The toxins usually used for conjugation are derived either from bacteria (e.g. *Pseudomonas* exotoxin A or diphtheria toxin (*3*, *4*)), or from plants (e.g. ricin or abrin (*5*)). Both types of toxins kill cells by inhibiting protein synthesis (*6*). To exert their effect these complexes must enter the cell, where only a portion of the internalized immunotoxin escapes degradation and reaches the cytoplasmic target. In some cases internalization can be a rate-limiting step, which reduces the immunotoxin efficacy. One way to overcome this problem is to use membrane-active toxins (*7*), such as hemolysins and cytolysins (*8*, *9*). These pore forming toxins attack the lipid phase of cell membranes disintegrating vital membrane functions. They could provide very powerful antitumoral drugs, when conjugated with an appropriate targeting molecule. Some examples of the construction of such molecules have been reported, using membrane damaging toxins of different origin e.g. from animals (cytolysins from sea anemones (*10*−*13*)), plants (*Pyrularia* thionin (*14*)) or from bacteria (*Bacillus thuringiensis* δ-endotoxin (*15*), *Staphylococcus aureus* α-toxin (*16*), *Bacillus anthracis* anthrax toxin (*17*)). However, the main problem of most of the immunotoxins constructed with membrane active proteins is the poor cellular specificity associated to the capacity of the toxin to bind to almost any cell membrane. The purpose of this study was to overcome much unspecificity. To this aim we present the construction of a modular inactive conjugate between a sea anemone cytolysin (the EqTII-I18C mutant) and avidin and its activation mediated by tumor cells proteases. To construct this tumor protease-activated pore-forming toxin we chose two classes of proteases, cathepsins and metalloproteinases (MMPs),[1] which are known to be associated to several tumors. Numerous reports in

the literature describe circumstantial evidence that cathepsin B and L contribute to tumor progression and metastasis (*18*, *19*). Cathepsin B is found at higher levels in a number of human cancers (i.e. colorectal, lung and bladder), suggesting that it may be useful as a diagnostic and prognostic marker. The MMPs are involved in a wide range of proteolytic events, in normal and pathological circumstances (*20*). Pathological processes involving MMPs include tumor growth and migration (*21*).

This approach is intended as a conceptual proof to demonstrate that a relatively simple chemistry could be used to conjugate a cytolysin to a ligand moiety via a peptide containing cleavage sites of tumor-associated proteolytic enzymes. We further demonstrated that the conjugate could be specifically cleaved by these enzymes, leading to its possible application as antitumoral drug. The advantage of the activable pore-forming system, for the construction of immunotoxins, is the reduction of the unspecific activity. In this way two mechanisms of target would be present in a single hybrid molecule, the recognizing of tumor cell through the ligand moiety and the specific activation of the toxin by the tumor-associated proteases.

EXPERIMENTAL PROCEDURES

Materials. *Actinia equina* equinatoxin II-I18C mutant was produced in an *E. coli* expression system as described previously (*22*). *N*-[6-(Biotinamido) hexyl]-3′-(2′-pyridyldithio)propionamide (biotin-HPDP) and bismaleimidohexane (BMH) were purchased from Pierce, the peptide NH_2-C-N-K-S-R-L-G-L-G-K-biotin-COOH was from Primm (Milan), cathepsin B, matrix metalloproteinase 7 (MMP-7), avidin, *N*-[(2*R*)-(hydroxamidocarbonylmethyl)-4-methylpentanoyl]-L-tryptophan methylamide (GM 6001) and cathepsin B substrate III (Z-R-R-AMC) from Calbiochem; 5,5′-dithio-bis-(2-nitrobenzoic acid) (DTNB or Ellman's reagent) from Acros; *trans*-epoxysuccinyl-L-leucylamido-(4-guanidino)butane (E64), dithiothreitol (DTT) and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were obtained from Sigma. The metalloproteinase specific substrate Mca-P-L-G-L-Dap(Dpn)-A-R-NH_2 was purchased from Bachem (catalog number M-1895), while Prionex (porcine hydrolyzed collagen of average mass 20 kDa) was purchased from Pentapharm Ltd.

Cell Lines. Cells used in these assays were ZR 751 (human breast carcinoma), MCF 7 (human breast adenocarcinoma) and HT 1080 (human fibrosarcoma) obtained from the Istituto Zooprofilattico Sperimentale (Brescia, Italy). After every week new cells were thawed and cultured in RPMI 1640 (ZR 751) or Eagle's minimum essential medium (MCF 7 and HT 1080) with 10% fetal bovine serum (FBS, EuroClone), 2 mM L-glutamine and 0.15 mg/mL gentamicin. The MCF 7 cell line was also supplemented with 1 mM sodium pyruvate. All reagents and media were obtained from Sigma.

Conjugation via HPDP. EqTII-I18C was incubated with biotin-HPDP in a 1:8 molar ratio in 20 mM Na_2HPO_4, 150 mM NaCl, 1 mM EDTA pH 7.4 for 90 min at room temperature. EqTII-I18C, that was S−S linked to biotin via a long spacer arm, was separated from unreacted HPDP using a HIC column (Metachem) equilibrated with 25 mM Na_2HPO_4, 0.5 M $(NH_4)_2SO_4$, pH 7. Elution was with a linear gradient of $(NH_4)_2SO_4$ decreasing from 100% to 0% in 15 min. When avidin was added, we obtained the following conjugated molecule: EqTII-I18C_S−S-$(CH_2)_2$CONH $(CH_2)_6$NH-biotin_avidin (or EqTII-I18C_biotin_avidin).

Conjugation Mediated by Ellman's Reagent or BMH. The cysteine of EqTII-I18C mutant was either activated by using the Ellman's reagent or covalently modified with the homobifunctional cross-linking reagent BMH. EqTII-I18C was incubated for 30 min at room temperature in 0.1 M Na_2HPO_4 pH 8 with Ellman's reagent in a probe to toxin molar ratio of 60:1. Alternatively, it was incubated in 20 mM Na_2HPO_4, 150 mM NaCl pH 7.0 with BMH for 30 min at room temperature in a probe:toxin molar ratio of 30:1. Excess of reagent was removed by desalting (Sephadex G-25, NAP-5 column, Pharmacia Biotech Amersham Bioscences). The resulting activated or modified EqTII-I18C was incubated with the biotinylated peptide in a peptide to toxin molar ratio of 40:1, at room temperature for 2 days, and again the excess of peptide was removed by gel filtration. An excess of avidin (avidin:biotinylated toxin in a 4:1 or 2:1 molar ratio) was added at room temperature, and after 1 h the resulting conjugate was purified from unbound components via HIC. The column was equilibrated with 25 mM Na_2HPO_4, 2 M $(NH_4)_2SO_4$ pH 7; the bilinear gradient of $(NH_4)_2SO_4$ was decreasing from 100% to 15% in 12 min and from 15% to 0% in 8 min. The concentration of the conjugate among the collected aliquots was estimated by measuring the absorbance at 280 nm and by titrating the hemolytic activity of the fractions before and after reduction with 2.5 mM DTT. The concentration of the conjugate was approximately calculated using a molar extinction coefficient of 132 840 M^{-1} cm^{-1} at 280 nm on the basis of a molar composition of one toxin per avidin molecule (confirmed by electrophoretic experiments, see Figure 3E). The conjugate produced with BMH was EqTII-I18C_S-maleimide-$(CH_2)_6$-maleimide-S-peptide-biotin_avidin, while by using Ellman's reagent, or no reagents at all, we obtained the following molecule: EqTII-I18C_S−S-peptide-biotin_avidin.

Enzymatic Digestion. Cathepsin B was first activated with 10 mM DTT at 37 °C for 15 min. For peptide digestion, a 1.2 mM peptide solution was incubated with activated cathepsin B (at final concentration of 3.5 μM) in 30 mM sodium acetate pH 5, or 0.35 mM peptide was incubated with 3.8 μM MMP-7 in 0.2 M NaCl, 50 mM Tris/HCl, 5 mM $CaCl_2$, 20 μM $ZnCl_2$ pH 7.6, both at 37 °C for 2 h. The specificity of the cleavage was checked by adding 50 μM E64 for cathepsin B or 8 μM GM6001 for MMP-7.

For conjugate digestion a 6.3 μM conjugate solution was incubated with activated cathepsin B (at final concentration of 0.9 μM) in 80 mM Na H_2PO_4 pH 5 or 2.8 μM conjugate was digested by 2.3 μM MMP-7 in 0.2 M NaCl, 50 mM Tris/HCl, 5 mM $CaCl_2$, 20 μM $ZnCl_2$ pH 7.6, at 37°C for 2 h. To check the specificity of the cleavage, parallel experiments were performed by adding 11.4 μM E64 or 4.7 μM GM6001, respectively.

In both cases the products were separated by hydrophobic interaction chromatography under the same conditions used for conjugate separation. The products of the conjugate digestion were also tested by hemolytic assays.

Mass Spectrometry Analysis. Digested peptides (same conditions as described above) were passed on a Jupiter C4 column by Phenomenex with a 15 min linear gradient from 5 to 95% acetonitrile in water. LC-MS analysis was performed on a Hewlett-Packard Series 1100 liquid chromatograph coupled to a Bruker Esquire-LC ion trap mass spectrometer equipped with an atmospheric pressure ESI interface. A Rheodyne 7725 (Cotati, CA) injection valve equipped with a 200 μL internal loop was used for the injections. The PDA (photodiode-array) detector (HP Series 1100) was set at a wavelength of 215 nm, and a 7:3 split of the column effluent was used to achieve a flow rate of 300 μL/min into the ESI source.

Hemolytic Assays. Hemolytic activity of EqTII-I18C and different conjugates was determined turbidimetrically at 650 nm with a microplate reader (UVmax from Molecular Devices, Sunnyvale, CA) supported by the computer program SOFTmax. Briefly, human RBC were prepared from fresh heparinized blood by washing thrice (700 g for 10 min) and resuspending in the saline buffer: 140 mM NaCl, 10 mM Tris/HCl, pH 7.4. Finally, the concentration of HRBC was adjusted to an apparent absorbance of 0.1 at 650 nm with the buffer. Toxin and conjugates were 2-fold serially diluted in saline buffer using flat-bottom 96-well microplates, previously treated for 30 min with 0.1 mg/mL Prionex to saturate the unspecific protein binding sites of plastic which can reduce toxin concentration. One volume of HRBC was added to each well, and the time course of hemolysis was followed for 30 min at room temperature. Percentage of hemolysis was determined as follows:

$$\text{hemolysis (\%)} = (A_{max} - A_{t10})/(A_{max} - A_{min}) \times 100$$

where A_{max} and A_{min} represent the absorbance values for intact and completely hemolysed RBC respectively and A_{t10} is the absorbance value in each well after 10 min from the beginning of the kinetic.

Electrophoretic Analysis. SDS−PAGE was performed according to Laemmli using precast minigels with density gradients ranging 8−25% (Amersham Pharmacia, Uppsala, Sweden). A semiautomatic horizontal unit (PhastSystem by Pharmacia) was used. Gels were stained with Coomassie brilliant blue followed by silver stain.

Fluorescence Measurements. Cathepsin B and MMP activities associated to the tumor cells were evaluated using specific fluorogenic peptides and choosing conditions as similar as possible to the citotoxicity test. In fact cells were prepared as in the cytotoxicity assay using the appropriated media without serum. In the cathepsin test 1×10^5 cells were incubated with cathepsin B substrate III (final substrate concentration 40 μM; $\lambda_{exc} = 320$ nm, $\lambda_{em} = 460$ nm) at room temperature and fluorescence was measured for 15 h every 5 min with a fluorescence microplate reader (Fluostar, SLT, Austria). In the MMP test, the quantity of cells used was between 0.6 and 0.9 $\times 10^5$ and the specific MMP substrate was at 10 μM. The fluorescence was monitored at $\lambda_{exc} = 320$ nm, $\lambda_{em} = 395$ nm for 30 min at 25 ± 3°C with a photon-counting fluorimeter (SPEX Fluoromax, JY Horiba, Edison, NJ). Ultramicro quartz cuvettes of 100 μL volume and 1 cm path length were used. In both tests the pH was about 7.

Tetrazolium-Based Assay of Cytotoxicity. In vitro toxicity against three tumor cell lines (MCF 7, ZR 751 and HT 1080) was measured by the MTT reduction assay. Cells were grown as monolayers in a humidified air atmosphere with 5% CO_2, at 37°C, and when reaching 80% confluence, they were trypsinized (2.5 g/L porcine trypsin in Hanks's balanced salt solution), washed three times, resuspended in the appropriate media (without FBS) and added to 96-microwell plates at similar cellular densities. The conjugate, treated with or without 1 mM DTT, was serially diluted (2-fold at each step) with appropriate medium without FBS on 96-well microtiter plates treated with Prionex. In some cases 0.1 mM MMP inhibitor GM6001 was added. All solutions used were filtered for sterility. A range 1.6 to 2.8×10^4 cells was added to each well in a final volume of 100 μL. Plates were then incubated at 37°C, 5% CO_2 for 2 h and then supplemented with 10% serum and incubated again for 16 to 38 h. MTT was finally added to each well (0.2 mg/mL), and the cells were cultured for two more hours before adding 100 μL of 10% SDS in 0.01 N HCl to dissolve the dark blue crystals. After overnight incubation under the same conditions, the optical density at 575 nm of each well was measured with a microplate reader (UVmax from Molecular Devices).

Percentage of cell viability was determined as follows:

$$\text{viability (\%)} = (A_s - A_0)/(A_c - A_0) \times 100$$

where A_s represents the absorbance value of the sample, A_c is the absorbance of nontreated cells (control) and A_0 is the blank value.

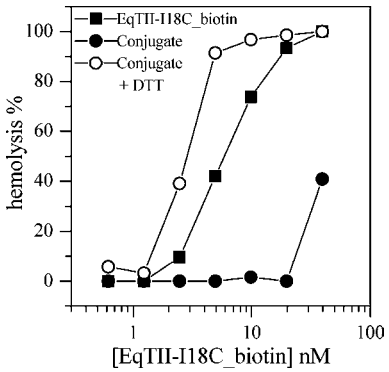

Figure 1. Hemolytic activity of the conjugate. The hemolytic activity of EqTII-I18C_biotin (squares) and the conjugate (EqTII-I18C_biotin_avidin) with or without 2.5 mM DTT (open or closed circles, respectively) was estimated using HRBC. The percentage of hemolysis was determined with a microplate reader after 10 min of interaction. The concentrations (nM) indicated are equivalent to the toxin content, and, in the case of the conjugate, they are the same because only one toxin molecule is present in the conjugate, as determined by SDS−PAGE (see Figure 3E).

Binding of the Conjugate to HRBC and Cells. To determine the binding of the conjugate to human red blood cells, the hemolytic activity of 0.19 μg/mL conjugate with or without 10 mM DTT was measured. Erythrocytes incubated with nonactivated conjugate (in the absence of DTT) were sedimented by centrifugation (3 min at 700 g), resuspended in 10 mM Tris/HCl 140 mM NaCl pH 7.4 and treated with or without 10 mM DTT. Binding to ZR 751 and HT 1080 cells was studied performing a citoxicity assay as described previously. The conjugate was serially diluted (2-fold at each step) beginning from the nontoxic concentration of 1.5 μg/mL, and cells were added. To activate the conjugate 10 mM DTT was added at different times (after 1, 2 and 3 h). Cell viability was then determined by MTT test.

RESULTS AND DISCUSSION

Inhibition of EqTII Activity by Conjugation with Avidin. As a preliminary step biotin was directly linked to EqTII-I18C by using biotin-HPDP. In this case, the addition of an excess of avidin to the biotinylated mixture removed the hemolytic activity (Figure 1, solid circles). Only at the highest concentration (about 40 nM), the fraction of biotinylated mutant treated with avidin showed a modest activity (6% of the DTT treated sample) due probably to the presence of a small amount of nonbiotinylated EqTII-I18C. The inactivation due to avidin was reversible. In fact, it was possible to restore the hemolytic activity by removing it with DTT (Figure 1, open circles). DTT reduced the disulfide bond between the EqTII cysteine and the biotin, thus releasing the active free toxin. The biotinylated EqTII-I18C appeared

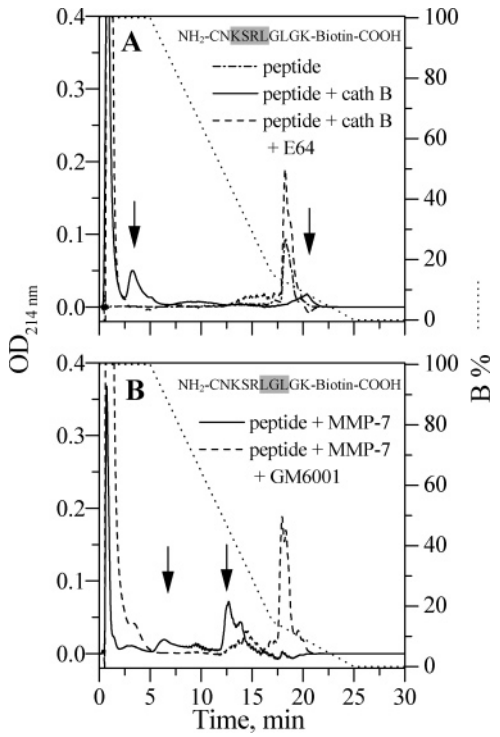

Figure 2. Separation of the peptide cathepsin/MMP digestion products. The peptide sequence is shown on top, and the cleavage sites for cathepsin B (KSRL) or MMP (LGL) are highlighted, respectively in A and B. A: Cathepsin B digestion. After 2 h of incubation of the peptide solution with activated cathepsin, the products were separated by HIC on a 50 × 4.6 mm C3 Metachem column at a flow rate of 1 mL/min. Samples were eluted with a gradient of Buffer B (2 M $(NH_4)_2SO_4$, 25 mM Na H_2PO_4, pH 7) in Buffer A (25 mM Na H_2PO_4, pH 7). The percentage of Buffer B present at any time is indicated by the dotted line. The solid line indicates the profile of the digested peptide (50 μg), while the dashed line corresponds to the same quantity of peptide combined with cathepsin and the specific inhibitor E64. The arrows indicate the main digestion products. The dashed−dotted line is referred to the peptide (25 μg) without any treatment. B: MMP-7 digestion. The conditions are the same as in A. 50 μg of the peptide was digested by MMP-7 in the presence (dashed line) or absence (solid line) of the specific MMP inhibitor GM6001. The arrows indicate the principal products derived from the cleavage.

to be slightly less hemolytic ($HC_{50} \cong 5.7$ nM) than EqTII-I18C released from the conjugate by DTT ($HC_{50} \cong 2.9$ nM). This could be due to a steric effect introduced by the presence of biotin which is removed by DTT. These experiments demonstrated that avidin, bound to the N-term of EqTII, was able to block the hemolysis by introducing a sterical hindrance into the mutant (the molecular weight of avidin, 66 kDa, is roughly thrice that of the toxin).

Construction of an Enzymically Activable Conjugate. *Choice of the Peptide.* To conjugate EqTII-I18C to avidin we next decided to use a biotinylated peptide containing a general cleavage sites for matrix metalloproteinases (MMPs) and cathepsin B, two classes of enzymes that are associated to tumor cells. The peptide sequence is given in Figure 2. The presence of one cysteine at the N-terminus allowed its coupling to the EqTII mutant; it was followed by an asparagine, that increased solubility and served to link the cysteine to the cathepsin B cleavage site: KSRL (*16*, *23*, *24*). The general MMP cleavage site, LGL (*21*), was inserted next. We have chosen this site because it could be cleaved by a large number of soluble MMPs (for example MMP-2, MMP-7, MMP-9) and by membrane MMPs such as MMP-14 (*25*, *26*). Moreover, the LGL sequence is present in the fluorescent metalloproteinase specific substrate we used to evaluate the MMPs activity of our cell lines. The remaining amino acids, GK, made the linking to biotin more flexible and introduced one additional charge to further increase solubility. Biotin was used for avidin binding.

That the enzymes could cut this peptide was confirmed by exposing it to human cathepsin B or MMP-7 and separating the digested products by hydrophobic interaction chromatography (Figure 2A and 2B, respectively). We chose MMP-7 as a representative member of the MMP family. The peak corresponding to the peptide disappeared almost completely from the chromatogram when incubated with cathepsin B or with MMP-7. Meanwhile, two main peaks appeared, marked by arrows in Figure 2, indicating digestion. On the contrary, when the peptide was incubated with the enzyme and the appropriated inhibitor, no cleavage was observed (comparison between the dashed and the dashed−dotted line, Figure 2A). We further demonstrated that the enzymatic cleavage was specific through LC-ESI-MS measurements. From the digestion with MMP-7 we found two major peaks which UV absorption well correlated with the MS signal. In fact, the fragments for LGK-biotin and LGLGK-biotin were detected as $[M + Na]^+$ ions at the nominal mass of 678 Da and at 848 Da respectively, as expected from the complete digestion. Similarly, when we treated the peptide with cathepsin B, three major peaks have been detected both by UV detector and by ESI ionization. In particular, by the latter technique $[M + Na]^+$ ions corresponding to the fragments (i) K-biotin at *m/z* 508, (ii) GK-biotin at *m/z* 565 and (iii) LGK-biotin at *m/z* 565 have been found in order of increasing elution time. These fragments derive from the carboxypeptidase action of the cathepsin B, which is preferred in the presence of a free C-term. It was possible to detect also LGLGK-biotin (*m/z* 848 as $[M + Na]^+$) and CNKSR (*m/z* 607 as M^+), the fragments expected from the classical endopeptidase activity of cathepsin B (*16*).

Preparation and Characterization of the Conjugate. EqTII-I18C was S−S linked to the biotinylated peptide. The disulfide bond between the cysteine of the mutant and the cysteine of the peptide, which formed spontaneously at low rate, was favored by activating the mutant with Ellman's reagent. As an alternative to the disulfide bond, we used BMH to form a thioether bond. This reagent increased the toxin−avidin distance, allowing the construction of a conjugate potentially more sensitive to the protease action. Furthermore, BMH was chosen to have a control conjugate free of the reducible disulfide bond. Unfortunately, this goal was only partially obtained since, from hemolytic assays, we noticed the permanence of some DTT-inducted activity, which could be attributed to the presence of spontaneously formed conjugate (not shown).

The toxin was first separated from the excess of reagent and then from the excess of peptide by filtration on Sephadex G25. The resulting fraction was incubated with an excess of avidin to give a conjugate which was separated from unreacted components by HIC (Figure 3A). As indicated by comparison with the chromatograms of free proteins, the conjugation mixture contained free toxin (nonbiotinylated and, possibly, some biotinylated, but not avidin bound), avidin and conjugate (marked by an arrow). In some cases avidin eluted as a double peak, the minor one corresponding to avidin bound to the peptide without toxin. All peaks, collected after HPLC, were tested for the hemolytic activity before and after

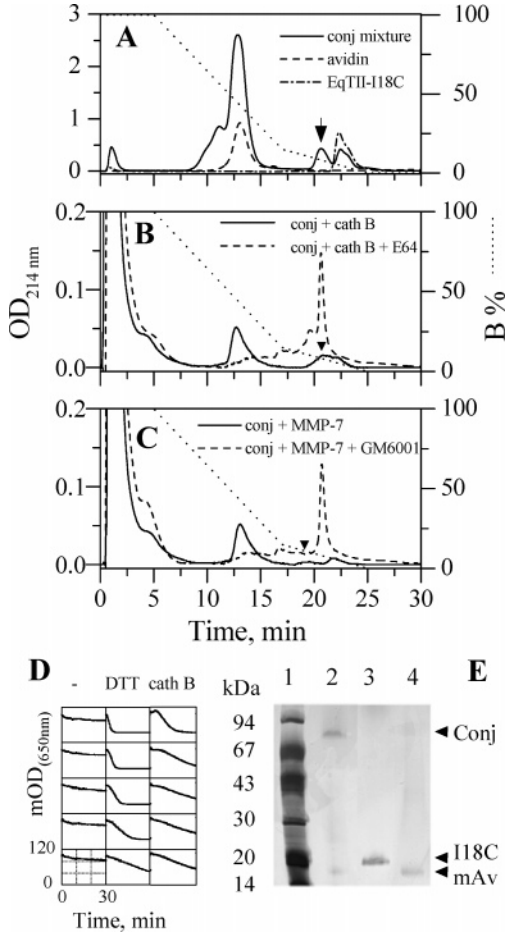

Figure 3. A: Purification and characterization of EqTII-I18C_S−S-peptide-biotin_avidin. EqTII-I18C and avidin, linked via the biotinylated peptide, were purified by HIC as in Figure 2. The solid line indicates the profile of conjugate reaction mixture (composted by 95 μg of toxin previously biotinylated and 1.1 mg of avidin), while the dashed−dotted line corresponds to free EqTII-I18C (180 μg) and the dashed one to free avidin (300 μg). The conjugate was in the peak indicated by the arrow as demonstrated by measuring its hemolytic activity and by SDS−PAGE 8−25% (Figure 3D and 3E, respectively). B, C: Separation of the cathepsin B/MMP-7 digestion products. The products of the conjugate digestion were separated by HIC (solid line), as in part A. Dashed line: conjugate (24 μg) incubated with cathepsin B or MMP-7 and the specific inhibitor, E64 or GM6001, respectively. The positions of the enzymes are marked by an arrowhead. D: Hemolytic activity of the conjugate alone (−), treated with DTT (DTT) or cathepsin B (cath B). It is reported the time course of the turbidity decrease of a HRBC suspension exposed to various doses of the conjugate, 2-fold diluted at each step from top to bottom. The conjugate concentration in the first well was 2.5 μg/mL for columns marked with "−" and DTT and 1.4 μg/mL for the column marked with cath B. The axis scales are the same for all the wells and are reported only on the bottom left one. Conditions of incubation with cathepsin B: 0.11 μM conjugate, 0.36 μM cathepsin; 2 hs at 37°C. E: SDS−PAGE analysis. The SDS−PAGE shows the conjugate (100 ng, lane 2), EqTII-I18C (100 ng, lane 3) and avidin (50 ng, lane 4). The bands indicated by arrows heads correspond approximately to MW of 86 kDa, 20 kDa and 16 kDa, as determined by comparison with standards (lane 1; the molecular weights corresponding to the different bands are reported on the left), and were identified as conjugate, EqTII-I18C and monomeric avidin.

reduction with DTT. This analysis confirmed the presence of the conjugate in the peak indicated by the arrow. In fact the protein in that fraction was able to permeabilize the erythrocyte membrane only after DTT reduction of the S−S bridge (Figure 3D). An HC_{50} of 1.1 nM of toxin was determined, for the reduced conjugate, after 30 min. As a control we observed that, under the same conditions, avidin was not hemolytic at all whereas the hemolytic activity of the mutant itself was always expressed independently of DTT. SDS−PAGE analysis of the purified conjugate under nonreducing conditions (Figure 3E, lane 2) confirmed the presence of high molecular weight compounds (around 90 kDa), as expected from the binding of one molecule of toxin (lane 3) to one molecule of avidin (lane 4, monomeric form). A minor band corresponding to monomeric avidin was also present. From the HPLC profiles (Figure 3A) we estimated that about 25% of the EqTII-I18C used was present in the conjugate. The yield varied from one preparation to another and sometimes was higher. The HPLC-purified conjugate was rechromatographed and it appeared to be free of other components (not shown).

Activation of the Conjugate by Human Cathepsin B and Matrix Metalloproteinase **7***.* That either human cathepsin B or MMP-7 were able to cleave the conjugate had been shown by HIC of the digestion products (Figure 3B and 3C). The HPLC profile demonstrated that cathepsin B and MMP-7 could cleave the conjugate releasing free avidin and toxin. In both cases, the first peak obtained (centered at about 13 min) corresponded to avidin (compare Figure 3A) while the peak corresponding to the free toxin was centered at about 22 min. The positions of the enzymes are marked by an arrowhead in Figure 3B and 3C, indicating that the cathepsin B peak (Figure 3B) was observed at the same position as the conjugate peak. The latest peak was still present when we treated it with the inhibitors (dashed line, Figure 3B and 3C), showing that the cleavage was specific.

In agreement, the hemolytic assay (Figure 3D, line marked by cathB) clearly demonstrated that cathepsin B can cut the linker peptide and restore the hemolytic activity of EqTII-I18C. The HC_{50} after 30 min, due to the mutant released by cathepsin B, was 1.0 nM (concentration of toxin), almost the same as that obtained by treating the conjugate with DTT (Figure 3D, line DTT). In a similar way we found that also trypsin could cleave the conjugate producing a hemolytic fragment ($HC_{50} \cong$ 0.8 nM; data not shown), thus confirming that the peptide inside the conjugate was accessible by enzymes.

Enzymatic Activity of ZR 751, HT 1080 and MCF 7 Tumor Cell Lines. All cell lines used were characterized for the presence of MMPs and cathepsin B activity in our experimental conditions using specific fluorogenic peptides (Figure 4). Cells were trypsinized, washed and resuspended in the appropriate culture media (without FBS) to reproduce similar conditions as the cytotoxicity assay. After addition of cells, the fluorescence of the substrate was monitored (Figure 4). The MMP activities, calculated as the relationship between the initial slopes and the total number of cells in the assay, of the three cell lines were quantitatively similar. The ratio between the enzymatic activities of ZR 751 and MCF 7, with respect of that of HT 1080 cells, was approximately one in both cases, with values ranging from 0.8 ± 0.2 for ZR 751 to 1.1 ± 0.6 for MCF 7 (mean of three experiments). Cathepsin B activities, instead, were different in the three lines. In particular, the higher activity was found for MCF 7 (10.0 ± 3.6 higher than HT 1080) and an intermediate value for ZR 751 (3.4 ± 0.8 higher than HT 1080). In our experimental conditions, MMP activity was always better than cathepsin activity (Figure 4).

To check if the resulting activity was due to the specific enzymes or if there was any unspecific cleavage, we

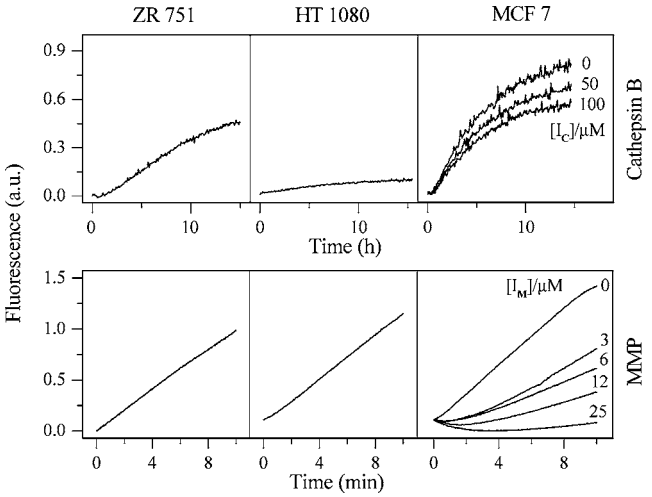

Figure 4. Cathepsin B and MMP enzymic activity associated to the tumor cell lines ZR 751, HT 1080 and MCF 7 evaluated with specific fluorogenic peptides. Upper panel: cathepsin B test. The fluorescence was measured every 5 min with a microplate reader, 1×10^5 cells were used and the substrate concentration was 40 μM. Lower panel: MMP test. A fluorimeter was used, the quantity of cells was between 0.6 and 0.9×10^5 and the substrate concentration was 10 μM. On the y axis fluorescence is represented as 10^6 cps. For MCF 7 cell line the activities in the presence of specific inhibitors was reported. I_C: cathepsin inhibitor (E64); I_M: MMP inhibitor (GM6001).

added appropriate inhibitors. The enzymatic activities were significantly reduced by the MMP inhibitor. As an example, MCF 7 MMP enzymatic activity was inhibited from 47 to 98% when the GM6001 inhibitor ranged from 3 to 25 μM. Some inhibition was also verified when the cathepsin inhibitor E64 was added. In this case MCF 7 enzymatic activity was inhibited by 16 or 30% using the inhibitor at a concentration of 50 and 100 μM, respectively. This suggested that the measured enzymatic activity was due, at least in part, to the specific enzymes studied.

Cytotoxic Effects of the Conjugate on the Tumor Cells. Contrary to the case of erythrocytes (Figure 5A, insert), even in the absence of DTT the conjugate displayed cytotoxic activity on the tumor cell lines studied (Figure 5). The MCF 7 cell line was the most sensitive, with an IC_{50} of 0.3 μg/mL of the conjugate in the absence and 0.2 μg/mL in the presence of DTT (Figure 5A). Both the other cell lines were less affected by the conjugate; in particular, the IC_{50} was 5.8 μg/mL for ZR 751 and 14.2 μg/mL for HT 1080 cells (Figure 5B and C).

This correlates nicely with the cathepsin B activity (see Figure 4), but not with MMP activity, that was similar in all three cell lines. However, by studying the effect of the specific MMP inhibitor GM6001 on the conjugate activity toward MCF 7 tumor cells, we observed that some MMP enzymatic activity was also involved in cytotoxicity. In fact, in the presence of 100 μM inhibitor and 0.2 μg/mL of conjugate (Figure 6) we observed that the cell fraction killed by the conjugate treated with the inhibitor was one-fifth in comparison with the one without inhibitor.

Binding of the Conjugate to the Cell Membrane. Finally, we wanted to evaluate if the conjugate was able to bind to the cells even when not permeabilizing them (Figure 7). The EqTII-I18C_S−S-peptide-biotin_avidin conjugate was added to HRBC at the concentration of 0.19 μg/mL (Figure 7A). The cells were then washed, resuspended in physiological buffer and treated or not with DTT. Only under reducing conditions we observed

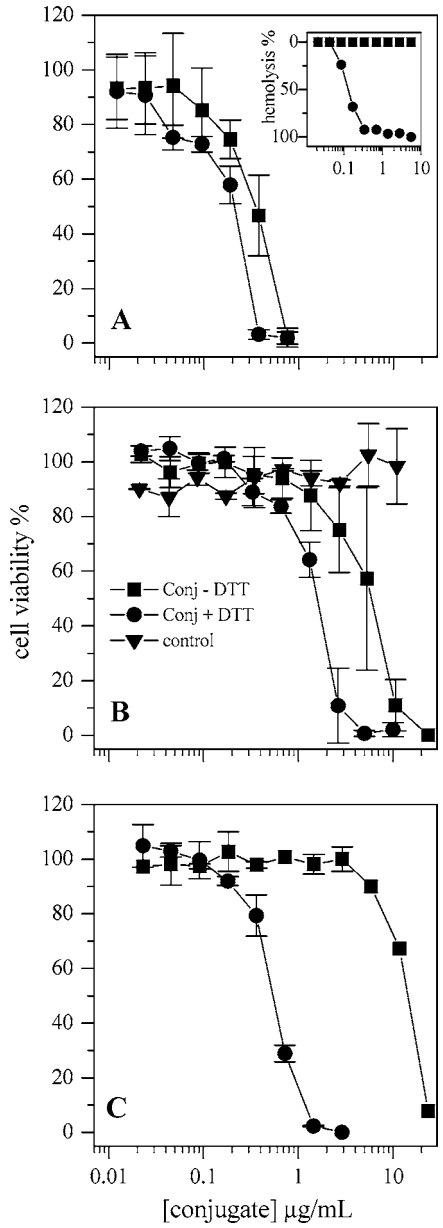

Figure 5. Cytotoxic effects of the conjugate toward cancer cells. The cytotoxic effect was evaluated on three tumor cell lines. Cells in a concentration ranging from 1.6 to 2.8×10^5 cells/mL were incubated at 37°C, 5% CO_2 for 2 h with different conjugate doses with (circles) or without (squares) 1 mM DTT and then supplemented with 10% serum. Triangles represent cells not incubated with conjugate (control experiment). Cells viability was measured after a minimum of 18 h and a maximum of 40 h from the addition of conjugate, by the MTT assay. Results represent the mean ± SEM of at least three experiments. In B and C the conjugate was produced by using BMH. HRBC are shown in the insert of panel A as an example of cells without any MMP or cathepsin enzymic activity. Hemolytic test was performed as in Figure 1. A: MCF 7; B: ZR 751; C: HT 1080.

hemolytic activity, indicating that the conjugate was indeed bound to the erythrocyte membrane but could not permeabilize them until activated by DTT. In this way, we could demonstrate that membrane-bound conjugate is stable and active for a long time; in fact even when DTT was added after 80 min, the permeabilization was complete. Similarly we found that, at sub-cytotoxic concentrations, the same conjugate could bind to tumor cells and that it could be activated by DTT even after 1 h from the washout (Figure 7B). We tested the time-course of this availability, finding that after 2 h the

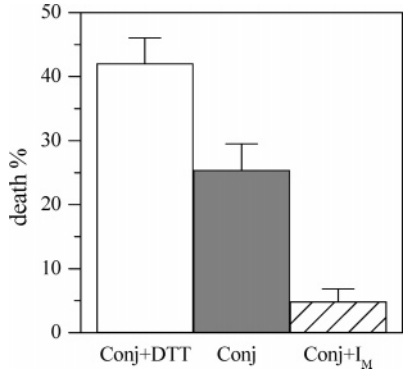

Figure 6. Inhibition of the conjugate activity toward MCF 7 cells. It is represented as the percentage of death of MCF 7 cells in the presence of the conjugate treated or not with 1 mM DTT (white and gray bars, respectively), or in the presence of MMP inhibitor (striped bar). Cells viability was measured by MTT test as in Figure 5. The concentration of the MMP specific inhibitor used in the experiment was 100 μM, while the cell suspension was 1.9×10^5 cells/mL. Results represent the mean $\pm$ SEM of three experiments.

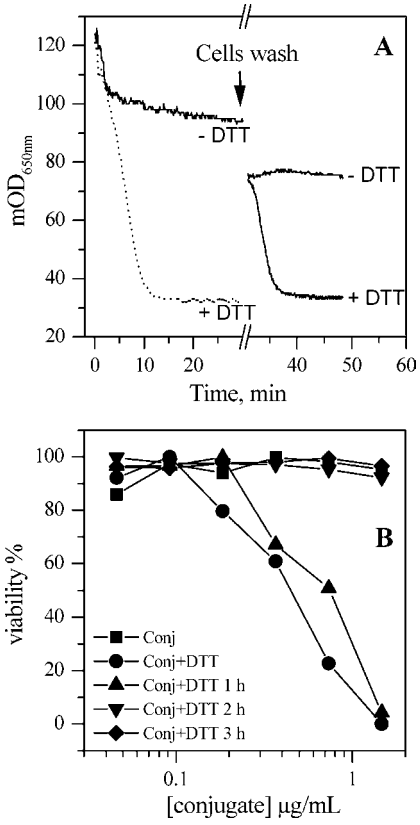

Figure 7. Binding of the EqTII-I18C_S−S-peptide-biotin_avidin conjugate to the cell membrane. Panel A. Binding to human red blood cells. Dotted line: hemolytic activity of 0.19 μg/mL conjugate with 10 mM DTT (the conditions are as in Figure 1). Solid lines: erythrocytes incubated with nonactivated conjugate (− DTT), sedimented by centrifugation (interruption of 10 min), resuspended and treated or not with 10 mM DTT. The hemolytic activity was followed for another 20 min. Panel B. Binding to human breast carcinoma cells (ZR 751). The conjugate was added at sub-cytotoxic concentration and was activated with 10 mM DTT at different times (1, 2, 3 h; up triangles, down triangles and diamonds, respectively). Viability assay was determined by the MTT test. Squares represent the conjugate without DTT and circles a conjugate immediately activated with DTT.

conjugate was no longer available for cleavage. This was true for ZR 751 (Figure 7) as well as for HT 1080 cells (data not shown).

CONCLUSIONS

The biotin−avidin conjugation method, pioneered for anticancer immunotoxins (*27*) and already exploited also for the construction of an antiparasite (*11*) and an anticancer immunotoxin (*12*), is presented here in a version with a linker-peptide. This has the advantage of being very versatile. Simply by changing the sequence of the biotinylated peptide it is possible, at least in principle, to activate a pore-forming toxin like EqTII onto different cell types. In fact, by introducing in the peptide the cleavage sequence for an enzyme expressed by a certain tumor cell, or even by tumor surrounding stromal cells, only in the proximity of that cell will the peptide be cleaved. The killer toxic moiety will be released, directly killing the tumor cell itself or the cells which support the tumor.

The use of peptides to construct immunotoxins was already described (*28*, *29*) but only to help the transport of the toxic moiety, or to improve the extent of covalent conjugation between an antibody and a toxin. Here we propose a new system, which is useful to specifically target the conjugate. In fact we could show that a peptide, containing the cleavage sites for cathepsin and MMP, renders the conjugate active against several tumoral cell lines expressing those enzymes, but not against erythrocytes, which are devoid of them. For the conjugation we selected EqTII-I18C mutant, because this links the avidin molecule to the N-terminal α-helix of EqTII (*30*), which is a crucial element for the toxin−membrane interaction and should be free to move for activity (*31*−*33*).

The most sensitive tumor cells were found to be MCF 7 which also express the highest enzymic activity. The extent of cytotoxicity on the different cell lines correlated with the amount of cathepsin B activity expressed; however, at least on MCF 7 cells, the conjugate activity was also significantly inhibited by the specific MMP inhibitor GM6001, suggesting a contribution of both cathepsin B and MMP to the conjugate activation. This conclusion is supported by the fact that erythrocytes, which do not possess such enzymes, are not damaged by the conjugate. At subtoxic concentrations, the conjugate is still capable of binding to the cells in a form that can be activated, e.g. by DTT, for at least 1 h. Such binding is not cell specific and may be mediated by the toxin moiety. To avoid such unspecific binding we are planning to select for the conjugation a different EqTII mutant, which could not bind to the cell surface. Attaching a biotinylated antitumor antibody to the avidin of such conjugate, we could produce a promising immunotoxin with two levels of specific activation: antibody targeting and enzymic activation.

ACKNOWLEDGMENT

Glucagon-like peptide-1-(7−36) (GLP-1) is a hormone derived from the proglucagon molecule, which is considered a highly desirable antidiabetic agent mainly due to its unique glucose-dependent stimulation of insulin secretion profiles. However, the development of a GLP-1-based pharmaceutical agent has a severe limitation due to its very short half-life in plasma, being primarily degraded by dipeptidyl peptidase IV (DPP-IV) enzyme. To overcome this limitation, in this article we propose a novel and potent DPP-IV-resistant form of a poly(ethylene glycol)-conjugated GLP-1 preparation and its pharmacokinetic evaluation in rats. Two series of mono-PEGylated GLP-1, (i) N-terminally modified PEG_{2k}-N^{ter}-GLP-1 and (ii) isomers of Lys^{26}, Lys^{34} modified PEG_{2k}-Lys-GLP-1, were prepared by using mPEG-aldehyde and mPEG-succinimidyl propionate, respectively. To determine the optimized condition for PEGylation, the reactions were monitored at different pH buffer and time intervals by RP-HPLC and MALDI-TOF-MS. The in vitro insulinotropic effect of PEG_{2k}-Lys-GLP-1 showed comparable biological activity with native GLP-1 ($P = 0.11$) in stimulating insulin secretion in isolated rat pancreatic islet and was significantly more potent than the PEG_{2k}-N^{ter}-GLP-1 ($P < 0.05$) that showed a marked reduced potency. Furthermore, PEG_{2k}-Lys-GLP-1 was clearly resistant to purified DPP-IV in buffer with 50-fold increased half-life compared to unmodified GLP-1. When PEG_{2k}-Lys-GLP-1 was administered intravenously and subcutaneously into rats, PEGylation improved the half-life, which resulted in substantial improvement of the mean plasma residence time as a 16-fold increase for iv and a 3.2-fold increase for sc. These preliminary results suggest a site specifically mono-PEGylated GLP-1 greatly improved the pharmacological profiles; thus, we anticipated that it could serve as potential candidate as an antidiabetic agent for the treatment of non-insulin-dependent diabetes patients.

INTRODUCTION

Glucagon-like peptide-1-(7−36) (GLP-1) is a proglucagon-derived peptide secreted from the L-cells in the gastrointestinal tract in response to orally ingested nutrients (*1*). Initial clinical interest in GLP-1 was based on its glucose-dependent insulinotropic effect, which was thought to be a potential advantage over conventional antidiabetic agents that secrete insulin via glucose-independent mechanism (*2*, *3*). GLP-1 also exerts actions suit for non-insulin-dependent diabetes mellitus (NIDDM) patients such as inhibition of glucagons secretion, inhibition of gastric emptying, and a decrease in appetite (*4*). Moreover, numerous recent studies indicated direct effects of GLP-1 on pancreatic β-cells. For example, GLP-1 is involved in β-cell growth and survival by stimulating cell proliferation and differentiation into new β-cells which could lead to increased β-cell mass (*5*, *6*). On the basis of the advantages as described above, GLP-1 has a great therapeutic potential to treat NIDDM diabetes. However, GLP-1 is quite unstable in vivo (half-life; < 2 min for iv injection) and clinical application requires frequent administration at high dosages. These limitations pose great challenges in the development of GLP-1 as an antidiabetic pharmaceutical agent.

The rapid clearance and degradation of GLP-1 in plasma is mainly due to N-terminal cleavage of the first two amino acids, His^8-Ala^9, by the enzyme dipeptidyl peptidase IV (DPP-IV) (*7*). Until now, the main approach that has been used to improve the therapeutic level of GLP-1 is development of enzyme-resistant GLP-1 analogues by substituting one or two amino acids of the peptide (*8*). Design of GLP-1 analogues showed a number of promising results; however, it still remains difficult to optimize conditions such as control of enzyme resistance and biological potency in vivo. Chemical conjugation of several substances to GLP-1 has been also proposed to improve clinical efficiency. For instance, fatty acid acylation, NN2211 (*9*), was found to extend action via binding to an existing serum protein derivative while albumin conjugation, CJC-1131 (*10*), showed prolonged half-life compared to the circulating half-life of albumin itself. Protein modification is one of the convenient alternative ways to improve therapeutic profiles of native proteins; however, little work was done with GLP-1.

We previously reported site specifically poly(ethylene glycol) (PEG)-modified salmon calcitonin (sCT) exhibited improved pharmacokinetic and pharmacodynamic profiles with pronounced stability compared to intact sCT in vitro and in vivo (*11*−*15*). PEG-modified proteins often have extended plasma half-lives, decreased proteolytic

degradation, and reduced immunogenecity (*16*, *17*). However, the nonspecific PEGylation process frequently results in substantial loss of biological activity when PEG binds around the protein's active sites (*18*). This may show inconsistent pharmacodynamic profiles. Therefore, it is important to strike a balance between biological stability and therapeutic activity of PEGylated proteins under physiological conditions. In this respect, we hypothesized that covalent coupling of PEG to a specific site of GLP-1 may improve the overall therapeutic profile of GLP-1 while maintaining biological activity. In this work, we have prepared and characterized novel PEGylated GLP-1 conjugates in vitro and investigated pharmacokinetic profiles in vivo.

MATERIALS AND METHODS

Materials. GLP-1 was purchased from Bachem (Torrance, CA). Succinimidyl propionate monomethoxypoly(ethylene glycol) (mPEG-SPA) and aldehyde monomethoxypoly(ethylene glycol) (mPEG-ALD) were purchased from Shearwater Polymers (Huntsville, AL). Trifluoroacetic acid (TFA) and acetonitrile (ACN) was purchased from Sigma (St. Louis, MO). All reagents and organic solvents used were at least ACS grade.

Preparation of Mono-PEGylated GLP-1 Conjugates. The positional isomers of mono-PEGylated GLP-1 conjugates were prepared and purified according to the procedures described previously (*11*). In brief, GLP-1 (100 μL, 1 mg/mL) in various 50 mmol/L buffer solutions was reacted with 2 mole excess of $mPEG_{2k}$-SPA (pH adjusted from 7.5 to 9.0 with 50 mmol/L Tris-HCl buffer) at room temperature for 1 h and $mPEG_{2k}$-ALD (pH adjusted from 4.5 to 5.5 with 50 mmol/L sodium acetate buffer) at 4 °C for 2 h, respectively. The mono-PEGylated GLP-1 conjugates were monitored and purified by reversed-phase high-pressure liquid chromatography (RP-HPLC) on X-tera C_{18} (4.6 × 250 mm, 5 μm, Waters, Milford, MA) at room temperature. The mobile phase consisted of 0.1% TFA in distilled water (eluent A) and ACN containing 0.1% TFA (eluent B). The mobile phase was run with a linear gradient from 30 to 60% eluent B for 20 min at a flow rate of 1 mL/min and the UV absorbance of the eluent was monitored at 215 nm. The HPLC fractions corresponding to respective peaks were collected separately, purged with nitrogen, and lyophilized.

Lys-C Digestion of Mono-PEGylated GLP-1. To determine the positions where the PEG molecules were attached, a lysyl endoproteinase, Lys-C, digestion was employed as described previously (*19*). Each purified mono-PEGylated conjugate was dissolved in 50 μL of triethylamine-HCl buffer (10 mmol/L; pH 7.4) to a concentration of 1 mg/mL. Following the addition of 50 μL of enzyme (1 mg/mL), the reaction was allowed to incubate for 1 h at 37 °C. To quench the digestion, 5 μL of 10% (v/v) TFA was added and reaction mixture was analyzed by MALDI-TOF MS.

MALDI-TOF MS. Molecular weight was obtained from MALDI-TOF mass spectrometry using a Voyager Biospectrometry Workstation (PerSeptive Biosystem, Framingham, MA). Samples were prepared by mixing 1 μL of aliquot with 2 μL of the matrix solution, a saturated solution of α-cyanohydroxycinnamic acid in 50% of water/ACN with 0.3% TFA. One microliter of the sample mixture was spotted into a well of the sample plate and dried by vacuum prior to mass spectrometry. Data for 2 ns pulses of the 337 nm nitrogen laser were averaged for each spectrum in a linear mode, and positive ion TOF detection was performed using an accelerating voltage of 25 kV.

Insulinotropic Actions from Isolated Rat Pancreatic Islets. Pancreatic islets were isolated from male Sprague−Dawley rats weighting 250−270 g by the modified method of Lacy and Kostianovsky (*20*). Briefly, anesthesia was induced by intraperitoneal injection of pentobarbital sodium (50 mg/kg). The donor pancreas was inflated by injection of cold Hank's balanced buffered salt solution (HBSS, pH 7.4, Sigma) containing 1.5 mg/mL type V collagenase (Sigma). Isolated islets were purified by centrifugation with a discontinuous Ficoll (Amersham Biosciences AB, Uppsala, Sweden) gradient at 2400 rpm for 25 min. Purified islets were cultured with RPMI-1640 culture medium (Sigma) supplemented with 10% fetal bovine serum (FBS, Gibco, Carlsbad, CA) and 1% penicillin−streptomycin (Gibco) at 37 °C with an atmosphere of 95% air and 5% CO_2. After the 2 day maintenance period, the islets were washed and incubated in a Krebs−Ringer bicarbonate buffer. Twenty islets were incubated for 2 h in 2 mL of KRB−HEPES at 37 °C with an atmosphere of 95% air and 5% CO_2, containing the respective stimulus. The insulin release was measured by a radioimmunoassay kit (Insulin Kit, ICN Pharmaceuticals, Orangeburg, NY).

Stability to DPP−IV in Vitro. GLP-1 (100 μL, 5 nmol/L) and an equivalent amount of purified mono-PEGylated GLP-1 were prepared in triethylamine·HCl buffer (10 mmol/L; pH 7.4). DPP-IV (5 mU, 900 μL) was added, and the solutions were incubated at 37 °C. At the indicated time points, 100 μL was removed from the reaction mixture, and reactions were terminated by the addition of 5 μL of 10% (v/v) TFA. Each sample was analyzed by MALDI-TOF MS and RP-HPLC as described.

Pharmacokinetics in Vivo. Male Sprague−Dawley (SD) rats were cannulated in jugular vein day before the experiment. The animals were randomly divided into four groups, and the GLP-1 and molar equivalent amount of mono-PEGylated GLP-1 dissolved in saline was intravenously (1 μg/kg) and subcutaneously (10 μg/kg) administered. Blood samples were drawn at predetermined time points in an ice-chilled polyethylene tube containing DPP-IV inhibitor (10 μL per mL of blood; Linco Research Inc., St. Charles, MO). The plasma samples were obtained by centrifugation and stored at −70 °C until assay. The concentration of GLP-1 in rat plasma was analyzed by a commercial sandwich enzyme-linked immunosorbent assay (ELISA) kit (Linco Research Inc.) with GLP-1 and PEGylated conjugates as standards. The peptide concentration beyond the calibration range was diluted by addition of blank rat plasma.

Data Analysis. Data are expressed as mean ± SD. The pharmacokinetic parameters were calculated from the plasma concentrations after administration. The area under the time curves was calculated using the linear trapezoidal method. Differences between treatments were evaluated using paired Student's t tests. $P < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Monitoring of PEGylation. The GLP-1 molecule has three possible sites for the PEGylation; they are the primary amino group of N-terminus (His^7) and two lysine residues (Lys^{26} and Lys^{34}) (Figure 1). Two different chemical approaches were used to PEGylate free amino functional group of the peptide. In the first approach, mPEG-SPA was used to form an amide bond with Lys^{26} and Lys^{34}. In the second approach, reductive alkylation was carried out by reaction mPEG-ALD with His^7, followed by $NaCNBH_3$ reduction. To determine the

optimized condition for PEGylation that would selectively label the target site, the feed molar ratio between GLP-1 and PEG was fixed as 1 to 2 and reactions were carried out at different pH and were monitored at different time intervals by HPLC over an 8 h period. For the lysine, pH was varied from 7.5 to 9.0 and for the histidine, pH was varied from 4.5 to 5.5. Figure 2 illustrates the RP-HPLC analysis of the reaction mixture obtained after the termination of the each reaction. Increasing the pH from 7.5 to 9.0 decreased the yield of PEG_{2k}-Lys-GLP-1, while decreasing the pH from 5.5 to 4.5 led to an increased yield of PEG_{2k}-N^{ter}-GLP-1. Selective pH affected the final yield of PEGylated product; however, the reaction time did not influence the production yield much. Each of the purified mono-PEGylated GLP-1 derivatives was then subjected to the lysyl endoproteinase, Lys-C, proteolysis to determine the positional substitution of PEG molecules. After incubation with Lys-C, reaction mixtures were directly characterized by MALDI-TOF MS (Figure 3). By peptide mapping (Table 1), it was confirmed that (i) purified PEGylated GLP-1 conjugates were purely monosubstituted and (ii) PEG_{2k}-Lys-GLP-1 consisted of two different isomers, PEG_{2k}-Lys^{26}-GLP-1 and PEG_{2k}-Lys^{34}-GLP-1. In addition, the amount of proteolytic fragment of Glu^{27}-Arg^{36} is more predominant than His^7-Lys^{34} (Figure 3C). MALDI-TOF MS is one of the direct determination techniques for the peptide content (*21*), and the result indicates that most of the PEG_{2k}-Lys-GLP-1 consisted of PEG_{2k}-Lys^{34}-GLP-1. This result well matches what we expected based on the natural characteristics of PEG molecule. Once PEG binds to Lys^{34}-GLP-1, the Lys^{26} position has a reduced chance to form a chemical bond with PEG due to the steric hindrances induced by the closely attached PEG molecule at the Lys^{34} position. However, we could not completely purify two different PEG_{2k}-Lys-GLP-1 isomers by using HPLC, mainly due to the small physicochemical differences between PEG_{2k}-Lys^{26}-GLP-1 and PEG_{2k}-Lys^{34}-GLP-1. Similarly, the chemical structure of N-terminally PEGylated PEG_{2k}-N^{ter}-GLP-1 was also confirmed, with good yield (Figure 3D,E, Table 1). After characterization of mono-PEGylated GLP-1 conjugates, the fractions were collected, pooled, and lyophilized. The BCA protein analysis was then carried out to determine the concentration of peptide.

Biological Activities. The influence of GLP-1 and mono-PEGylated GLP-1 conjugates on insulin secretion was investigated in isolated rat islets to determine biological activities indirectly in vitro. The primary physiological response to GLP-1 observed is glucose-dependent insulin secretion. Since the effect of GLP-1 under low glucose concentration (2.8 mmol/L) is not that significant compared to high glucose concentration (16.8 mmol/L), the biological activity of GLP-1 conjugates was evaluated under high glucose conditions. Culturing only islets in 16.8 mmol/L glucose resulted in increases in the rate of insulin secretion of 7.8 ± 1.2-fold per islet over those observed in the presence of 2.8 mmol/L glucose (Figure 4). Insulin release was clearly stimulated by the addition of 100 nmol/L GLP-1, a significant enhancement to 3.4 ± 0.7-fold ($p < 0.001$) per islet compared to without stimulant in 16.8 mmol/L glucose. The high concentration of peptide was chosen for in vitro study because the reported receptor binding (EC_{50}) value of GLP-1 is around 1 nmol/L and was also shows no further increase of insulin release in islets at concentrations above 100 nmol/L of GLP-1 (*22*). At equivalent molar concentrations of mono-PEGylated conjugates, PEG_{2k}-Lys-GLP-1 was at least as potent as native peptide in stimulating insulin secretion (306.6 ± 72.8 vs 368.9 ± 82.9 pmol/L, $P = 0.117$) and was significantly more potent than PEG_{2k}-N^{ter}-GLP-1 which showed 1.5 ± 0.5-fold increase of insulin secretion per islet compared to that without stimulant. It is well-known that certain residues or regions of residues are important for biological activity of therapeutic proteins, and for GLP-1, the N-terminus plays an important role in receptor binding which could directly affect the therapeutic action in vivo. It is postulated that conjugation of PEG moieties to the N-terminus of GLP-1 pro-

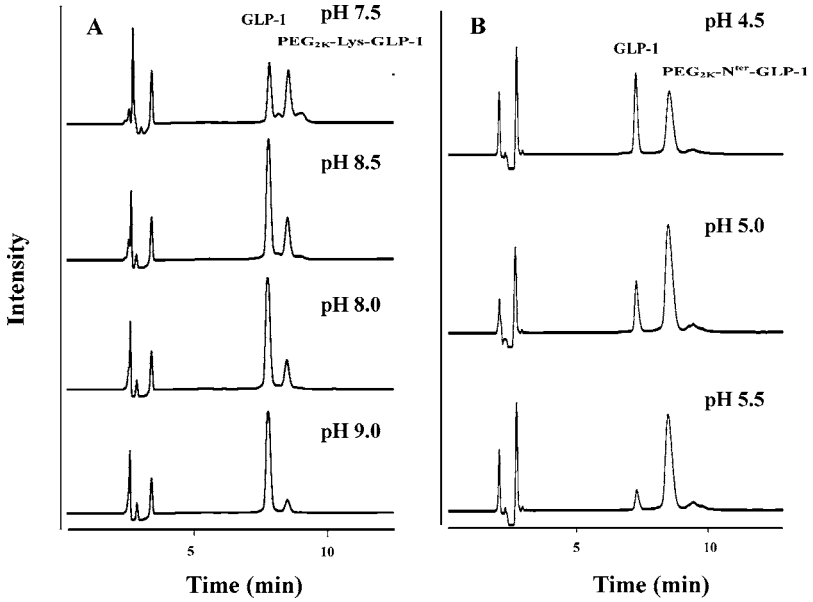

Figure 2. RP−HPLC analysis of the reaction mixture obtained by reaction of (A) mPEG-SPA and (B) mPEG-ALD with GLP-1 at different pHs as indicated. Analysis was performed on a X-tera C18 column with water/acetonitrile/TFA as eluent and a flow rate of 1 mL/min, and peaks were monitored at 215 nm.

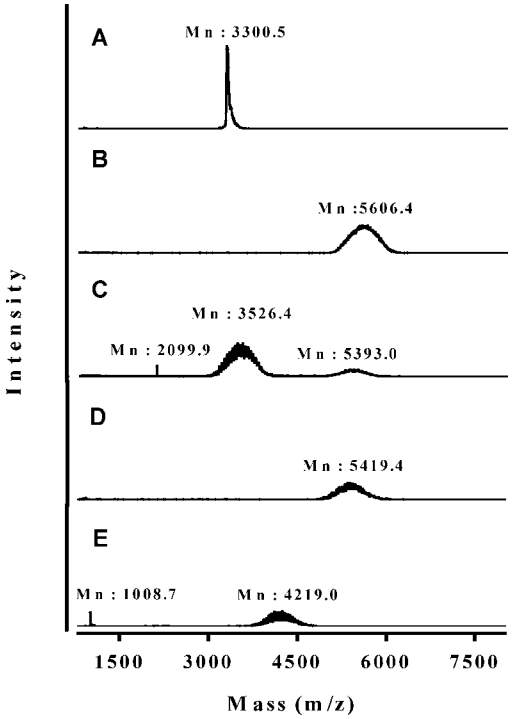

Figure 3. Mass analysis of (A) intact GLP-1, (B) purified PEG_{2k}-Lys-GLP-1, (C) proteolytic fragments of PEG_{2k}-Lys-GLP-1, (D) purified PEG_{2k}-N^{ter}-GLP-1, and (E) proteolytic fragments of PEG_{2k}-N^{ter}-GLP-1. Proteolysis was performed by incubating each purified peptide with lysyl endoproteinase, Lys-C, and the mass of each proteolytic fragment was directly evaluated by MALDI-TOF MS.

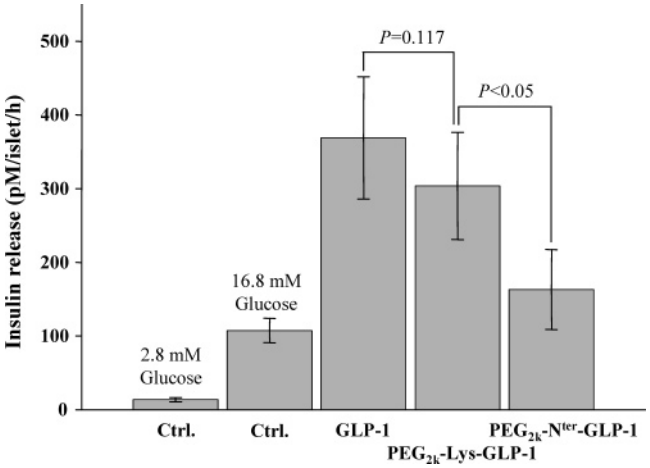

Figure 4. Stimulation of insulin secretion from rat pancreatic islets by 100 nM of GLP-1 and an equivalent amount of PEGylated GLP-1 conjugates. Rat islets were isolated by collagenase digestion, and static incubation of 20 islets per sample was performed for 2 h at 37 °C in the presence of 16.8 mM glucose (2.8 mM indicates basal). Insulin release was measured by RIA as described in Materials and Methods. Values are mean ± SD (n = 6−8).

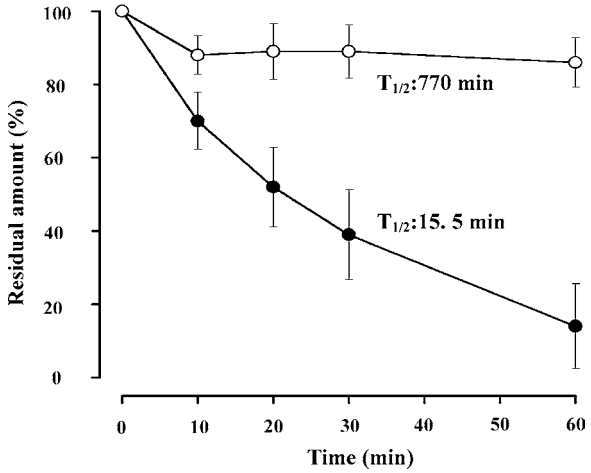

Figure 5. Stability of PEG_{2k}-Lys-GLP-1 toward enzymatic degradation by DPP-IV in comparison with intact GLP-1. Unmodified GLP-1 (●) and PEGylated GLP-1 (○) were incubated with purified DPP-IV at 37 °C. At the indicated time points, aliquots were subjected to analytical HPLC. The quantity of the peptide (peak area) at t = 0 was assigned to 100%. Values are mean ± SD (n = 3).

duces conformational disturbances mainly by steric hindrance, which may perturb the receptor−ligand interaction and lead to lower biological activity. Because N-terminally modified GLP-1 conjugates showed a markedly reduced potency in stimulating insulin secretion, PEG_{2k}-Lys-GLP-1 was selected for further experiments.

Stability of Mono-PEGylated GLP-1. Enzymatic resistance to DPP-IV of intact GLP-1 and PEG_{2k}-Lys-GLP-1 was evaluated. GLP-1 was degraded by the purified DPP-IV in vitro at 37 °C, with a half-life value of 15.5 min. In contrast, PEGylated GLP-1 revealed a significantly prolonged half-life compared to intact GLP-1 itself with a value of 770 min (Figure 5). Degradation profiles was also monitored and indirectly quantified by MALDI-TOF MS as GLP-1 (3297.1 Da) and N-terminally truncated GLP-1 metabolite, GLP-1 (9−36) amide (3087.1 Da) (Figure 6). The mass difference between two peaks (210.0 Da) corresponds to mass of cleaved two amino acids (His^7, Ala^8) at the N-terminals. The relative height of the metabolite peak was increased as time passes. At 10 min postincubation with DPP-IV, nearly one-third was recovered as GLP-1 (9−36), and at 60 min, most of the intact GLP-1 was degraded. In contrast, mono-PEGylated GLP-1 was significantly resistant to proteolytic enzyme. Most of the PEG_{2k}-Lys-GLP-1 remained in original form after 60 min incubation and could still be detected even at 2 h postincubation. From the literature, some of the N-terminally substituted GLP-1 analogues by addition of various different kinds of amino acids showed potent biological activity with decreased degradation profiles (*23*). However, this process generally needs a large screening process to search for analogues with balanced stability and activity. In the case of our system, PEG_{2k}-Lys-GLP-1, even simple selective attachments of PEG not far from the site of cleavage showed significantly improved proteolytic stability in vitro while maintaining

Table 1. Molecular Mass of PEGylated GLP-1 after Lys-C Protease Digestion As Determined by MALDI-TOF (calcd/found)

proteolytic fragment	calcd mass (GLP-1 std)	PEG_{2k}-N^{ter}-GLP-1	PEG_{2k}-Lys^{26}-GLP-1	PEG_{2k}-Lys^{34}-GLP-1
His^7-Lys^{26}	2098.2	4217.3/4219.0[a]	-	2098.2/2099.9

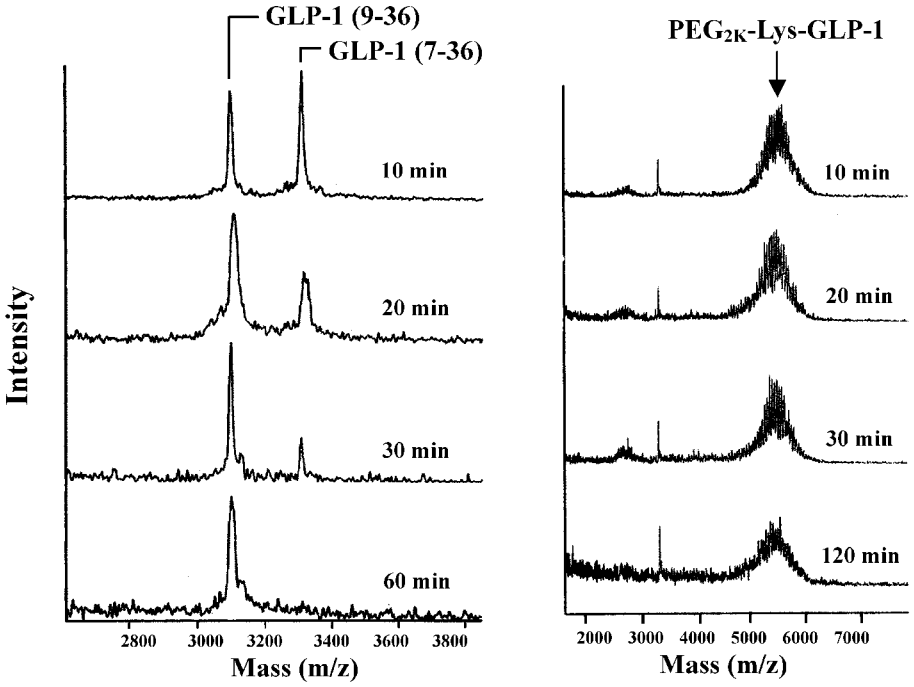

Figure 6. Mass spectra of DPP-IV-catalyzed (A) intact GLP-1 and (B) PEG_{2k}-Lys-GLP-1 upon degradation. Each peptide was incubated with purified DPP-IV, and reaction mixtures were monitored at different time intervals by MALDI-TOF MS over 2 h periods. GLP-1 (9−36) indicates the N-terminally truncated GLP-1 metabolite.

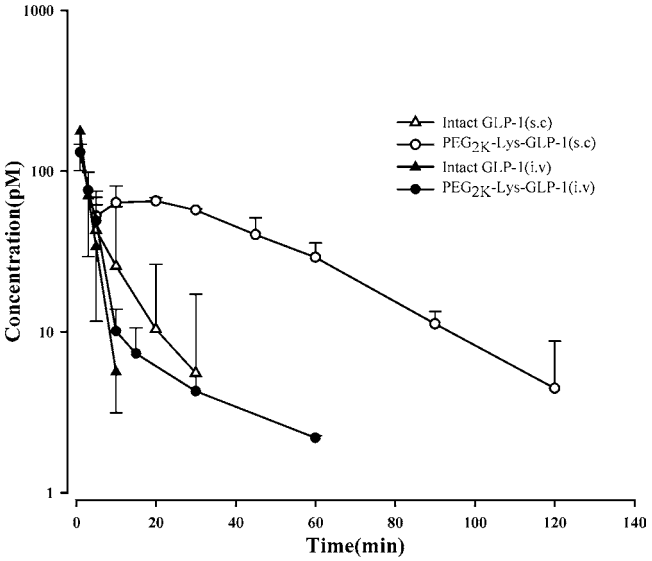

Figure 7. Plasma concentration of GLP-1 and PEG_{2k}-Lys-GLP-1 versus time after intravenous (1 μg/kg) and subcutaneous (10 μg/kg) injection in rats. Values are mean ± SD (n = 3).

biological activity, which is a decisive and potential advantage of our system in terms of efficiency.

Pharmacokinetics. The pharmacokinetic properties of GLP-1 and PEG_{2k}-Lys-GLP-1 were evaluated by non-compartmental and two-compartmental analysis following sc and iv administration in male SD rats, respectively. Figure 7 illustrates the plasma concentration profiles during 2 h experimental time periods, and pharmacokinetic parameters calculated from the data are summarized in Table 2. Plasma concentration of both intravenously administered GLP-1 and conjugate showed a biexponential disposition. Plasma activity of GLP-1 declined rapidly, with a half-life of 2.6 min, whereas the mono-PEGylated GLP-1 showed increased half-life by 10-fold, reduced clearance by 1.5-fold, and a 16-fold increase in mean residence time. Again, PEGylation had a profound effect on the pharmacokinetic parameters after sc administration as evident from the increase in the area under the curve (AUC) of the mono-PEGylated GLP-1. The plasma concentration of GLP-1 peaked 5 min after the sc injection; however, T_{max} of PEG_{2k}-Lys-GLP-1 observed 16 min after the injection. The pharmacokinetic profile of intact sc GLP-1 was unsuitable, showing a rapid peak followed by a fast decay in plasma, which is in accordance with human trials (*24*). In contrast, PEG_{2k}-Lys-GLP-1 showed a 2-fold increase in C_{max}, a 7.5-fold increase in AUC, and a 2.5-fold increase in half-life, noting a low variability among individuals. Consequently, PEG_{2k}-Lys-GLP-1 has a significantly improved plasma exposure and stability compared to intact GLP-1.

We have designed and characterized two series of mono-PEGylated GLP-1, PEG_{2k}-N^{ter}-GLP-1, and PEG_{2k}-

Individual data from sc and iv doses were analyzed by noncompartment and two-compartment models, respectively.

Lys-GLP-1. Biological activity was altered by site modification, in which PEG_{2k}-N^{ter}-GLP-1 showed a marked reduction in activity, whereas the PEG_{2k}-Lys-GLP-1 retained biological activity. The enzyme proteolytic stability of mono-PEGylated GLP-1 was significantly enhanced after PEGylation mainly by steric hindrance induced by the PEG molecule. When lead compound PEG_{2k}-Lys-GLP-1 was administered to rats, PEGylation improved the pharmacokinetic properties of the GLP-1. Increase in half-life and decrease in clearance resulted in substantial improvement in the plasma exposure of the mono-PEGylated GLP-1.

GLP-1 has been suggested to be a useful novel therapy in the treatment of NIDDM patients. However, the instability of GLP-1 against the proteolytic enzyme, DPP IV, is the most daunting factor for its therapeutic use as a new treatment modality. Although, the short metabolic stability of the native peptide can be offset by constant iv infusion, this does not fundamentally overcome the effect of proteolytic enzymes. Moreover, an iv infusion may constrain the potential use of GLP-1 in the clinical setting. Thus, the development of a prolonged-acting or slow release form of GLP-1 in vivo has been the focus of much recent research. In this respect, the enzyme-resistant form of site-specifically PEGylated PEG_{2k}-Lys-GLP-1 could serve as a potential GLP-1-based antidiabetic agent for clinical application.

While our prototype of PEGylated GLP-1 showed prolonged action in vivo compared with the native GLP-1, the total plasma residence time is still in the range of 1 to 2 h. Therefore, our further investigation will examine the effect of the molecular weight of PEG on extended metabolic stability of GLP-1 in vivo. In addition, pharmacodynamic responses using a NIDDM disease animal model are required to evaluate whether the improved half-life of PEGylated GLP-1 is sufficient for the treatment of diabetes.

Received September 16, 2004; Revised Manuscript Received December 23, 2004

A convergent synthetic approach was used to conjugate 2′,5′-oligoadenylate (2-5A, p5′A2′ [p5′A2′]$_n$p5′A) to phosphorodiamidate morpholino oligomers (morphants). To provide requisite quantities of 2-5A starting material, commercially and readily available synthons for solid-phase synthesis were adapted for larger scale solution synthesis. Thus, the tetranucleotide 5′-phosphoryladenylyl(2′→5′)adenylyl-(2′→5′)adenylyl(2′→5′)adenosine (p5′A2′p5′A2′]$_2$p5′A2′, tetramer 2-5A, **9**) was synthesized starting with 2′,3′-*O*-dibenzoyl-N^6,N^6-dibenzoyl adenosine prepared from commercially available 5′-*O*-(4-monomethoxytrityl) adenosine. Coupling with N^6-benzoyl-5′-*O*-(4,4′-dimethoxytrityl)-3′-*O*-(*tert*-butyldimethylsilyl) adenosine-2′-(*N*,*N*-diisopropyl-2-cyanoethyl)phosphoramidite, followed by oxidization and deprotection, generated 5′-deprotected dimer 2-5A. Similar procedures lengthened the chain to form protected tetramer 2-5 A. The title product **9** p5′A(2′p5′A)$_3$ (tetramer 2-5A) was obtained through phosphorylation of the terminal 5′-hydroxy of the protected tetramer and removal of remaining protecting groups using concentrated ammonium hydroxide−ethanol (3:1, v/v) at 55 °C and tetrabutylammonium fluoride (TBAF) in THF at room temperature, respectively. The 2-5A-phosphorodiamidate morpholino antisense chimera **11** (2-5A-morphant) was synthesized by covalently linking an aminolinker-functionalized phosphorodiamidate morpholino oligomer with periodate oxidized 2-5A tetramer (p5′A2′[p5′A2′]$_2$p5′A). The resulting Schiff base was reduced with cyanoborohydride thereby transforming the ribose of the 2′-terminal nucleotide of 2-5A N-substituted morpholine. RNase L assays demonstrated that this novel 2-5A-antisense chimera had significant biological activity, thereby providing another potential tool for RNA ablation.

INTRODUCTION

RNA is being pursued ever more vigorously as a target for drug discovery. This pursuit has been buttressed by the realization that the decay of mRNA can be key in the posttranscriptional regulation of gene expression (*1*, *2*). Antisense oligonucleotides are one such class of RNA-targeting agent. Since the first reports that antisense oligonucleotides could inhibit gene expression in a sequence specific manner, there has been widespread interest in antisense oligonucleotides as therapeutic agents (*3*−*7*). One such drug, Vitravene for drug-resistant cytomegalovirus retinitis, has been FDA approved, and about 20 antisense drugs are in clinical development (*8*). Of the many modifications of antisense that have been introduced, we have focused on one that recruits the 2-5A-dependent RNase L to destroy targeted RNA (*9*−*21*).

2′,5′-Oligoadenylates (2-5A) are formed from ATP when viral double-stranded RNA binds to 2′,5′-oligoadenylate synthetase (OAS) in interferon-treated cells. 2-5A plays a key role in the mechanism of interferon antiviral activity (*22*), as it provides an unambiguous signal to initiate RNA decay in mammalian cells through its activation of the latent 2-5A-dependent RNase L which degrades viral mRNA, resulting in an inhibition of protein synthesis. However, RNase L may not distinguish well between viral and cellular RNA substrates (*23*). To overcome the nonspecific action of RNase L, a 3′,5′-antisense oligodeoxyribonucleotide was attached to the 2′,5′-oligoadenylate activator of the 2-5A dependent RNase L. This 2-5A-antisense composite nucleic acid (2-5A-antisense) could target a particular chosen mRNA sequence and then destroy it through localized activation of the latent 2-5A-dependent RNase L (*9*−*14*, *23*−*26*).

2-5A-Antisense oligonucleotides have been employed in vitro and in vivo (1) to block respiratory syncytial virus (RSV) replication through targeting of RSV genomic and mRNAs and (2) to halt tumor proliferation by destruction of telomerase template RNA (*9*−*21*).

The purpose of the present undertaking was 2-fold. First, to increase the efficacy of 2-5A-antisense, modifications are sought that would improve the biological half-life of such molecules and also perhaps endow them with different pharmacokinetic properties from the phospho-

rothioate analogues employed in a number of the documented examples above. Second, it is well established that the biological action of most antisense oligonucleotides involve either a passive mechanism of steric blocking of translation or else rely on intervention of RNase H to degrade the hybrid molecule formed between the antisense drug and the target RNA sequence. In one view, it might be expected that higher potency of antisense agent would be associated with the catalytic mode of action (RNase H-mediated) since theoretically one molecule of antisense drug could effect the turnover of multiple molecules of target RNA substrate. In other words, steric blocking antisense agents may not achieve the same efficacy of action, all other factors being equal. For instance, two analogues of deoxyribose phosphodiester backbone oligonucleotides have been described, and these have greatly improved properties in many respects compared to the parent DNAs. These include the peptide nucleic acids (PNAs) and the phosphorodiamidate morpholino oligomers (PMOs, morphants, morpholino oligos). Each of these modifications has certain considerable theoretical pharmacodynamic and pharmacokinetic advantages over their deoxyribose phosphodiester relatives; nonetheless, no viable drug has arisen so far form these promising structural modifications. Insofar as we had previously shown that PNAs could be converted to catalytically active molecules by conjugation to 2-5A, we have turned our attention to the phosphorodiamidate morpholino oligomers. These morpholino analogues are DNA mimetics in which the five-membered sugar−phosphate backbone is replaced by six-membered morpholine backbone moieties joined by nonionic phosphorodiamidate intersubunit linkages (*27*−*29*). Morpholino analogues (morphants) of oligonucleotides have demonstrated superior resistance to enzymatic degradation, and they obey the Watson−Crick rules binding complementary DNA and RNA with high affinity and long physiological half-lives (*27*−*29*). In a variety of systems, they have demonstrated substantial competence in RNA ablation (*30*−*34*). To apply these latter properties to 2-5A-antisense and to endow morphants with a catalytic mode of action, we have prepared 2-5A-morphants, a new class of 2-5A-antisense.

MATERIALS AND METHODS

Reagents. Sodium periodate, sodium cyanoborohydride, and 1*H*-tetrazole were purchased from Aldrich (Milwaukee, WI). ChemGenes (Wilmington, MA) was the source for N^6-benzoyl-5′-*O*-dimethoxytrityl-3′-*O*-*tert*-butyldimethylsilyladenosine 2′-(*N*,*N*-diisopropyl-2-cyanoethyl)phosphoramidite (ANP-5681) and bis-cyanoethyl-*N*,*N*-diisopropylphosphoramidite. Deblocking mix (3% trichloroacetic acid in dichloromethane) and oxidizing solution (0.10 M iodine in tetrahydrofuran/pyridine/water) were purchased from Glen Research (Sterling, VA). Antisense reagents **10a** and **10b** were purchased from Gene Tools (Philomath, OR). Anhydrous THF, DMF, CH_3CN, and pyridine were purchased from Aldrich and were dried using standard methods and distilled before use. TLC was carried out on precoated silica gel thin layer sheets 60 F_{254} from EMD (Darmstadt, Germany). Flash chromatography (FC) was carried out on silica gel 60 Å, 70−230 or 220−400 meshes from EM. ^{1}H NMR (400.14 MHz), ^{13}C NMR (100.62 MHz), and ^{31}P NMR (169.99 MHz) spectra were recorded on Varian VNMR 400 spectrometer in $CDCl_3$ as indicated below. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS) was carried out on a Kratos MALDI III instrument at HT laboratories (San Diego, CA) and a Voyager DE Pro instrument at the Structural Mass Spectrometry Facility, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health (Bethesda, MD).

UV measurements were carried out on a HP 8452A spectrophotometer instrument. Concentrations of 2-5 A tetramer and 2-5 A-antisense were determined spectrophotometrically using the extinction coefficient ($\epsilon = 44.4 \times 10^3$). All reversed-phase HPLC analysis and purifications were conducted on a Varian Pro Star 210 and Beckman 406 instruments. Adsorbosphere ODS analytical (4.6 × 250 mm) and semipreparative (10 × 250 mm) C-18 and C-8 columns (Alltech Company) were used for the analysis and purification with the following respective buffers: A: 50 mM NH_4OAc or $NH_4H_2PO_4$ (pH 7.00); B: 50% MeOH/H_2O. Linear gradient elution was performed with flow rate of 1 mL/min for analytic and 5 mL/min for preparative application. For the purification of 2-5A tetramer, the deprotection mixture was pooled and evaporated in a Speedvac, and then the residue was desalted with a Sep-Pak C-18 cartridge (Waters).

Synthesis of 5′-Phosphoryladenylyl(2′→5′)adenylyl(2′→5′)adenylyl(2′→5′)adenosine (p5′A2′p5′A2′p5′A2′p5′A, 2-5A Tetramer). *N^6-Benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6,N^6-dibenzoyl-2′,3′-O-dibenzoyl adenosine (**3**).* 2′,3′-*O*-Dibenzoyl-*N*,*N*-dibenzoyladenosine (**1**, 150 mg, 0.22 mmol), N^6-benzoyl-5′-*O*-dimethoxytrityl-3′-*O*-*tert*-butyl-dimethylsilyl-adenosine 2′-(*N*,*N*-diisopropyl-2-cyanoethyl)phosphoramidite (ANP-5681, **2**, 500 mg, 0.5 mmol), and tetrazole (100 mg, 1.4 mmol) were added to a flask and then dried in a desiccator in vacuo overnight. The mixture was allowed to react in 1.5 mL of anhydrous acetonitrile under N_2 atmosphere for 6 h at room temperature followed by an additional 1 h in a water bath at 40−50 °C. The coupling product was oxidized with iodine reagent solution (8 mL), over 50 min at ambient temperature. The reaction mixture was then diluted with CH_2Cl_2 (45 mL) and washed with saturated $Na_2S_2O_3$ (60 mL). The aqueous phase was re-extracted with another aliquot of CH_2Cl_2 (6 × 25 mL), and the combined organic phase was dried (Na_2SO_4), evaporated, and then coevaporated with toluene (3 × 10 mL) and chloroform (3 × 10 mL) to remove residual pyridine. TLC analysis (CH_2Cl_2:MeOH, 30:1) indicated the starting material (**1**) had disappeared. The product was purified by column chromatography on silica gel (70−230 mesh, 60 Å) with a solvent gradient of hexane, CH_2Cl_2, and MeOH. A mixture of 250 mg 5′-dimethoxytritylated dimer and 5′-OH deprotected dimer was obtained. The above product mixture was deprotected with the deblocking solution (15 mL, 3% CCl_3COOH solution in CH_2Cl_2) at 0 °C for 15 min. The detritylation was stopped by the addition of saturated $NaHCO_3$ solution (75 mL), and the reaction mixture was extracted with dichloromethane (6 × 25 mL). The organic layer was dried ($MgSO_4$) and concentrated under reduced pressure. The crude product was purified by column chromatography on silica gel (70−230 mesh, 60 Å) with a solvent gradient of hexane, CH_2Cl_2, and CH_3OH to obtain pure 5′-OH dimer (**3**, 195 mg, 71%). Compound **3** on TLC gave an $R_f = 0.33$ (CH_2Cl_2:MeOH, 30:1).^{1}H NMR ($CDCl_3$): δ 0.01 (s, 3H, Si-CH_3), 0.02 (s, 3H, Si-CH_3), 0.78 (s, 3H, C-CH_3), 0.79 (s, 6H, 2 C-CH_3), 2.37−2.42 (m, 2H), 3.57−4.56 (m, 9H), 5.31−5.47 (m, 2H), 5.81−5.86 (m, 1H), 6.00−6.06 (m, 1H), 6.11 (dd, $J = 6.4$ Hz $J = 6.0$ Hz, 1H), 6.40 (d, $J = 5.2$ Hz, 1H), 7.16−7.39 (m, 15H, Bz-H), 7.71−7.83 (m, 10H, Bz-H), 8.14−8.55 (m, 4H, Ade-H), 9.16 (br, 1H, Ade-NH). ^{13}C NMR ($CDCl_3$): −5.1, −4.8, 17.8, 19.1, 19.2, 25.4, 25.5,

61.7, 62.4, 62.5, 66.9, 70.3, 71.9, 73.6, 73.7, 80.9, 86.2, 86.3, 87.7, 88.2, 116.0, 116.2, 124.2, 127.5−129.6 (m), 132.5, 132.8, 133.1, 133.5, 133.6, 133.7, 142.9, 143.5, 143.7, 149.9, 150.0, 150.8, 151.7, 151.8, 152.2, 152.5, 152.6, 164.6, 164.7, 164.8, 164.9, 165.1, 172.0, 172.1. ^{31}P NMR ($CDCl_3$): −0.86, 0.98. MALDI-TOF/MS (*m/z*): calcd for $C_{64}H_{62}N_{11}O_{15}PSi$: 1283.4; found 1283.4 ($M^+$).

*N^6-Benzoyl-3′-O-(tert-butyl-dimethylsilyl adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6,N^6-dibenzoyl-2′-O-,3′-O-dibenzoyladenosine (**4**)*. Compound **4** was obtained in a fashion similar to compound **3.** The 5′-OH dimer **3** (200 mg, 0.16 mmol) was coupled with N^6-benzoyl-5′-*O*-dimethoxytrityl-3′-*O*-*tert*-butyldimethylsilyladenosine 2′-(*N*,*N*-diisopropyl-2-cyanoethyl)phosphoramidite (**2**, 988 mg, 1.0 mmol) in the presence of tetrazole (143 mg, 2 mmol) under N_2. The resulting product then was oxidized with iodine solution and deprotected (dimethoxytrityl group removal) with 3% trichloroacetic acid in dichloromethane (18 mL). The product was purified by column chromatography on silica gel (200−400 mesh, 60 Å) employing a solvent gradient of hexane, CH_2Cl_2 and MeOH. The yield of trimer **4** was 254 mg (86.6%). ^{1}H NMR ($CDCl_3$): δ 0.00−0.07 (m, 12H, 4 Si-CH_3), 0.77−0.86 (m, 18H, 2 C$(CH_3)_3$), 2.49−2.56 (m, 4H), 3.60−4.08 (m, 11H), 4.38−4.62 (m, 4H), 5.39 (m, 3H), 5.92−6.42 (m, 5H), 7.17−7.43 (m, 21H), 7.72−7.86 (m, 11H), 8.29−8.58 (m, 4H), 9.00 (br, 1H, Ade-NH), 9.15 (br, 1H, Ade-NH). ^{31}P NMR ($CDCl_3$): −1.33 to −0.56 (m). MALDI-TOF/MS (*m/z*): calcd for $C_{90}H_{95}N_{17}O_{22}P_2Si_2$: 1883.5; found 1884.4 ($M^+ + 1$).

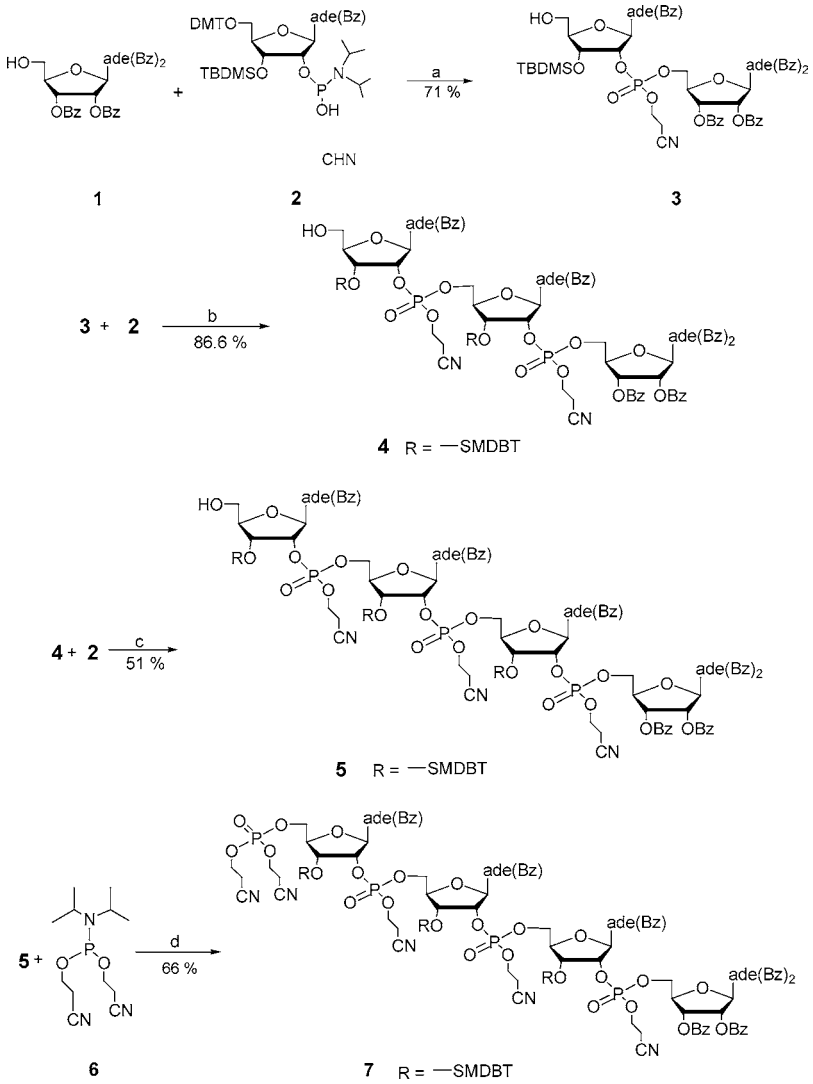
*N^6-Benzoyl-3′-O-(tert-butyl-dimethylsilyl) adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6,N^6-dibenzoyl-2′,3′-O-dibenzoyl adenosine (**5**)*. Following a procedure similar to the syntheses of compounds **3** and **4**, a dried mixture of 5′-OH trimer **4** (181 mg, 96 μmol), N^6-benzoyl-5′-*O*-dimethoxytrityl-3′-*O*-*tert*-butyldimethylsilyl-adenosine 2′-(*N*,*N*-diisopropyl-2-cyanoethyl)-phosphoramidite **2** (640 mg, 0.65 mmol), and tetrazole (100 mg, 1.4 mmol) was reconstituted with anhydrous acetonitrile (4.5 mL) under an N_2 atmosphere. After stirring for 6 h at room temperature, the reaction mixture was oxidized with the iodine solution (15 mL). The intermediate product was purified by column chromatography as described previously and then detritylated with 23 mL of cold 3% CCl_3COOH solution of dichloromethane in an ice−water bath. The product was again purified by column chromatography on silica gel (70−230 mesh, 60 Å) eluting with same solvent gradient. The final yield was 182 mg of solid product 5′-OH tetramer **5** (51% yield). ^{1}H NMR ($CDCl_3$): δ 0.01−0.07 (m, 18H, 6 Si-CH_3), 0.75−0.86 (m, 27H, 3 C$(CH_3)_3$), 2.40−2.59 (m, 6H), 3.82−4.67 (m, 21H), 5.35−6.43 (m, 10H), 7.19−8.60 (m, 43H), 9.35 (br, 3H, Ade-NH). ^{31}P NMR ($CDCl_3$): −1.63 to −0.56 (m). MALDI-TOF/MS (*m/z*): calcd for $C_{116}H_{128}N_{23}O_{29}P_3Si_3$: 2483.8; found 2484.8 ($M^+ + 1$).

*5′-O^P-Bis-(2-cyanoethyl)-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl)adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6-benzoyl-3′-O-(tert-butyl-dimethylsilyl) adenylyl-{2′-[O^P-(2-cyanoethyl)]-5′}-N^6,N^6-dibenzoyl-2′,3′-O-dibenzoyadenosine (**7**)*. The coupling and oxidation procedure was very similar to synthesis of dimer **3**. 5′-OH-unprotected tetramer **5** (182 mg, 73 μmol) was coupled with bis-cyanoethyl-*N*,*N*-diisopropylphosphoramidite **6** (197 mg, 0.73 mmol) in anhydrous acetonitrile (0.9 mL) in the presence of tetrazole (110 mg, 1.5 mmol) as catalyst for 7 h at room temperature under N_2 atmosphere. After the coupling reaction was complete, the oxidation of the reaction mixture was carried out with iodine solution (11 mL) for 50 min. The reaction mixture was diluted with 40 mL CH_2Cl_2 and washed with saturated $Na_2S_2O_3$ (50 mL). The aqueous phase was re-extracted with another CH_2Cl_2 (6 × 30 mL), and the combined organic phase was dried, evaporated, and coevaporated with toluene to remove pyridine. The product of reaction was purified by column chromatography on silica gel by elution with a gradient of hexane, CH_2Cl_2, and MeOH, and 130 mg of solid product tetramer **7** (yield 66%) was collected. ^{1}H NMR ($CDCl_3$): δ 0.014−0.04 (m, 18H, 6 Si-CH_3), 0.78−0.82 (m, 27H, 3 C$(CH_3)_3$), 2.40−2.60 (m, 10H), 3.86−6.43 (m, 22H), 7.11−8.60 (m, 43H), 9.18 (br, 3H, Ade-NH). ^{31}P NMR ($CDCl_3$): −1.34 to −0.54 (m).

*5′-Phosphoryladenylyl(2′→5′)adenylyl(2′→5′)adenylyl-(2′→5′)adenosine (**9**) (2−5A tetramer, p5′A2′p5′A2′p5′A2′-p5′A)*. Protected tetramer **7** (110 mg, 41 μmol) was incubated with NH_4OH−EtOH solution (3:1, 24 mL) at 55 °C for 24 h to remove the cyanoethyl and benzoyl protecting groups. The reaction mixture was evaporated to dryness under reduce pressure (cold water bath), and tetrabutylammonium fluoride (TBAF) in THF solution (1M, 10.5 mL) was added to the residue. The mixture was incubated at room temperature for 24 h, and then the solvent was evaporated completely in vacuo using a cold water bath (10 °C). Sterile water (10 mL) was added to the residue, and the solution was loaded into a C-18 Sep-Pak Cartridge (prewashed with 10 mL of MeOH and 12 mL of sterile H_2O). The cartridge was washed with water until no salt detected by UV (200 mL of H_2O was used). Deprotected tetramer **9** was then eluted with 50 mL of MeOH−H_2O (1:1), and the solution was evaporated completely under reduced pressure. Sterile water (6 mL) was added to above residue to yield a clear solution. The total amount of 2-5A tetramer (1460 OD_{260}) was determined by UV (80% yield). The retention time and purity were determined by HPLC analysis with a Beckman 406 instrument employing an Adsorbosphere ODS analytical (4.6 × 250 mm) C-8 (Alltech Company) with the following buffers: A: 50 mM $NH_4H_2PO_4$ (pH 7.00); B: 50% MeOH/H_2O. Linear gradient elution was performed (0 min, 0% B; 25 min, 50% B; 40 min, 100% B; 45 min, 100% B; 50 min, 0% B; 60 min, 0% B) with a flow rate of 1 mL/min. The retention time of tetramer **9** was 12.5 min, and the purity was 98% assessed at by detection at 260 nm. MALDI-TOF/MS (*m/z*): calcd for $C_{40}H_{50}N_{20}O_{25}P_4$: 1334.2; found 1335.3 ($M^+ + 1$).

Synthesis of 2-5A-Morpholino Antisense Chimera 11a and 11b. Sodium periodate solution (2 μL of 0.1 M in water, total of 0.2 μmol) was added in one portion to a solution of 2-5A-tetramer **9** (40 μL of 2.5 mM in water, 0.1 μmol, Na^+ form), and the resulting mixture was stirred in the dark at 0 °C for 30 min. To destroy the excess periodate, a $Na_2S_2O_3$ solution (4 μL of 0.1 M, total of 4 μmol) was added, and the resultant solution was maintained at 0 °C for an additional 10 min in the dark. A solution of phosphorodiamidate morpholino oligomers **10a** (25 μL of 2 mM in water, total of 0.05 μmol) was added, and the pH of the reaction mixture was adjusted to 8.6 with 0.1 M NaOH. The resulting mixture was stirred at 0 °C for 2 h, and then a sodium cyanoborohydride solution (2 μL of 0.5 M in water, total of 1 μmol) was added. This reaction mixture was kept at 0 °C for 1 h during which time the pH was maintained at 6.6 by addition of 0.5% HOAc. The resulting reaction mixture was stirred at 4 °C overnight. The reaction mixture was

Scheme 1[a]



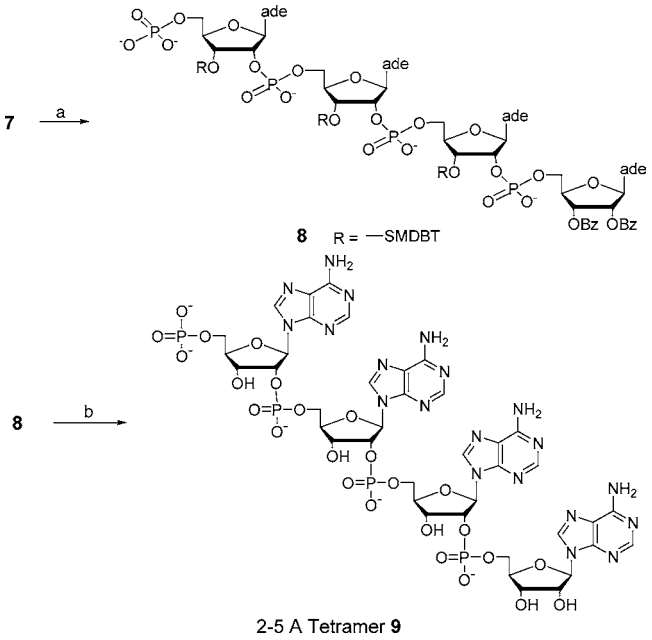
[a] Reaction conditions: (a) (i) 1*H*-tetrazole, anhydrous MeCN, N_2, rt; (ii) iodine solution, rt; (iii) 3% CCl_3COOH in CH_2Cl_2, 0 °C (three steps, 71% yield). (b) (i) 1*H*-tetrazole, anhydrous MeCN, N_2, rt; (ii) iodine solution, rt; (iii) 3% CCl_3COOH in CH_2Cl_2, 0 °C (three steps, 86.6% yield). (c) (i) 1*H*-tetrazole, anhydrous MeCN, N_2, rt; (ii) iodine solution, rt; (iii) 3% CCl_3COOH in CH_2Cl_2, 0 °C (three steps, 51% yield). (d) (i) 1*H*-tetrazole, anhydrous MeCN, N_2, rt; (ii) iodine solution, rt.

then diluted 10-fold with sterile water, and the conjugate product **11a** was purified by HPLC on an Adsorbosphere C-8 column (4.6 × 250 mm) (solvent A: 50 mmol $NH_4H_2PO_4$ (pH = 7.0); solvent B: MeOH/H_2O (1:1); 0 min, 0% B; 25 min, 50% B; 40 min, 100% B; 45 min, 100% B; 50 min, 0% B; 60 min, 0% B) at a flow rate of 1 mL/min. A total of 1.5 OD **11a** was obtained (A_{260}). The product was analyzed by MALDI-TOF mass spectrometry: (*m/z*, calcd for $C_{235}H_{360}N_{83}O_{101}P_{19}$: 6552.4; found 6552.5).

A similar procedure was employed in the synthesis of conjugate chimera **11b**. Purification of the product was performed on HPLC with adsorbosphere C-8 column using the same linear gradient program (A: 50 mmol NH_4OAc (pH = 7.0); B: MeOH/H_2O (1:1)). 1.01 OD of conjugate **11b** was obtained. The product was analyzed by MALDI-TOF mass spectrometry: (*m/z*, calcd for $C_{228}H_{349}N_{82}O_{100}P_{19}$: 6427.2; found 6427.2).

RNase L Activity. RNase L activity was determined by a fluorescence resonance energy transfer (FRET) method (*35*). The assay uses recombinant human RNase L produced in insect cells from a baculovirus vector and purified by FPLC columns (*36*). The cleavable substrate consists of a 36 nucleotide synthetic oligoribonucleotide sequence derived from respiratory syncytial virus with the fluorophore, FAM, at the 5′-terminus and black hole quencher-1 (BHQ-1), at the 3′-terminus (synthesized at Integrated DNA Technologies). The RNA sequence (6-FAM-UUA UCA AAU UCU UAU UUG CCC CAU UUU UUU GGU UUA-BHQ-1) contains several cleavage sites for RNase L (UU or UA). The test compounds or 2-5A were diluted to final concentrations of 1 nM, 3 nM, 10 nM, 30 nM, 100 nM, 300 nM, 1000 nM, and 3000 nM in DEPC treated water. Five microliters of each diluted sample was added in triplicate to 96-well black polystyrene microtiter plates (Corning) on ice. Forty-five microliters of the reaction mixture was added to each sample, and the plates were gently agitated for 10 s to mix and then were centrifuged briefly at 500 rpm. The assays contained 100 nM RNA probe, 25 nM RNase L, 25 mM Tris-HCl (pH7.4), 100 mM KCl, 10 mM $MgCl_2$, 50 μM ATP, and 7 mM 2-mercaptoethanol with and without 2-5A or analogues. RNase L was the last component added to the reaction mixtures. The plates were incubated at 20 °C protected from light. Fluorescence was measured at 5, 30, 60, and 90 min with a Wallac 1420 fluorimeter (Perkin-Elmer) (absorption 485 nm/emission 535 nm).

Scheme 2[a]

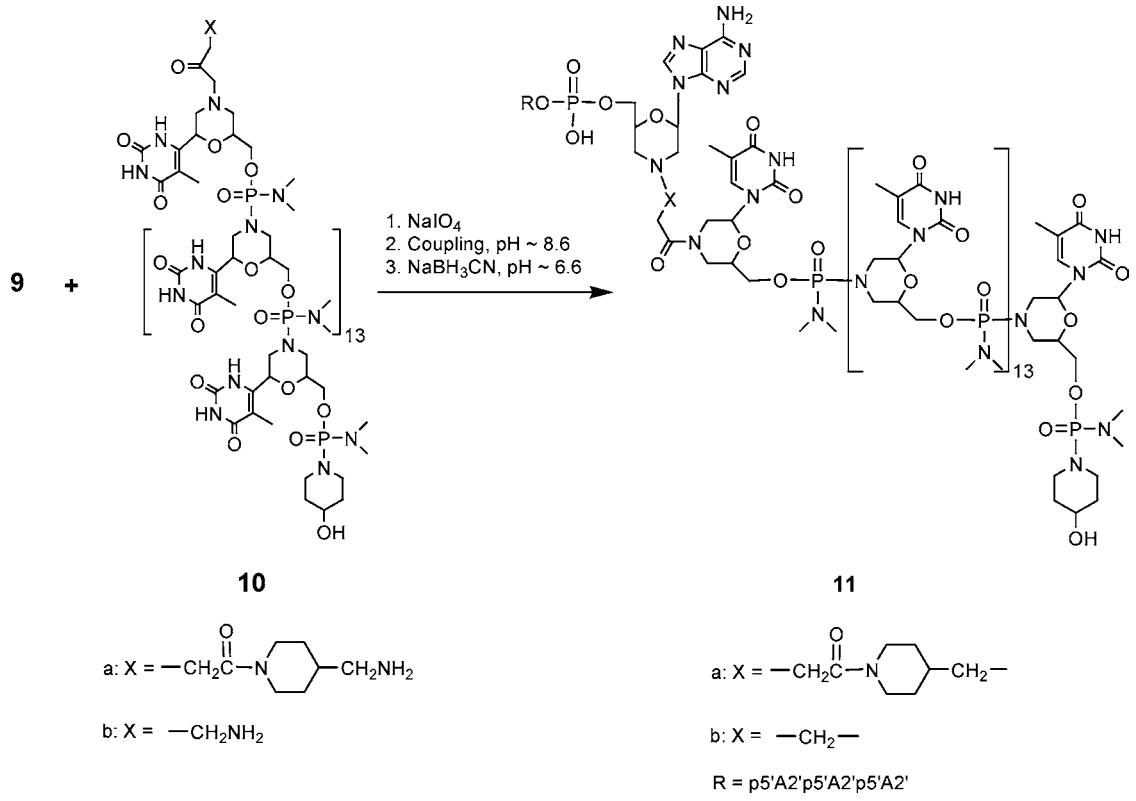


[a] Reaction conditions: (a) NH_4OH−EtOH (3:1), 55 °C; (b) 1 M tetrabutylammonium fluoride (TBAF) in THF, rt. (two steps of a and b, 80% yield).

RESULTS

Chemistry. *Synthesis of 2-5A Tetramer.* The target compound 2-5A tetramer **9** was synthesized by solution-phase phosphoramidite chemistry, and the synthesis, depicted in Schemes 1 and 2, was based upon a modified strategy of phosphoramidite methodology (*37*, *38*). 2′,3′-*O*-Dibenzoyl-N^6,N^6-dibenzoyl adenosine **1** was chosen as starting material for coupling with a commercially available N^6-benzoyl-5′-*O*-dimethoxytrityl-3′-*O*-*tert*-butyl-dimethylailyl-adenosine 2′-(*N*,*N*- diisopropyl-2-cyanoethyl)-phosphoramidite **2** at 5′-*O*-position in the presence of 1*H*-tetrazole in anhydrous acetonitrile at room temperature under nitrogen. Following oxidation by iodine solution and then detritylation with 3% CCl_3COOH in CH_2Cl_2, the corresponding dimer compound **3** was isolated in 71% yield. The deprotection of DMTr (dimethoxytrityl) group with 3% CCl_3COOH in CH_2Cl_2 was found to be much more effective than previous procedures using 80% acetic acid at room temperature (*38*). It was particularly important with relative higher concentration of reaction mixture in coupling step, because no reaction was observed with 10-fold less concentration, which was employed in the procedure for preparing the dimer **3**. Dinucleotide **3** was effectively coupled again with a higher mole ratio the building block **2** to yield the fully protected trinucleotide intermediate. After purified by flash column chromatography, the fully protected trimer was treated by 3% CCl_3COOH to produce trinucleotide **4** in 86.6% yield. The tetramer **5** was then prepared using the same coupling reaction, oxidation, and deprotection procedures from trimer **4** and phosphoramidite **2** with moderate yield (51.5%). The phosphorylation of the terminal 5′-hydroxy of tetramer **5** was also accomplished through the same coupling and oxidation procedure using commercially available bis-cyanoethyl-*N*,*N*-diisopropyl phosphoramidite **6** and afforded tetramer **7** with 66% yield (*39*). The deprotection of benzoyl and cyanoethyl groups was accomplished by treating of tetramer **7** with concentrated ammonium hydroxide−ethanol (3:1, v/v) at 55 °C for 9 h to produce tetramer **8** (Scheme 2). The *tert*-butyldimethylsily (TBDMS) silyl protection groups of **8** were removed by stirring with tetrabutylammonium fluoride (TBAF) solution in THF at room-temperature overnight (*33*). The final product was purified by a C-18 Sep-Pak Cartridge eluted with water and methanol−water (1:1) mixture to give a white solid **9** in 80% from

Scheme 3



7. The overall yield from **1** was 16.5%. The product 2-5A tetramer **9** was analyzed by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF/MS), and the observed molecular weight supported its structure. It was only a single peak by HPLC analysis [Beckman 406 instrument and an Adsorbosphere ODS analytical (4.6 × 250 mm) C-8 column were used with the following buffers: A: 50 mM $NH_4H_2PO_4$ (pH 7.00); B: 50% MeOH/H_2O. Linear gradient elution was performed with a flow rate of 1 mL/min], and it had the same retention time on HPLC as a standard sample of **9** made from solid-phase method.

Synthesis of 2-5A-Morpholino Antisense Chimera. The morpholine ring has been used to form conjugates between RNAs and several of other molecules, such as peptides (*40*), peptide nucleic acids (PNAs) (*20*), fluorescent labels (*41*), and a half-ribozyme (*42*). Morpholino-based oligonucleotides also have been prepared as antisense oligo agents (*43*). Our route to the synthesis of a 2-5A-morpholino antisense chimera is based on the well-known oxidation−reductive amination conjugation method (*44*−*49*). Thus, the chimera can be prepared from 2-5A tetramer through the oxidative cleavage of the five-membered ribose ring with sodium periodate followed by reductive coupling of the resulting dialdehyde with 5′-aminotether thymine morphant 15-mer to give a six-membered morpholine ring. These three steps were carried out sequentially in a single step without intervening purifications. It was very important to destroy all of the excess periodate before addition of T_{15}-Morpholino antisense due to its high oxidation susceptibility (*49*). The conjugate product 2-5A-Morpholino antisense chimera **11** was synthesized (Scheme 3) by using two different kind of linkages and purified by HPLC using an adsorbosphere C-8 column (column 4.6 × 250 mm, Alltech Company) and recorded at 260 nm. However, it should be noted that an adsorbosphere C-18 column (column 4.6 × 250 mm, Alltech Company) cannot be used to purify the antisense chimeras, because the product **11** adhered very strongly on the C-18 column. The conjugate products were analyzed by MALDI-TOF mass spectrometry, and the observed molecular weight supported its structure.

Biological Assays. To determine the biological activity of the 2-5A-morphants, ability to activate RNase L was determined by a fluorescence resonance energy transfer (FRET) method similar to that published earlier (*35*). The assay used recombinant human RNase L produced in insect cells from a baculovirus vector and purified to homogeneity with three successive FPLC columns (*36*). The cleavable substrate consists of a 36-nucleotide synthetic oligoribonucleotide sequence derived from respiratory syncytial virus with the fluorophore, FAM, at the 5′-terminus and black hole quencher-1 (BHQ-1), at the 3′-terminus (synthesized at Integrated DNA Technologies). The RNA sequence contains several cleavage sites for RNase L (UU or UA). A typical assay results in shown in Figure 1 and 2. In these figures, relative fluorescence is plotted vs concentration of either pure 2-5A tetramer as a standard, or against the concentration of 2-5A-morphant. Increase of fluorescence corresponds to RNA cleavage as the Quencher moiety is released as one fragment of the RNA chain and cannot quench the fluorophore at the other end of the parent chain. Two completely separate experiments are shown, one in each figure. Figure 1 shows the results with 2-5A-morphant (**11a**). The 2-5A-morpholino antisense chimera displayed an EC_{50} of about 100 nM with the standard 2-5A tetramer showing an EC_{50} of about 3 nM. Thus, **11a** was about 30 times less effective as an RNAse L activator

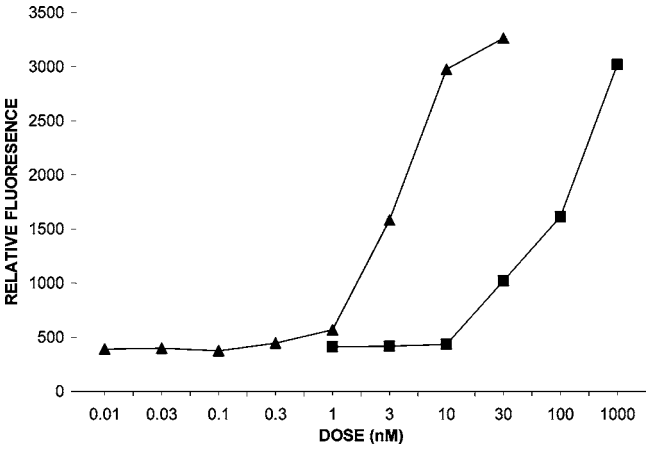


Figure 1. Standard curve dose−response of 2-5A tetramer **9** (▲) and 2-5A-T15-Morpholino antisense **11a** (■).

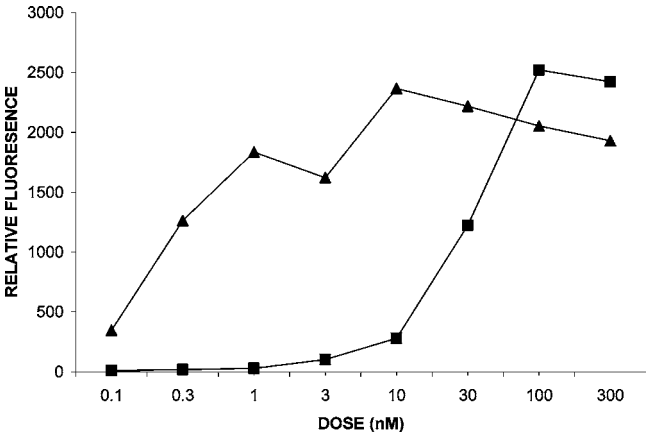

Figure 2. Standard curve dose−response at 90 min. 2-5A tetramer **9** (▲), 2-5A-T15-Morpholino antisense **11b** (■).

compared to parent 2-5A. In Figure 2 while 2-5A tetramer effected RNA substrate cleavage at an EC_{50} of approximately 0.3 nM, the 2-5A-morphant (**11b**) displayed an EC_{50} of about 30 nM.

DISCUSSION

To conjugate 2-5A to phosphorodiamidate morpholino oligomers, we first needed to prepare the 2-5A tetramer in reasonable amounts that would permit appropriate experimentation with development of conjugation chemistries and conditions. In fact, while various methodologies are reported in the literature, the generation of required synthons is no trivial procedure. Moreover, although synthons for solid-phase synthesis are commercially available, the overall yields of this solid-phase approach are only sub-micromoles using the presently available technology. Thus multiple solid-phase syntheses are required to provide a continual supply of 2-5A tetramer. We desired to develop a more practical approach to provide product 2-5A tetramer in a multiple micromole scale. We have successfully adapted synthetic conditions so that commercially available synthons can be used in solution phase to obviate the limitations of solid-phase synthesis. Herein we describe the synthesis of 2-5A tetramer on a multi-millimole scale in 98% purity.

The convergent synthesis strategy used to join 2-5A tetramer (**9**) to amino-derivatized phosphorodiamidate morpholino oligomers (**10a**, **10b**) was similar to that used to generate modified 2′,5′-oligoadenylates and 2-5A-PNAs. We employed an approach involving the periodate oxidation of 2′,5′-oligoadenylate to generate the terminal

dialdehyde, subsequent Schiff base formation with an aminolinker-bearing morpholino oligo, and finally reduction by cyanoborohydride. This route obviated the need for the development of a stepwise synthesis that would require synthons with RNA protecting groups compatible with morpholino oligo protection and coupling strategies.

We chose to synthesize prototype 2-5A-PMO conjugates with an all thymine PMO oligonucleotide analogue backbone in order to determine (a) if the PMO modification was compatible with RNase L activation and (b) the effect of linker variation on such activity if present. If the PMO and linkers were consistent with reasonable RNase L activation, then it would be possible to select specific virus- or cancer-related RNAs for 2-5A-PMO-antisense targeting. This investigational sequence is similar to that employed earlier to develop an effective inhibitor of respiratory syncytial virus (RSV) replication.

As is clear from Figures 1 and 2, both versions of the 2-5A-morpant conjugate are capable of activating RNase L albeit with reduced potency compared to parent 2-5A tetramer. These 30−100-fold reductions in RNase L activation ability, compared to unmodified 2-5A itself, are similar reductions in RNase L activation to that seen for other chimeric 2-5A-antisense constructs of similar chain length. This comparison is valid when evaluation was carried out against RNA substrates that were non-complementary to the antisense domain of 2-5A-antisense analogues. Thus for instance, in the case of the 2-5A-antisense chimera with an all DNA phosphodisester DNA antisense domain that did not complement the substrate RNA, RNase L activation ability was reduced by about 30-fold compared to parent 2-5A (*36*). When the antisense domain was a PNA that did not complement substrate RNA, then RNase L activation was reduced 60−100-fold (*20*). Greater activity has been observed when the antisense domain of the chimera targets specifically the RNA substrate. Thus a 2-5A-antisense molecule with an all phosphodiester DNA targeting a specific sequence of PKR RNA was only 3 times less active than parent 2-5A (*36*). This increase in activity against targeted substrate has been hypothesized to be related to a proximity effect due to creation of a new specific high affinity binding site (the antisense domain of the 2-5A-antisense chimera) on RNase L. In any case, it is clear from Figures 1 and 2 that 2-5A-morphants possess similar RNase L activation competence to previously described molecules of this genre. Furthermore, upon the basis of our experience with these assay determinations of EC_{50} and the fact that the experiments were completely independent, we do not ascribe any significant difference in RNase L activation competence to the two different 2-5A-morphants, **11a** and **11b**. Thus the linkage between the 2-5A and the morpholino antisense does not have a significant effect on biological activity, at least in this assay.

The results presented herein show that a convergent approach to 2-5A-phosphordiamidate morpholino oligomers (2-5A-morphants) is indeed possible. Moreover, the type of morpholino linkage generated by this periodate oxidation/Schiff base formation/cyanoborohydride reduction approach is compatible with reasonable activation of RNase L. Finally, these results suggest that the nature of the linker between the morpholino antisense domain and 2-5A moiety is likely of minimal importance.

These chimeric molecules, consisting of a 2′,5′-oligoadenylate activator of RNase L and a phosphordiamidate morpholino oligomer, combine the advantages of two previously separate strategies for RNA ablation. On one hand, the 2-5A domain of this conjugate recruits a constitutive cellular enzyme to the site of the targeted RNA molecule. On the other hand, the phosphordiamidate morpholino domain of the conjugate brings high resistance to degradation by enzymes of biological fluids, higher affinity for target RNAs, good water solubility, and greatly reduced synthetic production costs (*50*). In addition, morpholino oligos do not bind nonspecifically to many biological macromolecules, as do phosphorothioate oligos (*50*).

Ongoing studies will determine whether 2-5A-morphants have a significant future in antisense technology.

Polymer–DNA Hybrid Nanoparticles Based on Folate–Polyethylenimine-*block*-poly(L-lactide)

Chau-Hui Wang[†,‡] and Ging-Ho Hsiue*[,†]

Department of Chemical Engineering, National Tsing Hua University, Hsinchu, 300 Taiwan, ROC, and Polymer Technology Division, Union Chemical Laboratories, Industrial Technology Research Institute, Hsinchu, 300 Taiwan, ROC. Received October 13, 2004; Revised Manuscript Received January 25, 2005

The ability of amphiphilic block copolymers that consist of polyethylenimine (PEI) and poly(L-lactide) (PLLA) to modulate the delivery of plasmid DNA was evaluated. Folate–polyethylenimine-*block*-poly(L-lactide) (folate–PEI-PLLA) was synthesized by linking folic acid and PLLA to PEI diamine. Water-soluble polycation PEI provides gene-loading capability. Additionally, PEI is considered to exhibit high transfection efficiency and endosomal disrupting capacity. Hydrophobic PLLA that is incorporated into the gene delivery vector is believed to enhance the cell interactions and tissue permeability of the delivery system. Polymeric carrier containing folic acid is expected to be able to identify tumor surface receptors and transfect cells by receptor-mediated endocytosis. The results of agarose retardation assay indicated that the folate–PEI-PLLA began to form polyplexes at a polymer/DNA weight ratio (P/D) of over 10, whereas branched polyethylenimine (B-PEI) formed polyplexes with DNA at a ratio of above 1. The spherical particle morphology was supplemented with a particle size of approximately 100 nm at 10 P/D ratio. The results indicated that folate–PEI-PLLA with proper PEI/PLLA ratio effectively reduced cytotoxicity and maintained acceptable transfection efficiency. Low cytotoxicity of the folate–PEI-PLLA gives an advantage to high-dose administration.

INTRODUCTION

Nonviral gene carriers are considered to be safer to administer and to be able to be designed with more versatility than viral-gene carriers. Nonviral gene vectors such as cationic lipids and cationic polymers have been employed to deliver DNA, RNA, and oligonucleotides (ODNs) into cells (*1*–*3*). Branched polyethylenimine (B-PEI) is a polycation often used to condense DNA through electrostatic interactions. B-PEI exhibited high transfection efficiency, probably because it has a high buffering capacity. The proton sponge effect of B-PEI gives the polyplexes an endosomal disrupting capability, thus enhancing gene expression (*4*). On the other hand, linear polyethylenimine (L-PEI), which is synthesized by hydrolyzing poly(2-substituted-2-oxazoline), has been shown to have lower cytotoxicity but higher transfection efficacy than B-PEI (*5*). Fully hydrolyzed L-PEI is water-insoluble because it is crystalline. The water-soluble L-PEI can be prepared by the controlled acid hydrolysis of poly(2-ethyl-2-oxazoline) (*6*). PEI was also modified to be multifunctional by introducing polymer segments or targeting moieties to extend and enhance the release of the gene (*7, 8*).

Biodegradable polyesters such as poly(lactide) (PLA) and poly(lactide-*co*-glycolide) (PLGA) have been demonstrated to encapsulate DNA for sustained gene expression (*9*–*11*). Park et al. conjugated antisense ODN to biodegradable PLGA to yield an amphiphilic structure, which could form micelles in the aqueous phase (*12*). Furthermore, hydrophobic moieties are considered to improve the cell interactions and increase the tissue permeability of delivery systems. Kissel et al. prepared hyperbranched polyethylenimine-*g*-poly(ϵ-caprolactone)-*b*-poly(ethylene glycol) (*hy*-PEI-*g*-PCL-*b*-PEG) as gene vectors, and a high gene transfection efficiency was obtained by properly controlling the compositions of copolymers (*13*). Pluronics could also be incorporated into cell membranes as a result of the presence of the hydrophobic poly(propylene oxide) (PPO) chain (*14, 15*).

In this study, folate–polyethylenimine-*block*-poly(L-lactide) (folate–PEI-PLLA) was prepared as a new gene carrier. Partial hydrolysis of poly(2-ethyl-2-oxazoline) (PEOz) yielded water-soluble L-PEI with a high buffering capacity. PLLA and folic acid were conjugated to L-PEI to increase the transfection efficiency and reduce the cytotoxicity. The amphiphilic folate–PEI-PLLA copolymers condensed plasmid DNA and formed micelles in aqueous solution. The micelle core comprised PLLA segments and hydrophobic complexes. Moreover, the folate receptors were overexpressed on carcinomas (*16, 17*). Polymeric carrier that contained folic acid was expected to be able to identify tumor surface receptors and transfect cells by receptor-mediated endocytosis (*18*). Receptor targeting, endosomal disruption, improved cell permeability, and reduced cytotoxicity were combined for designing this nonviral gene vector. Synthesis, electrophoresis, surface morphology, and luciferase gene expression of folate–PEI-PLLA polyplexes were investigated in this work.

EXPERIMENTAL SECTION

Materials. Succinic anhydride and 4-(dimethylamino)pyridine (DMAP) were purchased from TCI Co., Ltd. pUHC 13-3 encoding for luciferase as a reporter gene was a gift from Prof. Jia-Ling Yang of National Tsing Hua University, Taiwan. Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), and trypsin−EDTA were the products of Gibco-BRL. Folate-free DMEM was purchased from Sigma. HeLa human adenocarcinoma cells were provided by Prof. Yu-Chen Hu of National Tsing Hua University, Taiwan. Dialysis tubing (MWCO 3500) was purchased from Spectrum Medical Industries, Inc.

Synthesis of Polyethylenimine (PEI) Diamine. Poly(2-ethyl-2-oxazoline) (PEOz) was synthesized by cationic ring-opening polymerization of 2-ethyl-2-oxazoline using 1,4-dibromo-2-butene as an initiator. A solution of 1,4-dibromo-2-butene (210 mg, 0.982 mmol) and 2-ethyl-2-oxazoline (10 mL, 98.86 mmol) in dry acetonitrile (30 mL) was heated to 100 °C and stirred for 16 h in an atmosphere of nitrogen. The living PEOz polymer chains were terminated by adding acetonitrile solution that contained NH_3 (0.12 N) at 0 °C; the solution was then stirred for 30 min. The polymer solution was filtered through the silica gel and was purified by precipitation in diethyl ether. After it had been completely dried, a powdery product was obtained. The molecular weight and polydispersity of PEOz diamine were analyzed by taking gel permeation chromatography (GPC) measurements.

PEOz diamine (2 g) was heated with a mixture of concentrated hydrochloric acid (11 mL, 35%) and water (16 mL) at 110 °C for 3 h. The pH of the polymer solution was adjusted to 9−10 by adding NaOH pellets. The product was then purified by dialysis for 3 days using cutoff dialysis tubing with a molecular weight of 3500. After it had been vacuum-dried, the product was stored at −20 °C. ^{1}H NMR (D_2O): δ 0.92 ($N(COCH_2CH_3)CH_2CH_2$), 2.25 ($N(COCH_2CH_3)CH_2CH_2$), 2.69 ($NHCH_2CH_2$), 3.40−3.50 ($N(COCH_2CH_3)CH_2CH_2$).

Synthesis of Monocarboxypoly(L-lactide) (PLLA-COOH). L-Lactide (4 g, 27.75 mmol) and benzyl alcohol (216 mg, 2 mmol) were polymerized with 1 wt % stannous octoate in dry toluene (2 mL) at 140 °C for 16 h under nitrogen. After being allowed to cool, the product was filtered using a syringe filter (0.22 μm) and then precipitated in *n*-hexane. The yielded PLLA-OH was vacuum-dried for 24 h.

PLLA-OH (1 g, 0.4 mmol), succinic anhydride (80 mg, 0.8 mmol), and DMAP (97.6 mg, 0.8 mmol) were dissolved in 1,4-dioxane (7 mL) and reacted in an atmosphere of nitrogen for 24 h at room temperature. The product was precipitated in *n*-hexane and reconstituted using tetrahydrofuran. After 0.1 N of HCl had been added, the polymer solution was poured into a large amount of distilled water. The precipitates were dissolved in tetrahydrofuran and then purified by precipitation in *n*-hexane. ^{1}H NMR ($CDCl_3$): δ 1.42 ($COCH(CH_3)O$), 3.75 ($COCH_2CH_2COOH$), 4.35 ($COCH_2CH_2COOH$) 5.19 ($COCH(CH_3)O$), 7.38 (C_6H_5).

Synthesis of Folate−Polyethylenimine-*block*-poly(L-lactide) (folate-PEI−PLLA). PEI diamine (500 mg, 0.167 mmol), PLLA-COOH (208 mg, 0.083 mmol), DMAP (40.8, 0.33 mmol), and DCC (69 mg, 0.33 mmol) were dissolved in DMSO (10 mL). The reaction was carried out in a nitrogen atmosphere at room temperature. After 24 h, folic acid (7.4 mg, 0.017 mmol), DMAP (40.8, 0.33 mmol), and DCC (69 mg, 0.33 mmol) were added into the mixture under nitrogen, and reacted at room temperature for a further 24 h. The unreacted PLLA-COOH and folic acid were purified by dialysis (with a molecular weight cutoff of 3500) in DMSO and distilled water for 3 days, respectively. Following lyophilization, the obtained folate−PEI-PLLA was stored at −20 °C.

Preparation of Polyplexes. A 5 μg amount of luciferase encoding plasmid pUHC-13-3 and the desired amount of polymer were each diluted in 100 μL of distilled water and gently mixed. The polyplex formulation was incubated at room temperature for 30 min before it was used. The particle size was analyzed by dynamic light scattering (DLS, Malvern Instrument Series 3000).

Gel Retardation Assay. Various formulations of polyplexes were prepared as previously described, before loading into the gel. The samples were electrophoresed on 1% agarose gel in 1X TRIS−boric acid−EDTA (TBE) buffer at 100 mV until the 1X loading dye ran through 80% of the gel. A 1 kb DNA marker (Violet) used for comparing the size of DNA was also run. The gel was stained with 0.5 μg/mL ethidium bromide for 45 min and analyzed using an UV transilluminator.

Atomic Force Microscopy. The surface morphology of polyplexes was analyzed by atomic force microscopy (AFM). The polyplex solution was diluted in 1 mL of distilled water and dropped on a silica wafer. After it was spin-coated with a spin coater, the sample was dried in the dry box for 2 days and in vacuo for 30 min before use.

Luciferase Transfection and Total Protein Assay. Human cervix carcinoma HeLa cells (2×10^5 cells/well) plated in six-well plates were incubated in DMEM media supplemented with 10% fetal bovine serum (FBS) in a humidified atmosphere of 5% CO_2 at 37 °C for 24 h. Transfection was conducted after the cells had become about 80% confluent. A 2 mL amount of growth medium that contained the DNA or polyplexes with a final amount of 5 μg of plasmid was incubated for 48 h at 37 °C. Following transfection, the cells were washed with cold PBS and then lysed with 400 μL of 1X cell lysis buffer. The cell lysate was then transferred into eppendorf tubes and centrifuged for 1 min at 12 000 rpm. Luciferase activity was measured in terms of relative light unit (RLU) using a 96-well plate luminometer (Wallac 1420 Multilabel Counter, Perkin-Elmer) and a luciferase assay kit (Promega). Total protein was measured at 595 nm using a BioRad protein assay.

In Vitro Cell Viability. Human cervix carcinoma HeLa cells (1×10^4 cells/well) were cultured onto a plate with 96 wells in DMEM media supplemented with 10% fetal bovine serum (FBS) in a humidified atmosphere of 5% CO_2 at 37 °C for 24 h. The growth medium was replaced with a medium that contained the desired amount of polymers. Cells were incubated for 24 h, and cell viability was assayed by adding 100 μL of medium that contained 10 μL of MTT PBS solution (5 mg/mL). After incubation for 4 h, the formazan crystals were dissolved in 100 μL of DMSO. The absorbance of each well was measured using a microplate reader (Stat Fax 2100, Awareness) at a test wavelength of 570 nm and a reference wavelength of 630 nm.

RESULTS AND DISCUSSION

Synthesis of Folate−PEI-PLLA. The PEOz was synthesized by cationic living polymerization with a bifunctional initiator 1,4-dibromo-2-butene (*19*). The reaction was terminated by adding NH_3 acetonitrile solution to introduce NH_2 functional groups to both ends

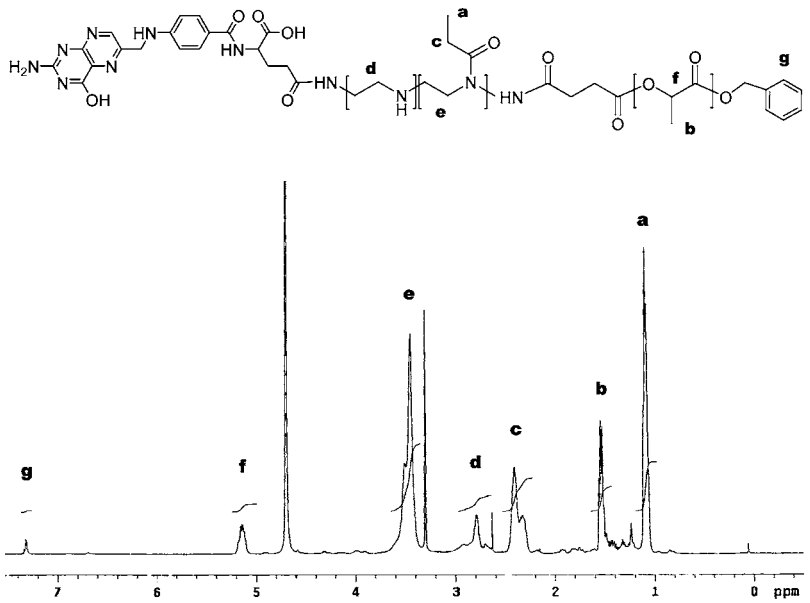

Figure 1. ^{1}H NMR spectrum of folate–PEI-PLLA.

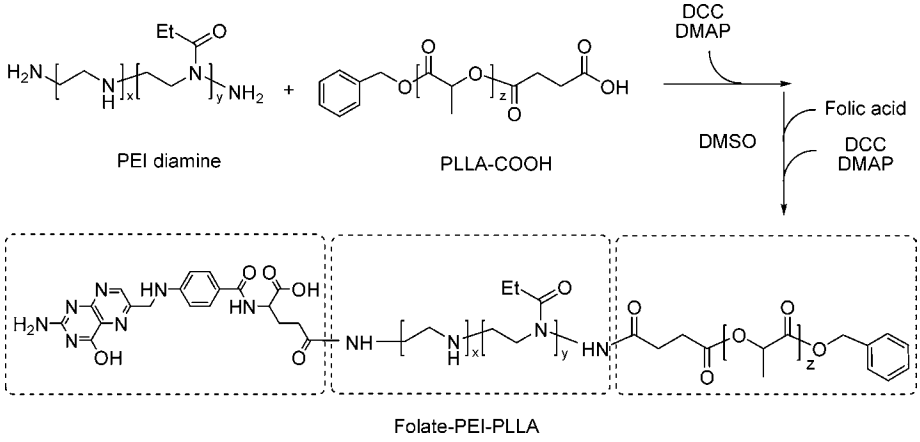
Scheme 1. Synthesis of Folate–PEI-PLLA by the DCC-Mediated Polycondensation Reaction



of polymer chains (*20*). The number average molecular weight (M_n) and polydispersity (PDI) determined by GPC were 9800 and 1.18, respectively.

Acid hydrolysis of the PEOz diamine was performed using hydrochloric acid. The percentage hydrolysis was estimated by comparing the integral peak area of the ethylenimine groups to *N*-propionylethylenimine groups. The molecular weight following hydrolysis was calculated from the percentage hydrolysis.

The L-lactide and benzyl alcohol were polymerized with stannous octoate. PLLA-OH was allowed to react with succinic anhydride in the presence of DMAP to prepare PLLA with a carboxyl group at the end of the chain (*21*). The M_n determined by GPC was 2500, and the PDI was 1.3.

The amphiphilic folate–PEI-PLLA copolymers were synthesized by the DCC-mediated polycondensation reaction of two oligomers: PEI diamine and PLLA-COOH (Scheme 1). The composition of folate–PEI-PLLA was varied to optimize the gene expression. Figure 1 presents the ^{1}H NMR spectrum of folate–PEI-PLLA. The molar ratio of PLLA to PEI was determined by the ratio between of the area under the peak of the methyl group in the PLLA block to that of the ethylene groups in the PEI block.

The folic acid content in folate–PEI-PLLA was measured using a UV/vis spectrophotometer. Folate–PEI-PLLA was dissolved in DMSO, and the absorbance at a wavelength of 289 nm was determined. The concentration of folic acid was calculated according to the calibration curve made from free folic acid. Both α- and γ-carboxyl groups on the folic acid have been reported to undergo coupling reactions, and only the γ-conjugate can bind to the folate receptor. The DCC-mediated polycondensation reaction involves about 80% γ-linked and 20% α-linked conjugates (*22*). Table 1 characterizes B-PEI, L-PEI, and folate–PEI-PLLA. The DLS analyses of the folate–PEI-PLLA and the DNA showed that no particle was formed before mixing them in solution.

Table 1. Characterizations of B-PEI, L-PEI, and Folate–PEI-PLLA

code	M_n (PEI)	hydrolysis (%)	PEI/PLLA (mol)	folic acid (mmol/g)	particle size (nm)
B-PEI	10000	–	–	–	68
L-PEI	5200	84	–	–	154
FEA1	5600	75	0.90	0.1100	156
FEA2	12600	66	0.93	0.0750	166
FEA3	3600	85	0.41	0.0421	110

Gel Retardation Assay. Agarose gel electrophoresis was performed to assess the influence of B-PEI, L-PEI, and folate–PEI-PLLA on DNA condensation. Figure 2 presents the gel retardation results for the polyplexes. Increasing the concentrations of the polymers reduced the electrophoretic mobility of the plasmid, by increasing

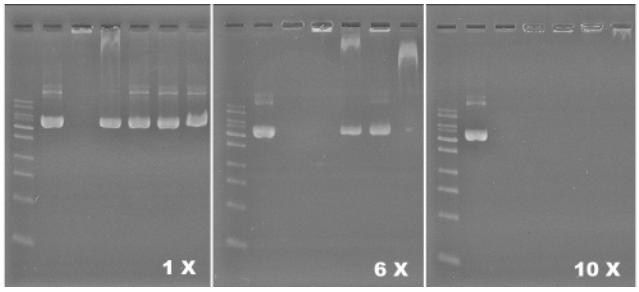


Figure 2. Gel retardation assay. Lane 1: DNA ladder, Lane 2: plasmid DNA, Lane 3: B-PEI/DNA polyplex, Lane 4: L-PEI/DNA polyplex, Lane 5: FEA1/DNA polyplex, Lane 6: FEA2/DNA polyplex, Lane 7: FEA3/DNA polyplex.

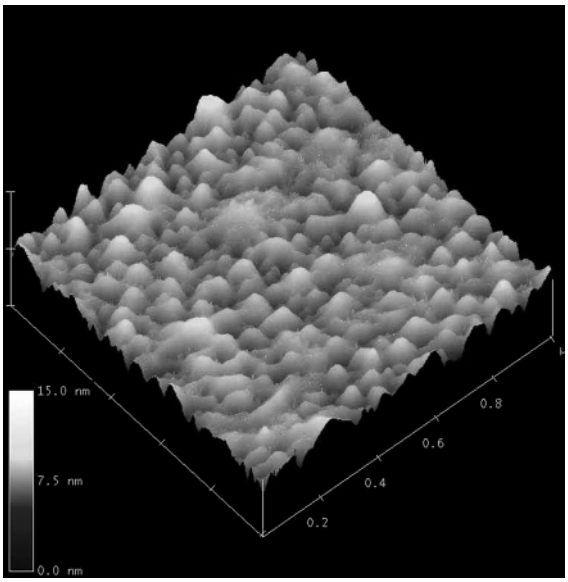

Figure 3. Atomic force microscopy (AFM) image of the folate−PEI-PLLA polyplexes (FEA3, P/D: 10).

DNA condensation and compaction. The B-PEI and L-PEI are completely retarded as can be seen as the polymer/DNA (P/D) ratio (w/w) approaches 1 and 6, respectively. The results of agarose retardation assay indicated that the DNA condensing capacity of folate−PEI-PLLA was slightly decreased. The folate−PEI-PLLA began to form polyplexes at a P/D ratio of above 10.

Atomic Force Microscopy. The surface morphology of folate−PEI-PLLA polyplex was determined by atomic force microscopy (AFM). Figure 3 shows an AFM image of folate−PEI-PLLA polyplexes (FEA3) spread on the silica wafer. The spherelike particles were around 100 nm in diameter at a P/D ratio of 10.

In Vitro Transfection. The transfection efficiencies of B-PEI, L-PEI, and folate−PEI-PLLA polyplexes prepared at various P/D ratios on HeLa human cervix carcinoma were evaluated. Transfection efficiency was determined by luciferase assay for the luciferase encoding plasmid. The total protein production, which was an indirect measure of induced toxicity, was analyzed to normalize the RLU. Figure 4 shows the luciferase gene expression of folate−PEI-PLLA at various P/D ratios on HeLa cells. The change in RLU is directly proportional to the amount of luciferase produced in the transfected cells. For a given amount of plasmid DNA (5 μg), increasing the amount of polymers increased the transfection efficiency. This result indicated that only FEA3 exhibited extensive luciferase gene expression. FEA1 and FEA2, which have relatively high PLLA contents, did not exhibit improved transfection efficiency. Figure 5 compares the luciferase gene expressions of B-PEI, L-PEI, and FEA3 polyplexes at various P/D ratios. For B-PEI and L-PEI polyplexes, luciferase expression in HeLa cells is stronger at a P/D ratio of above 3. FEA3 polyplex showed greater transfection at a P/D ratio of 7. Figure 6 shows the highest level of luciferase expression in naked DNA, B-PEI, L-PEI, and folate−PEI-PLLA. The results reveal that the appropriate gene carrier exhibited greater transfection efficacy than naked DNA. B-PEI and L-PEI

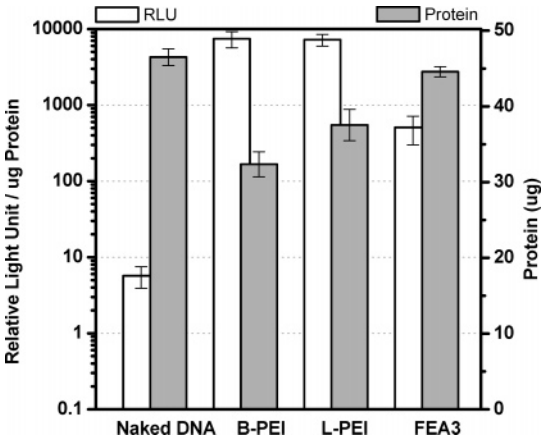

Figure 6. The highest level of luciferase expression in naked DNA, B-PEI, L-PEI, and folate−PEI-PLLA and their total protein productions (n = 3). B-PEI (P/D: 3), L-PEI (P/D: 3), FEA3 (P/D: 7).

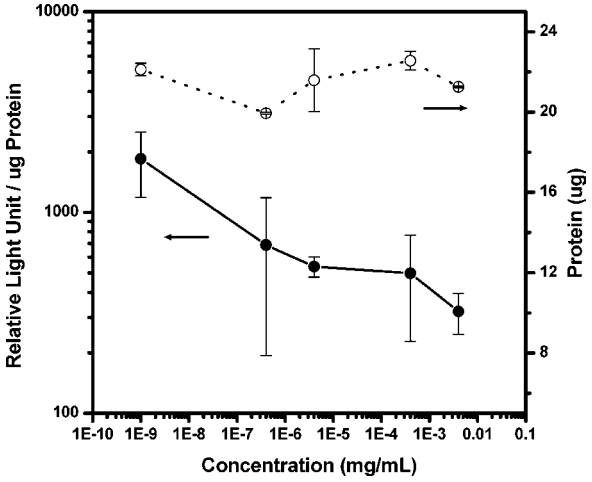

Figure 7. The luciferase gene expression of FEA3 polyplexes at different concentrations of free folic acid (n =3).

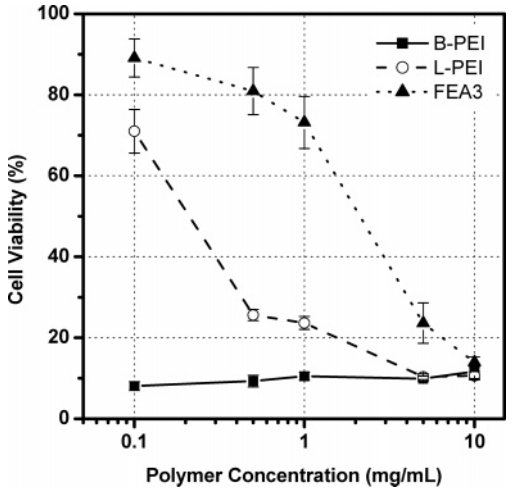

Figure 8. The cytotoxicity of B-PEI, L-PEI, and FEA3 on HeLa cells at various polymer concentrations (n = 6).

showed better gene expression than that of FEA3. In contrast, the protein production of FEA3 was similar to that of naked DNA, indicating that FEA3 had low cytotoxicity.

Folate−PEI-PLLA exhibited less transfection than B-PEI and L-PEI, so determining whether free folic acid suppresses transfection is important. It is not certain that HeLa cells have folate receptors. However, a number of publications have indicated that the folate receptors on HeLa cells are up-regulated ($>15 \times 10^6$ folate binding sites/HeLa cell) (*23*). As shown in Figure 7, free folic acid competed with FEA3 polyplexes in transfection. The common DMEM media contains 0.004 mg/mL of folic acid. The luciferase expression increased as the free folic acid concentration declined. The total protein production was maintained at about 22 μg, revealing that free folic acid did not affect cytotoxicity, and considerably inhibiting the endocytosis of FEA3.

Cell Viability. The in vitro cytotoxicity of B-PEI, L-PEI, and FEA3 at various concentrations was determined in the HeLa cell line by MTT assay. The wells that contained only the media and untreated polymer were regarded as positive controls, with a cell viability of 100%. The relative cell viability was determined as $[Abs]_{sample}/[Abs]_{control} \times 100$. Figure 8 reveals that B-PEI exhibited high toxicity, resulting in cell death. In contrast to B-PEI and L-PEI, the cell viability of FEA3 exceeded 80% at a concentration of 0.5 mg/mL. The efficacy of a gene carrier is depends partly on the corresponding toxicity of the polymer. The low cytotoxicity of folate−PEI-PLLA allows it to be safely administered.

CONCLUSION

In this work, a new polymeric gene carrier, folate−PEI-PLLA, was successfully synthesized. The introduction of PLLA and folic acid was expected to increase cell permeability and biocompatibility. However, polymers that contain relatively large amounts of high PLLA mediated gene transfer less efficiently than did B-PEI and L-PEI. Folate-PEI-PLLA effectively reduced toxicity on HeLa cells but also reduced the luciferase expression. Additionally, the morphology of folate−PEI-PLLA polyplex was spherical, thus unlike that obtained from the B-PEI polyplex. B-PEI formed a polyplex with DNA as an oblique sphere, which has been suggested to be able to enter the cell easily (*24*). Although biodegradable polyesters are commonly used to deliver plasmid DNA, their transfection efficiency compared with PEI has been rarely discussed. The results herein reveal that folate−PEI-PLLA with a proper PEI/PLLA ratio effectively reduced cytotoxicity and maintained an acceptable transfection efficiency. Low cytotoxicity of the folate−PEI-PLLA gives the advantage for the high dose amount of administration.

Synthesis and Evaluation of a Star Amphiphilic Block Copolymer from Poly(ϵ-caprolactone) and Poly(ethylene glycol) as a Potential Drug Delivery Carrier

Fei Wang,*,† Tatiana K. Bronich,‡ Alexander V. Kabanov,‡ R. David Rauh,† and Jacques Roovers§

EIC Laboratories, Inc., 111 Downey Street, Norwood, Massachusetts 02062, and Department of Pharmaceutical Science, University of Nebraska Medical Center, 986025 University Medical Center, Omaha, Nebraska 68198-6025. Received September 13, 2004; Revised Manuscript Received December 30, 2004

A star polymer composed of amphiphilic block copolymer arms has been synthesized and characterized. The core of the star polymer is polyamidoamine (PAMAM) dendrimer, the inner block in the arm is lipophilic poly(ϵ-caprolactone) (PCL), and the outer block in the arm is hydrophilic poly(ethylene glycol) (PEG). The star-PCL polymer was synthesized first by ring-opening polymerization of ϵ-caprolactone with a PAMAM-OH dendrimer as initiator. The PEG polymer was then attached to the PCL terminus by an ester-forming reaction. Characterization with SEC, ^{1}H NMR, FTIR, TGA, and DSC confirmed the star structure of the polymers. The micelle formation of the star copolymer (star-PCL−PEG) was studied by fluorescence spectroscopy. Hydrophobic dyes and drugs can be encapsulated in the micelles. A loading capacity of up to 22% (w/w) was achieved with etoposide, a hydrophobic anticancer drug. A cytotoxicity assay demonstrated that the star-PCL−PEG copolymer is nontoxic in cell culture. This type of block copolymer can be used as a drug delivery carrier.

INTRODUCTION

Micelles formed from amphiphilic block copolymers have recently attracted significant attention in diverse fields of medicine and biology. In particular, polymeric micelles have been developed as drug and gene delivery systems (*1*−*3*) as well as carriers for various contrasting agents in diagnostic imaging applications (*4*). In an aqueous environment, the hydrophobic blocks of the copolymer are expected to segregate into the core of the micelle, whereas the hydrophilic blocks form the corona or outer shell. Such a core−shell architecture of the polymeric micelles is essential for their utility as novel functional materials for pharmaceutical applications. The hydrophobic micelle core serves as a microenvironment for the incorporation of various therapeutic compounds; the corona, or outer shell, serves as a stabilizing interface between the hydrophobic core and the external medium. As a result, polymeric micelles can be used as efficient containers for reagents with poor solubility and/or low stability in physiological environments (*5*, *6*). Interest in polymeric micelles for drug delivery has increased rapidly since the late 1980s (*7*). Most of the work has focused on classical micelles formed by intermolecular aggregation of amphiphilic polymers as the drug delivery vehicle, and the advantages of using micelle structures as a drug delivery system have been demonstrated (*8*, *9*).

The major factors that influence the performance of polymeric micelles for drug delivery are loading capacity, release kinetics, circulation time, biodistribution, size, and stability (*2*). Micelle stability is particularly important. Recent studies have shown that the in vivo antitumor activity of a drug incorporated into the polymer micelles is positively correlated with the stability of micelles in vitro (*10*). The formation of classical micelles is thermodynamically favorable only above a specific concentration of the amphiphilic molecules (critical micelle concentration, cmc). Above the cmc, micelles are in dynamic equilibrium with the free copolymer molecules (unimers) in solution, continuously breaking and reforming (*11*). When the concentration of the copolymer is below the cmc, micelles tend to disassemble. Such thermodynamic instability of micelles below the cmc is one of the concerns for their application in vivo. A delivery system is subject to a severe dilution upon intravenous injection into an animal or human subject. In the bloodstream, under dilution, micelles begin to disassemble, causing changes in micelle structure and size. Therefore, controlling the release rate of drugs is difficult. Sudden dissociation of micelles may cause serious toxicity problems due to potentially large fluctuations in drug concentrations.

The problem associated with the classical micelle structure can be overcome by developing molecules in which the lipophilic components are covalently bound together within the micelle core. Core polymerization is an effective method to prevent dissociation of the block copolymer micelle. Kataoka's group has successfully employed this idea (*12*). In their study, the micelles were prepared from an amphiphilic block copolymer in which the hydrophobic block contained a polymerizable end group. After micellation, the end groups on the hydrophobic block were polymerized to form a stable core for the star-shaped polymer structure. The resulting micelles showed fairly high stability and maintained small size. As anticipated, the core polymerized micelle showed excellent solubilization of rather large molecules such as taxol (*13*).

Another approach developed recently by Uhrich et al. (*14*) with a three-arm star polymer composed of mucic acid substituted with fatty acid as the lipophilic inner block and with PEG as the hydrophilic outer block. This new type of molecule was capable of encapsulating a hydrophobic model drug in aqueous media. However, due to the structural constraints, the free volume of the hydrophobic core was limited, and only one or two drug molecules could be encapsulated in each micelle. A series of star block copolymers with the number of arms ranging from three to eight has also been synthesized (*15*). The arms were composed of block copolymer with PEG as the inner hydrophilic block and PCL as the outer hydrophobic block. The application of this type of copolymer as an injectable drug delivery system was reported (*16*). It was found that a reversible sol−gel transition process exists for this system, which is useful for drug delivery. However, such star copolymers do not form micelles in aqueous media because the hydrophilic block is located in the interior of the star. A recent paper (*17*) described the synthesis of a four-arm star block copolymer of PCL and PEG by the same route and similar chemistry as reported in this paper. Another paper (*18*) described the preparation of a four-arm star PCL-*b*-PEG polymer with diethylzinc catalyst. However, the molecular weight distribution of the block copolymer was unacceptably wide.

Many studies have been carried out using dendrimers as drug delivery systems (*19*). Star polymers with a dendrimer as the hydrophobic core and multiple PEG chains as the hydrophilic arms have been synthesized and investigated as unimolecular micelles for drug delivery by Fréchet and Kono (*20*, *21*). It has been demonstrated that the micelles with larger dendrimer core have a higher encapsulation capability than those with smaller cores. However, due to the structural limitations involved in the synthesis of dendrimers of higher generation, and the relatively compact structure of the dendrimers, it is difficult to increase significantly the size of the hydrophobic dendritic core in the dendrimer−PEG star polymer. Therefore, such dendrimer systems have limitations in terms of drug-loading capacity and delivery of compounds of large size.

In this paper, we describe the synthesis and micellar characterization of a novel amphiphilic star polymer. The core of this star polymer is a polyamidoamine (PAMAM) dendrimer; the inner block in the arm is lipophilic poly(ϵ-caprolactone) (PCL), and the outer block in the arm is hydrophilic poly(ethylene glycol) (PEG). First, a star PCL polymer was synthesized using the PAMAM-OH dendrimer as the initiator for ring-opening polymerization of ϵ-caprolactone. A PEG polymer was then attached to the terminal group of PCL by an ester-forming reaction. In this star polymer the arms consist of polymers that are biocompatible and biodegradable. The star structure of the polymers was confirmed by several physicochemical methods. To establish this system as a suitable drug carrier, the micellar properties of the star amphiphilic polymer in aqueous media were studied by fluorescence techniques and dynamic light scattering. The solubilization capacity of star-PCL−PEG micelles was evaluated using several highly hydrophobic compounds, such as pyrene and water-insoluble dye molecules. A series of entrapment experiments showed that various drugs could be incorporated in such micelles. These results indicate that the star-PCL−PEG micelle system is a promising drug carrier for the delivery of lipophilic drugs.

EXPERIMENTAL SECTION

Materials and Methods. PEG (M_n = 5000) with methoxy and carboxymethyl terminal groups was used as received from Shearwater Polymers. 4-(Dimethylamino)pyridinium 4-toluenesulfonate (DPTS) was synthesized as described (*22*). Dichloromethane was dried by stirring over and distilling from P_2O_5. All other reagents and solvents were used as received from Aldrich Chemical. Indomethacin (IMC), doxorubicin hydrochloride (DOX), and etoposide were purchased from Sigma (St. Louis, MO) and were used without further purification.

^{1}H NMR spectra were recorded on a Hitachi R-1500 FT-NMR spectrometer at 60 MHz. Infrared spectra were recorded on a Nicolet 750 FTIR spectrometer. UV−vis spectra were recorded on a HP 8452A UV−vis diode array spectrophotometer. Size exclusion chromatography (SEC) was used to determine the molecular weights, polydispersity, and degree of branching of the synthesized polymers. SEC measurements were conducted using a Hewlett-Packard series 1050 HPLC equipped with one Polymer Laboratories PL gel 5μ mixed-D column and a Hewlett-Packard 1047A refractive index detector, Viscotek T60 light scattering (LS), and viscosity detectors. Chloroform was used as the eluting solvent at a flow rate of 1 mL/min. It was found that chloroform was the eluent of choice. The block copolymer is poorly soluble or is retained on the column as indicated by trailing elution profiles in other common SEC solvents. Data analysis was performed using Viscotek Trisec GPC software version 3.0.

The thermal transitions of the polymers were determined using a Perkin-Elmer DSC7 differential scanning calorimeter under nitrogen purge. The samples were heated at a rate of 10 °C/min. The thermal stability of the prepared polymers was evaluated using a Perkin-Elmer TGA7 thermogravimetric analyzer under nitrogen purge with a heating rate of 20 °C/min.

Synthesis of the Star-PCL. A 100 mL three-neck flask equipped with a condenser and an argon gas inlet was charged with PAMAM-OH dendrimer generation 2 with 16 terminal OH groups (20 wt % solution in methanol, 5.76 mL, 0.304 mmol). Methanol was then removed under vacuum. A predetermined amount of ϵ-caprolactone (14.42 g, 126 mmol) followed by 15 mL of benzene was added into the reaction flask. The mixture was heated to reflux using a Dean−Stark trap for 30 min, and benzene was distilled off. The heating of the reaction mixture to 140 °C resulted in the dissolution of the dendrimer in ϵ-caprolactone. Five milligrams (0.012 mmol) of tin(II) 2-ethylhexanoate [$Sn(Oct)_2$] was then introduced into the reaction mixture followed by stirring at 115−120 °C for 20 h. The reaction mixture was cooled to room temperature, dissolved in THF, and precipitated into cold methanol. After drying, 15.4 g (100% yield) of a white solid product was obtained. The polymer was further purified by fractionation. Three grams of star-PCL was dissolved in 60 mL of THF in a round-bottom flask, and methanol was added until the solution became cloudy. The solution was heated in a water bath at 60 °C and became clear. About 10 mL of methanol was added to reach a cloudy point, and the mixture was transferred into a hot separation funnel and allowed to stand at room temperature for 3 days. The polymer solution separated into two layers, and the top layer was removed without disturbing the lower layer. The lower layer was diluted with THF and precipitated into cold methanol; 1.47 g of polymer was obtained: ^{1}H NMR ($CDCl_3$) δ 4.07 (t, 2H, OCH_2), 2.31 (t, 2H, $COCH_2$), 1.1−2

[m, 6H, $(CH_2)_3$]. The characteristic peaks of dendrimer and polymer were overlapping, and peak integration was inconclusive.

Synthesis of the Linear-PCL. The linear PCL was synthesized in a similar procedure using ϵ-caprolactone (14.42 g, 126 mmol), ethylene glycol (0.098 g, 1.57 mmol), and a few drops of $Sn(Oct)_2$. Isolation was conducted with the same procedure as described previously.

Synthesis of the Star-PCL-PEG. Star-PCL (1.3 g, 0.0253 mmol), PEG (2.64 g, 0.527 mmol), and DPTS (0.155 g, 0.527 mmol) were dissolved in 80 mL of dry CH_2Cl_2 by stirring at room temperature. Then diisopropylcarbodiimide (DIPC) (0.2 g, 1.58 mmol) was added into the reaction mixture via syringe. The reaction mixture was stirred overnight at room temperature. An additional amount of DIPC (0.15 g) was added to the reaction mixture followed by stirring for 5 days. The reaction was stopped, and fractionation was used to purify the star-PCL−PEG. Briefly, 20 mL of CH_2Cl_2 was added to dilute the product. Hexane was slowly added to the resulting solution at 45 °C until the appearance of cloudiness. Then the mixture was transferred into a hot separation funnel and was allowed to stand at room temperature. The top layer was removed, and the lower layer was diluted with CH_2Cl_2 and precipitated into hexane. Analysis of the polymer by ^1H NMR indicated that the sample contained excess PEG and other impurities. The product was refractionated: the entire product (~3.5 g) was dissolved in 100 mL of CH_2Cl_2 followed by the gradual addition of hexane until the mixture became cloudy. The resulting mixture was then heated in a 45 °C bath followed by the addition of more hexane until a stable cloudy point was reached and transferred into a hot separation funnel. The lower layer was diluted with CH_2Cl_2 and precipitated into hexane. After drying, 3.04 g (91% yield) of white solid product was obtained: ^1H NMR ($CDCl_3$) δ 4.07 (t, 2H, $COOCH_2$), 3.64 (s, 18.8H, OCH_2CH_2O), 2.31 (t, 2H, $COCH_2$), 1.1−1.9 [m, 6H, $(CH_2)_3$].

Preparation of Star-PCL−PEG Micelles. The star-PCL−PEG polymer was dissolved in DMF at ~100 mg/mL and stirred overnight at room temperature. Water was added in a dropwise fashion to the star-PCL-PEG solution in DMF. The addition of water was continued until the desired water content was achieved (12.5−25 vol % of DMF in the final mixture). The obtained solution was stirred overnight and then dialyzed against Milli-Q distilled water using Membra-Cel MD-25-03.5 membrane tubing. The dialysate water was exchanged every hour for the first 4 h and then every 6 h for the next 12 h. The concentration of star-PCL−PEG solutions was determined by UV spectroscopy. The absorption spectrum of star-PCL−PEG in a DMF/water mixture (50 vol % DMF content) has a characteristic peak at 281.7 nm. The absorption maximum of star-PCL−PEG undergoes a bathochromic shift to 288.4 nm in pure aqueous solutions. A calibration curve of standard solutions of star-PCL−PEG from 0.1 to 1.5 mg/mL was constructed by monitoring UV absorbance at 288.4 nm and used to determine the star-PCL−PEG concentration in aqueous solutions after dialysis ($Y = 0.00006 + 0.1679\,X$, $r^2 = 1.0$).

Micelle Characterization. Dynamic laser light scattering (DLS) measurements on the star-PCL−PEG micelles were carried out using a "ZetaPlus" zeta potential analyzer (Brookhaven Instrument Co.) equipped with the multiangle sizing option (BI-MAS) and with a 15 mW solid-state laser operated at a wavelength of 635 nm. All measurements were performed at 23 °C and at scattering angle of 90°. Software provided by the manufacturer was used to calculate the effective hydrodynamic diameters of the micelles. The apparent critical micelle concentration (C_{app}) was determined using pyrene as a fluorescent probe. Sample solutions were prepared by adding known amounts of pyrene in acetone to each of a series of empty vials. The amount of pyrene was chosen so as to give a pyrene concentration in the final solution of 6×10^{-7} M. After the evaporation of acetone, solutions of star-PCL−PEG of various concentrations in phosphate buffer saline (10 mM, pH 7.4, 0.14 M NaCl) were added to the probe. Samples were equilibrated upon shaking overnight at the desired temperature. Steady-state fluorescence spectra were recorded using a Shimadzu RF5000U spectrofluorophotometer with bandwidths of 1.5 nm for excitation and 3 nm for emission, respectively. For fluorescence emission spectra, λ_{ex} was 336 nm, and for excitation spectra, λ_{em} was 390 nm.

Solubilization of Water-Insoluble Dyes. Oil Red O (ORO) and 1-(*m*-tolylazo)-2-naphthylamine (Yellow OB) were used as model hydrophobic molecules for solubilization experiments. Appropriate amounts of the copolymer solutions of various concentrations were added to the vials containing a given amount of solid dye and were equilibrated upon shaking for 2 days. Test solutions were centrifuged to remove the residual insoluble dye. The amount of dye entrapped in the micelles was determined by measuring the absorbance at 510 nm for ORO and at 450 nm for Yellow OB, respectively.

Preparation of Drug-Loaded Micelles. Indomethacin (IMC) was incorporated into the copolymer micelles either by dialysis or by an oil/water emulsion method.

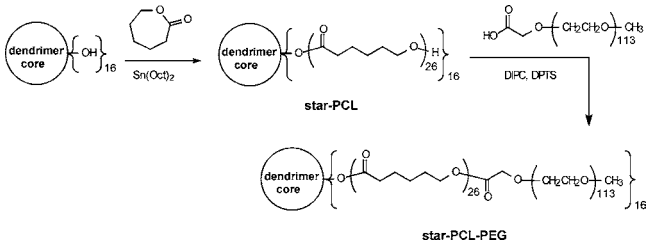
(1) Dialysis Method. One hundred milligrams of IMC dissolved in 1 mL of DMF was added to 14 mg of polymer in 2 mL of a DMF/water mixture (50 vol % DMF). The solution was stirred for 4 h at room temperature and then dialyzed against 2 L of distilled water using Membra-Cel MD-25-03.5 membrane tubing. The precipitate of free IMC was removed by centrifugation at 15000 rpm for 30 min.

(2) Oil/Water (O/W) Emulsion Method. One milligram of IMC dissolved in 100 μL of chloroform was added dropwise to 4 mL of aqueous dispersion of copolymer (7 mg) with vigorous stirring. The mixture was stirred in an open-air system to remove chloroform by evaporation and then stirred overnight. The precipitate of unbound IMC was removed by centrifugation at 15000 rpm for 30 min. The amount of IMC entrapped into the polymer micelles was determined by measuring the absorbance at 320 nm in ethanol/water (1:1) mixtures using calibration curves generated from standard solutions.

Doxorubicin hydrochloride (DOX) loaded micelles were prepared according to a modified dialysis method. Specifically, 0.5 mL of aqueous star-PCL−PEG dispersion with a concentration of 15.3 mg/mL in dialysis tubing was placed in a beaker containing 100 mL of solution of DOX (0.1 mg/mL). The beaker was covered with Parafilm and wrapped in foil, and its content was allowed to equilibrate with continuous stirring for 24 h. At the end of the equilibration period, the sample in the dialysis tubing was placed into another beaker and dialyzed against 650 mL of a solution of DOX (0.46 μg/mL) for 24 h. Copolymer micelles loaded with DOX were further analyzed by SEC using a Shimadzu LC-10AT HPLC system equipped with a TSK-Gel G5000PWXL column (7.8 mm × 30 cm). NaCl (0.05 M) was used as the eluting solvent at a flow rate of 1.5 mL/min. Determination of the concentration of star-PCL−PEG copolymer and DOX was done by measuring the absorbance at 288 and 485 nm, respectively.

Etoposide was incorporated into the copolymer micelles according to two methods.

Scheme 1. Synthesis of Star-PCL−PEG Polymer



(1) Solid Extraction. A measured volume of a methanol solution of etoposide was added to a vial, and the solvent was removed under vacuum, leaving a solid film of etoposide. A polymer micelle solution was agitated with etoposide for 24 h. After filtration, the total etoposide concentration in the micelle solution was determined by UV spectroscopy

(2) Solution Extraction. The stock solution of etoposide (19.2 mg/mL) in 1:1 (vol) acetonitrile/methanol was added slowly with agitation to the polymer solutions of various concentrations to obtain the final concentration of etoposide of 1.8 mg/mL (final concentrations of polymer of 3.7, 7.6, and 15.1 mg/mL). The initially clear solutions were shaken overnight at 27 °C, and the next day some precipitate was observed. The precipitate was removed by filtration, and the etoposide concentration in the solutions was determined by UV spectroscopy. The total etoposide concentration in the polymer micelle solution was determined by measuring the absorbance at 284 nm using calibration curves generated from known methanol solutions of etoposide.

Cytotoxicity Assay. Porcine kidney epithelial cells (LLC-PK) were seeded into 96-well plates at a density of 5000 cells/well. Etoposide (0.95 mg/mL) was solubilized in the 7.6 mg/mL solution of polymer micelles as described above. Solutions were filtered through 22 μm filters, without loss of etoposide as determined by the absorbance intensity at 284 nm. The cells were exposed to etoposide alone, polymer micelles alone, or etoposide in polymer micelle compositions for 24 h, followed by washing with PBS and maintenance in the medium 199 for an additional 72 h. The cytotoxic effects were evaluated using a standard MTT assay (*23*). All experiments were performed in eight repeats.

RESULTS AND DISCUSSION

Synthesis of Star-PCL−PEG Copolymer. The synthesis of the star amphiphilic polymer was carried out as outlined in Scheme 1. The synthesis of the star PCL polymer was conducted with the PAMAM-OH generation 2 dendrimer as the initiator for the ring-opening polymerization of ϵ-caprolactone with $Sn(Oct)_2$ as the catalyst. The targeted molecular weight for each PCL arm is 3000 Da, which corresponds to a degree of polymerization of 26. Therefore, the feed molar ratio of ϵ-caprolactone to the hydroxyl groups of the dendrimer core was 26. The $Sn(Oct)_2$ catalyst was added in a concentration of 1/200 relative to the amount of initiating hydroxyl groups, which is the optimum catalyst amount reported in the literature (*24*, *25*). The reaction was carried out in neat ϵ-caprolactone at 115 °C for 20 h. In this way, the polymerization was well controlled, and the molecular weight of each arm in the product was determined by the monomer/initiator ratio.

The star-PCL product was obtained in quantitative yield. SEC analysis indicated the existence of a small amount of low molecular weight fraction. Fractionation was used to purify the polymer. The prepared star-PCL has a molecular weight of ~50000 Da and contains 16 terminal hydroxyl groups at the arm ends. To facilitate the star polymer structure characterization, a linear PCL polymer with a relatively broad molecular weight distribution was also synthesized according to the same method using ethylene glycol as the initiator. This polymer has been used as an auxiliary calibration tool of the SEC system.

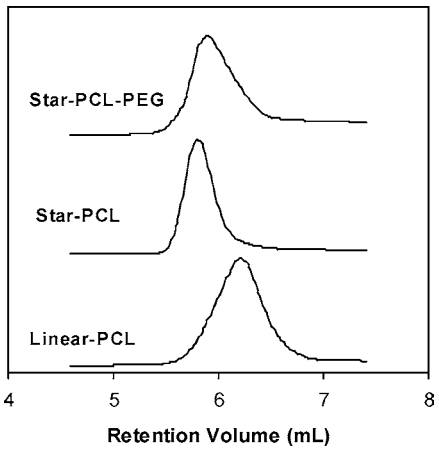


Figure 1. SEC chromatograms of linear-PCL, star-PCL, and star-PCL−PEG.

Table 1. SEC Results for the Polymers

	linear-PCL	star-PCL	star-PCL−PEG
theor mol wt	9200	51300	131300
wt-av mol wt, M_w	13000	53300	133000
no.-av mol wt, M_n	9500	49900	131000
polydispersity, M_w/M_n	1.37	1.07	1.02
intrinsic viscosity (dL/g)	0.362	0.303	0.489

The next step was to introduce hydrophilic PEG into the star-PCL polymer. A commercial PEG polymer with one end capped by a methoxy group and the other end by a carboxymethyl group was used. The carboxylic acid group in the PEG was used to react with the hydroxyl terminal groups of the star-PCL polymer to form the ester linkage and produce the desired final star-PCL−PEG. The coupling reaction was accomplished in dichloromethane at room temperature in the presence of DPTS and using DIPC as the activating agent for the carboxylic group (*22*). The advantages of this method are that reactions are conducted under very mild conditions, there is no need for preactivation of the carboxylic acid, and the product is formed in high yield. After the reaction was complete, the product was purified twice by fractionation to remove excess PEG and other impurities. The yield of the final star-PCL−PEG polymer was 91%.

Characterization of Star Polymers. The molecular weights of the synthesized polymers were determined by SEC and are summarized in Table 1. As can be seen, the molecular weight values of both star-PCL and star-PCL−PEG polymers agreed well with the calculated values (Table 1). The polydispersity of these star polymers was sufficiently narrow ($M_w/M_n < 1.07$).

The typical SEC chromatograms of the polymer samples are shown in Figure 1. The star-PCL sample is characterized by a narrower peak width when compared with linear PCL. This is consistent with the molecular weight distribution results for these two polymers. Comparison of the elution profiles for star-PCL and star-PCL−PEG samples revealed that star-PCL−PEG has a larger retention volume and a broader peak width compared with star-PCL. This is in apparent contradiction with the higher molecular weight and the narrow molecular

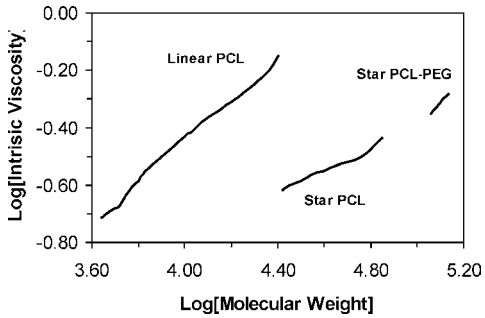

Figure 2. Log−log plot of intrinsic viscosities against molecular weight for linear and star polymers.

Table 2. g' Values Derived from Figure 2

	log[M]	$g' = [\eta]_{star}/[\eta]_{linear}$
star-PCL	4.60	0.32

	4.80	0.285
star-PCL−PEG	5.06	0.259
	5.113	0.271

weight distribution determined for this polymer. We believe that the broader peak width and slower elution of star-PCL−PEG from the SEC column are probably due to the presence of PEG blocks in the arms of star-PCL−PEG copolymer. Indeed, PEG has a relatively high affinity to the column packing material, causing it to elute at higher retention times. Elution with other solvents (such as THF) showed severe trailing elution profiles, thus confirming the adsorptive interaction between the star-PCL−PEG copolymer and the column. However, the molecular weight determined from the analysis of data from the light scattering detector does not depend on the retention volume, and we are confident that the estimated molecular weight and polydispersity values for the star polymers are accurate.

In addition to the molecular characteristics, the analysis of the SEC data also provided information on the intrinsic viscosity ($[\eta]$) of the dilute solutions of the polymers studied (Table 1). These data are presented in the form of the Mark−Houwink plot for linear and star polymers in Figure 2. The solution of the branched star-PCL polymer had a lower $[\eta]$ than the linear polymer, which has a lower molecular weight. This result is consistent with the more compact structure of the star-shaped polymer. For star polymers and linear polymers with the *same molecular weight*, the ratio of their intrinsic viscosities, $g' = [\eta]_{star}/[\eta]_{linear}$, known as the *shrinking factor*, is a function of the number of arms (f) in the star polymer (*26*). Several theories have been developed to predict a relationship between g' and f (*26*). The theoretically predicted values of g' decrease with branching. Substantial experimental data have been collected for different molecular weights of star polymers in various solvent systems (*26*). The data of Figure 2 yield $[\eta] = 1.14 \times 10^{-3}\ M^{0.628}$ dL/g for linear PCL. Here we use the extrapolated $[\eta]_{linear}$ values from this equation to obtain calculated g' values for the star polymers. The ratios $[\eta]_{star}/[\eta]_{linear} = g'$ are shown in Table 2 for different molecular weights of star-PCL and star-PCL−PEG. Experimental g' values for three different model star polymer systems with various degrees of branching taken from the literature are summarized in Table 3 (*26*, *27*). A comparison of the data in Tables 2 and 3 reveals that the g' values calculated for star-PCL and star-PCL−PEG are close to the experimental g' values for model star polymers with $f = 16$. It is important to note that there are no data on g' values for the PCL-based polymer system. Also, one should be aware that the g' parameter for the star-PCL−PEG polymer is derived as the ratio between the $[\eta]$ of the star polymer with block copolymer arms and the $[\eta]$ of a pure PCL linear polymer (extrapolated values from equation). Therefore, the comparison presented herein is based on different polymer systems, and it can be used only for qualitative consideration.

Table 3. Literature Experimental g' Values

f	polyisoprene in θ solvent	polyisoprene in good solvent	PEG polymer
8	0.54	0.43	0.46
12	0.43	0.32	
16			0.26
18	0.30	0.23	

Table 4. TGA and DSC Result of Polymers

	T_{dec} (°C)	T_m (°C)	ΔH_m (J/g)
linear-PCL	283	57	68
star-PCL	266	54	65
PEG	260	62	164
star-PCL−PEG	362	57	82

Spectroscopic measurements also confirmed the structures of the star polymer products. In the ^{1}H NMR spectrum of star-PCL, three major resonances attributed to the oxycarbonyl-1,5-pentamethylene repeat unit of a PCL $[-O-CH_2-(CH_2)_3-CH_2-CO-]_n$ are observed: the triplet peak at 4.07 ppm is assigned to methylene protons in the $-OCH_2-$ group; the triplet at 2.32 ppm is assigned to methylene protons adjacent to the carbonyl group; and the $-(CH_2)_3-$ protons are shown as a multiple peak from 1.9 to 1.1 ppm. The dendrimer core contributes only minor peaks due to its relatively low content. In the ^{1}H NMR spectrum of star-PCL−PEG, in addition to the peaks from PCL blocks, the single peak at 3.65 ppm is observed due to the methylene protons of oxyethylene units of PEG. The integrated peak area ratio of PEG and PCL for the purified star-PCL−PEG sample is consistent with the expected structure.

The IR spectrum of the star-PCL had a band characteristic for the ester carbonyl at 1734 cm^{-1} and a band for hydroxyl at 3500 to 3200 cm^{-1}. There is only one hydroxyl group per PCL chain, so the intensity of the hydroxyl band was low, reflecting the low content of −OH in the sample. In the IR spectrum of star-PCL−PEG, this −OH band has disappeared, confirming the conjugation of PCL and PEG blocks. A stronger band at 1112 cm^{-1} for C−O−C appeared, consistent with the addition of PEG ether units.

Thermal Behavior. The thermal behavior of the synthesized copolymers as well as linear-PCL and PEG samples was investigated using thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The results are summarized in Table 4. It is seen that both the linear polymers and the star-PCL are characterized by similar relatively low thermal stabilities due to the chain terminal groups (−OH and −COOH), which are subject to rapid thermal degradation. In contrast, star-PCL−PEG has stable chain terminal groups ($-OCH_3$), leading to a higher thermal stability. Therefore, the observed differences in the thermal stabilities of the synthesized polymers are consistent with their structures. The melting temperatures (T_m) and the heats of fusion (ΔH_m) of these polymers were determined from DSC data. The melting behavior of star-PCL, characterized by lower T_m and ΔH_m values compared to those of linear-PCL, probably reflected the branched nature of the star-PCL. Indeed, star branched polymers contain more defects caused by the core, which cannot be incorporated

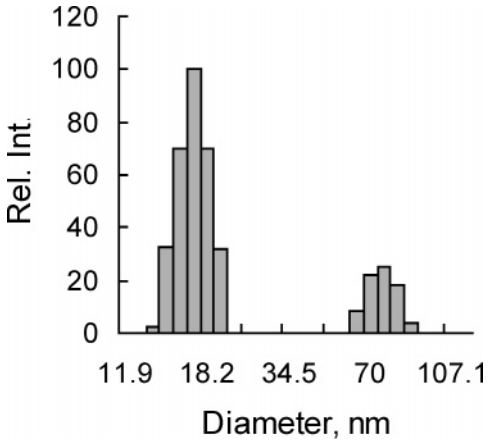

Figure 3. DLS graph of the micelle size distribution of star-PCL−PEG.

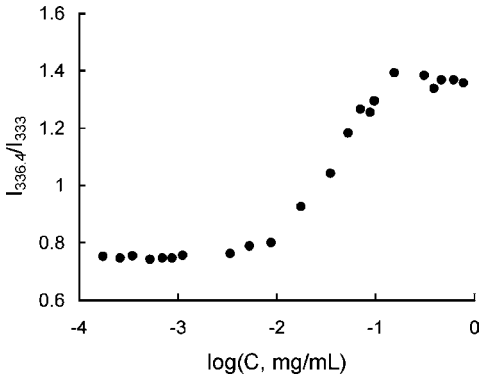

Figure 4. Dependence of intensity ratio $I_{336.4}/I_{333}$ (from pyrene excitation spectra) as a function of star-PCL−PEG concentration. [Py] = 6.0×10^{-7} M, λ_{em} = 390 nm, T = 37 °C.

in the crystallites. The DSC thermogram of star-PCL−PEG exhibited only a single melting peak characterized by T_m and ΔH_m values that were between those determined for star-PCL and PEG.

Micellar Properties of Star-PCL−PEG. The star-PCL−PEG polymer does not dissolve directly in water due to the hydrophobicity of the polycaprolactone core-forming block. For this reason, a dialysis method was employed to prepare polymeric micelles. The polymer was first dissolved in DMF, which is a good solvent for both PCL and PEG segments, and micellization was induced by the dropwise addition of water followed by dialysis.

The micelle size distribution of a polymer solution with a concentration of ~12 mg/mL was determined by DLS and is shown in Figure 3. It is a bimodal distribution with a smaller size component of ~16.9 nm (80%) and a large size component of ~75 nm (20%). These two components average to an overall effective hydrodynamic diameter of ~20.1 nm and a polydispersity index of 0.18. From the data presented in Table 1, the viscosity radius of the star-PCL−PEG can be calculated as R_v = 10.1 nm. Thus, the diameter determined from viscosity is 20.2 nm. Generally, the diameters determined from viscosity and DLS measurements are identical for star polymers (*26*). Because the SEC is performed in chloroform, both PCL and PEG segments are expanded. The DLS experiment is performed in water, however, and the PCL segment is contracted. Therefore, the nonaggregated star polymer in water should have a diameter of <20.2 nm. It appears thus that in all likelihood the small species in DLS with 16.9 nm diameter can be identified as the expected "unimolecular" micelle, and the large species with 70 nm diameter can be assigned to micelles formed from aggregated star polymers.

The association behavior of star-PCL−PEG copolymer in aqueous solutions was further characterized by a fluorescence technique using pyrene as a probe. This method is based on the sensitivity of the pyrene probe to the hydrophobicity and polarity of its microenvironment (*28*). In the presence of micelles or similar supramolecular aggregates, pyrene is solubilized within the interior of the hydrophobic core. As a result, significant changes in the spectroscopic properties are observed upon transfer of the probe from the aqueous environment to the nonpolar environment of the micelle core. First, the quantum yield of the fluorescence increases in the presence of the micelles. This effect is exhibited by an increase in the intensity of the fluorescence maximum at λ = 373 nm (I_1) in the emission spectrum of pyrene. Second, the vibrational fine structure of the emission spectrum undergoes changes. This effect is best characterized by the decrease in the ratio of the intensity of the vibrational band one to the vibrational band three (I_1/I_3), which is consistent with the decrease in polarity of the environment of the probe. Finally, the excitation spectra of pyrene are characterized by a red shift of the 333 nm (0,0) band. All of the key parameters characterizing the fluorescent properties of pyrene discussed above change sharply in a rather narrow range of star-PCL−PEG concentrations in aqueous solutions and then level off. Indeed, the (0,0) band in the excitation spectrum shifted from 333 to 336.4 nm, the total fluorescence intensity (I_1) increased, and the I_1/I_3 ratio decreased. For example, the change in the excitation spectrum of pyrene (characterized by a change of the $I_{336.4}/I_{333}$ intensity ratio) is presented in Figure 4 as a function of star-PCL−PEG concentration. It is seen that the $I_{336.4}/I_{333}$ values remain fairly constant below a certain concentration and then change substantially, reflecting the partitioning of the pyrene into the more hydrophobic environment. The onset of these changes can be considered as an apparent cmc (C_{app}) value. It is important to note that the analysis of all sets of data ($I_{336.4}/I_{333.2}$ ratio, I_1, and I_1/I_3 ratio) yielded essentially identical values for C_{app}, which is 3 mg/L. The determined C_{app} is in the same range as obtained for linear PCL−PEG copolymer (*29*) and the three- and four-arm star PCL−PEG copolymers (*17*). The existence of a C_{app} for star-PCL−PEG was consistent with the observation in the DLS data. This suggests that the larger associates composed of several copolymer molecules are formed in the aqueous dispersions of star-PCL−PEG. It is possible that such aggregates form as a result of the hydrophobic−hydrophobic interactions or van der Waals interactions between the exposed PCL cores of the individual star molecules.

A schematic picture of a possible aggregated micelle structure of star-PCL−PEG that may contribute to the existence of C_{app} is shown in Figure 5. Indeed, in the case of a star block copolymer with a low arm density (16 arms) the outer PEG shell most likely is too loose to outweigh the intermolecular association of the lipophilic PCL blocks. It is expected that when the number of arms in the star polymers increases significantly, the outer PEG blocks will form a tighter hydrophilic shell and reduce the tendency toward intermolecular micelle formation. The validation of this hypothesis is currently ongoing in our laboratories.

From the dependence of the fluorescence intensity of pyrene on star-PCL−PEG concentration the partitioning coefficient (P = 2410 ± 460) for pyrene in this micelle system was calculated as described (*30*). This value is 1

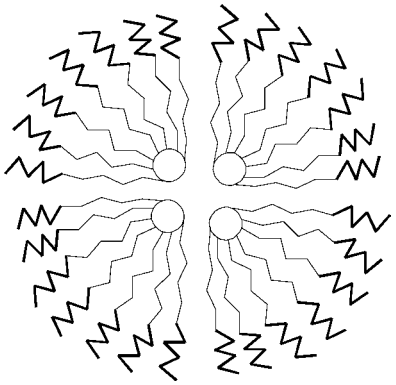

Figure 5. Possible aggregated micelle structure.

order of magnitude higher than was found for a linear PCL−PEG block copolymer system (*29*). The I_1/I_3 ratio was also used to characterize the polarity of the pyrene environment. The value measured for pyrene in a copolymer-free aqueous solution was ~1.8. As the concentration of the copolymer increased, the I_1/I_3 value decreased to ~1.49. This value corresponds to the polarity of ethyl acetate (I_1/I_3 = 1.45) (*28*) and seems to be reasonable for polyesters with moderate polarity, including PCL. These data suggest the preferential location of the pyrene probe in the hydrophobic environment of the PCL core of the micelles formed.

Evidence for excimer formation is another interesting feature of the pyrene fluorescence in the presence of star-PCL−PEG copolymer. At concentrations of star-PCL−PEG corresponding to C_{app}, there was an additional long-wavelength emission maximum of pyrene at $\lambda = 468$ nm. Excimer formation is rather unusual, taking into account the very low concentration (10^{-7} M) of the pyrene probe used in these experiments. Typically, such excimers can be observed at rather high concentrations (10^{-4}−10^{-3} M) of pyrene in aqueous media. A relatively high concentration of pyrene in the system is also needed to facilitate the formation of excimers in the micellar solutions (*31*). The excimer formation, which is a diffusion-limited process (*32*), suggests that the PCL core of star-PCL−PEG micelles probably afforded a rather small volume and that the PCL matrix is in the fluid (or liquid-crystalline) state.

Overall, the incorporation of a highly hydrophobic molecule, pyrene, reveals the suitability of this micelle system as a potential carrier for lipophilic compounds. Many experimental and theoretical studies have revealed that the greatest degree of solubilization of a compound within the micelle core will be reached when there is a close match between the degree of polarity and hydrophobicity of the compound and the micelle core (*2*). For this reason, we explored the incorporation of various hydrophobic substances, including drugs, into the star-PCL−PEG micelles.

Solubilization of Organic Dyes. The solubilization of water-insoluble dyes in the aqueous dispersions of star-PCL−PEG was studied in the range of concentration around the C_{app}. Figure 6 represents the data on solubilization of ORO dye as an example. It is important to note that even at a concentration of star-PCL−PEG lower than C_{app} the determined contents of dye in the test solutions were slightly higher compared to the polymer-free solutions. A similar behavior was also observed with Yellow OB dye. The solubilization of dyes in such dilute solutions of star-PCL−PEG copolymers is probably the result of incorporation of the dye in the PCL region of the intact star copolymer molecules. Therefore, this

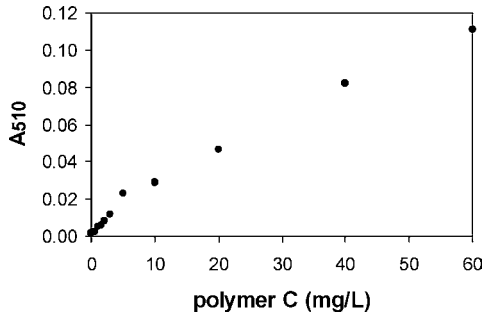

Figure 6. Absorbance of polymer/ORO solution at 510 nm against polymer concentration.

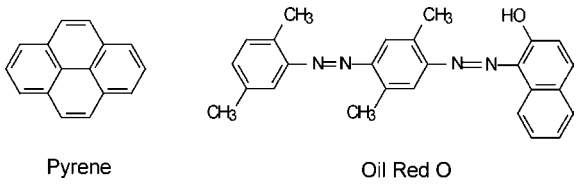

Figure 7. Structures of pyrene and Oil Red O.

observation confirmed the existence of a "unimolecular micelle." The amount of ORO detected in the solution increased almost monotonically as the concentration of star-PCL−PEG increased (Figure 6). In contrast to the pyrene solubilization experiments, the existence of C_{app} was not very pronounced in this study.

One of the possible explanations for such differences may be that the solubilization capacity of the PCL core with respect to pyrene is changing upon the transition from unimolecular micelle to multimolecular micelle. The hydrophobic core in the unimolecular micelle is smaller than the internal region of the multimolecular micelle. Therefore, a larger fraction of the core-forming chains in the unimolecular micelle will be exposed to the relatively hydrophilic environment. As a result, the volume of hydrophobic microphase that is available for partitioning of pyrene will be very small, and thus the concentration of pyrene in this phase would be too low to be detected. The association of several star molecules will cause an increase in the core size of the multimolecular micelle and thus provide for a larger loading capacity per micelle for pyrene. Furthermore, the compatibility between the solubilisate and the core-forming block should also be taken into account. It was shown previously that the partition coefficient for pyrene between micelles and water is higher in systems with cores of lower polarity (*33*). For instance, the partition coefficient of the order of 10^5 was reported for pyrene in polystyrene-*block*-PEG (*5*) and polystyrene-*block*-poly(acrylic acid) systems (*34*). Therefore, it is reasonable to expect that more polar compounds will be most easily loaded into micelles with more polar cores. Indeed, a comparison of the structures of ORO and pyrene (Figure 7) shows that the ORO molecule has more polar functional groups and should be more hydrophilic than pyrene. As a result, ORO may have a higher compatibility with the PCL core of the unimolecular micelle and incorporate into it more effectively than pyrene. Furthermore, it appears that the solubility of ORO in the PCL core of the micelle did not change drastically upon the transition from unimolecular micelle to multimolecular micelle. The apparent loading efficiency of star-PCL−PEG multimolecular micelles was ~6 wt % for both dyes studied.

Encapsulation of Drugs in Star-PCL−PEG Copolymer Micelles. The feasibility of using star-PCL−

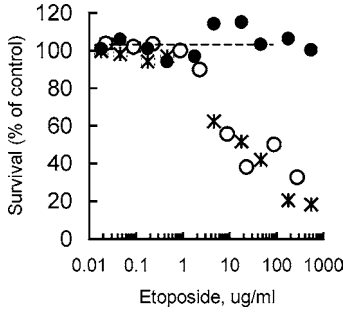

Figure 9. Cytotoxic effect of polymer micelles alone (●), free etoposide (∗), and etoposide in polymer micelles (○) in LLC-PK cells. Polymer concentrations in etoposide-free systems are the same as those at different etoposide dilutions.

Table 5. Loading of Etoposide in Star-PCL−PEG Micelle Systems

encapsulation method	polymer (mg/mL)	etoposide (mg/mL)	loading in polymer (% w/w)
solid extraction	0.38	0.15	7
solid extraction	3.7	0.92	22
solution extraction	7.6	0.95	11
solution extraction	15.1	0.95	6

PEG copolymer as a delivery carrier for lipophilic drugs was evaluated using IMC, DOX, and etoposide as the drug candidates. The IMC/star-PCL−PEG were obtained by dialysis and oil/water emulsion methods as described under Experimental Section. The experimentally determined IMC content entrapped into the star-PCL−PEG micelles was 5.4 wt % for the oil/water emulsion method and 9 wt % for the dialysis method. The loading capacity of 9 wt % corresponds to 33 IMC molecules per star copolymer molecule.

The encapsulation of DOX in star-PCL−PEG micelles was studied using SEC. The chromatograms of free and DOX-loaded star-PCL−PEG micelles are shown in Figure 8. The elution profile of free copolymer micelles revealed two sharp peaks (Figure 8, solid line). The peak at a retention time of ∼9.8 min was assigned to the aggregated polymer micelles, whereas the product eluting at 13.9 min was assigned to the intact unimolecular micelles. The ratio of the peak areas was ∼55:45. The chromatograms of DOX/copolymer samples detected at 288 nm (Figure 7, dotted line) were also characterized by two peaks (retention times of 9.5 and 13.8 min, respectively), but the peak areas ratio changed to ∼80:20. The elution profile of DOX/polymer samples detected at 485 nm, which is characteristic of DOX absorbance, was very similar, with a sharp peak at 9.7 min along with the small peak at 13.8 min (data not shown). These data indicated that DOX was incorporated into both types of star-PCL−PEG polymeric micelles. Furthermore, it is likely that incorporation of DOX enhanced the association of unimolecular micelles and that the majority of the drug was detected in the multimolecular copolymer micelles. The estimated amount of DOX encapsulated into copolymer micelles after elution from the column was ∼1.8 μg of DOX/mg of the copolymer. The contrast in loading level between IMC and DOX may be partially due to their acidity. IMC is an acid, DOX is a base, and the core of the star polymer is PAMAM, which contains 14 *tert*-amine bases. The acid−base interaction may contribute to the higher loading level for IMC.

A more hydrophobic anticancer drug, etoposide, was used to evaluate the encapsulation capacity of the star-PCL−PEG polymer. The results of different loading methods are summarized in Table 5. The etoposide concentrations in water and polymer micelle solutions were estimated by UV spectroscopy at 284 nm with the calibration curve obtained from methanol solution. We assume that the absorption coefficient of etoposide in water and in the micelle core is not very different from that in methanol solution. The saturated etoposide solubility in water was determined to be ∼0.12 mg/mL. The pure polymer solution has a small shoulder absorbance at 284 nm. The etoposide concentration loaded in micelles was determined from the absorbance at 284 nm after subtraction of the absorbance from the corresponding pure polymer solution and etoposide dissolved in water. A separate study determined that the organic solvent added (∼12 wt %) did not increase the solubility of etoposide in the absence of the polymer.

Significant amounts of etoposide can be incorporated in the polymer micelles. Interestingly, there is little dependence of etoposide solubility on the polymer concentration in the range studied, when the solution extraction method was used. Such behavior is typical for the incorporation of hydrophobic drugs in block copolymer micelles when there is a strong interaction between the drug and micelle core (*35*, *36*). The polymer micelle solutions remained stable over several days. Furthermore, they can be stored at 4 °C for at least 24 h without precipitation of etoposide.

Cytotoxicity Assay. This experiment examined whether etoposide incorporated in the polymer micelles can exhibit cytotoxic effects in cell culture. The results are presented in Figure 9. These data suggest that the polymer alone is not toxic, whereas etoposide incorporated in the micelles displays significant cytotoxic activity, comparable with that of the free etoposide (i.e., etoposide is released from the polymer micelles and acts on cells).

Concluding Remarks. In summary, we have successfully developed a high-yield, straightforward strategy for the synthesis of amphiphilic star-PCL−PEG polymers. The star structure was confirmed by SEC, spectroscopic, and thermal characterizations. The formation of unimolecular micelles from the 16-arm star polymer has been demonstrated by DLS and the dye solubilization study. The aggregation from unimolecular micelles into larger associated micelles has been observed in the DLS and pyrene fluorescence study. It is likely that the 16-arm star polymer forms a relatively loose outer PEG shell, which is not sufficient to hinder the intermolecular association of the inner hydrophobic PCL blocks. It is expected that more stable unimolecular micelles may be obtained when the number of arms in a star polymer increases to a higher number. It has been demonstrated that when the number of arms reaches 64, star polymers exhibit characteristics of a hard sphere, and the repulsion between the star molecules becomes much stronger (*37*).

We also demonstrated that lipophilic drugs can be encapsulated in the star-PCL−PEG micelles. A high loading level was achieved with more hydrophobic drugs, indomethacin and etoposide, whereas a relatively lower loading efficiency was achieved with a more hydrophilic drug, doxorubicin. A cytotoxicity assay demonstrated that the star-PCL−PEG polymer is nontoxic.

FPyME (1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione) was designed as a [^{18}F]fluoropyridine-based maleimide reagent for the prosthetic labeling of peptides and proteins via selective conjugation with a thiol (sulfhydryl) function. Its pyridinyl moiety carries the radioactive halogen (fluorine-18) which can be efficiently incorporated via a nucleophilic *hetero*aromatic substitution, and its maleimido function ensures the efficient alkylation of a free thiol function as borne by cysteine residues. [^{18}F]-FPyME (HPLC-purified) was prepared in 17−20% non-decay-corrected yield, based on starting [^{18}F]-fluoride, in 110 min using a three-step radiochemical pathway. The developed procedure involves (1) a high-yield nucleophilic *hetero*aromatic ortho-radiofluorination on [3-(3-*tert*-butoxycarbonylamino-propoxy)pyridin-2-yl]trimethylammonium trifluoromethanesulfonate as the fluorine-18 incorporation step, followed by (2) rapid and quantitative TFA-induced removal of the *N*-Boc-protective group and (3) optimized maleimide formation using *N*-methoxycarbonylmaleimide. Typically, 4.8−6.7 GBq (130−180 mCi) of radiochemically pure [^{18}F]FPyME ([^{18}F]-**1**) could be obtained after semipreparative HPLC in 110 min starting from a cyclotron production batch of 33.3 GBq (900 mCi) of [^{18}F]fluoride (overall radiochemical yields, based on starting [^{18}F]fluoride: 28−37% decay-corrected). [^{18}F]FPyME ([^{18}F]-**1**) was first conjugated with a small model hexapeptide ((*N*-Ac)KAAAAC), confirming the excellent chemoselectivity of the coupling reaction (CH_2SH versus CH_2NH_2) and then conjugated with two 8-kDa proteins of interest, currently being developed as tumor imaging agents (c-AFIM-0 and c-STxB). Conjugation was achieved in high yields (60−70%, isolated and non-decay-corrected) and used optimized, short-time reaction conditions (a 1/9 (v/v) mixture of DMSO and 0.05 M aq Tris NaCl buffer (pH 7.4) or 0.1 M aq PBS (pH 8), at room temperature for 10 min) and purification conditions (a gel filtration using a Sephadex NAP-10 cartridge or a SuperDex Peptide HR 10/30 column), both compatible with the chemical stability of the proteins and the relatively short half-life of the radioisotope concerned. The whole radiosynthetic procedure, including the preparation of the fluorine-18-labeled reagent, the conjugation with the protein and the final purification took 130−140 min. [^{18}F]FPyME ([^{18}F]-**1**) represents a new, valuable, thiol-selective, fluorine-18-labeled reagent for the prosthetic labeling with fluorine-18 of peptides and proteins. Because of its excellent chemoselectivity, [^{18}F]FPyME offers an interesting alternative to the use of the nonselective carboxylate and amine-reactive [^{18}F]reagents and can therefore advantageously be used for the design and development of new peptide- and protein-based radiopharmaceuticals for PET.

INTRODUCTION

Positron emission tomography (PET) is a high-resolution, sensitive, molecular, and functional imaging technique. It permits repeated, noninvasive assessment and quantification of specific biological and pharmacological processes and is the most advanced technology currently available for studying in vivo molecular interactions. PET plays an increasing role in both drug discovery and development of radiopharmaceuticals, by assessing (once labeled with a positron-emitter) their in vivo distribution, pharmacokinetics, and dynamics.

Complex high-molecular-weight bioactive chemical structures, such as single-stranded oligonucleotides, peptides, and proteins are more and more often proposed as radiopharmaceuticals, and their applications are rapidly gaining importance in nuclear medicine (*1*−*4*). Over the past decades, these agents have evolved from large proteins (e.g. intact polyclonal antibodies with low specificity) to monoclonal antibodies and fragments (with relatively higher specificity), to smaller molecular recognition units such as single-chain antigen-binding domain fragments, and finally to receptor-specific peptides, which have emerged as one of the most promising classes of radiopharmaceuticals for both scintigraphic applications and therapeutic purposes (*2*, *4*).

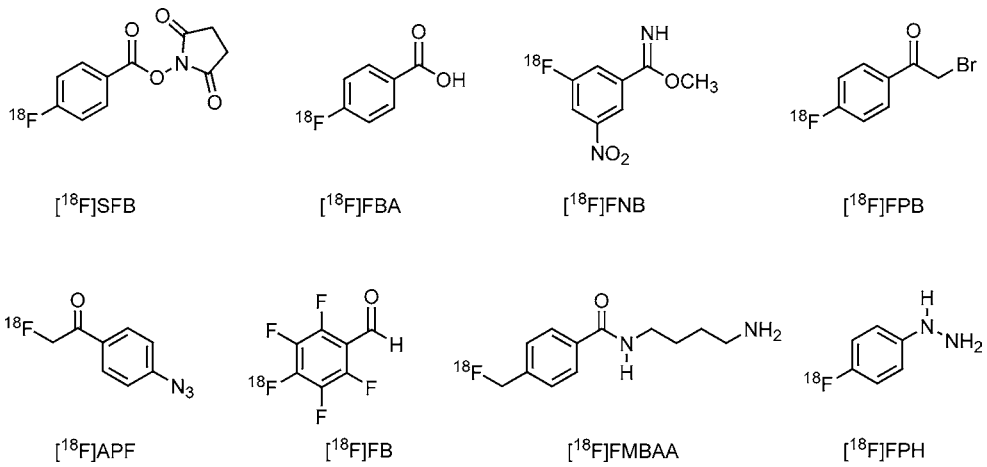

Figure 1. Chemical structures of *N*-succinimidyl 4-[18F]fluorobenzoate ([18F]SFB), 4-[18F]fluorobenzoic acid ([18F]FBA), 3-[18F]fluoro-5-nitrobenzimidate ([18F]FNB), 4-([18F]fluorophenacyl bromide ([18F]FPB), 4-azidophenacyl [18F]fluoride ([18F]APF), penta-[18F]-fluorobenzaldehyde ([18F]FB), 1-[4-([18F]fluoromethyl)benzoyl]-aminobutane-4-amine ([18F]FMBAA), and 4-[18F]fluorophenyl hydrazine ([18F]FPH),

Methods for radiolabeling these peptides and proteins have been of interest for several decades. Although many different radionuclides have been used to radiolabel proteins (*4*−*12*), the majority of labeled-protein studies have used radionuclides of iodine, principally iodine-125, iodine-123, and iodine-131. The latter radionuclides have properties which are adequate for a number of different applications (in vitro and in vivo imaging or therapy), are relatively easy to use, and are readily available at a nominal cost from commercial sources.

Peptides and proteins have also been labeled with positron-emitting radionuclides, even though fewer examples have been described in the literature. The short-lived positron-emitter fluorine-18 appears as the radionuclide of choice for the preparation of labeled bioactive peptides and proteins, as it is the case for conventional, low-molecular-weight radiotracers and radiopharmaceuticals (*13*−*16*). In regard of its physical and nuclear characteristics, fluorine-18 displays simple decay- and emission properties with a high positron abundance (97%). Compared with the other conventional short-lived positron-emitting radionuclides carbon-11, nitrogen-13, and oxygen-15, fluorine-18 has a relatively low positron emission energy (maximum 635 keV) and the shortest positron linear range in tissue (2.3 mm), resulting in the highest resolution in PET imaging. Its half-life (109.8 min) is long enough to give access to relatively extended imaging protocols compared to what is possible with carbon-11, therefore facilitating kinetic studies and high-quality metabolite and plasma analysis. Moreover, from a chemical point of view, it allows multistep synthetic approaches that can be extended over hours. These distinctive advantages, combined with its reliable multi-Curie production on widely implanted biomedical cyclotrons, have been effectively used for the labeling of various chemical structures (*13*−*16*).

Concerning peptides and proteins, the direct labeling of these macromolecules with fluorine-18 is, leaving aside some exceptions, not feasible and labeling is usually performed by conjugation of a prosthetic group, carrying the radioisotope, with a reactive function of the macromolecule. This strategy has the advantage of offering a wide choice of chemical routes, including drastic chemical conditions, for the preparation of the labeled prosthetic group entity, followed by the conjugation of the latter with a macromolecule using mild conditions needed to preserve the latter's integrity (*2*, *12*).

Several fluorine-18-labeled reagents have already been described in the literature (Figure 1). Most of them were designed for coupling to the peptide or protein via an amino function borne by an amino acid residue (*N*-terminus α-NH_2 or internal lysine ϵ-NH_2) or by an alkylamine linker. For example, the activated ester *N*-succinimidyl 4-[18F]fluorobenzoate ([18F]SFB) (*2*, *12*, *17*−*19*) is today probably the most often used prosthetic group introducing agent for the labeling of peptides and proteins via an acylation reaction, beside other carboxylic acids or esters, such as 4-[18F]fluorobenzoic acid ([18F]-FBA) (*20*), 2-[18F]fluoroacetic acid (*21*), or methyl 2-[18F]-fluoropropionate (*22*) (the latter two structures not shown). Other activated esters, such as *N*-succinimidyl 4-([18F]fluoromethyl)benzoate (*23*, *24*) and *N*-succinimidyl 8-[4′-[18F]fluorobenzyl)amino]suberate (*25*), have also been reported (structures not shown). Imidation reaction, using reagents such as 3-[18F]fluoro-5-nitrobenzimidate ([18F]FNB) (*26*), have been described. Finally, alkylation reactions using 4-[18F]fluorophenacyl bromide ([18F]FPB) (*26*) have been reported as well as photochemical conjugation using 4-azidophenacyl [18F]fluoride ([18F]APF) (*17*, *27*) and reductive amination using penta-[4-18F]fluorobenzaldehyde ([18F]FB) (*28*). A much smaller number of fluorine-18-labeled reagents for the coupling to the peptide or protein via another reactive function, the carboxylic acid function (*C*-terminus α-CO_2H or internal glutamic/aspartic acid α/β-CO_2H), have also been designed. To our knowledge, only two amines, 1-[4-([18F]-fluoromethyl)benzoyl]aminobutane-4-amine ([18F]FMBAA) (*29*) and 4-[18F]fluorophenylhydrazine ([18F]FPH) (*12*), have been described for these amidation reactions.

The free thiol function (also called sulfhydryl) is not very common in most peptides and proteins and is only present in cysteine residues (internal β-SH). Thiol-reactive agents have therefore been used to modify peptides and proteins at specific sites (*30*−*32*), providing a means of high chemoselectivity in contrast to the carboxylate and amine-reactive reagents described above. To our knowledge, to date, only two fluorine-18-labeled reagents have been described in an abstract by Shiue for the coupling to peptide or protein via alkylation of such a thiol function (*33*). In that work, the preparation of two *N*-substituted maleimides, 1-(4-[18F]fluorophenyl)pyrrole-2,5-dione ([18F]FPPD) and *N*-[3-(2,5-dioxo-2,5-dihydro-pyrrol-1-yl)phenyl]-4-[18F]fluorobenzamide ([18F]DDPFB),

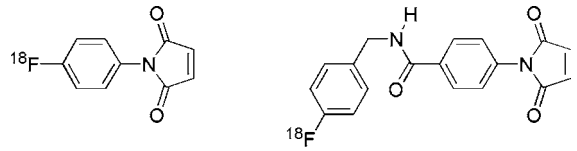

Figure 2. Chemical structures of 1-(4-[^{18}F]fluorophenyl)-pyrrole-2,5-dione ([^{18}F]FPPD) and *N*-[3-(2,5-dioxo-2,5-dihydro-pyrrol-1-yl)-phenyl]-4-[^{18}F]fluorobenzamide ([^{18}F]DDPFB).

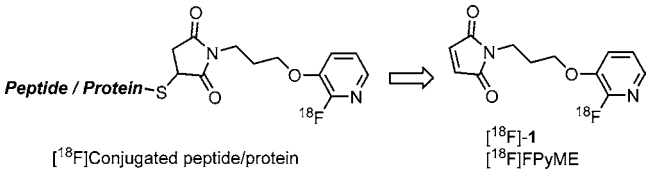

Figure 3. Fluorine-18-labeling design of peptide and protein via selective thiol alkylation using 1-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([^{18}F]FPyME, [^{18}F]-**1**).

was reported, and its coupling to proteins was briefly mentioned (Figure 2).

From a radiochemical point of view, all the above-mentioned fluorine-18-labeled reagents were prepared using the relatively restricted labeling strategies offered by *homo*aromatic and aliphatic nucleophilic substitution reactions (*14*, *15*). Recently, the scope of these nucleophilic radiofluorinations has been opened to *hetero*aromatic substitutions, particularly in the pyridine series (*34*). After evaluation and validation of the radiosynthesis of 2- and 4-[^{18}F]fluoropyridine as a model reaction (*35*, *36*), we and others have since applied successfully these nucleophilic *hetero*aromatic substitutions to the preparation of various PET radiotracers and radiopharmaceuticals (*34*), such as for example, the cholinergic $\alpha_4\beta_2$-subtype selective nicotinic radioligand 2-[^{18}F]fluoro-3-[2(*S*)-2-azetidinylmethoxy]pyridine (2-[^{18}F]F-A-85380) (*37*−*50*).

Considering chemical structures showing a fluoropyridinyl moiety, nucleophilic *hetero*aromatic substitution at the ortho-position with no-carrier-added [^{18}F]fluoride appears today as the more efficient method for the radiosynthesis of radiotracers and radiopharmaceuticals of high specific radioactivity when compared to *homo*aromatic or aliphatic nucleophilic radiofluorination. On the basis of these recent advances, we have designed a new [^{18}F]fluoropyridine-based maleimide reagent, [^{18}F]-**1** (1-[3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione, coded [^{18}F]FPyME, Figure 3) as a new fluorine-18-labeled reagent for the highly specific conjugation to peptides and proteins via thiol alkylation.

We herein report the design, selection, and synthesis of the nonlabeled fluoropyridinyl reagent (**1**, FPyME) as a reference, as well as the synthesis of the required nitro- and trimethylammonium trifluoromethanesulfonate derivatives as precursors for labeling with fluorine-18. We also present the radiosynthesis of [^{18}F]FPyME ([^{18}F]-**1**) using an efficient three-step radiosynthesis, involving a nucleophilic *hetero*aromatic ortho-radiofluorination as the fluorine-18 incorporation-step. In addition, we describe the conjugation of this maleimide reagent ([$^{18/19}$F]FPyME, [$^{18/19}$F]-**1**) with a small hexapeptide, (*N*-Ac)KAAAAC, chosen as a model peptide in order to confirm the chemoselectivity of the coupling reaction (CH_2SH versus CH_2NH_2). Finally, we present as applications to protein labeling, (a) the preparation of [^{18}F]c-AFIM-0, a selected 75-amino acid (∼ 8.8 kDa) mini-protein, derived from the specific binding domain of annexins for phosphatidylserine and (b) the preparation of [^{18}F]c-STxB, the nontoxic homopentameric B subunit (monomer size ∼ 8.0 kDa) of the bacterial (*Shigella dysenteriae*) Shiga toxin, both proteins being developed as tumor imaging agents.

EXPERIMENTAL SECTION

1. General. *Chemicals.* Chemicals were purchased from standard commercial sources (Aldrich, Fluka, or Sigma France) and were used without further purification, unless stated otherwise. Oxygen-18-enriched water ([^{18}O]H_2O, >95%) was purchased from CortecNet (Paris, France). (*N*-Ac)KAAAAC was custom-synthesized by Neosystem (France).

Analytical Methods. Thin layer chromatographies (TLCs) were run on precoated plates of silica gel $60F_{254}$ (Merck). The compounds were localized (1) when possible at 254 nm using a UV-lamp and/or (2) by dipping the TLC-plates in a 1% ethanolic ninhydrin solution and heating on a hot plate. Radioactive spots were detected using a Berthold TraceMaster 20 automatic TLC linear analyzer. Flash chromatographies were conducted on silica gel 63−200 μm (Merck) at 0.3 bar (Ar). High-pressure liquid chromatographies (HPLCs) were performed on Waters or Shimadzu systems: [HPLC A]: Equipment: a Waters 600 Pump, a Waters 600 Gradient Controller, a Shimadzu SPD10-AVP UV-multiwavelength spectrometer, and a Geiger-Müller detector; column: preparative SiO_2, Lichrosorb, Merck (250 × 27.0 mm; porosity: 7 μm); solvents and conditions: isocratic elution with heptane/EtOAc; temperature: RT; absorbance detection at λ = 254 nm. [HPLC B]: Equipment: a Waters 600 Pump, a Waters 600 Gradient Controller, a Shimadzu SPD10-AVP UV-multiwavelength spectrometer, and a Geiger-Müller detector; column: preparative C18, DeltaPak, Waters (300 × 19.0 mm; porosity: 15 μm); solvents and conditions: 0.1% aq TFA (v/v) and acetonitrile containing 0.1% TFA (v/v); linear gradient in 30 min from 100/0 to 65/35, flow rate: 10 mL/min; temperature: RT, absorbance detection at λ = 214 nm. [HPLC C]: Equipment: a Waters 600 Gradient Controller, a Waters 490E UV-multiwavelength spectrometer, and a Geiger-Müller detector; column: preparative Gel Filtration SuperDex Peptide HR 10/30, Amersham Pharmacia Biotech (300 × 10 mm); solvents and conditions: isocratic elution with aq PBS (20 mM KH_2PO_4; 150 mM NaCl) at pH 7.4; flow rate: 1 mL/min; temperature: RT; absorbance detection at λ = 214 nm. [HPLC D]: Equipment: a Waters 510 pump, a Shimadzu SPD10-AVP UV-multiwavelength spectrometer and a Geiger-Müller detector; column: semipreparative SiO_2 Zorbax Rx-SIL, Hewlett-Packard (250 × 9.4 mm; porosity: 5 μm); solvents and conditions: isocratic elution with heptane/EtOAc: 60/40 (v/v); flow rate: 5 mL/min; temperature: RT; absorbance detection at λ = 254 nm. [HPLC E]: Equipment: a Waters 600 Pump, a Waters 600 Gradient Controller, a Hewlett-Packard Series 1100 multiwavelength spectrometer and a Flow One Scintillation Analyzer Packard equipped with a positron dedicated cell for radioactivity monitoring; column: semipreparative C18, μBondapak, Waters (300 × 7.8 mm; porosity: 10 μm); solvents and conditions: 0.1% aq TFA (v/v) and acetonitrile containing 0.1% TFA (v/v); linear gradient in 15 min from 80/20 to 40/60, flow rate: 4 mL/min; temperature: RT, absorbance detection at λ = 214 nm. [HPLC F]: Equipment: a Waters 600 Gradient Controller, a Hewlett-Packard Series 1100 multiwavelength spectrometer and a Flow One Scintillation Analyzer Packard equipped with a positron-dedicated cell for radioactivity monitoring; column: preparative Gel Filtration SuperDex Peptide HR 10/30, Amersham Pharmacia Biotech (300 × 10 mm); solvents and conditions: isocratic elution with aq PBS

(20 mM KH_2PO_4; 150 mM NaCl) at pH 7.4; flow rate: 1 mL/min; temperature: RT; absorbance detection at λ = 214 nm. NMR spectra were recorded on a Bruker AMX (300 MHz) apparatus and on a Bruker Advance (400 MHz) apparatus using the hydrogenated residue of the deuterated solvents (CD_2Cl_2, δ = 5.32 ppm; DMSO-d_6, δ = 2.50 ppm and CD_3OD, δ = 3.35 ppm) and/or TMS as internal standards for ^{1}H NMR as well as the deuterated solvents (CD_2Cl_2, δ = 53.8 ppm; DMSO-d_6, δ = 39.5 ppm and CD_3OD, δ = 49.3 ppm) and/or TMS as internal standards for ^{13}C NMR. The chemical shifts are reported in ppm, downfield from TMS (s, d, t, q, q^5, dd, td, m, b for singlet, doublet, triplet, quadruplet, quintuplet, doublet of doublet, triplet of doublet, multiplet (or multi sharp-peak system), and broad, respectively). The mass spectra (MS) were measured on a Nermag R10−10 spectrometer (DCI/NH_4^+), a Quantum TCQ Discovery spectrometer (ES+), or a Perseptive Biosystem DE-RP MALDI-TOF Voyager spectrometer (ES+).

Miscellaneous. Radiosyntheses using fluorine-18, including the HPLC purifications, were performed in a 7.5-cm-lead shielded cell using a computer assisted Zymate robot system (Zymark corporation, USA).

Radioisotope Production. No-carrier-added aqueous [18F]fluoride ion was produced via the [^{18}O(p,n)^{18}F] nuclear reaction by irradiation of a 2 mL [^{18}O]water (>97%-enriched) target on a CGR-MeV 520 cyclotron (17 MeV proton beam) or on a IBA Cyclone-18/9 cyclotron (18 MeV proton beam) and was transferred to the appropriate hot cell. Target hardware: CGR-MeV 520 cyclotron: home-made, large volume, three-port, keyhole-shaped stainless steel/silver target holder (a complete description of this target hardware and -operation can be found in ref 81); IBA Cyclone-18/9 cyclotron: commercial, large volume, two-port, stainless steel target holder equipped with a domed-end niobium cylinder insert. Target to hot cell liquid-transfer system: 60 m PTFE line (0.8 mm internal diameter; 1/16 in. external diameter), 2.0 bar He drive pressure, transfer time 3−6 min). Typical production of [18F]fluoride at the end of bombardment for a 20 μA, 30 min (10 μA·h) irradiation: CGR-MeV 520 cyclotron: 550−650 mCi (20.3−24.0 GBq) and IBA Cyclone-18/9 cyclotron: 750−800 mCi (27.7−29.6 GBq).

2. Chemistry. Preparation of [(2-Nitropyridin-3-yloxy)alkyl]carbamic Acid *tert*-Butyl Esters (3a−e). *General Procedure.* To a solution of the appropriate (*N*-Boc-amino)alcohol (**2a−e**, 9−12 mmol) in THF (100−150 mL) were added 0.8 equiv of triphenylphosphine (MW: 262.29), 0.8 equiv of 3-hydroxy-2-nitropyridine (MW: 139.01), and dropwise 1.38 equiv of diisopropylazodicarboxylate (DIAD, MW: 202.21, d: 1.027). After stirring at room temperature for 24−28 h, the reaction mixture was concentrated to dryness and the residue was purified by column chromatography on silica gel. Elution with EtOAc/heptane (60/40 (v/v)) gave >90% pure [(2-nitropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl ester (**3a−e**). For analytical purposes only, an aliquot was further purified by preparative HPLC [HPLC A].

*[2-(2-Nitropyridin-3-yloxy)ethyl]carbamic Acid tert-Butyl Ester (**3a**).* The procedure described above was used with 2-(*N*-Boc-amino)ethanol (**2a**, 2.00 g) to give 1.35 g of **3a** as a pale-yellow oil (38%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.74. t_R (HPLC A, EtOAc/heptane: 50/50 (v/v), flow rate: 25 mL/min): 10.3 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.07 (bs, $w_{1/2}$ = 9.0 Hz, 1H); 7.55 (bs, $w_{1/2}$ = 7.0 Hz, 2H); 5.12 (b, 1H); 4.19 (t, J = 5.4 Hz, 2H); 3.52 (q, J = 5.4 Hz, 2H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.9 (C); 149.8 (C); 147.3 (C); 139.9 (CH); 129.3 (CH); 124.4 (CH); 79.9 (C); 69.6 (CH_2); 40.1 (CH_2); 28.5 (3×CH_3). MS (DCI/NH_4^+) $C_{12}H_{17}N_3O_5$: 284 [M + H$^+$].

*[3-(2-Nitropyridin-3-yloxy)propyl]carbamic Acid tert-Butyl Ester (**3b**).* The procedure described above was used with 3-(*N*-Boc-amino)propan-1-ol (**2b**, 2.00 g) to give 1.37 g of **3b** as a pale-yellow oil (40%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.19. t_R (HPLC A, EtOAc/heptane: 50/50 (v/v), flow rate: 25 mL/min): 11.5 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.06 (t, J = 3.3 Hz, 1H); 7.55 (d, J = 3.0 Hz, 2H); 4.20 (t, J = 5.7 Hz, 2H); 3.28 (q, J = 6.3 Hz, 2H); 2.03 (q^5, J = 6.3 Hz, 2H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.3 (C); 149.2 (C); 147.3 (C); 139.5 (CH); 129.2 (CH); 124.0 (CH); 79.2 (C); 68.3 (CH_2); 37.9 (CH_2); 29.5 (CH_2); 28.4 (3×CH_3). MS (DCI/NH_4^+) $C_{13}H_{19}N_3O_5$: 298 [M + H$^+$].

*[4-(2-Nitropyridin-3-yloxy)butyl]carbamic Acid tert-Butyl Ester (**3c**).* The procedure described above was used with 4-(*N*-Boc-amino)butan-1-ol (**2c**, 2.00 g) to give 1.19 g of **3c** as a pale-yellow oil (36%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.42. t_R (HPLC A, EtOAc/heptane: 50/50 (v/v), flow rate: 25 mL/min): 11.4 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.04 (t, $w_{1/2}$ < 2.0 Hz, 1H); 7.53 (bd, $w_{1/2}$ < 2.0 Hz, 2H); 4.73 (b, 1H); 4.15 (t, J = 6.6 Hz, 2H); 3.14 (q, J = 6.6 Hz, 2H); 1.84 (q^5, J = 6.6 Hz, 2H); 1.63 (q^5, J = 6.6 Hz, 2H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.2 (C); 149.8 (C); 147.3 (C); 139.3 (CH); 129.0 (CH); 123.9 (CH); 79.1 (C); 69.8 (CH_2); 40.2 (CH_2); 28.4 (3×CH_3); 26.8 (CH_2); 26.6 (CH_2). MS (DCI/NH_4^+) $C_{14}H_{21}N_3O_5$: 312 [M + H$^+$].

*[5-(2-Nitropyridin-3-yloxy)pentyl]carbamic Acid tert-Butyl Ester (**3d**).* The procedure described above was used with 5-(*N*-Boc-amino)pentan-1-ol (**2d**, 2.00 g) to give 0.93 g of **3d** as a pale-yellow solid (29%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.35. t_R (HPLC A, EtOAc/heptane: 50/50 (v/v), flow rate: 25 mL/min): 10.0 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.03 (t, J = 3.0 Hz, 1H); 7.53 (bd, 2H); 4.70 (b, 1H); 4.13 (t, J = 6.3 Hz, 2H); 3.09 (q, J = 6.3 Hz, 2H); 1.82 (q^5, J = 6.3 Hz, 2H); 1.60−1.40 (bm, 4H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.2 (C); 149.3 (C); 147.3 (C); 139.2 (CH); 128.9 (CH); 123.8 (CH); 78.9 (C); 70.0 (CH_2); 40.6 (CH_2); 30.0 (CH_2); 28.7 (CH_2); 28.4 (3×CH_3); 23.3 (CH_2). MS (DCI/NH_4^+) $C_{15}H_{23}N_3O_5$: 326 [M + H$^+$].

*[6-(2-Nitropyridin-3-yloxy)hexyl]carbamic Acid tert-Butyl Ester (**3e**).* The procedure described above was used with 6-(*N*-Boc-amino)hexan-1-ol (**2e**, 2.00 g) to give 1.25 g of **3e** as a pale-yellow solid (40%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.17. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 30 mL/min): 8.6 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 8.03 (t, J = 3.0 Hz, 1H); 7.52 (bd, 2H); 4.65 (b, 1H); 4.12 (t, J = 6.6 Hz, 2H); 3.07 (q, J = 6.6 Hz, 2H); 1.81 (q^5, J = 6.6 Hz, 2H); 1.70−1.30 (bm, 15H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.2 (C); 149.6 (C); 147.4 (C); 139.2 (CH); 128.9 (CH); 123.8 (CH); 78.9 (C); 70.1 (CH_2); 40.7 (CH_2); 30.3 (CH_2); 28.9 (CH_2); 28.5 (3×CH_3); 26.6 (CH_2); 25.8 (CH_2). MS (DCI/NH_4^+) $C_{16}H_{25}N_3O_5$: 340 [M + H$^+$].

Preparation of [(2-fluoropyridin-3-yloxy)alkyl]-carbamic Acid *tert*-Butyl Esters (4a−e). *General Procedure.* To a solution of the appropriate (*N*-Boc-amino)alcohol (**2a−e**, 9−12 mmol) in THF (100−150 mL) were added 0.8 equiv of triphenylphosphine (MW: 262.29), 0.8 equiv of 2-fluoro-3-hydroxypyridine (MW: 113.09), and dropwise 1.38 equiv of diisopropylazodicarboxylate (DIAD; MW: 202.21, d: 1.027). After addition, the reaction mixture was stirred at room temperature for 24−28 h. The reaction mixture was concentrated to dryness, and the residue was purified by column chromatography on silica gel. Elution with heptane/EtOAc (60/40 (v/v)) gave >90% pure [(2-fluoropyridin-3-yloxy)-

alkyl]carbamic acid *tert*-butyl ester (**4a**−**e**). For analytical purposes only, an aliquot was further purified by preparative HPLC [HPLC A].

