the low mobility of **T2** compared to **D1**. Cleaving the DNA sequences of the central module in a trimer and conserving the rest of the DNA sequences is ultimately proving that these structures are indeed held together by covalent bonds.

The modular approach using encoded LOMs, LOSMs, and TOMs as shown here and in previous publications (*2, 14*−*16*) provides a novel method for assembly of molecular nanostructures. By application of the reductive amination demonstrated here for the coupling between modules, we have been able to construct assemblies that have superior stability compared to the metal−salen-linked structures. If metals are incorporated into the tetrahydrosalen linkage, it will give structures with a rigidity comparable to metal−salens will be formed. The incorporation of metals will also give these macromolecular assemblies properties as potential conductors. The selective cleavage of disulfide groups to release the LOSM DNA sequences is an important new feature of these macromolecules, and the generated thiol groups can be used for further functionalization of the structures or for immobilization on gold surfaces. In particular, the free thiols in the terminal positions of this type of macromolecular nanostructure would enable the attachment to electrodes.

Single Cell Kinetics of Intracellular, Nonviral, Nucleic Acid Delivery Vehicle Acidification and Trafficking

Rajan P. Kulkarni,[†,‡] Swaroop Mishra,[§] Scott E. Fraser,[‡] and Mark E. Davis*[,§]

Option in Biochemistry and Molecular Biophysics, Division of Biology, and Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received March 16, 2005; Revised Manuscript Received May 10, 2005

Mechanistic understanding of the intracellular trafficking of nonviral nucleic acid delivery vehicles remains elusive. A live, single cell-based assay is described here that is used to investigate and quantitate the spatiotemporal, intracellular pH microenvironment of polymeric-based nucleic acid delivery vehicles. Polycations such as polyethylenimine (PEI), poly-L-lysine (PLL), β-cyclodextrin-containing polymers lacking or possessing imidazole termini (CDP or CDP-imid), and cyclodextrin-grafted PEI (CD-PEI) are used to deliver an oligonucleotide containing a single fluorophore with two emission lines that can be employed to measure the pH. Delivery vehicles were also sterically stabilized by addition of poly(ethylene glycol) (PEG) and investigated. The intracellular trafficking data obtained via this new methodology show that vectors such as PEI and CDP-imid can buffer the endocytic vesicles while PLL and CDP do not. Additionally, the PEGylated vectors reveal the same buffering capacity as their unstabilized variants. Here, the live cell, spatiotemporal mapping of these behaviors is demonstrated and, when combined with cell uptake and luciferase expression data, shows that there is not a correlation between buffering capacity and gene expression.

INTRODUCTION

There is renewed interest in replacing viral vectors with biocompatible, polymeric vectors for gene delivery and potential gene therapy in humans because of recent difficulties and costs with viral delivery vectors (*1*, *2*). Although viruses can be useful for ex vivo gene delivery, they present many problems for systemic, in vivo use, including stimulation of immune responses, potential pathogenicity, lack of designable targeting to specific tissues and cell types, and cost of manufacturing. By comparison, the polymeric vectors can be prepared so that they do not elicit an immune response and are capable of carrying nucleic acids of virtually any size. Additionally, the synthetic delivery vehicles can be targeted to specific cells using appropriate ligands (*3*−*6*).

The delivery efficiency of nonviral vectors is much lower than with viral vectors. Increasing the intracellular delivery efficiency of nonviral vectors remains one of the major challenges in nonviral nucleic acid delivery. For effective delivery, the vector must first reach the cell of interest. Once internalized by receptor-mediated endocytosis, the delivery system should actively transport the nucleic acid out of the endocytic pathway and allow for movement into the nucleus. At some point during the delivery process, the nonviral vector must release the nucleic acid payload, although it is unclear where unpackaging should occur to enable the most effective delivery. Thus, the synthetic vector must perform multiple functions for effective intracellular trafficking (*7*−*9*).

An important process of the intracellular trafficking of nonviral delivery vehicles is their behavior in the endocytic pathway. The vehicles enter into this pathway by endocytosis and must escape in order to avoid degradation by the lysosomal system (*10*−*12*). Little is known about the spatiotemporial pH changes that the vectors face as they travel intracellularly or how these changes affect delivery and expression (*13*, *14*). Certain polymers, such as polyethyleneimine (PEI), are said to exhibit a 'proton sponge' effect since they have titratable amine groups (pK_a values in the range of 4−7) and have the ability to buffer pH changes as endocytic vesicles acidify (*15*). Other polymers, such as poly-L-lysine (PLL) or β-cyclodextrin-containing polymers (CDP), do not possess this ability (*16*). Thus, it is important to understand how the delivery vectors respond to pH changes in the endocytic pathway and how those responses affect export to the cytoplasm to allow the cytoplasmic transport and nuclear delivery of the nucleic acid.

Prior studies examining endosomal pH changes utilized flow cytometry to look at averages of hundreds of cells simultaneously for different types of polyplexes (PLL and PEI) (*10*, *17*), or employed an indirect approach that depended on colocalization of dextrans (*18*). Here, we develop a new methodology to monitor the spatiotemporial pH experienced by nucleic acids in single cells using polymeric delivery vehicles. Our work differs from previous nucleic acid delivery studies in that we employ a single pH-sensitive fluorophore, SNARF-4F, directly conjugated to the nucleic acid of interest. This method avoids concerns about relative labeling density or interactions between multiple fluorophores, makes no assumptions regarding colocalization, and directly evaluates the pH microenvironment of the nucleic acid of interest. While valuable, previous studies involving average values from numerous cells do not offer the specificity of the single cell approach described below. Also, the

delivery particles that are in different locations in the cell, or endocytosed at different times, cannot be distinguished by cell averaging methods. In contrast, the single cell analysis method we present here using confocal laser scanning microscopy allows for direct examination of uptake of delivery particles in single cells in real time. Particles at different locations in the cell can easily be identified, and pH differences quantified, as nuclear transport of all types of particles is rather slow, and it can take on the order of tens of minutes for them to travel from the periphery of the cell to the nucleus.

Identifying pH differences as a function of delivery particle chemical composition and location within the cell will be important for better understanding of how trafficking occurs and may assist in the design process and search for more efficient delivery vectors. Here, we show that the pH microenvironment can be correlated to transfection progression and particle location through direct visualization. This method allows for monitoring of the entire pathway, from early internalization onward, and can be directly visualized in real time to measure individual differences among the cells.

MATERIALS AND METHODS

Labeled Oligonucleotide. A 21-base RNA phosphorothioate oligonucleotide was synthesized (Caltech Biological Synthesis Facility, Pasadena, CA) with sequence 5′-GACGUAAACGGCCACAAGUUC-3′. The 5′ end of the oligonucleotide was capped with the 5′-amino modifier 5 (Glen Research, Sterling, VA), supplying a 5′ terminal primary amine to which an NHS-ester of the SNARF-4F fluorophore could be reacted. To carry out this reaction, the dry oligonucleotide was resuspended in phosphate-buffered saline (pH 7.4). The pH-sensitive fluorescent molecule SNARF-4F-carboxylic acid (Molecular Probes, Eugene, OR) was converted to an NHS-ester by reaction with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) (1:1 molar equiv) and *N*-hydroxysulfosuccinimide (sulfo-NHS) (5:1 molar equiv) in MES buffer (pH 6.0) for 15 min. Subsequently, the oligonucleotide was added to the reaction mixture (10:1 molar equiv, SNARF-4F:oligonucleotide) and reacted for 2 h at room temperature in the dark. The SNARF-4F-labeled oligonucleotide was purified from unreacted SNARF-4F with CentriSep 20 columns (Princeton Separations, Adelphia, NJ). In multiple reactions, yield of labeled oligonucleotide was 50−60%.

Delivery Vectors. The β-cyclodextrin-containing polycation (CDP) and imidazole-terminated β-cyclodextrin-containing polycation (CDP-imid) were synthesized as described previously (*19*). Solutions of these cyclodextrin-containing polycations were prepared at 2.06 mg/mL in dH_2O. Branched polyethylenimine (bPEI) (25 kDa) (Aldrich, Milwaukee, WI) solution was formulated at 0.067 mg/mL in 20 mM HEPES buffer with 5% glucose. Poly-L-lysine (Sigma) solution was prepared at 0.06 mg/mL in 0.3 M NaCl. Cyclodextrin-grafted linear polyethylenimine (CD-PEI) was synthesized as described previously (*20*) and a solution formulated at 10 mg/mL in dH_2O. Lipofectamine (Invitrogen) was diluted to 0.025 mg/mL in Opti-MEM serum-free medium (Gibco/Invitrogen).

Formulation of Labeled Complexes. The SNARF-4F-labeled oligonucleotide was diluted in dH_2O to a concentration of 0.1 mg/mL. Polycation−oligonucleotide complexes were prepared by adding a polycation solution (as described above) to an equal volume of SNARF-4F-oligonucleotide. Complexes were then incubated at room temperature for 30 min. These conditions produce complexes at an *N*/*P* ratio of 10/1 for CDP and CDP-imid, 5/1 for bPEI, and 3/1 for poly-L-lysine. Lipoplexes were prepared by adding lipofectamine at a concentration of 25 μg/mL in Opti-MEM to the nucleic acid at a concentration of 10 μg/mL in Opti-MEM.

PEGylation of Complexes. An adamantane−poly(ethylene glycol)5000 conjugate (AD-PEG) was prepared as previously described (*19*). CDP complexes and CDP-imid complexes were salt-stabilized by the addition of 35 μg of AD-PEG (100 mg/mL in dH_2O) per microgram of oligonucleotide. bPEI complexes were salt-stabilized by addition of 4 μg of methoxy-PEG5000-succinimidyl propionate (Nektar, San Carlos, CA; 20 mg/mL in dH_2O) per microgram of oligonucleotide. Solutions were incubated at room temperature for an additional 30 min after PEGylation. For examples of these types of PEGylation methods and results of stabilization within cells, see ref 21.

Cells. HeLa cells were grown in 10-cm culture dishes (Becton-Dickinson) at 37 °C in a humid 5% CO_2 atmosphere. Each dish held 10 mL of growth media, which consisted of DMEM with 10% fetal bovine serum, 100 units/mL penicillin, 100 units/mL streptomycin, 10 mM HEPES, 0.1 mM nonessential amino acids, and 2 mM L-glutamine (Irvine Scientific). The cells were passaged once a week and plated onto glass-bottom tissue culture plates (Labtek) for each imaging experiment. The total medium volume per well was 0.7 mL after seeding, and the cells were incubated for 24 h before transfection.

Fluorescence Microscopy. An inverted Zeiss LSM 510 META confocal microscope was used for all fluorescence and brightfield measurements. A 63× oil objective (NA 1.4) was employed for all measurements. Excitation of the SNARF fluorophore was achieved with the 543 nm line of the He−Ne laser line supplied with the microscope. The fluorescence signal was detected by the PMTs within the META detector after passing through a variable confocal pinhole set to 2 Airy units (chosen to maximize the S/N ratio while minimizing out-of-plane light). The META detector allows for the emitted wavelengths to be separated into ∼10 nm bins of light. For the SNARF fluorophore, the collected emission light was separated into three distinct bins: 569−601 nm, 601−633 nm, and 633−687 nm.

pH Calibration Assay. Buffers with pH = 4.2, 5.0, 6.0, 7.0, and 8.0 were prepared as follows. The pH 4.2 and pH 5 buffers were made by adjusting the pH of a 0.2 M potassium acetate solution to the appropriate pH with glacial acetic acid. The pH 6.0 buffer was prepared by mixing 1.2 mL of 1 M Na_2HPO_4 and 8.8 mL of 1 M NaH_2PO_4. The pH 7.0 buffer was formulated by mixing 5.8 mL of 1 M Na_2HPO_4 and 4.2 mL of 1 M NaH_2PO_4. The pH 8.0 buffer was prepared by mixing 9.3 mL of 1 M Na_2HPO_4 and 0.7 mL of 1 M NaH_2PO_4. The pH of these latter three buffers was adjusted with 6 M NaOH. To determine the pH calibration curve, PLL, CDP, and CDP−PEG particles were incubated as follows. Aliquots (2 μL) of each polyplex solution (prepared as described above) were added to 100 μL of each buffer and allowed to equilibrate for at least 3 h. Each sample was then imaged under the microscope, as described, and the intensity measurements for each of the three bins were collected. The intensity values were normalized with respect to the middle bin (601−633 nm emission light) to generate calibration curves for the different pH values. The ratios of the intensity values of the 633−687 emission bin divided by those of the 569−601 emission bin do not differ significantly for all three types of particles

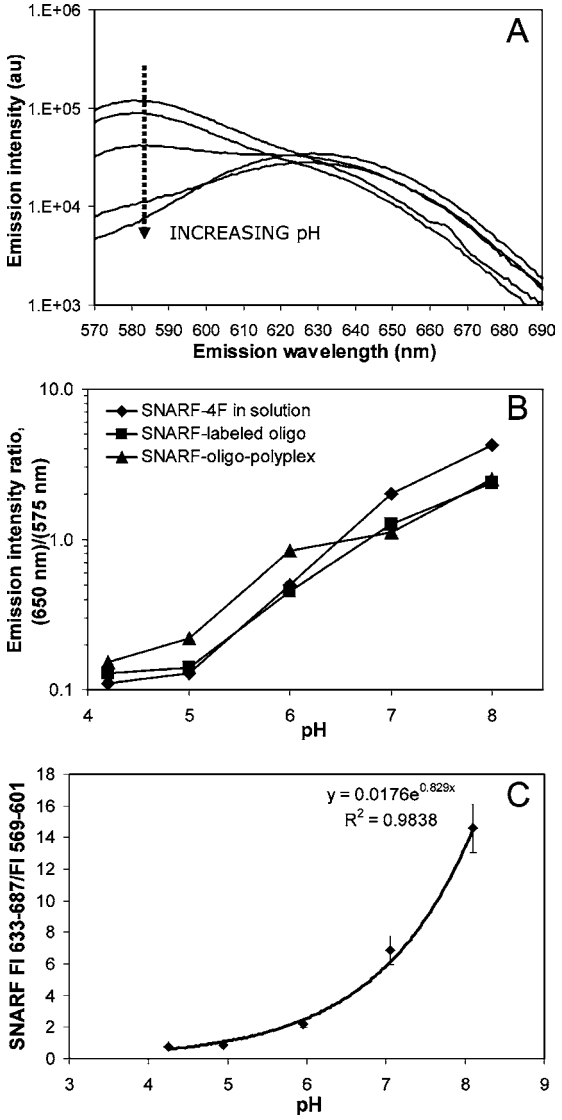

Figure 1. a: Fluorescence emission spectra of SNARF-4F as a function of pH. At low pH values, the peak at 575 nm is prominent, while the peak at 650 nm is low. As the pH rises, the 575 nm peak decreases in intensity, while the 650 nm peak rises to a maximum. pH measurements were taken in buffers with pH of 4.2, 5, 6, 7, and 8. b: Ratio of emission intensities for SNARF-4F dye. Attaching the dye to oligonucleotides or complexing the labeled oligonucleotides into particles does not appreciably change the emission spectrum of the dye, compared to free dye in solution. c: Mean fluorescence signal from 633 to 687 nm divided by signal from 569 to 601 nm for SNARF-4F as a function of pH for different particles in buffered solutions (see text).

at the same pH values; hence, we are able to use these ratios to determine intracellular pH.

In Vitro Transfection Imaging. After 24 h, the growth medium in each well was removed and replaced with an equal amount of Opti-MEM medium. A 2 μL amount of delivery particle-containing solution was then added to each well and placed in a 37 °C incubator for 2 h to allow for sufficient uptake. The cells were then imaged at 37 °C, with the fluorescence emission collected into three channels as previously described. Cells with delivery particles at different locations and stages of transport were imaged to generate a 'pH map' of the cell. Fluorescence intensity ratios were then calculated and compared to the calibrated pH values to determine the intracellular pH environment for each of the individual signals.

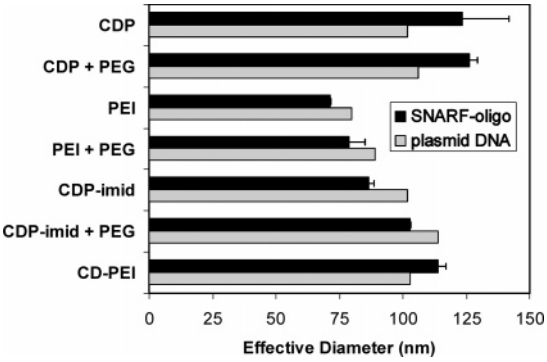

Figure 2. Average diameters of the various particles used in this study. Dynamic light scattering was employed to measure the effective diameters of the particles formulated. Most of these particles were formulated with an average effective diameter between 75 and 125 nm. Complexation of the polycation to either the SNARF-oligonucleotides or plasmid DNA resulted in particles of similar size.

Plasmid Uptake and Expression. The firefly luciferase-expressing DNA plasmid pGL3-Control Vector (5256 bp) was obtained from Promega (Madison, WI) and amplified using the Ultramobius 1000 kit (Novagen). One day prior to transfection, HeLa cells were plated at a density of 5×10^4 cells/mL in 24-well plates (1 mL/well). For transfection, polyplex solutions were diluted 10× in prewarmed Opti-MEM serum-free medium (Invitrogen), while lipoplex solutions were applied as formulated (in Opti-MEM). Uptake was assessed 4 h after transfection as described previously (*21*). Briefly, cells were transfected in duplicate with YOYO-1-labeled plasmid DNA, and the YOYO-1 fluorescence of viable cells was measured 4 h after transfection using a FACScalibur instrument (Becton Dickinson, Franklin Lakes, NJ). Expression of firefly luciferase was assayed as previously described (*22*). Briefly, the polyplex-containing medium was aspirated 4 h after transfection and replaced with regular growth medium equal to the original volume, and luciferase assays were conducted in triplicate 48 h after transfection.

RESULTS

Fluorescence pH Assay. The emission spectrum of SNARF-4F varies as a function of pH and has two peaks, one at 575 nm that increases in intensity as the pH declines, and one at 650 nm that increases in intensity as the pH increases; the crossover occurs at ~620 nm (Figure 1a). Thus, SNARF-4F can be used alone to monitor the pH in the range of 4−8, precisely the region useful for following the intracellular trafficking involving the endocytic pathway. SNARF-4F was conjugated to the 5′ end of an RNA phosphorothioate oligonucleotide and the pH sensitivity of the conjugate observed whether the labeled oligonucleotide was free in solution or was bound by a cationic polymer and condensed into delivery particles. SNARF-4F signals are approximately the same pH value independent of whether it is free in solution, conjugated to the nucleic acid or bound in a delivery vehicle (Figure 1b). The labeled oligonucleotide was used to prepare particles with a variety of nonviral gene delivery vectors; for most systems examined, the resulting particles were ~100 ± 25 nm in size (Figure 2), and the oligonucleotide exhibited stability against serum when packaged in delivery particles (data not shown). The intracellular trafficking of these fluorescently labeled particles was monitored in cultured cells as shown below.

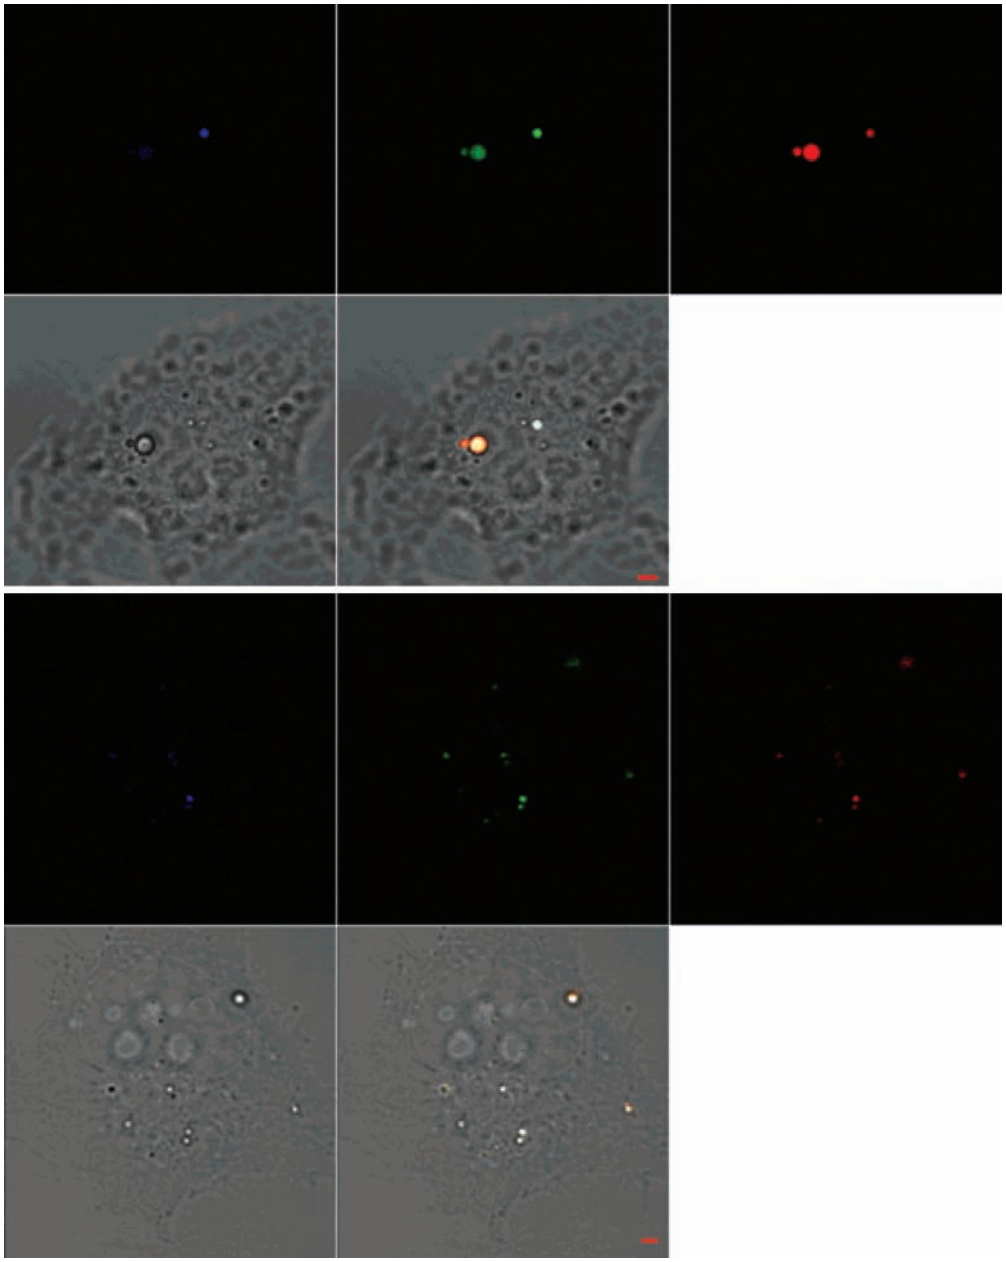

Figure 3. (Top) Image of PLL particles within cells after 2 h incubation. Blue represents the 569−601 nm channel, green the 601−633 nm channel, and red the 633−687 nm channel. In this case, the large spot has not acidified, while the smaller one to the right has acidified to pH 4.5. This image illustrates the inherent cell−cell variability of the uptake process, indicating that acidification does not occur uniformly or in a set time window. (Bottom) Image of PEI particles in a cell after 24 h incubation. The spots below the nucleus are at ~ pH 6, while the large one in the upper right corner is still at pH 7.5, suggesting that the particles in the upper right may have entered much later than the others. Scale bars = 1 μm.

To measure pH changes in cells via confocal microscopy, a META attachment was employed to separate the fluorescence emission into three wavelength bins (569−601, 601−633, and 633−687 nm). To generate a pH calibration curve, PLL and PEGylated CDP particles were prepared with the SNARF-4F RNA conjugate and were incubated in buffers with pH ranging from 4.2 to 8.1 and directly visualized under the microscope. The pH of the environment was quantitated by measuring the SNARF-4F emission in all three bins and sequentially calculating the ratios of all three bins compared to each other. The ratios did not differ significantly for PLL and PEGylated CDP particles in solution, and the data were combined to generate a single calibration curve. It was determined that the 633−687/569−601 nm ratio was the most sensitive to pH changes. An exponential curve was fit to these data points to determine an equation for calculating pH from the fluorescence intensity ratios, which was then used to determine intracellular endosomal pH values (Figure 1c).

By labeling the nucleic acids, and not the delivery vectors, the assay determines the pH environment of the delivered nucleic acids whether bound to the delivery vector or free in solution. It is relatively straightforward to directly visualize the SNARF-4F fluorescence when it is in a particle (Mishra et al. show high-resolution TEM and fluorescent confocal microscopy results that confirm vesicle containment of intact particles using some of the vector systems employed here (*21*)) as the signal appears as a round cluster. Figure 3 shows an example of intact PLL polyplexes after 4 h incubation and PEI polyplexes after 24 h incubation imaged within different regions of the cell. The pH is depicted colorimetrically in this image; those polyplexes experiencing a lower pH environment

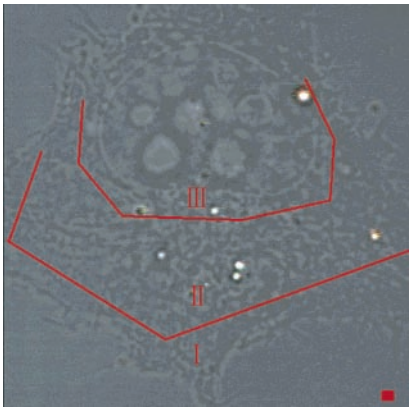

Figure 4. A schematic of a cell depicting the three regions (I, II, III) described in the text. Region I is the area of the cell within 2 μm of the cell membrane, region III is the region within 2 μm of the nucleus, and region II depicts the area in between. Scale bar = 1 μm.

appear more strongly blue colored whereas those experiencing a higher pH appear more strongly red colored. Diffuse staining indicative of unpackaged SNARF-oligonucleotide was not observed in these experiments, suggesting that unpackaged conjugate is diluted below the detection limit.

Intracellular pH Measurements. HeLa cells were exposed to the delivery particles for 2 h to allow for uptake and trafficking. While this time may seem long for endocytic processes, numerous reports have indicated that particle uptake and trafficking is notably slower (*6*, *10*). The media was then replaced to remove most of the free particles in solution, and the cells were incubated for up to 24 h before imaging. Because of the direct nature of our assay, it is not necessary to completely remove the free particles; in fact, particles that have entered more recently can be visualized and the endosomal pH values individually quantitated.

A major advantage of direct visualization is that different regions of an individual cell can be quantitated separately and not averaged into a bulk measurement. We have found that, early in the transfection process (less than 4 h), there appear to be regional differences in pH values within the cell (Figures 3 and 4). Specifically, the cytoplasm can be divided into three regions: region I, within 2 μm of the cell membrane; region II, the cytoplasmic region between the other regions; region III, within 2 μm of the nuclear membrane. We did not observe intact particles or labeled nucleic acids within the nucleus for any imaging condition. This is not unexpected for the CDP delivery systems, as Mishra et al. have shown that intact particles do not enter the nucleus (only released nucleic acids can be visualized in the nuclear compartment) (*21*).

As the particles are first internalized, their pH is uniformly high in region I for all examined classes of delivery vectors; however, the pH drops for PLL, CDP, and lipofectamine particles as they travel toward the nucleus (Figures 5 and 6). The reduction in pH for PLL is rather rapid and is complete by 2 h after initial incubation for those particles that reach region II. For the CDP vector, particles in region I are still at neutral pH after 4 h, those in region II are at an average pH of 6.1 with significant variability in pH, while those close to the nucleus have acidified by 4 h to an average pH of 5.2. Lipofectamine particles also display such an acidification, reaching an average pH of 4.6 by 16 h. Again, the average value does not tell a complete story; certain

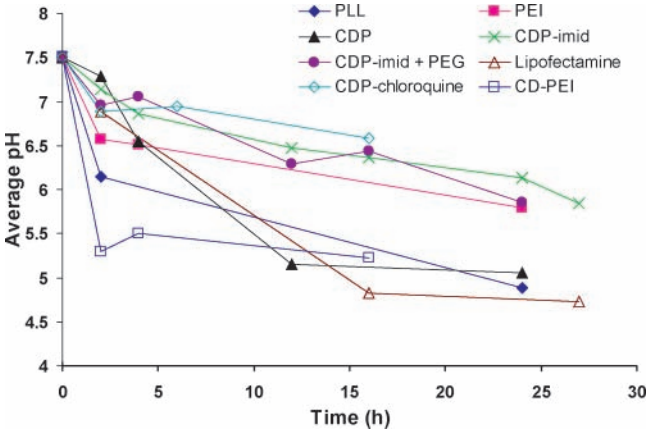

Figure 5. Plots of average pH of all cells and regions as a function of time.

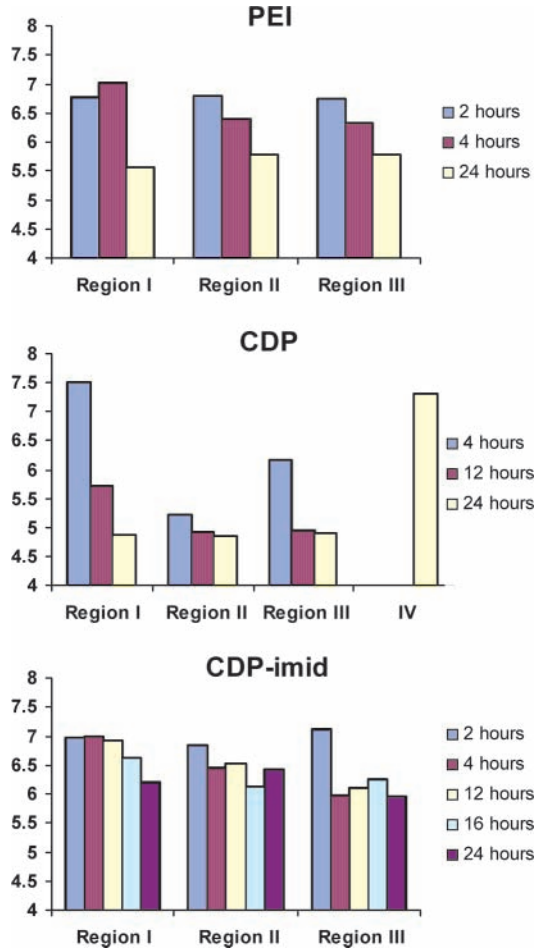

Figure 6. Regional pH values for PEI, CDP, and CDP-imidazole particles as a function of time and region within the cell. Greater variability can be seen for particles at earlier times and by region, highlighting the cell-to-cell variability inherent in these measurements.

particles in region II have fully acidified, while others are slower to do so.

In contrast, PEI particles display relatively consistent pH values for each time point, independent of region. Over time, the PEI particles do acidify from pH ~6.6 to ~5.8; however, the decrease is not as prominent as for PLL or CDP, which have acidified in all three regions by 24 h. Even at this time point, however, there are still a few cells (~1−4%) that show particles that are not acidified, possibly because they have entered the cells

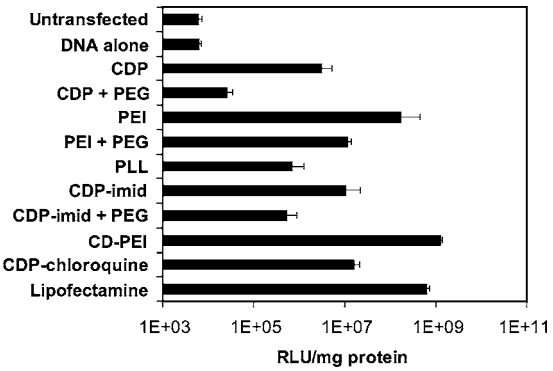

Figure 7. Gene delivery efficiency for each of the particles used in this study. The delivery vectors were complexed with plasmid DNA encoding luciferase, and used to transfect HeLa cells. The relative luciferase expression varies markedly for each type of particle. In general, stabilizing particles through PEGylation resulted in lower luciferase expression.

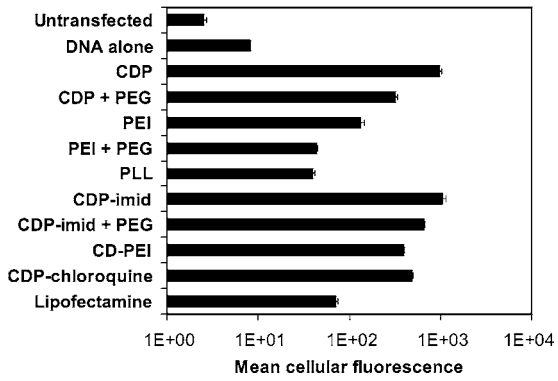

Figure 8. Measure of DNA uptake for each type of particle. Fluorescently labeled plasmid DNA was complexed with each type of delivery vector, and administered to HeLa cells. After 4 h, the cells were collected and analyzed by flow cytometry. The mean cellular fluorescence was used as a measure of DNA uptake.

only recently; these particles are indicated as being in region IV (see Figure 6). CD-PEI exhibits acidification to pH ~5.5 rather quickly, even in region I. However, it does not fully acidify below this pH, even after 16 h.

Although CDP particles do not buffer pH, modifications can be introduced to allow for buffering capacity. Conjugation of an imidazole group to the polymer termini produces CDP-imid, a vector that displays a limited buffering of pH. The acidification of CDP-imid particles occurs gradually, and even after 16 h, the average endosomal pH was ~6.3. Further acidification was observed to occur, with the average pH reaching ~6 by 24 h. Administration of chloroquine in conjunction with CDP particles resulted in a comparable buffering effect, with the pH remaining at ~6.6 even after 16 h.

Three types of particles (CDP, CDP-imid, PEI) permitted facile comparison between PEGylated and unPEGylated variants. Interestingly, differences between PEGylated and unPEGylated variants of the same polyplex type were minor. For instance, at 16 h after transfection, the average pH for PEGylated CDP-imid was ~6.4, while it was ~6.3 for the unPEGylated CDP-imid (Figure 4). Similar results were obtained for the other types of particles at each time point (data not shown).

Transfection Data. To explore the implications of the buffering behavior on the gene delivery efficiency of the examined delivery vectors, the delivery of luciferase plasmid DNA was employed. The examined delivery vectors generate similarly sized particles regardless of whether they are used to condense the SNARF-labeled oligonucleotide or plasmid DNA (Figure 2). The gene delivery activity of the various delivery vectors was assessed by transfecting cells with firefly luciferase-expressing plasmid DNA and assaying for luciferase expression (Figure 7). DNA uptake by cells was quantified using fluorescently labeled plasmid DNA and analysis by flow cytometry (Figure 8). The cellular fluorescence intensity can be correlated with relative uptake of plasmid DNA because the fluorescent label used (YOYO-1) was shown on a fluorimeter to be pH-insensitive (data not shown).

DISCUSSION

The fluorescence-based pH assay described herein provides the ability to follow and track individual particles within cells over time and thus gives insight into the nature of their trafficking within the cell. The development of this methodology was enabled by the facile labeling of the oligonucleotide and by the preservation of the label's pH sensitivity even when the conjugated oligonucleotides were condensed into delivery particles. Here, only a single fluorophore is used per nucleic acid molecule, thus avoiding the issue of uneven labeling (of nucleic acids or within particles) that can be present with two-fluorophore experiments.

Individual cells are examined in this assay, and particles residing in different zones within a given cell can be visualized and their local pH environment examined. Specifically, a 'pH map' of the delivery vectors can be determined as a function of the time-dependent spatial locations (i.e., close to the cell membrane, near the nucleus, or between) of the vectors as they traverse the cell. The relevance of this approach is demonstrated, for example, by the small percentage of cells showing PEI particles in region IV (those that are not acidified even after 24 h). In a bulk assay, this information would be lost, with such individual differences combined into a statistical average. Here, we directly access spatiotemporal information and use it to refine models of intracellular trafficking of delivery particles.

The current model of delivery vehicle transport through the cell suggests that the particles are first internalized within endosomal compartments, after which the compartments mature from early endosomes to late endosomes and finally to lysosomes; the pH of these compartments progressively declines until reaching pH ~4.5 (*10*, *17*, 23). Our results support this model of trafficking through the endocytic pathway by demonstrating and quantifying the reduction in pH experienced by delivered nucleic acids as they move through the cell. The ability of the delivery vehicles to circumvent or alter the steps of the endocytic pathway is of interest for understanding how efficiencies and transport rates are affected. Specifically, those particles that contain titratable amines at pH values between approximately 4 and 7 (such as PEI) are thought to buffer the endosomal compartments and prevent maturation into lysosomes. The buffering thus affects delivery. It is believed that those polymers that can buffer act as 'proton sponges' and promote osmotic swelling and lysis of endosomes. This lysis is speculated to allow endocytic pathway release that thus improves delivery efficiency (*11*, *15*).

In general, these models have been developed without an assessment of the spatial and temporal localization of the relevant pH changes. Each endosome is an individual entity and acidifies at a different rate that is

dependent upon cell type and other factors. Here, we specifically examine acidification within HeLa cells and find that spatial differences are prominent for CDP and PLL particles at early times (before 4 h). When these particles have trafficked for more than 12 h, they reach a pH of roughly 4.8−5.0 and show little difference regardless of position within the cell. These low pH values suggest that the endosomes have fully acidified and are at the lysosomal stage. For PEI, the spatial localization is less important than temporal differences, and the pH values are relatively constant throughout the cell for a given time point. After 24 h, the pH is ∼5.8, indicating that full acidification does not occur. For CDP-imid particles, the pH values are also relatively constant throughout the cell for a particular time point; the imidazole group acts to buffer the pH (relative to CDP particles), and the pH remains above 6 for almost 24 h (similar to PEI).

The uptake, intracellular trafficking, and gene delivery efficiency of PEGylated gene delivery particles differs from that of their unPEGylated variants (*21*). Comparing PEGylated CDP, PEGylated CDP-imid, and PEGylated PEI particles to their unPEGylated variants, we observe no significant differences in the extent or kinetics of acidification. This result indicates the PEG coating does not affect acidification or progression through the endocytic pathway. Retention of buffering capacity with the PEGylated particles is significant because systemic, in vivo administraton of nonviral gene delivery particles will require PEGylation or other means of salt-stabilization.

The relatively high delivery efficiency of PEI has been linked to its ability to act as a 'proton sponge', and there is evidence to support this hypothesis (*11*, *15*, *24*, *25*). Improvements in nonviral transfection efficiency in the presence of chloroquine have also provided credence to the 'proton sponge' hypothesis. It is shown here that chloroquine confers significant buffering activity to a vector system that otherwise readily acidifies. However, by comparing vectors with and without pH buffering capacity, it is clear that buffering capacity alone does not necessarily correlate with gene delivery efficiency. Despite similar pH buffering capacity, the three types of PEGylated particles generate reduced expression relative to their unPEGylated variants. The terminal imidazole group confers significant pH buffering capacity to CDP-imid that is not present for CDP; at the charge ratio examined here, the buffering activity does not correlate with significant improvements in transfection efficiency. Conversely, the significant buffering capacity of PEI is not seen in CD-PEI, but both vectors give strong expression, consistent with published results (*20*). The lack of correlation between buffering and gene expression has been observed by others (*13*, *26*). Forrest et al. revealed that acetylated PEI gave both reduced buffering capacity and improved transfection efficiency relative to unmodified PEI (*26*). (The buffering capacity of both CD-PEI and this acetylated PEI is reduced because some amine groups of PEI have been converted to other functionalities (*20*, *26*).) Also, recent reports have shown that new polymeric vectors designed with buffering capacity do not necessarily perform well as gene delivery vectors (*13*, *27*).

The data gathered here by a single-cell approach can be analyzed in aggregate for comparison with prior studies that have utilized flow cytometry to compile aggregate data. Our results in HeLa cells and those of Akinc and Langer in NIH 3T3 cells (*17*) both indicate that PEI shows a strong buffering capacity relative to PLL. This is consistent with a simple model where the titratable amines of PEI that are not present on PLL confer buffering capacity. In contrast, Forrest and Pack observed almost the opposite behavior, with PEI showing little to no buffering capacity as a function of cell line and PLL particles showing sharp variability as a function of cell line (*10*), including almost no reduction in pH in HepG2 cells even 15 h after transfection. Of note, fluorescently labeled nucleic acids were utilized in our study and that of Akinc and Langer, while Forrest and Pack conducted their experiments by fluorescently labeling the delivery vectors.

It has been widely observed that chloroquine treatment produces increases in transfection efficiency for many types of nonviral gene delivery particles (*16*, *28*), as seen in this study with CDP particles. The mechanism of this improvement is unclear. One possibility is that high intracellular or intravesicular concentrations of chloroquine induce the unpackaging of delivered nucleic acids from delivery vectors (*28*, *29*). Chloroquine is also known to buffer the vesicles of the endocytic pathway (*30*), and this buffering may inhibit the transfer of endocytosed gene delivery particles to lysosomes. Our results do not resolve the questions surrounding this mechanism, but they do show that chloroquine treatment inhibits acidification of intracellular CDP particles in HeLa cells. In the bulk assay of Akinc and Langer, chloroquine buffered the average pH of PLL particles in NIH 3T3 cells. In contrast to our results, their data included a sharp fluctuation where the average pH of the intracellular PLL particles dropped sharply to pH ∼4 in the first 2 h before rising upward in the next 2 h (*17*). The kinetics of chloroquine uptake may differ for the two cell lines. Although Forrest and Pack did not observe buffering by PEI, their bulk assay showed significant buffering when PEI transfection was accompanied by chloroquine (*10*).

When acidification of endocytic vesicles is buffered by gene delivery particles, the vesicles still progress through the endocytic pathway. PEI, for example, is shown here to demonstrate strong buffering capacity in a gene delivery particle. Lecocq et al. used centrifugation methods to show that intracellular PEI eventually colocalizes with the lysosomal marker cathepsin C (*31*). Kichler et al. observed that in vitro reporter gene expression was impaired when endosome acidification was inhibited with bafilomycin A1, indicating that, despite its buffering activity, PEI relies on the acidification process for transfection (*32*). Similarly, Singh et al. histidylated two cationic lipids to confer pH buffering and found that gene delivery with these lipids was less efficient in the presence of bafilomycin A1 (*33*).

Single-cell methods can supply new information on intracellular trafficking that will be useful in the design of improved gene delivery vectors. For example, various researchers have sought to enhance intracellular vector unpackaging by preparing acid-labile polycation−DNA particles (*14*, *34*). A detailed description of the spatial and temporal pH changes experienced by these particles in cells would indicate the probable intracellular location(s), timing, and extent of the particle degradation, thus facilitating refinement of the pH-sensitive vectors.

The compact, intense clusters of SNARF-4F fluorescence observed within cells are assumed to represent nucleic acids contained within vesicles. The small size of the SNARF-oligonucleotide suggests that the fluorescent signal from unpackaged intracellular oligonucleotides would appear diffuse. The absence of such diffuse staining could indicate that the majority of delivered nucleic acids remained within the delivery particles (*21*). Alternatively, the unpackaged oligonucleotide may present

a signal so diffuse that it is below the detection limit, or it may be rapidly degraded and/or expelled from cells.

One question that arises is why there might be any particles still remaining in region I (near the cell membrane) at 12 or even 24 h after transfection. One plausible explanation is that these particles have entered only a few hours earlier and have not had time to acidify. Particles in this category might have been stuck on the outer surface for hours before being endocytosed. However, this does not fully explain the existence of very low pH endosomes near the cell membrane. A second possibility is that such endosomes are trafficking very slowly toward the nucleus, or are traveling in a random trajectory and have fully acidified but happen to be close to the membrane when imaged. The particles must be transported along microtubules within endosomes in order to navigate the cytoplasm; the trajectories of these endosomes are often stochastic (*35*, *36*).

The advantages of the method presented here include the ability to directly visualize each cell and follow the internalization and endosome trafficking of delivery vehicles over time. This approach avoids or minimizes some of the problems of bulk imaging by flow cytometry that include quantitation of dead cells, presence of particles on the surface of the cell, and suppression of variability by intracellular region. The dynamics of the uptake and acidification process can be quantitated in both time and space, and any escape or other behavior monitored. By analyzing single cells, any variability in the process can be revealed and not buried in the overall average. This variability is especially evident at early times, as particles in certain spatial regions exhibit a broad range of pH values. We can also measure and segregate small subpopulations that would otherwise be combined into the statistical mean. Through the use of this assay, individual cells can be tracked for hours, and the spatial and temporal pH profile analyzed to better understand intracellular trafficking of nonviral gene delivery vectors. In summary, this new methodology has yielded data from which we have carried out further analyses of prior experiments performed in aggregate, quantified the differences in buffering capacity among a variety of delivery vectors, revealed that PEGylation does not significantly affect buffering capacity, and verified that chloroquine can confer buffering to gene delivery particles. The results presented here raise further questions about the role of pH buffering in the endocytic pathway and its importance to gene delivery efficiency.

Received March 19, 2005

A novel dual-labeled nanoparticle for use in labeling and tracking cells in vivo is described. We report the construction and characterization of these gadolinium−rhodamine nanoparticles. These particles are constructed from lipid monomers with diacetylene bonds that are sonicated and photolyzed to form polymerized nanoparticles. Cells are efficiently labeled with these nanoparticles. We have inoculated labeled tumor cells subcutaneouosly into the flanks of C3H mice and have been able to image these labeled tumor cells via MRI and optical imaging. Furthermore, the labeled tumor cells can be visualized via fluorescent microscopy after tissue biopsy. Our results suggest that these nanoparticles could be used to track cells in vivo. This basic platform can be modified with different fluorophores and targeting agents for studying metastisic cell, stem cell, and immune cell trafficking among other applications.

INTRODUCTION

The ability to localize transplanted cells in vivo and monitor their tissue biodistribution is prerequisite to an understanding of cellular migration after transplantation. Analysis of pathophysiological processes as diverse as the homing of T cells in response to pathogens or tumors, cancer cell metastasis, and tracking stem cells or transplanted cells require a fundamental understanding of the biology of cellular trafficking. One of the most promising areas of investigation that will benefit from the ability to noninvasively monitor cell migration and function over time is stem cell research. Stem cells have the capacity to differentiate into virtually any cell type in the body and therefore carry the potential to replace injured or diseased endogenous cell populations (*1*).

Among the most important issues related to the fate of transplanted cells are biodistribution, viability, and differentiation after reaching the target site. There is a great need to develop improved means of monitoring cell migration in vivo. Histological techniques, often utilized to determine the fate and migration of cells, lack the ability to serially track the full body distribution of the transplanted cells (*2*−*4*). A more recent methodology involves the use of polycationic transfection agents and superparamagnetic iron oxide particles for intracellular magnetic labeling of cells. While this technique may allow in vivo tracking of implanted cells via MRI, resolution limitations prevent the ability to characterize the transplanted cells at the cellular level (*5*−*7*). By using a modifiable nanoparticle platform, adapted in previous studies for targeted gene delivery and targeted radiotherapy (*8*), we tested the ability of similarly constructed nanoparticles to label and track cells in vivo. Gadolinium−rhodamine nanoparticles (Gd−Rd-NPs), a dual modality contrast agent, can potentially be used for serial monitoring of cell trafficking in vivo via MRI and/or in vivo optical imaging, MR/optical-guided tissue procurement, and fluorescence-enabled cellular characterization and isolation.

MATERIALS AND METHODS

Preparation of Monomers. *N*,*N*-Bis[[[[(13,15-pentacosadiynamido-3,6,9-trioxaundecyl)carbamoyl]methyl]-ethyl](carboxymethyl)amino]ethyl]glycine−gadolinium complex (Gd-lipid) was synthesized as previously described (*9*). All other lipids used for Gd−Rd-NP synthesis were obtained from Avanti polar lipids. 1,2-Dioleoyl-3-trimethylammonium-propane (DOTAP) and 1-palmitoyl-2,10,12-tricosadiynoyl-sn-glycero-3-phosphocholine (PC) were dissolved in chloroform (Sigma) to make 20 mg/mL stock solutions. Stock solutions of 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine-*N*-(Lissamine Rhodamine B Sulfonyl) (Liss-Rd) were prepared by dissolving 5 mg of the solid per milliliter of chloroform. All lipids were stored at −80 °C and thawed at room temperature prior to use.

Synthesis of Gadolinium−Rhodamine-Nanoparticles (Gd−Rd-NPs). Lipid monomer components (50% PC, 29% Gd-lipid, 1% Liss-Rd, 20% DOTAP) were mixed extensively and dried in vacuo while being shielded from

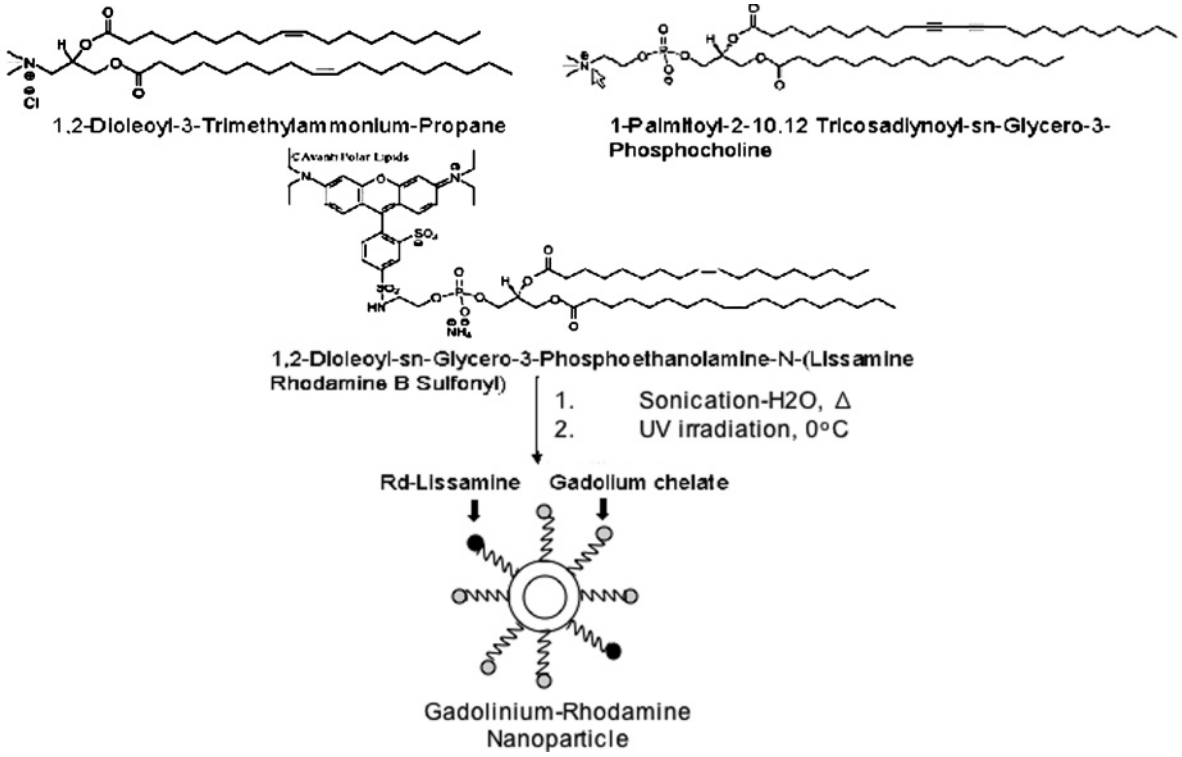

Figure 1. Diagram outlining key steps in the synthesis of the gadolinium−rhodamine nanoparticle.

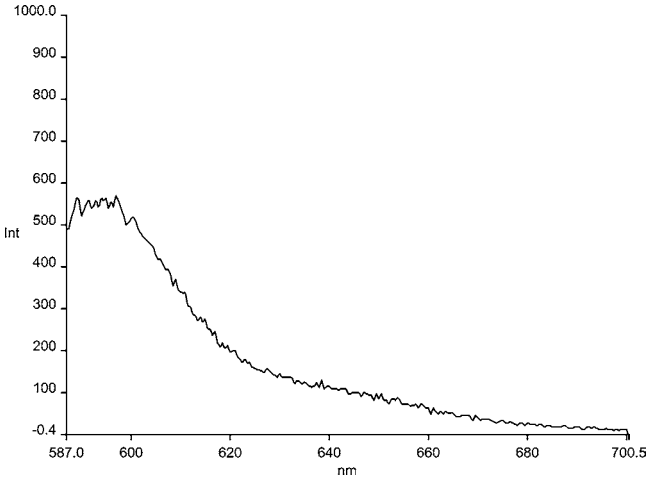

Figure 2. Fluorescence emission spectra of gadolinium−rhodamine nanoparticle in water. Plot of intensity (arbitrary units) vs wavelength (nm) depicting Gd−Rd-NP fluorescence after excitation at 570 nm.

light. The solid residue was resuspended with double-distilled water to a final lipid concentration of 15 mM and subsequently sonicated at 20 kHz (Branson 450 sonicator) while maintaining temperature above the gel-liquid crystal phase transition point. Polymerization of Gd−Rd-NPs was conducted at 0 °C under UV light (254 nm). The nanoparticles were then filtered through a 0.2 μm filter (Millipore) (Figure 1).

Physical Properties of Nanoparticles. Nanoparticle size was determined by dynamic laser light scattering using the Brookhaven particle size analyzer. Zeta potential was measured using a Zeta Potential analyzer (ZetaPALS, Brookhaven Instruments, NY).

Fluorescence Spectra. The fluorescence emission spectrum of the rhodamine-labeled nanoparticle was obtained using a LS 55 Luminescence spectrometer (PerkinElmer, Shelton, CT).

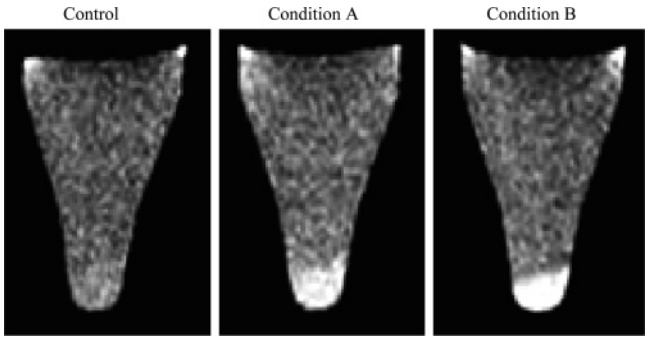

Figure 3. T1-weighted MR image of unlabeled, pelleted T47D breast cancer cells (~1.5×10^6) and pelleted cells labeled with gadolinium−rhodamine nanoparticle under conditions A or B. The average relative pixel intensity of the labeled versus unlabeled (control) cell pellets increases with labeling concentration of Gd−Rd-NPs.

Relaxivity Measurements. Relaxivity measurements were performed on a 4.7 T Bruker MR Scanner (Bruker, Houston, TX) at ambient temperature. The nanoparticle samples were diluted to concentrations of 2.17, 1.08, 0.54, 0.27, and 0.135 mM Gd with deionized water and transferred to a 200 μL-well plastic microtiter plate. T1 values were obtained from saturation recovery experiments performed with a standard spin−echo sequence and single slice acquisition (TR: 100, 200, 400, 600, 800, 1000, 1400, 2000 ms, TE: 15 ms). T2 values were obtained from spin−echo experiments with multislice acquisition (TR: 5 s, TE: 30 ms, number of echo images: 64). T1 and T2 were calculated using the ParaVision ISA tool to fit T1 recovery or T2 decay curve in circular region of interests for each sample. The resulting T1 and T2 values were averaged over the region of interest and plotted as 1/T1 or 1/T2 vs mM Gd^{3+}. The slope of these lines provides the molar relaxivity, R1 and R2, respectively.

Cell Labeling and in Vitro Imaging. Cell labeling was performed by incubating 60% confluent human T47D

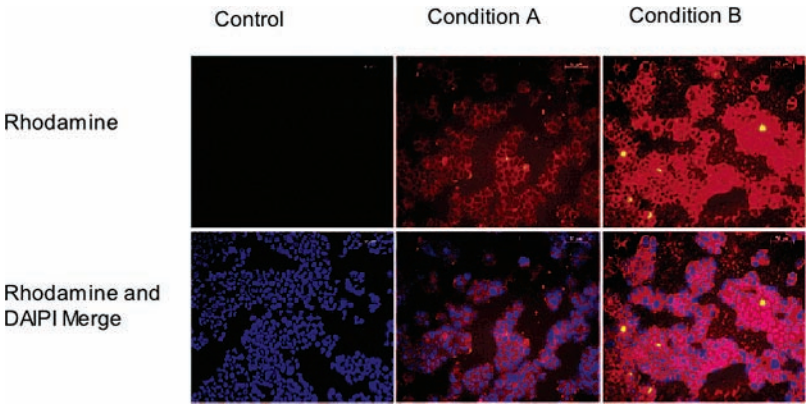

Figure 4. Fluorescence micrographs showing T47D breast cancer cell uptake of gadolinium−rhodamine nanoparticle in vitro. After 4 h of NP incubation, T47D cells demonstrate significant rhodamine fluorescence (RED). The amount of NP uptake into cells is proportional to the labeling concentration of the Gd−Rd-NP starting material (see Materials and Methods). Positive DAPI counterstaining (BLUE) indicates the viability of both Gd−Rd-NP-labeled and -unlabeled (control) cells.

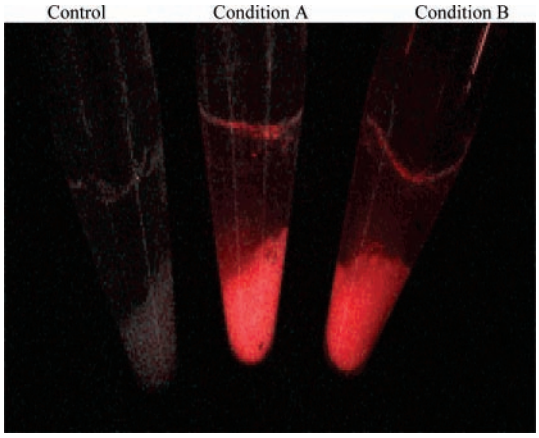

Figure 5. In vivo optical Imaging (Maestro *In Vivo* Multispectral Imaging System; Woburn, MA) of unlabeled cell pellet (left) and gadolinium−rhodamine nanoparticle-labeled cell pellets prepared under Conditions A (middle) and B (right).

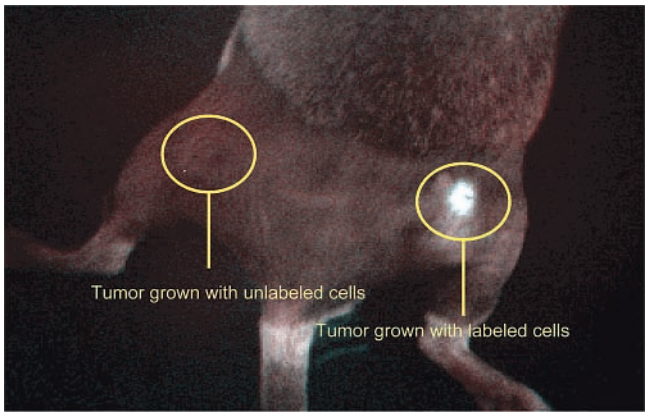

Figure 6. In vivo optical imaging (Maestro *In Vivo* Multispectral Imaging System; Woburn, MA) of mouse hind limb after inoculation with unlabeled tumor cells or gadolinium−rhodamine nanoparticle-labeled tumor cells. A female C3H mouse bearing unlabeled tumor (left flank) and Gd−Rd-NP-labeled tumor (right flank) imaged 7 days post subcutaneous inoculation (1×10^6 cells in each flank). Note that the fluorescent signal is localized only to the labeled tumor site and that no signal was received from the unlabeled (control) tumor.

breast cancer cells with Gd−Rd-NPs in 100 mm diameter culture dishes containing 5 mL of RPMI1640 culture medium supplemented with 10% fetal calf serum. Two different preparations of Gd−Rd-NPs were used for cell labeling studies: Condition A used a concentration of nanoparticles yielding 0.348 mM Gd3+ and 0.012 mM Rd; Condition B used a nanoparticle concentration yielding of 1.4 mM Gd3+ and 0.048 mM Rd. Labeling was carried out for 2 h in a cell culture incubator. Unlabeled (control) T47D cells were prepared under the same conditions excluding labeling with the nanoparticle. Prior to harvesting, cells were washed three times in PBS, trypsinized, and washed. Cells were then counted, transferred to 1.5 mL Eppendorf tubes at a concentration of $\sim 1.5 \times 10^6$ cells/tube, and pelleted. Each test tube was last topped with 0.5 mL of 4% gelatin. MRI of the cell pellets was conducted at 7 T using a T1-weighted SE sequence (as described above). In vivo optical imaging of the pellets was completed using the Maestro *In Vivo* Multispectral Imaging System (CRI, Woburn, MA). Cell labeling was also visualized using fluorescent microscopy. Labeled T47D breast cancer cells (under Conditions A and B described above) and unlabeled cells were prepared for fluorescence microscopy by plating in cultured chambers, washing the cells in PBS, and fixation in neutral 4% paraformaldehyde-PBS at room temperature. Prior to imaging, nuclei were counterstained with DAPI for ease of identification and demonstration of cell viability.

Tumor Inoculation and in Vivo Imaging. Approximately 1×10^6 Gd−Rd-NP-labeled tumor cells (Condition A) or an equivalent concentration of unlabeled (control) tumor cells were inoculated subcutaneously on opposite flanks of the hind legs of C3H mice. Seven days post inoculation the mice were imaged via MRI and in vivo optical imaging for anatomical visualization and localization of signal enhancement from labeled tumor cells.

RESULTS

Physical Properties of Nanoparticles: Gd−Rd-NPs are approximately 85 nm in diameter, and the polydispersity is 0.255. The zeta potential was determined to be 63 mV. Gd−Rd-NPs have an excitation maxima at 570 nm and peak fluorescence emission at ~595 nm in water (Figure 2). The R1 and R2 relaxivities for Gd−Rd-NP measured at 4.7T are 3.9 and 6.5, respectively.

Magnetic Resonance Imaging of Gd−Rd-NP-Labeled and -Unlabeled T47D Breast Cancer Cells. A T1-weighted MR image of pelleted, unlabeled. and Gd−Rd-NP-labeled T47D cells shows concentration dependent signal intensity enhancement secondary to cellular uptake of Gd−Rd-NPs (Figure 3). There is a 139% increase

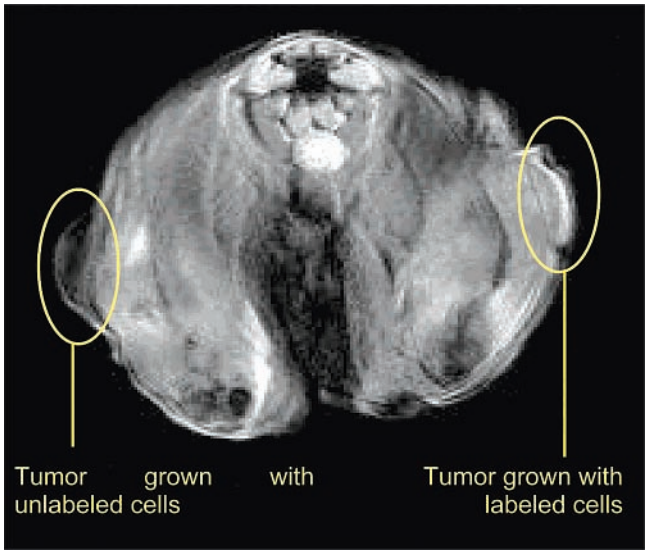

Figure 7. Axial MRI section of mouse 7 days after inoculation with unlabeled tumor cells and gadolinium−rhodamine nanoparticle-labeled tumor cells. Using the same mouse from Figure 4, a standard T1-weighted GEFI pulse sequence (TR = 30 ms, TE = 3 ms, matrix size = 256 × 256, 2 mm slice thickness) was used to acquire axial images over the entire body of the animal. Marked contrast enhancement can be visualized in the Gd−Rd-NP-labeled tumor vs unlabeled (control) tumor.

in average relative pixel intensity for T47D breast cancer cells labeled with Gd−Rd-NP under Condition A versus unlabeled (control), and a 146% increase for T47D cells labeled under Condition B.

Fluorescent Microscopy Gd−Rd-NPs-Labeled and -Unlabeled T47D Cells. Fluorescent microscopy reveals that the Gd−Rd-NPs accumulate in tumor cells after less than 2 h of incubation. Similar to MR images (Figure 3), Figure 4 demonstrates that the intensity of rhodamine fluorescence in breast cancer cells due to NP uptake is directly proportional to the fluorophore concentration in the Gd−Rd-NP starting material (Condition A vs B). Gd−Rd-NPs are endocytosed quickly by T47D cells and are evenly distributed in the cytoplasm. Morphologically identical DAPI staining of breast cancer cell nuclei is demonstrated in both labeled and unlabeled cells, further indicating cell viability after Gd−Rd-NP labeling

Optical Imaging of Cell Pellets. Gd−Rd-NP-labeled cell pellets visualized via the Maestro *In Vivo* Multispectral Imaging System demonstrate concentration dependent uptake of the NPs (Figure 5).

Whole Animal Optical Imaging. Similar subcutaneous tumor growth rates are observed on mouse flanks inoculated with either labeled or unlabeled T47D breast cancer cells (Figure 6). In vivo optical imaging of the whole mouse reveals fluorescent signal enhancement localized to the labeled tumor cells. In contrast, no signal is generated in tumors grown from unlabeled cells on the opposite flank.

Whole Animal Magnetic Resonance Imaging. Axial 2.0 mm slices across the mouse's body allow both the labeled and unlabeled tumors to be visualized in the same MR image (Figure 7). A representative image shows symmetrical contrast for anatomical structures about the long axis of the animal. However, using a T1-weighted pulse sequence, tumors grown from cells labeled with Gd−Rd NPs demonstrate marked signal enhancement compared to the unlabeled (control) tumor.

Histological Analysis. Histological sections of labeled and unlabeled tumor were prepared after in vivo imaging. Gd−Rd-NP-labeled tumor cells retain their optical properties as demonstrated by fluorescence microscopy (Fig-

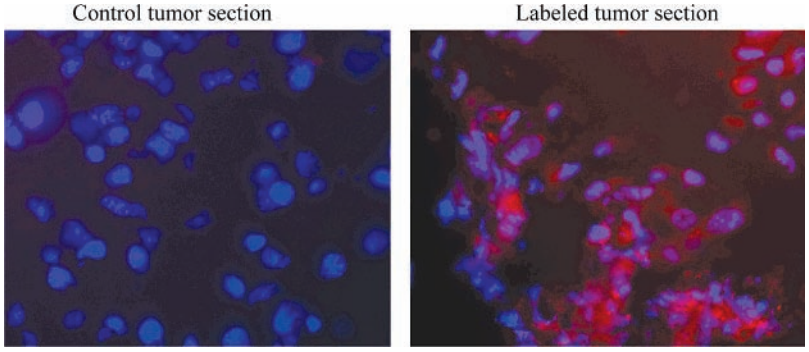

Figure 8. Fluorescence microscopy images of tumor cells from unlabeled and gadolinium−rhodamine nanoparticle-labeled tumor sections. Although the fluorescent signal is predominately localized to labeled tumor cells, some nonspecific labeling was noted upon sectioning.

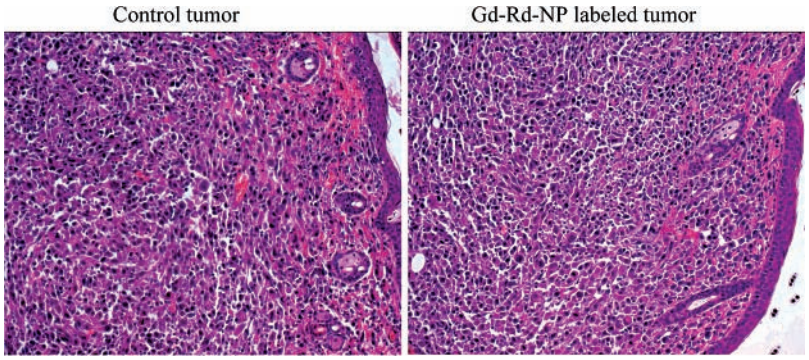

Figure 9. Light micrograph showing stained histological sections from mouse tumors grown from unlabeled tumor cells and gadolinium−rhodamine nanoparticle-labeled tumor cells. H&E stain demonstrates no change in cellular or tissue morphology between Gd−Rd-NP-labeled tumor sections and unlabeled (control) tumor sections.

ure 8). H&E staining of both the labeled and unlabeled tumor sections is indistinguishable: the labeled tumor cells showed no change in morphology and growth pattern as compared to unlabeled (control) cells (Figure 9).

DISCUSSION

In our experiments a novel fluorescent and paramagnetically labeled polymerized nanoparticle contrast agent, Gd−Rd-NPs, have been used to efficiently and quickly label tumor cells permitting detection by MRI, in-vivo optical imaging, and fluorescent microscopy. Gd−Rd-NPs offer the advantage of facilitating in vivo T1-weighted cellular imaging by MRI as well as detailed histological analysis through fluorescent microscopy. Cells labeled with Gd−Rd-NPs are viable and demonstrate little to no sign of altered cellular morphology. In addition, fluorescent labeling using Gd−Rd-NPs may also be used for isolation of cells via flow cytometry or laser capture microdissection. The ease of modification and complete control over synthesis conditions provided by our nanoparticle platform allows the construction of a myriad other nanoparticles with multiple labels and targeting moieties. Gd−Rd-NPs represent a new contrast material that provides facile cell labeling for noninvasive monitoring of cell migration and function using in vivo imaging techniques and histological analysis.

Synthesis and Evaluation of Insulin–Human Serum Albumin Conjugates

Karen Thibaudeau, Roger Léger,* Xicai Huang, Martin Robitaille, Omar Quraishi, Chantal Soucy, Nathalie Bousquet-Gagnon, Pieter van Wyk, Véronique Paradis, Jean-Paul Castaigne, and Dominique Bridon

ConjuChem Inc., 225 President-Kennedy Avenue, Montreal, QC, H2X 3Y8 Canada. Received April 1, 2005; Revised Manuscript Received May 18, 2005

A series of human insulin maleimido derivatives with short and long linkers was synthesized by exploiting the variations in the pK_a values and environment of the three amino groups present in the protein. The syntheses were accomplished in organic solvent because of maleimide's instability in basic aqueous media. The derivatives thus obtained were conjugated to the free thiol on Cys34 of human serum albumin (HSA) and purified. A structure–activity relationship based on in vitro receptor binding and activation results for this series of insulin–HSA conjugates showed that the best compounds were attached at the B1 position of insulin with either short or long linkers. Two conjugates were administered subcutaneously to streptozotocin-induced diabetic rats and found to possess blood glucose normalizing activity up to 8 h postadministration. The return to diabetic plasma glucose levels was not observed within the time frame of the experiment (48 h). In comparison, the insulin-treated group's normalization activity lasted 2 h and returned to a diabetic level at 8 h. The onset of the conjugate activities were delayed by 1 h when compared to the activity of human insulin. The study results led to the identification of CJC-1575 as a potent and long lasting human insulin analogue.

INTRODUCTION

Insulin is a vital endocrine hormone that binds to its cellular surface receptor, setting off a cascade of events culminating in glucose absorption from the blood. Low plasma levels of insulin lead to severe disorders such as types I and II diabetes. Type I diabetes is a life threatening disease where the patient must self-administer quick acting insulin for survival. In Type II diabetes, the therapeutic objective is glycemic control to reduce the onset of long-term pathological consequences. The treatment with insulin becomes necessary after the failure of lifestyle changes or glucose lowering drugs. A long lasting form of insulin will lead to better glycemic control and reduce the amount of injections, resulting in increased patient appreciation and compliance (*1*–*3*).

There are several known "long lasting" insulin drugs in various stages of development or available on the market. Some examples include slow release from the injection site (*4*), noncovalent binding to blood proteins through lipophilic interactions (*5*–*12*), PEGylation (*13*–*14*), or conjugation to a polymeric support (*15*). Alternatively, the conjugation of a maleimido derivative of a peptide to Cys34 human serum albumin (HSA) can prolong the presence of the bioactive species in plasma by protecting it against elimination through metabolic or excretion pathways (*16*–*21*). We became interested in the application of this methodology to human insulin, **1** (Figure 1), to demonstrate how a small protein can be coupled regioselectively to human serum albumin (HSA) and evaluate the new conjugate's properties.

An insulin–HSA fusion protein prepared through genetic engineering has recently been reported (*22*). The fusion protein has the insulin linked to the *N*-terminus of HSA and the two A and B chains tethered together by a peptidic chain. Edman degradation analysis identified the B chain amino acids sequence, indicating that the attachment of the insulin to HSA was at the C-terminus of the A chain. Although the resulting protein was bioactive, there was no further discussion of a structure–activity relationship (SAR) in the study. The product of conjugation of insulin to transferrin was also reported (*23*). In that study, the insulin was linked to transferrin by a disulfide-containing linking group attached to exposed lysine residues on both molecules. This nonregioselective technique can potentially cause important variations in biological responses due to a possible lack of batch-to-batch reproducibility.

Insulin contains two peptide chains with three disulfide bonds and three free amines. Hence, the challenge was to use insulin as a starting material and selectively attach a single maleimido group to each of the available amine sites. We report herein the synthesis of maleimido derivatives of human insulin, their conjugation to HSA, and the in vitro and in vivo biological evaluation of the conjugates.

EXPERIMENTAL PROCEDURES

Recombinant human insulin was obtained from ICN Chemicals as a 0.4% zinc salt. Flash column chromatography was carried out by using Biotage "40*i* flash chromatography" modular system. Unless otherwise specified, semipreparative HPLC purifications were done on a Waters "Breeze" system 1500 series using a Phenomenex luna (RP-18, 10 μ phenyl-hexyl 250 × 21.2 mm) column. The flow rate was 9.5 mL/min, and 9.5 mL fractions were collected. A gradient of acetonitrile (0.1%TFA) in water (0.1%TFA) was used with further details indicated within each compound's synthetic pro-

cedure. Outflow was monitored by UV absorbance at 214 and 254 nm. Fractions containing the desired product profile were identified by mass spectrometry. Preparative scale purification was done on a Gilson 690 system using a Phenomenex luna column (RP-18, 10 μ phenyl-hexyl 250 × 50.0 mm) using an acetonitrile (0.1% TFA)/water (0.1% TFA) as above. The flow rate was 50 mL/min, and 50 mL fractions were collected. Outflow was monitored by UV absorbance at 214 and 254 nm. Fractions containing the desired product profile were identified by mass spectrometry. LC/MS was performed using an Agilent 1100 series LC-MSD with a single quadrupole and an ESI electrospray source. The liquid chromatography part was done using a Vydac C18 (4.6 × 250 mm) column with a gradient of acetonitrile (0.1%TFA) in water (0.1%TFA) of 20−80% over 20 min. Automated Edman degradation (Applied Biosystems Procise 492 protein sequencer) and high-resolution mass spectroscopy analyses were done at the Sheldon Institute (Genome Quebec) of McGill University (Montreal, QC, Canada). Proton nuclear magnetic resonance spectra were gathered on a Varian 300 MHz Gemini instrument. SDS-PAGE electrophoresis was done on a SE 250 Mighty Small II (Pharmacia/Hoefer) using low range SDS−PAGE Molecular weight standards from BioRad (cat. # 161-0304).

***N*-Succinimidyl 3-Maleimidopropanoate, MPA-OSu, 8.** To 3-maleimidopropionic acid, **7** (20.5 g), *N*-hydroxysuccinimide (30.7 g), and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC, 51.1 g) in dichloromethane (300 mL) was added *N*-methylmorpholine (133 mL), and the mixture was stirred for 16 h at ambient temperature. The solvent was evaporated and the residue redissolved in dichloromethane (2 L). The organic layer was washed with 0.1 N HCl and brine and dried (Na_2SO_4). The solution was passed through a glass funnel filled with silica gel (1 kg). The silica gel was rinsed with dichloromethane (2 L) followed by a 1:1 dichloromethane/ethyl acetate mixture (4 L). The fractions containing product were combined, and the solvent was removed to give a white powder (23.7 g, 73%) (*24*). MS (*m/z*) 267 (M + 1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 2.78 (s, 4H), 2.98 (t, J = 7 Hz, 2H), 3.89 (t, J = 7 Hz, 3H), 6.70 (s, 2H).

8-(3-Maleimidopropionamido)octanoic Acid, MPA-OA, 9. **8** (6.02 g) was added to a solution of 8-aminooctanoic acid hydrochloride salt (3.95 g) in *N*,*N*-dimethylformamide (50 mL) in the presence of *N*-methylmorpholine (24 mL). The reaction mixture was stirred at ambient temperature for 16 h. The solvent was removed under vacuum. The residue was acidified by addition of 1 N HCl and the product extracted with ethyl acetate (2 × 500 mL). The combined extracts were washed with water and brine and dried (Na_2SO_4). The solvent was removed under reduced pressure, and the crude product (7.14 g) was used in the next step.

4-Nitrophenyl 8-(3-Maleimidopropionamido)octanoate, MPA-OA-OPNP, 10. Crude **9** (4.56 g) was dissolved in dichloromethane (100 mL). *N*-Methylmorpholine (3.2 mL) and *p*-nitrophenyl chloroformate (2.96 g) were added successively, and the reaction was stirred for 45 min at ambient temperature. The solvent was evaporated under reduced pressure, and the residue was taken up into dicholoromethane and divided into three portions. Each portion was injected into a Biotage flash column (40M) eluting with dichloromethane. The fractions containing product were combined and concentrated to give the desired product (4.2 g) as a white solid. Further purification was accomplished by recrystallization from ethyl acetate/hexane to give the desired product (3.14 g, 50%) as a white solid. MS (*m/z*) 432 (M + 1). Mp 149−150 °C. Thin-layer chromatography R_f = 0.31 (CH_2Cl_2/EtOAc 1:1). ^{1}H NMR (300 MHz, $CDCl_3$) δ 1.2−1.5 (m, 8H), 1.64−1.8 (m, 2H), 2.48 (t, J = 7 Hz, 2H), 2.57 (t, J = 7 Hz, 2H), 3.18 (m, 2H), 3.81 (t, J = 7 Hz, 2H), 5.50 (bs, 1H), 6.67 (s, 2H), 7.23 (m, 2H), 8.23 (m, 2H).

(A1)-MPA-insulin, 2. **1** (100 mg) was dissolved in *N*,*N*-dimethylformamide (2 mL) with trifluoroacetic acid

(100 μL). *N*-Methylmorpholine (200 μL) and **8** (9.2 mg, 2.5 equiv) were added, and the reaction was stirred for 2 h. The reaction was quenched by addition of water and adjusted to pH 4 with acetic acid. The precipitate was dissolved with water/acetonitrile (3:1, total volume 20 mL). The resulting solution was injected into semipreparative HPLC using a 27 to 31% acetonitrile gradient over 120 min. The fractions at t_R = 36−46 min were combined and lyophilized to give **2** as a white powder (40 mg) along with recovered **1** (23 mg). LC/MS t_R = 15.1 min. (*m/z*) 5958.0 (M + 4), UV (214 nm) purity >99%. HRMS calculated for $C_{264}H_{388}N_{66}O_{80}S_6$ + $4H^+$ 5958.696, found 5958.697.

(A1B29)-Bis-Boc-insulin, 11. 1 (1.0 g) was dissolved in anhydrous dimethyl sulfoxide (10 mL) and triethylamine (1.0 mL) under sonication. Boc_2O (84 mg, 2.2 equivalents) in dimethyl sulfoxide (0.5 mL) was added to the solution, and the reaction was stirred at ambient temperature for 30 min. The reaction was quenched by addition of acetic acid (14 mL) and water (100 mL). The resulting solution was injected into preparative HPLC using a 27 to 40% acetonitrile gradient over 60 min. The fractions at t_R = 38−47 min. were combined and lyophilized to give **11** as a white powder (674 mg, 65%). MS (*m/z*) 6007.8 (M + 4). HRMS calcd for $C_{267}H_{399}N_{65}O_{81}S_6$ + $3H^+$ 6006.766, found 6006.804.

(B1)-MPA-insulin, 3. 11 (51 mg) in *N*,*N*-dimethylformamide (3 mL) was treated with **8** (36 mg) in the presence of triethylamine (30 μL). The reaction was stirred for 2 h at ambient temperature. The solvent was removed under vacuum, and TFA (2 mL) added to the residue and stirred for 10 min. The TFA was evaporated, and the crude product was dissolved in water/acetonitrile (3:1). The resulting solution was injected into semipreparative HPLC using a 27 to 32% acetonitrile gradient over 120 min. The fractions at t_R = 58−59 min were combined and lyophilized to give **3** as a white powder (29 mg, 57%). LC/MS t_R = 15.7 min. (M/z) 5958.4 (M + 4), UV (214 nm) purity >99%. HRMS calcd for $C_{264}H_{388}N_{66}O_{80}S_6$ + $4H^+$ 5958.696, found 5958.671.

(B1)-MPA-OA-insulin, 4. 11 (1.0 g) was dissolved in *N*,*N*-dimethylformamide (20 mL) in the presence of *N*-methylmorpholine (300 μL). **10** (1.0 g) was then added, and the reaction was stirred at ambient temperature for 4 h in the dark. The reaction was quenched by precipitation with Et_2O (120 mL) and the precipitate isolated by centrifuge. The residue was treated with TFA (2 mL) for 10 min. The TFA was evaporated, and the crude product was dissolved in acetic acid (20 mL) and water (100 mL). The resulting solution was injected into preparative HPLC using a 27 to 40% acetonitrile gradient over 60 min. The fractions at t_R = 28−37 min were combined and lyophilized to give **4** as a white powder (654 mg, 63%). LC/MS t_R = 16.1 min. (*m/z*) 6099.6 (M + 4), UV (214 nm) purity >99%. HRMS calcd for $C_{272}H_{403}N_{67}O_{81}S_6$ + $3H^+$ 6098.803, found 6098.783.

(A1B1)-Bis-Boc-insulin, 12. 1 (74 mg) was dissolved in anhydrous dimethyl sulfoxide (2 mL) and acetic acid (46 μL). Boc_2O (6.9 mg, 2.5 equiv) was added to the solution, and the reaction was stirred for 5 h at ambient temperature. Water (15 mL) and acetonitrile (5 mL) were added to the reaction mixture, and the resulting solution was injected into semipreparative HPLC using a 27 to 40% acetonitrile gradient over 120 min. The fractions at t_R = 64−71 min were combined and lyophilized to give **12** (30 mg, 40%) as a white powder. MS (*m/z*) found 6006.8 (M + 4). HRMS calcd for $C_{267}H_{399}N_{65}O_{81}S_6$ + $3H^+$ 6006.766, found 6006.759.

(B29)-MPA-insulin, 5. 12 (30 mg) in *N*,*N*-dimethylformamide (2 mL) and *N*-methylmorpholine (100 μL) was reacted with **8** (10 mg) for 60 min. The solvent was removed under vacuum and the residue treated with TFA for 10 min. The TFA was removed under reduced pressure, the residue was dissolved in water/acetonitrile (3:1) and the solution injected into semipreparative HPLC using a 27 to 32% acetonitrile gradient over 120 min. The fractions at t_R = 39−49 min were combined and lyophilized to give **5** as a white powder (22.2 mg, 75%). LC/MS t_R = 13.1 min. (*m/z*) 5958.0 (M + 4), UV (214 nm) purity >99%. HRMS calcd for $C_{264}H_{388}N_{66}O_{80}S_6$ + $4H^+$ 5958.696, found 5958.690.

(B29)-MPA-OA-insulin, 6. 12 (20 mg) in *N*,*N*-dimethylformamide (1 mL) and *N*-methylmorpholine (100 μL) was reacted with **10** (20 mg) for 5 h at ambient temperature in the dark. The solvent was removed under vacuum and the residue treated with TFA for 10 min. The TFA was removed under reduced pressure, the residue was dissolved in water and the solution injected into semipreparative HPLC using a 27 to 31% acetonitrile gradient over 120 min. The fractions at t_R = 55−63 min. were combined and lyophilized to give **6** as a white powder (11 mg, 53%). LC/MS t_R = 15.6 min. (*m/z*) 6099.5 (M + 4), UV (214 nm) purity 97.8%. HRMS calcd for $C_{272}H_{403}N_{67}O_{81}S_6$ + $4H^+$ 6098.803, found 6098.858.

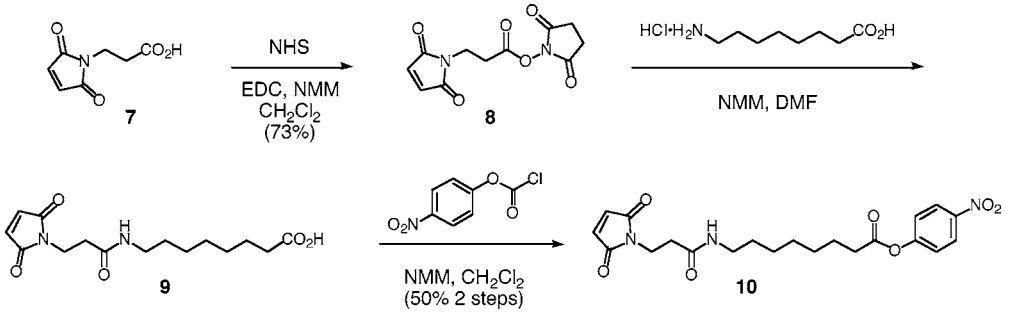
General Procedure for the Hydrolysis of Maleimide. The appropriate MPA-insulin (or MPA-OA-insulin) (20 mg) was dissolved in 10 mL of aqueous sodium hydroxide (0.1 N) and stirred at ambient temperature for 10 min. The reaction mixture was brought to pH 4 by addition of acetic acid. The resulting solution was injected into semipreparative HPLC using a 27 to 32% acetonitrile gradient over 120 min. The fractions at t_R = 45−54 min were combined and lyophilized to give the desired hydrolyzed material. The yields, purity, and mass analysis are described in Supporting Information.

Preparation of Conjugates. Each maleimido insulin derivative was solubilized in Nanopure water at a concentration of 10 mM then diluted to 1 mM into a solution of HSA (25%, Cortex-Biochem, San Leandro, CA). The samples were then incubated at 37 °C for 30 min. Prior to their purification, each conjugate solution was diluted to 5% HSA in 20 mM sodium phosphate buffer (pH 7) composed of 5 mM sodium octanoate and 750 mM $(NH_4)_2SO_4$.

Purification of Conjugates. Using an ÄKTA purifier (Amersham Biosciences, Uppsala, Sweden), each conjugate was loaded at a flow rate of 2.5 mL/min onto a 50 mL column of butyl sepharose 4 fast flow resin (Amersham Biosciences, Uppsala, Sweden) equilibrated in 20 mM sodium phosphate buffer (pH 7) composed of 5 mM sodium octanoate and 750 mM $(NH_4)_2SO_4$. When all flow through waste material was removed, a linear gradient of decreasing $(NH_4)_2SO_4$ concentration (750 to 0 mM) was applied over four column volumes. The fractions containing the conjugate were combined, desalted and concentrated using Amicon ultra centrifugal (30 kDa) filter devices (Millipore Corporation, Bedford, MA). The resulting solution containing purified conjugate was immersed into liquid nitrogen, lyophilized, and stored at −80 °C. The analytical results of the individual conjugates are displayed in Table 2 in the text.

SDS−PAGE of Conjugates. A sample (5 μg of protein/well) of the conjugates was subjected to nonreducing SDS−PAGE using a 10% (w/v) gel. A constant current 20 mA/gel for 1.5 h in separating gel was applied (*25*). The gels were then stained with 0.1% Coomassie Brilliant Blue R-250 for 30 min at room temperature, followed by

Scheme 1. Synthesis of Activated Maleimides with Different Chain Lengths



destaining in 10% (v/v) acetic acid and 30% (v/v) methanol in water.

Insulin Receptor Binding. Liver membranes from male Wistar rats (175 ± 25 g) were prepared in modified Na−K phosphate pH 7.4 buffer using standard techniques. Three milligram aliquots of membrane were incubated with 30 pM ^{125}I-insulin and the various other compounds for 16 h at 4 °C. Nonspecific binding was estimated in the presence of 1 μM insulin. Each compound was tested at 10^{-9}, 10^{-8}, 3.0×10^{-8}, 10^{-7}, 10^{-6}, and 10^{-5} M, and the insulin control had an extra concentration of 10^{-10} M. The membranes were filtered and washed three times with PBS buffer, and the filters were counted to determine the ^{125}I-insulin specifically bound.

Glucose Uptake Assay. Epidimymal fat tissue (0.03 g/mL) obtained from Wistar rats (175 ± 25 g) was degraded by collagenase in modified HEPES solution pH 7.4 at 37 °C. The test compounds at 10^{-9}, 10^{-8}, 10^{-7}, 10^{-6}, and 10^{-5} M and control (with an extra concentration of 10^{-10} M) were incubated with 500 μL aliquots of tissue in modified HEPES buffer pH 7.4 in the presence of D-[3-^{3}H]glucose (2.5 μCi/mL) at 37 °C for 2 h. The cells were harvested using GF/B filtermats, washed with PBS buffer, and dried, and the filtermats were counted to determine the cellular uptake of radioactive glucose.

Evaluation of Conjugates in Streptozotocin-Induced Diabetic Rats. Eight-week old male Sprague−Dawley rats (Charles River, St-Constant, QC, Canada) were administered a single intravenous injection of streptozotocin (60 mg/kg in 25 mM citrate/0.9% saline, pH4.5) to induce type I diabetes. Diabetic animals had mean blood glucose levels of 25.9 to 29.2 mM while glycemia ranged from 6.0 to 6.4 mM in normal rats. The test compounds (saline control, insulin 0.14 mg/kg, **3**−HSA and **4**−HSA 8.7 and 21.7 mg/kg) in 0.9% saline were administered as a single subcutaneous bolus injection in the dorsal area 2 days after streptozotocin treatment. Blood sampling was done via the tail tip, and glucose levels were measured using a hand-held glucometer (On Touch Ultra, Lifescan, Canada). The animals were supplied water and standard rat chow (Charles River Diet #5075) ad libitum and monitored throughout the experiment. Blood glucose levels were measured 30 min predose, 1, 2, 3, 4, 6, 8, 10, 11, 24, 30, and 48 h postdose.

Pharmacokinetics of 1 and 4−HSA. Subcutaneous pharmacokinetic profiles were done in 7−8 week old male Sprague−Dawley rats with body weights ranging 322−347 g. Each treatment group consisted of four rats. **4**−HSA was reconstituted in 0.9% saline while **1** was first dissolved in acidified water and further diluted to the required concentration with 0.9% saline. Blood samples were drawn at the following time points: −2, 10, 15, 20, 30, 40 min, 1, −2, 3 h and 2, 30 min, 1, 2, 4, 8, 24, 48, 72 h postadministration for **1** and **4**−HSA, respectively. Serum levels of **1** and **4**−HSA were determined using a human insulin ELISA kit (Linco Research, cat# EZHI-14K). The reference curves were generated with reference standards of known concentrations of **1** and **4**−HSA diluted in rat serum.

Ethics and Statistical Analyses. The experimental protocols were performed according to the Canadian Council on Animal Protection following approval by the Université du Québec à Montréal Institutional Committee on Animal Protection. All results are expressed as mean ± SEM or ± SD performed using GraphPad Prism software.

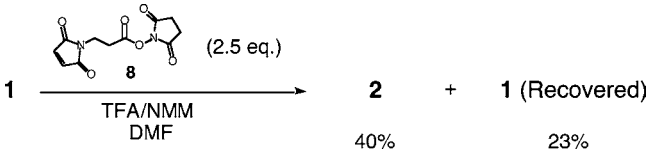
RESULTS AND DISCUSSION

Chemistry. The overall objective was to obtain the insulin−HSA conjugate with the best activity profile. In the case of the fatty acid and PEG derivatives, the focus was on the B1 or the B29 positions of **1** as points of attachment. This approach is in agreement with the proposed insulin receptor interaction (*26*). If direct acylation was to be used as a strategy, in most cases, the A1 position arose as the most abundant product from the mixture except when the C-terminal B30 was removed, which then favored acylation at B29 (*27*). In our approach, the exploitation of the pK_as (approximated as 11.1 for *N*ϵ-Lys B29, 8.4 for *N*α-Gly A1, and 7.1 for *N*α-Phe B1 in water) (*28*) and steric environments of the three amines was proposed as a means to selectively attach a single maleimidopropionamide (MPA) to each of the three individual positions of **1** as illustrated in Figure 1, more specifically A1 (**2**), B1 (**3** and **4**), and B29 (**5** and **6**).

Before initiating the synthesis of the insulin derivatives, two activated maleimide containing acylation reagents were prepared as described in Scheme 1. **8** was prepared from **7** using *N*-hydroxysuccinimide (NHS) and EDC (*24*). **8** was then used to prepare the longer linker maleimide by direct coupling to 8-aminooctanoic acid to give the intermediate **9** which was used crude in the next step. Attempts to make the succinimidyl ester of **9** led to purification difficulties and a tendency to decompose in aqueous media. **10** was ultimately made under mild conditions using *p*-nitrophenyl chloroformate (*29*−*30*) and was found to be easily purified and had a much improved stability profile.

Acylation using aqueous buffers could not be used in this strategy because of the tendency of the maleimido group to hydrolyze leading to a product that loses all ability to conjugate to HSA. This led to the development of buffer like conditions in *N*,*N*-dimethylformamide (DMF) with a mixture of trifluoroacetic acid (TFA) and *N*-methylmorpholine (NMM). These conditions were found to be convenient to solubilize the starting insulin and as a buffering medium. NMM has a lower pK_a than the ϵ amine on the B29 lysine. The latter will therefore, remain

Scheme 2. Synthesis of *N*α-A1-insulin MPA Derivative 2 Using Bufferlike Conditions in Organic Solvent



protonated while the α amine of the A1 glycine of insulin will have a larger portion of free amine at equilibrium resulting in more acylation product. The B1 phenylalanine is too sterically hindered to react and will require a different strategy.

As shown on Scheme 2, the A1 position remained the predominant product from the direct acylation of **1**. Compound **2** was obtained in 40% yield in a single step, along with 23% recovered starting insulin after purification. The remainder was a mixture of other positional isomers and bis-acylation products.

To obtain the other two B1 and B29 acylation products, a selective protection strategy was required. The bis *tert*-butyloxycarbamate (bis-Boc) A1 and B29 protection of **1** gave the best improvement in yield of the B1 derivatives. As shown in Scheme 3, intermediate **11** was prepared in 65% yield using a mixture of triethylamine and dimethyl sulfoxide as solvent and 2.5 equiv of di-*tert*-butyl dicarbonate (Boc_2O) (*31*−*34*).

Compound **11** was then converted to **3** and **4** using either **8** or **10**, respectively, under identical coupling conditions. The intermediate product from the acylation reaction was not isolated. Instead, the crude product was treated with TFA and purified. The final compounds **3** and **4** were obtained in similar yields of 57 and 63%, respectively.

Obtaining selective A1, B1 bis-Boc insulin **12** involved the addition of acetic acid to the reaction mixture (Scheme 4). In this case, the ammonium/free amine equilibrium in DMSO was such that only the lysine remained protonated throughout the process. **12** was obtained in low yield but enough material could be made to carry on. The completion of the syntheses of **5** and **6** was accomplished as described in Scheme 4. The yield of **5** was similar to the B1 acylation products but the conversion to **6** gave a slightly lower yield. Each synthesis was repeated to give multiple batches of **3**, **4**, **5**, and **6**, which were combined after examination of the purity profiles.

The demonstration of the position of attachment was done by Edman degradation. The amide bonds on maleimide were labile under high pH aqueous conditions used in routine automated Edman degradation. The study was therefore undertaken on the prehydrolyzed material to minimize any possible ambiguous results. The corresponding structures and compound numbers of the hydrolysis products are shown in Scheme 5, and the Edman degradation results are shown in Table 1.

The sequences read during the Edman degradation showed that in the case of **1** both chain amino acids were identified, indicating that no N-terminal amine was acylated. In the case of **13**, only the sequence associated with chain B was read, indicating that chain A was acylated. When this logic was applied to compounds **14** through **17**, it became possible to confirm that the initial maleimido derivative structures were correctly assigned.

Preparation of Insulin−HSA Conjugates. The conjugation of maleimido derivatives to Cys34 of HSA and subsequent purification using hydrophobic chromatography (*17*), where a purified conjugate is defined as free of starting HSA (mercaptalbumin and cystinylated albumin also termed "capped" HSA) and free of residual maleimido derivative of insulin, has recently become an efficient process. The conjugation step involved mixing the individual derivatives with 25% HSA and incubating for 30 min at 37 °C. The conjugation reactions were found to be very rapid, and there was no maleimide hydrolysis observed. Thereafter, the resulting mixtures were loaded directly onto a column packed with butyl sepharose 4 fast flow resin. The insulin−HSA conjugates adsorbed onto the hydrophobic resin whereas essentially all nonconju-

gated HSA eluted within the void volume of the column. Each conjugate was further purified from any free (unreacted) maleimido insulin derivatives by applying a linear gradient of decreasing ionic strength. The synthetic results are shown in Table 2.

The mass spectral analysis of starting HSA indicated that the MS peaks corresponding to the mercaptalbumin and capped albumin species were in a ratio of approximately 2:1, respectively. In the unpurified conjugate, the peaks corresponding to mercapatalbumin diminished while the conjugate peak appeared. Once purified, no residual unreacted HSA in either the mercaptalbumin or capped forms were found. The final products were stored as lyophilized powders.

Table 1. Edman Degradation of Hydrolyzed Insulin MPA Derivatives

		Edman degradation results (positions)			
compound	chain	1	2	3	4
1	**A**	Gly	Ile	Val	Glu
	B	Phe	Val	Asn	Gln
13	**A**	- -	- -	- -	- -
	B	Phe	Val	Asn	Gln
14	**A**	Gly	Ile	Val	Glu
	B	- -	- -	- -	- -
15	**A**	Gly	Ile	Val	Glu
	B	- -	- -	- -	- -
16	**A**	Gly	Ile	Val	Glu
	B	Phe	Val	Asn	Gln
17	**A**	Gly	Ile	Val	Glu
	B	Phe	Val	Asn	Gln

SDS−PAGE analysis of the HSA conjugates was done, and the results are shown in Figure 2. As illustrated, all the insulin−HSA conjugates had adequate purity profiles and migrated in the general area corresponding to proteins of molecular weights similar to albumin. A very faint band was observed above each conjugate as well as HSA. This band corresponds to HSA dimer and is often observed when analyzing HSA with gel electrophoresis.

In Vitro Evaluation. Insulin is produced in pancreatic Langerhans and acts by binding to the insulin receptor found on the surface of a variety of cell types. The insulin receptor is composed of two extracellular α units and two transmembrane β units. Insulin binds to the extracellular component causing the stimulation of tyrosine kinase activity of the β unit, leading to a cascade of phosphorylations that cause the activation of glycogen synthase as well as the translocation of glucose transporter 4 (GLUT4) to the cell membrane, thus initiating

the uptake of glucose into the cell (*35*). The optimum insulin derivative will be able to bind and activate the insulin receptor on the exterior of the cell at the lowest possible concentration, and the response will be the uptake of glucose from the surrounding medium in vitro or the lowering of plasma glucose in vivo.

The primary evaluation of conjugated insulin derivatives was done in vitro. The binding to the insulin receptor was accomplished using a homogenized rat hepatocyte membrane assay (*36*) as shown in Figure 3. The insulin receptor activation was measured in a glucose uptake assay on rat epididymal fat cells (*37*) as shown in Figure 4. The individual IC_{50} and EC_{50} values for receptor binding and glucose uptake, respectively, are shown in Table 3.

The structure−activity results from the in vitro evaluation of the five insulin−HSA conjugates indicate that B1 is the best position of attachment on insulin. The short linker on the A1 and B29 positions and the long linker on the B29 position caused large losses in binding affinity as demonstrated in the responses of **2**−HSA, **5**−HSA, and **6**−HSA, respectively. The short and long linker derivatives **3**−HSA and **4**−HSA, respectively, were essentially equipotent in the binding and glucose uptake assays. An approximately 10-fold loss versus **1** in glucose

uptake EC_{50} was observed for the two derivatives in this particular assay. Both conjugates were therefore chosen for in vivo evaluation.

In Vivo Evaluation. Type I diabetes was induced with STZ in free feeding Sprague−Dawley rats to an average basal blood glucose titer of >25 mmol/L. The blood glucose level was at an average of 5−6 mmol/L in normal nondiabetic rats. Each diabetic rat was administered a single bolus subcutaneous injection of **1**, **3**−HSA conjugate, **4**−HSA conjugate, or saline and were allowed to feed ad libidum. The blood glucose levels for all groups were monitored over a 2-day period. The dose of **1** was limited to 24 nmol/kg per animal to avoid more severe hypoglycemic events observed at higher doses. The experimental results are shown in Figure 5.

The glucose lowering effect of **1** was observed at the first time point (1 h). The glucose level proceeded to rise steadily after 2 h and returned to the STZ control group level by 8 h. It should be noted that in another experiment, **1** was injected at 120 nmol/kg and the glycemia returned to a diabetic level after 6−8 h as well (data not shown). **3**−HSA and **4**−HSA showed dose-dependent decreases in plasma glucose level where the effects reached their maximum between 4 and 6 h postadministration. At the highest doses, both conjugates were able to control the glucose level beyond 48 h.

Other parameters such as water and food intake as well as weight gain were monitored over the study period. The results showed that for both **3**−HSA and **4**−HSA, the three parameters resembled those from the normal rat group for the whole 48-hour data-gathering period.

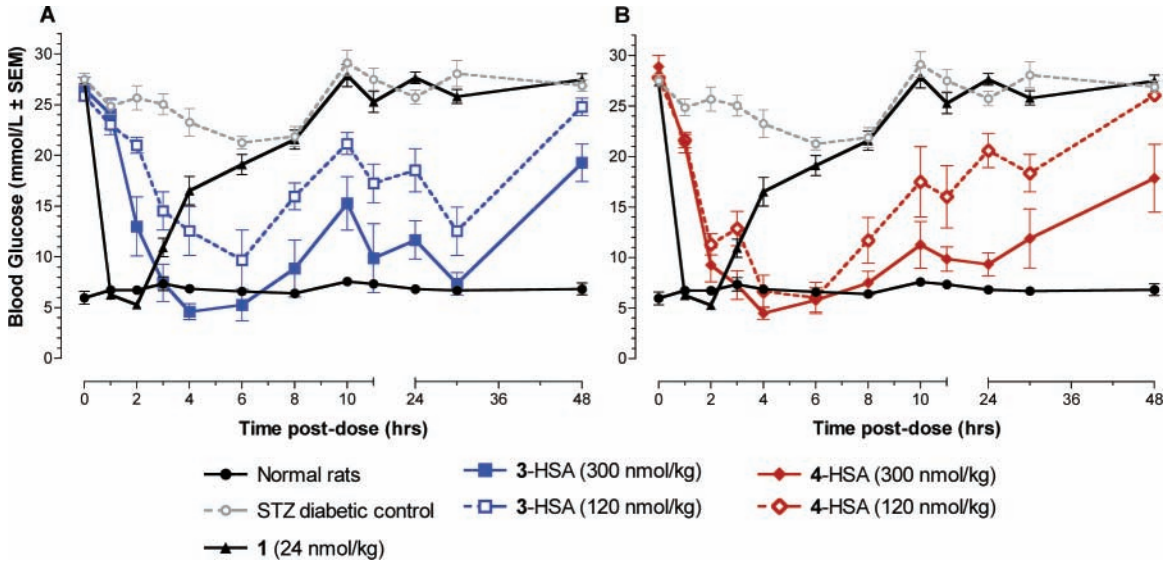

Figure 5. Glycemic control by insulin–HSA conjugates in streptozotocin (STZ)-induced type I diabetes in Sprague–Dawley rats. The results of plasma glucose measurements for **3**–HSA (A) and **4**–HSA (B). The insulin, STZ diabetic, and normal controls are the same in A and B.

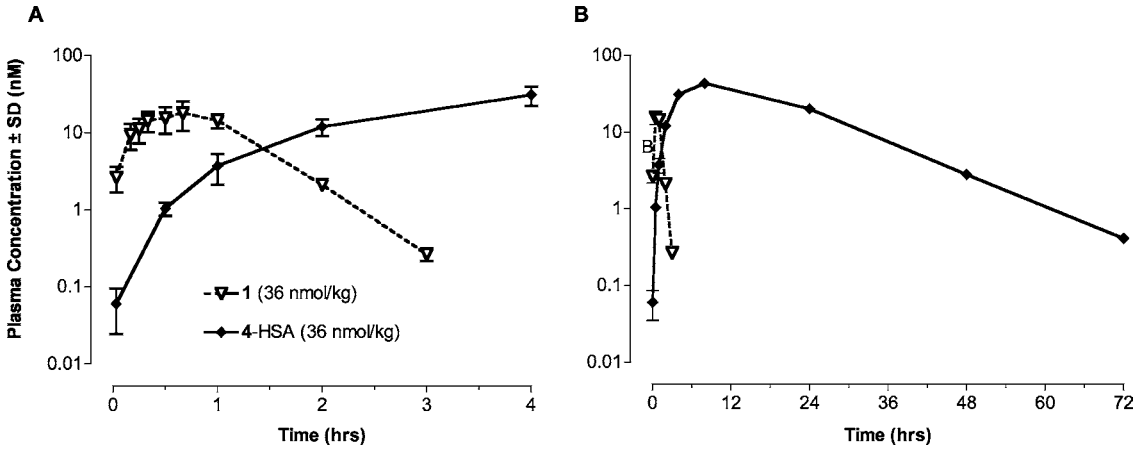

Figure 6. Pharmacokinetic profiles of **1** and **4**–HSA in normal Sprague–Dawley rats. The test compounds were administered subcutaneously, and plasma levels were monitored using a human insulin ELISA kit. Part A shows the first 4 h and part B the full 72 h.

Alternately, the diabetic control group as well as the one receiving insulin drank more water, ate less, and lost weight. It can be generalized that the STZ-induced diabetic animals returned to a normal feeding and weight gain pattern when administered insulin–HSA conjugates while the animals treated with **1** did not.

4–HSA was chosen for pharmacokinetic evaluation in normal rats using **1** for comparison. The plasma concentration as a function of time is shown in Figure 6.

When **1** was injected subcutaneously to rats, its peak plasma concentration was observed at 50 min and was no longer detectable after 3 h. On the other hand, the **4**–HSA plasma concentration peaked at 8 h and was still detectable at 72 h postadministration. These results correlate well with the glycemic control experiment where the peak glucose lowering activity was between 1 and 2 h for **1** and 4 and 6 h for **4**–HSA.

In summary, the three possible direct acylation positional maleimido derivatives of human insulin with either short or long linkers were synthesized. These derivatives were conjugated to HSA in good yield and purified using hydrophobic chromatography. In vitro analysis of the conjugates demonstrated that the B1 linking position of insulin led to the best overall binding and glucose uptake. Further in vivo evaluation identified **4**–HSA, also known as CJC-1575, as a delayed action and long lasting human insulin analogue. CJC-1575 is currently in preclinical development as a potential therapeutic agent.

Ligand-Directed Labeling of a Single Lysine Residue in hGST A1-1 Mutants

Sofia Hederos, Beatrice Karlsson, Lotta Tegler, and Kerstin S. Broo*

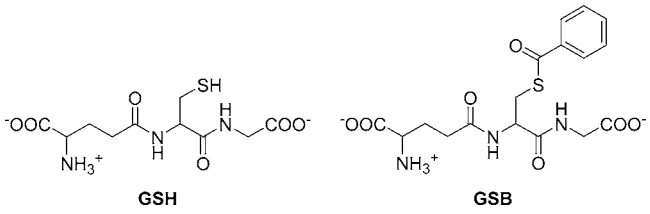
IFM Chemistry, Division of Organic Chemistry, Linköping University S-581 83 Linköping, Sweden .
Received April 12, 2005; Revised Manuscript Received June 7, 2005

Previously, we discovered that human glutathione transferase (hGST) A1-1 could be site-specifically acylated on a tyrosine residue (Y9) to form ester products using thiolesters of glutathione (GS-thiolesters) as acylating reagents. Out of a total of 20 GS-thiolester reagents tested, 15 (75%) are accepted by hGST A1-1 and thus this is a very versatile reaction. The present investigation was aimed at obtaining a more stable product, an amide bond, between the acyl group and the protein, in order to further increase the value of the reaction. Three lysine mutants (Y9K, A216K, and Y9F/A216K) were therefore prepared and screened against a panel of 18 GS-thiolesters. The Y9K mutant did not react with any of the reagents. The double mutant Y9F/A216K reacted with only one reagent, but in contrast, the A216K mutant could be acylated at the introduced lysine 216 with eight (44%) of the GS-thiolesters. The reaction can take place in the presence of glutathione and even in a crude cell lysate for five (28%) of the reagents. Through the screening process we obtained some basic rules relating to reagent requirements. We have thus produced a mutant (A216K) that can be rapidly and site-specifically modified at a lysine residue to form a stable amide linkage with a range of acyl groups. One of the successful reagents is a fluorophore that potentially can be used in downstream protein purification and protein fusion applications.

INTRODUCTION

Redesigning a protein scaffold to obtain a novel function is still a challenging task, even though progress has been made through rational design and combinatorial approaches (*1*−*5*). We have, along with some other groups (*6*−*12*), chosen to try to create new function by chemical modification of a protein scaffold to introduce an artificial group. We use the glutathione transferases (GSTs, EC 2.5.1.18)[1,2] as scaffolds in our reengineering experiments. They are detoxication enzymes (phase II) that catalyze the nucleophilic addition of glutathione (GSH, Scheme 1) to a wide range of hydrophobic electrophilic molecules (*13*−*16*). The proteins form homo- or heterodimers (*15*, *17*), and the mode of binding of GSH is basically conserved throughout the classes (*13*, *18*). The differences between the isoenzymes are primarily located in the promiscuous hydrophobic binding sites (H-sites) to provide a broad and overlapping substrate specificity (*19*). In the alpha class, the catalytic function is dependent on a conserved tyrosine residue (Y9) in the glutathione-binding site (G-site) that aids in the ionization of GSH to form the more reactive thiolate ion (*13*). The GSTs are close to ideal from a redesign aspect since they have modular features with specific binding of GSH in the G-site and an adjacent, promiscuous H-site. This, in combination with their high stability, ease of purification (*20*) and the extensive knowledge of structure−activity relationships (*21*) single out the GSTs as excellent candidates for chemical reengineering experiments.

Scheme 1



We have previously reported that a synthetic thiolester of glutathione (GS-thiolester) termed GSB (Scheme 1) is able to rapidly modify Y9 of human GST A1-1 (hGST A1-1, Figure 1) (*22*). The reaction is very precise and targets 1 out of 51 nucleophiles in the protein. Through a combinatorial screening process, we then expanded the number of GS-thiolesters that can modify Y9 of hGST A1-1 to a total of 15 reagents (*23*). The reagents include fluorescent probes and a unique aldehyde handle that can be used in further chemical derivatization experiments. This reaction was thus found to be very versatile, fast, and site-directed toward one residue in the protein with minimal side reactions. This is due to the glutathione-based backbone of the reagents that orients the suitably reactive thiolester functionality in close proximity to the reactive Y9 residue (*22*) while the adjacent, promiscuous H-site accepts a large variety of acyl groups. We can thus reengineer folded protein scaffolds with the goal of obtaining new function through the design and synthesis of appropriate GS-thiolesters.

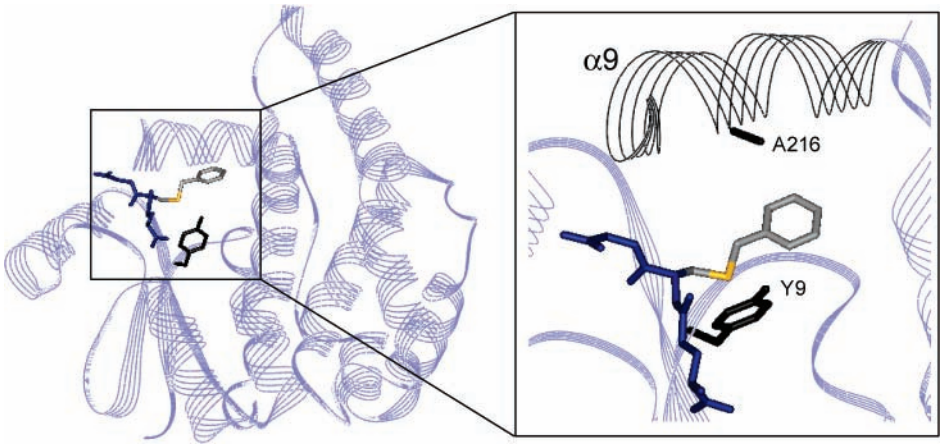

Figure 1. A close-up of the crystal structure (1GUH) of hGST A1-1 in a complex with *S*-benzylglutathione (*18*). The amino acids (Y9 and A216) subjected to mutation are shown in "stick" representation and helix 9 (α9) is also indicated in the figure. The protein is dimeric but shown here as a monomer for reasons of clarity of presentation.

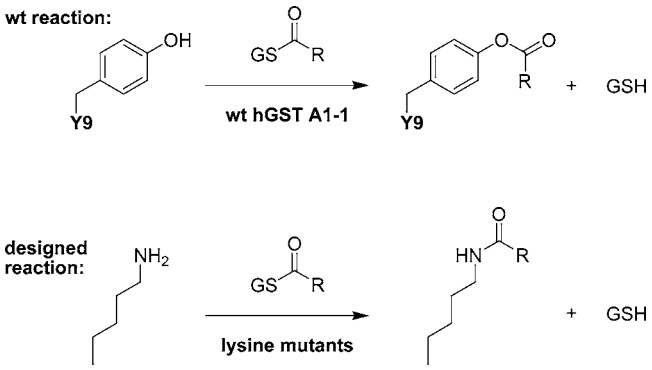
Scheme 2



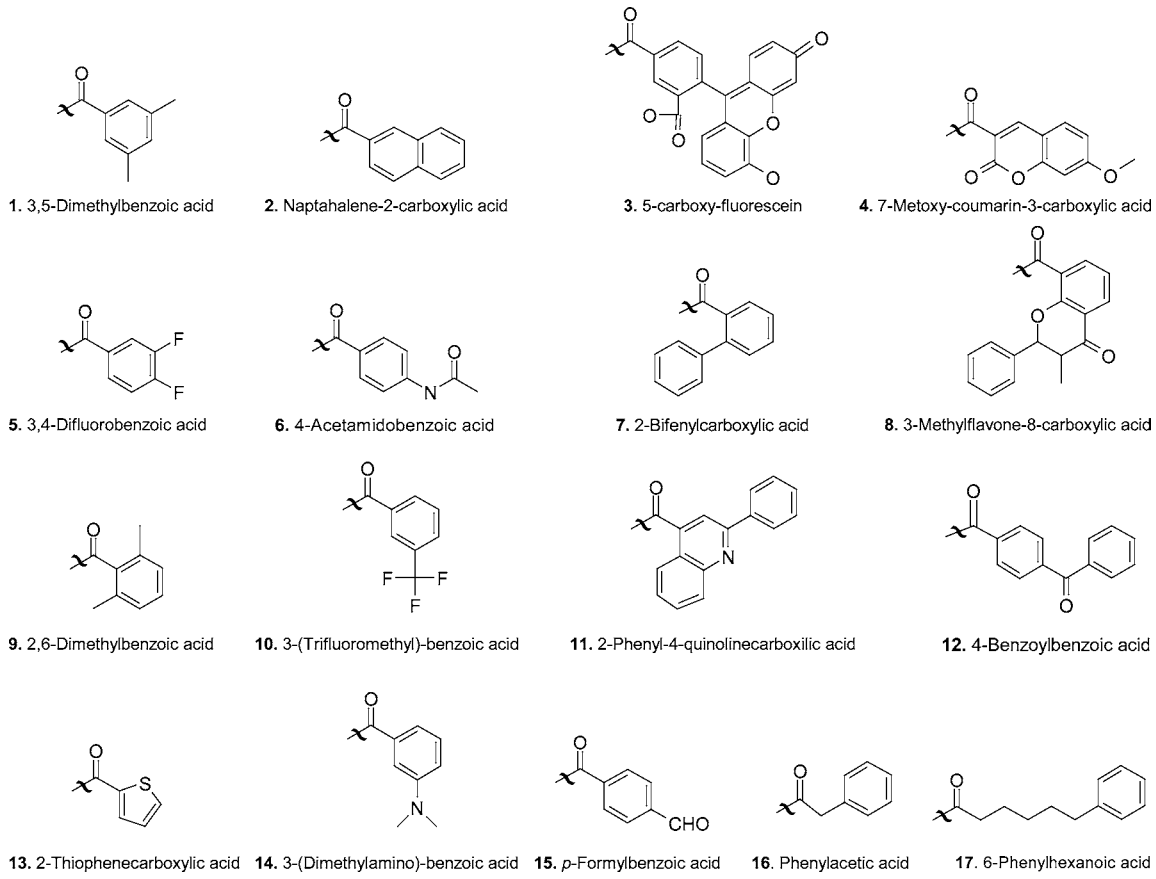
However, the reaction suffers some drawbacks mainly because the product is an ester formed from Y9 and the acyl group (Scheme 2). The product is unstable toward GSH (*22*), and addition of a fresh batch of another GS-thiolester to premodified protein results in scrambling of the acyl groups (*23*). Even though the benzoic acid-derived Y9-ester is stable, for other Y9-esters this bond is slowly hydrolyzed (*23*), and with this in mind we designed and prepared two lysine mutants of hGST A1-1, Y9K and A216K, that we hoped would form stable amide bonds with the acyl groups of the reagents (Scheme 2). The Y9K mutant is a straightforward change to see whether the targeted tyrosine could be directly substituted by a lysine. Position 216 was chosen because we have in another line of investigation found that a A216H mutant can, through a Y9-intermediate, function as a novel hydrolytic enzyme for GSB (*24*). We therefore knew that position 216 interacts with a Y9-ester and hoped that a potential intermediate could perhaps be transferred to a lysine residue. We also prepared a double mutant Y9F/A216K mainly for mechanistic reasons since we were interested in the role of the critical Y9 residue. We then screened these three mutants against a panel of 18 GS-thiolesters (Scheme 3 plus GSB) and used proteolytic digestion and MALDI-MS to investigate the outcome of the experiments. The reagents represents a broad range of sizes and physical properties (*23*) in order to increase the chances of finding reagents that are compatible with the lysine mutants, and also to not miss any potential information regarding reagent requirements.

MATERIALS AND METHODS

All chemicals and reagents used were of the highest purity available. All solid-phase syntheses were carried out in a VacMaster (International Sorbent Technology). The HPLC experiments were carried out using a Kromasil C_8-column (4.6 mm × 250 mm, Supelco Inc., Bellefonte, PA) attached to a Varian system with a ProStar 230 Delivery System, a ProStar 330 Photodiode Array Detector, controlled by the Varian LC Software. All masspectra were recorded using a MALDI-TOF MS (Voyager System 4212, Applied Biosystems) with detection in the positive mode. The UV measurements were performed using a Varian Cary 100 Scan UV−Visible spectrophotometer and analyzed with the CaryWin UV software. The syntheses of the reagents have been described before, and we used the stock solutions described in the previous report (*23*). The synthesis of the substrate GSB has also been described previously (*22*). All tripeptide reagents were analyzed with reversed-phase HPLC using a C_8 column and a shallow H_2O:ACN (both 0.1% TFA) gradient. The identities of the products were confirmed with MALDI-TOF MS using an α-cyano-4-hydroxycinnamic acid matrix with detection in the positive mode. The measured masses of the GS-thiolesters were in good agreement with the calculated masses.

Site-Directed Mutagenesis, Protein Expression, and Purification. The hGST A1-1 mutants were prepared by site-directed mutagenesis using the QuikChange kit (Stratagene). The vector pET-21a(+) with the hGST A1-1 gene inserted between the *Nde1* and *Sal1* restriction sites was used as template DNA, and mismatch oligonucleotide primers were purchased from DNA Technology A/S (Aarhus, Denmark). Mutants were identified by sequence analysis and the verified mutants were electroporated into *Escherichia coli* BL21(DE3) (Novagen, San Diego, CA). Protein expression of the mutants were performed in 1 L of 2 x YT medium with 100 μg/mL of ampicillin, and the expression was induced by 1 mM isopropyl β-thiogalactopyranoside followed by incubation at 37 °C for 3 h. The cells were harvested by centrifugation and lysed in an X-press (Biox), and the cell debris was then removed by centrifugation. The supernatant was desalted using PD-10 columns (Amersham Biosciences), and the proteins were purified by cation exchange chromatography as described previously (*25*) using a HiTrap SP column and an ÄKTA system (Amersham Biosciences, Piscataway, NJ). Purities were

Scheme 3



confirmed by SDS−PAGE, and the protein concentrations were determined spectrophotometrically using ϵ_{280} = 24 700 $M^{-1}\cdot cm^{-1}$ (*25*). The activities of the GSTs were tested with a standard assay (*26*) containing 1 mM each of 1-chloro-2,4-dinitrobenzene and GSH (pH 6.5 in 0.1 M NaP_i at 30 °C). The K_M measurements were performed in the same fashion using increasing concentrations (0.5 mM to 3.5 mM) of CDNB. The proteins were stored in NaP_i-buffered solutions containing NaCl and 10% glycerol at −80 °C or −20 °C until used in the experiments.

Fluorescence Measurements. Fluorescence measurements were performed on a Hitachi f-4500 fluorescence spectrophotometer, with excitation at 280 nm and emission scanning between 310 and 380 nm. The proteins were diluted to 1 μM in 100 mM NaP_i, pH 7.0, and the fluorescence spectrum of wt hGST A1-1 was also collected for comparison purposes (Supporting Information).