*[2-(2-Fluoropyridin-3-yloxy)ethyl]carbamic Acid tert-Butyl Ester (**4a**).* The procedure described above was used with 2-(*N*-Boc-amino)ethanol (**2a**, 2.00 g) to give 0.86 g of **4a** as a pale-yellow solid (27%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.55. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 25 mL/min): 8.1 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.71 (bs, $w_{1/2}$ = 9.0 Hz, 1H); 7.32 (t, J = 8.7 Hz, 1H); 7.13 (dd, J = 7.8 and 4.8 Hz, 1H); 5.05 (b, 1H); 4.09 (t, J = 8.7 Hz, 2H); 3.54 (q, J = 5.4 Hz, 2H); 1.42 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.1 (C); 154.0 (d, J^1_{F-C} = 235 Hz, C); 142.3 (d, J^2_{F-C} = 26 Hz, C); 137.8 (d, J^3_{F-C} = 13 Hz, CH); 123.2 (CH); 122.3 (CH); 79.7 (C); 68.9 (CH_2); 40.2 (CH_2); 28.4 (3×CH_3). MS (DCI/NH_4^+) $C_{12}H_{17}F_1N_2O_3$: 257 [M + H$^+$].

*[3-(2-Fluoropyridin-3-yloxy)propyl]carbamic Acid tert-Butyl Ester (**4b**).* The procedure described above was used with 3-(*N*-Boc-amino)propan-1-ol (**2b**, 2.00 g) to give 1.51 g of **4b** as a pale-yellow oil (49%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.44. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 25 mL/min): 10.2 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.68 (dt, J = 3.0 and 1.5 Hz, 1H); 7.28 (td, J = 7.8 Hz and 1.5 Hz, 1H); 7.10 (dd, J = 8.1 and 5.1 Hz, 1H); 4.07 (t, J = 6.3 Hz, 2H); 3.27 (q, J = 6.3 Hz, 1H); 1.98 (q^5, J = 6.4 Hz, 2H); 1.39 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.3 (C); 154.1 (d, J^1_{F-C} = 237 Hz, C); 142.5 (d, J^2_{F-C} = 27 Hz, C); 137.5 (d, J^3_{F-C} = 15 Hz, CH); 123.0 (CH); 122.2 (CH); 79.2 (C); 67.3 (CH_2); 38.0 (CH_2); 29.8 (CH_2); 28.5 (3×CH_3). MS (DCI/NH_4^+) $C_{13}H_{19}F_1N_2O_3$: 271 [M + H$^+$].

*[4-(2-Fluoropyridin-3-yloxy)butyl]carbamic Acid tert-Butyl Ester (**4c**).* The procedure described above was used with 4-(*N*-Boc-amino)butan-1-ol (**2c**, 2.00 g) to give 1.14 g of **4c** as a pale-yellow oil (38%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.36. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 20 mL/min): 5.9 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.69 (td, J = 1.5 and 3.0 Hz, 1H); 7.30 (t, J = 8.7 Hz, 1H); 7.11 (dd, J = 7.8 and 5.1 Hz, 1H); 4.76 (b, 1H); 4.05 (t, J = 4.5 Hz, 2H); 3.16 (q, J = 6.6 Hz, 2H); 1.84 (q^5, J = 6.9 Hz, 2H); 1.66 (q^5, J = 6.7 Hz, 2H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.8 (C); 153.9 (d, J^1_{F-C} = 235 Hz, C); 142.9 (d, J^2_{F-C} = 26 Hz, C); 137.3 (d, J^3_{F-C} = 13 Hz, CH); 123.0 (CH); 122.2 (CH); 79.5 (C); 69.3 (CH_2); 40.4 (CH_2); 28.5 (3×CH_3); 27.0 (CH_2); 26.6 (CH_2). MS (DCI/NH_4^+) $C_{14}H_{21}F_1N_2O_3$: 285 [M + H$^+$].

*[5-(2-Fluoropyridin-3-yloxy)pentyl]carbamic Acid tert-Butyl Ester (**4d**).* The procedure described above was used with 5-(*N*-Boc-amino)pentan-1-ol (**2d**, 2.00 g) to give 0.90 g of **4d** as a pale-yellow solid (31%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.43. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 20 mL/min): 5.4 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.68 (bs, J < 1.5 Hz, 1H); 7.28 (t, J = 8.1 Hz, 1H); 7.10 (dd, J = 5.1 and 7.8 Hz, 1H); 4.61 (b, 1H); 4.02 (t, J = 6.6 Hz, 2H); 3.10 (q, J = 5.7 Hz, 2H); 1.83 (q^5, J = 6.6 Hz, 2H); 1.60−1.40 (bm, 4H); 1.40 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 155.8 (C); 154.1 (d, J^1_{F-C} = 235 Hz, C); 142.3 (d, J^2_{F-C} = 25 Hz, C); 136.8 (d, J^3_{F-C} = 13 Hz, CH); 122.4 (CH); 121.8 (CH); 79.8 (C); 69.5 (CH_2); 40.3 (CH_2); 29.8 (CH_2); 28.6 (CH_2); 28.1 (3×CH_3); 23.1 (CH_2). MS (DCI/NH_4^+) $C_{15}H_{23}F_1N_2O_3$: 299 [M + H$^+$].

*[6-(2-Fluoropyridin-3-yloxy)hexyl]carbamic Acid tert-Butyl Ester (**4e**).* The procedure described above was used with 6-(*N*-Boc-amino)hexan-1-ol (**2e**, 2.00 g) to give 0.90 g of the **4e** as a pale-yellow oil (31%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.48. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 20 mL/min): 8.9 min. ^{1}H NMR (CD_2Cl_2, 298 K): δ: 7.68 (bs, 1H); 7.29 (t, J = 8.1 Hz, 1H); 7.11 (dd, J = 7.8 and 5.1 Hz, 1H); 6.82 (b, 1H); 4.02 (t, J = 6.6 Hz, 2H); 3.08 (q, J = 5.7 Hz, 2H); 1.83 (q^5, J = 6.6 Hz, 2H); 1.50 (bm, 6H); 1.41 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.0 (C); 154.4 (d, J^1_{F-C} = 235 Hz, C); 142.8 (d, J^2_{F-C} = 25 Hz, C); 137.2 (d, J^3_{F-C} = 13 Hz, CH); 122.9 (CH); 122.2 (CH); 79.0 (C); 70.1 (CH_2); 40.8 (CH_2); 30.3 (CH_2); 29.2 (CH_2); 28.5 (3×CH_3); 26.8 (CH_2); 25.9 (CH_2). MS (DCI/NH_4^+) $C_{16}H_{25}F_1N_2O_3$: 313 [M + H$^+$].

Preparation of [3-(2-Fluoro/nitro-pyridin-3-yloxy)]propylamines (5, 6). *General Procedure.* To a solution of the appropriate [3-(2- fluoro/nitro-pyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**3b** or **4b**, 0.5−5.0 mmol) in CH_2Cl_2 (1−10 mL) at 0−3 °C was added TFA (10−30% (v/v)). After stirring at room temperature for 1 h, the reaction mixture was concentrated to dryness to give the pure 3-(2- fluoro/nitro-pyridin-3-yloxy)propylamines (**5** and **6**, respectively) as their TFA salts (oils).

*[3-(2-Fluoropyridin-3-yloxy)]propylamine (**5**).* The procedure described above was used with [3-(2-fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**4b**, 0.40 g) to give 0.50 g of **5** as a pale-yellow oil (quantitative). ^{1}H NMR (CD_3OD, 298 K): δ: 7.51 (bs, $w_{1/2}$ = 5.0 Hz, 1H); 7.36 (bt, $w_{1/2}$ = 25.0 Hz, 1H); 7.04 (bd, $w_{1/2}$ = 15.0 Hz, 1H); 4.03 (bt, $w_{1/2}$ = 15.0 Hz, 2H); 2.99 (bt, $w_{1/2}$ = 15.0 Hz, 2H); 2.01 (bq, $w_{1/2}$ = 15.0 Hz, 2H). ^{13}C NMR (CD_3OD, 298 K): δ: 155.3 (d, J^1_{F-C} = 237 Hz, C); 144.3 (d, J^2_{F-C} = 24 Hz, C); 138.5 (d, J^3_{F-C} = 13 Hz, CH); 125.1 (CH); 123.8 (CH); 67.9 (CH_2); 38.6 (CH_2); 28.4 (CH_2). MS (DCI/NH_4^+) $C_8H_{11}F_1N_2O_1$: 171 [M + H$^+$].

*[3-(2-Nitropyridin-3-yloxy)]propylamine (**6**).* The procedure described above was used with [3-(2-nitropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**3b**, 1.50 g) to give 2.00 g of **6** as a yellow oil (quantitative). ^{1}H NMR (CD_3OD, 298.0K): δ: 8.04 (d, J = 3.0 Hz, 1H); 7.82 (d, J = 9.0 Hz, 1H); 7.65 (dd, 9.0 and 3.0 Hz, 1H); 4.30 (t, J = 6.0 Hz, 1H); 3.12 (t, J = 6.0 Hz, 2H); 2.15 (q^5, J = 6.0 Hz, 2H). ^{13}C NMR (CD_3OD, 298.0K): δ: 149.8 (C); 148.5 (C); 140.8 (CH); 130.9 (CH); 126.6 (CH); 68.6 (CH_2); 38.7 (CH_2); 28.1 (CH_2). MS (DCI/NH_4^+) $C_8H_{11}N_3O_3$: 198 [M + H$^+$].

Preparation of 1-[3-(2-Fluoro/nitropyridin-3-yloxy)propyl]pyrrole-2,5-diones (1, 7). *General Procedure.* To a solution of the appropriate 3-(2-fluoro/nitropyridin-3-yloxy)propylamine (**5** or **6**, 3−5 mmol) in THF (100−170 mL) was added 5.0 equiv of *N*-methoxycarbonylmaleimide. The mixture was stirred at reflux overnight. A precipitate was formed and filtered. The obtained filtrate was concentrated to dryness, and the residue was purified by column chromatography on silica gel. Elution with heptane/EtOAc (50/50 (v/v)) gave pure 1-[3-(2-halogeno-pyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**,**7**) as a white powder.

*1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME).* The procedure described above was used with 3-(2-fluoropyridin-3-yloxy)propylamine (**5**, 0.50 g) to give 0.55 g of **1** (FPyME) as a white powder (75%). R_f (EtOAc/heptane: 50/50 (v/v)): 0.40. t_R (HPLC D): 10.2 min. ^{1}H NMR (CD_2Cl_2, 298.0K): δ: 7.69 (bd, J = 3.0 Hz, 1H); 7.27 (t, J = 9.0 Hz, 1H); 7.11 (dd, J = 9.0 and 3.0 Hz, 1H); 6.69 (s, 2H); 4.04 (t, J = 6.0 Hz, 2H); 3.72 (t, J = 6.0 Hz, 2H); 2.11 (q^5, J = 6.0 Hz, 2H). ^{13}C NMR (CD_2Cl_2, 298.0K): δ: 171.2 (2×C); 154.1 (d, J^1_{F-C} = 235 Hz, C); 142.4 (d, J^2_{F-C} = 25 Hz, C); 137.7 (d, J^3_{F-C} = 13 Hz, CH); 134.5 (2×CH); 123.2 (CH); 122.2 (CH); 67.5 (CH_2); 35.4 (CH_2); 28.4 (CH_2). MS (DCI/NH_4^+) $C_{12}H_{11}F_1N_2O_3$: 251 [M + H$^+$].

*1-[3-(2-Nitropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**7**).* The procedure described above was used with 3-(2-nitropyridin-3-yloxy)propylamine (**6**, 1.00 g) to give 0.40

g of **7** as a white powder (28%). R_f (CH_2Cl_2/AcOEt: 60/40 (v/v)): 0.40. ^1H NMR (CD_2Cl_2, 298.0K): δ: 8.05 (bd, $w_{1/2}$ = 9.0 Hz, 1H); 7.51 (bd, J = 3.0 Hz, 2H); 6.67 (s, 2H); 4.13 (t, J = 6.0 Hz, 2H); 3.69 (q, J = 6.0 Hz, 2H); 2.11 (q^5, J = 6.0 Hz, 2H). ^{13}C NMR (CD_2Cl_2, 298.0K): δ: 171.1 (2xC); 149.5 (C); 147.5 (C); 139.6 (CH); 134.5 (2×CH); 129.0 (CH); 124.0 (CH); 68.0 (CH_2); 35.1 (CH_2); 28.4 (CH_2). MS (DCI/NH_4^+) $C_{12}H_{11}N_3O_5$: 278 [M + H^+].

*[3-(2-Dimethylaminopyridin-3-yloxy)propyl]carbamic Acid tert-Butyl Ester (**8**).* To a solution of 3-(*N*-Boc-amino)-propan-1-ol (**2b,** 0.31 g, 1.8 mmol) in THF (20 mL) were added 0.47 g of triphenylphosphine (MW: 262.29, 1.8 mmol, 1.0 equiv), 0.25 g of 2-(dimethylamino)-3-hydroxypyridine (MW: 138.00, 1.81 mmol, 1.0 equiv) and dropwise 0.35 mL of diisopropylazodicarboxylate (DIAD; MW: 202.21, d: 1.027, 1.8 mmol, 1.0 equiv). After stirring at room temperature for 24 h, the reaction mixture was concentrated to dryness and the residue was purified by column chromatography on silica gel. Elution with heptane/EtOAc (70/30 (v/v)) gave 0.23 g of **8** as a yellow oil (43%). For analytical purposes only, an aliquot was further purified by HPLC. R_f (EtOAc/heptane: 50/50 (v/v)): 0.35. t_R (HPLC A, EtOAc/heptane: 40/60 (v/v), flow rate: 35 mL/min): 8.6 min. ^1H NMR (CD_2Cl_2, 298 K): δ: 7.77 (dd, J = 4.8 Hz, 1H); 7.00 (dd, J = 7.8 Hz, J < 1.5 Hz, 1H); 6.72 (dd, J = 7.8 and 4.8 Hz, 1H); 4.02 (t, J = 6.0 Hz, 2H); 3.30 (q, J = 6.0 Hz, 2H); 2.93 (s, 6H); 2.00 (q^5, J = 6.0 Hz, 2H); 1.42 (s, 9H). ^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.6 (C); 153.7 (C); 146.2 (C); 139.0 (CH); 118.8 (CH); 115.9 (CH); 79.1 (C); 67.4 (CH_2); 41.1 (2×CH_3); 38.8 (CH_2); 32.3 (CH_2); 28.5 (3×CH_3). MS (DCI/NH_4^+) $C_{15}H_{25}N_3O_3$: 296 [M + H^+].

*[3-(3-tert-Butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (**9**).* To a solution of [3-(2-dimethylaminopyridin-3-yloxy)propyl]-carbamic acid *tert*-butyl ester (8, 0.4 g, 1.35 mmol) in toluene was added 0.2 mL of methanetrifluoromethylsulfonate (MW: 164.10, d: 1.45, 1.77 mmol, 1.3 equiv) at 0 °C. After 3 min, a precipitate was obtained and the reaction mixture was stirred at room temperature for 1 h. The precipitate was filtered and washed with Et_2O to give 0.58 g of **9** as a white powder (93%). ^1H NMR (CD_2Cl_2, 298 K): δ: 8.10 (bd, J = 3.3 Hz, 1H); 7.66 (d, J = 8.1 Hz, 1H); 7.60 (dd, J = 6.1 and 4.2 Hz, 1H); 4.31 (t, J = 6.3 Hz, 2H); 3.71 (s, 9H); 3.31 (q, J = 6.3 Hz, 2H); 2.12 (q^5, J = 6.3 Hz, 2H); 1.38 (s, 9H).^{13}C NMR (CD_2Cl_2, 298 K): δ: 156.6 (C); 147.7 (C); 142.6 (C); 139.0 (CH); 129.0 (CH); 124.6 (CH); 121.2 (q, J = 319 Hz, CF_3); 79.3 (C); 68.1 (CH_2); 37.5 (CH_2); 30.0 (CH_2); 28.4 (3×CH_3).

3. Peptide/Protein Chemistry: Conjugation with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (1, FPyME). Conjugation of (*N*-Ac)KAAAAC (P1) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (1, FPyME) at the Micromolar Scale. To 5.2 mg of (*N*-Ac)KAAAAC (**P1**, 9.0 μmol, MW: 575.69 g/mol), dissolved in a mixture of ethanol (450 μL), 50 mM aq phosphate buffer saline (PBS, at pH 6.5, 200 μL) and acetonitrile (450 μL), was added 4.5 mg of 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME, 18.0 μmol, 2 equiv). The reaction mixture was stirred at room temperature for 3 h and then purified by HPLC [HPLC B, t_R: 28.0 min]. The fractions containing the conjugated peptide, c-(*N*-Ac)KAAAAC (**c-P1**), were combined and then lyophilized, giving 2.0 mg of the conjugated peptide, c-(*N*-Ac)KAAAAC (**c-P1**). ^1H NMR (CD_3OD/D_2O, 50/50 (v/v)): δ: 7.65 (d, J: 4.8 Hz, 1H, Py); 7.53 (t, J: 9.6 Hz, 1H, Py); 7.27 (dd, J: 7.6 and 4.8 Hz, 1H, Py); 4.60 (m, 1H, α-CH-Lys); 4.31 (m, 1H, α-CH-Cys); 4.30−4.18 (4H, 4 × α-CH-Ala); 4.11 (m, 2H, CH_2O); 4.00 (ddd, J: 20.0 and 9.6 and 4.4 Hz, 1H, β-CH^1-Cys); 3.72 (m, 2H, CH_2N); 3.32 (m, 1H, β-CH^2-Cys); 3.25−3.10 (m, 2H, CH_2CO); 2.96 (m, 2H, ϵ-CH_2-Lys); 2.58 (m, 1H, CHCO); 2.09 (m, 2H, CH_2); 2.00 (s, 3H, *N*-Ac); 1.79 (m, 1H, β-CH^1-Lys); 1.74−1.60 (m, 3H, β-CH^2-Lys/δ-CH_2-Lys); 1.42 (m, 2H, γ-CH_2-Lys); 1.40−1.32 (m, 12H, 4 × β-CH_3-Ala). MS found: 826.3 (calcd: 825.91).

Conjugation of (*N*-Ac)KAAAAC (P1) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (1, FPyME) at the Submicromolar Scale. *(A) Preparation of (N-Ac)KAAAAC (**P1**) for Conjugation.* To 0.126 μmol (72.5 μg) of (*N*-Ac)KAAAAC (**P1**, MW: 575.69 g/mol, 36 μL of a 2.0 mg/mL or 3.5 μmol/mL solution) in aq Tris NaCl (50 mM Tris-HCl; 150 mM NaCl) at pH 7.4 was added 0.193 μmol of TCEP (1.5 equiv, 7 μL of a 7.9 mg/mL or 27.6 μmol/mL solution) in solution in the same buffer. The resulting solution was left standing at room temperature for 5 min.

*(B) Conjugation of (N-Ac)KAAAAC (**P1**) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME).* To 10 μL of DMSO containing 3−5 equiv of 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME, 190−315 μg) was added TCEP-treated (*N*-Ac)KAAAAC (**P1**, about 145 μg, without removal of the excess of TCEP) diluted in aq Tris NaCl, pH 7.4 (1 mL). The resulting solution was left standing at room temperature for 15 min, then the sample was purified by HPLC [HPLC B, t_R: 28.0 min].

Conjugation of AFIM-0 (P2) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (1, FPyME) at the Submicromolar Scale. *(A) Preparation of AFIM-0 (**P2**) for Conjugation.* To a solution of AFIM-0 (**P2**, 1.0 mg; MW: 8576.78 g/mol) in 1 mL of aq Tris NaCl (50 mM Tris-HCl; 150 mM NaCl) at pH 7.4 was added TCEP (0.3 mg, 10 equiv) in solution in the same buffer (500 μL). The resulting solution was left standing at room temperature for 15 min. The excess of TCEP was removed from the solution by gel filtration using a NAP-10 G25 Sephadex cartridge (Amersham Pharmacia Biotech). The TCEP-treated (reduction of S−S bond, regeneration of free SH function) AFIM-0 (**P2**) was eluted from the cartridge in 1.5 mL of aq Tris NaCl buffer (according to manufacturer's instructions) and used within 15 min after purification.

*(B) Conjugation of AFIM-0 (**P2**) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME).* To 100 μL of DMSO or acetonitrile containing 3−5 equiv of 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME, 42−71 μg) was added 750 μL of TCEP-treated AFIM-0 (**P2**, about 0.5 mg) in aq Tris NaCl, pH 7.4. The resulting solution was left standing at room temperature for 30 min, then the sample was purified by gel filtration using a NAP-10 G25 Sephadex cartridge (Amersham Pharmacia Biotech). The conjugated peptide, c-AFIM-0 (**c-P2**), was easily separated from nonreacted 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME) and was eluted from the cartridge in 1.5 mL of aq PBS (20 mM KH_2PO_4/150 mM NaCl; pH 7.4) according to manufacturer's instructions. For analytical purposes only, the conjugated peptide, c-AFIM-0 (**c-P2**), was further purified by chromatography on gel filtration [HPLC C, t_R: 14.5 min]. MS (ESI+): 8827.0 (theor.), 8830.5 (exp.).

*(C) Conjugation of STxB (**P3**) with 1-[3-(2-Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME).* To 10 μL of DMSO containing 1 equiv of 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (**1**, FPyME) was added 90 μL of STxB (**P3**, about 0.2 mg) in 0.1 M aq PBS at pH 8. The resulting solution was left standing at room temperature for 30 min, then the sample was purified by

dialysis against water. The conjugated peptide, c-STxB (**c-P3**), was characterized by RP-HPLC [HPLC E: t_R: 12.5 min] and gel filtration [HPLC F: t_R: 9.5 min]. MS (ESI+): 8043.0 (theor.), 8048.0 (exp.).

4. Radiochemistry. Preparation of the K[^{18}F]F-K_{222} Complex. To recover and recycle the [^{18}O]water target, 2 mL of aqueous [^{18}F]fluoride from the target holder was passed through an anion-exchange resin (Sep-Pak Light Waters Accell Plus QMA Cartridge in the chloride form, washed with 5 mL of 1M aq $NaHCO_3$, and then rinsed with 50 mL of water) by helium pressure (1.5−2.0 bar). Helium is blown through the column to maximally extract the [^{18}O]water. The [^{18}F]fluoride ion is then eluted from the resin using 1.0 mL of a 4.5 mg/mL aqueous K_2CO_3 solution into a Vacutainer tube containing 12.0 to 15.0 mg of Kryptofix222 (K_{222}: 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane). The resulting solution was then gently concentrated to dryness at 145−150 °C under a nitrogen stream for 10 min to give no-carrier-added K[^{18}F]F-K_{222} complex as a white semisolid residue.

If desired, the [^{18}F]fluoride ion production batch on the cartridge can also be divided into 2 to 12 aliquots in order to perform parallel syntheses. To do this, the [^{18}F]fluoride ion is eluted from the resin using 1.0 mL of a 4.5 mg/mL aqueous K_2CO_3 solution into an empty Vacutainer tube. To distribute equally this activity over n tubes (Vacutainer tube, $n = 2-12$), the quantity of K_2CO_3 was first adjusted to n times 4.5 mg with a 50.0 mg/mL aqueous K_2CO_3 solution and second, the total volume of the solution was adjusted to 2.0 mL with water. This new aqueous [^{18}F]fluoride solution was then equally distributed over the n tubes each containing 12.0 to 15.0 mg of Kryptofix222. Finally, the volume of each fraction was adjusted to 1.0 mL with water. The resulting solutions were then independently gently concentrated to dryness at 145−150 °C under a nitrogen stream for 10 min to give no-carrier-added K[^{18}F]F-K_{222} complex as a white semisolid residue.

[(2-[^{18}F]Fluoropyridin-3-yloxy)alkyl]carbamic Acid *tert*-Butyl Esters ([^{18}F]4a−e): Incorporation Studies with K[^{18}F]F-K_{222} Complex. *(A) General Procedure Using Conventional Heating.* A 600 μL amount of DMSO containing 10 to 17 μmol of the appropriate [(2-nitropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl ester **(3a−e)** as precursor for labeling was directly added into the Vacutainer tube containing the dried K[^{18}F]F-K_{222} complex. The tube (not sealed) was thoroughly vortexed (15 s) and then placed in a heating block (at 145 °C for 1 to 30 min) without stirring the contents. The reaction vessel was then cooled using an ice−water bath, and the remaining radioactivity was measured. A 90% to 95% level of the initial radioactivity placed in the vessel was still present. The resulting often dark-colored reaction mixture was then analyzed by radiochromatography. The reaction yield was calculated from the TLC-radiochromatogram and defined as the radioactivity area of the [(2-[^{18}F]fluoropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl ester ([^{18}F]**4a−e**) over total fluorine-18 radioactivity area ratio. (SiO_2-TLC: (A) eluent: EtOAc/heptane: 50/50 (v/v), R_f: [^{18}F]**4a−e**: 0.40−0.60 and R_f: [^{18}F]fluoride ion: 0.0; (B) eluent: EtOAc, R_f: [^{18}F]**4a−e**: 0.75−0.80 and R_f: [^{18}F]fluoride ion: 0.0).

(B) General Procedure Using Microwave Activation. A 600 μL amount of DMSO containing 10 to 17 μmol of the appropriate [(2-nitropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl ester **(3a−e)** as precursor for labeling was directly added into the Vacutainer tube containing the dried K[^{18}F]F-K_{222} complex. The tube (not sealed) was thoroughly vortexed (15 s) and then placed in a dedicated microwave oven (at 100 W, for 0.5 to 3 min) without stirring the contents. The remainder of the synthesis used the same procedure as described above.

Preparation of 1-[3-(2-[^{18}F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([^{18}F]-1, [^{18}F]FPyME). *(A) Procedure Using 3-(2-Nitropyridin-3-yloxy)propyl]carbamic Acid tert-Butyl Ester (**3b**) as Precursor for Labeling.* A 600 μL amount of freshly distilled DMSO containing 5.0 mg of 3-(2-nitropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester (**3b**) as the precursor for labeling was directly added into the Vacutainer tube containing the dried K[^{18}F]F-K_{222} complex. The tube (not sealed) was then thoroughly vortexed (15 s) and then placed in a heating block at 145 °C for 4 min without stirring the contents. The reaction mixture was diluted with 1 mL of water and transferred on a C18 Sep-pak cartridge (PrepSep R-C18, Fisher Scientific, activated beforehand with 2 mL of EtOH and then rinsed with 10 mL of water). The tube was rinsed twice with 1 mL of water which was also transferred and added to the diluted reaction mixture on the cartridge. After addition of another 2 mL of water, the whole was passed through the cartridge. The cartridge was washed with 1 mL of water and partially dried for 0.5 min by applying a nitrogen stream. The [3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester ([^{18}F]-**4b**) was eluted from the cartridge with 3 mL of CH_2Cl_2 into a 5 mL reaction vial containing 0.1 mL of TFA. Twice 1 mL of CH_2Cl_2 was used to wash the cartridge and to completely transfer [3-(2-[^{18}F]fluoropyridin-3-yloxy)propyl]carbamic acid *tert*-butyl ester ([^{18}F]-**4b**) (5% of the total radioactivity amount engaged in the fluorination process was left on the cartridge). The incorporation yield was also estimated after the C18 Sep-pak cartridge elution by the CH_2Cl_2 over total eluted radioactivity (DMSO/H_2O + CH_2Cl_2) ratio. The resulting CH_2Cl_2/TFA solution (50/1, v/v) was concentrated to dryness (at 65−75 °C under a gentle nitrogen stream for 4−6 min). The yield of deprotection was quantitative and no Boc-protected [^{18}F]-**4b** could be detected by radiochromatography (SiO_2-TLC, eluent: EtOAc, R_f: [^{18}F]-**4b**: 0.75 and R_f: [^{18}F]-**5**: 0.0). The above residue, containing 3-(2-[^{18}F]fluoropyridin-3-yloxy)propylamine ([^{18}F]-**5**) was redissolved in 2 mL of CH_2Cl_2 and concentrated again to dryness to minimize TFA presence (at 65−75 °C under a gentle nitrogen stream for another 2−3 min). The residue, containing [^{18}F]-**5**, was then redissolved in 0.25 mL of dioxane containing 25 mg of *N*-methoxycarbonylmaleimide. Aqueous sat. $NaHCO_3$ (0.75 mL) was then added to the solution, and the vessel was gently vortexed for 10 min at room temperature. The reaction mixture was diluted with 1 mL of aq 1M HCl and transferred onto a C18 Sep-pak cartridge (PrepSep R-C18, Fisher Scientific, activated beforehand with 2 mL of EtOH, rinsed with 10 mL of water, and loaded with 5 mL of water). The tube was rinsed twice with 1 mL of water which was also transferred and added to the diluted reaction mixture on the cartridge. The whole was passed through the cartridge. The cartridge was washed with 3 mL of water and partially dried for 0.5 min by applying a nitrogen stream. The 1-[3-(2-[^{18}F]fluoropyridin-3-yloxy)-propyl]pyrrole-2,5-dione ([^{18}F]-**1**, [^{18}F]FPyME) was eluted from the cartridge with 3 mL of CH_2Cl_2. Twice 1 mL of CH_2Cl_2 was used to wash the cartridge and to completely transfer [^{18}F]FPyME ([^{18}F]-**1**) (10−25% of the radioactivity amount was left on the cartridge). The resulting CH_2Cl_2 solution was partially (not to dryness) concentrated (at 65−75 °C under a gentle nitrogen stream for 2−4 min). The residue was diluted up to a volume of 1.0−1.5

mL with CH_2Cl_2 and HPLC-purified [HPLC D, t_R: 10.0−10.5 min] to give pure labeled [18F]FPyME ([18F]-**1**).

*(B) Procedure Using [3-(3-tert-Butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (**9**) as Precursor for Labeling.* A 600 μL amount of freshly distilled DMSO containing 4.0 mg of [3-(3-*tert*-butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium trifluoromethanesulfonate (**9**) as the precursor for labeling were directly added into the Vacutainer tube containing the dried K[18F]F-K_{222} complex. The tube (not sealed) was then thoroughly vortexed (15 s) and then placed in a heating block at 145 °C for 2 min without stirring the contents. The remainder of the preparation used the same procedure as described above.

Conjugation of (*N*-Ac)KAAAAC (P1) with 1-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([18F]-1, [18F]FPyME). Preparation of [18F]c-(*N*-Ac)KAAAAC ([18F]c-P1). To 50 μL of DMSO containing HPLC-purified [18F]FPyME ([18F]-**1**, freed from HPLC-solvents by concentration to dryness at 65−75 °C under a gentle nitrogen stream), was added TCEP-treated (*N*-Ac)KAAAAC (**P1**, about 72.5 μg, without removal of the excess of TCEP, see above) dissolved in aq Tris NaCl, pH 7.4 (1 mL). The resulting solution was left standing at room temperature for 10 min and then purified by HPLC [HPLC B, t_R: 28.0 min].

Conjugation of AFIM-0 (P2) with 1-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([18F]-1, [18F]FPyME). *(A) Preparation of [18F]c-AFIM-0 ([18F]**c-P2**).* To 100 μL of DMSO containing HPLC-purified [18F]FPyME ([18F]-**1**, freed from HPLC-solvents by concentration to dryness at 65−75 °C under a gentle nitrogen stream), was added 750 μL of TCEP-treated AFIM-0 (**P2**, about 0.5 mg, see above) in aq Tris NaCl, pH 7.4. The reaction mixture was gently vortexed for 5 min and then purified by gel filtration on a NAP-10 G25 Sephadex cartridge (Amersham Pharmacia Biotech). The conjugated and labeled peptide, [18F]c-AFIM-0 ([18F]**c-P2**), was easily separated from nonreacted [18F]FPyME ([18F]-**1**), if any, and was eluted from the cartridge in 1.5 mL of aq 0.9% NaCl according to manufacturer's instructions.

*(B) Formulation and Quality Control of Conjugated and Labeled [18F]c-AFIM-0 ([18F]**c-P2**).* The cartridge-fraction containing the conjugated and labeled peptide, [18F]c-AFIM-0 ([18F]**c-P2**), was diluted with physiological saline and finally sterile-filtrated on a 0.22 μm GS-Millipore filter (vented). As demonstrated by HPLC analysis [HPLC C], radiosynthesized conjugated and labeled [18F]c-AFIM-0 ([18F]**c-P2**) coeluted with an authentic sample of reference compound (fluorine-19-synthesized c-AFIM-0 (**c-P2**)). The radiolabeled product was found to be >90% radiochemically pure. The radiopharmaceutical preparation was shown to be free of nonreacted [18F]FPyME ([18F]-**1**) and radiochemically stable for at least 240 min.

Conjugation of STxB (P3) with 1-[3-(2-[18F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([18F]-1, [18F]-FPyME). *(A) Preparation of [18F]c-STxB ([18F]**c-P3**).* To 100 μL of DMSO containing HPLC-purified [18F]FPyME ([18F]-**1**, freed from HPLC-solvents by concentration to dryness at 65−75°C under a gentle nitrogen stream), was added 330 μL of STxB (**P3**, about 1 mg) in aq 1.0 M PBS at pH 8. After addition of another 570 μL of 1.0 M aq PBS at pH 8, the reaction mixture was gently vortexed for 5 min and then purified by gel filtration on a NAP-10 G25 Sephadex cartridge (Amersham Pharmacia Biotech). The conjugated and labeled peptide, [18F]c-STxB ([18F]**c-P3**), was easily separated from nonreacted [18F]-FPyME ([18F]-**1**), if any, and was eluted from the cartridge in 1.5 mL of aq 0.9% NaCl according to manufacturer's instructions.

*(B) Formulation and Quality Control of Conjugated and Labeled [18F]c-STxB ([18F]**c-P3**).* The cartridge-fraction containing the conjugated and labeled peptide, [18F]c-STxB ([18F]**c-P3**), was diluted with physiological saline and finally sterile-filtrated on a 0.22 μm GS-Millipore filter (vented). As demonstrated by HPLC analysis [HPLC E and F], radiosynthesized conjugated and labeled [18F]c-STxB ([18F]**c-P3**) coeluted with an authentic sample of reference compound (fluorine-19-synthesized c-STxB (**c-P3**)). The radiolabeled product was found to be >95% radiochemically pure. The radiopharmaceutical preparation was shown to be free of nonreacted 1-[3-(2-[18F]fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([18F]-**1**, [18F]FPyME) and radiochemically stable for at least 400 min.

RESULTS AND DISCUSSION

Chemistry. The synthesis of FPyME (**1**) as well as that of the nitro derivatives **3b** and **7** and the trimethylammonium derivative **9** as the various selected precursors for fluorine-18 labeling is outlined in Schemes 1−4.

The [(2-nitropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl esters (**3a**−**e**) and [(2-fluoropyridin-3-yloxy)alkyl]-carbamic acid *tert*-butyl esters (**4a**−**e**) were all synthesized using the following general method. The nitro derivatives (**3a**−**e**) were prepared in 29−41% yield via a Mitsunobu coupling reaction (*51*) from the corresponding commercially available (hydroxyalkyl)carbamic acid *tert*-butyl esters (**2a**−**e**) and 2-nitro-3-hydroxypyridine (*37*, *40*), in THF at room temperature, using triphenylphosphine (0.8 equiv) and diisopropylazodicarboxylate (1.4 equiv) (Scheme 1).

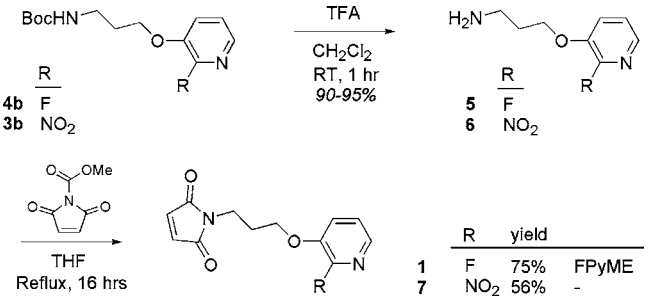
	n	yield
3a	2	38%
b	3	40%
c	4	40%
d	5	29%
e	6	41%

Analogously, the fluoro derivatives (**4a**−**e**) were prepared in 27−49% yield from the same corresponding (hydroxyalkyl)carbamic acid *tert*-butyl esters (**2a**−**e**) and 2-fluoro-3-hydroxypyridine (*37*, *40*) (Scheme 2).

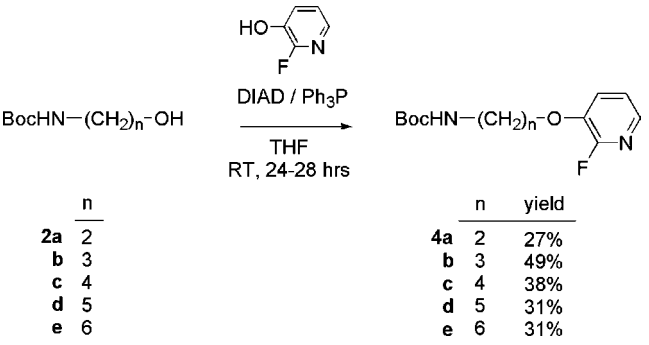
The identification of the propyl chain as the most appropriate alkyl spacer and therefore the selection of the fluorinated derivative **1** (FPyME) (Scheme 3) as well as the selection of the nitro derivatives **3b** and **7** and the trimethylammonium derivative **9** (Schemes 3 and 4) as possible precursors for fluorine-18 labeling will be discussed in the radiochemistry part below. The choice of these functions (nitro and trimethylammonium) as leaving groups in the radiofluorination process will also be discussed in that section.

Removal of the *tert*-butoxycarbonyl function of the propyl derivatives **4b** and **3b** was performed with trifluoroacetic acid (TFA) in dichloromethane at room temperature and gave the desired free amines **5** and **6** in 90−95% yield (Scheme 3). Treatment of **5** and **6** with

Scheme 3. Preparation of 1-[3-(2-[^{18}F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione (1, FPyME) and the Corresponding Nitro Derivative 7 as Precursor for Labeling



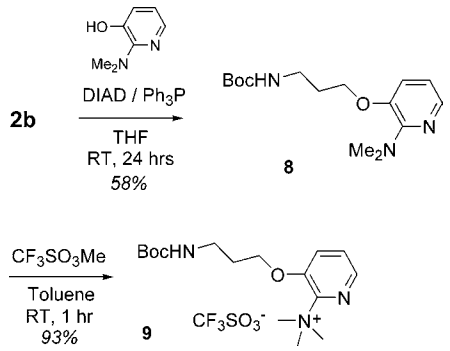
Scheme 2. Preparation of [(2-Fluoropyridin-3-yloxy)-alkyl]carbamic Acid *tert*-Butyl Ester (4a−e)



N-methoxycarbonylmaleimide in refluxing tetrahydrofuran gave the desired maleimides **1** (FPyME) and **7** in 75% and 56% yield, respectively (nonoptimized).

The dimethylamino derivative **8** was prepared in 58% yield, from the corresponding 2-(dimethylamino)-3-hydroxypyridine (*40*) under Mitsunobu conditions similar to those described above for the synthesis of **3a**−**e** and **4a**−**e** (Scheme 4). The trimethylammonium derivative **9** was cleanly obtained in 93% yield by methylation of the dimethylamine **8** using methyl trifluoromethanesulfonate (1.3 equiv) in toluene at 0 °C (Scheme 4).

Scheme 4. Preparation of [3-(3-*tert*-Butoxycarbonyl-aminopropoxy)pyridin-2-yl]trimethylammonium Trifluoromethanesulfonate (9)



The synthetic procedure of conjugation of peptides and proteins described below is based on the efficient and highly selective coupling reaction of free thiol functions (cysteine β-SH) and *N*-substituted maleimides reagents (*30*−*32*). The reaction involves addition of the thiol across the double bond of the maleimide to yield a thioether (see Figure 3). In contrast to haloacetamides, the most frequently class of thiol-reactive reagents used, maleimides do not react with functions of other amino acid residues such as methionine, histidine, or tyrosine (*30*−*32*). These reagents react rapidly (2 to 3 orders of magnitude higher in terms of rate constants (*52*) at near-neutral pH and usually can be coupled selectively in the presence of free amine function (*N*-terminus α-NH_2 or internal lysine ϵ-NH_2), which are relatively unreactive below pH 8.

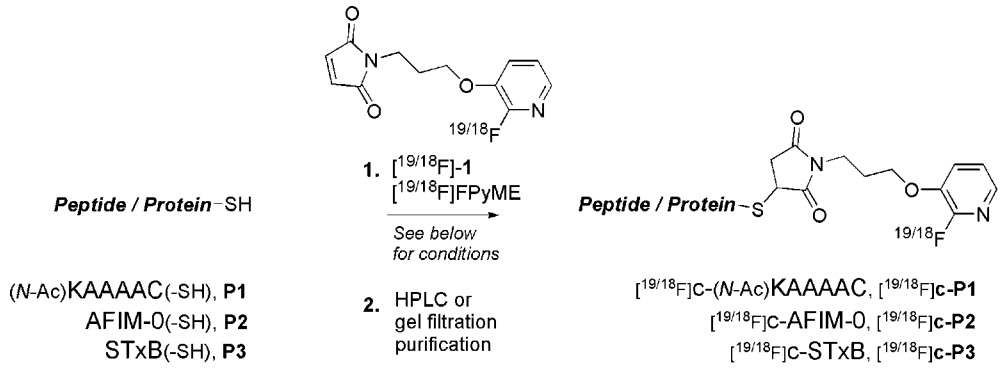
Table 1 summarizes the principal characteristics of the peptide and proteins (**P1**, **P2**, and **P3**) used as starting material in the present study and the corresponding conjugated peptide and proteins (**c-P1**, **c-P2**, and **c-P3**) that we have synthesized. Analytical data obtained for these conjugated macromolecules are also indicated.

The (*N*-Ac)KAAAAC peptide (**P1**) was chosen as model peptide in order to confirm the chemoselectivity of the conjugation reaction of our maleimide reagent (**1**, FPyME). Conjugation of the (*N*-Ac)KAAAAC peptide (**P1**) at a micromolar scale was carried out using 3−5 equiv of FPyME (**1**) in a 1/9 (v/v) mixture of DMSO and 0.05 M aq Tris NaCl buffer (pH 7.4) at room temperature for 15−30 min (Scheme 5). The conjugation yields, based on starting peptide, were determined by HPLC (C18 Delta-Pak column, Waters) and were greater than 90%. Using preparative RP-HPLC (same column), the nonlabeled conjugated peptide (**c-P1**, t_R: 28.0 min) was easily separated from the nonreacted material such as the starting peptide (t_R: 13.0 min) and the maleimide reagent **1** (FPyME, t_R: 33.0 min). Mass spectrometry confirmed the identity of the conjugated peptide c-(*N*-Ac)KAAAAC (**c-P1**), giving the expected calculated mass (See Table 1). Higher molecular weight species could not be detected, clearly confirming the mono-conjugation with the maleimide reagent. ^{1}H NMR confirmed the chemoselectivity of the conjugation. Only the thiol (SH) function from the cysteine residue was conjugated with the maleimide reagent (**1**, FPyME), the amine (-ϵ-NH_2) function from the lysine residue being unaffected: in ^{1}H NMR experiments, the chemical shift of both β-CH_2 protons borne by the cysteine residue had moved from 3.00 and 3.35 ppm (CH_2SH) to 3.32 and 4.00 ppm (CH_2SR) respectively, after alkylation, whereas the chemical shift of both ϵ-CH_2 protons borne by the lysine residue were unchanged (2.96 ppm). The chemical shift of the α-CH proton borne by the cysteine residue was also slightly moved from 4.39 to 4.31 ppm.

Conjugation of the (*N*-Ac)KAAAAC peptide (**P1**) at a submicromolar scale however required preactivation of the thiol function (S−S bond reduction using tris(2-carboxyethyl)phosphine hydrochloride (TCEP) for 5 min at room temperature in 0.05 M aq Tris NaCl buffer at pH 7.4) prior to the formal coupling step with the maleimide reagent (**1**, FPyME). To this TCEP-treated peptide (**P1**) was then simply added FPyME (**1**, 3−5 equiv) in DMSO, and the mixture was left standing at room temperature for 15−30 min. Using these experimental conditions, RP-HPLC showed again almost com-

Scheme 5. Peptide/Protein Conjugation with 1-[3-(2-[19/18F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([19/18F]-1, [19/18F]FPyME)



Conditions :
^{19}F : [^{19}F]-**1** (3-5 eq), aq. 50 mM Tris NaCl (pH 7.4) or aq. 0.1M PBS (pH 8.0) / DMSO : 9/1 (v/v), RT, 15-30 min
^{18}F : [^{18}F]-**1**, aq. 50 mM Tris NaCl (pH 7.4) or aq. 0.1M PBS (pH 8.0) / DMSO : 9/1 (v/v), RT, 5-10 min

plete consumption of starting peptide (t_R: 13.0 min), and the conjugation yields estimated both by HPLC and mass spectrometry analysis was greater than 90%.

The nonlabeled conjugated peptide (**c-P1**) was purified using preparative RP-HPLC and was easily separated from the nonreacted material (starting peptide at t_R: 13.0 min and excess of maleimide reagent at t_R: 33.0 min) as well as a new side-product at t_R: 26.0 min identified with mass spectrometry as TCEP-reduced FPyME (pyrrolidine-2,5-dione derivative, structure not shown). Mass spectrometry confirmed again the identity of the conjugated peptide c-(*N*-Ac)KAAAAC (**c-P1**).

The above-developed methodology was applied to the preparation of c-AFIM-0 (**c-P2**), a selected 75-amino acid (~ 8.8 kDa) miniprotein, derived from the specific binding domain of annexins for phosphatidylserine (*53*, *54*). This protein and its derivatives show high thermodynamic stability, reversible folding, and a high affinity for phosphatidylserine exposed at the external surface of biological membranes. They could be an interesting alternative to the use of fluorine-18-labeled annexin-V (*55*−*58*) and are currently developed by Bionexis Pharmaceuticals as selective fluorine-18-labeled imaging agents for the early detection of apoptosis (*53*, *54*, *59*−*62*).

Conjugation of the selected protein AFIM-0 (**P2**) was carried out using similar conditions to those described above (including a TCEP-treatment of the starting protein) with conjugation yields estimated quantitative by mass spectrometry analysis. The nonlabeled conjugated protein (**c-P2**) was separated from the nonreacted maleimide reagent (**1**, FPyME) by gel filtration using a Sephadex NAP-10 cartridge. Size-exclusion liquid chromatography on a Gel Filtration SuperDex Peptide HR 10/30 column showed a unique peak (t_R: 14.5 min) and absence of starting maleimide reagent (**1**, FPyME, t_R: 25.0 min). Mass spectrometry confirmed the identity of the conjugated protein c-AFIM-0 (**c-P2**), giving the expected calculated mass (see Table 1). Higher molecular weight species could also be detected, clearly confirming the mono-conjugation with the maleimide reagent.

The above-developed methodology was finally applied to the preparation of c-STxB (**c-P3**), the nontoxic homopentameric B subunit (monomer size ~ 8.0 kDa) of the bacterial (*Shigella dysenteriae*) Shiga toxin (*63*−*66*). This toxin is composed of two subunits, a catalytic A-subunit that inhibits protein biosynthesis by modifying ribosomal RNA, and a nontoxic homopentameric B-subunit. STxB binds to the cellular receptor of Shiga toxin, the glycosphingolipid globotriaosyl ceramide (Gb_3), that is expressed by human cancers, including a restricted set of lymphomas, and a wide range of solid tumors such as breast and ovarian carcinomas and testicular seminomas (*63*, *66*). STxB is currently developed by the Institut Curie as a selective tumor-targeting agent.

Conjugation of the selected protein STxB (**P3**) was carried out in a 1/9 (v/v) mixture of DMSO and 0.1 M aq phosphate buffer saline (PBS) at pH 8 (without TCEP pretreatment of the protein). Conjugation yields were estimated quantitative by mass spectrometry analysis. The nonlabeled conjugated protein (**c-P3**) was separated from the nonreacted maleimide reagent (**1**, FPyME) by dialysis against water. RP-HPLC on a C18 μBondapak column and size-exclusion liquid chromatography on a Gel Filtration SuperDex Peptide HR 10/30 column showed a unique peak (t_R: 12.5 min and 9.5 min, respectively) and absence of starting maleimide reagent (**1**, FPyME, t_R: 9.0 min and 45.3 min, respectively). Mass spectrometry confirmed the identity of the conjugated protein c-STxB (**c-P3**), giving the expected calculated mass (See Table 1). Higher molecular weight species could not be detected, clearly confirming the mono-conjugation with the maleimide reagent.

Radiochemistry. In a first set of experiments, the [(2-nitropyridin-3-yloxy)alkyl]carbamic acid *tert*-butyl esters (**3a**−**e**) were all evaluated for their effectiveness as precursors for fluorine-18-labeling using nucleophilic *hetero*aromatic fluorinations (Scheme 6) in order to

determine the influence of the alkyl chain length on the incorporation of fluorine into the pyridine ring. These nucleophilic *hetero*aromatic substitutions, like the aliphatic nucleophilic radiofluorinations, only require a good

leaving group and there is no need for an additional strong electron-withdrawing substituent for activation of the aromatic ring such as in the *homo*aromatic nucleophilic radiofluorinations. The nitro function was therefore selected for its high potential as leaving group in comparison with the corresponding halo substituents (*35*, *36*) and for its ease of preparation from commercially available starting materials (see above). Introduction of the fluorine-18 as no-carrier-added naked [^{18}F]fluoride anion was performed in dimethyl sulfoxide (DMSO) with the activated K[^{18}F]F-Kryptofix222 complex (*67*) as the radiofluorinating reactant (Kryptofix222 (K_{222}): 4,7,13,16,-21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane) by either conventional heating (at 145°C for 1 to 30 min) or microwave activation (at 100 W for 0.5 to 3 min). The radiochemical yields of fluorine-18 incorporation were calculated from the TLC-radiochromatogram and defined as the [^{18}F]fluoropyridine derivatives [^{18}F]-**4a**−**e** over total fluorine-18 activity area ratio.

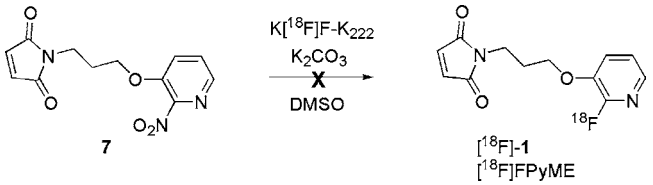
A DMSO solution (600 μL) containing 17 μmol (4.8−5.8 mg) of the appropriate precursor for labeling **3a**−**e** was transferred to 30−60 mCi of the dried K[^{18}F]F-K_{222} complex in a reaction vial (Vacutainer tube). The tube (not sealed) was then placed in a heating block at 145 °C for 1 to 30 min without stirring the contents or in a dedicated microwave oven at 100 W for 0.5 to 3 min.

Using conventional heating at 145 °C, all nitro derivatives (**3a**−**e**) were reactive under the conditions described above. Whatever the precursor used (**3a**−**e**), the incorporation yields increased with the reaction time up to 5 min and then almost leveled (very slowly decrease). In each run, the remaining radioactivity at the end of the experiment was measured and 85% to 95% of the initial radioactivity placed in the vessel was still present. At 5 min, excellent incorporation yields were observed for the propyl derivative **3b** (53−72% yield). Good incorporation yields were also observed for the butyl and pentyl derivatives (**3c** and **3d**), 41−57% and 38−53%, respectively, whereas moderate incorporation yields were observed for the hexyl derivative (**3e**, 17−35%). Only low incorporation yields were observed for the ethyl derivative (**3a**, 7−13%). At 15 min and 30 min for example, the incorporation yields observed for the propyl derivative **3b** were still high (50−65% and 45−55% yields, respectively). Using only 10 μmol of the nitro derivatives (**3a**−**e**) resulted in slightly lower incorporation yields. Using microwave irradiations at 100 W, comparable results to those described above were obtained for all nitro derivatives (**3a**−**e**) with the highest incorporation yields observed at 2 min and again the propyl derivative **3b** being the more reactive precursor for labeling (50−75% yield). No further efforts were made at this stage to optimize and further increase the observed yields.

On the basis of these results, the propyl alkyl chain was selected for the design of the maleimide final reagent (**1**, FPyME).

A first dedicated maleimide-containing precursor for fluorine-18-labeling, the nitro derivative **7** (1-[3-(2-nitropyridin-3-yloxy)propyl]pyrrole-2,5-dione), was therefore designed and synthesized (see above), expecting the use of a one-step radiochemical process. Introduction of fluorine-18 was attempted in DMSO (600 μL) containing 17 μmol (4.7 mg) of the nitro derivative **7** with the activated K[^{18}F]F−Kryptofix222 complex as the radiofluorinating reactant, by conventional heating only (at 145°C for 1 to 10 min). However, no incorporation of fluorine-18 could be detected by TLC or HPLC using these radiochemical conditions (similar to those described for the preparation of the [(2-[^{18}F]fluoropyridin-3-yloxy)-

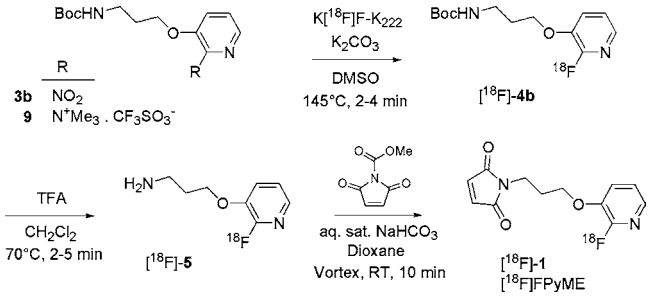
Scheme 7. Potential One-Step Process for the Preparation of 1-[3-(2-[^{18}F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([^{18}F]-1, [^{18}F]FPyME)



alkyl]carbamic acid *tert*-butyl ester ([^{18}F]-**4a**−**e**)) (Scheme 7), and the expected [^{18}F]FPyME ([^{18}F]-**1**) could not be isolated. This is probably due to the rapid decomposition of the maleimide ring (base-labile) to a mixture of nonreactive maleamic acids using the strong alkaline conditions required for the introduction of [^{18}F]fluorine as described above. A similar unsuccessful direct radiofluorination of a preformed maleimide was also reported by others (*33*). In view of these failures, the preparation of the corresponding *N*-trimethylammonium trifluoromethanesulfonate derivative ([3-[3-(2,5-dioxo-2,5-dihydropyrrol-1-yl)propoxy]pyridin-2-yl]trimethylammonium trifluoromethanesulfonate, structure not shown) was not attempted.

[^{18}F]FPyME ([^{18}F]-**1**) was therefore synthesized using the following three-step radiochemical process from the nitro derivative **3b** (Scheme 8).

Scheme 8. Preparation of 1-[3-(2-[^{18}F]Fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione ([^{18}F]-1, [^{18}F]FPyME) Using a Three-Step Process



The first radiochemical step, the introduction of fluorine-18 into the pyridine ring, was performed as described above, in DMSO (600 μL) containing the nitro derivative **3b** (17 μmol) and the activated K[^{18}F]F-K_{222} complex, and by conventional heating at 145°C for 5 min, giving the desired [^{18}F]fluoropyridine derivative **4b** in 45−60% (decay-corrected) isolated radiochemical yields with respect to starting [^{18}F]fluoride after C-18 Sep-pak purification. The second radiochemical step, the removal of the *N*-Boc-protective group, was rapidly (2−5 min) performed in a mixture of TFA and dichloromethane (1/50 (v/v)) at room temperature, quantitatively yielding the free amine [^{18}F]-**5**. The third and final step, the maleimide ring formation, was first performed using maleic anhydride (25 mg to 50 mg) in *o*-xylene (at 180−190°C) for 10 to 20 min, based on literature procedures (see for example ref 68; over fifty references can be found in the literature via a bibliographic search using Beilstein Commander 2000 version 5.0, copyright 1995−2000, MDL Information Systems GmbH). On the basis of TLC analysis, the desired maleimide [^{18}F]-**1** ([^{18}F]FPyME) was obtained in 19−41% radiochemical yields. The use of other described solvents and experimental conditions using maleic anhydride, such as refluxing THF (*69*, *70*), acetic acid at 100 °C (*71*, *72*), refluxing dioxane containing triethylamine (*73*, *74*), or refluxing methanol containing sodium

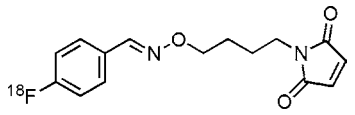
hydroxyde (*75*), gave systematically lower radiochemical yields when the desired maleimide [18F]-**1** ([18F]FPyME) could be detected at all.

Using instead of maleic anhydride, *N*-methoxycarbonylmaleimide (25 mg) in *o*-xylene (at 180−190°C) gave higher radiochemical yields (46−77%, based on TLC analysis) for 5 min of reaction only. However, HPLC purification (semipreparative SiO_2 Zorbax Rx-SIL, Hewlett-Packard) led to [18F]-**1** ([18F]FPyME) with radiochemical purity of only about 90% and with systematically lower isolated radiochemical yields that expected from the TLC analysis. The maleimido ring formation was then investigated again, and the following optimal conditions, based on literature procedures, were found (*76*−*78*): the free amine [18F]-**5** (3-(2-[18F]fluoropyridin-3-yloxy)propylamine) was treated with *N*-methoxycarbonylmaleimide (25 mg) in a strongly vortexed 3/1 (v/v) solution (1 mL) of aqueous saturated bicarbonate and THF at room temperature for 10 min. On the basis of TLC analysis, the desired maleimide [18F]-**1** ([18F]FPyME) was obtained in >90% radiochemical yields and was practically the only detectable product on the TLC chromatogram. C-18 Sep-pak trapping, followed by HPLC purification (semipreparative SiO_2 Zorbax Rx-SIL, Hewlett-Packard), gave radiochemically pure [18F]-**1** ([18F]FPyME) in 64−77% isolated yields, confirming the excellent radiochemical yields of maleimido formation obtained from the TLC analysis.

Finally, the three-step radiochemical process for the preparation of [18F]FPyME ([18F]-**1**) was further optimized (Scheme 8) using a more efficient and attractive precursor for labeling, the *N*-trimethylammonium trifluoromethanesulfonate derivative **9** ([3-(3-*tert*-butoxycarbonylaminopropoxy)pyridin-2-yl]trimethylammonium trifluoromethanesulfonate). This type of precursor for labeling has been used extensively already in nucleophilic *homo*- and *hetero*aromatic radiofluorinations (*13*−*15*). It is particularly suitable for its expected superior separation (using HPLC or SPE-cartridge) from the reaction product (the fluoro derivative [18F]-**4b** in this case) due to the large differences in the physicochemical properties. Moreover, the trimethylammonium function possesses higher potential as leaving group (*79*) in comparison with the corresponding nitro and especially halo derivatives, giving usually higher incorporation yields under milder conditions. Introduction of the fluorine-18 was therefore performed using only 8.7 μmol of the *N*-trimethylammonium trifluoromethanesulfonate derivative **9** (4 mg) in DMSO (600 μL) containing the activated K[18F]F-K_{222} complex by conventional heating at 145 °C for 2 min, giving the desired [18F]fluoropyridine derivative **4b** in 64−76% (decay-corrected) isolated radiochemical yields with respect to starting [18F]fluoride after C-18 Sep-pak purification. The remainder of the radiosynthesis used the same procedures as described above.

Typically, 4.8−6.7 GBq (130−180 mCi) of radiochemically pure [18F]FPyME ([18F]-**1**) could be obtained after semipreparative HPLC in 110 minutes starting from a 33.3 GBq (900 mCi) cyclotron production batch of [18F]-fluoride (overall radiochemical yields, based on starting [18F]fluoride: 28−37% decay-corrected and 17−20% non-decay-corrected).

According to the available literature, only one report exists on two fluorine-18-labeled maleimide reagents that have been prepared and used for prosthetic conjugation of proteins (*33*). In that abstract, the authors described the preparation of 1-(4-[18F]fluorophenyl)pyrrole-2,5-dione ([18F]FPPD, see Figure 2) and *N*-[3-(2,5-dioxo-2,5-dihydropyrrol-1-yl)phenyl]-4-[18F]fluorobenzamide ([18F]-DDPFB, see Figure 2).



[18F]FBABM

Figure 4. Chemical structure of *N*-[4-[(4-[18F]fluorobenzylidene)aminooxy]butyl]maleimide ([18F]FBABM).

[18F]FPPD was synthesized in four radiochemical steps from 1,4-dinitrobenzene and cesium [18F]fluoride. It was obtained in 15% decay-corrected overall radiochemical yield in 100 min total synthesis time (*33*). [18F]DDPFB was synthesized in three radiochemical steps from 4-nitrobenzonitrile and cesium [18F]fluoride and was obtained in only 10% decay-corrected overall radiochemical yield in 70 min total synthesis time (*33*).

During the preparation of this manuscript, another fluorine-18-labeled maleimide reagent was published (*80*). *N*-[4-[(4-[18F]Fluorobenzylidene)aminooxy]butyl]-maleimide ([18F]FBABM, see Figure 4) was synthesized in only two steps, involving the preparation of 4-[18F]-fluorobenzaldehyde, followed by its aminooxy-aldehyde coupling reaction to the fluorine-18-labeled maleimide reagent, with an overall radiochemical yield of about 35% (decay-corrected) within 60 min of radiosynthesis time. This new fluorine-18-labeled maleimide reagent ([18F]-FBABM) is a valuable alternative to the use of our [18F]-FPyME ([18F]-**1**) and is the first reported example of an oxime-containing radiotracer for PET.

Conjugation of the (*N*-Ac)KAAAAC peptide (**P1**, TCEP-treated) with the HPLC-purified [18F]FPyME ([18F]-**1**) (Scheme 5) was carried out in a 1/9 (v/v) mixture of DMSO and 0.05 M aq Tris NaCl buffer (pH 7.4) at room temperature for 10 min. The labeled conjugated peptide [18F]**c-P1** was obtained in >90% yield, based on starting [18F]FPyME ([18F]-**1**), and determined both by radio-TLC analysis and radio-HPLC analysis (C18 DeltaPak column, Waters). [18F]c-(*N*-Ac)KAAAAC ([18F]**c-P1**) was purified by preparative HPLC (C18 DeltaPak column, Waters). It was easily separated from starting (*N*-Ac)-KAAAAC (t_R: 13.0 min), nonreacted [18F]FPyME ([18F]-**1**), if any (t_R: 33.0 min), and traces of a fluorine-18-labeled side product, associated with the TCEP-reduced-[18F]-FPyME species (t_R: 26.0 min, see above). [18F]c-(*N*-Ac)-KAAAAC ([18F]**c-P1**) coeluted with reference nonlabeled standard and was obtained with a radiochemical purity greater than 99%. Conjugation of AFIM-0 (**P2**) was carried out using similar conditions to those described above (including a TCEP-treatment, but including a removal step of this reducing agent by gel filtration prior to the use of the protein) with conjugation yields estimated quantitative by radio-TLC analysis. The labeled conjugated protein (**c-P2**) was separated from nonreacted [18F]FPyME ([18F]-**1**), if any, by gel filtration using a Sephadex NAP-10 cartridge. Size-exclusion liquid radiochromatography on a Gel Filtration SuperDex Peptide HR 10/30 column showed a unique peak (t_R: 14.5 min), which coeluted with reference standard. Conjugation of STxB (**P3**) was carried out in a 1/9 (v/v) mixture of DMSO and 0.1 M aq PBS at pH 8 (without TCEP-treatment of the starting protein), with conjugation yields estimated quantitative by radio-TLC analysis. The labeled conjugated protein (**c-P3**) was separated from nonreacted [18F]-FPyME ([18F]-**1**), if any, by gel filtration using a Sephadex NAP-10 cartridge. RP-HPLC on a C18 μBondapak column and size-exclusion liquid radiochromatography on a Gel Filtration SuperDex Peptide HR 10/30 column showed a unique peak (t_R: 12.5 and 9.5 min, respectively), which coeluted with reference standard.

Typically, 1.11−1.29 GBq (30−35 mCi) of pure conjugated [^{18}F]peptide or protein (specific radioactivity > 37 GBq/μmol) could be obtained in 25−30 min starting from 1.85 GBq (50 mCi) of [^{18}F]FPyME ([^{18}F]-**1**) (60−70% non-decay-corrected isolated yield). The whole synthetic procedure has been fully automated on our Zymate robot system and took 130−140 min. As demonstrated by LC analysis, radiosynthesized labeled conjugated peptide and protein ([^{18}F]**c-P1**, [^{18}F]**c-P2** and [^{18}F]**c-P3)** coeluted with the authentic synthesized reference compounds. The fluorine-18-labeled peptide and proteins were found to be more than 99%, 90%, and 97% radiochemically pure, respectively. The preparations were shown to be free of radioactive starting reagent ([^{18}F]FPyME, [^{18}F]-**1**) and radiochemically stable for at least 240 min.

The conjugation yields to the macromolecules obtained with [^{18}F]FPyME ([^{18}F]-**1**) are also higher than those obtained for the conjugation of the previously reported *N*-[3-(2,5-dioxo-2,5-dihydropyrrol-1-yl)phenyl]-4-[^{18}F]fluorobenzamide ([^{18}F]PPFB, see Figure 2). Therefore, about 50% yield could be obtained for the conjugation step with a protein part from a monoclonal antibody fragment (*33*). No complementary details, such as solvent, reagent, and conditions used for the conjugation, reaction time, and purification process, were given.

Conjugation to a protein of the recently published *N*-[4-[(4-[^{18}F]fluorobenzylidene)aminooxy]butyl]maleimide ([^{18}F]-FBABM, see Figure 4) has not been reported so far. Conjugation yields to a small tripeptide (GSH) were comparable to those obtained with [^{18}F]FPyME ([^{18}F]-**1**) (about 70% decay-corrected radiochemical yield).

CONCLUSION

The objective of the present work was to develop a [^{18}F]-fluoropyridine-based thiol (sulfhydryl)-selective reagent for the prosthetic labeling with fluorine-18 of peptides and proteins, offering a new alternative with improved chemoselectivity to the use of the nonselective carboxylate and amine-reactive [^{18}F]reagents already existing.

FPyME (**1**, 1-[3-(2-fluoropyridin-3-yloxy)propyl]pyrrole-2,5-dione) was designed as a radiochemically feasible reagent, its pyridinyl moiety carrying the radioactive halogen (fluorine-18) which can be efficiently incorporated via a nucleophilic *hetero*aromatic substitution, and its maleimido function ensuring the efficient alkylation of a free thiol function as borne by cysteine residues. [^{18}F]-FPyME ([^{18}F]-**1**, HPLC-purified) was efficiently prepared in 17−20% non-decay-corrected yield (based on starting [^{18}F]fluoride) in 110 min using a three-step radiochemical pathway. The developed procedure involves a high-yield nucleophilic *hetero*aromatic ortho-radiofluorination as the fluorine-18 incorporation step and uses a trimethylammonium trifluoromethanesulfonate as the most efficient precursor leaving group for labeling (when compared to the parallely tested nitro precursor). [^{18}F]FPyME ([^{18}F]-**1**) was first conjugated with a small hexapeptide ((*N*-Ac)-KAAAAC, **P1**), chosen as a model peptide, and the chemoselectivity of the coupling reaction (CH_2SH versus CH_2NH_2) was confirmed. The labeling strategy was then applied with success to the preparation of two 8-kDa proteins of interest, currently being developed as tumor imaging agents ([^{18}F]c-AFIM-0, [^{18}F]**c-P2**; [^{18}F]c-STxB, [^{18}F]**c-P3**). Conjugation was achieved in high yields (60−70%, isolated and non-decay-corrected yields) and uses optimized, short-time reaction and purification conditions, both compatible with the chemical stability of the proteins and the relatively short half-life of the radioisotope concerned. The whole radiosynthetic procedure, including the preparation of the fluorine-18-labeled reagent, the conjugation with the protein, and the final purification, took 130−140 min.

Given these high radiosynthetic yields, [^{18}F]FPyME ([^{18}F]-**1**) represents a new, valuable, thiol-selective, fluorine-18-labeled reagent and can advantageously be used for the design and development of peptide- and protein-based radiopharmaceuticals for PET.

ACKNOWLEDGMENT

The authors wish to thank the cyclotron operators Mr. Daniel Gouel, Mr. Christophe Peronne, and Mr. Christophe Lechêne for performing the irradiations, as well as Ms. Badia Amekraz (Laboratoire de Spéciation des Radionucléides et des Molécules, DEN/DPC/SECR, CEA-Saclay, F-91191 Gif-sur-Yvette, France) and Drs. Alain Pruvost and Eric Ezan (Laboratoire d'Études du Métabolisme des Médicaments, DSV/SPI, CEA-Saclay, F-91191 Gif-sur-Yvette, France) for recording the MS spectra and Drs Delphine Patin, Wolfgang Faigle and Damarys Loew (Institut Curie, F-75248 Paris Cedex, France) for expert help in some of the experiments. The authors also wish to thank Dr. Dirk Roeda for proofreading the manuscript and suggesting linguistic corrections. This work was supported by the OLIM European program QLG1-CT-2000-00562 and by the European Molecular Imaging Laboratories network (EMIL; LSH-2004-503569).

Functionalization of Glucose at Position C-3 for Transition Metal Coordination: Organo-Rhenium Complexes with Carbohydrate Skeletons

Cécile Dumas,[†] Jeannine Petrig,[†] Luzia Frei,[†] Bernhard Spingler,[§] and Roger Schibli*[,†,‡]

Center for Radiopharmaceutical Science of the ETH-PSI-USZ, Paul Scherrer Institute, CH-5232 Villigen, Switzerland, Department of Chemistry and Applied Biosciences, ETH Zurich, CH-8093 Zurich, Switzerland, and Institute of Inorganic Chemistry, University of Zurich, CH-8057 Zurich, Switzerland. Received October 26, 2004

Novel 3-*O*-[1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose] and 3-*O*-[D-glucose] derivatives with an iminodiacetate (*N*,*O*,*O*), a histidinate, and an *N*-(acetetyl)picolylamine (*N*,*N*,*O*) chelating system for tridentate coordination of the organometallic $M(CO)_3$-fragment (M = Tc, Re) have been prepared. The chelates were introduced and assembled through reductive amination starting from 3-*O*-[1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose]-acetaldehyde. After deprotection, the pyranose derivatives were reacted with the precursor $[NEt_4]_2[ReBr_3(CO)_3]$ to afford the corresponding organometallic complexes in yields between 54% and 94%. The NMR, MS, and IR analyses corroborated the tridentate coordination of the organometallic metal center exclusively via the synthetic chelates. In the case of the *N*-(acetyl)picolylamine derivative, the coordinative properties were further confirmed by X-ray structure analysis of the first $Re(CO)_3$-D-glucofuranose complex. All glucose complexes unveiled good stability and solubility in organic and aqueous media.

INTRODUCTION

The coordination chemistry of carbohydrates with transition metal plays a significant role in processes such as transport and storage of metals as well as in the metabolism of toxic metals (*1*, *2*). However, from a coordination point of view, most of the native carbohydrate compounds possess functional groups with only weak donor capacities, which often can not effectively compete with, for example, water. Thus, functionalization with "artificial" chelating systems is necessary to produce more stable transition metal complexes. These features can be of pivotal importance for the development of novel pharmaceuticals with anti-proliferative and cytostatic properties displaying better biocompatibility and reduced side effects (*2*−*7*). Also, in the development of novel catalysts, carbohydrate-based ligand systems can lead to metal compounds with improved solubility in environmentally benign media (*8*). For both purposes (pharmaceuticals and catalysis), organometallic complexes with a carbohydrate skeleton are an interesting class of compound. Organometallic rhodium(III) and iridium(III) complexes of α-*N*-galactopyranose amino acids have been intensively investigated by Beck and co-workers (*9*, *10*). Dötz et al. have performed pioneering work on carbohydrate-based Fischer-type carbene complexes with a wide variety of transition metals (*11*−*14*).

We are interested in the development of novel, tumor-seeking (organometallic) compounds of technetium and rhenium for potential use in diagnostic and therapeutic radiopharmacy. For both elements, there exist radioactive isotopes (Tc-99m, and Re-186/188), which are very important in nuclear medicine. Recently, we have reported and structurally characterized the first examples of organo-technetium and -rhenium complexes of C-1 functionalized glucose derivatives (*15*). Experiments have shown that the complexes exhibit a high kinetic stability in human serum over a period of 24 h at 37 °C. Recently, other groups have described organometallic glucose and glucosamine complexes of technetium and rhenium, respectively, for potential use in radiopharmacy (*16*, *17*). However, our initial in vivo experiments have shown only low accumulation of the C-1 glucose complexes in cancer cells overexpressing Glut1 (the major transport system for glucose in humans) (*18*). This is presumably due to the fact that the hydroxyl group at the C-1 position is important for recognition and transport or glucose via Glut1. On the other hand, there is evidence that moderate modification at the C-3 and the C-6 positions is tolerated without complete loss of biological activity (*19*).

In the present work, we describe novel strategies for the syntheses of glucose derivatives functionalized at position C-3 with different tridentate metal chelating entities. The ligand systems are based on L-histidyl (**1**), iminodiacetic acid (**2**), and *N*-(acetyl)picolylamine (**3**) frameworks (Figure 1). The preparation, structural, and spectroscopic analyses of rhenium−tricarbonyl complexes of C-3 functionalized glucose derivatives are presented. The spectroscopic investigations of the stable and water-soluble fac-$Re(CO)_3$ complexes **13**−**15** have shown that in all of the cases the metal center coordinates tridentately via the chemically introduced anchor groups.

EXPERIMENTAL SECTION

Material and Methods. All chemicals were purchased of reagent grade and used without further purification. Dry THF was distilled from Na/benzophenone immediately before use. The precursor $(NEt_4)_2[ReBr_3(CO)_3]$ was synthesized according to the previously

published procedure (*20*). Tr-L-histidine methyl ester was synthesized according to the literature (*21*). Moisture-sensitive reactions were conducted in oven-dried glassware under a nitrogen atmosphere. All reactions were monitored by tin layer chromatography performed on Merck precoated silica gel (60 F254) plates and visualized using UV light and by applying a solution of potassium permanganate (1% in water). Amines were detected by ninhydrin (0.5% in methanol). Column chromatography was accomplished on Fluka silica gel 60 (0.062−200 mesh). HPLC analyses were performed on a Merck-Hitachi L-7000-system equipped with an L-7400 tunable absorption detector. A Macherey-Nagel C-18 reversed phase column (10 μm, 150 × 4.1 mm) was used. HPLC solvents consisted of aqueous 0.05 M TEAP (triethylammonium phosphate) buffer, pH = 2.25 (solvent A), and methanol (solvent B). The HPLC system started with 100% of A from 0 to 3 min. The eluent switched at 3 min to 75% A and 25% B and at 9 min to 66% A and 34% B followed by a linear gradient 66% A/34% B to 100% B from 9 to 20 min. The gradient remained at 100% B for 2 min before switching back to 100% A. The flow rate was 1 mL/min. The IR spectra were recorded on a Perkin-Elmer FT-IR 16PC. Mass spectra were measured on a Micromass VG Trio 2000 Operator. The NMR spectra were measured on a Varian Gemini 2000 (300 and 75 MHz for ^{1}H and ^{13}C, respectively). Unless otherwise specified, spectra were recorded in $CDCl_3$ as solvent, and chemical shifts were expressed in ppm relative to residual $CHCl_3$ at 7.27 ppm for ^{1}H and to $CDCl_3$ at 77.7 ppm for ^{13}C. The optical rotations were measured on a Polarimeter Perkin-Elmer 241. High-resolution mass spectroscopy and elemental analyses were performed at the Department of Organic Chemistry at the Federal Institute of Technology Zurich (ETHZ).

Synthesis of 3-*O*-[2-(L-Histidinato)ethyl]-α,*β*-D-glucopyranose, 1. Glucofuranose **8** (0.64 g, 0.92 mmol) was stirred at room temperature in H_2SO_4 (2 N, 3 mL) for 1 day. The solution was neutralized by addition of $Ba(OH)_2$, and the precipitate was separated by centrifugation. The ester was saponified by addition of NaOH (1 M, 1 mL) to the clear solution; after one night of stirring, the obtained solution was neutralized by addition of HCl (1 M, 1 mL). After evaporation of the water, the residual oil was dried in a desiccator. The solid was taken up in methanol (3 mL), and the insoluble particles were centrifuged. After evaporation to dryness of the supernatant, a white powder (0.24 g) was obtained. Yield 74%. ^{1}H NMR ([*d*^{6}]-DMSO, 50 °C): δ = 7.88 (s, 1H), 7.11 (s, 1H), 5.07 (d, *J* = 3.3 Hz, 0.5H), 4.46 (d, *J* = 7.5 Hz, 0.5H), 4.14−3.92 (m, 2H), 3.88−3.68 (m, 3H), 3.68−3.58 (m, 1H), 3.58−3.44 (m, 1H), 3.36 (t, *J* = 9.3 Hz, 1H), 3.29−3.13 (m, 4H), 3.08 (dd, *J* = 7.5, 15.0 Hz, 1H). Synthesis of 3-*O*-[Bis(carboxymethyl)aminoethyl]-α,*β*-D-glucopyranose, 2. Compound **2** was prepared from **11** according to the preparation of **1**. Yield 60%. ^{1}H NMR ([*d*^{6}]DMSO, 60 °C): δ = 4.05 (d, *J* = 3.3 Hz, 0.4H), 4.44 (d, *J* = 6.9 Hz, 0.6H), 4.17−3.85 (m, 2H), 3.85−3.65 (m, 3H), 3.61 (s, 2H), 3.60 (s, 2H), 3.55−3.39 (m, 1H), 3.38−3.08 (m, 2H), 3.09−2.84 (m, 2H). IR ($CHCl_3$): ν = 1634, 1402, 1120, 1078, 1040 cm^{-1}. MS (ES) *m/z* (%): 338 [M$^+$ − H]. Analysis Calcd for $C_{12}H_{21}NO_{10}$: C, 42.48; H, 6.24; N, 4.13. Found: C, 42.51; H, 6.74; N, 3.93.

Synthesis of 3-*O*-[2-Carboxymethyl-2-(pyridin-2-ylmethyl)aminoethyl]-α,*β*-D-glucopyranose, 3. Compound **3** was prepared from **12** according to the preparation of **1**. Yield 95%. ^{1}H NMR ([*d*^{6}]DMSO, 50 °C): δ = 8.73−7.85 (m, 4H), 4.95 (s, 1H), 4.90−4.50 (m, 2H), 4.47−4.06 (m, 2H), 4.40 (s, 1H), 3.92−3.66 (m, 2H), 3.64−3.45 (m, 3H), 3.33 (s, 2H), 2.82−2.39 (m, 2H). IR ($CHCl_3$) ν = 1638, 1400, 1124, 1080 cm^{-1}. MS (ES) *m/z* (%): 373 (100) [M + H]$^+$, 395 (80) [M + Na]$^+$. Anal. Calcd for $C_{16}H_{24}N_2O_8$: C, 51.60; H, 6.50; N, 7.52. Found: C, 51.62; H, 7.08; N, 6.27.

Synthesis of 3-*O*-[2-(Methyl-N$_{im}$-triphenylmethyl-L-histidinato)ethyl]-1,2:5,6-(*O*-isopropylidene)-α-D-glucofuranose, 8. Aldehyde **7** (1.15 g, 3.8 mmol) dissolved in dry methanol (17 mL) and $NaBH_3CN$ (0.24 g, 3.3 mmol) were added to a solution of *N*-triphenylmethyl-L-histidine (1.56 g, 3.8 mmol) in dry methanol (17 mL) in the presence of molecular sieves. After the mixture was stirred for 24 h at room temperature, the molecular sieves were filtered over a Celite pad and the organic layer was evaporated to dryness. The resulting oil was diluted in chloroform (49 mL), extracted with water (20 mL), and the aqueous layer was back extracted with chloroform (30 mL). The combined organic layer was dried over Na_2SO_4 and evaporated. The crude was purified by chromatography on silica gel AcOEt/MeOH (14:1) to afford a pale yellow oil (0.64 g). Yield 24%. mp 82−83 °C; $[\alpha]^{24}_D$ = 3.50 (*c* = 0.371 in MeOH). ^{1}H NMR ([*d*^{6}]DMSO, 75 °C): δ = 7.54−7.49 (m, 1H), 7.49−7.37 (m, 9H), 7.29−7.17 (m, 6H), 6.71 (s, 1H), 5.96 (d, *J* = 3.3 Hz, 1H), 4.69 (d, *J* = 3.9 Hz, 1H), 4.48−4.38 (m, 1H), 4.24 (dd, *J* = 3.1, 7.6 Hz, 1H), 4.21−4.06 (m, 2H), 4.01 (d, *J* = 3.0 Hz, 1H), 3.99 (dd, *J* = 5.1, 6.6 Hz, 1H), 3.85−3.67 (m, 1H), 3.74 (s, 2H), 3.71 (s, 3H), 3.19−3.91 (m, 4H), 1.61 (s, 3H), 1.53 (s, 3H), 1.45 (s, 3H), 1.41 (s, 3H). ^{13}C NMR: δ = 174.4, 142.5 (2C), 142.3, 138.8, 137.1, 129.6 (8C), 128.2 (7C), 119.7, 111.8, 109.0, 105.4, 82.5, 81.2, 75.3, 72.7, 67.3, 61.8, 54.7, 51.8, 47.3, 32.2, 27.0 (2C), 26.4, 25.6. IR (KBr): ν = 1737, 1491, 1445, 1373, 1163, 1073 cm^{-1}. HRMS calcd for $C_{40}H_{47}N_3O_8$, 697.8165; found, 697.8170.

Synthesis of 3-*O*-[(1-Methoxycarbonyl)aminoethyl]-1,2:5,6-(*O*-isopropylidene)-α-D-glucofuranose, 9. Compound **9** was prepared from **7** and glycine methyl ester according to the preparation of **8**. The crude layer was purified by chromatography on silica gel AcOEt to afford a colorless oil (0.64 g). Yield 55%. $[\alpha]^{24}_D$ = −12.14 (*c* = 0.400 in MeOH). ^{1}H NMR: δ = 5.86 (d, *J* = 3.6 Hz, 1H), 4.55 (d, *J* = 3.6 Hz, 1H), 4.32−4.27 (m, 1H), 4.12−4.07 (m, 2H), 4.01−3.96 (m, 1H), 3.90 (d, *J* = 3.0 Hz, 1H), 3.8−3.72 (m, 1H), 3.71 (s, 3H), 3.66−3.59 (m, 1H), 3.43 (s, 2H), 2.83−2.75 (m, 2H) 2.03 (s, 1H), 1.48 (s, 3H), 1.40 (s, 3H), 1.32 (s, 3H), 1.30 (s, 3H). ^{13}C NMR: δ = 173.2, 112.4, 109.7, 105.9, 83.0, 82.9, 81.9, 73.1, 70.5, 68.1, 52.4, 51.3, 49.3, 27.5, 26.9, 25.9. IR ($CHCl_3$): ν = 1740, 1210, 1076 cm^{-1}. HRMS calcd for $C_{17}H_{29}NO_8$, 375.4141; found, 375.4136.

Synthesis of 3-*O*-[2-(Pyridin-2-ylmethyl)aminoethyl]-1,2:5,6-(*O*-isopropylidene)-α-D-glucofuranose,

10. Compound **10** was prepared from **7** and picolylamine according to the preparation of **8**. The crude was purified by chromatography on silica gel AcOEt/MeOH (1:1) to afford a pale yellow oil. Yield 22%. $[\alpha]^{24}_D = -20.4$ (c = 0.206 in MeOH). ^{1}H NMR: δ =8.55−8.53 (m, 1H), 7.66−7.60 (m, 1H), 7.33 (d, J = 7.7 Hz, 1H), 7.16−7.12 (m, 1H), 5.87 (d, J = 3.9 Hz, 1H), 4.56 (d, J = 3.6 Hz, 1H), 4.35−4.28 (m, 1H), 4.11−4.03 (m, 2H), 4.00−3.95 (m, 2H), 3.93 (s, 2H), 3.88−3.79 (m, 1H), 3.77−3.64 (m, 1H), 2.87−2.79 (m, 2H), 2.33 (br s, 1H), 1.48 (s, 3H), 1.38 (s, 3H), 1.30 (s, 3H), 1.26 (s, 3H). ^{13}C NMR: δ = 160.5, 150.0, 137.1, 122.7, 122.6, 112.4, 109.7, 106.0, 83.1, 82.9, 81.9, 73.2, 70.5, 68.1, 55.8, 49.3, 27.5, 26.9, 25.9. IR ($CHCl_3$): ν = 1594, 1378, 1252, 1076, 1018 cm^{-1}. HRMS calcd for $C_{20}H_{30}N_2O_6$, 394.4620; found, 394.4617.

Synthesis of 3-*O*-[Bis-*N*-[(1-methoxycarbonyl)-methyl]aminoethyl]-1,2:5,6-(*O*-isopropylidene)-α-D-glucofuranose, 11. Triethylamine (0.15 mL, 1.07 mmol) and methyl bromoacetate (0.1 mL, 1.07 mmol) were added to a solution of **9** (0.27 g, 0.71 mmol) in THF (7.5 mL), and the solution was refluxed overnight. After being cooled, the mixture was filtered; the filtrate was then diluted with CH_2Cl_2 (10 mL) and washed with water (15 mL). The organic layer was dried over Na_2SO_4, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography on silica gel AcOEt/*n*-hexane (1:1). Yield 70%. $[\alpha]^{24}_D = -19.21$ (c = 0.400 in MeOH). ^{1}H NMR: δ = 5.83 (d, J = 3.6 Hz, 1H), 4.56 (d, J = 3.9 Hz, 1H), 4.28−4.22 (m, 1H), 4.12−4.04 (m, 2H), 4.01−3.96 (m, 1H), 3.96 (dd, J = 5.5, 8.5 Hz, 1H), 3.85 (d, J = 3.0 Hz, 1H), 3.81−3.74 (m, 1H), 3.69−3.65 (m, 1H), 3.69 (s, 6H), 3.61 (s, 4H), 3.03−2.90 (m, 2H), 1.48 (s, 3H), 1.40 (s, 3H), 1.32 (s, 3H), 1.30 (s, 3H). ^{13}C NMR: δ = 172.4, 112.4, 109.7, 105.9, 83.3, 82.9, 81.8, 73.1, 70.7, 68.0, 56.2, 54.7, 51.3, 27.2, 26.9, 26.0. IR ($CHCl_3$): ν = 1742, 1378, 1202, 1166, 1076, 1016 cm^{-1}. HRMS calcd for $C_{20}H_{33}NO_{10}$, 447.4767; found, 447.4759.

Synthesis of 3-*O*-[*N*-[(1-Methoxycarbonyl)methyl]-*N*-(pyridin-2-ylmethyl)aminoethyl]-1,2:5,6-(*O*-isopropylidene)-α-D-glucofuranose, 12. Compound **12** was prepared from **10** according to the preparation of **11**. AcOEt. Yield 81%. $[\alpha]^{24}_D = -21.6$ (c = 0.176 in MeOH). ^{1}H NMR: δ = 8.52−8.50 (m, 1H), 7.66−7.61 (m, 1H), 7.49 (d, J = 8.0 Hz, 1H), 7.16−7.12 (m, 1H), 5.80 (d, J = 3.6 Hz, 1H), 4.50 (d, J = 3.9 Hz, 1H), 4.28−4.22 (m, 1H), 4.11−4.01 (m, 2H), 3.98 (s, 2H), 3.98−3.92 (m, 1H), 3.66 (d, J = 2.8 Hz, 1H), 3.76−3.61 (m, 2H), 3.67 (s, 3H), 3.50 (s, 2H), 2.95−2.90 (m, 2H), 1.46 (s, 3H), 1.38 (s, 3H), 1.28 (s, 3H). ^{13}C NMR: δ = 172.5, 160.0, 149.9, 149.5, 137.2, 123.6, 122.9, 122.6, 112.4, 109.6, 105.7, 83.3, 83.0, 82.9, 82.0, 81.7, 73.1, 70.2, 68.0, 61.3, 56.0, 54.4, 52.2, 51.9, 27.6, 27.3, 27.0, 26.7, 25.8. RESULTS AND DISCUSSION

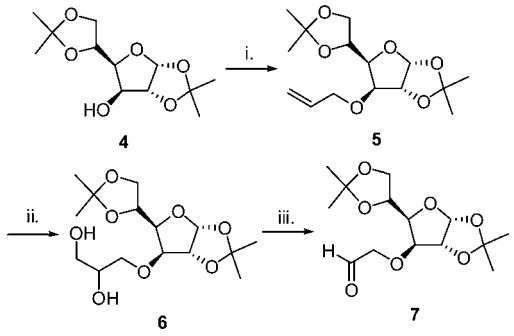
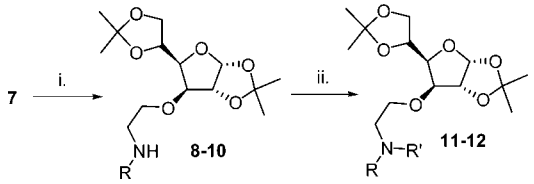
Syntheses of Glucose Derivatives. On the basis of our own and other groups experience about efficient and suitable ligand systems for stable, facial coordination of the $[M(CO)_3]$-moiety (M = ^{99m}Tc, ^{99}Tc, ^{188}Re, Re) (*22*−*25*), we were interested in C-3 functionalized glucose analogues with polyamino or polycarboxy functionalities. For the current studies, we recognized 3-*O*-acetaldehyde-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose **7** as a versatile intermediate for the synthesis of C-3 derivatized glucose analogues in relatively good yields with the above-mentioned chelating systems via reductive amination. Compound **7** was prepared from the commercially available 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose, diacetone-D-glucose **4**, in three steps similar to the previously published method by Zhong, with an overall yield of 51% (Scheme 1) (*26*). Compound **4** was converted in the first step to the allyl derivative **5** according to the method of Bessodes in the presence of KOH and the phase transfer catalyst 18-crown-6 in excellent yield (90%) (*27*). The diol **6** was prepared in the presence of *tert*-butyl-hydroperoxide with a catalytic amount of OsO_4. To remove OsO_4 from the reaction solution, silica gel was added. After purification, the product **6** was obtained in approximately 60% yield. If $NaHSO_3$ is used instead of silica gel, the protection groups of **6** are cleaved due to the low pH of the reaction after formation of the osmium sulfite adduct. After oxidative cleavage of the diol **6** with sodium periodate on silica gel, the aldehyde **7** could be isolated almost quantitatively.

Scheme 1[a]



[a] Reagents and conditions: (i) allyl bromide, KOH, 18-crown-6, THF, room temperature, 1 h, 90%; (ii) OsO_4, *t*BuOOH, NEt_4OH, *t*BuOH, 0−5 °C, 16 h, 60%; (iii) $NaIO_4$, silica, CH_2Cl_2, room temperature, 30 min, 94%.

Scheme 2[a]



[a] Reagents and conditions: (i) amine, $NaBH_3CN$, MeOH, room temperature, 24 h; (ii) $BrCH_2CO_2Me$, NEt_3, THF, reflux, 16 h.

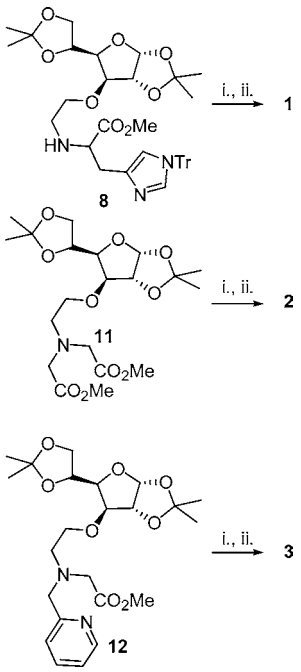
Table 1.

Product	Reactant	R	R'	Yield
8	H_3CO-His(τ-Tr)	H_3CO-Histamine(τ-Tr)	H	24 %
9	H_2N-CH_2-CO_2CH_3	CH_2-CO_2CH_3	H	55 %
10	H_2-NCH_2-(C_5H_4N)	CH_2-(C_5H_4N)	H	22 %
11	$BrCH_2$-CO_2CH_3	CH_2-CO_2CH_3	CH_2-CO_2CH_3	70 %
12	$BrCH_2$-CO_2CH_3	CH_2-(C_5H_4N)	CH_2-CO_2CH_3	81 %

For the three glucose derivatives **1**−**3**, the reductive amination was performed in dry methanol in the presence of $NaBH_3CN$ and molecular sieves (Scheme 2). The corresponding amines were used in a 4-fold excess. For the synthesis of the intermediate **8**, the N_ϵ-Tr-histidine methyl ester was used. We could show that the reaction works equally well for other ester protected amino acids such as L-methionine and N_ϵ-(Boc)-L-lysine (data not shown); however, for our radiopharmaceutical purpose, these derivatives were not suited. For the compounds **9** and **10**, the aldehyde **7** was reacted with glycine methyl ester or with 2-picolylamine, respectively. The Schiff's bases were in situ reduced with $NaBH_3CN$. After purification, the secondary amine functionalities of **9** and **10** were alkylated with methyl bromoacetate to afford the furanose intermediates **11** and **12** (Scheme 3 and Table 1). It is important to recognize that this efficient synthetic strategy can be applied to assemble a wide variety of other chelating systems, tailor-made for different transition metal centers and purposes.

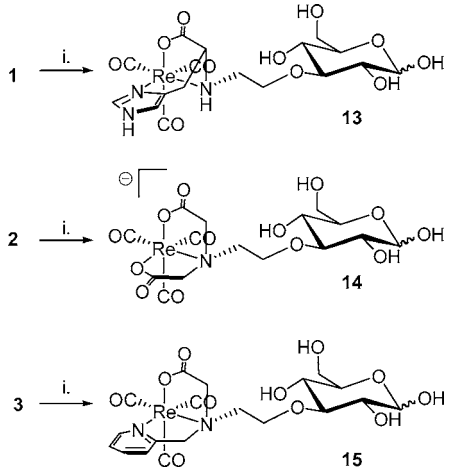
The acetonide protecting groups in compounds **8**, **11**, and **12** were removed according to a modified procedure reported by Roberts in the presence of 2 N H_2SO_4 at room temperature (*28*). The trityl protection group was cleaved concomitantly under these conditions. After 24 h, the reaction solutions were neutralized with $Ba(OH)_2$. The suspensions were centrifuged to separate $BaSO_4$. Saponification of the remaining methyl ester has been accomplished with 1 N NaOH. After evaporation of the

Scheme 3[a]



[a] Reagents and conditions: (i) H_2SO_4 (2 N), $Ba(OH)_2$, room temperature, 24 h; (ii) NaOH, HCl water, room temperature, 16 h, 60−95%.

Scheme 4[a]



[a] Reagents and conditions: (i) $[NEt_4]_2[ReBr_3(CO)_3]$, MeOH, 50 °C, 2 h, 54−94%.

solvent, the final products **1**−**3** could be isolated with yields ranging from 60% to 95%.

In the ^{1}H NMR spectra of the deprotected ligands **1**−**3**, the signals in the region between 2.5 and 4.00 ppm are usually poorly resolved due to the presence of a mixture of α- and β-anomers. Only the signals of the H-1 proton and those in the aromatic region (compounds **1** and **3**) and the intense singlet at 3.61 ppm of the four protons of the iminodiacetic acid moiety (compound **2**) could be unambiguously attributed. However, mass spectrometric analyses provided in all of the cases evidence for the proposed composition and molecular structure.

Syntheses of Organometallic Glucose Complexes. The rhenium precursor $[NEt_4]_2[ReBr_3(CO)_3]$ reacted readily with the functionalized glucose derivatives **1**−**3** under mild and stoichiometric conditions in methanol (Scheme 4). All reactions have been monitored by means of HPLC. Thereby, complete consumption of the starting material has been observed after 2 h at 50 °C. The rhenium−tricarbonyl carbohydrate complexes **13**−**15** were isolated as pale yellow-brown, moisture- and air-stable powders in yields between 54% and 94%. Their proposed composition was confirmed by microanalysis, (high-resolution) mass spectrometry, IR, ^{1}H, and ^{13}C NMR spectroscopy.

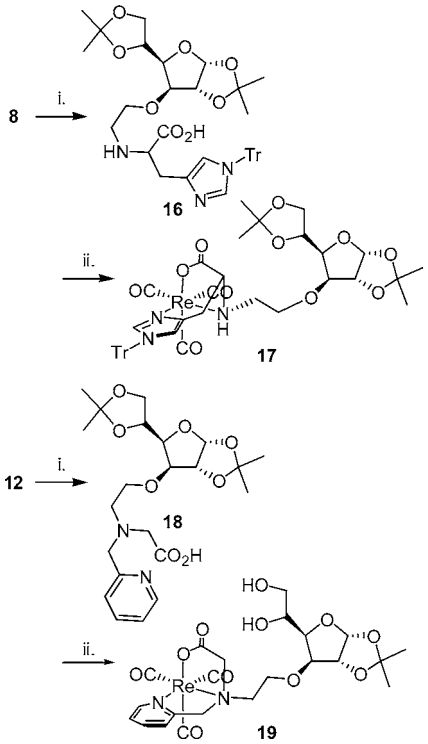
The IR spectra of the anionic (**14**) and neutral (**13** and **15**) complexes revealed the typical fac-$Re(CO)_3$ pattern with sharp and intense absorption between 2008 and 2026 cm^{-1} and broad and intense absorption between 1886 and 1910 cm^{-1}. The wavelengths for the CO ligands are significantly blue shifted as compared to the starting material $[ReBr_3(CO)_3]^{2-}$ (2000, 1886 cm^{-1}). The mass spectra of the complexes were obtained via ESI-MS. The mass peak of the molecular anion of **14** was detected at 606/608 mass unit, showing the isotopic envelop characteristic (2/3) of a mono anion with one rhenium atom (isotopic composition ^{185}Re 40%:^{187}Re 60%). Further mass peaks at 428/430 mass units arose from fragments of complex **14** lacking the entire sugar entity. Complex **13** was measured in the negative and complex **15** in the positive mode, where their molecular mass at 628/630 $[M - 1]^-$ and 663/665 $[M + Na]^+$ mass units, respectively, could be detected.

The ^{1}H NMR spectra of the complexes **13**−**15**, recorded at room temperature, were very complex due the presence of mixtures of anomers and isomers, respectively. When recorded at 50 and 75 °C, the signals of the α- and β-anomeric protons collapse to give sharper signals; however, the attribution of the other proton signals became more difficult under these conditions because they formed broad and overlapped multiplets. Still, the spectra allowed determination of the coordinative preferences of the organometallic center to different functional groups of the sugar derivatives **1**−**3**. Generally, for the protons of the pyranose ring, a chemical shift of <0.3 ppm was detected. Thus, it can be concluded that the rhenium center does not coordinate to hydroxyl groups of the glucose moiety. On the other hand, most of the protons of the chelating systems (iminodiacetic acid, *N*-acetyl picolylamine, and L-histidyl) revealed significant shifts toward lower field and/or additional coupling patterns after coordination of the $[Re(CO)_3]^+$-moiety. Thus, it can be concluded that, due to the dominant donor characteristics of the anchoring groups, the glucose derivatives behaved coordinatively very much like the corresponding abiotic ligands without the glucose entity reported earlier (*22*, *24*, *29*).

Preparation of Complexes 17 and 19. More detailed NMR analyses have been performed with the furanose derivatives **17** and **19**, because this facilitated the attribution of ^{1}H NMR signals and differentiation of the isomers. The methyl ester derivatives **8** and **12** were saponified in the presence of sodium hydroxide, and the resulting acids **16** and **18** were labeled with the rhenium precursor $[NEt_4]_2[ReBr_3(CO)_3]$ according to the method described for complexes **13**−**15** (Scheme 5).

For complexes **17** and **19**, the formation of two diastereomers was expected with *S* or *R* configuration at the α-amino group and the tertiary amine, respectively. Thus, in the NMR spectrum of complex **17**, for all CH-protons two sets of signals with approximately a 1:1 intensity ratio were observed. In addition, two unresolved α-NH multiplets at 5.95 and 5.60 ppm with an identical intensity ratio were observed. ^{1}H NMR correlation experiments (COSY) revealed that these two multiplets coupled with the proton of the α carbon and the CH_2 of the neighboring ethylene spacer. It is noteworthy that the proton of the rhenium-coordinated α-NH group is detectable even after several days in deuterated, protic

Scheme 5[a]



[a] Reagents and conditions: (i) NaOH, HCl water, room temperature, 16 h, 90−98%; (ii) $[NEt_4]_2[ReBr_3(CO)_3]$, MeOH, 50 °C, 2 h, 41−97%.

solvents. Surprisingly, only one set of ^{1}H NMR signals could be distinguished for complex **19**. Thus, it can be concluded that only one isomer has been formed. In addition, one of the two isopropylidene groups (facing the rhenium center) of ligand **18** has also been cleaved during the complex formation. This has been repeatedly observed for the reaction between $[ReBr_3(CO)_3]^{2-}$ and the ligand **18** under various conditions but never for compound **16** or, for example, **4** (performed as a control experiment). Whether this phenomenon is the reason for or is a consequence of the formation of a single diastereoisomer is unclear and debatable. However, the tridentate coordination of the metal core via the *N*-acetyl picolylamine chelate could be readily identified in the spectra. The singlets at 3.98 and 3.50 ppm of the two methylene protons of the pyridinyl group and the acetate protons in compound **12** converted into two AB spin systems detected at 4.65 and 4.56 ppm (methylene bridge of the pyridinyl group) and at 3.82 and 3.54 ppm (acetate group), which are partially overlaid by the other aliphatic protons. This feature can readily be explained be the nonequivalence of all four protons upon rigid coordination to the metal center, by virtue of their different chemical environment. This pattern is in accordance with the proposed tridentate coordination via the tertiary amine, the acetate function, and the pyridine nitrogen. Corresponding features have been previously reported by our group for the complex $[Tc(CO)_3(APPA)]$ (APPA = [(5-aminopentyl)pyridin-2-ylmethylamino]acetic acid) (*31*).

Crystal Structure of Complex 19. Because crystals of complexes **13**−**15** could not be obtained, attempts were undertaken to prepare the corresponding furanose complexes **17** and **19** in dry methanol. In the case of **19**, we could obtain crystals of X-ray quality. The colorless crystals of the *R*-N_α diastereoisomer were obtained by slow diffusion of ether into a methanolic solution of **19**. The molecular structure of compound **19** is shown in

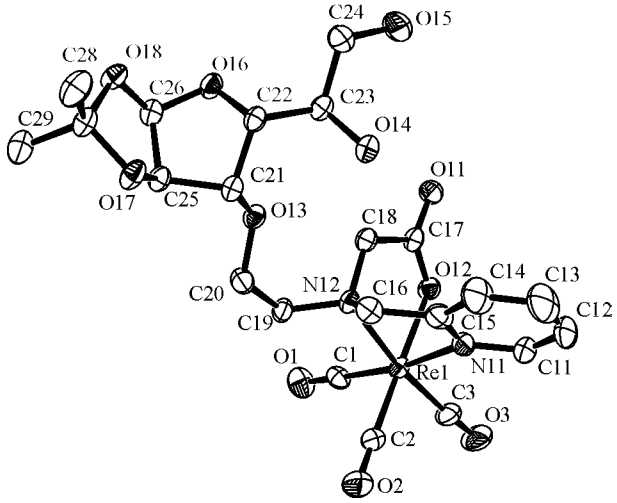


Figure 2. Molecular structure of complex **19** (*32*). Selected bond length and angles: Re(1)−C(2) 1.915(6) Å; Re(1)−C(1) 1.919(5) Å; Re(1)−C(3) 1.929(5) Å; Re(1)−O(12) 2.118(4) Å; Re(1)−N(11) 2.177(5) Å; Re(1)−N(12) 2.232(4) Å; C(2)−Re(1)−C(1) 88.6(2)°; C(2)−Re(1)−C(3) 88.7(2)°; C(1)−Re(1)−C(3) 89.3(3)°; C(2)−Re(1)−O(12) 174.8(2)°; C(1)−Re(1)−O(12) 95.79(19)°; C(3)−Re(1)−O(12) 94.2(2)°; C(2)−Re(1)−N(11) 93.5(2)°; C(1)−Re(1)−N(11) 170.5(2)°; C(3)−Re(1)−N(11) 100.0(2)°; O(12)−Re(1)−N(11) 81.71(16)°; C(2)−Re(1)−N(12) 97.79(19)°; C(1)−Re(1)−N(12) 94.71(18)°; C(3)−Re(1)−N(12) 172.4(2)°; O(12)−Re(1)−N(12) 79.02(14)°; N(11)−Re(1)−N(12) 75.83(17)°.

Figure 2 (*30*). The *N*-acetyl picolylamine ligand acts, as expected, as a tridentate *N*,*N*,*O* chelate coordinated to the rhenium−tricarbonyl center via the pyridine, the tertiary amine, and the deprotonated carboxylic acid functionality. The structure is in accordance with the ^{1}H NMR spectra of **19**. The complex reveals a distorted octahedral coordination sphere. Significant deviations can be found for the angles between the rhenium center and the coordinated heteroatoms (N(11)−Re(1)−N(12) 75.83(17)°; O(12)−Re(1)−N(11) 81.71(16)°; O(12)−Re(1)−N(12) 79.02(14)°), whereas the C−Re−C angles are close to the expected 90° (C(2)−Re(1)−C(1) 88.6(2)°; C(2)−Re(1)−C(3) 88.7(2)°; C(1)−Re(1)−C(3) 89.3(3)°). The three Re−C bond lengths are nearly equal within the standard deviation (1.92(7) Å). The same holds true for the two Re−N bond lengths (2.20(4) Å). The distance between Re(1) and O(12) is 2.118(4) Å long. The furanose ring adopts an envelope conformation. The remaining isopropylidene group points away from the metal center, whereas the diol functionality is oriented toward the metal center. However, no direct or indirect interaction of the furanose moiety with the metal chelate could be observed.

CONCLUSION

Due to the unique structural and chemical characteristics of carbohydrates, functionalized sugars can play an important role at the interface between transition metal chemistry and other disciplines of chemistry and biology. In this work, we could show that 3-*O*-acetaldehyde-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose is a versatile intermediate for the development of different metal chelating moieties. The spectroscopic (NMR and IR) experiments revealed that the glucose derivatives coordinated readily and exclusively to the organometallic rhenium−tricarbonyl entity via the introduced tridentate chelates. This holds true for the compounds in solution as well as in the solid state. The first X-ray structure of a rhenium−tricarbonyl glucofuranoside complex could be elucidated during this project. In vitro and in vivo experiments with the corresponding organo-technetium

and -rhenium complexes are currently in progress to assess their potential in radiopharmacy.

Modulation of Pharmacokinetics of Radioiodinated Sugar-Conjugated Somatostatin Analogues by Variation of Peptide Net Charge and Carbohydration Chemistry

Margret Schottelius,[†] Friederike Rau,[†] Jean Claude Reubi,[‡] Markus Schwaiger,[†] and Hans-Jürgen Wester*,[†]

Nuklearmedizinische Klinik und Poliklinik, Klinikum rechts der Isar, Technische Universität München, 81675 München, Germany, and Institute of Pathology, University of Berne, 3010 Berne, Switzerland. Received March 26, 2004; Revised Manuscript Received January 13, 2005

Sugar conjugation of biooactive peptides has been shown to be a powerful tool to modulate peptide pharmacokinetics. In the case of radiolabeled somatostatin analogues developed for in vivo scintigraphy of somatostatin receptor (sst) expressing tumors, it generally led to tracers with predominant renal excretion and low uptake in nontarget organs, and in some cases also with enhanced tumor accumulation. Especially with respect to endoradiotherapeutic applicability of these tracers, however, understanding the structural requirements for minimal kidney accumulation and maximal tumor uptake is important. The aim of this study was therefore the evaluation of the potential of specific glycoside structures in combination with reduced peptide net charge to reduce kidney accumulation without affecting tumor accumulation. Three glyco analogues of radioiodinated Tyr^3-octreotate (TOCA) with $z = 0$ were evaluated in a comparative study using [^{125}I]Mtr-TOCA ($z = +1$), the maltotriose-Amadori analogue of [^{125}I]TOCA, as a reference, [^{125}I]Glucuron-TOCA, the Amadori conjugate with glucuronic acid, and [^{125}I]Gluc-*S*- and [^{125}I]Gal-*S*-TOCA, the coupling products with glucosyl- and mannosyl-mercaptopropionate. In cells transfected with sst_1−sst_5, all three new analogues show sst-subtype binding profiles similar to I-Mtr-TOCA with high, but somewhat reduced, affinity for sst_2. In contrast, internalization into sst_2-expressing cells (in % of [^{125}I]Tyr^3-octreotide ([^{125}I]TOC)) as well as the $EC_{50,R}$ of unlabeled TOC for internalization determined in dual-tracer experiments are substantially enhanced for [^{123}I]Gal-*S*-TOCA and [^{123}I]Gluc-*S*-TOCA (internalization, 190% ± 12% and 265% ± 20%, respectively, vs 168% ± 6% of [^{125}I]TOC for [^{123}I]Mtr-TOCA; $EC_{50,R}$, 2.62 ± 0.07 and 2.96 ± 0.14, respectively, vs 1.81 ± 0.07 for [^{123}I]Mtr-TOCA). The tumor accumulation of [^{125}I]Gal-*S*-TOCA and [^{125}I]Gluc-*S*-TOCA in AR42J tumor-bearing nude mice 1 h p.i. is consequently very high (22.6 ± 2.2 and 26.2 ± 5.6%ID/g) and comparable to that of [^{125}I]Mtr-TOCA (25.1 ± 4.4%ID/g). [^{125}I]Glucuron-TOCA showed lower uptake in sst-expressing tissues than did [^{125}I]Mtr-TOCA, but considerably enhanced accumulation in nontarget organs such as liver, intestine, and kidney. Due to increased lipophilicity, hepatic and intestinal uptake 1 and 4 h p.i. of [^{125}I]Gal-*S*-TOCA and [^{125}I]Gluc-*S*-TOCA was also slightly higher than that of [^{125}I]Mtr-TOCA. Kidney accumulation, however, was reduced by approximately 50% for both compounds (2.6 ± 0.3 and 2.2 ± 0.4, respectively, vs 4.0 ± 0.7%ID/g at 1 h p.i.). Because no sugar-specific effect was detected in the latter case, it is concluded that general ligand pharmacokinetics and especially kidney accumulation of the tracers investigated are mainly determined by physicochemical characteristics such as lipophilicity, net charge, and also charge distribution ([^{125}I]Glucuron-TOCA vs [^{125}I]Gal-*S*- and [^{125}I]Gluc-*S*-TOCA). With respect to receptor targeting, however, the structure of the carbohydrate moiety plays an important role, leading to dramatically enhanced ligand internalization, especially in the case of [^{123}I]Gluc-*S*-TOCA. Taking into account the combined effects of the Gluc-*S*-moiety both on kidney and on tumor accumulation, this group seems to be a promising synthon for the synthesis of other radiolabeled peptide analogues with improved pharmacokinetics.

INTRODUCTION

That the introduction of carbohydrates into small bioactive peptides may have significant beneficiary impact on peptide pharmacokinetics has been demonstrated in a variety of studies. This approach has been successfully applied to improve drug delivery to the target tissues, either exploiting specific uptake mechanisms or enhanced peptide bioavailability. For example, enkephalin peptides glycosylated near or at the C-terminus were shown to elicit prolonged and profound analgesia in mice due to enhanced peptide delivery to the brain (*1*−*3*). Conjugation of Arg^8-vasopressin with alkyl-glucosides or -mannosides led to substantially enhanced and specific renal peptide uptake from blood (*4*). Furthermore, besides a stabilization toward enzymatic degradation in vivo, carbohydration of the tetrapeptide Gly−Gly−Tyr−Arg was shown to entail enhanced intestinal absorption of the peptide via the Na^+-dependent glucose transporter SGLT-1 (*5*). Enhanced bioavailability, both oral and intravenous, was observed for several other glycopeptides

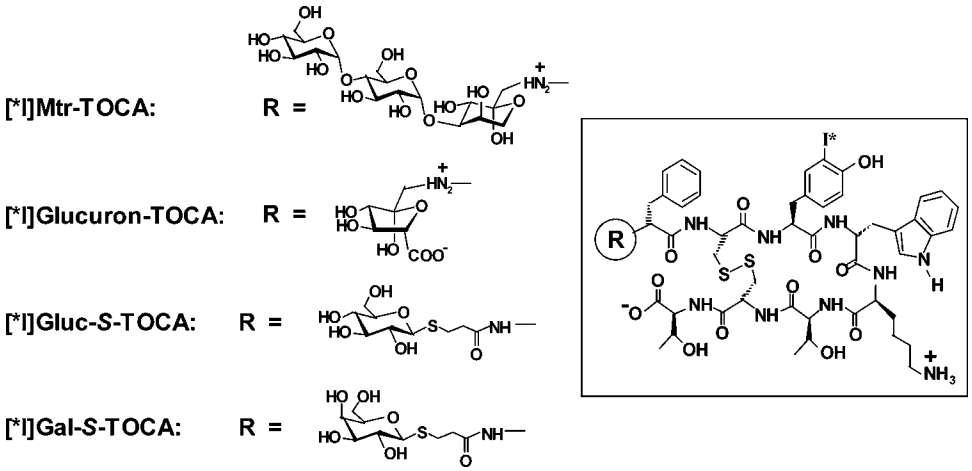

Figure 1. Structures of [^{125}I]Mtr-TOCA, [^{125}I]Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA.

such as an N-linked glycopeptide renin inhibitor (*6*), glycosylated vasopressin analogues (*7*), and several Amadori sugar derivatives of octreotide (*8*). This effect was attributed to enhanced in vivo stability of the peptides, a shift from hepatobiliary toward renal excretion, leading to higher plasma levels of the drug (*6*, *8*), and to improved absorption from the small intestine (*7*).

These findings also constitute the basis of the recent development of a series of radiolabeled, glycosylated octreotide (*9*−*15*) and RGD analogues (*16*, *17*) as receptor ligands for the in vivo scintigraphic detection of somatostatin receptor (sst) and $\alpha v\beta 3$-integrin expressing human malignancies, respectively. Especially the sst-receptors are of high clinical relevance in nuclear oncology, because many tumors, predominantly those of neuroendocrine origin, show overexpression of somatostatin receptors (*18*), and especially of the sst_2-subtype (*19*, *20*). This overexpression allows high-level targeting of sst-expressing tumors both for scintigraphic and for endoradiotherapeutic applications. For these purposes, however, radiolabeled sst analogues need to meet certain prerequisites: fast clearance kinetics, predominant renal excretion, as well as high receptor affinity and selectivity, all of which lead to high target-to-nontarget tissue ratios (tumor-to-nontumor ratios).

That these can be substantially improved by glycosylation has been demonstrated in the case of various radiolabeled Tyr^3-octreotide (TOC) and Tyr^3-octreotate (TOCA) derivatives, which have been modified with different aldoses via Amadori reaction. As compared to their nonglycosylated counterparts, all showed substantially reduced hepatobiliary clearance in favor of fast renal excretion. This effect was found to correlate with increasing carbohydrate size, with the maltose derivatives showing the lowest extent of nonspecific accumulation in nontarget tissues such as liver and intestine (*9*−*15*).

Interestingly, the influence of carbohydration on the biodistribution of [^{125}I]TOC and [^{125}I]TOCA was not only limited to the above expected effect. For both glucose analogues, [^{125}I]Gluc-TOC and [^{125}I]Gluc-TOCA, ligand internalization into sst-expressing cells was significantly enhanced as compared to the nonmodified parent peptide (*14*, *15*). This effect was also reflected in the increased tumor accumulation of these radioligands. Despite an internalization efficiency comparable to that of [^{125}I]-TOCA, however, the maltotriose analogue [^{125}I]Mtr-TOCA (Figure 1) showed the highest tumor accumulation in AR42J tumor-bearing nude mice of all glyco derivatives investigated (25.1 ± 4.4%ID/g at 60 min p.i., *11*).

Furthermore, although the glucose- and maltose-Amadori derivatives of [^{125}I]TOC showed an increasing preference of renal over hepatobiliary excretion, their renal accumulation remained unaffected as compared to [^{125}I]-TOC (*10*). This finding suggested that, because the peptides investigated all bear approximately the same net charge under physiological conditions (+1.8 to +2 (positive charges on d-Phe^1 and Lys^5)), charge-dependent endocytosis into renal tubular cells may be the main contributor to kidney accumulation of these peptides, rendering an influence of carbohydrate structure on kidney accumulation improbable. The contrary, however, was observed in the case of [^{125}I]TOCA and its sugar analogues, where both the glucose and the maltose analogues showed a reduction of kidney accumulation by up to 50% as compared to [^{125}I]TOCA and its maltotriose analogue [^{125}I]Mtr-TOCA (*15*), indicating a certain influence of the sugar moiety on renal tracer accumulation in these cases.

It was therefore of interest to investigate in more detail the physicochemical and structural requirements for combined optimization of both receptor targeting and maximal reduction of kidney uptake of radiolabeled TOCA derivatives. As demonstrated in a previous study using different ^{111}In-DTPA-conjugated octreotide analogues, reduction of peptide net charge can lead to reduced renal tracer accumulation (*21*). This methodology was therefore chosen to attempt a further reduction of kidney uptake of radioiodinated, glycosylated TOCA analogues. Two approaches leading to glycopeptides with a net charge $z = 0$ instead of $z = 1$ were investigated: introduction of an additional negative charge by Amadori reaction of TOCA with glucuronic acid, leading to Glucuron-TOCA (Figure 1), and "removal" of the N-terminal positive charge via an alternative glycosylation route, that is, N-terminal acylation, leading to Gluc-*S*- and Gal-*S*-TOCA (Figure 1). In the latter case, the glycosylation method was based on results of Suzuki et al., who had demonstrated that kidney accumulation of Arg^8-vasopressin could not only be specifically enhanced by conjugation with certain O- and S-alkyl-glycosides, but could also be significantly reduced, depending on the length of the alkyl chain and the structure of the carbohydrate used (*4*, *22*). In this study, the structure of the alkylglycoside was chosen such that renal targeting via the basolateral membrane was highly improbable (*22*, *23*), that is, a very short alkyl chain (mercaptopropionyl). Due to the higher in vivo stability of S- versus O-glycosides, this spacer was used to link two different carbohydrates to [^{125}I]TOCA to study eventual influences of carbohy-

drate structure on the pharmacokinetics of the corresponding radiolabeled peptide. All three new compounds were evaluated in detail in vitro and in vivo, and data on receptor affinity, ligand internalization, and pharmacokinetics, especially with respect to renal uptake and tumor accumulation, were compared to those obtained with [^{125}I]Mtr-TOCA.

EXPERIMENTAL PROCEDURES

Peptide Synthesis. *General Conditions.* TCP-resin was obtained from PepChem (Tübingen, Germany). Fmoc- and other amino acids were supplied by Novabiochem or Bachem (Heidelberg, Germany). All other organic reagents were purchased from VWR (Darmstadt, Germany), Alexis (Grünberg, Germany), Aldrich, or Fluka (Neu-Ulm, Germany). Solvents were used without further purification.

Solid-phase peptide synthesis was carried out manually using a flask shaker (St. John Associates Inc., USA).

Thin-layer chromatography was performed using Kieselgel 60 F_{254} TLC plates from Merck (Darmstadt, Germany). UV absorption at 254 nm was detected using a Fluotest UV lamp. Compounds that showed no UV absorption were detected by treating the TLC plate with a solution of 0.5 mL of anisaldehyde and 1 mL of concentrated sulfuric acid in 50 mL of acetic acid and subsequent heating to 150−200 °C.

Flash-chromatographic separations were carried out using silica gel 60 (particle size 0.04−0.063 mm) with a mesh of 230−400 from Fluka (Neu-Ulm, Germany).

Analytic RP-HPLC was performed on Nucleosil 100 C18 (5 μm, 125 × 4.0 mm) columns (CS GmbH, Langerwehe, Germany) using a Sykam gradient HPLC System (Sykam, Fürstenfeldbruck, Germany). The peptides were eluted applying various gradients of 0.1% TFA (trifluoroacetic acid) in H_2O (solvent A) and 0.1% TFA in acetonitrile (solvent B) in 15 min at a constant flow of 1 mL/min. UV-Detection was performed at 220 nm in a 206 PHD UV−vis detector (Linear Instruments Corp., Reno, NV). For radioactivity measurement, the outlet of the UV-photometer was connected to a NaI(Tl) well-type scintillation counter from EG&G Ortec (München, Germany).

Preparative RP-HPLC was performed on the same HPLC system using a Multospher 100 RP 18-5 (250 × 10 mm) column (CS GmbH, Langerwehe, Germany) at a constant flow of 5 mL/min.

Mass spectra were recorded on the LC-MS system LCQ from Finnigan (Bremen, Germany) using the Hewlett-Packard series 1100 HPLC system.

Mtr-TOCA. Mtr-TOCA was synthesized as described previously (*11*). Briefly, the sequence H_2N−D-Phe−Cys(Trt)−Tyr(tBu)−D-Trp−Lys(Dde)−Thr(tBu)−Cys(Trt)−Thr(tBu) was assembled on TCP-resin using a standard Fmoc-protocol. After cleavage from the solid support using TFA/H_2O/TIBS (triisobutylsilane) (95/2.5/2.5 (v/v/v)), Lys^5(Dde)-TOCA (TOCA(Dde)) was cyclized using H_2O_2 in an aqueous THF (tetrahydrofurane) solution at pH 7. Derivatization with maltotriose was performed via Maillard reaction and subsequent Amadori rearrangement by treating the Lys^5(Dde)-protected peptide with 5 equiv of maltotriose in methanol/acetic acid (95/5) at 60 °C. Subsequent removal of the Lys^5(Dde) protecting group was carried out using 2% of hydrazine hydrate in DMF (dimethylformamide). After product isolation via preparative HPLC, Mtr-TOCA was obtained in 23% yield (based on Lys^5(Dde)-TOCA).

HPLC (15%→45% in 15 min): t_R = 7.88 min; K' = 3.52.

Calculated monoisotopic mass for Mtr-TOCA ($C_{67}H_{94}N_{10}O_{27}S_2$) = 1534.6;

found: m/z = 1535.2 $[M + H]^+$, m/z = 1557.2 $[M + Na]^+$.

Glucuron-TOCA. The synthesis of Glucuron-TOCA was performed according to the procedure described for Mtr-TOCA. For the conjugation of Lys^5(Dde)-TOCA with glucuronic acid, 10 equiv of the carbohydrate was used.

Yield after preparative HPLC: 24%.

HPLC (10%→60% in 15 min): t_R = 10.7 min; K' = 4.79.

Calculated monoisotopic mass for Glucuron-TOCA ($C_{55}H_{72}N_{10}O_{18}S_2$) = 1224.4;

found: m/z = 1225.3 $[M + H]^+$, 1247.3 $[M + Na]^+$, 1263.1 $[M + K]^+$.

Gluc-S-TOCA and Gal-S-TOCA. Both 1-*S*-(2,3,4,6-tetraacetyl-glucopyranosyl)-3-mercaptopropionate (Gluc(4Ac)-*S*-OH) and 1-*S*-(2,3,4,6-tetraacetyl-galactopyranosyl)-3-mercaptopropionate (Gal(4Ac)-*S*-OH) were prepared according to the literature (*24*). Synthesis of the corresponding pentafluorophenyl (Pfp) active esters Gluc(4Ac)-*S*-OPfp and Gal(4Ac)-*S*-OPfp was carried out as described previously using *N*,*N*′-diisopropyl carbodiimide (1.1 equiv) and pentafluorophenol (1.1 equiv) in THF (*13*). For sugar conjugation of TOCA(Dde), the peptide (50−100 mg, 1 equiv) and Gluc/Gal(4Ac)-*S*-OPfp (1.1 equiv) were dissolved in 1−2 mL of DMF and stirred at room temperature for 2 h in the presence of 1 equiv of Hünigs Base. After product precipitation using Et_2O and washing of the precipitate with Et_2O, the respective glycosylated peptides were obtained in 46−67% yield. Gluc(4Ac)-*S*-TOCA(Dde): HPLC (30%→80% B in 15 min): t_R = 12.1 min; K' = 6.31. Gal(4Ac)-*S*-TOCA(Dde): HPLC (30%→80% B in 15 min): t_R = 12.0 min; K' = 6.42.

After Dde-deprotection for 10 min at room temperature, the peptides were precipitated using Et_2O (diethyl ether). For subsequent sugar deacylation, peptides were redissolved in 1 mL of methanol containing 0.5 equiv of KCN (*25*). Deacylation was complete after stirring at room temperature for 4−48 h. The product was then precipitated using Et_2O and purified via preparative HPLC, yielding Gluc-*S*-TOCA and Gal-*S*-TOCA in yields of 12−15% (based on TOCA(Dde)).

Gluc-*S*-TOCA: HPLC (20%→70% B in 15 min): t_R = 8.2 min; K' = 3.99.

Gal-*S*-TOCA: HPLC (20%→70% B in 15 min): t_R = 8.3 min; K' = 3.96.

Calculated monoisotopic mass for Gluc-*S*-TOCA and Gal-*S*-TOCA ($C_{58}H_{78}N_{10}O_{18}S_3$)

found: m/z = 1299.3 $[M + H]^+$, 1321.3 $[M + Na]^+$, 1337.2 $[M + K]^+$.

3-Iodo-Tyr^3-Reference Compounds. For the synthesis of the 3-iodo-Tyr^3-reference compounds, Fmoc−Tyr(tBu)−OH was replaced by Fmoc−3-iodo-Tyr(tBu)−OH during SPPS. All other reaction steps were performed analogously to the syntheses presented in the previous section.

I-Mtr-TOCA. HPLC (10%→60% B in 15 min): t_R = 11.2 min; K' = 6.33.

Calculated monoisotopic mass for I-Mtr-TOCA ($C_{67}H_{93}N_{10}O_{27}S_2I$) = 1660.5;

found: m/z = 1661.2 $[M + H]^+$.

I-Glucuron-TOCA. HPLC (10%→60% B in 15 min): t_R = 11.1 min; K' = 6.41.

Calculated monoisotopic mass for I-Glucuron-TOCA ($C_{55}H_{71}N_{10}O_{18}S_2I$) = 1350.3;

found: m/z = 1351.3 $[M + H]^+$, 1373.3 $[M + Na]^+$, 1389.2 $[M + K]^+$.

I-Gluc-S-TOCA. HPLC (20%→70% B in 15 min): t_R = 9.2 min; K' = 4.72.

Calculated monoisotopic mass for I-Gluc-*S*-TOCA ($C_{58}H_{77}N_{10}O_{18}S_3I$) = 1424.4;
found: *m/z* = 1425.6 $[M + H]^+$, 1447.6 $[M + Na]^+$, 1463.5 $[M + K]^+$.

I-Gal-S-TOCA. HPLC (20%→70% B in 15 min): t_R = 9.1 min; K' = 4.79.

Calculated monoisotopic mass for I-Gal-*S*-TOCA ($C_{58}H_{77}N_{10}O_{18}S_3I$) = 1424.4;
found: *m/z* = 1425.6 $[M + H]^+$, 1447.6 $[M + Na]^+$, 1463.5 $[M + K]^+$.

Peptide Radioiodination. Radioiodination was generally performed using the Iodogen method.

A solution of 100−200 μg of peptide in 200 μL of PBS (phosphate buffered saline, 0.1 M, pH 7.4) was transferred to an Eppendorf cap coated with 30 μg of Iodogen (Pierce, Rockford, USA). After the addition of 5−20 μL of solution of radioiodide (Amersham, Buckinghamshire, UK) in 0.05 M NaOH ([^{125}I]NaI (n.c.a.), 18−74 MBq; [^{123}I]-NaI (c.a.), 37−185 MBq), the cap was vortexed and the labeling reaction was allowed to proceed for 20 min at room temperature. The peptide solution was then removed from the insoluble oxidizing agent.

The radioiodinated peptides were purified via RP-HPLC using an isocratic solvent mixture of 25% ([^{123}I]-Mtr-TOCA), 28% ([^{123}I]Glucuron-TOCA), or 33% ([^{123}I]-Gluc-*S*-TOCA and [^{123}I]Gal-*S*-TOCA) EtOH (0.5% AcOH) in water (0.5% AcOH).

For the biodistribution experiments, an excess of absolute ethanol was added to the collected fraction, and the solvents were evaporated to dryness. The radioiodinated product was reconstituted in PBS to yield a solution of radiolabeled peptide with an activity concentration of approximately 370 kBq/100 μL.

For the paired-label internalization experiments, [^{125}I]-TOC and the respective ^{123}I-labeled radioligand were each separately redissolved in assay medium (containing 5% BSA) and diluted to an activity concentration of approximately 200 000 cpm/10 μL. A 1:1 (v/v) mixture of both solutions containing approximately 100 000 cpm/10 μL of each radioligand was then used for the internalization experiment.

In Vitro Studies. *sst-Receptor Binding Affinities.* Cells stably expressing human sst_1, sst_2, sst_3, sst_4, and sst_5 were grown as described previously (*26*). Cell membrane pellets were prepared, and receptor autoradiography was performed on pellet sections (mounted on microscope slides), as described in detail previously (*26*). For each of the tested compounds, complete displacement experiments were performed with the universal somatostatin radioligand ^{125}I-[Leu^8, D-Trp^{22}, Tyr^{25}]-somatostatin 28 using increasing concentrations of the unlabeled peptide ranging from 0.1 to 1000 nM. Somatostatin 28 was run in parallel as control using the same increasing concentrations. IC_{50} values were calculated after quantification of the data using a computer-assisted image processing system. Tissue standards (autoradiographic [^{125}I]microscales Amersham), containing known amounts of isotopes, cross-calibrated to tissue equivalent ligand concentrations, were used for quantification (*26*).

Internalization and Determination of $EC_{50,R}$. CHO cells stably transfected with human sst_2 (epitope tagged at the N-terminal end) were kindly provided by Dr. Jenny Koenig, University of Cambridge, UK. Cells were grown in DMEM/Nutrition Mix F-12 with Glutamax-I (1:1) (Gibco BRL) supplemented with 10% FCS and 500 mg/L Geneticin (Gibco BRL). For the preparation of the solutions used for the internalization studies containing various concentrations of unlabeled TOC, FCS was replaced by 5% BSA (Sigma, St. Louis, MO).

For cell counting, a CASY1-TT cell counter and analyzer system (Schärfe System GmbH, Reutlingen, Germany) was used.

Internalization experiments were carried out as previously described in detail (*13*). Briefly, after preconditioning of the cells (approximately 100 000 cells/well) with 190 μL of unsupplemented medium for a minimum of 15 min, 50 μL (per well) of DMEM (5% BSA) containing increasing concentrations of unlabeled TOC (Tyr^3-octreotide) was added, followed by the addition of approximately 100 000 cpm of both the respective ^{123}I-labeled glycosylated peptide and the reference [^{125}I]TOC in 10 μL of DMEM (5% BSA). Final TOC concentrations in the incubation medium used for the determination of the $EC_{50,R}$ were 0.1, 0.2, 0.5, 0.8, 1, 2, 4, 6, 8, 10, 12, 15, 20, 50, 100, 500, and 1000 nM. In a control experiment (n.c.a. conditions), TOC-free DMEM (5% BSA) was added. Nonspecific internalization was determined by including 5 μM unlabeled TOC. Experiments were carried out in triplicate for each concentration.

After incubation at 37 °C (10 min), the incubation medium was removed, and cells were rinsed with 250 μL of fresh medium. The combined medium fractions represent the amount of free radioligand. Receptor bound (acid releasable) radioactivity was then removed using 2 × 250 μL of ice-cold acid wash buffer (0.02 M NaOAc buffered with AcOH to pH = 5). The internalized activity was released by incubation with 250 μL of 1 N NaOH, tranferred to vials, and combined with 250 μL of PBS used for rinsing the wells. Quantification of the amount of free, acid-releasable, and internalized activity was performed in a γ-counter.

For numerical analysis of the EC_{50} of TOC for internalization, data for both the ^{123}I-labeled compound of interest and the reference [^{125}I]TOC in the same experiment were first corrected by the amount of nonspecific internalization, respectively, and then each normalized to the amount of internalized ligand in the absence of unlabeled competitor (100%). Data were fitted with a weighted two-parameter logistic function using Sigma Plot. To eliminate the influence of cell count and cell viability on the absolute EC_{50}-values, data are expressed as the ratio ($EC_{50,R}$) of the EC_{50} observed for the compound of interest (COI) and the EC_{50} found for [^{125}I]TOC in the same experiment ($EC_{50,R} = EC_{50}(COI)/EC_{50}([^{125}I]\text{-TOC})$).

Biodistribution Experiments. *Tumor Model.* The AR42J cell line as a transplantable rat pancreatic tumor model with high sst_2 somatostatin receptor expression (*27*) was used. AR42J cells were obtained from ECACC (European Collection of Cell Cultures, Salisbury, UK). Cells were maintained in RPMI 1640 (Seromed, Berlin, Germany) supplemented with 10% FCS (Seromed) and 2 mM L-glutamine (Gibco BRL Life Technologies, Karlsruhe, Germany). To establish tumor growth, cells were detached from the surface of the culture flasks using 1 mM EDTA in PBS, centrifuged, and resuspended in serum-free culture medium. Concentration of the cell suspension was (2.5−5) × 10^6 cells/100 μL serum. Into nude mice (Swiss nu/nu, female, 6−8 weeks, from Charles River WIGA GmbH (Sulzfeld, Germany)) was injected 100 μL of the cell suspension subcutaneously into the flank. Ten days after tumor transplantation, all mice showed solid palpable tumor masses (tumor weight 20−200 mg) and were used for the experiments.

Biodistribution Studies. The radiolabeled peptides, 370 kBq (10 μCi) in 100 μL of PBS (pH 7.4), were injected i.v. into a tail vein of nude mice bearing an AR42J tumor. For competition studies, 10 μg TOC (0.4 mg/kg) was co-

Table 1. Affinity Profiles of Somatostatin 28 and the Compounds Investigated for Human sst_1−sst_5 Receptors Using ^{125}I-[Leu^8, D-Trp^{22}, Tyr^{25}]-Somatostatin 28 as the Radioligand (Values Are IC_{50} ± SD [nM], Number of Experiments in Parentheses)

injected with the radioligands. The animals (groups of 3−4) were sacrificed 1 and 4 h postinjection, and the organs of interest were dissected. The radioactivity was measured in weighted tissue samples using a γ-Counter.

RESULTS

Peptide Synthesis. Solid-phase peptide synthesis using a standard Fmoc-protocol and HOBt/TBTU as coupling reagents yielded TOCA(Dde) and its 3-iodo-Tyr^3 analogue, I-TOCA(Dde), in 90−97% yield based on resin-bound Fmoc−Thr(tBu)−OH. Quantitative disulfide bridge formation was achieved within less than 30 min at room temperature using H_2O_2 in an aqueous THF-solution buffered to pH 7. While UV purity (220 nm) of crude cyclized TOCA(Dde) usually exceeded 93%, more side products were observed for the 3-iodo-Tyr^3-containing peptide (up to 20%). However, both peptides were used for the following reaction steps without further purification.

N-terminal glycosylation of the parent peptides with maltotriose (Mtr-) and glucuronic acid (Glucuron-) via Amadori reaction required reaction times of 16−20 h at 60 °C, and glycosylation yields usually did not exceed 85% (value based on the integration of product and precursor peaks in the reaction control RP-HPLC chromatograms (220 nm)). In contrast, N-terminal conjugation with the respective pentafluorophenyl active esters of (1-*S*-2,3,4,6-tetraacetyl-gluco/galactopyranosyl)-3-mercaptopropionate was quantitative within 30−45 min at room temperature.

Subsequent Dde-deprotection (and deacetylation in the case of Gluc-*S*- and Gal-*S*-TOCA), followed by preparative RP-HPLC purification, afforded all glycosylated TOCA derivatives as well as their 3-iodo-Tyr^3-counterparts in overall yields of 12−25% (based on nonglycosylated precursor) and in purities ≥98% (220 nm).

Radiolabeling. Due to the formation of radioiodinated side products, overall radiochemical yields of the ^{125}I- and ^{123}I-labeled peptides after RP-HPLC isolation were limited to 45−73%. Radiochemical purities of the isolated radioiodinated peptides, however, usually exceeded 98%.

The HPLC conditions applied allowed very efficient separation of the radioiodinated product from the unlabeled precursor ($\Delta t_R \geq 5$ min (*13*)) for all radioligands investigated. Thus, and because no coeluting carrier peak was observed in the labeled peptide peak in the quality control UV-chromatograms, the specific activity of the labeled peptides was assumed to be that of the radioiodide used for their preparation (≥2000 Ci/mmol for ^{125}I, ∼5000 Ci/mmol for ^{123}I).

In Vitro Studies. The affinities of I-Mtr-TOCA, I-Glucuron-TOCA, I-Gluc-*S*-TOCA, and I-Gal-*S*-TOCA to the five human sst-subtypes sst_1−sst_5 are summarized in Table 1 and compared to those of the reference I-TOC and of nonglycosylated I-TOCA. All sugar analogues show very high and comparable affinity to $hsst_2$, no affinity to $hsst_1$, and low to moderate affinity to $hsst_{3-5}$. As compared to I-TOCA, all glycosylated derivatives show significantly reduced affinities to $hsst_3$ and $hsst_5$. This effect, however, is more pronounced in the case of the Amadori analogues than for the two thioglycoside-modified peptides. Of the carbohydrated peptides investigated, I-Mtr-TOCA shows the highest $hsst_2$-specificity.

Table 2. Internalization (in % of the Reference [^{125}I]TOC) and Relative EC_{50} Values ($EC_{50,R}$) of Unlabeled TOC for Inhibition of the Internalization of [^{123}I]TOCA and the Sugar Analogues Investigated (CHO cells ($hsst_2$), 10 min Incubation, $n = 3$ in Three Separate Determinations, Mean ± SD)

	internalized [% of [^{125}I]TOC]	$EC_{50,R}$
[^{125}I]TOC	100	1
[^{123}I]TOCA	178.8 ± 6.9	1.70 ± 0.11
[^{123}I]Mtr-TOCA	168.0 ± 5.8	1.81 ± 0.07
[^{123}I]Gluc-*S*-TOCA	264.7 ± 20.3	2.96 ± 0.14
[^{123}I]Gal-*S*-TOCA	189.8 ± 11.7	2.62 ± 0.07

It has been shown in a previous study that the sst_2-affinity of radioiodinated sugar analogues of TOC and TOCA does not correlate with in vivo tumor accumulation (*13*). In contrast, both the internalization of a ligand in % of the reference [^{125}I]TOC, and the $EC_{50,R}$ of unlabeled TOC for ligand internalization ($EC_{50,R} = EC_{50}$(compound of interest):EC_{50}([^{125}I]TOC)) have been shown to be good predictive parameters for tumor uptake in vivo (*13*). Therefore, these two quantities have also been determined for the four compounds in this study (Table 2).

Internalization of all sugar analogues into $hsst_2$-expressing CHO cells was substantially increased as compared to the reference [^{125}I]TOC. For both [^{123}I]Mtr-TOCA and [^{123}I]Gal-*S*-TOCA, however, it remained almost unchanged as compared to nonmodified [^{123}I]TOCA (Table 2). Interestingly, the $EC_{50,R}$ of [^{123}I]Mtr-TOCA was also comparable to that of [^{123}I]TOCA, while it was significantly higher for [^{123}I]Gal-*S*-TOCA (2.6 vs 1.7). Only in the case of [^{123}I]Gluc-*S*-TOCA, however, was the very high $EC_{50,R}$ (3.0) also accompanied by dramatically enhanced ligand internalization (260% vs 170−190% of [^{125}I]TOC for all other TOCA analogues).

Biodistribution Studies. The biodistribution of [^{125}I]-Mtr-TOCA, [^{125}I]Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA in AR42J tumor-bearing nude mice 1 and 4 h postinjection is shown in Table 3. Clearance of all four glycopeptides from the circulation is very rapid, resulting in low blood activity concentrations (0.47−0.75%ID/g) already 1 h p.i. Of the four compounds investigated, [^{125}I]Glucuron-TOCA showed the highest blood activity level, and also high nonspecific accumulation in kidney, liver, and intestine, the latter being nearly twice as high as that observed for [^{125}I]Mtr-TOCA. For both [^{125}I]Gluc-*S*-TOCA and [^{125}I]Gal-*S*-TOCA, almost identical biodistribution in nontarget organs was observed at all time points. As compared to [^{125}I]Mtr-TOCA, these two compounds show slightly increased hepatic and intestinal uptake, but also a reduction in renal activity

Table 3. Biodistribution of [^{123}I]Mtr-TOCA, [^{123}I]Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA in AR42J Tumor-Bearing Nude Mice 1 and 4 h p.i. (Data Are %ID/g (mean ± SD, Groups of 3−4))

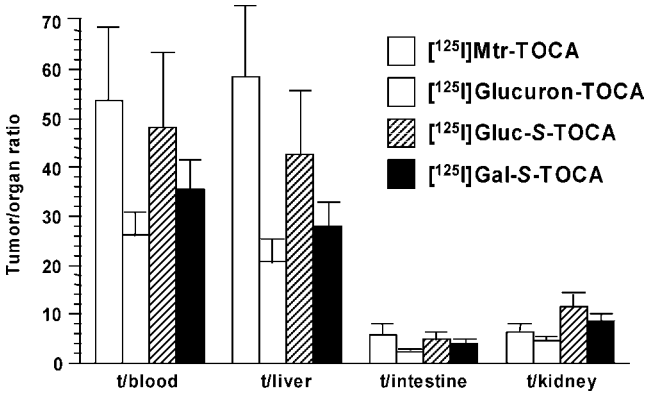

Figure 2. Tumor-to-organ ratios of [^{125}I]Mtr-TOCA, [^{125}I]-Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA in AR42J tumor-bearing nude mice 60 min p.i. (mean ± SD, n = 3−4).

accumulation by up to 45% and 60% at 1 and 4 h p.i., respectively.

For all four peptides, the observed decrease in hepatic activity within the observation period was accompanied by an increase in intestinal activity accumulation, indicating a certain contribution of hepatobiliary excretion to overall tracer clearance. The substantial drop in kidney activity levels between 1 and 4 h p.i. detected for all four carbohydrated TOCA analogues indicates that, despite predominant renal excretion of the radiopeptides, no real tracer accumulation, that is, uptake and retention in renal tissue, occurs.

Of the glycopeptides investigated, [^{125}I]Glucuron-TOCA showed the lowest, albeit still very high, accumulation in sst-expressing tissues, that is, stomach, adrenals, pancreas, and tumor. Interestingly, tracer uptake in stomach and pancreas was highest for [^{125}I]Gal-*S*-TOCA, whereas tumor accumulation of this peptide was slightly lower than that of [^{125}I]Mtr-TOCA and [^{125}I]Gluc-*S*-TOCA (22.6 vs 25.2 and 26.2%ID/g at 1 h p.i., respectively). In most cases, tumor-to-organ ratios are therefore highest for these compounds, both 1 (Figure 2) and 4 h p.i. Due to their particularly low renal accumulation, however, tumor/kidney ratios are highest for [^{125}I]Gluc-*S*-TOCA and [^{125}I]Gal-*S*-TOCA (11.7 and 8.7 vs 6.3 and 4.6 for [^{125}I]-Mtr-TOCA and [^{125}I]Glucuron-TOCA, respectively, at 1 h p.i.).

As expected for radioiodinated tracers, washout of the four glycopeptides investigated from sst-expressing tissues between 1 and 4 h p.i. was considerable. Interestingly, tumor retention of [^{125}I]Mtr-TOCA was significantly higher than that of the other three peptides; that is, 50% instead of 28−30% of the tumor-localized activity at 1 h p.i. were still found inside the tumor at 4 h p.i. in the case of [^{125}I]Mtr-TOCA.

Receptor-specificity of ligand accumulation in sst-positive organs was demonstrated in a competition study (Figure 3). Co-injection of 10 μg unlabeled TOC per mouse led to a dramatic and comparable reduction of ligand accumulation in stomach, adrenals, pancreas, and tumor to 7−13%, 22−30%, 8−14%, and 18−31% of control (1 h p.i.) for all compounds investigated.

DISCUSSION

Maximizing tumor targeting and minimizing nonreceptor-mediated accumulation in excretion organs generally are the most important goals in the development of new receptor-targeted peptide tracers for application in nuclear oncology. The first can only be achieved by strutural modifications of the receptor ligand itself; for example, in the case of various radiometalated and radiohalogenated analogues of the somatostatin receptor ligand Tyr^3-octreotide (TOC), the desired improvement of receptor-mediated ligand accumulation was achieved by substitution of Thr(ol)^8 by Thr^8, leading to Tyr^3-octreotate (TOCA) (*13*−*15*, *28*, *29*). Furthermore, conjugation of [^{125}I]TOC and [^{125}I]TOCA with, for example, glucose via Amadori reaction (*10*, *14*, *15*) or the substitution of ^{111}In by ^{68}Ga in chelator-conjugated TOC and TOCA (*30*) also led to enhanced internalization in vitro and tumor uptake in vivo.

Of course, nonspecific radioligand uptake in the excretion organs is also mainly determined by the physicochemical properties of the molecule itself such as lipophilicity and net charge, which are dependent on the labeling method and/or the nature of further functionalities introduced into the peptide. In contrast to receptor targeting, however, radioligand accumulation in nontarget organs can also be influenced "externally". For example, the high kidney uptake of radiometalated TOC analogues, which leads to high nephrotoxicity and thus limits the applicable dose, has been efficiently reduced by coinfusion of basic amino acids (Lys/Arg) (*31*). This methodology relies on the assumption that the positively charged amino acids compete for charge-dependent endocytosis into the renal tubular cells.

Recent studies indicated that significantly reduced kidney accumulation may also be achieved by a reduction of peptide net charge by amino acid substitution in radiometalated octreotide (*21*) as well as by certain carbohydrates N-terminally linked to [^{125}I]TOCA (*15*).

To assess the relative impact of both of the above modifications in the same molecule, three new glycosylated [^{125}I]TOCA analogues, [^{125}I]Glucuron-TOCA, [^{125}I]-Gluc-*S*-, and [^{125}I]Gal-*S*-TOCA (Figure 1), were evaluated in vitro and in vivo with particular focus on the single and combined effects of carbohydrate structure, reduced net charge, and different charge distribution on receptor

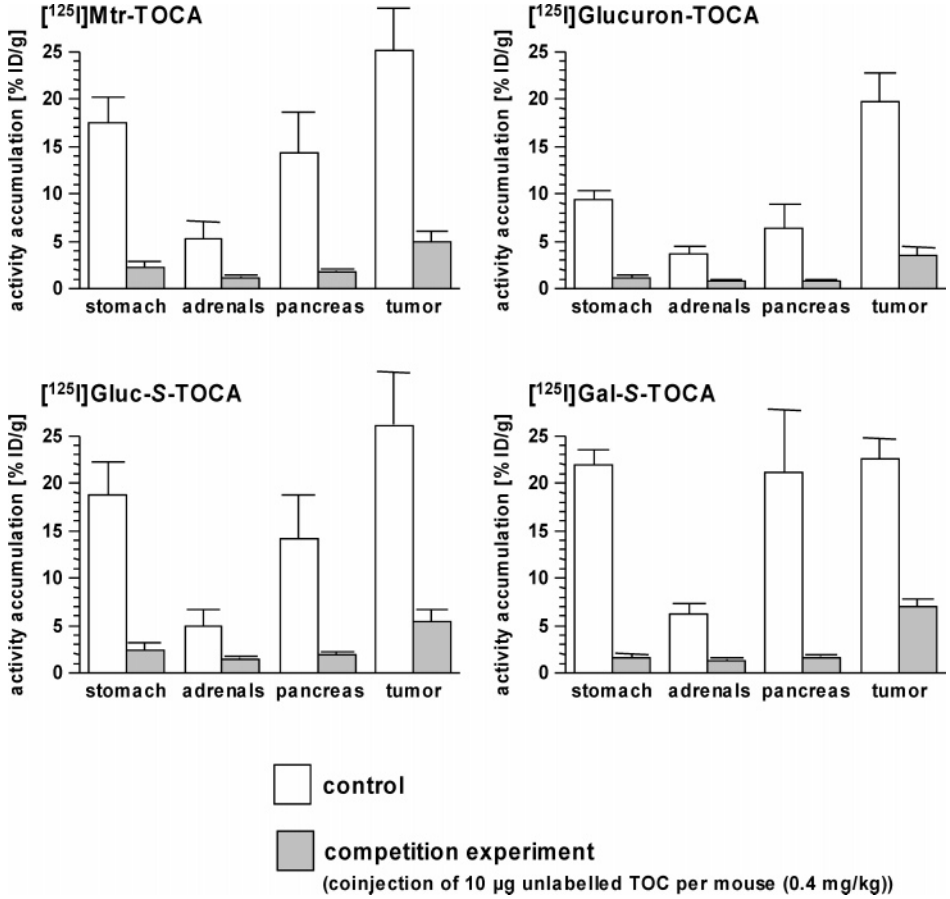

Figure 3. Effect of co-injection of 10 μg of unlabeled TOC per mouse (0.4 mg/kg) on the uptake of [^{125}I]Mtr-TOCA, [^{125}I]Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA in stomach, adrenals, pancreas, and tumor of AR42J tumor-bearing nude mice 60 min p.i. (mean ± SD, $n = 3$).

affinity, ligand internalization, and pharmacokinetics, and compared to the reference [^{125}I]Mtr-TOCA. In this context, the potential identification of carbohydrate structures that might be generally applicable for a reduction of peptidic radiotracer accumulation in the kidney, ideally without affecting its receptor affinity and tumor accumulation, was of major interest.

So far, the differences in the sst-affinity profiles of I-Glucuron-TOCA, I-Gluc-*S*-, and I-Gal-*S*-TOCA as compared to I-Mtr-TOCA cannot be attributed unambiguously to the influence of either carbohydrate structure or a charge effect. However, one indicator for a charge-dependent effect is the slightly reduced sst_2-affinity of I-Glucuron-TOCA, I-Gluc-*S*-TOCA, and I-Gluc-*S*-TOCA ($z = 0$) as compared to I-Mtr-TOCA ($z = +1$). A detailed study including four octreotide analogues with net charges $z = +1$ to $z = +3$ demonstrated a strong correlation between peptide net charge and ligand receptor affinity. The more electropositive charges are on the peptide, the higher is the effective concentration of the peptide at the negatively charged membrane, and thus the higher are the receptor affinity and also functional activity observed for the respective peptide analogue (*32*). A second indicator for the (indirect) influence of peptide net charge on the sst-affinity profile is the reduced sst_2-specificity of the three new glyco-peptides with $z = 0$. In the case of radiometalated TOC analogues, a lower hydrophilicity (induced by reduced net charge) leads to increased affinity to sst-subtypes 3−5 (*26*). The same seems to be the case especially for I-Gluc-*S*-TOCA and I-Gluc-*S*-TOCA. Both peptides show a lower hydrophilicity than I-Mtr-TOCA (log $P_{ow} = -1.67 \pm 0.02$ vs -1.73 ± 0.04), and both show substantially increased $hsst_3$ and $hsst_4$ affinities.

It has already been demonstrated in several studies (*13*, *28*, *29*, *33*) that the sst_2-affinity of an octreotide analogue is of limited predictive value for the efficiency of ligand internalization into sst_2-expressing cells. The same was observed in this study. While both [^{123}I]Gluc-*S*- and [^{123}I]Gal-*S*-TOCA showed reduced sst_2-affinity as compared to [^{123}I]Mtr-TOCA (Table 1), they exhibited an increase in internalization by a factor of 1.57 and 1.13, respectively (Table 2). Furthermore, the effective concentration of unlabeled TOC needed to inhibit ligand internalization to 50% of maximum (normalized to the value found for the internal standard [^{125}I]TOC in the same experiment), the $EC_{50,R}$, of [^{123}I]Gluc-*S*- and [^{123}I]-Gal-*S*-TOCA was also substantially increased (Table 2). Thus, both compounds have an enhanced ability to compete with unlabeled competitor for receptor binding and subsequent endocytosis into the cell and thus a higher internalization potency than [^{123}I]Mtr-TOCA. So far, it remains unclear as to what extent either the reduced net charge or the change in carbohydrate structure or both are responsible for the divergence between data for [^{123}I]Mtr-TOCA and the two thioglycoside analogues. In contrast to the sst-affinity profiles, however, which were very similar for both [^{123}I]Gluc-*S*- and [^{123}I]-Gal-*S*-TOCA, both the internalization and the $EC_{50,R}$ determined for these two compounds with identical charge distribution differ significantly. This finding indicates that, although the structure of the carbohydrate (Gluc vs Gal) has no significant influence on the binding

affinity to immobilized receptors (Table 1), it does have substantial impact on ligand internalization into live cells. This is supported by data from a previous study in which the glucose-Amadori analogues of [^{123}I]TOC and [^{123}I]TOCA, [^{123}I]Gluc-TOC and [^{123}I]Gluc-TOCA, exhibited a considerable enhancement of ligand internalization and $EC_{50,R}$ as compared to their corresponding maltose- and maltotriose-counterparts (*13*), although the glycopeptides from each series (TOC and TOCA) had identical net charge ($z = +2$ and $z = +1$, respectively).

In the same study, it has been demonstrated that ligand internalization and also the $EC_{50,R}$ represent more reliable predictive parameters concerning the in vivo tumor accumulation of radiolabeled octreotide analogues in AR42J tumor-bearing mice than their sst_2-affinity. Also, in the case of [^{125}I]Mtr-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA, tumor accumulation (Table 3) rather reflects the tendencies found for ligand internalization than those for sst_2-affinity, but differences in tumor accumulation are by far not as pronounced as the observed variation in ligand internalization efficiency. This is not surprising, however, taking into account that tumor accumulation of the peptides investigated is very rapid and takes place early after ligand administration. The relatively fast blood clearance of the peptides, however, leads to rapidly decreasing tracer levels in blood and thus prevents optimal exploitation of the enhanced internalization efficiency of, for example, [^{125}I]Gluc-*S*-TOCA as compared to [^{125}I]Mtr-TOCA. Altogether, both in vitro uptake of [*I]Mtr-TOCA, [*I]Glucuron-TOCA, [*I]-Gluc-*S*-TOCA, and [*I]Gal-*S*-TOCA into sst-expressing cells as well as their in vivo accumulation in sst-positive tissues seem to be mainly determined by the structure of the carbohydrate-modification introduced into the molecule, and not by the net charge of the respective peptide. This is not true, however, for the biodistribution of these tracers in nontarget organs.

In the case of both [^{125}I]Gluc-*S*-TOCA and [^{125}I]Gal-*S*-TOCA, the reduced net charge leads to a loss in hydrophilicity as compared to [^{125}I]Mtr-TOCA ($\log P_{ow} = -1.67 \pm 0.02$ vs -1.73 ± 0.04), which is reflected in the slightly increased accumulation of these tracers in liver and intestine. These data are in accordance with results from a previous study, which demonstrated a correlation between the lipophilicity ($\log P_{ow}$) of radioiodinated, glycosylated TOC analogues with peptide accumulation in these organs (*10*). Interestingly, the data obtained for [^{125}I]Glucuron-TOCA are in contradiction to this correlation. Due to its higher charge density, the peptide has a nearly identical $\log P_{ow}$ as compared to [^{125}I]Mtr-TOCA ($\log P_{ow} = -1.74 \pm 0.04$ vs -1.73 ± 0.04). Both hepatic and intestinal uptake of [^{125}I]Glucuron-TOCA, however, are increased by a factor of ≥ 2 as compared to the maltotriose analogue. Furthermore, instead of the expected reduction of kidney uptake due to reduced positive net charge, [^{125}I]Glucuron-TOCA showed an increase in renal accumulation. In contrast, both [^{125}I]Gluc-*S*-TOCA and [^{125}I]Gal-*S*-TOCA having the same peptide net charge as [^{125}I]Glucuron-TOCA ($z = 0$), albeit a significantly different charge distribution within the peptide, showed the anticipated reduction in renal activity accumulation by up to 50% as compared to the reference peptide [^{125}I]Mtr-TOCA. The same had been observed for the L-Asp^1 analogue of [^{111}In]DTPA-L-Phe^1-octreotide, which showed an activity accumulation in the kidney of only approximately 7%ID/g at 1 h p.i. in normal mice as opposed to approximately 16%ID/g found for the L-Phe^1-parent peptide (*21*).

Thus, based on these findings and on the results obtained with the two thioglycoside analogues investigated in this study, modulating peptide net charge can be efficiently used to modify ligand accumulation in the kidney. The unexpected biodistribution pattern of [^{125}I]-Glucuron-TOCA as compared to the other two peptides with $z = 0$, however, indicates that not only peptide net charge, but also charge distribution may have a substantial impact on peptide uptake not only in the kidney, but also in the other excretion organs. Interestingly, and in contrast to the results obtained with respect to receptor targeting both in vitro and in vivo, the exact carbohydrate structure only seems to have secondary influence on general ligand biodistribution and excretion of radiolabeled sst-ligands. This is illustrated by the nearly identical pharmacokinetics of [^{125}I]Gluc-*S*-TOCA and [^{125}I]Gal-*S*-TOCA found in this study and is also supported by data from previous investigations comparing the pharmacokinetics of different sugar analogues of [^{125}I]TOC and [^{125}I]TOCA (*10*, *15*). Especially in the case of the [^{125}I]-Gluc-*S*-TOCA/[^{125}I]Gal-*S*-TOCA-pair, however, this finding was unexpected. A large variety of approaches for high-level (pre)targeting of bioactive molecules to the liver rely on the specific internalization of galactosyl-modified compounds into parenchymal liver cells via a high-affinity receptor for asialoglycoproteins (*34*). Surprisingly, because liver accumulation of [^{125}I]Gal-*S*-TOCA is very low at all time points investigated and nearly identical to that of [^{125}I]Gluc-*S*-TOCA, this specific transport system does not seem to be targeted by [^{125}I]Gal-*S*-TOCA.

In conclusion, both the reduction of peptide net charge as well as the methodology employed for N-terminal carbohydrate conjugation of radioiodinated TOCA have a significant impact on peptide pharmacokinetics. The excretion profile and especially kidney accumulation of the four analogues investigated, [^{125}I]Mtr-TOCA, [^{125}I]-Glucuron-TOCA, [^{125}I]Gluc-*S*-TOCA, and [^{125}I]Gal-*S*-TOCA, were found to be dominated by physicochemical characteristics such as lipophilicity, peptide net charge, and charge distribution within the peptide. A substantial influence of these factors on accumulation in sst-expressing cells and tissues, however, was not detectable, whereas it was greatly dependent on the structure of the N-terminal carbohydrate moiety. In this context, conjugation of TOCA with the Gluc-*S*-moiety allowed the most efficient optimization of peptide pharmacokinetics as compared to the reference [^{125}I]Mtr-TOCA, a reduction of kidney accumulation by approximately 50%, and a substantial increase of ligand internalization in vitro and also of tumor uptake in vivo. The Gluc-*S*-group therefore seems to be a promising synthon for the synthesis of a variety of other neuropeptide analogues with improved pharmacokinetics.

Truman Memorial Veterans' Hospital, Columbia, Missouri 65201, Department of Radiology and Department of Internal Medicine, University of Missouri−Columbia School of Medicine, Columbia, Missouri 65211, and University of Missouri−Columbia Research Reactor Center, Columbia, Missouri 65211. Received August 26, 2004; Revised Manuscript Received January 6, 2005

Radiolabeling of biologically active molecules with the $[^{99m}Tc(CO)_3]^+$ unit has been of primary interest in recent years. With this in mind, we herein report symmetric (***L*^{1}**) and asymmetric (***L*^{2}**−***L*^{5}**) pyrazolyl-containing chelators that have been evaluated in radiochemical reactions with the synthon $[^{99m}Tc(H_2O)_3(CO)_3]^+$ (**1a**). These reactions yielded the radioactive building blocks $[^{99m}Tc(CO)_3(k^3\text{-L})]^+$ (L = ***L*^{1}**−***L*^{5}**, **2a**−**6a**), which were identified by RP-HPLC. The corresponding Re surrogates (**2**−**6**) allowed for macroscopic identification of the radiochemical conjugates. Complexes **2a**−**6a**, with log $P_{o/w}$ values ranging from −2.35 to 0.87, were obtained in yields of ≥90% using ligand concentrations in the 10^{-5}−10^{-4} M range. Challenge studies with cysteine and histidine revealed high stability for all of these radioactive complexes, and biodistribution studies in mice indicated a fast rate of blood clearance and high rate of total radioactivity excretion, occurring primarily through the renal-urinary pathway. Based on the framework of the asymmetric chelators, the novel bifunctional ligands 3,5-Me_2-pz$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$ (***L*^{6}**) and pz$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$ (***L*^{7}**) have been synthesized and their coordination chemistry toward $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**) has been explored. The resulting complexes, *fac*-$[Re(CO)_3(k^3\text{-L})]Br$ (***L*^{6}** (**7**), ***L*^{7}** (**8**)), contain tridentate ancillary ligands that are coordinated to the metal center through the pyrazolyl and amine nitrogen atoms, as observed for the other related building blocks. ***L*^{6}** and ***L*^{7}** were coupled to a glycylglycine ethyl ester dipeptide, and the resulting functionalized ligands were used to prepare the model complexes *fac*-$[Re(CO)_3(\kappa^3\text{-3,5-}Me_2\text{-pz}(CH_2)_2N(glygly)(CH_2)_2NH_2)]^+$ (**9/9a**) and *fac*-$[Re(CO)_3(\kappa^3\text{-pz}(CH_2)_2N(CH_2)_3(glygly)(CH_2)_2NH_2)]^+$ (**10/10a**) (M = Re, ^{99m}Tc). These small conjugates have been fully characterized and are reported herein. On the basis of the in vitro/in vivo behavior of the model complexes (**2a**−**6a**, **9a**, **10a**), we chose to evaluate the in vitro/in vivo biological behavior of a new tumor-seeking Bombesin pyrazolyl conjugate, [(***L*^{6}**)-G-G-G-Q-W-A-V-G-H-L-M-NH_2], that has been labeled with the $[^{99m}Tc(CO)_3]^+$ metal fragment. Stability, in vitro cell binding assays, and pharmacokinetics studies in normal mice are reported herein.

INTRODUCTION

The most recent approaches for radiopharmaceutical development are mainly based on the search for target-specific radiopharmaceuticals (*1*−*4*). This strategy involves the labeling of biologically relevant molecules, somehow related to a certain disease or disease type, and intends to improve the specificity of diagnosis and therapy in nuclear medicine (*1*−*4*).

Most of the hormonal messengers are peptides, which are involved in more fundamental biological processes than any other class of molecules, including the regulation of cellular growth and proliferation in normal as well as in tumor cells (*4*−*7*). Moreover, most tumor cells overexpress receptors for regulatory peptides, which are often specific for a certain tumor type (*5*−*7*). Many peptide receptors have already been identified and associated with a specific tumor type, stressing the interest in radiolabeling regulatory peptide analogues. Furthermore, the success obtained with the labeling of some of these peptides, such as somatostatin analogues, has encouraged further work in this field (*5*−*8*).

A recently introduced organometallic aquaion *fac*-$[M(CO)_3(H_2O)_3]^+$, M = Re, $^{99/99m}$Tc, has opened new perspectives for the labeling of different biomolecules (*9*−*11*). The attractiveness of this low-valent precursor results from its particularly high thermodynamic stability, that is, high substitution stability of CO ligands and substitution lability of water molecules, which can be easily replaced by a variety of mono, bis, and tridentate ligands of different size, shape, and donor atom sets (*12*−*19*). This versatility allows for the synthesis of different building blocks with physicochemical properties matched to the biologically relevant molecule.

As part of our ongoing work on the search for bifunctional chelators suitable for the labeling of peptides with

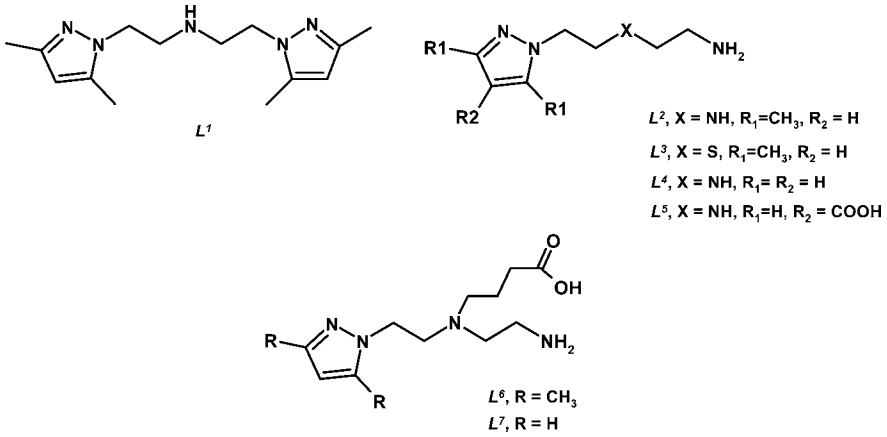
Chart 1. Pyrazolyl-Containing Ligands



the *fac*-$[^{99m}Tc(CO)_3]^+$ moiety, we have previously synthesized a family of asymmetric and symmetric pyrazolyl-containing ligands (***L*^{1}**–***L*^{3}** and ***L*^{5}**) (Chart 1) and explored their chemistry with the precursor $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**). This has led to the synthesis of different building blocks of the type *fac*-$[Re(CO)_3(k^3\text{-L})]^+$ (*20*–*22*).

As part of a study to select the most promising pyrazolyl-based chelators for further application on the labeling of biologically active peptides, we report herein on the synthesis, characterization, and biological evaluation of the corresponding ^{99m}Tc-building blocks, *fac*-$[^{99m}Tc(CO)_3(k^3\text{-L})]^+$. These complexes have been obtained by reaction of the *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ precursor with ***L*^{1}**–***L*^{5}**. Taking advantage of the versatility of these systems, we also describe the synthesis and characterization of the novel bifunctional pyrazolyl-based chelators ***L*^{6}** and ***L*^{7}** (Chart 1), as well as the synthesis and characterization of the respective tricarbonyl rhenium complexes. The utility of the new ligand frameworks ***L*^{6}** and ***L*^{7}** is further demonstrated herein by radiolabeling and biological evaluation of [(***L*^{6}**)-G-G-G-Q-W-A-V-G-H-L-M-NH_2], a GRPr specific analouge with tumor-targeting capability.

Bombesin (BBN) is a 14 amino acid peptide with very high affinity for the gastrin-releasing peptide receptor (GRPr). The function and in vivo distribution of the GRPr has been well established, showing expression in the central nervous system (CNS) and in peripheral tissues such as the pancreas or intestinal tract (*23*–*28*). The GRPr is also expressed on a variety of tumors including breast, prostate, pancreatic, and small-cell lung cancer (*23*–*28*). Therefore, radiolabeled BBN/GRP analogues such as [(***L*^{6}**)-G-G-G-Q-W-A-V-G-H-L-M-NH2] hold some potential to be used as site-directed diagnostic and/or therapeutic targeting motifs when radiolabeled with the appropriate radionuclide.

MATERIALS AND METHODS

All chemicals and solvents were of reagent grade and were used without further purification unless stated otherwise. Reactions were monitored by thin-layer chromatography (TLC) carried out on 0.25 mm Merck silica gel aluminum plates, using UV light as visualizing agent. Silica gel was used for column chromatography. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Unity 300 MHz spectrometer; ^{1}H and ^{13}C chemical shifts were referenced with the residual solvent resonances relative to tetramethylsilane. IR spectra were recorded as KBr pellets or in CsI cells on a Perkin-Elmer 577 spectrometer. The starting materials $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**), $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (**1a**), the ligands ***L*^{1}**–***L*^{3}** and ***L*^{5}**, and the complexes $[Re(CO)_3(k^3\text{-L})]Br$ (L = ***L*^{1}** (**2**), ***L*^{2}** (**3**), ***L*^{3}** (**4**), ***L*^{5}** (**6**)) were prepared according to published methods (*9*, *10*, *20*, *21*, *29*–*31*).

Peptide synthesis was performed on a Perkin-Elmer-Applied Biosystem model 432 automated peptide synthesizer employing traditional Fmoc chemistry. The preselected synthetic sequence was designed to produce the ***L*^{6}**-(X)-BBN conjugate with the following general structure ***L*^{6}**-X-Q-W-A-V-G-H-L-M-NH_2, where the spacer group, X = GlycylGlycylGlycine. The crude peptide was purified by HPLC, and the solvents were removed on a SpeedVac concentrator. Typical yields of the crude peptide were 80–85%. ES-MS was used to determine the molecular constitution of the ***L*^{6}**-(X)-BBN[7-14]NH_2 conjugate. Na[$^{99m}TcO_4$] was eluted from a ^{99}Mo/^{99m}Tc generator using 0.9% saline. HPLC analysis of the Re and ^{99m}Tc complexes was performed on a Shimadzu C-R4A chromatography system equipped with a Berthold-LB 505 γ-detector and with a tunable absorption UV detector. Separations were achieved on Nucleosil 250-4 100-10 C18 columns or on 250-4 100-5 C18 columns, using flows of 1 or 0.5 mL/min, respectively; UV detection, 254 nm; eluents, A-TFA 0.1%, B-MeOH; method, t = 0–3 min, 0% MeOH; 3–3.1 min, 0–25% MeOH; 3.1–9 min, 25% MeOH; 9–9.1 min, 25–34% MeOH; 9.1–20 min, 34–100% MeOH; 20–22 min, 100% MeOH; 22–22.1 min, 100–0% MeOH; 22.1–30 min, 0% MeOH. HPLC evaluation of the nonmetalated and metalated BBN-conjugate was performed using experimental conditions similar to those referenced above. However, the eluenting solvents were water with 0.1% TFA (A) and CH_3CN 0.1% TFA (B), and the wavelength of detection was 280 nm.

Synthesis of pz$(CH_2)_2$NH$(CH_2)_2NH_2$ (*L*^{4}). A solution of 1-(2-bromoethyl)pyrazole (*32*) (2.1 g, 12 mmol) in THF (10 mL) was added dropwise to a solution of ethylenediamine (14.4 g, 0.24 mol) in H_2O (20 mL). After refluxing for 4 h, the THF was removed under vacuum, and the residual water phase was washed with CH_2Cl_2. The aqueous phase was vacuum-dried with mild heating to eliminate some remaining ethylenediamine. Compound ***L*^{4}** was obtained as a yellow oil, which darkened to brown with heating. Yield: 924 mg, 50%. ^{1}H NMR (D_2O): 7.53 (d, H(3)pz, 1H); 7.45 (d, H(5)pz, 1H); 6.23 (t, H(4)pz, 1H); 4.14 (t, CH_2, 2H); 2.91 (t, CH_2, 2H); 2.77 (t, CH_2, 2H); 2.62 (t, CH_2, 2H). ^{13}C NMR (CD_3OD): 140.3 (C(3,5)pz); 131.9 (C(3,5)pz); 106.5 (C(4)pz); 52.48 (CH_2); 49.93 (CH_2); 41.60 (CH_2); 40.32 (CH_2). IR(ν/cm^{-1}) (CsI): 1651, 1094, 1034, 763.

Synthesis of 3,5Me$_2$-pz$(CH_2)_2$N$((CH_2)_3$COOH)$(CH_2)_2NH_2$ (*L*^{6}) and pz$(CH_2)_2$N$((CH_2)_3$COOH)$(CH_2)_2NH_2$ (*L*^{7}). *L*^{6}: An equimolar amount of BOC-ON in THF

was added dropwise to a solution of ***L²*** (4.0 g, 22.5 mmol) in THF (70 mL) at 0 °C, and the reaction mixture was left at this temperature for 3 h. A saturated aqueous solution of Na_2CO_3 and CH_2Cl_2 was added at room temperature, and the organic phase was separated, dried over anhydrous $MgSO_4$, and vacuum-dried. The yellow oil that was obtained, ***L²-Boc*** (5.7 g, 20 mmol), was dissolved in CH_3CN (60 mL), and an excess of K_2CO_3, KI, and ethyl 4-bromobutyrate was added. After 11 days at room temperature, the solution was filtered, vacuum-dried, and the residue was purified by column chromatography (ethyl acetate (50−100%)/hexane). The BOC protected derivative (4 g, 10.2 mmol) was dissolved in THF, and an excess of NaOH added and refluxed overnight, for saponification of the ethyl ester. The solution was neutralized with HCl (1 N), the solvents were removed, and the residue was extracted with CH_2Cl_2. The crude product was purified by column chromatography (MeOH (5−100%)/$CHCl_3$), and the pale yellow oil (2.2 g, 86%) was treated with an excess of TFA in CH_2Cl_2 to remove the BOC protecting group. Evaporation of the solvent, addition of H_2O, neutralization with 1 N HCl, and extraction with a small amount of MeOH led to a suspension, which, after being filtered off, was vacuum-dried yielding a pale yellow oil, which crystallizes upon standing. Yield: 2.07 g, 36%. ^{1}H NMR (CD_3OD): 5.83 (s, H(4)pz, 1H); 4.07 (t, CH_2, 2H); 2.98 (t, CH_2, 2H); 2.77 (t, CH_2, 2H); 2.70 (t, CH_2, 2H); 2.48 (t, CH_2, 2H); 2.26 (s, CH_3, 3H); 2.16 (s, CH_3, 3H); 2.00 (t, CH_2, 2H); 1.62 (q, CH_2, 2H). ^{13}C NMR (CD_3OD): 183.3 (COOH); 148.4 (C(3)pz); 141.0 (C(5)pz); 106.2 (C(4)pz); 54.1 (CH_2); 54.0 (CH_2); 52.0 (CH_2); 47.2 (CH_2); 38.5 (CH_2); 36.0 (CH_2); 24.8 (CH_2); 13.1 (CH_3); 10.9 (CH_3). IR (ν/cm^{-1}) (KBr): ν(C=O) 1694, 1559, 1442, 1210, 845, 804, 725.

L⁷*:** This compound was prepared as described for ***L⁶ (vide infra). Starting with 1.1 g (7 mmol) of ***L⁴*** in DMF, a brownish oil formulated as ***L⁷*** was obtained. Yield: 403 mg, 24%. ^{1}H NMR (D_2O): 7.58 (s, H(3)pz, 1H); 7.48 (s, H(5)pz, 1H); 6.25 (t, H(4)pz, 1H); 4.49 (t, CH_2, 2H); 3.64 (t, CH_2, 2H); 3.42 (t, CH_2, 2H); 3.25 (t, CH_2, 2H); 3.12 (t, CH_2, 2H); 2.30 (t, CH_2, 2H); 1.79 (q, CH_2, 2H). ^{13}C NMR (CD_3OD): 180.0 (COOH); 140.1 (C(3)pz); 131.8 (C(5)pz); 106.7 (C(4)pz); 54.9 (CH_2); 54.1 (CH_2); 52.0 (CH_2); 50.7 (CH_2); 38.6 (CH_2); 33.9 (CH_2); 23.9 (CH_2). IR (CsI) (ν/cm^{-1}): ν(C=O) 1685, 1442, 1209, 1138, 845, 803, 763.

Synthesis of 3,5Me₂-pz(CH₂)₂N(CH₂)₃(glygly-OEt)(CH₂)₂NH₂ (*L⁸*) and pz(CH₂)₂N(CH₂)₃(glygly-OEt)(CH₂)₂NH₂ (*L⁹*). Compounds ***L⁶-BOC*** or ***L⁷-BOC***, NEt_3 and HBTU, in the molar ratio 1:3:1, were dissolved in CH_3CN. To the resulting solutions were added equimolar amounts of glycylglycine ethyl ester (196 mg, 1 mmol). After reaction at room temperature, the solvent was evaporated and the residues were purified by column chromatography (MeOH (5−20%)/$CHCl_3$) or by dissolving the crude product in $CHCl_3$ and washing three times with H_2O. The BOC protecting group was removed with TFA. After 1 h at room temperature, the solvent was evaporated, and the residue was dissolved in H_2O and neutralized with NaOH(1N). Compound ***L⁸*** was obtained as a pale yellow oil upon evaporation of H_2O and purification by column chromatography (MeOH (20−50%)/$CHCl_3$). Compound ***L⁹*** was obtained as a yellow oil upon removal of H_2O and extraction with MeOH.

***L⁸*:** Yield: 179 mg, 45%. ^{1}H NMR (D_2O): 5.80 (s, H(4)pz, 1H); 4.04 (q, CH_2CH_3, 2H); 3.91 (t, CH_2, 2H); 3.85 (s, $NHCH_2$, 2H); 3.80 (s, $NHCH_2$, 2H); 2.81 (t, CH_2, 2H); 2.71 (t, CH_2, 2H); 2.59 (t, CH_2, 2H); 2.38 (t, CH_2, 2H); 2.10 (m, CH_2 + CH_3, 5H); 2.00 (s, CH_3, 3H); 1.53 (q, CH_2, 2H); 1.09 (t, CH_3, 3H). ^{13}C NMR (CD_3OD): 176.5 (CO); 172.3 (CO); 171.4 (CO); 148.5 (C(3)pz); 141.2 (C(5)pz); 106.3 (C(4)pz); 62.4 (CH_2); 54.0 (CH_2); 53.9 (CH_2); 52.0 (CH_2); 47.1 (CH_2); 43.2 (CH_2); 41.9 (CH_2); 38.6 (CH_2); 33.6 (CH_2); 23.8 (CH_2); 14.4 (CH_3); 13.2 (CH_3); 10.9 (CH_3). IR (CsI) (ν/cm^{-1}): ν(C=O) 1680, 1552, 1440, 1207, 1138, 1031, 842, 803, 724.

***L⁹*:** Yield: 121 mg, 33%. ^{1}H NMR (D_2O): 7.56 (d, H(3)pz, 1H); 7.46 (d, H(5)pz, 1H); 6.22 (t, H(4)pz, 1H); 4.46 (t, CH_2, 2H); 3.95 (m, CH_2CH_3, 2H); 3.72 (m, $2CH_2$, 4H); 3.59 (t, CH_2, 2H); 3.38 (t, CH_2, 2H); 3.22 (t, CH_2, 2H); 3.09 (t, CH_2, 2H); 2.25 (t, CH_2, 2H); 1.76 (m, CH_2, 2H); 1.02 (t, CH_3, 3H). ^{13}C NMR (CD_3OD): 176.2 (CO); 173.0 (CO); 172.0 (CO); 141.2 (C(3)pz); 132.3 (C(5)pz); 107.3 (C(4)pz); 62.4 (CH_2); 55.0 (CH_2); 54.6 (CH_2); 51.5 (CH_2); 47.8 (CH_2); 43.4 (CH_2); 41.7 (CH_2); 36.4 (CH_2); 33.5 (CH_2); 21.4 (CH_2); 14.4 (CH_3). IR (CsI) (ν/cm^{-1}): ν(C=O) 1677, 1426, 1202, 1135, 837, 800, 722.

Synthesis of the Re(I) Complexes (5 and 7−10). *General Method.* $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**) (100 mg, 0.130 mmol) was reacted with equimolar amounts of the compounds ***L⁴*** and ***L⁶−L⁹*** in refluxing H_2O for 2 h or overnight. The complexes precipitate as white solids from the aqueous solutions upon concentration and cooling. Compounds **5** and **7−10** were obtained in yields between 75% and 85%. With the exception of **10**, the characterization of all complexes was achieved by IR, ^{1}H, and ^{13}C NMR spectroscopies and ES/MS. The identification of **10** involved only IR and ES/MS.

[Re(CO)3(κ³-pz(CH₂)₂NH(CH₂)₂NH₂)]Br (5). ^{1}H NMR (D_2O): 7.82 (d, H(3)pz, 1H); 7.76 (d, H(5)pz, 1H); 6.54 (s, br, NH, 1H); 6.39 (t, H(4)pz, 1H); 4.86 (s, br, NH_2, 1H); 4.43 (m, CH_2, 1H); 4.16 (m, CH_2, 1H); 3.94 (s, br, NH_2, 1H); 3.50 (m, CH_2, 1H); 2.87 (m, CH_2, 1H); 2.71 (m, CH_2, 2H); 2.48 (m, CH_2, 1H); 2.08 (m, CH_2, 1H). ^{13}C-RMN (CD_3OD): 198.2 (ReCO); 194.8 (ReCO); 194.7 (ReCO); 146.6 (C(3)pz); 135.6 (C(5)pz); 108.7 (C(4)pz); 56.0 (CH_2); 49.0 ($2CH_2$); 41.8 (CH_2). Synthesis of the ^{99m}Tc(I) Complexes (2a−6a, 9a−11a). *General Method.* In a nitrogen-purged glass vial, 100 μL of a 10^{-3} or 10^{-4} M solution of the compounds ***L*^{1}**−***L*^{6}**, ***L*^{9}**, ***L*^{10}**, and [***L*^{6}**-(GGG)-Bombesin(7−14)NH_2] were added to 900 μL of a solution of *fac*-[^{99m}Tc(OH$_2$)$_3$(CO)$_3$]$^+$ (1−2 mCi) in PBS. The reaction mixture was incubated at 100 °C for 30−60 min and then analyzed by HPLC.

Cysteine and Histidine Challenge. Aliquots of 100 μL of the ^{99m}Tc complexes were added to 900 μL of 10^{-3} M cysteine or histidine solutions in PBS (pH 7.4) (final ligand concentration 10^{-5} M). The solutions were incubated at 37 °C, and aliquots were removed at 1, 2, 4, and 6 h, at which time HPLC analysis was run.

Lipophilicity. The lipophilicity of the compounds was evaluated by determination of the partition coefficient (*P*) in physiological conditions (*n*-octanol/0.1 M PBS, pH 7.4).

Biodistribution Analysis of Complexes 2a−6a and 9a,10a in Normal, CD-1, Mouse Models. Biodistribution studies were performed using groups of five female CD-1 mice (randomly bred, Charles River) weighing approximately 20−25 g each. Prior to administration, complexes were diluted with PBS pH = 7.4. Animals were intravenously injected with 100 μL (2.5−12.5 MBq) of each preparation via the tail vein and were maintained on normal diet ad libitum. At 5 min, 30 min, 1 h, and 4 h, mice were sacrificed by cervical dislocation. The administered dose and the radioactivity in the sacrificed animals were measured in a dose calibrator (Aloka, Curiemeter IGC-3, Tokyo, Japan). The difference between the radioactivity in the injected and sacrificed animal was assumed to be due to excretion, mainly urinary excretion. Blood samples were taken by cardiac puncture at sacrifice. Tissue samples of the main organs were then removed, weighed, and counted in a gamma counter (Berthold, LB2111,Germany). Accumulation of radioactivity in the tissues was calculated and expressed as percentage of the injected dose per total organ (% ID/total organ) and/or per gram tissue (% ID/g organ). For blood, bone, and muscle, total activity was calculated assuming that these organs constitute 6%, 10%, and 40% of the total weight, respectively. Urine was also collected at the time of sacrifice.

The in vivo stability of the complexes was assessed by urine and murine serum HPLC analysis, using the above referenced experimental conditions. Urine: the urine was collected at sacrifice time and filtered through a Millex GV filter (0.22 μm) before RP-HPLC analysis. Serum: Blood collected from mice was immediately centrifuged for 15 min at 3000 rpm at 4 °C, and the serum was separated. Aliquots of 100 μL of serum were treated with 200 μL of ethanol to precipitate the proteins. Samples were centrifuged at 4000 rpm for 15 min, at 4 °C. Supernatant was collected and passed through a Millex GV filter (0.22 μm) prior to RP-HPLC analysis. Liver homogenate: After injection, animals were kept for 1 h on normal diet ad libitum, and, immediately after sacrifice, the liver was excised and rapidly rinsed and placed in chilled 50 mM TRIS/0.2 M sucrose buffer, pH = 7.4, wherein it was homogenized. Aliquots (in duplicate) of the liver homogenate were treated with ethanol in a 2:1 EtOH/aliquot v/v ratio. The samples were then centrifuged at 25 000 rpm for 15 min at 4 °C, filtered through Millex GV (0.22 μm), and analyzed by HPLC, following the experimental conditions referred above.

In Vitro Cell Binding Affinity Studies of [^{99m}Tc-*L*^{6}-(GGG)-Bombesin(7-14)NH_2] (11a). *In Vitro Receptor Binding.* The IC_{50} (inhibitory concentration 50%) value of [***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] was determined by a competitive displacement cell binding assay using ^{125}I-Tyr^4-Bombesin as the radiolabel. Briefly, ∼3 × 10^6 cells (Suspended in D-MEM/F-12K media containing 0.01 M MEM and 2% BSA, pH = 5.5) were incubated at 37 °C for 1 h in the presence of 20 000 cpm ^{125}I-Tyr^4-Bombesin and increasing concentrations of nonradiolabeled conjugate. Upon completion of the incubation, the reaction medium was aspirated and the cells were washed four times with media. Cell-associated radioactivity was determined by counting in a Packard Riastar gamma counting system.

Internalization and Efflux Evaluation. In vitro internalization analysis of [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] was carried out by incubation of ∼3 × 10^6 cells (in D-MEM/F-12K media containing 0.01 M MEM and 2% BSA, pH = 5.5) in the presence of 20 000 cpm labeled conjugate at 37 °C for selected timepoints of 15, 30, 45, 60, and 90 min. Upon completion of the incubation, the reaction medim was aspirated and the cells were washed four times with media. Surface-bound radioactivity was removed by washing the cells with 0.2 N acetic acid/0.5 M NaCl (pH = 2.5). The percent of internalized, cell-associated, radioactivity as a function of time was determined by counting in a Packard Riastar gamma counting system. Efflux evaluation was performed after a 45 min internalization period. The cellular medium was washed (3×) with buffer (room temperature) and resuspended for further incubation. Selected sampling at 0, 15, 30, 45, 60, and 90 min postinternalization was performed by an initial cold buffer wash of the cells, followed by washing with acetic acid/saline (pH = 2.5 at 4 °C).

Biodistribution Analysis of [^{99m}Tc-*L*^{6}-(GGG)-Bombesin(7-14)NH_2] in Normal, CF-1, Mouse Models. The biodistribution study of [^{99m}Tc-***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] was determined in normal, CF-1 mice at the University of Missouri−Columbia. The mice were injected with 5 μCi (185 kBq) of the complex in 100 μL of isotonic saline via the tail vein. The mice were euthanized, and the tissues and organs were excised from the animals following at 1, 4, and 24 h postinjection (p.i.) Subsequently, the tissues and organs were weighed and counted in a NaI well counter and the percent injected dose (% ID) and % ID/g of each organ or tissue calculated. The % ID in whole blood was estimated assuming a whole-blood volume of 6.5% the total body weight.

RESULTS AND DISCUSSION

Pyrazolyl-Based ^{99m}Tc-Building Blocks. Following our previous work (*20*−*22*) and profiting from the ver-

satility of the symmetric (***L*^{1}**) and asymmetric (***L*^{2}**−***L*^{5}**) pyrazolyl-containing ligands, we evaluated the behavior of these compounds toward the *fac*-[^{99m}Tc(CO)$_3$]$^+$ moiety. We intended to assess the influence of using symmetric and asymmetric ligands, having different pyrazolyl substituents (−H, −CH_3, −COOH) and/or donor atom sets, on the physicochemical and biological properties of the corresponding ^{99m}Tc complexes.

The ligands ***L*^{1}**−***L*^{3}** and ***L*^{5}**, as well as the corresponding tricarbonyl rhenium complexes **2**−**4** and **6**, were already available, and their synthesis and characterization has been previously reported by our group (*20*, *21*). In contrast, the lighter member of this family of ligands, compound ***L*^{4}**, which was not described previously, has been obtained by refluxing 1-(2-bromoethyl)pyrazole with an excess of ethylenediamine in a mixture of THF/H_2O, and its characterization was done by ^{1}H and ^{13}C NMR spectroscopy. Reaction of the mixed halide-carbonyl $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**) with ***L*^{4}** in water yielded $[Re(CO)_3(k^3$-***L*^{4}**$)]$Br (**5**) (Scheme 1). The IR, ^{1}H, and ^{13}C NMR spectroscopic data obtained for **5** are compatible with the tridentate coordination mode of ***L*^{4}** and compare well with the results previously found for the complexes $[Re(CO)_3(k^3$-L$)]$Br (L = ***L*^{2}** (**3**), ***L*^{3}** (**4**)), which were characterized both in the solid state and in solution (Scheme 1) (*20*, *21*).

The ^{99m}Tc-building blocks $[^{99m}Tc(CO)_3(k^3$-L$)]^+$ (L = ***L*^{1}**−***L*^{5}** (**2a**−**6a**)) have been obtained by reacting $[^{99m}Tc(CO)_3(OH_2)_3]^+$ (**1a**) with aliquots of standard solutions of the corresponding pyrazolyl ligands, in a total volume of 1 mL (Scheme 1). The compounds formed were identified by comparing their HPLC chromatograms with the HPLC profiles of the analogues Re complexes, fully characterized either in the solid state and/or in solution (*20*, *21*).

The labeling conditions, the labeling yields, the log $P_{o/w}$, and the retention times for the ^{99m}Tc complexes are shown in Table 1. Under optimized labeling conditions, all complexes were obtained in almost quantitative yield (≥90%), with final concentration of the ligands (L) spanning from 10^{-4} to 10^{-5} M.

Complexes **2a**−**6a** were challenged in 1 mM cysteine and histidine solutions at 37 °C. The samples were analyzed by HPLC at 1, 2, 4, and 6 h, and the results obtained have confirmed a high stability for the complexes. Even for the less stable complex **2a**, almost no degradation or trans-chelation was observed, as can be confirmed by the data shown in Figure 1.

The biological distribution of the tricarbonyl complexes **2a**−**6a** was assessed in CD-1 mice at 5 min, 1 h, and 4 h after administration. Tissue distribution data of these complexes were expressed as the percentage of injected dose per gram of organ, and the uptake and clearance from most relevant organs can be overviewed in the histogram shown in Figure 2. Just for comparison, we also present in Table 2 the biodistribution of these complexes 4 h after administration. Total excretion of radioactivity over time is graphically represented in Figure 3.

The data show that all of the ^{99m}Tc-tricarbonyl complexes under study were rapidly cleared from blood and other main organs, primarily the renal-urinary pathway with a small portion retained in the hepatobiliary tract. The main differences in the biodistribution of the differ-

ent complexes are related to the clearance from tissues as well as to the rate of overall excretion. The highest retention of activity in all organs was observed for complex **2a** with most of the radioactivity retained in kidneys, liver, and intestines. The rate of injected dose cleared via the liver into the intestines is also slightly slower for **2a**, and consequently the total radioactivity excretion from whole animal body is significantly slower

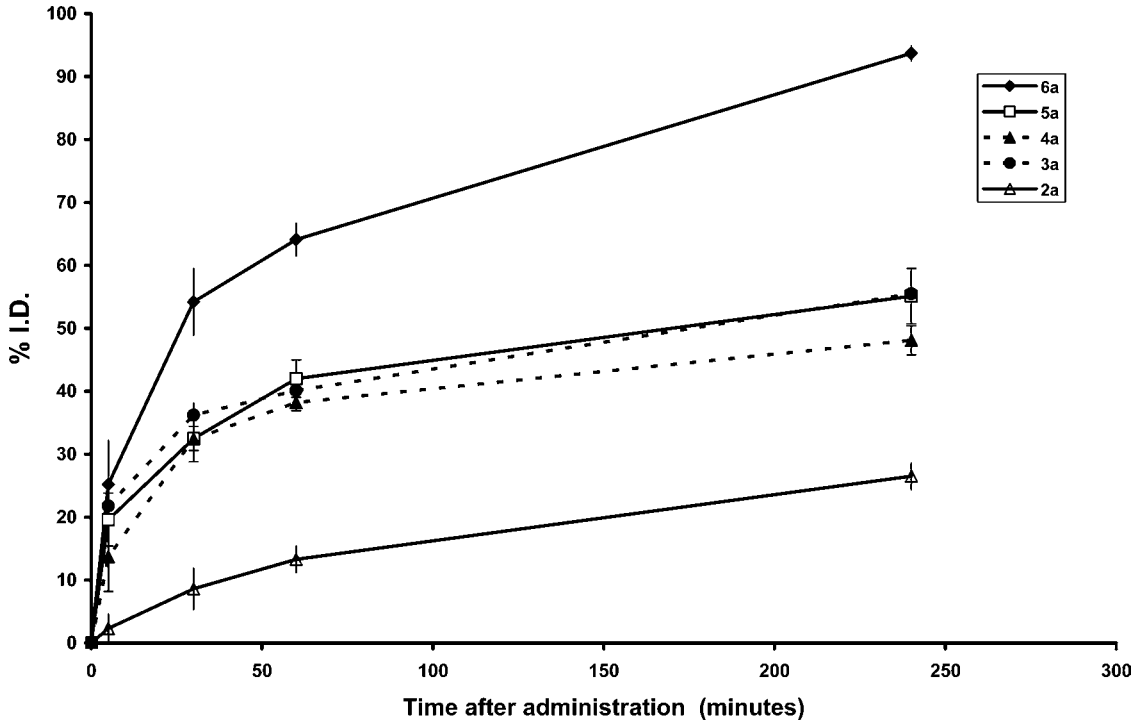

Figure 3. Total excretion for the tricarbonyl complexes **2a**−**6a**.

than for the other complexes (Figure 3). Complexes **3a**−**5a** have similar biological behavior in mice with few significant differences in their pharmacokinetics. As compared to these complexes, **6a** shows a faster clearance from the main organs and the total radioactivity excretion was relatively enhanced while the hepatic retention was reduced. Despite knowing that parameters other than lipo(hydro)philicity can affect the biodistribution profile, the predominant route of excretion, the urinary tract, seems to correlate with the log $P_{o/w}$ values found for the complexes (Table 1). The highest hepatic retention was found for **2a**, which has a log $P_{o/w}$ value of 0.87, while for **6a** which has a log $P_{o/w}$ value of −2.35 was observed a more rapid clearance and total excretion. The high hydrophilicity of **6a** and the rapid total radioactivity excretion may be related to the presence of the carboxylate group introduced in the 4-position of the pyrazolyl ring.

Bifunctional Pyrazolyl Chelators for the Labeling of Peptides. Taking into account the in vitro stability, lipophilicity, and biological profile of the building blocks previously described, we consider that all of the ligands, except for ligand **2a**, are very promising for labeling biologically active peptides. To have better insight into this aspect, we have decided to evaluate the possibility of preparing bifunctional chelators based on the ***L²*** and ***L⁴*** lead structures. By choosing these ligand frameworks, we also took into account that ***L²*** and ***L⁴*** allowed the synthesis of the ^{99m}Tc-building blocks with high specific activity (Table 1), being very similar in terms of biological profile and only slightly different in terms of molecular weight and lipophilicity.

The synthesis of the bifunctional pyrazolyl chelators involved the selective BOC protection of the primary amine functions of ***L²*** and ***L⁴***, followed by alkylation of the secondary amine with ethyl 4-bromobutyrate. 3,5-Me_2-pz$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$ (***L⁶***) and pz$(CH_2)_2$N$((CH_2)_3$COOH$)(CH_2)_2NH_2$ (***L⁷***), having a carboxylate group suitable for conjugation of tumor-seeking peptides, were finally obtained as yellow oils, after ester hydrolysis and removal of the BOC protecting group (Scheme 2).

Considering that the introduction of a pendant carboxylate group could modify the coordination mode of the pyrazolyl derivatives, we decided to study reactions of $(NEt_4)_2[ReBr_3(CO)_3]$ (**1**) with ***L⁶*** and ***L⁷***. Both ligands react promptly with **1**, leading to the formation of complexes $[Re(CO)_3(k^3$-L$)]$ (L = ***L⁶*** (**7**), ***L⁷*** (**8**)). On the basis of the splitting and chemical shifts of the ^{1}H and ^{13}C NMR resonances (vide experimental data), we concluded that in **7** and **8** the chelators ***L⁶*** and ***L⁷*** act as tridentate through the nitrogen atoms, similarly to the coordination mode found for the parent ligands ***L²*** and ***L⁴*** in complexes **3** and **5**, respectively (Scheme 1). These results prompted the coupling of the ***L⁶*** and ***L⁷*** to glycylglycine used as a peptide model, to prove the utility of these bifunctional chelators for labeling biologically relevant molecules.

The coupling of the dipeptide to ***L⁶*** and ***L⁷*** was achieved by reacting ***L⁶-BOC*** or ***L⁷-BOC*** with ethyl glycylglycine ester in the presence of HBTU and NEt_3, followed by deprotection of the primary amine and hydrolysis of the ester (Scheme 2). The coordination capability of the resulting functionalized ligands ***L⁸*** and ***L⁹*** toward the *fac*-$[M(CO)_3]$ (M = Re, ^{99m}Tc) moiety was evaluated by reacting these ligands with **1/1a** under aqueous conditions (Scheme 3). These reactions are accompanied by hydrolysis of the ester function of the glycylglycine fragment, and the complexes synthesized were *fac*-$[M(CO)_3(\kappa^3$-3,5-Me_2-pz$(CH_2)_2$N(glygly$)(CH_2)_2NH_2)]^+$ (**9/9a**) and *fac*-$[M(CO)_3(\kappa^3$-pz$(CH_2)_2$N$(CH_2)_3$(glygly$)(CH_2)_2NH_2)]^+$ (**10/10a**) (M = Re, ^{99m}Tc) (Scheme 3).

Compound **9** was characterized by ES/MS, IR, ^{1}H, and ^{13}C NMR spectroscopy, while the formulation of **10** was only established by ES/MS. The ^{99m}Tc complexes were characterized by comparing their radioactive traces on the HPLC with the UV traces of the analytically pure Re analogues.

The ^{99m}Tc-complexes **9a** and **10a** were obtained in high radiochemical purity, using final ligand concentrations

Table 3. Experimental Conditions for the Synthesis of Complexes 9a and 10a and Characteristics of the Complexes

complex	yield [%]	*c* [M]	*t* [min]	*T* (°C)	RT (min)[a]	log $P_{o/w} \pm s$
9a (***L*[8]**)	≥95	$(3-5) \times 10^{-5}$	60/30	100	19.2 (18.7)[b]	-1.12 ± 0.20
10a (***L*[9]**)	≥90	$(3-5) \times 10^{-5}$	60/30	100	17.2 (16.8)[b]	-2.11 ± 0.02

[a] The values in parentheses are for the rhenium complexes. [b] Nucleosil 250-4 100-10 C18 columns, flow of 1 mL/min.

in the $(3-5) \times 10^{-5}$ M range (Table 3), which are not significantly higher than the concentrations of ***L*[1]** and ***L*[4]** used to prepare the parent building blocks **3a** and **5a**. Hence, the attachment of the pendant arm at the central nitrogen does not strongly affect the coordination capability of these pyrazolyl-based chelators. Consistently, as complexes **3a** and **5a**, the glycylglycine functionalized complexes **9a** and **10a** also displayed a high robustness in cysteine and histidine challenge experiments.

In Table 4 are presented the biodistribution data of complexes **9a** and **10a** in CD-1 mice as percentage of injected dose per gram of organ, as well as the total radioactivity excretion as a function of time.

These results clearly indicate a biodistribution and pharmacokinetics for the glycylglycine functionalized complexes that are comparable to those found for building blocks **3a** and **5a**. However, for **9a** and **10a**, the enhanced urinary excretion, due to a lower retention of radioactivity in the kidneys over time, increased the percentage of overall excretion. To verify the in vivo stability of complexes **9a** and **10a**, serum, liver homogenate, and urine of the murines were also analyzed by radiometric HPLC. The murine serum, isolated from blood collected 30 min after i.v. administration, shows no pertechnetate, and more than 98% of the radioactivity could be assigned to complexes **9a** and **10a**. Furthermore, HPLC analysis of liver homogenate, from mice sacrificed 1 h after administration, also revealed that more than 98% of the radioactivity could be assigned to the ^{99m}Tc-tricarbonyl complexes **9a** and **10a**, indicating their resistance to

metabolic degradation. Analysis of urine collected at sacrifice time demonstrated again high in vivo stability of the complexes, because no metabolites could be detected. As an example, the HPLC chromatograms of biological samples collected from mice injected with **9a** are shown in Figure 4. The resistance to metabolic degradation in blood and liver, an organ rich in enzymes such as peptidases, and the excretion of the ^{99m}Tc tricarbonyl complexes intact into the urine demonstrate their high in vivo robustness.

To further demonstrate the utility of this family of bifunctional chelators in synthesizing receptor-avid peptide pyrazolyl conjugates, a GRP receptor-specific peptide (G-G-G-Q-W-A-V-G-H-L-M-NH_2) was chosen for coupling to ***L*^{6}**. The new conjugate was synthesized by SPPS and characterized by electrospray ionization mass spectrometry. The radiolabeled peptide conjugate [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] (**11a**) was obtained in high yield (≥95%) upon addition of 100 μL of a solution of the conjugate ($(3-5) \times 10^{-5}$ M) to a vial containing 900 μL of the precursor [^{99m}Tc(CO)$_3$(H_2O)$_3$], with heating (Figure 5). Radiochemical yields of the new ^{99m}Tc-conjugates were monitored by RP-HPLC. The chromatographic profile of metalated conjugate is shown in Figure 6. The chromatogram displays a single peak with a retention time of 14.6 min. This conjugate is stable in aqueous solution for time periods of ≥24 h.

Competitive binding displacement studies of [***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] demonstrated an IC_{50} value of 0.7 ± 0.2 nM. This value is very much comparable to

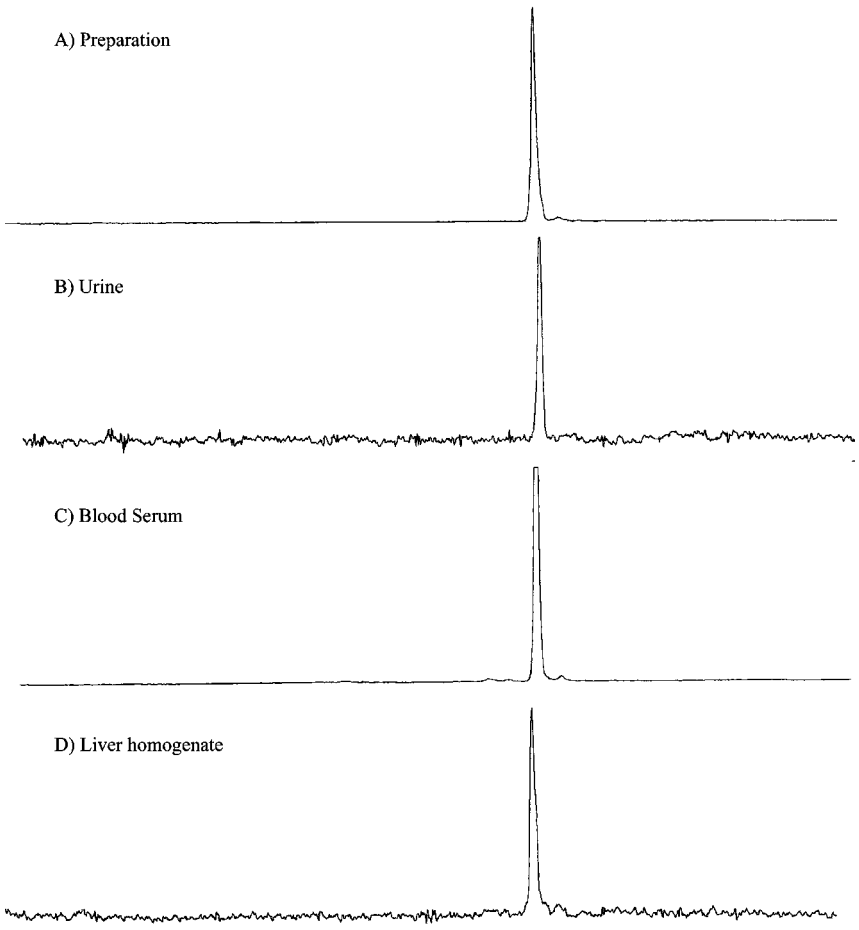

Figure 4. HPLC chromatogram for complex **10a**: (A) preparation, (B) urine, (C) blood serum, and (D) liver homogenate.

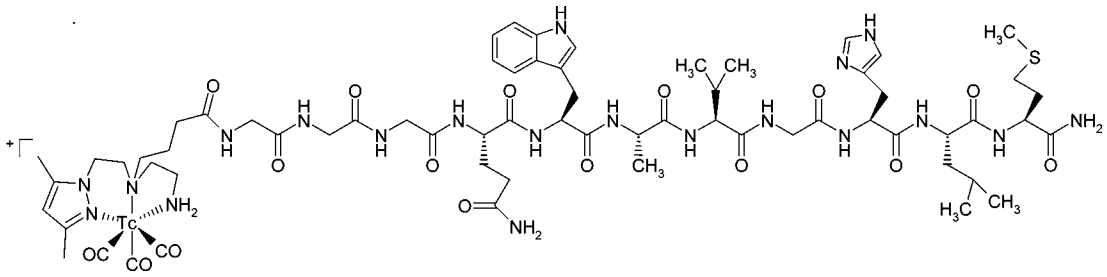

Figure 5. Metalated BBN analogue (**11a**).

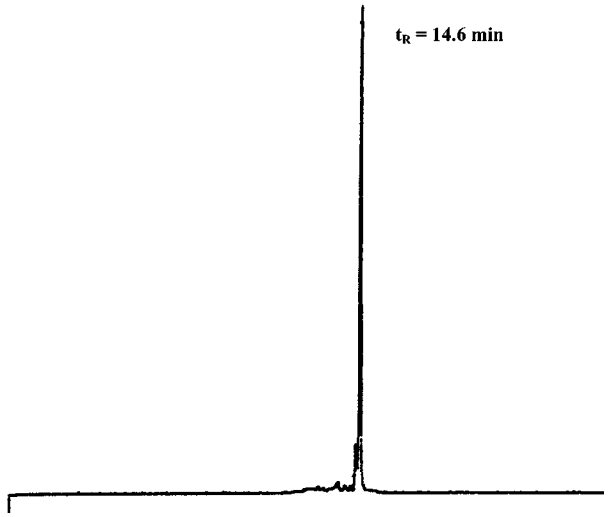

Figure 6. HPLC elution profile of the metalated BBN analogue [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH$_2$] (**11a**) (t_R, 14.6 min).

those previously reported for conjugates of this type (*33*−*36*).

Figure 7 summarizes the results of studies to assess the degree of uptake (internalization) of the new conjugate in PC-3 cells. At 90 min postincubation, the amout of internalized activity is ∼60% of the total activity administered. These data are considerably lower when compared to other conjugates of this type (*35*, *36*). Figure 8 summarizes the results of studies to assess the degree of trapping (efflux) of the [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH$_2$] (**11a**) in PC-3 cells. The total ^{99m}Tc activity associated with the cells after the 45 min incubation was measured following washing of the cells with the pH 7.4 incubation media. After washing these cells with the pH 2.5 buffer to remove surface-bound ^{99m}Tc activity, approximately 60% remained trapped by the cells. Results of measurements at 15, 30, 45, 60, and 90 min show that

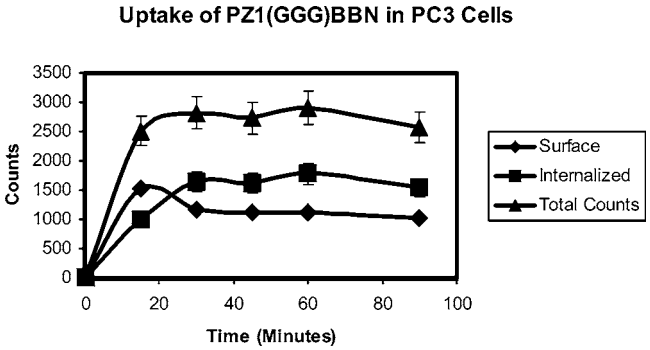

Figure 7. Internalization of [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH$_2$] (**11a**) in human prostate (PC-3) cancerous cells.

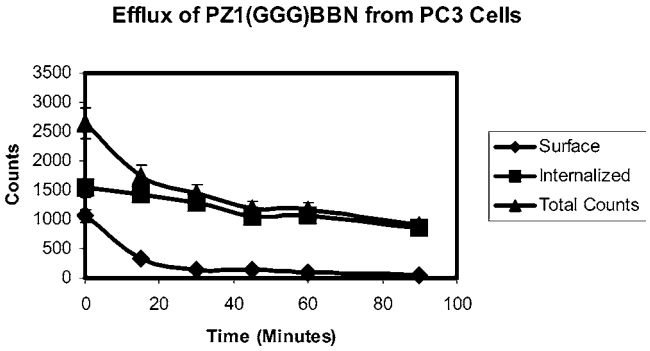

Figure 8. Efflux of [^{99m}Tc(CO)$_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH$_2$] (**11a**) in human prostate (PC-3) cancerous cells.

radioactivity does remain trapped by the cells, with approximately 45% of the ^{99m}Tc-activity associated with the cells at $t = 0$ remaining residualized at 90 min. Thus, at 90 min, approximately 66% of the activity remains residualized when normalized to the 60% trapped in the cells at $t = 0$. Efflux of this conjugate from PC-3 prostate tumor cells is comparable to other ^{99m}Tc(I)-conjugates of this type (*35*, *36*). The introduction of the pyrazolyl ligand

onto BBN[7-14]NH_2 has little or no effect on the efflux properties of the ^{99m}Tc-conjugate in GRP receptor-specific PC-3 cells as this new conjugate demonstrates uptake comparable to other ^{99m}Tc(I)-conjugates of this type (*35*, *36*).

Table 5 summarizes the results of the biodistribution studies in normal CF-1 mice at 1 h postintravenous injection for the [^{99m}Tc$(CO)_3$-***L*^{6}**-(GGG)-Bombesin(7-14)NH_2] conjugate. The conjugate was surprisingly hydrophilic with 71.9 ± 2.49% ID clearing via the renal-urinary pathway at 4 h p.i. The remainder of the radioactivity was cleared via the hepatobiliary pathway. There is no significant uptake or retention in the stomach, indicating that there is minimal, if any, in vivo dissociation of ^{99m}Tc from the pyrazolyl ligand to produce $^{99m}TcO_4^-$. Pancreatic tissue expresses the GRPr in high density. Therefore, the accumulation of ^{99m}Tc-activity in pancreatic tissue reflects the ability of these derivatives to target GRP receptor-expressing cells in vivo. Receptor-mediated pancreatic uptake of this ^{99m}Tc-conjugate was noticeably lower (i.e., 5.8 ± 0.87% ID/g at 1 h p.i.) when compared to other BBN conjugates designed and developed in our laboratory. This is presumably due to an increased rate of clearance from serum into the hepatobiliary system as compared to other more hydrophilic conjugates of similar structure (*33*−*36*). Kidney retention for the ^{99m}Tc-conjugate was found to be ∼2% ID/g. Blocking studies in which high levels of cold BBN[1-14] was administered 30 min prior to the ^{99m}Tc-ligands reduced the % ID/g uptake/retention in the pancreas at 1 h p.i. significantly, demonstrating the in vivo receptor specificity of this analogue for GRP-receptor expressing cells (data not shown).

CONCLUSION

The pyrazolyl-based chelators ***L*^{1}**−**L*^{5}** react with $(NEt_4)_2$-[$ReBr_3(CO)_3$] (**1**) and [^{99m}Tc$(H_2O)_3(CO)_3]^+$ (**1a**) forming well-defined complexes of the type [$M(CO)_3(k^3$-L)$]^+$. The ^{99m}Tc complexes are obtained in high yield, with high radiochemical purity, and are stable against cysteine and histidine exchange reactions. The biological profile and pharmacokinetics of these building blocks indicate that they were rapidly cleared from blood and other main organs into urine, mainly the renal-urinary pathway, with a small portion retained in the hepatobiliary tract. Most of these ligands can be functionalized through the primary or secondary amine as well as through the pyrazolyl ring. In this report, we have explored functionalization through the secondary amine. We have shown that the introduction of a pendant carboxylate arm on ***L*^{2}** and ***L*^{4}** does not change the coordination mode of the final bifunctional chelators. Furthermore, coupling of this ligand to a small peptide such as BBN(7-14)NH_2 does not change the high in vitro and in vivo stability of the metalated conjugates. This important requirement together with the favorable tissue distribution profile of the complexes/conjugate (i.e., rapid clearance from nontarget tissue, rapid urinary excretion, and low retention of radioactivity in the kidneys) are quite attractive features of these pyrazolyl derivatives. In summary, these results can be seen as proof-of-principle of the utility of tridentate and asymmetric pyrazolyl-based ligands as bifunctional chelators for labeling tumor-seeking peptides with the *fac*-[^{99m}Tc$(CO)_3]^+$ moiety. Moreover, the characteristics of the ligands are expected to allow a fine-tuning of the biological properties of the labeled tumor-seeking peptides.

ACKNOWLEDGMENT

We thank Mallinckrodt-Tyco Inc. for financial support. S.A. thanks Fundação para a Ciência e Tecnologia for a Ph.D. grant (BD/3052/2000). We would also like to acknowledge the research group of Dr. Timothy J. Hoffman at the Harry S. Truman Memorial Veterans' Hospital and the University of Missouri−Columbia for contributing effort toward the biodistribution analysis of the bombesin conjugates.

Received April 13, 2004; Revised Manuscript Received January 6, 2005

Synthetic peptidoliposomes have been designed and prepared according to a chemoselective ligation. Two aldehyde-functionalized lipidic anchors were synthesized and incorporated into the lipidic bilayers of unilamellar liposomes during their preparation. Complementary hydrazino acetyl peptides were synthesized on the solid phase using *N*,*N*′,*N*′-tri(*tert*-butyloxycarbonyl)-hydrazino acetic acid and further coupled to the aldehyde groups displayed at the surface of the vesicles. Coupling yields were measured by amino acid hydrolysis following total acid hydrolysis. The ligation methodology proved superior to the simple insertion of lipopeptides, which was performed for comparison in terms of yields, implementation, and reproducibility. To check whether the grafted-peptides were accessible and functional, cytoplasmic sequences of LAMP protein (lysosomal associated membrane protein), which is involved in intracellular membrane trafficking, have been selected. Using this model, we demonstrated in vitro the specific interaction of the synthetic LAMP-peptidoliposomes with the cytoplasmic adaptor protein AP-3, a result that contributes to the understanding of protein sorting in cells. Thus, these results clearly indicate the usefulness of such peptidoliposomes, easily prepared by hydrazone chemoselective ligation, as a tool for biological investigation.

INTRODUCTION

The modification of the surface properties of liposomes by peptides or proteins has been extensively studied (*1*−*3*). Considering peptides, most of the time, their stable anchorage into the phospholipid bilayers requires their derivatization by a lipidic foot (*4*, *5*) composed of at least two alkyl chains (*6*, *7*). However, it is a challenging task due to the generally low solubility of the resulting conjugates. To circumvent these difficulties, alternative strategies have been developed where the purified peptide is ligated to a functionalized lipidic anchor already inserted in the membrane (*8*). In these strategies, the chemical bond between anchor and peptide is often chosen among the amide (*9*) or thioether bonds (*3*, *5*, *10*−*12*), disulfide bridge (*13*), and, sometimes, imine bond (*14*). However, peptides are randomly oriented, usually by more than one side chain if their sequence comprises more than one lysine and/or cysteine.

Alternatively, the hydrazone bond has been proposed by some authors to site-specifically immobilize peptides or proteins onto vesicles or microspheres (*15*). Conjugates are prepared by mild periodate oxidation of N-terminus Seryl or Threonyl peptides (*16*) or sugar of antibodies' Fc fragment (*17*) followed by the incubation of the product with hydrazide-phosphatidylethanolamine (*18*) contained in the bilayers. Advantageously, this method does not require any activating agent, nor does it generate any side-product. The reverse reaction consisting of the coupling of amphiphilic aldehyde-like anchors with synthetic hydrazino acetyl peptides remains unprecedented (Scheme 1).

This strategy can now be envisaged because of the recent progress concerning the preparation of the latter compounds. In particular, the use of the *N*,*N*′,*N*′-tri(*tert*-butyloxycarbonyl)-hydrazino acetic acid allows the facile introduction of the hydrazino-group on peptides using solid-phase peptide synthesis (*19*, *20*). Notably, this approach does not require extra steps to functionalize the peptides after cleavage from the resin and purification as compared to the synthesis of glyoxyl-peptides. Moreover, sulfur-containing peptides are more easily accessible because no deleterious periodate oxidation is performed. At any case, this reverse strategy will probably complement and reinforce the attractiveness of the hydrazone chemoselective ligation.

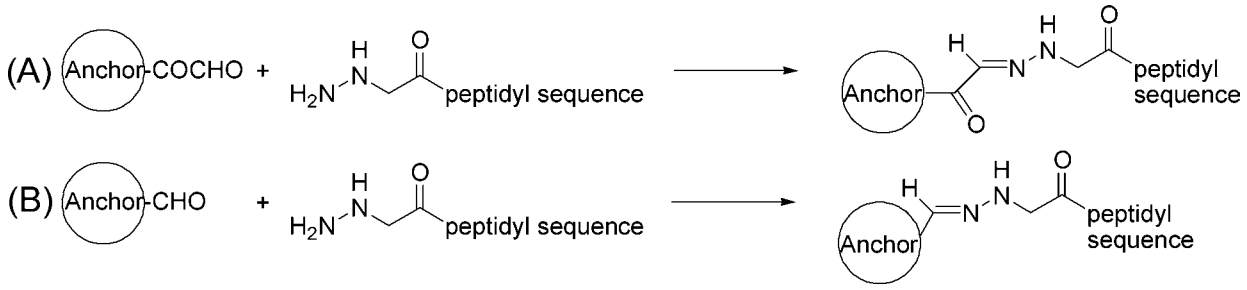
Scheme 1. α-Oxo Hydrazone (A) or Hydrazone Ligation Principles (B), and Corresponding Peptido Liposomes



To test its feasability, we recently reported the solid-phase synthesis of an α-oxo aldehyde anchor **1a** (Figure 1), within 25% overall yield. As expected, **1a** was successfully coupled to a model hydrazino acetyl peptide within 81% RP-HPLC conversion and 41% isolated yield in an organic-aqueous solution (*21*). Moreover, we recently performed a comprehensive physicochemical study of **1a** reactivity to form hydrazone bonds on colloids just as the stability of the latter (*22*). Briefly, we demonstrated in that paper that hydrazone ligation offered high chemoselectivity and versatility. As we intended to use the hydrazone ligation to target the controlled release of therapeutic agents by vesicles, an accurate measure of the ligation bond stability was performed to ensure it would stand long exposures to physiological conditions. The mechanism of the reaction in solution as well as in different self-organized systems (micelles, liposomes, and multilamellar vesicles) was investigated. In solution, submicromolar stability was achieved as well as half-lives of several weeks (as an example, the hydrolysis rate constants estimated at pH 7.4 and 25 °C gave for our ligation products half-lives of 23 to 800 days and should be long enough at 37 °C to touch and attach their cell target in vivo). The kinetics and stability were both enhanced in colloidal media thanks to autoassociation effects. Finally, the grafting of synthetic mannose receptor−ligands onto onion-like vectors to target human dendritic cells provided a first example of the efficiency of this strategy (*23*).

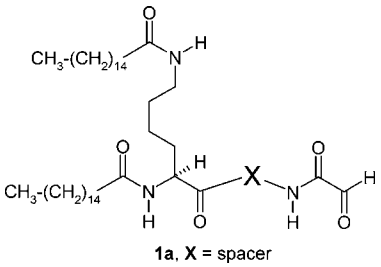


Figure 1. Amphiphilic α-oxo aldehyde **1a** (with X = Tyr−NH−$(CH_2)_3O[(CH_2)_2O]_2-(CH_2)_3$−NH−$COCH_2OCH_2CO$−Gly−NH−$(CH_2)_3$−).

To further demonstrate the usefulness and the versatility of our strategy, and particularly for probing biological processes, we describe herein the synthesis of a second aldehyde anchor (**1b**, Scheme 2), the inclusion of **1a** and **1b** into liposomes, and their reaction with hydrazino acetyl peptides, via α-oxo hydrazone (A) or hydrazone (B) bonds, respectively, to obtain peptidoliposomes (Scheme 1).

Peptido- or proteoliposomes have been used for various purposes in the cell biology of membranes, in particular to reconstitute in vitro several aspects of intracytoplasmic membrane trafficking. In eukaryotes, vesicular intracellular transport is mediated by several coat components (COPs) and adaptor proteins (APs), the latter functioning with clathrin (*32*−*35*). These cytosolic coat components bind to cytoplasmic domains of transmembrane proteins to segregate them into transport vesicles. Previously, the interaction of COPs had been reconstituted in vitro using chemically defined proteoliposomes (*36*−*38*).

The AP-3 complex interacts in vivo with a tyrosine-based sorting motif in the cytoplasmic domain of transmembrane LAMP (lysosomal-associated membrane protein) (*39*). We show here that AP-3 can specifically interact in vitro with liposomes onto which a synthetic cytoplasmic domain of LAMP has been coupled.

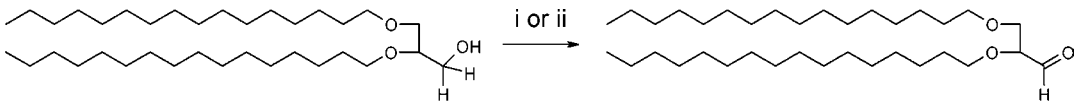
To demonstrate this, hydrazone-based peptidoliposomes were incubated with pig brain cytosol. These peptidoliposomes bore either the wild-type sequence of the LAMP cytoplasmic domain (wt) or a mutated sequence in which the key tyrosine residue of the sorting motif had been replaced by an alanine, thereby producing a nonfunctional sorting signal. In this context, AP-3 was specifically recruited onto wt LAMP-bearing liposomes, demonstrating that synthetic peptidoliposomes are excellent versatile tools for the in vitro study of membrane trafficking. More generally, in a context of reconstituted conditions in vitro, the necessity or the role of each partner, reagent, and/or condition can be studied.

EXPERIMENTAL PROCEDURES

Chemicals and Antibodies. All Fmoc protected amino acids (L-Arg(Pmc),[1] L-Asn(Trt), L-Asp(O*t*Bu), L-Gln(Trt), L-Glu(O*t*Bu), L-His(Trt), L-Lys(Boc), L-Lys(Fmoc), L-Ser(*t*Bu), L-Thr(*t*Bu), L-Tyr(*t*Bu)), coupling agents (HOBt, HBTU, BOP), and resins (Wang, Novasyn) were purchased from Novabiochem. Chemicals were from Sigma-Aldrich except cyanuric fluoride, which was from Lancaster. Solvents were from Acros.

Lipids (phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), and cholesterol (chol)) were from Avanti Polar Lipids. The antiprotease cocktail, GTP, and GTP-γ-S (the nonhydrolyzable GTP analogue) were from Roche Biochemicals, and reagents

Scheme 2. Solution-Phase Synthesis of Anchor 1b[a]



[a] Conditions and reagents: (i) Swern oxidation (35%); (ii) Dess−Martin oxidation (86%).

for chemiluminescence detection were from Pierce. The antibodies used in this study were as follows: affinity-purified rabbit polyclonal 2583 against the σ subunit of AP-3, recognizing a doublet on Western blots (the σ3 A and B isoforms); monoclonal antibody 100/3 against the γ-subunit of AP-1 (Sigma Immunochemicals); monoclonal antibody maD against the β subunit of COP I (Sigma Immunochemicals). The secondary antibodies used were goat anti-mouse and goat anti-rabbit conjugated to horseradish peroxidase (Sigma Immunochemicals).