Modification Reactions. The modification reactions were performed with 100 μM GS-thiolester and 10 μM GST in buffer (0.1 M NaP_i, pH 7). The wt protein was also incubated with the reagents as a positive control. The reaction was allowed to proceed at 25 °C for 5 h. To control the temperature, the incubation was performed in an Eppendorf Master cycler gradient.

In the case of A216K, further investigations were made with respect to the stability toward GSH. Premodified protein was incubated with 1 mM GSH for up to 26 h at 25 °C. Samples were withdrawn at five and 26 h and the mixtures were digested before MALDI-MS analysis. In a separate experiment GSH (1 mM) was added to the buffer (0.1 M NaP_i, pH 7.0) prior to adding A216K (10 μM) and GS-thiolester (100 μM). The mixtures were then incubated for 5 h at 25 °C before being subjected to MALDI-MS analyses.

Modification Reactions in *E. coli* Lysate. A lysate were prepared from *Escherichia coli* BL21(DE3) cells (Novagen) in 50 mL of 2 x YT medium grown at 37 °C for 12 h. The cells were harvested by centrifugation and resuspended in 0.1 M NaP_i, pH 7, containing Complete Mini EDTA-free protease inhibitor cocktail (Roche Diagnostics) and lysed by sonication. The modification reactions were carried out by adding A216K (25 μM) and GS-thiolester (250 μM) to the cell lysate, and the mixtures were then incubated for 5 h at 25°C. The lysate itself was also analyzed by MALDI-MS to identify lysate-specific peaks (Supporting Information).

Proteolytic Digestion of Modified GSTs. The digestions were performed in the following way: 5 μL of modification mixture was diluted with 13 μL buffer (50 mM NH_4CO_3, pH 7.8), 2 μL *Staphylococcus Aureus* V-8 Protease from Pierce Biotechnology, Inc., Rockford, IL (stock solution 1 $\mu g/\mu l$) was added, and the sample was incubated at 25 °C for up to 2 h. A control reaction was also performed for each protein, containing unmodified protein, buffer, and protease. The fragment that contains K216 has the sequence K_{216}RKIFRF and the Y9 fragment has the sequence AEKPKLHY_9FNARGRME with one missed cleavage. Following incubation, 0.5 μL of the reaction mixture was mixed with 0.5 μL of saturated α-cyano-4-hydroxycinnamic acid matrix and analyzed by MALDI-TOF MS (Voyager 4212, Applied Biosystems) with detection in the positive mode. In the lysate experiments, all mixtures were acidified using 0.1% TFA and desalted with C_{18} Zip Tips before being subjected to MALDI-MS analyses.

Mechanistic Studies. A216K (10 μM) and Y9F/A216K were each incubated with GSB (100 μM), and samples were withdrawn at various time points starting at t = 0 min and the last ones after 24 h incubation at

25 °C. In a separate experiment, A216K was also incubated with GS-4 in a similar fashion. The samples were immediately quenched with TFA and stored at −20 °C until digestion and analysis using MALDI-MS. The samples were digested both at pH 7.8 as described above and at pH 4 using 50 mM NH_4OAc as buffer. In this semiquantitative experiment we avoided using C_{18} Zip Tips since that would have artificially increased the amount of modified, i.e., more hydrophobic, fragment relative to unmodified fragment. The data were analyzed by dividing the area of the *m/z* peak resulting from the modified fragment containing either Y9 or K216 by that of the respective (unmodified + modified) fragment.

RESULTS

Fluorescence and Activity Measurements of the Lysine Mutants. The lysine mutants were prepared and purified according to previously published protocols. Only the A216K mutant showed substantial activity toward the standard substrate CDNB, about 32% of wt hGST A1-1 activity (Table 1). We tried to measure the K_M for CDNB but the substrate precipitated (at 3.5 mM) before the enzyme showed signs of saturation (Supporting Information). Fluorescence measurements indicate that the proteins are folded, even though the Y9K mutant displays a spectrum with a slightly red-shifted maximum (Supporting Information).

Addition of the GS-Thiolesters to the Lysine Mutants. The outcome of adding the GS-thiolesters to the lysine mutants of hGST A1-1 was investigated by MALDI-MS. Each reagent (100 μM) was incubated with each mutant (10 μM) at 25 °C for 5 h. The samples were then analyzed by MALDI-MS following proteolytic digestion. To simplify subsequent analyses we used *S. aureus* V-8 protease since it cleaves after glutamic acid residues (and aspartic acid depending on reaction conditions) and is thus unaffected by any covalent modification of a lysine residue. In general, if a residue becomes covalently modified, the mass of the fragment containing this residue will increase with the mass of the corresponding acid minus the mass of water (Scheme 2). For control purposes, all three mutants were also digested after incubation in buffer without addition of any GS-thiolester. The Y9K mutant was unaffected by the addition of the reagents (Table 2). The A216K mutant on the other hand reacted with eight (44%) of the reagents to form a new amide bond between the corresponding acyl group and K216 (Table 2, Figure 2). The Y9 residue of A216K was not modified at the end of the 5-h incubation (Supporting Information). The double mutant Y9F/A216K did react with one substrate, GSB, to form K216-modified protein (Table 2, Figure 2). A positive classification in Table 2 corresponds to more than 10% modified lysine-containing fragment relative to the parent fragment (unmodified fragment). This relatively low threshold was set because MALDI-MS is not a quantitative technique and also because we use the same screening conditions for all GS-thiolesters, and the reaction conditions are therefore not optimized for each individual reagent and protein combination. This threshold was discussed at length in our previous paper (*23*).

Stability of the K216 Modification Reaction toward GSH. The stability of premodified A216K with respect to added GSH was also investigated using the panel of GS-thiolesters. For each one of the eight successful reagents, 10 μM A216K was preincubated with a GS-thiolester (100 μM) for 5 h at 25 °C. After incubation, GSH was added to a final concentration of 1 mM, 10 times the concentration that has been shown to quantitatively remove the Y9-ester of wt hGST A1-1 within 10 min (*22*). The mixtures were then incubated for 26 h at 25 °C, and MALDI-MS experiments following digestion showed as expected that none of the acyl groups were removed by GSH (Table 3, Figure 3C). A more challenging experiment was then performed where GSH (1 mM) was added to A216K (10 μM) in buffer prior to addition of GS-thiolester reagent (100 μM). The mixtures were then incubated for 5 h at 25 °C before being analyzed with MALDI-MS. Out of the eight GS-thiolester reagents that could modify K216 in buffer; five were successful in the presence of GSH (Table 3, Figure 3D).

Modification Reactions in a Cell Lysate. In the case of wt hGST A1-1 we were able to label Y9 in an *E. coli* lysate (*22*). This reaction is, however, not so practical since the ester can be removed by addition of GSH. In light of the stability of the K216 modification toward GSH, we investigated the possibility of modifying A216K in a cell lysate. The protein (25 μM A216K) and the GS-thiolesters (250 μM) were added to lysed BL-21 (DE3) cells, and the mixtures were incubated at 25 °C for 5 h. To obtain reasonable signals, the mixtures had to be desalted using C_{18} Zip Tips before being subjected to MALDI-MS analyses. We found (Table 3, Figure 4) that five of the GS-thiolesters were able to modify K216 in lysed *E. coli* cells.

Mechanistic Studies Concerning A216K Modification. To investigate the mechanism of the reaction more closely, A216K (10 μM in 100 mM NaP_i, pH 7) was incubated with GSB and GS-4 (100 μM, respectively) at 25 °C. Samples were withdrawn at a number of time points, digested, and analyzed with MALDI-MS to obtain semiquantitative data regarding the amount of modification of each side-chain, Y9 and K216, respectively (Figure 5). The samples were digested both at pH 7.8 as usual and also at pH 4 in order to ensure the preservation of any unstable intermediates. The reaction with the double mutant Y9F/A216K was also analyzed in this fashion using GSB, the only substrate that modifies its K216 side-chain (Figure 6). Only in the reaction between GS-4 and A216K and only in the sample digested at pH 4,

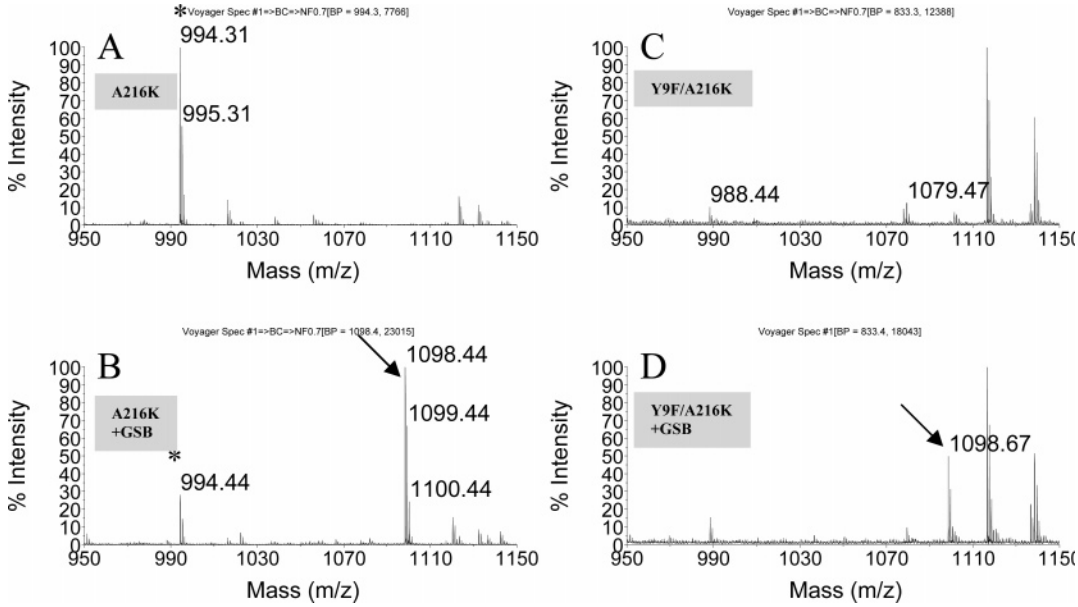

Figure 2. MALDI-MS spectra of proteolytic (*S. aureus* V-8) peptide fragments from (A) A216K; (B) A216K (10 μM) incubated with GSB (100 μM) for 5 h; (C) Y9F/A216K; and (D) Y9F/A216K (10 μM) incubated with GSB (100 μM) for 5 h. The *m/z* interval containing the K216 fragment (K_{216}RKIFRF) is shown in the figure. Parent fragments are indicated with asterisks, and modified fragments are highlighted with arrows. The parental fragment could not be detected for the Y9/A216K mutant.

could we observe a modified Y9 fragment. The modified Y9 fragment appeared to reach a maximum concentration around 30 min of incubation (Figure 7). We were not able to detect a Y9-intermediate in the reaction between GSB and A216K (Figure 5B).

DISCUSSION

The versatility, speed, and site-selectivity of the covalent modification reaction between Y9 of the hGSTs from the alpha class and numerous GS-thiolesters encouraged us to try to refine this reaction with respect to the stability of the end-product. We therefore prepared three lysine mutants of hGST A1-1 in the hope that at least one would be amenable to ligand-directed labeling in the folded state at the introduced lysine thus forming a stable amide bond. Since it is impossible to know beforehand what reagent (if any) would work, we chose to go about this in a combinatorial fashion and studied the outcome of adding a panel of 18 GS-thiolesters to these three mutants. As discussed previously, the GS-thiolesters vary widely in size, shape, hydrophobicity, and also reactivity (pK_a of the corresponding acid) (*23*).

A216K Shows GST Activity. Of the three mutants, only A216K shows any measurable GST activity toward the standard substrate CDNB (Table 1). The activity is only 32% of that of wt hGST A1-1, probably because helix 9 (α9) has to be folded over the H-site (Figure 1) during the catalytic cycle (*27*−*29*). The introduced K216 residue thus becomes positioned in the H-site, and this presumably lowers the hydrophobicity substantially and thus interferes with the binding of CDNB. In fact, the K_M for CDNB is too high to measure since CDNB precipitates at 3.5 mM, before the enzyme shows signs of saturation. This is in contrast to the wt protein that displays a K_M of 0.56 mM^{-1} for CDNB (*30*). It is not surprising that the enzymatic activity is demolished for Y9K and Y9F/A216K since this has previously been demonstrated when Y9 is mutated (*31*) (Table 1).

Lysine 216 Can Be Covalently Modified. Ideally, the covalent modification reaction should be as versatile as possible when it comes to accommodating different types of acyl groups since our goal is to chemically reengineer protein scaffolds toward novel functions. We were thus pleased to observe that the A216K mutant can be modified at the introduced K216 with as many as eight of the 18 GS-thiolesters in the panel (Table 2). The wt hGST A1-1 can be labeled at Y9 with 14 out of 18 reagents, and more than half of the GS-thiolesters work for both the wt protein and the A216K mutant even though different positions as well as different types of amino acid side-chains are targeted. The final target (K216) for this reaction is 1 out of 52 nucleophiles in the protein, and it is thus a very selective reaction. The extent of modification varies presumably at least in part due to the standardized conditions we used for all reactions. This is plainly visible when comparing the modification reactions between A216K and GSB and GS-4, respectively (Figure 6). After the standard 5 h of incubation, the yield is quantitative in the GS-4 reaction but the GSB reaction has only reached about 70% completion. The yield can thus most likely be fine-tuned since this was possible in the case of GSB and hGST A1-1 where the degree of modification was a function of both time and concentration of reagent (*22*).

The reason behind the high number of accepted acyl groups is of course the relaxed hydrophobic substrate specificity of the GSTs that originates from their biological function as detoxication enzymes. The combination

of a stringent G-site guiding the reagent and the adjoining promiscuous H-site undeniably makes the GSTs ideally suited as protein scaffolds in reprogramming experiments. It is interesting to note that a minor change at a carefully chosen position in the amino acid sequence of a protein (1 out of 222 residues) can lead to not just deterioration of the natural activity, something that is commonly found, but to a whole new function. We also observed this when we introduced a histidine residue at position 216, thus turning hGST A1-1 into a novel thiolester hydrolase (*24*).

Interestingly, only one reagent GS-16 (phenyl acetic acid, Figure 3) modifies K216 but not Y9 in the wt protein. This reagent was, however, found to be hydrolyzed to some extent in the presence of hGST A1-1, and it is quite probable that Y9 is acylated as an intermediate in this reaction (*23, 24*) and that the introduced lysine residue now quenches the reaction forming an amide bond instead.

We now have targeted a new position (216) thus leaving Y9 intact (Supporting Information and Figure 5), and this enhances our chances of developing new sensors and catalysts by the use of appropriate GS-thiolesters, since we can now choose to place the new functional group at either position Y9 (using the wt protein) or K216 (using A216K).

A Correlation between logP of the Acyl Group and the Activity of the GS-Thiolester. In our previous study we could not detect a systematic reason (size, reactivity, hydrophobicity, etc.) predicting the ability of a GS-thiolester to modify hGST A1-1. The reaction seemed pretty general, and we found only one reagent (GS-9) that was not able to modify any of the four alpha class hGSTs that we investigated. This acyl group (2,6-dimethylbenzoic acid) is di-ortho-substituted, and we concluded that GS-9 is too sterically hindered to function, especially since the di-meta-substituted analogue GS-1 (3,5-dimethylbenzoic acid) is an excellent derivatization reagent for all four proteins.

Unlike Y9 modification of wt hGST A1-1, there does, however, seem to be a correlation between the hydrophobicity of the acyl group and the ability to modify residue K216. The hydrophobicities of the acyl groups can be estimated using logP values (the partitition coefficient between water and *n*-octanol), the lower the logP value,

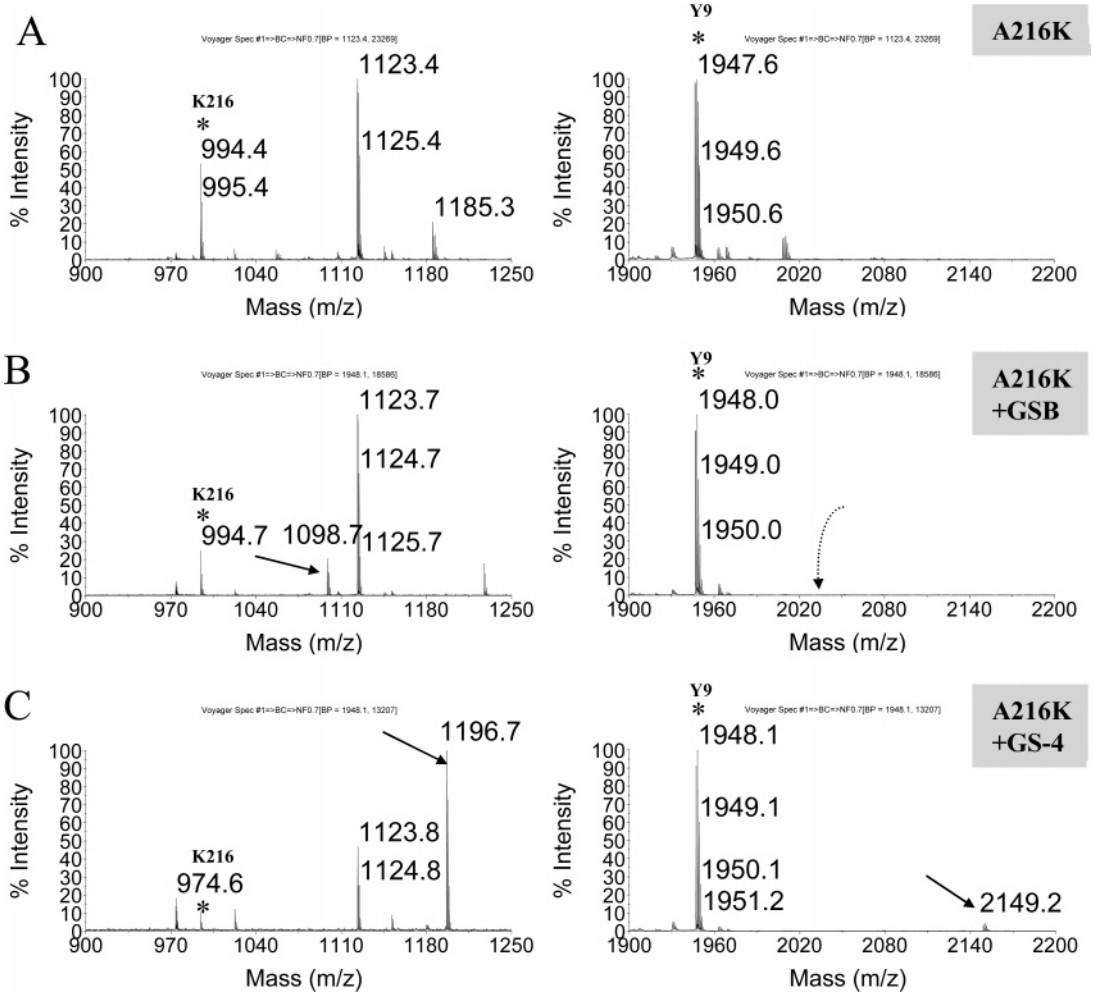

Figure 5. MALDI-MS spectra showing the reaction between A216K (10 μM) and GSB (100 μM) and GS-4 (100 μM), respectively. Time points were withdrawn, quenched with TFA and treated with protease (*S. aureus* V-8) at pH 4. The spectra show (A) A216K prior to the reaction; (B) A216K + GSB after 30 min of incubation and (C) A216K + GS-4 after 30 min of incubation. The *m/z* intervals that contain the K216 (K_{216}RKIFRF) and the Y9 fragments (AEKPKLHY$_9$FNARGRME, one missed cleavage) are shown for each reaction at $t = 30$ min. Parent fragments are indicated with asterisks, and modified fragments are highlighted with arrows. The mass (2051.1) that a modified Y9 fragment would have in the reaction between GSB and A216K is illustrated with a dotted arrow.

the more hydrophilic the acyl group. The logP values span a range from 1.3 (4-acetamidobenzoic acid) to 3.8 (2-phenyl-4-quinolinecarboxylic acid) and only the acids with a logP value below 2.3 are able to label K216 (Table 4). The exception is GS-9 even though it has a logP of 2.2, but this is not surprising as discussed above (*23*). This means that K216 cannot be modified with di-ortho-substituted or very hydrophobic GS-thiolesters, presumably due to the hydrophilic character of the lysine side-chain.

The size of the acyl group could perhaps also be of importance since most of the accepted acyl groups are among the smallest ones. However, the large 3-methylflavone-8-carboxylic acid (GS-8) is also able to modify K216, so this is not a very strict criterion, something that is not so surprising since the natural substrates of GSTs range widely in size and shape (*19*).

We now have some a priori knowledge that can guide us in the design of appropriate GS-thiolesters targeted for A216K derivatization. The acyl group should preferably have a logP below 2.3, and it should probably not be too large.

The K216 Modification Reaction is Resilient to GSH. One of the main drawbacks of the Y9 modification reaction using wt hGST A1-1 is that the product is an ester (Scheme 2) in equilibrium with added GSH. For example, addition of 100 μM GSH to 5 μM benzoic acid-modified hGST A1-1 quantitatively removes the acyl group within 10 min and thus shifts the equilibrium to the left (GSB and unmodified protein) (*22*). Hydrolysis of the Y9-ester is presumably also a problem for some of the reagents (*23*). Since an amide should be immune to addition of GSH if the reverse reaction is not catalyzed somehow, we added GSH to premodified A216K and were pleased to observe that the newly formed amide bond is completely stable toward added GSH. For five of the eight GS-thiolesters, the reaction could even take place in the presence of 1 mM GSH. This substantially increases the value of the reaction since we now have a stable end product that can be exposed to a variety of conditions and still survive.

The K216 Modification Reaction Can Be Carried Out in a Cell Lysate. It would be ideal if the labeling reaction could be carried out in crude bacterial lysate to avoid having to first purify the protein, modify it, and then purify the conjugate. Indeed, we were able to get the reaction to work in a lysate for some of the GS-thiolesters involved in Y9-modification of hGST A1-1 (*22*). We used an *E. coli* lysate and added A216K in order to know the protein concentration. The amount of protein

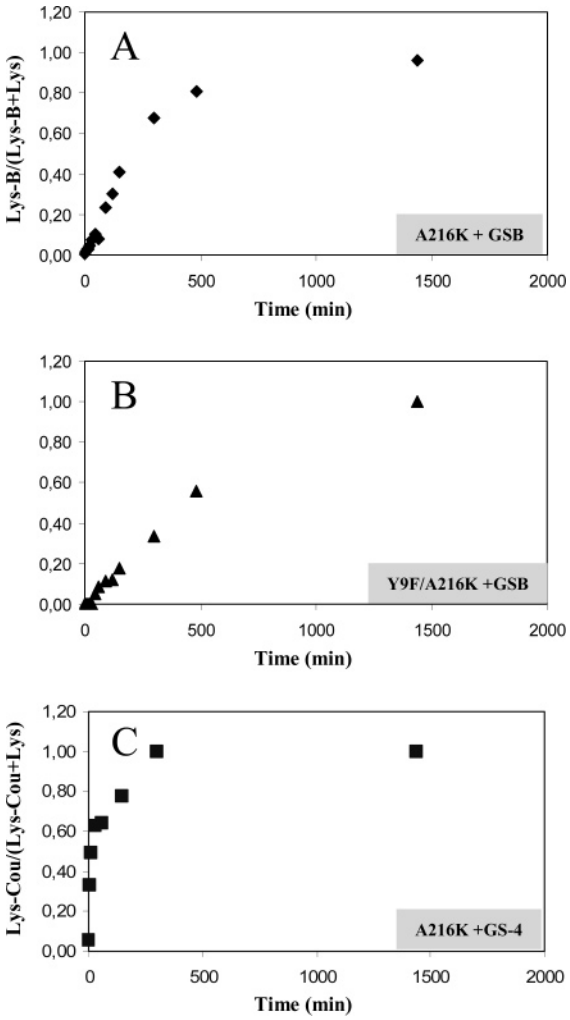

Figure 6. Semiquantitative analysis of the reactions between (A) A216K (10 μM) + GSB (100 μM); (B) Y9F/A216K (10 μM) + GSB (100 μM); and (C) A216K (10 μM) + GS-4 (100 μM) obtained from MALDI-MS experiments. Samples were withdrawn at the indicated time points, quenched with TFA and treated with protease (*S. aureus* V-8) at pH 7.8. The ratio of modified K216 fragment divided by the total amount of fragment (K216 + modified K216 fragment) is plotted vs time.

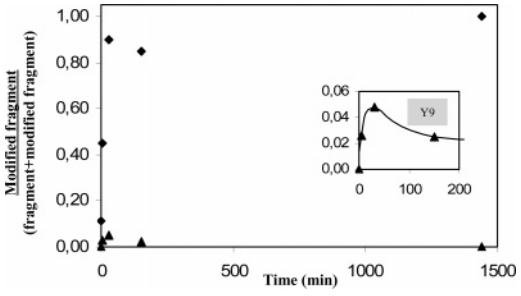

Figure 7. Semiquantitative analysis of the reaction between A216K (10 μM) + GS-4 (100 μM) obtained from MALDI-MS experiments. Samples were withdrawn at the indicated time points, quenched with TFA, and treated with protease (*S. aureus* V-8) at pH 4. The ratio of modified K216 fragment (◆) or Y9 fragment (▲) divided by the total amount of fragment (K216 + modified K216 fragment) or (Y9 + modified Y9 fragment) is plotted vs time. The inset is an expansion of the early time points showing the Y9-intermediate.

used (25 μM) is lower than what is achieved during normal expression of wt hGST A1-1 where the yield frequently is >100 mg of pure protein from 1 L of cell culture concentrated in 10 mL of buffer after harvesting

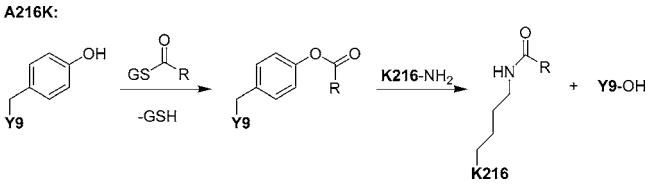
Scheme 4



the cells. Gratifyingly, five of the GS-thiolester reagents were able to modify K216 in protein-doped *E. coli* lysate. One of the reagents is a fluorophore (GS-4) that could potentially be used in downstream protein purification and protein fusion applications. Interestingly, the five successful reagents are the same ones as those that were able to modify K216 in the presence of GSH, indicating that the binding interactions are stronger for this subset compared to the three that only work in buffer alone (Table 3). We now have a robust reaction that can take place directly in a cell lysate and that is unaffected by the presence of GSH.

A Y9-Intermediate in the Reaction between A216K and GS-4. By collecting proteolytic data from early time points in the reaction between GS-4 and A216K, we could show that the reaction actually passes through an Y9-ester intermediate (Figures 5 and 7, Scheme 4). The amount of Y9-intermediate reaches a maximum at around 30 min (Figure 7). At any given time point, the amount of Y9-modified fragment is tiny, and we can therefore not report a separate rate constant for this step of the reaction.

Even though numerous time points were analyzed using proteolytic digestion both at pH 4 and 7.8, we were not able to detect any Y9-intermediate in the reaction between GSB and A216K. On the basis of the findings with GS-4, this could be due to a very fast intramolecular transfer from such a hypothetical intermediate to the lysine residue. However, we cannot exclude the possibility of a direct reaction between GSB and K216 since this is the only reagent that was able to modify the double mutant Y9F/A216K, albeit at a much slower rate (Figure 6). In any case, the hydroxyl group of Y9 speeds up the reaction between GSB and K216.

The Rate of the Modification Reaction of A216K Differs Greatly between Reagents. The reaction between A216K and GSB is much slower than the rate of modification of Y9 in wt hGST A1-1 (*22*). On the basis of semiquantitative MALDI-MS analyses, it takes roughly 200 min to reach 50% completion for K216-modification compared to about 20 min under similar reaction conditions in the wt reaction between GSB and Y9. In the case of GSB, we have thus increased the stability of the protein conjugate at the expense of the speed of the reaction. However, the rate is highly reagent-dependent

since the reaction between GS-4 and A216K is actually faster than the wt reaction with GSB. With GS-4 it takes approximately 10 min to reach 50% completion (Figure 6). This is even faster than the wt reaction with GSB, thus further adding to the value of the reaction. In any case, we have not decreased the yield of the reaction since it virtually goes to completion (Figure 6).

Why Does GSB React with Y9F/A216K? We do not know why Y9F/A216K reacts with GSB and no other reagent. It could be due to a more or less perfect fit that only in the case of GSB does the thiolester orient ideally with respect to K216. There might be unique binding properties in the case of GSB since other investigations by us (unpublished results) have also indicated that GSB is ideally suited as a substrate for the catalytic hGST A1-1 mutant A216H. This would be an effect similar to that of the mutant Y9F that displays some residual activity in the case of the natural GST activity (Table 1), even though the crucial hydroxyl group that aids in the ionization of GSH is removed (*31*).

CONCLUSIONS

We have introduced a single lysine at position 216 that can be site-specifically labeled by adding GS-thiolesters to the folded hGST A1-1 mutant. The resulting amide bond is stable, and the chemical labeling reaction can be carried out in the presence of GSH and even in a crude cell lysate. The set of reagents includes a fluorescent probe that could be utilized in future protein purification or fusion experiments. A more spectacular use would be to introduce a chemically reactive functional group that could take part in novel catalytic reactions.

Glutathione (γ-glutamyl-cysteinyl-glycine; GSH) is ubiquitous biological tripeptide with multiple functions and possible therapeutic uses. The oxidized disulfide form (GSSG) self-assembles into fibrillar aggregates and gels in organic solvents, but not in solvent mixtures with high water content. Here, the disulfide bond has been replaced with a pyrenyl moiety in order to test the ability of GSH to direct noncovalent self-assembly in H_2O, when combined with a hydrophobic driving force for aggregation. The resulting GSH-pyrene forms gels in 95% H_2O:5% DMSO. The γ-glutamyl group is critical for gelation, as it is with GSSG organo-gels, inasmuch as neither *S*-(pyrenyl)-cysteinyl-glycine nor the iodo-acetamido-pyrene precursor gels under any conditions studied. Circular dichroism and fluorescence spectroscopy indicate that the pyrene moieties cluster within the gels. Scanning and transmission electron microscopy reveal fibrous networks with individual strands of ~50−100 nm diameter. Saturation transfer difference (STD) NMR studies demonstrate that water interacts strongly with GSH-borne protons in both solution and gel states, but only the gels include water−pyrenyl interactions with significant residence times.

INTRODUCTION

Self-assembling gels have potential use in numerous bio-nanotechnologies including tissue engineering, biosensors, bioadhesives, and drug delivery (*1*−*13*). For several applications, bioactive peptide hydrogels with tunable sol−gel behavior are the desired endpoint. Recent examples of 'responsive' gels include vancomycin-sensitive Fmoc-D-ala-D-ala gels (*14*), and peptide gels triggered by enzymatic activity (*15*) or IR radiation (*16*). A significant challenge has been the design of low molecular weight (< ~1000 kDa) peptide-based systems that self-assemble in water, although a few examples based on amino acids or short peptides have been described (*16*−*20*). A design strategy that has yielded elegant self-assembled mesoscopic structures involves grafting orthogonal self-recognition elements into single molecules (*6*, *8*, *14*). Here, we report the utility of this strategy with the highly polar peptide of biological interest, glutathione (γ-glutamyl-cysteinyl-glycine, GSH), grafted onto pyrene. This expands the pool of low molecular weight hydrogelators to include a ubiquitous biomolecule with extremely diverse functions. We previously characterized organo-gels derived from GSSG (**1**, Figure 1, *19*). Upon gelation in DMF, DMSO, or MeOH, a specific local conformation of the −S−S− dihedral angle is favored, as suggested also for aroyl-cysteine derivatives (*21*). Furthermore, inter- and intramolecular hydrogen bonds at the γ-glutamyl group drive self-assembly of 75 nm wide nanofibers, which coincides with gelation. Therefore, we hypothesized that the highly polar γ-glutamyl group could be exploited as a self-recognition element, and, when combined with a sufficient hydrophobic driving force, GSH could provide a scaffold for low molecular weight peptide hydrogels. GSH is a major determinant of cellular thiol redox status, and it is a well-established antioxidant (*22*). GSH also has potential utility in cystic fibrosis therapy (*23*, *24*), and it is exploited widely as an affinity ligand for immobilizing fusion proteins on surfaces (*25*, *26*). Thus, GSH could provide a scaffold for hydrogels with novel therapeutic value or material applications.

Although there are an increasing number of examples of hydrogels incorporating biomolecules, very few mechanistic details of the self-assembly process have been elucidated, and kinetically relevant intermediates en route to gel formation have not been documented in any cases, to our knowledge. In particular it is unclear how solvent water is affected by the gelation agents and whether specific functional groups within the gelators are responsible. To address this aspect of gelation, we have utilized saturation-transfer NMR methods to monitor the site-specific interactions between water and gelator within the hydrogels. This method may be generally useful for understanding sol−gel behavior.

EXPERIMENTAL PROCEDURES

Materials and Chemicals. GSH, *S*-hexyl-GSH (**5**) and β-mercaptoethanol were purchased from Sigma (St. Louis, MO) and used without further purification. *N*-(1-Pyrene)iodoacetamide (**6**) was purchased from Molecular Probes (Eugene, OR).

The synthesis of **2** was achieved as follows: *N*-(1-pyrene)iodoacetamide (10 mgs, 0.025 mmol) was dissolved in DMSO (400 μL). To this solution was added GSH (2-fold molar excess), and the reaction mixture was stirred overnight protected from light. Excess water (10−15 mL) was added followed by centrifugation to isolate the GSH−pyrene conjugate as a solid pellet. The above procedure was repeated at least two times to ensure complete removal of excess GSH. The pellet

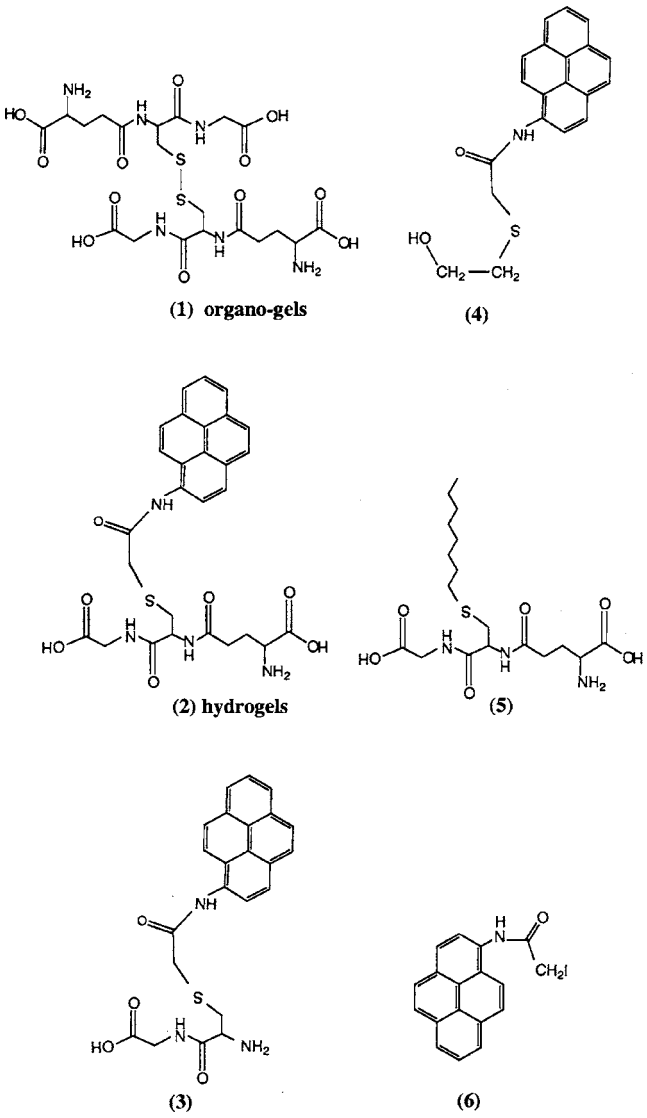

Figure 1. Structures of compounds compared in this work. **1** has been previously shown to form organo-gels.[19] **2** is a hydrogelator, as described within. Compounds **3**–**6** do not induce gelation under the conditions studied here.

obtained was then washed successively with acetonitrile and diethyl ether to obtain a gray solid. The solid was further dried to remove traces of water and ether (12 mgs, 82% yield). MS: calcd $M^+ = 564$, obsvd. $(M + 1)^+ = 565.2$. Compounds **3** and **4** were synthesized by an identical procedure, substituting either L-cysteine or β-mercaptoethanol for GSH.

Circular Dichroism. CD was performed with a Jasco J-720 spectropolarimeter with a scan rate of 50 nm/min and a path length of 2 mm, at 25 C. Samples were 1 mL containing 0.75 mM **2** in solvents described in the Figure 2 legend.

Fluorescence Spectroscopy. Fluorescence emission spectra were obtained with an SLM-Aminco 8100 fluorimeter, with slit widths of 4 nm, and excitation at 340 nm. Temperature was controlled with a circulating water bath.

Electron Microscopy. TEM was performed with a JEOL electron microscope at 80 keV. Gel samples were 'smeared' on a Formvar-coated copper grid (200 mesh, Fullam, Inc. Latham, N.Y.). The surface was washed briefly with EtOH and then stained for 1 min with 2% uranyl acetate in 95% EtOH. For SEM, gel samples were dried, sputter-coated, and placed on a polylysine-coated cover slip. Images were obtained at 15 keV on a JEOL 6300F scanning microscope.

^{1}H NMR. Saturation transfer difference experiments were performed on a Bruker AV500 system equipped with a H, C, F triple resonance probe, at 301 or 320 K at six saturation times (250 ms, 500 ms, 1 s, 2 s, 3 s, 4 s). Selective saturation of the water resonance was obtained by using a Gaussian cascade for the necessary saturation duration, followed by excitation sculpting for water suppression (*29*–*31*). Control spectra were obtained by placing the saturation frequency to −1.0 ppm followed by shifting the saturation frequency to the water resonance. Each experiment was conducted in an interleaved manner by collecting the control and saturated spectra in alternate scans and storing them in separate memory blocks, to average the effects of instrument instability over the period of the data collection. The STD amplification factor is defined here to be

$$\% \text{ amplification factor} = [I_0 - I_{sat}]/I_0 \times 100$$

where I_0 and I_{sat} are the spectral intensities of any single proton without and with water saturation, respectively.

Also, T1 relaxation measurements at 301 K were performed on a Bruker AV300 system. An inversion recovery sequence was employed to collect T1 data with a recycle delay of 10 s to ensure the complete recovery of magnetization at the end of each scan. The magnetization recovery curve given by

$$M_z = M_0\,[1 - 2 \times \exp(-t/\mathrm{T1})]$$

where M_z and M_0 are the magnetization vectors along the 'z' axis at time t and M_0 is in the initial net magnetization, respectively, was fitted to the data and T1 values were extracted. Care was taken to fit this single exponential recovery curve only in the initial rate regime to avoid the contamination of exchange rates on the measured T1 values (*27*–*29*). The NMR samples were prepared by using 30 mM solution of GSH pyrene in DMSO-d_6 followed by addition of water to get a 50:50 mixture. The samples were mixed well to get a homogeneous solution and then transferred immediately to a NMR tube.

The pulse sequence for the STD NMR experiment was adopted from 1D NOE difference pulse sequence developed by Meyer and co-workers (*27*). The on-resonance irradiation of water was performed at a chemical shift of 4.45 ppm. To minimize the error due to magnet instability, a reference spectrum was also collected simultaneously with off-resonance irradiation applied at −1 ppm, as no signals of GSH pyrene were observed in that region. The total numbers of scans was 256 with 16 'dummy' scans.

RESULTS

On the basis of the apparent selectivity of the γ-glutamyl group of GSSG in directing supramolecular self-assembly of organogels (*19*), we hypothesized that a hydrophobic moiety attached to GSH could provide a thermodynamic driving force for gelation in water. Analogues containing the γ-glutamyl group could provide a versatile range of gelators, in a manner analogous to the organo-gels derived from GSSG. Therefore, **2** was synthesized and its hydrogelation properties were **c**ompared to the des-γ-glutamyl analogue **3**, and to **4**, **5**, and **6** (Figure 1). Addition of H_2O to stock solutions of **2** in DMSO immediately yielded transparent, fluorescent gels. In solvents ranging from 95:5–40:60 (vol/vol) H_2O:DMSO, at

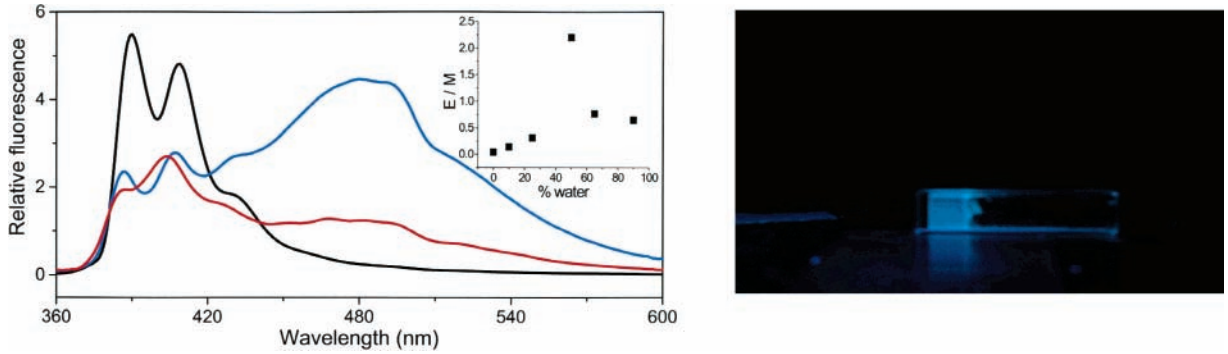

Figure 2. Left Panel: Fluorescence emission of **2** (0.75 mM) in different sol−gel states. The emission from excimers (485 nm) correlates with formation of gels. Black, 100% DMSO; red, 90:10 H_2O:DMSO; blue, 50:50 H_2O:DMSO. Inset: The maximal E/M ratio, 50:50 H_2O:DMSO yields the stiffest gels, but gels are formed even at 95:5 H_2O:DMSO. E/M = intensity at 485 nm/intensity at 390 nm. Excitation = 340 nm. Right Panel: Photograph of a fluorescent hydrogel (95:5 H_2O:DMSO) formed from 1 mM **2** in a cuvette lying on its side.

final concentrations of 1 mM to 10 mM, only **2** yielded transparent, fluorescent gels; in contrast, **1**, **3**, **4**, **5**, and **6** yielded clear solutions or precipitates, and no gels under any conditions studied. The uniqueness of **2** as a hydrogelator among the other analogues is interesting and reminiscent of the specificity observed for GSSG as an organogelator among structural congeners. The γ-glutamyl linkage may be useful in driving gelation in a wide variety of systems.

Fluorescence Characterization. Other pyrene-containing gelators have yielded excimer emission upon gelation, and this provides a convenient low resolution probe of pyrene-pyrene interactions (*7*, *30*). Gelation of **2** coincided with formation of a pyrene excimer fluorescence spectrum (485 nm) in contrast to monomer emission at 370−390 nm for the solution state (Figure 2). Although the absolute fluorescence intensity changed with solvent composition, the excimer:monomer ratio (E/M) clearly increased at higher ratios of H_2O:DMSO, with a maximum at 50:50 (Figure 2, inset). The E/M ratio corresponded well with the apparent stiffness of the gels, which was also maximal in this range. At 1 mM **2**, the gels were sufficiently stiff to remain in an inverted vessel even at 95:5 H_2O:DMSO.

Circular Dichroism. Ground-state chromophore interactions were monitored by circular dichroism (CD). Pyrene CD excitation bands at 290−400 nm were observed in the gel state, but not the solution state. The CD bands are characteristic of chiral pyrene complexes and indicate direct ground-state chromophore interaction (Figure 3). Although the rheological properties of these gels remain to be studied in detail, the temperature-dependent CD spectrum (Figure 3, inset) yields a T_m for gelation of 46 °C for 1 mM **2** in 90:10 H_2O:DMSO. Interestingly, there was a modest increase in ellipticity at 366 nm with increasing temperature, until the gel melted at ∼46 °C. Perhaps, the hydrophobic effect resulted in stronger, or more complete, pyrene−pyrene interactions with increasing temperature, until the gels melt at 46 °C.

In the previous work with GSSG gels a negative CD band at 240−250 nm was observed only in the gel state. In the sol state, a positive band was observed at this wavelength. On the basis of this, and comparison to CD spectra of cysteine-containing peptides (*31*), we assigned the negative CD band to the γ-Glu-Cys bond, which apparently is conformationally restricted in the gels. Due to the intense CD band of the pyrene groups, we were unable to observe this spectroscopic signature in the hydrogels from **2**.

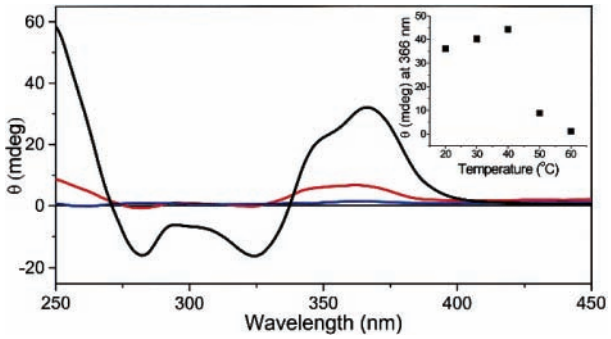

Figure 3. Sol-gel transition of **2** (0.75 mM) monitored by circular dichroism. The spectra are color coded as follows: Black, 20 °C, 90:10 H_2O:DMSO; red, 20 °C, 50:50 H_2O:DMSO; blue, 20 °C 100% DMSO. Inset: The CD bands at 260−400 nm are observed only in the gel state, and are lost at a T_m of 46 °C (90:10 H_2O:DMSO). The molar ellipticity at 366 nm represents the *y*-axis.

The temperature-dependent sol−gel conversion was reversible, although with a pronounced hysteresis requiring up to a few hours for gelation. At identical concentrations, neither **3**, **4**, **5**, or **6** in any H_2O/DMSO combination yielded fluorescent excimers or CD bands, further indicating the specificity of the γ-glutamyl-cys linkage in directing the self-assembly of pyrene complexes. As with the previously observed organo-gels (*19*), the γ-glutamyl-cys linkage is critical for the aqueous sol−gel transition of **2** among the pyrene derivatives studied.

Electron Microscopy. The mesoscale morphology of the gel state was monitored by transmission electron microscopy (TEM) and scanning electron microscopy of gel slices, which revealed highly branched fibrous networks, as observed for the GSSG organo-gels (Figure 4). Based on TEM and SEM, the width of individual strands is 50−100 nm, as also observed with the GSSG organo-gels. Possibly, the organo-gels and hydrogels share a similar supramolecular structure. Also evident in EM images were spherical masses of ∼50 nm diameter decorating the filamentous structures. Under all conditions studied, both morphologies were observed, suggesting multiple possible high order structures. We found no clear correlation between the relative fiber vs sphere morphology upon changing solvent composition or temperature. Both morphologies were observed also with the GSSG organo-gels, but with a significantly greater preference for fibers. The fiber morphology is clearly preferred in the hydrogels as well. The relative homogeneity of the fiber diameter suggests a highly specific self-assembly process, rather than a nonspecific aggrega-

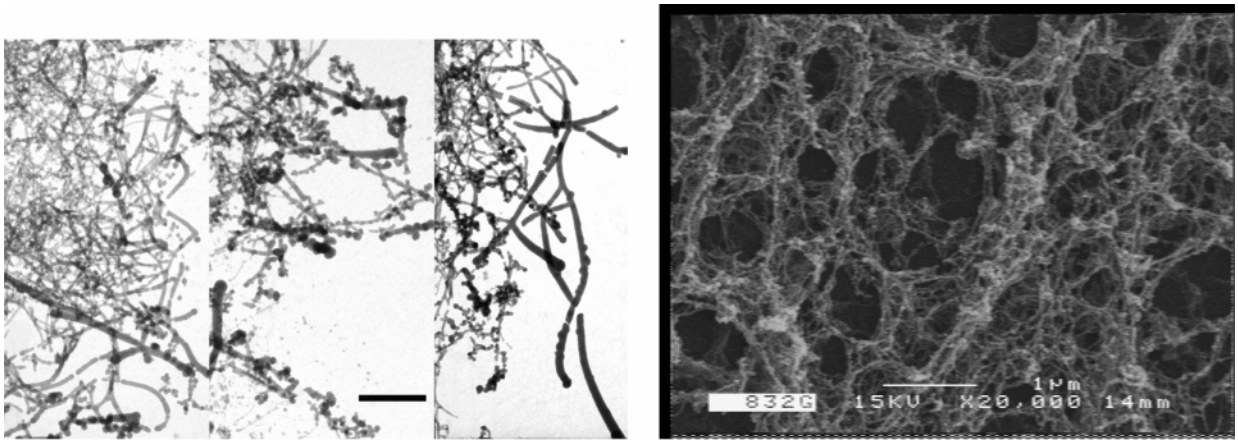

Figure 4. Electron microscopy of gels formed from **2**. Left three panels: TEM at increasing magnification. The branched fibrous network consists of strands approximately 50−100 nm in diameter. The bar in the center panel of the TEM micrographs is 1 μm. Right Panel: Scanning EM of a gel formed from 10 mM **2**.

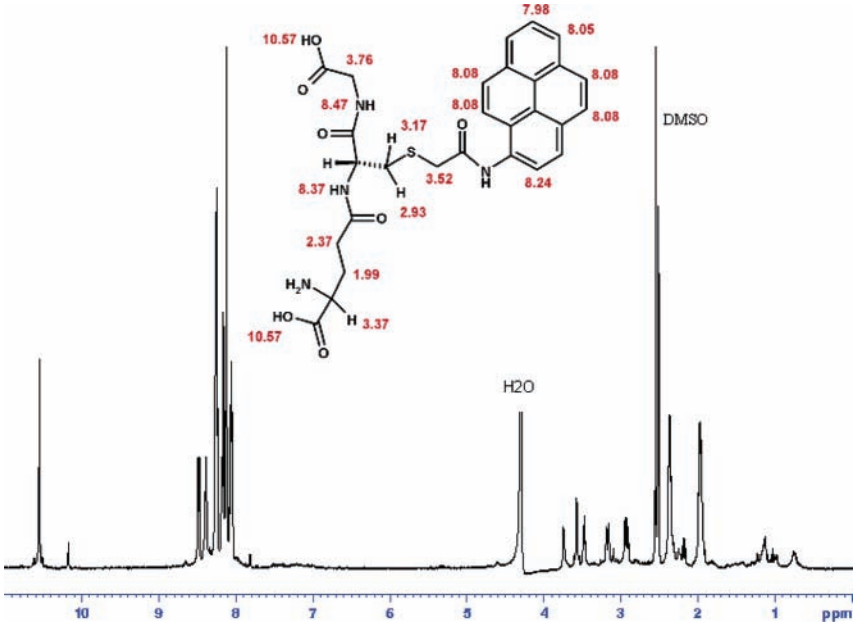

Figure 5. ^{1}H NMR spectrum of **2** in 50:50 H_2O:DMSO after gelation has started. The chemical shifts of the assignable protons are annotated on the chemical structure.

tion. Also, a high degree of branching is evident, which suggests the possibility of obtaining thermostable gels, by manipulation of the gelation kinetics. Although the EM images do not directly address the structure of gels in the hydrated state, the fact that no such fibers are observed in samples generated from **3**, **4**, **5**, or **6** suggests that fibril formation correlates with gelation.

^{1}H NMR. The properties of water within hydrogels remain uncharacterized. Because it is ultimately desirable to 'tune' these properties, additional methods are required to monitor solvent dynamics and solvent−gelator interactions (*32*). To identify specific water−gelator interactions with **2**, we performed saturation transfer difference (STD) ^{1}H NMR experiments, wherein the solvent water was irradiated with a saturating pulse, and the subsequent transfer of magnetization to GSH-pyrene protons was monitored. An analogous technique has been used to monitor the dynamics of protein−ligand interactions, with saturation transfer from the protein to the bound ligand (*27*−*29*). Because H_2O is absolutely required for the hydrogel formation from **2**, we have adapted the strategy to saturate water in the gels, and to look for differential saturation transfer or magnetization to the protons on **2**. In this strategy, water is the large reservoir of magnetization, which can be transferred to GSH-pyrene. With this strategy we were able to compare STD spectra in the gel state, in a sample that was just beginning to gel, and of the solution state, using the same sample after raising the temperature to 46 °C, just above the transition temperature. The former case represents a sample *in the process of gelling*, rather than a fully gelled sample. Therefore, the comparison between the spectra is only a qualitative indication of which protons are effected upon gelation and not a quantitative measure of changes in solvent interaction. To our knowledge, the dynamics of water in hydrogels have not been studied previously by this method.

The ^{1}H NMR spectrum of **2** in viscous fluid 'gels' is shown in Figure 5. It was not possible to record well-resolved NMR spectra in stiff gels in 95:5 H_2O:DMSO, so the NMR experiments were conducted at higher DMSO content. Under these conditions, gels begin to form but they are not sufficiently rigid to afford complete line broadening. To generate the STD spectrum, first the water signal was preirradiated for a sufficiently long time to achieve saturation, and a 1D spectrum was recorded. Next, a control spectrum was recorded without any presaturation on the water signal. The difference in

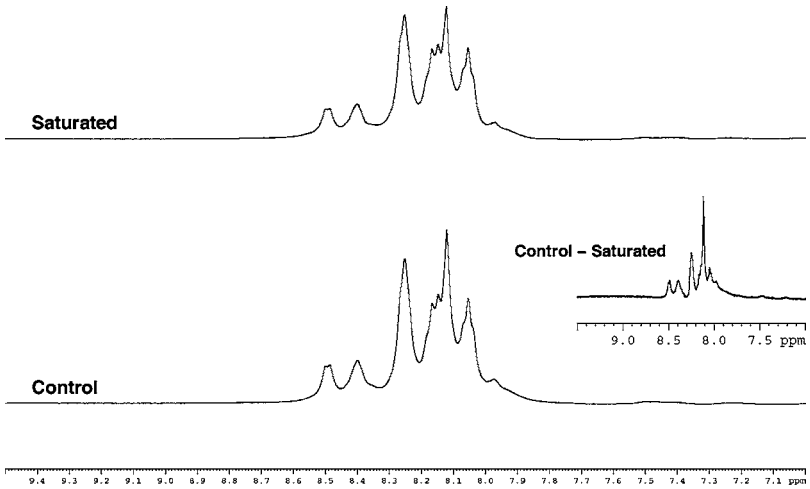

Figure 6. Aromatic region of the ^{1}H NMR spectrum of **2** in 50:50 H_2O:DMSO with off-resonance saturation (control) and on-resonance saturation of water (saturated) in 'fluid' gels. The inset is the STD spectrum for this spectral region.

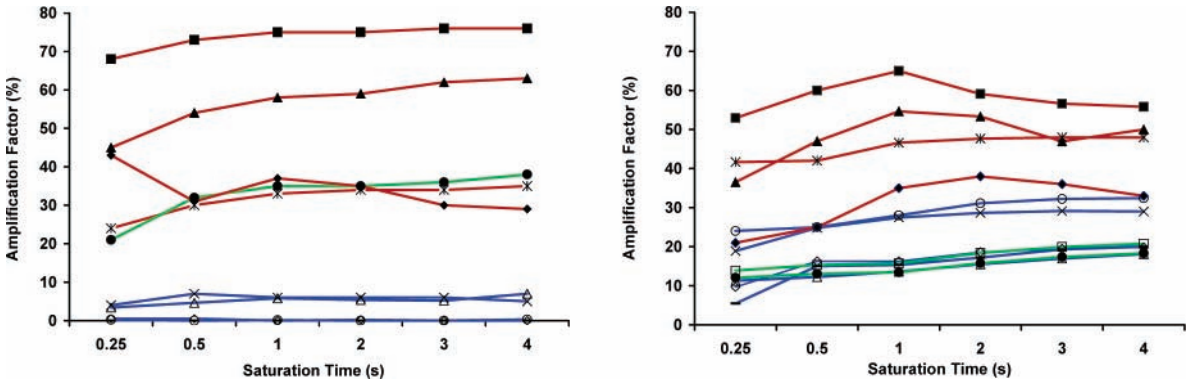

Figure 7. STD amplification factors vs t_{sat} in solution (left panel) and in gels (right panel). The red curves correspond to aliphatic protons on the GSH group, the blue curves are the aromatic protons on the pyrenyl group, and the green curves are the exchangeable amide protons. The specific protons are 8.24 ppm, open circles; 8.16 ppm, open triangles; 8.08 ppm, X's; 8.05 ppm, open diamonds; 8.01 ppm, crosses; 7.98 ppm, dashes; 3.17 ppm, closed squares; 2.93 ppm, closed triangles; 8.47 ppm, open squares; 8.37 ppm, closed circles.

intensity of resonances for the native spectrum of **2**, with off-resonance saturation minus the intensity of the spectrum with on-resonance water saturation yields an STD spectrum as also shown in Figure 6. The largest differences were observed for the protons on the GSH moiety, but they were readily apparent also for the aromatic pyrenyl protons in the gels, as shown in Figure 6.

The intensity of any individual proton resonance in the difference STD spectrum depends on the off-rate of the water from that site, the saturation time, and the concentration of the proton in the gel.

Water molecules tightly bound to specific protons, on the appropriate NMR time scale, can transfer magnetization. However, if the gelator protons interact too strongly with the water, then the magnetization will be transferred only from the small subset of water that is bound to it. More efficient saturation transfer is obtained for the entire population if the off-rate of water from the proton of interest is fast relative to the saturation time (t_{sat}), so that many water protons can interact with gelator, *but also slow enough to allow transfer of* magnetization. The STD amplification factor was calculated, as described in Experimental Procedures, for most of the protons in the 1D spectrum. We recorded the results for a range of presaturation times i.e., 250 ms to 4 s, and the STD amplification factors as a function of saturation times are plotted in Figure 7 for all the resolvable peaks from the GSH group, pyrenyl protons, and the observed amide protons of the GSH-pyrene gel. A few of the aliphatic peaks were not selected because they were too close to the water peak, thus hampering accurate determination of the peak intensity after saturation. Also, a few of the protons were not unambiguously assigned. For all protons, we observed that the maximum saturation transfer is already reached for a saturation time of 2 s.

In the solution state, all of the pyrenyl aromatic protons have very low STD amplification factors; some are 4-8% and others are essentially zero. For the GSH-borne aliphatic protons ($\delta = 2-3$ ppm), the amplification factors range from 30% to 70%, with the greatest magnetization transfer occurring with the protons on the β-carbon of the cysteinyl group. It is clear from these results that water only very transiently interacts with the aromatic protons (blue), if at all, but water does have significant residence times on the aliphatic protons in the GSH-moiety (red). The residence times of solvent water on aliphatic groups in peptides has been shown to increase when nearby groups are polar, as with the GSH peptide. In solution, only one amide proton is observed (8.37 ppm, cysteinyl amide). The other amides presumably are severely broadened due to chemical exchange.

Upon gelation, there is a dramatic redistribution of STD amplification factors. The maximum STD amplification factor ranges from 45% to 65% for the aliphatic peaks of interest in the GSH group (Figure 7, red). For the pyrenyl protons (Figure 7, blue) this range increases even more, to 15% − 30%. In the case of the amide protons,

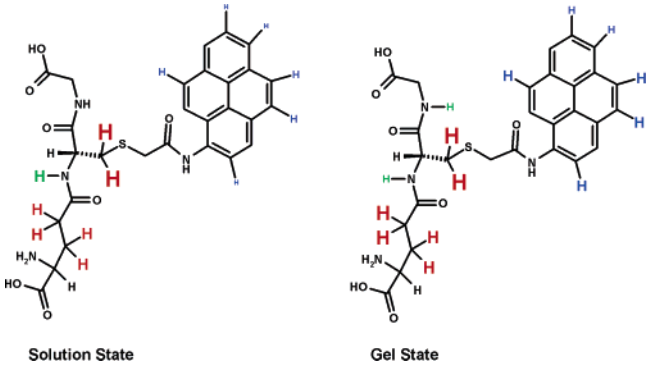

Figure 8. Schematic of changes in STD amplification factors upon gelation. The protons are color-coded as in Figure 7. The relative size reflects the relative amplification factors. The aromatic protons are strongly affected by gelation.