RP-HPLC Eluents. **A**: TFA 0.05% in H_2O. **B**: TFA 0.05% in CH_3CN/H_2O 80/20 (v/v). **C**: TFA 0.05% in propan-2-ol/H_2O 40/60 (v/v). **D**: CH_3CN/potassium phosphate buffer 50 mM, pH 7.21 20/80 (v/v). **E**: CH_3CN/potassium phosphate buffer 50 mM, pH 7.21 75/25 (v/v).

Buffers for Biological Experiments. F: 1.79 mL of citric acid 0.1 M + 3.21 mL of Na_2PO_4 0.2 M + 5 mL of water to reach 100 mM, pH 6.4. **G**: 25 mM Hepes-KOH pH 7.2 + 125 mM KOAc + 2.5 mM MgOAc + 1 mM DTT.

Synthesis of anchor 1a was performed as described in ref *21*.

Synthesis of Anchor 1b. Di-*O*-hexadecyl-rac-glyceraldehyde was obtained using Dess−Martin's oxidation reagent. CH_2Cl_2 was distilled over P_2O_5. Dess−Martin periodinane, 15% weight solution in CH_2Cl_2 (287 mg, 0.10 mmol), was added to a solution of di-*O*-hexadecyl-rac-glycerol (50 mg, 0.09 mmol) in CH_2Cl_2 (2 mL) under N_2, with stirring. After 30 min, the resulting suspension was diluted with 9 mL of CH_2Cl_2/heptane 2/1 (v/v) and added to 10 mL of 1 M NaOH. After 10 min of stirring, the organic layer was washed with water, dried over Na_2SO_4, and concentrated under reduced pressure. The white residue was purified by chromatography on silica gel (eluent: heptane/AcOEt 95/5 (v/v)) to give **1b** (43 mg, 86%) as a white solid. ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 9.24 (d, 1H, J = 1.4 Hz), 3.81 (ddd, 1H, J = 1.4, 4.0 and 5.4 Hz), 3.71 (dd, 1H, J = 4.0 and 10.5 Hz), 3.68 (dd, 1H, J = 5.4 and 10.5 Hz), 3.63 (dt, 1H, J = 6.7 and 9.2 Hz), 3.56 (dt, 1H, J = 6.6 and 9.2 Hz), 3.48 (dt, 1H, J = 6.5 and 9.3 Hz), 3.40 (dt, 1H, J = 6.6 and 9.3 Hz), 1.64 (q, CH_2, J = 6.6 Hz), 1.55 (q, CH_2, J = 6.9 Hz), 1.25 (br s, 26CH_2), 0.88 (t, 2 × 3H, J = 6.4 Hz, 2CH_3). ^{13}C NMR (75 MHz, $CDCl_3$) δ ppm: 203.3, 84.0, 72.1, 71.5, 70.0, 32.1, 29.9, 29.8, 29.6, 29.4, 26.2, 22.9, 14.3. TOF-PDMS: m/z 539 $[M + H]^+$.

Synthesis of the Dipalmitoyl Peptides 2a and 2b. A Fmoc/*t*Bu peptide synthesis was performed on 0.25 mmol of Wang resin in a 431A syntheziser (Applied Biosystems, UK) with a double coupling 4 equiv in situ activation of amino acid in the presence of HBTU (4 equiv), HOBt (4 equiv), DIEA (16 equiv), and Fmoc-protected amino acids to obtain the two expected Fmoc peptidyl resins. The last Fmoc was removed manually by a piperidine/NMP treatment 2/8 (v/v) within 2 and 20 min, and the resin was washed with NMP. Fmoc−Lys-(Fmoc)−OH was introduced manually as above. Following an ultimate deprotection, palmitic acid (8 equiv) reacted first under HBTU (8 equiv), HOBt (8 equiv) activation with DIEA (32 equiv) onto the deprotected diamino peptidyl resin. To prepare the second acylation, palmitic acid (8 equiv) was activated by cyanuric fluoride (32 equiv) in the presence of pyridine (8 equiv) under argon for 2 h in CH_2Cl_2/*t*BuOMe 4/1 (v/v) (*24*). Following an aqueous washing, CH_2Cl_2 was evaporated, and the fluoride was solubilized in DMF and reacted in parallel on the resins in the presence of DIEA (16 equiv) for 3 h. A total acid hydrolysis of the peptidyl resin conducted with HCl/propionic acid 1/1 (v/v) at 130 °C for 3 h gave quantification results as expected. The dipalmitoyl peptidyl resins were cleaved by TFA in the presence of H_2O/phenol/ethanedithiol/thioanisole: 0.5 mL/0.75 g/0.25 mL/0.5 mL in 10 mL of TFA for 2 h. Small amounts (37 mg out of 600 mg) of crude lipopeptides **2a** and **2b** were purified by preparative RP-HPLC (C3 Zorbax column, 300 Å, 1.8 μm, 15 × 500 mm, 4 mL min^{-1}, λ = 225 nm, 50 °C, eluents **A** and **B**, **B** 0 to 100% in 30 min, 100% **B** for 10 min). 7 mg of **2a** (19%) and 14 mg of **2b** (38%) were obtained. Identity was controlled by MALDI-TOF mass spectrometer and purity by RP-HPLC (C3 Zorbax, 4.6 × 200 mm, 1 mL min^{-1}, λ = 215 nm, 50 °C, eluents **A** and **B**, **B** 0 to 100% in 30 min, 100% **B** for 10 min). Total acidic hydrolyses in evacuated sealed tubes with 6 N HCl/phenol 10/1 (v/w) at 110 °C for 24 h followed by amino acid analysis were in agreement with expected results.

The synthesis of hydrazino acetyl peptides 3 was reported in refs *19*, *20* for other applications. Briefly, Fmoc−*t*Bu peptide syntheses were performed on 0.1 mmol of Wang resin in a Pioneer syntheziser (Applied Biosystems, UK) with a 10 equiv in situ activation of amino acid in the presence of HBTU, HOBt, DIEA, and protected amino acids to obtain the Fmoc peptidyl resins. Fmoc was removed automatically, and the deprotected N-terminal amine was acylated by *N*,*N*′,*N*′-tri(*tert*-butyloxycarbonyl)-hydrazino acetic acid using a HBTU/HOBt activation. TFA/H_2O/TIS 9.5/0.25/0.25 (v/v/v) allows the deprotection and cleavage of peptides **3** then precipitated in cold Et_2O, washed and purified by preparative RP-HPLC (C18 Nucleosil column, 15 × 500 mm, 4 mL·min^{-1}, λ = 225 nm, 50 °C, eluents **A** and **C**, **C** 0 to 100% in 30 min, 100% **C** for 10 min). The peptides' purities were controlled by RP-HPLC, and their identities were controlled on a MALDI-TOF spectrometer. **3a**: >95%, m/z observed 1446.6 ($[M + H]^+$). **3b**: >97%, m/z observed 1353.82 ($[M + H]^+$).

Chemoselective ligation between anchor 1a and LAMP wt peptide 3a in solution was performed as reported in ref *21*. Briefly, 4.5 mg of anchor **1a** (3.5 μmol) in $CHCl_3$/MeOH 1/1 (v/v) (105 μL) was added to 6.6 mg of hydrazino acetyl peptide **3a** (3.5 μmol) solubilized in propan-2-ol/acetate buffer 10 mM pH 5:8/2 (v/v) (500 μL) at 37 °C. For a better stirring of the suspension, 1.3 mL of propan-2-ol/acetate buffer 1/1 (v/v) was added. RP-HPLC analyses were performed on a C3 Zorbax column (4.6 × 300 mm, 1 mL·min^{-1}, λ = 215 nm, 70 °C, eluents **A** and **B**, gradient: 0−100% **B** over 30 min, 100% **B** for 5 min, 0% **B** for 10 min). After 3 h, the RP-HPLC conversion could be calculated as high as 81% on the basis of peptide **3a** disappearance. The crude compound was purified on a C3 Zorbax column, (15 × 500 mm, 4 mL·min^{-1}, λ = 225 nm, 50 °C, same eluents and gradients) to obtain 41% isolated yield.

Chemoselective Ligation between Di-*O*-hexadecyl-rac-glyceraldehyde 1b and LAMP wt Peptide 3a in Solution. 1b (1 mg, 1.8 μmol) and **3a** (3.53 mg, 1.8 μmol) were added to 330 μL of a mixture of $CHCl_3$/2-

[1]Abbreviations: Boc, tertiobutyloxycarbonyl; BOP, benzotriazole-1-yl-oxy-tris-(dimethylamino)-phosphonium hexafluorophosphate; DBU, 1,8-diazabicyclo [5,4,0]undec-7-ene; DIEA, diisopropylethylamine; DMAP, 4-*N*,*N*-(dimethylamino)pyridine; DMF, *N*,*N*-dimethylformamide; DMSO, dimethyl sulfoxide; DTT, dithiothreitol; ES-MS, electrospray mass spectrometry; Fmoc, 9-fluorenylmethyloxycarbonyle; HBTU, 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate; HOBt, *N*-hydroxybenzotriazole; IPT, isopropylidene tartrate; Mtt, 4-methyltrityl; NMP, *N*-methyl pyrrolidone; OSu, *N*-hydroxysuccinimide ester; Pam, palmitoyl; PE, phosphatidyl ethanolamine; *t*Bu, tertiobutyl; TFA, trifluoroacetic acid; TIS, triisopropyl silane; TNBS, 2,4,6-trinitrobenzenesulfonic acid.

Table 1. Peptide Sequences, Synthesis Yields, and Insertion (I) or Ligation (L) to Liposomes Yields (Measured by the Same Quantitative Method, by Amino Acid Analysis, Mean of Three Experiments)[a]

	name	sequence	synthesis yield	insertion or ligation to liposomes yield
2a	$(Pam)_2$-LAMP wild type (wt)	Pam−K(Pam)−GRKRSHAG**Y**QTI−OH	19%	<3% (I)
2b	$(Pam)_2$-LAMP mutant (Y-A)	Pam−K(Pam)−GRKRSHAG**A**QTI−OH	38%	<3% (I)
3a	LAMP wild type (wt)	H_2N−GGRKRSHAG**Y**QTI−OH	35%	44% (L)
3b	LAMP mutant (Y-A)	H_2N−GGRKRSHAG**A**QTI−OH	40%	58% (L)

[a] Liposomes compositions were as follows: (I) PC/PE/PS/chol 50/30/10/10 (by mol.); (L) PC/PE/PS/chol/anchor **1b** 40/30/10/10/10 (by mol.). Pam = palmitoyl.

methyl-2-propanol/citrate-phosphate buffer 10 mM, pH 5.19, 8/10/15 (v/v/v). The suspension was stirred at room temperature for 4 h and at 37 °C overnight. Conversion was estimated to 60% from analytical RP-HPLC. The resulting mixture was then diluted with water and lyophilized. The pale yellow powder was purified by RP-HPLC on a C3 Zorbax column (15 × 500 mm, 4 mL·min^{-1}, λ = 225 nm, 50 °C, eluents **D** and **E**, gradient: 0−100% over 40 min) to give the expected compound in about 15% isolated yield.

Functionalized Liposomes Preparation. Anchors **1a** or **1b** were solubilized in $CHCl_3$/MeOH 1/1 (v/v) at a 10 mM final concentration. A mixture of PC/PE/PS/chol/anchor **1a** or **1b** 40/30/10/10/10 (by mole) in a $CHCl_3$/MeOH 1/1 (v/v) solution was evaporated to dryness under a stream of nitrogen and resuspended in buffer **F** for further coupling to peptides such as 1 mL of suspension contains 5 μmol of total lipids and, among them, 0.5 μmol of anchor. After vigorous vortexing, the lipid suspension was submitted to 10 freeze-and-thaw cycles in liquid nitrogen and in a 37 °C water bath, respectively, and filtered through polycarbonate 400 nm-membranes to size the liposomes homogeneously. In control liposomes, anchor was replaced by PC.

Next, 0.5 μmol·mL^{-1} (1 equiv considering total anchor) of hydrazino acetyl peptide solution (3 mM in buffer **F**) was reacted to the suspension. The liposome/peptide mixture was left overnight at room temperature for coupling to occur, and unbound peptide was removed by gel filtration over a Sephadex G-25 column with buffer **G** (NAP 5 columns, Amersham Pharmacia Biotech).

Amino Acid Analysis. 100 μL of liposome suspensions was submitted to a 48 h total acid hydrolysis with 1 mL of HCl 6 N/phenol 10/1 (v/w) at 110 °C in the presence of 10 μL of norleucine 0.5 mM in evacuated sealed tubes. The quantification of each immobilized peptide was achieved by the determination of the subsequent amino acid composition using a Beckman amino acid analyzer model 7300 with ninhydrin detection.

Coat Protein Recruitment Assay. Pig brain cytosol was prepared from fresh brains obtained at the local slaughterhouse. Brain slices were transferred to homogenization buffer (25 mM Hepes-KOH pH 7.4, 250 mM sucrose, 1 mM EDTA supplemented with an antiprotease cocktail) on ice. Homogenization was done with a Waring blender in a 2-to-1 buffer-to-tissue (w/w) ratio. The crude homogenate was centrifuged at 4 °C at 3000*g* for 10 min, then at 10 000*g* for 20 min, and finally at 100 000*g* for 60 min. The final supernatant served as the cytosolic fraction and was flash-frozen in liquid nitrogen before storage at −80 °C. Before use, cytosol was rapidly thawed and desalted over Sephadex G-25 (PD-10) columns previously equilibrated with buffer **G**. Any aggregated material was then removed by centrifugation at 250 000*g* for 30 min at 4 °C.

Recruitment reactions were performed in siliconized microfuge tubes in a total volume of 200 μL. Typical recruitment reaction mixtures contained buffer **G** and a combination of gel-filtered cytosol (5 mg·mL^{-1} final), liposomes (200 μg·mL^{-1}), GTP (1 mM) or GTP-γ-S (0.1 mM), and/or ARF1 (ADP Ribosylation Factor-1, a myristoylated G-protein that acts as membrane anchor for the assembly of protein coats, 3 μg·mL^{-1} final). Tubes were kept on ice, and binding reactions were initiated by transfer at 37 °C. After 20 min, reactions were stopped on ice, and membranes were recovered by centrifugation at 4 °C for 15 min at 20 000*g*. Pellets were solubilized in SDS sample buffer, boiled for 5 min, and analyzed by SDS-PAGE followed by immunoblotting using the relevant antibodies. Visualization was performed by chemiluminescence, and quantitation was obtained by scanning and spot analysis with the NIH software version 1.60/PPC.

RESULTS AND DISCUSSION

Ligation versus Incorporation of Lipopeptides into Preformed Vesicles. In a first strategy, we envisaged the preparation of synthetic peptidoliposomes by mixing all liposomal components including the peptides as lipopeptides. To this aim, we envisaged the synthesis of peptidic sequences modified at the N-terminus position by two palmitoyl (Pam) groups using standard solid-phase protocols (*25*, *26*). The RP-HPLC purification of lipopeptides is often difficult due to their generally low solubility and to the line broadening induced by the fatty acid chain(s). Thus, the major difficulty we encountered during the lipopeptides' production was associated with the preparative RP-HPLC steps. The overall yields were modest and hardly reproducible. Thus, synthetic dipalmitoyl-peptides corresponding to the intracytoplasmic LAMP sequences **2a**, and its control **2b** where the tyrosine residue was replaced by alanine, were produced as Pam−L-Lys(Pam)-peptides under moderate to average yields (19% for **2a** and 38% for **2b**, Table 1).

Once obtained, **2a** and **2b** lipopeptides were inserted into preformed liposomes. No more than 3% insertion was reached, calculated by amino acid analysis following total acid hydrolysis (Table 1). This phenomenon was previously reported by Elliott and Prestwich (*27*). In their case, as much as 90% lipopeptide was aggregated in a micellar form rather than inserted into liposomes. A weak solubility and a propensity to aggregate are responsible for the bad insertion of lipopeptides into liposomes. Thus, due to synthetic difficulties, this strategy turned out to be unapplicable to systematic and iterative studies.

We then envisaged a second strategy based on the chemical ligation principle, where peptides are selectively attached onto liposomes. In a project aimed at anchoring various and sometimes complex polyfunctional molecules to lipid membranes, we have examined the utility of the hydrazone and α-oxo hydrazone bonds. The hydrazone link was chosen because it could be achieved in the absence of activating agent and did not generate any toxic

or remaining side-product. We immobilized synthetic hydrazine-like peptides onto aldehyde or α-oxo aldehyde-liposomes, a strategy that was unprecedented. This strategy not only required the design and synthesis of amphiphilic aldehyde-like anchors to be manipulated as lipids when preparing the liposome suspension (Figure 1), but also those of hydrazino acetyl peptides (Scheme 1). Concerning the ligation process, a first and comprehensive work had been performed on the thermodynamic and kinetic parameters of the reaction (*22*, see Introduction). In this study, the α-oxo hydrazone bond formed between vesicles and hydrazino compounds in aqueous buffer was found to be totally chemoselective and quantitative. Its stability in physiological conditions was in the submicromolar range, and nonspecific adsorption could be diminished to 10−15% on average. These results formed the basis of our present work.

Anchors' Design and Synthesis. A first anchor **1a** of type Pam−L-Lys(Pam)−spacer−CO−CHO was prepared as previously described (Figure 1 (*21*)). The difficulty in preparing amphiphilic compounds such as **1a** resides in the fine-tuning of the physicochemical properties to allow their solubilization, purification, and characterization. In addition, depending on the biomolecular interactions studied, the anchored peptide should be close to or distant from the membrane surface. Thus, to allow the spacer arm to be easily modulated, anchors of the type **1a** were elaborated on solid phase using standard Fmoc/*t*Bu protocols (*28*, *29*). Compound **1a** was isolated with a 25% overall yield.

A further anchor **1b** presenting the basic elements required for this application was synthesized in solution (Scheme 2). It contained a double hexadecyl arm to be inserted among liposome phospholipids and an aldehyde reactive head. Di-*O*-hexadecyl-rac-glyceraldehyde **1b** was first obtained starting from di-*O*-hexadecyl-rac-glycerol following Swern's oxidation procedure (*30*). **1b** was obtained after purification together with unreacted di-*O*-hexadecyl-rac-glycerol (35%). The reaction did not come to its completion, which was assigned to the poor solubility of the lipophilic molecules in cold CH_2Cl_2. Indeed, as high as 86% isolated yield could be obtained when the oxidation was performed at room temperature using Dess−Martin's reagent (*31*).

To summarize, two types of synthetic anchors are now available. Those of the type **1a** are versatile in such a way that four analogues were synthesized (10−50% overall yield according to the spacer X in 100−500 mg scale). Anchor **1b** is simple and cheap and was also obtained in a 100 mg scale. Some PE derivatives are currently under investigation. This should reinforce the interest of using a hydrazone bond in the preparation of peptidoliposomes.

Hydrazino Acetyl Peptides' Synthesis. In parallel, α-hydrazino acetyl peptides were automatically produced. Their sequences corresponded to a part of the cytoplasmic domain of the lysosome-associated membrane protein LAMP (wild-type LAMP, wt) or to a mutated sequence where the tyrosine sorting motif was replaced by an alanine (Table 1, entries **3a**,**b**). A conventional Fmoc/*tert*-butyl solid-phase peptide strategy (*28*, *29*) and our recently described tri-protected compound *N*,*N*′,*N*′-tri-(*tert*-butyloxycarbonyl)-hydrazino acetic acid, $(Boc)_2N-N(Boc)-CH_2-COOH$, were employed for the unambiguous introduction of the hydrazino acetyl group upon the selectively deprotected α-amino group of the N-terminal amino acyl resins (*19*, *20*). Each crude α-hydrazino acetyl peptide was easily purified by RP-HPLC, freeze-dried as a TFA salt, and could be thoroughly characterized by amino acid analysis, RP-HPLC, and MALDI-TOF-MS (yields **3a**, 35%, **3b**, 40%, amino acid analyses in accordance with expected results, RP-HPLC purity superior to 95%). It is noteworthy that hydrazino acetyl peptides are unstable in the presence of acetonitrile and should be purified with RP-HPLC eluents containing 2-propanol as was exposed in ref *19*.

Thus, the solid-phase synthesis of hydrazino acetyl peptides requires fewer steps than that of N-terminus glyoxylyl peptides, where a deleterious periodic oxidation and a second purification are necessary. Here, hydrazino acetyl peptides were readily obtained after cleavage from the resin and RP-HPLC purification. Moreover, in our hands, hydrazino acetyl peptide synthesis offered a total flexibility, and as many as 10 sequences from three models were easily assembled and functionalized in good yields.[2] These advantages are good reasons for applying the hydrazone chemical ligation.

In-Solution Ligation. 1a and **1b** were engaged in a chemoselective hydrazone ligation in solution with hydrazino acetyl peptide **3a** to control both the accessibility and the reactivity of the functional groups. The reaction of **1a** or **1b** with **3a** led to the formation of the corresponding α-oxo hydrazone with 81% and 60% RP-HPLC conversion and 41% and 15% isolated yield following RP-HPLC purification, respectively. Although successful, these two reactions remained very difficult to handle and required heating and a mixture of organo-aqueous solvents.

Ligation onto Liposomes. Ligation of hydrazino acetyl peptides proved to be more convenient and efficient onto vesicles, as anchors **1a** and **1b**'s aldehyde head seemed to be more "available" in liposomes than in organo-aqueous solution. These results are consistent with what we reported in our physicochemical study: when the ligation was performed in self-organized media, its speed and its stability were enhanced due to autoassociation of the reagents.

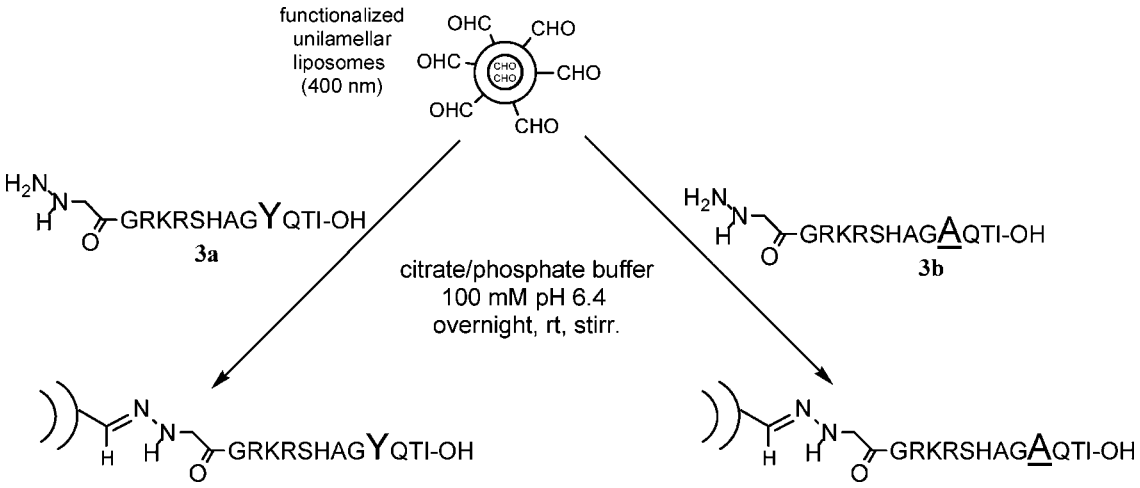
The liposomes were prepared by integrating 10% (mol/mol) of one of the anchors **1a** or **1b**. Assuming that the vesicles were unilamellar, 0.25 mM aldehyde functions could be reacted on the outer membrane (see Experimental Procedures for further numerical data). The proteoliposomes were obtained by simple stirring of the functionalized liposomes with the α-hydrazino acetyl peptides **3** (1 equiv toward total aldehydes, i.e., 2 equiv toward outer exposed aldehydes, Scheme 3). The incubation mixture was left overnight for the reaction to be completed. However, we routinely observed that 5 h were sufficient for a total conversion.

Unbound peptide was removed by gel filtration. The addition of the peptidic reagent and the workup imposed a 2.5-fold dilution of the liposome suspension. Thus, 0.1 μmol of peptides was the maximum to be anchored per milliliter of recovered liposome suspension.

Quantification of the amount of peptide associated to liposomes was performed by amino acid analysis following total acid hydrolysis using norleucine as an internal standard. As the medium was not totally homogeneous, the acidolysis was left over 48 h to be as complete as possible and the analyses were performed three times (three samples) for more accuracy.

[2]Baust, T., Bourel-Bonnet, L., Gras-Masse, H., and Hoflack, B. (2004) Selective assembly of AP-1 and AP-3 coats onto synthetic membranes: Requirement for ARF1, sorting signals of specific cargo transmembrane proteins and phosphatidylinositol-phosphates. Unpublished results.

Scheme 3. Onto-Liposome Ligation of Anchor 1b to Peptides 3a or 3b



Liposomes containing anchor **1b** (**1b**-liposomes) were first coupled to hydrazino peptide **3a**, and a reproducible 44% ± 3% coupling yield was measured (mean 44%, Table 1). When these vesicles were coupled to hydrazino peptide **3b**, the coupling yield was comprised between 49% and 70% (mean 58%, Table 1). Apart from uncomplete amino acid hydrolysis, these variations may be due to the dilution of the suspensions occurring during the purification by gel filtration.

Therefore, to further confirm these results, the peptide remaining in the supernatants after ligation onto **1b**-liposomes was quantified by RP-HPLC. The amount of recovered peptide was measured (assuming that the peptide amount that was not recovered was anchored onto the liposome) and was compared to the amino acid analyses of the suspensions. A good correlation could be established between the average amount of peptide remaining in the supernatant and that of the peptide present in the suspension (51% against 50%). Obtained either by RP-HPLC quantification or by amino acid analysis, these results demonstrate that ligation is greatly superior to insertion of lipopeptides for the preparation of peptidoliposomes. These results are reported in Table 1 (lanes **2a** and **2b** as compared to lanes **3a** and **3b**).

Biological Evaluation of the Vesicles. The scope of our strategy stretches to ligand/receptor interactions. We chose to illustrate it in the field of cellular biology. Precisely, our peptidoliposomes were used to reconstitute in vitro a particular aspect of membrane trafficking. In this work, we demonstrated that AP-3 complex can specifically interact in vitro with liposomes onto which the cytoplasmic domain of LAMP has been coupled.

Coat Recruitment Assay with the Peptidoliposomes. **1b**-Liposomes were coupled to **3a** or **3b**, two hydrazino acetyl dodecapeptides displaying either the tyrosine sorting motif of LAMP cytoplasmic tail or an alanine, respectively (Scheme 3). After the free peptide was eliminated by gel filtration, the suspensions were incubated with pig brain cytosol. Vesicles were recovered after centrifugation at high speed. After washing, specific monoclonal antibodies were used to detect and identify which cytosolic proteins were immobilized (in other words, "recruited") onto the liposomes by western blotting (Figure 2).

When comparing lanes (a) and (b) (LP control with no anchor and LP-LAMP Y-A exposing the anchored mutated peptide, respectively) to lane (c) (LP-LAMP wt exposing the anchored wt LAMP peptide), it becomes clear that AP-3 recruitment is higher when liposomes bear an intact LAMP cytosolic domain with a tyrosine-based sorting signal. Most notably, no AP-3 was recruited onto liposomes bearing the mutated LAMP peptide lacking the tyrosine sorting motif, emphasizing the specificity of our recruitment reaction. LP control represents liposomes without anchor (**1b** was replaced by PC, see Experimental Procedures) exposed to peptide **3a** and gel-filtered. For this type of suspension, the amino acid quantification was not reproducible, and peptide amounts wavered between 10% and 40%, due to peptide adsorption in a nonspecific manner. Because we observed that AP-3 could not be efficiently recruited onto these liposomes, we concluded that covalent binding of the peptide was necessary for the peptide to interact with the AP-3 coat. These results are consistent with some previously reported work. As an example, Pécheur and Hoekstra showed that liposomes' fusion could only happen when a fusion-inducing peptide was covalently bound to the lipid bilayer and not when it was adsorbed to the surface (*40*). We suggest that, in our case, this covalent binding allowed a correct exposition of the peptide to the cytosol, thus presenting the sorting motif in a proper way. Additional controls showed that, in the absence of peptide, even when the anchor **1b** was present, AP could not

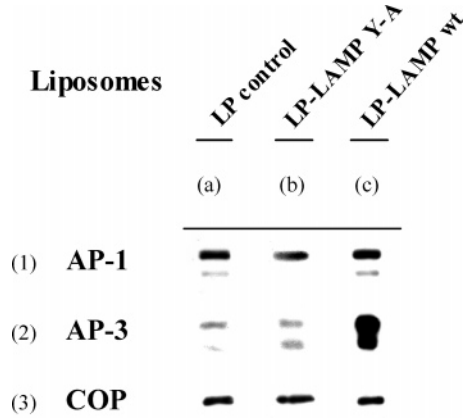


Figure 2. AP-3 membrane recruitment is LAMP-dependent. (a) LP control represents liposomes containing no anchor exposed to peptide **3a**. (b) LP-LAMP Y-A and (c) LP-LAMP wt were prepared with peptides **3b** and **3a**, respectively. After incubation with a pig brain cytosol, AP-1, AP-3, and COP bound to liposomes were detected by western blotting using specific antibodies.

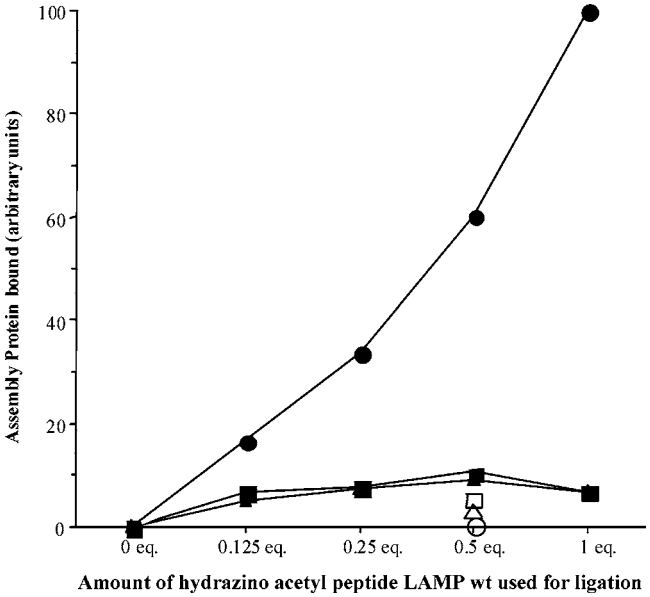

Figure 3. AP-3 membrane recruitment is dependent on the amount of peptide LAMP wt bound. Recruited protein detected: AP-3 (●), AP-1 (■), COP (▲). Open symbols correspond to the amount of AP-3 (○), AP-1 (□), and COP (△) recruited in the presence of 0.5 equiv of LAMP mutant (**3b**). Data are representative of duplicate experiments.

get recruited onto the liposomes, reinforcing the specificity of our recruitment reaction (see Supporting Information).

Selective AP-3 Recruitment onto LAMP-Peptidoliposomes Is a Function of LAMP Coupling Yield. 1b-Liposomes containing a fixed amount of lipidic anchor (10 mol %) were incubated with increasing amounts of LAMP wt peptide **3a**, and 1 equiv means 1 equiv toward the overall anchor (see experimental conditions for ligation). Figure 3 shows that AP-3 binding depends on the concentration of LAMP wt peptide present on liposomes. AP-3 binding onto liposomes exposing the mutated LAMP peptide was not observed, whatever the amount of mutated peptide was. This confirmed the specificity of our in vitro system.

CONCLUSION

We successfully prepared hydrazone-based peptidoliposomes. We designed and synthesized two different aldehyde-functionalized anchors able to covalently immobilize hydrazino acetyl peptides onto liposomes. This ligation strategy was more efficient and versatile than the direct insertion of lipopeptides into liposomes. Several types of peptidoliposomes could be prepared in parallel. As an example to illustrate the functionality of the vesicles, we have successfully reconstituted the selective interaction of the AP-3 coat with cytoplasmic domains of transmembrane proteins covalently immobilized on liposomes. This methodology can be applied to different coat components involved in different aspects of membrane trafficking and in a more general manner to any biological problem into which transmembrane or membrane-associated proteins are implicated.

ACKNOWLEDGMENT

We thank Dr. Pascale Chenevier for fruitful scientific discussions, and Frédéric Malingue, Eric Diesis, and Hervé Drobecq (UMR 8525) for technical assistance. We gratefully acknowledge financial support from the Ministère de la recherche (L.B.-B. received a young scientist "ACI jeune chercheur" financial support in 2001), Université de Lille 2, Centre National de la Recherche Scientifique (CNRS), Institut Pasteur de Lille, Agence pour la Recherche contre le Cancer (ARC), and Agence Nationale de Recherche sur le SIDA (ANRS).

Synthesis and Self-Alkylation of Isotope-Coded Affinity Tag Reagents

Zhidong Zhang, Patrick J. Edwards, Roger W. Roeske, and Lili Guo*

Department of Biochemistry and Molecular Biology, School of Medicine, Indiana University, Indianapolis, Indiana 46202. Received September 16, 2004

A pair of ICAT reagents, *N*-(13-iodoacetamido-2,2,3,3,11,11,12,12-octadeutero-4,7,10-trioxa-tridecanyl)-biotinamide (**8d**, ICAT-d_8) and *N*-(13-iodoacetamido-4,7,10-trioxa-tridecanyl)biotinamide (**8c**, ICAT-d_0), and an alternative pair of ICAT reagents, *N*-(10-iodoacetamido-2,5,5,6,6,9-hexadeutero-4,7-dioxa-decanyl)biotinamide (**8b**, s-ICAT-d_6) and *N*-(10-iodoacetamido-4,7-dioxa-decanyl)biotinamide (**8a**, s-ICAT-d_0), were successfully synthesized. A mixture of sodium borohydride and cobalt(II) chloride reduced the intermediate dinitrile to the diamine without loss of the deuterium labels, which occurred when Raney nickel was the reducing agent. The problem caused by unsymmetrical biotinylation of the intermediate diamine was solved by using the solid-phase method in which one end of the diamine was attached to a chlorotrityl chloride resin, followed by biotinylation of the resin-bound amine. The self-alkylation of ICAT reagents that accounted for their instability and their limitations in the applications was also studied.

INTRODUCTION

Quantitative proteomics has become very important because of its potential to determine properties of biological systems that are not determined by DNA or mRNA sequence analysis alone, but related to protein expression, subcellular location, posttranslational modification, and interactions, as well as the rate of change of these properties under specific conditions. This information can aid in the discovery of diagnostic or prognostic protein markers, therapeutic targets in understanding the initiation and progression of disease states (*1*−*4*).

One of the approaches in quantitative proteomics is based on stable isotope labeling of proteins or peptides and automated tandem mass spectrometry (MS/MS) (*5*, *6*). The isotope-coded affinity tag (ICAT) method developed by Aebersold and co-workers (*7*) is a pioneering step in this field. The ICAT reagents have three elements: an affinity tag (biotin), a linker containing stable isotopes (either eight H atoms (d_0) or eight deuterium atoms (d_8)), and a reactive moiety to react with sulfhydryl groups of cysteines in proteins. The protein mixtures from two sets of cell states (or tissue extracts) are independently labeled with the d_0 and d_8 ICAT reagents; the samples are combined, and then proteolytically cleaved. The ICAT labeled peptides are isolated by affinity chromatography on an avidin column and analyzed by microcapillary liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS/MS). Peptide sequence information is obtained by tandem mass spectrometry and computer searches of protein data banks. Quantification of proteins in two cell states is performed by comparing the intensity of the identical peptide peak pair from the two samples defined by the isotopic difference in the light and heavy reagent.

Although the ICAT reagent has been widely used in quantitative proteomics (*8*−*13*), synthesis of the ICAT reagent was not adequately described in the original papers (*7*, *14*). Our first attempt to reproduce the published synthesis resulted in considerable loss of the deuterium labels. Another problem was biotinylation of the diamines, in which a large excess of ether diamine was required to avoid formation of bis-biotinylation. Recently, a seven-step alternative synthesis of ICAT-d_8 was published by Perrin (*15*). Their orthogonal protection strategy overcame deuterium loss and allowed effective mono-biotinylation. We also like to report here our successful resolution of these problems to obtain the pair of pure ICAT reagents, *N*-(13-iodoacetamido-2,2,3,3,11,-11,12,12-octadeutero-4,7,10-trioxa-tridecanyl)bio tinamide (Scheme 1, **8d**, ICAT-d_8) and *N*-(13-iodoacetamido-4,7,10-trioxa-tridecanyl)biotinamide (Scheme 1, **8c**, ICAT-d_0), in reasonable yields. The synthetic scheme was also used to synthesize alternative ICAT reagents, *N*-(10-iodoacetamido-2,5,5,6,6,9-hexadeutero-4,7-dioxa-decanyl-)biotinamide (Scheme 1, **8b**, s-ICAT-d_6) and *N*-(10-iodoacetamido-4,7-dioxa-decanyl)biotinamide (Scheme 1, **8a**, s-ICAT-d_0). We also studied the self-alkylation of ICAT reagents, which accounted for their instability and their limitations in the applications.

EXPERIMENTAL PROCEDURES

General. Most of the reagents and solvents were obtained from Sigma-Aldrich (MO) or Fisher Scientific (NJ). 2-(1H-Benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), 1-hydroxybenzotriazole (HOBt), and *N*,*N*-diisopropylethylamine (DIEA) were purchased from Applied Biosystems (Warrington, UK). 2-Chlorotrityl chloride resin was from Novabiochem (CA). Trifluoroacetic acid (TFA) was obtained from Halocarbon (NJ) and distilled before use. Triisopropylsilane (TIS) was obtained from Sigma-Aldrich (MO).

Analytical reverse-phase HPLC was performed on a Varian model 5000 liquid chromatograph with a UV-100 detector unless otherwise specified. A Vydac C_{18} column (218TP54, 4.6 × 250 mm) was used at a flow rate of 1 mL/min. Preparative reverse-phase HPLC was carried out on a Waters-600E HPLC system fitted with a 486

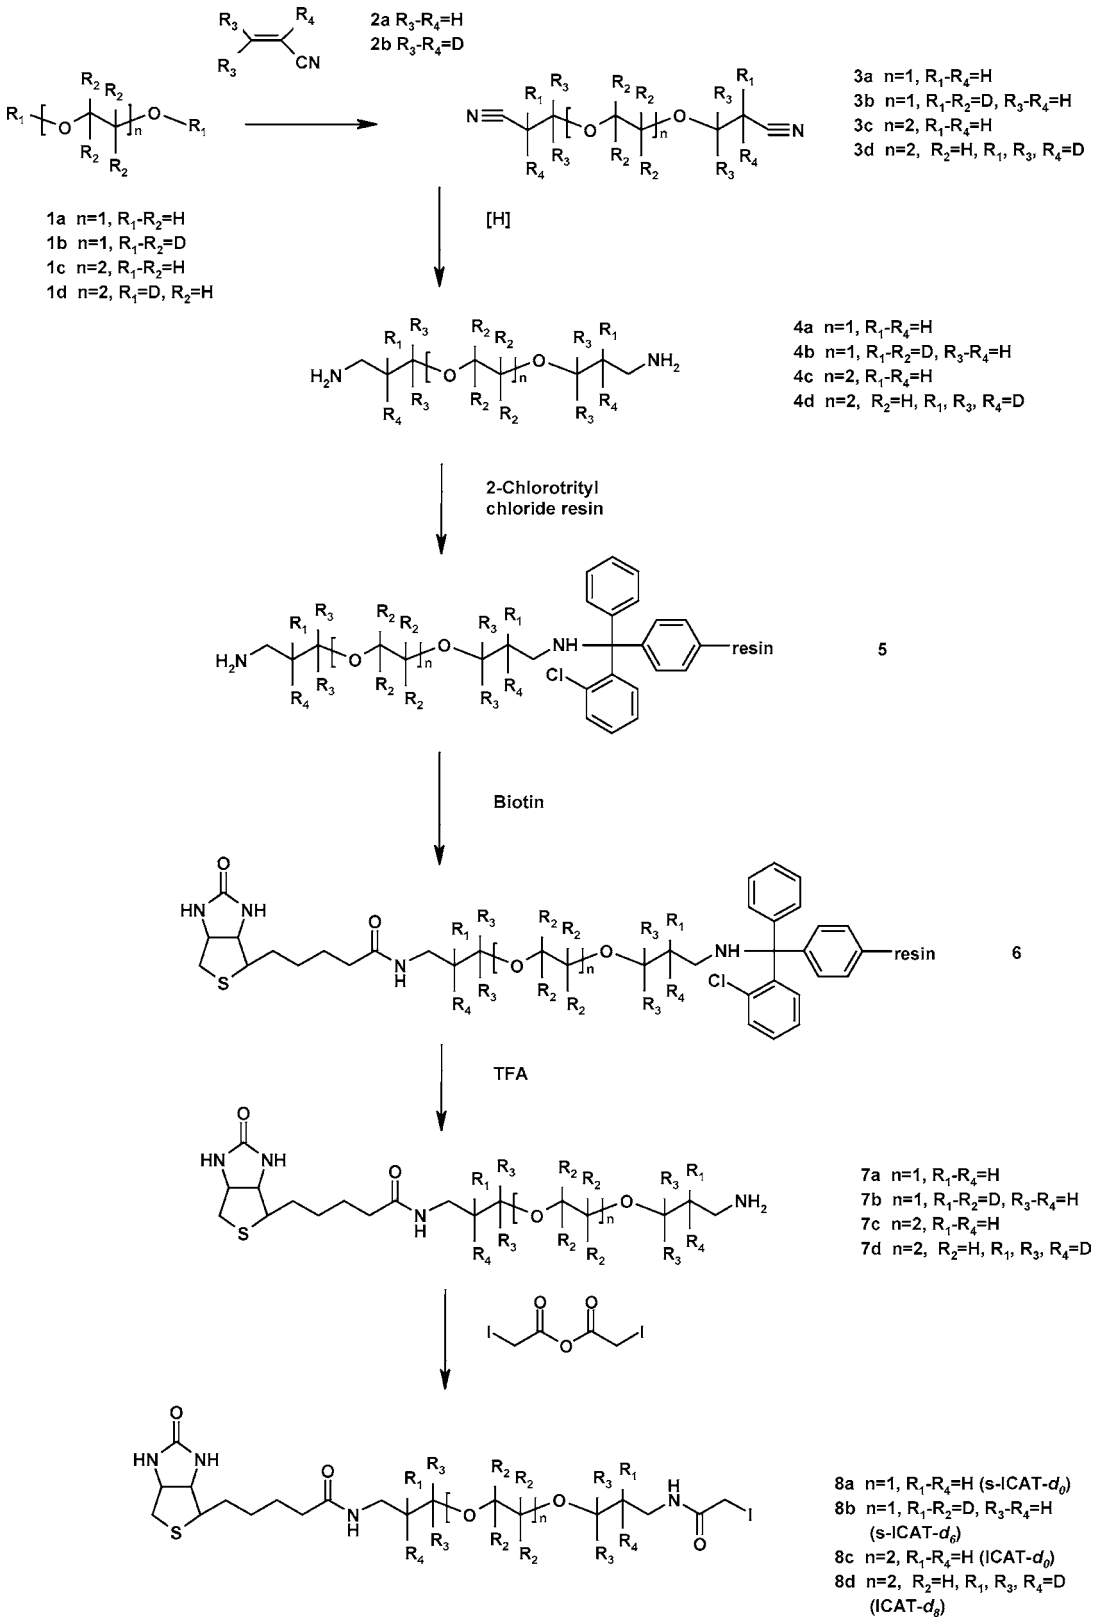
Scheme 1



tunable absorbance detector using a Vydac C_{18} column (218TP101550, 50 × 250 mm) at a flow rate of 15 mL/min. The absorbance was recorded at 214 nm wavelength, and a solvent system of A, 0.1% TFA in water, and B, 70% acetonitrile in water containing 0.09% TFA, was used both for analytical and for preparative HPLC. Flash chromatography was performed on a 5 × 60 cm column packed with Baker silica gel (40 μm average particle diameter) using 2% MeOH in $CHCl_3$ as eluting solvent. Electrospray ionization mass spectra (ESI-MS) were obtained on a Finigan LCQ LC/MS system. TLC was carried out on Merck Kieselgel 60 precoated plates and visualized by iodine absorption. 1-Butanol/acetic acid/water/pyridine (4/1/2/1 vol) was used as development solvent.

For study of self-alkylation of ICAT compounds, the solid samples of ICAT compounds were flushed with

nitrogen and stored at −20 °C. The solution samples were made in a concentration of 1 mg/mL solvent mixture and stored at room temperature. The reaction of self-alkylation was monitored by HPLC and ESI-MS. HPLC analysis was conducted on a Varian Prostar 210 system fitted with a Prostar 320 UV/vis detector using a Vydac C_{18} 218TP54 column at a flow rate of 1 mL/min. Solvent gradient was an isocratic 5% B for 5 min, then a linear gradient 5% to 60% B for 25 min.

Synthesis of Ether Dinitriles. *2,2,3,3,11,11,12,12-Octadeutero-4,7,10-trioxa-1,13-tridecanedinitrile (**3d**).* To a stirred solution of di(ethylene glycol-d_2) (**1d**) (2.54 mL, 26.7 mmol) in benzene (3 mL) was added sodium deuterioxide (4 drops of 40% solution in D_2O), followed by dropwise addition of a solution of acrylonitrile-d_3 (**2b**) (3.52 mL, 53.5 mmol) in benzene (3 mL) at room temperature over 20 min. After being stirred for 1 h, the reaction mixture was filtered and the solvent was removed by rotary evaporation. The residue was purified by flash chromatography, and a clear oil (4.85 g) was obtained in 82% yield. TLC: only one spot, R_f = 0.65. ESI-MS m/z = 221.1 $[M + H]^+$ (calc. 221.2).

Ether dinitriles **3a**, **3b**, and **3c** were prepared as **3d** from the appropriate glycol and acrylonitrile. The crude products were obtained in 96% or higher yields, and TLC showed only one spot with R_f at 0.65.

Reduction of Ether Dinitriles. *Synthesis of 2,2,3,3,-11,11,12,12-Octadeutero-4,7,10-trioxa-1,13-tridecanediamine (**4d**) with $NaBH_4$-Raney Nickel Catalyst.* To a stirred solution of **3d** (4.8 g, 21.8 mmol) in MeOH (20 mL) was added Raney 2800 nickel (8.5 g) followed by dropwise addition of a solution of $NaBH_4$ (1.76 g 46.5 mmol) in 8 M NaOH (40 mL) over 2.5 h. The reaction temperature was kept between 15 and 25 °C with a water bath, and the reaction was stopped 5 min after the H_2 bubbles ceased. The catalyst was filtered off and washed with MeOH (50 mL × 2). Washing and mother liquor were combined and concentrated in a vacuum. Solid KOH (19 g) was added to the residue, and the diamine product was salted out of solution as a light yellow oil. Crude product was separated and purified by vacuum distillation. Diamine (**4d**) (2.61 g, yield 52%) was collected at 150−152 °C/0.75 mmHg. TLC R_f = 0.22. ESI-MS m/z = 227.3 (main peak) $[M + H]^+$ (calc. 229.2).

4,7,10-Trioxa-1,13-tridecanediamine **4c** was prepared as for **4d** using **3c** as starting ether dinitrile and $NaBH_4$-Raney nickel as reducing reagent. Crude product was obtained in 79% yield. TLC R_f = 0.22. ESI-MS m/z = 221.2 $[M + H]^+$ (calc. 221.2).

*Synthesis of 2,2,3,3,11,11,12,12-Octadeutero-4,7,10-trioxa-1,13-tridecanediamine (**4d**) with $NaBH_4$−$CoCl_2$·6H_2O Catalyst.* To a stirred mixture containing **3d** (1.32 g, 6 mmol), $CoCl_2$·6H_2O (5.71 g, 24 mmol), and MeOH (60 mL) was added $NaBH_4$ (4.54 g, 120 mmol) in portions at room temperature over 15 min. The mixture was allowed to stir for 1 h. 6 N hydrochloric acid (15 mL) was added to dissolve the black precipitate formed (Co_2B), and then the mixture was made basic with 8 N NaOH (8 mL). The $Co(OH)_2$ precipitate and MeOH were removed by filtration and rotary evaporation, respectively. To the residue was added solid KOH (16 g), and the slurry was extracted with ether (40 mL × 4). The combined extracts were dried over Na_2SO_4 and evaporated to remove ether. A light yellow oil (1.0 g, 73%) was obtained. TLC R_f = 0.22. ESI-MS m/z = 229.3 $[M + H]^+$ (calc. 229.2). There were two impurity peaks, m/z = 212.3 and 440.6 $[M + H]^+$, which corresponded to the cyclic amine $O(CH_2CH_2OCD_2CD_2CH_2)_2NH$ (calc. 212.2), and the dimer of ether diamine **4d** $[H_2NCH_2CD_2CD_2O(CH_2CH_2O)_2CD_2CD_2CH_2]_2NH$ (calc. 440.5). The crude product was used for the next step of synthesis without vacuum distillation because the sample was too small to distill.

Ether diamines **4c**, **4a**, and **4b** were prepared by the same procedure as **4d** using $NaBH_4$−$CoCl_2$·6H_2O catalyst in yields 61−65%. TLC showed all three diamines had similar R_f values (0.22). ESI-MS m/z: for **4c**, 221.2 $[M + H]^+$ (calc. 221.2); for **4a**, 177.2 $[M + H]^+$ (calc. 177.2); for **4b**, 182.8 $[M + H]^+$ (calc. 183.2). ESI-MS also showed two impurities in the reduction products, which were cyclic amines and dimers of the ether diamine.

Solid-Phase Synthesis of *N*-(Amino-oxa-alkyl)-biotinamide. *N-(13-Amino-2,2,3,3,11,11,12,12-octadeutero-4,7,10-trioxatridecanyl)biotinamide (**7d**).* A solution of **4d** (0.99 g, 4.3 mmol) in 4 mL of CH_2Cl_2 was added to 254 mg, 0.43 mmol of 2-chlorotrityl chloride resin in a 30 mL reaction vessel having a glass frit (Peptides International, Inc., KY). The vessel was flushed with N_2 and then shaken at room temperature for 2 h. The reaction mixture was filtered, and the diamine-loaded resin was washed with CH_2Cl_2, MeOH, 20%DIEA in NMP, and NMP (15 mL × 4, each). The filtrate and CH_2Cl_2 washings were collected and treated with solid KOH followed by rotary evaporation to recover the unreacted **4d**. To the washed resin were added 2 M DIEA in NMP (1.29 mL, 2.58 mmol), 0.45 M HBTU/HOBt in DMF (4.5 mL, 2 mmol), and biotin (0.525 g, 2.15 mmol) in a mixed solvent of DMSO and NMP (vol ratio 1:1, 12 mL). The reaction vessel was flushed with N_2 and shaken at room temperature for 24 h, after which the Kaiser test was negative. The resin was separated by filtration and washed with a 1:1 (vol) solution of DMSO and NMP, NMP and CH_2Cl_2 (15 mL × 3, each). Compound **7d** was cleaved from resin with 20 mL of a cocktail solution containing TFA, CH_2Cl_2, and TIS in a volume ratio of 16:4:1. The reaction mixture was flushed with N_2 followed by shaking at room temperature for 2 h. The resin was removed by filtration, and the solvents were evaporated. The residue was extracted with ether (100 mL × 2), dissolved in H_2O (50 mL), and lyophilized. The crude **7d** was purified by preparative HPLC, using isocratic 5% solvent B for 30 min, then a linear gradient from 5% to 30% B in 330 min at a flow rate of 15 mL/min. After lyophilization, a colorless viscous liquid (57 mg) was obtained in 24% yield. HPLC showed only one peak at retention time (R_t) 18.65 min using isocratic 5% solvent B for 2.5 min, then a linear gradient from 5% to 30% B in 27.5 min at a flow rate of 1 mL/min. TLC R_f = 0.36. ESI-MS m/z = 455.4 $[M + H]^+$ (calc. 455.3).

N-(Amino-oxa-alkyl)biotinamides **7c**, **7a**, and **7b** were also prepared as **7d** with the above procedure using diamines **4c**, **4a**, and **4b** as starting materials, respectively. For **7c**: yield 18%, HPLC R_t = 18.65 min, TLC R_f = 0.38. ESI-MS m/z = 447.4 $[M + H]^+$ (calc. 447.3). For **7a**: yield 22%, HPLC R_t =16.88 min (obtained on a 130A Separation System of Applied Biosystems using Vydac 218TP52 column; running isocratic 10% B for 16 min and then a linear gradient 10−70% B for 30 min at a flow rate of 0.2 mL/min). TLC R_f = 0.37. ESI-MS m/z = 403.3 $[M + H]^+$ (calc. 403.2). For **7b**: yield 16%, HPLC R_t = 16.71 min (as done previously for **7a**), TLC R_f = 0.36. ESI-MS m/z = 409.5 $[M + H]^+$ (calc. 409.3).

Iodoacetylation of *N*-(Amino-oxa-alkyl) Biotinamide. *N-(13-Iodoacetamido-2,2,3,3,11,11,12,12-octadeutero-4,7,10-trioxa-tridecanyl)biotinamide (**8d**, ICAT-d_8).* To a solution of **7d** (55 mg, 0.097 mmol) in DMF (1 mL) was added DIEA (37 μL, 0.213 mmol) and a solution of

iodoacetic anhydride (37.7 mg, 0.107 mmol) in DMF (2 mL). The mixture was flushed with N_2 and stirred at room temperature for 3 h. The solvent was removed by rotary evaporation. The crude product was purified by preparative HPLC using isocratic 5% B for 50 min, then a linear gradient of 5−50% solvent B in 340 min at a flow rate of 15 mL/min. A light yellow solid was collected in a yield of 63% after lyophilization of the peak fractions. Analytical HPLC showed only one peak with a $R_t = 15.55$ min using isocratic 5% solvent B for 2.5 min, then a linear gradient of 5−60% solvent B for 27.5 min at a flow rate of 1 mL/min. TLC $R_f = 0.60$. ESI-MS $m/z = 623.3$ $[M + H]^+$ (calc. 623.2).

8c (ICAT-d_0), **8a** (s-ICAT-d_0), and **8b** (s-ICAT-d_6) were also prepared as **8d** (ICAT-d_8) with the above procedure using **7c**, **7a**, and **7b** as starting materials, respectively. For **8c**: yield 57%, HPLC $R_t = 15.61$ min, TLC $R_f = 0.60$, ESI-MS $m/z = 637.3$ $[M + Na]^+$ (calc. 637.2). For **8a**: yield 55%, HPLC $R_t = 22.78$ min (obtained on a 130A Separation System of Applied Biosystems using a Vydac 218TP52 column; running isocratic 10% B for 16 min and then a linear gradient 10−70% B for 30 min at a flow rate of 0.2 mL/min). TLC $R_f = 0.61$, ESI-MS $m/z = 571.3$ $[M + H]^+$ (calc. 571.1). For **8b**: yield 50%, HPLC $R_t =$ 22.56 min (as done previously for **8a**), TLC $R_f = 0.61$, ESI-MS $m/z = 599.4$ $[M + Na]^+$ (calc. 599.2).

RESULTS AND DISCUSSION

Synthesis of ICAT Compounds. As shown in Scheme 1, two pairs of ICAT compounds were prepared: one is compounds **8c** and **8d**, the classic ICAT-d_0 and ICAT-d_8 (*7*); the ICAT-d_8 was prepared from acrylonitrile-d_3 and di(ethylene glycol-d_2). Another pair is compounds **8a** and **8b**, termed s-ICAT-d_0 and s-ICAT-d_6 as they have a shorter linker than the classic one. The s-ICAT-d_6 was prepared with nondeuterated acrylonitrile and fully deuterated ethylene glycol as starting materials. The preparation of s-ICAT-d_0 and s-ICAT-d_6 was intended to lower the cost of the procedure. The use of acrylonitrile instead of its fully deuterated analogue may reduce the cost of starting materials by about 5-fold.

Synthesis of ICAT compounds began with the reaction of ethylene glycol or di(ethylene glycol) **1a**, **1b**, **1c**, and **1d** with acrylonitrile **2a** and **2b** to form ether dinitrile **3a**, **3b**, **3c**, and **3d** by Michael addition in benzene (*16*). After removal of solvent, the desired compounds were obtained in yield of 96% or higher and with good purity as shown on TLC (only one spot with R_f values around 0.65). These ether dinitriles were used in the next reaction without further purification.

Reduction of deuterated ether dinitrile to diamine is one of the crucial reactions in the synthesis because it may involve loss of deuterium by exchange with hydrogen. Gerber et al. prepared ether diamine **4d** by hydrogenation of ether dinitrile **3d** with Raney Ni catalyst (*14*). They found that the product was obtained in very low yield and with considerable exchange of deuterium (*17*). We also tried a mixture of Raney Ni and $NaBH_4$ to reduce **3d** to **4d**. The product was obtained in 53% yield after vacuum distillation. However, ESI-MS showed the main peak was diamine-d_6 ($m/z = 227.3$ $[M + H]^+$); about one-fourth of deuterium on the molecule was replaced by hydrogen during reduction. When the ratios of Ni and $NaBH_4$ to dinitrile were increased by 50%, the main peak in ESI-MS was diamine-d_4; the deuterium loss increased to 35%. These results of reduction and hydrogenation catalyzed by Raney Ni indicated that nickel may be responsible for deuterium loss in the reactions. Horner (*18*) investigated the H−D exchange process on Raney nickel in toluene. When Raney nickel was shaken for 16 h with a solution of toluene in cyclohexane under a deuterium atmosphere, hydrogen atoms both in the aromatic ring and in the methyl group of toluene could be exchanged by deuterium.

To overcome the problem, we tried several non-nickel-catalyzed reduction systems such as $LiAlH_4$ (*19*), AlH_3 (*20*), $H_3B{\cdot}S(CH_3)_2$ (*21*), and $NaBH_4-CoCl_2$ (*22*). We found that the best result was obtained with $NaBH_4-CoCl_2$. Satoh et al. first reported that nitriles could be easily reduced to primary amines with sodium borohydride-transition metal salts (e.g., $CoCl_2$) systems in MeOH (*22*). Ganem et al. studied the mechanism of $NaBH_4-CoCl_2$ reduction and concluded that the Cobalt boride formed in situ served as a true catalyst, strongly coordinating nitriles and activating them toward reduction by $NaBH_4$ (*23*, *24*). Dinitriles **3a**, **3b**, **3c**, and **3d** were reduced to diamines **4a**, **4b**, **4c**, and **4d** with $NaBH_4-CoCl_2$ in MeOH at room temperature. The reaction gave the desired products in 61−74% yields, and ESI-MS showed appropriate molecular weight with little loss of incorporated deuterium from deuterated diamines. Two impurities in the crude products were identified by ESI-MS as cyclic amines and dimers of diamine. These secondary amine byproducts are often seen in the reduction of nitriles when the reactions proceed stepwise (*19*, *25*). The crude diamines were used in the next step of synthesis without distillation.

Biotinylation of the symmetrical diamines is another crucial step in ICAT synthesis. Wilbur et al. prepared *N*-(13-amino-4,7,10-trioxatridecanyl)biotinamide, compound **7c**, by acylation of ether diamine **4c** with biotin tetrafluorophenyl ester in DMF in the presence of triethylamine (*26*). Aebersold et al. used this method to prepare its deuterated analogue **7d** in their study of ICAT reagent (*7*). A large excess of ether diamine must be used in this method to minimize formation of bis-biotin derivative of diamine. The excess of unreacted diamine is difficult to recover from the reaction mixture and results in a significant loss of diamine. Recently, Patel and Perrin described a new method to prepare **7d** (*15*). An orthogonally protected di(ethylene glycol)-d_8 linker was first prepared, and the linker was then extended by successive introduction of protected propylamine fragments. A monoamine was obtained by chemoselective deprotection and coupled with biotin pentafluorophenyl ester in DMF in the presence of DIEA. This method overcame the problem associated with the bis-biotinylation of diamine. However, the process involved a large number of reaction steps.

We wish to report a solid-phase biotinylation of diamine compounds. A 2-chlorotrityl chloride resin is loaded with 10 equiv of diamine relative to the resin in CH_2Cl_2. The reaction mixture was filtered, and the unreacted diamine was recovered by treatment of the filtrate with solid KOH to remove HCl followed by rotary evaporation to remove CH_2Cl_2. Because the loading reaction involved only resin, diamine, and CH_2Cl_2, the diamine could be recovered in quantitative yield. Biotinylation of the resin-bound amine was effected with 5 equiv of biotin relative to the resin in a solvent mixture of NMP, DMF, and DMSO in the presence of DIEA and HBTU/HOBt. The biotinylated amine was cleaved from resin with a cocktail containing TFA, CH_2Cl_2, and TIS in a volume ratio of 16:4:1. The crude product was purified by preparative HPLC. The biotin derivative of diamines **7a**, **7b**, **7c**, and **7d** were prepared by this

[a] The samples were stored under a nitrogen atmosphere at −20 °C for 1 year.

method from **4a**, **4b**, **4c**, and **4d**, respectively, in overall yields of 16−24% for the three steps of solid-phase synthesis. The low yield was caused by use of crude diamine in the synthesis. Compound **7c** was obtained in 43% yield if reagent diamine (Aldrich) was used. Analysis by HPLC, TLC, and ESI-MS showed the compounds to be quite pure and to have the correct molecular weight. Solid-phase synthesis overcame the problem of formation of bis-biotin derivative and difficult recovery of diamine and made the synthetic process simpler and easier.

Iodoacetylation of mono-biotinylated amine, the last step of ICAT synthesis, was carried out with iodoacetic anhydride in DMF in the presence of DIEA (*7*). After purification by HPLC, compounds **8d** (ICAT-d_8), **8c** (ICAT-d_0), **8b** (s-ICAT-d_6), and **8a** (s-ICAT-d_0) were obtained from **7d**, **7c**, **7b**, and **7a**, respectively, in yields of 50−63%. ESI-MS gave appropriate molecular weights with little loss of incorporated deuterium. TLC and HPLC analysis showed good purity for **8d** and **8**c and **a** considerable amount of dimeric sulfonium salts in **8a** and **8b**, which were formed during HPLC purification.

Self-Alkylation of ICAT Compounds. There are two functional groups in an ICAT molecule, dialkyl sulfide of biotin on one end and iodoalkyl of iodoacetamide on another end. Dialkyl sulfides are sufficiently nucleophilic to react with primary alkyl halides under mild conditions, frequently simply by mixing the reagents at room temperature (*27*). Thus, ICAT compounds may undergo self-alkylation between the dialkyl sulfide and iodoalkyl group, to give dimeric sulfonium salt by intermolecular alkylation and cyclic sulfonium salt by intramolecular alkylation (Scheme 2).

The self-alkylation of ICAT compounds results in a stability problem of the ICAT reagent. No dimeric or cyclic sulfonium salts were found by HPLC and ESI-MS in the crude product, most likely because the last step of ICAT synthesis was carried out in a nonaqueous medium and in the presence of a base (DIEA). Some dimeric sulfonium salts were formed during HPLC purification in a mixed solvent of acetonitrile and water with 0.1% TFA. The two s-ICAT compounds formed dimeric sulfonium salts more readily than the longer one, and it was difficult to obtain a pure product by HPLC in this solvent system. The undesired self-alkylation reaction proceeded not only in an aqueous solution but also in their solid state. Table 1 shows the analysis of ICAT samples which were stored at −20 °C for about 1 year. The HPLC and ESI-MS data demonstrated that about one-third to one-half of ICAT compounds were converted into dimeric sulfonium salts and a tiny amount of cyclic sulfonium salts.

The stability of ICAT compounds in different solvent systems was examined using s-ICAT-d_0 as an example.

Table 2. Effect of Different Solvent Systems on Stability of s-ICAT-d_0

days of storage at room temp	dimeric sulfonium salt %, HPLC				
	water 75% CH_3CN 25% TFA 0.1%	water 75% CH_3CN 25% NH_4OAc 0.01 M	water 67% MeOH 33% NH_4OAc 0.01 M	water 67% MeOH 33%	MeOH
0	32.1	32.4	34.3	33.1	32.6
4	39.3	37.9	36.7	36.5	20.0
14	57.4	54.9	46.3	47.9	11.5

Table 3. Regeneration of ICAT Compounds from Their Dimeric Sulfonium Salts (DSS) in MeOH

days of storage at room temp	composition %, HPLC							
	ICAT-d_8		ICAT-d_0		s-ICAT-d_6		s-ICAT-d_0	
	ICAT	DSS	ICAT	DSS	ICAT	DSS	ICAT	DSS
0	59.9	40.1	63.3	36.7	52.3	47.7	67.4	32.6
5	78.0	22.0	86.1	13.9	69.0	31.0	83.2	16.8
11	83.4	16.6	89.1	10.9	75.3	24.7	87.2	12.8
19	85.4	14.6	91.5	8.5	78.8	21.2	90.7	9.3
34	88.8	11.2	93.7	6.3	85.5	14.5	92.9	7.1
70	93.0	7.0	95.6	4.4	89.6	10.4	94.4	5.6

The results are in Table 2. The content of dimeric sulfonium salt was increased by 12.0−25.3% in all of the solvent systems containing water during 2 weeks of storage at room temperature. Neither the acidic buffer nor the neutral buffer showed any significant effect on reaction rates of self-alkylation in the mixed solvents used. The most interesting observation was the behavior of s-ICAT-d_0 in pure MeOH. Instead of self-alkylation, its dimeric sulfoniun salt was dealkylated into its monomer form at a quite rapid rate. The content of dimeric sulfonium salt was decreased from 32.6% to 11.5% in 2 weeks of storage in MeOH. This fact demonstrates that the self-alkylation reaction of ICAT compounds is reversible; the sulfonium salt can be dealkylated by the iodide ion, leading to the regeneration of ICAT compounds.

Both self-alkylation of ICAT compounds and dealkylation of its sulfonium salt are nucleophilic substitution reactions. The solvent that is used in a nucleophilic substitution reaction can have a profound effect on the rate of the reaction (*28*). In reactions in which product formation is favored by charge development in the transition state, solvents of high dielectric constant favor the process; conversely, in reactions in which reduction or dispersal of charge in the transition state favors product formation, solvents of low dielectric constant will favor the process. Thus, self-alkylation of ICAT compounds is greatly accelerated by solvents of high dielectric constant because charge is developed in the transition state and product; the dealkylation of ICAT sulfonium salts involving negatively charged nucleophiles, on the other hand, takes place more rapidly in solvents of low dielectric constant. Water has a much higher dielectric constant than MeOH (78 vs 33). Therefore, the equilibrium of the reversible reaction of ICAT self-alkylation will shift in favor of formation of the sulfonium salt in the solvent systems containing water and shift in favor of dealkylation in MeOH.

The conversion of ICAT sulfonium salts into their monomer forms in MeOH was further demonstrated by all four ICAT compounds studied (Table 3). The contents of dimeric sulfonium salt in the aged ICAT samples were reduced from 32.6% to 47.7% to about 5−10% in 70 days of storage in MeOH at room temperature. The regeneration treatment by MeOH or other solvents of low dielectric constant may provide a useful method for purification of ICAT compounds contaminated by their sulfonium salts.

Optimized Synthesis of Functionalized Fluorescent Oligodeoxynucleotides for Protein Labeling

Charles Goussu,[†,‡] Jean-Jacques Vasseur,[†] Hervé Bazin,[‡] Eric Trinquet,[‡] Fabrice Maurin,[‡] and François Morvan*[,†]

Laboratoire de Chimie Organique Biomoléculaire de Synthèse, UMR 5625 CNRS-UM II, Université de Montpellier II, CC008, Place E. Bataillon, 34095 Montpellier Cedex 5, France, and CIS Biointernational, Marcoule, BP 84 175, 30204 Bagnols/Cèze Cedex, France. Received October 18, 2004; Revised Manuscript Received January 31, 2005

Phthalimido-alkanol solid supports were rapidly prepared from solid supported phthalic anhydride and amino alcohol condensation induced by microwaves. These supports were used to synthesize 5′-fluorescent 3′-aminoalkyl oligodeoxynucleotides allowing a two-step deprotection necessary to avoid aminolink alkylation. After conversion into an NHS derivative using dissuccinimidyl suberate and an optimized isolation, they were conjugated with a protein.

INTRODUCTION

Although the labeling of proteins with fluorescent dyes is well documented and many prelabeled proteins are commercially available, it appears that the quality of the conjugates is not always satisfactory. The most common labeling method involves a selective acylation of an amino function (reaction of activated esters on ϵ-NH_2 from lysines). Since several reactive sites are available on a given protein, the reaction leads to a "statistical labeling" (*1*) resulting in a population of multiple labeled molecules (*2, 3*). The labeling ratio (number of dyes per protein) usually measured from the UV−visible spectrum of the purified conjugate is a macroscopic value corresponding to the average ratio for the population. Organic dyes such as fluoresceins, cyanines, or Alexa are often preferred since they have a minimum impact on the biological properties (e.g. immunoreactivity for a antibody) and the labeling process is straightforward. The state of the art in immunochemistry is to develop, in a reproducible manner, a conjugate in which the unlabeled protein is largely in the minority and most of the molecules bear two or more labels. This has an important impact on the fluorescent properties of the conjugates, since most of fluorescent dyes undergo fluorescence quenching due to the proximity between two dye molecules (*4, 5*). Although some sulfonated Cy5 are claimed to yield conjugates presenting a low level of dye dimerization (*6*) characterized by a reduced hypochromic D-band, we observed a 50% decrease in the quantum yield even at a dye/protein ratio of two for the labeling of IgG with commercial Cy5 *N*-hydroxysuccinimidyl (NHS) ester, following the recommended protocol (Amersham Biosciences) as previously observed by others (*7*) who reported that for a ratio of 2 to 3 Cy5 labels per IgG, some moderate fluorescence was obtained and IgG bearing six Cy5 label was almost nonfluorescent. Furthermore, overlabeling should be avoided since it also has a negative impact on the biological activity (binding constants) of macromolecules.

For all these reasons, it is highly desirable to find a way to avoid any detrimental interaction between individual fluorophores coupled to the same molecule. A few methods are known to ensure the controlled labeling of native proteins as antibodies, one possibility being the use of cyclodextrin−dye complex which allow multiple labeling with minimum fluorescence quenching (*8*). An alternative is the use of a fluorescent dye substituted by an oligonucleotide (ODN) moiety bearing a reactive linker enabling the conjugation of this probe to a target protein (*9*). For this unconventional application of ODNs, one needs is an efficient way to obtain doubly modified ODN bearing for example a Cy5 dye on its 5′-end and an aminoalkyl linker on its 3′-end. For routine labeling, these doubly modified ODNs should be readily available and it should be confirmed that the amino group is indeed fully unprotected and free of side-products. A linker bearing a primary amino group was chosen since it is the most versatile and can be converted into many reactive groups used in immunochemistry (e.g. NHS ester, maleimide, thiol, etc.) through the use of a panoply of homobifunctional reagents (e.g. dissuccinimidyl suberate, DSS) (*10*) or heterobifunctional reagents (e.g. succinimidyl *trans*-4-(*N*-maleimidylmethyl)cyclohexane-1-carboxylate: SMCC) which are widely used in immunochemistry and are commercially available.

ODNs with 3′-aminoalkyl arms are conveniently prepared through standard solid-phase synthesis on a 3′-amino-protected support which releases the free 3′-amino during the final deprotection (*11*−*15*). The 3′-amino support based on an immobilized 3-nitro-6-succinyloxymethylbenzoyl group (*15*) or an immobilized phthalimido protective group (*16*) is particularly attractive since it releases an enantiomerically pure ODN (as compared to some amino links (*12*) which give rise to resolvable diastereoisomers). Unfortunately, the former was synthesized with a very low yield from 6-nitrophthalide and *O*-(4,4′-dimethoxytrityl)-1-hexanol-6-amine. A solid support from phthalimido groups exhibits two main advantages: it cannot react with acetic anhydride during the capping step of the elongation process, and furthermore, the cyanoethyl groups can be removed from the support before the phthamilido cleavage, avoiding the reaction

3	**2**+ $NH_2(CH_2)_2OH$	150	150 °C	**3b**	67 μmol/g
4	**2**+ $NH_2(CH_2)_3OH$	150	150 °C	**3c**	59 μmol/g

of acrylonitrile with the free amine (*17*). Unfortunately, this support is expensive and its preparation requires three steps, with a crystallization and a chromatography step, to obtain the *p*-nitrophenyl active ester in 47% yield after which then reacts poorly with LCAA CPG (long chain aminoalkyl-controlled pore glass) to give a loading of only 20 μmol/g (*16*).

We developed a very convenient, rapid, and efficient synthesis of phthalimido alkyl alcohol solid supports. All the reactions were performed on the solid support; hence, workups consisted of only filtrations and washes. Several free alkyl alcohols reacted on the immobilized phthalic anhydride to give the corresponding solid supports with high loading (~60 μmol/g). Indeed, the hydroxyl function does not need to be protected since the reaction is chemoselective. From the solid support, 5′-fluorescent 3′-alkylamino ODN was synthesized, and by an optimized procedure it was conjugated with an antibody.

EXPERIMENTAL SECTION

Measurement of Cy5 Dye Concentrations. For sulfonated Cy5 dye and conjugates, the concentration were measured from the absorbance values at λ_{max} assuming a molar extinction coefficient of 250 000 M^{-1} cm^{-1} according to the product data sheet (Amersham Biosciences Cy5 monoreactive dye # PA25001) and literature (*18*). For nonsulfonated Cy5 dye linked to oligonucleotides, the concentrations was measured at λ_{max} assuming a molar extinction coefficient of 250 000 M^{-1} cm^{-1} according to the product data sheet (Amersham Biosciences Cy5 phosphoramidite).

Preparation of Phthalimido Alkyl Alcohol Solid Supports. One gram of LCAA-CPG (Sigma), pretreated for 2 h with 3% TCA in CH_2Cl_2 (*19*), was gently shaken with 63.2 mg (0.3 mmol) of 1,2-anhydrotrimellitic chloride and 105 μL (0.6 mmol) of diisopropylethylamine in 5 mL of CH_2Cl_2 for 3 h. The resin was filtered off, washed with CH_2Cl_2 and ether, and dried under vacuum. The resin was treated for 2 h with 10 mL of a mixture of Ac_2O, pyridine, THF (1:1:8, v/v/v) (Cap A) and 10% *N*-methylimidazole in THF (Cap B). The resin was filtered off, washed with CH_2Cl_2 and ether, and dried under vacuum. The resulting resin was mixed with 0.3 mmol of amino alcohol in 5 mL of DMF and heated in a microwave synthesizer (Discover from CEM Corporation) set at 300 W and 200 °C for 150 s, or in a domestic MW oven at 650 W for 6 × 20 s with a cooling of the mixture between two runs. The resin was filtered off, washed with CH_2Cl_2 and ether, and dried. Approximately 20 mg of the solid support was poured into a column, and then a standard thymidine phosphoramidite was incorporated and detritylated. The loading was determined at 498 nm by the assay of the dimethoxytrityl cation released. (Table 1).

Synthesis of 5′-Cy5,3′-Aminoalkyl Oligonucleotides. From the phthalimido alkyl alcohol solid support (1 μmol), the ODN was synthesized on a ABI 394 DNA synthesizer using standard reagents and 15 equiv of commercially available phosphoramidites. A standard elongation cycle was applied except that the first detritylation step was omitted since the solid support is hydroxyl free. Then, the Cy5 phosphoramidite (Amersham Biosciences) was incorporated using a coupling step of 120 s to ensure optimum coupling. Next, a treatment with a solution of 10% piperidine in CH_3CN was applied for 10 min to remove the cyanoethyl groups. After washes with CH_3CN, the supported ODN was treated overnight with aqueous concentrated ammonia in the dark. Ammonia was removed by evaporation under reduced pressure to yield a dark blue solution. Finally, the fluorescent aminoalkyl ODN was purified by HPLC on a Delta Pak column (Waters) 15 μm, C18, 100 Å, 7.8 × 300 mm, using a gradient of CH_3CN in 50 mM TEAAc, pH 7, 2 mL/min (Figure 2). UV-visible spectrum for Cy5-T_{15}-$(CH_2)_6$ NH_2 (0.1 M phosphate buffer, pH 7) λ_{max} = 265 600 (sh), 646 nm, $A_{265}/A_{646} = 0.639$, $A_{280}/A_{650} = 0.417$, $A_{600}/A_{650} = 0.38$.

MALDI-TOF Mass Spectrometry. MALDI-TOF mass spectra were recorded on a Voyager DE mass spectrometer (Perseptive Biosystems, Framingham, MA) equipped with an N_2 laser (337 nm). MALDI conditions are as follows: laser power 2400 (arbitrary units); accelerating voltage 24 000 V; guide wire 0.05% of accelerating voltage; grid voltage 94% of accelerating voltage; delay extraction time 550 ns and 100 scans averaged. All reported spectra here were obtained in negative ion mode and were not smoothed. THAP (trihydroxyacetophenone) as matrix; T_6-$(CH_2)_6$ NH_2 *m/z* for $C_{66}H_{92}N_{13}O_{43}P_6$: Calcd 1941.38; Found 1941.82; T_{15}-$(CH_2)_3NH_2$ *m/z* for $C_{153}H_{203}N_{31}O_{106}P_{15}$: Calcd 4637.08; Found 4633.78; Cy5-17mer-$(CH_2)_6$ NH_2: *m/z* for $C_{204}H_{258}N_{79}O_{98}P_{18}$: Calcd 5941.33; Found 5942.40.

Labeling of Antibody with Reference Cy5 Dye. The antibody to be labeled was dialyzed against pH 9 0.1 M carbonate–bicarbonate buffer and the concentra-

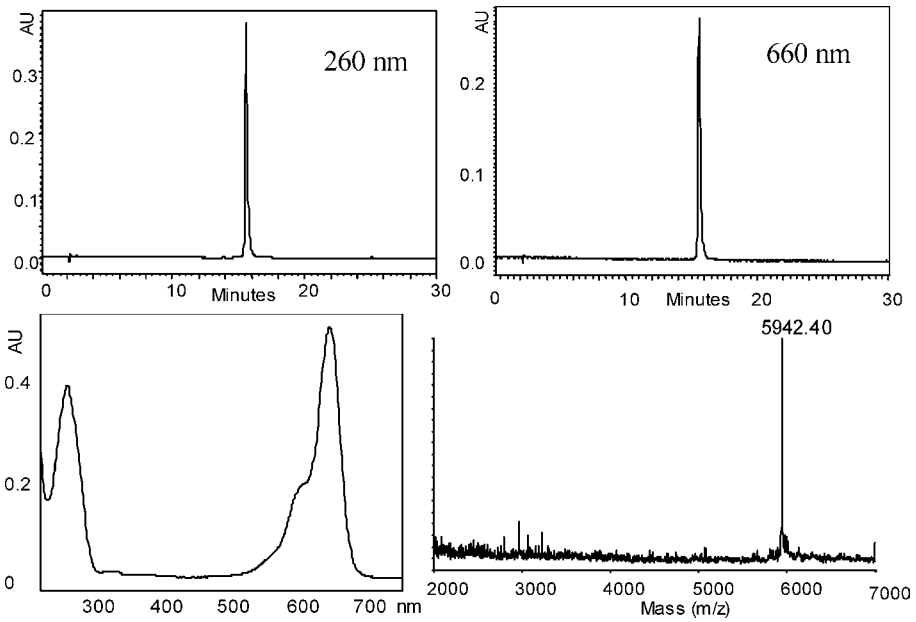

Figure 2. HPLC profiles at 260 and 660 nm of purified Cy5-GCG AAA AAA AAA AGC TC-$(CH_2)_6$-NH_2, UV/visible spectrum and MALDI-TOF mass spectrometry.

tion adjusted to 1 mg/mL. The NHS-activated Cy5 dye ('to label 1 mg of protein" Amersham Biosciences kit) was dissolved in DMSO, and several labeling reactions were performed, varying the number of equivalents of Cy5 added. After 30 min, the reaction mixture was separated by gel filtration over SD 200 in an HR10/30 column (Amersham Biosciences), eluting at 1 mL/min in 0.1 M phosphate buffer, pH 7. The protein concentrations in the void volume were calculated from A_{280} according to ϵ_{280} = 210 000 M^{-1} cm^{-1} for the antibody, taking into account the contribution of the Cy5 dye at 280 nm (0.05 × A_{650}) according to the manufacturer's instruction and literature (*18*). The dye over protein ratio (D/P) and the A_{600}/A_{650} ratio were calculated as previously described (*7*).

Conjugation of Cy5-oligonucleotides with Antibody. Starting with the 5′-Cy5 labeled ODN bearing a 3′ aminolinker (10 nmol) in 12 μL of 50 mM N−(3-sulfopropyl) morpholine (MOPS) pH 7.0, we added 4 μmol of DSS in 28 μL of DMF (Fluka), and the mixture was kept under vigorous mixing (Eppendorf vortexer) either at 20 °C for 5 h or at 4 °C for 16 h. The conversion into active ester was monitored by RP-HPLC for example the 5′-Cy5-$(dT)_{15}$-3′-hexylamine (Rt = 15 mn) gave the corresponding NHS-suberate derivative (Rt = 16.1 mn). Column Lichrospher RP-18 E 5 μm 125 × 4 mm, elution 1 mL/min, gradient 9.5% to 50% of CH_3CN in 25mM TEAAc in 30 min. The reaction mixture was then loaded on a NAP 5 column (Amersham Biosciences) equilibrated in 10 mM MOPS pH 6.0 (4 °C) to remove the excess DSS, and the exclusion fraction (1 mL) collected in a 2 mL eppendorf was then extracted by 1 mL of *n*-Butanol (vortexing, centrifuging and pipeting off the upper phase). The process was repeated three times and a fourth time after the addition of 1.5 mL *n*-Butanol and 2 min centrifuging (14 000 rpm) the Cy5-ODN-NHS ester was precipitated as a blue spot. The supernatant was removed and the precipitate was dried under vacuum (5 min, speed-Vac). This Cy5-ODN-NHS ester can be kept dried at −80 °C (or even −20 °C) for a few days with limited decomposition. The antibody (300 μg, 2 nmol) was added to the Cy5-ODN-NHS in 35 μL of 0.1 M sodium carbonate buffer pH 9, the reaction mixture was kept at room temperature for 30 min and then loaded on an HR10/30 Superdex 200 column (Amersham Biosciences). The elution was carried out with 0.1 M phosphate buffer pH 7, the fastest blue band (t_R = 10 min) containing the conjugate was collected and was well resolved from the excess of Cy5-ODN (t_R = 17 min). An initial Cy5-ODN-NHS/IgG ratio of 4 gave a conjugate (62% yield) for which the UV−visible spectrum (A_{650} = 0.286, A_{600} = 0.103, A_{280} = 0.236) indicated the conjugate contained an average of two cyanines (Cy5) per antibody. An initial Cy5-ODN-NHS/IgG ratio of 12 gave a conjugate (49% yield) for which the UV−visible spectrum (A_{650} = 0.463, A_{604} = 0.168, A_{280} = 0.283) indicates that the conjugate contained an average of five cyanines (Cy5) per antibody. The contribution at 280 nm due to the Cy5-T_{15} moiety is 0.435 × A_{650}. For long-term storage, 0.1% BSA (Sigma Bovine Serum Albumin "protease free") was added as stabilizer, and aliquots were stored at −20 °C. The conjugates (ca. 150 pmol) were analyzed on a Superdex 200 column connected to a diode array detector, and a single peak was detected for the conjugates in both conditions (t_R = 12 min for 5(Cy5-T_{15})−Ab and t_R = 12.7 min for 5(Cy5-T_{15})−Ab), the native antibody being eluted at t_R = 13.6 min. The conjugates were well resolved from the excess of hydrolyzed Cy5-ODN labeling reagent, so the A_{650}/A_{280} ratio could be used with confidence to assess the average number of Cy5 moieties covalently bound to the antibody. Furthermore, analysis of the conjugates by size exclusion chromatography showed a single species absorbing at 650 nm, and although the population of labeled antibodies was not resolved, the retention time (centroid of the population) had a tendency to become shorter when increasing the number of Cy5 moieties bound to antibodies.

Fluorescence Measurements. All measurements were performed in 0.1 M phosphate buffer, pH 7, at 20 °C. The Cy5-T_{15} used as reference and the two conjugates 2(Cy5-T_{15})−Ab and 5(Cy5-T_{15})−Ab obtained above were diluted (triplicates) to 100 nM chromophore concentration (A_{650} = 0.025) according to the A_{650} measured for the mother solutions. The fluorescence spectra were recorded on a LS50 fluorimeter, the excitation being set at 640 nm (10 nm slit), and scanning at 650−750 nm (5 nm slit). For each compound, the acquired spectra (triplicates) were averaged.

Scheme 1. Synthesis of Phthalimido Alkyl Solid Support[a]

RESULTS AND DISCUSSION

Since solution-phase synthesis requires time-consuming workup and purification, we developed a strategy on solid support using only commercially available reagents. Thus, the preparation of the phthalimido solid supports was convenient, easy, inexpensive, fast, and also versatile since any aminoalkyl alcohol or amino-PEG-alcohol (e.g. 2-(2-aminoethoxy)ethanol)) could be anchored. This method was applied to the preparation of phthalimido-ethyl, -propyl, and -hexanyl alcohol solid supports. Finally, using the phthalimido-hexanol solid support, a 5′-fluorescent 3′-amino ODN was synthesized, converted into an NHS derivative, and then conjugated with an antibody.

The solid supports **3a**−**c** were prepared in two steps (Scheme 1). The first step was the reaction of 1,2-anhydrotrimellitic acid chloride **1** (0.3 mmol) on CPG-LCAA (*19*) (1 g) to yield the phthalic anhydride CPG **2** within 3 h (*14, 20*). The resin was filtered off, washed, and dried. Unreacted amines were capped with commercial Cap A and Cap B solutions for 2 h. The resin was filtered off, washed, and dried. The key step was the formation of a phthalimido function which was performed under microwave irradiation (MW). It should be noted that a partial reaction yielding an amide linkage must be avoided since its hydrolysis under basic conditions is very long ($t_{1/2}$ = 17 500 h at 0.1 M NaOH at 30 °C) (*21*). Reactions of phthalic anhydride with amine occur with or without solvent by conventional heating (175−225 °C) (*16*) or by MW (*22, 23*). Note that the reaction is chemoselective since it occurs specifically with the amino moiety. In addition it was reported that reaction of phthalic anhydride with 6-amino-1-hexanol is faster when it occurred by MW than under conventional heating (*23*). Theoretically, since 6-amino-1-hexanol is a solid with a low melting point (56−58 °C), it could be used without solvent. In our case, to optimize the interaction between the solid supported phthalic anhydride and the 6-amino-1-hexanol, and later with the other alkylamino alcohol, DMF was selected as solvent. Reactions were performed with 0.3 mmol of alkylamino alcohol per gram of solid-supported phthalic anhydride **2** in 5 mL of dry DMF.

The reaction was first performed using a domestic MW oven (650W full power) by 6 × 20 s with a cooling of the mixture between two runs (to avoid bumping and spillage), yielding the expected solid support **3a** with a fairly high loading of 49 μmol per gram of resin (Table 1, entry 1). Initially, the loading was determined by dimethoxytritylation of a support sample followed by its detritylation and assay of the trityl cation at 498 nm. This method was deemed inefficient, because it was time-consuming and poorly reproducible. Thus, a coupling with commercial thymidine cyanoethyl diisopropylphosphoramidite was preferred, and the loading was determined from the cation released during a detritylation step. This method is fast and gives reproducible values. The reaction was also performed in a sealed tube using a microwave synthesizer with the temperature set at 200 °C, 300 W for 150 s (Table 1, entry 2).

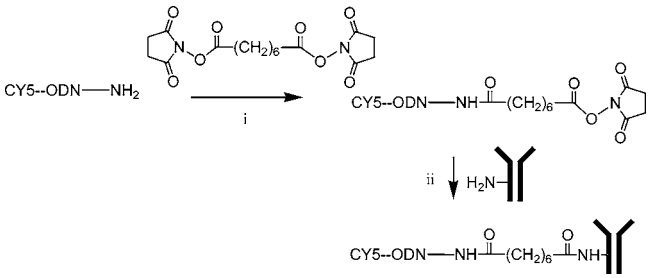
Next, the reaction was extended to ethanolamine and 3-amino-1-propanol, setting the microwave synthesizer at 150 °C, 300 W for 150 s (Table 1, entries 3 and 4). For all the solid supports, a similar loading was obtained around 60 μmol/g, demonstrating that reaction is fast and efficient.

The use of a microwave synthesizer for the preparation of the phthalimido-alkanol solid support is convenient and gives reproducible results and high loading. However, this solid support could also be prepared using a common domestic MW oven with a slightly lower but still high loading (49 μmol/g). Using this procedure, all the steps were performed on solid supports that allow rapid and easy workups. The use of MW speeds up the reaction, and several new solid supports were prepared in less than 1 day using inexpensive, commercially available reagents.

To evaluate the properties of the resins, a few short ODN T_6-NH_2 were synthesized on these various supports (Figure 1A), and for each the same trend was observed in the HPLC profiles. Longer ODNs were synthesized as T_{15}-$(CH_2)_3$-NH_2 (Figure 1B) and also a hetero ODN [5′-Cy5-d(GCG AAA AAA AAA AGC TC_3-$(CH_2)_6$-NH_2)], labeled with the cyanine Cy5 on its 5′ position (Figure 2). The syntheses were carried out on a 1 μmol scale using 15 equiv of phosphoramidite and regular reagents on an ABI 394 DNA synthesizer. The first detritylation step was omitted. The average yield was better than 98.5%. ODNs were deprotected by a two-step procedure. First, cyanoethyl groups were removed by a piperidine treatment (*24*) (10% piperidine in acetonitrile for 10 min at room temperature and washing) to remove the resulting acrylonitrile that could further react with the amino function (*17*). Then, on the partially deprotected ODN still attached to the CPG, a treatment with concentrated ammonia at 55 °C for 17 h for unlabeled ODN or 16 h at room temperature in the dark for the Cy5 ODN yielded the fully deprotected 3′-amino ODNs in solution (Figures 1 and 2), which were purified by HPLC. ODNs were characterized by MALDI-TOF MS (see Experimental Section).

The activation of amine-tethered ODN by homobifunctional reagents such as DSS (dissuccinimidyl suberate)

Scheme 2. Conjugation of Fluorescent Alkylamino ODN to Antibody[a]



[a] Reagents and conditions: i: 50 mM MOPS buffer, pH 7, DMF; ii: antibody, $NaHCO_3$ pH 9.

Table 2. A_{600}/A_{650} Ratios of Cy5 Dye−Antibody Conjugates

	Cy5/Ab ratio				
	0.73	1.32	2.64	3.56	5.40
A_{600}/A_{650}	0.353	0.394	0.490	0.592	0.613

[a] For free sulfonated Cy5 the A_{600}/A_{650} ratio is 0.315 (0.1 M phosphate buffer pH 7).

(*10*) or EGS (ethylene glycol−bis-succinic acid NHS ester) (*25*) is reported for the preparation of ODN−enzyme conjugates. However, the protocols described were not found to be satisfactory since the diafiltration process to remove reagent excesses was too slow, and extensive breakdown of the NHS ester was observed by HPLC monitoring. DSS was preferred (Scheme 2) since it is less reactive than EGS. It therefore leads to a more stable and storable ODN-NHS ester, and, as an intermediary, allows conjugation to proteins in a short time at pH 9. Thus, the Cy5-ODN-NH_2 in DMF and MOPS buffer, pH 7, was reacted with DSS. The isolation protocol combines the use of a fast size exclusion column and simple *n*-butanol extractions to yield an Cy5-ODN-NHS ester in a dry state allowing its storage and later use. The overall process can be easily scaled up and is highly reproducible. Finally, the Cy5-ODN-NHS ester was conjugated with antibody (Ab) in a pH 9 sodium carbonate buffer, and the Cy5-ODN−Ab conjugates were isolated by size exclusion chromatography. As reference compounds we prepared several conjugates using commercially available sulfonated Cy5 dye, for the free Cy5 dye in phosphate buffer we observed a A_{600}/A_{650} ratio of 0.315 which is in agreement with previous data (*7*), and as shown in Table 2 this ratio increased with the number of Cy5 dyes bound per antibody as previously reported (*7*). In contrast with the appearance of a higher 600 nm absorbance, increasing with the number of bound Cy5 dyes observed for antibodies labeled with sulfonated Cy5 and the concomitant loss of fluorescence efficiency (*7*), in the labeling strategy presented here we do not observe such a phenomenom. Ideally, the spectrophotometric properties of the dye in Cy5-ODN−antibodies should be compared with the nonsulfonated dye; unfortunately, this one is only available as a phosphoramidite and is not soluble in aqueous buffers, therefore the Cy5-ODN which is the closest related compound available is used as reference. The UV−visible spectrum of the commercial Cy5-phosphoramidite in acetonitrile showed a $\lambda_{max} = 644$ nm which is close to $\lambda_{max} = 645$ nm observed for the Cy5-ODNs in water or buffer; for the Cy5-phosphoramidite, the A_{600}/A_{650} ratio was 0.35 in acetonitrile solution. The UV−visible spectra of a conjugate containing two Cy5-ODN moieties per antibody displayed a A_{600}/A_{650} ratio of 0.36 which is very close to the value of 0.38 measured on a "free" Cy5-ODN molecule in which the cyanine dye was in a monomeric form. For a conjugate containing an average of five Cy5-ODN moieties per antibody, we observed that the A_{600}/A_{650} ratio was 0.37; again, this value was close to the one observed for the monomeric Cy5. The measured fluorescence intensity was $I_{665} = 140.9 \pm 4.3$ a.f.u. (arbitrary fluorescence units) for the 2(Cy5-T_{15})−Ab conjugate, $I_{665} = 141.1 \pm 3.8$ a.f.u. for 5(Cy5-T_{15})−Ab, and $I_{665} = 163.1 \pm 3.8$ a.f.u. for the reference Cy5-T_{15} oligodeoxynucleotide. These measurements performed at a constant chromophore concentration (100 nM) showed that the relative quantum yields of the Cy5 moieties were almost the same for both conjugates and only about 15% lower than compound Cy5-T_{15} taken as reference. This shows that using the new labeling strategy results in no loss of fluorescence efficiency, by increasing the number of bound Cy5-T_{15} units.

CONCLUSION

We developed a convenient, easy, inexpensive, fast, and versatile protocol for the preparation of phthalimido alkanol solid supports used for the synthesis of 3′ aminoalkyl-ODNs which can be labeled on their 5′ position with classic fluorescent dyes or other tags. This was exemplified on the 5′-Cy5-labeled ODN. After release from the solid support, the Cy5-labeled ODN was converted into an activated NHS ester and was conjugated with an antibody. By adjusting the molar excess of the reactive Cy5-ODN, conjugates exhibiting a dye-to-protein ratio up to five were isolated. Using this labeling strategy and in contrast with classical Cy5 antibody labeling, no decrease of the fluorescence efficiency was observed by increasing the number of dyes per antibody. This should ensure a higher brightness using the conjugates, for example as acceptors in fluorescent resonance energy transfer (FRET)-based immunoassays.

Received December 2, 2004; Revised Manuscript Received March 3, 2005

This review outlines the synthesis of covalent conjugates of oligonucleotides and their analogues that are obtained by reactions of carbonyl compounds with various nucleophiles such as primary amines, *N*-alkoxyamines, hydrazines, and hydrazides. The products linked by imino, oxime, hydrazone, or thiazolidine groups are shown to be useful intermediates for a wide range of chemical biology applications. Methods for their preparation, isolation, purification, and analysis are highlighted, and the comparative stabilities of the respective linkages are evaluated. The relative merits of incorporation of a carbonyl group, particularly an aldehyde group, into either the oligonucleotide or the ligand parts are considered. Examples of harnessing of aldehyde−nucleophile coupling for the labeling of nucleic acids are given, as well as their conjugation to various biomolecules (e.g. peptides and small molecule ligands), site-specific cross-linking of oligonucleotides to nucleic acid-binding proteins, assembly of multibranched supramolecular structures, and immobilization on functionalized surfaces. Future perspectives of bioconjugation and complex molecular engineering via carbonyl group addition−elimination reactions in nucleic acids chemistry are discussed.

INTRODUCTION

Structurally diverse conjugates of oligonucleotides have found numerous applications in different fields of molecular and cell biology. Molecules attached to oligonucleotides are often used as reporter groups, e.g. fluorescent (*1*, *2*), electrochemical (*3*, *4*), or spin (*5*−*7*) labels, for stabilization of double- or triple-helical structures, e.g. intercalators (*8*) and minor groove binders (*9*, *10*), and for increase of cellular uptake of conjugates, e.g. peptides (*11*−*13*), hydrophobic molecules (*14*), and certain carbohydrates (*15*).

There are two alternative approaches to the synthesis of modified nucleic acids: (a) automated solid-supported phosphoramidite or H-phosphonate oligonucleotide assembly using appropriately modified nucleoside or non-nucleoside derivatives (*16*−*18*), and (b) enzymatic incorporation of a 5′-triphosphate of a modified nucleoside (*19*).

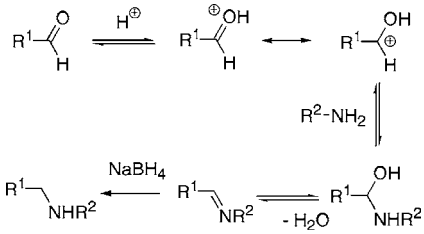
Scheme 1. Reductive Amination: Schiff Base (imine) Formation Followed by Reduction



Chemically synthesized oligonucleotides may be extended by polymerase chain reaction (PCR) or joined by chemical (*20*) or enzymatic (*21*) ligation. The triphosphate approach provides an opportunity for multiple incorporation of modified nucleoside 5′-triphosphate derivatives into either DNA or RNA. Unfortunately, this method is limited mainly to base-modified nucleoside derivatives, since most nucleoside modifications lead to an inability of the corresponding 5′-triphosphate to be incorporated by polymerases (*22*).

Three strategies are generally used for synthesis of oligonucleotide conjugates. The first approach requires synthesis of a nucleoside or non-nucleoside synthon followed by appropriate protection and phosphitylation. The phosphoramidite or H-phosphonate derivative is then incorporated into an oligonucleotide chain during solid-phase synthesis. The conjugated molecule needs to be stable during oligonucleotide synthesis and deprotection. A limitation of this approach is that a reasonably large-scale and multistep synthesis of a modified monomer is required. It seems to be optimal only for incorporation of those reporter or marker groups that are chemically robust and easily accessible synthetically.

The second approach employs fragment conjugation of a target molecule to fully protected support-immobilized oligonucleotide containing a free reactive group. This reactive function must be blocked with a protecting group that can be removed without affecting other protecting and anchoring groups of the oligonucleotide. Selective deprotection of the reactive group is followed by conjugation and then by cleavage and deprotection of the conjugate. Only certain selectively removable protecting groups/conditions for their removal have been used for preparation of oligonucleotide conjugates, such as allyloxycarbonyl (Alloc[1])/Pd (0) (*23*, *24*), fluorenylmethyloxycarbonyl (Fmoc)/morpholine (*25*, *26*), levulinoyl (Lev), and phthaloyl (Phth)/hydrazinium acetate (*24*, *27*), and photolabile protecting groups of the 2-nitrobenzyl type (*28*, *29*). In some cases, preliminary deblocking of internucleoside phosphates is needed to increase the solvation of the oligonucleotide chain and to remove reactive acrylonitrile that sometimes causes side-reactions. The approach is indispensable for synthesis of combinatorial libraries, especially in the case of hydrophobic ligands, since a large excess of the ligand can be used (*30*). However, the resultant conjugate also needs to be stable under the deprotection conditions.

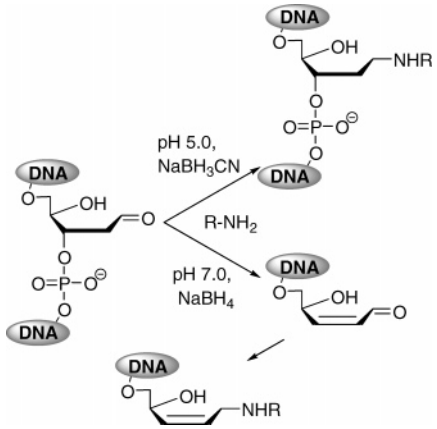
Scheme 2. Reductive Amination of an Apurinic Site with an Amine under Neutral or Acidic pH



In the third approach, conjugation of a deprotected and (if necessary) purified oligonucleotide is carried out in solution. This approach seems to be the most flexible, since no harsh treatment is required after the reaction. The main problem is the need for isolation of the conjugate from the reaction mixture. There are many different types of chemistry available for fragment coupling in solution. Oligonucleotides with amino or thiol groups are conjugated by amide, disulfide, or thioether bond formation (*16*), while those with electrophilic groups are rarely used because of the complicated synthesis of the appropriate derivatives (*31*). However in the case of complex biomolecules, regio- and chemoselectivity are the main concerns in the reaction. Chemoselective conjugation is widely used in peptide chemistry (*32*, *33*), carbohydrate chemistry (*34*), chemistry of nucleic acids (*35*), and steroids (*36*−*38*). During the past decade, a number of classical organic reactions, such as the Staudinger (*39*, *40*), Diels−Alder (*41*−*43*), and 1,3-dipolar cycloaddition reactions (*44*−*46*), have been applied successfully to the bioconjugation of nucleic acids. Extraordinary regioselectivity and high yields of the reactions make this approach the method of choice for biomolecular conjugation.

Here we describe the application of addition−elimination reactions of a carbonyl group, mainly an aldehyde group, with various nitrogen nucleophiles for chemoselective conjugation of the appropriately modified oligonucleotides. We discuss both the introduction of an aldehyde group into an oligonucleotide as well as into the molecule to be conjugated.

CONJUGATION VIA IMINE, OR SCHIFF BASE FORMATION FOLLOWED BY BOROHYDRIDE REDUCTION

Schiff base, or imine, formation followed by reduction, i.e. reductive amination, is widely used in total synthesis of natural products. The reaction is slower at low pH due to protonation of the amino group but may be carried out at neutral or mildly basic conditions. However, the reaction is reversible, so the imine should be reduced in situ to the secondary amine to drive it to completion (Scheme 1). Various borohydride reagents are used for the reduction, but sodium borohydride and sodium cyanoborohydride are by far the most common. Sodium cyanoborohydride is more stable in aqueous solution and is a milder reductant and thus is used more frequently.

Methods of synthesis of both amino (*16*, *18*) and aldehyde (*31*) oligonucleotides are reviewed elsewhere. Here we would like to outline the conditions of the

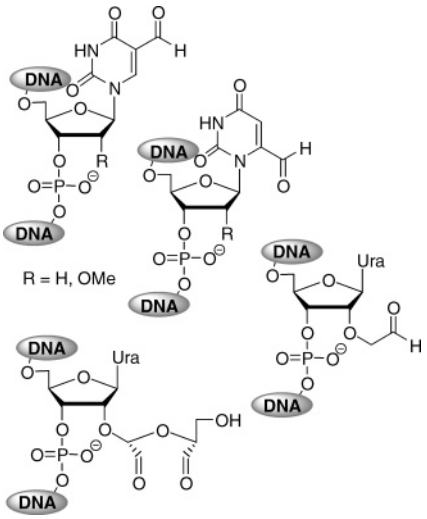
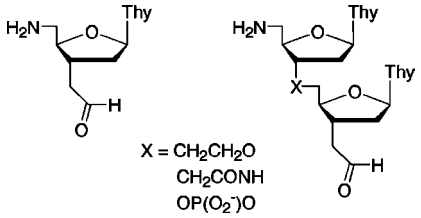


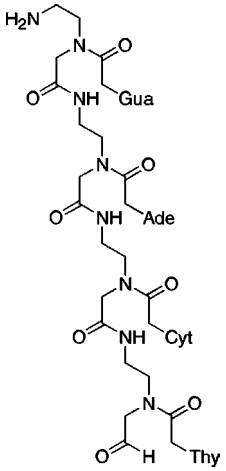
Scheme 7. Modified Nucleoside and Dinucleosides Used for Template-Directed Polymerization



reaction and emphasize the influence of both the nature and placement of an aldehyde group on the conjugate yield.

Probably, the most common example of reductive amination via Schiff base formation is aminooligonucleotide immobilization on various aldehyde-coated surfaces for DNA chip fabrication (*47*). This combination of reactive groups is more effective then the opposite due to nonspecific interactions between anionic oligonucleotides and positively charged surface (*48*). However in the case of aldehyde-coated surfaces, blocking of the unreacted aldehyde groups by aminooligoethyleneglycol decreases nonspecific oligonucleotide binding and provides better sensitivity during hybridization assays (*49*−*50*). Another reason for immobilization of aminooligonucleotides on the aldehyde surfaces has been the lack until recently of commercial availability of aldehyde phosphoramidites. Nevertheless, two common methods for the

Scheme 8. C-Terminal PNA Aldehyde



introduction of an aldehyde group into nucleic acids have been used.

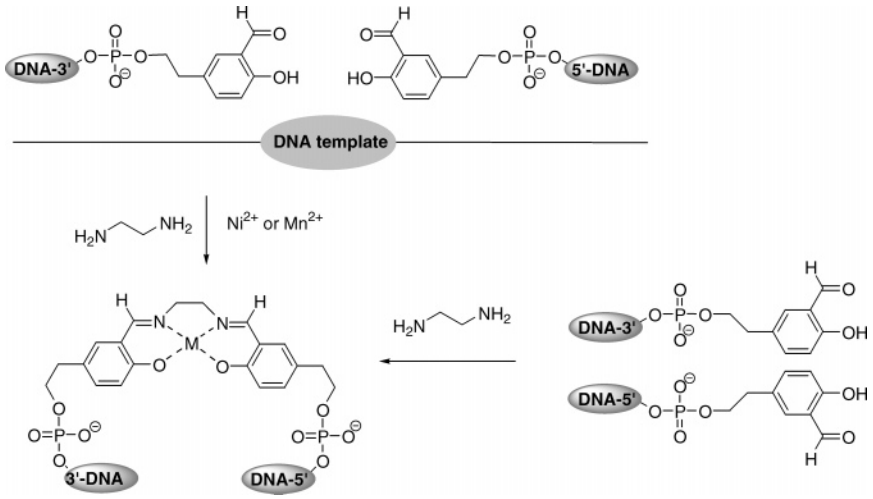
The most popular method for generation of an aldehyde group in native DNA is partial acidic depurination. Proudnikov et al. (*51*) demonstrated that DNA that contains apurinic, or AP, sites undergoes facile β-elimination under neutral conditions. However, reductive amination proceeds smoothly under slightly acidic pH (Scheme 2).

Vasseur et al. (*52*) demonstrated that reaction of the AP site with 3-aminocarbazole leads to a chain break followed by nucleophilic addition to α,β-unsaturated aldehyde (Scheme 3). Such complex processes have not been followed step by step by others, but Greenberg et al. (*53*) later observed an analogous process during interactions of a lysine residue of DNA glycosylase with ribonolactone at the 3′-end of an oligonucleotide. Later Manoharan et al. (*54*) conjugated a number of amines, including tripeptides and aminophenanthroline, to an AP site in oligodeoxyribonucleotides under reductive conditions, without giving the yields of the conjugates.

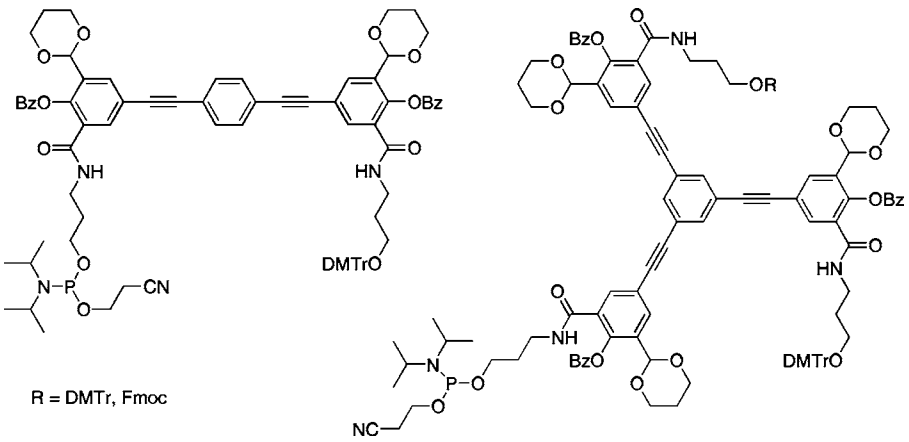
Another common method for generation of an aldehyde group in nucleic acids is periodate oxidation of the 3′-terminal ribonucleotide in native RNA, synthetic oligoribo- or oligodeoxyribonucleotides 3′-modified with a single ribonucleotide residue. Apart from conjugation of the resulting dialdehyde derivatives with amines, some β-elimination also takes place (*55*) (Scheme 4).

These approaches may be useful for immobilization of nucleic acids on a surface or on beads, where a large excess of oligonucleotide is normally used, but they are far from optimal for the synthesis of various oligonucleotide conjugates. However, Schiff base formation has been used to synthesize conjugates of oligonucleotides that contain an aldehyde group (Scheme 5) with alkaline phosphatase (*56*), methionine (*57*), 1-aminomethylpyrene, aminooligoethyleneglycol (*58*), and an aminoalkyl derivative of biotin (*59*, *60*). Sando et al. (*61*) applied a different approach, the conjugation of 5′-amino oligonucleotides with reducing carbohydrates. Phosphate and borate buffers that cover a wide basic pH range (6.8−9.5) were used. The yields of the conjugates varied from 50% to

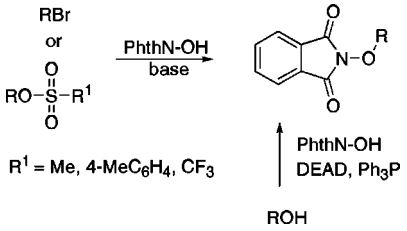
Scheme 9. Oligonucleotide Ligation by Metal-Directed Salen Complex Formation



Scheme 10. Phosphoramidites Used for Synthesis of Supramolecular Structures



Scheme 11. Synthesis of *N*-Hydroxyphthalimide Derivatives



quantitative, but a large excess of the amine is usually used. Sando et al. (*61*) emphasized the superiority of the borate buffer due to an increase in the reaction rate.

Kittaka et al. used modified oligonucleotides bearing aldehyde groups (Scheme 6) in the heterocyclic base for affinity modification of Rel/NF-kB (*62*−*64*), c-Myb (*65*), or RecA proteins (*66*, *67*). Schiff base formation with lysine residues significantly increased binding to the protein. However, oligonucleotides containing 6-formyl-2′-deoxy- and 6-formyl-2′-*O*-methyluridine were found to be ineffective due to significant duplex disturbance and low binding to proteins. The duplex structure was somewhere between A- and B-forms, as judged by CD-spectroscopy (*65*, *68*). More recently, oligonucleotides containing an aldehyde group at the 2′-position of a sugar residue were used for affinity modification of NF-kB protein (*69*, *70*) and DNA-methyltransferase SsoII (Vorobjeva, Zatsepin, Kubareva, Oretskaya, unpublished results). Also oligonucleotides with 2′-dialdehyde group were used in affinity modification of methyltransferases (*71*) and T7 RNA polymerase (*72*).

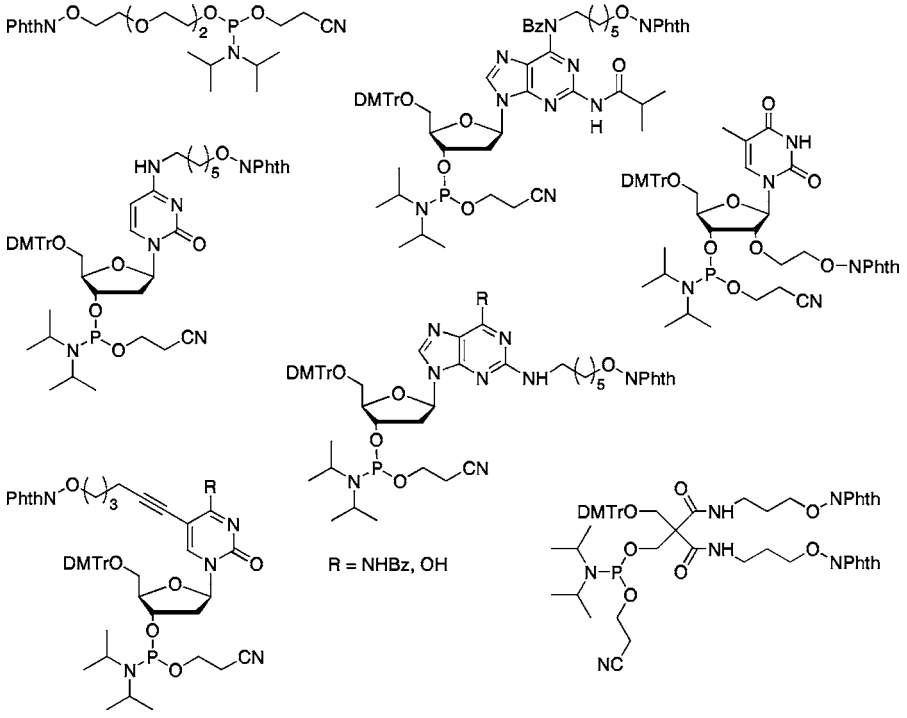
Recently Bugaut et al. (*73*) used oligonucleotides containing 2′-amino-2′-deoxyuridine for identification of duplex-stabilizing ligands bearing an aldehyde group by a dynamic combinatorial library approach. A number of aromatic aldehydes were added to DNA duplexes containing a 2′-amino-2′-deoxyuridine residue at the 3′- or 5′-terminus or in the middle of an oligonucleotide chain. The ratio of conjugates as a function of time was monitored by HPLC. Imines formed were reduced to the corresponding amines, which are analyzed more easily. It was demonstrated that the portion of product containing the most stable conjugate is increased, and that the rate of change of that portion is proportional to duplex stability.

During the past decade, interest in DNA template-directed organic synthesis has increased significantly (*21*, *74*−*77*). Earlier the main efforts were centered on chemical ligation of short oligonucleotides or monomeric nucleotides on a DNA template. Today DNA template-directed synthesis allows for regioselective chemical reactions, otherwise ineffective or even impossible in aqueous solution.

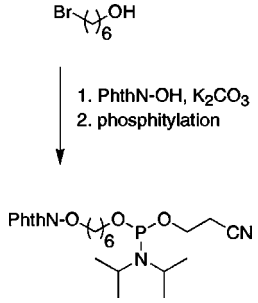
Lynn et al. (*78*, *79*) used Schiff base formation to ligate modified oligonucleotides. It was demonstrated that the imine reduction shifts the equilibrium toward products and allows the reaction to function in a catalytic mode due to significant destabilization of the duplex (*79*). Later Lynn et al. demonstrated oligomerization of a modified thymidine or thymidine dinucleoside that carry 5′-amino and 3′-aldehyde groups (Scheme 7) on an oligoadenylate template (*80*, *81*). It should be noted that the process was effective only if the template was in solution or immobilized on a polystyrene support, and was very sensitive to mismatches.

Liu et al. (*82*−*86*) used 5′- or 3′-aldehyde oligonucleotides for ligation on a DNA template with aminooligonucleotides or cross-linking to a modified matrix. The authors studied the dependence of the reaction yield on the structure of the template i.e. its length, presence of loops and reactive groups. Reductive amination showed a pronounced distance-dependence in the case of linear templates, but a lower distance-dependence was observed for a looped template. A number of subsequent ligations and cross-linkings with different templates allowed the synthesis of rather complex molecules conjugated to DNA (e.g. macrocyclic compounds (*85*, *86*)). Later Rosenbaum and Liu (*87*) carried out oligomerization of a PNA tetramer containing a C-terminal aldehyde group (Scheme

Scheme 12. Phosphoramidite Derivatives Obtained via Mitsunobu Reaction That Were Used for Synthesis of Aminooxyoligonucleotides



Scheme 13. Synthesis of a Protected Aminooxy Building Block by Nucleophilic Subsitution



8) on a long DNA template (40 nt). The process could be described as an artificial DNA replication.

Czlapinski and Sheppard (*88*, *89*) applied metal−salen complex formation for oligonucleotide ligation on a DNA template or ligation of self-complementary oligonucleotides (Scheme 9). Oligonucleotides containing 5′- or 3′-salicylaldehyde moieties, respectively, were ligated on a DNA template by ethylenediamine in the presence of Mn^{2+} or Ni^{2+}. The yields were up to 74% (compared with <4% in the absence of a template or metal ions). The ligation of self-complementary oligonucleotides did not depend on the presence of a metal ion or pH, probably due to preorganization of fragments because of salicylaldehyde participation in stacking interactions. Later, Ni−salen DNA derivatives were used for site-specific oxidative cleavage of DNA (*90*).

Later Gothelf et al. (*91*−*93*) synthesized a set of non-nucleoside phosphoramidites (Scheme 10) that may be used to construct 2D or 3D supramolecular structures containing metal−salen complex at a branching point. The distinct feature of the approach is a possibility of nanostructures formation followed by DNA removal. This may be used for preparation of novel 3D catalysts e.g. asymmetric catalysts (*94*, *95*).

CONJUGATION VIA OXIME FORMATION

Since Schiff bases are unstable under acidic or basic conditions, use of stronger nucleophiles and weaker bases such as *O*-alkyl hydroxylamines is preferred over the use of amines due to greater stability of the oximes formed (*96*, *97*). The increased nucleophilicity of an aminooxy group is determined by an α-effect, or the presence of a lone electron pair on the adjacent heteroatom (*98*). The weak basicity of an aminooxy group allows for its chemoselective conjugation in the presence of protonated amino groups at low pH. Here we will discuss methods for incorporation of an aminooxy group into oligonucleotides or conjugated molecules.

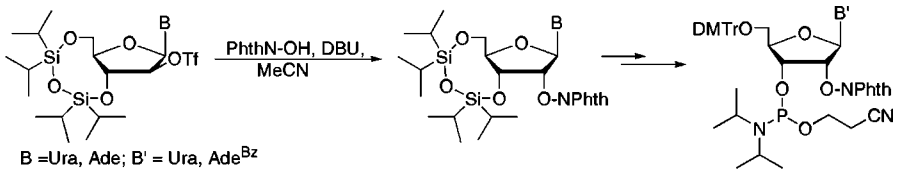
Synthesis of Oligonucleotides Containing an Aminooxy Group and Their Conjugation with Aldehydes. Incorporation of an aminooxy group into oligonucleotides requires synthesis of the appropriately blocked nucleoside or non-nucleoside phosphoramidite. The simplest way to incorporate an aminooxy group is through nucleophilic displacement of a primary hydroxylic group by *N*-hydroxyphthalimide under conditions of Mitsunobu reaction (*99*) or through alkylation of *N*-hydroxyphthalimide by aliphatic bromides/iodides or alkane/arene sulfonates (Scheme 11).

An approach based on a Mitsunobu reaction was applied by Lönnberg, Manoharan and others (*100*−*103*) (Scheme 12). Such a scheme seems to be preferable, since hydroxy derivatives of nucleosides are more available synthetically than the corresponding halo or sulfonate derivatives.

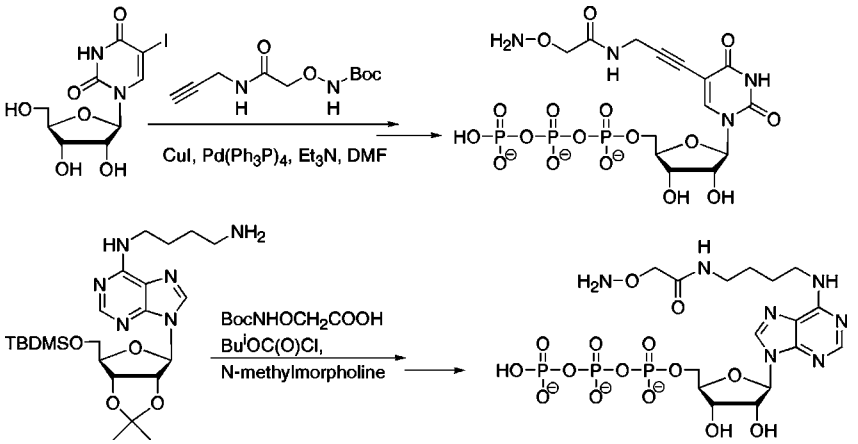
Some authors used nucleophilic substitution of an alkyl bromide for synthesis of a 5′-aminooxy-modifier (*104*, *105*) (Scheme 13). Easily accessible 6-bromohexanol was used as the starting material. However, a Mitsunobu reaction with *N*-hydroxyphthalimide proceeds smoothly only in the case of a primary hydroxyl group. Beigelman et al. (*106*) demonstrated that the yield of a 2′-substitution for a 5′,3′-blocked uridine is about 10%, while nucleophilic substitution of 2′-triflate derivatives of blocked arabinonucleosides by *N*-hydroxyphthalimide/DBU leads to 90% yields (Scheme 14).

An alternative approach was developed by Trevisiol et al. (*107*). A presynthesized aminooxy derivative was coupled to base-modified nucleosides either by a Sonogashira−Heck reaction or by acylation (Scheme 15).

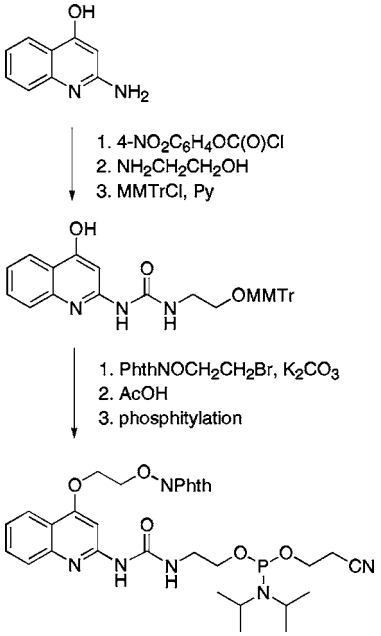
Scheme 14. Synthesis of Blocked 2′-Aminooxynucleosides by Nucleophilic Subsitution



Scheme 15. Synthesis of Ribonucleoside 5′-Triphosphates Containing an Aminooxy Group in the Heterocyclic Base



Scheme 16. Synthesis of Quinoline Phosphoramidite Derivative with Blocked Aminooxy Group



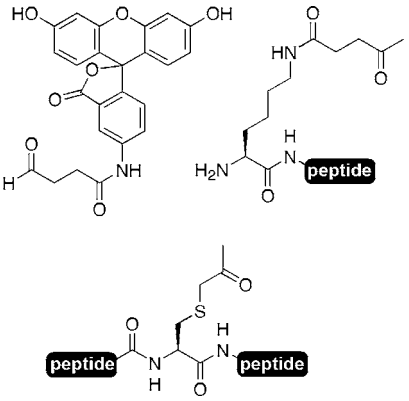
Commercial availability of *N*-Boc-aminooxyacetic acid makes this approach rather straightforward. The nucleosides were then converted into their corresponding 5′-triphosphates and introduced into RNA enzymatically.

A similar approach was applied by Miller et al. (*108*, *109*), who synthesized a quinoline-based phosphoramidite, which contains a blocked aminooxy group (Scheme 16) that has been introduced via a presynthesized alkyl bromide.

Although a phthaloyl protecting group is compatible with automated phosphoramidite oligonucleotide synthesis, substituted trityl groups have been used as an alternative in the synthesis of 5′-aminooxy oligonucleotides (Scheme 17). Deprotection of the 5′-phthaloyl group during ammonolysis makes reverse-phase (RP)-HPLC purification difficult and leads to side reactions with traces of aldehydes and ketones present in solution (*110*). A number of authors demonstrated formation of unidentified compounds under standard ammonolytic conditions (*101*, *108*). Preliminary deblocking of an aminooxy group by hydrazinolysis or ethylenediamine treatment is thus required. Cebon et al. (*104*) compared phthaloyl and trityl protecting groups for 5′-modification and demonstrated that detritylation was partial and depurination was observed under harsher conditions. N-Tritylated derivatives were obtained from *N*-phthalimido derivatives. Later, Defrancq and Lhomme (*105*) successfully used *N*-tritylaminooxy phosphoramidite for the 5′-modification. No depurination was observed under deprotection conditions (80% AcOH, 7 h). Despite the contradicting data, most authors prefer to use the phthaloyl group for aminooxy group protection.

Forget et al. (*111*) synthesized oligonucleotide−peptide conjugates via oxime formation. In this case an aminooxy group was introduced into the oligonucleotide and an aldehyde into the peptide or vice versa. As we emphasized earlier, an aminooxy group easily reacts with traces of aldehydes or ketones in buffers, so having the aminooxy group on the peptide seems to be preferable, due to the availability of peptides in larger quantities than oligonucleotides. In general, an excess of the aminooxy component is needed during oxime synthesis, since even distilled water contains traces of aldehydes (*112*, *113*). However, oligonucleotides containing an aminooxy group have been used successfully for conjugation with a number of carbonyl compounds including a fluorescein derivative (*105*) and peptides (*104*, *108*, *109*) (Scheme 18).

Scheme 18. Carbonyl Compounds Used for Conjugation with Aminooxy Oligonucleotides

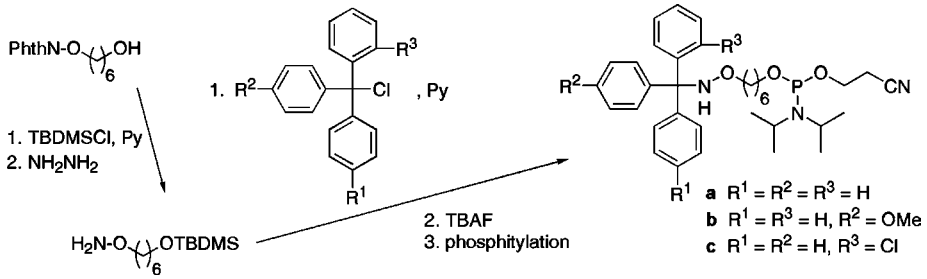


More recently, Edupuganti et al. (*114*) have used intramolecular oxime formation for cyclization of an oligonucleotide (Scheme 19). An aldehyde group was incorporated on the 3′-end and an aminooxy group on the 5′-end. Cyclization occurs spontaneously under mild acidic conditions. It should be noted that formation of concatemers was not observed.

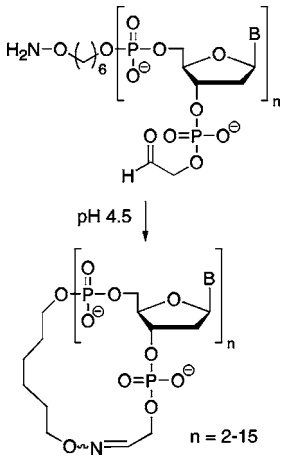
Lönnberg et al. (*101*, *102*) developed a solid-phase conjugation method by oxime formation of immobilized aminooxy oligonucleotides (Scheme 20). The phthaloyl protecting group was selectively removed by hydrazinium acetate followed by conjugation with retinal or 1-pyrenecarboxaldehyde. The resultant oximes were claimed to be stable during ammonolysis. Later the same methodology was applied for multiple conjugations with a mannose derivative (*102*).

Oligonucleotides bearing an aminooxy group at the 5′-end were used for immobilization on aldehyde-modified glass or gold surfaces (*101*, *115*, *116*) (Scheme 21). This method provides higher density and homogeneity of the

Scheme 17. Synthesis of N-Tritylated 5′-Aminooxy Phosphoramidite Series



Scheme 19. Synthesis of Cyclooligonucleotides by Oxime Formation



oligonucleotide array than traditional reductive amination (*117*) or de novo synthesis (*48*).

Conjugation of *O*-Alkylhydroxylamines with Aldehyde Oligonucleotides. This method was first used for qualitative or quantitative detection of abasic sites in DNA (Scheme 22). This DNA damage is a result of spontaneous acidic depurination or incomplete enzymatic repair (*118*). ^{14}C-Methoxyamine (*119*, *120*), aminooxyacetic acid (*121*), derivatives of 4-nitrophenol (*122*, *123*), biotin (*124*), or a number of dyes (*125*−*129*) bearing an aminooxy group were used in the assay. The reaction was usually carried out under neutral conditions to avoid additional depurination. Chakrabarti et al. (*130*, *131*) used a FRET technique to detect abasic sites proximal to each other. Also a synthetic AP site was used by Ito and Rokita (*132*−*134*) to attach an aminooxy derivative of *N*,*N*,*N*′,*N*′-tetramethyl-1,5-diaminonaphthalene. The conjugate was used for photoinduced cleavage of complementary DNA containing 5-bromo-2′-deoxyuridine. This assay was developed to screen aromatic amines for their ability to initiate charge transfer by reductive electron donation.

Later, aminooxy derivatives of a dansyl group or rhodamine were conjugated to aldehyde oligonucleotides

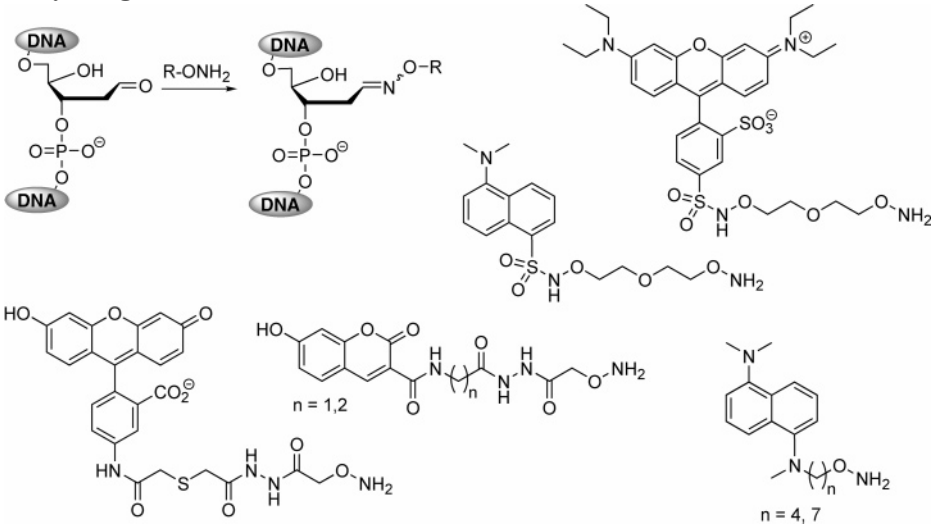
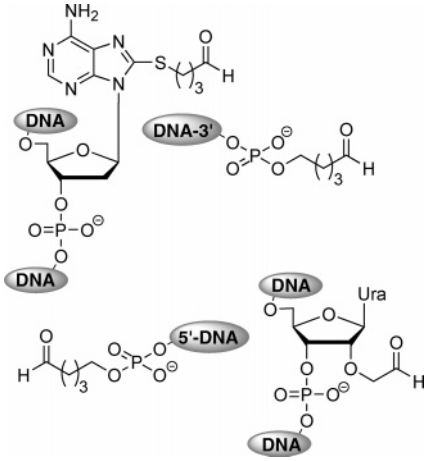
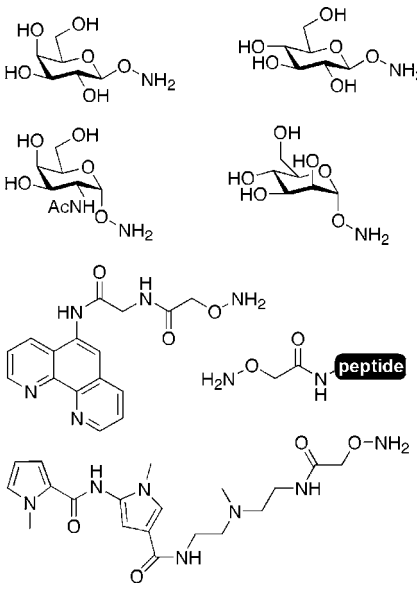
Scheme 22. Aminooxy Reagents for Modification of Abasic Sites



Scheme 23. Aldehyde Oligonucleotides Used for Oxime Formation



Scheme 24. Aminooxy Compounds Used for Oxime Formation



(Scheme 23) (*135*−*137*). 2D ^{1}H NMR spectra demonstrated that the oxime formed is a mixture of isomers (*Z*:*E* = 1:1) (*136*). 2′-Aldehydo oligonucleotides were applied to conjugation with peptides (*138*). Multiple incorporation of the 2′-modified nucleotides has been used to attach several peptide moieties. The same approach has been applied to conjugation with aminooxy carbohydrates (*136*, *139*), 1,10-phenanthroline (*140*), distamycin (*141*), and peptides (*111*, *138*) (Scheme 24).

Very recently Edupuganti et al. (*142*) developed a method for sequential conjugation of two different molecules (e.g. two peptides or fluorescent derivatives) to a modified oligonucleotide via an oxime linkage (Scheme 25). 3′,5′-Dialdehyde (Scheme 25A) or 3′-aldehyde, 5′-aminooxy (Scheme 25B) oligonucleotides were used for double conjugation.

A number of authors used ketones as the electrophilic components. Both keto group-modified oligonucleotides (*143*) and peptides (*104*) have been applied. In both cases the yields were good, but the reaction time was increased to 12−48 h compared to 1−3 h for aldehydes. Trevisiol et al. (*143*) used a number of the 5′-triphosphates (Scheme 26) for synthesis of modified RNAs followed by multiple labeling with an aminooxy fluorescein derivative.

Dey and Sheppard also used a similar approach (*144*). A wide range of compounds has been conjugated both to single- and double-stranded DNA (Scheme 27).

An oxime conjugation was used for synthesis of PNA−peptide conjugates (*145*). Ketone bis-PNA was conjugated with peptides bearing an aminooxy group either at the *N*-terminus or coupled to the ϵ-amino group of a lysine residue (Scheme 28). The reaction was carried out for 12 h with isolated yields for the conjugates of 15−20%.

CONJUGATION VIA HYDRAZONE FORMATION

Hydrazone formation seems to be the oldest method for coupling in biomolecular chemistry. The reaction of a hydrazino or hydrazido group with an aldehyde leads to hydrazone formation. Usually hydrazones are rather stable but in some cases reduction to hydrazine is needed. Sayer et al. (*146*) studied the rate of hydrazone hydrolysis as a function of the R^1 substituent (Scheme 29). It was demonstrated that an increase in electronegativity of R^1 leads to a decrease in hydrazone stability under acidic and basic conditions. Thus the stability of the hydrazone decreases in the order: aromatic hydrazine > aliphatic hydrazine > hydrazides.

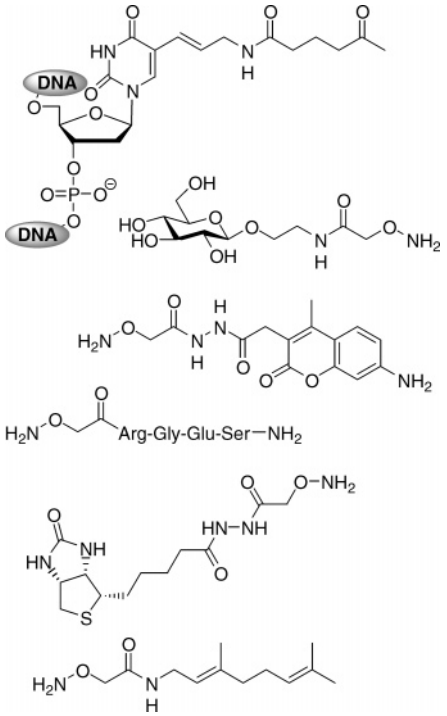
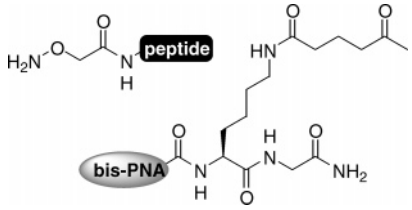


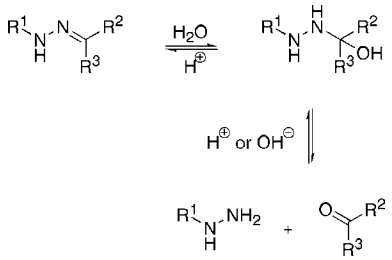
Scheme 28. Conjugation of a Keto Bis-PNA with an Aminooxypeptide



Since hydrazino/hydrazido group may be incorporated into either an oligonucleotide or a ligand, this section is divided into two parts covering both possible cases.

Synthesis of Hydrazido Oligonucleotides and Their Conjugation with Aldehydes. Most of the oligonucleotides containing hydrazide groups have been synthesized by hydrazinolysis of ester groups in nucleosides or oligonucleotides during a hydrazine-mediated deblocking reaction. In 1989 Ghosh et al. (*147*) synthesized a 5′-hydrazide derivative by coupling carbohydrazide to an activated 5′-phosphate group of an oligonucleotide

Scheme 29. Hydrolysis of a Hydrazone Linkage



(Scheme 30). These oligonucleotides have been used to conjugate 2,4-dinitrobenzaldehyde hapten and aldehyde-modified alkaline phosphatase. In the latter case, several oligonucleotides were attached to the enzyme.

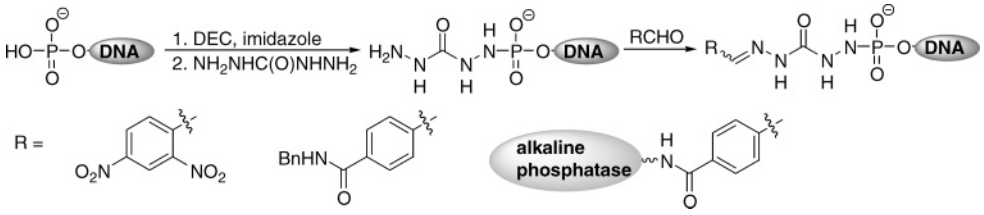
Oshevski (*148*) described synthesis of a 3′-hydrazide by phosphoramidate formation. The oligonucleotide containing a 4-aminomethylbenzhydrazide residue was ligated to a 5′-aldehyde oligonucleotide on a DNA template (Scheme 31). Usually the yields did not exceed 20% under optimal conditions, and no ligation was observed in the case of mismatches in a DNA template close to the ligation point. The system was proposed for SNP detection.

Raddatz et al. (*149*) synthesized a series of blocked hydrazide phosphoramidites by hydrazinolysis of esters followed by phosphitylation (Scheme 32). Also several phosphoramidites containing ester groups were prepared, and hydrazide formation was carried out during oligonucleotide deblocking step. Some of the derivatives carried two or four hydrazide moieties. The hydrazide oligonucleotides were conjugated to a peptide and used for DNA array preparation. It was shown that effectiveness of immobilization increased as the number of hydrazide groups per oligonucleotide increased.

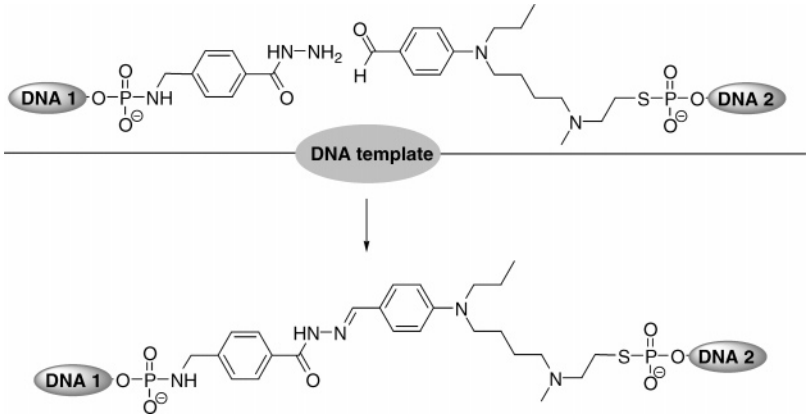
Later von Kiedrowski et al. (*150*) prepared a branched oligonucleotide with a defined structure by hydrazone formation with 1,3,5-benzenetricarboxaldehyde on a branched DNA template (Scheme 33). Sodium cyanoborohydride reduction slightly increased the yield. No reaction occurred without template.

Zubin et al. (*151*) attempted a synthesis of oligonucleotides containing a hydrazide group at the 2′-position of a sugar residue via a blocked uridine 2′-hydrazido phosphoramidite (Scheme 34). However, the authors reported only a conversion of the hydrazide group into the amide during ammonia treatment, even under milder conditions. This may be ascribed to the more electrophilic nature of the hydrazide.

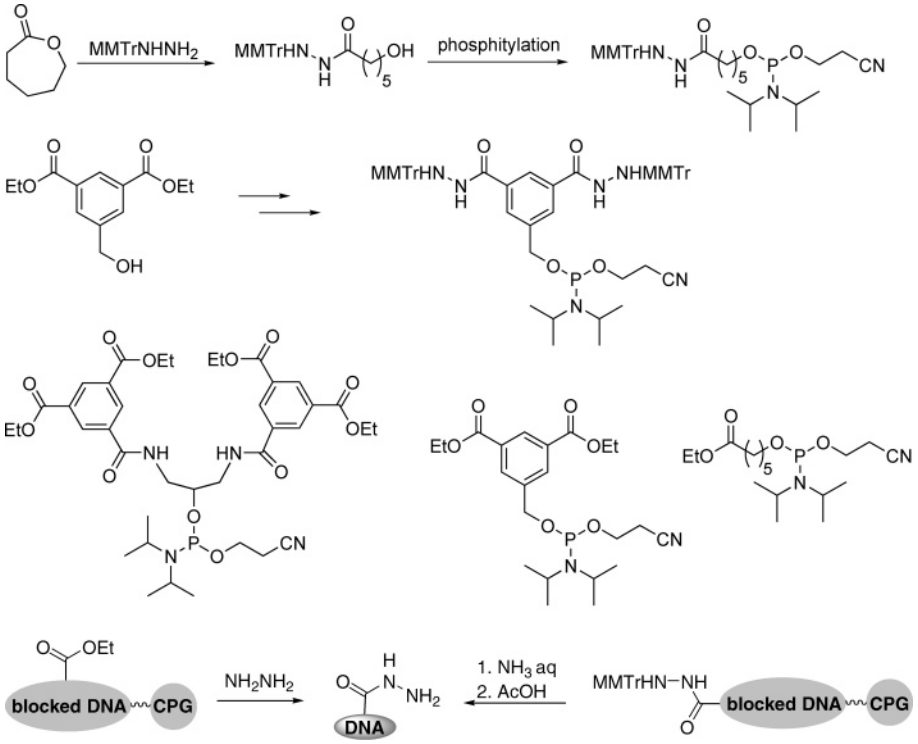
Scheme 30. Oligonucleotides Containing 5′-Carbohydrazide and Their Conjugation to Aldehydes



Scheme 31. Template-Directed Ligation of the 3′-Hydrazide and 5′-Aldehyde Oligonucleotides



Scheme 32. Phosphoramidite Building Blocks Used for Synthesis of Hydrazide Oligonucleotides. Generation of a Hydrazide Group in the Modified Oligonucleotides



Gao and Orgel (*152*) used hydrazone formation for the synthesis of a rigidly cross-linked base pair within an oligonucleotide sequence (Scheme 35). Introduction of a hydrazino group into the 4-position of a cytosine residue by transamination in the presence of bisulfite was followed by conjugation with the modified nucleoside containing a malondialdehyde group. Heterocyclic bases of the cross-linked pair are coplanar, and the geometry of the pair resembles that of native double-stranded DNA. These properties allow the oligomerization of activated nucleotides on a template cross-linked to the starting nucleoside. The product of the oligomerization reaction could be detached by an excess of hydrazine. Hydrazone reduction leads to a significant decrease in the yield of the ligation product.

Zhao et al. (*153*, *154*) demonstrated the application of commercially available 5′- and 3′-aldehydo or hydrazino oligonucleotides for DNA ligation, conjugation to modified antibodies or for immobilization on a modified glass surface (Scheme 36). This method for oligonucleotide immobilization was further used by Zhong et al. (*155*).

The commercial availability (Solulink, San Diego, CA) of *N*-hydroxysuccinimide esters of 6-hydrazinonicotinic acid and 4-formylbenzoic acid and the corresponding

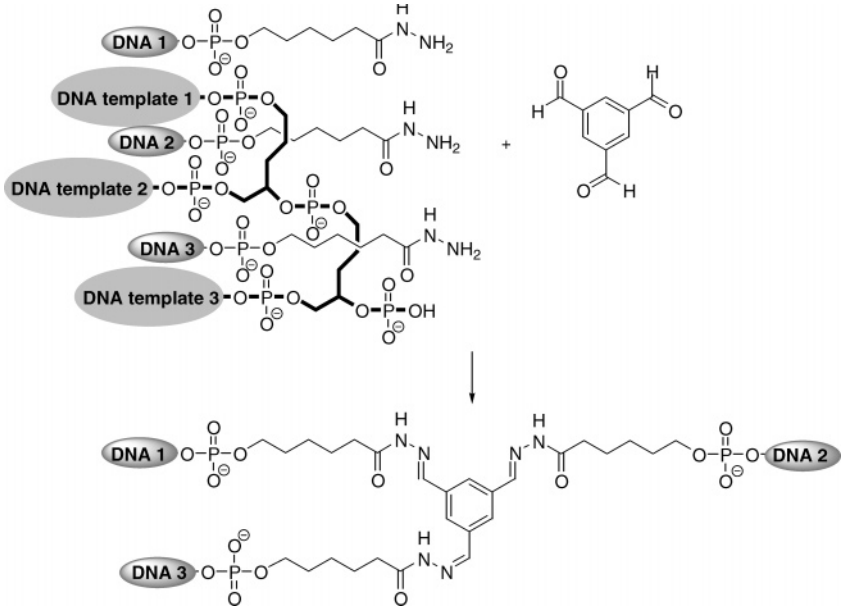
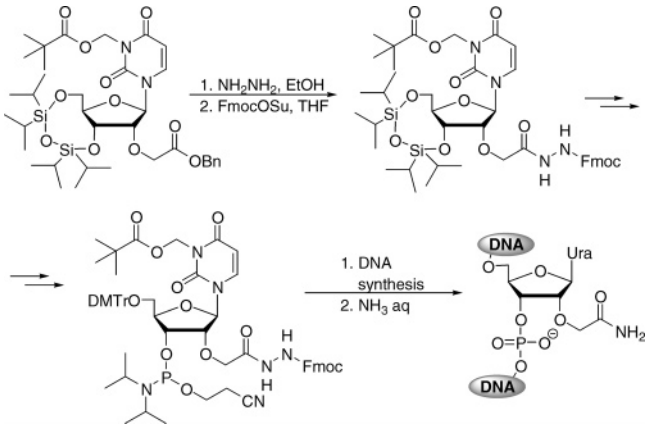


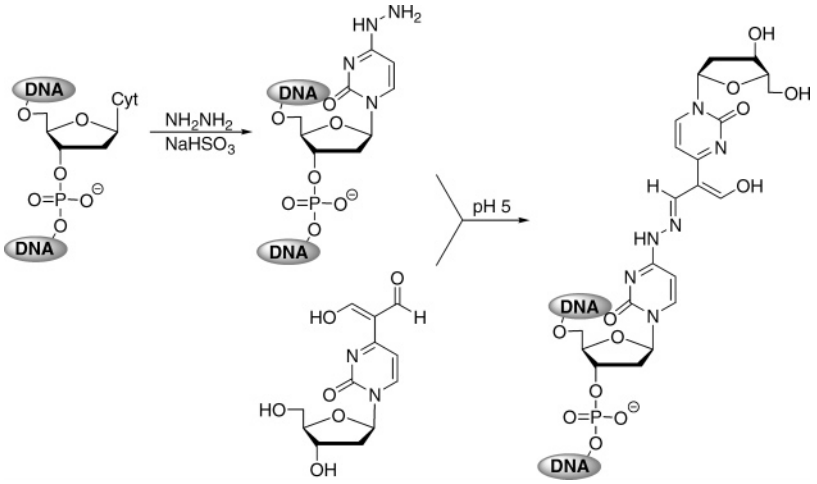
Scheme 34. An Attempt To Prepare the 2′-Hydrazide Oligonucleotides via a Presynthesized 2′-Hydrazide Synthone



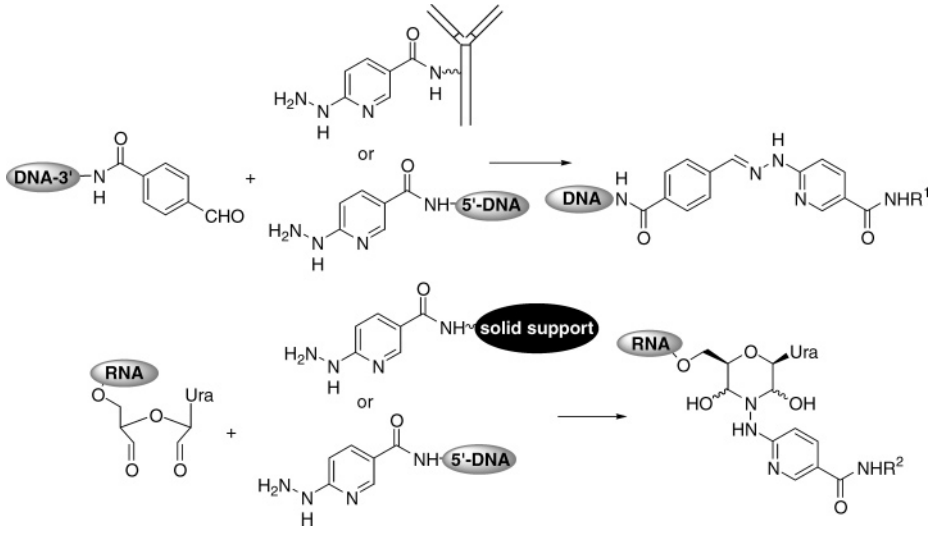
phosphoramidites that can be used for incorporation of an aldehyde or hydrazine group into oligonucleotides and other biomolecules may add significantly to the popularity of hydrazone coupling in nucleic acid chemistry.

Conjugation of Aldehyde Oligonucleotides with Hydrazines and Hydrazides. A number of publications describe conjugation of aldehyde oligonucleotides to hydrazines and hydrazides. Kremsky et al. (*156*) biotinylated a 5′-aldehyde oligonucleotide by hydrazone formation with biotin hydrazide. Later Sonveaux et al. (*59*, *60*) used the same scheme for oligonucleotides containing an aldehyde group in the middle of a sequence. In both cases the conversion was quantitative under reducing conditions. Melnyk et al. (*157*) used 5′-glyoxylyl oligonucleotides for conjugation with a hydrazino peptide (Scheme 37). A 5′-amino oligonucleotide was acylated by *O*,*O*′-diacetyl tartaric anhydride on solid phase. A glyoxylyl group was generated by periodate oxidation after oligonucleotide deprotection. Very recently a different scheme was used for the synthesis of 5′-glyoxylyl oligonucleotides by Defrancq et al. (*158*). An O,N-blocked serine residue was introduced into oligonucleotides by use of a phosphoramidite during standard DNA synthesis, followed by ammonolysis and periodate oxidation (Scheme 37). The presence of an electron-withdrawing amide group placed α to the aldehyde increases its reactivity and the stability of the resultant hydrazone. It was shown that ca. 50% conversion occurs in a few seconds and the reaction was complete in 15 min (*157*). However, the stability of the aldoxime linkage

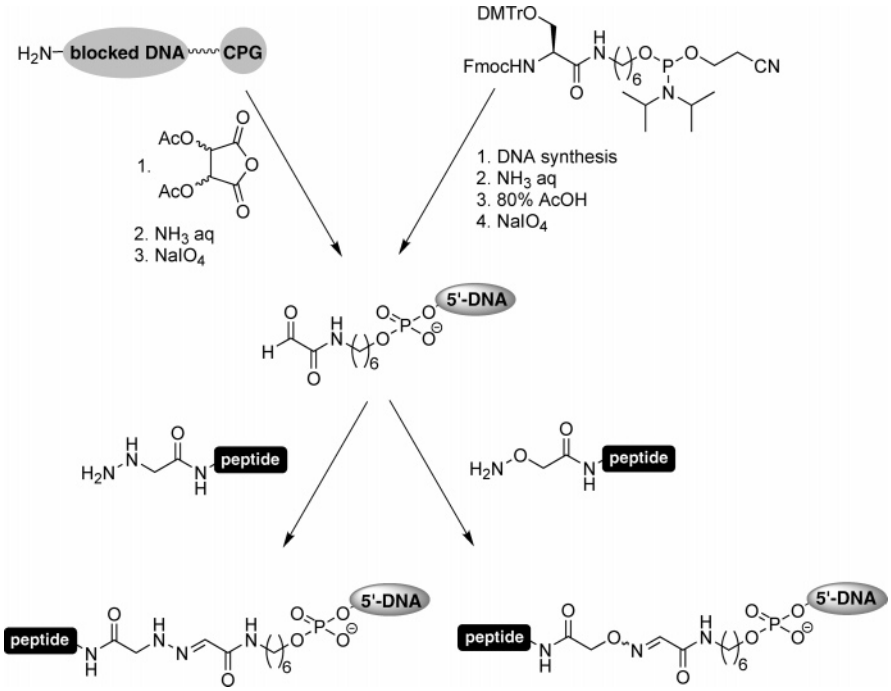
Scheme 35. Conjugation of *N*-Aminocytosine Oligonucleotide with Malondialdehyde Nucleoside



Scheme 36. Conjugation Reactions of Hydrazino and Aldehydo Oligonucleotides Prepared from a Commercially Available Set of Reagents



Scheme 37. Synthesis of 5′-Glyoxylyl Oligonucleotides and Conjugation with N-Terminal Hydrazino and Aminooxy Peptides



is lower at basic pH compared to other oxime linkages (*158*).

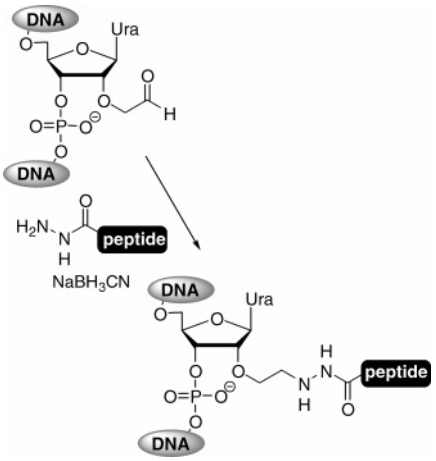
Incorporation of an aldehyde group onto the 5′-end of an oligonucleotide limits the number and position of conjugated moieties. An aldehyde group in the 2′-position of ribose provides an opportunity for multiple conjugation of hydrazides and hydrazines, as has been shown by Zatsepin et al. (*138*). However, the hydrazones formed were prone to hydrolysis in the neutral and basic pH range, and borohydride reduction was required (Scheme 38). More recently, oligonucleotide-containing aldehyde groups in the 2′-position of one or more arabinouridine residues have been prepared (*159*). It was demonstrated that a hydrazone formed by an aromatic hydrazine, 9-hydrazinoacridine, is more stable in comparison to hydrazones of aliphatic hydrazides and does not need reduction in order to be purified by HPLC.

Tetramethylrhodamine (TAMRA) hydrazine (Scheme 39) was used for DNA or RNA labeling through an AP site or through a 3′-periodate-oxidized ribose (*160*), respectively, as described previously for aminooxy derivatives. Labeling was carried out under acidic pH followed by sodium cyanoborohydride reduction. Later Manoharan et al. (*54*) also used an AP site to incorporate hydrazide derivatives of biotin, pyrene, and fluorescein. These authors generated an AP site enzymatically by treatment of DNA with uracil-DNA glycosylase.

Aldehyde oligonucleotides have been used many times for immobilization on hydrazide-modified surfaces. Kremsky et al. (*156*) and Schluep and Cooney (*161*, *162*) used aldehyde oligonucleotides for immobilization on hydrazide-modified latex or glass, respectively (Scheme 40). Hydrazone reduction led to an increase in the extent of immobilization.

Later glyoxylyl (*163*) and benzaldehyde (*164*) oligonucleotides were used for immobilization on a semicarbazide-modified glass (Scheme 41). Semicarbazide glass was synthesized either by hydrazine addition to the

Scheme 38. Synthesis of Oligonucleotide−Peptide Conjugates via Hydrazone Formation Followed by Reduction



Scheme 39. TAMRA Hydrazine

isocyanate glass (*163*) or via a direct silylation by the silane containing a blocked (*163*) or even a free (*164*) semicarbazide group. The first approach gave better homogeneity and higher density of the array. The hydrazones were rather stable over a wide pH range, but borohydride reduction again increased the shelf life of the DNA chips obtained.

CONJUGATION VIA REACTIONS OF ALDEHYDE OLIGONUCLEOTIDES WITH MISCELLANEOUS NUCLEOPHILES

As it was discussed above, reaction of a side-chain amino group in amino acids with aldehydes leads to an imine formation. However in the case of cysteine, the reaction is followed by intramolecular addition of the thiol group with concomitant thiazolidine formation (Scheme 42). This approach was used to synthesize a number of oligonucleotide−peptide conjugates (*111*, *138*, *141*). An aldehyde group was introduced onto the 5′-end of an oligonucleotide or into the 2′-position of a sugar moiety.

Zatsepin et al. (*165*) introduced a 2,3-diaminopropoxy group into the 2′-position of a sugar moiety and demonstrated a model conjugation with benzaldehyde via imidazolidine formation (Scheme 43). However, the imidazolidine is less stable than a thiazolidine both in basic and acidic conditions, so the application of the former has less general utility than that of the latter.

Liu et al. published a number of inspiring contributions (*82*−*84*, *166*, *167*) on use of DNA as a template for organic reactions. These authors explored Wittig reaction, nitroaldol condensation (Henry reaction), or oxazolidine formation (Scheme 44). The reactions were carried out in aqueous medium. The driving force seems to be a spatial proximity of the reactive groups on oligonucleotides. The groups were incorporated at adjacent positions on complementary oligonucleotides or in contiguous oligonucleotides bound to a DNA template. It is evident that these methods would allow for adaptation of many types of reaction from classical organic chemistry for modification of nucleic acids.

CONCLUSIONS

Analysis of the literature demonstrates that the most widely used approach that involves carbonyl group addition−elimination reactions for synthesis of oligonucleotide conjugates is still Schiff base (imine) formation followed by borohydride reduction. Usually the yields are not quantitative and a number of side reactions occur, but the accessibility of starting materials makes this approach rather popular. The method is especially effective for conjugation or immobilization of native DNA and RNA. However, in the case of chemically synthesized oligonucleotides the oxime and hydrazone formation are

Scheme 41. Synthesis of the Semicarbazide Glass and Immobilization of the 5′-Benzaldehyde or Glyoxylyl Oligonucleotides on It

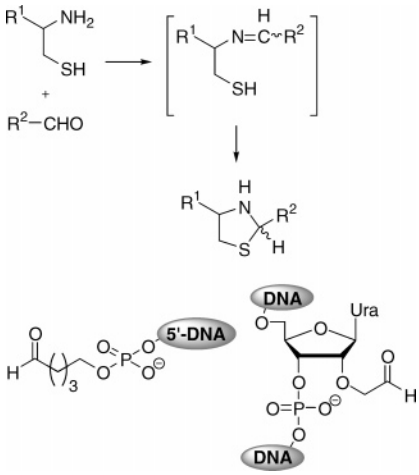
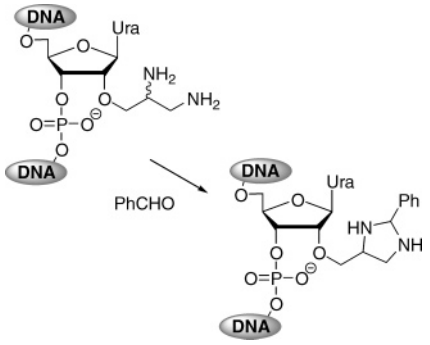


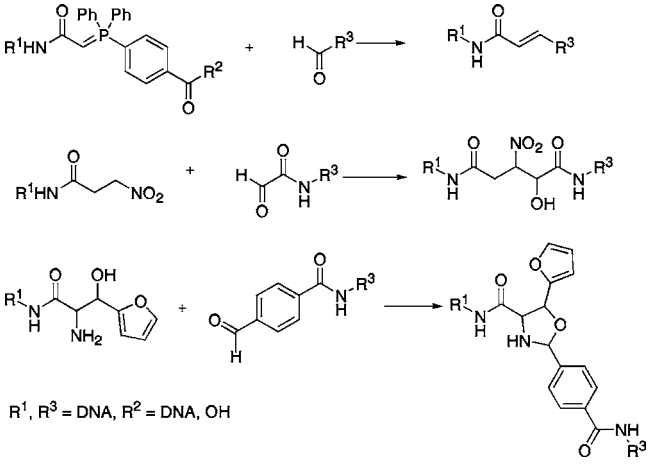
Scheme 43. Conjugation of the 2′-(2,3-Diaminopropoxy) Oligonucleotides with Benzaldehyde



evident alternatives. As emphasized above, in most cases the compounds are stable enough and no reduction is needed. Only a small excess of the nucleophilic component is required during oxime or hydrazone synthesis, which makes the approach cost-effective. Side-reactions of *O*-alkyl hydroxylamines with traces of aldehydes and ketones in water are avoided by use of a small excess of aminooxy compound. Due to such considerations, the incorporation of an aldehyde group into the oligonucleotide chain seems to be the best route, because the molecules to be conjugated can normally be used in excess. Aminooxy oligonucleotides are more attractive for immobilization on aldehyde-coated surfaces, since the density of the array is higher compared to reductive amination. Aromatic hydrazines seem to be a good choice for hydrazone conjugation, since these form the most stable linkages in comparison to aliphatic hydrazines or hydrazides. However, in some cases a borohydride reduction is mandatory, e.g. when basic treatment is involved. Ketones are generally a poorer alternative to aldehydes. Although ketones are more stable to oxidants and milder reductants, and keto-derivatives of the oligonucleotides can be synthesized more easily, the lower reactivity of ketones makes their conjugation with amino compounds less practical. The possibility of conjugation with double-stranded nucleic acids could find broad application in the case of siRNA modification.

In this review we highlighted the most significant contributions published to date in the field of application of addition−elimination reactions of a carbonyl group with nitrogen nucleophiles for nucleic acid chemistry. It is evident that there are now much more numerous

Scheme 44. DNA Ligation via Wittig or Henry Reaction or Oxazolidine Formation



choices either in reagents or in chemical methods available to prepare nucleic acids conjugates that are purposefully constructed to meet the requirements of any particular biological application.

ACKNOWLEDGMENT

The authors thank Drs. A. Yu. Tomashevsky, University of Virginia, Charlottesville, VA, and A. Zamyatnin, Swedish University of Agricultural Sciences, Uppsala, Sweden, for their valuable assistance in preparation of this review for publication. The review has been written within the framework of the Program "Universities of Russia", Project No. UR.05.02.547, and with the financial support of the Wellcome Trust CRIG 069419 and the Russian Foundation for Basic Research Project 03-04-48957.

Inhibition of Membrane-Associated Methyltransferases by a Cholesterol-Based Metal Chelator

Heather B. Hodges, Mingkang Zhou, Saubhik Haldar, Jessica L. Anderson, David H. Thompson,* and Christine A. Hrycyna*

Department of Chemistry and Purdue Cancer Center, Purdue University, 560 Oval Drive, West Lafayette, Indiana 47907. Received February 1, 2005

We have designed, synthesized, and characterized a metal chelating compound that is based on the structure of cholesterol and contains the high affinity metal chelating group, lysine nitrilotriacetic acid (Lys-NTA). Using the enzyme isoprenylcysteine carboxylmethyltransferase (Icmt) from yeast as a model integral membrane metalloenzyme, we find that this agent potently inhibits Icmt activity with an IC_{50} value between 35 and 75 μM, which is at least 40 times more potent than the best known Icmt metal chelating inhibitor, Zincon. We propose that the rigid hydrophobic cholesterol moiety promotes partitioning into the membrane, enabling the metal-binding NTA group(s) to inactivate the enzyme by metal chelation. Because this compound is based on a naturally occurring membrane lipid and appears to chelate metals buried deeply within water insoluble environments, this agent may also be useful as a general tool for identifying previously unappreciated metal dependencies of other classes of membrane proteins.

Metalloproteins are essential to biological systems, playing critical roles in processes ranging from oxygen transport to signal transduction. The metals within these proteins can serve as structural components or as active site catalytic centers. Although many identified metalloproteins are membrane-spanning proteins, possessing one or more hydrophobic domains, the relative water solubility of standard metal chelators used to probe membrane protein function suggests that many other membrane proteins may have gone unrecognized as metalloproteins. In this study, we report the development of a cholesterol-based chelator that may serve as an excellent tool for identifying the metal dependence of membrane proteins. This molecule (**7**) contains the high affinity metal chelating group, lysine nitrilotriacetic acid (Lys-NTA), covalently linked via an N^{ϵ}-carbamoyl linkage to cholesterol through the 3-hydroxyl on ring A (Chart 1). Other classes of chelator lipids coupled to Lys-NTA, such as NTA-dioctadecylamine (NTA-DODA) (*1*) or imidodiacetic acid (IDA) (*2*), have been synthesized and used previously for targeting biomolecules to artificial membranes and for organizing both soluble and membrane-associated histidine-tagged biomolecules at lipid interfaces to form two-dimensional arrays (*1*–*15*).

We used the isoprenylcysteine carboxylmethyltransferase (Icmt) from *S. cerevisiae*, Ste14p, as the model enzyme for this study. Ste14p is a 26 kDa endoplasmic reticulum (ER) membrane-spanning enzyme responsible for the posttranslational carboxylmethylation of CaaX motif proteins (*16*–*19*). Preliminary evidence suggests that Ste14p and its mammalian Icmt counterparts are dependent upon metals for activity (*20*, *21*). Although concentrations of EDTA up to 100 mM have no effect on activity, treatment of crude membranes with relatively high concentrations (10–50 mM) of *o*-phenanthroline eliminate the catalytic activity, presumably by chelation and perhaps removal of the metal from the enzyme (*20*, *21*). Lower concentrations of the more hydrophobic chelator compound 2-[5-(2-hydroxy-5-sulfophenyl)-3-phenyl-1-formazyl]benzoate (Zincon) were more effective, demonstrating 50% inhibition at approximately 3 mM (*21*). Taken together, these data suggest that more membrane-permeable, polycyclic, hydrophobic chelators would be increasingly effective at inhibiting these methyltransferases. In particular, we hypothesized that chelating moieties linked to naturally occurring membrane components may be most efficacious.

The compounds shown in Chart 1 were synthesized (*22*) to determine the molecular properties that are required to successfully inhibit Ste14p activity (see Supporting Information for the detailed synthesis of cholesterol-Lys-NTA (**7**)). Methyltransferase assays were performed essentially as described (*23*–*26*) with minor modifications. The assay mixture contained a total volume of 60 μL and a final Tris-HCl concentration of 100 mM, pH 7.5. All reactions contained 20 μM *S*-adenosyl-[^{14}C-*methyl*]-methionine (SAM) and 5 μg of membrane protein from Ste14p-overexpressing yeast strains (*21*). Inhibition curves were generated by varying the amount of potential inhibitor compound in each reaction

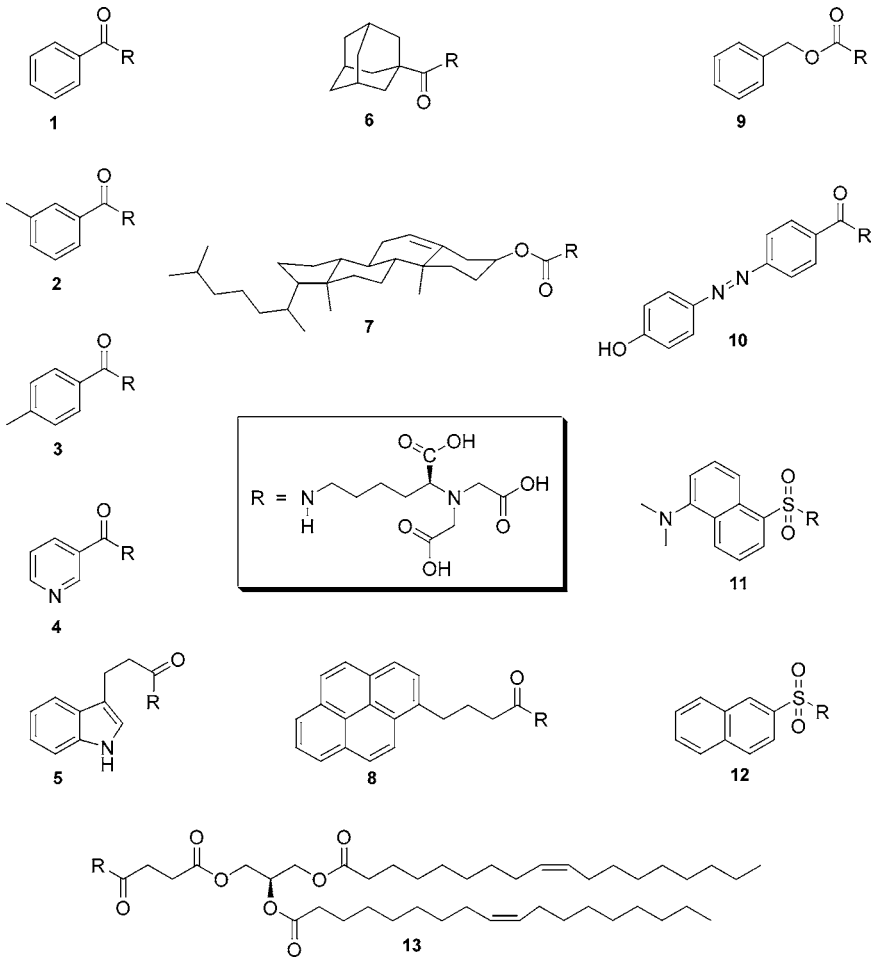
Chart 1. Metal-Chelating Organic Compounds Tested as Inhibitors on Ste14p Activity in Vitro[a]



[a] Benzoic-Lys-NTA (**1**); *m*-toluic-Lys-NTA (**2**); *p*-toluic-Lys-NTA (**3**); nicotinic-Lys-NTA (**4**); indole-3-acetic-Lys-NTA (**5**); adamantane-Lys-NTA (**6**); cholesterol-Lys-NTA (**7**); 1-pyrenebutyric-Lys-NTA (**8**); benzylcarbamoyl-Lys-NTA (**9**); azo-Lys-NTA (**10**); dansyl-Lys-NTA (**11**); 2-naphthalenesulfonyl-Lys-NTA (**12**); 1,2-dioleoyl-sn-glycero-3-[*N*-(5-amino-1-carboxypentyl)iminodiacetic acid)succinyl] (DOGS)-NTA (**13**) (Avanti Polar Lipids, Inc.)

in the presence of *N*-acetyl-*S*-farnesyl-L-cysteine (AFC), the methyl accepting substrate, at 33 μM, which is twice the K_m for the yeast Ste14p enzyme in membranes. Membranes were preincubated for ~5 min with inhibitor compounds on ice prior to the addition of AFC and SAM. The reactions were then incubated at 30 °C for 30 min and stopped with the addition of 50 μL of 1 M NaOH/1% (v:v) SDS. One hundred microliters of this mixture was spotted on folded filter paper (5.5 cm × 1.5 cm) and lodged in the neck of a scintillation vial containing 10 mL of scintillation fluid. Hydroxide ion forms a tetrahedral intermediate with the newly formed ^{14}C-methyl ester on the methyl acceptor. This intermediate then eliminates ^{14}C-methanol that diffuses into the scintillation fluid below. The filters were pulled out after 2−3 h, and the vials were shaken well and counted in a liquid scintillation analyzer.

In this study, we found that only cholesterol-Lys-NTA (**7**) was effective in inhibiting the in vitro methyltransferase activity of Ste14p (Table 1, Figure 1). The Ste14p protein used in these experiments contains a 10 histidine repeat at the N-terminus followed by a triply iterated *myc* epitope tag (His-Ste14p) (*21*). These tags were engineered to aid in purification and identification of Ste14p by immunoblot analysis. The inhibition by each compound is shown in Table 1 and is represented as the percent methyltransferase activity remaining upon treatment with 1 mM of the respective compound compared

Table 1. Percent Activity of Ste14p in Vitro in the Presence and Absence of 1 mM Inhibitor Compounds

compound no.	percent activity	compound no.	percent activity
no inhibitor	100 ± 2.6	**7**	5.8 ± 2.5
1	108 ± 2.2	**8**	108 ± 1.2
2	111 ± 1.9	**9**	112 ± 1.3
3	108 ± 1.7	**10**	112 ± 4.1
4	111 ± 2.2	**11**	104 ± 1.9
5	108 ± 3.4	**12**	122 ± 4.6
6	107 ± 1.8	**13**	76.2 ± 4.6

to the untreated control reaction. We further examined the concentration dependence of inhibition by **7** on methyltransferase activity and determined the IC_{50} value to be ~75 μM (Figure 1), which is nearly 40 times more potent than the best known Icmt inhibitor, Zincon. The relative potency of this compound compared to EDTA and *o*-phenanthroline can be attributed to both the hydrophobicity of the cholesterol moiety ligated to the chelating agent Lys-NTA and the rigidity of the fused ring system. We propose that the rigid hydrophobic cholesterol moiety promotes partitioning into the membrane, enabling the metal-binding NTA groups to inactivate the enzyme by metal chelation. The only other compound that demonstrated any inhibitory ability (~25% inhibition; Table 1) was the commercially available DOGS−NTA (**13**), another compound that resembles a naturally occurring membrane lipid. The relative ineffectiveness of DOGS−NTA as an inhibitor may be due to the flexibility of this

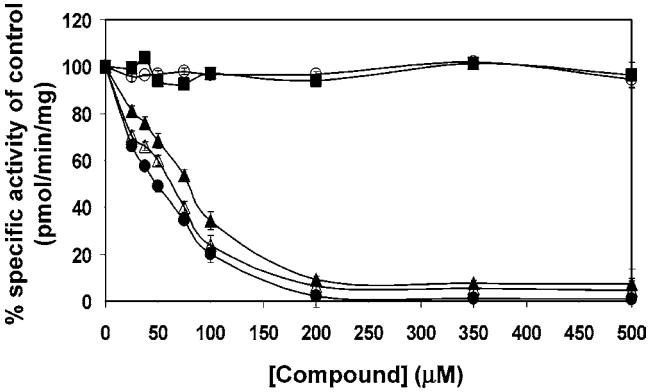


Figure 1. Concentration dependent inhibition of Ste14p-dependent methyltransferase activity by compound **7** and related compounds. Three Ste14p variants were used: His-Ste14p, untagged Ste14p and Ste14p^{C99S,C121S,C126S}. Assays were performed with 5 μg crude membrane protein expressing one of these variants in the presence of 33 μM *N*-acetyl-S-farnesyl-L-cysteine (AFC) and the activity was quantified by the in vitro vapor diffusion methyltransferase assay (*23, 26, 28*). To normalize for batch to batch and variant to variant differences in enzymatic activity, the inhibition data is presented as the percent of the control reactions that lacked inhibitor. His-Ste14p in the presence of **7** (▲); Cholesterol-Lys-NTA trimethyl ester (○); or cholesterol (■). Compound **7** incubated with untagged Ste14p (●) or Ste14p^{C99S,C121S,C126S} (△). Each experiment was performed in duplicate a minimum of two times. Error bars report standard error.

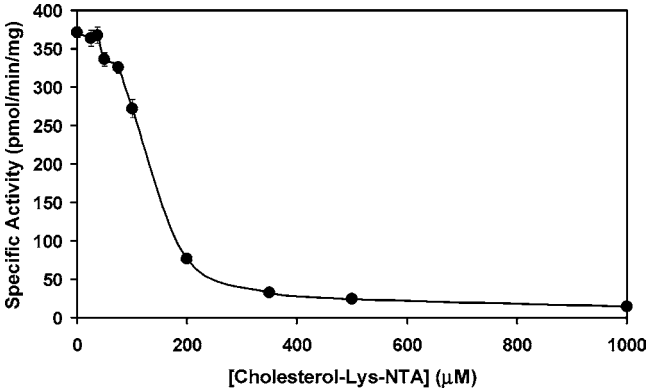

Figure 2. Concentration dependent inhibition of His-hIcmt-dependent methyltransferase activity by compound **7**. Assays were performed with 5 μg of crude membrane protein expressing His-hIcmt in the presence of 33 μM AFC, and the activity was quantified by the in vitro vapor diffusion methyltransferase assay. Each experiment was performed in duplicate a minimum of two times. Error bars are reported as standard error.

compound that may preclude access of the NTA group to the hydrophobic metal binding region of the protein.

Because the Ste14p protein used in these experiments contains a 10 histidine repeat at the N-terminus followed by a triply iterated *myc* epitope tag, we needed to ensure that the inhibition we observed with the cholesterol-Lys-NTA compound (**7**) was not due to interaction with the tags on Ste14p. Therefore, we constructed and expressed an untagged version of the Ste14p protein and performed similar methyltransferase assays in the presence and absence of **7**. These results demonstrated that the untagged wild-type protein is also inhibited by **7** in a concentration dependent manner with an IC_{50} of ~45 μM (Figure 1), suggesting that interaction of **7** with the tags is not responsible for the inhibition.

To further substantiate our hypothesis that **7** is inhibiting via metal chelation, we examined the effects of unmodified cholesterol and cholesterol-Lys-NTA trimethyl ester as inhibitors. In the latter compound, the carboxylic acids in the NTA portion of the molecule are methyl-esterified and thus unable to engage in metal chelation. The addition of increasing concentrations of either cholesterol or cholesterol-Lys-NTA trimethyl ester to the reaction had no inhibitory effect on Ste14p methyltransferase activity (Figure 1). These data further support the hypothesis that the inhibition mechanism of **7** is via metal chelation. An alternative hypothesis suggesting that Ste14p methyltransferase inhibition arises from a detergent effect of the hydrophobic NTA derivatives is not supported by our findings since the DOGS−NTA compound, a superior detergent to cholesterol-Lys-NTA, only inhibits ~25% of the methyltransferase enzymatic activity at 1 mM (Table 1).

Cysteine and histidine residues are common chelating ligands in proteins. To assess the importance of cysteines in the activity of Ste14p as well as in the ability of **7** to inhibit activity, a mutant of Ste14p was constructed that had all three naturally occurring cysteines mutagenized to serine (Ste14p^{C99S,} Ste14p^{C121S,} Ste14p^{C126S}). This cysteine-less Ste14p variant was expressed equally to the untagged wild-type protein as determined by immunoblot analysis (see Supporting Information). Our data further demonstrate that **7** inhibits the cysteine-less mutant with an IC_{50} of ~35 μM, a value comparable to that for the untagged wild-type enzyme (Figure 1). Taken together, these data suggest that the cysteine residues in Ste14p are not essential for activity and that other amino acids in Ste14p must be ligated to the metal ion in the protein structure.

We further examined the ability of **7** to inhibit the activity of the human homologue of Ste14p, hIcmt. Ste14p and hIcmt share 41% identity and 63% similarity overall, suggesting that their three-dimensional structures and mechanisms of action are similar. In fact, human Icmt expressed in yeast functionally complements a Δ*ste14* deletion strain (*27*). By analogy to the His-Ste14p experiments, an epitope tagged variant of hIcmt (His-hIcmt) containing a 10 histidine repeat at the N-terminus followed by a triply iterated *myc* epitope tag was expressed in *S. cerevisiae* and assayed for activity in the presence and absence of increasing concentrations of **7** (Figure 2) (*21*). The calculated IC_{50} for inhibition of His-hIcmt with **7** is ~135 μM (Figure 2). These data not only suggest that the human and yeast enzymes both have similarly accessible metal ions and, thus, three-dimensional structures, they also show that **7** should prove to be a excellent tool for studying the metal dependence of other members of the Icmt family of enzymes.

We report here that the novel compound cholesterol-Lys-NTA (**7**) exhibits great potential as a tool for characterizing the metal dependence of the Icmt family of enzymes. Although outside the scope of this initial study, complete certainty of the efficacy of **7** as a membrane metalloenzyme probe will come with the successful identification of the chelated metal. We are currently developing a strategy to extract the cholesterol−Lys-NTA−metal complex from reconstituted vesicles containing purified Ste14p (*21*) and are seeking to identify the metal by inductively coupled plasma mass spectrometry. Because **7** is based on a naturally occurring membrane lipid and appears to chelate metals buried deeply within water insoluble environments, this agent may also be useful as a general tool for identifying previously unappreciated metal dependencies of other classes of membrane proteins.

ACKNOWLEDGMENT

We would like to thank Kathryn Solka and Hilary Frase for preliminary data and Olvia C. Colon-Villafane for plasmid construction and protein expression. This work was supported by a grant from the National Pancreas Foundation (to C.A.H) and the Indiana 21st Century Fund (to C.A.H, and D.H.T).

Supporting Information Available: The chemical synthesis of the compound **7** as well as a description of the cloning procedures, immunoblot assays, and enzymatic assay is available free of charge via the Internet at http://pubs.acs.org.

Transferrin-Mediated Gold Nanoparticle Cellular Uptake

Pei-Hui Yang,[†,§] Xuesong Sun,[†] Jen-Fu Chiu,[‡] Hongzhe Sun,*[,†] and Qing-Yu He*[,†]

Department of Chemistry and Open Laboratory of Chemical Biology, and Institute of Molecular Biology, University of Hong Kong, Hong Kong . Received September 18, 2004; Revised Manuscript Received February 10, 2005

Targeted drug delivery is an important research area in specific therapy. Transferrin-conjugated nanoparticles are an attractive formulation as a vehicle for specific cellular uptake and targeted drug delivery. In this report, atomic force microscopy imaging was used to visualize the process of cellular uptake of transferrin-coupled gold nanoparticles on the surfaces of live cells for the first time. High-resolution images were captured, showing the endocytosis of transferrin-conjugated nanoparticles taking place during the process of internalization. This specific transferrin-mediated nanoparticle uptake was validated by confocal scanning imaging and transferrin competition experiments.

Targeted entry into cells is an important area of research in drug delivery and therapy (*1*–*4*). Site-specific delivery of drugs and therapeutics can significantly reduce drug toxicity and increase therapeutic effects. To realize efficient and specific cellular drug delivery, one strategy is to modify or conjugate drug with a ligand that can be efficiently taken up by target cells via receptor-mediated endocytosis (*5*). Transferrin (TF)[1] is such a suitable "ligand" for conjugating drugs, since it can be specifically recognized and taken up by TF receptors actively expressed on the surface of various tumor cells (*6*). The transferrin−receptor interaction has therefore been exploited as a potential efficient pathway for the cellular uptake of drugs and genes (*7*–*9*).

Nanoparticles have also been considered as effective delivery vehicles and extensively studied for delivering drugs, genes, diagnostics, and vaccines into cells of interest (*10*–*12*). Nanoparticles cross-linking with proteins have demonstrated better stability and efficiency for cellular uptake. Nanoparticle−TF conjugation is thus an attractive formulation for specific cellular uptake and targeted drug delivery.

Atomic force microscopy (AFM) is a surface analytical technique that can generate nanoscale topography by scanning a fine silicon tip across the surface. Because it can perform high-resolution imaging under physiological conditions in a nondestructive manner, AFM has developed into a powerful tool for studying the structural details of biological systems (*13, 14*). While the use of AFM to characterize the morphology of nanoparticles and biophysical properties of cells has previously been reported, the imaging of the nanoparticle uptake into cells is a rarely studied area. In this report we used AFM to visualize the process of cellular uptake of TF-conjugated gold nanoparticles on the surfaces of live cells for the first time.

Gold nanoparticles were synthesized according to a modified literature method (*15*). These nanoparticles were characterized by transmission electron micrography and powder X-ray diffraction. They were then covalently coupled to TF molecules by mercaptoacetic acid (*16*). Measurements with dynamic laser light scattering showed that these nanoparticles have sizes of 20.2 ± 0.6 nm for Au alone and 96.7 ± 2.0 for TF-derivatized Au−TF particles, indicating that multiple coupling of Au to TF or aggregation for some of the Au−TF particles occurred. When the Au−TF nanoparticles were incubated with human nasopharyngeal carcinoma cells (NPC, SUNE1) (*17*) under physiologically relevant conditions, a phenomenon of nanoparticle internalization into cells was visualized by a multimode AFM with a Nanoscopy IIIa controller (Veeco/Digital Instruments, Santa Barbara, CA) (Figure 1). The AFM image captured after 5-h incubation shows that cellular uptake was partially proceeding, leading to a "bumpy" surface (Figure 1C). The process of the nanoparticle uptake by NPC cells can be further observed by AFM imaging in a "zoom in" scale. The high-resolution image in Figure 1D demonstrated how the endocytosis is taking place. While a couple of clear holes indicated that the endocytosis may be just completed in these areas, cellular uptake halfway through the internalization process for some of the Au−TF nanoparticle cluster was vividly visualized. To our knowledge, this is the first time that the cellular process of nanoparticle uptake has been observed by AFM.

To validate the nanoparticle internalization into NPC cells, a Zeiss 410 (Germany) confocal laser scanning microscope (excitation at wavelength 488 nm and emission at wavelength 515 nm) was utilized to capture the fluorescence images of the cells after incubation with fluorescence-labeled Au−TF nanoparticles. The emission of the labeled TF nanoparticles produces green fluorescence. Its position and intensity represent the location

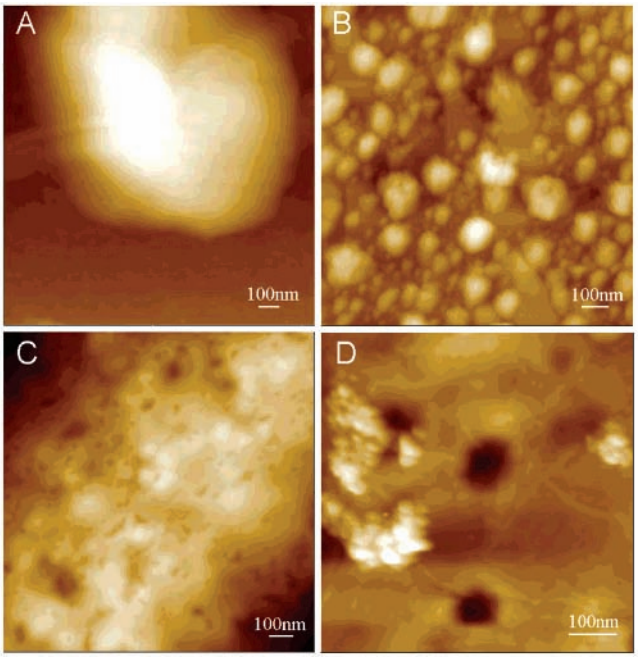

Figure 1. AFM images demonstrate Au−TF nanoparticle uptake by NPC cells. (A) A single NPC cell; (B) Au−TF nanoparticles on a NPC cell surface at the beginning of incubation; (C) NPC cell surface after incubation with Au−TF nanoparticles for 5 h; and (D) "zoom in" AFM image of cell surface after incubation with Au−TF for 5 h, showing nanoparticle uptake during the process of endocytosis.

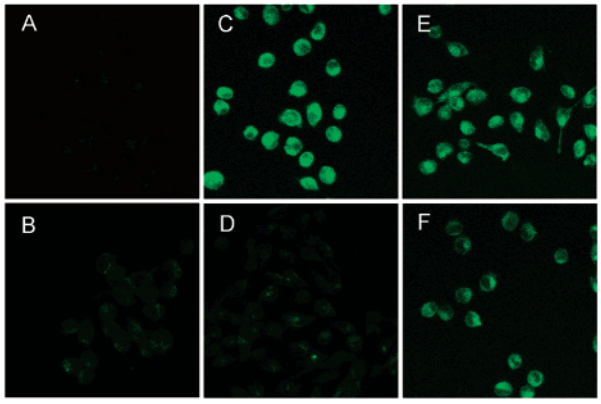

Figure 2. Confocal cell images show that Au−TF nanoparticles were internalized into the cellular plasma of NPC cells via TF−receptor interaction pathway (5-h treatment). (A) Control cells without Au−TF nanoparticles; (B) cells treated with Au nanoparticles alone; (C) cells incubating with Au−TF nanoparticles; (D) cells treated with Au−albumin nanoparticles; (E and F) cells cotreated with different proportions of Au−TF verses holo-TF (1:2 and 1:5, respectively).

and relative concentration of the labeled TF nanoparticles. Figure 2 shows confocal images for cells treated under different conditions for 5 h. Control cells (Figure 2A) and cells treated with Au nanoparticles alone (Figure 2B) reasonably displayed little fluorescence. In contrast, very bright fluorescence was observed in cells incubated with Au−TF (Figure 2C), clearly indicating that alot of Au−TF nanoparticles were taken up into cells, with most of the internalized nanoparticles localizing in the cytoplasm compartment. At the same time, the NPC cells were still healthy after taking up the nanoparticles. Moreover, a control study showed that the fluorescence-labeled Au−TF particles did not have detectable changes

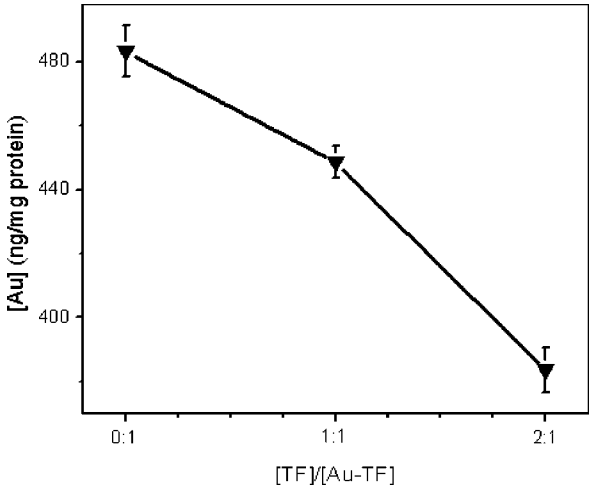

Figure 3. Nanoparticle concentrations at different ratio of holo-TF verses Au−TF. [Au−TF] were fixed at 10 μM.

in sizes after incubation with the cell culture medium for 24 h, revealing the high stability of the covalently TF-derivatized particles during the experiments.

Since nanoparticle uptake into cells could go through different processes including phagocytosis, fluid-phase endocytosis, and receptor-mediated endocytosis, we performed control studies with fluorescence-labeled Au−albumin and competition experiments with natural full-length transferrin (holo-TF) to verify whether the internalization of the TF-coupled nanoparticles was mediated via the specific TF−receptor interaction pathway. As shown in Figure 2D, cells incubated with Au−albumin displayed only little minor fluorescence, and compared to that in Figure 2C, fluorescence intensities significantly decreased in the cells cotreated with Au−TF and excess holo-TF (Figure 2E,F). These results evidently implicate the specific nanoparticle cellular uptake through TF−receptor interaction.

Other supporting evidence was derived from ICP-MS measurements of the nano−Au contents in cells treated with different proportions of holo-TF/Au−TF. Three different concentration ratios (0:1, 1:1, and 2:1) of holo-TF verses Au−TF were introduced into the cell culture. Total cell lysates digested from the harvested NPC cells were used for determination of Au concentration in cells by ICP-MS (7500 series, Agilent). Figure 3 clearly shows that the Au concentration in the cells significantly decreased with regard to the increase of holo-TF concentration in the cell culture. These data, together with the above confocal results, strongly suggest that at least part of the TF-coupled nanoparticles were internalized into cells via TF-receptor mediated endocytosis.

The TF−receptor cycling pathway has long been considered to be an effective "delivery system" into cells, and many cytotoxic agents have been conjugated to TF as potential anticancer therapeutics (*6, 9*). Our present data demonstrated that TF−receptor-mediated nanoparticle delivery into cells really occurred, and that the endocytosis process can be directly visualized through AFM imaging. In light of a recent study showing that TF binds the receptor ectodomain to form the TF−receptor complex (*18*), it is possible that TF conjugation with nanoparticles at certain positions is tolerable for the endocytosis, since the ectal binding mode of TF−receptor reduces space restrictions. That being the case, our present observations provide useful information for better design of nanodrugs and their targeted delivery.

The Peptide Route to Multifunctional Gold Nanoparticles

Zhenxin Wang,[†] Raphaël Lévy,[†,‡] David G. Fernig,[‡] and Mathias Brust[†,*]

Centre for Nanoscale Science, Department of Chemistry and School of Biological Sciences, The University of Liverpool, Liverpool, UK. Received February 21, 2005; Revised Manuscript Received April 8, 2005

Extremely stable, peptide-capped gold nanoparticles with two different biomolecular recognition motifs expressed on their surface have been prepared, and their specific and selective binding to artificial, DNA-modified target particles and to DNA and protein microarrays has been demonstrated. Stabilization and biofunctionalization has been achieved in a single preparative step starting with citrate-stabilized gold hydrosols and a derivatization cocktail of peptide-capping ligands, which carry the functionalities of choice.

Exploiting the optical properties of nanoparticles for the development of ultrasensitive detection and imaging methods in the biomedical sciences is becoming increasingly important (*1*−*3*). Particularly attractive is the use of Au and Ag nanoparticles in resonant light scattering (RLS) and photothermal microscopy, which are able to image single particles (*4*−*7*). The latter technique is capable of detecting particles at least as small as 2 nm in complex biological environments. For these applications, attaching the biomolecular recognition motif of interest to the nanoparticles has to be readily achieved, and, most importantly, the probes must not bind nonspecifically to each other or to anything else present in the system under investigation. In addition, introducing multiple functionalities would be of great value, as it provides more flexibility for multiplexing in bioanalytical applications and new tools to control the bottom-up assembly of nanostructures.

Here we demonstrate that multiply functional peptide-stabilized gold nanoparticles are readily obtained in a one-step surface coating procedure and that the respective surface functionalities can be selectively addressed on a microarray. The particles are of the stability typical for peptide capping (*8*) and show no indication of nonspecific binding as established by transmission electron microscopy (TEM), UV−vis spectroscopy, and microarray imaging even under testing conditions of ionic strength (see Supporting Information). In contrast to most previously reported approaches, stabilization and functionalization of the particles are independent of each other, while both are achieved in a single step. Functionality is simply introduced by including a proportion of stabilizing peptide to which a functionality of choice has been attached. Therefore, the number of recognition functions present on each particle could be altered and even reduced to a single or very few moieties without compromising the stability of the particles.

We have previously reported the preparation of peptide-capped gold nanoparticles and their functionalization with biotin (see also Supporting Information) (*8*). We now take advantage of the generality of the peptide route and demonstrate that it provides a fast and simple approach to DNA functionalization and to bifunctional nanoparticles carrying both DNA and biotin moieties. These functionalities were chosen for being already well established in nanoparticle systems and thus predictable in their recognition properties (*1*−*7*, *9*−*26*).

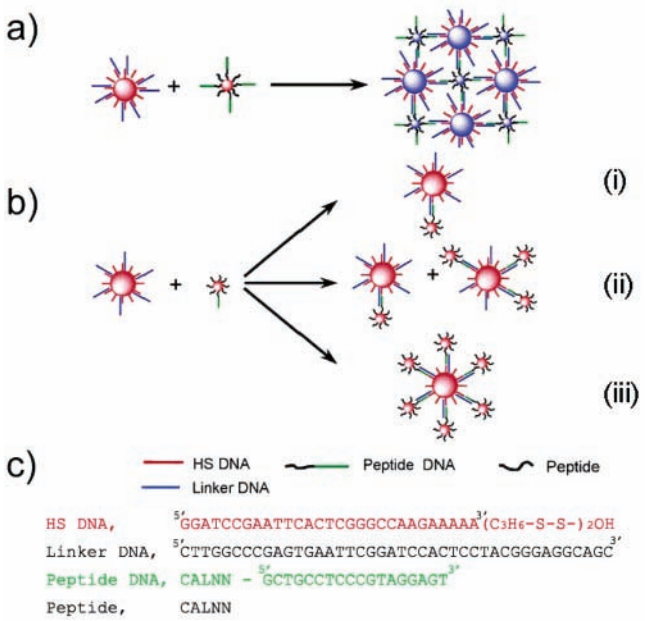

Figure 1. Nanoparticle binding scenarios and sequences of DNA and functionalized peptides. (a) 13 nm DNA-functionalized small particles with high DNA loading (>3%) binding to 40 nm DNA-stabilized large particles to form extended aggregates. (b) 13 nm DNA functionalized small particles with intermediate DNA loading (0.3−1%) binding to DNA-stabilized 40 nm large particles at a small particle to large particle ratio of (i) 10:1, (ii) 30:1, and (iii) 100:1. (c) Sequences of DNA and functionalized peptides used. Peptides are in the conventional N- to C-terminal orientation.

Thirteen nanometer gold nanoparticles were prepared via the classical citrate reduction route (*27*, *28*). Stabilization and DNA functionalization was achieved by adding an aqueous mixture of the CALNN (cysteine, alanine, leucine, asparagine, asparagine) capping peptide and a CALNN−DNA conjugate (18 base single-stranded DNA) followed by centrifugation to purify the material.

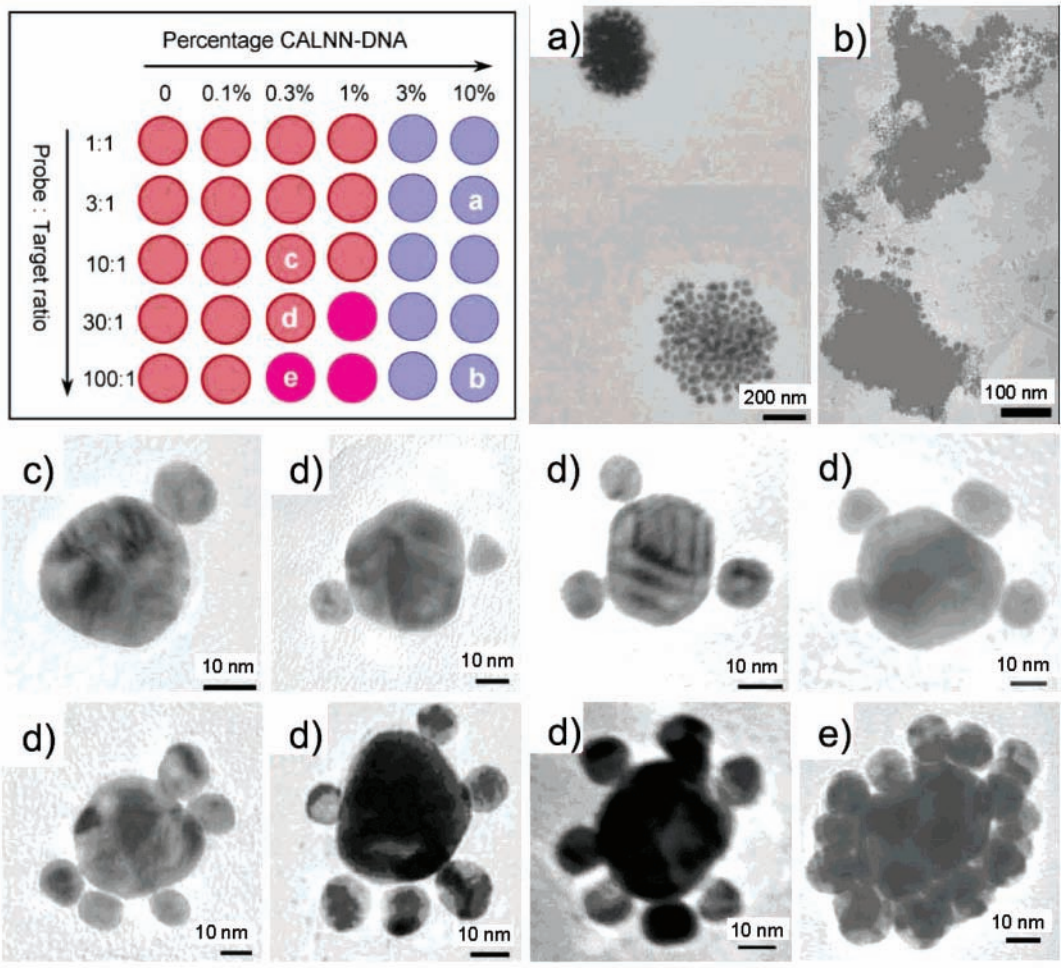

Figure 2. Dependence of the aggregation of small (probe) and large (target) particles on the experimental conditions. Varying both the DNA loading of the small particles and the small particle to large particle ratio affects the perceived color of the solutions (top left panel) and the type of aggregates formed (see selected TEM images, labels correspond to those in the top left panel). Blue color indicates the formation of extended aggregates (a and b), red indicates either no aggregation or the formation of large particles labeled by a small number of small particles (c and d), and purple indicates the formation of a dense shell of small particles around individual large particles (e).

The specific recognition properties of these particles were investigated by binding to standard Mirkin-type (*9*) 40 nm gold nanoparticles via a three-strand system. The 40 nm particles were stabilized by a shell of thiol-modified (ss) DNA, which was then hybridized to a linker strand of 42 bases to leave 18 bases as an overhanging recognition sequence. This sequence was chosen to be complementary to the DNA on the peptide-capped particles. DNA hybridization then leads to particle aggregation, demonstrating the successful DNA functionalization of the peptide-capped particles.

In an attempt to control the number of DNA molecules per nanoparticle, we systematically varied the proportion of CALNN−DNA in the stabilization mixture. We also changed the relative abundance of 40 and 13 nm particles in the hybridization buffer. Possible binding scenarios for these different experimental conditions are schematically suggested in Figure 1, and the range of different nanostructures found experimentally by TEM is shown in Figure 2. It was found that the formation of very different aggregated structures was controlled by these two parameters. At a glance, this is best confirmed by optical spectroscopy or simply by visual inspection of the aqueous reaction mixtures. The formation of extended aggregates is observed already for relatively low DNA loadings, i.e., whenever the concentration of CALNN−DNA in the stabilizing mixture reaches 3% in total ligands (40 nM) or more. This aggregation behavior has been confirmed from a one-to-one ratio to a 100-fold excess of complementary particles in the solution. The transition from a well-dispersed system to complete aggregation happens rather suddenly. Close to the proportion of CALNN−DNA in the stabilization mixture required for the formation of precipitates, structures, in which two or more large particles were bound to each other via small particles were regularly observed. The formation of extended aggregates is readily monitored by a clearly perceptible color change of the solutions from red to blue followed by the slow precipitation of the material. On the contrary, at a CALNN−DNA concentration of 1.4 nM (0.1% of total number of ligands) or less no specific binding was observed in the system, even with a 100-fold excess of small particles. The parameter space in which pairs between large and small particles were obtained was remarkably narrow. Isolated aggregated structures of a discrete number of small particles bound to a single large particle were obtained only for intermediate concentrations (4−14 nM, i.e., 0.3−1% of total number of ligands) of CALNN−DNA in the stabilizing mixture. Within this narrow range the binding number of small particles per large particle is chiefly determined by the relative proportion of small particles in the system, as illustrated by the bar diagrams in Figure 3. Depending on the relative excess of small particles, aggregates with binding

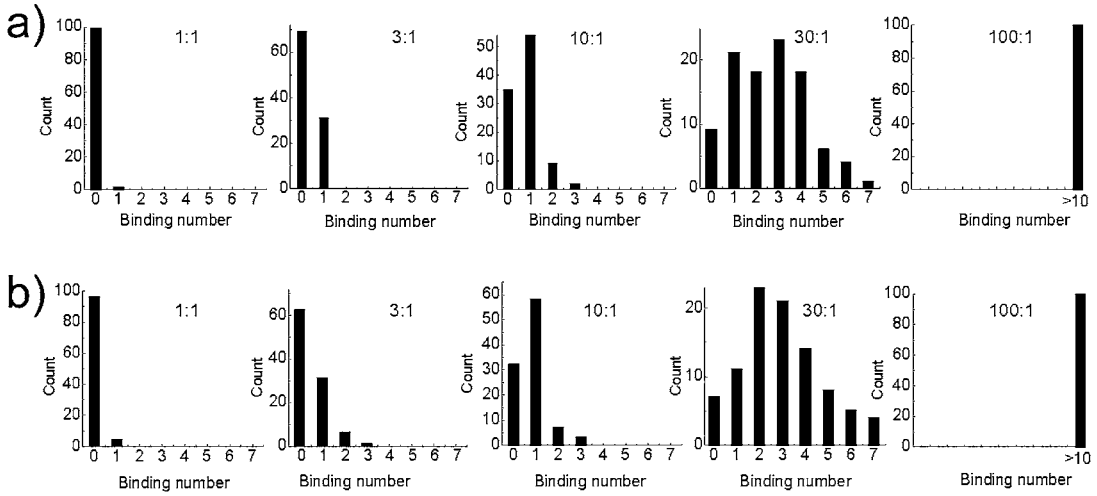

Figure 3. Dependence of small particle to large particle binding numbers on the applied small particle to large particle ratio. Experimentally found binding number distributions (by TEM) are shown for small particle to large particle ratios from 1:1 to 100:1 for a DNA loading of the small particles of (a), 0.3% and (b), 1%.

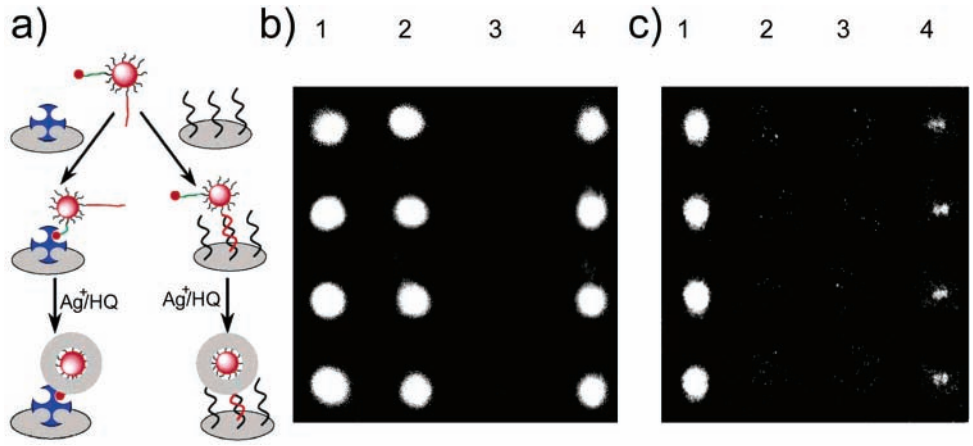

Figure 4. Schematic representation of DNA and protein microarrays labeled with bifunctional gold nanoparticles followed by silver enhancement (a). Light scattering images of protein microarray (b) and DNA microarray (c) after silver enhancement. In b, avidin was spotted on column 1, 2, and 4, while protein A was spotted as a nonspecific control on column 3; in c, perfectly matched DNA was spotted on column 1, three-base-mismatched DNA was spotted on column 2, two-base-mismatched DNA was spotted on column 3, and one-base-mismatched DNA was spotted on column 4.

numbers from 1 to ca. 100 small particles per large particle could be prepared. The limiting case is the formation of a complete shell of small particles around each large particle as shown in Figure 2e. Aggregates with such high binding numbers also led to a perceptible color change of the solution from red to purple without subsequent precipitation. Core−shell nanostructures of large particles surrounded by small particles are stable in solution for weeks and are readily isolated from excess small particles by centrifugation.

These experiments may mimic the attachment of gold nanoparticle probes to target structures in biological systems and map out the conditions required to achieve effective labeling. More importantly, they provide guidance for the preparation of nanoparticles with two or more different specific recognition groups attached. Such multifunctionality of nanoparticles has been reported previously for nonbiomolecular functionalities on monolayer protected clusters (MPCs) (*18*, *29*−*31*). Niemeyer et al. have shown that multifunctionality can be achieved by the use of different DNA sequences on one particle and also reported that a relatively low loading of the particles with DNA is sufficient to achieve very efficient specific binding (*19*). Here we demonstrate that different types of biomolecular recognition groups, i.e., biotin and DNA, can be readily incorporated in a single stabilization/functionalization step via our peptide route. Guided by the results obtained for the DNA only system we have chosen to include 70 nM (5% of total number of ligands) CALNN-DNA (18 base recognition sequence) and 70 nM (5% of total number of ligands) CALNNGK(biotin)G in the stabilization mixture. This should lead to high reactivity of the particles toward both complementary DNA and avidin. To demonstrate the binding specificity of these bifunctional particles, we prepared a protein microarray containing spots with avidin as well as control spots with protein A, and a DNA microarray containing spots with complementary DNA, as well as control spots with DNA possessing mismatches of one, two, and three bases. After binding of the particles the microarrays were exposed to a silver enhancement step, i.e., electroless deposition of metallic silver on the gold particles, which act as nucleation sites (*32*). The microarrays were read by measuring the intensity of scattered light using a Qiagen High-light System. The results of specific binding of the bifunctional particles to these microarrays are shown in Figure 4. It was found that the particles bind to both avidin and to complementary DNA with high specificity. Importantly, no evidence for significant nonspecific binding was found (detailed data in Supporting

Information). DNA with a one base mismatch is still weakly detected, which is consistent with the expected remaining recognition properties of this DNA. No binding to DNA with a mismatch of two or more bases is detected.

In conclusion, we have developed a straightforward route to stable gold nanoparticles, both with single and with dual biological functionality. The particles exhibit the specific recognition properties of the biological functionalities they carry without any indication of nonspecific binding or particle aggregation. While the stability of the particles does not depend on the number of functional groups introduced, functionalization and stabilization are achieved in a single step where the relative abundance of functional peptides in the stabilization mixture appears to control the number of functionalities introduced into the peptide ligand shell of the particles. The large difference in the chemical nature of the recognition motifs used in this study suggests that this approach should be easily extended to a variety of peptide and peptide conjugate labels, including the large number of peptides recognizing with high specificity and affinity biological and nonbiological structures.

Enhanced Oligonucleotide Binding to Self-Assembled Nanofibers

Mustafa O. Guler,[†] Jonathan K. Pokorski,[†] Daniel H. Appella,[†] and Samuel I. Stupp*[,†,‡,§]

Department of Chemistry, Department of Materials Science and Engineering, and Feinberg School of Medicine, Northwestern University, 2220 Campus Drive, Evanston, Illinois 60208 . Received February 24, 2005; Revised Manuscript Received March 23, 2005

A peptide nucleic acid/peptide amphiphile conjugate (PNA−PA) that self-assembles into fiber-shaped nanostructures was designed to bind oligonucleotides with high affinity and specificity. Oligonucleotide binding to PNA−PA nanofibers was studied using fluorescence polarization, and thermal stability was examined by UV−vis measurement of duplex melting temperatures. The self-assembled PNA−PA DNA system was observed to bind more strongly than the corresponding DNA−DNA duplex. We also observed single base specificity with a 16 °C in thermal stability. As expected from the previous PNA studies, PNA−PA RNA binding is also stronger than the corresponding RNA−RNA duplex.

Recent developments in molecular biology demonstrate the importance of RNA isolation and detection experiments such as Northern analysis (*1*, *2*), nuclease protection assays (*3*), RT-PCR (reverse transcription−polymerase chain reaction) (*4*), RNA mapping (*5*), and in vitro translation (*6*). Among the different methodologies used to separate and purify RNA sequences for genetic research, isolation of mRNA containing polyadenylic (poly A) regions plays an important role in detection and quantification of low-copy mRNAs (*7*). Therefore, developing isolation tools for poly A-containing mRNAs using thymine-functionalized high molecular weight polymers (e.g. cellulose, polystyrene beads) has been an active area of research (*8*, *9*). Hydrogels derived from self-assembled molecules that specifically bind oligonucleotides are interesting targets for new biomaterials (*10*). In this study, we exploit the nanoscale structure of self-assembled nanofiber networks as an approach to bind poly A sequences.

We have designed and synthesized a novel peptide nucleic acid/peptide amphiphile conjugate (PNA−PA). These molecules contain a peptide nucleic acid segment followed by a peptide sequence terminated by an alkyl segment. The PNA−PA molecules self-assemble upon increasing pH to above pH 7 to form a self-supporting gel consisting of a network of nanofibers. This behavior is similar to that of peptide amphiphiles (PAs) reported previously by our laboratory which self-assemble after pH changes or electrolyte neutralize or shield molecular charges (*11*−*16*). The PNA−PA was designed to contain a KGGGAAAK peptide sequence since nanofiber formation is promoted by intermolecular β-sheets among peptide amphiphiles (*17*). Branching at one of the lysine residues was used to provide an attachment point for the PNA recognition unit on the self-assembled nanofibers and also to increase water solubility (see Figure 1). PNA was chosen over DNA for several reasons (*18*−*23*). First, the uncharged PNA backbone results in thermally stronger PNA−DNA and PNA−RNA duplexes and triplexes than DNA-DNA and RNA-RNA counterparts, especially at very low ionic strength. Second, PNA synthesis is compatible with solid-phase peptide synthesis (SPPS) used for PAs.

The PNA−PA was synthesized by SPPS. Branching of the peptide headgroup was achieved by using orthogonal protecting group chemistry for the amines at the α and ϵ positions of a lysine residue. A poly-thymine PNA heptamer was then built on the PA. The PNA−PA was found to be soluble in water at pH 4. Solutions with concentrations over 1 wt % were observed to form self-supporting gel by increasing the pH above 7. Gel formation was found to be reversible when pH was reduced to 4. Transmission electron microscopy (TEM) and circular dichroism (CD) spectroscopy were used to characterize the supramolecular structure of the PNA−PA. TEM micrographs of the PNA−PA revealed formation of uniform nanofibers with a diameter of 8 ± 1 nm and lengths ranging from 100 nm to several micrometers, as shown in Figure 2 and also in Supporting Information. Circular dichroism spectra of the self-assembled PNA−PA revealed a β-sheet signal at 215 nm ($n\pi^*$ transition) resulting from hydrogen bonding between the peptide segments (see Supporting Information) (*24*). As expected, the PNA segment did not show any CD signal given its achiral structure.

The thermal stability of duplexes formed by nucleotide oligomers and PNA−PA nanofibers was determined by their melting temperature (T_m) using UV to detect their thermal denaturation (*25*). Compared to previous work with PNAs, the PNA−PA nanofibers formed stronger complexes with both polyadenylic DNA and RNA heptamers (*26*, *27*). This resulted in a ca. 25 °C increase in T_m over the corresponding polythymine PNA heptamer (Table 1). Furthermore, the PNA−PA retained sequence specificity when tested with 5′-AAATAAA-3′ single strand DNA (ssDNA). This complex melted at 55.5 °C, which is ca. 16 °C lower than the melting temperature of the fully matched sequence when bound to PNA−PA nanofibers.

Oligonucleotide binding to the PNA−PA was also tested with fluorescence polarization with 5′-AAAAAAA-3′-fluorescein ssDNA. The fluorescence polarization of

Table 1. T_m Data for PNA−PA/Oligonucleotide Complexes[a]

T_m (°C)	PNA_2DNA	PNA_2RNA	mismatch	ΔT_m (°C)
PNA−PA	71.4	73.8	55.5	−15.9
PNA[b]	44.4[b]	48.3[b]		

[a] Conditions for T_m measurement: 10 mM TAPS, 0.1 mM EDTA, and 150 mM NaCl, pH 8.5, UV measured at 260 nm from 90 °C to 25 °C, in 1 °C increments. Strand concentrations were 5.0 μM in PNA and 2.5 μM in the complementary oligonucleotide. ΔT_m represents the difference in melting temperature between the complementary DNA and the DNA with the indicated mismatch. Mismatch represents 5′-AAATAAA-3′ ssDNA. [b] Data adopted from ref (*26*).

fluorescein-tagged polyadenylic ssDNA heptamer was measured to be 0.4 ± 2 milli-Polarization (mP), with an increase to 33 ± 2 mP observed in the presence of self-assembled PNA−PA nanofibers. We attribute this increase to reduced rotational freedom of the tagged DNA sequence, indicative of binding to the self-assembled nanofibers. Fluorescence polarization of fluorescein alone in the presence of the PNA−PA was measured as 0.1 ± 2 mP, indicating an absence of nonspecific binding of the dye to the PNA-PA nanofibers.

We have reported a peptide nucleic acid/peptide amphiphile conjugate that binds to oligonucleotides with high affinity and specificity after self-assembly into nanostructures. Because the nanostructures are easily endocytosed by cells (*28*), this type of hybrid material could be attractive in biomedical research for applications such as RNA interference studies and gene silencing, mRNA separation and purification, as well as potential sensor applications that require strong and specific binding to oligonucleotides. Longer peptide nucleic acid sequences could be of interest for RNA interference applications; however, further study will be necessary to determine if these sequences can be incorporated without distrupting peptide amphiphile self-assembly. Small interfering RNAs (siRNAs) incorporate into protein complexes that are critical in mRNA destruction and translation regulation (*29*). The self-assembling nanostructures described here can be potentially useful in this context, however the siRNA sequence presented on the nanostructures must be released in cytoplasm and be able to complex to proteins without affecting their functions. Further studies are underway to explore other PNA−PA sequences and their behavior under physiological conditions.

ACKNOWLEDGMENT

This work was funded by the US Department of Energy (DoE) under award No. DE-FG02-00ER54810, NSF Nanoscale Science and Engineering Center (NSEC) (EEC-0118025), and J.K.P. was supported by Northwestern University's NIH Biotechnology Training Grant (T32GM008449). We thank the Electron Probe Instrumentation Center for use of its Hitachi H-8100 transmission electron microscope and the Keck Biophysics Facility for use of its Jasco J-715 CD spectrometer and Beacon 2000 fluorescence polarization system at Northwestern University. We also thank Mukti Rao and Liang-Shi Li for TEM and James Hulvat for his helpful discussions.

Structural and Biophysical Characterization of the 40 kDa PEG−Interferon-α_{2a} and Its Individual Positional Isomers

Christophe Dhalluin, Alfred Ross, Luc-Alexis Leuthold, Stefan Foser, Bernard Gsell, Francis Müller, and Hans Senn*

F. Hoffmann-La Roche AG Department of Pharma Research CH-4070 Basel, Switzerland Received September 15, 2004; Revised Manuscript Received March 8, 2005

The human recombinant Interferon-α_{2a} (IFNα_{2a}) is a potent drug (Roferon-A) to treat various types of cancer and viral diseases including Hepatitis B/C infections. To improve the pharmacological properties of the drug, a new pegylated form of IFNα_{2a} was developed (PEGASYS). This 40 kDa PEG-conjugated IFNα_{2a} (^{40}PEG−IFNα_{2a}) is obtained by the covalent binding of one 40 kDa branched PEG-polymer to a lysine side chain of IFNα_{2a}. ^{40}PEG−IFNα_{2a} is a mixture of mainly six monopegylated positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively. Here we report the detailed structural and biophysical characterization of ^{40}PEG−IFNα_{2a} and its positional isomers, in comparison with IFNα_{2a}, using NMR spectroscopy, analytical ultracentrifugation, circular dichroism, fluorescence spectroscopy, and differential scanning calorimetry. Our results show that the three-dimensional structure of IFNα_{2a} is not modified by the presence of the polymer in all positional isomers constituting ^{40}PEG−IFNα_{2a}. Regardless of where the PEG-polymer is attached, it adopts a very mobile and flexible random coil conformation, producing a shield for the protein without a permanent coverage of the protein surface. Hydrodynamic data indicate that the protein-attached PEG has a slightly more compact random-coil structure than the free PEG-polymer. Our results also provide evidence of significant structural and physicochemical advantages conferred by the pegylation: increase of the effective hydrodynamic volume and modification of the molecular shape, higher temperature stability, and reduced tendency for aggregation. These results are of tremendous pharmacological interest and benefit as was clinically shown with PEGASYS. This study constitutes a new standard for the characterization of pegylated proteins and enables an important step toward the understanding on a molecular level of the binding of ^{40}PEG−IFNα_{2a} and its positional isomers to its cellular receptors.

INTRODUCTION

In the 1970s, pegylation was developed to enhance the bioavailability of therapeutic proteins (*1*). In this process, an inert, nontoxic, and water-soluble poly(ethylene glycol) (PEG)-polymer,[1] linear or branched, is attached to a therapeutic protein via a covalent linkage, mostly at lysine or histidine residues located on the surface of the native protein (*2*−*4*). This process has been shown to alter the biochemical and pharmacological properties of the resulting PEG-conjugated proteins (*5*, *6*). It leads to a protein with improved solubility and temperature stability (*7*), enhanced stability against enzymatic degradation (*8*, *9*), increased serum half-life (*10*), decreased renal clearance (*11*), and immunogenicity (*12*, *13*) and thus enhanced biological effectiveness (*14*, *15*) when compared with the unmodified protein.

Today one of the major health concerns worldwide is the chronic Hepatitis C Virus (HCV) infection. It is estimated that 180 million people are infected with HCV (*16*). This infection is the leading cause of chronic liver disease and hepatocellular carcinoma, and the main indication for liver transplantation in the United States and Western Europe (*17*). Until recently the primary therapy for the treatment of chronic HCV infection remained subcutaneous injections of recombinant human Interferon-α (IFNα) in combination with the oral antiviral agent ribavirin (*14*, *18*). It was realized that the pharmacokinetic properties of IFNα proteins are the major factors limiting the efficacy of the treatment: the protein is rapidly degraded, diffuses widely throughout the entire body and has a high rate of renal clearance (*19*, *20*). As a result, after one subcutaneous injection the serum half-life of Interferon-α_{2a} (IFNα_{2a}) is short (ranging from 4 to 8 h) and the serum concentration decreases

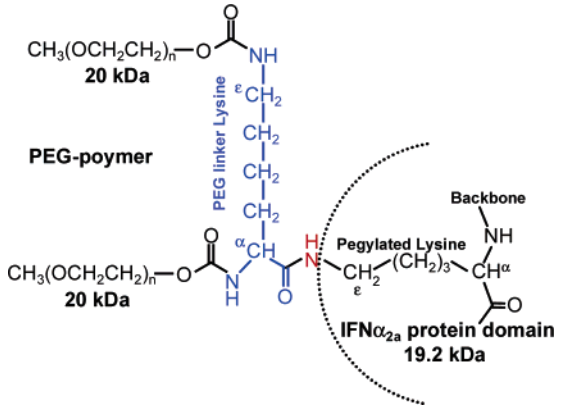

Figure 1. Schematic representation of a monopegylated positional isomer molecule of ^{40}PEG–IFNα_{2a}: one 40 kDa branched PEG-polymer is covalently attached to IFNα_{2a} by an amide bond at the ϵ-amino group (in red) of a lysine residue of IFNα_{2a}. The IFNα_{2a} protein and the PEG-polymer are schematically separated by a dotted line. In the PEG-polymer, the two 20 kDa PEG branches (n = 420–510) are linked by a lysine molecule (in blue), also called PEG-linker lysine, via urethane bonds, one at the α-amide group and the other at the ϵ-amide group of the PEG-linker lysine. IFNα_{2a} contains 11 lysine residues (K23, K31, K49, K70, K83, K112, K121, K131, K133, K134, and K164). Potentially 11 monopegylated positional isomers plus one at the N-terminus may be formed. However, only six positional isomers constitute more than ~98% of the mixture (*28*). In the ^{15}N-labeled positional isomer samples, the nitrogen nuclei of the protein domain including the $N_\epsilon H$ group of the pegylated lysine are ^{15}N, whereas the one of the PEG-linker lysine are ^{14}N.

below its detection limit after 24 h (*21*, *22*). Thus, even though the current HCV treatment requires up to three subcutaneous injections weekly, the virus has extended periods when it is not exposed to a therapeutic concentration of the drug (*14*, *15*). This results in a treatment regimen that places a significant burden on the patient, negatively impacting quality of life and often interfering with compliance.

In the early 1990s, the pegylation of IFNα_{2a} for the HCV treatment was first attempted with a 5 kDa linear PEG-polymer linked by a urea bond to lysine side chains of the protein.[23] However, the pharmacological properties and efficacy of this first generation of pegylated IFNα_{2a} were not significantly improved over that obtained with unmodified protein (*24*).

Within the past several years, the influence of various PEG structures on the in vitro biological activity have been investigated (*2*, *25*, *26*). These results showed an important correlation between the PEG-polymer characteristics and the pharmacological properties. On the basis of this knowledge, second-generation pegylated IFNα drugs were developed by two companies. The biophysical charactersation for a 12 kDa PEG IFNα_{2b} construct (Intron A) was reviewed by Wang et al. (*27*). Here we focus on the ^{40}PEG–IFNα_{2a} (PEGASYS) construct recently developed (*24*) in house. It is obtained by covalent binding of one 40 kDa branched PEG-polymer via an amide bond to a lysine side chain of the protein (Figure 1). ^{40}PEG–IFNα_{2a} is a mixture of mainly six monopegylated positional isomers (*28*). It exhibits a superior efficacy over IFNα_{2a} with significantly increased serum half-life, and because of its increased size a reduced renal clearance, resulting in a strong antiviral response throughout a once weekly dosing schedule (*29*, *30*). In patients with chronic HCV and liver cirrhosis, ^{40}PEG–IFNα_{2a} monotherapy achieves a sustained virological response close to four times higher than conventional IFNα_{2a} (*14*). In late 2002, PEGASYS was approved by the FDA for HCV treatment.

On a structural level, the molecular bulk conferred by the PEG-polymer may effectively shield the protein surface (*9*). On one hand, these effects enhance serum half-life and reduce renal clearance, which in turn tend to potentiate the biological efficacy of the pegylated protein versus the unmodified form (*10*). On the other hand, the attached PEG may sterically and thermodynamically interfere with the ability of the protein to interact with its cellular receptors, which exert the biological effectiveness (*9*, *31–33*). The overall biological response to the pegylated protein is consequently dependent upon a balance of these competing factors.

Previous studies reporting biological activities showed an unavoidable reduction in specific activities upon pegylation (*23*, *32*, *34*). As far as ^{40}PEG–IFNα_{2a} is concerned, it exhibits an approximately 30-fold reduced in vitro biological activity in the antiviral assays relative to IFNα_{2a} (*24*). However, substantial variations in the in vitro antiviral activity were observed when the individual positional isomers were isolated and compared (*28*). It is anticipated that these activity variations are due to differences in the kinetics and thermodynamics of the interaction between each positional isomer and Interferon receptors. These observations clearly highlight the need to investigate the structural, kinetic, and thermodynamic properties of ^{40}PEG–IFNα_{2a} and its positional isomers, that influence the interaction with its cellular receptors and therefore its biological activity (*35*). In view of the tremendous value of pegylated therapeutic proteins in medicine, it is quite surprising that few data are available on their structure, stability, and interaction with their receptors (*23*, *31–34*). In this study we report the detailed structural and biophysical characterization of ^{40}PEG–IFNα_{2a} and its positional isomers using NMR spectroscopy, analytical ultracentrifugation (AUC), circular dichroism (CD), fluorescence spectroscopy, and differential scanning calorimetry (DSC). The results are also compared with those obtained with unmodified IFNα_{2a}. These data constitute the basis and form an essential collection of knowledge, on which the interaction of ^{40}PEG–IFNα_{2a} with its cellular receptors can be understood. The results of the study of the interaction between ^{40}PEG–IFNα_{2a} and its individual positional isomers with the extracellular domain of the receptor IFNAR2 are reported in the accompanying publication (*36*).

Further improvements in the development of medically relevant therapeutic proteins critically depend on this type of knowledge and may lead to a third generation of structurally modified pegylated protein drugs.

MATERIALS AND METHODS

Materials. The standard material of the recombinant human Interferon-α_{2a}, Roferon-A (IFNα_{2a}) (19.2 kDa, 165 amino acids) (*37*, *38*) and the 40 kDa branched PEG-conjugated-IFNα_{2a}, PEGASYS (^{40}PEG–IFNα_{2a}) (*24*), and the *N*-hydroxysuccinimide ester derivative of a 40 kDa branched PEG-polymer reagent (*39*) used for the pegylation reaction were obtained from the Biopharmaceuticals Production Department of Hoffmann-La Roche Inc.. For the purpose of the NMR analysis, uniformly ^{15}N-labeled IFNα_{2a} (^{15}N-IFNα_{2a}) was produced in *E. coli* expression system and purified as previously reported (*37*, *40*). The ^{15}N-IFNα_{2a} was subsequently pegylated using the standard pegylation procedure (*24*) that is only summarized here: ^{15}N-IFNα_{2a} is reacting with the 40 kDa branched PEG-polymer reagent. The PEG molecule

is attached on surface exposed ϵ-amino group of lysine residues via an amide bond. The pegylation reaction product is subsequently purified to remove the excess of PEG-reagent, reaction byproducts, and pegylated ^{15}N-IFNα_{2a} oligomers. This procedure results in a mixture of monopegylated ^{15}N-IFNα_{2a} conjugates (one IFNα_{2a} molecule with one 40 kDa PEG molecule). As the PEG-reagent is reacting nonspecifically with any of the IFNα_{2a} lysine side chains, the pegylation reaction results in potentially 11 positional isomers (plus the N-terminus) with different yield. Very recently, a combination of an analytical ion exchange separation procedure, peptide mapping and MALDI-TOF (matrix-assisted laser desorption/ionization time-of-flight) mass spectrometric analyses showed that ^{40}PEG−IFNα_{2a} is composed mainly of nine bioactive positional isomers of monopegylated IFNα_{2a}: four major isomers modified at K31, K134, K131, K121; two minor isomers modified at K164 and K70; three very minor isomers modified at K83, K49, and K112 (*28*).

The reaction product of monopegylated positional ^{15}N-isomers, as well as the ^{40}PEG−IFNα_{2a} standard product, was subjected to preparative ion-exchange (IEX) separation methods that enabled the isolation of the four major and two minor unlabeled and ^{15}N-labeled positional isomers. First, a cation exchange FPLC (fast-protein liquid chromatography) method (100 mg of material injected) was applied to separate pure positional isomers modified at K31, K134, and K70, respectively. With this method, an elution peak containing the positional isomers modified at K131, K121, and K164 was also collected. This elution peak was then further purified by a preparative (IEX) separation method (3 mg injected material per run). In final, the four major and two minor positional unlabeled and ^{15}N-labeled isomers modified at K31, K134, K131, K121, K164, and K70, respectively, were separated in milligram amount (varying from 2 to 20 mg) with a purity over 97% as checked by analytical ion-exchange HPLC. The molecular weight of IFNα_{2a} protein, based on the amino acid content, is 19241.28 Da. IFNα_{2a} and ^{40}PEG−IFNα_{2a} extinction coefficient is 1.00 mL·mg^{-1}·cm^{-1} and 1.05 mL·mg^{-1}·cm^{-1}, respectively. Sample concentrations for ^{40}PEG−IFNα_{2a} are given in mass of protein per unit of volume. In the manuscript, IFNα_{2a} and ^{40}PEG−IFNα_{2a} are referring to standard materials (see above) and the positional isomers to the four major and two minor monopegylated positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively.

Analytical Ultracentrifugation. Prior to the AUC measurement, IFNα_{2a} and ^{40}PEG−IFNα_{2a} solutions were dialyzed in 10 mM potassium phosphate 0.02% NaN_3 pH 3.7 and subjected to a preparative centrifugation (Beckman UZ Kontron apparatus, 2 h, 300 000 g, 6 °C) to ensure the removal of aggregates. The protein concentration was measured by UV absorbance (280 nm) as being 0.80 mg·mL^{-1} and 1.60 mg·mL^{-1} for IFNα_{2a} and ^{40}PEG−IFNα_{2a}, respectively. A solution of 40 kDa branched PEG-polymer 1.00 mg·mL^{-1} was equally dialyzed against the buffer solution specified above.

The knowledge of the partial specific volume v_{bar} (mL·gr^{-1}) of IFNα_{2a} and ^{40}PEG−IFNα_{2a} was required for the evaluation of the AUC data. In principle v_{bar} for a protein can be calculated from its amino acid sequence (*41*), but for ^{40}PEG−IFNα_{2a} the presence of the PEG-polymer does not allow this calculation. v_{bar} of IFNα_{2a}, ^{40}PEG−IFNα_{2a}, and the 40 kDa branched PEG-polymer was experimentally determined by measurement of the density of the solute and the buffer solution. Measurements were performed using a five-digit precision density-meter DMA-4500 Anton Paar at 20 °C (±0.01 °C). The eq 1 allowed the determination of v_{bar} with c the total material concentration (g·mL^{-1}), ρ and ρ_0 the density (g·mL^{-1}) of the solute and dialysis buffer solution, respectively.

$$v_{bar} = \frac{1}{\rho_0}\left(1 - \frac{\rho - \rho_0}{c}\right) \quad (1)$$

Sedimentation equilibrium experiments were performed with a XL-A AUC apparatus (Beckman Instruments, Palo Alto, CA) at 20 °C equipped with UV absorption optics on IFNα_{2a} and ^{40}PEG−IFNα_{2a} to determine the molecular weight MW and second virial coefficient B. The data were analyzed using the DISCREEQ (*42*) and Beckman software packages. The molecular weight of a protein can be determined in a sedimentation equilibrium experiment independently of the protein shape (*43*, *44*). At the equilibrium between sedimentation and diffusion a radial gradient of concentration in the measurement cell is formed. By radial scanning (r = 5.8−7.2 cm) of the sample UV absorbance at 280 nm, the molecular weight MW (Da) of the solute in an ideal and noninteracting system can be extracted from the eq 2,

$$\mathrm{MW} = \frac{2RT}{(1 - \rho_0 v_{bar})\omega^2}\frac{\partial(\ln c)}{\partial r^2} \quad (2)$$

with c the concentration, R (8.31 J·K^{-1}·mol^{-1}) the gas constant, T (K) the absolute temperature, v_{bar} (mL·g^{-1}) the partial specific volume of the solute, ρ_0 (g·mL^{-1}) the solvent density, and ω (rpm) the rotor angular velocity (22 000 rpm and 12 000 rpm for IFNα_{2a} and ^{40}PEG−IFNα_{2a}, respectively).

The second virial coefficient B (L·mol·g^{-2}) of IFNα_{2a} and ^{40}PEG−IFNα_{2a} was evaluated as well. In solution the solute molecules can interact with one another (also called nonideality) (*43*, *44*), because of the finite size and the charges they carry. With a real solution of a single solute, the measured molecular weight obtained from the slope of (ln c) versus r^2 is an apparent molecular weight $MW_{app.}$. The dependency on the solute concentration is given in eq 3,

$$\mathrm{MW}_{app.} = \frac{\mathrm{MW}}{\left(1 + c\frac{\partial(\ln \gamma)}{\partial c}\right)} \quad (3)$$

with MW the true molecular weight and (ln γ) the logarithm of the activity expressed as polynomial of c with ($\ln \gamma = B \times \mathrm{MW} \times c + C \times \mathrm{MW} \times c^2 + \ldots$). For the low concentration range, higher orders can be neglected therefore the eq 3 becomes:

$$\mathrm{MW}_{app.} \approx \frac{\mathrm{MW}}{1 + B \times \mathrm{MW} \times c} \quad (4)$$

The apparent molecular weight $MW_{app.}$ was measured at different solute concentration c (0.1, 0.2, 0.4, 1.0, 1.5, and 1.9 mg·mL^{-1}) of IFNα_{2a} and ^{40}PEG−IFNα_{2a}. By the measurement of the second virial coefficient B of the solute, relevant information about the strength of intermolecular interaction is revealed. The sign of B discriminates repulsive from attractive interaction and describes the strength of the solute−solute interactions (*45*). For a solute with B positive, solute−solvent interactions are

preferred over solute−solute contacts. In contrast for a negative B the opposite holds true.

The sedimentation coefficient S of IFNα_{2a} and ^{40}PEG−IFNα_{2a} was measured at 20 °C by AUC sedimentation velocity experiment using the apparatus as described above. S (in Svedberg unit [10^{-13} s]) represents the speed at which solute molecules are sedimenting to the bottom of the centrifuge cell under the influence of a strong force field during the experiment. The net sedimentation behavior of macromolecules in the centrifugal force is described by the Svedberg equation:

$$S = \frac{\partial r}{\partial t}\left(\frac{1}{r\omega^2}\right) = \frac{MW \times (1 - \rho_0 v_{bar})}{N_{av} f} = \frac{MW \times D_T \times (1 - \rho_0 v_{bar})}{RT} \quad (5)$$

The rate of sedimentation dr/dt is dependent on the centrifugal force $r\omega^2$. S is expressed with the partial specific volume of the molecule v_{bar}, the molecular weight MW, the Avogadro number N_{av}, the shape of the macromolecule by its frictional coefficient f, the density of the buffer ρ_0, the gas constant R, the absolute temperature T, and the translational diffusion coefficient D_T. The Stokes−Einstein relationship (*46*) (eq 6) was used to derive the right-hand term in the Svedberg equation.

$$D_T = RT/N_{av} f \quad (6)$$

Upon high angular velocity of the rotor (40 000 rpm), the sedimentation leads to formation of a solute concentration gradient in the form of boundaries recorded in UV absorbance at 280 nm by successive radial scanning in time (r = 5.8−7.2 cm). For an ideal and noninteracting system, the sedimentation coefficient S can be extracted, using the second moment boundary spreading method with the Beckman software package, by the analysis of the rate of movement of the midpoint of the boundaries (*43*, *44*). S of the 40 kDa branched PEG-polymer was measured at 20 °C by sedimentation velocity experiment using the apparatus as described above equipped with an interference optical device under an angular rotor velocity of 60 000 rpm.

The sedimentation coefficient S provides a description of the hydrodynamic shape of the molecule by the frictional coefficient f. Using the Stokes−Einstein relationship (eq 6), the frictional coefficient for a sphere, f_0, can be calculated with:

$$f_0 = 6\pi\eta R_0 = 6\pi\eta\left(\frac{3 \times MW \times v_{bar}}{4\pi N_{av}}\right)^{1/3} \quad (7)$$

with η the viscosity of the solution and R_0 the radius of the sphere defined with:

$$\frac{4\pi}{3}R_0^{\,3} = \frac{MW \times v_{bar}}{N_{av}} \quad (8)$$

Thus, the Svedberg relationship (eq 5) can be used to calculate the sedimentation coefficient of a sphere, S_0, as function of MW, v_{bar}, ρ_0, and η to obtain:

$$S_0 = \frac{MW \times (1 - \rho_0 v_{bar})}{6\pi\eta N_{av}\left(\frac{3 \times MW \times v_{bar}}{4\pi N_{av}}\right)^{1/3}} \quad (9)$$

Substituting the values of all the constants (η for water at 20 °C) using eq 9 yields the sedimentation value for a sphere in terms of MW, v_{bar}, ρ_0, and η.

$$S_0 = 0.012 \times (1 - \rho_0 v_{bar}) \times \left(\frac{MW^2}{v_{bar}}\right)^{1/3} \quad (10)$$

S_0 is the maximum sedimentation coefficient that can be obtained for a molecule of a given mass, because a sphere has the minimum surface area in contact with solvent. Consequently a spherical molecule has a minimum frictional coefficient f_0. The ratio of the sedimentation coefficient predicted for a sphere, S_0, to the experimental S is f/f_0 which can be interpreted for the molecule like its maximum shape asymmetry from a sphere.

Differential Scanning Calorimetry. The DSC method was used to monitor the thermal unfolding transition of IFNα_{2a} and ^{40}PEG−IFNα_{2a}. Prior to the measurement, the protein solutions were dialyzed in 20 mM sodium acetate/50 mM NaCl/0.02% NaN_3, pH 5.0, and subjected to a preparative centrifugation (as described above) to ensure the removal of aggregates. The protein concentration was measured by UV absorbance (280 nm) as being 0.82 mg·mL^{-1} and 0.60 mg·mL^{-1} for IFNα_{2a} and ^{40}PEG−IFNα_{2a}, respectively. DSC experiments were conducted with a MicroCal (Northampton, MA) microcalorimeter by measuring the difference of energy uptake between the sample cell and a reference cell that contains only dialysis buffer upon an increase of the temperature by 1 °C per minute from 20 °C to 85 °C. The denaturation melting temperature T_m was determined at the maximum of the heat capacity.

Circular Dichroism. The CD measurements were performed for IFNα_{2a} and ^{40}PEG−IFNα_{2a} using a Jobin-Yvon CD-6 spectrometer equipped with a temperature-controlled water bath. Prior to the measurement, the protein solutions were dialyzed in 10 mM potassium phosphate/0.02% NaN_3, pH 3.7, and subjected to a preparative centrifugation (as described above) to ensure the removal of aggregates. The protein concentration was measured by UV absorbance (280 nm) as being 0.80 mg·mL^{-1} and 1.60 mg·mL^{-1} for IFNα_{2a} and ^{40}PEG−IFNα_{2a}, respectively. The protein backbone absorption band (195−260 nm) and the protein aromatic absorption band (250−350 nm) were recorded at 20 °C in 0.05 and 1.00 cm path length cylindrical cell, respectively. The Cotton effect was plotted as $\Delta\epsilon$ that is related to the mean molecular ellipticity Θ [deg·cm^2·dmol^{-1}] by the relationship $\Theta = 3298.8 \times \Delta\epsilon$. Buffer baseline recorded prior the CD measurement of the protein solution was subtracted from the protein data to minimize the effects of UV lamp drifts. The secondary structure content of the proteins was estimated from the absorption band (195−240 nm) using the Provencher method (*47*). It involves the simulation of the CD spectrum of the protein of interest as a linear combination of the CD spectra of 16 proteins whose secondary structures are known from X-ray crystallography.

Fluorescence Spectroscopy. The fluorescence measurements were performed for IFNα_{2a} and ^{40}PEG−IFNα_{2a} at room temperature with a SLM 8100 fluorometer. Prior to the measurement, the protein solutions were dialyzed in 10 mM potassium phosphate 0.02% NaN_3 pH 3.7 and subjected to a preparative centrifugation (as described above) to ensure the removal of aggregates. The protein concentration was measured by UV absorbance (280 nm) as being 0.80 mg·mL^{-1} and 1.60 mg·mL^{-1} for IFNα_{2a} and ^{40}PEG−IFNα_{2a}, respectively. The fluorescence emission

spectra were recorded between 300 and 450 nm, with excitation at 283 nm.

NMR Spectroscopy. NMR measurements were performed at 25 °C on a Bruker DRX-800 MHz spectrometer, equipped with *xyz*-axis pulse field gradient triple resonance probe-head, and on a DMX-600 MHz spectrometer, equipped with *z*-axis pulse field gradient triple resonance cryo-probe-head. Data were processed and analyzed with XWIN NMR 2.6 and NMRPipe (*48*).

NMR samples of the following materials were prepared: ^{15}N-labeled and unlabeled IFNα_{2a}; ^{40}PEG−IFNα_{2a}; the ^{15}N-labeled and unlabeled positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively. The NMR samples were prepared using the following procedure: preparative centrifugation (as described above); dialysis in 50 mM acetic acid, pH 3.5, 0.02% NaN_3, at 6 °C; concentration to 1 mL volume; dialysis in H_2O, pH 3.5 (HCl), 0.02% NaN_3, at 6 °C; dialysis in an aqueous solution containing protease inhibitors (H_2O/D_2O, 9/1) pH 3.5 (HCl), 0.02% NaN_3, at 6 °C; preparative centrifugation for 1 h at 185 000 g at 6 °C; readjustment of the pH to 3.5 (HCl). The final concentration of the samples ranged from 0.35 mM to 0.60 mM in 5 mm NMR sample tubes. A NMR sample of the 40 kDa branched PEG-polymer was prepared. An amount of 8.5 mg of *N*-hydroxysuccinimide ester derivative of the 40 kDa branched PEG-polymer reagent used for the pegylation reaction was diluted in 550 μL of H_2O, pH 12 (NaOH), 0.02% NaN_3, and stirred overnight at 6 °C to hydrolyze the *N*-hydroxysuccinimide ester derivative. The solution was subsequently dialyzed in (H_2O/D_2O, 9/1) pH 3.5 (HCl), 0.02% NaN_3, overnight at 6 °C. The resulting dialyzed solution of PEG-polymer free of *N*-hydroxysuccinimide derivative was then transferred with a concentration of ~0.38 mM to a 5 mm NMR tubes.

In all the NMR experiments the water signal suppression was performed using the WATERGATE scheme (*49*). For all the samples, a 1D ^{1}H NMR spectrum was acquired at 600 MHz with 8990 Hz sweep-width (1024 scans) and 2048 acquisition points zero-filled to 4096 points and subjected to a squared sine-bell window function shifted by 60°.

For the samples of PEG-polymer and the positional ^{15}N-isomers, 2D ^{1}H-DQ and 2D ^{15}N-filtered ^{1}H-TOCSY were acquired at 600 MHz to derive the ^{1}H assignment of the linker lysine in the PEG-polymer (Figure 1) (*50*, *51*). The linker lysine remains unlabeled (^{14}N) at the Nα and Nϵ positions, as only IFNα_{2a} was labeled with ^{15}N. 2D ^{1}H-DQ was recorded with 1536 t_2 acquisition points (96 scans) and 512 t_1 increments and spectral width of 14 and 24 ppm in F2 and F1 dimensions, respectively. ^{15}N-Decoupling was performed by a 180° pulse (carrier frequency at 118 ppm for ^{15}N) and the GARP scheme (*52*) during t_1 and t_2 evolution period, respectively. 2D ^{15}N-filtered ^{1}H-TOCSY with DIPSI-2 (*53*) for spin-lock (52 ms for mixing time) was recorded with 1536 t_2 acquisition points (64 scans) and 512 t_1 increments with a spectral width of 12 ppm in both dimensions. A postacquisition ^{15}N-filtration was performed by the implementation of a ^{15}N-filter during the experiment (carrier frequency at 118 ppm for ^{15}N) combined with an interleaved acquisition method (*54*). Because of the ^{15}N-filter, only ^{14}N- and carbon-attached proton resonances are visible along the F2-dimension in the aromatic region of the spectrum. For the 2D ^{1}H-DQ, ^{15}N-filtered ^{1}H-TOCSY and 2D [^{1}H−^{15}N]-TROSY-HSQC (see below), the t_2 and t_1 time domains were zero-filled to the next power of two and subjected to a squared sine-bell window function shifted by 60°.

For the samples of ^{15}N-IFNα_{2a} and the positional ^{15}N-isomers, 2D [^{1}H−^{15}N]-TROSY-HSQC was acquired at 800 MHz to derive the ^{1}H and ^{15}N chemical shift of the amides in the positional isomers (*55*). The experiments were recorded with 1536 t_2 acquisition points (96 scans) and 512 t_1 increments spectral width of 15 and 24 ppm in ^{1}H and ^{15}N (carrier frequency at 118 ppm), respectively. The ^{1}H and ^{15}N chemical shift of the ϵ-amide group N$_\epsilon$H of the pegylated lysine in the protein domain of the positional isomers was derived from these experiments. The chemical shift perturbation Δppm of the backbone amides due to the PEG-polymer in each positional isomers was evaluated as follows (eq 11) where $\Delta(^1\mathrm{H})$ and $\Delta(^{15}\mathrm{N})$ are the backbone amide chemical shift differences in ^{1}H and ^{15}N, respectively, between ^{15}N-IFNα_{2a} and the positional ^{15}N-isomers.

$$\Delta\mathrm{ppm} = 1/2[(\Delta(^1\mathrm{H}))^2 + (\Delta(^{15}\mathrm{N}))^2/25]^{1/2} \qquad (11)$$

To assess the shielding effect of the PEG-polymer on ^{1}H/^{2}H exchange of the protein, NMR saturation transfer experiments (*56*) were acquired by recording 2D [^{1}H−^{15}N]-TROSY-HSQC spectra with and without presaturation (50 Hz) of the water signal during 3 s.

For ^{15}N-IFNα_{2a} and the positional ^{15}N-isomers, 3D ^{15}N-edited [^{1}H−^{1}H]-NOESY (*57*) was acquired to derive the NOE internuclear distance connectivities within the protein and between the former and the PEG-polymer. 3D ^{15}N-edited [^{1}H−^{1}H]-NOESY were recorded at 800 MHz using 100 ms mixing time, 2048 acquisition points (8 scans), 90 increments for ^{1}H and 40 increments for ^{15}N (carrier frequency at 118 ppm) with spectral widths of 15, 12, and 24 ppm, respectively. The indirect time dimension in ^{1}H and ^{15}N were doubled by linear prediction and zero-filled to the next power of two and subjected to a squared sine-bell window function shifted by 60° and 90°, respectively.

For IFNα_{2a}, ^{40}PEG−IFNα_{2a} and the 40 kDa branched PEG-polymer samples pulse field gradient−(longitudinal eddy current) PFG-(LED) (*58*) NMR experiment was recorded to derive the translational diffusion coefficient D_T. Self-diffusion is defined as translational motion reflecting the random motions (Brownian movement) of a molecule in the absence of a concentration gradient. D_T is indicative of hydrodynamic properties and molecular size. The PFG-(LED) NMR method is suitable for D_T measurements of macromolecules because it is designed to minimize the T_2 relaxation effects by storing the magnetization along the *z*-axis during the translational diffusion period, so that relaxation depends primarily on T_1 which is much longer than T_2 for macromolecules. The experiment was acquired with 1D ^{1}H-spectra recorded at 600 MHz with 12000 Hz sweep-width (64 scans) and 32 k acquisition points zero-filled to 64 k and subjected to an exponential window function (line-broadening factor of 1 Hz) before FT. In the experiment the magnitude of *z*-gradient pulses is increased in successive 1D ^{1}H-spectra where the signal intensity is attenuated due to the translational diffusion. The decrease in signal intensity I, normalized to the signal in the absence of gradient I_o, is given by (*59*):

$$\frac{I}{I_o} = \exp(-\gamma^2 G^2 \delta^2 D_T(\Delta - \delta/3)) \qquad (12)$$

with γ the ^{1}H gyromagnetic ratio (2.68 10^4 Gauss^{-1}·s^{-1}), Δ the diffusion period (300 ms), δ the gradient duration (2 ms), and G the gradient magnitude varying from 0% to 100% (calibrated to 57.6 G·cm^{-1}). The determination of D_T (cm^2·s^{-1}) allows the calculation of a hydrodynamic

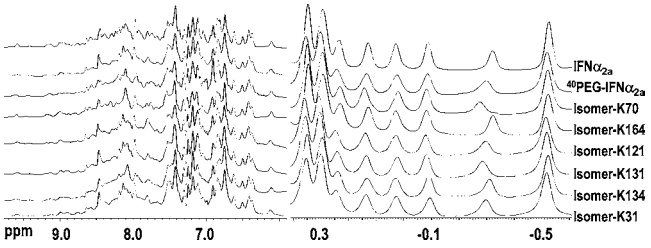

Figure 2. Aromatic (left) and aliphatic (right) regions of the 1D ^{1}H NMR spectra recorded at 600 MHz for IFNα_{2a}, ^{40}PEG–IFNα_{2a} and the positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively. In this representation, amplitudes in the aliphatic region are rescaled, with respect to the aromatic region, by a factor ~4.

radius R_H (nm) of a sphere with equivalent translational diffusion constant using the Stokes–Einstein equation:

$$R_H = \frac{k_B T}{6\pi\eta D_T} \qquad (13)$$

with k_B the Boltzmann constant, T (K) the absolute temperature, and η the viscosity taken to be that of water at 25 °C (*46*, *60*).

RESULTS

NMR Structural Analysis of the Protein Domain of Pegylated IFNα_{2a}s. The 1D ^{1}H NMR spectra of IFNα_{2a} and ^{40}PEG–IFNα_{2a} are extremely well superimposable in the resolved regions (Figure 2). The ^{1}H linewidth for ^{40}PEG–IFNα_{2a} is broader (+5 Hz) as compared to IFNα_{2a}, but much less broad than expected for a 60 kDa protein (*61*). The spectral identity in the 2D ^{1}H-NOESY spectra of the two samples is also remarkable. However, because ^{40}PEG–IFNα_{2a} is a mixture of positional isomers, NMR data do not resolve structural differences that may exist. Detailed NMR based structural comparison was achieved using NMR data of isolated positional isomers.

The individual 1D ^{1}H NMR spectra of the six isolated positional isomers of ^{40}PEG–IFNα_{2a} display a similar dispersion of signals in the aromatic and aliphatic regions with broader ^{1}H-line-width (+5 Hz) as compared to IFNα_{2a} (Figure 2). The perturbation of the PEG-polymer on the IFNα_{2a} protein structure (*40*) was evaluated by the mapping of the chemical shift perturbation Δppm (eq 11) of the backbone amide ^{1}H- and ^{15}N-resonances for each amino acid derived from 2D ^{15}N-TROSY-HSQC spectra for the positional ^{15}N-isomers as compared to ^{15}N-IFNα_{2a}. This is illustrated in Figure 3 for the ^{15}N-Isomer-K31. The chemical shift perturbation plotted for all the amino acid sequence shows that the perturbation is small (maximum 0.12 ppm in the Isomer-K31) and localized to the attachment site of the PEG-polymer at K31 and surface regions close by in space (Figure 4). The same holds true for most of the positional isomers, as shown in Figure 4. Only the Isomer-K164 displays a chemical shift perturbation spread more widely over the protein surface. K164 is located at the C-terminal end of the polypeptide chain which is known to be highly flexible (*40*).

For each positional ^{15}N-isomer, a 3D ^{15}N-edited [^{1}H–^{1}H]-NOESY spectrum was recorded. The analysis of the 3D spectra showed that all amino acid residues experiencing chemical shift perturbation display unaltered NOE internuclear ^{15}NH-based distance connectivities when compared with IFNα_{2a}. The same also holds true, as expected, for all the nonshifted ^{15}NH resonances. This is illustrated in Figure 5 for the ^{15}N-Isomer-K31 for which the residue H34 displays chemical shift perturbation because it is close to the pegylated lysine K31. The ^{1}H-resonance of this amide displays the same NOE internuclear distance connectivities as in ^{15}N-IFNα_{2a}: the long-range NOE connectivity cross-peak between the resonance of the amide proton of H34 and the degenerated resonances of the two methyl groups of V142 is shown. For no positional isomer could a NOE internuclear distance connectivity be detected between the ethylene glycol units (OCH_2CH_2) or the two terminal groups (OCH_3) of the PEG-polymer and the amides of the protein backbone.

NMR Structural Analysis of the Pegylated Protein-lysine and the 40 kDa Branched PEG-polymer. For all the positional ^{15}N-isomers, the ^{1}H and ^{15}N chemical shift of the ϵ-amide group of the pegylated lysine of the protein domain (Figure 1) was unambiguously assigned by the identification of additional cross-peaks ($^{15}N_\epsilon/^{15}N_\epsilon H$) in the 2D ^{15}N-TROSY-HSQC spectra when compared to the IFNα_{2a} reference spectrum (Figure 3 and

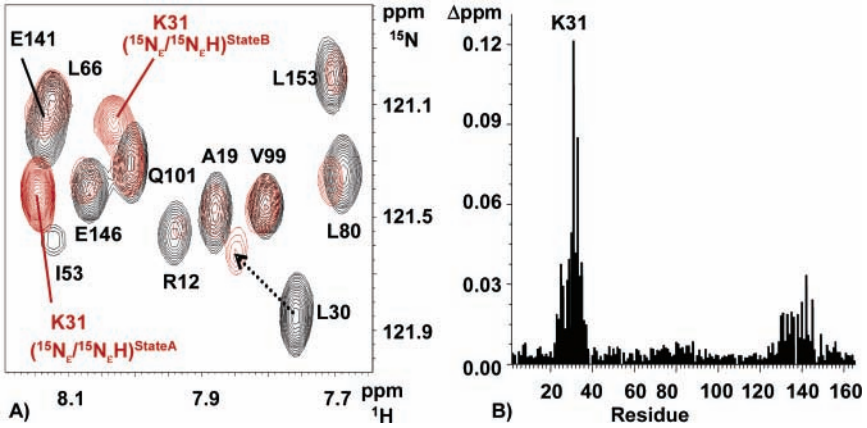

Figure 3. (A) Section of the superimposed 2D ^{15}N-TROSY-HSQC spectra recorded at 800 MHz for ^{15}N-IFNα_{2a} (black) and the positional ^{15}N-Isomer-K31 (red). As an example the amide of L30 close to the pegylated lysine K31 shows significant ^{1}H and ^{15}N chemical shift changes (black dotted arrow) whereas residues far away from the pegylated site do not display chemical shift perturbation. Two cross-peaks ($^{15}N_\epsilon/^{15}N_\epsilon H$) are observed for the ϵ-amide group of the pegylated lysine K31. Based on the relative intensity ratio (Table 1), these cross-peaks are assigned as the conformational State-A and State-B of the ϵ-amide group of the pegylated lysine. At the contour level of the spectrum for the positional ^{15}N-Isomer-K31 the existing cross-peak for I53 is not visible. (B) Chemical shift perturbation Δppm (eq 11) of the backbone amides due to the PEG-polymer for the Isomer-K31 as a function of the amino acid sequence.

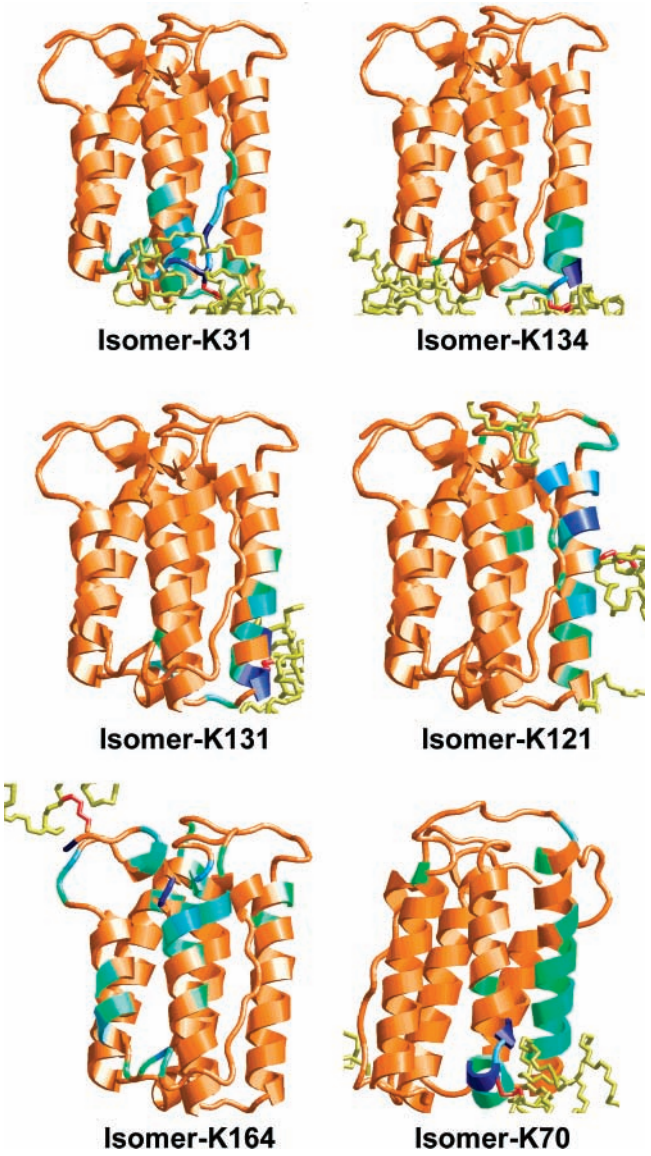

Figure 4. Ribbon representation of IFNα_{2a} structure (*40*) in the positional isomers modified at K31, K134, K131, K121, K164, K70, respectively. Amino acid residues that experience backbone amide chemical shift perturbation Δppm (eq 11) due to the PEG-polymer, are color-coded from dark blue for the most pronounced changes (0.12 ppm ≥ Δppm ≥ 0.08 ppm) gradually to light green for the small changes (0.04 ppm ≥ Δppm ≥ 0.01 ppm). The side chain of the pegylated lysine is colored in red. For each positional isomer, one possible r.c. conformation of the 40 kDa branched PEG-polymer (in yellow) was calculated but only partly represented for clarity. The polymer conformation was calculated as an on-lattice SAW (see also Figure 8).

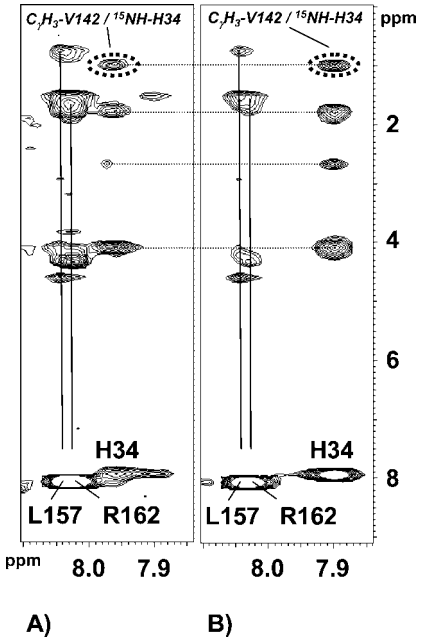

Figure 5. Region of a selected [^{1}H−^{1}H]-plane from the 3D ^{15}N-edited [^{1}H−^{1}H]-NOESY spectra recorded at 800 MHz for ^{15}N-Isomer-K31 (A), and ^{15}N-IFNα_{2a} (B). The planes correspond to the ^{15}N-shift (120.3 ppm) of the residue H34. This residue that is close to the pegylated lysine in the Isomer-K31 showed backbone amide chemical shift perturbation in ^{1}H but no change in ^{15}N. The ^{1}H-resonance of the amide of H34 displays the same NOE internuclear distance connectivities in both molecules: a long-range NOE connectivity between the amide of H34 and the degenerated resonances of the two methyl groups of V142 is circled as an example.

Table 1). The ^{1}H assignment to this position was further confirmed by the observation of direct and remote cross-peaks for $^{15}N_\epsilon H$ in the 2D ^{1}H-DQ spectra (*50*) (data not shown): these cross-peaks are again missing in the 2D ^{1}H-DQ reference spectrum of ^{15}N-IFNα_{2a}. As shown in Figure 3, two ($^{15}N_\epsilon/^{15}N_\epsilon H$) cross-peaks are observed for the ϵ-amide group of the pegylated lysine K31 with a ∼6.5:3.5 relative intensity ratio. The same holds true for the ^{15}N-Isomer-K134 and -K121 with a ∼5.5:4.5 relative intensity ratio in both isomers (Table 1). No correlation cross-peak is observed between the two $^{15}N_\epsilon H$ signals in the 3D ^{15}N-edited [^{1}H−^{1}H]-NOESY spectra. The structural origin of this peak duplication indicates a highly localized conformational heterogeneity of the pegylated lysine of the protein domain. For the ^{15}N-Isomer-K131, -K164, -K70 only one ($^{15}N_\epsilon/^{15}N_\epsilon H$) cross-peak is observed for the ϵ-amide group of the pegylated lysine (Table 1). The peak duplication is here either not resolved or not occurring (see Discussion).

For all the positional ^{15}N-isomers and the free PEG-polymer samples, the 1D ^{1}H NMR spectra display for the two 20 kDa PEG branches of the polymer (Figure 1) a unique, very intense, and sharp resonance line (∼5 Hz) at 3.60 ppm for the ethylene-glycol units (OCH_2CH_2) and a sharp but much less intense resonance line at 3.27 ppm for the two terminal groups (OCH_3).

The ^{1}H chemical shifts of the PEG-linker lysine for all the samples were obtained from analysis of the 2D ^{1}H-DQ and ^{15}N-filtered ^{1}H-TOCSY spectra. In the aromatic region of the ^{15}N-filtered ^{1}H-TOCSY spectra along the F2-dimension, only the ^{14}N-attached proton resonances, namely $N_\alpha H$ and $N_\epsilon H$ of the amide groups of the PEG-linker lysine, are seen. For all the samples, two ^{1}H-resonances are observed for $N_\alpha H$ and $N_\epsilon H$ of the PEG-linker lysine (Table 1 and Figure 6). They derive from a cis/trans isomerization of the urethane bond (*62*−*64*) at the α- and ϵ-amide groups of the PEG-linker lysine (Figure 6). This isomerization was confirmed by the observation of conformational exchange cross-peaks between both conformations of the amide groups in 2D-^{1}H-NOESY (*65*) and 2D-^{1}H-ROESY (*66*) spectra (data not shown). The isomerization rate was estimated on the PEG-polymer sample from the signal separation (∼240 Hz) as lying in the millisecond time range (∼5 ms < $1/k_{ex}$ < ∼50 ms). The trans and cis conformations of each of the urethane bond at the α- and ϵ-positions were assigned to be populated in the ratio ∼9:1, based on the relative intensity ratio of ($N_\alpha H/C_\alpha H$) and ($N_\epsilon H/C_\epsilon H_2$) cross-peaks, respectively (Table 1). This ratio is substantially different from the ratio derived from the localized conformational

Table 1. ^{1}H Chemical Shift (ppm) of $N_\alpha H$, $C_\alpha H$, $N_\epsilon H$, and $C_\epsilon H_2$ from the α- and ϵ-Amide Groups of the Linker Lysine in the 40 kDa Branched PEG-polymer and the Positional Isomers[a]

[a] Measured from 2D ^{15}N-filtered ^{1}H-TOCSY and 2D ^{1}H-DQ spectra. ^{15}N and ^{1}H chemical shift (ppm) of $^{15}N_\epsilon$ and $^{15}N_\epsilon H$, respectively, from the ϵ-amide group of the pegylated lysine in the protein domain of the positional isomers identified from 2D ^{15}N-TROSY-HSQC and 2D ^{1}H-DQ spectra. [b] Populations based on the relative intensity ratio of the two cross-peaks for ($^{15}N_\epsilon/^{15}N_\epsilon H$) in the 2D ^{15}N-TROSY-HSQC spectra: the cross-peaks with the highest and lowest intensity were assigned as deriving from the two conformational states called State-A and State-B, respectively, of the ϵ-amide group of the pegylated lysine. [c] Populations based on the relative intensity ratio of the two cross-peaks for ($N_\alpha H/C_\alpha H$)^{trans} observed at the α-amide group of the PEG linker lysine in the 2D ^{15}N-filtered ^{1}H-TOCSY spectrum. [d] Trans and cis populations are in the ratio (~9:1), respectively, according to the relative intensity ratio of the cross-peaks ($N_\alpha H/C_\alpha H$) and ($N_\epsilon H/C_\epsilon H_2$) of the PEG linker lysine observed in the 2D ^{15}N-filtered ^{1}H-TOCSY spectra. [e] Only one set of cross-peaks is observed. The signals are not split in the 2D ^{15}N-TROSY-HSQC and 2D ^{15}N-filtered ^{1}H-TOCSY spectra.

heterogeneity of the pegylated lysine, where the conformational exchange is also slow.

An additional duplication of ^{1}H-resonances of the linker lysine of the polymer for $N_\alpha H$ is also observed for the Isomer-K31, -K134, and -K121. This is illustrated in Figure 6 with the ^{15}N-filtered ^{1}H-TOCSY spectrum of ^{15}N-Isomer-K121: doubling of both $N_\alpha H^{trans}$ and $N_\alpha H^{cis}$ is observed with a relative intensity ratio ~5.5:4.5 in both cases. This ratio is identical to the one observed at the neighboring group $^{15}N_\epsilon H$ of the pegylated K121 of the protein. For the Isomer-K31 and -K134 this doubling is observed only for the ^{1}H-resonance of $N_\alpha H^{trans}$ with a relative intensity ratio ~6.5:3.5 and ~5.5:4.5, respectively. For the Isomer-K131, -K164, and -K70, the ^{1}H-resonance of $N_\alpha H^{trans}$ and $N_\alpha H^{cis}$, respectively does not show any doubling.

Biophysical Characterization of IFNα$_{2a}$, ^{40}PEG–IFNα$_{2a}$ and the 40 kDa Branched PEG-polymer. The data reflecting the biophysical characterization of IFNα$_{2a}$, ^{40}PEG–IFNα$_{2a}$ and the free 40 kDa branched PEG-polymer are collected in Table 2. They are derived from the determination of the following parameters: the partial specific volume v_{bar} by densitometry; the molecular weight MW, the second virial coefficient B, and the sedimentation coefficient S by AUC; the denaturation melting temperature T_m by DSC; the secondary structure content by CD; the translational diffusion coefficient D_T by PFG-(LED) ^{1}H NMR spectroscopy.

The partial specific volume v_{bar} of IFNα$_{2a}$ and the 40 kDa branched PEG-polymer (Table 2) are in good agreement with the value calculated from the amino acid content (0.739 mL·gr^{-1}) (*41*) and values reported for other PEG-polymers (*67*), respectively. ^{40}PEG–IFNα$_{2a}$ presents a v_{bar} that corresponds approximately to the mass weighted average of v_{bar} of IFNα$_{2a}$ and the PEG-polymer. The knowledge of v_{bar} for IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$ allowed the determination of the molecular weights, by AUC to be 19.2 kDa and 58.9 kDa, respectively.

The second virial coefficients B for IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$ are of opposite sign with a negative and positive value, respectively (Table 2). It is interesting to note that literature values of B for PEG-polymers are positive as well (*68*, *69*), indicative that the B value of ^{40}PEG–IFNα$_{2a}$ is dominated by the properties of the PEG-polymer rather than IFNα$_{2a}$.

The sedimentation coefficient S of IFNα$_{2a}$ and the 40 kDa branched PEG-polymer are in the range of S values for globular proteins (*43*, *44*) and other PEG-polymers (*70*, *71*) of similar size. ^{40}PEG–IFNα$_{2a}$ presents a S value between, but closer to, the one of the PEG-polymer than of IFNα$_{2a}$ (Table 2). For the positional isomers modified at K31, K134, K131, and K121, the sedimentation coefficient S was also measured and gave values comparable to ^{40}PEG–IFNα$_{2a}$ (data not shown).

The thermal unfolding transition from the native to the denaturated state monitored by DSC (Figure 7.A) is, for IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$, an irreversible process. For ^{40}PEG–IFNα$_{2a}$, the baseline of the DSC scan displays a normal profile. In contrast, the strongly dropping baseline observed for IFNα$_{2a}$ highlights an aggregation process that starts in the early phase of the unfolding transition and dominates beyond the denaturation melting temperature T_m. As compared to IFNα$_{2a}$, ^{40}PEG–IFNα$_{2a}$ is more stable throughout the thermal denaturation with a slightly elevated T_m and a substantially reduced tendency for aggregation. This is indicated by the difference of the shape of the denaturation curve. The extraction of the enthalpy of unfolding is not possible due to the irreversibility of the denaturation process.

The CD spectra for IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$ recorded in the backbone and aromatic absorption region are identical over a broad range of pH values (pH 3.5 to 8). One example for sample conditions close to those of the NMR samples is shown in Figure 7, parts C and D, respectively. The same holds true for the fluorescence spectra (Figure 7B). Analysis of the CD spectra in the backbone absorption region shows that IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$ present ~75% of α-helix secondary structure (*40*, *47*). The unfolding and refolding process was monitored by the acquisition of CD spectra in the backbone absorption region during a thermal denaturation-renaturation cycle from 20 °C to 80 °C and back. These CD spectra showed ~41% and ~61% of α-helix secondary structure for IFNα$_{2a}$ and ^{40}PEG–IFNα$_{2a}$ respectively, after completing the cycle. It must be noted

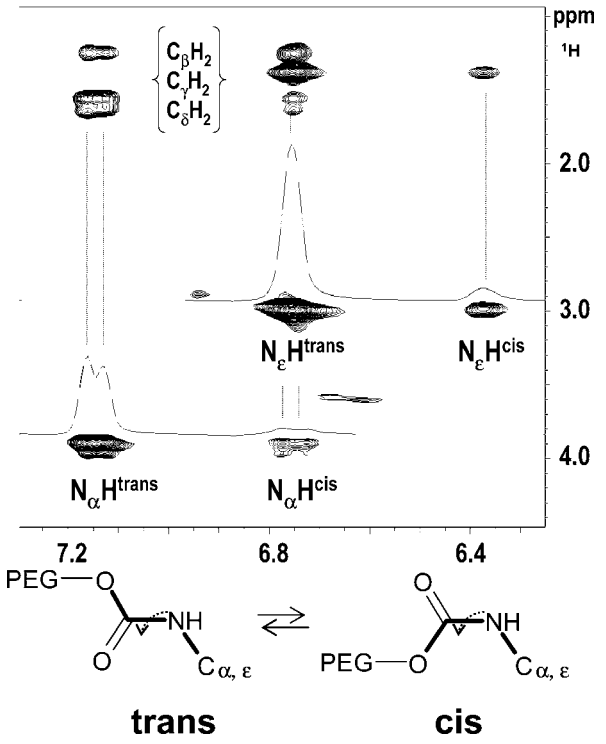

Figure 6. Section of the 2D ^{15}N-filtered ^{1}H-TOCSY spectrum for the positional^{15}N-Isomer-K121 recorded at 600 MHz. In this region of the spectrum along the F2-dimension only the ^{14}N-attached $N_\alpha H$ and $N_\epsilon H$ proton resonances of the amide groups of the unlabeled PEG-linker lysine are seen. Because of the cis/trans isomerization of the urethane bond (in bold) at the α- and ϵ-amide groups of the PEG-linker lysine, two resonances for $N_\alpha H$ and $N_\epsilon H$ are observed: namely $N_\alpha H^{trans}$, $N_\alpha H^{cis}$ and $N_\epsilon H^{trans}$, $N_\epsilon H^{cis}$, respectively. The cis/trans assignment is based on the relative intensity ratio of the cross-peaks ($N_\alpha H/C_\alpha H$) and ($N_\epsilon H/C_\epsilon H_2$). Because of the concomitant existence of two conformational states for the neighboring ϵ-amide group of the pegylated lysine, an additional doubling is observed for $N_\alpha H^{trans}$ resonance of the PEG-linker lysine as shown with the 1D trace at $\delta(C_\alpha H) = 3.89$ ppm: the two peaks have a relative intensity ratio ~5.5:4.5. The same observation holds true for the resonance $N_\alpha H^{cis}$. In contrast the 1D trace at $\delta(C_\epsilon H_2) = 2.96$ ppm does not show any doubling for the resonance $N_\epsilon H^{trans}$ and $N_\epsilon H^{cis}$. This group is structurally more remote than the ϵ-amide group of the pegylated lysine. The chemical shift region for the ^{1}H-resonances of $C_\beta H_2$, $C_\gamma H_2$ and $C_\delta H_2$ is reported with a bracket. Below the spectrum the cis/trans isomerization of the urethane bond at the α- and ϵ-amide groups of the PEG-linker lysine is schematically shown.

however that α-helical recovery does not necessarily imply a return to correctly folded protein.

The NMR-measured translational diffusion coefficients D_T of IFNα$_{2a}$ and the 40 kDa branched PEG-polymer (Table 2) are in agreement with values reported for globular proteins and other PEG-polymers (*72*−*74*). In contrast, D_T of ^{40}PEG−IFNα$_{2a}$ corresponds, neither to a 60 kDa globular protein nor to a 60 kDa PEG-polymer. The D_T of ^{40}PEG−IFNα$_{2a}$ lies much closer to that of the 40 kDa branched PEG-polymer.

The hydrodynamic parameters v_{bar}, S and D_T experimentally determined by independent methods for IFN-α$_{2a}$, ^{40}PEG−IFNα$_{2a}$ and the 40 kDa branched PEG-polymer (Table 2) are consistent with the corresponding molecular weight calculated using the Svedberg and Stokes−Einstein relationships (eqs 5 and 6 in Materials and Methods, respectively).

The calculation of the hydrodynamic radius R_H of the sphere with equivalent translational diffusion coefficient and the maximum shape asymmetry from a sphere f/f_0 reveals important differences of hydrodynamic properties, i.e., molecular size and shape, between IFN-α$_{2a}$, ^{40}PEG−IFNα$_{2a}$ and the 40 kDa branched PEG-polymer (Table 2). Surprisingly, R_H of the 60 kDa pegylated protein is smaller than the one observed for the free 40 kDa PEG-polymer.

DISCUSSION

Overall Structure of the Protein Domain in Pegylated IFNα$_{2a}$. The 1D ^{1}H NMR spectra of the six isolated positional isomers and IFNα$_{2a}$ are fully superimposeable and almost identical in the resolved regions. The integrity of the IFNα$_{2a}$ fold in the positional isomers was also confirmed by fluorescence and CD spectra (data not shown). For each positional isomer, the chemical shift perturbation Δppm (eq 11) induced by the PEG-polymer on the IFNα$_{2a}$ protein structure is small and localized to the PEG-polymer attachment site and surface regions close by in space. Only the Isomer-K164 displays Δppm changes which are more spread over the protein surface (Figure 4). This may be caused by the higher flexibility of the PEG-attachment site at K164 that is located in the most mobile part of the protein at the C-terminus (*40*). The observed chemical shift perturbations on the protein structure probably do not reflect structural changes or differences to IFNα$_{2a}$ for any of the positional isomers. No structural differences in IFNα$_{2a}$ could be detected among the positional isomers, as the same NOE internuclear distance connectivities in the 3D ^{15}N-edited [^{1}H−^{1}H]-NOESY spectra of the positional isomers are observed as in IFNα$_{2a}$. This also holds true for the residues displaying PEG-polymer induced chemical shift perturbations. The NOE spectral analysis for all the positional isomers further showed that no NOEs could be identified between the PEG-polymer and the amides of the protein backbone, indicative that there is no stable contact between the protein surface and the two branches of the PEG-polymer.

As no experimental result so far was found that indicates resolvable structural differences among and between the positional isomers and IFNα$_{2a}$, the alteration of the protein structure by the attached 40 kDa branched PEG-polymer is very minor if at all. Nevertheless, the physical bulk of the PEG-polymer, although not interacting in a defined and stable manner, produces a shield around some areas of the protein merely by its exclusion volume. This shielding effect may interfere with the ability of the protein to bind to its cellular receptors (*9*, *31*−*33*, *36*). Indeed, the antiviral activity of the individual positional isomers of ^{40}PEG−IFNα$_{2a}$ is reduced to various degrees depending on the PEG-attachment site (*28*).

The acidic pH (3.5) of all the NMR samples causes a slow exchange rate, of the order of minutes, for the surface and solvent exposed amide protons of the IFNα$_{2a}$ protein domain with water (*61*). An acidic pH is needed to obtain resolved NMR spectra. These conditions do not allow the assessment of the differential shielding by the PEG-polymer of the protein surface by ^{1}H/^{2}H exchange NMR experiments (*56*).

The moderately broader lines (+5 Hz) of the ^{1}H-resonances for the positional isomers, when compared to IFNα$_{2a}$, indicate that the molecular tumbling of the positional isomers does not at all correspond to that of a 60 kDa protein. With respect to ^{1}H-dipolar relaxation, these pegylated IFNα$_{2a}$ isomers behave like a protein with ~25 kDa apparent molecular weight. The modest line-broadening can be explained only by a highly independent motion of both the protein domain and the PEG-polymer (see below).

Table 2. Hydrodynamic Properties and Thermal Stability of IFNα2a, ^{40}PEG–IFNα2a and the 40 kDa Branched PEG-polymer

properties	IFNα_{2a}	^{40}PEG–IFNα_{2a}	40 kDa branched PEG-polymer

[a] Determined by densitometry. v_{bar} for IFNα_{2a} was also calculated based on the amino acid sequence to 0.739 mL·g^{-1} (*41*). [b] Determined by AUC. [c] Ratio of frictional coefficients f/f_0 equal to the ratio of S_0/S, with S_0 the calculated value for a sphere with corresponding mass and S the experimental value (*44*). [d] Determined by PFG-(LED) ^{1}H NMR spectroscopy (*57*). [e] Hydrodynamic radius of the sphere with equivalent translational diffusion coefficient D_T calculated using the Stokes–Einstein equation. [f] Determined by analysis of the CD spectra at 20 °C (*47*). [f] Protein solutions experienced a thermal denaturation cycle from 20 °C to 80 °C and back to 20 °C monitored by CD. At this latter temperature the amount of α-helix content was evaluated (*47*). [g] Determined by DSC. [h] From ref 24. [i] From ref 68.

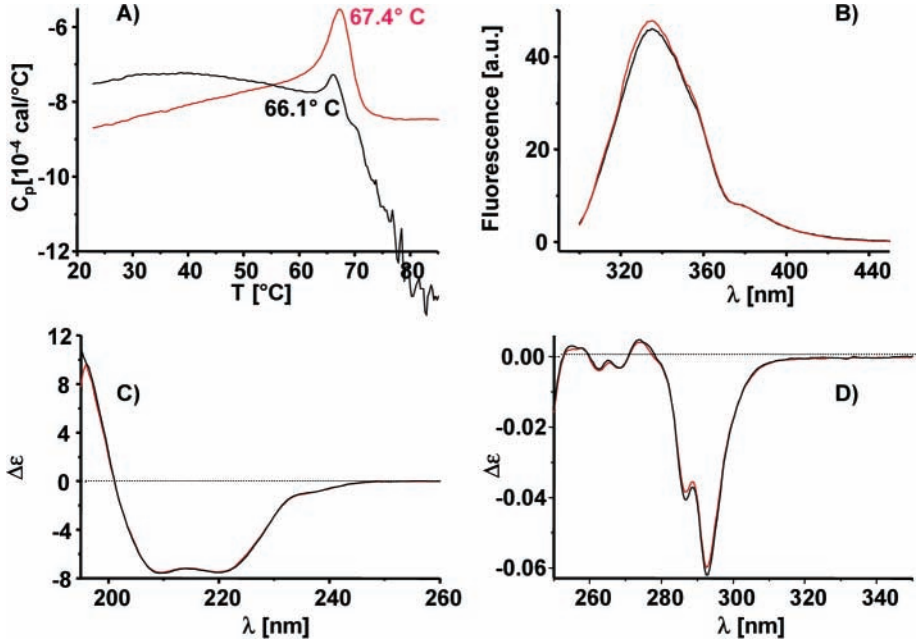

Figure 7. (A) DSC scans of the unfolding transition of IFNα_{2a} (black) and ^{40}PEG–IFNα_{2a} (red). The denaturation melting temperature T_m is evaluated at the maximum of the heat capacity. (B) Fluorescence emission spectra recorded at room temperature after excitation at 283 nm of IFNα_{2a} (black) and ^{40}PEG–IFNα_{2a} (red). (C) CD spectra recorded at 20 °C of IFNα_{2a} (black) and ^{40}PEG–IFNα_{2a} (red) in the backbone absorption region, and (D) in the aromatic absorption region. Optical spectra as shown in B and C were also acquired for the individual positional isomers modified at K31, K134, K131, and K121, leading to identical results (data not shown).

Structure of the 40 kDa Branched PEG-polymer and the Pegylated Lysine. Weak coupling of motions of the protein domain and the PEG-polymer is further supported by the observation of an unique set of sharp resonance lines in the 1D ^{1}H NMR spectra for the PEG-units and the two terminal groups (OCH_3) with identical line-widths and chemical shifts in all the samples including free PEG-polymer. This shows that the polymer molecule adopts a very flexible and mobile random coil (r.c.) conformation, that seems neither to be influenced by IFNα_{2a} nor depends on the pegylation site. Hydrodynamic data indicate, however, that the protein attached-PEG seems to be slightly more compact than the free PEG-polymer (see below). A snapshot of such a highly dynamic system is shown in Figure 8 based on the IFNα_{2a} structure and Self-Avoiding-Walk (SAW) (*75*) model for the polymer conformation.

Despite the very flexible structure of the PEG-polymer, local points of rigidity exist. In all the positional isomers and the free PEG-polymer a cis/trans isomerization was observed at the urethane bonds, one at the α- and the other at the ϵ-position of the PEG-linker lysine (Figure 1). The same ratio ~9:1 of trans and cis populations, respectively was observed in free PEG-polymer and for all the positional isomers independently of the pegylation site. Interestingly, in the Isomer-K121 an additional conformational heterogeneity was indicated by a doubling of the ^{1}H-resonance for $N_\alpha H^{trans}$ and $N_\alpha H^{cis}$ with relative intensity ratio of ~5.5:4.5 reflected in both signals. For the Isomer-K31 and -K134, only the doubling of the ^{1}H-resonance for $N_\alpha H^{trans}$ was observed with the relative intensity ratio of ~6.5:3.5 and ~5.5:4.5, respectively. For the Isomer-K131, -K164, and -K70, the signal splitting is not resolved or not present. For all the three positional isomers which showed the additional splitting of the $N_\alpha H$ linker signal, a corresponding doubling with identical intensity ratio was observed for the cross-peaks of the neighboring $^{15}N_\epsilon H$ of the pegylated lysine (Figure 3). These cross-peaks could be assigned to two conformational states, arbitrarily called State-A and State-B, according to their higher and lower intensity, respectively. The observation of two ($^{15}N_\epsilon/^{15}N_\epsilon H$) cross-peaks for

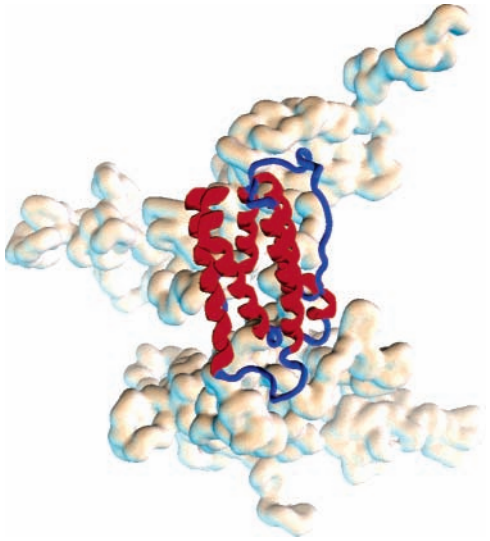

Figure 8. Three-dimensional model of one positional isomer pegylated at K164 of ^{40}PEG−IFNα_{2a}. The model is based on the NMR solution structure of IFNα_{2a} which is shown as a ribbon with α-helices in red and connecting loops and turns in blue (*40*). The r.c. conformation of the two 20 kDa branches of the PEG-polymer was calculated as an on-lattice SAW (*75*) using the molecular modeling package MOLOC (*84, 85*). It must be noted that the polymer molecule experiences a very high number of conformations, therefore this representation is only one snapshot of a single possible conformation. The polymer is reported as a solid Gaussian−Connolly molecular surface in white-grey computed with the MOE software (Chemical Computing Group Inc., Montreal, Canada). The impact of the time-averaged structural envelope of the ensemble of r.c. conformations for the polymer is further evaluated in the accompanying publication with respect to the binding to the extracellular domain of the receptor

the ϵ-amide group of the pegylated lysine coincides with the duplication of the ^{1}H-resonance for N_αH of the PEG-linker lysine. The same relative intensity for the split lines of N_αH of the PEG-linker lysine and of the neighboring $^{15}N_\epsilon$H of the pegylated lysine indicates that a common conformational process is responsible for both duplication of signals. As no conformational exchange was observed between State-A and -B on the time scale accessible by NMR, these two states are either in a very slow dynamic exchange or stable over time. This is in contrast with the cis/trans isomerization of the two neighboring urethane bonds, where for both α- and ϵ- positions, a conformational exchange takes place within the millisecond time range ($\sim$5 ms < $1/k_{ex}$ < $\sim$50 ms). State-A and -B may be caused by a slow cis/trans isomerization of the peptide bond linking the IFNα_{2a} protein to the polymer (Figure 1).

Hydrodynamic Properties of ^{40}PEG−IFNα_{2a} As Compared To IFNα_{2a} and the 40 kDa Branched PEG-polymer. The favorable pharmacological properties of ^{40}PEG−IFNα_{2a} are intimately related to the molecular structure and thermodynamic properties of the branched PEG, as discussed here and in the accompanying publication (*36*). The pegylation of the protein with the 40 kDa branched PEG-polymer alters the hydrodynamic properties of IFNα_{2a} dramatically (Table 2): both sedimentation S and translational diffusion D_T coefficients are substantially smaller in the modified protein. The hydrodynamic radius R_H expands three to four times and the overall shape of the pegylated molecule becomes highly asymmetric (see f/f_0 values). By the same token, the conformation of the protein domain remains unchanged, as was shown by detailed NMR structural analysis of the positional ^{15}N-isomers as compared to IFNα_{2a}.

The size difference of the pegylated protein when compared with the unmodified IFNα_{2a} is clearly reflected in the change of D_T. The observed decrease in the D_T value, however, is much higher than expected from MW consideration alone. The 60 kDa pegylated IFNα_{2a} shows diffusion properties very similar to globular proteins with MW's of approximately 300 kDa (*72*, *73*). If the effective hydrodynamic volumes are compared, the 40 kDa branched PEG-polymer is approximately 60 times larger ($R^3_H{}^{PEG}/R^3_H{}^{IFN\alpha 2a}$) and less densely packed ($1/\upsilon_{bar}$) than IFNα_{2a}. As the polymer has the unique property to 'bind' two to three water molecules per ethylene glycol unit (*76*), its r.c. structure is dynamically associated with a large cloud of water molecules. These hydrodynamic properties of the PEG-polymer are effectively transferred to IFNα_{2a} upon pegylation, leading to a molecular particle with an effective hydrodynamic volume that has increased approximately 40 times. Unexpectedly, however, the 40 kDa PEG-polymer is self-diffusing $\sim$1.1 times slower than ^{40}PEG−IFNα_{2a} that is 1.5 times higher in molecular weight. Attaching the polymer to the protein can be interpreted as leading to a reduction of the effective hydrodynamic volume of the PEG molecule by $\sim$30%. The protein attached-PEG, while keeping its very flexible and mobile r.c. conformation, seems to adopt a slightly more compact conformation than the free PEG-polymer in solution. Polymer branching can lead to compaction for entropic reasons (*77*, *78*). In our case, attaching a protein to the two PEG-chains at its 'branching' site could be formally viewed as increasing the branching of the polymer. However, the compaction can also be explained enthalpically by assuming a small attractive interaction between the polymer and the protein. To decide between the two compaction mechanisms is not possible based on our current experimental evidence.

The significant differences for the sedimentation coefficient S measured by AUC further show that pegylation changes the hydrodynamic shape of the pegylated protein. As expected, ^{40}PEG−IFNα_{2a} sediments faster than the 40 kDa PEG-molecule but, surprisingly, slower than IFNα_{2a}, despite its bigger molecular weight. Therefore, the overall shapes, of IFNα_{2a} and ^{40}PEG−IFNα_{2a} must be very different. In the sedimentation experiment with ^{40}PEG−IFNα_{2a}, the PEG-moiety can be envisaged as a 'parachute' slowing down the sedimentation rate. The changes in hydrodynamic shape can be assessed from S by the ratio f/f_0 that gives a measure of the maximum shape asymmetry from a sphere (*44*). The value f/f_0 of 1.02 for IFNα_{2a} indicates that the hydrodynamic shape of the protein is very close to a sphere. In contrast, the value f/f_0 of 3.76 for the 40 kDa branched PEG-polymer shows that the hydrodynamic shape of the polymer alone is very asymmetric. This is in agreement with theoretical calculations of polymer structures by SAW showing highly asymmetric molecular shapes (*79*, *80*). The attachment of the PEG to the protein creates a molecule with a hydrodynamic shape less asymmetric than the free PEG-polymer with a f/f_0 value of 2.59. Further experimental evidence based on hydrodynamic modeling might allow a tentative approximation of the molecular shape of the 40 kDa branched PEG-polymer and ^{40}PEG−IFNα_{2a} to a hydrodynamic equivalent oblate or prolate ellipsoid of revolution.

The uniquely tailored hydrodynamic properties and shape of ^{40}PEG−IFNα_{2a} are of extreme pharmacological interest and benefit as clinically shown with PEGASYS. The shielding of the protein by the polymer may effectively prevent, by steric hindrance, large molecules such as antibodies (*9*) or receptors (*33*, *36*) from reaching

the protein surface. The recognition of pegylated proteins by the immune system is reduced, and in parallel also the immunogenicity of the protein drug (*9*, *81*). Similarly, the increased resistance of pegylated proteins toward proteolytic degradation (*9*) is mediated by PEG through its large volume close to the protein surface which excludes other large molecules. Pegylation makes the molecular shape of a protein looks much larger than the actual MW of the pegylated protein might suggest. In this way, pharmacological properties related to size, e.g. the renal clearance of the drug, can critically be modulated and tuned. It is known that the size cutoff for a protein to be filtered out from the blood circulation by the kidney, is lower than 300 kDa (*11*, *82*). The enhanced and prolonged bioavailability of the ^{40}PEG–IFNα_{2a} drug in the body (*83*) can thus be directly related to hydrodynamic properties of the pegylated protein.

The second virial coefficient B is a description of the solute–solute interaction strength in solution. The opposite sign of B for IFNα_{2a} and ^{40}PEG–IFNα_{2a} shows that the molecules have a completely different aggregation behavior (*45*). For IFNα_{2a}, intermolecular solute–solute interactions are preferred, i.e., they are attractive, whereas for ^{40}PEG–IFNα_{2a} these interactions are repulsive, as solvent–solute interactions prevail. Again, these favorable properties are caused by the highly hydrated polymer and are effectively transferred to ^{40}PEG–IFNα_{2a}, creating a molecule with reduced tendency for aggregation. This becomes noticeable if the thermal unfolding of ^{40}PEG–IFNα_{2a} is compared with IFNα_{2a}. As shown by DSC and CD, ^{40}PEG–IFNα_{2a} has a significantly reduced tendency for heat induced irreversible aggregation, coupled with a slightly elevated denaturation melting temperature T_m (Table 2). At 20 °C, IFNα_{2a} and ^{40}PEG–IFNα_{2a} present ~75% of α-helix secondary structure. After a melting (80 °C) and cooling (20 °C) cycle, more α-helix secondary structure is recovered for ^{40}PEG–IFNα_{2a} (~61% α-helix) than for IFNα_{2a} (~41% α-helix). The prevention of aggregation in protein drugs is crucial for the preservation of the native protein fold. The increased stability contributes to the favorable pharmacokinetic and immunological properties that are a consequence of the improved hydrodynamic properties of the pegylated protein.

Summarizing the hydrodynamic properties (v_{bar}, B, S, f/f_0, D_T, and R_H), one can see that the covalent attachment of an unstructured, mobile, and highly flexible PEG-polymer molecule of appropriate size on a compact structured protein causes an efficient transfer of favorable hydrodynamic properties of the PEG-polymer to the pegylated protein. The modification of IFNα_{2a} by the 40 kDa branched PEG-polymer provides a shield for the protein domain without changing the three-dimensional structure and conformation of the protein. The pegylation does alter the size and shape of the molecule, significantly increasing the effective hydrodynamic volume. It also improves the physicochemical properties of the protein, resulting in higher temperature stability and reduced tendency for aggregation. The small changes of the NMR ^{1}H-resonance line-width of IFNα_{2a} and the unchanged line-width observed for PEG in ^{40}PEG–IFNα_{2a} show that the protein and PEG domains behave independently.

CONCLUSION

Here, we reported the detailed structural and biophysical characterization by NMR spectroscopy, AUC, CD, fluorescence spectroscopy, and DSC of ^{40}PEG–IFNα_{2a} and its positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively, as compared to IFNα_{2a}. Our results show that the three-dimensional structure of IFNα_{2a} is not modified by the presence of the attached 40 kDa branched PEG-polymer in any positional isomer of ^{40}PEG–IFNα_{2a}. Regardless of where the PEG-polymer is attached, it adopts a very mobile and flexible r.c. conformation, producing a shield for the protein without a permanent coverage of the protein surface. This shield can be best envisaged by a large excluded volume close to the protein surface. This volume is visible to other large molecules, e.g. antibodies, proteases or receptors, approaching this part of space. Our results also provide evidence of significant structural and physicochemical advantages conferred by the pegylation to IFNα_{2a}: alteration of the hydrodynamic properties by increase of the effective hydrodynamic volume and modification of the molecular shape, higher temperature stability, and reduced tendency for aggregation. These properties are of tremendous pharmacological interest and benefit as clinically shown with PEGASYS.

Finally, our work represents a new standard for the characterization and quality-control of pegylated proteins, and it can be foreseen that this will have a significant impact in the pegylation area which plays an increasingly important role in new pharmaceutical applications. In the future, further investigations, particularly IFNα_{2a} receptor binding studies, are clearly needed for a better understanding of the relationship between the structure and the biological function of ^{40}PEG–IFNα_{2a} and its positional isomers. Ultimately, this knowledge might lead to selectively engineered positional pegylated IFNα_{2a} with unique and optimized properties.

ACKNOWLEDGMENT

We would like to thank D. Brugger, Dr. F. Danel, J. Kohler, E. Kusznir, and A. Schacher for their help in obtaining materials and for experimental work. We gratefully acknowledge Drs. T. Schreitmüller, K. Weyer, and B. Wipf for constant support. For stimulating discussions and help many thanks to Drs. P. Gerber, S. E. Harding (Nothingham University), W. Huber, W. Klaus, and T. Schulz-Gasch. We thank Dr. D. Banner for a careful reading of the manuscript.

Structural, Kinetic, and Thermodynamic Analysis of the Binding of the 40 kDa PEG−Interferon-α_{2a} and Its Individual Positional Isomers to the Extracellular Domain of the Receptor IFNAR2

Christophe Dhalluin,‡ Alfred Ross,‡ Walter Huber, Paul Gerber, Doris Brugger, Bernard Gsell, and Hans Senn*

F. Hoffmann-La Roche AG Department of Pharma Research CH-4070 Basel, Switzerland. Received September 15, 2004; Revised Manuscript Received March 8, 2005

Type-I Interferons exert antiviral and antiproliferative activities through the binding to a common cell surface receptor comprising two subunits, IFNAR1 and IFNAR2. Human recombinant Interferon-α_{2a} (IFNα_{2a}) is a potent drug (Roferon-A) used to treat various cancers and viral diseases including Hepatitis B/C infections. To significantly improve the pharmacological properties of the drug, a pegylated form of IFNα_{2a} was developed (PEGASYS). This 40 kDa PEG-conjugated IFNα_{2a} (^{40}PEG−IFNα_{2a}) is obtained by the covalent binding of one 40 kDa branched PEG-polymer to a lysine side-chain of IFNα_{2a}. Here, we report the detailed structural, kinetic, and thermodynamic analysis of the binding to the extracellular domain of the receptor IFNAR2 of ^{40}PEG−IFNα_{2a} and its isolated positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively, in comparison with unmodified IFNα_{2a}. Our binding studies, using the surface plasmon resonance technique, show that the pegylation does not abolish the binding to the receptor, but significantly reduces the affinity mainly due to a change of the association rate. The results are supported by modeling and simulation of the binding, using Self-Avoiding-Walk calculations for the polymer conformations. A correlation between the structural parameters and the kinetic and thermodynamic parameters of the binding of the positional isomers could be established. For the Isomer-K31 and -K164, the PEG-polymer attachment point is located in proximity to the binding interface, and the isomers display affinity in the range 150−520 nM in an enthalpy-driven binding process. In contrast for the Isomer-K134, -K131, -K121, and -K70, the PEG-polymer is attached remotely from the binding interface, and the isomers exhibit a higher affinity (32−76 nM) in an entropy-driven binding process. This study constitutes an essential collection of knowledge on which the interaction of ^{40}PEG−IFNα_{2a} and its positional isomers with its cellular receptors can be better understood.

INTRODUCTION

Type-I Interferons (IFNs)[1] are a family of homologous cytokines that potently elicit an antiviral and antiproliferative state in cells (*1*). Human type-I IFN α/β bind to a common cell surface receptor consisting of two transmembrane subunits, IFNAR1 and IFNAR2 (*2*, *3*), to form a ternary complex (Figure 1). IFNAR2 is the major ligand binding component of the receptor complex, exhibiting nanomolar affinity to both IFNα and IFNβ (*4*). While IFNAR2 binds IFNs, such as Interferon-α_{2a} (IFNα_{2a}) with high affinity ($K_D \sim 2-10$ nM), the intrinsic binding affinity of IFNAR1 to IFNα_{2a} is low ($K_D > 100$ nM). The ternary complex mediates activation of numerous genes

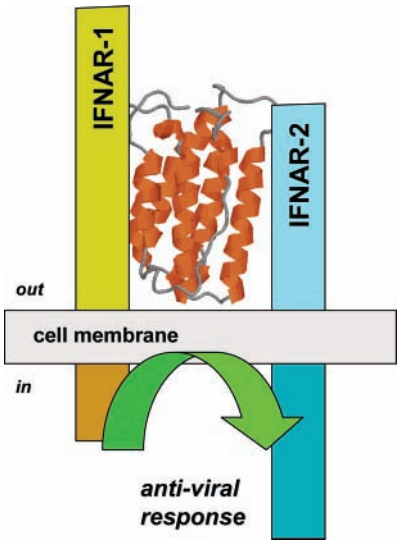

Figure 1. Schematic diagram showing the ternary complex formed by the binding of INFα_{2a} to the human IFN α/β receptor comprising two transmenbrane subunits, IFNAR1 and IFNAR2. The IFNα_{2a} structure (*35*) is reported as a ribbon with α-helices in orange and connecting loops and turns in light gray.

through different transduction pathways (*5*). Various expression profiles are induced by IFNs, apparently through the same receptor with particular differences between IFNα and IFN*β*. However, the molecular mechanisms underlying the functional differences between IFNs remain elusive.

IFNs are currently one of the classes of human proteins most widely used as therapeutic agents, approved to treat various types of cancer and viral diseases. Since 1986, the medical potential of recombinant human IFNα_{2a} has been recognized and the drug (Roferon-A) approved for the treatment of malignant melanoma, renal cell carcinoma, chronic myelogenous leukaemia, non-Hodgkin's lymphoma, and Hepatitis B/C infections (*8*, *9*). Today, a major worldwide health concern is infection by Hepatitis C Virus (HCV). The factors limiting the efficacy of IFNα in the treatment of HCV are the pharmacokinetic properties of IFNα, that lead to a short serum half-life of the drug: the protein is rapidly degraded, diffuses widely throughout the entire body, and has a high rate of renal clearance (*10*, *11*).

One successful way to overcome these limitations has been the use of pegylation, the process by which an inert, nontoxic, and water soluble poly(ethylene glycol) (PEG)-polymer is covalently attached to a therapeutic protein (*12*–*15*).

An earlier developed pegylated IFNα_{2a} was obtained with a 5 kDa linear PEG-polymer (*16*). However, this first generation of pegylated IFNα_{2a}, ^{5}PEG–IFNα_{2a}, did not exhibit significant improvements, in terms of pharmacological properties and efficacy, with respect to unmodified IFNα_{2a} (*13*). Based on the latest advancements in pegylation technology and a better empirical basis of the correlation existing between the PEG-polymer characteristics and the resulting pharmacological properties of the modified protein (*12*, *17*, *18*), a second generation of pegylated IFNα_{2a} drug was developed, ^{40}PEG–IFNα_{2a} (PEGASYS) (*13*). Here, by the covalent binding of one 40 kDa branched PEG-polymer to a lysine side-chain of the protein, a mixture of mainly six monopegylated positional isomers with distinct in vitro antiviral activity is obtained (*19*). The drug has a superior efficacy over IFNα_{2a}, with increased serum half-life and reduced renal clearance (*9*, *20*). PEGASYS received FDA approval for the HCV treatment in late 2002.

Understanding the molecular basis of the in vitro biological activity of ^{40}PEG–IFNα_{2a} requires quantitative and qualitative interpretation of the structural, kinetic, and thermodynamic binding parameters for the interaction of the individual positional isomers with the receptors IFNAR1 and IFNAR2.

Very recently, the NMR solution structure of the extracellular domain of the receptor IFNAR2 (IFNAR2^{EC}) has been solved and a model of the IFNα_{2a}/IFNAR2^{EC} complex reported, presenting a molecular basis for the IFN binding mechanism (*21*). The IFNAR2^{EC} binding site is formed by an extensive and predominantly hydrophobic patch, which interacts with a matching hydrophobic surface of IFNα_{2a}, while complementary adjacent motifs of alternating charged side-chains provide specific recognition.

In an accompanying publication we present the structural and biophysical characterization of the individual positional isomers of ^{40}PEG–IFNα_{2a} (*22*). In this study, we establish the correlation between the structural parameters and the kinetic and thermodynamic parameters of the binding of the positional isomers to IFNAR2^{EC}. The results are compared to those obtained for IFNα_{2a} and ^{5}PEG–IFNα_{2a}. In addition, we present results on the time-course of the digestion of IFNα_{2a} and ^{40}PEG–IFNα_{2a} by trypsin that provide evidence for the PEG-polymer protection against proteolytic degradation. The interpretation of the experimental results is supported by modeling and simulation of the binding of the positional isomers with the polymer conformations mimicked as Self-Avoiding-Walk (SAW) constructs (*23*). The data presented here constitute an important step toward understand the rules that govern the in vitro antiviral activity of the different positional isomers of ^{40}PEG–IFNα_{2a} and may support in the future the development of a third generation of pegylated IFNα_{2a} or other pegylated proteins.

MATERIALS AND METHODS

IFNα_{2a}, Pegylated IFNα_{2a} and Polymer Materials. The standard recombinant human Interferon-α_{2a}, Roferon-A (IFNα_{2a}) (19.2 kDa, 165 amino acids) (*8*, *24*), the 40 kDa branched PEG-conjugated IFNα_{2a}, PEGASYS (^{40}PEG–IFNα_{2a}), and the 5 kDa linear PEG-conjugated IFNα_{2a} (^{5}PEG–IFNα_{2a}) were obtained from the Biopharmaceuticals Production Department of Hoffmann-La Roche Inc., as well the PEG-polymer reagents used for the pegylation reactions, the *N*-hydroxysuccinimide ester derivative of a 40 kDa branched PEG-polymer, and the pyridinyl carbamate derivative of a 5 kDa linear PEG-polymer (*13*, *16*, *25*). In ^{5}PEG–IFNα_{2a} and ^{40}PEG–IFNα_{2a}, the PEG-polymer is attached nonspecifically on surface exposed ϵ-amino group of lysine residues via an urea bond and an amide bond, respectively (*13*, *16*). The final product of the respective pegylation reactions is a mixture of monopegylated IFNα_{2a} conjugates with potentially 11 lysine positions of modification (plus the N-terminus).

Very recently, an ion-exchange HPLC separation procedure of the positional isomers of ^{40}PEG–IFNα_{2a} has been developed, and it has been shown that ^{40}PEG–IFNα_{2a} is composed of nine bioactive isomers (*19*). Using this isolation method, the four major isomers modified at K31, K134, K131, K121 and the two minor isomers modified at K164 and K70 were separated with a purity of over 97% as determined by analytical ion-exchange HPLC. These six positional isomers have been extensively analyzed structurally (*22*) and constitute approximately ~98% of the protein mixture.

The molecular weight of IFNα_{2a} protein, based on the amino acid content, is 19241 Da. The calculated extinction coefficients of IFNα_{2a} and ^{40}PEG–IFNα_{2a} are 1.00 mL·mg^{-1}·cm^{-1} and 1.05 mL·mg^{-1}·cm^{-1}, respectively. The sample concentration for the pegylated IFNα_{2a}s is given in mass of protein per unit of volume. In this work, the positional isomers refer to the four major and two minor monopegylated positional isomers of ^{40}PEG–IFNα_{2a} modified at K31, K134, K131, K121, K164, and K70, respectively.

Production of the Extracellular Domain of IFNAR2 Receptor and Complex Formation with IFNα_{2a}. IFNAR2^{EC} was produced in an *E. coli* expression system and purified by ion-exchange and size-exclusion chromatography as previously described (*26*). The expression yield was ~5 mg of protein per gram of biomass. The molecular weight of IFNAR2^{EC} protein (216 amino acids ending with the sequence SESAES) determined by electro-spray-ionization mass specrometry was 24621 Da. This is in agreement with the expected mass of 24628 Da. Analytical Size-Exclusion Chromatography (SEC) on a Superdex-75 HR10/30 (Pharmacia Biotech) in 20 mM TRIS/HCl, 100 mM NaCl at pH 8.4 coupled to a Minidawn

Light-Scattering (LS) detector system (Wyatt Technology, Germany) showed that IFNAR2^{EC} was monomeric and aggregate-free in solution.

As previously described (*27*), a (1:1) stoichiometric complex IFNα_{2a}/IFNAR2^{EC} was prepared and purified by SEC-LS with a molecular weight of ~44.5 kDa. By performing an analytical RP-HPLC run of the complex IFNα_{2a}/IFNAR2^{EC}, the activity of IFNAR2^{EC} was determined to be over 95%.

Experimental Details of Surface Plasmon Resonance. The binding affinity of IFNα_{2a}, ^{5}PEG−IFNα_{2a}, ^{40}PEG−IFNα_{2a}, and its positional isomers for IFNAR2^{EC} was determined by SPR measurements on a Biacore-3000 (Biacore, Sweden) instrument at 10, 17, 25, 30, and 37 °C. For all the samples, the measurement was repeated in duplicate or triplicate at nine different concentrations ranging from 0.6 nM to 1500 nM. The BIAevaluation program (Biacore, Sweden) was used to analyze and fit the experimental data to a (1:1) biomolecular interaction model with mass transport limitation. The binding affinity of the free 5 kDa linear and 40 kDa branched PEG-polymers was evaluated at 25 °C.

The receptor IFNAR2^{EC} was labeled with biotin before being immobilized on a streptavidin containing sensor surface (SA sensor, Biacore-3000). Biotinylation was performed by mixing a 0.8 mM solution of biotinamidocaproate-*N*-hydrosuccinimide ester (Fluka) in DMSO to the IFNAR2^{EC} solution (0.1 mg·mL^{-1} in 10 mM HEPES buffer at pH 8.4) to get a final concentration of 20 μM of biotinylated reagent. After 1 h of reaction, the solution was dialyzed overnight in 10 mM HEPES buffer at pH 8.4 to remove excess biotin. Immobilization was performed by contacting the biotinylated protein solution, diluted to 0.01 mg·mL^{-1}, with the SA sensor surface. For the binding experiments, the amount of immobilized protein was controlled via the contact time: 200 RU were immobilized, corresponding to approximately 0.2 ng·mm^{-2} of IFNAR2^{EC}. The sample and running buffer for the binding experiments was 10 mM HEPES, 150 mM NaCl, 3 mM $CaCl_2$, 0.005% polysorbate-20 at pH 8.4 with a flow velocity of 50 μL·min^{-1}. The acquisition sampling rate was 5 points per second. Between the measurements no regeneration of the sensor surface was needed because of the fast dissociation process. Typical sensorgram responses are shown in Figure 2.

Data Analysis of SPR: Equilibrium Binding and Kinetic Rate Constants. The equilibrium dissociation constant $K_{Deq.}$ was determined after analysis of the equilibrium SPR response with the Scatchard analysis: the ratio of the sensor response to the ligand concentration was plotted versus the sensor response, and the resulting slope of the straight line provided the equilibrium association constant $K_{Aeq.} = 1/K_{Deq.}$. The association and dissociation rates, k_{on} and k_{off}, were determined by fitting the time dependent association and dissociation phases with a mathematical model for a (1:1) complex formation. $K_{Dkin.}$ was calculated as k_{off}/k_{on}. In case of fast association, k_{on} could not be evaluated with a reliable fitting of the association phase. In such a case, only k_{off} was obtained by the fitting of the dissociation phase by a monoexponential decay curve. The $K_{Deq.}$ value determined by the Scatchard analysis of the equilibrium sensor response was then used to calculate k_{on} via the expression $k_{on} = k_{off}/K_{Deq.}$. Results obtained are presented in Table 1.

Equilibrium Thermodynamics of the Binding to IFNAR2^{EC}. Upon binding of IFNα_{2a} and the pegylated IFNα_{2a}s to IFNAR2^{EC}, the change in free energy $\Delta G°$ is related to the enthalpy change $\Delta H°$, the entropy change

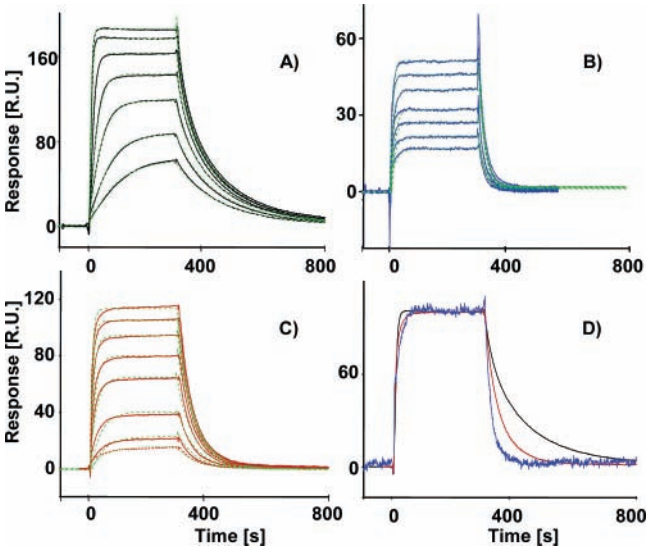

Figure 2. Sensorgram response of binding affinity measured by SPR with immobilized IFNAR2^{EC} at 25 °C in contact with: (A) IFNα_{2a} at concentrations 100, 80, 40, 20, 10, 5, and 2.5 nM, respectively (black line); (B) Isomer-K31 at concentrations 1000, 800, 600, 400, 300, 200 and 150 nM, respectively (blue line); (C) Isomer-K70 at concentrations 300, 290, 150, 120, 70, 40, 15, and 7.5 nM, respectively (red line). For panels A, B, and C, the green dashed lines represent the result of global fits using a (1:1) biomolecular interaction model. Panel D presents the overlay of the 100 nM sensorgram response of binding kinetics with immobilized IFNAR2^{EC} in contact with IFNα_{2a}, the Isomer-K31 and -K70, colored in black, blue, and red lines, respectively. For comparison, the maximum sensorgram response at equilibrium was adjusted to the same level.

Table 1. Kinetic Parameters k_{on}, k_{off}, $K_{Dkin.}$ (= k_{off}/k_{on}), and $K_{Deq.}$ of the Binding to IFNAR2^{EC} of IFNα_{2a}, ^{40}PEG−IFNα_{2a} and Its Individual Positional Isomers, and ^{5}PEG−IFNα_{2a}[a]

	k_{on} 10^5 M^{-1}·s^{-1}	k_{off} 10^{-2} s^{-1}	$K_{Dkin.}$, nM	$K_{Deq.}$, nM
IFN$_{\alpha 2a}$	27.0	1.3	5.0	5.5
^{40}PEG−IFNα_{2a}[b]	1.6	2.0	121	124
Low Affinity (LA) Isomer				
Isomer-K31	1.0	5.2	520	500
Isomer-K164	2.3	3.3	150	150
High Affinity (HA) Isomer				
Isomer-K134	2.7	2.1	76	77
Isomer-K131	4.8	1.9	40	43
Isomer-K121	5.3	2.1	39	40
Isomer-K70	5.5	1.8	32	32
^{5}PEG−IFNα_{2a}[c]	7.4	1.3	17	17

[a] SPR measurements were done at 25 °C. For all the values, the standard error is ±10%. [b] ^{40}PEG−IFNα_{2a} is a mixture of mainly six monopegylated positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively, representing ~98% of the mixture (*19*). [c] ^{5}PEG−IFNα_{2a} is a mixture of 11 monopegylated positional isomers modified at all the lysine positions (*16*).

$\Delta S°$, and the equilibrium association constant $K_{Aeq.}$ according to the eq 1 with R the gas constant (1.99 × 10^{-3} kcal·K^{-1}·mol^{-1}).

$$\Delta G° = \Delta H° - T\Delta S° = -RT \ln K_{Aeq.} \quad (1)$$

If the enthalpy change does not vary with the temperature, the van't Hoff plot of ln $K_{Aeq.}$ versus 1/T results in a straight line of slope $\Delta H°/R$.

$$\ln K_{Aeq} = -\Delta H°/RT + \Delta S°/R \quad (2)$$

Although the intercept, $\Delta S°/R$, provides the entropy, a better alternative is to use eq 1. However $\Delta H°$ and $\Delta S°$

Table 2. Thermodynamic Parameters $\Delta G°$, $\Delta H°$, and $T\Delta S°$, for the Binding to IFNAR2^{EC} of IFNα_{2a}, ^{40}PEG–IFNα_{2a} and Its Individual Positional Isomers, and ^{5}PEG–IFNα_{2a}[a]

	$\Delta G°$, kcal·mol^{-1}	$\Delta H°$, kcal·mol^{-1}	$T\Delta S°$, kcal·mol^{-1}	ΔCp°, kcal·mol^{-1}·K^{-1}
IFNα_{2a}	−11.2	−5.7	5.5	−0.2
^{40}PEG–IFNα_{2a}[b]	−9.4	−3.7	5.7	n.d.[d]
Low Affinity (LA) Isomer				
Isomer-K31	−8.6	−6.5	2.1	−0.5
Isomer-K164	−9.3	−6.0	3.3	−0.6
High Affinity (HA) Isomer				
Isomer-K134	−9.7	−3.0	6.7	−0.2
Isomer-K131	−10.0	−4.6	5.4	−0.5
Isomer-K121	−10.1	−3.6	6.5	−0.1
Isomer-K70	−10.2	−4.6	5.6	−0.4
^{5}PEG–IFNα_{2a}[c]	−10.6	−5.4	5.2	−0.4

[a] The values were derived from the van't Hoff analysis of the temperature dependence of the binding affinity data at equilibrium. $T\Delta S°$ is calculated at 25 °C. The temperature dependence of the enthalpy and entropy was evaluated by the determination of ΔCp°. The standard errors for $\Delta G°$, $\Delta H°$, TΔS° were estimated to be in the 10% range, and that of ΔCp° was estimated to be in the 100% range. This estimated was done by a replicate of the K_d(T) series of IFN$_{\alpha 2a}$ which showed a experimental error on K_d in the 10% range. This experimental error was used as noise in a Monte Carlo simulation of the fit parameters of the van't Hoff equation. [b] ^{40}PEG–IFNα_{2a} is a mixture of mainly six monopegylated positional isomers modified at K31, K134, K131, K121, K164, and K70, respectively, representing ~98% of the mixture (*19*). [c] ^{5}PEG–IFNα_{2a} is a mixture of 11 monopegylated positional isomers modified at all the lysine positions (*16*). [d] n.d. = not determined.

very often show temperature variations, resulting in a non-zero value of the heat capacity change ΔCp°. Within the temperature range relevant for the study of such associations, ΔCp° itself does not vary with temperature. The temperature dependence of the equilibrium association constant, $K_{Aeq.}$, is then taken into account by introducing ΔCp° in the integrated van't Hoff eq 3.

$$\ln(K_{Aeq.}/K°) = [(\Delta H° - T_o.\Delta Cp°) \times (1/T_o - 1/T) + \Delta Cp° \ln(T_o/T)]/R \quad (3)$$

Here, a nonlinear fitting of the experimental data provides $\Delta H°$ and ΔCp°. Thus, ΔG° and $\Delta S°$ were calculated using eq 1. The standard temperature T_o was taken to 25 °C. Thermodynamic parameters are summarized in Table 2.

Monitoring of the in Vitro Digestion of IFNα_{2a} and ^{40}PEG–IFNα_{2a} by Trypsin. The in vitro digestion of IFNα_{2a} and ^{40}PEG–IFNα_{2a} by trypsin at room temperature was monitored by successive RP-HPLC runs spaced in time. RP-HPLC experiments were conducted with a Hewlett-Packard 1050 HPLC system equipped with a Supelco-C5 column (4.6 mm inner diameter × 150 mm length) from Sigma-Aldrich. Proteins were eluted using a gradient of acetonitrile in 0.08% trifluoroacetic acid and water in 0.1% trifluoroacetic acid at a flow rate of 0.25 mL·min^{-1} and monitored by absorbance at 214 nm.

Prior to measurement, IFNα_{2a} and ^{40}PEG–IFNα_{2a} solutions were dialyzed in 20 mM TRIS 0.02% NaN_3 at pH 7.4 and subjected to a preparative centrifugation to ensure the removal of aggregates. The protein solutions were subsequently diluted to a concentration of 0.25 mg·mL^{-1} measured by UV absorbance (280 nm). Bovine pancreas trypsin of sequencing grade quality was purchased from Roche Diagnostics (Penzberg, Germany). This serine protease specifically cleaves peptide bonds at C-terminally arginine and lysine at an optimum working pH of 8.0. A stock solution of 1 mg·mL^{-1} of trypsin was prepared in the buffer specified above. In individual sealed vials, the digestion was triggered by mixing a specific amount of trypsin solution to 1 mL of IFNα_{2a} and ^{40}PEG–IFNα_{2a} solutions at 0.25 mg·mL^{-1}, respectively, to make a molar ratio (1:40; trypsin:protein). After 1 h of incubation, the first RP-HPLC chromatogram was recorded by injecting an aliquot of 60 μL from the vials. The monitoring of the in vitro digestion of IFNα_{2a} and ^{40}PEG–IFNα_{2a} by trypsin was subsequently performed by time-spaced injections of 60 μL from the content of the vials over the time-course of the digestion. Each chromatogram provided a snapshot of the digestion at different times with decreasing signals derived from intact IFNα_{2a} and ^{40}PEG–IFNα_{2a}, respectively, and new increasing signals derived from peptide fragments. IFNα_{2a} and ^{40}PEG–IFNα_{2a} proteins displayed the same retention times in all their respective chromatograms. Digestive time-courses are shown in Figure 3.

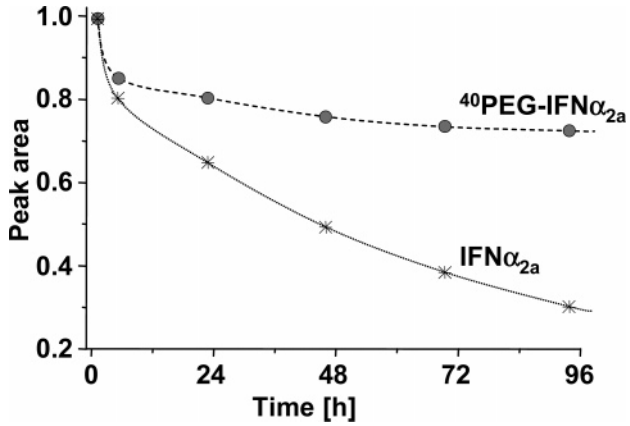

Figure 3. Time-course of the in vitro digestion of INFα_{2a} and ^{40}PEG-INFα_{2a}, respectively by trypsin monitored with successive RP-HPLC runs. For each time point, an aliquot (60 μL) of the incubation solution was injected. For both proteins tested, the concentration was 0.25 mg·mL^{-1} in 20 mM TRIS 0.02% NaN_3 at pH 7.4. The molar ratio (trypsin:protein) was (1:40). In the RP-HPLC chromatograms, the area of the elution peak, derived from the intact protein, was normalized with respect to the area of elution peak for the first time-point, i.e., 1 h after incubation.

Self-Avoiding-Walk and Simulation of the Binding to IFNAR2^{EC}. To structurally understand the differences observed for IFNAR2^{EC} binding data of ^{40}PEG–IFNα_{2a} and its positional isomers with respect to IFNα_{2a}, a simple kinetic model (*28*) and numerical simulations of the protein-polymer construct were used. In the simulation, proteins are modeled as hard spheres of defined radii and the polymer-chains represented as an ensemble of on-lattice SAWs. All molecular modeling calculations were performed using the molecular modeling package MOLOC on a PC-workstation (*29*, *30*).

In a brute force on-lattice representation of a single PEG-polymer chain the grid in use has to encompass as many shells as there are bonds in the chain to prevent undesired compaction of the SAW. This requires, for a 40 kDa single PEG chain of ^{40}PEG–IFNα_{2a} a grid dimension of 465 (units) × 3 (bonds) = 1395 shells, not tractable by use of the computational power available. Basic polymer theory (*31*) shows that a long polymer-chain can be represented by a much smaller number of nodes if the unit length of the grid is defined by a properly selected statistical length that is related to the typical direction correlation distance of the polymer.

To define this statistical length, 1000 SAWs of 72 steps were enumerated on a diamond lattice (dmd) of 72 shells;

thus, the SAWs are never restricted by hitting the boundary as they start at the origin. Artifactual compaction of SAWs is excluded.

Direction correlation distance was extracted from distance, i.e., number of steps, dependent walk direction correlation function, evaluated from the SAW ensemble. The number of steps over which these correlation functions decayed to e^{-1} was 1.163.

For the definition of the statistical length needed, connection with real PEG chain was made by the experimental finding that the ratios for populations of gauche and trans steps is 90% for the O−C−C−O conformation and 10% for the C−O−C−C links (*32*). Thus, the real PEG chain loses its direction of propagation approximately every third step, i.e., every monomer. From this estimate and the direction correlation length of 1.163, diamond lattice walks of ∼465 steps (equal to the mean number of units in a 20 kDa PEG-chain) were considered. Thus, a reduction in the number of lattice shells by a factor of 3, corresponding to a reduction in computational time by a factor of 3^3 was achieved. The size of the SAWs is well below the dimension of the corresponding lattices. Errors introduced from walks bouncing off the lattice surface are prevented.

Due to the scaling of lengths described above, IFNα_{2a} has to be represented by a sphere of size 4.36 lattice bond distances. The spheres were placed such that the lattice origin was at the surface of the sphere. All walks started from this origin and could not penetrate to lattice vertexes inside the sphere. 4000 SAWs were generated.

To evaluate the activation entropic contribution to the free energy of protein−protein association, a purely entropic model was used. In this model, a test sphere representing an approaching protein, e.g. a receptor or a protease, of varying radius was placed in the lattice box in surface-contact with IFNα_{2a} sphere. This was done at various azimuth angles θ with respect to the starting point of the SAWs at the surface of the IFNα_{2a} sphere. Sphere size and angle dependent contributions were obtained by counting the fraction of SAWs that did not penetrate the test sphere. Thus, the likelihood that a protein in surface-contact with the protein part of the pegylated construct intersects with the polymer was evaluated. This measure was calculated as the fraction of an ensemble of SAWs intersecting with a test sphere in contact with the pegylated protein but positioned at different locations with respect to the origin of the SAWs. The result can be displayed as an intersection probability $p(\theta)$ expressed as an activation entropic contribution $\Delta S^{\ddagger}(\theta)$ to the free energy of association by a simple Boltzmann like relationship given by $p(\theta) \propto \exp(-\Delta S^{\ddagger}(\theta)/k_B)$, with k_B the Boltzmann constant. To test the influence of the lattice type used, we repeated all simulations with a simple (sc) a body (bcc) and a face-centered (fcc) cubic lattice. It turned out that the type of lattice has only a minor influence on the fraction of intersecting walks. Averages over all lattice types were used for further discussion. Results are shown in Figures 4 and 5.

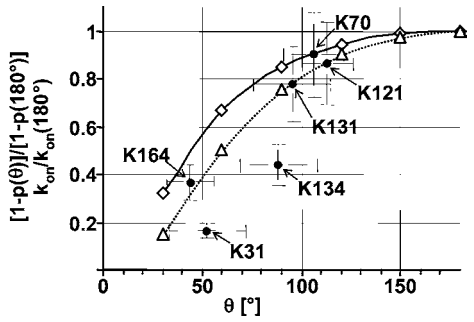

Figure 4. Normalized probability of nonintersection $[1 - p(\theta)]$ of an ensemble of SAWs of the PEG-chains with a test sphere positioned in surface contact with the INFα_{2a} sphere at an azimuth angle θ with respect to the origin of the SAW (see Materials and Methods). The origin is defined at the center of the INFα_{2a} binding epitopes of IFNAR2^{EC} (see text). The normalization is done with respect to a SAW starting on the opposite side of the sphere contact point given by $[1 - p(180°)]$. Two simulations are included: diamond-shaped points connected by a solid line, the diameter of the test sphere was the same as the INFα_{2a} sphere; triangles connected by a dashed line, the diameter of the test sphere was doubled. Lines are shown to guide the eye. Filled circles represent angle corrected ratios $k_{on}/k_{on}(180°)$ of experimental k_{on} values of the positional isomers. $k_{on}(180°)$ is defined by $k_{on}(180°) = {}^{121}k_{on} \times p(113°)/p(180°)$, with ${}^{121}k_{on}$ the association rate of the Isomer-K121. The θ-angles are extracted from the literature (*21*). The definition of the *x*- and *y*-error bars is given in the text.

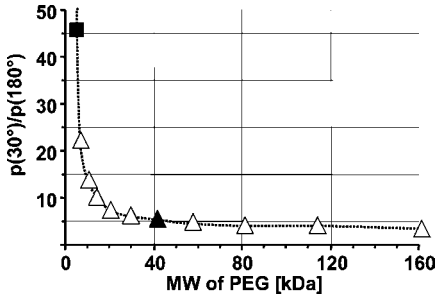

Figure 5. Simulation of the intersection probability $p(30°)$ of an ensemble of SAWs of various PEG-polymers with a test sphere (same radius as the INFα_{2a} sphere) positioned in surface-contact with the INFα_{2a} sphere at an azimuth angle of 30° normalized to $p(180°)$ in dependence on the molecular weight of a PEG-polymer (see Materials and Methods). Clearly seen is the plateau of this ratio for a molecular weight beyond 20 kDa. Line is shown to guide the eye. The filled square and triangle correspond to a 5 kDa and 40 kDa PEG-polymer, respectively.

RESULTS AND DISCUSSION

Experimental Results: Kinetics and Thermodynamics of the Binding to IFNAR2^{EC}. SPR experiments provided essential data for dissecting out the kinetics and mechanisms involved in the binding of IFNα_{2a}, ^{5}PEG−IFNα_{2a}, ^{40}PEG−IFNα_{2a}, and its positional isomers to IFNAR2^{EC}. All the proteins, including the receptor IFNAR2^{EC}, were obtained and used in a highly pure monomeric and aggregate-free form (see Materials and Methods section) (*22*). For all the samples, the SPR sensograms displayed a very good signal-to-noise ratio with an increase in the rate and extent of the binding with increasing protein concentrations. Typical sensorgrams for the binding to IFNAR2^{EC} of varying concentrations of IFNα_{2a} and the positional isomers modified at −K31 and −K70 are illustrated in Figure 2. For all the samples, $K_{Dkin.}$, k_{on}, and k_{off} could be calculated. The binding affinity data extracted from the SPR measurements at 25 °C for IFNα_{2a}, ^{5}PEG−IFNα_{2a}, ^{40}PEG−IFNα_{2a}, and its individual positional isomers are reported in Table 1. Neither the free 5 kDa linear PEG-polymer nor the free 40 kDa branched PEG-polymer displayed any SPR response indicative of an affinity to the receptor (data not shown).

IFNα_{2a} binds to IFNAR2^{EC} with a very high affinity ($K_{Dkin.}$ = 5 nM). This is in agreement with previously reported values and the model recently proposed for the complex IFNα_{2a}/IFNAR2^{EC} (*21*, *27*, *33*, *34*). Here, the binding involves hydrophobic patches of IFNα_{2a} interacting with matching hydrophobic surfaces of IFNAR2^{EC},

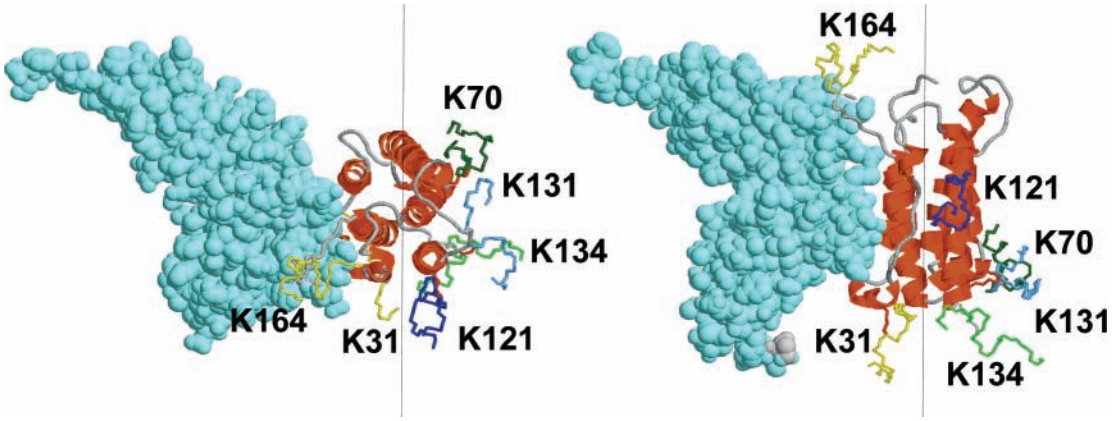

Figure 6. Representation of the complex structure INFα_{2a}/IFNAR2^{EC} obtained by the docking of the two individual NMR structures (*21*, *35*). The model has been described and documented in ref 21. The IFNAR2^{EC} structure is reported as a space-fill representation. The IFNα_{2a} structure is reported as a ribbon with α-helices in orange and connecting loops and turns in light gray. At the lysine positions known to be pegylated in the positional isomers of ^{40}PEG-INFα_{2a}, two short PEG-chains are represented as on-lattice SAWs of 20 steps using the molecular modeling package MOLOC (*29*, *30*). The PEG-chains of the class-LA isomers at K31 and K164 are colored in yellow. The PEG-chains of the class-HA isomers at K134, K131, K121, and K70 are colored in light green, light blue, dark blue, and dark green, respectively. Separation between the class-LA and -HA isomers is indicated by a dashed line. These figures were generated using the RasMol program (*48*).

while complementary adjacent motifs of alternating charged side-chains guide the two proteins in a fast association to form a tight complex.

Compared to IFNα_{2a}, the binding affinity of ^{5}PEG–IFNα_{2a} to the receptor is ~3.4-fold reduced, mainly due to a ~3.6-fold decrease of the association rate. This must be attributed to the 5 kDa linear PEG-polymer. Once bound, ^{5}PEG–IFNα_{2a} dissociates with the same k_{off} as IFNα_{2a}. For ^{40}PEG–IFNα_{2a}, the binding affinity for the receptor is ~24-fold reduced with respect to IFNα_{2a}. Again, this is mainly due to a change of the association rate: k_{on} decreases by ~16.8-fold while k_{off} remains essentially unaltered. All these results clearly show that the pegylation significantly reduces the affinity of the pegylated IFNα_{2a} for IFNAR2^{EC} without abolishment of the binding, and that the affinity is PEG-size dependent. However, as ^{40}PEG–IFNα_{2a} as well as ^{5}PEG–IFNα_{2a} is a mixture of monopegylated positional isomers (*16*, *19*), the kinetic parameters extracted results from the weighted contributions of all the components in the mixture. Therefore, only a careful analysis of the binding of the individual isomers to the receptor can provide a clear interpretation of the kinetic binding parameters for ^{40}PEG–IFNα_{2a} (see below). For ^{5}PEG–IFNα_{2a}, the isolated positional isomers were not available.

Each positional isomer of ^{40}PEG–IFNα_{2a} exhibits different binding affinity for IFNAR2^{EC}, ranging from 32 nM to 520 nM (Table 1). The losses of binding affinity are clearly attributable to the 40 kDa branched PEG-polymer and are dependent on the pegylation site. One can identify among the positional isomers two classes with respect to the kinetic binding process. The first class, called the class-LA (LA for low affinity), comprises the Isomer-K31 and -K164, that bind to the receptor with lower affinities (150–520 nM). In contrast, the second class, called the class-HA (HA for high affinity), comprises the Isomer-K134, -K131, -K121, and -K70, that interact with the receptor with higher affinities (32–76 nM). The two classes are directly related to two different areas of location of the pegylation sites (Figure 6). For the class-LA isomers, the PEG-polymer attachment point is located in proximity to the IFNAR2^{EC} binding interface (*21*). A high steric hindrance of the protein–protein contacts due to the PEG-polymer seems therefore to be responsible for the reduced binding affinity of these isomers. This especially holds true for the Isomer-K31 that carries the polymer close to a hot-spot region for the interaction with IFNAR2^{EC} (*33*, *34*). For the class-HA isomers, the PEG-polymer is attached remotely with respect to the binding interface. This leads to lower reduction of binding affinities, certainly due to lower steric hindrance by the polymer.

In all the isomers, the affinity losses are controlled by a substantial change of the association rate combined with a moderate change of the dissociation rate. The models, presented in the molecular modeling and simulation section, explain nicely the reduction in k_{on} experimentally observed for the class-LA and -HA isomers by ~16-fold and ~6-fold, respectively. As far as the dissociation rate k_{off} is concerned, only the class-LA isomers present notable differences with respect to IFNα_{2a}: the Isomer-K31 and -K164 are released from the complex ~4-fold and ~2.5-fold faster than IFNα_{2a}, respectively. Again these differences are attributed to the location sites of the PEG-polymer. The attachment of the PEG-polymer at the binding interface may favor a faster release of the isomer than in the case where the polymer is located on the opposite side of the interface (Figure 6). Moreover, it is known that the charges contribute to the binding affinity to IFNAR2^{EC} (*21*, *33*, *34*). Thus for the Isomer-K31, the removal of one charge by pegylation of K31 might increase the dissociation rate. In the Isomer-K164, the high mobility of the C-terminal segment of IFNα_{2a} (*35*) may bring the pegylated residue K164 near to the binding interface. Thus, the removal of one charge might also contribute in this isomer to increase k_{off}.

Experimental Results: Temperature Dependence of the Equilibrium Thermodynamics of the Binding to IFNAR2^{EC}. The thermodynamic analysis of the temperature dependence of the binding affinity data at equilibrium, derived from SPR measurements, was performed using the van't Hoff analysis. The free energy ΔG°, the enthalpy change $\Delta H°$, the entropy change $\Delta S°$, and the specific heat capacity ΔCp° of the binding of IFNα_{2a} and pegylated IFNα_{2a}s to IFNAR2^{EC} at equilibrium could be determined. The thermodynamic parameters at equilibrium ΔG°, $\Delta H°$, $\Delta S°$, and ΔCp° are reported in Table 2.

The high affinity binding of IFNα_{2a} to IFNAR2^{EC} is a slightly enthalpy-driven process as the free energy of binding, $\Delta G° = -11.2$ kcal·mol^{-1}, results from an enthalpy contribution of $\Delta H° = -5.7$ kcal·mol^{-1}. The

formation of electrostatic and hydrophobic contacts and hydrogen bonds between the two molecules account for this exothermic interaction ($\Delta H° < 0$), accompanied by an increase of entropy $\Delta S°$ also favorable for binding. This large entropy contribution suggests that the binding may involve a burial of hydrophobic surface, an increase in the conformation freedom of the proteins and/or a release of bound water molecules (*36*, *37*). Water release is consistent with a charge compensation occurring at the binding interface upon complex formation. In the IFNα_{2a}/IFNAR2^{EC} model, important electrostatic contacts are responsible for driving the two proteins in a tight complex (*21*).

The binding of ^{5}PEG−IFNα_{2a} to IFNAR2^{EC} is also a slightly enthalpy-driven process, with enthalpy and entropy losses of ∼5% and ∼10%, respectively, when compared to IFNα_{2a}. These low $\Delta H°$ and $\Delta S°$ variations show the similarities of the thermodynamic binding process. In contrast for ^{40}PEG−IFNα_{2a}, the binding to IFNAR2^{EC} is entropy-driven. But it must be noted that this change in character is mostly caused by a loss of enthalpy by ∼35% while the entropy remains unaltered. To provide a detailed description of the thermodynamics of binding of ^{40}PEG−IFNα_{2a}, each individual positional isomer was analyzed (see below).

Upon binding to IFNAR2^{EC}, all the positional isomers of ^{40}PEG−IFNα_{2a} gained enthalpy and entropy. With respect to the relative importance of electrostatic and hydrophobic contacts involved, this suggests that the isomers interact with IFNAR2^{EC} globally in a similar manner as IFNα_{2a}. Interestingly, the class-LA binds to the receptor, like IFNα_{2a}, in an enthalpy-driven binding process. In contrast the binding for the class-HA members, like ^{40}PEG−IFNα_{2a}, is entropy-driven. As compared to IFNα_{2a}, the class-LA isomers present a mean enthalpy gain of ∼10%. In contrast, the class-HA isomers display a mean enthalpy loss of ∼30%. Whether these trends of $\Delta H°$ change are due to alterations of remotely located surface charges and/or charges involved in the binding cannot be decided with the data available. The differences in $\Delta H°$ can also be attributed to differences in the details of the hydration of the proteins and the PEG-polymer involved (*38*, *39*). An obvious possibility to explain the significant loss of entropy by ∼50% for the class-LA isomers, is the reduced number of conformations accessible to the PEG-polymer due to the steric hindrance of mobility arising from IFNα_{2a} and IFNAR2^{EC}, and vice-versa (*36*, *40*).

Experimental Results: PEG-Polymer Protection against Proteolytic Degradation. To evaluate the PEG-polymer protection against proteolytic degradation, the in vitro digestion of IFNα_{2a} and ^{40}PEG−IFNα_{2a} by trypsin was monitored by RP-HPLC. As illustrated in Figure 3, the area of the normalized signal of intact ^{40}PEG−IFNα_{2a} in the chromatograms decreases ∼7-fold slower than IFNα_{2a}. This shows a reduction of the in vitro proteolytic degradation due to the pegylation of IFNα_{2a}. By imposing a steric hindrance on the protein, the PEG-polymer limits with a large excluded volume the accessibility for protease. The increased stability against proteolytic degradation was also reported for other pegylated proteins (*41*, *42*).

Molecular Modeling and Simulation of Binding to IFNAR2^{EC}. The reduction in binding affinity by a factor of ∼24 observed for the ^{40}PEG−IFNα_{2a}/IFNAR2^{EC} complex, as compared to its IFNα_{2a} counterpart, is mainly determined by a corresponding difference in the association rate k_{on} (Table 1). In general the kinetics of the formation of a protein−protein complex can be explained by the following determinants. The collision rate, at which two partners meet, is controlled by the concentration of the two molecules. Under diffusion-limited conditions, the collision rate is independent of the molecular weight of the partners and their relative orientation. This rate constitutes an upper limit and is defined in water at 300 K by $k_{collision} \approx 6.6 \times 10^9$ $M^{-1}\cdot s^{-1}$ (*28*). If each hit of two molecules would lead to a complex, this value is the expected k_{on} of the binding process. However, k_{on} values for real proteins are often substantially lower, as productive complex formation depends on a correct position and relative orientation of the two partners with respect to each other. A correct preorientation of the binding partners can, for example, be achieved by long-range electrostatic interactions assuming a freely accessible binding area. In this case, the two binding partners can interact and lower the free-energy of the complex compared to the unbound state. In the case of the IFNα_{2a}/IFNAR2^{EC} complex, it is estimated that only one out of approximately 2400 collisions leads to an active complex. This reduction is related to the ratio of the interaction surface to the overall surface of the proteins involved. It has been shown that k_{on} scaling is expected to be proportional to R_H^{-2}, with R_H being the hydrodynamic radius (*28*). With the R_H scaling argument given above and using experimental R_H values, k_{on} for ^{40}PEG−IFNα_{2a} was estimated to be reduced ∼10-fold compared to IFNα_{2a} (*22*). Thereby, it is assumed that the size of the contact area and the long-range interactions between the proteins are not altered by the presence and location of the PEG-polymer. Already, this simple kinetic model provides a rough estimate for the expected drop of k_{on} and K_D for pegylated proteins. It has to be emphasized that this reduction in k_{on} proportional in R_H^{-2} cannot be circumvented by optimized positioning of the polymer with respect to the binding interface.

Further reduction of k_{on} is expected if the polymer is attached near to or at the edge of the binding interface, due to steric hindrance of the formation of specific protein−protein contacts. This holds true in the case of the class-LA isomers (Table 1). But also the variations in k_{on} between all the isomers in both cases can be rationalized as a consequence of different steric interactions in the process of complex formation due to spatial differences among the positional isomers. In our model elaborated in this work, hindrance is represented as the likelihood that a protein, e.g. IFNAR2^{EC}, in surface-contact with the protein domain of the pegylated construct intersects with the polymer. This likelihood was calculated as the fraction of an ensemble of SAWs intersecting with a test sphere in contact with the pegylated protein. The test sphere is positioned at different locations defined by an azimuth angle θ with respect to the origin of the SAWs. The result is displayed as an intersection probability $p(\theta)$ expressed as an activation entropic contribution $\Delta S^{\ddagger}(\theta)$ to the free energy of association (see Materials and Methods). Thus $[1 - p(\theta)]$ defines the fraction of an approaching protein that can form an active complex.

Pictorially, it is clear that the protection of a surface-element located on the surface of the IFNα_{2a} sphere against a contact with an approaching protein is more pronounced if the PEG-polymer attachment point is located close in space. The normalized function $[1 - p(\theta)]/[1 - p(180°)]$ is reported for two test sphere radii in Figure 4. It is a measure to rate the additional repulsive effect of the different isomers of ^{40}PEG−IFNα_{2a} as compared to the hypothetical most remotely attached polymer position, i.e., for $\theta = 180°$. In the complex of

IFNAR2^{EC} with the positional isomers, the starting points for the SAWs are defined by the azimuth angle θ between the PEG-polymer attachment point and the center of the binding interface (*21*). The reference k_{on} value for the hypothetical isomer at $\theta = 180°$, $k_{on}(180°)$, was calculated by scaling k_{on} of the Isomer-K121 ($\theta = 113°$) by the factor $p(113°)/p(180°)$. A relative contribution for the destabilization of the complex is reported for each individual positional isomer with k_{on} in Figure 4 by $k_{on}/k_{on}(180°)$. It must be noted that the definition of the center of the binding interface is somewhat arbitrary. This reflects itself in angular θ-error bars given for the experimental data points in Figure 4. This SAW based-model can semiquantitatively explain the experimental differences in k_{on} observed for the various isomers (Table 1). Especially, the experimental factor ~5.5 for the isomer dependent k_{on} variations is nicely reproduced with this simulation. In addition, the model predicts that only a factor below ~10 in k_{on} can be gained for hypothetical pegylation at θ ~180° compared to pegylation at the rim (θ ~30°) of the binding interface. Of high importance is the finding that if the pegylation is performed at an angle of at least ~40° away from the ridge of the binding interface, i.e., θ ~70°, only a ~2-fold reduction in k_{on} is expected compared to the sterically most favorable case with $\theta = 180°$ (Figure 4). The azimuth angles of all the isomers, with the exception of the Isomer-K31 and -K164, lie in this range. These two isomers display a small θ angle, as their pegylation sites are located at or close to the rim of the binding interface. However, for the Isomer-K164, it must be noted that the pegylation site resides in the highly flexible C-terminal region of the protein (*35*); therefore, it is not clear whether the extracted angle really represents an accurate value valid for the complex. One is tempted to increase the θ-angle for the Isomer-K164 by approximately ~15° still representing a conformation accessible for the flexible C-terminus without steric clash.

Only the Isomer-K31 and -K134 experience a k_{on} reduced by a factor ~2.0 compared to the prediction of the SAW model (Figure 4). For the Isomer-K31, the deviation is in line with the argument that the removal of a charge on the side-chain influences the long-range interactions needed for the prepositioning of the proteins to support complex formation. Whether the same holds true for the Isomer-K134 is not clear.

To summarize, the variations in k_{on} observed for IFNα_{2a} and the individual positional isomers of ^{40}PEG–IFNα_{2a} (Table 1) can be explained with reasonable accuracy by taking into account (a) the size (R_H) of the unpegylated and pegylated IFNα_{2a} (*22*) and (b) the differences in steric hindrance encountered between IFNAR2^{EC} and the positional isomers in the process of complex formation. The first effect can be semiquantitatively explained by the rigid-body association model (*28*), and the second effect by the SAW based-model elaborated above. Only this latter model can convincingly explain the observed variations in binding affinities and association rates for the positional isomers.

The SAW based-model can also make a prediction of the steric effect for different sizes of PEG-polymer attached at various θ-angles on intermolecular interaction. Figure 5 shows the ratio $p(30°)/p(180°)$, expressing the relative hindrance at two extreme angles of PEG attachment site (see above) in dependence on the polymer molecular weight. This dependence becomes independent of the molecular weight of the polymer above 20 kDa. Therefore, very similar if not identical angle dependencies are expected for k_{on} of proteins modified with polymer-chains larger than 20 kDa. For smaller PEG-chains a more pronounced θ-dependence is observed (Figure 5). A substantially higher reduction of k_{on} relative to the relaxed position at $\theta = 180°$ is expected, if PEG-chains smaller than 20 kDa were attached close to the binding interface, e.g. in case of a ~5 kDa PEG-chain, the variations $p(30°)/p(180°)$ are ~6-times larger than that expected for a 20 kDa PEG-chain.

In all the positional isomers investigated here, the PEG-polymer attachment site lies well outside or close to the rim of the binding epitopes of IFNα_{2a}. If the attachment site were to be within the binding region, very pronounced effects on the binding affinity, association and dissociation rates would be expected. In this particular case, the flexible polymer-chain would severely prevent the correct alignment and interaction of the two binding partners, by its steric bulk. In IFNα_{2a}, no lysine (with the exception of K31 known to lie close to a hot-spot region of binding) is directly within this critical region (*27*, *33*). For the stability and endurance of the complex, the strength of the electrostatic, hydrogen bond, van der Waals and hydrophobic (dehydration) interactions are of high importance. These effects, however, have only a minor effect on k_{on} (see above), having a higher importance once the complex is formed.

Pharmacological Effects and Molecular Properties. The reduction in receptor binding affinity of pegylated IFNα_{2a} has direct implications on the in vitro biological activity. In the in vitro antiviral assay an approximately ~3-fold and ~30-fold lower specific activity was observed for ^{5}PEG–IFNα_{2a} and ^{40}PEG–IFNα_{2a}, respectively (*16*, *19*). In the in vivo situation, this PEG-size dependent effect is more than counterbalanced by the two following positive findings: (a) the prolongation of PEG-chains goes in hand with an increase in stability and protection against proteolytic degradation, and (b) bigger particles experience a reduction in renal clearance by glomerular filtration (*41*–*43*). Both effects also depend critically on the size of the attached-PEG-polymer. The size of the pegylated protein particle is given by the hydrodynamic radius R_H, and as it is dominated by a long polymer chain, it increases with MW$^{3/5}$, with MW the polymer molecular weight (*22*, *31*, *44*). The simple kinetic model described above predicts a increased protection against proteolytic degradation roughly proportional in ~R_H^2 (~MW$^{1.2}$). An estimate of the protection against the proteolytic degradation thus predicts a decrease of the digestion rate of ^{40}PEG–IFNα_{2a} by a factor ~10 as compared to IFNα_{2a}, in good agreement with the experimentally observed reduction of the in vitro digestion rate by a factor of ~7 (Figure 3). Previously, it has been shown that the pegylation of IFN$_{\alpha 2a}$ reduces the tendency of the protein for aggregation (*22*). Here, the same rigid-body association model predicts that the self-aggregation of pegylated IFN$_{\alpha 2a}$ by protein–protein interactions is reduced by a scaling factor ~R_H^{-4}. This remains to be confirmed experimentally. Due to the low concentration of the drug in the body, aggregation is expected to be of minor importance after the substance is administered. However, reduced aggregational property is essential while the protein is maintained in its formulation at higher concentration. It is well conceivable that this R_H^{-4} dependence also relates to the substantially reduced rate of self-digestion if a polymer is attached on proteases (*45*, *46*). Steric hindrance of protein approach brought about by the large hydrodynamic volume of the PEG-polymer (*22*) can also account for the significantly improved immunological properties of ^{40}PEG–IFNα_{2a} (*9*), as the immune system requires the recognition of the antigen.

Clinical data show that the half-life of ^{40}PEG−IFNα_{2a} in the blood is at least by a factor of ∼8 longer than IFNα_{2a} (*20*). The new drug PEGASYS has superior efficacy over IFNα_{2a}. The reduced receptor affinity of ^{40}PEG−IFNα_{2a} and its correspondingly reduced in vitro antiviral activity is thus more than compensated by the dramatically increased efficacy due to the significantly improved half-life in the blood.

Impact for Future Molecular Design of Pegylated Proteins. The data, presented in this work and the accompanying paper (*22*), provide a solid collection of knowledge on variously pegylated IFNα_{2a}. They contribute to a better understanding of the molecular framework responsible for improved structural stability, binding interaction, and pharmacological properties of pegylated proteins in general. Thus, future research and technology to optimize and tailor the pharmacological properties of proteins by pegylation may be rationally guided. Some of the methods presented already constitute new indispensable tools in the quality control of pegylated IFNα_{2a}s (*22*). For design purposes, the dependence of the intermolecular association rate k_{on} on polymer size found ($\sim 1/R_H^2 \propto 1/MW^{1.2}$), and its modulation by the spatial location of the PEG attachment site are of great interest. If possible the PEG-polymer attachment sites should be located as remotely as possible from the protein binding interface, but angles above ∼40° away from the rim of the binding interface already lead to only a minor decrease of the association rate k_{on} as compared to the maximum value achievable by a given size of the PEG-polymer. The angle dependent effect is expected to be more pronounced for polymer chains of lower molecular weight (<20 kDa). If the size of proteins that interact with the pegylated-protein drugs increases, the angular dependencies of k_{on} become more pronounced (Figure 4), but the dependency on PEG-size decreases (data not shown). Thus, the θ-dependent shielding is more critical in the case of interaction with large protein-receptors than with smaller proteins or enzyme substrates. The simulations presented may also help to decide about the feasibility of single versus multiple pegylation sites in dependence of PEG-polymer MW and structural details of molecular recognition.

Conclusion. Here, we report a detailed analysis of the binding to IFNAR2^{EC} of ^{40}PEG−IFNα_{2a} and its positional isomers modified at K31, K134, K131, K121, K164, and K70 respectively, as compared to IFNα_{2a} and ^{5}PEG−IFNα_{2a}. Our results clearly show that the affinity for the receptor is PEG-size dependent with no abolishment of the binding, and that the pegylation significantly reduces the affinity mainly due to a change of the association rate k_{on}. These results are in agreement with modeling and simulation of the binding, based on SAW calculation. A correlation between the structural parameters and the kinetic and thermodynamic parameters of the binding of the positional isomers could be established. For the Isomer-K31 and -K164, the PEG-polymer attachment point is located in proximity of the binding interface, and the isomers display the lower affinity in an enthalpy-driven binding process. In contrast, for the Isomer-K134, -K131, -K121, and -K70, the PEG-polymer is attached remotely from the binding interface and the isomers exhibit the higher affinity in an entropy-driven binding process. With the RP-HPLC monitoring of the time-course in vitro digestion of IFNα_{2a} and ^{40}PEG−IFNα_{2a} by trypsin, we also provided evidence for a decrease of the proteolytic degradation due to pegylation.

With the work presented in this study we compiled a solid collection of knowledge regarding the structural, kinetic, and thermodynamic parameters of the binding of ^{40}PEG−IFNα_{2a} and its positional isomers to IFNAR2^{EC}. This constitutes a molecular basis for a better understanding of receptor binding mechanisms and the relationship between the structure and the biological function of the positional isomers.

At this level of the knowledge, relating the variations in the in vitro antiviral activity (Foser 2003) of the positional isomers with the structural, kinetic, and thermodynamic parameters of their binding to IFNAR2^{EC} is highly speculative and out of scope of this study. Indeed even if the putative binding interface between IFNα_{2a} and the receptor IFNAR1 could be postulated (*21*, *47*), essential binding affinity data defining the interaction to the second receptor IFNAR1 and other data are yet to be determined. All these data taken together will help in the future to potentially identify pegylation sites of enhanced in vitro biological activity where the PEG-polymer is most remotely attached with respect to both IFNAR1 and IFNAR2 binding sites. This could lead to a third generation of pegylated IFNα_{2a}.

ACKNOWLEDGMENT

We would like to thank J. Kohler for her help in experimental work, Drs. P. Bailon and G. Ehrlich for giving us the 5 kDa PEG-conjugated IFNα_{2a} material, and Drs. J. Anglister and J. Chill for providing us the coordinates of the IFNα_{2a}/IFNAR2^{EC} complex structure prior to publication. We acknowledge Drs. S. Foser, W. Klaus, T. Schreitmüller, R. Thoma, and K. Weyer for fruitful discussions and Dr. H. Jacobsen for his help and advice to produce and cleave the receptor protein. We thank Dr. D. Banner for a careful reading of the manuscript.

Oligomeric Fluorescent Labels for DNA

Andrea Cuppoletti, Younjin Cho, Jin-Seong Park, Christoph Strässler, and Eric T. Kool*

Department of Chemistry, Stanford University, Stanford, California 94305-5080. Received September 17, 2004; Revised Manuscript Received March 21, 2005

In an effort to find fluorescent labels that have large Stokes shifts and increased emission intensity, a strategy for fluorescence labeling of DNA was explored in which multiple individual fluorophores are incorporated at adjacent positions at the end of a DNA probe. To encourage close interactions, hydrocarbon and heterocycle fluorophores were substituted at C-1 of deoxyribose, replacing the DNA base. The C-glycosides studied contained the well-known fluorophores terphenyl, pyrene, and terthiophene. For comparison, a commercial fluorescein−dU nucleotide was examined. Oligomeric labels containing up to five fluorophores were tested. Interestingly, all four dyes behaved differently on multiple substitution. Fluorescein displayed strong self-quenching properties, with the quantum yield dropping severalfold with each additional substitution and with a constant, small Stokes shift. In contrast, pyrene showed increases in quantum yield on addition of more than one fluorophore and yielded efficient long-wavelength emission on multiple substitution, with Stokes shifts of >130 nm. Oligomeric terphenyl labels gave a small progressive red shift in absorption and a marked red shift in emission wavelength and showed a strong increase in brightness with more monomers. Finally, terthiophene oligomers showed self-quenching combined with increasing Stokes shifts. Overall, the results suggest that some oligomeric fluorescent labels exhibit properties not available in common fluorescein class (or other commercial) labels, such as large Stokes shifts and increasing brightness with increasing substitution.

INTRODUCTION

Because of the expanding demands placed on fluorescent labels, there has been a growing interest in finding ways to make new fluorescent molecules and to expand the properties of existing ones. Among the properties that are desirable in various applications are emission intensity, ease of preparation and conjugation, water solubility, varied excitation and emission wavelengths, and large Stokes shifts (*1*, *2*).

We have adopted a new strategy for the discovery of fluorescent labels for biomolecules that, in principle, may favorably affect these properties. This strategy involves the synthesis of oligomeric strings of fluorophores on a DNA-like phosphodiester scaffold. In these oligomeric molecules the fluorophores replace the DNA bases (*3*−*5*). This has the effect of encouraging close physical and electronic interactions, including face-to-face stacked interactions, such as commonly occur in DNA itself. In principle, such a close arrangement may enhance electronic communication between the individual fluorophores, resulting in useful changes in fluorescence characteristics in the oligomeric dye as a whole (*4*, *5*). In addition, these molecules are simple to assemble, because DNA synthesizers can place them in varied number and ordering using well-optimized chemistry and with automated methodology. Moreover, the charged nature of the DNA backbone encourages water solubility, and many conjugates can be prepared using commercial chemistry and reagents.

Previous studies have explored combinations of oligomeric fluorescent deoxyribosides and did not involve conjugation to nucleic acids (*4*, *5*). Here we report an exploratory study of such oligomeric dyes in the DNA context, using four different fluorophores as monomers and using only homooligomers to avoid mixed effects. Three of the monomers are nucleoside-like molecules in which fluorophores (terphenyl, pyrene, terthiophene) replace the DNA base (*3*). For comparison we also studied oligomers of fluorescein in a commercial conjugate with deoxyuridine. All were studied as conjugates adjacent to the same DNA probe sequence. We found a surprising variation in fluorescence properties, both with different fluorophores and with different numbers of the same fluorophore. Some of the new properties observed in the oligomeric dyes are not present in commercially available monomeric labels, and so such fluorescent oligomers may have potentially useful applications in labeling of biomolecules.

MATERIALS AND METHODS

Preparation of Deoxyribosides. Terphenyl, pyrene, and terthiophene α-deoxyribosides and their 5′-dimethoxytrityl-3′-phosphoramidite derivatives were prepared as previously described (*3*, *6*). Fluorescein−dT-phosphoramidite was purchased from Glen Research.

Synthesis of Oligonucleotides. DNA oligonucleotides were synthesized on an Applied Biosystems 392 synthesizer using standard β-cyanoethylphosphoramidite chemistry. Natural β-cyanoethylphosphoramidites were purchased from Glen Research or ABI and used as received. The solid support used was 3′-phosphate-ON support (Glen Research), which allows for 3′ placement of nonnatural nucleosides. After synthesis, oligonucleotides were deprotected and removed from the solid support with concentrated ammonia at 55 °C for 12 h. Oligomers were then purified by preparative denaturing polyacrylamide gel electrophoresis. The DNA was visualized by UV shadowing, and the bands containing the

Published on Web 04/26/2005

desired product were excised, crushed with a glass rod, and soaked in 0.2 M NaCl for 12 h. The solution was then filtered and placed in dialysis tubing (VWR, Spectra/Por MWCO 1000, or 500, as appropriate.). The solution was dialyzed for 24 h, in 6 h periods, with 2 L of Millipore water. Most of the samples were then further purified by HPLC, column PRP-1 Hamilton, C18 reverse phase, acetonitrile/K_2PO_4 buffer as the eluent, with a gradient from 9:1 to 75:25. The samples were again dialyzed against water, lyophilized, and redissolved in a Tris−boric−EDTA (TBE) buffer solution (pH 7.0).

Absorption Spectra. Absorption spectra were measured on a Cary 1 UV−visible spectrophotometer. In a general experiment a quartz cuvette with a 1 cm length path, equipped with a Teflon stopper, was charged with 0.5−1.0 mL of a solution of the oligonucleotide in TBE buffer (pH 7.0). All spectra collected were corrected for background and solvent absorption.

Fluorescence Spectra. Fluorescence spectra were measured on a Spex Fluorolog-3 spectrophotometer. In a general experiment a quartz cuvette with a 1 cm length path, equipped with a Teflon stopper, was charged with 0.5−1.0 mL of a solution of the oligonucleotide in TBE buffer (pH 7.0). All slits were set to 1 nm except in photobleaching experiments (20 nm), and all spectra collected were corrected for instrument response, background, and solvent emission. The samples were prepared to have an optical density (OD) of ≤0.05 at the excitation wavelength, to minimize internal absorption. Fluorescence quantum yields, ϕ_f, were calculated according to the equation $\phi_f = \phi_s(I_0 OD_s \eta_0^2)/(I_s OD_0 \eta_s^2)$, where the subscript s refers to the standard, the subscript 0 refers to the sample, η is the refractive index of the medium, I is the corrected integrated fluorescence, OD is the optical density at the excitation wavelength, and ϕ_s is the fluorescence quantum yield of the standard [fluorescein, quantum yield = 0.90 in 0.1 N NaOH (*7*)].

Thermal Denaturation Studies. The solution for the thermal denaturation studies contained a one-to-one ratio of the two complementary oligomers in 1× TBE buffer at pH 7.0 containing 0.1 mM EDTA, 200 mM KCl, and 5 mM $MgCl_2$. The solution was heated at 90 °C and allowed to cool slowly at room temperature prior to the melting experiment. The studies were carried out in a Teflon-stopped quartz cuvette with a 1 cm length path, under nitrogen atmosphere on a Cary 1 UV−visible spectrophotometer equipped with a thermoprogrammer. Absorbance was monitored while the temperature was raised from 5 to 80 °C at a rate of 0.5 °C/min.

RESULTS

Structures and Design. The structures of the four fluorescent monomers in this study are shown in Figure 1, and the absorption and emission spectra for these are given in Figures 2 and 3. Data are presented in Table 1. The three fluorophore deoxyribosides have been prepared previously (3) but were not incorporated into DNA, nor have they been studied as homooligomers. Also studied for comparison was a fluorescein dye conjugate of dU, which (like the above) can be incorporated into DNA at any position. Fluorescein was chosen for comparison because it is probably the most commonly used fluorescent dye in DNA conjugates. As reported previously (*3*), the fluorescence characteristics of the monomeric fluorescent deoxyribosides are very similar to those of published data for the dyes without attachment to deoxyribose. One significant difference, however, is that fluorescein has a molar absorptivity approximately twice

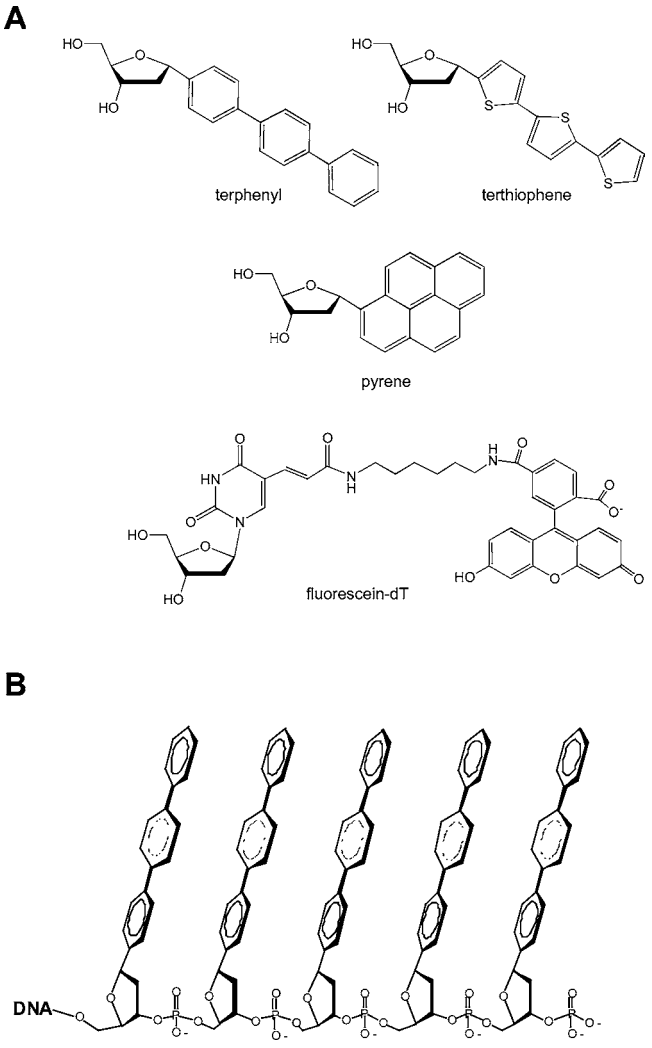

Figure 1. Structures of fluorescent deoxyribosides in this study (a) and example of an oligofluor label (b), showing the structure of a penta (terphenyl) label conjugated to DNA.

those of the other monomeric dyes. In addition, the quantum yields for fluorescein and pyrene are quite high, whereas those of terphenyl and terthiophene are moderate in air-saturated methanol (3).

Short octamer DNA sequences (5′-dTCAGGTTC) were prepared with the dyes placed at the 3′ end. This sequence was chosen because it previously has been useful in fluorescence hybridization studies in our laboratory (8). We prepared oligomers containing either one, two, or three fluoresceins or one through five fluorophore deoxyribosides containing terphenyl, pyrene, or terthiophene. The conjugated DNAs were purified by gel electrophoresis. Intact incorporation of each new dye into DNA was confirmed by mass spectrometry.

Absorption and Emission Properties. Studies of the fluorescence properties of these labels were then carried out in this single-stranded DNA sequence. Special care was taken (by varying the concentration) to study the properties under conditions at which no significant aggregation was taking place. It was found that at high concentrations (i.e., >50 μM) there was concentration dependence of the fluorescence emission for some of the more hydrophobic cases (for example, five pyrenes or five terthiophenes), which suggests interstrand aggregation behavior. At the low concentrations at which fluorescence was characterized (ca. <1.0 μM) we saw no such concen-

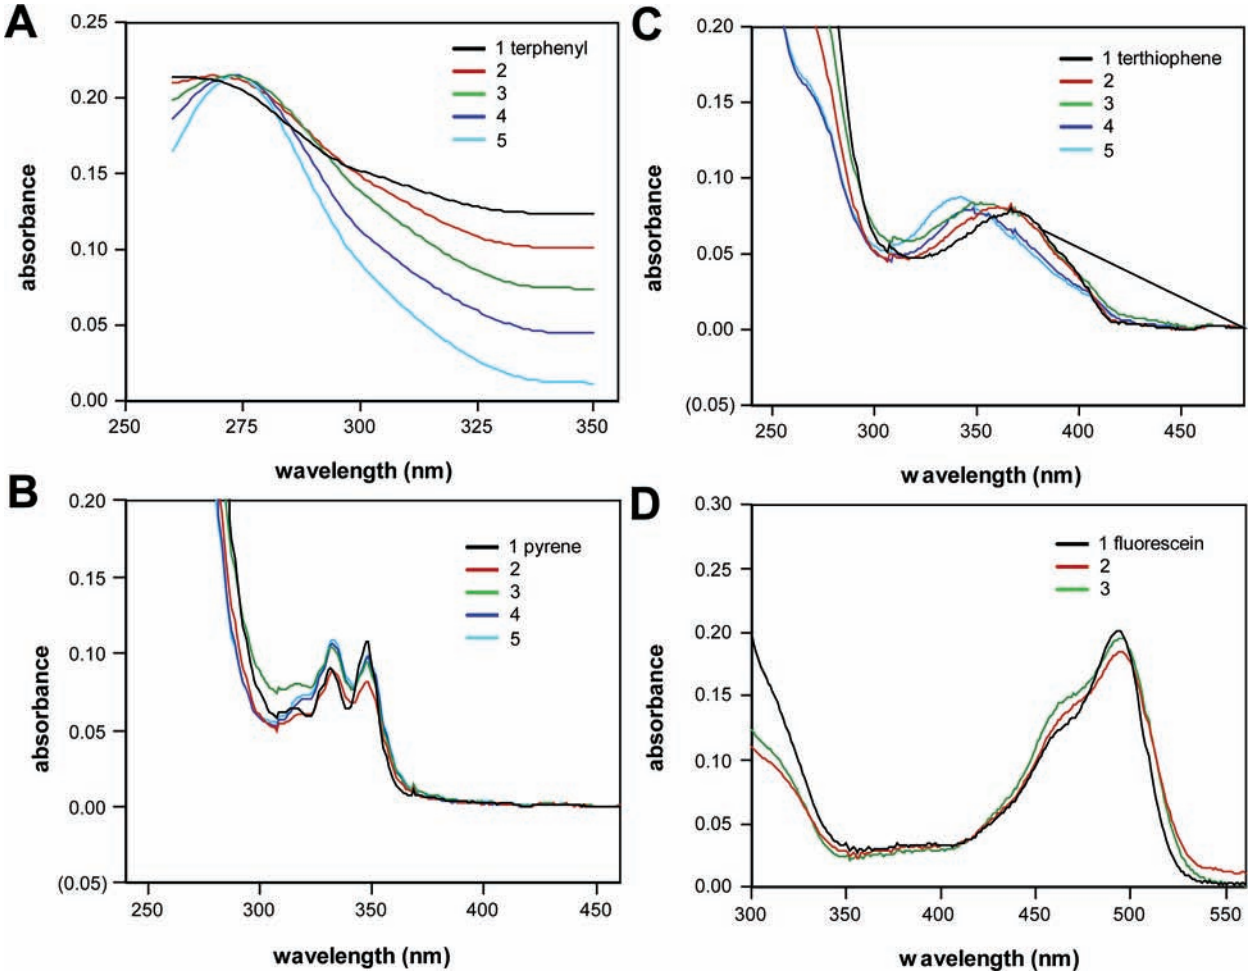

Figure 2. Absorption spectra of the oligofluors in this study conjugated to an octamer oligonucleotide. Spectra for increasing numbers of dyes are shown at matched absorbance to aid in comparison of peak shapes and wavelengths. Data were taken in water.

tration dependence, establishing that these are properties of single-strand species.

Absorption spectra (in water) for each dye series are shown in Figure 2. In the three fluorophore deoxyriboside series there was significant evidence of ground-state electronic interactions between the dyes. The terphenyl series showed a significant red shift with increasing monomer number, from 264 to 273 nm, although overlap with the normal DNA absorption at 260 nm interfered with analysis somewhat. The pyrene series showed a small red shift with increasing numbers and a decreasing peak-to-valley ratio, both of which lend evidence of ground-state association between pyrenes (9). The terthiophene series, by contrast, displayed a marked blue shift with increasing numbers of monomers, from 373 to 342 nm, suggesting significant structural organization in the oligomer (see Supporting Information). Finally, the fluorescein control showed no significant change in absorption wavelength or peak shape with increasing numbers, thus providing no evidence of organized ground-state structure.

The temperature dependence of absorption was also measured for these single-stranded oligomers (Figure S1 in the Supporting Information). In general, we found a small increase in absorption (at the peak maximum) for the three fluorophore deoxyriboside monomer series. However, the effect was small, showing <5% hyperchromicity on increasing temperature over the range from 10 to 80 °C.

The steady-state fluorescence properties of the same four oligomeric series were then characterized in water. The full data are listed in Table 1, and emission spectra are plotted in Figure 3. We took no steps to deoxygenate the solutions because our long-term goal is the development of fluorescent properties that can be applied without the exclusion of air. The data for the terphenyl series showed increasing fluorescence intensity (on an equal absorbance basis) and a large red shift with increasing numbers of monomers (from 344 to 383 nm). The excitation spectra showed a progressively larger red shift with increasing number of dyes, suggestive of a cooperative effect among the dyes in the oligomer (*10*, *11*). The overall Stokes shift increased markedly from 80 to 110 nm over the series with one to five dyes (Figure 4).

The pyrene series was markedly different than the terphenyl series and showed long-wavelength emission, suggestive of excimer emission (*9*, *12*) in all cases with two or more units. As the number of monomers increased, the excimer-to-monomer ratio increased markedly, and the cases with four and five pyrenes showed little remaining monomer emission (Table S1). The Stokes shift abruptly jumped from 28 nm (when only monomer fluorescence is observed) to ~133 nm through the series (Figure 4).

Finally, the terthiophene series showed a different behavior from either of the above two series. Substantial quenching was observed with increasing numbers (Figure 3) (although not as marked as for fluorescein, see below), a phenomenon that partially compensated for the increase in absorbance as the numbers of dyes increased. As with terphenyl we observed a red shift with increasing

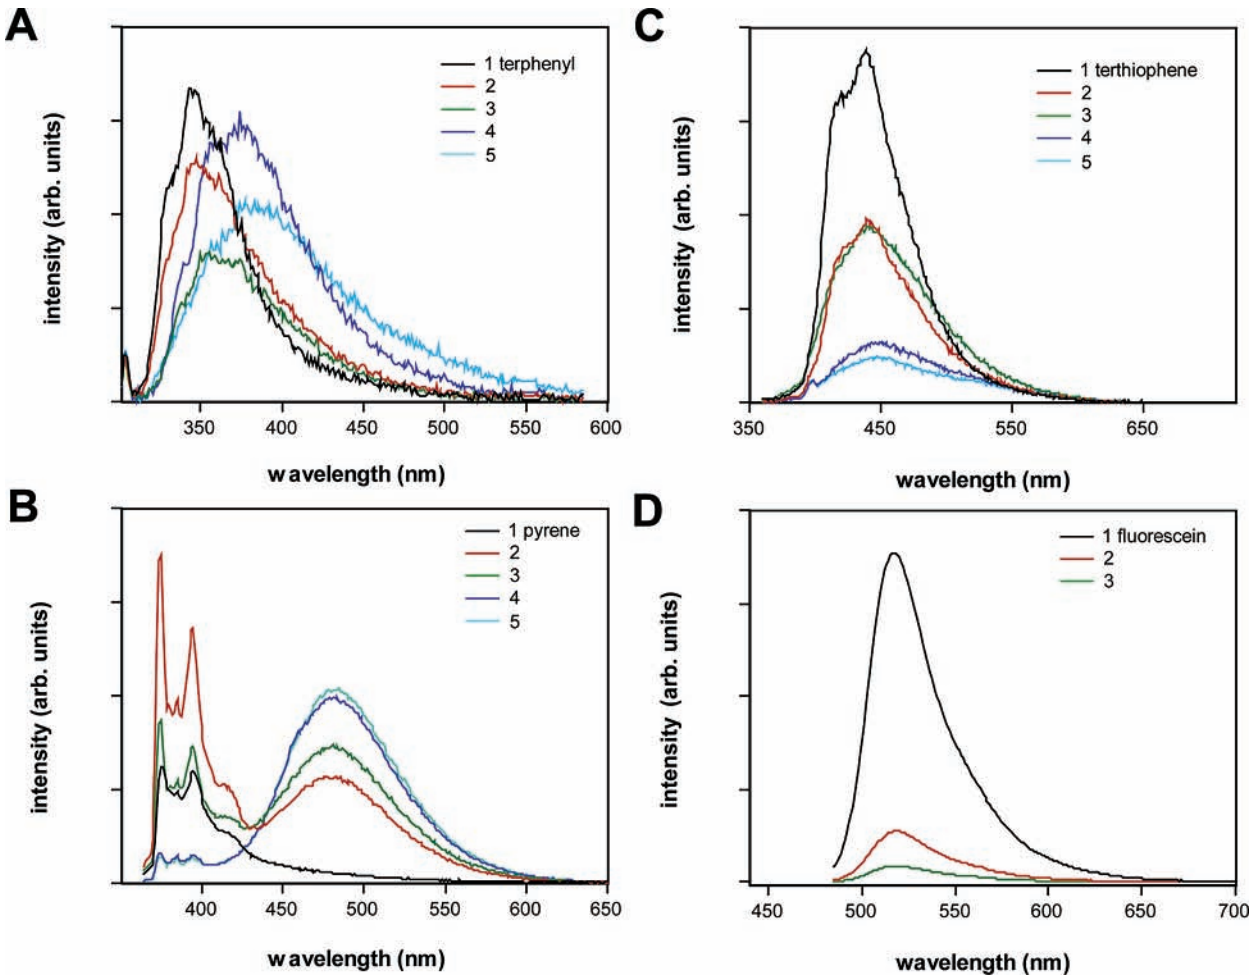

Figure 3. Emission spectra in water for oligofluors conjugated to DNA. Data are shown for matching absorbance at the excitation wavelength. Excitation wavelengths were 275 nm (terphenyl series), 340 nm (pyrene series), 350 nm (terthiophene series), and 480 nm (fluorescein series).

[a] Fluorophores (X) are present in the DNA sequence 5′-dTCAGGTTC(X). [b] Conditions: oligonucleotide dissolved in 1× Tris−borate−EDTA buffer, pH 7.0, 25 °C. [c] Absorptivities are estimates based on addition of absorptivities of the individual chromophores and do not take into account hypochromicity (which is observed to be <5%, see Figure 3).

numbers of monomers, although the total shift in fluorescence maximum was significantly smaller, at ~7 nm (from 440 to 447 nm). Combined with the strong blue shift in absorbance, however (see above), this resulted in large Stokes shifts that increased strongly [from 67 to 105 nm over the series (Figure 4)].

For comparison, the results with multiple substitution of fluorescein are also plotted (Figure 3). Consistent with

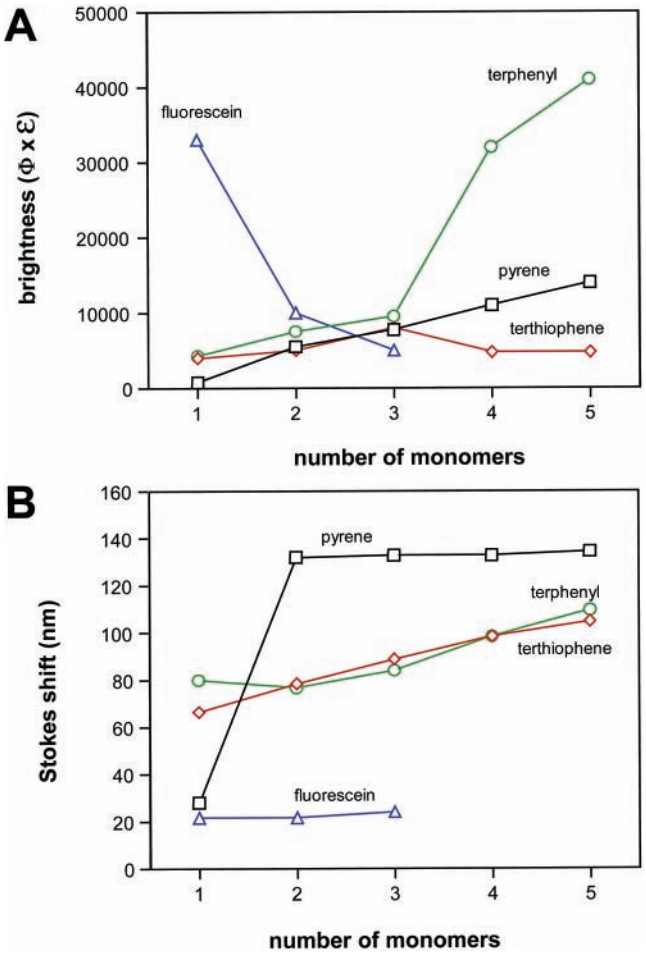

Figure 4. Trends with increasing numbers of monomer fluorophores conjugated to DNA: (a) relative emission intensity of the labels ("brightness" is calculated as quantum yield multiplied by molar absorptivity); (b) changes in Stokes shifts with increasing numbers of monomer fluorophores. See Table 1, note *b* for conditions.

earlier observations (*12*), strong quenching of emission was observed with the adjacent substitution of more than one fluorophore. Thus, as the numbers of dyes increased, quantum yield dropped markedly (Figure 3 and Table 1). There was little or no associated red or blue shift.

CD Spectra. More evidence of structural and electronic interactions was obtained from CD spectra of the DNA-conjugated oligomeric dyes in the series. Figure S2 shows the data for the three fluorescent deoxyriboside series. For the terphenyl series, the CD measurements revealed a strong exciton splitting with four and five monomers, suggesting an organized structure in the oligomeric dyes (see Supporting Information for details). The terthiophene series showed a similar behavior (Figure S2), but with maximum structural organization seen at three dyes. The oligomeric pyrene series displayed a different behavior in the CD spectra, with a general lack of exciton splitting except with two chromophores.

Effects of Buffer Conditions. Recent experiments have suggested that oligomeric fluorophores might be able to respond to varying physical conditions in solution with changes in fluorescence (*5*). We therefore explored the effects of varying environment (buffer pH and ionic strength) on oligomers of the two most promising new fluorophores, terphenyl and pyrene, with comparison to fluorescein as the FAM−thymidine conjugate. We tested monomeric, dimeric, and trimeric labels. Data at varied ionic strength for the trimers are shown in Figure S3, using sodium chloride concentrations ranging from 0 to 1000 mM. Results showed that there was essentially no change in emission for any of the trimeric fluorophores.

Data for varied pH are shown in Figure S4. The effects of pH were tested at values of 4, 7, and 11; results showed that all three oligomeric dyes gave greatest emission intensity at pH 7 and 11, but all three sets showed lower emission intensity at pH 4. Cases with one to three fluorescein labels gave no apparent change in emission spectrum with lowered pH, save for markedly lowered emission intensity (see data for trimer; data for monomer and dimer are not shown but are similar). Pyrene labels also gave no change in emission wavelength, but excimer emission bands were less intense at pH 7 than at pH 11, and at pH 4 the excimer band (490 nm) was nearly completely lost, whereas the monomer emission (380 nm) appeared to be unaffected. Finally, terphenyl oligomers (particularly the trimer) gave an increasing red shift, and moderately increasing intensity, with increasing pH from 4 to 7 to 11.

Photobleaching and Wavelength Shifts with Light Exposure. We also evaluated the response of trimeric dyes involving terphenyl, pyrene, and fluorescein to long-term light exposure, to measure their susceptibility to photobleaching in air-saturated buffer. The labels were excited at their absorption maxima over a period of hours in a fluorescence spectrometer, and emission intensity was measured over time (Figure S5). Results showed that the FAM−T trimer gave the slowest photobleaching under these conditions, with a half-life of ~7.5 h. Both the terphenyl and pyrene oligomers showed similar bleaching rates at their emission maxima, with half-lives of 2.8 and 3.3 h, respectively. However, the three trimers were markedly different in their wavelength responses: fluorescein simply dropped in emission intensity while keeping its spectral shape and wavelength constant. In contrast to this, the pyrene trimer shifted its spectrum markedly, losing its excimer band and keeping its monomer emission band intact. Thus, the pyrene trimer changed its color from green to blue, similar to what was observed recently for certain combinatorial fluorophores (5). The terphenyl trimer, in contrast to the above two results, shifted its emission to the red (from 355 to 390 nm) after the long-term UV exposure. Thus, all three oligomeric labels behaved differently during long-term irradiation.

Stabilization of DNA Hybridization. Finally, to evaluate how the attachment of such nonnatural α-oriented deoxyribosides might affect the hybridization properties of DNA, we carried out a simple duplex hybridization between the octamer DNA sequence and its complement, with a single overhanging fluorescent residue to evaluate inherent properties with the shortest variants of the labels. We tested dyes at the 3′ end and 5′ end of the DNA. Interestingly, the data showed (Table 2) that all cases increased the stability of hybridization. The order of stabilization at the 3′ end was α-pyrene > α-terphenyl > α-terthiophene. Like the previously studied pyrene β-deoxyriboside in 5′-end substitutions (*14*), the 3′-α-pyrene increased T_m markedly, in this case by 11.4 °C for a single substitution and giving 2.3 kcal/mol of thermodynamic stabilization. This is a greater stabilization than previously reported for the naturally oriented β isomer of the pyrene nucleoside at the 5′ end of DNA (albeit in a different sequence context) (*14*). At the 5′ end, the order of stabilization was terphenyl > pyrene; in this case, terphenyl added 10.3 °C of thermal stability, similar to the large stabilization by pyrene at the opposite end.

DISCUSSION

One of the major goals of this study was to evaluate whether pure oligomeric labels composed of terphenyl, pyrene, or terthiophene might offer potentially useful properties in nucleic acid labeling that single or multiple standard labels (such as fluoresceins) do not. Clearly the answer to this question is positive, in several respects. First, fluorescein and other common commercial dyes are known to self-quench in multiple DNA substitutions (*13*), and thus incorporation of multiple fluorescein labels into a biomolecule does not lead to increased detection sensitivity, unless the labels are separated by relatively large distances to ameliorate quenching (*15*). The current experiments with fluorescein confirmed this. In the present molecular design, the distance between fluorophores is minimized and the molecules are small. We find, not surprisingly, that this close arrangement has different effects on the quantum yield (and, thus, overall brightness, defined as quantum yield multiplied by molar absorptivity), depending on the fluorophore. The plots in Figure 4 show clearly that two of the new oligomeric labels (containing pyrene or terphenyl) exhibit increasing brightness with increasing numbers; the terphenyl labels emit more intensely than can be achieved in this system with the very successful and widely used dye fluorescein. It remains to be seen whether further increasing numbers could yield still further enhancements. Of course, the emission intensity of the label is directly related to the sensitivity of detection of biomolecules at low concentrations. It is also an important issue in single-molecule fluorescence studies.

Another practical issue in the intensity of labeling of nucleic acids is the fact that nucleobases themselves often quench fluorescence. For example, the above oligomeric pyrene labels are significantly quenched by attachment to DNA, consistent with previous studies of pyrene conjugates (*16*). Our experiments showed that quantum yields were higher by ∼30-fold for the oligomeric labels alone (data not shown). On the other hand, the present terphenyl labels are not markedly quenched by attachment to DNA. Interestingly, even for cases that are markedly quenched we have observed that certain spacer molecules can help "insulate" such oligomeric fluorophores from quenching by DNA (A. Cuppoletti et al., manuscript in preparation). Nevertheless, in a practical sense one must consider the effect of the molecule being labeled on the fluorescence characteristics of the reporter molecule.

Beyond the relative brightness of the labels, the oligomeric fluorophores in this study also offer other potentially useful differences in comparison to commercial fluorescein labels. Stokes shifts in this series are all markedly increased relative to that of fluorescein. Indeed, Stokes shifts are often small (∼20−30 nm) for most commercial monomer dye molecules. This small separation between excitation and emission often causes interference between the excitation source and the light being observed, and one often must work on the shoulders of the absorption and emission peaks to avoid such difficulties. In the cases of the oligomeric dyes containing pyrene or terphenyl, one has examples of bright labels with Stokes shifts of >100 nm. Thus, in a practical sense one can easily avoid interference between excitation and emission light.

In a different approach for the use of multiple labels for DNA, recent work in other laboratories has shown that fluorescence resonance energy transfer (FRET) can occur through more than two fluorophores (*17*−*19*). As with the current approach, the multi-FRET approach uses three or more dyes and yields large Stokes shifts. One advantage of the current strategy is that the labels are incorporated alone, whereas multi-FRET requires separation between the dyes and thus larger molecules.

Some of the current fluorophores have been examined previously in aggregated states or in other situations in which they are interacting closely with another of the same fluorophore. The aggregation of pyrenes has been extensively studied in many molecular settings and has been reviewed (*9*). The main difference between the present oligomeric pyrene dyes and previous cases is the high efficiency of excimer formation using the DNA backbone. A number of other cases of multiple pyrenes in DNA or peptides are known (*20*−*23*).We know of few other cases in which excimer/monomer ratios are this high, except in pyrene crystals and polymers (*9*, *23*). For one comparison, a dimeric pyrene molecule is offered commercially as a label (*24*), but it has an excimer-to-monomer ratio of ∼1 , well below those described here. We surmise that the DNA backbone is especially well suited to arranging these aromatic molecules in a stacked arrangement, and the spectroscopic data add support to this notion.

Whitten and co-workers (*25*) have shown in non-nucleic acid systems that weak $\pi-\pi$ stacking interactions among terphenyl groups are nevertheless responsible for the generation of large and well-ordered structures. Saturated fatty acids or phospholipids functionalized with terphenyl groups were found to generate supramolecular aggregates where the dyes assumed a pinwheel structure to maximize an edge-to-face interaction, resulting in an H-type aggregation. Other studies have also reported on the hydrophobic aggregation of terphenyl (*26*, *27*).

We know of only one previous case of terthiophene being used as a nucleic acid label (*3*) and no cases of its multiple use. However, in solids and in polymers, workers have observed a blue shift of the terthiophene absorption maxima and quenching of the fluorescence (*28*−*31*), similar to the effects observed here.

In a practical sense, we expect that oligomeric labels such as those containing pyrene or terphenyl may be useful for their large Stokes shifts and their emission intensity. They can, of course, be used in labeling of DNAs and RNAs by direct addition on a synthesizer. However, we anticipate that they also may be useful in labeling other biomolecules such as proteins or antibodies. There are several commercially available chemical conjugating groups (usually applied to oligonucleotides) that should allow the ready functionalization of these molecules for attachment to other species.

In Vitro and in Vivo Evaluation of Hydrophilic Dendronized Linear Polymers

Cameron C. Lee,[†] Masaru Yoshida,[†,§] Jean M. J. Fréchet,[†] Edward E. Dy,[‡] and Francis C. Szoka*[,‡]

Center for New Directions in Organic Synthesis, Department of Chemistry, University of California, Berkeley, California 94720-1460, and Department of Biopharmaceutical Sciences & Pharmaceutical Chemistry, University of California, San Francisco, California 94143-0446. Received September 23, 2004; Revised Manuscript Received April 8, 2005

Rigid-rod dendronized linear polymers consisting of a poly(4-hydroxystyrene) backbone and fourth-generation polyester dendrons were evaluated in vitro and in vivo to determine their suitability as drug delivery vectors. Cytotoxicity assays indicated that the polymers were well tolerated by cells in vitro. Biodistribution studies of the polymers in both nontumored and tumored mice revealed that as for random coil linear polymers, renal clearance was a function of polymer size, with significant urinary excretion observed for a 67 kDa dendronized polymer. High accumulation in organs of the reticuloendothelial system was exhibited by a dendronized polymer with a very high molecular weight (M_n = 1740 kDa), but was not as significant for smaller polymers with M_n = 67 kDa and M_n = 251 kDa. The rank order for tumor accumulation of the polymers on a percent injected dose per gram tumor basis was 251 kDa ~ 1740 kDa > 67 kDa. These data will help guide the selection of highly functionalizable rigid-rod dendronized polymers with pharmacokinetic properties appropriate for use as drug carriers.

INTRODUCTION

Polymers, both natural and synthetic in origin, have attracted attention as drug delivery vehicles due to their ability to favorably alter the biological properties of attached therapeutic agents (*1*). For example, polymer–drug conjugates may have increased blood circulation half-lives, reduced toxicities, and increased solubilities relative to the parent drugs (*2*). In addition, high molecular weight (MW) polymers can exhibit enhanced accumulation in tumor tissues relative to normal tissues. This phenomenon is termed the enhanced permeation and retention effect (EPR effect), and its occurrence is attributed to the "leaky" blood vessels and poorly developed lymphatic drainage system present within tumor tissues (*3*).

To date, the carriers that have been most extensively investigated for drug delivery applications are linear polymers such as poly(ethylene oxide) (PEO) (*4*) and poly(*N*-(2-hydroxypropylmethacrylamide)) (HPMA) (*5*, *6*). However, increasing attention is being given to new, more highly branched structures such as dendrimers and star polymers with the hope that interesting effects of architecture on biological properties may be discovered (*7*–*14*). Dendronized linear polymers, a recent addition to the branched polymer family, are linear polymers that bear dendrons at each repeat unit along their backbones (Figure 1). It is believed that as the sizes of the pendant dendrons increase, so do the interactions between adjacent dendrons, and at higher generations these macromolecules attain extended conformations and can be described as somewhat rigid, cylindrical rods (*15*). Dendronized polymers may be interesting scaffolds for drug delivery as the large number of functionalizable peripheral groups on the dendrons should allow for very high levels of drug loading, and furthermore it has been suggested that the shape and multivalency of a macromolecule can influence its biological properties (*16*–*20*). However, in contrast to dendrimers, few biological studies of dendronized linear polymers have been reported to date (*21*–*23*). Here we describe the cytotoxicity, biodistribution, and pharmacokinetics of synthetic, water-soluble, rigid-rod dendronized linear polymers consisting

of a poly(4-hydroxystyrene) backbone and fourth-generation polyester dendrons in normal and tumored mice (Figure 1). To the best of our knowledge, this constitutes the first report on the in vivo biodistribution of dendronized polymers.

MATERIALS AND METHODS

Materials. Unless otherwise noted, reagents and solvents were obtained from commercial suppliers and used without further purification. Polymers **1**−**3** were prepared as previously reported (*24*, *25*).

Characterization. Analytical size exclusion chromatography (SEC) in *N*,*N*-dimethylformamide (DMF) with 0.2% LiBr was performed at 70 °C at a nominal flow rate of 1.0 mL/min on a chromatography line calibrated with linear poly(ethylene oxide) (PEO) standards (6450−529500 Da) and fitted with two 7.5 × 300 mm PLgel mixed-bed C columns (5-μm particle size). The SEC system used when determining PEO-equivalent MWs consists of a Waters 510 pump, a Waters U6K injector, and a Waters 410 differential refractive index detector thermostated at 35 °C. The SEC system for determining absolute MWs consists of a Waters 510 pump, a 7125 Reodyne injector, a Wyatt DAWN-EOS multi-angle laser light scattering detector (laser of λ = 690 nm), and a Wyatt Optilab differential refractive index detector. Light scattering data were analyzed using Astra software from Wyatt, and SEC data using the differential refractive index detector were analyzed using Millennium software from Waters.

Volume-average particle diameters were determined using dynamic light scattering. Experiments were performed at least three times at 25 °C in saline solution with a Zetasizer Nano ZS (Malvern Instruments) equipped with a 4 mW He−Ne laser at 633 nm.

Radioactivity from ^{125}I was quantified with a 1480 Wallac Wizard 3 Automatic Gamma Counter. Counts emitted from samples contained in screw-cap scintillation vials were measured over the course of one minute and were recorded as counts per minute (cpm).

Cytotoxicity of 1−3. Cell toxicity studies were performed at the UC Berkeley Tissue Culture Facility. MDA-MB-231 human breast cancer cells were seeded in 96-well plates at a density of 1.6×10^4 cells per well in 100 μL of DMEM with 10% FBS (DMEM + FBS). After incubation overnight (37 °C, 5% CO_2), the medium was removed by aspiration and replaced with fresh medium (100 μL) containing 0−3.0 mg/mL of polymers **1**−**3**. These solutions also contained antibiotics (1% penicillin−streptomycin). (Each of the polymers used in these experiments was purified prior to use by size exclusion chromatography on a PD-10 column, followed by lyophilization.) Following incubation for 48 h, the medium was aspirated off and replaced with 100 μL of fresh medium and 20 μL of a 5 mg/mL MTT solution. The cells were incubated for 4 h, after which time the medium was removed, leaving behind purple crystals. These crystals were dissolved in 200 μL of DMSO and 25 μL of glycine buffer (0.1 M glycine, 0.1 M NaCl, pH 10.5). The absorbance values at 520 nm were measured using a SpectraMAX 190 microplate reader. (Molecular Devices). The percent viability of cells in treated wells relative to nontreated cells was calculated and represents the average value over four wells (Figure 2).

Synthesis of Tyramine-Functionalized Dendronized Polymers 1−3. 1, **2**, or **3** was dissolved in 1 mL of anhydrous pyridine and reacted overnight with a solution containing 5−7 mol % (relative to hydroxyls) of 4-nitrophenyl chloroformate in 1 mL of CH_2Cl_2. The solvent was evaporated, and the polymer was dissolved in 2 mL of anhydrous *N*,*N*-dimethylformamide. An excess of 4-(2-aminoethyl)phenol (tyramine) and 1 mol equiv of anhydrous triethylamine was added to the solution and was stirred overnight. The polymers were purified of low MW contaminants by dialysis in Spectra/Por regenerated cellulose membranes (MWCO = 8000, Spectrum Laboratories) against distilled water. The presence of tyramine groups was confirmed by ^{1}H NMR analysis of a lyophilized aliquot of the solution retained in the dialysis membrane. The aromatic protons appear at 6.6 and 6.9 ppm, and the benzylic protons appear at 2.6 ppm.

Table 1. Molecular Weights, Sizes, and Pharmacokinetic Parameters for 1−3 Measured in Mice.

	SEC-MALLS[a] (kDa)		SEC[b] (kDa)			DLS
	M_n	M_w	M_n	M_w	PDI	D[c] (nm)
1	67.0	69.0	13.7	16.0	1.16	5.8
2	251	260	38.2	45.2	1.18	10.0
3	1,740	1,890	190.0	242.0	1.27	15.7

[a] Absolute MWs. [b] Relative PEO MWs from SEC in DMF. [c] Mean volume-average diameter.

Radioiodination of Tyramine-Functionalized Polymers 1−3. Tyramine functionalized **1**, **2**, or **3** were iodinated as previously described (*8*, *26*), resulting in solutions of radiolabeled polymer in HBS (10 mM HEPES/Cl, 140 mM NaCl, pH 7.4). Non-polymer-bound ^{125}I was removed by ion exchange chromatography on Bio-Rad AG 1-X-2 resin (chloride form), and polymers were separated from residual low MW radioactive contaminants by size exclusion chromatography on Bio-Rad 10DG desalting columns that had been equilibrated with HBS. The initial, high-MW fractions were collected and pooled. The specific activities of the solutions for the biodistribution experiments in nontumored mice were measured to be 23, 3, and 35 μCi/mL for polymers **1**, **2**, and **3**, respectively, and for the biodistribution experiments in tumored mice the activities were 15, 26, and 16 μCi/mL, respectively. The final concentration of polymer in the solutions was 0.8 mg/mL.

Biodistribution of 1−3 in Nontumored Mice. Polymer solutions (200 μL) were administered intravenously to 6−8 week-old CD-1 female mice (three mice per experimental group). The mice were sacrificed at six different times following injection for biodistribution analyses: 10, 30, 90, 540, 1440, and 2880 min postinjection. The blood (collected by heart puncture), heart, lungs, liver, stomach, spleen, intestines, kidney, and carcass (divided into three portions) were weighed, and the amount of radioactivity present in each organ was quantified. For the 24- and 48-h time points, mice were housed in metabolic cages to allow for the collection of urine and feces. The amount of radioactivity recovered was on average 86 ± 9% of that injected; we attribute the nonquantitative recoveries to injection variability. The data were corrected for radioactive decay and plotted as % of injected dose per gram of organ versus time and as % of injected dose per organ versus time for each organ (Figure 3).

The % of the injected dose per gram (% ID/g) of blood versus time curve was analyzed using a two-compartment model, since ln[% ID/g] versus time curves clearly displayed two different rates of decay for early and late time points. The pharmacokinetic parameters for the two-compartment model were estimated using the residuals method (*27*). A complete list of pharmacokinetic parameters is presented in Table 2.

For urine analysis at 24 h, 1.0 mL of urine was loaded onto a PD-10 column and eluted in 1.0 mL fractions to

Table 2. Pharmacokinetic Parameters for 1−3[a]

	1	2	3
$t_{1/2,\beta}$ (h)	14 ± 2	19 ± 2	44 ± 9
$t_{1/2,\alpha}$ (h)	0.9 ± 0.2	1.3 ± 0.9	1.1 ± 0.6
k_{21} (min^{-1})	0.0040 ± 0.0003	0.0054 ± 0.0005	0.0055 ± 0.0007
k_{12} (min^{-1})	0.007 ± 0.002	0.003 ± 0.006	0.004 ± 0.006
k_{el} (min^{-1})	0.0025 ± 0.0006	0.0010 ± 0.0007	0.0005 ± 0.0003
C_o (% ID/g)	40 ± 3	41 ± 4	38 ± 5
V_1 (g blood)	2.5 ± 0.2	2.5 ± 0.2	2.6 ± 0.3
$AUC_{0-\infty}$ (% ID·min·g^{-1})	16000 ± 3000	40000 ± 4000	80000 ± 20000

[a] Parameters were extracted from %ID/g blood curves assuming a two-compartment model, where the concentration of radioactivity in the blood is represented by the equation: $C = Ae^{-\alpha t} + Be^{-\beta t}$. Values for A, α, B, and β were calculated using the residuals method (*27*). Definitions: $t_{1/2,\beta}$, elimination half-life; $t_{1/2,\alpha}$, distribution half-life; k_{21}, rate of polymer loss from central to peripheral compartment; k_{12}, rate of polymer loss from peripheral to central compartment; k_{el}, rate of elimination from the central compartment; C_o, concentration of polymer in central compartment after injection but before clearance or loss to peripheral compartments; V_1, apparent volume of the central compartment; $AUC_{0-\infty}$, area under the % ID/g blood curves from zero to infinity.

separate high MW components from lower ones by size exclusion chromatography. Radioactivity was found to elute from the column in two major fractions. The first fractions (1−6) contained high MW species, and the second fractions (7 and above) contained low MW species. The recovery of radioactivity from the columns was quantitative. The percent of the recovered radioactivity found in the high MW fractions for mice given polymers **1**, **2**, and **3**, were 99%, 85%, and 76%, respectively.

For feces analysis at 24 h, ∼400 mg of feces were weighed into a tube containing zirconia beads and 1.0 mL of HBS. The tube was capped, and the feces were homogenized using a Bead Beater (Biospec) for 200 s at 5000 rpm. The solids were centrifuged out, and 50−250 μL of the supernatant was removed, loaded onto a PD-10 column, and eluted in 1.0 mL fractions in the same manner as for the urine analysis. The recovery of radioactivity from the column was quantitative. Again, the first fractions (1−8) contained high MW species, and the second fractions (9 and above) contained low MW species. The percent of the recovered radioactivity found in the high MW fractions in the feces for mice given polymers **1**, **2**, and **3**, was 97%, 91%, and 95%, respectively.

Biodistribution of 1−3 in Tumored Mice. Female 8-week old BALB/c mice were inoculated with C26 tumor cells via subcutaneous injection in the right hind flank on day zero (1×10^6 cells in 50 μL of cell media). On the twelfth day postinoculation, when the tumors were ∼5 mm in diameter, polymer solutions (200 μL) were administered intravenously to the mice (three mice per experimental group). The mice were housed in metabolic cages to allow for the collection of urine and feces, and at 24 h postinjection the mice were sacrificed and the blood (collected by heart puncture), heart, lungs, liver, stomach, spleen, intestines, kidney, tumor, leg muscle, and carcass (divided into three portions) were weighed, and the amount of radioactivity present in each tissue type was quantified. The amount of radioactivity recovered was on average 80 ± 9% of that injected; we attribute the nonquantitative recoveries to injection variability. The data were corrected for radioactive decay and plotted as % of injected dose per gram of organ and as % of injected dose per organ for each organ (Figure 5).

RESULTS AND DISCUSSION

Polymer Synthesis and Characterization. Three dendronized polymers were prepared starting with poly(4-hydroxystyrene) having different backbone lengths (5, 17, and 130 kDa) and low polydispersity indices (PDIs < 1.3). Dendronization was carried out using the previously reported divergent route up to the fourth-generation polyester dendron in each case (Figure 1) (*24*, *25*). The absolute and relative MWs of each polymer, as measured by size exclusion chromatography (SEC), are given in Table 1. The MWs measured by SEC relative to PEO calibration standards are much lower than their absolute MWs measured using an online multiangle laser light scattering (MALLS) detector; PEO-equivalent MWs are reported here because they provide an estimate of the hydrodynamic sizes of the dendronized polymers. The dimensions of the polymers were also measured using dynamic light scattering (DLS) and are presented in Table 1.

In Vitro Cytotoxicity Studies. To determine the biocompatibility of the dendronized polymers, toxicity experiments were performed in vitro with MDA-MB-231 human breast cancer cells. After a 48 h incubation period, cell viability was evaluated using the MTT assay (Figure 2). Over the concentration range investigated, the polymers did not exhibit high levels of toxicity, with greater than 85% cell viability at a concentration of 0.25 mg/mL and greater than 70% viability at the highest concentration tested (3.00 mg/mL).

In Vivo Biodistribution Studies in Nontumored Mice. After determining that cells were viable in the presence of the dendronized polymers, in vivo experiments were performed to determine their time-dependent biodistribution profiles in mice. To track the polymers in vivo, a small fraction of the peripheral hydroxyl groups of each dendronized polymer were statistically converted to tyramine carbamates, and the polymers were then radiolabeled with ^{125}I as previously described (*8*, *26*).

Polymer solutions were administered intravenously to 6−8 week-old CD-1 female mice, and their tissue distribution profiles were monitored over time. Polymer **1** showed little tissue-specific accumulation as a function of time (Figures 3a,b). The kidney was the only organ having elevated polymer levels relative to other den-

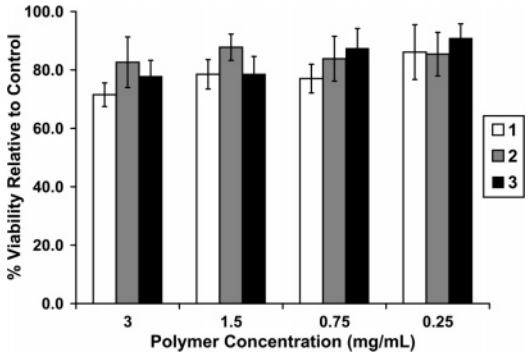

Figure 2. Toxicity of polymers **1**−**3** toward MDA-MB-231 cells.

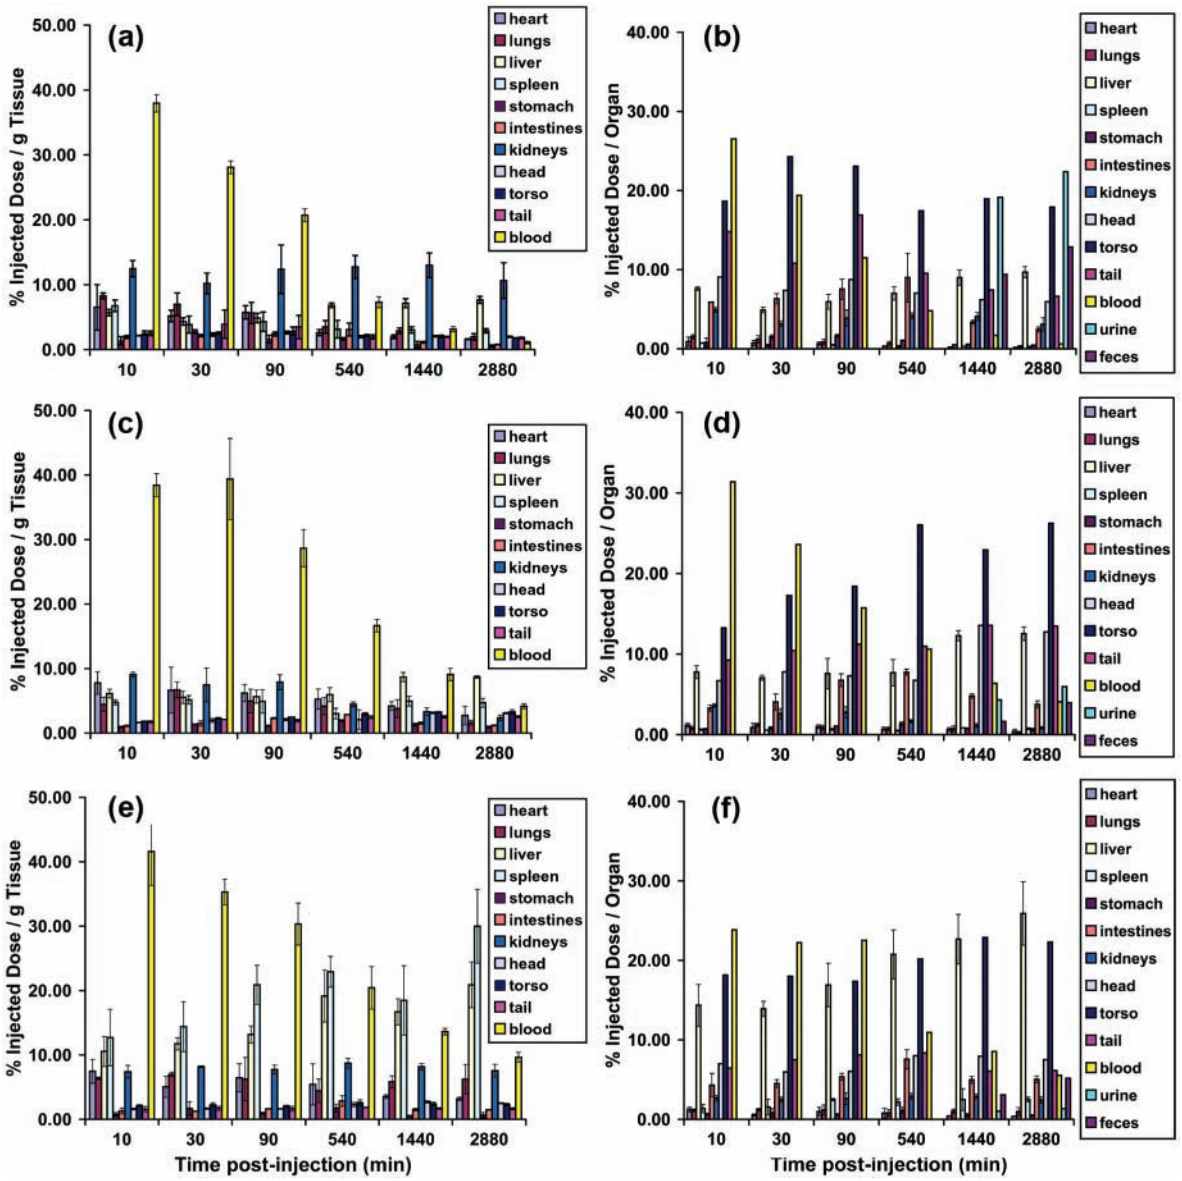

Figure 3. Biodistribution of (a−b) **1**, (c−d) **2**, and (e−f) **3** in CD-1 mice, plotted as % injected dose per gram of tissue versus time and % injected dose per organ versus time. The values at 10 min in (a) and the values at 30 min in (e) are averages for two mice, and the error bars therefore represent the range of two values. In b, d, and f, error bars have been omitted from the head, torso, tail, and blood values because the volume/mass recovered from these tissues can vary widely from mouse to mouse. Error bars have been omitted from the feces and urine values because the respective excrements for each time point were not collected individually but were pooled together.

dronized polymers studied (% injected dose/g (%ID/g) > 10%). This kidney accumulation was accompanied by substantial renal clearance, with 19% and 22% of the injected radioactivity excreted into the urine after 24 and 48 h. The small increase in the amount of radioactivity present in the urine 48 h postinjection when compared to the amount present 24 h postinjection indicates that the majority of the polymer was excreted within the initial 24 h. After determining that the data was best described by a two-compartment distribution model, the elimination half-life of **1** was calculated to be 14 h (Table 2).

A notable feature of this experiment is the lack of significant liver accumulation. Previous biodistribution experiments in which the radiolabel was placed at the periphery of a PEO star polymer suffered from rapid accumulation in the liver, a finding that was attributed to the interaction of exposed iodophenols with complementary receptors (*26*). In the present case, however, the radiolabeled phenols are likely shielded within the dense branches of the dendronized structure. It is also possible that a small number of defects (lack of dendron growth) along the poly(4-hydroxystyrene) backbone lead to iodination of the highly encapsulated phenolic backbone itself.

As shown in Figures 3c,d, polymer **2** showed no unusual tissue accumulation. Compared to polymer **1**, the amount of radioactivity lost in the urine was significantly lower for polymer **2**, with only 6% of the initial dose present in the urine after 48 h. Consequently, the lack of renal clearance resulted in increased blood concentrations of radioactivity for **2** throughout the experiment, with an elimination half-life of 19 h, and in total only 10% of the initial dose was excreted in the urine and feces combined after 48 h.

The biodistribution profile of the largest evaluated dendronized polymer **3** differed significantly from that of the previous two polymers (Figures 3e,f). Like **2**, polymer **3** was cleared very slowly from the body, with only 6.5% excreted after 48 h (urine + feces). The elimination half-life for this high MW polymer was 44 h. Most striking was the steady increase in polymer concentra-

tions in the liver and spleen with time. In these organs, maximum polymer concentrations of 21% ID/g in the liver and 30% ID/g in the spleen were reached 48 h after injection. In comparison, mice given polymers **1** or **2** had 3% or 5%, respectively, in the spleen, and 8% or 9%, respectively, in the liver. Previous studies have shown that as polymer MW increases PEO is taken up by Kupffer cells (*28*) and poly(vinylpyrrolidone) is taken up by macrophages (*29*) to a greater extent, and a high level of uptake in reticuloendothelial cell-rich organs is not uncommon for large particles such as liposomes and nano/microparticles (*30*).

In the case of particles, uptake is believed to be caused either by filtration in the spleen if their diameters are greater than 200 nm, or by opsonization (absorption of phagocytosis-stimulating proteins) (*31*). If we consider that the size of **3** measured by DLS is ~16 nm, it seems unlikely that splenic filtration is occurring, unless polymer aggregation occurs in vivo. However, filtration should not be ruled out, as this polymer is expected to be much less flexible than a nondendronized polymer of an equivalent hydrodynamic size, and its end-to-end dimensions might not be accurately represented in DLS measurements (*25*). While opsonization is another possibility, it would be surprising, as this behavior was not observed for the two other polymers that have the same surface functionality. Further examination will be necessary to deduce the source of the high reticuloendothelial system accumulation of **3**, and to determine whether this uptake is caused by the molecular size, shape, surface chemistry, or some combination of the three.

It is important to note that in the urine, SEC analysis revealed that for mice given polymers **1**, **2**, and **3**, 99%, 85%, and 76% of the total excreted radioactivity was associated with high MW species (Figure 4a), respectively, while in the feces, greater than 90% of water-soluble radioactivity was attributable to high MW compounds (Figure 4b). We were unable to assess the high/low MW nature of the radioactivity that remained insoluble in the feces by this method; however, we were able to estimate the amount of radioactivity that was made soluble as ~100%, ~60%, and ~20% from the feces of mice given polymers **1**, **2**, and **3**, respectively. Since the water solubilities of the dendronized polymers decrease as the polymer chain length increases, and because we would expect small molecule radioactive components to have good water solubility, we believe that the low solubility of radioactivity found in the feces of mice treated with larger polymers indicates that the insoluble radioactivity is associated with high MW material. The small quantity of low MW species excreted by the mice does not amount to more than a few percent of the total injected dose, and therefore we are confident that our data reflects the biodistribution behavior of the polymers and not that of free iodine.

Overall, the results indicate that polymer **1** was small enough to pass through pores of the renal membrane, while polymers **2** and **3** were too large to undergo this process (*32*). Therefore, the apparent MW cutoff for glomerular filtration is between 67 and 251 kDa (M_n) for these fourth-generation dendronized polymers. If the hydrodynamic sizes of these polymers relative to PEO (as measured by SEC, Table 1) are considered, their blood clearance rates are consistent with the reported nominal MW cutoff for PEO of 30−40 kDa (*33*).

In Vivo Biodistribution Studies in Tumored Mice. Recently, Uzgiris has speculated that due to enhanced reptation, linear polymers with extended backbone conformations may be able to more easily traverse the porous capillary walls found in tumor tissues than would a linear polymer in a predominantly coiled conformation (*19*, *20*). Since the dendronized linear polymers presently under study have been shown to have extended conformations in solution (*25*), preliminary biodistribution experiments were performed in BALB/c mice bearing subcutaneous C26 tumors at a single 24 h time point to determine their propensity for tumor accumulation. Polymers **1**, **2**, and **3** were found to be present in the excised tumors at concentrations of 6%, 18%, and 14% ID/g, respectively (Figure 5). The significantly lower concentration of **1** found in the tumor is likely a consequence of its shorter blood circulation half-life. In contrast, **2** and **3** have increased access to the tumor vasculature due to their long-circulating nature and thus have sufficient time for the EPR effect to take place (*34*), resulting in higher concentrations of polymer in the tumors. Interestingly, the polymer concentration in the tumor for **3** was not statistically different from that of **2**, even though it is 7-fold larger in mass and has a 2-fold longer blood elimination half-life. The levels of tumor accumulation found for **2** and **3** are comparable with those of drug carriers based on liposomes (*35*) and are among the highest published values for this tumor model. At present we are unable to determine whether the conformations of the polymers have any effect on their ability to access the interstitial space of the tumor due to a lack of relevant model polymers. Studies seeking to answer this question are underway.

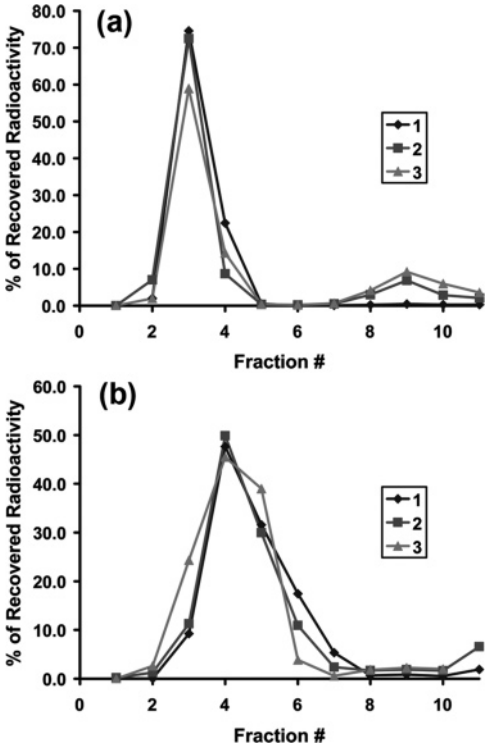

Figure 4. (a) Size exclusion chromatography of urine collected from mice 24 h postinjection. Fraction no. 11 is actually the sum of fractions 11−20. (b) Size exclusion chromatography of the soluble materials from homogenized feces collected from mice 24 h postinjection. For polymers 1 and 2, fraction no. 11 is actually the sum of fractions 11−20. For polymer 3, fraction no. 10 is actually the sum of fractions 10−19.

Conclusions. In conclusion, we have shown that highly functionalizable, nontoxic, dendronized polymers represent a promising new scaffold for polymeric drug delivery systems. As with linear polymers, a positive correlation was observed between the size of the dendronized polymer and its blood circulation time. The long-

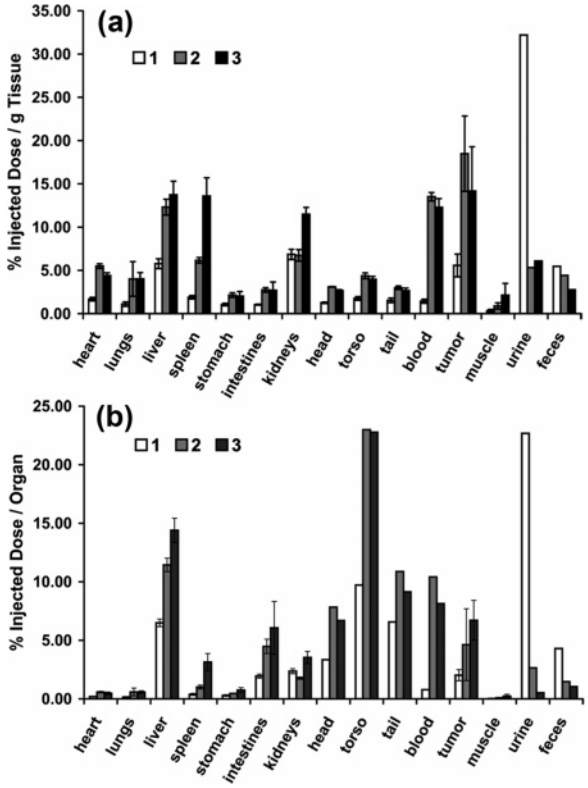

Figure 5. Biodistribution of **1**, **2**, and **3** in BALB/c mice bearing subcutaneous C26 tumors, plotted as (a) % injected dose per gram of tissue versus time and (b) % injected dose per organ versus time. Error bars have been omitted from the head, torso, tail, and blood values because the volume/mass recovered from these tissues can vary widely from mouse to mouse. Error bars have been omitted from the feces and urine values because the respective excrements for each time point were not collected individually but were pooled together. In a, the mean concentrations of radioactivity in the tumor were significantly different between **1** and **2** and **1** and **3** ($P < 0.05$) but not **2** and **3** ($P = 0.16$).

circulating nature of these high MW polymers is advantageous for their development as drug carriers since it has been shown that enhanced tumor accumulation is observed for polymers with long circulation half-lives, a feature that was successfully demonstrated in our preliminary biodistribution experiments. Therefore, future work will focus on the application of these novel polymers as carriers of anticancer drugs. In addition, as total body clearance of the higher MW polymers was low (≤10%), future studies will utilize polymers with degradable backbones to prevent long-term accumulation (*36*).

ACKNOWLEDGMENT

Financial support of this research by the National Institutes of Health (GM 65361 and EB 002047) is acknowledged with thanks. Fellowship support for M.Y. from the Japan Society for the Promotion of Science (JSPS) is gratefully acknowledged. We thank De Li for assistance with size exclusion chromatography studies, and we also thank Ann Fischer at the University of California Tissue Culture Facility for assistance with cell studies.

Near-Infrared Optical Imaging of B16 Melanoma Cells via Low-Density Lipoprotein-Mediated Uptake and Delivery of High Emission Dipole Strength Tris[(porphinato)zinc(II)] Fluorophores

Sophia P. Wu,[†] Intae Lee,[‡] P. Peter Ghoroghchian,[†,§] Paul R. Frail,[†] Gang Zheng,[‡] Jerry D. Glickson,[‡] and Michael J. Therien*[,†]

Received October 28, 2004; Revised Manuscript Received March 17, 2005

Meso-to-*meso* ethyne-bridged tris[(porphinato)zinc(II)] (**PZn$_3$**) near-infrared (NIR) fluorophores (λ_{em}^{max} ~800 nm) can be rendered sufficiently amphiphilic to enable their facile incorporation into the hydrophobic core of the apo form of low-density lipoprotein (apo-LDL). These NIR fluorophores are notable in that they manifest low energy excited states polarized exclusively along the long axis of the supermolecule, broad spectral coverage of the visible and high energy NIR spectral domains, intense $S_0 \rightarrow S_1$ transition moments, and comparably large $S_1 \rightarrow S_0$ emission dipole strengths. The reconstituted LDL(**PZn$_3$**) proteins can be used to deliver rapidly hundreds of copies of **PZn$_3$** to a given murine B16 melanoma cell via LDL receptor-mediated endocytosis. **PZn$_3$**-based NIRFs and their corresponding LDL(**PZn$_3$**) proteins have been shown to display minimal cytotoxicity. Confocal NIR fluorescence microscopy evinces that B16 cells can be imaged at very low doses (~nM) of NIRF. The highly attractive photophysical properties of **PZn$_3$** and closely related chromophores, coupled with their lack of toxicity and compatibility with uptake into apo-LDL and subsequent rapid delivery to B16 cells via LDLr-mediated endocytosis, suggest the potential utility of this platform for NIR optical imaging of cancer cells in vivo.

INTRODUCTION

The utilization of near-infrared (NIR) probes in cancer prevention/detection strategies has attracted attention due to the facts that (i) light scattering in tissue decreases with the reciprocal of the fourth power of wavelength (λ^{-4}), (ii) the NIR spectral domain provides a substantial optical window where hemoglobin and water absorption are minimal, and (iii) such optically based imaging technology, if realized, would presumably be inexpensive, mobile, and free of the biological effects associated with radiological probes (*1*, *2*). Key to making such a modality a viable means to image deep tissue is the development of strategies that enable adequate NIR optical signal output per cellular recognition event.

Deep tissue optical imaging requires both delineation of drastically superior fluorescent probes and delivery platforms that guarantee emissive signatures orders of magnitude greater than that provided by a single NIR fluorophore (NIRF). With respect to conventional NIRFs, indocyanine green (ICG), currently the only FDA-approved NIR imaging dye, suffers from both a modest fluorescence quantum yield (*3*) and a dominance of nonradiative excited state dynamics in physiological environments (*4*, *5*). Fluorescence-based optical imaging within the NIR spectral window (~710−950 nm) thus requires the development of new classes of biologically compatible chromophores that emit at long wavelengths with high emission dipole strengths; ideally, such NIRFS should possess emission maxima (λ_{em}^{max}) ≥ 800 nm to permit maximal photon penetration of living tissues (*6*−*8*).

Targeted NIR contrast agent delivery for in vivo optical imaging has exploited NIRF coupling to (i) peptide conjugates preferentially activated by cancer cells (*9*, *10*), (ii) receptor specific peptides that include somatostatin analogues (*11*−*14*), and (iii) monoclonal antibodies (*15*, *16*). While successful targeting and imaging of neoplastic tissue via each of these approaches has been demonstrated, these methods typically rely upon cell surface receptor recognition events involving conjugates featuring a single NIRF.

A promising method for packaging and delivery of multiple fluorophores involves reconstitution of NIRFs into the core of low-density lipoprotein (LDL) (*17*−*20*). LDL, an endogenous constituent of blood, is a particle 20−30 nm in diameter containing a core of neutral cholesterol esters and triglycerides surrounded by a polar shell of phospholipids, unesterified cholesterol, and apolipoprotein B100 that is recognized by the LDL receptor (LDLr) (*21*). Because of the high cholesterol demand of rapidly dividing cells, a number of tumor cells, such as acute myeloid leukemia, epidermoid cervical cancer, and squamous lung tumor, overexpress LDLr (*22*). This fact, coupled with the observation that LDL, due to its nanoscale dimensions, penetrates even solid tumors (*17*), has made it an attractive platform for delivery of a wide range of hydrophobic compounds (*23*, *24*) that include antitumoral drugs (*20*, *25*−*28*), photodynamic therapy

agents (*18*, *19*, *29*, *30*), and imaging dyes (*31*, *32*) to neoplastic tissues.

We report herein the reconstitution of LDL with *meso*-to-*meso* ethyne-bridged tris[(porphinato)zinc(II)] (**PZn_3**) fluorophores. These NIRFs and their structurally related analogues manifest low energy excited states polarized exclusively along the long axis of the supermolecule (*33*−*42*), intense $S_0 \rightarrow S_1$ transition moments, and comparably large $S_1 \rightarrow S_0$ emission dipole strengths (*33*, *36*, *37*, *40*). We show further via in vitro experiments that **PZn_3**-containing LDL particles deliver the core NIRFs to murine B16 melanoma cells via the LDLr pathway, which can be subsequently imaged using scanning fluorescence confocal microscopy.

EXPERIMENTAL PROCEDURES

Synthesis. All manipulations were carried out under nitrogen previously passed through an O_2 scrubbing tower (Schweitzerhall R3-11 catalyst) and a drying tower (Linde 3 Å molecular sieves) unless otherwise stated. Air sensitive solids were handled in a Braun 150-M glovebox. Standard Schlenk techniques were employed to manipulate air sensitive solutions. CH_2Cl_2 and tetrahydrofuran (THF) were distilled from CaH_2 and K/4-benzoylbiphenyl, respectively, under N_2. *N*,*N*-Dimethylformamide (DMF) and triethylamine (TEA) were dried over $MgSO_4$ and KOH, respectively, and distilled under reduced pressure. Absolute ethanol was used as received from Fisher Scientific. All NMR solvents were used as received. The catalysts tris(dibenzylideneacetone)dipalladium(0) and triphenylarsine ($AsPh_3$) were purchased from Strem Chemicals and used as received. 1-Hydroxybenzotriazole (HoBt) and *N*-methylmorpholine (NMM) (Acros) as well as (benzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyBOP) (Nova Biochem) were used as received. 5,15-Bis[[5′,10′,20′-bis[3,5-di(3,3-dimethyl-1-butyloxy)phenyl]porphinato)zinc(II)]ethynyl]-10,20-bis-[3,5-di(9-methoxy-1,4,7-trioxanonyl)phenyl]porphinato)-zinc(II) (**PZn_3a**), (5-ethynyl-10,20-bis[3′,5′-bis(3,3-dimethyl-1-butyloxy)phenyl]porphinato)zinc(II) (**1**), (5,15-dibromo-10,20-bis[3′,5′-bis(3,3-dimethyl-1-butyloxy)-phenyl]-porphinato)zinc(II) (**2**) (*38*), [5-ethynyl-10,20-diphenyl-porphinato]zinc(II) (**3**) (*34*, *43*), and 5-androsten-17β-amino-3β-yl oleate (**4**) (*29*) were synthesized according to literature procedures.

Chemical shifts for ^{1}H NMR spectra are reported relative to residual protium in the deuterated solvents ($CDCl_3$, $\delta = 7.24$ ppm; DMF-d_7, $\delta = 8.03$ ppm; pyridine-d_5, $\delta = 8.74$ ppm; and DMSO-d_6, $\delta = 2.50$ ppm). The number of attached protons is found in parentheses following the chemical shift value. Flash and size exclusion column chromatography were performed on the benchtop, using, respectively, silica gel (EM Science, 230−400 mesh) and Bio-Rad Bio-Beads SX-1 as media. Electrospray ionization (ESI-MS) data were obtained in the University of Pennsylvania Chemistry Mass Spectrometry Facility. Fast atom bombardment (FAB) mass spectrometry was performed at the Mass Spectrometry Center of Drexel University, while matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectra were obtained using a Perspective Voyager DE instrument in the Laboratory of Dr. William DeGrado (Department of Biophysics and Biochemistry, University of Pennsylvania). Samples for MALDI-TOF mass spectra were prepared as micromolar solutions in THF; dithranol or 1,4-bis(5-phenyoxazol-2-yl)benzene (Aldrich) was utilized as the matrix.

Instrumentation. Electronic spectra were recorded on an OLIS UV−vis/NIR spectrophotometry system that is based on the optics of a Cary 14 spectrophotometer. Emission spectra were recorded on a SPEX Fluorolog luminescence spectrophotometer that utilized a T-channel configuration with a red sensitive R2658 Hamamatsu PMT and liquid nitrogen-cooled InGaAs and extended InGaAs detectors; these spectra were corrected using a calibrated light source supplied by the National Bureau of Standards. NMR spectra were recorded on either 250 MHz AC-250 or 360 MHz DMX-360 Brüker spectrometers. Confocal microscopy experiments were performed at the Bioengineering Confocal and Multiphoton Core Facilities at the University of Pennsylvania using a Biorad Radiance 2000-MP laser scanning confocal microscope and a Nikon Eclipse TE-300 CCD camera.

(4-Formyl-phenoxy)acetic Acid Ethyl Ester (5). The reaction conditions for this precursor are analogous to those reported in the literature (*44*). A 200 mL round-bottom flask was charged with of 4-hydroxybenzaldehyde (6.5 g, 53 mmol), ethyl bromoacetate (9.78 g, 58.5 mmol), potassium carbonate (8.08 g, 58.5 mmol), and 100 mL of acetone. The reaction mixture was brought to a gentle reflux overnight. It was then diluted with water and extracted thrice with ethyl ether. The combined ether layers were then washed three times with 2 M KOH solution and once with water. The organic layer was then dried over Na_2SO_4 and evaporated to yield a yellow oil (15.3 g, 90% yield based on mass of 4-hydroxybenzaldehyde). ^{1}H NMR (250 MHz, $CDCl_3$): δ 9.88 (s, 1 H), 7.82 (d, 2 H, $J = 4.6$ Hz), 7.0 (d, 2 H, $J = 4.6$ Hz), 4.69 (s, 2 H), 4.25 (q, 2 H, $J = 7.0$ Hz), 1.25 (t, 3 H, $J = 7.0$ Hz) ppm. HRMS (M^+): 208.0734 (calcd 208.0735).

5,15-Di[((4-ethyl ester)methyleneoxy)phenyl]porphyrin (6). 2,2′-Dipyrrylmethane (*45*, *46*) (1.54 g, 10.5 mmol) and **5** (2.19 g, 10.5 mmol) were brought together in a 2 L round-bottom flask containing 1.5 L of dry methylene chloride and a magnetic stir bar under N_2. Triflouroacetic acid (0.16 mL, 2.1 mmol) was added to this mixture; the flask was then covered with aluminum foil and stirred at room temperature for 14 h. 2,3-Dichloro-4,5-dicyanoquinone (3.58 g, 15.75 mmol) was added to the methylene chloride solution, and the mixture was allowed to stir for 15 min before the solvent was removed under reduced pressure. The reaction mixture was then purified by silica chromatography using 99:1 CH_2Cl_2:methanol as the eluant, to give 1.5 g of the isolated product (43% yield based on 1.54 g of the dipyrrylmethane starting material). Vis (CH_2Cl_2) λ_{max} nm (log ϵ): 408 (5.37), 504 (4.17), 539 (3.79), 577 (3.75), 632 (3.37). ^{1}H NMR (250 MHz, $CDCl_3$): δ 10.29 (s, 2 H), 9.37 (d, 4 H, $J = 4.65$ Hz), 9.07 (d, 4 H, $J = 4.65$ Hz), 8.16 (d, 4 H, $J = 7.95$ Hz), 7.28 (d, 4 H, $J = 7.95$ Hz) 5.53 (s, 4 H), 4.40 (q, 4 H, $J = 7.28$ Hz), 1.42 (t, 6 H, $J = 7.30$ Hz), −3.02 (broad s, 2 H) ppm. HRMS (MH^+): 667.2573 (calcd 667.2537).

5,10-Dibromo-10,20-di[((4-ethyl ester)methyleneoxy)phenyl]porphyrin (7). In a 1.0 L round-bottomed flask, **6** (600 mg, 0.9 mmol) was dissolved in 500 mL of methylene chloride. *N*-Bromosuccinimide (320 mg, 1.8 mmol) was then added to the stirring porphyrin solution. The reaction was allowed to proceed for 15 min and quenched by the addition of 30 mL of acetone. The solvents were removed, and the recovered reaction mixture was purified by silica chromatography using methylene chloride as the eluent. Three bands were isolated; the fastest moving band was isolated as the title compound (590 mg, 80% yield based on 600 mg of **6**). Vis ($CHCl_3$) λ_{max} (log ϵ): 415 (5.05), 510 (4.10), 545 (3.78), 586 (3.58) 642 (3.18) nm. ^{1}H NMR (250 MHz, $CDCl_3$): δ 9.60 (d, 2 H, $J = 4.7$ Hz), 8.83 (d, 2H, $J = 4.6$), 8.16 (d,

4H, $J = 7.95$ Hz), 7.28 (d, 4H, $J = 7.95$ Hz) 4.92 (s, 4H), 4.40 (q, 4 H, $J = 7.28$ Hz), 1.42 (t, 6 H, $J = 7.30$ Hz), −2.75 (broad s, 2 H).

[5,10-Dibromo-10,20-di[((4-ethyl ester)methyleneoxy)phenyl]porphinato]zinc(II) (8). Compound **7** (500 mg, 0.6 mmol) and zinc acetate (658 mg, 3 mmol) were refluxed in 400 mL of chloroform in a 1 L round-bottom flask equipped with a magnetic stir bar and a reflux condenser. The reaction was monitored by optical spectroscopy and was complete within 2 h. Once the solvents were evaporated, the reaction mixture was passed down a short silica column with methylene chloride as the eluent. The first band to elute is the desired product (506 mg, 95% yield based on 500 mg of **7**). Vis ($CHCl_3$) λ_{max} (log ϵ): 420 (5.38), 550 (4.10), 590 (3.33) nm. ^{1}H NMR (250 MHz, $CDCl_3$): δ 9.60 (d, 2H, $J = 4.7$ Hz), 8.83 (d, 2H, $J = 4.6$ Hz), 8.0 (d, 4H, $J = 7.95$ Hz), 7.26 (d, 4H, $J = 7.95$ Hz), 4.89 (s, 4H), 4.40 (q, 4 H, $J = 7.28$ Hz), 1.39 (t, 6 H, $J = 7.30$ Hz).

[5,10-Dibromo-10,20-di[((4-carboxy)methyleneoxy)phenyl]porphinato]zinc(II) (9). A 100 mL round-bottom flask was charged with **8** (100 mg, 0.112 mmol) and dissolved in 80 mL of 3:1 THF:EtOH solution. An aqueous solution of KOH (63 mg, 1.12 mmol, 5 mL) was added to the stirred solution. The reaction mixture was refluxed for 2 h, following which the solvents were removed under reduced pressure. The resulting mixture was dissolved in ~20 mL of water and acidified by dropwise addition of concentrated HCl to pH 3. The resulting purple precipitate was filtered and dried to give the desired product (86 mg, 92% yield, based on 100 mg of the dihalogenated (porphinato)zinc(II) starting material). Vis (DMSO) λ_{max} (log ϵ): 435 (5.44), 571 (4.11), 614 (4.07) nm. ^{1}H NMR (250 MHz, DMF-d_6): δ 9.70 ppm (d, 4 H, $J = 4.65$ Hz), 8.90 (d, 4 H, $J = 4.63$ Hz), 8.17 (d, 4 H, $J = 8.4$ Hz), 7.45 (d, 4 H, $J = 8.6$ Hz), 5.09 (s, 4 H) ppm. ESI-MS (MH^+): 830.3 (calcd for $C_{36}H_{22}Br_2N_4O_6Zn$, 830.9). FAB-MS (M^+): 829.6 (calcd 829.9).

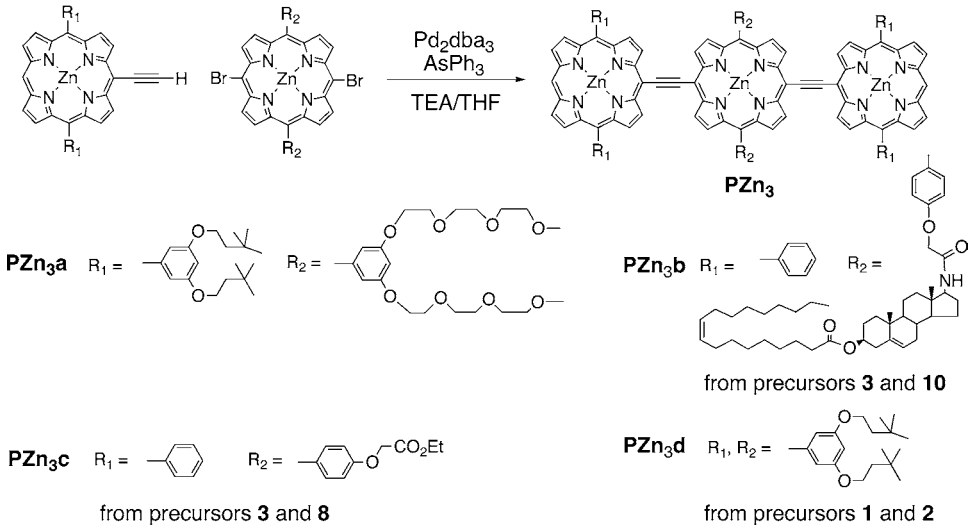
[5,10-Dibromo-10,20-di[((4-5-androsten-17β-amino-3β-yl oleate)methyleneoxy)phenyl]porphinato]zinc-(II) (10). [5,10-Dibromo-10,20-di[((4-carboxy)methyleneoxy)phenyl]porphinato]zinc(II) (**9**) (31 mg, 0.0373 mmol), PyBOP (43 mg, 0.0821 mmol), HoBt (11 mg, 0.0821 mmol), and NMM (25 μL, 0.224 mmol) were dissolved in 5 mL of DMF at room temperature and stirred under argon for 30 min. 5-Androsten-17β-amino-3β-yl oleate (**4**) (47 mg, 0.078 mmol), dissolved in approximately 10 mL of DMF, was transferred under Ar to the porphyrin-containing solution. The reaction mixture was stirred at ambient temperature and allowed to proceed until the TLC showed that all of the porphyrin starting material had been consumed (~22 h). The mixture was then diluted with ethyl acetate and washed three times with brine. The combined organic phases were dried over $MgSO_4$ and evaporated. The residue was chromatographed on silica gel using 3:2 hexanes:THF as the eluant, following which it was rechromatographed on silica gel using 99:1 CH_2Cl_2:MeOH as the eluant. The product was isolated as a green solid (12 mg, 38% yield based on 31 mg of **9**). Compound **10** was used immediately in the subsequent cross-coupling reaction described below. Vis (CH_2Cl_2) λ_{max}(log ϵ): 420 (5.38), 550 (4.16), 590 (3.69) nm. ^{1}H NMR (250 MHz, $CDCl_3$): 9.71 (d, 4 H, $J = 4.75$ Hz), 8.84 (d, 4 H, $J = 4.66$ Hz), 8.00 (d, 4 H, $J = 8.41$ Hz), 6.80 (d, 4 H, $J = 7.92$ Hz), 5.40 (s, 4 H), 5.34 (m, 6 H), 5.05 (m, 2 H), 4.65 (m, 2 H), 2.28 (m, 12 H), 1.98 (m, 22 H), 1.3−0.8 (m, cholesteryl oleate alkyl H) ppm. MALDI-TOF MS (M^+): 1936.2 (calcd for $C_{112}H_{152}Br_2N_6O_8Zn$, 1935.6).

5,15-Bis[[5′,-10′,20′-bis((4-5-androsten-17β-amino-3β-yl oleate)methyleneoxy)phenyl]porphinato)-zinc(II)ethynyl]-10,20-(diphenyl)porphinato)zinc-(II)(PZn_3b). Compound **10** (22 mg, 0.0116 mmol), **3** (14 mg, 0.0243 mmol), Pd_2dba_3 (2.7 mg, 0.0029 mmol), $AsPh_3$ (7.1 mg, 0.0232 mmol), and TEA (0.3 mL) were dissolved in THF (20 mL) in a 50 mL Schlenk tube and subjected to three freeze−pump−thaw degas cycles. The mixture was heated at 40 °C under Ar overnight, during which time the solution changed from purple to brown. The solution was then diluted with ethyl acetate, washed three times with water, dried over $MgSO_4$, and evaporated. The residue was purified by flash chromatography on silica gel, using 3:2 hexanes:THF as the eluant, following which it was rechromatograhed on silica gel using CH_2Cl_2 as the eluant. The isolated product was recrystallized from THF/hexanes to give 12 mg of the product (38% yield, based on 22 mg of compound **10**). Vis (CH_2Cl_2) λ_{max} (log ϵ): 421 (5.06), 489 (4.93), 768 (4.61) nm. ^{1}H NMR (99:1 $CDCl_3$:pyridine-d_5): δ 10.44 (d, 4 H, $J = 4.65$ Hz), 10.37 (d, 4 H, $J = 4.65$ Hz), 10.09 (s, 2 H), 9.27 (d, 4 H, $J = 4.43$ Hz), 9.13 (d, 4 H, $J = 4.63$ Hz), 9.01 (d, 4 H, $J = 4.50$ Hz), 8.96 (d, 4 H, $J = 4.43$ Hz), 8.27 (m, 8 H), 7.78 (m, 12 H), 7.36 (d, 4 H, $J = 8.58$ Hz), 6.72 (d, 4 H, $J = 9.18$ Hz), 5.31 (br s, 4 H), 4.84 (s, 6 H), 4.10 (m, 2 H), 3.83 (m, 2 H), 2.30 (m, 12 H), 2.0−0.8 (m, cholesteryl oleate alkyl H) ppm. MALDI-TOF MS (M^+): 2894.0 (calcd for $C_{180}H_{190}N_{14}O_8Zn_3$, 2894.3).

5,15-Bis[(5′,-10′,20′-diphenyl)porphinato)zinc(II)-ethynyl]-10,20-bis[(4-ethyl ester)methyleneoxy)phenyl]porphinato)zinc(II) (PZn_3c). [5-Ethynyl-10,20-diphenylporphinato]zinc (II) (**3**) (50 mg, 0.0885 mmol), **8** (38 mg, 0.0421 mmol), Pd_2dba_3 (9.6 mg, 0.0105 mmol), $AsPh_3$ (26 mg, 0.0842 mmol), THF (20 mL), and TEA (0.1 mL) were brought together in a 50 mL Schlenk tube under Ar and stirred overnight at 50 °C. The reaction mixture was diluted with ethyl acetate, washed three times with water, dried over $MgSO_4$, and evaporated. The residue was chromatographed on silica gel using 3:2 hexanes:THF as the eluant, following which the product was recrystallized from THF/hexanes to yield **PZn_3c** (66 mg, 83% yield based on 38 mg of **8**). Vis (THF) λ_{max} (log ϵ): 412 (5.42), 494 (5.51), 548 (4.34), 576 (4.33), 776 (5.07) nm. ^{1}H NMR (360 MHz, 50:1 $CDCl_3$:pyridine-d_5): 10.46 (d, 2H, $J = 4.7$ Hz), 10.36 (d, 2H, $J = 4.5$ Hz), 10.05 (s, 2H), 9.26 (d, 2H, $J = 4.2$ Hz), 9.13 (d, 2H), 9.04 (d, 2H, $J = 4.5$ Hz), 8.96 (d, 2H, $J = 4.8$ Hz), 8.27 (m, 10H), 7.78 (m, 8H), 4.95 (s, 2H), 4.43 (q, 4H, $J = 7.2$ Hz), 1.43 (t, 6H, $J = 7.1$ Hz). MALDI-TOF MS (M^+): 1826.0 (calcd for $C_{108}H_{68}N_{12}O_6Zn_3$, 1826.0).