Table 1. Representative T1 Relaxation Times and STD Amplification Factors

peak position (ppm)	T1 (s)	STD amplification factor
2.37 (GSH)	0.26	48%
8.16 (pyrene)	0.97	18%
8.47 (NH)	0.44	21%

the maximum STD amplification factors are 18% for the peak at 8.37 ppm and 20% for the peak at 8.47 ppm, which is now observed. Presumably, the amide proton at 8.47 ppm in the gel, which is not observed in solution, reflects a decrease in the chemical exchange rate of this proton. Regardless of the complexity for amide protons, as discussed further below, there is a clear and significant difference in saturation transfer from water to different protons of GSH-pyrene upon gelation with a marked increase in the amplification factors for the aromatic pyrenyl protons (Figure 7). It is striking that the data cluster into groups defined by the 'type' of proton. The aliphatic GSH protons (red) have the highest amplification factors in both solution and gel states. The aromatic pyrenyl protons (blue) have near zero amplification factors in solution but become spread over a wide range including some with factors as high as 30%, in the gels. For the single amide proton observed in both states, the amplification factor actually decreases upon gelation. These data are presented schematically in Figure 8, where the structure of **2** includes protons with sizes scaled according to their STD amplification factors, in the solution vs gel state.

The recovered STD amplification factors must be considered in the context of T1 relaxation processes. The slower on/off rate of H_2O from the atoms it interacts with can lead to larger transfer of saturation from H_2O, whereas efficient T1 relaxation process counteracts the saturation transfer process. Therefore, we measured T1 relaxation times. Table 1 summarizes the results, with exemplary values, and demonstrates that GSH aliphatic protons relax most efficiently and in contrast the pyrenyl protons relax slowly. The NH proton's relaxation time is intermediate between them. Despite the efficient relaxation of GSH-associated protons, their maximum achievable STD amplification factor for the gels is about 2- to 2.5-fold larger than for pyrenyl protons or the NH protons. On the basis of the relative T1 and STD amplification factors of GSH and pyrene, it must be true that H_2O has higher affinity for GSH backbone than for pyrene group, and the residence time of H_2O interacting with the GSH group is longer. This leads to increased saturation transfer efficiency for the GSH group protons (48%) when compared with the pyrenyl group (18%), despite the faster T1 relaxation processes. A similar conclusion is true for all other aliphatic, nonexchangeable, GSH-associated protons as seen from Figure 7. Figure 7 clearly shows that the STD amplification factors are distinctly different for GSH-borne protons, when compared with pyrenyl protons. Apparently, solvent water does not interact with the pyrenyl protons, or it does only extremely transiently in solution. Most importantly, gelation correlates specifically with stronger water interactions with the pyrenyl group, without much effect on the GSH−water interactions.

Considering the NH protons, their chemical exchange with a large reservoir of 'saturated' protons should lead to larger saturation transfer and large amplification factors. This situation is in stark contrast to the scenario, where the faster on/off rate of water leads to less efficient saturation transfer efficiency in the case of protons of GSH or pyrene. Given the fact that distinct NH resonances are observed in the case of the GSH-pyrene gel system, the chemical exchange of the NH protons falls in the 'infrequent' or the so-called 'slow' exchange regime (*33*−*35*). In fact, with identical solvent conditions, but in the sol state, the amide resonances are not observed and they appear only when the sample begins to gel. Clearly, the amide−solvent chemical exchange reactions are much slower in the gel state than in the sol state, as expected. This may indicate the participation of the amides in intermolecular hydrogen bonds that are formed uniquely in the gel state. Thus, the gelation process itself would be expected to decrease the amplification factors from a theoretical maximum at which chemical exchange was sufficiently slow to allow for transfer, but sufficiently fast to allow transfer to a large population of GSH amide protons. In short, the magnetization transfer from solvent to amide protons is more complex than the other protons on the gelator, and the interpretation is ambiguous. Table 1 suggests that the efficiency of the exchange process of NH with water seems to lie between the saturation transfer efficiency of GSH and pyrene.

For a gel system like the GSH-pyrene, the average viscosity is clearly higher than that of a solution. This also means that the time scale of random fluctuations in such gels is larger than that of solutions, and therefore spin lattice relaxation times for gel systems around room-temperature lie close to the T1 minimum on the T1 vs correlation time graph (*33*). From this perspective, when the T1 values for two groups such as GSH and pyrene within the same molecule differ substantially, it generally translates into a significant difference in their time scales of motion. Apparently, the GSH portion of the molecule is more mobile than the pyrenyl group in the gels.

DISCUSSION

A common design strategy exploited for the preparation of self-assembling hydrogels includes the combination within a single amphiphilic molecule of hydrophobic groups and water-soluble components. Here, we have applied the term 'hydrogel' to our system which includes 5% organic solvent as a lower limit, but which has an absolute requirement for the addition of water to initiate gelation. Numerous examples of hydrogelators include short peptides or sugars as the hydrophilic component (*1*). We have extended this strategy by incorporation of the polycyclic aromatic hydrocarbon pyrene to the 'unusual' peptide GSH. The gels described here are interesting for several reasons.

Of primary interest is the use of GSH derivatives. GSH has numerous biological functions including antioxidant

roles, detoxification, and enzyme regulation. Of course, many of these functions require the free thiol group contained in GSH, and the hydrogelator described here (**2**) has lost this group. However, these results provide proof-of-principle that GSH conjugates can be hydrogelators, and is it reasonable to expect that the thiol group of other hydrogelating GSH-conjugates could be recovered by simple changes in pH or temperature, or enzymatically. Several types of chemical linkage to the GSH thiol are known to be reversible (*36*). Thus, although we have initiated the exploration of GSH-based hydrogels with **2**, other GSH-conjugates are easily imagined that could be 'cycled' through the hydrogel state and the biologically functional state with a free thiol. Speculatively, in fact, GSH-conjugates with nontoxic, or even therapeutically useful, hydrophobic removable groups could be used as slow release formulations for delivery of GSH itself, which has been widely used as an antioxidant and potential therapeutic for cystic fibrosis (*23*, *24*). Furthermore, GSH-conjugates may be directly useful as therapeutic anticancer adjuvants, without the need for a free thiol group (*37*, *38*), and it is conceivable that hydrogel formulations could have utility. In such applications, the GSH released from the 'conjugate gels' would not reform gels, but would simply mix with the endogenous pools of GSH. Furthermore, immobilized GSH analogues are widely used in protein purification protocols that exploit glutathione S-transferase (GST)-fusion technology (*25*, *26*). For these purposes, a free thiol group on GSH is not a strict requirement, and it is possible that hydrogels bearing pendant S-linked GSH peptides could immobilize GST-fusion proteins, thus providing a strategy for delivery of engineered proteins to hydrogel surfaces. Although the current work does not achieve such putative 'applications', it does suggest their feasibility.

A second important aspect of this work is the extension of the previously reported specificity of the γ-glutamyl group as a self-assembly unit to hydrogels. As we observed previously with GSSG in organic solvent, the γ-glutamyl group is uniquely able to drive hydrogelation within the series of analogues studied here that contain the same hydrophobic moiety. Although the molecular basis for this apparent specificity remains unknown, it could, in principle, be exploited in non-GSH γ-glutamyl-containing hydrogelators, once it is adequately understood. We are careful to note that, although the previously described organo-gels and the gelation of **2** in water both exhibit an apparent specificity for the γ-glutamyl group and both exhibit similar gross structures, the specific molecular interactions in the two type of gel may be different.

A critical, and general, aspect of hydrogels that has not been experimentally addressed in sufficient detail is the structure and dynamics of water sequestered in them (*32*). It is likely that a complete understanding of solvent dynamics in hydrogels would facilitate control over their sol−gel properties. Although it is generally accepted that hydrogels 'entrap' large amounts of water on a molar basis, there are few experimental data that provide details of the behavior of solvent at the molecular level. The STD NMR spectra represent initial steps toward such an understanding, and a potential general method to probe local solvent dynamics in other hydrogel systems.

In the case of covalently bonded ^{1}H atoms, which are part of either the GSH or the pyrene group, the two important factors that affect the efficiency of magnetization transfer from the H_2O are the on/off rate of water to/from these atoms and the spin−lattice relaxation time (T1) experienced by these atoms. While the on/off rates determine the affinity with which water is binding to the group of atoms under consideration and the residence time of their complex, the T1 value is dependent on the dynamic state of the same. As a matter of fact, these two processes counteract each other so that, while the resonances from the atoms that have strong affinity to the saturated water get saturated themselves, the spin−lattice relaxation process restores the magnetization of these atoms to their equilibrium values. While similar processes exist also for the exchangeable NH protons, it is necessary to recognize a subtle difference between the mechanism of saturation transfer from H_2O to the amide protons and the covalent-bonded protons in GSH or pyrene. In the case of NH protons the 'chemical exchange' process includes detachment of the proton from the NH group and replacement by a solvent proton. If the spin of this exchanged ^{1}H were to be in a 'saturated' state, the resulting NH group inherits this state of saturation. Thus, for the amide protons the STD amplification factor is also a function of the chemical exchange rates.

Although the spectroscopic methods used here do not provide a high-resolution structural model for the arrangement of **2** within gels, taken together they do suggest a general picture in which pyrenyl groups are aggregated within a central core of fibers that are coated on the periphery with the GSH moieties. Obviously, the dimensions of fibers observed by SEM are too large to correspond to individual molecule of **2** arranged in a linear array, and many molecules of **2** must self-assemble laterally as well as along the major axis of the fibers. The 'close-packed' pyrenes, apparently, do not interact with solvent as effectively, and they are relatively rigid compared to the more mobile GSH moieties, which lie on the outside of the fibers and have access to solvent. However, although the interaction of water with the pyrenyl groups is 'less strong' the formation of gels coincides with a significant increase in the pyrenyl−water interactions, which are essentially absent in the solution state. It is likely that solvent networks are stabilized in the gels, and these networks span the hydrogen bonding groups on GSH and the aromatic pyrenyl groups. Further structural characterization is required to understand how this 'low resolution' model accommodates the apparent essentiality of the γ-glutamyl groups and their presumed participation in intermolecular hydrogen bonds. A critical demonstration of the STD results is that the hydrophobic moieties are not excluded from interactions with solvent water in the gels. Rather, the pyrene groups specifically participate in 'new' solvent interactions in the gel state, presumably through cooperative interactions with the GSH groups. Furthermore, the STD experiments here suggest parallels between hydrogelation and protein solvation (*39*), wherein hydrophobic aromatic groups can interact strongly with water when nearby polar residues can also participate, and this is likely to be the critical feature of gelators.

TECHNICAL NOTES

Thiol-Functionalized Polymeric Micelles: From Molecular Recognition to Improved Mucoadhesion

Marie-Hélène Dufresne,[†] Marc A. Gauthier,[‡] and Jean-Christophe Leroux*[,†]

Received January 12, 2005; Revised Manuscript Received April 20, 2005

Surface-modified colloids which can selectively interact with biological species or surfaces show promise as drug delivery systems. However, the preparation of such targeted devices remains challenging, especially when considering polyion complex micelles for which side reactions with the ionic core components (typically carboxylic acid or amino groups) can occur. To solve this issue, an innovative synthetic strategy is proposed and used to prepare an asymmetric poly(ethylene glycol)-*block*-poly-(2-(*N*,*N*-dimethylamino)ethyl methacrylate) copolymer presenting a thiol group at the end of the poly-(ethylene glycol) chain. Thiol groups are highly appealing given that they react almost exclusively and quantitatively with maleimides under physiological conditions, thereby facilitating the chemical functionalization of the copolymer. The simplicity of the derivatization procedure is illustrated by preparing model biotin-capped copolymers. The biotinylated copolymers are shown to self-assemble with an oligonucleotide in aqueous media to form polyion complex micelles with biotin groups at their outer surface. These micelles are capable of molecular recognition toward streptavidin. Alternatively, thiol-decorated (nonderivatized) micelles are prepared and show improved mucoadhesion through the formation of disulfide bonds with mucin. Finally, intermicellar disulfide bonds are generated under oxidative conditions to promote the formation of stimuli-responsive micellar networks.

INTRODUCTION

Colloids which can selectively interact with biological species or surfaces show promise as nanoscopic biosensors, diagnostic tools, and therapeutic devices. For instance, liposomes decorated with monoclonal antibodies are currently being investigated as immunosensors (*1*) and targeted drug carriers (*2*). Other examples include folate-decorated lipid nanoparticles which have been studied for their greater antitumor activity (*3*), and polyester nanoparticles which achieve specific cellular interaction through ligands attached to their surface via avidin−biotin coupling (*4*, *5*). Polymeric micelles (10−100 nm) are yet other examples of colloids which would greatly benefit from surface modification. Polymeric micelles typically result from the self-assembly of amphiphilic copolymers in a selective solvent above a threshold concentration (*6*). Micellization can also proceed through the complexation, neutralization, and self-association of oppositely charged polyions (*7*), these structures being referred to as polyion complex micelles (PICM). Both polymeric micelles and PICM possess core−shell architectures with sequestering capabilities which account for their use as solubilizers (*8*, *9*), DNA delivery vectors (*10*), and bionanoreactors (*11*). If nanocarriers such as micelles have the ability to passively accumulate in specific pathological areas, their therapeutic efficiency can be further enhanced by attaching targeting devices on their surface (*12*, *13*). However, the surface modification of micelles can be very challenging, especially for PICM given that their ionic core components (typically amino or carboxylic acid groups) can interfere with conventional coupling reactions.

Surface-functionalization of colloids with recognition molecules is typically achieved using bifunctional spacers which obey standard acid/amine coupling chemistry. Drawbacks of such procedures include poor labeling efficiency, defects in the tethered structure, and formation of side products which are often difficult to eliminate. An alternative (and preferred) strategy is to synthesize heterotelechelic polymers directly from functionalized initiators. For instance, Bes et al. have used glucose and galactose derivatives to initiate the polymerization poly-(ethylene glycol) (PEG) methyl ether methacrylate and benzyl methacrylate (*14*). The resulting block copolymers were shown to form tethered micelles in the presence of water and were capable of selective affinity for a lectin column. Alternatively, Kataoka's group has devoted significant effort into designing heterobifunctional PEG macroinitiators which can be discriminately modified at one chain end. Among such macroinitiators, α-acetal-ω-methanesulfonate PEG and α-acetal-ω-hydroxyl PEG were successfully used to prepare cationic block copolymers which self-assembled with DNA into acetal- and

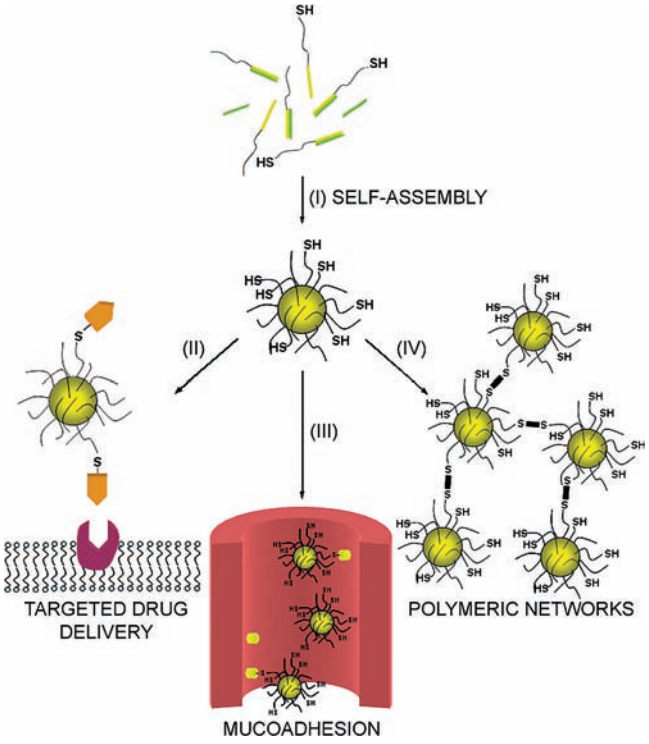

Figure 1. Preparation and uses of thiolated PICM. Oppositively charged copolymers (cationic copolymer shown in yellow and anionic biomacromolecule shown in green) self-assemble in aqueous media into surface-modified polymeric micelles (I). These micelles can be reacted with proteins or antibodies for targeted drug delivery applications (II) or used as such for improved mucoadhesion (through the formation of disulfide bonds with mucus) (III) and formation of redox-sensitive polymeric networks (IV).

aldehyde-decorated PICM (*15*, *16*). In light of this, we propose an alternate synthetic scheme for the preparation of a heterotelechelic macroinitiator possessing a thiol group at one extremity and a hydroxyl group at the other (namely α-*tert*-butanethio-ω-hydroxyl PEG, *t*Bu-S-PEG-OH). This work further illustrates how *t*Bu-S-PEG-*block*-poly((*N,N*-dimethylamino)ethyl methacrylate) (*t*Bu-S-PEG-*b*-PDMAEMA) copolymers can be used to prepare targeted micelles, mucoadhesive assemblies, and redox-sensitive polymeric networks (Figure 1). The synthetic approach proposed herein judiciously takes advantage of thiols for biorelated applications. Terminal thiol groups are very interesting given their ability to react selectively and quantitatively with maleimides or thiols under physiological conditions, thereby facilitating the functionalization of the polymer (*17*, *18*). Thiols have also been used in the biomedical field in order to increase the mucoadhesion of drug delivery systems (*19*) and to stabilize nanoassemblies through the formation of disulfide bridges (*20*).

EXPERIMENTAL PROCEDURES

Materials. A 20-mer antisense phosphorothioate oligodeoxirobonucleotide (ODN; 5′-GTTCTCGCTGGTGAGTTTCA-3′) and its fluorescein-labeled derivative (labeled at the 5′ end via a phosphorothioate bond) were prepared by Medicorp Inc. (Montreal, QC, Canada). Streptavidin-coated plates (binding capacity of ≥12 pmol biotin per well) were obtained from Thermo Electron Corporation (Vantaa, Finland). Porcine stomach mucin immobilized on a polygalactose gel was purchased from EY Laboratories Inc. (San Mateo, CA) and transferred to Bio-Spin chromatography columns (Bio-Rad Laboratories Ltd, Mississauga, ON, Canada). The 4-hydroxyazobenzene-2-carboxylic acid reagent (HABA; used for the spectrometric determination of biotin levels) was bought as a ready-to-use HABA/avidin lyophilized powder (Sigma-Aldrich Canada Ltd, Oakville, ON, Canada). All other chemicals were purchased from Sigma-Aldrich and used as received, except for the following: tetrahydrofuran (THF) was dried over sodium with benzophenone as indicator; *tert*-butyl mercaptan was dried over calcium oxide, distilled under argon, and stored over molecular sieves; ethylene oxide (EO) was passed through a sodium hydroxide column, dried over CaH_2, and cryodistilled prior to use; triethylamine was dried over potassium hydroxide and purified by distillation; 2-(*N,N*-dimethylamino)ethyl methacrylate (DMAEMA) was vacuum-distilled prior to polymerization.

Techniques. ^{1}H NMR spectra were recorded on a Bruker NMR spectrometer operating at 300 MHz. Solutions were either prepared in deuterated chloroform ($CDCl_3$) or water (D_2O). Gel permeation chromatography (GPC) measurements were performed in THF using an Alliance GPCV 2000 system (Waters, Milford, MA) equipped with a differential refractive index detector. Adequate molecular weight separation was achieved using three Waters Styragel columns (HR1, HR3, and HR4) in series at a flow rate of 1.0 mL/min and a temperature of 40 °C. A calibration curve was obtained with near-monodisperse PEG standards. The mean hydrodynamic diameter, size distribution, and scattering intensity of the micelles were determined using a Malvern Autosizer 4800 equipped with a 488-nm uniphase argon-ion laser (Malvern Instruments, Worcestershire, U.K.). Measurements were performed in triplicate at a scattering angle of 90° and a temperature of 25 °C. The CONTIN program was used to extract size distributions from the autocorrelation functions.

Synthesis of Asymmetric *t*Bu-S-PEG-OH. *tert*-Butyl mercaptan was used to initiate the anionic polymerization of EO in the presence of various molar ratios of potassium naphthalene. Anhydrous THF, potassium naphthalene (0.3 M solution in THF), and *tert*-butyl mercaptan were loaded into a sealed 100-mL round-bottom flask. The components were allowed to react for at least 10 min to ensure the formation of thiolates (evidenced as white precipitates), at which point liquid EO was added using a two-head needle. The polymerization reaction was carried out for 48 h, and the product was recovered by precipitation in diethyl ether. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.68 (250H, m, $(CH_2CH_2O)_n$), 2.75 (2H, t, $CH_2SC(CH_3)_3$), 1.89 (s, CH_2CH_2OH), 1.33 (9H, s, $CH_2SC(CH_3)_3$). Trifluoroacetic anhydride was added to the NMR tube in order to shift the signal of the methylene group adjacent to the terminal hydroxyl group and allow for the determination of the thiol functionalization degree. ^{1}H NMR ($CDCl_3$ with 7.5% (v/v) trifluoroacetic anhydride) δ (ppm): 4.50 (2H, t, CH_2OCOCF_3), 3.68 (250H, m, $(CH_2CH_2O)_n$), 2.75 (2H, t, $CH_2SC(CH_3)_3$), 1.33 (9H, s, $CH_2SC(CH_3)_3$).

Synthesis of Block Ionomers. PEG ($M_n = 2000$, $M_w/M_n = 1.08$) and *t*Bu-S-PEG-OH ($M_n = 2900$, $M_w/M_n = 1.03$) were converted to atom transfer radical polymerization (ATRP) macroinitiators by reaction with 2-bromoisobutyryl bromide *(21)*. Basically, PEG was dissolved in anhydrous THF and stirred for 15 min in the presence of triethylamine (10 equiv). 2-Bromoisobutyryl bromide (4 equiv) was then added dropwise and the reaction carried out for 48 h at room temperature. The crude product was solubilized in dichloromethane and purified by successive washings with 10% HCl, 1 N NaOH, and brine.

The organic phase was dried over magnesium sulfate and the ATRP macroinitiator precipitated in diethyl ether. The polymerization reactions were then carried out as follows: the macroinitiator (1 equiv), DMAEMA (15 equiv), *N*,*N*,*N*′,*N*′,*N*″-pentamethyldiethylenetriamine (1.4 equiv), and Cu(I)Br (0.7 equiv) were solubilized in THF and degassed for 20 min with argon. The polymerization reaction was initiated by bringing the reaction medium to 60 °C for 16 h, after which the copper catalyst was removed by filtration through a silica gel column. Polymers were purified by dialysis (molecular weight cutoff of 3500) and recovered by freeze-drying. MeO-PEG_{45}-*b*-$PDMAEMA_{17}$: $M_n = 4800$, $M_w/M_n = 1.23$. ^{1}H NMR (D_2O) δ (ppm): 4.14 (34H, broad s, $COOCH_2CH_2N(CH_3)_2$), 3.67 (180H, m, $(CH_2CH_2O)_n$), 3.35 (3H, s, $CH_3O(CH_2CH_2O)_n$), 2.71 (34H, broad s, $COOCH_2CH_2N(CH_3)_2$), 2.30 (102H, broad s, $COOCH_2CH_2N(CH_3)_2$), 2.10−1.70 (34H, m, $(CH_2C(CH_3))_n$), 1.20−0.78 (6H, s, $C(CH_3)_2(CH_2C(CH_3))_n$) + 51H, m, $(CH_2C(CH_3))_n$)). *t*Bu-PEG_{66}-*b*-$PDMAEMA_{15}$: M_n = 5300, $M_w/M_n = 1.11$. ^{1}H NMR (D_2O) δ (ppm): 4.14 (30H, broad s, $COOCH_2CH_2N(CH_3)_2$), 3.67 (264H, m, $(CH_2CH_2O)_n$), 2.70 (30H, broad s, $COOCH_2CH_2N(CH_3)_2$), 2.30 (90H, broad s, $COOCH_2CH_2N(CH_3)_2$), 2.10−1.70 (30H, m, $(CH_2C(CH_3))_n$), 1.30 (9H, s, $(CH_3)_3S(CH_2CH_2O)_n$), 1.20−0.78 (6H, s, $C(CH_3)_2(CH_2C(CH_3))_n$) + 45H, m, $(CH_2C(CH_3))_n$)).

Synthesis of Thiol-Terminated Block Ionomer. The terminal thiol group was recovered by successive cleavage of the *t*Bu unit in DMSO/trifluoroacetic acid (TFA) (*22*) and reduction of the disulfide bond obtained thereafter. The polymer was first dissolved in a 10/90 (v/v) mixture of DMSO/TFA to a final polymer concentration of 20 mg/mL. The deprotection reaction was conducted for 3 h, after which the TFA was removed by rotary evaporation. The crude polymer extract was then purified by dialysis (to remove all traces of DMSO) and the product recovered by freeze-drying. This procedure allowed for the conversion of the *t*Bu-PEG_{66}-*b*-$PDMAEMA_{15}$ to its disulfide analogue. Free thiol groups were generated by reacting the oxidized polymer with an excess of sodium borohydride in ethanol for 16 h. The reaction was stopped by the addition of a 10% HCl/ethanol solution and the solvent removed under reduced pressure. The thiolated polymer was purified by passage through a Sephadex G25 column and recovered by freeze-drying. The thiol loading was determined to be 82 μmol/g of polymer using Ellman's reagent (the loading was calculated against a cysteine calibration curve).

Synthesis of Biotin-Terminated Block Ionomers. The thiolated polymer was dissolved in degassed phosphate-buffered saline pH 7.4 to a final polymer concentration of 5 mg/mL. Biotin-maleimide (4-fold excess) was then added, and the coupling reaction was carried out overnight. The excess biotin was removed by passage through a Sephadex G25 column and the polymer recovered by freeze-drying. The amount of biotin in the copolymers was determined by monitoring the change in absorbance accompanying the displacement of HABA by biotin from the HABA/avidin complex. The coupling efficiency was calculated to be 97%.

Preparation of PICM. The copolymers (PEG_{45}-*b*-$PDMAEMA_{17}$, HS-PEG_{66}-*b*-$PDMAEMA_{15}$, or biotin-PEG_{66}-*b*-$PDMAEMA_{15}$) and the ODN were separately dissolved in 10 mM Tris HCl pH 7.4. PICM were obtained by addition of the copolymer solution to the ODN solution to a final N/P ratio of 1.5.

Molecular Recognition Experiments. Biotinylated (with 5 mol % biotin-PEG_{66}-*b*-$PDMAEMA_{15}$) and nonbiotinylated PICM were prepared using the fluorescently labeled ODN. The complexes were loaded into streptavidin-coated wells in the presence or absence of free biotin (6-fold excess) and allowed to react for 1 h at 37 °C. Unbound micelles were removed by three washings with a 50 mM phosphate buffer at pH 6.8. The proportion of bound micelles was evaluated by dosing the fluorescence of the ODN using a Safire plate reader (Tecan, Medford, MA; $\lambda_{ex} = 494$ nm, $\lambda_{em} = 518$ nm). Significant differences between the binding of the groups were evaluated by analysis of variance followed by Dunnett's multiple comparison test. Data were considered to differ significantly when $p < 0.05$.

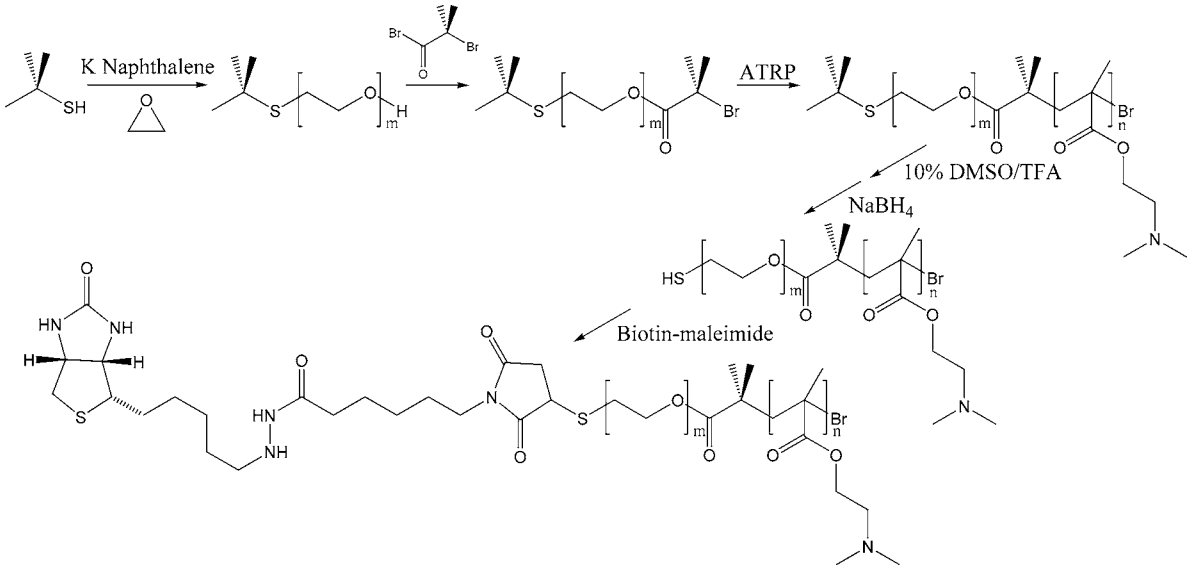
Mucoadhesion Experiments. Immobilized porcine stomach mucin was treated with 25 mM dithiothreitol and extensively washed to generate free thiol groups. Thiolated (with 25 mol % HS-PEG_{66}-*b*-$PDMAEMA_{15}$) and nonthiolated PICM were immediately applied to the resin in the presence or absence of exogenous thiols (100-fold excess cystein) and allowed to react for 1 h at 37 °C. Unbound micelles were eluted by successive washings with 10 mM Tris HCl pH 7.4. The fluorescent ODN was dosed in each elution fraction to evaluate the proportion of bound micelles. At the end of the experiment, the ODN was massively eluted using a 0.1 M carbonate solution at pH 10 (condition known to disrupt micelles (*23*)) to recover 100% of the applied material.

Aggregation of Thiolated Micelles. The sensitivity of thiolated (with 50 mol % HS-PEG_{66}-*b*-$PDMAEMA_{15}$) PICM toward oxidative (air) conditions was monitored by measuring time-dependent changes in their mean hydrodynamic diameter by dynamic light scattering (DLS). Nonthiolated PICM served as a reference. The effect of exogeneous thiols and an antioxidant on micelle aggregation was evaluated by preparing thiolated micelles in the presence of 5 mM mercaptoethanol and 2.8 mM ascorbic acid, respectively.

RESULTS AND DISCUSSION

Polymer Synthesis. The proposed synthetic route allows for the preparation of a thiol-terminated PEG-*b*-PDMAEMA copolymer from a *t*Bu-S-PEG-OH macroinitiator (Scheme 1). *t*Bu-S-PEG-OH was synthesized by initiating the anionic polymerization of EO with *tert*-butyl mercapatan. Potassium naphthalene was used to activate the sulfhydryl and was found to have an effect not only on the reaction kinetics but also on the degree of end functionalization. It is seen in Figure 2 that a potassium naphthalene/*tert*-butyl mercaptan molar ratio of 1/1 yields complete monomer conversion but is very sensitive to water contaminants (with only 23% of the chains possessing a terminal thiol group). By reducing the proportion of potassium naphthalene, it is possible to gain control over the selectivity of the initiation reaction. However, this is achieved at the expense of the monomer conversion which only reaches 57% (when the potassium naphthalene/*tert*-butyl mercaptan ratio is 0.4/1). Subsequent reactions were therefore conducted using 50 mol % potassium naphthalene, as this metalation level gave nearly quantitative degrees of thiol functionalization (>95%) while maintaining a reasonable rate of polymerization. Polymers with molecular weight distributions lower than 1.05 were typically obtained. The molecular weight of the *t*Bu-S-PEG-OH polymer was controlled by varying the monomer to initiator molar ratio. A typical ^{1}H NMR spectrum of *t*Bu-S-PEG-OH in $CDCl_3$ is presented in Figure 3A. The peak of the *tert*-butyl protons is seen at 1.32 ppm while that of the methylene protons

Scheme 1. Synthetic Route to the Preparation of Thiol-Terminated and Biotin-Terminated Block Ionomers



adjacent to the thioether appears at 2.74 ppm. The degree of end functionalization was estimated by derivatizing the hydroxyl group of *t*Bu-S-PEG-OH to a trifluoroacetate using trifluoroacetic anhydride (*24*). The formation of the trifluoroacetate shifted the peak of the adjacent methylene group downfield, thus separating it from the other methylene protons of PEG and allowing its quantification relative to the *tert*-butyl group.

PEG monomethoxyether and *t*Bu-S-PEG-OH were then converted to ATRP macroinitiators and used to prepare copolymers with varying PEG/DMAEMA molar ratios (*25*). More specifically, the copolymers selected for this study were composed of MeO-PEG_{45}-*b*-$PDMAEMA_{17}$ ($M_w/M_n = 1.23$) and *t*Bu-S-PEG_{66}-*b*-$PDMAEMA_{15}$ ($M_w/M_n = 1.11$). The *t*Bu-S-PEG-OH segment ($M_n = 2900$) was designed to be longer than the PEG monomethoxyether ($M_n = 2000$) so that the thiol groups or ligands would protrude from the micelle surface and be readily available for interaction. Indeed, studies conducted on PEGylated liposomes modified with a transduction protein revealed that the ligand needed to be accessible and nonshielded for efficient cellular interaction (*26*). In turn, the number of DMAEMA units was kept below 20. PICM prepared from polymers with longer DMAEMA chain lengths yielded aggregated micelles with broader size distributions (data not shown). Figure 3B presents the ^{1}H NMR spectrum of *t*Bu-S-PEG_{66}-*b*-$PDMAEMA_{15}$ in D_2O, where the terminal *tert*-butyl protons are clearly seen at 1.30 ppm. The terminal thiol group was recovered by cleavage of the *tert*-butyl group in oxidative conditions (DMSO/TFA) followed by reduction of the disulfide bond thereby obtained.

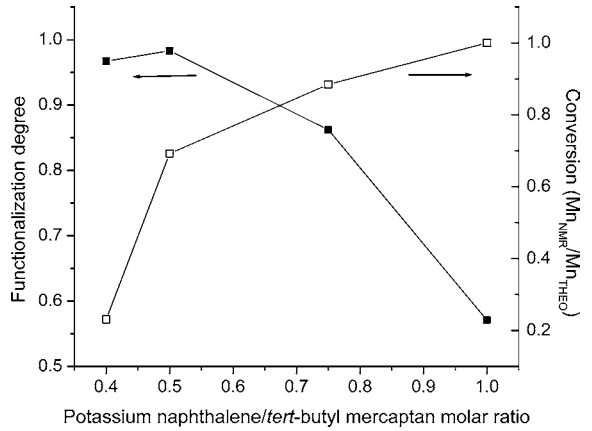


Figure 2. Effect of the potassium naphthalene/*tert*-butyl mercaptan molar ratio on the chain end functionalization and monomer conversion.

Molecular Recognition. A copolymer capped with biotin was prepared to demonstrate the ease with which targeted micelles can be generated. The functionalized copolymer was obtained through the direct coupling of HS-PEG_{66}-*b*-$PDMAEMA_{15}$ with a maleimide derivative of biotin. PICM composed of 5 mol % biotin-PEG_{66}-*b*-$PDMAEMA_{15}$, PEG_{45}-*b*-$PDMAEMA_{17}$, and the fluorescein-labeled ODN were prepared and found to have diameters of ~50 nm. Similar micelles made of PEG_{45}-*b*-$PDMAEMA_{17}$ and heparin (as the polyanion) have been previously prepared and shown to self-assemble into spherical entities, as determined by atomic force microscopy (*23*). The ability of the biotinylated PICM to molecularly recognize streptavidin was studied by loading the micelles into streptavidin-coated wells. The proportion of

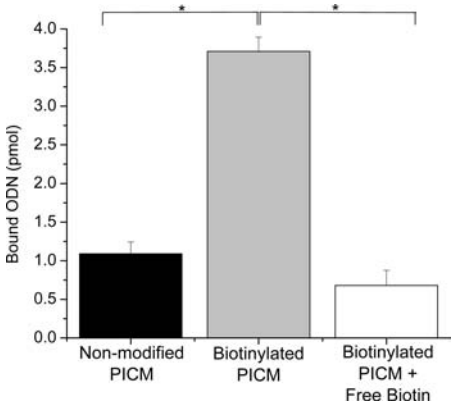

Figure 4. Affinity experiment showing the ability of biotinylated PICM to molecularly recognize streptavidin. Biotinylated micelles bound preferentially to streptavidin relative to nonmodified micelles. Binding of the biotinylated micelles was hindered in the presence of a 6-fold excess free biotin. Mean ± SD ($n = 4$), * $p < 0.05$, Dunnett test.

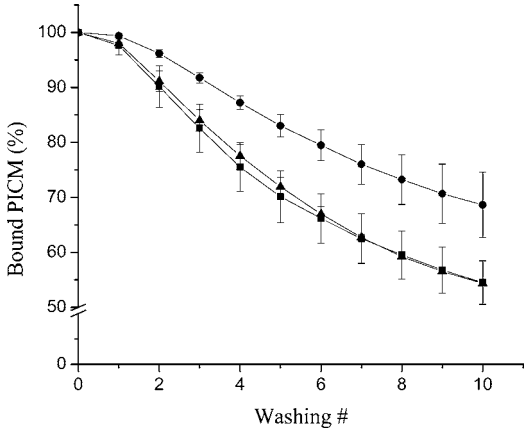

Figure 5. Retention of nonthiolated PICM (square) and thiolated PICM (circle) on an immobilized mucin matrix as a function of the number of washings. Thiolated PICM were also loaded on the resin in the presence of exogenous thiols (triangle) to evidence the role of the formation of disulfide bonds in the mucoadhesion. The quantity of bound micelles is expressed relative to the amount loaded. Mean ± SD ($n = 3$).

bound micelles was evaluated by dosing the fluorescence of the ODN. The latter is representative of the amount of adhered PICM, given that it is a structural component of the micelles. Figure 4 reveals that the adhesion of PICM bearing 5 mol % biotin to streptavidin increased by a factor of 4 relative to biotin-free micelles. This result suggests that, as expected, the biotin molecules are located at the surface of the micelles and are available for interaction. The nonspecific binding observed for the nontargeted micelles probably results from electrostatic interactions between streptavidin and the micelle core components. As shown in Figure 4, the binding of the biotinylated PICM was greatly reduced in the presence of free biotin, confirming the specificity of the interaction. Such a protocol could be applied for the straightforward attachment of other homing devices including monoclonal antibodies and peptides via thioether linkages.

Mucoadhesion. Another application stemming from the presence of surface sulfhydryl groups is the preparation of mucoadhesive particles for peroral drug delivery. Work by Bernkop-Schnürch and co-workers (*19*) suggests that it is possible to increase the residence time of a drug delivery system in the gastrointestinal tract by modifying it with thiol groups. Surface-exposed thiols are thought to form disulfide bonds with cysteine-rich subdomains of mucus glycoproteins (*27*). We have therefore evaluated the ability of thiolated PICM to covalently bind mucin. Figure 5 presents the elution profile of thiolated and nonthiolated micelles applied on a mucin matrix. While 70% of the thiolated micelles were still found to adhere to the matrix after 10 washings, half of the nonthiolated micelles were released by that time. The improved mucoadhesion of the thiolated micelles can be ascribed to their increased interaction with mucin. Although seemingly marginal, this difference in mucoadhesion is in fact appreciable, considering that PEG itself is oftentimes used as an adhesion promoter. For instance, De Ascentiis et al. found that incorporation of PEG chains in poly(2-hydroxyethyl methacrylate) microspheres significantly improved their mucoadhesion due to the penetration of the PEG chains across the mucosa−polymer interface (*28*). Likewise, Shojaei et al. were able to enhance the mucoadhesion of poly(acrylic acid) films by adding PEG chains to the formulation (*29*). In light of this, it is not surprising that the nonthiolated micelles themselves displayed mucoadhesion. Another consideration is the fact that the thiolated micelles examined in this study possessed a lower thiol density (30 μmol thiol/g of micelles) than other thiolated systems studied in the literature (400−780 μmol thiol/g of polymer) (*27*). Figure 5 also reveals that the adhesion of the functionalized PICM was impaired in the presence of a large excess of cysteine, with the thiolated micelles displaying an elution profile equivalent to that of the nonthiolated micelles. This observation reinforces the concept of mucoadhesion being promoted by the formation of disulfide bonds between the mucin and particle. Indeed, free cysteine molecules act as disulfide bond breaking agents which could cleave or prevent the formation of disulfide bonds between the mucin and micelles. However, the thiolated micelles maintained their ability to bind to mucin in the presence of a small excess of cysteine (data not shown), suggesting that in vivo mucoadhesion may not be affected by the presence of protein digests.

Aggregation of Thiolated Micelles. If covalent bonds were formed between thiol-decorated micelles and the mucus, it is likely that they will also form between micelles. This was confirmed by studying the time-dependent stability of thiolated and nonthiolated micelles. The initial hydrodynamic diameter of the nonthiolated micelles was 60 nm while that of the thiolated micelles was 45 nm. The difference in size can be attributed to the different EO to DMAEMA molar ratios of the copolymers. A representation of the size distribution of the thiolated micelles prior to oxidation is given in Figure 6A. A marked association of the thiolated micelles occurred after 6 h in oxidative (air) conditions, as observed by an increase of their mean diameter (Figure 6B). This aggregation was delayed in the presence of 2-mercaptoethanol and hindered in the presence of ascorbic acid (an antioxidant), clearly demonstrating that it is driven by the formation of intermicellar disulfide bonds. Furthermore, treatment with 15 mM dithiothreitol promoted the dissociation of the aggregates. The size of the micellar assemblies went from 100 to 65 nm within minutes of treatment with dithiothreitol, demonstrating the redox sensitivity of the system. Concomitantly, the reduction in size was associated with a marked decrease of the polydispersity index of the micelles (0.17 vs. 0.07). The aggregation of the chains achieved through disulfide bridges is potentially interesting for the design of depot formulations and eventually hydrogels. It can be hypothesized that covalently bridged micelles administered subcutaneously could be individually released in a sus-

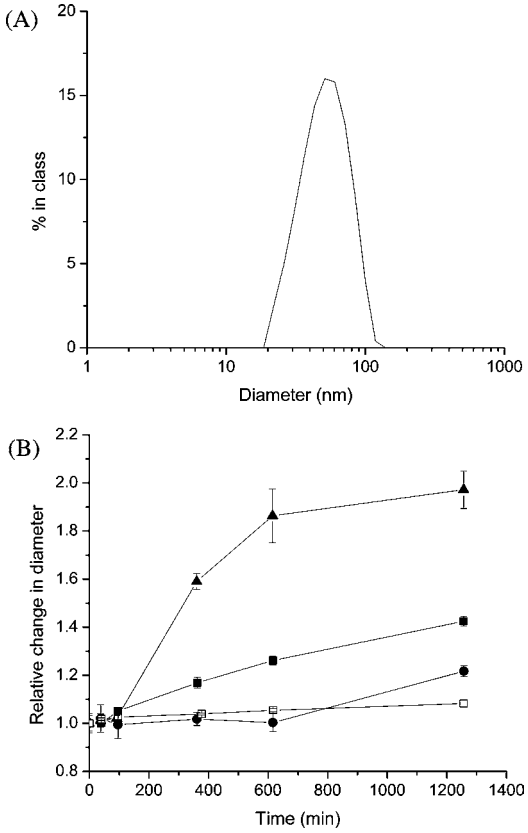

Figure 6. (A) Representation of the size distribution of thiolated micelles prior to oxidation. (B) Variations in the hydrodynamic diameters of nonthiolated PICM (open square) and thiolated PICM (triangle) as a function of time as determined by DLS. The presence of 5 mM 2-mercaptoethanol (square) and 2.8 mM ascorbic acid (circle) hindered the formation of disulfides between micelles. Changes in the hydrodynamic diameter of the micelles are normalized to their initial values for ease of comparison. Mean ± SD ($n = 3$).

tained fashion upon cleavage of the disulfide bonds in the reducing extracellular environment. These results further indicate that, when oral applications are sought, the thiolated micelles could be stored in the presence of an antioxidant to preserve their integrity and mucoadhesive activity.

CONCLUSION

This work demonstrates the ease with which thiol-bearing PICM can be prepared and tailored for specific applications. The thiol groups were reacted with a maleimide derivative of biotin to produce targeted nanoparticles capable of molecular recognition. Alternatively, the thiol-decorated micelles were used as such to improve the mucoadhesion of the system or to form stimuli-responsive micellar networks fitted as a depot formulation. This synthetic approach could be easily adapted to the preparation of thiolated anionic or amphiphilic block copolymers and will undoubtedly facilitate the preparation of various surface-modified nanoparticles.

Polyelectrolyte Complex Micelles Composed of *c-raf* Antisense Oligodeoxynucleotide−Poly(ethylene glycol) Conjugate and Poly(ethylenimine): Effect of Systemic Administration on Tumor Growth

Ji Hoon Jeong,[†] Sun Hwa Kim,[†] Sung Wan Kim,[‡] and Tae Gwan Park*,[†]

Department of Biological Sciences, Korea Advanced Institute of Science and Technology, Daejeon 305-701, Korea (South), and Center for Controlled Chemical Delivery (CCCD)/Department of Pharmaceutics and Pharmaceutical Chemistry, University of Utah, Salt Lake City, Utah 84112. Received November 9, 2004; Revised Manuscript Received May 5, 2005

An antisense oligodeoxynucleotide (ODN) delivery system based on polyelectrolyte complex (PEC) micelles composed of an ODN−poly(ethylene glycol) (PEG) conjugate and polyethylenimine (PEI) was demonstrated. The PEC micelles having a core/shell structure were spontaneously formed in an aqueous solution by ionic interactions between ODN part in the conjugate and PEI. The ODN/PEI polyelectrolyte complex formed an inner core while PEG chains surrounded it as a shell. The morphology of the micelles was visualized as a separate sphere by atomic force microscopy (AFM). When the micelles containing a *c-raf* antisense ODN were intravenously administered into tumor-bearing nude mice, significant antitumor activities against human lung cancer were observed. The intravenously injected micelles also showed significantly higher accumulation level in the solid tumor region compared to that of naked ODN.

INTRODUCTION

Novel drug delivery systems based on self-assembled polymeric micelles have drawn much attention due to their unique properties in therapeutic applications (*1*−*6*). Polymeric micelles, mostly prepared from various hydrophobic and hydrophilic A−B type di-block copolymers, are generally composed of a hydrophobic core and a surrounding hydrophilic shell (*7*, *8*). Alternatively, polyelectrolyte complex micelles were prepared by using a di-block copolymer composed of a charged polymer segment and a hydrophilic PEG segment. Macromolecules having counterions were interacted to form a polyelectrolyte complex core with generating a PEG shell. The small size (usually less than 100 nm) and surrounding hydrophilic corona structure provide the micelles with a possibility to escape from opsonization and the clearance by reticuloendothelial system (RES) (*9*, *10*). These properties also permit the micellar carriers to have enhanced permeability through loosened interendothelial junctions in the vicinity of solid tumors (*11*).

Antisense ODN has been thought to be a promising therapeutic agent for treatment of various diseases including cancer. However, the therapeutic effect of antisense ODN in vivo has not been as efficient as expected due to several inherent properties of ODN, which are susceptibility to enzymatic degradation and limited uptake into target tissue (*12*−*14*). To improve the cellular uptake, various kinds of cationic carriers were utilized to produce nanosized complex particulates that can be more readily endocytosed into cells than naked ODN. The formation of polyelectrolyte complexes between ODN and cationic lipids or polymers was a prerequisite step for enhancing the cellular uptake. Among the cationic polymers, PEG-*b*-poly(L-lysine) di-block copolymer (*15*) and PEG-grafted PEI (*16*) were used to form polyelectrolyte complex (PEC) micelles by interacting with ODN. These systems could provide ODN with an improved stability against nuclease attacks (*17*). Nevertheless, the stability of the polyelectrolyte complex micelles in the bloodstream has been issued as a major obstacle for in vivo applications (*18*).

Previously, we have shown efficient *c-myb* and *c-raf* antisense ODN delivery systems based on PEC micelles, which were formed by combining ODN−PEG conjugate and cationic fusogenic peptide (*19*) or polycations (PEI, poly(L-lysine), and protamine) (*19*, *20*). The PEC micelles having a spherical shape with about 70 nm in diameter could be efficiently transported within cells and could significantly inhibit the growth of smooth muscle cells and tumor cells in a dose-dependent manner. Moreover, when the PEC micelles containing *c-raf* ODN were administered intratumorally, they exhibited superior tumor suppression effect compared to naked ODN. In this study, *c-raf* antisense ODN PEC micelles were administered intravenously using an animal tumor model to explore their antitumor activities and tissue distribution behaviors.

EXPERIMENTAL PROCEDURES

Materials. Twenty-base oligonucleotides (ODN) with 5′-terminal amine group (antisense *c-raf* ODN, TCCCGCCTGTGACATGCATT; random ODN, TCACATTGGCGCTTAGC-CGT) and fluorescence-labeled *c-raf* ODN (AATGCATGTCACAGGCGGGA) with a complementary sequence to antisense *c-raf* ODN were purchased from Bioneer (Daejeon, Korea). *N*-Hydroxylsuccinimide-derivatized methoxy-poly(ethylene glycol) (mPEG-NHS,

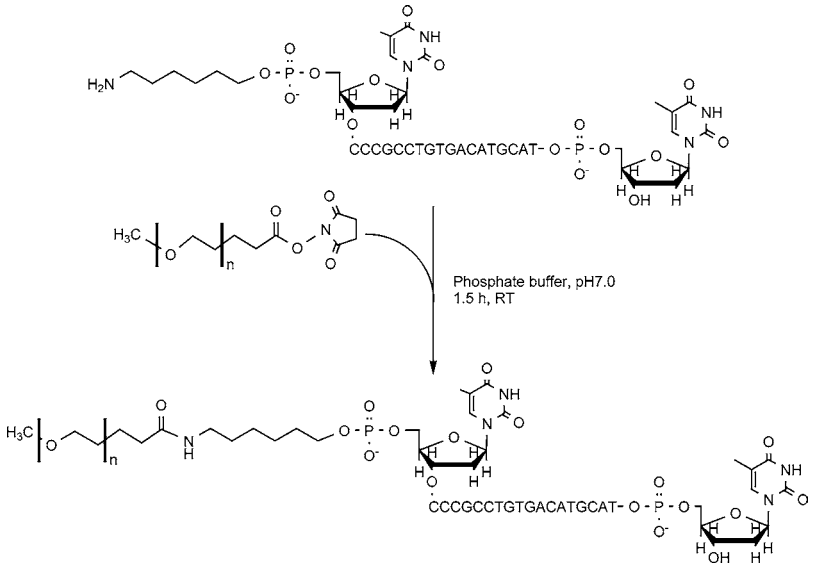
Scheme 1. A Synthetic Scheme of ODN−PEG Conjugate



MW 2000) was obtained from Nektar (Huntsville, AL). Polyethylenimine (branched PEI, MW 25 000) was purchased from Aldrich (Milwaukee, WI). Cell culture materials, Roswell Park Memorial Institute 1640 medium (RPMI 1640), and fetal bovine serum (FBS) were purchased from Invitrogen (Carlsbad, CA). All other chemicals were of analytical grade and used without further purification.

Synthesis of ODN−PEG Conjugate. To synthesize ODN−PEG conjugate, 5′-amine-derivatized ODN (1 mg, 180 nmol) was mixed with mPEG-NHS (M_w 2000, 1 mg, 540 nmol) in sodium phosphate buffer (10 mM NaH_2PO_4/Na_2HPO_4, 100 mM NaCl, pH 7.0). After 1.5 h incubation at room temperature, the resulting product was dialyzed against deionized water (MWCO 5000). The synthesis of ODN−PEG conjugate was analyzed by reversed-phase chromatography, which was carried out on C18 column (200 × 4.6 mm, Waters, Milford, MA) with detection at 260 nm using a gradient from 5% acetonitrile in 0.1 M triethylammonium acetate to 50% acetonitrile in 0.1 M triethylammonium acetate with a flow rate of 1.0 mL/min at 56 °C. The conjugate fraction of the ODN−PEG was about 65%. The fractionated conjugate was analyzed by using a matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry (Voyager DE-STR, Perkin-Elmer Biosystems, Boston, MA). The matrix for the ODN−PEG conjugate was α-cyano-4-hydroxycinnamic acid.

Formation and Characterization of Polyelectrolyte Complex Micelles. Polyelectrolyte complex (PEC) micelles between ODN−PEG conjugate and polyethylenimine were formed as previously described (*20*). Briefly, the ODN−PEG conjugate diluted in PBS was filtered through 0.2 μm filter (Millipore, Bedford, MA) and mixed with PEI solution at a nitrogen/phosphate (N/P) ratio of 2.5:1. The micelles were incubated for 30 min to stabilize the complexes. The PEC micelles were visualized by using atomic force microscopy (AFM). The micelle solution was dropped on a clean mica surface and air-dried at room temperature. AFM analysis was carried out in a constant tapping mode by using Nanoscope II (Digital Instruments, Woodbury, NY). A standard Nanoprobe silicon single-crystal lever was used as a cantilever, and a constant force mode was used with a scan speed at 0.5 Hz. The scanning image was collected in 0.5 × 0.5 μm area.

Cell Culture. Human lung carcinoma cells (A549 cells) were purchased from the Korean Cell Line Bank (Seoul, Korea). A549 cells were maintained in RPMI 1640 medium, supplemented with 100 units/mL penicillin, 100 μg/mL streptomycin, and 10% fetal bovine serum. The cells were cultured as a monolayer in a humidified atmosphere containing 5% CO_2 at 37 °C. For mice injection, A549 cells were grown until confluence, detached with trypsin/EDTA, washed three times with PBS, and resuspended in PBS.

Tumor Growth Regression Studies. To generate an animal tumor model, A549 cells (1×10^6 cells) were injected subcutaneously into rear flanks of seven-week old female nude mice (*nu/nu*, Charles River Laboratories, Wilmington, MA). When a minimum tumor volume reached about 30 mm^3, various ODN formulations (naked antisense ODN, antisense ODN polyelectrolyte complex micelles, or mismatched ODN polyelectrolyte complex micelles) were intravenously administered via a tail vein at 2.5 mg kg^{-1} $injection^{-1}$ at predetermined time intervals. Tumor growth was monitored by measuring perpendicular diameters three times a week. The tumor volumes were determined as previously described (*21*). Statistical significance was evaluated by using a Student's *t*-test and defined as $P < 0.05$.

Assay of ODN Accumulated in Tumor. Fluorescein-labeled ODN was prepared as previously described (*20*). Fluorescein-labeled ODN−PEG/PEI polyelectrolyte complex micelles (0.1 mg) were administered to tumor-bearing nude mice via a tail vein. A group of mice were sacrificed at 3, 12, and 24 h after the injection. The tumor tissues were ground in a hypotonic solution by using a tissue homogenizer, centrifuged, and filtered through 0.45 μm filter membrane (Millipore, Bedford, MA). In vivo deposition of ODN in tumor was determined by measuring fluorescence intensity monitored from the tissue extract using spectrofluorometry (SLM-AMINCO 8100, SLM Instruments Inc., Urbana, IL) and expressed as a percent initial dosage per gram tissue.

RESULTS AND DISCUSSION

A synthetic scheme of ODN−PEG conjugate is shown in Scheme 1. *c-raf* antisense ODN derivatized with an amine group at a 5′ terminal end was conjugated with a mPEG-NHS derivative to form an ODN−PEG conjugate.

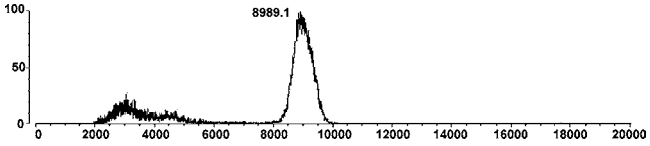


Figure 1. MALDI-TOF analysis of ODN−PEG conjugate purified by reversed-phase chromatography.

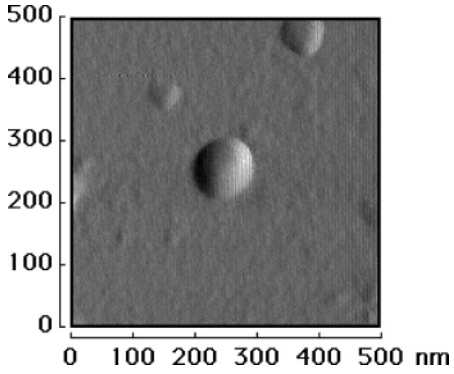

Figure 2. Atomic force microscopy (AFM) image of the polyelectrolyte complex micelles formed by the interaction between ODN−PEG and PEI.

The conjugation efficiency was ca. 65% as determined by reversed-phase HPLC. An average molecular weight of the purified conjugate analyzed by MALDI-TOF MS was 8989.1, which corresponds to the molecular weight sum of ODN and PEG (Figure 1).

Polyelectrolyte complex micelles (PEC micelles) could be formed by ionic interactions between the ODN−PEG conjugate and polyethylenimine (PEI). The ODN part of the conjugate interacted with PEI to form a charge-neutralized ODN/PEI complex core, while the hydrophilic PEG segment of the conjugate surrounded it. The formation and characterization of the PEC micelles were previously reported (*19*, *20*). The hydrodynamic diameter of the PEC micelles determined by dynamic light scattering (DLS) was ca. 70 nm with a narrow size distribution as described previously (*20*). The morphology of the PEC micelles was a round shaped structure as visualized on mica surface by using AFM (Figure 2). The size of PEC micelles observed by AFM was very consistent with that determined by DLS.

We previously showed that the antisense ODN−PEG conjugate containing a noncleavable linkage between ODN and PEG could hybridize with its corresponding complementary sense ODN sequence like naked antisense ODN (*20*). The thermal melting behavior of antisense ODN−PEG/sense ODN duplex was the same as that of antisense ODN/sense ODN duplex, indicating that the presence of a PEG chain adjacent to ODN segment did not perturb the antisense/sense ODN hybridization process. When the antisense *c-raf* ODN−PEG/PEI conjugate PEC micelles were treated with human ovarian cancer A2780 cells, they exhibited a dose-dependent antiproliferative activity. Furthermore, they showed significant retardation of tumor growth after intratumoral administration. In this study, the antitumor activity of systemically administered PEC micelles containing *c-raf* antisense ODN was investigated using nude mice having subcutaneously implanted human lung carcinoma cells (A549). Compared to control groups (mice treated with a saline solution, naked antisense ODN, and PEC micelles containing mismatched ODN with a random sequence), antisense ODN PEC micelles suppressed tumor growth significantly. The PEC micelles containing *c-raf* antisense ODN noticeably retarded the tumor growth after 10 days (Figure 3). This could be attributed to passive targeting effect of the nanosized PEC micelles by an enhanced permeation and retention (EPR) effect. The leaky vascular structure in solid tumor causes facilitated penetration and accumulation of nano-particulates. Polymer conjugates, liposomes, and polymeric micelles containing various anticancer agents showed increased accumulation in solid tumors (*22*−*24*). Likewise, the PEC micelles with ca. 70 nm in diameter were expected to penetrate into the interstitial space between loosened endothelial cell junctions and to accumulate in the tumor site that has insufficient lymphatic drainage. Figure 4 shows significant amount of the PEC micelles containing *c-raf* ODN accumulated in the tumor compared to naked ODN. After 12 h, the PEC micellar formulation showed about 3-fold higher local deposition amount of ODN in the tumor compared to that of naked ODN. Highly flexible PEG layers surrounding the PEC micelles could also play an important role in prolonging their circulation time in blood stream by suppressing nonspecific adsorption of opsonins and other serum proteins and by avoiding the recognition of reticuloen-

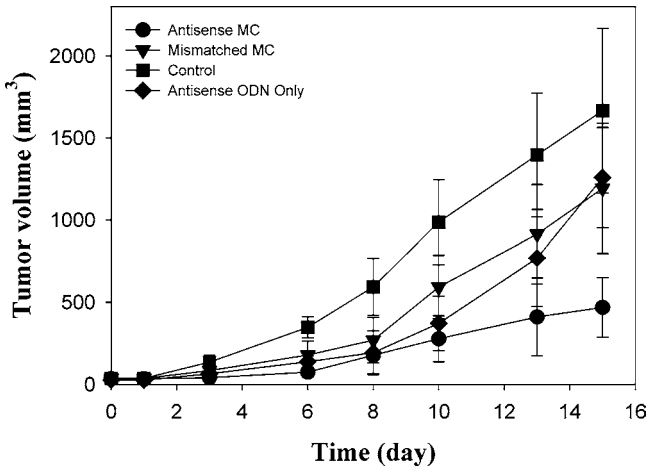

Figure 3. Effect of ODN−PEG/PEI polyelectrolyte complex micelles containing antisense *c-raf* ODN on the growth of A549 tumors in nude mice ($n = 4$−6). Tumors were allowed to grow until a mean volume of tumor reached 0.1 cm^3 before treatment. Each ODN formulation was administered through tail vein at 2.5 mg kg^{-1} $injection^{-1}$. The ODN formulations were injected at day 1, 3, 6, 8, 10, 13, and 15.