5,15-bis[[(5′,-10′,20′-bis[3,5-di(3,3-dimethyl-1-butyloxy)phenyl]porphinato)zinc(II)]ethynyl]-10,20-bis-[(3,5-di(3,3-dimethyl-1-butyloxy)phenyl)porphinato]zinc(II) (PZn_3d). Compounds **1** (84 mg, 0.0885), **2** (46 mg, 0.0421 mmol), Pd_2dba_3 (9.6 mg, 0.0105 mmol), $AsPh_3$ (26 mg, 0.0842 mmol), and TEA (0.1 mL) were dissolved in THF (20 mL) in a 50 mL Schelnk tube and reacted overnight under Ar at 60 °C. The reaction mixture was then diluted with $CHCl_3$, washed three times with water, dried over $CaCl_2$, and evaporated. The residue was chromatographed on silica gel using 17:3 hexanes:THF as the eluant. Trace amounts of a butadiyne-bridged bis-[(porphinato)zinc(II)] contaminant were removed via size exclusion chromatography using THF as the eluant to give 97 mg of the product (82% yield based on 46 mg of **2**). Vis (THF) λ_{max} (log ϵ): 416 (4.85), 493 (4.99), 542 (4.00), 563 (3.97), 760 (4.54) nm. ^{1}H NMR (250 MHz, 50:1 $CDCl_3$:pyridine-d_5): 10.41 (d, 4H, $J = 4.75$ Hz), 10.34 (d, 4H, $J = 4.25$ Hz), 10.03 (s, 2H), 9.23 (d, 8H, $J = 4.5$ Hz),

Scheme 1. Synthetic Route to NIRFs



9.13 (d, 4H, $J = 4.5$ Hz), 9.05 (d, 4H, $J = 4.0$ Hz), 7.45 (m, 12H), 6.87 (s, 6H), 4.19 (t, 24H, $J = 7.4$ Hz), 4.16 (s, 6H), 1.83 (t, 24H, $J = 7.4$ Hz), 0.96 (s, 108H). MALDI-TOF MS (M^+): 2823.7 (calcd for $C_{112}H_{200}N_{12}O_{12}Zn_3$, 2823.4).

LDL Reconstitution. A modified version of the classic Krieger reconstitution procedure (*47*) was used. Human LDL was purchased from either Dr. Sissel Lund-Katz, who purified it from serum of patients with familial hypercholesteremia at the Children's Hospital of Philadelphia (*48*), or from Intracel Corporation (Frederick, Maryland). Prior to reconstitution, 1.9 mg of LDL, stored in 150 mM NaCl with 0.01% EDTA at pH 7.2, was dialyzed at 4 °C against a PBS buffer (137 mM NaCl, 2.7 mM KCl, 10 mM phosphate, pH 7.4) containing 0.3 mM EDTA, following which it was lyophilized in the presence of 25 mg of starch in a test tube pretreated with an antiwetting agent (Sigmacote). Endogeneous lipids were extracted by vortexing the lyophilized apoprotein/starch mixture with 5 mL of heptanes. The LDL-containing suspension was centrifuged at 2000 rpm for 10 min, and the supernatant was discarded. This procedure to extract LDL core lipids was repeated two more times. After the heptanes layer was removed for the final time, 6 mg of the appropriate **PZn$_3$**-based NIRF dissolved in 200 μL of benzene was added to the LDL pellet and incubated at 4 °C for 90 min. The organic solvents were then removed under a stream of Ar at −15 °C over a 30 min period. The reconstituted LDL was solubilized by briefly sonicating the residue in 2 mL of tricine buffer (10 mM, pH 8.4); this solution was incubated at 4 °C for 24 h. Starch and excess protein were removed by low-speed centrifugation (2000 rpm) at 4 °C for 10 min. The supernatant was collected and further clarified by centrifuging at 9000 rpm for two 10 min periods. The concentration of the reconstituted LDL solutions was determined by the Lowry method (*49*). Reconstituted LDL was stored under a nitrogen atmosphere at 4 °C. The integrity of the LDL(**PZn$_3$**) protein solutions, as determined from measurements of fluorescence intensity, remained constant over 8 weeks.

Cytotoxicity Experiments. The in vitro cytotoxicities of **PZn$_3$a**, **PZn$_3$b**, and their corresponding reconstituted LDL(**PZn$_3$**) protein solutions [LDL(**PZn$_3$a**) and LDL(**PZn$_3$b**)] were determined using a clonogenic assay. B16 melanoma cells from a cell line that overexpresses LDLr (generously provided by Dr. Theodore van Berkel, Leiden University, The Netherlands) were plated on six well plates overnight for cell attachment. Cells were exposed to DMSO solutions of **PZn$_3$a**, **PZn$_3$b**, and solutions (10 mM tricine, pH = 8.4) containing the analogous reconstituted LDL(**PZn$_3$**) proteins for 3 h, 24 h, and 8 days (no rinse). After exposure, the cells were twice rinsed with HBSS and then added to DMEM media supplemented with 10% fetal bovine serum and 25 mM HEPES buffer. After incubation for 8 days, the media were discarded and the cells were fixed with 5 mL of 99.5% ethanol for 10 min, rinsed three times with water, stained with 2% crystal violet for 10 min, and rinsed again with water. Clones with more than 50 cells were counted as survivors. The surviving fraction was calculated for the clonogenic assay.

Cellular Uptake and Imaging. B16 murine melanoma cells (2×10^4) were plated into two well chamber slides and incubated for 3 days at 37 °C prior to treatment with LDL(**PZn$_3$a**) and LDL(**PZn$_3$b**). The cells were incubated with the reconstituted dye solutions (1 μg/mL) for 1 h and subsequently washed twice with HBSS prior to fixing with absolute EtOH for 10 min at ambient temperature. The slides were then sealed and mounted for confocal imaging.

RESULTS AND DISCUSSION

Synthesis. The synthesis of **PZn$_3$**-based NIRFs is outlined in Scheme 1 (*33*, *38*, *50*). Because of the oxidative instability of cholesteryl oleate, reactions involving 5-androsten-17β-amino-3β-yl oleate-modified (porphinato)zinc(II) species proceeded in lower yields relative to analogous syntheses of **PZn$_3$** NIRFs lacking ancillary steroidal groups (**PZn$_3$a**, **PZn$_3$c**, and **PZn$_3$d**). Because endogeneous LDL lipids are completely displaced during its reconstitution, the NIRFs utilized for LDL reconstitution reactions must be sufficiently lipophilic in order to circumvent nonspecific leakage and aggregation of the reconstituted LDL (*22*). Furthermore, solubility of the **PZn$_3$**-based NIRFs in apolar organic solvents is also crucial for incorporation into the LDL interior. All the **PZn$_3$** ancillary substituents highlighted in Scheme 1 satisfy these constraints.

Note that the 4′-arylester groups of **PZn$_3$c** provide functionality for conjugation to moieties that engender augmented lipophilic character. **PZn$_3$b**, which bears two 5-androsten-17β-amino-3β-yl oleate esters, was synthesized from synthetic precursors to **PZn$_3$c** to determine the extent to which such modifications impact LDL

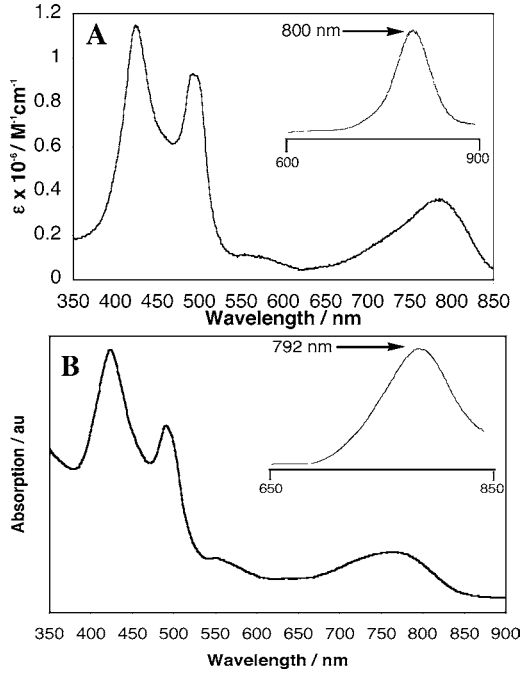


Figure 1. Electronic absorption and emission spectra of tris[(porphinato)zinc(II)] fluorophores. (A) Cholesteryl oleate-conjugated NIRF **PZn$_3$b** in benzene solvent. (B) Reconstituted LDL(**PZn$_3$a**) in tricine buffer (10 mM, pH 8.4). Corrected emission spectra, labeled with the emission wavelength maximum, are shown in the insets.

reconstitution with these tris[(porphinato)zinc(II)] species and affect subsequent cellular uptake by B16 murine melanoma cells. Previous studies demonstrated the utility of this approach for driving incorporation of cytotoxic and phototoxic agents into the LDL interior and facilitating their respective release into cells via LDLr-mediated endocytosis (*17*, *25*, *29*, *31*, *51*, *52*), consistent with the fact that oleoyl residues are abundant components of native LDL (*53*).

LDL Reconstitution. Following the modified Krieger protocol for LDL reconstitution outlined above (see Experimental Procedures) (*47*), NIRFs **PZn$_3$a** and **PZn$_3$b** were successfully incorporated into the LDL lipid core. Neither **PZn$_3$c** nor **PZn$_3$d** was taken up into apo-LDL under these conditions. These experiments suggest that without the cholesteryl oleate lipid anchor, **PZn$_3$c** lacks the hydrophobicity necessary to drive LDL incorporation; furthermore, it is apparent that the increased **PZn$_3$d** hydrophobicity relative to that of successfully-incorporated **PZn$_3$a** neither enhances nor guarantees successful reconstitution. This result may indicate that **PZn$_3$d** amphiphilicity has decreased below the threshold required for LDL compatibility; qualitatively similar observations emerge from structure−activity relationships delineated for amphiphilic drugs, which often show that potency is parabolically related to lipophilicity (*54*−*56*). Alternatively, disparate NIRF solvational environments that trace their genesis to the nature of the **PZn$_3$** *meso*-aryl-pendant solubilizing groups may serve as a key determinant of the extent to which **PZn$_3$a** and **PZn$_3$d** are taken up into apo-LDL under these conditions (*53*).

Figure 1 displays representative optical spectra of **PZn$_3$**-based NIRFs in low dielectric strength solvent and for reconstituted LDL(**PZn$_3$**) proteins. These optical spectra display absorptive and emissive signatures characteristic of extensive π conjugation and exciton coupling, similar to those elucidated for closely related compounds in higher dielectric strength media (*33*−*42*). These features include substantial B-state ($S_0 \rightarrow S_2$ absorption) domain spectral breadths, high oscillator strength, low energy Q-derived $S_0 \rightarrow S_1$ transitions, and correspondingly intense $S_1 \rightarrow S_0$ fluorescence emission bands. Assuming that the electronic absorption extinction coefficients of these NIRFs within the LDL hydrophobic core are similar to those determined previously in hydrophobic solvents, we estimate that ~30 chromophores are incorporated per LDL protein; note that this result is consistent with previous data that show that similar copy numbers of a range of amphipathic drugs are internalized into LDL using analogous reconstitution methodologies (*25*, *27*, *52*, *57*).

With respect to other classes of NIRFs that have been incorporated into the LDL core (*29*, *31*), note that the electronic absorption characteristics of these **PZn$_3$**-based chromophores include unusually comprehensive coverage of the UV, visible, and high energy NIR regions of the solar spectrum. Because **PZn$_3$** and related chromophores exhibit rapid $S_2 \rightarrow S_1$ internal conversion rate constants ($\tau_{ic} \sim 150$ fs), which are 1 order of magnitude faster than that manifested by conventional porphyrin monomers, formation of the low energy emitting state thus occurs within the ultrafast time domain, regardless of whether these species are excited within their lowest energy absorption band or within the higher lying B-state manifold (*36*, *40*); hence, optical excitation of the dyes could be performed at any wavelength between 400 and 800 nm.

Cytotoxicity of PZn$_3$a, PZn$_3$b, and Their Corresponding Reconstituted LDL(PZn$_3$) Proteins. The in vitro cytotoxicities of **PZn$_3$a**, **PZn$_3$b**, and their corresponding reconstituted LDL(**PZn$_3$**) proteins [LDL(**PZn$_3$a**) and LDL(**PZn$_3$b**)] were determined using a clonogenic assay. These data show that these conjugates display no apparent toxicity to murine B16 cells, as evident from the respective cellular survival rates determined as a function of time following exposure (Figure 2).

Murine B16 melanoma cells have been shown to bind LDL with affinity similar to human parenchymal cells and are thus good models for evaluating the effectiveness of LDLr-mediated delivery (*58*, *59*). Note that the Figure 2 data do not allow determination of IC_{50} values for **PZn$_3$a**, **PZn$_3$b**, LDL(**PZn$_3$a**), or LDL(**PZn$_3$b**) at 3 or 24 h of exposure, due to their apparent relative nontoxicity. The IC_{50} value determined for **PZn$_3$a** at 8 days of exposure was ~70 μg/mL, while that for **PZn$_3$b** was 45 μg/mL. The cytotoxicities for both **PZn$_3$a** and **PZn$_3$b** increased slightly as a function of exposure time. Note that the toxicity profiles of **PZn$_3$a** and **PZn$_3$b** contrast with that determined for tetrakis[(4-sulfonatophenyl)-porphinato]zinc(II) on G361 human melanoma cells (IC_{50} > 125 μg/mL, $t_{exposure}$ = 60 min) (*60*). Furthermore, the 50% inhibitory concentrations for both LDL(**PZn$_3$a**) and LDL(**PZn$_3$b**) were greater than 1000 ng/mL at 8 days of exposure. The benign nature of these fluorophore-reconstituted lipoproteins is similar to that established previously for in vitro toxicity studies of 3,3′-dioctadecylindocarbocyanine-labeled LDL (DiI-LDL) on MRC^5 human fetal fibroblasts (*61*).

Recent cytotoxicity studies of the FDA-approved NIR contrast agent, ICG, on human retinal pigment epithelium cells (RPE) showed that exposure to ICG at 100 μg/mL for 3 h resulted in approximately 20% cell death (*62*). After exposure to ICG at 5 mg/mL for the same amount of time, no cells survived. Even at a very short exposure time of 3 min at 0.5 mg/mL of ICG, RPE cell survival rate was modestly reduced to 92.8% (*63*). In contrast, no

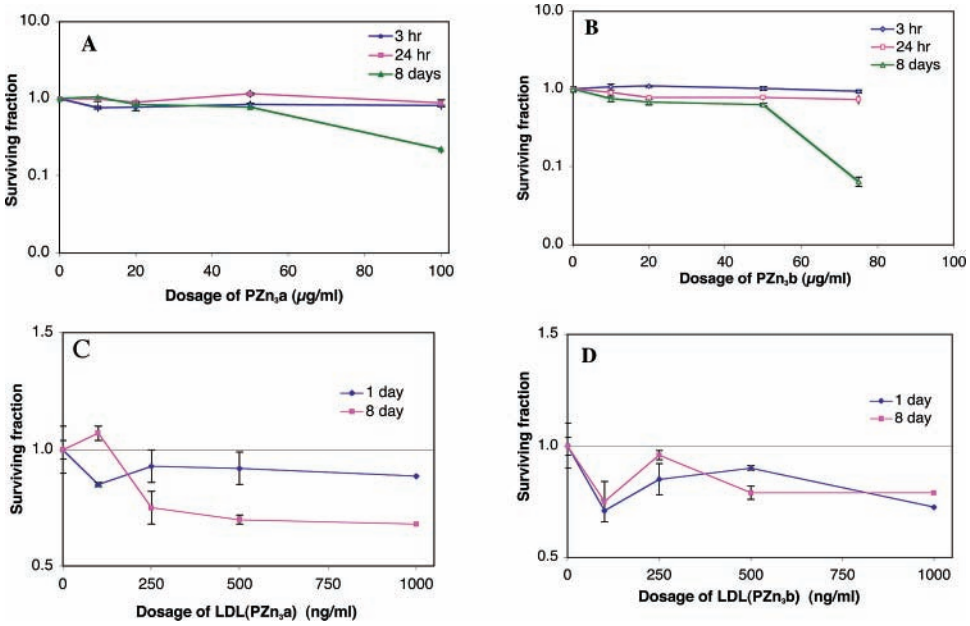

Figure 2. Time-dependent cytotoxicity of **PZn$_3$**-based NIRFs on B16 melanoma cells determined by a clonogenic assay for (A) **PZn$_3$a**, (B) **PZn$_3$b**, (C) LDL(**PZn$_3$a**), and (D) LDL(**PZn$_3$b**). Clones with more than 50 cells were counted as survivors. Data points represent means ± standard errors and were obtained from at least four independent experiments.

Table 1. Qualitative Comparison of in Vitro Experimental Conditions Required to Generate NIR Confocal Fluorescence Microscope Images of Tumor Cells Qualitatively Similar to that Depicted in Figure 3B as a Function of NIRF, Delivery Platform, Dose, Exposure Time, and Emission Wavelength

Entry	Contrast Agents	Delivery Platform	Tumor Cell Line	Dose of Dye	Exposure Time	λ_{emit} (nm)	Ref.
A		LDL	B16 Melanoma	60 nM	1 h	792	*This Work*
B		LDL	Hepato-blastoma G2	3 μM[a]	3 h	720	29, 64
C		Somatostatin Receptor	RIN38 SSTR2[b]	1 μM[c]	1 h	780	11, 13
D		Proteolytic Enzyme Activation[d]	LX-1[e]	3.5 μM	15 min	700	9
E		Glucose Transporter	9L Glioma	50 μM	30 min	720	50

[a] Calculated from a cell culture treatment using [LDL(dye)] = 20 μg/mL, in which each reconstituted LDL protein is calculated to contain ~75 dye molecules (*29*, *64*). [b] Somatostatin receptor subtype 2 transfected rat insulinoma pancreatic tumor. [c] Incubation of dye–peptide conjugate was performed at 4 °C. [d] Fluorescence signal generated through the action of proteolytic enzymes preferentially expressed in tumor tissues that release cyanine dyes from a protein/polymer matrix in which NIR fluorescence was previously quenched. [e] XG human lung carcinoma.

significant toxicity can be detected for either **PZn$_3$a** or **PZn$_3$b** on B16 cells even after 24 h of exposure at 100 and 80 μg/mL concentrations, respectively. These data suggest that the **PZn$_3$** family of fluorophores, as well as related structural analogues of these species, may prove suitable for in vivo studies.

Confocal Microscopy. Cellular uptake of the LDL reconstituted dye solutions was visualized using laser scanning confocal fluorescence microscopy (Figure 3). Figure 3A,C,E shows transmission images of B16 melanoma cells, while panels B, D, and F illustrate their corresponding cellular NIR fluorescence images. As

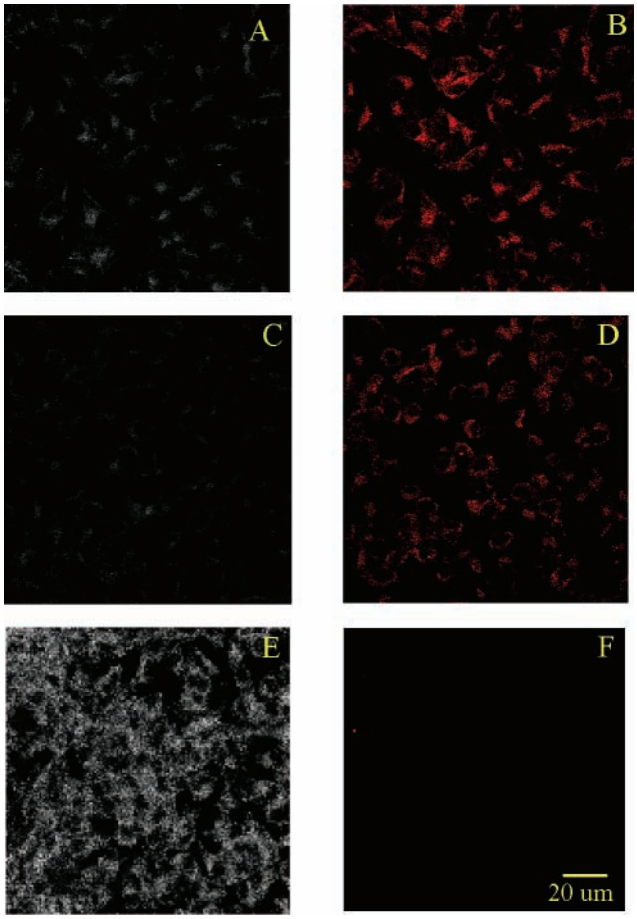

Figure 3. Confocal microscope images of B16 cells. (A) Transmission image of B16 cells treated with LDL(**PZn$_3$a**). (B) Fluorescence image of panel A. (C) Transmission microscopy image of B16 cells treated with LDL(**PZn$_3$b**). (D) Fluorescence image of panel C. (E) Transmission microscopy image of B16 cells incubated in culture medium to which aliquots of DMSO solutions of **PZn$_3$a** (1 μg/mL) were added. (F) Fluorescence image of panel E. Experimental conditions: B16 cells (2.5×10^4) were incubated at 37 °C for 3 days and then treated with solutions of LDL(**PZn$_3$**) (1 μg/mL; 10 mM tricine buffer, pH 8.4) for 1 h at ambient temperature. Following cellular washing and fixing with EtOH (see Experimental Procedures), slides were sealed and mounted. All images were taken at the same magnification using $\lambda_{ex} = 488$ nm and a 700 nm long pass filter.

Figure 3 clearly demonstrates, both LDL(**PZn$_3$a**) and LDL(**PZn$_3$b**) were internalized by B16 cells within 1 h; intense fluorescence signals were detected throughout the cellular membranes of the B16 cells. When B16 cells were incubated in culture medium to which aliquots of DMSO solutions of **PZn$_3$a** and **PZn$_3$b** (1 μg/mL) were added, no emission was detected from the cells (Figure 3E,F), indicating that the NIRF uptake highlighted by the Figure 3 data is mediated solely via LDLr-mediated endocytosis.

The low doses of dye ([LDL(**PZn$_3$**)] = 1 μg/mL = 2 nM protein; [NIRF] = 60 nM) used to obtain the confocal images highlight the emissive characteristics of the **PZn$_3$**-based NIRFs and the utility of LDL as an efficient vehicle for delivery of multiple copies of these fluorophores to a single cell. The short incubation time required for fluorophore uptake in these experiments demonstrates the rapid internalization of LDL through the B16 cells' overexpressed LDLrs, a characteristic displayed by many tumor types (*22*).

Table 1 highlights treatment conditions required for previously studied biomolecule−dye conjugates to obtain qualitatively similar confocal NIR fluorescence images of in vitro-targeted cancer cells. In vitro cellular delivery of the NIRF pyropheophorbide via the glucose transporter (Table 1, entry E) requires 20-fold greater concentration of fluorophore to generate a confocal image similar in quality to that obtained for delivery of the same dye via LDL reconstitution and subsequent LDLr-mediated endocytosis (Table 1, entry B) (*50*). Note that the amount of LDL-reconstituted pyropheophorbide necessary to generate NIR fluorescence confocal images similar to that shown in Figure 3B,D is at least 50 times higher than that used in this study (Table 1, entry A) (*29*). Because (i) dye doses cited in Table 1 do not necessarily correspond to the minimal amount necessary for obtaining a suitable fluorescence image and (ii) parameters such as instrument sensitivity, imaging acquisition times, and camera settings cannot be directly compared, we emphasize that the experimental data comparisons highlighted Table 1 are qualitative in nature. Nonetheless, the small concentration of **PZN$_3$** fluorophore required to obtain the in vitro images shown in Figure 3B,D underscore the promise of this NIR emissive platform for imaging applications.

CONCLUSIONS

We have shown that *meso*-to-*meso* ethyne-bridged tris-[(porphinato)zinc(II)] (**PZn$_3$**) NIRFs can be rendered sufficiently amphiphilic to enable their facile incorporation into the hydrophobic core of apo-LDL. These reconstituted LDL(**PZn$_3$**) proteins can be used to deliver rapidly hundreds of copies of **PZn$_3$** to a given B16 melanoma cell via LDLr-mediated endocytosis. **PZn$_3$**-based NIRFs and their corresponding LDL(**PZn$_3$**) proteins display minimal cytotoxicity. Confocal NIR fluorescence microscopy evinces that B16 cells can be imaged at very low doses (~nM) of NIRF. The highly attractive photophysical properties of **PZn$_3$** and closely related chromophores, coupled with their lack of toxicity and compatibility with uptake into apo-LDL and subsequent rapid delivery to B16 cells via LDLr-mediated endocytosis, suggest the potential utility of this platform for NIR optical imaging of cancer cells in vivo.

ACKNOWLEDGMENT

This research was supported by the National Cancer Institute (N01-CO-29008). J.D.G. acknowledges support from the National Cancer Institute (R24-CA83105-05 and P20-CA86255), and G.Z. thanks NASA and NCI (N01-CO-37119) for funding. S.P.W. is grateful to the National Science Foundation for an Access Science Predoctoral Fellowship. P.P.G. acknowledges predoctoral fellowship support from the NIH Medical Scientist Training Program (MSTP) and the Whitaker Foundation. We are indebted to Gladys Gray-Board for her assistance with the confocal microscopy experiments, to Dr. Sissel Lund-Katz of the Children's Hospital of Philadelphia for LDL, to Dr. Hui Li for guidance in the LDL reconstitution experiments, and to Dr. Theo van Berkel of Leiden University for providing the B16 melanoma cell line that overexpresses LDLr.

We developed functional polymer latex particles that can catch and cleave mismatched DNA selectively and propose a new mismatch detection system using the functional particles. The aimed particles possess two functional units composed of mismatch binding protein (MutS) and an anthraquinone derivative (AQ), a light-activated agent that photocleaves dsDNA. Use of the functional particles made it possible to discriminate complementary and mismatched DNAs and photocleave mismatched DNA selectively. The efficiency of photocleavage of mismatched DNA by the functional particles increased with UV irradiation time. It was also found that the functional particles were reusable and had dissociation constants (K_d) of 1000 and 68.5 nM for G/C homoduplex and G/T heteroduplex, respectively. Using the functional partcles and a dsDNA-binding fluorescent dye, SYBR-Gold, we could construct the system for detection of mismatched DNA that was 40 base pairs. The functional particles prepared in this study will be an absolutely new tool for mismatch detection in DNA diagnosis.

1. INTRODUCTION

A large number of human genetic diseases and single-nucleotide polymorphisms (SNPs) are caused by gene mutations including single-base substitutions and small additions or deletions (*1*, *2*). Therefore it is very meaningful to detect such gene mutations as early as possible, and rapid, easy to handle, and high-throughput mismatch detection methods are urgently demanded. To date, different approaches for constructing mismatch detection systems that are useful and unique have been reported (*3*−*7*). In our previous study, we proposed an application of affinity latex particles for efficient purification of several DNA binding proteins (*8*, 9), single-stranded DNA and RNA (*10*), and for constructing a DNA diagnosis system (*11*−*13*). Also, we developed protein- and peptide-carrying affinity latex particles and purified several proteins by using the particles (*14*). In this study, we developed functional polymer latex particles that can catch and cleave mismatched DNA selectively and propose a new mismatch detection system using the functional particles. These functional particles need to have functional units to discriminate complementary and mismatched DNAs and to cleave mismatched DNA that is caught. As the unit of discriminating complementary and mismatched DNAs, MutS protein was selected. The MutS protein is a crucial element of DNA mismatch repair (MMR) system in many organisms such as *Escherichia coli* (*15*). MutS is the 97 kDa protein that can specifically recognize and bind all possible single-base mismatches, as well as 1−4 base insertion or deletion loops (*16*, *17*). On the other side, as the unit for cleaving mismatched DNA, an anthraquinone derivative (AQ) is selected. AQ is a light-activated agent that cleaves double-stranded DNA (*18*, *19*). AQ has two separate oxidative pathways: electron transfer from a nearby base and hydrogen atom abstraction from the deoxyribose component of the nucleic acid backbone. The former leads to GG-selective cleavage of dsDNA by intercalated AQ, and the latter leads to non-sequence-selective cleavage of dsDNA by nonintercalated AQ. In this report, we present the preparative method of the functional particles that are composed of polymer latex particles, MutS protein, and AQ and the characterization results. The intended functional particles offer several distinct advantages: (1) Composed of polymer latex particles, they are easy to handle, separate, and collect compared to other devices such as hybrid enzyme. (2) The extremely small diameter of the particles (200 nm) provides a large surface area, giving the particles a relatively high capacity (*20*). (3) MutS protein is expected to be more stable because of being immobilized on the particle surface. (4) By means of photocleavage of mismatched DNA by AQ, a mismatch detection system constructed using the functional particles is easy and simple. These functional particles carrying AQ-MutS hybrid on their surface will be an absolutely new device for mismatch detection, as shown in Figure 1.

2. EXPERIMENTAL PROCEDURE

2.1. Materials. For preparation of polymer latex particles, styrene (St), glycidyl methacrylate (GMA), divinylbenzene (DVB), and 2,2′-azobis(2-amidinopropane-)HCl (V-50) were purchased from Wako Pure Chemicals Co. (Tokyo, Japan). St and GMA were distilled at 46 °C/21.5 mmHg and 33 °C/2 mmHg, respectively. DVB was used without further purification. Ethyleneglycol diglycidyl ether (EGDE), *p*-toluenesulfonyl chloride (TsCl), and pyridine for improvement of the particle surface were purchased from Wako Pure Chemicals Co. (Tokyo, Japan). Histidine-tagged MutS protein (MutS-$(His)_6$) was

expressed from *E. coli*. For quantification of protein, the BCA protein assay reagent kit was purchased from Pierce (USA).

Oligonucleotides 5′-ACTTGTGTTAGTTCGAGCTGGT-TGCGTACTCAAGAGTGAT-3′(RM40N-GG), 5′-ATCACT-CTTGAGTACGCAACCAGCTCGAACTAACACAAGT-3′-(RMc40N-CC), 5′-ATCACTCTTGAGTACGCAACTAGCTC-GAACTAACACAAGT-3′(RMc40M-CT), and 5′-ATC-ACTCTTGAGTACGCAACTCAGCTCGAACTAA-CACAAGT-3′(RMc41M-CTC) were chemically synthesized by JBios (Japan). The picogreen dsDNA quantification reagent kit and SYBR-Gold nucleic acid gel stain were purchased from Molecular Probes (The Netherlands). As an anthraquinone derivative (AQ), 2-hydroxymethylanthraquinone (AQ-CH_2OH) was purchased from Tokyo Kasei Kogyo (Japan). Lumi-Phos530, a formulation of the dioxetane substrate 4-methoxy-4-(3-phosphonophenyl)spiro[1,2-dioxetane-3,2′-adamantane] and streptavidin-alkalinephosphatase conjugate (SA-AP) were purchased from Wako Pure Chemicals Co. (Tokyo, Japan) for the chemiluminescence assay.

2.2. Buffers. The following buffers were prepared and used for each process. Immobilization buffer: 10 mM sodium phosphate buffer (pH 7.5), 150 mM NaCl, and 5% (v/v) glycerol. Washing buffer: 10 mM sodium phosphate buffer (pH7.5), 500 mM NaCl, and 5% (v/v) glycerol. DNA-binding buffer: 10 mM sodium phosphate buffer (pH 7.5), 150 mM NaCl, 5% (v/v) glycerol, 5 mM $MgCl_2$, and 0.005% (w/v) tween20. DNA-releasing buffer: 10 mM sodium phosphate buffer (pH 7.5), 150 mM NaCl, 5% (v/v) glycerol, 5 mM EDTA, and 0.005% (w/v) tween20.

2.3. Preparation of Polymer Latex Particles. Basic polymer latex particles (SG particles) were prepared by soap-free emulsion polymerization. St, GMA, and DVB were copolymerized in a soap-free aqueous medium using V-50. Ammonia was reacted with the epoxy groups of the SG particles as a joint, at 70 °C, pH 11 for 24 h. The resulting particles carrying amino groups were reacted with EGDE at 30 °C, pH 11 for 24 h to give a spacer on the particle surface. Then epoxy groups of the ends of the EGDE spacers were hydrolyzed to hydroxyl groups at 40 °C, pH 2 for 24 h. Finally, we introduced tosyl(*p*-toluene sulfonyl) groups according to the method described previously (*21*). The hydrodynamic size of these particles was measured by photon correlation spectroscopy (PCS), using PA3000 from Ohtsuka Electronics Co., Ltd. (Japan). The size and appearance of these particles were observed by transmission electron microscopy (TEM).

2.4. Immobilization of MutS Protein onto Tosylated Particles. Tosylated particles (5 mg) were washed three times with 400 μL of immobilization buffer and mixed with 40, 100, 200, 400, and 800 μg of MutS-$(His)_6$ in 400 μL of immobilization buffer. The coupling reaction was carried out at 4 °C for 4 h. The particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min and washed with 400 μL of washing buffer three times. The amount of immobilized MutS-$(His)_6$ was determined by quantifying the MutS in the supernatant and three consecutive wash solutions by using the BCA protein assay reagent kit. This protein assay reagent enables the quantification of as little as 10 μg/mL MutS-$(His)_6$. Remaining active tosyl groups were blocked and deactivated with 1 mL of immobilization buffer containing 2 mM 2-amino-2-hydroxymethyl-1,3-propanediol (Tris) and were then stored at 4 °C (MutS-immobilized particles).

2.5. Ability of MutS-Immobilized Particles to Discriminate Complementary and Mismatched DNA. MutS-immobilized particles (1 or 0.5 mg) were washed three times with 200 μL of DNA-binding buffer and mixed with various amouns of dsDNAs; RM40N-GG/RMc40N−CC (G/C complementary DNA), RM40N-GG/RMc40M-CT (G/T mismatched DNA) or RM40N-GG/RMc41M-CTC (T-bulge DNA) in 200 μL of DNA-binding buffer (*11*). The binding reaction was carried out at 37 °C for 24 h. The particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min. The amount of dsDNA binding to MutS-immobilized particles was determined by quantifying dsDNA remaining in the supernatant using the picogreen dsDNA quantification reagent kit. The reagent enables the quantification of as little as 25 pg/mL for dsDNA.

2.6. Affinity Elution of dsDNA Bound to MutS-Immobilized Particles. After the binding reaction, MutS-immobilized particles were suspended in DNA-releasing buffer at 37 °C for 24 h. Then the particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min and washed three times with 200 μL of DNA-releasing buffer. The amount of dsDNA eluting from MutS immobilized on the particle surface was determined by quantifying the dsDNA in the supernatant and three consecutive wash solutions using the picogreen dsDNA quantification reagent kit.

2.7. AQ Conjugation to MutS-Immobilized Particles. 2-Hydroxymethylanthraquinone was activated with *p*-toluenesulfonyl chloride to conjugate with MutS-immobilized particles. AQ conjugation to MutS-immobilized particles was carried out at 4 °C for 4 h in immobilization buffer. After conjugation, AQ-MutS-immobilized particles were centrifuged in a microcentrifuge at 12 000*g* for 10 min and washed three times with immobilization buffer. The amount of binding AQ was determined by its maximum absorption with $\lambda_{max} = 330$ nm of the supernatant and three consecutive wash solutions.

2.8. Ability of AQ-MutS-Immobilized Particles To Photocleave Mismatched DNA Selectively. AQ-MutS-immobilized particles (0.5 mg) were washed three times with 200 μL of DNA-binding buffer and mixed with various amount of G/C complementary DNA or G/T mismatched DNA in 200 μL of DNA-binding buffer. The binding reaction was carried out at 37 °C for 24 h. The particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min. The amount of dsDNA binding to AQ-MutS-immobilized particles was determined by quantifying dsDNA remaining in the supernatant using the picogreen dsDNA quantification reagent kit. Additionally, the particles were redespersed

Table 1. Diameter and Transmission Electron Micrograph (TEM) Image of a Series of the Particles

in 200 μL of DNA-binding buffer and irradiated with 365 nm UV light for 30 or 60 min. Then the particles were suspended in 200 μL of DNA-binding buffer at 85 °C for 2 h to denature MutS immobilized on the particle surface. After denaturation, the particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min and washed three times with 200 μL of DNA-binding buffer. The amount of dsDNA detached from AQ-MutS immobilized on the particle surface was determined by quantifying the dsDNA in the supernatant and three consecutive wash solutions using the picogreen dsDNA quantification reagent kit.

2.9. **Chemiluminescence Assay.** Biotinylated RM40N-GG was purchased and hybridized with RMc40N-CC or RM40N-CT (Bio-G/C complementary DNA or Bio-G/T mismatched DNA). After the binding and photocleaving reactions of it with AQ-MutS-immobilized particles, 200 μL of 20mU/ml SA-AP solution was added and incubated for 30 min at room temperature to complete the biotin−avidin reaction. Then the particles were collected by brief centrifugation in a microcentrifuge at 12 000*g* for 10 min and washed three times with 200 μL of DNA-binding buffer. After the dispersion of the particles was diluted, a 120 μL aliquot of Lumi-Phos530 was added to the Bio-DNA and SA-AP complex. The alkalinephosphatase-catalyzed dephosphorylation of the dioxetane substrate was followed to proceed in the dark for 1 h at room temperature. The mixture was then transferred to a cuvette and the chemiluminescent signal (CL signal) was measured by a luminometer.

2.10. Construction of Mismatch Detection System using AQ-MutS-Immobilized Particles. AQ-MutS-immobilized particles (40 μg) and various amounts of G/C complementary DNA or G/T mismatched DNA were added in 200 μL of DNA-binding buffer. The mixture was kept standing at 37 °C for 6 h and irradiated with 365 nm UV light for 60 min. Then a dsDNA-binding fluorescent dye, SYBR-Gold, was added to the mixture, and the mixtue was dropped in a 96-well microtiter to measure the fluorescence with a spectrometer.

3. RESULTS AND DISCUSSIONS

3.1. Preparation of Tosylated Particles and Immobilization of MutS Protein onto the Particles. We had previously developed affinity latex particles composed of a poly(glycidyl methacrylate) (polyGMA)-covered GMA-styrene (St) copolymer core (SG particles) that were originally used for affinity purification (*8*, *9*). To reduce steric hindrance, we introduced ethyleneglycol diglycidyl ether (EGDE) as a spacer after aminolysis of the epoxy groups on the particle surface. For protein immobilization, we introduced tosyl groups after hydrolysis of epoxy groups of the ends of EGDE spacers on the particle surface. The diameters of initial, intermediate, and final particles by PCS and TEM are shown in Table 1. SG particles and the series of modified SG particles were monodisperse. The fact that the final particles were monodisperse indicated EGDE was immobilized without interparticle cross-linking (*14*). Introducing the EGDE spacer makes the particle surface hydrophilic, thus minimizing nonspecific protein binding (*8*) and also gives the particle chemical and physical stability in organic solvents (*14*). According to the elementary analysis, the tosylated particles had 456 μmol of tosyl groups/g particles (11 units/nm^2) on the surface.

In this study, there are two possible ways to prepare the functional particles. One way is to immobilize MutS onto the polymer latex particles first and then to conjugate AQ to MutS-immobilized particles, and the other is to immobilize AQ-MutS hybrid prepared beforehand onto the polymer latex particles. In the latter way the AQ-MutS hybrid after being immobilized on the particles had lost its mismatch binding activity (data not shown), so that we decided to adopt the former way. Immobilization of MutS onto tosylated particles was carried out at pH 7.5 and 4 °C for 4 h. The coupling of protein with the tosyl group has some advantages: (1) The coupling reaction can be performed at neutral pH and at 4 °C. (2) The amino, thiol, and imidazole groups of protein directly react with the carbon atoms of the tosyl end of the spacer, so that side reactions hardly occur during the coupling

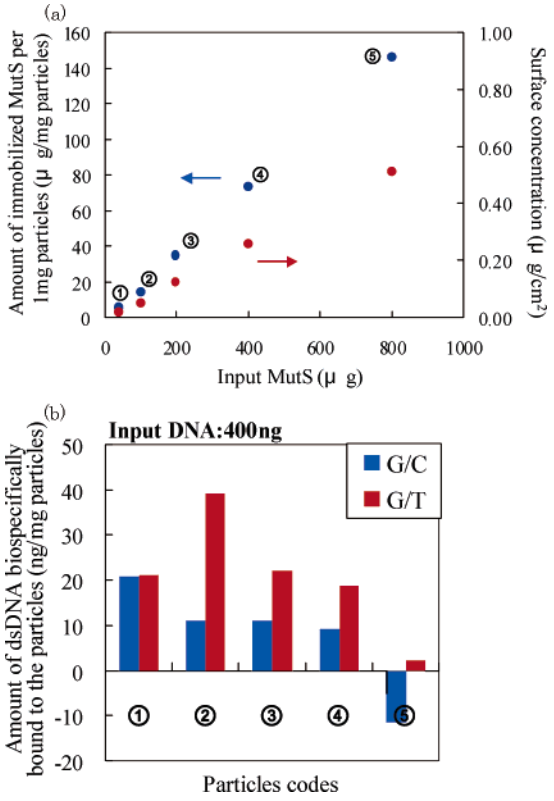

Figure 2. (a) Immobilization of MutS onto tosylated particles. (b) Amount of dsDNA bound to various MutS-immobilized particles. Binding reaction was performed at 37 °C for 30 min in IB containing 5 mM $MgCl_2$. (Amount of dsDNA biospecifically bound to MutS = amount of dsDNA adsorbed on MutS-immmobilized particles − amount of dsDNA adsorbed on bare particles.)

reaction. (3) Protein is covalently coupled to spacers through a carbon−nitrogen or a carbon−sulfur bond, which is expected not to be broken by hydrolysis (*22*). Figure 2a shows that the amount of MutS immobilized onto the particles increased proportionally to the charged amount. Amount of MutS immobilized on the particles was ① 5.5, ② 14.3, ③ 34.9, ④ 73.1, and ⑤ 145.7μg/mg particles, which corresponds to ① 0.02, ② 0.05, ③ 0.12, ④ 0.26, and ⑤ 0.51μg/cm^2, respectively. The apparent density of MutS molecules on the particle was calculated to be ① 0.3, ② 0.8, ③ 1.8, ④ 3.8, and ⑤ 7.5 molecules/nm^2, assuming that the surface is flat. The values of the latter two, 3.8 and 7.5 molecules/nm^2, are too large to imagine the presence of MutS immobilized on the particle in a single layer. Using the series of MutS-immobilized particles, an experiment of discriminating complementary and mismatched DNAs was carried out. Figure 2b shows amounts of dsDNA biospecifically bound to MutS-immobilized particles at 37 °C for 30 min. It is clear that the difference in the amounts between complementary and mismatched DNA binding to code- ② particles was highest among the series of MutS-immobilized particles. That is, code- ② particles had the highest ability to discriminate complementary and mismatched DNA. It is concluded that there is an appropriate amount of MutS immobilized on the particles. If the amount of MutS immobilized on the particles is low, fewer DNA binding sites are present on the particles, so less DNA is captured. On the other hand, if amount of MutS immobilized on the particles is high, MutS molecules are too close to each other to allow DNA binding to all MutS molecules. Therefore the highest ability of MutS-immobilized particles to discriminate complementary and mismatched DNA would be obtained by immobilizing MutS with the density at which it retain its natural conformation.

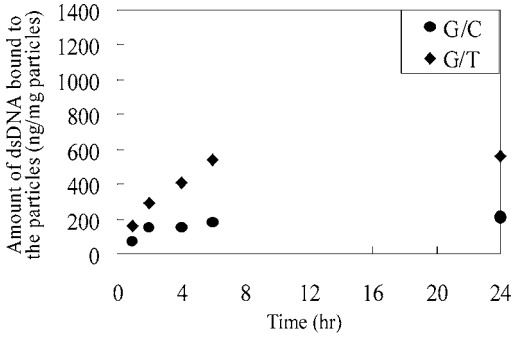

Figure 3. Time dependence of binding reaction of dsDNA with MutS-immobilized particles. Binding reaction was performed at 37 °C for 1, 2, 4, 6, and 24 h in DNA-binding buffer.

3.2. Improvement of MutS-Immobilized Particles. To improve the ability of MutS-immobilized particles to discriminate complementary and mismatched DNA, some of active tosyl groups of tosylated particles were reacted with 2-amino-2-hydroxymethyl-1,3-propanediol (Tris) before immobilization of MutS onto tosylated particles. Masking of some of the active tosyl groups with Tris before immobilization caused an increase in the amount of mismatched DNA caught by MutS on the particles, as well as the ability of MutS-immobilized particles to discriminate complementary and mismatched DNA. This would be because MutS was prevented from being immobilized at multiple points on the particles by the Tris-masking treatment before immobilization, so its native conformation remained, and/or the surface of MutS-immobilized particles was positively charged owing to Tris-masking treatment, so anionic dsDNA was easy to interact with the particles electrostatically. Therefore we prepared MutS-immobilized particles in this way afterward.

Figure 3 shows time dependence of the binding reaction of dsDNA with MutS-immobilized particles at 37 °C. The result indicates that MutS-immobilized particles caught more dsDNA, both G/C complementary and G/T mismatched DNAs, with increasing binding reaction time, and the amounts of dsDNA bound to the particles became a plateau within 24 h. From this result, we adopted 24 h as the sufficient binding reaction time at which binding reaction of dsDNA with MutS-immobilized particles was considered to be at equilibrium at 37 °C.

3.3. Ability of MutS-Immobilized Particles To Discriminate Complementary and Mismatched DNAs and Affinity Elution of dsDNA Bound to MutS-Immobilized Particles. In the experiment for discriminating complementary and mismatched DNAs using MutS-immobilized particles, the ability of MutS-immobilized particles to discriminate complementary and mismatched DNAs (DM) was defined as follows:

$$\mathrm{DM}\ (\%) = \left(1 - \frac{\text{amount of particle-bound complementary DNA}}{\text{amount of particle-bound mismatched DNA}}\right) \times 100 \quad (1)$$

Figure 4a shows the amount of dsDNA bound to MutS-immobilized particles at 37 °C for 24 h and DMs calculated by eq 1. DMs were 79% and 86% for G/T mismatched DNA and T-bulge DNA, respectively. The difference between the two can be explained by the reported property of MutS that the order of its binding

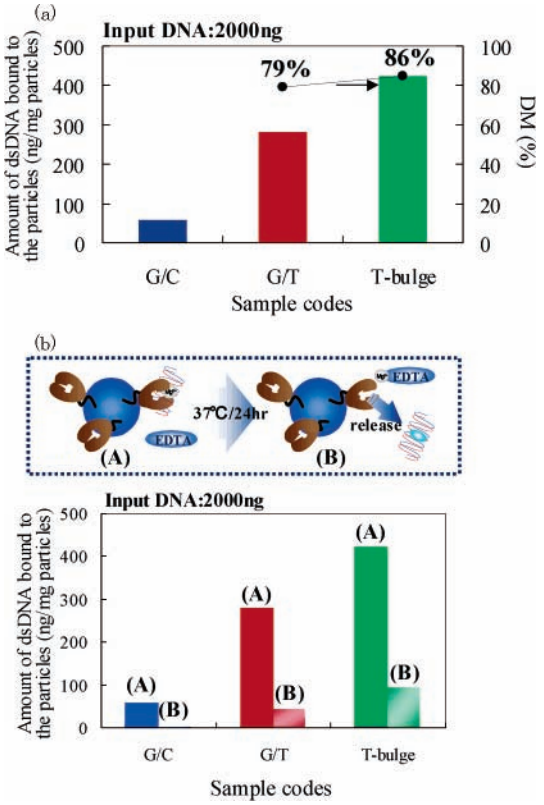

Figure 4. (a) Amount of dsDNA bound to MutS-immobilized particles and ability to discriminate complementary and mismatched DNAs (DM) of MutS-immobilized particles. Binding reaction was performed at 37 °C for 24 h in DNA-binding buffer. (b) Amount of dsDNA bound to MutS-immobilized particles before and after elution.

affinity to different mismatches is ΔT > GT > GG > AA ≈ TT ≈ TC > CA > GA > CC > GC (*23*). The result indicates that MutS immobilized on the particles could have similar relative binding affinity to free MutS. The experiments were carried out using MutS-immobilized particles on which MutS was immobilized to the particle through the EGDE spacer. The spacer could afford MutS immobilized on the particles to act freely, so MutS-immobilized particles could retain their mismatch binding activity as described in other reports; MutS immobilized by binding to nitrocellulose (*24*) or Trx-His_6-Linker peptide-Strep-tag II-Linker peptide-MutS (THLSLM) immobilized on the chip matrix coated with streptavidin through the Strep-tag II-streptavidin binding reaction (*25*). The EGDE spacer is considered to have the appropriate chain length and hydrophilicity for protein immobilization.

Figure 4b shows the amount of dsDNA bound to MutS-immobilized particles before and after elution using EDTA; the amount of dsDNA bound to the particles after elution has obviously decreased. This result means that dsDNA bound to MutS-immobilized particles was eluted by chelating effect of EDTA. That is, Mg^{2+} contributes to the formation of dsDNA and MutS hybrid (*26*), and the above-mentioned affinity elution was due to a drastic decrease of binding affinity for dsDNA of MutS owing to chelation of Mg^{2+} with EDTA.

Taking advantage of this affinity elution using EDTA, we tried reusing MutS-immobilized particles. A series of binding and eluting treatment was performed three times, and the amount of dsDNA bound to MutS-immobilized particles and DMs in each cycle are shown in Figure 5. It is found from Figure 5 that MutS-

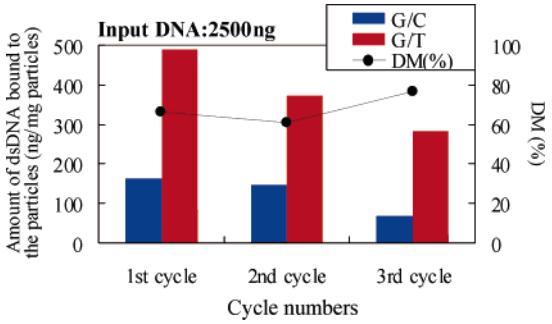

Figure 5. Comparison of ability (DM) to discriminate complementary and mismatched DNAs of MutS-immobilized particles for each cycle. Binding reaction was performed at 37 °C for 24 h in DNA-binding buffer.

immobilized particles were reusable for three continuous uses. In each cycle DM was about 70% but the amount of dsDNA bound to the particles decreased as the number of times increased. This is due to incompleteness of affinity elution using EDTA, shown in Figure 4b. That is, some of MutS immobilized on the particles was occupied by dsDNA remaining after elution, and consequently the substantial amount of MutS immobilized on the particles that was expected to be usable in next cycle had decreased.

3.4. Preparation and Characterization of AQ-MutS-Immobilized Particles. Conjugation of AQ to MutS-immobilized particles was carried out at 4 °C through tosyl chloride activation (*22*). A series of hybrid particles, AQ-MutS-immobilized particles carrying different amounts of AQ, were prepared, and first their ability to discriminate complementary and mismatched DNAs was examined at 37 °C for 24 h. Figure 6a and b shows the number of bound AQ per MutS immobilized on the particles and the amount of dsDNA bound to AQ-MutS-immobilized particles and DMs calculated by eq 1. It is found from Figure 6a and b that the amount of binding AQ had little effect on the DM. The series of AQ-MutS-immobilized particles had the same DMs as MutS-immobilized particles. That is, there is retention of mismatch binding activity of MutS immobilized on the particles after conjugation of AQ.

Second, the activity of AQ-MutS-immobilized particles to photocleave mismatched DNA was assessed by using the series of AQ-MutS-immobilized particles mentioned above. The results in Figure 7 show us that AQ-MutS-immobilized particles with more AQ cleaved more mismatched DNA and suggest that AQs bound to MutS immobilized on the particles retained their activity to photocleave dsDNA. This cleavage of mismatched DNA occurred upon irradiation with 365 nm light. There are two mechanisms in the cleavage of mismatched DNA by AQ on UV irradiation. The one is base selective cleavage and the other is nonselective. The fomer takes place with the aid of piperidine, which contributes electron transfer to AQ from a base near the intercalated AQ, whereas the latter takes place through hydrogen atom abstraction from the deoxyribose component of the nucleic acid backbone by nonintercalated AQ (*18*, *19*). The spontaneous cleavage of mismatched DNA in the present system suggested that the cleavage was the nonselective mechanism by the nonintercalated AQ. Using the AQ-MutS-immobilized particles that had the highest activity to photocleave mismatched DNA, time dependence of the binding reaction of dsDNA with the particles at 37 °C was also examined. The results in Figure 8 indicate that the particles caught more dsDNA with increasing binding reaction time, and the amounts of dsDNA bound to the

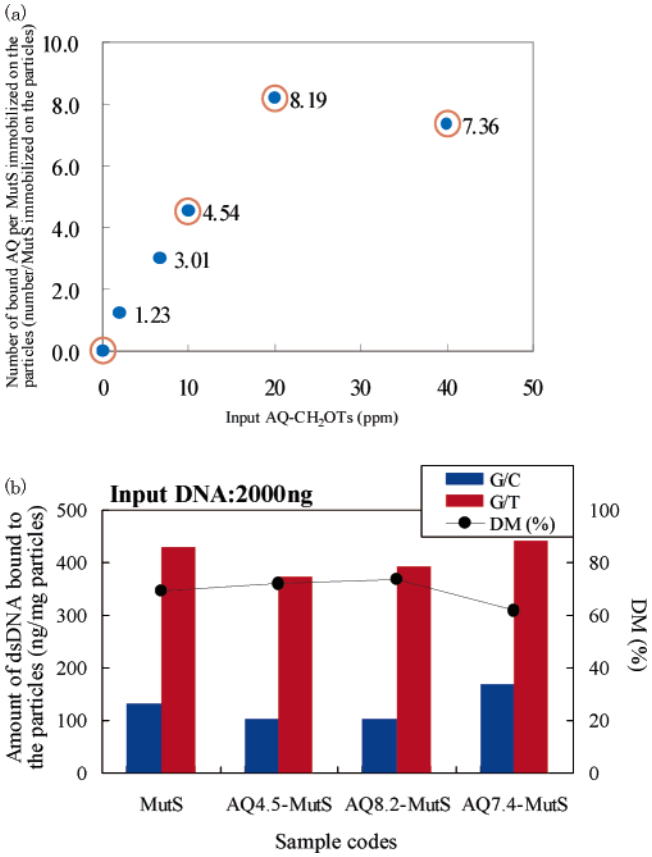

Figure 6. (a) AQ conjugation to MutS-immobilized particles. (b) Comparison of ability (DM) to discriminate complementary and mismatched DNAs among AQ-MutS-immobilized particles with different amount of AQ. Binding reaction was performed at 37 °C for 24 h in DNA-binding buffer.

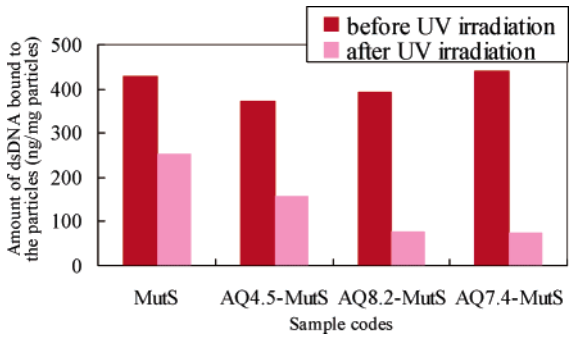

Figure 7. Comparison of ability to photocleave mismatched DNA among a series of AQ-MutS-immobilized particles.Photocleaving reaction was performed at 25 °C for 30 min in DNA-binding buffer. After photocleaving reaction, reaction buffer was treated at 85 °C for 2 h to denature MutS immobilized on the particles.

particles became a plateau within 24 h. From this results, as the sufficient binding reaction time we adopted 24 h, when the binding reaction of dsDNA with the AQ-MutS-immobilized particles was considered to be at equilibrium at 37 °C like MutS-immobilized particles. Then values for the dissociation constant (K_d) for the G/C homoduplex and G/T heteroduplex of AQ-MutS-immobilized particles were determined by Scatchard analysis. The K_d values were 1000 and 68.5 nM for the G/C homoduplex and G/T heteroduplex, respectively. These results indicate that the particles had a high affinity for G/T heteroduplex, and the specificity value corresponding to the quotient $K_{d(G/C)}/K_{d(G/T)}$ was 14.6 (*27*). On the other hand, K_d values of MutS-immobilized particles were 909.1 and 65.4 nM

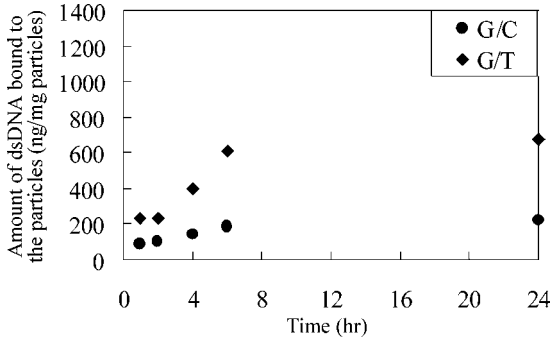

Figure 8. Time dependence of binding reaction of dsDNA with AQ-MutS-immobilized particles. Binding reaction was performed at 37 °C for 1, 2, 4, 6, and 24 h in DNA-binding buffer.

for for G/C homoduplex and G/T heteroduplex, respectively. The K_d values of AQ-MutS-immobilized particles were as same as those of MutS-immobilized particles. In this experiment we evaluated AQ-MutS-immobilized particles using a fluorescence assay that was indirect. Therefore we needed to revaluate the particles using another assay, that is, the chemiluminescence assay mentioned below.

3.5. Chemiluminescence Assay for Characterization of AQ-MutS-Immobilized Particles. The chemiluminescence assay was composed of biotinylated DNA, streptavidin-alkalinephosphatase conjugate (SA-AP), and Lumi-Phos530. In this assay a chemiluminescent reaction is triggered by enzymatic reaction by SA-AP bound to biotinylated DNA through biotin−avidin interaction. It was reported that as little as mamoles (10^{-21} mol) of alkalinephosphatase was detected without particle influence on chemiluminescent signals under a low particle concentration using Lumi-Phos530 (*28*). Therefore the chemiluminescence assay is considered to be a highly sensitive and direct method that can detect dsDNA caught by MutS immobilized on the particles. The results in Figure 9 show that AQ-MutS-immobilized particles could discriminate G/C complementary and G/T mismatched DNAs and cleave G/T mismatched DNA caught by MutS selectively upon UV irradiation. It is also found that the DM of AQ-MutS-immobilized particles was 96.9%, the same as that of MutS-immobilized particles, and the efficiency of photocleavage of G/T mismatched DNA increased with UV irradiation time. That is, AQ-MutS-immobilized particles retained the mismatch binding activity of MutS and photocleaving activity of AQ. It is due to washing of the particles for elimination of nonspecific adsorbed SA-AP in the chemiluminescence assay that the DM calculated in the chemiluminescence assay was higher than in the fluorescence assay. It is confirmed that DM increased because the amount of dsDNA nonspecifically bound to the particles decreases as time of washing increases (data not shown). Fluorescence and chemiluminescence assays proved that AQ-MutS-immobilized particle could catch and cleave mismatched DNA selectively.

3.6. Construction of Mismatch Detection System using AQ-MutS-Immobilized Particles. Finally we tried to construct a new mismatch detection system using AQ-MutS-immobilized particles. The mismatch detection system consisted of AQ-MutS-immobilized particles, and a dsDNA-binding fluorescent dye, SYBR-Gold, was tested. Figure 10 shows relative fluorescence intensity of G/C complementary and G/T mismatched DNAs before and after UV irradiation. Only the spot of G/T mismatched DNA caught by AQ-MutS-immobilized particles and UV irradiated was bright, that is, weak in fluorescence. The

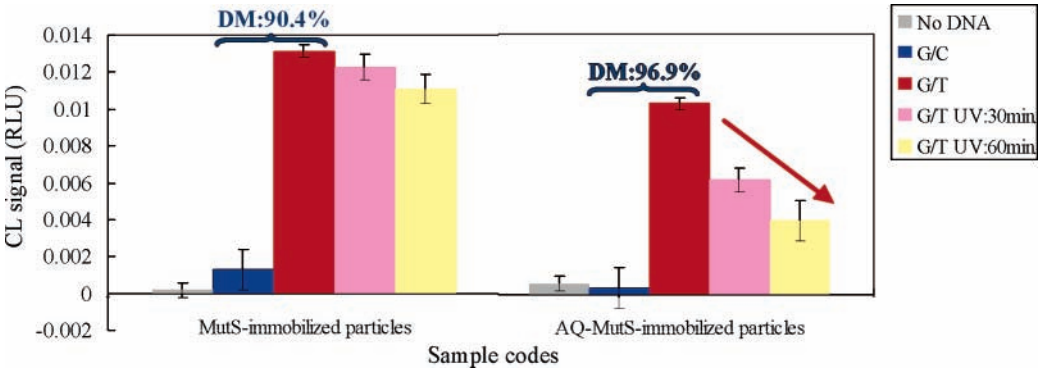

Figure 9. Ability to discriminate complementary and mismatched DNAs and photocleave mismatched DNA using AQ-MutS-immobilized particles. Binding reaction was performed at 37 °C for 24 h in DNA-binding buffer. Photocleaving reaction was performed at 25 °C for 30 and 60 min in the same buffer.

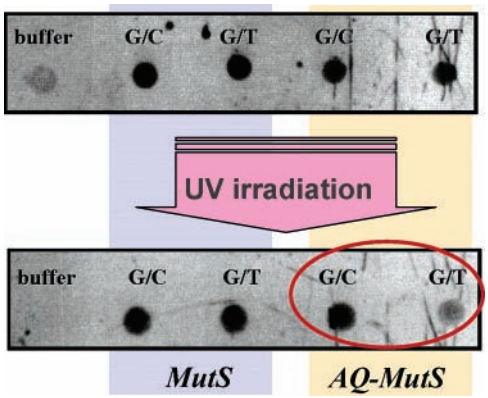

Figure 10. Relative fluorescence intensity of G/C complementary and G/T mismatched DNAs (2.22 nM) before and after UV irradiation in the mismatch detection system using AQ-MutS-immobilized particles (200 ng/μL) and a dsDNA-binding fluorescent dye, SYBR-Gold. Binding reaction was performed at 37 °C for 6 h in DNA-binding buffer and photocleaving reaction was performed at 25 °C for 60 min in the same buffer.

results in Figure 10 suggest that AQ-MutS-immoblized particles cleaved G/T mismatched DNA selectively upon UV irradiation for 60 min. This system enables the detection of mismatched DNA with 40 base pairs by decrease of relative fluorescence intensity after UV irradiation. Clearer all-or-none detection could be done if we carried out the experiment using more AQ-MutS-immobilized particles, although in such a case a step to separate the particles from supernatant should be necessary before measurement. Our system is expected to be practically usable even in diluted dispersion when the 40-mer DNA amplified by PCR is applied. In comparison with other methods to discriminate mismatch DNA (*3*−*7*), our method is simple, regardless of the chain length of sample DNA in theory, and needs no large-scaled instruments. The storage stability of the dispersion of AQ-MutS-immobilized particles was guaranteed for more than 3 months judging from the reproducible results obtained after long storage. In conclusion, we could propose a new mismatch detection system and show that AQ-MutS-immobilized particles would be a useful tool for mismatch detection in DNA diagnosis.

4. CONCLUSIONS

This work proposes a new mismatch detection system by the usage of functional polymer latex particles that can catch and cleave mismatched DNA selectively. We showed that the functional polymer latex particles carrying MutS, mismatch binding protein, and anthraquinone derivative (AQ), a light-activated agent that photocleaves dsDNA, could discriminate G/C complementary and G/T mismatched DNAs and cleave G/T mismatched DNA selectively upon irradiation with 365 nm light. The efficiency of photocleavage of G/T mismatched DNA increased as the number of AQ bound to MutS immobilized on the particles increased and as UV irradiation time extended. In this paper the system consisting of AQ-MutS-immobilized particles and a dsDNA-binding fluorescent dye, SYBR-Gold, was able to detect mismatched DNA with 40 base pairs. The functional particles developed in this work are an absolutely new tool for mismatch detection in DNA diagnosis.

Protein microarray technologies provide a means of investigating the proteomic content of clinical biopsy specimens in order to determine the relative activity of key nodes within cellular signaling pathways. A particular kind of protein microarray, the reverse-phase microarray, is being evaluated in clinical trials because of its potential to utilize limited amounts of cellular material obtained through biopsy. Using this approach, cellular lysates are arrayed in dilution curves on nitrocellulose substrates for subsequent probing with antibodies. To improve the sensitivity and utility of reverse-phase microarrays, we tested whether a new reporter technology as well as a new detection instrument could enhance microarray performance. We describe the use of an inorganic fluorescent nanoparticle conjugated to streptavidin, Qdot 655 Sav, in a reverse-phase protein microarray format for signal pathway profiling. Moreover, a pegylated form of this bioconjugate, Qdot 655 Sav, is found to have superior detection characteristics in assays performed on cellular protein extracts over the nonpegylated form of the bioconjugate. Hyperspectral imaging of the quantum dot microarray enabled unamplified detection of signaling proteins within defined cellular lysates, which indicates that this approach may be amenable to multiplexed, high-throughput reverse-phase protein microarrays in which numerous analytes are measured in parallel within a single spot.

INTRODUCTION

The pathophysiology of cancer is effected, in part, by proteins elaborated by diseased and normal cells within the tumor microenvironment (*1*). An important milestone in understanding tumorigenic processes is uncovering the nature of tumor cell signaling pathways (*2*). Certain classes of proteins form noncovalent associations, or networks, that comprise signaling pathways. With each association, one protein (a kinase) confers a posttranslational modification such as phosphorylation on its binding partner. This type of interaction is a fundamental means of cellular communication in a cellular environment and underlies the development of malignancy through potentiation of cellular motility, invasiveness, motility, proliferation, and evasion of apoptosis.

Reverse-phase protein microarrays (RPMAs; Figure 1) are an emerging high-throughput technology that offer a means to quantitatively measure both protein levels and posttranslational modifications of signaling proteins in clinical specimens (*3*−*6*). Current genomic techniques are unable to measure such modifications, which are important determinants of protein activity. In this assay, the lysates contain heterogeneous protein mixtures, or analytes, obtained from laser capture microdissected tumor cells extracted from individual patient specimens.

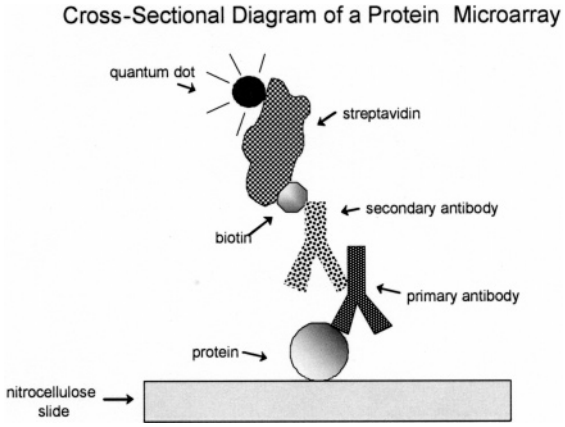

Figure 1. Reverse-phase microarray. In the RPMA, proteins extracted from cellular lysates are arrayed onto a nitrocellulose substrate and probed with a primary antibody. In turn, a biotinylated secondary antibody recognizes the presence of the primary antibody. The biotinyl groups are then detected by streptavidin linked to reporter molecules such as quantum dots or enzymes such as HRP that carry out catalyzed reporter deposition for signal amplification.

These lysates are noncovalently immobilized onto an array surface such as nitrocellulose and then probed by a variety of techniques. This reverse-phase format enables the measurement of low-abundance proteins from a minute amount of scarce clinical samples (on the order of nanoliters) and allows the clinical investigator or clinical lab specialist to compare numerous distinct patient samples, various clinical stages of cancer, mor-

phological subtypes, and uninvolved tissues in parallel for side-by-side comparisons of protein activity and signal pathway analysis.

The analytes are detected using an interacting molecule such as a recombinant protein, an antibody, small molecules such as drugs, DNA aptamers, or phage display libraries. Because the analytes can be analyzed in a denatured or native protein format, antibodies useful for western blotting to detect sequential epitopes can be utilized in addition to antibodies employed in ELISAs for conformational epitopes. In fact, RPMAs are especially useful in measuring phospho-specific events since these epitopes are usually masked and require denaturation of the target molecule prior to analysis. The presence of a bound primary antibody can then be visualized through the use of several technologies. For example, the presence of a bound biotinylated antibody can in turn be detected by streptavidin linked to a reporter molecule. This allows a single reporter system to be applied to various, different primary probes. Whereas DNA microarrays benefit from nucleic acid amplification for increased sensitivity, proteins cannot be similarly amplified. Therefore, the detection systems for protein arrays must have a built-in signal enhancement step. A variety of conventional labeling techniques, including radioactivity (*7*), chromagens, and fluorescence (*8*, *9*), have been used to report the presence of proteins on arrays. However, in their current forms, they often have significant limitations in terms of their sensitivity, dynamic range, durability, speed, safety, and ability for multiplexing.

When investigating clinical specimens, a reporter system with a broad dynamic range is required so that disparate quantities of input material can be effectively measured under a single format or experiment in which detection saturation is not easily achieved. A common means of expanding the dynamic range of a protein assay is through the use of fluorescent reporter molecules, and there is an abundance of commercially available organic fluorophores that have been used to tag biological molecules. Unfortunately, many organic fluorescent molecules lack the sensitivity of amplified chromogenic systems and are highly susceptible to photobleaching. Application of emerging nanotechnologies to biology and medicine has produced an alternative class of fluorescently labeled probes through the conjugation of inorganic fluorophores called quantum dots (QDs) to biological interacting molecules (*10*−*12*). QDs are fluorescent, semiconducting nanocrystals, ranging in size from 1 to 10 nm. These nanoparticle labeling agents possess broadband excitation bandwidths with narrow emission bandwidths, large extinction coefficients, and very high quantum yields that result in bright fluorescence. Because of these factors, QDs have distinct advantages over organic fluorescent reporter molecules. Moreover, due to their resistance to photobleaching, QDs produce signals that can be time averaged.

To evaluate methods that could increase the sensitivity and potential for multiplexing the reverse-phase microarray technology, we tested whether QDs could be used as reporter agents using this methodology. Further, we investigated the utility of hyperspectral image analysis in detecting primary, unamplified QD signals (*13*, *14*), which could dramatically improve the chances for high-throughput and rapid analysis. We report here the coupling of QD reporter molecules and hyperspectral imaging techniques that results in the detection of primary, unamplified signals in assays probing for the presence of signaling proteins present in cellular extracts. The detection of numerous unamplified signals within the same protein spot heralds the approach of truly multiplexed quantitative microarray assays for protein activity. This approach has potential utility in clinical settings, enabling selection of personalized therapeutic regimes (*15*).

MATERIAL AND METHODS

Cellular Lysate Preparation. Whole cell lysates were prepared in the following manner. Jurkat cells (clone E6-1, ATCC, Manassas, VA) were grown in RPMI 1640 media (Invitrogen, Carlsbad, CA) supplemented with 10% heat inactivated fetal bovine serum supplemented with 1 mM L-glutamine. Jurkat cells (3×10^6) were then treated with 0.5 μg/mL anti-Fas antibody (Upstate, Waltham, MA) per 1 mL of media at 37 °C in 5% CO_2 for 6 h in order to induce apoptosis. Treated Jurkat cells were harvested by centrifuging the cells at 4 °C for 10 min at 1000 rpm. Subsequently, the cells were washed twice in cold phosphate buffered saline (PBS). The cell pellets were then lysed in a buffer consisting of T-PER (Pierce, Rockford, IL), 2x Tris-glycine SDS loading buffer (Invitrogen, Carlsbad, CA), and β-mercaptoethanol (Sigma, St. Louis, MO). The cellular lysates were vortexed, centrifuged, and stored at −20 °C. A431 cell lysates generated from cells treated with EGF were purchased from a commercial source (BD Biosciences, Chicago, IL).

Reverse-Phase Microarrays. The reverse-phase microarrays were generated as previously described (*6*). Lysates, diluted 1:1 in sample buffer (1 mL of T-PER extraction buffer added to 950 μL of 2x SDS sample buffer and 50 μL of β-mercaptoethanol), were arrayed on nitrocellulose-coated FAST glass slides (Schleicher & Schuell Bioscience, Keene, NH) using a GMS 417 pin-and-ring arrayer (Affymetrix, Santa Clara, CA) that utilizes 500 μm^2 pins. The lysates were arrayed in serial dilutions with a negative control (sample buffer only) included. Approximately 1.5 nL per spot was arrayed, and the slides were stored at −20 °C in a desiccated environment (Dreirite, W. A. Hammond, Xenia, OH) or used immediately.

Immunostaining Procedure. Once the slides were arrayed, they were placed into 1X Re-Blot, mild solution (Chemicon, Temecula, CA), for 15 min to relax protein structure. After the Re-Blot was removed, the slides were washed two times for 5 min each in PBS. The slides were placed into I-Block dissolved in PBS/0.1% Tween-20 for at least 2 h (Applied Biosystems, Foster City, CA) and were then immunostained using an automatic slide stainer (Autostainer Dako Cytomation, Carpinteria, CA) using manufacturer-supplied reagents. Briefly, the slides were incubated for 5 min with hydrogen peroxide and then rinsed with high-salt Tris-buffered saline (CSA Buffer, Dako) supplemented with 0.1% Tween-20. The slides were blocked with avidin block solution for 10 min, rinsed with CSA buffer, and then incubated with biotin block solution for 10 min. After another CSA buffer rinse, a 5 min incubation with Protein Block solution was followed with air-drying. The slides were then incubated with either a specific primary antibody diluted in Dako Antibody Diluent or, as a control, only DAKO Antibody Diluent for 30 min. The primary polyclonal antibodies used in the study were specific for ERK and phosphoERK (Cell Signaling Technology, Inc., Beverly, MA) at dilutions of 1:2000 as demonstrated by western blots (data not shown). The slides were washed with CSA buffer. A secondary biotinylated goat anti-rabbit IgG H+L antibody (1:5000) (Vector Labs, Burlingame, CA) was incubated with the arrays for 15 min. For amplification

purposes, the slides were washed with CSA buffer and incubated with streptavidin−biotin complex for 15 min. After another wash with CSA buffer, the Amplification Reagent was added and incubated for 15 min.

For slides developed using the chromogen system, after washing with CSA buffer, streptavidin−horseradish peroxidase (HRP) was added for 15 min, followed by a CSA buffer rinse; slides were incubated in diaminobenzidine (DAB) chromogen diluted in Dako DAB diluent for 5 min. After the chromogen incubation, the slides were washed in deionized water and imaged using a text scanner. For slides developed using QDs and catalyzed reporter amplification instead of streptavidin HRP, pegylated-Qdot 655-PEG-Sav or nonpegylated-Qdot 655-Sav diluted in QD Buffer was incubated for 15 min on the slides (QD reagents obtained from Quantum Dot Corporation, Hayward, CA). The slides probed with QDs were visualized using 254 nm epifluorescent UV lamps in a FluorChem cabinet system (Alpha Innotech, San Leandro, CA). The emission signal was visualized using a 655 nm narrow bandwidth emission filter (Omega Optical, Brattleboro, VT). Signal intensities for both the chromogen and fluorescent systems were measured and quantified using ImageQuant (version 5.2) (Molecular Dynamics) data analysis software.

A noncommercial hyperspectral imaging microscope was used for detecting proteins labeled without the use of catalyzed reporter amplification (*13*). Arrayed slides were pretreated with 1X Re-Blot and I-Block as described above followed by avidin and biotin blocking and then incubation with the DAKO Protein Block solution. After a 30 min incubation with the primary antibodies and subsequent incubation with the biotinylated secondary antibody, the slides were then exposed directly to the pegylated-Qdot 655-PEG-Sav reagent for 15 min. After being washed, the slides were dried and analyzed on the hyperspectral imaging system using a spectrophotometer coupled to a CCD camera. The slit width was 50 μm, and a 100 W Hg lamp was used for excitation. Continuous spectra between 549 and 666 nm were collected for each array.

Calibration of Hyperspectral Imaging System. During the imaging of the unamplified slides on the hyperspectral imaging system, slightly shorter wavelengths were observed from those reported by the manufacturer. To determine whether those values were a result of our imaging system or image analysis package, we calibrated our system using two monochromatic light sources. Briefly, the hyperspectral imaging microscope was configured with the *f*/6.5, $^1/_2$ meter spectrometer and cooled CCD camera. (For the original slide measurements, it was configured with a *f*/1.2 holographic spectrometer, photointensifier, and cooled CCD camera.) The measurement was made by first illuminating an unamplified specimen slide and recording the fluorescence emitted by the QDs used in the labeling reactions. The excitation illumination was provided via an Olympus U-MWIB filter cube (excitation 460−490 nm and emission LP 515 nm). Next, red (632.8 nm) and green (532 nm) lasers were directed through the microscope objective lens and similarly recorded on the same CCD camera array. The QD and laser spectra are overlayed pixel by pixel (Figure 5A). The wavelength scale calibration is provided by the known laser wavelengths. The wavelength measurement of the QD peak was determined from a simple Gaussian fit of the peak. The instrument function of the spectrometer was not subtracted from the spectra before a fit was made, but a spectral image of a non-QD region was subtracted from the data image before fitting the spectra. Ten peaks were measured from different areas of the image cube acquisition. An error of ~1 nm from the measurements and an estimated QD product uncertainty of ~1 nm give a combined error of ~1.414 nm.

RESULTS

Streptavidin-conjugated quantum dots were incorporated into a standard reverse-phase microarray assay to determine their utility as reporter molecules for this type of high-throughput proteomic test (*3*, *6*, *16*). Qdot 655 streptavidin conjugates were used to detect the presence of bound primary antibody/biotinylated secondary antibody complexes on protein lysates arrayed on nitrocellulose surfaces using an Affymatrix robotic arrayer. As a test system, a Jurkat T-cell population was treated with anti-FAS antibody, which induces apoptosis (*17*). This population of induced cells expresses detectable levels of activated ERK signaling protein based on previous laboratory experience and provided an excellent testing system for phosphoactivation of signaling proteins (data not shown).

Scanning/Detection Modalities. After blocking unbound nitrocellulose sites, arrays bearing immobilized cellular lysates were incubated with a rabbit anti-human ERK antibody. Following the washing steps, a biotinylated goat anti-rabbit secondary antibody was incubated for detection of bound anti-ERK primary antibody. To serve as background controls, identical slides were incubated without primary antibody (antibody diluent only). A secondary biotinylated anti-rabbit antibody was then incubated with the arrays. After washing, signal enhancement utilizing catalyzed signal amplification (CSA) was performed. Signal amplification via catalyzed biotinyl tyramide deposition is an effective tool for enhancing the sensitivity of immunoassays and has been previously shown to be useful in detecting intracellular signaling proteins using reverse-phase microarrays (*18*). Subsequently, the arrays were incubated with the Qdot 655 streptavidin reagent. The QD-probed array was scanned using an Alpha Innotech FluorChem imager using an excitation wavelength of 254 nm and emission measured at 655 nm (Figure 2A,C). Several scanning modalities were employed (data not shown), with the most effective signal-to-noise achieved using an Omega Optical filter made for assessment of 655 nm fluorescent emissions (20 nm bandwidth centered at 655 nm with added heavy blocking of wavelengths in the IR and UV ranges).

Nonspecific QD Interactions. While strong signals were observed within the protein spots after incubation with the primary, secondary, and streptavidin reagents, a similar signal was also present on spots incubated only with secondary reagent and the Qdot 655 streptavidin conjugate (Figure 2A). A similar level of background staining was not found in assays performed with the same secondary antibody reagent and a streptavidin-horseradish peroxidase conjugate followed by chromagen deposition with DAB (data not shown). The Qdot 655 streptavidin conjugate signal was restricted to the protein spots and was not present on the blocked nitrocellulose surface, indicating that molecular constituents of the cellular protein extracts were strongly binding to the QD conjugates in a dose-dependent manner.

Reduction of Nonspecific Binding Using Pegylated QD Conjugate. To decrease nonspecific binding, a modified form of streptavidin-conjugated QDs, Qdot 655-PEG-Sav, was used as the detection molecule in the

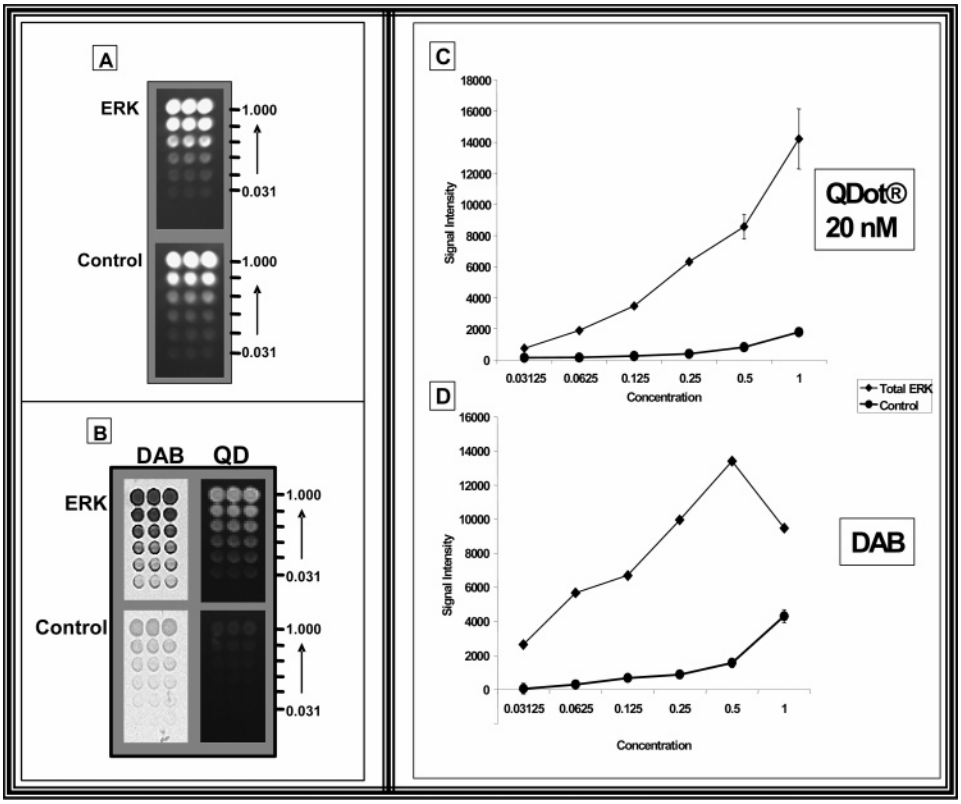

Figure 2. Protein extract binding properties of Qdot-655-SAV conjugates. Jurkat cell lysates, from cells treated with anti-FAS antibody, were arrayed upon nitrocellulose slides in serial dilutions. The array surfaces were then probed with anti-Erk antibody and subjected to biotinyl tyramide amplification. (A) Qdot-655-SAV conjugate (10 nM) was incubated on the arrays. The Qdot-655-SAV conjugate bound equally well to protein spots incubated with anti-ERK antibody or with buffer alone. (B−D) Then, either streptavidin-HRP (B, D) or Qdot 655-PEG-Sav (B, C) (20 nM) were incubated on the arrays. The signal produced by the amplified QDs resulted in a signal intensity per protein spot comparable to that of the standard colorimetric signal (DAB). Low background binding by the pegylated QD was observed. For visualization, the slides probed with QDs were excited using 254 nm UV light for 2 min and visualized using a 655 nm narrow-bandwidth (20 nm) emission filter.

RPMA format. This modification involved the introduction of poly(ethylene glycol) groups onto the streptavidin−quantum dot conjugates. In contrast to the nonpegylated form of the streptavidin-quantum dot conjugate, Qdot 655-PEG-Sav markedly improved the assay by decreasing the intrinsic binding characteristics of the streptavidin QDs to the protein spots (Figure 2B). Only in the presence of a bound primary antibody did Qdot 655-PEG-Sav bind strongly to the protein spots, indicating that the QD signals were limited to the presence of exogenously added biotinylated secondary antibody. Moreover, an identical array was concomitantly analyzed using the chromogen-based assay with DAB deposition as the reporter mechanism, and this also showed a similar staining pattern. The chromogen-based assay was scanned for quantitation using a standard 12-bit text scanner (Figure 2B), while the Qdot-probed array was scanned using an Alpha Innotech FluorChem imager using an excitation wavelength of 254 nm and emission measured at 655 nm (Figure 2C). The QD assay produced an antigen-dependent signal that was linear with a wide dynamic range. Detectable signal was present within the same analyte concentration range observed with the DAB-based chromogenic system; however, the text imaging system was unable to effectively measure the relative amount of chromagen that was deposited at higher protein concentrations due to saturation of the chromagen signal. The QD reporting system, on the other hand, performed well at higher signal intensities, and the dynamic range was significantly broader than the colorimetric method.

Generation of Time-Averaged Signals. One limitation of chromogen-based microarray assays is that only one time period for the development of signal through chromagen deposition can be chosen, and it must be committed to prior to assay performance. This can be a complicating factor in complex assays wherein multiple cellular lysates are arrayed on the same substrate with varying amounts of target proteins present in different dilution curves. The stability of QDs, in addition to their resistance to photobleaching, allows them to be imaged multiple times, for extended periods of time, to capture the linear portions of markedly different dilution curves located on the same array surface. To demonstrate the time-dependence of the quantum dot signal, Jurkat cell lysates, from cells treated with anti-FAS antibody (Figure 3A,B), were arrayed in serial dilutions. The array surfaces were then probed with the anti-ERK antibody. An amplification step followed with deposition of biotinyl tyramide. Qdot 655-PEG-Sav (10 nM) was then incubated on the arrays. The same slide was exposed to UV excitation (254 nm) at 30, 45, and 60 s time intervals. Increasing excitation times increased the signal emission by the QDs, while the background produced by the controls did not increase significantly. This experiment demonstrates the versatility of QDs in generating time-averaged signals. The titration of exposure times allowed the linear portions of various dilution curves to be elucidated in the same assay. Such control over the exposure time cannot be achieved with chromogenic assays, where only one development time is possible.

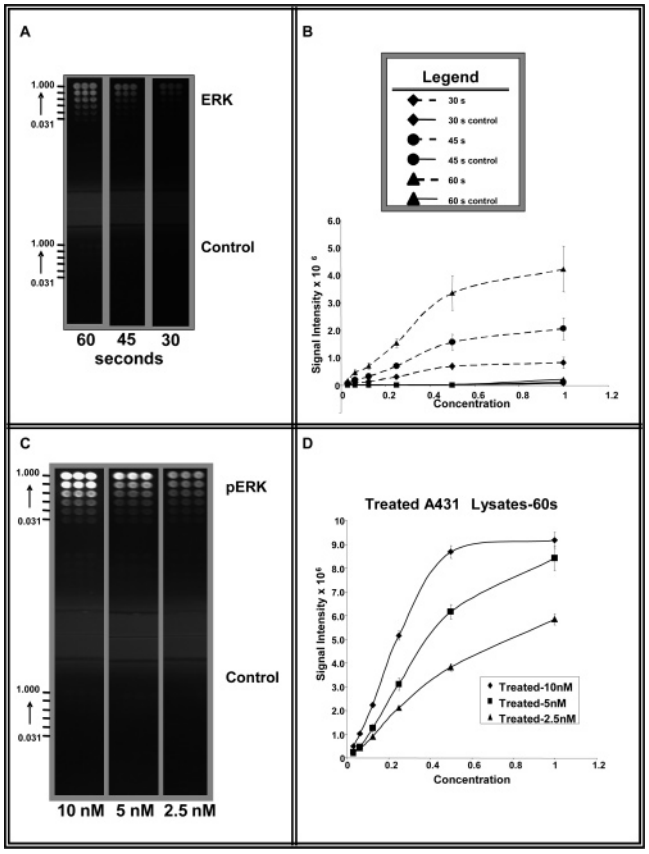

Figure 3. Concentration and time dependence of quantum dot reporter reagents. (A, B) Jurkat cell lysates, from cells treated with anti-FAS antibody, were arrayed upon nitrocellulose slides using serial 1:1 dilutions, probed with an anti-ERK antibody, and subjected to biotinyl tyramide amplification. For background controls, identical slides were incubated without antibody (antibody diluent only). Following the antibody probes, either streptavidin−HRP or Qdot 655-PEG-Sav (10 nM) were then incubated on the arrays. Flourescent slides were exposed to UV excitation (254 nm) at 30, 45, and 60 s time intervals. Increasing excitation times increased the signal emission by the QDs, while the background produced by the controls did not increase significantly. (C, D) EGF-treated A431 lysates were arrayed upon nitrocellulose slides in 1:1 serial dilutions and probed with anti-phosphorylated ERK antibody. For background controls, identical slides were incubated without antibody (antibody diluent only). Following the antibody probes, the slides were then incubated with either streptavidin−HRP or Qdot 655-PEG-SAv. The QD reagent was used at concentrations of 10, 5, and 2.5 nM. A clear dose dependence, based on the amount of QD conjugate added to the system, was observed.

Application of QDs to Alternative Cellular Lysates. To demonstrate the broader applicability of QD detection reagents in reverse-phase arrays, an alternative cellular lysate population was chosen. An epidermal growth factor-treated A431 epidermoid tumor cell line was arrayed on nitrocellulose slides in serial dilutions. The immobilized lysates were then probed with a rabbit anti-human polyclonal antibody that detects phosphorylated ERK (pERK), an activated form of the ERK signaling protein. A secondary biotinylated anti-rabbit antibody was then incubated with the arrays. Again, for the background control, no primary antibody was incubated on the array prior to the addition of a biotinylated anti-rabbit secondary antibody. After an amplification step using the biotinylated tyramide system, the slides were then incubated with Qdot 655-PEG-SAv at varying concentrations (10, 5, and 2.5 nM). The QD-treated slides were then subjected to 254 nm UV excitation, and a 655 nm narrow bandwidth filter was used during imaging (Figure 3C,D). While treated A431 cells did not reveal large increases in total ERK protein levels compared to untreated controls, a large increase in pERK levels was detected after exposure of the cells to EGF (data not shown). EGF is known to lead to phosphorylation of ERK protein (19); this demonstrates the utility of the assay for measuring posttranslational modifications and, thus, protein activation, which is not possible with genomic assays such as DNA microarrays. This experiment also demonstrated that the Qdot 655-PEG-SAv reagent could be applied to an alternative cellular lysate. Furthermore, the dose dependence of the QD signal was demonstrated by greater signal production, with increasing concentration, for a given protein.

Hyperspectral Imaging of QD Microarrays. With present imaging modalities, QD signals are undetectable when used in an unamplified system in RPMAs (data not shown). Hyperspectral imaging enables high-sensitivity scanning for the presence of multiple fluorophores (*13*, *14*). To this end, we tested whether the hyperspectral imager could detect significant signals from unamplified QD RPMA (Figure 4A−D). Indeed, a clear, significant QD signal above background was detected on an unamplfied microarray surface. Further, this measurement was performed on a microarray experiment that had been performed over six months previously, demonstrating the long life of these reporter molecules. Of note, the imaging analysis from our wavelength-calibrated system revealed that the peak emission spectrum was located at 648 nm, rather than the 655 nm emission specified by the supplier, indicating a slight blue-shift in the emission spectrum in our assays (Figure 4E).

Because of the stability of QD emissions over time, several different measurements of the microarrays can be taken at different times to enable optimization of the measurements or for verification of the measurements by different researchers. The hyperspectral image shown below (Figure 4), which had better S/N than at other dates of scanning, revealed a lower-than-expected emission maximum for the QDs (Figure 4E). This experiment indicated that the peak fluorescence of the 655-PEG-SAv reagent, when scanned at that date, was approximately 648 nm. The calculated combined error in our system due to an error of measurement of ~1 nm and an estimated QD product uncertainty of ~1 nm was ~1.414 nm, suggesting a true decrease in the emission wavelength from that reported by the company. To determine whether those measured values resulted from errors in the detection system, a two-laser calibration was performed (Figure 5A). Interestingly, a time-dependent decrease in peak maximum is apparent from the different measurements (Figure 5B).

DISCUSSION

One fundamental goal of clinical proteomics is the development of high-throughput tools that enable limited amounts of patient tissue specimens to be probed for the presence of molecular derangements. RPMAs represent one type of several high-throughput proteomic platforms currently being developed for use in clinical trials. This array format has shown great promise for phosphoproteomic profiling by effectively measuring cellular signaling events. Given the limited amount of material available in biopsy tissue specimens, there is an ongoing effort to improve the sensitivity, robustness, and versatility of RPMAs, so that the maximum amount of information can be extracted from patient specimens. The development of more sensitive detection technologies for

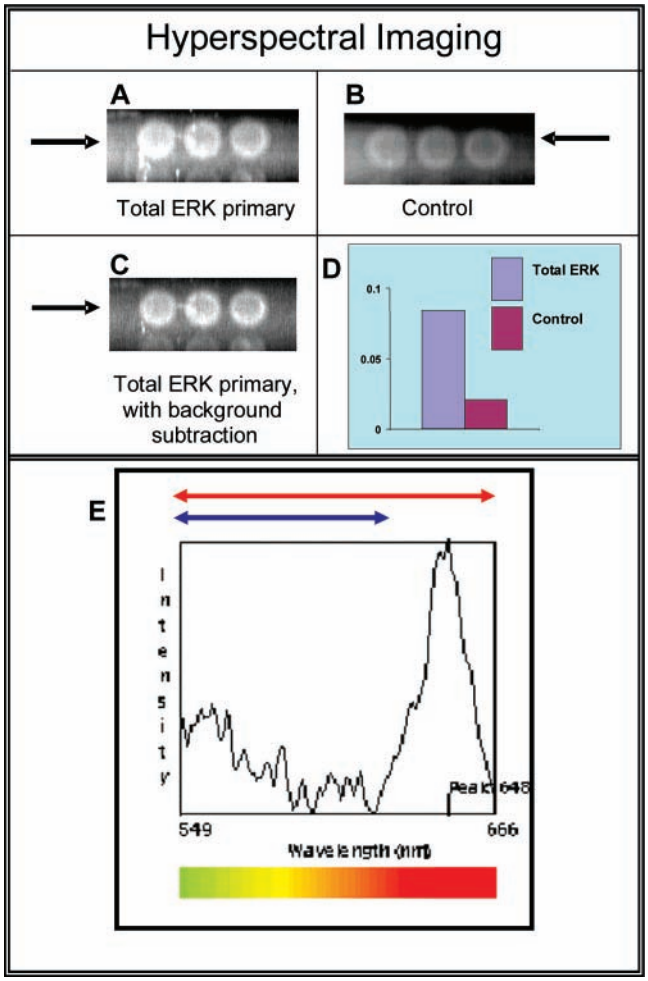

Figure 4. Hyperspectral imager detection of unamplified QD signal. Jurkat cell lysates, from cells treated with anti-FAS antibody, were arrayed upon nitrocellulose slides in a serial dilution. The array surfaces were then probed with anti-ERK antibody. As a background control, an identical slide was incubated without antibody (buffer only). A secondary biotinylated goat anti-rabbit antibody was then incubated with the arrays. Then, Qdot 655-PEG-Sav (20 nM) was incubated with the arrays. The signal produced by the unamplified QDs resulted in a signal detectable by hyperspectral imaging (A, C). Low background binding by the pegylated QD was observed (B). Relative fluorescence intensity is plotted in (D) to compare the signal from the array probed with the primary antibody (A) and the array without the primary antibody (B). The background, non-QD-dependent fluorescence (blue arrow in Figure 4E) was subtracted from the entire continuous spectrum (red arrow in Figure 4E) collected between 549 and 666 nm, resulting in an image signal mostly comprised of QD 655 nm-dependent light. Note, the peak emission spectrum was at 648 nm, an apparent blue-shift from the reported 655 nm peak from the commercial source (E).

protein arrays is being aided by recent developments in nanotechnology.

QDs are a recent example of an emerging nanotechnology. These nanoparticle-scale semiconductor crystals have wide excitation properties and narrow bandwidth emissions, which are generated primarily from elements in Groups II−VI or III−V of the periodic table (*20*, *21*). The emission wavelength can be tuned from the blue to the near-infrared by varying the size and chemical composition of QDs. Also for the same composition of QDs, the smaller the QD, the shorter its emitted wavelength. QDs have higher molar extinction coefficients when excited in the lower wavelength region of the spectrum. For example, QD 605 streptavidin conjugates (by Quantum Dots Corporation, Hayward, CA) have extinction coefficients ranging from 650 000 M^{-1} cm^{-1} at 600 nm to 3 500 000 M^{-1} cm^{-1} at 400 nm and even higher coefficients when excited with higher energy photons. In contrast, fluorescein has a maximum extinction coefficient of 80 000 M^{-1} cm^{-1} (*22*).

Coupled with their dimensional similarity to biomacromolecules, QD conjugates have been shown to be well suited as potential agents for molecular profiling and imaging (*10*, *11*, *20*−*22*). The quantum yields of most organic dye molecules are often decreased upon conjugation to biomolecules. However, higher quantum yields of QD conjugates (up to 80%) that remain unaffected by conjugation to biomolecules have been reported (*22*). Of note, QDs have been used in the development of a filtration-based protein microarray technique that can overcome the diffusion limit and enhance the overall performance of protein microarrays (*23*). The arrays used in that study consisted of an immobilized protein that bound a labeled analyte. Such an array, a forward-phase array, is not optimal for the analysis of heterogeneous clinical specimens and can suffer from lack of unmatched antibody affinities on a single array. The RPMA, as used in our present study, may be a more clinically applicable assay system in that the proteins from cellular lysates are arrayed directly onto a substrate, and since each analyte is measured one at a time, a direct comparison between patients, cell types, or therapeutic response can be evaluated. Direct immobilization of limited target proteins is required in order to realize protein microarrays in a clinical setting. This heterogeneous protein mixture requires a much more sensitive assay than is required for the capture (or forward-phase array) format.

One of the challenges in using QDs for biological studies is the design of hydrophilic QDs that can adapt to various biological environments. Surface coatings such as poly(ethylene glycol) and peptides have been used to decrease nonspecific binding, in the case of PEG, and to provide targeting motifs, in the case of peptides (*24*). QDs coated using an amphiphilic poly(acrylic acid) polymer or PEG are stable in vivo yet have different circulating half-lives (*25*). In the present study, pegylation of streptavidin-conjugated QDs improved the specificity of the binding interactions. Nonpegylated conjugates demonstrated high background binding to protein spots, which was not found with the pegylated conjugate.

QDs have symmetrical, narrow emission peaks unlike organic dyes, which possess asymmetrical and wider emission peaks, especially in the red region of the spectrum. Moreover, the large Stokes shifts between the excitation and emission spectra result in little autofluorescence when using a single common excitation wavelength in the high-UV range for all the different QD colors used in the same assay. These properties lead to minimal overlap, reducing spectral cross-talk between adjacent colors and enabling the possibility of simultaneous analysis of multicolor QDs with multiple narrow bandwidth filters. However, hyperspectral imaging tolerates overlapping spectral signatures. The characteristic property of simultaneous excitation of multicolor QDs with a single light source without appreciable energy transfer among different molecules makes them attractive for numerous biological applications. As it is possible to produce QDs with various emission wavelengths, one potential use of this reporter system is for highly parallel multiplex probing of numerous proteins on a single array. An important step forward toward this goal is the integration of hyperspectral imaging, which enables the detection of mutltiple unamplified QD wavelengths in

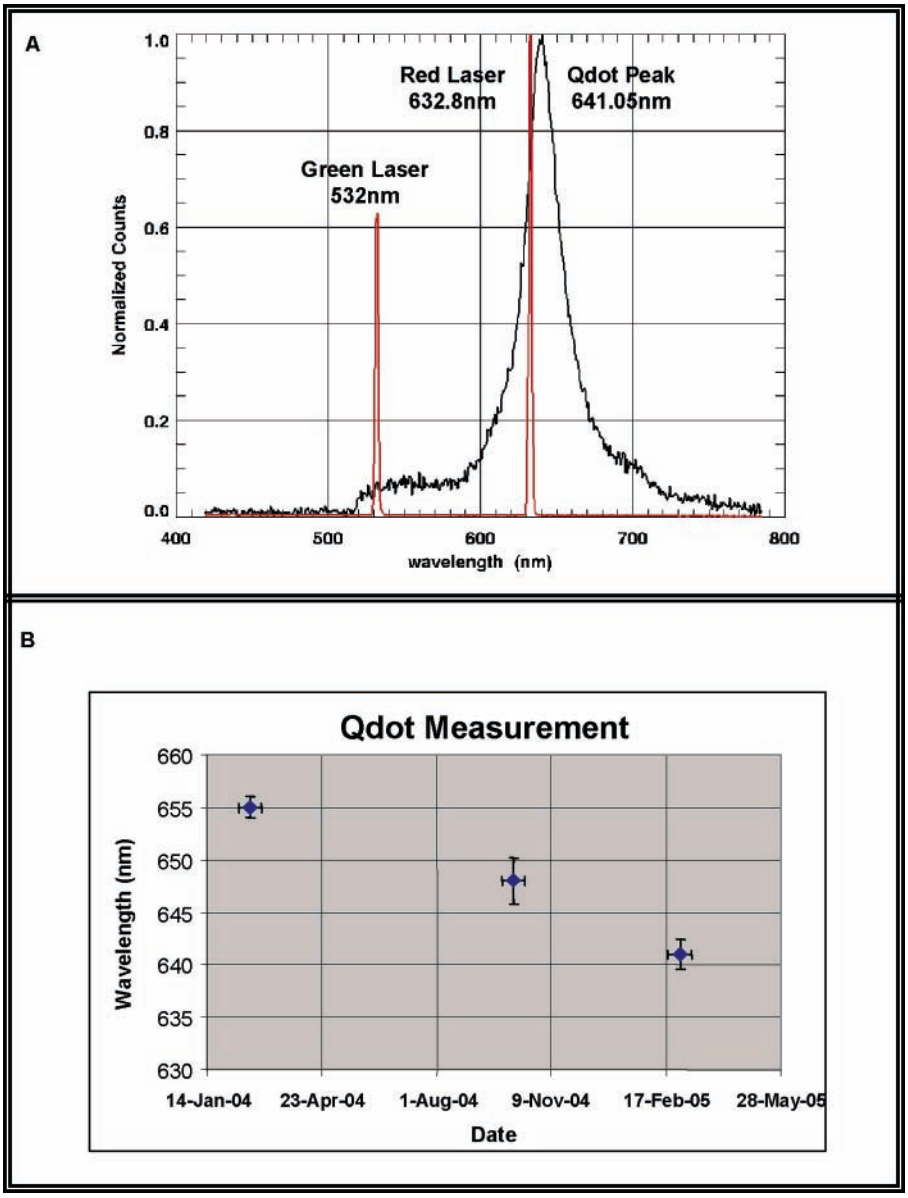

Figure 5. Overlay of laser calibration with the pixel to pixel Qdot signal measurement with the hyperspectral imaging microscope. Green (532 nm) and red (632.8 nm) lasers were used to calibrate the hyperspectral imaging microscope. The figure displays a pixel by pixel overlay of the QD and laser spectra (A). Multiple peaks were measured from different areas of the image acquisition cube. From the figure, the peak intensity of the QD is at 641 nm, which indicates a slight blue-shift of the 655 nm reported by the manufacturer when taking into account a combined error of ~1.414 nm. A plot of the measurements of the maximum wavelength vs time of measurement indicates a time-dependent decrease in the wavelength, possibly revealing erosion of the outer QD shell (B).

parallel. Because this imaging technique measures spectral signatures over a given bandwidth and does not simply count photons passed through a narrow-bandwidth filter, overlapping fluorescent spectra can be read in parallel on a single protein spot in our assay format. One can now envision the multiplexed analysis of the same area of a microarray probed with various QD-conjugated biomolecules, each with a distinct emission peak. Thus, the amount of information that can be gleaned from a single RPMA is dramatically enhanced. Integration of QD technology into protein microarray platforms will likely provide a means for subtle measurements of intracellular signaling pathways while surveying multiple molecular targets simultaneously through multiplexing at subcellular localization resolution.

QDs have remarkably high photochemical stability and can withstand numerous illumination cycles compared to organic fluorophores that get bleached much more rapidly, as exemplified by the extended analytical shelf life of our protein arrays. Extended integration times are thus possible, as are improved signal-to-noise ratios, enhanced sensitivity, enhanced quantitation, and increased assay reliability. For clinical samples in which the concentrations of target proteins may vary considerably, one array may need to be exposed multiple times in order to image widely varying concentrations of analytes. The QDs promote tailored imaging at multiple time intervals for each array on the basis of the signal level present within each sample. Chromogenic arrays do not permit this flexibility, and organic fluorophores rapidly degrade upon repeated imaging. Of note in this study, the QD signal showed remarkable longevity, with unamplified signal present over six months after the initial testing using a hyperspectral imager analyzer. This quality is a very attractive attribute as the protein microarray moves toward clinical usage; however, there may be a time-dependent change in wavelength associated with this signal.

A change in QD wavelength has been reported before, and a mechanism has been suggested. Ballou et al. (2004) pointed out that QD coatings do break down and do remain fluorescent for at least four months (*25*). If the PEG shell of the Qdot 655-PEG-Sav reagent erodes and the ZnS shell is breached or eroded, the Cd and Se atoms could wear down in addition. One report described ZnS shell erosion of QDs with a resultant blue-shift of the emission wavelength (*26*). However, this change was not described for the 655 nm quantum dot, and the shift shown is not large enough to account for the 14 nm we see in our last microarray scan by hyperspectral imaging. On the basis of published data (*26*), the wavelength changes ~43 nm for each 1 nm diameter change of CdSe. Our 14 nm change corresponds to a reduction in diameter of 3.2 Å; such a depth of erosion could be due to the removal of just 3 Cd and/or Se atoms from the surface of the core.

In conclusion, the potential for multiplexed assays, detection of unamplified signals, expanded dynamic range, and robustness under repeated and varying exposure periods makes QD nanoparticles especially suitable for clinical proteomics applications. The hyperspectral image analyzer enables a broadened use of QDs in RPMAs because of its sensitivity and multiplexing characteristics. Technological advances such as integration of QDs and hyperspectral imaging into RPMAs for molecular network analysis will hasten the advance of personalized assessments of patient tumor cells.

ACKNOWLEDGMENT

The authors wish to thank Theresa Harper (Quantum Dot Corporation) for her input into this study. Also, they wish to thank Mary Winters for providing Jurkat cell lysates. Animesh Nandi and Johanne Pastor provided insightful critiques of the manuscript. This work was supported by the University of Texas Southwestern Center for Proteomics Research contract from the NHLBI and the Hudson Foundation.

Received December 7, 2004; Revised Manuscript Received March 18, 2005

Reactive phosphorylcholine polymers, which can recognize biosynthetic cell-surface tags, were synthesized to control cell attachment. Human promyelocytic leukemia cells (HL-60) with unnatural carbohydrates as cell-surface tags were harvested by treatment with *N*-levulinoylmannosamine (ManLev). The attachment of ManLev-treated HL-60 cells to 2-methacryloyloxyethyl phosphorylcholine (MPC) polymers with hydrazide groups was studied. HL-60 cells, which are nonadhesive, did not attach to any polymer surface without ManLev treatment. In contrast, ManLev-treated HL-60 cells attached to a poly[MPC-*co*-*n*-butyl methacrylate (BMA)-*co*-methacryloyl hydrazide (MH)] (PMBH) surface following 15 min of incubation. The cells that attached to the PMBH surface retained their native morphology and viability for 24 h of incubation. On the other hand, approximately half of the HL-60 cells that attached to the poly(BMA-*co*-MH) (PBH) surface died. These results suggest that MH units in the polymer act as anchors for cell attachment and MPC units help to preserve cell viability on a polymer surface. The coculture of ManLev-treated HL-60 and fluorescence-stained human uterine cervical cancer cells (HeLa) was carried out on polymer surfaces. ManLev-treated HL-60 cells specifically attached to the PMBH surface. In contrast, both HL-60 and HeLa cells were observed on the PBH surface. The control of cellular interactions with synthetic polymers may be useful for the future development of cell-integrated biosensors and biomedical devices.

INTRODUCTION

Synthetic polymers capable of selectively recognizing proteins or cells play important roles in cell separation, biosensors, and the development of biomedical materials (*1*, *2*). In general, few synthetic polymers can recognize a specific biomolecule or cell in vivo because of the complexity of the environment.

Using physicochemical and biological approaches, various surface conditions, such as a wettability gradient (*3*), topological patterns (*4*, *5*), and peptide-immobilization (*6*−*13*) have been applied to control cell attachment. Particularly, Arg-Gly-Asp (RGD)-immobilized surfaces have been extensively studied to control cell adhesion with ligand−receptor interactions (*6*, *11*−*13*). While these approaches have been quite successful, the selectivity of RGD is limited because the RGD sequence is not unique for a specific cell. Moreover, the control of cell attachment to a solid surface has been mainly studied with adhesive cells, and there have been few reports on systems for nonadhesive cells such as leukemia cells (*14*).

Synthetic polymers with an affinity for a cell surface at a submolecular level may be useful for controlling cell/polymer interactions (*15*). Most of these polymers are water-soluble and are used to immobilize the cell surface. For example, lipophilic anchors (*14*), chemical immobilization (*16*, *17*), and ligand−receptor interactions (*18*) have been studied. Through fixation of these polymers on solid surfaces, controlled cell attachment can be achieved. However, the recognition of a specific cell by a synthetic polymer is still limited because most of the cell/polymer interactions proposed are seen with a wide variety of cells, in contrast to unique interaction with a specific cell type. Also, some approaches cannot be applied under physiological conditions because nonspecific interaction with plasma protein often interferes with the specificity of materials for a cell membrane.

In a living cell, carbohydrates on the cell surface contribute to most communications between the cell and its environment (*19*). Therefore, it may be possible to control cell functions with polymers, which can affect carbohydrate interaction with a cell surface. For the recognition of a specific cell, tagging of carbohydrates on the cell membrane, as well as the polymer design, may be effective.

The incorporation of unnatural carbohydrates into living cells provides an opportunity to study the specific contributions of sialic acid and its *N*-acyl side chains to sialic acid-dependent ligand−receptor interactions at a submolecular level. Bertozzi and co-workers have expressed unnatural functional groups, i.e., acetyl, levulinoyl, and azideacetyl groups, on living cell surfaces through the glycosylation of unnatural monosaccharides (*20*−*23*). Since the initial demonstration of cell-surface engineering with *N*-levulinoylmannosamine (ManLev),

this technique has been applied to the development of targeted imaging reagents (*24*) and methods for gene transfer (*25*). This tagging technique has led to great progress in cell biology and biomedical science (*26*). Sadamoto and co-workers immobilized the cell surface of bacteria using an unnatural cell-surface precursor (*27*). The adhesion of surface-engineered bacteria onto a concanavalin A-immobilized substrate has also been enhanced (*28*). The ability of noncanonical amino acids to introduce novel chemical functionalities into proteins and cells has been explored by Tirrell and co-workers (*29*−*31*). They recently reported an alternate strategy for the detection of noncanonical amino acids, in which azidohomoalanine is incorporated into the *Escherichia coli* outer membrane protein OmpC (*32*, *33*).

We have been studying 2-methacryloyloxyethyl phosphorylcholine (MPC) polymers synthesized as biomimetics of biomembrane structures (*34*−*37*). MPC polymers have a surface that resists nonspecific protein adsorption and cell adhesion, i.e., "biofouling" (*38*, *39*). Biofouling reduces the functionality of a material and can induce an unexpected bioreaction. Further, it has been shown that cells in contact with MPC polymers do not exhibit activation or an inflammatory response (*40*, *41*). However, an MPC polymer has not yet been used as a substrate for a biorecognition surface.

We report here a novel strategy for controlling selective cell attachment and detachment even in nonadhesive cells by using biomimetic polymer surface engineering and cell-surface engineering. To this end, we designed reactive biomimetic MPC polymer surfaces with hydrazide groups, which can react selectively with unnatural ketone-containing carbohydrate as a cell surface tag. Figure 1 shows a schematic representation of selective cell attachment through the recognition of a cell-surface tag. The MPC polymer surface prohibits nonspecific interaction with plasma protein that often interferes with the specificity of the interaction of materials with a cell membrane. Hydrazide groups on the MPC polymer surface react with ketone groups on the cell surface even in cell culture medium. The surface tags on living cells can be introduced in the presence of ManLev by surface engineering (*20*−*25*). In this study, we synthesized MPC polymers with hydrazide groups, prepared and characterized the polymer surface, and controlled cell attachment onto their surfaces.

MATERIALS AND METHODS

Polymer Synthesis. Methyl methacrylate and *n*-butyl methacrylate (BMA) were purified by conventional distillation. Other reagents and solvents were obtained commercially in extra-pure grade and used without further purification. 2-Methacryloyloxyethyl phosphorylcholine (MPC) was synthesized as previously reported (*42*). Methacryloyl hydrazide (MH) was synthesized by reacting methyl methacrylate (0.25 mol, 25 g) and hydrazine monohydrate (0.15 mol, 7.5 g) at 0 °C. Unreacted MMA was removed at 0 °C/10 mmHg, and MH was purified by recrystallization from toluene. ^{1}H NMR (500 MHz, ppm in $CDCl_3$) MH: 6.90 (s; NH, 1H), 5.70, 5.30(s; CH═, 1H), 3.90 (s; NH_2, 2H), 1.90 (s; CH_3, 3H).

N-Levulinoylmannosamine (ManLev) was synthesized as previously described (*21*).

Poly(MPC-*co*-BMA) (PMB), poly(BMA-*co*-MH) (PBH), and poly(MPC-*co*-BMA-*co*-MH) (PMBH) were synthesized by radical polymerization using 2,2′-azobisisobutyronitrile (AIBN) as an initiator (*38*, *42*). BMA was used as a comonomer because it makes it possible to process a polymer membrane. The mole fraction of monomer units in the polymer was determined by phosphorus analysis and elemental analysis. The number-averaged and weight-averaged molecular weight of polymers were determined with a Tosoh gel-permeation chromatography (GPC) system with a refractive index detector and size-exclusion columns (Polymer Laboratories Ltd.), MIXED-C with a poly(ethylene glycol) standard (PEG, Tosoh standard sample) in CH_3Cl/methanol (6/4,vol/vol). The results of polymerization are summarized in Table 1.

Preparation of Sample Plates for the Cell Culture Experiment. The poly(ethylene terephthalate) (PET) plates (14 mm in diameter; Wako Pure Chemical Industries, Ltd., Osaka, Japan) were immersed in an ethanol or chloroform solution of the polymer (0.5 wt %) and dried

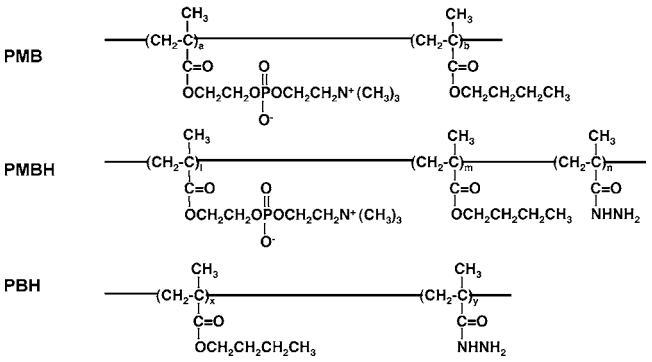

Figure 2. Chemical structures of polymers synthesized in this study.

under a vapor atmosphere of the solvent at room temperature for 30 min. This procedure was repeated twice, and the plates were then dried in vacuo. The surface properties of polymer-coated PET plates were analyzed by surface contact angle measurement (G-1; Erma, Tokyo, Japan) and X-ray photoelectron spectroscopy (XPS) (ESCA-200; Scienta, Uppsala, Sweden) with AlKα (takeoff angle 90°). Survey scan spectra of C_{1s}, O_{1s}, N_{1s}, and P_{2p} were taken.

Cell Culture Experiment. Human promyelocytic leukemia cells (HL-60) were purchased from Health Science Research Resources Bank and maintained in RPMI1640 with 10% fetal bovine serum at 37 °C in a humidified atmosphere of air containing 5% CO_2. The concentration of HL-60 was adjusted to 1.5×10^5 cells/mL. The medium was changed with that containing 10 mM ManLev, and the cells were stored for 3 days. The cells were then washed with fresh medium and centrifuged to remove free ManLev in the medium. The expression of ketones on the cell membrane was confirmed by fluorescence staining with 5 mM Alexa Fluor 350 hydrazide (Molecular Probes, OR).

ManLev-treated HL-60 cells were resuspended with fresh medium, and the concentration was adjusted to 1.0×10^5 cells/mL. The suspension (1 mL) was seeded on PMB, PMBH, and PBH and incubated for 15 min, 2, 4, and 24 h. The cells were then washed twice with fresh medium and observed by phase-contrast microscopy.

To investigate the stability of cells attached to the surface, the surface was rinsed twice with culture medium after a 2-h incubation of ManLev-treated cells on a polymer surface, and cell culture was continued for various periods.

The density of cells attached to the surface was counted in five randomly chosen areas on each polymer surface. A statistical analysis was performed with Student's *t*-test.

Sialidase Treatment. ManLev-treated HL-60 cells were in contact with PMBH5 as mentioned above. After a 2-h incubation of ManLev-treated HL-60 cells on a polymer surface, the surface was rinsed twice with fresh medium to remove nonattached cells. The polymer sample was soaked in 900 μL of fresh medium. Sialidase buffer (20mM HEPES, 140 mM NaCl, pH 6.8) was prepared, and the concentration of sialidase was adjusted to 1 U/mL. The sialidase buffer (100 μL) was added to each medium and stored at 37 °C for 30 min. The surface of the polymer was observed by phase-contrast microscopy. To identify the density of ketones on the cell membrane, cells were stained with 5 mM Alexa Fluor 488 hydrazide (Molecular Probes, Eugene, OR) and analyzed by flow cytometry (Becton Dickinson FACSCalibur).

Cytotoxicity Test. The viability of adherent HL-60 cells on a polymer surface was investigated with a LIVE/DEADViability/Cytotoxicity kit (Molecular Probes, OR). After a 2-h incubation of ManLev-treated HL-60 cells on a polymer surface, the surface was rinsed twice with fresh medium to remove nonattached cells. The cell culture was then continued for various durations. The cells attached to the polymer surface were then stained with 1 μM calcein dye and 2 μM ethidium homodimer-1 (EthD-1) dye. The samples were incubated for 15 min at 37 °C and observed by phase-contrast and fluorescence microscopy (IX-70, OLYMPUS, Tokyo, Japan). The number of attached cells and the percentage of live cells were determined in five randomly chosen areas on each polymer surface. A statistical analysis was performed with Student's *t*-test.

Coculture Experiment. Human uterine cervical cancer cells (HeLa) were purchased from Riken Cell Bank and maintained in RPMI1640 with 10% fetal bovine serum at 37 °C in a humidified atmosphere of air containing 5% CO_2. The contents of the flasks for cell maintenance were detached by trypsin treatment and a cell suspension containing 1.0×10^5 cells/mL in D-PBS was prepared. 5-(and-6)-Carboxyfluorescein diacetate, succinimidyl ester (CFSE, 50 μM) was added to the suspension, and the cells were stored for 15 min. The suspension was then centrifuged to remove free CFSE. CFSE-stained HeLa cells and ManLev-treated HL-60 cells were mixed in fresh medium, and their concentrations were adjusted to 1.0 X 10^4 and 1.0×10^5 cells/mL, respectively. The mixed cells were seeded on polymer surfaces and cocultured for 24 h. After being rinsed with the culture medium, the polymer surfaces were immediately observed by phase-contrast and fluorescence microscopy.

Detection of Fibronectin Adsorbed onto the Surface. The adsorption of bovine serum fibronectin from the cell culture medium onto the polymer surface was detected by a method based on the antigen/antibody reaction with enzyme-labeled immunoglobulin (*37*). Briefly, polymer-coated PET plates were placed in a 24-well tissue culture plate and secured with a silicone rubber ring. They were left in contact with PBS overnight at room temperature for equilibration of the surface. The cell culture medium was added to each well after the removal of PBS and kept there for 1 h at 37 °C; the PET plates were then rinsed with PBS. A bovine serum albumin (BSA, Sigma Chemical, St. Louis, MO) solution (1 wt % BSA in PBS) was used as a blocking reagent to inhibit any undesirable reactions and nonspecific adsorption with the following antibodies. The PET plates were kept at 4 °C for 3 h and then rinsed with PBS. After the BSA solution was removed, the plates were incubated with the primary antibodies [1 wt % BSA solution containing rabbit immunoglobulin of anti-bovine fibronectin (polyclonal, TELIOS, Pharmaceutical Inc., San Diego, CA)] for 60 min at 37 °C. The plate was rinsed with PBS. The secondary antibody (goat anti-rabbit immunoglobulin, Sigma Chemicals, St. Louis, MO) labeled with horseradish peroxidase (HRP) was then poured into each well, and the wells were stored for 60 min at 37 °C. The plates were transferred to new wells and placed in contact with 3,3′,5,5′-tetramethylbentizine (TMBZ) solution (Color formation kit, SUMILON, Tokyo, Japan) at 25 °C for 10 min in the dark. Absorbance of the TMBZ solution at 450 nm was measured using a microplate reader (Model 450, BIO-RAD Laboratories, Richmond, CA). A statistical analysis was performed with Student's *t*-test.

RESULTS AND DISCUSSION

Characterization of Polymers and Polymer Surfaces. To control cell-attachment, polymer surfaces with reactive units in a phosphorylcholine surface were designed. The hydrazide group was selected as a reaction site for a ketone group on the cell surface. Figure 2 shows the structures of polymers synthesized in this study. The polymerization of 2-methacryloyloxyethyl phosphorylcholine (MPC), *n*-butyl methacrylate (BMA), and methacryloyl hydrazide (MH) occurred in ethanol or ethanol/tetrahydrofuran (THF) mixture. As indicated in Table 1, the composition of each monomer unit could be controlled with the feed. Amphiphilic copolymers containing various amounts of hydrazide groups were obtained. PET plates coated with the synthesized polymers were prepared by the solvent evaporation technique. Elemental analysis of polymer-coated PET surfaces was performed by X-ray photoelectron spectroscopy (XPS). In the case of PET plates coated with MPC polymers, nitrogen and phosphorus peaks were observed at 402.5 and 133.0 eV, respectively (Figure 3). These are attributed to the phosphorylcholine group in the MPC units. Moreover, nitrogen peaks at 399.0 and 400.0 eV due to hydrazide groups were also observed on the surface of PMHB. The

surface mole fraction of MH units was determined from the XPS elemental concentration, and the amount was almost constant regardless of the bulk concentration when the MH unit mole fraction in the feed was more than 2 mol %, as shown in Table 1. The water contact angles of the polymer surface are summarized in Table 2. The receding contact angle for the MPC polymers was lower than those for PBH and PBMA. MH unit mole fractions within the range of 2−5 mol % did not affect the water contact angles.

A phosphorylcholine surface with hydrazide groups was prepared by coating a PET plate with PMBH.

Attachment of HL-60 Cells to a Polymer Surface. In this study, HL-60 cells were used as typical nonadhesive cells. The expression of ketone groups on the cell surface was confirmed by treatment with Alexa Fluor 350 hydrazide. This compound stained the cell membrane of ManLev-treated HL-60 cells, but not that of ManLev-untreated HL-60 cells, as shown in Figure 4.

Figure 5 shows phase-contrast micrographs of the polymer surfaces after incubation (2 h) with HL-60 cells that had been pretreated with or without ManLev. ManLev-untreated HL-60 cells did not attach to any of the polymer surfaces. ManLev-treated HL-60 cells did not attach to the control PMB surface. In contrast, ManLev-treated HL-60 cells attached to both the PMBH and PBH surfaces.

The surface densities of adherent cells on polymer surfaces as a function of time after incubation are summarized in Figures 6 and 7. On polymer surfaces with hydrazide groups, cell attachment occurred after 15 min of incubation and the density was stable for 2 h. The density of cells attached to PMBH surfaces increased with an increase in the surface mole fraction of MH units.

The number of HL-60 cells attached to PMBH decreased after 24 h of incubation, as shown in Figure 7.

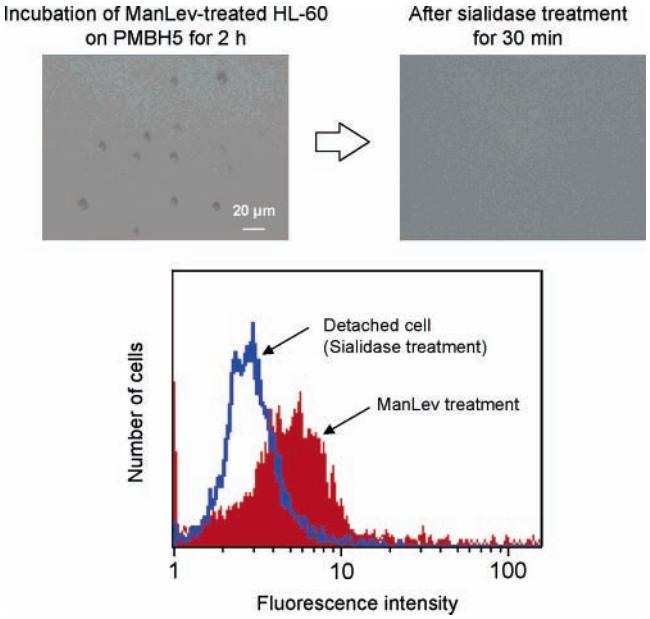

Figure 8. Effect of sialidase treatment on ManLev-treated HL-60 cells attached on PMBH5.

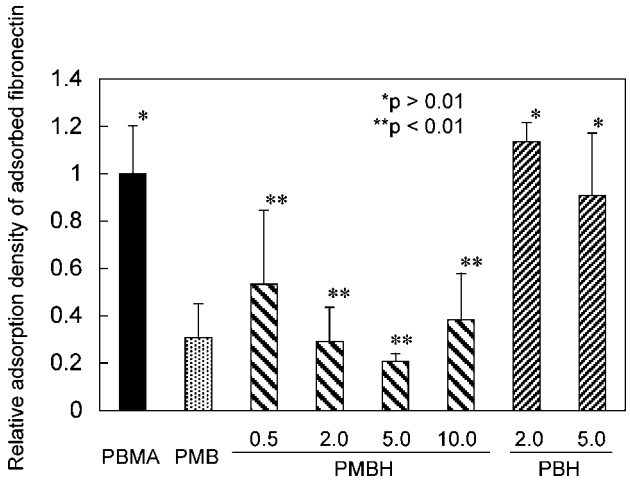

Figure 9. Relative density of fibronectin adsorbed on polymer surfaces from 10% FBS. PBMA = 1.0.

The cell-surface ketone groups decreased to 50% of their initial level at 48 h (*21*). Cell attachment was affected by the density of cell-surface ketone groups. On the other hand, the detachment of cells from the PBH surface was not observed until 48 h of incubation. The metabolic function of HL-60 cells attached to PBH may be affected by the surface. After 72 h of incubation, almost all of the attached cells were detached from the polymer surfaces.

The reactivity of ketone groups on a cell surface with hydrazide groups was confirmed in previous reports (*20*, *43*). In addition, ManLev-treated HL-60 cells did not attach to PMBH or PBH upon further incubation in fresh medium (without ManLev) for 3 days before contact with the polymers (data not shown) because of the depletion of ketone groups from the cell surfaces. The detachment of cells from PMBH by enzyme treatment for 30 min, every cell was detached from the PMBH5 surface as shown in Figure 8. The surface density of ketone groups on the cell membrane of cells detached from a polymer surface was lower than that of ManLev-treated cells. All of these results suggest that cells attached to polymer surfaces through the reaction of ketone groups in carbo-

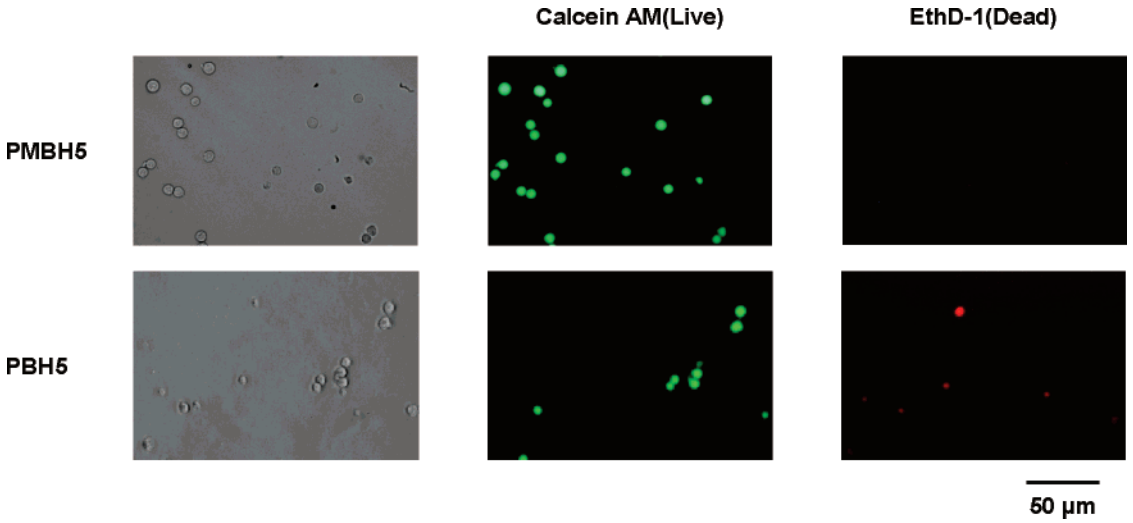

Figure 10. Micrographs of viability of adherent cells on polymer surfaces.

hydrates on the cell surface and hydrazide groups on the polymer surface.

The PMBH surface showed a much greater attachment of cells than the PBH surface, even with the same amount of hydrazide groups. The density on PMBH was approximately three times greater ($p < 0.01$ at 2 and 4 h of incubation) than that on PBH, as shown in Figure 7.

We also studied interaction between MPC polymer and plasma protein. When the mole fraction of MPC units in a polymer was around 0.3, nonspecific protein adsorption was effectively reduced and the extent of adsorption from human plasma was approximately 0.4 μg/cm^2, which is lower than the extent of monolayer adsorption of albumin (lit. 0.9 μg/cm^2) (*38*, *44*). In contrast, the amount of protein adsorbed on PBMA was more than 1.0 μg/cm^2. It has also been clarified that protein in contact with MPC polymer does not undergo denaturation (*39*). We measured the amount of serum protein adsorbed on polymer surfaces to better understand the difference in cell adhesion on PMBH and PBH. As shown in Figure 9, the amount of fibronectin adsorbed onto PBH was the same as that adsorbed onto PBMA, but was significantly greater than that on PMBH. Thus, on the PBH surface, the amount of adsorbed serum proteins would be greater than the amount of monolayer adsorption.

The hydrazide groups on the PMBH surface were not covered with serum protein, and these groups are effective for recognition of the cell surface. On the other hand, the adsorbed proteins on PBH hid hydrazide groups on the polymer, which resulted in a decrease in the density of cell attachment because the surface properties of PBH were similar to those of PBMA (Table 2), which shows a large amount of protein adsorption from plasma (*38*). The PMBH surface could effectively catch HL-60 cells and did not have an adverse effect on cell function.

Viability of Cells Attached to a Polymer Surface. Figure 10 shows phase-contrast and fluorescence microscopy images of polymer surfaces after incubation with HL-60 cells for 24 h. On the PMBH surface, almost all of the adherent cells were stained with calcein (green image) and keep their spherical shape. On the other hand, some of the adherent cells on PBH were stained with EthD-1 (red image) and were deflated. The percentage of live cells attached to the polymer surface is summarized in Figure 11. On the PMBH surface, more than 80% of the cells were alive. However, about 50% of the cells that adhered to PBH were dead. The biological

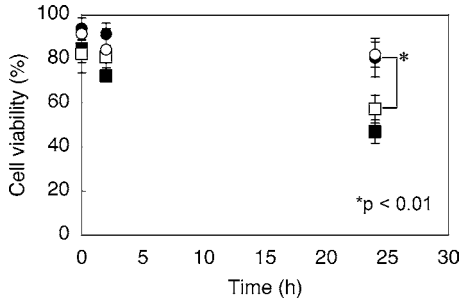

Figure 11. Time-dependence of viability of adherent cells on polymer surfaces. Open circle: PMBH2, filled circle: PMBH5, open square: PBH2, filled square: PBH5.

functions of HL-60 cells in contact with polymer surfaces were retained.

When we previously measured the cytoplasmic free calcium concentration in platelets in contact with an MPC polymer surface, the calcium concentration was unaffected and stayed at its native value (*34*). Moreover, the inflammatory response of differentiated HL-60 cells that adhered to the MPC polymer surface was investigated by the determination of IL-1β mRNA (*41*). While the expression of IL-1β mRNA from adherent cells was observed on conventional polymer materials, secreted mRNA was not observed on the MPC polymer surface, which has an MPC unit mole fraction of more than 0.2. MPC units on a polymer surface probably act to maintain the native condition of attached cells.

Coculture of HL-60 and HeLa Cells on a Polymer Surface. To clarify the possibility of using a polymer surface to recognize specific cells with cell-surface tags, the coculture of ManLev-treated HL-60 cells with native HeLa cells was examined. HeLa cells are a typical cancer cell and nonspecifically adhere to a conventional polymer surface through cell-binding proteins adsorbed on the surface. Figure 12 shows phase-contrast and fluorescence microscopy images of polymer surfaces after the coculture experiment. Cell adhesion was completely suppressed on the PMB surface. On the other hand, both HL-60 and HeLa cells were observed on PBH. HL-60 cells selectively attached to PMBH, while HeLa cells did not. The adhesion of HeLa to a polymer surface is closely associated with the adsorption of cell-binding proteins, such as fibronectin, fibrinogen, and vitronectin, on the surface because these proteins have an RGD binding site for integrin of the cell membrane (*45*). On PMBH, the

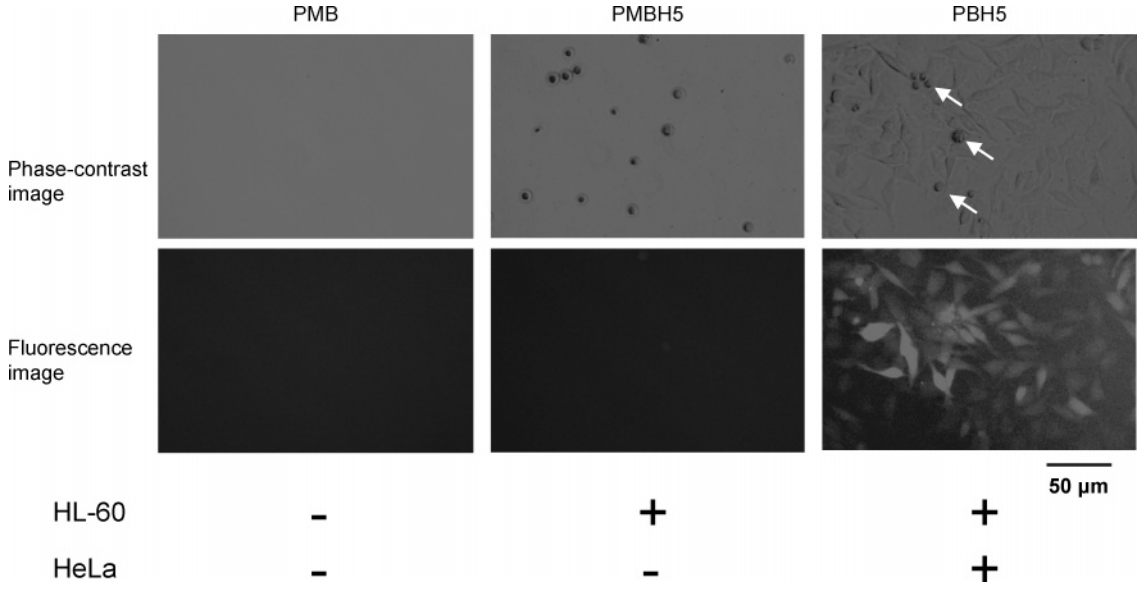

Figure 12. Phase-contrast and fluorescence micrographs of polymer surfaces after the coculture experiment. White arrows represent HL-60.

adhesion of HeLa cells was reduced due to fibronectin-resistance, as shown in Figure 9. It has been previously reported that MPC polymer can nonspecifically reduce plasma protein adsorption (*46*). The nonfouling property of the MPC polymer surface is quite important for achieving specific interaction with a cell.

These results indicate that cell-surface recognition by a polymer surface is evident in both single- and two-cell systems. Such recognition on an MPC polymer surface was effective in a multiple-cell system because the MPC polymer surface rejects the adhesion of cells without tags. Moreover, the control of cell attachment can be applied to a wide variety cells because the expression of unnatural carbohydrates on cell surfaces has been observed on various types of cells (*21*).

CONCLUSION

The present work describes a new cell-recognition surface that works through the coupling of ketone groups on the cell membrane with hydrazide groups on the phosphorylcholine polymer. This cell attachment was specific, and cells were recovered by the depletion of cell-surface tags. On a phosphorylcholine polymer surface, cell viability was effectively retained. Moreover, controlled cell attachment was not affected by the presence of serum protein. The control of cell attachment in a multicellular system was also demonstrated.

Prescher and co-workers recently reported that cell-surface modification with monosaccharides could be applied in a living animal (*47*). Tagging of cancer cells in vivo may be possible through cell-surface engineering because cancer cells have a higher metabolic flux than normal cells (*26*). It has been reported that nanoparticles coated with MPC polymer were not recognized by macrophages (*48*), and they could be used as long-term circulating drug carriers in the blood stream. It may be possible to develop a novel drug targeting system if the functionalities for recognizing cell-surface tags of a cancer cell or a specific tissue can be put on nanoparticles. Moreover, various types of polymer materials using MPC, such as films (*49*), fibers (*50*), nanoparticles (*51*), and micelles (*52*), can be prepared. Cell-surface recognition with MPC polymer promises to be an important technology in drug delivery and bioreactor systems.

In Vivo Imaging of Activated Endothelium Using an Anti-VCAM-1 Magnetooptical Probe

Andrew Tsourkas,† Vivek R. Shinde-Patil,† Kimberly A. Kelly, Pratik Patel, Allison Wolley, Jennifer R. Allport, and Ralph Weissleder*

Center for Molecular Imaging Research, Department of Radiology, Massachusetts General Hospital and Harvard Medical School, 149 13th Street, Charlestown, Massachusetts 02129-2060. Received January 7, 2005; Revised Manuscript Received March 25, 2005

It has been suggested that vascular cell adhesion molecule-1 (VCAM-1) could serve as an early marker for inflammation of the endothelium. The ability to noninvasively image VCAM-1 could thus be a useful tool to diagnose a number of inflammatory diseases at early stages. Here we demonstrate that magnetooptical nanoparticles conjugated to anti-VCAM-1 antibodies can be used to specifically detect VCAM-1 expression on endothelial cells in culture and in vivo. Elevated VCAM-1 expression was detected on cultured murine heart endothelial cells by both fluorescence and magnetic resonance, while only basal expression levels were detected on murine dermal endothelial cells. Intravital microscopy of a murine inflammatory model injected with the VCAM-1 targeted nanoparticles revealed specific labeling of the activated endothelium, with labeling kinetics yielding a maximum vessel wall signal 6 h after injection. In contrast, nontargeted nanoparticles did not exhibit any specific labeling of the endothelium. These studies suggest that the developed nanoparticle would be useful for MR and optical detection of activated endothelium.

INTRODUCTION

The ability to noninvasively image cell surface receptors in vivo provides a promising approach for the early detection and characterization of disease (*1*–*5*). One particularly appealing application is the imaging and identification of host response biomarkers. An inflammatory response of the endothelium is characterized by the expression of a repertoire of inducible adhesion molecules that are tightly regulated both spatially and temporally (*6, 7*). Thus, cell surface molecules that have a significant role in the adhesion of mononuclear leukocytes to sites of inflammation could serve as imaging targets for contrast reagents. Potential candidates include vascular cell adhesion molecule-1 (VCAM-1), P-selectin, and E-selectin (*3, 8*–*11*). VCAM-1 is of particular interest, because it has been found to selectively bind to classes of leukocytes found predominately during the early stages of inflammation (*7, 12*). To date, several attempts have been made to image VCAM-1 expression with radiolabeled antibodies; however, these methods have been limited by low target-to-background ratios (*9, 13*). Therefore, there is a need to develop alternative methods for imaging VCAM-1, ideally with improved sensitivity and resolution.

In this study, we tested whether cross-linked dextran-coated iron oxide (CLIO) nanoparticles labeled with the near-infrared fluorochrome Cy5.5 and conjugated with an anti-VCAM-1 antibody (VCAM−NP) could be used to image TNF-α activated endothelium in an inflammatory murine ear model. Analogous nanoparticles with rat IgG substituted for anti-VCAM-1 antibodies were used as controls for nonspecific labeling. Magnetic resonance and optical imaging of two murine primary endothelial cell types with different VCAM-1 expression levels validated the applicability and targeting specificity of VCAM−NP in vitro. Furthermore, intravital microscopy and subsequent immunohistochemistry on a murine inflammatory model demonstrated the potential for imaging VCAM-1 expression using antibody-conjugated nanoparticles in vivo.

EXPERIMENTAL PROCEDURES

Synthesis and Characterization of Nanoparticles. Superparamagnetic monocrystalline nanoparticles consisting of an iron oxide core and an aminated cross-linked dextran coating (CLIO) were synthesized as previously described (*14, 15*). The iron oxide core size was 3−5 nm in diameter (approximately 9000 Fe centers per particle, assuming a spherical geometry), as previously determined (*16*). The average nanoparticle diameter was determined to be 32.5 nm by laser light scattering (Zetasizer 3000, Malvern Instruments Inc.). The relaxivity of the nanoparticles (R1 = 21.53 mM^{-1} s^{-1}, R2 = 54.2 mM^{-1} s^{-1}) was measured using a 0.47 T tabletop minispec (NMS120, Bruker). The number of amines per nanoparticle was approximately 40, as quantified by methods described previously (*17*).

Cy5.5 (0.5 mg) was suspended in 50 μL of DMSO and added dropwise to 1 mL of CLIO (5 mg of Fe) in PBS, pH 7.4, to yield fluorescent CLIO. The sample was mixed overnight at room temperature and in the dark. The CLIO−Cy5.5 conjugate was purified by extensive dialysis against PBS, pH 7.4, at 4 °C. The Cy5.5 concentration was determined according to the manufacturer's instructions (ϵ = 250 000 at 674 nm). The final iron concentration was determined by dissolution of the iron oxide core in 6 N HCl and 0.03% hydrogen peroxide and comparing absorbance measurements at 410 nm (minus the contri-

bution from Cy5.5) to known standards. The total iron content was determined by comparing the measured absorbance (minus the contribution from Cy5.5) to known standards. On the basis of the measurement of 9000 Fe centers per nanoparticle, the number of Cy5.5 molecules per nanoparticle was determined to be approximately 10.

Synthesis of NHS−COOH. Suberic acid (1.742 g, 10 mmol) was added to 0.61 mL of trimethylacetyl chloride (5 mmol). To this was added 20 mL of anhydrous dichloromethane. The solution was stirred on ice for 5 min. Then 0.73 mL of triethylamine (5.25 mmol) was added, and the solution was mixed for 2 h on ice under nitrogen (flask 1). In a separate flask, 0.575 g of NHS (5 mmol) was suspended in 10 mL of tetrahydrofuran and mixed under nitrogen (flask 2). After the contents of flask 1 had mixed for 2 h, the two flasks were combined. The solution was mixed on ice until cool (approximately 5 min). Then, 0.73 mL of triethylamine (5.25 mmol) was added and the solution was mixed for 2 h on ice under nitrogen. The sample was centrifuged at 2500 rpm for 10 min and allowed to stand for 30 min. The sample separated into two phases, and the bottom phase was collected and filtered through a 0.45 μm syringe filter. Aliquots of the product were placed in 1.5 mL tubes, desiccated overnight, and subsequently stored at −20 °C.

Carboxylating CLIO (CLIO−COOH). Amine-containing CLIO−Cy5.5 (0.5 mg) was diluted into a 1 mL 50/50 mixture of PBS (pH 7.4) and DMF. This was added to approximately 50 μmol of dry NHS−COOH. The sample was vortexed until the NHS−COOH was completely suspended, and it was then incubated overnight in the dark. Four volumes of 2-propanol were then added, and the sample was centrifuged at 2000*g* for 2 min. The supernatant was removed, and the pellet was resuspended in DMF. The 2-propanol precipitation procedure was repeated two more times, but the pellet was resuspended in PBS (pH 7.4). Additional purification was performed by repeatedly filtering the nanoparticles on a Microcon YM-50 centrifugation column (Millipore) and resuspending in PBS (pH 7.4).

Antibodies. M/K-2.7 hybridoma cells (ATCC, Catalog No. CRL-1909) that secrete rat anti-mouse anti-VCAM-1 monoclonal antibodies were batch cultured in a CellLine Apparatus (BD Biosciences) according to the manufacturer's instructions. Antibody secreted into the media (2−20 mg/culture batch) was recovered and concentrated by affinity purification using IgG purification columns (Pierce Chemical), dialyzed into PBS, and stored at −20 °C. Rat IgG control antibody was purchased from Sigma.

CLIO-Antibody Conjugation. Purified carboxylated nanoparticles (0.1 mg) were precipitated in four volumes of 2-propanol. The suparnatant was removed, and the pellet was resuspended in 50 μL of MES buffer (pH 6.0) (50 mM MES, 0.5 M NaCl). To this were added 10 μL of 200 mM EDC and 10 μL of 500 mM Sulfo-NHS. The sample was mixed at room temperature for 1 h. Then the nanoparticles were precipitated in four volumes of 2-propanol and resuspended in 100 μL of 5 mg/mL anti-VCAM-1 antibody or rat IgG. The sample was mixed overnight at 15 °C in the dark. Nanoparticle−antibody conjugates (VCAM−NP and IgG−NP, respectively) were purified from unbound antibodies by isolating the conjugates by magnetic separation on a MACs MS column (Miltenyi Biotech). The nanoparticle−antibody conjugates were eluted in PBS (pH 7.4). The nanoparticle concentration was determined as described above, and the antibody concentration was determined by performing a BCA assay according to the manufacturer's instructions. Labeling ratios of 0.63 mg of IgG per mg of Fe and 0.87 mg of anti-VCAM per mg of Fe were measured.

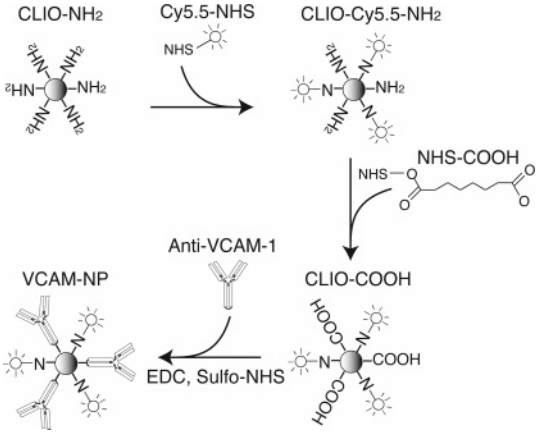

Figure 1. Schematic of VCAM−NP synthesis. Superparamagnetic monocrystalline nanoparticles consisting of an iron-oxide core and an aminated cross-linked dextran coating (CLIO−NH_2) were labeled with the near-infrared fluorochrome Cy5.5. Next the remaining free amines were converted to carboxyls (CLIO−COOH). Anti-VCAM-1 antibodies were then attached using EDC/Sulfo-NHS chemistry (VCAM−NP).

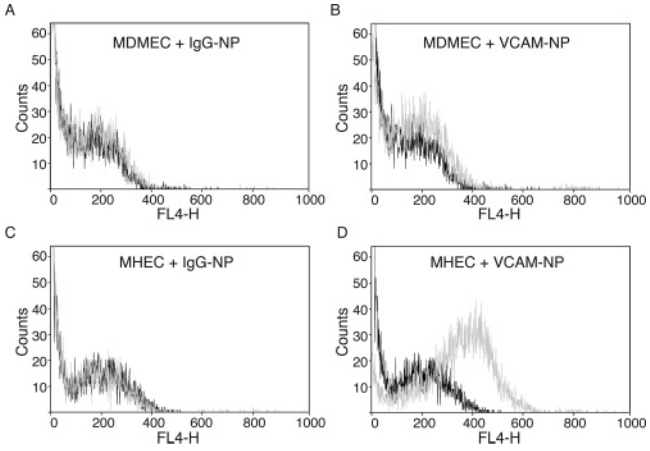

Figure 2. FACS analysis of murine dermal endothelial cells (MDMEC) and murine heart endothelial cells (MHEC). A suspension of each endothelial cell phenotype was incubated with IgG−NP or VCAM−NP for 30 min. Positive labeling was determined by detecting of Cy5.5 fluorescence in the FL4-H channel. Cells labeled with either IgG−NP or VCAM−NP (as indicated in the figure) are represented by the gray lines. Unlabeled cells are represented by the black lines. High expression levels of VCAM-1 expression were only evident on the MHEC (panel D). Cells labeled with IgG−NP (panels A and C) did not exhibit any fluorescence, indicating the absence of nonspecific labeling/uptake.

Cell Culture and Flow Cytometry (FACS). Murine heart endothelial cells (MHEC) and murine dermal endothelial cells (MDMEC) were isolated and propagated as described previously (*18*). Cells were grown to confluence on gelatin-coated six-well plates (six wells each) and then incubated with either murine tumor necrosis factor-α (mTNF-α, 120 ng/mL) or vehicle for 4.5 h. Endothelial monolayers were washed 3× with HBSS (prewarmed to 37 °C), harvested by brief (30 s) trypsinization, and recovered in ice-cold FACS buffer (RPMI containing 5% FCS). Endothelial cells were washed by centrifugation at 4 °C for 5 min and then incubated in either 25 μg/mL anti-VCAM-1 (on 100 μL of VCAM−NP), 25 μg/mL IgG (on 100 μL IgG−NP), or vehicle (control) for 30 min at 37 °C. Analogous control experiments were performed with 10 μg/mL anti-VCAM-1 antibody and 10 μg/mL IgG

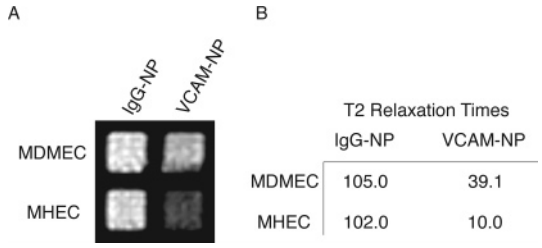

Figure 3. MR analysis of MDMEC and MHEC labeled with either VCAM−NP or IgG−NP. (A) Cross-sectional MR image of MDMEC and MHEC lysates in 384-well plates. MDMEC and MHEC were incubated with either VCAM−NP or IgG−NP for 30 min. Following a 3× wash in PBS, the cells were lysed and pipetted into a 384-well plate and T2-weighted images were acquired. MR images were obtained using a 4.7 T superconducting magnet (Bruker) and performing multiecho spin−echo sequences (TR/Te = 2000/3.5 ms × 40). (B) T2 relaxation times (21 °C; 4.7 T) determined for the MDMEC and MHEC lysates.

directly labeled with Cy5.5 (i.e. without nanoparticle) to confirm the level of VCAM-1 expression on each cell type. Incubated cells were washed 2× in cold FACS buffer and 1× in cold DPBS alone, fixed in 100 μL of 2% paraformaldehyde (in DPBS) and stored at 4 °C in the dark. Samples were analyzed by flow cytometry (10 000 cells/sample) on a Becton Dickinson FACSCalibur (San Jose, CA) using the FL-4 channel to detect the Cy5.5 label on the nanoparticles. Cell isolation, labeling, and FACS analysis were performed in duplicate.

MR Imaging. MHEC and MDMEC were grown to confluence in six-well plates and then harvested as described above. MHEC and MDMEC were pooled separately into two tubes, centrifuged at 4 °C for 10 min, and resuspended in 500 μL of DMEM containing 5% FCS. Each cell suspension was then split into two 250 μL aliquots. One pair of MHEC and MDMEC aliquots were incubated in 100 μL of 100 μg/mL IgG on IgG−NP, while the second pair were incubated in 100 μL of 100 μg/mL anti-VCAM-1 on VCAM−NP for 30 min at 37 °C. Following incubation, the cells were washed three times in DMEM containing 5% FCS, lysed, and pipetted into 4 wells of a 384-well plate. MR images of the wells were obtained on a 4.7 T superconducting magnet (Bruker) using multiecho spin−echo sequences (96 × 96 matrix, 3.0 cm FOV, 1 mm slice thickness, TR 2000 ms, Te_1 = 3.5 ms × 40 echoes). The T2 relaxation time of each sample was determined as previously described (*19*).

Intravital Confocal Microscopy and Immunohistochemistry. C57B1/6 mice (n = 6) were injected subcutaneously in the left ear with 5 ng of mTNF-α in 10 μL of saline. After 24 h, the animals were anesthetized with isoflurane (1−2%) and injected intravenously (retino-orbital) with either VCAM−NP (n = 2) or IgG−NP (n = 2) at a dosage of 165 μg of Fe in 150 μL of PBS (pH 7.4). The ears of each animal were imaged on a Nikon EF600N microscope equipped with a BioRad Radiance 2100 confocal system at 1, 6, and 24 h following nanoparticle injection using a 40× water immersion objective. Fluorescence images of the vasculature were acquired with a z resolution of 1 μm and a depth of 25 μm in the Cy5.5 channel. Identical settings were used for the acquisition of all confocal images. Images used in the figures represent the brightest cross-sectional image of the stack of images. The two animals that were not injected with nanoparticles were sacrificed by CO_2 asphyxiation at the 6 h time point for histology. The other four animals were sacrificed upon completion of imaging at the 24 h time point. The ears were removed from each of the animals and sections stained for CD31 and VCAM-1. Digital images were acquired on a Nikon Eclipse E400 upright microscope equipped with an Insight color camera using a 40× objective.

RESULTS AND DISCUSSION

Endothelial host response is one of the earliest and most consistent biomarkers of many diseases. One promising molecular marker for identifying sites of early-stage inflammation is VCAM-1. Here, we developed a magnetofluorescent nanoparticle capable of detecting VCAM-1 expression by both magnetic resonance and optical imaging. This would allow disease screening by MR imaging and after surgical identification of diseased areas by intraoperative fluorescence imaging. Specifically, we coupled a near-infrared fluorochrome (Cy5.5) and an anti-VCAM-1 antibody to cross-linked dextran-coated iron oxide (CLIO) nanoparticles (Figure 1). CLIO nanoparticles provide an attractive platform for creating targeted imaging probes because of their high stability, superparamagnetic properties for MR contrast, and their controllable chemistry for surface modification. The CLIO nanoparticles utilized in this study were synthesized with aminated functional groups introduced onto the dextran to facilitate bioconjugation. Each nanoparticle was labeled with approximately 10 Cy5.5 fluorochromes. The remaining unconjugated amines were converted to carboxyl groups, and rat anti-mouse anti-VCAM-1 antibodies were covalently conjugated to the nanoparticles using carbodiimide (EDC) and sulfo-NHS chemistry (VCAM−NP). In parallel, Cy5.5 labeled CLIO nanoparticles were

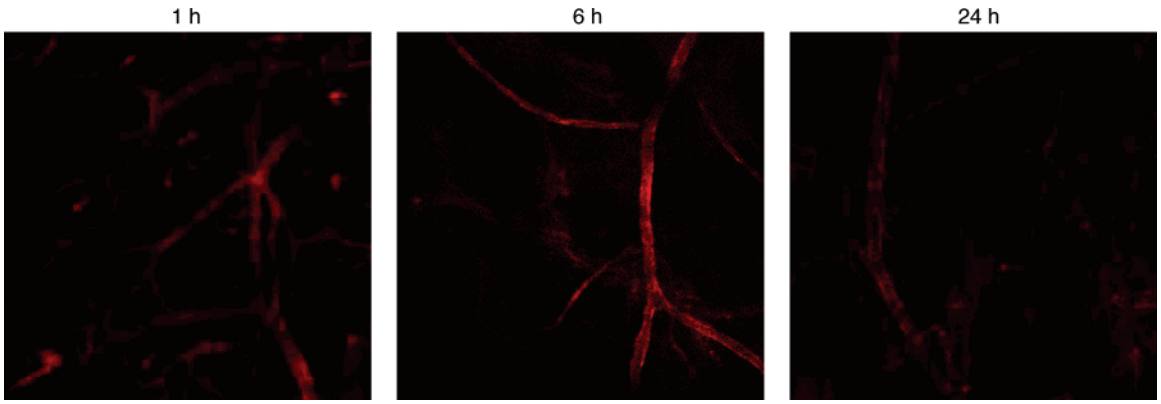

Figure 4. Fluorescence confocal microscopy images of mTNF-α activated endothelium in a C57B1/6 mouse 1, 6, and 24 h after injection of VCAM−NP. The left ears of C57B1/6 mice were injected with mTNF-α. After 24 h, VCAM−NP was introduced via retino-orbital injection. Representative fluorescence images of the left ear at 1, 6, and 24 h postinjection are shown. At 1 h, most of the nanoparticles still appear to be in circulation; however, by 6 h VCAM−NP is clearly localized at the endothelial wall.

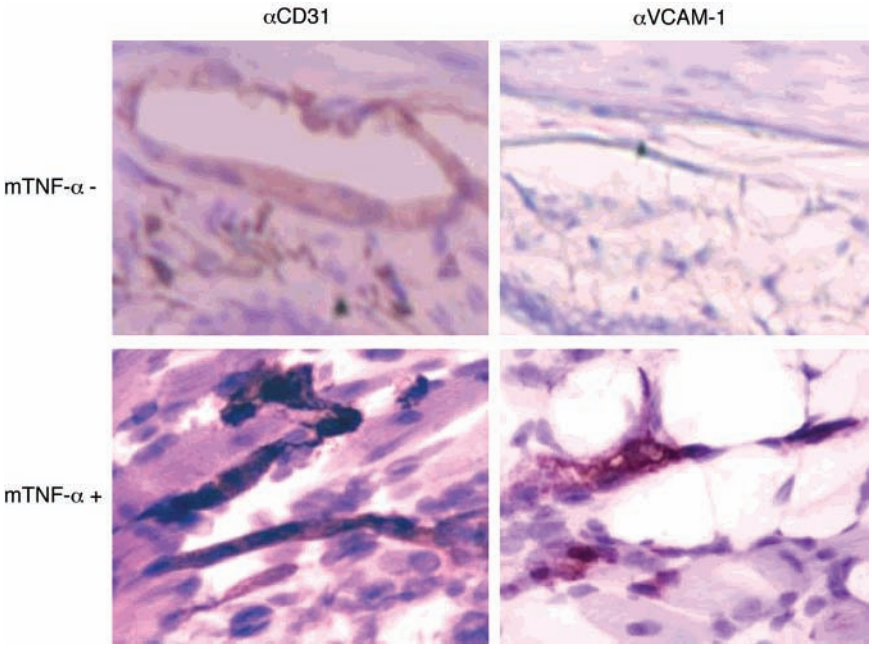

Figure 5. Immunohistochemical analysis of normal and mTNF-α activated ears. Adjacent serial sections of ears 30 h following mTNF-α treatment revealed the up-regulation of VCAM-1 in endothelial cells. Endothelial cells from untreated ears did now show any appreciable VCAM-1 staining.

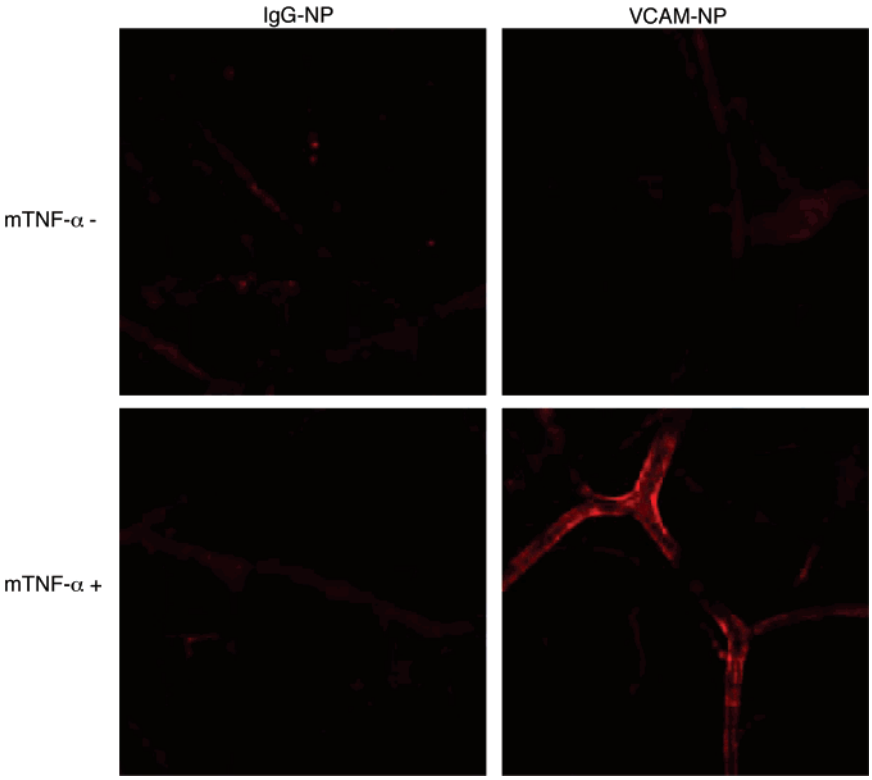

Figure 6. Fluorescence confocal images of normal and mTNF-α activated ears 6 h following administration of either IgG−NP or VCAM−NP. Specific staining of the endothelium is only seen in the activated ear of animals injected with VCAM−NP. Small amounts of IgG−NP can be detected in circulation, but no fluorescence appears to be localized to the endothelium.

similarly labeled with rat IgG (IgG−NP), as a negative control. Labeling ratios of 0.63 mg of IgG per mg of Fe and 0.87 mg of anti-VCAM-1 per mg of Fe were measured.

To evaluate the ability of the targeted nanoparticles to detect the expression of VCAM-1 on endothelial cells, a model system was established using primary cultures of MDMEC and MHEC. MDMEC has previously been shown to naturally express low levels of VCAM-1 in culture unless activated by agents such as TNF-α, while MHEC expresses constitutively high levels of VCAM-1 in culture (*20*). Each cell line was grown to confluence in culture and labeled with either VCAM−NP or IgG−NP. FACS analysis demonstrated a significant shift in fluorescence solely for the MHEC labeled with VCAM−NP (Figure 2). No shift was evident for either cell line when labeled with IgG−NP, indicating little cell uptake and nonspecific binding during the 30 min labeling procedure.

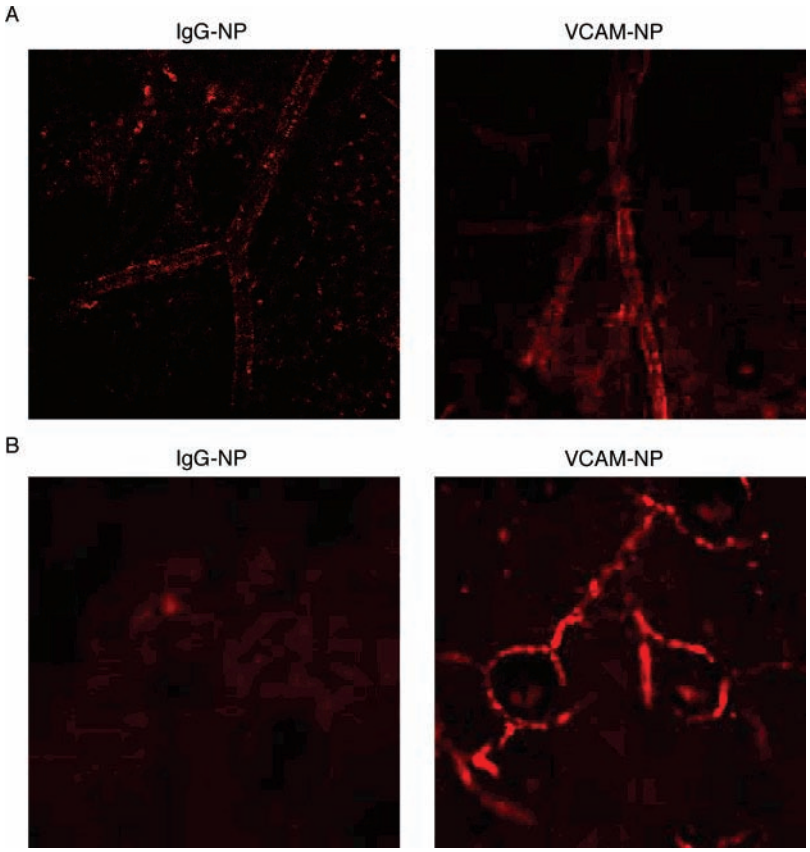

Figure 7. Fluorescence confocal images of mTNF-α activated ears 24 h following administration of either IgG−NP or VCAM−NP. (A) At 24 h postinjection of IgG−NP, nonspecific uptake of the nanoparticles along the activated endothelium can be detected in some of the larger vessels by fluorescence confocal microscopy. Activated endothelium targeted with VCAM−NP, however, still maintains a greater level of labeling, as exhibited by the brighter fluorescence signal. (B) IgG−NP cannot be detected in the microvasculature of the mTNF-α activated endothelium (at 24 h), while VCAM−NP still elicits a bright fluorescence signal, particularly in the microvasculature surrounding hair follicles.

A statistically insignificant shift in fluorescence was observed with MDMEC labeled with VCAM−NP, which could be attributed to low levels of VCAM-1 expression, but is at the fringe of the detection limit of this system. Similar results were seen in analogous experiments conducted with anti-VCAM-1 antibody and IgG directly labeled with Cy5.5 (i.e. without nanoparticle).

In addition to detecting VCAM-1 expression by flow cytometry, we also detected endothelial VCAM-1 expression by MRI. Specifically, following the labeling of MDMEC and MHEC with VCAM−NP or IgG−NP in culture, the cells were lysed and the extracts imaged in a 384-well plate using a 4.7 T MR scanner (Figure 3). MHEC labeled with VCAM−NP exhibited a substantially reduced T2 relaxation time (T2 = 10.0 ms, 21 °C, 4.7 T) compared with MDMEC and MHEC incubated with IgG−NP (T2 = 105.0 ms, 21 °C, 4.7 T). A low T2 relaxation time is indicative of superparamagnetic nanoparticles present in the sample. The MDMEC that were labeled with VCAM−NP also demonstrated a reduced relaxation time (T2 = 39.1 ms, 21 °C, 4.7 T), which could, again, be attributed to low levels of VCAM-1 expression. Although this VCAM-1 expression on MDMEC was far less evident by FACS analysis, it should be noted that FACS records fluorescence on a per cell basis, most likely resulting in a higher threshold for detection than in pooled cell samples and making it difficult to detect low levels of bound contrast agents (i.e. VCAM−NP).

The ability of VCAM−NP to detect activated endothelium in vivo was evaluated by intravenously administering the nanoparticles in a murine inflammatory model. Specifically, the endothelium in the left ear of C57B1/6 mice was activated by injection of mTNF-α. After 24 h, either VCAM−NP or IgG−NP was introduced intravenously by retino-orbital injection. The vasculature of the left (mTNF-α positive) and right ear (mTNF-α negative) was then imaged at 1, 6, and 24 h postinjection via intravital confocal microscopy. The greatest degree of cell surface labeling with VCAM−NP in the mTNF-α activated ear was observed at the 6 h time point (Figure 4). Fluorescence from VCAM−NP clearly localized to the endothelium. Conversely, at 1 h most of the nanoparticles were still in the circulation and there was no clear sign of cell surface receptor labeling. At 24 h, the VCAM−NP was localized at the endothelium, but the signal had grown faint, most likely from dissociation of the anti-VCAM-1 antibodies from their target. Immunohistochemistry confirmed the upregulation of VCAM-1 expression at 6 h (Figure 5).

Analysis of all the fluorescent confocal images of the vasculature at 6 h postinjection demonstrate the specific binding of VCAM−NP only to the endothelium of the mTNF-α activated ear (Figure 6). VCAM−NP did not appear to bind to the endothelial surface of the vasculature in the unactivated ear, while IgG−NP did not label the vasculature in either ear. However, a low fluorescent signal was detected within the vessel lumen in all acquired images, indicative of residual circulating nanoparticles at this time point. Nonetheless, activated endothelium could easily be identified with VCAM−NP.

It should be noted that, at 24 h postinjection, IgG−NP also localized to the mTNF-α activated vasculature

to a small extent (Figure 7A). This is in agreement with previous reports of the nonspecific uptake and accumulation of CLIO at sites of inflammation by 24 h postinjection (*21*−*23*). However, a brighter signal still existed along the activated endothelium of animals injected with VCAM−NP.

Another interesting observation at 24 h was the extensive labeling, with VCAM−NP, of the mTNF-α activated microvasculature surrounding the hair follicles (Figure 7B). This could be the result of improved binding efficiency at the lower flow rates in the microvasculature or possibly an increased level of VCAM-1 expression per endothelial cell in the microvasculature. Surprisingly, however, there was no indication of fluorescence due to nonspecific uptake of IgG−NP in the activated microvasculature, in contrast to what was observed in some of the larger vessels. Further, no fluorescent signal was detected from IgG−NP in either ear (data not shown).

In conclusion, we have demonstrated a simple method for the attachment of near-infrared fluorochromes and whole antibodies to nanoparticles for intravital use. The anti-VCAM-1 antibodies retained activity following conjugation and were shown to specifically target endothelial cells expressing high levels of VCAM-1 by both FACS analysis and MR imaging of cell lysates. Further, effective delivery and labeling of activated endothelium was demonstrated in vivo using a murine inflammatory model. The VCAM−NP localized specifically to regions of the vasculature overexpressing VCAM-1, as determined by intravital microscopy and immunohistochemistry. The acquisition of bright fluorescent images suggests that fluorescently labeled CLIO nanoparticles could provide an alternative to other fluorescent tags for in vivo optical imaging. CLIO nanoparticles, however, also maintain the unique ability to provide MR contrast for deep tissue imaging, and their nontoxicity makes them a viable option for clinical applications.

Received January 13, 2005; Revised Manuscript Received April 1, 2005

A trifunctional bioconjugate consisting of the SV40 nuclear localization signal (NLS) peptide, an aliphatic triamine ligand, and the DNA intercalating pyrene has been synthesized and quantitatively labeled with $[^{99m}Tc(OH_2)_3(CO)_3]^+$. The radiotoxicity of the resulting nucleus-targeting radiopharmaceutical on B16F1 mouse melanoma cells has been investigated to evaluate the activity of Auger and Coster–Kronig electrons on the viability of cells. We found a dose-dependent significant radiotoxicity of the nucleus-targeting radiopharmaceutical clearly related to the low energy decay of ^{99m}Tc. These principal results imply a possible therapeutic strategy based on the use of the low-energy Auger electron-emitting ^{99m}Tc radionuclide attached to nucleus-targeting molecules and comprising an intercalator. Highly efficient DNA targeting vectors could complement the usual role of ^{99m}Tc in diagnostic applications. The Auger electrons emitted by the ^{99m}Tc nuclide induce DNA damage leading ultimately, through a mitotic catastrophe pathway, to necrotic cell death. Non-DNA-targeting ^{99m}Tc complexes display much lower radiotoxicity.

INTRODUCTION

Targeted radionuclide therapy is a very attractive strategy that specifically delivers therapeutic radiation doses to tumors without causing significant toxicity to normal tissue. Still, in reality this approach is often limited by the inevitable damage induced to healthy untargeted tissues such as bone marrow, liver, and kidneys by the high-energy particles commonly employed (*1*–*5*). In addition to α- or β^--emitters, the application of low-energy high-LET (linear energy transfer) Auger electron emitters has been proposed. This approach requires the radionuclide to be conjugated to carriers that specifically internalize and reach the DNA of targeted cancer cells to induce lethal DNA damage (*6*–*8*). Respective studies have been published in this context, in particular with ^{125}I and ^{111}In but also other radionuclides (*9*–*13*). The short path length of low-energy Auger electrons reduces the overall damage caused in nontargeted tissue. Moreover, in radiodrug metabolites DNA targeting and binding properties are often affected or lost; thus, they will display a lower radiotoxicity, damage to kidney and liver (*10*). The therapeutic advantage of Auger electron- versus α^- or β^--emitting radionuclides has been demonstrated clinically for several nuclides but only in theory for ^{99m}Tc (*2*, *14*–*17*). This radionuclide emits besides its well-known γ-radiation an average of four Auger or Coster–Kronig electrons per decay, according to the radiation spectra calculated by Howell (*18*). These data provide more complete Auger electron spectra than the ones given by MIRD and ICRP which do not consider the very low-energy N- and O-shell electrons. We recently demonstrated that ^{99m}Tc induces in vitro double-strand breaks in circular dsDNA when carried in its direct vicinity by DNA binding moieties such as intercalators (*19*). These results were the first experimental evidence that ^{99m}Tc possesses an unexpected potential for systemic radiotherapy, complementing its widely known diagnostic applications. As an extension of this study, it was intriguing to confirm the radiotoxic potential of DNA targeting ^{99m}Tc complexes also on the cellular level.

P = Proline, K = Lysine, R = Arginine, V = Valine, G = Glycine

We present in this paper the first in vitro experimental evidence that ^{99m}Tc complexes with nuclear targeting and DNA binding functionalities such as compound **1** (Scheme 1) have a pronounced radiotoxic effect on cultured mouse melanoma B16F1 cells. The nucleus targeting property has been analyzed by single cell fluorescence microscopy (with its nonradioactive Re analogue **3**) as well as with radioactivity-based cell uptake experiments.

EXPERIMENTAL PROCEDURES

Chemicals and solvents were purchased from Fluka AG Buchs Switzerland or Aldrich and used without further

purification. All reactions were performed under N_2 or Ar. $Na^{99m}TcO_4$ was eluted from a $^{99}Mo/^{99m}Tc$ Generator (Mallinckrodt) in 0.9% saline.

^1H and ^{13}C NMR spectra were recorded on Varian Gemini 300 or Bruker DRX500 spectrometers at 300 and 75 MHz, or 500 and 125 MHz, respectively. The reported chemical shifts (in ppm) are relative to solvent protons as reference.

Fluorescence Microscopy. Single cell fluorescence microscopy was performed on a Zeiss Axiovert microscope equipped with Hamamatsu camera. Costaining was performed by mounting the cells on a glass plate with glycerol/PBS (phosphate buffer in 0.9% NaCl) containing 1 μg/mL of DAPI (4′,6-diamidino-2-phenylindole).

Cell Uptake Experiments. About 10^6 exponentially growing B16F1 melanoma cells were incubated in six-well plates in a humidified 5% CO_2 atmosphere at 37° in DME medium (supplemented with 10% FBS, 100 U/mL of penicillin, and 100 g/mL of streptomycin) containing 10 MBq of the carrier-free compound of interest. After 5 h, the medium was removed and the cells rinsed with 3 mL of PBS. The cells were then incubated on ice for 5 min with 3 mL of NP-40 lysis buffer (10 mM Tris, pH 7.4; 10 mM NaCl; 5 mM $MgCl_2$; 0.5% NP-40). This solution was then transferred to an Eppendorf tube and gently vortexed to prevent the formation of cell aggregates. The nuclei were collected by centrifugation at 500*g* for 5 min at 4 °C. The nuclear pellet was resuspended in 3 mL of NP-40 lysis buffer as previously described (*20*). The nuclei were again collected by centrifugation at 500*g* for 5 min at 4 °C. All fractions (wells, growth medium, lysis buffer, and nuclei pellet) were assayed for radioactivity using a Veenstra VDC-304 ionization chamber.

HPLC was performed on a Merck L7000 system using a Macherey-Nagel EC 250/3 Nucleosil 100−5 C18HD column for nonradioactive and a Macherey-Nagel EC 250/3 Nucleosil 100−5 C18 column for radioactive compounds. HPLC solvents were 0.1% trifluoroacetic acid (solvent A) and MeOH HPLC grade (solvent B). Gradient: 0−3 min: 100% A; 3.1−9 min: 75% A, 25% B; 9.1−20 min: linear gradient from 66% A (34% B) to 0% A (100% B); 20−28 min: 100% B; 28.1−30: 100% A. Flow rate: 0.5 mL/min, detection at 250 nm and/or with a γ-detector for the radiolabeled compounds.

Radiotoxicity Experiments. About 2000 exponentially growing B16F1 melanoma cells per well were incubated in 96-well plates in a humidified 5% CO_2 atmosphere at 37° in 100 μL of DME medium (supplemented with 10% FBS, 100 U/mL of penicillin, and 100 g/mL of streptomycin) containing the desired amount of the carrier-free compound of interest. After 5 to 9 days, the supernatant was removed and 100 μL of freshly diluted WST-1 (4-[3-(4-iodophenyl)-2-(nitrophenyl)-2*H*-5-tetrazolio]-1,3-bezene disulfonate) solution was added. The plates were incubated for 30−60 min at 37° in a humidified 5% CO_2 atmosphere. Cell viability was evaluated by measurement of the absorption at 450 nm using a Dynatech MR5000 plate reader.

***N*-(2-Aminoethyl)-*N*′-pyrene-1-ylmethylethane-1,2-diamine (4).** Pyrene-1-carbaldehyde (1.08 g, 4.69 mmol) and diethylenetriamine (1.452 g, 1.528 mL, 14.07 mmol) were dissolved in 50 mL of EtOH. About 25 mL of CH_2Cl_2 was added until the solution became clear. After addition of 5 g of molecular sieves of 3 Å pore diameter, and stirring for 36 h at r.t., the solution was cooled to 0 °C, and $NaBH_4$ (355 mg, 9.38 mmol) was added in small portions. After 12 h, excess of $NaBH_4$ was quenched with a few drops of H_2O. The solution was filtered, and the solvents from the filtrate were evaporated under vacuum. The resulting oil was purified by flash chromatography (CH_2Cl_2/MeOH/25% NH_4OH, 10:3:0.3) to afford 649 mg (2.06 mmol) (44%) of a light yellow oil. ^1H NMR ($CDCl_3$, 300 MHz): δ 8.22 (d, 1H), 8.07 (d, 2H), 8.01 (m, 2H), 7.90 (m, 4H), 4.34 (s, 2H), 2.99 (s, 4H), 2.74 (t, 2H), 2.66 (t, 2H), 2.60 (t, 2H), 2.51 (t, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 133.4, 131.1, 130.6, 130.5, 128.9, 127.5, 127.3, 126.9, 125.8, 125.0, 124.9, 124.8, 124.6, 124.5, 123.0, 51.1, 50.6, 48.5, 40.6. MS (ESI): *m/z* 318.27 [$(M + H^+)$, calcd for $C_{21}H_{24}N_3^+$ 318.20]. HPLC t_R = 17.8 min. TLC R_f = 0.15 (CH_2Cl_2/MeOH/25% NH_4OH, 100:30:3).

(2-Aminoethyl)-[2-(*tert*-butoxycarbonylpyrene-1-ylmethylamino)ethyl]carbamic Acid *tert*-Butyl Ester (5). 2-Acetyl-5,5-dimethylcyclohexane-1,3-dione (Dde) (316 mg, 1.73 mmol) was added to a solution of **4** (500 mg, 1.58 mmol) in 20 mL of EtOH. The solution was stirred at r.t. for 3 h. Di-*tert*-butyl pyrocarbonate ($(BOC)_2O$) (759 mg, 3.48 mmol) was added to the solution, and stirring was continued for 5 h. A 5 mL amount of a 25% aqueous hydrazine solution was added to the reaction mixture. After 2 h the solvent was removed in vacuo. The resulting oil was dissolved in 15 mL of CH_2Cl_2, filtered, and dried again. Purification by flash chromatography (CH_2Cl_2/MeOH, 10:1) yielded 752 mg (1.45 mmol) (92%) of a light brown slightly sticky solid. ^1H NMR ($CDCl_3$, 300 MHz) δ 8.30−7.70 (m, 9H), 5.23 (s, 2H), 3.47−3.10 (br, 10H), 1.43 (s, 18 H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ 155.4, 131.1−130.6 (br), 129.2, 128.9, 128.1, 127.2, 125.9, 125.1, 124.8, 124.6, 123.3−122, 80.6, 48.7−42.9 (br), 39.6, 28.4. MS (ESI) *m/z* (%) 518.00 (100) [$(M + H)^+$], 417.96 (10) [$(M + H)^+$-BOC], calcd 518.29, 418.24. HPLC t_R = 23.5 min. TLC R_f = 0.15 (CH_2Cl_2/MeOH, 10:1).

[2-(*tert*-Butoxycarbonylpyren-1-ylmethylamino)-ethyl]-{2-[4-(1,3-dioxo-1,3-dihydroisoindol-2-yl)butylamino]ethyl}carbamic Acid *tert*-Butyl Ester (6). A 20 mL aqueous suspension containing 2 g of KF and 2 g of Celite was stirred for 1 h at room temperature. The solvent was then removed under vacuo. The resulting powder was subsequently resuspended in acetonitrile and dried in high vacuum several times to remove any trace of water. The KF/Celite mixture obtained was then added to a solution containing 820 mg (1.59 mmol) of **5** in 25 mL of dried acetonitrile. After 1 h stirring at room temperature, the suspension was heated until reflux. *N*-(4-Bromobutyl)phthalimide (305 mg, 1.08 mmol) of and 178 mg (1.19 mmol) of NaI were then added to the boiling solution, which was then further refluxed in the dark for 14 h. The reaction mixture was then filtered and cooled. After removal of the solvent, the product was purified by flash chromatography (CH_2Cl_2/MeOH/25% NH_4OH, 100:3:0.5) to yield 503 mg (0.72 mmol) (65%) of a light yellow solid.^1H NMR ($CDCl_3$, 300 MHz) δ, 8.09 (m, 5H), 7.91 (m, 4H), 7.67 (m, 2H), 7.53 (m, 2H), 5.21 (s, 2H), 3.60 (m, 2H), 3.38 (br, 2H), 3.19 (br, 2H), 3.06 (br, 1H), 2.79−2.66 (m, 4H), 2.45 (s, 2H), 1.54 (s, 9H), 1.43 (s, 13H). ^{13}C NMR ($CDCl_3$, 75 Hz) δ 168.4, 155.7, 133.9, 132.0, 131.3, 131.0, 130.8, 127.9, 127.4, 126.1, 125.3, 125.0, 124.7, 123.1, 79.9, 77.4, 61.9, 53.4, 48.7, 47.7, 47.5, 37.6, 37.5, 30.8, 29.7, 28.3, 27.0, 26.1, 25.0, 24.5. MS (ESI) *m/z* (%) 719.80 (100) [$(M + H)^+$], calcd 719.37. HPLC t_R = 24.3 min. TLC R_f = 0.52 (CH_2Cl_2/MeOH/25% NH_4OH, 10:1:0.1).

{2-[(4-Aminobutyl)-*tert*-butoxycarbonylamino]-ethyl}-[2-(*tert*-butoxycarbonylpyrene-1-ylmethylamino)ethyl]carbamic Acid *tert*-Butyl Ester (7). Di-*tert*-butyl-pyrocarbonate (77 mg, 0.35 mmol) in 3 mL of absol ethanol was slowly added to an ice-cooled solution of **6** (169 mg, 0.23 mmol) in 3 mL of abs. ethanol. The

reaction mixture was then stirred overnight at room temperature. Excess $(BOC)_2O$ was then hydrolyzed by adding a few drops of water. A 25% hydrazine aqueous (1 mL) solution was added to the reaction mixture. After a further 3 h of stirring, the solvent was removed in vacuo and the resulting crude product was purified by flash chromatography (CH_2Cl_2/MeOH/25% NH_4OH, 10:1:0.1) to afford 126 mg (0.18 mmol) (78%) of the compound **7** as a light yellow oil. ^1H NMR ($CDCl_3$, 300 MHz) δ 8.20−8.06 (m, 5H), 8.0−7.92 (m, 4H), 5.23 (s, 2H), 3.44−3.0 (br m, 10H), 2.93 (s, 2H), 2.71 (s, 2H), 1.55 (s, 4H), 1.45 (s, 9H), 1. 40 (s, 18H). ^{13}C NMR ($CDCl_3$, 75 MHz) δ 155.1, 155.0, 130.2, 130.1, 130.0, 129.5, 127.8, 127.3, 126.1, 125.2, 125.1, 124.6, 80.3, 80.0, 77.3, 47.5, 46.9, 45.5, 45.3, 44.9, 44.5, 43.8, 41.5, 41.3, 30.0, 29.8, 29.4, 29.1, 28.3, 25.8, 25.0. MS (ESI) *m/z* (%) 689.30 (100) [$(M + H)^+$], 1376.43 (22) [$(M_2)^{+\cdot}$], calcd 689.42, 1376.84. HPLC t_R = 23.8 min. TLC R_f = 0.24 (CH_2Cl_2/MeOH/25% NH_4OH, 10:1:0.1).

Compound 8. A solution containing 20 mg (0.0107 mmol) of $PZ_1-KZ_2-KZ_2-KZ_2-RZ_3-KZ_2-V-G-G$ (Z_1 = Fmoc, Z_2 = BOC, Z_3 = Pbf), 11 mg (0.016 mmol) of **7**, and 17 mg (0.0321 mmol) of PyBOP in 3 mL of dichloromethane was stirred for 8 h at room temperature. After addition of 3 μL (2.2 mg) (0.0217 mmol) of triethylamine, the solution was further stirred for 8 h. After removal of the solvent in vacuo, the crude product was purified by preparative HPLC to afford 8 mg (0.005 mmol) (29%) of compound **8** as a light yellow oil. MS (ESI): 1272.47 (100) [$(M + 2H)^{2+}$], calcd 1272.22. HPLC: t_R = 28.3

Compound 2. A solution containing 8 mg (0.005 mmol) of **8** in 2 mL of TFA/TIS/water (95%/2.5%/2.5%) was stirred for 2 h at room temperature. After removal of the solvent in vacuo, the resulting crude product was dissolved in 2 mL of 20% piperidine in DMF. This solution was stirred for 45 min at room temperature. After removal of the solvent in vacuo, the resulting crude product was purified by preparative HPLC to afford 400 μg (0.4 μmol) (9%) of compound **2**. MS (ESI): 1367.8 (100) [$(M + H)^+$], calcd 1367.92. HPLC: t_R = 18.1.

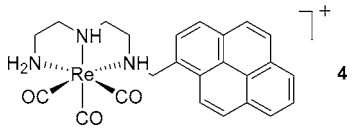
Radiolabeling. The precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared as described elsewhere (*21*). Compound **1** was prepared from **2** and $[^{99m}Tc(OH_2)_3(CO)_3]^+$ as follows: 100 μL of a 10^{-4} M solution of **2** was added to a saline solution (900 μL) containing the radiolabeling precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ in a sealed vial under N_2. The vial was heated to 90 °C for 30 min and cooled in an ice bath. Radiochemical yield was better than 95%; quality control was performed by HPLC with a gradient as described in the beginning, t_R = 22.5 min.

RESULTS AND DISCUSSION

The trifunctional compound **2** (Scheme 2) comprises a SV40 nuclear localizing signal (NLS) peptide known to carry cargo molecules to the nucleus of living cells, a pendant DNA-intercalating pyrene moiety, and a triamine tridentate ligand which is used for later labeling with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ or its rhenium surrogate to yield compounds **1** and **3**, respectively (*21*−*25*). According to the biological properties of SV40, this conjugate is expected to cross the cellular and nuclear membranes of any type of cell and to bind through the pyrene functionality to cellular DNA. The Auger electrons emitted by the ^{99m}Tc nuclide in the direct vicinity of cellular DNA would then induce enough DNA damage, and in particular double-strand breaks, to lead to the death of the cell.

Synthesis. The bioconjugate **2** comprising the SV40 NLS peptide, a pendant DNA-intercalating pyrene moiety, and a triamine tridentate ligand was synthesized with standard protecting group procedures according to Scheme 2. Compound **2** reacts in water with $[M(OH_2)_3(CO)_3]^+$ (M = ^{99m}Tc (*21*), Re (*26*)) to form the ^{99m}Tc-labeled complex **1** and nonradioactive Re complex **3** in quantita-

Scheme 3. Structure of Compound [Re(4)(Co)3]$^+$



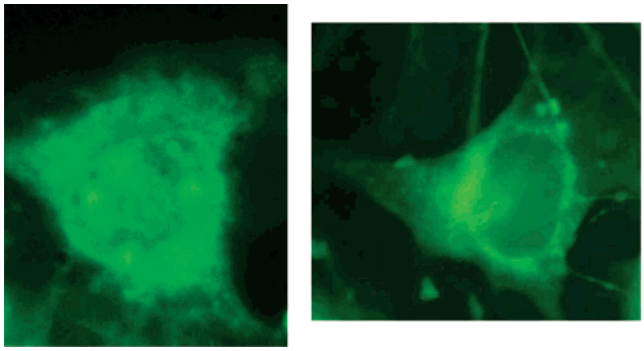


Figure 1. Cellular distribution of compound **3** (left) and **4** (right) observed with a fluorescence microscope after 5 h incubation. Only compound **3**, which is a bioconjugate with the SV40 NLS peptide, accumulates in the nucleus.

tive yields. The aliphatic triamine ligand has been chosen since it forms a small monopositively charged complex supporting electrostatic interaction to the negatively charged DNA backbone. Compounds **1** and **3** possess a rather rich stereochemistry since they exist as four diastereomeric pairs of enantiomers. The structure of the complex will influence the biological behavior of the bioconjugate; however, since it is not a direct part of the targeting portion, we expected the influence to be rather small. The d^6 low spin nature of the M(I) center renders the complex very robust, and no decomposition was observed at low pH values or under physiological conditions.

Nuclear Localization. The ability of complex **3** to target nuclear DNA of cultured cells was determined by single cell fluorescence microscopy, making use of the strong fluorescing emission properties of pyrene. A negative control experiment was performed with the cationic complex [Re(**4**)(CO)3]$^+$ (*19*) which bears the pyrene moiety and the ^{99m}Tc tricarbonyl core but lacks the NLS peptide required for nuclear localization (Scheme 3). Thus, this compound should not enter the cellular nucleus. Figure 1 shows the images of single B16F1 mouse melanoma cells taken after 5 h of incubation in the growth medium containing compounds **3** and **4** in a concentration of 10^{-5} M. Expectedly, the images reveal that complex **3** accumulates in the nucleus while compound **4** does not.

Besides qualitative visualization, we also aimed at quantification of cell uptake in the nucleus with the ^{99m}Tc compound **1**. About 10^6 B16F1 adherent cells were incubated in 3 mL of growth medium containing 5 MBq (8×10^{-11} M) of **1**. As is the case for all cell studies described herein, compound **1** was purified by HPLC after synthesis and before incubation. Therefore, so-called no carrier added radiopharmaceutical was applied and no cold, unlabeled material was present. After 5 h, cell membranes were lysed under mild conditions, and intact nuclei were separated by centrifugation. The radioactivity present in the different fractions (growth medium, cell membrane and cytoplasm, nuclei, and well plastic walls) was measured. About $3.5 \pm 0.5\%$ of **1** was present in the nucleus while $14.0 \pm 0.9\%$ was found in the cytoplasm and/or the cell membrane. The remaining 82% stayed in the growth medium or bound to the vial. According to

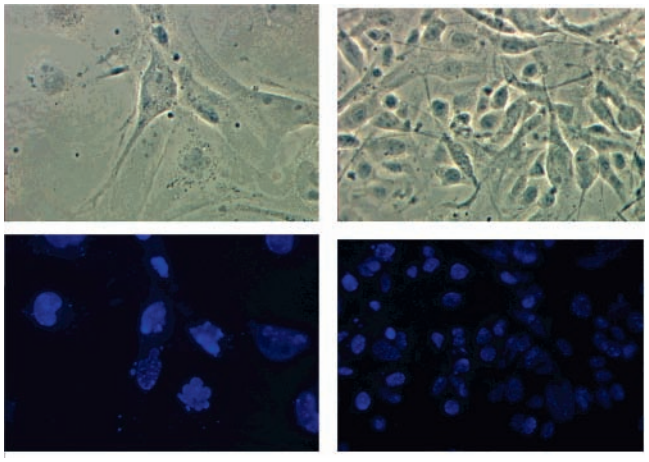

Figure 2. White light (top) and DAPI staining fluorescence (bottom) images of mouse melanoma B16F1 cells after 5 days incubation with compound **1** (left) and [^{99m}TcO$_4$]$^-$ (right) (same enlargement). Micronuclei are clearly visible after incubation with compound **1**.

the initial concentration of bioconjugate and with the specific activity of ^{99m}Tc, an average of about 5×10^3 molecules or ^{99m}Tc radionuclides did, thus, reach every nucleus.

The nucleus uptake is related to the presence of the SV40 peptide. Under the same conditions, less than 1% of [^{99m}TcO$_4$]$^-$ or the cationic complex [^{99m}Tc(diethylenetriamine)(CO)$_3$]$^+$ were found in the cytoplasm and the cell membrane, while for both no significant amount was detected in the nucleus.

Radiotoxicity. Radiotoxicity of ^{99m}Tc based on its Auger electron emission has been described only punctually (*27*, *28*). The radiotoxic effect of ^{99m}Tc complex **1** was studied by incubating cells (about 3000 cells per well in a 96-well plate) in 100 μL of growth medium containing different activities of this compound. To avoid any chemical effect or saturation of the cells with unlabeled trifunctional ligand **2**, complex **1** was purified by HPLC prior to addition to the cells. As control experiments, non-DNA-targeting [^{99m}TcO$_4$]$^-$ and [^{99m}Tc(diethylenetriamine)(CO)$_3$]$^+$ were used as references in the same experimental setup. Furthermore, to rule out any chemical cytotoxicity induced by the pyrene unit or the technetium tricarbonyl complex, cells were incubated with the same concentration of the nonradioactive Re complex **3**. Overall concentrations of the hot and cold compounds are in the nanomolar range. After 36 h of incubation, the growth medium was removed and replaced by fresh medium to allow the cells to recover. After 5 and 9 days, images of the cells were taken (Figures 2 and 3) and the fraction of surviving cells was determined by WST-1 based colorimetric assay (Figure 4).

At a radioactivity concentration of 35 MBq/100 μL (1.75×10^{-8} M) of complex **1**, virtually 100% of the cells died within 9 days; no outgrowth of viable cells could be seen anymore. Interestingly, the cell death process was very slow. It has to be considered at this point, that the radioactivity ^{99m}Tc ($T_{1/2} = 6$ h) approaches zero after 48 h (8 half-life times). Cells gradually increased in size about 24 h after beginning of incubation. These cells were no longer capable of division, but colorimetric assays showed that they were still viable. They continued to increase in size, becoming huge, and then gradually began to die after about 5 days. At that time, staining with (4′,6-diamidino-2-phenylindole) clearly showed nuclear damage and in some cells formation of micronu-

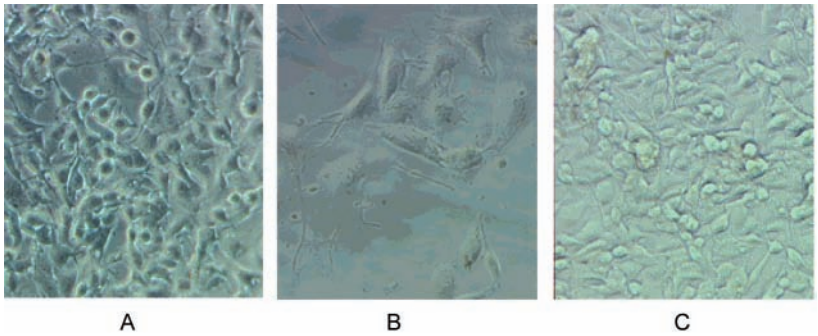

Figure 3. Images (same enlargement) of cells taken 5 days after incubation with 10 MBq/100 μL of (A) $[^{99m}TcO_4]^-$, (B) complex **1**. (C) Untreated cells. While cells treated with $[^{99m}TcO_4]^-$ are healthy and reproductively active, those treated with **1** show typical swelling and micronuclei formation and are also no longer capable of division.

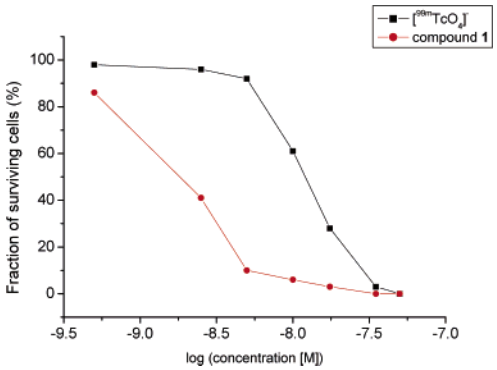

Figure 4. Dose−response for compound **1** and $[^{99m}TcO_4]^-$.

clei (Figure 2). These observations (cell swelling, micronuclei formation) are typical of either radiation-induced mitosis-linked death or radiation-induced cell senescence. Both mechanisms, which usually result from radiation-induced DNA damage, ultimately lead to cell necrosis (*29*, *30*). With the same radioactivity (35 MBq/100 μL), non-nucleus-targeting $[^{99m}TcO_4]^-$ and $[^{99m}Tc(diethylenetriamine)(CO)_3]^+$ displayed a much lower radiotoxic effect than compound **1**. Cellular division was delayed, probably due to cell cycle arrest, but recovery with exponential growth was observed within a few days. The same concentration (1.75×10^{-8} M) of nonradioactive Re complex **3** displayed no cytotoxicity at all, which clearly rules out any chemotoxic effect.

The radiotoxic effect reduces with decreasing amount of ^{99m}Tc radioactivity. Cells incubated with 10 MBq/100 μL (5×10^{-9} M) of compound **1** also displayed typical cell swelling and formation of micronuclei (Figure 3). After 5 days of incubation, about 6% of the cells, as compared to untreated cells, were still viable. After day 6, a few cells recovered and regrew in an exponential way. Incubation with 10 MBq/100μL of non-nuclear-targeting $[^{99m}TcO_4]^-$ and $[^{99m}Tc(diethylenetriamine)(CO)_3]^+$ did not induce any cell swelling at all (Figure 3). After 5 days about 60% of the cells were found to be viable. Concentrations as low as 1.4 MBq/100 μL (7×10^{-10} M) of either compound **1** or $[^{99m}TcO_4]^-$ and $[^{99m}Tc(diethylenetriamine)(CO)_3]^+$ had almost no effect on cell proliferation.

Figure 4 shows the dose−response relationship for compound **1** and $[^{99m}TcO_4]^-$. From these curves, LD_{50} values of about 1.8×10^{-9} M in and 1.2×10^{-8} M, respectively, can be estimated. This demonstrates that the radiotoxicity of the nuclear targeting compound **1** is about 10 times higher as compared to $[^{99m}TcO_4]^-$. This factor can be significantly higher, if a more efficient nuclear targeting agent is found.

CONCLUSION

In conclusion, we have demonstrated with single cell fluorescence microscopy and distribution assays that trifunctional complex **1** targets and accumulates in the nucleus of B16F1 mouse melanoma cells. We further showed that, at equal doses, compound **1** has a much stronger radiotoxic effect than non-nuclear-localizing ^{99m}Tc complexes. Morphological changes of the dying cells, such as cell swelling and formation of micronuclei, are typical of either radiation-induced mitosis-linked cell death or radiation-induced cell senescence, both phenomena resulting from DNA damage. The radiotoxic effect of **1** is most likely due to the induction of DNA strand breaks by the Auger electrons of ^{99m}Tc and is, thus, the first experimental evidence on the cellular level that ^{99m}Tc possesses a potential for systemic radionuclide therapy, complementing its widely known diagnostic application.

The amount of ^{99m}Tc radioactivity applied in our experiments was still relatively large or, in other words, the uptake of ^{99m}Tc too small or too slow to become therapeutically relevant. On the other hand, we could show that a small number of ^{99m}Tc radionuclides taken up in the nucleus leads to cell death. In our current work, we are studying nucleus targeting compounds which have a very high and fast uptake in order to reduce the radioactivity needed to achieve a site-specific, therapeutic effect. Combination of such labeled compounds with cell receptor targeting molecules aims at tumor cell-specific uptake.

Cross-Linking between Thymine and Indolyl Radical: Possible Mechanisms for Cross-Linking of DNA and Tryptophan-Containing Peptides

Petar M. Mitrasinovic*

Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J3. Received February 22, 2005; Revised Manuscript Received March 31, 2005

As experimentally observed in γ-irradiated aqueous solutions of tryptophan-containing peptides in the presence of DNA, a fast electron (or hydrogen atom) transfer from the DNA restores an intact tryptophan residue at the expense of the DNA integrity. Alternatively, addition of the deprotonated electron-deficient indolyl radical to the DNA, followed by subsequent rearrangement, may lead toward DNA/tryptophan-containing peptide cross-linking. Herein, possible reaction mechanisms for thymine−indolyl radical cross-linking are proposed. The consistent use of the contact spin density distribution is the key virtue of this work. The Becke 3, Lee, Yang, and Parr (B3LYP) density functional theory (DFT) method is employed to investigate the feasibility of the proposed cross-linking mechanisms. A possible complete reaction mechanism consists of a combination of the C_5-hydroxylated thymine and indolyl radicals forming the initial cross-linked product, a hydrogen transfer within the initial cross-linked product by use of a bridging water molecule, and a dehydration step. The overall thermodynamics of the free energy profiles at 0 and 298 K are similar and display differences of magnitude for the hydrogen-transfer reaction. Temperature may be a key factor influencing the overall mechanism. The skeletal structures and contact spin densities on the heavy atoms of the tryptophan side chain and indolyl radicals are essentially equal. Hence, it is believed that a direct combination of the C_5-hydroxylated thymine and tryptophan radicals should form the initial cross-linked product, as far as addition of the tryptophan radical to the DNA is concerned.

INTRODUCTION

Various agents and processes such as drugs (*1*), ionizing radiation (*2*), and autoxidation (*3*) induce damage to DNA in vitro and in vivo. Reactive oxygen species (ROSs), such as singlet oxygen ($^1O_2$), hydrogen peroxide (H_2O_2), superoxide anion ($O_2^{\bullet -}$), hydroxyl radical ($^\bullet$OH), and hydroperoxyl radical (HOO$^\bullet$), are able to disturb the oxidant−antioxidant balance, influencing many pathological conditions, such as cancer (*4*−*8*), Alzheimer's disease (*9*, *10*), and Parkinson's disease (*11*). Up to 10^3 oxidative damaging events upon the DNA of each cell in the human body can occur every day (*12*). Presumably, the $^\bullet$OH radical is the most damaging (*12*, *13*). The importance of radiation biology to probe the oxidative effects of hydroxyl radicals has been recognized by biologists and chemists (*14*, *15*). ROSs attack DNA bases and proteins inside the nucleus and generate bioradicals, protein and DNA (sugar or base) radicals, as primary products that may lead to chain breaks and DNA−DNA or DNA−protein cross-links. DNA−protein cross-links have been observed in living cells and isolated chromatin (*16*−*18*). However, in the overall consideration of DNA damage and its consequences, cross-linking is by no means a minor process.

Several model systems (*19*−*25*), composed of pyrimidine bases and various amino acids in aqueous solution, have been separated and characterized via capillary gas chromatography−mass spectrometry. Hydroxyl radical-induced cross-links between cytosine and tyrosine (*22*), between thymine (Thym) and tyrosine (*19*), and between thymine and lysine (*23*) have been investigated in greater detail. The final step in possible reaction mechanisms is unknown for the cytosine (or thymine)/tyrosine system. On the basis of the identified final products, possible reaction pathways have been hypothesized (*20*, *22*, *25*). The energetic and thermodynamic arguments have been used to investigate the formation of cytosine−tyrosine cross-links (*26*). There are indications that ionizing radiation-induced cross-linking occurs most likely between DNA bases and the aromatic or positively charged amino acids of histone (*27*). These specific amino acids have been singled out because they participate in the formation of the DNA−protein complex (*28*). Physically, negatively charged amino acids, such as glutamic and aspartic acids, are expected to be far away from the negatively charged DNA strand in the DNA−histone complex. Consequently, the probability of a cross-link formation is minimal. In general, the kinetics and mechanisms of the cross-linking reactions have not received their deserved attention and are currently little understood.

The fundamental idea behind this study is as follows. The question of how DNA binding affects the formation and reactions of the tryptophan (indolyl) radicals in peptides and proteins has been previously addressed via pulse radiolysis technique (*29*). The pulse radiolysis study of a γ-irradiated aqueous solution of tryptophan (Trp) peptides in the presence of DNA has revealed that the kinetics of the oxidized Trp residue is best described by the first-order decay rationalized by a fast electron (or hydrogen atom) transfer from DNA to the oxidized Trp. This mechanism is formally identical to the electron transfer observed in proteins from tyrosine residues to oxidized Trp (*30*). Alternatively, addition of the deprotonated electron-deficient indolyl radical (Ind$^\bullet$) to the DNA, followed by subsequent rearrangement, may be

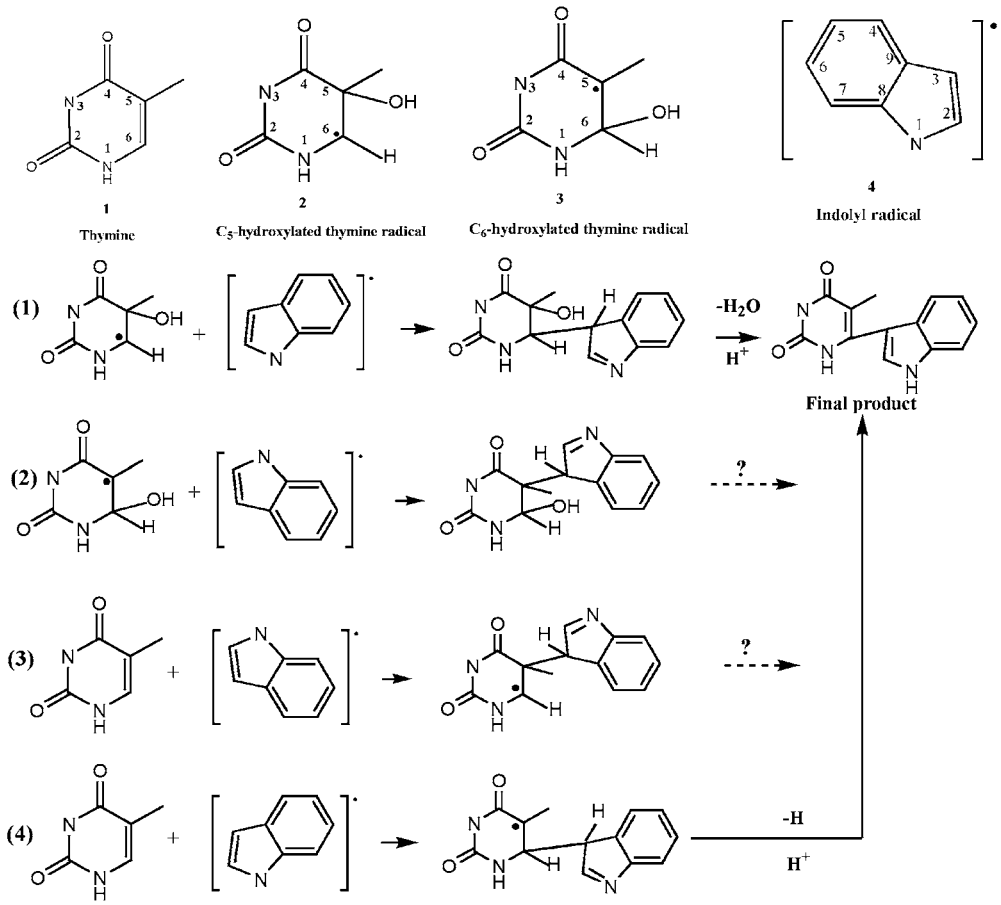
Scheme 1. Proposal of the Cross-Linking Reaction Mechanisms of Thymine, C_5-Hydroxylated Thymine Radical, C_6-Hydroxylated Thymine Radical, and Indolyl Radical



proposed, leading to DNA/tryptophan-containing peptide cross-linking.

Several computational chemistry methods have been contrasted to density functional theory methods in terms of whether DFT is able to predict reliable geometries (*31*) and reaction barriers (*32*). The unrestricted Hartree−Fock (UHF) and MP2 levels of theory, if employed to study free radicals, show spin contamination problems. Although the B3LYP method may have some problems in locating transition structures (TSs) when the reaction barrier is very low, the B3LYP method is able to describe potential energy surfaces (*33*). In this context, DFT methods are well established to the study of large biological systems (*34*−*39*).

This paper is outlined as follows. First, possible reaction mechanisms for the formation of cross-links between thymine and the indolyl radical are proposed (Scheme 1). Second, DFT methods are employed to investigate the feasibility of the proposed reaction pathways. Finally, the nature of the cross-link-bonded interaction in the final product is explored by use of the topological features of the electron density. A slanted prime has been used throughout the text to denote atoms originally on the indolyl radical moiety.

PROPOSAL OF REACTION MECHANISMS

Radiation-generated hydroxyl radicals have been experimentally established by pulse radiolysis to react rapidly with thymine (*40*). The prevailing mode of this interaction is addition to the C_5-C_6 double bond of thymine with a preference for C_5 (*41*). Abstraction of hydrogen at the methyl group, bonded to C_5 of thymine, is preferable to a much lesser extent (*42*, *43*). The majority contact spin density at C_3' of the indolyl radical (Figure 1c) is consistent with the observed site for radical attack on Ind• (*44*, *45*). Therefore, thymine, C_5-hydroxylated thymine radical [denoted C(C_5OH)], C_6-hydroxylated thymine radical [denoted C(C_6OH)], and indolyl radical can be considered as being the most likely reactants participating in the formation of the Thym−Ind• cross-links. We propose four possible reaction steps (Scheme 1) leading to the initial cross-linked products: (1) the combination of the C(C_5OH) and indolyl radicals, (2) the combination of the C(C_6OH) and indolyl radicals, (3) the addition of the indolyl radical to C_5 of thymine, and (4) the addition of the indolyl radical to C_6 of thymine. In each of the mechanisms, the final cross-linked product is presumably formed via several steps of the reaction.

METHODOLOGY

All geometry optimizations were carried out with the B3LYP/6-31G(d,p) hybrid DFT method using the GAUSSIAN 98 suite of programs (*46*). A combination of Becke's three-parameter hybrid exchange functional (*47*), as implemented in GAUSSIAN 98 (*48*), and the Lee−Yang−Parr correlation functional (*49*) gives the B3LYP functional. The restricted (RB3LYP) and unrestricted (UB3LYP) B3LYP procedures were used for closed-shell and open-shell systems, respectively. Vibrational frequencies and zero-point vibrational energies (ZPVEs) were computed at the same level of theory. Relative energies were determined by both performing single-point calculations at the B3LYP/6−311(2df,p) level using the optimized geometries and including the zero-point vibrational energy, that is, B3LYP/6-311(2df,p)//B3LYP/

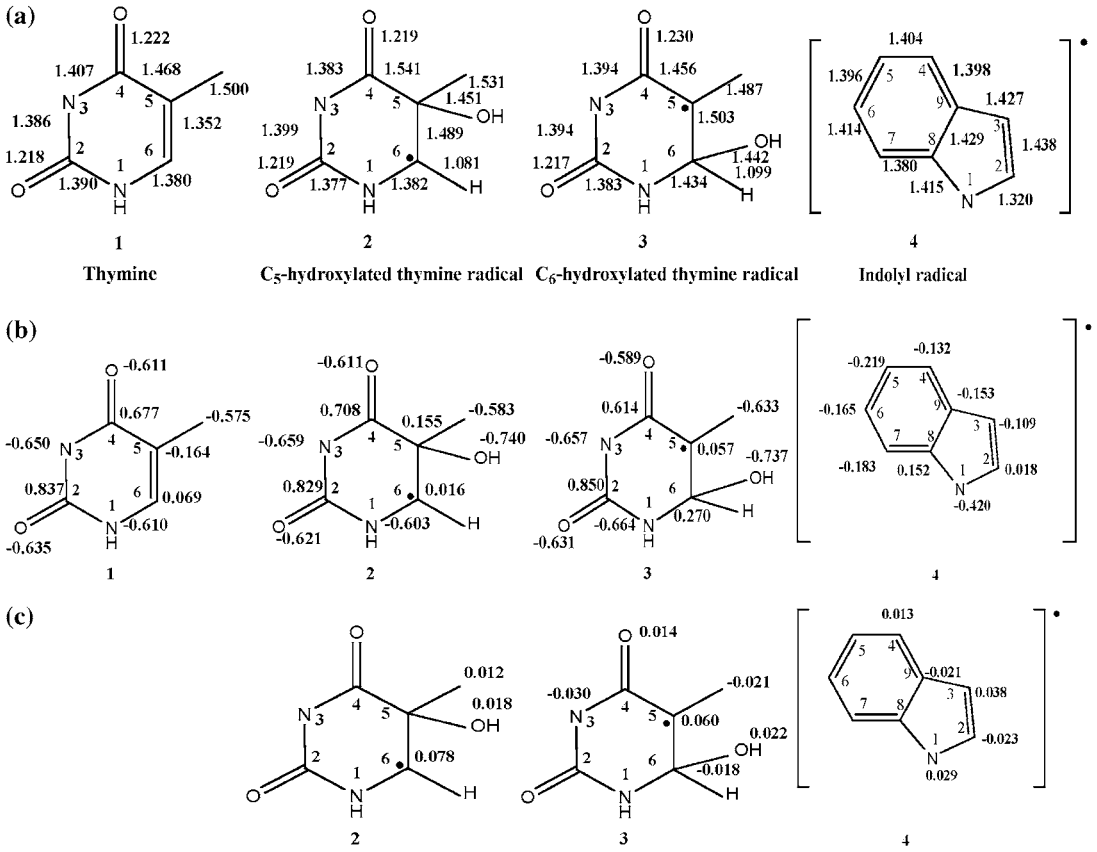


Figure 1. (a) B3LYP/6-31G(d,p) optimized structures (bond lengths) of thymine (**1**), C_5-hydroxylated thymine radical (**2**), C_6-hydroxylated thymine radical (**3**), and indolyl radical (**4**). (b) Natural charges on the heavy atoms of **1**−**4**. (c) Contact spin densities on the heavy atoms of **2**−**4**. Only values numerically larger than 0.01 and less than −0.01 are shown.

6-31G(d,p) + ZPVE. The potential energy profiles were constructed along the lowest energy pathways in redundant internal coordinates (*50*). The points on the path were generated by two successive linear interpolations, first between the reactant and transition structure and then between the transition structure and product. The central point is optimized to the transition structure. The entropy contribution to the free energy at 298 K was extracted from frequency calculations. All energies are given in kilojoules per mole (kJ mol^{-1}). All bond lengths are expressed in angstroms (Å).

The solvent effect on the reaction mechanisms was treated by way of the polarizable dielectric model (DPCM) (*51*) as implemented in GAUSSIAN 98 with a dielectric constant of 78.39 for H_2O and by performing single-point calculations at the B3LYP/6-311(2df,p) level on the optimized gas-phase structures.

The calculations pertaining to the topological features of the total electron density were carried out by use of the program EXTREM (*52*). The contact spin densities were calculated by the program EXTREM. The natural charges were computed by GAUSSIAN 98. The natural charges obtained in this way were shown to be both sufficiently stable to computational parameters (*53*) and insensitive to the particular basis set (*54*). Figures were generated using the program MOLEKEL (*55*). Figure 5 only was generated using the program MOLDEN (*56*). The consistent use both of the physically meaningful natural charges and of the contact spin density throughout the paper makes our work fundamentally different from that reported in ref *26*. The previously reported strategy is based upon the Mulliken charges and spin density having a nonphysical background. Table 1 is a clear indicator speaking in favor of the present approach.

Table 1. Contact Spin Density Partitioning between the Thymine and Indolyl Radical Moieties in Compounds 3a, 3b, 3c, 4a, 4b, and 4c

moiety	3a	3b	3c	4a	4b	4c
Contact Spin Density						
thymine	0.001	0.038	0.076	−0.002	0.013	0.047
indolyl radical	0.012	0.074	0.051	0.018	0.057	0.037
Mulliken Spin Density[a]						
thymine	−0.002	0.511	0.921	−0.004	0.512	0.946
indolyl radical	1.002	0.489	0.079	1.004	0.488	0.054

[a] From left to right, note a decreasing trend of the Mulliken spin densities for the indolyl radical moiety, in contrast to the trend of the contact spin densities. Most importantly, the trends of the contact and Mulliken spin densities, associated with the changes in the molecular energy along the reaction pathways, do not agree. A similar trend of the Mulliken spin densities previously reported speaks in favor of the arbitrary (nonphysical) background of that analysis (*26*).

FEASIBILITY OF THE CROSS-LINKING MECHANISMS

Reactivity of the Reactants. The B3LYP/6-31G(d,p) optimized structures of thymine (**1**), C_5-hydroxylated thymine radical (**2**), C_6-hydroxylated thymine radical (**3**), and indolyl radical (**4**) are given in Figure 1a. The natural charges and contact spin densities on the heavy atoms of **1**−**4** are shown in Figure 1b,c, respectively.

The C_5−C_6 bond (1.352 Å) of thymine is much shorter than the C−C bond in benzene (1.396 Å) (*57*) and has a more localized double-bond character. The natural charge at C_5 is negative (−0.164), whereas that at C_6 is slightly positive (+0.069). The natural charge separation is a consequence of the heteroatom positions within the thymine molecule. As a substantial selectivity toward an electron-rich center determines the addition of the •OH

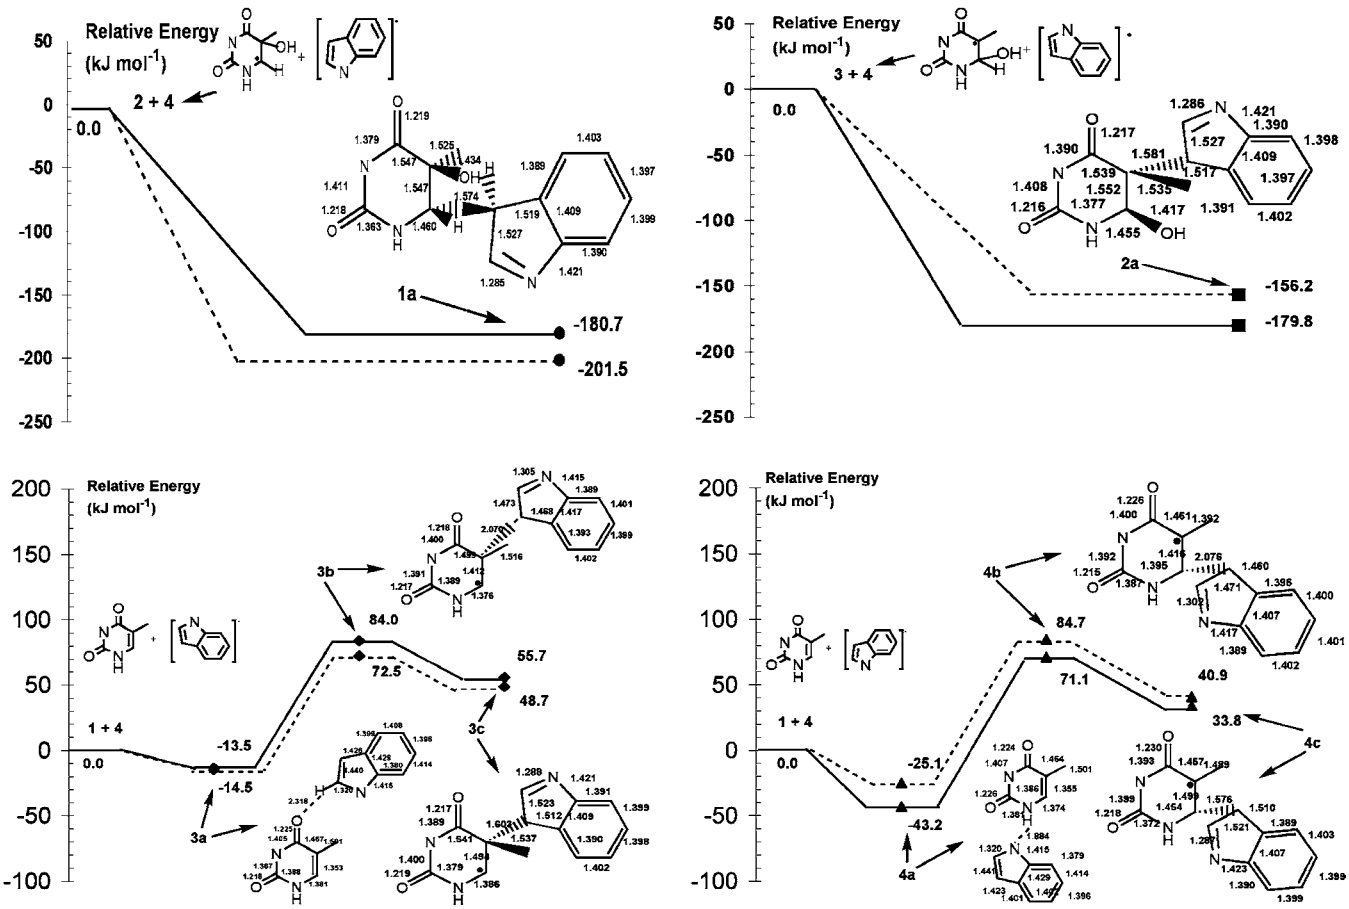

Figure 2. Calculated energy profiles for the initial reaction steps of (a, top left) mechanism 1 (**2** + **4**), (b, top right) mechanism 2 (**3** + **4**), (c, bottom left) mechanism 3 (**1** + **4**), addition to C_5 of thymine, and (d, bottom right) mechanism 4 (**1** + **4**), addition to C_6 of thymine, in the gas phase (solid line) and in aqueous solution (dashed line) at 298 K and 1 atm.

radical to a polarizable double bond (*58*), the C_5 site can be viewed as favorable for the •OH addition to thymine (*59*). The C_5 atom of thymine is methyl (Me) group-substituted with the ∠(C_4−C_5−methyl C) of 117.7°. The C_5 site, as less accessible, is expected to affect the energetics of the •OH addition reaction. Thus, a bulky substituent needs to be forced into an out-of-plane position.

The OH group at C_5 of **2** is pushed away from the ring plane with the C_5−O bond distance being 1.451 Å. The geometry of **2** displays a half-chair conformation with C_5 being the chair-back. The formation of a tetrahedral C_5 center in **2** weakens the N_1−C_6 and C_2−N_3 bonds and strengthens the N_1−C_2 and N_3−C_4 bonds with respect to those in **1**. At the same time, the C_6 atom becomes both pyramidal by ∼20° [∠(N_1−C_6−C_5−H on C_6) = 159.9°] and a localized radical center with a contact spin density of 0.078.

The six-membered ring of **3** shows a half-chair conformation with C_6 being the chair-back. The OH group is pushed behind the ring with the C_6−O bond distance being 1.442 Å. The formation of a tetrahedral C_6 center in **3** weakens the C_2−N_3 bond and strengthens the N_1−C_2, N_3−C_4, and C_4−C_5 bonds with respect to those in **1**. Consequently, C_5 is both pyramidal by ∼9° [∠(C_4−C_5−C_6-methyl C) = 171.2°] and a localized radical center with a contact spin density of 0.060.