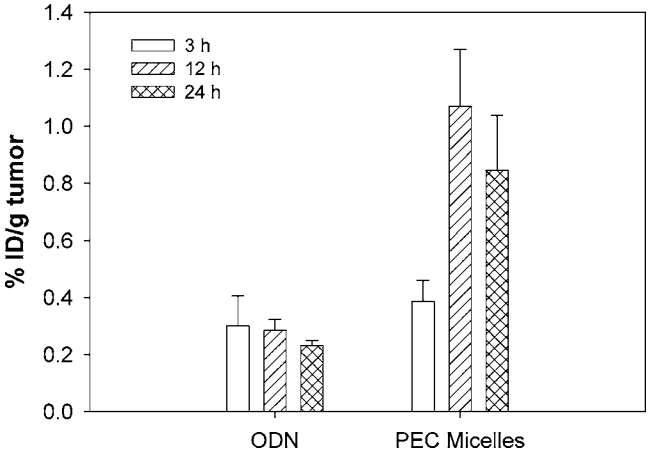

Figure 4. Accumulation of ODN−PEG/PEI PEC micelles in solid tumor after intravenous administration. Each ODN formulation containing 0.1 mg ODN was administered through mouse tail vein. The amount of ODN in each organ was measured by spectrofluorometric analysis and was shown as percent initial dose per gram of tumor.

dothelial systems (RES). The PEC micelles formed from the interaction between an ODN−PEG conjugate and linear-type PEI were reported to be stable against nuclease attack and showed minimal adsorption of serum proteins (*25*).

This study demonstrated that the PEC micelles containing a *c-raf* antisense ODN, which were spontaneously formed by the interaction between ODN−PEG conjugate and PEI in an aqueous milieu, could significantly reduce the growth of tumor after systemic administration. The PEC micelle also showed enhanced accumulation in the tumor. This suggests that the ODN delivery system based on PEC micelles could be successfully used for systemic antisense ODN delivery for treatment of cancer.

Oligonucleotides Conjugated to Short Lysine Chains

Johannes Winkler, Ernst Urban, and Christian R. Noe*

Department of Medicinal Chemistry, Universität Wien, Althanstrasse 14, 1090 Wien, Austria.
Received November 10, 2004; Revised Manuscript Received April 15, 2005

A new method for synthesizing oligonucleotide peptide conjugates by an in-line approach is presented. A phosphorothioate oligonucleotide with the sequence of bcl-2 targeted Oblimersen by employing a modified 2′-amino-2′-desoxy-uridine nucleotide bearing a succinyl linker at the 2′ position was prepared. The carboxyl group was protected for solid-phase synthesis as the benzyl ester. Ester cleavage was afforded by a phase transfer reaction using palladium nanoparticles as catalyst and cyclohexadiene as hydrogen donor. Short tails of up to three lysyl residues were conjugated to the oligonucleotide by an inverse stepwise peptide synthesis. The conjugates were characterized by HPLC, mass spectrometry, and circular dichroism. Influence of lysyl tails on CD spectra were minimal. Melting profiles revealed only minimal destabilizing effects on duplexes by conjugation of peptides.

INTRODUCTION

The aim of the antisense strategy (*1*) is the sequence specific inhibition of a gene by hybridization of a single-stranded oligonucleotide to the complementary mRNA in order to prevent the expression of the corresponding protein product. Besides the inhibition of translation by binding to the mRNA to give double-stranded nucleic acid, activation of the RNA degrading RNAse H is a key effect of antisense substances (*2*, *3*). In addition to this pharmacodynamic effect, which is determined by the nucleotide sequence of the antisense oligonucleotide, sufficient pharmacokinetic properties of these substances are essential for achieving the desired effect.

Unmodified phosphodiester oligonucleotides lack sufficient stability against degradation by mainly exo- but also endonucleases and are therefore not suited for therapy. Numerous modifications have been introduced and tested for their binding affinity and biological properties (*4*, *5*). Initially, modifications of the phosphodiester backbone were the main field of activity. Phosphorothioate oligonucleotides, often called antisense molecules of the first generation, possess better stability against enzymatic degradation. Although their hybridization properties are poorer than that of natural oligonucleotides, their advantageous pharmacokinetic characteristics and the ability to activate RNAse H made them a promising new class of antisense molecules (*6*). The first approved antisense drug, fomivirsene (*7*), and most of the substances currently in various phases of clinical trials (*8*) are phosphorothioate oligonucleotides.

Oblimersen sodium is one of the most progressed antisense drugs in clinical trials (*9*). A large multicenter phase III study against malignant melanoma, in which Oblimersen was administered in combination with the standard dacarbazine treatment, was recently concluded. Despite an increase in progression-free survival (PFS), Genta withdrew its appeal for approval after a review by the FDA advisory committee, because median survival, the primary end-point, was not prolonged statistically significantly (*10*). Still other phase III trials against several cancer types are ongoing.

Oblimersen is a phosphorothioate oligonucleotide targeted to the first six codons of the open reading frame of Bcl-2 (*11*). Bcl-2 is an important inhibitor of apoptosis (*12*) and has been shown to be overexpressed in a large numbers of tumors. Because of its phosphorothioate backbone, a 5′-TC dinucleotide, and two distinct CpG motifs, some non-antisense effects may contribute to the antiproliferative action of Oblimersen. A sequence-specific true antisense effect has been shown in some in vitro and in vivo experiments (*13*−*15*), while others reported that the cytostatic properties are independent from the antisense effect (*16*, *17*).

The second generation of antisense oligonucleotides bears modifications at the 2′-position (*18*−*20*). Oligonucleotides with an alkoxy substituent in position 2′ proved to be stable against DNA or RNA cleaving enzymes. This increased stability has been explained by the steric hindrance, which inhibits the attack of nucleases at the phosphate groups. Base pairing properties decrease with increasing length of alkyl substituent. 2′-Ethylene glycol-modified oligonucleotides showed better base pairing properties (*6*, *21*), and the 2′-methoxy ethyl group is particularly suited. As a drawback, 2′-O-substitued oligonucleotides proved to be unable to catalyze enzymatic degradation of the complementary RNA by activation of RNAse H (*22*). Hence, so-called gapmere oligonucleotides, bearing modified nucleotides at both the 3′ and 5′ end, but with an unmodified region of at least five nucleotides between, were introduced. They provide good stability against exonucleases while the unmodified region is sufficient to activate RNAse H (*23*).

Zwitterionic antisense oligonucleotides are seen as the third generation. Introduction of a 6-aminohexyl group at the 2′ position not only increases stability against enzymatic degradation, but also minimizes the electrostatic repulsion of the sense and antisense strands leading to improved hybridization affinity (*24*).

Other more rigorous modifications include substitution of the polyanionic phosphate backbone by peptides (PNA), change of the ribose moiety to morpholino groups (MNA) (*25*), and introducing a methylene bridge between oxygen

2′ and carbon 4′ of the carbohydrate to increase rigidity of the backbone (locked nucleic acids, LNA) (*26*, *27*).

Lately, the focus in improving oligonucleotide properties has been shifted toward conjugation of ligands (*28*). This approach allows a directed change of molecule characteristics enhancing binding affinity or pharmacokinetic parameters such as hydrophobicity and improvements in biodistribution or cellular uptake. A large number of ligands has successfully been ligated to oligonucleotides, among them lipophilic molecules such as cholesterol (*29*) and lipids (*30*), vitamin B_6 (*31*), a synthetic ligand to the asialoglycoprotein receptor for tissue and cell-specific targeting to parenchymal liver cells (*32*), and various proteins (*28*). Conjugates of oligonucleotides with penetratins (*33*) or signal peptides acquire increased uptake rates due to the membrane dislocation properties of these peptides. Conjugation of a PNA to a monoclonal antibody of the rat transferrin receptor via the biotin streptavidin complex enabled the transport through the blood−brain barrier (*34*). Attachment of arginine rich SV40 nuclear localization signal efficiently transported DNA as well as PNA (*35*, *36*). Conjugates with either a 35 amino acid basic sequence of the HIV Tat protein or a 16 amino acid basic sequence from the *Drosophila antennapedia* protein improved cellular uptake of antisense phosphorothioate oligonucleotides without loss of specificity to target RNA (*37*, *38*). It has been firmly established that an increase in cellular uptake of oligonucleotides can be achieved by conjugation or complexation of the oligonucleotide to poly-L-lysine (*39*−*42*). A tail of one, two, or four lysine moieties at the 5′-end of a PNA oligonucleotide improved cellular uptake (*43*). The extent of uptake was dependent on the number of conjugated lysine monomers. The affinity to the target sequence was not increased nor was the nuclear translocation process influenced. It was concluded that the lysine chain improved the transport through the cell membrane or enhanced the release from endosomes.

Herein, we report the conjugation of oligonucleotides with short lysyl chains. The majority of oligonucleotide peptide conjugates have been prepared by linkage at either the 3′ or the 5′ end of the oligonucleotide (*28*). The two components were either synthesized independently by distinct solid-phase syntheses and ligated afterward or on the same solid phase by sequential stepwise synthesis. Commonly used linkers are disulfides (*44*−*46*), maleimides, thioethers, and amides (*28*). In an in-line synthesis, first described by Haralambidis (*47*), the peptide and oligonucleotide are synthesized sequentially on automatic synthesizers. Using an acid labile amino protection group, a possibility for stepwise peptide synthesis at the 5′-end of an oligonucleotides prepared on the same solid support was described (*48*).

Conjugation at the 2′ position of the carbohydrate moiety of the oligonucleotide has previously been achieved by use of the 6-aminohexyl (*49*, *50*) and 4-aminopropyl linkers (*51*). Ligands have been coupled to the primary amino group by amide bonds or the use of a chloroformate or carbonate to give a carbamate or by an active ester to give an amide (*49*). Recently, a procedure for the attachment of amines to an allyl-protected carboxyl linker attached at the 2′-position of uridine has been published (*52*). The allyl ester was removed by treatment with Pd(0) and morpholine. Subsequently, several small peptides were coupled to the free carboxyl group.

Our approach relies closely on the previously published procedure for a fluoresceine oligonucleotide conjugate *(53)*. We derivatized 2′-amino-2′-desoxy-uridine with succinic anhydride to give the hemisuccinate. Protection of the carboxyl group for the solid-phase synthesis was achieved by preparing the corresponding benzyl ester. This nucleotide building block was incorporated in an oligonucleotide at the 3′ terminus. Conjugation of fluorescein was done after deprotection of the carboxyl group by a catalytic phase transfer reaction with palladium nanoparticles and 1,4-cyclohexadiene as the hydrogen donor. After establishing this simple and convenient procedure for conjugating ligands at the 2′ position of a 3′-terminal uridine nucleoside of an oligonucleotide, we decided to expand this method into the field of oligonucleotide peptide conjugates. For the preparation of oligonucleotide peptide conjugates, protein synthesis had to be achieved in N to C, the inverse direction. We designed a suitably protected lysine synthon to build up short peptide strands at the hemisuccinate. In addition to the synthesis, we present data of circular dichroism spectroscopy and binding affinity to the sense strand.

EXPERIMENTAL PROCEDURES

Reagents were used in standard quality for synthesis. Acetonitrile was heated over potassium carbonate and distilled, followed by heating over calcium hydride and distillation. Dichloromethane was dried over phosphorus pentoxide and distilled. Melting points were measured on a Kofler melting point apparatus and are uncorrected. NMR spectra were recorded on a Bruker Avance 200 MHz or a Varian Unity 300 MHz machine. Shifts are reported relative to the solvent peak ($CHCl_3$ in $CDCl_3$: δ 7.26 and 77.00), coupling constants are in Hz. Spin multiplicities are given with the following abbreviations: s singlet, d doublet, t triplet, q quartet, m multiplet. Thin-layer chromatography (TLC) was performed using silica gel 60-F_{254} precoated aluminum plates by Merck. Spots were visualized by UV.

***N*(ϵ)-Trifluoracetyl-L-lysine Benzyl Ester 2.** *N*(ϵ)-Trifluoracetyl-L-lysine (**1**, 300 mg, 1.24 mmol) was triturated with *p*-toluenesulfonic acid monohydrate (480 mg, 2.52 mmol) and 7 mL of benzyl alcohol. The resulting paste was dissolved in 18 mL of benzene and heated to reflux for 18 h. The arising water was removed from the reaction by a Soxhlet apparatus filled with molecular sieve (4 Å). After cooling, the solvent was removed in vacuo. The reaction product was crystallized by adding 10 mL of diethyl ether. After cooling at 4 °C overnight, the precipitate was collected by filtration and dried in vacuo to give the *p*-toluenesulfonic acid salt of *N*(ϵ)-trifluoracetyl-L-lysine benzyl ester (**2**, 570 mg, 91%). The free base was gained by extraction with saturated sodium bicarbonate solution.

Loading of Solid Support. TentaGel-NH_2 (230 mg, 60 μmol free NH_2-groups), purchased from Fluka, was loaded with succinyl modified uridine **3** and *N*,*N*′-diisopropylcarbodiimide, 1-hydroxy-1*H*-benzotriazole, and 4-(dimethylamino)pyridine as described earlier (*53*). Degree of loading was around 190 μmol/g.

Oligonucleotide Synthesis. Standard phosphoroamidites and tetrazole solution were obtained from Carl Roth GmbH & Co. KG. Oligonucleotide syntheses were carried out on a ABI 392 Applied Biosystems DNA/RNA-Synthesizer in standard 1 μmol scale in DMT[1]-on mode. Coupling of the first nucleotide to solid-supported modified nucleoside was prolonged to 2 min. Sulfurization was done with tetraethyldiuram disulfide, which was purchased from Sigma and recrystallized (*54*). For the synthesis of phosphorothioates, the sulfurization step was performed before capping. 1*H*-Tetrazol was used as activation reagent. Other reagents used for DNA synthesis were obtained in analytical quality and purified before use.

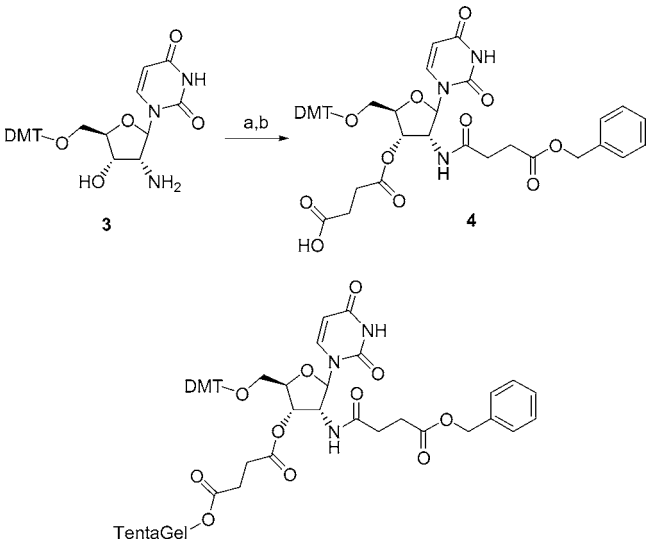
Preparation of Oligonucleotide−Lysine Conjugates. The synthesis column was removed from the synthesizer and opened. The resin-bound oligonucleotide was transferred to an 5 mL reaction tube of a Quest 210 manual synthesizer. Cleavage of the benzyl protecting group was achieved by phase-transfer hydrogenation with PVP-stabilized palladium nanoparticles (0.7 mL) (*53*) and 1,4-cyclohexadiene (0.05 mL) as hydrogen donor. Cyclohexadiene was added to the PVP-stabilized suspension of palladium, and the resulting solution was microfiltrated (0.22 μm) to ensure no precipitated palladium was applied to the resin. The reaction mixture was stirred at room temperature for 3 h.

The resin was washed three times with methanol and three times with DMF. Prior to coupling, the carboxyl group was activated by a solution of 1-hydroxy-1*H*-benzotriazole (0.4 mg, 3.0 μmol) and *N*,*N*′-diisopropylcarbodiimide (1.1 mg, 8.7 μmol) in 1 mL of DMF. The mixture was stirred for 3 h, and the solution was again filtered off. Coupling was done by adding a solution of 1-hydroxy-1*H*-benzotriazole (0.4 mg, 3.0 μmol), *N*,*N*′-diisopropylcarbodiimide (0.4 mg, 8.7 μmol), and lysine building block **2** (2.0 mg, 6.0 μmol) in 1 mL of DMF and stirring for 18 h. The resin was washed three times with DMF and three times with water. For the preparation of conjugates with two and three lysines, the deprotection and coupling procedures were repeated. For cleavage and deprotection of oligonucleotides, 2 mL of concentrated ammonia was added and the mixture was heated to 55 °C for 18 h. The solution was filtered, and the solvent was evaporated in vacuo.

Purification and Analyses of Oligonucleotides. Oligonucleotide concentrations were determined by measuring OD_{260} in a Hitachi U3000 spectrophotometer. Molar extinction coefficents were calculated as the sum of nucleotides (A: 15400, G: 11700, C: 7300, T: 8800, U: 9950).

Initial purifications of DMT-on oligonucleotides were done with Poly-Pak columns obtained from Carl Roth GmbH & Co. KG according to manufacturer except for elution, which was done with 20% acetonitrile. Analytical HPLC was performed on a Nucleosil CC 250/4 100−5 C18 column with the following gradient system: A: 0.1 M triethylammonium acetate in water, B: 0.1 M triethylammonium acetate in 80% acetonitrile, linear gradient 10−40% B in 0−30 min, flow rate 1 mL/min. If the purity after Poly-Pak-purification was deemed insufficient, preparative HPLC was performed on a LiChrosphere 100 RP-18 using the same gradient as for analytical HPLC.

Scheme 1. Synthesis and Structure of Solid-Phase-Bound Starter Nucleotide 4[a]



[a] Reagents and conditions: (a) benzyl succinyl ester, DIC, HOBt, THF, rt; (b) succinic anhydride, pyr, 30 °C.

Mass spectrometric analysis was done on a Kratos seq MALDI mass spectrometer. Sample preparation was done following the method described by Pieles et al. (*55*). One microliter of sample (100 pmol/μL in water) was briefly vortexed with 10 μL of a 0.5 M solution of 2,4,6-trihydroxyacetophenone in ethanol and 5 μL of a 0.1 M solution of di-ammonium hydrogen citrate. One microliter of this mixture was spotted on the target and allowed to air-dry. The mass spectrometer was run in the negative ion and reflectron mode, and spectra were usually obtained by summing up 100 single laser pulses.

Circular dichroism spectrometry was performed on a Jasco J-810 spectropolarimeter equipped with a Neslab RTE 7 thermostatic unit. Oligonucleotides were diluted to a 9 μM solution in 0.15 M NaCl and 0.01 M Tris-HCl (pH 7.0) buffer. CD spectra were collected from 320 to 210 nm using a quartz cuvette (Hellma 100-QS) with a path length of 1 mm. Duplexes were measured after heating the equimolar mixture of complementary strands to 50° for 10 min and subsequent slow cooling to room temperature.

Melting temperatures (T_m) of the duplexes were determined in the Jasco J-810 by slowly heating from 30 to 90 degrees (50 °C/h) and recording CD at 248 nm or OD at 260 nm as a function of temperature. Melting curves showed cooperative form and T_m were obtained from the maxima of the first derivative plots. Temperatures given are that of the cuvette holder.

RESULTS

Conjugation of cationic peptides has been shown to improve properties of antisense oligonucleotides and enhance their efficacy. The synthesis of nucleoside building block **4** was described earlier (Scheme 1). It proceeds straightforward from 2′-amino-2′-desoxy-uridine by reac-

Table 1. HPLC Retention Times and Melting Temperatures of Oligonucleotide Duplexes with the Complementary DNA Strands

	HPLC retention time (min)	T_m (°C)
antisense-DNA		78.7 ± 0.1
Oblimersen	19.13	69.5 ± 1.3
4	17.95	65.5 ± 0.8
4	18.06	67.4 ± 0.1
5	18.37	67.6 ± 1.0
6	18.56	68.2 ± 0.4

tion with succinic acid mono benzyl ester with an excellent selectivity for the amino group (*53*).

For peptide synthesis, a suitable lysine derivative had to be protected at the carboxyl group and the ϵ-amino function. We decided that the trifluoracetyl group was well suited for masking the terminal amino group, because it can be cleaved in the same step as the nucleic base protecting groups (*56*). Because attachment is conducted after complete assembly of the oligonucleotide, the reported replacement of the trifluoracetyl group by the acetyl capping reagent (*57*) is of no importance. Additionally, no cleavage of peptide bonds was reported to occur using concentrated ammonia for deprotection (*58, 59*).

Easily available *N*(ϵ)-trifluoracetyl-L-lysine (**1**) was reacted with benzyl alcohol under catalysis of *p*-toluenesulfonic acid to give benzyl ester **2** (Scheme 2).

A fluorescent dye was successfully coupled to the succinic linker by using a 3-fold excess of DIC and HOBt as catalysts (*53*). Coupling of **2** to solid bound deprotected modified nucleoside monomer using the same conditions gave only poor yields of 30−40% as judged by HPLC analysis. Thus, we used an optimized protocol for inverse solid-phase peptide synthesis (*60*). After a prior activation step with an 8-fold excess of DIC and a 3-fold excess of HOBt, coupling was achieved with 3-fold excesses each of DIC, HOBt, and **2**. This procedure resulted in good yields when tried with solid bound nucleoside monomer.

Consequently, it was employed for conjugating short lysine tails to an 18mer all-phosphorothioate oligonucleotide (**4**) with a sequence according to that of

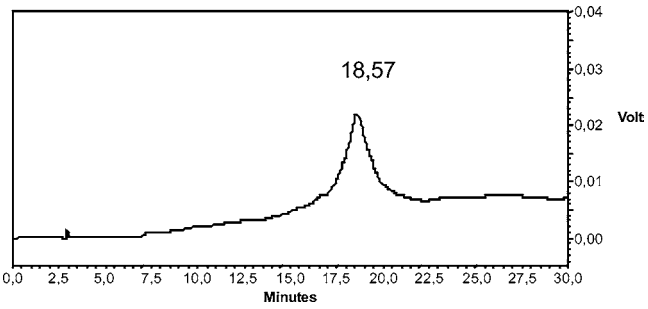

Figure 1. HPLC of oligonucleotide trilysine conjugate **7**.

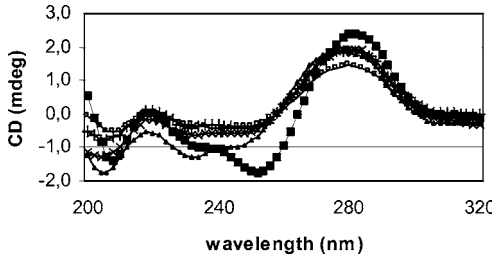

Figure 2. CD spectra of single strands of **4** (+), **5** (▲), **6** (○), **7** (×), and Oblimersen (■).

Oblimersen (5′-TCTCCCAGCGTGCGCCA*U*-3′). Conjugates containing one (**5**), two (**6**), and three (**7**) lysyl residues were prepared (Scheme 3). Purification was achieved using Poly-Pak-cartridges and the standard protocol. HPLC analysis with a reversed phase column showed clear differences in retention times of the three products and unconjugated oligonucleotide. With increasing number of lysyl residues, the retention times were prolonged as can be seen in Table 1. Due to the broad peaks of phosphorothioate oligonucleotides, no reliable measurement of coupling yields could be determined. For example, Figure 1 shows the HPLC chromatogram of trilysyl oligonucleotide **7**. Structures were verified by MALDI mass spectrometry.

CD spectra of the conjugation products were recorded and compared to that of Oblimersen and unconjugated succinyl modified oligonucleotide **4**. All single stranded oligomers gave relatively weak CD curves (Figure 2) with only a well-defined positive band around 280 nm that showed small variability for all substances. In the far UV region of 200−250 nm, a small positive band could be observed at 220 nm, while generally negative CD values were recorded in that area. No straightforward relation of spectra with lysyl substitution could be detected.

Duplexes with complementary unmodified phosphodiester DNA were prepared by mixing of single strands in equimolar amounts in 0.01 M Tris buffer (pH 7.0) with 0.15 M concentration of NaCl. To ensure completion of duplex binding, the mixture was heated to 50 °C for 10 min and subsequently cooled. The formation of duplexes was verified by comparing the spectra of single strands and duplexes recorded at 10 °C (*53*). All oligonucleotides gave nearly identical CD curves (Figure 3). Comparison of the CD values at 200 nm shows smaller results for lysine substituted oligonucleotides, although there is no simple correlation with the number of substitutions.

To determine hybridization affinity and duplex stability, melting profiles were recorded either using CD value at 248 nm or UV absorption at 260 nm. Both methods gave cooperative curves with identical melting temperature. A minimum of four distinct profiles were recorded for each oligonucleotide. Melting temperature of modified oligonucleotides were generally lower than that of control

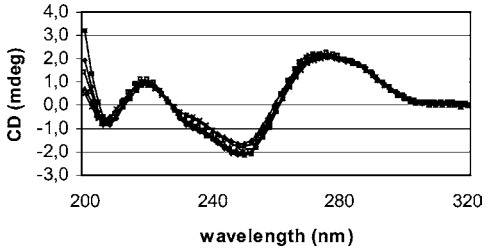

Figure 3. CD spectra of duplexes of **4** (+), **5** (▲), **6** (○), **7** (×), and Oblimersen (■) with sense-DNA.

Oblimersen. Lysyl-substituted substances gave higher melting points than unconjugated oligonucleotide **4**.

DISCUSSION

Our method for preparing oligonucleotide conjugates proved to be easy and convenient for the synthesis of a fluoresceine conjugate (*53*). Herein, we show that it is also a versatile method and can be employed for conjugation of at least short peptides in an in-line approach. Sequential solid-phase synthesis of first the oligonucleotide and then a peptide chain of up to three lysyl residues has been achieved. Preparation of lysyl building block was straightforward. Protection of Lys gamma amino function was accomplished as trifluoracetyl amide. This group is cleaved in the same deprotection step as nucleic base masking groups with concentrated ammonia. Because the trifluoracetyl-protected amine is introduced after complete oligonucleotide synthesis, no side products due to transamination caused by the capping reagent are generated (*57*). The carboxyl function was protected as a benzyl ester, because a cleavage protocol by phase transfer-catalyzed reaction has been established for succinyl linker modified oligonucleotide (*53*). The deprotection reaction was completed after 3 h at room temperature.

Initially, we tried coupling the lysyl building block to solid-bound monomer by direct reaction with DIC and HOBt, but the yields of around 40% were disappointing. Therefore, we decided to use a protocol published for the inverse N to C peptide synthesis (*60*), which resulted in nearly quantitative yields. Prior to coupling, free carboxyl group was activated with a large excess of DIC (8-fold) for 3 h. Coupling was performed with a 3-fold excess of DIC, HOBt, and lysine building block **2** with a reaction time of 18 h. No further optimization attempts were made, although switching to other reagents such as HATU/TMP may result in shorter coupling times (*61*, *62*). Peptide synthesis in the so-called inverse direction usually results in poorer yields than synthesis in established C to N direction. Additionally, a certain extent of racemization is often imminent. Therefore, for preparing conjugates of **4** with larger peptides, distinct syntheses of the components followed by ligation seems to be the favorable option. But for peptides consisting of up to three amino acids, the danger of racemization can be neglected. Even very short cationic peptides have an enhancing influence on the properties of antisense oligonucleotides, especially on cell uptake (*43*).

Conjugates of modified oligonucleotide **4**, bearing the sequence of Oblimersen, targeted to apoptosis inhibitor bcl-2 with one, two, and three lysyl residues were prepared by this procedure. HPLC analyses gave broad peaks because of the diastereomeric attributes of phosphorothioate oligonucleotides. Although exact quantification of coupling yields was therefore impossible, successful conjugation with good yields was proved by changes in retention times. No shoulders on the peaks could be detected. Coinjection of unsubstituted conjugate **4** with lysyl modified conjugates **5**−**7** revealed the presence of two different substances. MALDI analyses confirmed the successful conjugation, as the expected masses were found. The mass of mono- or dilysyl substituted oligonucleotide could not be found in the MALDI mass spectrum of **7**.

CD spectra of single strands were quite similar in their shape showing a B-DNA type curve. Phosphorothioate oligonucleotides generally give lower intensities in CD than phosphodiester DNA (*53, 63*). Positive cotton effect at 280 nm, an indicator of base stacking, was practically identical in all substances. No characteristic curve was observed in the far UV region (200−250 nm) indicating no pronounced secondary structure. No clear influence of lysine substitution could be detected. At neutral pH, poly-L-lysine gives a typical random coil CD spectrum with low intensities in the wavelength region over 210 nm, whereas at lower wavelength, an intense negative band centered at 195 nm is observed (*64*). Although CD values of lysyl-substituted oligonucleotides at 200 nm are lower than that of Oblimersen, there is no correlation with the number of lysyl residues. Measurement at this wavelength was considerably noisy due to the increasing absorption of sodium chloride. No substantial influence on the CD curve is caused by the introduction of short lysyl chains, because the concentration of conjugates **5**−**7** is too low for a reliable measurement of peptide secondary structure. With regard to the short peptide strand, the concentration of conjugate **7** is around 3 μg/mL. A typical concentration for recording peptide CD spectra is 500 μg/mL (*60*).

CD spectra of duplexes with sense DNA exhibited less differences between **5**−**7** and Oblimersen. A well defined helical structure with characteristics of B-DNA is obviously caused by the DNA strand. Differences between conjugates and Oblimersen are minimized. Again, lysyl substitution does not seem to influence CD values. The 18 mer oligonucleotide presumably is extremely dominant concerning CD spectroscopy over the short lysine tail with a maximum of three amino acids.

Melting point determination was done by temperature-dependent measurement of either CD value or UV absorption. Oblimersen gives a melting temperature of 69.5 °C, 9.2 °C lower compared to phosphodiester oligonucleotide (*53*). Unconjugated oligonucleotide **4** shows a decrease of 4 °C. Substitution of the free carboxyl group with lysine increases the duplex stability. Melting point of **7** is only 1.3 °C lower than that of Oblimersen and very similiar to that of a fluoresceine conjugated oligonucleotide (*53*). Differences between **5**, **6**, and **7** are small and partly within standard deviation, but a tendency toward duplex stabilization by an increasing number of lysine monomers can be observed. This effect can be explained by partial neutralization of the negatively charged phosphate backbone by cationic terminal amino groups of lysine. The electrostatic repulsion of the two strands is thus decreased. This stabilizing effect evidently overcomes the destabilizing effect of the increasing steric bulk in the minor groove. On the other hand, the increasing steric hindrance seems to be responsible for the somewhat lower increase in melting temperature than expected.

In conclusion, our previously reported procedure for preparing oligonucleotide conjugates has been shown to be suitable for preparing conjugates with short peptide tails in an in-line approach. Increasing length of the oligolysyl chain resulted in both better base pairing ability, reflecting the high potential of conjugated basic

peptides to improve the therapeutical properties of nucleic acid analogues. The conjugation of oligolysyl chains to the 3′-terminal 2′-position altered physical and biological properties only to a minimal extent and is therefore a technique to specifically enhance oligonucleotides characteristics by ligating functional or cationic peptides or proteins.

Dipartimento di Chimica, Biochimica e Biotecnologie per la Medicina, Università di Milano, via Saldini 50, I-20133 Milano, Italy. Received April 5, 2005; Revised Manuscript Received June 16, 2005

The first total synthesis of α-D-glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline using a short "one-pot" assembly of its 1,4,5-trisubstituted 3-hydroxypyridinium ring is reported.

INTRODUCTION

This paper describes the first total synthesis of the optically pure α-D-glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline (Glc-Gal-PYD, **1**; Figure 1), a natural glycosylated analogue of the collagen cross-linked pyridinoline **2a**, recently found in human synovium by Gineyts et al. (*1*). Glc-Gal-PYD, **1**, appears to be specific of human synovium, and its levels are considered strongly predictive markers of joint destruction progression in various diseases, including rheumatoid arthritis (*1*−*4*). Moreover, Glc-Gal-PYD, **1**, with its attractive and challenging structure, rich in stereogenic centers in both the amino acidic and the glycosidic portions, represents an attractive goal for organic chemists.

Although several different strategies for the synthesis of pyridinoline **2a**, the aglycone portion of Glc-Gal-PYD (**1**), and of its congener deoxypyridinoline **2b** have been published (*5*, *6*), starting from simple amino acids, no attempt was reported until now to synthesize the important glycoconjugate **1**, which, in principle, could be obtained by glycosylation of an appropriate aglycone such as **3** (*6*, *7*) with a glucosyl-galactosyl donor or, in a longer route, with a galactosyl donor having a participating and orthogonally cleavable protective group at position 2, which should allow a successive extension of the glycosylation in the 2 direction of galactose.

Moreover, herein we report a completely different procedure for the synthesis of Glc-Gal-PYD, **1,** adopting, as a key step, the "one-pot protocol" for the assembly of its 1, 4, 5-trisubstituted 3-hydroxypyridinium ring, originally reported by us (*5*, *8*, *9*).

EXPERIMENTAL PROCEDURES

General Methods. Nuclear magnetic resonance spectra were recorded at 303 K on Bruker AM-500 spectrometer operating at 500.13 MHz for ^{1}H and 125.76 MHz for ^{13}C. Chemical shifts are reported in parts per million (ppm, δ units) and are referenced to residual $CHCl_3$ (δ_H = 7.24 ppm) and to $CDCl_3$ (δ_C = 77.0 ppm) for solutions in $CDCl_3$ or to internal CH_3OD (δ_H = 3.30 ppm and δ_C = 49.0 ppm) for solutions in D_2O. ^{1}H NMR data are tabulated in the following order: number of protons, multiplicity (s, singlet; d, doublet; bs, broad singlet; m, multiplet), coupling constant(s) in hertz, assignment of proton(s). The ^{1}H and ^{13}C resonances were assigned by ^{1}H decoupling, ^{1}H−^{1}H COSY, and ^{1}H−^{13}C correlation experiments.

Optical rotations were taken on a Perkin-Elmer 241 polarimeter, and $[\alpha]_D$ values are given in 10^{-1} deg cm^2 g^{-1}.

Mass spectra were obtained using a Finnigan LCQdeca (ThermoQuest) ion trap mass spectrometer fitted with an electrospray source (ESI). The spectra were collected in continuous flow mode by connecting the infusion pump directly to the ESI source. Solutions of compounds were infused at a flow rate of 5 mL/min. The spray voltage was set at 5.0 kV in the positive and at 4.5 kV in the negative ion mode with a capillary temperature of 220 °C. Full-scan mass spectra were recorded by scanning a *m/z* range of 100−2000.

All reactions were monitored by thin-layer chromatography (TLC) carried out on 0.25 mm E. Merck silica gel plates (60 F_{254}) using UV light, 50% sulfuric acid or 0.2% ninhydrin in ethanol, and heat as developing agents. E. Merck 230−400 mesh silica gel was used for flash column chromatography (*10*).

Preparation of *tert*-Butyl (2*S*,5*R*)-6-Amino-2-benzyloxycarbonylamino-5-[(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-(1→2)-(3,4,6-tri-*O*-benzyl-β-D-galactopyranosyl)]hexanoate, 5. To a stirred solution of anhydrous $SnCl_2$ (240 mg, 1.27 mmol) in anhydrous tetrahydrofuran (8 mL), PhSH (496 μL, 4.84 mmol) and Et_3N (4.96 μL, 3.56 mmol) were added. Then, *tert*-butyl (2*S*,5*R*)-6-azido-2-benzyloxycarbonylamino-5-[(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-(1→2)-(3,4,6-tri-*O*-benzyl-β-D-galactopyranosyl)]hexanoate, **4** (1.00 g, 0.75 mmol), was added. After the reaction was stirred at 25 °C for 1 h, the solvent was evaporated, and the crude residue was purified by rapid chromatography with elution of the byproducts with dichloromethane−methanol (100:8, v/v) and the glycosylated amine **5** (834 mg; *Y* = 85%) with dichloromethane−methanol (100:10, v/v). The amine **5**, an oil, showed the following: $[\alpha]^{20}_D$ +30.5 ($CHCl_3$, *c* 1). ^{1}H NMR δ_H (500 MHz, $CDCl_3$): 5.60 (1H, d, *J* 3.3 Hz, H_{glu}-1), 4.56 (1H, d, *J* 7.7 Hz, H_{gal}-1), 4.16 (1H, dd, *J* 10.2 and 3.3 Hz, H_{gal}-2), 4.09 (1H, m, H_{lys}-2), 2.84 (1H, dd, *J* 13.3 and 2.1 Hz, H_{lys}-6a), 2.59 (1H, dd, *J* 13.3 and 6.1 Hz, H_{lys}-6b). ^{13}C NMR δ_C ($CDCl_3$): 171.1 ($CO_2{}^t$Bu), 155.9 ($NHCO_2{}^t$Bu), 101.7 (C_{gal}-1), 95.7 (C_{glu}-1), 53.9(C_{lys}-2), 44.9 (C_{lys}-6). ESI-MS (positive) *m/z*: 1331.6

Preparation of Completely Protected α-D-Glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline, 7. To a solution of the *tert*-butyl (2*S*,5*R*)-6-amino-2-benzyloxycarbonylamino-5-[(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-(1→2)-(3,4,6-tri-*O*-benzyl-β-D-galactopyranosyl)]hexanoate, **5** (600 mg, 0.46 mmol), in CH_3CN (30 mL) containing Na_2CO_3 (900 mg, 8.5 mmol), the protected bromoketone **6** (436 mg, 1.15 mmol) was added, and the mixture was stirred under nitrogen for 6 h. At this time, the disappearance of both the starting glycosylated amine **5** and the initially formed monoalkylated product was observed (TLC, CH_2Cl_2/MeOH 100/5 v/v; R_f = 0.28 and 0.72, respectively). Then, the solvent was evaporated under vacuum, and the crude residue was recovered with MeOH (30 mL) and was vigorously shaken under a slight pressure of oxygen (1.3 atm) at room temperature for 60 h. At this time, the mixture was diluted with dichloromethane (50 mL) and filtered on a pad of Celite. Evaporation of the solvent afforded a crude residue, which was purified by rapid chromatography on silica. Elution with dichloromethane−methanol (100:4, v/v) afforded the protected glycosylated pyridinoline **7** (537 mg; $Y = 62\%$) as a resinous material: $[\alpha]^{20}_D$ +28.2 ($CHCl_3$, *c* 1). UV λ_{max}(EtOH)/nm (ϵ/dm^3 mol^{-1} cm^{-1}): 258.5 (5175), 340 (5962). ^{1}H NMR δ_H (500 MHz, $CDCl_3$): 5.41 (1H, d, *J* 3.5 Hz, H_{glu}-1), 4.54 (1H, d, *J* 7.4 Hz, H_{gal}-1), 4.12−4.06 (4H, overlapping, H_{1chain}-1a, H_{1chain}-1b, H_{4chain}-2, H_{5chain}-3), 3.26 (1H, dd, *J* 11.7 and 11.7 Hz, H_{4chain}-1a), 2.85 (1H, dd, *J* 11.7 and 2.5 Hz, H_{4chain}-1b). ^{13}C NMR δ_C ($CDCl_3$): 171.2, 171.2, 170.5 (3 × $CO_2{}^t$Bu), 156.0 (C-3), 143.6, 140.7, 136.3, 130.2 (pyridinium ring carbons), 103.3 (C_{gal}-1), 96.0 (C_{glu}-1), 56.6, 53.7, 53.6 (3 × amino acidic α-carbons). ESI-MS (positive) *m/z*: 1911.0 (24%), 1910.0, (55%), 1909.2 (100%), 1908.5 (91%; M + Na^+), 1888.5 (13%), 1887.5 (21%), 1886.5 (17%; M + H^+).

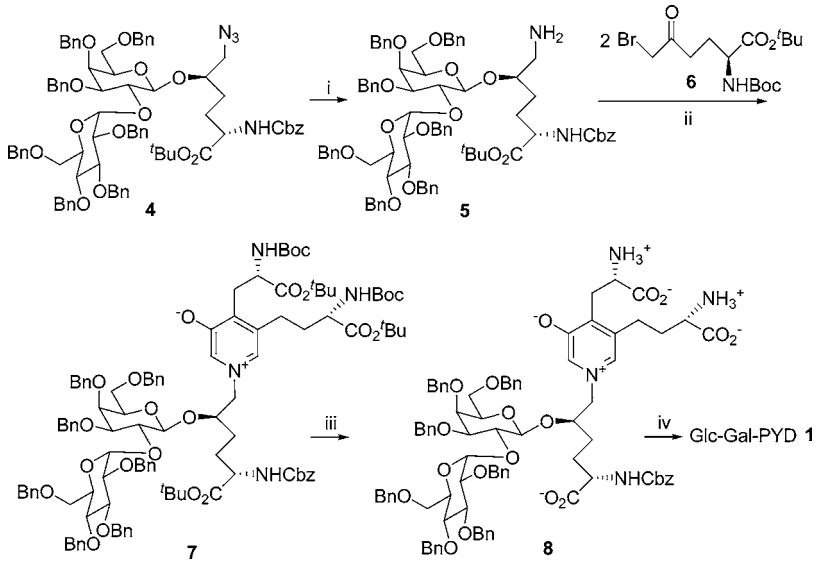
Preparation of α-D-Glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline, 1, by Successive Regeneration of the Protected Functionalities. *i. Preparation of the Partially Protected Glc-Gal-PYD **8**.* The completely protected Glc-Gal-PYD **7** (400 mg; 0.212 mmol) was dissolved in triflouroacetic acid−water (8 mL, 95:5, v/v), and the resulting solution was stirred at 25 °C for 1.5 h. Evaporation of the mixture afforded the partially protected Glc-Gal-PYD **8** as its tetrafluoroacetate salt (389 mg; $Y = 93\%$) as a glass: $[\alpha]^{20}_D$ +33.4 ($CHCl_3$, *c* 1). ^{1}H NMR δ_H (500 MHz, CD_3OD): 8.25, 8.21 (2H, 2 × bs, pyridinium ring protons), 5.43 (1H, d, *J* 2.9 Hz, H_{glu}-1), 4.46 (1H, d, *J* 8.0 Hz, H_{glu}-1), 4.12 (1H, m, H_{1chain}-2), 4.02 (1H, dd, *J* 8.8 and 8.8 Hz, H_{1chain}-5), 3.78−3.74 (2H, overlapping, H_{gal}-1 and H_{5chain}-3). ^{13}C NMR δ_C (CD_3OD): 175.2, 171.2, 170.5 (3 × $CO_2{}^t$Bu), 161.3 (q, *J* 37.5 Hz, CF_3COO), 157.0 (C-3), 141.8, 141.4, 138.2, 130.0 (pyridinium ring carbons), 117.4 (q, *J* 298 Hz, CF_3COO), 103.2 (C_{gal}-1), 97.4 (C_{glu}-1), 54.5, 53.3, 52.2 (3 × amino acidic α-carbons). ESI-MS (positive) *m/z*: 1519.8 (41%), 1518.8 (90%), 1517.8 (100%; M + H^+), 1540.7 (16%), 1539.6 (16%; M + Na^+).

*ii. Preparation of the α-D-Glucopyranosyl-(1→2)-β-D-galactopyranosyl-O-pyridinoline, **1**.* The partially protected Glc-Gal-PYD **8** (390 mg, 0.20 mmol) dissolved in aqueous HCl (100 mL, 10^{-3} M) was hydrogenated in the presence of $PdCl_2$ (100 mg) at 25 °C and atmospheric pressure. When the absorption of hydrogen was completed, the mixture was filtered over a pad of Celite, and the solution was lyophilized to afford the expected α-D-glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline, **1** (170 mg; $Y = 92\%$), as its tetrahydrochloride salt dihydrate ($C_{29}H_{46}N_4O_{18}$·4HCl·2H_2O), an amorphous solid: $[\alpha]^{20}_D$ +47.6.0 (H_2O, *c* 1). ^{1}H NMR δ_H (500 MHz, D_2O): 8.31, 8.29 (2H, 2 × bs, pyridinium ring protons), 5.32 (1H, d, *J* 3.8 Hz, H_{glu}-1), 4.51 (1H, d, *J* 7.7 Hz, H_{gal}-1), 4.33 (1H, m, H_{1chain}-2), 4.15 (1H, dd, *J* 6.3 and 6.3 Hz, H_{5chain}-3), 4.08 (1H, dd, *J* 6.3 and 6.2 Hz, H_{1chain}-5), 3.81 (1H, d, *J* 3.5 and <1 Hz, H_{gal}-4), 3.54 (1H, dd, *J* 9.8 and 7.7 Hz, H_{gal}-2), 3.48 (1H, dd, *J* 9.5 and 3.8 Hz, H_{glu}-2), 3.37 (1H, dd, *J* 9.5 and 9.5 Hz, H_{glu}-4), 3.08 (1H, ddd, *J* 14.7, 11.9, and 5.4 Hz, H_{5chain}-1a), 2.93 (1H, ddd, *J* 14.7, 11.5, and 5.6 Hz, H_{5chain}-1b). ^{13}C NMR δ_C (CD_3OD): 172.7, 172.4, 171.8 ((3 × CO_2H), 155.8 (C-3), 141.3, 141.1 (C-4 and C-5), 137.9, 131.1 (C-2 and C-6), 102.8 (C_{gal}-1), 98.5 (C_{glu}-1), 76.7 (C_{1chain}-2), 75.5 ((C_{gal}-5), 75.4 (C_{gal}-2), 73.8 (C_{glu}-3), 72.6, 72.5 (C_{glu}-2 and C_{glu}-5), 72.1 (C_{gal}-3), 70.4 (C_{glu}-4), 69.7 (C_{gal}-4), 65.1 (C_{1chain}-1), 61.7 (C_{gal}-6), 61.4 (C_{glu}-6), 53.6 (C_{1chain}-5), 53.4 (C_{5chain}-3), 52.3 (C_{4chain}-2), 30.8 (C_{5chain}-2), 28.4 (C_{1chain}-3), 28.1 (C_{4chain}-1), 26.5 (C_{5chain}-1), 26.4 (C_{1chain}-4). ESI-MS (positive) *m/z*: 777.4 (3%), 776.5 (7%), 775.5 (26%; M + Na^+), 755.6 (7%), 754.6 (32%), 753.6 (100%; M + H^+).

RESULTS AND DISCUSSION

For the total synthesis of α-D-glucopyranosyl-(1→2)-β-D-galactopyranosyl-*O*-pyridinoline (Glc-Gal-PYD), we first performed some unsuccessful explorative experiments in which the direct glycosylation of the protected aglycone **3**, previously prepared in our laboratory (*6, 7*), was studied. However, after some efforts, we observed that this strategy presents some objective difficulties. First of all, an obvious competitive glycosylation of the phenolic group and of the lysine hydroxy group of the aglycone **3** occurs. Moreover, other problems arose from the fact that the formation of the *O*-galactoside bond of **1** requires an exclusive β-stereoselection, which appeared difficult to reach in the absence of a suitable participating group at the 2-position of the galactose. Fortunately, as shown in Scheme 1, we subsequently have found a successful and concise synthesis, which involves, as a key step, the "one-pot assembly" of the 1,4,5-trisubstituted 3-hydroxypyri-

Scheme 1. Synthesis of Glucogalactopyridinoline[a]



[a] Reagents and conditions: (i) $SnCl_2$, PhSH, Et_3N, THF, 25 °C, 1 h, 85%; (ii) Na_2CO_3, MeCN, 25 °C, 6 h, then Na_2CO_3, O_2, MeOH, 25 °C, 60 h, 62%; (iii) TFA, 25 °C, 1.5 h, 93%; (iv) H_2, $PdCl_2$, aq. HCl 10^{-3} M, 25 °C, 92%.

dinium ring of **1** using as starting building blocks the protected (*11, 12*) glycosylated hydroxylysine **4** and the bromoketone derivative **6** (*8*).

At the beginning, while we were confident about the general scope of our "one-pot" protocol, we were quite uncertain about its successful application to our synthesis. In fact, the "one-pot" formation of the pyridinium ring of the target compound **1** should carry the amino group of the glycosylated hydroxylysine **5** into a series of cascade reactions leading to the formation of the aromatic ring. In particular, the prolonged basic conditions required for the final formation of the pyridinium ring by oxidative aromatization could be critical for the stability of the carbohydrate portion of **5**. In fact, the susceptibility of benzylated sugars and of *O*-glycopeptides to the base-catalyzed β-elimination of a glycan has been widely documented by us (*13*) and by others (*14*). Moreover, our protocol (Scheme 1) works as planned, and we successfully obtained the desired compound Glc-Gal-PYD, **1**, in amounts and purity suitable for its use in biological experiments.

The glycosylated hydroxyazide **4**, prepared by elaboration of L-glutamic acid (*11*, *12*), followed by a stereoselective introduction of the disaccaridic portion in two steps, was reduced to the glycosylated hydroxylysine **5** in quantitative yields and in a short time (1 h), using a tin(II) complex prepared by treatment of $SnCl_2$ with appropriate amounts of thiophenol and triethylamine in acetonitrile (*15*). These conditions were selected as the more favorable in terms of reaction time and yield, after some less satisfactory attempts performed using inter alia triphenylphosphine or polystyrene-linked triphenylphosphine (*16*) or a thiolytic reduction catalyzed by diisopropylethylamine (*17*).

The glycoside **5** was successively reacted with an excess (1:2.5 molar ratio) of the bromoketone derivative **6** (*8*) in CH_3CN containing solid Na_2CO_3 to obtain in "one pot" the glycoconjugate **7**, containing a 3-hydroxypyridinium ring. The reaction was continued until the disappearance of both the starting glycosylated amine and the initially formed monoalkylated product (TLC). Successively, the CH_3CN was replaced by MeOH, and the resulting mixture was vigorously shaken under a slight pressure of oxygen (1.3 atm) at room temperature for 60 h. These conditions, which are different from those described in the general protocol for the synthesis of 3-hydroxy-4,5-disubstituted pyridines from a cyclic compounds (*5*, *8*), afforded the best yields of the final compound **7**. In fact, when the previously reported bases (K_2CO_3) or air in place of oxygen for the alkylation, followed by self-condensation of the initially formed diketo amine, were used, less satisfactory yield were obtained and the reaction times were noticeably longer (4 days). This appeared to be due to the final step including the formation of the intermediate cyclic α,β-unsaturated ketone (*8*) and its aromatization to the final fluorescent compound **7**. In fact, comparable yields were obtained when the reaction was initially performed in CH_3CN and in the presence of K_2CO_3 and then this salt was substituted by Na_2CO_3 before changing the solvent with MeOH. Most probably, the solubility in methanol of Na_2CO_3, relatively higher than that of K_2CO_3, and the increased solubility of the pure oxygen, due to its higher partial pressure (with respect to the air oxygen), accelerate the reaction and avoid the formation of byproducts (evident in TLC as nonfluorescent compounds) formed by side reaction. Standard work-up and chromatographic purification on silica afforded then the 3-hydroxypyridinium derivative **7** (in 62% yields, as a resinous material). This showed the correct elemental analysis and molecular ion, together with appropriate UV and NMR evidence, which support the presence of the 3,4-hydroxypyridinium ring (λ_{max} 340.0 and 258.5 nm in EtOH; ^{13}C signals at 156.0, 143.6, 140.7, 136.3 and 130.2 ppm). On the other hand, the presence of the intact β-galactosidic and α-glucosidic bonds was confirmed by the expected resonances and coupling constants of the anomeric protons in the ^1H NMR spectra (two doublets at 4.54 ppm with $J = 7.4$ Hz and at 5.41 ppm with $J = 3.5$ Hz), attributed to the anomeric protons of the galactosyl and glucosyl portions, respectively.

The presence in compound **7** of the three amino acidic functionalities was supported by the ^{13}C resonances of the carboxylic groups and of the α-carbons (signals at 56.6, 53.7, and 53.6 ppm).

Treatment of compound **7** with trifluoracetic acid regenerates all the carboxylic groups and the amino groups at the amino acid chains at position 4 and 5, thus

affording the benzylated derivative **8**. Finally hydrogenolysis of the surviving benzyloxy and *N*-carbobenzyloxy groups afforded the title compound **1** in high yield (total *Y* from **4** = 45%).

It is worth pointing out that the hydrogenolysis of the benzyloxy groups of the benzyl derivative **8** with palladium on carbon (10%) under several sets of conditions (also acidic) was unexpectedly unsuccessful, although palladium on carbon works well in the deprotection of benzyl derivatives of pyridinolines (*5*−*9*) and glycosylated hydroxylysines (*11*, *12*). In contrast, when the reaction was performed in acidic water under the catalysis of $PdCl_2$, the desired compound **1** was obtained without evident inhibition of the catalyst by the pyridine group present in the starting compound or by the amine group initially formed by the hydrogenolysis. On the other hand, all attempts where the hydrogenolytic cleavage of all benzyloxy groups was performed before the acidic hydrolysis of the *tert*-butyl esters were unsatisfactory.

The obtained glycoconjugate **1** shows the expected physicochemical properties and behavior in HPLC and mass-spectrometry analyses, under the conditions described by Gyneyts et al. (*1*), superimposable to that of Glc-Gal-PYD present in the urine of a patient with rheumatoid arthritis.

In conclusion, herein we report the first synthesis and complete characterization of Glc-Gal-PYD, **1**, an important hallmark of human joint diseases. The synthesis of this collagen cross-link represents a confirmation of the structure assigned to the native Glc-Gal-PYD and allows us to generate the compound in amounts suitable for biological studies.

SYNTHESIS OF THIOL-REACTIVE LIPOPEPTIDE ADJUVANTS. INCORPORATION INTO LIPOSOMES AND STUDY OF THEIR MITOGENIC EFFECT ON MOUSE SPLENOCYTES

Pages 541−553. The synthesis of Pam_2GAG (**19**) and Pam_2GAG-Mal (**21**) was based on the publication by J. W. Metzger et al. (1991) *Int. J. Pept. Protein Res. 38,* 545−554. Unfortunately we have discovered since that it contains errors in configuration assignments. For example, on page 552 of their publication the authors state that "Reaction with *S*-(−)-glycidol yields the respective *R*-configurated *S*-glycerylcyteinyl derivative". This is incorrect, and for this particular compound *R*-(−)-glycidol should be used as starting material. This error invalidates the configuration attributed to the stereochemically pure lipopeptides synthesized according to Metzger et al. The consequences for our own work are that compounds **19** and **21** are (*S*)-configured instead of (*R*) as published and thus are expected to be less biologically active than anticipated.

Cationic Lipophosphoramidates and Lipophosphoguanidines Are Very Efficient for in Vivo DNA Delivery

Erwann Picquet,[†] Karine Le Ny,[†] Pascal Delépine,[‡] Tristan Montier,[‡] Jean-Jacques Yaouanc,[†] Dominique Cartier,[†] Hervé des Abbayes,[†] Claude Férec,[‡] and Jean-Claude Clément*,[†]

Le Gorgeu, C.S. 93837, F-29238 Brest Cedex 3, France, and INSERM, U 613, Université de Bretagne Occidentale, C.S. 2653, F-29275 Brest Cedex, France. Received March 29, 2005; Revised Manuscript Received August 5, 2005

Two new families of cationic lipids were designed and synthesized for gene delivery, namely "lipophosphoramidates" and "lipophosphoguanidines", whose efficiency was noteworthy. The most efficient have an arsonium cation as the polar head, and the unsaturated lipidic tails (e.g. oleyl) gave the better in vivo results (mice lungs).

INTRODUCTION

Although currently less efficient than viral vectors, synthetic vectors can encapsulate and, theoretically, carry out large genetic material (>100 kb) and do not lead to immunogenic response, hence a growing investment in the search for nonviral vectors with increased efficiency and lower toxicity. Among those, cationic lipids hold, together with polymers, the most important place (*1*). In these lipids, one must note that, with a few exceptions, the cationic or polycationic charge is always carried by nitrogen atoms. As an exception, precisely, we showed that in the case of cationic phosphonolipids, the replacement of an ammonium by a phosphonium or an arsonium polar head led to an increased efficiency (up to 7 times according to the cell lines tested) and decreased cytotoxicity (*2*).

Going on with our search for even more efficient vectors, we looked into the possibility of using the intrinsic properties of cells for designing synthetic vectors possessing a weak linker between the lipidic part and the polar cationic head, to split off the lipidic part after cell internalization. Indeed, the pH decrease, from more than 7 extracellular to 5−6 in endosomes and about 4 in some late lysosomes, is well established. Such a principle was recently described in novel cationic lipids incorporating an acid-sensitive acylhydrazone linker (*3*). Another example was the incorporation of an acid-labile vinyl ether linkage in the lipidic part of the cationic lipid (*4*). Something similar was recently described in the case of polymers: linear polyethyleneimine (PEI) reticulated with a linker including two ester bonds susceptible to hydrolysis at physiological conditions was more efficient and less toxic than reticular PEI (*5*).

In the field of phosphorylated compounds, the hydrolysis of the P(O)−N bond is well documented (*6*), and the

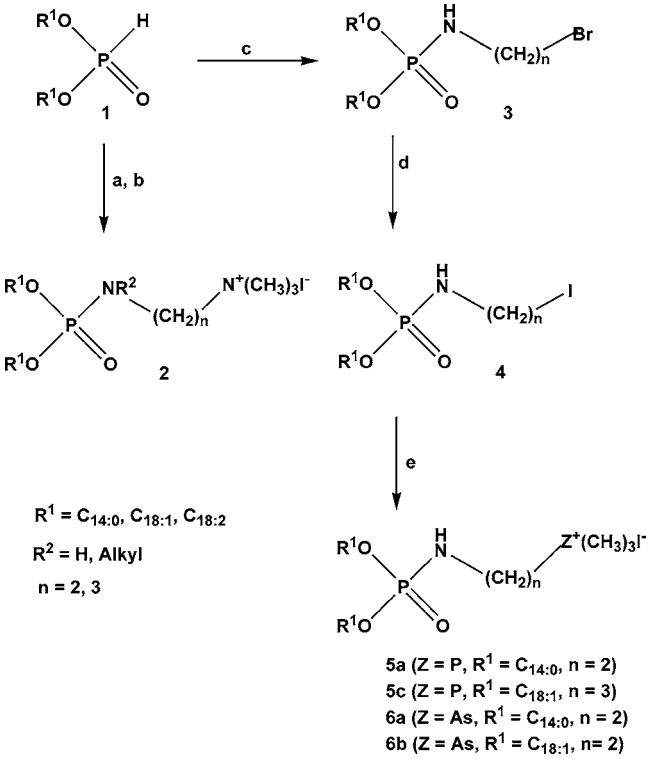
Scheme 1. Synthesis of Cationic Lipophosphoramidates[a]



[a] (a) $R^2HN(CH_2)_n$-$N(CH_3)_2/CCl_4$; (b) CH_3I, RT, 12 h; (c) $H_2N(CH_2)_nBr$,HBr/CCl_4; (d) NaI/acetone; (e) for Z = P: $(CH_3)_3P$/THF, 40 °C, 2 days; for Z = As: $(CH_3)_3As$, neat, 45 °C, 1 week.

dialkyl phosphite group is sometimes used as a protecting group for amines (*7*) and polyamines (*8*). Deprotection generally occurs easily in dilute mineral acids, but the P−N bond shows a relative stability in organic and Lewis acids (*7a*). Moreover and more significant, the enzymatic hydrolysis of the P−N bond of phosphoramidates by phosphoramidases active at pH 3.5−7.5 is well established (*9*).

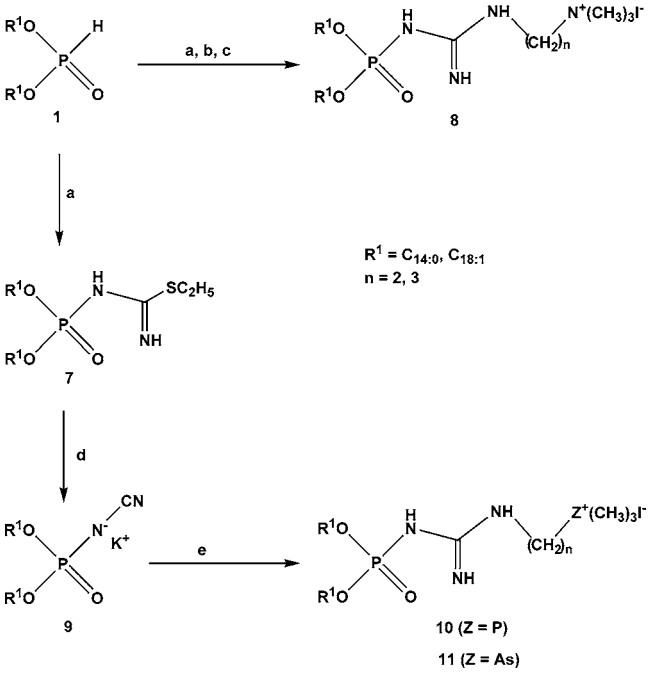
Taking these facts into account, we designed and synthesized two novel families of DNA monocationic carriers, namely "lipophosphoramidates" and "lipophosphoguanidines".

RESULTS

The main route leading to phosphoramidates is the reaction of a hydrogen phosphite with an amine, in the presence of CCl_4, under phase-transfer catalysis conditions (*10*) or not (*11*). We adapted these two procedures for reacting lipidic phosphites **1** with various diamines to get, after quaternisation with methyl iodide, a set of "lipophosphoramidates" **2** with an ammonium cation. Replacement of diamines by bromoalkylamines led to bromoalkylphosphoramidates **3**. After metathesis Br → I for increased reactivity, compounds **4** were reacted with trimethylphosphine or trimethylarsine, thus leading to lipophosphoramidates with trimethylphosphonium **5** or trimethylarsonium **6** cations, respectively (Scheme 1).

Hydrolysis of phosphoguanidines has been known for a long time because of many studies about conversion of phosphocreatine to creatinine and inorganic phosphate (*12*). With the same purpose as for lipophosphoramidates, we designed and synthesized cationic "lipophosphoguanidines". The first step of their synthesis was adapted for lipidic phosphites **1** from those of simple phosphoguanidines, i.e., the phosphorylation of 2-ethyl-2-thiopseudourea (*13*). Subsequent reaction with unsymmetrical diamines followed by quaternization of the terminal amine led to lipophosphoguanidines **8** with an ammonium cation (Scheme 2).

Scheme 2. Synthesis of Cationic Lipophosphoguanidines[a]



[a] (a) 2-Ethyl-2-pseudothiourea; (b) $H_2N(CH_2)_nN(CH_3)_2$; (c) CH_3I; (d) K_2CO_3/HgO; (e) $H_3N^+(CH_2)_nZ^+(CH_3)_3I^-$.

Dibenzyl (or diphenyl) phosphoryl isothioureas undergo ethanethiol elimination when reacted with sufficiently basic amines in the presence of HgO (*14*). In the case of lipophilic phosphoryl isothioureas **7**, replacement of amines by K_2CO_3 led to isolable potassium salts **9** which, upon reaction with aminoalkylphosphonium or arsonium hydrobromides led directly to "cationic lipophosphoguanidines" with a trimethyl phosphonium (**10**) or arsonium (**11**) cation, respectively (*15*).

Several examples of cationic lipids **2**, **5**, and **6** were submitted to transfection activity assays (*16*): in vitro (HeLa, CHO cell lines or CF nasal polyps primary cultures) and in vivo (mice lung). For in vitro experiments with HeLa cell line and CF primary culture, the luciferase activity was measured 2 days after transfection, using a chemiluminescent assay. For CHO, the percentage of GFP^+ cells was measured by Facs flow analysis. Whatever cell or technique used (*17*), the activity with lipid **6b** ($R^1 = C_{18:1}$, $n = 2$) or **8a** ($R^1 = C_{14:0}$, $n = 3$), for instance, was systematically 20−25% greater than DOTAP or Lipofectine, two commercial references, and corresponded to 25−30% of GFP^+ viable cells. More significant were the results of in vivo assays on mice lung (Figure 1) (the lipid-to-DNA charge ratio used was 4, as this ratio had been previously shown to be the optimal (*18*)). Lipids **5a** ($R^1 = C_{14:0}$, $n = 2$), **5c** ($R^1 = C_{18:1}$, $n = 3$), **6a** ($R^1 = C_{14:0}$, $n = 2$), and **6b** exhibit a luciferase expression up to 3600 times higher than DOTAP (*19*).

As checked on a model compound (**2**, $R^1 = C_2H_5$, $R^2 = CH_3$, $n = 3$, for solubility reasons) the acid-catalyzed hydrolysis of the P−N bond is not very fast (4 days for 100% P−N hydrolysis at pH = 2). So, the total hydrolysis of the P−N bond seems unnecessary to get the high levels of in vivo observed efficiency, since the highest expression levels were reached within 24 h (in vivo) or 48 h (in vitro).

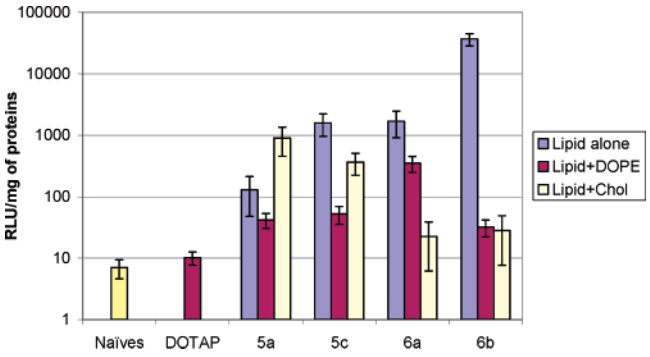


Figure 1.

But it may also be presumed that these noteworthy in vivo results are due to an enzymatic activity (which remains to be proved), accelerating the rate of the P−N bond hydrolysis, which does not work in vitro. Since this relevant efficiency seems accompanied by a weak cytotoxicity, a more complete biological evaluation is currently under investigation from our group.

(15) Both lipophosphoramidates and lipophosphoguanidines gave satisfactory ^{1}H, ^{31}P, and ^{13}C NMR spectra.

(16) Cationic lipids were dissolved in chloroform in glass vials. Chloroform was then evaporated by vacuum, resulting in a dry lipid film. Sterile pyrogen-free distilled water was added in appropriate amounts to the lipid. The vials were then sealed and stored overnight at 4 °C. The resulting solution was sonicated for 10 min in a bath sonicator. The plasmid and lipid were then combined and incubated for 30 min at room temperature to form the lipoplexes.

(19) For in vivo mice lung assays, the following protocol was implemented: Five-week-old female Swiss mice were used. Once anesthetized by ether inhalation, each mouse received 200 μL of the lipoplex solution containing 50 μg of plasmid encoding luciferase as an intravenous bolus in the tail vein. Lungs were harvested 24 h after injection. Each tissue was crushed in a mortar cooled by liquid nitrogen and incubated with lysis buffer (Promega) for 30 min. A centrifugation at 10 000*g* was performed, and supernatant luciferase activity was assayed in a 'MLX microtiter plate luminometer' (Dynex technologies) using a 'luciferase assay system' (Promega). Five mice were used for each time point. The total protein concentration of these supernatants was measured with the 'Coomassie Plus Protein Assay Kit' (Pierce). Results are expressed in RLU per mg of total proteins.

A Novel Fluorescent Probe: Europium Complex Hybridized T7 Phage

Chin-Mei Liu, Qiaoling Jin, April Sutton, and Liaohai Chen*

Biosciences Division, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois 60439.
Received April 6, 2005; Revised Manuscript Received August 8, 2005

We report on the creation of a novel fluorescent probe of europium-complex hybridized T7 phage. It was made by filling a ligand-displayed T7 ghost phage with a fluorescent europium complex particle. The structure of the hybridized phage, which contains a fluorescent inorganic core surrounded by a ligand-displayed capsid shell, was confirmed by electron microscope, energy-dispersive X-ray analysis (EDX), bioassays, and fluorescence spectrometer. More importantly, as a benefit of the phage display technology, the hybridized phage has the capability to integrate an affinity reagent against virtually any target molecules. The approach provides an original method to fluorescently "tag" a bioligand and/or to "biofunctionalize" a fluorophore particle. By using other types of materials such as radioactive or magnetic particles to fill the ghost phage, we envision that the hybridized phages represent a new class of fluorescent, magnetic, or radioprobes for imaging and bioassays and could be used both in vitro and in vivo.

Fluorescent probes play important roles in biology, medicine, and biotechnology (*1*, *2*). Conventionally, a fluorescent probe is made by chemically conjugating a fluorophore molecule or a quantum dot to a biomolecule (such as an affinity reagent). Recently, a few unconventional probes have been developed. For instance, researchers at a number of laboratories have explored the use of aequorea-derived fluorescent proteins (AFP) (*3*, *4*). As an alternative to AFP, tetracysteine-biarsenical labeling also has been demonstrated as a very useful probing tool (*5*). In both cases, the "fluorophores" (fluorescent proteins, such as AFP and tetracysteine-biarsenical complex) are fused to the affinity regents by molecular biology methods instead of chemical conjugation.

The concept for a hybridized phage probe is based on the fact that certain tailed phages build their protein shells first and subsequently condense the nucleic acid within them (*6*). As a result, an empty capsid ("ghost phage" or "pseudo phage") from the tailed phage is stable without interior DNA. The architecture of a ghost phage can function as a unique nanocontainer for uniform fabrication of a nanosized functional (fluorescent, magnetic, or radioactive, etc.) particle inside. Consequently, such a hybridized system contains a functional core and a capsid protein shell.

We chose to use a tailed icosahedral T7 bacteriophage for fabricating a hybridized phage. Structurally, T7 phage consists of a capsid shell, a head−tail connector, tail, and tail fibers. The morphogenesis of T7 and its DNA package have been well documented in the literature, thanks to the major contributions by Dr. William Studier (*7*, *8*). It was demonstrated that empty capsid shells of T7 were assembled prior to the DNA packaging and can be isolated at the early stage of the lytic infection. Given the diameter of T7 phage (approximately 55 nm); a ghost T7 phage provides a cavity of ∼40 nm, which can be used to accommodate fluorescent materials, thus leading to a fluorescent material hybridized T7 phage.

An intrinsic advantage of using fluorescent material hybridized T7 phage as a fluorescence probe is that it has the capability to carry a specific affinity reagent against virtually any target molecules via phage display technology (*9*−*11*). In phage display, ligands (such as recombinant antibody fragments, cDNA-encoded segments, or combinatorial peptides chains) are expressed as fusions to a capsid protein present on the surface of viral particles. Libraries of millions to billions of phage particles, each displaying a different fusion protein, are screened (usually by affinity selection) for members displaying the desired properties or binding affinities. Normally, three rounds of screening (biopanning) processes will yield the isolation of a specific binding phage against the target molecule. Subsequently, one can make the corresponding ghost phage and use the ghost as the container to host the fluorescence material inside the ghost to form a hybridized phage. The approach of constructing a fluorescent core and ligand displayed capsid shell structure provides a revolutionary way to "tag" a fluorescence material with affinity reagents or to "functionalize" a bioligand with fluorescence. Thus, the hybridized phage represents a novel class of fluorescent probe.

Among the fluorophores used in the fluorescent probes, the lanthanide complex (such as europium or terbium complex) exhibits unique spectral characteristics (*12*). Lanthanide complexes are superior to conventional organic fluorophores because they have very sharp emission spectra with more than a 300-nm Stoke shift, plus an extremely long fluorescence lifetime (∼1 ms), which can be easily detected by time-resolved fluorescence spectroscopy. Thus, lanthanide complexes are the ideal fluorophores to overcome the problems associated with background fluorescence in a biological sample. However, making a lanthanide probe, like making other fluorescence probes, involves chemically conjugating a ligand

molecule (affinity reagent) to the chelator molecule, which requires cumbersome synthetic efforts.

In this study, we used a special T7 phage, on which 415 copies of a 15-mer peptide (termed as S-tag) were displayed on its capsid (Novagen). The interaction of S-tag with a 104 amino acid (aa) S-protein derived from pancreatic ribonuclease A has well been characterized in the literature (*13*). After producing the corresponding T7 ghost phage, we were able to synthesize a europium-complex particle inside the ghost phage. Given the unique photophysical properties of europium complex, the hybridized phage can be followed by using both conventional and time-resolved fluorescence spectrometers. Most importantly, the fluorescence hybridized phage retains the binding affinity to the target protein.

T7 ghost was made by osmotic shocking the normal T7 phage. Since the density of encapsulated T7 DNA (~450 mg/mL) is at least 5-fold higher than that in metaphase chromatin (*14*), the DNA of T7 will burst to the outside after the T7 capsid is disrupted by the osmotic shock. By rapidly diluting pure T7 phages (10^{12} pfu/mL) with a sodium sulfate solution (3 M) in the presence of DNAase, it was found that the osmotic shock caused the escape of DNA debris (as a result of DNAase activity) from the capsid shell. However, the integrity of capsid shell remained after removing the osmotic shocking conditions. The shocked phage particles were collected by ultracentrifuging (60 000 rpm for 1 h at 4 °C). The ghost phages were then separated from the normal virus particles by banding in a cesium chloride density gradient (42% CsCl banding position for normal phage and 20.8% CsCl band position for the ghost phage), followed by dialyzing against the PBS buffer solution to remove cesium chloride. Capillary zone electrophoresis also confirmed the generation of T7 ghost phage. On the basis of the peak areas of the ghost particle and survived phage, it was estimated the yield of ghost phages generated by osmotic shock was 55%.

To visualize the ghost particles, phage samples prepared from the above methods were negatively stained with uranyl acetate (1%) and examined by transmission electron microscope (TEM, Philips CM-120). As shown in Figure 1 (A and a), the packing of DNA inside a normal T7 phage is very tight, thus preventing uranyl acetate presented at the virus core of intact viruses, as shown by the brighter contrast on the image. On the contrary, the ghost T7 particles are slightly shrunk, with an average diameter of 48 nm. Since uranyl acetate can diffuse inside the capsid, ghost particles have darker contrast in the middle (Figure 1, B and b). Most of the ghost particles observed did not possess any tails; thus, we assumed that the tails became detached from the particles during the osmotic shock.

Europium-complex hybridized phage particles were synthesized by the reaction of europium ions with either naphthoyltrifluoroacetone (NTA) or dicarboxylic anthraquinone (DCAQ) in the presence of ghost T7 phage (*15*). In brief, ghost T7 particles (0.4 mg/mL) were incubated with 4 mM of europium ions in an acetate acid buffer solution (pH = 8.0) for 1 h. 4 mM of NTA or DCAQ in the same in acetate acid buffer solution was then introduced, and the resulting solution was incubated for 3 h. During the incubation, insoluble europium−NTA or europium−DCAQ complex particles were formed. As the size of the particles increased, the diffusion of europium-complex particles inside the ghost phage were limited by the permeable size of capsid shell; thus, larger europium-complex particles were stuck inside the ghost phage and continued to grow until the particles occupied the entire interior space of the ghost. The formed hybridized phage was purified by using magnetic beads coated with S-protein. Because of the specific interaction between the S-tag displayed T7 ghost and S-protein, the hybridized phages were immobilized on the surface of the beads. Europium-complex particles formed outside the phage were washed away with the acetate acid buffer solution containing 4 mM of NTA or DCAQ solution using a magnetic separator. Finally the hybridized phage was released from the beads using a competing assay by introducing T7 tag elution buffer (T7 Tag affinity purification Kit, Novagen).

The formed europium complex hybridized phage particles have the typical Eu(III) complex luminescence feature. The emission peak is centered at 617 nm when excited at 370 nm, which can be attributed to the $^5D_0 \rightarrow {}^7F_2$ transition (Figure 2A). Thus, the specific binding function of the hybridized phage against S-protein can be verified by a time-resolved fluorescence immunosorbent assay. An intact T7 phage, which went through the same procedures as making a europium complex hybridized phage, was used as a control. Both types of phages (hybridized and intact) were added to the microtiter plate wells coated with the S-protein and incubated at room temperature for 2 h. After the wells were washed three times with TBS, the fluorescence signals of the plate were recorded by a plate reader (Wallac 1420 Victor multiabel counter) equipped with a time-resolved fluorescence detector. As shown in Figure 2B, we observed a strong time-resolved fluorescence signal in the sample of hybridized phage, indicating the strong binding between the S-protein and the hybridized phage (blue line). On the other hand, intact T7 phage only showed very weak signal because of the lack of europium complex (red line). At the same time, a conventional ELISA, using 50 μL of S-protein labeled with horseradish peroxidase (HRP) and ABTS solution for visualization, was also conduced, and the ELISA confirmed the binding of both samples to the S-protein (data not shown here).

To visualize the hybridized phage particles, the samples were loaded onto a freshly glow discharged TEM grid and imaged directly without negatively staining. As demonstrated in Figure 3A, hybridized T7 phages with uniform europium particles inside were dominated on the TEM

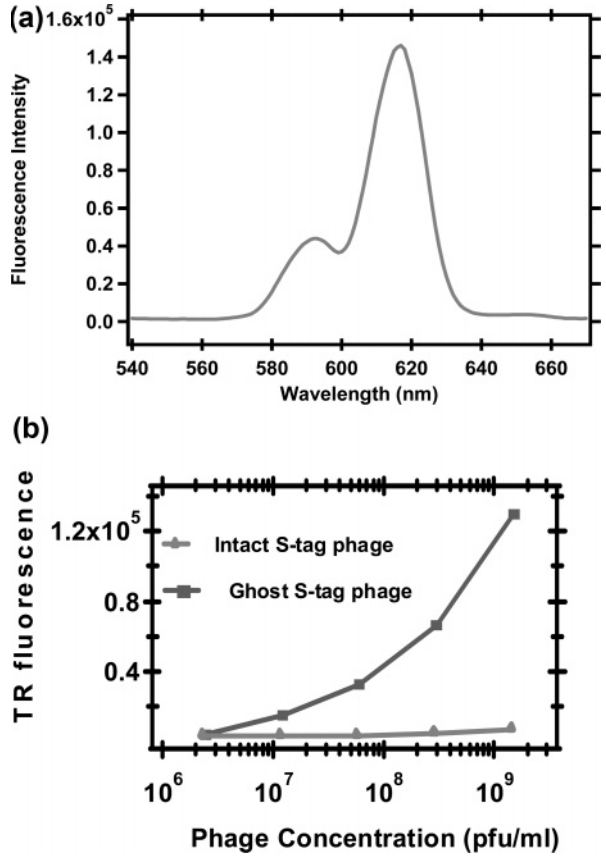

Figure 2. (A) Fluorescence spectrum of europium complex hybridized T7 phage particles. (B) Time-resolved fluorescence immunosorbent assay.

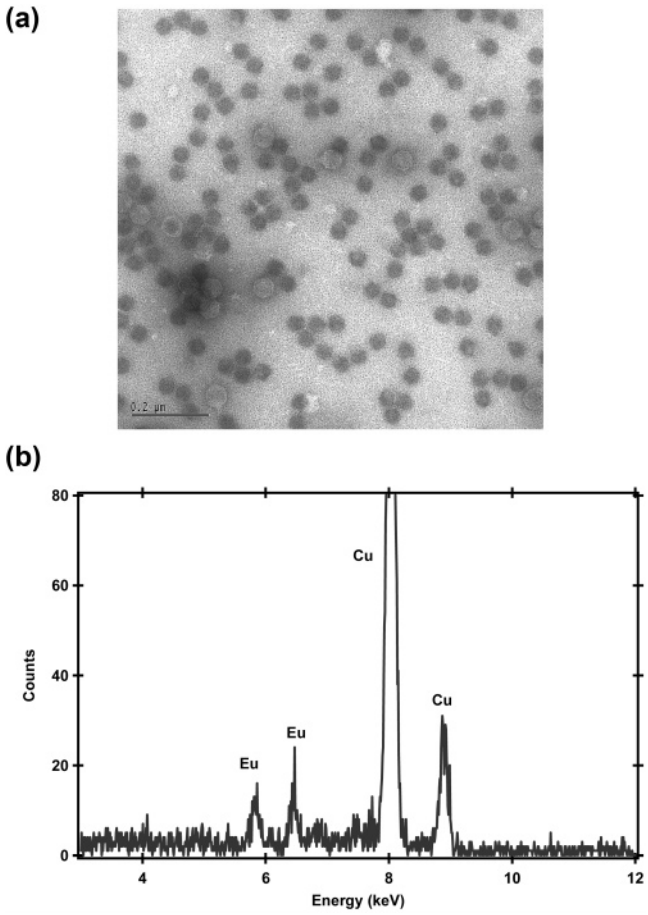

Figure 3. (A) TEM image of europium-complex hybridized T7 phages (scale bar = 200 nm). (B) EDX spectrum indicating the dominated europium element inside T7 ghosts.

images. The size of europium-complex particles inside the ghost T7 is about ~35 nm in diameter with excellent monodispersed size distribution. EDX analysis confirmed the presence of europium (Figure 3B) as the major element inside the ghost T7.

Since the fabrication of europium-complex hybridized T7 involves loading the cavity of T7 ghost with europium ions, a negatively charged phage capsid will help to attract Eu^{3+} ions, thus facilitate the synthesis of europium-complex particles inside the T7 ghost. Although it is hard to describe the exact interior charge nature of the T7 ghost, we estimated that T7 capsid is negatively charged when it is in the solution of neutral pH (~7) or above. This is supported by the fact that the capsid of T7 is made of many (up to eight) capsid proteins. The isoelectric point (pI) of major capsid protein (P10) is 6.0, and the pIs of dominated internal protein (P15 and P16) of T7 capsid are 5.4 and 6.6, respectively (*16*). The negatively charged nature of the T7 ghost phage at neutral or base conditions benefits the loading of cationic europium ions, and so europium complex particles can be efficiently synthesized inside the T7 ghost.

It should be noted that the observed time-resolved fluorescence signal is almost 3 orders of magnitude higher than the background noise and nonspecific signals in the time-resolved fluorescence immunosorbent assay experiments. Compared to a conventional ELISA assay, the europium-complex hybridized phage provides a superior signal-to-noise ratio as a fluorescent probe.

In summary, we have demonstrated the generation of a europium-complex hybridized T7 phage. As a new class of fluorescent probe, hybridized phages have monodispersed europium-complex particle core inside and uniform affinity reagent displayed capsid shell outside. Currently, we are expanding the scope of hybridized phage and have been successful in synthesizing cobalt metal and rhenium oxide (an analogue to ^{99}technetium oxide due to similar chemical properties of these two elements) hybridized phages. Since the inorganic cores in the hybridized phages are fully surrounded by the capsid proteins, in principle, the hybridized phage should be biocompatible in vivo. We envision that the hybridized phage will be the next generation of probing reagents for bioassay, biosensor, targeted reagent delivery, and medical imaging.

ACKNOWLEDGMENT

The preparation and characterization of the stable human serum albumin (HSA)-C_3 isomer of tris-malonic acid [C_{60}]fullerene complex is reported. Other than the anti-fullerene antibody, a stable protein−fullerene complex with a native protein has never been observed. This study may provide valuable answers to the growing concern regarding the effects of carbonaceous nanomaterials on human health on one hand and, on the other, may lead to the development of novel antioxidant therapeutic agents, radiopharmaceuticals, and components for bioelectronic devices.

INTRODUCTION

Since the discovery of fullerenes (*1, 2*), a broad range of bioactivity was found for various fullerene-derived materials. This includes antiviral and antibacterial properties, antioxidant and neuroprotective activities, cell signaling and apoptosis, and compounds with the potential to be developed as anticancer drugs and diagnostic agents (*3*−*6*). A number of fullerene derivatives were reported to interact with proteins (*7*−*11*) and even function as enzyme inhibitors (*3*−*6, 12*). However, other than the anti-fullerene antibody (*13*), a stable and well-defined protein−fullerene complex with a native protein has never been observed. Here we report the preparation and structural and functional characterization of a complex formed between human serum albumin (HSA) and the *eee*-isomer of tris-malonic acid [C_{60}]fullerene (CF) (*14*). The study of such complexes may provide valuable answers to the growing concern regarding the effects of carbonaceous nanomaterials on human health (*15*−*16*) on one hand and, on the other, may lead to the development of novel functional biomaterials.

EXPERIMENTAL PROCEDURES

Complex Preparation. CF was synthesized according to the previously reported methods (*17*−*19*). Fatty acid and globulin free HSA, fine chemicals and solvents were purchased from Sigma-Aldrich. A solution of 100.0 mg of HSA and 3.1 mg of CF (3.0 μmole) in 1.5 mL of tris-acetate buffer (100 mM, pH 7.2) was incubated for 12 h at RT. Then, the complexation solution was loaded on a Sephadex G-25 gel-permeation column (Pharmacia Biotech) or on HPLC TSK-GEL column (as described below) and noncomplexed CF was removed by elution with a tris-acetate buffer (1.0 M, pH 7.2). The buffer concentration was reduced by reloading the complex-containing fraction on the second Sephadex G-25 column and eluting the complex with a tris-acetate buffer (1.0 mM, pH 7.2). The resulting solution of the complex was lyophilized for storage and further experiments. After reconstitution in water, the complex concentration in solution was determined by UV−vis spectroscopy and a BioRad protein assay (Bio-Rad Lab). All UV−vis spectra were recorded at RT on a S-3150 diode array spectrophotometer (Scinco).

Size-Exclusion Chromatography. Size-exclusion high performance liquid chromatography of a monomeric HSA, CF and HSA−CF complex was performed on a 300 × 7.8 mm G3000SW_{XL} TSK-GEL column (Tosoh Biosep) using a tris-acetate buffer (100 mM, pH 7.2) as the isocratic eluent. All HPLC analyses and separations were performed on the SpectraSYSTEM equipped with a UV6000-LP diode array detector (ThermoFinnigan).

Time-Resolved FRET Spectroscopy. Time-resolved fluorescence was measured using the time-correlated single-photon counting (TCSPC) technique. As an excitation source, we used a CW mode-locked Nd:YAG-pumped dye laser (Coherent Nd:YAG Antares and a 702 dye laser), providing a high repetition rate (>1 MHz) of short pulses (2 ps at full width half-maximum, fwhm). The (TCSPC) detection system is based on a Hamamatsu 3809U, photomultiplier, Tennelec 864 TAC, Tennelec 454 discriminator and a computer-based multichannel analyzer (nucleus PCA-II). The overall instrumental response was about 50 ps (fwhm). Measurements were taken at 10 nm spectral width.

RESULT AND DISCUSSION

Complex Formation. The HSA–CF complex formation was obtanied at physiological pH, by incubation of the fatty acid free native HSA solution with a 2-fold excess of CF. The resulting HSA–CF complex was found to be stable enough to be purified by size-exclusion liquid chromatography, and sustained variations in pH, lyophylization, and reconstitution. The size-exclusion chromatorgaphic conditions, suitable for separation of HSA protein monomers and dimers, were used for analysis and purification of the complex from an excess of an unbound CF ligand. Under these conditions the retention time (RT) of the HSA–CF complex elution (Figure 1a) closely resembled the RT of a ligand-free monomeric HSA (Figure 1b), while the complex's UV–vis spectrum clearly indicated incorporation of fullerene chromophore (Figure 1c). The excess of the noncomplexed CF was eluted much later, with the RT and UV–vis spectrum (Figure 1d) matching a separately analyzed CF reference standard.

UV–vis analysis and standard BioRad assay of the purified HSA–CF complex revealed that only a single CF molecule is bound by a monomeric HSA host. These findings were confirmed by electrospray mass spectroscopy analysis, unambiguously showing that the molecular mass of the complex (Figure 2a) corresponds to a sum of masses of monomeric HSA (Figure 2b) and one CF ligand (see Supporting Information, Figure S1).

Binding Constant by Fluorescence Titration Studies. To quantitatively determine the stability of the

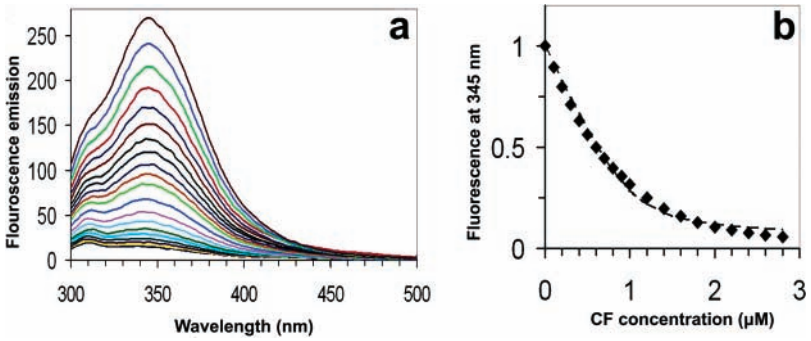

Figure 3. (a) Reduction in HSA's Trp_{214} fluorescence during a titration with CF. To 1 μM of HSA solution in 10 mM tris acetate buffer (pH 7.2) were added (solution concentration of CF was increased from 0 to 2.8 μM) aliquots of CF until no substantial changes in the emission intensity were detected. The excitation was performed at λ = 280 nm, and emission was measured at λ_{max} = 345 nm. (b) Graph describing the intensity of the HSA's fluorescence emission (at 345 nm) as a function of CF concentration (◆) and calculated binding isotherm (intermittent line).

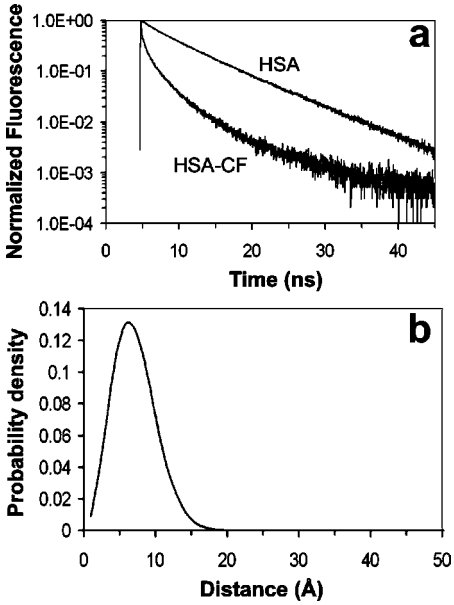

Figure 4. (a) Experimental fluorescence decay curves of monomeric HSA (blue) and HSA−CF complex (black). The excitation was performed at $\lambda = 280$ nm and emission was measured at $\lambda_{max} = 345$ nm. (b) The distance distribution between the HSA's Trp_{214} and the CF.

complex, a binding study was performed by gradual addition of CF to HSA. The HSA−CF complex formation was measured by monitoring the HSA's Trp_{214} fluorescence quenching in solution, upon addition of the CF aliquots (Figure 3a). Fitting the titration results to a theoretical rectangular hyperbola curve (binding isotherm), calculated by nonlinear least-mean-square algorithm (*20*), produced a binding constant for CF of 1.2×10^7 M^{-1} (Figure 3b).

tr-FRET Experiments and CF Location Assessment. To assess the intramolecular distance between HSA's Trp_{214} donor and the CF acceptor in the complex, time-resolved fluorescence decay (tr-FRET) experiments of ligand-free HSA protein and HSA−CF complex were performed (Figure 4a). Theoretical decay curves were calculated by numerical solution of the second-order differential equation for each tr-FRET experiment and fitted to the corresponding experimental curves (*21, 22*). The distance distribution function was obtained from simultaneous global analysis of two experimental fluorescence decay curves, using the Marquardt nonlinear least-squares method (Figure 4b, for calculation details see Supporting Information) (*22,23*). It was found that in HSA−CF complex the mean distance between the Trp_{214} donor and CF acceptor is 7.1 Å (with fluctuations of ±3.4 Å).

Calculations and Docking Studies. An additional attempt to estimate the location of CF in HSA's three-dimensional structure was based on the molecular docking program. Coordinates of the known structure of the HSA protein (*24*) and a Hartree−Fock energy-minimized structure of the CF ligand (see Supporting Information) were used for building plausible docking models of the complex. The PatchDock program was applied without using any a priori data indicating a CF putative binding site (*25*). An examination of generated docking models revealed that the eight highest ranked solutions posi-

Figure 5. (b) Close-up view of the CF-binding pocket in HSA's subdomain IIA, showing close proximity between the HSA's Trp_{214} (in blue) and the CF ligand (in red).

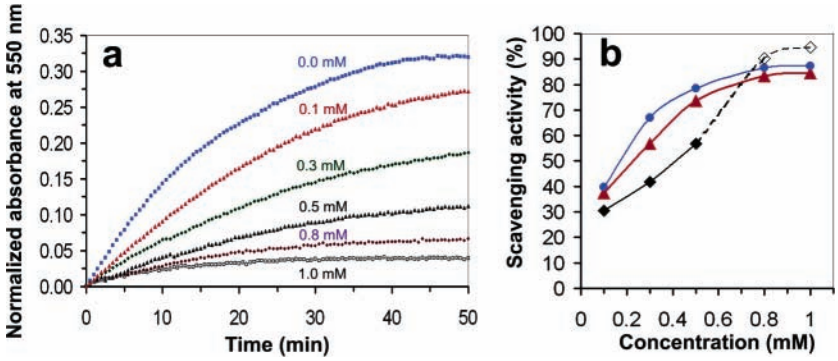

Figure 6. (a) Graph presenting changes in concentrations of Cytochrome *c* (Fe^{II}) at pH 7.4 (monitored at 550 nm), due to superoxide scavenging activity of HSA−CF complex added at various concentrations (0−1.0 mM of the complex). (b) Graph comparing the scavenging activity of the free HSA (●), the HSA−CF complex (red ▲), and the noncomplexed CF (◆) at various concentrations. Scavenging activity is defined as $([V - b] \times 100/V)$, where V is the rate of cytochrome *c* (Fe^{II}) formation during the linear phase (0−7 min) of a control experiment (without antioxidants); and b is the rate of cytochrome *c* (Fe^{II}) formation during the linear phase in the presence of tested antioxidants in various concentrations. Scavenging activity of the noncomplexed CF, at concentrations above 0.6 mM (◇), was found to be unusually high, possibly due to assay readings interference by CF's absorbance or CF clusters formation.

tioned CF in the same cavity, with differences mostly in the ligand's orientation. In all these models, the CF was found located at a distance of approximately 5 Å from the Trp_{214} residue (Figure 5), which is in excellent agreement with our tr-FRET experiments' global analysis.

Determination of SOD-like Activity for Complex by in Vitro Xanthineoxidase/Cytochrome C Assay. CF was extensively investigated as a free radical scavenger in vitro (*17*−*19*) and in vivo (*26*) and was recently described as a superoxide dismutase mimetic (*27*). Free HSA protein has also been reported to have antioxidant activity (*28*). To examine the antioxidant properties of the new HSA−CF complex, a standard xanthine oxidase/cytochrome *c* assay was utilized (Figure 6a) (*29, 30*). It was found that the ability of HSA−CF complex to quench superoxide radicals was slightly lower than that of the free HSA protein and was measurably higher than of the free CF ligand (Figure 6b). Although no additive antioxidant activity was observed for the HSA−CF complex, the free radical scavenging capabilities of the HSA protein were almost unaffected.

Our experimental data and docking calculations lead to the conclusion that an amphiphilic, negatively charged CF ligand is bound in the HSA's subdomain IIA (a binding site formed by hydrophobic side chains with the entrance to the pocket surrounded by positively charged residues) (*31, 32*). The binding constant of the CF was found to be comparable with published values for other organic molecules that strongly bind to same site of HSA, such as bilirubin (9.5×10^7 M^{-1}), iodipamide (9.9×10^6 M^{-1}), and 3-carboxy-4-methyl-5-propyl-2-furanpropanoate (1.3×10^7 M^{-1}) (*32*). We believe that, in addition to improved water solubility and biocompatibility, stable protein−fullerene derivative complexes have the potential to be developed as antioxidant therapeutic agents, target-specific radiopharmaceuticals, or components for future bioelectronic devices.

A Nanoparticle-Based Model Delivery System To Guide the Rational Design of Gene Delivery to the Liver. 1. Synthesis and Characterization

Stephen R. Popielarski, Suzie H. Pun,† and Mark E. Davis*

Chemical Engineering, California Institute of Technology, Pasadena, California 91125. Received April 14, 2005

Nonviral gene delivery systems are amenable to forming colloidal particles with a wide range of physicochemical properties that include size, surface charge, and density and type of ligand presented. However, it is not known how to best design these particles without having a set of physicochemical design constraints that have been optimized for the intended gene delivery application. Here, a nanoparticle-based model delivery system is developed that can mimic the surface properties of nonviral gene delivery particles, and this model system is used to define design constraints that should be applied to next generation gene delivery particles. As a test case, a well-defined nanoparticle-based system is developed to guide the rational design of gene delivery to hepatocytes in the liver. The synthetic scheme utilizes monodisperse polystyrene particles and provides for variation of mean particle size and particle size distribution through variation in reaction conditions. The nanoparticles are PEGylated to provide stability in serum and also incorporate targeting ligands, e.g., galactose, at tunable densities. Four nanoparticles are synthesized from uniformly sized polystyrene beads specifically for the purpose of identifying design constraints to guide next generation gene delivery to the liver. These four nanoparticles are Gal-50 and Gal-140, that are galactosylated 50 and 140 nm nanoparticles, and MeO-50 and MeO-140, that are methoxy-terminated 50 and 140 nm nanoparticles. All four particles have the same surface charge, and Gal-50 and Gal-140 have the same surface galactose density. The availability of galactose ligands to receptor binding is demonstrated here by agglutination with RCA_{120}.

INTRODUCTION

Gene therapy promises to revolutionize the clinical treatment of countless genetic disorders (*1*), including many diseases of the liver (*2*). Though human gene therapy of liver diseases is still in its infancy, preclinical studies in animal models of disease have demonstrated proof of concept results in nearly all varieties of liver diseases that are conceptually amenable to gene therapy treatment (*3*−*6*).

However, numerous investigators have identified the importance of carefully designing and controlling the properties of gene delivery systems for selectively targeting the liver. A prerequisite to selective targeting is particle stability in vivo and the minimization of nonspecific uptake. We and others have previously demonstrated the importance of PEGylation (PEG: poly(ethylene glycol)) to stabilize polyplexes and to reduce their nonspecific uptake (*7*). Nonspecific uptake of particles is commonly due to rapid clearance by cells of the mononuclear phagocytic system (*8*) and adhesion to the endothelial lining of the vascular system (*9*). Such undesirable uptake is minimized by surfaces with little or no protein adsorption. In particular, certain proteins called opsonins interact with phagocyte receptors and promote recognition by scavenger cells of the reticuloendothelial organs. Phagocytosis is frequently initiated by adsorption of opsonins onto the surface of particles followed by complement activation or other recognition, leading to internalization by macrophages and intracellular processing. Dunn et al. (*10*) have demonstrated that interaction of PEGylated polystyrene nanoparticles with nonparenchymal liver cells in vitro decreased with higher surface densities of PEG and also resulted in longer circulation times following intravenous injection into rats.

By formulating PEGylated cyclodextrin-based gene-delivery particles under different conditions, the size, surface charge, and ligand density of the final gene delivery particle can all readily be adjusted (*11*). However, the power of this flexibility cannot be maximized without a set of physicochemical design constraints that have been optimized for the intended gene-delivery application. In particular, we are interested in generating a set of design requirements to guide gene delivery to the liver. In this pursuit, we describe herein the development of a nanoparticle-based model system that will facilitate the systematic identification of relevant physicochemical properties that alter the hepatic distribution of nanoparticles. Further, this nanoparticle-based model is intended to mimic the surface properties achievable with nonviral delivery systems but specifically with the linear, cyclodextrin-based gene delivery system developed in our laboratory (*12*−*15*). As such, the model system will be PEGylated and must facilitate variation of parameters such as particle size, surface charge, and ligand type and density.

In the present work, we detail the synthesis and characterization of PEGylated nanoparticles with tunable physicochemical properties. The synthesized nanoparticles are slightly anionic to minimize nonspecific uptake in vivo, and galactose will be used as a targeting ligand since galactose receptors in vivo are almost exclusively

found in the liver. In particular, four nanoparticles will be described that are appropriate for uptake experiments: Gal-50 and Gal-140 are galactosylated nanoparticles with diameters of 50 and 140 nm, while MeO-50 and MeO-140 are methoxy-terminated 50 and 140 nm nanoparticles. Through the use of these nanoparticles, the effects of nanoparticle size and surface presentation of galactose on hepatic distribution in mice can be explored, and the results of in vitro and in vivo uptake experiments are presented in Part 2 of our work (*16*).

MATERIALS AND METHODS

Fmoc-PEG$_{5000}$-NHS was purchased from Nektar (San Carlos, CA) and used as received. All other reagents and solvents were obtained from commercial suppliers and were used as received, unless specifically noted. Matrix-assisted, laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF) was performed on a PerSeptive Biosystems Voyager DE PRO BioSpectrometry Workstation (PerSeptive Biosystems; Framingham, MA) in the positive ion mode using a 2,5-dihydroxy benzoic acid matrix. HPLC was performed on an Agilent 1100 Series HPLC (Agilent Technologies; Palo Alto, CA) with a Prevail C18 5μm column (Alltech; Deerfield, IL) and a SEDEX Model 75 Evaporative Light Scattering (ELS) detector (Richard Scientific; Novato, CA).

Synthesis of Galactose-PEG$_{5000}$-amine. (**1**, Scheme 1). 4-Aminophenyl β-D-galactopyranoside (1.79 g, 6.38 mmol) and Fmoc-PEG$_{5000}$-NHS (2.17 g, 0.43 mmol) were dissolved in about 16 mL of phosphate-buffered saline (PBS, pH 7.4, 137 mM sodium chloride, 10 mM phosphate, 2.7 mM potassium chloride). Sulfo-NHS (97 mg, 0.44 mmol) was added, the pH was adjusted to pH 7.8, and the reaction was stirred at ambient temperature. After 6 h, EDC was added (435 mg, 2.27 mmol), and the reaction was stirred for an additional 48 h. The crude reaction mixture was dialyzed in 500 molecular-weight cutoff (MWCO) Float-A-Lyzers (Pierce; Rockford, IL) against water for 2 days with twice daily dialysate changes. The solution was dried on a rotary evaporator at temperatures not exceeding 35 °C. Deprotection of the amine was accomplished by stirring the off-white product in 50 mL of 25% piperidine in DMF for 4 h at room temperature. The solution was then concentrated under reduced pressure at temperatures not exceeding 40 °C. The viscous liquid was transferred to polypropylene centrifuge tubes and water was added. Centrifugation and filtration through a 0.2 μm HT Tuffryn Membrane filter (VWR; West Chester, PA) resulted in complete Fmoc removal from the crude reaction mixture. The solution was subjected to extensive dialysis in 500 MWCO Float-A-Lyzers before being lyophilized to dryness. Purity was confirmed by HPLC-ELS and MALDI-TOF mass spectroscopy. Final yield: 1.25 g, 59%.

Synthesis of PEGylated-polystyrene Nanoparticles. (**2**, Scheme 2). Fluorescein-embedded PEGylated-polystyrene nanoparticles were synthesized by reaction of Fluospheres (Molecular Probes; Eugene, OR) with MeO-PEG$_{5000}$-NH$_2$ or Galactose-PEG$_{5000}$-NH$_2$ (**1**). Two sizes of Fluospheres were used as starting materials in this work. Fluospheres (28 nm) were used to synthesize PEGylated nanoparticles with final diameters up to 60 nm, while nanoparticles up to 160 nm were synthesized by PEGylation of 105 nm Fluospheres. Fluospheres (28 nm) were sonicated then centrifuged at 14 000*g* for 20 min prior to use. All Fluospheres were sonicated immediately before being added to reaction vials. Typically, 500 μL of a 2% Fluosphere suspension (3.21 μmol COOH for 105 nm Fluospheres) is added to 32 mg of MeO-PEG$_{5000}$-NH$_2$ (6.42 μmol) in a 1.5 mL Eppendorf tube and mixed to dissolve the PEG. Sulfo-NHS (6.3 mg) (Pierce) is added to each tube, and 200 mM borate buffer, pH 8.2, is added up to 1 mL total volume per tube. The pH of each reaction tube is adjusted to pH 7.80, and then 1.0 mg of EDC (5.13 mmol) is added to each tube and vortex mixed for 6 h. Purification of 50 nm nanoparticles was accomplished by dialysis in 100k MWCO DispoDialyzers (Pierce) against a variety of salt solutions starting with 3 M NaCl and ending with PBS. A minimum of seven dialysate changes were performed until no free PEG was detected by HPLC-ELS. Workup of 140 nm nanoparticles was accomplished by cold centrifugation and repeated washes in salt solutions ranging from 4 M NaCl to final resuspension in PBS. Bead concentrations were determined by comparison to fluorescence of known concentrations of as-received Fluospheres on a SpectraFluor Plus fluorescence plate reader (Tecan; Research Triangle Park, NC) with FITC filters (ex: 485 nm; em: 530 nm). Yields: 50 nm nanoparticles, typically 40%; 140 nm nanoparticles, typically 70%.

Particle Size and ζ-Potential Measurements. Colloidal particle size was determined by photon correlation spectroscopy in 150 mM NaCl at a wavelength of 532 nm, scattering angle of 90°, and refractive index of 1.59 using a ZetaPALS instrument (Brookhaven Instruments; Holtsville, NY). Ten measurements on each diluted nanoparticle sample were taken, and the mean hydrodynamic diameter was reported. Nanoparticles (50 nm) were typically measured at 1×10^{13} particles/mL while 140 nm nanoparticles were typically measured at 1.5×10^{10} particles/mL. ζ-Potential measurements were calculated from electrophoretic mobilities using the Smoluchowski

equation. Nanoparticle electrophoretic mobilities were measured in 150 mM NaCl using a ZetaPALS instrument with the following conditions: fluid refractive index 1.334, electric field 5.41 V/cm and adjusted to a conductance of 15.0 mS. Three samples were each measured seven times, and the mean ± standard deviation of each was reported.

Determination of Galactose Surface Density. Concentration of galactose on the surface of nanoparticles was determined with the Amplex Red Galactose/Galactose Oxidase Assay Kit (Molecular Probes; Eugene, OR) by comparison to standard curves of galactose in solution with unmodified polystyrene beads. The reaction was allowed to proceed for a minimum of 120 min before final absorbance readings were taken due to the different rates of reaction of galactose oxidase with galactose in solution versus with surface-immobilized galactose.

RCA_{120} Lectin Agglutination. A suspension of 5.4×10^{12} nanoparticles in 500 μL of PBS was added to 4.7×10^{14} molecules of RCA_{120} lectin (Sigma-Aldrich; St. Louis, MO) in 500 μL of PBS. Each lectin has two identical binding sites, for a total of 9.5×10^{14} galactose binding sites per experiment. Agglutination was monitored by measurement of absorbance at 560 nm. After 30 min, 8×10^{18} molecules of galactose were added in 100 μL of PBS to disaggregate the system.

TEM of Nanoparticles. Nanoparticles in water were applied to 400-mesh, freshly glow-discharged, carbon-coated copper grids for 45 s. After this time, excess water was removed by blotting with filter paper, and the sample was negatively stained with 2% uranyl acetate for 45 s before blotting. A Philips 201 electron microscope, operated at 80 kV, was used to record images.

Serum-Induced Nanoparticle Aggregation. Mouse serum (Sigma) was incubated in 96-well plates at 37 °C and 5% CO_2 for a minimum of 2 h before use. Nanoparticles (5×10^{10}) were added to each 90 μL of equilibrated sera, and aggregation was monitored by measurement of absorbance at 560 nm at 37 °C.

RESULTS AND DISCUSSION

Gal-PEG_{5000}-NH_2 Synthesis and Characterization. Fmoc-PEG_{5000}-NHS was converted to high-purity Gal-PEG_{5000}-NH_2. The reaction was driven to completion by a large excess of 4-aminophenyl β-D-galactopyranoside and an additional dosing of carbodiimide coupling agent, EDC. Optimum reaction pH in NHS-mediated peptide coupling reactions is a tradeoff between the amide formation rate and the rate of hydrolysis of the activated NHS-ester. PEG_{5000}-NH_2 has a pK_a of about 9.2 (*17*) and NHS-esters on the PEG chains deactivate quickly, especially above a pH of about 8. An optimal pH of about 7.8 was determined for this reaction. While the concentration of Fmoc-PEG_{5000}-NHS did not significantly influence reaction yield, supplementation with additional Sulfo-NHS and EDC was necessary to reactivate any carboxylic esters on the PEG that had hydrolyzed.

The purity of the final purified compound was determined by HPLC-ELS, as shown in Figure 1. Peaks representing starting materials (Figure 1a) and intermediates were resolved relative to the Gal-PEG_{5000}-NH_2 peak (Figure 1b). Purity was typically greater than 98%, as determined by HPLC.

MALDI-TOF mass spectroscopy also confirmed that the reaction went to completion. Primary peaks in the MALDI-TOF spectra (Figure 2) line up well with predicted molecular weights (Table 1) of Fmoc-PEG_{5000}-NHS

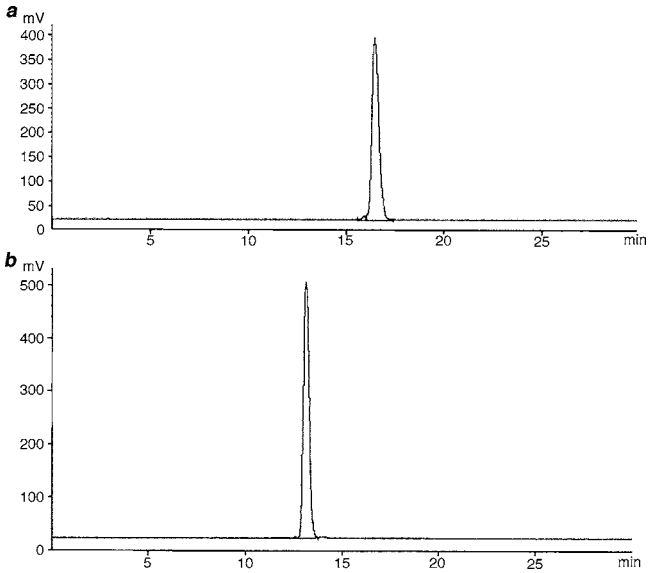

Figure 1. HPLC spectra of (a) Fmoc-PEG_{5000}-COOH and (b) Gal-PEG_{5000}-NH_2.

122	5802.3	5805.1	5736.5	5733.1

The primary population of peaks in Figure 2 is from $[M + Na]^+$, while the subpopulation comes from $[M + H]^+$. In addition to MALDI-TOF, the average molecular weight per galactose of the final product was determined to be about 5500 with the Amplex Red Galactose Assay Kit, as expected for nearly complete galactosylation of the PEG. Thus, the molecular weight determined from this technique compares well with the results of MALDI-TOF analysis.

PEGylated Nanoparticle Synthesis and Characterization. Most previous reports of PEGylating carboxy-polystyrene nanoparticles used 1 μm beads or larger (*17*−*20*). These large particles are relatively insensitive to reaction conditions, and broadening of particle size distribution was not reported. Ploehn and Goodwin (*21*) PEGylated smaller carboxy-polystyrene beads (115 and 347 nm diameter), but no indication was given that polydispersity was monitored during that reaction. For the current purpose of determining physicochemical design parameters for next generation gene delivery vectors, polydispersity of the final PEGylated nanoparticles should be low, monomodal, and well-defined. We were interested in working with nanoparticles with hydrodynamic diameters in the range of about 45−150 nm. These relatively small polystyrene beads were found to be much more sensitive to reaction conditions than larger 200 nm beads, thus requiring careful study to identify reaction and purification conditions that resulted in pure nanoparticles with desired mean diameter, particle size distribution, and extent of surface PEGylation.

The extent of PEGylation, and hence the final nanoparticle hydrodynamic diameter, was controlled by varying the concentrations of PEG and EDC during nanoparticle synthesis, as shown by the results given in Figure 3. While varying the concentration of PEG in the reaction simply shifted the final mean particle size without affecting the distribution, EDC concentrations above about 15 mM resulted in significant broadening of the particle size distribution.

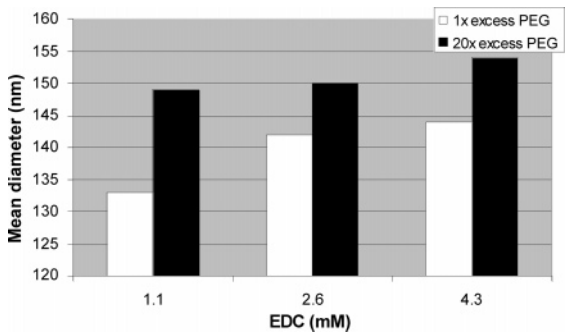

Figure 3. Mean hydrodynamic diameters following PEGylation of 105 nm Fluospheres with different reagent concentrations.

By carefully controlling reaction conditions, nanoparticles could be synthesized with size distributions (Figure 4b) that closely match those of the cyclodextrin-based gene delivery particles (Figure 4a) they intend to mimic. PEGylated nanoparticles larger than 105 nm can be synthesized with very tight monodisperse distributions under appropriate reaction conditions (Figure 4c). The polydispersity of the 50 nm nanoparticles and polyplexes is about 0.06, while that of the 140 nm nanoparticles is about 0.005. Low polydispersities such as these allow the effect of nanoparticle size on biodistribution to be clearly determined.

TEM imaging of unmodified nanoparticles validated the particle sizes measured by photon correlation spectroscopy (PCS). Particle size of unmodified polystyrene nanoparticles was found to be in good agreement between TEM and PCS measurements. This was expected, given the spherical shape of the particles and hence the appropriateness of the Stokes−Einstein expression to relate the diffusion coefficient, which is measured by PCS, to the particle size. Further, PCS measurements of particle size were performed at various concentrations

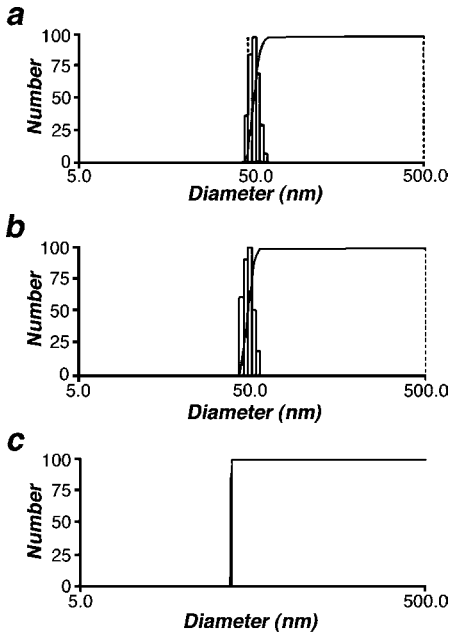

Figure 4. Histograms of nanoparticle hydrodynamic diameter distributions, as measured by PCS in 150 mM NaCl, for (a) 50 nm PEGylated polyplexes, (b) 50 nm PEGylated nanoparticles, and (c) 140 nm PEGylated nanoparticles.

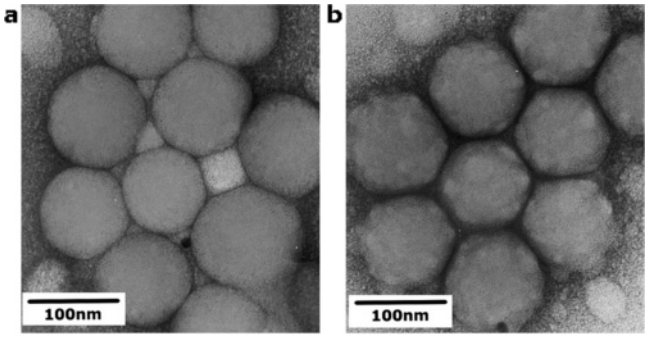

Figure 5. TEM images of (a) unmodified 105 nm Fluosphere nanoparticles and (b) PEGylated 105 nm polystyrene nanoparticles.

to ensure the accuracy of the reported result (*22*), and insignificant difference was found between these measurements.

As seen in the TEM images in Figure 5a, unmodified polystyrene Fluospheres adopt a close-packed arrangement with direct polystyrene-polystyrene contact between beads, while PEGylated nanoparticles (Figure 5b) are separated by darkly stained PEG coronas and avoid polystyrene−polystyrene contact. Because the nanoparticles must be dried for TEM analysis, the PEG layer is dehydrated and the diameter of PEGylated nanoparticles as determined by TEM is significantly smaller than their hydrodynamic diameter. Further evidence of consistent surface PEGylation was provided by our inability to separate PEGylated polystyrene nanoparticles into multiple populations by hydrophobic interaction chromatography, as described by Gbadamosi et al. (*23*). Moghimi demonstrated (*24*) that it is critical for the entire nanoparticle surface to be PEGylated to minimize nonspecific uptake of nanoparticles by the reticuloendothelial system. It is also important that the PEGylated nanospheres be well-shielded to avoid aggregation in serum. Additionally, the monodispersity of the 105 nm Fluospheres is evident from this image.

The stability of aqueous suspensions of 220 nm PEGylated polystyrene nanoparticles has been shown to increase dramatically for particles with hydrodynamic layer thicknesses of between 10 and 15 nm (*25*). The impact of PEGylated surfaces is even more critical in salt solution, where the Debye screening length will be much shorter than the hydrodynamic layer thickness. In 150 mM NaCl, for example, the Debye screening length is about 0.8 nm. As such, any charge−charge repulsion that originated from the particle surface in pure water will no longer be influential, and the PEG layer is entirely responsible for sterically shielding the particles. In the present work, 140 nm PEGylated nanoparticles were synthesized by grafting PEG onto 105 nm polystyrene nanoparticles, resulting in hydrodynamic layer thickness of slightly more than 15 nm. As such, this PEG corona is expected to provide near maximum protection against nanoparticle flocculation. Similarly, 50 nm PEGylated nanoparticles synthesized from 28 nm polystyrene have approximate hydrodynamic layer thicknesses of 11 nm. The decreased hydrodynamic thickness of PEG with the same molar mass on the smaller beads can be explained by the increased available angular segment volume with increased surface curvature (*26*). PEG_{5300} has a radius of gyration of 3.2 nm and an interfacial overlap concentration, $\sigma_{ol} = (\pi R_g^2)^{-1} = 0.031$ chains/nm^2 (*27*). The nanoparticles used in this study have a PEG surface density of about 0.14 chains/nm^2, that is much higher than σ_{ol} so it is expected that significant interactions are occurring between polymer chains on the nanoparticle surface. This interaction manifests itself as a PEG layer that is considerably thicker than $2R_g$, the expected PEG thickness in the absence of polymer chain interaction.

Table 2. Fifty-Nanometer PEGylated Nanoparticles with Different Surface Densities of Galactose for Use in RCA120 Agglutination Assay

no. of beads per experiment	no. of galactose per bead	pmol galactose per cm^2	total no. of galactose per experiment	total no. of RCA_{120} binding sites per experiment

Availability of Galactose for Receptor Binding. As discussed earlier, galactose was used as a targeting ligand on some of the PEGylated nanoparticles. The surface density of galactose on the nanoparticles can be controlled by varying the ratio of Gal-PEG_{5000}-NH_2 to MeO-PEG_{5000}-NH_2 in the reaction. Further, the overall ratio of PEG-NH_2 to carboxylate groups enabled nanoparticles with different galactose moieties to be presented on the surface of nanoparticles through attachment via a 5000 Da PEG chain. To test whether the galactose moieties are accessible to bind large proteins, the particles were exposed to RCA_{120}. RCA_{120} is a 120 000 Da lectin with two identical and independent galactose binding sites per molecule (*28*). Five 50 nm PEGylated nanoparticles were synthesized for this study with different surface densities of galactose, as shown in Table 2. When RCA_{120} lectin is mixed with an appropriate number of galactosylated nanoparticles, agglutination is expected to occur. This effect is schematically illustrated in Figure 6, where lectins can be seen cross-linking galactosylated nanoparticles. This cross-linked network scatters light, and progress of agglutination can be monitored by measuring absorbance at 560 nm. Agglutination should be rapidly reversible by the addition of free galactose.

By fixing the numbers of lectin molecules and nanoparticles in all experiments, the effect of galactose surface density on agglutination can be seen (Figure 7). Turbidity, expressed as absorbance at 560 nm, is found to increase more quickly and to a greater extent for nanoparticles with a higher surface density of galactose than for comparable nanoparticles with lower surface densities of galactose. For nanoparticles with less than about 13 pmol galactose/cm^2, there are comparable numbers of galactose binding sites available on the RCA_{120} lectin and galactose available on the surface of nanoparticles, and no agglutination is observed. While this result may indicate that all galactose molecules are not accessible to binding, the general availability of nanoparticle-bound galactose for protein binding is confirmed for the higher values.

As compared to the rapid network disruption associated with galactose addition to the agglutinated solution (Figure 7), addition of an equal volume and concentration of glucose does not disrupt the cross-linked network (Figure 8). The only effect caused by addition of 100 μL of a glucose solution to the cuvette is related to dilution and is identical to the effect of adding 100 μL of water. It is thus confirmed that agglutination is due to interaction between nanoparticle-bound galactose and RCA_{120} lectin molecules.

Description of Nanoparticles for Uptake Studies. It has thus far been demonstrated that nanoparticles can

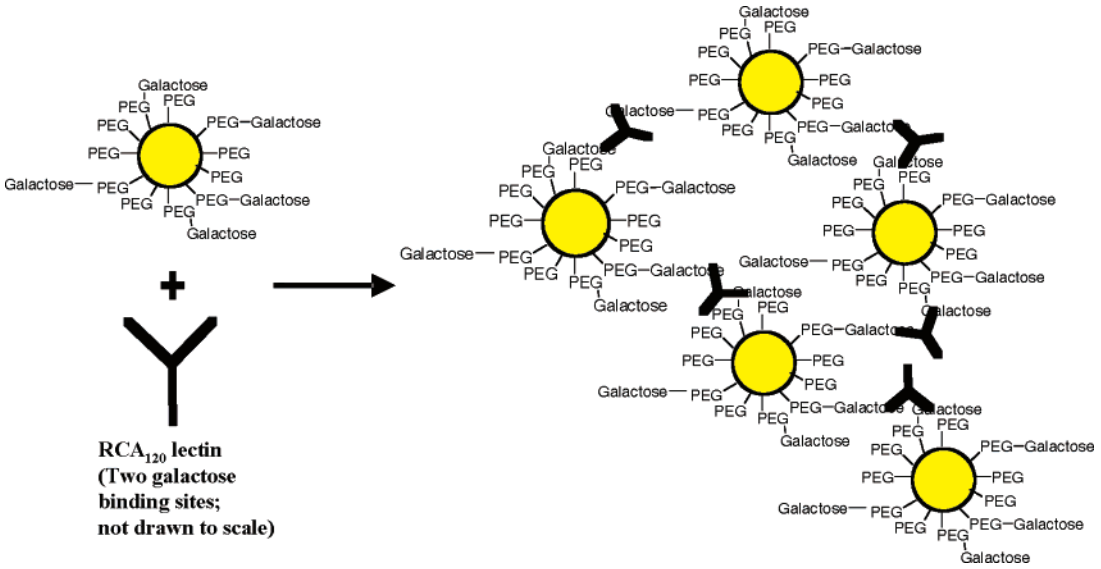

Figure 6. Schematic illustration of nanoparticle agglutination as a result of RCA_{120} lectin binding galactosylated nanoparticles.