On the basis of pulse radiolysis measurements (*60*, *61*), possible reactions of the C(C_5OH) and C(C_6OH) radicals were generally proven to be very fast.

To the best of my knowledge, experimental geometries and spin densities for the indolyl radical are unknown. The skeletal structure of **4** is planar. The structure of **4** has been previously investigated by use of the Slater (*62*), Vosko, Wilk, and Nusair (*63*) (SVWN)/6-31G(d) and B (*64*) LYP (*65*)/6-31G(d) DFT methods (*36*). The B3LYP/6-31G(d,p) geometry used in this paper shows satisfactory agreement with the BLYP/6-31G(d) geometry, with the bonds in Figure 1a being shorter by ∼0.01 Å than those previously reported (*36*). The N_1'−C_2' and C_4'−C_5' bonds show the largest shortenings of 0.018 and 0.012 Å, respectively. Besides, the geometry of the indolyl radical can be considered as being unique in some respect. By both removing a hydrogen atom from indole to form the indolyl radical and removing an electron from indole to form the indolyl radical cation, I have attempted to investigate the changes experienced by the optimized structure of indole. Although a pattern of the changes of interatomic distances for the indolyl radical has been similar to that for the indolyl radical cation, removing a hydrogen atom from indole alters both σ bonding and the identity of the singly occupied molecular orbital. Although the elongation and contraction of most bond distances for the indolyl radical cation with respect to those of indole are predictable on the basis of the nodal structure of indole's highest occupied molecular orbital, the structural changes for the indolyl radical are not predictable from the π orbitals of indole (*36*). Hence, the changes in the electron density distribution appear to be of vital importance for the understanding of the structural changes displayed by Ind• with respect to indole.

The majority contact spin density (0.038) at C_3' of **4** is consistent with the observed site for radical attack on the indolyl radical (*44*, *45*) and contrasts with the

extremely large spin density on N_1' obtained by use of the restricted open-shell Hartree−Fock effective core potential (ROHF-ECP) method (*65*). This supports our proposal that the C_3' site of **4** is the most likely reactive site for the addition of **2** or **3** to **4**.

Initial Step of the Cross-Linking Mechanisms. Hereafter, the proposed reaction pathways are considered as competitive reactions. The energy profiles for the direct combination of **2** and **4** in forming **1a** and for the direct combination of **3** and **4** in forming **2a** are shown schematically in Figure 2a,b, respectively. The B3LYP/6-31G-(d,p) optimized structures (bond lengths) of **1a** and **2a** are given in the same figures. Including scans of the singlet and triplet energy surfaces, all attempts to locate transition structures for the formation of **1a** and **2a** were unsuccessful. The radical combination forming the product **1a** is energetically favorable by 180.7 kJ mol^{-1}, whereas that forming the product **2a** is energetically favorable by 179.8 kJ mol^{-1}. Thus, product **1a** is slightly more energetically favorable by ∼0.9 kJ mol^{-1} than product **2a**. The direct combination of the C(C_5OH) and indolyl radicals occurs with a small or effectively no barrier.

The energy profile for the addition of **4** to C_5 of **1** to form the most stable conformer of the product **3c** is shown schematically in Figure 2c. The B3LYP/6-31G(d,p) optimized structures (bond lengths) of **3a**, **3b**, and **3c** are shown in the same figure. The resulting reactant complex **3a** is 13.5 kJ mol^{-1} lower in energy than the isolated reactants. The formation of the cross-linked product **3c** involves an activation barrier of 97.5 kJ mol^{-1} via TS **3b**. Product **3c** lies 55.7 kJ mol^{-1} higher in energy than the reactant system.

The spin partitioning between the thymine and indolyl radical moieties of **3a**, **3b**, and **3c** is shown in Table 1. The thymine ring has a contact spin density of 0.038 in **3b** and of 0.076 in **3c**, 0.035 and 0.083 of which is localized at C_6, respectively. Due to the formation of a localized C_6 radical center, **3b** and **3c** are higher in energy than the isolated reactants. Whereas the C_5-C_3' bond length in TS **3b** is 2.070 Å, the C_5-C_3' bond length in **3c** is 1.603 Å. However, the Mulliken spin densities given in Table 1 need to be viewed with more care. Following the data (from **3a** to TS **3b)** in Table 1, the contact spin densities show an increase of the spin over both thymine (from 0.001 to 0.038) and the indolyl radical (from 0.012 to 0.074), whereas the Mulliken spin densities show an increase of the spin over the thymine moiety (from −0.002 to 0.511) and a decrease of the spin over the indolyl radical moiety (from 1.002 to 0.489). The contact spin density of thymine moiety in **3c** is larger by 0.038 than that in **3b**, whereas the contact spin density of the indolyl radical moiety in **3c** is smaller by 0.023 than that in **3b**. In contrast to the trend (from **3a** to **3c** via **3b**) of the contact spin densities for the indolyl radical moiety, the Mulliken spin densities show a decreasing (and nonphysical) trend because of known difficulties (*66*, *67*) with this method for determining spin population.

The energy profile for the addition of the indolyl radical to C_6 of thymine to form the most stable conformer **4c** of the product is given schematically in Figure 2d. The B3LYP/6-31G(d,p) optimized structures (bond lengths) of **4a**, **4b**, and **4c** are shown in the same figure. The resulting reactant complex **4a** lies 43.2 kJ mol^{-1} lower in energy than the isolated reactants. The formation of the cross-linked product **4c** involves an activation barrier of 114.3 kJ mol^{-1} via TS **4b**. Product **4c** lies 33.8 kJ mol^{-1} higher in energy than the isolated reactants. The contact spin density over the thymine moiety is 0.013 in **4b** and 0.047 in **4c**, 0.036 and 0.058 of which is localized at C_5, respectively. Due to the formation of a localized C_5 radical center, **4b** and **4c** are higher in energy than the reactant system. Whereas the C_6-C_3' bond length in TS **4b** is 2.076 Å, the C_6-C_3' bond length in **4c** is 1.576 Å. Because there is a free N−H in thymine that may interfere with the reaction mechanisms, the use of thymine to mimic DNA is questionable in some respects. As a matter of fact, this interference is seen in Figure 2d, where a hydrogen bond formation involving N−H is proposed. Although an N-1 methylated thymine may be a better candidate, some activation barrier will remain and will not affect the conclusion on the most likely reaction pathway leading to the initial cross-linked product.

Table 2. Calculated Entropy, Free Energy, and Enthalpy Changes for Various Reaction Steps at 298 K and 1 atm

starting point	final point	ΔS_{298K} (kJ mol^{-1} K^{-1})	ΔG_{298K} (kJ mol^{-1})	ΔH_{298K} (kJ mol^{-1})
2 + **4**	**1a**	−0.203	−125.4	−185.9
3 + **4**	**2a**	−0.218	−120.8	−185.8
1 + **4**	**3a**	−0.117	24.4	−10.5
1 + **4**	**3b**	−0.181	136.8	82.9
1 + **4**	**3c**	−0.179	109.5	56.2
1 + **4**	**4a**	−0.138	0.0	−41.1
1 + **4**	**4b**	−0.171	122.9	71.9
1 + **4**	**4c**	−0.163	82.7	34.1
1a	**1b**	−0.003	142.1	141.2
1a	**1c**	−0.001	−74.6	−74.9
1a + H_2O	**1d**	−0.129	7.6	−30.8
1a + H_2O	**1e**	−0.146	144.4	100.9
1a + H_2O	**1f**	−0.092	−76.9	−104.3
1c	**1g** + H_2O	0.167	−86.4	−36.6

It is noted that product **4c** is ∼21.9 kJ mol^{-1} lower in energy than product **3c** and that TS **4b** is ∼12.9 kJ mol^{-1} lower in energy than TS **3b** (see Figure 2). More importantly, the formation of the cross-linked product **3c** involves an activation barrier of 97.5 kJ mol^{-1} via TS **3b**, whereas the formation of the cross-linked product **4c** involves an activation barrier of 114.3 kJ mol^{-1} via TS **4b** (see Figure 2). Thus, the computed energy surfaces suggest that the addition of the indolyl radical to thymine prefers the C_5 site over C_6.

The effects of the solvent on the potential energy surface were investigated by single-point DPCM/B3LYP/6-311G(2df,p) calculations with a dielectric constant of 78.39 for water. The energy profiles of the four mechanisms including solvation are shown in Figure 2 by a dashed line. Solvation reduces the activation energy barriers of mechanisms 3 and 4 from 97.5 and 114.3 to 87.0 and 109.8 kJ mol^{-1}, respectively. The solvated products **1a** and **3c** have lower relative energies (−201.5 and 48.7 kJ mol^{-1}) than in the gas phase (−180.7 and 55.7 kJ mol^{-1}), whereas the solvated products **2a** and **4c** have higher relative energies (−156.2 and 40.9 kJ mol^{-1}) than in the gas phase (−179.8 and 33.8 kJ mol^{-1}).

The calculated entropy changes (Table 2) of the initial steps of the four mechanisms are negative, and the calculated free energy changes (Table 2) of the reactions at 298 K suggest that the reactions are more favorable at 0 K than at 298 K. The initial steps of mechanisms 3 and 4 have larger barriers than the initial steps of

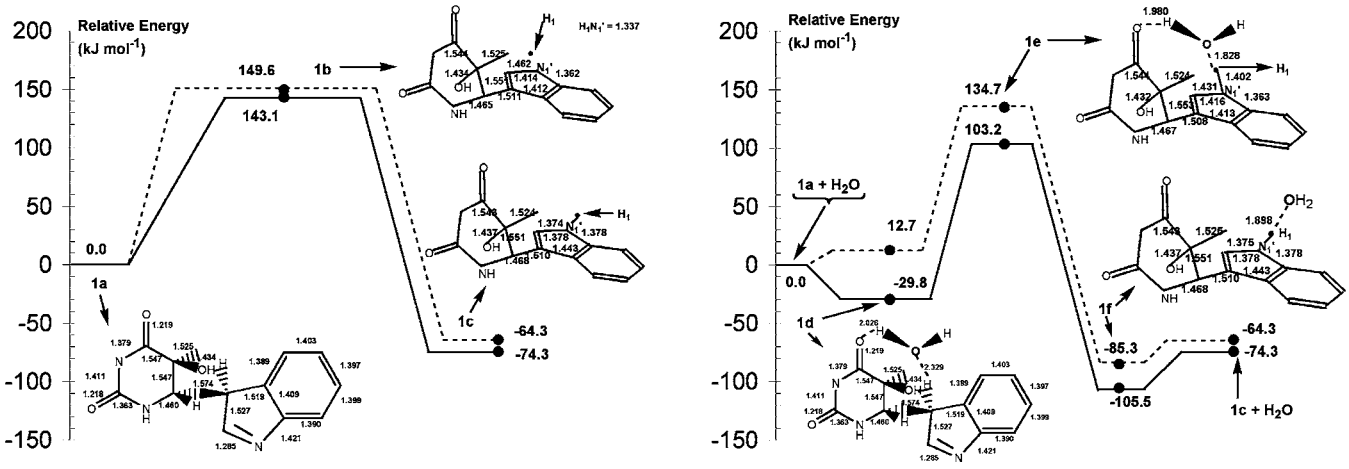

Figure 3. Calculated energy profiles of the hydrogen (H_1) transfer from C_3' to N_1' (a, top) for mechanism A and (b, bottom) for mechanism B in the gas phase (solid line) and in aqueous solution (dashed line) at 298 K and 1 atm.

mechanisms 1 and 2, both in the gas phase and in solution, are thermodynamically unfavorable, and their possible diastereomers have not been considered. Of mechanisms 3 and 4, mechanism 3 is thermodynamically more favorable both in the gas phase and in solution. The initial step of mechanism 1 is energetically more favorable both in the gas phase and in solution than that of mechanism 2. These high-energy, short-lived radicals (**2** and **4**) are supposed to exist next to each other at exactly the same time and in the correct orientation for their combination. Although the intermediates for the radical recombination mechanism contain three chiral centers, the formation of other diastereomers has not been considered due to its nonsubstantial impact (within 1 kcal mol^{-1}) on the solvated relative energies. Thus, the possible reaction steps proceeding from intermediate product **1a** are considered below.

Hydrogen Transfer. Two possible reaction mechanisms (Figure 3) for an internal hydrogen (denoted H_1) transfer from carbon (denoted C_3') to nitrogen (denoted N_1') within the initial cross-linked product **1a** are considered: (A) direct hydrogen transfer from C_3' to N_1' and (B) hydrogen transfer from C_3' to N_1' by way of a bridging water molecule. I have attempted to consider a concerted reaction mechanism for a hydrogen transfer from C_3' to N_1' within **1a**, but all attempts to locate a TS linking **1d** and **1f** (see Figure 3) were unsuccessful. Because the OH group at C_5 of the thymine moiety in **1d** is in an out-of-plane position, the hydroxyl group does not seem to be able to partake in a possible concerted hydrogen-transfer reaction occurring on the opposite side of the ring plane between C_3' and N_1'.

The calculated potential energy surface of mechanism A is shown in Figure 3a. The formation of the hydrogen-transferred product **1c** via TS **1b** can occur with an activation barrier of 143.1 kJ mol^{-1}. **1c** is 74.3 kJ mol^{-1} lower in energy than **1a**. Due to the high barrier, this pathway is unlikely. The distance between H_1 and N_1' in **1a** is ~3.025 Å. It would be difficult for the direct transfer of H_1 from C_3' to N_1' to take place over such a distance. As the reaction is supposed to be carried out in aqueous solution, water molecules may be involved in the hydrogen-transfer reaction. Hence, mechanism B is proposed to explore the role of a water molecule in the hydrogen transfer.

The calculated energy profile of mechanism B is shown in Figure 3b. Initially, **1a** interacts with a water molecule, forming hydrogen-bonded complex **1d** that lies 29.8 kJ mol^{-1} lower in energy than the isolated reactants. The oxygen atom at C_4 of the thymine moiety and the H−O part of the water molecule form a hydrogen bond in **1d** with a length of 2.026 Å. Product complex **1f** can form via TS **1e** with an activation barrier of 133.0 kJ mol^{-1}. The barrier of mechanism B is lower than the barrier of 143.1 kJ mol^{-1} of mechanism A. Two hydrogen bonds are present in TS **1e**. First, the hydrogen bond of 2.026 Å in **1d** gets stronger in TS **1e** with a bond length of 1.980 Å. Second, the oxygen atom of the water molecule and H_1−N_1' form a hydrogen bond having a length of 1.828 Å. The H_1−N_1' distance in **1e** is 1.402 Å. **1f** is 105.5 kJ mol^{-1} lower in energy than the isolated reactants. The hydrogen bond length between N_1'−H_1 and OH_2 in **1f** is 1.898 Å. The cost for isolating **1c** + H_2O from **1f** is 31.2 kJ mol^{-1}. It is clear that the water molecule acts as a catalyst in this particular situation. It is concluded that mechanism B is preferred over mechanism A. In addition, hydrogen-bonding interactions play a key role in the hydrogen-transfer reaction step.

The calculated entropy changes at 298 K of the two hydrogen-transfer reactions are given in Table 2. The calculated free energy changes of the reactions at 298 K (Table 2) suggest that the reactions are less favorable at 298 K than at 0 K.

Single-point DPCM/B3LYP/6-311G(2df,p) calculations with a dielectric constant of 78.39 for water have been employed to investigate solvent effects. The barriers for mechanisms A and B in aqueous solution are 149.6 and 122.0 kJ mol^{-1}, respectively. The solvation-included barrier of mechanism A is higher than the barrier of 143.1 kJ mol^{-1} of mechanism A in the gas phase. The barrier of mechanism B in aqueous solution is lower than the barrier of 133.0 kJ mol^{-1} of mechanism B in the gas phase. It is concluded that mechanism B is the preferred pathway both in the gas phase and in solution.

Dehydration of Intermediate 1c. Dehydration of **1c** leads to the final cross-linked product **1g**, as given in Figure 4. The oxygen atom of the OH group at C_5 of the thymine moiety is denoted by O_1. The dehydration step proceeds by a standard reaction sequence, such as protonation at O_1, loss of water at C_5, and deprotonation at C_6. This is an acid-catalyzed reaction. The formation of the final product **1g** at 298 K via dehydration of **1c** is energetically favored by 42.9 kJ mol^{-1}, whereas the computed entropy change is 0.167 kJ mol^{-1} K^{-1} (Table 2). The free energy difference from 0 to 298 K is favorable for the dehydration step.

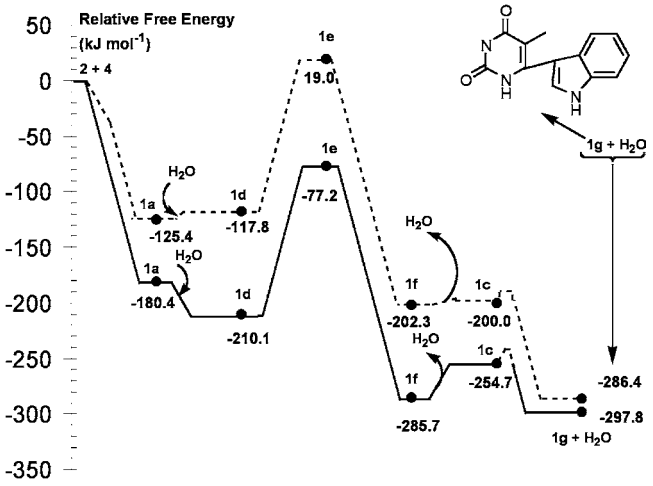

Figure 4. Calculated free energy profiles of the complete reaction mechanism at 0 K (solid line) and 298 K (dashed line) in the gas phase at 1 atm.

Complete Cross-Linking Mechanism at 0 and 298 K. The free energy profile at 0 and 298 K of the most favorable energy surface for the complete reaction mechanism is shown in Figure 4. In the segment of **1d** → **1f**, the water is partaking in the complexes. Although the free energy profiles at the two temperatures display differences of magnitude in the segment of **1d** → **1c**, the overall thermodynamics at 0 and 298 K are similar. Because of the entropy contribution to the free energy, temperature may be a central factor influencing the overall mechanism.

NATURE OF THE CROSS-LINK IN FINAL PRODUCT **1g**

I will begin with the natural charges of C_6 and C_3'. The C_6 atom of the thymine moiety has a natural charge of +0.212 and is quite positive. The C_3' atom of the indolyl radical moiety has a natural charge of −0.036 and is slightly negative or essentially neutral. The picture, which emerges from the natural charges of the atoms, is that the C_6-C_3' bond is not charge-separated to a great extent. It is also possible to determine charge separation between the two moieties by summing the corresponding natural charges of atoms. The natural charge partitioning between the thymine and indolyl radical moieties in **1g** is Thym(−0.077)−Ind•(+0.077). Clearly, the cross-link between the two moieties is not substantially charge-separated in its nature, but shows an inclination toward a mild electrostatic character. In this particular situation, the indolyl radical acts as a donor while thymine acts as an acceptor. According to the quantum theory of atoms in molecules (QTAIM), a necessary and sufficient condition for the existence of a through-space-bonded interaction is the existence of a bond path (*68*). A bond path is defined as a line of the highest electron density linking a pair of atoms. The AIM analysis confirms the existence of a C_6-C_3' bond path with the C_6-C_3' bond path length (1.4710 Å) being in agreement with the geometric C_6-C_3' bond length (1.4709 Å) in the final cross-linked product. The point of a line of the highest electron density, determined by the condition that the gradient of the electron density is equal to zero, is the bond critical point. The topological features of the electron density at this point provide quantitative information on the characteristics of a bond. The position of the C_6-C_3' BCP is shown in Figure 5. A small electron density of 1.8569 eÅ^{-3} at the BCP between C_6 and C_3' in **1g** is slightly larger than those (0.7−0.9 eÅ^{-3}) typically associated with weak bonds in donor−acceptor complexes. The second derivative or Laplacian of the electron density, $\nabla^2\rho(r)$, shows where the electron density is locally concentrated [$\nabla^2\rho(r) < 0$] and depleted [$\nabla^2\rho(r) > 0$] and contains a large amount of chemical information. The Laplacian has a value of −17.9232 eÅ^{-5}, indicating a local charge concentration at the BCP between C_6 and C_3' in the final cross-linked product.

TRYPTOPHAN SIDE CHAIN AND INDOLYL RADICALS

The calculated structures and contact spin densities on the heavy atoms of the tryptophan side chain and

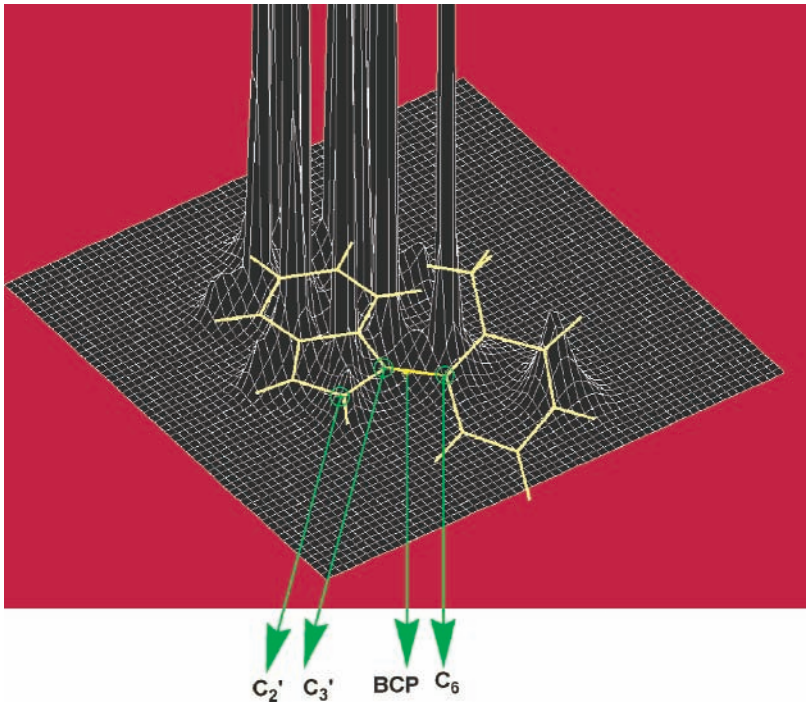

Figure 5. Cut of the electron density in the final product **1g**. C_6, C_3', and C_2' are in the plane of the cut. The position of the C_6-C_3' bond-critical point (BCP) is nicely visible. The C_6-C_3' bond path length is 1.4710 Å. The C_6−BCP distance is 0.7518 Å.

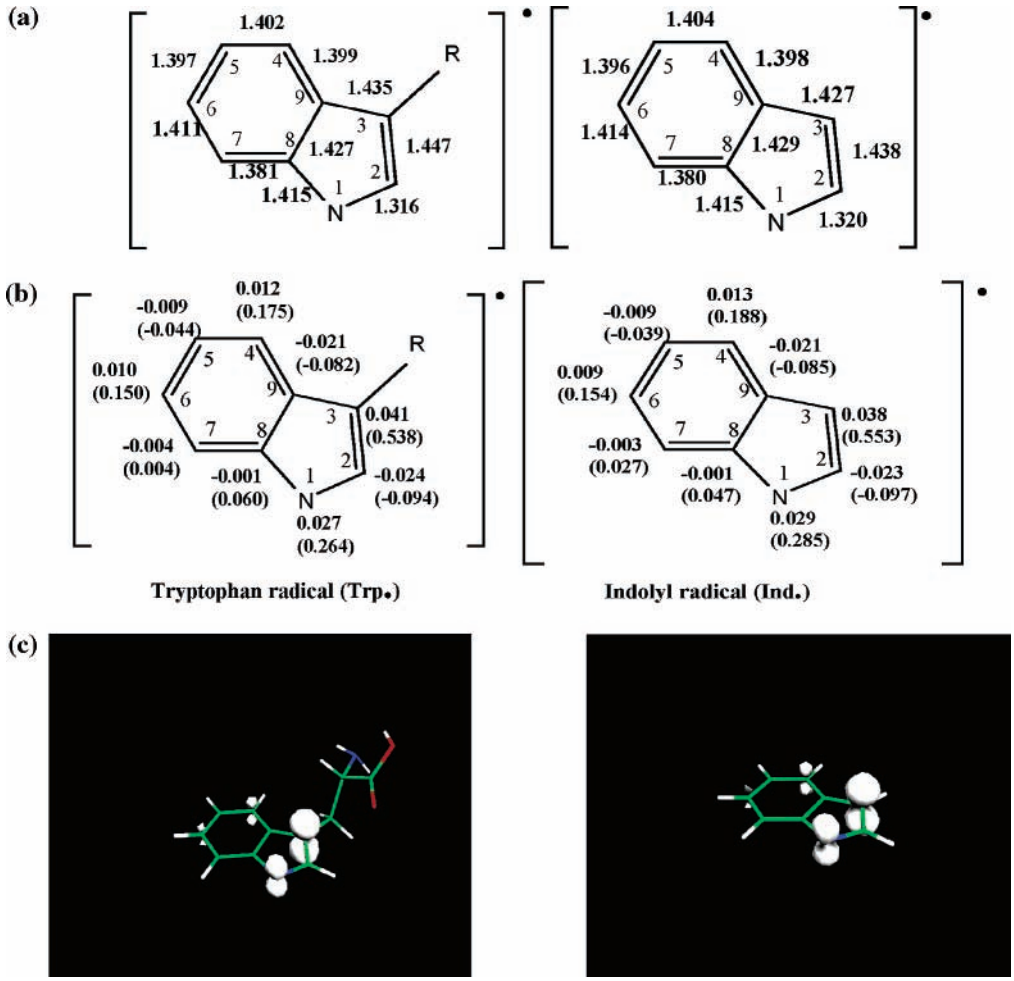

Figure 6. Tryptophan side chain and indolyl radicals: (a) B3LYP/6-31G(d,p) optimized structures (bond lengths); (b) contact spin densities on the heavy atoms [the Mulliken spin densities (in parentheses) show substantial discrepancies (note carbon 7) for the two radicals due to a nonphysical background of the method (*66*, *67*) for determining spin population]; (c) isosurface plots of the contact spin densities.

indolyl radicals are shown schematically in Figure 6. The side chain on the carbon C_3' of the tryptophan radical is $-CH_2-CH(NH_2)-COOH$. Clearly, the optimized geometries and contact spin density distributions of the two radicals are essentially equal. Thus, we believe that the direct combination of the C_5-hydroxylated thymine and tryptophan radicals should form the initial cross-linked product, as far as a chiral addition of the tryptophan radical to the DNA is concerned. It is also important to note the Mulliken spin densities given in parentheses in Figure 6. Several substantial discrepancies between the values are quite obvious, of which that at carbon 7 is the most conspicuous. Whereas the contact spin densities indicate a vanishing spin down at nucleus 7 in either case, the Mulliken spin densities show a vanishing spin up of 0.004 for the tryptophan radical and a substantially larger spin up of 0.027 for the indolyl radical. The Mulliken spin densities confirm the arbitrary (nonphysical) background of this population analysis (*66*, *67*).

CONCLUSIONS

The reaction mechanisms for the cross-linking of thymine and indolyl radical have been proposed.

The direct combination of the C_5-hydroxylated thymine and indolyl radicals is suggested to be the preferred mechanism in aqueous solution with a small or effectively no barrier in forming the initial cross-linked product, which is energetically more favorable by 45.3 kJ mol^{-1} than that formed by the direct combination of the C_6-hydroxylated thymine and indolyl radicals. The indolyl radical additions to C_5 and C_6 of thymine are suggested to be thermodynamically unfavorable in forming the initial cross-linked product.

Hydrogen-bonding interactions are suggested to play a key role in the hydrogen-transfer reaction by way of a bridging water molecule within the initial cross-linked product.

The formation of the final product **1g** via dehydration of **1c** is energetically favorable by 42.9 kJ mol^{-1}. The calculated entropy change at 298 K is 0.167 kJ mol^{-1} K^{-1}, and the free energy difference from 0 to 298 K is favorable for the dehydration reaction step.

Although bulk solvation has significant impact on the energetics of the cross-linking mechanisms, the preferred mechanism is suggested to be the same both in the gas phase and in solution.

The cross-link between the indolyl radical (donor) and thymine (acceptor) moieties in the final product is not substantially charge-separated in its nature, but shows an inclination toward a mild electrostatic character.

N-(2-Hydroxypropyl)methacrylamide Copolymers of a Glutathione (GSH)-Activated Glyoxalase I Inhibitor and DNA Alkylating Agent: Synthesis, Reaction Kinetics with GSH, and in Vitro Antitumor Activities

Zhe-Bin Zheng,[†] Guozhang Zhu,[†] Heekyung Tak,[†] Erin Joseph,[‡] Julie L. Eiseman,[‡] and Donald J. Creighton*,[†]

Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore, Maryland 21250, and University of Pittsburgh Cancer Center, Pittsburgh, Pennsylvania 15213. Received February 13, 2004; Revised Manuscript Received March 28, 2005

The incorporation of anticancer prodrugs into polyacrylamide conjugates has been shown to improve tumor targeting via the so-called "enhanced permeability and retention" effect. This strategy has now been expanded to include two different classes of glutathione (GSH)-activated antitumor agents prepared by radical polymerization of *N*-(2-hydroxypropyl)methacrylamide (HPMA) with 2-methacryloyloxy-methyl-2-cyclohexenone (**7**) and/or with *S*-(*N*-4-chlorophenyl-*N*-hydroxycarbamoyl-thioethyl)-methacrylamide (**8**), followed by treatment with 3-chloroperoxybenzoic acid, to give the HPMA copolymers of **7** and the **8**-sulfoxide, respectively. In aqueous-buffered solution at pH 6.5, GSH reacts rapidly with poly-HPMA-**8**-sulfoxide ($k \approx 2.3$ mM^{-1} min^{-1}) to give *S*-(*N*-4-chlorophenyl-*N*-hydroxycarbamoyl)glutathione (**1**), a tight-binding transition state analogue inhibitor of the antitumor target enzyme glyoxalase I ($K_i = 46$ nM), or with poly-HPMA-**7** ($k \approx 0.02$ mM^{-1} min^{-1}) to give the electrophilic antitumor agent 3-glutathio-2-methylenecyclohexenone (**4**). Indeed, B16 melanotic melanoma in culture is inhibited by poly-HPMA-**8**-sulfoxide and by poly-HPMA-**7** with IC_{50} values of 168 ± 8 and 284 ± 5 μM, respectively. These values are significantly greater than those of the unpolymerized prodrugs suggesting that the cytotoxicity of the polymer prodrugs might be limited by slow cellular uptake via pinocytosis. This prodrug strategy should be applicable to a range of different GSH-based antitumor agents.

INTRODUCTION

A conceptually important strategy for improving tumor targeting during cancer chemotherapy is to use high molecular weight copolymer prodrugs to better direct the drug to tumor tissue via the so-called "enhanced permeability and retention" (EPR)[1] effect (for reviews, see ref *1*). This effect arises, in part, from the tendency of high molecular weight copolymer prodrugs (>70 000 Da) to remain in circulating plasma longer than low molecular weight drugs and from the fact that blood vessels in rapidly growing tumors are more permeable to high molecular weight species than are blood vessels in normal, established tissues. Once concentrated in tumor tissue, the copolymer prodrug can then enter tumor cells by endocytosis.

The challenge is to design copolymer prodrugs that will release the antitumor agents into the cell cytosol after endocytosis. A frequently used design strategy is to covalently attach the drug to the polymer via a peptide linkage, which will undergo catalyzed hydrolysis when the copolymer prodrug-filled endosomes fuse with the peptidase-filled lysosomes. The free drug is then available to diffuse out of the lysosomes into the cell cytosol. Indeed, prodrug conjugates of poly-*N*-2-(hydroxypropyl)-methacrylamide (HPMA) have been designed to deliver the anticancer drugs doxorubicin (*2*), daunomycin (*3*), and 5-fluorouracil (*4*) and the DNA alkylating agent melphalan (*5*) into tumor cells. Moreover, some of these conjugates are now entering phase I/II clinical trials (*6*). Nevertheless, a potential limitation of this approach is that cleavage of the peptide bond in the linker tends to be a slow process taking several hours (*2*).

An alterative strategy that avoids reliance on lysosomal peptidases is to use lysosomal thiols such as GSH and/or cysteine as cleaving agents after endocytotic uptake of appropriately designed copolymer prodrugs (*7*). This approach is particularly interesting because GSH concentrations are often elevated by as much as 2-fold in tumor tissues (*8*−*10*) vs normal tissues, which are in the range of 2−8 mM (*10*, *11*). Moreover, some drug resistant tumors overexpress GSH by as much as 10-fold (*12*). Thus, these concentration differences could give rise to preferential activation of the copolymer prodrug in tumor cells vs normal cells. The adventitious activation of the copolymer prodrug in circulating human plasma should be minimal, as GSH concentrations are typically 1−2 μM (*13*). To test the feasibility of this strategy, we have been working to prepare copolymer prodrugs that will react with GSH to give two different classes of GSH

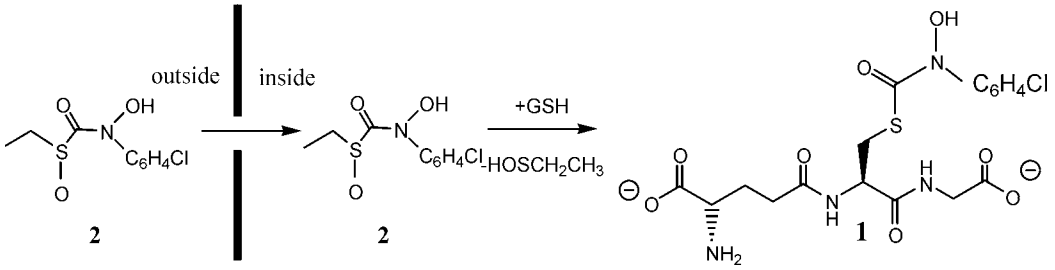
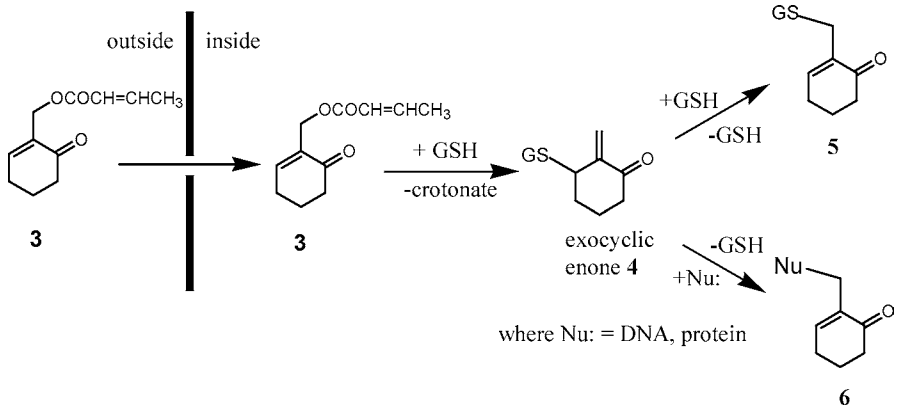


Scheme 2



derivatives currently undergoing development as a new generation of antitumor agents (*14*−*17*).

The first class of antitumor agents are transition state analogue inhibitors of the human methylglyoxal-detoxifying enzyme glyoxalase I (hGlxI) (*18*); e.g., *S*-(*N*-4-chlorophenyl-*N*-hydroxycarbamoyl)glutathione (**1**, K_i = 46 nM) (*19*). Previous work has shown that this compound can be delivered into tumor cells either as a [glycyl, glutamyl] diethyl ester prodrug **1**$(Et)_2$ (*20*) or as the membrane permeable sulfoxide prodrug *S*-(*N*-4-chlorophenyl-*N*-hydroxycarbamoyl)ethyl sulfoxide **2**, which undergoes an acyl interchange reaction with GSH to give **1** (Scheme 1) (*21*).

Both prodrugs are cytostatic and cytotoxic to several different tumor cell lines in vitro, apparently because inhibition of GlxI by the enediol analogue **1** results in the accumulation of cytotoxic methylglyoxal. The basis of the exceptional sensitivity of tumors to methylglyoxal toxicity is not well-understood but appears to arise, in part, from extensive covalent modification of heat shock protein 27 (Hsp27), which induces caspase-dependent differentiation and apoptosis (programmed cell death) in tumor cells (*22*). Methylglyoxal is also potentially genotoxic, as methylglyoxal has been demonstrated to covalently modify nucleotide bases (*23*, *24*).

The second class of antitumor agents includes electrophilic endocyclic enones such as 2-crotonyloxymethyl-2-cyclohexenone (**3**), which rapidly diffuses across cell membranes and, once inside the cell, undergoes a Michael addition reaction with intracellular GSH to give the reactive exocyclic enone **4** (Scheme 2) (*25*, *26*).

This species can potentially react with either free GSH to give **5** or form covalent adducts with proteins and/or nucleic acids (**6**) critical to cell viability. Indeed, mass spectral studies show that in the presence of GSH compound **3** alkylates the exocyclic amino groups of nucleotide bases composing single-stranded oligonucleotides (*27*).

However, neither of the prodrug strategies described above is designed to deliver antitumor agents specifically to tumor tissue. For example, in vivo efficacy studies show that intravenous administration of **1**$(Et)_2$ to tumor-bearing mice inhibits the growth of B16 melanotic melanoma, PC3 prostate tumors, and HT29 human colon tumors (*28*). While there were no significant side effects detected in these short-term efficacy studies, intravenous administration of **1**$(Et)_2$ results in the appearance of **1** in all major organs of tumor-bearing mice. This could give rise to significant side effects during long-term administration of drug.

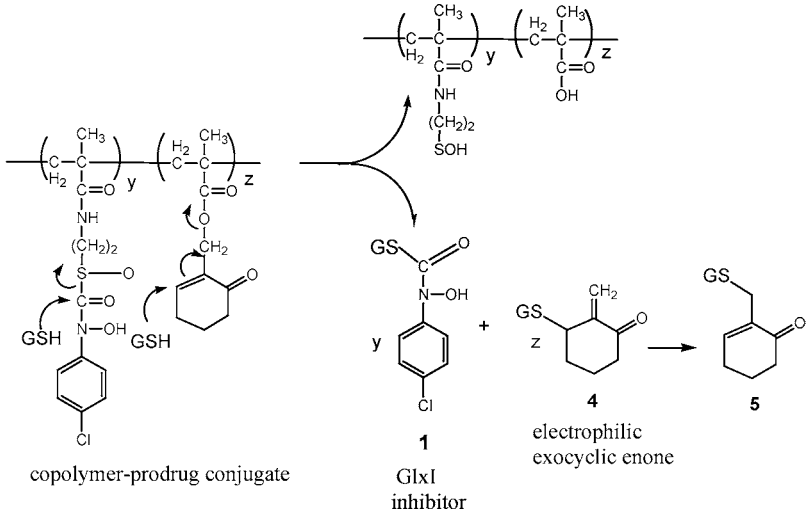
Here, we describe for the first time the synthesis, physicochemical properties, and in vitro antitumor activities of two lead HPMA copolymer prodrugs, which rapidly release **1** and/or the reactive exocyclic enone **4** in neutral aqueous solutions of GSH.

EXPERIMENTAL PROCEDURES

Analytical Instrumentation. NMR spectra were taken on a GE QE-300 NMR spectrometer. IR spectra measured with a ThermoNicolet Avatar 370 FTIR spectrometer using a Pike MIRacle ATR accessory (AMTIR crystal). Mass spectral data were obtained at the Center for Biomedical and Bio-organic Mass Spectrometry, Washington University. UV spectra were recorded using a Beckman DU 640 spectrophotometer. High-performance liquid chromatography (HPLC) was carried out using a Waters HPLC System composed of a 600 Controller, Delta 600 Pumps, and 996 photodiode array detector. Analytical HPLC was performed using a Waters Nova-Pak C_{18}, 4 μm, 3.9 mm × 150 mm column or Symmetry C_{18}, 5 μm, 4.6 mm × 150 mm column. Preparative HPLC was performed using a SymmetryPrep C_{18}, 7 μm, 19 mm × 150 mm column. The molecular weights of the HPMA copolymers were estimated by gel permeation chromatography (GPC) using a high-performance gel permeation column (Tricorn Superose 12 10/300 GL) from Amersham Biosciences.

Materials. Dextran molecular weight standards were purchased from Sigma Chem. Co. (1000, 5000, and 12 000

Scheme 3. Mechanism for Generating t.s. Analogue 1 and Exocyclic Enone 4 from Copolymer−Prodrug Conjugate in the Presence of GSH



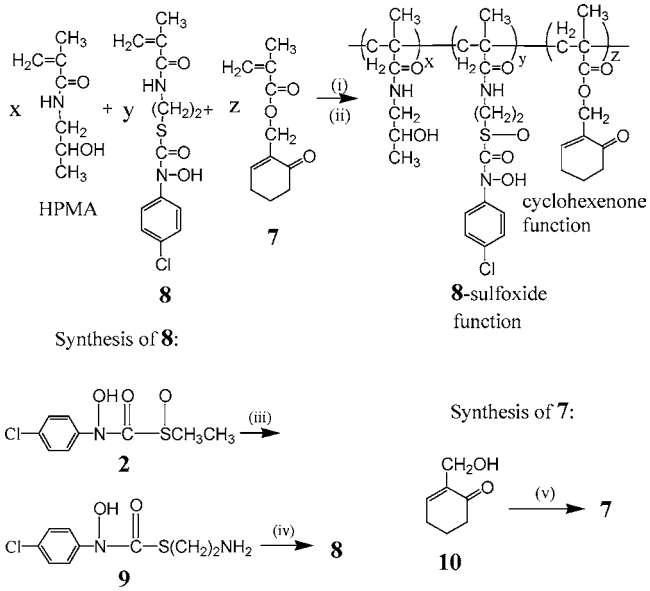
Da) and Polysciences, Inc. (40 000 Da). Lyophilized human serum and GSH were purchased from Sigma Chem. Co. HPMA was purchased from Polysciences, Inc. Azobisisobutylnitrile (AIBN), methacryloyl chloride, 4-methylmorpholine, and 3-chloroperoxybenzoic acid (80−85% pure) were purchased from Aldrich Chem. Co. All other reagents were of the highest purity commercially available.

***S*-(*N*-4-Chlorophenyl-*N*-hydroxycarbamoyl)thioethylamine (9).** To a solution of *S*-(*N*-4-chlorophenyl-*N*-hydroxycarbamoyl)ethyl sulfoxide (**2**) (*21*) (495 mg, 2 mmol) in a mixture of 12 mL of methanol and 12 mL of phosphate buffer (0.1 M, pH 7.5) was added a solution of cysteamine (990 mg, 12.9 mmol) in 5 mL of phosphate buffer (0.1 M, pH 7.5). The mixture was stirred at 0 °C for 1 h. The precipitate was collected by filtration, washed with water, and dried under vacuum to give the final product as a white solid; yield 86% (424 mg). ^{1}H NMR (300 MHz, methanol-d_4/TMS): δ 3.01 (2H, t, J = 6.6 Hz), 3.50 (2H, t, J = 6.6 Hz), 7.32 (2H, d, J = 9.2 Hz), 7.61 (2H, d, J = 9.2 Hz). HRMS (ESI): *m/z* 247.0294 (calcd for $C_9H_{12}N_2O_2SCl$: 247.0308). [Note added in proof: This procedure must form the thiol ester and not the amide because the "sulfoxide"-containing copolymers (synthesized using **9**; Scheme 4) react with free GSH to give the enediol analogue **1** at rates similar to those observed for the reaction of GSH with the simple sulfoxide **2** to give **1** (Scheme 1); see Discussion.]

***S*-(*N*-4-Chlorophenyl-*N*-hydroxycarbamoylthioethyl)methacrylamide (8).** To a stirring solution of **9** (410 mg, 1.66 mmol) in 26 mL of anhydrous dimethyl formamide and 13 mL of pyridine at 0 °C was added slowly over 30 min methacryloyl chloride (318 μL, 3.29 mmol), and the reaction mixture was stirred at room temperature for an additional 20 min. The solvent was removed in vacuo, and the residue was fractionated by reverse-phase HPLC, using 50% acetonitrile in water, containing 0.1% trifluoroacetic acid, as a running solvent. The product peak was collected and dried under vacuum overnight to give the final product as a white solid; yield 51% (269 mg). ^{1}H NMR (300 MHz, methanol-d_4/TMS): δ 1.90 (3H, s), 3.00 (2H, t, J = 6.6 Hz), 3.45 (2H, t, J = 6.6 Hz), 5.34 (1H, br s), 5.67 (1H, br s), 7.32 (2H, d, J = 9.2 Hz), 7.59 (2H, d, J = 9.2 Hz). HRMS (ESI): *m/z* 337.0379 (calcd for $[M + Na]^+$, $C_{13}H_{15}N_2O_3NaSCl$: 337.0390).

2-Methacryloyloxymethyl-2-cyclohexenone (7). To a stirring solution of 2-hydroxymethyl-2-cyclohexenone

Scheme 4. Synthesis of HPMA Polyacrylamide Conjugates of 7- and 8-Sulfoxide[a]



[a] Reagents and conditions: (i) AIBN/acetone, 55 °C; (ii) 3-chloroperoxybenzoic acid; (iii) mercaptoethylamine/methanol−phosphate buffer (pH 7.5); (iv) methacryloyl chloride/pyridine; and (v) methacryloyl chloride/4-methylmorpholine.

10 (*29*) (504 mg, 4 mmol) and 4-methylmorpholine (1 mL, 9 mmol) in 10 mL of CH_2Cl_2 at 0 °C was added methacryloyl chloride (0.79 mL, 8 mmol) dropwise over about 30 min. The reaction mixture was allowed to stir for an additional 20 min. The solvent was removed in vacuo, and the crude product was fractionated by preparative reverse phase HPLC using 40% acetonitrile in water, containing 0.1% trifluoroacetic acid, as a running solvent. The product peak was collected and brought to dryness under vacuum to give the final product as a colorless oil; yield 66% (515 mg). ^{1}H NMR (300 MHz, acetone-d_6): δ 1.96 (3H, s), 2.03 (2H, p, J = 6.2), 2.48 (2H, t, J = 7.33 Hz), 2.42−2.60 (2H, m), 4.84 (2H, s), 5.58 (1H, br s), 6.13 (1H, br s), 7.01 (1H, t, J = 4.3 Hz). HR-FABMS (3-NBA/Li): *m/z* 201.1100 (calcd for $[M + Li]^+$, $C_{11}H_{14}O_3Li$: 201.1103).

Copolymer P1. The methacryloyl derivative **8** (41 mg, 0.13 mmol), HPMA (110 mg, 0.77 mmol), and AIBN (6 mg) were dissolved in 0.75 mL of acetone under argon in

a closed vial and incubated at 50−55 °C for 24 h. The white precipitate was recovered by filtration and was dried under vacuum for 30 min. The crude product was dissolved in 0.25 mL of methanol and then precipitated by the slow addition of excess acetone:diethyl ether (3:1). The precipitation procedure was repeated, and the precipitate was dried under vacuum overnight; yield 63 mg. A portion of the residue (30 mg) was dissolved in 1 mL of methanol at 0 °C, and 3-chloroperoxybenzoic acid (5.6 mg, 0.017 mmol) in 0.05 mL of diethyl ether was slowly added dropwise to this solution. The reaction mixture was allowed to stir for an additional 1 h at 0 °C. The solvent was removed in vacuo, the residue was dissolved in 0.2 mL of methanol, and the desired product precipitated by the slow addition of 5 mL of excess diethyl ether. The precipitation procedure was repeated twice more, and the product was dried under vacuum overnight to give the final product; yield overall from **8** and HPMA, 12 mg. IR (ATR, AMTIR): br 3352, 2973, 2934, 2907, s 1636, s 1526, s 1487 (S−O), 1202 cm^{-1}.

Copolymers P2 and P3. These copolymers were prepared by the same general procedure used to prepare **P1**, with reaction mixtures having the following composition. **P2**: **8** (21 mg, 0.067 mmol), HPMA (76 mg, 0.53 mmol), and AIBN (2 mg) dissolved in 0.4 mL of acetone. Acetone was used as a precipitant during the precipitation procedures; mass yield 29%. IR (ATR, AMTIR): br 3349, 2972, 2930, 2886, s 1636, s 1527, 1487 (S−O), 1203 cm^{-1}. **P3**: **8** (42 mg, 0.13 mmol), HPMA (282 mg, 2 mmol), and AIBN (18 mg) dissolved in 1.6 mL of acetone; yield 32 mg. IR (ATR, AMTIR): br 3353, 2972, 2934, 2905, s 1638, s 1527, 1487 (S−O), 1202 cm^{-1}.

^{1}H NMR (300 MHz, Methanol-d_4/TMS) Spectra of P1−P3. The spectra were all very similar to one another, with significant line broadening due to the high molecular weights of the copolymers. The chemical shift assignments were based on comparisons with the NMR spectra of poly-HPMA and **8**; relative integrated intensities varied as a function of the mol % of the **8**-sulfoxide function: δ 1.01 [s, $CH_3C(C)_3$], 1.16 (d, CH_3CO-), 1.6−2.0 [m, $-(CH_2)-$HPMA], 2.9−3.3 (m, $-NCH_aH_bCO-$; $N-CH_2CH_2-S$), 3.87 (m, −HCO−), 7.40 (d, arom. H, meta to Cl), 7.70 (d, arom. H, ortho to Cl). The mol % of the **8**-sulfoxide function in the different polymers was estimated from the integrated intensities of the aromatic ring protons (δ 7.40, 7.70) vs that of H−C−O (δ 10.02): **P1**, ∼10; **P2**, ∼9; and **P3**, ∼5.

Copolymers P4−P6. These copolymers were prepared by the same general procedure used to prepare **P1** with the exception that the oxidation step with 3-chloroperoxybenzoic acid was not used. **P4**: **7** (68 mg, 0.351 mmol), HPMA (100 mg, 0.702 mmol), and AIBN (9 mg) dissolved in 0.8 mL of acetone; yield 38 mg. IR (ATR, AMTIR): br 3366, 2970, 2931, m 1723 (C=O, cyclohexenone function), s 1639, s 1527, 1175, 1138 cm^{-1}. **P5**: **7** (44 mg, 0.227 mmol), HPMA (130 mg, 0.907 mmol), and AIBN (9 mg) dissolved in 0.7 mL of acetone; yield 112 mg. IR (ATR, AMTIR): br 3362, 2970, 2929, m 1724 (C=O, cyclohexenone function), s 1639, s 1528, 1199, 1138 cm^{-1}. **P6**: **7** (15 mg, 0.076 mmol), HPMA (87 mg, 0.61 mmol), and AIBN (5 mg) dissolved in 0.5 mL of acetone; yield 52 mg. IR (ATR, AMTIR): br 3354, 2971, 2931, m 1721 (C=O, cyclohexenone function), s 1637, s 1527, 1201, 1137 cm^{-1}.

^{1}H NMR (300 MHz, Methanol-d_4/TMS) Spectra of P4−P6. The spectra were all very similar to one another, with significant line broadening due to the high molecular weights of the copolymers (Figure 1). The chemical shift assignments were based on comparisons with the NMR spectra of poly-HPMA, **7**, and **8**; relative integrated intensities varied as a function of the mol % of the cyclohexenone function derived from **7**: δ 1.01 [s, $CH_3C(C)_3$], 1.16 (d, CH_3CO-), 1.6−2.0 [m, $-(CH_2)-$HPMA], 2.0−2.15 [m, $-(C(4)H_2)-$cyclohex-2-enone ring], 2.45−2.60 [m, $-(C(5)H_2, C(6)H_2)-$cyclohex-2-enone ring], 2.9−3.3 (m, $-NCH_aH_bCO-$; $N-CH_2CH_2-S$), 3.87 (m, −HCO−), 7.2−7.3 (t, vinyl-H). The mol % of the cyclohexenone function was estimated from the integrated intensities of the cyclohexenone ring protons $C(5)H_2$, $C(6)H_2$ (δ 9.85), vs that of H−C−O (δ 10.02): **P4**, ∼27; **P5**, ∼20; and **P6**, ∼12.

Copolymer P7. A solution of **7** (15 mg, 0.076 mmol), **8** (24 mg, 0.076 mmol), HPMA (87 mg, 0.61 mmol), and AIBN (6 mg) in 0.6 mL of acetone under argon in a closed vial was heated at 50−55 °C for 24 h. The white precipitate was recovered by filtration and brought to dryness to give 70 mg of crude product. The crude product was dissolved in 2 mL of methanol at 0 °C, and 3-chloroperoxybenzoic acid (9.1 mg, 0.042 mmol) in 0.1 mL of diethyl ether was added dropwise. The reaction mixture was allowed to stir for an additional 1 h, the solvent was removed in vacuo, and the residue was dissolved in 0.4 mL of methanol. The product was precipitated by the dropwise addition of acetone:diethyl ether (3:1). The precipitation procedure was repeated, and the final copolymer product was dried under vacuum overnight; yield 52 mg. IR (ATR, AMTIR): br 3364, 2970, 2930, m 1721(C=O, cyclohexenone function), 1638, 1527, s 1487 (S−O), 1200, 1137 cm^{-1}.

Copolymer **P8** was prepared by the same general procedure used to prepare **P7** starting with a reaction mixture composed of **7** (16 mg, 0.084 mmol), **8** (26 mg, 0.084 mmol), HPMA (191 mg, 1.336 mmol), and AIBN (12 mg) dissolved in 1.2 mL of acetone; yield 91 mg. IR (ATR, AMTIR): br 3365, 2971, 2931, m 1723(C=O, cyclohexenone function), 1639, 1527, s 1482 (S−O), 1201, 1138 cm^{-1}.

^{1}H NMR (300 MHz, Methanol-d_4/TMS) Spectra of P7 and P8. The spectra were both similar to one another, with significant line broadening due to the high molecular weights of the copolymers (Figure 1). The chemical shift assignments were based on comparisons with the NMR spectra of poly-HPMA, **7**, and **8**; relative integrated intensities varied as a function of the mol % cyclohexenone and **8**-sulfoxide functions: δ 1.01 [s, $CH_3C(C)_3$], 1.16 (d, CH_3CO-), 1.6−2.0 [m, $-(CH_2)-$HPMA], 2.0−2.15 [m, $-(C(4)H_2)-$cyclohex-2-enone ring], 2.45−2.60 [m, $-(C(5)H_2, C(6)H_2)-$cyclohex-2-enone ring], 2.9−3.3 (m, $-NCH_aH_bCO-$), 3.87 (m, −HCO−), 7.2−7.3 (t, vinyl-H), 7.40 (d, arom. Hs, meta to Cl), 7.70 (d, arom. Hs, ortho to Cl). The mol % of the **8**-sulfoxide and the cyclohexenone functions were estimated from the integrated intensities of the aromatic ring protons (δ 7.40, 7.70) and cyclohexenone ring protons $C(5)H_2$, $C(6)H_2$ (δ 2.5), vs that of H−C−O (δ 3.9). For **P7**: mol % **8**-sulfoxide, ∼2%; cyclohexenone function, ∼2%. For **P8**: mol % **8**-sulfoxide, ∼6%; cyclohexenone function, ∼6%.

***S*-(*N*-4-Chlorophenyl-*N*-hydroxycarbamoyl)propylsulfoxide (2a).** To *S*-(*N*-4-chloro-phenyl-*N*-hydroxycarbamoyl)ethylsulfoxide (**2**) (*21*) (150 mg, 0.61 mmol) in 3 mL of pyridine on ice was added thiopropane (138 mg, 1.187 mmol). The reaction mixture was brought to room temperature and stirred for 30 min, and aqueous 1.6 N HCl (15 mL) was slowly added to the stirring reaction mixture. The reaction mixture was extracted with methylene chloride (3 × 10 mL), the organic layer was dried over sodium sulfate, and the solvent was removed in vacuo. The residue was crystallized from hexane to give the synthetic intermediate *S*-(*N*-4-chlorophenyl-*N*-hy-

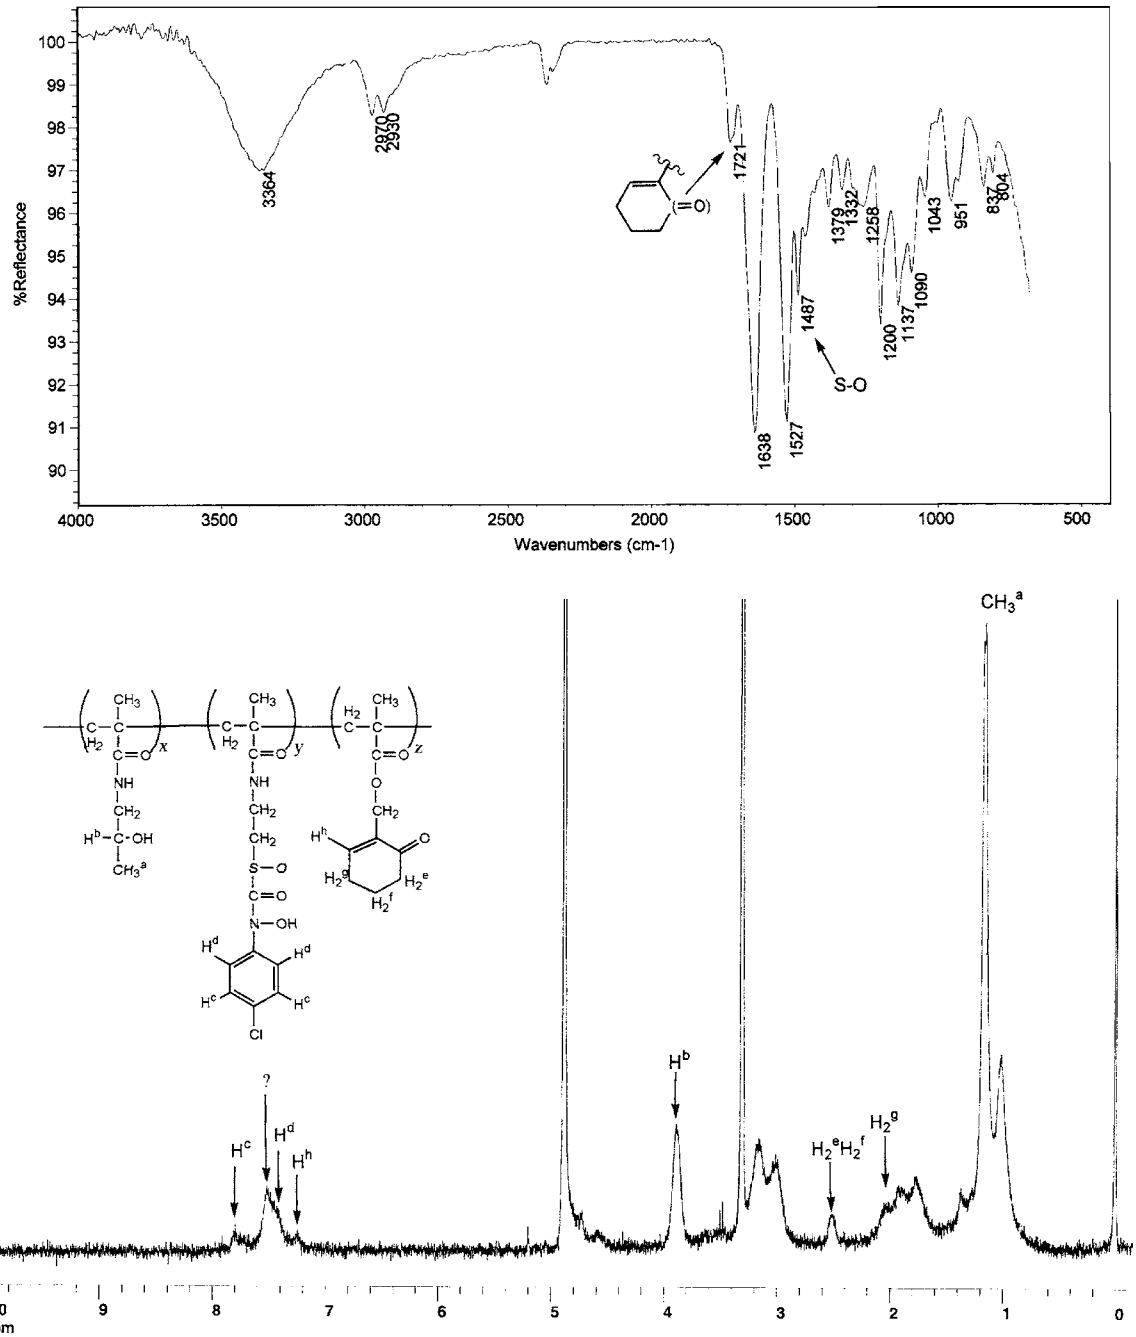


Figure 1. Spectral data for HPMA-copolymer P7 containing both the sulfoxide and the 2-methylenecyclohexenone functions: (top) IR (ATR, AMTIR); (bottom) ^{1}H NMR 300 MHz (methanol-d_4/TMS) spectra. Spectral lines unique to the three functional groups in the copolymers are indicated in the spectra. Other assignments may be found in the Experimental Procedures.

droxycarbamoyl)thiopropyl ester as light brown crystals (yield 41%). The ester (0.252 mmol) was dissolved in 2 mL of diethyl ether to which was added dropwise 3-chloroperoxybenzoic acid (0.248 mmol) in 2 mL of diethyl ether. The white precipitate was collected and washed with diethyl ether to give the final product; the yield from the intermediate ester was 48%. ^{1}H NMR (300 MHz, methanol-d_4/TMS): δ 0.99 (3 H, t, J = 7.3 Hz), 1.73 (2 H, m), 3.04 (2 H, m), 7.37 (2 H, d, J = 9.2 Hz), 7.68 (2 H, d, J = 9.2 Hz).

***S*-(*N*-4-Chlorophenyl-*N*-hydroxycarbamoyl)butylsulfoxide (2b).** This compound was prepared by a procedure analogous to that used to prepare **2a**; yield 29%. ^{1}H NMR (300 MHz, $CDCl_3$/TMS): δ 0.87 (3 H, t, J = 7.3 Hz), 1.40 (2 H, m), 1.70 (2 H, m), 3.08 (2 H, m), 7.37 (2 H, d, J = 8.8 Hz), 7.69 (2 H, d, J = 8.8 Hz).

Determination of the Molecular Weights of the Copolymer Prodrugs. The number average molecular weight (M_n), weight average molecular weight (M_w), and polydispersity (M_w/M_n) of the HPMA copolymers were obtained by high-performance GPC (*30*). The gel permeation column was eluted with 50 mM sodium phosphate buffer (pH 7.0) containing 0.25 M NaCl at a flow rate of 1 mL/min. Molecular weights were interpolated from standard curves (log M_n and log M_w vs retention time) obtained using polydextran molecular weight standards.

Determination of mol % Sulfoxide and Cyclohexenone Functions in the Copolymers. Ethanolic solutions of copolymer were prepared, and 20 μL aliquots were mixed with 80 μL of 10 mM GSH in potassium phosphate buffer (0.1 M, pH 7.5) and incubated at room temperature for 10 min to convert the **8**-sulfoxide and/

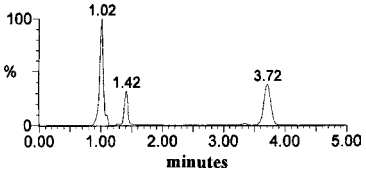

Figure 2. Elution profile from a reverse phase HPLC column (Waters Symmetry C_{18} 5 μm column, 4.6 mm $\times$ 150 mm) of a reaction mixture obtained after incubating **P8** (Table 1) with 10 mM GSH in potassium phosphate buffer (0.1 M, pH 6.5) for 15 min. Abscissa: percent total absorbency (200−400 nm). Peaks at 1.02, 1.42, and 3.72 min correspond to GSH, the GSH-2-methylcyclohexenone adduct **5**, and the transition state analogue **1**, respectively. Running solvent: 25% acetonitrile in water containing 0.1% TFA.

or cyclohexenyl functions to **1** and the GSH adduct **5**, respectively. A 10 μL aliquot of this solution was then fractionated by reverse phase HPLC (Nova-Pak C_{18}, 4 μm, 3.9 mm $\times$ 150 mm column). For the analysis of **1**, the running solvent was 25% acetonitrile in water, containing 0.1% trifluoroacetic acid; for **5**, the running solvent was 13% acetonitrile in water, containing 0.1% trifluoroacetic acid. The areas under the peaks corresponding to **1** and **5** were converted to mole quantities by comparison with standard curves of peak areas vs moles of authentic **1** and **5** injected onto the same column. The amounts of **1** and **5** were then used to calculate mol fractions of **8**-sulfoxide and cyclohexenyl groups in the original copolymer.

Kinetics of Drug Release. Reactions were initiated by the introduction of ethanolic solutions of copolymer into cuvettes containing at least a 20-fold excess of GSH over the equivalents of **8**-sulfoxide and/or cyclohexenyl groups in degassed/N_2-saturated potassium phosphate buffer (0.1 M), pH 6.5, 25 °C. Rate constants were calculated from the first-order decrease in absorbency at 305 and 235 nm resulting from the loss of **8**-sulfoxide and cyclohexenyl groups, respectively (Figure 3).

Stability of Copolymers in Human Serum. To 0.45 mL of human serum at 37 °C was added **P8** to an initial concentration of approximately 1 mM in **8**-sulfoxide and cyclohexenyl groups. As a function of time, 30 μL aliquots of the incubation mixture were transferred to 20 μL of potassium phosphate buffer (0.1 M, pH 7.5) containing 1.6 mM GSH to convert the **8**-sulfoxide and cyclohexenyl functions to **1** and **5**, respectively. After incubation at room temperature for 5 min, the samples were deproteinized by the addition of 100 μL of ethanol. The protein precipitate was sedimented by centrifugation at 13000*g*, and the supernatant was fractionated by reverse phase

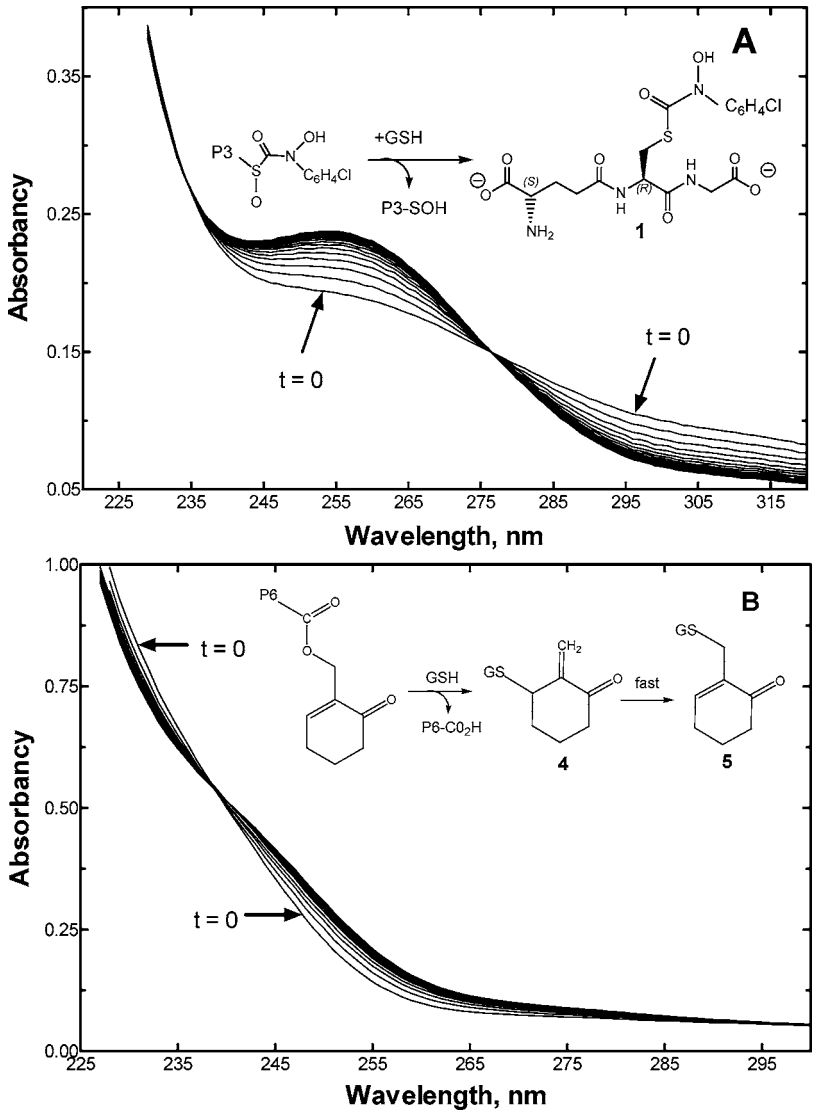

Figure 3. Time-dependent change in the UV spectrum of (A) **P2** (0.025 mM in **8**-sulfoxide) in potassium phosphate buffer (0.1 M, pH 6.5), GSH (0.5 mM), EDTA (0.05 mM), and 2.5 vol % ethanol at 25 °C (spectral scans taken every 25 s) and of (B) **P6** (0.05 mM in **7**) in potassium phosphate buffer (0.1 M, pH 6.5), GSH (1.0 mM), and 5 vol % ethanol at 25 °C (spectral scans taken every 10 min).

HPLC, as described above. The transition state analogue **1** and the GSH adduct **5** were quantitated, as described above. The rate constants were calculated from the first-order rate of loss of **8**-sulfoxide or cyclohexenyl groups as a function of the time.

In Vitro Cytotoxicity Studies. Murine B16 melanotic melanoma was obtained from the DCT Tumor Repository (NCI—Cancer Research and Development Center, Frederick, MD) and was maintained in RPMI 1640 medium containing L-glutamate (Gibco, BRL, Gaithersburg, MD), supplemented with 10% heat-inactivated fetal calf serum and gentamycin (10 μg/mL), under 37 °C humidified air containing 5% CO_2. Under these conditions, B16 cells have a doubling time of about 26 h. For the toxicity studies, cells in logarithmic growth were introduced into 24 well plates at a density of 2×10^4 cells/mL in the absence and presence of drug spanning the IC_{50} values. After 72 h, the cells were washed with Hank's balanced salt solution without Ca^{2+}, treated with trypsin for 10 min at 37 °C, and concentrated by centrifugation, and cell densities were determined with a Coulter Counter. Cell viabilities were determined by the trypan blue exclusion method (*31*).

Reported IC_{50} values (mean ± standard deviation of triplicate determinations carried out in three separate assays on different days) were calculated using the Hill equation and the program Adapt (*32*).

RESULTS

Synthetic Methods. Two new classes of HPMA copolymer prodrugs have been prepared, which employ the same prodrug chemistry previously used to generate the transition state analogue inhibitor of GlxI (**1**) and exocyclic enone **4** in the presence of GSH (Scheme 3).

The prodrugs were prepared by radical polymerization of variable amounts of 2-methacryloylmethyl-2-cyclohexenone **7** and *N*-(4-chlorophenyl-*N*-hydroxycarbamoylthioethyl)methacrylamide **8** with HPMA, followed by treatment with 3-chloro-peroxybenzoic acid to oxidize the thioester function to a sulfoxide (Scheme 4).

Repeated precipitation from methanol/diethyl ether solution gave copolymer preparations that were free of unreacted **8**-sulfoxide and/or **7** by HPLC. The yields were in the range of 28−64%. The polyacrylamide monomers were prepared by an extension of published procedures (*21*, *25*). IR and NMR spectroscopy (e.g., Figure 1) confirmed the chemical identities of the polymers.

The 1487 and 1721 cm^{-1} bands were assigned to the S−O and C=O stretching frequencies of the **8**-sulfoxide and cyclohexenenone functions, respectively, on the basis of comparisons with the IR spectra of **2** and **10**. The integrated intensities of the resonances shown in the NMR spectrum could be used to calculate approximate values for the mol % compositions of the copolymers. However, more precise values were obtained by reacting the copolymers with GSH and quantitating the GSH adducts **1** and **5** after isolation by HPLC (see the Experimental Procedures).

Kinetics of Drug Release. Incubation of the HPMA copolymers with GSH produced a time-dependent increase in product species, which comigrated with authentic samples of transition state analogue **1** and GSH-2-methylcyclohexenone adduct **5** monitored by reverse phase HPLC; e.g., Figure 2.

The rate constants for formation of these species correlated well with the first-order rate of decrease in absorbency at 305 and 235 nm, corresponding to the loss of the sulfoxide and cyclohexenone functions of the copolymers, respectively (Figure 3).

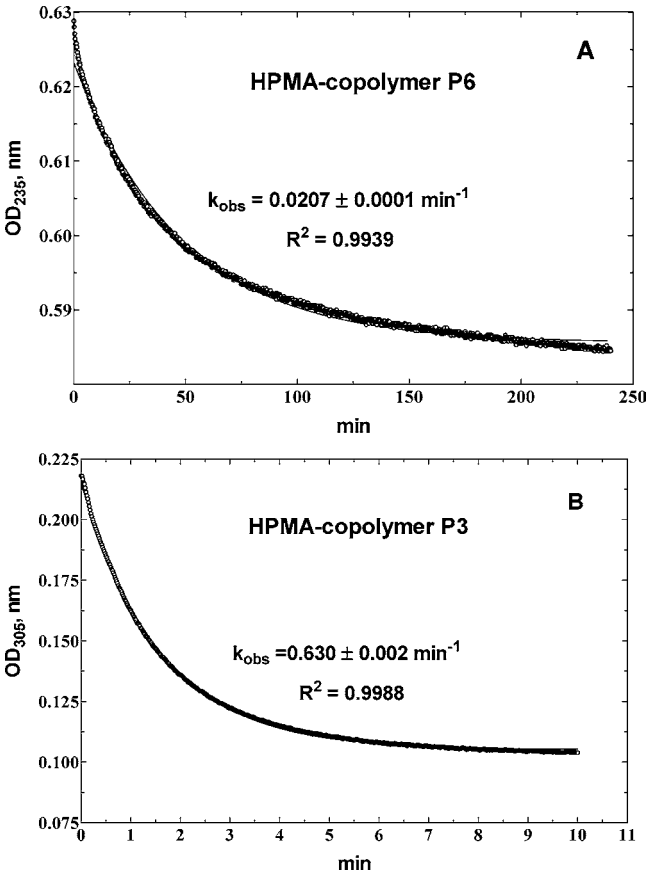

Figure 4. Rate profiles for the reaction of (A) copolymer **P6** (0.05 mM in cyclohexenyl equivalents) with GSH (1 mM) and of (B) copolymer **P3** (0.025 mM in **8**-sulfoxide equivalents) with GSH (0.5 mM). Conditions: Potassium phosphate buffer (0.1 M, pH 6.5), 25 °C. The rate constants given in the figures are the best-fit values to the expression for a first-order exponential decay (solid line through the data).

These wavelengths were selected for the kinetic analyses, as they permit the independent assessment of the rates of loss of each functional group in copolymers containing both functional groups. The rates of formation of **5** and **1** from copolymers containing variable amounts of either the cyclohexenyl and/or the **8**-sulfoxide groups conform to first-order kinetics over 4−5 half-lives (e.g., Figure 4) (Table 1).

Stabilities in Human Plasma. The likely chemical stabilities of the **8**-sulfoxide and cyclohexenyl groups in the copolymers under physiological conditions were estimated by determining the time-dependent loss of these groups from **P8** during incubation human serum at 37 °C. The half-lives for loss of the **8**-sulfoxide and cyclohexenyl groups were determined to be 6.6 ± 0.7 and 37.5 ± 7.5 min (n = 3), respectively.

In Vitro Efficacy Studies. Both the HPMA-**8**-sulfoxide copolymer and the HPMA-**7** copolymer inhibit the growth of B16 in a concentration range where the HPMA polymer alone shows no activity (Figure 5).

Therefore, growth inhibition must result from the prodrug component of the copolymer. Not unexpectedly, the in vitro efficacies of the unpolymerized prodrugs exceed those of the copolymer prodrugs (Table 2).

The simple ethyl, propyl, and butyl sulfoxide prodrugs (**2**−**2b**) have IC_{50} values that are roughly 5−10-fold lower than that of HPMA-**8**-sulfoxide (**P1**), while the IC_{50} value of **3** is over 7000-fold lower than that of HPMA-**7** (**P4**).

Table 1. Mol % Compositions and Spectrophotometrically Determined Second-Order Rate Constants (k_2) for the Reaction of GSH with the Sulfoxide and Cyclohexenone Functions of Different Copolymer Prodrugs[a]

copolymer designation	sulfoxide (mol %)	cyclohexenone (mol %)	M_n (Da) $\times 10^{-3}$	M_w/M_n	k_2 (−sulfoxide) (mM^{-1} min^{-1})	k_2 (−cyclohexenone) (mM^{-1} min^{-1})
P1	8.7 ± 0.30		2.80	1.41	1.85 ± 0.12	
P2	5.2 ± 0.03		7.44	1.47	2.54 ± 0.04	
P3	1.5 ± 0.04		26.5	1.55	2.38 ± 0.07	
P4		19.4 ± 0.7	13.5	1.51		0.015 ± 0.001
P5		12.0 ± 0.4	30.0	1.56		0.015 ± 0.002
P6		6.4 ± 0.1	31.5	1.57		0.021 ± 0.003
P7	4.3 ± 0.03	4.6 ± 0.2	15.4	1.52	2.49 ± 0.051	0.021 ± 0.001
P8	3.6 ± 0.04	1.9 ± 0.01	26.9	1.55	2.11 ± 0.074	0.021 ± 0.001

[a] Kinetic constants were calculated from the first-order rate of loss of the functional group under pseudo-first-order conditions (>20-fold excess of GSH) and are the average of triplicate determinations ± standard deviation. Conditions: potassium phosphate buffer (0.1 M, pH 6.5), 25 °C.

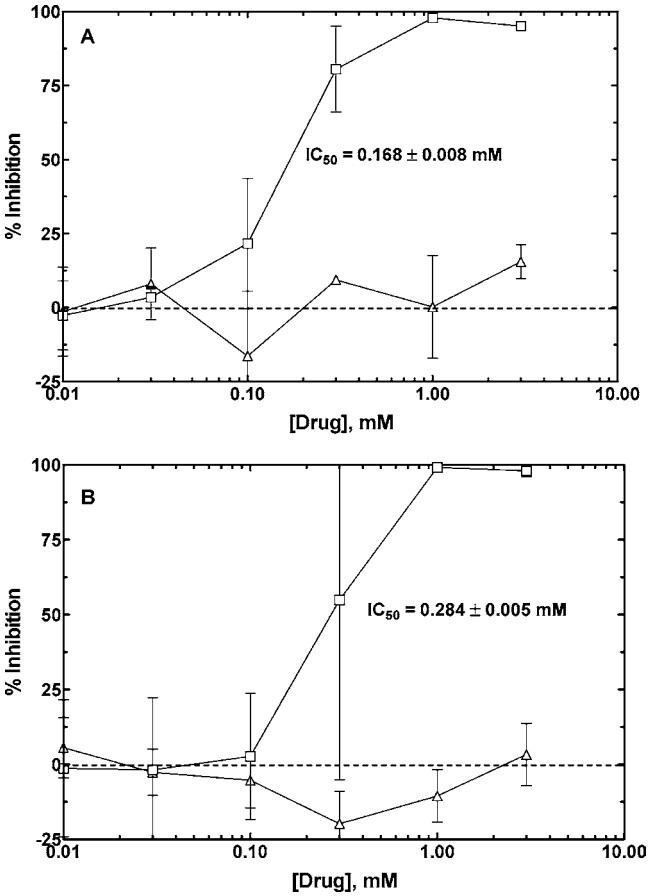

Figure 5. Growth inhibition of B16 melanoma in the presence of (A) **P1** or (B) **P4**. Data for copolymer drug conjugates are indicated by squares; data for polymer controls with no appended drugs are indicated by triangles. The drug concentration is calculated, on the basis of equivalents of drug/L. For conditions, see the Experimental Procedures.

In contrast, the IC_{50} values for **P1**, **P4**, and the copolymer containing both prodrugs (**P7**) differ by no more than a factor of 3.

DISCUSSION

The central outcome of this work is that the kinetic properties and antitumor activities of the lead compounds described here support the feasibility of using HPMA copolymers to deliver cytotoxic GSH derivatives into tumor cells.

Kinetic Properties of the HPMA Copolymers. HPMA copolymers are well-designed to serve as platforms for delivering GSH-activated prodrugs into cells via endocytosis. The reaction between excess GSH and the copolymers to form the GlxI inhibitor **1** or the alkylating agent **4** follows simple first-order kinetic behavior over several half-lives (e.g., Figure 4). This indicates that the copolymers exist primarily in an open or extended conformation in solution, which allows free access of GSH to the reactive groups appended to the copolymers. Moreover, the polyacrylamide backbone does not interfere significantly with the reaction between the GSH and the **8**-sulfoxide function, as the rate constants for reaction of GSH with copolymers **P1**−**P3** (Table 1) are at least as large as that reported for the reaction of GSH with the simple sulfoxide derivative **2** (Scheme 1): $k = 1.84 \pm 0.07$ mM^{-1} min^{-1}, potassium phosphate buffer (0.1 M, pH 7.5), 25 °C (*21*). Indicative of a small steric effect on the reaction of GSH with the cyclohexenone functions of **P4**−**P6**, the rate constants are about 3-fold smaller than that reported for the reaction of GSH with the crotonate ester **3** (Scheme 2): $k = 0.068 \pm 0.001$ mM^{-1} min^{-1}, potassium phosphate buffer (0.1 M, pH 6.5), 25 °C (*17*). Therefore, the ~100-fold greater reactivities of the sulfoxide- vs cyclohexenone-containing copolymers reflect primarily the different intrinsic chemical reactivities of the functional groups with GSH and not the steric properties of the polymer backbone.

Finally, there is little difference in the kinetic properties of the copolymers having either different molecular weights or different mole fractions of the appended sulfoxide or cyclohexenone functions (Table 1). Therefore, loading of the HPMA polymer with high levels of prodrug will not adversely affect the kinetic properties of the copolymers. Not surprisingly, the sulfoxide and cyclohexenone functions in the mixed function copolymers **P7** and **P8** independently react with free GSH, as the rate constants for the individual reactive groups are similar in magnitude to those for the copolymers containing only one of the reactive groups (Table 1).

Model for Endocytotic Drug Delivery. There is a substantial body of evidence indicating that endocytosis is the dominant mechanism for delivering HPMA copoly-

Table 2. In Vitro Inhibition of B16 Melanotic Melanoma by Different HPMA Copolymer−Prodrug Conjugates vs the Monomeric Prodrugs

compound	IC_{50}[a] (μM)
Copolymer Prodrugs	
HPMA-**8** sulfoxide (**P1**)	168 ± 8
HPMA-**7** (**P4**)	284 ± 5
HPMA-(**8**-sulfoxide/**7**) (**P7**)	107 ± 9
Monomer Prodrugs	
cyclohexenone **3**[b] (Scheme 2)	0.04 ± 0.01
ethyl sulfoxide **2** (Scheme 1)	35 ± 8
propyl sulfoxide **2a**	29 ± 5
butyl sulfoxide **2b**	15 ± 2

[a] Values are means (± SD) of three experiments each of which was carried out in triplicate. [b] Value taken from ref *26*.

mers into tumor cells (*1*). In the past, HPMA copolymers were designed to depend on intralysosomal peptidases to cleave the linker between the HPMA and the drug to allow the drug to diffuse into the cytoplasm of the tumor cell. In the present study, thiols rather than peptidases function to liberate the drugs into the cytoplasm of the tumor cell. While there are no good estimates of the steady state concentrations of specific thiols inside the lysosomes of mammalian cells, there is ample evidence to indicate that lysosomes contain highly specific transporter systems for importing cysteine and cysteinyl dipeptides such as cysteinyl-glycine into lysosomes (*33*). For example, a highly specific cysteine-dependent transporter has been found in human fibroblast lysosomes with a $K_m = 0.5$ mM, and evidence has been presented for the efflux of cystine and cysteine from these lysosomes (*34*). An important role of cysteine is to activate intralysosomal thiol-dependent proteases that function to breakdown proteins taken up by endocytosis. Early evidence that GSH also stimulates intralysosomal protein breakdown was attributed to a GSH transporter in the lysosomal membrane (*35*). However, subsequent studies indicate that some or perhaps all of the activation is due to breakdown of GSH to cysteinylglycine, which is subsequently transported into the lysosomes (*36*). Therefore, the presence of a GSH transport system in lysosomes has not been firmly established at this time.

In Vitro Efficacy. The antitumor activities of the HPMA copolymer prodrugs listed in Table 2 are most likely due to the copolymers themselves and not to toxic contaminants in the copolymer preparations. Antitumor activity is unlikely to arise from unreacted sulfoxide-**8** and/or **7** (Scheme 4), as neither NMR nor HPLC analysis of the copolymer preparations indicates that these species are present. Conceivably, **1** and/or **4** might form in the growth medium during the efficacy studies, due to reaction of the copolymers with contaminating GSH (arising from cell lysis). However, this is an unlikely source of antitumor activity, because highly charged S-substituted GSH derivatives such as **1** and **4** do not readily diffuse across cell membranes near neutral pH (*20*). Thus, the observed antitumor activities most likely result from processing of the HPMA copolymers inside tumor cells, during endocytosis.

The in vitro antitumor activity of sulfoxide copolymer **P1** (Table 2) implies the presence of intralysosomal GSH to react with **P1** to give the cytotoxic transition state analogue inhibitor **1**. This follows from reports that yeast GlxI is highly specific for GSH and will not use cysteine or cysteinylglycine as cofactors (*37*). Conceivably, the cysteine and/or cysteinylglycine homologues of **1** might form inside the lysosomes, diffuse across the lysosomal membrane into the cytosol, and then form **1** via acyl interchange with cytosolic GSH. This kind of cofactor specificity is not required to explain the cytotoxicity of the cyclohexenone-containing copolymer **P7**, as intralysosomal GSH, cysteine, or cysteinylglycine could all react with **P7** to give cytotoxic exocyclic enones.

Both the sulfoxide- and the cyclohexenone-containing copolymer prodrugs are significantly less potent than the low molecular weight prodrugs designed to enter cells by diffusion across the cell membrane. HPMA-**8** sulfoxide **P1** is about 6.5-fold less potent than sulfoxides **2**, **2a**, and **2b**, and HPMA-**7** (**P4**) is about 7×10^3-fold less potent that the simple substituted cyclohexenone **3**. This is not a new phenomenon. For example, the HPMA copolymer of 6-(3-aminopropyl)ellipticine (APE) is >75-fold less potent than APE with B16F10 melanoma in vitro, although the copolymer is significantly more potent in tumor-bearing mice (*38*). This has been attributed to the slow rate of endocytotic uptake of the copolymer and the slow rate of peptide hydrolysis of the linker, which can have half-lives on the order of many hours. Likewise, endocytotic uptake of the copolymers described in the current study might be a slow process; the rate constants for formation of **1** and **4** at pH 5.3 will be approximately 50-fold smaller than the rate constants that apply in the cytosol with a pH of 7. Moreover, efficacy might also be limited by the rate of expulsion of the prodrugs from the lysosomes into the cytoplasm of the cell. Thus, the chemotherapeutic potential of the copolymer prodrugs is difficult to appreciate prior to completion of in vivo efficacy studies.

Drug Delivery Strategies. The stability of the copolymer prodrugs in circulating human plasma is another important aspect of drug efficacy in humans. The approximate half-lives for the reaction of the sulfoxide- and cyclohexenone-containing copolymers with free GSH (~2 μM) (*13*) that applies in circulating human plasma at pH 7.5 are estimated to be about 175 and 17400 min, respectively, using the rate constants in Table 1. However, these half-lives are significantly longer than the half-lives of 7 and 38 min determined for the loss of the sulfoxide and cyclohexenone functions, respectively, when the copolymers are incubated in noncirculating human plasma. Therefore, the chemistry associated with the latter process is most significant in determining the bioavailability of the copolymer prodrugs to tumor cells. Compounds with such short half-lives in circulating plasma would be poor candidates for optimizing drug pharmacokinetics via controlled release. The HPMA copolymer prodrugs undergoing clinical evaluation at this time have half-lives in circulating plasma on the order of hours (*39*). However, continuous infusion might still be used to optimize the plasma pharmacokinetics of less stable copolymer prodrug conjugates and allow tumor targeting via the EPR effect. Finally, the lead compounds containing mixed functional groups (**P7**, **P8**) provide a precedent for the application of copolymer prodrugs in combination chemotherapy.

ACKNOWLEDGMENT

This work was supported by a grant from the NCI (CA 59612) and a grant from Maryland Technology Development Corporation. We thank Diana S. Hamilton and Ellyn Sharkey of this laboratory for preparing the starting materials for the syntheses of **8** and **7**.

Received March 28, 2004; Revised Manuscript Received December 3, 2004

Surface modification of cationic lipoplexes has been carried out by means of a postgrafting reaction. The original lipoplexes described comprise a cationic lipid, a neutral lipid, poly(ethylene glycol)–cholesterol (with or without a targeting ligand) and DNA. Modifying their surface via a chemical, postgrafting reaction did not alter their size (~100 nm) nor their ability to compact DNA, but did give a reduced zeta potential (~0 mV) to afford surface neutral particles. With the modified lipoplexes nonspecific NIH3T3 cell surface binding in vitro was inhibited. Intravenous injection of the neutralized lipoplexes in mice showed decreased accumulation of the particles in the lung as compared to PEGylated cationic lipoplexes. Tumor targeting was also achieved in vivo by the addition of an RGD-PEG-Cholesterol as a lipid-ligand in the postgrafted lipoplex formulation.

INTRODUCTION

Liposomes have been widely investigated for their potential clinical use, as they can be used as vectors for a various range of compounds. To allow them to efficiently associate with DNA, cationic lipids have been introduced to form the lipid bilayer. Cationic lipoplexes have been part of an expanding research area over the past decade due to their favorable DNA association as well as their cellular interactions (*1*). However, while they have proven very efficient in vitro they have suffered from problems in vivo, namely rapid elimination from the circulation due to interactions with proteins, opsonins, and the reticuloendothelial system (RES)[1] (*2*).

Methods to help alleviate these problems have included the incorporation of poly(ethylene glycol) (PEG) in liposome preparation. PEG, when grafted onto a lipid or cholesterol moiety and included in liposome preparation, offers colloidal stability due to its bulky, hydrophilic chain (*3*). Lipid-PEG has also shown to be useful at masking some of the positive charges on the surface of cationic lipoplexes. However, while PEG does indeed mask some of the positive charges, it has been found that the particles are still subject to unfavorable interactions with blood components and continue to suffer from rapid elimination from the circulation (*4*). The reduction of positive charges has been achieved by the addition of negatively charged PEG–lipids which helps to afford a more neutral surface charge and allows for enhanced stability in serum (*5*).

Other methods employed to increase the efficacity of lipoplexes in vivo have been to include a targeting moiety in conjunction with PEG–lipids in liposome preparation. One recent example includes the addition of a PEGylated, folate-bearing lipid into liposome formulation, in which folate-targeted complexes restored gene transfer activity in tumors but where the activity in the lung was reduced as compared to nontargeted lipoplexes (*6*). In the case of immunoliposomes, it was found that coupling an antibody to the distal ends of PEG allowed for improved target binding ability (*7*). Some of the more recent and efficient models have involved the preparation of PEG derivatives that are available for surface functionalization by a coupling reaction with target-specific antibodies after liposome formation. Several different chemistries have been used with success for such "postgrafting" strategies (*8*–*11*).

In our case, taking advantage of the lipid cationic charges to associate DNA, grafting was carried out postlipoplex formation. Our goal was to prepare surface neutral particles by means of a "postgrafting" reaction on the surface of preformed lipoplexes. The neutrality of the lipoplexes was expected to render the particles more stable with regard to their blood circulation lifetime, which would then lead to their passive accumulation in tumor tissue.

MATERIALS AND METHODS

Materials. L-α-Dioleoylphosphatidylethanolamine (DOPE), L-α-dioleoylphosphatidylethanolamine–lissamine rhodamine B (DOPE–lissamine rhodamine B), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) were purchased from Avanti Polar Lipids. Cationic lipid 2-(3-[bis(3-aminopropyl)amino]propylamino)-*N*-ditetradecylcarbamoylmethylacetamide (RPR209120B) (*12*), cholesteryl carbonate–poly(ethylene glycol)$_{42}$-OH (Chol-PEG$_{42}$),

and cholesteryl carbamate−poly(ethylene glycol)$_{75}$−(ACDCRGDCFCG)-COOH (Chol−PEG$_{75}$−RGD-4C) (*13*) were synthesized as described in the Supporting Information. Organic solvents chloroform and ethanol were purchased from Merck. H_2O for injection was purchased from Cooperative Pharmaceutique Française. HEPES was purchased from Sigma. Sulfo-NHS acetate and Slide-A-Lyzer dialysis cassettes were purchased from Pierce.

Preparation of Cationic Liposomes (thin-film method). The cationic lipid RPR209120B (16.82 mg, 20 μmol), DOPE (14.88 mg, 20 μmol), and DOPE−lissamine rhodamine B (0.52 mg, 0.4 μmol, 1% total lipid) were dissolved in chloroform, and the solvent was removed under reduced pressure on a rotary evaporator. The resulting thin film was further dried on the rotary evaporator at 5 mbar for 2 h in order to remove any remaining solvent. The film was rehydrated in 2 mL of H_2O for injection by gentle rotation overnight at room temperature to afford a final concentration of 10 mM. The particles were sonicated to afford a homogeneous size distribution of approximately 100−150 nm as measured by dynamic light scattering on a Coulter N4 Plus (Coulter, Beckman).

Preparation of Cationic Liposomes (ethanol injection method). The cationic lipid RPR209120B (16.82 mg, 20 μmol), DPPC (14.68 mg, 20 μmol), and DOPE−lissamine rhodamine B (0.52 mg, 0.4 μmol, 1% total lipid) were dissolved in absol ethanol. Their total volume was adjusted to 3.5 mL by the further addition of ethanol. This mixture was then added dropwise to 35 mL of H_2O with vigorous stirring and left to stir overnight. The excess solvent was removed under reduced pressure on a rotary evaporator until only a 2 mL quantity remained (corresponding to a concentration of 10 mM). The size of the resulting lipoplexes is of the order of 90−100 nm.

Postinsertion of Chol−PEG$_{42}$ in Cationic Liposomes. To functionalize the surface of the liposomes, all of the PEG−lipids were introduced via a postinsertion method. The Chol−PEG$_{42}$ (105 μL, 0.125 μmol) was dissolved in 40 mM HEPES pH 7.5 and added to the cationic liposomes (295 μL, 2.5 μmol) mixture dropwise with vortexing and left to incubate at 37 °C for 2 h.

Preparation of DNA/Vector Lipoplexes. Lipoplexes were prepared in 5% glucose with a charge ratio (+/−) = 5. Plasmid DNA (pCMVCAT) (500 μL, 0.5 g/L, 10% glucose) was added to RPR209120B/DOPE/Chol−PEG$_{42}$ or RPR209120/DPPC/Chol−PEG$_{42}$ cationic liposomes (400 μL, 5 mM total lipids) dropwise with constant vortexing. HEPES (100 μL, 1 M, pH 7.5) was then added to the complex with rapid vortexing, and the samples were left to incubate for 24 h at room temperature.

The insertion of lipid−PEG into the cationic liposome prior to DNA addition was assessed by an indirect method: indeed, if the lipid−PEG was not inserted into the outer bilayer of the liposome, the complex would aggregate upon the addition of 10 mol equiv of sulfo-NHS acetate per mole of RPR209120B (i.e. 5 equiv of sulfo-NHS acetate per primary amine of RPR209120B).

Reaction of the Lipoplexes with Sulfo-NHS Acetate. Sulfo-NHS acetate (3.24 mg, 10 equiv, 12.5 μmol) was added to lipoplex RPR209120B/DOPE/Chol−PEG$_{42}$/DNA or RPR209120B/DPPC/Chol−PEG$_{42}$/DNA (1 mL, 1 equiv, 1.25 μmol RPR209120B) buffered with 100 mM HEPES at pH 7.5. The reagent was added as a powder, and the resulting mixture was gently mixed by inverting the reaction tube several times to aid dissolution. The reaction mixture was left to incubate for 1 h at room temperature with occasional gentle mixing. The reaction complex was then transferred to Slide-A-Lyzer dialysis cassettes and dialyzed overnight against 5% glucose and 100 mM HEPES.

Preparation of Targeting Postgrafted Lipoplexes. First, Chol−PEG$_{42}$ lipids (105 μL, 0.125 μmol) were dissolved in 40 mM HEPES pH 7.5 and added to the cationic liposomes (190 μL, 2.5 μmol) mixture dropwise with vortexing and left to incubate at 37 °C for 2 h. Then, plasmid DNA (pCMVCAT) (500 μL, 0.5 g/L, 10% glucose) was added to RPR209120B/DOPE/Chol−PEG$_{42}$ or RPR209120/DPPC/Chol−PEG$_{42}$ cationic liposomes (295 μL, 5 mM total lipids) dropwise with constant vortexing. HEPES (100 μL, 1 M, pH 7.5) was then added to the complex with rapid vortexing, and the samples were left to incubate for 24 h at room temperature. Sulfo-NHS acetate (3.24 mg, 10 equiv, 12.5 μmol) was added to the lipoplex (895 μL, 1 equiv, 1.25 μmol of RPR209120B) buffered with 100 mM HEPES at pH 7.5; the lipoplexes were incubated and purified as described above. Finally, to prepare the RGD lipoplexes, the Chol−PEG$_{75}$−RGD-4C was dissolved in 40 mM HEPES pH 7.5 (105 μL, 0.125 μmol) and was added to postgrafted lipoplexes (895 μL) with vortexing, and the samples were left to incubate for 24 h at room temperature. The Chol−PEG$_{75}$−RGD-4C was inserted postacetate reaction and postdialysis in order to avoid any unwanted side-reactions taking place.

Size of Complexes/Zeta Potential of Complexes. The size of the complexes was determined by dynamic light scattering on a Coulter N4 Plus. Typically 10 μL of complex was added to 800 μL of H_2O for injection for each sample measured, mean value are given for 90°, 1 min equilibration, 3 min run.

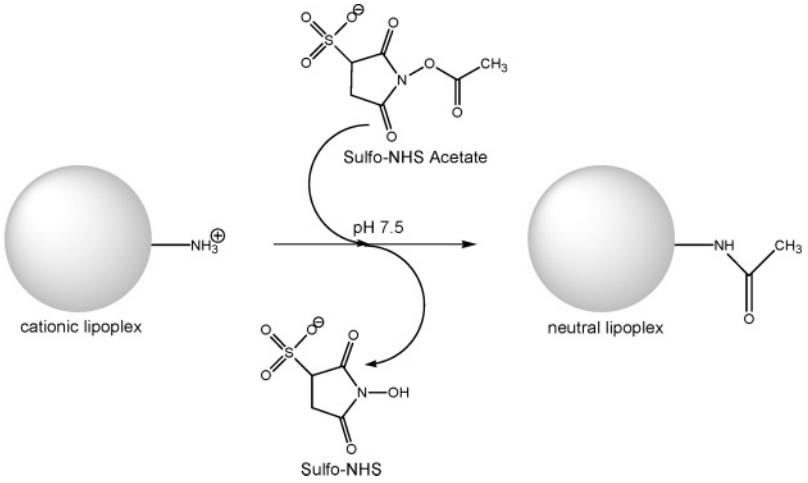
The zeta potential measurements were performed on a Malvern Zetasizer 3000. Samples of 1 mL containing 100 μL of complex (5 mM) in 20 mM NaCl were injected in the cell and subjected to 5 × 8 s measurements.

Transmission Electronic Microscopy. The lipoplexes prepared as described (Concentration divided by 10) were loaded on a Formvar/carbon copper grid 200 mesh from Agar Scientific. Uranyl acetate was used to stain the samples. Analyses were performed on a microscope JEOL, JEM 100S.

In Vivo Distribution in Normal or Tumor-Bearing Mice. Six-week-old female C57B1/6 mice (Charles River) were anesthetized by intraperitoneal injection of a mix of ketamine (85.8 mg/kg; Merial) and xylazine (3.1 mg/kg; Bayer) diluted in 150 mM NaCl. A 200 μL volume of rhodamine-labeled lipoplexes (50 μg of DNA, 250 nmol cationic lipids in 5% glucose) was injected into the mouse tail vein. Blood was collected by cardiac puncture at appropriate intervals (30 min, 1, 2, and 6 h after injection), and mice were euthanized at the end of the sample taking. In the distribution study, mice were sacrificed at 30 min and at 1, 2, and 6 h after injection and the liver, spleen, and lungs were removed, weighed, and homogenized in pH 7.4 phosphate-buffered saline (PBS, 5 mL/g tissue). Experiments were conducted following NIH recommendations for animal experimentation and Aventis local ethic committee on animal care and experimentation.

Rhodamine-labeled lipids were extracted according to Takeuchi et al. (*14*) from 100 μL of blood or tissue homogenates with 3 mL of $CHCl_3$−MeOH (1:1, v/v) by vigorous mixing during 30 min for blood and 40 min for tissue homogenates followed by centrifugation (3000 rpm, 10 min). The fluorescence intensity corresponding to DOPE−rhodamine was assayed on the supernatant with a fluorospectrophometer (Fluoromax 2, Jobin Yvon, λ_{exc} 550 nm/λ_{em} 590 nm). The amount of lipoplexes in the blood or tissue homogenates was evaluated with a

Scheme 1. Illustration of the Postgrafting Strategy with Sulfo-NHS Acetate



calibration curve of the initial lipoplexes containing 1% DOPE−rhodamine and expressed as the remaining percentage of injected dose.

Lewis lung and colon carcinoma tumors kindly provided by Aventis Pharma (Vitry/Seine, France) were implanted subcutaneously in the right flank of six-week-old female C57B1/6 mice (Charles River), and 10−14 days later, biodistribution studies were undertaken as previously described.

Reporter Gene Expression in Lungs and PO_2 Colon Carcinoma. Six-week-old female C57B/16 mice (Charles River) were anesthetized by intraperitoneal injection of a mix of ketamine (85.8 mg/kg) and xylazine (3.1 mg/kg) diluted in 150 mM NaCl. A 200 μL volume of rhodamine-labeled lipoplexes (50 μg of DNA, 250 nmol of cationic lipids in 5% glucose) was injected into the mouse tail vein. Mice were sacrificed at 24 h postinjection, and lungs and PO_2 colon carcinoma were harvested, weighed, and homogenized in 1 mL of PBS using an Ultra Thurax (Diax 600, Heidolph, Fisher). The samples were centrifuged (1000 rpm, 30 min, 4 °C), and the amount of Chloramphenicol acetyl transferase (CAT) transgene expressed was determined using a standard enzyme-linked immunosorbent assay (ELISA) kit (Roche Diagnostics).

RESULTS

Postgrafting Method. Reaction of Cationic PEGylated Lipoplexes with Sulfo-NHS Acetate. Sulfo-NHS acetate is traditionally used on proteins to irreversibly block primary amines and form stable amides; it is very reactive toward primary amines between pH 7−9 and less reactive toward secondary amines. The postgrafting method consists of DNA/vector lipoplex preformation followed by reaction with an excess of sulfo-NHS acetate to mask the cationic charges (Scheme 1). One can predict that masking all cationic charges on the lipoplex will lead to particle aggregation due to a lack of electrostatic repulsion. The insertion of a PEG−lipid in lipoplex formulation is therefore necessary to maintain particles with a small diameter, and we have used cholesterol−PEG_{42} (Chol−PEG_{42}) in the present study. The pH at which the postgrafting experiments are carried out is low enough to prevent the acetylation of DNA (a pH between 8.5 and 9.0 is required for DNA acylation). Reactions can be carried out in a buffered medium, and they proceed readily at room temperature. The successive steps involved in lipoplex preparation used in the present postgrafting study are shown (Scheme 2), and the non-commercial lipids used in their formulation are illustrated (Scheme 3).

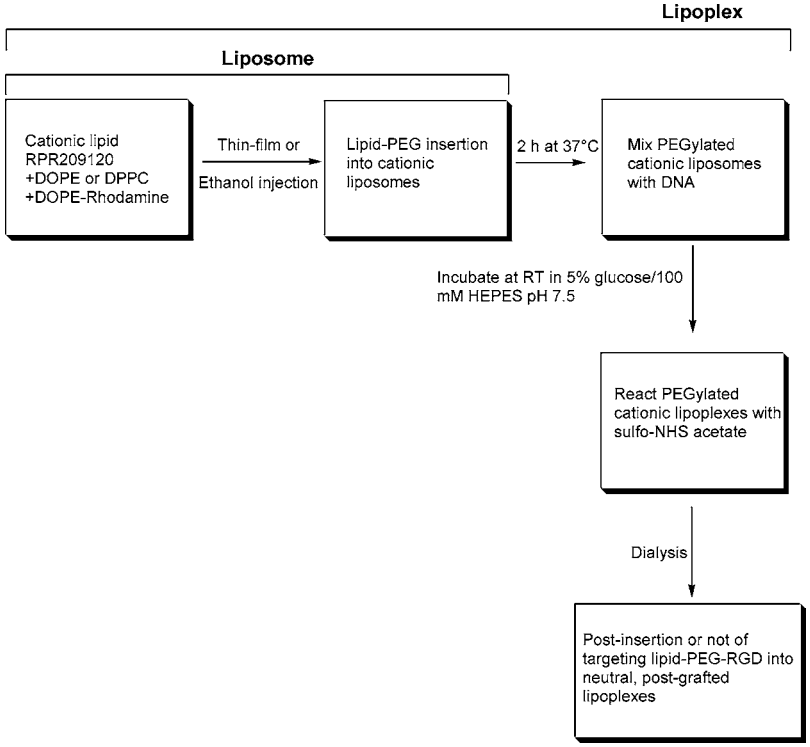
To optimize the reaction conditions for postgrafting sulfo-NHS acetate on lipoplexes, initial experiments were carried out with various molar ratios. The following molar equivalents (1:1, 5:1, 10:1, and 50:1) of sulfo-NHS acetate versus cationic lipid were investigated (Table 1).

The size of the unreacted PEGylated particles, prepared by the thin-film method, was approximately 131 nm, and their zeta potential was +16.42 mV. These results are in good agreement with previous reports. It can be shown that while the addition of PEG−lipid in lipoplex preparation does reduce the zeta potential of the particles, it does not completely mask the surface charges, and residual positive charges can still be measured (*5*). The size of the postgrafted particles gradually increased to approximately 189 nm (with 50 mol of sulfo-NHS acetate per mole of RPR209120B), and their zeta potential was reduced to approximately zero. In the case where lipoplexes were reacted with 50 equiv of sulfo-NHS acetate, the zeta potential of the particles was reversed to −15 mV, and we could see a partial DNA release on agarose gel electrophoresis as indicated by the ethidium bromide (EtBr) fluorescence increase (Table 1).

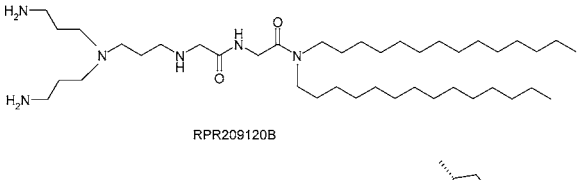
The particles, both modified and unmodified, were stable for more than 60 days with respect to their size (approximately 150 nm for both types of particles) and their zeta potential (approximately +5 mV for particles modified with 10 mol of sulfo-NHS acetate per mole of RPR209120B and approximately +12 mV for unmodified particles) (data not shown).

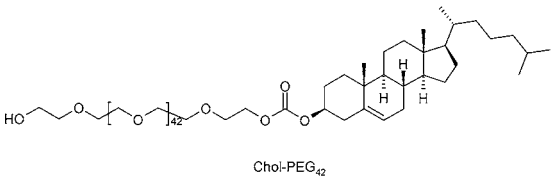
Acetylation Yield of Postgrafted Complexes. The lipids of postgrafted complexes were extracted and subjected to analysis (experimental details can be found in the Supporting Information). The degree of acetylation of lipid RPR209120B in the complexes was evaluated by LC-MS and it was found that the postgrafting procedure produced a mixture of compounds. Two corresponding peaks were determined, of which the major peak (65%) contained a mixture of both the starting lipid and the diacetate. The minor peak (35%) was found to be the triacetate. These results are in good agreement with the results above. A certain amount of unreacted starting lipid in the postgrafted complex is required to continue to compact DNA, and the ethidium bromide assay shows that this is indeed the case (Table 1). The proportions of diacetate and triacetate found in the extracted mixture are also what would be expected due to their reactivities and relative position within the complexes.

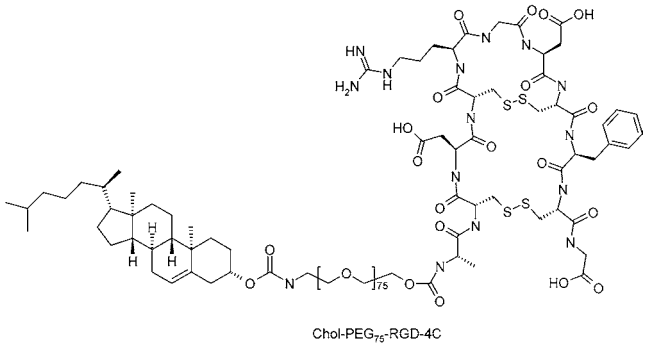
Scheme 2. Illustration of the Successive Lipoplex Preparation Steps Used in the Present Postgrafting Study



Scheme 3. The Cationic Lipid RPR209120B, Cholesterol−PEG_{42} (Chol−PEG_{42}) and Cholesterol−PEG_{75}−RGD-4C (Chol−PEG_{75}−RGD-4C)







Characterization of the Postgrafted Lipoplexes for Both in Vitro and in Vivo Experiments. From these results above, it was established that postgrafting up to 10 mol of sulfo-NHS acetate per mole of cationic lipid RPR209120B on the surface of preformed lipoplexes did not alter their size nor their ability to compact DNA, yet it did afford surface-neutral particles as demonstrated by their zeta potential. For biological studies, we chose to use these conditions, and we prepared postgrafted lipoplexes containing or not containing a Cholesterol−PEG_{75}−RGD-4C (Chol−PEG_{75}−RGD-4C) targeting lipid.

Table 1. Physicochemical Data Corresponding to the Reaction of Different Amounts of Sulfo-NHS Acetate on PEGylated Cationic Lipoplexes[a]

molar ratio sulfo-NHS acetate/ cationic lipid	zeta potential (mV)	EtBr (relative fluorescence)	particle size (nm)
0	16.42	4.6	131
1	−2.19	5.7	151
5	−0.36	10.2	168
10	−2.09	11.0	169
50	−15.0	13.1	189

[a] The molar equivalents (1:1, 5:1, 10:1, and 50:1) of sulfo-NHS acetate versus cationic lipid RPR209120B were investigated. Lipoplexes comprised RPR209120B/DSPE−PEG_{42}(10%)/DNA with a charge ratio (+/−) = 5 and were prepared by the thin-film method.

It was necessary to use a HEPES buffer concentration of 100 mM in order to maintain the pH at ∼7.4 during and after the reaction with sulfo-NHS acetate since it is subject to hydrolysis, which releases acetic acid and sulfo-*N*-hydroxysuccinimide.

Liposomes were prepared either by film formation followed by rehydration or by the ethanol injection method (see Materials and Methods and Scheme 2). While Chol−PEG_{42} was inserted in the cationic liposomes before sulfo-NHS acetate postgrafting in order to maintain the colloidal stability of the neutralized lipoplexes, the targeting lipid, Chol−PEG_{75}−RGD-4C, was inserted after the postgrafting reaction. Size and zeta potential of the final complexes for in vivo studies were measured (Table 2).

Cationic lipoplexes, prepared by the ethanol injection method, gave a measured zeta potential of +39.7 ± 1.1 mV, which was reduced to +12.5 ± 0.9 mV by addition of 5% Chol−PEG_{42} in the formulation. Insertion of lipid−PEG_{42} in the film during the preparation of the liposomes led to similar results (+16 mV, Table 1).

By reacting sulfo-NHS acetate with the surface amine moieties of preformed PEGylated lipoplexes, neutral

Table 2. Size and Zeta Potential Data of Non-targeted and Targeted Lipoplexes Used for Biological Experiments[a]

type of complex	size (nm)	zeta potential (mV)
cationic lipoplex	109.8 ± 24.1	+39.7 ± 1.1
lipoplex + 5%Chol−PEG_{42}	125.2 ± 50.9	+12.5 ± 0.9
lipoplex + 5%Chol−PEG_{42} + postgrafting	96.9 ± 29.6	+1.2 ± 0.9
lipoplex + 5%Chol−PEG_{42} + postgrafting + 5%Chol−PEG_{75}−RGD-4C	211 ± 89.9	−3.4 ± 1.0

[a] Liposomes were prepared by the ethanol injection method. Cationic lipoplex comprised RPR209120B/DPPC/DNA; lipoplex + 5%Chol−PEG_{42} comprised RPR209120B/DPPC/Chol−PEG_{42}(5%)/DNA; lipoplex + 5%Chol−PEG_{42} + postgrafting comprised RPR209120B/DPPC/Chol−PEG_{42}(5%)/DNA and was reacted with sulfo-NHS acetate; lipoplex + 5%Chol−PEG_{42} + postgrafting + 5%Chol−PEG_{75}−RGD-4C comprised RPR209120B/DPPC/Chol−PEG_{42}(5%)/DNA, was reacted with sulfo-NHS acetate followed by insertion of Chol−PEG_{75}−RGD-4C (5%). All above lipoplexes were prepared with a charge ratio (+/−) = 5.

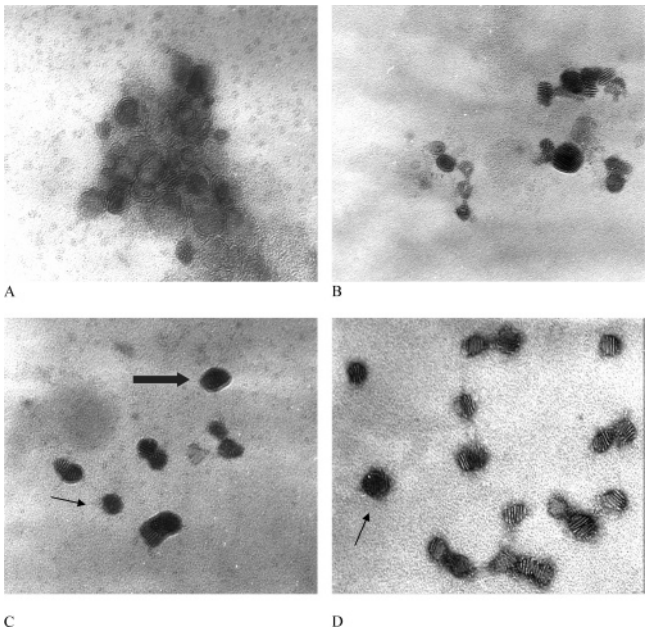


Figure 1. TEM pictures of lipoplexes obtained by negative staining. A. Liposomes (film) RPR209120B/DOPE/Chol−PEG_{42}-(5%)/DNA B. Same liposomes as in A + sulfo-NHS acetate postgrafting; C. Liposomes (ethanolic injection) RPR209120B/DPPC/Chol−PEG_{42}(5%)/DNA. D. Same liposomes as in C + sulfo-NHS acetate postgrafting.

particles were obtained (zeta potential = +1.2 ± 0.9 mV). When lipoplexes were reacted with sulfo-NHS acetate, and Chol−PEG_{75}−RGD-4C was further added to the preformed complexes, the zeta potential was reduced to −3.4 ± 1.0 mV (Table 2); this value is in agreement with the presence of two aspartic acids and a free C-terminal carboxylate function in the RGD moiety.

Electronic transmission microscopy was carried out for acetylated and nonacetylated particles prepared by the thin-film and the ethanolic injection methods (Figure 1).

No structural differences between postgrafted and non postgrafted particles were observed, indicating that the postgrafting process does not alter the particle structures. However, the surface of postgrafted particles appears slightly changed with enhanced lamellas. By laser diffraction size measurement, postgrafted particles appeared larger than the non postgrafted ones (within 10−20 nm increase), and we obtained smaller particles by the ethanol injection method as compared to the film-hydration method. As an example, the isolated particles in C and D represent 20 and 40 nm in diameter, respectively. On some of the particles, an outer layer probably corresponding to the PEG shielding was clearly visualized (large gray arrow on C).

Lipoplex Pharmacokinetics after iv Injection. Intravenous injections of PEGylated cationic lipoplexes versus PEGylated postgrafted lipoplexes were performed in mice bearing subcutaneous 3LL Lewis Lung tumors. The postgrafted complexes, where the liposome component was prepared via the thin-film method, showed an increased amount of postgrafted complex in the circulation by a factor of 7 at the end of 30 min and by a factor of 5 after 1 h. There was also a marked decrease in the uptake of acetylated, postgrafted particles in the lung. However, there was no significant passive accumulation in the tumor (Figure 2). As already observed, most of the rhodamine signal was recovered in the RES (5).

The postgrafted complexes, where the liposome component was prepared via the ethanol injection method, did not show as dramatic a difference in circulation time as compared to nonacetylated particles. The smaller size achieved with these particles might be the main reason for this. A different liposome flexibility due to the preparation might also influence this difference (*15*). Nevertheless, there was again a decrease in lung uptake of the acetylated particles (data not shown).

Targeting with RGD−PEG−Lipid. The postgrafting strategy afforded lipoplexes with a longer circulation lifetime, but at the same time, as could be expected, diminished their cell membrane interactions required for transfection. We thus postulated that the addition of an integrin-targeting ligand in lipoplex formulation may help to restore their accumulation in the tumor. Experiments were performed on mice bearing PO_2 tumors validated for their $\alpha v \beta 3$ integrin expression in the tumor vasculature.

An increased trend of lipoplex accumulation in the tumor when an RGD-4C ligand was added to the formulation was noted as compared to the same formulation of postgrafted complexes without RGD (Figure 3). Taking the Chol−PEG_{75}−RGD-4C liposome as a control, an increase of 5- and 2-fold in the tumor were measured, 30 min and 1 h postinjection, respectively, for the liposome + Chol−PEG-RGD-4C + postgrafting particles. This increased liposome accumulation was reflected in an increased gene expression for both cationic PEGylated lipoplexes and PEGylated postgrafted lipoplexes bearing a Chol−PEG-RGD-4C targeting moiety (Figure 4). However, no statistically significant difference was observed for transgene expression between the nonneutralized or acetate-neutralized targeted lipoplexes.

DISCUSSION AND CONCLUSIONS

Improving the circulation lifetime of iv injected cationic lipid/DNA complexes is of great interest. Cationic lipids are excellent vectors for DNA due to both their ability to efficiently compact negatively charged DNA at a certain charge ratio, as well as their favorable cellular interactions which lead to transfection in vitro. However, in vivo cationic lipid efficacy is hampered by their nonspecific interactions with blood components and their rapid elimination from the circulation (*4*). The addition of PEG in lipoplex formulation has achieved less positively charged particles, with respect to their surface charge (i.e. their zeta potential), but this has been found to be insufficient to completely mask any residual cationic charges on the lipoplex surface, which are still subject to unfavorable blood component interactions.

The original postgrafting method presented here was validated as a way to compact DNA and obtain neutral particles while maintaining their size. Binding experiments performed at 4 °C on NIH3T3 cells with fluorescent particles showed no fluorescence for postgrafted complexes while nonspecific fluorescence was observed for nonacetylated complexes (data not shown) (*16*). This confirmed the potential of sulfo-NHS acetate lipoplex neutralization to decrease nonspecific cell interaction.

Our postgrafted formulations included PEG−lipids for steric stabilization of the particles. This strategy allowed the incorporation of a lipid−PEG-ligand without protocol modification. Incorporation of Chol−PEG_{75}−RGD-4C into the formulation increased lipoplex tumor delivery. Although an increase in tumor transfection was observed in RGD-targeted formulations, neutralized particles were not superior to nonneutralized ones. This might result from incomplete DNA release or less efficient transfection by neutralized particles. The use of a cytotoxic drug or an antiangiogenic plasmid (*17*) instead of a DNA model would be an alternative and a more straightforward manner to assay the potential advantage of the present formulation for therapeutic use, as only a release at the level of the vessels would be required to starve the tumor. Integrins have been shown to be overexpressed by the inflammed endothelium (*18*), which would be easier to

reach for particles. It has been reported that RGD-targeted liposomes can act as a site-specific drug delivery system to tumor endothelial cells in vitro, which was demonstrated by increased binding, as well as redirecting targeted liposomes containing doxorubicin to angiogenic endothelial cells in vivo which led to inhibited tumor growth (*19*). Thus, in the present case, the targeted particles possibly accessed the tumoral endothelium without reaching the tumor cells. Experiments are currently being undertaken to determine the localization of the particles in and around the tumor.

The postgrafting strategy reported here has succeeded in further reducing the zeta potential of cationic lipoplexes (to approximately 0 mV) to afford surface neutral particles and has allowed for a longer lifetime of the complexes in vivo. Despite increased circulation time in the blood, no passive accumulation in 3LL tumors was measured. Insertion of a targeting Chol−PEG_{75}−RGD-4C succeeded in PO_2 tumor targeting and increased DNA expression. Ways of triggering DNA release in the target are now in process.

Synthesis and Biological Properties of Insulin−Deoxycholic Acid Chemical Conjugates

Seulki Lee, Kwangmeyung Kim, Tadiparthi Suresh Kumar, Jisook Lee, Sang Kyoon Kim, Dong Yun Lee, Yong-kyu Lee, and Youngro Byun*

Department of Materials Science and Engineering, Gwangju Institute of Science and Technology, 1 Oryong-dong, Buk-gu, Gwangju, 500-712, Korea. Received June 2, 2004; Revised Manuscript Received March 23, 2005

Bile acids have been considered very useful in the preparation of new pharmaceuticals, and more recently in the preparation of peptide and protein drugs because of their natural chemical and biological properties. In this study, we modified recombinant human insulin by covalently attaching deoxycholic acid (DOCA) derivatives in order to synthesize orally active insulin analogues. DOCA derivatives, namely succinimido deoxycholate and succinimido bisdeoxycholyl-L-lysine were prepared and site specifically conjugated at Lys^{B29} of insulin. The resultant insulin conjugates, [N^{B29}−deoxycholyl] insulin (Ins−DOCA) and [N^{B29}−bisdeoxycholyl-L-lysil] insulin (Ins−bisDOCA), were studied for their chemical, structural, and biological properties. Their chemical properties were determined by HPLC, MALDI-TOF mass spectroscopy, and dynamic light scattering. Lipophilicity and self-aggregation behavior of insulin conjugates were enhanced with increasing number of labeled bile acid. The far-ultraviolet region of circular dichroism spectra showed no significant change of the tertiary structure of insulin in aqueous solution due to conjugation. Competitive insulin binding assay with HepG2 cells revealed that monosubstituted insulin conjugates still retained high binding affinity to the insulin receptor. When the insulin conjugates were intravenously administered (0.33 IU/kg) to streptozotocin (STZ)-induced diabetic rats, the conjugates showed sustained biological activity for a longer period with the similar lowest blood glucose level (glucose nadir), compared to native insulin. In further studies, the resulting new insulin conjugates will be investigated for their oral efficiency as a long-acting insulin formulation for the treatment of diabetic patients.

INTRODUCTION

Insulin is the primary hormone utilized for treatment of virtually all types of diabetic patients. Insulin can be administered only by parenteral injection; however, conventional injectable insulin replacement therapy has several therapeutic risk factors, such as poor compliance and unsatisfactory metabolic regulation in diabetic patients (*1*, *2*). Many attempts have therefore been made to enhance therapeutic performance of insulin using various delivery systems (*3*−*5*). However, these alternative delivery methods of insulin still have many problems mainly due to natural characteristics of insulin such as physicochemical instability, increased susceptibility to proteolysis, solubility, large molecular weight, and limited ability to traverse biological barriers (*6*, *7*).

To overcome these limitations, several kinds of chemical modifications of insulin have been proposed. For instance, lipid modification of insulin could improve solubility and showed extended-action via binding to an existing serum protein (*8*−*10*). In addition, poly(ethylene glycol), 9-fluorenylmethoxycarbonyl, transferrin, polysialic acid, and poly(ethylene glycol)-alkyl linker chemically conjugated insulin derivatives showed improved therapeutic profiles, such as solubility, enzymatic stability, circulation half-life, or permeability against mucosal membrane (*11*−*16*).

Among all the different alternative route of insulin delivery, peroral formulation is the most preferable for its significantly pronounced therapeutic and patient acceptability. In our previous study, deoxycholic acid (DOCA)-conjugated heparin was highly absorbed in the intestine without damaging the tissue structure of the mucous membrane (*17*, *18*). More recently, we have prepared a new oral delivery carrier based on bile acid which improves the oral bioavailability of human insulin (*19*). Based on substantiated observations that associated bile acids could enhance the absorption of poorly permeable macromolecules in the intestine, we have designed site-specific DOCA-conjugated insulin analogues. DOCA is one of the bile acids which are natural compounds consisting of a facially amphiphilic steroid nucleus with a hydrophobic β-side and a hydrophilic α-side. They are synthesized from cholesterol in the liver, released in the small intestine, and returned to the liver by absorption through the bile acid transporter (*20*, *21*). Bile acids have been considered in the preparation of new drugs because bile acid-conjugated materials can retain the properties of bile acids, such as amphiphilicity, capacity of self-assembling, high chemical stability, and binding ability to bile acid transporters in the intestine (*22*, *23*). Taken together, this spectrum of properties gives the therapeutic peptide a unique pharmacological profile that is attractive for developing new orally active formulations.

In this respect, we hypothesized that covalent coupling of bile acid to a specific site of insulin may improve the therapeutic profiles of insulin while maintaining its biological activity. We synthesized, in this study, site specifically labeled insulin−DOCA conjugates and char-

acterized their biological activity in vitro and in vivo, respectively.

EXPERIMENTAL PROCEDURES

Materials. Human crystalline zinc insulin (Zn^{2+} insulin) was purchased from Serologicals Corp. (Norcross, GA) and used without further purification. (3-[^{125}I]-Iodotyrosyl^{A14})-insulin (human recombinant) was obtained from Amersham Biosciences Corp. (Piscataway, NJ). Deoxycholic acid (DOCA), L-lysine ethyl ester, *N*,*N*′-dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), tetrahydrofuran (THF), anhydrous *N*,*N*-dimethylformamide (DMF), triethylamine (TEA), ethyl acetate (EtOAc), absolute ethanol (EtOH), ammonium bicarbonate (NH_4HCO_3), magnesium sulfate anhydrous ($MgSO_4$), and streptozotocin (STZ) were purchased from Sigma-Aldrich Co. (St. Louis, MO). Before use, THF was distilled from sodium benzophenone. All reagents and organic solvents used were at least ACS grade.

Preparation of DOCA Derivatives. *Succinimido Deoxycholate*. DOCA (200 mg, 0.5 mmol) and NHS (76 mg, 0.67 mmol) were dissolved in anhydrous THF (20 mL). DCC (136 mg, 0.67 mmol) was added and stirred at 4 °C for 6 h. After urea derivatives were filtered, the filtrate was poured into cold *n*-hexane (120 mL) and the precipitate was dried in a vacuum. The synthesized succinimido deoxycholate was obtained as white powder. ^{1}H NMR, 350 MHz, $CDCl_3$: 0.59 (s, 3H, 18-Me); 0.86 (s, 3H, 19-Me); 0.91 (d, 3H, 21-Me); 1.03−2.50 (25H, steroidal H); 2.81 (s, 4H, CH_2CH_2); 3.78 (m, 1H, 3β-H); 4.06 (br s, 1H, 12β-H). MALDI-MS: calcd MW, 489.6; found, 490.

Succinimido Bisdeoxycholyl-L-lysine. A suspension of L-lysine ethyl ester HCl (50 mg, 0.24 mmol) in anhydrous DMF (15 mL) containing TEA (140 μL, 1 mmol) was stirred at room temperature for 30 min, followed by addition of DOCA (190 mg, 0.48 mmol) and NHS (71 mg, 0.62 mmol). DCC (129 mg, 0.62 mmol), dissolved in anhydrous DMF (5 mL), was added dropwise to the mixture and then stirred at room temperature for 12 h. The mixture was filtered, and the filtrate was diluted with EtOAc (40 mL). The organic mixture was successively washed with 15 mL of 0.5 N HCl, distilled water, 0.5 N NaOH, and distilled water. The dried products were dissolved in EtOH (10 mL) containing saturated NaOH and allowed reaction followed by refluxing on a stream bath at 60 °C for 6 h. After filtration at room temperature, the filtrate was added dropwise to a cold acid solution (pH 3). The precipitates were filtered, washed, and dried in a vacuum. Finally, bisdeoxycholyl-L-lysine was obtained as white powder. The carboxylic group of bisdeoxycholyl-L-lysine was activated by NHS as described above to obtain succinimido bisdeoxycholyl-L-lysine. ^{1}H NMR, 350 MHz, $CDCl_3$−CD_3OD: 0.58 (s, 6H, 2 × 18-Me); 0.84 (s, 6H, 2 × 19-Me); 0.92 (d, 6H, 2 × 21-Me); 1.05−2.40 (56H, steroidal 50H, 3 × CH_2); 2.75 (s, 4H, CH_2CH_2); 2.98 (m, 2H, CH_2−NHCO); 3.61 (m, 2H, 2 × 3β-H); 4.16 (br s, 1H, 2 × 12β-H); 4.47 (s, 1H, C*H*-NHCO); 7.73 (br s, 1H, CH_2−N*H*CO); 7.96 (br s, 1H, CH−N*H*CO). MALDI-MS: calcd MW, 992.4; found, 991.

Preparation of Insulin Conjugates. *[N^{B29}−Deoxycholyl] Insulin*. This conjugate was synthesized according to a modified method used for the acylation of insulin with fatty acid (*9*). Briefly, Zn^{2+} insulin (100 mg, 17 μmol) was dissolved in DMF/H_2O (6 mL, 3/2 v/v, pH 10) at room temperature. Succinimido deoxycholate (12.6 mg, 25.8 μmol) was dissolved in anhydrous DMF (1 mL) and added to the insulin solution. Apparent pH was adjusted constantly by the addition of 1 N NaOH. After 30 min, the reaction was quenched by addition of distilled water, and the pH was adjusted to 2 with 1 N HCl. The reaction mixture was immediately filtered, dialyzed against 0.01% of NH_4HCO_3, and lyophilized. The lyophilized sample was further purified by preparative reversed-phase HPLC (Shimadzu, Tokyo, Japan) with a Shim-pack Prep-ODS column (20 mm × 250 mm). The mobile phase consisted of 0.1% TFA in distilled water (eluent A) and acetonitrile containing 0.1% TFA (eluent B). The mobile phase was run with a linear gradient from 35 to 45% eluent B for 15 min at a flow rate of 10 mL/min, and the UV absorbance of the eluent was monitored at 280 nm.

[N^{B29}−Bisdeoxycholyl-L-lysil] Insulin. Zn^{2+} insulin (100 mg, 17 μmol) and succinimido bisdeoxycholyl-L-lysine (25.7 mg, 25.8 μmol) were treated and purified as described above. The mobile phase of preparative reversed-phase HPLC was run with a linear gradient from 45 to 55% eluent B for 15 min at a flow rate of 10 mL/min.

Characterization. *MALDI-TOF Mass Spectroscopy*. Molecular weight was obtained from MALDI-TOF mass spectrometry using a Voyager Biospectrometry Workstation (PerSeptive Biosystem, Framingham, MA). Samples were prepared by mixing 2 μL of aliquot with 2 μL of the matrix solution, a saturated solution of α-CHCA in 50% of water/acetonitrile with 0.3% TFA. One microliter of the sample mixture was spotted into a well of the sample plate and dried by vacuum prior to mass spectrometry. Data for 2 ns pulses of the 337 nm nitrogen laser were averaged for each spectrum in a linear mode, and positive ion TOF detection was performed using an accelerating voltage of 25 kV.

Structural Verification. Insulin and the conjugates were incubated with trypsin (1 mg/mL) at 37 °C for 2 h. This treatment was expected to cleave the Arg−Gly bond in the β-chain of insulin. After incubation, the mixture was acidified with 0.1% TFA to quench the reaction and the mass of resulting proteolytic fragment was determined by using MALDI-TOF mass spectrometry.

Circular Dichroism. All samples were prepared in 10 mmol HCl at concentrations of 0.1 mmol and filtered through a 0.2 μm syringe filter. A Jasco J-720 spectropolarimeter (Tokyo, Japan) was used, and three to five scans were averaged before the final spectrum was acquired. The data (ellipticity in mdeg) was then transformed to mean residue ellipticity (θ_m) using the expression, $\theta_m = (\theta M)/(Cl)$, where θ is the observed ellipticity (mdeg), M is the mean residue molecular weight (g/mol), C is the protein concentration (g/mL), and l is the optical path length (cm).

Dynamic Light Scattering. The characteristics of self-aggregates of insulin analogues in PBS (pH 7.4) were investigated by dynamic light scattering at a wavelength of 488 nm with an Ar ion laser (Cyonics, San Jose, CA). The scattered light was measured at an angle of 90° and was collected with Multi-8 correlator (Malvern Instruments Ltd., U.K.). The hydrodynamic radius was analyzed by using the PCS software provided by the same company.

Competitive Insulin Receptor-Binding Assay. The biological activities of the insulin conjugates were determined using a competitive receptor-binding assay at steady state (*24*). HepG2 human hepatoma cell line (ATCC, Rockville, MD) were cultured at 37 °C in a 5% CO_2-humidified atmosphere in culture flasks with Dulbecco's modified Eagle's Medium (DMEM) supplemented with 10% fetal calf serum, 2 mM glutamine, 50 μg/mL streptomycin, and 50 U/mL penicillin. For binding stud-

ies, cells were seeded on 24-well plates at a density of 4×10^5 cells/well. Cells were used after 3 days when confluence was reached. Cells were washed twice with cell-binding media (DMEM containing 20 mM Hepes and 0.1% human albumin, pH 7.4), and competitive binding of unlabeled insulin and conjugates at steady state was measured by 2 h incubation at 4 °C with 1 mL binding media containing 25 pM [^{125}I]-insulin as the radio ligand in the presence of various concentrations of unlabeled insulin and the conjugates. Incubation was performed at 4 °C to inhibit endocytosis of receptor-bound insulin and the conjugates. After incubation, cells were washed twice with cold PBS, extracted with 1 mL of 1 N NaOH, and an aliquot of 100 μL was transferred into a glass tube for γ-radiation counting. All assays were made in triplicate. Nonspecific binding was determined in the presence of 10^{-6} M unlabeled insulin. The results were analyzed according to the four-parameter logistic model, and the affinity of the each conjugate was expressed relative to that of native insulin. The concentration giving half-maximal inhibition of receptor-bound tracer (IC_{50}) was also estimated.

In Vivo Hypoglycemic Effect. We followed the National Institutes of Health (NIH) guidelines for the care and use of laboratory animals (NIH publication 85-23 Rev. 1985). After an initial 3-day acclimation period, male Sprague−Dawley rats weighing from 230 to 250 g were fasted for 12 h before inducing diabetes mellitus. Diabetes was induced by a single intraperitoneal injection of STZ (in citrate buffer, pH 4.5) at 70 mg/kg. Five days after the STZ treatment, the test solutions (insulin, 0.33 IU/kg, 0.4 mL/kg and the equivalent amount of the conjugates) were administered intravenously into the tail vain. Blood samples for the analysis of blood glucose were taken from the tail veins and determined immediately on fresh samples by using a one touch blood glucose monitoring system (Glucocard II, Arkray, Kyoto, Japan).

Binding of Insulin Conjugates to Serum Albumin. Binding of insulin conjugates to serum albumin was assessed using size exclusion chromatography (7.8 mm $\times$ 300 mm Ultrahydrogel 250, Waters). Elution profiles were obtained for insulin and the conjugates (both 5 μmol) in the absence and presence of bovine serum albumin (BSA; 25 μmol; Sigma). The mobile phase was run with distilled water for 20 min at a flow rate of 0.5 mL/min, and the UV absorbance of the eluent was monitored at 280 nm.

Statistical Analysis. Data are expressed as mean $\pm$ SE. Student's t-test was performed, and a value of $p < 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

Synthesis and Characterization of Insulin Conjugates. The succinimidyl ester of two kinds of DOCA derivatives, succinimido deoxycholate and succinimido bisdeoxycholyl-L-lysine, were synthesized and conjugated to the ϵ-amino group of Lys^{B29} insulin. Since the pK_a's of two N-terminal α-amino groups of insulin are reported as 8.4 and 7.1 for Gly^{A1} and Phe^{B1}, respectively, and above 9.8 for ϵ-amino group of Lys^{B29}, insulin could be selectively labeled to Lys^{B29} in a base condition (*9*, *11*, *25*). Conjugates were prepared in a basic (pH 10) 60% DMF solution, where the amino groups of Lys^{B29} are most reactive.

The conjugate was obtained with above 99% purity (Figure 2) with above 45% product yield. The molecular weight of conjugates analyzed by MALDI-TOF mass spectroscopy (calculated molecular weight/measured molecular weight; for insulin, Ins−DOCA and Ins−bisDOCA were 5807/5805.2, 6181.6/6176.3 and 6679.4/6679.7, respectively) clearly indicated that both conjugates were purely monosubstituted. Native insulin and purified insulin conjugates were subjected to the trypsin digestion to determine the positional substitution of DOCA derivatives. It was expected that proteolytic fragment with a DOCA derivative attached to it should result in a shift in retention time compared to the respective unlabeled fragment. By peptide mapping using HPLC and MALDI-TOF, it was confirmed that both bile acid derivatives were labeled at Lys^{B29} of insulin (Table 1).

Retention time in HPLC profiles of insulin, Ins−DOCA, and Ins−bisDOCA was 22.87, 28.13, and 33.83 min, respectively. Calculated lipophilic index (lipophilic index = $\log((t_R - t_0)/t_0)$; t_0, retention time of solvent) of insulin,

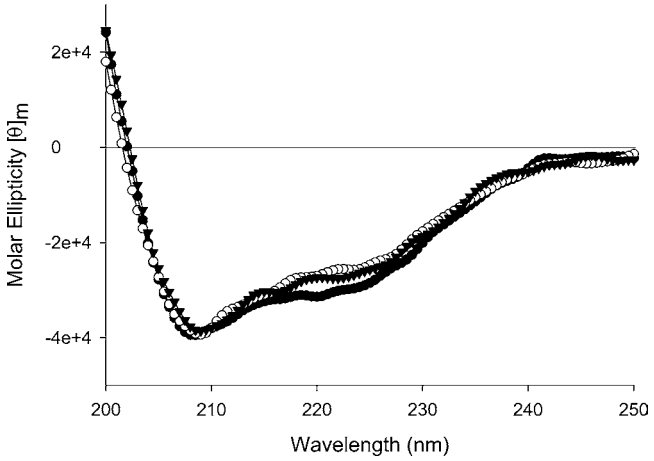

Figure 3. Far-UV−CD spectra of Zn^{2+} insulin (○), Ins−DOCA (●), and Ins−bisDOCA (▼). Solutions were prepared in 10 mmol HCl to a protein concentration of 0.1 mmol.

Ins−DOCA, and Ins−bisDOCA was 0.701, 0.806, and 0.898, respectively. The lipophilic indices of conjugates were higher than that of native insulin, indicating that these derivatives were more lipophilic compared to native insulin. In addition, the lipophilicity of the conjugates increased with increasing number of DOCA molecules that were chemically attached.

Circular dichroism (CD) spectroscopy has been applied to evaluate the conformational change of insulin conjugates (Figure 3). Because insulin conjugates showed higher self-aggregation behavior mainly due to the labeled bulky hydrophobic DOCA derivatives, insulin conjugate samples for CD analysis were prepared in acid condition to maintain a monomeric form and clear solution. The far-UV−CD band at 208 nm primarily arises from α-helix structure, and 223 nm is for component of the β-structure. The ratio between both bands ($[\phi]_{208}/[\phi]_{223}$) can be used to inform a qualitative measure of overall conformation structure of insulin and conjugates. The $[\phi]_{208}/[\phi]_{223}$ ratio value for insulin, Ins−DOCA, and Ins−bisDOCA was 1.32, 1.49, and 1.38, respectively. The spectral characteristics of the conjugates indicated that conjugation of DOCA derivatives to insulin does not alter the overall tertiary structure of native peptide.

Competitive Insulin Receptor-Binding Assay. Human hepatoma cell line HepG2 has been chosen as a model for the in vitro studies of insulin-receptor binding of insulin conjugates. The HepG2 cells maintain the function of differentiated liver cells, and the relative binding affinities for the insulin receptor in HepG2 cells are consistent with the relative metabolic potencies shown by fat cells (*26*, *27*). The competition curves of insulin or the conjugates to insulin receptors on intact HepG2 cells are shown in Figure 4. The absolute mean value of IC_{50} for the insulin receptor was 1.28×10^{-9} M for insulin, 3.37×10^{-9} M for Ins−DOCA, and 2.24×10^{-9} M for Ins−bisDOCA. Therefore, monosubstituted insulin conjugates still retained high binding affinity to the insulin receptor.

In Vivo Hypoglycemic Effect. The pharmacodynamic activity of insulin conjugates was evaluated in STZ-induced diabetic rats. Figure 5 illustrates the blood glucose level following intravenous injection of insulin and the conjugates. Reduction in glucose level for insulin, Ins−DOCA, and Ins−bisDOCA was 46.1 ± 7.9%, 41.1 ± 8.7%, 39.0 ± 11.1%, respectively. Compared to native insulin, insulin conjugates did not show any differences in glucose nadir. Although the glucose nadir was similar

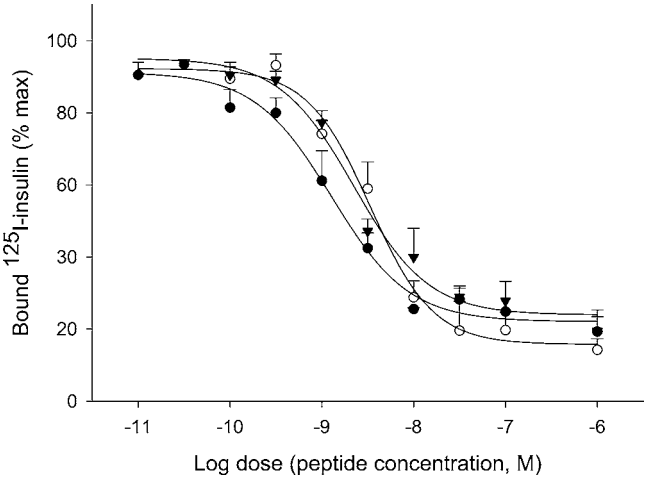

Figure 4. Inhibition of ^{125}I-insulin binding to HepG2 cells by native insulin and synthetic insulin conjugates. Insulin and conjugates were incubated with HepG2 cells as described under Experimental Procedures. Zn^{2+} insulin (●), Ins−DOCA (○), and Ins−bisDOCA (▼). Results are mean ± SE (n = 3).

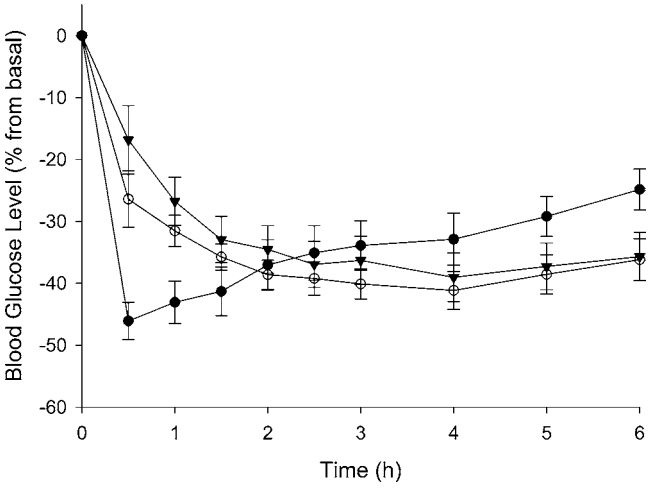

Figure 5. Blood glucose response following intravenous administration of insulin (0.33 IU/kg, ●, n = 5) and an equivalent amount of Ins−DOCA (○, n = 8) and Ins−bisDOCA (▼, n = 8) prepared in 10 mmol PBS. Samples were injected into the tail vein of STZ-induced diabetic rats. Results are mean ± SE.

to that of native insulin, the conjugates induced a slower rate of the blood glucose levels for Ins−DOCA and Ins−bisDOCA, were slowly reduced, and were maintained at low level for about 6 h, while the blood glucose level of native insulin was rapidly decreased after insulin injection and increased again. Therefore, the duration of the blood glucose lowering effect of the conjugates seemed to be sustained compared to native insulin.

To evaluate whether sustained biological action of the conjugates is responsible for existing serum protein (e.g., albumin) binding ability derived by conjugated DOCA, the binding affinity of insulin conjugates to serum albumin was evaluated using a size exclusion chromatography. Figure 6 illustrates the elution profiles of BSA, human insulin, and the conjugates in the absence (Figure 6A) and presence (Figure 6B) of BSA. It was hypothesized that, if insulin conjugates could bind to the BSA, the elution position of the conjugates would be identical to that of BSA. As shown in Figure 6, the elution position of insulin and the conjugates changed slightly; however, it was nearly unaffected by the presence of BSA. This result confirmed that the insulin conjugates did not bind

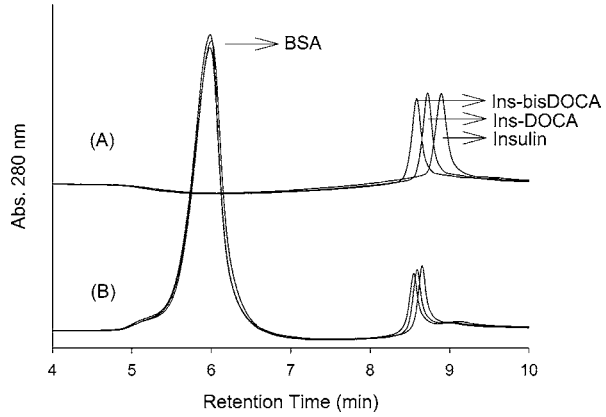

Figure 6. Size exclusion chromatography assessment of binding of insulin and insulin conjugates to bovine serum albumin (BSA). (A) Insulin and insulin conjugates (5 μmol), run separately, and (B) insulin and insulin conjugates (5 μmol) + BSA (25 μmol), run separately.

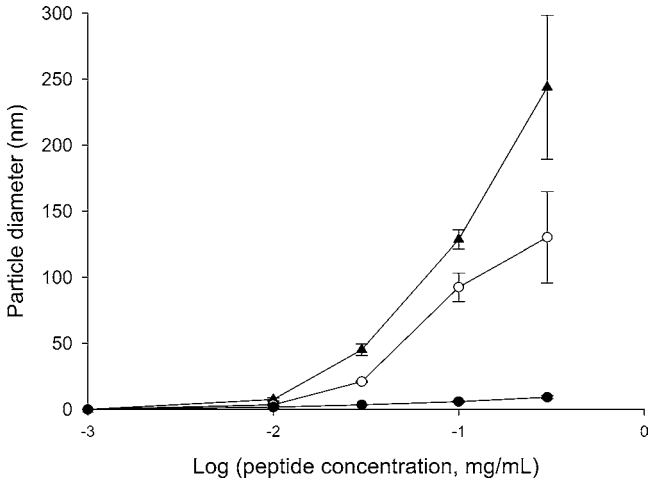

Figure 7. Size distribution profiles of insulin and conjugates at various concentrations determined by dynamic light scattering. Solutions were prepared in 10 mmol PBS at 25 °C for insulin (●), Ins−DOCA (○), and Ins−bisDOCA (▼).

to serum albumin, and the sustained action of the conjugate was not related to the binding affinity with albumin.

On the other hand, the sustained biological action of the insulin conjugates could be explained by the self-association profile of the conjugates. We introduced bulky hydrophobic region to the surface of the peptide. Labeled DOCA derivatives have high capacity of self-assembling (by combining an amphiphilic steroid nucleus with the reactivity of the side groups of DOCA), and these could increase hydrophobic aggregation behavior above a certain concentration. Consequently, different physical states of insulin in solution might impact its pharmacological profile. In view of the degree of aggregation of insulin conjugates in PBS, DLS measurement was selected to characterize self-association properties.

As illustrated in Figure 7, insulin conjugates showed higher aggregation behavior compared to insulin and possessed mean hydrodynamic diameter of 130 and 240 nm for Ins−DOCA and Ins−bisDOCA, while native insulin showed negligible size distribution. The tendency of aggregation was reversible and decreased by dilution. As the mole ratio of the conjugated DOCA molecules to insulin was increased, the aggregate size of insulin conjugates increased. Self-aggregated states correspond to unusual micelle-like structures that result biologically inactive. However, when the aggregate form slowly gets dissociated due to dilution in the blood stream, the conjugate's biological activity would gradually appear. Therefore, different glucodynamic profiles of insulin conjugates in vivo could be explained by the aggregation property of the insulin conjugates.

In conclusion, we have successfully conjugated two different kinds of DOCA derivatives to Lys^{B29} of insulin. The lipophilicity and self-aggregation behavior of insulin were enhanced by increasing the number of conjugated bile acid. The overall tertiary structure of insulin was preserved after conjugation, and it still retained high binding strength to the insulin receptor despite the fact that a bulky group of bile acid derivatives was attached to it. The insulin conjugates showed a gradual biological response, increased duration of action, and increased residence time compared to native insulin due to the high order of aggregation properties.

Beyond the development of orally active insulin formulation based on bile acid acylation techniques, our concern was to develop site-specific bile acid-conjugated insulin analogues which can maintain their biological activity while bearing the properties of bile acid. To this end, we have designed and prepared biologically active DOCA-conjugated insulin analogues. Furthermore, we have found that chemically bound bile acid could prolong the biological activity of native insulin in the physiological condition. The potential of our DOCA−insulin conjugates for oral delivery is under evaluation using in vivo models, and we anticipate that our new insulin conjugates would be applied to enhance the clinical efficiency of the present treatment for diabetic patients.

Detection of Lipopolysaccharide and Lipid A Employing a Spermine–Pyrene Conjugate

Guilford Jones II* and Hui Jiang

Department of Chemistry and Photonics Center, Boston University, Boston, Massachusetts 02215
Received October 18, 2004; Revised Manuscript Received March 3, 2005

An amphiphilic fluorescent spermine–pyrene conjugate (Sp–Py) is shown to interact with lipopolysaccharide (LPS) or lipid A in aqueous solution. This complexation was studied by UV/visible absorption and steady-state fluorescence spectroscopy. In the presence of LPS or lipid A, Sp–Py displayed self-aggregation, resulting in the appearance of chromophore dimer absorption and fluorescence at the expense of probe monomer features. The equivalent weight of LPS or lipid A and the binding constants for Sp–Py complexation were estimated. The change of the ratio of monomer to dimer emission with concentration of LPS or lipid A indicated that Sp–Py is a sensitive fluorescence probe for the endotoxins in aqueous media.

INTRODUCTION

Lipopolysaccharides (LPS) are the integral constituents of the outer membrane of Gram-negative bacteria. In nature, they are amphiphilic, consisting of hydrophilic polysaccharide and lipophilic lipid moieties. The polysaccharide region is composed of three separate domains: an inner core, an outer core, and an O-specific chain or O-polysaccharide (*1*–*3*). The lipid moiety, or lipid A, consists of diphosphorylated glucosamine disaccharide, carrying a number of higher fatty acid chains. Lipid A is the cause of most of the toxic effects associated with the endotoxins (*1*–*3*). The presence of covalently bound phosphate groups and acidic sugars in lipid A and in the core renders LPS a highly anionic polyelectrolyte (*3*). On the basis of the amphiphilic and anionic properties of LPS, David et al. proposed that cationic amphiphilic molecules represent potentially ideal ligands for complexation with LPS and studied the interactions of LPS with a number of classes of structures, including proteins (*4*), peptides (*5*), pharmaceuticals (*6*), and other synthetic polycationic amphiphiles (*7*). Among these compounds, lipopolyamines elicit special interest, since at physiological pH, polyamines (e.g. spermine and spermidine) exist as polyammonium ions and play many important biological roles (*8*). In fact, lipopolyamines have been used in gene transfer (*9*) and complexation with DNA (*10*, *11*), as well as LPS or lipid A (*7*, *12*).

There are few reports that deal with the interaction of dyes with LPS or lipid A. Such studies have the purpose of probing the properties of LPS molecules in solution or developing simple and sensitive detection methods. Most of the studies have focused on cationic cyanine dyes (*13*–*15*), because the absorption spectra for their complexes with LPS undergo shifts to shorter wavelengths. Pinacyanol chloride shows a similar shift upon LPS binding (from 600 to 495 nm) (*16*). Little work has been reported on the characterization of the interactions between dyes and LPS using fluorescence spectroscopy (*16*).

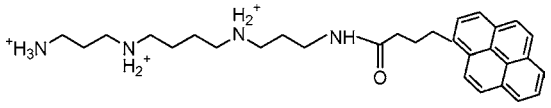
Chart 1. Structure of Sp–Py (Protonated Form)



There are a number of biochemically based assays for LPS or lipid A in different environments, among which *Limulus* amebocyte lysate (LAL) and enzyme-linked immunosorbent assay (ELISA) are the most common and useful ones. However, these methods are generally time-consuming and labor-intensive. The absorption spectral blue shifts of certain compounds upon LPS binding (*13*–*17*) can provide a simple and fast alternative. Recently, fluorescent proteins have also been developed as biosensors for bacterial endotoxins (*18*, *19*).

Here we report the characterization of an amphiphilic spermine–pyrene conjugate (Sp–Py; Chart 1) for LPS or lipid A binding and detection studies. The cationic spermine moiety provides three positive charges near neutral pH, whereas the 1-pyrenebutyric acid amide (PBA) moiety serves as both a lipophilic pendant and chromophore. Sp–Py is shown to be a sensitive fluorescent indicator for LPS or lipid A in aqueous solution.

MATERIALS AND METHODS

Spermine, ethyl trifluoroacetate, di-*tert*-butyl dicarbonate (Boc), 1-pyrenebutyric acid *N*-hydroxysuccinimide ester (PBA-HSIE), trifluoroacetic acid (TFA), lipopolysaccharides (LPS) (rough strains) from *Salmonella minnesota* Re 595 (Re mutant), and lipid A (diphosphoryl form) from *Escherichia coli* F583 (Rd mutant) were all purchased from Sigma-Aldrich and used without further purification.

Synthesis and Characterization of Sp–Py. The synthesis of Sp–Py is shown in Scheme 1. The unsymmetrically protected spermine intermediate **1** was synthesized by following a reported procedure (*10*, *11*) and characterized by ^{1}H NMR and HRMS. 1-Pyrenebutyric acid *N*-hydroxysuccinimide ester (PBA-HSIE) (120 mg, 0.31 mmol) and **1** (120 mg, 0.24 mmol) were dissolved in

2 mL of distilled DMF, and the reaction mixture was stirred at 40 °C for 25 h. The crude product was purified by flash chromatography (SiO_2, petroleum ether−ethyl acetate gradient from 70:30 to 0:100), and a light yellow oil of **2** was obtained (60 mg, yield 33%). To **2** (60 mg, 0.078 mmol) in 2 mL of dichloromethane (DCM) was added 2 mL of trifluoroacetic acid (TFA), and the solution was stirred at room temperature for 2 h (*10*, *11*). A brown oily residue was obtained after the solution was concentrated and lyophilized. The crude product was purified by preparative RP-HPLC over a Vydac C_{18} column using a water (0.05% TFA)−acetonitrile (0.05% TFA) gradient to afford the final product Sp−Py (35 mg, yield 95%). Matrix-assisted laser desorption/ionization (MALDI) MS: found 473.961 ($M^+ + 1$); calcd for $C_{30}H_{41}N_4O$ 473.673 ($M^+ + 1$). ^{1}H NMR (400 MHz, DMSO-d_6): δ 1.58 (4H, s, CH_2); 1.74 (2H, t, CH_2); 1.86 (2H, t, CH_2); 2.03 (2H, t, CH_2); 2.25 (2H, t, CH_2); 2.87 (10H, s, CH_2); 3.14 (2H, d, CH_2); 3.32 (2H, CH_2, overlap with H_2O); 7.90−8.40 (9H, m, Ar *H*). ^{13}C NMR (300 MHz, D_2O): δ 17.74 (*C*H_2); 18.86 (*C*H_2); 20.65 (*C*H_2); 21.61 (*C*H_2); 27.32 (*C*H_2); 30.42 (*C*H_2); 30.79 (*C*H_2); 31.65 (*C*H_2); 39.64 (*C*H_2); 41.64 (*C*H_2); 41.99 (*C*H_2); 118.54 (Ar *C*); 119.34 (Ar *C*); 120.20 (Ar *C*); 121.60 (Ar *C*); 121.91 (Ar *C*); 122.46 (Ar *C*); 122.76 (Ar *C*); 123.01 (Ar *C*); 123.40 (Ar *C*); 124.80 (Ar *C*); 125.78 (Ar *C*); 126.32 (Ar *C*); 131.13 (Ar *C*); 172.44 (*C*═O).

Sp−Py and buffer stock solutions were prepared in Milli-Q water. LPS and lipid A stock solutions were prepared in 4:1 (v:v) THF/CH_3OH. Absorption spectra were recorded on a Beckman DU-640B spectrophotometer. Steady-state fluorescence emission and excitation spectra were obtained using a PTI (Photon Technology International, Inc.) fluorimeter equipped with Felix software.

RESULTS AND DISCUSSION

Complexation of Sp−Py with LPS or Lipid A. In phosphate buffer solution (pH 7.4), 5.0 μM Sp−Py shows only monomer absorption and fluorescence (Figure 1), indicating that conjugation with spermine does not appreciably affect the photophysical properties of the parent 1-pyrenebutyric acid (PBA). With the choice of a low concentration of Sp−Py (e.g. micromolar), and consistent with the electrostatic repulsion expected for the charged spermine moiety at pH 7.4, ground-state Sp−Py dimer or excimer formation is not observed. In the presence of 3.75 μg/mL of LPS or 5.00 μg/mL of lipid A, both absorption and emission spectra change. The absorption spectrum shows band broadening and a small shift to the red of peak absorptivity. The fluorescence spectrum shows both weaker monomer emission and a broad structureless band centered at about 474 nm, which is ascribed to pyrene excimer or dimer fluorescence

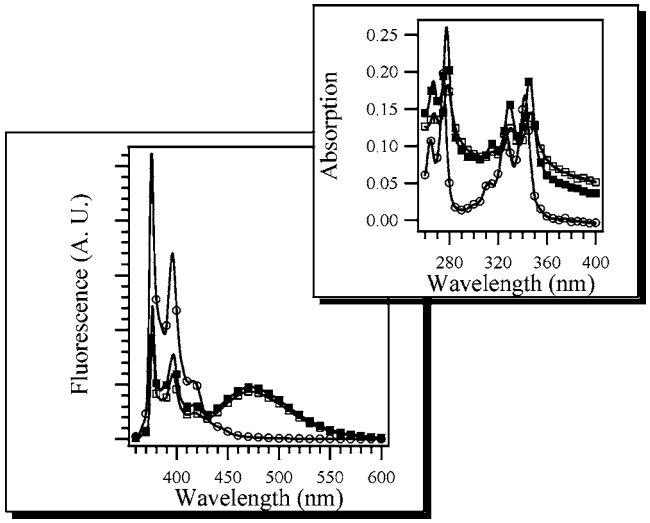

Figure 1. Absorption and emission spectra obtained for 5.0 μM Sp−Py in the absence (○) and presence of 3.75 μg/mL of LPS (■) or 5.00 μg/mL of lipid A (□) in 2 mM pH 7.4 phosphate buffer solution (excitation at 347 nm).

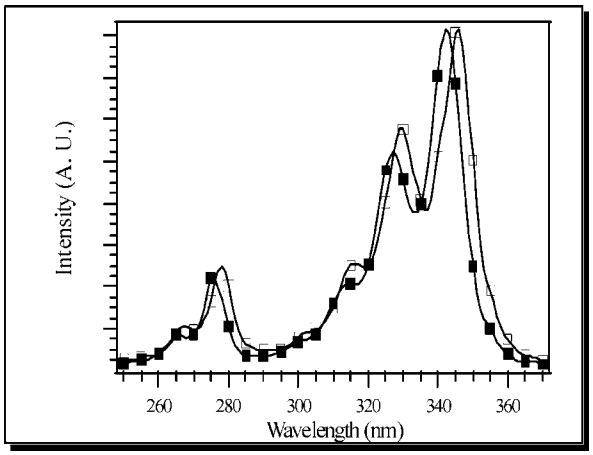

Figure 2. Uncorrected excitation spectra obtained for 5.0 μM Sp−Py in the presence of 3.75 μg/mL of LPS or 5.00 μg/mL of lipid A: (■) monitored at 376 nm; (□) monitored at 474 nm.

(*20*−*22*). However, the absorption and excitation (Figure 2) spectral change excludes the possibility of excimer formation via a bimolecular encounter of a ground-state Sp−Py and the excited state of the conjugate.

These spectral changes reflect the ground-state aggregation of pyrene chromophores in LPS or lipid A microdomains. Due to the binding of Sp−Py to LPS or lipid A, the electrostatic repulsion between spermine moieties is diminished and the local concentration is enhanced, so that two pyrene moieties (2 Sp−Py) can aggregate. This feature is clearly shown in the fluorescence spectra, which display increasing dimer emission at the expense of monomer emission. Since the intensity ratio of monomer to dimer emission (I_{376}/I_{474}, see below) shows a limiting value, it appears that not all bound Sp−Py can achieve chromophore stacking; thus, there is residual monomer fluorescence. As the absorption spectra indicate, there is some light scattering observed (turbidity is visible) for moderately concentrated solutions (e.g., 6 μg/mL). When higher concentrations of LPS or lipid A are utilized (e.g., 10 μg/mL), precipitation occurs (observable loss of chromophore).

If the Sp−Py monomer emission monitored at 376 nm is plotted against volume of added LPS or lipid A stock solution (2.5 mg/mL), an equivalent point is obtained

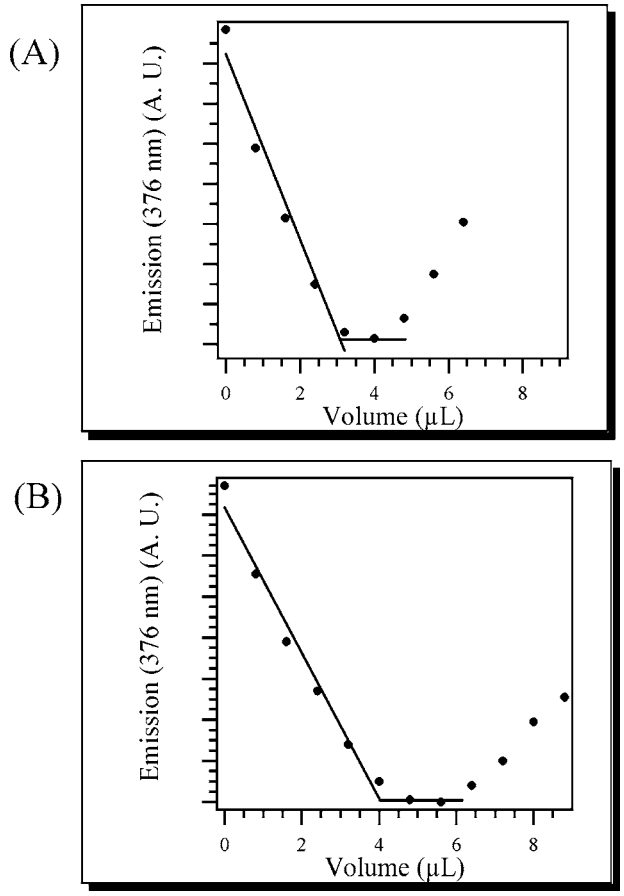

Figure 3. Fluorimetric titration of Sp−Py with LPS or lipid A (A): [Sp−Py] = 9.8 μM, [LPS] = 2.5 mg/mL; (B) [Sp−Py] = 7.4 μM, [lipid A] = 2.5 mg/mL.

(Figure 3). Before this point, the monomer fluorescence decreases progressively upon addition of an increasing amount of LPS or lipid A. Beyond the equivalent point, the monomer fluorescence is partially restored, consistent with the provision of an increased number of available interaction sites and a redistribution of the bound monomer vs dimer probe species. If the equivalent weight for LPS or lipid A is defined as the average mass of LPS or lipid A corresponding to 1 mol of bound Sp−Py, the equivalent weight can be determined using this equivalent point: i.e., the total mass of added LPS or lipid A divided by the moles of the chromophore conjugate. From the data in Figure 3, the equivalent weights are found to be about 400 Da for LPS and 700 Da for lipid A, respectively. Because lipid A is only one of the two moieties of LPS, LPS should have a higher molecular weight than lipid A. The opposite pattern of equivalent weights found for LPS and lipid A indicates that one LPS molecule binds more Sp−Py counterions than lipid A does. For comparison, using a similar treatment, the equivalent weight of *Klebsiella O3* LPS was found to be 830 Da for several dye−LPS complexes (*16*). The calculated equivalent weight of lipid A (700 Da) for Sp−Py is less than half of the approximate molecular weight provided by the supplier (about 1700−1800 Da), which indicates that two or more Sp−Py molecules can interact with one lipid A molecule. This finding is consistent with the formation of Sp−Py dimers in the presence of LPS or lipid A. One should note that the equivalent weight deduced by this spectroscopic titration method is phenomenological and does not provide specific information regarding binding site structure.

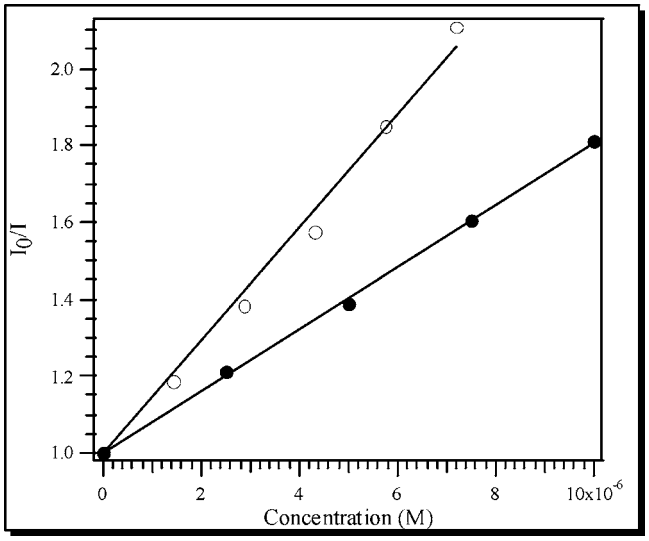

Figure 4. Stern−Volmer plot for the quenching of Sp−Py fluorescence (monitored at 376 nm) with LPS (●) or lipid A (○).

A similar dye aggregation phenomenon, on binding to polyelectrolytes, has been observed frequently and interpreted using cooperative binding theory (*23*, *24*). The elementary binding process can be expressed as

$$\mathrm{D} + \bullet\bullet\mathrm{U}\bullet\bullet \leftrightarrows \bullet\bullet\mathrm{O}\bullet\bullet \qquad (1)$$

where D stands for free dye monomers, U for unoccupied binding sites, and O for occupied binding sites. For the initial nucleation of binding, namely

$$\mathrm{D} + \mathrm{UUU} \leftrightarrows \mathrm{UDU} \qquad (2)$$

the intrinsic binding constant can be expressed as

$$K^{\ddagger} = [\mathrm{UDU}]/([\mathrm{D}][\mathrm{UUU}]) \qquad (2a)$$

For the binding of a second dye molecule in the nearby site, namely

$$\mathrm{D} + \mathrm{UDU} \leftrightarrows \mathrm{DDU} \qquad (3)$$

the cooperative binding constant can be expressed as

$$K = [\mathrm{DDU}]/([\mathrm{D}][\mathrm{UDU}]) \qquad (3a)$$

Since dye aggregation can promote the binding, K is generally larger than $K^{\ddagger}$. The ratio of the two binding constants reflects the degree of cooperativity (*23*). In the current case, since the absorption and emission spectral changes are induced by the Sp−Py dimer formation after binding to LPS or lipid A, the cooperative binding theory can be applied, provided that one Sp−Py is assumed to interact with one binding site (consequently, 1 equiv of LPS or lipid A corresponds to 1 mol of binding sites as well) and that two binding sites are close enough so that two pyrene moieties on two different Sp−Py molecules can interact with each other.

The cooperative binding constants associated with Sp−Py and LPS or lipid A interactions can be determined by Stern−Volmer analysis of the monomer fluorescence data (*25*). As shown in Figure 4, the ratio of the fluorescence intensity of the dye solution (I_0) to the intensity of the dye−target (LPS or lipid A) mixture (I) is plotted against the concentration (evaluated on the basis of the equivalent weight data above) of the added target which acts as the quencher (Q). Using the

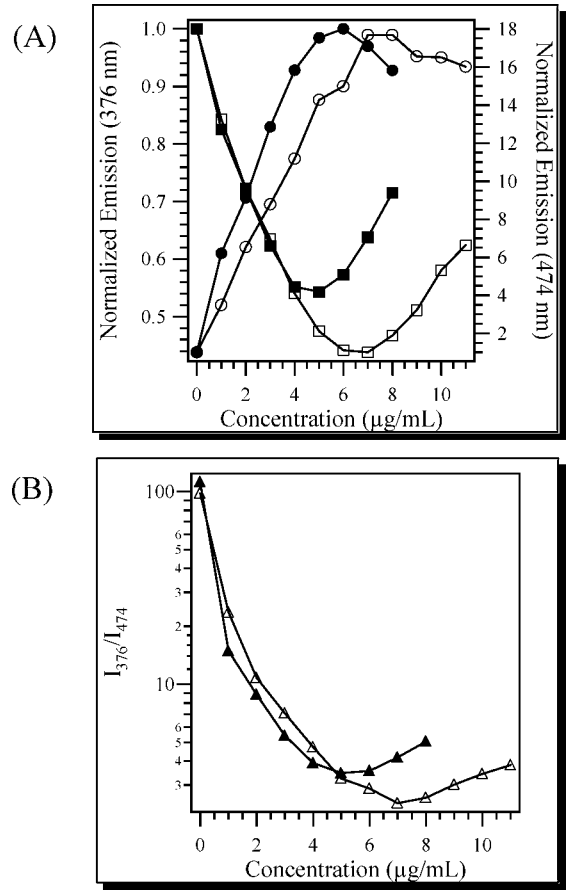

Figure 5. Fluorescence changes obtained for Sp−Py in the presence of LPS ([Sp−Py] = 9.8 μM) or lipid A ([Sp−Py] = 7.4 μM) in 2 mM pH 7.4 phosphate buffer: (A) Sp−Py monomer (■) and dimer (●) in the presence of LPS and Sp−Py monomer (□) and dimer (○) in the presence of lipid A; (B) Sp−Py monomer/dimer ratio in the presence of LPS (▲) and in the presence of lipid A (△).

Stern−Volmer equation

$$I_0/I = 1 + K_{sv}[Q] \quad (4)$$

the cooperative binding constants ($K = K_{sv}$, the slope of the best linear fit) are determined to be 8.1×10^4 M^{-1} for LPS and 1.5×10^5 M^{-1} for lipid A. These values are somewhat higher than the binding constants evaluated using a similar method for two other dye−LPS complexes (5.1×10^4 and 2.6×10^4 M^{-1} found for LPS complexes with acridine orange and safranin O, respectively) (*16*).

Application of Sp−Py to LPS or Lipid A Detection. The decrease of Sp−Py monomer emission or increase of the dimer emission in the presence of LPS or lipid A can be used for the detection of these endotoxins in aqueous solution. Figure 5A shows the normalized emissions of Sp−Py monitored for monomer (at 376 nm) and dimer (at 474 nm) versus LPS or lipid A concentration. For both LPS and lipid A, the normalized monomer emission decreases with increased target concentration until the equivalent point is reached. The dimer emission shows the opposite trend. About 0.5 μg/mL of target can induce a 10% change in monomer emission. If the ratio of monomer to dimer emission (I_{376}/I_{474}) is plotted against the target concentration, higher sensitivity can be achieved. As shown in Figure 5B, both LPS and lipid A induce a similar change. However, 0.5 μg/mL of target can induce a 50% alteration in the emission ratio. In particular, the change is dramatic with the initial addition of analyte. This method can provide a sensitive ratiometric fluorescence detection assay for LPS or lipid A in aqueous solution, with a limit of detection estimated to be in the 10−100 ng/mL (ppb) range.

CONCLUSION

The amphiphilic fluorescent spermine-pyrene conjugate (Sp−Py), in the presence of LPS or lipid A in aqueous solution, shows chromophore ground-state aggregation, resulting in dimer absorption and fluorescence emission at the expense of monomer spectral features. From fluorimetric titration data, the equivalent weights for LPS and lipid A were determined to be 400 and 700 Da, respectively. Binding constants were estimated by Stern−Volmer analysis of the monomer fluorescence quenching. For detection purposes, either the pyrene monomer fluorescence decrease or the dimer fluorescence increase can be used. The change of the ratio of the monomer to dimer emission was shown to be an especially sensitive parameter, with a limit of detection estimated in the range 10−100 ng/mL (ppb).

Received October 19, 2004; Revised Manuscript Received March 18, 2005

A facile, one-step synthesis of cationic block copolymers of poly(2-*N*-(dimethylaminoethyl) methacrylate) (pDMAEMA) and copolymers of poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO) has been developed. The PEO−PPO−PEO−pDMAEMA (L92−pDMAEMA) and PEO−pDMAEMA copolymers were obtained via free radical polymerization of DMAEMA initiated by polyether radicals generated by cerium(IV). Over 95% of the copolymer fraction was of molecular mass ranging from 6.9 to 7.1 kDa in size, indicating the prevalence of the polyether-monoradical initiation mechanism. The L92−pDMAEMA copolymers possess parent surfactant-like surface activity. In contrast, the PEO−pDMAEMA copolymers lack significant surface activity. Both copolymers can complex with DNA. Hydrodynamic radii of the complexes of the L92−pDMAEMA and PEO−pDMAEMA with plasmid DNA ranged in size from 60 to 400 nm, depending on the copolymer/DNA ratio. Addition of Pluronic P123 to the L92−pDMAEMA complexes with DNA masked charges and decreased the tendency of the complex to aggregate, even at stoichiometric polycation/DNA ratios. The transfection efficiency of the L92−pDMAEMA copolymer was by far greater than that of the PEO−pDMAEMA copolymer. An extra added Pluronic P123 further increased the transfecton efficacy of L92−pDMAEMA, but did not affect that of PEO−pDMAEMA.

INTRODUCTION

The development of gene therapy relies on designing optimal systems for nucleic acid transfer and expression, cationic polymers being a promising alternative to viral vectors (*1*). Because the latter are toxic and immunogenic, nonviral strategies toward gene transfection are becoming more and more attractive. A variety of synthetic, polycationic polymers have become available; they demonstrate adequate safety profiles and can complex large plasmids, forming polymer−DNA complexes (polyplexes). Some of the polyplexes have superior transfection efficiency and serum sensitivity compared to the lipid−DNA complexes (lipoplexes) (*2*−*4*). These considerations make polycations a compelling target for future exploration in nonviral gene delivery (*5*). Polycations bind to nucleic acids due to the formation of cooperative systems of salt bonds between the cationic groups of the polycation and phosphate groups of the DNA. Great efforts have been undertaken to improve the efficiency of the polycations, but, as yet, satisfactorily effective polymer systems have still to be achieved. One of the promising strategies toward creating more effective polycationic systems that complex DNA forming polyplexes (*6*) involves attachment of hydrophilic polymers such as poly(ethylene oxide) (PEO) (*7*, *8*). The modification of the polyplexes with PEO shields positive surface charges and creates a steric barrier against self-aggregation and unfavorable interactions with albumin, complement factors, or cellular components in the bloodstream. The modification of such polyplexes may reduce the potential of nonspecific interactions, such as opsonization or deposition due to cationic surface charges. Block copolymers of cationic polymers and PEO form complexes with DNA that are more acceptable to systemic administration than complexes of the unmodified polycations and DNA (*9*, *10*). Furthermore, copolymers of PEO and poly(propylene oxide) (PPO) such as PEO−PPO−PEO (tradename Pluronic), when bonded to polycations, provide additional advantages to the resulting copolymers from the efficiency standpoint (*11*−*15*).

The Pluronic−polycation copolymers and oligonucleotides spontaneously associate into polyion complex micelles with a hydrophobic core formed by neutralized polyions and a hydrophilic shell formed by PEO. Such complexes are sufficiently stable in solution despite complete neutralization of charge and exhibit elevated levels of transgene expression (*12*). Thus far, the synthetic route toward the polycation−Pluronic copolymers involved chemical activation of the hydroxyl termini of Pluronic followed by conjugation with the primary amino groups of the polycation and separation of the conjugated copolymer from the parent Pluronic (*7*). Such a synthetic route involves several steps, each followed by purification of products, and results in fairly polydisperse copolymers. In the present work, we aimed at development of a more straightforward synthetic route that would enable one-step synthesis of a wide range of polyether−polycation copolymers, wherein the polycation may be optionally

devoid of the primary amino groups. The synthesis we opted to use involved the generation of polyether radicals that act as an initiator for the free radical polymerization of a cationic monomer, 2-(dimethylamino)ethyl methacrylate (DMAEMA). The DMAEMA possesses tertiary amino groups, and its polymers are known for their capacity to complex and transfect DNA (*16*). An analogous "oxyanionic polymerization" involving the use of potassium alcoholates such as monohydroxy-capped poly(alkylene oxide)s in the role of macroinitiators for the polymerization of DMAEMA resulting in PEO−pDMAEMA copolymers has been reported (*17*). Such a polymerization proceeds in rigorously dry THF, which is oftentimes an experimental hurdle. Instead, in the synthetic route explored herein we used free radical polymerization of DMAEMA initiated by the Pluronic radicals generated by the redox reaction of the Pluronic with cerium(IV) in water. The major thrust of the present work has been the development of a facile, one-step synthetic route resulting in desired block copolymers of well-defined molecular weight. This synthetic route is applicable to a variety of vinyl monomers as well as hydroxyl-terminated polyethers. Herein, a relatively hydrophobic Pluronic L92 (PPO content of 80%) was chosen as a representative example of the Pluronic family of the surface-active copolymers because of its high modification activity toward cell membranes. The resulting L92−pDMAEMA copolymers were demonstrated to possess a good transfection capability for plasmid DNA when compared with a routinely used Lipofectamine and were much more active compared to their PEO−pDMAEMA counterparts.

EXPERIMENTAL PROCEDURES

Materials. Pluronic L92 (average composition, EO_8-$PO_{52}EO_8$) and P123 (average composition, $EO_{19}PO_{69}EO_{19}$) were received from BASF Corp. (Mount Olive, NJ) and used without further treatment. 2-(Dimethylamino)ethyl methacrylate (DMAEMA, 98%), ammonium cerium(IV) nitrate (98.5%), 2,2′-azobisisobutyronitrile (AIBN, 98%), nitric acid (70%), poly(ethylene glycol) (average M_n = 3350) were all obtained from Sigma-Aldrich Co. (St. Louis, MO) and were used without further purification. Plasmid DNA encoding β-galactosidase (pCMV-β) was obtained from Clontech BD Biosciences (Palo Alto, CA), whereas Lipofectamine 2000 reagent was purchased from Invitrogen (Carlsbad, CA). Deuterated solvents were obtained from Cambridge Isotope Laboratories (Andover, MA), and all other chemicals were received from commercial sources and were of the highest purity available.

Methods. *Polymer Synthesis.* The polymerization with the cerium ion redox system and DMAEMA monomer was carried out in a three-neck flask equipped with a stirrer, a reflux condenser, and a nitrogen inlet/outlet. In a typical polymerization procedure, DMAEMA (5.0 g), Pluronic L92, or poly(ethylene glycol) (5.0 g) and 1 mL of 70% nitric acid were dissolved in 70 mL of deionized water, and the solution was deoxygenated by nitrogen flow and thermostated at 55 °C with stirring for 1 h. The reaction was started by injecting 3.278 g (6 mmol) of cerium(IV) ammonium nitrate dissolved in 3 mL of 0.5 M HNO_3. The reaction was allowed to proceed for 4 h under nitrogen flow and stirring. The resulting polymer was repeatedly precipitated by the addition of 1 M NaOH, redissolved in 0.01 M HCl, and dialyzed against a large excess of 0.01 M HCl solution in deionized water using dialysis tubing (Spectrum Laboratories, Inc., molecular weight cutoff, 3500). The overall yields of the polyether copolymer were 91 and 94% in the cases of L92−pDMAEMA and PEO−pDMAEMA, respectively. To prove the suggested mechanism of polymerization via formation of polyether radicals due to the presence of cerium(IV), a control experiment without Ce^{4+} was conducted. Namely, polymerization in a mixture of DMAEMA and Pluronic L92 identical to the described above was induced by the addition of 1 mmol of AIBN in acetone. A viscous solution was obtained after the polymerization conducted at 55 °C for 8 h. The solution was precipitated using 1 M NaOH, and the precipitate and the supernatant were separated. The precipitated polymer was dissolved in 0.1 M HCl, and the procedure of precipitation was repeated twice. The resulting polymer was analyzed by ^{1}H NMR, which found no presence of the polyether. This proved that to obtain the L92−pDMAEMA copolymer the Pluronic radicals must be generated. It was also observed that on the addition of Ce^{4+} solution to DMAEMA in the same range of concentrations used in the above polymerization, no polymer was formed within 8 h at 55 °C, indicating the absence of homopolymerization.

Copolymer Characterization. Proton NMR spectra of polymer solutions in D_2O/DCl were acquired on a Bruker AMX400 spectrometer. To obtain the apparent pK_a of the polymers, a titration was performed at 25 ± 1 °C using a 736 GP Titrino potentiometric titration system (Metrohm Ltd., Herisau, Switzerland). Titration of the copolymers in their acidic form was carried out in a degassed 75 mM NaCl solution with 0.1 M NaOH as a titrant, at 0.5 wt % polymer concentration. The titration was carried out slowly for several hours to allow for proper equilibration. The apparent dissociation constant (pK_a) and the degree of ionization (α) were calculated from experimental potentiometric titration data using the Henderson−Hasselbach expression (*18*). Surface tension measurements of the copolymer solutions at certain pH values were accomplished using a Kruss USA model K11 tensiometer applying the Wilhelmy plate method. In the surface tension measurements, the L92−pDMAEMA copolymers were additionally purified by repeated precipitation in 1 M NaOH followed by the removal and drying of the polymer and redissolution in deionized water. No traces of unattached Pluronic copolymers in these species was detected by HPLC. Molecular weight (MW) determination was accomplished using size exclusion chromatography. Polymer samples were precipitated in 1 M NaOH, dried, and redissolved in dimethylformamide (DMF) at 1 mg/mL. The MW of the copolymers was measured in DMF using a Hewlett-Packard series 1100 HPLC system with a refractive index detector and two PLgel Mixed E columns (Polymer Laboratories, Inc., Amherst, MA). Run parameters were as follows: injection volume, 100 μL; flow rate, 1 mL/min; temperature, 40 °C. Calibration curves were developed using a PEG calibration kit (Polymer Laboratories, Inc.).

Preparation and Characterization of Copolymer/Plasmid DNA Complexes. The DNA/copolymer complexes were prepared by adding 3.1 μL of 3.2 mg/mL pCMV-βgal plasmid DNA solution in water to 997 μL of an appropriate copolymer solution in 10 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) buffer (pH 7.0) followed by vortexing and equilibration of a sample overnight. Series of samples containing L92−pDMAEMA and PEO−pDMAEMA copolymers, as well as L92−pDMAEMA+Pluronic P123 (1:5 weight ratio), were thus prepared. The resulting DNA/copolymer solution was filtered using a 0.2 μm membrane filter (Pall Gelman Labs). The ratio of the copolymer to DNA in the complex (N/P) was expressed via the ratio of equivalents of DMAEMA units to the number of nucleotides in DNA.

The nucleotide average molecular mass was assumed to be 324 g/mol (*19*).

Measurements of the potential at the surface of shear (ζ-potential) and dynamic light scattering experiments of the copolymer as well as DNA/copolymer complex solutions were performed at 25 ± 0.1 °C using a ZetaPals zeta potential analyzer and a BI-200SM goniometer, a BI-9000 correlator, and a Spectra Physics He−Ne model 127 laser operating at a scattering angle of 90° and a wavelength of incident light of 633 nm at a power of 50 mW. All of the above instruments were from Brookhaven Instruments Co. Measurements were performed at least in triplicate, and intensity-average hydrodynamic diameter (D_h) and Smoluchowski ζ-potential values calculated by the built-in software are reported herein.

Cell Transfection. Chinese hamster ovary cells (CHO-K1) obtained from the American Type Culture Collection (Manassas, VA) were grown in F-12 nutrient mixture supplemented by 10% FCS (both from Invitrogen). The cells were seeded in a 24-well plate (Nunc, Roskilde, Denmark) 1 day prior to the transfection at a density of 1×10^5 cells/cm^2 in 500 μL of the growth medium. The cells were 90−95% confluent at the time of transfection. The cells were then transfected with a pCMV-β for the β-galactosidase expression following the manufacturer's protocol developed for Lipofectamine 2000. Lipofectamine 2000 is a liposome-containing formulation combining two lipids such as cationic (2,3-dioleyloxy-*N*-[2(sperminecarboxamide)ethyl]-*N*,*N*-dimethyl-1-propanaminium trifluoroacetate) (DOSPA) and neutral dioleyl phosphatidylethanolamine (DOPE). Lipofectamine is frequently used as an industry standard to compare transfection efficiencies of synthetic vectors (*20*). The L92−pDMAEMA and PEO−pDMAEMA were used at different copolymer/DNA weight ratios ranging from 0.6 to 35. The complex of L92−pDMAEMA with Pluronic P123 was also used as a transfection reagent at a ratio of copolymer to P123 of 1:5, 1:50, or 1:500 (w/w). This complex was prepared by mixing (1:1 dilution, v/v) L92−pDMAEMA, 0.1% aqueous solution (pH 7.5), with an aqueous solution of P123, pH 7.5. Dilution of copolymers and copolymer−Pluronic complexes was performed in microcentrifuge tubes of a serum-free medium (50 μL), so that concentration of the transfection reagents ranged from 10 μg/mL to 1 mg/mL. Plasmid DNA solution was also diluted in serum-free medium to a concentration of 16 μg/mL. After a 5-min incubation at room temperature, the DNA solution (50 μl) was added to each tube containing solution of transfection reagents and mixed gently, and after 20 min of equilibration at room temperature, 100 μL of either Lipofectamine/DNA, polycation/DNA, or polycation and P123/DNA complexes was added to each well containing cells with 500 μL of fresh growth medium supplemented with the appropriate amount of FCS. The cells were exposed to the transfection mixture for 3 h. The transfection medium was then removed and replaced with F12 supplemented with 5% FCS. Cells were incubated at 37 °C in a CO_2 incubator (Revco Technologies, Asheville, NC) for 24−72 h.

The effects of the L92−pDMAEMA and Pluronic P123 on the CHO cell growth were further examined by the cell viability tests. The 50% confluent CHO cells were incubated with polymer at final concentrations ranging from 1 μg/mL to 10 mg/mL. After 3 days of incubation at 37 °C, the number of viable cells was measured to determine the concentration of L92−pDMAEMA or Pluronic P123 leading to the death of 50% of the cell population (LD_{50}). The LD_{50} determined for the L92−pDMAEMA was 50 μg/mL, whereas the Pluronic P123 did not show any toxic effects on the CHO cells even at concentrations up to 10 mg/mL. All of the experiments described herein were conducted at polycation concentrations below the LD_{50}.

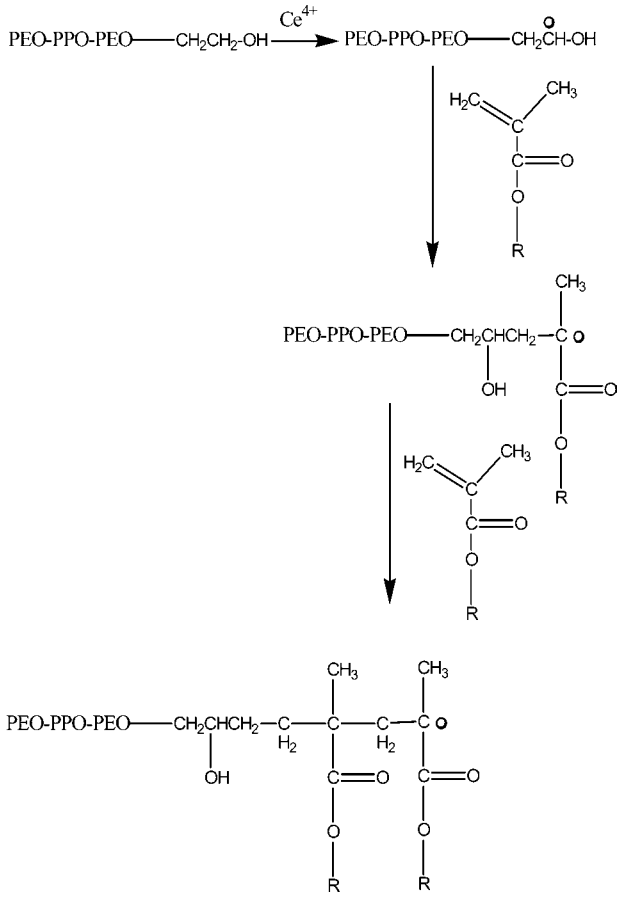
The β-galactosidase Enzyme Assay System kit (Promega, Madison, WI) combined with a BCA Protein Assay Reagent kit (Bio-Rad Laboratories, Inc., Richmond, CA) was used for assaying β-galactosidase activity in lysates prepared from the transfected cells following the assay protocol from the manufacturer. In brief, after 24−72 h of transfection, the cells were rinsed twice with PBS and lysed for 15 min at room temperature by a lysis buffer, containing 25 mM Tris (pH 7.8), 2 mM CDTA, 2 mM dithiothreitol, 10% glycerol, and 1% Triton X-100. The resulting cell lysate was scraped from all areas of the plate surface, transferred to a microcentrifuge tube, vortexed, and centrifuged at top speed (20000*g*) for 2 min at 4 °C. The cell lysate (150 μL) was then mixed with 150 μL of Assay 2X buffer, containing 200 mM sodium phosphate (pH 7.3), 2 mM $MgCl_2$, 100 mM β-mercaptoethanol, and 1.33 mg/mL of *o*-nitrophenyl-β-D-galactopyranoside (ONPG) substrate. β-Galactosidase converts the colorless ONPG substrate into galactose and the chromophore *o*-nitrophenol, yielding a bright yellow solution. The mixtures were incubated at 37 °C until a yellow color developed (within ~1 h), and then the reaction was stopped by the addition of 1 M sodium carbonate solution (500 μL). Electronic absorbance was read at 420 nm in a quartz spectrophotometer cuvette using a SpectraMax Plus^{384} high-throughput microplate spectrophotometer (Molecular Devices Corp., Sunnyvale, CA). The β-galactosydase activity was calculated as nanomoles of β-galactose formed per minute per milligram of lysate at 37 °C, according to the instruction manual. The electronic absorbance units were also used as a measure of the β-galactosidase expression. All data were obtained in triplicate.

RESULTS AND DISCUSSION

Polymer Synthesis and Structure. The polymerization of DMAEMA was carried out using a redox system consisting of Ce^{4+} ions and Pluronic or PEG. The cerium ion−alcohol redox reaction leads to the formation of a radical on the carbon atom linked with the hydroxyl group (*21*). It has been shown that in the case of a polymeric alcohol, PEG, as a reducing agent, the formation of the radicals takes place at the terminal carbon atom and not along the polyether chain (*22*). Drawing an analogy between PEG and PEO−PPO−PEO copolymers, we depicted the polymerization as shown in Scheme 1. In the first step, a redox reaction occurs between Ce^{4+} and the $-CH_2OH$-terminal group of the PEO segment, generating a free radical in a position of the hydroxide. The radical thus formed is transferred from the polymer chain to the DMAEMA monomer, and the polymerization propagates. Formation of diradicals is possible, but their relative content is minor, according to the literature data (*10*, *21*−*23*). The presence of diradicals, if any, can lead to the formation of copolymers of higher molecular weight. In the present study, we were able to validate the polymerization mechanism by size exclusion chromatography (SEC) and NMR.

Figure 1 depicts typical SEC chromatograms of L92−pDMAEMA and PEO−pDMAEMA copolymer samples, calibrated in molecular weights. Peaks centered at 7100 (94.7% total area) and 10500 (5.3%) Da as well as 6950 (94.7%) and 10100 (5.2%) Da were observed in the case of the L92−pDMAEMA and PEO−pDMAEMA copoly-

Scheme 1. Initiation and Propagation Steps in the Free Radical Polymerization Leading to pDMAEMA−Pluronic Block Copolymers



mers, respectively. The polydispersity index calculated by the instrument's software using an absolute MW calibration curve was in the range of 1.22−1.25, in accord with the previously observed formation of relatively monodisperse copolymers resulting from polyoxyethylene-radical-induced polymerization of DMAEMA (*10*, *17*, *24*). On the basis of the average MW of the Pluronic L92 and PEG being 3720 and 3350 Da, respectively, ∼95% of either copolymer is a product of polyether-monoradical formation, resulting in "diblock" Pluronic−pDMAEMA or PEG−pDMAEMA structure. About 5% of the resulting polymers of either species are the result of the polyether-diradical formation, resulting in the bonding of two polyether segments to the forming pDMAEMA chain, with corresponding peaks observed in the 10 kDa area in the SEC chromatograms (Figure 1). The length of the pDMAEMA block is 22 or 23 units in L92−pDMAEMA or PEO−pDMAEMA, respectively, in the main fractions of these copolymers. These calculations are supported by the nitrogen content measurements: N, found, 4.15% (calcd, 4.26%) for the L92−pDMAEMA and N, found, 4.75% (calcd, 4.61%) for the PEO−pDMAEMA copolymer, respectively.

Using ^{1}H NMR spectroscopy, we were able to verify the structure of the pDMAEMA−L92 copolymers resulting from polymerization (Scheme 1, Figure 2). As is seen in Table 1, the proton ratios measured by NMR corresponded to the proposed structure quite well. The average number of DMAEMA units bonded to the one L92 segment was calculated from the ratio of the backbone methylene protons in these units, respectively (Table 1). At $y = 1$ (one Pluronic segment), we obtained

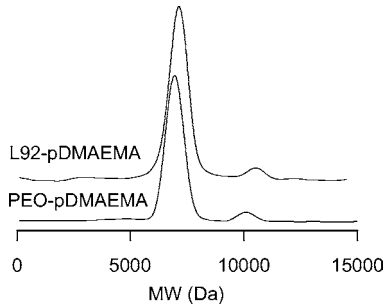


Figure 1. Typical size exclusion chromatographs of L92−pDMAEMA and PEO−pDMAEMA copolymers in DMF. For SEC conditions, see Experimental Procedures.

Chart 1. Structure of the pDMAEMA-L92 Copolymer

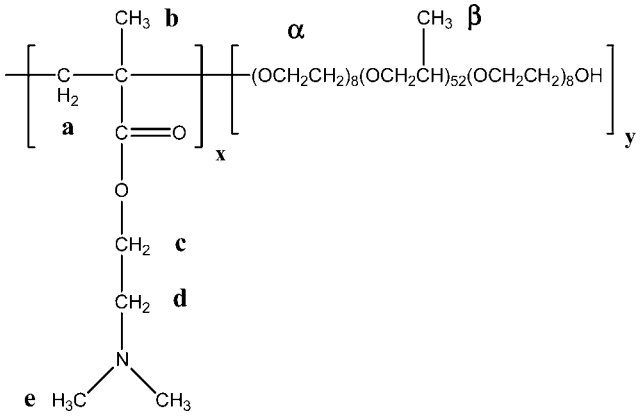

Table 1. Structure of Copolymers Obtained from ^{1}H NMR

structural element	protons[a]	calcd	found from NMR
DMAEMA	a:b:c:d:e	1.0:1.5:1.0:1.0:3.0	1.0:1.1:1.1:1.0:3.2
L92	α:*β*	1.08:1.00	1.06:1.00
DMAEMA/L92, mol/mol	a:α	*x*:84*y*	0.9:3.3 *x* = 22.9 *y* = 1

[a] For proton designations, see Chart 1.

the expression $x/84 = 0.9/3.3$, and thus $x = 23$; that is, 1 Pluronic segment is bound to 23 DMAEMA units on average. This is in excellent agreement with the $x = 22$ found from SEC. Importantly, no protons belonging to the methylene or methyl groups of the polyether were observed in the NMR spectrum of the sample synthesized in the absence of Ce^{4+} followed by the Pluronic removal by dialysis (see spectrum C in Figure 2). These observations further confirm the mechanism of the copolymer formation via cerium(IV)-induced initiation (Scheme 1).

Self-Assembling Properties of the Copolymers. Having confirmed the structure of the copolymers resulting from the cerium-initiated copolymerization of polyethers with DMAEMA, we embarked on the study of their properties that are of importance for complexation with DNA and transfection. To assess the polyelectrolyte properties of the novel copolymers, potentiometric titration of their aqueous solutions was conducted. The titration curves yielded the apparent pK_a and ionization degree (α) of the titratable (tertiary amino) groups. The intrinsic dissociation constant (K_0) was found by extrapolating pK_a to $\alpha = 0$ in the pK_a versus α curves. (*18*). The pK_0 values of the L92−pDMAEMA and PEO-DMAEDMA were found to be 7.1 and 7.4, respectively. A shift to lower pK_0 in the case of the L92−pDMAEMA can be explained by the effect of Pluronic lowering the dielectric constant

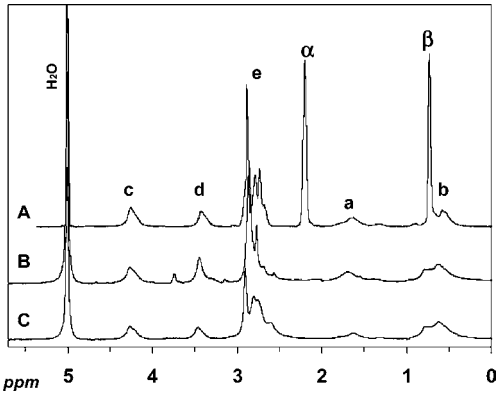

Figure 2. ^{1}H NMR (400 MHz) spectra of pDMAEMA−L92 (A), pDMAEMA (B), and pDMAEMA/L92 blend after dialysis (C) in D_2O/5 mM DCl. Protons are labeled as shown in Scheme 1.

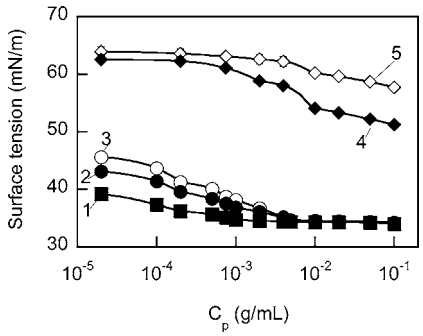

Figure 3. Equilibrium surface tension of the Pluronic L92 (1), L92−pDMAEMA (2, 3), and PEO−pDMAEMA (4, 5) copolymers as a function of the copolymer concentration (C_p) at 25 °C. Dependencies 1, 3, and 5 were obtained at pH 5.0, and dependencies 2 and 4 were measured at pH 7.0, in triplicate. Standard deviations are shown.

of the microenvironment of the amino groups. In contrast, the pK_o of the PEO−pDMAEMA copolymer roughly corresponded to the pK_a = 7.4−7.8 reported for the pDMAEMA polymer (*16*), indicating that PEO block alone has a lesser effect on the ionization of the pDMAEMA than PEO−PPO−PEO when bonded with the polycation. The DMAEMA monomer possesses a notably higher pK_a of 8.0−8.4 than its homo- and copolymers because of the neighboring effect (*25*); that is, the presence of some protonated side chains reduces the ability of the remaining dimethylamino groups to become protonated.

The presence of the hydrophobic PPO segments in the structure of the polyether segments of the copolymers leads to profound differences in the surface activity of the L92−pDMAEMA and PEO−pDMAEMA copolymers in aqueous solutions (Figure 3). The surface activity of the L92−pDMAEMA copolymers was comparable to that of the parent L92 surfactant, with the critical micellization concentrations (cmc) of 5×10^{-3} and 2×10^{-3} g/mL measured for the L92−pDMAEMA and L92 copolymers, respectively. The obtained cmc of the Pluronic L92 corresponded well with the literature data, previously reported for 37 and 15 °C (*26*−*28*). Higher ionization of the copolymer at pH 5.0 resulted in lower surface activity than at pH 7.0 throughout the concentration range. The PEO−pDMAEMA copolymers possessed dramatically lower surface activity than their L92−pDMAEMA counterparts at both pH values studied. At pH 5.0, where the copolymer is highly ionized, a very minimal surface activity was observed. At pH 7.0, which is closer to pK_a of the copolymer, the pDMAEMA segment becomes more

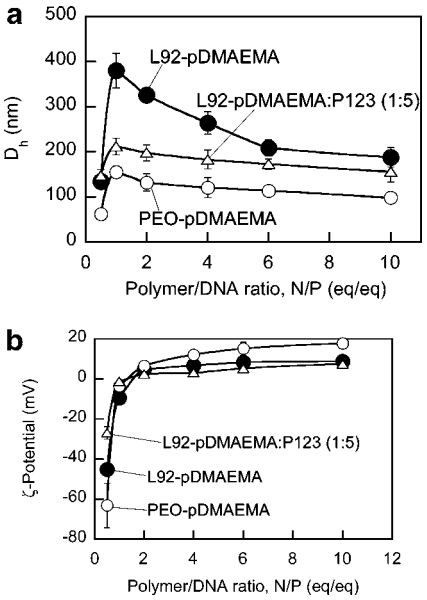

Figure 4. Hydrodynamic diameter (D_h) (a) and ζ-potentials (b) of the complexes formed between pCMV-βgal plasmid DNA and polycationic copolymers L92−pDMAEMA and PEO−pDMAEMA as well as a mixture of L92−pDMAEMA and Pluronic P123 (1:5 wt/wt) as a function of the polymer/DNA (N/P) ratio. The N/P ratio is expressed via the ratio of the equivalents of DMAEMA units in the copolymer to the nucleotide units in the DNA. Measurements were conducted in triplicate at 25 °C in 10 mM HEPES solution at pH 7.0. Standard deviations are shown.

hydrophobic and, thus, more of the copolymer adheres to the air−water interface, lowering the measured surface tension. Similar effects of pH on surface activity have been observed with block copolymers of DMAEMA and methyl methacrylate (*29*). The apparent cmc of the PEO−pDMAEMA was ∼0.01 g/mL at pH 7.0 and could not be measured at pH 5.0. We hypothesized that the observed differences in the surface activity of the PEO- and Pluronic-based polycations could have an effect on the ability of the copolymers to serve as nonviral transfection agents, because surfactants such as Pluronics can fuse with the cell membranes, thus decreasing their microviscosity, which leads to an enhancement of the transmembrane transport that is likely involved in the transfection mechanism (*30*). As shown in the forthcoming parts of the work, we indeed observed enhanced transfection with the L92−pDMAEMA copolymers.

Complexation of the polycationic copolymers with plasmid DNA was studied by assessing the average hydrodynamic diameter as well as ζ-potential of the particles of the formed complexes (Figure 4). Within the range of concentrations studied, no precipitation was observed at any N/P ratio. A significant increase in the average particle size was observed upon neutralization of the complexes when a 1:1 stoichiometry was reached, and then the particle size gradually decreased and leveled off as particles became positively charged. The complexes of the L92−pDMAEMA with pCMV-βgal plasmid DNA had larger hydrodynamic diameters than any other complexes throughout the N/P range studied (Figure 4), with the solution at N/P = 1.0 being faintly opaque. Intermolecular associations of the hydrophobic segments of the complexes were evidently more prevalent with the L92−pDMAEMA copolymer. Notably, the addition of the relatively hydrophilic Pluronic P123, which forms mixed micelles with L92, reduced the size of the aggregates and their electrokinetic mobility (Figure 4). The excess of

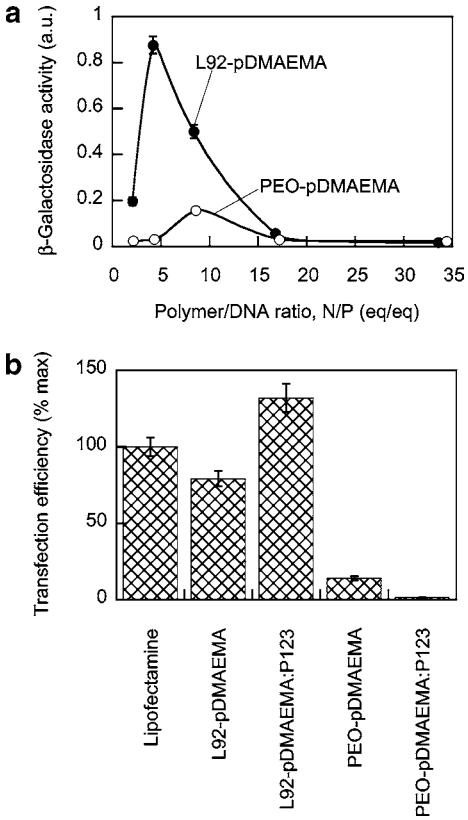

Figure 5. Transfection of CHO cells by pCMV-βgal using L92−pDMAEMA and PEO−pDMAEMA copolymers, mixtures of L92−pDMAEMA or PEO−pDMAEMA with 0.005% Pluronic P123 and Lipofectamine as transfection agents (TA). In (a), the 95% confluent CHO cells were transfected with the complexes of L92−pDMAEMA and plasmid DNA at different polymer/DNA (N/P) ratios, expressed in equivalents of charged groups in the copolymer and DNA. The β-galactosidase activity was assayed 48 h after the transfection using the ONPG assay. In (b), the effect of the transfection agents was calculated as the maximum β-galactosidase activity relative to the maximum enzyme activity achieved with the Lipofectamine. All assays were conducted under identical conditions 72 h after the transfection. Measurements were performed in triplicate, and standard deviations are shown. Statistical significance of the results for each experiment was calculated using Student's t test (all reported data were characterized by $P < 0.01$).

Pluronic P123 masked the charges of the particles as compared to the L92−pDMAEMA/DNA complexes without Pluronic addition. No opacity in the solutions with P123 was observed, even at the stoichiometric N/P = 1.0. Such a stabilizing effect of the presence of the Pluronic P123 on the stabilization of the polycation/DNA complex has been previously reported with other polycationic systems (*7*, *12*).

Cell Transfection. As shown in Figure 5, the L92−pDMAEMA copolymer significantly enhances cell transfection in the N/P ratio ranging from 2 to 34, exhibiting a maximum level of β-gal expression at the N/P ratio of 4. Pluronic P123 significantly increased the level of transfection when added to the L92−pDMAEMA composition, resulting in 1.7- and 1.3-fold higher β-gal expressions when compared to the effects of L92−pDMAEMA alone and Lipofectamine, respectively.

In contrast to the effects of the L92−pDMAEMA copolymer, the PEO−pDMAEMA copolymer resulted in only very weak β-galactosidase expression, and Pluronic 123 when added to this formulation did not increase the transfection efficacy (Figure 5b).

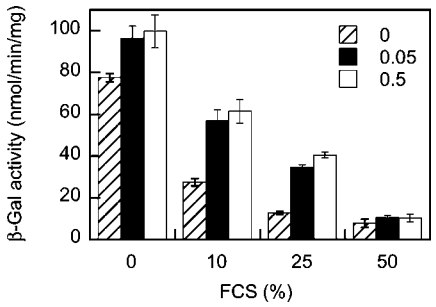

Figure 6. Effect of FCS concentration in the medium on β-galactosidase transfection activity. The CHO cells were transfected with L92−pDMAEMA/pCMV β-gal (4:1, w/w) complexes with or without Pluronic P123, added at 0.05 or 0.5%. The media contained increasing levels of serum from 0 to 50% FCS. The β-galactosidase activity was calculated as nanomoles of β-galactose formed per minute per milligram of lysate at 37 °C by using ONPG as a substrate. All data were obtained in triplicate. Numbers stand for 0, 0.05, and 0.5% of Pluronic P123 added.

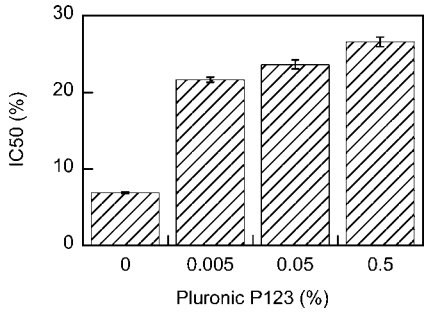

Figure 7. Effect of Pluronic P123 on reduction of the serum-mediated inhibition of transfection. The CHO cells were transfected with L92−pDMAEMA/pCMV β-gal (4:1, w/w) complexes with or without added Pluronic P123 (0.005, 0.05, or 0.5%). The results are presented via FCS concentration resulting in 50% inhibition of transfection activity of L92−pDMAEMA−pCMV−β-gal complex without the addition of P123 in serum-free conditions (IC_{50}, percent). All data were obtained in triplicate.

The efficacy of cell transfection by means of cationic polymers is often diminished by serum. However, it has been demonstrated (*7*) that conjugation of polycations such as poly(ethylene imine) (PEI) with polyethers results in copolymers capable of forming stable complexes in serum. Furthermore, addition of Pluronics to PEI−DNA complexes has been shown to alleviate the reduction of serum-mediated gene transfer to murine fibroblasts (*31*). We reasoned that the addition of Pluronic P123 that we observed to significantly enhance the efficiency of transfection (Figure 5b) can help in reducing the deleterious effects of serum. Therefore, the ability of L92−pDMAEMA to mediate DNA transfer at various serum concentrations in the transfection medium was studied. The media tested contained increasing levels of serum from 0 to 50% and Pluronic P123 from 0 to 0.5%. As is seen in Figure 6, the L92−pDMAEMA copolymer alone is more serum-sensitive than the L92−pDMAEMA-P123 complex, when used as a transfection reagent. Addition of FCS to the transfection medium at a 10% level resulted in 2.8- and 1.3-fold lower β-gal expressions when compared to the serum-free medium, when L92−pDMAEMA alone or L92−pDMAEMA−P123 complex was used, respectively. Pluronic P123 increased the transfection activity dramatically and at the same time reduced the serum-mediated inhibition of the DNA transfer.

Figure 7 shows the effect of Pluronic P123 on the transfection activity of the L92−pDMAEMA−DNA complex in the serum-containing medium. The results were

reported as the percentage of FCS in the transfection medium necessary to cause 50% inhibition of the transfection activity of L92−pDMAEMA−DNA without Pluronic in serum-free conditions (IC_{50}). Remarkably, as little as 0.005% Pluronic P123 helped to increase the IC_{50} from 7 to 22%. This certainly proves shielding of the copolymer−DNA complexes from the serum by added Pluronic species. One might attribute this protective effect to a steric barrier that Pluronic assemblies with the copolymer−DNA complex create toward the complex−serum interaction (*31*).

CONCLUDING REMARKS

A simple synthetic procedure for the free radical polymerization of DMAEMA initiated by polyether radicals that are generated by cerium(IV) has been developed. The procedure results in block copolymers of pDMAEMA and polyethers with high yields. The copolymers of Pluronic L92 with pDMAEMA are highly surface-active at pH 5.0 and 7.0, whereas the PEO−pDMAEMA copolymer is slightly surface-active only at pH 7.0, at which it is sufficiently hydrophobic. The complexes of the L92−pDMAEMA are larger than those of the PEO−pDMAEMA throughout the polymer/DNA range studied. The results shown in Figure 5 demonstrate that the L92−pDMAEMA enables transfection efficacy of the plasmid DNA comparable to that achieved with lipid-based formulations such as Lipofectamine. Furthermore, the addition of Pluronic P123 further increases the carrier efficacy and reduces serum-mediated inhibition of DNA transfer. We have previously reported that cationic polymers conjugated with nonionic amphiphilic polymers such as PEI−Pluronic provide plasmid DNA with transfection efficiency similar to that achieved using lipid-based systems in in vitro settings. Such copolymers are quite beneficial when used for systemic administration. The new L92−pDMAEMA carrier evaluated in this study has demonstrated analogous in vitro properties. This polymer, however, is a product of a one-step, robust polymerization procedure, which represents a significant advantage compared to the PEI−Pluronic carriers that are produced by a complex and poorly controlled conjugation chemistry.

The ability of Pluronic P123 added to the L92−pDMAEMA/DNA complex to further enhance the transfection efficacy is likely related to the above-described stabilizing effect of this polymer leading to a reduction in the particle size of the L92−pDMAEMA/DNA (see Figure 4). This benefit, although well seen in the in vitro system, may be much more pronounced upon a systemic administration of the formulation.

The in vivo performance of L92−pDMAEMA and its combination with Pluronic P123 and other similar block copolymers as DNA delivery systems is presently being evaluated in our laboratories.

Received October 26, 2004; Revised Manuscript Received February 10, 2005

Development of new radiopharmaceuticals based on rhenium-188 depends on finding appropriate ligands able to give complexes with high in vivo stability. Rhenium(III) mixed-ligand complexes with tetradentate/monodentate ('4 + 1') coordination of the general formula [Re(NS_3)(PRR′R″)] (NS_3 = tris-(2-mercaptoethyl)amine and derivatives thereof, PRR′R″ = phosphorus(III) ligands) appear to be among the promising tools to achieve this goal. According to this approach, we synthesized and characterized a series of rhenium model complexes. In vitro stabilities of the corresponding rhenium-188 complexes were determined by incubating 2−3 MBq or alternatively 37 MBq of the complexes in phosphate buffer, human plasma, and rat plasma, respectively, at 22 °C or 37 °C, followed by checking the amount of $^{188}ReO_4^-$ formed after 1 h, 24, and 48 h by thin-layer chromatography. The rate of perrhenate formation varied over a wide range, depending primarily on the nature of the phosphorus(III) ligand. Physicochemical parameters of the corresponding nonradioactive rhenium complexes were analyzed in detail to find out the factors influencing their different stability and furthermore to design new substitution-inert '4 + 1' complexes. Tolman's cone angle of phosphorus(III) ligands and the lipophilic character of the inner coordination sphere were found to be crucial factors to build up stable rhenium '4 + 1' complexes. Additional information useful to describe electronic and steric properties of these compounds were selected from electronic spectra (wavelength of the Re→S charge-transfer band), cyclovoltammetric measurements ($E°$ of the Re^{III}/Re^{IV} couple), and NMR investigations (^{31}P chemical shift of coordinated P(III) ligands).

INTRODUCTION

Rhenium-188 is an attractive candidate for therapeutic applications in oncology due to its nuclide properties ($E_{\beta max}$ = 2.1 MeV, $t_{1/2}$ = 16.9 h) and its daily availability from a $^{188}W/^{188}Re$ generator (*1*−*3*). To exploit the potencies of this nuclide, target-specific radiotherapeuticals must be developed to accumulate the radioactivity in the tumor and to spare healthy tissue from radiation. This can be achieved by linking a radionuclide-bearing chelate to a target-seeking biomolecule. Being capable to control the biodistribution requires kinetically inert and metabolically stable complexes. Despite some rhenium-188 tricarbonyl complexes with tridentate ligands (*4*) and in some cases $^{188}Re(O)MAG_3$ that show fairly good stability both in vitro and in vivo (*5*−*7*), antioxidation stability at high level of radioactivity remains one of the most important questions in rhenium radiopharmacology.

A promising approach for attaching rhenium-188 to biomolecules is the so-called '4 + 1' mixed ligand system (*8*). Here a rhenium(III) center is coordinated by the tetradentate tris(2-mercaptoethyl)amine chelator (NS_3) or a derivative thereof and a phosphorus(III) compound or an isocyanide as monodentate ligand. The latter also serves as a linker for coupling target-specific biomolecules such as peptides, antibodies, and oligonucleotides (Figure 1).

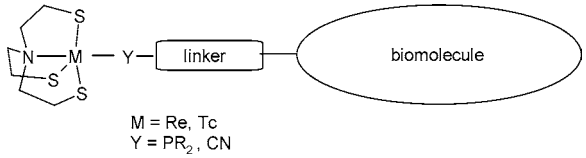

Figure 1. The '4 + 1' mixed ligand approach.

Until now, '4 + 1' complexes of technetium and rhenium with the NS_3 chelator tris(2-mercaptoethyl)-amine and several isocyano or phosphine ligands were predominantly of lipophilic character (*9*, *10*). Development of more hydrophilic rhenium complexes may help to minimize exposure of radiation-sensitive organs by fast excretion of radioactive metabolites and furthermore enables radiolabeling of water-soluble biomolecules such as antibodies and peptides in aqueous solution. A first attempt to produce more hydrophilic '4 + 1' complexes was published recently by our group, involving the preparation of a tetradentate NS_3 ligand bearing a carboxyl group (*11*).

In the present work we report on the extension of the '4 + 1' system using different monodentate phosphorus-

(III) ligands, including both lipophilic and hydrophilic tertiary phosphines and phosphites (see Scheme 1). Moreover, the use of the unsubstituted NS_3 chelator compared with substituted NS_3 ligands bearing a carboxyl group (NS_3COOH) and an isopropyl amide (NS_3-$CONH^iPr$), respectively, offers the possibility of fine-tuning the system. We evaluated the potentials of the resulting complexes as tools for therapeutic purposes. Therefore, in vitro stabilities, which we defined as the amount of perrhenate formed after incubation of the rhenium-188 complexes at low (2−3 MBq) or medium (37 MBq) activity level in phosphate buffer, human plasma, and rat plasma, were determined. Physicochemical parameters of the corresponding nonradioactive rhenium complexes were analyzed in detail to find out trends useful to explain the different in vitro stabilities of various rhenium-188 complexes. Results of this analysis were used to design complexes of superior in vitro stability.

EXPERIMENTAL PROCEDURES

General. All solvents and commercially available substances were of reagent grade and used without further purification. Commercially available phosphines and phosphites are dimethylphenylphosphine **1** and 4-(diphenylphosphino)benzoic acid **5** (Aldrich), tris(2-cyanoethyl)phosphine **3** and tris(*o*-tolyl)phosphite **6** (Alfa Aesar). Diphenylphosphino acetic acid **4** was synthesized according to the method described by Jarolim et al. (*12*). Syntheses of the tetradentate ligand tris(2-mercaptoethyl)amine (NS_3) and rhenium complex **Re1** were reported elsewhere (*8*). Tris(2-mercaptoethyl)amine was isolated and applied as the oxalate. 2-[Bis(2-mercaptoethyl)amino]-3-mercaptopropionic acid (NS_3COOH) was prepared as hydrochloride salt by double N-alkylation of *S*-benzylcysteine (*11*). $^{188}ReO_4^-$ was eluted from a $^{188}W/^{188}Re$ generator (Oak Ridge National Laboratories, Oak Ridge, TN).

Instrumentation. Nuclear magnetic resonance spectra were recorded on a 400 MHz Varian Inova 400 spectrometer. The ^1H and ^{13}C chemical shifts are reported relative to residual solvent signals or TMS as reference. ^{31}P chemical shifts are reported relative to H_3PO_4 as external reference. Mass spectrometric measurements were performed with a Micromass Tandem Quadropole Mass Spectrometer (Quadro LC) operating in the MS mode. Mass spectral data were recorded in the positive ESI mode. About 10^{-4} mol of the sample dissolved in 1.0 mL of methanol or acetonitrile were injected at a flow rate of 5 μL/min.

Elemental analyses were performed on a LECO Elemental Analyzer CHNS-932. Cyclic voltammetry was carried out in dichloromethane solutions (1×10^{-3} mol dm^{-3}) with [n-Bu_4N][ClO_4] (0.1 mol dm^{-3}) as supporting electrolyte, at a stationary platinum-disk electrode (area ca. 1.28 mm^2), which was cleaned after each run, with scan rate 0.2 V s^{-1} at 293 K. Potentials were measured relative to an Ag-wire pseudoelectrode using the Fc/Fc^+ couple as internal reference. Controlled potential coulometries of dichloromethane solutions were performed using an Amel model 721 integrator, in a H-shaped cell containing, in arm 1, a platinum-gauzed working electrode, and an Ag/Ag^+ reference isolated inside a salt bridge by a medium glass frit and, in arm 2, an auxiliary platinum-foil electrode. UV/vis spectra were recorded on a SPECORD S10 spectrometer (Carl Zeiss Jena).

HPLC analysis and purification of rhenium-188 complexes were performed using a Perkin-Elmer instrument consisting of a Turbo LC System with a quaternary pump (Series 200 LC Pump) and a programmable absorbance detector model 785A.

Nonradioactive rhenium complexes were monitored by their UV absorption at 254 nm, and rhenium-188 complexes by γ-ray detection (Bohrloch, NaI(Tl) crystal).

Synthesis of {[2-(Diethylamino)ethyl]phosphinediyl}dimethanol 2. To a solution of 0.001 mol of diethyl [2-(diethylamino)ethyl]phosphonate, synthesized according to the method of Kosolapoff et al. (*13*), in 5 mL of dry diethyl ether, at 0 °C, was added 1.5 mL of a 1 mol/L $LiAlH_4$ solution (diethyl ether) dropwise via syringe. After the mixture was stirred at 0 °C under an argon atmosphere for 0.5 h about 3 mL of H_2O was added. The organic layer was separated, and the aqueous layer was extracted two times each with 3 mL of diethyl ether. The solvent of the combined organic solutions was removed in an argon stream. To the remaining oil were added 3 mL of degassed EtOH, 250 μL (0.003 mol) of a formaldehyde solution (37% in H_2O/MeOH), and 0.5 mL of 3 N

aq HCl. After being stirring at room temperature overnight, the solvent was stripped in vacuo, yielding 88% of a colorless viscous oil. Phosphine **2** was liberated in situ during the complex synthesis step.

General Synthesis Procedure for the Preparation of Rhenium Complexes Re3, Re4, Re6. To a solution of 0.1 mmol of tris(2-mercaptoethyl)ammonium oxalate (NS_3) and 0.3 mmol of the phosphine/phosphite in 5 mL of methanol (for **Re3**) or acetonitrile (for **Re4** and **Re6**) was added 0.1 mmol (26.8 mg) of NH_4ReO_4 (dissolved in ca. 200 μL of concentrated HCl for **Re3** and **Re4**). The reaction mixture was refluxed under an argon atmosphere for 2 h. The solvent was removed in vacuo and the residue purified by column chromatography (silica). Eluents were chloroform/ethyl acetate (90:10) for **Re3**, chloroform/ethyl acetate/TFA (90:10:0.1) for **Re4**, and *n*-hexane/ethyl acetate (50:50) for **Re6**. Crystals suitable for X-ray structure analysis were obtained by slow solvent evaporation of chloroform solutions of **Re3**, **Re4**, or **Re6.**

UV/vis (CH_2Cl_2): $\lambda_{max}(\log \epsilon) = 356$ (3.0), 418 (3.2), 524 (2.4). ^{1}H NMR ($CDCl_3$) 2.17 (s, 9 H, CH_3), 2.91 (bs, 12 H), 6.95 (m, 3 $H_{arom.}$), 7.05 (m, 3 $H_{arom.}$), 7.11 (d, J = 7.32 Hz, 3 $H_{arom.}$), 7.55 (d, J = 8.06 Hz, 3 $H_{arom.}$). ^{13}C NMR ($CDCl_3$) 17.22 (s, 9 C, CH$_3$), 44.08 (d, J = 6.10 Hz, 3 C, SCH$_2$), 59.06 (s, 3 C, NCH$_2$), 121.40 (d, J = 3.82 Hz, 3 $C_{arom.}$), 123.33 (s, 3 $C_{arom.}$), 126.42 (s, 3 $C_{arom.}$), 130.65 (d, J = 4.58 Hz, 3 $C_{arom.}$), 130.80 (s, 3 $C_{arom.}$), 151.99 (d, J = 8.39 Hz, 3 $C_{arom.}$). ^{31}P NMR ($CDCl_3$) 115.54 (s). ESI-MS (*m/z*): 733 $[M]^+$.