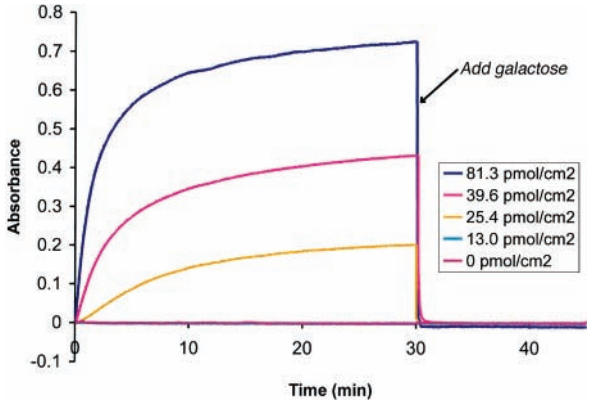

Figure 7. Turbidity increase due to agglutination of galactosylated 50 nm nanoparticles with RCA_{120} lectin. Galactose (100 μL of 140 mM solution) in PBS is added at 30 min.

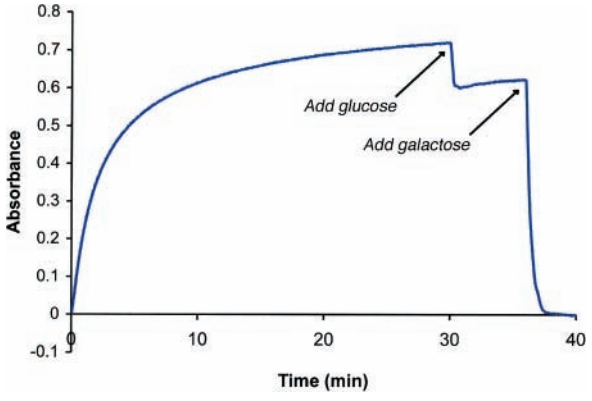

Figure 8. Turbidity increase of 50 nm nanoparticle with 81.3 pmol/cm^2 surface galactose density due to agglutination with RCA_{120} lectin. Glucose (100 μL of 140 mM solution) in PBS is added at 30 min, and then 100 μL of 140 mM galactose in PBS is added at 35 min.

be synthesized with a wide range of physicochemical properties. However, a select few must be chosen for in vitro and in vivo uptake experiments. Four nanoparticles were selected for this role, and their properties are detailed in Table 3.

Nanoparticles with mean diameters of 50 and 140 nm were selected for use because (1) cyclodextrin-based gene delivery particles can be conveniently synthesized in the range of about 45 nm to about 150 nm, so the nanoparticles selected for use in the present study approximate the bounds of that range, (2) access to hepatocytes through the hepatic sinusoidal wall requires passage through endothelial-cell pores that are estimated at 150−200 nm (*29*), and (3) 50 nm is below the 70 nm cutoff that has been proposed for neutral liposome uptake via ASGPr (*30*). The effect of galactose presentation on the surface of the nanoparticles were investigated for 50 and 140 nm nanoparticles with galactose surface densities of 25−30 pmol/cm^2. Galactosylated 50 and 140 nm nanoparticles are referred to as Gal-50 and Gal-140. The equivalent nontargeted nanoparticles have methoxy terminated PEG chains and are referred to as MeO-50 and MeO-140.

Table 3. Summary of Physicochemical Properties of the Four Nanoparticles To Be Used in Uptake Experiments

bead name	mean diameter (nm)	ζ-potential (mV)	galactose surface density (pmol/cm^2)
Gal-50	51.5	-2.7 ± 1.8	25.4
MeO-50	53.5	-2.7 ± 2.8	0
Gal-140	138.1	-2.6 ± 2.1	30.6
MeO-140	138.7	-3.2 ± 2.3	0

All nanoparticles in Table 3 have slightly anionic surface potentials (at the plane of hydrodynamic shear) to minimize nonspecific uptake. Cationic particles are internalized nonspecifically through proteoglycan receptors and may stick to anionic cell surface membranes, while highly anionic polystyrene nanoparticles have increased nonspecific uptake by scavenger receptors following complement activation (*31*, *32*). Unmodified, carboxylated, polystyrene beads (as-received starting material) have ζ-potentials of approximately −45 mV. The PEGylated nanoparticles have mean ζ-potentials of about −3 mV. These surfaces are nearly neutral due to the combined effect of carboxylate group conversion to amides on the nanoparticle surfaces and PEG shielding of the surface charge.

Serum Aggregation of PEGylated Nanoparticles. To investigate the effect of particle size on specific uptake phenomena, the nanoparticles must remain dispersed in the presence of serum. They also must not bind serum opsonins with great affinity, as such binding has been shown to increase the hepatic uptake of 50 and 500 nm polystyrene nanoparticles (*33*).

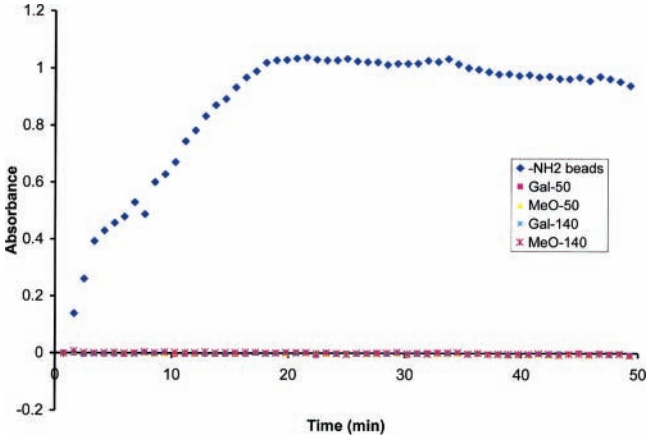

Figure 9. Nanoparticle aggregation in the presence of active mouse serum.

If serum proteins bind the surface of nanoparticles, cross-linking between nanoparticles would be expected to occur. Since many serum proteins are anionic, cross-linking should be more significant for cationic nanoparticles. For this reason, amino-modified polystyrene nanoparticles were used as a positive control in serum stability studies. As shown by the data in Figure 9, amine-functionalized nanoparticles cross-linked quickly and extensively in active mouse serum, while the PEGylated nanoparticles did not. The role of serum proteins in inducing aggregation of the amine-functionalized nanoparticles is supported by the lack of aggregation of any of the nanoparticles in PBS. Despite considerable effort, aggregation of the PEGylated nanoparticles could not be induced under any conditions.

CONCLUSIONS

Here, we report the synthesis and characterization of PEGylated polystyrene nanoparticles. These nanoparticles have slightly anionic surface potentials to minimize nonspecific interactions with cells and tissues in vivo. The synthetic scheme allows for the variation of mean particle size and particle size distribution through changes in reaction conditions. The nanoparticle synthesis is also amenable to incorporation of various ligand types with variable surface densities. The synthesized nanoparticles are shown to have PEGylated surfaces that resist aggregation in serum. Finally, the availability of galactose to receptor binding is demonstrated by agglutination with RCA_{120}.

Nanoparticles were synthesized here specifically for the purpose of identifying design constraints to guide next generation gene delivery to the liver. In preparation for in vitro and in vivo uptake experiments, four nanoparticles were prepared: Gal-50 and Gal-140 that are galactosylated 50 and 140 nm nanoparticles, and MeO-50 and MeO-140 that are methoxy-terminated 50 and 140 nm nanoparticles. Through the use of these nanoparticles, the effects of nanoparticle size and presence of galactose on the nanoparticle surface on the biodistribution in liver are explored in Part 2 of this work (*16*).

Received April 14, 2005; Revised Manuscript Received August 3, 2005

In Part 1 of our work (*1*), four nanoparticles were synthesized specifically for the purpose of identifying design constraints to guide next generation gene delivery to the liver. The four nanoparticles are Gal-50 and Gal-140 (galactosylated 50 and 140 nm nanoparticles) and MeO-50 and MeO-140 (methoxy-terminated 50 and 140 nm nanoparticles). All four particles have the same surface charge, and Gal-50 and Gal-140 have the same surface galactose density (ca. 25−30 pmol/cm^2). Here, the hepatocyte uptake in vitro and hepatic distribution in vivo of these four nanoparticles is investigated. With freshly isolated hepatocytes, Gal-50 nanoparticles are taken up to a greater extent than are MeO-50, and both 50 nm beads are taken up to a much greater extent than either of the 140 nm nanoparticles. In mice, about 90% of the in vivo dose of Gal-140 nanoparticles is found within the liver 20 min after tail-vein injection. TEM and immunohistochemistry images confirm that Gal-140 nanoparticles are primarily internalized by Kupffer cells, though isolated examples of a few Gal-140 in hepatocytes are also observed. Gal-50 nanoparticles are overwhelmingly found in vesicles throughout the cytoplasm of hepatocytes, with only isolated examples of Kupffer cell uptake 20 min after tail vein injections in mice. Despite similar surface charge and ligand density, 50 nm nanoparticles are primarily found in hepatocytes while 140 nm nanoparticles are primarily observed in Kupffer cells. These results clearly show that slightly anionic, galactose-PEGylated nanoparticles with 25−30 pmol/cm^2 galactose should be about 50 nm in diameter to preferentially target hepatocytes while they should be about 140 nm in diameter to selectively target Kupffer cells.

INTRODUCTION

Gene therapy has the potential for treating numerous liver diseases (*2*). To prepare effective gene therapeutics for liver diseases, the therapeutics must target cells in the liver. Investigators have identified the importance of carefully designing and controlling the properties of nonviral gene delivery systems for targeting the liver. In Part 1 of our work, the synthesis and characterization of galactose-containing, slightly anionic PEGylated polystyrene nanoparticles are described, and these well-defined particles are appropriate for in vitro and in vivo biodistribution experiments to target liver (*1*). In particular, four nanoparticles were selected for in vivo experiments, and their properties are shown in Table 1.

Here, the in vitro hepatocyte uptake and in vivo hepatic distribution of the four nanoparticles described in Table 1 are determined. Comparable 50 nm nanoparticles and 140 nm nanoparticles that differ only in the presence of galactose on their surfaces allow the effect of galactose on biodistribution to be identified. Galactose is utilized as the targeting ligand in this work because galactose receptors are almost exclusively found in the liver, though both hepatocytes and Kupffer cells display galactose receptors. Hepatocytes abundantly express an asialoglycoprotein receptor (ASGPr) that selectively recognizes galactose and *N*-acetylgalactosamine (GalNAc) residues on small molecules, proteins, and particles. Kupffer cells abundantly express a galactose-particle receptor (GPr) that primarily recognizes galactose residues bound to solid surfaces without recognizing small galactosylated molecules (*3*). While both ASGPr and GPr recognize galactosylated particles, uptake via these receptors is differentially affected by particle size. While an upper size limit of about 70 nm has been proposed for ASGPr-mediated uptake of particles (*4*), Kupffer cells preferentially internalize 500 nm particles over 80 nm particles (*5*). Gal-50 is below the proposed cutoff in size for ASGPr-mediated uptake, while Gal-140 is above this critical size and may also be recognized more readily by the Kupffer cell GPr.

Table 1. Summary of Physicochemical Properties of the Four Nanoparticles To Be Used in Uptake Experiments

bead name	mean diameter (nm)	ζ-potential (mV)	galactose surface density (pmol/cm^2)
Gal-50	51.5	−2.7 ± 1.8	25.4
MeO-50	53.5	−2.7 ± 2.8	0
Gal-140	138.1	−2.6 ± 2.1	30.6
MeO-140	138.7	−3.2 ± 2.3	0

In vitro uptake experiments used here are with freshly isolated hepatocytes as compared to hepatocellular carcinoma cell lines to provide results that more closely

represent hepatocyte uptake in vivo. By their nature, carcinoma cells divide much more rapidly than nononcogenic hepatocytes, and their uptake mechanisms are altered accordingly. Since we are interested in studying nanoparticle uptake and distribution in hepatic tissue, use of primary hepatocytes will more closely approximate the uptake response of hepatocytes in vivo than would immortalized cell lines. Furthermore, many cultured cell lines have been cultured for extended periods of time, resulting in heterogeneous populations of cells. Microarray comparison of mRNA expression levels of whole rat liver, several rat liver cell lines, and primary cultured hepatocytes indicated that the cell lines were most dissimilar from whole liver, and that they also differed significantly from primary hepatocytes (*6*). In addition, the duration of culture had a profound effect on mRNA levels. Significant differences in ethanol toxicity (*7*), transferrin internalization rate (*8*), and ASGPr receptor levels have also been reported between hepatocellular carcinoma cell lines and normal hepatocytes. For example, HepG2 cells, a human malignant hepatic cell line, have only about 225 000 ASGPr per cell. Rat hepatocytes have approximately 550 000 ASGPr total per cell. Although HepG2 cells present 87% of the total cellular ASGPr on the cell surface (*9*), only about 250 000 (*10*) of the hepatocyte ASGPr are expressed on the cell surface while the additional 300 000 constitute an intracellular pool. This intracellular pool of ASGPr has been implicated in intracellular trafficking and processing of receptor and ligand, including a role in transport in the secretory pathway following ligand internalization (*11*). Therefore, immortalized cell lines such as HepG2 do not provide an ideal in vitro system to guide in vivo hepatic biodistribution studies, and freshly isolated hepatocytes will be used in this work.

In vitro uptake into hepatocytes is assayed both as adherent cells, to compare the dose fraction internalized by the cells, and as suspended cells to study the kinetics of nanoparticle association with hepatocytes. In vivo hepatic distribution is determined by collection of liver tissue and analysis by transmission electron microscopy (TEM) and immunohistochemistry, that allow for the visualization of liver sections from mice that received tail-vein injections of the different nanoparticles described in Table 1.

MATERIALS AND METHODS

Animals. Female Balb/c mice were obtained from Charles River Laboratories (Wilmington, MA) and were approximately 10−15 weeks old at the time of the study. The animals were fed autoclaved LabDiet 5010 (Purina Mills; St. Louis, MO) and drank reverse osmosis, 1 ppm chlorine, autoclaved water from bottles. The mice were housed on ventilated racks with autoclaved nestlets and Aspen Chip bedding (Nepco; Warrensburg, NY) on a 13-h light cycle at 72−76 °F and 30−70% humidity. Caltech specifically complies with the recommendations of the *Guide for Care and Use of Laboratory Animals* with respect to restraint, husbandry, surgical procedures, feed and fluid regulation, and veterinary care. The animal program at Caltech is AAALAC accredited.

Hepatocyte Isolation. Mouse hepatocytes were isolated from female Balb/c mice (18−25 g, 10−15 weeks old) by the standard two-step perfusion with collagenase by the Cell Culture Core of the USC Research Center for Liver Diseases, as previously described (*12*). Briefly, mice were anesthetized with pentobarbital sodium (60 mg/kg), and the liver was perfused via the portal vein at 3 mL/min first with Ca^{2+} and Mg^{2+}-free perfusion buffer (10 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES), 137 mM NaCl, 5 mM KCl, 0.5 mM NaH_2PO_4, and 0.4 mM Na_2HPO_4, pH 7.2) for 3 min and then with perfusion buffer supplemented with 5 mM $CaCl_2$ and 0.05% (w/v) collagenase (type IV; pH 7.5) for 3 min. The liver was then carefully removed, and its capsular membrane was gently peeled off. The dispersed cells, in cold Hank's−HEPES buffer containing 0.1% BSA, were filtered through cotton mesh and allowed to settle. Dead parenchymal hepatocytes were removed by density gradient centrifugation on Percoll (Amersham Biosciences; Piscataway, NJ) to give parenchymal cells of >90% purity and >90% viability, as determined by trypan blue exclusion. Appropriate numbers of hepatocytes, as described in the following sections, were transferred to collagen-coated dishes that were maintained at 37 °C with 95% humidity and 5% CO_2. After 1 h, the unattached cells were removed by aspiration, and culture medium changes were performed daily thereafter. Complete hepatocyte media consisted of Dulbecco's Modified Eagle's Medium/F12 without phenol red (Invitrogen; Carlsbad, CA), supplemented with L-methionine, 100 U/mL penicillin, 0.1 mg/mL streptomycin, 0.25 mg/mL amphotericin B (Invitrogen), and 9% fetal bovine serum.

Nanoparticle Uptake by Adherent Hepatocytes. Following hepatocyte isolation, 100 000 hepatocytes were transferred to each well of collagen-coated 24-well plates. After a minimum of 24 h of incubation in complete medium, hepatocytes were incubated in OptiMem (Invitrogen) that does not contain any Cu^{2+} or Zn^{2+} ions for 2 h prior to experimentation, to allow the hepatic asialoglycoprotein receptor (ASGPr) to adopt an accessible conformation and to achieve maximum uptake potential (*13*). The medium in each well was then replaced with the appropriate nanoparticle-containing medium, or PBS-containing medium for wells to be used in the preparation of standard curves. Hepatocytes were incubated in 200 μL of Optimem containing 7.5×10^9 nanoparticles/mL for 40 min. After this time, the medium was removed, and cells were washed with cold HEPES buffer then lysed with 1X Cell Culture Lysis Reagent (Promega; Madison, WI). Fluorescence of the soluble portion of the cell lysates was measured and compared to standard curves prepared by adding known numbers of beads to hepatocyte cell lysates.

Preparation of Suspended Hepatocytes. Following hepatocyte isolation, about 7×10^6 hepatocytes were transferred to a collagen-coated 10 cm^2 dish and incubated for a minimum of 24 h in complete medium. Hepatocytes were detached with trypsin−EDTA (Invitrogen), spun down at 400*g* for 5 min, and resuspended at 2×10^6 cells/mL in complete hepatocyte media in 50 mL polypropylene tubes, 10 mL total per tube, with 40 μm polypropylene Falcon Cell Strainers (Fisher; Hampton, NH) to minimize contamination while permitting gas exchange. After incubating at 37 °C and 5% CO_2 overnight, hepatocytes were spun down, washed with HEPES buffer, and resuspended in Optimem with 3% fetal bovine serum in polypropylene tubes. Following 2 h incubation in media lacking Cu^{2+} or Zn^{2+} ions, hepatocytes were spun down, resuspended in Optimem, and aliquoted for experimentation. Experimental details concerning data collection are described in the following section.

Flow Cytometry Analysis of Nanoparticle Uptake Kinetics. Single cell suspensions of 2×10^6 hepatocytes per mL were prepared as described above and kept on ice prior to analysis. Immediately before use, cell suspensions were warmed to 37 °C, nanoparticles were added

to the FACS tube, and analysis was started within 10 s. Flow cytometry analyses were performed using a BD Bioscience FACSCalibur (San Jose, CA) equipped with a 488 nm argon laser and a 635 diode laser and Cellquest software. Dead cells, aggregates, and Kupffer cells were removed from the analyses by live gating on forward and side scatter. Green fluorescence emitted by the beads was measured with a 530/30 nm band-pass filter. Autofluorescent cells were removed by using a red channel measured by a 585/42 nm band-pass filter to gate out bright cells. Flow rates were kept constant at 35 μL per minute. Per cell mean fluorescence from gated cells was analyzed by downloading the Cellquest list mode data file to FlowJo (Tree Star Inc.; Ashland, OR), gating the cells, and then exporting the gated data to Microsoft Excel. Mean fluorescence signals were averaged over all cells analyzed in 5 s intervals. The percentage of FITC-positive cells was calculated based on the ratio of the number of FITC-positive cells in each 5 s interval to the total number of cells counted in that interval. FITC mean values are normalized by the number of fluorescein equivalents per bead.

Bulk Liver Uptake of Nanoparticles. Twenty minutes after tail-vein injection of 100 μL of saline containing 8×10^{11} nanoparticles per 20 g mouse, mice were sacrificed and their livers were immediately excised, weighed, and split into two comparable pieces. Each piece was then transferred to individual Lysing Matrix D tubes (Qbiogene; Irvine, CA) and subjected to three cycles of mechanical agitation in a FastPrep FP120 instrument (Qbiogene). Cellular membranes were disrupted by three freeze−thaw cycles, and an additional cycle of mechanical agitation resulted in homogeneous liver samples that were lyophilized to dryness. FITC was subsequently extracted into chloroform for comparison to a standard curve. Standard curves were created by adding a known number of nanoparticles to liver pieces from untreated mice, followed by identical homogenization and extraction processing to the samples described above. Data as shown represent tissue uptake of nanoparticles, that has been determined by subtracting the approximate fluorescence due to nanoparticles in liver blood vessels from the fluorescence of the wet liver tissue. All experiments were repeated in triplicate.

TEM Imaging of Liver Tissue. For electron microscopy, excised liver tissue was cut into 1 mm^3 cubes and fixed in 2% glutaraldehyde in 100 mM sodium cacodylate buffer (pH 7.4). After being washed in a sodium cacodylate buffer, the tissue was postfixed in 1% osmium tetroxide in sodium cacodylate buffer for 1 h. After being rinsed, the tissue was embedded in Epon-Spurr resin. Thin sections were prepared, contrasted with uranyl acetate and lead citrate, and observed on a Hitachi 600 electron microscope (Hitachi Ltd.; Tokyo, Japan).

Overlay of Fluorescence and TEM Images. Mouse parenchymal liver cells were isolated as described above. Cells were seeded at a density of 3×10^5 cells per collagen-coated glass cover slip in six-well culture plates. After a minimum of 24 h incubation in complete medium, hepatocytes were incubated in OptiMem (Invitrogen) for 2 h prior to experimentation. Medium in each well was then replaced with 200 μL Optimem containing 7.5×10^9 nanoparticles/mL and incubated for 40 min. Cells were then washed with HEPES buffer and fixed in 2.5% glutaraldehyde for 2 h at room temperature. Glass cover slips were mounted with Vectashield mounting media (Vector Laboratories; Burlingame, CA). To identify the same cell for light microscopy and TEM, spots were made with an ultrafine tipped pen on the cell-containing cover slip.

Immunohistochemical Staining. Mice received a 100 μL tail-vein injection containing 8×10^{11} nanoparticles per 20 g mouse weight. The injection was performed over less than 5 s using a 26-gauge needle in all cases. Twenty minutes after the injection of nanoparticles, mice were sacrificed and their livers were immediately excised, embedded in Tissue-Tek OCT embedding compound (Sakura Finetek USA; Torrance, CA), and stored in 2-methylbutanol on dry ice. Frozen liver sections were cut 12 μm thick, and two sections were placed on each slide for imaging. Remaining blocks were stored at −80 °C. The slides were washed with PBS to remove OCT, and a perimeter was drawn around each pair of sections with an ImmEdge pen (Vector Laboratories). Each section was then fixed with 4% paraformaldehyde and rinsed with TBS (100 mM Tris and 150 mM NaCl, adjusted to pH 7.4). Slides were incubated with blocking buffer, and then any biotin or streptavidin in the sections was blocked with the Streptavidin/Biotin Blocking Kit (Vector Laboratories) and rinsed with TBS. Continuing with TBS washes between each step, slides were sequentially incubated with donkey blocking buffer, goat anti-ASPGR1 antibody (Santa Cruz Biotechnology; Santa Cruz, CA), donkey anti-goat IgG-biotin (Santa Cruz Biotechnology), and finally QDot655 streptavidin conjugate (Quantum Dot Corp.; Hayward, CA). Following a final set of TBS washes, slides were mounted with Vectashield Mounting Medium with DAPI (Santa Cruz Biotechnology) nuclear stain.

Immunohistochemistry Imaging. Images were acquired at the CHLARI Congressman Julian Dixon Cellular Image Core with a Leica DM RXA microscope using a HC Plan 20x/0.70NA Ph2 DIC C objective lens, 1.25× optovar, and Koehler illumination (Leica Microsystems Inc.; Bannockburn, IL). A SKY/CD-300/VDS-1300 spectral imager with EasyFISH software (Applied Spectral Imaging, Inc.; Carlsbad, CA) was used. The 640 × 480 pixel images were acquired with 2 × 2 binning (1.039 μm/pixel). All images acquired during a single session for each size nanoparticle were captured with identical exposure times and saved as 16-bit/channel EasyFISH files. Images were also saved as 24-bit RGB color images using constant slope contrast settings for each channel. Phase contrast and GFP images were acquired using a Chroma 41004 filter set (HQ480/40x, Q505LP dichroic, HQ535/50m), DAPI images were acquired using a Chroma 41001 filter set (HQ480/40x, Q505LP, HQ535/50m) (Chroma Technology Corp.; Brattleboro, VT), and QD655 images were acquired with a Leica N2.1 filter set 513832 (BP515-560, 580, LP590).

RESULTS AND DISCUSSION

In Vitro Uptake Results. Hepatocytes have access to high concentrations of amino acids and other nutrients from the digestive tract and endogenous protein catabolism, as well as a rich network of endoplasmic reticulum that enables their efficient secretory processes (*14*). As such, hepatocytes are the primary site of secretory protein synthesis in the body and are accordingly involved in many disease states. Hepatocytes are therefore a highly desirable target for gene therapy.

Nanoparticle uptake into cultured hepatocytes can provide an initial indication of the effect of size and galactose targeting on hepatic uptake. Besides the complex microenvironment in the liver surrounding each

Table 2. In Vitro Uptake of Nanoparticles by Freshly Isolated Hepatocytes, as Quantified by the Overall Fluorescence of Cell Lysates by Comparison to a Standard Curve Also Using Hepatocyte Lysates

nanoparticle type	% dose in hepatocyte lysate
Gal-50	21.9
MeO-50	9.0
Gal-140	1.6
MeO-140	1.5

hepatocyte, as compared to the loosely packed monolayer of hepatocytes in culture, freshly isolated hepatocytes were found to have only 17% of their ASGPr on the cell surface (*15*) as compared to between 40% and 60% ASGPr presentation for hepatocytes in the liver. After incubation at 37 °C, the receptor distribution in isolated hepatocytes has been reported to approach 50% on the cell surface with the remainder associated with intracellular Golgi, microsomal, and lysosomal membranes (*16*). To minimize the transient nature of these effects, hepatocytes were incubated in complete hepatocyte medium, as described in Materials and Methods, for a minimum of 24 h prior to use.

Nanoparticle uptake by plated hepatocytes was assayed by measuring the fluorescence of whole cell lysates after incubating freshly isolated hepatocytes with nanoparticles and washing with chilled HEPES buffer. In all in vitro uptake experiments, hepatocytes were incubated for 2 h in media that does not contain any Cu^{2+} or Zn^{2+} ions. McAbee and Jiang (*13*) have demonstrated that these ions result in the reversible accumulation of inactive ASGPr both intracellularly and on the cell surface, so hepatocytes were incubated at 37 °C and washed in the absence of Cu^{2+} or Zn^{2+} before experiments were initiated.

The results of nanoparticle uptake into plated hepatocytes are shown in Table 2. It is apparent that nanoparticles with 50 nm diameters are taken up to a much greater extent than are those with 140 nm diameter. The presence of galactose on 140 nm beads has no apparent effect, with about 1.5% of each MeO-140 and Gal-140 dose being internalized by hepatocytes. Galactose presentation does, however, significantly affect the uptake of 50 nm beads. While about 9% of MeO-50 nanoparticles were internalized during the course of the experiment, greater than 20% of Gal-50 nanoparticles were internalized. These results presented in Table 2 are consistent with the findings of Rensen et al. (*4*) that hepatocytes preferentially internalize targeted liposomes with diameters less than about 70 nm. In place of glycolipid-containing liposomes, the present work makes use of slightly anionic PEGylated nanoparticles that closely mimic the surface properties of stabilized gene delivery polyplexes. Since PEGylation is commonly required to achieve long circulation times of nanoparticles in vivo, the results obtained with this system are expected to directly translate to a wide variety of gene and drug delivery systems.

When formation of endocytic vesicles is accompanied by uptake of extracellular fluid along with any macromolecules or particles present, uptake is said to occur by fluid-phase endocytosis, or pinocytosis. Vesicles resulting from pinocytosis are generally less than 100 nm in diameter, so it can be speculated that the fairly high uptake of nontargeted 50 nm nanoparticles by hepatocytes in vitro may at least partially be due to pinocytosis.

To help guide in vivo experiments and to better understand in vitro uptake, nanoparticle uptake kinetics were monitored with suspended, freshly isolated hepatocytes, and the results are shown in Figure 1. This experiment confirms the results obtained with plated hepatocytes. Gal-140 and MeO-140 are taken up only minimally compared to the 50 nm nanoparticles (Figure 1a), and no difference in uptake was seen in 140 nm beads (Figure 1b) displaying galactose or methoxy on their surfaces. Once again, uptake of the nontargeted MeO-50 nanoparticles does occur, but Gal-50 are taken up to a greater extent. At least 10 nanoparticles were associated with each hepatocyte within 30 s of their addition to the hepatocyte suspension (data not shown). This result is not unreasonable considering that ASGPr clustering has been observed within 15 s of ligand introduction (*17*), approximately 50% of ASGPr-ligand complexes are internalized within 3 min (*15*, *18*) and that at saturation, each hepatocyte can take up 5×10^6 ligands by ASGPr per hour (*10*).

Following pinocytic uptake by hepatocytes in vivo, vesicles follow one of three distinct paths (*19*). About 80% of pinocytosis material is rapidly exchanged with extracellular fluid, about 18% is processed deeper into the cell, and about 2% is secreted into bile. The fraction of internalized fluid that is regurgitated back into plasma does so with $t_{1/2}$ about 1−2 min in hepatocytes. This $t_{1/2}$ is considerably shorter than is seen in macrophages, fibroblasts or adipocytes. Based on these uptake results, it is estimated that hepatocytes pinocytose the equivalent of 20% or more of their volume and at least 5 times their plasma membrane surface area each hour (*19*). This high recycle rate of pinocytosed materials has also been confirmed with suspended rate hepatocytes (*20*), and the shape of the MeO-50 uptake curve in Figure 1a can be explained by this mechanism (*21*). For the first 30−60 s of hepatocyte exposure to MeO-50 nanoparticles, uptake is proceeding quickly without significant nanoparticle release back into the extracellular fluid. However, an average pinosome recycling time of about 1−2 min means that increasing amounts of pinocytosed material is released after about 60 s until steady-state conditions are reached after about 200 s. Under steady-state conditions, 80% of all pinocytosed material is rapidly recycled while 20% is retained within the cell and contribute to ongoing increases in cell fluorescence. As such, an initial region of linearly increasing uptake is expected to occur until about 30−60 s, at which time a transition to another linear uptake region with a shallower slope is observed after about 200 s. The MeO-50 kinetic uptake curve shown in Figure 1a matches this description.

The shape of the Gal-50 uptake curve is similar to that of MeO-50 (Figure 1a). This can be understood if the primary mechanism of uptake of Gal-50 in vitro is also pinocytosis, but with additional ASGPr-mediated uptake as well. Suspended rat hepatocytes have been shown (*20*) to uptake transferrin primarily by pinocytosis, despite the presence of a transferrin receptor on their cell surface. Nearly 80% of transferrin uptake was attributed to pinocytosis, with the remainder coming through receptor-mediated endocytosis. The half-time for internalization via the ASGPr is about 180 s (*22*), with an average time to recycle to the cell surface of about 4 min (*9*). Because of the similarity of these two uptake processes and the suggested dominant role of pinocytosis on uptake, it is expected that Gal-50 is internalized to a greater extent than MeO-50, but that the shape of the two kinetic uptake curves is similar. In the presence of Cu^{2+} and Zn^{2+} ions, uptake of Gal-50 and MeO-50 is indistinguishable (data not shown), suggesting that the difference in uptake between the two nanoparticles is ASGPr-mediated.

Optimization of Experimental Conditions for In Vivo Experiments. To allow direct comparison between

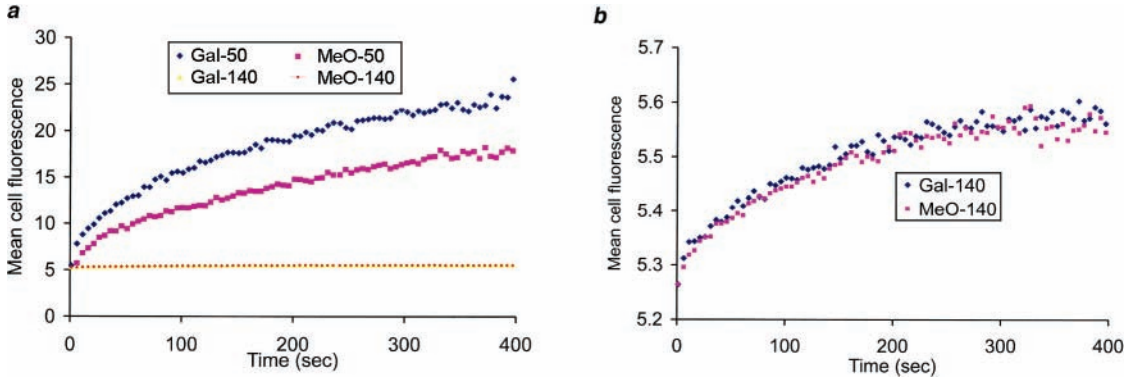

Figure 1. Kinetics of nanoparticle uptake by suspended hepatocytes, as analyzed by flow cytometry. (a) Uptake of 50 and 140 nm nanoparticles are shown on the same scale. (b) Uptake of 140 nm nanoparticles are shown on an expanded scale.

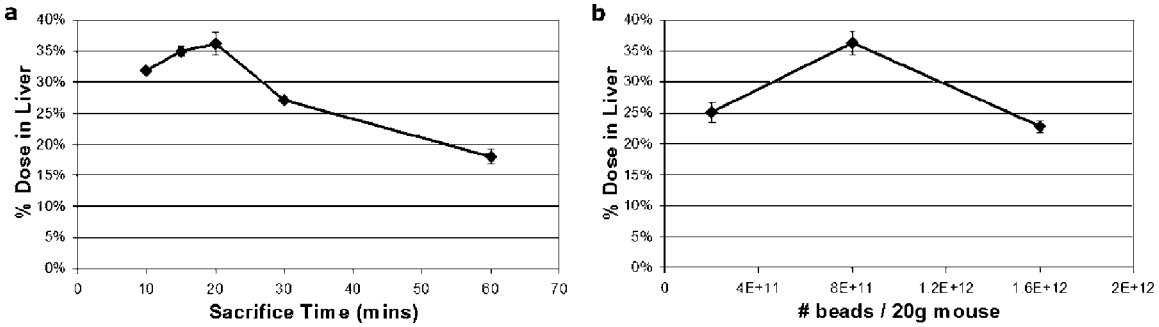

Figure 2. Optimization of experimental conditions for in vivo experiments by assaying total fluorescence of mouse liver following homogenization of liver and extraction of fluorophore. (a) Determination of optimal time between tail-vein injection of nanoparticles and liver removal. 8×10^{11} Gal-50 nanoparticles were injected via tail-vein per 20 g mouse, two mice per group, and sacrificed at the time shown. (b) Determination of optimal bead dose. Mice received tail-vein injections of Gal-50 nanoparticles and were sacrificed 20 min postinjection.

all in vivo experiments, a set of experimental conditions was identified that maximizes hepatic uptake following injection of nanoparticles. For this purpose, Gal-50 nanoparticles were utilized. The percentage of the injected dose in the liver was determined by homogenizing the livers of two mice per set of experimental conditions and extracting the fluorescent dye in chloroform.

Nanoparticles can be administered in a variety of ways to mice. Since hepatic uptake is desired, direct injection into the liver can be accomplished via portal vein or inferior vena cava. While portal vein injections are possible in humans, unnecessary surgical procedures are preferentially avoided. Therefore, the nanoparticles are introduced into systemic circulation and pass through the liver with the general blood flow. Tail-vein injection in mice is the most convenient method of introducing materials into the mouse circulation and is used in all in vivo experiments. Injection of large volumes relative to the circulating blood volume of the mouse have been found to result in transiently increased cell membrane permeability (*23*) that could obscure the effects of nanoparticle-size galactose presence. Therefore, low-pressure tail-vein injections of nanoparticles (100 μL per 20 g mouse) are employed here for all in vivo experiments.

As shown in Figure 2, Gal-50 accumulates in the liver up to about 20 min, after which time its amount decreases. The effect of the Gal-50 dose on liver uptake was also investigated, over a dose range that is reasonable for nonviral gene delivery particles. On the basis of the results of these liver uptake experiments, it was determined that 8×10^{11} beads in 100 μL of saline per 20 g mouse would be administered via tail-vein injection, with liver removal 20 min postinjection.

Bulk Liver Uptake of Nanoparticles. As in the previous experiment, the uptake of nanoparticles into liver tissue can be determined by homogenizing the liver and extracting the fluorescent dye. The comparison of bulk liver uptake of each nanoparticle is shown in Figure 3. It is apparent that galactosylated nanoparticles are taken up to a much greater extent than are nongalactosylated nanoparticles, which is as expected given the unique presence of galactose receptors in the liver on hepatocytes and Kupffer cells. In particular, nearly the entire dose of Gal-140 is found in the liver, as compared to about one-third of the Gal-50 dose. Concentrations of both MeO-50 and MeO-140 in the liver are quite low. In vitro, neither of the two types of 140 nm beads were internalized to a significant extent by hepatocytes, but it is clear that Gal-140 nanoparticles are taken up by the liver in vivo. As shown in the following sections, Kupffer cells are primarily responsible for Gal-140 uptake in vivo.

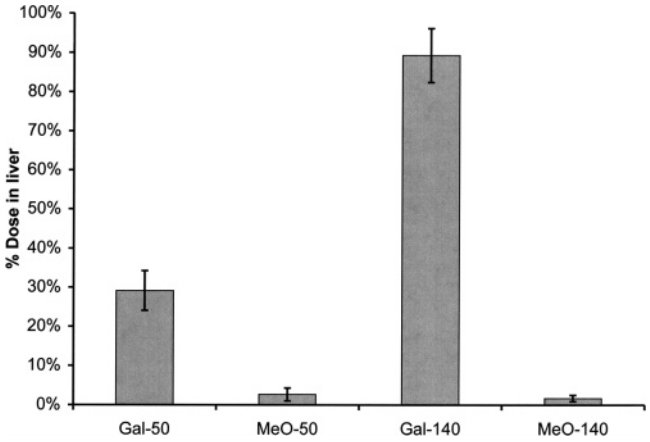

Figure 3. Overall uptake of nanoparticles into hepatic tissue. Results are shown as mean ± standard deviation of three mice per group.

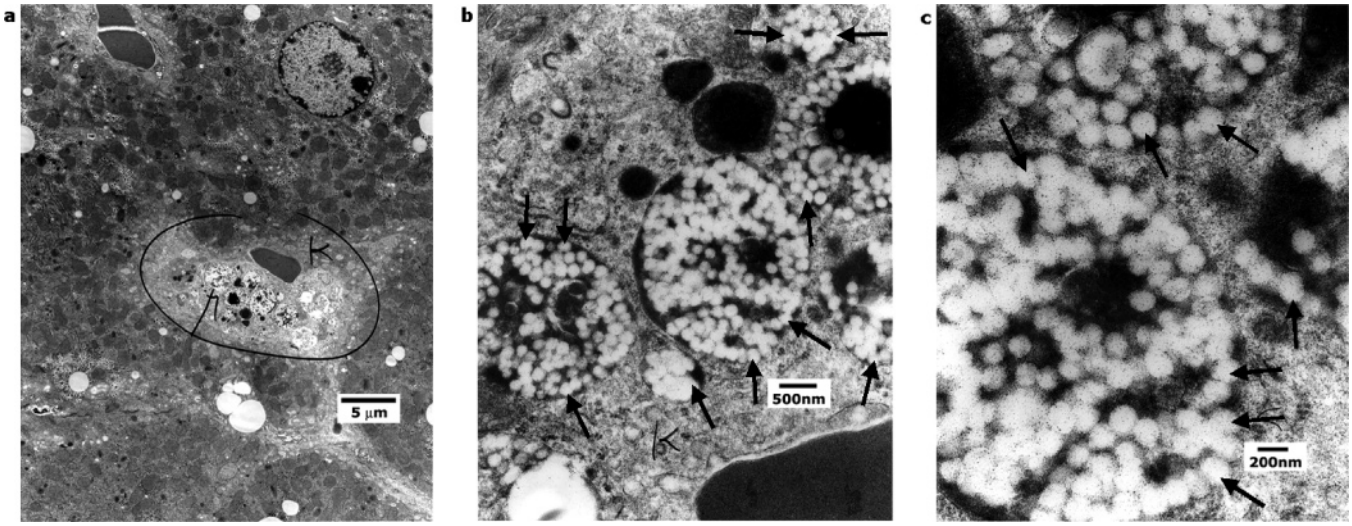

Figure 4. TEM images taken of the same 20 nm thick liver section following tail-vein injection of 8×10^{11} Gal-140 nanoparticles per 20 g mouse at scope magnifications of (a) 2000×, (b) 15 000×, and (c) 30 000×. Examples of individual nanoparticles are labeled with arrows in parts b and c.

TEM Imaging Following Tail-Vein Injection of Nanoparticles. Bulk liver uptake experiments indicated significant differences in the uptake of targeted and nontargeted nanoparticles, but gave no indication of the hepatic distributions. TEM analysis of liver cross-sections following tail-vein injection of nanoparticles provided information on hepatic distribution and intracellular trafficking of the nanoparticles. All images are representative of the overall hepatic distribution for each type of nanoparticle.

Hepatic Distribution of 140 nm Nanoparticles. Figure 4 shows TEM images of a 20 nm thick section of liver tissue that had been exposed to Gal-140 by tail-vein injection of these nanoparticles. The image in Figure 4a shows six hepatocytes surrounding a single Kupffer cell (marked 'K'). Hepatocytes are polyhedral cells with eight or more surfaces and regular, round nuclei that represent about 60% of the cells in the liver but almost 80% of hepatic volume since they are the largest of the cells. Kupffer cells are hepatic macrophages that have irregular nuclei and generally are located in the lumen of hepatic sinusoids adjacent to hepatocytes. Kupffer cells are in direct contact with the bloodstream and represent about 10% of the cells in the liver.

Though isolated examples of Gal-140 in hepatocytes could be found (images not shown), only a few beads are found per cell in those cases, while nearly all Kupffer cells contain a large number of internalized beads as shown in Figure 4b. This image clearly demonstrates Kupffer cell uptake of Gal-140, with hundreds of nanoparticles in each of the large phagocytic compartments (Figure 4c). At 8×10^{11} nanoparticles injected per 20 g mouse, approximately 50 000 nanoparticles are being injected per Kupffer cell in the liver. Since the Kupffer cell galactose-particle receptor has been documented to endocytose as many as 4200 galactosylated particles per cell per minute (*24*), the large number of nanoparticles observed per cell is reasonable.

Nanoparticle aggregation is not observed in Figure 4c, despite extremely concentrated conditions in the confines of phagocytic compartments. This provides additional evidence that the nanoparticles are stable and do not aggregate or fall apart either in serum or intracellularly, confirming the results of in vitro stability assays. The size stability in vivo allows the direct correlation of nanoparticle size with uptake results.

Unlike Gal-140, MeO-140 nanoparticles are not taken up to a great extent by any hepatic cells. In fact, most cells did not contain any MeO-140 beads, and few examples could be found of aggregates of MeO-140. However, of the cells that contained nanoparticles, MeO-140 were primarily internalized by Kupffer cells (images not shown).

Hepatic Distribution of 50 nm Nanoparticles. TEM images of liver sections following exposure to 50 nm nanoaparticles were quite different than those exposed to Gal-140. Neither MeO-50 or Gal-50 were found concentrated in Kupffer cells, though liver that was exposed to Gal-50 had an unusually large number of 100−200 nm vesicles throughout the cytoplasm of most hepatocytes, as shown in Figure 5b. As compared to hepatocytes from mice that received tail-vein injection of MeO-50 (Figure 5a), which contain occasional vesicles in the cytosol, hepatocytes exposed to Gal-50 contain many hundreds of clearly defined vesicles.

The result that Gal-140 are much more concentrated in Kupffer cells than are Gal-50 is consistent with literature reports that Kupffer cells tend to uptake 80 nm particles much more slowly than they internalize 500 nm particles (*5*). However, identification of individual nanoparticles in the hepatocyte vesicles is not as clear in the case of Gal-50 as it was for Gal-140. It is therefore critical to demonstrate that vesicles as shown in Figure 5b do in fact contain nanoparticles.

To confirm that the vesicles shown in Figure 5b contain nanoparticles, the same cell was imaged by both fluorescence microscopy and by TEM. By carefully marking and photographically documenting the cell of interest, the same cell could be identified following workup for TEM. In Figure 6, the capability of the technique is demonstrated by imaging the same cell with light microscopy and TEM. The nuclei and overall cell membrane shape, as well as relation to adjacent cells (not visible in Figure 6), confirm that the same cell may be identified and imaged on separate microscopes on separate days. Any slight differences in cell morphology may be attributed to the fact that the entire thickness of the cell is photographed with the light microscope, while only a thin section is imaged by TEM.

By comparing green regions seen by fluorescence microscopy of a plated hepatocyte in vitro with vesicle-containing regions seen by TEM, it was confirmed that

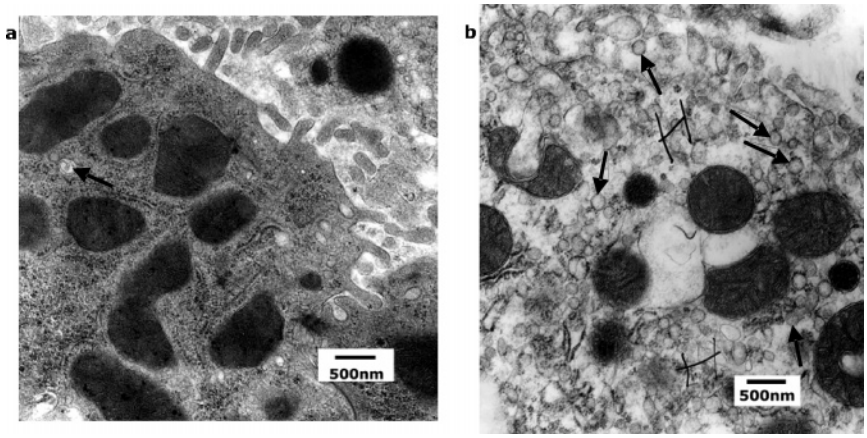

Figure 5. TEM images of hepatocytes following tail-vein injection of (a) MeO-50 and (b) Gal-50 nanoparticles, 8×10^{11} per 20 g mouse. Examples of individual vesicles are labeled with arrows.

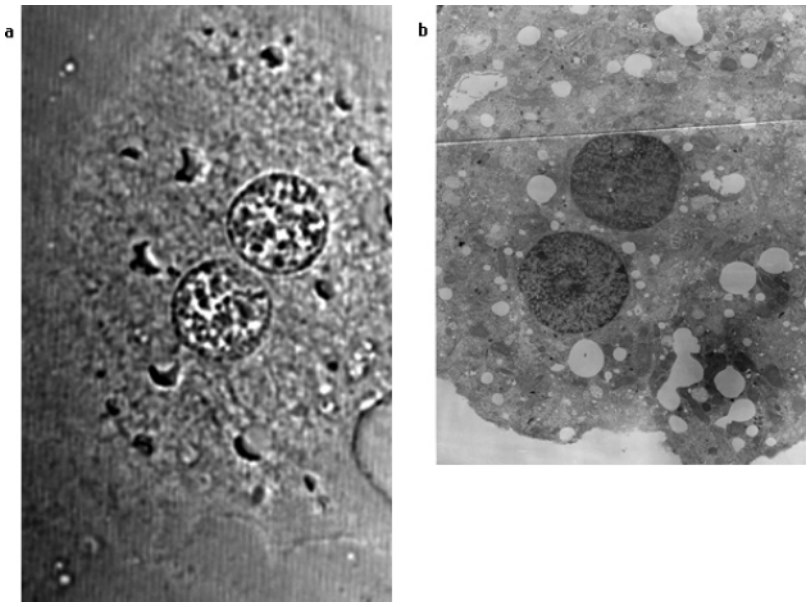

Figure 6. Comparison of images of the same cell, obtained by (a) confocal microscopy and (b) TEM.

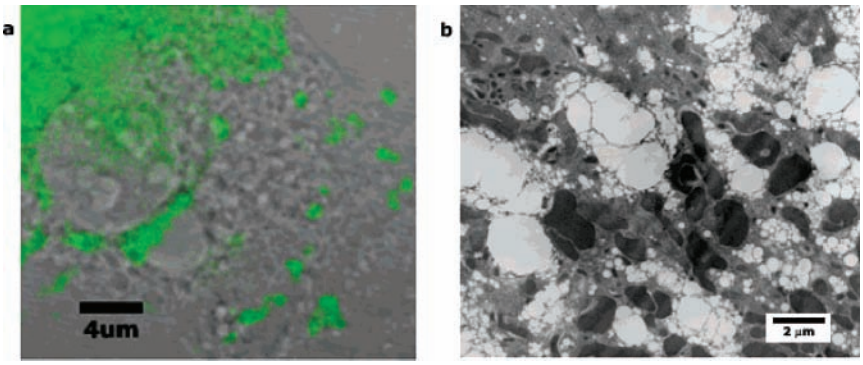

Figure 7. Imaging of a hepatocyte, 24-h postisolation that had been exposed to Gal-50 nanoparticles. Comparison of (a) light and fluorescence images and (b) TEM image of the green perinuclear region on the top left side of part a.

the vesicles in hepatocytes exposed to Gal-50 in vivo contain nanoparticles. In Figure 7a, the majority of a hepatocyte is seen by fluorescence and light microscopy. This plated hepatocyte was exposed to Gal-50 in vitro before being fixed with glutaraldehyde and imaged by confocal microscopy. Heavy-metal staining of the cell and embedding in Epon resin allowed TEM to be taken of the same cell. Since all nanoparticles used in these experiments have FITC embedded in their polystyrene core, they show up as green in the fluorescence image (Figure 7a). From this image it is apparent that the majority of Gal-50 beads are in the perinuclear region of the cell. When perinuclear regions of the cell are magnified by TEM (Figure 7b), an unnaturally large number of vesicles are seen. There are few vesicles in regions of the hepatocyte that do not show up green by fluorescence, so it is apparent that the green fluorescence originates from the large number of intracellular vesicles. Isolated clusters of vesicles on TEM show up as bright spots by fluorescence, while clusters in close proximity, as shown

in Figure 7b, show up as diffuse green regions by fluorescence. Analogous to the situation seen in vivo following injection of Gal-50, individual nanoparticles cannot be easily identified inside vesicles, but green fluorescence is clearly originating from these vesicles. We therefore conclude that Gal-50 nanoparticles are trapped within the vesicles observed by TEM.

Hepatocytes and Kuppfer cells are not the only hepatic cells capable of internalizing nanoparticles. Under the appropriate conditions, both hepatic stellate cells (HSC) and liver sinusoidal endothelial cells (LSEC) display phagocytic behavior. Following hepatic injury, hepatic stellate cells (HSC) differentiate into an activated phenotype that is capable of taking up 1 μm carboxylate-modified latex particles (*25*). Despite liver enzyme assays indicating no toxicity associated with the nanoparticles used in this study (data not shown), and hence no reason for HSC activation, HSC uptake of nanoparticles was considered and excluded based on TEM and FACS results (data not shown). LSEC have been shown to nonspecifically internalize a number nanoparticles, including lecithin-coated 240 nm polystyrene beads (*26*), uncoated 240 nm and 330−800 nm polystyrene beads (*27*), and 12 nm iron oxide nanoparticles (*28*). Furthermore, LSEC are indicated in the efficient ingestion and rapid degradation of naked pDNA in vivo and in vitro (*29*). Despite intense scrutiny, no evidence could be found of LSEC association or internalization of the PEGylated nanoparticles employed in this study.

By TEM, a significant difference in hepatic distribution and uptake of 50 and 140 nm nanoparticles that present either galactose or methoxy moieties on their surface was confirmed. Although TEM provides a very detailed view of intracellular trafficking, it is limited by the small area that can be examined at a time and by lack of scalability, thus preventing conclusions to be drawn concerning distribution of the nanoparticles across the cross-sectional area of the liver.

Immunohistochemistry Following Tail-Vein Injection of Nanoparticles. To provide a more general view of the liver, an immunohistochemical staining (IHC) procedure was developed. This technique is scalable in that processing may be done to multiple slides simultaneously. Twenty minutes after nanoparticles were injected via tail-vein into mice, the liver was embedded in OCT blocks and stored in 2-methylbutanol on dry ice. Liver sections (12 μm thick) were cut from the OCT blocks, excess OCT was dissolved away, and endogenous biotin activity was blocked. ASGPr was then stained red through a three-component antibody system. Goat anti-ASGPr1 was used as the primary antibody to provide a target for attachment of a donkey anti-goat IgG-biotin antibody. Since exogenous biotin was already blocked, incubation with QDot655-streptavidin and subsequent washes permitted specific visualization of the ASGPr receptor in the red fluorescence channel. Blocking of exogenous biotin was critical to minimize nonspecific binding of QDot655-streptavidin to liver tissue. Finally, slides were stained with DAPI-containing VectaShield mounting media, providing blue staining to nucleic acids in cell nuclei.

In Figure 8, an example of the ASGPr staining pattern is placed on a TEM image of normal mouse liver. ASGPr is expressed primarily on the hepatocytic basal and lateral membranes, which are directed toward the perisinusoidal and pericellular spaces and make up about 75% of the hepatocyte circumference. The density of ASGPr on these surfaces is 7- to 14-fold higher than on the apical surfaces (*30*, *31*). Staining is therefore expected around

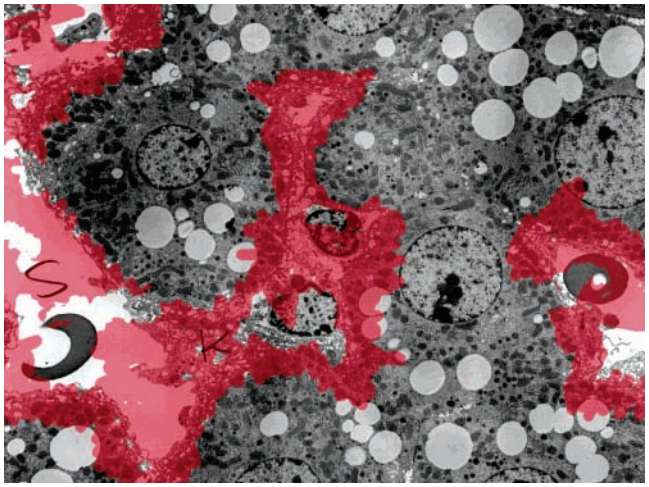

Figure 8. Illustration of the staining that results from the immunohistochemical staining of the hepatic asialoglycoprotein receptor (ASGPr).

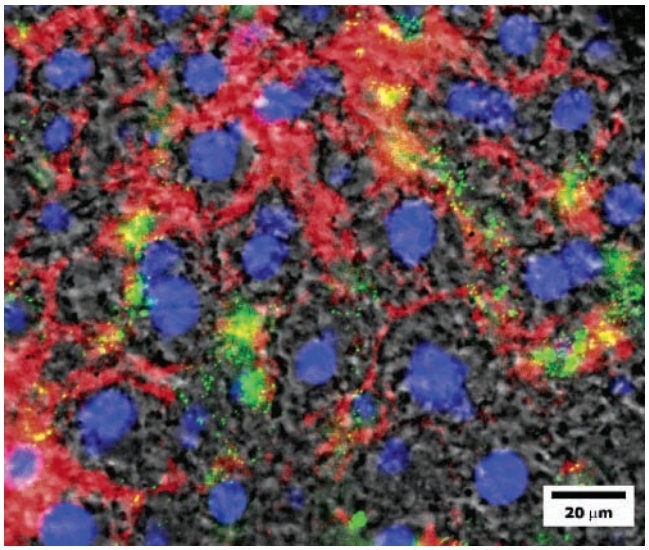

Figure 9. Immunohistochemistry image of 12 μm-thick section of mouse liver following tail-vein injection of 8×10^{11} MeO-140 nanoparticles. ASGPr is stained red, nuclei are blue, and nanoparticles are green/yellow.

the perimeter of sinusoids and around Kupffer cells, but hepatocyte−hepatocyte junctions should remain largely unstained. Additionally, sections used for IHC are 12 μm thick, so the three-dimensionality of the sinusoids must also be considered. Liver sinusoids have an average diameter of about 7.3 μm (*32*); thus, it is likely that hepatocyte membranes located just above or below sinusoids are partially included in the 12 μm thick IHC section. It is therefore probable that sinusoidal endothelial cells are included in the red-stained regions. Similarly, since Kupffer cells tend to border sinusoids and sinusoid-facing perimeters of hepatocytes, it is to be expected that many Kupffer cells will also be stained red.

A representative immunohistochemistry image obtained after tail-vein injection of MeO-140 nanoparticles into mice is shown in Figure 9. In this image, a sinusoid is seen running from the top center of the image toward the bottom right corner before wrapping around a pair of hepatocyte nuclei and returning toward the top-center. Along the length of this sinusoid, a large number of individual MeO-140 beads can be seen. The situation just described is similar to that seen in sinusoids running vertically down the left side and center of the image, in

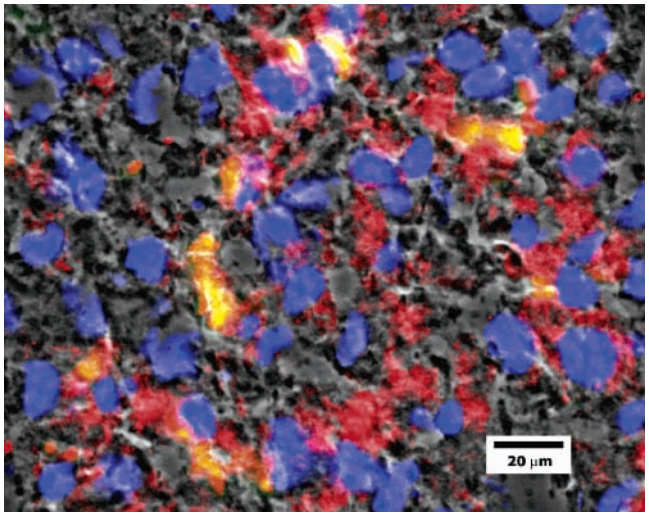

Figure 10. Immunohistochemistry image of 12 μm-thick section of mouse liver following tail-vein injection of 8×10^{11} Gal-140 nanoparticles. ASGPr is stained red, nuclei are blue, and nanoparticles are green/yellow.

which the nanoparticles do not appear to be aggregated. Few examples of MeO-140 aggregation could be found, indicating that these beads are largely present in hepatic sinusoids and are not internalized to any great extent in hepatic cells. This situation is similar to that observed for MeO-50 beads (not shown). No difference in nanoparticle distribution or density was observed between regions near the portal vein inlet to the liver and regions near the hepatic vein outlet.

The immunohistochemistry image obtained following Gal-140 injection is much different. In the image shown in Figure 10, large aggregates of nanoparticles are observed. These aggregates show up as yellow due to bright green overlaying red. While both MeO-140 and Gal-140 are shown to primarily overlay sinusoidal or Kupffer cell regions of the liver, the massively aggregated state of Gal-140 point to uptake by either Kupffer or sinusoidal endothelial cells since no mechanism exists for particle aggregation in the sinusoids. By TEM, no evidence of nanoparticle uptake into endothelial cells could be found, so the massive aggregates of Gal-140 nanoparticles are concluded to be resident in Kupffer cells. This result supports the conclusion drawn from TEM studies. Immunohistochemistry provides the ability to image a 1−2 cm cross-section of liver, permitting the distribution of beads to be seen across the liver from portal-vein inlet to hepatic-vein outlet. While both sized methoxy-beads are seen in sinusoids in similar concentrations across the liver, a somewhat higher concentration of Gal-140 beads are observed near the portal-vein inlet to the liver. This observation is consistent with the observation that Gal-140 are taken up into cells while MeO-50 and MeO-140 remain largely in the sinusoids.

In agreement with the TEM observations presented, immunohistochemistry on liver tissue from mice that received tail-vein injections of Gal-50 nanoparticles shows that Gal-50 are primarily internalized by hepatocytes (Figure 11). In this image, a pair of sinusoids is seen running from the bottom right corner of the image diagonally toward the upper left corner. Unlike the images taken following injection of any of the other beads, few Gal-50 beads are seen to overlap red-stained regions of liver. The majority of nanoparticles in this image have been internalized by hepatocytes, including all nanoparticles surrounded by red circles. A few Gal-50 nanoparticles may be in sinusoidal spaces or in Kupffer cells, located near the center of the image and toward the bottom right, where the green fluorescence overlays the red ASPGr staining, but the majority of Gal-50 are internalized by hepatocytes.

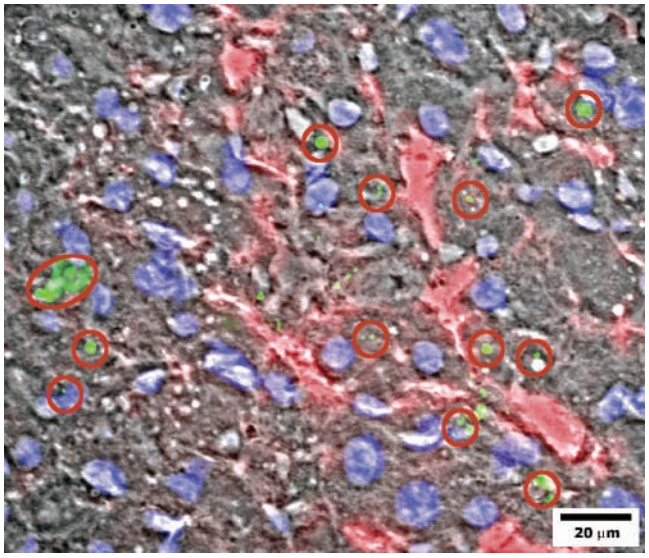

Figure 11. Immunohistochemistry image of 12 μm-thick section of mouse liver following tail-vein injection of 8×10^{11} Gal-50 nanoparticles. ASGPr is stained red, nuclei are blue, and nanoparticles are green/yellow.

CONCLUSIONS

Here, hepatocyte uptake in vitro and hepatic distribution in vivo of four slightly anionic, PEGylated-polystyrene nanoparticles were investigated. Slightly anionic surface charge is utilized to minimize nonspecific proteoglycan-mediated uptake or interaction with anionic cell surface membranes. In freshly isolated hepatocytes, Gal-50 nanoparticles are taken up to a greater extent than are MeO-50, but both 50 nm beads are taken up to a much greater extent than 140 nm nanoparticles, whether they contain galactose or not. About 90% of the in vivo dose of Gal-140 nanoparticles is found within the liver 20 min after tail-vein injection. TEM and immunohistochemistry images confirm that Gal-140 are primarily internalized by Kupffer cells, though isolated examples of a few Gal-140 in hepatocytes can also be found. Gal-50 nanoparticles are overwhelmingly found in vesicles throughout the cytoplasm of hepatocytes, with only isolated examples of Kupffer cell uptake. Despite similar surface charge and ligand density, 50 nm nanoparticles are primarily found in hepatocytes while 140 nm nanoparticles are primarily seen in Kupffer cells. It is therefore clear that slightly anionic, galactose-PEGylated nanoparticles should be about 50 nm in diameter to preferentially target hepatocytes while they should be about 140 nm in diameter to selectively target Kupffer cells.

ACKNOWLEDGMENT

We are grateful to Dr. Hide Tsukamoto for generously offering the services of his lab to isolate nonparenchymal liver cells and for helpful discussions. Dr. Rochelle Diamond went out of her way to assist with in vitro FACS experiments, and we thank George McNamara of the CHLARI Image Core for advice and assistance in acquiring images following immunhistochemical staining.

Properties of Isonucleotide-Incorporated Oligodeoxynucleotides and Inhibition of the Expression of Spike Protein of SARS-CoV

Zhanli Wang, Jifeng Shi, Hongwei Jin, Liangren Zhang,* Jingfeng Lu, and Lihe Zhang

National Research Laboratory of Natural and Biomimetic Drugs, School of Pharmaceutical Sciences, Peking University, Beijing 100083, China. Received September 21, 2004; Revised Manuscript Received April 11, 2005

Antisense oligonucleotides are recognized to be very efficient tools for the inhibition of gene expression in a sequence specific way. For the discovery of a novel efficient way to modify oligonucleotides, a series of single isonucleotide-incorporated antisense oligodeoxynucleotides have been synthesized, in which an isonucleotide was introduced at different positions of the sequences. The binding behaviors of modified oligodeoxynucleotides to the complementary sequence were studied by UV, CD, and molecular dynamics simulation. The results showed that although the incorporated isonucleotides at certain positions of the sequence interfere with the binding ability to a different extent, B-form duplexes were maintained and the binding abilities of the 3′-end-modified duplexes were better than the corresponding mismatched duplexes. The digestion of modified oligodeoxynucleotides by snake venom phosphodiesterase showed that an isonucleotide strongly antagonizes hydrolysis. The DNA/RNA hybrid formed by a modified oligodeoxynucleotide and its target RNA could activate RNase H. The 3′-end-modified antisense oligodeoxynucelotides inhibited S-glycoprotein expression of SARS-CoV at the mRNA levels in insect Sf9 cells. This study indicated the possibility of designing a novel and effective antisense oligodeoxynucleotide by incorporating an isonucleotide at the 3′-end of the sequence.

INTRODUCTION

Since the first report of the inhibition of Rous sarcoma viral replication by an antisense oligonucleotide in a cell culture in 1978 (*1*), antisense technology has been rapidly developed either in studying gene function or in developing genetic therapy. As a class of potential therapeutic agents, antisense oligonucleotides have been developed for the treatment of diseases such as cancer, inflammation, and virus infection (*2*, *3*). The first antisense drug (Vitravene/formivirsen) was approved by FDA for the treatment of CMV retinitis in patients with AIDS in 1998, and there are also dozens of antisense therapeutics in clinical trials (*4*). As antisense technology progressed to become a therapeutic option, several drawbacks have emerged that negatively affect its therapeutic efficacy. For example, natural oligodeoxynucleotides are readily degraded in the serum or in vivo and show poor uptake by the cell membrane. To improve the biostability of oligonucleotides, chemical modification is widely used. Among the modifications, the phosphorothioate oligodeoxynucleotide is most frequently used, which is resistant to nuclease digestion, is recognized by RNase H, and is easyily mass-produced. Though phosphorothioate oligodeoxynucleotides are currently used as the standard choice of chemically modified oligodeoxynucleotides, its non-sequence-specific protein binding leads to significant side effects, including complement activation, thrombocytopenia, inhibition of cell−matrix interaction, or reduction of cell proliferation (*5*). To overcome these limitations, intensive efforts were focused on the development of other kinds of chemically modified oligonucleotides, which were named as a second generation of oligonucleotides. For example, modifications of the 2′ position of riboses with electronegative substituents such as the 2′-*O*-(2-methoxy)ethyl (MOE) group (*6*) or a 2′-*O*,4′-*C*-methylene bridge (locked nucleic acid; LNA) were performed (*7*). Since such ribose modifications confer an RNA-like conformation to the oligonucleotide, they increase the target RNA binding affinity and cellular uptake. But on the other hand, the RNA-like conformation leads to the disappearance of the oligonucleotide's ability to activate RNase H which is considered to be an important pathway of antisense action. Therefore, the 2′-ribose-modified oligonucleotide has been successfully introduced only in the format of mixed-backbone analogues, in which the modified nucleotides are placed at the ends to leave an RNase H-compatible DNA gap (*8*).

Isonucleosides represent a novel class of nucleoside analogues in which the nucleobase is linked to various positions of ribose other than C-1′. Because of the shift of N-glycosidic bond, the chemical and enzymatic stabilities of the nucleoside are increased. Previous studies showed that homo-oligoisonucleotides antagonized the hydrolysis of snake venom phosphodiesterase. Furthermore, some kinds of homo-oligoisonucleotides also showed strong binding abilities to their complementary sequences though they were a little weaker than the native counterpart (Figure 1**a**, **b**, **c**) (*9*−*12*). The results suggested that antisense oligonucleotide constructed from isonucleotide could antagonize the hydrolysis of nuclease and give acceptable binding ability. A practical way is to build a mixed backbone, in which the isonucleotide is placed at the critical position of the sequence. 3′-Exonuclease is the most common nuclease in vivo. The isonucleotide-modified oligodeoxynucleotide at the 3′-end will provide a model for studying the effects of isonucleotide-modified antisense oligonucleotide. In this study, an 18-mer antisense sequence 5′- AAC ATC TCC TGA GGG AAC −3′, which was complementary to the mRNA region encoding spike (S) glycoprotein of the SARS-CoV (22398−22415bp) (*13*, *14*), was designed based on the reported strategy (*15*, *16*). An isonucleotide was incorporated at the 3′-end or

center of the sequence (Figure 1). The effects of the isonucleotide-modified antisense oligonucleotides on the binding ability, nuclease degradation, and RNase H activity were investigated. Molecular dynamics simulation was used to evaluate the effects of incorporation of isonucleotide on the regularity of duplex formation. Meanwhile, the oligodeoxynucleotide with an isonucleotide incorporated at the center of the sequence and mismatched oligonucleotides were also used as controls. It was reported that the existence of hydroxymethyl group on the isonucleotide could affect the binding ability of duplex formation very obviously (*11*), the allyl group-protected isonucleotide was also used for studying the effect of a hydroxyl group on the duplex formation of modified oligonucleotides.

EXPERIMENTAL SECTION

General. Chemical reagents were purchased from Acros or Sigma Co. Column chromatography was performed on silica gel (200−300 mesh; Qingdao Chemical Co.). UV spectra were recorded with a Varian Cary 300 Bio UV-visible spectrophotometer. NMR spectra were recorded on a Varian VXR-300 or Varian Inova-500 with TMS as internal standard. FAB-MS was determined with a VG-ZAB−HS.

Synthesis. *6′-O-Benzoyl-1′-dimethoxytrityl-4′-deoxy-3′-O-(2-cyanoethyl-N,N-diisopropyl)phosphoramidite-4-(N⁶-benzoyladenin-9-yl) -2′,5′-anhydro-*L*-mannitol (**3**).* All reagents were deoxygenated before use. 6′-*O*-Benzoyl-1′-dimethoxytrityl-4′-deoxy-4-(*N*⁶-benzoyladenin-9-yl)-2′,5′-anhydro-L-mannitol (**2**) (460 mg, 0.58 mmol) was dissolved in dry THF (8 mL) under an atmosphere of argon. Diisopropylethylamine (DIPEA) (0.41 mL, 2.5 mmol) was added at 0 °C, followed by adding dropwise 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphordiamidite (0.28 mL, 0.88 mmol). Ten minutes later, a white precipitate appeared. After the mixture was kept at room temperature for 30 min, methanol (1 mL) was added and white precipitate disappeared in 10 min. The solution was diluted with EtOAc (25 mL) and extracted with 5% $NaHCO_3$ (10 mL × 2), saturated aqueous NaCl (10 mL × 1), and deionized H_2O (10 mL × 1) in turn. The aqueous phase was extracted with EtOAc (15 mL), and the combined organic layer was dried with anhydrous Na_2SO_4. After filtration and concentration, the residue was applied to flash silica gel chromatography eluting with cyclohexane/ dichloromethane/acetic acetate (10:1:1−4:1:1, 0.5% Et_3N) to give compound **3** (485 mg, white foam, 84%).

*6′-O-Allyl-1′-O-dimethoxytrityl-4′-deoxy-3′-O-(2-cyanoethyl-N,N-diisopropyl)phosphoramidite-4′-(N⁶-benzoyladenin-9-yl)-2′,5′-anhydro-*L*-mannitol (**6**).* Compound **6** was prepared from 6′-*O*-allyl-1′-*O*-dimethoxytrityl-4′-deoxy-4′-(*N*⁶-benzoyladenin-9-yl)-2′,5′-anhydro-L-mannitol (**5**) in a similar approach to the preparation of compound **3** from **2** in 84.0% yield as white foam.

Solid-Phase Synthesis of Oligodeoxynucleotides. Oligodeoxynucleotide synthesis was carried out in 1 μmoL scale with a DNA synthesizer model 392 (Applied Biosystem) applying regular phosphoramidite chemistry. The isonucleotide monomer (compound **3** or **6**) was incorporated into the proper position based on the requirement of the oligodeoxynucleotide sequence. Cleavage and deprotection of the oligomers were performed in concentrated ammonium at 50 °C for 24 h. The crude product was purified by 15% PAGE (7 moL·L^{-1} urea) and desalted by C18 column. The pure oligonucleoties were lyophilized and stored at −20 °C.

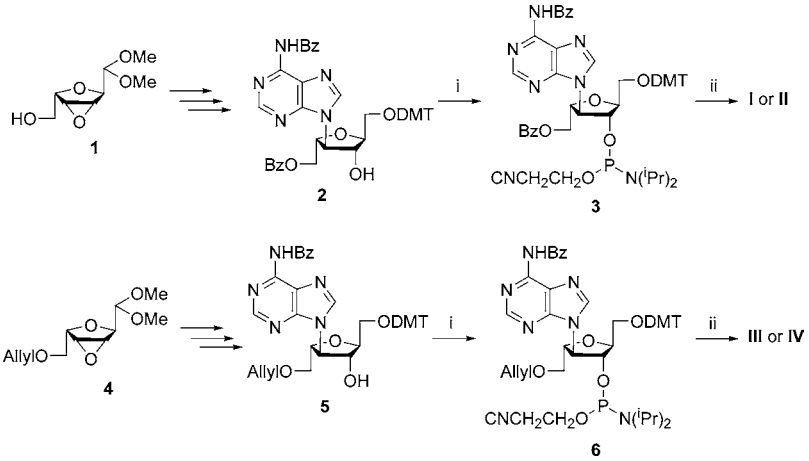
Thermal Denaturation and Circular Dichroism Studies. Oligodeoxynucleotide and its complementary sequence at an equivalent concentration (6 μmoL·L^{-1}) were heated to 80 °C in the buffer solution (0.14 M NaCl, 0.01 M Na_2HPO_4, pH 7.2, 1.0 M EDTA) and then cooled to room-temperature slowly. The hyperchromicity curves of the hybridized duplex were recorded on a Varian Cary 300 Bio UV-visible spectrophotometer. CD spectra were recorded by a JASCO J-715 spectropolarimeter at 15 °C in a thermostatically controlled 1 cm cuvette.

Molecular Modeling. All calculations were performed on an SGI OCTANE 2 workstation. The initial structures of DNA duplexes were built from the canonical B-form structure using Insight II simulation program. The AMBER 7.0 suite of molecular simulation programs and ff99 force field were used in the computations (*17*). The molecular mechanical parameters of isonucleotides were obtained using Gaussian 98 program under HF/6-31G** level of theory. The constructed oligodeoxynucleotide duplex was immersed in a periodic TIP3P water box, which extended 10 Å away from any solute atom. This yielded about 4400 water molecules used for solvation. To neutralize the negative charges of simulated molecules, Na^+ counterions were placed next to each phosphate group.

Molecular dynamics (MD) simulations were carried out by using the SANDER module of AMBER 7.0 with SHAKE algorithm applied to hydrogen atoms. Each simulation began with 1000 steps of minimization followed by 25 ps of equilibration dynamics at 300 K with full constraints on duplex and a 9-Å nonbonded Lennard−Jones cutoff. The duplex then was gradually allowed to relax by sequentially lowering restraints. The final production simulations of 1.5 ns for duplexes **I/VI**, **II/VI**, **III/VI**, or **IV/VI** and 1.0 ns for duplex **V/VI** were performed at constant pressure (1 atm) and temperature (300 K). The final structure of each duplex was obtained from the averaged structure of the last 800 ps of molecular dynamics calculation followed by 1000 steps of minimization. All duplexes were analyzed with CURVES 5.3 program.

Nuclease Resistance Analysis. The modified and unmodified oligodeoxynucleotides were 5′-^{32}p labeled with [γ-^{32}p]ATP using T_4 polynucleotide kinase. Labeled material was purified by gel electrophoresis on 20% 7M urea polyacrylamide gels. ^{32}p-labeled DNA was incubated with 100 ng of snake venom phosphodiesterase I in buffer,

Scheme 1. Synthesis of Isonucleotide-Incorporated Oligodeoxynucleotides[a]



[a] Reagents and conditions: (i) DIPEA, 2-cyanoethyl *N*,*N*,*N*′,*N*′-tetraisopropylphosphorodiamidite, THF, rt; (ii) solid-phase DNA synthesis.

which contained 50 mM Tris-HCl (pH 8), 5 mM $MgCl_2$ at 21 °C. Total reaction volume was 50 μL. After 10 min, aliquots were mixed with 100 μL of stop solution which contained 0.05% (w/v) bromophenol blue and 0.05% (w/v) xylene cyanol in 95% formamide. Aliquots were subjected to 20% polyacrylamide gel electrophoresis and visualized by autoradiography.

In Vitro Transcript of SARS Fragment. The 75 nt of SARS-CoV DNA fragment corresponding to nucleotides 22380 to 22455 was generated by PCR amplification using the DNA template (gift from Beijing Institute of Genomics) and primers 5′-ATT TAG GTG ACA CTA TAG AAC CTC TAA TTT CAG GG-3′ (sense primer) or 5′-CTC CAA AAG GAC ACA AGT TTG TAA-3′(antisense primer). Sp6 promotor sequence was introduced at the 5′-end by the use of primers. All PCR products were sequenced prior to in vitro transcription. Transcription was performed directly from PCR-amplifying DNA fragments using sp6 RNA polymerase. RNAs were purified by gel electrophoresis on 20% 7 M urea polyacrylamide gels.

RNase H Cleavage. The in vitro transripted RNAs of SARS fragment were 5′-^{32}p labeled with [γ-^{32}p]ATP as described above. ^{32}p-labeled RNA and the modified or unmodified oligonucleotides were incubated with 0.5 units of RNase H and 50 units of RNase inhibitor in buffer for 30 min at 21 °C. The buffer contained 50 mM Tris-HCl (pH 8), 10 mM $MgCl_2$, and 5 mM DTT. Loading buffer (30% glycerol with 0.14 nM bromophenol blue, and 0.19 nM xylene cyanol FF) was added, and samples were loaded on a 20% polyacrylamide gel and run at room temperature and recorded by autoradiography.

Infection of Sf9 Cells with Viruses and Antisense Oligonucleotides Treatment. Sf9 cells (fall armyworm ovary, *S. frugiperda*) were cultured in Sf-900 II SFM medium (Sigma) supplemented with 10% heat-inactivated fetal bovine serum (FBS) at 27 °C. The recombinant baculoviruses routinely propagated and titrated by plaque assay in Sf9 cells and working virus stocks were stored frozen in the dark at −80 °C.

Sf9 cells were subcultured prior to antisense oligodeoxynucleotide treatment and maintained in logarithmic growth phase with viability of 98%. The oligodeoxynucleotide was added to Sf9 cells after the recombinant baculoviruses inoculated for 24 h. Each monolayer of Sf9 cells at 7×10^4 cells/well in six-well plates were transfected with oligodeoxynucleotide by liposome-mediated transfection with lipofectamine (Invitrogen). After 4 h, the medium was replaced with SFM medium supplemented with 10% heat-inactivated fetal bovine serum, and culture was continued with fresh medium containing the oligodeoxynucleotide. Plates of each transfected group were treated with recombinant baculoviruses. The same amounts of viruses were inoculated at 27 °C as control.

RT-PCR Analysis. Total RNA was extracted from control and antisense oligonucleotide-treated cells using Trizol (Invitrogen). RNA concentrations were determined spectrophotometrically from the absorbencies of samples at 260 nm. RT-PCR was performed using the SuperScript One Step RT-PCR System (Invitrogen) following the instructions of the manufacturer. Forward and reverse primers for SARS gene were 5′-CCA CCT CTG CTC ACT GAT GAT AT-3′ and 5′-CCT TGT TAA ATT GGT TGG CGA TTT GTT-3′, respectively, which amplified a fragment of 205 bp. GAPDH mRNA was used as an internal control, and the primers were 5′-CGG GAA ACT GTG GCG TGA TGG-3′ (forward) and GTC GCT GTT GAA GTC AGA GGA GA-3′ (reverse). The expected product was 292 bp. RT-PCR was performed using 100 ng of total RNA. Each reaction contained 0.2 μM forward and reverse gene-specific primers in addition to reagents present in the SuperScript PCR buffer. RNA was reverse-transcribed for 50 min at 42 °C and then subjected to 30 cycles of PCR (94 °C, 30 s; 55 °C, 40 s; 72 °C, 50 s). Samples were analyzed on 2% agarose gels.

Western Blot Analysis. Protein samples were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS−PAGE) and transferred to nitrocellulose membrane (Amersham Pharmacia Biotech). The membrane was blocked with 5% skim milk in TBST (20 mM Tris-HCl [pH 7.4], 150 mM NaCl, 0.1% Tween 20), reacted with anti-His antibody (Qiagen) at a 1:1000 dilution. Proteins were detected using horseradish peroxidase-conjugated anti-mouse immunoglobulin G (Sigma) and an enhanced chemiluminescence detection system (ECL; Amersham Pharmacia Biotech).

RESULTS AND DISSCUSSIONS

Synthesis. The phosphoramidite **3** and **6** were synthesized from the corresponding epoxides **1** and **4**, respectively (Scheme 1) (*18*). Compound **3**. ^{1}H NMR (500 MHz, DMSO-d_6) δ 0.58 (d, J = 7.0 Hz, 3H, CH_3), 0.74 (d, J = 6.5 Hz, 3H, CH_3), 0.92 (d, J = 7.0 Hz, 6H, CH_3), 1.18 (t, J = 7.0 Hz, 2H, CH_2CN), 2.41 (m, 2H, CH), 3.27 (m, 2H, H-1′), 3.45 (m, 2H, $-POCH_2$), 3.70 (s, 6H, OCH_3), 4.30 (m, 1H, H-2′), 4.53 (m, 2H, 6′-CH_2), 5.01 (m, 1H,

H-5′), 5.20 (m, 1H, 4′-H) 5.32 (m, 1H, 3′-H), 6.89 (d, J = 8.5 Hz, 4H, Ph-H), 7.21−7.40 (m, 8H, Ph-H), 7.55−7.65 (m, 7H, Ph-H), 7.78 (m, 2H, Ph-H), 8.05 (m, 2H, Ph-H), 8.67 (s, 1H, H-2), 8.69 (s, 1H, H-8), 11.20 (s, 1H, 6-NH). ^{31}P NMR: 151.7, 152.5. Compound **6:** ^{1}H NMR (500 MHz, DMSO-d_6): δ 0.56 (d, 3H, CH_3), 0.74 (d, J = 7.0 Hz, 3H, CH_3), 0.92 (d, J = 6.5 Hz, 6H, CH_3), 1.18 (t, J = 7.0 Hz, 2H, CH_2CN), 2.41 (m, 2H, 2CH), 3.20−3.38 (m, 4H, $POCH_2$, H-1′), 3.60 (m, 2H, H-6′), 3.75 (s, 6H, OCH_3), 3.99 (m, 2H, OCH_2 (allyl)), 4.21 (m, 1H, H-2′), 4.77 (m, 1H, H-5′), 5.02−5.20 (m, 2H, H-3′, H-4′), 5.22 (m, 2H, CH_2=), 5.85 (m, 1H, =CH), 6.90 (m, 5H, Ph-H), 7.20−7.34 (m, 7H, Ph-H), 7.48−7.65 (m, 9H, Ph-H), 8.05 (t, J = 5 Hz, 2H, Ph-H), 8.63 (s, 1H, H-2), 8.71 (s, 1H, H-8), 11.19 (s, 1H, 6-NH). ^{31}P NMR: 150.5, 150.1.

The isonucleotide-incorporated oligodeoxynucleotides were synthesized by using phosphoramidite solid-phase strategy. The syntheses were performed in an automated DNA/RNA synthesizer on a 1 μmol scale according to the regular phosphoramidite protocol except for a prolonged coupling time to ensure an adequate coupling yield when using phosphoramidite **3** or **6**. For convenience, the synthesis was started with commercially available cytosine-loaded controlled pore glass (CPG). The coupling efficiency was determined by the release of DMT, and the yield was over 92% for coupling isonucleotide phosphoramidite. After cleavage from the solid support and removal of the protecting groups with concentrated aqueous ammonia, the oligodeoxynucleotides were purified by PAGE and desalted by a C18 column. Four kinds of isonucleotide-incorporated oligonucleotides were synthesized, in which the isonucleotide was at the 3′-end or in the center of the sequence, and the 6′-OH of isonucleotide was free or protected by an allyl group. All oligonucleotides were confirmed by MALDI-TOF mass spectroscopy, and the masses were in good agreement with the calculated values. MALDI-TOF MS: **I**, 5590.2 (M + Na, calcd 5590.4); **II**, 5589.7 (M + Na, calcd 5590.4); **III**, 5548.5 (M + Na, calcd 5549.8,); **IV**, 5549.1 (M + Na, calcd 5549.8).

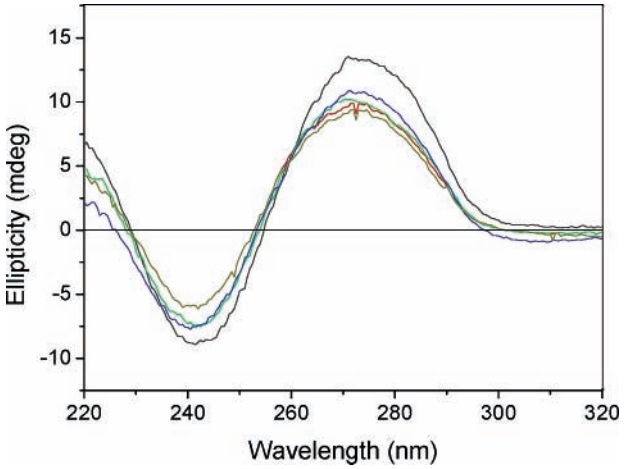

Figure 3. CD spectra of duplexes formed by the isonucleotide-modified oligodeoxynucleotides and their complementary sequence. Red, **I/VI**; green, **II/VI**; dark yellow, **III/VI**; blue: **IV/VI**; black, **V/VI**.

Binding Behaviors with Oligodeoxynucleotide. Thermal denaturation study was used to evaluate the duplex stability formed by isonucleotide-incorporated oligodeoxynucleotide and its complementary sequence (Figure 2). The result showed that the single isonucleotide incorporation interfered with the stability of the formed duplex, which depends on the position of incorporation. When isonucleotide was at the 3′-end of the sequence (**I**, **III**), the T_m value decreased about 3 °C compared with its natural counterpart (Table 1). When isonucleotide was in the center of the sequence (**II**, **IV**), the T_m value decreased about 7 °C. The different stabilities of the hybrid duplex might result from the different neighbor influence. When isonucleotide was at the end of the sequence, the effect would mainly involve one side of base pair, whereas when isonucleotide was in the central position of the sequence, the effects involve the base pairs of two sides. Comparing to the consecutive isonucleotide-incorporated oligonucleotide, which leads to a decrease of T_m of about 0.4 °C (*11*), single isonucleotide incorporation resulted in a more intensive decrease of duplex stability. The previous finding showed that the 6′-OH of the isonucleotide could stabilize the duplex formed by the homo-oligoisonucleotide and its complementary sequence. In this study no obvious difference was observed when the 6′-OH of the isonucleotide was free or protected, which indicated herein that the single 6′-OH did not affect the stability of duplex significantly. For comparison, one to three nucleoside-mismatched sequences (**VII**−**XII**) were also investigated. The results showed that when the isonucleotide was located at 3′-end, the duplex was more stable than the corresponding mismatched sequences, whereas when isonucleotide was located at the center of the sequence, the duplex was less stable than the corresponding single-nucleoside-mismatched sequence but was more stable than multi-nucleoside-mismatched sequence.

Circular dichroism (CD) spectra showed that the hybrid duplex formed by modified oligodeoxynucleotides and their complementary sequence possessed very similar conformations (Figure 3). Different from the consecutive isonucleotide-incorporated oligonucleotide, which formed a distorted B-form duplex when hybridized with

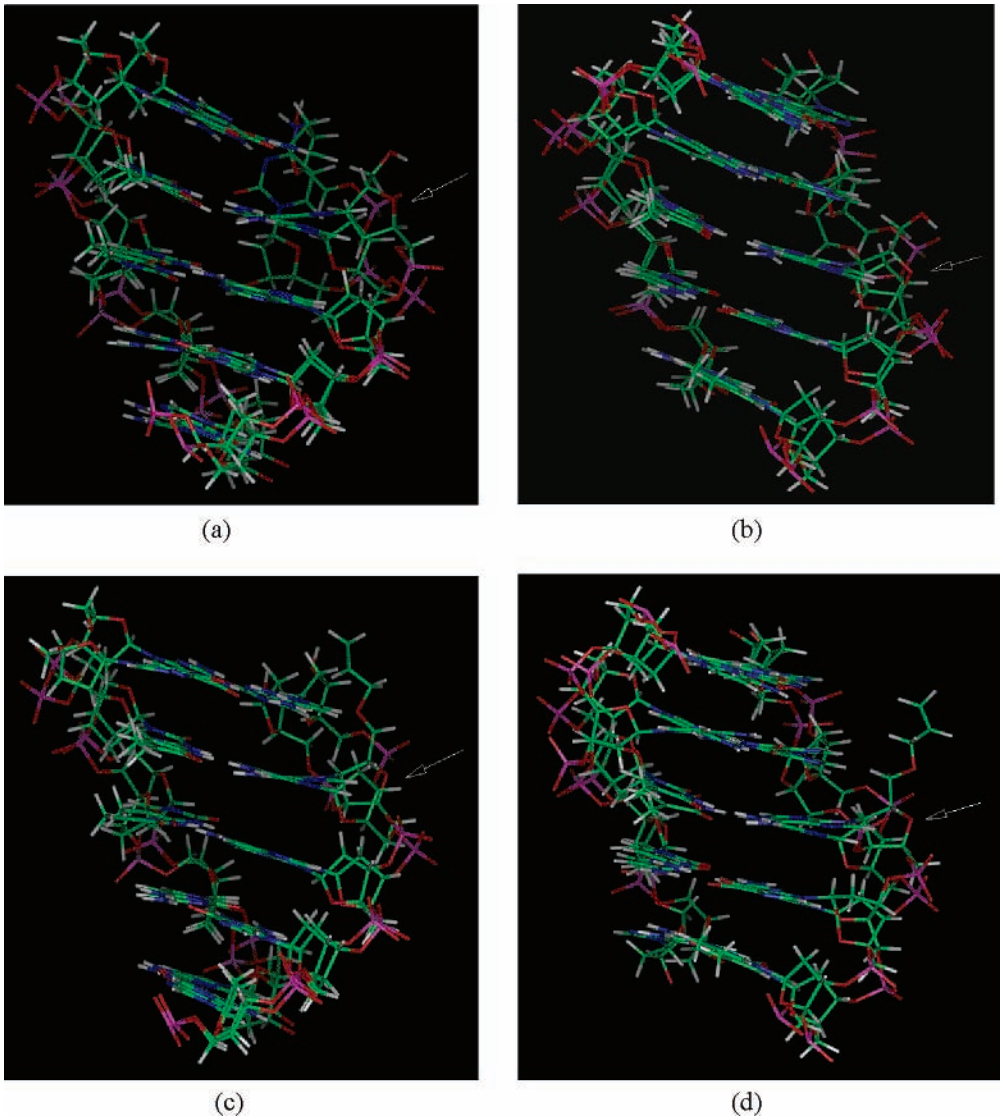

Figure 4. Overlap of simulated structures of isonucleotide-modified oligodeoxynucleotide-formed duplex with the native DNA duplex. The structures are from the part of the averaged structure of the last 800 ps molecular dynamics simulation. White arrows point to the position of the isonucleotide. (a) **I/VI**, (b) **II/VI**, (c) **III/VI**, (d) **IV/VI**.

its complementary sequence, the single isonucleotide-modified oligodeoxynucleotides formed typical B-form duplexes such as natural oligodeoxynucleotides. The computer simulation results also showed that B-form duplexes were maintained during the entire course of simulation. The result indicated that the incorporation of isonucleotide into the oligodeoxynucleotide might only lead to the local conformational change of the duplex. The averaged structure of the native DNA duplex was overlapped with the isonucleotide-modified duplexes, respectively. It clearly indicated that the helical parameters for the modified oligonucleotide duplexes were very similar to the native DNA duplex. The presence of the isonucleotides A_1 or A_2 mainly affected the local conformation of phosphorodiester backbone (Figure 4).

Strand−strand interactions of the five simulated DNA duplexes (**I/VI, II/VI, III/VI, IV/VI, and /V/VI**) were investigated (Table 2). The interaction energy (E_{inter}) was obtained from the total energy of the duplex (E_{duplex}) subtracted by the sum of two individual strands ($E_{strand1}$, $E_{strand2}$), i.e., $E_{inter} = E_{duplex} - (E_{strand1} + E_{strand2})$, and here the energy is composed of nonbonded van der Waals interaction and electrostatic interaction. The amount of interaction energy reflected the binding ability of oligodeoxynucleotide with its complementary sequence. The results indicated that the native DNA duplex **V/VI** possessed the strongest nonbonded interaction, and the duplexes **I/VI** and **III/VI** possessed stronger nonbonded interaction than duplexes **II/VI** or **IV/VI**. The calculated results were in good agreement with the thermal denaturation results.

Table 2. The Interaction Energy (kcal/mol) of the DNA Duplexes from the MD Trajectories[a]

duplex	E_{duplex}	$E_{strand1}$[b]	$E_{strand2}$[c]	E_{inter}
I/VI	−1156.1	−441.0	−386.4	−328.7
II/VI	−973.6	−325.7	−323.9	−324.0
III/VI	−1084.1	−418.2	−337.7	−328.2
IV/VI	−1121.2	−394.9	−404.0	−322.3

Nuclease Hydrolysis and RNase H Cleavage. The hydrolysis behaviors of 5′-^{32}P-labeled isonucleotide-incorporated oligodeoxynucleotides by snake venom phosphodiesterase (SVPDE) were observed by gel electrophoresis (Figure 5). The results showed that the controlled

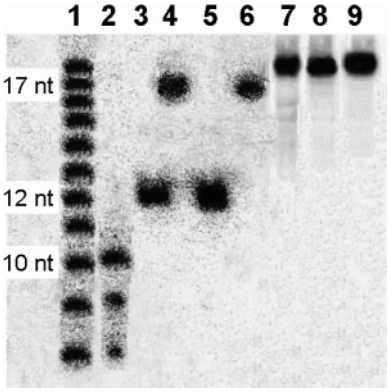

Figure 5. Autoradiogram of SVPDE digestion profiles of oligodeoxynucleotides. Lanes 1−6: marker, **V**, **II**, **I**, **IV**, **III**, respectively. Lanes 7−9: undigested oligonucleotide **V**, **I**, **III**, respectively.

natural oligodeoxynucleotide was completely hydrolyzed to small fragments after 10 min digestion, whereas the isonucleotide-incorporated oligodeoxynucleotide **I** or **III** was hydrolyzed to the 17-mer residues, and **II** or **IV** was hydrolyzed to 12-mer residue under the same conditions. The size of the hydrolyzed residues of the modified oligodeoxynucleotides was in accordance with the incorporation position of isonucleotide, i.e., the hydrolysis was inhibited at the point of isonucleotide substitution. The hydroxyl free or protected isonucleotides (**I** or **III**) have similar properties. Compared with some modified oligodeoxynucleotide, such as 2′-*O*-[2-(guanidium)ethyl]-modified oligonucleotide, which needs to have at least two consecutive modified nucleotides at the 3′-terminus for maintaining acceptable stability against exonuclease digestion (*19*), isonucleotide modification showed a much better antagonistic property. The result indicated that either hydroxymethyl free or protected isonucleotide could antagonize the activity of phosphodiesterase. It implied that an enzymatic stable oligonucleotide could be constructed by incorporating isonucleotide to the ends of oligodeoxynucleotide.

RNA cleavage by RNase H in the DNA/RNA hybrid was investigated (Figure 6). After the hybrid duplexes were digested by RNase H for 30 min, DNA/RNA hydrids showed different digestion patterns. Though the digested RNA fragments have not been investigated in this study, the efficiency of RNase H digestion in the presence of different oligodeoxynucleotides could be determined by measuring the intact RNA band in each lane. In general, the extent of the target RNA cleavage by RNase H in the hybrids formed by isonucleotide-modified DNA/RNA duplexes is higher than in the natural DNA/RNA. Both kinds of isonucleotide-modified oligodeoxynucleotides yielded similar RNA cleavage patterns. The results showed that the efficiency of RNase H cleavage in the presence of free or allyl-protected hydroxymethy isonucleotide-modified or unmodified oligodeoxynucleotides were in the order of allyl (**III**, **IV**) > free (**I**, **II**) > normal (**V**). It was reported that the efficiency of RNase H digestion was dependent on the feasibility of the formation of the DNA/RNA/RNase H complex, which was associated with many factors, such as the necessity of an A-form duplex, the width of the minor groove, and the duplex stability (*20*). Our result implied that the modified oligodeoxynucleotide sequences **III** and **IV** were more suitable for the formation of the DNA/RNA/RNase H complex. It was in inverse accordance with their binding abilities to the complementary sequences. The

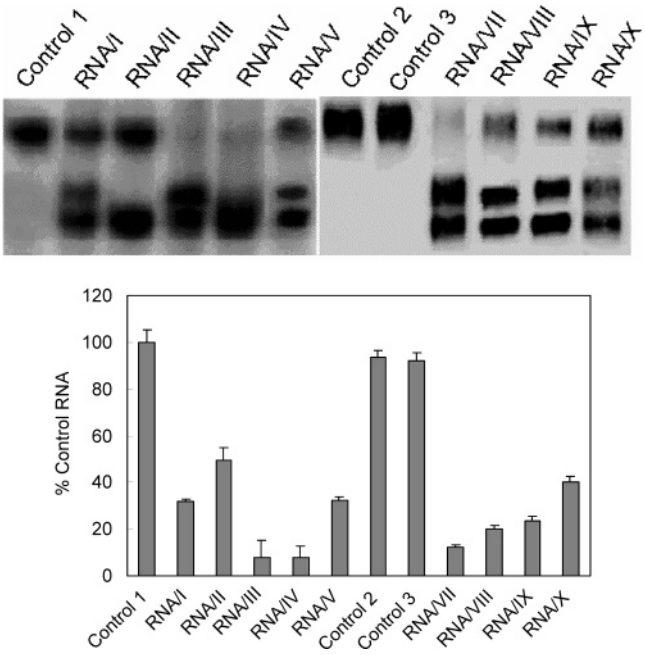

Figure 6. Autoradiogram of 5′-end-[γ-^{32}P]-labeled RNA treated with RNase H in the presence of isonucleotide-incorporated antisense oligodeoxynucleotide or mismatched antisense oligonucleotide. Control 1: RNA, control 2: RNA + RNase H, control 3: RNA + **V**.

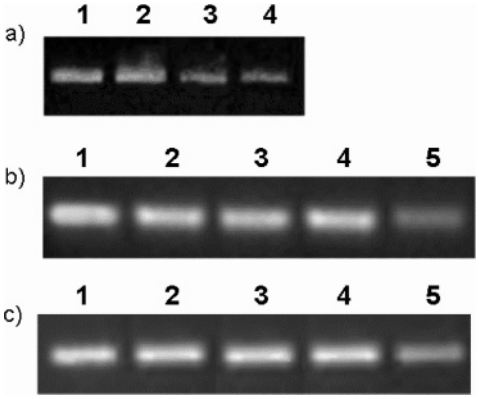

Figure 7. Effects of modified or mismatched antisense oligodeoxynucleotides on SARS coronavirus spike protein gene mRNA expression upon treatment at 50 μmol/L for 36 h. (a). sequences with nucleotides mismatched at the 3′-end (**VII**, **VIII**, **IX**, and **X**) also showed some efficient digestions.

Antisense-Induced Down-Regulation of S Protein. To determine the effect of 3′-isonucleotide-modified antisense oligodeoxynucleotides on gene expression of SARS coronavirus spike protein, Sf9 cells were transfected with 50 μM of oligodeoxynucleotides **I**, **III**, and **V** or mismatched controls **VII**−**IX**, and total RNA was isolated after 36 h. The level of SARS RNA was determined by RT-PCR. A remarkable decrease in gene expression of spike protein was observed in the cells treated by modified oligodeoxynucleotide **I** or **III**, whereas no obvious change was observed after the cell was treated by controlled native or mismatched antisense oligonucleotide (Figure 7).

The concentration dependence of gene expression in samples incubated with various concentrations of oligodeoxynucleotide **I** or **III** was investigated (Figure 8).

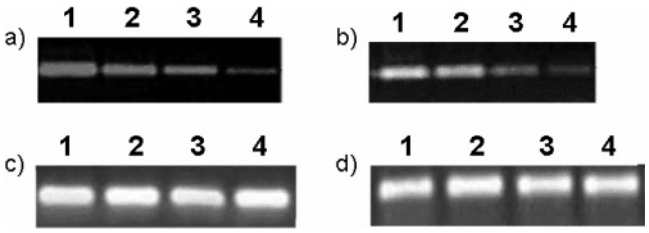

Figure 8. Effects of various concentrations of isonucleotide-incorporated antisense oligodeoxynucleotide on SARS coronavirus spike protein gene mRNA or on GAPDH mRNA after 36 h of treatment. Lanes 1−4: 0, 1, 10, 100 μmol/L, respectively. (a) (SARS-CoV, **I**), (b) (SARS-CoV, **III**), (c) (GAPDH, **I**), (d) (GADPH, **III**).

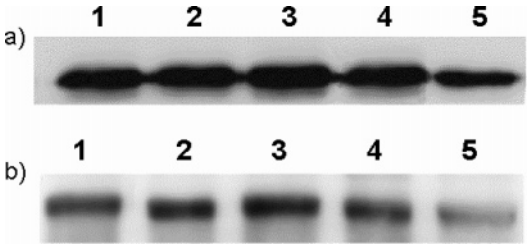

Figure 9. Effects of oligonucleotide on SARS coronavirus spike protein gene protein levels upon treated at 50 μmol/L for 36 h. Lane 1: negative control, lane 2−4: **VII**−**IX**, lane 5: **I** (a), **III** (b).

These data indicated that the modified oligodeoxynucleotide was able to inhibit transcription of the endogenous spike protein gene and was more effective than the native counterpart. We also measured the levels of glyceraldehyde-3-phosphate dehydrogenase (GAPDH). As expected, the expression of the GAPDH was not affected in these treated samples (Figure 8c,d). Western blot showed that modified oligodeoxynucleotides **I** and **III** decreased the protein expression remarkably and that **III** was stronger than **I**, whereas one to three mismatch controls (**VII**, **VIII**, **IX**) had almost no effect on the gene expression protein levels (Figure 9).

In conclusion, isonucleotide-modified oligodeoxynucleotides strongly antagonized the hydrolysis of snake venom phosphodiesterase. Furthermore, the modified antisense oligodeoxynucleotide also activated the RNase H though the incorporation of an isonucleotide into the oligodeoxynucleotide which led to a change of local conformation of the duplex. It was found that the 3′-isonucleotide-modified antisense oligodeoxynucelotides inhibited S glycoprotein expression of SARS-CoV at the mRNA levels in the insect Sf9 cells. The inhibition was dependent upon the concentration of the antisense oligomer. Therefore, this study provided a new strategy of designing a novel and effective antisense oligodeoxynucleotide by incorporating an isonucleotide at the 3′-end of the sequence.

ACKNOWLEDGMENT

This work was supported by the National Natural Science Foundation of China (20132030, SFCBIC 20320130046). Insect cell Sf9 and the recombinant baculoviruses used in this study were kindly provided by Professor Jianguo Chen (Peking University, Beijing, China).

Micropattern Printing of Adhesion, Spreading, and Migration Peptides on Poly(tetrafluoroethylene) Films To Promote Endothelialization

Virginie Gauvreau[†] and Gaétan Laroche*[,†,‡]

Unité de Biotechnologie et de Bioingénierie, Centre de Recherche de l'Hôpital Saint-François d'Assise, C.H.U.Q., 10 rue de l'Espinay, Québec, Québec, Canada, G1L 3L5, and Département de Génie des Mines, de la Métallurgie et des Matériaux, Centre de Recherche en Science et en Ingénierie des Macromolécules, Faculté des sciences et génie, Université Laval, Québec, Québec, Canada, G1K 7P4. Received November 26, 2004; Revised Manuscript Received May 6, 2005

We report here the development of an original multistep micropatterning technique for printing peptides on surfaces, based on the ink-jet printer technology. Contrary to most micropatterning methods used nowadays, this technique is advantageous because it allows displaying 2D-arrays of multiple biomolecules. Moreover, this low cost procedure allies the advantages of computer-aided design with high flexibility and reproducibility. A Hewlett-Packard printer was modified to print peptide solutions, and Adobe Illustrator was used as the graphic-editing software to design high-resolution checkerboard-like micropatterns. In a first step, PTFE films were treated with ammonia plasma to introduce amino groups on the surface. These chemical functionalities were reacted with heterobifunctional cross-linker sulfo-succinimidyl 4-(*N*-maleimidomethyl)cycloexane-1-carboxylate (S-SMCC) to allow the subsequent surface covalent conjugation of various cysteine-modified peptides to the polymer substrate. These peptidic molecules containing RGD and WQPPRARI sequences were selected for their adhesive, spreading, and migrational properties toward endothelial cells. On one hand, our data demonstrated that the initial cell adhesion does not depend on the chemical structure and combination of the peptides covalently bonded either through conventional conjugation or micropatterning. On the other hand, spreading and migration of endothelial cells is clearly enhanced while coconjugating the GRGDS peptide in conjunction with WQPPRARI. This behavior is further improved by micropatterning these peptides on specific areas of the polymer surface.

INTRODUCTION

The surface of cells displays a complex combination of receptors and ligands to mediate cell adhesion, spreading, migration, proliferation, and communication. These receptors and ligands are protein molecules that clasp one another like a lock and a key. Typically, receptors are proteins integrated in the cell membrane with domains extending beyond the membrane either or both inside and outside the cell. Ligands are proteins integrated in a neighboring cell membrane, part of the extracellular matrix or freely diffusing in the cell environment. Via receptor and ligand links, cells attach to each other and to the matrix to form tissue structure. Ligands from the milieu may code for a cell to adhere, to migrate, to grow and proliferate, or even to die. A well-known example of this is the $\alpha_5\beta_1$ integrin receptor that attaches with fibronectin proteins of the extracellular matrix, more specifically at the RGD binding site (*1*). A multitude of different receptors are present on the surface of a single cell at any given moment. Likewise, an impressive diversity of ligands are present on the extracellular matrix.

For over a decade, various proteins have been immobilized on polymer surfaces to enhance endothelial cells adhesion (*2*−*5*). Multiple strategies have been employed to that end, the most common being adsorption or grafting of fibronectin (*6*−*8*) and RGD peptides (*9, 10*). The common point between these strategies is that they all aim to mimic the extracellular matrix normally supporting and interacting with cells, hence possibly leading to a better integration and a more natural host response to the biomaterial.

It is known that vascular grafts that could support a layer of endothelial cells would have better resistance to thrombosis and graft stenosis in long-term applications (*11, 12*). In this study, RGD type peptides were grafted on the PTFE surface because this sequence is widely acknowledged as a cell-binding signal (*13, 14*), the goal being to promote in vivo endothelialization of ePTFE arterial prosthesis. RGD was originally identified as the fibronectin receptor sequence of the integrin $\alpha_5\beta_1$, but nowadays it has been identified as a recognition motif for various ligands of several different integrins (*15*). It is found in numerous plasma and extracellular matrix proteins such as fibronectin, vitronectin, and type I collagen (*1*). Massia et al. in the 1990s have investigated human umbilical vein endothelial cells (HUVECs) attachment, spreading, and cytoskeletal organization on substrates covalently grafted with RGD peptides (*4*). They observed that this strategy enhanced cell adhesion on substrates such as glycophase glass, poly(ethylene terephthalate) (PET), and poly(tetrafluoroethylene) (PTFE) that were otherwise repellent to cells.

Fundamental to the development of biologically integrated biomaterials is the ability to display a micropat-

terned array of several specifically targeted ligands to mimic the extracellular matrix on the polymer surfaces. Since 1978, with MacAlear and Wehrung, who applied the photoresist technology from the semiconductor industry to create patterns on an underlying compressed proteinaceous layer (*16, 17*), several other techniques have been examined in the fields of micro- and nanopatterning to create two-dimensional arrays of proteins or other biologically active molecules on surfaces. These techniques include photoresist lithography, photochemistry, and self-assembled monolayers (*18*).

While each of these micropatterning techniques may be useful for some applications, each also has inherent limitations, for the most part concerning multiple protein binding, nonspecific binding, and immobilization of proteins while retaining their maximum biological activity (*18*).

In most cases, protein micropatterning is simply about immobilization through physical adsorption of proteins to a surface (*19, 20*). Entropy drives protein adsorption which always results from attractive forces such as ionic, hydrophobic, or van der Waals interactions (*21*). A more stable means to immobilize proteins to surfaces is to covalently bind the proteins to the surfaces via the use of heterobifunctional cross-linkers such as silanes (*22*), which bind at one end to a glass surface via a silanol group and to a protein at the other end via a variable pendant group. Finally, another way to provide a stable immobilization of proteins to surfaces is through the use of high-affinity ligand pairs such as avidin−biotin (*23*).

The central hypothesis of this study was that adhesion, spreading, and migration signals should be simultaneously present on the surface of arterial grafts to promote complete integration and endothelialization. Thus, in addition to RGD adhesion peptides, spreading and migration peptides should be present on the surface. The amino acid sequence WQPPRARI originating from the 33kDa fragment of the A chain of fibronectin was recognized in the literature (*24, 25*) for enhancing adhesion, spreading and migration of endothelial cells. It was therefore selected as the second signal to be grafted on the PTFE surface for the purpose of this study.

In this work, surface modifications were performed on Teflon (PTFE) films since small diameter arterial grafts are in general made of ePTFE, i.e., microporous or expanded PTFE. The first step of our approach consisted in an ammonia plasma treatment allowing the incorporation of amino groups on the PTFE surface. These highly reactive functionalities were conjugated, in a second step, with the heterobifunctional cross-linker Sulfo-SMCC, thus introducing maleimide functionalities on the PTFE surface. To exploit the very straightforward reaction between these maleimido groups and thiolic groups, the various peptides were synthesized with a cysteine at their terminal end. This study was thus performed with the peptide sequences CRGD, CGRGDS, and CWQPPRARI. Next, to graft this variety of specifically targeted peptides simultaneously on the polymer surface, we chose to develop a novel multistep micropatterning technique based on the ink-jet printing technology. This very advantageous ink-jet microprinting technique is an ultralow cost procedure that allows the flexibility of computer-aided design. The color cartridge of a commercial Hewlett-Packard printer (HP DeskJet 5500) was simply modified to print the biological peptide solutions according to a defined micropattern designed using Adobe Illustrator as the graphic-editing software. This micropatterning technique enabled rapid and precise deposition of both adhesion and migration peptides on PTFE films.

EXPERIMENTAL SECTION

Materials. Poly(tetrafluoroethylene) (Teflon or PTFE) films 0.05 mm thick were purchased from Goodfellow (Huntingdon, England). Vapor-phase chemical derivatization was performed with 5-bromosalicylaldehyde purchased from Sigma, St Louis, MO. The cross-linker sulfosuccinimidyl-4-(*N*-maleidomethyl)cyclohexane-1-carboxylate (S-SMCC) to be grafted on the PTFE surface was also obtained from Sigma. The various peptide sequences (CRGD, CGRGDS, CRGE, CRGDY, and CWQPPRARI) grafted on the polymer surface were synthesized by Service de synthèse de peptides de l′est du Québec, CHUQ, Québec, QC, Canada. Peptide solutions were prepared in phosphate-buffered saline (PBS) and glycerol that were purchased from VWR Canlab, Ville Mont-Royal, QC, Canada and Laboratoire MAT, Montréal, QC, Canada, respectively. The buffer solutions were prepared in filtered, deionized water (Nanopure system) while fine adjustments of the pH were made by adding either 0.1 M of HCl or NaOH to reach the desired value. CRGDY peptides were iodated using Iodo-Beads Iodination Reagent from Pierce, Brockville, ON, Canada, and sodium iodide from Sigma. All chemicals were of commercial grades of highest purity and were used without further purification.

The cell culture experiments were performed with human umbilical vein endothelial cells (HUVECs) recolted and cultured at our lab. The culture medium M199 supplemented with 0.09 g/L of heparin sodium salt and the porcine gelatin were purchased from Sigma. This medium was also supplemented with fetal bovine serum (FBS) provided by Wiscent, St-Bruno, Qc, Canada, and endothelial cell growth supplement (ECGS) provided by VWR Canlab. Cells were cultured in 25 cm^2 tissue culture-treated polystyrene flasks or plated in 48-well culture plates from BD Falcon. Trypsin-EDTA used to detach the cells from the culture surfaces was purchased at Invitrogen Canada inc., Burlington, ON, Canada. Rezasurine purchased from Sigma was used for fluorescence emission. Products required for HUVECs fixation and staining procedures including formaldehyde, bovine serum albumin (BSA), Saponine, 4′,6-diamidino-2-phenylindole (DAPI), Rhodamine−Phalloidine, and Tween 20 were also acquired from Sigma.

Methods. *Ammonia Plasma Treatment.* The ammonia radiofrequency (rf) plasma treatment and system apparatus were previously described elsewhere (*26, 27*). Briefly, the treatments were performed at a rf power of 20 W and a pressure of 300 mTorr for 100 s using high purity ammonia gas. The 3 cm × 3 cm PTFE films were held by a Teflon-made circular sample holder and treated in a cylindrical plasma chamber. Using such a plasma configuration and geometry allows to modify only the internal side of the film.

Surface Functionalization. The cross-linker S-SMCC was reacted with the ammonia plasma-treated film in 3 mg/mL of reagent in PBS 0.2 M at pH 7.4. The reaction was then allowed to proceed for 2 h in a nitrogen environment and under low light intensity to protect the reagents against UV-induced degradation. The characterization of this reaction has been presented elsewhere (*28*). Briefly, this reaction is complete and allows the introduction of maleimido groups on the PTFE surface. These functions were used to subsequently conjugate the

peptides through a sulfhydryl containing N-terminal Cystein residue.

Peptide Solutions. The peptide sequences CRGD, CGRGDS, CRGE, CRGDY, and CWQPPRARI were synthesized and solutions of 10 μg peptide/μL of PBS 0.2M at pH 7.4 containing 7.5% glycerol were prepared. Glycerol was added to prevent rapid evaporation of the solution when the peptides were printed and to adjust the peptide solution viscosity to a value similar to that of the ink normally used by the printer. These solutions were used either to print the peptides or homogeneously conjugate them on the polymer surface. The occurrence of the peptide graftings on the SMCC-conjugated surfaces was ascertained by iodating a tyrosine-containing peptide (CRGDY) using Iodo-Beads and sodium iodide (*29*) using one bead to iodinate 0.2 mg of peptides. CRGDY peptides were first iodated and then grafted to the PTFE surface. The I3d XPS signal was used to confirm the peptide conjugation.

Ink-Jet Printer. A commercial HP 5500 Deskjet printer was modified to print the peptide solutions. We carefully chose this printer because it offered an optimized resolution up to 4800 dots per inch (dpi) according to the manufacturer and most importantly because the cartridges were not monocoque, as are most of the new generation cartridges. Therefore, these cartridges could be refilled easily. First, the top of the tricolor cartridge HP#57 was cut so as to leave the contour in place, since it was essential to click the cartridge back in the cradle; the internal sponges made of polyurethane foam were then removed as well as the little grids and filter-papers covering the wells. The cartridges were then extensively washed with deionized water and ethanol. The peptide solutions were then deposited with micropipets directly into the wells situated very next to the printhead.

Calibration of the Printer. The ink-jet printer drivers interpret the colors drawn on the computer screen that intrinsically work in RGB (red, green, blue) color-space, or additive light, to print them with a CMYK (cyan, magenta, yellow, black) color cartridge, or subtractive light. Therefore, it is essential to carefully calibrate the printer so that it prints pure color, or in this case, pure peptide and not a mixture of the peptide solutions. It is recommended to work in RGB color space if the artwork will only be displayed on-screen in the case of a web-site for example, and in CMYK if the work will be printed with a commercial printer (*30*), as the HP DeskJet 5500 used in this study. However, we tried both modes, looking at every printed surface with an optical microscope, and surprisingly it appeared that pure colors could be achieved more easily by working in RGB. Since the HP Deskjet printer used is targeted at the mass market, its drivers are probably not as trustwothy, in regard to color-space translation, as those of a real four-color-process commercial CMYK laser printer. Adobe Illustrator graphic-editing software was used to design the desired patterns and define the pure colors. In the RGB mode, fine color adjustments are obtained by adjusting the intensity of each color, or wavelength, on a scale from 0 to 255 (8 bits). The full spectrum of colors is then achieved by combination of the three scales. Since we are in the additive color space, 0, 0, 0 of red, green, blue would give black, and 255, 255, 255 would give white. On the basis of this knowledge, and verifying the printed surfaces with an optical microscope, we obtained pure cyan with 0, 255, 255, pure magenta with 255, 0, 255, and pure yellow with 255, 255, 0. However, printing 255, 255, 0 for example, meaning 100% yellow, deposited too much ink on the surface, and independent droplets combined together. For that reason, we reduced the quantity of ink for each droplet by incrementing the third factor to 100 (ex.: 255, 255, 100), therefore obtaining a lighter color.

Grafting Peptides in Solution and Printing Peptides. The same peptide solutions were use for control, i.e., peptides homogeneously conjugated on the polymer surface, and for printing. Conventional in-solution grafting was performed using 1 mL of the peptide solutions for each 1 cm^2 of plasma-treated SMCC-grafted PTFE films. The reaction was performed for 120 min at room temperature under mechanical agitation. To graft the peptides through the micropatterning technique, 30 μL of the solution of the individual peptide were micropipetted directly into the adjacent wells of the printer cartridge. The peptides were then printed on the ammonia plasma-treated SMCC-grafted PTFE films according to the micropattern designed using Adobe Illustrator software. Squares of 300 μm width of both adhesion peptides and spreading and migration peptides were printed next to the other just like a checkerboard. Concerns about the viscosity and the wetting properties of the peptide solutions affecting the quality of the arrays were considered. Moreover, to ensure the covalent grafting of the peptides to SMCC-grafted PTFE, the individual peptide spots had to remain in the aqueous form and not evaporate too rapidly. The viscosity of the solution was therefore adjusted with 7.5% glycerol (*31*). Printed surfaces were maintained in a humidification chamber for 120 min at room temperature.

X-ray Photoelectron Spectroscopy (XPS) Characterization. Immediately following the ammonia plasma treatment, samples of the aminated PTFE film were cut in a glovebox purged with dry nitrogen. These samples were analyzed by XPS without delay to assess the exact atomic composition of the surface following the plasma treatment. SMCC grafted surfaces, as well as all the peptide-grafted surfaces, were also analyzed by XPS after having been vacuum-dried overnight at ambient temperature. The XPS spectra were recorded using a PHI 5600-ci spectrometer (Physical Electronics, Eden Prairie, MN). A monochromatic aluminum X-ray source (1486.6 eV) at 400 W with neutralizer was used to record the survey spectra while high-resolution spectra were obtained using the monochromatic magnesium X-ray source (1253.6 eV) at 400 W without charge neutralization. The detection was performed at 45° with respect to the surface normal.

Amine Quantification. Samples of ammonia plasma-treated films were used to quantify the amine surface concentration through vapor-phase chemical derivatization using 5-bromosalicylaldehyde as described elsewhere (*26*). Briefly, the reaction was performed at 85 °C for 2 h in a sealed glass tube in which a 1 cm-thick bed of soda-lime glass beads was used to separate the reagent from the reactive surface. The surfaces were then vacuum-dried overnight at 40 °C and analyzed by XPS.

Endothelial Cell Culture. HUVECs were cultured in a 25 cm^2 tissue culture-treated polystyrene flasks covered with porcine gelatin. The culture medium M199 with heparin was supplemented with FBS and ECGS, and the cells were grown in a 37 °C incubator with a humidified atmosphere of 5% CO_2 and 95% air. For cell culture experiments, modified PTFE films of 27 mm^2 (5.86 mm of diameter) were deposited in a 48-well microplate and HUVECs were seeded at 50 000 cells/well for adhesion tests and 25 000 cells/well for proliferation tests. Adhesion measurements were performed for 2 h in a serum-free M199 medium to ensure that RGD peptides grafted to the surface, and not the serum protein contained in the medium, favored HUVEC adhesion to PTFE. For

spreading and migration measurements, the serum-free medium was removed from the wells after 2 h of adhesion and replaced by a fresh culture medium supplemented with serum and growth factor. Spreading and migration tests were performed for 72 h.

Counting the Number of HUVECs Adhered to Surfaces. After 2 h of adhesion, HUVECs seeded on different surfaces were detached in order to evaluate the number of cells capable of adhesion on the various peptide-grafted PTFE surfaces. The culture medium and nonadhered cells were first aspirated from the wells. The surfaces were then rinsed twice with PBS and the rinse transferred to new wells to prevent detachment and counting of cells adhered to the well walls. Cells were then detached from the surface using 90 μL of trypsin-EDTA per well and incubated at 37 °C for 3 min. Trypsin activity was then inhibited with 10 μL of FBS per well. Aliquots were withdrawn from each well, and cells were counted the usual way using a hemacytometer.