General Synthesis Procedure for the Preparation of Re2, Re5, Re7, Re8. The rhenium precursor $[Re(tu)_6]Cl_3 \times H_2O$ was synthesized by the method described by Gambino et al. (*14*). The monodentate ligand, tris(2-mercaptoethyl)ammonium oxalate (NS_3) (0.1 mmol, 28.6 mg), and $[Re(tu)_6]Cl_3 \times H_2O$ (0.1 mmol, 76.7 mg) were dissolved in 10 mL of methanol. For the synthesis of **Re2**, 100 μL triethylamine was added to the mixture to convert the phosphonium salt into the corresponding tertiary phosphine **2**. The solution was refluxed under an argon atmosphere for 3 h. After being cooling to room temperature, the reaction mixture was filtered and the solvent stripped in vacuo. **Re2** was purified by column chromatography (silica, acetone/chloroform/triethylamine (66:33:0.1)). In the case of **Re5**, **Re7**, and **Re8**, the crude product, which was impured by its methyl ester derivatives, was dissolved in a mixture of 3 mL of dioxane and 1 mL of 1 N NaOH and refluxed for 3 h. The reaction mixture was then acidified with 0.1 N HCl and the product extracted with chloroform. After evaporation of the solvent, the complex was further purified by silica column chromatography (*n*-hexane/ethyl acetate/TFA (50:50:0.1). Crystals of **Re2** suitable for X-ray structure analysis were obtained by slow solvent evaporation of a solution of **Re2** in methylenchloride/*n*-hexane.

Re2. Yield: 31% dark-green crystals. Mp: 159−162 °C. UV/vis (CH_2Cl_2): $\lambda_{max}(\log \epsilon) = 340$ (2.9), 461 (3.0), 592 (2.2). ^{1}H NMR ($CDCl_3$) 1.19 (t, J = 7.33 Hz, 6 H, CH_3), 2.59 (m, 2 H, PCH_2CH$_2$), 2.87 (q, J = 7.33 Hz, 4 H, NCH_2-CH$_3$), 2.90 (bs, 12 H), 3.06 (m, 2 H, NCH_2CH$_2$), 4.22 (m, 4 H, CH_2OH). ^{13}C NMR ($CDCl_3$) 8.90 (s, 2 C, CH$_3$), 21.64 (d, J = 26.70 Hz, 1 C, PCH$_2$, 46.18 (s, 2 C, NCH$_2$), 47.32 (d, J = 4.58 Hz, 3 C, SCH$_2$), 50.21 (d, J = 12.17 Hz, 1 C, NCH$_2$), 59.74 (s, 3 C, NCH$_2$), 73.17 (d, J = 28.23 Hz, 2 C, CH$_2$OH). ^{31}P NMR ($CDCl_3$) 16.50 (s). ESI-MS (*m/z*): 575 $[M + H]^+$.

Re5. Yield: 25% dark-green crystals. Mp: >120 °C (decomp). UV/vis (CH_2Cl_2): $\lambda_{max}(\log \epsilon) = 457$ (3.3), 591 (2.6). ^{1}H NMR ($CDCl_3$) 2.87 (bs, 12 H), 7.28 (m, 6 $H_{arom.}$), 7.45 (m, 4 $H_{arom.}$), 7.53 (d, J = 7.51 Hz, 2 $H_{arom.}$), 7.98 (d, J = 8.24 Hz, 2 $H_{arom.}$). ^{13}C NMR ($CDCl_3$) 47.12 (s, 3 C, SCH$_2$), 60.54 (s, 3 C, NCH$_2$), 128.04 (d, J = 6.87 Hz, 4 $C_{arom.}$),129.15 (s, 1 $C_{arom.}$),129.42 (m, 4 $C_{arom.}$), 134.02 (d, J = 9.16 Hz, 2 $C_{arom.}$), 134.46 (d, J = 9.15 Hz, 4 $C_{arom.}$), 143.31 (d, J = 47.30 Hz, 2 $C_{arom.}$), 151.56 (d, J = 54.93 Hz, 1 $C_{arom.}$), 171.00 (s, 1 C, C(O)). ^{31}P NMR ($CDCl_3$) 30.68 (s).

Re7. Yield: 36% dark-green crystals. Mp: >145 °C (decomp). UV/vis (CH_2Cl_2): $\lambda_{max}(\log \epsilon) = 455$ (3.0), 586 (2.2). ^{1}H NMR ($CDCl_3$) 2.47 (m, 1 H), 2.76 (m, 3 H), 3.09 (m, 2 H), 3.22 (m, 1 H), 3.40 (dd, J = 13.64, 4.85 Hz, 1 H), 3.51 (m, 1 H), 3.63 (m, 2 H), 7.30 (m, 6 $H_{arom.}$), 7.44 (m, 6 $H_{arom.}$), 7.93 (dd, J = 8.24, 1.28 Hz, 2 $H_{arom.}$). ^{13}C NMR ($CDCl_3$) 46.46 (d, J = 3.05 Hz, 1 C, SCH$_2$), 48.96 (d, J = 5.34 Hz, 1 C, SCH$_2$), 50.53 (d, J = 4.58 Hz, 1 C, SCH$_2$), 55.85 (s, 1 C, NCH$_2$), 57.25 (s, 1 C, NCH$_2$), 70.44 (s, 1 C, NCH), 128.13 (d, J = 9.92 Hz, 4 $C_{arom.}$), 129.05 (d, J = 1.53 Hz, 1 $C_{arom.}$), 129.55 (m, 4 $C_{arom.}$), 134.10 (d, J = 11.44 Hz, 2 $C_{arom.}$), 134.47 (d, J = 11.44 Hz, 4 $C_{arom.}$), 142.69 (d, J = 47.30 Hz, 2 $C_{arom.}$), 151.83 (d, J = 41.96 Hz, 1 $C_{arom.}$), 171.82 (s, 1 C, C(O)), 175.23 (s, 1 C, C(O)). ^{31}P NMR ($CDCl_3$) 29.94 (s).

Re8. Yield: 29% dark-green crystals. Mp: >155 °C (decomp). ESI-MS (*m/z*): 772 $[M]^+$.

X-ray Data Collection and Processing. The X-ray data were collected at room temperature (293 K) on a SMART-CCD diffractometer (SIEMENS), using graphite monochromatized Mo K_α radiation (λ = 0.71073 Å). A summary of the crystallographic data of **Re2**, **Re3**, **Re4**, and **Re6** is given in Table 1. The positions of the non-hydrogen atoms were determined by the heavy atom technique. After anisotropic refinement of these positions,

the hydrogen positions were calculated according to ideal geometries. Empirical absorption corrections were made using psi scans. Most of the calculations were carried out in the SHELXTL system with some local modifications. Selected bond lengths and angles are reported in Table 2.

CCDC 253461 (**Re2**), CCDC 253462 (**Re3**), CCDC 253463 (**Re4**), and CCDC 253464 (**Re6**) contain the supplementary crystallographic data for this paper.

These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033.

Synthesis Procedure for ^{188}Re Complexes. Synthesis was carried out via the EDTA intermediate as previously described by Seifert and co-workers (*11*).

^{188}Re-EDTA. 3−5 mL of perrhenate eluate from a ^{188}W/^{188}Re generator were added together with 0.5 mL of 0.1 N HCl to a kit vial containing 5 mg of EDTA, 5 mg of mannitol, and 1.0 mg of $SnCl_2$ in freeze-dried form under nitrogen. After 20−30 min at room temperature the complex formation is finished. Yield: >95% (TLC).

'4 + 1' ^{188}Re Complexes. A 0.3 mg amount of the appropriate NS_3 derivative and 0.05−0.20 mg of phosphine, dissolved in a mixture of 0.5 mL of water and 0.5 mL of methanol, were added with a syringe to the ^{188}Re-EDTA preparation, and the solution was heated at 50 °C (**Re4**, **Re5**, **Re6**) or 75 °C (**Re1**, **Re2**, **Re3**, **Re7**, **Re8**) for 30 min. Radiochemical yield: 50−90% (TLC), except **Re6**: 20−30%. The preparations were purified for stability studies by HPLC using the following methods.

*Method 1 (**Re1, Re2, Re3, Re5**)*: Hypersil ODS (10 μm, 250 × 8 mm, Knauer), 3 mL/min; solvent A: methanol; solvent B: 0.01 M phosphate buffer pH 7.4 (PBS); gradient elution: 0−10 min 0 to 100% A (**Re1**, **Re3**) or 0−10 min 30 to 100% A (**Re2, Re5**).

*Method 2 (**Re4, Re7, Re8**)*: PRP-1 (10 μm, 250 × 10 mm, Hamilton); 3 mL/min; solvent A: acetonitrile + 0.1% trifluoro acetic acid (TFA); solvent B: water + 0.1% TFA; gradient elution: 0−10 min 30 to 100% A.

*Method 3 (**Re6**)*: Zorbax 300 SB−C18 (5 μm, 250 × 9.4 mm, Agilent); 3 mL/min; solvent A: acetonitrile + 0.1% TFA; solvent B: water + 0.1% TFA; gradient elution: 0−10 min 30 to 100% A.

Thin-layer chromatography (TLC) was performed using RP-18 silica gel strips (Merck) and methanol/0.01 M phosphate buffer pH 7.4 (90:10) for **Re1**−**Re3** or acetonitrile/water/TFA (80:20:0.1) for **Re4**−**Re8** as mobile phases. All compounds show R_f values between 0.4 and 0.6. The strips were scanned with a raytest Rita radioanalyzer.

Stability Studies. The in vitro stability was determined by adding 2−3 MBq or 37 MBq of the relevant pure ^{188}Re complex, dissolved in 100 μL of propylene glycol, to (i) 400 μL of phosphate buffer (PBS) pH = 7.4; (ii) 200 μL of human plasma + 200 μL of phosphate buffer (PBS) pH = 7.4; (iii) 200 μL of rat plasma + 200 μL of phosphate buffer (PBS) pH = 7.4. The samples containing 2−3 MBq were incubated at room temperature (22 °C), the 37 MBq samples at 37 °C.

All compounds were investigated at low activity level due to the low radiation exposure and easy performance

of the experiments. Only stable complexes have been investigated under harsher conditions. We chose the same conditions as those published by Schibli et al. (*4*), enabling the comparison of the results.

RESULTS

Rhenium Chemistry. *Synthesis*. As outlined in Scheme 1, the nonradioactive Re(III) '4 + 1' model complexes can be prepared using two different methods: (A) reduction−substitution reactions starting from ammonium perrhenate (*8*) or (B) ligand-exchange reactions starting from the hexakisthiourea Re(III) precursor. In the first case, an equimolar amount of NS_3 and an excess of phosphorus(III) ligand, dissolved in methanol (or acetonitrile for carboxyl group-bearing ligands and phosphites), react under reflux (2 h) with an acidic solution of perrhenate (without addition of HCl for phosphite ligand **6**) under an argon atmosphere to afford stable Re(III) '4 + 1' complexes.

Alternatively, equimolar amounts of $[Re(tu)_6]Cl_3$, NS_3 and phosphine react in refluxing methanol to give analogous Re(III) '4 + 1' complexes in moderate yields. Both procedures are characterized by a typical change in color from colorless perrhenate to green or reddish, indicating the reduction from Re(VII) to Re(III) (method (A)), or from brownish to yellow-green in the case of ligand-exchange reactions (method (B)).

Characterization. The Re(III) complexes have been characterized by means of (i) elemental analyses, which are in good agreement with the proposed formulation, (ii) cyclic voltammetry, (iii) spectroscopic measurements, comprising UV/vis and multinuclear NMR, (iv) mass spectrometry, and (v) X-ray structure analyses of four representative complexes including unsubstituted NS_3 and phosphines **2**, **3**, or **4** and phosphite **6** (complexes **Re2**, **Re3**, **Re4**, and **Re6**).

The diamagnetism shown by this class of Re(III) complexes is in agreement with low-spin d^4 trigonal bipyramidal configuration (vide infra, X-ray description). Thus, NMR spectra of **Re1**−**8** exhibit a sharp ^{31}P singlet, which moves significantly downfield, by 30−40 ppm, upon coordination in phosphine containing complexes **Re1**−**5** and **Re7**−**8** compared to the values shown by uncoordinated ligands (see Table 4). On the contrary, such a singlet moves upfield by 16 ppm in the unique case of the coordinated phosphite in **Re6**. ^{1}H and ^{13}C spectra of Re(III) '4 + 1' complexes show signals both in the aromatic and in the aliphatic regions, consistent with the formulation. In particular, proton spectra of complexes comprising the unsubstituted NS_3 ligand (**Re1**−**6**) are dominated by a broad signal at δ 2.9 ppm, characteristic for the NS_3 ethylene arms. Incorporation of a carboxyl group or a substituted carboxyl function in the NS_3 framework causes such a signal to become a series of multiplets falling in the 2.4−3.7 ppm region (complexes **Re7** and **Re8**; see Figure 2).

[a] Taken or estimated from ref 18. [b] Most intensive band in the vis region. [c] Data estimated from Rahman (*19*) who corrected the 132° value reported by Tolman (*18*).

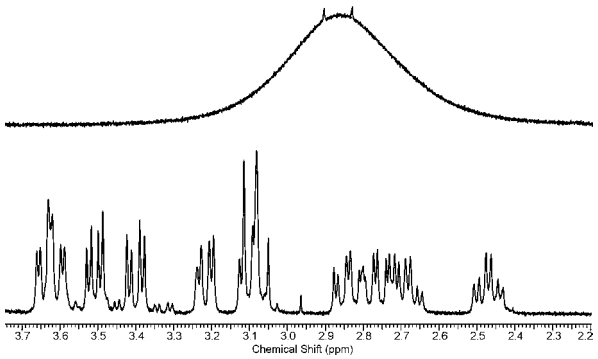

Figure 2. ^{1}H NMR spectra of **Re5** (above) and **Re7** (below) in the region 2.2−3.7 ppm.

The UV/vis spectra of **Re1**−**8** are characterized by intense absorption bands at approximately 420−460 nm (ϵ approximately 1000), and less intense absorptions (ϵ approximately 250) in the 520−590 nm region. The energy associated with these absorptions indicates that the former bands correspond to metal to ligand (Re→S) charge-transfer transitions, whereas less intense bands correspond to d−d transitions. Both absorption bands are responsible for the green or reddish color of these complexes and move to shorter wavelengths in the phosphite-containing complex **Re6** (see Table 4), indicating that the energy involved in the transfer for **Re6** is higher compared to the energy implicated in phosphine complexes.

The molecular structure of four representative examples of five-coordinate Re(III) '4 + 1' complexes, **Re2**, **Re3**, **Re4**, and **Re6**, were investigated in the solid state by X-ray diffraction methods. A summary of the crystallographic data is given in Table 1, and selected bond lengths and angles are reported in Table 2. As outlined in Figures 3−6, the four complexes adopt a trigonal-bipyramidal geometry. The three NS_3 thiolate sulfurs form the trigonal plane, and the amine nitrogen of the chelate ligand and the phosphine phosphorus occupy the apical positions. These structures strictly resemble those

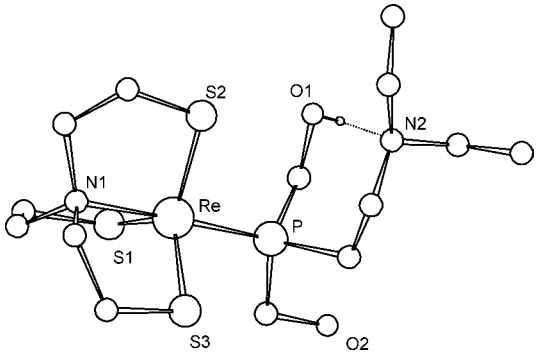

Figure 3. Molecular structure of **Re2**.

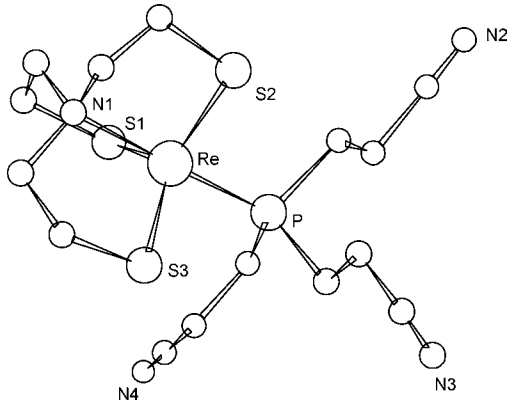

Figure 4. Molecular structure of **Re3**.

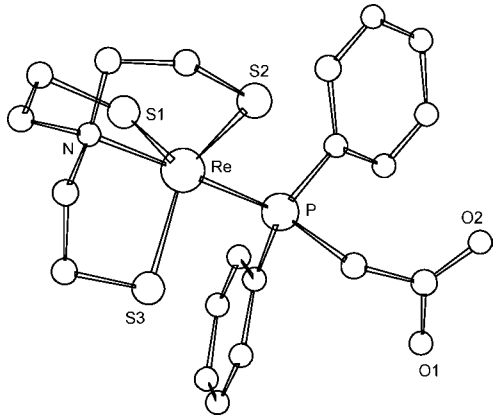

Figure 5. Molecular structure of **Re4**.

of rhenium complexes and its second-row congener technetium, in which the monodentate phosphine ligand has been replaced by various isocyanide groups (*8*−*10*). Angles and bond distances comprising the [Re(NS_3)] fragment, as well as the linearity of the N−Re−P spin, compare well with those reported in technetium complexes and do not deserve further comment. The Re−P bond distance elongates going from phosphite (**Re6**, Re−P = 2.2228(13) Å) to phosphine complexes (**Re3**, Re−P = 2.291(4); **Re2**, Re−P = 2.297(2); **Re4**, Re−P = 2.301(4) Å). For **Re2**, a hydrogen bond between one of the hydroxyl groups and the nitrogen in the backbone of the monodentate P(III) ligand is observed (see Figure 3). This additional contact may further diminish the steric hindrance of this ligand (vide infra). For **Re3**, both Δ and Λ conformers were found. For clarity reasons, only the latter is displayed in Figure 4.

The cyclovoltammetric profile of each complex recorded in CH_2Cl_2 shows only a reversible one-electron process in the anodic region which can be assigned, by coulometric experiments, to the formation of Re(IV), presumably accessing the $5d^3$ system. The oxidation process occurs in the region from −0.05 to +0.19 V for phosphine-containing complexes. The unique phosphite complex **Re6** is more difficult to oxidize by approximately 200−400 mV than similar phosphine complexes, corroborating the view that phosphite-containing compounds could be more stable toward reoxidation to perrhenate.

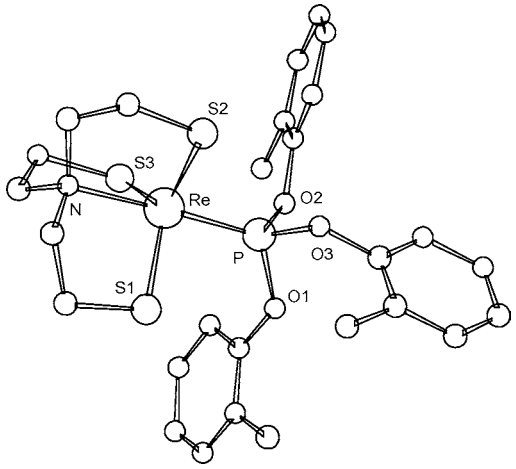

Figure 6. Molecular structure of **Re6**.

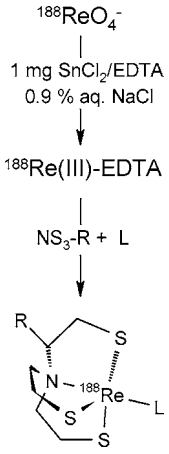
Scheme 2. Carrier-Free Preparation of ^{188}Re '4 + 1' Complexes



Rhenium-188 Chemistry and Stability Studies. *Preparation of the ^{188}Re Complexes.* A two-step procedure was used for the synthesis of '4 + 1' ^{188}Re complexes. At first a ^{188}Re(III)-EDTA intermediate complex was formed by reduction of $^{188}ReO_4^-$ with 1 mg of $SnCl_2$ in acidic solution (pH < 3). This labile intermediate species was converted to the '4 + 1' complex in a second step by contemporary addition of the NS_3/P ligands (Scheme 2). The yields were not optimized and were between 50 and 90% for phosphine complexes and 20−30% for phosphite complex **Re6**, as assessed by TLC. Comparison of retention times obtained by means of parallel radiometric and photometric detection of nonradioactive rhenium complexes and rhenium-188 complexes established the identity of the complexes prepared at millimolar and nanomolar concentrations.

Stability Studies. In vitro stabilities were determined by incubating 2−3 MBq of rhenium-188 complexes in phosphate buffer, human serum, and rat serum at room temperature. The amount of formed $^{188}ReO_4^-$ was determined by TLC analysis. Stabilities for **Re1**−**Re8** are shown in Table 3 and graphically illustrated in Figure 7.

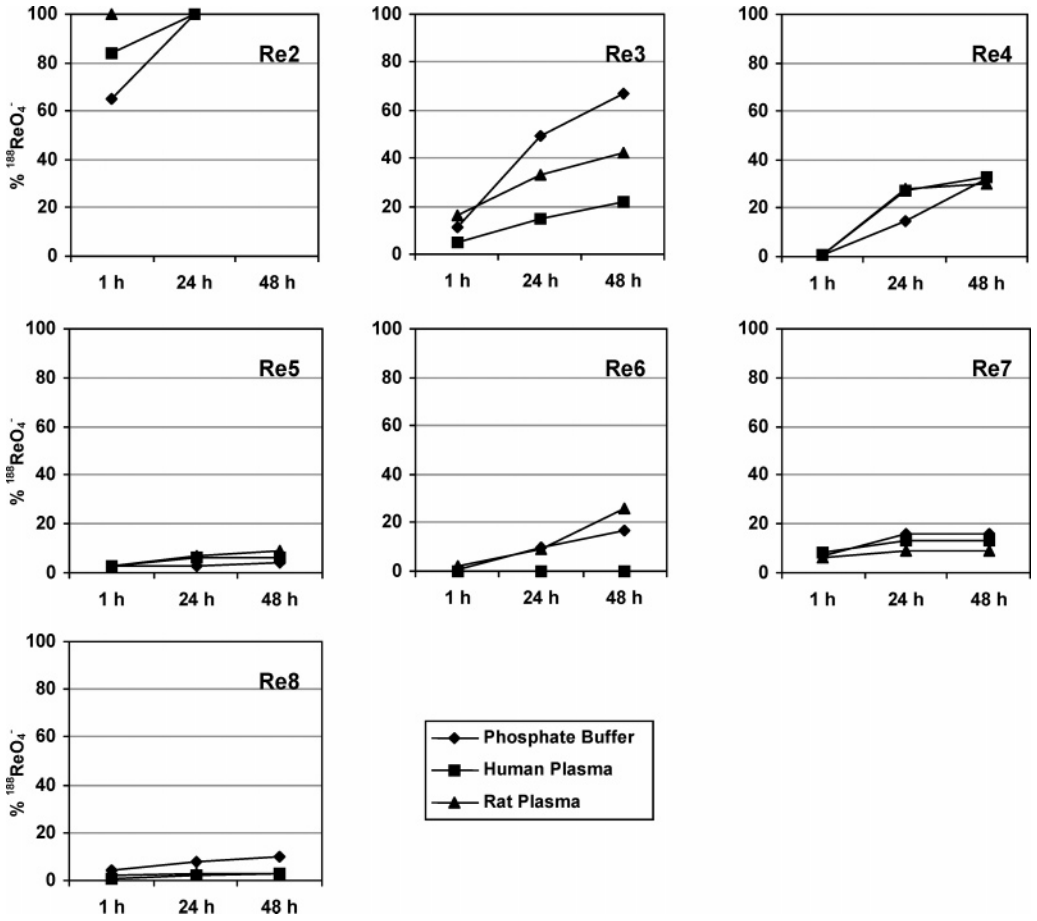


Figure 7. In vitro stabilities of ^{188}Re complexes **Re2**−**Re8** (standard deviations are omitted for clarity).

Re 5, which can be easily attached to biomolecules via an amide bond, was one of the most stable compounds at low activity level. Its in vitro stability was therefore further investigated under harsher conditions using 37 MBq of the complex and incubation at 37 °C in human plasma. The following amounts of $^{188}ReO_4^-$ were found (% $^{188}ReO_4^-$, means ± SD, $n = 3$): 9 ± 1 (1 h); 16 ± 1 (24 h); 19 ± 2 (48 h).

DISCUSSION

M(III) '4 + 1' complexes (M = Tc, Re) with NS_3 and isocyano ligands synthesized so far were predominantly lipophilic compounds (*9*, *10*). Development of more hydrophilic '4 + 1' species would be an important result (i) to favor renal excretion of radioactive metabolites in order to minimize exposure of radiation-sensitive organs and (ii) to open the possibility for labeling of antibodies and peptides in aqueous media. By using phosphorus(III) compounds (tertiary phosphines and phosphites of different size and lipophilicity, see Scheme 1) instead of isocyano ligands, another class of stable Re(III) '4 + 1' complexes was easily accessible.

Nonradioactive rhenium complexes were synthesized either starting from perrhenate or by using a prereduced rhenium(III) thiourea precursor, whereas rhenium-188 complexes were prepared using a method recently described by Seifert and co-workers (*11*). Since the direct reduction of $^{188}ReO_4^-$ with NS_3 and phosphorus(III) ligands in the presence of $SnCl_2$ led to a large amount of reduced/hydrolyzed rhenium-188 compounds, we preferred an alternative way based on the formation of a prereduced ^{188}Re(III)-EDTA complex as a labile intermediate. Following ligand-exchange with the contemporary addition of NS_3/P(III) ligands, '4 + 1' complexes were obtained with up to 90% radiochemical purity.

In vitro stability of these ^{188}Re '4 + 1' agents was found to be very unpredictable, but strongly dependent on the nature of the monodentate P(III) coligand (Figure 7). For example, lipophilic **Re1** was completely reoxidized to $^{188}ReO_4^-$ within 1 h. Similarly, the most hydrophilic complexes **Re2** bearing the hydroxymethyl phosphine and **Re3** comprising the cyanoethyl phosphine were not stable as well, giving large amounts of perrhenate. Conversely, more lipophilic complexes such as **Re5** and **Re6** were found to produce only little amounts of $^{188}ReO_4^-$ in all investigated media. Differences between stabilities of **Re3** and **Re6** in human plasma, rat plasma, and phosphate buffer give rise to the assumption that the in vitro stability is influenced by both biological and chemical factors. The former can be specific enzymes responsible for the cleavage of chemical bonds and/or the free radicals scavenger capability of plasma components such as human serum albumin (*15*−*17*).

With the aim of understanding the strikingly different in vitro stability of these ^{188}Re '4 + 1' compounds, we prepared the corresponding nonradioactive rhenium complexes **Re1**−**Re8**, collected a series of significant physicochemical parameters (compiled in Table 4), and tried to find out which factors may govern the production of substitution-inert or hydrolyzable species. In this connection, we evidently focused our attention on the coordinated P(III) ligand.

The influence of steric and electronic properties of phosphorus(III) ligands on complex reactivity has been investigated over the past decades (see a comprehensive review article published by Tolman (*18*)) according to the

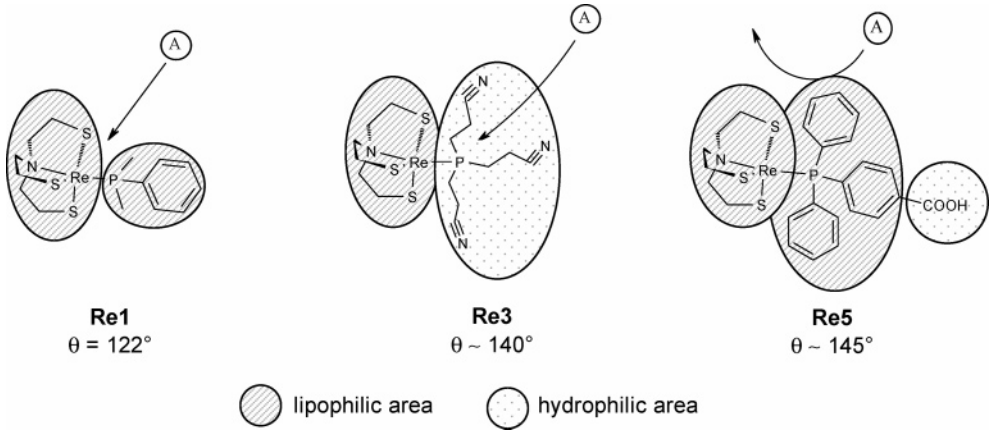

Figure 8. Possible attack of a reactive water-derived species (A) on Re '4 + 1' complexes of varying steric properties.

essential role played by transition metal−phosphorus(III) ligand complexes in homogeneous catalysis. Even if steric and electronic effects are always synergistically related and their individual analysis is difficult to perform, we tried to examine physicochemical parameters one at a time.

Considering the ^{31}P NMR shift ongoing from noncoordinated to coordinated P(III) ligands in the '4 + 1' rhenium complexes, we observed that the electron density at the P atom decreases in the case of tertiary phosphines (downfield shift) and increases in the case of phosphites (upfield shift). This electron delocalization directly influenced the $E°$ of the Re^{III}/Re^{IV} couple: for example, the phosphite complex **Re6** was harder to oxidize by 200−400 mV compared to all of the phosphine complexes. In principle, this property could be associated with the high in vitro stability exhibited by phosphite-containing **Re6**, even if complexes showing $E°$ values approaching the Fc/Fc^+ reference couple (ca. 0.00 mV, for instance **Re5** and **Re8**) were quite stable in vitro as well. The analysis of the electronic spectra confirms the difference between phosphine and phosphite complexes regarding their electron-withdrawing ability, but does not provide unambiguous information to discriminate between complexes of high and low in vitro stability. The observation that complexes showing better resistance to oxidation (higher $E°$ values) are more stable in vitro toward oxidation to perrhenate appears rather obvious and seems to be only one of the factors influencing the in vitro stability.

Much more information comes out from the analysis of steric factors. As pointed out by Tolman (*18*), the thermodynamic stability and kinetic inertness of most transition metal complexes including phosphorus(III) ligands is dominated by steric effects. The Tolman's cone angle θ (*18*, *20*) is the parameter utilized to describe the steric hindrance of these ligands. θ is the interior linear angle of a cone centered 2.28 Å from the center of the P atom and the edges of the cone tangential to the outermost van der Waals radii of the ligand. If we correlate θ with the amount of $^{188}ReO_4^-$ formed (Table 4), it can be seen that the in vitro stability of **Re1**−**Re8** strongly depends on this parameter. In fact, only P(III) ligands with θ values comprised in the 140−145° range afforded stable, sterically tight rhenium-188 compounds. In contrast, complexes including both lipophilic or hydrophilic phosphine ligands with smaller cone angles (**Re1**, **Re2**) were thermodynamically accessible in the sense that they formed in a good yield and could be completely characterized at macroscopic level with cold rhenium from common organic solutions, but were labile and gave rise to complete reoxidation to perrhenate in the presence of water. For **Re2**, it has to be considered that the hydrogen bond in the phosphine's backbone (see Figure 3) may induce a further decrease of the cone angle supporting further its instability in vitro. Analogously, phosphite ligands $P(OEt)_3$ (θ = 109°) and $P(O^iPr)_3$ (θ = 130°) taken from ref 18, which were expected to yield more stable Re '4 + 1' complexes on the basis of electronic considerations, showed high instability with reoxidation to perrhenate in water solutions, either at macroscopic and carrier-free levels. These findings indicate that, despite the thermodynamic stability exhibited by this class of trigonal bipyramidal Re '4 + 1' compounds, the inertness in aqueous solution appeared to be the critical factor to consider for their overall stability.

As sketched in Figure 8, only complexes incorporating a tailored P(III) ligand are able to generate, along with the thiolate sulfurs of the NS_3 ligand, an appropriate hydrophobic core around the rhenium. Only these complexes (i.e. **Re5** or **Re8**) are kinetically inert in aqeous solution. Less encumbering P(III) ligands (smaller θ) produced instead complexes (i.e. **Re1**) amenable to attack for steric reasons, and, analogously, more hydrophilic Re '4 + 1' species (i.e. **Re3**) with a suitable P(III) cone angle were subjected to hydrolysis for solubility reasons. Despite this speculation, the mechanism could be tentatively assigned as associative: the attack of a reactive water-derived species, formed under the influence of radiation, was followed by the release of the P(III) ligand, crumbling of the $Re(NS_3)$ moiety, and reoxidation to perrhenate. Radiation and formation of radicals should be considered for causing instability of rhenium-188 complexes in vitro. The fact that the amount of perrhenate is increasing with increasing activity concentration (see **Re5** in Figure 9) supports our interpretation.

On the opposite side, P(III) ligands with larger cone angles such as the lipophilic triisopropylphosphine (θ = 160°) or the hydrophilic triphenylphosphine-3,3′,3″-trisulfonic acid (θ ~155°) did not form Re '4 + 1' compounds, indicating that overencumbered ligands cannot efficiently reach the $Re(NS_3)$ moiety.

According to the above data, hydrophilicity of the whole complex, which still remained an important goal of this study, had to be introduced by means of suitable functional groups on the periphery of the molecule, either on the monodentate phosphine and/or on the chelate NS_3 framework. The increase of the overall hydrophilicity in '4 + 1'-type compounds has already been demonstrated in analogous Tc complexes (*11*) by insertion of a carboxyl group into the NS_3 chelate. The incorporation of a carboxyl group could also serve for the conjugation of

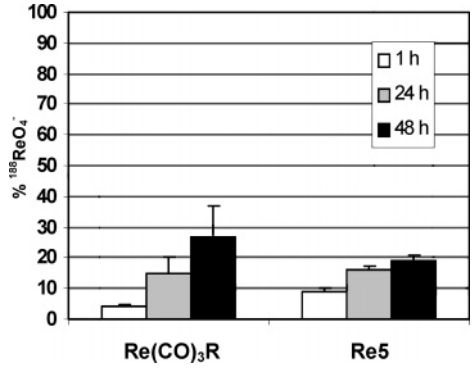

Figure 9. Comparison of in vitro stabilities of $^{188}Re(CO)_3$\{[(di-1*H*-imidazol-2-ylmethyl)amino] acetic acid\} (*4*) and **Re5** after incubation in human plasma at 37 °C.

biomolecules. Such peripheral variation does not affect the in vitro stability of the complexes. For example, **Re7** and **Re8**, carrying a free carboxyl group or an amide group onto the NS_3 backbone exhibited higher hydrophilicity (**Re7** ≫ **Re8** > **Re5**) but comparable in vitro stability than their unsubstituted analogue **Re5**.

Only few and mostly imprecise data on the stability of ^{188}Re complexes are found in the literature. Complexes with mercaptoacetyl triglycine ($^{188}Re(O)MAG_3$) and those of the HYNIC system were found to be unstable in vitro and in vivo by our and other groups (*21*−*23*). Contrarily, some groups found high in vitro and in vivo stability of $^{188}Re(O)MAG_3$ even at high activity concentration (*5*−*7*). Schibli and co-workers reported on the in vitro stability of ^{188}Re-tricarbonyl complexes incorporating different tridentate ligands (*4*), but utilizing higher activity and higher temperature (37 MBq, 37 °C). We compared the in vitro stability of **Re5** under these conditions with that displayed by the most stable tricarbonyl complex having [(di-1*H*-imidazol-2-ylmethyl)amino]-acetic acid as tridentate ligand and found similar in vitro stabilities (Figure 9).

CONCLUSION

A series of Re(III) '4 + 1' complexes, [$ReNS_3$)(PRR′R″)], containing a tetradentate NS_3 chelator and a monodentate phosphorus(III) coligand (tertiary phosphine or phosphite) has been prepared both at macroscopic level with nonradioactive rhenium and at carrier-free level with ^{188}Re. In vitro stabilities of ^{188}Re '4 + 1' complexes in human plasma, rat plasma, and in phosphate buffer depend primarily on the nature of the phosphorus(III) coligand. Several physicochemical parameters of homologous rhenium complexes including Re^{III}/Re^{IV} redox potentials and electronic and NMR spectra, together with scrutiny of the steric hindrance of P(III) ligands, were consequently analyzed in order to rationalize the in vitro behavior. The Tolman's cone angle θ was found to be the crucial factor in the formation of substitution-inert Re(III) '4 + 1' complexes. Only tertiary phosphines and phosphites with cone angles in the range between 140 and 145° gave rise to agents stable in vitro. Obviously, the steric hindrance of these P(III) coligands along with the lipophilic nature of the three coordinated thiolate sulfurs generates a hydrophobic area around the Re(III) center which prevents hydrolysis and reoxidation to perrhenate. Hence, the initial idea to synthesize overall hydrophilic Re '4 + 1' compounds was changed, and, while preserving a lipophilic core in the inner coordination sphere, hydrophilicity was introduced into the periphery of the complex by insertion of carboxylic functions, either at the NS_3 framework and/or at the monodentate phosphine ligand. ^{188}Re '4 + 1' complexes of this formulation were found to be sufficiently stable toward reoxidation in phosphate buffer as well as in rat plasma and human plasma, both at low and high activity levels. Therefore, we consider these agents as promising candidates for the development of ^{188}Re radiotherapeutics.

ACKNOWLEDGMENT

We thank G. Wunderlich (Klinik und Poliklinik für Nuklearmedizin, TU Dresden) for providing a $^{188}W/^{188}Re$ generator and the Deutscher Akademischer Austauschdienst (DAAD) for financial support.

Received November 19, 2004; Revised Manuscript Received February 15, 2005

Two novel N-substituted-3β-phenyltropane alkaloids have been labeled with iodine-125 for use as irreversible probes of dopamine transporter (DAT) binding sites. One contains an iodoaryl azide moiety for photolabeling, while the other bears an iodoaryl isothiocyanate for direct conjugation. Both radioligands were prepared in a one-flask procedure by electrophilic radioiodination of the corresponding aniline under no-carrier-added conditions, followed either by diazotization and treatment with sodium azide, or by addition of thiophosgene under basic conditions. Specifically, (−)-*N*-[4-(3-[^{125}I]iodo-4-azidophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane ([^{125}I]MFZ-2-24) and (−)-*N*-[4-(3-[^{125}I]iodo-4-isothiocyanophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane ([^{125}I]MFZ 3-37) were synthesized. Isolation by reversed-phase HPLC and solid-phase extraction gave good average yields of [^{125}I]MFZ-2-24 (67%, $n = 5$) and [^{125}I]MFZ-3-37 (45%, $n = 3$) with high radiochemical purities (96−99%) and specific radioactivities (>2000 mCi/μmol). The utility of the radioligands was demonstrated by their covalent linkage to rat striatal membranes, and immunoprecipitation of a single radiolabeled band at 80 kDa corresponding to the full-length DAT.

INTRODUCTION

The dopamine transporter (DAT)[1] is an 80 kDa phosphoprotein, thought to have 12 transmembrane domains (TMs), that is regulated by protein kinases, controls synaptic dopamine concentrations, and plays a pivotal role in locomotion (*1*, *2*). Inhibition of dopamine uptake also is recognized as a critical determinant of the reinforcing properties and abuse liability of cocaine and other stimulants (*3*, *4*). Thus, the identification of therapeutic DAT inhibitors that block the actions of stimulant drugs of abuse with minimal disruption of normal dopaminergic function is a topic of current interest (*5*, *6*). In fact, dopamine, cocaine, amphetamine, and other structural classes of DAT ligands bind to recognition sites that seem to be at least partially discrete based upon functional, chimera, and mutagenesis studies.

Accordingly, we have been developing irreversible ligands to assess and differentiate the features of DAT binding domains at the molecular level. These ligands include several radioiodinated photoaffinity probes: [^{125}I]RTI-82 (*7*, *8*), a tropane alkaloid congener of cocaine; [^{125}I]DEEP (*7*,*9*) and [^{125}I]AD-96-129 (*10*) which are based upon GBR12,909; and [^{125}I]GA-2-34 (*11*), a benztropine with key pharmacophores drawn from both of the other structural classes (Figure 1). Studies to date confirm that distinct regions of the DAT primary sequence are labeled covalently depending upon ligand framework. In brief, [^{125}I]RTI-82 becomes incorporated specifically in TMs 4−6, [^{125}I]DEEP and [^{125}I]GA-2-34 preferentially attach to TMs 1−2, and [^{125}I]AD-96-129 labels TMs 1−2 and 4−6 to about the same extent (*12*, *13*). The data for [^{125}I]AD-96-129 suggests that TMs 1−2 and 4−6 should be close together in the three-dimensional structure of the DAT and, by comparison to the results from [^{125}I]DEEP, demonstrates the sensitivity of DAT binding to modest structural modifications (*13*).

Interestingly, [^{125}I]GA-2-34 and [^{125}I]RTI-82 attach covalently to different TMs even though they both have a tropane ring system (*12*). This finding is consistent with work showing that benztropines exhibit potent DAT binding but do not display a behavioral profile like that

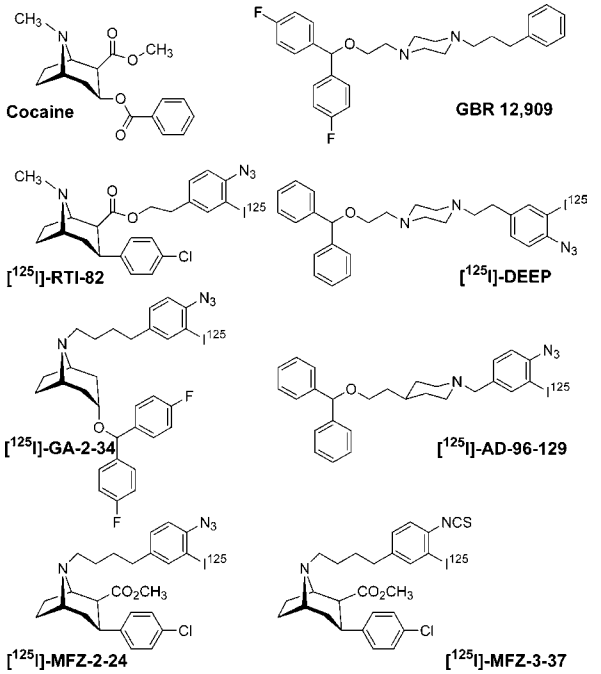

Figure 1. Structures of the cocaine and GBR 12 909 scaffolds, the DAT photoaffinity labels whose sites of incorporation have been identified, and the new irreversible ligands, [^{125}I]MFZ-2-24 and [^{125}I]MFZ-3-37.

of cocaine (*14*, *15*) and comparative molecular field analyses indicating different DAT binding requirements for benztropines and cocaine (*16*, *17*). As discussed by Zou et al. (*18*), [^{125}I]GA-2-34 and [^{125}I]RTI-82 might bind to discrete DAT recognition sites or might bind to the same site but covalently label different domains because of differing spatial orientations of the aryl azide substituents (cf. Figure 1). Therefore, a complementary RTI-82 analogue, MFZ-2-24, was prepared where the *N*-methyl was replaced by a butyl linker to an aryl azide moiety as found in GA-2-34. Nonradioactive MFZ-2-24 displayed high, reversible binding affinity (IC_{50} 33 nM vs [3H]-WIN35,428) for the human DAT expressed in mammalian cell line HEK 293 and the structurally related isothiocyanate, MFZ-3-37, covalently bound to human DAT in washout experiments (*18*). In the present study, we report the synthesis of [^{125}I]MFZ-2-24, MFZ-3-37, and [^{125}I]MFZ-3-37 (Figure 1). We also demonstrate, by photoaffinity and direct labeling of rat striatal DAT, their potential as tools for molecular characterization of DAT binding domains.

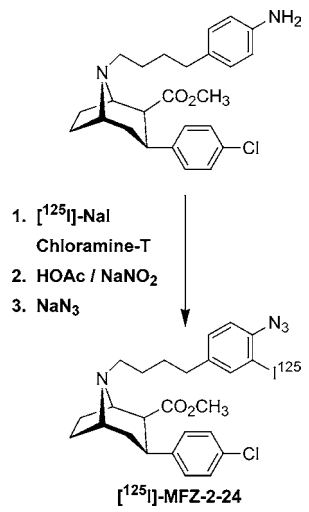
EXPERIMENTAL PROCEDURES

General. Fully characterized, nonradioactive samples of tropane alkaloids were prepared as previously described (*18*). Other chemicals and solvents were the best grade available and were used as received from commercial sources. No-carrier-added [^{125}I]NaI was obtained from Amersham Corp. (1 mCi/10 μL; NaOH solution, pH 8−12). HPLC equipment consisted of a Rheodyne 7125 injector, Waters 510EF pumps, Waters 490 UV absorbance detector (λ 254 nm), a flow-through NaI(Tl) crystal scintillation detector comprised of EG&G Ortec components, Shimadzu CR-3A integrating recorders, and a Rainan Dynamax system for digital recording. Waters C-18 Nova-Pak columns, protected by matching guard columns, were used for preparative and analytical HPLC. Activated Waters SEP−PAK Light *t*-C-18 cartridges were employed for solid-phase extraction. Radioactivity was measured with a radioisotope dose calibrator (Capintec CRC-15W) using similar counting geometries or correction factors for each reading. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC-300 instrument. Proton chemical shifts are reported as parts per million (δ) relative to internal tetramethylsilane (δ = 0.00 ppm). Carbon chemical shifts are reported as parts per million (δ) relative to deuterated chloroform (δ = 77.0 ppm). Infrared spectra were recorded as a neat film on NaCl plates using a Perkin-Elmer 1600 FTIR spectrometer. Microanalyses were performed by Atlantic Microlab, Inc. (Norcross, GA) and agree within 0.4% of calculated values.

(−)-*N*-[4-(3′-Iodo-4′-isothiocyanophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane (MFZ-3-37). (−)-*N*-[4-(3′-Iodo-4′-aminophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane (*18*) (0.24 g, 0.43 mmol) was dissolved in a biphasic mixture of $CHCl_3$ (25 mL) and water (10 mL) containing $NaHCO_3$ (0.16 g). The mixture was cooled to 0 °C, and freshly distilled thiophosgene (0.56 mmol, 1.3 equiv) was added with vigorous stirring. After 3 h, the reaction was brought to ambient temperature, the layers were separated, and the aqueous phase was extracted with $CHCl_3$ (3 × 10 mL). The combined organic extracts were dried (K_2CO_3) and concentrated in vacuo. The residue was purified by flash column chromatography ($CHCl_3$/MeOH/NH_4OH; 98:2:1) to afford 0.22 g (84%) of product that was converted to the salt with methanolic HCl. $[\alpha]^{25}_D$ −22.7 (*c* 1.1, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ 7.60 (s, 1H), 7.26−7.10 (m, 6H), 3.68 (m, 1H), 3.46 (s, 3H), 3.35 (m, 1H), 3.00−2.82 (m, 2H), 2.60−2.50 (m, 3H), 2.27−1.95 (m, 4H), 1.78−1.55 (m, 5H), 1.37 (m, 2H); ^{13}C NMR ($CDCl_3$) δ 26.0, 28.8, 34.2, 34.5, 35.3, 51.4, 523.2, 53.6, 61.8, 63.2, 94.4, 127.0, 128.4, 129.1, 129.7, 131.8, 132.9, 139.6, 142.2, 144.2, 172.2; IR (neat): 2076 (br, s), 1744.7(s) cm^{-1}; Anal. ($C_{26}H_{28}N_2O_2$-ClIS·HCl·2H_2O) C, H, N.

(−)-*N*-[4-(3′-[^{125}I]Iodo-4′-azidophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane ([^{125}I]MFZ-2−24). In a representative procedure, (−)-*N*-[4-(4′-aminophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane (*18*) (50 μL, 3.0 mM) in NaOAc buffer (pH 4.0; 0.3 M) containing MeOH (33%, *v*/*v*) was added to a glass vial and sealed with a Teflon-faced septum. [^{125}I]NaI (20 μL, 2.09 mCi; ca. 1.0 nmol) was added, followed by aqueous *N*-chloro-4-toluenesulfonamide (Chloramine-T) trihydrate (10 μL, 3.5 mM). The mixture was incubated for 30 min at ambient temperature, chilled in an ice/methanol bath, and then diluted with cold HOAc (50 μL, 3.0 M) followed by cold $NaNO_2$ (25 μL, 0.5 M). After 15 min at −10 °C, NaN_3 (25 μL, 0.5 M) was added, and the mixture was allowed to warm to ambient temperature and stand for 15 min before a $Na_2S_2O_5$ (5 μL, 50 mM) quench. The contents were withdrawn by syringe, and combined with MeOH (2 × 100 μL) rinses of the reaction vessel for HPLC purification using a C-18 column (Waters Nova-Pak, radial compression module, 8 × 100 mm, 6 μm). Using a mobile phase of MeOH (21%), CH_3CN (21%), and a water (58%) solution containing Et_3N (2.1% *v*/*v*) and HOAc (2.8% *v*/*v*) at a flow rate of 5 mL/min, [^{125}I]MFZ-2-24 eluted with a retention time (t_R = 34.3 min, k' = 56) corresponding to nonradioactive MFZ-2-24 and was resolved from radioactive and nonradioactive side products. The radioligand was collected in a 22.5 mL volume, diluted to 50 mL with distilled water, and passed through an activated solid-phase extraction cartridge that was flushed with water (2.5 mL), to remove salts, and then with air. Elution of the cartridge with MeOH (1.1 mL) provided 1.49 mCi (71%) of [^{125}I]MFZ-2-24. Analytical

Scheme 1. Synthesis of [^{125}I]MFZ-2-24



HPLC of 0.20 mCi aliquots, taken from the HPLC mobile phase after the preparative collection, used the same HPLC column with a mobile phase of MeOH (30%), CH_3CN (30%) and the aqueous mixture (40%) at 4 mL/min. [^{125}I]MFZ-2-24 ($t_R = 5.1$ min, $k' = 12$) had no radiochemical impurities, and specific radioactivities up to 2104 mCi/μmol were calculated based upon comparisons with standard samples. The relation of mass to the HPLC UV response was validated by a six-point linear curve ($r^2 = 0.99$) for nonradioactive MFZ-2-24 that bracketed the region of interest (0.036−1.8 nmol). Only minor decomposition (ca. 5%) was noted after storage at −20 °C in the dark for 19 weeks.

(−)-*N*-[4-(3′-[^{125}I]Iodo-4′-isothiocyanophenyl)butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane ([^{125}I]-MFZ-3-37). As described above, *N*-[4-(4′-aminophenyl)-butyl]-2β-carbomethoxy-3β-(4-chlorophenyl)tropane (50 μL, 3.0 mM) was treated with [^{125}I]NaI (25 μL, 2.81 mCi) and Chloramine-T trihydrate (10 μL, 7.0 mM) for 30 min at ambient temperature and then chilled in an ice/methanol bath. The mixture was made basic with $NaHCO_3$ (50 μL, 0.5 M), and thiophosgene (1.14 μL, 15 μmol) in $CHCl_3$ (50 μL) was added. After vortex mixing, the vessel was incubated at −20 °C for 120 h in a freezer and then warmed to ambient temperature. A homogeneous solution was obtained by adding 1.0 mL of the mobile phase to be used for HPLC: MeOH (25%), CH_3CN (25%), and a water (50%) solution containing Et_3N (2.1% *v*/*v*) and HOAc (2.8% *v*/*v*). Using a flow rate of 8 mL/min and a semipreparative C-18 column (Waters Nova-Pak, 7.8 mm × 30 cm, 6 μm), [^{125}I]MFZ-3-37 eluted with an appropriate retention time ($t_R = 53.8$ min, $k' = 52$), and was resolved from radioactive and nonradioactive side products. The radioligand (1.90 mCi) was collected in a 40 mL volume, diluted to 133 mL with distilled water, and passed through an activated solid-phase extraction cartridge that was flushed with water (2.5 mL), and then with air. Elution of the cartridge with MeOH (1.5 mL) provided 1.53 mCi (54%) of [^{125}I]MFZ-3-37. Analytical HPLC (Waters Nova-Pak, radial compression module, 8 × 100 mm, 6 μm) using a mobile phase of MeOH (30%), CH_3CN (30%), and a water (40%) solution containing Et_3N (2.1% *v*/*v*) and HOAc (2.8% *v*/*v*) at a flow rate of 4 mL/min showed a high degree of chemical and radiochemical purity (>96%) for the radioligand ($t_R = 10.6$ min, $k' = 26$). The specific radioactivity was estimated as 2000 mCi/μmol based upon comparisons with standard samples of nonradioactive material. The MeOH was removed by evaporation under a stream of argon at 45 °C, and replaced with CH_3CN.

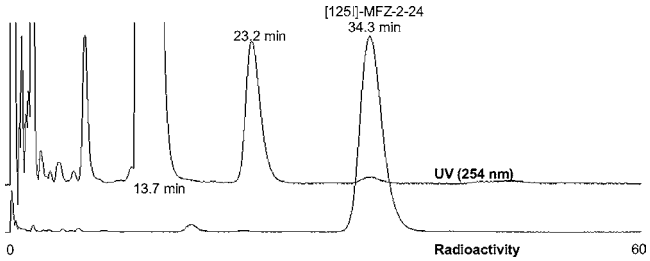


Figure 2. HPLC chromatogram for isolation of [^{125}I]MFZ-2-24.

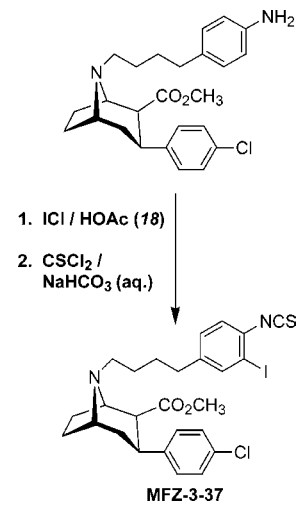
Covalent Labeling and Immunoprecipitation of DAT. Covalent labeling and immunoprecipitation of DAT with [^{125}I]MFZ-2-24 and [^{125}I]MFZ-3-37 were performed, with minor modifications, as previously described for other irreversible labels (*12*, *13*). Briefly, male Sprague Dawley rats were decapitated, and striatal tissue was removed from the brain, weighed, and homogenized (Polytron) in sucrose-phosphate (SP) buffer (10 mM sodium phosphate, 0.32 M sucrose; pH 7.4). Homogenates were centrifuged (20 000*g*, 12 min; 4 °C), and the pellet was washed twice and resuspended to 20 mg/mL, original wet weight, in ice-cold SP buffer. Radioligands were added to the membrane suspension at a final concentration of 5 nM, and then incubated for 2 h at 0 °C. Aryl azide [^{125}I]MFZ-2-24 was covalently attached to DAT by irradiating the sample with ultraviolet light for 45 s. This step was omitted for the isothiocyanate [^{125}I]MFZ-3-37. Membranes were washed twice with SP buffer, and the final pellet was resuspended to 20 mg/mL in sample buffer (50 mM Tris-HCl, pH 6.8, containing 2% sodium dodecyl sulfate (SDS), 0.60 M dithiothreitol (DTT), 30% glycerol, and 0.001% bromphenol blue) for immunoprecipitation and electrophoresis. DTT and other reducing agents were omitted from samples labeled with [^{125}I]-MFZ-3-37. The solubilized DATs were immunoprecipitated with antiserum 16 as previously described in detail (*12*, *13*). Total binding and immunoprecipitated samples were subjected to electrophoresis on a 10% SDS-polyacrylamide gel, followed by autoradiography using Hyperfilm MP film for 1 to 4 days at −80 °C. Animals were housed and cared for in accordance with guidelines established by the Institutional Animal Care and Use Committees, and the National Institutes of Health.

RESULTS AND DISCUSSION

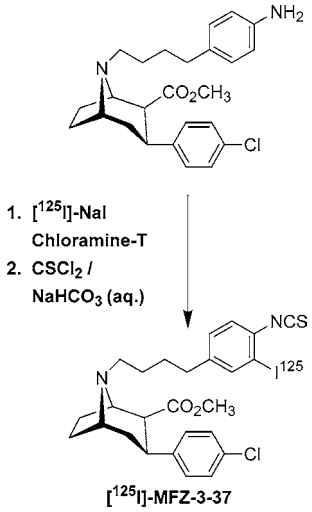
The radiosynthesis of [^{125}I]MFZ-2-24 proved straightforward (Scheme 1). We followed the three-step, one-flask methodology developed by Wilson (*9*) for production of [^{125}I]DEEP that has been applied successfully to several radioiodinated photoaffinity labels for the DAT (*8*, *10*, *11*). In brief, electrophilic radioiodination of the aniline (*18*) was accomplished by treatment with [^{125}I]NaI under no-carrier-added conditions at ambient temperature for 30 min using chloramine-T as oxidant at pH 4. The incorporation of radioiodine was >90%. Acidification with HOAc, followed by treatment with $NaNO_2$ at −10 °C, formed the diazonium salt in situ. A solution of NaN_3 was added and the mixture warmed to ambient temperature to liberate the aryl cation. Trapping of this reactive intermediate by azide concluded the sequence.

One major radioiodinated product was formed that displayed a chromatographic profile on reversed-phase, ion-pair HPLC ($t_R = 34.3$ min, $k' = 56$; Figure 2) that was identical to that of a characterized sample of

Scheme 2. Synthesis of MFZ-3−37



Scheme 3. Synthesis of [^{125}I]MFZ-3-37



nonradioactive MFZ-2-24 prepared as previously described (*18*). Conditions for purification on an analytical column were chosen so the [^{125}I]MFZ-2-24 was resolved fully from radioactive and nonradioactive side products. The major nonradioactive materials were assigned as the corresponding azide (t_R = 13.7 min, k' = 22) and chloroazide (t_R = 23.2 min, k' = 38) taking into consideration the synthetic route, relative HPLC retention profiles and data from previous studies (*8*, *9*). Model reactions conducted without radioiodine showed that the putative azide was the sole product in the absence of chloramine-T, and that the proportion of the putative chloroazide grew with increasing amounts of chloramine-T. The amount of chlorination is relatively small and is a common side reaction when *N*-chloroamine oxidants are used for radioiodinations (*19*).

Over a series of runs, isolated yields of [^{125}I]MFZ-2-24 ranged from 58 to 73%, and averaged 67% (n = 5). Specific radioactivities were near the theoretical value (2175 mCi/μmol) for the radioiodine employed. Calculations were based upon comparisons of HPLC UV absorbance peak areas for aliquots of [^{125}I]MFZ-2-24 having known radioactivity to that of standards of nonradioactive material. The [^{125}I]MFZ-2-24 was radiochemically pure by HPLC, and found to be stable in buffered methanol during prolonged storage (>2 half-lives) at −20 °C in the dark.

To expand the scope of possible DAT labeling experiments, we also chose a radioiodinated isothiocyanate as a target ligand. A tropane-based isothiocyanate with appropriate properties would not require photoactivation for irreversible DAT binding and would covalently label nucleophilic amino acid residues in close proximity to the binding site(s). As shown in Scheme 2, we prepared MFZ-3-37, the isothiocyanate congener of MFZ-2-24, by treatment of the known iodoaniline (*18*) with thiophosgene in a biphasic mixture of $CHCl_3$ and aqueous $NaHCO_3$. Extractive work up, followed by column chromatography and formation of the HCl salt, gave MFZ-3-37 in 84% yield.

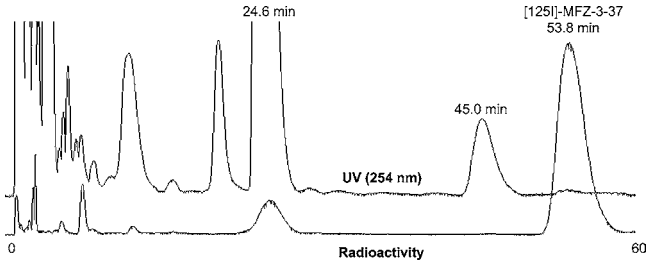


Figure 3. HPLC chromatogram for isolation of [^{125}I]MFZ-3-37.

Despite the high yields often noted for this transformation on a macroscopic scale, yields at the no-carrier-added level can be quite low, and there are relatively few examples of radiolabeled isothiocyanates. For instance, de Costa and colleagues obtained only a 13% yield for conversion of a tritiated aniline to an isothiocyanate for irreversible radiolabeling of kappa-opioid receptors (*20*). Moreover, isothiocyanate and thiourea functionalities are known to interfere with various radiohalogenation techniques (*21*). Even with a highly activated substrate, *p*-methoxyphenyl isothiocyanate, carefully optimized yields for chloramine-T-promoted radioiodination were only 15−20%, and the reaction required ultrasonication for 2 h (*22*). Nonetheless, the radioiodinated *p*-methoxyphenyl isothiocyanate developed by Dewanjee et al. proved useful for conjugation with oligonucleotides (*22*). Thus, there are certain general constraints on the preparation of radiolabeled isothiocyanates. However, our present case logically calls for simple radioiodination of an activated aromatic system as the first step, and we further planned to minimize synthetic manipulations over the two-step process to reduce mechanical losses. In practice, we developed a one-flask method where electrophilic radioiodination (vide supra) of the anilino precursor was followed by basification of the chilled reaction mixture with aqueous $NaHCO_3$ and treatment with a solution of thiophosgene in $CHCl_3$ at −20 °C for 120 h (Scheme 3).

After warming to room temperature, the biphasic mixture was made homogeneous by adding the mobile phase to be used for semipreparative, reversed-phase HPLC. The major radioactive material, assigned as [^{125}I]-MFZ-3-37, eluted with an appropriate retention time (t_R = 53.8 min, k' = 52) and was resolved from radioactive and nonradioactive side products (Figure 3). The two major nonradioactive materials observed are likely to be the isothiocyanate (t_R = 24.6 min, k' = 23) and the chlorinated isothiocyanate (t_R = 45.0 min, k' = 43) (vide supra). The radioligand was isolated in up to 54% yield with high specific radioactivity and >96% radiochemical purity. The average yield for three runs was 45%; thus, sufficient [^{125}I]MFZ-3-37 is available for various DAT studies. An aprotic solvent, acetonitrile, was used for extended storage to minimize potential hydrolysis.

With radioligands in hand, we turned our attention to a set of experiments designed to demonstrate covalent

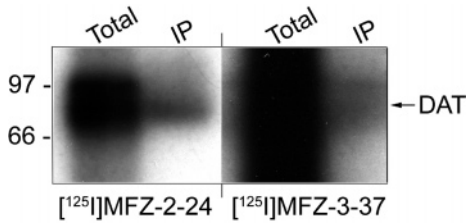

Figure 4. Irreversible labeling of rat striatal DAT with [^{125}I]-MFZ-2-24 and [^{125}I]MFZ-3-37. Membranes were incubated with the indicated compounds and irradiated in the case of [^{125}I]MFZ-2-24. The solubilized proteins were subjected to electrophoresis directly (Total) or immunoprecipitated (IP) with serum 16, followed by autoradiography. The arrow indicates the migration of the DAT at about 80 kDa based upon molecular mass standards.

radiolabeling of rat striatal DAT. Incubation of membranes with either [^{125}I]MFZ-2-24 followed by ultraviolet irradiation, or with [^{125}I]MFZ-3-37 treatment alone, resulted in incorporation of the radioligands into membrane proteins (Figure 4). Levels of total binding similar to that displayed by the aryl azide, [^{125}I]MFZ-2-24, are routinely found for other DAT photoaffinity labels (*7*, *11*−*13*). Much higher levels of total binding, involving numerous proteins, were noted for [^{125}I]MFZ-3-37. This result is in accord with the more indiscriminate nature of covalent labeling of an isothiocyanate to various biological nucleophiles.

For both radioligands, immunoprecipitation of the solubilized membranes with an antibody, serum 16, that is highly specific for amino acids 42 to 59 in the N-terminal DAT tail (*23*, *24*) resulted in the extraction of a single radioactive band. This band migrates at about 80 kDa, a molecular mass appropriate for the full-length rat striatal DAT. Other studies using a nonimmunogenic serum (*24*) that does not precipitate the radiolabeled DAT band, as well as pharmacology studies using specific peptide blockers, are consistent with the identity of the radiolabeled protein as the DAT (data not shown). Together, the results demonstrate that both [^{125}I]MFZ-2-24 and [^{125}I]MFZ-3-37 become attached covalently to the DAT and can be used as tools to help elucidate DAT binding domains. In fact, recent trypsin proteolysis and detailed epitope-specific immunoprecipitation studies show that [^{125}I]MFZ-2-24 is complementary to [^{125}I]RTI-82 and primarily labels N-terminal TMs 1−2 accompanied by only a small fraction, <5%, of covalent labeling of TMs 4−6 of rat striatal DAT (*25*, *26*). [^{125}I]MFZ-2-24 also labels the human DAT stably expressed by HEK 293 cells, and HPLC and mass spectrometry studies are underway in an effort to identify the specific amino acid residues that are photolabeled (*26*, *27*).

Adenosine 2′-Monophosphate, 5′-*O*-[*S*-(4-Succinimidylbenzophenone)-thiophosphate]: A New Photoaffinity Label for the Coenzyme Site of Porcine NADP-Specific Isocitrate Dehydrogenase

Peychii Lee and Roberta F. Colman*

Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716.
Received November 19, 2004; Revised Manuscript Received February 16, 2005

A new photoaffinity label, adenosine 2′-monophosphate, 5′-*O*-[*S*-(4-succinimidyl-benzophenone)-thiophosphate] (2′-P-AMPS-Succ-BP), has been synthesized by an initial thiophosphorylation of 2′-AMP with $PSCl_3$ to form 2′-AMP-5′-thiophosphate (2′-AMP-5′-SP), followed by a coupling reaction of 2′-AMP-5′-SP with benzophenone-4-maleimide to produce 2′-P-AMPS-Succ-BP. This product and its precursor were characterized by thin-layer chromatography, ^{31}P NMR, phosphorus analysis, and electron-spray mass spectroscopy. 2′-P-AMPS-Succ-BP functions as a photoaffinity label of porcine NADP-specific isocitrate dehydrogenase. To obtain reaction with other amino acids, Cys269 and Cys379, the most reactive cysteines of this enzyme, were mutated to yield a double mutant enzyme (C269A/C379S) exhibiting comparable activity and kinetic parameters to those of wild-type enzyme. 2′-P-AMPS-Succ-BP inactivates C269A/C379S enzyme upon UV irradiation. The reaction exhibits a nonlinear relationship of k_{inact} versus [2′-P-AMPS-Succ-BP] with $K_R = 12\ \mu M$ and $k_{max} = 0.0275\ min^{-1}$. NADP, NADPH, or 2′-monophospho-adenosine 5′-diphosphoribose protects the enzyme against 2′-P-AMPS-Succ-BP inactivation. The ligand protection studies suggest that 2′-P-AMPS-Succ-BP binds to the porcine enzyme at the site best occupied by NADP/NADPH. The dimeric C269A/C379S isocitrate dehydrogenase incorporates 1.0 mol of 2′-P-[^{35}S]AMPS-Succ-BP/mol enzyme dimer concomitant with *complete* loss of enzyme activity. The new photoaffinity label may be generally useful to identify important amino acid residues of NADP-specific enzymes.

INTRODUCTION

Locating enzyme active sites is critical in understanding the relationship between enzymes' structures and their functions and in designing potential drug candidates. Recent advances in bioinformatics provide tools such as sequence homology analysis and protein structure prediction to identify critical amino acids involved in enzyme functions. However, these computational predictions may not be effective in comparing enzymes isolated from distant sources (such as prokaryotes vs eukaryotes). Affinity labels are reagents which are structurally similar to enzyme ligands but contain a reactive functional group (*1*). The affinity label initially forms a reversible enzyme−reagent complex which mimics the enzyme−ligand complex. Subsequently, the reactive functional group of the affinity label forms a covalent bond with the side chain of an adjacent amino acid. Unlike X-ray crystallography which determines enzyme structure in crystalline state, affinity labeling is conducted in solution, where enzymatic catalysis occurs in nature. On the basis of their chemical structures, NAD(P) affinity labels can be categorized into three groups: analogues based on the entire nicotinamide adenine dinucleotide structure, on the nicotinamide mononucleotide moiety alone, or on the adenine nucleotide fragment of the coenzyme (*2*). 8-(4-Bromo-2,3-dioxobutylthio)NAD (8-BDB-TNAD),[1] periodate-oxidized NADPH, and 2-azido-NAD are compounds that belong to the first group. 8-BDB-TNAD, synthesized previously in this laboratory, contains a bromodioxobutyl group that can react with nucleophilic side chains of lysine, tyrosine, cysteine, glutamate, aspartate, histidine, methionine, and arginine (*3*). The compound 5′-*p*-(fluorosulfonyl)benzoyl-8-azidoadenosine (5′-FSBAzA), a bifunctional affinity label with a structure similar to adenosine, is capable of interacting with amino acids through its sulfonyl group or photoreactive azido group (*4*).

Here, we report the synthesis of a new photoaffinity labeling reagent, adenosine 2′-monophosphate, 5′-*O*-[*S*-(4-succinimidyl-benzophenone)thiophosphate] (2′-P-AMPS-Succ-BP), which is structurally similar to NADP, as shown in Figure 1. 2′-P-AMPS-Succ-BP contains the same adenosine 2′-monophosphate moiety as in NADP and thus should be effective for NADP-specific (in contrast to NAD-specific) dehydrogenases. When compared with the extended form of NADP, the 5′-thiophos-

phoryl group and one of the carbonyls of the succinimidyl ring of 2′-P-AMPS-Succ-BP occupies the same position as the α- and β-phosphoryl groups of NADP, respectively. One of the phenyl rings of the affinity compound is located in the vicinity of the nicotinamide ribose, and the second phenyl group may correspond to or be close to the position of the nicotinamide of NADP. The phenyl rings of 2′-P-AMPS-Succ-BP can interact with amino acids of the enzyme through hydrophobic interaction or an aromatic ring stacking interaction (*5*). The carbonyl group of benzophenone can covalently react with a C−H side chain of any amino acid near the functional group (*6*). In contrast to affinity labels with 4-bromo-2,3-dioxobutyl functional groups, which react only with nucleophilic amino acids, the new affinity label can react photochemically with the side chain of any amino acid that is located near its carbonyl group. We have previously used photoaffinity labels with benzophenone groups, such as glutathionyl *S*-[4-(succinimidyl)benzophenone (GS-Succ-BP) to identify catalytically important methionine residues in rat liver glutathione S-transferase (*7*) and adenosine 5′-*O*-[*S*-(4-succinimidyl-benzophenone)thiophosphate] (AMPS-Succ-BP) to reveal a critical arginine residue at the allosteric ADP site of bovine liver glutamate dehydrogenase (*5*).

Isocitrate dehydrogenase catalyzes the oxidative decarboxylation of isocitrate to α-ketoglutarate. The proposed catalytic mechanism of isocitrate dehydrogenase involves an initial oxidation of isocitrate to oxalosuccinate by the removal of a proton from the C-2 hydroxyl of isocitrate, followed by the transfer of a C-2 hydride to the nicotinamide ring of NADP. In the second step of the reaction, the β-carboxylate of oxalosuccinate is released as CO_2, which is followed by a protonation of its β-carbon to form α-ketoglutarate (*8, 9*). NADP-specific porcine heart mitochondrial isocitrate dehydrogenase (EC1.1.1.42) is a homodimer. Each monomer is composed of 413 amino acids with a subunit molecular weight of 46 600 Da (*10*−*12*).

The X-ray crystal structure of porcine mitochondrial NADP-dependent isocitrate dehydrogenase, complexed with the substrates isocitrate and Mn^{2+}, has been solved at a resolution of 1.85 Å (*13, 14*). However, since the enzyme was not crystallized with coenzyme, there is little direct information regarding the coenzyme site of this porcine enzyme. Here, we describe the specific covalent reaction of 2′-P-AMPS-Succ-BP with porcine isocitrate dehydrogenase in the region of the active site best occupied by the coenzymes NADP/NADPH.

EXPERIMENTAL PROCEDURES

Materials. Yeast adenosine 2′-monophosphate (free acid), 4-(*N*-maleimido)benzophenone, triethanolamine hydrochloride, NADP, Sephadex G-50, ampicillin, trimethyl phosphate, thiophosphoryl chloride, trifluoroacetic acid, and isobutyric acid were purchased from Sigma-Aldrich Chemical Corporation. Triethylamine, sodium sulfate, manganous sulfate, maltose, acrylamide/bisacrylamide mixture, glycine, acetonitrile, DNA grade agarose, sodium acetate, barium acetate, ethanol, EDTA, boric acid, Tris, ethidium bromide, IPTG, tryptone, yeast extract, and agar were from Fisher Scientific. AG 50W−X4 cation-exchange resin, concentrated Protein Dye Reagent, Coomassie blue, and TEMED were from Bio-Rad Laboratories. DL-Isocitrate was obtained from USB. Deuterium oxide was from Cambridge Isotope Laboratories, Inc. QIA prep spin miniprep kit and QIAquick gel extraction kit were purchased from Qiagen. Amylose resin, *Escherichia coli* TB1 cells, Vent DNA polymerase, T4 DNA ligase, BamHI, and BlpI were obtained from New England Biolabs. Matrex Gel Red A resin and Amicon YM-10 filtration membrane were from Millipore. SDS−PAGE low molecular weight markers were purchased from Pharmacia Biotech. [^{35}S]Sulfur in toluene was obtained from Amersham Pharmacia Biotech. DEAE-cellulose anion-exchange resin (DE52) was from Whatman. Human plasma thrombin was from Enzyme Research Laboratories. QuikChange XL site-directed mutagenesis kit was purchased from Stratagene. Oligonucleotides for site-directed mutagenesis and sequencing were purchased from Biosynthesis Incorporated.

Synthesis of Adenosine 2′-Monophosphate, 5′-Thiophosphate. Adenosine 2′-monophosphate, 5′-thiophophate (2′-AMP-5′-SP) was synthesized by thiophosphorylation of the 5′-hydroxyl group of adenosine 2′-monophosphate with thiophosphoryl chloride. The free acid of adenosine 2′-monophosphate (2′-AMP; 0.24 mmol) was dissolved in 3.2 mL of trimethyl phosphate, and the pH of the solution was adjusted to 5.0 with triethylamine. Thiophosphoryl chloride ($PSCl_3$, 2.4 mmol) was gradually added to the reaction mixture. Periodically, the pH of the reaction mixture was checked by pH paper and readjusted to 5.0 by addition of triethylamine. 2′-AMP was completely dissolved in 15 min. The reaction was allowed to proceed at room temperature for 3 h. At the end of the reaction, thiophosphorylated 2′-AMP was converted to its barium salt by adding 1 mL of 0.4 M barium acetate per 0.4 mL of reaction mixture, followed by the addition of 4 mL of ethanol containing 200 μL of triethylamine (*15*). The precipitate was washed once with 4 mL of 70% ethanol and dried overnight. Barium was removed from the thiophosphorylated 2′-AMP precipitate by a method described previously (*16*). Briefly, the barium salts of thiophosphorylated 2′-AMP were dissolved in 4 mL of 1 M acetic acid. Concentrated sulfuric acid was added to the solution to convert barium to barium sulfate precipitate and this salt was separated by centrifugation from the thiophosphorylated 2′-AMP. The pH of the supernatant was adjusted to 8.0 with concentrated ammonium hydroxide. The supernatant was diluted 100-fold with distilled water and applied to a DE52 column (1.5 cm × 50 cm), which had previously been equilibrated with 10 mM NH_4HCO_3, pH 8.0. 2′-AMP-5′-SP was separated from other thiophosphorylation byproducts by a linear gradient formed by 350 mL of 10 mM NH_4HCO_3, pH 8.0 and 350 mL of 0.5 M NH_4HCO_3, pH 8.0. Gradient separation was monitored both by absorbance at 260 nm and thin-layer chromatography (TLC). Samples from fractions and a standard 2′-AMP solution were applied to a Kodak polyester TLC plate coated with cellulose containing fluorescent indicator. The mobile phase for TLC separation was isobutyric acid/H_2O/NH_4OH (66/33/1). 2′-AMP-5′-SP was eluted by the NH_4HCO_3 gradient from the DE52 column as the last of the three peaks. Fractions containing adenosine 2′-AMP-5′-SP were pooled and dried using a rotary evaporator. The 2′-AMP-5′-SP was dissolved in 5 mL of 1 M acetic acid, applied to an AG 50W X-4 column (H^+ form, 1 cm × 40 cm), and eluted with

distilled H_2O. The fractions with high absorbance at 260 nm were collected and dried using a rotary evaporator.

Synthesis of Adenosine 2′-Monophosphate, 5′-*O*-[*S*-(4-Succinimidyl-benzophenone)thiophosphate]. Adenosine 2′-monophosphate, 5′-*O*-[*S*-(4-succinimidyl-benzophenone)thiophosphate] (2′-P-AMPS-Succ-BP) was synthesized by a method similar to that described previously for adenosine 5′-*O*-[*S*-(4-succinimidyl-benzophenone)thiophosphate] (AMPS-Succ-BP) which lacks the 2′-phosphate (*5*). 2′-AMP-5′-SP (10 μmol) was dissolved in 0.4 mL of distilled H_2O, and the pH of the solution was adjusted to 5.0 with triethylamine. The 2′-AMP-5′-SP solution was gradually added to benzophenone-4-maleimide (BP-MAL, 11 μmol), which had been dissolved in 0.6 mL of acetonitrile. The coupling reaction was allowed to proceed at room temperature in an aluminum foil-covered vial with constant stirring for 5 h. The reaction mixture was lyophilized, redissolved in 1 mL of distilled H_2O, and centrifuged to remove any insoluble BP-MAL. The supernatant was subjected to reversed-phase high-performance liquid chromatography (HPLC) purification. The chromatography was conducted using a Varian model 5000 system equipped with a Vydac C_{18} column (0.46 × 25 cm). The column was equilibrated with H_2O (solvent A) at a flow rate of 1 mL/min. After the sample injection, the column was further washed with H_2O for 30 min to remove unreacted 2′-AMP-5′-SP, followed by a linear gradient from 0 to 40% acetonitrile (solvent B) for 80 min, and finally a linear gradient from 40 to 90% solvent B for 50 min. Fractions containing 2′-P-AMPS-Succ-BP (eluted from the HPLC column at 10−15% acetonitrile) were pooled, lyophilized, and dissolved in a small volume of 10 mM triethanolamine hydrochloride, pH 7.4 buffer for storage at −80°C.

Synthesis of Radioactive 2′-P-[^{35}S]AMPS-Succ-BP. Radioactive sulfur was introduced into thiophosphoryl chloride ($PSCl_3$) by a modification of the method of Slama et al. (*17*). Briefly, 2.5 mCi of [^{35}S]sulfur in toluene was pipetted into a glass vial with a Teflon screw cap and dried using argon gas. $PSCl_3$ (50 μL, 0.49 mmol) was added to the dried [^{35}S]sulfur, and the mixture was sealed and heated at 110 °C in a sand bath for 48 h. A 1.91 mmol (195 μL) amount of nonradioactive $PSCl_3$ was added to the reaction mixture, and the synthesis of radioactive 2′-P-AMPS-Succ-BP was carried out using the same procedures described above for the nonradioactive 2′-P-AMPS-Succ-BP.

Phosphorus Analysis. The organic phosphorus content of 2′-P-AMPS-Succ-BP was determined chemically by the method described previously (*18*). Briefly, 100 μL phosphorus standard solutions, ranging from 2 nmol to 20 nmol, or 100 μL 2′-P-AMPS-Succ-BP samples, were first hydrolyzed by 20 μL of 10 N H_2SO_4 at 190 °C for 2 h. After 2 h of hydrolysis, 50 μL of 30% H_2O_2 was added to the sample and incubated at 190 °C for 1 h. The hydrolyzed samples were mixed with 800 μL freshly prepared malachite green and ammonium molybdate solution, and the absorbance at 600 nm was measured using a Bio-Rad titer plate reader.

Site-Directed Mutagenesis of Porcine Isocitrate Dehydrogenase. It is known that porcine mitochondrial NADP-specific isocitrate dehydrogenase has reactive cysteines (*8*). To facilitate reaction of 2′-P-AMPS-Succ-BP with other amino acids, the reactive cysteines were replaced by the non reactive alanine or serine. Site-directed mutagenesis to obtain mutants C74A, C115A, C269A, and C379S was performed by a two-stage PCR megaprimer method as described previously (*19, 20*). The oligonucleotides used for site-directed mutagenesis were C74A forward primer: 5′-GTGGCTGTCAAGGCGGC-CACCATCACC-3′, C115A reverse primer: 5′-GTGG-GATGTTCTTCGCGATGATGGGC-3′, C269A forward primer: 5′-CGTGTGGGCCGCGAAGAACTACGATG-3′, and C379S forward primer: 5′-ACCTGGCGGGCTCTAT CCATGGCCT-3′, where the mutated sequences are underlined. The BlpI forward primer sequence is 5′-GGC-GTGCTGAGCGCAGGTATTAACGCCGCCAGTCCG-3′ and the BamHI reverse primer sequence is 5′-CTAGAGGATCCTTACTACTGCCGGCCCAGAG-CTCTGTC-3′. C269A/C379S double mutant was generated using a QuikChange XL site-directed mutagenesis kit. Plasmid isolated from the C379S mutant was used as the DNA template for a PCR reaction. A pair of complementary primers, C269A forward primer (sequence as shown above) and C269A reverse primer: 5′-CGTAG TTCTTCGCGGCCCACACGAAG-3′, were used to introduce the mutation sequence at residue 269 to the plasmid C379S. All mutants were confirmed by BigDye terminator cycle sequencing performed at the DNA Sequencing Facility, University of Delaware.

Enzyme Expression and Purification. Wild-type, C115A, C269A, and C379S isocitrate dehydrogenases were expressed in *E. coli* TB1 cells and purified to homogeneity by amylose column chromatography, thrombin digestion, Matrex Gel Red column chromatography, and by a second amylose column (*19, 20*). Mutants C74A and C269A/C379S enzymes were purified to homogeneity by amylose column chromatography, thrombin digestion, and DE52 column chromatography, as described (*21*). The purity of wild-type and mutant isocitrate dehydrogenase was determined by electrophoresis on a 10% polyacrylamide gel containing 0.1% SDS as denaturant (*22*). N-Terminal sequencing of the purified enzyme was performed on an Applied Biosystems gas-phase sequenator (Model Procise) equipped with an on-line microgradient delivery system (Model 140C) and a computer (Model 610 Macintosh).

Circular Dichroism of Wild-type and Cysteine Mutant Enzymes. The secondary structure of cysteine mutants was measured using a Jasco model J-710 spectropolarimeter as described previously (*20*). The purified enzymes (~0.3 mg/mL) were first dialyzed against 25 mM triethanolamine hydrochloride, pH 7.7 buffer containing 75 mM sodium sulfate and 10% glycerol. The final concentrations of the enzymes were determined by a Coomassie blue dye binding assay (*23*), using wild-type porcine isocitrate dehydrogenase as the protein standard. Each sample (350 μL) was pipetted into a 0.1 cm path length quartz cuvette. The ellipticity of each sample was measured by scanning the sample 5 times between 200 and 250 nm at 0.1 nm increments. The molar ellipticity, $[\theta]$, was calculated from the equation: $[\theta] = \theta/(10nCl)$, where θ is the measured ellipticity, n is the number of amino acids per enzyme subunit (413 for porcine isocitrate dehydrogenase), C is the molar concentration of the enzyme, and l is the cell path length in cm.

Enzyme Activity Assay and Determination of Kinetic Parameters. The specific activity of isocitrate dehydrogenase was determined at 25 °C by measuring the time-dependent increase in absorbance at 340 nm which results from the reduction of NADP to NADPH. The standard assay solution contained 4 mM DL-isocitrate, 100 μM NADP, and 2 mM $MnSO_4$ in 30 mM triethanolamine hydrochloride, pH 7.4 buffer in a total volume of 1 mL. To determine the K_m for NADP of wild-type and mutant enzymes, DL-isocitrate and $MnSO_4$ concentrations were fixed at 4 mM and 2 mM, respec-

tively. To determine the K_m for isocitrate, NADP was fixed at 100 μM and $MnSO_4$ at 2 mM. The K_m for $MnSO_4$ was determined using an assay solution containing 4 mM DL-isocitrate and 100 μM NADP. The 2′-P-AMPS-Succ-BP was evaluated as a reversible inhibitor of isocitrate dehydrogenase by measuring the K_m for NADP and isocitrate of C269A/C379S enzyme in the presence of a constant 2′-P-AMPS-Succ-BP (150 μM) without UV irradiation. The data were analyzed by a Lineweaver−Burk plot to obtain K_m and V_{max} values.

Inactivation of Mutant Isocitrate Dehydrogenase C269A/C379S with 2′-P-AMPS-Succ-BP. Mutant isocitrate dehydrogenase C269A/C379S (0.1 mg/mL, 2.15 μM enzyme subunit) was preincubated in 30 mM triethanolamine hydrochloride, pH 7.4 buffer for 15 min prior to the addition of 5−205 μM 2′-P-AMPS-Succ-BP. An aliquot of the inactivation mixture (0.3 mL) was pipetted into each well of a microtiter plate, which had been placed on top of an ice bed, and irradiated with long-wave (365 nm) UV light generated by a Spectroline, model ENF-240C lamp which had been placed directly on the top of the microtiter plate. At various times, 2 μL aliquots of the inactivation mixture were withdrawn and added to 1 mL of standard assay solution to measure the residual enzyme activity. An enzyme incubated and irradiated in the absence of 2′-P-AMPS-Succ-BP was used as a control. To study the ability of active site ligands to protect C269A/C379S enzyme against inactivation by 20 μM 2′-P-AMPS-Succ-BP, the enzyme was preincubated with ligands for 15 min in 30 mM triethanolamine HCl, pH 7.4 buffer, prior to the addition of 2′-P-AMPS-Succ-BP.

Incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into Mutant Isocitrate Dehydrogenase C269A/C379S. Isocitrate dehydrogenase C269A/C379S (0.1 mg/mL, 2.15 μM enzyme subunit) was incubated with 40 μM 2′-P-[^{35}S]-AMPS-Succ-BP in 30 mM triethanolamine hydrochloride, pH 7.4 buffer and irradiated by a UV lamp at 365 nm, as described above. At various times, 2 μL aliquots of the inactivation mixture were withdrawn to test for residual enzyme activity and another 0.5 mL were pipetted onto a 5-mL Sephadex G50 spin column, which had previously been equilibrated with 0.1 M triethanolamine hydrochloride, pH 7.7 buffer containing 300 mM Na_2SO_4 and 10% glycerol, to remove excess 2′-P-[^{35}S]AMPS-Succ-BP by the gel centrifugation method (*24*). The incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into C269A/C379S enzyme at time zero was determined by addition of the compound without any UV irradiation. The enzyme concentration was determined by a dye-binding Bradford method (*23*). The incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into the enzyme was determined by measuring the radioactivity of enzyme aliquots using a Packard Tri-Carb liquid scintillation counter (Model 4640).

Ultrafiltration Measurements. The binding stoichiometry of native and 2′-P-AMPS-Succ-BP-modified C269A/C379S for NADPH or isocitrate was determined by an ultrafiltration method described previously (*25*−*27*). Briefly, native or modified C269A/C379S (1.0−1.3 mg/mL, 22−28 μM enzyme subunit) in 100 mM triethanolamine hydrocholoride, pH 7.7 buffer, containing 300 mM Na_2SO_4 and 10% glycerol, were mixed with either NADPH (63−97 μM) or isocitrate solution (90−140 μM) in a total volume of 1 mL. The binding mixture was incubated at 25 °C for 15 min prior to being transferred to an Amicon centricon YM-10 (molecular weight cutoff: 10 000 Da). Ultrafiltration was conducted at 3000*g* for 1 h and 0.5 mL of the filtrate was collected for measurements. The initial NADPH concentration and the free NADPH in the filtrate were measured spectrophotometrically by using an extinction coefficient of 6200 M^{-1} cm^{-1} for NADPH at 340 nm. The concentrations of isocitrate in the initial incubation mixture and the filtrate were determined indirectly by measuring the maximum change in $A_{340\,nm}$ generated by wild-type isocitrate dehydrogenase in a total of 1 mL assay solution containing 50−100 μL of the initial incubation mixture or the free isocitrate filtrate, 100 μM NADP, and 2 mM $MnSO_4$ in 30 mM triethanolamine hydrochloride, pH 7.4; no other isocitrate was added. The bound isocitrate (or NADPH) was calculated from the difference between total and free isocitrate (or NADPH).

RESULTS

Characterization of Adenosine 2′-Monophosphate, 5′-*O*-[*S*-(4-succinimidyl-benzophenone)thiophosphate] and Its Precursors. The synthesis of 2′-P-AMPS-Succ-BP was accomplished by initial thiophosphorylation of 2′-AMP with $PSCl_3$ to yield 2′-AMP-5′-SP, followed by coupling of 2′-AMP-5′-SP with BP-MAL to generate the final product, 2′-P-AMPS-Succ-BP. 2′-AMP-5′-SP was separated from its precursor and reaction byproducts by applying the thiophosphorylation mixture on a DE52 anion exchange column. Three peaks were eluted from the DE52 column using an NH_4HCO_3 gradient elution. The first peak has an R_f value of 0.46 on a cellulose TLC sheet with isobutyric acid/H_2O/ammonium hydroxide as the mobile phase; the second peak has an R_f value of 0.33, and the third peak has an R_f value of 0.13. The precursor, 2′-AMP, has an R_f value of 0.49. Phosphorus determinations indicated that the second and third peaks from the DE52 column each contains 2 mol of phosphorus per mole compound, with the compound's concentration being determined spectrophotometrically ($\epsilon_{259\,nm}$ = 15 400 M^{-1} cm^{-1}).

The ^{31}P NMR spectrum of the third eluted peak has two dominant peaks centered at 43.6 and 4.2 ppm, while the second eluted peak has two dominant peaks centered at 2.1 and 7.4 ppm. Adenosine 5′-*O*-thiomonophosphate (5′-AMPS) obtained from commercial sources exhibits a single peak at 43.8 ppm in its ^{31}P NMR spectrum. The reported chemical shifts of the phosphorus of 2′-AMP and 5′-AMPS were 4.34 and 42.93 ppm, respectively (*28*). Thus, the TLC, phosphorus determination, and ^{31}P NMR results indicate that the third peak eluted from the DE52 column is the thiophosphorylation product, 2′-AMP-5′-SP.

2′-P-AMPS-Succ-BP was synthesized by a reaction of 2′-AMP-5′-SP with BP-MAL at room temperature for 5 h, and was purified using reversed phase HPLC. The ^{31}P NMR spectrum of 2′-AMP−5′-S-Succ-BP shows, in addition to 2′-phosphate peak of 4.2 ppm, a new chemical shift of 16.7 ppm, as compared to 43.6 ppm for its precursor 2′-AMP-5′-SP, and this value is close to the reported chemical shifts of the 5′-phosphorus of adenosine 5′-*O*-(*S*-methyl thiophosphate) ($AMPSCH_3$) (22.9 ppm) and AMPS-Succ-BP (22.6 ppm) (*5, 28*). The reversed-phase HPLC-purified 2′-AMP-5′-S-Succ-BP (in H_2O containing 0.1% TFA) exhibits a mass of 721.1 when subjected to electron-spray mass spectroscopy (Thermo Finnigan model LCQ Advantage). This determined mass is close to the calculated formula weight of 720.5. Thus, the results from NMR and electron-spray mass spectrometry demonstrate that the fractions collected from the HPLC separation contain the final product, 2′-P-AMPS-Succ-BP, shown in Figure 1. The phosphorus content of 2′-P-AMPS-Succ-BP was determined chemically after hydrolysis by H_2SO_4 (2 mol of phosphorus/mol of reagent, consistent with

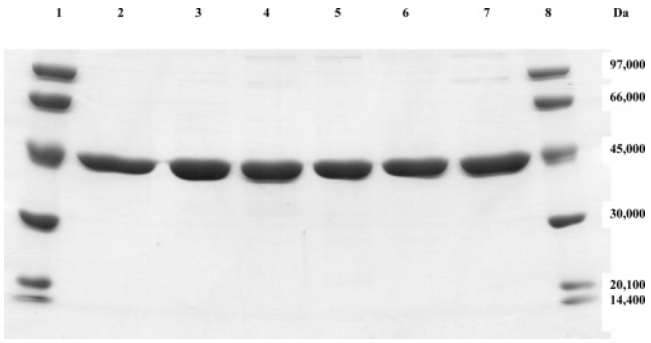

Figure 2. SDS−PAGE of purified wild-type and cysteine mutant isocitrate dehydrogenases. Lanes 1 and 8 are molecular weight markers, which contains trypsin inhibitor (20.1 KDa), carbonic anhydrase (30 KDa), ovalbumin (45 KDa), albumin (66 KDa), and phosphorylase b (97 KDa). Lane 2: wild-type; Lane 3: C74A; Lane 4: C115A; Lane 5: C269A; Lane 6: C379S; and Lane 7: C269A/C379S.

that of its precursor, 2′-AMP-5′-SP), and this value was used to calculate the extinction coefficient of the photoaffinity reagent. 2′-P-AMPS-Succ-BP exhibits maximum absorbance at 259 nm with an extinction coefficient of 28 000 M^{-1} cm^{-1} as measured in 10 mM triethanolamine hydrochloride, pH 7.4, which is close to the reported extinction coefficient for AMPS-Succ-BP (30,700 M^{-1} cm^{-1}) in 50 mM PIPES, pH 7.0 (*5*).

Purification of Wild-type and Mutant Porcine Isocitrate Dehydrogenases. Wild-type and mutant enzymes were expressed in *E. coli* TB1 cells and purified as described in Experimental Procedures. The purified enzymes were homogeneous, as shown by SDS−PAGE (Figure 2). Both wild-type and mutant enzymes exhibit a single band on 10% SDS−PAGE gel with a molecular weight of about 45 kDa, which is close to the calculated subunit molecular weight of porcine isocitrate dehydrogenase based on its amino acid sequence (46.6 kDa) (*11*). The purity of the prepared enzymes was further confirmed by N-terminal sequencing. All enzymes contain the correct N-terminal sequence of porcine isocitrate dehydrogenase, which is distinguished from *E. coli* isocitrate dehydrogenase in 9 out of the first 10 amino acids.

Secondary Structures of Wild-type and Mutant Porcine Isocitrate Dehydrogenases. The secondary structures of wild-type and cysteine mutant enzymes were determined using circular dichroism. All of the cysteine mutants have CD spectra similar to that of wild-type enzyme (data not shown). Wild-type and mutant enzymes all exhibit minima of molar ellipticity at 210 and 225 nm, indicating appreciable α-helix in their structures. The CD results indicate that mutations at selected cysteine residues do not cause significant change in the enzyme's secondary structure.

Specific Activities and Kinetic Parameters of Wild-type and Mutant Isocitrate Dehydrogenases. We have previously used *N*-ethylmaleimide (NEM) to label four cysteines of porcine isocitrate dehydrogenase: Cys74, Cys115, Cys269, and Cys379 (*29*). In the presence of isocitrate and Mn^{2+}, only Cys379 was modified by NEM and the modified enzyme retained its full activity, suggesting that Cys379 is not required for enzyme function. On the contrary, modifying Cys269 by NEM greatly reduces the enzyme activity, suggesting that Cys269 is involved in enzyme function. To evaluate the importance of these four cysteines in the function of porcine isocitrate dehydrogenase, each cysteine was replaced either by alanine or serine. The specific activities of wild-type and mutant enzymes were determined using

Table 1. Specific Activities and Kinetic Parameters of Wild-type and Mutant Isocitrate Dehydrogenases[a]

enzyme	specific activity[b] (μmol/min/mg protein)	K_m (NADP)[b] (μM)	K_m (isocitrate)[b] (μM)	K_m (Mn^{2+})[b] (μM)
wild-type[c]	38.6 ± 2.8	8.8 ± 0.3	7.4 ± 0.9	0.3 ± 0.1
C74A	21.2 ± 1.8	10.1 ± 0.4	15.3 ± 2.2	0.3 ± 0.1
C115A	28.3 ± 1.4	7.8 ± 1.8	8.2 ± 1.2	0.3 ± 0.1
C269A	35.1 ± 2.9	6.7 ± 1.3	8.9 ± 2.5	0.4 ± 0.0
C379S	37.8 ± 1.4	7.9 ± 0.9	10.4 ± 1.7	0.2 ± 0.0
C269A/C379S	39.2 ± 1.4	9.4 ± 0.4	9.7 ± 1.3	0.4 ± 0.0

[a] The standard assay solution contained 4 mM DL-isocitrate, 100 μM NADP, and 2 mM $MnSO_4$ in 30 mM triethanolamine hydrochloride, pH 7.4 buffer in a total volume of 1 mL. The specific activity and kinetic parameters were measured as described in Experimental Procedures. [b] Specific activities and kinetic parameters are expressed as mean ± standard deviation (SD). [c] The specific activity and kinetic parameters for the wild-type enzyme were determined previously (*21*).

substrate concentrations which saturate their individual sites, as described in Experimental Procedures. Table 1 shows the specific activities and K_m values for isocitrate, NADP, and Mn^{2+} of wild-type and cysteine mutant enzymes. C269A, C379S, and C269A/C379S mutant enzymes exhibit comparable specific activities to that of wild-type enzyme. Mutations at Cys74 or Cys115 result in a small decrease in mutant enzyme specific activity; they retain 55% and 73%, respectively, of wild-type enzyme residual activity. Replacement of cysteine at positions 74, 115, 269, or 379 does not markedly alter the K_m values for NADP, isocitrate, or Mn^{2+}. These results indicate that none of these four cysteine residues is directly involved in porcine isocitrate dehydrogenase catalysis or substrate binding.

To evaluate whether the new nucleotide analogue binds to NADP-specific isocitrate dehydrogenase, 2′-P-AMPS-Succ-BP was tested (without UV irradiation) as an inhibitor of the conversion of isocitrate to α-ketoglutarate catalyzed by the C269A/C379S enzyme. Measurement of the initial velocity as a function of the NADP concentration in the presence of the constant concentration of 150 μM 2′-P-AMPS-Succ-BP yields the same V_{max} but an increase in the apparent K_m for NADP to 47.7 μM, as compared to 9.4 μM (Table 1, last line) in the absence of 2′-P-AMPS-Succ-BP. Thus, 2′-P-AMPS-Succ-BP exhibits the characteristics of a competitive inhibitor with respect to NADP, with a K_I of 36.9 μM. Since the presence of 150 μM 2′-P-AMPS-Succ-BP increased the apparent K_m value for NADP of C269A/C379S enzyme, subsequent measurements for the apparent K_m value for isocitrate in the presence of the affinity reagent were conducted in assay solution containing 400 μM NADP. Measurement of the initial velocity as a function of the isocitrate concentration in the presence of the constant concentration of 150 μM 2′-P-AMPS-Succ-BP gave the comparable V_{max} and apparent K_m for isocitrate as those in the absence of the photoaffinity compound (K_m=13.8 μM in the presence of 2′-P-AMPS-Succ-BP versus K_m = 9.7 μM in the absence of the affinity label). Thus, 2′-P-AMPS-Succ-BP is not a competitive inhibitor with respect to isocitrate.

Photoinactivation of C269A/C379S Enzyme by 2′-P-AMPS-Succ-BP. Irradiation of the C269A/C379S enzyme (0.1 mg/mL, 2.15 μM enzyme subunit) in the presence of 10 μM 2′-P-AMPS-Succ-BP in 30 mM triethanolamine hydrochloride, pH 7.4 at 0 °C, results in a time-dependent inactivation of the enzyme, as shown in Figure 3 (○). In contrast, control enzyme, irradiated under the same conditions but in the absence of 2′-P-

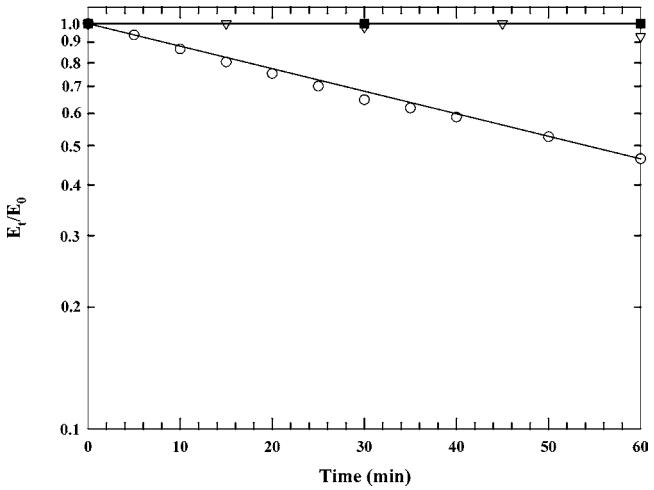

Figure 3. Photoinactivation of C269A/C379S enzyme by 2′-P-AMPS-Succ-BP. 0.1 mg/mL of C269A/C379S was either incubated on ice in the presence of 10 μM 2′-P-AMPS-Succ-BP (○) or in the absence of reagent (▽) during UV irradiation at 365 nm. The enzyme was also incubated with 10 μM 2′-P-AMPS-Succ-BP in the absence of UV irradiation (■). At various times, small aliquots were withdrawn and assayed for residual enzyme activity.

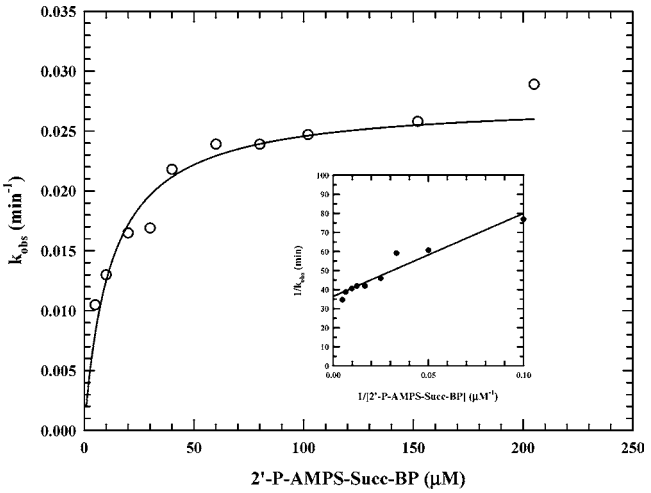

Figure 4. Dependence of inactivation rate constant of C269A/C379S mutant isocitrate dehydrogenase on the concentration of 2′-P-AMPS-Succ-BP. C269A/C379S mutant (0.1 mg/mL) was incubated with 5−205 μM 2′-P-AMPS-Succ-BP in 30 mM trithanolamine HCl, pH 7.4. The rate constants were determined from the first 60 min of reaction. Inset is the double reciprocal plot of $1/k_{obs}$ against 1/[2′-P-AMPS-Succ-BP].

AMPS-Succ-BP, shows no activity loss over the same incubation time (Figure 3, ▽). In the absence of UV light, the enzyme also retains its activity completely, even in the presence of 2′-P-AMPS-Succ-BP (Figure 3, ■). These results indicate that 2′-P-AMPS-Succ-BP acts as a photoaffinity label for porcine isocitrate dehydrogenase, requiring UV light to produce inactivation. 2′-P-AMPS-Succ-BP, which had been UV-irradiated for 3 h prior to addition to the inactivation mixture, produced comparable time-dependent inactivation of porcine isocitrate dehydrogenase to that seen with "fresh" 2′-P-AMPS-Succ-BP. This result indicates that 2′-P-AMPS-Succ-BP still retains its ability to function as a photoaffinity label during the 3 h irradiation period.

Isocitrate dehydrogenase C269A/C379S (0.1 mg/mL, 2.15 μM enzyme subunit) was incubated on ice with 5 to 205 μM 2′-P-AMPS-Succ-BP. The apparent rate constant (k_{obs}) of photoinactivation was calculated from the slope of $\ln(E_t/E_0)$ versus time, where E_t is the enzyme activity at time t and E_0 is the enzyme activity at time zero. A nonlinear relationship is observed when the inactivation rate constant (k_{obs}) is plotted versus the concentration of 2′-P-AMPS-Succ-BP (Figure 4), suggesting the initial formation of a reversible enzyme-ligand complex, prior to the irreversible modification. At high concentrations of 2′-P-AMPS-Succ-BP, the mutant enzyme is saturated with the reagent and the rate constant approaches a maximum (k_{max}). This type of inactivation kinetics can be described by the equation (*2*):

$$1/k_{obs} = 1/k_{max} + K_R/k_{max}\,(1/[2'\text{-P-AMPS-Succ-BP}]) \quad (1)$$

The maximum rate of inactivation (k_{max}) is 0.0275 min^{-1} and the apparent dissociation constant (K_R) is 12 μM. We had previously synthesized AMPS-Succ-BP, a similar photoaffinity label, but which lacks the 2′-phosphate of its adenosine ribose (*5*). AMPS-Succ-BP inactivates wild-type NADP-specific isocitrate dehydrogenase upon UV irradiation, but only at much higher concentrations; it has a higher K_R value as compared to 2′-P-AMPS-Succ-BP (K_R = 870 μM for AMPS-Succ-BP). The results indicate the required presence of a 2′-phosphate at the adenosine ribose for proper binding of the reagent to NADP-specific porcine isocitrate dehydrogenase.

Table 2. Effect of Active Site Ligands on Photoinactivation of C269A/C379S Mutant Isocitrate Dehydrogenase by 20 μM 2′-P-[^{35}S]AMPS-Succ-BP[a]

ligand added to incubation mixture	k_{obs} (min^{-1})	k_+/k_-
(1) None	0.0179	1.00
(2) 10 μM NADPH	0.0023	0.13
(3) 50 μM NADPH	0.0000	0.00
(4) 50 μM NADH	0.0211	1.18
(5) 100 μM NADP	0.0056	0.31
(6) 200 μM NADP	0.0025	0.14
(7) 100 μM ATPR	0.0000	0.00
(8) 100 μM isocitrate + 100 μM $MnSO_4$	0.0000	0.00

[a] Reaction was conducted on ice in 30 mM triethanolamine hydrochloride, pH 7.4, as described in Experimental Procedures. The value of k_+/k_- is the ratio of the rate constant for photoinactivation in the presence of an active site ligand to that in its absence.

Effect of Ligands on the Inactivation Rate of C269A/C379S Mutant Enzyme by 20 μM 2′-P-AMPS-Succ-BP. The ability of active site ligands to protect C269A/C379S isocitrate dehydrogenase (0.1 mg/mL, 2.15 μM enzyme subunit) against inactivation by 20 μM 2′-P-AMPS-Succ-BP is recorded in Table 2. The concentrations of NADP, NADPH, and isocitrate plus Mn^{2+} used in the studies were high compared to their K_m values determined in this study (K_m = 9.4 μM for NADP, K_m = 9.7 μM for isocitrate, and K_m = 0.4 μM for Mn^{2+} of C269A/C379S enzyme, Table 1). Both NADP and NADPH protect C269A/C379S enzyme against 2′-P-AMPS-Succ-BP inactivation, and the protection is concentration dependent (Table 2, lines 2, 3 and lines 5, 6). NADPH, which has a higher affinity for porcine isocitrate dehydrogenase (*32*), protects the cysteine mutant enzyme against inactivation at lower ligand concentration than does NADP. NADH (50 μM), which has the same maximum absorbance at 340 nm as does 50 μM NADPH but binds weakly to porcine isocitrate dehydrogenase, does not provide any protection to C269A/C379S enzyme against inactivation (line 4). This result indicates that the observed protection by enzyme active site ligands is due to the competitive binding of ligands with 2′-P-

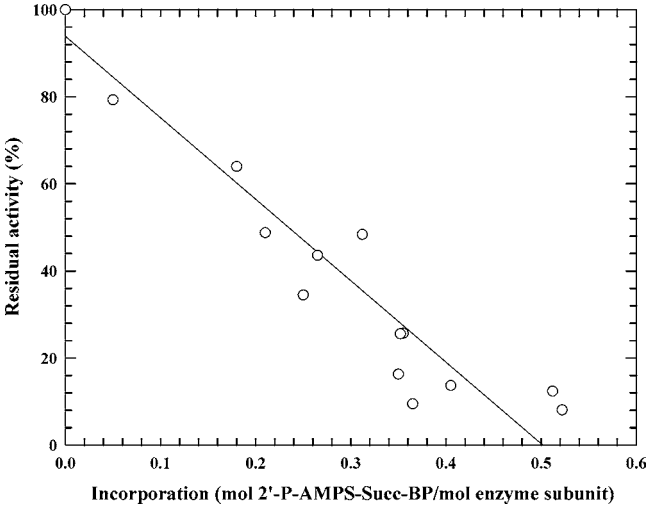

Figure 5. The incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into C269A/C379S mutant enzyme as a function of the percentage of residual activity. The enzyme was incubated with 40 μM reagent, as described in Experimental Procedures. Aliquots were removed at various times for measurement of residual activity and amount of reagent incorporation. Extrapolation to complete inactivation of the enzyme yields 0.5 mol of reagent incorporation per mol of enzyme subunit.

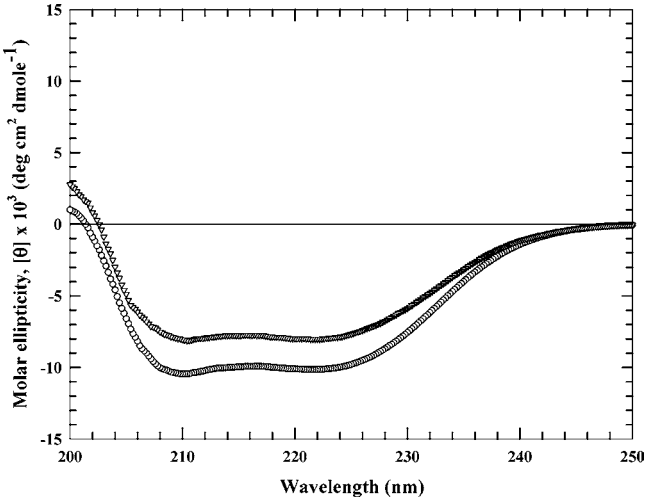

Figure 6. Circular diochroism (CD) spectra of isocitrate dehydrogenase. The CD spectra of C269A/C379S (○) and 2′-P-AMPS-Succ-BP-modified C269A/C379S (▽) were measured and the molar ellipticity was calculated as described in Experimental Procedures.

AMPS-Succ-BP for the enzyme site and is not due to the absorbance of UV light at 340 nm by the reduced coenzyme. 2′-Monophospho-adenosine 5′-diphosphoribose (ATPR), an NADP analogue which lacks the nicotinamide ring of NADP, has previously been shown to bind tightly to isocitrate dehydrogenase (*33*). ATPR completely protects the enzyme against inactivation (line 7). These protection studies suggest that 2′-P-AMPS-Succ-BP acts as a photoaffinity label and that it binds to the mutant enzyme in the region of the active site best occupied by coenzyme, NADP/NADPH. The enzyme also retains its full activity when 100 μM isocitrate plus 100 μM Mn^{2+} are present in the inactivation mixture (line 8). The complete protection provided by isocitrate and Mn^{2+} may be due to the proximity between the isocitrate and NADP sites of the porcine enzyme as well as the previously reported weakened binding of NADPH by the porcine enzyme in the presence of isocitrate and Mn^{2+} (*8, 9, 32*).

Incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into C269A/C379S Enzyme. A time-dependent incorporation of 2′-P-[^{35}S]AMPS-Succ-BP into the C269A/C379S enzyme was observed concomitant with the decrease in enzyme activity. Figure 5 shows a plot of percentage of residual activity versus 2′-P-[^{35}S]AMPS-Succ-BP incorporation. The line can be extrapolated to 0% residual activity to yield 0.5 mol of 2′-P-[^{35}S]AMPS-Succ-BP incorporated per mol of enzyme subunit (or 1 mol of reagent/mol enzyme dimer) when the enzyme loses all activity.

Characteristics of 2′-P-AMPS-Succ-BP-Modified Enzyme. The CD spectrum of 2′-P-AMPS-Succ-BP inactivated C269A/C379S enzyme (~17% residual activity and 0.4 mol reagent incorporated/mol enzyme subunit) is shown in Figure 6. The shape of the CD spectrum of the modified C269A/C379S enzyme is very similar to that of unmodified C269A/C379S enzyme. However, the magnitude of the molar ellipticity of the modified enzyme is much less than that of unmodified enzyme, indicating that the modified enzyme contains less α-helical structure as compared to that of unmodified enzyme.

The binding stoichiometry for NADPH or isocitrate of native and 2′-P-AMPS-Succ-BP-modified C269A/C379S isocitrate dehydrogenases determined by ultrafiltration are compared in Table 3. Native C269A/C379S isocitrate dehydrogenase binds 0.97 mol of NADPH or D-isocitrate/mol of enzyme subunit (or 1.94 mol of NADPH or D-isocitrate/mol of enzyme dimer), which is in agreement with the binding stoichiometry of wild-type enzyme determined previously by fluorescence titration and ultrafiltration (*27, 33*). 2′-P-AMPS-Succ-BP-modified C269A/C379S enzyme is capable of binding 0.41 mol of D-isocitrate/mol enzyme subunit and 0.51 mol of NADPH/mol enzyme subunit (or 0.82 mol of D-isocitrate/mol enzyme dimer and 1.02 mol of NADPH/mol enzyme dimer). These ligand binding results for the 2′-P-AMPS-Succ-BP-modified C269A/C379S enzyme are similar to those of wild-type enzyme modified with 2-BDB-TA-2′,5′-DP or 2-BDB-TϵA-2′,5′-DP (*25, 26*) and implies that 2′-P-AMPS-Succ-BP occupies only one of the two active sites of isocitrate dehydrogenase dimer.

Table 3. Binding Stoichiometry of D-Isocitrate and NADPH to Native C269A/C379S and 2′-P-AMPS-Succ-BP-Modified C269A/C379S Isocitrate Dehydrogenases[a,b]

enzyme	mol of bound D-isocitrate/mol of enzyme subunit	mol of bound NADPH/mol of enzyme subunit
native	0.97	0.97
modified	0.41	0.51

[a] Isocitrate dehydrogenase was modified as described in Experimental Procedures. The modified enzyme had 20−23% residual activity. The ultrafiltration experiments were performed at 25 °C in 50 mM triethanolamine hydrocholoride, pH 7.7 buffer, containing 150 mM Na_2SO_4 and 10% glycerol. [b] Wild-type NADP-dependent isocitrate dehydrogenase has previously been shown to bind 0.98 mol of D-isocitrate/mol of enzyme subunit and 1.00 mol of NADPH/mol of enzyme subunit under the same conditions (*27*).

DISCUSSION

The coenzyme site of porcine mitochondrial isocitrate dehydrogenase has been studied previously using the affinity labels, 2-(4-bromo-2,3-dioxobutylthio)-1, N^6-ethenoadenosine 2′,5′-bisphosphate (2-BDB-TϵA-2′,5′-DP), 2-[(4-bromo-2,3-dioxobutyl)thio]adenosine 2′,5′-bisphosphate (2-BDB-TA-2′,5′-DP), and 2-[(3-bromo-2-oxopropyl)thio]adenosine 2′,5′-bisphosphate (2-BOP-TA-

2′,5′-DP) (*10, 25, 26, 31*). Each of these affinity labels is an adenosine analogue with a reactive bromoketo group linked to the C2 position of adenine and is capable of revealing active site residues in the vicinity of the nicotinamide ring of NADP. 2-BDB-TϵA-2′,5′-DP causes rapid inactivation of the porcine isocitrate dehydrogenase which is prevented by NADP or NADPH, and Cys379 is the residue modified by the compound (*10, 31*). The results suggested that Cys379 is involved in isocitrate dehydrogenase catalysis and it is located at the NADP site of the enzyme. In contrast, modification of the porcine enzyme with the small NEM indicates that Cys379 is not essential for catalysis while Cys269 may be involved in enzyme catalysis (*29*). To clarify the roles of Cys269 and Cys379 in isocitrate dehydrogenase catalysis, we replaced these cysteines with alanine and serine, respectively. Cys74 and Cys115, which have been partially modified by NEM, were also chosen for site-directed mutagenesis. C74A, C115A, C269A, and C379S mutant enzymes all exhibited comparable activity and kinetic parameters to those of wild-type enzyme, which suggest that none of the four cysteines is involved in the porcine enzyme catalytic function, but that they may reside close to the enzyme active sites. The nucleotide affinity label still may occupy the active site even though it modifies a proximal but nonessential cysteine(s), which may explain the previously observed inactivation by the large reagents (*30*). In this study, we generated a double mutant (C269A/C379S) by replacing the two most reactive nonessential cysteine residues with either alanine or serine. The resulting double mutant enzyme has similar specific activity as well as kinetic parameters to those of wild-type enzyme. However, the C269A/C379S mutant enzyme, similar to the NEM-modified porcine isocitrate dehydrogenase (*30*), is not inactivated by 2-BDB-TA-2′,5′-DP (data not shown). The results indicate that the two mutated cysteines had been the targets of 2-BDB-TA-2′,5′-DP. We have used C269A/C379S enzyme in our photoaffinity labeling experiments to promote reaction with other amino acids.

Here, we describe a new affinity label, 2′-P-AMPS-Succ-BP, which modifies the active site of porcine isocitrate dehydrogenase. 2′-P-AMPS-Succ-BP is structurally similar to 2′-AMP and contains a succinimidyl benzophenone thiophosphate moiety adjacent to the C5′ position of the adenosine ribose. The approximate length of the benzophenone moiety is about 10Å (*6*), which is close to the distance (14 Å) between the adenine and nicotinamide rings of NADP in the *E. coli* isocitrate dehydrogenase crystal structure (*34*). Although more than one conformation is possible of 2′-P-AMPS-Succ-BP, in the extended form shown in Figure 1 the photoreactive carbonyl oxygen would be positioned toward the nicotinamide site. Upon UV irradiation, the reactive carbonyl group can react indiscriminately with any amino acid in its vicinity. Our results show that 2′-P-AMPS-Succ-BP functions as an affinity label for the coenzyme site of porcine isocitrate dehydrogenase.

Porcine isocitrate dehydrogenase reacted with by 2-BDB-TA-2′,5′-DP, 2-BOP-TA-2′,5′-DP or 2-BDB-TϵA-2′,5′-DP exhibits a biphasic inactivation: a fast inactivation protected by NADP followed by a slow inactivation which is prevented by isocitrate and Mn^{2+}. This indicates that the affinity labels bind to the enzyme at more than one region of the active site (*10, 26*). In contrast, the photoinactivation of the porcine enzyme by 2′-P-AMPS-Succ-BP shows a monophasic inactivation, implying that the new affinity label targets a single active site on the porcine enzyme. Actually, our active site ligand protection studies and kinetic parameters determined in the presence of 2′-AMP-5′-S-Succ-BP further suggest that the photoaffinity label competes with NADP for the coenzyme site of the porcine enzyme. The nonlinear relationship between the initial inactivation rate constant and the 2′-P-AMPS-Succ-BP concentration indicates the reversible binding of 2′-P-AMPS-Succ-BP to C269A/C379S enzyme (with a K_R of 12 μM) prior to irreversible inactivation. This K_R value (obtained at ice temperature) is comparable in magnitude to the K_m value for NADP (9.4 μM, determined in this study) of C269A/C379S enzyme, suggesting that the enzyme has similar affinity for the reagent as for its natural substrate, NADP. The coenzyme preference of dehydrogenases is determined by the interaction between the enzyme and the 2′-phosphate of NADP and the 2′- and 3′-hydroxyls of NAD (*35*). The ^{31}P NMR studies on the porcine enzyme indicate that the 2′-phosphate of enzyme-bound NADP is present in its dianionic form and likely interacts with a nearby positively charged amino acid(s) (*36*). Previous site-directed mutagenesis studies of porcine isocitrate dehydrogenase reveal that Arg314 and His315 may interact with the 2′-phosphate of NADP via electrostatic interaction (*21, 27*). Similar electrostatic interactions between the 2′-phosphate of NADP and positively charged side chains (His and Arg) were also observed in *E. coli* and *A. vinelandii* isocitrate dehydrogenases (*9, 34, 37*).

Porcine isocitrate dehydrogenase has very low affinity for NAD (K_m = 12.2 mM) as compared to its preferred coenzyme, NADP (K_m = 8.8 μM) (*21, 38*). AMPS-Succ-BP, which contains a hydroxyl group at the C2′ position of the adenosine ribose similar to that of NAD, would be expected to bind poorly to this porcine enzyme. Our studies did show that AMPS-Succ-BP exhibits a much higher K_R value (870 μM) for the porcine enzyme as compared to that of 2′-P-AMPS-Succ-BP (12 μM), which further implies the contribution of the 2′-phosphate of the reagent to the binding of the compound to the NADP-specific porcine enzyme.

The target site of 2′-P-AMPS-Succ-BP is revealed by examining the protective effects of active site ligands against inactivation by the compound. The complete protection by NADP, NADPH, and ATPR indicate that 2′-P-AMPS-Succ-BP occupies the coenzyme site of porcine isocitrate dehydrogenase, as might be expected from the striking similarity in structures between the coenzymes and the reagent. Alternatively, the porcine isocitrate dehydrogenase may adopt a closed active site structure upon NADP binding, similar to that of the *A. vinelandii* enzyme crystal structure complexed with NADP and the active site conformational changes may prevent the binding of 2′-P-AMPS-Succ-BP to the porcine enzyme (*37*). However, our kinetic studies conducted in the presence of 2′-P-AMPS-Succ-BP suggest that the affinity reagent competes with NADP for the same region on the porcine enzyme, consistent with the conclusion that 2′-P-AMPS-Succ-BP targets the coenzyme site of porcine isocitrate dehydrogenase.

The complete protection provided by isocitrate and Mn^{2+} against inactivation by a *nucleotide* analogue may appear to be anomalous. However, the proposed mechanisms for isocitrate dehydrogenase suggest that the nicotinamide ring of NADP must be close to the isocitrate site in order to extract a hydride from isocitrate (*8, 9*). A conformational change near the coenzyme site upon NADP binding and a 45° rotation of the bond between C4 and C5 of isocitrate in order to accommodate the NADP binding are observed in the *E. coli* isocitrate dehydrogenase crystal structure (*34*). Additionally, isoci-

trate and Mn^{2+} have been shown to weaken the binding of NADPH to the porcine enzyme (*32*); the substrate and coenzyme sites appear to interact, although they clearly cannot be identical. In our studies, the higher K_I (36.9 μM) for 2′-P-AMPS-Succ-BP determined in the complete assay as a competitive inhibitor with respect to NADP, as compared with the K_R (12 μM) for 2′-P-AMPS-Succ-BP determined from the photoinactivation in the absence of isocitrate and Mn^{2+}, is in agreement with the previously observed inhibition by substrates of the binding of NADPH by the porcine enzyme. The K_m for isocitrate in the current studies (measured with 2′-P-AMPS-Succ-BP present) was determined at elevated concentrations of NADP (400 μM), which would have excluded the binding of 2′-P-AMPS-Succ-BP and yielded the result that 2′-P-AMPS-Succ-BP did not compete kinetically with isocitrate. Thus, the proximity between the NADP and isocitrate sites and the inhibitory effects of isocitrate and Mn^{2+} upon the binding of NADPH to the porcine enzyme may account for the observed protection by isocitrate and Mn^{2+} against 2′-P-AMPS-Succ-BP inactivation of isocitrate dehydrogenase. We consider that the affinity label 2′-P-AMPS-Succ-BP reacts at the coenzyme site.

Incorporation measurements indicate that only one of the two active sites of the isocitrate dehydrogenase dimer is occupied by 2′-P-AMPS-Succ-BP concomitant with complete loss of enzymatic activity. The active site located in the other subunit of the inactivated enzyme is still capable of binding D-isocitrate or NADPH, as demonstrated by the ligand binding stoichiometry studies. The X-ray crystal structures of several isocitrate dehydrogenases reveal that the enzyme active sites consist of residues from both subunits of the homodimer (*9, 14, 34*). Modification of one active site of the porcine enzyme with 2′-P-AMPS-Succ-BP may introduce conformational changes to the other active site. Our CD studies reveal that modified enzyme does contain less α-helical structure than that of native enzyme. An increase in protein fluorescence was reported previously when porcine isocitrate dehydrogenase bound NADP, adenosine 2′,5′-bisphosphate or 2′-phosphoadenosine 5′-diphosphoribose, reflecting a conformational change (*33*). The maximum fluorescence enhancement was observed when one coenzyme site per enzyme dimer was occupied; addition of more NADP did not further change the protein fluorescence (*33*). Similar conformational changes may prevent the productive catalysis by the other active site on the enzyme modified by 2′-P-AMPS-Succ-BP, even though it can still bind ligands. In our reagent incorporation studies, the enzyme was incubated with 40 μM of 2′-P-AMPS-Succ-BP for 80 min, sufficient to almost completely abolish enzyme activity. Under these conditions, 2′-P-AMPS-Succ-BP occupies only one of the active sites per enzyme dimer; these results do not exclude the possibility that the compound can react with the half unmodified subunit, but it could not further inactivate an already inactive enzyme.

Previously synthesized affinity labels for the coenzyme site of porcine NADP-specific isocitrate dehydrogenase either contain only the adenosine ribose fragment of the coenzyme (e.g., 2-BDB-TA-2′,5′-DP, 2-BOP-TA-2′,5′-DP, and 2-BDB-TϵADP), have limited reactivities with amino acid side chains (e.g., periodate-oxidized NADP), or lack the 2′-phosphate for proper coenzyme binding (e.g., 8-BDB-TNAD) (*3, 10, 26*). In contrast, 2′-P-AMPS-Succ-BP contains the critical 2′-phosphate at its adenosine ribose ring and a succinimidyl-benzophenone thiophosphate to structurally mimic the nicotinamide moiety of coenzyme, NADP. 2′-P-AMPS-Succ-BP can covalently react with any amino acid through its carbonyl group of benzophenone upon UV irradiation (*6*). The new photoaffinity label thus complements the existing NADP affinity labels and has potential applications in other NADP-specific enzymes.

ACKNOWLEDGMENT

This work was supported by NIH Grant R01 HL 67774. The authors would like to thank Drs. Yu-Chu Huang and Melissa Vargo for performing N-terminal sequencing, Dr. Shi Bai for determining the ^{31}P NMR of 2′-P-AMPS-Succ-BP, and Dr. John Dykins for his help in acquiring the mass spectrum of the affinity label.

Received November 22, 2004; Revised Manuscript Received March 28, 2005

Mixed − ligand model complexes of general formula [^{99m}Tc(O)(κ^3-PNX)(κ^1-SPh))] [X = O (**1a**), S (**2a**)] were prepared in a one-step procedure from [$^{99m}TcO_4^-$] using stannous chloride as reducing agent. Stability studies and challenge experiments with glutathione showed that complex **2a** presented promising features for pursuing animal studies. The activity in the brain (% dose injected/organ) at 5 min (0.14% ± 0.03) and 120 min (0.11% ± 0.02) pi encouraged the synthesis of several mixed-ligand "3 + 1" oxo complexes of general formula [M(O)(κ^3-PNS)(κ^1-SL))] (M = ^{99m}Tc, **3a**−**6a**, Re, **3**−**6**), in which the tridentate ligand is the heterofunctionalized phosphine 2-(diphenylphosphanyl)-*N*-(2-thioethyl)benzamide (PNS) and the co-ligands are different arylpiperazine derivatives (HSL1−HSL4). The ^{99m}Tc complexes have been characterized by comparison of their retention times in the HPLC chromatogram (γ-detection) with the retention times of the analogous Re complexes (UV detection at 254 nm). The ^{99m}Tc complexes, obtained with radiochemical purity higher than 95%, after HPLC purification, are stable in saline, 0.01 M PBS (pH 7.4), rat plasma (4 h, 37 °C), and glutathione (10 mM solutions, 2h, 37 °C). Binding affinity and selectivity for 5-HT_{1A} receptors (relative to the 5-HT_{2A} receptor) were determined, complex **5** demonstrating the best values (IC_{50} for the 5-HT_{1A} 2.35 ± 0.02 nM; competitor 5-HT_{2A} 372 ± 11 nM). Biodistribution and stability studies in mice indicated a preferred hepatobiliary excretion, a high in vivo stability, but a poor brain uptake.

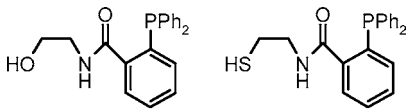
INTRODUCTION

One of the major challenges in the development of new specific radiopharmaceuticals based on ^{99m}Tc, the radionuclide of choice in nuclear medicine, is to bind a biomolecule to the metal center without drastically modifying its biological activity and metabolism. The development of ^{99m}Tc-based radiopharmaceuticals for studying the receptor function in the central nervous system (CNS) requires neutral and lipophilic complexes to facilitate their penetration through the blood−brain barrier (BBB), maintaining the affinity and selectivity for the neuroreceptor. Despite the difficulties, several approaches have been investigated to achieve that purpose (*1*−*3*). The successful development of [^{99m}Tc]TRODAT-1 as a ^{99m}Tc-radiopharmaceutical for imaging the dopamine transporters in the human brain was a very encouraging result (*4*, *5*).

The so-called "3 + 1" approach has been thoroughly investigated in the past few years for the design and preparation of specific radiopharmaceuticals of rhenium and technetium (*6*−*10*). This method uses tridentate dithiolate ligands HSESH (E = S; NR; O) and monodentate thiolate (HSR) co-ligands to stabilize the core $[Tc(O)]^{3+}$ and to form neutral and lipophilic complexes of general formula [Tc(O)(SES)(SR)].

However, one of the problems associated with the use of such systems is the low stability of these complexes against thiolated nucleophiles such as glutathione. In fact, although stable in PBS solutions, they presented low stability in vivo. Challenge experiments against glutathione (GSH) showed that their in vivo instability is mediated by the nucleophilic substitution of the monodentate co-ligand by glutathione with formation of the hydrophilic complex [^{99m}Tc(O)(SES)(SG)] (E = S, NR). Such instability was considered to be strongly dependent on the nature of the tridentate/monodentate ligands but, so far, no tri/monodentate pair has been found to overcome this problem (*11*−*13*).

Scheme 1



H_2PNO H_2PNS

The (tri)bidentate heterofunctionalized phosphines, 2-(diphenylphosphanyl)-*N*-(2-hydroxyethyl)benzamide (H_2-PNO) and 2-(diphenylphosphanyl)-*N*-(2-thioethyl)benzamide (H_2PNS) (Scheme 1), which are quite versatile in terms of charge and denticity toward the $[M{=}O]^{3+}$ core, form "3 + 1" mixed-ligand oxo complexes of general formula [Re(O)(PNX)(SR)] (X = O, S) with different thiolated monodentate co-ligands, some of them presenting a high stability (*14*−*16*).

Visualization of brain serotonin receptors, particularly the 5-HT_{1A} subtype, is of great interest since these receptors are implicated in various neuropsychiatric diseases (*17*, *18*). The aim of our work is the preparation of novel mixed-ligand ^{99m}Tc oxo complexes with potential for in vivo assessment of 5-HT_{1A} receptors.

Herein we report on the synthesis, characterization, and biological evaluation of mixed-ligand model complexes of general formula [^{99m}Tc(O)(κ^3-PNX)(κ^1-SPh))] [X = O (**1a**), S (**2a**)]. The complexes [M(O)(κ^3-PNS)(κ^1-SL)] (M = ^{99m}Tc, **3a**−**6a**, Re, **3**−**6**), anchored by the H_2PNS ligand and by several thiolated arylpiperazine derivatives (HSL1-HSL4) will also be described (Scheme 4). The binding affinity and specificity of **3**−**6** for the $5HT_{1A}$ receptors, the in vitro and in vivo stability, and the biokinetics of **3a**−**6a** are also reported.

EXPERIMENTAL SECTION

Materials and Methods. Unless otherwise stated, all chemicals were of reagent grade and were used without further purification. The heterofunctionalized phosphines, 2-(diphenylphosphanyl)-*N*-(2-hydroxyethyl)benzamide (H_2PNO), 2-(diphenylphosphanyl)-*N*-(2-thioethyl)-benzamide (H_2PNS), and succinimido 3-[(triphenylmethyl)-thio]propionate, were prepared as previously reported (*14*, *15*, *19*). The monothiols, thiophenol, *p*-aminothiophenol, mercaptopropionic acid, benzylmercaptane, cyclohexanethiol, and L-glutathione (GSH), were commercially available. [^{n}Bu$_4$N][Re(O)Cl$_4$], [Re(O)Cl$_3$(PPh$_3$)] and [Re(O)(κ^3-PNX)(κ^1-SPh))] (X = O (**1**), = S (**2**)) were prepared according to literature methods (*20*, *21*, *14*, *15*). Sodium pertechnetate was obtained in saline solution from a commercial ^{99}Mo/^{99m}Tc generator (MDS Nordion S.A., Belgium or Mallinckrodt).

Elemental analysis was performed on a Perkin-Elmer automatic analyzer. Infrared spectra were recorded in the range 4000−200 cm^{-1} on a Perkin-Elmer 577 spectrometer from KBr pellets. The ^{1}H and ^{31}P NMR spectra were recorded on a Varian Unity 300 MHz spectrometer; ^{1}H chemical shifts were referenced relative to tetramethylsilane and the ^{31}P chemical shifts to external 85% H_3PO_4 solution. The NMR samples were prepared in $CDCl_3$, chemical shifts are given in ppm. Mass spectrometric analyses were carried out on a Micromass Tandem Quadrupole Mass Spectrometer (Quattro LC) operating in the MS mode. Mass spectral data were recorded at the negative and positive ESI mode using a cone voltage of 20 or 60 V. About 0.1 mg of the sample dissolved in 1.0 mL methanol/water (50/50), and 0.05% formic acid was infused at a flow rate of 5 μL/min.

Chemical reactions were monitored by thin-layer chromatography (TLC) on Merck plates precoated with silica gel 60 F_{254}. Spots were visualized either by UV light and/or Ellman's reagent for thiols. Column chromatography was performed in silica gel 60 (Merck). High performance liquid chromatography (HPLC) analysis was performed on a Perkin-Elmer system coupled with two detectors: a UV−Vis detector, LC 290, Perkin-Elmer (UV detection for ligands and Re complexes at 254 nm) and a γ-detector (LB 509, Berthold) for ^{99m}Tc compounds. Separations were achieved on a reversed phase (RP) Hypersil ODS column (4.0 × 250 mm, 10 μm) eluted with a binary gradient system with a flow rate of 1.0 mL/min. Mobile phase A is methanol while mobile phase B is 0.01 M phosphate buffer (pH 7.4). The elution profile used was a linear gradient starting with 75% A/25% B to 95% A/5% B in 10 min, and this composition was held for 5 min. The ^{99m}Tc model complexes were analyzed by TLC using two different chromatographic systems: (a) Silufol/(BuOH/MeOH/water/ammonia) (60/20/20/1); (b) Silufol/saline.

Synthesis of Monodentate Thiolate Ligands Bearing Arylpiperazine Derivatives. *3-Mercapto-1-[4-(2-methoxyphenyl)-piperazin-1-yl]propan-1-one (HSL2).* Ph$_3$CSCH$_2$CH$_2$C(O)PIP (where PIP is 4-(2-methoxyphenyl)-piperazin-1-yl): 1-(2-Methoxyphenyl)piperazine (0.29 g, 1.5 mmol) was dissolved in 5 mL of dichloromethane and stirred at room temperature (r.t.) under a nitrogen atmosphere. A solution of succinimido 3-[(triphenylmethyl)thio]propionate (0.67 g, 1.5 mmol) dissolved in the same solvent (10 mL) and triethylamine (110 μL, 1.5 mmol) was added dropwise. After 22 h the reaction was completed, a diluted solution of HCl was added, and the reaction mixture was extracted three times with dichloromethane. The organic phase was collected, washed with water, dried over $MgSO_4$, filtered, and vacuum-dried. A viscous oil, which afforded a white solid after being vacuum-dried, was obtained (0.70 g, 90%). IR (cm^{-1}, KBr): 1635 (C═O), 1490, 1240, 1200, 750, 700. ^{1}H NMR (δ, ppm, $CDCl_3$): 2.14 (t, 2H, CH_2), 2.56 (t, 2H, CH_2), 2.94 (br s, 4H, CH_2), 3.34 (br s, 2H, CH_2), 3.70 (br s, 2H, CH_2), 3.85 (s, 3H, OCH_3), 7.03−6.85 (m, 4H, CH_{ar}), 7.42−7.14 (m, 15H, CH_{ar}). Elemental analysis: $C_{33}H_{34}O_2N_2S$ calcd, C 75.83, H 6.56, N 5.36. found, C 75.14, H 8.30, N 4.96.

Ph$_3$CSCH$_2$CH$_2$C(O)PIP (0.30 g, 0.58 mmol) was dissolved in 10 mL of trifluoroacetic acid (TFA) and cooled in an ice bath, and triethylsilane (0.2 mL 1.2 mmol) was added. The color of the initial solution (yellow) discharged, and a white precipitate was formed. After stirring for 15 min more, the solution was diluted with a mixture of hexane/water. The aqueous phase was separated, washed three times with hexane, and extracted three times with dichloromethane (25 mL). The organic phase was collected, washed with a saturated solution of sodium bicarbonate and water, and finally dried over $MgSO_4$. After filtration, the solvent was evaporated and the colorless oil obtained became a white solid on standing. This compound was formulated as HSL2 based on the analytical data (0.12 g, 74%). IR (cm^{-1}, KBr): 1635 (C═O), 1490, 1240, 1200, 750, 700. ^{1}H NMR (δ, ppm, $CDCl_3$): 1.75 (t, 1H, SH), 2.68 (t, 2H, CH_2), 2.82 (q, 2H, CH_2), 3.05−2.99 (m, 4H, CH_2), 3.63 (t, 2H, CH_2), 3.79 (t, 2H, CH_2), 3.85 (s, 3H, OCH_3), 7.03−6.86 (m, 4H, CH_{ar}). Elemental analysis: $C_{14}H_{20}O_2N_2S$ calcd, C 59.99, H 7.19, N 9.99 S 11.43, found, C 58.99, H 6.80, N 9.92 S 11.04.

Synthesis of 3-[4-(2-Methoxyphenyl)piperazin-1-yl]propane-1-thiol (HSL3). To a solution of Ph$_3$CSCH$_2$CH$_2$C(O)PIP (346 mg, 0.66 mmol) in dichloromethane (10 mL) was added dropwise 1 M borane−methyl sulfide solution (2.6 mL, 2.6 mmol) and the mixture stirred for 18 h at room temperature, under nitrogen atmosphere. The reaction mixture was cooled and methanol added dropwise until gas formation was ceased. The solvent was evaporated under vacuum, dichloromethane was added, and the mixture was refluxed for 15 min. After removal of the solvent, the crude product obtained was purified by column chromatography (silica gel), using as eluent dichloromethane/methanol (9:1). Ph$_3$CSCH$_2$CH$_2$CPIP was obtained as a white solid, after removing the solvent under vacuum (0.24 g, 72%). After deprotection, as above-described for HSL2, compound HSL3 was obtained as a white solid (0.12 g, 74%). IR (cm^{-1}, KBr): 1490, 1240, 1200, 750, 700. ^{1}H NMR (δ, ppm, $CDCl_3$): 1.40 (t, 1H, SH), 1.83 (q, 2H, CH_2), 2.51 (t, 2H, CH_2), 2.57 (t, 2H, CH_2), 2.64 (br s, 4H, CH_2), 3.01 (br s, 4H, CH_2), 3.84 (s, 3H, OCH_3), 6.95−6.82 (m, 4H, CH_{ar}). Elemental analysis: $C_{14}H_{22}ON_2S$ calcd, C 63.12, H 8.32, N 10.52, S 12.03, found, C 62.99, H 9.10, N 9.92 S 11.04.

Synthesis of 4-Mercapto-N-{3-[4-(2-methoxyphenyl)piperazin-1-yl]propyl}benzamide (HSL4). Triphenylmethylmercaptobenzoic Acid*:* Triphenylmethanol (1,04 g, 4 mmol) was added to a suspension of mercaptobenzoic acid (0.62 g, 4 mmol) in TFA yielding a yellow solution. After 1 h at room temperature, under stirring, the solution was

evaporated to dryness. The resulting yellow solid was dissolved with ethyl acetate and washed with 3 N NaOH solution, water, a saturated solution of sodium bicarbonate, and finally with brine. The organic phase was dried over $MgSO_4$, filtered, and after vacuum-drying, triphenylmethylmercaptobenzoic acid was obtained as a solid (1.54 g, 97%). The compound was used without any further purification.

Triphenylmethyl(mercaptobenzoyloxy)succinimide: Triphenylmethylmercaptobenzoic acid (1.41 g, 3.55 mmol) and *N*-hydroxysuccinimide (0.87 g, 7.4 mmol) were dissolved in dichloromethane (20 mL), and dicyclohexylcarbodiimide (1.54 g, 7.4 mmol) dissolved in the same solvent was added dropwise. After 4 h the reaction was complet (TLC/ethyl acetate/hexane (1:1)) and the urea formed was removed by filtration through Celite. The solution was vacuum-dried and the solid obtained recrystallized from ethyl acetate. The white solid obtained was formulated as triphenylmethyl(mercaptobenzoyloxy)succinimide, based on analytical data (1.48 g (85%). ^{1}H NMR (δ, ppm, $CDCl_3$): 2.85 (s, 4H, CH_2), 7.00 (d, $J = 8.1$ Hz, 2H, CH_{ar}), 7.24−7.38 (m, 15H, CH_{ar}), 7.70 (d, $J = 8.1$ Hz, 2H, CH_{ar}). Elemental analysis: $C_{30}H_{23}O_4NS$ calcd, C 73.02, H 4.66, N 2.83 S 6.49, found, C 72.21, H 5.47, N 2.24, S 7.07.

Triphenylmethyl(mercaptobenzoyloxy)succinimide (0.25 g, 0.5 mmol), 4-(3-aminopropyl)-1-(methoxyphenyl)piperazine (0.13 g, 0.5 mmol), and triethylamine (50 μL) reacted in dichloromethane (30 mL) at room temperature, under nitrogen atmosphere. After 18 h, the reaction was complete. A diluted solution of HCl was added and the aqueous phase extracted three times with dichloromethane. The organic phase was collected, washed with water, and dried over $MgSO_4$. After evaporation of the solvent a white solid was obtained, which after deprotection of the thiol group was formulated as HSL4 (0.11 g, 75%). IR (cm^{-1}, KBr): 1630 (C=O), 1590, 1240, 740, 695. ^{1}H NMR (δ, ppm, $CDCl_3$): 2.00 br s, 2H, CH_2), 2.85 (br s, 2H, CH_2), 2.99 (br s, 4H, CH_2), 3.26 (br s, 4H, CH_2),), 3.60 (br s, 2H, CH_2), 3.84 (s, 3H, OCH_3), 7.85−6.86 (m, 8H, CH_{ar}), 8.41 (t, 1H, NH). Elemental analysis: $C_{21}H_{27}O_2N_3S$ calcd, C 65.45, H 7.01, N 10.91 S 8.31, found, C 64.95, H 8.02, N 10.77, S 9.16.

General Procedure for the Preparation of Re Complexes. To a stirred suspension of $[Re(O)Cl_3(PPh_3)_2]$ in a 0.15 M methanolic solution of sodium acetate (10 mL) was added a mixture of H_2PNS with the corresponding thiolated aryl piperazine derivative in the same solution (5 mL). The suspension was stirred and refluxed for 1 h, yielding a dark brown solution. After cooling to room temperature, the reaction mixture was diluted with dichloromethane and with a 0.01 M HCl solution. The aqueous phase was then extracted three times with dichloromethane, and the organic phases were collected. After drying over magnesium sulfate, the solution was filtered and the solvent evaporated. The dark brown residue obtained was washed three times with diethyl ether and purified by chromatography using a silica gel column and a mixture of methanol−chloroform as eluent.

[Re(O)(PNS)(SL2)] (4). IR (cm^{-1}, KBr): 1630 (C=O), 1600 (C=O), 970 (Re=O), 745, 690. ^{1}H NMR (δ, ppm, $CDCl_3$): 8.13 (m, 1H, CH_{ar}), 7.67−7.18 (m, 12H, CH_{ar}), 7.03−6.85 (m, 4H, CH_{ar}), 6.79−6.73 (m, 1H, CH_{ar}), 5.05 (m, 1H, CH of tridentate ligand), 4.15 (m, 2H, SCH_2), 3.84 (s, 3H, OCH_3), 3.73 (br s, 4H, CH_2 of piperazine), 3.01−2.92 (m, 2H, CH_2 of piperazine, CH_2 of monodentate ligand, CH of tridentate ligand), 2.78−2.69 (m, 1H, CH of tridentate ligand), 2.19 (m, 1H, CH of tridentate ligand); ^{31}P NMR (δ, ppm, $CDCl_3$): 20.0. ^{99m}Tc Complexes. *[^{99m}Tc(O)(PNO)(SPh)] (**1a**).* The preparation of the complexes at the tracer level was accomplished in a one step procedure, starting with [$^{99m}TcO_4^-$] and using stannous chloride as reducing agent. The following general procedure was used: A mixture of propylene glycol (50 μL), ethanol or acetonitrile (1300 μL), 0.5 mg (4.5×10^{-6} mol) of thiophenol, 0.05 mg (1.43×10^{-7} mol) of H_2PNO, 0.1 N NaOH (200 μL), 20 μL of a $SnCl_2$ solution (1.0−2.0 mg $SnCl_2$ dissolved in 5 mL 0.1 N HCl), and 0.5 mL of [^{99m}Tc]pertechnetate eluate (100−200 MBq) was heated at 37 °C over 20 min. The reaction mixture was analyzed by HPLC, using the conditions described above and also by TLC using two different chromatographic systems: (a) Silufol/(BuOH/MeOH/water/ammonia) (60/20/20/1); (b) Silufol/saline. Yields > 90% were obtained.

The complexes were purified by HPLC on a semi-preparative Hypersil ODS column (Hypersil 120 ODS, 250 × 8 mm, 10 μm, flow rate 2.0 mL/min) using a linear gradient (t[min]/%A: (5/75), (10/95), (10/95) of methanol (A)/0.01 M phosphate buffer (pH 7.4) (B).

Characterization of the ^{99m}Tc complexes was accomplished by chromatographic correlation (HPLC) with the corresponding rhenium complexes, previously described (*14*, *15*).

*[^{99m}Tc(O)(PNS)(SPh)] (**2a**).* In the case of the H_2PNS ligand, the "3 + 1" mixed-ligand complex is not formed under alkaline conditions. So, the same procedure described above was used but in the absence of NaOH. Compound [^{99m}Tc(PNS)(SPh)] was obtained in relatively good yield (>90%).

[$^{99/99m}$TcO(PNS)(SPh)]. Complex [$^{99/99m}$TcO(PNS)(SPh)] was prepared as described for **2a,** using a [$^{99m}TcO_4^-$] eluate enriched with ^{99}Tc (10^{-8} or 10^{-7} mol $^{99}TcO_4^-$). The characterization was done by HPLC using the Re complex as a surrogate and also by mass spectrometry.

General Procedure for the Preparation of ^{99m}Tc Complexes (3a−6a). The ^{99m}Tc complexes were prepared by direct reduction of pertechnetate with stannous chloride. The following general procedure was used: 50 μL of propylene glycol (PG), 1300 μL of ethanol, 0.03−0.05 mg of the monodentate ligand, 0.001 mg (1.4×10^{-6} mol) of H_2PNS, and 20 μL of a $SnCl_2$ solution (2.0−3.0 mg of $SnCl_2$ dissolved in 5 mL of 0.1 N HCl) were added

to 0.5 mL (100−200 MBq) of [^{99m}Tc]pertechnetate eluate. The reaction mixture was heated at 40−50 °C for 20 min. The ^{99m}Tc complexes were analyzed by HPLC using a reversed-phase Hypersil 120 ODS column (250 × 4 mm, 10 μm). The column was eluted using methanol/water as mobile phase at 1.0 mL/min flow rate and with a linear gradient of 70−100% methanol over 10 min followed by 10 min at 100% of methanol. These complexes were also analyzed by TLC using two different chromatographic systems: (a) silica gel/acetone; (b) silica gel/saline.

The compounds were purified on a semipreparative Hypersil ODS column (250 × 8 mm, 10 μm) using methanol/water as mobile phase (flow rate: 2 mL/min) and with a linear gradient of 70−100% methanol over 10 min followed by 10 min at 100% of methanol. The fractions were collected and analyzed in the analytical column. The purified complexes, after removal of the organic solvent, were reconstituted with 0.1 M PBS 7.4, and 100 μL of PG was added. The characterization of the ^{99m}Tc complexes was accomplished by chromatographic correlation (HPLC) with the corresponding rhenium complexes.

General Procedures for Stability Studies in Vitro. *Challenge with GSH*. 100 μL (approximately 10 MBq) of the purified ^{99m}Tc complex was mixed with 100 μL of a 2 mM or 20 mM solution of GSH in 0.1 M phosphate buffer (pH 7.4). The mixture was incubated at 37 °C for 5−120 min and analyzed by HPLC. Samples without GSH were also analyzed and used for comparison. HPLC analyses were carried out using the experimental conditions above-described.

Stability in Rat Plasma. Blood collected from mice in heparinized polypropylene tubes was immediately centrifuged for 15 min at 2000 rpm at 4 °C and the plasma collected. The ^{99m}Tc complex (100 μL, ≈10 MBq) was added to fresh rat plasma (1 mL), and the mixture was incubated at 37 °C. At appropriate periods of time (5 min, 30 min, 1, 2, and 4 h), 100 μL aliquots (in duplicate) were sampled and treated with 200 μL of ethanol to precipitate the proteins. Samples were then cooled at 4 °C and centrifuged at 3000 rpm for 15 min at 4 °C. The supernatant was separated from the precipitate, and the sediment was washed twice with ethanol (1 mL) and counted in a gamma counter. The activity in the sediment was compared with the total activity used, and the percent of complex bound to proteins was calculated. The supernatant was analyzed by HPLC, using the experimental conditions above-described.

Stability in Whole Human Blood. To whole human blood (1 mL), collected in heparinized polypropylene tubes, was added a solution of the ^{99m}Tc-complex (≈10 MBq), and the mixture was incubated at 37 °C. Samples were taken 5 min, 1 h, and 4 h after incubation and centrifuged 15 min at 2000 rpm at 4 °C. The plasma was separated and ethanol was added in a 2:1 (v/v) ratio. The samples were centrifuged at 3000 rpm, and the supernatant was analyzed by HPLC.

Receptor Binding Assays on Rat Brain Homogenates. The $5HT_{1A}$ receptor binding assays were performed using [^{3}H]-8-OH-DPAT as radioligand and rat hippocampus homogenate. The binding assay was carried out in a final volume of 2.5 mL of Tris-HCl buffer (50 mM, pH 7.4, 0.1% ascorbic acid, 2 mM $CaCl_2$) containing 0.10 nM [^{3}H]-8-OH-DPAT, membrane homogenate (about 20 μg/mL protein), and various concentration of the rhenium complexes **3**−**6.** The complexes were dissolved in DMSO up to 1 nM and then diluted with buffer. Nonspecific binding was defined as the amount of [^{3}H]-8-OH-DPAT bound in the presence of serotonin (Sigma). The samples were incubated in triplicates at 20 °C for 120 min. The incubation was terminated by rapid filtration through GF/B glass fiber filters (Whatman) using a 30-port Brandel Cell Harvester. The filters were rapidly washed with four portions of ice-cold buffer, transferred into 10 mL of scintillation fluid (Ultima-Gold, Packard), and analyzed for radioactivity.

The $5HT_{2A}$ receptor binding assays: The cortex of rat brain was homogenized in ice-cold buffer (50 mM tris-HCl, pH 7.6) with an Ultra-Turrax T 25. The homogenate was centrifuged at 20 000*g* for 10 min. The resulting pellet was resuspended and centrifuged under the above conditions. After repeating the same procedure, the pellet was resuspended in 10 mL of buffer and stored at −20 °C.

[^{3}H]Ketanserin (from NEN) was used as a radioligand. The binding assay was carried out in a final volume of 5 mL of Tris-HCl buffer, pH 7.6, containing 0.12 nM [^{3}H]-ketanserin, membrane homogenate (about 20 μg/mL protein), and various concentrations of the Re complexes. The complexes were dissolved in DMSO up to 1 nM and then diluted with buffer. Nonspecific binding was defined as the amount of [^{3}H]ketanserin bound in the presence of 1 μM mianserin (Sigma). The samples were incubated in triplicates at 20 °C for 60 min. Incubation, filtration, and counting of the samples were the same as described above.

General Procedures for in Vivo Studies. *Biodistribution Studies.* The in vivo behavior of the ^{99m}Tc complexes was evaluated in groups of 3−5 female CD-1 mice (randomly bred, Charles River) weighing approximately 20−25 g each. Animals were intravenously injected with 100 μL (1−3 MBq) of each preparation via the tail vein and were maintained on normal diet ad libitum. At 5 min and 1 h mice were killed by cervical dislocation. The radioactive dosage administered and the radioactivity in the sacrificed animal were measured in a dose calibrator (Aloka, Curiemeter IGC-3, Tokyo, Japan). The difference between the radioactivity in the injected and sacrificed animal was assumed to be due to excretion, mainly urinary excretion. Blood samples were taken by cardiac puncture at sacrifice. Tissue samples of the main organs were then removed and counted in a gamma counter (Berthold). Biodistribution results were expressed as percent of injected dose per organ (% I.D./total organ). For blood, bone, and muscle, total activity was calculated assuming that these organs constitute 6, 10, and 40% of the total weight, respectively. The remaining activity in the carcass was also measured in a dose calibrator. In vivo stability was just assessed by murine serum RP-HPLC analysis. For that, blood was centrifuged and serum separated and analyzed by HPLC after treatment with ethanol, as described above for the stability in whole human blood.

RESULTS AND DISCUSSION

Preparation of [^{99m}Tc(O)(PNX)(SPh)] (X = O, 1a; X = S, 2a). For the introduction of stable mixed-ligand oxometal complexes with ^{99m}Tc/Re, namely those of the "3 + 1" type, with adequate physicochemical and biological characteristics for CNS receptor targeting, we have prepared oxorhenium complexes of the type [Re(O)-(κ^2-PNX)(κ^1-SR)] (X = O, S) anchored by the heterofunctionalized phosphines H_2PNO and H_2PNS, and by different monodentate thiol co-ligands (*14*). To check whether this type of approach could be extended to the no carrier added level, we have used complexes [^{99m}Tc(O)(PNX)-(SPh)] (X = O, **1a**; X = S, **2a**) as models. These ^{99m}Tc

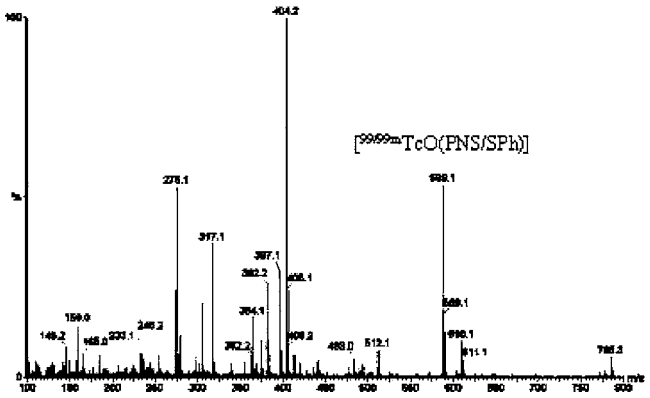

Figure 1. ES/MS of [99/99mTcO(PNS/PhS)]: *m/z* (found) 588 (M + 1), *m/z* (calcd) 587 for [TcO(PNS/PhS)] ($C_{27}H_{23}NO_2PS_2Tc$).

X = O, M = Re (**1**), ^{99m}Tc (**1a**)
X = S, M = Re (**2**), ^{99m}Tc (**2a**)

complexes have been prepared in a one-step procedure, by direct reduction of $[^{99m}TcO_4]^-$ with stannous chloride in the presence of thiophenol and of the corresponding tridentate H_2PNO or H_2PNS ligands (Scheme 2).

To maximize the radiochemical yield of **1a** and **2a**, the labeling conditions were optimized, namely the concentration, tridentate/monodentate ligand molar ratios, and pH. When dealing with H_2PNS, the main radiochemical impurity was the complex $[^{99m}Tc(O)(\kappa^3\text{-PNS})(\kappa^1\text{-HPNS})]$, formed due to the κ^3,κ^1-coordination versatility of PNS. This radiochemical impurity has been identified by comparing its retention time in the HPLC with that of the fully characterized analogue Re complex [Re(O)-(κ^3-PNS)(κ^1-HPNS)] (*14*). Although being a less critical factor, the concentration of thiophenol also has to be controlled in order to minimize the formation of the homoleptic complex $[^{99m}Tc(O)(SPh)_4]^-$. Regarding pH, **1a** requires alkaline conditions for its formation, while **2a** is formed at a lower pH value (pH ~ 6).

After optimization of the labeling conditions, complexes **1a** and **2a** were obtained in yields higher than 90%, with only 1−3% of reduced hydrolyzed technetium and with no free pertechnetate, as indicated by TLC and HPLC.

Characterization of [99mTc(O)(PNX)(SPh)] (X = O, 1a; X = S, 2a). The characterization of **1a** and **2a** was done by comparing their retention times in the HPLC (γ detection: **1a**, 6.3 min; **2a**, 9.1 min) with the corresponding retention times of the analogous Re complexes **1** and **2** (UV detection − 254 nm, **1**: 6.3 min, **2**: 9.0 min). For unambiguous identification of **2a**, the complex [99/99mTc(O)(PNS)(SPh)] was synthesized using a $[^{99m}TcO_4]^-$ eluate enriched with 10^{-8} or 10^{-7} mol of $[^{99}TcO_4]^-$. As can be seen in the ES/MS spectrum shown (Figure 1) a significant peak appears at *m/z* 588 (M + 1), which correlates well with the value *m/z* of 587 calculated for [99TcO(PNS)(SPh)].

Stability and in Vivo Behavior of [99mTc(O)(PNX)-(SPh)] (X = O, 1a; X = S, 2a). The in vitro stability of the model complexes **1a** and **2a** was evaluated in physiological solutions (saline, 0.01 M PBS pH 7.4, at 37 °C) and in the presence of glutathione (1 and 10 mM solutions, 37 °C).

Complex **1a** decomposes to more hydrophilic species during incubation in saline or PBS at 37 °C, and only

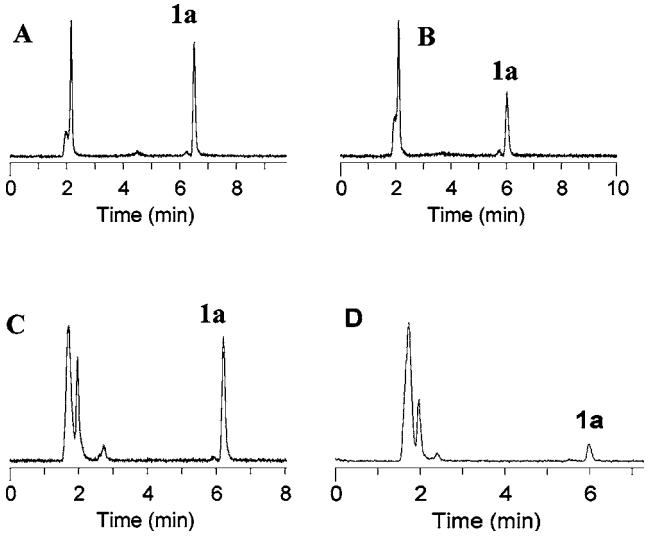

Figure 2. Stability studies of [99mTcO(PNO/SPh)] (**1a**) by HPLC. In saline at 37 °C: A, after 30 min; B, after 60 min; against 1 mM glutathione solution at 37 °C: C, after 30 min; D, after 60 min;

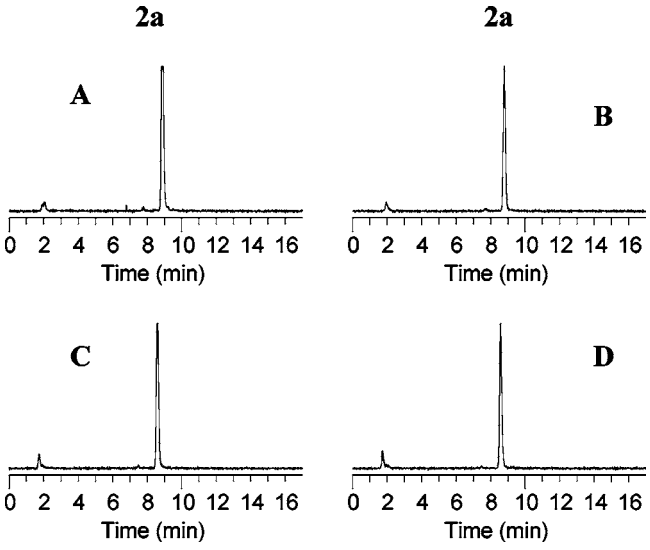

Figure 3. Stability studies of [99mTcO(PNS/SPh)] (**2a**) by HPLC. In saline at 37 °C: A, 30 min; B, 120 min; against 1 mM glutathione solution, at 37 °C: C, 5 min; D, 120 min.

43% or 33% of **1a** remains intact after 30 or 60 min incubation, respectively (Figure 2). Challenge experiments against glutathione revealed that **1a** decomposes also to more hydrophilic unknown radiochemical species even faster than in saline or PBS solutions.

On the contrary, complex [99mTc(O)(PNS)(SPh)] (**2a**) is stable in saline, in 0.01 M PBS pH 7.4 (1:1 dilutions), and also in the presence of glutathione (1 and 10 mM solutions, 2 h, 37 °C) (Figure 3). On the basis of these results, which confirm clearly the importance of the donor atom sets on the stabilization of the "3 + 1" mixed-ligand complexes, complex **2a** was chosen to pursue our studies.

The overall general biodistribution profile for **2a** is shown in Table 1. This complex, despite presenting a high liver uptake, also shows some initial brain uptake (0.14 ± 0.03% ID/organ, 5 min. pi), which does not decrease significantly with time (2 h after injection: 0.11 ± 0.02% ID/organ).

These results, encouraged the use of the tridentate H_2PNS ligand for the preparation of ^{99m}Tc mixed-ligand complexes bearing antagonists of the 5-HT_{1A} receptors.

Table 1. Biodistribution of ^{99m}TcO(PNS/SPh) in Wistar Rats (n = 5) at 5 and 120 min pi (%ID/organ ± SD)

	% injected dose/organ ± SD	
organ	5 min pi	120 min pi
brain	0.14 ± 0.03	0.11 ± 0.02
spleen	0.95 ± 0.25	0.35 ± 0.11
kidney	4.16 ± 0.22	7.52 ± 0.41
heart	0.93 ± 0.08	0.46 ± 0.03
lung	1.88 ± 0.16	0.80 ± 0.11
liver	51.30 ± 1.40	26.60 ± 1.60

To achieve this goal, several thiolated arylpiperazine derivatives containing the 1-(2-methoxyphenyl)piperazine unit, a fragment of the potent and selective 5-HT_{1A} antagonist WAY 100635 moiety, were prepared and used as monodentate co-ligands (Scheme 3).

Syntheses and Characterization of the Ligands HSL2−HSL4. The ligand HSL1 was prepared as previously described (*14*). The monothiolates HSL2 and HSL3 were synthesized by a coupling reaction between 3-[(triphenylmethyl)thio]propionate and 1-(2-methoxyphenyl)piperazine, followed by deprotection of the thiol group or by reduction of the amide group with borane−methyl sulfide followed by deprotection, respectively.

The synthesis of HSL4 involved the activation of the protected mercaptobenzoic acid with *N*-hydroxysuccinimide in the presence of *N*,*N*′-dicyclohexylcarbodiimide and conjugation of the resulting compound with 4-(3-aminopropyl)-1-(methoxyphenyl)piperazine. Deprotection of the thiol group with triethylsilane in trifluoroacetic acid afforded HSL4.

Compounds HSL2−HSL4 have been thoroughly characterized by the usual analytical techniques. The main feature of the IR spectra of HSL2 and HSL4 is the presence of a strong band at 1635 cm^{-1} (HSL2) and 1630 cm^{-1} (HSL4) assigned to the carbonyl amide stretching vibration. This band is absent in the IR spectrum of HSL3, confirming the reduction of the carbonyl group. The ^{1}H NMR spectra of HSL2−HSL4 present all the expected resonances, including a triplet which appears at δ 2.58 in the NMR spectrum of HSL3, confirming the presence of the methylene group formed due to the reduction of the carbonyl function. In the ^{1}H NMR spectrum of HSL2 and HSL3 also appears a triplet at 1.75 and 1.40, respectively, assigned to the thiol group.

Syntheses and Characterization of the Complexes [Re(O)(PNS)(SL)] (4−6). The "3 + 1" mixed-ligand oxorhenium complexes (**4**−**6**) were synthesized by reacting $[Re(O)Cl_3(PPh_3)_2]$ with the tridentate ligand H_2-PNS in the presence of HSL2−HSL4, as previously described for compound **3** (Scheme 4) (*14*). The synthesis was carried out under nitrogen atmosphere, to avoid the oxidation of the thiol or of the phosphine ligands.

The molar ratio $[Re(O)Cl_3(PPh_3)_2]/H_2$PNS/HSL has to be maintained at 1:1:1 to minimize the formation of the subproduct [Re(O)(κ^3-PNS)(κ^1-HPNS)] (*14*). All the complexes were fully characterized by elemental analysis, IR, ^{1}H and ^{31}P NMR spectroscopy, and HPLC.

The IR spectra of compounds **4**−**6** exhibit strong bands in the range 970−975 cm^{-1} assigned to the ν(Re=O) stretching vibration. These values compare well with the values found for the same stretching vibration in compound **3** and also in other compounds of the "3 + 1" type stabilized by the PNS tridentate ligand and different monodentate co-ligands (970−980 cm^{-1}) (*14*, *16*). Another common feature to all the IR spectra is the presence of two strong absorption bands, typical of the phenylphosphine moiety, which appear in the range 745−750 and 690−700 cm^{-1} (*22*, *14*). In the IR spectra of **4** and **6** also appears a strong band at ν 1630 cm^{-1} and ν 1640 cm^{-1}, respectively, assigned to the carbonyl group of the monodentate co-ligand.

The ^{31}P NMR spectra of complexes **4**−**6** present only one singlet, which appears in the range δ 19.6−20.0 ppm, being comparable with the values previously reported for other "3 + 1" oxo complexes with the [PNS/S] donor atom set (*14*−*16*). These resonances, assigned to the tridentate ligand H_2PNS, are low-field shifted relative to the value found for the corresponding free ligand (δ −9.4 ppm), clearly indicating that the phosphorus atom is involved in the coordination to the metal.

The ^{1}H NMR spectra of complexes **4**−**6** reveal four sets of multiplets, integrating for one proton each, due to the methylenic protons of the H_2PNS ligand, which are diastereotopic due to the asymmetry introduced in the molecule by the oxo group. The resonances due to the aromatic rings of the H_2PNS and of the co-ligand appear in the expected range.

Preparation of the Complexes [^{99m}Tc(O)(PNS)(SL)] (3a−6a). Complexes **3a**−**6a** were synthesized using the procedure described for the model complex **2a.** After optimizing the concentration of the tridentate ligand, **3a**−**6a** were obtained in relatively high yields (80−95%) and were identified by comparing their retention times (γ detection) with the retention times of the well-characterized analogous rhenium complexes (**3**−**6**) (Table 2).

Stability of the ^{99m}Tc Complexes (3a−6a). Complexes **3a** −**6a** are stable in saline and in 0.01 M PBS (pH 7.4) solutions at least for 6 h (both at room temperature and at 37 °C). As mentioned above, the main drawback associated with the "3 + 1" complexes of the type [TcO(SES)(SR)] (E = S, O, NR) is their instability toward the presence of thiolated nucleophiles, like glutathione (*11*−*13*). For the first time, we found that complexes of the "3 + 1" type (**3a**−**6a**) do not exchange with glutathione, even in the presence of concentrated solutions (1 mM and 10 mM GSH), also remaining intact in fresh rat plasma and in whole human blood (37 °C, 4 h) (Figure 4). Comparing our results with others previously reported, the high stability found for **2a**−**6a** can only be assigned to the electronic and/or steric factors imposed by the tridentate PNS ligand. However, as referred to above, complex **1a** is not stable in the presence of GSH, despite being anchored by the analogous tridentate PNO ligand. This finding led us to conclude that the stability found for complexes **2a**−**6a** is certainly due to the electronic properties of the PNS ligand. The combination of a soft π-donor, like sulfur, and a soft π-acceptor, like phosphorus, most probably promotes a strong bond between the metal center and the sulfur atom of the co-ligand, leading to a less electrophilic and more stable complex. Nevertheless, a better understanding of these results would need MO theoretical calculations.

Lipophilicity. The lipophilicity of all the complexes was evaluated by determination of the partition coefficient (P) in physiological conditions (n-octanol/0.1 M phosphate buffer pH 7.4). The results obtained, expressed as log $P_{o/w}$, are presented in Table 2. All the compounds are lipophilic and the values found (log $P_{o/w}$ = 1.70−2.01) are in the range normally accepted for the complexes to be able to cross the BBB (log $P_{o/w}$ = 0.5−2.5) (*3*). The lipophilicity found for **3a** (1.70) and for **6a** (2.01) relates well with the presence of an aliphatic and an aromatic group in **3a** and **6a**, respectively.

In Vitro Receptor Binding Studies. To evaluate the effect of the chemical modifications introduced in the monodentate ligand, and the effect of the chelate unit,

[a] Other HPLC conditions: column Hypersil 120 ODS (250 × 4 mm, 10 μm,1 mL/min); mobile phase methanol/0.02% Et_3N in water; gradient: 50−100% methanol over 10 min followed by 10 min at 100% methanol.

the binding affinity of the complexes **3**−**6** for the 5-HT_{1A} and 5-HT_{2A} receptors was determined. Their affinity for the 5-HT_{1A} receptor subtype was assessed in vitro on the basis of their ability to displace [^{3}H]-8-OH-DPAT, a potent and specific 5-HT_{1A} receptor agonist, from 5-HT_{1A} binding sites in rat hippocampal homogenates.

The IC_{50} values for the tested compounds are presented in Table 3. The Re complexes **3** and **6** had moderate affinity for the 5-HT_{1A} receptors (**3**, IC_{50} 120 ± 1.1 nM **6**, 79.3 ± 11 nM). Substitution of the ethylenic chain of complex **3** (in HSL1) by the aromatic ring in complex **6** (in HSL4) increased the affinity for the 5-HT_{1A} receptors. Complex **5** presents the highest affinity and selectivity for the 5-HT_{1A} receptors (IC_{50} for 5-HT_{1A} 2.35 ± 0.02 nM; competitor 5-HT_{2A} 372 ± 11 nM). This value is similar to the reported value for the parent compound WAY 100635 (IC_{50} = 2.2 nM), suggesting that the affinity of the *o*-methoxyphenylpiperazine moiety for 5-HT_{1A} receptors is not reduced by its functionalization with a thiol group and by the presence of the $[Re(O)(PNS)]^+$ metal fragment (*18*). A further important criterion for the potential application of this type of *biocomplexes* is the selectivity of the pharmacophore for the 5-HT_{1A} receptors. According to Halldin et al., ideally the affinity of a radioligand should be highest for the site of interest by more than 1 order of magnitude (*23*). Compound **5** presents a selectivity toward the 5-HT_{2A} receptors which is over 150-fold. Complex **4** completely lost affinity for the 5-HT_{1A} receptors**,** must probably due to the presence of the carbonyl function in the monodentate ligand, which seems to prevent the access to the receptor-binding site.

Biodistribution. The in vivo behavior of the ^{99m}Tc complexes (**3a**−**6a**) was evaluated in mice at 5 and 60 min post intravenous injection. Figure 5 shows the tissue distribution results expressed as % I.D./total organ in the most relevant organs. These results indicate a similar pattern for all the complexes under study, showing a slow clearance from organs such as blood and muscle and a slow rate of total radioactivity excretion from whole animal body (less than 12% of total injected dose 1 h after administration). All the complexes have high initial blood and muscle uptake that slowly clear, mainly via the hepatobiliary pathway. Complex **4a** presents a quite fast blood and muscle clearance when compared to **3a**, **5a**, and **6a**. As expected for lipophilic compounds, there is a very high and rapid liver uptake that decreases over the time with a significant amount of injected dose cleared into the intestines. The low kidney uptake associated to the low total radioactivity excretion indicates that those complexes are mainly eliminated through the hepatobiliary tract with quite low urinary elimination.

Despite being neutral and lipophilic, all the complexes (**3a**−**6a**) present low brain uptake (%I.D./organ ≤ 0.2%, 5 min after administration) and no significant retention of the radioactivity is observed. HPLC analysis of the murine serum collected after 5 min and 1 h postinjection indicated that all the complexes remain intact in circulation, confirming their high in vivo stability.

Despite the good perspectives related to the charge, lipophilicity, and in vitro and in vivo stability of the complexes, they are not able to cross the BBB, which would enable the in vivo assessment of 5-HT_{1A} receptors.

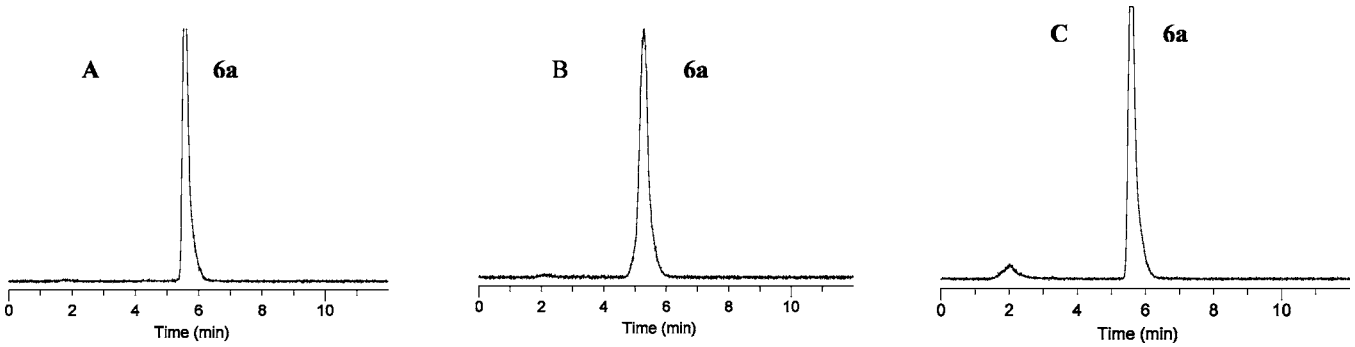

Figure 4. HPLC chromatograms of **6a** (A); (B) after incubation with rat serum, 37 °C, 4 h; (**C**) after incubation with 10 mM gluthathione solution, 2 h, 37 °C.

Table 3. IC_{50} (nM) Values for the Tested Compounds 3a−6a

	IC_{50} (nM)		
complex	5-HT_{1A} ([^{3}H]OH-DPAT)	5-HT_{2A} ([^{3}H]-ketanserin)	5-HT_{2A}/5HT_{1A}
3a	120 ±1.1	860 ± 51	7.16
4a	15170 ± 532	148 ± 50	< 0.01
5a	2.35 ± 0.02	372 ± 11	158.3
6a	79.3 ±1.2	542 ± 15	6.8

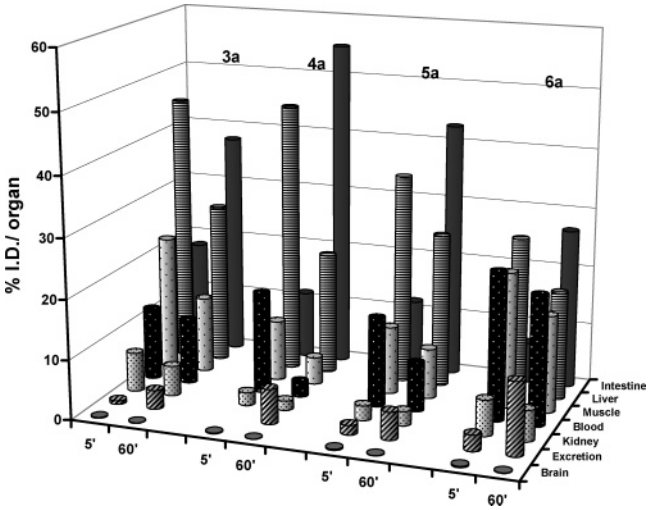

Figure 5. Biodistribution results in mice (% injected dose/ organ) for complexes **3a**−**6a**.

This can be due to the presence of the chelate moiety that influences the properties of the whole molecule in an unclear manner. Finding rules for or, better, relations between structure parameters of metal complexes to allow passage through the BBB is an important goal but has hardly been investigated so far. Attempts to interpret the BBB transport of Tc complexes on the basis of rough physicochemical parameters such as lipophilicity and basicity have not been successful.

CONCLUDING REMARKS

We were able to prepare the "3 + 1" oxotechnetium(V) complexes **1a** and **2a** at the nca level, using the heterofunctionalized phosphines H_2PNO and H_2PNS as tridentate ligands, and thiophenol as monodentate co-ligand. These model complexes present different in vitro stability, confirming the importance of the donor atom set.

Using the tridentate H_2PNS ligand, several "3 + 1" oxotechnetium(V) complexes bearing 5-HT_{1A} receptor-binding ligands have been prepared in good yields and high radiochemical purity (>95%). All are stable in saline, PBS pH 7.4, rat plasma, and human serum. No exchange with glutathione was observed, even when high concentrations of this nucleophile are used. This is a remarkable feature for this type of complex, and these are the first examples of "3 + 1" complexes presenting no transchelation toward glutathione. One of the complexes (**5/5a**) also showed a remarkable affinity and selectivity for the 5-HT_{1A} receptors (IC_{50} for 5-HT_{1A} 2.35 ± 0.02 nM; competitor 5-HT_{2A} 372 ± 11 nM; 5-HT_{1A}/5-HT_{2A} = 158.3), comparable to the corresponding values found for the [^{11}C]-WAY 100635 (IC_{50} for 5-HT_{1A} 2.2 nM). These results confirmed the possibility of preparing metal complexes without affecting the affinity and selectivity of the biomolecules for the corresponding receptors. Unfortunately, despite displaying adequate characteristics, such as neutrality, high lipophilicity, and high in vitro and in vivo stability, none of the complexes cross the BBB, as demonstrated by biodistribution studies in mice. This topic is an open field and deserves considerable attention. Such work is of the highest importance, when aiming at the development of brain-related metallo-(radio)pharmaceuticals.

ACKNOWLEDGMENT

The key role played by PI3 kinase in cancer, hormone action, and a host of other biological functions suggests that specific inhibitors whose disposition could be ascertained in vivo would be useful in biological research or, potentially, for imaging PI3K in a clinical setting. Wortmannin (Wm, **1**) is an inhibitor of PI3 kinase with high specificity for this enzyme. We synthesized three modified Wm probes, a biotinylated Wm (**7a**), a 4-hydroxy-3-iodophenylated Wm, which was obtained both unlabeled (**7b**) and labeled with ^{125}I (**8**), and a fluoresceinated Wm (**7c**), through modification at C-11, and evaluated their inhibitive activity as inhibitors of PI3 kinase. Biotinylated (**7a**) and 4-hydroxy-3-iodophenylated Wm's (**7b**) had IC_{50}s for PI3K of 6.11 and 11.02 nM, respectively, compared to an IC_{50} for Wm of 1.63 nM. Fluoresceinated Wm (**7c**) lost considerably more activity than the other derivatives, with an IC_{50} of 64.9 nM. The ^{125}I labeled 4-hydroxy-3-iodophenylated Wm (**8**) could be detected after reaction with an immunoprecipitate of PI3 kinase. The activity of these reporter Wm's is discussed in relationship to earlier findings on the pharmacological activity of Wm derivatives and the ability of inhibitors to fit into the ATP pocket of PI3 kinase.

INTRODUCTION

Specific inhibitors of enzymes whose position can be monitored in cells have been widely used to elucidate the role an enzyme plays in biological processes (*1*−*5*). The key role played by PI3 kinase in cancer (*6*−*8*), hormone action (*9*, *10*), and a host of other biological functions (*11*−*14*) suggests that specific inhibitors, whose disposition could be ascertained, would be useful in biological or pharmaceutical research or, potentially, for imaging PI3 kinase in a clinical setting. Wortmannin (Wm) is a fungal product that is a specific inhibitor of PI3 kinase which can covalently react with a lysine in the ATP binding site of the enzyme (Figure 1) (*15*−*17*). Wm consists of a steroid-like ring system with two features that make the synthesis of Wm derivatives a challenging task. First, the furan ring, subject to attack by the epsilon amino group of lysine in the active site of PI3 kinase, can react with other nucleophiles (*18*), and this can occur in an unintended fashion. Second, the six-membered lactone ring of Wm, roughly comparable to the A ring of steroid ring system (Figure 1), is extremely sensitive to base (*19*).

Our goal was therefore to overcome these challenging features of Wm chemistry and synthesize Wm derivatives modified at C11 that might serve as "reporter Wm's," that is compounds that retained the ability of the parent Wm to inhibit PI3 kinase but with the potential to detect their position after application to a biological system. Three approaches to reporter Wm's were investigated: (i) biotinylated Wm (**7a**) was synthesized that might be detected by the Western blot method; (ii) a 4-hydroxy-3-iodophenyl Wm (**7b**) was synthesized, with nonradioactive iodine for enzyme inhibition studies and as an ^{125}I labeled (**8**) compound for autoradiography, and (iii) a fluorescent Wm (**7c**) was synthesized, for detection by fluorescence microscopy. All were made by selective modification at C-11 of Wm that had previously been shown to have little effect on the ability of Wm to inhibit PI3K (*20*). Our results show that biotinylated (**7a**) and 4-hydroxy-3-iodophenylated (**7b**) Wm's retained a good inhibitory activity for PI3K compared to the parent, but the inhibitory activity of fluoresceinated Wm (**7c**) was reduced. The relationship of these findings to earlier pharmacological and crystallographic studies of Wm's interaction with PI3 kinase are discussed.

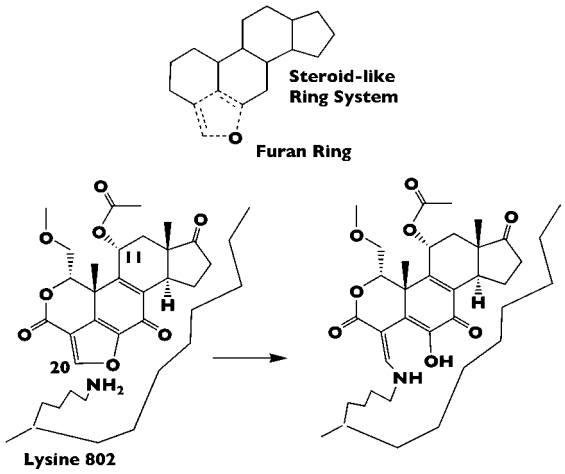

Figure 1. Wortmannin structure and reaction with PI3 kinase. Wortmannin is a steroid-like compound with a furan ring (top) that reacts with a lysine in the active site of PI3 Kinase (bottom). The positions of C-11 and C-20 on wortmannin are shown.

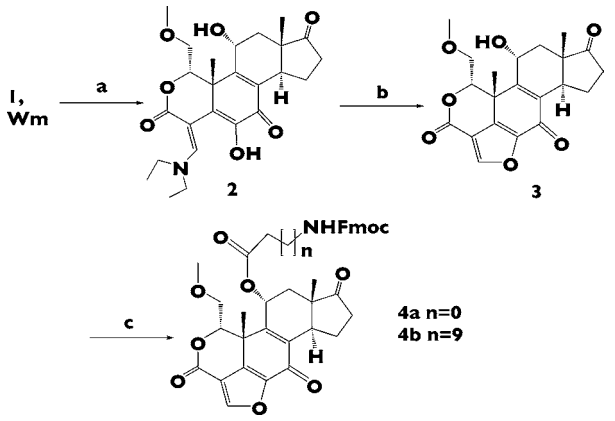
Scheme 1. Synthesis of Intermediates Used To Obtain C11-Modified Wm Probes[a]



[a] Reagents and conditions: (a) **1**, diethylamine, methanol, room temperature, 20 h; (b) 1,4-dioxane, 1 N HCl, room temperature, 22 h (75% based on wortmannin); (c) *N*-Fmoc glycine chloride (for **4a**) or *N*-Fmoc-11-aminoundecanoyl chloride (for **4b**), pyridine, dichloromethane, room temperature, overnight, (94.6% for **4a**, 89.0% for **4b**).

EXPERIMENTAL METHODS

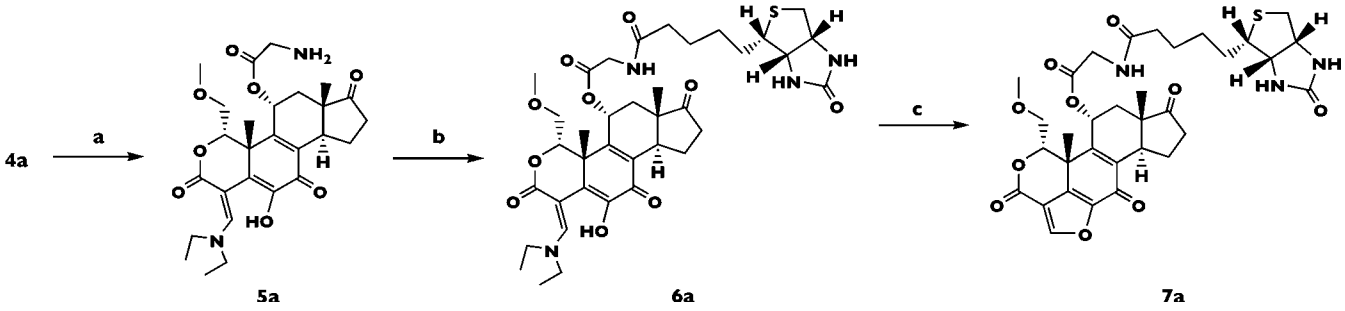
General. Wortmannin was a gift of the Natural Products Branch of the NCI. All reagents (Aldrich, or NovaBiochem) and solvents (Aldrich) were of standard quality and used without further purification unless indicated. Acetonitrile for HPLC analysis was obtained as HPLC grade from Fisher Scientific. Silica gel for column chromatography was conducted with 60−200 mesh silica gel (J. T. Baker Inc.). FITC was from Molecular Biosciences. Iodogen was purchased from Pierce and $Na^{125}I$ was from Amersham Bioscience. NMR was performed on a Varian 400 MHz instrument with $CDCl_3$ as solvent, while mass spectra were obtained on a Micromass LCT instrument with time-of-flight ESI technique. HPLC separations were accomplished on a Varian ProStar 210 gradient pumping system with a variable-wavelength PDA 330. HPLC separations were carried out on reversed-phase C18 column (VYDAC, Millipore) with water (0.1% trifluoroacetic acid,) (buffer A) and acetonitrile (containing 20% buffer A) (buffer B) as elution buffer. Three variations of this were employed. *System 1*: buffer A/buffer B (80:20) for 5 min, then linear gradient of buffer A/buffer B (80:20−0:100) over 30 min and then isocratic for 5 min, flow: 6.0 mL/min, λ_{max}: 255 nm; *System 2*: buffer A/buffer B (50:50) for 5 min, linear gradient of buffer A/buffer B (50:50−25:75) over 25 min and then isocratic for 5 min, flow: 4.9 mL/min, λ_{max}: 255 nm. *System 3*: buffer A/buffer B (70:30) for 5 min, linear gradient of buffer A/buffer B (70:30−0:100) over 45 min and then isocratic for 5 min, flow: 4.9 mL/min, λ_{max}: 440 nm.

The C11-modified Wm's were synthesized in two steps. First the Fmoc-protected intermediates **4a** or **4b** were synthesized, which were stable when stored at −20 °C for at least 3 months (Scheme 1). In a second step, the Fmoc group was removed, and the amino group was modified by the attachment of biotin (**7a**, Scheme 2), 4-hydroxy-3-iodophenylacetic acid (**7b**, Scheme 3), or FITC (**7c**, Scheme 4). The potency of the three C11-modified Wm probes as inhibitors for PI3 K was then ascertained. We also synthesized a ^{125}I version of C11 4-hydroxy-3-iodophenyl Wm (**8**) as shown in Scheme 5.

Synthesis of Intermediates 4a or 4b. *Steps a and b, Scheme 1*, were accomplished by slight modifications of published procedures (*20*). Wm (0.107 g, 0.25 mmol) was dissolved in anhydrous methanol (6 mL) with diethylamine (0.1 mL) and the furan ring opened within 10 min as indicated by the yellowish color appearance. A second portion of diethylamine (0.5 mL) was added for desacetylation of C-11 at room temperature for 20 h. After removal of methanol and diethylamine by evaporation under reduced pressure, the residue was dissolved in 1,4-dioxane (10 mL) and the furan ring closed to obtain compound (**3**). This was accomplished with 1.6 mL of aqueous 1 N HCl at room temperature in 22 h. Compound **3** was purified by silica gel column chromatography eluting with a gradient ethyl acetate/hexane with a yield of 75%. *Step c, Scheme 1*. The acylation of the C11-hydroxy group was accomplished by dissolving **3** (0.077 g, 0.2 mmol) in dichloromethane (2 mL) and anhydrous pyridine (1 mL) and using a 4-fold excess of either *N*-Fmoc glycine chloride (0.252 g, 0.8 mmol, for **4a**) or a 3-fold excess of *N*-Fmoc-11-amino-undecanoyl chloride (0.264 g, 0.6 mmol for **4b**), stirring at room temperature for overnight. **4a** and **4b** were purified by silica gel column chromatography as above. A sticky solid was obtained after the solvent was removed by evaporation. Both products were obtained by the addition of sufficient hexane to the dichloromethane solution to induce precipitation and were off-white solids for long-term storage (**4a**: 0.126 g, 94.6% and **4b**: 0.14 g, 89.0%). The structures of **4a** and **4b** were identified by NMR and HR-MS spectrometry. Selected data: **4a**: HR-MS: $C_{38}H_{35}NO_{10}$, calcd 666.2339 ($M + H^+$), found: 666.2342; ^1H NMR ($CDCl_3$, 400 MHz): 0.95 (3H, s, C*H*$_3$-13), 1.50−1.60 (1H, m, *H-12*), 1.74 (3H, s, C*H*$_3$-10), 2.01−2.07(1H, m, *H-16*), 2.20−2.30 (1H, m, *H-15*), 2.56−2.66 (2H, m, *H-12*, *H-16*), 2.81−2.88 (2H, m, *H-14*, OC*H*$_2$), 3.13 (3H, s, C*H*$_3$O), 3.14−3.21 (1H, m, *H-15*), 3.39 (1H, d, $J = 12$ Hz, OC*H*$_2$), 3.84, 3.89 (1H, dd, $J_1 = 6$ Hz, $J_2 = 18.4$ Hz, NHC*H*$_2$CO), 4.13, 4.18(1H, dd, $J_1 = 6$ Hz, $J_2 = 18.4$ Hz, NHC*H*$_2$CO), 4.22 (1H, t, $J = 6.4$ Hz, COOCH$_2$C*H*), 4.48 (2H, d, $J = 6.4$Hz, COOC*H*$_2$CH), 4.72(d, $J = 7.2$ Hz, *H-1*), 5.63 (1H, t, $J = 6$ Hz, N*H*), 6.21(1H, dt, $J_1 = 8.4$ Hz, $J_2 = 2.8$ Hz, *H-11*), 7.27−7.41 (4H, m), 7.58 (2H, t, $J = 7.6$ Hz, Ar*H*), 7.74 (1H, dd, $J_1 = 3.2$ Hz, $J_2 = 7.2$ Hz, Ar*H*), 8.28 (1H, s, *H-21*); ^{13}C NMR ($CDCl_3$, 100 MHz): 14.5, 22.9, 26.5, 35.7, 35.0, 40.7, 43.0, 44.0, 47.1, 49.2, 59.6, 67.0, 71.2, 72.9, 88.8, 114.1, 120.0, 124.8, 124.9, 127.0, 127.1, 127.7, 127.7, 140.9, 141.3, 141.4, 142.6, 143.7, 144.8, 148.8, 150.2, 156.4, 157.4, 169.0, 172.5, 215.9. **4b**: HR-MS: $C_{47}H_{53}NO_{10}$, calcd 792.3747 ($M + H^+$), found: 792.3746. ^1H NMR($CDCl_3$, 400 MHz): 0.98 (3H, s, C*H*$_3$-13), 1.28−1.67 (17H, m, OOCCH$_2$(C*H*$_2$)$_8$CH$_2$NH, *H-12*), 1.73 (3H, s, C*H*$_3$-10), 1.99−2.14 (1H, m, *H-16*), 2.20−2.31 (1H, m, *H-15*), 2.33−2.42 (2H, m, OOCC*H*$_2$), 2.56−2.63 (2H, m, *H-12*, *H-16*), 2.86−2.98 (1H, m, *H-14*), 3.00−3.12 (1H, dd, $J_1 = 6.8$ Hz, $J_2 = 11.2$ Hz, CH$_3$OC*H*$_2$), 3.17 (6H, b, OC*H*$_3$, NHC*H*$_2$, *H-15*), 3.45 (1H, dd, $J_1 = 11.2$ Hz, $J_2 = 2$ Hz, CH$_3$OC*H*$_2$), 4.22 (1H, t, $J = 6.8$ Hz, OCH$_2$C*H*Ar), 4.40 (2H, d, $J = 6.8$ Hz, OC*H*$_2$CHAr), 4.76 (1H, dd, $J_1 = 6.8$ Hz, $J_2 = 2$ Hz, *H-1*), 4.81 (1H, b, N*H*), 6.18 (1H, dt, $J_1 = 9.2$ Hz, $J_2 = 2.4$ Hz, *H-11*), 7.31 (2H, t, $J = 7.2$ Hz, Ar*H*), 7.40 (2H, t, $J = 7.2$ Hz, Ar*H*), 7.60 (2H, d, $J = 7.2$ Hz, Ar*H*), 7.77 (2H, d, $J = 7.2$ Hz, Ar*H*), 8.24 (1H, s, *H-21*); ^{13}C NMR: 14.6, 22.9, 24.7, 26.5, 26.7, 29.0, 29.2, 29.2, 29.3, 29.4, 30.0, 34.4, 35.7, 36.1, 40.7, 41.1, 44.1, 47.3, 49.2, 59.4, 66.5, 69.9, 72.8, 88.5, 114.3, 120.0, 125.0, 127.0, 127.6, 140.2, 141.3, 142.9, 144.0, 144.8, 149.7, 150.0, 156.4, 157.7, 172.2, 172.7, 216.3.

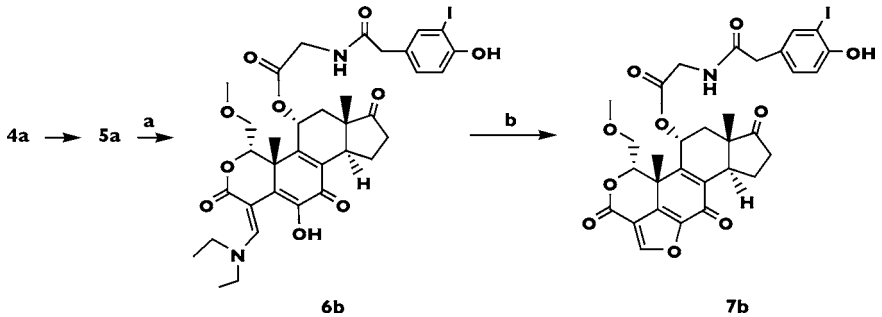
Synthesis of C11 Biotinylated Wm (7a): *For step a, Scheme 2*, a solution of **4a** (6.7 mg, 0.01 mmol) in anhydrous dichloromethane (1 mL) was added diethylamine (0.2 mL, 1.9 mmol). After stirring for 6 h at room

Scheme 2. Synthesis of C11 Biotinylated Wm (7a)[a]



[a] Reagents and conditions: (a) **4a**, diethylamine, dichloromethane, room temperature, 6 h (58.2% for **5a**); (b) **5a**, biotin, HATU, HOBT, DMF, CH_2Cl_2, r. t.; (c) 1 N HCl, DMF, 1,4-dioxane, 48 h (total yield 28.5%, based on 41.9 μmol of **4a**).

Scheme 3. Synthesis of C11 4-Hydroxy-3-iodophenyl Wm (7b)[a]

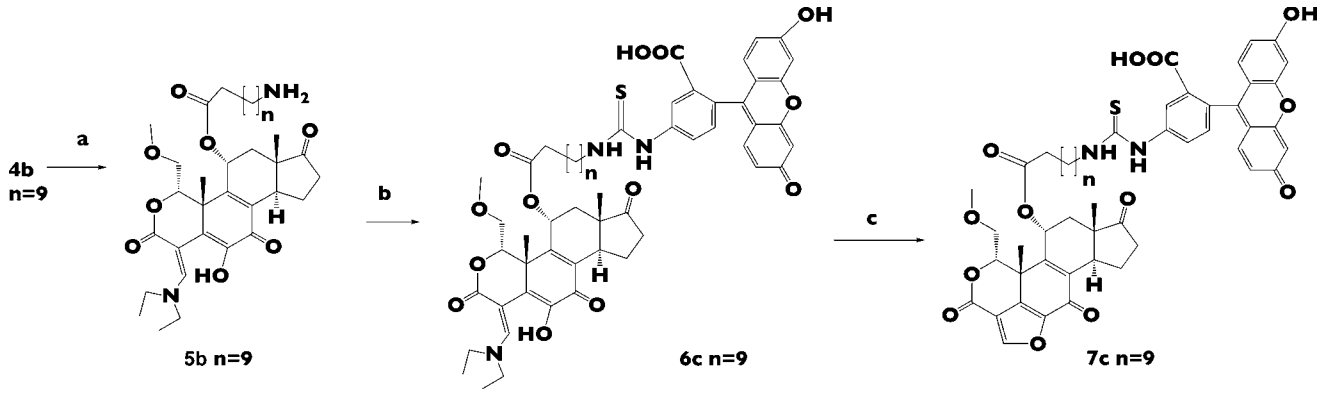


[a] Reagents and conditions: (a) **5a**, EDC, 4-hydroxy-3-iodophenylacetic acid, room temperature, 20 min; (b) 1,4-dioxane, 1 N HCl, 24 h (17.3%, overall, 0.01 mmol **4a** based).

temperature, a single major spot was obtained by silica gel TLC (CH_2Cl_2:MeOH/100:5). The solution containing **5a** was extracted with an acidic aqueous phase (3 × 5 mL 1 N HCl) and followed by the removal of impurities in the aqueous phase with dichloromethane (2 × 2 mL) extraction. The aqueous layer was then brought to pH 8 with $NaHCO_3$ powder, followed by extraction of **5a** into dichloromethane (3 × 5 mL). The solution was then dried over Na_2SO_4, and the volume was reduced to 0.5 mL with N_2 stream. Compound **5a** was characterized by HR-MS: $C_{27}H_{36}N_2O_8$, calcd 517.2550 ($M + H^+$), found 517.2552. *For step b, Scheme 2*, HATU (24.3 mg, 0.0639 mmol) and biotin (15.4 mg, 0.0633 mmol) were dissolved in anhydrous dichloromethane (3 mL) and DMF (2 mL), and the mixture was stirred at room temperature for 20 min. To this was added **5a** dissolved in 0.5 mL of anhydrous dichloromethane (0.0419 mmol based on **4a**). The mixture was stirred for 72 h at room temperature. *For step c, Scheme 2*, for the closure of the furan ring, dichloromethane was removed by evaporation and 1,4-dioxane (2 mL) was added to the remaining DMF solution. This was followed by addition of 1 N HCl in water (5 mL), and the mixture, which consisted of a single phase, was stirred at room temperature for 48 h. The mixture was extracted with dichloromethane (4 × 5 mL), and the organic layer was washed by water (2 × 5 mL). The organic layer was then dried over Na_2SO_4, and the volume was reduced by vacuum, followed by a final purification with RP-HPLC by System 1. An off-white solid was obtained by precipitation with hexane from a solution of dichloromethane. (8 mg, 28.5% overall, 0.0419 mmol based on **4a**). Selected data for compound **7a**: HR-MS: $C_{33}H_{39}N_3O_{10}S$, calcd 670.2434 (M + 1), found: 670.2435. ^{1}H NMR ($CDCl_3$, ppm): 0.96 (3H, s, C*H*$_3$-13), 1.26 (2H, m, $COCH_2CH_2CH_2CH_2CH_2$), 1.63−1.75 (8H, m, CH_3-13, H-12, $COCH_2CH_2CH_2CH_2CH_2$), 2.01−2.10 (1H, m, H-16), 2.18−2.38 (3H, H-15, CH_2CO), 2.52−2.68 (2H, m, H-12, H-16), 2.76−2.79 (1H, d, J = 12 Hz, SCH_2), 2.86−2.98 (2H, m, H-14, SCH_2), 2.95−3.08 (1H, b, SC*H*), 3.19 (5H, b, OCH_3, OCH_2, H-15), 3.50 (1H, d, J = 7.2 Hz, OCH_2), 3.92−4.13 (2H, m, COCH_2NH), 4.42 (1H, b, NHC*H*CH), 4.61 (1H, b, H-12), 5.02 (1H, b, NHC*H*CH_2), 6.00−6.20 (2H, b, NH, H-11), 6.54 (1H, b, NH), 7.08 (1H, b, NH), 8.27 (1H, s, H-21). ^{13}C NMR ($CDCl_3$, ppm): 14.8, 23.2, 25.5, 26.6, 28.1, 31.2, 35.2, 36.0, 40.6, 41.0, 41.9, 44.2, 49.4, 55.6, 59.8, 60.8, 62.2, 71.8, 73.2, 88.7, 114.5, 140.8, 143.2, 145.0, 149.2, 150.4, 158.0, 164.7, 169.6, 172.8, 174.3, 216.7.

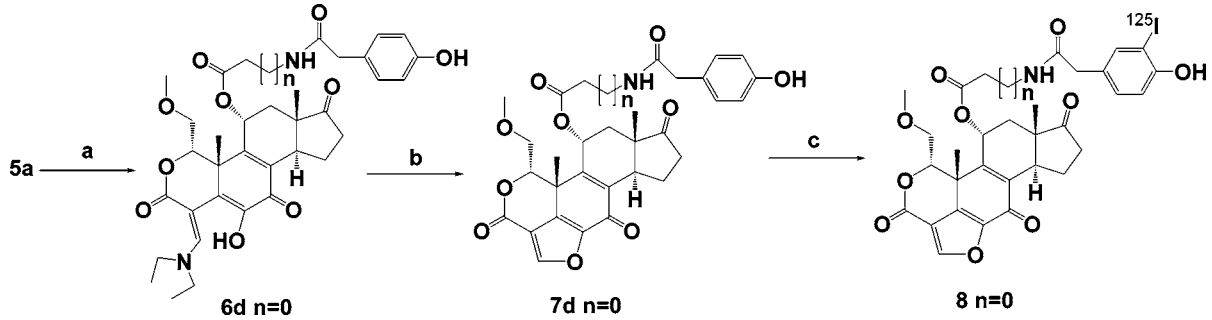
Synthesis of C11 4-Hydroxy-3-iodophenylated Wm (7b). Compound **5a** was prepared as above. *For step a, Scheme 3*, EDC (1-[3-(dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride) (3.8 mg, 0.02 mmol) and 4-hydroxy-3-iodophenyl acetic acid (5.4 mg, 0.02 mmol) were dissolved in anhydrous dichloromethane (0.5 mL) and stirred for 10 min. To this solution was added **5a** (0.01 mmol based on **4a**), prepared in anhydrous dichloromethane (0.5 mL). The mixture was stirred at room temperature for 20 min. *Step b, Scheme 3*, furan ring closure, was performed as above. The final product was purified with RP-HPLC by *system 2*. An off-white solid was obtained by precipitation with hexane from a solution of dichloromethane. (1.6 mg, 22.7% for **7b** overall, 0.01 mmol **4a** based). Selected data for **7b**: HR-MS: $C_{31}H_{30}INO_{10}{\cdot}NH_4^+$, calcd 721.1258, found 721.1262. ^{1}H NMR (CDCl3, 400 MHz): 0.92 (3H, s, C*H*$_3$-13), 1.41−1.47 (1H, m, *H-12*), 1.72 (3H, s, C*H*$_3$-10), 1.97−2.08 (1H, m, *H-16*), 2.23−2.33 (1H, m, *H-15*), 2.55−2.62 (2H, m, *H-12, H-16*), 2.79−2.83 (1H, m, *H-14*), 2.87−2.91 (1H, m, OCH_2), 3.15−3.22 (1H, m, *H-15*), 3.27 (3H, s, CH_3O), 3.29−3.58 (3H, m, OCH_2, ArCH_2CO), 3.85 (1H, dd, J_1 = 5.6 Hz, J_2 = 18 Hz, NHCH_2CO), 4.18(1H, dd, J_1 = 5.6 Hz, J_2 = 18 Hz, NHCH_2CO), 4.73 (1H, d, J = 6.4 Hz, *H-1*), 5.64 (1H, broad, O*H*), 6.15 (1H, td, J_1 = 8 Hz, J_2 = 2.4 Hz, *H-11*), 6.32 (1H, t, J = 5.6 Hz, N*H*), 6.91 (1H, d, J = 8.4 Hz, Ar*H*), 7.17 (1H, dd, J_1 = 3 Hz, J_2 = 8.4 Hz Ar*H*), 7.54 (1H, d, J = 3 Hz, ArH) and 8.27 (1H, s, *H-21*). ^{13}C NMR: ($CDCl_3$, 100 MHz): 14.7, 23.1, 26.6, 35.9, 36.3, 40.5, 41.0, 42.0, 44.2, 49.3, 60.2, 71.3, 73.3, 77.4, 86.0,

Scheme 4. Synthesis of C11 Fluorescein Wm (7c)[a]



[a] Reagents and conditions: (a) **4b**, diethylamine, dichloromethane, room temperature, 6 h (35.3%). (b) **5b**, fluorescein 5(6)-isothiocyanate, DMF, DIPEA, room temperature, overnight; (c) 1 N HCl, 1,4-dioxane, room temperature, 24 h, (8.9%, overall, 0.02 mmol **4b** based).

Scheme 5. Synthesis of ^{125}I Labeled C11 4-Hydroxy-3-iodophenylated Wm (8)[a]



[a] Reagents and conditions: (a) **5a**, EDC, 4-hydroxyphenylacetic acid, room temperature, 20 min; (b) 1,4-dioxane, 1 N HCl, 24 h (17.3%, overall, 0.01 mmol **4a** based); (c) **7d**, NaI-125, iodogen, phosphate buffer (0.5 M, pH 7.4), room temperature, 1−2 min, (more than 85% based on NaI-125).

89.4, 114.3, 115.3, 115.7, 128.6, 130.9, 131.4, 138.5, 139.1, 141.2, 142.8, 145.0, 149.0, 150.4, 154.7, 157.6, 168.8, 171.4, 172.8, and 216.0 (rotomer could be observed).

Synthesis of C11 Fluorescein Wm (7c). The reaction of **5a** with FITC and NHS esters of fluorescein was unsuccessful, presumably on steric grounds, so **5b** with an 11-carbon spacer between the primary amine and Wm was synthesized for fluorescein attachment (Scheme 4). *Fmoc Deprotection of 4b*. To **4b** (9.6 mg, 0.01 mmol) in anhydrous dichloromethane (1 mL) was added diethylamine (0.2 mL). After stirring for 6 h at room temperature, the solvent was evaporated under reduced pressure. The residue was fractioned by preparative silica gel TLC plate (dichloromethane:MeOH:triethylamine = 100:10:1). A yellow foam was obtained after the purification which contains trace amount of impurities generated during the concentration (2.3 mg, 35.3%). Compound **5b** was characterized by HR-MS: $C_{36}H_{54}N_2O_8$, calcd 643.3958 ($M + H^+$), found 643.3943.

For step b, Scheme 4, **5b** (0.02 mmol based on **4b**) and fluorescein 5(6)-isothiocyanate (15.6 mg, 0.04 mmol) were dissolved in DMF (1 mL) with diisopropylethylamine (0.05 mL) and stirred at room temperature for overnight. The closure of the furan ring (step c) was as above, with a final purification by HPLC with System 3. A brown solid was obtained (1.7 mg, 8.9% overall yield, based on 0.02 mmol **4b**). The proton NMR of **7c** lacked some structural detail due to the mixture of 6(5)-isomers in the starting FITC. However, key structural information was obtained confirming the structure **7c**: (1) a singlet at 11.94 ppm indicated the hydroxyl proton on the carboxylic acid fragment of fluorescein; (2) a singlet at 8.27 ppm indicated the furan ring was closed as in Wm; (3) a broad peak at 6.18 ppm indicated that C-11 hydroxy group was acylated; (4) strong peaks at the higher field overlapped with each other, indicating the existence of the 11-amino-undecanoyl ester linkage between Wm and fluorescein. The HR-MS supported the structure **7c**: $C_{53}H_{54}N_2O_{13}S$: calcd 959.3427 ($M + H^+$), found, 959.3434. UV absorbance (λ_{max} = 449.79 nm in methanol) and fluorescence spectra (λ_{ex} = 450 nm, λ_{em} = 515.9 nm in methanol) further indicated the presence fluorescein.

Synthesis of ^{125}I Labeled C11 4-Hydroxy-3-iodophenylated Wm (8). Compound **5a** was converted to **7d** with the similar procedures as **7b** without the isolation of **6d** except the application of 4-hydroxyphenyl acetic acid as one of the reactants (Scheme 5). **7d** was purified by reverse-phase HPLC (system 2) and identified by NMR and MS techniques**.** Iodination of the **7d** was accomplished by using iodogen (1,3,4,6-tetrachloro-3α,6α-diphenylglycoluril) as the oxidant in the precoated tubes for 1−2 min. A stock solution of iodogen in dichloromethane with 0.5 μg/μL concentration (10 μL) was transferred to a V-shape vial. An iodogen precoated tube was made by blowing the above vial to dry with N_2 flow. Then phosphate buffer (0.5 M, pH 7.0) (10 μL) was added to the vial. A solution of 125-NaI (1 μL, 400−500 μCi) and a solution of **7d** in DMSO (1 μg/μL) (1 μL) were added sequentially. The mixture was vortexed for 1−2 min.

PI3 Kinase Assay. The assay was that of Cantley and co-workers with minor modifications (*21*). Briefly, CHO-K1 cells were lysed with lysis buffer (25 mM Tris-HCl pH 7.4, 150 mM NaCl, 1% NP-40, 1 mM EDTA, 20 mM NaF, 10 mM NaPPi, 50 mM β-glycerophosphate, 1 mM DTT, 1 mM Na_3VO_4, 1 mM PMSF, 4 μg/mL each of leupeptin, aproteinin, and pepstatin). The lysate was

clarified by centrifugation, and PI3K was immunoprecipitated overnight at 4 °C with a rabbit polyclonal antiserum against the p85 regulatory subunit of PI3K. The immunoprecipitate was captured on protein-A Sepharose beads and washed thrice with IP wash buffer (25 mM Tris-HCl pH 7.4, 150 mM NaCl, 1% NP-40, 1 mM EDTA, 20 mM NaF, 10 mM NaPPi, 50 mM β-glycerophosphate) and thrice with kinase assay buffer (20 mM Tris-HCl pH 7.4, 100 mM NaCl, 0.5 mM EGTA). The immunoprecipitated PI3K was preincubated with a lipid substrate mix of phosphatidylserine, phosphatidylinositol, pnosphatidylinositol 4-phosphate, and phosphatidylinositol 4,5-bisphosphate (in HEPES pH 7.4 30 mM, EGTA 1 mM) at room temperature for 10 min with or without the presence of Wm. Kinase reaction was initiated with the addition of γ-[32]P-ATP (in HEPES pH 7.4 30 mM, $MgCl_2$ 10 mM and ATP 0.5 mM) and allowed to proceed for 10 min at room temperature before termination with 4 M HCl. The phospholipid products were extracted with MeOH:$CHCl_3$ (1:1). The organic fraction contained the phospholipids that were separated by TLC with 2 M acetic acid:*n*-propanol (35:65) as solvent. Phospholipid signal was quantified using a phosphoimager screen. The percent inhibition of enzyme activity as a function of Wm concentration was analyzed to yield IC_{50}s using a four-parameter fit on GraphPad Prism software.

Reaction of C11-Modified Wm's with Proteins. ^{125}I labeled C11 4-hydroxy-3-iodophenylated Wm (**8**) was reacted with PI3K purified by immunoprecipitation as above. Briefly, 300 μg lysate was incubated with 1000 nM **8** (250 μCi) for 30 min at 4 °C. Proteins were then solubilized in reducing SDS sample buffer and resolved by SDS−PAGE. Gels were dried and visualized by exposure to a phosphorimager cassette for 18 h. For the reaction of C11 biotinylated Wm with BSA, 10 mg/mL in PBS was reacted with 10 or 100 μM of either C11 biotin Wm or as a positive control the *N*-hydroxysuccinimide ester of biotin (Pierce Chemical, Rockford IL) for 1 h at 37 °C. Two micrograms of protein was then subjected to SDS−PAGE followed by reaction with avidin-horseradish peroxidase (Pierce Chemical) diluted 1/20 000 in PBS containing 0.05% Tween 20 (2 h, RT, shaking). Visualization was with 3,3′-diaminobenzidine and 4-chloro-1-naphthol (Sigma-Aldrich, St. Louis, MO) at 20 mg of each, in 100 mL of PBS with 20 μL of 30% hydrogen peroxide.

RESULTS

The synthetic strategy of C11 reporter Wm's has several key features. Wm was reacted in a polar solvent methanol with diethylamine to form a C20-modified and C-11-desacetylated adduct (**2**) which was converted to the furan ring-closed derivative **3** according to the method of Creemer et al. (*20*). Compound **3** was reacted with *N*-Fmoc-glycyl acid chloride or *N*-Fmoc-11-aminododecanoyl acid chloride to yield **4a** and **4b**, respectively, with decent yields, quality, and stability. These compounds were stable during storage at −20 °C for at least 3 months and were obtained in high yield (50−70%). An instability was noted when the storage of **5a** and **5b** was attempted. Due to the base sensitivity of the compound, Fmoc deprotection was accomplished with milder base diethylamine in nonpolar solvent dichloromethane, which removed the Fmoc group and opened the furan ring in a useful manner. Reaction of FITC with **4a** was unsuccessful, presumably on steric grounds, so **4b** was synthesized with an 11-carbon spacer between the primary amine and Wm structures. The furan ring reformed readily in acidic conditions.

Table 1. Inhibition of PI3 Kinase by C11 Reporter Wm's

compound	IC_{50} (nM)[a]
Wm (**1**)	1.63 (1.52−1.75)
C11 biotinylated Wm (**7a**)	6.11 (5.31−7.03)
C11 4-hydroxy-3-iodophenylated Wm (**7b**)	11.02 (9.95−12.2)
C11 fluoresceinated Wm (**7c**)	64.9 (54.2−77.8)

[a] 95% confidence intervals within parentheses.

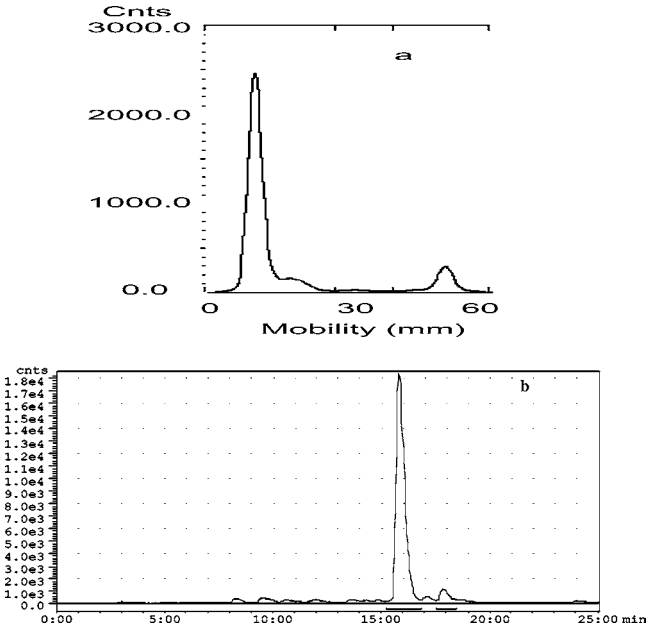


Figure 2. Iodination of C11−4-hydroxyphenylated Wm (**7d**). (a) TLC scan after iodination of **7d**. A reverse phase-TLC with C18-modified silica gel was developed with a mixture of PBS and methanol (2:1). (b) HPLC of the iodination of **7d** with γ-ray detector, C18-modified silica gel column (4.6 × 250 mm), and gradient was from water:acetonitrile 80:20 to 15:85 in 25 min. The peak of radioactivity at 15.48 min corresponded to the peak of C11 4-hydroxy-3-iodophenylate Wm (**7b**) as the internal standard with UV detector at 15.50 min.

The three C11 reporter Wm's were then analyzed for their ability to inhibit PI3 kinase as summarized in Table 1. An IC_{50} of 1.63 nM for Wm (**1**) was obtained, in good agreement with the IC_{50} of 1.8 nM reported earlier (*20*). The C11 biotinylated Wm (**7a**) and C11 4-hydroxy-3-iodophenyl Wm (**7b**) had IC_{50}s of 6.11 and 11.02 nM, respectively, modestly higher than Wm, while the C11 FITC Wm (**7c**) had an IC_{50} to 64.9 nM.

We used a C11 4-hydroxyphenyl Wm (**7d**) as substrate for iodination with 125-NaI by the iodogen method as shown in Scheme 5. About 85−100% of iodine reacted with **7d** as shown by the larger peak of low mobility in Figure 2a. The smaller peak of high mobility was identified as radioactive iodide. The iodinated mixture was further characterized by HPLC using a radioactive detector as shown in Figure 2b. The major peak at 15.48 min had been verified with the retention time consistency with **7b** at 15.50 min by using **7b** as an internal standard with a UV detector.

We next examined whether our C11 ^{125}I labeled 4-hydroxy-3-iodophenyl Wm (**8**) could be detected after reaction with proteins, and whether it could indicate the molecular weight of the protein with which it reacted. C11 ^{125}I labeled 4-hydroxy-3-iodophenyl Wm (**8**) was reacted with a p85 immunoprecipitate from CHO cells as shown in Figure 3. After reaction, radioactivity was

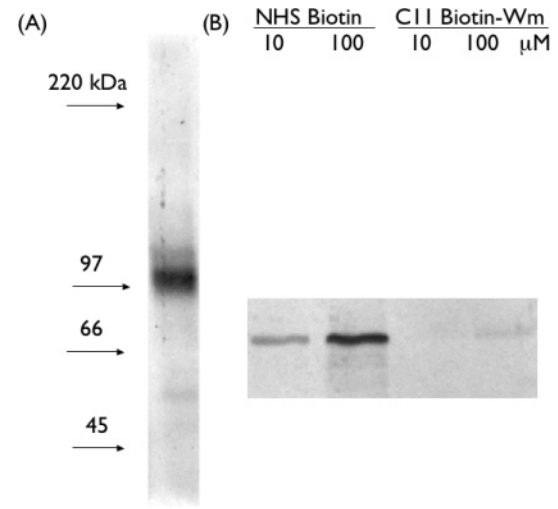

Figure 3. Visualization of the reaction of C11-modified Wm's with proteins. (A) The C11 ^{125}I 3-iodo-4-hydroxyphenyl Wm (**8**) was reacted with purified PI3K, subjected to SDS−PAGE and visualized by autoradiography. Molecular markers were myosin, phosphorylase, bovine serum albumin, and ovalbumin. (B) The C11 biotinylated Wm (**7a**) or the *N*-hydroxysuccinimide ester of biotin at 10 or 100 μM was reacted with purified bovine serum albumin at 10 mg/mL (2 h, 37 °C), subjected to SDS−PAGE and visualized with an avidin-horseradish peroxidase and substrate.

detectable and was associated with a band of about 100 kDa, which is a mobility similar to that expected for p110 catalytic subunit of PI3K (Figure 3A). We also examined the ability of our C11 biotinylated Wm (**7a**) to be detected after exposure to a non-PI3K protein, bovine serum albumin (BSA), under conditions of high protein (20 mg/mL) which would favor this reaction. As a positive control, BSA was reacted with the *N*-hydroxysuccinimide (NHS) ester of biotin. As shown in Figure 3B, only a trace amount of biotinylated BSA was seen with 100 μM C11 biotinylated Wm. Thus both C11 ^{125}I labeled 4-hydroxy-3-iodophenyl Wm (**8**) and the C11 biotinylated Wm (**7a**) are Wm probes that can be used to monitor the reactivity of Wm with proteins.

DISCUSSION

The inhibition of PI3 kinase with C11-modified Wm's can be evaluated in light of previous studies of Wm-based PI3 kinase inhibitors. Creemer et al. found that the replacement of the C11 acetyl group (CH_3COO) with a variety of modestly larger functional groups yield compounds with lower IC_{50}s than Wm (**1**). For example replacement of the C11 acetyl with a propyl group (CH_3-CH_2COO) yielded an IC_{50} of 0.38 nM, while removal of the acetyl group (11-*O*-desacetylwortmannin) had an IC_{50} of 10 nM (Wm IC_{50} = 1.8 nM). These results are supported by the crystal structure of the Wm binding in the ATP site of PI3 kinase, indicating hydrophobic amino acid side chains in the vicinity of the C11 interact favorably with small hydrophobic groups and unfavorably with the hydrophilic hydroxyl group of 11-*O*-desacetylwortmannin (*16*). The modest increase in IC_{50}s we obtained for the C11 biotinylated (**7a**) and 4-hydroxy-3-iodophenyl Wm's (**7b**), 3.7 and 6.8-fold respectively, suggest these compounds slightly exceed the constraints of the PI3 kinase Wm binding site for C11 modifications. The larger C11-fluorescein-modified Wm (**7c**) we synthesized appears to exceed the constraints of the C11 pocket, evident by a 39.8-fold increase in IC_{50}. Thus PI3 kinase binds C11-modified Wm's, provided the modification remains about the size of a biotin moiety or smaller and suggest that future C11 Wm probes must utilize small and hydrophobic modifications at C11, to maximize their interaction with ATP site of PI3 kinase.

A goal of this work was to determine whether various reporter Wm's might inhibit PI3 kinase sufficiently to permit their use with in vivo systems. It would be reasonable to evaluate these probes in vivo, in light of the affinities and losses in affinity often associated with the synthesis of radioactive steroids (*22*−*24*). In addition, our results suggest that the design of further fluorescent C11 Wm's that have a high affinity for PI3 kinase might be possible, but that the size of the modification and fluorochrome should be kept as small as possible.

Example of Fatty Acid-Loaded Lipoplex in Enhancing in Vitro Gene Transfer Efficacies of Cationic Amphiphile[§]

Bharat Kumar Majeti,[†] Priya Prakash Karmali,[†] Sunkara Sakunthala Madhavendra,[‡] and Arabinda Chaudhuri*,[†]

Division of Lipid Science and Technology, and Electron Microscopy Center, Indian Institute of Chemical Technology, Hyderabad 500 007, India. Received December 31, 2004; Revised Manuscript Received April 5, 2005

Herein, we report on the design and synthesis of a novel nontoxic cationic amphiphile *N*,*N*-di-n-tetradecyl-*N*-[2-[*N*′,*N*′-bis(2-hydroxyethyl)amino]ethyl]-*N*-(2-hydroxyethyl)ammonium chloride (lipid **1**) whose in vitro gene transfer efficacies in CHO, COS-1, MCF-7, and HepG2 cells are remarkably enhanced when used in combination with 30 mole percent added myristic acid. Reporter gene expression assay using *p*-CMV-SPORT-*β*-gal reporter gene revealed poor gene transfer properties of the cationic liposomes of lipid **1** and cholesterol (colipid). However, the in vitro gene delivery efficacies of lipid **1** were found to be remarkably enhanced when the cationic liposomes of lipid **1** and cholesterol were prepared in the presence of 30 mole percent added myristic acid (with respect to lipid **1**) as the third liposomal ingredient. The whole cell histochemical X-gal staining of representative CHO cells further confirmed the significantly enhanced gene transfer properties of the fatty acid-loaded cationic liposomes of lipid **1** and cholesterol. Electrophoretic gel patterns in the gel mobility shift assay supports the notion that better DNA release from fatty acid lipoplexes might play a role in their enhanced gene transfer properties. In addition, such myristic acid-loaded lipoplexes of lipid **1** were also found to be serum-compatible up to 30% added serum. Taken together, our present findings demonstrate that the transfection efficacies of fatty acid-loaded lipoplexes are worth evaluating particularly when traditional cationic liposomes prepared with either cholesterol or DOPE colipids fail to transfect cultured cells.

INTRODUCTION

Designing safe and efficacious reagents for transferring genes into body cells continue to remain as the key challenge in gene therapy. Contemporary gene transfection vectors are broadly classified into two categories: viral and nonviral. Viral vectors, although remarkably efficient, suffer from numerous biosafety-related disadvantages including generation of replication-competent virus, possible inflammatory and immunogenic responses against the virus structural components, etc. (*1*−*8*). In addition, viral vectors have a low insert-size limit for the therapeutic genes they can pack inside. Conversely, because of their least immunogenic nature, robust manufacture, ability to deliver large pieces of DNA, and ease of handling and preparation techniques, cationic amphiphiles are increasingly being demonstrated as the alternative nonviral transfection vectors of choice (*9*−*39*), our own work included (*31*−*39*). However, a major limitation of cationic transfection lipids is their poor transgene expression efficacies. To this end, previously reported structure−activity investigations have demonstrated that presence of one or two 2-hydroxyethyl functionalities in the polar headgroup regions of cationic amphiphiles, in general, imparts high in vitro gene transfer properties to cationic amphiphiles (*33*, *36*, *39*−*40*). Inspired by these early reports, in the present investigation, we designed and synthesized a novel cationic lipid *N*,*N*-di-n-tetradecyl-*N*-[2-[*N*′,*N*′-bis(2-hydroxyethyl)amino]ethyl]-*N*-(2-hydroxyethyl)ammonium chloride (lipid **1**, Figure 1) and evaluated its in vitro gene transfer efficacies in multiple cultured cells including CHO, COS-1, MCF-7, and HepG2 using pCMV-SPORT-*β*-gal plasmid as the reporter gene. As delineated below, except in CHO cells at lipid:DNA charge ratio of 0.3:1, lipid **1** was found to be poorly transfecting when used in combination with equimolar cholesterol as co-lipid in COS-1, MCF-7, and HepG2 cells across the entire lipid:DNA charge ratios of 9:1 to 0.3:1. Electrophoretic gel patterns in the gel mobility shift assay indicated the

existence of strong binding interactions between DNA and the cationic liposomes of lipid **1** and equimolar cholesterol across the lipid:DNA charge ratios of 9:1 to 1:1 and existence of moderate binding interactions even at the low lipid:DNA charge ratio of 0.3:1. In other words, the findings in the gel mobility shift assay hinted that poor gene transfer efficacies of lipid **1** might originate due to such strong lipid:DNA interactions. Toward reducing strong binding interactions between the cationic liposomes of lipid **1** and DNA, we decided to use myristic acid as an additional liposome ingredient with the assumption that the negatively charged carboxyl group of the added myristic acid would be able to reduce the overall positive charge of the resulting liposome. Consistent with such a rationale, not only the in vitro gene transfer efficacies of such myristic acid-loaded lipoplexes of lipid **1** were observed to be remarkably enhanced in all four cell lines, but the enhanced gene transfer properties of the resulting fatty acid-loaded lipoplexes were also found to be serum-compatible in the presence of up to 30% added serum. Herein, we report on the enhanced gene transfer efficacies and serum compatiblity of the myristic acid-loaded lipoplexes of lipid **1** compared to their acid-lacking counterparts in CHO, COS-1, MCF-7, and HepG2 cells. Taken together, our present findings demonstrate that the transfection efficacies of fatty acid-loaded lipoplexes are worth evaluating particularly where traditional cationic liposomes prepared with either cholesterol or DOPE colipids fail to transfect cultured cells.

EXPERIMENTAL PROCEDURES

Materials and Methods. The FABMS analyses were performed on a Micromass AUTOSPEC-M mass spectrometer (Manchester, UK) with OPUS V3, 1X data system. Data were acquired by liquid secondary ion mass spectrometry (LSIMS) using *m*-nitrobenzyl alcohol as the matrix. ^{1}H NMR spectra were recorded on a Varian FT 200 MHz or AV 300 MHz. 1-Bromotetradecane and n-tetradecylamine were procured from Lancaster (Morecambe, England). Column chromatography was performed with silica gel (Acme Synthetic Chemicals, India, 60−120 mesh), and Amberlyst A-26 was purchased from Lancaster (Morecambe, UK). Cell culture media, fetal bovine serum, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), poly(ethylene glycol) 8000, *o*-nitrophenyl-*β*-D-galactopyranoside(ONPG), agarose, cholesterol, and cell culture lysis buffer were purchased from Sigma, St. Louis, MO. Lipofectamine 2000 was purchased from invitrogen. NP-40 and antibiotics were purchased from Hi-media, India. Unless otherwise stated, all reagents were purchased from local commercial suppliers and were used without further purification. Purity of the final lipid (**1**) was determined by analytical HPLC (Shimadzu Model LC10A) using a PARTISIL 5 ODS-3 WCS analytical column (4.6 × 250 mm, Whatman Inc., Clifton, NJ) in two different mobile phases. One solvent system (A) was methanol**:**water in the ratio 98:2 (v/v) for 20 min with a flow rate of 0.9 mL/min. The other solvent system (B) was methanol (100%) for 20 min with a flow rate of 0.9 mL/min. Peaks were detected by UV absorption at 219 nm. The target lipid (**1**) showed more than 95% purity. The retention times for lipid **1** in mobile phase A and B were 2.75 min and 2.27 min, respectively.

Synthesis of *N*,*N*-Di-n-tetradecyl-*N*-[2-[*N*′,*N*′-bis-(2-hydroxyethyl)amino]ethyl]-*N*-(2-hydroxyethyl)-ammonium Chloride (Lipid 1, Figure 1). *N*-(aminoethyl)-*N*,*N*-di-n-tetradecylamine (**I**, 1 g, 2.212 mmol, prepared as described previously (*35*)) was stirred at room temperature with an excess amount of chloroethanol (3 mL) for 5 min. NaOH (885 mg, 22.12 mmol) dissolved in water (3 mL) was added to the reaction mixture, and it was heated at 85 °C for 36 h. Excess 2-chloroethanol was removed on a rotary evaporator by repeated addition of methanol. Column chromatographic purification using 60−120 mesh silica gel and 5−7% methanol in chloroform as eluent afforded 260 mg (19%) of the title compound as a white solid. ^{1}H NMR (300 MHz, $CDCl_3$) δ/ppm = 0.90 [t, 3H, C*H*$_3$(CH$_2$)$_{13}$], 1.20−1.45 [bs, 44H, (C*H*$_2$)$_{11}$], 1.60−1.80 [m, 4H, N(CH$_2$C*H*$_2$)], 2.65−2.80 [bs, 4H, N(C*H*$_2$CH$_2$OH)], 3.00−3.15 [bs, 2H, NCH$_2$C*H*$_2$N], 3.30−3.50 [bs, 4H, NC*H*$_2$(CH$_2$)$_{12}$], 3.60−3.80 [bs, 8H, NCH$_2$C*H*$_2$-OH, NC*H*$_2$CH$_2$N, quaternary NC*H*$_2$CH$_2$OH], 4.00−4.15 [bs, 2H, quaternary NCH$_2$C*H*$_2$OH]. FABMS (LSIMS)**:** *m*/*z*: 586 [M + 1]$^+$ for $C_{36}H_{77}O_3N_2$.

Plasmids. pCMV-SPORT-*β*-gal plasmid was amplified in DH5α strain of *Escherichia coli*, isolated by an alkaline lysis procedure and finally purified by PEG-8000 precipitation as described previously (*41*). The purity of plasmid was checked by A_{260}/A_{280} ratio (around 1.9) and 1% agarose gel electrophoresis.

Cells and Cell Culture. COS-1 (SV 40 transformed African green monkey kidney cells)**,** CHO (Chinese hamster ovary), MCF-7 (human breast adenocarcinoma cell), and HepG2 (human hepatocarcinoma) cell lines were procured from the National Centre for Cell Sciences (NCCS), Pune, India. Cells were cultured at 37 °C in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum, 50 *μ*g /mL penicillin, 50 *μ*g/mL streptomycin, and 20 *μ*g/mL kanamycin in a humidified atmosphere containing 5% CO_2.

Preparation of Liposomes and Lipid−DNA Complexes. The cationic lipid and cholesterol in 1:1 mole ratio or the cationic lipid, cholesterol, and myristic acid in 1:1:0.3 mole ratio were dissolved in chloroform in a glass vial. The solvent was removed with a thin flow of moisture-free nitrogen gas, and the dried lipid film was then kept under high vacuum for 8 h. The dried lipid film was hydrated in sterile deionized water in a total volume of 3 mL at cationic lipid concentration of 1 mM for a minimum of 12 h. Liposomes were vortexed for 1−2 min to remove any adhering lipid film and sonicated in a bath sonicator (ULTRAsonik 28X) for 2−3 min at room temperature to produce multilamellar vesicles (MLV). MLVs were then sonicated with a Ti-probe (using a Branson 450 sonifier at 100% duty cycle and 25 W output power) for 1−2 min to produce small unilamellar vesicles (SUVs) as indicated by the formation of a clear translucent solution.

Transfection Biology. Cells were seeded at a density of 20000 cells (for CHO, MCF-7, HepG2) and 15000 cells (for COS-1) per well in a 96-well plate 18−24 h before the transfection. 0.30 *μ*g of pDNA was complexed with varying amounts of lipids (to give ± ratios of 0.3:1, 1:1, 3:1, and 9:1) in plain DMEM (total volume made up to 100 *μ*L) for 20−30 min. While evaluating the transfection efficiencies of the lipids in the presence of serum, the complexes were diluted with 100 *μ*L of DMEM containing either 20% or 60% FBS to give a final concentration of 10% and 30% serum, respectively. After 3 h of incubation, the medium was replaced by 200 *μ*L of DMEM containing 10% FBS. The medium was changed to complete medium containing 10% FBS after 24 h, and the reporter gene activity was estimated after 48 h. Cells were washed with PBS (100 *μ*L) and lysed in 50 *μ*L lysis buffer [0.25 M Tris-HCl (pH 8.0), 0.5% NP40]. The *β*-galactosidase activity per well was estimated by adding 50 *μ*L of 2×-substrate solution [1.33 mg/mL of ONPG, 0.2 M sodium phosphate

(pH 7.3) and 2 mM magnesium chloride] to the lysate in a 96-well plate. Absorbance of the product *o*-nitrophenol at 405 nm was converted to β-galactosidase units by using the calibration curve constructed using the pure commercial β-galactosidase enzyme. The transfection values reported are the average values from two replicate experiments performed in the same plate on the same day. The values of β-galactosidase units for duplicate experiments carried out on the same day varied within 20−30%. Each transfection experiment was performed two times on two different days. The day to day variation in transfection efficiency was mostly within 2−3-fold and was dependent on the cell density and condition of the cells. The transfection profiles obtained on different days were identical.

Toxicity Assay. Cytotoxicity of lipid **1** was assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay as described earlier (*42*)**.** The cytotoxicity assay was performed in a 96-well plate by maintaining the same ratio of number of cells to amount of cationic lipid, as used in the transfection experiments. MTT was added 3 h after addition of cationic lipid to the cells. Results were expressed as percent viability = [A_{540}(treated cells) − background/ A_{540}(untreated cells) − background] × 100.

Gel Mobility Shift Assay. The DNA binding ability of the cationic lipid **1** was assessed by the gel mobility shift assay on a 1% agarose gel. 0.60 μg of pCMV-β-gal was complexed with varying amounts of cationic lipids (using the indicated lipid:DNA charge ratios in Figure 6) in a total volume of 40 μL in HEPES buffer, pH 7.40, and incubated at room temperature for 20−25 min. 8 μL of 6× loading buffer (0.25% bromophenol blue, 40% sucrose) was added to it, and 20 μL of the resultant solution was loaded in each well. The samples were electrophoresed at 90 V for approximately 3 h, and the DNA bands were visualized by staining for 30 min with ethidium bromide solution.

X-Gal Staining. Cells expressing β-galactosidase were histochemically stained with the substrate 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal) (Figure 3) as described previously (*34*). Briefly, 48 h after transfection with lipoplexes in 96-well plates, the cells were washed two times (2 × 100 μL) with phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4) and fixed with 0.5% glutaraldehyde in PBS (225 μL). After 15 min incubation at room temperature, the cells were washed again with PBS three times (3 × 250 μL) and subsequently were stained with 1.0 mg/mL X-gal in PBS containing 5.0 mM $K_3[Fe(CN)_6]$, 5.0 mM $K_4[Fe(CN)_6]$, and 1 mM $MgSO_4$ for 2−4 h at 37 °C. Blue colored cells were identified by a light microscope (Leica, Germany).

Transmission Electron Microscopy. Transmission electron microscopy was performed on a FEI Tecnai 12 TEM apparatus operated at 100 KV. Liposomes or lipoplex samples were transferred onto an ultrathin carbon-coated copper grid by placing the grid on top of a 10 μL drop of the sample for 1 min. After removing the excess fluid from one side, the grid was placed on a 20 μL water drop for a 30 s wash. The excess fluid was removed, and the grid was placed for 1 min on a 20 μL drop of freshly filtered uranyl acetate (1.33%). Once again, the excess fluid was wicked away, and the grid was air-dried.

RESULTS

Chemistry. The mixed tertiary-primary amine precursor (**I**, Figure 1) was prepared by reacting *N*,*N*-di-n-tetradecylamine with *N*-*tert*-butyloxycarbonyl-2-bromoethylamine in ethyl acetate in the presence of anhydrous potassium carbonate followed by acid deprotection as described previously (*35*). Lipid **1** was synthesized by quaternizing the mixed tertiary-primary amine precursor (**I**, Figure 1) with excess 2-chloroethanol. The unreacted 2-chloroethanol was removed under vacuum, and the column chromatographic purification of the residue afforded pure target lipid **1**. Presence of quaternized nitrogen center in lipid **1** was confirmed from the disappearance of the two triplet peaks in the ^{1}H NMR spectrum of precursor **I** (Figures S1 and S2, Supporting Information) associated with the three methylene units directly attached to its tertiary nitrogen atom. The molecular ion peak in FAB mass spectrum (M + 1 586, Figure S3, Supporting Information) and the relative integration peak areas in the ^{1}H NMR spectrum of lipid **1** (Figure S2, Supporting Information) clearly showed that the primary amine group of precursor **I** was covalently modified with only two 2-hydroxyethyl groups when treated with excess 2-chloroethanol. Purity of lipid **1** was confirmed by reversed phase HPLC analysis using two different mobile phases (Figure S4, Supporting Information).

Contrasting Transfection Efficacies of Fatty Acid-Loaded Lipoplexes and Their Acid-Lacking Counterparts. The in vitro gene transfer efficacies of lipid **1** were first measured by the reporter gene expression assay using equimolar cholesterol as colipid, and pCMV-SPORT-β-gal plasmid as the reporter gene, in COS-1, CHO, MCF-7, and HepG2 cells across the lipid:DNA charge ratios 9:1−0.3:1 in the absence of any added fatty acids. Except in CHO cells at lipid:DNA charge ratio of 0.3:1, the gene transfer efficacies of lipid **1** were found to be significantly less than that of LipofectAmine 2000, one of the most widely used commercially available liposomal transfection kits (Figure 2, parts A−D, open bars). Contrastingly, the efficacies of lipid **1** in transfecting all four cell lines were remarkably enhanced when 30 mole percent myristic acid (with respect to lipid **1**) was used as an added liposomal ingredient (Figure 2, parts A−D, filled bars). While in both MCF-7 and COS-1 cells, myristic acid-loaded liposomes of lipid **1** were found to be optimally transfection efficient around 0.3:1 lipid **1**:DNA charge ratio (Figure 2, parts A and C, filled bars), the highest efficacies of the acid-loaded liposomes of lipid **1** in transfecting CHO and HepG2 cells were found to be at lipid **1**:DNA charge ratios of 1:1 and 3:1, respectively (Figure 2, parts B and D, filled bars). In all four cell lines, the optimal transfection efficiencies of fatty acid-loaded liposomes of lipid **1** were observed to be better than or comparable to that of LipofectAmine 2000 (Figure 2, parts A−D, filled bars). Interestingly, the most extensively used colipid in cationic lipid-mediated gene delivery, namely 1,2-dioleyol-*sn*-glycerophosphatidylethanolamine (DOPE), was found to be ineffective in imparting any gene transfer properties to lipid **1** (data not shown). The superior transfection profile of fatty acid-loaded liposomes of lipid **1** was further confirmed by the whole cell histochemical X-gal staining of the representative CHO cells. Consistent with the findings in the reporter gene expression assays as summarized in part B of Figure 2, the number of transfected X-gal stained cells at lipid **1**:DNA charge ratio of 1:1 was found to be significantly higher with fatty acid-loaded liposomes of lipid **1** (Figure 3).

Serum-Compatible Transfection Properties of Fatty Acid-Loaded Lipoplexes of Lipid 1. In stark contrast to the commonly observed serum incompatibility

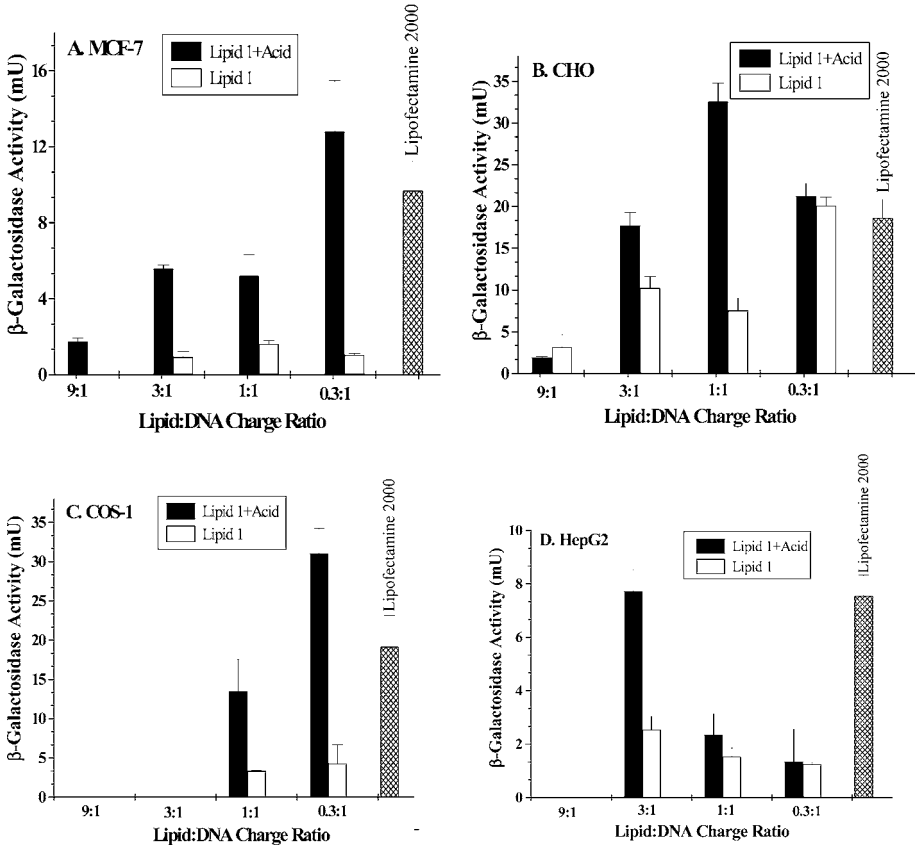

Figure 2. In vitro transfection efficiencies of lipid **1** using reporter gene expression assays. MCF-7 (A), CHO (B), COS-1 (C), and HepG2 (D) cells were transfected with lipid **1** and cholesterol (as colipid) both in the presence and in absence of added myristic acid at lipid:colipid:myristic acid mole ratio of 1:1:0.3 and 1:1:0, respectively. The transfection efficiencies of the lipid **1** were compared to that of commercially available Lipofectamine 2000. Units of β-galactosidase activity were plotted against the varying lipid to DNA (+/−) charge ratios. The transfection values shown are average of duplicate experiments performed on the same day. Details of transfection assays are as described in the text.

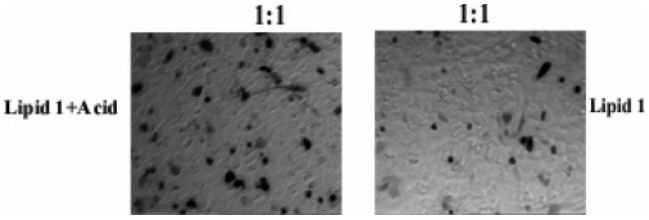

Figure 3. The whole cell histochemical X-gal staining of transfected CHO cells. CHO cells were transfected with lipid **1** (both in the presence and in absence of added myristic acid at lipid:cholesterol:myristic acid mole ratio of 1:1:0.3 and 1:1:0, respectively) at lipid:DNA charge ratio of 1:1. Cells expressing β-galactosidase were stained with X-gal as described in the text.

of cationic transfection lipids, myristic acid-loaded liposomes of lipid **1** were found to be serum-compatible (up to 30% added serum). The most encouraging serum-compatible transfection profiles were observed in MCF-7 and CHO cells at lipid **1**:DNA charge ratios of 9:1 and 3:1. In MCF-7 cells, at both the lipid:DNA charge ratios, the fatty acid-loaded liposomes remained remarkably transfection efficient up to 30% added fetal bovine serum practically without any loss of transfection efficiency (Figure 4, parts A and B). However, transfection efficacies were compromised with more than 30% added serum (data not shown). Most notably, at the high lipid **1**:DNA charge ratio of 9:1, the transfection efficacies of fatty acid-loaded liposomes of lipid **1** were found to be remarkably enhanced compared to their non-fatty acid counterparts in the presence of 30% added serum in both MCF-7 and CHO cells (Figure 4, parts A and C). Interestingly, the serum-compatible high transfection efficacies of fatty acid-loaded liposomes of lipid **1** (compared to their non-fatty acid counterparts) in COS-1 cells were observed only at lower lipid:DNA charge ratios of 0.3:1 up to 30% added serum and in HepG2 cells at 9:1 lipid:DNA charge ratios up to 10% added serum (data not shown).

Physicochemical Characterizations of Liposomes and Lipoplexes. Sizes and Zeta Potentials. Toward gaining insights into whether varying sizes and global surface charges of both the fatty acid-loaded of liposomes of lipid **1** and its non-fatty acid counterparts might play some role behind their contrasting transfection profiles, lipoplex sizes and surface potentials were measured in the presence of DMEM by dynamic laser light scattering instrument equipped with zeta-sizing capacity. Interestingly, the average sizes of both the lipoplexes (fatty acid-loaded lipoplexes and lipoplexes with no added fatty acids) were found to be within the range 200−270 nm for lipid:DNA charge ratios 0.3:1 and 1:1 (detail size data of lipoplexes measured across the lipid:DNA charge ratios are provided in Table 1). However, at 3:1 lipid:DNA charge ratio, lipoplexes with no fatty acid ingredient were found to be significantly bigger (>900 nm) than those containing fatty acids (about 260 nm, Table 1). At 9:1 lipid:DNA charge ratios, both the lipoplexes (with and without added fatty acids) grew big in size (>950 nm, Table 1).

Transmission Electron Microscopy. With a view to gaining insights into whether the fatty acid-loaded lipoplexes as wells as their acid-lacking counterparts

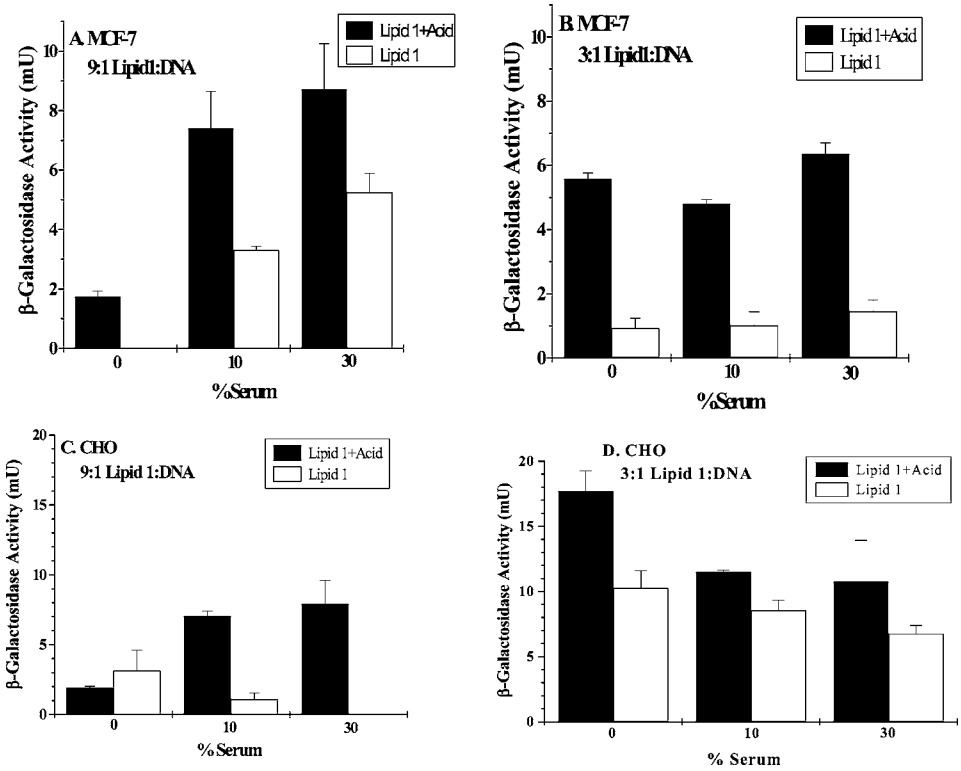

Figure 4. Serum-compatible transfection efficacies of fatty acid-loaded liposomes. In vitro transfection efficiencies of lipid **1** both in the presence and in absence of added myristic acid were measured with 10% and 30% added serum in MCF-7 and CHO cells at lipid:cholesterol:myristic acid mole ratio of 1:1:0.3 or 1:1:0 at lipid:DNA charge ratio of 9:1 (A and C) and 3:1 (B and D). Details of transfection experiments are as described in the text.

Table 1. Hydrodynamic Diameters and Zeta Potentials of Liposomes and Lipoplexes for Lipid 1 in DMEM[a]

Lipids		lipid:DNA (1:0)	lipid:DNA (0.3:1)	lipid:DNA (1:1)	lipid:DNA (3:1)	lipid:DNA (9:1)
Lipid **1**	size (nm)	119.6 ± 0.2	247.2 ± 1.9	207.9 ± 5.1	911.8 ± 77.6	960.3 ± 54.1
	zeta potential (mV)	31.3 ± 0.9	−8.1 ± 3.5	−36.1 ± 1.2	22.3 ± 3.4	27.7 ± 4.6
Lipid **1** + Acid	size (nm)	117.5 ± 3.1	269.6 ± 3.5	204.5 ± 3.7	261.1 ± 8.6	1022.8 ± 107
	zeta potential (mV)	27.9 ± 2.3	−29.5± 2.1	−35.1± 1.6	−18.7 ± 3.2	17.6 ± 3.7

[a] Sizes and Zeta potentials were measured by laser light scattering technique using Zetasizer 3000HS_A (Malvern Instruments, UK) in DMEM. Values shown are the averages obtained from three (size) and ten (zeta potential) measurements.

possess distinctly different morphologies that could possibly play important role behind their contrasting transfection profiles (Figures 2 and 3), we carried out negative staining transmission electron microscopic investigation. The transmission electron micrographs (TEM) of the representative acid-loaded and acid-lacking liposomes and lipoplexes (prepared using lipid: DNA charge ratio of 3:1) indeed revealed some distinct morphological differences. Although fatty acid-loaded liposomes revealed the existence of the usual closed lamellar morphologies (part A, Figure 5), the TEM picture of their acid-lacking counterparts, in addition to showing such regular closed lamellar structures (micrograph not shown), showed the presence of stacked sheets of bilayers containing channel-like structures between (part B, Figure 5). Most notably, the lipid:DNA complexes (lipoplexes) prepared from both these acid-lacking liposomes showed the presence of neither any aggregated sheets of bilayers nor any regular closed bilayer structures. The transmission electron micrographs of the acid-lacking lipoplexes displayed the presence of non-bilayer clustered complexes (Figure 5, part D). Existence of such clustered structures for lipoplexes have previously been reported in the cryo-TEM studies on lipoplexes by Smisterova et al. (*43*). Interestingly, the TEM picture of the fatty acid-containing lipoplexes showed the presence of extensive network of non-bilayer structures (Figure 5, part C).

Gel Mobility Shift Assay. Toward understanding the role of lipid:DNA electrostatic binding interactions (if any) in modulating the in vivo transfection efficacies of fatty acid-loaded liposomes of lipid **1** and their acid-lacking counterparts, gel mobility shift assays were performed using lipoplexes prepared across the wide range of lipid:DNA charge ratios of 9:1 to 0.1:1. The band intensities of the free DNA (unassociated or loosely bound with lipoplexes) particularly for acid-loaded lipoplexes with lipid:DNA charge ratios 1:1 and 0.3:1 were found to be significantly higher than the corresponding bands for acid-lacking lipoplexes (Figure 6)

Cell Viabilities. With a view to understand whether varying cell viabilities could be responsible behind the remarkably superior transfection profiles of myristic acid-loaded liposomes of lipid **1** compared to its acid-lacking counterpart liposomes, cell viabilities of both the lipoplexes were measured using MTT-based cell viability assays in representative MCF-7 cells across the lipid:DNA charge ratios of 9:1 to 0.3:1. Interestingly, both the lipoplexes showed more than 90% cell viabilities up to lipid:DNA charge ratios of 3:1 and slightly reduced cell viabilities (more than 75%) at lipid:DNA charge ratio of 9:1 (Figure 7). Thus, varying cell viabilities of the acid-loaded and acid-lacking lipoplexes were ruled out as a possible cause for their contrasting gene delivery efficacies.

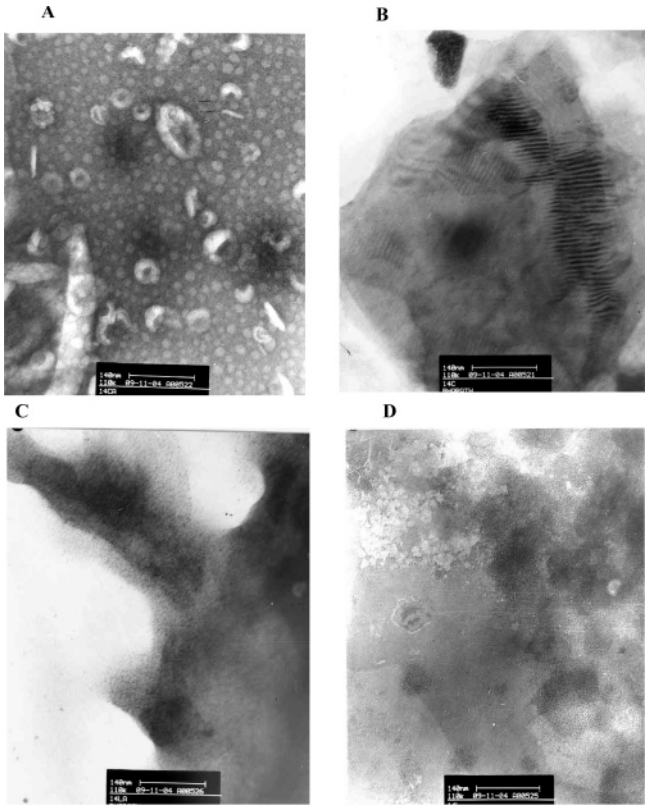

Figure 5. Transmission electron micrographs of liposomes and lipoplexes. Liposomes with loaded fatty acid (A), liposomes without added fatty acid (B), myristic acid-loaded lipoplex of lipid **1** (C), and acid-lacking lipoplex of lipid **1** (D). Lipoplexes were prepared at lipid:DNA charge ratio of 3:1 as described in text. Bars correspond to 140 nm.

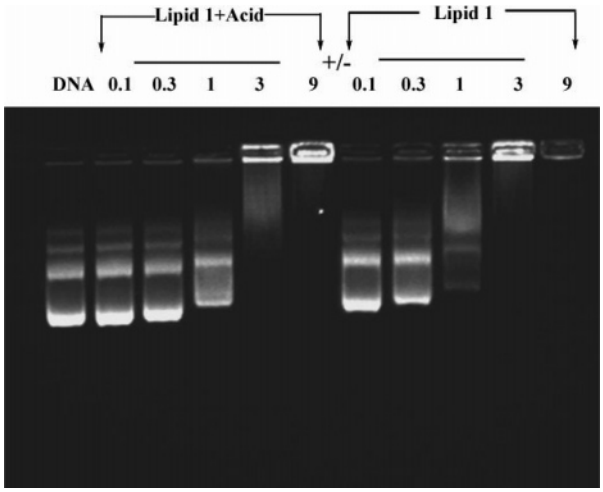

Figure 6. Gel retardation assay. Electrophoretic gel patterns for DNA associated with lipoplexes of lipid **1** prepared from myristic acid-loaded liposomes and liposomes containing no added acid. The lipid:DNA charge ratios are indicated at the top of each lane. The details of treatment are as described in the text.

DISCUSSION

In the present investigation, we report on the remarkably enhanced in vitro gene transfer properties of a novel cationic amphiphile namely, *″ N*,*N*-di-n-tetradecyl-*N*-[2-[*N*′,*N*′-bis(2-hydroxyethyl)amino]ethyl]-*N*-(2-hydroxyethyl)ammonium chloride (lipid **1**, Figure 1) when used in combination with 30 mole percent added myristic acid.

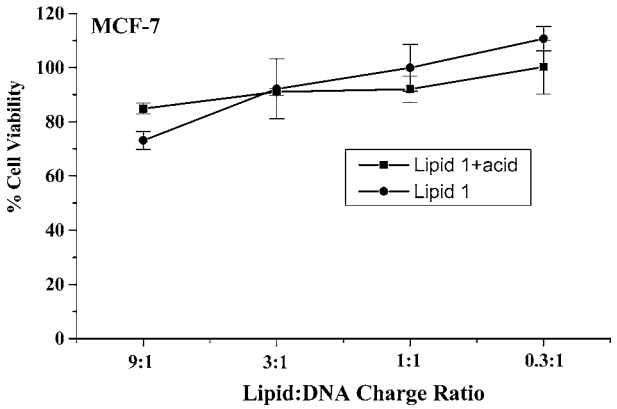

Figure 7. MTT assay-based percent cell viabilities of both acid-loaded and acid-lacking lipoplexes in representative MCF-7 cells. The percent cell viability values shown are average of triplicate experiments performed on the same day. Details of treatment are described in the text.

Except in CHO cells, in the absence of added myristic acid, lipid **1** essentially failed to transfect COS-1, HepG2, and MCF-7 cells (Figure 2) when used in combination with cholesterol. The electrophoretic gel pattern observed in the gel mobility shift assay revealed strong DNA-binding characteristics of cationic liposomes prepared with lipid **1** and equimolar cholesterol (Figure 6). We reasoned that the compromised transfection properties of lipid **1** used in combination with cholesterol might, in part, originate from such strong lipid **1**:DNA electrostatic interactions (capable of preventing optimal DNA release from the lipoplexes inside the cell cytoplasm). With such a rationale in mind, we decided to reduce the overall positive surface charge of cationic liposomes prepared with lipid **1** and cholesterol by using myristic acid as an additional third liposomal ingredient (hoping that the negatively charged carboxylate headgroup of the added fatty acid might be able to reduce the overall positive surface charge of the liposomes and thereby would be able to weaken the strong electrostatic interaction between acid-lacking liposomes and DNA). The transfection results summarized in Figures 2 and 3, taken together, convincingly demonstrated that 30 mole percent added myristic acid was indeed capable of imparting high gene transfer properties to the poorly transfecting acid-lacking liposomes of lipid **1**. Not only were the in vitro gene transfer efficacies of such myristic acid-loaded lipoplexes of lipid **1** observed to be remarkably enhanced in all four cell lines at optimal lipid:DNA charge ratios, but the enhanced gene transfer properties of the resulting fatty acid-loaded lipoplexes were also found to be serum-compatible in the presence of up to 30% added serum (Figure 4). Keeping in view the commonly used high lipid:DNA charge ratios (6:1 to 12:1) in systemic applications of cationic transfection lipids, the remarkably enhanced transfection efficacies of the fatty acid-loaded liposomes of lipid **1** in MCF-7 and CHO cells at 9:1 lipid:DNA charge ratio in the presence of 30% added serum (Figure 4, parts A and C) justifies future studies aimed at exploring the in vivo potential of the presently described myristic acid-loaded lipoplex of lipid **1**.

In presence of serum, the high transfection profiles of cationic amphiphiles are, in general, found to be severely compromised (*44*−*50*). The usual serum incompatibility of cationic transfection lipids are believed to begin via adsorption of negatively charged serum proteins onto the positively charged cationic liposome surfaces (*48*, *50*−*52*). The serum-compatible transfection properties of the present fatty acid-loaded lipoplexes of lipid **1** may partly

originate from their overall reduced positive surface charge. Clearly, future studies aimed at probing serum protein binding with both fatty acid liposomes as well as with their acid-lacking counterparts will be needed to gather further mechanistic insights into the origin of the serum compatibility of the presently described myristic acid-loaded lipoplexes.

The size data support the notion that the poorly transfecting or essentially transfection-incompetent nature of acid-lacking lipoplexes at 3:1 and 9:1 lipid:DNA charge ratios (Figure 2) as well as the transfection incompetent nature of the fatty acid-loaded lipoplexes with 9:1 lipid:DNA charge ratios in absence of serum in all four cell lines (Figure 2) might be related to their big sizes (difficult for the cells to endocytose). Except for lipoplexes with 1:1 lipid:DNA charge ratio, the global surface charges of the fatty acid-loaded lipoplexes were found to be significantly lower than those of the acid-lacking lipoplexes (Table 1). Such lower surface potentials of the fatty acid-loaded lipoplexes up to 3:1 lipid:DNA charge ratios (compared to their acid lacking counterparts) strongly support our above-mentioned rationale of using fatty acid as an additional liposomal ingredient toward imparting enhanced transfection efficacies of lipid **1** lipoplexes.

A possible origin of the extensive network structure of fatty acid-loaded lipoplexes as revealed in its transmission electron micrograph (Figure 5, part C) could be that the fatty acid's negatively charged carboxylate headgroup functionality, in addition to neutralizing the positive charge of cationic amphiphiles, may get involved in the formation of an extensive hydrogen-bonding network with the multiple hydroxyl headgroup functionalities of the neighboring cationic lipids. Such an extensive network of non-bilayer structures might reduce the extent of negatively charged serum proteins adsorption onto the lipoplex surface and thereby imparting serum-compatibility to fatty acid loaded liposomes of lipid **1**. However, details of how such subtle ultrastructural differences between the non-bilayer morphologies of fatty acid-loaded and acid-lacking lipoplexes contribute to their contrasting gene transfer profiles remain unclear at this point of investigation.

The electrophoretic gel pattern observed in the gel mobility shift assay (Figure 6) are consistent with the notion that fatty acid-loaded lipoplexes are more DNA-releasing than their acid-lacking counterparts. This observation is consistent with the superior transfection properties of the fatty acid-loaded lipoplexes partly originating from the enhanced DNA release. In summary, our present findings demonstrate that use of fatty acid-loaded lipoplexes containing low mole percent added fatty acid (with respect to cationic lipid) holds promise toward overcoming the usual serum incompatibity of cationic lipids in nonviral gene therapy.

In conclusion, we have designed a novel nontoxic cationic amphiphile whose in vitro gene transfer efficacies in CHO, COS-1, MCF-7, and HepG2 cells are remarkably enhanced when used in combination with 30 mole percent added myristic acid. In addition, such myristic acid-loaded lipoplexes of lipid **1** were also found to be serum-compatible up to 30% added serum. Taken together, our present findings demonstrate that the transfection efficacies of fatty acid-loaded lipoplexes are worth evaluating particularly when traditional cationic liposomes prepared with either cholesterol or DOPE colipids fail to transfect cultured cells.

Received January 24, 2005; Revised Manuscript Received March 17, 2005

The major task in proteomics is to understand how proteins interact with their partners. The photo-cross-linking technique enables direct probing of protein−protein interaction. Here we report the development of three novel sulfhydryl-reactive benzophenone photoprobes of short "arm" length, each with a substitution of either amino, iodo, or nitro at the para-position, rendering the benzophenone moiety directly radioiodinatable. Their potential for study of protein−protein interaction was assessed using the inhibitory subunit of rod cGMP phosphodiesterase (PDEγ) and the activated transducin α subunit (Gαt-GTPγS) as a model system. These photoprobes proved to be stable at neutral pH and dithiothreitol-cleavable in addition. The PDEγ constructs derivatized at the C-terminal positions with these probes could be readily purified, had unaltered PDEγ functional activity, and were shown to photo-cross-link to Gαt-GTPγS with an efficiency as high as 40%. Additionally, the amino benzophenone probe was radioiodinated, facilitating sensitive detection of label transfer. The uniquely combined features of these benzophenone photoprobes promise robust and flexible methods for characterization of protein−protein interaction, either by mass spectrometry when a nonradioactive label is available or by autoradiography when using radioiodinated derivatives.

INTRODUCTION

The signaling pathway for visual excitation in rod photoreceptors represents a prototypical G-protein cascade comprising the seven-transmembrane receptor (rhodopsin), the heterotrimeric G-protein (transducin), and the effector (phosphodiesterase, PDE6[1]). The interaction between the trandsducin α subunit (Gαt) and the inhibitory γ subunit of PDE6 (PDEγ or Pγ) is a key step. Upon activation by photoexcited rhodopsin, GTP-loaded Gαt activates PDE6 by binding to PDEγ. This signaling event eventually leads to the generation of the electrical response of the photoreceptor cell (*1*). On the other hand, the Gαt/PDEγ interaction is also required for rapid termination of the rod photoresponse (*2*). The conversion of the activated transducin to its inactive state is greatly accelerated by the ninth member of the regulators of G-protein signaling family (RGS9), whose action requires the association of transducin with PDEγ (*2*, *3*). Therefore, information concerning the Gαt/PDEγ interaction is critical for understanding the molecular mechanisms of visual transduction, and, most likely, other G-protein pathways.

Much has been learned about regulation of visual transduction. The atomic structures of activated Gαt alone (*4*, *5*) and complexed with the PDEγ C-terminal half and the catalytic domain of RGS9 (*6*) have greatly enriched our knowledge about interactions of these two signaling proteins. However, due to a lack of atomic structure of the complex of Gαt and full-length PDEγ, it remains a challenging task to uncover important details of a "real" signaling state of the Gαt/PDEγ interaction. While X-ray crystallography and nuclear magnetic resonance (NMR) can offer detailed information about protein−protein interactions, the stability issue and large size of a protein complex add extra difficulty for solving its atomic structure. Some alternative approaches such as photo-cross-linking, however, offer a powerful approach for discovering the missing pieces of the puzzle.

A radiolabeled cleavable photoprobe, [^{125}I]-ACTP ([^{125}I]-*N*-[(3-iodo-4-azidophenyl propionamido-*S*-(2-thiopyridyl)]-cysteine), which contains an azide photophore, has been applied for the structural study of Gαt (*7*), Gαt/PDEγ interaction (*8*), and PDE6 $\alpha\beta$ subunits/PDEγ interaction (*9*). Azides have been conventionally taken as the primary choice of photoreactive group by many researchers since it can be prepared very easily. However, shorter UV wavelengths required for activation of azide photoprobes sometimes cause significant damage to proteins, and azide photoprobes are not efficient since the singlet phenylnitrenes are short-lived (*10*). A photoprobe with an aryldiazonium moiety is more efficient than its azide

derivative but less stable (*11*). In contrast, the benzophenone photophore has distinct advantages. It can be activated in a reversible manner via excitation−relaxation cycles at 350−360 nm, avoiding UV damage, and only C−H bonds within 3.1 Å of the carbonyl oxygen are modified. Moreover, the benzophenone group is stable to common protic solvents, reacts only with target proteins, and generally leads to highly efficient single-site photocovalent modification (*12*). Noncleavable benzophenone photoprobes have been used for defining protein−protein interactions of Gαt/PDEγ (*13*, *14*) and other proteins (*15*−*18*) by photo-cross-linking and mass spectrometry (MS). The proteins cross-linked with the noncleavable photoprobes cannot be separated, resulting in complexity in identification of photoinsertion sites. Cleavable benzophenone photoprobes suited for photo-cross-linking/label transfer experiments are therefore highly desirable.

Here we report the development of three cleavable benzophenone photoprobes each with a methanethiosulfonate (MTS) group, which is highly sulfhydryl-reactive (Figure 1). To illustrate the use of these probes, they were employed to derivatize the single-cysteine PDEγ constructs for cross-linking with Gαt-GTPγS. Their potential for study of protein−protein interactions was assessed using PDEγ/Gαt-GTPγS as a model system. As an additional feature, the amino-benzophenone probe was shown to be radioiodinatable. A noniodinatable benzophenone derivative has been reported for immobilization of ion channels (*19*, *20*), but it is not suitable for radiolabel transfer. To our knowledge, the photoprobes developed in this study are the only reported sulfhydryl-reactive, cleavable, and radioiodinatable benzophenone photoprobes that are optimized for protein−protein interaction studies through a photo-cross-linking/label transfer methodology.

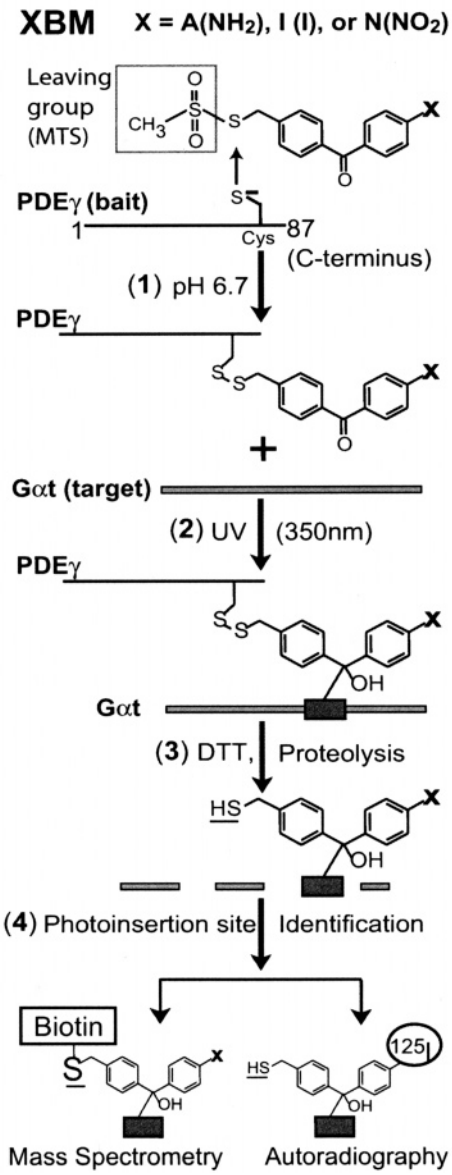

Figure 1. Schematic strategy of protein−protein interaction analysis by photo-cross-linking/label transfer using cleavable benzophenone photoprobes. PDEγ/Gαt interaction is presented as a model system. Solid line, PDEγ. Bar, Gαt. Box, photoinsertion-containing proteolytic fragment of a target protein. DTT-reversed sulfhydryl (underlined) can be made available for addition of a biotin or fluorescent tag.

EXPERIMENTAL PROCEDURES

General. All yields refer to isolated products after purification. Products were characterized by spectroscopy data (IR, ^{1}H NMR spectrum, CHN analyses, melting and boiling point). ^{1}H NMR spectra were recorded at 300 MHz. The spectra were measured in $CDCl_4$ unless otherwise stated, relative to TMS (0.00 ppm). BPMTS (benzophenone-4-carboxamidocysteine methanethiosulfonate) was purchased from Toronto Research Chemicals. Na^{125}I was from Perkin-Elmer as carrier-free radioiodide (2200 Ci/mmol, 5 mCi/20 μL in 0.1 N NaOH). All other chemicals and reagents were from Sigma-Aldrich unless stated elsewhere.

Synthesis of 4-Methyl-4′-nitrobenzophenone (1). In a 500 mL round-bottomed flask to a stirred solution of toluene (300 mL) and 4-nitrobenzoyl chloride (20 g, 108 mmol) was added aluminum chloride (18.7 g, 140 mmol). The resulting red solution was stirred at room temperature for 90 min, and then 5 mL of water was added dropwise and the mixture was stirred for 20 min. The reaction mixture was washed with water (2 × 100 mL) and 10% $NaHCO_3$ (2 × 100 mL) and dried ($Mg SO_4$). The solvent was evaporated under reduced pressure with a rotary evaporator to a pale yellow solid (22.3 g). The resulting residue was recrystallized from methylenechloride/hexane to produce 19.8 g of compound **1** (80%) as light yellow needles. Mp: 119−120 °C. ^{1}H NMR: δ 8.36 (d, J = 8.8 Hz, 2 H), 7.9 (d, J = 8.1 Hz, 2 H), 7.70 (d, J = 8.0 Hz, 2 H), 7.31 (d, J = 8.0 Hz, 2 H), 2.50 (s, 3 H). Anal. Calcd for $C_{14}H_{11}NO_3$: C, 69.70; H, 4.60; N, 5.81. Found: C, 69.80; H, 4.70; N, 5.80.

Synthesis of 4-Bromomethyl-4′-nitrobenzophenone (2). In a 250 mL round-bottomed flask to a stirred solution of CCl_4 (100 mL) and compound **1** (2.4 g, 10 mmol) were added *N*-bromo succinimide (NBS) (2.0 g, 11 mmol) and 2,2′-azobisisobutyronitrile (AIBN) (10 mg). The resulting mixture was refluxed for 38 h. After cooling, the white precipitate of succinimide was filtered and the solvent was evaporated to a brown solid. The resulting residue was purified by column chromatography on silica gel (CH_2Cl_2/hexane, 1:1 v/v) to produce 2.1 g of compound **2** (66%). Mp: 124−125 °C. ^{1}H NMR: δ 8.40 (d, J = 8.8 Hz, 2 H), 7.9 (d, J = 7.9 Hz, 2 H), 7.70 (d, J = 8.1 Hz, 2 H), 7.55 (d, J = 8.1 Hz, 2 H), 4.54 (s, 2 H). Anal. Calcd for $C_{14}H_{10}BrNO_3$: C, 52.52; H, 3.15; N, 4.38. Found: C, 52.60; H, 3.20; N, 4.30.

Synthesis of Sodium Methanethiosulfonate ($MeSO_2SNa$). A mixture of sodium methanesulfonate ($MeSO_2Na$) (5 g, 42.0 mmol) and sulfur (1.56 g, 48.8 mmol) in methanol (300 mL) was treated under reflux conditions for 30 min, at which time all of the sulfur had

dissolved. Removal of the solvent gave sodium methanethiosulfonate as a white powder. IR (KBr): 1320, 1220, and 1100. ^{1}H NMR (D_2O): δ 3.30 (s, 3 H).

Synthesis of 4-Methanethiosulfinate Methyl-4′-nitrobenzophenone (NBM) (3). In a 100 mL round-bottomed flask to a stirred solution of methanol (30 mL) and compound **2** (0.44 g, 1.46 mmol) was added sodium methanethiosulfonate (0.2 g, 1.7 mmol). The resulting mixture was refluxed for 3 h until compound **2** disappeared on TLC (toluene/diethylamine, 20:1 v/v). After cooling, the precipitate was filtered and the solvent was evaporated under reduced pressure. The resulting residue was purified by column chromatography on silica gel (toluene/diethylamine, 20:1) to produce 0.39 g of compound **3** (80%). Mp: 156−158 °C. ^{1}H NMR: δ 8.40 (d, J = 8.8 Hz, 2 H), 7.9 (d, J = 7.9 Hz, 2 H), 7.70 (d, J = 8.1 Hz, 2 H), 7.55 (d, J = 8.1 Hz, 2 H), 4.42 (s, 2 H). Anal. Calcd for $C_{15}H_{13}NO_5S_2$: C, 51.28; H, 3.70; N, 3.99; S, 18.23. Found: C, 51.20; H, 3.80; N, 4.10; S, 18.30.

Synthesis of 4-Methanethiosulfinate Methyl-4′-aminobenzophenone (ABM) (4). In a 100 mL round-bottomed flask a stirred solution of methanol (30 mL) and compound **3** (0.35 g, 1.0 mmol) and 10% Pd−C (80 mg) was reduced with hydrogen gas at room temperature for 10 h until compound **3** disappeared on TLC (toluene/diethylamine, 4:1). After cooling, the precipitate was filtered and the solvent was evaporated under reduced pressure. The resulting residue was purified by column chromatography on silica gel (toluene/diethylamine, 4:1) to produce 0.31 g of compound **4** (98%). Mp: 178−180 °C. ^{1}H NMR: δ 7.9 (d, J = 7.9 Hz, 2 H), 7.55 (d, J = 8.1 Hz, 2 H), 7.30 (d, J = 8.1 Hz, 2 H), 6.90 (d, J = 8.8 Hz, 2 H), 4.42 (s, 2 H), 3.52 (s, 2 H, NH_2). Anal. Calcd for $C_{15}H_{15}NO_3S_2$: C, 56.07; H, 4.67; N, 4.36; S, 19.94. Found: C, C, 56.20; H, 4.60; N, 4.50; S, 20.10.

Synthesis of 4-Methanethiosulfinate Methyl-4′-iodobenzophenone (IBM) (5). In a 50 mL round-bottomed flask a cooled stirred solution of water (30 mL) and compound **4** (0.16 g, 0.5 mmol) was treated with $NaNO_2$ (52 mg, 0.75 mmol) and 1 mL of concentrated HCl. The resulting mixture was stirred at 0 °C for 30 min and then with NaI (113 mg, 0.75 mmol). After 30 min the product was extracted with ethyl acetate (3 × 10 mL). The extracts were pooled and dried with $MgSO_4$, and the solvent was evaporated into an orange oil with a rotary evaporator. The resulting residue was purified by column chromatography on silica gel (toluene/diethylamine, 4:1) to produce 140 mg of compound **5** (65%), as an oil. ^{1}H NMR: δ 7.9 (d, J = 7.9 Hz, 2 H), 7.55 (d, J = 8.1 Hz, 2 H), 7.30 (d, J = 8.1 Hz, 2 H), 7.25 (d, J = 8.8 Hz, 2 H), 4.42 (s, 2 H). Anal. Calcd for $C_{15}H_{13}IO_3S_2$. C, 41.67; H, 3.01; S, 14.81. Found: C, 41.80; H, 3.20; S, 14.70.

Preparation of the Benzophenone−PDEγ Photoprobes. The constructs for expressing the full-length wild type (wt) PDEγ (single cysteine at position 68) (*14*) and the single-cysteine mutants were generated as described previously (*9*). The plasmids were transformed into *E.coli* strain BL21 DE3 cells (Novagen) for overexpression. Induction by 1 mM IPTG was initiated at an optical cell density of ∼1.5 (OD_{600}) and continued for an additional 4−6 h at 30 °C. Expressed PDEγ constructs were first purified through a column of chitin beads (New England Biolabs), and then further purification was achieved (>95%) by reversed-phase HPLC (Waters) using a self-packed column of POROS 20 R2 resin (PerSeptive Biosystems).

The lyophilized pure PDEγ after POROS column purification was used for derivatization. Benzophenone photoprobes were dissolved in acetonitrile to prepare stock solutions immediately before the derivatization reactions. A typical reaction includes 150 μM PDEγ, 50 mM NaH_2PO_4, pH 6.7, 60% acetonitrile, and 3 mM benzophenone compound. The reaction was incubated at room temperature under argon for 1 h and quenched with 0.1% TFA, then loaded to a Vydac C4 column for reversed-phase HPLC. A gradient of 1% acetonitrile per 8 min with 0.1% TFA was used to separate the derivatized PDEγ from the underivatized population at a flow rate of 1 mL/min. All the steps were carried out in dim room light. The benzophenone−PDEγ product eluted at ∼47% acetonitrile was lyophilized and stored at −80 °C.

Functional Assay of the Benzophenone−PDEγ Photoprobes. Transducin GTPase activity was determined by using a single-turnover technique as described previously (*21*). The assays were conducted at room temperature (22−24 °C) in a buffer containing 25 mM Tris-HCl (pH 8.0), 140 mM NaCl, and 8 mM $MgCl_2$. The urea-treated ROS membranes, lacking endogenous activity of RGS9, were used as a source for the photoexcited rhodopsin required for transducin activation. The reactions were initiated by the addition of 10 μL of 0.6 μM [^{32}P] GTP (∼10^5 dpm/sample) to 20 μL of urea-treated ROS membranes (20 μM final rhodopsin concentration) reconstituted with transducin heterotrimer (1 μM) and recombinant RGS9-Gβ5 complex (0.5 μM). The reactions were performed in either the absence or presence of PDEγ derivatives (1 μM). The reaction was stopped by the addition of 100 μL of 6% perchloric acid. The ^{32}Pi formation was measured with activated charcoal. The assays were conducted in the absence of reducing agent because of the disulfide linkage between the benzophenone group and PDEγ.

Photo-Cross-Linking of the Benzophenone−PDEγ Photoprobes with Gαt-GTPγS. Gαt-GTPγS was prepared as previously described (*8*). Briefly, rod outer segment membranes were prepared from frozen dark-adapted bovine retinas (from J. A. & W. L. Lawson Co.), and the Gαt-GTPγS subunit was released using GTPγS and purified on Blue Sepharose CL-6B, as described by Kroll et al. (*22*). Coomassie Blue staining demonstrated that the Gαt subunit was more than 95% pure on SDS-polyacrylamide gel electrophoresis (PAGE).

Photo-cross-linking reactions were carried out in HEPES buffer (10 mM HEPES pH 7.5, 100 mM NaCl, 5 mM $MgCl_2$) containing Gαt-GTPγS (5 μM) and benzophenone−PDEγ derivative at a desired concentration. The reaction mixture contained in a 1.7 mL ultraclear microcentrifuge tube (Axygen) was dark-incubated on ice for 15 min and then illuminated at 350 nm and ∼4 °C in a RPR-100 Rayonet photochemical reactor (Southern New England Ultraviolet) for various times (5 min dark interval after each 10 min UV light). The cross-linked proteins were separated from the un-cross-linked by nonreducing 15% SDS-PAGE.

Preparation of Radioiodinated Benzophenone−PDEγ Photoprobes. [^{125}I] IBM was synthesized based on the Sandmeyer method for preparation of [^{127}I] IBM (compound **5**) as described above. In standard scale reactions, $NaNO_2$ (3 mg, 43 μmol) was dissolved in 20 μL of H_2O, and 6 μL of HCl (1 N) was added. Into this solution was added ABM (0.3 mg, 1.0 μmol) in acetonitrile immediately after HCl addition. The mixture was stirred at room temperature for 10 min, and then a 15 μL NaOH solution (0.1 N) containing Na^{127}I (0.3 mg, 2 μmol) and 0.5 mCi Na^{125}I was added and incubated for 30 min at room temperature with occasional vortexing. The reaction mixture was then extracted three times with 200 μL of

ethyl acetate. The extracts were pooled and purified by TLC (silica gel, toluene/diethylamine, 20:1 v/v). The radioactive band that comigrated with [^{127}I] IBM on the TLC plate was extracted with ethyl acetate, dried under N_2 gas, and redissolved in 50 μL of acetonitrile. A 10 μL portion of this solution was used to derivatize wt-PDEγ (50 μg, 5 nmol) in 50 mM phosphate buffer for 1.5 h at pH 6.7 and room temperature. The [^{125}I] IBM−PDEγ derivative was purified using an AutoSeq G50 spin column (Pharmacia).

An alternative radioiodination that yields ^{125}I-ABM was carried out using chloramine T. For a standard reaction, ABM (1 mg, 3 μmol) in 30 μL of methanol was mixed with 20 μL of sodium acetate (0.5 M, pH 5.6). Into this solution was added 2 μL of Na^{125}I (0.5 mCi) followed by 2 μL of HCl (0.1 N), and then 30 μL of chloramine T (30 μg, 0.13 μmol) was immediately added. The reaction was incubated at room temperature for 10 min and then stopped by adding 100 μL of $Na_2S_2O_5$ (0.5 mg, 2.6 μmol). Product extraction, purification, and PDEγ derivatization were performed as described in the above [^{125}I] IBM−PDEγ preparation. Photolabeling of Gαt-GTPγS by ^{125}I-ABM, as essentially described in "Photo-Cross-Linking of the Benzophenone−PDEγ Photoprobes with Gαt-GTPγS" above, was detected on a reducing SDS-PAGE 15% gel by PhosphorImager (445 SI, Molecular Dynamics).

Other Methods. Electrospray ionization mass spectrometry (ESI MS) of the HPLC-purified PDEγ samples was performed in the Mass Spectrometry Facility of the Chemistry Department at the University of Wisconsin−Madison. The mass spectra were obtained with a Micromass (Beverly, MA) LTC mass spectrometer. This instrument uses a time-of-flight analyzer. Aliquots with added methanol were sprayed with a sample cone set at 20 V. The samples in a piece of glass capillary were inserted directly into the source, and the resulting vapor was bombarded with 70 eV electrons. Perfluorokerosene was used for calibration.

For Western blotting, proteins were separated by nonreducing 15% SDS-PAGE and transferred to a PVDF membrane (Millipore, 0.45 μm) and analyzed using anti-PDEγ (N-terminus) (Affinity BioReagents), horseradish peroxidase (HRP)-conjugated IgG, and enhanced chemiluminescence (ECL) reagents obtained from Pierce. The same blot was stripped and reprobed using anti-Gαt (N-terminus) (Affinity BioReagents).

Gαt concentration was measured by the Bradford method using BSA as a standard. PDEγ concentration was also measured by the Bradford method but corrected based on the 280 nm spectrophotometric measurement and extinction coefficient of 6990. Protein amount on the scanned Coomassie gels was quantified using NIH Image 1.62.

RESULTS AND DISCUSSION

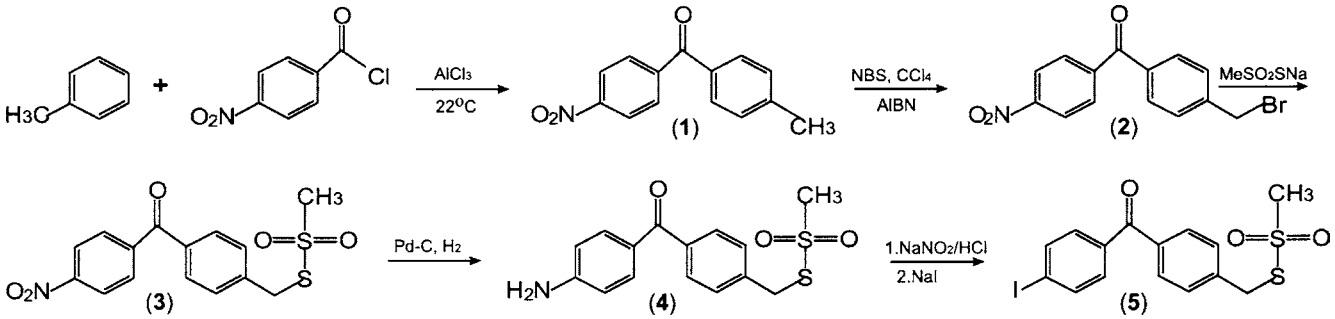
Practical Considerations. Photo-cross-linking is a straightforward technique to investigate protein (or peptide)−protein interaction. In recent years, the interest in this technique has been raised again as a result of the development of more efficient photophores and the emergence of proteomics (*10, 12, 23*−*25*). Combined with other techniques such as modern mass spectrometry, the photo-cross-linking technique is useful not only for identifying protein interaction sites but also for obtaining structural information of proteins (*26*−*29*).

The principle of a photo-cross-linking/label transfer approach for characterization of protein−protein interaction is illustrated in Figure 1, using PDEγ/Gαt as a model system. A benzophenone probe is used to derivatize a single cysteine that is site-specifically engineered on a bait protein, PDEγ (Step 1). The benzophenone-derivatized bait protein is mixed with its interaction target protein, Gαt, to form a complex, and subjected to UV light to cross-link the two proteins (Step 2). The photoinserted target protein is separated from the bait protein by reducing with DTT (dithiothreitol) and then proteolyzed (Step 3). The photoinsertion site on the target protein is identified, either by MS when a nonradioactive label is available or by autoradiography when using a radiolabeled photoprobe (Step 4). In this strategy, label transfer following photo-cross-linking is advantageous because the bait protein that is cross-linked to the target protein can be removed by DTT reversal, and the contamination of the bait protein in the analysis of the photoinsertion site on the target protein can thus be avoided. Furthermore, the free sulfhydryl of the photoprobe released by DTT reversal can be used for adding a tag, such as a biotin group, permitting affinity purification of the photoinserted proteolytic fragments for MS analysis (*30*) (Grant, J. E. and Ruoho, A. E., 2005, unpublished data obtained using IBM-derivatized PDEγ). Since the tag is added to the photoprobe after photolabel transfer, a possible impairment of the tag on the function of bait protein can be avoided.

Therefore, a photoprobe favored for protein−protein interaction studies is expected to be not only stable and efficient but also sulfhydryl-reactive, cleavable, and tagged with a label convenient for purification or detection yet exerting minimum impairment on the function of bait protein. Several comparative studies have shown that reliable and reproducible high-efficiency labeling of target proteins is obtained using tetrafluorophenyl azides, trifluoromethylphenyl diazirines, and benzophenone photoprobes, but the benzophenone photophore performs the best (*12*, *25*, *31*). We thus have chosen benzophenone as the photophore for our photoprobes. Of the sulfhydryl-reactive groups, MTS is the most rapidly reacting. MTS is also distinguished by its high selectivity for cysteinyl sulfhydryls, its ability to effect quantitative and complete conversion to the mixed disulfide, and the general reversibility of the disulfide bond (*32*). For radiolabel transfer experiments, an ^{125}I-labeled benzophenone photoprobe may be prepared since ^{125}I has often been used as a radiolabel due to its high sensitivity and relatively small size. Since the PDEγ C-terminal half has been suggested to be the major domain interacting with activated Gαt (*6*, *8*, *13*, *33*−*35*), we linked the benzophenone probes to single cysteines engineered at the PDEγ C-terminal positions for cross-linking with Gαt-GTPγS.

High-Yield Chemical Synthesis of the Bezophenone Photoprobes. As shown in Scheme 1, 4-methyl-4′-nitrobenzophenone (compound **1**) was prepared by Friedel−Crafts reaction of 4-nitrobenzoyl chloride with toluene in the presence of $AlCl_3$ at room temperature with an 80% yield. Compound **1** was converted to 4-bromomethyl-4′-nitrobenzophenone (compound **2**) by NBS in CCl_4 in the presence of a catalytic amount of AIBN as a free radical initiator. Reaction of compound **2** with sodium methanethiosulfinate in refluxing methanol produced NBM (compound **3**) with an 80% yield. NBM was reduced to the corresponding amine derivative ABM (compound **4**) by Pd−C in methanol at room temperature with a 98% yield and then converted to IBM (compound **5**) with a 65% yield by treating with $NaNO_2$/HCl and then with NaI at room temperature.

Scheme 1. Synthetic Scheme of the Benzophenone−MTS Photoprobes[a]



[a] NBS: *N*-bromo succinimide; AIBN: 2,2′-azobisisobutyronitrile.

The Benzophenone−PDEγ Photoprobes Were Readily Prepared, Purified, and Fully Functionally Active. Stability of photoprobes is an important issue for their biochemical applications. Importantly, all three benzophenone−MTS compounds with a para-position substitution of an amino (ABM), iodo (IBM), and nitro (NBM) group, respectively (Figure 1), were found to be stable at pH 6.7; for example, IBM stayed as a single peak on the HPLC chromatogram even after overnight incubation in phosphate buffer at pH 6.7 and room temperature. BPMTS, however, showed a significant breakdown product after 1 h incubation (data not shown). We thus carried out the PDEγ derivatization reactions using the benzophenone compounds at pH 6.7, taking advantage of their superb stability. As indicated by the chromatograms in Figure 2A, B, and C, after a 1 h room-temperature incubation with PDEγ (73C), reactions were ~70% completed with all three compounds, as estimated by the underivatized and derivatized PDEγ peaks. In fact, the derivatization reaction can be 100% completed after 2.5 h at room temperature, as demonstrated by the reaction using wt-PDEγ and IBM (Figure 2E). The benzophenone−PDEγ derivatives were well separated from the underivatized PDEγ population and unreacted free compounds by reversed-phase HPLC with a Vydac C4 column. Derivatization of PDEγ with all three benzophenone compounds shifted the PDEγ peak to ~4 min later than underivatized PDEγ, although these compounds have different hydrophobicity, as evidenced by different HPLC retention times (Figure 2A, B, and C).

An additional beneficial feature of the benzophenone probes is their UV absorption property, which is very different than PDEγ. As is evident in the HPLC chromatograms (Figure 2), the ratio of absorption by the benzophenone group at 215 nm versus 280 nm was approximately 1. In contrast, the 215 nm/280 nm absorption ratio of PDEγ was greater than 20, but the benzophenone adduct to PDEγ molecule changed this ratio to <10. The benzophenone-derivatized PDEγ peak can thus be easily recognized by its 215 nm/280 nm absorption ratio even without additional characterization following DTT reversal or MS determination.

However, since the linkage between the benzophenone moiety and the single cysteine of PDEγ is a mixed disulfide, we have further confirmed the mixed disulfide derivatized PDEγ samples by a DTT reversal reaction. After 1 h incubation of IBM-73C with 50 mM DTT, the PDEγ peak was shifted back to the exact position of underivatized PDEγ, and the 215 nm/280 nm absorption ratio was also converted back to >20 (Figure 2D). Furthermore, when the molecular mass of the derivatized PDEγ products was determined by ESI MS, the major population, as shown in the mass spectrum of either IBM-73C or IBM-87C, was highly consistent with the predicted mass (Figure 3A). A minor population, with the measured mass lower than the major population by 131, is very likely the PDEγ population with the N-terminal methionine excised by the ribosome-associated methionyl-aminopeptidase during the posttranslational processing in *E.coli* (*36*). The N-terminal methionine-removed PDEγ population had unaltered function (data not shown). Taken together, the ESI MS data further verified that

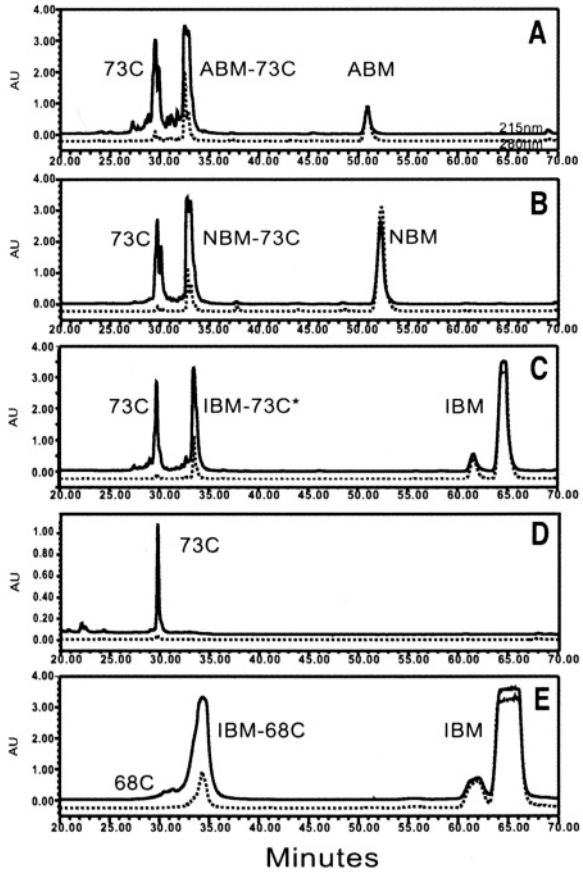


Figure 2. HPLC purification of PDEγ derivatized with the benzophenone photoprobes. The HPLC (Vydac C4 column) chromatograms are shown as absorptions at 215 nm (upper, solid) and 280 nm (lower, dashed). AU, relative absorption unit. A, B, and C: Purification of PDEγ (73C) derivatized with ABM, NBM, and IBM, respectively. The underivatized PDEγ (73C) fractions were eluted at 29.5 min; the derivatized products were at ~33.5 min. D: DTT reversal of IBM-73C, which was taken from a portion of the 33.5 min peak in C (asterisk-marked). IBM-73C was incubated with 50 mM DTT at room temperarure and pH 7.5 for 1 h and then applied to HPLC under the same conditions as in C. E: Purification of the IBM-68C derivative. The derivatization reaction was conducted at room temperature for 2.5 h, with 150 μM PDEγ, 50 mM NaH_2PO_4, pH 6.7, 60% acetonitrile, and 3 mM benzophenone compound.

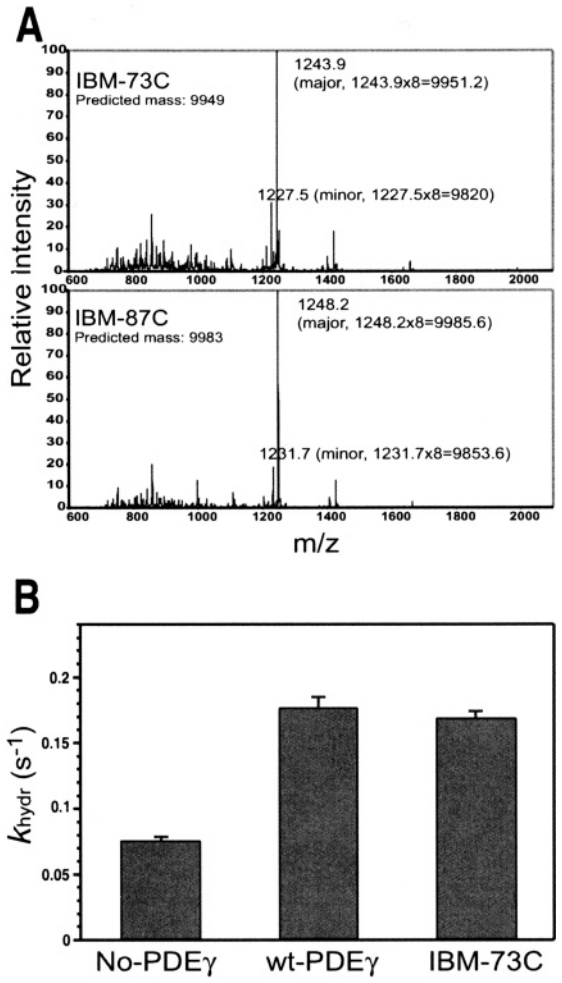

Figure 3. Characterization of the benzophenone−PDEγ photoprobes. A: ESI mass spectra of IBM-73C (upper panel) and IBM-87C (lower panel). The intensity of the major MS peak is taken as 100%. The predicted masses were calculated using PeptideMass of ExPASy (Swiss Institute of Bioinformatics). A measured mass is an *m/z* value multiplied by charge, as indicated in parentheses. B: Functional activity of IBM-73C. The RGS9 stimulated GTPase activity of transducin was measured in single-turnover assays in the absence of PDEγ (No-PDEγ) and in the presence of either wild-type PDEγ (wt-PDEγ) or IBM-derivatized PDEγ (IBM-73C). The rate constants of GTP hydrolysis (k_{hydr}) were determined from the single-exponential fits of the reaction time course and plotted as bars. Error bars represent SE of exponential analysis.

the benzophenone−PDEγ derivatives were highly purified and homogeneous.

One great concern for the application of photoprobes is whether the addition of a photoreactive group to a bait protein affects its function. Since PDEγ is known to be an essential component for accelerating the GTP hydrolysis activity of Gαt (*1*, *37*), the functional integrity of the benzophenone-derivatized PDEγ preparations was assayed by analyzing their abilities to potentiate the activity of RGS9/Gβ5 in stimulating Gαt-GTPase. Our data indicate that the derivatization of PDEγ at position 73 with IBM did not affect the function of PDEγ (Figure 3B). This was most likely due to the short length of the benzophenone photoprobe and the structural similarity of the benzophenone moiety to the phenylalanine residue at position 73 on wt-PDEγ.

The Benzophenone−PDEγ Photoprobes Specifically Cross-Linked to Gαt-GTPγS with High Efficiency. The photo-cross-linking reactions using benzophenone−PDEγ photoprobes and Gαt-GTPγS were

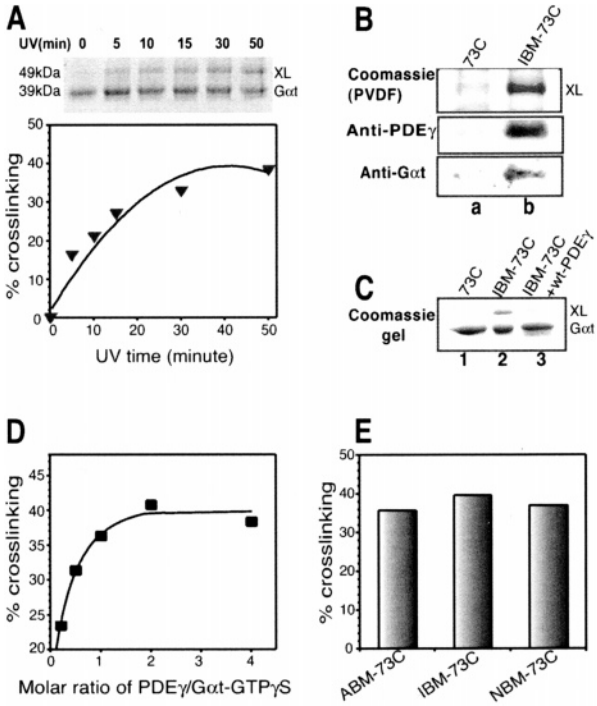

Figure 4. Specific photo-cross-linking of the benzophenone−PDEγ photoprobes with Gαt-GTPγS. Following UV photolysis, the reaction contents were separated by 15% SDS-PAGE in the absence of DTT and then stained with Coomassie Blue R-250. Percentage of cross-linking was calculated as the ratio of the protein amount in the cross-linked band versus total protein present in both the cross-linked and the un-cross-linked bands. A: Photo-cross-linking time course. The cross-linking reactions were performed with IBM-73C and Gαt-GTPγS (molar ratio 1.5:1) under UV light (as described in the "Experimental Procedures") for various times as indicated on top of the Coomassie-stained SDS-PAGE. The background from the dark control (0 min) is subtracted. XL, cross-linking. B: Western blotting of the cross-linked Gαt/PDEγ complex. Photo-cross-linking reactions were performed under conditions similar to A, using PDEγ that was not derivatized (lane a) or derivatized (lane b) with IBM. After 20 min UV photolysis, the reaction was subjected to Western blotting, as described in the "Experimental Procedures". C: Photo-cross-linking was conducted under UV for total 30 min with Gαt and 73C (lane 1), IBM-73C (lane 2), and IBM-73C after 10 min preincubation (on ice) of wt-PDEγ in 5-fold excess (lane 3). The ratio of IBM-73C/Gαt was 1.5:1. D: PDEγ/Gαt molar ratio dependence of photo-cross-linking. The cross-linking reactions were performed at various IBM-87C/Gαt-GTPγS ratios under UV light for a total of 30 min. E: Photo-cross-linking of Gαt-GTPγS with different benzophenone-73C photoprobes. The cross-linking reactions were performed under UV for a total of 30 min with a PDEγ/Gαt-GTPγS molar ratio of ~1.5:1.

conducted to test the specificity and cross-linking efficiency of the photoprobes (Figure 4). As shown in Figure 4A, UV photolysis of the Gαt/PDEγ reaction mixture generated a band on the Coomassie-stained gel with a molecular size of approximately 50 kDa, the sum of Gαt (~40 kDa) and PDEγ (~10 kDa). This cross-linked complex was confirmed to contain both Gαt and PDEγ by Western blotting (Figure 4B). The cross-linked species was not observed in the dark control (0 min) (Figure 4A), nor with the underivatized 73C construct (Figure 4B), and was inhibited by preincubation of wt-PDEγ with Gαt (Figure 4C), indicating specificity of cross-linking. Moreover, the cross-linking of IBM-73C with Gαt-GTPγS was saturable with regard to photolysis time (Figure 4A) and photoprobe concentration (Figure 4D), further demonstrating the cross-linking specificity.

The maximum efficiency of cross-linking between the benzophenone−PDEγ photoprobes and Gαt-GTPγS was as high as 40% (Figure 4A and D); a comparison of the 73C derivatives of the three benzophenone photoprobes indicated similar cross-linking efficiencies (Figure 4E). The efficient cross-linking of the PDEγ C-terminal positions with Gαt-GTPγS further supports the previous observations that the PDEγ C-terminal half is a major domain interacting with Gαt-GTPγS (*33*−*35*).

The high efficiency of specific photo-cross-linking of the benzophenone photoprobes is a valuable feature, since a common problem using the photo-cross-linking approach is the low efficiency of the photolysis event that produces only trace amounts of labeled peptides after proteolysis. This often means that a number of unlabeled fragments mask the specifically labeled fragments and result in difficult purification of these complex digestion mixtures (*10*). The exceptionally high cross-linking efficiency of the benzophenone probes used in this study is likely to circumvent this problem. Besides the high photoreactivity of the benzophenone photophore, the short arm length (estimated 8−10 Å from the modified cysteinyl α-carbon) of these photoprobes is likely to be an additional factor leading to high cross-linking efficiency. These probes are probably the shortest stable benzophenone photoprobes that can be synthesized, considering that they have only one carbon between the disulfide bond and the benzophenone moiety. A similar but shorter benzophenone compound that we synthesized with no carbon between the sulfur and the benzophenone moiety (4-methanethiosulfonate benzophenone) turned out to be unstable at neutral pH (data not shown). A shorter arm length is usually favorable for cross-linking studies since the photoinsertion site reflects a more precise protein−protein interaction position, a property not held by BPMTS, which has a longer arm length.

The Directly Radioiodinated Amino-Benzophenone Photoprobe Offered a Sensitive Detection of Label Transfer to Gαt-GTPγS. While the benzophenone photoprobes proved to be substantially useful in probing photoinsertion sites on Gαt-GTPγS from derivatized PDEγ, through a biotin tag added to the photoprobe after photolysis (Grant, J. E. and Ruoho, A. E., 2005, unpublished data), detection of label transfer through autoradiography is a convenient approach under some circumstances. We therefore explored this possibility for extended applications of these benzophenone photoprobes.

Since the nonradiolabeled iodobenzophenone photoprobe ([^{127}I] IBM) was synthesized using ABM as starting material, we radioiodinated ABM in order to generate a radiolabeled benzophenone photoprobe. One approach that was used was to follow the [^{127}I] IBM synthesis protocol described in the Experimental Procedures to generate [^{125}I] IBM (Figure 5A). As shown in Figure 5B, the purified radiolabeled product comigrated on TLC with the standard [^{127}I] IBM control, indicating the product to be [^{125}I] IBM. In addition, PDEγ derivatized with the radioiodinated IBM was disulfide cleavable by DTT (Figure 5C), further characterizing it as [^{125}I] IBM. A second approach was through the use of a mild oxidizing agent, chloramine T, by which Na^{125}I was "activated" and added ortho to the amino-benzophenone group of ABM, yielding the product ^{125}I-ABM (Figure 5D). This probe derivatized a single-cysteine PDEγ construct in a manner that was sensitive to DTT reversal (data not shown). The PDEγ derivatives of the ^{125}I-labeled benzophenone probes were readily purified from free Na^{125}I by size-exclusion

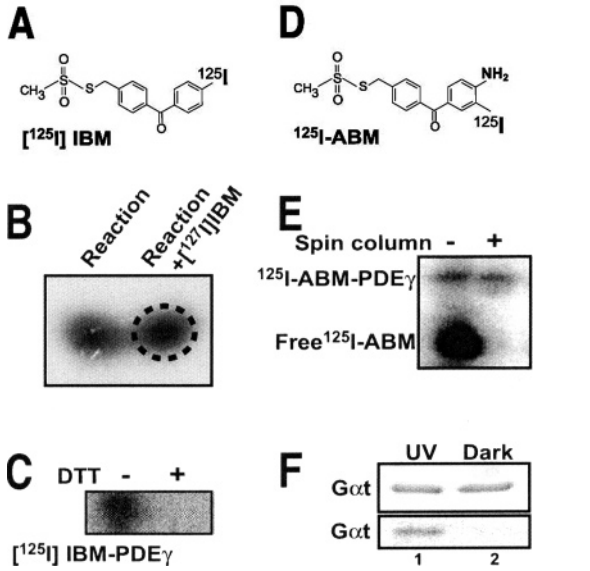

Figure 5. Preparation of radioiodinated benzophenone−PDEγ photoprobes. A: Molecular structure of [^{125}I] IBM. B: Autoradiogram of TLC purification of [^{125}I] IBM. Left lane, [^{125}I] IBM reaction; right lane, comigration of the [^{125}I] IBM reaction and the pure [^{127}I] IBM control whose position is indicated by the dashed ring. C: Autoradiogram of [^{125}I] IBM-PDEγ in the dark on a SDS-PAGE gel run without and with DTT. D: Molecular structure of ^{125}I-ABM. E: Autoradiogram of a SDS-PAGE gel showing the purification of ^{125}I-ABM-PDEγ with a spin column (right lane) as compared with the sample before purification (left lane). F: Photolabel transfer to Gαt-GTPγS (2 μM) from ^{125}I-ABM-68C (3 μM). The proteins after photolysis (lane 1) or dark incubation on ice (lane 2) were separated by 15% reducing SDS-PAGE. Upper panel, Coomassie-stained gel; lower panel, autoradiogram.

chromatography using spin columns (Figure 5E), which offers a sensitive detection of label transfer to Gαt-GTPγS from derivatized PDEγ (see Figure 5F).

An indirect way of photoprobe radiolabeling has been reported previously which involved derivatization of the DTT-reversed sulfhydryl of a reversible thiol-reactive photoprobe using [^{3}H]-*N*-ethylmaleimide, but this method suffers from the need to block unlabeled free sulfhydryls first and an unfortunate problem involving a high radioactive background (*11*). Another way of indirect photoprobe radiolabeling was to radioiodinate a peptide at a site away from a benzophenone photoprobe incorporated in the peptide, as previously reported (*38*). The radiolabel, however, can be lost if unwanted proteolytic cleavage separates the radioiodinated residue from the benzophenone cross-linking site. The direct radiolabeling of benzophenone reported here is therefore advantageous.

While biotin and fluorescent groups may provide alternate labeling approaches, their bulkiness often greatly impairs the function of derivatized bait proteins, thus limiting their applications. The ^{125}I radiolabel, on the other hand, is exceptionally sensitive yet relatively small and can be directly added to the benzophenone moiety with minimal effects on the function of PDEγ.

Summary. The data presented in this study indicate that the novel benzophenone photoprobes that have been developed in our laboratory are suitable for protein−protein interaction analysis through a photo-cross-linking/label transfer strategy. These probes are short in length, stable at neutral pH, and DTT-cleavable. The PDEγ constructs derivatized with these probes could be readily purified and had unaltered function (as demonstrated by the IBM-73C derivative). Photo-cross-linking of PDEγ and Gαt-GTPγS through these photoprobes was

highly efficient. In addition, the amino-benzophenone photoprobe (ABM) was radioiodinatable, facilitating sensitive detection of photoinserted proteins, and this probe is potentially a module for adding additional functional groups to the amino on benzophenone. These combined features favor convenient identification of photoinsertion sites. Since these benzophenone probes can be linked through a disulfide bond to an engineered cysteine on a given protein in a site-specific manner, they may have broad applications for investigation of protein−protein interactions.

ACKNOWLEDGMENT

This work was supported by an NIH Grant (NIH GM33138) to A.E.R. and an NIH Grant (EY12859) to V.Y.A. We thank Dr. Martha M. Vestling, director of the Mass Spectrometry Facility, Department of Chemistry, University of Wisconsin−Madison, for performing ESI MS and data processing. Thanks also go to Dr. Jennifer E. Grant in the laboratory of A.E.R. for the wt-PDEγ/intein construct.

Effects of Side Chain Configuration and Backbone Spacing on the Gene Delivery Properties of Lysine-Derived Cationic Polymers

Sarah E. Eldred,[‡] Margaret R. Pancost,[‡] Karin M. Otte,[‡] David Rozema,[§,*] Shannon S. Stahl,[‡,*] and Samuel H. Gellman[‡,*]

Department of Chemistry, University of Wisconsin—Madison, 1101 University Ave., Madison, Wisconsin 53706, and Mirus Corporation, 505 S. Rosa Road, Madison, Wisconsin 53719. Received January 25, 2005; Revised Manuscript Received April 3, 2005

A series of lysine-based oligomers (18 residues) that differ in side chain configuration or side chain spacing along the backbone was tested for DNA transfection activity. Although materials constructed from lysine are not the most effective polymeric transfection agents, we have chosen L-lysine-based molecules as a starting point because this system allows us to examine the functional effects of incremental changes in polycation structure. The oligomer constructed from β^3-homolysine (β^3-hLys) and that from α-D-lysine were superior to an α-L-lysine 18-mer in gene delivery assays. This improved activity is attributed to the fact that the α-L-peptide is a protease substrate while the other 18-mers are not. This conclusion is supported by the effects of chloroquine on transfection activity, based on the protease inhibition activity of chloroquine. To our knowledge, these results represent the first direct comparison of a D-lysine oligomer with an L-lysine oligomer in the context of gene delivery. Poly(β^3-hLys) was synthesized from the ring opening polymerization of the corresponding lactam. The DNA transfection ability of this polymer was compared with that of commercially available poly(L-lysine) (PLL). In each case the polymer was more active than the corresponding oligomer.

INTRODUCTION

Techniques for efficient delivery of foreign DNA into cells could lead to gene therapies for many human disorders, but realizing this potential will require improvement relative to current gene delivery methods (*1*). Injection of naked DNA into the body results in its rapid clearance and degradation, which precludes therapeutic efficacy (*2*–*3*). A further problem is that naked DNA is only poorly taken up by cells because of the large persistent length (stiffness) of this anionic biopolymer. Therefore, a delivery vehicle or "vector" is required. Viral vectors are among the most efficient gene delivery vehicles, but concerns about their safety have curtailed their use in clinical trials (*1*, *3*). Nonviral vectors are safer, but they suffer from lower transfection efficiencies (*4*).

Two classes of nonviral vectors are being investigated for gene delivery: cationic lipids and cationic polymers. Neutral polymers have been used in transfections but only when coupled to adenoviruses (*5*). The lipids can be effective, but inconsistencies in their preparation and difficulties in their purification have led to irreproducible transfection results in some cases (*4*, *6*). Additionally, minor lipid modifications, desirable in terms of analyzing structure–activity relationships, can be difficult to achieve. A further problem is that lipid–DNA interactions are relatively weak and unstable in the presence of serum proteins (*2*). Polycations, on the other hand, are relatively easy to prepare, modify, and formulate with DNA. Thus, polycationic gene delivery vectors have received widespread attention (*7*–*14*). Much research has focused on increasing the uptake of vector–DNA complexes ("polyplexes") by attaching cell-adhesive ligands to the vectors in order to take advantage of receptor-mediated endocytosis. Another common transfection strategy has been to enhance endosomolysis (following polyplex uptake) by the incorporation of pH buffering or membrane-lytic agents into the vector. Less studied are the factors that control the intracellular dissociation of DNA from the cationic polymer, which is ultimately required for transcription and which may be important for transfection (*15*–*22*).

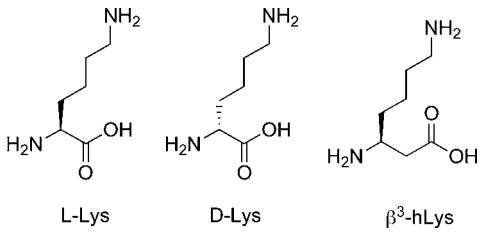

Figure 1. Amino acid building blocks.

We have undertaken a fundamental study of the effects of cationic polymer structure on transfection efficiency, using several lysine-based oligomers and analogous polymers. Poly(L-lysine) (PLL) and L-lysine oligomers are well-known to condense DNA, and to provide modest gene delivery to cells in culture (*23*–*25*). Although the activity of L-lysine-based polycations is inferior to that of other cationic polymers, we have chosen L-lysine-based molecules as a starting point because this system allows us to examine incremental changes in polycation structure. We have examined both the effect of changing the configuration of the side chain attachment point (use of D-lysine in place of L-lysine) and the effect of altering the backbone (use of β^3-homolysine (β^3-hLys) in place of lysine) on gene delivery activity (Figure 1).

Oligomers and polymers of L-Lys are substrates for proteolytic enzymes, while polycations comprising D-Lys or β^3-hLys are not (*26*−*28*). Therefore, comparisons among these three polycations should indicate whether proteolytic degradation is favorable or unfavorable with regard to delivery efficacy. (Comparisons among the Lys- and β^3-hLys-derived cations probe more subtle effects of polymer structure on delivery.) Polymer degradation too early in the uptake process would presumably be detrimental to transfection efficiency, but such degradation in later stages might enhance the necessary DNA unpacking. The effect of delivery vehicle degradation has received relatively little attention, even though poly(D-lysine) is commonly used in gene delivery studies instead of poly(L-lysine) (*29*). Side chain configuration effects have been examined elsewhere to track the intracellular fate of plasmid DNA during transfection (*30*), but to our knowledge the present study is unique in comparing the transfection efficacy of well-defined enantiomeric lysine oligomers and in extending the comparison from side chain configuration to side chain spacing along the backbone.

EXPERIMENTAL PROCEDURES

General. All commercially available compounds were purchased from Aldrich and used as received unless otherwise noted. Fmoc-Lys(Boc)-OH (D and L versions) was purchased from Nova Biochem. Anhydrous CH_2Cl_2 was obtained from Fisher Scientific in FisherPak containers. It was passed through a solvent purification system prior to use (*31*). ^{1}H and ^{13}C NMR spectra were recorded on Bruker AC-300 MHz (75 MHz for ^{13}C) spectrometers, and $CDCl_3$ was purchased from both Cambridge Isotope Laboratories, Inc., and Aldrich. The chemical shifts (δ) are given in parts per million relative to internal TMS (0 ppm for ^{1}H) and $CDCl_3$ (77.23 ppm for ^{13}C). IR spectra were recorded on a Bruker Tensor 27 IR instrument with an ATR attachment (Pike Technologies). MALDI-TOF-MS was performed using a Bruker REFLEX II spectrometer with a 337 nm laser using the α-cyano-4-hydroxycinnamic acid matrix. HPLC purification was performed using a Shimadzu instrument equipped with a reverse phase C_4-silica column. Flash chromatography was performed on silica gel 60 (particle size 0.040−0.063 nm, 200−400 mesh ASTM, purchased from Sorbent Technology). Polymer molecular weight was determined by Dr. Michelle Chen at Wyatt Technologies using GPC with Shodex SB guard columns along with a Wyatt DAWN EOS multiangle light scattering detector and a Wyatt Optilab rEX concentration detector.

Oligomer Synthesis. β-Amino acid residues were synthesized according to literature procedures (*32*−*34*). Peptide oligomers were synthesized using standard Fmoc solid-phase peptide synthesis techniques with HBTU activation on Rink amide resin (Applied BioSystems) on a Synergy automated synthesizer (Applied Biosystems). The resin-bound peptides were cleaved from the solid support and deprotected simultaneously by using trifluoroacetic acid. The peptides were precipitated by evaporation of the deprotection solution and addition of excess cold anhydrous diethyl ether. The peptide products were purified by reverse-phase HPLC and analyzed using MALDI-TOF-MS.

Lactam 7. β^3-hLys (*32*−*33*) **5** (1 equiv) was cyclized following the general procedure of Huang and co-workers (*35*). Briefly, **5** was placed in a round-bottomed flask with 2-chloro-1-methylpyridinium iodide (1.1 equiv), and CH_3CN was added to make the reaction 0.01 M in substrate. Triethylamine (2.2 equiv) was then added, and the reaction was refluxed under nitrogen for 24 h. The solvent was then removed by rotary evaporation, and the residue was purified by column chromatography in ethyl acetate/hexanes. ^{1}H NMR ($CDCl_3$) δ 1.33−1.81, m, 15H; 2.57, dq J = 14.7, 1.2 Hz, 1H; 3.06, ddd J = 15.0, 5.1, 2.4 Hz, 1H; 3.13, q J = 6.6 Hz, 2H; 3.61, qd J = 4.8, 2.4 Hz, 1H; 4.51, br s, 1H; 6.0, br s, 1H. ^{13}C NMR ($CDCl_3$) δ 23.62, 28.63, 30.08, 35.23, 43.72, 48.21, 77.66, 156.24, 168.14. FTIR (ATR): 1518 cm^{-1} (amide II); 1689 cm^{-1} (carbamate); 1791 cm^{-1} (amide I); 3366 cm^{-1} (N−H). MS-ESI: m/z = 265.1 $[M + Na]^+$ (Calculated m/z = 242.2 $[M]^+$.)

Poly(β^3-hLys). In the glovebox, lactam **7** (1 equiv) was placed in a round-bottomed flask with $Sc(NTMS_2)_3(THF)_3$ (2.5%) and anhydrous CH_2Cl_2 to make the reaction 0.02 M in substrate. The flasks were sealed, removed from the glovebox, and stirred at RT for 24 h. After 24 h the flasks were opened, and the contents were poured into diethyl ether to precipitate the polymer. The polymer was collected by filtration. Deprotection was accomplished by stirring in trifluoroacetic acid until the polymer dissolved (usually 2−3 days). The deprotected polymer was dialyzed against DI H_2O with MW 1000 cutoff membranes and then lyophilized. ^{1}H NMR (D_2O) δ 1.33−1.66, br m, 6H; 2.38, br s, 2H; 2.96, t J = 7.5 Hz, 2H; 4.10, br s, 1H. FTIR (ATR): 1561 cm^{-1} (amide II); 1646 cm^{-1} (amide I); 1676 cm^{-1} (TFA); 3280 cm^{-1} (N−H). Molecular weight was determined using GPC. M_n = 62 000, M_w = 93 000, PDI = 1.5.

Transfections. Plasmid DNA pCIluc (10 μg/mL, pCIluc is prepared according to a published procedure (*36*) where the luciferase reporter gene was under the cytomegalovirus promoter) in 0.25 mL of 5 mM HEPES pH 7.5 was complexed with polymers at a weight ratio of 1:2.66 DNA:polymer (N:P ratio of 1:3.5 using the TFA salt molecular weight for the polycation). Other weight ratios were tested and gave similar results. The DNA complexes were then added (100 μL) to wells containing cultured cells (mouse hepatoma Hepa-1clc7 cells or monkey kidney COS-7 cells, obtained from the American Type Culture Collection (ATCC)) in Dulbecco's modified Eagle Media containing 10% fetal bovine serum. The cells were allowed to incubate for 48 h. The percentages of well surface area covered with cells were then determined using an Olympus CK2 inverted microscope. We have previously found (*37*) that assays of cell toxicity using confluency and methylthiazolyldiphenyltetrazolium bromide (MTT) give, within error, equivalent results. Due to the ease of measurement and the ability to assay toxicity and transfection using the same sample, confluency was used as a measure of toxicity in our studies. Cells in each well were 85−100% confluent at the time of the assay, indicating that the oligomers and polymers tested were noncytotoxic at the levels used for transfection. The cells were harvested and assayed for luciferase expression as previously reported (*38*) using a Lumat LB 9507 (EG&G Berthold, Bad-Wildbad, Germany) luminometer. Reported data is an average of at least six trials.

Chloroquine Studies. Transfection studies with chloroquine were performed in a manner identical to that used in the non-chloroquine studies, save for the addition of 80 μM chloroquine to the wells along with the polyplexes. In these cases, the medium was changed after 2 h, and the cells were allowed to incubate for 46 h more.

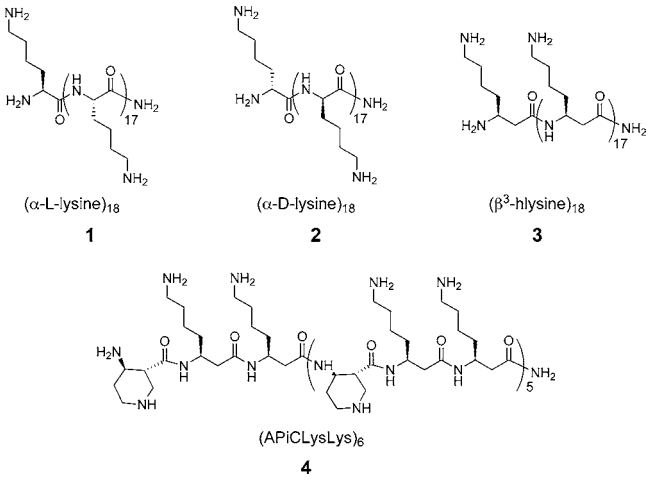
DNA Titration Assays. The collapse of TMR-labeled DNA was assessed using a quantitative assay based on condensation-induced quenching of a fluorophore covalently attached to DNA (*39*). Briefly, tetramethyl rhodamine-labeled DNA (TMR-DNA) was synthesized

using tetramethyl rhodamine LabelIT (Mirusbio Corp) according to manufacturer's protocol at a 1:1 DNA:TMR weight ratio. TMR-DNA (10 μg) was mixed with increasing quantities of polymers in 0.5 mL of 10 mM HEPES, pH 7.5. After addition of the polymer, TMR fluorescence of the samples was measured using a Cary spectrofluorometer (excitation wavelength (λ_{ex}) of 546 nm; emission wavelength (λ_{em}) of 576 nm) at room temperature. A similar method was used to carry out the NaCl titration study. Polyplexes were generated using a 1:2.66 TMR-DNA:oligomer ratio, and the TMR fluorescence was measured following NaCl additions.

Particle Sizing. Particles comprised of DNA and polycations were formulated in 20 mM HEPES buffer pH 7.5 at a DNA:polycation ratio of 1:2.66 at a DNA concentration of 10 μg/mL. The size of the particles was assayed by light scattering at 532 nm using a Brookhaven Instruments Corporation, ZetaPlus Particle Sizer, I90.

RESULTS AND DISCUSSION

Activity Comparisons among 18-Mers. Our studies compared (α-L-Lys)$_{18}$ (**1**), which is known to be modestly active in gene delivery (*23*−*25*), with (α-D-Lys)$_{18}$ (**2**), and the homologue of (**1**), (β^3-hLys)$_{18}$ (**3**). We also examined β-peptide **4**, the analogue of **3**, in which β^3-hLys at one-third of the positions is replaced with a more rigid but still cationic residue, *trans*-4-aminopiperidine-3-carboxylic acid (APiC (*34*)). Transfection assays with hepa cells indicated that the β-oligomers (**3** and **4**) and (α-D-Lys)$_{18}$ (**2**) outperformed (α-L-Lys)$_{18}$, but that the two β-peptides were comparable to one another (Table 1). Because the APiC monomer is more difficult to prepare than is β^3-hLys (*34*), subsequent β-peptide studies were limited to molecules containing exclusively β^3-hLys.



Transfections of both hepa and COS cells showed enhanced activity for both **2** and **3** relative to **1** (Table 1). The hepa cell line was chosen because of long-term interest in gene delivery to hepatocytes, while the COS cell line was selected to demonstrate generality (COS cells are not hepatocytes) and because the transfection properties of COS cells are well-known. In the transfection assays, cells were plated into wells at 40−50% confluency, as determined by light microscopy. At the conclusion of the 48-h incubation period, the confluency of the cells was again determined by light microscopy. Previous work (*37*) has shown that any toxic effects of transfection agents will be manifested as low confluency after the incubation period, and that confluency is comparable to an MTT assay as an indicator of toxicity (or lack thereof). In our studies, all cells were between 85 and 100% confluent at the end of the 48-h incubation period, indicating that the oligomers used were not cytotoxic at the levels employed for transfection.

Table 1. DNA Transfection Activity of Oligomers 2−4 Relative to 1[a]

entry	oligomer	cell line	transfection relative to **1** (no chloroquine)	transfection relative to **1** (with 80 μM chloroquine)
1	**2**	hepa	2.3 ± 0.6	0.5 ± 0.2
2	**3**	hepa	4.1 ± 1.5	0.6 ± 0.5
3	**4**	hepa	4.2 ± 1.9	−
4	**2**	COS	24 ± 10	1.1 ± 0.2
5	**3**	COS	32 ± 10	1.3 ± 0.04

[a] Transfections were performed at a DNA:oligomer ratio of 1:2.66. Data reported is an average of at least six trials. Errors are one standard deviation from the mean.

Our primary goal was to determine the relative transfection efficiencies of a set of related lysine-based oligocations. This information is intended to illuminate the relationship between polycation structure and transfection efficacy and thereby provide a basis for developing more effective transfection agents in the future. Since the crucial observations in this case are the *relative* transfection efficiencies among oligomers **1**−**4**, and not the absolute transfection results, the data have been normalized to the transfection efficiency of oligomer **1**.

The results in Table 1 show that **2** and **3** are superior to **1** for both hepa cells (entries 1 and 2) and COS cells (entries 4 and 5), but that the advantage is larger for COS cells. We cannot explain this difference. The most important point, however, is that for both cell types (α-D-Lys)$_{18}$ and (β^3-hLys)$_{18}$ display enhanced activity relative to (α-L-Lys)$_{18}$.

Chloroquine Effects. Chloroquine is a well-known transfection-boosting reagent that has been used to promote endosomal escape by DNA−cation polyplexes (*40*). It is hypothesized that chloroquine's favorable effect derives from its buffering activity, which prevents the normal endosomal acidification process and causes release of the endosomal contents into the cytoplasm (*4*, *40*, *41*). Not surprisingly, transfection assays of 18-mers **1**−**3** conducted in the presence of chloroquine led to overall activity enhancements relative to assays conducted without chloroquine. More interesting is the observation that the transfection ability of protease-sensitive L-Lys 18-mer **1** has a significantly greater enhancement relative to those of **2** or **3** in the presence of chloroquine. The activity of **1** is greater than or equal to the activity of enantiomer **2** or β-peptide **3** when chloroquine is used with either hepa cells (Table 1, entries 1−2) or COS cells (Table 1, entries 4−5). As in the absence of chloroquine, cells were 85−100% confluent at the completion of the 48 h incubation period; thus, the chloroquine concentration we used does not exert significant toxic effects.

Chloroquine acts as a protease inhibitor in addition to its buffering ability (*16*, *42, 43*). We attribute chloroquine's greater enhancement of transfection by **1**, relative to the effects on **2** or **3**, to the protease inhibition activity of chloroquine. L-Lys 18-mer **1** should be readily degraded by cellular proteases while D-Lys 18-mer **2** and β^3-hLys 18-mer **3** should be intrinsically resistant to proteolysis. Previous research has shown that L-Lys oligomers shorter than 18 units are not effective for DNA transfection (*44*); therefore, it is reasonable to assume that the fragments of oligomer **1** would not be effective for transfection. Our observations concerning chloroquine's enhancement suggest that in the case of protease-labile delivery vectors,

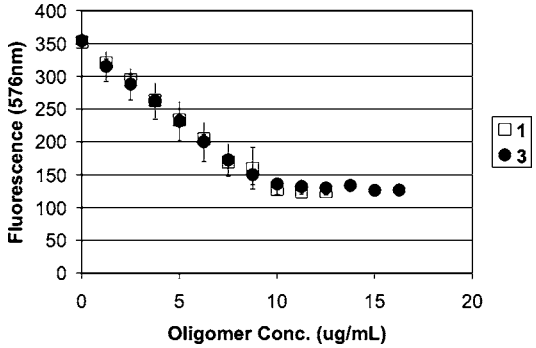


Figure 2. Quenching of fluorescent DNA as a function of amount of added oligomer for **1** and **3**. Error bars are one standard deviation from the mean. Full condensation was reached at a DNA:oligomer weight ratio of 1:1.

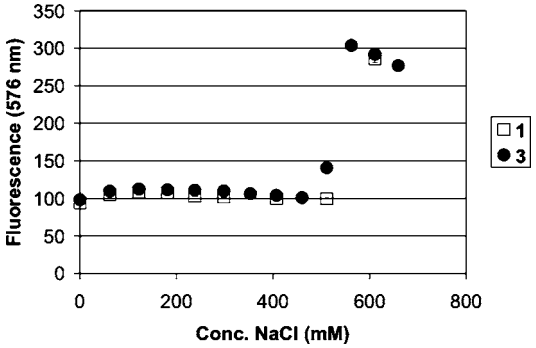

Figure 3. Effect of NaCl concentration on polyplex stability for polyplexes formed between fluorescently labeled DNA and **1** or **3**. Error bars are one standard deviation from the mean.

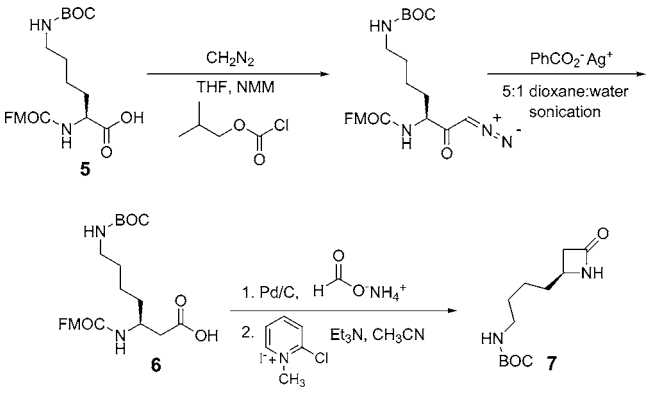
pH-buffering is not the only activity of chloroquine responsible for increased transfection activity. The differential effect of chloroquine within polycation series **1**−**3** is consistent with our hypothesis that the superior gene delivery activity of **2** and **3** relative to **1** in the absence of chloroquine stems from the chemical instability of **1** in cellular fluids. Since the polycation must dissociate from the DNA at some point within the cell to allow transcription, and since cleavage of the polycation should encourage dissociation from the DNA, it is not obvious a priori whether proteolytic degradation of the cationic vector would enhance or diminish delivery efficiency. Our results suggest that breakdown of a polycationic delivery vector can impede transfection.

Evaluation of DNA−Oligocation Interactions. In an effort to elucidate the origin of the difference in gene delivery activity among 18-mers **1**−**3**, we compared DNA polyplex formation with these oligomers. Complexes formed at a 1:2.66 DNA:oligomer ratio (effective for transfection) were found to be indistinguishable in size. Polyplexes generated from **1** had an average diameter of 48 nm, polyplexes from **2** had an average diameter of 60 nm, and polyplexes from **3** had an average diameter of 58 nm. These differences are not significant.

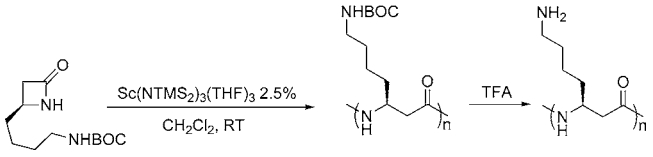
We used titration experiments to probe the efficiency of DNA-polycation complexation (*39*). In these experiments, varying amounts of polycation are added to fluorescently labeled DNA. Polycation-induced condensation of the DNA is detected as a decrease in fluorescence. When the fluorescence reaches a steady minimum, we assume that the DNA is fully condensed. Figure 2 shows that the results for **1** and **3** are identical; results for **2** (not shown) were also indistinguishable. These findings indicate that the DNA−polycation ratios in these polyplexes are not altered by backbone spacing or side chain configuration. In addition, the observation that the same level of quenching is reached for both polycations indicates that the average distance between flourophores is the same, which implies that the condensed-DNA particles have very similar packing and structure.

A third experiment was performed in order to compare the stabilities of the polyplexes. Polyplexes formed between fluorescently labeled DNA and oligocation **1**, **2**, or **3** were exposed to increasing concentrations of NaCl in order to determine the salt concentration required to "unpack" the polyplex (as indicated by an increase in fluorescence). In the absence of polycation, high salt concentrations result in a nominal increase in fluorescence; however, this increase is gradual as a function of salt concentration, unlike the sharp rise seen in Figure 3 at approximately 550 mM NaCl. The magnitude of the change is much smaller in the absence of polycation than in its presence. Figure 3 shows that the results for **1** and **3** are identical; results for **2** (not shown) were indistinguishable. Thus, the strength of DNA−oligocation association is not influenced by the variation in backbone spacing of side chains or side chain configuration. Overall, we find no significant differences among polyplexes formed between DNA and 18-mers **1**−**3** can be detected by three distinct measurements.

Scheme 1



Scheme 2



Cationic Polymers. The transfection efficacy for lysine polymers depends on molecular weight, and an oligomer containing only 18 residues is expected to be less effective on a weight basis than are longer polymers (*23*−*25*). We examined higher molecular weight polymers of β^3-hLys in order to determine whether a similar trend would be observed in these cases as well. Commercially available poly(L-lysine) (PLL) was used as a positive control for comparison with poly(β^3-hLys) prepared in our laboratory. We selected 70 and 188 K PLL as our control polymers in order to bracket the molecular weight of the poly(β^3-hLys) (93 K).

The poly-β-peptide was synthesized by metal-catalyzed ring-opening polymerization of a protected β-lactam (*45*). Synthesis of this β-lactam begins with a commercially available protected form of amino acid L-lysine (**5**), which is homologated using the Arndt−Eistert sequence to provide β-amino acid **6** (Scheme 1) (*32*−*33*).

Table 2. DNA Transfection Activity of Poly(β^3-hLys) Relative to PLL[a]

entry	polycation	cell line	relative transfection
1	poly(β^3-hLys)	hepa	13 ± 8 (relative to 70 K PLL)
2	poly(β^3-hLys)	hepa	18 ± 5 (relative to 188 K PLL)
3	poly(β^3-hLys)	COS	11 ± 3 (relative to 70 K PLL)
4	poly(β^3-hLys)	COS	9 ± 7 (relative to 188 K PLL)

[a] Transfections performed at a DNA: oligomer ratio of 1:2.66. Data reported is an average of at least six trials. Errors are one standard deviation from the mean.

Deprotection and cyclization then yield β-lactam **7** (*35*). Polymerization of **7** leads to the side chain-protected polymer (Scheme 2).

Deprotection with trifluoroacetic acid followed by dialysis provides poly(β^3-hLys) with M_n = 62 000 and M_w = 93 000 (PDI = 1.5). Transfection assays with hepa cells (Table 2, entries 1−2) show that poly(β^3-hLys) outperforms both PLL controls. Studies with COS cells (Table 2, entries 3−4) indicate superiority of poly(β^3-hLys) over both 70 and 188 K PLL.

CONCLUSIONS

We have shown that oligomers or polymers of D-Lys or β^3-hLys are more effective gene delivery agents than are analogous oligomers or polymers of L-Lys for cultured cells. This difference in activity appears to result from the fact that proteases can degrade vectors composed of L-Lys, while vectors composed of D-Lys or β^3-hLys are not susceptible to proteolysis. By several measures, the polyplexes formed between DNA and 18-mers of L-Lys, D-Lys or β^3-hLys do not differ significantly from one another. Our results indicate that premature breakdown of a cationic oligomer or polymer used to package DNA for delivery can diminish gene transfer activity.

ACKNOWLEDGMENT

This work was supported in part by the NSF Collaborative Research in Chemistry Program (CHE-0404704). Initial phases of the research were supported by seed funding (UW-Madison MRSEC) and by an Industrial and Economic Development Research grant from UW-Madison. We thank Dr. Michelle Chen of Wyatt Technologies for polymer molecular weight characterization.

Solid-Phase Synthesis of Oligonucleotides Labeled with Luminescent Lanthanide(III) Chelates

Lassi Jaakkola,[†] Jari Peuralahti,[†] Harri Hakala,[†] Jenni Kunttu,[†,‡] Pekka Tallqvist,[†,‡] Veli-Matti Mukkala,[†] Alice Ylikoski,[†] and Jari Hovinen*[,†]

PerkinElmer Life and Analytical Sciences, Wallac Oy, P.O. Box 10, FIN-20101 Turku, Finland, and Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received January 26, 2005; Revised Manuscript Received March 23, 2005

The synthesis of phosphoramidite building blocks that allow introduction of luminescent europium(III), terbium(III), dysprosium(III), and samarium(III) chelates to oligonucleotides on the solid phase is described. Several labeled oligonucleotides using these building blocks were prepared, and the photophysical properties of these bioconjugates were investigated.

INTRODUCTION

The development of stable and luminescent lanthanide(III) chelates has enabled the use of homogeneous assay technologies based on time resolution (*1*). Thus, time-resolved fluorescence quenching assays based on energy transfer from a lanthanide(III) chelate to a nonfluorescent quencher have been applied in various assays of hydrolyzing enzymes (*2*−*4*) as well as for nucleic acid detection (*5*, *6*). The different photochemical properties of europium, terbium, dysprosium, and samarium chelates enable development of even multiparametric homogeneous assays (*4*, *6*).

The biomolecule conjugates used in the homogeneous quenching assays have to be extremely pure, since even small amounts of fluorescent impurities considerably increase the luminescence backround and reduce the detection sensitivity. Thus, it is highly desirable to perform the biomolecule conjugation on the solid phase, since most of the impurities can be removed by washings when the biomolecule is still anchored to the solid support, and after release to the solution, only one chromatographic purification is required.

We have already reported a solid-phase method for the labeling of oligopeptides (*7*) and oligonucleotides (*8*, *9*). The approach involves synthesis of oligonucleotide and oligopeptide building blocks, which can be introduced to the biomolecule structure using commercial oligonucleotide and oligopeptide synthesizers by phosphoramidite and Fmoc chemistries, respectively. Upon completion of the chain assembly, the oligomers are deprotected and finally treated with the appropriate lanthanide(III) citrate producing the desired biomolecule conjugates. We report here the synthesis of various building blocks which extend our labeling strategy to the preparation of synthetic oligonucleotides labeled with photoluminescent europium, terbium, samarium, and dysprosium chelates. The photophysical properties of these biomolecule conjugates are also presented.

EXPERIMENTAL PROCEDURES

General Methods. Adsorption column chromatography was performed on columns packed with silica gel 60 (Merck) or basic aluminum oxide (Aldrich; 150 mesh, Brockmann I). Reagents for oligonucleotide synthesis were purchased from Proligo. 2-Acetyl-6-methylpyridine was purchased from HetCat (Switzerland). NMR spectra were recorded on a Bruker 250 spectrometer operating at 250.13 MHz for ^{1}H and on a JEOL LA 400 spectrometer operating at 161.9 MHz for ^{31}P. The signal of TMS was used as an internal (^{1}H) and H_3PO_4 as an external (^{31}P) reference. Coupling constants are given in hertz. ESI-TOF mass spectra were recorded on an Applied Biosystems Mariner instrument. Luminescence measurements were measured with a PerkinElmer LS-55 luminescence spectrometer equipped with a Hamamatsu R928 red-sensitive photomultiplier tube. IR and UV spectra were recorded on a PerkinElmer Spectrum One and a Shimazu UV-2100 instrument, respectively. Melting points were analyzed on a Gallenkamp apparatus and are uncorrected.

(*E*)-3-(Dimethylamino)-1-(6-methylpyridin-2-yl)-prop-2-en-1-one, 1. A mixture of 2-acetyl-6-methylpyridine (10.0 g, 74.0 mmol) and *N*,*N*-dimethylformamide dimethyl acetal (10.5 mL, 74.0 mmol) was heated at 105 °C for 7 h. The mixture was allowed to cool to room temperature, and all volatiles were removed in vacuo. The residue was suspended in petroleum ether (bp 40−60 °C), filtered, washed with petroleum ether, and dried. Yield: 10.63 g (75%). Mp: 100 °C. ^{1}H NMR ($CDCl_3$): δ 7.93 (2H, 2d, J 6.4 and 12.9); 7.90 (1H, d, J 12.5); 7.67 (1H, t, J 7.6); 7.22 (1H, d, J 7.6); 6.47 (1H, d, J 12.9) 3.16 (3H, br s); 3.00 (3H, br s); 2.61 (3H, s). ESI-TOF-MS for $C_{11}H_{15}N_2O$ $(M + H)^+$: calcd 191.12, found 191.11. λ_{max}/nm (EtOH): 254, 355.

2-Methyl-6-(1*H*-pyrazol-3-yl)pyridine, 2. Compound **1** (5.97 g, 31.4 mmol) was dissolved in ethanol (35 mL). Hydrazine monohydrate (1.80 mL, 36.9 mmol) was added, and the mixture was stirred at ambient temperature for 20 h. The mixture was concentrated in vacuo and diluted with water (25 mL). The precipitate formed was filtered, washed twice with water, and dried. Yield: 4.41 g (87%). Mp: 115 °C. ^{1}H NMR ($CDCl_3$): δ 11.46 (1H, br); 7.64 (1H, d, J 1.8); 7.62 (1H, t, J 7.6); 7.51 (1H, d, J 7.6); 7.09 (1H, d, J 7.7); 6.76 (1H, d, J 2.1); 2.59 (3H, s). ESI-TOF-MS

Published on Web 04/27/2005

for $C_9H_{10}N_3$ $(M + H)^+$: calcd 160.09, found 160.09. λ_{max}/nm (EtOH): 248, 285.

2,2′-(1*H*-Pyrazole-1,3-diyl)bis(6-methylpyridine), 3. A mixture of compound **2** (4.57 g, 28.7 mmol) and 2-bromo-6-methylpyridine (3.34 mL, 28.7 mmol) was heated at 190 °C for 15 h. The mixture was then cooled to room temperature and diluted with water (25 mL). The mixture was warmed to 50 °C, and the pH of the solution was adjusted to 9 with solid sodium carbonate. The solution was cooled on an ice bath, and the precipitate formed was collected by filtration and washed with cold water. The precipitate was redissolved in the mixture of ethanol (7 mL) and water (25 mL) and allowed to cool on an ice bath. The precipitate formed was filtered and washed with cold water and dried in vacuo over silica gel. The crude product was purified by silica gel column chromatography (eluent petroleum ether, bp 40−60 °C/ethyl acetate 5:1 v/v). Yield: 4.81 g (67%). Mp: 151 °C. ^{1}H NMR ($CDCl_3$): δ 8.67 (1H, d, *J* 2.4); 7.92 (2H, dd, *J* 3.3 and 7.9); 7.67 (2H, m); 7.13 (1H, br d, *J* 7.6); 7.12 (1H, d, *J* 2.7); 7.06 (1H, br d, *J* 7.6); 2.65 (3H, s); 2.58 (3H, s). ESI-TOF-MS for $C_{15}H_{15}N_4$ $(M + H)^+$: calcd 251.13, found 251.11. λ_{max}/nm (EtOH): 300.

2,2′-(1*H*-Pyrazole-1,3-diyl)bis(6-methylpyridine) 1,1′-Dioxide, 4b. Compound **3** (6.40 g, 44.0 mmol) was dissolved in acetic acid (50 mL). Magnesium monoperoxyphthalate hexahydrate (80%; 18.15 g) was added, and the mixture was stirred at 80 °C for 8 days. The mixture was cooled to room temperature, and the precipitate formed was removed by filtration. The solution was evaporated to dryness and coevaporated with butanol. The residue was suspended in CH_2Cl_2 (400 mL) and washed with saturated $NaHCO_3$. The organic phase was dried over Na_2SO_4 and concentrated. Purification on silica gel column chromatography (eluent from 3.5 to 15% (v/v) of MeOH in CH_2Cl_2) gave 7.66 g (62%) of compound **4b** as a solid. Mp: 188 °C. ^{1}H NMR ($CDCl_3$): δ 9.38 (1H, d, *J* 2.7); 8.16 (1H, dd, *J* 2.9 and 7.6); 8.02 (1H, dd, *J* 2.2 and 8.3); 7.83 (1H, d, *J* 2.7); 7.35−7.19 (4H, m). 2.63 (3H, s); 2.61 (3H, s). ESI-TOF-MS for $C_{15}H_{15}N_4O_2$ $(M + H)^+$: calcd 283.12, found 283.14. λ_{max}/nm (EtOH): 224, 256, 273, 310.

2,2′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(6-methylpyridine) 1,1′-Dioxide, 5. Compound **4b** (2.0 g, 7.09 mmol) was dissolved in the mixture of water (5 mL) and nitric acid (5 mL). Iodine (1.86 g, 7.33 mmol) was added, and the mixture was heated at reflux for 4 h before being cooled to ambient temperature. Chloroform (20 mL) was added, and the solution was basified with 1 M NaOH. The organic phase was separated, and the aqueous phase was washed with ethanolic chloroform (1:4, v/v; 3 × 15 mL). The combined organic layers were dried over Na_2SO_4. The product was purified by silica gel column chromatography (eluent MeOH in CH_2Cl_2, from 3:97 to 15:100, v/v). Yield: 1.27 g (80%). Mp: 226 °C dec. ^{1}H NMR ($CDCl_3$): δ 9.48 (1H, s); 7.95 (1H, dd, *J* 2.4 and 7.8); 7.40−7.19 (5H, m); 2.61 (6H, 2 s). ESI-TOF-MS for $C_{15}H_{14}IN_4O_2$ $(M + H)^+$: calcd 409.02, found 409.05. λ_{max}/nm (EtOH): 244, 295.

6,6′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(pyridine)-2,2′-bis(methanol), 6. Compound **5** (2.33 g, 5.7 mmol) was dissolved in acetic anhydride (15 mL), and the mixture was heated at reflux for 2.5 h, cooled to room temperature, and concentrated. The residue was dissolved in methanolic potassium hydroxide (1 M, 15 mL) and was stirred for 45 min at room temperature and concentrated. The residue was partitioned between water (20 mL) and 10% methanolic dichloromethane (100 mL). The organic phase was separated, and the aqueous phase was extracted twice with dichloromethane. The combined organic phases were dried and concentrated to give 1.40 g (63%) of compound **6**. It was used for the next step without further purification. An analytical sample was purified on silica gel (eluent 10% MeOH in CH_2Cl_2, v/v). Compound **6**. Mp: 164 °C. ^{1}H NMR (DMSO-d_6): δ 8.84 (1H, s); 8.08−7.84 (5H, m); 7.54 (1H, d, *J* 7.0); 7.48 (1H, d, *J* 7.3); 5.56 (1H, t, *J* 5.8); 5.47 (1H, t, *J* 5.8); 4.69 (2H, d, *J* 5.8); 4.63 (2H, d, *J* 5.7). ESI-TOF-MS for $C_{15}H_{14}IN_4O_2$ $(M + H)^+$: calcd 409.02, found 409.00. λ_{max}/nm (EtOH): 204, 229, 300.

2,2-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(4-chloro-6-methylpyridine), 7. Compound **5** (0.15 g, 0.37 mmol) was dissolved in anhydrous dioxane (10 mL). Phosphorus oxychloride (0.6 mL, 17.8 mmol) was added, and the mixture was heated overnight at reflux, cooled to room temperature, and concentrated in vacuo. Purification on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate, 5:1, v/v) gave 0.11 g (65%) of compound **7**. Mp: 160 °C. ^{1}H NMR ($CDCl_3$): δ 8.73 (1H, s); 7.90 (1H, d *J* <1); 7.88 (1H, d, *J* 1.8); 7.29 (1H, d, *J* 1.7); 7.09 (1H, d, *J* 1.7); 2.65 (3H, s); 2.54 (3H, s). ESI-TOF-MS for $C_{15}H_{12}Cl_2IN_4$ $(M + H)^+$: calcd 444.95, found 444.99.

2,2′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(6-bromomethylpyridine), 8. Phosphorus tribromide (0.21 mL; 2.2 mmol) was added in dry DMF (15 mL) on an ice−water bath, and the mixture was stirred for 10 min. Compound **6** (0.42 g, 1.0 mmol) was added, and the mixture was stirred for 30 min at room temperature. All volatiles were removed in vacuo. The residue was dissolved in dichloromethane, washed with satd $NaHCO_3$, and dried over Na_2SO_4. Purification on silica gel using dichloromethane as the eluent yielded 0.5 g of compound **7** (94%). ^{1}H NMR ($CDCl_3$): δ 8.79 (1H, s); 7.99 (1H, d, *J* 8.0); 7.96 (1H, d, *J* 7.6); 7.84 (1H, t, *J* 7.5); 7.80 (1H, t, *J* 7.6); 7.49 (1H, d, *J* 7.6); 7.37 (1H, d, *J* 7.6); 4.68 (2H, s); 4.54 (2H, s). ESI-TOF-MS for $C_{15}H_{12}Br_2IN_4$ $(M + H)^+$: calcd 532.85, found 532.87.

Tetramethyl 2,2′,2″,2‴-{[6,6′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(pyridine)-2,2′-diyl]bis(methylenenitrilo)}tetrakis(acetate) 9. *Method A*. Compound **8** (0.47 g, 0.88 mmol) was dissolved in dry acetonitrile (20 mL). Anhydrous potassium carbonate (1.2 g) and iminoacetic acid methyl ester (0.31 g, 1.94 mmol) were added, and the mixture was heated at reflux for 2.5 h, cooled to room temperature, and filtered. The filtrate was concentrated in vacuo, and the product was purified on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate, from 5:1 to 10:7; v/v). Yield: 0.45 g (74%). *Method B.* Compound **12** (10.5 g, 26.4 mmol) was suspended in dry THF (300 mL). Borane−THF complex (300 mL, 1 M in THF) was added, and the mixture was stirred overnight at room temperature. The excess of borane was destroyed with methanol (*caution*: foaming), and all volatiles were removed in vacuo. The residue was dissolved in methanolic hydrochloric acid (450 mL, 1.25 M), stirred for 2 h at room temperature, and concentrated. The residue was suspended in dry THF, filtered, and dried to give the amine **13** as pentahydrochloride. It was then suspended in dry acetonitrile (200 mL). Anhydrous K_2CO_3 (84 g) and methyl bromoacetate (12.4 mL, 0.13 mol) were added, and the mixture was heated overnight at 60 °C. The mixture was cooled to room temperature, filtered, and washed with acetonitrile. The filtrate was concetrated in vacuo, dissolved in dichloromethane, washed with satd $NaHCO_3$, dried over Na_2SO_4, and concentrated. Purification on silica gel (eluent MeOH/CH_2Cl_2, 3:97, v/v) gave 12.5 g (68%) of compound **9**. ^{1}H NMR ($CDCl_3$): δ 8.72 (1H, s); 7.94 (2H, 2 d, *J* 7.6); 7.83 (1H, t, *J* 7.4); 7.79 (1H, t, *J*

7.6); 7.63 (1H, dd, *J* 7.7 and < 1); 7.49 (1H, dd, *J* 7.3 and < 1); 4.18 (2H, s); 4.08 (2H, s); 3.73 (6H, s); 3.72 (6H s and 4H, s); 3.68 (4H, s). ESI-TOF-MS for $C_{27}H_{32}IN_6O_8$ $(M + H)^+$: calcd 695.13, found 695.12. λ_{max}/nm (EtOH): 228, 302.

2,2′-(1*H*-Pyrazole-1,3-diyl)bis(pyridine) 1,1′-Dioxide, 10. Oxidation of 2,2′-(1*H*-pyrazole-1,3-diyl)bis(pyridine) (*10*) with magnesium monoperoxyphthalate hexahydrate yielded the title compound (62%). It was spectroscopically identical with material synthesized according to ref 10.

2,2′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(pyridine) 1,1′-Dioxide, 11. Iodination of compound **10** (13.4 g, 52.7 mmol) as described above for compound **4b** yieded 14.3 g (71%) of compound **11**. Mp > 250 °C. ^{1}H NMR ($CDCl_3$): δ 9.49 (1H, s); 8.34 (2H, m); 8.06 (1H, dd, *J* 1.9 and 8.5); 7.50 (1H, dd, *J* 2.7 and 7.3); 7.35 (4H, m); 7.22 (1H, m). ESI-TOF-MS for $C_{13}H_{11}IN_4O_2$ $(M + H)^+$: calcd 380.98, found 380.98. λ_{max}/nm (EtOH): 291, 264 (sh), 246. ν_{max} (film)/cm^{-1}: 1251 (N → O).

2,2′-(4-Iodo-1*H*-pyrazole-1,3-diyl)bis(pyridine)-6,6′-dicarbonitrile, 12. Compound **11** (13.2 g, 34.7 mmol) was suspended in dry dichloromethane (350 mL). Trimethylsilyl cyanide (46 mL, 0.35 mol) was added during 5 min, and the mixture was stirred for an additional 10 min at room temperature. Benzoyl chloride (16 mL, 0.14 mol) was added dropwise, and the mixture was stirred overnight at room temperature and concentrated to half volume. K_2CO_3 (10%, 400 mL) was added, and the mixture was stirred for 2 h at room temperature. The precipitate formed was filtered, washed with cold water, and dried in vacuo. Yield: 11.6 g (84%). ^{1}H NMR ($CDCl_3$): δ 8.79 (1H, s); 8.31 (1H, d, *J* 8.5 and <1); 8.30 (1H, dd, *J* 8.1 and < 1); 8.02 (1H, dd, *J* 7.5 and 8.5); 7.95 (1H, dd, *J* 7.7 and 8.1); 7.73 (1H, dd, *J* 7.7 and 1.0); 7.66 (1H, dd, *J* 7.5 and <1). ESI-TOF-MS for $C_{15}H_9IN_6$ $(M + H)^+$: calcd 398.99, found 398.98. λ_{max}/nm (EtOH): 306, 245. ν_{max} (film)/cm^{-1}: 2235 (C≡N).

Tetramethyl 2,2′,2″,2‴-{[6,6′-[(4-(3-hydroxy-1-propyn-1-yl)-1*H*-pyrazole-1,3-diyl)bis((pyridine)-2,2′-diyl]bis(methylenenitrilo)}tetrakis(acetate), 14. Compound **9** (0.44 g, 0.63 mmol) was dissolved in dry DMF (5 mL) and deaerated with argon. $Pd(PPh_3)_2Cl_2$ (9 mg, 0.013 mmol), CuI (5 mg, 0.026 mmol), propargyl alcohol (43 μL, 0.76 mmol), and piperidine (2 mL) were added, and the mixture was deaerated for an additional 10 min before being heated overnight at 40 °C in dark. All volatiles were removed in vacuo, and the residue was dissolved in dichloromethane, washed with water, dried (Na_2SO_4), and purified on silica gel (eluent MeOH/CH_2Cl_2, 1:9, v/v). Yield: 0.34 g (85%). ^{1}H NMR ($CDCl_3$): δ 8.74 (1H, s); 8.02 (1H, d, *J* 7.9); 7.99 (1H, d, *J* 7.9); 7.83 (1H, t, *J* 8.0); 7.78 (1H, t, *J* 7.6); 7.54 (1H, d, *J* 7.9); 7.49 (1H, d, *J* 7.5); 4.54 (2H, s); 4.19 (2H, s); 4.08 (2H, s); 3.73 (6H, s); 3.71 (6H, s and 4H, s); 3.69 (4H, s). ν_{max} (film)/cm^{-1}: 2243w (C≡C). ESI-TOF-MS for $C_{30}H_{35}N_6O_9$ $(M + H)^+$: calcd 623.25, found 623.27.

Tetramethyl 2,2′,2″,2‴-{[6,6′-[(4-(3-hydroxy-1-propyl)-1*H*-pyrazole-1,3-diyl)bis((pyridine)-2,2′-diyl]bis(methylenenitrilo)}tetrakis(acetate), 15. Compound **14** (0.32 g, 0.51 mmol) was dissolved in methanol (30 mL) and deaerated with argon for 5 min. Pd/C (10%; 40 mg) was added, and then the mixture hydrogenated at atmospheric pressure for 7 h. (Note: The use of higher pressure caused the decomposition of the desired product.) The mixture was filtered through Celite and concentrated in vacuo. Purification on silica gel (eluent MeOH/CH_2Cl_2, 1:9, v/v) yielded 0.20 g (63%) of the title compound. ^{1}H NMR ($CDCl_3$): δ 8.44 (1H, s); 7.99 (1H, dd, *J* 6.7 and <1); 7.94 (1H, d, *J* 8.0); 7.81 (1H, t, *J* 7.7); 7.80 (1H, t, *J* 7.6); 7.62 (1H, dd, *J* 7.6 and <1); 7.44 (1H, d, *J* 7.0); 4.11 (2H, s); 4.09 (2H, s); 3.72 (6H, s); 3.71 (6H, s); 3.69 (4H, s); 3.65 (4H, s); 3.62 (2H, t, *J* 5.2); 3.05 (2H, t, *J* 6.7); 1.91 (2H, p). ESI-TOF-MS for $C_{30}H_{39}N_6O_9$ $(M + H)^+$: calcd 627.28, found 627.28.

5′-*O*-(4,4′-Dimethoxytrityl)-2′-deoxy-3-{tetramethyl 2,2′,2″,2‴-{[6,6′-[(4-(3-propyl)pyrazole-1″,3″-diyl)-bis(pyridine)-2,2′-diyl]bis(methylenenitrilo)}tetrakis-(acetato)}uridine, 17. Compound **15** (0.46 g, 0.73 mmol), 5′-*O*-(4,4′-dimethoxytrityl)-2′-deoxyuridine (0.50 g, 0.95 mmol), and triphenylphosphine (0.23 g, 0.88 mmol) were dissolved in dry THF (5 mL). Diethyl azodicarboxylate (170 μL, 1.07 mmol) was added dropwise, and the mixture was stirred for 2 h at room temperature before being concentrated in vacuo. Purification on silica gel (eluent: petroleum ether, bp 40−60 °C: ethyl acetate/triethylamine, 1:5:1, v/v/v) gave 0.80 g (97%) of compound **17**. ^{1}H NMR ($CDCl_3$): δ 8.74 (1H, s); 7.95−7.22 (tot. 12H); 6.83 (4H, d, *J* 8.9); 6.35 (1H, t, *J* 6.7); 5.46 (1H, d, *J* 7.9); 4.54 (1H, m); 4.13 (2H, s); 4.09 (2H, s); 4.06 (1H, m); 3.78 (3H, s); 3.71 (12H, s); 3.69 (2 · 4H s); 3.42 (2H, m); 3.00 (2H, t, *J* 7.6); 2.60 (2H, m); 2.51 (1H, m); 2.22 (1H, m); 2.06 (2H, m). ESI-TOF-MS for $C_{60}H_{67}N_8O_{15}$ $(M + H)^+$: calcd 1139.47, found 1139.45.

4′-(6-Hydroxyhexyl-1-oxy)-2,2′:6′,2″-terpyridine 1,1″-Dioxide, 20. Compound **19** (2.62 g, 7.5 mmol) was dissolved in dichloromethane (100 mL). 3-Chloroperbenzoic acid (6.50 g, 37.5 mmol; 55%) was added, and the mixture was stirred overnight at room temperature. The mixure was dried over Na_2SO_4 and concentrated. Purification on basic alumina using dichloromethane containing 3% methanol (v/v) as the eluent followed by precipitation from diethyl ether gave the bis-*N*-oxide **20** (2.2 g, 77%). Mp: 168 °C. ^{1}H NMR ($CDCl_3$): δ 8.58 (2H, s); 8.33 (2H, dd, *J* < 1 and 6.6); 8.24 (2H, dd, *J* 2.2 and 7.8); 7.39 (2H, dt, *J* 1.2 and 7.5); 7.33 (2H, dt; *J* 2.4 and 7.5); 4.17 (2H, t, *J* 6.6); 3.62 (2H, t, *J* 6.1); 3.17 (1H, br. s); 1.84 (2H, p, *J* 6.8); 1.59 (2H, p, *J* 6.8); 1.47 (4H, m). ESI-TOF MS for $C_{21}H_{24}N_3O_4^+$ $(M + H)^+$: calcd 382.18, obsd 382.18.

4′-(6-Hydroxyhexyl-1-oxy)-2,2′:6′,2″-terpyridine 2,6″-Dicarbonitrile, 21. Compound **20** (2.25 g, 5.9 mmol) was dissolved in dichloromethane (120 mL). Trimethylsilyl cyanide (5.95 g, 60 mmol) was added, and the mixture was stirred for 5 min at room temperature, after which time benzoyl chloride (3.37 g, 24 mmol) was added dropwise during 20 min and the mixture was stirred for 1 h at room temperature. An aqueous 10% solution of K_2CO_3 (80 mL) was added, and stirring was continued for 1 h. The organic layer was separated, and the aqueous phase was extracted twice with dichloromethane. The combined dichloromethane layers were dried over Na_2SO_4 and concentrated. Purification on silica gel (eluent 5% MeOH in CH_2Cl_2, v/v) followed by precipitation from diethyl ether yielded the title compound (1.9 g, 81%). Mp: 169−170 °C. ^{1}H NMR ($CDCl_3$): δ 8.81 (2H, dd, *J* <1 and 8.0); 8.08 (2H, s); 8.00 (2H, t, *J* 7.8); 7.75 (2H, dd, *J* 1 and 7.5); 4.26 (2H, t, *J* 6.4); 3.71 (2H, t, *J* 6.3); 1.93 (2H, p, *J* 6.5); 1.64 (5H, m and br s). ESI-TOF MS for $C_{23}H_{22}N_5O_2$ $(M + H)^+$: calcd 400.18, obsd 400.18. ν_{max} (KBr)/cm^{-1}: 2237 (C≡N). λ_{max}/nm (EtOH): 213, 250, 386.

Tetramethyl 2,2′,2″,2‴-{[4′-(6-Hydroxyhexyl-1-oxy)-2,2′:6′,2″-terpyridine-6,6″-diyl]bis(methylenenitrilo)}-tetrakis(acetate), 23. Compound **21** (1.0 g, 2.5 mmol) was dissolved in dry THF (20 mL), and the mixture was deaerated with argon. Borane−THF complex (24 mL; 1 M) was added during 5 min, and the mixture was stirred overnight at room temperature. The excess of borane was destroyed by careful addition of methanol (100 mL).

When the foaming had ceased, all volatiles were removed in vacuo. The residue was dissolved in satd methanolic HCl (50 mL), stirred for 2 h at room temperature and concentrated. The residue was triturated with diethyl ether and filtered to give compound **22** as pentahydrochloride (ESI-TOF MS for $C_{23}H_{30}N_5O_2$ $(M + H)^+$ calcd 408.24, found 408.21). The residue was dissolved in dry DMF (15 mL). Anhydrous K_2CO_3 (1.0 g) and methyl bromoacetate (0.89 mL, 6.0 mmol) were added, and the mixture was stirred for 2 h at room temperature and concentrated. The residue was suspended in dichloromethane, washed with water, and dried over Na_2SO_4. Purification was performed on silica gel (eluent petroleum ether bp 40−60 °C/ethyl acetate/triethylamine 2:5:1, v/v/v). ESI-TOF MS for $C_{35}H_{46}N_5O_{10}$ $(M + H)^+$: calcd 696.32, found 696.31. ^{1}H NMR ($CDCl_3$): δ 8.50 (2H, d, *J* 7.9); 8.00 (2H, s); 7.83 (2H, t, *J* 7.8);7.58 (2H, d, *J* 7.5); 4.24 (2H, t, *J* 6.3); 4.16 (4H, s); 3.72 (12H, s); 3.71 (8H, s); 3.69 (2H, t); 1.90 (4H, m); 1.54 (4H, m).

Diethyl 2,2′-(4-Bromo-6-bromomethyl-2-pyridylmethylenenitrilo)bis(acetate), 26. 4-Bromo-2,6-bis(bromomethyl)pyridine (**25**; 3.10 g, 9.0 mmol) was dissolved in dry acetonitrile (80 mL). Potassium carbonate (6.2 g) and iminodiacetic acid methyl ester (0.77 g, 4.8 mmol) were added, and the mixture was stirred for 3.5 h at 60 °C, filtered, and concentrated. Purification was performed on silica gel (eluent petroleum ether, bp 40−60 °C/ethyl acetate from 15:1 to 2:5, v/v). Yield: 1.65 g (43%). ^{1}H NMR ($CDCl_3$): δ 7.76 (1H, s); 7.51 (1H, s); 4.46 (2H, s); 4.04 (2H, s); 3.72 (6H, s); 3.63 (4H, s). ESI-TOF-MS for $C_{13}H_{17}Br_2N_2O_4$ $(M + H)^+$: calcd 422.96, found 422.94.

Tetramethyl 2,2′,2″,2‴-{[6-(Hydroxyhex-1-ylimino]bis(methylene)bis(4-bromopyridine-6,2-diyl)bis(methylenenitrilo)}tetrakis(acetate), 27. Compound **26** (1.60 g, 3.77 mmol) and 6-aminohexan-1-ol (0.46 g, 3.96 mmol) were dissolved in dry DMF (35 mL). *N,N*-Diisopropylethylamine (3.3 mL) was added, and the mixture was stirred for 3 h at 60 °C before being cooled to room temperature and concentrated in vacuo. The residue was dissolved in dichloromethane, washed with water, and dried over Na_2SO_4. Purification on silica gel (eluent 10% MeOH in CH_2Cl_2, v/v) yielded the title compound (1.0 g, 66%) as an oil. Compound **27**. ^{1}H NMR ($CDCl_3$): δ 7.66 (2H, s); 7.58 (2H, s); 7.52 (2H, d, *J* 1.8); 4.00 (4H, s); 3.73 (4H, s); 3.70 (12H, s); 3.61 (8H, s); 3.60 (2H, m); 2.51 (2H, t, *J* 6.6); 1.54 (4H, m); 1.30 (4H, m). ESI-TOF-MS for $C_{32}H_{45}Br_2N_5O_9$ $(M + H)^+$: calcd 802.19, found 802.19.

Tetramethyl 2,2′,2″,2‴-{[6-(hydroxyhex-1-ylimino]bis(methylene)bis[4-(2-furyl)pyridine-6,2-diyl)]bis(methylenenitrilo)}-tetrakis(acetate), 28. Compound **27** (0.53 g, 0.66 mmol) and 2-(tributylstannyl)furan (0.44 mL, 1.39 mmol) were dissolved in dry DMF, and the mixture was deaerated with argon for 15 min. $(Ph_3P)_4Pd$ (76 mg, 0.066 mmol) was added, and the mixture was stirred at 90 °C for 3.5 h, allowed to cool to room temperature, and concentrated. The residue was dissolved in dichloromethane, washed twice with 1 M Na_2CO_3, dried, and concentrated. Purification on silica gel (eluent 10% MeOH in CH_2Cl_2, v/v) yielded the title compound (0.44 g, 86%) as an oil. Compound **28**. ^{1}H NMR ($CDCl_3$): δ 7.81 (2H, s); 7.68 (2H, s); 7.52 (2H, d, *J* 1.8); 6.92 (2H, d, *J* 3.2); 6.51 (2H, dd, *J* 1.8 and 3.2); 4.06 (4H, s); 3.82 (4H, s); 3.70 (12H, s); 3.65 (8H, s); 3.57 (2H, t, *J* 6.6); 2.60 (2H, t, *J* 6.6); 1.80 (1H, br s); 1.54 (4H, m); 1.33 (4H, m). ESI-TOF-MS for $C_{40}H_{52}N_5O_{11}$$(M + H)^+$: calcd 778.40, found 778.40.

Tetramethyl 2,2′,2″,2‴-{{[6-(4-Methoxytrityloxy)hex-1-ylimino]bis(methylene)bis(4-bromopyridine-6,2-diyl)}bis(methylenenitrilo)}tetrakis(acetate), 30. Compound **27** (0.46 g, 0.6 mmol) was dried by coevaporation with dry pyridine and dissolved in the same solvent (15 mL). MMTr-chloride (0.28 g, 0.9 mmol) was added, and the mixture was stirred overnight at room temperature and concentrated in vacuo. The residue was dissolved in dichloromethane, washed with satd $NaHCO_3$, and dried over Na_2SO_4. Purification on silica gel (eluent petroleum ether/ethyl acetate, from 5:1 to 1:1, v/v) yielded 0.44 g (59%) of compound **30**. ^{1}H NMR ($CDCl_3$): δ 7.66 (2H, d, *J* 1.4); 7.58 (2H, d, *J* 1.4); 7.43 (4H, m); 7.44 (4H, m); 7.28 (8H, m); 6.82 (2H, d, *J* 8.3); 4.00 (4H, s); 3.79 (3H, s); 3.72 (4H, s); 3.70 (12H, s); 3.60 (8H, s); 3.02 (2H, t, *J* 6.6); 2.49 (2H, t, *J* 7.3); 1.61 (2H, m); 1.51 (2H, m); 1.28 (4H, m). ESI-TOF-MS for $C_{52}H_{62}Br_2N_5O_{10}$ $(M + H)^+$: calcd 1074.28, found 1074.26.

Tetramethyl 2,2′,2″,2‴-{{[6-(4-Methoxytrityloxy)hex-1-ylimino]bis(methylene)bis[4-(2,4,6-trimethoxyphenyl)pyridine-6,2-diyl]}bis(methylenenitrilo)}-tetrakis(acetate), 31. Compound **30** (0.39 g, 0.38 mmol) and 2,4,6-trismethoxyphenylboronic acid (0.24 g, 1.14 mmol) were dissolved in dry DMF, and the mixture was deaerated with argon. $(Ph_3P)_4Pd$ (17 mg, 0.015 mmol) and Cs_2CO_3 (0.42 g, 1.3 mmol) were added, and the mixture was heated overnight at 95 °C. The cooled mixture was concentrated in vacuo, and the residue was dissolved in dichloromethane, washed with satd $NaHCO_3$, and dried over Na_2SO_4. Purification on silica gel (eleuent 10% MeOH in CH_2Cl_2) yielded the title compound. ^{1}H NMR (DMSO-d_6): δ 7.63 (2H, s); 7.35 (2H, s); 7.32−7.17 (12H, m); 6.86 (2H, d, *J* 8.9); 6.25 (4H, s); 3.90 (4H, s); 3.81 (4H, s); 3.71 (3H, s); 3.57 (18H, s) 3.49 (12H, s); 3.34 (8H, s); 2.87 (2H, t, *J* 5.2); 2.44 (2H, t, *J* 6.4); 1.44 (4H, m); 1.18 (4H, m). ESI-TOF-MS calcd for $C_{70}H_{84}N_5O_{16}^+$ 1250.59, found 1250.54.

Tetramethyl 2,2′,2″,2‴-{{(6-Hydroxyhex-1-ylimino)bis(methylene)bis[4-(2,4,6-trimethoxyphenyl)pyridine-6,2-diyl]}bis(methylenenitrilo)}tetrakis(acetate), 32. Compound **31** (0.14 g, 0.11 mmol) was dissolved in dichloromethane (5 mL). Trifluoroacetic acid (0.25 mL) was added, and the mixture was strirred for 3 h at room temperature. Methanol (10 mL) was added, and all volatiles were removed in vacuo. Purification on silica gel (eluent MeOH/CH_2Cl_2, from 1:9 to 1:5, v/v) yielded compound **32**. ^{1}H NMR ($CDCl_3$) δ 7.52 (2H, s); 7.32 (2H, s); 4.06 (4H, s); 3.85 (8H, s); 3.68 (18H, s); 3.66 (4H, s); 3.53 (12H, s); 3.52 (2H, m); 2.58 (2H, m); 1.52 (8H, m).

Synthesis of the Phosphoramidites. General Procedure. The predried alcohol (**15**, **17**, **23**, **28**, and **32**) and 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphordiamidite (1.5 equiv) were dissolved in dry acetonitrile. 1*H*-Tetrazole (1 equiv; 0.45 M in acetonitrile) was added, and the mixture was stirred for 30 min at room temperature before being poured into 5% $NaHCO_3$ and extracted with dichloromethane and dried over Na_2SO_4. Purification on silica gel (eluent: petroleum ether, bp 40−60 °C: ethyl acetate/triethylamine, 2:5:1, v/v/v) yielded the desired phosphoramidites. Compound **18** was a solid, and the non-nucleosidic phosphoramidites were oils. Compound **16**. ^{31}P NMR ($CDCl_3$): δ 149.3. ESI-TOF-MS for $C_{39}H_{56}N_8O_{10}P$ $(M + H)^+$: calcd 827.39, found 827.37. Compound **18**. ^{31}P NMR ($CDCl_3$): δ 152.5 (0.5 P), 152.1 (0.5 P). ESI-TOF-MS for $C_{69}H_{84}N_{10}O_{16}P$ $(M + H)^+$: calcd 1339.58, found 1339.85. Compound **24**. ^{31}P NMR ($CDCl_3$): δ 147.7. ESI-TOF-MS for $C_{44}H_{64}N_7O_{11}P$ $(M + H)^+$: calcd 896.43, found 896.32. Compound **29**: ^{31}P NMR ($CDCl_3$): δ 148.6. ESI-TOF-MS for $C_{49}H_{69}N_7O_{12}P$ $(M + H)^+$: calcd 978.47, found 978,32. **33**: ^{31}P NMR ($CDCl_3$):

δ 149.0. ESI-TOF-MS for $C_{59}H_{85}N_7O_{16}P$ $(M + H)^+$: calcd 1178.58, found 1178.43.

Synthesis and Purification of the Oligonucleotide Conjugates. The oligonucleotides were assembled on an Applied Biosystems 3400 instrument on a 1.0 μmol scale using phosphoramidite chemistry and recommended protocols. The phosphoramidites (**16**, **24**, **29**, and **33**) were coupled to the 5′-terminus of the oligonucleotide sequence (coupling time 10 min, concentration 0.2 M). As the chain assembly was completed, the oligonuleotides were deprotected by first treating the solid support with 0.1 M NaOH for 4 h at room temperature. Ammonium chloride (1.0 M) was then added, and the solution was concentrated in vacuo. The residue was treated with concentrated ammonia for 16 h at 55 °C, after which time aqueous lanthanide citrate (5 equiv per ligand) was added, and the mixture was kept for 90 min at room temperature. Desalting by gel filtration followed by denaturing PAGE yielded the oligonucleotide conjugates (**35**−**41**). The following oligonucleotides were synthesized

5′-X-AAT CAG ACT GTT CAA GAC-3′ (**35**)
5′-X TGA CAG CGA CGT GGA T-3′ (**36**, **37**)
5′-X TCT CCA TCA AAT TCA TTT-3′ (**38**)
5′-X ATC TTC TAA ATC TGC GTT-3′ (**39, 41**)
5′-XAAT GTA GTC CCT GGA A-3′ (**40**)

where X is the position of the label (for structures of X, see Table 1).

RESULTS AND DISCUSSION

Synthesis of the Oligonucleotide Labeling Reactants. Preparation of the phosphoramidite building blocks that enable introduction of luminescent europium(III), terbium(III), samarium(III), and dysprosium(III) chelates to synthetic oligonucleotides on solid phase is outlined in Schemes 1-4. The key steps are discussed below.

The terbium(III) chelate based on 2-(3-(pyridin-2-yl)-1*H*-pyrazol-1-yl)pyridine (**A**, Chart 1) has excellent photophysical properties including high luminescent quantum yield and relatively high energy of its lowest triplet state (*10*). To use this chelate for biomolecule derivatization, the synthetic route had to be modified. Several approaches were investigated, and the most useful ones are demonstrated in Scheme 1. Accordingly, 6-methyl-2-acetylpyridine was initially converted to (*E*)-3-(dimethylamino)-1-(6-methylpyridin-2-yl)prop-2-en-1-one (**1**) by treatment with *N,N*-dimethylformamide dimethyl acetal. It was then cyclized to **2** with hydrazine hydrate followed by reaction with 2-bromo-6-methylpyridine giving rise to **3**, which was subsequently oxidized to the corresponding di-*N*-oxide with magnesium monoperoxyphthalate in glacial acetic acid (*11*). Interestingly, while the mono-*N*-oxide **4a** was formed readily, a prolonged reaction time (8 days at 80 °C) was required for the preparation of the di-*N*-oxide **4b**. The use of *m*-chloroperbenzoic acid as the oxidant (*10*) resulted in even longer reaction times.

To attach linker arms to the pyrazole moiety, a method for the preparation of the corresponding 4-halogenated precursor is needed. While iodination of **4b** with KI/I_2 (*12*) was not successful, the classical HIO-assisted iodination (*13*) occurred readily giving rise to **5**. It was essential to convert **3** to **4b** prior to iodination, since the 4-iodo derivative of **3** was not stable during the rather drastic conditions needed for oxidation. Treatment of **5** with acetic anhydride followed by base-catalyzed hydrolysis (*14*) gave the dimethanol **6**, which was converted almost quantitatively to the corresponding dibromide **8** by reaction with PBr_3 in dry DMF. It is worth noting that reaction of **4b** with $POBr_3$ or the free-radical bromination with NBS (*15*) were not successful. Reaction of **4b** with phosphorus oxychloride (*15, 16*), in turn, did not yield the corresponding 6,6″-bis(chloromethyl) derivative, but the undesired dichloride **7** (*11*). Reaction of **7** with iminodiacetic acid dimethyl ester gave **9** in high yield.

An alternative route for the preparation of the key intermediate **9** involves iodination of 1,3-di(pyridyl)-pyrazole *N,N*″-dioxide, **5** (*10*) and its conversion to the corresponding 6,6′-dicarbonitrile **12** by treatment with trimethylsilylcyanide and benzoyl chloride followed by borane reduction. Reaction of the amine **13** with methyl bromoacetate in acetonitrile in the presence of potassium carbonate gave **9** in high yied.

The rest of the synthesis was straightforward. Reaction of **9** with propargyl alcohol in the presence of copper(I) iodide and $Pd(Ph_3P)_2Cl_2$ as catalysts gave **14**. The highest coupling yield was obtained using DMF as the solvent and piperidine as the base. The reaction could be performed at ambient temperature demonstrating the power of iodine as the leaving group in Sonogashira reaction. Catalytic hydrogenation over Pd/C yielded **15**. It was then phosphitylated to **16** by treatment with 2-cyanoethyl *N,N,N′,N′*-tetraisopropylphosphordiamidite in dry acetonitrile using 1*H*-tetrazole as the catalyst. Alternatively, **15** was initially converted to the nucleoside **17** by reaction with 2′-deoxy-5′-*O*-(4,4′-dimethoxytrityl)-uridine in the presence of triphenylphosphine and diisopropylazodicarboxylate (*8*) and then phosphitylated to give **18**, a nucleosidic phosphoramidite designed for multilabeling of oligonucleotides.

Terpyridine-based lanthanide(III) chelates are among the best luminescent europium(III) chelates used as nonradioactive markers in a wide variety of routine and research applications (*10, 15*−*19*). One of the structures is shown in Chart 1. We have also synthesized the corresponding nucleosidic and non-nucleosidic phosphoramidites and oligopeptide building blocks and demonstrated their suitability to the preparation of labeled oligonucletides and oligopeptides (*7*−*9*). Here, we wanted to simplify the synthetic procedure by omitting the central phenyl ring from the structure by connecting the linker arm to 4′-positon via an ether linkage. The ether function, in turn, is known to increase the energy of the lowest triplet state of the ligand (*10*), an important parameter effecting on the luminescent quantum yield of the europium(III) chelate. Accordingly, the terminal pyridine moieties of 4′-(6-hydroxyhexyloxy)-2,2′:6′,2″-terpyridine **19** (*20*) were oxidized with *m*-chloroperbenzoic acid to give the *N,N*″-dioxide **20** in high yield. In strict contrast to the oxidation of **3**, the reaction was completed in few hours at ambient temperature. The modified Reissert−Henze reaction (*21*) converted **20** to the 6,6″-dicarbonitrile **21**. The reaction was completed in 1 h at room temperature. Prolonged reaction time caused partial benzoylation of the ω-hydroxy group. However, this side reaction was not crucial, since the ω-benzoyl group was cleaved during borane reduction to give **22**, followed by carboxymethylation to the tetraester **23** with methyl bromoacetate in the presence of potassium carbonate as the base. Phosphitylation as described above yielded the corresponding phosphoramidite, **24**.

Certain ligands with furylpyridine and trismethoxyphenylpyridine subunits form highly luminescent chelates with europium as well as with terbium and dys-

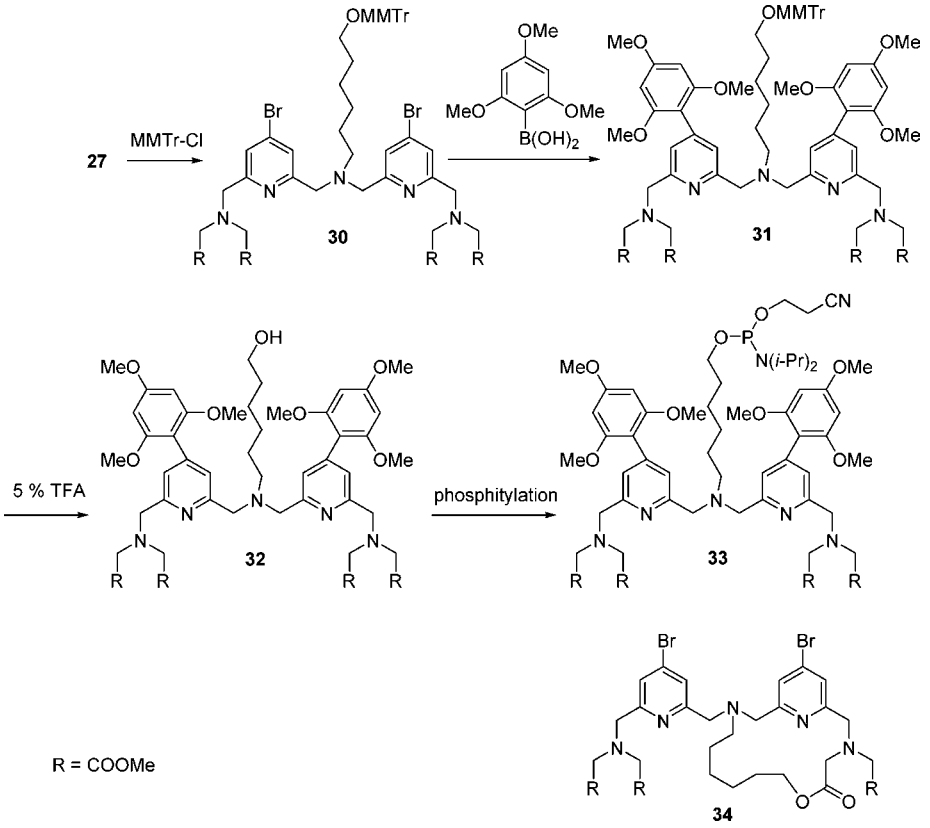
prosium, respectively (structures **C** (*22*) and **D** (*23*) in Chart 1). Thus, these chromophores were chosen as key elements of the next oligonucleotide labeling reactants. Their syntheses are desribed in Schemes 3 and 4. Initially, 4-bromo-2,6-bis(bromomethyl)pyridine, **25** (*24*), was allowed to react with an equimolar amount of iminodiacetic acid dimethyl ester to yield the monobromide **26**, which was further allowed to react with 0.5 equiv of 6-aminohexan-1-ol giving **27** in moderate yield. The palladium(0)-catalyzed Stille reaction of **27** with tributylstannylfuran gave **28**, which was finally converted to the corresponding phosphoramidite **29** as above. The corresponding trismethoxyphenyl derivative **33** was obtained analogously, but the ω-hydroxy group of **27** was protected as a MMTr-ether prior to coupling to 2,4,6-trimethoxybenzeneboronic acid in the presence of cesium carbonate and tetrakis(triphenylphosphine)palladium(0). Without protection, formation of the ester derivative **34** (structure tentatively assigned based on MS analysis) was a serious side reaction in the Suzuki reaction.

Syntheses of the Oligonucleotide Conjugates. Syntheses of the oligonucleotide conjugates were performed with a standard oligonucleotide synthesizer using phosphoramidite chemistry (*8*, *9*). Upon completion of the syntheses, the conjugates were deprotected and converted the corresponding lanthanide(III) chelates by treatment with appropriate lanthanide(III) salts. The oligonucleotides were purified on gel electrophoresis. According to mass spectrometric analyses, the observed molecular weights of the biomolecule conjugates were in accordance with the proposed structures.

Photophysics. The measured excitation and emission wavelengths as well as the decay times (τ) and luminescence yields ($\epsilon\Phi$) of chelates coupled to oligonucleotides (**35**−**41**) are shown in Table 1. The measurements were carried out in Tris buffer containing 0.9% NaCl at pH

Scheme 4. Synthesis of the Oligonucleotide-Labeling Reactant Based on Trismethoxyphenylpyridine Subunits



7.75. The luminescence yields were measured by a relative method described earlier (*10*, *26*). The observed emission spectra were typical for lanthanide chelates corresponding to the $^5D_0 \rightarrow {}^7F_j$, $^4G_{5/2} \rightarrow {}^6H_j$, $^5D_4 \rightarrow {}^7F_j$, and $^4F_{9/2} \rightarrow {}^6H_j$ transitions for Eu^{3+}, Sm^{3+}, Tb^{3+}, and Dy^{3+}, respectively. The main emission lines of chelates were centered as usual around 617 (Eu^{3+}), 645 (Sm^{3+}), 544 (Tb^{3+}), and 575 nm (Dy^{3+}). The only exception was **35**, which has 695 nm peak slightly more intense than that of 617 nm. The decay times were normal for nonadentate chelates except that of chelate **40**, which has surprisingly short decay time. The luminescence yields of studied chelates were high compared to earlier published results. The ether function of **35** decreased the excitation wavelength and increased the luminescence yield compared to parent compound (*10*). Although the luminescence yield of **35** was high, the luminescence yield of **36** was still over four times higher. Therefore, the **36** is the brightest stable, directly luminescent europium(III) chelate published, according to our knowledge. When the ligand of **36** was used with samarium(III) ion, i.e., compound **37**, the luminescence yield obtained was high compared to earlier published results (*18*, *26*, *27*). The terbium(III) chelates **38** and **39** also had high luminescence yields, **39** having two times higher than **38**. The ligand structures of **38** and **39** were applied also with dysprosium(III) ion (**40** and **41**). The luminescence yields obtained were high, although the decay time of **40** was surprisingly short. It is worth noting that although the decay times are shorter and luminescence yields much lower in the case of samarium and dysprosium chelates than in the case of europium and terbium chelates, they are valuable when multiparametric assays are developed (*4*, *6*, *28*).

We are currently studying the use of the biomolecule conjugates synthesized in multiparametric TruPoint assays. These results will be published in due course.

Received February 12, 2005; Revised Manuscript Received March 29, 2005

We have identified a UDP-glucose-binding site within human UDP-glucose dehydrogenase (hUGDH) by photoaffinity labeling with a specific probe, [^{32}P]5N$_3$UDP-glucose, and cassette mutagenesis using a synthetic hUGDH gene. Photolabel-containing peptides were generated by photolysis followed by tryptic digestion and isolated using the phosphopeptide isolation kit. Photolabeling of these peptides was effectively prevented by the presence of UDP-glucose during photolysis, demonstrating a selectivity of the photoprobe for the UDP-glucose-binding site. Amino acid sequencing and compositional analysis identified the UDP-glucose-binding site of hUGDH as the region containing the sequence, ASVGFGGSXFQK, corresponding to A268−K279 of the amino acid sequence of hUGDH. The unidentified residue, X, can be designated as a photolabeled C276 because the sequences including the cysteine residue in question have a complete identity with those of other UGDH species known. The importance of the C276 residue in the binding of UDP-glucose was further examined with mutant proteins at the C276 site. The mutagenesis at C276 has no effect on the expression of the mutants (C276G, C276K, C276E, C276L, and C276Y). Enzyme activities of the C276 mutants were not measurable under normal assay conditions, suggesting an important role for the C276 residue. No incorporation of [^{32}P]5N$_3$UDP-glucose was also observed for the mutants. These results indicate that C276 plays an important role for efficient binding of UDP-glucose to hUGDH.

INTRODUCTION

UDP-glucose dehydrogenase (UGDH;[1] EC 1.1.1.22) is an NAD$^+$-linked oxidoreductase that catalyzes, in vertebrates, the unique pathway forming UDP-glucuronate from UDP-glucose. UDP-glucuronate is one of the main substrates in glycosaminoglycan synthesis. Because the UDP-glucuronate supply is a limiting step in glycosaminoglycan synthesis, it was recently postulated that any modification of UGDH activity may influence the proteoglycan structure and function (*1*). For example, the mutation inactivation of the *Drosophila* gene (*sugarless* or *suppenkasper*) suppresses the Wingless activity in developing pups (*2*), confirming the role of glycosaminoglycans in growth-factor-signaling mechanisms. In addition to providing the glucuronate and iduronate moieties of glycosaminoglycans, UDP-glucuronate is the required substrate for glucuronidation of many substances, including xenobiotics, opioids, androgens, and heme proteins, through the action of UDP-glucuronosyl transferases in the liver (*3*).

Among UGDH, the most information is known regarding the bovine liver UGDH. This protein is proposed to act as a homohexamer of 52-kDa subunits, described as a "trimer of dimers" (*4*, *5*). The human enzyme cDNA codes for 494 amino acids and has 27% homology to its *Escherichia coli* ortholog, with identical consensus sequence for the NAD$^+$-binding site (*6*). The cloned murine and bovine cDNAs share over 97% identity with the human sequence (*7*, *8*). Recently, the recombinant human UGDH has been cloned, expressed, and affinity-purified (*9*). The enzyme is active as a hexamer with some evidence for assembly in a trimer of dimers as has been proposed for the bovine enzyme. Steady-state kinetic constants were established and found to be comparable with previously published data in the bovine system (*4*, *10*−*12*).

All forms of the enzyme are known to catalyze the same reaction. The mechanism used by the bovine liver UGDH is thought to involve an initial oxidation of the C-6 hydroxy of UDP-glucose to form an aldehyde intermediate and NADH (*10*, *11*). It has been suggested that the aldehyde is bound via an imine linkage with a lysine residue (*10*). The second oxidation is initiated by the addition of an active-site cysteine thiol to the aldehyde to form a thiohemiacetal intermediate (*11*). A hydride transfer from the intermediate to NAD$^+$ then takes place to produce an enzyme-bound thioester intermediate and a second molecule of NADH. In a final irreversible step, the thioester is hydrolyzed to give the product UDP-glucuronate. The streptococcal enzyme is believed to form a covalent intermediate specifically between the product of the first oxidation and C260 within the active site, which is required for the second oxidation. This residue

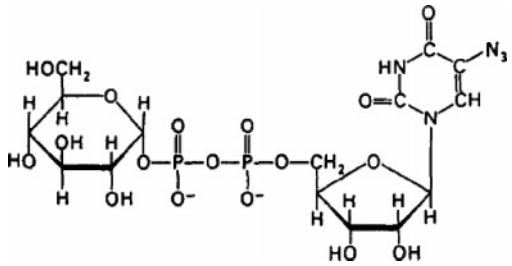
Chart 1. Structure of $5N_3$UDP-Glucose



is uniformly conserved across all species and corresponds to C276 in the human enzyme (*9*). However, direct evidence for the binding of C276 with UDP-glucose has not been reported.

Identification of the nucleotide binding sites of a variety of proteins has been advanced by the use of nucleotide photoaffinity analogues that selectively insert into a site upon photoactivation with ultraviolet light (*13*−*16*). The 5-azidopyrimidine analogues of both uridine and deoxyuridine were synthesized and used in the study of UTP and dTTP binding proteins and in the production of 5-azidodeoxyuridine-containing DNA used for investigations on protein−DNA interactions (*17*). Because of the role of nucleotide diphosphate sugars in several aspects of metabolism and in the synthesis of important macromolecules, a model azidonucleotide sugar analogue, [^{32}P]5-azidouridine 5′-diphosphoglucose ([^{32}P]$5N_3$UDP-glucose) (Chart 1), has been widely used to identify and characterize UDP-glucose-binding proteins (*18*−*21*).

In the present work, we have identified the UDP-glucose-binding site of human UGDH using a photoaffinity labeling with $5N_3$UDP-glucose and cassette mutagenesis using a synthetic hUGDH gene (*22*). This study shows that C276 is an active catalytic residue and critically involved in the substrate binding in the human UGDH.

EXPERIMENTAL PROCEDURES

Materials. UDP-glucose, NAD^+, ampicillin, isopropyl thio-β-D-galactoside, phenylmethanesulfonyl fluoride, and L-1-tosylamido-2-phenylethyl chloromethyl ketone-treated trypsin were purchased from Sigma Chemical Co. Human UGDH gene (pHUGDH) has been chemically synthesized and expressed in *E. coli* as a soluble protein in our laboratory (*22*). $5N_3$UDP-glucose was purchased from ALT, Inc. (Lexington, KY). [β-^{32}P]$5N_3$UDP-glucose (specific activity, 24 mCi/μmol) was synthesized by a procedure described elsewhere (*23*). Pre-cast gels for SDS−PAGE were purchased from Novex. All other chemicals and solvents were of reagent grade or better.

Bacterial Strains. *E. coli* DH5α (*24*) was used as the host strain for plasmid-mediated transformations during the assembly of the synthetic *hUGDH* gene (pHUGDH) and for cassette mutagenesis. *E. coli* BL21 (DE3) (*25*) was used for high level expression of the recombinant hUGDH.

Photoaffinity Labeling of hUGDH. Photoaffinity labeling of wild-type hUGDH and mutant proteins were performed as described elsewhere with a slight modification (*14*, *22*). For saturation studies, 100 μg of the wild-type hUGDH in 10 mM Tris-acetate at pH 8.0 was incubated with various concentrations of [^{32}P]$5N_3$UDP-glucose in Eppendorf tubes for 5 min. For competition studies, 100 μg of enzyme was incubated with various concentrations of UDP-glucose for 10 min in the same buffer prior to the addition of 120 μM [^{32}P]$5N_3$UDP-glucose and then allowed to incubate with the photoprobe for 5 min as described above. The samples were irradiated with a handhold 254-nm UV lamp for 90 s twice at 4 °C. The reaction was quenched by the addition of ice-cold trichloroacetic acid (final 7%). The reaction mixtures were kept on the ice bath for 30 min and centrifuged at 10 000*g* for 15 min at 4 °C. The pellets were resuspended with SDS−PAGE sample buffer. After SDS−PAGE, the gels were dried and subjected to autoradiography at −80 °C followed by densitometry scanning of labeled bands.

Tryptic Digestion and Isolation of Photolabeled Peptide. To determine the site modified by [^{32}P]$5N_3$UDP-glucose, 1.0 mg of wild-type hUGDH and mutant proteins in 10 mM Tris acetate at pH 8.0 was incubated with 120 μM [^{32}P]$5N_3$UDP-glucose for 5 min at 4 °C. The mixtures were irradiated twice for 90 s. The reaction was quenched by the addition of ice-cold trichloroacetic acid (final 7%) and kept at 4 °C for 15 min. The protein was precipitated by centrifugation at 10 000*g* for 15 min at 4 °C, and the pellet was resuspended in 75 mM NH_4HCO_3 at pH 8.5 containing 2 M urea. The enzymes were proteolyzed by the addition of 30 μg of trypsin and kept at room temperature for 3 h after which 30 μg of trypsin was added again. After 3 more hours at room temperature, 40 μg of trypsin was added, and the digestion mixture was kept at 25 °C overnight. To validate that the isolated peptide was specific for the UDP-glucose-binding site and could be protected from photomodification, the hUGDH proteins were separately photolyzed in the presence of 150 μM UDP-glucose and proteolyzed as described above. The tryptic-digested peptides were separated by the "Phosphopeptide Isolation Kit" from Pierce Biotechnology (Rockford, IL) following the protocol of the manufacturer and sequenced by the Edman degradation method.

Construction and Characterization of C276 Mutants. Cassette mutagenesis at the C276 site was performed using a synthetic human hUGDH gene, pHUGDH. The plasmid DNA was digested with *Nhe*I and *Eco*NI to remove a 60 base-pair fragment that encodes amino acids 269−287, and vector DNA was purified by electrophoresis using 1% low melting point agarose. The 60 base-pair *Nhe*I/*Eco*NI fragment was replaced with five 60 base-pair synthetic DNA duplexes containing a substitution on both DNA strands at positions encoding C276 to make C276G, C276K, C276E, C276L, and C276Y mutants. Mutagenic oligonucleotides were annealed, ligated, and transformed into DH5α as described above, and C276 mutants were identified by DNA sequencing using plasmid DNA as a template. Each of these mutants has been expressed in *E. coli* strain DE3, purified to homogeneity as described above, and has had its steady-state kinetic parameters determined. The gene expression level of C276 mutant proteins in the crude extracts was examined by Western blot using monoclonal antibodies against the hUGDH and compared with that of wild-type hUGDH.

Protein Purification and Enzyme Assay. For purification of the wild-type and mutant enzymes, fresh overnight cultures of DE3/pHUGDH were used to inoculate 1 L of Luria−Bertani (LB) containing 100 μg of ampicillin/mL. DE3/pHUGDH was grown at 37 °C until the A_{600} reached 1.0, and then isopropyl thio-β-D-galactoside was added to a final concentration of 1 mM. After isopropyl thio-β-D-galactoside induction, DE3/pHUGDH was grown for an additional 3 h at 37 °C and then harvested by centrifugation. Cell pellets were suspended in 100 mL of 100 mM Tris-HCl at pH 7.4, 1 mM EDTA, and 5 mM dithiothreitol and lysed with a sonicator. Cellular debris was removed by centrifugation, and the

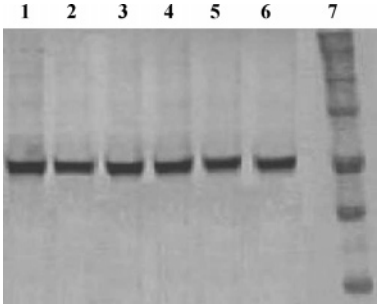


Figure 1. Western blot analysis of wild-type and C276 mutants. The supernatants of the crude extracts were submitted to SDS−PAGE and immunoblotted as described under the Materials and Methods. The final amount of total proteins loaded on each lane was 0.1 mg. Lane 1, wild-type hUGDH; lanes 2−6, C276G, C276K, C276E, C276L, and C276Y, respectively; lane 7, prestained marker proteins.

crude extract was loaded onto a Blue Sepharose CL-6B column that was equilibrated with buffer A (20 mM Tris/HCl at pH 6.5, 5 mM $MgCl_2$, and 10 mM β-mercaptoethanol). The column was washed with buffer A until the breakthrough peak of protein had been eluted. The enzyme was then eluted by a gradient up to 500 mM NaCl. The fractions containing hUGDH were pooled and concentrated, and the buffer changed to buffer B (50 mM Tris/HCl at pH 8.0, 0.5 mM EDTA, and 10 mM β-mercaptoethanol) using Amicon concentrator and then applied to a FPLC Resource-Q column equilibrated with buffer B. The enzyme was then eluted using a linear gradient made with buffer B in an increasing concentration of NaCl (from 0 to 300 mM) at 3 mL/min. The fractions containing hUGDH were pooled and concentrated. The purified enzymes were analyzed by SDS−PAGE and recognized by Western blot using monoclonal antibodies against the hUGDH.

hUGDH activity was performed spectrophotometrically by measuring the reduction of NAD^+ in the presence of UDP-glucose at 340 nm as described previously (*22*). Reactions were performed in a total volume of 1 mL with hUGDH adjusted to give a measured rate of less than 0.04 absorbance units/min. One unit of hUGDH activity was defined as the amount of enzyme required to reduce 2 μmol of NAD^+/min at pH 8.7 at room temperature.

RESULTS

Construction and Characterization of C276 Mutants. In this work, the functional role of C276 residue was examined by cassette mutagenesis using a synthetic human UGDH gene. For this study, the mutant human UGDHs containing Gly, Lys, Glu, Leu, or Tyr at the cysteine 276 site have been expressed in *E. coli* as a soluble protein, purified, and characterized. The 60 base-pair *Nhe*I/*Eco*NI fragment was replaced with five 60 base-pair synthetic DNA duplexes containing a substitution on both DNA strands at positions encoding C276. These substitutions made the mutant hUGDHs C276G, C276K, C276E, C276L, and C276Y. These mutants were designed to have different sizes, hydrophobicities, and ionizations of the side chains at each position. Analysis of crude cell extracts by Western blot showed that C276 mutant plasmids encoding an amino acid substitution at position 276 directed the synthesis of a 57-kDa protein that interacted with monoclonal antibodies raised against hUGDH at almost identical levels for all mutant hUGDHs and wild-type hUGDH (Figure 1). These results indicate that the mutagenesis at the C276 site has no effects on expression of the different mutant hUGDHs. Catalytic activity of hUGDH point mutants was measured under standard reaction conditions and found to be negligible, suggesting an important role for the C276 residue (Table 1). This observation is consistent with results of the analogous C260S streptococcal point mutant, which lacked activity to an unquantified degree (*26*, *27*). In addition, no incorporation of [^{32}P]5N_3UDP-glucose was also observed for the C276E mutant. These results indicate that C276 plays an important role for efficient binding of UDP-glucose to human UGDH.

Table 1. Kinetic Properties of Wild-Type and C276 Mutants Observed with UDP-Glucose and 5N_3UDP-Glucose

	UDP-glucose		5N_3UDP-glucose	
	specific activity[a] (nmol min^{-1} mg^{-1})	K_m (μM)	specific activity[a] (nmol min^{-1} mg^{-1})	K_m (μM)
wild type	157.22	17.03	108.42	56.17
C276G	0.36	nd[b]	nd	nd
C276K	0.34	nd	nd	nd
C276E	0.47	nd	nd	nd
C276L	0.68	nd	nd	nd
C276Y	0.34	nd	nd	nd

[a] Specific activities of the mutants were not detectable under standard reaction conditions and found less than 1% activity relative to the wild-type enzyme after measuring activity for 3 h. [b] nd = not detectable because of the extremely low activities.

Table 2. Photoinactivation of the Enzyme by 5N_3UDP-Glucose[a]

additions	hv	relative activity[b] (%)
no addition	−	100 ± 2[c]
5N_3UDP-glucose	−	68 ± 3
UDP-glucose	+	95 ± 2
5N_3UDP-glucose	+	11 ± 3
UDP-glucose and 5N_3UDP-glucose	+	89 ± 4

[a] A total of 3 μM enzyme, 120 μM 5N_3UDP-glucose, 1 mM NAD^+, and 1 mM UDP-glucose were used. The data represent the mean of three independent experiments with the difference expressed as a ±deviation. [b] Mean of triplicates. [c] The activity of the untreated control was equal to 157 nmol min^{-1} (mg of protein)$^{-1}$.

Photoaffinity Labeling of hUGDH. The reactive amino acid involved in the direct binding of UDP-glucose to hUGDH was identified by photoaffinity labeling with [^{32}P]5N_3UDP-glucose. The ability of a nucleotide analogue to mimic the natural nucleotide in its binding properties to the enzyme is essential to secure the specificity of photoinsertion into the active site. To show that 5N_3UDP-glucose could mimic the stimulatory properties of UDP-glucose, the photoanalogue should be able to activate hUGDH in the absence of activating light. When assayed with NAD^+ as a coenzyme, 5N_3UDP-glucose was able to activate the wild-type hUGDH, although maximal activity with 5N_3UDP-glucose (108 nmol min^{-1} mg^{-1}) was ~70% of the maximal activity obtained with UDP-glucose (157 nmol min^{-1} mg^{-1}) (Table 1). The K_m for 5N_3UDP-glucose was 56 μM, which was also comparable with the K_m value for UDP-glucose (17 μM). These results show that the azidonucleotide, 5N_3UDP-glucose, is able to elicit biological effects on the wild-type hUGDH as the natural nucleotide, UDP-glucose. The ability to mimic a native compound before photolysis has an advantage over determination of the enzyme function after modification. The ability of 5N_3UDP-glucose to inhibit hUGDH activity by photoinsertion upon irradiation under different conditions was investigated (Table 2). hUGDH activity was slightly affected by UV light under these conditions. In the presence of 120 μM 5N_3UDP-glucose, 89% of the enzyme activity was lost after 5 min of photolabeling.

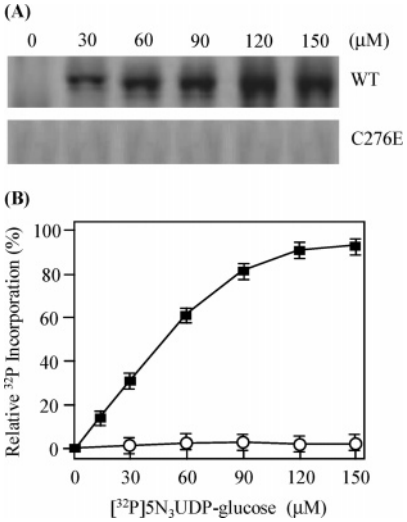

Figure 2. Saturation of photoinsertion of [^{32}P]5N$_3$UDP-glucose into hUGDH. Wild-type hUGDH and C276E mutant in the reaction buffer were separately photolabeled with the indicated concentrations of [^{32}P]5N$_3$UDP-glucose subjected to SDS−PAGE. (A) Autoradiograph. (B) Densitometry readings of the resulting autoradiograph. ^{32}P incorporations into proteins were expressed in autoradiograph. Data are expressed relative to the value in the absence of [^{32}P]5N$_3$UDP-glucose (control) being assigned 100%. Wild-type (■). C276E mutant (○).

When the enzyme was photolyzed in the presence of 1 mM UDP-glucose, only 11% of the enzyme activity was lost. These results suggest that the 5N$_3$UDP-glucose was photoinserting into a UDP-glucose-binding site on hUGDH in a specific manner.

To show specificity of the photoprobe−protein interaction, saturation of photoinsertion should be observed. For demonstrating saturation effects with the photoprobe, the purified enzymes were photolabeled with increasing concentrations of [^{32}P]5N$_3$UDP-glucose (Figure 2A). Under the experimental conditions described, saturation of photoinsertion with [^{32}P]5N$_3$UDP-glucose occurred at around 120 μM photoprobe (Figure 2B). The data in Figure 2 demonstrate the apparent K_d value of approximately 45 μM, which is in reasonably good agreement with the K_m value (56 μM) for 5N$_3$UDP-glucose (Table 1). The results in Figure 2 indicate the saturability of the UDP-glucose-specific site of hUGDH with this photoprobe and therefore decrease the possibility of nonspecific photoinsertion. No photoaffinity labeling of [^{32}P]5N$_3$UDP-glucose was measured for C276 mutants under the same experimental conditions for the wild-type enzyme (parts A and B of Figure 2). Because almost identical results were obtained with all five different mutants at the position of C276, only the results obtained with C276E are shown. These results are consistent with the postulated role of C276 in UDP-glucose binding and support its position in the reaction mechanism for the human enzyme.

Prevention of [^{32}P]5N$_3$UDP-Glucose Photoinsertion into hUGDH by Various Competitors. The studies were performed to examine the ability of the constituents of the sugar nucleotide to compete with [^{32}P]5N$_3$UDP-glucose for photolabeling of the UDP-glucose-binding site of hUGDH (Figure 3). The results show that uracil, uridine, and glucose had a poor protective effect on the labeling, while UDP and UDP-glucose strongly inhibited photoinsertion (Figure 3).

To further demonstrate specific labeling of hUGDH, the wild-type hUGDH was photolabeled with [^{32}P]5N$_3$-UDP-glucose in the presence of increasing UDP-glucose

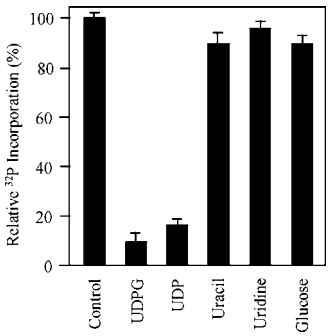

Figure 3. Prevention of [^{32}P]5N$_3$UDP-glucose photoinsertion into hUGDH by various competitors. Wild-type hUGDH and C276E mutant in the reaction buffer were separately photolabeled with 120 μM [^{32}P]5N$_3$UDP-glucose in the presence of competitors (200 μM) and subjected to SDS−PAGE. Densitometry readings of the resulting autoradiograph to quantitate the labeling of hUGDH was carried out as indicated in Figure 2. Because no photolabeling was observed with C276 mutants even in the absence of competitors, only the results obtained with the wild-type enzyme are expressed.

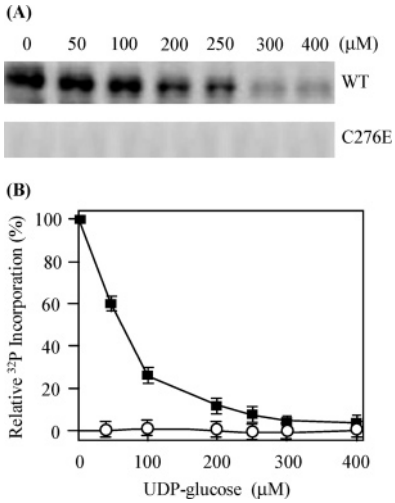

Figure 4. Effect of UDP-glucose on photoinsertion of [^{32}P]5N$_3$-UDP-glucose into hUGDH. Wild-type hUGDH and C276E mutant in the reaction buffer were separately photolabeled with 120 μM [^{32}P]5N$_3$UDP-glucose in the presence of the indicated concentrations of UDP-glucose and subjected to SDS−PAGE. (A) Autoradiograph. (B) Densitometry readings of the resulting autoradiograph. ^{32}P incorporations into proteins were expressed in autoradiograph. Data are expressed relative to the value in the absence of UDP-glucose (control) being assigned 100%. Wild-type (■). C276E mutant (○).

concentrations. As shown in the results of the competition experiments, UDP-glucose was able to protect photolabeling from [^{32}P]5N$_3$UDP-glucose (Figure 4A). As competitor concentrations increased from 50 to 400 μM in the presence of 120 μM [^{32}P]5N$_3$UDP-glucose, the photoinsertion of the probe into the hUGDH became reduced (Figure 4B) with a K_d value of approximately 60 μM, which is in reasonably good agreement with the K_m value for UDP-glucose (Table 1). These results of photoinsertion studies (Figures 2−4) show the specificity and utility of [^{32}P]5N$_3$UDP-glucose as a good probe for determining the UDP-glucose-binding site.

Identification of the UDP-Glucose-Binding Site. To identify the peptides modified by [^{32}P]5N$_3$UDP-glucose, the enzymes were photolabeled twice in the absence or presence of 150 μM UDP-glucose and digested with trypsin. [^{32}P]5N$_3$UDP-glucose is a probe that, on photolysis, generates a very reactive nitrene that has the capacity of photoinserting into any residue. The photo-

[a] The amino acids are denoted by the single-letter code. [b] The amino acid numbering is that of the mature human UGDH (*7*).

labeled hUGDH was separated from most of the noncovalently bound nucleotide by acid precipitation and proteolyzed by trypsin. After overnight trypsin digestion of hUGDH modified with [^{32}P]5N$_3$UDP-glucose, the digested samples were purified by the "Phosphopeptide Isolation Kit" from Pierce Biotechnology (Rockford, IL). The radioactive peptides were eluted with 100 mM ammonium bicarbonate at pH 9 containing 0.3 M ammonium hydroxide and 20% acetonitrile. Photolabeling of the peptide was prevented by the presence of UDP-glucose during photolysis. When 150 μM UDP-glucose was originally present in the incubation mixture, ~95% of the radioactivity of the eluent was eliminated. These results demonstrate a selectivity of the photoprobe and suggest that the radioactive fractions represent a peptide in the UDP-glucose-binding domain of the hUGDH. The radioactive fractions were collected and identified by amino acid sequence analysis.

The amino acid sequence analysis revealed that the radioactive eluent contained the amino acid sequence ASVGFGGSXFQK. As judged by comparison with the amino acid sequence of various UGDHs (Table 3), this peptide was identified as residues 268−279 of hUGDH. The symbol X indicates a position for which no phenylthiohydantoin-amino acid could be assigned. The missing residue, however, can be designated as a photolabeled cysteine because the sequences including the cysteine residue in question have a complete identity with those of the other UGDH species known. Because the photolabeled peptides are tryptic digests, it was expected to produce a sequence ending with Arg or Lys. The amino acid composition of the photolabeled peptide revealed that the peptide had a composition that was compatible with that of the tryptic peptide spanning residues Ala268−Lys279 with an exception that there was a significant reduction in cysteine (data not shown). On the basis of information obtained on the amino acid sequence determination and composition analysis of the isolated peptide, we suggest that the attachment site of [^{32}P]5N$_3$-UDP-glucose is C276. Unlike the wild-type hUGDH, no peptides containing amino acids around the 276 position were detected with the C276E mutant. Once again, these results demonstrate selectivity of the photoprobe for the UDP-glucose-binding site and suggest that C276 is critically involved in the binding of [^{32}P]5N$_3$UDP-glucose to human UGDH.

DISCUSSION

The majority of previous studies on UGDH have focused on the bovine liver enzyme, and until recently very little was known about the human enzyme. The structure of the enzyme is well-conserved between the species and phyla. The cloned mammalian proteins from different species showed an overall 97% identity (*8*). The human enzyme cDNA codes for 494 amino acids and has 27% homology to the *E. coli* ortholog. The conserved amino acids are uniformly distributed along the molecule. Very recently, mechanistic details for the human enzyme were acquired by a combination of site-directed mutagenesis, activity measurements, and homology modeling (*9*, *22*). On the basis of the model of the active site of *Streptococcus pyrogenes* UGDH, Sommer et al. (*9*) have reported that C276 of human UGDH is essential for the second oxidation and suggested its role as a catalytic residue. However, direct evidence for the involvement of the C276 residue in substrate binding has not been addressed yet. In the present work, we have identified an amino acid residue in the UDP-glucose-binding domain of hUGDH by cassette mutagenesis and photoaffinity labeling with [^{32}P]5N$_3$UDP-glucose. The azidosugar nucleotide has the distinct advantage over a classic chemical probe in that the photoactive group is not reactive without exposure to the proper wavelength of light (Table 2). As it has been described (*28*), the 5-azidouridine derivative of UDP-glucose did not produce long-lived reactive intermediates in aqueous solutions. The result, showing no labeling of hUGDH when the probe is subjected to photolysis before the addition of the enzyme (data not shown), eliminates the existence of any long-lived chemically reactive intermediate that could be involved in covalently modifying enzymes. The selectivity and specificity has been successfully utilized to locate the specific base-binding domains of nucleotide-binding site peptides of many proteins (*13*−*22*).

The specificity of [^{32}P]5N$_3$UDP-glucose and the utility of this probe as a good candidate for determining the UDP-glucose-binding site were further supported by the following. First, in the absence of activating light, 5N$_3$UDP-glucose is a substrate for hUGDH (Table 2). The ability to mimic a native compound before photolysis has an advantage over determination of the enzyme function after modification. Second, the photoinsertion into hUGDH was saturated with [^{32}P]5N$_3$UDP-glucose. Saturation of photoinsertion with [^{32}P]5N$_3$UDP-glucose occurred at around 120 μM photoprobe (Figure 2). Third, the prevention of photoinsertion of [^{32}P]5N$_3$UDP-glucose by UDP-glucose demonstrates that the photoprobe is inserting into a specific UDP-glucose site within hUGDH (Table 2 and Figure 4). In addition, the sites of attachment of the photoaffinity label were more precisely defined by generating small peptide fragments of the labeled protein and separating the labeled peptides. For separation of the ^{32}P-labeled peptide fragments generated in the proteolytic digest, the "Phosphopeptide Isolation Kit" from Pierce Biotechnology was successfully carried out.

There were differences in the biochemical properties between wild-type hUGDH and C276 mutants. Catalytic activities of the hUGDH point mutant at the 276 site were not measurable under normal assay conditions and found less than 0.1% activity relative to wild-type enzyme

after measuring activity for 3 h (Table 1). This result suggests a possibility that the loss of enzymatic activity is due to a change in binding of UDP-glucose in the C276 mutants. In addition, no detectable amounts of photoaffinity labeling (Figure 2 and Figure 3) and no photolabeled peptides (Table 3) were observed for C276 mutants when treated with [^{32}P]5N$_3$UDP-glucose both in the presence and absence of UDP-glucose under the same experimental conditions as the wild-type enzyme. The results from the Western blot analysis show that the mutagenesis at the C276 site has no effects on expression or stability of the mutant (Figure 1). Therefore, the results with cassette mutagenesis and photoaffinity labeling techniques suggest that the loss of enzyme activities of C276 mutants is mainly caused by its inability to bind UDP-glucose and C276 is required for efficient base binding of UDP-glucose to hUGDH.

Both C276 and D280 are situated in the strictly conserved active-site signature sequence, GGxCxxxD (Table 3), that is characteristic of UGDH. The strictly conserved glycine pair preceding C276 suggests that main-chain conformations inaccessible to nonglycine residues are required for proper orientation of the catalytic nucleophile during catalysis. This is well-precedented within the aldehyde dehydrogenase extended family where a strictly conserved glycine residue precedes the catalytic cysteine and is necessary to allow the polypeptide chain to "twist back on itself" (*29*). The existence of an active-site cysteine residue has been well-documented in the case of UGDH from beef liver. Thiol modification studies using iodoacetate (*30*), 5-[[(iodoacetamido)ethyl]amino]naphthalene-1-sulfonic acid (*31*), 5,5′-dithiobis-(2-nitrobenzoate] (*11*), iodoacetamidofluorescein (*32*), and 6,6′-dithionicotinate (*33*) all indicate that a cysteine is required for catalysis. The observation that the cysteine is protected from modification by the addition of UDP-glucose or UDP-xylose suggests that it is located in the active site (*30*, *34*). The iodoacetate-labeling experiments clearly indicate that one thiol has been modified during the inactivation process and support the notion that a cysteine is in the proper vicinity to participate in covalent catalysis. Proteolytic digestion and sequencing studies on the iodoacetate-labeled bovine enzyme have indicated that C275 (C276 in the human enzyme) supplies the reactive thiol (*32*, *35*). This C276 thiol is within hydrogen-bonding distance of the 6′-hydroxyl of UDP-glucose and is located approximately for catalysis. When the protein sequence of the bovine enzyme is compared with that of the other known UGDHs, the cysteine is strictly conserved. This observation strongly indicates that C276 is the active-site thiol.

Competitive binding experiments showed that the substrate UDP-glucose protected against photolabeling of hUGDH (Figures 3 and 4). The inhibitor substrate UDP showed a similar protection against insertion, while uridine, uracil, and glucose were poor competitors (Figure 3). These results indicate that, although the interaction of the position 5 of the uridine ring with a neighboring amino acid residue at the UDP-glucose-binding site allows the specific photolabeling, the other interaction may occur between the pyrophosphate or a phosphate moiety of UDP-glucose and another amino acid residue at the binding site. Further studies using various mutated forms of hUGDH should make it possible to identify the residues involved in the binding of the sugar nucleotide phosphate.

The construction of a synthetic gene encoding hUGDH and the high level of hUGDH expression as a soluble protein in *E. coli* will enable us to generate a large number of site-directed mutations at several positions in the coding region and facilitate the purification of large quantities of mutant proteins for biochemical and structural studies. The combination of genetic and photolabeling techniques could be used to address a broad range of questions relating to the structure and function of human UGDH.

Generation of an Intensely Potent Anthracycline by a Monoclonal Antibody–β-Galactosidase Conjugate

Michael Y. Torgov,[†] Stephen C. Alley,[†] Charles G. Cerveny,[†] David Farquhar,[‡] and Peter D. Senter[†,*]

Seattle Genetics, 21823 30th Drive SE, Bothell, Washington 98021, and University of Texas M.D. Anderson Cancer Center, Houston, TX, 77025. Received February 14, 2005; Revised Manuscript Received April 1, 2005

The L49 monoclonal antibody against the p97 antigen on melanomas and carcinomas was chemically conjugated to *E. coli* β-galactosidase (β-gal), forming a largely monomeric conjugate with preserved enzymatic activity. The resulting L49–β-gal conjugate was used to activate (*N*-[(4″*R*,*S*)-4″-hexyloxy-4″-(1‴-*O*-β-D-galactopyranosyl)butyl]daunorubicin) (**1**), a derivative of daunorubicin that has low cytotoxicity and high chemical stability. Addition of the conjugate to the prodrug resulted in an increase in cytotoxicity of approximately 10^5-fold, a level of activation that is higher than any mAb–enzyme/prodrug combination yet described. Furthermore, the released drug had an IC_{50} value of approximately 10 pM, making it significantly more potent than the vast majority of clinically approved anticancer drugs. The potential of this enzyme/prodrug combination for cancer therapy is discussed.

INTRODUCTION

A considerable amount of research has surrounded the use of monoclonal antibody (mAb)–enzyme conjugates for the activation of anticancer prodrugs (*1, 2*). This approach to cancer chemotherapy, referred to as ADEPT (antibody-directed enzyme prodrug therapy) involves two separate steps to achieve therapeutic efficacy. Initially, a mAb–enzyme conjugate is administered, which localizes within the tumor mass and clears from the systemic circulation over time. In the second step an anticancer prodrug is administered, which circulates throughout the body and is converted to active drug by the mAb–enzyme conjugate. Depending on the tumor to nontumor conjugate ratio, the prodrug can be very well-tolerated, and high intratumoral drug concentrations are obtained (*1–4*). The strength of this approach is evident from not only the large number of mAb–enzyme/prodrug combinations that have preclinical activity, but also from the indications of efficacy in early-stage clinical trials (*1, 5*).

One of the interesting aspects of ADEPT is that it allows not only for intratumoral generation of clinically approved drugs such as doxorubicin (*6*), paclitaxel (*7*), etoposide (*8*), 5-fluorouracil (*4*), and melphalan (*9*) but also of drugs that would be too toxic for use in a nontargeted form. Such drugs include potent minor groove binders (*10*), bis-iodomustards (*11*), cyanide (*12*), and the marine natural product palytoxin (*13*). The rationale for generating highly potent drugs is that the amount of localized enzyme within solid tumors is likely to be very low (*14*), and this will restrict the number of drug molecules that are generated. Therefore, maximal therapeutic efficacy is likely to be obtained through the intratumoral generation of highly potent cytotoxic agents. ADEPT systems that lead to such drugs would not only require a high tumor to nontumor conjugate ratio, but also a prodrug with greatly attenuated toxicity.

In this paper, we describe a mAb–β-galactosidase (β-gal[1]) conjugate for the activation of an intensely potent daunorubicin derivative. Previous studies have shown that treatment of a galactosyl derivative of daunorubicin (**1**, Figure 1A) with unconjugated β-gal released a daunorubicin derivative that was 100–1000 times more potent than unmodified daunorubicin (*15, 16*). This enzyme has also been used to release such agents as CC-1065 derivatives (*10, 17*) and daunorubicin (*18*). The only mAb-conjugated form of β-gal used for prodrug activation involved a derivative of 5-fluorouridine (*19*). Here, we extend these findings by demonstrating that **1** can be activated by as much as 10^5-fold by a mAb–β-gal conjugate that binds to the p97 antigen on melanomas and some carcinomas. This represents one of the highest cytotoxic differentials between a prodrug and potent drug for application in ADEPT.

EXPERIMENTAL PROCEDURES

General Analytical Methods and Materials. The murine L49 mAb was obtained as previously described (*20*). *E. coli* β-gal was purchased from Calbiochem (San Diego, CA). *N*-(ε-maleimidocaproic acid)hydrazide (EMCH), DTNB, and the BCA protein assay reagent were from Pierce (Rockford, IL). (*N*-[(4″*R*,*S*)-4″-Hexyloxy-4″-(1‴-*O*-β-D-galactopyranosyl)butyl]daunorubicin) (**1**) and (*N*-(5,5-diacetoxypent-1-yl)doxorubicin) (**5**) were prepared as previously described (*15, 16*). Protein concentrations of unmodified L49 and β-gal were determined by UV absorption spectrometry at 280 nm, and those of conjugated enzyme were determined using the BCA protein assay reagent. All measurements were made against known concentrations of β-gal as a reference standard.

Oxidation of L49 and Conjugation to β-Gal. $NaIO_4$ (final concentration 12.5 mM) was added to L49 in 50 mM sodium acetate (pH 5.5) and 50 μM methionine. The reaction was allowed to proceed in the dark for 50 min at ambient temperature. The oxidized L49 was desalted and buffer exchanged into PBS using a PD-10 column (Amersham Biosciences, Piscataway, NJ). EMCH was

then added at a 50-fold molar excess over L49 and allowed to react for 4 h at ambient temperature with 10% DMSO present to ensure the solubility of EMCH. L49−EMCH was then purified using a PD-10 column pre-equilibrated with PBS. The number of the introduced maleimide residues was determined by treating with 50 μM cysteine and quantitating the remaining unreacted cysteine with DTNB. β-Gal was added to L49−EMCH at 0.5:1 enzyme to antibody molar ratio, and the reaction was allowed to incubate overnight at 4 °C. The conjugate was purified from unreacted L49 by SEC HPLC on a TSKgel G3000SW column (Tosoh Bioscience, Montgomeryville, PA) using PBS containing 10 mM $MgSO_4$ as the mobile phase. After concentration, the L49−β-gal conjugate was stored at 4 °C.

Amino Acid Analysis for the Determination of Conjugation Ratio. Amino acid analysis was performed on the L49−β-gal conjugate by the molecular structure facility at the University of California at Davis. The experimental mole fraction of each amino acid in the conjugate (MF_{AAA}) was determined from these data. The theoretical mole fraction of each amino acid was calculated from the primary amino acid sequence of L49 (MF_{L49}) and β-gal ($MF_{\beta-gal}$). The stoichiometry of the L49−β-gal conjugate (X moles of L49 per 1 mole of β-gal) is related to the experimental and theoretical mole fraction by eq 1:

$$MF_{AAA} = \frac{Xm MF_{L49} + 1n MF_{\beta-gal}}{Xm + 1n} \quad (1)$$

where m and n are the number of occurrences of the amino acid in L49 and β-gal, respectively. Solving for X for each amino acid yielded an average value of 0.7 mol of L49 per mole of β-gal.

Enzyme Activity Assays. β-Gal activity of the conjugate was measured using 4-methylumbelliferyl-β-D-galactopyranoside (4-MUG) or **1** as substrates. Dilutions of the enzyme or the conjugate (1 μg per data point) in 25 μL of PBS with 10 mM $MgSO_4$ were incubated for 5 min at 37 °C and then mixed with an equal volume of the substrate in the same buffer. The final substrate concentration varied from 80 to 8 μM. During a 20 min incubation course at 37 °C, 50 μL aliquots were taken and quenched with an equal volume of methanol. Aliquots (100 uL) were analyzed by HPLC on a 4.6 × 150 mm, 4u Synergi MAX-RP 80 column (Phenomenex, Torrance, CA) using the following gradient at 1 mL min^{-1}: solvent A 0.1% trifluoroacetic acid in H_2O; solvent B 0.1% trifluoroacetic acid in acetonitrile; a 10-min linear gradient from 10% A to 90% A. Peak areas at 495 or 315 nm for **1** and 4-MUG, respectively, were used to calculate concentrations of the product based on the peak area at time infinity. Eady−Hofstee plots of velocity versus the ratio of velocity and substrate concentration were used to calculate V_{max} and K_m.

In Vitro Cytotoxicity Assay. H3677 melanoma cell line seeded at a density of 2×10^3 per well in a 96-well plate and allowed to adhere overnight in RPMI 1640 medium containing 10% FBS in the absence of antibiotics. Serial dilutions of the L49−β-gal conjugate and an L49 control were added, incubated for 1 h at room temperature, and then washed. The prodrugs **1** or **5** were then added for 24 h. Cultures were washed and grown for an additional 92 h, at which point Alamar Blue (Biosource International, Camarillo, CA) was added to 10% of the total culture volume. Cells were incubated for 4 h, and dye reduction was measured on a Fusion HT fluorescent plate reader (Packard Instruments, Meriden, CT).

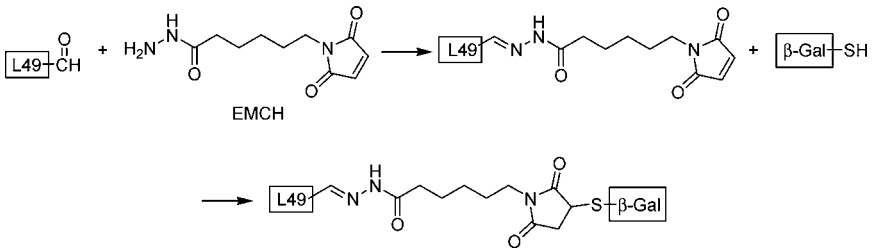

Figure 2. Mechanism of conjugate formation. L49 oxidized with sodium periodate (L49-CHO) reacts with EMCH to form L49–EMCH. The endogenous thiols of β-gal (β-gal-SH) then reacts with the maleimide to form the L49–β-gal conjugate.

RESULTS AND DISCUSSION

Prodrug Design. The structure of the known daunorubicin analogue **1** (*16*) is shown in Figure 1. This previously reported compound has been shown to give rise to an intensely potent metabolite in the presence of β-gal. In phosphate buffer at 37 °C, **1** is slowly degraded with a half-life of 49 h (*16, 21*). The proposed mechanism of action is that hemiacetal **2**, formed by the cleavage of the glycosyl bond of **1**, spontaneously loses hexanol to form aldehyde **3,** which then spontaneously cyclizes leading to the generation of iminium ion **4** (Figure 1A). Figure 1B shows the mechanism of formation of **6**, a compound related in structure to **4**, from *N*-(5,5-diacetoxypent-1-yl)doxorubicin (**5**) (*15*). Thus, compound **5**, which was designed to be hydrolyzed by cellular esterases, can be used to gauge the potential differences in cytotoxic activities between **1** and the unstable hydrolysis product **4**. DNA interstrand cross-links in HL-60 human leukemia cells have been shown and proposed for compound **5** and **1**, respectively (*15, 22*). Thus, these compounds differ mechanistically from the topoisomerase II inhibitor daunorubicin.

L49–β-Gal Conjugate Preparation. *E. coli*-derived β-gal is a tetrameric enzyme composed of 116 kDa monomers that has previously been used successfully for anticancer prodrug activation (*19, 23*). The enzyme has a neutral pH optimum while mammalian β-gal has optimal activity under acidic conditions (*24, 25*). Bacterial and mammalian β-gal activities have been successfully distinguished in transgenic mice by carefully controlling pH (*26*). Because of these differences in pH optima, it was anticipated that the prodrugs would undergo minimal nonspecific activation when administered in vivo.

To prepare the L49–β-gal conjugate, the carbohydrates of L49 were oxidized with sodium periodate, generating aldehydes on the heavy chain in the vicinity of the hinge region. The aldehydes were subsequently reacted with *N*-(ε-maleimidocaproic acid)hydrazide (EMCH) to yield a maleimide-activated antibody. These were coupled with β-gal, which contains endogenous sulfhydryl groups (Figure 2). L49 was added in a 2-fold excess with respect to the enzyme to minimize the amount of unreacted enzyme remaining after the conjugation reaction. The resulting conjugate, whose formation was manifested by the forward shift relative to the β-gal peak, was purified from unreacted L49 by size-exclusion HPLC (Figure 3A).

SDS–PAGE analysis further confirmed the presence of the cross-linked material (Figure 3B). β-gal is a tetramer composed of 116 kDa monomers. The conjugation conditions were targeted toward 1:1 cross-linking ratio, e.g. a single antibody molecule per enzyme tetramer. Therefore, under both reducing and nonreducing conditions, a dominant 116 kDa β-gal band is present that corresponds to the non-cross-linked subunit in the enzyme tetramer. A cross-linked product represented by two bands of approximately 160 kDa is consistent with

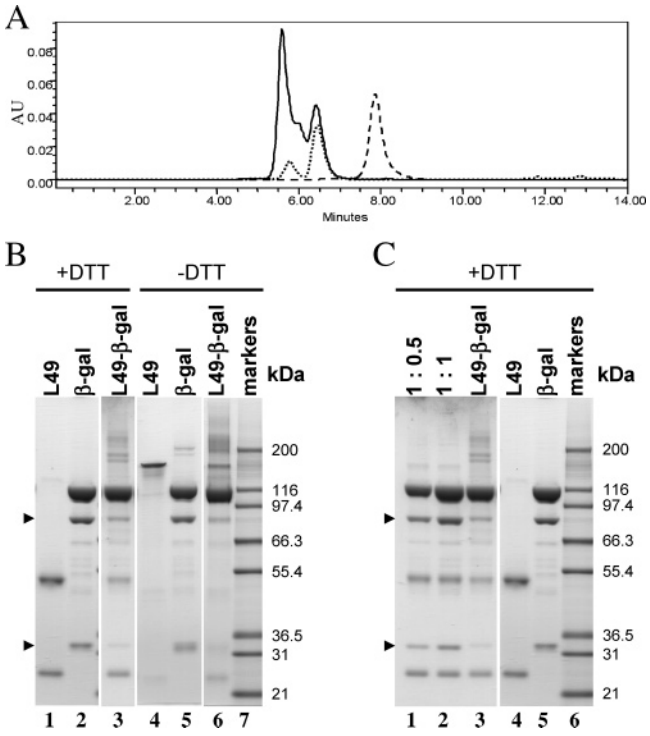

Figure 3. A. Size-exclusion chromatography HPLC traces for L49–β-gal conjugate (solid line), β-gal (dotted line), and L49 (dashed line) using PBS with 10 mM $MgSO_4$ as a mobile phase. B. SDS–PAGE (4–12%) of L49, β-gal, and L49–β-gal conjugate under reducing (with DTT) and nonreducing (without DTT) conditions. The arrowheads represent a contaminant present in the enzyme preparation. Lane 1, L49 with DTT; lane 2, β-gal with DTT; lane 3, L49–β-gal conjugate with DTT; lane 4, L49 without DTT; lane 5, β-gal without DTT; lane 6, L49–β-gal conjugate without DTT; and lane 7, molecular weight markers. C. SDS–PAGE (4–12%) of authentic mixtures of β-gal and L49 compared to L49–β-gal conjugate. All lanes are under reducing conditions. The arrowheads represent a contaminant present in the enzyme preparation. Lane 1, 1:0.5 mixture of β-gal and L49; lane 2, 1:1 mixture of β-gal and L49; lane 3, L49–β-gal conjugate; lane 4, L49; lane 5, β-gal; lane 6, molecular weight markers.

the expected combined size of a single enzyme subunit and a L49 heavy chain. In addition, under reducing conditions both heavy and light antibody chains are present in the lane with conjugate. However, their relative intensities are skewed toward the light chain due to sequestration of the heavy chain into conjugate (compare lane 1 and 3).

Amino acid analysis performed to assess the antibody-to-enzyme ratio revealed that the conjugate is composed of 0.7 mole of L49 per 1 mole of enzyme. When L49 and β-gal were mixed at different molar ratios and compared by SDS PAGE to the conjugate, it was confirmed that the composition of the conjugate lies between 0.5 and 1 molecule of L49 per molecule of the enzyme tetramer, consistent with the amino acid analysis data (Figure 3C).

Table 1. Enzyme Kinetic Parameters of L49 and L49−β-Gal[a]

		β-gal activity	
compound	substrate	K_m (μM)	V_{max} (μM·min^{-1}·mg^{-1})
β-gal	**1**	38 ± 22	0.052 ± 0.025
	4-MUG	22	89.6
L49−β-gal	**1**	60 ± 16	0.035 ± 0.01
	4-MUG	21.4	78.4

[a] Values shown are the average of a minimum of two independent experiments, except for 4-MUG (performed once).

Enzyme Activity. To test the enzyme activity, either **1** or 4-methylumbelliferyl-β-D-galactopyranoside (4-MUG) was added at concentrations ranging from 8 to 80 μM to β-gal or the L49−β-gal conjugate. Aliquots were precipitated with methanol and the substrate conversion was monitored by reversed-phase HPLC. The results, summarized in Table 1, demonstrate that the K_m and V_{max} values on both substrates were similar for the conjugate and free enzyme. This indicates that the conjugation chemistry did not impair the enzymatic activity of β-gal in the L49−β-gal conjugate. It should be noted that the specific activity values are in good agreement with those reported for a related molecule, gal−DNC4 (*21*). The slow rate of drug release most likely involves hydrolysis of the glycosidic bond as the rate limiting step, as significantly improved release kinetics were obtained using 4-MUG, which incorporates a better leaving group.

In Vitro Studies. The cytotoxic activities of L49−β-gal in combination with **1** were determined using the p97 positive H3677 human melanoma cell line. Cells were preincubated with the conjugate for 1 h, washed to remove the unbound material, and then exposed to **1** for a total of 24 h. Following the drug removal, the cytotoxic effects relative to untreated cells were determined using Alamar Blue as an indicator of cell viability. *N*-(5,5-Diacetoxypent-1-yl)doxorubicin (**5**) was used as a control in the assay since it generates the active doxorubicin iminium ion **6**, analogous to the daunorubicin iminium ion **4** generated from **1**. The difference in cytotoxicity between **5** and **1** was approximately 10^5-fold. Consistent with published data (*15*), **5** had an IC_{50} value of 20 pM (Figure 4A). In contrast, the IC_{50} of prodrug **1** alone was 0.8 μM. Preincubation of cells with L49 in the presence of prodrug **1** did not have any effect on the cytotoxicity of **1**. However, when the L49−β-gal conjugate was used, **1** exhibited cytotoxicity similar to **5**. These data are consistent with the conclusions that **4** is generated as a result of galactoside cleavage, and that the galactoside of **1** is completely cleaved by β-gal.

Next, we sought to establish the minimal concentration of the conjugate required to attain complete prodrug activation. Serial dilutions of the conjugate were incubated with the cells as described above, and any unbound conjugate was removed by washing. The prodrug **1** was then added at a constant concentration of 10 nM, significantly lower than its IC_{50} value. The assay demonstrated that a conjugate concentration of 40 nM (6 μg/mL) led to 50% cell kill (Figure 4B). Thus, the two assays show that efficient prodrug activation is achieved and that the difference in prodrug and drug toxicity is pronounced.

CONCLUSIONS

We have demonstrated that a chemical conjugate of L49−β-gal activates **1**, with a cytotoxic differential of approximately 5 orders of magnitude. This degree of prodrug activation has not been demonstrated previously

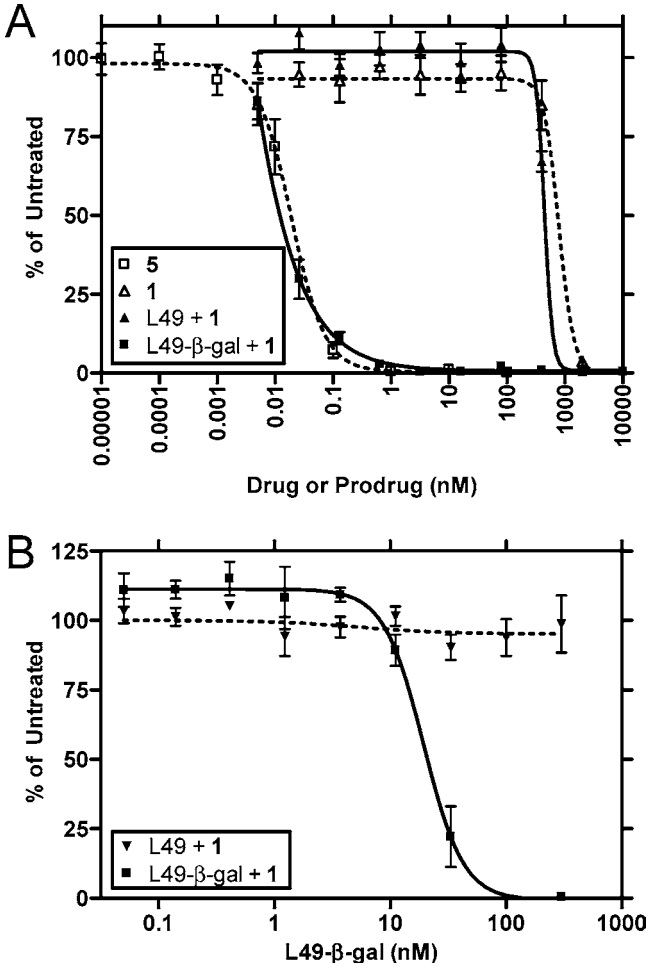

Figure 4. In vitro cytotoxicity of **1** and **5** on H3677 cells detected by Alamar Blue reduction. Cells were treated with L49 or L49−β-gal conjugate for 1 h, washed, and then treated with **1** or **5**. A. Cells were treated with 100 nM of L49 or L49−β-gal conjugate and the concentration of **1** or **5** varied. Open squares, **5**; open triangles, **1**; closed triangles, L49 plus **1**; closed squares, L49−β-gal plus **1**. B. Cells were treated with varied concentration of L49 or L49−β-gal conjugate and then 10 nM **1**. Open squares, **1** plus L49; closed squares, **1** plus L49−β-gal.

in other ADEPT systems, which typically provide differences in the range of 10 to 100-fold (*1, 2*). The results reported here strongly suggest that attachment of the β-gal residue to daunorubicin leads to almost complete drug inactivation, and that the glycosidic bond is highly stable under the conditions used in the in vitro assay. These are necessary requirements in developing an ADEPT system involving a highly potent drug component. An additional feature of this system that distinguishes it from many other ADEPT systems is that the released drug is capable of circumventing the MDR phenotype (*15*). This latter property is critical, since it is highly likely that most patients who receive mAb−enzyme/prodrug combinations will have already been treated extensively with conventional chemotherapy. While drug potency has not yet been shown to be a critical parameter for therapeutic efficacy in ADEPT, it may well be if, as expected, very small percentages of the injected conjugate accumulate within solid tumor masses.

The results reported here justify future studies surrounding the in vivo activities of L49−β-gal/galactosyl−daunorubicin combinations. It is expected that optimization will require the development of an engineered fusion protein containing an L49 fragment, since such

molecules have demonstrated much higher tumor to normal tissue ratios than chemically derived conjugates (*20, 27*). In addition, forms of β-gal that are minimally immunogenic will be of greatest clinical utility. The development of molecules such as these will be the subject of future investigations.
